It is sometimes found that in the presence of a longer chained surfactant another surfactant does not form micelles, but acts simply as a solubilized amphiphilic solute (2). SHS forms micelles only weakly (16) and in the presence of SOS is probably not totally available as "surfactant", i.e. micellar component. If the concentration unit were chosen as [SOS] + 0.5[SHS], then the R curve for the equimolar system would more nearly coincide with the pure surfactant values. In other words, the distribution of SHS to SDS monomers in the mixed micelle formed from equimolar solutions was probably closer to 1:2 than 1:1.

The third system examined was the equimolar SLS–SOS system where the carbon chain difference is four carbon atoms. The pure surfactants have markedly different cmc values: 4×10^{-3} mol dm^{-3} for SLS and 0.115 mol dm^{-3} for SOS, both in 10^{-3} mol dm^{-3} Ni^{2+} (6), and the cmc for the mixed system in the same concentration of Ni^{2+} is 8×10^{-3} mol dm^{-3} from the C_{max} value. When R values are plotted against the total surfactant concentration, in the region above the cmc for pure SOS, the three curves for SLS, SOS, and equimolar SLS–SOS are indistinguishable (Fig. 3). From the previous discussion for the SLS–SDS system, a 1:1 micelle is probably being formed in the SLS–SOS system also.

In the fourth system studied, equimolar SOS–SOSO, mixing the two surfactants brings about only a change in headgroup, sulfonate or sulfate. In Fig. 4 are shown the R curves for the equimolar SOS–SOSO system with the pure surfactant curves included. As with the SLS–SDS and SLS–SOS systems, the rate enhancement behaviour over the entire mixed micellar range for this system is consistent with a random mixing of SOS and SOSO monomers in the micellar unit. This system displayed the most ideal behaviour of the systems investigated.

Complete kinetic analyses were performed on the equimolar SLS–SDS, SLS–SOS, and SOS–SOSO systems where the R curve behaviour points to 1:1 mole ratio micelles. The values of K_{PADA} found through solubility measurements, K_{Ni} through the murexide technique, and V_s through computer-fitting eq. [1] are listed in Table 1 along with the corresponding values for the pure surfactants.

The partitioning constants in Table 1 give no indication that any major changes in hydrophobic attraction or surface potential are occurring in the formation of these mixed micelles. The reaction volumes are similarly uninteresting although V_s for the equimolar SLS–SOS system is, within experimental error (roughly 10% in V_s), identical to that for pure SLS. The longer chained surfactant may essentially define the size of the mixed micelle when the head group of both surfactants is the same.

Thus, the only hint at synergistic effects in these simple mixed micellar systems is a slight increase in the maximum in the rate enhancement for the probe reaction over either of the R_{max} values for the pure surfactants. It is difficult to know what this means since this is a problematic micellar concentration region (5). However, in the mixed micelles investigated in this work the differences in the surfactants are only slight so that more dramatic differences may lead to greater increases in rate enhancement maxima.

Dynamic stereochemistry of 2,3,12,13-tetrathia- and -tetraselena[4,4]metacyclophanes[1]

KEITH R. DIXON AND REGINALD H. MITCHELL[2]
Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received August 24, 1981[3]

KEITH R. DIXON and REGINALD H. MITCHELL. Can. J. Chem. **61**, 1598 (1983).

2,3,12,13-Tetrathia- and -tetraselena[4,4]metacyclophanes exhibit temperature dependent ^{1}H nmr spectra in which the methylene resonances change from AB spectra in the low temperature limit to singlets at higher temperatures. Coalescence temperatures are 256 and 208 K, respectively, and a complete line-shape analysis yields $\Delta G^{0\ddagger}_{298}$ (thia) = 53.2 kJ mol^{-1} and $\Delta G^{0\ddagger}_{298}$ (selena) = 46.5 kJ mol^{-1}. The spectra and thermodynamic data are interpreted in terms of a mechanism involving interconversion of *syn* conformers with little or no involvement of the *anti* conformers previously assumed to dominate in this type of molecule.

KEITH R. DIXON et REGINALD H. MITCHELL. Can. J. Chem. **61**, 1598 (1983).

Les spectres de rmn du ^{1}H des tétrathia-2,3,12,13 et des tétraséléna[4,4]métacyclophanes dépendent de la température. Dans ces spectres la résonance du méthylène qui donne un spectre du type AB à basse température devient un singulet à température plus élevée. Les températures de coalescence sont respectivement de 256 et de 208 K et une analyse complète de la forme des raies donne $\Delta G^{0\ddagger}_{298}$ (thia) = 53,2 kJ mol^{-1} et $\Delta G^{0\ddagger}_{298}$ (selena) = 46,5 kJ mol^{-1}. On interprète les spectres et les données thermodynamiques en fonction d'un mécanisme qui fait intervenir une interconversion des conformères *syn* avec peu ou pas du tout de participation des conformères *anti* qui présumément dominent dans ce type de molécule.

[Traduit par le journal]

Introduction

The static and dynamic stereochemistry of cyclophanes has been of particular synthetic and theoretical interest for more than 20 years, and has been extensively reviewed (1).

Stereochemical assignments in the larger [*m*,*n*]cyclophanes are not trivial and one cannot necessarily assume that the *anti* conformer is the most stable, as it appears to be for [2,2]metacyclophane, **1** (2). For example, relatively recent papers have shown that **2** is coplanar and isomerizes via a stepped *anti* conformer (3) and that both the thiacyclophane **3** (4) and the selena analogue **4** (5) are *syn* (**3***a*, **4***a*) in the solid state as well as in solution. In these latter cases there appears to be little evidence for participation of the *anti* conformers **3***b*, **4***b*. Newkome and Kawato (3) have pointed out that whenever the metacyclophane bridges possess functionality that restricts the rotational freedom, e.g. CH_2—X—X—CH_2, deviations from the *anti* stepped mode might occur. Moreover very recently the trithia-bridged compound **5** has also been reported to be *syn* (6).

It thus seemed pertinent to examine the bis(disulphide) **6** and the bis(diselenide) **7** in light of this data, and at the same time to undertake a study of the mechanisms and thermodynamics of the dynamic processes occurring in these molecules. Such a study is of additional interest since the literature does not appear to contain any previous comparisons between thia- and selena-cyclophanes.

Results

The tetraselenide, **7**, was prepared as previously described (7). The ^{1}H nmr spectra at 180 K show the methylene protons as an "AB" pattern (with J_{AB} typical of a geminal coupling) and as temperature is increased, the pattern coalesces to a single peak. Our spectra show no significant differences from those published (7) and hence are not reproduced again here. However, these results were previously thought to be produced by a rapid interchange between *syn* and *anti* conformers, with restricted rotation of the methylene bridges, whereas the more detailed analysis of the present paper suggests a new interpretation of the dynamic stereochemistry (see Discussion). Our line-shape analysis also provides full thermodynamic parame-

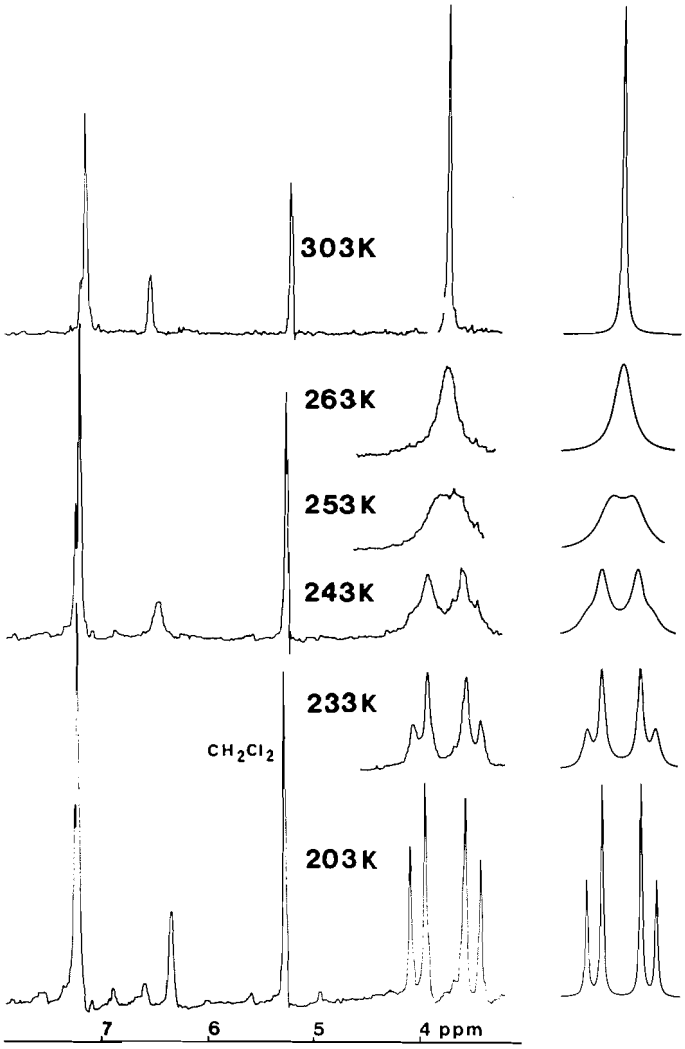

FIG. 1. Temperature variation of the ^{1}H nmr spectrum for **6** in $CDCl_3$–CD_2Cl_2 (1:2) solution. Computer-simulated line shapes for the methylene resonances are shown on the right.

ters where the previous work included only an estimate of $\Delta G^{\ddagger}$ (42.6 kJ mol^{-1}) obtained from measurement of the coalescence temperature (208 K).

The tetrasulphide, **6**, was prepared by the method of Chan and co-workers (8) and had identical properties to those reported previously (2, 9). Sato *et al.* (2) made no mention of temperature dependence of the ^{1}H nmr spectra, but we have found a variation of the methylene proton patterns similar to that described above for the tetraselenide, **7**. Moreover, the resonances due to the internal and external aromatic protons remain essentially unchanged[4] during the changes in the methylene resonances, a clear indication that *syn* $\rightleftharpoons$ *anti* interchange is not occurring. The methylene proton spectra are shown in Fig. 1, together with simulated spectra obtained from the DNMR3 computer programme (10).

Preliminary simulations of spectra in the low temperature ranges established the following parameters:

6: J_{AB} = 12.9 Hz; ν_{AB} = 44.0 Hz; T_2 = 0.13 s
7: J_{AB} = 11.0 Hz; ν_{AB} = 37.4 Hz; T_2 = 0.08 s

[4]Except for a slight broadening of the internal proton resonance at intermediate temperatures, an effect treated in detail in the Discussion.

TABLE 1. Rate constants determined by line-shape analysis at various temperatures for **6** and **7**

6		**7**	
Temperature (K)	Rate (s^{-1})	Temperature (K)	Rate (s^{-1})
203	0.4	183	4
223	4	187	7
233	15	191	12
238	23	195	22
243	40	199	32
245.5	50	203	44
248	60	205	56
250.5	80	207	65
253	95	209	83
255.5	115	213	120
258	140	218	200
263	220	223	300
273	500		
303	4000		

Also, these preliminary results indicated that ν_{AB} does not vary significantly with temperature. The correct choice of ν_{AB} is of course well-defined by the spectra until near the coalescence point, but at higher temperatures the choice of ν_{AB} and rate constant (k) become critically interrelated and the necessity to assume that ν_{AB} is constant places limitations on the ultimate reliability of the rate data. The other important parameter is the choice of transverse relaxation time ($T_2 = 1/(\pi w)$ where w = width at half-height of peaks not broadened by exchange). This parameter choice has a critical effect in the low temperature region, where resolution of J_{AB} is collapsing but the A and B regions are still resolved, but in this region the correct choice is fairly clearly indicated by the low temperature limit spectra. Line width probably decreases as temperature is increased, possibly due to the viscosity broadening at the lower temperatures, but fortunately once A and B begin to coalesce, the choice of T_2 is not critical. Consequently, this probably does not represent a significant limitation on the reliability of the data. Once the preliminary parameters were established, careful matching of observed and calculated spectra for both **6** and **7** yielded the rate constants given in Table 1, and Eyring plots of ln (k/T) against $1/T$ (Fig. 2). produced the following least-squares straight lines:

6: $\ln (k/T) = -(5438)(1/T) + 20.52$
correlation coefficient, R_c = 0.9992
7: $\ln (k/T) = -(4139)(1/T) + 18.89$
correlation coefficient, R_c = 0.9973

Comparison of these equations with the standard transition-state theory equation (11):

$$\ln (k/T) = \frac{-\Delta H^{0\ddagger}}{R} (1/T) + \frac{\Delta S^{0\ddagger}}{R} + \ln (k/h)$$

then enabled $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and hence $\Delta G^{\ddagger}$ to be calculated, and these parameters are summarized in Table 2. This table also includes Arrhenius activation energies, E_a, which were derived from the slopes of Arrhenius plots (ln k against $1/T$) assuming:

$$\ln k = -E_a/R\ (1/T) + \ln A$$

Few line-shape analyses (12) have been made on thiacyclophanes; the simpler $\Delta\nu$, T_c method (13) to obtain $\Delta G^{\ddagger}$ at the coalescence temperature is usually resorted to (see, for

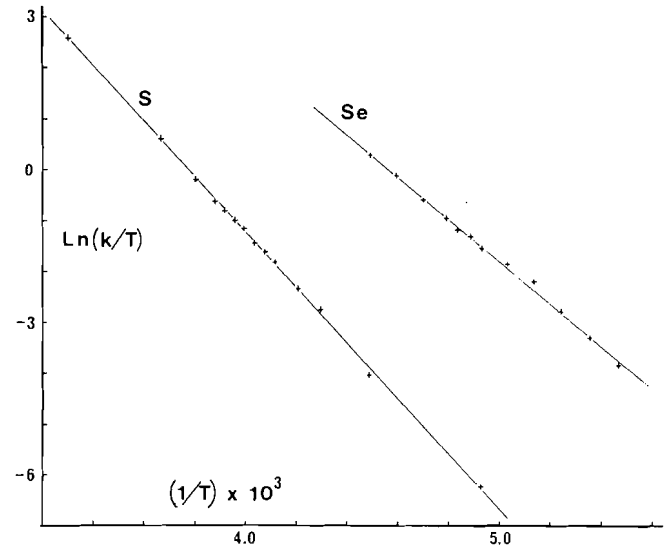

FIG. 2. Plots of ln (k/T) against $1/T$ for **6** (lower plot labelled S) and **7** (upper plot labelled Se).

TABLE 2. Thermodynamic parameters for **6** and **7**

Parameter	**6**	**7**
E_a (kJ mol^{-1})	47.3	36.1
$\Delta H^{0\ddagger}$ (kJ mol^{-1})	45.2	34.4
$\Delta S^{0\ddagger}$ (J K^{-1})	−26.9	−40.5
$\Delta G^{0\ddagger}_{298}$ (kJ mol^{-1})	53.2	46.5

TABLE 3. Comparison of line-shape analysis and T_c method of determining $\Delta G^{\ddagger}_{T_c}$ for **6** and **7**

	6	**7**
$\Delta\nu$ (Hz)	44.0	37.4
T_c (K)	256.0	209.0
$\Delta G^{\ddagger}_{T_c}$ (calcd. as ref. 13) (kJ mol^{-1})	50.6	41.3
$\Delta G^{\ddagger}_{T_c}$ (calcd. from data in Table 2) (kJ mol^{-1})	52.1	42.9

example, ref. 14). The simple method is strictly valid only for coalescing singlets but in the present "AB" case good agreement with line-shape analysis is found (Table 3) even though the coupling constant is relatively large compared to the chemical shift ($\nu_{AB}/J_{AB} \sim 4$).

Discussion

The chemical shifts of the internal aryl hydrogens, H_i, of **6** and **7** are very similar to those found in the known *syn* conformers, **3** and **4**, and are quite different from that in the *anti* conformer, **10** (see Table 4). Also, in the known *anti*-**9**, the outer aryl hydrogens appear as a multiplet, whereas in **3**, **4**, **6**, **7**, and **8** the corresponding resonances are all singlets. This suggests that, of the possible conformers illustrated in Fig. 3, the stable forms of **6** and **7** are more likely to by *syn* conformers such as A–E than *anti* conformers F and G. An *anti*-coplanar conformer H (similar to **2**) could also yield a chemical shift for H_i in the region normally associated with *syn* conformers, since the internal aryl protons are well removed from the shielding region of the other aromatic ring, just as they are in *syn* conformers. However, inspection of models shows that conformer H is unlikely for **6** and **7** because in these molecules (unlike **2**) H_i would strongly interact with the chalcogenide bridges, causing distortion towards the stepped *anti* conformers F and G, moving H_i into the shielding region of the other aromatic ring and towards a more typically "*anti*" chemical shift. Also, we have been unable to differentiate H_A and H_B in **6** (see H) even at 250 MHz, whereas this was possible in a derivative of **2** (3).

Other important considerations are: (a) the preferred C—S—S—C dihedral angle of about 90° (15), which means that conformers such as C probably need not be considered further, and (B) the fact that the low temperature limit spectra for **6** and **7** show only two types of methylene protons, which probably excludes conformers D, E, and G.

Of the remaining possibilities, A and B, the latter seems more likely because of the chemical shift similarity between **3** and **4** and **6** and **7**. In the solid state **3** and **4** both have conformations similar to B in which the heteroatoms are as distant as possible from H_i (4, 5), and in A the surrounding of H_i by the four heteroatoms would be expected to cause a substantial chemical shift (5). Additional support for these conclusions has now been obtained by X-ray crystallography. The subsequent paper (16) reports that in the solid state **6** is indeed basically the *syn* conformer represented by B, except that the aromatic rings are inclined to each other at a dihedral angle of 101° rather than being exactly parallel. The conformation found by X-ray is shown in structure **11**.

The dynamic process now needs to be explained, with B as the preferred conformer. As the temperature is raised, the non-equivalent protons of B (see structure **11**) are rendered equivalent. In order for this to happen (*i*) the aromatic rings must fold outward by rotation of the aromatic–methylene carbon bonds, passing through a coplanar state, and (*ii*) rotation about the X—X bridges must occur to invert these. Whilst these processes could occur together to give a planar intermediate such as H as a "transition state", a less energetic process would seem to be sequential. This might also explain the behaviour of the internal proton resonances (see Fig. 1): for **6**, the H_i singlet is at δ 6.38 at the low temperature limit, broadens slightly at intermediate temperatures, and then sharpens again at the high temperature limit, these changes being accompanied by a slight downfield shift to δ 6.63. This is expected for the above mechanism, with the broadening due to relatively slow rates involving more than one intermediate conformer with approximately coplanar rings. A minor amount of another conformer could also be involved, where signals are lost in the spectrum noise. The evidence is, however, completely convincing that a *syn* ⇌ *anti* exchange is not occurring. Thus the presence of *syn* and *anti* conformers at low temperature, exchanging rapidly at higher temperatures, would require two H_i resonances in the low temperature limit, and a low temperature *syn* form ex-

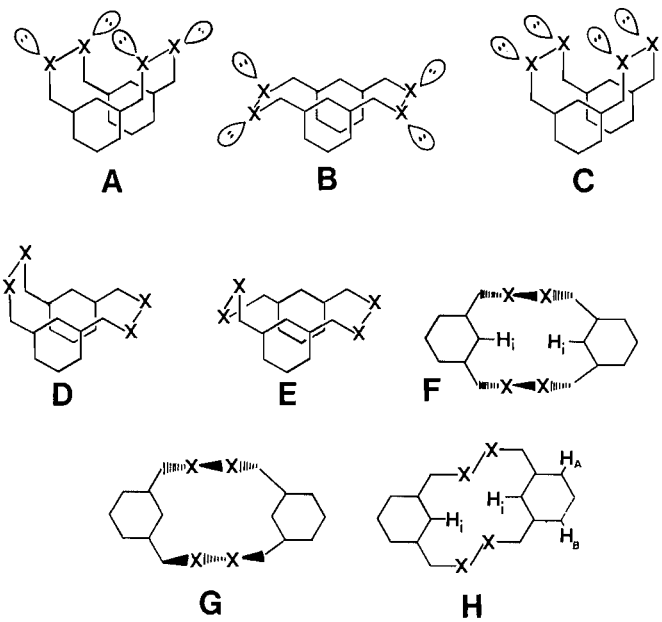

FIG. 3. Probable major conformations of **6** and **7**.

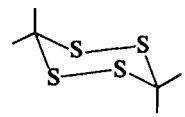
changing with a new *anti* conformer at high temperature would require an upfield shift of H_i towards the typical *anti* value of δ 5.0 (see Table 4).

While it is well known (17) that there are pitfalls in determination of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ by line-shape analysis, we believe the differences observed (Table 2) for **6** and **7** are worthy of some comment. Examination of molecular models suggests no particular strain barriers to any of the above processes, but the various bond rotation processes are expected to occur more easily for the selenaphane relative to the thiaphane because the longer bonds to selenium (18) will result in a general reduction in steric interactions. One particular consequence is that the internal hydrogens will pass each other more easily as the aromatic rings become coplanar in the selenaphane. Thus, the higher enthalpy of activation (Table 2) for **6** relative to **7** is to be expected on this mechanism. The more negative entropy of activation in the selenaphane, **7**, is more difficult to interpret, but it probably also results from the greater "floppiness" produced by the longer bonds, necessitating more molecular ordering to achieve the transition state.

It is also of interest to consider why the analogous compounds **3** and **4**, with monochalcogenide bridges, both show singlet methylene bridge resonances down to <180 K. While this could be due simply to accidental chemical shift equivalence, it seems more likely to us that a dynamic process similar to that described above is operating, but at a faster rate in **3** and **4**. Bushweller *et al.* (19) have pointed out that the presence of adjacent atoms possessing lone pairs leads to substantial enhancement of the barrier to ring inversion in 6-membered rings, including the tetrathiacyclohexane, **12**. Thus, rotation about the X—X bonds in **6** and **7** may represent a significant barrier due to lone pair interactions and rates would be faster in the monochalcogenide bridged species, **3** and **4**. Additionally, the more complex sequences of bond rotations occurring in the dichalcogenide bridge species, **6** and **7**, probably have a statistically lower probability ("pre-exponential effect") and hence the rates are slower. The diselenide bridge compound, **7**, would be faster than the disulphide bridges, **6**, because of the longer Se—Se bond.



12

In conclusion, in these bis(dihetero) [4,4] bridged cyclophanes, *syn* conformers are the more stable low temperature forms. At higher temperatures the methylene bridge protons are rendered equivalent by a dynamic process which probably involves intermediates with approximately coplanar aromatic rings. The *anti* conformers which have usually been described for simple metacyclophanes are not involved to any significant extent.

Experimental

The complexes **6** and **7** were prepared as previously described (7, 8). The ^{1}H nmr spectra were recorded at 90 MHz on a Perkin–Elmer R32B spectrometer. Samples were dissolved in 1:2 $CDCl_3$–CD_2Cl_2 and CH_2Cl_2 was added as internal reference.

Simulated line shapes were calcualted by the DNMR3 computer programme (10) on an IBM 3031 computer and plotted on a Tektronic 4013 graphics screen for preliminary work or a Calcomp 1039 drum-plotter for final data.

The crystal and molecular structure of 2,3,12,13-tetrathia[4,4]metacyclophane[1]

KATHY A. BEVERIDGE, GORDON W. BUSHNELL, AND REGINALD H. MITCHELL[2]
Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received January 24, 1983

KATHY A. BEVERIDGE, GORDON W. BUSHNELL, and REGINALD H. MITCHELL. Can. J. Chem. **61**, 1603 (1983).

Conformations in a variety of cyclophane structures are discussed, as determined by X-ray diffraction in crystals and by ^{1}Hmr in solution. Established nomenclature is brought forward (*syn*/*anti* and *synclinal*/*anticlinal*) and used to deal with an intermediate case which has been examined by both techniques. The crystal and molecular structure of the title compound, $C_{16}H_{16}S_4$, is determined and refined to $R = 0.0497$. The crystal is orthorhombic, space group *Pbca*, $a = 16.593(2)$, $b = 10.018(2)$, $c = 19.407(3)$ Å at 25(2)°C, $Z = 8$, $D_{calc} = 1.386$ g cm^{-3}. The molecular conformation in the crystal is *anticlinal* with a dihedral angle between the benzene rings of 101°. The benzene rings are displaced laterally by 0.727 Å and the sequence of torsion angles is similar in the two bridging chains.

KATHY A. BEVERIDGE, GORDON W. BUSHNELL et REGINALD H. MITCHELL. Can. J. Chem. **61**, 1603 (1983).

On discute des conformations des diverses structures du cyclophane, telles que déterminées par diffraction de rayons-X et par la rmn du ^{1}H en solution. On reprend la nomenclature établie (*syn*/*anti* et *synclinal*/*anticlinal*) et on l'utilise pour traiter un cas intermédiaire que l'on a étudié à l'aide des deux techniques. On a déterminé la structure du crystal et la structure moléculaire du composé mentionné dans le titre, $C_{16}H_{16}S_4$, et on les a affinées jusqu'à une valeur de $R = 0{,}0497$. Le cristal est orthorombique et appartient au groupe d'espace *Pbca*, avec $a = 16{,}593(2)$, $b = 10{,}018(2)$, $c = 19{,}407(3)$ Å à 25°C(2), $Z = 8$, $D_{calc} = 1{,}386$ g cm^{-3}. Dans le cristal, la conformation moléculaire est *anticlinale* avec un angle dièdre de 101° entre les noyaux de benzène. Les noyaux benzéniques sont déplacés latéralement de 0,727 Å et l'ensemble des angles de torsion est identique dans les deux chaînes pontées.

[Traduit par le journal]

Introduction

The preceding paper (1) discusses the variable temperature ^{1}Hmr spectra of the bis-disulphide **1** in comparison to related cyclophanes, in terms of the dynamics of the possible conformational processes occurring in solution in the molecule. This paper reports the structure of **1** in the solid state as determined by X-ray diffraction. This is also of special interest since no crystal structure of a [4,4]metacyclophane appears to have been reported in the literature. Indeed, the literature on crystal structures of the higher cyclophanes is fairly scant; related examples worthy of comment are the octasulphide (paracyclophane) **2** (2) and the tetrasulphide (paracyclophane) metal complex **3** (3), as well as the [4,2]cyclophane **4** (4) and [3,3]cyclophanes **5** (4) and **6** (5).

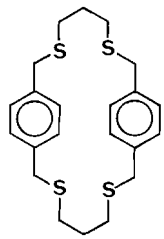
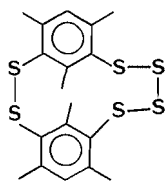
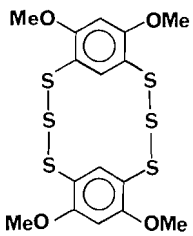
2



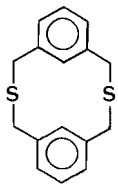
3



4



5



6

Of necessity the benzene rings of the two paracyclophanes **2** and **3** are *syn*, however, metacyclophanes can exist in *syn* or *anti* conformers. In some cases, e.g., **7** and **8**, both conformers are capable of independent existence and can be isolated (6). In the case of **6** only one state, probably a rapidly averaging mixture of conformers, is found in solution, while in the solid state **6** is found as the *syn* conformer (5). Likewise **5** was found in the solid state to be *syn* (4), whereas the [4,2]cyclophane **4** was found to be *anti* (4). While no crystal structure data is available on the oxa[4,4]cyclophane **9**, solution ^{1}Hmr spectroscopic data indicate the *anti*-coplanar structure to be pre-

ferred (7). As discussed in the preceding paper, [1]Hmr did not clearly distinguish between a *syn* or an *anti* relatively-extended conformer for **1**. This information was thus sought for **1** by determination of the crystal structure.

syn, *anti* Nomenclature in phanes

Despite the fact that the nomenclature of phanes has been described in detail (8) and the stereochemistry of phanes has been reviewed (9), almost nothing has been said about the use of *syn* and *anti* to describe (6) compounds such as **8** and **7**. Indeed, in these particular cases the use of the terms *syn* and *anti* referring to the relative orientations of the benzene rings is quite clear and leads to no confusion. Although the original assignments of structure of, for example, **7** and **8**, were made by [1]Hmr (6, 10), subsequent X-ray crystal studies have borne them out (11). A problem arises, however, with higher cyclophanes which can adopt conformations in between these two extremes. Consider the three conformers depicted by **A**, **B** and

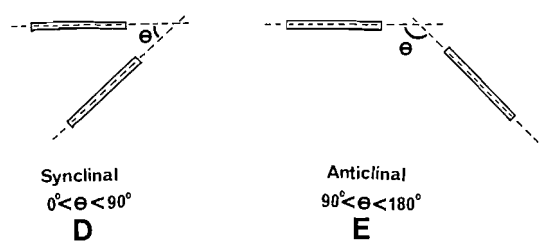
*Estimated standard deviations are given in parentheses.

C. Assignment of structure by ^{1}Hmr would lead to both **A** and **B** being referred to as *syn* conformers, since in either case the internal protons would not be exceptionally shielded by the opposite benzene ring, i.e., would appear at δ 6.2–7.2. Only when the angle between the planes of the benzene rings is sufficiently obtuse and the two substituents have passed each other is it that the substituent of one ring extends into the strongly shielded region (12) of the opposite ring (δ 4.0–5.5). Only in this case would the conformer likely be regarded as *anti*. Clearly the angle required to achieve this will vary for various substituents and is somewhat subjective depending upon how shielded the author feels the internal substituents are. For example, in the previous paper we have concluded that **1** is a *syn* conformer on the basis of ^{1}H nmr data coupled with the X-ray data determined below. In fact, the solid state **1** corresponds most closely to conformer **B** and thus from a crystallographer's viewpoint would be considered an *anti*-cyclophane. We thus here propose a solution to this dilemma, which might be useful in future studies of the higher cyclophanes, and makes use of the terms *synclinal* (*sc*) and *anticlinal* (*ac*) already established in organic stereochemistry nomenclature (13).

If the dihedral angle between the two benzene ring planes of the phane is $0 < \theta \leq 90°$, we suggest the conformer be known as *synclinal*, **D**, and if $90 < \theta < 180°$, the conformer be known



as *anticlinal*, **E**. As will be seen below, **1** then becomes an *anticlinal* conformer.

Experimental

X-ray measurements

A small colourless block-shaped crystal (0.18 × 0.28 × 0.21 mm) was mounted along the *b*-axis on a glass fibre and subjected to Weissenberg and precession photography using CuK_α radiation. The crystal was then transferred to a Picker 4-circle diffractometer using Zr-filtered MoK_α radiation and automated with a PDP-11/10 computer. The unit cell was refined by least squares from the 2θ values of 8 pairs of reflections in the range 19–35°. The crystal data are:

$C_{16}H_{16}S_4$ Mol. Wt. 336.54

Orthorhombic, space group *Pbca* (No. 61), a = 16.593(2), b = 10.018(2), c = 19.407(3) Å, V_{cell} = 3226(1) Å^3, T = 25(2)°C, Z = 8 molecules per cell, D_{meas} = 1.385 g cm^{-3}, D_{calc} = 1.386 g cm^{-3} (flotation in CCl_4/*m*-xylene), μ = 5.38 cm^{-1} (λ = 0.71069 Å), crystal shape by face indices and perpendicular distances to a central origin: ±(101), 0.090 mm; ±(10$\bar{1}$), 0.1005 mm; ±(010), 0.141 mm. Intensity measurements were by a step scan of 200 steps of 0.01° in 2θ, counting for 0.25 s per step, with a background counting time of 25 s at each end of the scan. One octant of the reciprocal space sphere was measured out to 2θ = 40°. Three standard reflections, 400, 020, 006, preceded each batch of 50 measurements and were used in the scaling of the data. The stability of the standard counts was excellent. Lorentz and polarization corrections were applied to 1759 measurements and those for which $I < \sigma(I)$ were rejected leaving 1229 reflections in the file. Absorption corrections were not necessary, and were not applied.

Structure determination

The crystallographic program SHELX-76 kindly supplied by Dr G. Sheldrick was used for this work (14). Atomic scattering factors were for the neutral atoms (15), and the correction for anomalous dispersion was included (16). The structure was solved by direct methods and refined by the method of least squares minimizing $\sum w\Delta^2$ where $\Delta = ||F_o| - |F_c||$, and $w = 1/(\sigma^2(F) + 0.001F^2)$. The refinement proceeded normally and all atoms including the hydrogen atoms were found. The thermal vibration was treated isotropically for hydrogen and anisotropically for the heavier atoms. 245 parameters were determined from 1229 measurements. The convergence was satisfactory with a maximum shift/esd of 0.20 and the final residuals were R =

†$\chi^{2} = \sum_{i} p_i^{2}/\sigma^{2}(p_i)$ summing over all atoms, i, in the plane.

0.0497, $R_w = \sum\sqrt{w}\Delta/\sum\sqrt{w}F_o = 0.0456$, $R_g = \sqrt{(\sum w\Delta^{2}/\sum wF_o^{2})} = 0.0506$. The final difference map had a maximum of 0.25 e Å^{-3} and a minimum of −0.33 e Å^{-3}. The structure factor tables have been deposited together with the temperature parameters, the bond lengths and angles involving the hydrogen atoms, and selected intermolecular distances.[3]

Discussion

The fractional atomic coordinates and isotropic temperature parameters are given in Table 1. Figure 1 is an ORTEP drawing of the molecule. Table 2 contains the bond lengths, all of which are quite normal. The S—S bond lengths are accurate enough to make comparison with other literature values interesting and for **1** are very similar to those of S1—S2 of **2** (2) and are approximately 0.03 Å shorter than those of the more strained examples **4** and **5** (4). The C—S bonds in the disulphide bridges of **1** are only marginally longer than those of **6** (5) or **8** (11), and are similar to other C—S values (17).

Bond angles are given in Table 3, and here we begin to see in the sulphur angles an approximate symmetry in the bridging chains, with the relationships being S(1) to S(4) and S(2) to S(3). The angles at methylene carbon atoms C(1) and C(17) are

similar as are those of C(7) and C(11). The angles in Table 3(c) show that a distinction can be made between those external to the 14-ring having a mean value of 122.3(3)° and those in the 14-ring with a mean value of 119.4(3)°. In Table 3(d) the benzene ring angles are just above 120° (mean = 121.9(3)°) at the central carbon atoms C(8), C(18), C(4), C(14) and a little less at sides (mean 119.0(2)°). This small effect has been noted in other metacyclophanes (5, 11).

The results of the mean plane and torsion angle calculations are given in Table 4. The benzene rings are planar to within the accuracy of this structure determination. The angle between the normals to the planes is 79°, and θ in **E** is thus 101°. Since this angle is >90°, the conformer is best regarded as *anticlinal*, despite the fact that from a ^{1}Hmr viewpoint (as discussed above) it might be regarded as *syn*. In contrast, the angle θ for **6** is 20.6° and for **8** is 10.3°, clearly both are *syn* or *synclinal* conformers.

It is interesting that planes 4 and 5 are nearly coincident (see constants $A-D$, and the dihedral angle of 3.5°) and very close to being at 90° to plane 3. This suggests a convenient reference system for the molecule, without implying coplanar sets of atoms. In the case of plane 3 the displacements of the atoms from the mean plane given in Table 4(c) are quite small, and considering that the atoms defining this plane are widely spaced, this suggests only small angular rotations about axes perpendicular to the planes of the benzene rings. The bridging chains restrict such rotation. The perpendicular line segment between the skew lines C(4)—C(8) and C(14)—C(18) was calculated to be 0.727 Å, and this is a reasonable indication of the lateral displacement of one benzene ring relative to the other. The displacements of the methylene carbon atoms from the benzene ring planes are toward the same side as the sulphur atoms. The perpendicular distances are asymmetric across each benzene ring individually, and show an approximate symmetry relating C(1) to C(17) and C(7) to C(11). The torsion angles along the bridging chains are arranged in Table 4(e) to show the approximate symmetry. The C—C—C—S torsion angles are 90–98°, close to a right angle. The S—S lone pair repulsion forces the C—S—S—C torsion angle to be 80–84°, consistent with the range 74–110° found (18) for other disulphides. The S—S—C—C angles are 11–14° below the idealized values of 60° and 180°.

Conclusions

In the solid state, **1** exists as an *anticlinal*-conformer, with the angle θ of **E** (between the benzene ring planes) being 101°. This is sufficiently far from 180° to make the interpretation of solution ^{1}Hmr data more difficult, in that the internal hydrogen atoms are not shielded as in most *anti*-conformers of small bridge metacyclophanes. The terms *synclinal* and *anticlinal* are proposed to describe metacyclophane conformations.

An investigation based on X-ray fiber diffraction and conformational analysis methods has provided a proposed chain conformation and crystalline structure for lichenan, a poly β(1→3) cellotriose. The analysis of the fiber diagram of the hydrated form of lichenan led to a trigonal unit cell of dimension $a = b = 9.92$ Å and c (fiber axis) = 42.03 Å, with cellotriose as the asymmetric unit and six cellotriose residues per unit cell. A unit cell of the dry form is also trigonal with $a = b = 9.36$ Å and $c = 42.03$ Å. A right-handed threefold helix made up of three cellotriose residues was derived from a comparison of experimental helical parameters with isoenenergy conformational maps made by plotting dihedral angles (ϕ, ψ) at the β(1→3) linkage. A virtual bond approach was also used to arrive at the proposed conformation which is stabilized by intramolecular hydrogen bonds between all carbohydrate units. The refinement of geometrical and packing parameters produced results consistent with an antiparallel arrangement of the two chains corresponding to a space group symmetry of $P3_1$. The naturally occurring copolysaccharides known as mixed (1→3) and (1→4) β-glucans from the cell walls of barley endosperm have been shown to crystallize in the same fashion as lichenan.

I. TVAROSKA, K. OGAWA, Y. DESLANDES et R. H. MARCHESSAULT. Can. J. Chem. **61**, 1608 (1983).

Une étude basée sur la diffraction de rayons-X de la fibre et sur les méthodes d'analyse conformationnelle permet de proposer une conformation de la chaîne et de la structure cristalline du lichénane, un poly β cellotriose (1→3). L'analyse du diagramme de fibre de la forme hydratée du lichénane conduit à une maille élémentaire trigonale de dimension $a = b = 9{,}92$ Å et c (axe de la fibre) = 42,03 Å avec le cellotriose comme unité asymétrique et 6 unités cellotriose par maille élémentaire. Une maille élémentaire de la forme non hydratée est également trigonale avec $a = b = 9.36$ Å et $c = 42{,}03$ Å. On a déduit une hélice ternaire droite comprenant trois unités cellotriose à partir d'une comparaison des paramètres hélicoidaux expérimentaux avec les cartes conformationnelles d'isoénergie obtenues en traçant les angles dièdres (ϕ, ψ) au niveau du lien β(1→3). On a également utilisé une approche de liaison virtuelle pour arriver à la conformation proposée que se stabilise par des liaisons hydrogènes intramoléculaires entre toutes les unités de carbohydrate. L'amélioration des paramètres géométriques et des paramètres d'entassement donne des résultats qui s'accordent avec un arrangement anti-parallèle des deux chaînes correspondant au groupe d'espace de symétrie $P3_1$. On montre que les copolysaccharides naturels, connus comme étant des mélanges de β glucanes (1→3) et (1→4) provenant des parois des cellules de l'endosperme de l'orge, cristallisent comme le lichénane.

Introduction

The crystalline structure and microfibrillar morphology of cellulose has been extensively investgated. While this β(1→4) linked glucan is universally acknowledged as the dominant skeletal material of the plant world, it is now obvious that other glycans have important structural roles in the biological world (1). In algal (2) and fungal cell walls (3) the β(1→3) linkage is associated with a helical structure capable of wide variations in flexibility (4). The ultimate in structural rigidity of β(1→3) linked glycans is a triple helical structure (2, 5–7). It is of considerable interest, therefore, to examine a regular copolysaccharide containing both the β(1→4) and β(1→3) linkage such as found in lichenan (Fig. 1). Structural studies (8) on the product from Iceland Moss have established an ideal structure for lichenan as a poly β(1→3) cellotriose. It is to be noted that this strutural perturbation of cellulose leads to a drastically modified solubility, e.g. lichenan is soluble in water and dimethyl sulfoxide (DMSO).

Although it is sometimes referred to as a white amorphous powder, there is a published record (9) of X-ray diffraction from lichenan as early as 1930. At that time it was recorded as a powder pattern and interpretated as similar to β-cellulose, an early terminology for regenerated cellulose (10). As will be seen below, the analogy between lichenan and regenerated cellulose was valid although it would have been more precise to refer to "water" cellulose, the rare hydrate of cellulose which is found in freshly regenerated material (11). A fiber diagram would have revealed that the two equatorial reflections of "water" cellulose, as found in lichenan fibers, are on the first layer line rather than the equator. This observation had an important influence in establishing the structure which we will propose.

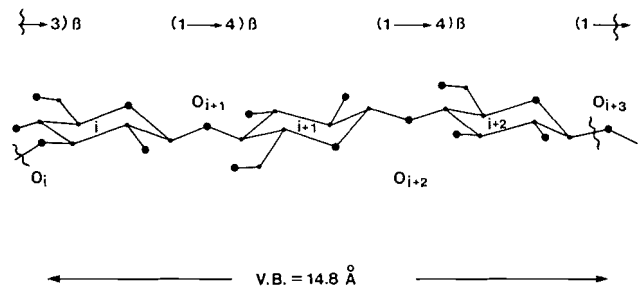

FIG. 1. A schematic representation of the lichenan repeating unit; the virtual bond length (V.B. = 14.8 Å) corresponding to the distance between O_{i+3} and O_i is indicated.

Although the ideal structure (12) for lichenan is a poly β(1→3) cellotriose the material is considered different from the general category of mixed (1→3) ,and (1→4) β-glucans which generally are thought to have a statistical distribution of linkages with predominance of the (1→4) linkage. Thus β-glucans are substitutionally perturbed cellulose structures with a ratio of

(1→3) to (1→4) linkages of about 1:2.5. Accordingly, in this study, the crystallization properties deduced for lichenan were compared to those of a typical barley glucan.

Experimental

Samples

The starting material was Iceland Moss (*Cetraria islandica*) purchased from Pennick Co., New York; the purification procedure followed was that of Perlin and Suzuki (8). The samples were characterized by ^1H and ^{13}C nmr which showed that the sample corresponded to a regular copolysaccharide of cellotriose units linked by β(1→3) linkages (12) (Fig. 1).

A second sample of lichenan was prepared according to the same procedure at a later date. This sample was purchased from Sigma Chemical (Prod. No. L-6133) and the ratio of (1→4) to (1→3) linkages was 1.5 to 1.6 as measured by Professor M. Takagi (Osaka Prefecture University) using methylation analysis and the alkaline OPD method (13).

A sample of barley glucan from Biocon (Australia) Pty. Ltd., batch NO. 80147, was kindly provided by Prof. B. A. Stone of La Trobe University. This sample was reported to have a molecular weight in the range (14) of 150 000. Enzymatic degradation (14) methods provided a measure of the (1→4) to (1→3) ratio which was 2.33, and analysis of the enzymatically derived sequence information supports the concept of a statistical structure (14). This sample was studied by X-ray diffraction methods in the same way as lichenan.

Film preparation and orientation

An attempt to prepare a film by evaporation of a 6% aqueous solution of lichenan on a clean glass plate yielded a noncontinuous film. A continuous film was prepared by evaporation (vacuum oven at 50°C, 3 h) of a 10% DMSO solution which gave a brown-colored, flexible film.

The DMSO cast film was stretched in 80% (vol.%) isopropanol − H_2O at room temperature by loading the film with an appropriate weight. The stretched film (2.25 times), was subsequently air-dried under tension. Then the film kept under tension was annealed in 75% methanol − H_2O at 173°C in a sealed bomb. After this treatment the film was washed in methanol and air-dried.

Efforts to increase crystallinity by mild hydrolysis treatment (H_2O or aqueous 0.001 to 0.1 *N* HCl was painted on the film at room temperature) were of no avail. These studies, however, allowed us to establish that there was no isopropanol or methanol trapped in the films.

All X-ray data on an oriented annealed film were recorded after the film was conditioned at least 24 hours at 98% relative humidity. Density of such films was measured by flotation in a toluene − carbon tetrachloride density gradient column. X-ray studies on the dry polymorph were performed by drying the oriented film in vacuum over P_2O_5 for at least 24 hours.

Method of conformational analysis

The coordinates of the various atoms in the cellotriose unit (henceforth the "residue") which is our repeating unit (8, 12) (Fig. 1), have been calculated by using the bond distances and bond and torsional angles from the crystal structure of cellobiose (15). The coordinates of the residue were obtained by covalently joining two cellobiose units "head-to-tail" with all glycosidic torsional angles (ϕ_i ψ_i) being made identical. The ultimate reducing end glucose was then discarded, leaving only the coordinates of a cellotriose starting residue with end-to-end distance or virtual bond (V. B.), $O_i(3)\cdots O_{i+3}$ (3), of 14.8 Å. This value is about 2.5% lower than the maximum conformationally allowed end-to-end distance, which would be 15.2 Å. Another, more extended model of cellotriose with a β(1→4) glycosidic angle $\tau = 120°$ and an end-to-end distance of 15.05 Å has been considered also. The structure of the residue was kept constant in the conformational analysis part of the calculations, including an intramolecular hydrogen bond between O(3) and O(5) of contiguous residues. However, during the crystal structure refinement the program (cf. below) allowed adjustment of the residue geometry.

The unpublished proposal of the IUPAC−IUB Subcommission on Polysaccharide Nomenclature[5] has been used for the notation of the atoms and conventions of torsional angles in this paper.

For the two-dimensional conformational energy map the glycosidic torsional angles are $\phi = \theta[H_{i+2}(1), C_{i+2}(1), O_{i+3}(3)]$ and $\psi = \theta[C_{i+2}(1) O_{i+3}(3), O_{i+3}(3), C_{i+3}(3), H_{i+3}(3)]$; the potential energy has been computed by taking into account the following contributions; van der Waals E_{nb}, torsional E_{tors}, hydrogen bond E_{hb}, and glycosidic valence angle, $\tau_L = \tau(C_{i+2}(1), O_{i+3}(3), C_{i+3}(3)]$, deformation E_{def}. The total potential energy E_{tot} of a given conformation is expressed as a sum of these contributions.

$$E_{tot} = E_{nb} + E_{tors} + E_{hb} + E_{def}$$

The van der Waals interactions between nonbonded atoms were evaluated using Lennard−Jones (6−12) potential functions, with the parameters proposed by Scott and Scheraga (17, 18). Threefold intrinsic torsional potential expressions were used for rotations around the $C_{i+2}(1)$—$O_{i+3}(3)$ and $O_{i+3}(3)$—$C_{i+3}(3)$ bonds, with barriers of 0.899 and 2.7 kcal mol^{-1} respectively (19, 20). Hydrogen bond energies were calculated by an empirical (21) inverse third power expression $E_{hb} = -55.0/R^3$ where R is the distance between oxygen atoms and should lie between 2.6 Å and 3.2 Å. The energy term for valence angle deformation at the glycosidic angle has been taken as harmonic in the displacement from a reference (strain-free) value τ_0.

$$E_{def}(\tau_L) = \tfrac{1}{2} k_\tau (\tau_L - \tau_0)^2$$

Both τ_0 and the force constant k_τ has been treated as constant throughout the calculation with values 109.28 deg and 0.0487 kcal mol^{-1} deg^{-2}, respectively.

Models of lichenan having left or right chirality, the appropriate helix symmetry, n, and advance per residue, h, with the above defined geometry were generated from a virtual bond analysis (22). The virtual bond method has allowed us to examine possible relative orientations of contiguous residues with the required helical parameters imposed by the chosen n and h. The virtual bond in this case is defined as the vector joining bridge-atoms at the ends of a cellotriose unit (Fig. 1). Different conformations were generated by a rotation (δ) about the virtual bond. The starting position ($\delta = 0°$) has been chosen so as to place the atom C(1) in the xy plane. The step interval for δ rotation was 1°.

For determining the position of the chains in the unit cell we have tested suitable models for the crystal structure of lichenan by a packing analysis approach. Each model was packed into the unit cell while minimizing the function (23, 24).

$$Y = \sum_{i=1}^{I} \frac{r_i - r_{0i}^{\,2}}{SD_i^{r}} + \sum_{j=1}^{J} \frac{\theta_j - \theta_{0j}^{\,2}}{SD_j^{\theta}} + \sum_{k=1}^{K} \frac{\Phi_k - \Phi_{0k}^{\,2}}{SD_k^{\Phi}} + \frac{1}{W^2} \sum_{\substack{l=1 \\ m=2}}^{L,M} \omega_{lm} (d_{lm} - d_{0lm})^2$$

where r_i are bond lengths, θ_i bond angles, Φ_k conformational angles, and d_{lm} nonbonded distances for the i, j, k, l, m corresponding variables in the monomer residue, while r_{0i}, θ_{0j}, Φ_{0k} and SD_i^r, SD_j^θ, SD_k^Φ are their standard values and standard deviations, respectively, obtained from the known crystal structure of cellobiose (15) and ω_{lm} are scaling factors (24). The d_{0lm} were previously determined by Zugenmaier and Sarko from packing of known crystal structures of carbohydrates (24).

patterns of the hydrate form, e.g. the same sample at 10% relative humidity (R.H.) compared to 98% was less oriented and slightly less crystalline. There was evidence of the influence of H_2O on the pattern (or hydration of the "continuous" type) since the base plane of the unit cell increases steadily with relative humidity. Table 1 shows the variation of the strongest equatorial spacing (d_{100}) with relative humidity.

The diffraction pattern (Fig. 2) shows a strong meridional reflection with a spacing of 4.67 Å, which we have chosen to interpret as the average advance per glucose, hence 14.01 Å per cellotriose in the chain. The single strong equatorial reflection present had a spacing of 8.59 Å, which is similar to the strongest equatorial spacing in the "water" cellulose unit cells described by Warwicker and Wright (11). The fiber diagram was indexed (cf. Table 2) on the basis of a trigonal unit cell with $a = b = 9.92$ Å and c (fiber axis) = 42.03 Å. The measured density of 1.48 g/cm^3 is consistent with a unit cell containing six cellotriose residues and eighteen molecules of water, i.e. about one water molecule per glucose unit.

One very weak reflection on the equator (d-spacing = 5.76 Å) could not be indexed with the trigonal unit cell; it required an orthorhombic unit cell, obtained by enlarging the trigonal cell to twice its volume. This very weak reflection was ignored in the study.

Additional studies on oriented film samples subsequent to the above analysis have confirmed and amplified the above experimental data. For example, an annealed lichenan film of the second sample (Sigma) gave similar diffraction patterns to those observed with the first sample. But when the film was X-rayed in vacuum, it clearly showed additional meridional reflections, (003) and (006), with spacings of 14.0 and 7.0 Å, respectively. A reflection at 8.5 Å may possibly be a (005) or a (105) reflection. This confirms the use of the cellotriose unit as asymmetric residue in this analysis. The unit cell of the dry form is trigonal with $a = b = 9.36$ Å and $c = 42.03$ Å.

The following structure refinement is based on the experimental data from Fig. 2*a*. At this point it should be mentioned that barley glucan yielded the same kind of X-ray fiber diffraction pattern as lichenan. In general a lower degree of lateral order was present.

Energy contour maps

To obtain information on the conformational space accessible for different τ_L, energy contour maps for these angles were calculated. The maps were obtained by fixing τ_L at different values: 110.0°, 115.8°, 117.5°, and 122.0°, respectively. The energy was computed over 10° intervals (in proximity of the minima over 3° intervals) of ϕ and ψ. For simplicity, the energy contours have been drawn only for the energy values 3.0, 6.0, 9.0, and 12.0 kcal/mol above the absolute minimum energy. The helical parameters n and h were also calculated and contours of *iso-n* (for $n = 2.5$, 3, 4, and 5) and *iso-h* (for $h = \pm 13.0$, ± 13.5, ± 14.0, and ± 14.5 Å) were superposed on energy contour maps. Conformational energy maps for poly

β(1→3) cellotriose are shown in Figs. 3–5. While the overall features of the maps for different τ_L are similar, differences in detail are found. Only a small percentage of the conformational space lies within the 6 kcal/mol relative energy contour. The maps demonstrate how this area increases with glycosidic angle τ_L. In all cases, this area can be divided into three regions surrounding the individual minimum energy conformation. The lowest energy regions are always in the neighborhood of the conformations (38.0, 163.0), (38.0, −7.0), and (168.0, 13.0). An interesting finding from these maps is that for $\tau_L = 110.0°$ these regions are separated by a surface with relative energy higher than 12 kcal/mol. However, for $\tau = 115.8°$ two minima, and for $\tau_L > 117.5$ all three minima are connected by a 9 kcal/mol contour, which means that the transition barrier between these minima is lower than 9 kcal/mol. The maps also show that the enlargement of the angle τ_L causes a significant change in the position of the absolute minimum energy conformation (marked by X). This is a reflection of the flexibility introduced by the β(1→3) linkage into the cellulose backbone.

The influence of the value of the glycosidic angle on the magnitude of the individual terms in the total energy and number of contacts for the above described three conformations is shown in Table 3. Increasing τ_L from 110.0 to 122.0° increases the contribution of the valence angle deformation energy term from 0.01 kcal/mol to 7.68 kcal/mol which is one of the reasons for a different value of the total energy within the same conformation.

For a given τ_L one of the most important factors for a stabilization of the conformation is the presence of intramolecular hydrogen bonds. Five types of intramolecular hydrogen bonds between contiguous residues were possible: $O_{i+2}(5)\cdots O_{i+3}(2)$; $O_{i+2}(5)\cdots O_{i+3}(4)$; $O_{i+2}(2)\cdots O_{i+3}(4)$; $O_{i+2}(6)\cdots O_{i+3}(2)$; and $O_{i+2}(6)\cdots O_{i+3}(4)$, respectively. The influence of this energy term on the total energy can be seen in Table 3.

The detailed analysis of all contributions to the nonbonding energy term shows, as one could expect, that the most important ones are from interactions between the i+2 and the i+3 glucose unit, i.e. across the β(1→3) linkage. We can, therefore, compare our results with published data for laminaribiose (β(1→3) glucan) (25, 26), and indeed the shape of the preferred area for poly(β(1→3) cellotriose) is in general agreement with the map obtained by Sathyanarayan and Rao (25) although a preferred area at (38.0°, 163.0°) was not present in their map. These authors also considered only four types of intramolecular hydrogen bonds. However, from our calculation, it follows that the geometrical arrangement for the oxygen atom $O_{i+2}(6)$ in some conformations allows hydrogen atoms of $O_{i+3}(2)$ or $O_{i+3}(4)$ hydroxyls to form a hydrogen bond with the $O_{i+2}(6)$ atom. The crystal and molecular structure of laminaribiose proposed by Takeda *et al.* (26) shows that its conformation can be described as (27.9, −37.5°) with a glycosidic angle of 118.2°. The conformation lies in the low energy region (Figs. 3–5 and Table 3) and is stabilized by an intramolecular hydrogen bond between the O(4′) and O(5) atoms with a distance of 2.78 Å between oxygens.

Helical parameter maps superposed on the conformational energy contours show that a right-handed helix is preferred and conformations corresponding to helical structures of this chirality are mostly in proximity to one (38.0, −7.0) of the three minimum energy conformations in Figs. 3, 4 and 5. For instance, for a glycosidic angle $\tau_L = 115.8°$ (Fig. 4), the 3_1 helix corresponds to two points in φ, ψ conformational space: (69.0,

3.0) and (125.0, −59.0). Only the first of them, however, lies in the low energy region. The absence of the *iso-n* contour corresponding to a twofold helix shows that there is no such conformation for poly(β(1→3) cellotriose) allowed within the present geometry of the residue and angular interval $110° \leq \tau_L \leq 122°$.

Virtual bond method

From the meridional reflection (d = 4.67 Å) it follows that helix repeat distances equal to the following values: 28.02 Å, 70.05 Å, 42.03 Å, 98.07 Å, and 64.04 Å correspond, respectively, to helices: $\pm 2_1$, $\pm 5_2$, $\pm 3_1$, $\pm 7_2$, and $\pm 4_1$. All these helices have been analyzed by the virtual bond method. The results show that the existence of the lichenan chain in a twofold helix with repeat distance 28.02 Å was possible only for a glycosidic angle $\tau_L \geq 136°$. If another, more extended, type of geometry for the cellotriose unit in lichenan is used (with virtual bond length equal to 15.04 Å), the condition for a 2_1 helix is achieved when τ_L is 128.0° or greater. This limitation justifies elimination of the twofold helix conformation with repeat distance 28.02 Å from further consideration. The $\pm 5_2$, $\pm 7_2$, and $\pm 4_1$ helices were also eliminated based on energy calculations. For a right-handed threefold helix the allowed conformations of the chain with τ_L in the range 110°−122° are found for a rotation about the virtual bond in the degree interval $194° \leq \delta \leq 356°$ and correspond respectively to the conformational subspace with $-62° \leq \phi \leq 125°$ and $-62° \leq \psi \leq 62°$. From these conformations, however, only a few in the range $301° \leq \delta \leq 342°$ are possible because of energy considerations. The more stable 3_1 helix (right-handed) of lichenan is at $\delta = 328°$ which corresponds to $\tau_L = 115.8°$, $\phi = 72.5°$, and $\psi = 1.5°$ with helix energy $E_{hel} = -1.6$ kcal/mol. In this conformation the 3_1 helix is stabilized by an intramolecular hydrogen bond: $O_{i+2}(5) \cdots O_{i+3}(4)$. The distance between these oxygen atoms is 2.74 Å and the corresponding hydrogen bond energy is 2.26 kcal/mol. The coordinates of the asymmetric unit (cellotriose) are reported in Table 4.

Crystal structure refinement of lichenan

From the X-ray diffraction pattern and the conformational analysis it follows that lichenan has two right-handed threefold helical chains in its trigonal unit cell. The X-ray data are consistent with six trigonal space groups: $P3_1$, $P3_121$, $P3_2$, $P3_221$, $P3_112$, and $P3_212$. Two of the possibilities, $P3_212$ and $P3_112$, may be rejected for stereochemical reasons as they would require antiparallel (coaxial) double helices, which is not sterically possible. From the virtual bond analysis it follows that left-handed helices can be eliminated and therefore two other space groups, $P3_2$ and $P3_221$, can be rejected also. The final choice of space group is between $P3_1$ and $P3_121$. In both remaining space groups, $P3_1$ and $P3_121$, the two lichenan chains are located with helix axis coaxial with the threefold screw axis parallel to c at ($x_f = 1/3$, $y_f = 2/3$) and ($x_f = 2/3$, $y_f = 1/3$). In respect to this, three different models of the crystal structure are possible: in the $P3_1$ space group two different models with two independent parallel or antiparallel chains, in the $P3_121$ case two antiparallel chains with a twofold screw axis relating them along the short diagonal of the unit cell. From conformational and X-ray data it is impossible to distinguish between these three choices, hence each model was studied separately by varying the usual packing parameters (the relative axial rotation and translation of both chains) to find the most probable model based on energy considerations.

The foregoing conformational analysis has provided the most probable single chain conformation and this has been used as a starting point in the refinement of the crystal structure. At first, only rotation and translation for parallel and antiparallel chain models of the lichenan structure were considered. Once the minimum packing energy for these variables was found, other variables (e.g. ϕ, ψ, τ, side group rotation, glycosidic bond length) connected with the residue geometry were taken

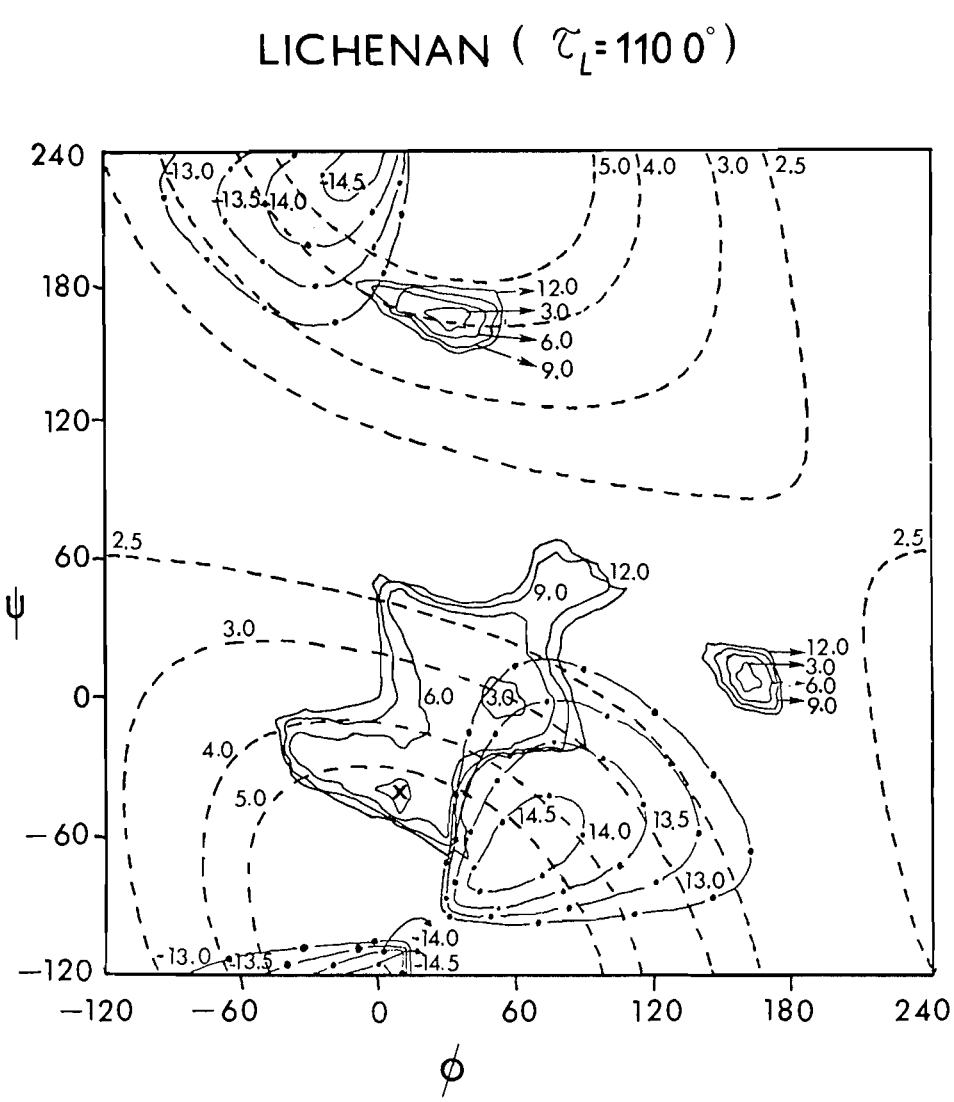

FIG. 3. A ϕ, ψ conformational energy map for $\beta(1\rightarrow3)$ cellotriose. The isoenergy contours are in kcal/mol over the lowest energy conformation (denoted by X); the curves of *iso-h* (-·-·-·) and *iso-n* (---) are superposed on energy contours. Left handed helices are indicated by $-h$. Glycosidic angle τ_L = 110.0°.

into consideration.

For the model with two antiparallel chains related by a two-fold screw symmetry operation (space group $P3_121$) we always found some unacceptably short intermolecular contacts. The removal of this restriction during the refinement always resulted in a change of position for one of the chains and yielded an energetically more acceptable packing arrangement. The energy based preference of antiparallel chains for the less symmetrical space group, $P3_1$, in comparison to the more symmetrical $P3_121$ led to the conclusion that the most probable space group is $P3_1$. The final values of the geometrical parameters which developed in refinement of the two most probable models of the crystal structures of lichenan, one for antiparallel and one for parallel chains, are shown in Table 5 together with values of the starting model of the chain. Both models have no short contacts between different chains and their interchain energy factors are very similar, 3.65 and 5.86, respectively. However, there is a large difference in the internal helical stability of the models. The helix energies (E_{hel}) are, respectively, −1.48 kcal/mol and 16.69 kcal/mol, thus the antiparallel model is considerably favored. The antiparallel model has two types of intramolecular hydrogen bonds: two between individual glucose units in the cellotriose residue [$O_i(5)\cdots O_{i+1}(3)$; $O_{i+1}(5)\cdots O_{i+2}(3)$] and one between the cellotriose residues across the $\beta(1\rightarrow3)$ linkage [$O_{i+2}(5)\cdots O_{i+3}(4)$]. Very weak intermolecular hydrogen bonds, $O_i(6)\cdots O_i(6)$ (r = 3.5 Å), between different chains were detected.

Since only the base plane of the unit cell underwent change as a function of relative humidity (Table 1) and c (fiber axis) is the same in both unit cells, it is suggested that the molecular conformation is not affected by water and we assume that water molecules are located between the lichenan chains in the corners of the unit cell as in hydrate cellulose (11) and $\beta(1\rightarrow4)$ xylan (27).

The proposed model of the lichenan crystal structure has been determined by refinement of only 17 variables describing the geometry of the helical chain and position of the chain in the unit cell. A full refinement would have required consideration of 162 variables and positioning 330 atoms not counting the water molecules. If the latter were included, it would be 226 variables and 348 atoms. This would probably have

E_{Hel} (kcal/mol)	−1.63	−1.48	16.69

yielded a lower helix energy; however, without better X-ray diffraction data the excessive computer time involved was not justified.

Discussion

Lichenan is an example of a homoglucan which could be classified as a substitutional copolymer. By a periodic change

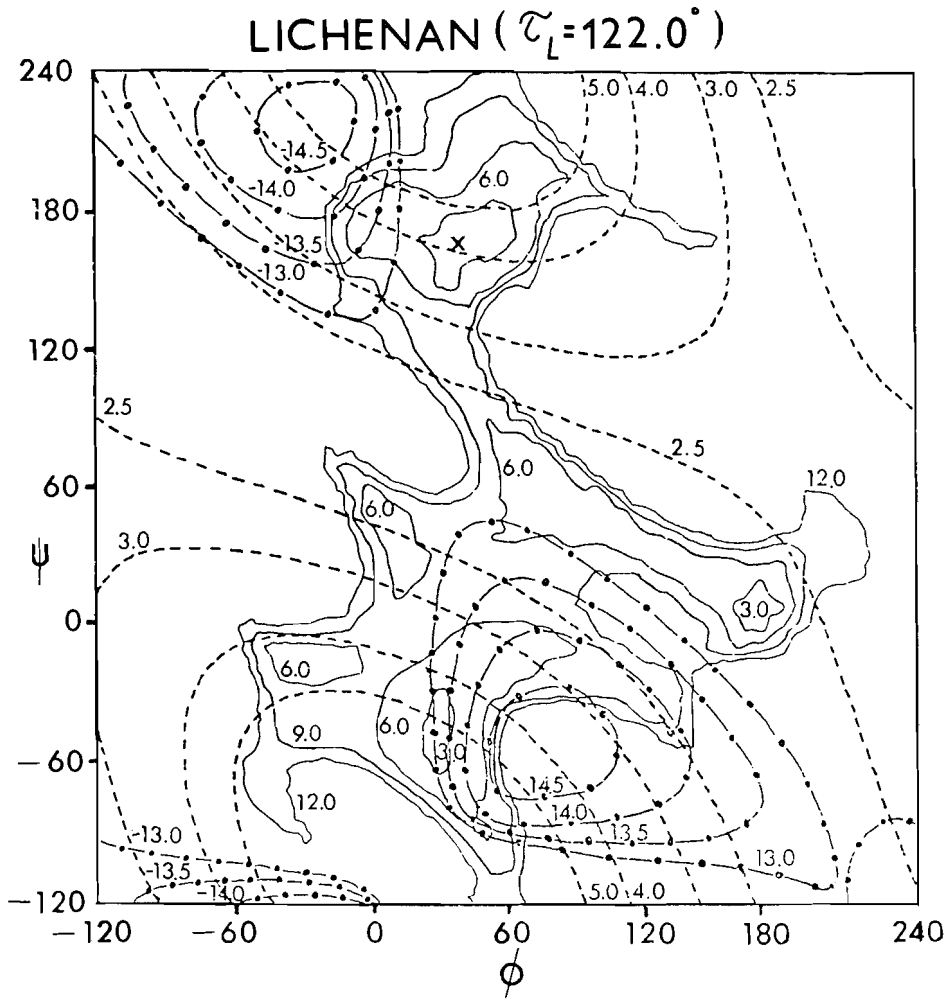

FIG. 5. The same as for Fig. 3 except for τ_L = 122.0°.

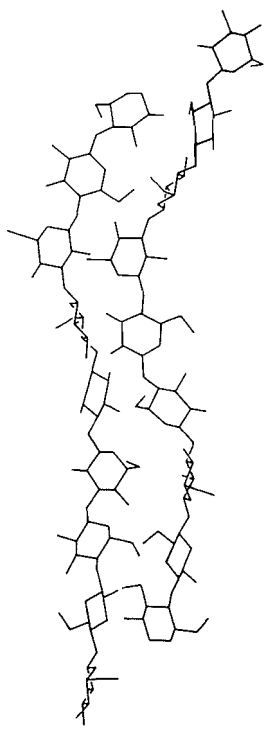

FIG. 6. The projection of lichenan unit cell onto (110) plane. The chains have antiparallel polarity.

in every third glycoside bond a considerable change in its physical properties is achieved compared to those of cellulose. The crystal structure still bears resemblance to cellulose but it is a regenerated cellulose hydrate rather than the familiar native cellulose structure. The packing, as shown in Fig. 6, gives rise to a compact structure wherein, at any level of the *c* axis, the inclined cellotriose moieties mesh with their neighbors to form long sheets of close-packed units. Because of the threefold axis along each chain, the same picture is obtained on viewing along different directions of the unit cell. Since intermolecular forces are weak, judging from interchain distances, the actual structure is perhaps paracyrystalline or sheet-like rather than truly three-dimensional. The cellulose II structure, which lichenan resembles, has strong intermolecular hydrogen bonds of slightly unequal strength in two nearly perpendicular directions. Since both β(1→3) and β(1→4) glucans are used as cell wall skeletal materials in fungi and plants respectively, it is not surprising to find this hybrid molecule in a cell wall role. Clearly, the structural requirements of a moss are minimal compared to shrubs and trees, so the lesser tendency in lichenan than in cellulose to organize and crysallize probably has a functional basis.

Of considerable interest was the fact that barley glucan, with a greater predominance of (1→4) linkages, crystallized in exactly the same fashion as lichenan. Indeed the patterns displayed less lateral order, i.e. greater line broadening. This suggests that the overall degree of crystallinity of the barley

glucan is less than for the chemically more regular lichenan. Two explanations can be proposed: the straightforward one is that the X-ray pattern of barley glucan corresponds only to the regular poly(cellotriose) segments. The other is based on structural accommodation similar to the isomorphous replacement concept. This concept would imply that the crystal structure is able to accommodate statistically occurring β(1→3) linkages because the extended chain cellulose segments produce a sheet-like packing of hydrate cellulose domains.

Barley glucan derives intermolecular cohesiveness from this cellulose hydrate packing but the low perfection and hydratability preserve the needed cell wall permeability characteristics. Thus, by adjusting the ratio of (1→4) to (1→3) linkages and their regularity, a change in a cell wall functional property, e.g. permeability, or strength, or deformability, can be achieved.

Reaction of methanethiol with species produced in a microwave discharge through water vapor

C. H. CHANG, P. L. GOODFRIEND,[1] M. D. BENTLEY, and R. J. ANDEREGG
Department of Chemistry, University of Maine at Orono, Orono, ME 04469, U.S.A.

Received August 4, 1982[2]

C. H. CHANG, P. L. GOODFRIEND, M. D. BENTLEY, and R. J. ANDEREGG. Can. J. Chem. **61**, 1617 (1983).

The products of reaction of methanethiol with species produced by passage of water vapor through a microwave discharge were studied. Mass spectrometric analysis demonstrated the presence of SO_2, CH_3SSCH_3, CH_3SSSCH_3, $CH_3SSSSCH_3$, $CH_3SSCH_2SCH_3$, $CH_3SCH_2SCH_3$, and S_8. These products are consistent with a mechanism involving abstraction of hydrogen from CH_3SH by OH and other radicals as the important primary process.

C. H. CHANG, P. L. GOODFRIEND, M. D. BENTLEY et R. J. ANDEREGG. Can. J. Chem. **61**, 1617 (1983).

On étudie les produits de la réaction du méthanethiol avec les espèces produites par le passage de la vapeur d'eau à travers une décharge de microondes. L'analyse par spectroscopie de masse démontre la présence du SO_2, du CH_3SSCH_3, du CH_3SSSCH_3, du $CH_3SSSSCH_3$, du $CH_3SSCH_2SCH_3$, du $CH_3SCH_2SCH_3$ et du S_8. Ces produits sont en accord avec un mécanisme qui implique comme processus primaire important l'enlèvement d'hydrogène à partir du CH_3SH par le groupe OH et par d'autres radicaux.

Introduction

Problems resulting from emission of organic sulfur compounds into the atmosphere from biogenic sources, industrial plants, and sewage treatment plants (1) have stimulated intense interest in the detailed chemistry of these compounds in the atmosphere. In particular, the oxidation of organic sulfur compounds is a major contributor to acid rain. It is believed that the sequence of reactions in which sulfur compounds are degraded is initiated primarily by reaction with OH radicals (2) although reaction with O atoms may also play a role to a lesser extent (3).

Clearly, it is important to know the identity of the products of the elementary reactions involved both in determining the fate of the sulfur compounds and in elucidating reaction mechanisms. In spite of this fact, there is very little published information about the reaction products, with most recent studies having dealt with the kinetics of the reactions (2–5).

The object of the investigation reported here has been to identify the products of the reaction of OH radicals with methanethiol, CH_3SH. Because the generation of OH radicals in sufficient concentration to produce enough product for analysis necessarily generates other free radicals as well, it was necessary to run a series of control experiments to attempt to unravel the reactions of CH_3SH with other species.

Product analysis of the reaction of photolytically produced OH radicals with CH_3CH_2F was carried out by Singleton *et al.* (6). These experiments were possible since there was no interference from the photolysis of the CH_3CH_2F. Cvetanovic *et al.* (7) studied the products of gas phase reactions of CH_3SH, C_2H_5SH, CH_3SSCH_3, and CH_3SCH_3 with O atoms produced by the mercury sensitized photodecomposition of N_2O. The OH plus CH_3SH system does not lend itself to this approach, either by continuous or flash photolysis.

The production of OH radicals by an electrical discharge through water vapor was pioneered by Oldenberg (8) who was able to monitor OH concentration for as long as 1/8 of a second after the discharge. In a critical study of OH concentrations produced in discharges through water vapor, Kaufman and DelGreco (9, 10) found that the concentration of H atoms is much higher than the concentrations of OH radicals, but that OH is continuously regenerated throughout the flow system. They presented a method of producing OH radicals in higher initial concentrations by reaction of H atoms with NO_2:

[1] $H + NO_2 \rightarrow OH + NO$

The presence of NO_2 and NO complicates the interpretation of the reaction products. Consequently, the choice was made to use a microwave discharge in water vapor as the source of OH radicals. Unlike the situation in a kinetics experiment in which the rate is followed by monitoring OH concentration as a function of time, continuous generation of OH along the flow is helpful in the product analysis experiment. It is necessary, however, to examine separately the products of reactions with H atoms alone, etc. The work was therefore broadened to include control experiments as well. The investigation included product analyses of the following systems.

1. Argon alone was passed through the microwave discharge and mixed with CH_3SH.
2. H_2 gas dissociated to atoms in a microwave discharge was allowed to react with CH_3SH.
3. Water vapor, both alone and with argon carrier gas, was passed through a microwave discharge and the resulting products allowed to react with CH_3SH downstream from the discharge.
4. The same as 3 above with ^{18}O enriched water.
5. Ar, with and without H_2, was passed through the microwave cavity, mixed with NO_2, and allowed to react with CH_3SH.

The results of these experiments are described in the present paper.

Experimental

Radicals were produced by passing the gases to be dissociated through an Evenson microwave cavity powered by an HV15A Scintillonics Inc. power supply [2450 MC]. Except in a few control experiments, an argon carrier gas was used. The argon was supplied by Liquid Carbonics Co. and had a stated purity of 99.998 percent.

The system reaction chamber was constructed from quartz tubing (2.5 cm od). In each experiment, the whole system was first evacuated to a pressure of less than 200 μm, and was pumped continuously during the reaction. Water vapor or H_2 was premixed with argon

before passing through the microwave discharge region, and methanethiol was added 6 cm downstream from the position of the microwave discharge.

When argon was used as a carrier gas, the flow was adjusted to maintain the discharge in the region of the microwave cavity without excessive "channeling". Although the flow rate was not measured and presumably varied somewhat from run to run, twenty-two replications of the Ar − H_2O experiment, and seventeen of the Ar − H_2 experiment gave uniformly reproducible results. Flows of H_2 were adjusted so as to give the discharge the characteristic red color of the Balmer α line. Distilled water was placed in a storage trap and degassed gradually. $H_2{}^{18}O$, which was transferred from the ampoule to a storage trap, was also degassed. Water vapor was entrained in the flow of gas at its vapor pressure at room temperature. When water alone (without argon) was used, it was allowed to boil off at room temperaure at the reduced pressure of the system. The $H_2{}^{18}O$ was supplied by the Isotopes Division of KOR Inc. and had a quoted isotopic purity of 97 percent.

The methanethiol used in the experiments was purified by trap to trap distillation on a vacuum line, and its purity shown to be greater than 99.9 percent by capillary gas chromatography. Prior to introduction into the vacuum chamber, CH_3SH was distilled into the reservoir under vacuum and condensed at liquid nitrogen temperature. It was allowed to come to room temperature, and its introduction into the mixing region was controlled by its vapor pressure.

After mixing in the reaction region, the gases were passed through cold traps at liquid nitrogen temperature where products were accumulated.

Quartz windows on the reaction chamber allowed observation of intense emission of the 3064 Å band of the OH radical when the flow was adjusted so that the discharge was moved into the reaction chamber. The detector was a Jarrell Ash plane grating spectrograph. Although Kaufman and DelGreco (9) showed that discharges in water are far less efficient in generating OH radical concentrations than reactions of H atoms with NO_2, our attempts to use the H + NO_2 reactions led to complex mixtures of complicated products with or without the H atoms present. It was therefore discarded as a technique for the purposes of this investigation. In spite of the fact that the focus of Kaufman and DelGreco's argument was to dismiss the water discharge as a source of OH, their results show OH present and reformed in the flow system in concentrations sufficient to yield observable products in our experiments. Because of the sensitivity of the gc−ms system and the fact that products were accumulated over an extended period of time, the low concentration of OH radicals was less of a limitation.

For analysis of the products, the trap was allowed to warm to room temperature, removed from the line, and a septum inserted. The gas phase was sampled at room temperature using a gas syringe and injected directly into the gas chromatograph of the gc−ms system. For analysis of the less volatile materials, tetrahydrofuran (20 μL) was injected into the trap at room temperature. A portion of the resulting solution of products was injected into the gc−ms for analysis. A yellow solid residue remained in water experiments. Samples of this material were removed from the trap and introduced into the mass spectrometer directly.

Analysis of products was performed using a Hewlett−Packard 5985B gas chromatograph/mass spectrometer system. The gas chromatograph was fitted with a 30 m × 0.32 mm fused silica capillary column, wall coated with Durabond DB-1 (J and W Scientific). The entire effluent of the gas chromatograph was directed into the source of the mass spectrometer which was maintained at 200°C. Helium was used as carrier gas at a flow of 1−2 mL/min. Both the splitless injector and the interface transfer line were maintained at or above 250°C. The column temperature was held at 60°C for five minutes and then linearly programmed at 8°/min to 280°C. For very volatile materials, such as SO_2, the gc oven temperature was held constant at 30°C.

Results

In many of the experiments with dissociated water vapor, a blue chemiluminescent glow was observed in the mixing region, but was not studied spectroscopically.

Interesting phenomena were observed in the traps at liquid nitrogen temperature. In both the hydrogen and water vapor experiments, a band of pink material was observed which disappeared on warming. On several occasions, traps in water vapor experiments have exploded. Thus intermediates from the reactions are apparently trapped at low temperature. Wet chemical tests with iodide on the material in the traps showed no indications of peroxides or other strong oxidizers.

In the control experiments in which argon alone was passed through the microwave discharge and interacted with methanethiol, no evidence of chemical reaction was observed and no reaction products were found. In all of the other types of experiments, reaction products were observed. Reaction products were identified by mass spectrometry. The molecular formulae were verified by analysis of the isotope ratios of the molecular ion and its isotope peaks. The mass spectra of all identified products are in agreement with published spectra. The abbreviated mass spectra (2 most abundant peaks in each 14 amu) were as follows.

CH_3—S—S—CH_3 *m/z* (%): 42 (40), 45 (66), 48 (9), 61 (15.6), 71 (24), 72 (23.5), 79 (80), 81 (6.2), 94 (100), 96 (9.2) (published spectrum in ref. 11).

CH_3—S—S—S—CH_3 *m/z* (%): 45 (13), 47 (9.6), 49 (2), 61 (5.2), 64 (11.3), 72 (1.9), 79 (35), 80 (11.2), 94 (2.6), 96 (0.8), 111 (16.5), 113 (2.3), 126 (100), 128 (13.8) (published spectrum in ref. 11).

CH_3—S—CH_2—S—CH_3 *m/z* (%): 45 (29.7), 46 (10.6), 59 (4.4), 61 (100), 62 (3.7), 63 (5.1), 76 (1.1), 78 (1.7), 92 (0.7), 93 (1.6), 108 (49), 110 (4.2) (published spectrum in ref. 12).

CH_3—S—CH_2—S—S—CH_3 *m/z* (%): 48 (3.7), 61 (100), 63 (7.7), 64 (6.6), 78 (3.6), 79 (8.1), 93 (3.9), 94 (2.6), 140 (8.3), 142 (1.1) (published spectrum in ref. 13).

CH_3—S—S—S—S—CH_3 *m/z* (%): 45 (41), 47 (26), 49 (7.3), 61 (17), 64 (43), 72 (13), 79 (100), 80 (11), 91 (5.6), 94 (30.4), 111 (11.2), 112 (3), 126 (9), 128 (1.8), 140 (1.3), 158 (68.8), 159 (3.9), 160 (12.5) (published spectrum in ref. 14).

It should be noted, however, that some possible low molecular weight products, such as methane, would not have been separated and detected under the chromatographic conditions used.

The results of the experiments are presented in Table 1. With argon alone, no reaction products were observed. Hydrogen experiments produced CH_3—S—S—CH_3 as the only identifiable species. Dimethyl disulfide, dimethyl trisulfide (CH_3—S—S—S—CH_3), dimethyl tetrasulfide

TABLE 1. Products obtained in this study

*Reaction of CH_3SH with radicals generated from NO_2 yielded complex mixtures of products which were not analyzed. See text.

(CH_3—S—S—S—S—CH_3), and SO_2 were identified as major products in the water experiments. Minor products CH_3—S—CH—S—CH_3 and CH_3—S—CH_2—S—S—CH_3 and a deposit of S_8 in the trap were also found in the water experiments. In the $H_2{}^{18}O$ experiments, the only observed species to contain ^{18}O was $S^{18}O_2$. When NO_2 was used, with or without H atoms, complex mixtures of products were formed, but not analyzed.

Discussion

Clearly, with the experimental arrangement used for these studies, reaction of CH_3SH with excited argon atoms was not a factor. No reaction products were observed in the Ar experiments, and Ar did not affect the results of the H_2O experiments. The only major product from the H-atom experiments was CH_3SSCH_3, which can be simply explained by the following reactions:

[2] $H + CH_3SH \rightarrow CH_3S + H_2$

[3] $2CH_3S \rightarrow CH_3SSCH_3$

The product mixture resulting from the experiments with water vapor also had CH_3SSCH_3 as a major component, but also contained SO_2, S_8, CH_3SSSCH_3, $CH_3SSSSCH_3$, and small amounts of $CH_3SCH_2SSCH_3$ and $CH_3SCH_2SCH_3$. It is significant that no oxygen-containing species other than SO_2 and certainly H_2O (although it was not determined) were observed. The possibility that some of the sulfur-containing species were actually oxygen-containing species was ruled out by both S isotope ratio calculations in mass spectra and the $H_2{}^{18}O$ labeling experiments.

Because no oxygenated sulfur species, other than SO_2, were observed in this investigation, we feel a mechanism involving abstraction as a primary step is reasonable, although attack on sulfur could also be postulated. Attack at sulfur has been observed in the reaction of OH and CH_3—S—CH_3 (15), as well as in the attack of O atoms on CH_3—SH (7), and the reaction of H atoms on CH_3—S—CH_3 and CH_3—S—S—CH_3 (16). In any case, the oxygen in our experiments is found only in SO_2 and not in more complex molecular species.

Finally, it should be noted that the rate of reaction of either O or OH with CH_3—S—S—CH_3 is much higher than the rate of reaction with CH_3—SH (2, 3). If substantial quantities of CH_3—S—S—CH_3 were built up, subsequent products could be a result of further reaction of CH_3—S—S—CH_3 with radicals generated in our discharge.

Acknowledgements

We wish to thank Dr. John Toth for running mass spectrometric analyses on the reaction products.

OSVALD KNOP, T. STANLEY CAMERON, MARGARET ANN JAMES, and MICHAEL FALK. Can. J. Chem. **61**, 1620 (1983).

In an effort to advance our understanding of the principles governing the structures of and the hydrogen bonding in alkylammonium hexachlorostannates(IV), $(R_nNH_{4-n})_2SnCl_6$, we have determined the room-temperature crystal structures of $(Me_2NH_2)_2SnCl_6$ and $(Me_3NH)_2SnCl_6$ (variants of the antifluorite structure); $(EtNH_3)_2SnCl_6$ and $(n\text{-}PrNH_3)_2SnCl_6$ (*anti*-CdI_2 type, with orientational disorder in the Et compound); and $(n\text{-}Pr_3NH)_2SnCl_6$. We have also studied the infrared spectra in the regions of the NH and ND stretching fundamentals, between 10 and 293 K, of these five compounds and of $(MeNH_3)_2SnCl_6$, $(Me_3NH)_2SnBr_6$, $(Et_2NH_2)_2SnCl_6$, $(n\text{-}Bu_3NH)_2SnCl_6$ and, in less detail, the mixed-anion salt $(n\text{-}Pr_2NH_2)_3(SnCl_6)Cl$. The spectra are often complicated by Fermi resonance involving absorptions diagnostically critical for the strength and type of N—H···Cl bonding and for the site symmetry at the N atom. In this respect they are less useful than the corresponding spectra of the unsubstituted ammonium compounds reported previously. Several of the spectra provide striking examples of temperature-tuned Fermi resonance of NH and ND vibrations. The N—H···Cl bonds are invariably trifurcated, bifurcated, or at least highly bent; these characteristics give rise to anomalous temperature dependence of the frequencies of the NH and ND stretching fundamentals. Temperature-induced transitions were detected in $(Me_2NH_2)_2SnCl_6$ ($T_{tr} \sim 100$ K), $EtNH_3)_2SnCl_6$ ($T_{tr} \sim 125$ K), and $(Et_2NH_2)_2SnCl_6$ ($T_{tr} \sim 330$ K). The specific results for the ten compounds studied are discussed in detail. The discussion also includes the limits of usefulness of the isotopic dilution technique; symmetry aspects of the cation–anion packing in alkylammonium hexahalometallates(IV); symmetries of the arrangements of the $SnCl_6$ octahedra; the geometry of hydrogen bonding in $(R_nNH_{4-n})_2SnCl_6$; and the possibility of detection of the presence of hydrogen bonding from molecular volume trends.

OSVALD KNOP, T. STANLEY CAMERON, MARGARET ANN JAMES et MICHAEL FALK. Can. J. Chem. **61**, 1620 (1983).

Pour mieux comprendre les principes régissant les structures et la liaison hydrogène des hexachlorostannates(IV) d'alkylammonium $(R_nNH_{4-n})_2SnCl_6$, nous avons déterminé, à la température de la pièce, les structures cristallines du $(Me_2NH_2)_2SnCl_6$ et du $(Me_3NH)_2SnCl_6$ (des variantes de la structure antifluorine); du $(EtNH_3)_2SnCl_6$ et du $(n\text{-}PrNH_3)_2SnCl_6$ (de type CdI_2 *anti* avec un désordre rotationnel dans le composé Et); et du $(n\text{-}Pr_3NH)_2SnCl_6$. Nous avons également étudié les spectres infrarouges dans les régions d'élongation fondamentale du NH et du ND entre 10 et 293 K, de ces cinq composés et des composés suivants: $(MeNH_3)_2SnCl_6$, $(Me_3NH)_2SnBr_6$, $(Et_2NH_2)_2SnCl_6$, $(n\text{-}Bu_3NH)_2SnCl_6$ et, avec moins de détail, ceux du sel à l'anion mixte, $(n\text{-}Pr_2NH_2)_3(SnCl_6)Cl$. Les spectres sont souvent compliqués par la résonance de Fermi qui implique les absorptions caractéristiques important pour la force et le type de liaison N—H···Cl et pour la symétrie de site de l'atome N. A cet égard ils sont moins utiles que les spectres correspondants des composés ammonium non substitués rapportés antérieurement. Plusieurs spectres fournissent des exemples frappants de résonance de Fermi des vibrations du NH et du ND contrôlée par la température. Les liaisons N—H···Cl sont invariablement trifurquées, bifurquées ou au moins fortement déformées; ces caractéristiques donnent lieu à une influence anormale de la température sur les fréquences des élongations fondamentales du NH et du ND. On a décelé des transitions induites par la température dans le $(Me_2NH_2)_2SnCl_6$ ($T_{tr} \sim 100$ K), dans le $(EtNH_3)_2SnCl_6$ ($T_{tr} \sim 125$ K) et dans le $(Et_2NH_2)_2SnCl_6$ ($T_{tr} \sim 330$ K). On discute en détail des résultats spécifiques obtenus pour les dix composés étudiés. La discussion porte également sur les limites de l'utilité de la technique de dilution isotopique; sur les aspects de la symétrie de l'entassement cation-anion dans les hexahalométallates(IV) d'alkylammonium; sur les symétries des arrangements du $SnCl_6$ octaédrique; sur la géométrie de la liaison hydrogène dans le $(R_nNH_{4-n})_2SnCl_6$ et sur la possibilité de détecter la présence d'une liaison hydrogène à partir des tendances du volume moléculaire.

[Traduit par le journal]

The ratio of the N-hydrogen to the chlorine atoms in the alkylammonium hexachlorostannates(IV), $(R_nNH_{4-n})_2SnCl_6$, varies from $\frac{1}{3}$ (for $n = 0$) to zero (for $n = 4$). This provides for the formation of N—H···Cl hydrogen bonds of a variety of types. In the specific case of $n = 3$, the implications of the existence of the unique N-hydrogen for the ir manifestations of the hydrogen bonding have been discussed earlier (1), with particular reference to $(Et_3NH)_2SnCl_6$.

We have now extended that investigation to other alkylammonium hexachlorostannates, with a view to obtaining a clearer understanding of the effect of the alkyl substitution on the crystal architecture of modified alkylammonium hexahalometallates(IV) in general and on the hydrogen bonding in such compounds in particular. To assist in the interpretation of the newly obtained ir spectra of the compounds marked * below, we have determined, or redetermined, the crystal structures of five additional compounds (marked †), so that structural *and* spectroscopic comparisons are now possible in three unbroken series: $(NH_4)_2SnCl_6$ (2–4), *$(MeNH_3)_2SnCl_6$ (1MHS) (5, 6), *†$(Me_2NH_2)_2SnCl_6$ (2MHS) (7, 8), *†$(Me_3NH)_2SnCl_6$ (3MHS) (9), $(Me_4N)_2SnCl_6$ (4MHS) (2, 9), *†$(EtNH_3)_2SnCl_6$ (1EHS) (10), *$(Et_2NH_2)_2SnCl_6$ (2EHS), $(Et_3NH)_2SnCl_6$ (3EHS) (1), $(Et_4N)_2SnCl_6$ (4EHS) (11), *†(n-$PrNH_3)_2SnCl_6$ (1PHS), *(n-$Pr_2NH_2)_2SnCl_6$ (2PHS),[2] *†(n-$Pr_3NH)_2SnCl_6$ (3PHS), *(n-$BuNH_3)_2SnCl_6$ (1BHS) (plus *$(Me_3NH)_2SnBr_6$). The results, which are reported and discussed in the following, include several striking examples of temperature-scanned Fermi resonance (FR) of NH and ND vibrations.

Crystal structures

Crystal data of the compounds studied in this work are listed in Table 1. Details of the structure refinements will be found under Experimental.

$(Me_2NH_2)_2SnCl_6$

2MHS, which was measured by Ries (12) and described as orthorhombic pseudotetragonal (D_{2h}, axial ratio 1.0158:1:1.9661), corresponds to the denser of the two forms of $(Me_2NH_2)_2PtCl_6$, both reported as having point-group symmetry D_{2h} (cf. ref. 12 and literature cited therein). We have found no mention of polymorphism of 2MHS in the literature and no evidence of it in our own work.

The essential features of the 2MHS structure were established by Corey and Wyckoff (7). However, on repeating the structure determination we discovered that the systematic absences were compatible with the space group *Pmnn* but not with the $Pmn2_1$ claimed in ref. 7. Inspection of Table 2 shows that Corey and Wyckoff's choice of the positional parameters effectively corresponds to solving the structure in *Pmnn*, the centrosymmetric supergroup of index 2 of $Pmn2_1$ (with *Pmnn* in standard setting, $P2_1nm \subset Pnnm$). *Pmnn* would thus have been the natural choice in ref. 7, had it not been for the presence of a few reflections indicative of $Pmn2_1$ which eventually turned out to be spurious. For comparison, we refined the structure both in *Pnnm* and $P2_1nm$ (Tables 2 and 3[3]). The N—H and C—H bond lengths were constrained and the Me groups were refined as rigid bodies. The $R(P2_1nm)$ and $R_w(P2_1nm)$, 0.046 and 0.043, respectively, were both slightly higher than those for the refinement in *Pnnm* (Table 1). Predictably, the positional and thermal parameters of atoms like C(1) and C(2) etc. in $P2_1nm$, related by $4(g)(Pnnm) \rightarrow [2(a) + 2(a)](P2_1nm)$ and $8(h)(Pnnm) \rightarrow [4(b) + 4(b)](P2_1nm)$, were highly correlated.

Table 2 also shows the results of a recent structure determination of 2MHS in *Pnnm* by Ben Ghozlen *et al.* (8), which came to our attention only when our own refinements were completed. Apart from the difference arising from the different treatment of the H atoms (unconstrained refinement leading to the expectedly short but chemically unreasonable N—H bond lengths in ref. 8), the two sets of positional parameters agree to within one esd in each individual value; the esd's of ref. 8 are roughly half as large as ours owing to about twice the volume of data.

The structure consists of sheets of almost regular $SnCl_6$ octahedra held together by hydrogen bonds in such a way that each Me_2NH_2 group is symmetrically hydrogen-bonded to two $SnCl_6$, and each $SnCl_6$ is the recipient of hydrogen bonds from four Me_2NH_2 (Fig. 1). The hydrogen bonds (Table 4) may be described as asymmetrically trifurcated or perhaps closer to out-of-plane bifurcated. The $[(Me_2NH_2)_2SnCl_6]^0_\infty$ sheets are fitted together by sheets of the Me(2) groups, whilst the H(11) hydrogens of Me(1) groups reach into spaces between the octahedra in an $SnCl_6$ sheet.

$(Me_3NH)_2SnCl_6$

The gross features of the 3MHS structure were determined as early as 1929 by Wyckoff and Corey (9), who described it as a lower-symmetry ($Pa3$) variant of the antifluorite ($Fm3m$)

[a]The parameters of the H atoms (except those marked *) have been multiplied by 10^3. The uncertainties are single esd's in units of the last digit. Second entry under *Pnnm* is from ref. 8. Transformations: $abc(Pnnm) \rightarrow \bar{b}ca(Pmn2_1$, ref. 7), $abc(Pnnm) \rightarrow cba(Pmnn$, ref. 8); $xyz(Pnnm) \rightarrow \bar{y} + y(Sn), z, x$ ($Pmn2_1$, ref. 7); $xyz(Pnnm) \rightarrow zyx(Pmnn$, ref. 8); $y(Sn) = 0.2502$.

[b]Parameters from ref. 7: Cl(2) = −Cl(1), 0.140, 0.820, 0; Cl(3) = −Cl(4), 0.065, 0.190, 0; N(2) = −N(1), 0.370, 0.310, 0; C(2) = −C(1), 0.355, 0.125, 0; C(4) = −C(3), 0.280, 0.375, 0.

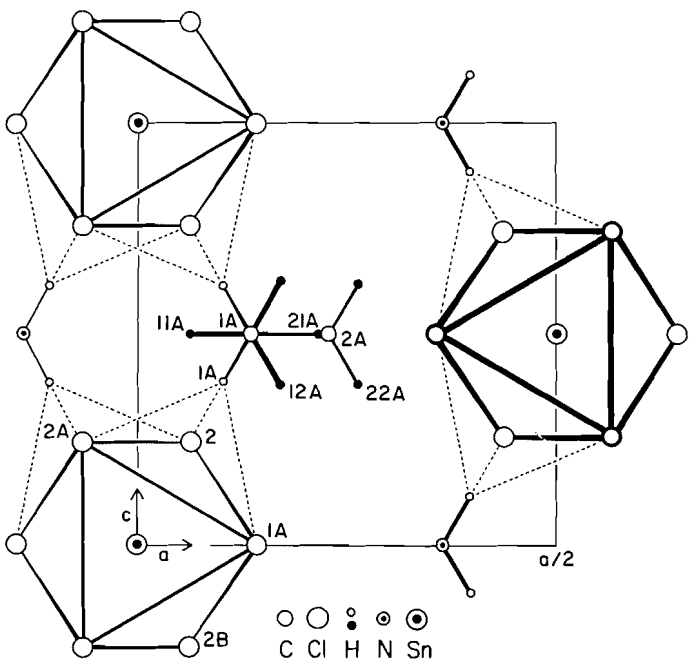

FIG. 1. Hydrogen bonding in 2MHS. Projection on 010. The N(1) atom is eclipsed by C(1A). For distances and angles see Table 4.

4MHS arrangement, noting a slight displacement of the $SnCl_6$ octahedra by rotation about their respective threefold axes.

The intensities were collected in orthorhombic symmetry ($Pbca \subset Pa3$) and the structure was refined in both *Pbca* and $Pa3$. The N—H and C—H bond lengths were constrained and the Me groups were refined as rigid bodies. The refinement in *Pbca* gave slightly higher *R*'s than for $Pa3$ (Table 1), but otherwise the positional parameters were very close to those obtained in the refinement in $Pa3$, presumed to be the correct space group.

The results of the refinement in $Pa3$ (Table 5) confirm the previous (9) partial determination. There was no indication of disorder in the structure. The bond distances and interatomic contacts (Table 6 and Fig. 2*A*) are unexceptional. The $SnCl_6$ octahedra are practically regular, with the Sn—Cl bonds rotated away from the unit-cell edges. The N—H vectors are in the threefold axes, with the H atoms engaged in symmetrically trifurcated N—H···Cl bonds. Unlike in $(NH_4)_2SnCl_6$ (2–4), the N—H vectors are directed at the Sn atoms; the Me groups point, asymmetrically, away from the Sn atoms. Each $SnCl_6$ octahedron is associated with two Me_3NH groups to form centrosymmetric $Me_3NH\cdots Cl_3SnCl_3\cdots HNMe_3$ units. The H···H separation across the Sn atom is ca. 6.5 Å. Other H_N neighbours of an H_N atom are also ca. 6.5 Å away; their respective N—H vectors are at tetrahedral angles to the reference N—H bond. The H···Cl contacts of the Me groups are shown in Fig. 2*B*. The shortest of these, 2.87 Å, is between H(11) and Cl(1A) (in Fig. 2*B*, H(21) and Cl(1B)), the corresponding C—H(11)—Cl(1A) angle being ca. 138°.

$(EtNH_3)_2SnCl_6$

This salt and the corresponding chloroplatinate were reported many years ago by Wyckoff (10) as hexagonal ($P\bar{3}m1$, $Z = 1$) and described as layer structures resembling that of the trigonal form of $(NH_4)_2SiF_6$. Only the metal and Cl positions were established. The N positions were inferred, and the Et groups were considered "rotating".

[b]Isotropic temperature factor.

The present structure determination (Table 7) has confirmed these findings. With the N—C(1) bond placed on a threefold axis, and constraining the N—H, N—C, and C—C bond lengths and the CNH and NCC angles, the C(1)—C(2) bond was found to be orientationally disordered with respect to the threefold axis. The thermal parameters of C(1) were about twice, and those of C(2) about three times, those of the N atom. A difference Fourier section at the height of C(1) with this atom and all the hydrogens omitted from F_c shows a slight triangularity of the inner contours of the local maximum centred on the threefold axis (Fig. 3, top). A corresponding section at the height of C(2) with this atom and all the hydrogens omitted displays clearly a threefold maximum (Fig. 3, bottom). The shortest possible distance between C(2) sites is only 1.96 Å (Fig. 4), hence the instantaneous distribution of the C(1)—C(2) orientations in the crystal must be governed by the necessity to avoid simultaneous occupation of sites at this distance. Because of the disorder no attempt was made to refine the alkyl hydrogens. For comparison, the structures of the corresponding *iso*-propyl and *tert*-butyl salts are being examined.

Each N-hydrogen engages in a nearly symmetrically trifurcated N—H···3Cl bond. The H···Cl distances (Table 8) are comparable to that in $(NH_4)_2SnCl_6$, 2.79 Å (13). The nature of the disorder is commented upon later in this paper.

(n-PrNH$_3$)$_2$SnCl$_6$

The structure of this compound has not been determined previously, but from optical measurements (12) the crystal was concluded to belong to the C_{2h} point group.

The systematic absences indicated space groups $P2_1/m$ or $P2_1$, $Z = 2$. Refinement in $P2_1$, with constraints on N—H, C—H, N—C, C—C, and the HNH and HNC angles, and with anisotropic temperature factors on all atoms except the hydrogens, resulted in $R = 0.028$. However, the y coordinates of several of the nonhydrogen atoms were close to $\frac{1}{4}$ and the $SnCl_6$ octahedron appeared to be practically mirror-symmetric (Table 9), so the refinement was repeated in $P2_1/m$ with these atoms in 2(*e*), and again in $P2_1/m$ with these atoms having the same coordinates as in the $P2_1$ refinement but in a twofold disorder with respect to reflection in the $y = \frac{1}{4}$ plane. The R values for these two refinements (anisotropic but H not included) were 0.048 and 0.041 respectively, with esd's of the carbon U_{ii} 3–4 times as large as in the $P2_1$ refinement. Thus while the structure in its gross features is pseudo-$P2_1/m$, the true space-group symmetry is $P2_1$. The proximity to $P2_1/m$ caused the inverse matrix in the $P2_1$ refinement to be ill-conditioned. Con-

parameters (Table 10).[3] The Sn—Cl distances in the noncentrosymmetric $SnCl_6$ octahedron range from 2.41 to 2.45 Å, and the acute ClSnCl angles of vicinal Cl atoms from 87.6 to 90.0°.

(n-$Pr_3NH)_2SnCl_6$

No crystallographic information appears to be available on 3PHS in the literature. For the corresponding chloroplatinate two forms were reported by Ries (12), one triclinic (from MeOH) and another, less dense, of D_{2h} symmetry (from aqueous solution above 30°C). The 3PHS structure described below would seem to correspond to the triclinic form.

3PHS has a large monoclinic cell, with all atoms in general positions. In the refinement the N—H, N—C, C—C bond lengths and the NCC and CCC angles were constrained. With the alkyl hydrogens not included the structure refined to $R = 0.063$ (anisotropic temperature factors on Sn and Cl, isotropic on all the other atoms). The refinement was not continued beyond this stage (see below). The positional parameters are listed in Table 12, the thermal parameters in Table 13,[3] and interatomic distances and bond angles in Table 14.

The $SnCl_6$ octahedra are noncentrosymmetric but not severely distorted. The Cl···Cl edge distances range from 3.35 to 3.48 Å and the ClSnCl angles subtending the edges, from 88.3 to 91.4°. The cations have umbrella-like, pseudotrigonal conformations: the midpoints of the N—C and C—C bonds in the three extended N—C—C—C zig–zag chains in each of the two nonequivalent cations are approximately coplanar (Fig. 6). This implies that the *n*-Pr_3NH dipoles effectively coincide with the N—H bonds.

The structure may be regarded as consisting of two interpenetrating systems of centrosymmetric pairs of *n*-Pr_3NH groups (Fig. 7). The cations are hydrogen-bonded to the $SnCl_6$ octahedra by strongly bent N—H···Cl bonds, which indicates

[a]Primed atoms: $(\bar{x}, \frac{1}{2} + y, 1 - z)$ + A(0, 1, 0), B(0, 0, 1), C(0, $\bar{1}$, 1), D(0, $\bar{1}$, 0).
[b]esd = 0.009 Å; *, considered hydrogen-bonded.
[c]esd = 0.02 Å.
[d]esd = 3°.

that hydrogen bonding in this crystal is not an important structure-determining factor and that its optimization in the circumstances produces at best an inefficient hydrogen-bonding geometry (Fig. 6). Although the N(1′)—H(1′)—Cl(1) angle is ca. 136°, there is no other suitable Cl acceptor within a reasonable bonding distance,[4] and the H(1′)···Cl(1) distance is ~2.89 Å. The N(2)—H(2)—Cl(3) angle is larger, ca. 150°, and the H(2)···Cl(3) separation is ~2.38 Å. In addition, there is a Cl(5) atom ca. 3.17 Å away from H(2), but the N(2)—H(2)—Cl(5) angle, ~128°, is too small for the N(2)—H(2)···Cl bond to be considered effectively bifurcated. The two nonequivalent $n\text{-}Pr_3NH$ units are *cis* to the $SnCl_6$ octahedron, in contrast to the *trans* configurations found in 3MHS and 3EHS and in fact in all the alkylammonium hexachlorostannates so far studied (see section on Structural principles).

The Sn(1)—Cl(1)—H(1′) angle corresponding to the H(1′)···Cl(1) distance of ~2.89 Å is ~126° and thus quite small if the N(1′)—H(1′)···Cl(1) bond is considered as highly bent but not bifurcated. A small MC1H angle in alkylammonium compounds is, however, not without precedent: the Cd—H(1)—Cl(2′) angle in the orthorhombic phase of $(Me_3NH)CdCl_3$ is only 105(3)° (Fig. 1 of ref. 15), and the Cl(2′)···H(1)—N bond is normal, not appreciably bent.

Examination of the CNC angles (Table 14) reveals a considerable departure from the tetrahedral angle and a considerable variation at each N atom, particularly at N(1), 91–136°. These deviations from the expected values are large and difficult to account for in view of the realistic constraints on the N—C and C—C bond lengths in the refinements. Refinement of the structure both with additional constraints and without any constraints did not improve the cation geometry. The unusually large thermal parameters of some of the C atoms (and the esd's in general) suggest that the cations at room temperature possess appreciable flexibility and that this may be the reason preventing the proposed — otherwise chemically reasonable — structure from being refined further. It is also possible that the crystal contains a certain degree of disorder of an undetermined nature.

[4]Cl(4E), at ~5.36 Å from H(1′), is at an N(1′)—H(1′)—Cl(4E) angle of ~138° (Table 14).

Infrared spectra

Survey spectra in the range of 4000–200 cm^{-1}, at room temperature and 10 K, were recorded for all the compounds listed in the Introduction. Since our interest is mainly in hydrogen bonding, we are reporting only the spectra in the region of NH and ND stretching fundamentals of the alkylammonium ions. Different levels of deuteration were employed to suit particular purposes; the D contents stated refer to replacement of the N-hydrogens by D. Spectra of the trialkylammonium salts will be dealt with first, partly because they are an extension of the previous work on 3EHS (1), but also because they illustrate most clearly temperature-tuned FR, a feature common, to a varying extent, to all the spectra.

Trialkylammonium salts

[a]Primed atoms: $x, y-1, z$; Cl(4E), $\frac{1}{2}-x, y-\frac{1}{2}, \frac{1}{2}-z$.

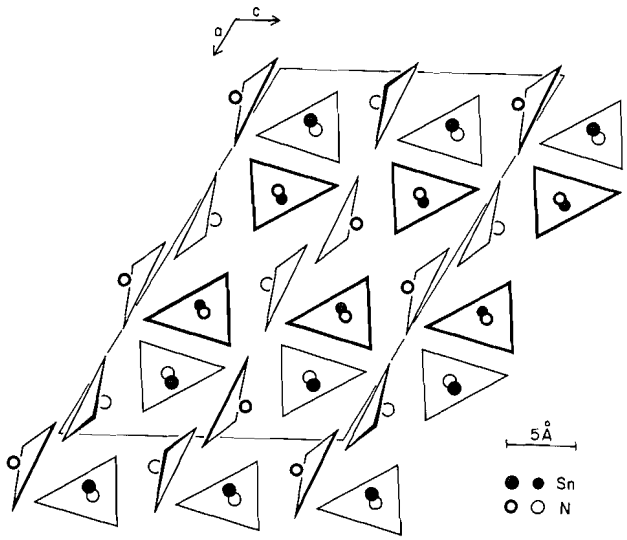

FIG. 7. Schematic presentation of the organization of the 3PHS structure (see text). Projection on 010. Each triangle represents a n-Pr_3NH group; the vertices correspond to the positions of the three terminal carbons. Only the Sn atoms of the $SnCl_6$ octahedra are shown.

3MHS structure are the same as those of $(NH_4)_2SnCl_6$ (see section on Structural principles), and the N—H···3Cl bond is in both cases symmetrically trifurcated. The difference is in the N—H···Cl distance, which in 3MHS is shorter than in the ammonium compound, 2.71 Å as against 2.79 Å, and in the direction of the N—H vectors, which in 3MHS point at, but in $(NH_4)_2SnCl_6$ away from the Sn atoms. As a result, in 3MHS the single N—H bond per cation participates in the formation of discrete hydrogen-bonded $[Me_3NH]^+\cdots{}^-[Cl_3SnCl_3]^-\cdots{}^+[HNMe_3]$ groupings, so that the crystal may be formally regarded as a pseudomolecular crystal consisting of electroneutral $[A^+B^{2-}A^+]$ units arranged and oriented in a way resembling the molecules in a CO_2 crystal. This is quite different from the tetrahedrally uniform and coincident charge- *and* hydrogen-bonding interactions between nearest-neighbour NH_4^+ and $SnCl_6^{2-}$ in the typically ionic ammonium salt. The effect of lattice compression on the NH and ND frequencies (cf. ref. 13) should thus be expected to be significantly less pronounced. The direction of change in the NH and ND stretching frequencies in 3MHS relative to the ammonium salt is difficult to predict, as it depends not only on the crystal-determined features but also on the difference in the intrinsic hydrogen-bond *donor* strength of NH_4^+ and Me_3NH^+.

Spectrum of 3MHS. The band shapes in the NH and ND stretching regions were virtually independent of the degrees of deuteration (Fig. 8), indicating a near absence of vibrational coupling between NH (or ND) vibrations of neighbouring Me_3NH^+ ions. Spectra at any convenient H/D ratio may therefore be used for correlation of spectral and crystallographic features.

At 10 K the ND stretching fundamental ν(ND) was a very narrow ($\Delta\nu_{1/2} = 2.1$ cm^{-1} for the best mull, cf. Fig. 8) singlet at 2370.3(2) cm^{-1} (Fig. 9*A*). The adjacent small peaks correspond to overtone and combination levels of Me_3ND^+. They appear to borrow some, possibly most, of their intensity from ν(ND) through moderately weak FR. Since Me_3ND^+ has 36 fundamental internal vibrations and hence 666 binary overtone and combination levels, in principle all of them distinct, matching of minor spectral features with specific band assignments seemed subject to considerable ambiguity and was not

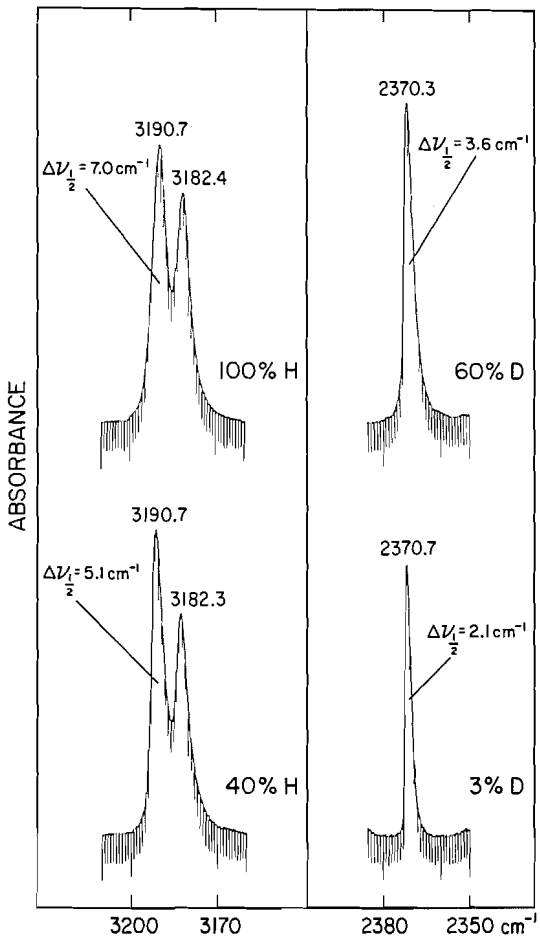

FIG. 8. Effect of isotopic dilution on the spectrum of 3MHS at 10 K, in the region of the NH (left) and ND (right) stretching fundamentals.

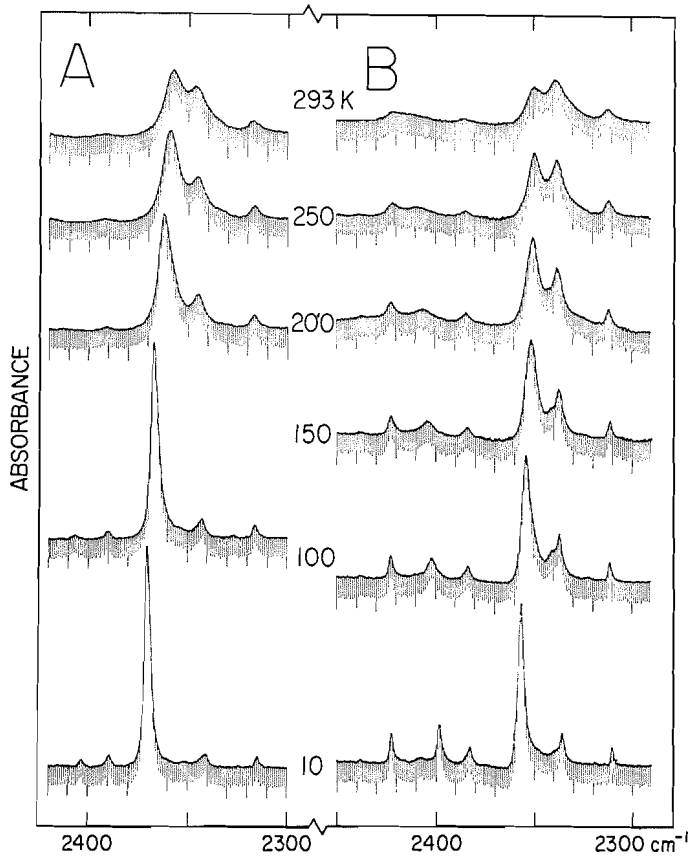

FIG. 9. The ND stretching fundamental of (*A*) $(Me_3NH)_2SnCl_6$ (3% D) and (*B*) $(Me_3NH)_2SnBr_6$ (18% D) at different temperatures.

attempted.

With increasing temperature ν(ND) gradually shifted to lower wavenumbers, while the small companion bands shifted, more slowly, to higher wavenumbers (Fig. 9*A*). As a result of this differential movement the overtone bands on the high-wavenumber side of ν(ND) kept losing intensity while those on the low-wavenumber side were growing. By the time room temperature was reached the now much broader ν(ND) was in close resonance with its nearest overtone neighbour on the low-wavenumber side, producing a doublet, at 2357.6(5) and 2347.7(6) cm^{-1}, with a 57:43 intensity ratio. The unperturbed position ν^0(ND) of the fundamental was calculated (see Experimental) to be 2353.3(9) cm^{-1}, with a FR constant $2W$ of 9.8 cm^{-1}. The position of the unperturbed ν(ND) had therefore shifted by −17.0(9) cm^{-1} on going from 10 to 293 K.

The NH stretching fundamental ν(NH) (Fig. 10*A*) started off at 10 K as a FR doublet, at 3190.7(2) and 3182.3(2) cm^{-1}, with an intensity ratio of 58:42. This corresponds to ν^0(NH) = 3186.5(3) cm^{-1} and $2W$ = 8.3 cm^{-1}. With increasing temperature ν(NH) gradually moved out of resonance. Between 80 and 200 K it was a singlet, in weak resonance with the neighbouring overtone levels. Above 200 K it began to approach closely the overtone on the low-wavenumber side and move steadily into close FR. The doublet observed at room temperature was at 3163(2) and 3157(2) cm^{-1}, with an intensity ratio of 51:49, corresponding to $2W$ = 6(2) cm^{-1}, ν^0(NH) = 3160(3) cm^{-1}, and a shift of −26(3) cm^{-1} on warming the sample from 10 K to room temperature.

$(Me_3NH)_2SnBr_6$ was examined mainly to see if its spectrum supported our interpretation of the 3MHS spectrum. This was found to be the case. The behaviour of the NH and ND stretching fundamentals was, except for details of FR, basically the same as in 3MHS, so even though the structure of the bromo compound has not been determined, it is reasonable to conclude that $(Me_3NH)_2SnBr_6$ is isostructural with 3MHS. As in the 3MHS case, the stretching bands were practically independent of the degree of deuteration.

The ν(ND) fundamental, which at 10 K was a narrow ($\Delta\nu_{1/2}$ = 3.5 cm^{-1}) singlet at 2356.8(2) cm^{-1} (Fig. 9*B*), with increasing temperature gradually entered into resonance with an overtone at about 2336 cm^{-1}, to become a close doublet near room temperature. The components of this resonance doublet at 293 K were at 2349.2(6) and 2338.2(6) cm^{-1}, with an intensity ratio of 45:55. From this we deduced ν^0(ND) = 2343.1(9) cm^{-1} and $2W$ = 11 cm^{-1} at 10 K; the temperature shift $\Delta\nu^0$(ND) from 10 to 293 K was −13.7(9) cm^{-1}.

The triplet observed in the NH stretching region at 10 K (Fig. 10*B*) consisted of a central ν(NH) peak at 3162.1(2) cm^{-1} and side peaks at 3177 and 3155 cm^{-1}, the latter two being overtones in moderately weak FR with ν(NH). On increasing the temperature ν(NH) shifted to lower wavenumbers and the intensity of the 3177 cm^{-1} peak gradually vanished, while that of the 3155 cm^{-1} peak increased. By ca. 220 K a 1:1 doublet (in full resonance, $2W$ = 9.5 cm^{-1}) was observed. At still higher temperatures the relative intensity of the low-wavenumber component increased, indicating that ν(NH) has now shifted past the position of the overtone and that the resonance was now decreasing. At room temperature the band was a broad

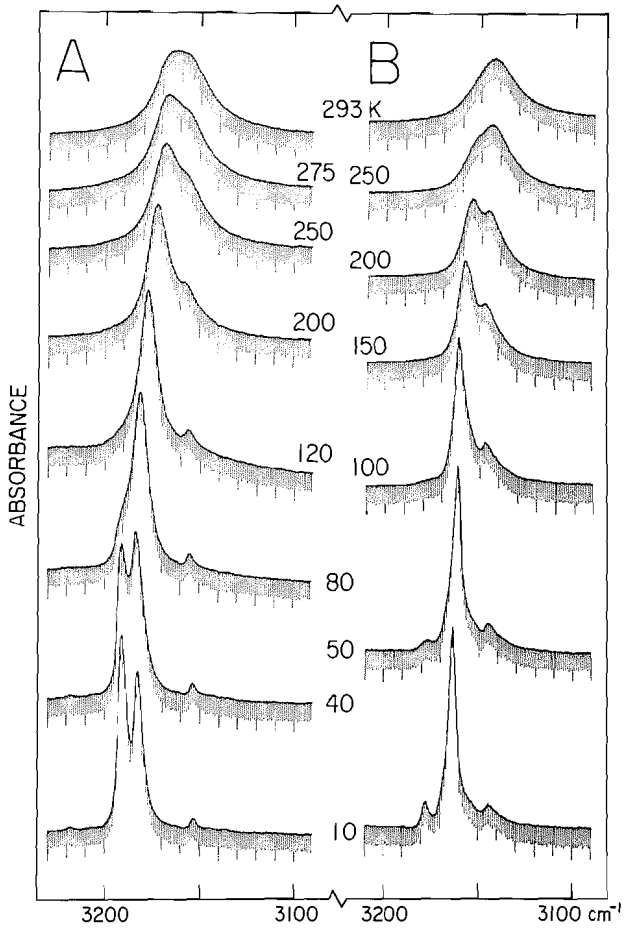

FIG. 10. The NH stretching fundamental of (*A*) $(Me_3NH)_2SnCl_6$ (0% D) and (*B*) $(Me_3NH)_2SnBr_6$ (0% D) at different temperatures.

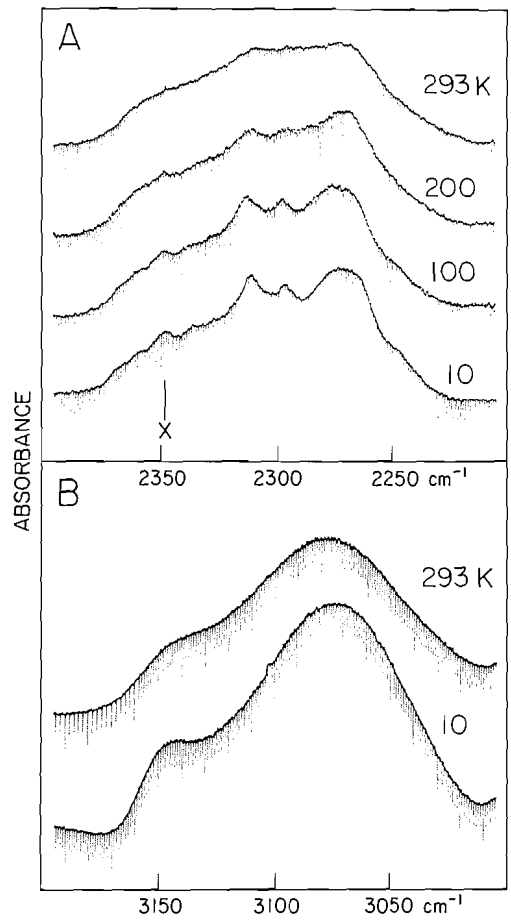

FIG. 11. The NH stretching fundamental of 3PHS (0% D) (*B*) and the ND stretching fundamental of 3PHS (68% D) (*A*) at different temperatures. The band marked X is present in the spectrum of the undeuterated compound.

singlet centred at 3142.0(8) cm^{-1}, hence the full temperature shift was $-20.1(8)$ cm^{-1}.

$(Et_3NH)_2SnCl_6$

Although the spectrum of 3EHS has already been reported (1), we return to it here in order to examine details of the FR. In this salt, too, coupling of the NH (or ND) stretching vibrations is virtually absent: ν(NH) was a singlet at all temperatures between 10 and 293 K. It shifted from 3117.8 at 10 K to 3109.7 cm^{-1} at 293 K, a total of $-8.1(5)$ cm^{-1}. The ND stretch was a Fermi doublet, with $2W = 24.2$ cm^{-1} and ν^0(ND) = 2317.0 and 2311.3 cm^{-1} at 10 and 293 K respectively. The total shift of $-5.3(7)$ cm^{-1} matches well the corresponding shift for ν(NH) derived directly from the spectra.

(n-$Pr_3NH)_2SnCl_6$

In this crystal the two nonequivalent N atoms at sites of C_1 symmetry ideally should give rise to two NH (or ND) stretching absorptions.

At 10 K the ND stretching fundamental consisted of three broad bands, centred at 2312(1), 2297(1), and 2273(2) cm^{-1} (Fig. 11*A*). The first two appeared to be the components of a Fermi doublet with an intensity ratio of 53:47. On this assumption $2W = 15$ cm^{-1} and ν^0(ND) = 2305(1) cm^{-1}. The band at 2273 cm^{-1} was much broader and positioned much lower than most of the ND fundamentals we have encountered in this work. It would thus appear to originate in a more strongly hydrogen-bonded ND group than that giving rise to the doublet; the only candidate is the highly asymmetrically bifurcated N(2)—H(2)···Cl(3) grouping, with H···Cl ~ 2.38 Å and NHCl ~ 150°. Increasing temperature gradually broadened all three bands, with only very small wavenumber shifts. At 293 K the resonance doublet had peak maxima at 2309(2) and 2295(2) cm^{-1} and an intensity ratio close to unity, yielding ν^0(ND) = 2302(2) cm^{-1} and an overall temperature shift of $-3(2)$ cm^{-1}. The corresponding position of the low-lying band was 2272(2) cm^{-1}, with a temperature shift of $-1(2)$ cm^{-1}.

The ν(NH) fundamental contained only two resolved features (Fig. 11*B*). The broad and intense band at 3074 cm^{-1} clearly is the counterpart of the 2273 cm^{-1} ND band (the isotopic ratio is 3074/2273 = 1.352). The 2312 cm^{-1} component of the ND doublet appears to have its counterpart in the NH band at ca. 3142 cm^{-1} at 10 K, the position of this band shifting slightly to lower wavenumbers with increasing temperature, ca. 3138 cm^{-1} at 293 K. The additional intensity between the bands at 3074 and 3142 cm^{-1} may correspond to the second component of the ND doublet. The NH bands were broader than the corresponding ND bands, and this resulted in a more severe overlap of the features in the NH stretching region and precluded a more accurate description of these features.

(n-$Bu_3NH)_2SnCl_6$

The crystal structure of 3BHS has not been determined. A preliminary survey of the spectra showed broad NH and ND bands strongly resembling those of 3PHS. The ND stretching fundamental at 10 K was centred at 2295(3) cm^{-1} and shifted

293 K, which yields an overall shift of $-9(4)$ cm^{-1}.

Monoalkylammonium salts

The band shapes of the NH and ND stretching fundamentals of 1RHS were highly dependent on the degree of deuteration (Fig. 12). This is largely due to the coupling of H (or D) motions *within* the cations: the spectrum in the NH region is derived from the NH groups of the RNH_3^+, RNH_2D^+, and $RNHD_2^+$ ions, and that in the ND region contains contributions from the ND groups of the RND_3^+, $RNHD_2^+$, and RNH_2D^+ ions, the relative intensities of the individual absorptions varying with the D content of the sample. Isotopic dilution was thus required to obtain structurally useful information on individual hydrogens.

$(MeNH_3)_2SnCl_6$

In this crystal ($R\bar{3}m$, single type of $MeNH_3^+$), the site symmetry at the N atom is C_{3v} both at room temperature and at 120 K (i.e. below the temperature of the only transition detected between 20 and 300 K, 154.3 K) (6, 16–18). The H atoms could not be located in the difference Fourier maps, but the three equivalent N$\cdots$Cl distances of 3.46 Å and the six equivalent N$\cdots$C distances of 3.59 Å (all at room temperature), together with the assumption of staggered cation conformation and of tetrahedral CNH angles, lead to the supposition (6) that the three hydrogens engage in trifurcated N—H$\cdots$3Cl bonds (Figs. 13 and 14). These bonds are nearly symmetric, H$\cdots$Cl = 2.64 Å (1×) and 2.80 Å (2×), NHCl = 136° (1×) and 133° (2×) if d(N—H) is taken to be 1.02 Å. The spectroscopic expectation for the $MeNH_2D^+$ probe ion would thus be a single

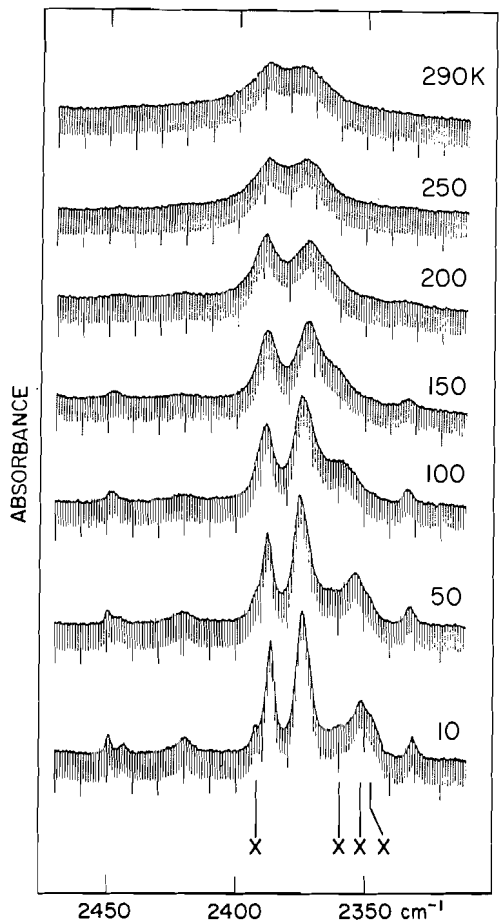

FIG. 15. The ND stretching fundamental of 1MHS (2% D) at different temperatures. Bands marked X occur also in the spectrum of the undeuterated compound.

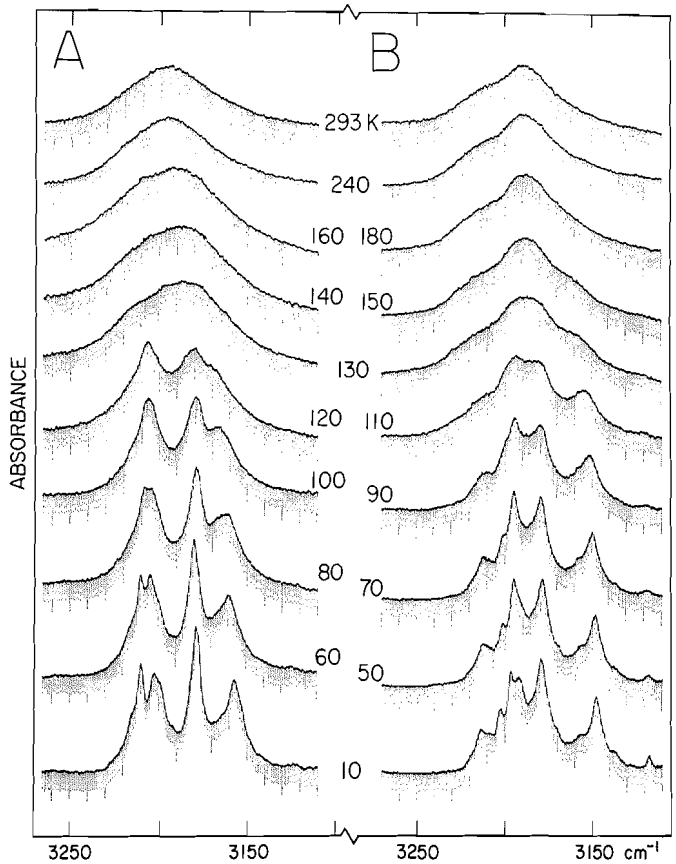

FIG. 16. The NH stretching fundamentals of (*A*) 1EHS (90% D) and (*B*) 1PHS (90% D) at different temperatures.

ND stretching absorption. Its frequency should decrease with increasing temperature, but perhaps not in the same way as in 3MHS and $(NH_4)_2SnCl_6$ because of the different librational mobility of the $MeNH_3^+$ ion and the possible torsional–oscillatory interaction of the NH_3 and CH_3 groups (cf., for example, ref. 19).

The spectrum of $MeNH_2D^+$ in 1MHS (2% D) at 10 K (Fig. 15) contained in the ND stretching region a doublet at 2386.7(2) and 2374.6(3) cm^{-1}, with an intensity ratio of 31:69. Assuming that the doublet is due to FR, $\nu^0(ND)$ = 2378(1) cm^{-1}, $2W$ = 11.2 cm^{-1}.[5] The four small peaks nearby (at 2449.5, 2443.3, 2419.5, and 2331.0 cm^{-1}) are clearly due to overtone and combination levels in much weaker resonance with ν(ND). Temperature increase had only a minor effect on the spectral features: $\nu^0(ND)$ at 293 K is 2381(2) cm^{-1}, which yields 3(2) cm^{-1} for the total shift between 10 and 293 K, an uncertain but apparently positive value. There was no indication in the spectra of any phase transition.

The NH stretching fundamental of the $MeNHD_2^+$ probe ion at high D levels also was a doublet (Fig. 12), with components at 3220.3(2) and 3206.0(2) cm^{-1} and an intensity ratio of 40:60 at 10 K. Assuming it to be a Fermi doublet, $\nu^0(NH)$ = 3211.5(8) cm^{-1} and $2W$ = 13.4 cm^{-1}. Increasing temperature brought only a gradual broadening of the bands, with almost no change in the positions or intensities of the doublet components.

$(EtNH_3)_2SnCl_6$

The space group $P\bar{3}m1$ of 1EHS at room temperature is only statistical. The local symmetry at a N atom in the orientationally disordered structure is effectively no higher than C_s (with H—N—C(1)—C(2) in the mirror plane) and strictly only C_1. The expected NH (or ND) stretching absorption of the $EtNHD_2^+$ (or $EtNH_2D^+$) probe ion will depend on how strongly the CH_3 group affects the NH stretching vibration. In principle the stretching band is expected to be a 2:1 doublet, unresolved if the effect of the CH_3 on the equivalence of the three N-hydrogens is small, resolved (though probably closely spaced) if the effect is appreciable.

At 10 K the ν(NH) fundamental of $EtNHD_2^+$ consisted of four well-separated peaks at 3210.2(2), 3202.3(4), 3178.6(2), and 3157.1(4) cm^{-1}, plus at least two other, partially resolved, features (Fig. 16*A*). This multiplet is probably too wide and too complex to be the result of only one stretching fundamental in resonance with a number of overtone or combination levels. The distribution of ir absorption intensity is consistent with at least three and probably six distinct NH fundamentals, possibly with minor complications from FR. The changes in the band shapes from 10 to 125 K were gradual. Several of the features of the 10 K spectrum broadened and eventually coalesced, and the 3202 and 3211 cm^{-1} bands underwent a thermal collapse analogous to that observed recently in the spectra of $(NH_4)_2Cr_2O_7$ (22).

[5]For the presumably isostructural $(MeNH_3)_2PtCl_6$ the corresponding $\nu^0(ND)$ estimate is 2375 cm^{-1} (20). References 20 and 21 contain further spectroscopic results on the $MeNH_3^+$ ion, including a normal-coordinate analysis in C_{3v} symmetry.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12

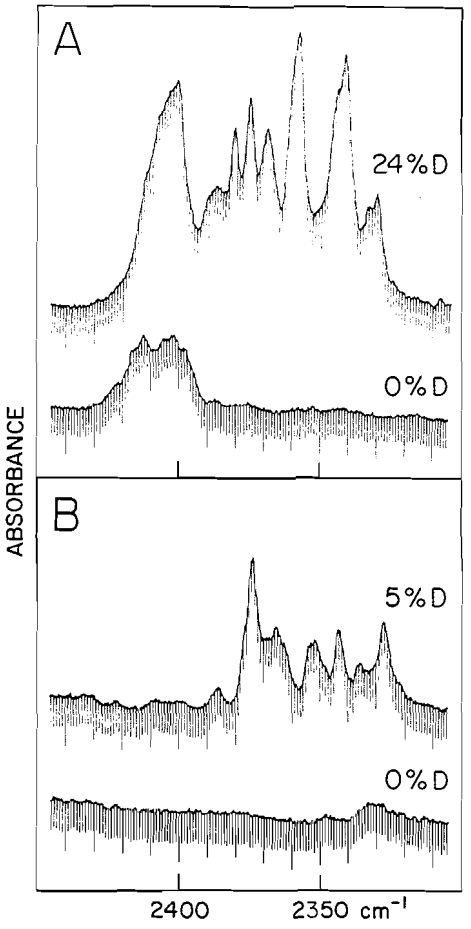

FIG. 17. The ND stretching fundamentals of (*A*) 1EHS (24% D) and (*B*) 1PHS (5% D) at 10 K, with their respective 0% D baselines.

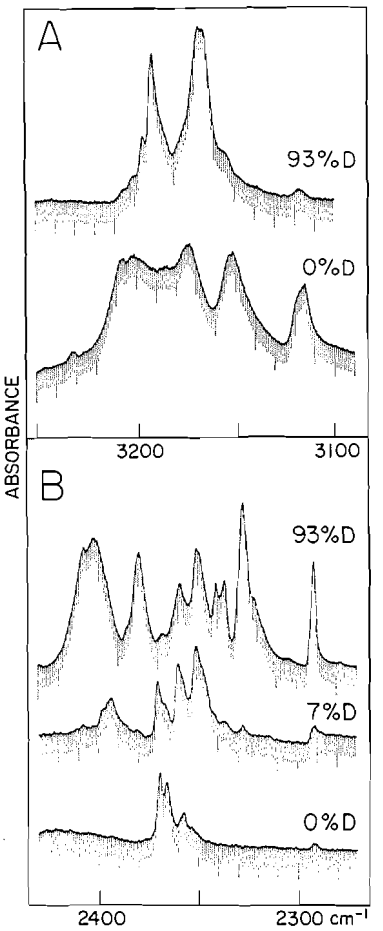

FIG. 18. Effect of isotopic dilution on the spectrum of 2MHS at 10 K in the region of the NH (*A*) and ND (*B*) stretching fundamentals.

At 125(5) K the ν(NH) multiplet changed sharply into a symmetric singlet ($\Delta\nu_{1/2}$ = 50 cm^{-1}). This change appears to correspond to a transition to a high-temperature phase in which the three N-hydrogens of a cation, nonequivalent at low temperatures, are statistically equivalent. The ν(NH) singlet in the high-temperature phase shifted from 3186(2) cm^{-1} at 130 K to 3196(2) cm^{-1} at 293 K.

The corresponding ND stretching region in the spectrum of the $EtNH_2D^+$ probe ion (Fig. 17*A*) is complicated by the strong background absorption of the undeuterated species as well as by FR.

(n-PrNH$_3$)$_2$SnCl$_6$

The hydrogens of the two nonequivalent N atoms (each of symmetry C_1) all engage in bifurcated or trifurcated N—H···Cl bonds, with H···Cl distances ranging from 2.44 to 3.16 Å (Table 11). The ν(ND) stretching fundamental of the *n*-$PrNH_2D^+$ probe ion would therefore be expected to consist of six components, with frequencies of the same order as that of $\nu_1(NH_3D^+)$ in $(NH_4)_2SnCl_6$, ~2375 cm^{-1}.

The spectrum of the *n*-$PrNH_2D^+$ ion at low D concentration at 10 K contained a complex absorption in the ND stretching region, with at least ten peak ranging from 2386 to 2327 cm^{-1} (Fig. 17*B*). As in the case of 1EHS, we seem to be dealing here with six ND fundamentals plus complications from FR and baseline absorption. However, in contrast to 1EHS, the spectral features — largely broadening and coalescence of most bands — changed with increasing temperature gradually, with no evidence of a phase transition below room temperature.

The 10 K spectrum of the *n*-$PrNHD_2^+$ ion at high D concentration corresponded, in the NH stretching region, more closely to the expected six components. The peak centres ranged from 3213.5(7) to 3147.6(3) cm^{-1} (Fig. 16*B*). As the the temperature increased, these features broadened and some partially coalesced, but at least two distinct features remained even at room temperature. There was no evidence of any sharp spectral change that might indicate a phase transition.

Dialkylammonium salts

As in the case of 1RHS, the band shapes of the NH and ND stretching fundamentals of the dialkyl salts were found to depend strongly on the degree of deuteration of the sample (Fig. 18) and isotopic dilution had to be resorted to.

(Me$_2$NH$_2$)$_2$SnCl$_6$

The C_s site symmetry of the N atoms and the equivalence of the two bifurcated N—H···2Cl bonds in the room-temperature structure lead to the expectation, ideally, of single NH and ND absorptions with frequencies which will decrease with increasing temperature.

The NH stretching fundamental of the Me_2NHD^+ probe ion at 10 K consisted of a doublet at 3191.1(2) and 3167.6(4) cm^{-1} (Fig. 19*A*). An additional feature, at 3165.8(6) cm^{-1}, was present at 10 K but disappeared by 50 K. Increasing temperature gradually reduced the doublet spacing until at 100 K only a singlet, at 3185.2(8) cm^{-1}, was observed. Above that temperature, which appears to correspond to a transition, the singlet gradually moved to lower wavenumbers and at 293 K ended up at 3181.7(8) cm^{-1}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

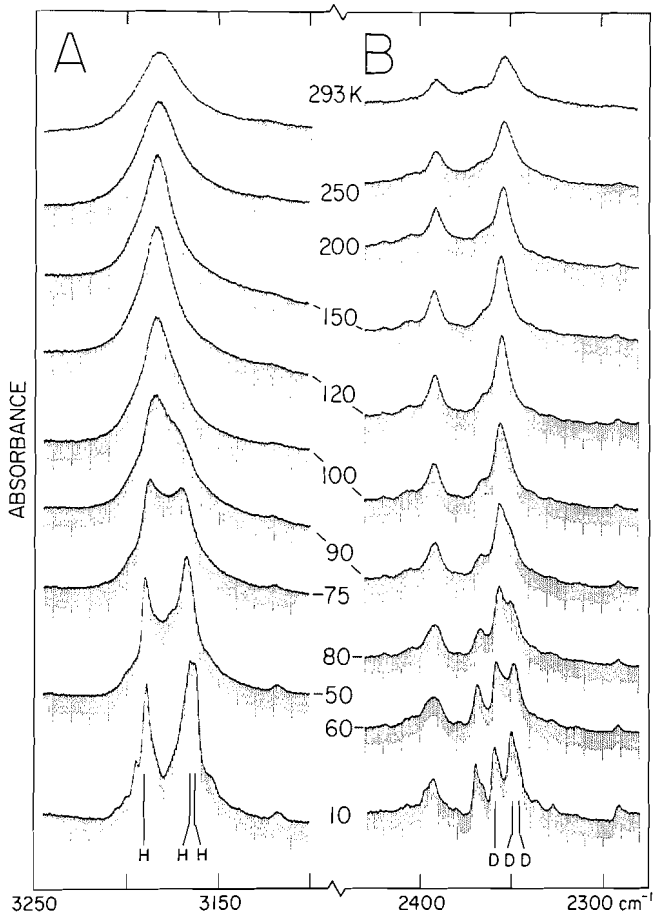

FIG. 19. The NH stretching fundamental of 2MHS (93% D) (*A*) and the ND stretching fundamental of 2MHS (9% D) (*B*) at different temperatures. Only the bands marked H and D are due to the Me_2NHD^+ probe ion.

The corresponding ND stretching fundamental also was essentially a doublet at low temperatures, with main components at 2359.2(3) and 2350.0(3) cm^{-1} (Fig. 18*B*). The additional small ND feature, at 2347.4(8) cm^{-1} at 10 K, was absent above 40 K. Bands at 2370 and 2366 cm^{-1} belong to the main isotopic species $Me_2NH_2^+$, while those at 2398, 2393, 2337, and 2327 cm^{-1} probably originated in a small amount of the $Me_2ND_2^+$ species. With increasing temperature the doublet collapsed, at first gradually and then sharply, to a singlet at 2355.7(4) cm^{-1} at 100 K. This singlet then slowly shifted to 2352.6(10) cm^{-1} at 293 K (Fig. 19*B*). These changes are entirely analogous to those in ν(NH).

The evolution with temperature (Fig. 20) seems to indicate that below 100 K two types of N-hydrogens are present, with different environments. The gradual collapse of the doublet below this temperature is remarkably similar to that observed for $(NH_4)_2SnBr_6$ (Fig. 10 of ref. 23). The sharp emergence of a singlet at ca. 100 K then corresponds to a transition in which the two hydrogens become equivalent.

The cause of the additional doubling of the lower-wavenumber component between 10 and 40 K is either FR or — more likely, as it occurs for both ν(NH) and ν(ND) — the nonequivalence of two types of $Me_2NH_2^+$ ions.

$(Et_2NH_2)_2SnCl_6$

The crystal structure of 2EHS (C_{2h}, ref. 24) has not yet been determined. The NH and ND stretching fundamentals of the Et_2NHD^+ probe ion at 10 K (Fig. 21) showed a marked resemblance to the corresponding spectra of 2MHS: ν(NH) consisted mainly of a doublet at 3146.9(3) and 3117.4(3) cm^{-1}, with two weaker bands at lower wavenumbers, possibly due to overtone levels enhanced by FR. The corresponding ND stretching fundamental (Fig. 21*B*) also was a doublet, at 2325.5(3) and 2313.5(3) cm^{-1}, the additional bands being mostly accounted for as due to $Et_2NH_2^+$ and small amounts of $Et_2ND_2^+$. Some minor extra features may be due to Et_2NHD^+ through FR.

As in the case of 2MHS, the doublets seem to correspond to a loss of equivalence of the NH_2 hydrogens, but the reason for the greater intensity of the high-wavenumber component is not clear.

Both doublets underwent a gradual collapse as the temperature was raised (Fig. 20). Unlike for 2MHS, however, this process was continuous up to room temperature. The evolution with temperature points to the existence of a transition in the vicinity of 330 K.

(n-$Pr_2NH_2)_2SnCl_6$

The crystal structure of 2PHS is not yet known. Ries (12) reported the crystal symmetry of the chloroplatinate and the bromoplatinate (dimorphic) to be C_{2h}.

The spectrum of our preparation was unusual. The undeuterated material had bands at 3220 and 3100 cm^{-1} which match similar doublets in the spectra of 2MHS and 2EHS and are due to the antisymmetric and symmetric stretching of NH_2 groups. However, in addition to this absorption in the accustomed region the spectrum also exhibited an intense absorption (*Y* in Fig. 22) with the main peak at 2780 cm^{-1}. This is 300–400 cm^{-1} below the NH stretching fundamentals of the other hexachlorostannates examined, the spectra of the latter showing in this region only weak bands due to binary combinations of CH deformation modes.

On deuteration the intensity of band *Y* and that of the "regular" NH stretching absorptions decreased (Fig. 22). This reduction of intensity was accompanied by the appearance of one group of bands in the 2360–2200 cm^{-1} region (corresponding to "regular" ND stretching) and another, equally intense, in the 2160–2020 cm^{-1} region (*Z* in Fig. 22). The latter group is clearly the ND stretching analog of the *Y* bands. The changes produced by deuteration indicate that *Y* and *Z* owe their intensities to NH and ND stretching, respectively. Their frequencies are comparable to those of the NH and ND stretching modes in Et_3NHCl, in which the unique, straight N—H···Cl bond is much shorter than the N—H···Cl bonds in the alkylammonium hexachlorostannates (results to be published and ref. 25; unpublished work by R. C. Lord quoted in ref. 26; ref. 27).

These spectral features were sufficiently unexpected to warrant a closer look at the identity of our presumed 2PHS preparation (see Experimental). A crystal-structure determination, intially not contemplated at this stage, revealed the product to be not 2PHS but the "adduct" of 2PHS and *n*-Pr_2NH_2Cl, $(n\text{-}Pr_2NH_2)_3(SnCl_6)Cl$. The implications of this finding will be reported elsewhere.

Discussion

Infrared spectra

Low-temperature transitions

The existence of low-temperature transitions in 2MHS (T_{tr} ~ 100 K), 2EHS (T_{tr} ~ 330 K), and 1EHS (T_{tr} ~ 125 K) is recognizable from a clear change in the appearance of the NH

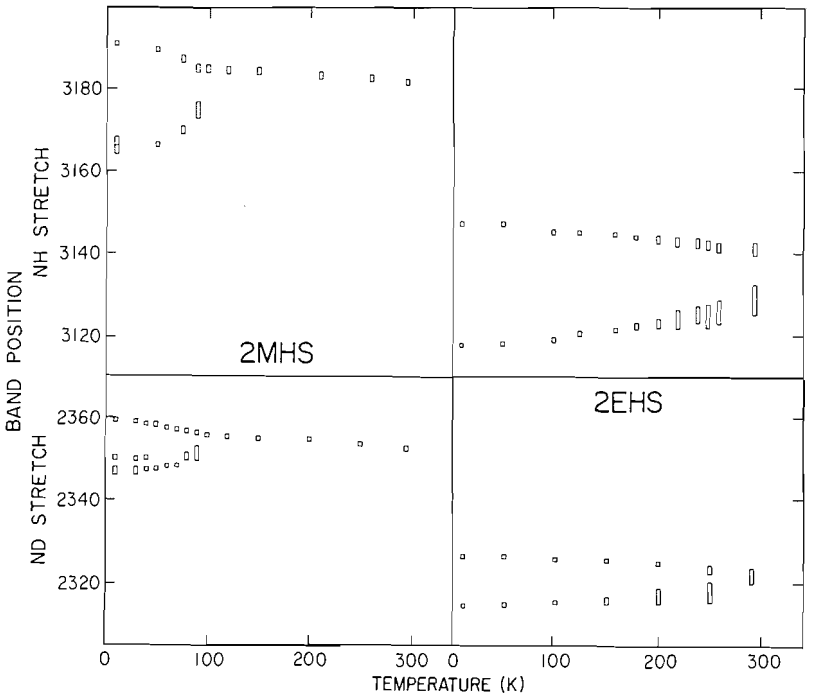

FIG. 20. Positions of the absorption maxima vs. temperature for 2MHS (from Fig. 19) and 2EHS (from Fig. 21).

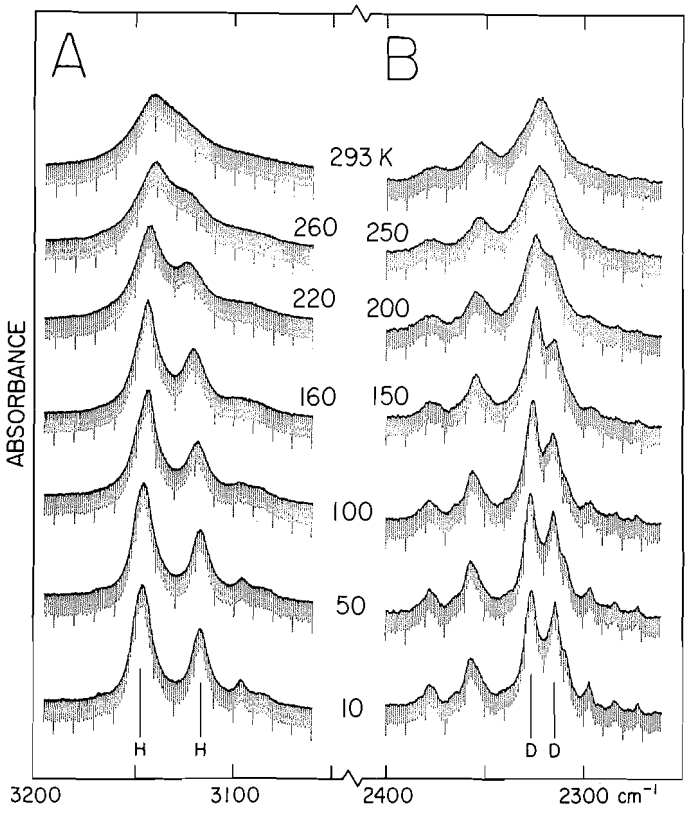

FIG. 21. The NH and ND stretching fundamentals of 2EHS at different temperatures. (*A*) 2EHS (95% D); (*B*) 2EHS (11% D). Only the features marked H and D are due to the Et_2NHD^+ probe ion.

and ND absorptions in each of the spectra (Figs. 16*A*, 17, and 20).[6] None of these transitions seems to have been reported previously. No indication of low-temperature transitions between 10 and 293 K was discernible in the spectra of 1MHS, 1PHS, and 3MHS. The spectra of 2PHS and 2BHS were inconclusive in this respect.

1MHS. It is not surprising that the transition at 154.3 K detected in 1MHS by ^{35}Cl nqr (16) and by calorimetric and ir (18) as well as crystallographic (6) measurements was not observed in our NH and ND stretching spectra.[7] This transition is of a subtle and unusual nature: it occurs between phases of the same space-group symmetry, without doubling of the unit cell, and manifests itself crystallographically by a discontinuity in the temperature variation of c (Fig. 23). At the same time the Cl spin–lattice relaxation time decreases sharply as T_{tr} is approached from either side, but the proton relaxation time and its second moment remain practically unaffected (28). Only one ^{35}Cl resonance was present on either side of T_{tr}, hence all Cl atoms are crystallographically equivalent in both phases (16). The total ΔS_{tr}, $1.60(18)R$, is large enough for a transition of the order–disorder type, and the critical properties also are consistent with an order–disorder mechanism (18). It is suggested (18) that the reorientational motion of the $CH_3NH_3^+$ ion changes at T_{tr} from a weakly-hindered rotation at $T > T_{tr}$ to a more restricted motion at $T < T_{tr}$, but beyond this the nature and cause of the transition remain unexplained.

1EHS. The transition in this compound is almost certainly associated with orientational ordering of the Et groups. In that case the orientational disorder at $T > T_{tr}$ must be dynamic rather than frozen-in static, as cooling would be unlikely to produce an ordered arrangement from a disorder which already is frozen in at room temperature.

2RHS. The transitions in 2MHS and 2EHS appear to be of the same type (Fig. 20). The doublet produced from the single stretching absorption in 2MHS on cooling consists of a high-frequency component only slightly above the singlet absorp-

[6]Spectroscopic evidence of a transition at ~180 K in $(n\text{-}Pr_2NH_2)_3(SnCl_6)Cl$ will be discussed elsewhere.

[7]Similarly, no changes attributable to the transition in the vicinity of 125 K (16) were observed in the spectra of $(MeNH_3)_2PtCl_6$ (20).

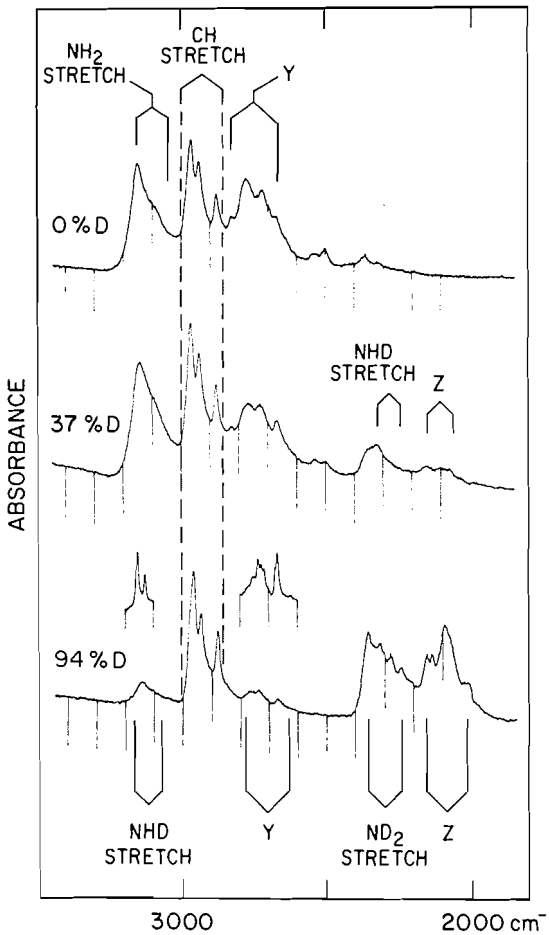

FIG. 22. Spectra of "2PHS" (= $(n\text{-}Pr_2NH_2)_3(SnCl_6)Cl$) in the region of NH and ND stretching fundamentals (fluorocarbon mulls at room temperature). For bands marked *Y* and *Z* see text. The two inserts refer to the 94% D sample at 10 K.

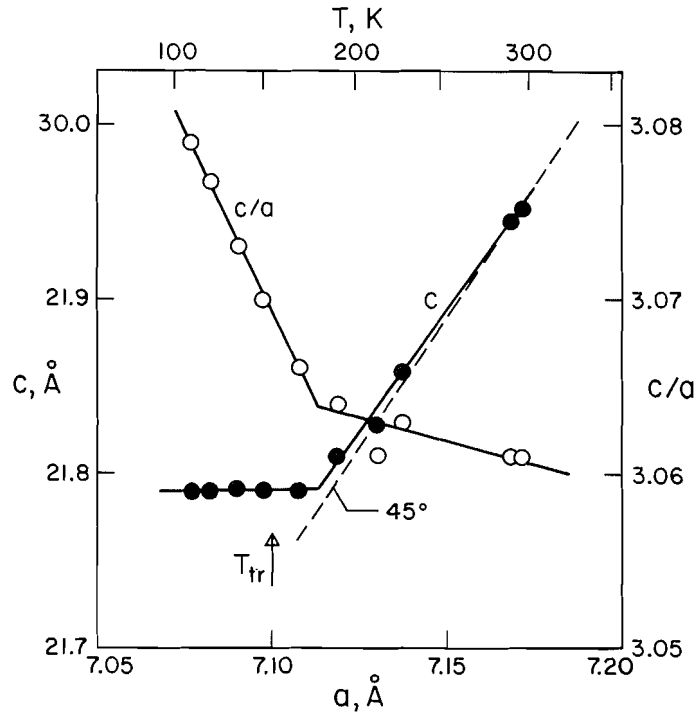

FIG. 23. Variation of the unit-cell dimensions and the axial ratio of 1MHS with temperature (data taken from ref. 6).

tion, and a low-frequency component noticeably below the original singlet. In 2EHS the transition does not take place within the temperature interval studied, but otherwise the evolution of ν with T is similar. In 2MHS, where the room-temperature structure is well established, the transition appears to destroy the equivalence of the N-hydrogens. This could be achieved either by reducing the C_s symmetry of the cation in the upper phase to C_1, or by splitting the original set of $Me_2NH_2^+$ ions into two subsets (both with site symmetry C_s or C_2, or one with C_s and the other with C_2), but in any event cooling through T_{tr} results in a strengthening of some (probably half) of the N—H···Cl bonds, all of which are undifferentiated at $T > T_{tr}$. An analogous situation may exist in 2EHS, except that the strengthening must be present already in the room-temperature structure. The spectrum of this salt will be discussed further when we have completed the crystal-structure determination now in progress.

Hydrogen bonding

The variation, with composition, of the isolated (and Fermi-unperturbed) ND stretching frequency at 10 K is shown in Fig. 24; the NH stretching frequency varies in an analogous manner. The complications due to FR, to the existence of low-temperature transitions and to the presence of extraneous features in the NH and ND stretching regions preclude clear-cut general statements about the effect of alkyl substitution in the ammonium ion on the strength of hydrogen bonding. In fact, almost all the information which can be extracted from the ND spectra of Fig. 24 could have been obtained by inspection from the NH stretching fundamentals of the undeuterated samples. This is an important — and not advantageous — difference from the situation in ammonium compounds, where isotopic dilution in most cases is essential.

The range of the ν(ND) fundamental in compounds investigated[8] is about 2380–2270 cm^{-1}, i.e. not above $\nu_1(NH_3D^+)$ of $(NH_4)_2SnCl_6$ (4). Insofar as one can speak of discernible trends in this group of spectra, the least ambiguous indication of a trend is present in the 3RHS series. Both ν(NH) and ν(ND) decrease with the increasing mean linear unit-cell dimension $\bar{a} = (V/Z)^{1/3}$ (Fig. 25). The decrease is steep from Me to Et but levels off after Et and seems to tend to a steady value in the vicinity of 2300 cm^{-1} for ν(ND) and 3080 cm^{-1} for ν(NH). This steady value for ν(ND) is in the general region of the extrapolated "free-ion" $\nu_1(NH_3D^+)$ value in ammonium halides (13).

The variation of ν(NH) and ν(ND) of 3RHS with temperature merits attention. For NH_4 compounds containing symmetrically trifurcated hydrogen bonds a plot of the difference $\Delta\nu_1(NH_3D^+) = \nu_1(10\text{ K}) - \nu_1(293\text{ K})$ vs. d(H···X) (Fig. 8 of ref. 4) revealed a quasiexponential correlation: the shorter the trifurcated H···X distance in this common-cation, variable-anion series, the larger $\Delta\nu_1(NH_3D^+)$, i.e. the more pronounced the decrease of ν(ND) with increasing temperature. A corresponding plot for the variable-cation, common-anion 3RHS series cannot be produced because of the ambiguity in choosing the appropriate d(H···X) when the trifurcation is asymmetric or the hydrogen-bonding geometry even more dissimilar. Furthermore, d(H···X) spans a much narrower range in the 3RHS

[8]Disregarding the lower-frequency group of ND absorptions in $(n\text{-}Pr_2NH_2)_3(SnCl_6)Cl$ (initially taken for 2PHS). This group originates in H···Cl^- interactions.

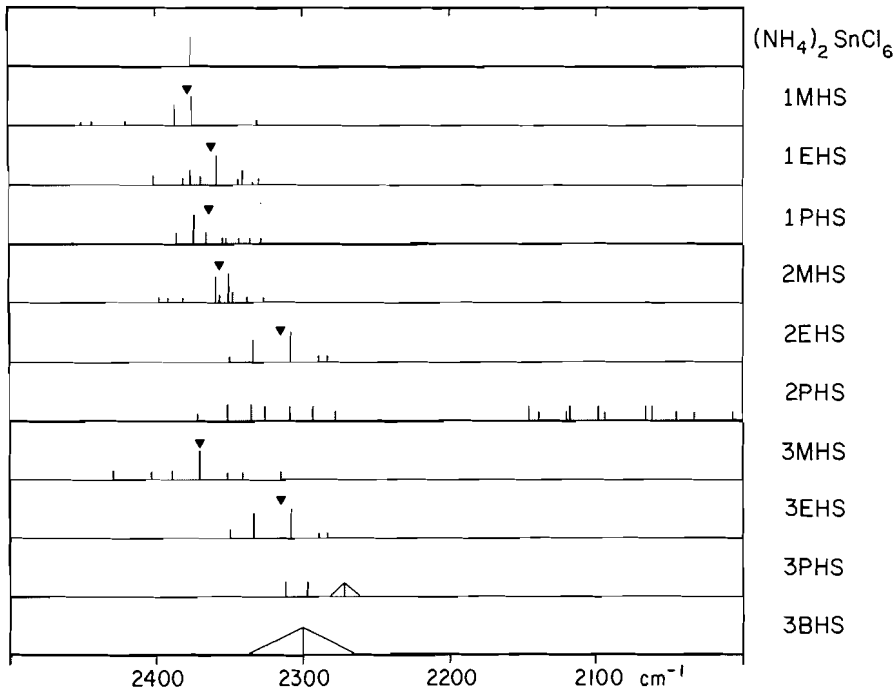

FIG. 24. Synoptic presentation of the ND stretching absorptions at 10 K. Triangles indicate the calculated positions of ND stretching fundamentals unperturbed by Fermi resonance. 2PHS in reality refers to $(n\text{-}Pr_2NH_2)_3(SnCl_6)Cl$ (see text).

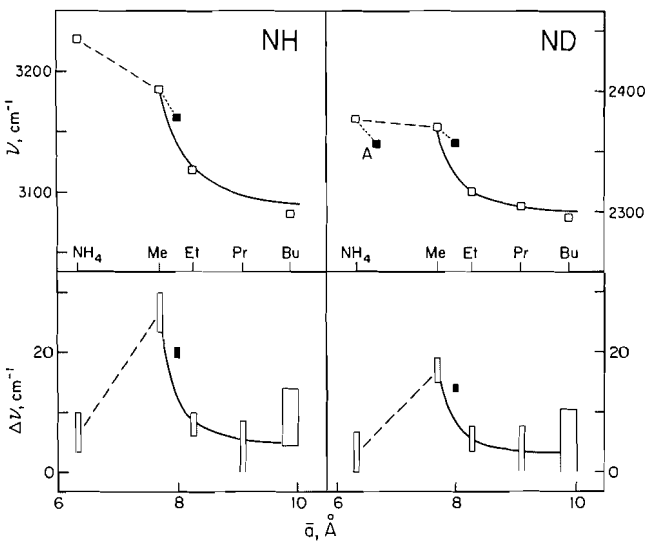

FIG. 25. Variation of ν(NH) and ν(ND) (top) and $\Delta\nu = \nu(10\text{ K}) - \nu(293\text{ K})$ (NH and ND) (bottom) of 3RHS with the mean linear unit-cell dimension $\bar{a}$. Open rectangles, 3RHS; full rectangles, $(Me_3NH)_2SnBr_6$; *A*, $(NH_4)_2SnBr_6$. The $\bar{a}$(3BHS) value is estimated.

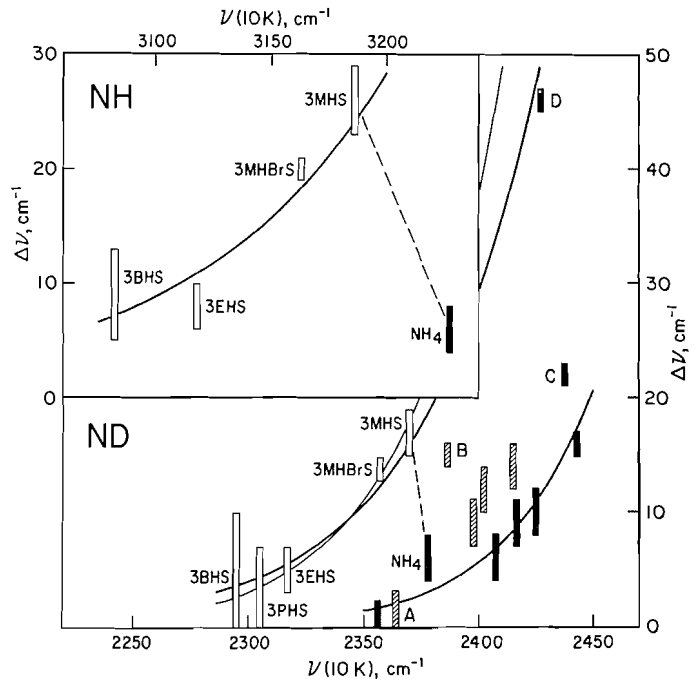

FIG. 26. Variation of $\Delta\nu = \nu(10\text{ K}) - \nu(293\text{ K})$ (NH and ND) of 3RHS (open rectangles) with ν(NH) and ν(ND). Ammonium compounds containing symmetrically (full rectangles) and asymmetrically (shaded rectangles) trifurcated N—H···X bonds are included for comparison. *A*, NH_4BPh_4 (58); *B*, bifurcated N—H···2O bond in taurine (29); *C*, NH_4CuSO_3 (4); *D*, NH_4SnF_3 (4); 3MHBrS = $(Me_3NH)_2SnBr_6$. A reliable ν(NH) value for 3PHS could not be established.

than in the NH_4 series (2.2–2.9 Å) and a local variation due to causes specific to a particular 3RHS structure might, in a narrow d(H···X) range, be mistaken for a general trend. However, a $\Delta\nu$ vs. $\bar{a}$ plot (Fig. 25) shows a trend similar to that for ν vs. $\bar{a}$, i.e. indicative of an overall volume effect, with a monotonic variation for 3RHS but a strikingly different behaviour for $(NH_4)_2SnCl_6$.

The similarity of the variation of $\Delta\nu$ and that of ν with $\bar{a}$ suggests that the intermediary of the external dimensional parameter can be eliminated by relating the quantities derived from the spectra alone, viz. by plotting $\Delta\nu$ against ν. In this plot (Fig. 26) $(NH_4)_2SnCl_6$ again occupies a special position, but the ν(ND) points for 3RHS show a clear trend in that $\Delta\nu$ increases with ν. $(Me_3NH)_2SnBr_6$ fits in this series in spite of the difference in anion. For ν(NH) the trend is less convincing because of the absence of a point for 3PHS (see above) in

conjunction with the large uncertainty in $\Delta\nu$(3BHS). However, the existence of the trend is supported by the features of the corresponding $\Delta\nu$ vs. ν plot for ammonium compounds included for comparison in Fig. 26. This plot contains all the NH_4 compounds involving symmetrically trifurcated N—H···X bonds for which the isotopically isolated $\nu_1(NH_3D^+)$ (i.e. ν(ND)) frequency is known, plus a few instances of N—H···X bonds which are trifurcated but not symmetrically, and also the asymmetrically bifurcated N—H···2O bond in taurine. In spite of the variety of anions the same trend as in the 3RHS series is observed — a clear increase of $\Delta\nu$(ND) with ν(ND). Since the ν(ND) values of the NH_4 compounds fall in a higher wavenumber region, the point for $(NH_4)_2SnCl_6$ occupies its natural place in this series.

These observations can be summarized as follows: ν increases with decreasing $\bar{a}$ both for 3RHS and NH_4 compounds, and $\Delta\nu$ increases with ν in both groups. The explanation of the increase of ν with decreasing $\bar{a}$ in these ionic crystals is to be looked for in the effect on ν of the dominance of the Coulombic lattice compression and economy of packing over that of an increase in the acceptor strength of X, the two effects working in opposite directions. The existence of this overcompensation is well documented for cubic $(NH_4)_2MX_6$, all of which contain symmetrically trifurcated N—H···3X bonds (13, 29). In 3MHS and 3EHS hydrogen bonds connect each anion with two cations to form quasi-electroneutral units, thus giving rise to a "molecular" $[R_3NH\cdots Cl_3SnCl_3\cdots HNR_3]$ crystal. In such crystals one might expect the H···X distance to be governed more closely by the X acceptor than in the corresponding NH_4 compounds, where the structure is spatially more homogeneous, and consequently ν to decrease with the increasing acceptor strength of X. This appears, however, not to be the case, for on replacing Cl in 3MHS by Br (to form the presumably isostructural analog) ν decreases. Thus even here the variation in the spacing of the ionic charges in the crystal is the decisive factor determining the trend in ν: the minimum separation of the centroids of negative charge (as measured by the shortest Sn···Sn distances at room temperature) is 7.10 Å in $(NH_4)_2SnCl_6$, 7.49 Å in $(NH_4)_2SnBr_6$, 8.63 Å in 3MHS, 8.95 Å in $(Me_3NH)_2SnBr_6$ (estimated from densities), and 8.54 and 9.58 Å in 3EHS (mean, 9.06 Å).

The increase in the temperature shift $\Delta\nu$ with ν (Fig. 26) is tentatively accounted for by the variation of the H···X distance with the angular displacement α of the NH vector pivoting about N (Fig. 27). At very low temperatures this vector is in a quasi-static equilibrium position with respect to the X atoms of a trifurcated N—H···3X bond. With increasing temperature the H atom undergoes momentary displacements toward one of the acceptor atoms at a time, as a result of a bending motion of the NH bond and a librational motion of the cation as a whole (4, 13, 29). The relative importance of each motion depends on details of the hydrogen bonding and on the librational mobility of the cation.

Fitting the ν(ND) points for the symmetrically trifurcated N—H···3X bonds in cubic $(NH_4)_2MX_6$ (MX = SiF, SnCl, SnBr) and trigonal $(NH_4)_2MF_6$ (M = Ge, Sn, Ti) in Fig. 26 to an exponential function gives $\Delta\nu(ND) = 1.47 \times 10^{-28} \exp 0.02741\nu(ND)$, $r^2 = 0.834$, which suggests the existence of a correlation. If, in a first approximation, it is assumed that a certain increase in temperature, e.g. from 10 to 293 K, produces in these crystals a comparable increase in the angular amplitude α by which the NH vector is displaced pivoting about the stationary N atom toward X at a constant N—H bond

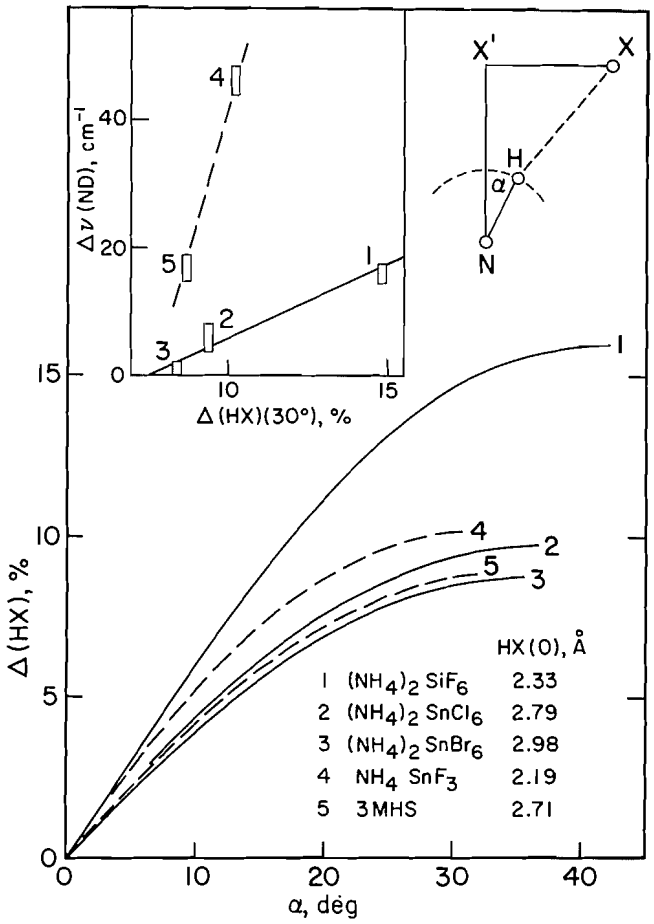

FIG. 27. Variation of $\Delta(HX) = -100[HX(\alpha) - HX(0)]/HX(0)$ of the H···X distance in a symmetrically trifurcated N—H···X bond with the angular displacement α of the NH vector of constant length pivoting about N. In NH_4SnF_3 and 3MHS there is an Sn atom on the NX′ trigyre above X′; in $(NH_4)_2SiF_6$, $(NH_4)_2SnCl_6$, and $(NH_4)_2SnBr_6$ this atom is absent. $X\cdots X' = d(X\cdots X)/\sqrt{3}$. Inset: plot of $\Delta\nu$(ND) against Δ(HX) (30°).

length, then the percentage decrease in the instantaneous H···X distance is larger for X = F than for X = Cl or Br (Fig. 27) and the difference grows with α, i.e. with temperature. Thus for $\alpha = 10°$ the ratio of the percentage decrease in H···X in $(NH_4)_2SiF_6$ to that in $(NH_4)_2SnCl_6$ is ~1.40, for $\alpha = 20°$ it is ~1.62, and for $\alpha = 30°$, ~1.74. Since a shortening of the H···X distance results in a stronger H···X bond, ν(NH) and ν(ND) must decrease with increasing α, and the ν observed at a particular temperature is a measure of this amplitude for a particular X (for $\alpha = 30°$ see inset of Fig. 27).

In the 3RHS series the hydrogen bond is symmetrically trifurcated in only two of the five compounds, viz. 3MHS and the presumably isostructural $(Me_3NH)_2SnBr_6$. However, *all five* $\Delta\nu$(ND) vs. ν(ND) points appear to form a coherent set (Fig. 26). Fitting them to an exponential function yields $\Delta\nu(ND) = 3.397 \times 10^{-25} \exp 0.02499\nu(ND)$, $r^2 = 0.984$; and similarly, $\Delta\nu(NH) = 2.675 \times 10^{-15} \exp 0.01153\nu(NH)$, $r^2 = 0.844$. Since the HX(0) (i.e. $d(H\cdots X)$ at $\alpha = 0°$) distances and the Δ(HX) vs. α curves for 3MHS and $(NH_4)_2SnCl_6$ are not greatly different (Fig. 27), the reason for the much larger $\Delta\nu$(ND) and $\Delta\nu$(NH) in 3MHS cannot be sought in the H···X distance and its variation alone. The structures of 3MHS and $(NH_4)_2SnCl_6$ differ in two important respects: the librational mobility of the cation in 3MHS is reduced because of the bulk and mass of the

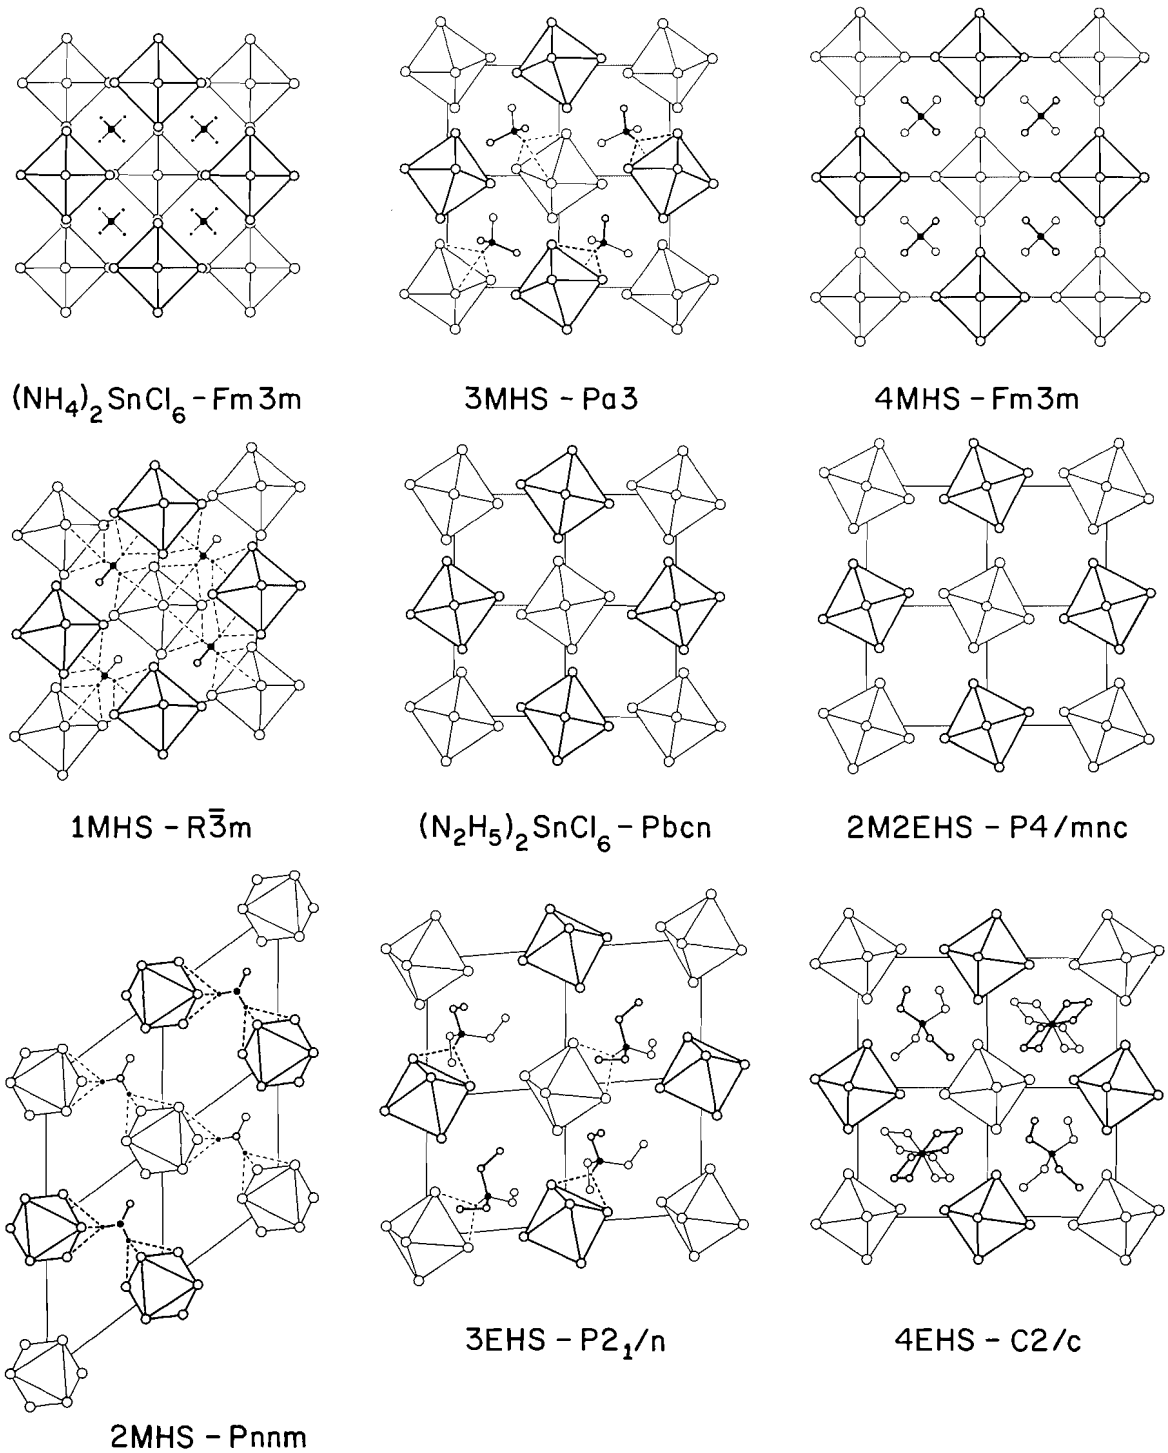

FIG. 28. $(R_nNH_{4-n})_2SnCl_6$ structures deriving from the *Fm*3*m* antifluorite structure. The projected lower half of the unit cell in each case is made to correspond to the lower four octants of the $(NH_4)_2SnCl_6$ antifluorite unit cell. The top half (not shown) is related by a symmetry operation appropriate to the respective space group. References: 2MHS, 3MHS, see text; $(NH_4)_2SnCl_6$, 2, 3; 1MHS, 6; 4MHS, 2; 3EHS, 1; 4EHS, 11; 2M2EHS, 44; $(N_2H_5)_2SnCl_6$, 43. The structure determinations of the two last-named compounds are incomplete and only the $SnCl_6$ octahedra are shown. In the 2MHS projection carbons C(1) coincide with the nitrogens. Alkyl hydrogens are not shown.

CH_3 groups, and the NH vector points at the Sn atom in 3MHS (H···Sn = 3.28 Å) but away from it in $(NH_4)_2SnCl_6$. In this 3MHS resembles NH_4SnF_3 (4), in which the NH_4^+ ion is anchored by three strong equivalent N—H···F bonds to different anions, while the NH vector, on a threefold axis, points at an Sn atom, H···Sn = 2.87 Å (*D* in Fig. 26); $\Delta\nu$(ND) in this fluoride is the largest reported to date, ~46 cm^{-1}. Indeed, the five 3RHS points *and D* can be fitted to an exponential function just as satisfactorily ($r^2 = 0.982$, $\Delta\nu(ND) = 5.21 \times 10^{-22} \exp 0.02183\nu(ND)$) as the 3RHS points alone. Whether this is fortuitous or indicative of a general trend we cannot say at present.

Fermi resonance and the limits of usefulness of the isotopic dilution technique

Temperature-tuned FR has been found to occur, to a greater or lesser extent, in the spectra of all the alkylammonium hexa-

halostannates(IV) we have examined to date, but in 3MHS and its bromo analog the phenomenon is particularly striking. This is because (*1*) several overtone levels are involved; (*2*) the fundamental *and* the overtone absorptions are sharp, at least at low temperatures; and (*3*) temperature shifts of the absorption frequencies are large relative to level spacings and bandwidths.

While in unsubstituted ammonium compounds use of the isotopic dilution technique (4, 13, 29) has resulted in avoiding, in the ND stretching region of the NH_3D^+ probe ion, complications from FR, this should probably be regarded as a felicitous collusion of circumstances rather than a rule. The likelihood that eligible overtones or combination bands of fundamentals of NH_4^+ or small inorganic anions will fall between 2450 and 2200 cm^{-1} is not great, but if such an encroachment does occur the complication can usually be dealt with. If necessary, the NH stretching absorption of the NHD_3^+ probe ion in a very highly deuterated crystal can be examined instead. Spectra of the alkylammonium salts of composite anions are different in this respect. The NH or ND stretching region or both are as a rule invaded by absorptions due to overtones or combination bands of the cation, of symmetry species suitable for FR interaction. When the FR is temperature-tuned, recognition of its presence is facilitated and the resonance can, in favourable cases, be analyzed and the position of the unperturbed ND or NH stretching fundamental extracted, as with 1MHS and the three 3RHS discussed above. Failing this, a complete deuteration of the alkyl part of the cation may lead to removal of the objectionable FR.[9] Unfortunately, increasing complexity of the alkyl may render the spectral regions of interest intractable and their analysis resistant to remedies which would be successful in the simple cases. The difficulty becomes serious when the ND stretching absorptions fall below 2300 cm^{-1}, i.e. when the hydrogen bonding is in a range ordinarily considered as medium strong, and was found prohibitive in our attempts to analyze the isotopically isolated NH and ND spectra of ω-aminoalkanesulfonic acids (G. Keresztury, O. Knop, and M. Falk, unpublished results).

Structural principles

Dimensions of the $SnCl_6$ octahedra

The $SnCl_6$ octahedra in $(R_nNH_{4-n})_2SnCl_6$ are on the whole quite regular. The weighted mean of the Sn—Cl distances in ten structures of recent vintage is 2.425(12) Å (a total of 72 occurrences corresponding to 28 different values; conventional refinement). Correction for thermal motion would increase the individual d(Sn—Cl) values to a different extent, depending on the structure and on the model assumed. For example, in $(NH_4)_2SnCl_6$ the uncorrected value of 2.421 Å is raised to 2.428–2.430 Å on the riding model (2, 3) and to 2.445 Å on the independent-motion model (2). In 4MHS, however, the uncorrected value, 2.402 Å, is increased to 2.446 Å (riding model) and 2.489 Å (independent motion) (2), i.e. an increase of 1.8% and 3.6% respectively compared with 0.3% and 1.0% for $(NH_4)_2SnCl_6$. For other compounds the corrected d(Sn—Cl) values are not available.

Cation–anion packing: antifluorite type

The alkylammonium hexachlorostannates(IV) differ, structurally, from simple ionic $A^+{}_2B^{2-}$ crystals mainly in that both A and B are composite ions. The most symmetric, though not the densest, packing of A^+ and B^{2-} in simple ionic crystals is realized in the cubic ($Fm3m$) antifluorite arrangement characterized by A···4B and B···8A coordinations (30). This type of packing, with or without distortion, is widely represented among $[A]_2[MX_6]$ compounds (A, alkali or other univalent cation; X, halogen).

In the hexachlorostannates (Fig. 28), the antifluorite structure may be visualized as based on a fcc cell in which the corners and face centres are occupied by regular $SnCl_6$ octahedra with orientations consistent with the $Fm3m$ symmetry. When this unit cell is divided into eight equivalent cubic subcells, the octahedra occupy alternate corners of these small cubes and each of the subcells contains one cation. This highly symmetric structure is exemplified by $(NH_4)_2SnCl_6$ (2, 3) and 4MHS (2, 9), in which the site symmetry at the centres of the subcells is the same as the symmetry of the free cation, T_d.[10] With Et_4N^+, even though the ion could realize an effective T_d symmetry in the crystal *dynamically* or by static orientational disorder (a possibility which might exist above room temperature), a higher packing density can be achieved by a conformation of lower symmetry. The cation symmetry observed in 4EHS is in fact only C_2 (11). The antifluorite lattice is preserved but it is distorted to monoclinic. In addition, the carbons closest to N in one of the two nonequivalent Et_4N^+ ions can occupy alternative positions, which results in a disorder on that nitrogen sublattice (Fig. 28). As the alkyl chain in R_4N^+ lengthens, the possibility of existence of structural alternatives increases. This is illustrated by the following pairs of dimorphs (the densest form is listed first):

$(Et_4N)_2MCl_6$	M = Sn	C_{2h} (39); cubic ? (24)
	M = Pt	C_{2h} (12); cubic ? (39)
$(n\text{-}Pr_4N)_2MCl_6$	M = Sn	C_i (24); D_{2h} (24)[11]
	M = Pt	C_i (12); D_{2h} (39)
$(n\text{-}Pr_4N)_2MBr_6$	M = Sn	D_{4h} (39); ? (39)
	M = Pt	C_{2v} (39); monoclinic (39)
$(i\text{-}Bu_4N)_2PtCl_6$ (39)		C_{2h}; ?

The possibility cannot be excluded that even for 4MHS the true unit cell is larger than the $Fm3m$ ($Z = 4$) cell derived from $(NH_4)_2SnCl_6$, and that the structure may in fact have a more complicated arrangement of the $SnCl_6$ octahedra. The symmetry of $(Me_4N)_2TeBr_6$ has been reported (40) as $Fd3c$ ($Z =$

[9]In the case of 1MHS this did not result in a useful simplification. The spectrum of $(CD_3NH_3)_2SnCl_6$ in the NH stretching region was essentially identical with that of the undeuterated compound, and that in the ND stretching region was even more complex than for $(CH_3NH_3)_2SnCl_6$.

[10]The same symmetry has been reported for $(Me_4N)_2CeCl_6$ (31), $(Me_4N)_2PtF_6$ (32), and, with reservations, for $(Me_4N)_2PtCl_6$ (33). However, for $(Me_4N)_2SiF_6$ at room temperature the structure appears to be of symmetry $I4/m \subset Fm3m$, with the SiF_6 octahedra in a "ferro" arrangement (34). The $Fm3m$ symmetry also appears to occur in a number of $(Me_4N)_2MX_6$ chlorides and bromides where M is a 5*f* element (Th, Pa, U, Pu) and in the high-temperature form of $(Et_4N)_2PuCl_6$ (35–37), while the corresponding $(Et_4N)_2MCl_6$ and $(Et_4N)_2PaBr_6$ at room temperature crystallize in $Fmmm \subset Fm3m$ (36, 37). $(Et_4N)_2PaF_6$ is dimorphic, fcc and tetragonal, the latter form (isostructural with the U compound) probably related to $Fm3m$; $(Et_4N)_2PaOCl_5$ is stated to be monoclinic, $C2/c$ or Cc, and related to $(Et_4N)_2PaCl_6$ (38).

[11]The difference between the densities quoted for the two forms of 4PHS in ref. 24, 1.548 and 1.314 g/cm^3, is so large that the possibility of a misprint (1.548 instead of 1.348?) is not excluded, especially as a density of 1.548 g/cm^3 is significantly higher than that of either form of the corresponding chloroplatinate.

32) and that of $(Me_4N)_2ReBr_6$ as $I4_1/acd \subset Fd3c$ (11). The observation, in $(Me_4N)_2PtCl_6$, of extra reflections not indexable on $Fm3m$ ($Z = 4$) suggests (33, 40) that the symmetry of this structure, too, may be $Fd3c$ ($Z = 32$), and there are indications (2, 40) that this might also be the case for 4MHS.

When the maximum symmetry of the free cation is no longer T_d, the $Fm3m$ symmetry of the crystal is lowered and the cubic subcells may become cuboids. At the same time the $SnCl_6$ octahedra will undergo distortion and rotational displacements about the Sn atom, but they remain centrosymmetric. This is observed for $MeNH_3^+$ and Me_3NH^+. Both cations have trigonal symmetry, and one might expect the overall cubic symmetry to be maintained if the cations were to align themselves in such a way that their threefold axes coincided with the threefold axes of a cubic unit cell of $Fm3m$ subgroup symmetry. However, while the trigonal symmetry of the cation is prominent in both the 1MHS and 3MHS structures, in 1MHS the overall symmetry is reduced to $R\bar{3}m$ (a noncubic subgroup of $Fm3m$),[12] whereas in 3MHS the trigonal cation does take advantage of the possibility of alignment along the trigyres of a cubic unit cell, but in a space group ($Pa3$) which is not a subgroup of $Fm3m$. A lowering of the crystal symmetry is not observed in the cubic 1M3EHS (9); however, the structure has not yet been determined and it is likely that the $MeEt_3N^+$ ions (C_{3v} in their highest-symmetry conformation) in this crystal are orientationally disordered.[13]

Cation–anion packing: other types

The effect of an additional lowering of the cation symmetry will depend also on the shape of the cation. With small alkyls (Me, Et) the space-group symmetry may be unrelated to $Fm3m$ but the antifluorite arrangement will be preserved, as in 2MHS, 3EHS, and even $(N_2H_5)_2SnCl_6$ (43) and probably 2M2EHS (44).[14] However, the cation shape begins to compete with the cation symmetry: Et_3NH^+ in its most symmetric conformation is trigonal but 3EHS is monoclinic (1). On the other hand, cation shape or size or both appear to be the structure and symmetry determining factors when the alkyl contains three or more C atoms. Thus the structure of 3PHS not only is monoclinic, but it no longer is based on the antifluorite arrangement: the zig-zag *n*-propyl chains are "linearly" extended (cf. Figs. 6 and 7),[15] resulting in a cation shape which appears to match poorly the shape of the $SnCl_6$ octahedra and leads to a different type of anion lattice. Moreover, the octahedra are not centrosymmetric.

An arrangement different from the antifluorite is also observed in the trigonal 1EHS (ref. 10, this work). This compound (and the monoclinically distorted 1PHS) has a layer structure of the *anti*-CdI_2 type, similar to that observed in the room-temperature form of the trigonal $(NH_4)_2SiF_6$ and in $(MeNH_3)_2TeCl_6$ (46). Interestingly, the last-named crystal transforms on cooling into an antifluorite $R\bar{3}m$ phase, presumably isostructural with 1MHS (46).[12] The corresponding $(MeNH_3)_2MCl_6$ (M = Pd, Pt, Sn, Se, Pb), $(MeNH_3)_2MBr_6$ (M = Pd, Pt, Sn, Se), and $(MeNH_3)_2PtI_6$ at room temperature are all of the antifluorite ($R\bar{3}m$) type and all undergo low-temperature transitions (47).

Orientation of the $SnCl_6$ octahedra

In recent years much attention has been paid to the nature and mechanism of solid-state transitions in antifluorite A_2MX_6 halides (cf. for example, refs. 48 and 49). Many, probably most, of these transitions are characterized by cooperative rotational displacements of the MX_6 octahedra from their orientation in the $Fm3m$ phase (e.g. in K_2SnCl_6, ref. 50), with the attendant formation of "ferro" (in-phase rotations) or "antiferro" (anti-phase rotations) arrangements of the MX_6 orientations on the original M lattice complex $Fm3m$. Consideration of such arrangements is relevant also for the alkylammonium hexachlorostannates.

Of the nine antifluorite-type room-temperature structures listed in Table 15 and schematized in Fig. 28, five (2MHS, 2M2EHS, 3EHS, 4EHS, and $(N_2H_5)_2SnCl_6$) have antiferro arrangements of the $SnCl_6$ octahedra, but their space groups are not "zellengleiche" subgroups (and in two cases *no* subgroups) of $Fm3m$. This raises the question of whether these room-temperature structures should be regarded as low-temperature variants of structures of higher symmetry presumed to exist above room temperature. Nothing is known at present about transitions above room temperature in these crystals, but if they do occur, what is the relationship of the two structures involved in a transition?

Clearly the highest possible symmetry would be $Fm3m$, as actually observed for $(NH_4)_2SnCl_6$[16] and 4MHS (but see above). Since in considering the arrangement of the $SnCl_6$ rotational orientations only the anion sublattices are involved, the problem is one of determining (*a*) the lattice complex LC formed by the Sn atoms; (*b*) the equivalence of the $SnCl_6$ orientations on the LC imposed by the space group SG; and (*c*) the formal relationship of the SG symmetry to that of the LC. When the antiferro order involves only two orientations, the LC|SG relationship defines a dichromatic (black-white, Shubnikov) space group of type IV (51) based on a dichromatic Bravais lattice. The chromatic translation of this lattice, together with the site symmetry at Sn, then describes the geometry of the antiphase rotations, the colour change corresponding to the change of sense of the rotational displacement. Thus if a transition exists, between room temperature and the melting or decomposition temperature of the crystal, and if it is of the antiferro to "*para*" type, the SG symmetry of the high phase would be expected to be that of the appropriate LC as specified in the LC|SG column of Table 15.

In $(NH_4)_2MX_6$ the cation is known not to be the causative factor in $Fm3m \rightarrow$ antiferro transitions, as such transitions for a given MX_6 occur equally in A_2MX_6 with A a structureless alkali ion. To what extent an alkylammonium ion participates, through hydrogen bonding, in the antiferro–*para* rearrangements on the anion lattice is not known.

The $SnCl_6$ orientation in $(NH_4)_2SnCl_6$, 1MHS ($R\bar{3}m \subset$

[12]The $R\bar{3}m$ the structure of 1MHS and other methylammonium hexahalometallates(IV) may be described as of the *anti*-$CdCl_2$ (C 19) type. The relationship of the *anti*-$CdCl_2$ to the antifluorite structure is discussed in ref. 41.

[13]The structure of 3MEHS also is of the fcc type (42).

[14]The tetragonal ($P4/mnc$) partial structure proposed for 2M2EHS contains an antifluorite $SnCl_6$ lattice (44). However, it requires that the cation be of D_2 symmetry, which the ion clearly does not possess. The structure would thus have to be orientationally disordered, but for a complete disorder one would expect the two dimensions of the pseudocubic cell ($C4/mcn$, $a_{cub} = a_{tetra}\sqrt{2} = 12.82$ Å, $c_{cub} = c_{tetra} = 14.12$ Å) to be more closely similar.

[15]Full extension of *n*-propyl chains is also encountered in (*n*-Pr_4N)Br, where the *n*-Pr_4N^+ ion has S_4 symmetry (45).

[16]Cubic $(NH_4)_2SnCl_6$ is known not to undergo a transition on cooling to 10 K (4, 49, 61).

TABLE 15. Space groups (SG) of the antifluorite-type $(R_nNH_{4-n})_2SnCl_6$ and the corresponding site symmetries (SS) at the Sn atoms and the Sn lattice complexes (LC)

Compound	SG	SS	LC[a]	LC|SG[b]
$(NH_4)_2SnCl_6$	$Fm3m$	$m3m$	$Fm3m$	
1MHS	$R\bar{3}m$[c]	$\bar{3}m$	$R\bar{3}m$	
2MHS	$Pnnm$[d]	$2/m$	$Immm$	$P_Inmm-Immm\|Pnnm$
3MHS	$Pa3$[d]	$\bar{3}$	$Fm3m$	
4MHS	$Fm3m$	$m3m$	$Fm3m$	
2M2EHS	$P4/mnc$[c]	$4/m$	$I4/mmm$	$P_I4/mnc-I4/mmm\|P4/mnc$
3EHS	$P2_1/n$[d]	$\bar{1}$	$C2/m$	$P_A2_1/c-A2/m\|P2_1/c$
4EHS	$C2/c$[d]	$\bar{1}$	$C2/m$	$C_c2/c-2C2/m\|C2/c$
$(N_2H_5)_2SnCl_6$	$Pbcn$[c]	2	$Cmcm$[f]	$C_Amcm-Fmmm\|Cmcm$[f]

[a]All the LC's are either $Fm3m$ or subgroups of $Fm3m$. They are all invariant except $Cmcm$ which has one degree of freedom. See also *f*.

[b]Shubnikov group indicating the chromatic Bravais translation.

[c]Subgroup of $Fm3m$.

[d]Not a subgroup of $Fm3m$.

[e]Not a "zellengleiche" subgroup of $Fm3m$.

[f]$Fmmm$ if $y[Pbcn, 4(c)] = \frac{1}{4}$; $Fmmm \subset Fm3m$. Otherwise $P_Cbcn-Cmcm|Pbcn$ and $C_Amcm-Fmmm|Cmcm$.

$Fm3m$) and 4MHS are to be regarded in this context as of the *para*, or "neutral", type. Although the LC in 3MHS is $Fm3m$, the Bravais lattice is not dichromatic, as it involves more than one chromatic translation, and the arrangement of the $SnCl_6$ orientations is to be viewed as *multiply* antiferro.

Geometry of the hydrogen bonding

On the principle that all N-hydrogens and Cl atoms in $(R_nNH_{4-n})_2SnCl_6$ will participate in hydrogen bonding to the maximum possible extent the type and connectivity of the hydrogen bonds would be expected to be determined primarily by the $H_N:Cl = (4 - n)/3$ ratio and by the tendency of all the Cl atoms to participate in the hydrogen bonding equitably. The cation:anion ratio being constant regardless of n, the existence of $[R_nNH_{4-n}\cdots Cl_3SnCl_3\cdots H_{4-n}NR_n]$ groupings containing the maximum possible number of *intra* but forming no *inter* hydrogen bonds would seem possible. Such groupings indeed occur in 3MHS and 3EHS, where they are centrosymmetric and the hydrogen bonds are respectively trifurcated and bifurcated. Similar groupings occur also in 3PHS, but their geometry in this crystal is highly distorted. However, they do not occur in the other compounds.

In 1MHS and 1EHS each RNH_3 engages in three trifurcated N—H···Cl bonds, each to a *different* $SnCl_6$, to form infinite two-dimensional hydrogen-bond networks (Figs. 4, 13, 14). Each $RNH_3\cdots Cl_3SnCl_3\cdots H_3NR$ sandwich thus contains two layers of equivalent H_N atoms, one layer on each side of the Sn layer. The difference between 1MHS and 1EHS is only in the size of R (i.e. in the vertical separation of the Sn layers) and in the orientational disorder of the Et groups in 1EHS at room temperature. The shape and size of R probably also determine the type of cation/anion packing, viz. *anti*-$CdCl_2$-type in 1MHS and *anti*-CdI_2 type in 1EHS (see above and ref. 41). In 1PHS the packing also is of the *anti*-CdI_2 type, though less recognizably so than in 1EHS: the existence of two types of cations, each occurring in two vertical orientations, results in a pseudohexagonal unit cell with a base four times that of the simple "*anti*-CdI_2" cell (Fig. 5*A*); some of the hydrogen bonds are asymmetrically bifurcated rather than trifurcated (Fig. 5*B*).

Similarly, in 2MHS only trifurcated hydrogen bonds are observed, this time connecting the $SnCl_6$ octahedra to infinite linear chains (Figs. 1 and 28). Given the observed propensity for trifurcated or bifurcated bonds, the facts known to date may be summarized by saying that a cation in an alkylammonium hexachlorostannate may be expected to form $4 - n$ trifurcated (or bifurcated) N—H···X bonds. The connectivity of the resulting hydrogen-bond system may then be described as three-dimensional ($n = 0$, $(NH_4)_2SnCl_6$), two-dimensional ($n = 1$, 1RHS), one-dimensional ($n = 2$, 2MHS), or "zero-dimensional" ($n = 3$, isolated groupings as in 3RHS). Work is in progress to determine whether situations of mixed dimensionality exist.

Is the presence of hydrogen bonding evident in molecular volume trends?

Where a reliable structure determination of an alkylammonium hexachlorostannate is not available, some idea of the general effect of the cation geometry on packing density can be obtained from a scrutiny of the volume per formula unit V_1. The densities of many compounds of this class were measured, with these considerations in mind, with considerable accuracy long before the advent of X-ray diffraction (12, 14, 24, 39). The set for the hexachloroplatinates is more extensive than that for the hexachlorostannates, and since in practically all the known cases the hexachloroplatinate is isomorphic with the corresponding hexachlorostannate, conclusions from the platinates will be taken as valid also for the stannates. Irregularities in the expected trends in V_1 would be thought to be indicative of the effect of hydrogen bonding.

The V_1 values calculated from the densities given in refs. 12, 14, 24, and 39 agree, with few exceptions, surprisingly well with the unit-cell volumes per formula unit $V/Z = \bar{a}^3$ where the latter are known. The differences amount to less than 1% for 7 of the 10 stannates for which the comparison can be made. For 1MHS and 2MHS they are larger, 1.7 and 1.3% respectively, but still acceptable; for M3EHS the difference of 2.8% does not rule out the possibility that the density and the X-ray determination may have been carried out on different polymorphs of this salt. For the platinates the comparison can be made for only four compounds and the overall accuracy is more difficult to assess.[17]

The V_1 are displayed in different ways in Figs. 29–32.

[17]Curiously, the poorest agreement in the platinate series, 4.8%, obtains for $MeNH_3^+$, the same cation that shows a significant discrepancy in the stannate series.

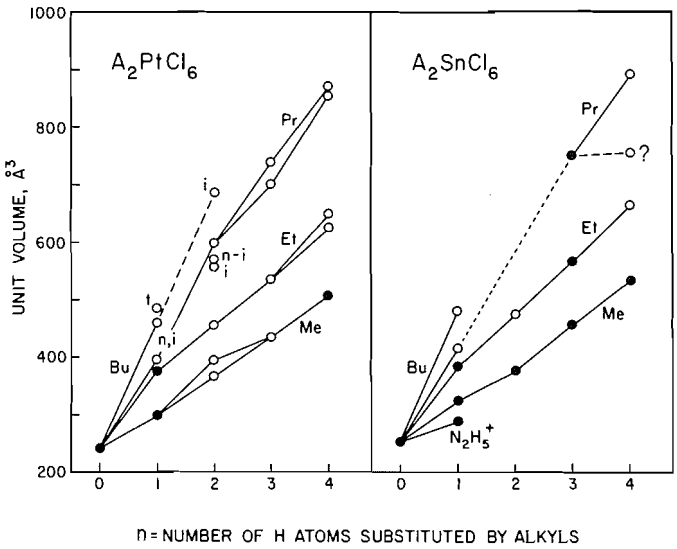

FIG. 29. A_2MCl_6 (A = R_nNH_{4-n} or N_2H_5; R = Me, Et, Pr, Bu; M = Pt, Sn): effect of progressive alkyl substitution on the volume per formula unit V_1. Full circles, V_1 calculated from unit-cell dimensions; open circles, V_1 calculated from density. Note the existence of polymorphs.

Progressive replacement of the ammonium hydrogens by the same alkyl results in a steady increase in V_1 (Fig. 29); the trends in the Pt and Sn series are closely parallel. Inspection of the Me_nNH_{4-n} and Et_nNH_{4-n} series shows that the introduction of the first alkyl perturbs the $(NH_4)_2MCl_6$ structure more for Et than for Me, but the additional alkyl groups increase V_1 almost linearly, although to different extents: the V_1 increments per CH_2 are ~35 Å^3 for the Me, ~23 Å^3 for the Et, and ~28 Å^3 for the *n*-Pr series. They all are much larger than the estimate of 17 Å^3 for the CH_2 volume increment in *purely molecular*, single-constituent crystals of organic compounds forming homologous series (52). The reason for these large increments is undoubtedly to be looked for in the tendency of the ionic structures to adopt packings distinguished by minimizing electrostatic interactions between ionic charges at the cost of reducing the maximum *geometrically* achievable packing density. This may be likened to the effect — acting in the opposite direction — of hydrogen bonding which is responsible for the open structures of NH_4F and ice.

The effect on V_1 of X in $(R_3NX)_2MCl_6$ (X = H, Me, Et, *n*-Pr, *n*-Bu, *n*-Am; M = Pt, Sn) (Fig. 31) does not lend itself to a straightforward interpretation. However, it appears that when at least one of the three R groups in the cation is *n*-Pr, the V_1 trend becomes indifferent to X to the extent that it is quasi-linear, or at least non-decreasing, relative to the increasing number of C atoms in X. This indicates that X = H does not produce an anomalous packing density, which in turn implies that hydrogen bonding in the individual R_3NH compounds is unimportant as a structure-affecting factor and probably very weak and of unfavourable geometry. In the Me_3NX series it is difficult to decide whether the initial steep increase from X = H to X = Me and Et reflects primarily the contracting effect of H or an unusually large increment due to the inability of the small alkyl, Me or Et, to assume a "folded" conformation and thus reduce its space requirements, always remembering that the Coulombic interaction will tend to make V_1 as small as possible in the circumstances. The same tendency is observed in the Me_2EtNX, $MeEt_2NX$, and Et_3NX series.

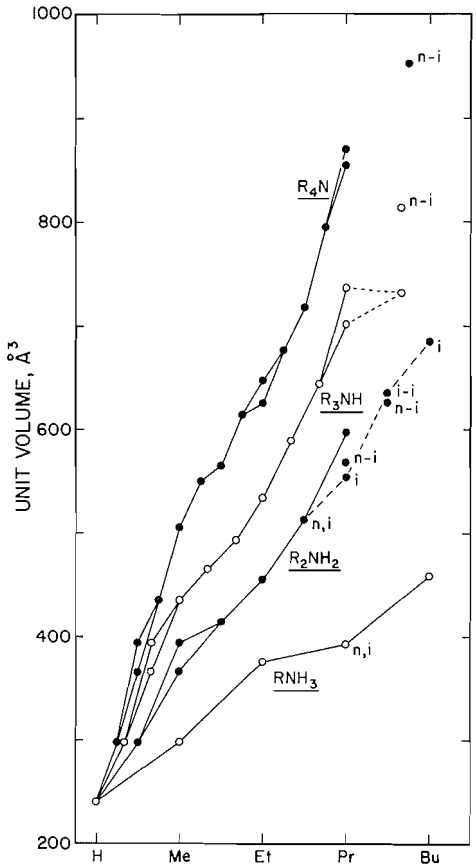

FIG. 30. A_2PtCl_6: effect of alkyl substitution on V_1. A = RNH_3, R_2NH_2, R_3NH, R_4N; binary combinations of neighbouring alkyls (H–Me, Me–Et, Et–Pr, Pr–Bu) are included. The alkyls are normal (*n*) unless indicated otherwise (*i*, *iso*). Note the existence of polymorphs.

In any event, when looking for an indication of significant hydrogen bonding in V_1 comparisons, one must have a clear *a priori* notion of what ought to be the magnitude of the V_1 increment that would be indicative of the presence of such bonding. Figure 32 brings to light three important factors. First, if every H_N formed a hydrogen bond, and if the formation of the bond resulted in a significant volume contraction, one would expect that, in a group of *cation-isomeric* A_2PtCl_6, V_1 would be smallest for A richest in H_N and largest for a fully alkylated cation. However, Fig. 32 shows that $V_1(Me_2NH_2) > V_1(EtNH_3)$, $V_1[Et(n\text{-}Pr)NH_2] > V_1(MeEt_2NH)$, and the V_1 of $n\text{-}Pr_2NH_2$, $(i\text{-}Pr)(i\text{-}Bu)NH_2$, $i\text{-}Bu_2NH_2$, $n\text{-}Pr_3NH$, and $Et(i\text{-}Bu)_2NH$ are all larger than the V_1 of the respective fully alkylated isomers with the same number of C atoms.

Secondly, since polymorphs occur, one cannot be certain that, in cases where only one form has been described, another form does not exist which might have a lower V_1 and thus possibly invalidate a conclusion reached for a group of isomeric A_2MCl_6 in ignorance of this polymorph.

Thirdly, the V_1 differences *between polymorphs* of a particular compound may be larger than those *between isomers* in a group, regardless of whether or not hydrogen bonding is present. This point is illustrated in Fig. 32 and Table 16. It is seen that the V_1 differences between polymorphs can amount to as much as 7–8% and that even for fully alkylated cations for which hydrogen bonding is not possible. For comparison, for the cubic/trigonal $(NH_4)_2SiF_6$, ΔV_1 = 6.5%, whereas for the

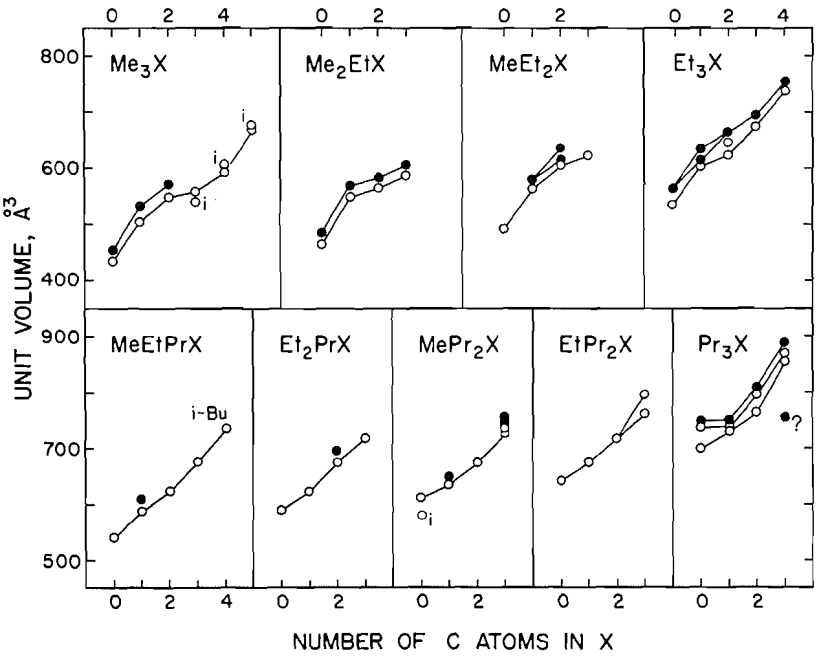

FIG. 31. $(R_3NX)_2MCl_6$ (M = Pt, Sn): effect of substitution (X = H, Me, Et, Pr, Bu, Am) on V_1. Full circles, Sn; open circles, Pt. With the exception of X = H all the compounds are quaternary salts with no possibility of hydrogen bonding.

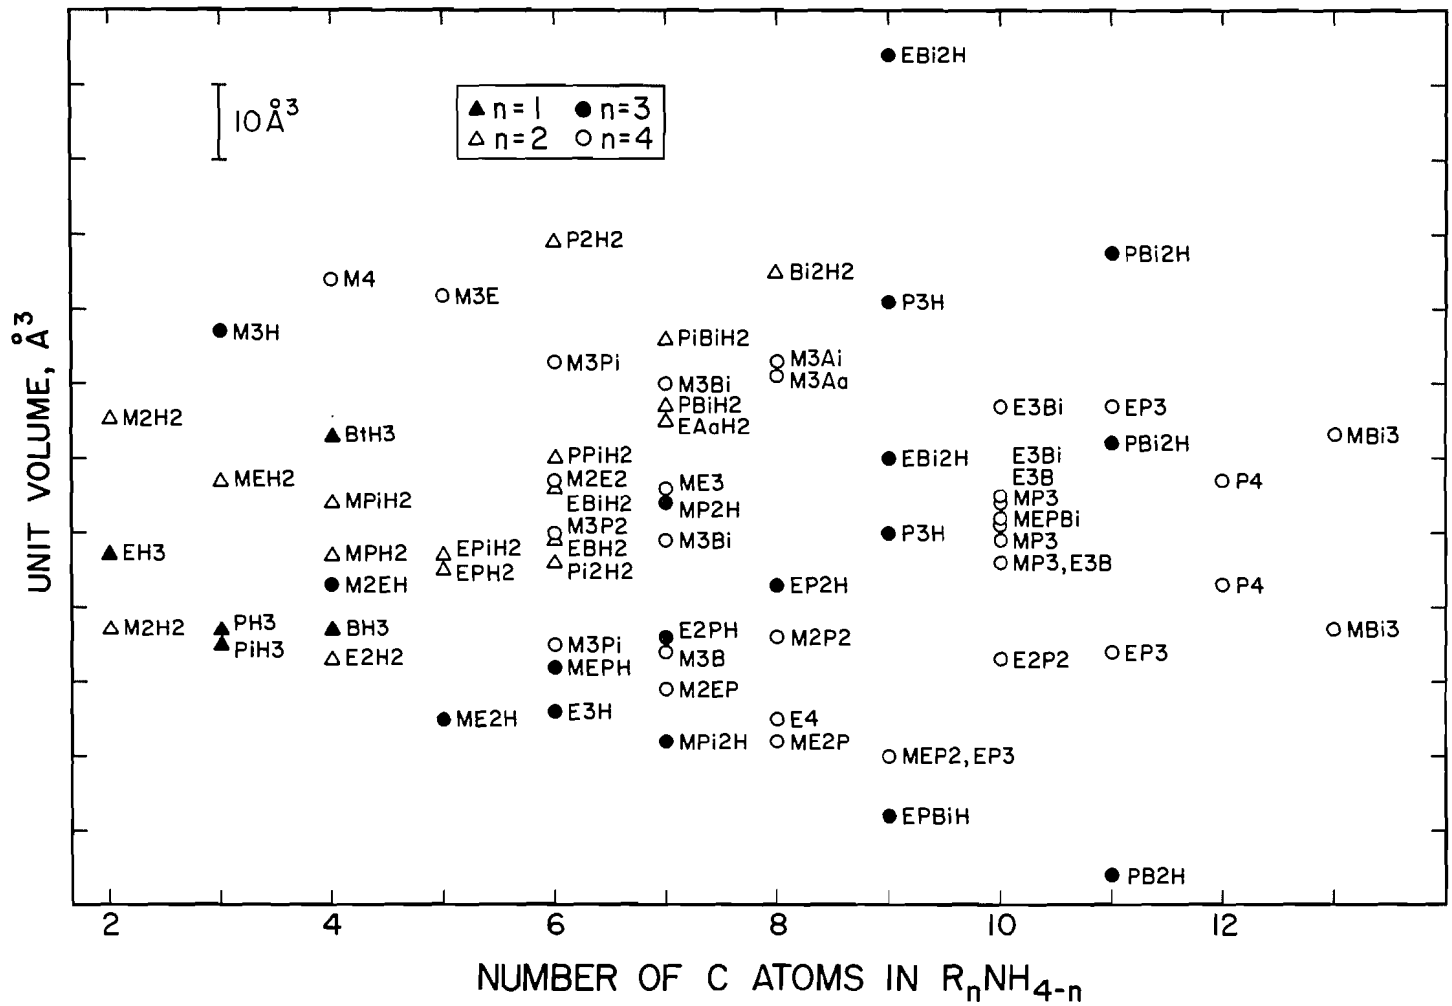

FIG. 32. Effect of isomerism on the V_1 of $(R_nNH_{4-n})_2PtCl_6$. M = Me, E = Et, P = *n*-Pr, B = *n*-Bu, A = *n*-Am, i = iso, a = active; EBi2H stands for Et(*i*-Bu_2)NH etc. The origin of the V_1 scale varies from compound to compound; comparisons are to be made only within a column.

TABLE 16. Difference in the volume per formula unit V_1 (Å^3) for A_2PtCl_6 dimorphs[a]

A	ΔV_1	$100\Delta V_1/V_1$
Me_2NH_2	27.7	7.6
$Me_3(i\text{-Pr})N$	40.9	7.5
$Me_3(i\text{-Bu})N$	21.1	3.5
$n\text{-Pr}_3NH$	36.2	5.2
$Et(i\text{-Bu})_2NH$	53.6	7.5
$Et_3(n\text{-Bu})N$	8.1	1.1
$Et_3(i\text{-Bu})N$	12.0	1.6
$Me(n\text{-Pr})_3N$	5.5	0.8
$(n\text{-Pr})(i\text{-Bu})_2N$	23.1	2.9
$Et(n\text{-Pr})_3N$	33.0	4.3
$n\text{-Pr}_4N$	14.3	1.7
$Me(i\text{-Bu})_3N$	25.9	3.3

[a]Calculated from densities (12, 14, 24, 39). Cations arranged by increasing number of C atoms in A. V_1 refers to the denser form.

cubic/trigonal $(NH_4)_2SnF_6$, $\Delta V_1 = -4.2\%$ (cf. ref. 29). In purely molecular crystals (52) the differences are, for example, 2.4–4.0% for the acridine polymorphs, 3.9% for phenazine, 0.6% for p-$C_6H_4Cl_2$; and about the same when hydrogen bonding is present, e.g. ca. 3.9% for resorcinol, 2.7% for oxalic acid, and 1.3–1.7% for the glycine polymorphs, always relative to the densest form. The claim cannot thus be made that the presence and extent of hydrogen bonding are recognizable from V_1 trends and comparisons.

This conclusion is implicit in the belief that the primary structure-determining factor is the maximization of the overall packing density consistent with a minimization of the Coulombic energy, even if the result is a poor hydrogen-bonding geometry, as exemplified by the structure of 3PHS.

Experimental

Preparation

The salts were prepared by combining a solution of the amine in 95% EtOH with an equivalent amount of an aqueous solution of H_2SnCl_6 (or H_2SnBr_6) containing a small excess of HCl (or HBr) to counteract possible hydrolysis. The crystals obtained by slow evaporation at room temperature were recrystallized from 50% EtOH acidified with HCl or HBr. Deuteration was achieved by similar recrystallization from D-containing solutions.

Surprisingly, the ir spectrum of the product intended to be 2PHS was of a type different from all the other spectra, in that it contained NH and ND stretching frequencies far lower than any previously encountered in an alkylammonium hexachlorostannate (see above) and, in fact, lower than the NH and ND stretching frequencies of n-$PrNH_3Cl$. The starting material was verified by ^{13}C nmr to be n-Pr_2NH of high purity, but the elemental analysis of the product indicated a considerably higher C content than required for 2PHS, with smaller discrepancies in the H, N, and Cl contents. To resolve the difficulty we determined only quite recently the crystal structure of the product, with the result (details to appear shortly) that the compound studied turned out unexpectedly to be $(n\text{-}Pr_2NH_2)_3SnCl_7 = (n\text{-}Pr_2NH_2)_3(SnCl_6)Cl$, analogous with $(NH_4)_3(SiF_6)F$ (53) and $K_3(SiF_6)F$ (54), in satisfactory agreement with the elemental analysis. It is interesting that none of the other hexachlorostannates showed, under comparable conditions of preparation, any tendency to form a chloride adduct, and that three different preparations designed to yield 2PHS, each followed by one or more recrystallizations, resulted in the adduct. Efforts to prepare authentic 2PHS are under way.

Structure determination

A CAD-4 four-circle diffractometer was used in the determination of the unit-cell dimensions and in the intensity collection. The intensities were reduced by routine procedures (55). Lorentz and polarization corrections were applied but no absorption or extinction corrections. The scattering factors for neutral atoms were taken from ref. 56. The structures were solved using the SHELX system (57).

In each case the Sn atoms were located from the E-map and all other nonhydrogen atoms were found on a subequent Fourier map. Full-matrix least-squares ($w\Delta F^2$ = minimum) refinement was carried out with isotropic temperature factors on heavy atoms until R was reduced to a reasonably low value. After locating the hydrogens (from a difference Fourier map or from structural considerations), refinement was continued with anisotropic temperature factors on the nonhydrogen atoms and isotropic factors on the hydrogens, unless stated otherwise. The anisotropic temperature factor is defined as

$$T = \exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{23}klb^*c^* + 2U_{13}hla^*c^* + 2U_{12}hka^*b^*)]$$

Where a refinement was carried out with constraints on bond lengths, the distances were assigned at 1.02 Å for N—H, 1.08 Å for C—H, 1.48 Å for N—C, and 1.54 Å for C—C, within limits appropriate to each case (57). To constrain HNH angles to tetrahedral, appropriate H···H distances (1.66 Å) were assigned.

Lists of structure factors (Tables 17–21) have been deposited.[3]

Infrared spectra

Spectra were recorded on a Perkin-Elmer model 180 spectrophotometer fitted with a closed-cycle He refrigerator. Suitable samples were obtained by mulling finely ground crystals with fluorocarbon or hydrocarbon oil. The mulls were sandwiched between KBr or CaF_2 plates. KBr pellets were used for survey spectra in the 4000 to 200 cm^{-1} region.

Analysis of Fermi resonance

In the spectra complicated by FR the position of the unperturbed NH or ND stretching fundamental was derived from the positions and relative intensities of the FR multiplet as follows. The observed wavenumber separation, $D = \nu_1 - \nu_2$, of a pair of vibrational levels undergoing FR is given by

$$[1] \quad D^2 = d^2 + 4W^2$$

where $d = \nu^0_1 - \nu^0_2$ is the separation of the unperturbed levels in the absence of resonance and W is the FR constant (59, 60). The separation that would be observed if the two unperturbed levels coincided (i.e. $d = 0$) is $2W$. When a fundamental at ν^0_1 and of inherent intensity I^0 is perturbed by an overtone level at ν^0_2, of negligible inherent intensity, the intensity ratio of the perturbed doublet is, from first-order perturbation theory,

$$[2] \quad I_2/I_1 = (D - d)/(D + d)$$

where $I_1 + I_2 = I^0$, $I_1 \geq I_2$. The two transitions are shifted equally and in opposite directions, so that

$$[3] \quad \nu^0_1 + \nu^0_2 = \nu_1 + \nu_2 = 2\bar{\nu}$$

From eqs. [1]–[3],

$$[4] \quad W = [(I_1I_2)^{1/2}/(I_1 + I_2)]D$$

$$[5] \quad \nu^0_1 = (I_1\nu_1 + I_2\nu_2)/(I_1 + I_2)$$

i.e. the position of the unperturbed fundamental is simply the weighted mean of the observed Fermi doublet. This can be generalized to Fermi multiplets, so long as the participating overtone levels have negligible intensities compared to the intensity of the fundamental.

POSTSCRIPT. A redetermination of the crystal structure of 4MHS at 160 and at 295 K has in fact shown (62) that 4MHS above its T_{tr} = 149(7) K has a unit cell of $Fd3c$ symmetry, corresponding to an octuple $Fm3m$ cell, with the $SnCl_6$ octahedra rotated with respect to the cubic translation axes. In this respect 4MHS thus resembles $(Me_4N)_2TeBr_6$. Structure determination below T_{tr}, at 115 K, seems to indicate that the symmetry of the low-temperature phase of 4MHS is not higher than tetragonal.

A systematic study on volumetric interactions of cyclohexanone with various aliphatic hydrocarbons

B. CHAWLA,[1,2] RAM PARKASH, AND S. K. SURI

Department of Chemistry, Indian Institute of Technology, Hauz Khas, New Delhi-110 016, India

Received June 14, 1982

B. CHAWLA, RAM PARKASH, and S. K. SURI. Can. J. Chem. **61**, 1647 (1983).

Excess volumes of mixing, V^E, for binary mixtures of cyclohexanone with *n*-hexane, *n*-heptane, *n*-octane, *n*-nonane, *n*-decane, *n*-dodecane, *n*-tetradecane, and *n*-hexadecane at 25°C were determined from the precise and accurate experimental density data. The sign and magnitude of V^E were discussed in terms of the strength of the unlike interactions present in the binary mixtures.

Excess volumes of mixing of equimolar concentration ($V^E_{0.5}$) were also obtained. Attempts were made to interpret $V^E_{0.5}$ in terms of the size and polarity of the constituent molecule. The two effects could not be separated, but a good linear relation between $V^E_{0.5}$ and the solubility parameter was found.

B. CHAWLA, RAM PARKASH et S. K. SURI. Can. J. Chem. **61**, 1647 (1983).

Utilisant des données précises de densité expérimentales on a déterminé les volumes en excès de mélange V^E des mélanges binaires de cyclohexanone avec le *n*-hexane, le *n*-heptane, le *n*-nonane, le *n*-décane, le *n*-dodécane, le *n*-tétradécane et le *n*-hexadécane à 25°C. On discute du signe et de l'ordre de grandeur de V^E en fonction de la force des interactions contraires présentes dans les mélanges binaires.

On a également obtenu les volumes en excès de mélange de concentration équimolaire ($V^E_{0.5}$). On a essayé d'interpréter le ($V^E_{0.5}$) en fonction de la dimension et de la polarité de la molécule fondamentale. On ne peut pas séparer les deux effets, mais on a trouvé une bonne corrélation linéaire entre $V^E_{0.5}$ et la paramètre de solubilité.

[Traduit par le journal]

1. Introduction

Since the excess volume, V^E, of a binary mixture of a polar solute in a nonaqueous solvent is the result of unlike/like interactions (between the two molecules) governed by the combined contributions (such as size and polarity of the constituents), the V^E data do not show any obvious relationship with the properties of the constituents (1–4). In order to compare the experimental V^E values with the properties of the constituents, one must break V^E values into two major contributions such as, $V^E_{(size)}$ and $V^E_{(polarity)}$, which require V^E data from systematic studies on volume changes of binary mixtures. However, only a few such studies (but not exhaustive) have been reported in the literature (5, 6). Therefore, with a view to understand the factors determining the unlike interactions between the molecules of mixtures, we report in this paper the excess volumes of mixing of cyclohexanone with *n*-hexane, *n*-heptane, *n*-octane, *n*-nonane, *n*-decane, *n*-dodecane, *n*-tetradecane, and *n*-hexadecane at 25°C.

2. Experimental

Materials

Commercially available cyclohexanone, *n*-hexane, *n*-heptane, *n*-octane, *n*-nonane, *n*-decane, and *n*-dodecane of stated purity more than 99% were purified before their use according to established procedures (7). *n*-Tetradecane and *n*-hexadecane, samples of highest purity, were obtained from Koch-Light Lab. and Sigma Chemical Co., respectively, and were used without further purification. The purified reagents were stored under a dry nitrogen atmosphere during their use. The boiling points, densities, and refractive indices of the reagents agreed closely with the accepted literature values (7, 8). The amount of water present in each of these reagents was determined by a Karl Fischer Titrator, Model Aquatest IV (Photovolt Corporation, New York) and was found to be less than 0.01%. The reagents which were found to have more than 0.01% water were dried over activated 4A molecular sieves.

Apparatus and procedure

The values of V^E at 25°C were calculated from the experimental densities which were measured with a Vibrating-Tube Digital Density Meter (9) Model DMA 602/DMA-60 from Anton Paar, Austria. Water from a constant temperature bath was circulated through the metal block of the density meter at a flow rate of 3 $dm^3\ min^{-1}$. The thermal stability of the bath was better than $\pm 1 \times 10^{-3}$°C and was maintained by a Tronac PTC-40 proportional temperature controller. The density meter was calibrated with water and dry air every day. The density of water at 25°C was taken as 0.9970429 g cm^{-3} from Wagenbreth and Blanke (10).

Since differential measurements were performed, it was ensured that equal volumes of both the sample and the reference liquid were used by carefully completely filling the measuring cell (U-tube). It was ensured that there was no microbubble of air left inside the U-tube. The ports were finally plugged with small Teflon stoppers, which prevented any loss of liquid by vaporization. After the measurements, the sample was removed and the U-tube was then flushed with an appropriate cleaning solvent (e.g. acetone, alcohol, etc.), followed by air-drying with the help of the built-in pump. The reproducibility of the measurements was generally better than 3×10^{-5} g cm^{-3}. The details of the experimental technique for the preparation of solutions have been described earlier (11). The maximum uncertainty in the excess volumes of mixing data is expected to be less than ± 0.008 $cm^3\ mol^{-1}$.

3. Results and discussion

The excess volumes of mixing, V^E, for the binary mixtures as a function of solution composition at 25°C are recorded in Table 1 and plotted as a function of composition of cyclohexanone in Fig. 1. Along with experimental excess volumes, V^E_{exptl}, the calculated excess volumes, V^E_{calcd}, and δV^E ($V^E_{exptl} - V^E_{calcd}$) are also reported in Table 1 for all the systems at all solution compositions. The V^E_{calcd} are based on eq. [1]

$$[1]\quad V^E = X_1(1 - X_1)[A + B(2X_1 - 1) + C(2X_1 - 1)^2 + D(2X_1 - 1)^3 + E(2X_1 - 1)^4]$$

where X_1 is the mole fraction of cyclohexanone and A, B, C, D, and E are constants. The values of constants A, B, C, D, and

$C_6H_{10}O + C_{16}H_{34}$	3.5922	0.4914	1.7789	0.3598	−1.5567	±0.008

E were evaluated by fitting experimental values of V^E and X_1 to eq. [1] by a least-square computer programme and are given in Table 2. The standard deviations, $\sigma(V^E)$ (defined in the usual way), of the V^E values are given in Table 2. These constants can be taken to represent the experimental results because the standard deviations for all the systems are observed to be comparable with the estimated uncertainties in the experimental determinations of V^E.

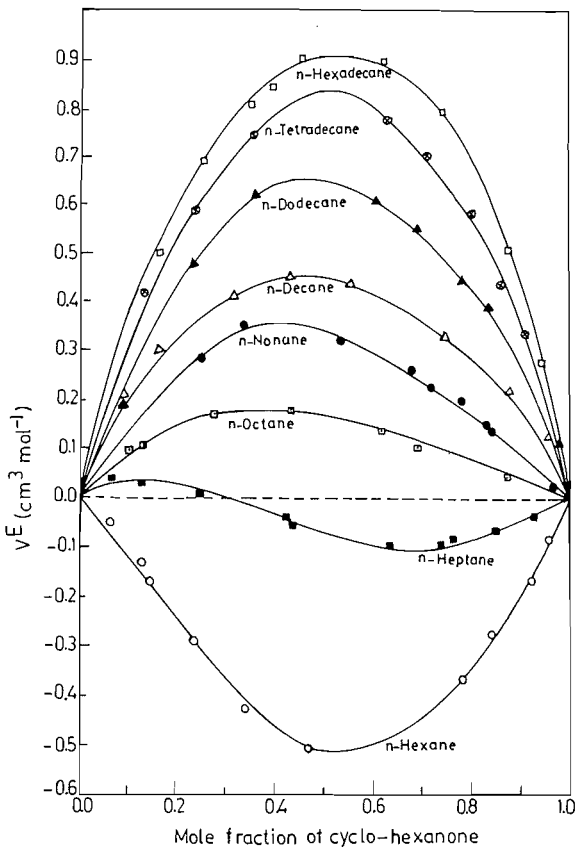

FIG. 1. Excess volumes of mixing, V^E, as a function of the composition for binary mixtures of cyclohexanone with various aliphatic hydrocarbons at 25°C.

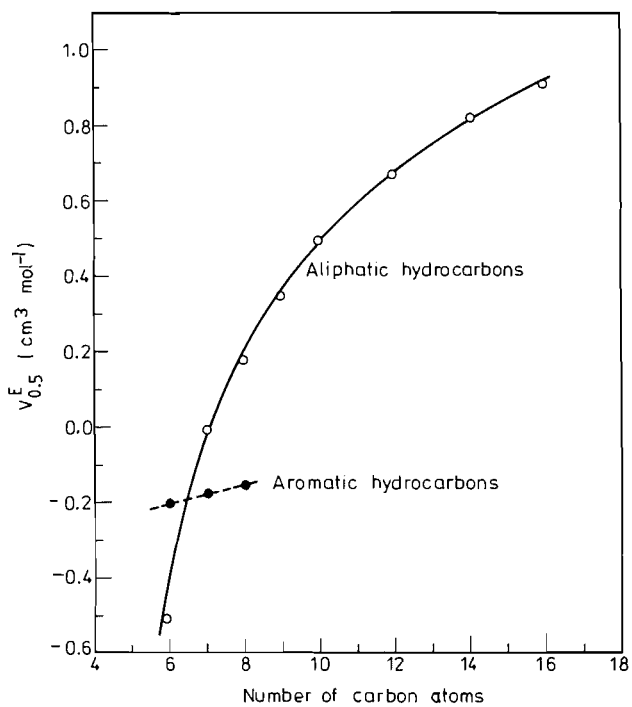

FIG. 2. Excess volumes at equimolar concentration, $V^E_{0.5}$, versus the number of carbon atoms in hydrocarbons.

It is observed from Fig. 1 that V^E varies almost symmetrically with the mole fraction of cyclohexanone and shows a maximum somewhere around equimolar concentration for each of the binary mixtures studied except for that of cyclohexanone and *n*-heptane. The excess volumes of mixing for mixtures of *n*-octane, *n*-nonane, *n*-decane, *n*-dodecane, *n*-tetradecane, and *n*-hexadecane with cyclohexanone are positive over the entire composition range. The positive V^E values

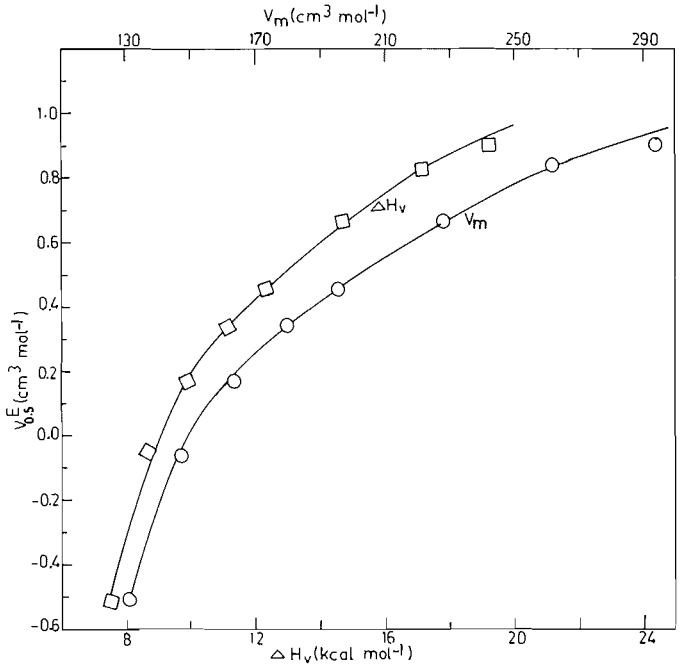

FIG. 3. Excess volumes at equimolar concentration, $V^E_{0.5}$, versus heats of vaporization and molar volumes of hydrocarbons at 25°C.

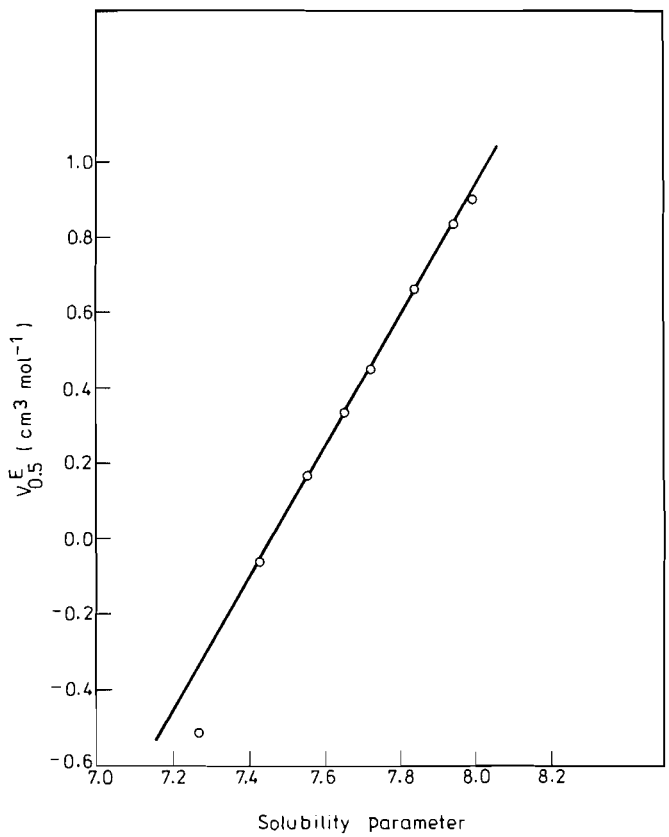

FIG. 4. Excess volumes at equimolar concentration, $V^E_{0.5}$, versus solubility parameters of hydrocarbons at 25°C.

TABLE 3. Molar volumes, V_m, heats of vaporization, ΔH_v, solubility parameter, $[(\Delta H_v - RT)/V_m]^{1/2}$, of various hydrocarbons and excess volumes at equimolar concentration, $V^E_{0.5}$, of $C_6H_{10}O$ + hydrocarbon systems at 25°C

Hydrocarbon	V_m ($cm^3\ mol^{-1}$)	ΔH_v[a] (kcal mol^{-1})	$[(\Delta H_v - RT)/V_m]^{1/2}$ (cal $cm^{-3})^{1/2}$	$V^E_{0.5}$ ($cm^3\ mol^{-1}$)
n-Hexane	131.61	7.54	7.27	−0.514
n-Heptane	147.47	8.74	7.43	−0.063

[a]Reference 12.
[b]Reference 13.

indicate that the unlike interactions present in these systems are weak. Furthermore, the increase in the value of V^E with the increasing size of the hydrocarbon (from *n*-octane to *n*-hexadecane) is taken to be an indication of a decrease in the strength of unlike interactions. On the other hand, the negative values of V^E for the cyclohexanone + *n*-hexane system is suggestive of the presence of stronger unlike intermolecular interactions as compared to those of other higher hydrocarbon systems under investigation. However, the positive V^E at lower concentrations and negative afterwards (see Fig. 1) for cyclohexanone + *n*-heptane system is suggestive of its intermediate behaviour.

To the best of our knowledge, there are no data available in the reported literature for the excess volumes of mixing of any of binary mixtures under investigation to compare with our results.

From Fig. 1, it is clear that V^E values at equimolar concentration ($V^E_{0.5}$) for the binary mixtures of cyclohexanone with various hydrocarbons are the best representations of the intermolecular interactions present in these mixtures. Therefore, the $V^E_{0.5}$ values obtained are compared with the molar volumes, the heats of vaporization, and the solubility parameters of the hydrocarbons in Table 3.

The increase in the value of $V^E_{0.5}$ with increasing size of hydrocarbon as shown in Fig. 2 ($V^E_{0.5}$ versus number of carbon atoms of hydrocarbon) is not linear. The increase in $V^E_{0.5}$ is sharp from C_6 to C_7 and it slows down with further increase in the carbon atoms. Recently, similar behaviour has been observed for tetrahydrofuran + hydrocarbon and triethylamine + hydrocarbon systems by Suri (2, 3). For the sake of comparison, we have also plotted in Fig. 2 the $V^E_{0.5}$ for cyclohexanone + aromatic hydrocarbons (4), and it is observed that the change in $V^E_{0.5}$ with the increase in carbon atoms is very small as compared to those of the aliphatic hydrocarbon systems.

The linear increase in molar volume and heat of vaporization of hydrocarbons with the increase in number of their carbon atoms reveals that neither of the two major causes (V^E_{inter} or V^E_{geom}) is alone responsible for the non-linear increase in $V^E_{0.5}$ with increasing size of hydrocarbons (Fig. 2). This was further supported with the observed non-linear behaviour of $V^E_{0.5}$ versus heats of vaporization and molar volumes of hydrocarbons (Fig. 3). The linear relation between $V^E_{0.5}$ and the solubility parameter (Fig. 4) suggests that the dipoles present in these mixtures are responsible for the nonlinear increase of $V^E_{0.5}$ observed therein. Therefore, separation and quantification of the contribution due to the increasing size of the hydrocarbon to $V^E_{0.5}$ is not possible from these sets of data alone. Further attempts in this direction are in progress and will be discussed somewhere else.

3-Methylpyridine complexes of cobalt(II) and nickel(II) hexafluorophosphate and hexafluoroarsenate. Crystal and molecular structure of $Ni(H_2O)_2(3\text{-}CH_3C_5H_4N)_6(PF_6)_2$

RAYMOND M. MORRISON, ROBERT C. THOMPSON, AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received October 21, 1982

RAYMOND M. MORRISON, ROBERT C. THOMPSON, and JAMES TROTTER. Can. J. Chem. **61**, 1651 (1983).

Reaction of aqueous solutions containing Co^{2+} or Ni^{2+} and PF_6^- or AsF_6^- with excess 3-methylpyridine yields crystals of compounds of composition $M(H_2O)_2(3mpy)_6(EF_6)_2$. Blue crystals of diaquohexakis(3-methylpyridine)nickel(II) hexafluorophosphate, $C_{36}H_{46}F_{12}NiN_6O_2P_2$, are monoclinic, a = 10.497(1), b = 20.074(3), c = 21.836(5) Å, β = 103.93(2)°, Z = 4, space group Cc. The structure was determined with Mo$K\alpha$ CAD4 diffractometer data by direct methods, and refined by full-matrix least-squares procedures to R = 0.048 for 2723 reflections with $I \geq 3\sigma(I)$. The structure consists of $\{Ni(3mpy)_4[(OH_2)(3mpy)]_2\}^{2+}$ cations and PF_6^- anions. The cation contains a NiN_4O_2 chromophore with water molecules occupying *trans* positions of a distorted octahedron about nickel. One additional 3-methylpyridine molecule is H-bonded to each of the water molecules with O—H...N distances of 2.717(11) and 2.719(11) Å. Weak interaction of each water molecule via its second hydrogen atom with a PF_6^- ion is indicated by the positioning of the anions. The O—H...F distances are 2.958(11) and 2.959(11) Å. Two other complexes of this type, where M is Ni and E is As and where M is Co and E is P, are reported here and on the basis of spectroscopic and magnetic studies are assigned structures similar to the Ni/P complex.

Decomposition of the *aquo* complexes under mild conditions yields compounds of composition $M(3mpy)_4(EF_6)_2$. $Ni(3mpy)_4(PF_6)_2$ is assigned a square planar structure with weakly interacting PF_6^- anions in axial positions. Both $Co(3mpy)_4(EF_6)_2$ complexes, where E is P or As, have tetrahedral $[Co(3mpy)_4]^{2+}$ cations and non-coordinated anions.

RAYMOND M. MORRISON, ROBERT C. THOMPSON et JAMES TROTTER. Can. J. Chem. **61**, 1651 (1983).

Les solutions aqueuses contenant du Co^{2+} ou du Ni^{2+} et du PF_6^- ou du AsF_6^- réagissent avec un excès de méthyl-3 pyridine en donnant un composé cristallin le $M(H_2O)_2(3mpy)_6(EF_6)_2$. Les cristaux bleus d'hexafluorophosphate de diaquohexakis (méthyl-3 pyridine) nickel(II) $C_{36}H_{46}F_{12}NiN_6O_2P_2$ sont monocliniques et appartiennent au groupe d'espace Cc avec a = 10,497(1), b = 20,074(3), c = 21,836(5) Å, β = 103,93(2)°, Z = 4. On a déterminé la structure par des méthodes directes en utilisant un diffractomètre de type Mo$K\alpha$ CAD4 et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à une valeur de R = 0,048 pour 2723 réflexions avec $I \geq 3\sigma(I)$. La structure comprend des cations de $\{Ni(3mpy)_4[(OH_2)(3mpy)]_2\}^{2+}$ et des anions PF_6^-. Le cation contient un chromophore NiN_4O_2 avec les molécules d'eau en positions *trans* dans un octaèdre déformé autour du nickel. De plus la méthyl-3 pyridine est liée par des liaisons hydrogène à chaque molécule d'eau avec des distances O—H...N de 2,717(11) et de 2,719(11) Å. La position des anions témoigne d'une faible interaction de chaque molécule d'eau avec l'ion PF_6^- par l'intermédiaire de son second atome d'hydrogène. Les distances O—H...F sont de 2,958(11) et de 2,959(11) Å. On rapporte deux autres complexes de ce type où M = Ni et E = As et où M = Co et E = P, et en se basant sur les études spectroscopiques et magnétiques on leur attribue une structure semblable à celle du complexe Ni/P.

La décomposition des complexes *aqueux* dans des conditions douces conduit à des produits de composition $M(3mpy)_4(EF_6)_2$. On attribue une structure plan-carrée au complexe $Ni(3mpy)_4(PF_6)_2$ avec une faible interaction des anions en positions axiales. Les deux complexes de $Co(3mpy)_4(EF_6)_2$ où E = P ou As ont des cations $[Co(3mpy)_4]^{2+}$ tétraédriques et des anions non coordonnées.

Introduction

Earlier communications on synthesis, structure, and bonding in cobalt(II) and nickel(II) complexes containing PF_6^- and AsF_6^- have been concerned with pyridine (py) and 4-methylpyridine (4mpy) derivatives (1–4). PF_6^- and AsF_6^- complexes of the type $Co(py)_4A_2$ and $Ni(py)_4A_2$ contain non-coordinated anions (2, 4); in contrast, the anions are co-ordinated in the corresponding perchlorates (5, 6) leading to the conclusion that the EF_6^- ions should be assigned weaker ligating abilities than ClO_4^-. Consistent with this is the observation that, although species such as $[Co(py)_6]^{2+}$ and $[Ni(py)_6]^{2+}$ are not obtainable in the solid state with ClO_4^- as the counter anion, these species are found in the solid state in combination with PF_6^- and AsF_6^- (2, 4).

The work with 4-methylpyridine complexes yielded crystalline materials suitable for X-ray studies (3, 4, 7) and led to some interesting comparisons with the pyridine derivatives (and in turn prompted the present extension of the work). Whereas reaction of excess pyridine with aqueous solutions containing cobalt(II) or nickel(II) and the EF_6^- anions gives six-coordinate complexes of the type $[M(py)_6](EF_6)_2$ (2), reactions involving 4-methylpyridine under similar conditions form compounds of composition $[M(H_2O)_2(4mpy)_8](EF_6)_2$. Structurally related to the perchlorate complex, $[Ni(H_2O)_2(4mpy)_4](ClO_4)_2$ (8), these compounds are six-coordinate and have *trans* coordinated water molecules each of which is strongly H-bonded to two additional 4-methylpyridine ligands (3). Another interesting comparison concerns $[Ni(py)_4](AsF_6)_2$ and $[Ni(4mpy)_4](AsF_6)_2$. The pyridine complex has been found to undergo a structural change at low temperatures to a form which contains coordinated AsF_6^-, while no such phenomenon is observed for the 4-methylpyridine analogue (4). Finally, comparisons of the electronic spectra of related 4-methylpyridine and pyridine complexes showed that whereas the greater basicity of 4-methylpyridine (pK_a of 6.02 compared to 5.17 for pyridine (9)) appears to result in a significant increase in energy in the electronic absorption bands of $Cu(4mpy)_4(EF_6)_2$ complexes over the pyridine analogues (10), it has no detectable effect on the electronic spectra of analogous cobalt and nickel compounds (3).

To investigate the effect of varying neutral ligand basicity further and to explore the possible effects of steric crowding in the neutral ligands, we studied other methylpyridine complexes of cobalt and nickel. We were unable to isolate stable

2-methylpyridine analogues (where steric crowding effects are presumably too great, leading to instability); however, several 3-methylpyridine (3mpy; pK_a = 5.68 (9)) complexes were isolated and characterized.

Experimental

Materials

3-Methylpyridine was refluxed over barium oxide for 24 h then distilled at atmospheric pressure. Other materials were reagent grade and used as received.

All products were found to be unstable in air. All manipulations were performed in an inert atmosphere box filled with dry nitrogen.

Preparations

Diaquohexakis(3-methylpyridine)cobalt(II) and nickel(II) hexafluorophosphate and hexafluoroarsenate, $M(H_2O)_2(3mpy)_6(EF_6)_2$

These compounds were obtained by the method described previously for the preparation of the 4-methylpyridine complexes of composition $M(H_2O)_2(4mpy)_8A_2$ (3). In the present work, however, instead of using a 2:1 ratio of NH_4PF_6 (or $KAsF_6$) to metal nitrate, the ratio employed was about 2.5:1. The addition of excess salt was found to improve the crystallization which took place within about a week. The crystals (orange–red for cobalt and blue for nickel) were washed with a solution of 5 mL 3-methylpyridine in 50 mL water. Since they tended to lose 3-methylpyridine on prolonged exposure to the atmosphere or to a vacuum, the crystals were stored in sealed vials while still "wet" with the washing liquid. Just prior to further use the crystals were dried for about 15 min *in vacuo* at room temperature. Subsequent decomposition under these "dry" conditions was sufficiently slow for all but one of the compounds that reliable elemental analysis, spectral and magnetic data could be obtained.

$Co(H_2O)_2(3mpy)_6(AsF_6)_2$ was, however, so unstable as a "dry" solid that it could not be properly characterized. Its composition is not known for certain but is assumed to be as indicated by analogy with the other complexes prepared in the same manner. The ultimate product of its decomposition under vacuum is, as described below, $Co(3mpy)_4(AsF_6)_2$.

Tetrakis(3-methylpyridine)cobalt(II) hexafluoroarsenate and hexafluorophosphate, $Co(3mpy)_4(EF_6)_2$

These compounds were obtained as violet powders from the corresponding dried $Co(H_2O)_2(3mpy)_6(EF_6)_2$ complexes by grinding to a fine powder in the inert atmosphere box followed by pumping *in vacuo* for 24 h. No heating was required. The compounds are extremely hygroscopic.

Tetrakis (3-methylpyridine)nickel(II) hexafluoroarsenate, $Ni(3mpy)_4(AsF_6)_2$

$Ni(H_2O)_2(3mpy)_6(AsF_6)_2$ was ground to a fine powder in the inert atmosphere box and then dried under vacuum and at room temperature for 24 h. The light blue–yellow powder was then transferred to the dry-box where it was placed in a flask containing a large excess of chloroform. Upon stirring, the suspended material changed to an orange–yellow powder which was filtered, washed with chloroform, and dried *in vacuo*.

Analyses

C, H, and N analyses were obtained by P. Borda of the Department of Chemistry, The University of British Columbia. Analytical data are given in Table 1.

Spectroscopic and magnetic susceptibility measurements

Infrared spectra, electronic spectra, and magnetic susceptibility data were obtained using equipment and methods described previously (3).

X-ray crystal analysis

Crystals of $Ni(H_2O)_2(3mpy)_6(PF_6)_2$ are unstable in air and were sealed in 0.3 mm diameter Lindemann capillaries for study. The initial Weissenberg and precession photographs indicated a monoclinic space group and the systematic absences (*hkl*: $h + k = 2n + 1$; *h*0*l*: $l = 2n + 1$ ($h = 2n + 1$); 0*k*0: ($k = 2n + 1$)) gave the space group as Cc (C_s^4, No. 9) or $C2/c$ (C_{2h}^6, No. 15). Intensity statistics were ambiguous, but observation of significant intensity differences between *hk*0 Friedel pairs indicated space group Cc.

The crystal chosen for data collection was mounted in a random orientation on the Enraf-Nonius CAD4 computer-controlled diffractometer equipped with monochromated Mo$K\alpha$ (λ = 0.71069 Å) X-ray source; 25 reflections were found automatically in reciprocal space and indexed to a triclinic unit cell. A simple transformation of the unit cell was needed to give the *C*-centered monoclinic cell indicated by the preliminary photographs. The crystal data are:

$C_{36}H_{46}F_{12}N_6NiO_2P_2$ fw = 943.5

monoclinic, space group Cc, a = 10.497(1), b = 20.074(3), c = 21.836(5) Å, β = 103.93(2)°, V = 4466 Å^3, Z = 4, ρ_{calcd} = 1.41, μ(Mo$K\alpha$) = 11.9 cm^{-1}.

The reflection intensities were collected in the range $2 \leq 2\theta \leq 50°$ with an ω scan, scan angle (1.10 + 0.35 tan θ)°, extended 25% on both sides to provide background counts, with a horizontal aperature of (1.75 + tan θ) mm. Three orientation control reflections were measured every 100 reflections and the orientation matrix recalculated if the scattering vector was greater than 0.1° from the calculated position. Three intensity control reflections were measured every 3600 seconds of X-ray exposure time; during the data collection, the mean of their intensities varied randomly ±1.3%. In the data reduction, Lorentz-polarization (LP) corrections were applied and an estimated standard deviation was assigned: $\sigma^2(I) = S + 4(B_1 + B_2) + (dI)^2$, where S = scan count and B_1 and B_2 = background counts; d was adjusted during the refinement, with a final value of 0.076. Of the 4054 reflection data collected (including *hk*0 Friedel pairs), 2723 (67%) had $I \geq 3\sigma(I)$.

The structure was solved by direct methods applied in space group $C2/c$. The largest peak on the *E*-map, at 1/2, 1/8, 1/4, apparently corresponded to the Ni atom on a special (*e*) position of C_2 symmetry; two further peaks of about one-quarter the height of the Ni atom could be interpreted as two independent half-phosphorus atoms separated by only 2.8 Å. This would represent a disordered structure and a more reasonable interpretation in terms of Cc was confirmed by further analysis. C, N, O, and F atom positions were determined from electron-density maps phased on Ni and 2P, and the structure was refined by full-matrix least-squares procedures, with scattering factors from ref. 11, and anomalous dispersion corrections for Ni and P (choice of the correct axial directions gave good agreement between F_o and F_c for the *hk*0 Friedel pairs; reversed choice of axis gave

distinctly poorer agreement, within Friedel pair differences in the wrong sense for most reflections). The weights were taken as $w = 1/\sigma^2(F)$, and final R and R_w were 0.048 and 0.061, respectively, for the 2723 reflections with $I > 3\sigma(I)$ (0.051 and 0.063, respectively, for opposite sense of a and c axis). For all 4054 reflections, $R = 0.091$. A final difference map had maximum fluctuations of +0.4 and −0.2 e Å^{-3}. The final positional and thermal parameters are given in Tables 2 and 3,[1] respectively. The observed and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

Results and discussion

Syntheses

The reaction of aqueous solutions containing Co^{2+} or Ni^{2+} and PF_6^- or AsF_6^- with excess 3-methylpyridine results in the crystallization, over a period of about one week, of complexes of composition $M(H_2O)_2(3mpy)_6(EF_6)_2$. These materials lose 3-methylpyridine on prolonged exposure, at room temperature, to the atmosphere or to a vacuum. The cobalt(II) complexes are particularly unstable; the hexafluoroarsenate decomposed so readily at ordinary temperatures that its characterization was not possible and both it and the hexafluorophosphate derivative readily gave the $Co(3mpy)_4(EF_6)_2$ complexes when subjected to a dynamic vacuum at room temperature. By comparison (3), the related 4mpy complexes, $Co(H_2O)_2(4mpy)_8(EF_6)_2$ require elevated temperatures for complete conversion to $Co(4mpy)_4(EF_6)_2$. The nickel complexes, $Ni(H_2O)_2(3mpy)_6(EF_6)_2$, are slightly more stable than the cobalt analogues; on exposure to a dynamic vacuum for 24 h at room temperature they yield mixtures of starting material and $Ni(3mpy)_4(EF_6)_2$ product. Complete conversion of the hexafluoroarsenate to $Ni(3mpy)_4(AsF_6)_2$ was obtained here by stirring a sample of the mixtures in chloroform, a procedure not unlike that used to prepare the corresponding pyridine derivative (4).

Crystal structure analysis

The question of whether the materials of composition $M(H_2O)_2(3mpy)_6(EF_6)_2$ contain MN_6 chromophores or MN_4O_2 chromophores with non-coordinated 3-methylpyridine ligands was resolved through a single crystal X-ray diffraction study of $Ni(H_2O)_2(3mpy)_6(PF_6)_2$. The stucture consists of $\{Ni(3mpy)_4[(OH_2)(3mpy)]_2\}^{2+}$ cations and PF_6^- anions. The cation (Fig. 1) contains a NiN_4O_2 chromophore with water molecules occupying *trans* positions of a distorted octahedron about nickel. Four of the 3-methylpyridine ligands are bonded to nickel and the other two are connected, through hydrogen bonds, one to each of the coordinated water molecules. The O—H.....N distances of 2.719(11) and 2.717(11) Å (Table 4) are shorter than the value 2.812 Å found in $Ni(NCS)_2(qn)_4(H_2O)_2$, a complex containing similarly bonded quinoline molecules (12). The 3-methylpyridine moieties are all planar, within experimental error, and the bond distances and angles in the rings are similar to those found in a microwave study of pyridine (13). The Ni—N distances (Table 4) are 2.114–2.135(8), mean 2.122 Å, and Ni—O are 2.103(6) and 2.102(8) Å. These distances compare with Ni—N = 2.18 Å and Ni—O = 2.13 Å in the quinoline complex (12). The *trans* bonds show slight deviations from linearity (178.2, 178.5, 178.7°), but overall the distortion of the chromophore is not very great and the symmetry of the ligand field about nickel may be reasonably described as D_{4h}.

Close examination of the structure provides evidence for significant cation–anion interaction in this complex (Fig. 1).

[1]Anisotropic thermal parameters (Table 3), full listing of bond lengths and angles, and structure factors are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

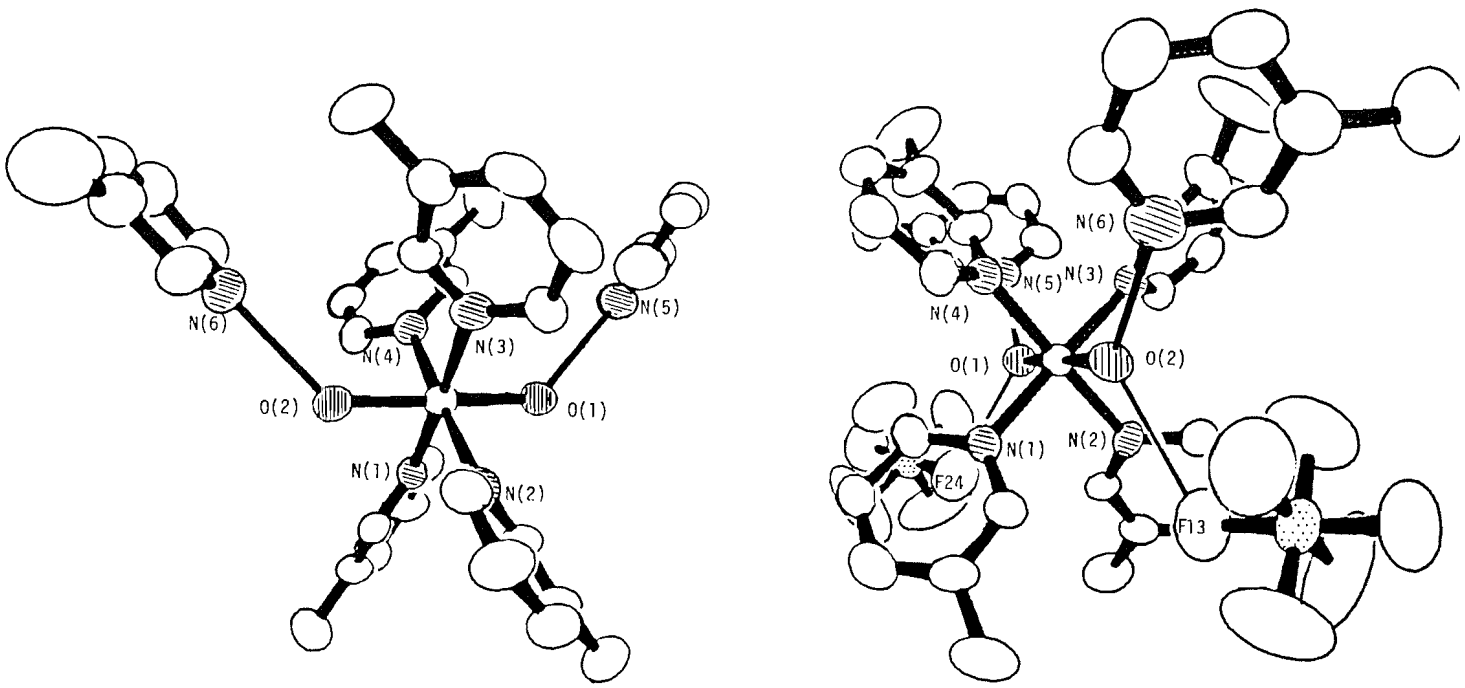

FIG. 1. Two views of $[Ni(H_2O)_2(3mpy)_6]^{2+}$; the right-hand view includes the PF_6 groups. All atoms drawn with 50% probability thermal ellipsoids.

Each water molecule is clearly hydrogen bonded to a 3-methylpyridine ligand through one of its hydrogen atoms. Interaction of each water molecule via its second hydrogen atom with a PF_6^- ion is indicated by the positioning of the anions. The hydrogen bonding involved here, however, must be considered very weak. The O—H...F distances of 2.958(11) and 2.959(11) Å observed in this complex are significantly longer, for example, than the values 2.38 Å, 2.44 Å, and 2.41–2.49 Å observed in $KH_2PO_3.HF$ (14), $KF.(CH_2CO_2H)_2$ (15), and $KF.CH_2(CO_2H)_2$ (15), respectively, and are just outside the range of 2.56 to 2.86 Å observed in a number of metal fluoride hydrates (16).

The ligands are oriented so that the $Ni(3mpy)_4O_2$ grouping has approximate D_2 symmetry; inclusion of the hydrogen-bonded 3mpy molecules and the PF_6^- ions gives roughly C_2 symmetry for the whole complex of one cation and two anions (Fig. 1), although there is no required crystallographic symmetry (C_1). The complex are further linked together in the crystal only by van der Waals forces.

The geometries at the O atoms are not far from planar, with mean angles Ni—O...N = 132.0(3), Ni—O...F = 115.5(3), N...O...F = 110.4(3), sum = 358°.

The PF_6^- ions exhibit typical large thermal motion. The thermal parameters are smallest for the F atoms involved in the interactions with the water molecules, F(13) and F(24), and the atoms *trans* to these in the octahedral anion, F(12) and F(25); for these atoms the U(isotropic) values (Table 2) are all about 0.12 Å^2 (corresponding to rms displacements of about 0.35 Å), while for the other four atoms of each PF_6^- ion, U(isotropic) = 0.14–0.21 Å, with individual U_{ij} values (Table 3) as high as 0.37 Å (rms displacement 0.6 Å). The weak O—H...F interactions therefore appear to be strong enough to anchor the PF_6^- ions, with the main thermal motion being librations (or rotations) about the F(13)...F(12) and F(24)...F(25) axes. The P—F(13) and P—F(24) bonds are the longest among the P—F bonds at 1.576(8) and 1.581(8) Å respectively; however, the differences from the other P—F bonds are not statistically significant, and all these P—F distances are probably affected by libration errors. The P—F...O angles are 115.1(5)°.

Although we do not have X-ray data for the other two aquo-complexes studied here, the magnetic properties and electronic and vibrational spectra of both of them (to be discussed below) are consistent with their having the same basic structure as $Ni(H_2O)_2(3mpy)_6(PF_6)_2$.

Electronic spectra and magnetism

The assignment of electronic spectra and calculation of ligand field and magnetic parameters (Table 5) were performed as described previously (3). The three $M(H_2O)_2(3mpy)_6(EF_6)_2$ complexes exhibit electronic spectra which may be assigned assuming O_h symmetry about the metal. Although the X-ray studies on the nickel hexafluorophosphate derivative show clearly that the chomophore involved is of the MO_4N_2 type, the symmetry lowering is not sufficient to give rise to detectable band splitting. The calculated Dq values for all three of these complexes are significantly greater than the values for the corresponding $M(py)_6(EF_6)_2$ compounds (2). This is consistent with our earlier studies on 4-methylpyridine complexes where we found that the MN_4O_2 complexes had higher Dq values than those with MN_6 chromophores, and supports our earlier contention (3) that greater steric crowding associated with having six heterocyclic ligands bonded directly to the metal as in the pyridine complexes leads to longer and therefore weaker metal–ligand bonds. A comparison of analogous six-coordinate 3mpy and 4mpy complexes shows that in spite of the similarity in chromophores (MN_4O_2) the Dq values are not simply related to ligand base strength. The 3mpy complexes consistently have higher Dq values in spite of the fact that 4mpy is a stronger base (9). Clearly differences in the axial ligand groups and small differences in bond lengths, bond angles and, possibly, the pitch of the heterocyclic ligands, which affects the extent of π-electron delocalization (10), dom-

inate here.

The magnetic properties of the $M(H_2O)_2(3mpy)_6(EF_6)_2$ compounds (Table 5) are generally consistent with spin-free six-coordinate complexes. In the case of $Co(H_2O)_2(3mpy)_6(PF_6)_2$ the temperature dependence of the magnetic moment (Table 6) provides a measure of the distortion of the ligand environment from regular octahedral stereochemistry. There is excellent agreement between measured magnetic moments and those calculated using the four parameter approach of Figgis *et al.* (17) for spin-free cobalt(II) in an axially compressed tetragonal environment. The parameter values (Table 6) are the same to within experimental error as those calculated for the structurally similar $Co(H_2O)_2(4mpy)_8(EF_6)_2$ complexes (3).

$Ni(3mpy)_4(AsF_6)_2$ is yellow, diamagnetic (over the range 300 to 80 K), and shows a single absorption band in the visible region (Table 5) with a maximum close in energy to that observed for the 4mpy analogue. The complex clearly involves square planar $[Ni(3mpy)_4]^{2+}$ cations and non-coordinated anions. While the corresponding $Ni(py)_4(AsF_6)_2$ has been shown to undergo a structure change at low temperature to a paramagnetic form involving coordinated anions (4) this 3mpy complex, like its 4mpy analogue, undergoes no such change.

The magnetic properties and electronic spectra of the $Co(3mpy)_4(EF_6)_2$ compounds (Table 5) are consistent with spin-free tetrahedral cobalt(II). The differences in Dq and B values between these complexes and analogous pyridine (2) and 4-methylpyridine (3) complexes cannot be considered significant. This shows that in spite of the greater basicity of the methylpyridine ligands and in spite of the potential for greater steric crowding in the 3-methylpyridine complexes, the coordinating properties of these three ligands are not sufficiently different to produce a measurable effect in the electronic spec-

tra of these tetrahedral species. It is interesting to note that in complexes of the type $ML_4(EF_6)_2$ (where M is Co, Ni, or Cu, L is py, 3mpy, or 4mpy, and E is P or As), only in the case of the $CuL_4(EF_6)_2$ series has it been possible to relate changes in electronic spectra to the relative coordinating strengths of the pyridine-type ligands (10). Changing the neutral ligand alters the tetragonality of the copper complex and although the change is very small in this case, the dependence of the energy of the maximum in the electronic spectra on tetragonality is clearly sufficiently great for the effect to be seen.

Infrared spectra

Bands arising primarily from anion vibrations and those due to vibrations associated with the 3mpy ligands are relatively easy to distinguish. The anion bands, assigned on the basis of O_h symmetry, are listed in Table 7. The criteria for non-coordinated EF_6^- anions, given previously (3), are met for all complexes with the possible exception of $Ni(3mpy)_4(AsF_6)_2$. As we found for analogous py and 4mpy complexes, the ν_1 and ν_2 vibrations of the nickel complex appear with medium intensity, indicative of weak cation–anion interaction (10).

The infrared spectra of the aquo complexes in the OH stretching region are particularly interesting. All three complexes exhibited a strong very broad OH stretching absorption with a maximum centred around 2850 cm^{-1} and a sharper intense band around 3570 cm^{-1} (Fig. 2). This is consistent with the presence of two types of OH bonds, one involving relatively strong H-bonding to 3-methylpyridine and resulting in the band at 2850 cm^{-1} and the other involving weak H-bonding to PF_6^- and giving the 3570 cm^{-1} band. In comparison, the 4-methylpyridine complexes of composition $M(H_2O)_2(4mpy)_8(EF_6)_2$ have structures in which the axial water molecules have both protons strongly H-bonded to 4-methylpyridine groups (3) and these compounds (Fig. 2) exhibit only one broad band, presumably comprising both the symmetric and the asymmetric HOH stretching, centred around 3000 cm^{-1}. An example of a related complex in which none of the protons of the water molecules are H-bonded to a strong base is $Ni(H_2O)_2(4mpy)_4(ClO_4)_2$. This complex exhibits a strong band at 3420 cm^{-1} with a shoulder at 3280 cm^{-1} assignable to HOH asymmetric and symmetric stretches respectively (8).

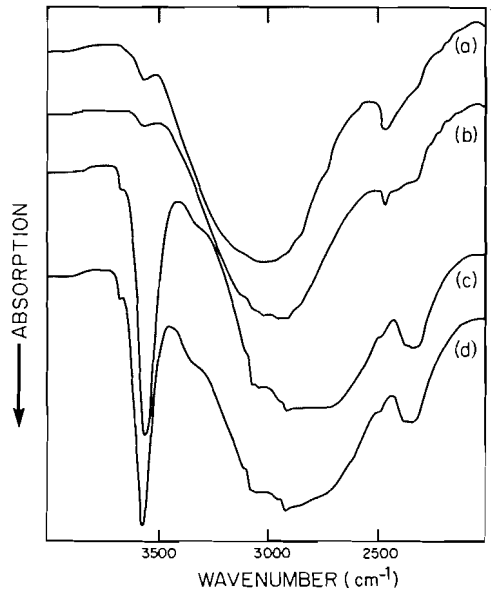

FIG. 2. Infrared spectra, 4000 to 2000 cm^{-1} region, hexachlorobutadiene mull: (a) $Ni(H_2O)_2(4mpy)_8(PF_6)_2$, (b) $Co(H_2O)_2(4mpy)_8(PF_6)_2$, (c) $Co(H_2O)_2(3mpy)_6(PF_6)_2$, (d) $Ni(H_2O)_2(3mpy)_6(PF_6)_2$.

A quadruply bonded dimolybdenum compound containing a novel bridging and chelating hexadentate ligand

KENNETH R. BREAKELL, STEVEN J. RETTIG, ALAN STORR, AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received December 7, 1982

KENNETH R. BREAKELL, STEVEN J. RETTIG, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **61**, 1659 (1983).

The synthesis, physical properties, and molecular structure of $(N_2C_3H_5)^+[Mo_2(\mu\text{-}CH_3CO_2)[CH_3Ga(N_2C_3H_3)O]_4]^- \cdot 2(C_4H_8O)$ are reported. Crystals of pyrazolium (μ-acetato)[1,3,5,7-tetramethyl-1,3,5,7-tetrakis(pyrazol-1-yl)cyclotetragalloxanato(4−)]dimolybdate(II)-bis(tetrahydrofuran) are orthorhombic, a = 10.638(2), b = 32.779(4), c = 12.617(1) Å, Z = 4, space group *Cmcm*. The structure was solved by Patterson and Fourier syntheses and was refined by full-matrix least-squares procedures to R = 0.032 and R_w = 0.041 for 1957 reflections with $I \geq 3\sigma(I)$. The structure consists of THF molecules and $(N_2C_3H_5)^+[Mo_2(\mu\text{-}CH_3CO_2)[CH_3Ga(N_2C_3H_3)O]_4]^-$ ion-pair units, the latter displaying exact C_{2v} symmetry. The pyrazolium cation is joined to the complex anion by a pair of strong N—H···O hydrogen bonds (H···O = 1.49(6) Å). The Mo_2^{4+} unit is bridged by a single acetato group, the remaining coordination sites being occupied by the hexadentate bridging and chelating $[CH_3Ga(N_2C_3H_3)O]_4^{4-}$ ligand. Bond lengths are: Mo—Mo = 2.127(1), Mo—N = 2.151(3), Mo—O = 2.090(4) and 2.115(4), Ga—O = 1.853(2) and 1.861(2), Ga—N = 1.961(3), and Ga—C = 1.950(6) Å.

KENNETH R. BREAKELL, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **61**, 1659 (1983).

On rapporte la synthèse, les propriétés physiques et la structure moléculaire du $(N_2C_3H_5)^+[Mo_2(\mu\text{-}CH_3CO_2)[CH_3Ga(N_2C_3H_3)O]_4]^- \cdot 2(C_4H_8O)$. Les cristaux de (μ-acéto)[tétraméthyl-1,3,5,7 tétrakis-1,3,5,7 (pyrazol-1) cyclotétragalloxanato-(4−)] dymolybdate(II) bis (tétrahydrofuranne) de pyrazolium sont orthorhombiques et appartiennent au groupe d'espace *Cmcm* avec a = 10,638(2), b = 32,779(4), c = 12,617(1) Å, Z = 4. On a résolu la structure par les synthèses de Patterson et de Fourier et on la affinée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de R = 0,032 et de R_w = 0,041 pour 1957 réflexions avec $I \geq 3\sigma(I)$. La structure comprend des molécules de THF et la paire d'ions $(N_2C_3H_5)^+(Mo_2(\mu\text{-}CH_3CO_2)[CH_3Ga(N_2C_3H_3)O]_4]^-$. La paire d'ion exhibant une symétrie exacte C_{2v}. Le cation pyrazolium est lié à l'anion complexe par deux fortes liaisons hydrogène du type N—H···O (H···O = 1,49(6) Å). Un groupe simple acétato forme un pont avec l'ion Mo^{4+}, les autres sites de coordination étant occupés par le ligand hexadendate $[CH_3Ga(N_2C_3H_3)O]_4^{4-}$ qui forme un pont et qui chélate également. Les longueurs de liaison sont de: Mo—Mo = 2,127(1), Mo—N = 2,151(3), Mo—O = 2,090(4) et 2,115(4), Ga—O = 1,853(2) et 1,861(2) Ga—N = 1,961(3) et Ga—C = 1,950(6) Å.

Introduction

A recent report has highlighted the growing importance of the field of metal–metal bonded species and in particular has illuminated the special place of the Cr triad in its development (1). Multiply bonded dimolybdenum species have been particularly amenable to study and of these, compounds having a quadruple bond between the two metal atoms have received a great deal of attention. This paper describes the synthesis and structure of a dimolybdenum complex having a Mo≡Mo quadruple bond, a bridging acetato group, and an unusual bridging and chelating hexadentate ligand.

Experimental

Starting materials

Air-sensitive materials were handled in a glove box under an atmosphere of oxygen-free, dry nitrogen, or in a nitrogen-blanketed apparatus. Tetrahydrofuran (THF) was dried by refluxing over lithium aluminum hydride and was used immediately following distillation. Dimolybdenum tetraacetate was prepared by a standard route (2) and the $Na^+[CH_3Ga(N_2C_3H_3)_3]^-$ ligand was prepared as a THF solution as detailed elsewhere (3).

Reaction of $Mo_2(CH_3CO_2)_4$ with $Na[CH_3Ga(N_2C_3H_3)_3]$

A slurry of $Mo_2(CH_3CO_2)_4$ (0.753 g, 1.76 mmol) in THF was reacted with a 50.0 mL aliquot of ligand solution $Na^+[CH_3Ga(N_2C_3H_3)_3]^-$ (1.09 g, 3.53 mmol). After stirring for several minutes the reaction mixture, initially orange, became a dark wine-red color. Slow evaporation of THF solvent from the filtrate from this reaction yielded a tacky purple solid and numerous orange crystals (approximately 30% yield). The latter were found to be suitable for X-ray diffraction studies providing precautions were taken to prevent air-exposure. Selected crystals were mounted in glass capillaries which were then sealed off under an atmosphere of nitrogen gas. The results of the structure determination are reported below. From more sporting physical methods the following information was obtained: *Anal.* Calcd. for $(N_2C_3H_5)^+[Mo_2(\mu\text{-}CH_3CO_2)[CH_3Ga(N_2C_3H_3)O]_4]^- \cdot 2(C_4H_8O)$: C 30.7, H 4.3, N 12.3; found: C 30.5, H 4.3, N 12.1.

Mass spectrum (Varian MAT CH4 spectrometer)

With a probe temperature of approximately 220°C and at 70 eV signals due to the parent ion (M^+ where M = $(N_2C_3H_5)^+[Mo_2(\mu\text{-}CH_3CO_2)[CH_3Ga(N_2C_3H_3)O]_4]^-$) and the $(M - Me)^+$ ion could be clearly seen even though multi-line signals (23 peaks over 25 mass units) arise from all the possible isotopic combinations of four Ga and two Mo atoms.

Nuclear magnetic resonance (Varian XL 100 FT spectrometer)

The ^1H nmr spectrum of the complex showed clearly the presence of pyrazolyl (2.35 d, 2.61 d, 3.94 t), acetato methyl (8.86 s), and gallium methyl (9.96 s) moieties in addition to signals due to the THF molecules (8.58 m, 6.43 m). (τ values realtive to $\tau_{C_6H_6}$ = 2.84; $J_{HCCH} \approx 2$ Hz for pyrazolyl protons.)

X-ray crystallographic analysis of $(N_2C_3H_5)^+[Mo_2(\mu\text{-}CH_3CO_2)\text{-}[CH_3Ga(N_2C_3H_3)O]_4]^- \cdot 2(C_4H_8O)$

A crystal bounded by the six faces (followed by their distances in mm from a common origin): (0 1 2), 0.150, (0 −1 2), 0.213, ±(2 −6 1), 0.252, ±(2 6 −1), 0.200 was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 40–46°) measured on a diffractometer with MoKα$_1$ radiation (λ = 0.70930 Å). Crystal data at 22°C are:

$C_{29}H_{48}Ga_4Mo_2N_{10}O_8$ fw = 1135.52

Orthorhombic, a = 10.638(2), b = 32.779(4), c = 12.617(1) Å, V = 4399.7 Å^3, Z = 4, ρ_c = 1.714 g cm^{-3}, $F(000)$ = 2256, μ(MoKα) = 29.99 cm^{-1}. Absent reflections: hkl, $h + k$ odd, and $h0l$, l odd. Space group *Cmcm* (D_{2h}^{17}, No. 63) from structure analysis.

Intensities were measured with graphite-monochromated MoKα radiation (λ = 0.71073 Å) on an Enraf-Nonius CAD4-F diffractometer. An ω–0.33θ scan at 1.01–6.71° min^{-1} over a range of (0.60 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 60°. The intensities of three check reflections, measured every 3600 s throughout the data collection, remained constant to within 2.5%. After data reduction,[1] an absorption correction was applied using the Gaussian integration method (4, 5). Transmission factors ranged from 0.412 to 0.751 for 268 integration points. Of the 3489 independent reflections measured, 1957 (56.1%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The centrosymmetric space group *Cmcm* was indicated by the *E*-statistics and by the Patterson function, from which the heavy-atom coordinates were determined. Coordinates of all atoms except those associated with the solvent molecules were easily located from subsequent difference maps. These atoms were refined (H isotropic, other anisotropic) to $R = 0.051$, at which point the location of the two solvent molecules could be deduced. The THF molecules occupy two independent sites (A and B) in the lattice, each of which lies at the intersection of two mirror planes. Site A lies halfway between two mirror-related complex molecules roughly along the Mo—Mo axis and is centered at approximately 1/2, 0.18, 1/4. The A site is at least fourfold disordered with one THF molecule having its mean plane approximately in the *bc* plane while the second molecule has two carbon atoms (C(A2)) in common with the first and is oriented roughly at a right angle to the first molecule (in the *ab* plane). The B site lies along the twofold axis of the complex beyond the acetato methyl group (the protons of which are also, and necessarily, twofold disordered) and has its centre at approximately 0, 0.44, 1/4. At the B site there are three different orientations, two of which have O(B1) and C(B1) in common, the third containing O(B2), C(B3), and O(B1) (the latter position occupied by both C and O). The relative site occupancy factors for all THF atoms were estimated from relative heights on the difference map and were not refined; their appropriateness may be judged by the magnitudes of the final isotropic thermal parameters. The eleven independent atoms comprising the two solvent molecules were included in subsequent cycles of refinement. The scattering factors of ref. 6 were used for non-hydrogen atoms and those of ref. 7 for hydrogen atoms. Anomalous scattering factors from ref. 8 were used for the Mo and Ga atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of refinement. Convergence was reached at $R = 0.032$ and $R_w = 0.041$ for 1957 reflections with $I \geq 3\sigma(I)$. For all 3489 reflections $R = 0.088$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.04 and 0.44σ respectively. The maximum parameter shift was associated with the x coordinate of C(A3). The mean error in an observation of unit weight was 1.100. A final difference map revealed a peak of 0.77 e $Å^{-3}$ near Mo and a peak of 0.74 e $Å^{-3}$ near the C(A3) position, the remainder of the map being essentially featureless. The final positional and thermal parameters appear in Tables 1 and 2[2] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2]

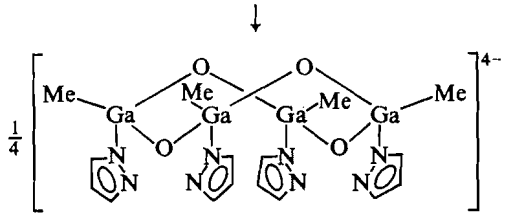
Results and discussion

Earlier reports (3, 9, 10) have described the synthesis and coordination chemistry of the tridentate anionic methyl(tris-pyrazolyl)gallate ligand, $CH_3Ga(N_2C_3H_3)_3^-$. In the present study this anion was reacted with dimolybdenum tetraacetate in an attempt to replace two of the bridging acetato groups in that molecule with the gallate ligands according to the stoichiometric equation:

$$Mo_2(CH_3CO_2)_4 + 2Na^+[CH_3Ga(N_2C_3H_3)_3]^- \rightarrow [CH_3Ga(N_2C_3H_3)_3]_2Mo_2(CH_3CO_2)_2 + 2Na^+CH_3CO_2^-$$

It was then hoped to study in detail the coordination geometry of the gallate ligand and in particular to investigate any possible axial interactions at the molybdenum centres. In an earlier report a similar reaction was probed using the tris-pyrazolyl borate anion, $HB(N_2C_3H_3)_3^-$, as reactant (11). In that investigation the desired reaction proceeded smoothly to replace two bridging acetato groups by borate ligands. The latter acted as bidentate chelating ligands at each Mo atom with the third pyrazolyl group of one of the ligands being weakly interacting with one of the metal atoms in an axial position. Since there were no steric requirements to prevent such an interaction at both molybdenum atoms it was proposed at that time that, for electronic reasons, quadruply bonded pairs of Mo atoms have little tendency to bind electron donors in coaxial positions. The weak interaction found at one Mo centre was argued to arise from conformational necessity rather than from any desire of the metal atom to enter into an axial bonding arrangement. The present study was initiated to probe further this reluctance of such dimolybdenum units to bind axially positioned ligands. The gallate ligand employed here, whilst similar to the $HB(N_2C_3H_3)_3^-$ ligand in many respects, has been shown to exhibit somewhat different behavior in related complexes, primarily due to the disparity between the Ga—N and B—N bond lengths (3, 9, 10, 12). It was hoped, therefore, that these differences might manifest themselves in some small but subtle changes in any resulting dimolybdenum species prepared via the above reaction. However, it became rapidly obvious from early spectral measurements that the desired reaction had not been accomplished. Indeed it required the crystal structure determination to enable us to rationalize this collection of data. The structure which materialized from the X-ray work was, to say the least, surprising and totally unique in the field of quadruply bonded dimolybdenum units. The initial molecule has retained but one bridging acetato group with the remaining six coordination positions being taken up by oxygen and nitrogen atoms from, in effect, a hexadentate chelating and bridging methyl gallium pyrazolyl oxo ligand (see below). The origin of this ligand is not known but could have arisen because of traces of water in the THF solvent. The overall transformation would involve loss of two pyrazole molecules and a tetramerization of the resultant oxo species.

$$[CH_3Ga(N_2C_3H_3)_3]^- + H_2O \rightarrow [CH_3Ga(N_2C_3H_3)O]^- + 2N_2C_3H_4$$



The formation of such an eight-membered $(Ga—O)_4$ ring is not without precedent and indeed the structure of the tetramer $[(CH_3)_2Ga(OH)]_4$ is well documented (13). In the present scheme the formally Mo(II) centres are thus neutralized by the 4− charge on the hexadentate ligand. The bridging acetato

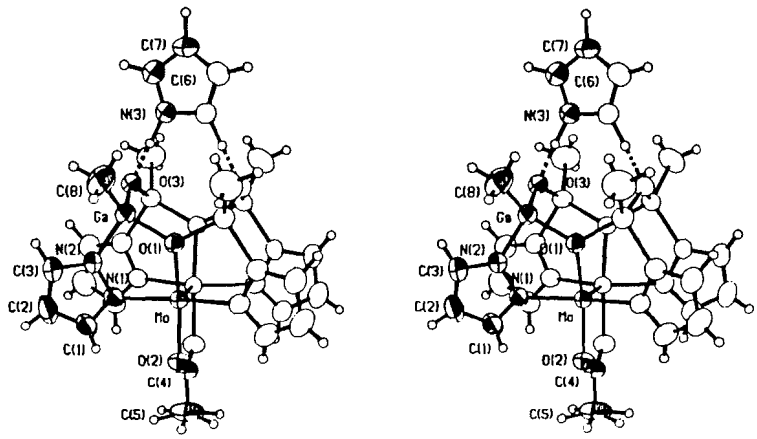

FIG. 1. Stereoscopic view of the ion-pair unit $(N_2C_3H_5)^+[Mo_2(\mu\text{-}CH_3CO_2)[CH_3Ga(N_2C_3H_3)O]_4]^-$, 50% probability thermal ellipsoids shown for the non-hydrogen atoms. Hydrogen atoms have been assigned artificially small thermal parameters for the sake of clarity.

ligand is then formally counterbalanced by a positive pyrazolium ion $N_2C_3H_5^+$ which is strongly hydrogen-bonded to the two oxygens of the $(Ga—O)_4$ ring which are not coordinated to Mo atoms. The origin of the oxo species is not known with any certainty but previous examples of "adventious" water creeping uninvited into similar reactions have been documented. Thus the 3,5-dimethylpyrazolyl based ligand $[CH_3Ga(N_2C_5H_7)_3]^-$ was very prone to conversion to the hydroxy species $[CH_3Ga(N_2C_5H_7)_2(OH)]^-$ in sterically demanding situations even when rigorous attempts to eliminate water had been made (14). More recently the reaction of $Mo_2(CH_3CO_2)_4$ with $Na^+(C_2H_5)_2B(N_2C_3H_3)_2^-$ has been reported to result in the incorporation of $[(C_2H_5)_2B(N_2C_3H_3)(OH)]^-$ ligands in the dimolybdenum product, a purely unexpected result attributed to adventious water entry into the reaction medium (15).

Crystal structure of $(N_2C_3H_5)^+[Mo_2(\mu\text{-}CH_3CO_2)\text{-}[CH_3Ga(N_2C_3H_3)O]_4]^-\cdot 2(C_4H_8O)$

The crystal structure consists of ion-pair units $(N_2C_3H_5)^+[Mo_2(\mu\text{-}CH_3CO_2)[CH_3Ga(N_2C_3H_3)O]_4]^-$ (Fig. 1) and THF molecules. The pyrazolium cation is linked by a pair of strong N—H···O hydrogen bonds to the two uncoordinated oxygen atoms of the $(Ga—O)_4$ ring (N(3)—H(N)···O(3), H···O = 1.49(6), N···O = 2.665(6) Å, N—H···O = 178(5)°). Each ion-pair unit is associated with two others through a system of weak C—H···O interactions across adjacent centres of symmetry, resulting in an infinite linear arrangement extending along the crystallographic *a* axis (C(6)—H(6)···O(3) $(-x, -y, -z)$, H···O = 2.42(10), C···O = 3.436(8) Å, C—H···O = 179(7)°). One of the partially occupied site A THF oxygen atoms is involved in a very weak axial interaction with the Mo_2^{4+} system: Mo—O(A1) = 2.85(2) Å, Mo′—Mo—O(A1) = 169.3(5)°. All other nonbonded distances correspond to normal van der Waals interactions.

The ion-pair complex possesses exact $m2m$ (C_{2v}) symmetry, the conformation about the Mo—Mo axis being exactly eclipsed. One mirror plane contains the two Mo atoms, the non-hydrogen atoms of the acetato group, and the O(1) atoms of the $(Ga—O)_4$ ring while the second mirror plane bisects the metal–metal bond and contains the pyrazolium cation and the O(3) atoms of the $(Ga—O)_4$ ring. At each Mo atom a pair of fused five-membered MoOGaNN chelate rings is formed (each having an O-envelope conformation). These chelate rings are linked to those associated with the other Mo atom by single-atom bridges between Ga atoms and by three-atom bridges between O atoms.

The Mo—Mo distance of 2.127(1) Å lies near the middle of the range of known Mo≣Mo quadruple bond lengths (from 2.037(2) Å in $Mo_2[(C_5H_4N)NC(O)CH_3]_4$ (16) to 2.183(2) Å in $Mo_2(allyl)_4$ (17)). The Mo—Mo distance reported here is equal (within experimental error) to the value of 2.129(1) Å reported for the complex $Mo_2(CH_3CO_2)_2[(C_2H_5)_2B(N_2C_3H_3)_2]_2$ (18), in which each Mo atom has an N_2O_2 donor set comprising the basal plane. Several factors influencing the length of Mo≣Mo quadruple bonds have been noted. Substitution of two μ-RCO_2 groups of $Mo_2(\mu\text{-}RCO_2)_4$ (Mo—Mo = 2.091(2), 2.090(4), and 2.093(2) Å respectively for R = H (19), CH_3 (20), and CF_3 (21)) by chelating ligands (L) leads to an increase of about 0.036 Å in the Mo—Mo bond length (22) for compounds of the type $Mo_2(\mu\text{-}CH_3CO_2)_2L_2$ (Mo—Mo = 2.129(1), 2.129(1), and 2.131(1) Å respectively for L = $(C_2H_5)_2B(N_2C_3H_3)_2$ (18), $C_5H_7O_2$ (23), and $C_6H_5NC(CH_3)C(H)C(CH_3)O$ (24)). Further lengthening of the metal–metal bond is known to result (16) from substitution of all bridging RCO_2 ligands (for example: Mo—Mo = 2.156(1) Å in $Mo_2[(C_2H_5)_2B(N_2C_3H_3)_2]_2$-$[(C_2H_5)_2B(N_2C_3H_3)(OH)]_2$ (15)), or in cases where a significant axial interaction is present (the weak axial interaction in the present structure is not expected to have any significant effect). In spite of what is known about the dimolybdenum system, predictions of Mo—Mo bond lengths, especially in cases where new types of ligands are involved, still cannot be made (16).

The Mo—N(pyrazolyl), Mo—O(μ-acetato), and Mo—O(1) distances of 2.151(3), 2.115(4), and 2.090(4) Å are similar to those reported for related structures (15, 16–24). It is interesting to note that the Mo—O bond to the $[CH_3Ga(N_2C_3H_3)O]_4^{4-}$ ligand is significantly shorter than that to the acetato group, the near planarity at O(1) suggesting the possibility of π-interactions with both the dimolybdenum system and with the gallium atoms. In fact both Ga—O distances (Ga—O(1) = 1.853(2) and Ga—O(3) = 1.861(2) Å) are considerably shorter than the mean Ga—O distance of 1.96 Å reported for $[(CH_3)_2Ga(OH)]_4$ (13). The Ga—N (1.961(3) Å), Ga—C (1.950(6) Å), and all other bond lengths and angles are as expected.

The pyrazolium cation lies in a mirror plane and is thus exactly planar while the pyrazolyl ring is planar within experi-

Electron and ion transport in gaseous methanol and water: density and temperature effects[1]

NORMAN GEE AND GORDON R. FREEMAN
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received September 30, 1982

NORMAN GEE and GORDON R. FREEMAN. Can. J. Chem. **61**, 1664 (1983).

Electron and cation mobilities in methanol and water vapor measured at $293 \leq T$ (K) ≤ 617 were used to estimate the corresponding momentum transfer cross sections. The electron cross sections correlate with the square of the dipole moment. Unlike the nonpolar gases, where the average cross section for electrons $\sigma_{ave,e}$ is only 0.01–0.1 times that for cations $\sigma_{ave,+}$, methanol has $\sigma_{ave,e} \approx 0.5\sigma_{ave,+}$ and water has $\sigma_{ave,e} \approx \sigma_{ave,+}$. The thermal electrons exchange energy with the molecules mainly through molecular rotational modes, as opposed to elastic modes.

The onset of electron quasilocalization in the saturated vapor occurs at $n_{ql} \approx 5 \times 10^{25}$ molecules/m^3 ($n_{ql}/n_c \approx 0.010$) in methanol and 3×10^{25} ($n_{ql}/n_c \approx 0.003$) in water. These are about 10-fold lower densities than in hydrocarbons, where $n_{ql}/n_c \approx 0.1$. The Ioffe–Regel limit for quasifree states gives $n_{ql} \approx 0.36 \times (Tn\mu_e)_{ql}$, which holds quite well when the gas molecules are relatively rigid. However, for flexible molecules such as the *n*-alkanes larger than propane, the Ioffe–Regal limit predicts too large values for n_{ql}.

The density normalized mobility of cations $n\mu_+$ in saturated methanol vapor is constant at 1.02×10^{21} molecules/m V s up to 67×10^{25} molecules/m^3 (25 Amagats). In saturated water vapor $n\mu_+ = 1.87 \times 10^{21}$ molecules/m V s up to 30×10^{25} molecules/m^3 (11 Amagats).

NORMAN GEE et GORDON R. FREEMAN. Can. J. Chem. **61**, 1664 (1983).

On a mesuré les mobilités du cation et de l'électron dans des vapeurs de méthanol et d'eau à des températures comprises entre 293 et 617 K dans le but d'évaluer les sections droites de transfert du moment correspondant. Les sections droites de l'électron sont en accord avec le carré du moment dipolaire. Contrairement aux gaz non polaires, où la section droite moyenne de l'électron $\sigma_{ave,e}$ est seulement de 0,01 à 0,1 fois celle des cations $\sigma_{ave,+}$, le méthanol a une section droite de $\sigma_{ave,e} \approx 0{,}5\sigma_{ave,+}$ et l'eau une section droite de $\sigma_{ave,e} \approx \sigma_{ave,+}$. Les électrons thermiques échangent principalement de l'énergie avec les molécules à travers les modes de rotation moléculaires, par opposition aux modes élastiques.

Le début de la quasi localisation de l'électron dans la vapeur saturée se situe à $n_{ql} \approx 5 \times 10^{25}$ molécules/m^3 ($n_{ql}/n_c \approx 0{,}010$) dans le méthanol et à 3×10^{25} ($n_{ql}/n_c \approx 0{,}003$) dans l'eau. Ces valeurs représentent des densités 10 fois inférieures à celles des hydrocarbures où $n_{ql}/n_c \approx 0{,}1$. La limite de Ioffe–Regel des états quasi libres donne $n_{ql} \approx 0{,}36$ $(Tn\mu_e)_{ql}$ qui est très valable quand les molécules gazeuses sont relativement rigides. Cependant, dans le cas des molécules flexibles tels les *n*-alcanes, homologues supérieurs du propane, la limite de Ioffe–Regel prédit de trop fortes valeurs de n_{ql}.

La densité normalisée de mobilité des cations $n\mu_+$ dans la vapeur saturée de méthanol est constante à 1,02 $\times 10^{21}$ molecules/m V s jusqu'à 67×10^{25} molecules/m^3 (25 Amagats). Dans la vapeur d'eau saturée $n\mu_+ = 1{,}87 \times 10^{21}$ molecules/m V s jusqu'à 30×10^{25} molecules/m^3 (11 Amagats).

[Traduit par le journal]

Introduction

The contribution of the molecular electric dipole moment D to the net interaction of electrons and ions with organic fluids has recently been assessed in the series propane, propene, and dimethyl ether (1). Each of these molecules has an anisotropic polarizability that makes a major contribution to the net charge – induced dipole interaction. The permanent dipole affects the magnitude but not the nature of the overall charge–molecule interaction. It had similarly been concluded from conductance, scavenging, and spectroscopic studies that the behavior of extra electrons in nonspherelike, nonpolar molecular liquids differs in degree but not in kind from that in polar liquids (2–6).

In liquid hydrocarbons that have gas phase dipole moments up to 0.5 D (debye) the effect of polarity is masked by the effect of the physical shape (degree of sphericity) of the molecule (7). The shape correlates with the depth of the solvation potential well. The well is deeper with molecules that are less spherelike, because such molecules tend to have more anisotropic polarizabilities and their rotation in the liquid phase is more hindered. In the low density gas phase the effect of molecular shape on electron scattering is the opposite of that in the dense liquid. Electrons with energies <0.10 eV are more strongly scattered by more spherelike molecules (8).

When the molecular dipole moment is greater than about 1.0 D, as in dimethyl ether, electron behavior in both the low and high density fluids begins to be dominated by the dipole moment (1). In alcohols and water the strongly polar OH group dominates the electron behavior. The relative effects of different groups are evidenced by decreasing electron mobilities and increasing optical absorption energies of solvated electrons as one proceeds through the series alkanes, ethers, alcohols (1, 2, 4–6, 9–12). The ability of OH groups to cluster together may be responsible for the observed electron (13) and ion (14) behavior in saturated water vapor. Clustering effects, and their sensitivity to temperature, appear to be greater in water vapor (13, 14) than in organic vapors (1, 7, 15).

To obtain more information about the effect of the OH group, the previous series (1) has been extended from dimethyl ether (H_3COCH_3) to methanol (H_3COH) and water (HOH). Earlier studies of ion and electron mobilities in these vapors (13, 14, 16–24) were over more limited ranges of temperature and density than those in the present work, except a study of electrons in water vapor which reached a higher density but had a smaller temperature range (13).

Experimental

Water was fractionally distilled in sequence from acidic dichro-

mate, basic permanganate, and from no reagent. About 300 cm^3 of the triply distilled water was poured into an electrolysis cell (6 cm^2 plate electrodes separated by 3 cm) that formed part of a grease-free vacuum line. The cell contained 5 g of methyl viologen hydrate crystals (Aldrich Chemical Co.). After sealing the filling tube with a flame, the sample was degassed by evacuation and stirring for 45 min (25), electrolysed at 0.5 V for two days, then distilled under vacuum into a trap containing 3 g of potassium hydroxide (BDH Analar grade). The potassium hydroxide had been melted under vacuum and sputtered to degas it. The aqueous hydroxide solution was further degassed by stirring under vacuum. When water samples were needed they were distilled from the hydroxide solution into the irradiation cell.

Methanol (Aldrich Gold Label, spectrophotometric grade) was deaerated by bubbling about 100 cm^3 of it with UHP argon (Matheson) for about 30 min at the rate of ~3 dm^3/min through a sintered glass frit. The half-life of solvated electrons in the liquid was 3.0 μs at 298 K (pulse dose 6×10^{16} eV/g). The methanol was stored under UHP argon at a pressure slightly greater than atmospheric. To prepare a sample, methanol was transferred without contact with the atmosphere, into a previously evacuated vacuum line and degassed by several trap-to-trap distillations, the receiver at 77 K being continually open to high vacuum.

The radiolysis conductance cell, temperature control, and pulse conductance measuring systems have been described previously (9, 26–28). A 30, 100, or 300 ns pulse of 1.7 MeV X rays delivered a dose of 0.3, 1, or 3×10^{11} eV/g, respectively, to the sample. The electron flight times were about 100-fold smaller than those of the ions. The former were measured with the aid of an amplifier that had a 0–97% rise time of 60 ns (27); the latter were measured with a slower, more sensitive amplifier (15, 26).

The mobilities were determined with both positive and negative applied voltages to check for effects of adventitious fields. No voltage polarity effect was identified. The value of the thermal electron mobility at a given (n, T) is typically the average of fourteen measurements covering a ≳10-fold range of voltage. Each ion mobility is the average of about ten measurements over a ≳5-fold voltage range. The mean deviation of electron mobilities from the mean is 2%, and of ion mobilities is 4%.

The physical properties of gaseous water and methanol were taken from ref. 29. No gas densities were given for methanol at T <333 K. However, at 333 K < T <373 K tabulated densities were an average of 8% higher than those calculated from the vapor pressures and the ideal gas equation. So at 293 K < T <333 K densities were taken to be 8% higher than those calculated from the vapor pressure and the ideal gas equation.

Results

Electron mobilities μ_e in water and methanol vapors at various densities are plotted against inverse temperature in Fig. 1. The saturated vapor density increases with increasing temperature, so the mobilities decrease sharply (triangles in Fig. 1). In a constant density vapor the electron mobility increases gently with increasing temperature, for both water and methanol.

Cation mobilities μ_+ in the vapors (Fig. 2) are two orders of magnitude lower than those of electrons, but the temperature coefficients are similar (compare Figs. 1 and 2).

The mobilities in Figs. 1 and 2 were measured at electric field strengths E/n < 10 Td (Td = 10^{-21} V m^2/molecule), where they are independent of field strength (Fig. 3). Electron mobilities increase at E/n > 12 Td in methanol vapor and at >24 Td in water vapor (Fig. 3).

The density normalized mobilities of electrons in a given vapor at room temperature agree with those reported earlier (16, 17, 20, 22, 23), within 10%.

The density normalized electron mobilities in the saturated

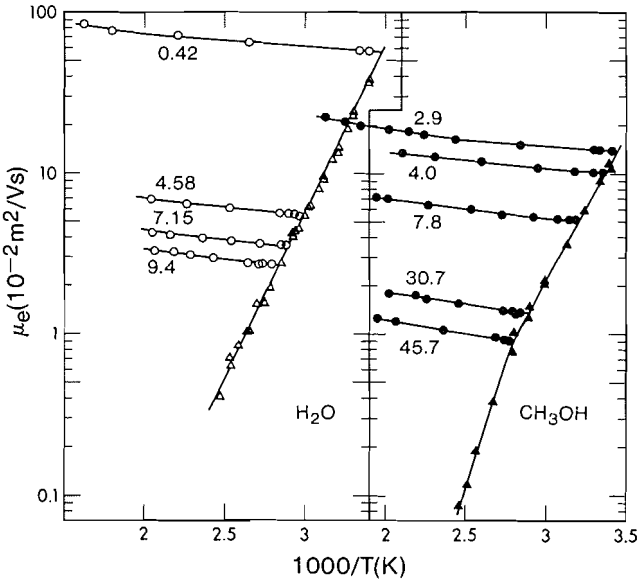

FIG. 1. Arrhenius plots of electron mobilities at different gas densities. ○, ●, nonsaturated vapor at the density indicated ($n/10^{24}$ molecule m^{-3}). △, ▲, coexistence vapor, density increases with increasing T.

vapors are nearly constant at $n < 5 \times 10^{25}$ molecules/m^3 in methanol and $<3 \times 10^{25}$ molecules /m^3 in water. At higher densities $n\mu_e$ decreases (Fig. 4). At 396 K and $n = 4.1 \times 10^{25}$ molecules/m^3 the electrons in water vapor were partially consumed by reaction, with a first half-life of 1.0 μs measured at both 700 and 3000 V/cm. The time τ required for the electron current to fall to zero was therefore less than the flight time t_d over the distance l between the electrodes. The value of τ decreased less rapidly than E^{-1}. "Apparent" values of the mobility were estimated from $l^2/V\tau$, plotted against V^{-1} and

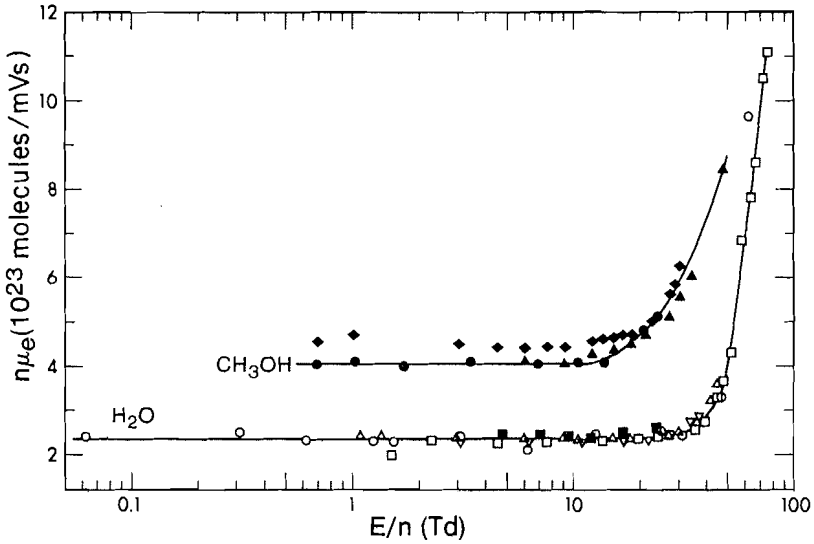

FIG. 3. Electric field dependence of electron mobilities, normalized for gas density n. Td = 10^{-21} V m^2/molecules. The following data represent (ref., T/K, $n/10^{24}$ m^{-3}). Methanol: ● (this work, 294, 2.9), ▲ (22, 293, 0.06–0.8), ◆ (23, 300, <4.6). Water: ■ (this work, 294, 0.4), ○ (16, 300, 0.04–0.8), △ (17, 293, 0.06–0.5), □ (20, 298, 0.02–0.1), ▽ (23, 300, <0.9). The results are for nonsaturated vapors at 297 ± 4 K.

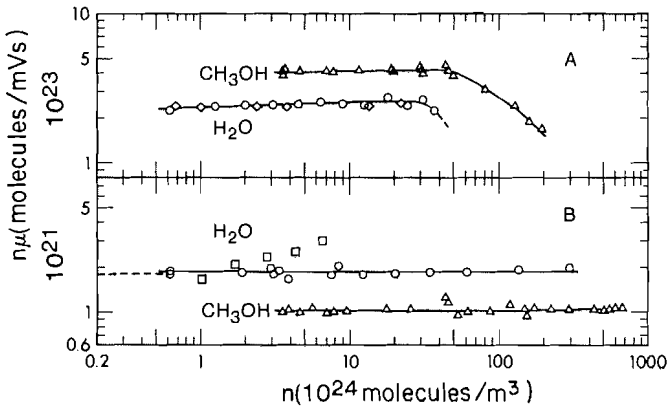

FIG. 4. Density dependence of density normalized mobilities in the saturated vapors. A, electrons: △, ○, this work; ◇, water, ref. 13; B, ions: △, ○, this work; □, water, ref. 14. ---, nonsaturated water vapor, 293 K, ref. 17.

extrapolated to $V^{-1} = 0$. The results indicated that $n\mu_e$ decreases rapidly at $n > 4.0 \times 10^{25}$ molecules/m^3. The normalized cation mobilities $n\mu_+$ are constant up to the highest densities studied, which were 30×10^{25} molecules/m^3 for water and 67×10^{25} molecules/m^3 for methanol. In the context of the density of the critical fluid n_c (1), the maximum densities just mentioned correspond to only $n/n_c = 0.028$ and 0.13, respectively.

Discussion

1. Low density gases

(a) Field dependence threshold and the contribution of inelastic scattering. The electron mobilities increase at high fields (Fig. 3). The threshold $(E/n)_e^{thr}$ for field dependence is ~12 Td in methanol and ~24 Td in water vapor. The ratio of the threshold drift velocity, $v_d^{thr} = \mu E^{thr}$, to the speed of sound c_0 in the gas reflects the relative contribution of inelastic components to the electron scattering (27, 30–33). For low density gases (34),

[1] $$c_0 = (\gamma kT/M)^{1/2}$$

where γ is the heat capacity ratio (35), k is Boltzmann's constant, and M is the molecular mass. The threshold fields in the low density gases are listed in Table 1 for water, methanol, dimethyl ether, propene, and propane. Although the molecular electric dipole moments in this series vary by a factor of 22 (36), the density normalized mobilities $n\mu_e$ by a factor of 71, and the threshold fields $(E/n)_e^{thr}$ by a factor of 100, the threshold drift velocities v_d^{thr} vary by only a factor of 2 (Table 1). The effect of a larger dipole moment is to increase the electron scattering cross section and to decrease $n\mu_e$ (37), so that a higher E/n is needed to reach the threshold electron drift velocity.

The ratio v_d^{thr}/c_0 is similar in each of the gases of the series (Table 1). The values 10–16 are much greater than unity and indicate that the energy gained by the electrons through acceleration in the electric field is removed mainly by inelastic collisions with the molecules at $T \gtrsim 300$ K. At thermal energies (~0.02 eV) the inelastic molecular mode is rotational excitation.

Threshold drift velocities for field dependence of ion mobilities are similar to those for electrons (15, 27, 33). The threshold field $(E/n)_+^{thr}$ for ions can be estimated using eq. [2] (33):

[2] $$(E/n)_+^{thr} \approx (3kT/M)^{1/2}/n\mu_+$$

The factor $(3kT/M)^{1/2}$ in eq. [2] is the root-mean-square velocity of the molecules. It is ~60% greater than the speed of sound in polyatomic molecular gases. The present data for 297 K yield $(E/n)_+^{thr} \approx 640/1.88 \times 10^{21} = 340 \times 10^{-21}$ V m^2/molecule = 340 Td in water vapor and $480/1.02 \times 10^{21} = 470$ Td in methanol vapor. These fields are higher than the maxima used in the present or earlier work (17, 19, 21), and explains the observed field independence of the ion mobilities.

(b) Temperature dependence and scattering cross sections. The temperature dependence of the mobility at low fields reflects the energy dependence of the momentum transfer cross sections σ_m (16, 38–40). The electron mobility may be approximately represented by eq. [3] (39):

$$[3] \quad n\mu_e = \frac{-4\pi e}{3m}\int_0^\infty \frac{v^2}{\sigma_{m,e}}\frac{df_0}{dv}dv$$

where e and m are the electron charge and mass, v is the electron velocity relative to that of the molecules, $\sigma_{m,e}$ is the

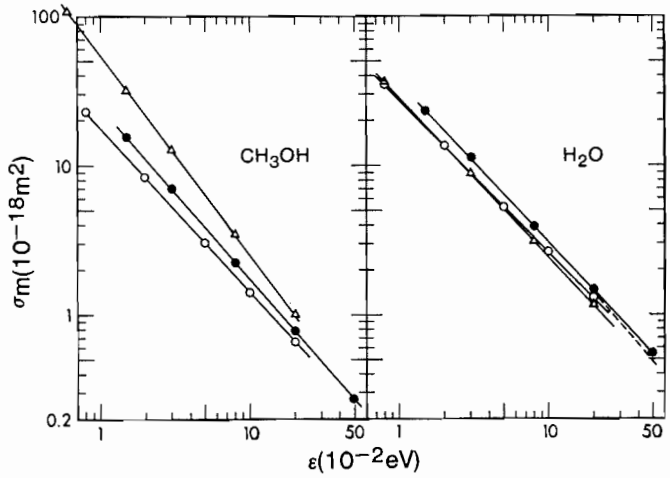

FIG. 6. Energy dependence of electron (○, ●) and cation (△) momentum transfer cross sections. ●, estimated from equation [4]; ○, △, from [7]. ----, H_2O from ref. 16 increased 1.08-fold.

electron momentum transfer cross section of the molecule, and f_0 is the isotropic term in the velocity distribution. For a Maxwellian distribution $f = (m/2\pi kT)^{3/2}\exp(-mv^2/2kT)$ and one obtains:

$$[4] \quad n\mu_e = \frac{8\pi e^2}{3m}\left(\frac{m}{2\pi kT}\right)^{5/2}\int_0^\infty \frac{v^3}{\sigma_{m,e}}\exp\left(-\frac{mv^2}{2kT}\right)dv$$

The present low density $n\mu_e$ data are plotted against temperature in Fig. 5. The values for water agree with those reported earlier (13, 16, 17, 20, 23, 24) within about ±3%. The values for methanol agree with those in ref. 22, but are ~9% lower than those in refs. 23 and 24. Equation [4] was fitted to the data in Fig. 5 by numerical manipulation (1, 7) to obtain $\sigma_{m,e}$ as a function of v, or of energy $\epsilon = \frac{1}{2}mv^2$, for water and methanol molecules. The cross sections are plotted in Fig. 6 (closed circles). The reliability of the cross sections depends on the sensitivity of the integral in eq. [4] to a change in $\sigma_{m,e}$. At 455 K, near the middle of the temperature range, the integral for methanol reaches 2% of its final value at $\epsilon = 0.02$ eV, and 97% at 0.3 eV. For water at 455 K the integral goes from 2 to 98% of its final value between $\epsilon = 0.02$ and 0.3 eV. The electron scattering cross sections are relatively unreliable outside this energy zone.

Scattering by point dipoles would give $\sigma_{m,e} \propto \epsilon^{-1}$ (37). The actual energy dependence is a bit steeper:

methanol

[5] $\sigma_{m,e}(10^{-19}\ \text{m}^2) = 1.20\epsilon^{-1.15}$

water

[6] $\sigma_{m,e}(10^{-19}\ \text{m}^2) = 2.6\epsilon^{-1.07}$

where $0.02 \leq \epsilon \leq 0.3$ eV. The mobilities calculated from these cross sections are shown as lines in Fig. 5. Cross sections for water in ref. 16 gave $n\mu_e$ values about 8% higher than those obtained in the present work. The cross sections from ref. 16 were increased by 8% and plotted in Fig. 6 for comparison; the corresponding values of $n\mu_e$ are shown as the dashed curve in Fig. 5.

The equation relating the ion mobility $n\mu_+$ to momentum transfer cross sections $\sigma_{m,+}$ is [7] (38, 40):

$$[7] \quad n\mu_+ = \frac{3e\sqrt{\pi}}{8M_r}\left(\frac{2kT}{M_r}\right)^{5/2} \Big/ \int_0^\infty v^5\sigma_{m,+}\exp\left(-\frac{M_r v^2}{2kT}\right)dv$$

where M_r is the ion–molecule reduced mass. The ion mobilities are plotted against temperature in Fig. 7. Fitting eq. [7] to the mobilities by numerical integration over progressively adjusted $\sigma_{m,+}$ distributions (1, 7) resulted in the cross sections shown in Fig. 6 (triangles). The ion mass was taken equal to the molecular mass M, although it was probably greater than that due to clustering, $ROH_2^+(ROH)_n$. The true value of M_r was therefore between M and $M/2$. The sensitive energy range for the $\sigma_{m,+}$ fitting procedure was about 0.008 to 0.2 eV, which is somewhat lower than the sensitive range for the electron cross sections:

methanol

[8] $\sigma_{m,+}(10^{-19}\ \text{m}^2) = 1.10\epsilon^{-1.34}$

water

[9] $\sigma_{m,+}(10^{-19}\ \text{m}^2) = 2.06\epsilon^{-1.07}$

Curiously, for water the electron momentum transfer cross section is 26% larger than the ion scattering cross section at the same energy (Fig. 6). For nonpolar molecules electron momentum transfer cross sections (7, 16, 22, 27, 28, 30, 31) are usually 1–2 orders of magnitude smaller than ion momentum transfer cross sections at the same energy (15). For polar gases the electron cross sections are usually similar to but smaller than the ion cross sections at the same energy (1, 13, 16, 22–24). Cross sections for scattering ions are greater than those for scattering neutral molecules (Table 2 and ref. 41). To elucidate the unusual case of electron and ion scattering by

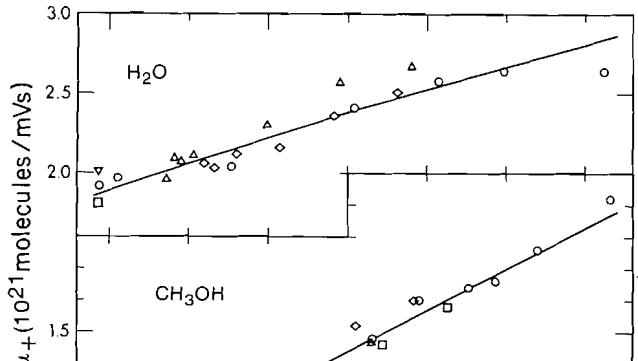

FIG. 7. Temperature dependence of density normalized mobilities of ions in nonsaturated vapors. The lines were calculated from eq. [7] using the corresponding cross sections in Fig. 6. The following numbers represent (ref., $n/10^{24}$ molecule m^{-3}): CH_3OH: ○ (this work, 2.9), △ (this work, 4.0), □ (this work, 7.8), ◇ (this work, 30.7). Average deviation from line, 2.6%. H_2O: □ (17, 0.03–0.50), ▽ (19, 0.53), ○ (this work, 0.42), △ (this work, 4.58), ◇ (this work, 9.4). Average deviation from line, 3.1%.

water, two points should be considered. (*i*) The cations are probably clustered to some extent (21, 42), which would increase the reduced mass and decrease the estimated values of $\sigma_{m,+}$. This would increase the unusual inverted difference between the estimated electron and ion cross sections. Although there is no direct evidence that electrons are clustered by molecules under the present conditions, the formation of transient anions as in [10] would increase the time-averaged mass of the negative charge, and thereby increase the effective cross section estimated on the basis of the electron mass:

[10] $e^- + (ROH)_n \rightleftharpoons (ROH)_n^-$

where $n = 1, 2, \cdots$. The large cross section of water is mainly attributable to the large dipole moment (see next section), but [10] might make some contribution that causes the water points in Fig. 8 to fall below the line. (*ii*) The ion and electron cross sections were calculated from different equations, respectively [4] and [7], involving different approximations. The same set of ($n\mu$, T) data generates somewhat larger values of σ_m from eq. [4] than from [7]. It has been suggested (43, 44) that when

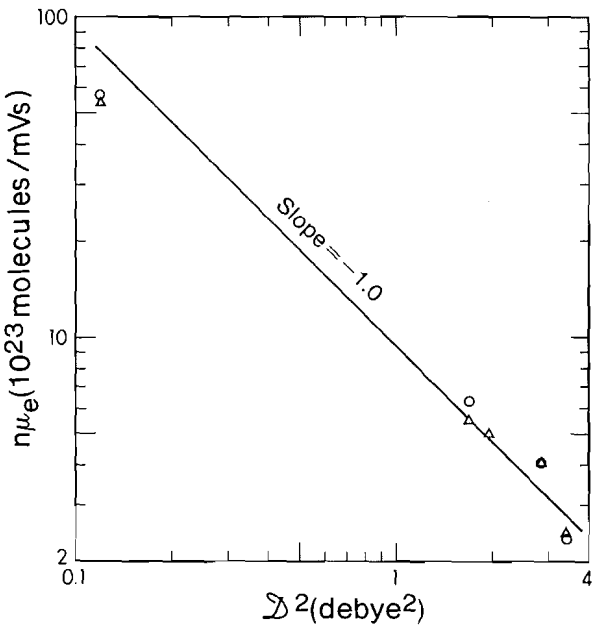

FIG. 8. Correlation of density normalized electron mobility with the square of the molecular dipole moment D^2. ○, low density gases at 297 ± 2 K (Table 1); △, low density saturated vapors at the middle of the experimental low density range. The gases reported from left to right are propene (46), dimethyl ether (1), ammonia (45), methanol, and water.

inelastic processes make a major contribution to electron scattering, as they do in the present systems, eq. [7] is more appropriate than [4]. Values of $\sigma_{m,e}$ obtained from [7] are accordingly shown in Fig. 6 for comparison. The corresponding equations are, for $0.008 \leq \epsilon \leq 0.2$ eV:

methanol

$$[11] \quad \sigma_{m,e}(10^{-19}\ \mathrm{m}^2) = 1.12\epsilon^{-1.10}$$

water

$$[12] \quad \sigma_{m,e}(10^{-19}\ \mathrm{m}^2) = 2.5\epsilon^{-1.02}$$

These cross sections used in [7] give the same mobilities as do [5] and [6] in [4], respectively, within <0.5%.

The above points can be summarized by rewriting [4] and [7] in terms of average velocities $\langle v \rangle$ and average cross sections σ_{ave} (15, 30):

$$[13] \quad n\mu_e = \left(\frac{8}{3\pi}\right)\left(\frac{e}{m}\right)\frac{1}{\langle v \rangle}\frac{1}{\sigma_{ave,e}}$$

where

$$[14] \quad \sigma_{ave,e} = \langle v \rangle / \langle v/\sigma_{m,e} \rangle$$

and

$$[15] \quad n\mu_+ = \left(\frac{3}{4}\right)\left(\frac{e}{M_r}\right)\frac{1}{\langle v \rangle}\frac{1}{\alpha_{ave,+}}$$

where

$$[16] \quad \sigma_{ave,+} = \langle v^3\sigma_{m,+} \rangle / \langle v^3 \rangle$$

and

$$[17] \quad \langle v \rangle = (8kT/\pi M_r)^{1/2}$$

For electron scattering, M_r in [17] equals m. The numerical coefficients in eqs. [13] and [15] have a ratio $(8/3\pi)/(3/4) = 1.13$, so a given set of $n\mu$, M_r, and $\langle v \rangle$ values would give σ_{ave} from [13] 1.13 times larger than that from [15]. Actually, the different averaging procedures inherent in [4] and [7] lead to slightly different apparent energy dependences of σ_m, so the difference between cross sections at a given energy obtained from a set of ($n\mu$, T) data can be somewhat greater than 13%.

(c) Dipole moment dependence. The value of $n\mu_e$ in polar gases varies approximately as the inverse square of the molecular dipole moment D^{-2} (37). This is shown for water, methanol, ammonia (45), dimethyl ether (1), and propene (46) in Fig. 8, for both nonsaturated (at 297 K) and saturated vapors.

2. Density dependence

In the low density saturated vapors of methanol and water, that is, at low temperatures, the value of $n\mu_e$ is approximately independent of n (Fig. 4). The same is true in many substances (1, 7, 27, 30, 31, 45). The slight increase of $n\mu_e$ with n (Fig. 4) is due to the concomitantly increasing temperature.

In methanol at $n > 5 \times 10^{25}$ molecules/m^3 the value of $n\mu_e$ decreases (Fig. 4). This signals the onset of quasilocalization of the electrons. Ioffe and Regel (47) pointed out that the electron cannot be considered to be quasifree when the mean free path L is smaller than the de Broglie wavelength λ of the particle. The threshold density n_{ql} for quasilocalization can therefore be compared with the Ioffe–Regel limit through the equation

$$[18] \quad L \approx \lambda$$

or

$$[19] \quad (n_{ql}\sigma_{ave,e})^{-1} \approx h/m\langle v \rangle$$

whence

$$[20] \quad n_{ql} \approx m\langle v \rangle / h\sigma_{ave,e}$$

where h is Planck's constant. From eqs. [13], [17], and [20] one obtains

$$[21] \quad n_{ql} \approx 0.36(Tn\mu_e)_{ql}$$

Mott and Davis (48) misquote (or discretely correct?) the Ioffe–Regel limit as $L \approx \lambda\!\!\!^{-} = \lambda/2\pi$, which would predict n_{ql} values 2π times larger than those of eq. [21]. It is difficult to choose between the forms so we kept the original, as did other workers (13).

A plot of n_{ql} against $(Tn\mu_e)_{ql}$ for a number of polar and nonpolar saturated vapors is shown in Fig. 9. The points that fall near the line for eq. [21] correspond to relatively rigid molecules, whether they are polar or nonpolar: water, methanol, dimethyl ether (1), propene (46), propane (46), ethane (49), methane (30), and xenon (27). The points for flexible molecules such as *n*-butane (7), *n*-pentane (31), and *n*-hexane (50) have values of n_{ql} about an order of magnitude lower than those predicted by the Ioffe–Regel limit.

It should be noted that the Ioffe–Regel criterion depends only on the average density and the temperature. It does not take into account the density fluctuations that occur in the vapors near the vapor–liquid coexistence curve, and which are largely responsible for quasilocalization in nonpolar gases such as xenon (27), methane (30), and ethane (49). Heating the nonpolar vapor to remove it from the vapor–liquid coexistence region reduces the extent of quasilocalization (27), and increases the value of n_{ql} by an amount that has not been measured yet.

Heating the strongly polar vapors water (13) and ammonia (45) in the unsaturated region apparently increases n_{ql} by

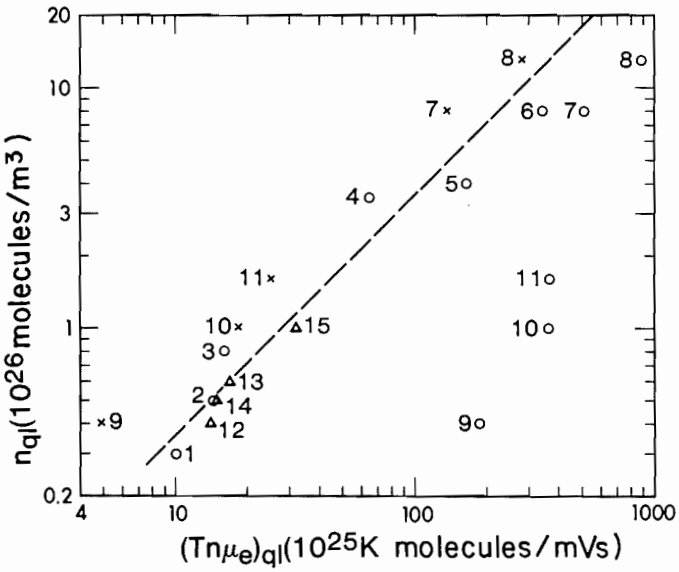

FIG. 9. Correlation between threshold density for quasilocalization n_{ql} and $(Tn\mu_e)_{ql}$ in saturated vapors (○). *1*, water, 387 K; *2*, methanol, 360 K; *3*, dimethyl ether, 292 K (1); *4*, xenon, 215 K (27); *5*, propene, 303 K (46); *6*, methane, 156 K (30); *7*, propane, 338 K (46); *8*, ethane, 284 K (49). The dashed line represents eq. [21]. Also included are: *9*, *n*-hexane 362 K (50); *10*, *n*-pentane, 360 K (31); *11*, *n*-butane, 332 K (7). Unsaturated vapors (△): *12* and *13*, water, 463 and 523 K (13); *14* and *15*, ammonia, 300 and 460 K (45). ×, $(n_{ql}/n_c)(Tn\mu_e)_{ql}$ for the C_2-C_6 *n*-alkanes.

amounts that conform to the Ioffe–Regel criterion (Fig. 9). The large scattering cross sections of the polar molecules seem to minimize the effect of clusters in the quasilocalization process.

For the C_2 to C_6 *n*-hydrocarbons the deficit of n_{ql} below that predicted by eq. [21] increases as the carbon chain length increases. The values of n_{ql} in ethane to *n*-hexane vary as $\bar{\alpha}^{-3}$, rather than as $\bar{\alpha}^{-2}$ which might have been expected for clustering due to induced dipole – induced dipole interactions. Although the reason is unclear, multiplying the ethane to *n*-hexane $(Tn\mu_e)_{ql}$ values by n_{ql}/n_c shifts the values to just above the Ioffe–Regel line (Fig. 9).

Potentiometric analysis of humic substances and other colloids

PAUL A. ARP

Department of Forest Resources, University of New Brunswick, Fredericton, N.B., Canada E3B 6C2

Received November 16, 1982

PAUL A. ARP. Can. J. Chem. **61**, 1671 (1983).

The acid–base behaviour of colloidal suspensions of γ-Al_2O_3, TiO_2 (rutile), high surface-charge latex, and humic substances in water is reexamined by using a Nernst-like model and two electrostatic models to simulate the proton-affecting surface potential. The Nernst-like model is based on the assumption that the proton-affecting surface potential is proportional to the Nernst potential. The other models are based on conventional double-layer assumptions. All models yield numerically consistent information about (*i*) number of chemically discernible functional groups (or collections of funetional groups), (*ii*) their dissociation constants and concentrations, (*iii*) the free H^+- (or OH^--) concentrations in the suspending medium, (*iv*) surface area of colloidal substance, and (*v*) surface potential (and charge) as function of p*h*. Potentiometric analyses are performed on documented titration curves by employing a modified version of the ACBA (acid–base) program developed by Arena *et al*. The goodness-of-fit information provided by this program suggests that the Nernst-like model is particularly useful for generating and verifying estimates for surface capacities as function of p*h*.

PAUL A. ARP. Can. J. Chem. **61**, 1671 (1983).

On a étudié de nouveau le comportement acide–base des suspensions colloïdales de γ-Al_2O_3, de TiO_2 (rutile), d'un latex à grande charge de surface, et des substances humiques dans l'eau, en utilisant un modèle de type Nernst et deux modèles électrostatiques pour simuler le potentiel de surface influencé par le proton. Le modèle de type Nernst se base sur la supposition que le potentiel de surface influencé par le proton est proportionnel au potentiel de Nernst. Les autres modèles se basent sur l'hypothèse conventionnelle de la couche double. Tous les modèles fournissent des informations numériques importants au sujet: (*i*) du nombre de groupes fonctionnels que l'on peut distinguer chimiquement (ou d'un ensemble de groupes fonctionnels), (*ii*) de leurs constantes de dissociation et de leurs concentrations, (*iii*) des concentrations en H^+ (ou OH^-) libres dans la suspension, (*iv*) de la surface du colloide et (*v*) du potentiel de surface (et de la charge) en fonction du pH. On a effectué des analyses potentiométriques sur les courbes de titration connus en utilisant un version modifiée du programme ACBA (acide–base) mis au point par Arena et ses collaborateurs. L'information adéquate fournie par ce programme suggère que le modèle de type Nernst est particulièrement utile pour engendrer et vérifier les évaluations des capacités de surface en fonction du pH.

Introduction

The acid–base behaviour of colloidal materials such as oxide suspensions, humic substances, and polyelectrolytes in general may be influenced by (*i*) association–dissociation equilibria of proton-carrying functional groups, (*ii*) electrostatic attraction or repulsion due to charges located on the molecules, (*iii*) intra- and intermolecular hydrogen bonding, (*iv*) burial of acidic groups in hydrophobic environments (Veis (1)). The objective of this paper is to show that the acid–base behaviour of substances with rigid or near-rigid microstructure (i.e. restricted molecular motion relative to nearest neighbour interactions among the various H^+-ion adsorption/desorption sites) appears to be controlled by chemical equilibria, with electrostatic contributions becoming effective at high surface charge density. The analysis is based on a reinterpretation of published titration curves using the ACBA-program developed by Arena *et al*. (2) specifically modified to take acid–base affecting surface potentials into account. The modified version is verified by comparison with the chemical modelling exercise described by Westall and Hohl (3) using γ-Al_2O_3- and TiO_2-titration curves as case studies. The analysis is then applied to the reexamination of a monofunctional latex surface and several humic substances.

Theory

(a) General

The proton dissociation–association behaviour of rigid or near-rigid colloidal substances subjected to titration is perhaps best understood once the proton association constant

$$[1] \quad K_i = K_{0i} \exp(-F\Psi^s/RT)$$

of each chemically discernible functional group ($i = 1, 2, \ldots N_L$) is determined. Here, each K_{0i} represents the intrinsic proton-association constant of a particular group and Ψ^s is the proton-affecting surface potential. In the following, two electrostatic models and one non-electrostatic model are described by which Ψ^s, K_{0i}, and K_i may be obtained in a numerically consistent way by potentiometric analysis.

(b) The diffuse double layer

The electrostatic potential near a charged interface — according to the Gouy–Chapman theory for flat surfaces — is given by

$$[2] \quad \Psi = \frac{2RT}{F} \ln \frac{\coth(F\Psi^s/4RT) + \exp(-\kappa x)}{\coth(F\Psi^s/4RT) - \exp(-\kappa x)}$$

where x is distance from the surface and

$$[3] \quad 1/\kappa = (\epsilon\epsilon_0 RT/2000I)^{1/2}/F$$

is the "characteristic" thickness (Debye length in m) of the diffuse ion–layer at the interface. Also, R is the universal gas constant (= 8.31 J/mol deg K); F is Faraday's constant (= 96 487 C/mol), T is absolute temperature (K), ϵ is the dielectric constant of the suspending medium ($\approx$ 80 for water at 25°C), ϵ_0 is the permittivity of free space (= 8.85×10^{-12} F/m), and I is the ionic strength of the suspending medium (mol/L). The interfacial charge density — as predicted by the same theory — is given by

$$[4] \quad \sigma = -\epsilon\epsilon_0[d\Psi/dx]_{x=0}$$
$$= (1/\lambda)(8000\epsilon\epsilon_0 RTI)^{1/2} \sinh(F\Psi^s/2RT) + \sigma_R$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

The charge density, in addition, may also be obtained from the titration relationship

$$[5]\quad \sigma(\text{exp}) = \frac{T_\sigma F}{SC} = \left[\frac{v \cdot C_h^T + V_0(C_h^0 + \sum C_{Ai}^{0+})}{v + V_0} - h + \frac{K_W}{h}\right]\frac{F}{SC}$$

and from the principles of mass action (i.e., eq. [1]) and charge conservation, i.e.

$$[6]\quad \sigma(\text{calcd}) = \frac{F}{SC^0}\left[\sum_{i=1}^{N_L}\frac{K_{0i}C_{Ai}^0 h}{K_{0i}h + \exp(F\Psi^s/RT)} - \sum C_{Ai}^{0-}\right]$$

where T_σ is the analytical interfacial acid (base) concentration (equiv./L), σ_R is the surface charge density at an appropriate reference potential Ψ_R^s, h is the free H^+-ion concentration of the suspending medium, K_W is the ionic product of water, v is the volume of titrant added to titrand (also to be denoted as $v(\text{exp})$), V_0 is the initial volume of titrand, C_h^T is the analytical acid concentration of the titrant, C_h^0 is the initial analytical acid concentration of the titrand, $\sum C_{Ai}^{0+(-)}$ is the initial sum concentration of all functional groups that may assume positive (negative) charges (for reasons of simplicity only one positive or negative charge per group is allowed), S is surface area of colloidal substance (m^2/g), and

$$[7]\quad C = C^0/(1 + v/V_0)$$

is the colloidal concentration (g/L). The surface potential, therefore, can be obtained from eqs. [4] and [5], with a check provided by eq. [6] to assess the quality of the assumed $\sigma - \Psi^s$ relationship for each tritration point. The λ-parameter of eq. [4] may be considered as an adjustable constant signifying (*i*) that the proton-adsorbing surface may not be flat (or smooth) and (*ii*) that the adsorbed H^+- and OH^--ions have finite size, with diameters similar to that of water molecules or H_3O^+-ions ($\simeq$3 Å). More specifically, the empirical relationship

$$[8]\quad \sigma = (8000\epsilon\epsilon_0 RTI)^{1/2} \times \left(\frac{1}{1 + a\kappa}\sinh\frac{F\Psi^s}{2RT} + \frac{2}{b\kappa}\tanh\frac{F\Psi^s}{4RT}\right) + \sigma_R$$

derived from Loeb *et al.* (4) for spherical particles surrounded by an ionic double layer may be used instead of eq. [4] to calculate Ψ^s. Here, a is the width of the surface-fixed solvent- (water-) layer, and b is the average particle radius, or — more generally — the radius of the effective curvature for irregularly shaped particles or rough surfaces. For small potentials, i.e. $F\Psi^s/4RT \ll 1$, eq. [8] reduces to eq. [4] with

$$1/\lambda = \left(\frac{1}{b\kappa} + \frac{1}{1 + a\kappa}\right)$$

Combining eqs. [4], [5], and [7] yields

$$[9]\quad \Psi^s = (2RT/F)\sinh^{-1}[f(T_\sigma - T_\sigma^R)(1 + v/V_0)]$$

with

$$[10]\quad f = \lambda F(8000\epsilon\epsilon_0 RTI)^{-1/2}/SC^0$$

as an adjustable parameter, and $T_\sigma^R = T_\sigma$ when $\Psi^s = 0$.

(c) The constant capacitance model

The constant capacitance model is in all respects identical to the diffuse double layer model except that $\sinh(F\Psi^s/2RT)$ is linearized so that

$$[11]\quad \Psi^s = (2RT/F)[f(T_\sigma - T_\sigma^R)(1 + v/V_0)]$$

(d) The pseudo-Nernst model

The law of mass action involving all proton-adsorbing surface groups is given by

$$[12]\quad K = K_1^{a_1}K_2^{a_2}K_3^{a_3}\ldots = K_{01}^{a_1}K_{02}^{a_2}K_{03}^{a_3}\ldots \times \exp[-(a_1 + a_2 + a_3\ldots)F\Psi^s/RT] = \left(\frac{1 - \alpha_1}{\alpha_1}\right)^{a_1}\left(\frac{1 - \alpha_2}{\alpha_2}\right)^{a_2}\left(\frac{1 - \alpha_3}{\alpha_3}\right)^{a_3}\ldots h^{(-a_1 - a_2 - a_3\ldots)}$$

where α_i denotes the h-dependent degree of dissociation for each functional group, and

$$a_i = C_{Ai}/C_{A1} \text{ with } C_{Ai} = C_{Ai}^0 V_0/(v + V_0)$$

Equation [14], therefore, yields yet another way for expressing the surface potential, i.e.

$$[13]\quad \frac{F\Psi^s}{RT} = \ln\frac{h}{h^0} + \sum_{i=1}^{N_L} C_{Ai}^0 \ln\frac{1 - \alpha_i}{\alpha_i}\Big/\sum_{i=1}^{N_L} C_{Ai}^0$$

with

$$[14]\quad \ln h^0 = -\sum_{i=1}^{N_L} C_{Ai}^0 \ln K_{0i}/\sum_{i=1}^{N_L} C_{Ai}^0$$

It appears from [13] that the potential-determining H^+- (or OH^--) ions produce a surface potential different from the expected particle (Nernst) potential given by

$$[15]\quad F\Psi^p/RT = \ln h/h^0$$

To illustrate, set $N_L = 1$ in [13] and obtain

$$[16]\quad F\Psi^s/RT = \ln h/h^0 - \ln(1 - \alpha_1)/\alpha_1 = F\Psi^p/RT - \ln(1 - \alpha_1)/\alpha_1$$

with $h_0 = 1/K_{0i}$. For $N_L = 2$ and $C_{A1} = C_{A2}$, it follows that

$$[17]\quad \frac{F\Psi^s}{RT} = \ln\frac{h}{h^0} - \frac{1}{2}\ln\frac{1 - \alpha_1}{\alpha_1}\frac{1 - \alpha_2}{\alpha_2}$$

with $h^0 = (K_{01}K_{02})^{-1/2}$. Furthermore, h^0 coincides with the point of zero potential (or zero charge) when the two groups involved assume equal but opposite charges.

Equation [16] has found extensive and successful use in analyzing the acid–base behaviour of many monofunctional surfaces, especially micelles and monolayers (5–7), and certain globular proteins (1, 8). Less successful is the application of eq. [16] to polyfunctional surfaces encountered, e.g., with oxide suspensions, most biopolymers, and humic substances because several degrees of dissociation are involved. Oxide surfaces tend to be bifunctional (amphoteric) yielding a "pseudo-Nernst" potential near $h \simeq h^0$ (de Hek *et al.* (9); Healy and White (10)) approximately given by

$$[18]\quad \Psi^s \simeq \mu^*(RT/F)\ln h/h^0$$

with

$$\mu^* = \mu/(1 + \mu)$$

and

TABLE 1. Formulae for charge and differential capacitance for the constant-capacitance (cc), diffuse double layer (dl), and pseudo-Nernst (pn) surface models*

Type of model	σ	$C = d\sigma/d\Psi^s$
cc	Eq. [11]	A/λ
d	Eq. [4]	$(A/\lambda)\cosh(F\Psi^s/2RT)$
pn, general	$\frac{F}{SC^0}\left[\sum_{i=1}^{N_L} C_{Ai}/B - \sum C_{Ai}^{0-}\right]$	$\left(\frac{F}{SC^0}\right)\left(\frac{F}{RT}\right)\sum_{i=1}^{N_L} C_{Ai}\exp(F\Psi^s/\mu RT)/(B^2K_{ai}h^0)$
pn, monofunctional surface	$\sigma_m[1 + \exp(F\Psi^s/\mu RT)] = \sigma_m/[1 + (h/h^0)^{1-\mu}]$	$(A/\lambda)[\cosh(F\Psi^s/\mu RT)]^{-2}$
pn, amphoteric surface	$\frac{2\sigma_m \sinh(F\Psi^s/\mu RT)}{\beta + 2\cosh(F\Psi^s/\mu RT)}$	$(A/\lambda)(\beta + 2)\frac{2 + \beta\cosh(F\Psi^s/\mu RT)}{[\beta + 2\cosh(F\Psi^s/\mu RT)]^2}$

*$A = (F/2RT)(8000\epsilon\epsilon_0 RTI)^{1/2}$; $B = 1 + \exp(-F\Psi^s/\mu RT)/(K_{0i}h^0)$; $\sigma_m = FC_{A1}/SC^0$; $\beta = \sqrt{K_{01}/K_{02}} + \sqrt{K_{02}/K_{01}}$.

$$\mu = 4fC_{A1}^0 h^0 K_{01}(1 + h^0K_{01})^{-2}$$
$$= 4fC_{A2}^0 h^0 K_{02}(1 + h^0K_{02})^{-2}$$

obtained from eqs. [4] and [6] by Taylor expansion of $F\Psi^s/RT$ with respect to $\Delta \ln h = \ln h/h^0$. Equation [18] thus provides a charge-independent way for assessing Ψ^s of amphoteric surfaces near the point of zero charge. The same equation, in a general sense, may also be viewed as a "pseudo-Nernst" surface model to yield Ψ^s by considering $\mu^* = \mu/(1 + \mu)$ as an adjustable parameter, with μ given by

$$\mu = 2fh^0\sum_{i=1}^{N_L} K_{0i}C_{Ai}/(1 + h^0K_{0i})^2$$

and h^0 by eq. [14].

(e) Model-by-model comparison

Each model produces a different $\sigma-\Psi^s$ relationship, yet all three models converge to the same form when $\Psi^sF/RT \ll 1$, i.e.

$$[19]\quad \left(\frac{2RT}{F}\right)\frac{\sigma_{exp} - \sigma_R}{(8000\epsilon\epsilon_0 RTI)^{1/2}} = \frac{\Psi^s_{cc}}{\lambda_{cc}} = \frac{\Psi^s_{dl}}{\lambda_{dl}} = \frac{\Psi^s_{pn}}{\lambda_{pn}}$$

with cc, dl, and pn denoting the possibility that each model may produce a different λ-value. The following major differences exist between the three models.

(*i*) The dl-model limits Ψ^s to

$$[20]\quad (F\Psi^s_{dl}/RT)_{max,\ min} = \pm 2\sinh^{-1}\{f_{dl}[\sum C_{Ai}^{0+(-)} + T_\sigma^R(1 + \nu/V_0)]\}$$

on the low and high side of ph^0, respectively. The cc-model also curbs the surface potential but the pn-model does not.

(*ii*) The differential surface capacitance $C = d\sigma/d\Psi^s$ predicted by the dl-model (see Table 1 and Fig. 1) passes through a single minimum at $\Psi^s_{dl} = 0$ with no inflection points locatable on either side of this minimum. The pn-model, in contrast, predicts a maximum or minimum for C_{pn} at $\Psi^s_{pn} = 0$. For example, the pn-capacitance for amphoteric surfaces passes through a maximum at $\Psi^s_{pn} = 0$ provided $\beta \leq 4$. Otherwise C_{pn} (max) is found at

$$(F\Psi^s_{pn}/RT)_{max} = \pm\mu_{pn}\cosh^{-1}(\beta/2 - 4/\beta)$$

with

$$C_{pn}(max) = A\beta^2/[8\lambda_{pn}(\beta - 2)]$$

(*iii*) The differential capacitance associated with the dl-model approaches a limiting value with increasing absolute surface potential. The pn-model, in contrast, predicts that the surface capacitance vanishes at high and low surface potentials.

(f) Parametric estimation

Any Ψ^s-generating model may be used to predict the behaviour of each K_i-value once accurate estimates for h, K_{0i}, C_h^T, C_h^0, C_{Ai}^0, K_W, and f are secured. Such estimates may be obtained by employing a non-linear least-squares method to interpret a titration curve associated with a particular colloidal substance for its parametric information content. The least-squares method — according to Arena *et al.* (2) — may be based on minimizing the error-square sum of the difference between actual and calculated added titrant volumes, i.e., minimize

$$U = \sum_{k=1}^{N_T}[v_k(exp) - v_k(calcd)]^2$$

where N_T denotes the total number of titration steps. An explicit expression for v_k(calcd), i.e.

$$[21]\quad v_k(calcd) = -\frac{V_0}{h_k - K_W/h_k - C_h^T}\left\{h_k - K_W/h_k - C_h^0 + \sum_{i=1}^{N_L}\left[\frac{C_{Ai}^0K_{0i}h_k}{h_kK_{0i} + \exp(F\Psi^s_k/RT)} - C_{Ai}^0np_i^0\right]\right\}$$

is obtained from the titration relationships

$$A_{ik} = a_{ik} + h_ka_{ik}K_{0i}\exp(-F\Psi^s_k/RT)$$
$$= V_0\cdot C_{Ai}^0/(v_k + V_0)$$

and

$$H_k = h_k - K_W/h_k + h_k\sum_{i=1}^{N_L} a_{ik}K_{0i}\exp(-F\Psi^s_k/RT)$$
$$= [v_k\cdot C_h^T + V_0\cdot(C_h^0 + np_i^0\cdot C_{Ai}^0)]/(v_k + V_0)$$

Here np_i^0 is the number of protons bound per functional group (limited to one for reasons of simplicity), and A_{ik} and a_{ik}, respectively, are the analytical and free (i.e., unprotonated) concentrations of each functional group at the kth titration point; H_k represents the corresponding analytical concentration for the total acidity of the titrant. The free H^+-ion concentration, i.e., h_k, may be obtained potentiometrically by employing the equation

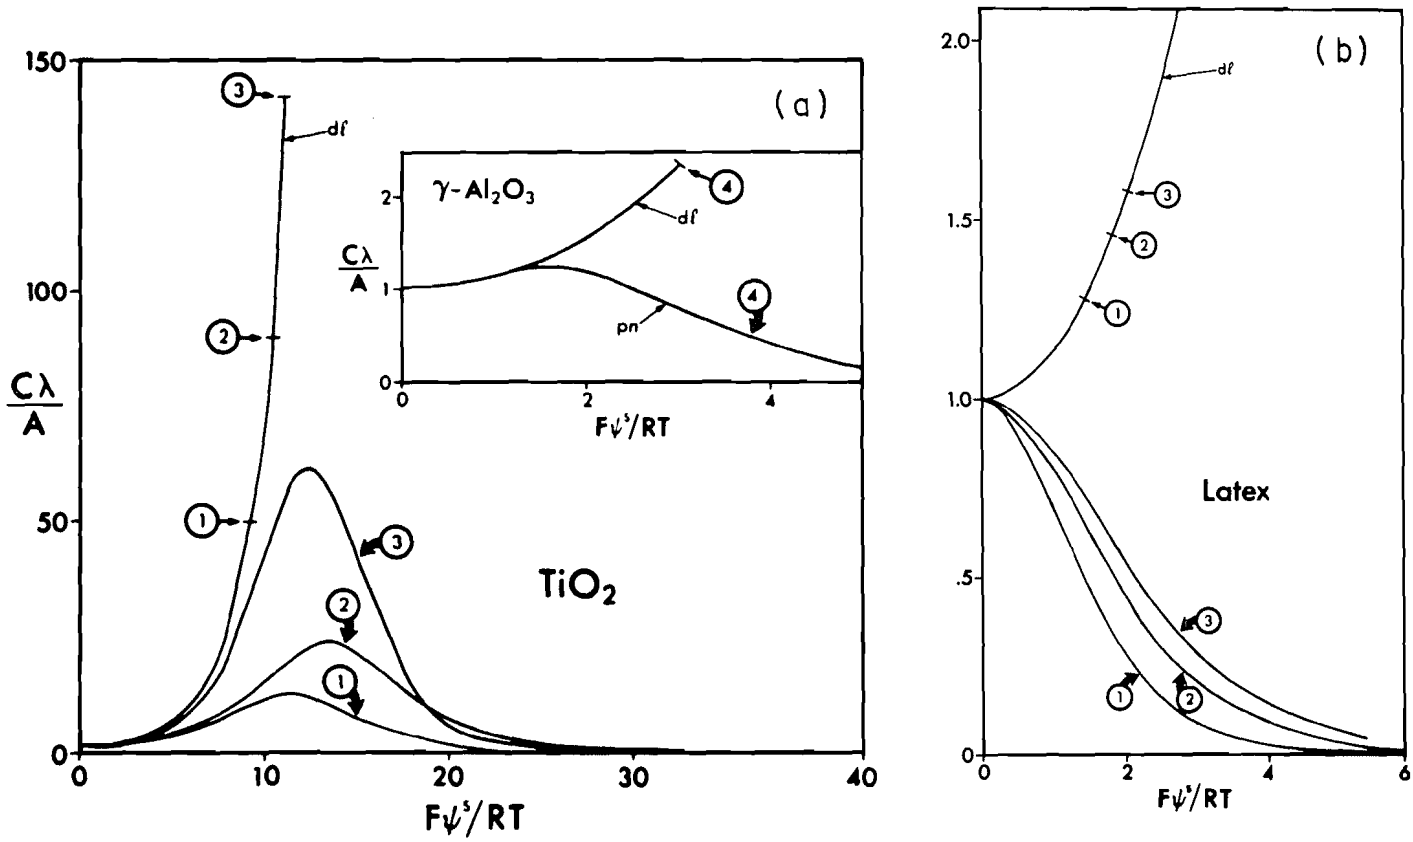

FIG. 1. Plot of $C\lambda/A$ versus $F\Psi^s/RT$ for TiO_2 and γ-Al_2O_3 (part *a*) and for a monofunctional latex surface (part *b*) according to the dl-model (upper curve) and pn-model (lower curves) when $I = 0.1$, 0.01, and 0.001. Each case for I is denoted here by ① (or ④), ②, and ③, respectively. Also, each curve is calculated by using the appropriate equation and information provided by Tables 1 and 3. Dashes through the dl-lines identify $(C_{dl}\lambda/A)_{max}$ and $(F\Psi^s_{dl}/RT)_{max}$ for each value of I.

$$E_k = E_0 + s_L \ln h_k + j_A h_k$$

where E_k is the electromotive force measured (e.g.) with glass and calomel electrodes, and E_0, s_L, and j_A represent additional parameters also requiring least-squares refinement.

The acid–base (ACBA) computer program in ref. 2 minimizes U when $\Psi^s = 0$. Only slight adjustments to the basic algorithm, however, need to be made to minimize U when $\Psi^s \neq 0$ and employing models based on the double layer theory or the modified Nernst equation (i.e., eq. [18]). These methods, as seen below, produce nearly identical results for the characterization of surface acidity although the pseudo-Nernst model may be preferred because of its ability to fit the experimental data particularly well. Furthermore, the optimal f-values, in principle, may be used to determine S and b provided that (*i*) the H^+-ions are the only surface-potential generating ions in the suspending medium, (*ii*) there are no permanent, p*h*-independent charges associated with the surface, and (*iii*) the substance of interest is not subjected to extensive shrinking and swelling due to the uncoiling of polymeric microstructure during the course of the titration. Both S and b may be found from experimental f-versus-I data using the relationship

$$[22] \quad \frac{\kappa}{1 + a\kappa} = -\frac{1}{b} + \frac{1}{S}\frac{F\kappa}{f(8000\epsilon\epsilon_0 RTI)^{1/2}C^0} = -\frac{1}{b} + \frac{1}{S}g$$

and plotting (or regressing) $\kappa/(1 + a\kappa)$ versus g with slope and intercept yielding the surface area (m^2/l) and the effective surface curvature of the colloid–solution interface, respectively.

Procedure

A number of published titration curves (Table 2) providing sufficient information for rigorous analysis were selected, magnified (approximately 3×), and digitized with a TRS-80 digitizer yielding a precision of approximately ±0.05 mm per $x-y$ coordinate measurement. Between 25 to 60 well-spaced titration points per curve were obtained and submitted to the modified ACBA-program for analysis. Optimal values for f and μ^* corresponding to minimal U-values were found by scanning either f (for cc- and dl-calculations) or μ^* (for pn-calculations) through a range of feasible values while simultaneously refining all other titration parameters of interest. Also analyzed were the surface charge – p*h* isotherms (Figs. 3 and 4 in ref. 10) for the monofunctional, high-charge carboxylic acid latex studied by Ottewill and Yates (11).

Discussion

(a) Amphoteric surface

Shown in Table 3 is a model-by-model comparison between reported and refined titration parameters for γ-Al_2O_3 and TiO_2. It appears that the general agreement among the various numerical estimates for K_{01}, K_{02}, C_h^0, and ph^0 is satisfactory, but that there are major discrepancies for f, μ, λ, and μ^*. A substantial portion of these differences, however, can be traced to model-dependent differences in $1/\lambda$. To check this algebraically and numerically, set

$$\frac{\kappa}{1+a\kappa} = -\frac{1}{b_{dl}} + \frac{1}{S}g_{dl}$$

$$= -\frac{1}{b_{pn}} + \frac{1}{S}g_{pn} = -\frac{1}{b_{pn}} + \frac{1}{S}g_{dl} + \Delta\left(\frac{1}{b}\right)_{pn}$$

$$= -\frac{1}{b_{cc}} + \frac{1}{S}g_{cc} = -\frac{1}{b_{cc}} + \frac{1}{S}g_{dl} + \Delta\left(\frac{1}{b}\right)_{cc}$$

and calculate

$$\Delta\left(\frac{1}{b}\right)_{pn} = \frac{1}{b_{pn}} - \frac{1}{b_{dl}}$$

and

$$\Delta\left(\frac{1}{b}\right)_{cc} = \frac{1}{b_{cc}} - \frac{1}{b_{dl}}$$

from

$$\Delta\left(\frac{1}{b}\right)_m = \kappa\Delta\left(\frac{1}{\lambda}\right)_m = \frac{F^2}{2\epsilon\epsilon_0 RTSC^0}\Delta\left(\frac{1}{f}\right)_m$$

$$= \frac{2F^2C_{A1}}{\epsilon\epsilon_0 RTSC^0}\Delta\left(\frac{\sqrt{K_{01}/K_{02}}}{\mu}\right)_m$$

$$= \frac{2F^2C_{A1}}{\epsilon\epsilon_0 RTSC^0}\Delta\left[\sqrt{K_{01}/K_{02}}\left(\frac{1}{\mu^*} - 1\right)\right]_m$$

by using the appropriate values for each parameter from Table 3. Inspection of the results will show that $\Delta(1/b)_m$ for either m = pn or m = cc remains nearly constant for the three ionic strengths considered (see also Fig. 2). The refined titration parameters are therefore internally consistent. It is thus possible to convert the parametric results peculiar to one model to those of another model by knowing the precise values for $\Delta(1/b)_m$ and h_m^0 (3).

Each model produces an acceptable fit between the actual and calculated titration volumes, as indicted by the standard deviation values

$$SD_U = \sqrt{U/(N_T - N_V)}$$

shown in Table 3 ($N_V \equiv$ number of refined titration parameters). In particular, note that

$$SD_U^{pn} < SD_U^{cc} < SD_U^{dl}$$

The pseudo-Nernst model, in fact, is capable of producing a nearly random residual for v(calcd) − v(exp). Furthermore, a good U-fit, according to eqs. [5], [6], and [21], also implies a good σ-fit, i.e.

$$SD_\sigma = \sqrt{[\sigma(\text{exp}) - \sigma(\text{calcd})]^2/(N_T - N_V)}$$

$$\simeq SD_U(C_h^T - h + K_w/h)(F/SC^0V_0)$$

The pn-model, therefore, yields an experimentally acceptable $\sigma-\Psi^s$ relationship, thereby implying that (*i*) the proton-affecting surface potential is not limited to a constant value at high and low p*h*-values, and (*ii*) that the surface capacitance of the oxide surfaces is expected to vanish at high and low surface potentials (recall Fig. 1). Surface potential and capacitances obtained by ζ-potential measurements, however, may still be limited to constant, non-zero values at high and low p*h*-values because (*i*) such measurements probe the diffuse ion-layer potential at the plane of shear (i.e., at $x \simeq 20$ Å), but not at the $x = 0$ plane where proton adsorption and desorption takes place, (*ii*) the approximate ζ-potential predicted by each model via eq. [20] is remarkably insensitive to the type of surface model employed (see Table 3), (*iii*) the exact potential–distance relationship at $x = 0$ is generally unknown, but can be expected to depend on the physical and chemical properties of the underlying surface, the surrounding solution, and type of ions nearby in addition to the electrostatic conditions imposed on the surface by the surrounding ion-layers.

The model-dependent $\kappa/(1 + a\kappa)$-versus-g plots for TiO_2 appear to yield straight, parallel lines (Fig. 2), with a slope corresponding to a surface area of 20 m^2/g in exact agreement with crystallographic and tritium exchange determinations

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

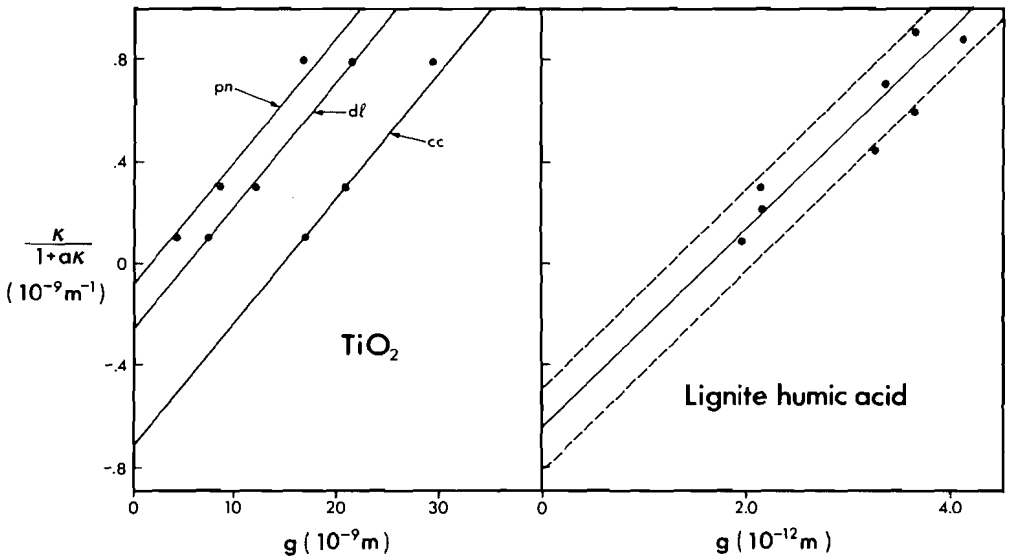

FIG. 2. Plots of $\kappa/(1 + a\kappa)$ versus g for TiO_2 (3) and lignite humic acid (23). The latter plot (pn-model only) is generated by assuming that the functional group concentrations C_{A3}, C_{A4}, and C_{A5} are given by 74, 80, and 60 mequiv./100 g, respectively (see Table 6). Also, $C_h^0 = 39$ mequiv./100 g.

done for the same suspension as reported in ref. 3. Each model, however, produces a different intercept and therefore a different effective radius for surface curvature, i.e.

$$b^s_{cc} = 1.4 \text{ Å} < b^s_{dl} = 37 \text{ Å} < b^s_{pn} = 100 \text{ Å} < b^s_{geom} = 352 \text{ Å}$$

where b^s_{geom} is the geometric radius assuming a spherical particle shape and a particle density of 4.26 g/cm^3 (12). Rutile particles, however, are strongly acicular (13) so that the λ-parameter appearing in eq. [9] should actually be interpreted by the electrostatic expression

$$[23] \quad \lambda = b\kappa\left[\frac{K_0(a'\kappa)}{a'\kappa K_1(a'\kappa)} + \ln\left(\frac{a'}{b}\right)\right]$$

with $a' = b + a$ and $K_0(a'\kappa)$ and $K_1(a'\kappa)$ as modified Bessel functions of the second kind (8). Solving eq. [23] for b (now the effective radius of the rod-shaped particles to be denoted b^R_m) by numerical analysis yields the following values in Å-units:

$$I = 0.1 \qquad b^R_{cc} = 3.0 < b^R_{dl} = 16 < b^R_{pn} = 112$$
$$I = 0.01 \qquad b^R_{cc} = 3.1 < b^R_{dl} = 13 < b^R_{pn} = 33$$
$$I = 0.001 \qquad b^R_{cc} = 3.3 < b^R_{dl} = 12 < b^R_{pn} = 33$$

The geometric rod-radius is given by $b^R_{geom} = 235$ Å. Both electrostatic interpretations of the best-fitted λ-values thus yield particle radii substantially below geometric expectations, thereby suggesting that the acid–base affecting surface potential (or surface capacitance, see Table 3) may not be purely electrostatic, at least not in a straightforward sense. The similarity between the various b-values for a specific model, however, provides an important guide to the analysis of potentiometric titration curves of colloidal substances as shown above. The only inconsistency relevant to this concept occurs with the pn-model at $I = 0.1$, but numerical analysis reveals a strong dependence of b on λ near $\lambda = 1.24$ such that (e.g.) $b^R_{pn} = 160$ Å at $\lambda = 1.26$ and $b^R_{pn} = 35$ Å at $\lambda = 1.12$.

The surface area and effective surface curvature for γ-Al_2O_3, unfortunately, cannot be obtained from the single $I = 0.1$ titration, but the acid–base association behaviour of this colloid appears to be well established with all three models producing effectively the same numbers.

General experience in applying the three models to the γ-Al_2O_3 and TiO_2-titration curves indicated that the dl-model seems to have the best convergence behaviour, yielding unambiguous optimal f-values in most cases. The other two models are prone to produce "false" minima as illustrated in Table 3 for TiO_2 ($I = 0.1$) with and without C^0_h as an additional refinable parameter. The inclusion of C_{A1} ($= C_{A2}$) as refinable parameter did not affect the convergence behaviour of any model, in each case yielding the same surface site concentrations as specified in Table 3.

(b) Monofunctional surface

The σ–ph data in ref. 11 for a monofunctional latex surface can be related to the pn-relationship

$$\log(\sigma_m/\sigma - 1) = -(1 - \mu^*)\text{p}h + (1 - \mu^*)\text{p}h^0$$

as shown in Fig. 3. The agreement between the experimental points and the best-fitted straight lines is excellent except when σ is small. The slope and (or) intercept of each line may therefore be used to determine μ* and other parameters (see Table 4).

The choice of locating the $\Psi^s_R = 0$ reference potential at $\sigma = \sigma_m/2$ is perhaps unusual although consistent with eq. [16]. The reference potential normally associated with the $\sigma = 0$ conditions is such that $\Psi^{s'}$ in

$$[24] \quad K = K'_0 \exp(-F\Psi^{s'}/RT)$$

may reflect the "true" electrostatic potential of the surface, with K'_0 as the intrinsic proton association constant when the degree of dissociation given by $\alpha = \sigma/\sigma_m$ is equal to zero. By invoking a constant capacitance model, i.e.

$$\sigma = (1/\lambda)(8000\epsilon\epsilon_0 RTI)^{1/2} F\Psi^{s'}/2RT$$

it follows that

*pn-model prediction.
†Adjusted K_0-values by invoking cc-model.
‡Activity-coefficient adjusted K_0'- or K_{0i}-values (i = 1, 2).

$$\log K = \log K_0' + 1.737\mu\alpha$$

and therefore

$$\log K_0 = \log K_0' + 0.869\mu$$

The resulting values for log K_0' — see Table 4 — appear to be less dependent on I than log K_0. In fact, the remaining differences could possibly be due to the expected ionic strength effect on activity coefficients γ_{sh}, γ_s, and γ_h (see Table 5), suggesting that the equilibrium constant

$$[25]\quad K_0^0 = K_0'\gamma_{sh}/\gamma_s\gamma_h = a_{sh}/a_s a_h$$

can now be determined by an experimental procedure. Further evidence supporting this possibility comes from examining the pn-model predictions for K_{01} and K_{02} associated with the rutile–water interface as shown in Table 5, with K_{02}^0 given as above, and K_{01}^0 given by

$$[26]\quad K_{01}^0 = K_{01}\gamma_{sh2}/\gamma_{sh}\gamma_h = a_{sh2}/a_{sh}a_h$$

To produce nearly constant values for K_0^0, K_{01}^0, and K_{02}^0 it is assumed (tentatively) that γ_s and γ_{sh} follow the ionic-strength dependent trend associated with trivalent anions and cations. Other factors also accounting for at least part of the variation in log K_0' may be due to (*i*) surface complexation of counterions (especially at high ionic strength), and (*ii*) chemisorption of other surface-potential generating ions present in the supporting electrolyte either as impurities or as intended constituents (see Davis *et al.* (14)).

The general applicability of the pn-model for assessing the surface potential behaviour of a latex surface is also substantiated by the fact that the predicted maximum $\Psi^{s'}$-values for the equivalent dl-model agree well with measured ζ potentials of latex colloids with similar site density (Table 4 and ref. 10). The maximum surface potential, in this case, is given by

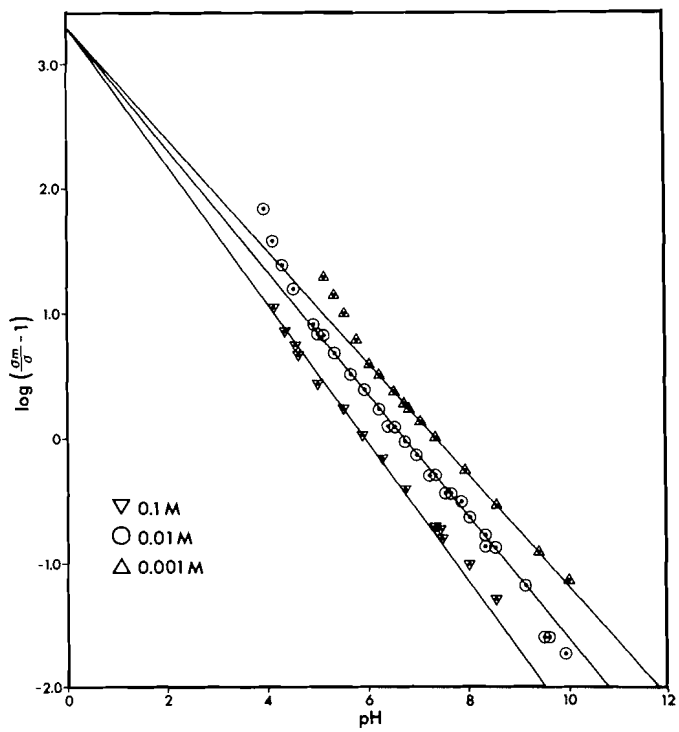

FIG. 3. Plot of log $(\sigma_m/\sigma - 1)$ versus ph for the latex colloid analyzed by Ottewill and Yates (11). Superimposed on the experimental points are the best-fitted straight lines with a common intercept at ph = 0.

$$\Psi_m^{\wedge} = \Psi_{dl}^{\wedge}(\max) - \Psi_{dl}^{\wedge}(\min) = 4RT/F \sinh^{-1} \mu$$

The resulting $\Psi_m^{\wedge}$-values, in turn, are adjusted to the corresponding ζ-potentials by using eq. [2] and setting $x = 20$ Å.

(c) Humic substances

Quantitative information regarding the acid–base behaviour of humic substances following pn-model analysis of the corresponding titration curves (Table 2) is collected in Table 6. Analyses via the dl- and cc-models lead to similar (but not identical) results analogous to the pattern described above for oxide suspensions. The results in Table 6 are arranged into eight groups depending on the value of each K_0-constant to facilitate comparison among the various substances examined.

Optimal parametric precision in terms of asymptotic standard deviations calculated for each refined parameter is in most cases better than 20% as long as the titration curve in question is not "overspecified". Overspecification may occur when the estimates of some of the parameters to be refined are strongly correlated with one another. Estimates for K_{0i} and C_{Ai} in general tend to be weakly correlated, but a sudden lack of resolution for some of these parameters appears whenever N_L — the postulated number of chemically discernible groups — exceeds a critical value $N_{L_{max}}$. Evaluation of $N_{L_{max}}$ is carried out by examining each titration curve with the modified ACBA-program using incremental N_L-values (one at a time) from $N_L = 1$ to $N_L = N_{L_{max}} + 1$. By so doing it is found that $N_{L_{max}}$ appears to depend on (*i*) the type of humic substance analyzed, and (*ii*) the p*h*-range considered.

The fact that individual functional groups can be resolved with excellent precision (provided $N_L \leq N_{L_{max}}$) is surprising. Each distinct section of a titration curve of humic matter is likely to represent not one functional group but a collection of groups with a range of overlapping K_0-values (15). The following suggestions are offered to guide proper interpretation of Table 6. (*i*) Each K_{0i}-value may be taken to represent an average K_0-value for each chemically discernible collection of functional groups thereby identified. (*ii*) Quantitative information regarding the range of K_0-values per collection of groups cannot be obtained by the approach outlined above. It is suspected, however, that this range depends on N_L, and should be minimal when $N_L = N_{L_{max}}$. For example, decreasing N_L progressively from $N_{L_{max}}$ to 1 must lead to an increased effect of $\Psi^{\wedge}$ on K_i (see below), thereby broadening the K_i-range for each collection of groups considered.

In the subsequent discussion the term "group" may be freely interchanged with the term "collection of groups" with the understanding that the quantitative evaluation of the actual range of groups per collection remains, as yet, unresolved. It should also be remembered that each group within a particular collection is assumed to dissociate or associate at most one H^+-ion as expressed by eqs. [6], [12], [13], and [14].

Podsolic fulvic acid

Gamble's titration curve (15) yields at most four chemically discernible groups (or collections of groups) over the experimental p*h*-range from 2.9 to 11.4. Restricting evaluation to 3, 2, and 1 groups increases the implied *f*-value (i.e., $\Psi^{\wedge}$-potential) with only a slight loss in overall goodness-of-fit. A model with just one group operating, therefore, appears to fit the titration data nearly as well as the almost purely chemical model with four groups. A one-group model, however, implies that the log *K*-versus-α relationship given by

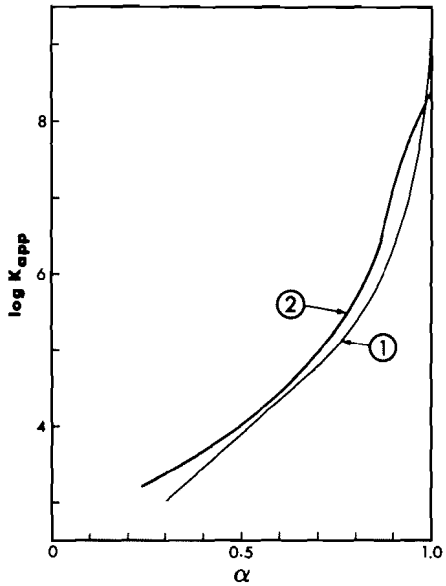

FIG. 4. Plots of log K_{app} versus α for soil fulvic acid (15) when represented by one (lower curve) and four (upper curve) chemically discernible collections of functional groups. Similar plots for two and three chemically discernible collections of groups fall between the two curves shown.

$$\log K = \log K_0' + 2fC_{Al}\alpha$$

$$= \log K_0' + \frac{0.869\lambda F C_{Al}}{SC^0(8000\epsilon\epsilon_0 RTI)^{1/2}}\alpha$$

should be linear. Yet actual plots of "apparent" pK (i.e., ph + log $(1 - \alpha)/\alpha$) versus calculated, N_L-dependent α-values are invariably curved (16, 17) and in general agreement with the multigroup prediction ($N_{L_{max}} = 4$) shown in Fig. 4. Furthermore, the shape of these curves does not seem to depend on ionic strength (18) thereby suggesting that (*i*) electrostatic effects on proton adsorption (desorption) are weak and (*ii*) that the nearest neighbour interactions among the various proton adsorption sites should not be affected by macrostructural rearrangements of each humic molecule as caused by changes in surface potential and ionic strength. Large changes in nearest neighbour interactions, however, are expected to occur on flexible polymer electrolytes during the uncoiling of such substances in aqueous solutions at low ionic strength. In fact, the accompanying pK_{app}-versus-α plots tend to be convex rather than concave (19–21). The uncoiling of humic substances at low ionic strength (and at high ph-values, see Ghosh and Schnitzer (22)) is therefore probably limited to the uncoiling of macromolecular structure, leaving the Ψ^s-determining core(s) of the basically aromatic humic molecule intact.

Soil humic acid

Van Dijk's titration curve (23) yields at most five chemically discernible groups (or collections of groups) over the ph-range from 3.2 to 11.2. The humic substance involved appears to be less acidic than the fulvic acid above, but tends to be more complex in the upper ph-range, with each of the three K_0-values indicating strong phenolic and enolic group characteristics. This titration curve was analyzed twice, each time over a differently restricted ph-range (i.e., 3.2 to 10 and 4.7 to 11.2) to illustrate that the deletion or inclusion of certain groups is affected by the ph-range considered once the total number of refinable K_0- and C_A-values is fixed. The K_0-values and concentrations of the common groups, however, remain numerically consistent with respect to one another.

Lignite humic acid

The potentiometric behaviour of a humic acid extracted from surface-weathered lignite was documented by Stevenson (24) over an ionic strength range from 0.001 to 0.2 N and a restricted ph-range from 3.7 to 8.0. Three proton-yielding groups are identifiable within this range as shown in Table 6, all three groups being similar to corresponding groups in Van Dijk's soil extract. All K_0-values, concentrations, and f-values are unexpectedly consistent over the I-range considered. Refining the K_0-values by keeping all concentrations fixed, however, leads to I-dependent f-values such that the plot of $\kappa/(1 + a\kappa)$ versus g (Fig. 2) yields a sloping scattergram with a best-fitted slope of 0.39×10^{-3} g/m^2. The surface-area estimate for lignite humic acid is therefore $\simeq$ 2600 m^2/g. The scatter observed in this plot probably relates to the procedures employed in generating and digitizing the underlying titration curves. For example, each titration curve was constructed from the ph-readings of ten specially prepared solutions. At least twice as many points were taken from each such curve to allow potentiometric analysis via the modified ACBA-program. Rigorous interpretation of these data beyond the comments above is therefore not possible.

Soil fulvic acid fractions

Davis and Mott (16) fractionated a soil fulvic acid extract into a polysaccharide and non-polysaccharide fraction. They also titrated these fractions forward (with 0.1 N NaOH) and backward (with 0.1 N HCl) thereby generating four types of titration curves, each of which was further repeated for low and high organic-matter concentrations. The following points may be noted from Table 6: (*i*) Individual K_0-values are not much affected by forward or backward titration, or by colloid concentrations. They are, however, affected by type of fraction. (*ii*) The polysaccharide fraction gained a new group at log $K_0 \simeq 4.3$ in exchange of an equivalent loss of concentration associated with its log $K_0 \simeq 9.2$ group on backward titration. (*iii*) Reduced resolution for the log $K_0 \simeq 1.9$ group in the non-polysaccharide fraction leads to overestimates of C_{Al} and initial free base content (i.e., C_h^0) associated with the corresponding titrand solutions.

It was proposed (16) that Fraction I should experience OH^--induced oxidation when subjected to ph-values exceeding 8, possibly leading to formation of saccharinic acid. Fraction II with an ash content of 9.9% (by oven-dried weight) was also observed to consume additional OH^--ions when left standing at ph-values in excess of 7.0, but the humic substance involved appeared to remain unchanged. The results of Table 6 evidently substantiate these claims.

In summary, it is suggested that the acid–base behaviour of humic matter appears to be controlled by a number of identifiable collections of functional groups. Electrostatic forces are also present, but their effects on proton adsorption in terms of refined f-values, surface charge densities, and maximum dl-model potentials appear to be consistently small in comparison with similar values for oxide surfaces (see Table 7). Humic colloids, perhaps, distinguish themselves from other polymers on account of microstructural rigidity and irregularity thereby implying I- and ph-independent (or nearly independent) and presumably unchanging nearest neighbour interactions among the various proton adsorption/desorption sites. Davis and Mott

(16), Young *et al.* (17), Burch *et al.* (25), Wilson and Kenney (26), and Gamble (15, 27) have also discussed the acid–base behaviour of humic substances in terms of electrostatic and chemical models. Their interpretations, however, are largely based on restricting modelling to at most two chemically discernible collections of groups, with basic information obtained from potentiometric titration curves by way of Gran-plot procedures or some other technique for end-point detection. No such restriction, in principle, is encountered in the modified ACBA-procedure employed above, thereby facilitating a quantitatively rigorous presentation of many chemical and electrostatic features affecting humic substances.

Concluding remarks

Application of the modified ACBA program to the interpretation of potentiometric titration curves of colloidal substances with rigid or near-rigid macrostructure and/or microstructure may lead to an improved understanding of the acid–base behaviour of such substances. The success of the pn-model to fit titration data as published in the literature is particularly noteworthy in view of its general performance and similarity to the Nernst equation. It is possible that this model may form an important conceptual link between "particle" potentials accessible by electrochemical measurement and "surface" potentials made available by ζ-potential measurement and double layer theory. For example, one may represent the electrochemical potential ($\tilde{\mu}$) for the H^+-ion equilibrium within a particle (p), at the colloid surface (s) and throughout the surrounding solution far removed from the surface (l) as follows:

$$\tilde{\mu}_p = \mu_p + F\Psi^p = \tilde{\mu}_s = \mu_s + F\Psi^s = \tilde{\mu}_l = \mu_l + F\Psi^l$$

with $\mu_m = \mu_m^0 + RT \ln a_m$ as the chemical potential for H^+ at m = p, s, and l. Setting $a_p = 1$ (i.e., unit activity for H^+-ions in particle medium) and $\Psi^l = 0$ (by convention), it follows that

$$\Psi^s = (RT/F) \ln a_l/a_s + \text{constant}$$

and

$$\Psi^p = (RT/F) \ln a_l/a_p + \text{constant}$$

$$= \frac{RT}{F}\int_{a_l^0}^{a_l} \frac{d\Psi^p}{d \ln a_l} = \frac{RT}{F} \ln a_l/a_l^0 \simeq \frac{RT}{F} \ln h/h^0$$

The particle potential Ψ^p (or Nernst potential) is therefore not identical with the surface potential Ψ^s. Moreover, Ψ^s may not be purely electrostatic, because the electrochemical expression

[27] $\tilde{\mu} = \mu + F\Psi$

involves a customary but non-thermodynamic assumption (28). Also, surface potentials according to diffuse double-layer models are based on electrostatic assumptions, whereas the pn-model assumes that

[28] $\Psi^s = \mu^* \Psi^p$

The pn-model, therefore, imparts a non-electrostatic component to Ψ^s which reduces to a constant when $F\Psi^s/RT \ll 1$, i.e., when the cc-, dl-, and pn-models merge (see eq. [19]). Perhaps it is of interest to further explore the pn-model by reinterpreting some of the many published surface capacitance – surface charge (or surface potential) relationships, and among these especially those with "humps" (29). One example offered to facilitate reinterpretation of electrochemical data is obtained by invoking the constant surface capacitance assumption in connection with eq. [18]. This yields

[29] $\sigma \simeq k \ln h/h^0$

with

$$k = 2(FC_{Al}/SC^0)(1 - \mu^*)/(2 + \beta)$$
$$= (8000\epsilon\epsilon_0 RTI)^{1/2}/\lambda$$

valid for amphoteric surfaces. This equation applies reasonably well to data derived from potentiometric titrations of aged oxide suspensions at high ionic strength (9). Equation [29], in turn, provides a simple way for calculating the degree of dissociation $\alpha = 1 - \alpha_1 - \alpha_2$ for amphoteric surfaces (10) at any ph near ph^0, i.e.

$$\alpha \simeq \frac{1 - \mu^*}{1 + \beta/2} \ln \frac{h}{h^0}$$

Slightly more complicated expressions may be obtained for σ and α when applying the diffuse double-layer model to eq. [18]. In addition, similar expressions apply to amphoteric surfaces and substances affected by potential-generating ions other than H^+. Finally, cation-exchange reactions of the type

$$SH + M^+ = SM + H^+$$

may also be examined by empirically generalizing eq. [18] to

[30] $F\Psi^s/RT = \mu^* \ln [(h + K_{MH}M)/h^0]$

with M as cation concentration and $K_{MH} = [H][SM]/[M][SH]$ as cation exchange constant (30). The approach suggested here is therefore general, and may be used as a basis for further analysis of a great variety of electrochemical systems.

Flowing afterglow measurements of rate constants and ionic products are reported which explore the influence of step-wise hydration on the reactivity of the hydroxide anion in the gas phase at 296 ± 2 K. Rate constants have been measured for the reactions of $OH^-.(H_2O)_n$ and/or $OD^-.(D_2O)_n$ with CO_2, SO_2, CH_3OH, C_2H_5OH, C_2H_2, CH_3COCH_3, CH_3NO_2, and HCN, in most instances for values of n from 0 to 3. The reactions with CO_2 and SO_2 involve ligand addition or exchange and the results of their study corroborate earlier measurements. The remaining reactions proceed by proton transfer. For these reactions the results establish trends in reactivity as a function of step-wise hydration when relative acidity is preserved and when a reversal occurs in the relative acidity upon hydration. The fast hydrated acid–base reactions were observed to establish interesting hydrated product ions many of which underwent secondary reactions involving the exchange of H_2O or D_2O for the reagent molecule.

ASIT B. RAKSIT et DIETHARD K. BOHME. Can. J. Chem. **61**, 1683 (1983).

On rapporte les mesures de phosphorescence d'écoulement des constantes de vitesse et des produits ioniques. Ces mesures permettent d'étudier l'influence d'une hydratation par étape sur la réactivité de l'anion hydroxyde en phase gazeuse à 296 ± 2 K. On a mesuré les constantes de vitesse des réactions de $OH^-.(H_2O)_n$ et/ou de $OD^-.(D_2O)_n$ avec les molécules suivantes: CO_2, SO_2, CH_3OH, C_2H_5OH, C_2H_2, CH_3COCH_3, CH_3NO_2 et HCN et ceci pour des valeurs de n allant de 0 à 3 dans la plupart des cas. Les réactions avec CO_2 et SO_2 impliquent l'addition ou l'échange de ligand et les résultats de leur étude corroborent les mesures antérieures. Les réactions avec les autres substances se font par transfert de proton. Dans le cas de ces réactions, les résultats établissent la tendance de la réactivité en fonction de l'hydratation par étape lorsqu'on protège l'acidité relative et lorsqu'il se produit une inversion de l'acidité relative durant l'hydratation. On a observé des réactions rapides acide–base hydraté afin d'identifier les ions hydratés intéressants dont plusieurs subissent des réactions secondaires qui impliquent, dans le cas du réactif, un échange de H_2O ou de D_2O.

[Traduit par le journal]

Introduction

The hydroxide ion is an important base in solution chemistry and has become so as well in gas-phase ion chemistry. In the gas phase the bare hydroxide ion has a high basicity and a high reactivity which are now both well established (1) and much is known of the reactivity of the hydrated species in solution. In this study we explore the influence of step-wise hydration on the intrinsic reactivity of the hydroxide ion in the gas phase, primarily with measurements of the specific rates and ionic products of reactions of type [1]

$$[1] \quad OH^-.(H_2O)_n + AH \rightarrow A^-.(H_2O)_m + (n - m + 1)H_2O$$

for values of n = 1 to 3. The measurements were carried out using a flowing plasma mass spectrometer (flowing afterglow) system (2, 3) which allows the hydrated species to be produced in an inert atmosphere in thermalized and controlled amounts and to be identified and monitored with a mass spectrometer. The reagent acids, AH, were chosen to span a range in overall energetics sufficient to establish the pattern of reactivity which emerged from these studies. The observed trends in reactivity begin to bridge the gap between the gas phase and solution. For a number of acids reaction [1] was observed to be followed by further ion chemistry which exhibits a clear tendency of the solvent aggregate of the solvated ions to evolve to a state of maximum stability by solvent exchange and solvent addition reactions.

Experimental

The experiments were carried out in a flowing plasma mass spectrometer (flowing afterglow) system. Details of the instrument together with the method of operation and data analysis have been reported elsewhere (2, 3). The hydrated hydroxide ions were established by introducing water vapour, either H_2O or D_2O, past the electron gun in either a flowing helium or hydrogen plasma. Ions were hydrated upstream by reactions of type [2] at total pressures of ca.

$$[2] \quad OH^-.(H_2O)_n + H_2O + He(H_2) \rightarrow OH^-.(H_2O)_{n+1} + He(H_2)$$

0.4 Torr and thermalized by collisions with the buffer gas molecules prior to the reaction region. The reacting mixture was sampled through a small orifice mounted at the tip of a nose cone situated at the end of the reaction region and mass analysed with a quadrupole mass spectrometer. The observed variations of the reactant ion signals as a function of neutral reagent addition provided the raw data from which the rate constants were derived.

The partial pressure of the added water vapour was varied from ca. 0.005 to 2 mTorr in order to achieve a wide range in the initial relative population of the hydrated hydroxide ions. The hydroxide ion was observed to add up to three water molecules at the operating conditions of the experiments reported here. In deriving rate constants from the observed decays of $OH^-.(H_2O)_n$ account was taken of the initial decay which could arise due to the depletion of the precursor ion $OH^-.(H_2O)_{n-1}$. The magnitude of the depletion could be assessed in those studies in which the daughter ion $OH^-.(H_2O)_n$ did not react with the added neutral reagent. In many experiments D_2O was used in place of H_2O to avoid overlap of ion signals, particularly of $OH^-.(H_2O)_n$ and $Cl^-.(H_2O)_{n-1}$ and of $OH^-.(H_2)_2$ and $CN^-.HCN$.

Results

The results of the measurements are summarized in Tables 1 and 2. The sources of uncertainty associated with the determination of the rate constants have been described previously (2, 3). The following section describes the measurements in

TABLE 1. Rate constants[a] measured for binary reactions of $OH^-.(H_2O)_n$ with CO_2 and SO_2 at 296 ± 2 K

n	CO_2	SO_2[b]
1	≥0.4	1.0±0.3 (≥0.5)
2	0.54±0.22	1.2±0.3 (≥0.5)
3	0.56±0.22	1.2±0.4 (1.2±0.5)
2, 3, 4[c]	0.6	2

[a]In units of 10^{-9} cm^3 $molecule^{-1}$ s^{-1}.
[b]Values in parentheses apply to $OD^-.(D_2O)_n$.
[c]Reference 4.

more detail. They are presented in order of increasing acidity of the reagent acids. The reactions with CO_2 and SO_2 were investigated in part to assess the performance of the instrument. Previous flowing afterglow measurements for these two reactions carried out primarily in O_2 buffer gas were available for comparison (4).

CO_2, SO_2

The unsolvated hydroxide ion rapidly associates with CO_2 and SO_2 in the gas phase to form the anions of carbonic and sulphurous acid, respectively, via reactions [3] and [4] where M is a third body.

[3] $OH^- + CO_2 + M \rightarrow HCO_3^- + M$

[4] $OH^- + SO_2 + M \rightarrow HSO_3^- + M$

Reaction [3] was investigated in H_2 buffer gas at total pressures in the range 0.276 to 0.582 Torr while reaction [4] was studied in a He buffer with OH^- between 0.320 and 0.447 Torr and with OD^- between 0.317 and 0.567 Torr. Figure 1 displays the observed pressure dependencies for the apparent binary rate constants which were measured. The slopes of these plots provide ternary rate constants of (1.0 ± 0.3) and (4.2 ± 1.3) × 10^{-27} cm^6 $molecule^{-2}$ s^{-1} for reactions [3] and [4], respectively. A comparison with the previously reported measurements indicates the H_2 to be slightly more effective as a stabilizing third body for HCO_3^- than O_2 which in turn is more effective than He: rate constants of 7.6 and 2.5 × 10^{-28} cm^6 $molecule^{-2}$ s^{-1}, respectively, have been reported for the latter two buffer gases (4). Our results also indicate that the relative effectiveness of O_2 and He in stabilizing HCO_3^- is approximately the same as that in stabilizing HSO_3^-: a rate constant of 1.0 × 10^{-26} cm^6 $molecule^{-2}$ s^{-1} has been reported for reaction [4] with M = O_2 (4).

The hydrated hydroxide ions were observed to undergo the binary ligand exchange reactions [5] and [6] reported

[5] $OH^-.(H_2O)_n + CO_2 \rightarrow HCO_3^-.(H_2O)_m + (n - m)H_2O$

[6] $OH^-.(H_2O)_n + SO_2 \rightarrow HSO_3^-.(H_2O)_m + (n - m)H_2O$

previously by Fehsenfeld and Ferguson (4). In writing these reactions allowance has been made for the excess energy in these exothermic reactions to cause some of the H_2O to be "boiled-off" and so permit m to take on values from 0 to $n - 1$. In the present experiments in which the flowing plasma contained a mixture of $OH^-.(H_2O)_n$ ions with n = 0 to 3, product ions were observed for m = 0, 1, and 2 but the latter in only relatively trace amounts. The rate constants determined from these experiments are summarized in Table 1. They compare favourably with the values obtained previously by Fehsenfeld and Ferguson (4).

CH_3OH

We have reported previously that the bare hydroxide ion rapidly removes a proton from methanol in the gas phase, k = (2.2 ± 0.6) × 10^{-9} cm^3 $molecule^{-1}$ s^{-1} (5). Also hydration of the OH^- was observed to promote the reverse of reaction [7]. Measurements of the equilibrium constant for reaction [7]

[7] $OH^-.(H_2O)_n + CH_3OH \rightleftharpoons CH_3O^-.(H_2O)_n + H_2O$

for n = 1, 2, and 3 provided insight into the shift of the position of equilibrium for this reaction with hydration (6). Reaction [7] is rapid, $k > 10^{-9}$ cm^3 $molecule^{-1}$ s^{-1}, for n = 0 to 3 and the product ions quickly undergo secondary reactions with CH_3OH which displace H_2O in the solvation shell as is indicated by reaction [8]. In this study the measurements were repeated with

[8] $CH_3O^-.(H_2O)_n + CH_3OH \rightleftharpoons CH_3O^-.(H_2O)_{n-1}.CH_3OH + H_2O$

$OD^-.(D_2O)_n$ ions derived from heavy water and a very similar behaviour was observed. The semi-logarithmic decays recorded for these solvated ions and the formations of product ions were indicative of fast reactions of type [9] for n = 0 to 4. Increased curvature was apparent in the decays of

[9] $OD^-.(D_2O)_n + CH_3OH \rightarrow CH_3O^-.(D_2O)_n + HOD$

$OD^-.(D_2O)_n$ with increasing values of n which may be attributed to reverse reactions with the source gas D_2O which was present in the reaction tube in large excess to the HOD generated by reaction [9], viz to reactions of type [10]. Plots of the ion

[10] $CH_3O^-.(D_2O)_n + D_2O \rightarrow OD^-.(D_2O)_n + CH_3OD$

concentration ratios $[CH_3O^-.(D_2O)_n]/[OD^-.(D_2O)_n]$ against flow of CH_3OH exhibited linearity at higher flows of CH_3OH. Normally such linearity would be indicative of equilibrium but in this case the linearity is a consequence of the rate equalities [11] rather than the equilibrium equalities [12], and thus pro-

[11] $k_9[OD^-.(D_2O)_n][CH_3OH] = k_{10}[CH_3O^-.(D_2O)_n][D_2O]$

[12] $k_9[OD^-.(D_2O)_n][CH_3OH] = k_{-9}[CH_3O^-.(D_2O)_n][HOD]$

vides a measure of k_9/k_{10} rather than k_9/k_{-9}. Values for k_9/k_{10} of ≥ 5.3 × 10^2, ≥1.7 × 10^2, 22, and 10 were obtained for n = 1, 2, 3, and 4, respectively. These are close to the values of ≥1.3 × 10^3, 1.5 × 10^2, and 25 for n = 1, 2, and 3 which were obtained previously for k_7/k_{-7} and are thus indicative of a negligible isotope effect.

The product ions of reaction [9] were observed to rise and then fall at higher additions of methanol concomitant with the production of ions with masses corresponding to the cluster ions $CH_3O^-.(D_2O)_{n-1}.CH_3OH$ with n = 1, 2, and 3. These observations can be attributed to rapid solvent exchange reactions of type [13] and indicate a preference for methanol over heavy water in the solvation of CH_3O^-.

[13] $CH_3O^-.(D_2O)_n + CH_3OH \rightarrow CH_3O^-.(D_2O)_{n-1}.CH_3OH + D_2O$

CH_2CCH_2, $C_6H_5CH_3$

Allene and toluene have equal acidities in the gas phase (7). We have reported previously that the bare hydroxide ion will abstract a proton from these two acids with essentially unit efficiency and that hydration of the bare ion with just one molecule of water lowers this efficiency by more than a factor of 10^3 (7).

[a]Rate constants and their estimated accuracies are given in units of 10^{-9} cm^3 molecule^{-1} s^{-1}. The numbers in brackets refer to reactions with $OD^-.(D_2O)_n$.

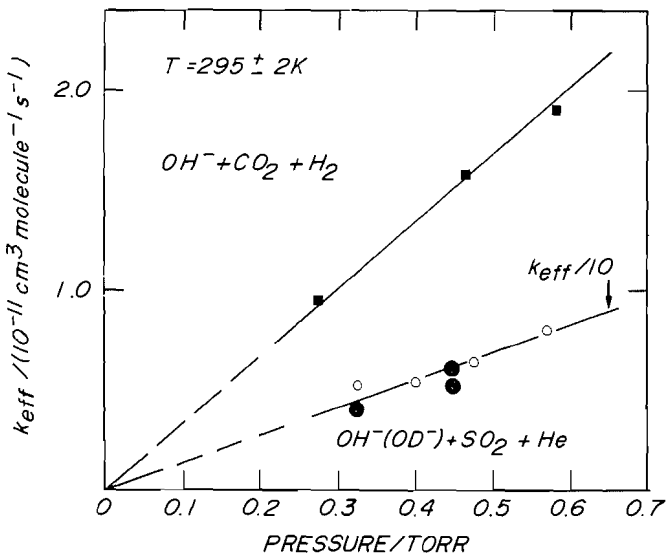

FIG. 1. Observed dependence of the effective two-body rate constant on the total pressure for the association of $OH^-(OD^-)$ with CO_2 and SO_2 at 295 ± 2 K. The open circles refer to measurements made with OD^-.

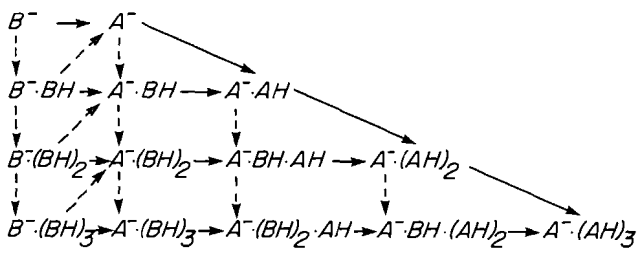

FIG. 2. A general scheme representative of the possible solvated ion chemistry proceeding under flowing afterglow conditions for the acid–base reactions investigated in this study. The solid horizontal arrows represent solvated acid–base or solvent exchange reactions with AH. The dashed vertical arrows represent possible solvent addition reactions with BH. The dashed diagonal arrows represent possible solvated acid–base reactions with a concomitant "boiling-off" of solvent BH.

C_2H_5OH

The reactivities of $OH^-.(H_2O)_n$ and $OD^-.(D_2O)_n$ observed for their reactions with ethanol were similar to those observed for methanol. Rapid proton transfer reactions of type [14] were indicated for $n = 1$ to 3. The measured rate constants are listed

[14] $OD^-.(D_2O)_n + C_2H_5OH \rightarrow C_2H_5O^-.(D_2O)_n + HOD$

in Table 2. Also the hydrated ethoxide ions were observed to react further by solvent exchange reactions of type [15]. At

[15] $C_2H_5O^-.(D_2O)_n + C_2H_5OH \rightarrow C_2H_5O^-.(D_2O)_{n-1}.C_2H_5OH + D_2O$

still higher flows of ethanol, ion signals were observed to rise at $m/e = 137$ and 157 and finally at $m/e = 183$. This behaviour is consistent with still further displacement of D_2O by C_2H_5OH to ultimately establish ethoxide ions solvated exclusively by ethanol as is indicated by the general scheme shown in Fig. 2. All of the ions indicated in this scheme were observed for BH = D_2O and AH = C_2H_5OH.

C_2H_2

We have reported previously that OH^- rapidly abstracts a proton from acetylene to produce C_2H^- (8). The results of the present study indicate that this reactivity is extremely sensitive to the degree of hydration. As is evident from the observations recorded in Fig. 3, the reactivity remains high with the addition of one molecule of water to OH^- but the addition of a second molecule of hydration leads to an abrupt drop in reactivity by more than two orders of magnitude. For reactions of type [16] and the heavy water analogues, our observations indicate that

[16] $OH^-.(H_2O)_n + C_2H_2 \rightarrow C_2H^-.(H_2O)_n + H_2O$

$k \geq 1 \times 10^{-9}$ cm^3 molecule^{-1} s^{-1} for $n = 0$ and 1 but $k \leq 1 \times 10^{-11}$ cm^3 molecule^{-1} s^{-1} for $n = 2$ and 3. An ion with a mass corresponding to the product of reaction [17] was clearly identified. The curvature in the decay of $OD^-.D_2O$ in Fig. 3 is

[17] $OD^-.D_2O + C_2H_2 \rightarrow C_2H^-.D_2O + HOD$

caused by the rapid occurrence of the reverse reaction [18] with D_2O which is in large excess over the HOD produced by

[18] $C_2H^-.D_2O + D_2O \rightarrow OD^-.D_2O + C_2HD$

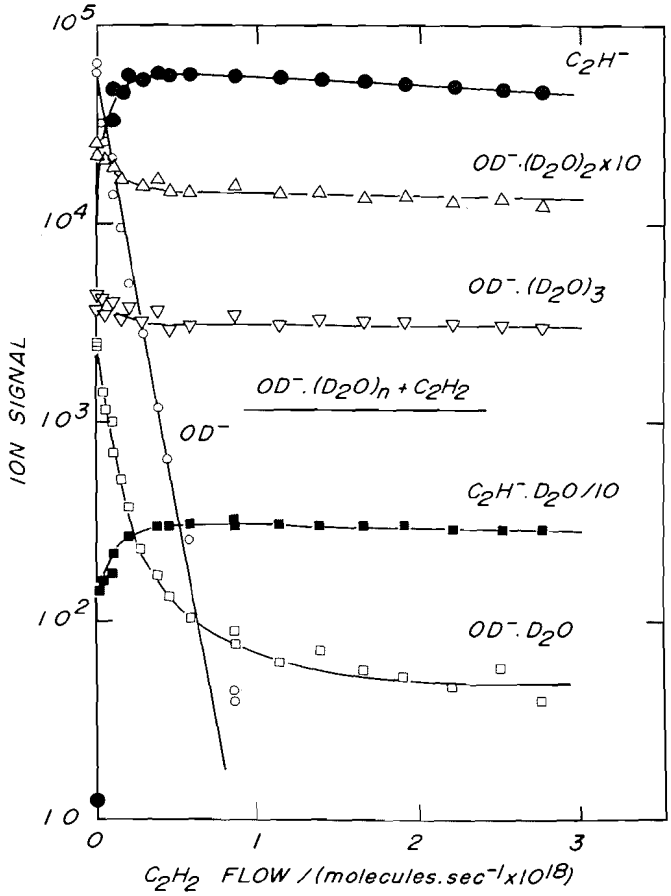

FIG. 3. Observations recorded for the reactions of $OD^-.(D_2O)_n$ with acetylene in a He buffer. T = 296 K, P = 0.331 Torr, $\bar{v}$ = 8.1 × 10^3 cm s^{-1}, L = 46 cm, and the flow of D_2O is approximately 2 × 10^{19} molecules s^{-1}.

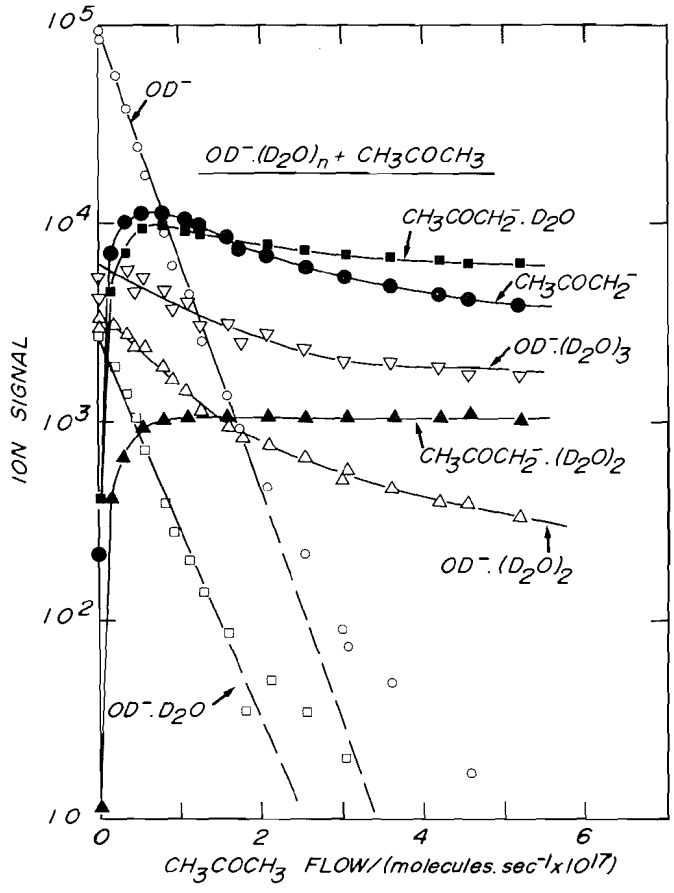

FIG. 4. Observations recorded for the reactions of $OD^-.(D_2O)_n$ with acetone in a He buffer. T = 295 K, P = 0.316 Torr, $\bar{v}$ = 8.0 × 10^3 cm s^{-1}, L = 46 cm, and the flow of D_2O is approximately 2 × 10^{19} molecules s^{-1}.

reaction [17]. A fit to this curvature provided lower limits for k_{17}/k_{18} of 8 × 10^2 and for k_{17} of 1 × 10^{-9} cm^3 $molecule^{-1}$ s^{-1}. The slight decays observed initially in the profiles for $OD^-.(D_2O)_2$ and $OD^-.(D_2O)_3$ are attributable to the depletion in the reaction region of their precursor ions, $OD^-.D_2O$ and $OD^-.(D_2O)_2$, respectively. The $C_2H^-.D_2O$ did not react further to exchange D_2O for C_2H_2.

CH_3COCH_3

Figure 4 illustrates the reactivities of $OD^-.(D_2O)_n$ towards acetone. OD^- and $OD^-.D_2O$ are seen to react rapidly with acetone with a concomitant rise in the $CH_3COCH_2^-$ and $CH_3COCH_2^-.D_2O$ ion signals. The rate constants for both of these reactions were measured to be ≥ 3 × 10^{-9} cm^3 $molecule^{-1}$ s^{-1} (see Table 2). Reaction [19] and the analogous reactions [20] and [21] with D_2O appeared to

[19] $OH^-.(H_2O)_2 + CH_3COCH_3 \rightleftharpoons CH_3COCH_2^-.(H_2O)_2 + H_2O$

[20] $OD^-.(D_2O)_2 + CH_3COCH_3 \rightarrow CH_3COCH_2^-.(D_2O)_2 + HOD$

[21] $CH_3COCH_2^-.(D_2O)_2 + D_2O \rightarrow OD^-.(D_2O)_2 + CH_3COCH_2D$

achieve equilibrium under the conditions employed in these experiments. The corresponding ion ratio plots were linear and provided values for k_{19}/k_{-19} = 3 × 10^2 and for k_{20}/k_{21} = 4 × 10^2. The situation for the reaction of $OD^-.(D_2O)_3$ is somewhat uncertain. There is a slight decay in the $OD^-.(D_2O)_3$ signal initially but it appears to level off at moderate flows of acetone. This behaviour was interpreted to reflect the removal of the $OD^-.(D_2O)_2$ percursor ion in the reaction region and a low reactivity for the $OD^-.(D_2O)_3$, $k \leq 1 \times 10^{-11}$ cm^3 $molecule^{-1}$ s^{-1}. The product ion $CH_3COCH_2^-.(D_2O)_3$ did not appear to be produced. An alternative interpretation would involve a reverse reaction of the $CH_3COCH_2^-.(D_2O)_3$ with D_2O which strongly favours a net production of $OD^-.(D_2O)_3$. At the flows of D_2O and acetone employed this would still imply an equilibrium constant for reaction [22] or the analogous reactions with D_2O

[22] $OH^-.(H_2O)_3 + CH_3COCH_3 \rightleftharpoons CH_3COCH_2^-.(H_2O)_3 + H_2O$

of less than unity.

CH_3NO_2

The ions $OH^-.(H_2O)_n$ and $OD^-.(D_2O)_n$ with n = 0 to 3 all were observed to react rapidly with nitromethane in the manner indicated by reaction [23].

[23] $OH^-.(H_2O)_n + CH_3NO_2 \rightarrow CH_2NO_2^-.(H_2O)_m + (n - m + 1)H_2O$

All of the corresponding product ions, viz. $CH_2NO_2^-.(H_2O)_n$ and $CH_2NO_2^-.(D_2O)_n$ with n = 0 to 3, were observed to be produced but product distributions for the individual hydrated ions could not be ascertained. The rate constants measured for the disappearance of the reactant ions are given in Table 2. Exchange of H_2O or D_2O for CH_3NO_2 was observed at higher flows of CH_3NO_2 in secondary switching reactions such as reactions [24] and [25] but no attempt was made to follow the

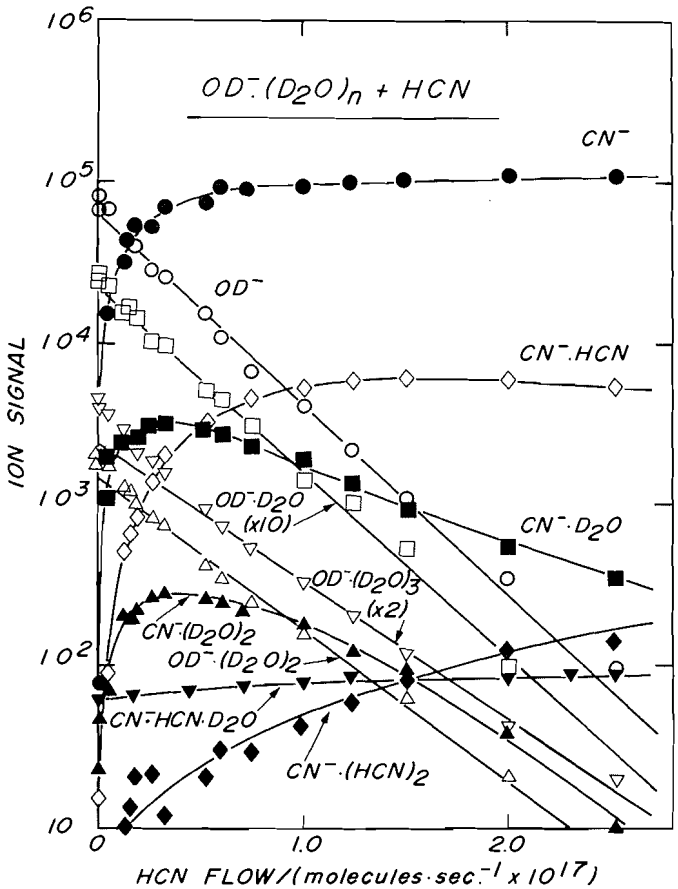

FIG. 5. Observations recorded for the reactions of $OD^-.(D_2O)_n$ with HCN in a He buffer. T = 298 K, P = 0.337 Torr, $\bar{v}$ = 7.3 cm s^{-1}, L = 46 cm, and the flow of D_2O is approximately 3 × 10^{19} molecules s^{-1}.

[24] $CH_2NO_2^-.D_2O + CH_3NO_2 \rightarrow CH_2NO_2^-.CH_3NO_2 + D_2O$

[25] $CH_2NO_2^-.(D_2O)_2 + CH_3NO_2 \rightarrow CH_2NO_2^-.D_2O.CH_3NO_2 + D_2O$

kinetics of these processes in detail.

HCN

Figure 5 shows the influence of hydration on the reaction of the hydroxide ion with HCN observed under flowing afterglow conditions. The primary reactions which were observed may be interpreted in terms of eq. [26]. The ions $OD^-.(D_2O)_n$ were all observed to react very rapidly with HCN with rate constants

[26] $OD^-.(D_2O)_n + HCN \rightarrow CN^-.(D_2O)_m + (n - m)D_2O + HOD$

$\geq 3 \times 10^{-9}$ cm^3 $molecule^{-1}$ s^{-1}. Similar results were obtained with $OH^-.(H_2O)_n$ except for n = 2 in which case the decay of the ion was obscured by the rise in the secondary product ion $CN^-.HCN$. Product ions for reaction [26] were observed for m = 0, 1, and 2. There was no evidence for the formation of $CN^-.(D_2O)_3$ to match the initial $OD^-.(D_2O)_3$ signal. Apparently the fast reaction of this latter ion leads to the "boil-off" of at least one molecule of D_2O.

Both $CN^-.D_2O$ and $CN^-.(D_2O)_2$ were observed to undergo rapid secondary reactions involving the exchange of D_2O for HCN as indicated in reactions [27] to [29].

[27] $CN^-.D_2O + HCN \rightarrow CN^-.HCN + D_2O$

[28] $CN^-.(D_2O)_2 + HCN \rightarrow CN^-.D_2O.HCN + D_2O$

[29] $CN^-.D_2O.HCN + HCN \rightarrow CN^-.(HCN)_2 + D_2O$

Discussion

Previous measurements carried out in our laboratory have clearly established the intrinsic reactivity of the bare hydroxide ion in the gas phase towards a variety of oxygen and carbon acids (5). Here we have scrutinized changes in this reactivity as a function of step-wise hydration. The bare hydroxide ion is allowed to build up a hydration shell by successive additions of water molecules upstream in a flowing He or H_2 buffer gas at low total pressures (ca. 0.3 Torr). The resulting $OH^-.(H_2O)_n$ ions then participate in hydrated ion–molecule reactions with the added neutral as they enter the reaction region downstream. The hydrated product ions have an opportunity to establish solvated ions of higher stability by solvent exchange or solvent addition reactions. The overall reaction scheme initiated by acid–base reactions is summarized in Fig. 2.

The mode of reaction of OH^- with CO_2 and SO_2 was observed to change upon hydration from three-body association to a binary switching reaction. Both three-body association reactions are relatively fast as in both instances ions of high stability are formed: the reaction with CO_2 is likely to yield the covalently bonded bicarbonate ion, $OCO(OH)^-$, and the bisulfite ion, $OSO(OH)^-$, is likely to be formed in the reaction with SO_2. The binary switching or ligand exchange reactions with the hydrated hydroxide ions proceed close to the collision limit. The higher rate constants for SO_2 can be attributed to its permanent dipole moment and also SO_2 has a slightly higher polarizability than CO_2. Application of the average-dipole-orientation (ADO) theory (9, 10) to the collisions of $OH^-.(H_2O)_n$ with SO_2 and the Langevine theory (11) to the collisions of $OH^-.(H_2O)_n$ with CO_2 yields ratios of collision rate constants for SO_2 to CO_2 which are approximately equal to 2 for n = 1, 2, and 3. These ratios are in accord with the ratios of the reaction rate constants determined in this study.

The product distributions associated with each specific degree of hydration were not resolved in this study, but, as in the earlier results reported by Fehsenfeld and Ferguson (4), the recorded product spectra indicated a strong bias towards formation of unsolvated HCO_3^- and HSO_3^-, and more so in the latter case. The same reactions have recently been investigated in tandem mass spectrometry studies at collision energies less than 1 eV (CM) in which the ions with a specific degree of solvation were selected with a mass spectrometer before they were allowed to react (12). The results of these studies also indicated very little retention in the product ions of the water of hydration of the reactant ions. With the exception of the reaction of $OH^-.(H_2O)_3$ with CO_2 which produced primarily $HCO_3^-.H_2O$, the reactions of $OH^-.(H_2O)_{1,2,3}$ with CO_2 and SO_2 were observed to produce predominantly the unhydrated product ions HCO_3^- and HSO_3^-, respectively. It has been suggested that the excess energy available in these reactions is sufficient to cause the water of hydration to be "boiled-off" in the course of the reaction (4).

The reaction of hydroxide ions with CO_2 makes a significant contribution to the total rate of disappearance of CO_2 in aqueous solution at pH values above about 7.5, and above pH 10 it predominates (13). The analogous reaction with SO_2 apparently does not compete to a measurable degree with the normal hydration of SO_2 by H_2O which is 100 million times as rapid as that of CO_2 (14). Reaction [30] has a reported rate constant in aqueous solution at 25°C of 6.0 × 10^3 M^{-1} s^{-1} or 1.0 × 10^{-17}

[30] $OH^-(aq) + CO_2(aq) \rightarrow HCO_3^-(aq)$

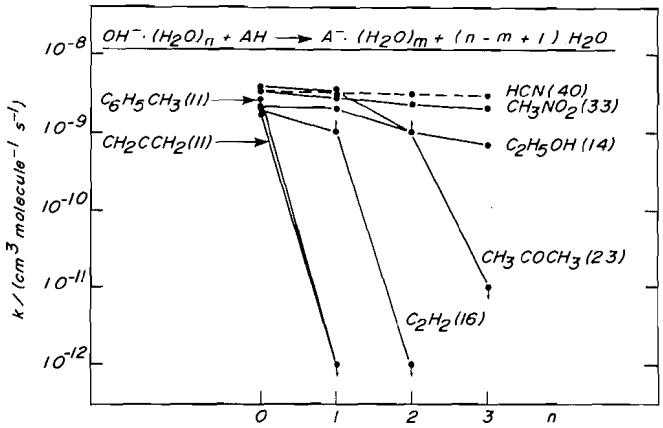

FIG. 6. Observed trends in the rate constants for reactions of hydrated hydroxide ions with acids, AH, as a function of step-wise hydration. The values indicated in parentheses correspond to the relative intrinsic acidities of the acids AH and H_2O, i.e. $-\Delta G^0$ (in kcal mol^{-1}) for the unhydrated reactions at 298 K.

cm^3 $molecule^{-1}$ s^{-1} with an apparent Arrhenius activation energy of 13.25 kcal mol^{-1} (15). This is in contrast with the observations for reaction [5] between hydrated hydroxide ions, $OH^-.(H_2O)_n$, and CO_2 in the gas phase which indicate reaction on essentially every collision.

The rate constants measured in this study for the reactions of hydrated hydroxide ions with acids, AH, are presented graphically in Fig. 6. As this figure clearly illustrates, hydration of the highly reactive bare hydroxide ion results in either a slight or a precipitous reduction in the specific rate of reaction, the latter occurring after the addition of three, two, or even just one molecule of water. The following examination of the overall energetics of these reactions suggests that these trends in reactivity with degree of hydration are thermodynamically rather than kinetically controlled.

The intrinsic exoergicities of the acid–base reactions investigated in this study span a range from 11 to 40 kcal mol^{-1}. The differences in gas-phase acidity indicated in Fig. 6 represent average values derived from the absolute gas-phase acidities based on pulsed-ICR (16) and flowing afterglow measurements (7, 17, 18). Hydration of the hydroxide ion acts to decrease the reaction exoergicity and can render the reaction endoergic unless it is offset by the hydration energy of the conjugate base that is produced (and the hydration energy of possible hydrated neutral products). The standard enthalpies and free energies of hydration for $OH^-.(H_2O)_n$ are available from gas-phase measurements (they are reported here as positive quantities and so refer to the removal of water molecule from the hydrated ion): they are 25, 16.4, 15 and 19, 10, and 7.5 kcal mol^{-1}, for n = 1, 2, and 3, respectively (19). In contrast, the hydration energies of the conjugate bases produced in the reactions which were investigated are generally not known. Values of 13.8 and 7.9 kcal mol^{-1} are available for the standard enthalpy and free energy of hydration of CN^- with one water molecule (19). Also a calculated value of 18 kcal mol^{-1} is available for the binding energy (ΔE) of $C_2H^-.H_2O$ (20) which allows us to estimate the overall energetics for the reaction of $OH^-.H_2O$ with C_2H_2. But because of the sparsity of energies of hydration, we can only surmise the thermodynamic situation for the majority of the reactions investigated.

Allene and toluene are the acids closest in intrinsic acidity to that of water. The carbanions produced by their deprotonation appear to have energies of hydration insufficient to compensate for the high hydration energy of OH^- in spite of the intrinsic exoergicity of 11 kcal mol^{-1}. The weak hydration of carbanions is not unexpected (21). Our results suggest a standard free energy of hydration for $C_6H_5CH_2^-$ and $C_3H_3^-$ of less than 8 kcal mol^{-1}. The sharp drop by more than three orders of magnitude in the specific rate for deprotonation observed with the addition of just one molecule of water is therefore a manifestation of an immediate reversal in the relative acidity of these two carbon acids and water.

A similar reversal in relative acidity is apparent with acetylene but in this case two molecules of water are required to drive the proton transfer endoergic. The unhydrated reaction is exoergic by 16 kcal mol^{-1} which alone is almost enough to compensate for the free energy of hydration of OH^- and thus to render exoergic the formation of unhydrated C_2H^-. Transformation of the calculated energy of hydration, ΔE = 18 kcal mol^{-1}, into an enthalpy of hydration (20) and correction for the entropy change for the association of H_2O to C_2H^- estimated to be -20 cal mol^{-1} deg^{-1} (19) yields an estimated standard free energy of hydration for C_2H^- of 9 kcal mol^{-1}. Reaction [31] is thus estimated to be exoergic by 6 kcal mol^{-1}. This is in

[31] $OH^-.H_2O + C_2H_2 \rightleftharpoons C_2H^-.H_2O + H_2O$

reasonable accord with the value of 4 kcal mol^{-1} which may be derived from the measured ratio of rate constants of 8×10^2 obtained in this study for the similar reaction with heavy water and neglecting isotope effects. An average value of 5 kcal mol^{-1} for the exoergicity of reaction [31] yields an upper limit of 5 kcal mol^{-1} for the standard free energy for removal of H_2O from $C_2H^-.(H_2O)_2$ if the failure to observe a reaction between $OH^-.(H_2O)_2$ and C_2H_2 is attributed to endoergicity.

Figure 6 suggests that a reversal in relative acidity also occurs with acetone, delayed in this case until the addition of at least three water molecules to OH^-. This result is consistent with the early observations of a relative acidity for acetone and water in the gas-phase which is reverse to that observed in aqueous solution (22), and with a rate constant of only 4.5×10^{-22} cm^3 $molecule^{-1}$ s^{-1} reported for the reaction of hydroxide ions with acetone in aqueous solution (23).

No reversals in relative acidity were observed with ethanol, nitromethane, and hydrogen cyanide. Ethanol is an oxygen acid whose conjugate base is expected to be strongly hydrated. This accounts for the continued high reactivity of the hydrated hydroxide ions towards ethanol in contrast to the falloff in reactivity observed for the reactions with acetylene and acetone which are intrinsically more exoergic. Nitromethane and hydrogen cyanide are intrinsically the strongest of the acids investigated. The intrinsic exoergicities of the proton-transfer reactions with these two acids are extremely high allowing for almost total "boil-off" of the water of hydration up to n = 3: reaction [23] is exoergic for m down to $n - 2$ and reaction [26] is exoergic for m = 0, viz. no retention of water. Thus, while the order of acidity between H_2O and ethanol is preserved primarily by the strong hydration of $C_2H_5O^-$, the order between H_2O and both HCN and CH_3NO_2, whose conjugate bases are expected to be more weakly hydrated, is preserved largely as a result of the much higher intrinsic exoergicities. Again these results are consistent with rate measurements made in solution and with known solution acidities. For example, the reaction between hydroxide ions and HCN is extremely rapid in aqueous solution proceeding at close to the diffusion limit, $k = 6 \times 10^{-12}$ cm^3 $molecule^{-1}$ s^{-1} (23).

We have recently reported a parallel study of the gas-phase

reactivity of methoxide ions solvated with methanol towards the same acids used in the present experiments (7). There is good correlation with the observations and interpretations reported here and, taken together, the studies of these two systems have provided new insight into the transition in the kinetics of acid–base reactions between the gas-phase and solution (24).

ERWIN BUNCEL, RICHARD A. RENFROW, and MICHAEL J. STRAUSS. Can. J. Chem. **61**, 1690 (1983).

Reaction between the title compound **2** and 2,6-dimethylaniline, or *N*,*N*-dimethylaniline, gives rise to spectrally observable Meisenheimer type σ-complexes in which bonding has occurred between the *para* carbon of the aromatic amine and the benzotriazole moiety of **2**; however, aniline reacts at the picryl moiety to give the product of displacement **5**, via the aniline nitrogen as the nucleophilic atom.

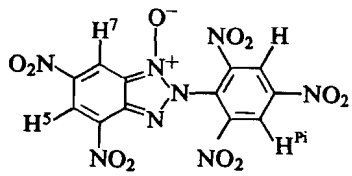
ERWIN BUNCEL, RICHARD A. RENFROW et MICHAEL J. STRAUSS. Can. J. Chem. **61**, 1690 (1983).

La réaction du composé **2** avec la diméthyl-2,6 aniline ou la *N*,*N*-diméthylaniline conduit à des complexes σ du type Meisenheimer que l'on peut observer par spectroscopie et dans lesquels la liaison s'établit entre le carbone en position *para* de l'amine aromatique et la portion benzotriazole du composé **2**. Cependant, l'aniline réagit au niveau de la portion picryle en donnant le produit de déplacement **5** par l'intermédiaire de l'azote de l'aniline qui joue le rôle de nucléophile.

[Traduit par le journal]

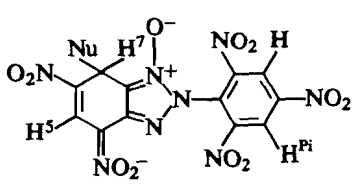
Electron-deficient nitroaromatics such as 1,3,5-trinitrobenzene (TNB) are known to interreact with a variety of nucleophilic reagents to give Meisenheimer type σ-complexes, a number of which have been fully characterized (1). Extension of the studies to heterocyclic systems such as the nitrobenzofuroxan derivatives has been of interest in part because of the known antileukemic and immunosuppressive activities of these compounds, which have been considered to result from σ-complex formation by intracellular thiol and amino functions of aminoacids and proteins (2). Recent studies have shown that the nitrobenzofuroxans form highly stable σ-complexes with a number of nucleophiles (3) and 4,6-dinitrobenzofuroxan (**1**) has thus been termed a super-electrophile.

1

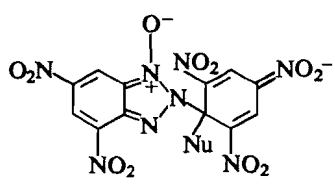


2

We have recently prepared the title compound **2** with a view of examining its reactivity towards nucleophiles, in comparison with 4,6-dinitrobenzofuroxan as well as conventional electrophiles such as TNB. Interestingly, we found (4) that attack by several nucleophiles occurs at both the benzotriazole and the picryl ring moieties, the former process giving rise to spectrally observable σ-complexes **3**, the latter to displacement products (PicNu) via the intermediate adducts **4**.



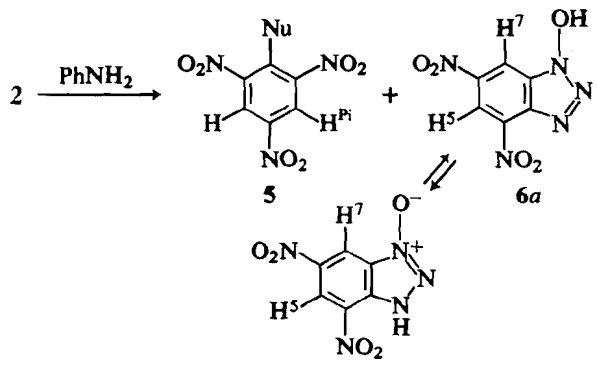
3



4

We have now extended the study to aromatic amines and have observed both these modes of reactivity. However, an unexpected regioselectivity has been observed in the reaction of aniline as compared to 2,6-dimethylaniline or *N*,*N*-dimethylaniline, the former undergoing attack only at the picryl ring and the latter two only at the benzotriazole moiety. Moreover, the σ-complexes formed with the latter two amines are not nitrogen-bound but are the carbon-bound species. The ambident behaviour of aromatic amines observed in this system is reminiscent of the first report on ambident reactivity in σ-complex formation, in the reaction of phenoxide ion with TNB (5).

Reaction of **2** with one equivalent of aniline in $(CD_3)_2SO$ as followed by ^1H nmr spectroscopy was found to result in the rapid disappearance of the resonances due to **2** (δ: 9.78 (s, 2H, H^{Pi}), 9.72 (d, 1H, J = 2.5 Hz, H^5), 9.36 (d, 1H, J = 2.5 Hz, H^7)) and the appearance of signals characteristic of the substitution product **5** (Nu = PhNH) (δ: 9.20 (s, 2H, H^{Pi}), 7.40 (m, 5H, ArH)), as well as **6***a* or **6***b* (δ: 9.36 (d, 1H, J = 2.5 Hz, H^5), 9.15 (d, 1H, J = 2.5 Hz, H^7)), as formed according to the equation:



5 **6***a* **6***b*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12

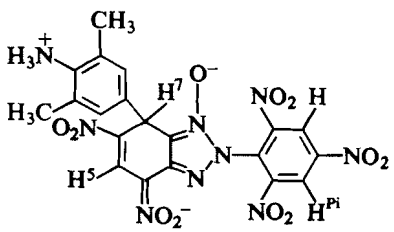
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

Use of two equivalents of aniline gave rise to **5** and the anion of **6** (δ: 9.13 (d, 1H, J = 2.5 Hz, H^5), 9.05 (d, 1H, J = 2.5 Hz, H^7)). The anion is converted into its protonated form on addition of trifluoroacetic acid.

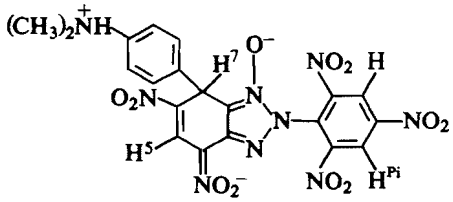
The observed overall preference for attack by aniline at the picryl moiety over the benzotriazole moiety is presumably the result of a combination of a facile formation of adduct **4** (Nu = PhNH) and its subsequent rapid irreversible decomposition. In comparison, nucleophilic addition at the benzotriazole moiety to give **3** could be expected to be kinetically and thermodynamically disfavored, judging by the results of our previous work on the interaction of aniline with TNB (6).

It seemed possible that attack at the picryl centre of **2** could be disfavored through structural modification in the aromatic amine, leading to unfavorable steric interactions in the process. A plausible candidate in this context appeared to be 2,6-dimethylaniline, since with this amine the transition state in formation of **4** would experience severe buttressing interactions between the methyl groups and the *ortho* nitro groups of the picryl moiety as well as the NO_2 group at C4 of the benzotriazole moiety. This expectation was borne out, at least in part, by the results.

Thus the addition of one equivalent of 2,6-dimethylaniline to a solution of **2** in $(CD_3)_2SO$ gave rise to a strongly coloured solution indicative of the formation of a σ-complex. However, the nmr characteristics of the species produced show that bonding has occurred not via nitrogen but via the *para* carbon of the aniline moiety. Thus the disappearance of the resonances due to **2** on addition of the amine corresponded to the appearance of signals characteristic of **7**, i.e. δ: 9.49 (s, 2H, H^{Pi}), 9.00 (s, 1H, H^5), 5.59 (s, 1H, H^7), 7.23 (s, 2H, ArH), 2.35 (s, 6H, CH_3). The conversion to **7** was rapid and complete.



7



8

The facile formation of the carbon-bonded adduct **7** suggested the possibility that *N*,*N*-dimethylaniline might react likewise to yield **8** and the results showed this to be the case. The identity of **8** was shown by the following nmr characteristics of the species as formed in $(CD_3)_2SO$ solution: δ: 9.48 (s, 2H, H^{Pi}), 9.00 (s, 1H, H^5), 5.70 (s, 1H, H^7), 7.61 (s, 4H, ArH), 3.19 (s, 6H, CH_3). The formation of **8** as a spectrally observable species represents the first recorded case of a Meisenheimer complex formed by the tertiary amine and is also, to our knowledge, one of very few examples of the formation of zwitterionic Meisenheimer complexes.

Thus the present work has revealed a marked contrast in the reactivity of the title compound **2** versus the reactivity of TNB as the standard electrophile in Meisenheimer complex formation. TNB does not react with *N*,*N*-dimethylaniline at all and it interacts with aniline so weakly that there is a requirement for catalysis by a tertiary amine which serves to deprotonate the initially formed zwitterionic N-bound adduct, thereby stabilizing the anionic anilide σ-complex (7). Formation of the stable zwitterionic carbon-bound σ-complexes **7** and **8** from the interaction of the aromatic amines with **2** is definitive of the powerful electrophilic properties of this novel heterocyclic system.

Energy transfer by an exchange mechanism in fluid solutions. A generalized treatment

J. M. G. MARTINHO AND J. C. CONTE

Centro de Química-Física Molecular, Complexo I, Instituto Superior Técnico, Av. Rovisco Pais, 1000 Lisboa, Portugal

Received August 16, 1982[1]

J. M. G. MARTINHO and J. C. CONTE. Can. J. Chem. **61**, 1693 (1983).

Energy transfer in solution by an exchange mechanism has been analysed. The diffusion equation with an added sink term describing the energy transfer process was solved for steady-state conditions using the radiation boundary condition. The transfer rate constant so obtained takes into account the possibility that the reaction does not occur during an encounter. In the limit the equations contain the cases of totally absorbing and totally reflecting barriers. The short range effects were analysed and their influence was introduced under new boundary conditions.

J. M. G. MARTINHO et J. C. CONTE. Can. J. Chem. **61**, 1693 (1983).

On a analysé le transfert d'énergie en solution selon un mécanisme d'échange. En utilisant la condition limite de radiation, on a résolu l'équation de diffusion qui décrit le transfert d'énergie dans l'état stationnaire en incluant dans cette équation un terme d'affaiblissement. La constante de vitesse ainsi obtenue tient compte de la possibilité de non réaction lors de la rencontre. A la limite l'équation contient les cas de barrières totalement absorbées et totalement réfléchies. On a analysé les effets à courte distance et on a introduit leur influence en deça des conditions de frontière nouvelle.

1. Introduction

The transfer of electronic energy between an energy donor (D) and an energy acceptor (A) takes place essentially by one of the two mechanisms: Coulomb interaction (1, 2) and exchange interaction (2). When the electronic transitions of the donor and acceptor are allowed (e.g. singlet–singlet transfer) the transfer is usually of the first type. For spin forbidden transitions (e.g. triplet–triplet transfer) the mechanism of transfer is of the exchange type. In this case, discussed by Dexter (2), the transfer probability per unit time, $w(r)$, depends exponentially on the relative distance between the donor and the acceptor. The same exponential dependence on distance is found in the study of electron transfer reactions (3).

Formerly studied in rigid systems (4), this transfer has also been the subject of study in solutions (5, 6). It has been shown that the transfer rate constant depends on the energy difference between the donor and the acceptor triplet states. For energy transfer processes, where this difference is lower than 5 kcal mol^{-1}, the back transfer process must also be considered (7).

However, even for the cases where the back transfer is unimportant, the values obtained for the transfer rate constant in fluid solutions are lower than those predicted by the theory of diffusion controlled reactions (8). Wagner and Kochevar (9) have shown that the diffusion controlled limit is only reached for viscosities greater than 3 cP. There is evidence (10, 11) that for high viscosities the rate constant is greater than the diffusion limit.

In this paper the diffusion equation for steady state conditions is solved with a sink term describing the energy transfer processes. We use adequate boundary conditions that take into account short range effects and also the possibility that the reaction does not occur during an encounter.

2. Energy transfer in solution

Let us assume, following Dexter (2), that the probability of transfer per unit time between an energy donor and an acceptor at a distance r is given by

$$[1] \quad w(r) = A \exp\left(-\frac{2r}{L}\right)$$

where A (s^{-1}) is a constant depending on the properties of the donor–acceptor pair and L is the mean effective Bohr radius of the pair.

Following the excitation of the solution with a δ-pulse of electromagnetic radiation, the excited donor molecules (concentration c_D^*) are able to transfer their energy to the acceptor molecules (concentration c_A) with probability $w(r)$. Using a statistical analysis developed by Waite (12) for the study of partially diffusion controlled reactions, Gösele and co-workers (13, 14) obtained, for the normalized distribution function of the pairs D_i–A_j, the following equation

$$[2] \quad \frac{\partial}{\partial t} U_{ij} = D \Delta U_{ij} - w(r) U_{ij}$$

where D is the sum of the diffusion coefficients of the donor and the acceptor. For a process with spherical symmetry, the rate constant for the energy transfer process is given by

$$[3] \quad k(t) = 4\pi D R_c^2 \left(\frac{\partial U_{ij}}{\partial r}\right)_{r=R_c} + \int_{r=R_c}^{\infty} w(r) U_{ij} 4\pi r^2 \, dr$$

where the first term gives the component of the transfer at the encounter distance R_c, and the second term gives the component of the transfer due to exchange interactions for distances greater than R_c.

In this approach the short-range caging effects are not considered. These effects were studied by Northrup and Hynes (15), for the partially diffusion controlled reactions under steady-state conditions. These authors considered that the diffusion equation should be modified to include the effect of the mean potential $u(r)$ of a pair of reacting molecules and also the dependence of the diffusion coefficient on the separation of reacting molecules which is due to dynamical correlations.

We will consider first the standard diffusion eq. [2] and we will return to this problem later.

For excitation by means of radiation from a conventional source it is reasonable to assume a uniform distribution of donor and acceptor molecules. Then all U_{ij} are identical and we have the boundary condition

$$[4] \quad U(r, t = 0) = 1 \qquad r > R_c$$

We need another boundary condition at the encounter distance. The so-called Smoluchowski's boundary condition (16)

[1]Revision received February 8, 1983.

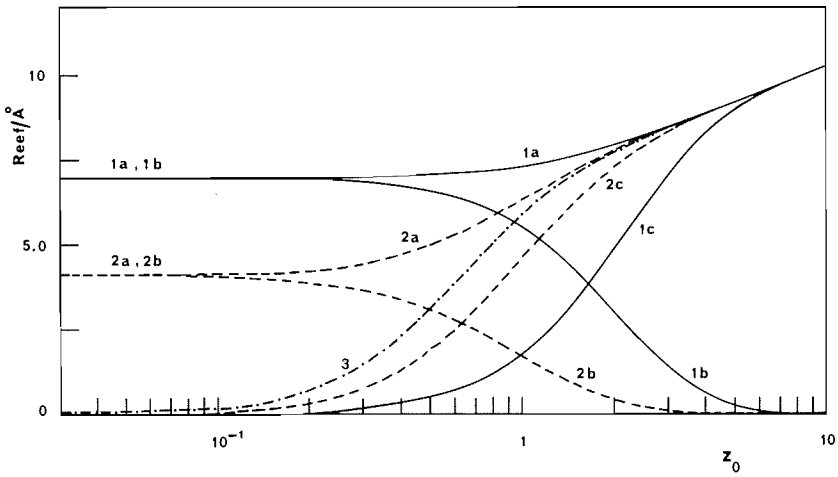

FIG. 1. Variation of the transfer effective distance, R_{eef} with z_0, for L = 1.5 Å, R_c = 7.0 Å, and different values of β: 1, β = 1.0 × 10^{15} cm^{-1}; 2, β = 2.0 × 10^7 cm^{-1}; 3, β = 0 cm^{-1}; a, R_{eef} according to eq. [15]; b, R''_{eef} according to eq. [16]; c, R'_{eef} according to eq. [17].

[5] $U(r = R_c, t) = 0$

has been used quite often, implying that the probability of reaction at the encounter distance, R_c, is unity. However, this probability, γ, depends on the rate constant for the reaction at the encounter, k_{te}, and on the rate constant for the dissociation of the pair, k_{-D}, according to the relationship

[6] $$\gamma = \frac{k_{te}}{k_{te} + k_{-D}}$$

For solvents of low viscosity (η ≈ 1 cP) k_{-D} is of the order of 10^{11} s^{-1} and k_{te} is usually lower. Then γ is less than one and so it is necessary to reconsider the use of boundary conditions (5). If we assume that the probability of reaction of the pairs at the encounter distance is proportional to the probability that they lie in a thin spherical shell of thickness ΔR, we obtain the so-called radiation boundary condition (12, 17, 18)

[7] $$4\pi D(R_c + \Delta R)^2 \left(\frac{\partial U}{\partial r}\right)_{r = R_c + \Delta R} = k_c U(R_c, t),\ \Delta R \to 0$$

where $k_c = 4\pi R_c^2\, \Delta R\, K$ represents a specific rate constant for the pair disappearance in the spherical shell due to a collision process with rate constant K (s^{-1}).

Equation [2] with conditions [4] and [7] has no analytical solution. However, it is possible to obtain a solution for long times, where the steady-state approximation ($\partial U/\partial t = 0$) is valid. If we make the substitutions

[8] $v = Ur$

[9] $$z^2 = \frac{AL^2}{D} \exp\left(-\frac{2r}{L}\right)$$

we obtain from [2] the Bessel equation

[10] $$z^2 \frac{d^2v}{dz^2} + z \frac{dv}{dz} - z^2 v = 0$$

which gives, under conditions [4], [7], and $U(r \to \infty, t) = 1$

[11] $$U(z) = \frac{L}{r}\left\{K_0(z) - \frac{L(1 + \beta R_c)K_0(z_0) - z_0 R_c K_1(z_0)}{L(1 + \beta R_c)I_0(z_0) + z_0 R_c I_1(z_0)} I_0(z)\right\}$$

where

[12] $$z_0^2 = \frac{AL^2}{D} \exp\left(-2\frac{R_c}{L}\right)$$

is the value of z for the encounter distance R_c, $K_\nu(z)$ and $I_\nu(z)$ are the modified Bessel functions of second and first kind, respectively, of order ν and argument z, and

[13] $$\beta = \frac{k_c}{4\pi D R_c^2}$$

is a parameter which takes into account the fact that the probability of reactions at the encounter may be less than one.

The rate constant can be obtained by substitution of eq. [11] into eq. [3]. However, we can obtain a more adequate form for $k(t)$ applying Gauss's theorem to eq. [3], and then

[14] $$k(t) = 4\pi D \lim_{r \to \infty}\left(r^2 \frac{\partial U}{\partial r}\right) - \int_{R_c}^{\infty} \frac{\partial U}{\partial t} 4\pi r^2\, dr$$

from which we get the rate constant for long times

[15] $$k_\infty = k(t \to \infty) = 4\pi D R_c \left\{1 + \frac{L}{R_c}\left[E + \ln\left(\frac{z_0}{2}\right) + \frac{L(1 + \beta R_c)K_0(z_0) - z_0 R_c K_1(z_0)}{L(1 + \beta R_c)I_0(z_0) + z_0 R_c I_1(z_0)}\right]\right\}$$

where E is Euler's constant (E = 0.57721 . . .).

The rate constant k_∞ is the sum of two terms (see eq. [3]). The first, k_D, is the component for the encounter distance and, due to the boundary condition used (see eq. [7]), is given by

[16] $$k_D = k_c U(z_0) = 4\pi D R_c \frac{L\beta R_c}{L(1 + \beta R_c)I_0(z_0) + z_0 R_c I_1(z_0)}$$

The second, k_E, takes into account the transfer processes for distances greater than R_c, and is given by

[17] $$k_E = 4\pi D R_c \left\{1 + \frac{L}{R_c}\left[E + \ln\left(\frac{z_0}{2}\right) + \frac{L(1 + \beta R_c)K_0(z_0) - z_0 R_c K_1(z_0) - \beta R_c^2}{L(1 + \beta R_c)I_0(z_0) + z_0 R_c I_1(z_0)}\right]\right\}$$

Figure 1 shows the values of the effective distance for the transfer

$$R_{eef} = \frac{k_\infty}{4\pi D}$$

as a function of z_0 for different values of β and $R_c = 7$ Å. The contributions for the encounter distance R_{ecf}^{D} and greater distances R_{ecf}^{k} are also presented in the figure. Three different regions can be seen: for high values of the diffusion coefficient ($z_0 < 0.1$), all the transfer processes take place at the encounter and the rate constant is given by

$$[18] \quad k_\infty \simeq 4\pi D R_c \frac{\beta R_c}{1 + \beta R_c}$$

Then, taking eq. [13] into account one obtains

$$[19] \quad \frac{1}{k_\infty} = \frac{1}{k_c} + \frac{1}{4\pi D R_c}$$

It is thus possible to obtain k_c as well as the encounter distance R_c. The value of k_c is the value of the rate constant for very large diffusion coefficients and so it will approach the value obtained in the vapour phase.

For small values of the diffusion coefficients ($z_0 > 5$), almost all of the transfer processes occur at distances greater than R_c and

$$[20] \quad k_\infty = 2\pi D L \left[2E + \ln\left(\frac{AL^2}{4D}\right)\right]$$

For intermediate values of $z_0 (0.1 < z_0 < 5)$ both transfer processes are important and k_∞ must be evaluated from eq. [15].

The present analysis shows that, as indicated in the introduction, R_{ecf} values depend on the diffusion coefficient and may be greater or less than R_c. For an instantaneous reaction at the encounter and large diffusion coefficients ($z_0 \ll 1$) the effective distance is given by R_c.

Some results published by André *et al.* (10) show that the effective distance can be greater than R_c, as with the quenching of POPOP by CBr_4 in mixtures of cyclohexane and cyclohexanol. In other systems (19), however, the authors found for the effective distance the actual R_c value. This difference was interpreted (19) as being due to short range effects which are analysed below.

2.1. *The effect of transient terms*

The relationships considered so far are valid for times large enough so that the steady-state approximation can be considered a reasonable approximation. Butler *et al.* (20) have shown that the steady state is reached for $t_\infty \gg R_{ecf}^2/\pi D$. For shorter times, a time dependent equation of the form

$$[21] \quad k(t) = 4\pi D R_{ecf}\left[1 + \frac{R_{ecf}}{\sqrt{\pi D t}}\right]$$

already obtained in the study of diffusion controlled reactions, must be a good approximation. Butler *et al.* (20) have shown, from numerical integration of eq. [2] with Smoluchowski's boundary condition, that this is true for values of $t > 10L^2/4D$. For short times, $t < L^2/4D$, they have shown that material diffusion can be neglected and then the theoretical treatment developed by Inokuti and Hirayama (21) should be adequate. Recently Allinger and Blumen (22) have studied the effect of material diffusion on the energy transfer by an exchange mechanism and obtained for the decay function a complex equation that certainly is a good approximation for values of $t < 10L^2/4D$.

The theoretical equations presented in the literature cover all times following excitation. Now there is a need for experimental decay studies to test these theoretical results.

2.2. *Influence of short range effects*

In the preceding sections we neglected the presence of short range effects. These effects, which must include cage effects, orientational and steric effects, are important but very complex to treat, mainly because our knowledge of the structure of liquids is limited. Then, to take these effects into account, we use a simplified model that was proposed by André *et al.* (23) to treat the partially diffusion controlled reactions. We assume that short range effects can be isolated in a spherical shell of thickness $\Delta R = R' - R_c$, where there is no diffusion and the transfer occurs with a rate constant K' (s^{-1}) independent of distance. In the outer region ($r > R'$) the system is well described by eq. [2]. Then we must use the boundary condition (23)

$$[22] \quad 4\pi D R'^2 \left(\frac{\partial U}{\partial r}\right)_{r=R'} = K' V_1 U(R', t) + V_1 \left(\frac{\partial U}{\partial t}\right)_{r=R'}$$

where $V_1 = 4/3\ \pi (R'^3 - R_c^3)$ is the volume of the spherical shell.

The rate constant is given by

$$[23] \quad k(t) = \int_{R_c}^{R'} K'\ U(R', t)\ 4\pi r^2\, dr + \int_{R'}^{\infty} w(r)\ U(r, t)\ 4\pi r^2\, dr$$

$$= 4\pi D R'^2 \left(\frac{\partial U}{\partial r}\right)_{r=R'} - V_1 \left(\frac{\partial U}{\partial t}\right)_{r=R'} + \int_{R'}^{\infty} w(r)\ U(r, t)\ 4\pi r^2\, dr$$

which can be put in the form

$$[24] \quad k(t) = 4\pi D \lim_{r\to\infty}\left(r^2 \frac{\partial U}{\partial r}\right) - V_1 \left|\frac{\partial U}{\partial t}\right|_{r=R'} - \int_{R'}^{\infty} \frac{\partial U}{\partial t} 4\pi r^2\, dr$$

For steady-state conditions, the last two terms in eq. [24] are zero and then we obtain, by solving eq. [2], the rate constant

$$[25] \quad k'_\infty = 4\pi D R' \left\{1 + \frac{L}{R'}\left[E + \ln\left(\frac{z'_0}{2}\right) + \frac{L(1 + \beta' R') k_0(z'_0) - z'_0 R' k_1(z'_0)}{L(1 + \beta' R') I_0(z'_0) - z'_0 R' I_1(z'_0)}\right]\right\}$$

which is identical to eq. [15], if we replace R_c by R', z_0 by z'_0 (which is the value of z for R'), and β by $\beta' = K' V_1/4\pi D R'^2$.

For high viscosities ($z'_0 \gg 1$) this equation reduces to eq. [20] that predicts a linear variation of R_{ecf} with $(-\ln D)$. For low viscosities ($z'_0 \ll 1$) we get an equation similar to eq. [19] with $|k_c| = K' V_1$ and a value R' in place of R_c. This is in accordance with the results presented by Butler and Pilling (11) and André *et al.* (10).

2.3. *Theoretical decay curves and quantum yields*

The decay curves of the donor in the presence of the acceptor must contain three terms: a term describing the decay due to radiative and non-radiative processes of the donor in the absence of the acceptor, a second term due to the "static" energy transfer process in the shell, and a dynamic term describing the energy transfer process in the outer region ($r > R'$). Due to the static term the concentration of donor molecules at $t = 0$ is given by $c_D^*(0) \exp(-N V'_1 c_A)$, where $c_D^*(0)$ is the concentration

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

of the initially excited molecules, N is Avogadro's number, and V_1' is a reacting volume which is related to the volume of the shell and also to the rate constant k_c'. If there is an instantaneous reaction in the shell ($k_c' \rightarrow \infty$) then V_1' is reduced (23, 24) to the shell volume V_1. The dynamic process is described for sufficiently long times by the rate constant

$$[26] \quad k(t) = 4\pi DNR_{ref}\left[1 + \frac{R_{ref}}{\sqrt{\pi Dt}}\right]$$

The decay function, after a δ-pulse of excitation, is then given by

$$[27] \quad c_D^*(t) = c_D^*(0)\exp(-NV_1'c_A)\exp\left[-\frac{t}{\tau_0} - k_0c_At\left(1 + \frac{2R_{ref}}{\sqrt{\pi Dt}}\right)\right]$$

with $k_0 = 4\pi DN\,R_{ref}$, and τ_0 the decay time of the donor in the absence of the acceptor. The quantum yield is given by (23)

$$[28] \quad \Phi_D \simeq \Phi_D^0 \times \frac{I(\lambda)\exp(-NV_1'c_A)}{1 + k_0\tau_0c_A}$$

where Φ_D^0 is the quantum yield of the donor in the absence of the acceptor and

$$[29] \quad \lambda = \frac{2}{\pi^{1/2}}\frac{k_0\tau_0c_A}{(1 + k_0\tau_0c_A)^{1/2}}\frac{R_{ref}}{(D\tau_0)^{1/2}}$$

with

$$[30] \quad I(\lambda) = 1 - \frac{1}{2}\lambda\pi^{1/2}\exp\left(\frac{\lambda^2}{4}\right)\operatorname{erfc}\left(\frac{\lambda}{2}\right)$$

From the experimental decay curves we can obtain the effective distance R_{ref}, and the diffusion coefficient D. The effective distance can be compared with the theoretical values predicted by eqs. [15] and [25] and hence it is possible to obtain some information about the presence or absence of short range effects. From the quantum yields we can confirm the results obtained from the decay curves and also obtain the reacting volume V_1'.

3. Conclusions

The present work is a general treatment for the energy transfer processes in solution by an exchange mechanism, which incorporates as particular cases some other treatments.

In the continuous limit eq. [15] is reduced for large values of β ($\beta R_c \gg 1$) to the case of a totally absorbing barrier, which is the result already obtained by Pilling and Rice (25), i.e.,

$$[31] \quad k_\infty = 4\pi DR_c\left\{1 + \frac{L}{R_c}\left[E + \ln\left(\frac{z_0}{2}\right) + \frac{k_0(z_0)}{I_0(z_0)}\right]\right\}$$

For fast diffusing, the rate constant obtained by Allinger and Blumen (22)

$$[32] \quad k_\infty = \int_{R_c}^{\infty} 4\pi r^2 A\exp\left(-\frac{2r}{L}\right)dr = \pi AL\exp\left(-\frac{2R_c}{L}\right)[2R_c^2 + 2LR_c + L^2]$$

is easily obtained from eq. [15] if we let $z_0 \rightarrow 0$ (large values of D) for the case of a totally reflecting barrier ($\beta = 0$).

From eq. [25] we can obtain, if we neglect the energy transfer processes for $r > R'$, the results obtained by André *et al.* (23) for steady-state conditions.

The treatment developed does not take into account the possibility of back transfer. This transfer is important for low exothermic processes and complicates the analysis. A theoretical treatment recently presented by Balzani *et al.* (26) explains reasonably well the known experimental results obtained in fluid solutions.

Received October 20, 1982

CARLOS GONZALEZ, ROBERT GREENHOUSE, RAMON TALLABS, and JOSEPH M. MUCHOWSKI. Can. J. Chem. **61**, 1697 (1983).

The 2-chloroethyl and 2-phenylsulfonylethyl moieties are versatile protecting groups for the pyrrole nitrogen atom. The 2-chloroethyl group is easily attached under phase transfer conditions using 1,2-dichloroethane. The 2-phenylsulfonylethyl moiety is readily appended under both phase transfer and homogeneous solution conditions using 2-phenylsulfonylethyl chloride **5**. Deprotection of the *N*-(2-chloroethyl)pyrroles is accomplished by means of efficient three-step, one-pot sequences via the *N*-vinyl compounds **3** and subsequent degradation of the *N*-(1-hydroxyethyl) compounds **4** or the acetoxymercuration derivatives **5** obtained therefrom. The 2-phenylsulfonylethyl group is excised by a reverse Michael reaction using sodium hydride or DBN as the base.

The utility of the 2-chloroethyl protecting group is exemplified in a synthesis of benzyl cyclopenta[*b*]pyrrole-5-carboxylate **13** from 1-(2-chloroethyl)-4-oxotetrahydroindole **2***d*.

CARLOS GONZALEZ, ROBERT GREENHOUSE, RAMON TALLABS et JOSEPH M. MUCHOWSKI. Can. J. Chem. **61**, 1697 (1983).

Les unités chloro-2 ethyle et phénylsulfonyl-2 éthyle sont des groupes protecteurs versatiles pour l'atome d'azote du pyrrole. On attache facilement le groupe chloro-2 éthyle, dans des conditions de transfert de phase, en utilisant de dichloro-1,2 éthane. On fixe rapidement le groupe phénylsulfonyl-2 éthyle dans des conditions de transfert de phase et en solution homogène en utilisant le chlorure de phénylsulfonyl-2 éthyle **5**. On réalise la déprotection des *N*-(chloro-2 éthyle)pyrroles en trois étapes efficaces dans un seul récipient par l'intermédiaire des composés *N*-vinyliques **3** et de la dégradation subséquente des composés *N*-(hydroxy-1 éthyl) **4** ou des dérivés d'acétoxymercuriation du composé **5**. On élimine le groupe phénylsulfonyl-2 éthyle au moyen d'une réaction de Michael inverse en utilisant l'hydrure de sodium ou le DBN comme base.

On démontre l'utilité du groupe protecteur chloro-2 éthyle en synthétisant, pour les besoins du laboratoire, le carboxylate-5 de benzyleyclopenta[*b*]pyrrole **13** à partir du (chloro-2 éthyle)-1 oxo-4 tétrahydroindole **2***d*.

[Traduit par le journal]

In connection with synthetic studies in progress in these laboratories, it became necessary to develop general methodology for the protection of the pyrrole nitrogen atom. This need arose because the protecting groups currently in use are either of limited applicability or the general utility thereof is unknown. For example, the benzyl group has been used as a pyrrole N-protector on several occasions (1) but sodium in liquid ammonia is required to remove it and many functional groups would not survive these conditions. The 3,4-dimethoxybenzyl moiety, scission of which is effected with 5% sulfuric acid in trifluoroacetic acid containing excess anisole, is reported (2) to be useful for the N-protection of certain polysubstituted pyrroles, but no further examples of the application of this group have been published. The benzyloxymethyl moiety (3) has considerable potential for pyrrole N-protection. It is easily attached (benzyl chloromethyl ether/NaH) and removed (hydrogenolysis, then aqueous base), however, its applicability has only been demonstrated for diethyl pyrrole-3,4-dicarboxylate.[3] The β-(methoxyethoxy)-methyl group is said (1*c*) to serve as an N-protector, but the removal thereof has not been described. Various acyl residues, such as acetyl (1*b*), benzoyl (1*b*), and benzenesulfonyl (1*b*, 4) have been employed to block position-1 in pyrroles, however, these electron-withdrawing entities drastically alter the nucleophilic character of the heterocyclic ring system. Finally, it has recently been shown (5) that the readily removable (chromous acetate) *N*,*N*-dimethylamino) group functions as a useful pyrrole N-blocking moiety. Unfortunately, each pyrrole derivative thus protected must be synthesized *de novo*.

The ideal pyrrole N-protector should be inexpensive and easy to put on and take off in the presence of a wide variety of functional groups. It should itself be inert to a broad spectrum of reactions and should not significantly reduce the nucleophilicity of the pyrrole system. In a previous publication from these laboratories, an instance of the use of the 2-chloroethyl moiety as a pyrrole nitrogen protecting group was described (6). The present work reports on the optimized conditions for the attachment and removal of that moiety as well as the 2-phenylsulfonylethyl group. In addition, a brief account of the 2-phenylsulfinylethyl unit as a potential pyrrole N-blocking group is given. Of the three groups, the 2-chloroethyl moiety comes the closest to fulfilling the requirements stipulated above.

The 2-chloroethyl unit was readily appended, in high yields (see Table 1) to the nitrogen atom of various pyrrole derivatives **1** under phase transfer conditions using 1,2-dichloroethane as the organic phase and reactant, with tetra-n-butylammonium iodide as the phase transfer agent. One technique which was devised for the cleavage of the blocking group from **2** was based on the previous observations (6) that **2** could be dehydrochlorinated to **3** and the *N*-vinyl group could be removed therefrom in a two-step sequence via the carbinolamine der-

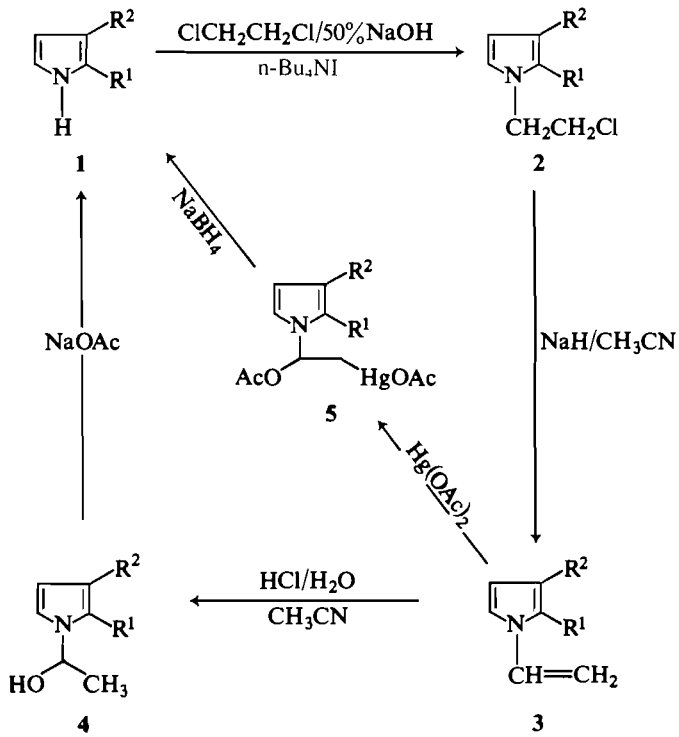
[a]Not analysed for nitrogen.
[b]This and all the other solid compounds were crystallized from dichloromethane–hexane.
[c]*m/e* 175.0222; 177.0193 (calcd. for $C_7H_{10}{}^{35}ClNS$, 175.0221; $C_7H_{10}{}^{37}ClNS$, 177.0190).
[d]Prepared from **5** and the sodium salt of the pyrrole. See experimental section.

ivative **4**. Thus, reaction of the chloroethyl compounds with sodium hydride, in DMF or acetonitrile at room temperature, produced the *N*-vinylpyrroles which on hydration with aqueous hydrochloric acid[4] in acetonitrile provided the 1-hydroxyethyl compounds **4**. These substances were converted into the deprotected pyrroles on heating with sodium acetate in aqueous acetonitrile.[5] Although intermediates **3** and **4** could be isolated,[6] it was not necessary to do so. The yields in each step were in excess of 90% and therefore the entire reaction sequence was routinely carried out in one pot. By this procedure the *N*-(2-chloroethyl)pyrroles **2***a* and **2***b* were transformed into pyrrole-2 carboxaldehyde and 2-benzoylpyrrole **1***a* and **1***b* in 71% and 85% yield, respectively.

For pyrroles which did not bear a nuclear deactivating substituent, the acidic conditions required to convert the *N*-vinyl compound **3** into the carbinolamine **4** were too vigorous to permit the survival of the pyrrole moiety. In these cases **3** was reacted with excess mercuric acetate and the supposed acetoxy mercury compound **5** was cleaved, in the same pot, with sodium borohydride. It was not determined if the borohydride reagent was, in fact, a necessary ingredient in this deprotection sequence, i.e. **5** itself is expected to be cleaved under alkaline conditions. A specific example of the utilization of this modification of the deblocking process is described at the end of this section (see Scheme 4). Further study of the process is clearly in order.

The 1-(2-phenylsulfonylethyl)pyrroles **6** were prepared from 2-phenylsulfonylethyl chloride and the pyrroles by the phase



SCHEME 1

transfer technique, or from 2-phenylsulfonylethyl chloride and the sodium salts of the pyrroles in DMF solution (see Table 1). The removal of this blocking group was effected with sodium hydride or DBN (1,5-diazabicyclo[4.3.0]-non-5-ene) in DMF solution at room temperature. Thus, pyrrole-2-carboxaldehyde and 2-benzoylpyrrole were obtained from **6***a* and **6***b* in 75% and 84% yield, respectively, using the sodium hydride process.[7]

A brief study was made of the use of the 2-phenylsulfinylethyl unit as a pyrrole N-blocking group. For example, 1-(2-phenylsulfinylethyl)-2-benzoylpyrrole **8** could be pre-

[4]*N*-vinylindoles have similar acid sensitivity (7).
[5]Silver benzoate was used for the previously reported example (6).
[6]For example, **3***b* and **4***b* were isolated as oils in greater than 95% yields and were characterized by ir and nmr spectroscopy. Thus, the *N*-vinyl compound **3***b* had ir (chloroform) absorptions at 1645 (C=C) and 1630 (C=O) cm^{-1}, and nmr (deuteriochloroform) resonances for the olefinic hydrogens at δ 5.11 (dd, 2H, J_{gem} = 0 Hz, J_{cis} = 9 Hz, J_{trans} = 16 Hz) and 7.90 (dd, 1H, J_{cis} = 9 hz, J_{trans} = 16 Hz, partially obscured by C_6H_5 multiplet). The hydroxyethyl derivative **4***b* showed ir (chloroform) bands at 3480 (OH), 3400 (OH), and 1605 (C=O) cm^{-1}, and nmr (deuteriochloroform) absorptions at δ 1.75 (d, 3H, *J* = 6 Hz, CH_3) and ~ 6.3 (m, 2H, CHOH). Analogous compounds were isolated and rigorously characterized in the above mentioned publication (6).

[7]The 2-phenylsulfonylethyl group has recently been used for the protection of the 3′-phosphodiester function in oligodeoxyribonucleotide synthesis (8).

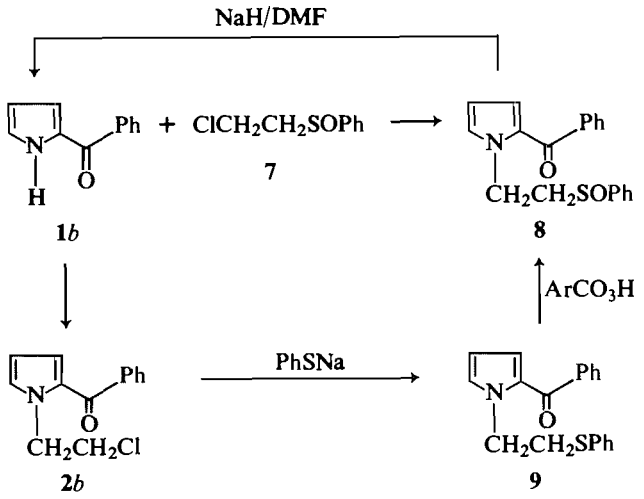
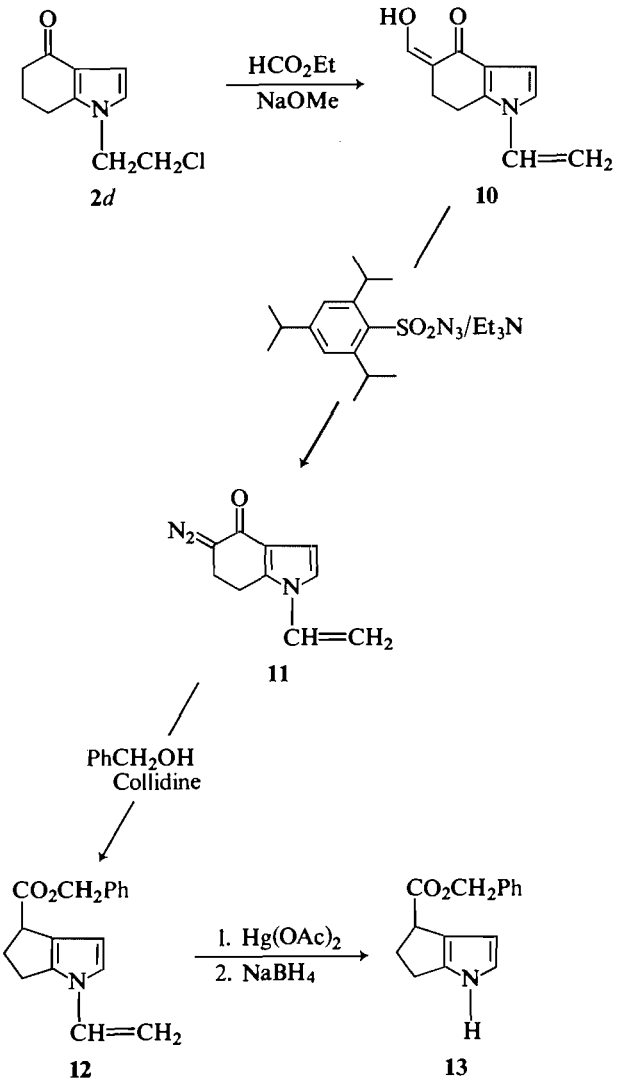


SCHEME 3



SCHEME 4

pared directly from 2-benzoylpyrrole and 2-phenylsulfinylethyl chloride **7**, or by *m*-chloroperbenzoic acid oxidation of the sulfide **9**. Although the sulfoxide **8** was converted into the *N*-vinyl compound **3***b* on heating in xylene containing excess pyridine, the removal of the *N*-2-phenylsulfinylethyl group was best effected under reverse Michael conditions using sodium hydride as the base. Thus, the use of the 2-phenylsulfinylethyl moiety as a means of protecting the 1-position of pyrroles is at least feasible.

Except for their sensitivity to strong bases and powerful nucleophiles, the susceptibility of *N*-(2-chloroethyl)pyrroles to various reaction conditions parallels that of the corresponding *N*-alkylpyrroles. Thus, those N-protected pyrroles not bearing a deactivating substituent can be acylated (e.g. with ethyloxalyl chloride (9)), and 2-acylpyrroles can be methoxymethylated at C-4 in strongly acidic media (e.g., dimethoxymethane/hydrochloric acid (1 *N*) in acetic acid – benzene/reflux (9)), or reduced with sodium borohydride in methanol solution ($\leq$ 0°C) to the alcohol without affecting the protecting group.[8] As implied by the latter reaction, the 2-chloroethyl group is relatively stable to methanolic sodium hydroxide but more vigorous conditions (sodium methoxide in tetrahydrofuran/room temperature (see below)) cause dehydrohalogenation to the *N*-vinyl compounds, which are, however, resistant to further degradation under these conditions. Indeed, provided that the reaction medium is basic, the *N*-vinyl moiety is also a useful protecting group (see below). The chloro group can be displaced by powerful nucleophiles. Of particular interest is the conversion of *N*-(2-chloroethyl)-2-benzoylpyrrole **2***b* into the sulfide **9** with sodium thiophenolate. The *N*-(2-phenylsulfenylethyl) moiety is itself a useful blocking group which has the added advantage that it is not susceptible to degradation by bases. It can be removed after oxidation to the sulfoxide (see above) or the sulfone.

The synthesis of benzyl cyclopenta[*b*]pyrrole-5-carboxylate **13** in five steps from 1-(2-chloroethyl)-4-oxotetrahydroindole **2***d* is illustrative of the utility of the 2-chloroethyl protecting group. Thus, the sodium methoxide promoted reaction of **2***d* with ethyl formate, in tetrahydrofuran solution at room temperature, caused both formylation at C-6 and dehydrohalogenation of the chloroethyl moiety. The generation of the *N*-vinyl group at this early stage in the reaction sequence

was not problematical because the subsequent steps, prior to deprotection, were effected under basic conditions. The *N*-vinyl hydroxymethylene ketone **10** was converted into the α-diazoketone **14** with 2,4,6-triisopropylbenzenesulfonyl azide in the presence of triethylamine and the diazo compound was transformed into the ring-contracted benzyl ester **12** in hot (175°C) collidine containing benzyl alcohol. Cleavage of the vinyl group from **12** by prior hydration to the carbinolamine was not possible because of the sensitivity of this pyrrole, and presumably other non-inductively stabilized pyrroles, to degradation under acidic conditions. The acetoxymercuration procedure, though not optimized, obviated this difficulty. It is noteworthy that the synthesis of **13** could not be accomplished without blocking the pyrrole nitrogen atom of **1***d*.

Experimental

The melting points were determined in a Mel-Temp apparatus and are corrected. The infrared spectra were measured in chloroform solution with a Perkin–Elmer model 237 grating infrared spectrophotometer. The ultraviolet spectra were recorded in methanol with a Perkin–Elmer model 402 ultraviolet visible spectrometer. The nmr spectra were obtained with a Varian T-60 spectrometer in deuteriochloroform solution. The chemical shifts are expressed as ppm (δ) from internal tetramethylsilane. The high resolution mass spectrum was obtained with a Varian MAT 311A spectrometer.

Starting materials

Pyrrole-2-carboxaldehyde was purchased from the Aldrich Chemical Co. Literature procedures were followed to prepare 2-benzoylpyrrole (10), 2-methylthiopyrrole (11), 4-oxo-4,5,6,7-tetrahydroindole (12), 2-phenylsulfenylethyl chloride (13), 2-phenylsulfinylethyl chloride (14), and 2-phenylsulfonylethyl chloride (15).

*Synthesis of 1-(2-chloroethyl)pyrroles. 1-(2-Chloroethyl)pyrrole-2-carboxaldehyde, 2*a

The synthesis of compound **2***a* was typical. Fifty percent aqueous sodium hydroxide (5 mL) was added, at 0°C, to a stirred solution of pyrrole-2-carboxaldehyde (0.500 g, 5.26 mmol) and tetrabutylammonium iodide (1.89 g, 1 equiv.) in 1,2-dichloroethane (10 mL). For all cases except **2***c* (see below), the mixture was then heated to reflux temperature, with vigorous stirring, where it was maintained for 1 h. For **2***c* the reaction mixture was kept at room temperature for 8 h. The cooled mixture was diluted with water and extracted with dichloromethane. The organic phase was washed successively with 2 *N* hydrochloric acid and water and then it was dried over sodium sulfate and evaporated *in vacuo*. The residue was percolated through a short column of silica gel using hexane – ethyl acetate (85:15) as the percolating solvent. The product was obtained as a colorless oil (0.780 g, 94%) homogeneous by tlc; uv: 207 (2400), 258 (7410), 288 (14 500) nm; ir: 1660 cm $^{-1}$; nmr δ: 3.75 (t, 2H, J = 7 Hz), 4.60 (t, 2H, J = 7 Hz), 6.10 (dd, 1H, $J_{3,4}$ = 4.0 Hz, $J_{4,5}$ = 2.5 Hz), 7.06 (m, 2H), 9.40 (s, 1H). The physical data for this and all the other compounds are found in Table 1.

Synthesis of 1-(2-phenylsulfonylethyl)pyrroles

A. *Phase transfer technique. 1-(2-Phenylsulfonylethyl)-2-benzoylpyrrole* **6**b

The general procedure is exemplified by that used for the title compound. The process utilized was identical to that described for the synthesis of compound **2***a* except that 2-phenylsulfonylethyl chloride (3 equiv.) in benzene solution was used. The product was purified by percolation through silica gel using hexane – ethyl acetate (3:2) as the percolating solvent; uv: 221 (12 600), 251 (8510), 265 sh (6370), 273 (6170), 305 (13 800) nm; ir: 1625 cm $^{-1}$; nmr δ: 3.43 (t, 3H, J = 7 Hz), 4.60 (t, 3H, J = 7 Hz), 6.16 (dd, 1H, $J_{3,4}$ = 4.0 Hz, $J_{4,5}$ = 3.0 Hz), 6.73 (dd, 1H, $J_{3,4}$ = 4.0 Hz, $J_{3,5}$ = 1.6 Hz), 6.97 (t, $J_{4,5}$ = 3.0 Hz, $J_{3,5}$ = 1.6 Hz), 7.17–7.93 (m, 10H).

B. *From the sodium salt of the pyrrole in DMF solution. 1-(2-Phenylsulfonylethyl)-4-oxo-4,5,6,7-tetrahydroindole* **6**d

The oxo compound **1***d* (0.500 g, 3.7 mmol) was added to a stirred suspension of 50% sodium hydride (in mineral oil, 0.098 g, 1.1 equiv.) in anhydrous DMF (5 mL) maintained in a nitrogen atmosphere at room temperature. When gas evolution had ceased, 2-phenylsulfonylethyl chloride (1.51 g, 2 equiv.) was added and stirring was continued for 16 h. The solvent was removed *in vacuo* (for compounds **6***a* and **6***c*, the mixture was diluted with ether (60 mL) and washed with water) and ethyl acetate was added to the residue. The mixture was filtered, and the filtrate was dried over sodium sulfate and evaporated *in vacuo*. The residue was subjected to tlc on silica gel using hexane – ethyl acetate (3:7) as the developing solvent. The tlc pure solid was obtained in 91% yield; uv: 219 (15 500), 250 (10 500), 266 (8510), 272 (8510) nm; ir: 1660 cm $^{-1}$; nmr δ: 1.93–2.97 (m, 6H), 3.15 (t, 2H, J = 7.5 Hz), 4.34 (t, 2H, J = 7.5 Hz), 6.53 (s, 2H), 7.54–8.02 (m, 5H).

1-(2-Phenylsulfinylethyl)-2-benzoylpyrrole 8

A. *Phase transfer technique*

The synthesis of **8** was carried out as described for **6***b* except that the alkylation was effected with 2-phenylsulfinylethyl chloride (1.1 equiv.) at room temperature (benzene) for 24 h. The crude product was subjected to column chromatography on silica gel using hexane – ethyl acetate (3:2) as the developing solvent to give the sulfoxide **8** in 86% yield; uv: 212 (12 600), 248 (9550), 305 (10 700) nm; ir: 1620 cm^{-1}; nmr δ: 3.34 (m, 2H, J = 6.6, 14 Hz), 4.74 (t, 2H, J = 6.6 Hz), 6.13 (dd, 1H, $J_{3,4}$ = 3.9 Hz, $J_{4,5}$ = 2.6 Hz), 6.70 (dd, 1H, $J_{3,4}$ = 3.9 Hz, $J_{3,5}$ = 1.8 Hz), 7.05 (t, 1H, $J_{4,5}$ = 2.6 Hz, $J_{3,5}$ = 1.8 Hz), 7.28–7.75 (m, 10H).

B. m-*Chloroperbenzoic acid oxidation of* **9**

m-Chloroperbenzoic acid (85%, 0.217 g, 1.07 mmol) was added portionwise to a stirred solution of the sulfide **9** (0.330 g, 0.98 mmol) in anhydrous dichloromethane (50 mL) cooled in an ice-bath. One hour following the completion of the addition an additional quantity of the oxidant (0.040 g) was added to consume a small amount of starting material shown to be present by tlc. After a further 20 min the solution was washed with saturated sodium bicarbonate solution, and the organic phase was combined with a dichloromethane extract of the aqueous phase and dried over sodium sulfate. The solvent was removed *in vacuo* leaving an oil (0.277 g, 88%) which was spectroscopically identical to the sulfoxide **8** prepared by method A.

1-(2-Phenylsulfenylethyl)-2-benzoylpyrrole 9

Sodium hydride in mineral oil (50%, 0.239 g, 4.98 mmol) was added to a stirred solution of thiophenol (0.500 g, 4.55 mmol) in anhydrous DMF (10 mL) maintained in a nitrogen atmosphere. After 1 h, 1-(2-chloroethyl)-2-benzoylpyrrole (1.166 g, 4.79 mmol) was added all at once and stirring was continued for 2 h. The solution was diluted with ether and then washed well with water. The organic phase was dried over sodium sulfate and evaporated *in vacuo*. The residue was subjected to tlc on silica gel using hexane – ethyl acetate as the eluting solvent. The product (1.24 g, 88%) was obtained as an oil; uv: 213 (17 400), 253 (15 500), 306 (13 800) nm; ir: 1628, 1578, 1525 cm^{-1}; nmr δ: 3.42 (t, 2H, J = 6.7 Hz), 4.61 (t, 2H, J = 6.7 Hz), 6.17 (dd, 1H, $J_{3,4}$ = 4.0 Hz, $J_{4,5}$ = 3.0 Hz), 6.75 (dd, 1H, $J_{3,4}$ = 4.0 Hz, $J_{3,5}$ = 1.6 Hz), 6.79 (t, 1H), 7.17–7.87 (m, 10H).

Deprotection of the N-*(2-chloroethyl)pyrroles*

A. *Conversion of* N-*(2-chloroethyl)pyrrole-2-carboxaldehyde* **2**a *into pyrrole-2-carboxaldehyde* **1**a

Sodium hydride (60%, 0.139 g, 3.48 mmol) was added to a stirred solution of the chloro compound (0.500 g, 3.18 mmol) in dry acetonitrile (15 mL) maintained in a nitrogen atmosphere. The solution was heated at 50°C for 2 h, cooled to room temperature, and 6 *M* hydrochloric acid (5.3 mL, 31.8 mmol) was added dropwise. After 6 h at room temperature, a solution of sodium acetate (2.9 g, 35.4 mmol) in water (5 mL) was added and the solution was heated at reflux temperature for 0.5 h. The solution was diluted with water and then extracted with ether. The extract was washed with water, dried over

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

sodium sulfate, and evaporated *in vacuo*. The crude product was subjected to tlc on silica gel using hexane – ethyl acetate (9:1) as the developing solvent. The product (0.182 g, 71%, tlc homogeneous) was crystallized from dichloromethane–hexane to give the aldehyde (0.166 g) with mp 42–43°C.

B. *Conversion of* N-*(2-chloroethyl)-2-benzoylpyrrole* **2**b *into 2-benzoylpyrrole* **1**b

Sodium hydride in mineral oil (60%, 0.038 g, 0.95 mmol) was added, at 50°C, to a stirred solution of the chloro compound (0.200 g, 0.86 mmol) in dry acetonitrile (15 mL) maintained in a nitrogen atmosphere. After 0.5 h at this temperature, 50% hydrochloric acid (3 mL, 18 mmol) was added. After an additional 0.5 h, a solution of sodium acetate (1.91 g, 23 mmol) in water (2.5 mL) was added and the solution was heated at reflux temperature for 0.25 h. The cooled solution was extracted with dichloromethane, and the extract was dried over sodium sulfate and evaporated *in vacuo* to give 2-benzoylpyrrole (0.124 g, 85%) with mp 76–77°C.

Deprotection of the N-*(2-phenylsulfonylethyl)pyrroles*

A. *Sodium hydride*

Sodium hydride in mineral oil (60%, 1.1 equiv.) was added to a stirred solution of the phenylsulfonyl compound (1 equiv.) in anhydrous dimethylformamide (7 mL/mmol) at room temperature (nitrogen atmosphere). After 2.5 h the solution was diluted with ether, the mixture was washed with water, and the organic phase was dried over sodium sulfate and evaporated *in vacuo*. The crude product was purified by crystallization (dichloromethane–hexane for 2-benzoylpyrrole) or column chromatography on silica gel (hexane – ethyl acetate (4:1); 2-formylpyrrole) followed by crystallization (ether–hexane; 2-formylpyrrole).

B. *Diazabicyclo[4.3.0]non-5-ene*

The procedure was identical to that described above except that diazabicyclo[4.3.0]non-5-ene (5–7 equiv.) and diethylamine (10 equiv.) were used instead of sodium hydride. In this way, 2-benzoylpyrrole was obtained in 83% yield, after tlc on silica gel using hexane – ethyl acetate (4:1) as the eluting solvent followed by crystallization as above.

Conversion of N-*(2-phenylsulfinylethyl)-2-benzoylpyrrole* **8** *into 2-benzoylpyrrole*

A solution of the sulfoxide **8** (0.600 g, 1.86 mmol) in anhydrous DMF (5 mL) was added to a stirred suspension of 60% sodium hydride (in mineral oil, 0.082 g, 2.05 mmol) in dry DMF (10 mL) maintained in an atmosphere of nitrogen. After 4 h at room temperature, water was added and the product was extracted into ethyl acetate. The aqueous phase was saturated with sodium chloride and extracted with benzene. The combined extracts were dried over sodium sulfate and evaporated *in vacuo*. The residue was purified by tlc on silica gel using hexane–ether (2:3) as the developing solvent. This process yielded 2-benzoyl pyrrole (0.290 g, 91%) with mp 78°C.

1-Vinyl-4-oxo-4,5,6,7-tetrahydroindole-4-carboxaldehyde **10**

A solution of the chloro compound **2***d* (14.2 g, 71.8 mmol) in dry tetrahydrofuran (40 mL) was added to a stirred suspension of sodium methoxide (15.5 g, 290 mmol) in anhydrous tetrahydrofuran (100 mL) containing anhydrous ethyl formate (21.5 g, 290 mmol). After 2 h at room temperature, water was added and the solution was acidified to pH 4 with 1 *M* hydrochloric acid. The product was extracted into ethyl acetate, and the extract was dried over sodium sulfate and evaporated *in vacuo*. The solid which remained was crystallized from ethyl acetate – hexane to give material (12.7 g, 93%) with mp 98.5–100°C; uv: 239 (14 500), 274 (12 600), 322 sh (5010) nm; ir: 1641, 1585 cm^{-1}; nmr δ: 2.72 (m, 4H), 4.95 (d, 1H, J_{cis} = 9.0 Hz), 5.28 (d, 1H, J_{trans} = 15.4 Hz), 6.68 (d, 1H, $J_{2,3}$ = 3.1 Hz), 6.86–7.25 (m, 1H), 7.06 (d, 1H, $J_{2,3}$ = 3.1 Hz), 7.32 (s, 1H). *Anal.* calcd. for $C_{11}H_{11}NO_2$: C 69.83, H 5.86, N 7.40; found: C 69.56, H 5.94, N 7.47.

1-Vinyl-4-oxo-5-diazo-4,5,6,7-tetrahydroindole **11**

A suspension of 2,4,6-triisopropylbenzenesulfonyl azide (15) (22.8 g, 73.8 mmol) in anhydrous dichloromethane (40 mL) was added to a stirred solution of **10** (12.7 g, 67.1 mmol) in dry dichloromethane (100 mL) containing triethylamine (14.1 g, 141 mmol) at 0°C. The mixture was stirred at room temperature for 20 h, water was added, and the organic phase was dried and evaporated *in vacuo*. The residue was subjected to column chromatography on neutral alumina (500 g, Fluka, Act II) and the product (9.5 g, 76%) was eluted with ethyl acetate – hexane (1:1). On crystallization from ethyl acetate – hexane, a bright yellow solid was obtained with mp 84–86°C; uv: 206 (6150), 241 (9190), 269 sh (6150), 326 (8820) nm; ir: 2055, 1650, 1615 cm^{-1}; nmr δ: 3.01 (m, 4H), 4.93 (dd, 1H, J_{gem} = 1.1 Hz, J_{cis} = 9.0 Hz), 5.26 (dd, 1H, J_{gem} = 1.1 Hz, J_{trans} = 15.6 Hz), 6.67 (d, 1H, $J_{2,3}$ = 3.1 Hz), 6.81–7.07 (m, 1H), 6.99 (d, 1H, $J_{2,3}$ = 3.1 Hz). *Exact Mass* (high resolution mass spectrum) calcd. for $C_{10}H_9N_3O$: 187.0746; found (ms): 187.0749.

Benzyl 1-vinylcyclopenta[b]pyrrole-5-carboxylate **12**

A solution of the diazo compound (3.47 g, 17.6 mmol) in collidine (15 mL) containing benzyl alcohol (6 mL) was heated in an oil bath maintained at 175°C for 20 min. The cooled solution was diluted with ether, washed with 1 *N* hydrochloric acid, dried, and evaporated *in vacuo*. The residue was subjected to column chromatography on silica gel using hexane – ethyl acetate (7:3) to elute the oily, somewhat unstable product (1.93 g, 41%); uv: 217 (13 700), 248 (14 600) nm; ir: 1734, 1651 cm^{-1}; nmr δ: 2.79–3.07 (m, 2H), 3.90 (m, 1H), 4.62 (dd, 1H, J_{gem} = 1.3 Hz, J_{cis} = 9.7 Hz), 5.03 (dd, 1H, J_{gem} = 1.3 Hz, J_{trans} = 15.3 Hz), 5.21 (s, 2H), 6.14 (d, 1H, $J_{2,3}$ = 3.0 Hz), 6.76 (dd, 2H, J_{cis} = 9.7 Hz, J_{trans} = 15.3 Hz), 6.85 (d, 1H, $J_{2,3}$ = 3.0 Hz), 7.43 (s, 5H); mass spectrum *m/e* 267 (M^+). *Anal.* calcd. for $C_{17}H_{17}NO_2$: C 76.38, H 6.41, N 5.24; found: C 75.92, H 6.53, N 5.11.

Benzyl cyclopenta[b]pyrrole-5-carboxylate **13**

A solution of the *N*-vinyl compound **12** (1.00 g, 37.5 mmol) in acetonitrile (25 mL) was added to a solution of mercuric acetate (3.7 g, 106 mmol) in 10% aqueous acetonitrile (25 mL) and the solution was stirred at room temperature until the reaction was complete by tlc (0.5 h). Sodium borohydride (0.57 g) was then added in portions and, when the vigorous reaction had subsided, the mixture was filtered through Celite. The filtrate was diluted with saturated sodium chloride solution and extracted with ethyl acetate. The extract was dried, the solvent was removed *in vacuo*, and the residue was percolated through a short column of silica gel using hexane – ethyl acetate as the percolating solvent mixture. The product (0.593 g, 66%) was obtained as an oil; uv: 217 (8910), 241 (5750), 266 (457), 268 (309) nm; ir: 3515, 3420, 1733 cm^{-1}; nmr δ: 2.78 (m, 4H), 3.77–4.09 (m, 1H), 5.18 (s, 2H), 6.06 (d (after D_2O exchange), 1H, J = 2.8 Hz), 6.69 (d (after D_2O exchange), 1H, J = 2.8 Hz), 7.41 (s, 5H). *Anal.* calcd. for $C_{15}H_{15}NO_2$: C 74.67, H 6.27, N 5.81; found: C 74.99, H 6.36, N 5.67.

Sulphurous negative ions in a fuel-rich, CH_4-O_2 flame with OCS additive

JOHN M. GOODINGS, KAMAL ELGUINDI, AND DIETHARD K. BOHME
Department of Chemistry, York University, 4700 Keele Street, Downsview, Ont., Canada M3J 1P3

Received December 15, 1982

JOHN M. GOODINGS, KAMAL ELGUINDI, and DIETHARD K. BOHME. Can. J. Chem. **61**, 1703 (1983).

Sulphurous negative ions S^-, SH^-, SO^-, SO_2^-/S_2^-, SO_3^-, HSO_3^-, SO_4^-, and HSO_4^- were observed when 0.2% of carbonyl sulphide (OCS) was added to a conical, laminar, premixed, fuel-rich (equivalence ratio $\phi = 2.15$) CH_4-O_2 flame burning at atmospheric pressure. Profiles were obtained of ion concentration vs. distance along the flame axis by sampling the flame through a pinhole into a quadrupole mass spectrometer. Some of the ion signals observed in the flame reaction zone are very large, particularly that for HSO_4^-. None of the sulphurous ions detected contain carbon. Of those listed above, only S^-, SH^-, SO^-, and SO_2^- persist downstream through the burnt gas. The sulphurous ions are formed by chemical ionization processes of neutral sulphurous intermediates reacting with the naturally-occurring ions present in any hydrocarbon flame. The ion chemistry is discussed, as is the underlying neutral chemistry of sulphur relevant to the flame environment. The ion profiles show the rapidity with which OCS is oxidized through SH and SO to SO_2 even within the reaction zone of this fuel-rich flame. No evidence was obtained for the presence of sulphuric or sulphurous acids, and the presence of S_2 was not confirmed.

JOHN M. GOODINGS, KAMAL ELGUINDI et DIETHARD K. BOHME. Can. J. Chem. **61**, 1703 (1983).

On a observé des ions sulfureux négatifs: S^-, SH^-, SO^-, SO_2^-/S_2^-, SO_3^-, HSO_3^-, SO_4^- et HSO_4^- lorsqu'on ajoute 0,2% de sulfure de carbonyle (OCS) à la flamme de CH_4-O_2, conique, laminaire, prémélangée et enrichie (rapport d'équivalence $\phi = 2,15$) brûlant à la pression atmosphérique. On a obtenu les profils de la concentration en ions en fonction de la distance le long de l'axe de la flamme en injectant des échantillons de flamme à travers un trou d'épingle dans un spectromètre de masse quadrupolaire. Quelques uns des signaux observés dans la zone de réaction de flamme sont très intenses, particulièrement ceux du HSO_4^-. Les ions sulfureux détectés ne contiennent pas de carbone. Parmi ceux mentionnés, seuls S^-, SH^-, SO^- et SO_2^- existent encore dans le courant gazeux qui brûle. Les ions sulfureux se forment par ionisation chimique des intermédiaires sulfureux neutres qui réagissent avec les ions que l'on trouve habituellement dans n'importe quelle flamme d'hydrocarbure. On discute de la chimie de l'ion en tant que chimie neutre sous-jacente du soufre se rapportant à l'environnement de la flamme. Les profils de l'ion révèlent la rapidité avec laquelle le OCS est oxydé par l'intermédiaire du SH et du SO en SO_2 même à l'intérieur de la zone de réaction de cette flamme riche en combustible. On n'a pas de preuve de la présence d'acides sulfuriques ou sulfureux, et on n'a pas pu confirmer la présence de S_2.

[Traduit par le journal]

Introduction

The release of sulphur compounds into the troposphere through the use of sulphur-bearing fossil fuels for industrial and domestic heating, power generation, and transportation constitutes the major man-made sources of air contaminants. The effects on human health and vegetation have long been recognized. Besides being phytotoxic with the obvious damage to plants through acid rain, high levels of sulphur compounds have been linked to a variety of environmental and health problems (1). For example, SO_2 is a severe irritant to the eyes, mucous membranes, and skin, the irritant effects being caused by the rapidity with which SO_2 forms sulphurous acid on contact with moist surfaces. Present measures to combat SO_x emissions from combustion operations through the selection of low-sulphur fuels or by sulphur removal from the exhaust are costly. The inevitable need to use high-sulphur coal in the future points to the desirability of controlling sulphur emissions at the source.

This work attempts to trace the early chemistry of formation of sulphur compounds in a hydrocarbon flame. Sulphur ions resulting from the reaction of naturally-occurring flame ions with sulphurous neutral species are detected by sampling the flame at atmospheric pressure into a mass spectrometer. These ions, produced from fast ion–molecule reactions, can be used as an in-situ probe of the underlying neutral chemistry of combustion. The objective of this phase of the study is to explore the formation and disappearance of negative sulphurous ions in, and downstream of, the reaction zone of a fuel-rich, CH_4-O_2 flame doped with 0.2% of carbonyl sulphide (OCS). Pairs of ion concentration profiles are measured along the axis of conical flames with and without OCS additive to reveal the presence of sulphurous ions. Both the neutral chemistry and the ion chemistry of sulphur relevant to the flame are discussed.

Experimental

All of the ion concentration measurements were performed on the same CH_4-O_2 flame of fuel-rich composition (equivalence ratio $\phi = 2.15$) whose ion chemistry we have studied extensively in the past (2, 3). It was of the laminar premixed type with a conical luminous reaction zone (height $\approx$ 5 mm, base diameter $\approx$ 3 mm, thickness $\approx$ 0.3 mm) to facilitate ionic sampling along the flame axis into a mass spectrometer. The flame has an adiabatic flame temperature of 2460 K and a burnt gas velocity of approximately 1 m s^{-1}. It was stabilized at atmospheric pressure on a simple, tubular, quartz burner (2.3 mm id) surrounded by a flowing argon shield to minimize the entrainment of atmospheric air. For this work, provision was made to add 0.22 mol% of OCS to the premixed gas; it could be added or removed without altering the flame. All gases were used straight from the cylinders without further purification ($CH_4 > 99.0\%$, $O_2 > 99.6\%$, Ar $> 99.9\%$, OCS $> 97.5\%$). The burner was mounted on a motor-driven carriage with accurate axial alignment and calibrated drive providing spatial resolution of ± 0.02 mm along the flame axis (designated z) for ion profile measurements.

The flame – ion mass spectrometer has been described previously in detail (2). The flame burned against a 60°, conical, chromium, sampling nozzle of orifice diameter ca. 0.1 mm mounted in a water-cooled flange of the type described by Hayhurst and Telford (4). The sampled ions pass through two stages of differential pumping into a quadrupole mass filter. The mass-analyzed ions are detected with a parallel-plate Faraday cage connected to a vibrating reed electrometer having a grid-leak resistance of 10^{11} ohms. The ion signal magnitudes in the figures are quoted in volts based on the detected ion current passing through 10^{11} ohms. We have adopted a normalization technique different from that used previously. The profiles shown in the figures include a correction for mass discrimination in the filter against

ions of high m/e measured at high resolving power (unit resolution); the mass discrimination increases with increasing resolving power. The groups of negative sulphurous ions are sufficiently well spaced such that each group could be measured at very low resolving power as a broad single "peak". The individual m/e's within a group measured at high resolving power are normalized to the signal magnitude of the "peak" at low resolving power. The $H_xSO_4^-$ group yields the largest negative ion signal we have ever observed. The dynamic range of sensitivity of the apparatus is five orders of magnitude. A method has been described (2, 5) for locating a reproducible origin ($z = 0$) in the *flame* (not referred to the burner) corresponding to the downstream edge of the luminous reaction zone on the flame axis. In this way, a family of ion profiles at different mass numbers m/e can be accurately overlaid on the distance scale z.

It should be pointed out that some ion signals are subject to distortion during sampling by the mass spectrometer. The flame gas is cooled in passing through the thermal boundary layer surrounding the sampling orifice, and again during the expansion to supersonic velocity which proceeds for a few orifice diameters just inside the sampling nozzle. This can affect the signal ratio of two ions participating in a fast ion–molecule reaction having a reaction time (relaxation time) comparable to, or less than, the sampling time (of order 1 μs). In these circumstances, the ratio will change to some extent during sampling in favour of the product ion in the exothermic direction of the reaction. An extreme case is the production of hydrate ions, since a large water concentration in the flame produces a high rate of hydration. In the present study where some of the sulphurous ions of relatively high molecular weight may result from clustering reactions with sulphur dioxide, their signals may be enhanced by cooling during sampling. However, such enhancements are not expected to affect the interpretation of the sulphurous flame chemistry. These sampling effects for flames have been discussed in a series of papers by Hayhurst *et al.* of which refs. 6–8 are particularly relevant.

Neutral sulphur chemistry in hydrocarbon flames

A complete review of the reactions of neutral sulphurous species will not be attempted here. However, relevant reactions studied by a number of workers are listed in Table 1; where the temperature dependence is known, the rate constants have been calculated at 2000 K. The reactions are drawn from Westley's table of recommended rate constants for chemical reactions occurring in combustion (9). The sulphur chemistry is summarized in the reaction flow diagram given in Fig. 1.

Initially, the OCS additive is attacked by O and H atoms to form SO and SH, respectively (reactions [1] and [2]), whose rates may be nearly equal in our flame. In any case, SH is rapidly attacked by O in reaction [4*a*] to yield the same SO product. In turn, SO can react with O_2 or O (reactions [5*a*] and [6]) to give the major product SO_2. The back reaction [5*b*] can regenerate SO from SO_2, but should be very slow early in the reaction zone. The reaction of H with SO_2 does not regenerate SO, but adds rather slowly [7] to form HSO_2. This completes what might be regarded as the main-line sulphur chemistry; namely,

$$OCS \rightarrow (SH) \rightarrow SO \rightarrow SO_2$$

Sulphur is further involved in minor side-line chemistry. Sulphur atoms can be produced by H and O radical attack on both SO and SH (reactions [8*c*], [9*a*], [10*a*], and [4*b*]). However, SO is regenerated by reaction of S atoms with O_2 by [9*b*] or with OH by [8*a*]. The regeneration rate of SH by reaction [10*b*] involving S with H_2 may be comparable downstream despite its small rate constant due to the high concentration of H_2 (0.4 mole fraction) in the fuel-rich burnt gas (2).

As a second side-line, diatomic sulphur S_2 can be formed by reaction [11*a*] of S with SH, but is destroyed by the reverse reaction [11*b*] with H atoms. A further sink for S_2 is its reaction [12*b*] with O atoms to form SO; the reverse reaction [12*a*] as a source of S_2 can be disregarded. Reaction [3] of OCS with S is a significant source of S_2 only if the concentration of S becomes appreciable before OCS is exhausted. Thus, S_2 feeds back rapidly into the main-line sulphur chemistry, and its steady-state concentration in the fuel-rich flame is expected to be low.

A third side-line concerns H_2S. The only reaction listed by Westley (9) for its production is [13] involving the reaction of the SH radical with itself. However, several sink reactions are known for the destruction of H_2S by H, OH, and CH_3 radicals (reactions [14], [15], and [16], respectively). As an aside, we do have evidence for the presence of H_2S in the flame from the positive ion chemistry where we detect H_3S^+, presumably arising from proton transfer to H_2S. Under the fuel-rich flame conditions, it is possible that the reverse of reaction [14] constitutes the major source of H_2S since the concentration of H_2 is high in the burnt gas.

An obvious question is the degree to which the reactions are balanced in different parts of the flame linking the pairs of species SH/H_2S, SH/S, S_2/S, SO/S, and SO/SO_2. An indication is given by some of the ion profiles below which show a similar tailing out downstream in the burnt gas. It will be noted that Table 1 and Fig. 1 do not mention any sulphurous species containing carbon. Their inclusion is not thought to be warranted because, in general, the rates of reactions listed in Westley (9) of C, CH, CH_2, etc. with sulphurous species are low due to the small steady-state concentrations of the hydrocarbon neutrals. Also, addition reactions similar to [7] are known from the chemistry of the stratosphere near 220 K for the formation of HSO_3 from OH + SO_2 + M, and SO_3 from O + SO_2 + M (13, 14); the SO_3 so formed combines with water to form sulphuric acid. However, we do not have any evidence for these processes occurring at flame temperatures.

Results

Figure 2 shows total positive and total negative ion profiles with, and without, the injection of 0.2% of OCS into the premixed flame gas. In these and subsequent ion profile data, the conical flame is sampled into the mass spectrometer along its axis (distance z in mm); the flame reaction zone near the tip of the cone occupies the region from approximately $z = -0.3$ to 0 mm. The total positive ion profile shows little change in magnitude or peak shape with OCS injection. However, the total negative ion profile shows a dramatic increase in magnitude of the upstream peak (4. 5 ×) with the addition of 0.2% of OCS and a much greater persistance of the downstream peak into the burnt gas region of the flame.

Figures 3–7 inclusive present profiles for sulphurous negative ion species at individual m/e. Each figure gives data for a group of similar ions; the groups are ordered according to increasing mass. Figure 3 shows profiles for the H_xS^- group ($x = 0, 1$). In the absence of OCS, the profile at 32 amu is due to O_2^-, and shows a single peak upstream. With OCS injection, the profile becomes double-peaked. The upstream peak falls to a magnitude of one-third and shifts slightly in the downstream direction; evidently O_2^- acts as a source or reagent ion for the production of sulphurous negative ions by ion–molecule reactions. In addition, a new peak due to S^- appears downstream and tails out into the burnt gas. It is apparent from this and other profiles which show similar tailing behaviour that some of the sulphurous negative ions involve species of relatively high

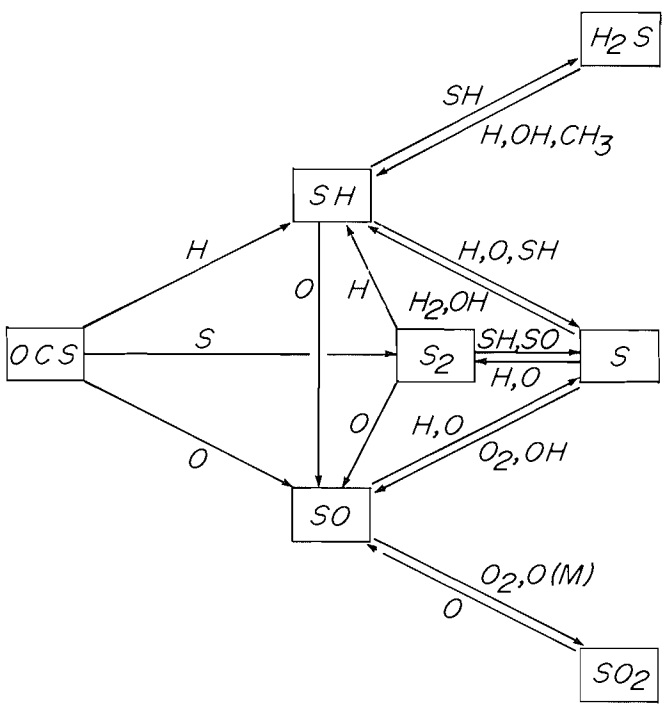

FIG. 1. Reaction scheme for sulphur chemistry in a fuel-rich, hydrocarbon flame.

electron affinity (EA) which can better withstand collisional electron detachment at the high temperature of the burnt gas.

In the absence of OCS, a small single peak is observed at 33 amu in the reaction zone due to HO_2^-. With OCS injection, the much larger double-peaked profile shown in Fig. 3 arises due to SH^- with a small contribution from $^{33}S^-$. Recall that sulphur has four stable isotopes; namely, ^{32}S (natural abundance = 95.0%), ^{33}S (0.76%), ^{34}S (4.22%), and ^{36}S (0.014%). Other isotopic species of sufficient natural abundance to make significant contributions to some of these profiles include deuterium D (0.015%), ^{17}O (0.037%), and ^{18}O (0.0204%). For example, the double-peaked profile at 34 amu can be derived from $^{32}SD^-$, $^{34}S^-$, and $^{33}SH^-$; these sulphurous species will account for all of the downstream portion, whereas the upstream peak is further complicated by a small and unknown contribution from the $O^-.H_2O$ hydrate. Similar considerations will apply to the profile at 35 amu, but in this case the profile magnitude indicates contributions from $OH^-.H_2O$ and also $^{35}Cl^-$ present as an impurity. The mass assignments including isotopic contributions for all of the negative sulphurous ion profiles measured are summarized by groups in Table 2.

Consider now the small, double-peaked profiles at 48 amu shown in Fig. 4. In the absence of OCS, the upstream and downstream peaks are attributed to O_3^- and C_4^-, respectively. With OCS injection, the decrease and shift of the upstream peak presumably indicates the involvement of O_3^- as a source of sulphurous negative ions, as noted above for O_2^-. The increase in the downstream peak may be indicative of SO^-. However, the clear evidence for SO^- is the tail of the profile which persists far downstream into the burnt gas. Corroborative evidence from $^{34}SO^-$ at 50 amu is obscured by the presence of $O_2^-.H_2O$.

With reference to Fig. 5, in the absence of OCS, the signal detected at 64 amu is negligible and that at 66 amu is very small. With OCS injection, the fairly large profile at 64 amu

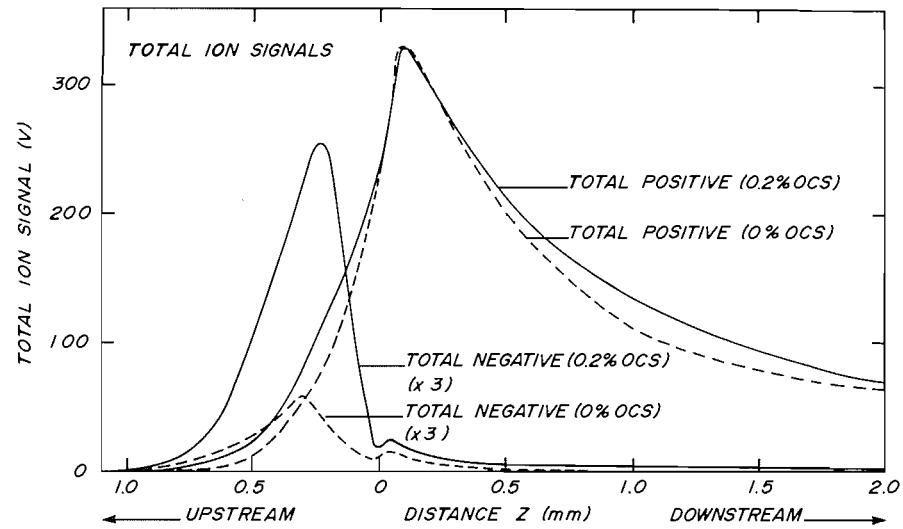

FIG. 2. Total positive and negative ion profiles with, and without, 0.2% OCS additive.

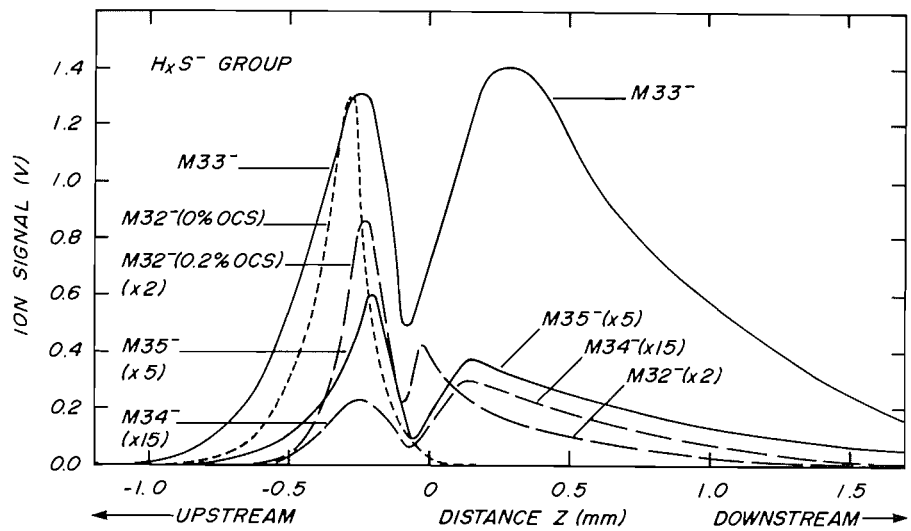

FIG. 3. Negative sulphurous ion profiles: isotopic species of S⁻ and SH⁻. All profiles are taken with the addition of 0.2% of OCS except for one profile at −32 amu as indicated.

could be attributed to SO_2^- or S_2^-. However, the relative size and similar shape of the profile at 66 amu identifies both peaks as being almost entirely due to SO_2^- and not S_2^-; this serves as an excellent example of the utility of isotopes for species identification.

The $H_xSO_3^-$ group ($x = 0, 1$) of ions is shown in Fig. 6. When OCS is not present, the signals at 80–83 amu are all negligibly small. When 0.2% of OCS is added, large profiles are observed. The single-peaked pair at 80 and 82 amu are attributed to $^{32}SO_3^-$ and $^{34}SO_3^-$, respectively; the latter contains minor contributions from other isotopic species as well. The double-peaked pair of profiles at 81 and 83 amu are identified mainly as $H^{32}SO_3^-$ and $H^{34}SO_3^-$, respectively, although other isotopic species will contribute. As a clue to the ion chemistry dicussed in the next section, it is noteworthy that the profile observed for O^- at 16 amu (not shown here) is single-peaked, while that for OH^- at 17 amu (also not shown) is double-peaked (15). Thus, it is credible that the ions observed in this group are the cluster ions $O^-.SO_2$ and $OH^-.SO_2$.

Similarly for the $H_xSO_4^-$ group ($x = 0, 1$) of ions shown in Fig. 7, the signals at 96–99 amu with OCS absent were negligibly small. With OCS injection, sulphurous negative ion profiles were observed, all single-peaked and one of them very large. They derive, in order of increasing mass 96–99 amu, from $^{32}SO_4^-$, $H^{32}SO_4^-$, $^{34}SO_4^-$, and $H^{34}SO_4^-$ with a number of other isotopic contributions indicated in Table 2. In fact, the peak for HSO_4^- at 97 amu is the largest negative ion signal we have ever observed. In the absence of OCS, the profile for O_2^- at 32 amu (Fig. 3) and the very small one for HO_2^- at 33 amu (not shown) are both single-peaked (15). In keeping with the cluster ion interpretation mentioned in the previous paragraph, the $H_xSO_4^-$ ions might conceivably arise as $O_2^-.SO_2$ and $HO_2^-.SO_2$ clusters.

In summary, the parent negative ions for which profiles were obtained include S^-, SH^-, SO^-, $SO_2^-(S_2^-)$, SO_3^-, HSO_3^-, SO_4^-, and HSO_4^-. Somewhat surprisingly, we were unable to obtain any evidence for sulphurous negative ions containing carbon in the fuel-rich flame.

Discussion of the sulphurous negative ion chemistry

It remains to discuss the probable ion–molecule reactions which are relevant to the sulphurous negative ions observed.

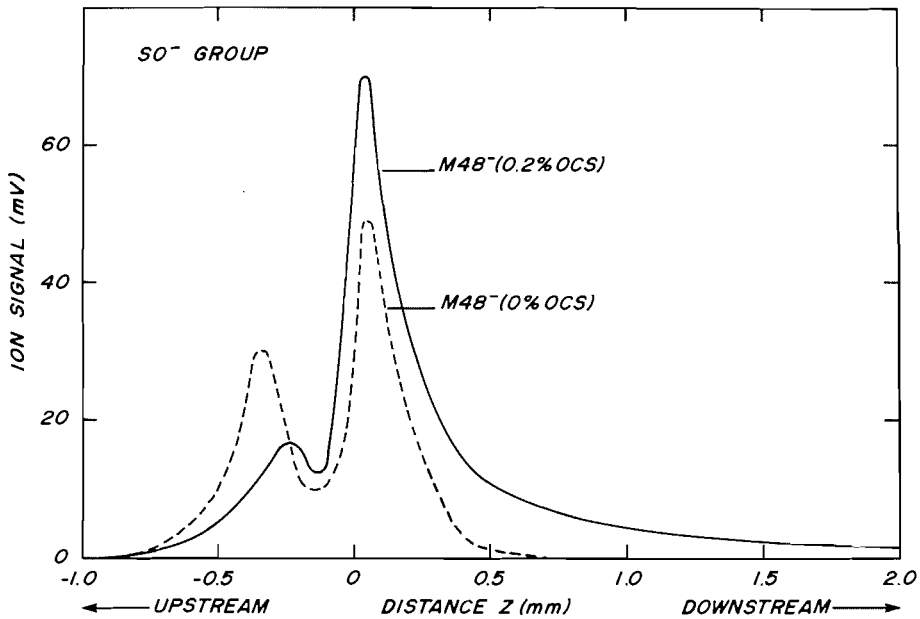

FIG. 4. Negative sulphurous ion profiles: SO⁻.

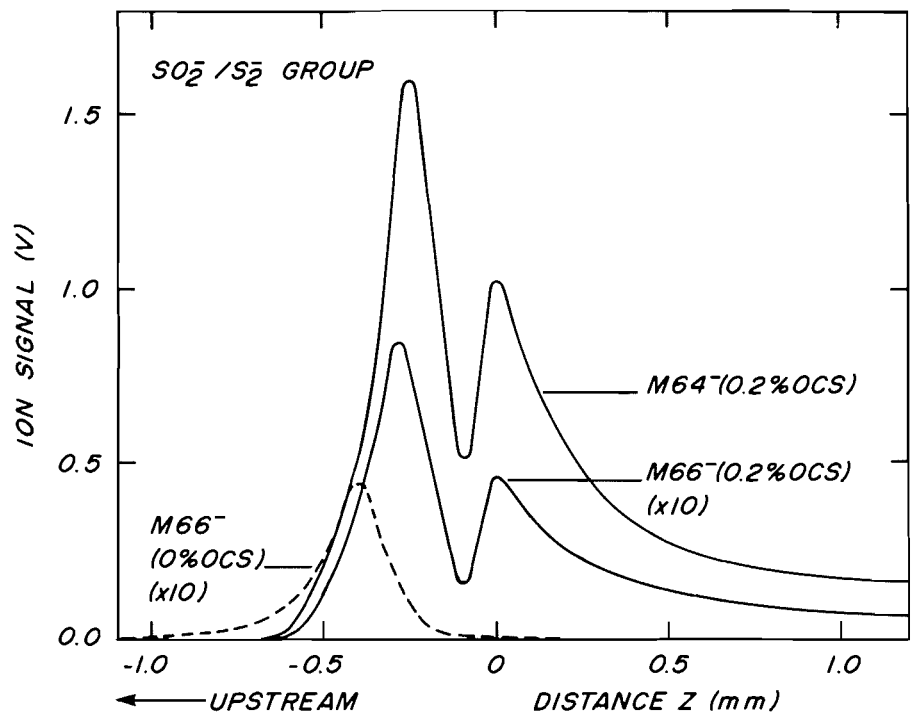

FIG. 5. Negative sulphurous ion profiles: isotopic species of SO_2^- (S_2^-). Also shown is the signal at −66 amu in the absence of OCS additive.

Those which have been studied previously by other workers, usually at room temperature, are listed in Table 3. Many are drawn from the compilation by Albritton (16). The discussion of the ion chemistry reveals the sulphurous neutral species expected to be present in the flame as intermediates and products.

There is general agreement that the main primary source of ions in a hydrocarbon flame is the chemi-ionization reaction (27, 28)

[17] $CH + O \rightarrow HCO^+ + e^-$

The negative ion chemistry commences upstream with three-body attachment of the electrons released in reaction [17] to O_2 molecules (3)

[18] $e^- + O_2 + M \rightarrow O_2^- + M$

In this study, one might expect sulphurous negative ions to arise initially by dissociative electron attachment to OCS. There are five plausible reaction channels to form O^-, C^-, S^-, SO^-, and CS^-; for example

[19] $e^- + OCS \rightarrow S^- + CO$

Although some of them have been observed at relatively high energies using electron beams (29, 30), all will be endothermic

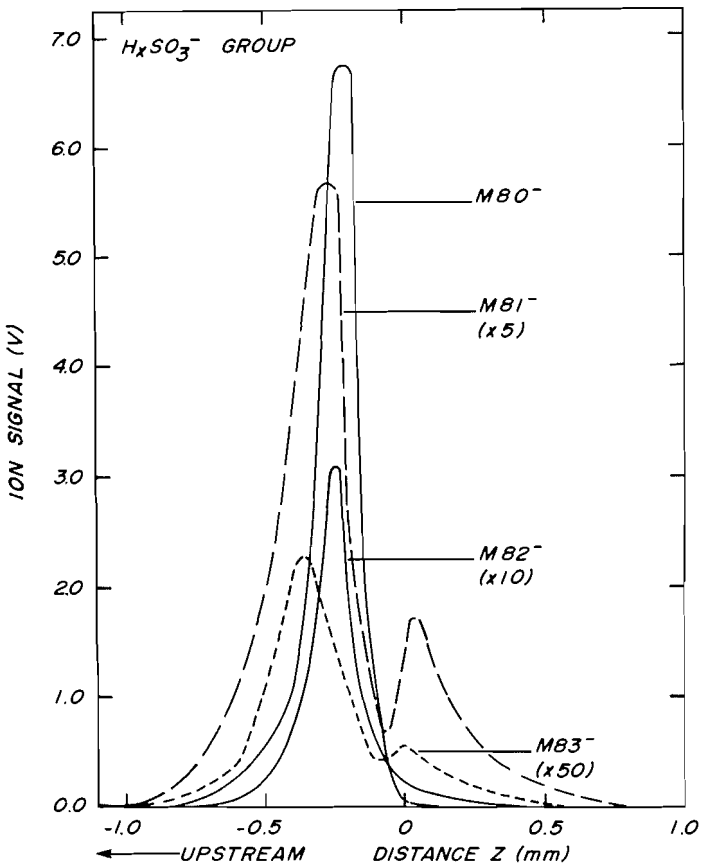

FIG. 6. Negative sulphurous ion profiles: isotopic species of SO_3^- and HSO_3^-. All profiles are taken with the addition of 0.2% of OCS.

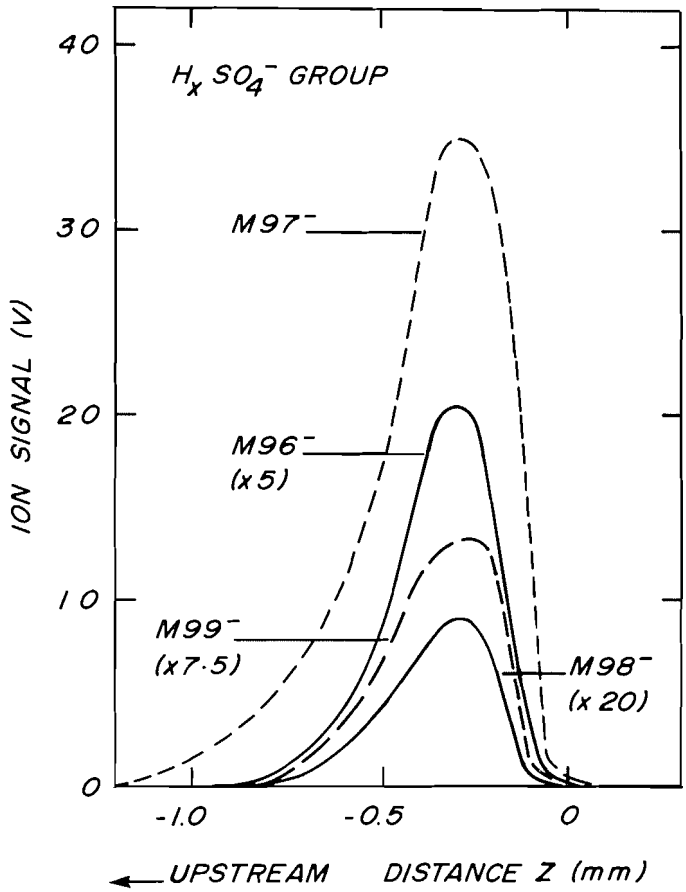

FIG. 7. Negative sulphurous ion profiles: isotopic species of SO_4^- and HSO_4^-. All profiles are taken with the addition of 0.2% of OCS.

at normal flame temperatures. Of the five, reaction [19] is the most favourable with an endothermicity of approximately 25 kcal mol^{-1}.

However, several of the sulphurous neutrals invoked in Fig. 1 have electron affinities (EA) greater than that of O_2, and can give rise to some of the observed sulphurous ions by charge transfer reactions

$$[20]\quad O_2^- + SH \rightarrow SH^- + O_2 \qquad EA(SH) = 2.319\ eV \qquad (31)$$

$$[21]\quad + SO \rightarrow SO^- + O_2 \qquad EA(SO) = 1.09\ eV \qquad (32)$$

$$[22]\quad + SO_2 \rightarrow SO_2^- + O_2 \qquad EA(SO_2) = 1.097\ eV \qquad (33)$$

$$[23]\quad + S \rightarrow S^- + O_2 \qquad EA(S) = 2.077\ eV \qquad (34)$$

Reaction [22] has a high rate constant measured at 300 K given in Table 3. It is perhaps significant that SH^- (Fig. 3) and SO^- (Fig. 4) originate farther upstream than do SO_2^- (Fig. 5) and S^- (Fig. 6) in keeping with the sequence of neutral reactions presented in Fig. 1. Also, SH^- could logically be formed by proton transfer from H_2S to a strong base such as OH^-

$$[24]\quad OH^- + H_2S \rightarrow SH^- + H_2O$$

It is not possible to differentiate between SH^- formed by proton transfer from H_2S or by charge transfer to SH. In addition, SO_2^- and SO^- could be formed by atom transfer reactions

$$[25]\quad O_2^- + OCS \rightarrow SO_2^- + CO$$

$$[26]\quad \rightarrow SO^- + CO_2$$

Both are exothermic, although reaction [26] involves a good deal of chemical rearrangement.

As was mentioned in presenting the Results for the $H_xSO_3^-$ and $H_xSO_4^-$ groups, some of the remaining sulphurous ions can be formed in clustering reactions with SO_2

$$[27]\quad OH^- + SO_2 + M \rightarrow HSO_3^- + M$$

$$[28]\quad HO_2^- + SO_2 + M \rightarrow HSO_4^- + M \qquad EA(HSO_4) > 4.5\ eV \qquad (21)$$

Reaction [27] has the very high rate constant measured at 296 K given in Table 3. Viggiano *et al.*'s determination (21) of a lower limit for $EA(HSO_4)$ based on Benson's somewhat uncertain value (35) for the bond dissociation energy of sulphuric acid $D(H—HSO_4) = 4.5$ eV means that dissociative electron attachment to H_2SO_4

$$[29]\quad e^- + H_2SO_4 \rightarrow HSO_4^- + H$$

would be exothermic, certainly near room temperature. The fact that the HSO_4^- profile (Fig. 7) does not persist downstream is strong evidence that sulphuric acid is not a major product in the burnt gas of the flame. The very large signals obtained for HSO_4^- in the reaction zone are not surprising in view of the very high values of $EA(HSO_4)$; once HSO_4^- forms by SO_2 clustering according to reaction [28], it will be very stable against loss by charge transfer to SH, SO, SO_2, etc. Also, if HSO_4^- is formed in the reaction zone by proton abstraction from H_2SO_4 by the strong base OH^-

$$[30]\quad OH^- + H_2SO_4 \rightarrow HSO_4^- + H_2O$$

the HSO_4^- profile ought to be double-peaked like that for OH^-

[a]Rate constants are given in units of cm^3 molecule^{-1} s^{-1}, or cm^6 molecule^{-2} s^{-1} where appropriate.
[b]The measurement uncertainty is ±30%.
[c]The measurement uncertainty is ±40%.
[d]The measurement uncertainty is +100%, −50%.
[e]SO_4^-* designates the less stable isomer of SO_4^-.

or HSO_3^-. Presumably HSO_4^- is lost near the end of the reaction zone because the flame attains maximum temperature and the H atom concentration rises (2, 36), both of which favour associative detachment of electrons by the reverse (endothermic) direction of reaction [29]. All things considered, the large signal detected for HSO_4^- does not provide evidence for the presence of sulphuric acid in the flame. It probably forms, however, in the cool, wet, gaseous envelope surrounding the flame proper.

Other ion–molecule reactions listed in Table 3 have been measured which can form ions of the $H_xSO_3^-$ and $H_xSO_4^-$ groups. Some of these might be regarded as switching reactions or anion transfer

[31] $CO_3^-(O^-.CO_2) + SO_2 \rightarrow SO_3^-(O^-.SO_2) + CO_2$

[32] $HCO_3^-(OH^-.CO_2) + SO_2 \rightarrow HSO_3^-(OH^-.SO_2) + CO_2$

[33] $O_3^-(O^-.O_2) + SO_2 \rightarrow SO_3^-(O^-.SO_2) + O_2$

[34] $O_2^-.H_2O + SO_2 \rightarrow SO_4^-(O_2^-.SO_2) + H_2O$

Certainly all of the reagent ions in reactions [31]–[34] have been observed in the fuel-rich flame with OCS absent (3, 15). In addition, a fast proton transfer reaction akin to [30] involving O^- as the proton acceptor has been measured (21)

[35] $O^- + H_2SO_4 \rightarrow HSO_4^- + OH$

Also, SO_4^- can be produced by a clustering reaction of SO_2^- with O_2

[36] $SO_2^- + O_2 + O_2 \rightarrow SO_4^-* + O_2$

although the less stable isomer of SO_4^- is formed, designated SO_4^-* (19). Its reaction with H atoms has been observed to produce two channels (22)

[37a] $SO_4^-* + H \rightarrow HO_2^- + SO_2$

[37b] $\rightarrow SO_2^- + HO_2$ major channel at 296 K

Many other reactions involving the $H_xSO_3^-$ and $H_xSO_4^-$ ions undoubtedly exist, but have not been measured to date.

Several examples involving the loss of sulphurous species by associative electron detachment have been measured

[38] $S^- + CO \rightarrow e^- + OCS$

[39] $S^- + O_2 \rightarrow e^- + SO_2$

[40] $SH^- + H \rightarrow e^- + H_2S$

[41a] $O^- + SO_2 \rightarrow e^- + SO_3$

[41b] $\rightarrow SO_2^- + O$ major channel at high energy

Reactions [38]–[40] have been measured at room temperature. The behaviour of reaction [41] as a function of energy or temperature may by typical and significant for flames. Although associative detachment may dominate at room temperature, a different ion–molecule reaction channel may become the major one at high temperature; e.g. charge transfer in the case of reaction [41]. In general, most of the sulphurous negative ions observed are logical candidates for associative detachment reactions with prominent flame neutrals such as H, O, OH, H_2, CO, etc. It is difficult to imagine that such reactions have large rate constants at flame temperatures in view of the large signals obtained for most of the sulphurous negative ions observed.

With regard to the burnt gas region downstream, the HSO_3^- profile (Fig. 6) persists to some extent in keeping with the interpretation of its formation as a cluster ion of OH^- with SO_2 by reaction [27]. The similarity to the OH^- profile was mentioned near the end of the section on Results. However, four of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

the ion profiles (S^- and SH^- in Fig. 3, SO^- in Fig. 4 and SO_2^- in Fig. 5) persist far downstream through the burnt gas where no negative ions are detected in the same flame with OCS absent. From the electron affinities given beside reactions [20]–[23], a mechanism can be envisaged involving formation by three-body electron attachment primarily to SO_2, with subsequent charge transfer to SH, S, and SO, balanced by loss processes involving associative electron detachment with H, O, and CO, and collisional detachment. Such a network of reactions is reasonable to account for the persistent steady-state profiles observed for these four ionic species. It is consistent with the presence throughout the burnt gas of the sulphurous neutral species, SH, SO, SO_2, and S.

Conclusions

A number of conclusions may be drawn from this work pertaining to both the ion chemistry and the neutral chemistry of sulphur in flames.

Ion chemistry

(*1*) Most of the sulphurous negative ion chemistry seems to be understandable in terms of the relatively few ion–molecule reactions involving sulphurous species measured to date near room temperature.

(*2*) Negative ion clustering and switching (or anion transfer) reactions with SO_2 appear to be prominent.

(*3*) None of the sulphurous negative ions detected contain carbon, even under fuel-rich conditions.

(*4*) For analytical purposes concerned with the mass-spectrometric monitoring of sulphur in flames, very large signals of HSO_4^- were detected around the flame reaction zone. Persisting downstream through the burnt gas, SH^- and SO_2^- are the logical candidates.

Neutral chemistry

(*5*) The profiles show that all of the expected sulphur compounds — $SH(H_2S)$, SO, $SO_2(S_2)$, S — are present *early in the flame reaction zone*. The rates of the chemical reactions summarized in Fig. 1 which interconvert these species must be fast in the flame environment, since OCS is rapidly oxidized to SO_2 even under fuel-rich conditions.

(*6*) The main-line neutral sulphur chemistry in the flame appears to follow the sequence OCS → (SH) → SO → SO_2. The species S, S_2, and H_2S are involved in chemical side-lines. No direct evidence was obtained for S_2, however.

(*7*) No evidence was obtained for H_2SO_4 or H_2SO_3 in the flames proper, although they will undoubtedly form in the cooler, wet region adjacent to the combustion envelope.

The thermal decomposition of azobenzene

DONALD BARTON, MICHAEL HODGETT, PAUL SKIRVING, MICHAEL WHELTON, KEITH WINTER, AND CATHY VARDY
Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received March 17, 1982[1]

DONALD BARTON, MICHAEL HODGETT, PAUL SKIRVING, MICHAEL WHELTON, KEITH WINTER, and CATHY VARDY. Can. J. Chem. **61**, 1712 (1983).

The rate of nitrogen formation during the thermal decomposition of azobenzene in static and stirred-flow systems was measured over the temperature range of 368.9°C to 437.4°C. The first order rate constant was found to be given by the expression

$$k = 10^{16.6\pm0.5} \exp(-278{,}000 \pm 7000/8.314T)\ s^{-1}$$

A consideration of the equilibrium constant between *cis*-azobenzene and *trans*-azobenzene, and the rate of attainment of equilibrium, leads to the conclusion that a small concentration of *cis*-azobenzene is always present, at equilibrium with the *trans* isomer. Since the *cis* isomer is likely to be more reactive than the *trans* isomer the rate constant cannot be ascribed to the *trans* isomer alone. No effect of variation of surface-to-volume ratio could be detected. Some preliminary experiments in which toluene and ethylene were employed as additives indicated that these did not affect the rate of formation of nitrogen. Nevertheless, because of a certain amount of scatter in the results, a small effect could not be excluded. There were at least nine products, in addition to nitrogen.

DONALD BARTON, MICHAEL HODGETT, PAUL SKIRVING, MICHAEL WHELTON, KEITH WINTER et CATHY VARDY. Can. J. Chem. **61**, 1712 (1983).

On a mesuré la vitesse de formation de l'azote lors de la décomposition thermique de l'azobenzène dans des systèmes à écoulement statique et à écoulement perturbé dans un intervalle de température allant de 368,9°C à 437,4°C. On a trouvé que l'expression suivante donne la constante de vitesse d'ordre un:

$$k = 10^{16.6\pm0.5} \exp(-278{,}000 \pm 7000/8{,}314T)\ s^{-1}$$

En tenant compte de la constante d'équilibre entre l'azobenzène *cis* et l'azobenzène *trans*, et de la vitesse à laquelle cet équilibre est atteint, on conclut qu'une faible concentration d'azobenzène *cis* est toujours présente en équilibre avec l'isomère *trans*. Puisque l'isomère *cis* est ordinairement plus réactive que l'isomère *trans*, on ne peut attribuer la constante de vitesse à l'isomère *trans* uniquement. On ne peut pas déceler l'effet d'une variation de surface sur le rapport du volume. Quelques expériences préliminaires dans lesquelles on a utilisé le toluène et l'éthylène comme additifs indiquent que ces additifs n'affectent pas la vitesse de formation de l'azote. Néanmoins, on ne peut pas exclure un léger effet à cause d'une certaine dispersion dans les résultats. Il y a au moins neuf produits en plus de l'azote.

[Traduit par le journal]

Introduction

Even though azobenzene should occupy the position of the prototype substance in gas-phase reactions of aromatic azo compounds, as does azomethane for aliphatic azo compounds, little attention has been given to its gas-phase reactions. This situation appears to have arisen from the fact that M. J. Jaquiss and M. Szwarc were unable to detect any reaction in flow systems with toluene, up to, apparently, 700°C (1). Subsequently the supposition of extreme unreactivity appeared a number of times in the literature, reinforcing this belief. Several years ago, while preparing for an investigation of azobenzene in the gas phase, we found the report by Inokawa *et al.* (2), in which the discovery of accelerated thermal decomposition of 1,2-dichloroethane by azobenzene in the temperature range of 400°C to 500°C was described. We selected 400°C for our first experiment and found that nitrogen was evolved at a rate which was convenient for study using an ordinary static system. Since that time the reactivity of azobenzene has been clearly confirmed by Leiba and Oref, who pyrolyzed it in sealed glass tubes (3). Another reference to its reactivity appeared in Engel's review (4) of aliphatic azo compounds which cited the work of Louw and Rothuizen (5) who had studied the gas-phase phenylation of arenes using, among other substances, azobenzene as a source of phenyl radicals at 500°C. In retrospect we can see that its reactivity had been well established. Of course, because of the size of the azobenzene molecule, it did not attract interest in connection with energy transfer processes, as did azomethane; moreover, the low volatility of such substances tends to discourage their investigation in the gas phase.

The original reason for starting this investigation was to determine the usefulness of azobenzene as a source of phenyl radicals, although it soon became apparent that the reaction would be inherently interesting and that comparison with reactions of other azo compounds would be important.

Experimental

Both static and stirred-flow systems were used. The experiments which were carried out on the static system are classified as either preliminary or regular experiments, for reasons which will be explained.

Materials

For the preliminary experiments zone-refined azobenzene, obtained from the Aldrich Chemical Company, was used without treatment. For all other reported experiments azobenzene, obtained from British Drug Houses, catalogue number B15005-30, was first crystallized from methanol, then zone refined, then sublimed, and finally zone refined again. This method of purification is essentially that of Cammenga *et al.* (6), except that zone refining was carried out in air rather than in argon. No impurities were detected using thin-layer chromatography. Phillips research grade of ethylene was used without treatment, as was toluene-d_8, obtained from Merck Sharp and Dohme Canada Limited.

TABLE 1. Order and rate constants for benzene formation

Temperature, °C	Number of runs	Order	ln k*
386.0±0.2	7	0.89±0.07	−15.52±0.21
413.4±0.3	22		−13.01±0.31
423.5±0.2	17	0.86±0.07	−11.91±0.17

*k is defined as $k = (-[C_6H_6]/t)/[C_{12}H_{10}N_2]_i$. Errors here and in the other tables are standard deviations.

Static system

The experiments which were carried out on the static system employed two spherical Pyrex reaction vessels which were almost identical except that one contained Pyrex tubes. Those parts of the vacuum system which were exposed to azobenzene or condensable products were contained in an air bath which was thermostatted at 155°C to 160°C. Capacitance manometers were used for measuring pressure and calibrated Chromel–Alumel thermocouples were used for measuring temperature (7). Nitrogen was collected in a gas burette and sometimes removed for analysis by mass spectrometer. The benzene, in a number of experiments, was swept from a trap to a gas chromatograph, and the accumulated solid products were examined by thin-layer chromatography.

Preliminary experiments are so designated because greased stopcocks were used and a slight uptake of azobenzene by grease was observed during some of these experiments. The regular experiments are those in which metal valves with polyimide seats and gaskets were used in appropriate places. Arrhenius parameters for nitrogen formation were derived from results of regular experiments.

Flow system

The reaction vessel, similar to that described by Mulcahy and Williams (8) for stirred-flow systems, was made of quartz, with a volume of 1316 cm^3. The flow sequence was so designed that no valves or stopcocks were used on the upstream side of the reaction vessel, and valves with Viton diaphragms were used in suitable places on the downstream side. Appropriate parts were contained in an air bath. Temperature and pressure measurements and collection of nitrogen were carried out as described for the static system. Collection periods were usually in the range of 30 to 60 minutes.

Results

Products

All of the reported products are those obtained from experiments in which the extent of reaction was quite low. On the flow system the ratio of yield of nitrogen to the number of moles of azobenzene passing through the reaction vessel varied from 0.003 to 0.03. On the static system the corresponding ratio was generally in the range from 0.01 to 0.05. The fraction of azobenzene reacted is likely greater than these ratios suggest since various products containing nitrogen are observed.

Products passing through a liquid nitrogen trap

Molecular nitrogen is plentiful, as is usual in pyrolysis of azo compounds. A number of samples of this fraction from the static system were examined by mass spectrometer. Hydrogen was always found although the concentration was not very reproducible. At 413.4°C the mean concentration of hydrogen in nitrogen, from 18 experiments, was 0.64% and, at 423.5°C, 1.6% from 24 experiments. No other products could be found in this fraction.

Products passing through a trap at 0°C

The accumulated products, a small drop, from all of the reported experiments on the flow system were subjected to mass spectrometric and proton magnetic resonance analysis. The spectra were consistent with the presence of aniline and benzene. Small amounts of other products or impurities could also be detected. The yield of benzene relative to nitrogen increased over an extended time.

It is worth mentioning at this point that much effort was wasted by using B.D.H. azobenzene, without further purification, on the flow system. Not only did the composition of the products seem somewhat different than that from the purified azobenzene but, also,the rate of nitrogen formation was different. In fact, the rate of nitrogen formation could be increased by increasing the flow rate at low extent of reaction. This observation is consistent with the presence of an impurity which reacts almost to completion, producing nitrogen. Untreated azobenzene had been used because the flow system consumed so much material that a sufficient supply of purified azobenzene for numerous runs could not be maintained.

The remaining fraction

Most of this fraction could be easily distilled or sublimed with the exception of a small amount of black material, which nevertheless was volatile enough to find its way from reaction vessel to trap. The 1005 cm^3 reaction vessel on the static system remained clean, indicating that little or no breakdown to carbon took place.

Qualitative analysis of this fraction was started, but by no means completed, using thin-layer chromatography followed by mass spectrometric examination of the fractions. Six products were evident although more may eventually be found. One has the mass spectrum reported in the literature for carbazole and another that reported for diphenylamine (9). A third and fourth have mass spectra which one would expect of phenylazobenzene and of triphenylamine. The other two have not been identified. Biphenyl was not found but the possibility still exists that it may have been missed.

Rate of reaction

All data on rate of reaction were obtained from experiments in which the extent of reaction was small, as described above.

Benzene

The results are shown in Table 1, in which $[C_{12}H_{10}N_2]_i$ is the initial concentration of azobenzene.

Nitrogen

The results from the static system which were used to obtain the Arrhenius parameters for nitrogen formation were treated in the following way. Yield of nitrogen as a function of time was obtained for various initial concentrations of azobenzene and the slopes of the yield vs. time plots were obtained by linear regression analysis. Because small negative intercepts were often observed, the lines were not forced to pass through the origin. Reaction orders at three temperatures were obtained by means of ln−ln plots using the slopes of the yield vs. time plots and the initial concentrations of azobenzene. Rate constants which are obtained from such ln−ln plots are extremely sensitive to the order. Therefore the data were treated in a

*The origin of each rate constant is explained in the text
†Abbreviations: s, static system; f, flow system.

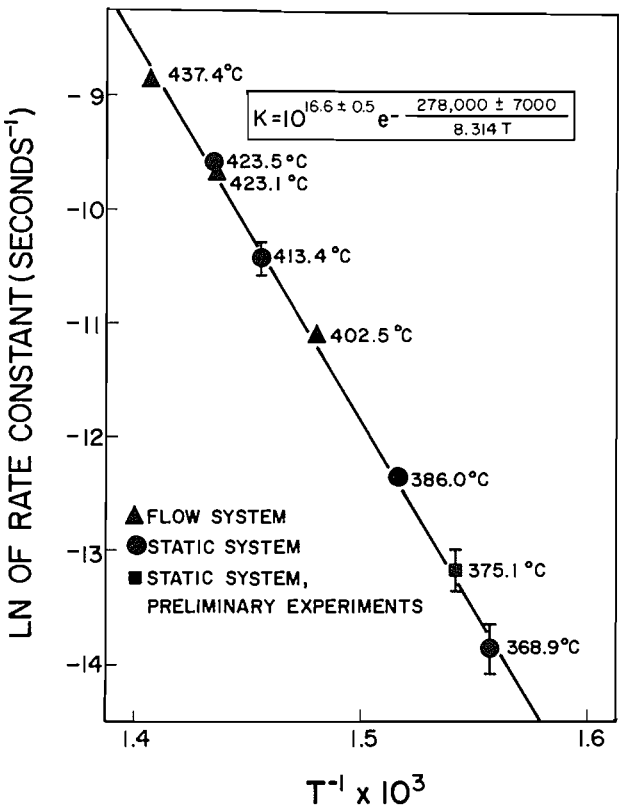

FIG. 1. Arrhenius plot for nitrogen formation. The results of preliminary experiments were not used to determine the Arrhenius parameters. The bars represent standard deviations of rate constants. If none are shown they are smaller than the data symbols.

self-consistent way by defining the rate constant as $k = S/[C_{12}H_{10}N_2]_i$ s^{-1}, in which S represents the slope of the yield–time line. The data are thus forced to fit a first order rate expression. The mean rate constant from several concentrations of azobenzene, at each temperature, was then calculated. Because yield vs. time data were not available from the flow system, the rate constants were defined as $k = ([N_2]/t)/[C_{12}H_{10}N_2]$ s^{-1}. $[C_{12}H_{10}N_2]$ is calculated from the total pressure in the reaction vessel. The data for nitrogen are summarized in Table 2 and the Arrhenius plot is shown in Fig. 1.

Effect of variation of surface-to-volume ratio

The number of experiments carried out in the packed vessel was too small to allow treatment of data by the yield vs. time method. Therefore the rate constants were defined by the expression $k = ([N_2]/t)/[C_{12}H_{10}N_2]_i$. In order to facilitate comparison of the results with those found using the unpacked vessel, the results from the unpacked vessel were treated in the same way, using only those experiments in which the initial pressures were equal to or greater than those in the packed vessel. Reaction times of experiments in both vessels were sufficiently long to avoid appreciable effects of the apparent induction period. The results are shown in Table 3. No effect of surface is evident.

TABLE 3. Effect of surface-to-volume ratio on rate of formation of nitrogen

Area, cm^2	Volume, cm^3	Temperature, °C	Number of runs	ln k*
1147	980	369.0±0.2	6	−13.97±0.30

Effect of toluene and ethylene

We wish to emphasize that these results were obtained from the preliminary experiments, that is, those in which greased stopcocks were used, and some error in concentration of azobenzene is possible due to dissolution in the grease. Nevertheless, the mean rate constant in the absence of additives is almost identical to that found from the Arrhenius plot of the data from the regular experiments in which polyimide seated and gasketted valves were used, as can be seen in Fig. 1. This correspondence allows confidence to be placed in the results of the preliminary experiments. With due consideration to the errors, as seen in Table 4, no effect is apparent. A small effect, such as that observed for ethylene on azomethane (11) would be obscured by these errors. The rate constants are defined as in the previous section.

Comments on the results of Leiba and Oref

The Arrhenius parameters which were reported by Leiba and

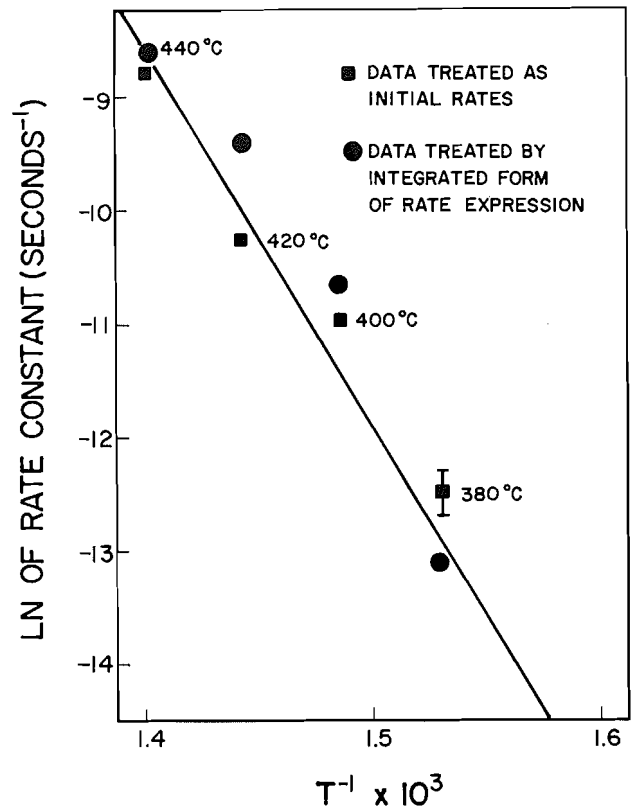

FIG. 2. The results of Leiba and Oref treated as initial rate data. The error at 380°C is standard deviation. Their reported rate constants are also shown. The line is *our* Arrhenius plot.

Oref (3) are not the same as ours. There are, however, certain problems connected with their data, and the treatment of their data, which led us to the conclusion that their Arrhenius parameters are suspect. Leiba and Oref reported the results of twenty-one experiments in which weighed samples of azobenzene were heated in sealed glass ampoules. After being heated for various lengths of time, the ampoules were cooled and the yields of nitrogen were determined. The results were fitted to the integrated form of the first order rate expression by assuming, implicitly, that the number of moles of nitrogen was equal to the number of moles of azobenzene which had reacted. Leiba and Oref, who postulated the existence of involatile nitrogen-containing products, did not, apparently, consider this problem of stoichiometry when treating their data. There is also a possibility that the stoichiometry is a function of time, because reactive intermediates such as amines and azo compounds are likely to be present. Therefore, the integrated form of the rate expression may not be applicable.

Other reasons for avoiding the integrated form of the rate expression become apparent when their data for the ratio $[N_2]/[C_{12}H_{10}N_2]_i$ are plotted as a function of time. Even though the initial pressures differ among the various runs this would be a legitimate plot of first order data, which should be concave with respect to the time axis. An examination of the data obtained at 380°C reveals that the extent of reaction, as measured by the yield of nitrogen, is small, $[N_2]/[C_{12}H_{10}N_2]_i$ being less than 0.03. Due to errors of measurement or other factors, a definite increase in yield as time progresses is not apparent. The use of an integrated form of the rate expression under these circumstances should not be expected to produce a significant rate constant. In order to compare their results with ours, the yields of nitrogen were treated as initial rate measurements. The mean of six rate constants at 380°C is plotted in Fig. 2, in which the solid line represents the Arrhenius plot of our results. Their result, using the integrated form, is also shown and is seen to be similar to that using initial rates, and is also very close to our Arrhenius plot, which is surprising when the scatter and small extent of reaction are considered.

An examination of the data obtained at 400°C and at 420°C reveals additional problems. At 400°C the rate is essentially the same for all points, and at 420°C the rate clearly increases as time progresses and then becomes constant, so in neither case can information be obtained from the integrated form. If, however, the first two data at 400°C, and the first at 420°C, are treated as initial rates, the two rate constants straddle our Arrhenius plot, as can be seen in Fig. 2. At 440°C the extent of reaction is large and the rate clearly decreases as time progresses, so that if the problem of stoichiometry is ignored, an integrated rate expression may be applied. There are too few data, however, to definitely establish the order in this way. Nevertheless, the rate constant which was calculated by Leiba and Oref from the measurements at 440°C coincides precisely with our Arrhenius plot. In addition, the first point, when treated as an initial rate, yields a rate constant which is also very close to our Arrhenius plot. In summary, therefore, the treatment of these data by means of the integrated form of the first order rate expression cannot be expected to produce results of any significance except, possibly, at 440°C. On the other hand, estimates of the initial rates produce rate constants which are self-consistent and also in reasonable agreement with ours.

Discussion

Products

The following reactions account for the products which have been identified so far.

Although hydrazines have been observed among the products of decomposition of azoalkanes, they may be too reactive to be observed here because the temperature is rather high. For

$$C_6H_5N{=}NC_6H_5 \rightarrow 2C_6H_5\bullet + N_2$$
$$C_6H_5\bullet + C_6H_5N{=}NC_6H_5 \rightarrow C_6H_6 + C_6H_5N{=}NC_6H_4\bullet$$
$$C_6H_5 + C_6H_5N{=}NC_6H_4\bullet \rightarrow C_6H_5N{=}NC_{12}H_9$$
$$C_6H_5\bullet + C_6H_5N{=}NC_6H_5 \rightarrow (C_6H_5)_2N{-}\dot{N}C_6H_5$$
$$(C_6H_5)_2N{-}\dot{N}C_6H_5 + C_6H_5N{=}NC_6H_5 \rightarrow (C_6H_5)_2N{-}NH(C_6H_5) + C_6H_5N{=}NC_6H_4\bullet$$
$$(C_6H_5)_2N{-}NH(C_6H_5) \rightarrow (C_6H_5)_2N\bullet + (C_6H_5)HN\bullet$$
$$(C_6H_5)_2N\bullet + C_6H_5N{=}NC_6H_5 \rightarrow (C_6H_5)_2NH + C_6H_5N{=}NC_6H_4\bullet$$
$$(C_6H_5)HN\bullet + C_6H_5N{=}NC_6H_5 \rightarrow C_6H_5NH_2 + C_6H_5N{=}NC_6H_4\bullet$$
$$(C_6H_5)_2N\bullet + C_6H_5\bullet \rightarrow (C_6H_5)_3N$$

example, the rate constant for decomposition of phenylhydrazine is $k = 10^{15.5} \exp(-214000/8.314T)$ s^{-1} (10), as measured by the toluene carrier technique, so that the concentration of hydrazines of similar reactivity would remain low. One possible source of hydrogen, the reaction of diphenylamine to produce carbazole, is shown. This reaction might take place at the surface, the rate being very erratic.

The ratio of benzene to nitrogen increases as the extent of reaction increases, Such behaviour may be ascribed to decomposition of products, producing benzene, or to an increased rate of hydrogen abstraction by phenyl radicals, relative to addition, as products accumulate. Benzene formation has a very strong temperature dependence as would be consistent with competitive addition and abstraction reactions, the abstraction reactions having the greater activation energy. Because of the probable difficulty in recovery of benzene, it is best not to give too much quantitative significance to the benzene data.

Nitrogen

As a basis for discussion we assume that nitrogen, at low extent of reaction, arises directly from azobenzene, and that any contribution of chain reactions is negligible. The results of experiments in which ethylene or toluene was present support this assumption, although a small effect of additives cannot be excluded.

Equilibrium constant for isomerization

Although the equilibrium constant for isomerization in the gas phase is unknown, a good estimate can be made. Cammenga *et al.* (6) found $\Delta H^{\ominus}$ (298.15 K) of the reaction *trans*-$C_{12}H_{10}N_2$(g) → *cis*-$C_{12}H_{10}N_2$(g) to be +47.8 kJ mol^{-1}. If $\Delta S^{\ominus}$ and $\Delta C_p^{\ominus}$ are small, as may be true for such reactions (e.g. see the properties of some alkenes, ref. 12), then $K_p \simeq \exp(-47800/8.314T)$. The estimated equilibrium constants at the upper and lower limits of temperature achieved in this study are listed in Table 5. Even if allowance were made for small values of $\Delta S^{\ominus}$ and $\Delta C_p^{\ominus}$, the *trans* isomer would clearly predominate.

Relaxation time for isomerization

Although the *trans* isomer is predominant at equilibrium, both in the air bath and reaction vessel, the question of the rate of attainment of equilibrium, following introduction into the reaction vessel, is an important one. Rates of isomerization have been measured in organic solvents but not in the gas phase. Since the rate constants are not very dependent upon the nature of the solvent, the assumption has been made that they are applicable to the gas phase. The rate constant for isomerization from the *cis* to the *trans* forms in benzene, for example, is $k = 2.10 \times 10^{11} \exp(-97490/8.314T)$ s^{-1} (13). This rate constant, along with the estimated equilibrium constants, allows estimates to be made of the rate constants in both directions and the relaxation times, as listed in Table 5. Therefore, when azobenzene is introduced into the reaction vessel from the air bath, relaxation is likely to be rapid. It was considered possible that the apparent induction period might be connected in some way to isomerization,[2] but the relaxation time is too short for this to be so. Of course, if our estimate of the relaxation time is much too low, the argument is invalid.

Rate of decomposition of the two isomers

Engel described two limiting kinds of azo compounds, classified according to their rates of isomerization and decomposition (4). One kind has a low activation energy for isomerization, relative to decomposition, and the other, a high activation energy for isomerization relative to decomposition. Azobenzene is evidently an example of the former. Measurement of the separate rate constants for decomposition of this kind appears to be impossible because of the rapid rate of interconversion of the isomers. If the assumption is made, as Engel did for the azoalkanes, that the transition states for decomposition are identical, an enthalpy − activation energy − entropy diagram may be constructed as in Fig. 3. Then by using the transition state formulation of the rate constant, $k = (ekT/h) \exp \Delta S^{\ddagger}/R \exp(-E/RT)$, for each isomer along with $K_p = \exp \Delta S^{\ominus}/R \exp(-\Delta H^{\ominus}/RT)$ and $E_c + \Delta H^{\ominus} = E_t$ and $\Delta S_c^{\ddagger} + \Delta S^{\ominus} = \Delta S_t^{\ddagger}$, where *c* and *t* represent *cis* and *trans* isomers, it is easily shown that one-half of the nitrogen arises from the *cis* isomer and one-half from the *trans* isomer.[3] The rate constant for decomposition of the *trans* isomer would therefore be equal to one-half of the observed rate constant, $k_t = 2.06 \times 10^{16} \exp(-278000/8.314T)$ s^{-1}. In order to estimate k_c an accurate expression for K_p is needed. Nevertheless, the estimate already made may be used to give $k_c \simeq 2.06 \times 10^{16} \exp(230000/8.314T)$ s^{-1}. It is clear that the observed rate constant may not be simply ascribed to the *trans* isomer, even though the concentration of the *cis* isomer is very small over the entire temperature range.

TABLE 5. Estimated values of rate constants and equilibrium constants for the isomerization reaction *trans*-$C_{12}H_{10}N_2$(g) ⇄ *cis*-$C_{12}H_{10}N_2$(g)

Parameter	Value at 368.9°C	Value at 437.4°C
K_p	1.29×10^{-4}	3.06×10^{-4}
k(*cis* → *trans*)	2.46×10^{3} s^{-1}	1.43×10^{4} s^{-1}
k(*trans* → *cis*)	3.15×10^{-1} s^{-1}	4.38 s^{-1}
Relaxation time	4.06×10^{-4} s	6.99×10^{-5} s

π-Bond energy of nitrogen

It is interesting to calculate the second π-bond energy of nitrogen by using data from studies of thermal decomposition of several azo compounds. This is done using the sequence of reactions

[1] $C_6H_5N{=}NC_6H_5 \rightarrow C_6H_5N{=}N\cdot + C_6H_5\cdot$

[2] We are grateful to Dr. Robert Back for emphasizing this point.

[3] The mechanism of nitrogen formation is assumed to be

$$trans\text{-}C_{12}H_{10}N_2 \underset{k_b}{\overset{k_f}{\rightleftharpoons}} cis\text{-}C_{12}H_{10}N_2$$

$$trans\text{-}C_{12}H_{10}N_2 \xrightarrow{k_t} N_2 + 2C_6H_5\cdot$$

$$cis\text{-}C_{12}H_{10}N_2 \xrightarrow{k_c} N_2 + 2C_6H_5\cdot$$

A complete solution of this mechanism has been reported by Seeman and Farone (15). If equilibrium is maintained between the two isomers, the rate expression has the simple form

$$d[N_2]/dt = \{(k_t + k_c K_p)/(K_p + 1)\}[C_{12}H_{10}N_2]$$

The sum of the concentrations of the two isomers is $[C_{12}H_{10}N_2]$ and $K_p = k_f/k_b$. If, in addition, $K_p \ll 1$, $d[N_2]/dt = (k_t + k_c K_p) \times [C_{12}H_{10}N_2]$, and $[C_{12}H_{10}N_2]$ becomes essentially the concentration of the *trans* isomer. In the transition state formulation $k_t = k_c K_p$ if the transition states are identical, and the rates of formation of nitrogen from the two isomers become equal.

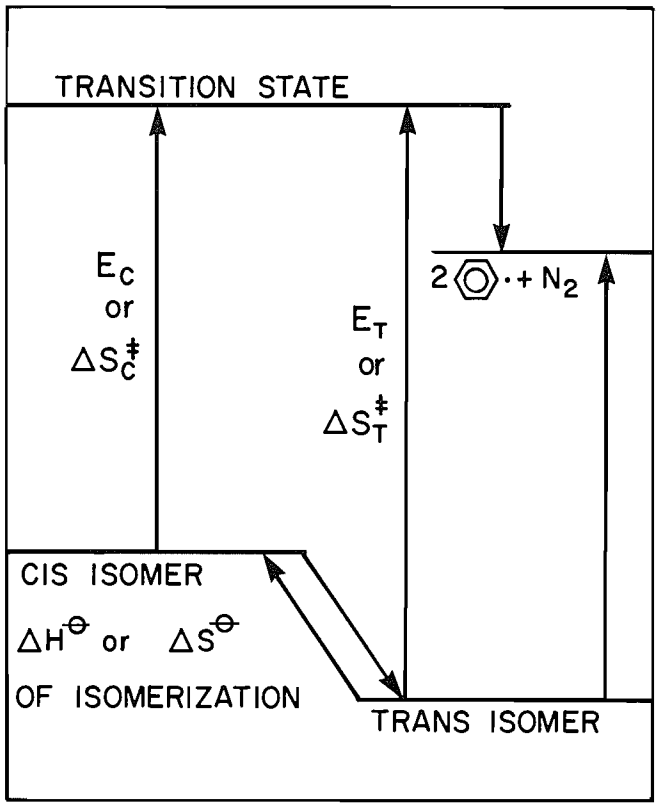

FIG. 3. Path diagram for decomposition of the two isomers following Engel's argument. Symbols are defined in the text.

[2] $C_6H_5N{=}N\cdot \rightarrow C_6H_5\cdot + \cdot N{=}N\cdot$

[3] $\cdot N{=}N\cdot \rightarrow N_2$

Reactions [2] and [3] are usually written as a single reaction but are now written as two in order to emphasize what is meant by the π-bond energy, $-\Delta H_3^{\ominus}$ (14). The enthalpy change of reaction [4]

[4] $C_6H_5N{=}NC_6H_5 \rightarrow 2C_6H_5\cdot + N_2$

is equal to the sum of the others, and if $\Delta H_1^{\ominus} \simeq \Delta H_2^{\ominus} = E$, where E is the Arrhenius activation energy, $\Delta H_3^{\ominus} = \Delta H_4^{\ominus} - 2E$. Benson had calculated $-\Delta H_3^{\ominus}$ using data for azomethane and obtained a value of the π-bond energy which he thought to be a reasonable upper limit, 338 kJ mol^{-1} (see ref. 10, p. 32). If two-bond rupture occurs, the effect is expected to be a lowering of E, since reactions [2] and [3] together are exothermic, signifying that $\Delta H_1^{\ominus} > E$ and therefore that $-\Delta H_3^{\ominus} > 338$ kJ, which was thought to be unreasonably high. Subsequently the enthalpy of formation of a number of azoalkanes was found from combustion studies and, as a result, a better estimate of the enthalpy of formation of azomethane was made (16). Only the enthalpy of formation of azoisopropane was available to Benson, and even that has been appreciably revised (17). In the meantime, Engel and Bishop obtained a lower value of $-\Delta H_3^{\ominus}$ or E_π, using different values of E and enthalpy of formation of azomethane (18).

The resulting estimates of the second π-bond energy, at the median temperature of each study, are listed in Table 6.

It is astonishing to find that values of $\Delta H_3^{\ominus}$ which are calculated from independent data, arising from such different substances as azobenzene and azomethane, are practically identical, and that such different values of E and $\Delta H_4^{\ominus}$ generate values of $\Delta H_3^{\ominus}$ which are so close to one another. If the π-bond energy is actually that found from azomethane and azobenzene data, we conclude, using this model, that there is an appreciable contribution of two-bond rupture in the decomposition of azoisopropane and azoethane.

TABLE 6. Second π-bond energy of N_2,* kJ mol^{-1}

	T	$\Delta H_4^{\ominus}$	E	$\Delta H_3^{\ominus}$
Azoisopropane	573 K	120±9	197±3	−273±10
Azoethane	573 K	128±9	205±2	−282±9
Azomethane	552 K	142±11	232±3	−322±12
Azobenzene	675 K	241±9	278±7	−315±16

*Data and references may be obtained from the Depository or the authors.

Such a conclusion should be treated cautiously for at least two reasons. It is very difficult to be certain that Arrhenius parameters of elementary reactions have been observed. For example, even azomethane, the most thoroughly studied of all, may well have a lower activation energy than that found in the presence of nitric oxide (for a comment on this possibility see ref. 19). For azobenzene, only preliminary evidence as to the effect of additives is available. In addition, an entirely different interpretation of the decomposition of three azoalkanes was considered by Gowenlock *et al.* (20). They concluded, from appearance potentials of radicals, that E is greater than $\Delta H_1^{\ominus}$. Besides, the radical $\cdot N{=}N\cdot$ was considered to be like the $A\,^3\Sigma_u^+$ spectroscopic state with energy E^*, and that if a radical such as $C_6H_5N{=}N\cdot$ is formed, E should be equal to $\frac{1}{2}(E^* + \Delta H_4)$, much greater than observed values.

Donor numbers: ^{27}Al quadrupole relaxation as a measure of solvent donicity towards the sodium ion

MARION C. DAY,[1] JAMES H. MEDLEY, AND NASEER AHMAD
Department of Chemistry, Louisiana State University, Baton Rouge, LA 70803, U.S.A.

Received November 4, 1982

MARION C. DAY, JAMES H. MEDLEY, and NASEER AHMAD. Can. J. Chem. **61**, 1719 (1983).

A new method is presented for the determination of solvent donicity towards the sodium ion that avoids solvent–solvent interactions. Using the system

$NaAlEt_4$–benzene–donor

the response of the ^{27}Al quadrupole relaxation to anion symmetry as a function of donor:Na^+ ratio is monitored by both ^{27}Al line widths and methylene ^{1}H absorptions. The assumption is made that anion symmetry is dependent on the cation–anion interaction which is dependent on the stability of the donor–Na^+ solvates. The ordering of donors is found to differ from the generally accepted listing. A ranking of seventeen donors is given.

MARION C. DAY, JAMES H. MEDLEY et NASEER AHMAD. Can. J. Chem. **61**, 1719 (1983).

On présente une nouvelle méthode de détermination du caractère donneur du solvant envers l'ion sodium, qui élimine les interactions solvant–solvant. Utilisant le système

$NaAlEt_4$–benzène–donneur

on a enregistré la réponse de relaxation quadrupolaire du ^{27}Al à la symétrie de l'anion en fonction du rapport donneur: Na^+ en faisant appel à la fois à la largeur de la raie du ^{27}Al et aux absorptions du ^{1}H du méthylène. On pense que la symétrie de l'anion dépend de l'interaction cation–anion qui est fonction de la stabilité des produits de solvation du système donneur–Na^+. On trouve que l'arrangement des donneurs diffère du schéma généralement accepté. On présente une classification comprenant dix-sept donneurs.

[Traduit par le journal]

Introduction

The importance of solvent donicity to the study of ionic solutions in nonaqueous media is certainly well accepted today with the Gutmann donor numbers being the most commonly used representation (1). This is simply ΔH of the reaction

[1] $D + SbCl_5 \rightarrow SbCl_5D$

Obviously ΔH of this reaction does not give a complete measure of the complexing ability of the donor, D. Nevertheless, it does seem to give a reasonable measure of the desired quantity. Extensions of the Gutmann scale have been made using a variety of techniques (2), but Gutmann distinguishes between donor numbers determined by eq. [1], and values obtained by alternative methods (2). The extended Gutmann scale is now generally used regardless of the Lewis acid. But one cannot help but question the general applicability of the scale, particularly towards small cations such as Li^+, Na^+, and K^+, where the ion–solvent interaction may be more reasonably considered as ion–dipole.

This question appeared to be resolved as a result of the ^{23}Na nmr chemical shift studies of Erlich, Roach, and Popov (3). They observed the ^{23}Na chemical shifts of sodium tetraphenylborate in eleven different solvents and noted a linear relationship between the chemical shifts and the Gutmann donor numbers. This was later extended to sixteen different donors (4). However, a complication arose when Greenberg and Popov later found that pyridine (py) appeared to be a much weaker donor than either dimethylsulfoxide (DMSO) or tetramethylurea (TMU) (5). Both of these have lower donor numbers than pyridine, yet in the mixed solvent systems of DMSO–py and TMU–py, the Na^+ ion was preferentially solvated in each case by the supposed weaker donor. Greenberg and Popov rationalized these results by means of solvent structure arguments (5). It was later reported from this laboratory that py is, in fact, a relatively poor donor towards the Na^+ ion (6) and this was supported by Popov (7).

In our studies of the sodium ion, we have noted a number of donors that seem to be out of line with those listed in the extended Gutmann scale. And, although we find many that do agree with those of Gutmann as well as with the ^{23}Na chemical shift study of Popov and co-workers, our observations indicate that the extended Gutmann donor numbers are not generally applicable to the sodium ion. This is unfortunate in light of the strong interest in solution studies of the sodium ion.

We have taken advantage of the unique behavior of the system

$NaAlEt_4$–benzene–donor

to determine donicities toward the sodium ion. In this study we are observing the line widths at half height of the ^{27}Al nmr band as a function of donor:Na^+ ratio. Because of the ^{27}Al quadrupole ($I = 5/2$), the relaxation rate is strongly dependent on the symmetry of the $AlEt_4^-$ ion, and this is dependent on the cation–anion interactions. If the cation is totally solvated, the anion will assume t_d symmetry (8), but if a site is available on the cation, the resultant ion–ion interaction will lead to an electric field gradient and a corresponding line broadening of the ^{27}Al signal.

The ^{27}Al quadrupole relaxation is also reflected in the ^{1}H nmr spectra, and this offers an additional probe of the symmetry of the $AlEt_4^-$ ion (8*b*). In samples containing anions with cubic symmetry, the methylene absorption appears as a well defined nine-line pattern representing the fortuitous overlapping of resonances resulting from essentially equal spin–spin interactions of methylene protons with both the neighboring methyl protons and the aluminum nucleus. Conversely, in samples containing

highly distorted anions, the $^{27}Al-{}^1H$ spin–spin interactions are not observed in the ^1H nmr spectra. Rather, the resonance collapses to a 1,3,3,1 quartet resulting from the remaining $^1H-{}^1H$ spin interaction. The two extremes, a nine-line pattern representing anionic t_d symmetry and a quartet corresponding to the highly distorted anion, as would occur in the presence of a strong donor and a weak donor respectively, are logically related to solvent-separated and contact ion-pairs (8).

Experimental procedures

The preparation of $NaAlEt_4$, benzene, and the samples is described elsewhere (9). Propylene carbonate (PC) and dimethylcarbonate (DMC) were distilled over molecular sieves. The other solvating agents[2] were distilled over CaH_2 and handled as described earlier (6, 9). ^1H noise decoupled ^{27}Al nmr spectra were obtained on a Bruker WP-200 FTNMR Spectrometer with a broad band tunable probe. The spectra were acquired using 2 K data points over a spectral window of 500 Hz for a digital resolution of 0.5 Hz. Spectra with very broad resonances were acquired using a 1000 Hz spectral window. The ^1H spectra were obtained on a Varian A60A spectrometer. In most instances the salt concentrations were 0.30 M. However, solutions of strong donors in these systems tend to form two liquid phases in benzene at certain D:Na^+ ratios. Consequently, where two phasing is restrictive, the concentration will vary, except for the DMSO systems, ranging up to a maximum of 0.60 M. For the DMSO systems, much higher concentrations occur (4:1 D:Na^+ = 2.14 M and 6:1 D:Na^+ = 1.25 M). No corrections have been made for solution viscosity. Except for the DMSO systems, it is felt that viscosity does not significantly affect the interpretation of the data. The viscosities of those systems tested were of the order of 1 cp at both the 4:1 and 6:1 ratios of D:Na^+. For DMSO, the viscosity was approximately 10 cp at the 4:1 ratio and 2 cp at the 6:1 ratio.

[2]Hexamethylphosphoramide (HMPA); dimethylsulfoxide (DMSO); dimethylformamide (DMF); dimethylacetamide (DMA); 1-methyl-2-pyrolidone (1M-2PY); trimethylphosphate (TMP); tetramethylurea (TMU); 1,3-propanediamine (1,3PDA); dimethoxyethane (DME); acetonitrile (AN); tetrahydrofuran (THF); pyridine (py); diethylether (DEE); triethylamine (TEA); quinuclidine (QN).

Results and discussion

In Table 1, the ^{27}Al line widths at half height are given at donor:Na^+ ratios of (*a*) 4:1, (*b*) 6:1, and (*c*) with donor as solvent. The nine-line pattern characteristic of solvent separated ion-pairs is also presented. The symbolism for the nine-line pattern is shown in Fig. 1. The well-defined pattern symbolized by S represents a highly symmetrical $AlEt_4^-$ ion. For those designated as M and W, a high degree of symmetry is also assumed. In contrast, the quartet shows the methylene resonance in a highly distorted $AlEt_4^-$ ion. By considering both the ^{27}Al line widths and the methylene proton resonances (nine-line pattern), we propose the order of donicities towards the sodium ion listed in Table 1. The only donor whose position is clearly questionable is DMSO. The data indicate it should be placed below DMA or perhaps TMU. However, considering the affects of viscosity on the spectra, there seems to be no basis for changing its position from that in the Gutmann scale at this time.

We have chosen the data based on the 4:1 D:Na^+ ratio for our primary evaluation. Whether the solvation number of the Na^+ ion is 4 or 6 with a given donor, the four-coordinated species is capable of forming a predominantly solvent-separated ion-pair (6*b*). This point is supported by a con-

For personal use only.

sideration of the ^1H nmr spectra of the DMF, DMA, and TMU solvates. In this series, the 4:1 solvate with TMU should clearly form a more sterically hindered cation toward the anion than either DMF or DMA. Yet we observe that both the ^{27}Al line widths and the appearance of the nine-line pattern indicate that TMU is the weakest donor of the three. This logically can be attributed to equilibria of the type

$$Na^+ \cdot 4D \leftrightharpoons Na^+ \cdot 3D + D$$
$$Na^+ \cdot 3D + AlEt_4^- \leftrightharpoons [Na^+ \cdot 3D/AlEt_4^-]^0$$

There several particularly interesting points to note. First one can see that the listing can be divided into four general groups. (*1*) Strong donors: HMPA–TMU; (*2*) intermediate donors: PC; 1,3PDA; and DME; (*3*) moderate donors: AN–DMC; (*4*) weak donors: DEE–QN. It seems reasonable to conclude that any of the donors from DMC to HMPA will form predominately solvent-separated ion-pairs in the respective pure solvent. One may then expect that differences in ionic behavior in these pure solvents could more reasonably be attributed to solvent dielectric constant than to specific ion–solvent interaction.

It should also be noted that nitrogen donors are especially poor donors towards the sodium ion. On the extended Gutmann DN scale, TEA and py are considered to be very strong donors, and they may be towards $SbCl_5$. But this is not the case towards the sodium ion. We reported the poor donor ability of TEA towards the sodium ion in 1968 (10), and it is confirmed in this study. In an earlier study, Garst and co-workers, using the ketyl spectra of sodium benzophenone ketyl in a variety of solvents, also observed that both py and TEA are poor donors towards the sodium ion (11). Popov *et al.* have attributed the poor donicity of py to a sodium ion (hard) – nitrogen (soft) hard–soft acid–base behavior (7).

Among those we have studied, there are five donors that show quite different relative solvating ability towards the sodium ion than expected from the extended Gutmann donor number scale. These are TMU, AN, py, PC, and TEA. The most striking is TEA which has the highest DN on the extended Gutmann scale, 61. Yet it is among the poorest donors towards the sodium ion.

Finally, it is tempting to use the ^{27}Al line widths to imply solvation numbers for the sodium ion. It may well be that for the strong donors this is possible. However, it is far from certain. We are presently extending this study in combination with ^{23}Na nmr measurements with the intent of determining solvation numbers and are also applying this technique to the determination of a donor scale towards the lithium ion.

Received December 16, 1982

JOHAN K. TERLOUW, JOHN L. HOLMES, and F. P. LOSSING. Can. J. Chem. **61**, 1722 (1983).

The gas phase pyrolyses of crotonic and acrylic-trifluoroacetic anhydrides were shown to yield ethylidene ketene [$CH_3CH{=}C{=}C{=}O$] and methylene ketene [$CH_2{=}C{=}C{=}O$], respectively. The former was identified via the collisional activation mass spectrum of its molecular ion. The ionization energies of the two ketenes, 8.68 and 9.12 ± 0.05 eV respectively, measured using energy selected electrons, lead to 215 and 233 kcal mol^{-1} for their ionic heats of formation.

JOHAN K. TERLOUW, JOHN L. HOLMES et F. P. LOSSING. Can. J. Chem. **61**, 1722 (1983).

La pyrolyse en phase gazeuse de l'anhydride crotonique et de l'anhydride acrylic-trifluoroacétique donne respectivement le cétène éthylidène [$CH_3CH{=}C{=}C{=}O$] et le cétène méthylène [$CH_2{=}C{=}C{=}O$]. On a identifié le premier par l'intermédiaire du spectre de masse d'activation collisionnelle de son ion moléculaire. Les énergies d'ionisation des deux cétènes, 8,68 et 9,12 ± 0,05 eV respectivement, mesurées en utilisant des électrons d'énergie convenable, conduisent à des chaleurs ionique de formation de 215 et de 233 kcal mol^{-1}.

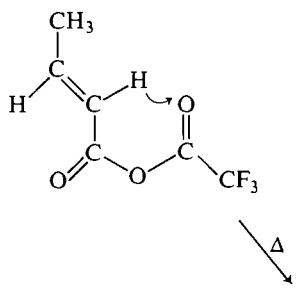
Introduction

In a recent publication (1) on the characterization and properties of isomeric $[C_4H_4O]^{+\cdot}$ ions, it was proposed that the low pressure, short contact-time pyrolysis of the mixed anhydride of crotonic and trifluoroacetic acids should yield ethylidene ketene (*a*), buta-1,2-dienone, $CH_3CH{=}C{=}C{=}O$. The gas-phase ion chemistry of its isomer vinyl ketene, (*b*), had been



$$CH_3CH{=}C{=}C{=}O + CF_3COOH$$

described earlier (2). In these experiments (1) the pyrolysis oven was attached to the electron monochromator and associated quadrupole mass spectrometer apparatus (3) used to measure ionization (IE) and appearance energies (AE); $\Delta H_f[CH_3CH{=}C{=}C{=}O]^{+\cdot}$ was reported to be 202 kcal mol^{-1}, IE = 8.07 eV.

Since the completion of our study (1), Bock and co-workers (4) have published the pyrolytic formation of vinyl and ethylidene ketenes by means of photoelectron spectroscopy (PES). Ethylidene ketene was only observed using the short contact time, low pressure pyrolysis (760 K) of an ethylidene malonate (5-ethylidene-2,2-dimethyl-1,3-dioxane-4,6-dione). At longer contact times, vinyl ketene, the thermodynamically more stable product, predominated. The vertical IE of (*a*) was given as 8.9 eV; the presence of (*b*) (vertical IE = 8.4 eV) and/or other pyrolysis products made uncertain the identification of the vertical band for (*a*) but its satisfactory assignment was aided by MNDO calculations. MNDO calculations were also used to estimate $\Delta H_f[CH_3CH{=}C{=}C{=}O]$ = 12 kcal mol^{-1}; this together with the above IE gives $\Delta H_f[CH_3CHC{=}C{=}O]^{+\cdot}$ = 217 kcal mol^{-1}.

However, both our and Bock's pyrolytic methods lack a detection system which can establish the structural identity of ionized pyrolysis products. Because of this shortcoming of our equipment and in view of the disagreement between the above two IE values, a pyrolysis inlet system of similar design to that used for the thermochemical measurements (3) was built and attached to the ion source of the Utrecht VG ZAB-2F mass spectrometer. Collisional activation (CA) mass spectra could now be used to examine ions of m/z = 68 and having the molecular formula $[C_4H_4O]^{+\cdot}$.

We report here the solution of the above problem together with thermochemical data for ionized methylene ketene, $[CH_2{=}C{=}C{=}O]^{+\cdot}$, a small molecule of potential interest in interstellar chemistry. Neutral methylene ketene has been made by Blackman *et al.* (5) in a series of microwave spectroscopic studies of substituted ketenes. The flash vacuum pyrolyses of diphenylmethyl propiolate, 2′,2′-dimethylspiro[bicyclo[2,2,1]hept-5-ene-2,5′-[1,3]dioxan]-4′,6′-dione and acrylic anhydride all yielded the desired product. The latter was the best source, being efficiently (albeit incompletely) pyrolyzed at 680–730 K and 0.2–0.5 Torr. Pyrolysis conditions are clearly important in such work; Bock and co-workers (4) could not observe methylene ketene for this pyrolysis in their apparatus, obtaining instead the ketene's decomposition products, acetylene and carbon monoxide, together with acrylic acid.

Although deemed unsuitable for post-pyrolysis trapping experiments (6), we find the mixed anhydrides to be particularly satisfactory for mass spectrometric investigations because of their relatively high volatility and the absence of interference from the cogenerated unsaturated acid.

Results and discussion

Production and identification of ethylidene ketene

Table 1 shows the effect of pyrolysis temperature on relative

ion product yields, measured using the apparatus described in ref. 3. 920 K was the optimum temperature for maximum pyrolytic yield of C_4H_4O. At higher temperatures the yield fell and C_3H_4, the probable decomposition product (loss of CO), increased. Note that *m/z* 68 and *m/z* 53 are only minor peaks in the normal (room temperature) mass spectrum. Experiments performed using the ZAB-2F mass spectrometer's pyrolytic inlet system gave similar product distributions as the temperature was raised. Pyrolysis temperatures were not directly comparable because of differences in thermocouple positions in the two ovens. As can be seen from Table 2, the CA mass spectrum of *m/z* 68 ions produced at optimum pyrolysis conditions is dominated by peaks at *m/z* 39, 40, and 53. The latter peak, loss of $CH_3^{\cdot}$, is also prominent in the corresponding normal mass spectrum (Table 1). This CA mass spectrum, which is very different from all those reported previously (1), is deemed to be that of ionized ethylidene ketene; the peak at *m/z* 53 is certainly highly structure diagnostic. Only $[CH_3COC{\equiv}CH]^{+\cdot}$ displayed an intense *m/z* 53 ion in its normal and CA mass spectra (1) to yield the same fragment ion by simple bond cleavage:

$$[CH_3COC{\equiv}CH]^{+\cdot} \rightarrow CH_3^{\cdot} + HC{\equiv}C{-}\overset{+}{C}{=}O$$
$$[CH_3CH{=}C{=}C{=}O]^{+\cdot} \rightarrow CH_3^{\cdot} + HC{\equiv}C{-}\overset{+}{C}{=}O$$

These new observations render invalid our earlier proposal (1) that the CA mass spectrum of $[C_4H_4O]^{+\cdot}$ ions produced from the dissociative ionization of itaconic and citraconic anhydrides and the methyl ester of allene carboxylic acid have the ethylidene ketene structure.

Essentially no ethylidene ketene was generated at temperatures ca. 250 K above optimum (see Table 2). This was concluded from the normal mass spectrum where, although *m/z* 68 was still present, *m/z* 53 had vanished. Also present were new peaks (e.g. *m/z* 44, 66) arising from complex pyrolyses. The CA mass spectrum of these *m/z* 68 ions resembles that of vinyl ketene more closely than that of any of the other fourteen $[C_4H_4O]^{+\cdot}$ ions reported previously (1). The imperfect match between the relative abundances of *m/z* 42 and 40, both of which arise from unimolecular as well as collisionally induced fragmentations, may well be due to internal energy effects, to which the former are always sensitive. The possible coproduction of other $[C_4H_4O]$ isomers cannot, however, entirely be ruled out. Note that Bock and co-workers (4) observed that at long contact times ethylidene ketene was also replaced by vinyl ketene.

Thermochemistry of ionized ethylidene ketene and methylene ketene

The ionisation energy (IE) of $[CH_3CH{=}C{=}C{=}O]$ was measured using energy selected electrons (3) at the optimal condition for its production (Table 1); IE = 8.68 ± 0.05 eV. $\Delta H_f[CH_3CH{=}C{=}C{=}O]$ = +15.1 kcal mol^{-1}, by additivity (7) and using a $(CO)_d$ term = −17.7 kcal mol^{-1}, a revised value because of a change in $\Delta H_f[CH_2CO]$ from −14.6 (8) to −11.4 kcal mol^{-1} (9). Whence, $\Delta H_f[CH_3CH{=}C{=}C{=}O]^{+\cdot}$ = 215 kcal mol^{-1}. The above IE is to be compared with the *vertical* IE of Bock and co-workers (4), 8.9 eV. They chose a MNDO calculation to obtain ΔH_f for the neutral ketene = +12 kcal mol^{-1}; these results give $\Delta H_f[CH_3CH{=}C{=}C{=}O]^{+\cdot}$ = 217 kcal mol^{-1}.

The AE of *m/z* 53, $[HC{\equiv}C{-}\overset{+}{C}{=}O]$, was also measured, 11.02 ± 0.05 eV; $\Delta H_f[HC{\equiv}C{-}C{=}O]$ = 234 kcal mol^{-1} ($\Delta H_f[CH_3^{\cdot}]$ = 34 kcal mol^{-1} (8)), a result which compares favorably with that obtained from the AE of *m/z* 53 from $CH_3COC{\equiv}CH$ (1), 230 kcal mol^{-1}.

The pyrolysis of acrylic-trifluoroacetic anhydride was used to generate methylene ketene at an optimum temperature of 1020 K. The base peak in the normal mass spectrum of the anhydride is *m/z* 55 and *m/z* 54 is absent. At the optimum pyrolysis temperature, *m/z* 55 and *m/z* 54 display similar abundances, indicating that the pyrolysis is incomplete. However, at higher temperatures the $CH_2{=}C{=}C{=}O$ yield falls as a result of its decomposition to C_2H_2 and CO. $\Delta H_f[CH_2{=}C{=}C{=}O]^{+\cdot}$ = 233 kcal mol^{-1} from IE = 9.12 ± 0.05 eV and $\Delta H_f[CH_2{=}C{=}C{=}O]$ = 22.8 kcal mol^{-1}, again from additivity (ref. 7 and see above).

The effect of methyl substitution in ionized methylene ketene is to reduce $\Delta H_f[ion]^{+\cdot}$ by 18 kcal mol^{-1}, substantially less than the same replacement on ketene itself, 25 kcal mol^{-1} ($\Delta H_f[CH_2{=}C{=}O]^{+\cdot}$ = 210 kcal mol^{-1} (8, 9); $\Delta H_f[CH_3CH{=}C{=}O]^{+\cdot}$ = 185 kcal mol^{-1} (IE = 8.95 eV (12); $\Delta H_f[CH_3CH{=}C{=}O]$ = −21.5 kcal mol^{-1} (ref. 7, and see above)). The effect on ketene is typical of the methyl substitution – ion size relationship discussed elsewhere (13), but the effect on methylene ketene is lower than expected by ca. 7 kcal mol^{-1}. This discrepancy could arise from an inadequacy in the additivity terms for such molecules or from the charge distribution being different from that obtaining in the simple ketenes.

It is useful also to compare $\Delta H_f[CH_2{=}C{=}C{=}O]^{+\cdot}$ and $\Delta H_f[CH_2{=}C{=}O]^{+\cdot}$ with those of the isoelectronic ions $[CH_2{=}C{=}CH_2]^{+\cdot}$, ΔH_f = 269 kcal mol^{-1} (8) and $[CH_2{=}C{=}C{=}CH_2]^{+\cdot}$, ΔH_f = 293 kcal mol^{-1} (IE = 9.2 ± 0.05 eV (10, 11), $\Delta H_f[CH_2{=}C{=}C{=}CH_2]$ = 81 kcal mol^{-1} (7)). Thus $\Delta(\Delta H_f)$ for the oxy-ions, 23 kcal mol^{-1}, is within experimental error the same as that for the isoelectronic hydrocarbon ions, 24 kcal mol^{-1}.

Experimental

The pyrolysis oven, electron monochromator, and associated apparatus for measuring IE and AE values has been described (3). The CA mass spectra were obtained using a VG ZAB-2F mass spectrometer by conventional means (14). The pyrolysis oven for the ZAB instrument was constructed of silica, electrically heated, and with a high temperature zone of ca. 2.5 cm length. The exit from the oven into the ion source was situated ca. 3.5 cm from the ionizing electron beam in a

An iterative technique for calculating surface tensions of non-electrolyte solutions

DOUGLAS E. GOLDSACK AND BRIAN R. WHITE
Department of Chemistry, Laurentian University, Sudbury, Ont., Canada P3E 2C6

Received July 8, 1982[1]

DOUGLAS E. GOLDSACK and BRIAN R. WHITE. Can. J. Chem. **61**, 1725 (1983).

The surface tension of mixtures of organic non-electrolytes of high polarity difference has been shown to be calculable to within a 1% average error using a Newton–Raphson iterative technique to solve the implicit Butler equations for the surface concentrations combined with a better approximation to the surface density of the pure components through an anisotropic surface model. Application of these same techniques to aqueous systems was attempted with some success. However, significant deviations between observed and calculated surface tensions for some binary aqueous systems still remain. It is suggested that these deviations could be accounted for by the inclusion of non-ideal behaviour in the surface and bulk phases.

DOUGLAS E. GOLDSACK et BRIAN R. WHITE. Can. J. Chem. **61**, 1725 (1983).

On montre que l'on peut calculer la tension de surface des mélanges de non électrolytes organiques ayant une grande différence de polarité, avec une marge d'erreur de 1%. On utilise la technique itérative de Newton–Raphson pour résoudre les équations implicites de Butler relatives aux concentrations de surface combinées avec une meilleure approximation en ce qui a trait à la densité de surface des composés purs dans un modèle de surface anisotropique. On a essayé, avec un certain succès, d'appliquer ces mêmes techniques aux systèmes aqueux. Cependant on a encore observé des écarts importants entre les tensions de surface observées et calculées de quelques systèmes aqueux binaires. On suggère que ces écarts sont dûs à l'inclusion d'un comportement non idéal dans la surface et dans les phases encombrées.

Introduction

An earlier study (1) has shown that the surface tension, σ, of binary mixtures of organic non-electrolytes could be calculated with an explicit equation to within 1–3% error for most systems. This equation consists of a linear component and a first and second order deviation term given by:

$$[1] \quad \sigma = \sigma_1 X_1 + \sigma_2 X_2 + RTX_1X_2\Delta\left[\frac{(A_2A_1)}{A_1A_2}\right] - \frac{RT}{2}X_1X_2\Delta^2\left[\frac{A_1X_1 + A_2X_2}{A_1A_2}\right]$$

where σ_1 and σ_2 are the surface tensions, A_1 and A_2 are the molar surface areas, and X_1 and X_2 are the bulk liquid mole fractions of components 1 and 2 respectively, R is the gas constant and T is the absolute temperature. The term Δ is a dimensionless parameter defined by:

$$[2] \quad \Delta = \frac{(\sigma_2 - \sigma_1)A_1A_2}{(A_1X_1 + A_2X_2)RT}$$

This equation assumes a monolayer model for the surface of the liquid, as well as ideal solution behaviour in both the surface and bulk liquid phases. Furthermore, when volume fraction statistics were substituted for mole fraction statistics, no significant improvement in predicting the surface tension of these binary mixtures was noted (1).

Equation [1] was found to be generally useful only for non-polar–non-polar and polar–non-polar binary systems for which $(\sigma_2 - \sigma_1) < 10$ ergs/cm^2. For polar–non-polar systems where $(\sigma_2 - \sigma_1) > 20$, eq. [1] was found to be inapplicable because the mathematical approximations used in deriving eq. [1] are not valid. For these types of systems, only implicit equations in σ are valid, and these equations are intractible.

Since there is a great deal of interest in aqueous systems of non-electrolytes, particularly for biological applications, and since such systems generally have $(\sigma_2 - \sigma_1)$ values much greater than 20 ergs/cm^2 as well as large differences in molar volumes, it would be useful to find a general mathematical approach for determining the surface tension of such mixtures. The purpose of this paper is to outline such a mathematical approach, and to show to what extent the ideal solution approximation for both the surface and bulk phases can be applied to these extremely polar–non-polar mixtures. It will also be shown that the use of surface volumes, as determined from the anisotropic surface model (2) rather than bulk liquid volumes, for calculating the molar surface area values, A_i, results in a substantial improvement in the calculated surface tensions of such systems.

Theory

If it is assumed that the surface layer can be treated as a separate phase, and if it is further assumed that the bulk liquid and surface phases are ideal, then the surface tension of a binary liquid mixture is given by:

$$[3] \quad \sigma = \sigma_1 + \frac{RT}{A_1}\ln\frac{X_{1S}}{X_{1B}}$$

$$[4] \quad \sigma = \sigma_2 + \frac{RT}{A_2}\ln\frac{X_{2S}}{X_{2B}}$$

where X_{1S}, X_{2S} and X_{1B}, X_{2B} are the mole fractions of component 1 and 2 respectively in the surface and bulk phases. These equations are known as the Butler equations (3). If eqs. [3] and [4] are multiplied by X_{1B} and X_{2B} respectively and added, the resulting surface tension equation then consists of a linear term containing known bulk liquid concentrations and non-linear terms due to the free energy of mixing.

$$[5] \quad \sigma = (\sigma_1X_{1B} + \sigma_2X_{2B}) + X_{1B}\frac{RT}{A_1}\ln\frac{X_{1S}}{X_{1B}} + X_{2B}\frac{RT}{A_2}\ln\frac{X_{2S}}{X_{2B}}$$

If a method existed for measuring or calculating the surface concentrations X_{1S} or X_{2S}, then it would be possible to predict directly the surface tension of any binary liquid system. It has been shown previously (1) that the introduction of a dimensionless parameter, Δ, which was first used by Prigogine *et al.*

[1]Revision received February 18, 1983.

(4), led to an explicit equation for σ in terms of bulk concentrations given by the following relation:

$$[6] \quad \sigma = \sigma_1 X_1 + \sigma_2 X_2 + \frac{X_1 RT}{A_1} \ln (1 + X_2\Delta) + \frac{X_2 RT}{A_2} \ln (1 - X_1\Delta)$$

where

$$[7] \quad \Delta = \frac{(\sigma_2 - \sigma_1)A_1 A_2}{(A_1 X_1 + A_2 X_2)RT}$$

and X_1, X_2 without the subscripts refer to bulk liquid concentrations only. The use of the parameter Δ is restricted to solutions where $X_1\Delta$ and $X_2\Delta$ are significantly smaller than unity. Under these conditions eq. [6] can be expanded to yield:

$$[8] \quad \sigma = (\sigma_1 X_1 + \sigma_2 X_2) + RTX_1X_2\Delta\left[\frac{(A_2 - A_1)}{A_1A_2}\right] - RTX_1X_2\Delta^2\left[\frac{A_1X_1 + A_2X_2}{A_1A_2}\right]$$

For most non-electrolyte organic systems, the parameter Δ is less than unity for $(\sigma_2 - \sigma_1) < 10$ ergs/cm^2, and eq. [8] is found to predict the surface tension of binary mixtures of such systems to within 1 to 3% error. However, for systems with $(\sigma_2 - \sigma_1) > 20$ ergs/cm^2, particularly aqueous systems, the Δ approach cannot be used since the approximations $X_1\Delta$ and $X_2\Delta < 1$ do not apply. Attempts at using implicit equations with linear first approximations to σ for such systems failed. Therefore a more direct method of solving the implicit functions of σ must be used for these type of systems. Such an approach is outlined as follows.

Since for a binary system,

$$[9] \quad X_{1S} + X_{2S} = 1$$

the Butler equations [3] and [4] can be equated and rearranged as follows by defining a molar surface area ratio $r = A_1/A_2$:

$$[10] \quad \left(\frac{X_{2S}}{X_{2B}}\right)^r \left(\frac{X_{1B}}{X_{1S}}\right) = \exp\left[\frac{(\sigma_1 - \sigma_2)A_1}{RT}\right] = K_1$$

If eq. [10] can be solved for the mole fraction of one surface component, then the surface tension of a binary system can be predicted using eq. [5] and this known surface mole fraction.

It has been previously shown (1) that the molar surface areas, A_i, can be calculated from bulk molar volumes, V_{iB}, by the following relation:

$$[11] \quad A_i = 1.021 \times 10^8 V_{iB}^{2/3}$$

where A_i is given in units of cm^2/mol. This relation assumes that the molar volume of the surface layer, V_S, is equal to that of the bulk liquid molar volume, V_B, for each component. However, it has been shown that a better approximation for the surface molar volume is given by an equation derived from an anisotropic surface model (2):

$$[12] \quad V_S = V_C^{3/5} V_B^{2/5}$$

where V_C is the critical molar volume of the substance. For this improved model of the surface molar volume, the molar surface area would be related to the bulk liquid molar volume by:

$$[13] \quad A_i = 1.021 \times 10^8 V_{iC}^{6/15} V_{iB}^{4/15}$$

Both estimates for calculating these molar area values have been tested in this study. The values of V_C for all the systems studied were taken from Reid *et al.* (5) except for sulfolane which was estimated using Lydersen's method as outlined by Reid *et al.*

For many organic systems the ratio of the molar surface areas, r, is approximately unity. For these cases, assuming r is unity, eq. [10] can be solved explicitly for the surface mole fraction of any component, and yields:

$$[14] \quad X_{1S} = \frac{X_{1B}}{X_{1B} + X_{2B}K_1}$$

$$[15] \quad X_{2S} = \frac{X_{2B}}{X_{2B} + \frac{X_{1B}}{K_1}}$$

With these approximations for X_{1S} and X_{2S}, eq. [5] for the surface tension of a binary system can now be written in explicit form as:

$$[16] \quad \sigma = (\sigma_1 X_1 + \sigma_2 X_2) - \frac{RT}{A}\left[X_1 \ln (X_1 + X_2K_1) + X_2 \ln \left(X_2 + \frac{X_1}{K_1}\right)\right]$$

Equation [16] reveals a negative deviation from the linear surface tension term similar to that of the Δ parameter approach given in eq. [8]. Calculations of the surface tensions of binary organic systems has shown that eq. [16] with $A_2 = A_1 = A$ yields the same surface tension values as the Szyszkowski equation (1).

For those systems where r cannot be approximated by unity, the surface mole fraction can still be obtained from eq. [10] by use of the Newton–Raphson iterative technique (6). This technique is particularly useful for calculating the surface tension of aqueous systems. For most aqueous nonelectrolyte mixtures not only is the r factor significantly different from unity, but also the surface tension differences are much larger than 10 ergs/cm^2 which limits the usefulness of the Δ parameter approach.

To make use of the Newton–Raphson iterative technique, eq. [10] is first rearranged in terms of the known quantities K_1, X_{1B}, X_{2B}. The unknown quantity X_{1S} is then calculated through a difference function $f(X_{1S})$:

$$[17] \quad f(X_{1S}) = \frac{X_{1S}}{(1 - X_{1S})^r} - C$$

where C is a known quantity for any solution given by:

$$[18] \quad C = \frac{X_{1B}}{X_{2B}^r K_1}$$

This difference function will have an exact value of zero when the quantity X_{1S} has been determined exactly.

The Newton–Raphson technique then allows the mole fraction of component 1 in the surface phase, X_{1S}, to be obtained from a first approximation estimate, given as X_{1S}^0 and a deviation term:

$$[19] \quad X_{1S} = X_{1S}^0 - \frac{f(X_{1S}^0)}{f'(X_{1S}^0)}$$

where

$$[20] \quad f'(X_{1S}^0) = \frac{1 + (r - 1)X_{1S}^0}{(1 - X_{1S}^0)^{r+1}}$$

Bringing together eqs. [17] through [20] then yields for X_{1S} the final relation:

$$[21] \quad X_{1S} = X^0_{1S} + \left[\frac{C(1 - X^0_{1S})^{r+1} - X^0_{1S}(1 - X^0_{1S})}{1 + (r - 1)X^0_{1S}}\right]$$

The value of X_{1S} obtained from the first iteration is then used to replace X^0_{1S} and the calculation is repeated until no further change in the value of X_{1S} occurs. Generally this requires three or four iterations.

It may be noted that the Newton–Raphson technique as applied to the determination of the surface mole fraction is parallel to and an improvement on the first order approximation used by Prigogine *et al.* (4). In their approximation, the surface mole fraction X_{1S} was given by:

$$[22] \quad X_{1S} = X_{1B} + X_{1B}X_{2B}\Delta$$

Similarly the Newton–Raphson approach can be written as:

$$[23] \quad X_{1S} = X_{1B} - \frac{f(X_{1B})}{f'(X_{1B})}$$

where the bulk mole fraction X_{1B} has been used as a first approximation for X^0_{1S} in eqs. [19] and [20].

Equation [21] combined with eq. [5] was applied to a variety of aqueous and non-aqueous systems using both estimates of the molar surface areas given by eqs. [11] and [13]. These data are presented in Tables 1 through 3 and displayed as deviations from the linear surface tension dependence in Figs. 1 and 2.

Discussion

As a check on the validity of the iterative technique for calculating the surface tension of binary systems, several organic systems with $(\sigma_1 - \sigma_2) < 10$ ergs/cm^2 were tested using both the Δ approach (eq. [8]) and the Newton–Raphson technique (eqs. [5] and [21]). The results of these calculations are given in Table 1. No significant difference is found between either of these techniques. However for both approaches, use of the anisotropic formula for the molar surface area in most cases generates a slight improvement in the surface tension values between observed and calculated over those predicted using bulk liquid molar area values.

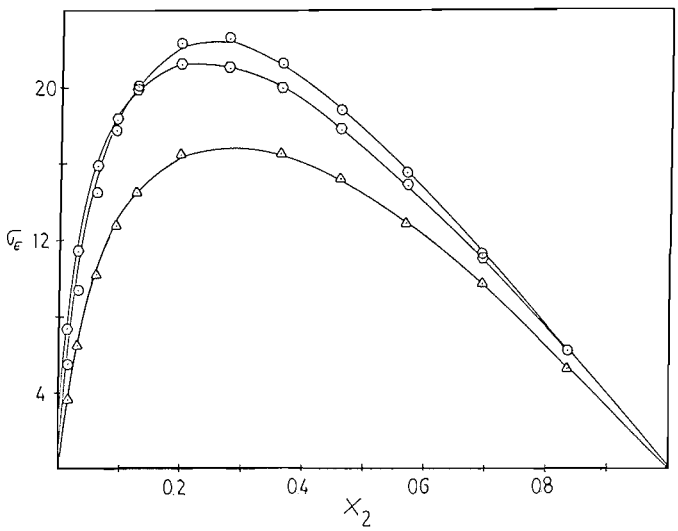

FIG. 1. Excess surface tension of water + methanol at 30°C. △, excess surface tension calculated with eq. [11] to approximate the molar surface area; ⊙, excess surface tension calculated with eq. [13] for the molar area; ⊙, represents the experimental excess surface tension defined as $\sigma_E = X_1\sigma_1 + X_2\sigma_2 - \sigma_{exp}$.

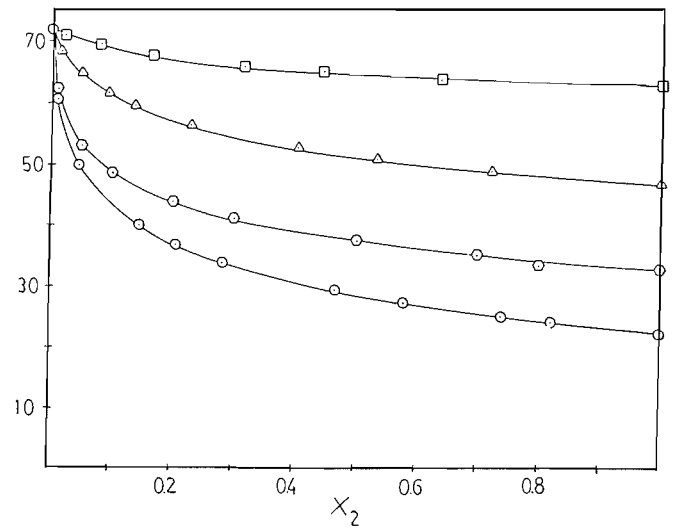

FIG. 2. Plot contrasting the magnitude of the drop in surface tension, for four binary non-electrolyte systems of varying surface tension differences. ⊡, water + glycerol; △, water + ethylene glycol; ⊙, water + dioxane; ⊙, water + ethanol.

As the surface tension difference ($\sigma_1 - \sigma_2$) increases and the r factor deviates more significantly from unity, the improvement between observed and calculated values is more noticeable when surface molar area values are employed. For example with the benzene–isooctane system at 30°C, $(\sigma_1 - \sigma_2) = 9.64$ and $r = 0.662$. Using the Δ approach, the average percent error between observed and calculated surface tensions decreases from 1.51% to 0.98% on changing from bulk to surface volumes for calculation of the molar surface areas. The comparable errors using the iterative technique are 1.67% and 0.45%.

For values of $\sigma_1 - \sigma_2$ much larger than 20 ergs/cm^2 the iterative technique showed much better agreement between observed and calculated surface tensions. For instance, the glycerol–ethanol system, with a $\sigma_1 - \sigma_2$ value of 40.5 ergs/cm^2, was detailed in ref. 1 and a poor fit was shown to occur with the Δ approach, whereas the iterative approach yields an average error of about 1% particularly when surface molar area values are calculated via the anisotropic surface model. Similar statements can be made about the sulfolane–ethanol system with a $\sigma_1 - \sigma_2$ value of 28.1 ergs/cm^2. Table 2 gives more details of the concentration dependence of the surface tension of these two systems in terms of the above mentioned calculations. These tests indicated that the iterative technique could be applied generally and, in particular, should be applicable to a series of aqueous systems with large $\sigma_1 - \sigma_2$ values.

Table 3 gives a more detailed comparison of the Δ and iterative approach for six aqueous systems. Since $\sigma_1 - \sigma_2$ for these systems is much greater than 20 ergs/cm^2, the mathematical approximations used in deriving eq. [8] are not valid for these systems. However, it is useful to contrast this explicit Δ equation with the iterative equation to indicate the order of magnitude of improvement to be expected with a mathematically exact (though more complex) relation for σ for these systems.

For all aqueous systems the iterative approach yields a better calculated value of the surface tensions than does the Δ method by at least a twofold decrease in average % error. Furthermore, the use of molar surface volumes for calculating the molar surface areas again shows that a significant decrease occurs in the difference between observed and calculated surface tension values over those calculated using the bulk molar liquid volume approximation. These points are more clearly illustrated in Fig. 1 where the deviation from the linear surface tension terms for observed and calculated surface tensions for the aqueous methanol system is plotted.

Figure 2 illustrates the most interesting characteristic of aqueous surface tension plots, i.e. the rapid drop in surface tension at very low mole fractions of solute for a wide variety of organic solutes. This rapid drop has been a source of consternation for some time since no simple obvious explanation could

account for this effect.

In fact, it seems that this effect is due to two factors: all aqueous non-electrolyte systems have r values very much different than unity, ca. 0.35 to 0.6 in these cases, as well as a very large difference in $\sigma_1 - \sigma_2$ values (ca. 50 ergs/cm^2). The combination of these two factors results in this rapid drop in surface tension at low mole fractions of solute for aqueous systems.

This can be seen clearly from Fig. 2 which contrasts the surface tension curves for several aqueous non-electrolyte systems. This point can also be shown mathematically from eq. [8]. The rapid drop in surface tension is proportional to the slope of the $\sigma - X_2$ curve, i.e., to $d\sigma/dX_2$. From eq. [8], $d\sigma/dX_2$ is given by:

$$[24] \quad \frac{\partial \sigma}{\partial X_2} = (\sigma_2 - \sigma_1) \times \left\{1 + \left[\frac{(1 - 2X_2)(rX_1 + X_2) - X_1X_2(1 - r)}{(rX_1 + X_2)^2}\right] \times \left[(1 - r) - \frac{(\sigma_2 - \sigma_1)A_1}{2RT}\right]\right\}$$

For the systems illustrated in Fig. 2, at a fixed mole fraction, it is found that the dominant term governing this slope is $(\sigma_2 - \sigma_1)$. Hence the rapid drop in aqueous non-electrolyte systems is primarily due to the magnitude of the surface tension difference between the two components of the system.

It is noted that there is still a substantial error remaining in the calculated values of the surface tension of some aqueous systems. It must be remembered, however, that the equations used for calculating the surface tensions of these mixtures are based on the assumption that the bulk and surface phases are ideal; that is, the heat of mixing of these systems is zero and hence the activity coefficient effects are negligible. It is probable that this assumption is not valid for these aqueous systems, e.g., water–ethanol, water–acetone.

Conclusions

The iterative technique for calculating surface tensions of systems of high polarity difference (large $\sigma_1 - \sigma_2$ values) is an improvement over the explicit Δ function approach first utilized by Prigogine *et al.* (4) and more completely expanded upon (1). Furthermore, the anisotropic surface model (2) for calculating molar surface areas improves the agreement between observed and calculated surface tensions for a large variety of systems. There is no significant difference between the iterative technique or the Δ function approach for calculating the surface tensions of mixtures of systems with low polarity differences, e.g. $(\sigma_1 - \sigma_2) < 10$ ergs/cm^2. However, for organic liquid systems with large polarity differences, e.g. $\sigma_1 - \sigma_2 > 20$ ergs/cm^2, the iterative technique combined with the anisotropic molar surface area equation, is able to account for the surface tensions of such mixtures to within 1–2% error.

For aqueous non-electrolyte systems, where the $\sigma_1 - \sigma_2$ values are significantly greater than 20 ergs/cm^2, even the combination of the iterative technique along with the better estimated molar surface area values is unable to account totally for the surface tension concentration curves. Hence, further work needs to be done on the temperature dependence of aqueous non-electrolyte systems with a view to elucidating the effects of surface orientation and/or heat of mixing on the activity coefficients of such solutions in the surface and bulk liquid phases.

β-Lactams. XI. Synthesis of *N*-phosphorylated mono- and bicyclic β-lactams[1]

GEORGE JUST, DENISE DUGAT, AND WHI-YU LIU
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received November 8, 1982

GEORGE JUST, DENISE DUGAT, and WHI-YU LIU. Can. J. Chem. **61**, 1730 (1983).

Starting from appropriately substituted monocyclic β-lactam, *N*-phosphorylated mono- and bicyclic β-lactams have been synthesized.

GEORGE JUST, DENISE DUGAT et WHI-YU LIU. Can. J. Chem. **61**, 1730 (1983).

Des β-lactames mono- et bicycliques *N*-phosphorylés ont été synthétisés à partir de β-lactames monocycliques.

Some time ago (2, 3), we postulated that the ring strain of penicillins and cephalosporins, which seems to be responsible for the high frequency of β-lactam ir absorption and hence also for their chemical and biological reactivity, may be replaced by electronic activation, and that properly activated monocyclic β-lactams should possess antibacterial activity. As part of this continuing program, we described the synthesis of bicyclic β-lactam **5**, in which the β-lactam nitrogen is directly attached to a phosphate. Because of the importance of the recently described *N*-sulfated monobactams (4), we also describe the synthesis of *N*-phosphorylated monobactams **21***b* and **24***b* using methodology developed for the preparation of **5**.

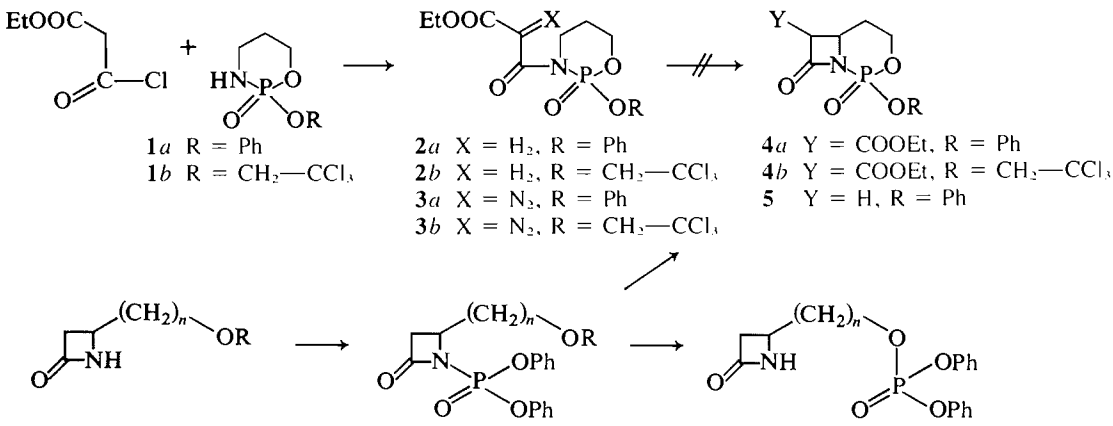
Phenyl cyclophosphoramidate **1***a* was treated with ethyl malonyl chloride (5) to give **2***a* in excellent yield (6). Amide **2***a* underwent base catalyzed diazo exchange with *p*-toluenesulfonyl azide (7) to afford **3***a*. We next attempted to form the β-lactam **4***a* by a carbene insertion reaction, a method pioneered by Corey and Felix (8) and extensively applied by Lowe and co-workers (9) to the synthesis of a variety of bicyclic β-lactams. Irradiation of the α-diazo-amide **3***a* at 0°C in carbon tetrachloride using a Rayonet photochemical reactor, with maximum output at 350 mμ, led to a complicated reaction mixture. The infrared spectrum did not show any diazo or β-lactam absorptions at 2200 or ~1750 cm^{-1}, respectively. Using flash chromatography, one of the less polar spots isolated proved to be phenol. Since phenol absorbs in the ultraviolet spectrum at 210 mμ and 270 mμ, we suspected that it might interfere with the carbene insertion reaction under the photolysis condition. We therefore decided to replace the phenoxy moiety by a trichloroethyl group. This protecting group can be removed in the presence of a β-lactam (10), and should not absorb light.

Addition of 3-amino-1-propanol and triethylamine to trichloroethyl dichlorophosphate, prepared *in situ* by reaction of trichloroethyl alcohol and triethylamine with phosphorus oxychloride, afforded the cyclophosphoramidate **1***b*, in 93% yield, after flash chromatography. It was coupled, as before, with ethyl malonyl chloride to give amide **2***b*. The diazo compound **3***b* was obtained in a manner analogous to that of its corresponding phenyl derivative **3***a*.

Irradiation as described before, or treatment with copper in toluene or rhodium acetate in methylene chloride (11), gave a mixture of products which were not identified.

In a second, more successful series of reactions, alcohol **7***a* (12) was transformed to its tetrahydropyranyl ether **7***b* (13). Reaction of **7***b* with *n*-butyllithium at −78°C in dry tetrahydrofuran, followed by addition of diphenylchlorophosphate, gave the reactive diphenylphosphoramidate **9** in 80% yield. Deprotection with pyridinium *p*-toluenesulfonate (13) gave alcohol **11**, clearly characterized by its nmr spectrum.

Reaction of diphenylphosphoramidate **11** with anhydrous cesium fluoride[2] in *tert*-butanol gave the cyclized β-lactam **5**, in 20% yield, along with phenol and β-lactam **13**, as the sole side products that could be isolated. Attempts to improve the yield of the reaction and to eliminate the side product **13** were



1*a* R = Ph
1*b* R = CH_2—CCl_3

2*a* X = H_2, R = Ph
2*b* X = H_2, R = CH_2—CCl_3
3*a* X = N_2, R = Ph
3*b* X = N_2, R = CH_2—CCl_3

4*a* Y = COOEt, R = Ph
4*b* Y = COOEt, R = CH_2—CCl_3
5 Y = H, R = Ph

6 *n* = 1, *a* R = H, *b* R = THP
7 *n* = 2, *a* R = H, *b* R = THP

8 *n* = 1, R = THP
9 *n* = 2, R = THP
10 *n* = 1, R = H
11 *n* = 2, R = H

12 *n* = 1
13 *n* = 2

in vain. This suggested that perhaps the β-lactam nitrogen was in part acting as the leaving group, during treatment with CsF, instead of the phenoxide anion.

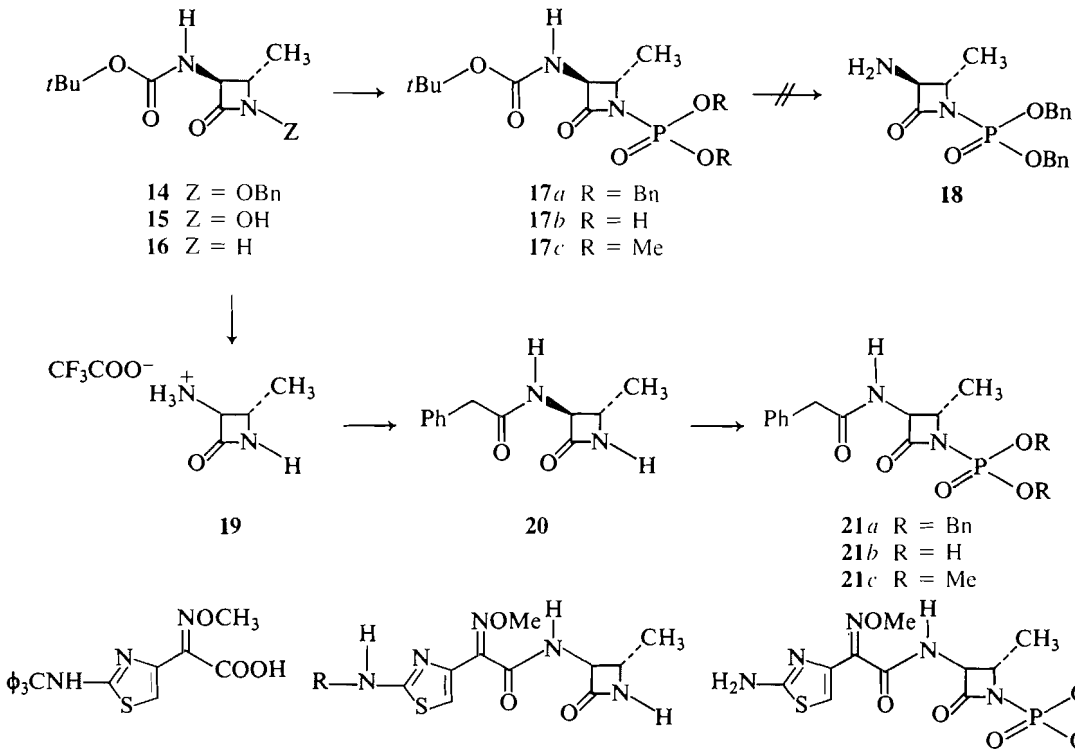
Both structures **5** and **13** were proven by 200 MHz ^{1}H nmr spectra and by mass spectrometry, which showed *m/e*'s due to loss of ketone. In addition, monocyclic β-lactam **13** was prepared by reaction of alcohol **7***a* with diphenylchlorophosphate. Attempts to hydrolyze this material to the free phosphoric acid failed.

When this sequence was repeated using alcohol **6***a* (**6***a* → **6***b* → **8** → **10** → **11** → **12**), obtained by sodium borohydride reduction of 4-carbobenzyloxyazetidinone kindly provided by Dr. Christensen, Merck Laboratories, no bicyclic lower homolog corresponding to **5** was obtained, and only monocyclic diphenylphosphate **12** was isolated. The latter was identical to **12**, prepared from alcohol **6***a* and diphenylchlorophosphate.

The formation of monocyclic β-lactam, although conceptually simple, was fraught with experimental difficulties due to the acid-lability of the N—P bond. β-Lactam **16**, prepared by adaptation of known procedures (15) via the sequence **14** → **15** → **16**, was phosphorylated with dibenzylchlorophosphate in a manner similar to that described before. Catalytic hydrogenolysis of dibenzylphosphate **17***a* in methanol over Pd/C at 1 atm gave after 1 h the phosphoric acid **17***b* which was characterized by conversion to its dimethylester **17***c* using diazomethane. Deblocking of the *t*-BOC group of **17***a* under a variety of acidic conditions did not lead to the expected amine **18**. Instead, either N—P bond cleavage (trifluoroacetic acid (16)), or opening of the β-lactam ring (*p*-toluenesulfonic acid, ethyl acetate (17)) was observed.

Therefore, **16** was hydrolyzed in trifluoroacetic acid (16) at 0°C to the ammonium salt **19**. Reaction of **19** with phenylacetyl chloride (18) gave β-lactam amide **20**. Formation of a mono anion by means of butyllithium at −78°C, followed by addition of dibenzylchlorophosphate, gave phosphorylated β-lactam **21***a*. Catalytic debenzylation using 10% Pd/C in methanol gave the phosphoric acid **21***b* which could be characterized, as was acid **17***b*, by conversion to its methyl ester **21***c*.

Similarly, compound **19** was transformed in phosphoric acid **25***b* in the following manner. First, reaction of **19** with the



appropriate acid **22** (19) was carried out in THF/CH_2Cl_2, using *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ) (20) as coupling agent. Deblocking of the trityl group by formic acid in a methanolic solution led, after 1 h refluxing, to β-lactam **24** in 83% yield. The dibenzylphosphate **25***a*, isolated by phosphorylation of **24** as described before, was hydrogenolyzed under two different conditions, both requiring long reaction times. Thus, under the first set of conditions, previously used (10% Pd/C, hydrogen at 1 atm, methanol), debenzylation gave, after 10 h, the phosphoric acid **25***b* which could be isolated as free acid or as its triethylamine salt **25***d*. Under the second set of conditions (hydrogen at 1 atm, 1 equiv. of $KHCO_3$ in THF−ethanol−water (ref. 21)), hydrogenolysis provided after 6 h the corresponding monopotassium salt **25***e*.

All compounds reported gave good, interpretable nmr and mass spectra except for **25***a*, **25***b*, and **25***c*, where mass spectra could not be interpreted.

None of the *N*-phosphates tested had notable antibacterial activity when compared to Squibb's monobactam SQ 26.776 or piperacillin.

In view of the extensive work of the Squibb group on phosphorylated monobactams (monophosphams) recently described

(22), we do not plan to do any further work in the monophospham area.

Experimental

Thin-layer chromatography was performed on Merck Silica Gel 60 aluminum-backed plates. Flash chromatography was done with Woelm Silica (32–63 μ) using predistilled solvents. Melting points were determined on a Gallenkamp block and are uncorrected. Optical rotations were measured in a 1 dm cell on a Perkin–Elmer 141 polarimeter. Nuclear magnetic resonance spectra were recorded on Varian T-60, T-60A, and XL-200 spectrometers. Infrared (ir) spectra were run on a Perkin–Elmer 297 spectrophotometer. Mass spectra were taken on HP5984A or LKB 9000 spectrometers.

Phenyl cyclophosphoramidate **1**a

To 3-amino-1-propanol (1 g, 13.3 mmol) in dry methylene chloride (20 mL) was added pyridine (3.16 g, 40 mmol) and phenyldichlorophosphate (2.8 g, 13.3 mmol) at 0°C. The mixture was stirred at room temperature for 18 h. The solution was washed with water (2 × 15 mL), dried ($MgSO_4$), and evaporated. The residue was purified by flash chromatography (ethyl acetate) to afford 2.24 g (79%) of **1***a* as a colorless oil. Infrared (film) ν_{max}: 3250 (NH, amide), 1590, 1485, 1260, 1210 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.2–2.4 (m, 2H, CH_2), 2.8–3.7 (m, 2H, CH_2N), 4.1–4.7 (m, 3H, NH, CH_2O), 7.32 (s, 5H, C_6H_5); ms (70 eV, 69°C), *m/e* (‰): 213 (643, $M^{+\cdot}$), 120 (382, $M^{+\cdot} - C_6H_5O^{\cdot}$).

Amide **2**a

To a solution of **1***a* (1.44 g, 6.76 mmol) in THF (10 mL), ethyl malonyl chloride (1.02 g, 6.78 mmol) in THF (5 mL) was added. The reaction was followed by means of tlc. When starting material disappeared (~15 h), the solvent was evaporated. The residue was introduced into a flash chromatography column to afford 1.85 g (84%) of **2***a* as a colorless oil. Infrared (film) ν_{max}: 1740 (C=O, ester), 1690 (C=O, amide) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.24 (t, 3H, CH_3), 1.6–2.5 (m, 2H, $NCH_2CH_2CH_2O$), 3.0–3.6 (m, 1H, CHN), 3.83, 3.90 (2s, 2H, CH_2CO), 4.11 (q, 2H, CH_3CH_2), 4.1–4.9 (m, 3H, CH_2O, CHN), 7.30 (s, 5H, C_6H_5); ms (20 eV, 20°C), *m/e* (‰): 327 (20, $M^{+\cdot}$), 234 (1000, $M^{+\cdot} - C_6H_5O^{\cdot}$).

Diazo-amide **3**a

To a solution of **2***a* (1.85 g, 5.66 mmol) in acetonitrile (20 mL) containing triethylamine (0.63 g, 6.24 mmol) was added *p*-toluenesulfonyl azide (1.18 g, 5.98 mmol) at 0°C. The mixture was stirred for 40 h at room temperature. The solvent was evaporated below 30°C and replaced by methylene chloride (40 mL). After being washed with 0.4 *N* potassium hydroxide, water, dried ($MgSO_4$), and evaporated, the residue was purified by flash chromatography (petroleum ether – ethyl acetate, 1:1) to afford 1.70 g (85%) of **3***a* as a yellow oil. Infrared (film) ν_{max}: 2135 (N_2), 1730 (C=O, ester), 1690, 1650, 1590, 1490 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.30 (t, 3H, CH_3), 1.6–2.5 (m, 2H, CH_2), 3.2–3.8 (m, 1H, NCH), 4.30 (q, 2H, CH_3CH_2), 4.0–4.7 (m, 3H, NCH, $NCH_2CH_2CH_2O$), 7.23 (s, 5H, C_6H_5); ms (20 eV, 60°C), *m/e* (‰): 353 (32, $M^{+\cdot}$), 325 (245, $M^{+\cdot} - N_2$), 260 (77, $M^{+\cdot} - C_6H_5O^{\cdot}$), 253 (341), 94 (1000).

Trichloroethyl cyclophosphoramidate **1**a

A solution of 2,2,2-trichloroethyl alcohol (0.49 g, 3.28 mmol) and triethylamine (0.33 g, 3.27 mmol) in anhydrous tetrahydrofuran (3 mL) was added dropwise at −78°C into phosphorus oxychloride (0.5 g, 3.27 mmol) in THF (5 mL) under nitrogen atmosphere. After stirring 0.5 h, the temperature slowly increased to room temperature within 1 h and the mixture was cooled again to −78°C. To the cooled mixture, a solution of 3-amino-1-propanol (0.245 g, 3.26 mmol) and triethylamine (0.693 g, 6.86 mmol) in THF (3 mL) was added. The mixture was allowed to warm to room temperature and stirred for another 4 h. The tetrahydrofuran was evaporated. The residue was added to methylene chloride (50 mL) and water (40 mL). The organic layer was washed with 1% HCl (30 mL), dried ($MgSO_4$), and evaporated. The crude product was purifed by flash chromatography (ethyl acetate) to obtain 0.81 g (93%) of **1***b* as a light yellow oil. Infrared (film) ν_{max}: 3250 (NH), 1420, 1335, 1260, 1100 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.5–2.5 (m, 2H, $NCH_2CH_2CH_2O$), 3.0–3.7 (m, 2H, NCH_2), 4.1–4.8 (m, 3H, $NHOCH_2$), 4.50 (d, 2H, CH_2CCl_3, J = 7 Hz); ms (70 eV, 20°C), *m/e* (‰): 273 (4, $M^{+\cdot}$ + 6, Cl_3^{37}), 271 (18, $M^{+\cdot}$ + 4, $Cl_1^{35}Cl_2^{37}$), 269 (55, $M^{+\cdot}$ + 2, $Cl_2^{35}Cl_1^{37}$), 267 (57, $M^{+\cdot}$, Cl_3^{35}), 120 (1000, $M^{+\cdot} - OCH_2CCl_3^{\cdot}$).

Amide **2**b

This compound was obtained from **1***b* via the procedure for the preparation of **2***a*, in 90% yield after flash chromatography (petroleum ether – EtOAc, 1.5:1). Infrared (film) ν_{max}: 1735 (C=O, ester), 1690 (C=O, amide), 1330, 1300 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.30 (t, 3H, CH_3), 1.7–2.3 (m, 2H, $NCH_2CH_2CH_2O$), 3.1–3.7 (m, 1H, NCH), 3.8–4.8 (mb, 3H, OCH_2, NCH), 3.90, 4.04 (2s, 2H, CH_2), 4.20 (q, 2H, CH_3CH_2), 4.70 (d, 2H, OCH_2CCl_3, J = 7 Hz); ms (70 eV, 37°C), *m/e* (‰): 385 (15, $M^{+\cdot}$ + 4, $Cl_1^{35}Cl_2^{37}$), 383 (36, $M^{+\cdot}$ + 2, $Cl_2^{35}Cl_1^{37}$), 381 (38, $M^{+\cdot}$, Cl_3^{35}), 234 (194, $M^{+\cdot} - OCH_2CCl_3^{\cdot}$).

Diazo-amide **3**b

Compound **3***b* was obtained from **2***b* via the procedure for the preparation of **3***a*, in 80% yield after flash chromatography (petroleum ether – EtOAc, 1.5:1). Infrared (film) ν_{max}: 2115 (N_2), 1720 (C=O, ester), 1650 (C=O, amide, 1330 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.30 (t, 3H, CH_3), 1.6–2.3 (m, 2H, $NCH_2CH_2CH_2O$), 3.1–3.8 (m, 1H, NCH), 3.8–4.8 (m, 5H, NCH, CH_2O, OCH_2CH_3), 4.80 (d, 2H, OCH_2CCl_3, J = 7 Hz); ms (70 eV, 51°C), *m/e* (‰): 272 (14, $M^{+\cdot} - EtOOCCN_2CO^{\cdot}$ + 6, Cl_3^{37}), 270 (44, $M^{+\cdot} - EtOOCCN_2CO^{\cdot}$ + 4, $Cl_1^{35}Cl_2^{37}$), 268 (81, $M^{+\cdot} - EtOOCCN_2CO^{\cdot}$ + 2, $Cl_2^{35}Cl_2^{37}$), 266 (14, $M^{+\cdot} - EtOOCCN_2CO^{\cdot}$, Cl_3^{35}).

β-*Lactam* **7**b

A solution of β-lactam **7***a* (4.39 mg, 3.82 mmol) and dihydropyran (482 mg, 5.73 mmol) in dry methylene chloride (10 mL) containing pyridinium *p*-toluenesulfonate (PPTS) (96 mg, 0.382 mmol) was stirred for 8 h at room temperature. The solution was diluted with ether and washed with half-saturated brine to remove the catalyst. After drying and evaporation of the solvent, flash chromatography (ethyl acetate) gave 410 mg (54%) THP ether **7***b*. Infrared (film) ν_{max}: 3300 (NH), 1760 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.4–2.1 (m, 8H, CH_2CH_2O, $CHCH_2CH_2CH_2$), 2.49 (ddd, 1H, CHHCO, J_{gem} = 13 Hz, J_{trans} = 2.2 Hz, J_{NH} = 1.1 Hz), 3.10 (ddd, 1H, CHHCO, J_{gem} = 13 Hz, J_{cis} = 4.2 Hz, J_{NH} = 1.1 Hz), 3.3–4.1 (m, 5H, CHNH, $2CH_2O$), 4.6 (bm, 1H, $CH_2OCHOCH_2$), 6.3–6.7 (bs, 1H, NH); ms (70 eV, 20°C), *m/e* (‰): 199 (99, $M^{+\cdot}$), 99 (103, $M^{+\cdot} - HOCH(CH_2)_4O$), 85 (1000, THP^+).

β-*Lactam* **9**

Under a nitrogen atmosphere, a solution of β-lactam **7***b* (253 mg, 1.27 mmol) in dry THF (5 mL) was cooled to −78°C and treated with n-BuLi (1 equiv.) in THF. After being stirred for 10 min, diphenyl chlorophosphate (342 mg, 1.27 mmol) was added dropwise, and stirring, at −78°C, was continued for a period of 30 min. The reaction mixture was warmed to room temperature by itself. After adding methylene chloride (20 mL), the organic layer was washed with water (2 × 15 mL), dried ($MgSO_4$), and evaporated. The residue was purified by flash chromatography (petroleum ether – ethyl acetate; 1:1.5) to afford 438 mg of β-lactam **9** in 80% yield. Infrared (film) ν_{max}: 1790 (C=O, β-lactam) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.2–2.1 (m, 8H, CH_2CH_2O, $CH_2CH_2CH_2$), 2.6–3.0 (m, 2H, CH_2CO), 3.1–4.0 (m, 5H, CHN, CH_2O, CH_2O), 4.2 (b, 1H, CH), 7.00 (s, 10H, $2C_6H_5$).

β-*Lactam* **6**b

Compound **6***b* was obtained from β-lactam **6***a*, via the procedure for the preparation of **7***b*, in 80% yield after flash chromatography (EtOAc). Infrared (film) ν_{max}: 3280 (NH), 1750 (C=O, β-lactam) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.2–2.0 (m, 6H, $OCH(CH_2)_3$), 2.51 (app.bd, 1H, COCHH, J_{gem} = 14 Hz), 2.96 (2ddd, 1H, COCHH, J_{gem} = 14, J_{cis} = 4 Hz, J_{NH} = 1.5 z), 3.2–4.0 (m, 4H, OCH_2, OCH_2), 4.48 (bs, 1H, OCH), 6.7–7.0 (bs, 1H, NH); ms (70 eV, 19°C), *m/e* (‰): 185 (21 $M^{+\cdot}$), 85 (1000, THP^+).

β-*Lactam* ***8***

This compound was obtained from **6***b*, via the same procedure as for the preparation of **9**, in 85% yield used for the next reaction without purification. Infrared (film) ν_{max}: 1795 (β-lactam), 1595, 1490 (aromatic C=C), 1290 (P=O) cm $^{-1}$; ^{1}Hmr ($CDCl_3$) δ: 1.1−2.0 (m, 6H, $CH_2CH_2CH_2$), 2.9−3.2 (m, 2H, CH_2CO), 3.2−4.0 (m, 5H, $2OCH_2$, NCH), 4.2−4.5 (m, 1H, OCH), 7.12 (s, 10H, $2C_6H_5$); ms (70 eV, 76°C), *m/e* (‰): 417 (54, $M^{+\cdot}$), 333 (47, $M^{+\cdot}$ − DHP), 275 (287 ($M^{+\cdot}$ − $CH_2CHCH_2OTHP^{\cdot}$), 94 (936, $C_6H_5OH^{+\cdot}$), 77 (1000).

β-*Lactam* ***10***

Compound **10** was obtained from **8** via the procedure for the preparation of **11**, in 60% yield after flash chromatography (petroleum ether − EtOAc, 1:2.5). Infrared (film) ν_{max}: 3600−3200 (OH), 1790 (C=O, β-lactam), 1590, 1485 (aromatic C=C), 1280 (P=O) cm $^{-1}$; ^{1}Hmr ($CDCl_3$) δ: 2.5−3.4 (m, 2H, CH_2CO), 3.2−3.5 (b, 1H, OH, exchangeable with D_2O), 3.5−3.7 (m, 2H, CH_2OH), 4.0−4.1 (m, 1H, CHN), 7.27 (s, 10H, $2C_6H_5$); ms (70 eV, 26°C), *m/e* (‰): 333 (165, $M^{+\cdot}$), 275 (820, $M^{+\cdot}$ − CH_2CHCH_2OH), 233 (280 $(O)P(OC_6H_5)_2^+$), 94 (664, $C_6H_5OH^{+\cdot}$), 77 (1000).

β-*Lactam* ***11***

A solution of THP ether **9** (180 mg, 0.42 mmol) and pyridinium *p*-toluenesulfonate (PPTS) (20 mg, 0.08 mmol) in absolute ethanol (5 mL) was stirred at 55°C (oil bath temperature) for 5 h. The solvent was evaporated *in vacuo*, and the residue was chromatographed (EtOAc − petroleum ether, 2:1) to afford 124 mg (85%) of β-lactam **11**. Infrared (film) ν_{max}: 3450 (OH), 1790 (C=O, β-lactam) cm $^{-1}$; ^{1}Hmr 200 MHz ($CDCl_3$ and D_2O) δ: 1.6−2.0 (m, 2H, CH_2CH_2OH), 2.79 (ddd, 1H, COC*H*H, J_{gem} = 16 Hz, $J_{cis} = J_{PH} \simeq 3$ Hz), 3.22 (ddd, 1H, COC*H*H, J_{gem} = 16 Hz, $J_{trans} = J_{PH} \simeq 6$ Hz), 3.4−3.8 (m, 2H, CH_2OH), 4.0−4.2 (m, 1H, NCH), 7.38 (m, 10H, $2C_6H_5$); ms (70 eV, 56°C), *m/e* (‰): 347 (101, $M^{+\cdot}$), 276 (961, $M^{+\cdot}$ − CH_2=CH−$(CH_2)_2OH$ + 1), 254 (117, $M^{+\cdot}$ − $OC_6H_5^{\cdot}$), 77 (1000).

Bicyclic β-*lactam* ***5***

To a solution of **11** (150 mg, 0.43 mmol) in *t*-BuOH (2 mL) was added CsF (66 mg, 0.43 mmol). After stirring at room temperature for 2 h, the solvent was evaporated. Ethyl acetate was added. The mixture was washed with brine, dried, and evaporated to afford 22 mg (20%) of β-lactam **5**, after flash chromatography (petroleum ether − EtOAc, 1:2); mp 103°C; ir (CH_2Cl_2) ν_{max}: 1760 (C=O, β-lactam), 1590, 1490, 1190 cm $^{-1}$; ^{1}Hmr (acetone-d_6) δ: 1.8−2.2 (m, 2H, CH_2), 2.90 (app.dd, 2H, CH_2CO), 3.8−5.0 (m, 3H, CH, CH_2O), 6.9−7.5 (m, 5H, C_6H_5); ^{1}Hmr 200 MHz (acetone-d_6 and D_2O) δ: 1.8−2.2 (m, 2H, CH_2), 2.8−3.0 (m, 2H, CH_2O), 3.9−4.1 (m, 1H, CH), 4.3−4.7 (m, 2H, CH_2O), 6.9−7.5 (m, 5H, C_6H_5); ms (70 eV, 82°C), *m/e* (‰): 254 (372, $M^{+\cdot}$ + 1), 212 (1000, $M^{+\cdot}$ − CH_2=C=O).

β-*Lactam* ***13***

To a solution of alcohol **7***a* (150 mg, 1.3 mmol) and pyridine (162 mg, 1.43 mmol) in CH_2Cl_2 (10 mL) was added dropwise diphenyl chlorophosphate (349 g, 1.3 mmol). After stirring for 2 h the solution was washed with water (3 × 5 mL) and brine (8 mL), dried ($MgSO_4$), and evaporated to give 392 mg (87%) of β-lactam **13** after flash chromatography. Infrared (film) ν_{max}: 1765 (C=O, β-lactam), 1590, 1490 (C=C, aromatic) cm $^{-1}$; ^{1}Hmr 200 MHz ($CDCl_3$) δ: 1.8−2.2 (m, 2H, CH_2), 2.60 (ddd, 1H, COC*H*H, J_{gem} = 15 Hz, J_{trans} = 2 Hz), 3.05 (ddd, 1H, COCH*H*, J_{gem} = 15 Hz, J_{cis} = 5 Hz, J_{NH} = 2 Hz), 3.6−3.8 (m, 1H, CH), 4.2−4.6 (m, 2H, CH_2O), 6.3 (bs, 1H, NH), 7.1−7.5 (m, 10H, $2C_6H_5$); ms (70 eV, 55°C), *m/e* (‰): 347 (46, $M^{+\cdot}$), 305 (437, $M^{+\cdot}$ − CH_2=C=O), 304 (203, $M^{+\cdot}$ − OCNH).

Alcohol ***6***a

To a solution of 4-carbobenzyloxyazetidinone (0.205 g, 1 mmol) in methanol (10 mL) was added sodium borohydride (114 mg, 3 mmol) in portions. After stirring at room temperature for 18 h, concentrated HCl was added dropwise to neutralize to pH 5. The precipitate was filtered off and the filtrate was evaporated to dryness. The residue was purified by flash chromatography (EtOAc − methanol, 10:1) to afford 0.05 g (50%) of alcohol **6***a*. Infrared (film) ν_{max}: 3400−3000 (NH, OH), 1730 (C=O, β-lactam) cm $^{-1}$; ^{1}Hmr (acetone-d_6) δ: 2.6 (dd, 1H, COC*H*H, J_{gem} = 15 Hz, J_{trans} = 2Hz), 2.9 (m, 1H, COCH*H*, J_{gem} = 15 Hz, J_{cis} = 5 Hz, J_{NH} = 1.5 Hz), 3.5−3.9 (m, 3H, CH_2O, CH), 4.2 (bs, 1H, OH), 7.3 (bs, 1H, NH); gc−ms (TMS derivative), *m/e* (‰): 245 (24, $M^{+\cdot}$, di-TMS derivative).

β-*Lactam* ***12***

Diphenyl chlorophosphate (0.31 mL, 1.48 mmol) was added dropwise to a solution of alcohol **6***a* (149 mg, 1.48 mmol) and triethylamine (0.21 mL) in anhydrous tetrahydrofuran (5 mL). After stirring for 0.5 h methylene chloride (20 mL) was added to the reaction mixture. The organic layer was washed with water (2 × 15 mL), dried ($MgSO_4$), and evaporated to dryness. The residue was purified by flash chromatography (EtOAc) to afford 438 mg (89%) of β-lactam **12**. Infrared (film) ν_{max}: 3260 (NH), 1780 (C=O, β-lactam), 1590, 1490 (aromatic C=C), 1290 (P=O) cm $^{-1}$; ^{1}Hmr ($CDCl_3$) δ: 2.51 (ddd, 1H, C*H*HCO, J_{gem} = 15 Hz, J_{trans} = 3 Hz, J_{NH} = 1.5 Hz), 2.83 (ddd, 1H, C*H*HCO, J_{gem} = 15 Hz, J_{cis} = 4 Hz, J_{NH} = 1.5 Hz), 3.5−3.8 (m, 1H, CHN), 3.9−4.3 (m, 2H, CH_2O), 6.6 (bs, 1H, NH), 7.00 (s, 10H, $2C_6H_5$); ms (70 eV, 55°C), *m/e* (‰): 333 (34, $M^{+\cdot}$), 291 (1000, $M^{+\cdot}$ − CH_2=C=O), 94 (861, $C_6H_5OH^{+\cdot}$), 77 (820, $C_6H_5^{+\cdot}$).

*4-Methyl-3-[(*tert*-butoxycarbonyl)amino]-1-hydroxyazetidinone* ***15*** (ref. 15*b*)

Compound **14** (1.53 g, 5 mmol) was dissolved in 140 mL of methanol and hydrogenated at 1 atm of H_2 in the presence of 10% Pd/C (140 mg); filtration and evaporation gave **15** as a white solid; mp 143−145°C (recrystallized from ether−hexanes); $[\alpha]_D^{20}$ −30.8° (*c* 1.05, CH_3OH); ir (Nujol) ν_{max}: 3350 (NH), 1775 (CO, β-lactam), 1685 (CO, *t*-BOC) cm $^{-1}$; ^{1}Hmr (CD_3OD) δ: 1.4 (d, 3H, CH_3, *J* = 6.5 Hz), 1.46 (s, 9H, *t*-Bu), 3.76 (9d, 1H, CHMe, *J* = 6.5, 1.5 Hz), 4.0 (br m, 1H, C*H*NH), 4.8 (br s, 2H).

*4-Methyl-3-[(*tert*-butoxycarbonyl)amino]azetidinone* ***16*** (ref. 15*b*)

Compound **15** (1.92 g, 8.9 mmol) was dissolved in 18 mL of CH_3OH and added to 73 mL of H_2O at pH 7. While the mixture was stirred under N_2 and the pH maintained at 7 by dropwise addition of 3 *N* NaOH solution, 36 mL (4 equiv.) of a 15% aqueous solution of $TiCl_3$ (BDH) was added dropwise. After the addition was completed, stirring was continued for 3 h. The aqueous mixture was then adjusted to pH 8 and extracted with three 30-mL portions of ethyl acetate. The combined ethyl acetate was washed with brine, dried over $MgSO_4$, filtered, and evaporated. The residue was recrystallized from ethyl acetate − hexanes to give 0.77 g (3.85 mmol, 43%) of **16**; mp 123−125°C; $[\alpha]_D^{20}$ −60.5° (*c* 1.1, CH_3OH); ir ($CHCl_3$) ν_{max}: 3440 and 3320 (NH), 1760 (CO β-lactam), 1710 (CO, *t*-BOC) cm $^{-1}$; ^{1}Hmr ($CDCl_3$) δ: 1.4 (d, 3H, CH_3, *J* = 6.5 Hz), 1.45 (s, 9H, *t*-Bu), 3.68 (qd, 1H, C*H*Me, *J* = 6.5, 1.5 Hz), 4.16 (dd, 1H, C*H*NH, *J* = 7.0, 1.5 Hz), 5.85 (d, 1H, NH amide, *J* = 7.0 Hz), 7.0 (br s, 1H, NH β-lactam).

*4-Methyl-3-[(*tert*-butoxycarbonyl)amino]-1-dibenzylphosphoryl-2-azetidinone* ***17***a

Under a nitrogen atmosphere, a solution of β-lactam **16** (150 mg, 0.75 mmol) in dry THF (15 mL) was cooled at −78°C and treated with n-BuLi (1.1 equiv.). The reaction mixture was stirred for 20 min and a solution of dibenzyl chlorophosphate (266 mg, 0.9 mmol) in THF (2 mL) was added dropwise; stirring at −78°C was continued for 1 h. The solution was allowed to warm up to −10°C. The solvent was removed and, after adding ethyl acetate, the organic layer was washed twice with brine, dried on $MgSO_4$, and evaporated. The residue was purified by flash chromatography (ethyl acetate − hexanes, 45:55) to afford 208 mg of β-lactam **17***a* in 60% yield; $[\alpha]_D^{20}$ −3.9° (*c* 1.35, CH_3OH); ir ($CDCl_3$) ν_{max}: 3300 (NH), 1785 (CO β-lactam), 1710 (CO *t*-BOC), 1270 (P=O) cm $^{-1}$; ^{1}Hmr ($CDCl_3$) δ: 1.33−1.43 (s + d, 12H, *t*-Bu + CH_3), 3.70−4.20 (m, 3H, CH—CH, NH), 5.0−5.2 (2d, 4H, $2CH_2$, J_{P-OCH_2} = 9 Hz), 7.3 (s, 10H, $2C_6H_5$); ms (70 eV, 80°C), *m/e* (‰), 304 (110, $M^{+\cdot}$ − *t*-BOCNHCHCO + 1,

$M^{+\cdot}$ − *t*-BOCNHCHCHCH$_3$ + 1), 157 (70, *t*-BOCNHCHCO$^+$, *t*-BOCNHCHCHCH$_3^+$), 107 (40, $C_6H_5CH_2O^+$), 101 (350, *t*-BuOCO$^+$), 91 (880, $C_6H_5CH_2^+$), 57 (1000, *t*-Bu$^+$, $\overline{CH_2—CO—NH}^{+\cdot}$, $\overline{CH_2—CHMe—NH}^{+\cdot}$).

*4-Methyl-3-[(*tert*-butoxycarbonyl)amino]-1-phosphoryl-2-azetidinone* **17**b

Dibenzylphosphoramidate **17***a* (40 mg, 0.087 mmol) was dissolved in methanol (5 mL) and hydrogenated for 1 h at 1 atm of H_2 in the presence of 10% Pd/C (5 mg). After filtration and evaporation, the residue was washed with chloroform (3 × 1 mL) to afford 22 mg of amidophosphoric acid **17***b* in 90% yield; pH (CH_3OH solution) 2.5−3; ir ($CHCl_3$) ν_{max}: 3450−2600 (OH), 3350 (NH), 1760 (CO β-lactam), 1705 (CO *t*-BOC), 1250 (P=O) cm^{-1}; ^{1}Hmr 200 MHz (D_2O) δ: 1.33 (s, 9H, *t*-Bu), 1.43 (d, 3H, CH_3, J = 6.5 Hz), 3.7−5.0 (m, 5H); ms (70 eV), *m/e* (‰): 497 (120, $M^{+\cdot}$ + 1 + 3TMS), 397 (120), 395 (740, $M^{+\cdot}$ − *t*-BuOCO + 3TMS), 340 (370, $M^{+\cdot}$ − *t*-BOCNHCHCO + 1 + 3TMS, $M^{+\cdot}$ − *t*-BOCNHCHCHCH$_3$ + 1 + 3TMS), 323 (150, $M^{+\cdot}$ − *t*-BuO + 3TMS), 101 (20, *t*-BuOCO$^+$), 73 (1000, *t*-BuO$^+$), 57 (340, *t*-Bu$^+$, $\overline{CH_2—CO—NH}^{+\cdot}$, $\overline{CH_2—CHMe—NH}^{+\cdot}$).

*4-Methyl-3-(*tert*-butoxycarbonyl)amino]-1-dimethylphosphoryl-2-azetidinone* **17**c

To a suspension of β-lactam phosphoric acid **17***c* (8.5 mg, 0.03 mmol) in CH_2Cl_2 (1 mL) was added dropwise at 0°C a solution of diazomethane (2.5 equiv.) in ether. The reaction mixture was warmed to room temperature by itself. After evaporation of the solvent 10 mg of dimethylphosphoramidate **17***c* were obtained in a quantitative yield; ir ($CHCl_3$) ν_{max}: 3450 (NH), 1780 (CO β-lactam), 1715 (CO *t*-BOC), 1270−1180 (P=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.3−1.45 (s + d, 12H, *t*-Bu + CH_3), 3.6−4.4 (m, 2H, CH—CH), 3.8−4.0 (2d, 4H, 2 OCH_3, $J_{P—OCH_3}$ = 12 Hz), 5.2 (br d, 1H, NH); ms (70 eV), *m/e* (‰): 235 (60 $M^{+\cdot}$ − *t*-BuO), 157 (20, *t*-BOCNHCHCO$^+$, *t*-BOCNHCHCHCH$_3^+$), 152 (460, $M^{+\cdot}$ − *t*-BOCNHCHCO + 1, $M^{+\cdot}$ − *t*-BOCNHCHCHCH$_3$ + 1), 109 (80, $\overline{PO(OMe)_2}^{+\cdot}$), 101 (245, *t*-BuOCO$^+$), 57 (1000, *t*-Bu$^+$, $\overline{CH_2—CO—NH}^{+\cdot}$, $\overline{CH_2—CHMe—NH}^{+\cdot}$).

β-*Lactam* **19**

β-Lactam **16** (200 mg, 1 mmol) was dissolved in trifluoroacetic acid (1 mL) at 0°C. After stirring for 10 min, the acid was removed by evaporation and the residue washed with carbon tetrachloride (3 × 1 mL); ir (film) ν_{max}: 3450−2680 (NH, OH), 1770 (CO β-lactam), 1670 (CO) cm^{-1}; ^{1}Hmr (CD_3COCD_3) δ: 1.5 (d, 3H, CH_3, J = 6.5 Hz), 3.8−4.4 (m, 3H, C*H*Me, NH_2), 5.05 (d, 1H, C*H*NH, J = 1.5 Hz).

4-Methyl-3-phenylacetamido-2-azetidinone **20**

To a solution of β-lactam **19** (214 mg, 1 mmol) and pyridine (237 mg, 3 mmol) in dry methylene chloride (20 mL) was added, dropwise under nitrogen, phenylacetyl chloride (232 mg, 1.5 mmol) in 5 mL methylene chloride. After the addition was complete the solution was stirred for 3 h, washed with pH 4.5 buffer (KH_2PO_4) and water, dried ($MgSO_4$), and evaporated. The crude product was purified by flash chromatography (ethyl acetate) to afford a colorless solid (50 mg) in 23% yield; mp 138−140°C; $[\alpha]_D^{20}$ −36.0° (*c* 0.65, CH_3OH); ir ($CHCl_3$) ν_{max}: 3420 and 3300 (NH), 1760 (C=O β-lactam), 1670 (C=O amide), 1600 (C=C) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.5 (d, 1H, CH_3, J = 6.5 Hz), 3.4−3.7 (m, 3H, CH_2, C*H*Me), 4.5 (dd, 1H, C*H*NH, J = 6.0, 2.0 Hz), 6.5 (br s, 1H, NH β-lactam), 6.8 (d, 1H, NH amide, J = 6.0 Hz), 7.3 (s, 5H, C_6H_5); ms (70 eV), *m/e* (‰): 175 (380, $C_6H_5CH_2CONHCHCO^+$, $\underline{C_6H_5CH_2CONHCHCHMe^+}$), 91 (670, $C_6H_5CH_2^+$), 57 (1000, $\overline{CH_2—CO—NH}^{+\cdot}$, $\overline{CH_2—CHMe—NH}^{+\cdot}$).

4-Methyl-3-phenylacetamido-1-dibenzylphosphoryl-2-azetidinone **21**a was prepared from β-lactam **20** as described for **17***a*, in 30% yield after flash chromatography (EtOAc−hexanes, 60:40); ir ($CHCl_3$) ν_{max}: 3400 (NH), 1780 (CO β-lactam), 1670 (CO amide), 1270−1180 (P=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.5 (d, 3H, CH_3, J = 6.5 Hz), 3.65 (s, 2H, CH_2), 3.75−4.1 (m, 1H, C*H*Me), 4.2−4.4 (dd, 1H, C*H*NH, J = 7.0, 2.0 Hz), 5.1−5.3 (2d, 4H, $2CH_2$, J = 9 Hz), 6.1 (d, 1H, NH, J = 7.0 Hz), 7.4 (s, 15H, $3C_6H_5$); ms (70 eV), *m/e* (‰): 478 (150, $M^{+\cdot}$), 304 (140, $M^{+\cdot}$ − $C_6H_5CH_2CONHCHCO$ + 1, $M^{+\cdot}$ − $C_6H_5CONHCHCHMe$ + 1), 281 (490), 175 (490, $C_6H_5CH_2CONHCO^+$, $\underline{C_6H_5CH_2CONHCHCHMe^+}$), 91 (1000, $C_6H_5CH_2^+$), 57 (170, $\overline{CH_2—CONH}^{+\cdot}$, $\overline{CH_2CHMe—NH}^{+\cdot}$).

4-Methyl-3-phenylacetamido-1-phosphoryl-2-azetidinone **21**b was prepared from β-lactam **21***a* as described for **17***b*. Yield: 85%; pH (CH_3OH solution) 3.5; ir (Nujol) ν_{max}: 3450−3000 (OH, NH), 1750 (C=O β-lactam), 1650 (C=O amide), 1200 (P=O) cm^{-1}; ^{1}Hmr (CD_3OD) δ: 1.5 (d, 3H, CH_3, J = 6.5 Hz), 3.6 (s, 2H, CH_2), 3.7−4.6 (m, 3H, CH—CH, NH), 7.3 (s, 5H, C_6H_5).

4-Methyl-3-phenylacetamido-1-dimethylphosphoryl-2-azetidinone **21**c was prepared from β-lactam **21***b* as described for **17***c*; ms (70 eV), *m/e* (‰): 327 (5, $M^{+\cdot}$ + 1), 175 (10, $C_6H_5CH_2CONHCHCO^+$, $C_6H_5CH_2CONHCHCHMe^+$), 152 (1000, $M^{+\cdot}$ − $C_6H_5CH_2CONHCHCO$ + 1, $M^{+\cdot}$ − $C_6H_5CH_2CONHCHCHMe$ + 1), 109 (20, $\overline{PO(OCH_3)_2}^+$), 91 (380, $C_6H_5CH_2^+$), 57 (70, $\overline{CH_2CONH}^{+\cdot}$, $\overline{CH_2—CHMe—NH}^{+\cdot}$).

β-*Lactam* **23**

To a solution of β-lactam **19** (1.07 g, 5 mmol) in 150 mL of dry THF−CH_2Cl_2 (1:2) was added triethylamine (0.60 g, 6 mmol) at 0°C and under nitrogen. The reaction mixture was stirred for 1 h and allowed to warm to room temperature. Then two solutions, trityl acid **22** (2.66 g, 6 mmol) in 30 mL dry CH_2Cl_2 and EEDQ (1.48, 6 mmol) in 20 mL dry CH_2Cl_2, were successively added dropwise. After stirring for a period of 15 h, the solvent was removed and ethyl acetate added. The organic layer was washed with a 4% $NaHCO_3$ solution (2 × 20 mL) and brine, dried ($MgSO_4$), and evaporated. The crude material was purified by flash chromatography (EtOAc−hexanes 75:25) to afford 0.98 g of β-lactam **23** in 38% yield; mp 135−140°C; $[\alpha]_D^{20}$ −31.4° (*c* 1.35, CH_3OH); ir ($CHCl_3$) ν_{max}: 3420 and 3360 (NH), 1765 (CO β-lactam), 1680 (CO amide) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.5 (d, 3H, CH_3, J = 6.5 Hz), 4.0 (s, 3H, OCH_3), 3.5−4.0 (qd, 1H, C*H*Me, J = 6.5, 2.0 Hz), 4.4−4.6 (dd, 1H, C*H*NH, J = 6.0, 2.0 Hz), 6.2 (s, 1H, NH β-lactam), 6.6 (s, 1H, CH=), 7.1 (d, 1H, NH amide), 7.3 (s, 15H, $3C_6H_5$).

β-*Lactam* **24**

Trityl β-lactam **23** (485 mg, 0.92 mmol) in 75 mL of methanol − formic acid (4:1) was refluxed for 1 h. After evaporation of the solvent, the crude material was washed with carbon tetrachloride to give 227 mg (0.80 mmol, 86%) of amino β-lactam **24**; mp 125−130°C (dec.); $[\alpha]_D^{20}$ −70.5° (*c* 2.47, CH_3OH); ir ($CHCl_3$) ν_{max}: 3480, 3410, 3300 (NH), 1760 (CO β-lactam), 1670 (CO amide), 1600 (C=C) cm^{-1}; ^{1}Hmr (CD_3COCD_3) δ: 1.4 (d, 3H, CH_3, J = 6.5 Hz), 3.6−4.0 (m, 4H, OCH_3, C*H*Me), 4.5−4.7 (dd, 1H, CHNH, J = 8.0, 2.0 Hz), 6.72 (s, 1H, CH=), 6.92 (br s, 2H, NH_2), 7.5 (s, 1H, NH β-lactam), 8.4 (d, 1H, NH amide); ms (70 eV), *m/e* (‰): 283 (80, $M^{+\cdot}$), 252 (100, $M^{+\cdot}$ − OCH_3), 240 (150, $M^{+\cdot}$ − CONH, $M^{+\cdot}$ − MeCHNH), 126 (1000), 125 ($H_2N—C=N—C—C\equiv N$, 99 (S—CH)), 83 (300), 57 (250).

N-*dibenzylphosphoryl* β-*lactam* **25**a was prepared from compound **24** (227 mg, 0.8 mmol) following the procedure described for **17***a*. However, in the present case, the organic layer was washed with a 4% $NaHCO_3$ solution and brine. The crude compound was purified by flash chromatography (EtOAc) to afford 150 mg of β-lactam **25***a* in 35% yield; $[\alpha]_D^{20}$ −18.4° (*c* 1.05, CH_3OH); ir ($CHCl_3$) ν_{max}: 3480, 3380 (NH), 1780 (CO β-lactam), 1670 (CO amide), 1600 (C=C), 1190 (P=O) cm^{-1}; ^{1}Hmr 200 MHz ($CDCl_3$) δ: 1.43 (d, 3H, CH_3, J = 6 Hz), 3.89 (s, 3H, OCH_3), 4.15 (qd, 1H, C*H*Me, J = 6.0, 2.0 Hz), 4.62 (dd, 1H, C*H*NH, J = 7.0, 2.0 Hz), 5.11−5.17 (2d, 4H, $2CH_2$, $J_{P—OCH_2}$ = 8 Hz), 5.76 (s, 2H, NH_2), 6.66 (s, 1H, CH=), 7.22 (m, 10H, $2C_6H_5$), 8.11 (br d, 1H, NH, J = 7 Hz); ms (70 eV), *m/e* (‰): 187 (180), 167 (110), 149 (370), 107 (170), 100 (830), 97

(160), 91 (1000, $C_6H_5CH_2^+$), 83 (103), 79 (100), 69 (680), 57 (760), 55 (610), 45 (250).

N-*phosphoryl* β-*lactam* **25**b was prepared from **25***a* (47 mg, 0.086 mmol) according to the method given for **17***b*. After 10 h of reaction, filtration, and evaporation, the crude material was recrystallized in MeOH−EtOAc (1:3) to give phosphoric acid **25***b* in 80% yield; pH (MeOH solution) 5.5; $[\alpha]_D^{20}$ 26.3° (*c* 0.18, CH_3OH); ir (KBr) ν_{max}: 3600−2900 (NH, OH), 1745 (CO β-lactam), 1665 (CO amide), 1210 (P=O) cm^{-1}; ^{1}Hmr 200 MHz (CD_3OD) δ: 1.47 (d, 3H, CH_3, J = 6.5 Hz), 3.93 (s, 3H, OCH_3), 3.47−3.77 (m, 1H, C*H*Me), 4.2−4.4 (m, 1H, C*H*NH), 6.8 (s, 1H, CH=), 7.22−7.47 (m, 5H, NH_2, NH, 2OH); ms (70 eV), *m/e* (‰): 368 (40), 97 (110), 91 (200), 83 (180), 69 (370), 57 (450), 55 (410), 44 (1000).

N-*dimethyl phosphoryl* β-*lactam* **25**c was prepared from compound **25***b* as described for **17***c*; ms (70 eV), *m/e* (‰): 279 (60), 167 (120), 149 (280), 130 (120), 121 (110), 97 (160), 95 (120), 91 (110), 85 (150), 83 (220), 81 (250), 73 (360), 71 (330), 69 (655), 57 (780), 55 (680), 43 (1000).

Triethylamine salt **25**d was obtained by addition of triethylamine (5 mg, 0.05 mmol) to a solution of acid **25***b* (9 mg, 0.025 mmol) in 1 mL MeOH. After stirring for 5 min, the solvent was removed to afford 13 mg of β-lactam **25***d* in 92% yield; ir (KBr) ν_{max}: 3550−3300 (NH), 1745 (CO β-lactam), 1660 (CO amide), 1610 (C=C), 1245, 1205 (P=O) cm^{-1}; ^{1}Hmr (CD_3OD) δ: 1.3−1.5 (t + d, 9H, $2CH_2$—CH_3, CH_3, J = 7.5, 6.5 Hz), 3.1 (q, 4H, $2CH_2$—Me, J = 7.5 Hz), 3.5−4.6 (m, 5H, C*H*Me, C*H*NH, OCH_3), 6.85 (s, 1H, CH=), 7.3 (m, 5H, 3NH, NH_2).

Monopotassium salt **25**e

Dibenzylphosphoramidate **25***a* (5.4 mg, 0.01 mmol) was dissolved in 2 mL THF−EtOH (1:1) and 12 μL of a 1 *M* aqueous solution of $KHCO_3$ (0.012 mmol) was added. The mixture was hydrogenated for 6 h in the presence of 20% Pd(OH)/C (3 mg). After filtration and evaporation, the residue was washed with ethyl acetate to afford 3.8 mg (95%) of potassium salt **25***e*; ir (KBr) ν_{max}: 3600−2900 (OH, NH), 1745 (CO β-lactam), 1655 (CO amide), 1595 (C=C), 1250 (P=O) cm^{-1}.

Infrared spectra of crystalline *n*-alkanes. Changes observed during the phase I → phase II transition[1]

HECTOR L. CASAL, DAVID G. CAMERON, AND HENRY H. MANTSCH
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received August 6, 1982[2]

HECTOR L. CASAL, DAVID G. CAMERON, and HENRY H. MANTSCH. Can. J. Chem. **61**, 1736 (1983).

Detailed measurements of the changes in the infrared spectra of *n*-nonadecane and *n*-heneicosane on transition from the orthorhombic to the so-called "hexagonal" or "rotator" phase are reported.

HECTOR L. CASAL, DAVID G. CAMERON et HENRY H. MANTSCH. Can. J. Chem. **61**, 1736 (1983).

On rapporte les mesures détaillées des changements observés dans les spectres infrarouges du *n*-nonadécane et du *n*-hénéicosane lors de la transition de la phase orthorhombique à la soi-disant phase "hexagonale" ou "rotateur".

Introduction

The normal alkanes undergo a variety of solid–solid phase transitions (1, 2). In particular, odd-numbered *n*-alkanes undergo a transition from a low temperature orthorhombic crystal form (phase I) to a high temperature form (phase II), sometimes referred to as the "rotator" or "hexagonal" phase.

In this paper we report on the changes induced in the infrared spectra of *n*-nonadecane (n-$C_{19}H_{40}$) and *n*-heneicosane (n-$C_{21}H_{44}$) by the phase I to phase II transition. The nature of this transition is relevant to two general areas of study.

Firstly, the properties of phase II are of intrinsic interest. Studies have shown that the chains undergo hindered rotation (1, 3, 4), that *gauche* bonds are present (5–7), and that there exists interchain vibrational coupling (8). All these effects are both chain length and temperature dependent. Secondly, the transition is relevant to studies of the properties of model biomembranes. The hydrated diacylphosphatidylcholines exhibit a "pretransition" some 2–10°C below the temperature of the gel to liquid-crystal transition. A variety of changes can be monitored in the infrared spectra of these lipids and, to a first approximation, parallel those observed at the phase I to phase II transition of *n*-alkanes, and as the temperature is raised in phase II (9, 10).

Experimental

n-Nonadecane and *n*-heneicosane were gifts from R. G. Snyder. The preparation and purification have been described (11); their purity was determined by gas–liquid chromatography to be higher than 99.7%. The sample of n-1,1,1,17,17,17-hexadeuteroheptadecane (n-$C_{17}H_{30}D_6$) was a gift from L. C. Leitch; its purity was higher than 99.5%.

Temperature regulation was achieved with a thermostated cell mount (12). Spectra of thin (2–10 μm) films between KBr windows were recorded on a Digilab FTS-15 Fourier transform infrared spectrometer equipped with a wide range mercury cadmium telluride detector (Infrared Associates, New Brunswick, NJ). Six hundred scans, recorded with a maximum optical path difference of 1 cm, were co-added, triangularly apodized, zero-filled once, and Fourier transformed to yield a resolution of 1 cm^{-1} and an encoding interval of 0.5 cm^{-1}.

Frequencies and full-width at half-height (FWHH) were determined by the methods previously described, using three data points for the centre of gravity computation (13).

[1]NRCC No. 20700.

[2]Revision received March 3, 1983.

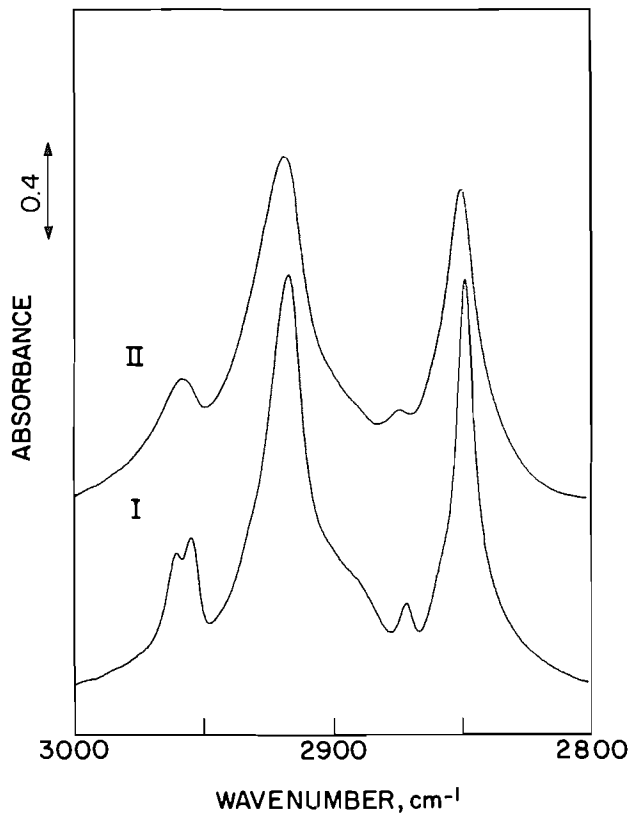

FIG. 1. C—H stretching region of the infrared spectrum of n-$C_{21}H_{44}$ in phase I (lower trace, 1°C) and phase II (upper trace, 36°C).

Results

In Table 1 we list the frequencies and assignments (14, 15) of the infrared spectra of phase I and phase II *n*-nonadecane and *n*-heneicosane.

The temperature dependence of the spectra is discussed below; as the thermotropic behaviour of the two *n*-alkanes is essentially the same, detailed data are only presented for n-$C_{21}H_{44}$.

C—H stretching

The C—H stretching region of the infrared spectrum of solid n-$C_{21}H_{44}$ is shown in Fig. 1; the bottom trace is the spectrum of phase I (1°C) and the top trace is that of phase II (36°C).

Figure 2 shows the temperature dependence of the intensities, frequencies, and widths of the antisymmetric and

TABLE 1. Frequencies (cm $^{-1}$) of the bands in the infrared spectra of n-$C_{19}H_{40}$ and n-$C_{21}H_{44}$ in phase I and phase II[a]

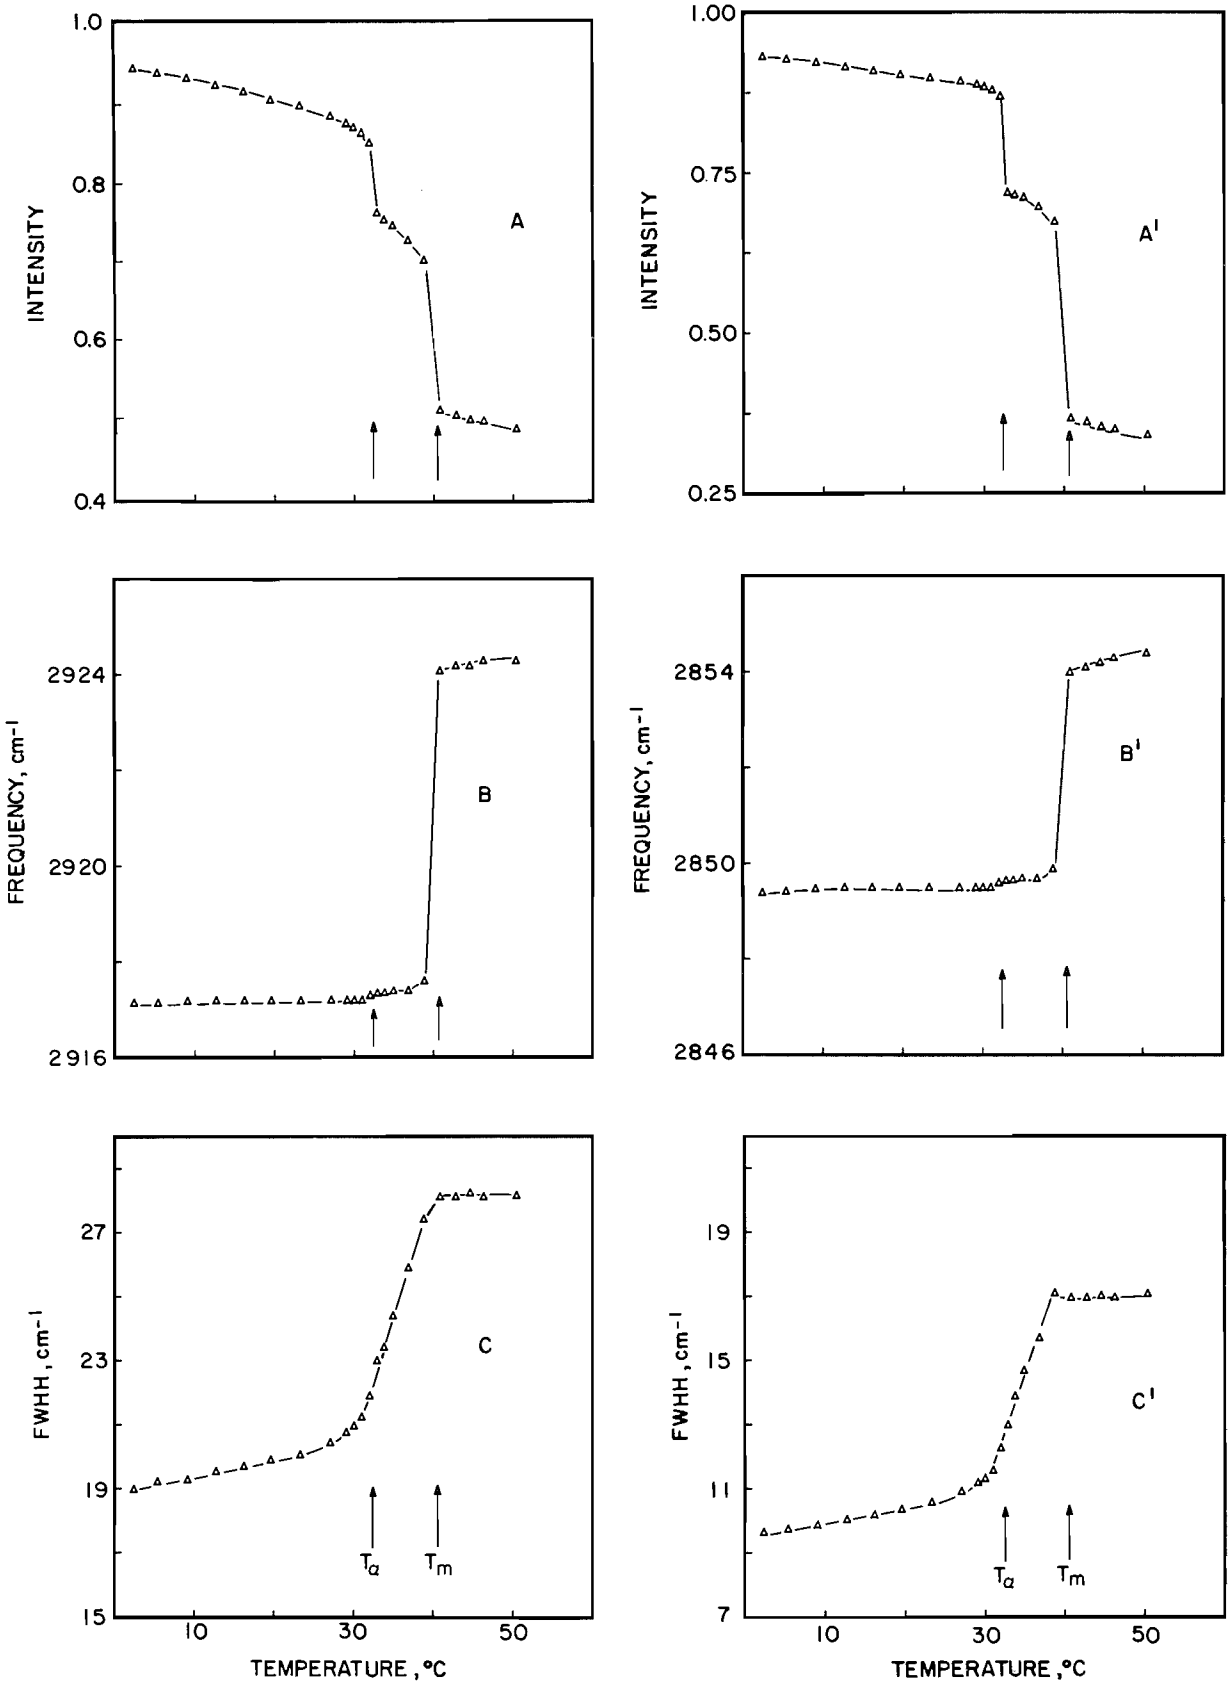

FIG. 2. Temperature dependence of the antisymmetric CH_2 (A, B, C) and symmetric CH_2 (A', B', C') stretching bands in the spectrum of n-$C_{21}H_{44}$: A and A', integrated intensity (baselines from 2947 to 2878 cm^{-1} (A), and 2866 to 2806 cm^{-1} (A')); B and B', frequency; C and C', full width at half height (FWHH) (baseline from 3000 to 2800 cm^{-1}). In this and all other plots T_α indicates the temperature of the phase I $\rightarrow$ phase II transition, and T_m indicates the melting point. Note that the intensity scales are arbitrary, and only meant to convey information on the change of integrated intensity for a given band. Comparisons of absolute values between different figures cannot be made.

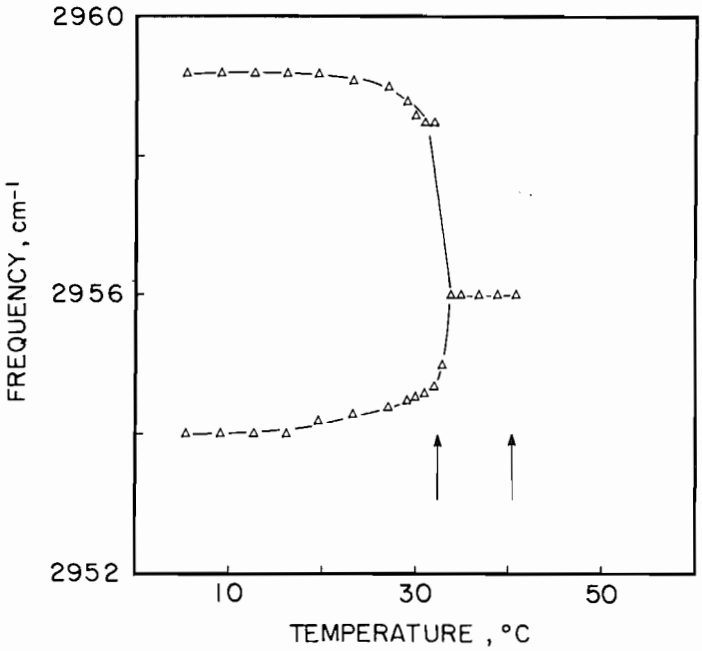

FIG. 3. Temperature dependence of the frequency of the components of the methyl antisymmetric stretching mode in the spectrum of n-$C_{21}H_{44}$.

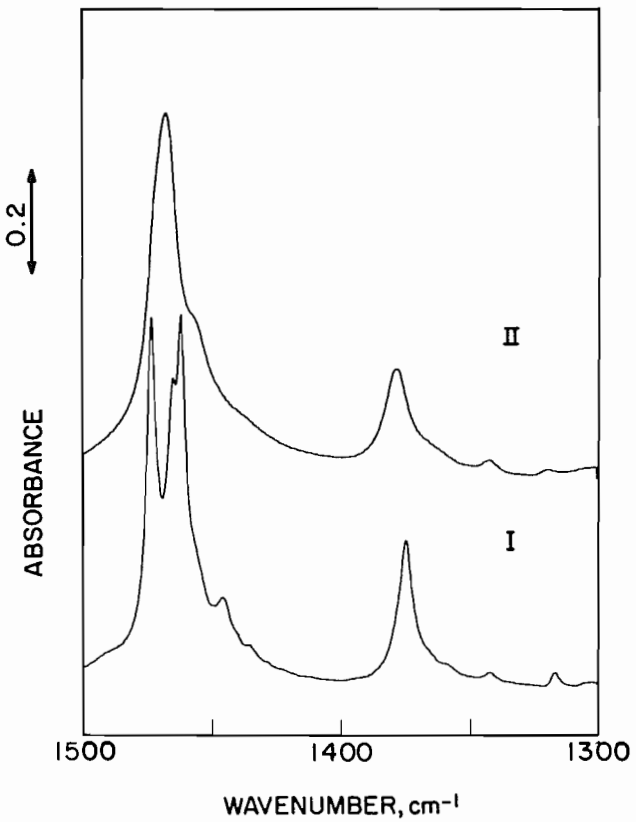

FIG. 4. 1500–1300 cm^{-1} region of the spectrum of n-$C_{21}H_{44}$ in phase I (1°C) and phase II (36°C).

symmetric CH_2 stretching bands. Quite dissimilar behaviour is observed for these parameters. The intensities decrease steadily as the temperature is raised in phase I and phase II, and there is an abrupt change at 32.5°C, the transition temperature (T_α). In contrast, the frequencies are almost the same in phase I and phase II, the shifts at 32.5°C being small (0.2 cm^{-1}).

The values of the FWHH also vary steadily in both phases. However, in contrast to the discontinuities in the intensity and frequency plots at T_α, there is merely a change in the gradient of the bandwidth plot.

The frequencies of the in-plane and out-of-plane components of the methyl asymmetric stretching mode versus temperature are plotted in Fig. 3. The separation between the two components starts to decrease at ~25°C, and at T_α the two components collapse into one band.

CH_2 scissoring and CH_3 bending

The HCH scissoring and CH_3 bending bands are observed in the 1500–1300 cm^{-1} region, shown in Fig. 4 for n-$C_{21}H_{44}$. The principal results of transition from phase I to phase II are a major reduction in the degree of crystal field splitting of the HCH scissoring mode (8) and a slight increase in intensity at 1450 cm^{-1}. Parallel changes are observed in the CH_2 rocking bands (see below) and have been reported in detail in ref. 8.

Figure 5 shows the temperature dependence of the integrated intensity of the 1520–1420 cm^{-1} region. The intensity includes a contribution from the asymmetric methyl bending at 1465 cm^{-1}. However, a similar increase in integrated intensity at T_α was observed in the spectra of n-$C_{17}H_{30}D_6$, hence the data of Fig. 5 can be taken as representative of the HCH scissoring bands.

CH_2 wagging

The methylene wagging band progression is observed in the 1380 to 1180 cm^{-1} region, as shown in Fig. 6 for n-$C_{21}H_{44}$. The transition to phase II results in changes in the intensities, widths, and frequencies of all components of the progression. Excepting for W_{11} (1342 cm^{-1}), the intensities decrease. The apparent increase in the intensity of this band is due to the occurrence in phase II of a band (~1343 cm^{-1}) due to the wagging of CH_2 groups adjacent to *gauche* defects (16). Other bands present only in phase II and associated with *gauche* defects (16) are observed at 1300 and 1275 cm^{-1}. We also note that the apparent absence of T_{17} (1190 cm^{-1}) in phase II is due to overlap of T_{17} with W_1 (1196 cm^{-1}) in this phase.

Figure 7 shows plots of temperature versus the integrated intensity, frequency, and width of the W_2 band in the spectrum of n-$C_{21}H_{44}$, its thermal behaviour being representative of the CH_2 wagging bands. The transition to phase II results in an abrupt shift to higher frequency of about 2 cm^{-1}, broadening (~25%), and a major reduction in intensity (~40%). A feature evident in this figure is that both the frequency and FWHH start changing well below the temperature of transition, paralleling the early onset of changes in the methyl stretching bands (Fig. 3).

CH_2 rocking and twisting

The methylene rocking band progression extends from 1170 to 720 cm^{-1}; this region of the spectrum of n-$C_{21}H_{44}$ in phase I and phase II is shown in Fig. 8. Transition to phase II results in greatly reduced splitting of the progression bands and decreased integrated intensities.

The spectrum of phase II contains additional bands characteristic of nonplanar conformers, which are not present in the spectrum of phase I. They appear at 875 and 958 cm^{-1} (CH_3 rock, C—C stretch); 1078 cm^{-1} (CH_2 wag, C—C stretch); 1162 cm^{-1} (CH_2 rock, CH_3 rock), and at 755, 783, and 832 cm^{-1} (CH_2 rock). The subject of nonplanar conformers in phase II n-alkanes is discussed in ref. 6.

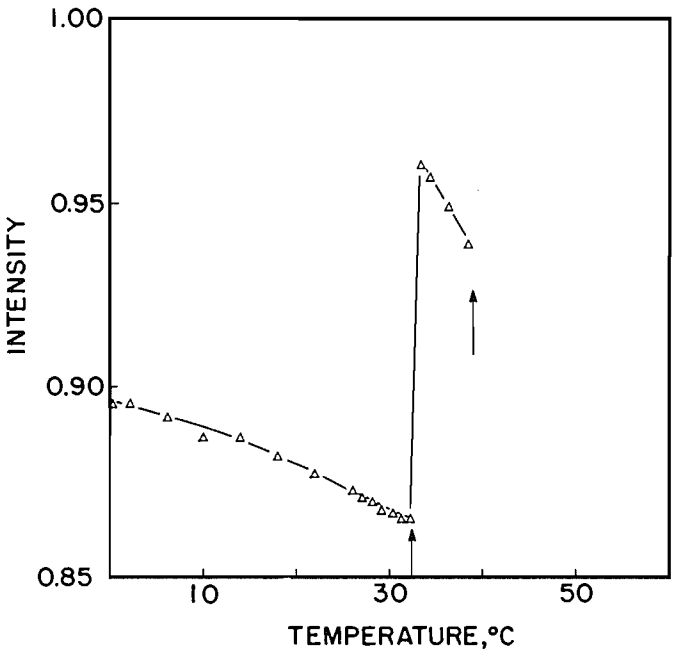

FIG. 5. Temperature dependence of the intensity of the 1470 cm^{-1} region of the spectrum of n-$C_{21}H_{44}$. The intensity was measured using a baseline from 1520 to 1420 cm^{-1} (see note on Fig. 2 caption).

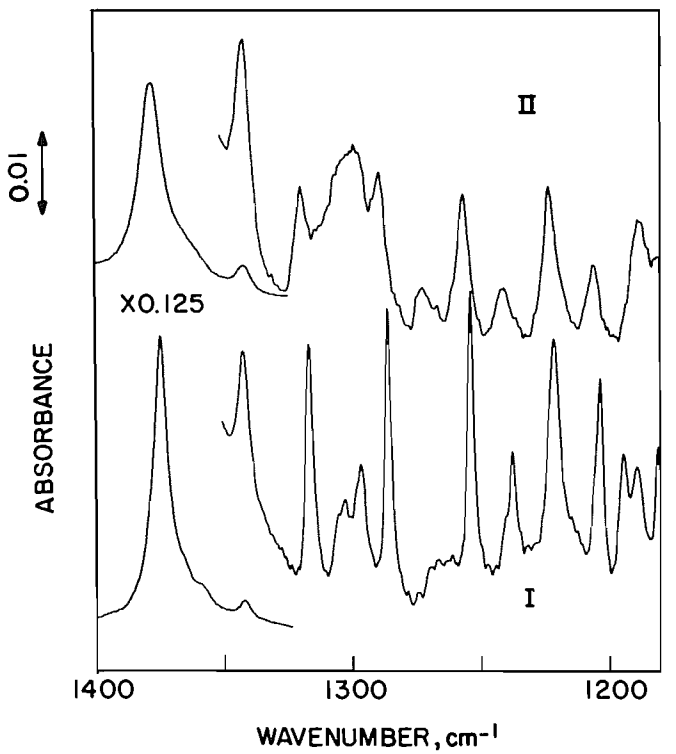

FIG. 6. Methylene wagging band progression, 1400–1180 cm^{-1} region of the spectrum of n-$C_{21}H_{44}$ in phase I (1°C) and phase II (36°).

Plots of temperature versus the integrated intensity of the P_{11} component of the CH_2 rocking progression, and of the methyl symmetric in-plane rocking band of n-$C_{21}H_{44}$ are shown in Fig. 9. As for the CH_2 stretching, scissoring, and wagging modes, the intensity of the methyl rocking mode (Fig. 9*B*) is not constant in phase I, but decreases with increasing temperature. In contrast, the intensity of the CH_2 rocking band (Fig. 9*A*) is

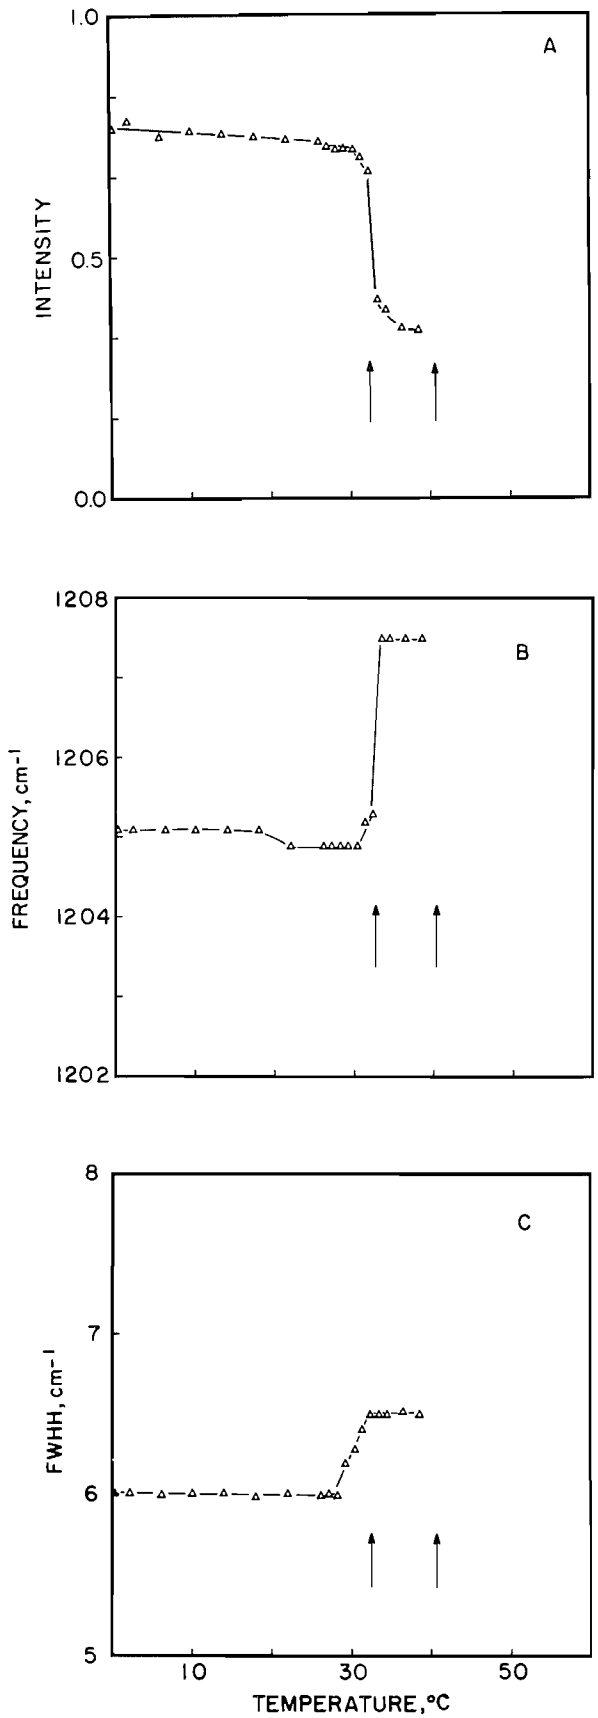

FIG. 7. Temperature dependence of the W_2 component of the CH_2 wagging band progression of n-$C_{21}H_{44}$: *A*, intensity (see note on Fig. 2 caption); *B*, frequency; *C*, FWHH (baseline from 1216 to 1200 cm^{-1}).

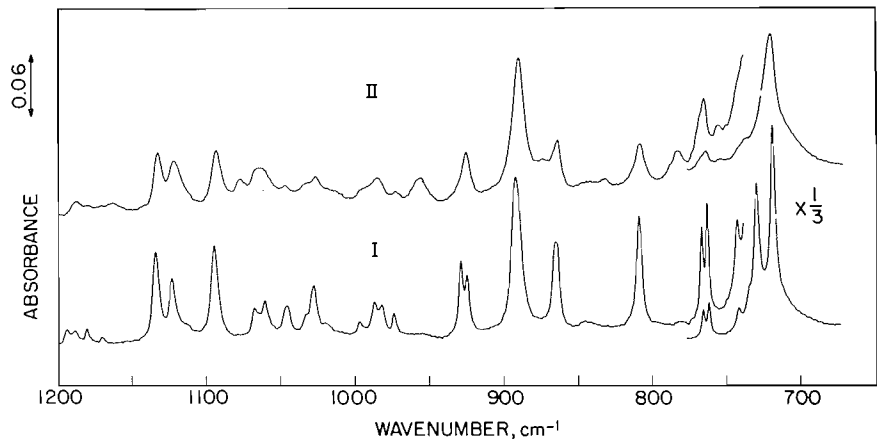

FIG. 8. Methylene rocking band progression, 1200–700 cm^{-1} region of the spectrum of n-$C_{21}H_{44}$ in phase I (1°C) and phase II (36°).

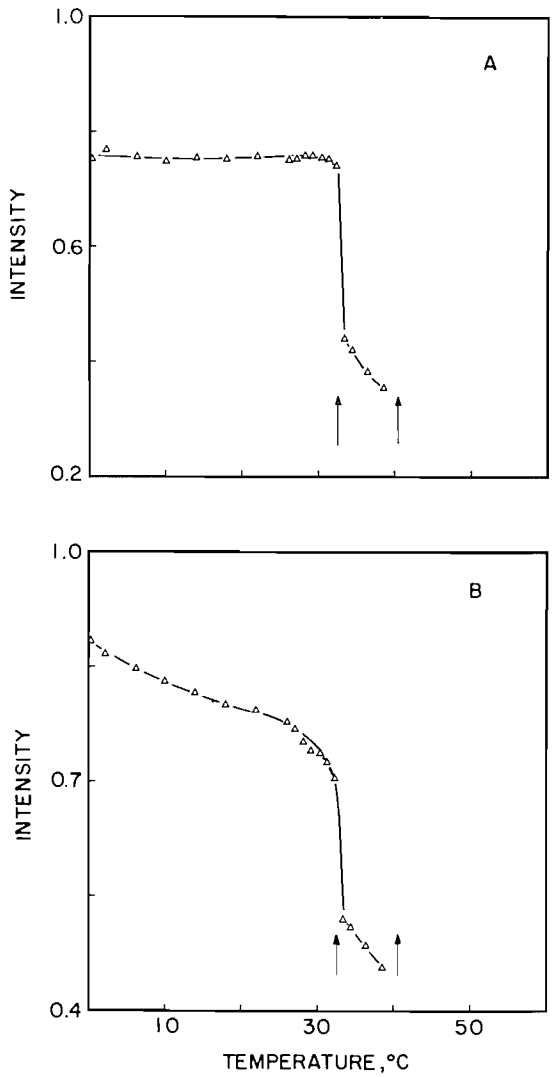

FIG. 9. Temperature dependencies of the intensities of A, the P_{11} component of the methylene rocking progression (baseline from 820 to 800 cm^{-1}) and B, the methyl symmetric in-plane rocking band of n-$C_{21}H_{44}$ (baseline from 906 to 880 cm^{-1}) (see note on Fig. 2 caption).

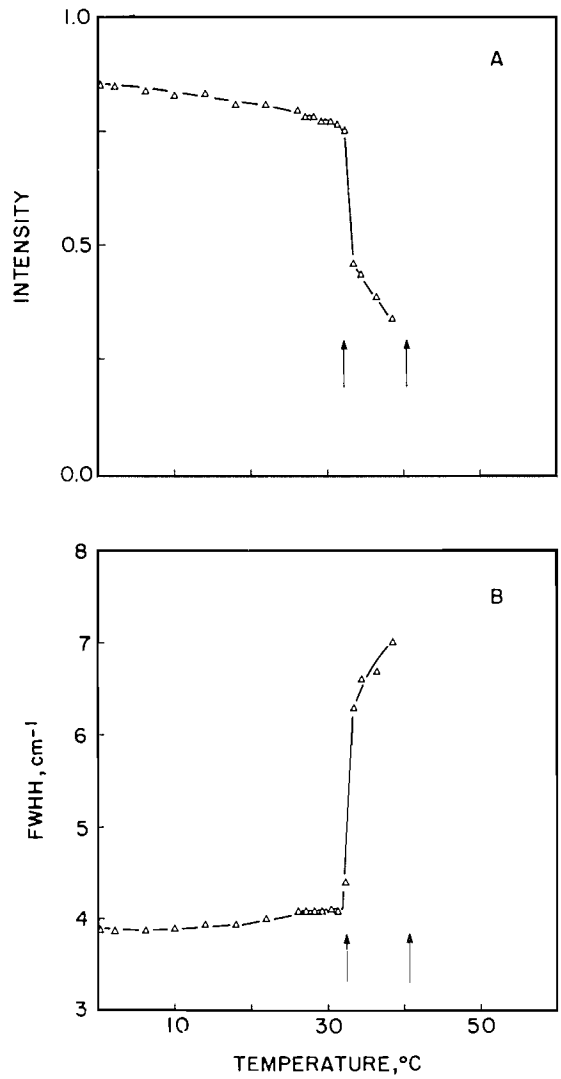

FIG. 10. Temperature dependence of the R_3 component of the C—C stretching band progression of n-$C_{21}H_{44}$: A, intensity (see note on Fig. 2 caption); B, FWHH (baseline from 1108 to 1085 cm^{-1}).

constant in phase I. The transition to phase II is marked by a large, abrupt decrease in intensity with a further decrease within phase II. In Fig. 9B we also note that, as with other methyl bands (Figs. 3 and 7), the gradient of the plot changes at about 25°C, well below the phase transition temperature.

The CH_2 twisting band progression (1300–1170 cm^{-1}) is very weak and overlapped by the methylene wagging band

TABLE 2. Changes in integrated intensity and density of n-$C_{21}H_{44}$ at T_α, and in phases I and II, with increasing temperature

	% Change at T_α	Rate of change, % °C^{-1}	
		Phase I	Phase II
Band[a]			
d and d'	−12	−0.3	−1.2
W_2	−40	−0.3	−3.0
P_{11}	−30	−0.2	−4.0
β	−24	−0.5	−2.0
Density[b]	−4.5	−0.1	−0.3

[a]The abbreviations are the same as those in Table 1.
[b]Calculated from changes in the unit cell volume (17).

progression (Fig. 6). In general, the transition results in a decrease in intensity, and little change in frequency (Table 1).

C—C stretching

The C—C stretching band progression is observed in the 1150–950 cm^{-1} region, shown in Fig. 8.

The temperature dependencies of the intensity and width of the R_3 component of the progression of n-$C_{21}H_{44}$ are shown in Fig. 10. The data are similar in form to those observed for the CH_2 wagging bands, except that at T_α the frequency decreases rather than increases (Table 1). The possibility that the temperature dependence of the band is affected by coupling with the methyl symmetric in-plane rocking mode (11) was eliminated by the observation of similar behaviour by the R_3 band in the spectrum of n-$C_{17}H_{30}D_6$.

Discussion

These data demonstrate that the transition from phase I to phase II results in changes in all bands in the infrared spectrum. Compared to the spectral changes resulting from melting of the alkanes, these are relatively minor. The only generalized major trend is a reduction in integrated intensity on transition to phase II. In this regard the overall increase in intensity in the 1520–1420 cm^{-1} region reflects the increased intensity near 1450 cm^{-1}; examination of difference spectra shows that the bands near 1470 cm^{-1} decrease in integrated intensity.

In general, the overall changes result from the reduction in intermolecular interactions on transition, and the increased mobility and slight conformational disorder in this phase. As indicated in the Introduction, the detailed structure of phase II is dependent on both chain length and temperature, and requires further elucidation. However, there are several trends evident in these data which point to potential areas of study.

Firstly, the rates of change of density and of the integrated intensities of several bands in phases I and II, and during the transition, are summarized in Table 2. In general, the integrated intensity changes much more rapidly than the density. There is no readily available explanation for this behaviour, particularly in phase I where there is no perturbation by *gauche* rotamers, and the chain mobility is minimal.

Secondly, at least three of the plots (Figs. 3, 7*C*, and 9*B*) show the onset of change several degrees below the transition temperature.

Thirdly, some bandwidth plots do not show an abrupt discontinuity; rather, the width increases over a range of a few degrees. The extreme case of this is observed in the plots (Figs. 2*C* and 2*C'*) derived from the CH_2 stretching bands, where the transition is only marked by a change in gradient.

Finally, there are major reductions in the intensities, and shifts in the frequencies of the components of the CH_2 wagging progression as a result of transition to phase II. It has been suggested that the intensities of these bands provide a suitable monitor of the number of *gauche* bonds in a primarily *trans* chain (18). However, in these systems the introduction of an average population of one *gauche* bond per chain (6) is simultaneous with a 40% reduction in the integrated intensities of the CH_2 wagging bands (Fig. 7 and Table 2). Consequently, a simple, direct correlation between wagging intensity and population of *gauche* bonds cannot be made.

The spectrum of F_2CSe has been surveyed over the 700–200 nm wavelength region and three distinct absorptions identified. These are the spin-allowed $\tilde{A}^1A_2 \leftarrow \tilde{X}^1A_1$ and spin-forbidden $\tilde{a}^3A_2 \leftarrow \tilde{X}^1A_1$ overlapping $n \rightarrow \pi^*$ transitions, λ_{max} = 434 nm, and the orbitally-allowed $\tilde{B}^1A_1 \leftarrow \tilde{X}^1A_1$ $\pi \rightarrow \pi^*$ transition, λ_{max} = 236 nm. Vibrational assignments for the band systems have been made and the out-of-plane energy levels analyzed in terms of a quadratric-Lorentzian double minimum potential. The barriers to inversion for the $\tilde{A}^1A_2/\tilde{a}^3A_2$ states were found to be 2483/2923 cm^{-1} and the out-of-plane angles 30.1/31.4 deg. The singlet–triplet separation was $E(\tilde{A}^1A_2) - E(\tilde{a}^3A_2)$ = 671 cm^{-1}. The $\tilde{B}^1A_1$ system displays continuous structure and was not subject to a vibrational analysis.

On a étudié le spectre du F_2CSe dans l'intervalle de longueur d'onde allant de 700 à 200 nm et on identifié trois absorptions distinctes. Ce sont: les absorption de spin permis le spin $\tilde{A}^1A_2 \leftarrow \tilde{X}^1A_1$, et de spin interdit $\tilde{a}^3A_2 \leftarrow \tilde{X}^1A_1$, les transitions de recouvrement $n \rightarrow \pi^*$, λ_{max} = 434 nm, et la transition permise orbitalement $\tilde{B}^1A_1 \leftarrow \tilde{X}^1A_1$ $\pi \rightarrow \pi^*$, λ_{max} = 236 nm. On a identifié les vibrations et on a analysé les niveaux d'énergie hors du plan en fonction du potentiel minimum double du type quadratique-Lorentzien. On a trouvé que les barrières à l'inversion des états $\tilde{A}^1A_2/\tilde{a}^3A_2$ sont de 2483/2923 cm^{-1} et les angles hors du plan sont de 30.1/31.4 degrés. La séparation singulet triplet est: $E(\tilde{A}^1A_2) - E(\tilde{a}^3A_2)$ = 671 cm^{-1}. Le système $\tilde{B}^1A_1$ montre une structure continue et n'est pas sujette à une analyse vibrationnelle.

Introduction

The electronic structures of molecules containing the carbonyl or thiocarbonyl chromophores have been the subject of extensive research (*1*, 2). While techniques such as inelastic electron scattering and photoelectron spectroscopy have been employed for this purpose, much of the information about the electronic states has come from optical absorption and emission spectroscopy.

The visible and ultraviolet spectra of thiocarbonyl molecules are characterized by two absorptions. In the region 700–400 nm, the thiocarbonyl halides display a weak absorption, $f \simeq 10^{-4}$, which is attributed to the promotion of an electron from the nonbonding sulphur n orbital to an antibonding π^* orbital localized in the C=S bond. A second much stronger absorption, $f \simeq 10^{-1}$, is found in these molecules at 280–240 nm. The strength of this absorption and its position in the spectrum has led to its assignment, $\pi \rightarrow \pi^*$.

The addition of an electron to the π^* orbital increases the electron density at the carbon atom with the result that the $n\pi^*$ and $\pi\pi^*$ states are usually nonplanar. The potential function which describes the out-of-plane distortion in these states contains a set of minima at the equilibrium position which are separated by a potential barrier at the planar configuration. It is the heights of these barriers to molecular inversion which has been the subject of some interest. The creation of a partially filled π^* orbital results in a destabilization of the double bond, with the nominal bond order of 2 for the $\tilde{X}$ ground state falling to 1.5 for the $\tilde{A}$ and $\tilde{a}$ $n\pi^*$ states and to 1.0 for the $\pi\pi^*$ state. The changes in vibrational frequency on electronic excitation are a reflection of the differences in structure in the combining states. The correlation of the frequencies among the carbonyl and thiocarbonyl molecules can be used to elucidate their structural and dynamical differences.

The purpose of the present work was to extend the literature which exists on the spectroscopy of the carbonyl and thiocarbonyl compounds to the selenocarbonyl series of molecules. Selenocarbonyl difluoride, F_2CSe, is the only known tetratomic in this class of molecules (3). The ground state structure (4) and vibrational frequencies (5) have been investigated but no information is available on the electronic spectroscopy. It was hoped that a study of the visible and uv spectra could lead to information about the structure and bonding in the lower electronic excited states of the C=Se group.

Experimental

Selenocarbonyl difluoride was prepared by the pyrolysis of $(F_2CSe)_2$ dimer in a spiral tube at 200°C. The polymeric material $(F_2CSe)_x$ was warmed to 150°C to form the dimer. The preparation of this material has been described by Haas (3). The monomer and the cyclic dimer were separated by trap-to-trap distillation immediately before the spectra were recorded.

Survey spectra of F_2CSe were recorded over the 700–200 nm region with a Cary 14 spectrophotometer. The structured bands of the transition centered at 434 nm were clearly observed with a 10 cm cell at a pressure of 22 Torr, while only 1 Torr was needed to record the spectrum at 236 nm.

Medium resolution spectra of the lower region were photographed with a 6 meter Ebert spectrograph (6) at a reciprocal linear dispersion of 1.30 nm/cm. The path length of the cell was 90 cm, and at room temperature 70 and 12 Torr pressures were used which are equivalent to 8.3×10^{-2} and 1.4×10^{-2} m-atm path length × pressure respectively. Spectra were also recorded at −78°C at 6.0×10^{-3} m-atm. A 450 W Xe arc was used as a continuous source of radiation, and lines from a Fe–Ne hollow cathode lamp for calibration. Profiles of the absorption bands were obtained from the negatives with a single beam microdensitometer. The frequencies (in cm^{-1}) of the bands

which were assigned in this study are shown in Table 1. This listing represents about 80% of the bands observed in the 527–540 nm region.

Results and assignments

Electronic assignment

Figures 1 and 2 show the survey spectra of F_2CSe which were recorded with the Cary-14 spectrophotometer. These absorption bands appear in the uv–visible region and can be classified by their intensity, frequency, and structure. The first absorption occurs in the visible region, and it consists of an extensive series of vibronic bands which extend from 500 to 350 nm. The maximum oscillator strength for this system is $f = 3.5 \times 10^{-4}$. At higher energies a second system is observed which is completely free from vibrational structure. This strong system, $f = 2.5 \times 10^{-2}$, is centered at 240 nm. The oscillator strengths were calculated from the observed gas pressures in the cell. It was assumed that the sample was pure, and that the cyclic dimer did not introduce a measurable partial pressure. A third system was observed as the onset of an absorption at 200 nm.

The low energy absorption has the characteristics of a transition which is not allowed by electric dipole selection rules. The ground state with filled electronic shells has A_1 symmetry, and an electronically forbidden transition would terminate only on an A_2 upper state. The first observed system is assigned to the spin forbidden and spin allowed transitions $\tilde{a}^3A_2 \leftarrow \tilde{X}^1A_1$ and $\tilde{A}^1A_2 \leftarrow \tilde{X}^1A_1$ respectively. The singlet and triplet states arise from the promotion of an electron from the nonbonding n orbital on the selenium to the antibonding π^* orbital. The assignment of the second system comes from an analogy to the thiocarbonyl halide molecules. This group of molecules displays an intense absorption system in the 270 nm region. The assignment of these bands to the z polarized $\pi \rightarrow \pi^*$ $\tilde{B}^1A_1 \leftarrow \tilde{X}^1A_1$ transition is now well established (2). This is the assignment which is given to the $\lambda_{max} = 240$ nm band shown in Fig. 2. Our assignment of the third system is more tentative. While MO calculations are not available for this molecule, simple considerations would place the $n \rightarrow 3s$ Rydberg promotion as the third transition in the spectrum.

Vibrational analysis of the $\tilde{a}^3A_2 \leftarrow \tilde{X}^1A_1$ *electronic transition*

The starting point for the vibrational analysis of the first absorption spectrum was the recognition of two major factors. The first of these relates to the higher atomic number of selenium $z = 34$ compared to sulphur $z = 16$. The greater electron density at the Se atom relaxes the $\Delta S = 0$ selection rule with the result that the singlet–triplet transition is expected to contribute to the intensity of the low energy end of the spectrum. The other major assumption which was used in the initial assignment is that the molecule is nonplanar in the excited singlet and triplet states and the spectrum displays the characteristics of inversion doubling. Moreover, the combination of a planar ground state and a nonplanar excited state should give rise to strong activity to the Q_4 mode leading to progressions in ν_4' and ν_4''. Transitions from quanta of ν_4'' would appear weakly in the spectrum as hot bands. A comparison of the spectrum observed at room temperatures and that recorded at dry ice temperature revealed the hot band intervals which are collected together in Table 2. From the selection rules for the singlet–triplet transition, the hot band interval is given as 0_0^0–$4_1^1 = \nu_4'' - \Delta$. The difference between the observed intervals and ν_4'' is a measure of the inversion doubling splitting Δ. For example, 4_0^6–$4_1^7 =$ 565 cm^{-1}, and as $\nu_4'' = 575$ cm^{-1} then $\Delta = 10$ cm^{-1}. This is a relatively small value of the inversion doubling splitting and indicates a substantial barrier in the $\tilde{a}$ state.

The assignment of the out-of-plane mode for the upper electronic state, ν_4', began at the low energy end of the absorption. It is here that the spectrum is expected to consist of bands from the $\tilde{a}^3A_2 \leftarrow \tilde{X}^1A_1$ transition. In this region, the band pattern was complex and many combinations of intervals were possible candidates for a vibrational assignment. However, it was observed that the bands appeared to consist of two distinct types, a set of sharp double-headed features and a set of more diffuse single-headed bands. A successful set of frequency differences was obtained by combining the wavenumbers of pairs of bands with similar rotational contours. An interval of 540 ± 5 cm^{-1} was found which was common to 21 frequency differences. These intervals could be grouped into smooth progressions of up to five members. The strength of these progressions and their lengths in the spectrum allow us to make an assignment to ν_4'. The drop in the frequency from 575 to 540 cm^{-1} is to be anticipated for a system which undergoes a loss of molecular planarity on electronic excitation. Frequency differences between various vibrational levels of the upper state are given in Table 3. A clear progression of five members in an interval of 543 cm^{-1} was found to lock onto a pair of features at 19018 and 18990 cm^{-1}. This was the first band that was observed in the long path length experiments and was assigned to the 0_0^0 origin band. Other bands of the $\tilde{a}^3A_2 \leftarrow \tilde{X}^1A_1$ system appeared as

doublets in the spectrum with a peak separation of about 30 cm^{-1}. This behaviour is similar to what has been observed in the corresponding transition in F_2CS (7).

In the $n \rightarrow \pi^*$ electronic transition, the promoted electron is placed into the π^* antibonding orbital. The result is a destabilization of the structure in which the selenocarbonyl group is reduced from a bond order of 2 to 1.5. It would be anticipated that ν_1 would decrease in value from its ground state of 1287 cm^{-1} and display well characterized intervals of about 1000 cm^{-1}. One such interval was located in the spectrum with a frequency of 1156 cm^{-1} in combination with other excited state levels.

Higher members were not observed because the weaker singlet–triplet bands merge into the stronger bands of the singlet–singlet transition. The modes ν_5 and ν_6 of b_2 vibrational species would not be expected to be present in the spectrum, and are not observed.

Vibrational analysis of the $\tilde{A}^1A_2 \leftarrow \tilde{X}^1A_1$ *electronic transition*

The $\tilde{A}$ and $\tilde{a}$ states have a common electronic configuration and differ only in the spins of the n and π^* electrons. The orbitals occupied by these electrons occupy different regions of space and consequently their interaction is small. The result is that the exchange energy required to elevate the molecule from the $\tilde{a}$ system to the $\tilde{A}$ system is small, less than 1000 cm^{-1}. The molecular structure and the force constants in the two states should be similar. As a consequence, it was possible to use the vibrational intervals and the intensity patterns of the $\tilde{a} \leftarrow \tilde{X}$ system as a template for the assignment of the $\tilde{A} \leftarrow \tilde{X}$ system. A major difference is that the hot band intervals are larger than the ground state frequency, ν_4'', by the inversion doubling splitting, $4_0^1-4_1^0 = \nu_4'' + \Delta$. Hot band intervals are tabulated in Table 2. The progressions in ν_4' extending back to the vibronic suborigins are given in Table 3. The spectrum could be followed out to 2500 cm^{-1} of vibrational excitation. At that point the bands become too diffuse for further analysis. The observed frequencies for the $\tilde{A}$ state are close to those of the $\tilde{a}$ state. For example, in the $\tilde{a}/\tilde{A}$ states, ν_1 = (1156/1129), ν_2 = (671/662), ν_3 = (397/388), and ν_4 = (543/539).

Potential energy functions for the inversion mode

The vibrational levels of the ν_4' in the $\tilde{a}^3A_2$ and $\tilde{A}^1A_2$ states are presented in Table 4. The potential for the out-of-plane problem can be treated as a one-dimensional function which implies that the interactions of this mode with the remaining vibrational modes can be neglected. In this study, three different functions were used in the fit of the calculated set of levels to the observed levels. The initial calculation employed a model function which was constructed from an harmonic oscillator term perturbed by a Gaussian barrier. This potential has been used to describe the inversion modes of a number of pyramidal molecules (1). In this case, the model function was unsuitable in that it yielded a set of energy levels which were highly anharmonic for all values of the adjustable parameters. In a second calculation, a quartic oscillator term was added to the potential to reduce the vibrational energies at higher values of the vibrational quantum number. This procedure was found to be ineffective even for very large contributions from the quartic oscillator term. In the third trial function, a satisfactory fit to the observed levels was obtained. The potential function in this case consisted of the harmonic oscillator perturbed by a Lorentzian barrier

$$V(z) = AZ^2 + B/(C + Z^2)$$

where Z is the reduced coordinate defined by Chan and Stelman (8). The best fit to the $\tilde{A}^1A_2/\tilde{a}^3A_2$ data came from the parameters $A = 81.4/81.7$, $B = 24500/29000$, $C = 5.0/5.2$. Observed and calculated energy manifolds of ν_4' are shown in Table 4. The systematic increase in the residuals (obsd − calcd) with the vibrational quantum number of the earlier calculations has been eliminated. The barriers in the double well functions of the $\tilde{A}^1A_1$ and $\tilde{a}^3A_2$ states were 2483 and 2923 cm^{-1} respectively, while the corresponding values for Z_m, the minima in the functions, were 3.514 and 3.692. The relationship between the mass adjusted coordinate, z, and the normal coordinate is $Q = (h/4\pi\nu_0)^{1/2}z$ which leads to values of Q_m at the potential minima of 1.304×10^{-20} and 1.0806×10^{-20} $g^{1/2}$ cm, respectively. The out-of-plane coordinate Q_4 is related to the angle displacement θ through the reduced mass relationship:

$$Q_4(\theta) = \int_0^{\theta}[\mu(\theta)]^{1/2}\, r\,d\theta$$

where the reduced mass is that of Jones and Coon (9). In this model calculation, it is assumed that Q_4 is derived from the internal coordinate, θ, which is defined, and the angle between

the CSe bond and the line meeting the FCF angle. The geometric parameters used in the reduced mass were those of the ground state structure (4). For the states $\tilde{A}^1A_2/\tilde{a}^3A_2$, θ_m = 30.1/31.4 deg.

Discussion

Table 5 presents values for the barrier heights of the tetra-atomic carbonyl and thiocarbonyl compounds along with those of selenocarbonyl difluoride. There are large variations in the barriers for this group of molecules and it is apparent that the heights are sensitive to the nature of the attached group. It is possible to extend Walsh's rules (10) to these groups of molecules. The principle on which his correlation is based is that the MO energy of the system decreases (more stable) when electron density flows from a p type AO to an s type AO. The variation in the heights of the barriers should parallel the $2p_\pi$ and $2s$ density changes at the carbon atom. The substitution of the electronegative halogen group for hydrogen stabilizes the σ MO and leaves the π MO relatively unaffected. This perfluoro effect has been observed in the photoelectron spectrum of H_2CO and F_2CO (17). The σ MO's in these compounds belong to the a_1 and b_2 representations while the π and π^* MO's are of b_1 species. When the molecule is distorted from the planar C_{2v} symmetry to the nonplanar form, the a_1 and b_1 representations correlate with a' and a_2 and b_2 with a'' of the C_s point group. In a nonplanar system, the $\sigma-\pi$ distinction is no longer valid and the electron density is pulled from the O, S, and Se atoms to the C atom by the electronegative substituent. The result is that there is a net charge flow from the $2p_\pi$ to the $2s$ carbon AO and from the viewpoint of the Walsh postulate a change in electron density in this direction would result in a nonplanar distortion at the carbon centre. The electronegativity of the H/Cl/F groups in $H_2CO/Cl_2CO/F_2CO$ parallel the barrier heights 316/3170/8200. The barrier height decrease from S/Se of 3076/2483 is not unexpected. This is a consequence of the larger and more diffuse orbitals of Se relative to S which are capable of accommodating π^* density which would normally flow to the C centre.

The excited state vibrational frequencies

The F_2CSe frequencies in the $\tilde{X}$, $\tilde{A}$, and $\tilde{a}$ states are given in Table 6 along with the frequencies of F_2CS and F_2CO. The behaviour of the ν_1(C=X) stretching mode can be explained in terms of the ratios of the frequency drop on excitation $\tilde{A}/\tilde{X}$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

They are: F_2CO 1030/1929.9, F_2CS 1100.6/1365.2, F_2CSe 1129/1287. That is, the reduction in frequency is greater for carbonyl compounds followed by the thio and selenocarbonyl compounds. If ν_1 is assumed to be a valence vibration in the $\tilde{X}$ and $\tilde{A}$ states, it is possible to predict the change in bond length on excitation through the use of the empirical rule $\omega r^3 =$ constant (18). For the C=O/C=S/C=Se groups, the bond length extensions are 0.272/0.118/0.077 Å. The C=X bond lengths can be considered in terms of a two-step process, removal of an electron from the n orbital and the addition of the electron to the π^* orbital. Information about the first process comes from the photoelectron spectrum. In the PES of F_2CO (17), the ionization of the n electron leads to a reduction in ν_1(C=O), $\tilde{A}/\tilde{X}$ of 1550/1929.9 cm^{-1} whereas in F_2CS (19), the ν_1(C=S) frequency changes very little (1370/1365.2). The conclusion follows that the n orbital in F_2CS is nonbonding while in F_2CO it is bonding. The shift in ν_1(C=X) frequency on $n \rightarrow \pi^*$ electronic excitation reflects the antibonding nature of the π^* orbital in F_2CS and both the bonding nature of the n orbital and antibonding character of the π^* orbital in F_2CO.

Singlet–triplet interval

The correlation of the singlet–triplet intervals among the carbonyl, thiocarbonyl, and selenocarbonyl molecules is of interest (Fig. 3). In the series $H_2CO/H_2CS/Cl_2CS/F_2CS/F_2CSe$ (1, 20, 15, 7), the singlet–triplet intervals are respectively 3000/ 1887/1224/1286/671 cm^{-1}. The intervals can be approximated as twice the exchange integral, and depend on the repulsions between the unpaired n and π^* electrons. The larger and diffuse orbitals of Se relative to S and O provide additional space for the unpaired electrons which lowers the repulsion and decreases the singlet–triplet gap.

Received December 28, 1982

WALTER J. CHAZIN, LAWRENCE D. COLEBROOK, and JOHN T. EDWARD. Can. J. Chem. **61**, 1749 (1983).

The ^{1}H relaxation pathway analysis of strychnine and some strychnine sulfonic acids has been carried out by spin-lattice relaxation and nuclear Overhauser effect difference measurements. Some previously reported ^{1}H chemical shifts and coupling constants for strychnine are shown to be in error. New assignments for positions 15, 17, 18, and 20 have been made. Proposed sites of substitution of the sulfonic acids have been verified, and the previously undetermined stereochemistry of one of the acids has been established.

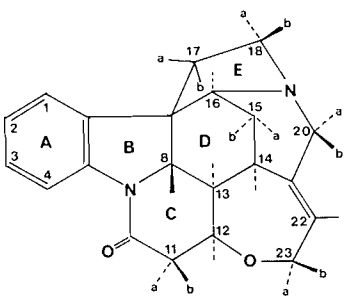
WALTER J. CHAZIN, LAWRENCE D. COLEBROOK et JOHN T. EDWARD. Can. J. Chem. **61**, 1749 (1983).

Faisant appel aux mesures de relaxation spin-réseau et de différence d'effet Overhauser nucléaire, on a mesuré le processus de relaxation du ^{1}H de la strychnine et de quelques acides sulfoniques dérivés de la strychnine. On montre que quelques-uns des déplacements chimiques et des constantes de couplage du ^{1}H de la strychnine rapportés antérieurement sont erronés. On a fait de nouvelles attributions pour les positions 15, 17, 18 et 20. On a vérifié les sites de substitution proposés pour les acides sulfoniques et on a établi la stéréochimie de l'un des acides que l'on n'avait pas encore établie.

[Traduit par le journal]

Introduction

In 1908–1909, Leuchs and Schneider (1) obtained three mono sulfonic acids (designated SSA-I, -II, and -III) on work-up of the solution obtained by bubbling sulfur dioxide through a warm aqueous solution of strychnine (I)[2] containing suspended manganese dioxide. Although Leuchs and his collaborators continued to study these sulfonic acids for more than 30 years (2), little became known of their structures, other than that SSA-I was not sulfonated on the aromatic ring or at the 11-position, until further studies were undertaken by one of us (J.T.E.) (3).



On repeating Leuchs' procedures, the same three strychnine sulfonic acids were isolated. X-ray crystallographic analysis of a sample of SSA-I obtained at this time showed it to have the sulfonic acid group located at the allylic 14-position (4).

On the basis of pH measurements, ^{13}C nmr spectra, and chemical arguments, the locations of the sulfonic acid groups in SSA-II and SSA-III were assigned as the vinylic 22-position and the allylic 20-position, respectively (3). The stereochemistry of substitution at position 20 in SSA-III was not established.

We have recently undertaken an evaluation of the potential of ^{1}H spin-lattice relaxation rate (R_1) measurements for the determination of the structure and stereochemistry of organic molecules (5, 6), and decided that this technique would be useful in the analysis of the structure of the strychnine sulfonic acids. Such measurements are used to analyze dipolar relaxation pathways, which are directly related to the three-dimensional structure of the molecule. When necessary, specific relaxation pathways can be identified by nuclear Overhauser effect (nOe) enhancements (7).

Initially, chemical shift assignments were made by comparison with published data on strychnine (8). However, as the analysis of the ^{1}H R_1 data was being refined, some anomalies in the published assignments became apparent.[3] As a result, it was decided that a re-evaluation of the ^{1}H nmr spectrum of strychnine was necessary, before completing the structure determinations of the strychnine sulfonic acids. These studies are reported in a separate section, below.

Relaxation pathway analysis

In dilute solution (typically 0.1 M, or less) in a nonviscous, deuterated solvent, the spin-lattice relaxation of protons in organic molecules of mol. wt. < 1000 is dominated by dipole–dipole interactions with the other protons in the molecule. The rate equation for dipolar relaxation of a proton j is given by:

$$[1] \quad R_{1_j} = K[\sum_i (1/r_{ij})^6 \tau_{c_{ij}}] \qquad i \neq j$$

where K is the product of a number of constants, the r_{ij}'s are

[1]Author to whom correspondence may be addressed.

[2]The conventional structure used here for strychnine represents the entantiomer of the natural material.

[3]Tavernier *et al.* (9) reported that the geminal coupling constant for the C-17 protons had been incorrectly assigned in the literature (8).

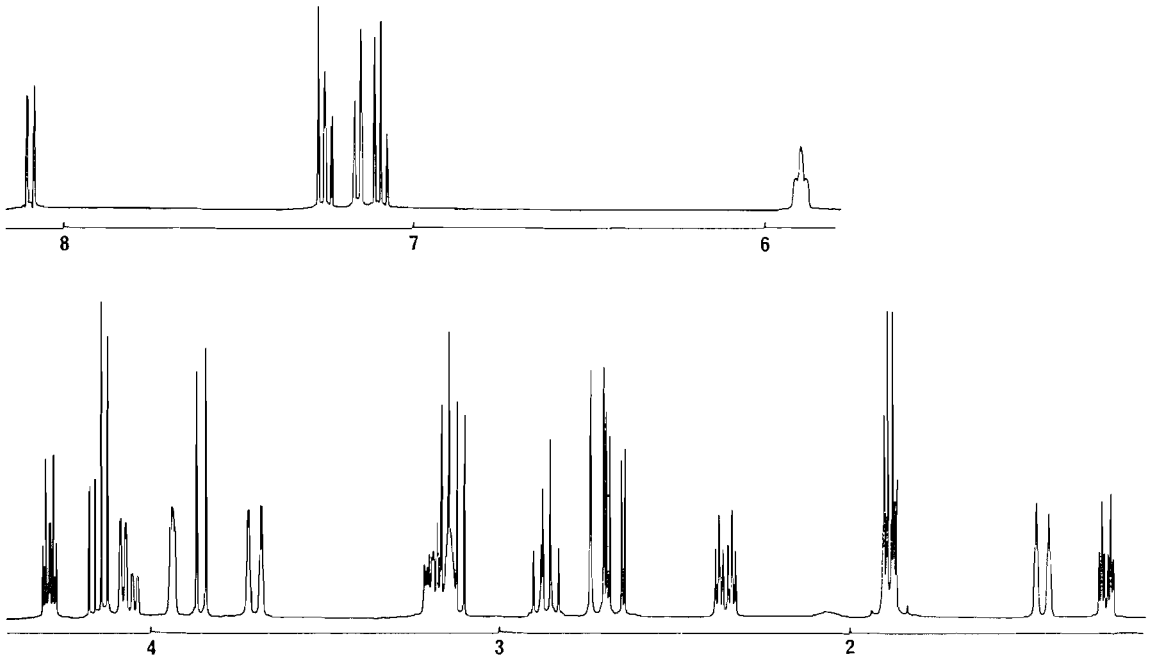

FIG. 1. Resolution enhanced 400 MHz ^{1}H spectrum of strychnine, 0.1 *M* in $CDCl_3$. Upper trace, low field region; lower trace, high field region.

the internuclear distances between the proton j under consideration and the other protons in the molecule, and the $\tau_{c_{ij}}$'s are the rotational correlation times for the r_{ij} internuclear vectors. Each term in this expression constitutes a specific dipolar relaxation pathway.

For rigid, isotropically tumbling molecules all of the relaxation vectors will have the same τ_c, so that the ratio of R_1 values for any protons in the molecule depends only on inter-proton distances:

$$[2]\quad \frac{R_{1_j}}{R_{1_k}} = \frac{\sum_i (1/r_{ij})^6}{\sum_i (1/r_{ik})^6} \qquad \begin{matrix} i \neq j \\ i \neq k \end{matrix}$$

The inverse sixth power dependence on internuclear distance implies that relaxation contributions are significant only for the nearest neighbors of a particular proton. In consequence, R_1 values and nOe enhancement factors are extremely sensitive to *local* structure and stereochemistry. Due to the unique location of each proton in the molecule, there is a unique set of relaxation pathways which characterize each proton. In many instances the various relaxation pathways to and from a particular proton can be found, through the use of nOe and R_1 experiments, thereby establishing its identity.

Relaxation pathways may be evaluated semi-quantitatively for these molecules, assuming that the molecules tumble isotropically, and by measuring internuclear distances on Dreiding molecular models. Relative R_1 values can be calculated directly from [2], while relative nOe enhancements can be predicted from an evaluation of each $(1/r_{ij})^6$ term.

These calculations serve as an invaluable aid in the interpretation of the experimental data, but their limitations in terms of quantitative comparative analysis are obvious. Interpretation of the experimental data is not based upon a single measurement but on trends seen in several measurements. The use of several observations to obtain information on a single site compensates for inaccuracies associated with calculations based on a model and for experimental errors.

Results and discussion

A re-evaluation of the ^{1}H nmr assignments of strychnine

The previous assignments of the ^{1}H nmr spectrum of strychnine (8) were made at 250 MHz using a combination of aromatic-solvent-induced chemical shift changes, selective deuteration, double resonance techniques, and computer simulation of spectra. Interpretation of the ^{1}H spectrum of strychnine (Fig. 1) in the present study was based on relaxation pathway analysis and was facilitated by the greater chemical shift dispersion at 400 MHz. In agreement with the preliminary analysis of the ^{1}H R_1 values of the strychnine sulfonic acids, a comparison of the experimental and calculated ^{1}H R_1 values of strychnine suggested that the stereochemical assignments of the geminal proton pairs at positions 15, 18, and 20 should be reversed.

Relaxation pathway analysis was carried out in order to establish characteristic relaxation pathways for each proton of interest. Although both ^{1}H R_1 and nOe difference (nOed) (10, 11) experiments were used, the nOe data proved more definitive. The following discussion, therefore, centres on the nOe experiments. The measured enhancements were analyzed with the aid of calculated enhancements although, in fact, most of the nOe factors could be interpreted by simple inspection of molecular models. At least one key enhancement could be identified for all protons irradiated except H-12 (Table 1). A key enhancement is defined as (1) an nOe enhancement which serves to identify either the transitions irradiated or the transitions enhanced, or (2) an nOe enhancement which identifies a unique relaxation pathway having implications concerning the overall molecular structure. The final assignments were checked by computer simulation of portions of the spectrum.

The signals due to the isolated C-20 methylene group, adjacent to nitrogen, were originally assigned (8) as the simple AB pattern (with some long range coupling) at 3.70 and 2.72 ppm. The C-15 proton signals (1.46 and 2.36 ppm) were assigned by comparison with the spectrum of 11a,11b,16-d_3-strychnine (8). These assignments have recently been confirmed by 2D hetero-

23b	22	23a	

[a]Spectra were determined at 400 MHz at ambient temperature (about 20°C) on non-degassed 0.1 *M* solutions in $CDCl_3$ and DMSO-d_6. Except for cases where overlap of signals in one solvent (e.g. H-17a and H-17b in $CDCl_3$) prevented individual measurements, nOe enhancements were observed for both solvents.

[b]Negative enhancements arise from the three-spin effect (17), and depend on the choice of experimental conditions.

[c]$CDCl_3$ only.

[d]DMSO-d_6 only.

[e]In $CDCl_3$ solution there is a small chemical shift difference between H-17a and H-17b. Since their transitions could not be irradiated separately, a single experiment measuring the enhancements from both protons was carried out. The enhancements could be measured separately for a DMSO-d_6 solution, since the chemical shift dispersion is greater.

and homo-correlation methods.[4]

Although there is no question as to the assignment of these four signals to the C-20 and C-15 protons, respectively, the problem of the stereochemistry of the assignments was not satisfactorily resolved.

The key relaxation pathways among the protons at C-15, 18, 20, 22, and 23 are indicated on the partial structure (Fig. 2). Irradiation of the downfield (3.70 ppm) H-20 signal produced an nOe enhancement of the downfield (2.36 ppm) H-15 signal (Fig. 3). Based on calculated nOe values, it is clear that the only significant relaxation pathway for one of the C-20 protons with one of the C-15 protons is between H-20a and H-15a. Irradiation at 2.36 ppm gave the expected enhancement to the signal at 3.70 ppm, further corroborating the assignment. For additional proof, the other C-20 proton, H-20b, was identified by key nOe enhancements to and from H-18b (2.87 ppm) and the vinylic proton, H-22. Since the assignment of H-22 is unambiguous, the above experiments verify the assignments of both H-18b and H-20b. In addition, H-15b (1.46 ppm) was characterized by enhancements to and from H-13 (unambiguously identified previously (ref. 8 and footnote 4)).

The nuclear Overhauser effects to and from H-20b and H-18b served as an entry into the ABMX system of protons 17a, 17b, 18a, and 18b. This spin system was initially analyzed from spectra of a DMSO-d_6 solution because, in this solvent, the four signals were more clearly separated and the C-17 protons were less tightly coupled than in $CDCl_3$ solution. Calculations predicted that these protons could be differentiated by their nOe enhancements. Experimental results (Table 1) verify that H-18b has effective relaxation pathways to H-8, H-22, and H-20b, whereas H-18a has an effective pathway to H-16. The C-17 protons were also distinguished by large key enhancements between H-17a and H-1, and between H-17b and H-8 (Table 1).[5]

Attempted computer simulation, using the program LAOCOON III (12), of the DMSO-d_6 ABMX spectrum, with an H-17a,17b geminal coupling constant at the previously reported (8) value of 0.2 Hz, failed to produce a reasonable fit. When the simulation was repeated starting from a more normal value (13*a*) of −13 Hz for the geminal coupling constant, the calculation converged rapidly to an excellent fit to the experimental spectrum.

The information obtained from the DMSO-d_6 spectrum was then correlated with the $CDCl_3$ spectrum. The relative ^1H R_1 values and the nOe enhancements for the C-18 geminal protons were measured; analysis of these data led to assignment of the signals. A LAOCOON III simulation yielded an excellent fit to the experimental spectrum. The set of corrected assignments

[4]S. Wehrli. Personal communication.

[5]The existence of an efficient inter-ring relaxation pathway between the aromatic ring proton, H-1, and H-17a provides structural information about the strychnine molecular framework. The close proximity of H-17a on a bridging ring is partially responsible for the observation that H-1, on the apparently isolated aromatic system, relaxes much faster than the corresponding proton at position 4, and even faster than H-2 and H-3, which have more close neighbouring protons on the aromatic ring. There is also an efficient inter-ring relaxation pathway between H-1 and H-16. It should be noted that the usual two-dimensional representation [1] of the strychnine structure gives a misleading impression of the relative placement of H-1 with respect to H-16 and H-17a.

and coupling constants obtained by this analysis is given in Table 2.

A final point of interest concerns the coupling (0.9 Hz, see Table 2) between the vinylic proton, H-22, and the C-20 proton with a signal at 3.70 ppm, originally assigned to H-20b (8). The dihedral angle between H-20b and the plane of the double bond is very close to 0°. The presence of any measurable coupling between H-22 and H-20b would, therefore, be unusual (13*b*). When the stereochemistry of the original assignments at C-20 was reversed, this coupling constant no longer appeared to be anomalous. The dihedral angle between H-20a and the plane of the double bond is about 100°, so a small (<3 Hz), but significant, coupling is to be expected (13*b*).

The nOe enhancements discussed above were critical in determining that the assignments of the chemical shifts of the geminal proton pairs at positions 15, 18, and 20 should be reversed, and that the coupling constant assignments for the geminal protons at C-17 should be revised. The power of the nOed technique to determine selected details of structure and stereochemistry has been clearly demonstrated.

Strychnine sulfonic acids

SSA-I was used in the present study as a model compound to evaluate the viability of the relaxation pathway analysis technique, since its structure has been unambiguously established by X-ray crystallography (4). Using only ^{1}H R_1 data, it was possible to verify the previously assigned (3) sites of substitution of SSA-II and SSA-III, and to establish the stereochemistry of the sulfonic acid group of SSA-III. This stereochemical assignment has been verified by nOed experiments.

Proton chemical shifts assignments for the acids were made initially by comparing the 400 MHz ^{1}H spectra with the spectrum of strychnine in DMSO-d_6 and $CDCl_3$. NOed experiments and computer simulations were employed to analyze the spectrum of SSA III. Verification of the structural assignments was achieved by comparing experimental (Table 3) and calculated R_1 values of protons in the immediate vicinity of the sites of substitution, as outlined above.

Since replacement of a hydrogen atom by a sulfonic acid group changes the moments of inertia of the molecule, there are corresponding differences in correlation times for tumbling (τ_c) which affect the measured R_1 values. For this reason, normalization (6) of the R_1 values is necessary before intercomparisons may be made. The normalizing proton is chosen

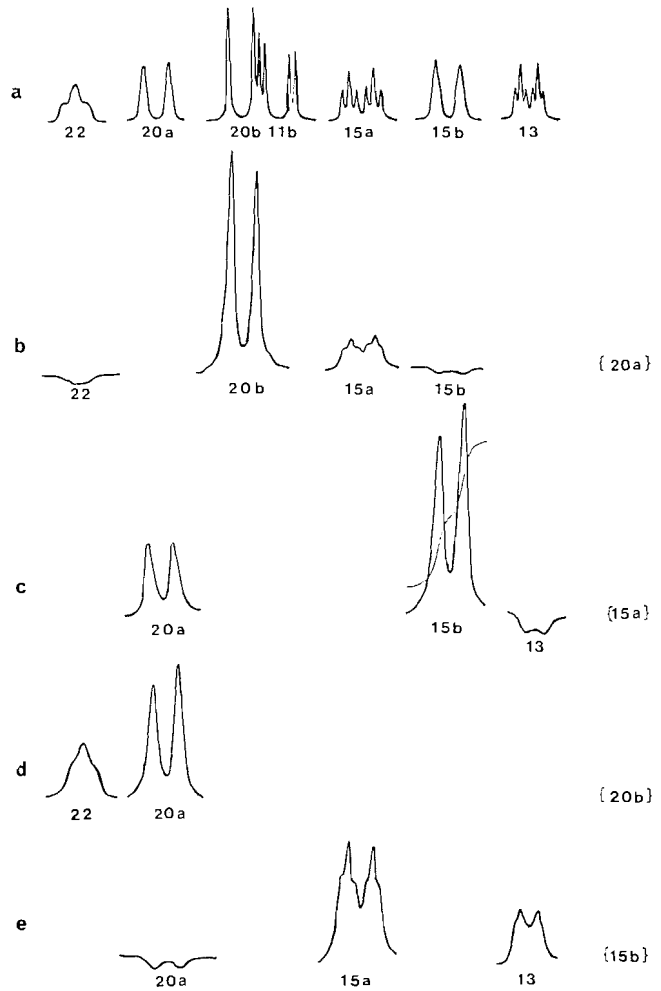

FIG. 3. Selected nOed measurements used to establish assignments of H-15a, H-15b, H-20a, and H-20b: (a) normal spectrum, 0.1 *M* in $CDCl_3$, (b)–(e) nOed measurements on same sample with proton irradiated indicated at right {}.

to be at a position remote from the site(s) of substitution, so that its intrinsic R_1 will not be directly influenced by the substituent. This procedure will also compensate for differences in experimental conditions (e.g. temperature) in different sets of measurements. Inter-comparisons between the R_1 values of strychnine and the sulfonic acids were avoided because strychnine is insufficiently soluble in the common solvent, D_2O, chosen for the sulfonic acids.

Since SSA-I and SSA-II were sparingly soluble in D_2O, it proved necessary to add a drop of NaOD solution to improve their solubility. This created a complication in that the hydrogen atoms at position 11 are acidic, and were replaced by deuterium. Reductions in the R_1 values of H-8 (16%), H-12 (19%), and H-13 (5%) of these compounds were expected, because deuterium has only about 6.3% of the relaxation efficiency of protium. These factors were easily accounted for in the calculations.

Strychnine sulfonic acid I

The site of substitution (C-14) of SSA-I may be inferred from the disappearance of the ^{1}H signal (3.14 ppm) attributed to H-14 in strychnine,[6] and the resulting change in the appearance of multiplets arising from protons coupled to H-14 (i.e.

[6]In DMSO-d_6 solution containing one drop of 40% DCl/D_2O.

TABLE 2. Revised ^{1}H chemical shifts and coupling constants for strychnine[a]

Proton	^{1}H chemical shifts[b]	Coupling constants, J (Hz)[c]
15a	2.36	15a,15b = −14.5 15a,16 = 4.9 15a,14 = 4.0
15b	1.46	15b,16 = 2.0 15b,14 = 1.0
17a	1.88	17a,17b = −15.5 17a,18a = 8.4 17a,18b = 11.7
17b	1.89	17b,18a = 0.1 17b,18b = 6.9
18a	3.19	18a,18b = −10.1
18b	2.87	
20a	3.70	20a,20b = −14.7 20a,22 = 0.9
20b	2.72	

[a]The remaining assignments were in agreement with those in ref. 8. Chemical shifts and coupling constants for the 17 and 18 protons were determined by spectral simulation, using the program LAOCOON III (12). The other values were measured directly from the spectra.
[b]In ppm from TMS, $CDCl_3$ solutions.
[c]Negative signs were assumed for geminal coupling constants.

H-13, H-15a, H-15b). Calculation of the effect of replacement of H-14 on the R_1 values of neighboring protons predicted reductions in the R_1 values of H-12 (11%), H-13 (20%), H-15a (10%) and H-15b (7%). A significant effect on the R_1 value of H-23a (10%) was also predicted, but was not measurable for experimental reasons.[7] Analysis of the R_1 value of H-12 is complicated by the effect of deuteration of 11a and 11b, but the magnitude of this influence could be established by comparing the H-12 R_1 values (Table 3) of SSA-II (deuterated) and SSA-III (nondeuterated). The difference in H-12 R_1 values of SSA-II and SSA-I could then be attributed to the effect of substitution at position 14. On comparing the other R_1 values of SSA-I with those of SSA-II, the reductions predicted by the calculations were apparent. A large decrease in the R_1 value of H-13 and smaller decreases in the R_1 values of H-15a and H-15b were observed. This unique combination of effects on measured R_1 values is in complete agreement with the assignment of position 14 as the site of substitution.

Strychine sulfonic acid II

Initial verification of the site of substitution in SSA-II was provided by the disappearance of the characterisic H-22 vinyl proton signal (5.90 ppm) of strychnine,[6] accompanied by only minor changes in the appearance of other signals. The only R_1 value showing a significant reduction was that of H-20b (Table 3). Calculations identified H-20a (65%), H-18b (16%), and H-22 (16%) as the major contributors to the relaxation of H-20b, thereby establishing three possible sites of substitution. H-22 was the logical choice because substitution at 20a would reduce the R_1 of H-20b to a much greater extent than had been observed, and substitution at 18b would cause substantial R_1 effects on other protons, in particular H-18a and H-8. Calculation of the effect on other protons from replacement of H-22 predicted significant decreases in R_1 values *only* for H-20b and H-23b. For practical reasons,[7] an R_1 value for H-23b could not be measured, but there was agreement between the calculated and observed influences on H-20b. Hence, for this molecule, the R_1 evidence clearly indicated that substitution has occurred at position 22.

TABLE 3. Normalized R_1 values[a] of the strychnine sulfonic acids[b]

Proton	Strychnine sulfonic acid I	II	III

[f]R_1 value not measurable (see footnote 7).

Strychnine sulfonic acid III

The site of substitution (C-20) of SSA-III could be inferred from the ^{1}H spectrum, the only two substantial differences with respect to the spectrum of strychnine being the loss of the AB pattern of the H-20 signals (3.70 and 2.72 ppm),[6] and the appearance of a sharp singlet, shifted significantly downfield (6.0 ppm). The loss of two signals from the spectrum without

[7]In SSA-I, the H-23a signal is in close proximity to the residual HOD signal of the solvent, and a reliable R_1 value could not be obtained. The spread of saturation power from solvent suppression has the effect of reducing the intensity of the H-23a signal and making the apparent R_1 value larger. The same problem also arises for the H-23b signal of SSA-II.

significant effects on coupling constants directly implied that substitution had occurred at position 20, since this is the only site with magnetically isolated (i.e. with no vicinal coupling constants) geminal protons. The large downfield shift of the remaining proton signal is consistent with a geminal relationship with the sulfonic acid substituent. The assignment was in agreement with the previous studies on SSA-III (3).

A powerful and efficient means of determining the stereochemistry at C-20 is to evaluate the relaxation pathways of the remaining proton. Figure 2 summarizes the most important pathways (arrows) available to H-20a and H-20b. Calculation of the effects on the R_1 values of neighboring protons for substitution at 20a indicated significant reductions in the R_1 values of H-20b (65%) and H-15a (16%). The corresponding calculation for substitution at 20b indicated significant reductions in the R_1 values of H-20a (74%), H-18b (14%), and H-22 (41%). A clear distinction between the possibilities should, therefore, be possible.

Close inspection of the spectrum of SSA-III indicated that changes in the magnitudes of the coupling constants of the 17 and 18 protons are induced by substitution, implying a change in the geometry of ring E, and possible changes in the efficiencies of the relaxation pathways for H-18b. Together with an observed reduction in the normalized R_1 value of H-18b, there were corresponding changes in the relative R_1 values of H-17a, H-17b, and H-18a. This complication led to uncertainty in the prediction of the relaxation contribution from H-20b, so that the R_1 value of H-18b could not be used as a basis of the assignment. Since there was no spectral evidence of a conformational change affecting any other protons, a distinction between the two sites of substitution, 20a and 20b, was made based on the R_1 values of H-15a and H-22.

Comparison of the R_1 values (Table 3) of SSA-III with SSA-I and SSA-II showed that the R_1 value of H-22 was not affected, but that of H-15a was reduced. The reduction in the R_1 value of H-15a relative to that of its geminal neighbor, H-15b, is a good indication that H-15a has been substantially affected. Consistency in the R_1 values of H-14 and H-16 suggested that there was no significant change in ring geometry affecting H-15a and H-15b. It is clear, therefore, that the site of substitution in SSA-III is 20a.

To substantiate this assignment, the nOed spectrum was measured for irradiation of the remaining H-20 resonance. This experiment was ideal from a practical standpoint, since the signal was completely isolated from the rest of the spectrum, and from a theoretical standpoint since the specific relaxation pathways of this proton could be characterized. A large enhancement was seen for H-22, and a small enhancement for H-18b. These nuclear Overhauser enhancements clearly establish that the irradiated resonance arises from a proton located at 20b (Fig. 2), thus confirming that the site of substitution in SSA-III is 20a.

Conclusions

The ^{1}H nmr spectrum of strychnine has been reassigned and the structures and stereochemistry of the three strychnine sulfonic acids are now clearly established. This study illustrates the ability of relaxation pathway analysis, used in conjunction with a simple mathematical model which enables the prediction of relative relaxation rates, to provide structural and stereochemical information on complex organic molecules. The experiments may be carried out easily and rapidly, using a modern, high field spectrometer. Degassing is unnecessary if qualitative information is to be obtained. In the first level of analysis (R_1 measurements) there is a high information content in that the relaxation rates of all protons in a molecule are obtained in a single experiment. If necessary, specific information on relaxation pathways (i.e. on relationships to near neighbors of a particular proton) may then be obtained by the more time-consuming, but more selective and sensitive, nOed experiment.

Experimental

Strychnine was obtained from commercial sources (Sigma Chemical Co.). The preparation and isolation of the three strychnine sulfonic acids have been described elsewhere (3). The compounds were dried overnight under reduced pressure at 120°C over P_2O_5. Nondegassed, 0.1 *M* solutions in $CDCl_3$, D_2O, and DMSO-d_6 were used for the nmr experiments. The solutions were not degassed because the intramolecular relaxation contribution from dissolved oxygen, which is expected to be equivalent for all protons in the molecules (6), should not affect qualitative results. In a molecule of the size and rigidity of strychnine, intramolecular ^{1}H dipolar relaxation is very efficient, so the effects of dissolved oxygen are small.

All spectra were measured at 400 MHz at ambient temperature (about 20°C), using a Bruker WH-400 spectrometer (Montreal Regional High Field NMR Laboratory). Free induction decays (fids) were accumulated into 16K (nOe experiments) or 32K (normal spectra, R_1 data sets) word data blocks with frequency windows of 4000 Hz, quadrature detection, and phase cycling. R_1 values were determined by the null point method (6), using the inversion–recovery pulse sequence (14, 15) with simultaneous suppression of the residual solvent peak when necessary. The absolute accuracy of R_1 measurements is typically ±10%, but, within a single experiment, the relative R_1 values can be determined to a precision of better than ±5%. Calculations to determine nOe and relative R_1 values were carried out on a Hewlett–Packard 1000 computer, using inter-proton distances measured from Dreiding molecular models.

Steady-state nOe difference spectra were obtained using a slightly modified version of the method of Hall and Sanders (10), who acquired nOe spectra for four chemical shifts with a single control. Our method is designed for efficient qualitative studies, emphasizing acquisition of an entire set of nOed spectra for the molecule under study. Difference spectra were obtained for up to eight different chemical shifts (on-resonance acquisitions), using only a single control (off-resonance acquisition). The acquisition of eight fids rather than four (10) after the equilibration period further improves efficiency by reducing the number of these equilibration periods by half. With these modifications and computer control of the decoupler, a complete set of nOe spectra could be obtained in a single overnight run (about 10 hours). It should be noted that this method requires that drift be kept to a minimum for clean subtraction, so that the high stability of a superconducting magnet is necessary. Irradiation times were about 5 $\times T_1$, although accurate data can be acquired with significantly shorter irradiation periods.

The nOe difference spectra were then produced by subtraction of the reference free induction decay from the decay containing the nOe information. Both data sets were subjected to exponential multiplication corresponding to line broadening of 0.8–1.5 Hz, before Fourier transformation. Substantial line broadening optimized the quality of the difference spectra, particularly for tall, narrow lines. The resultant nulling of unenhanced signal was very satisfactory, as had been reported previously by Hall and Sanders (10). These workers also suggested the use of subsaturating power levels to achieve frequency selectivity. This proved to be satisfactory for most experiments. When complete selectivity could not be achieved, the approach taken was to acquire additional experiments in which changes in the decoupler power or frequency were made (16). By correlating the effects on enhancements to the changes in experimental conditions, specific relaxation pathways could usually be determined. Occasionally, the presence of negative nOe enhancements (see Fig. 3)

arising from three-spin effects (17) was also helpful in establishing specific relaxation pathways.

Acknowledgments

This work was supported by operating grants from the Natural Sciences and Engineering Research Council of Canada, which also provided funding towards the purchase of the 400 MHz spectrometer. One of us (W.J.C.) wishes to thank the Ministry of Education, Province of Quebec, for a Fellowship. We are indebted to Dr. S. Wehrli, Bruker Instruments, Inc., for copies of the 2D correlation spectra of strychnine. We wish to thank Dr. C. Rodger for helpful discussions and Bruker Spectrospin (Canada) Ltd. for the use of facilities to carry out corroborative experiments.

The structure of 2,7-(11,22-diono-12,15,18,21-tetraoxa-9,24-dithia)-hexadecylene-naphthalene was investigated by ^{1}H and ^{13}C nmr and mass spectrometry. An X-ray structural investigation indicated the dissymmetric ansa structure of this compound in the crystalline state.

LIDIA PRAJER-JANCZEWSKA, KRYSTYNA RUDOLF, TADEUSZ LIS, MARIAN JANCZEWSKI et JANINA BISKUP. Can. J. Chem. **61**, 1756 (1983).

Faisant appel à la spectrométrie de masse et à la rmn du ^{1}H et du ^{13}C, on a étudié la structure du (diono-11,22 tetraoxa-12,15,18,21 dithia-9,24)-2,7 hexadécylène-naphtalène. Une étude par cristallographie de rayons-X indique que ce composé à l'état cristallin présente une structure de type ansa disymétrique.

[Traduit par le journal]

Introduction

The title macrolide (Fig. 1) was obtained with ca. 10% yield from the precursor, 2,7-naphthalene dithioglycolic acid dichloride (1).

The possibility of the arrangement of some related poly-oxathia-alkylene dionic chains over the plane of the naphthalene ring offers an interesting problem in the projected series of compounds, especially in the case in which the chains are bonded to two rings of the naphthalene moiety. This will, of course, be the reason for the ability of these compounds to complex with different types of substances and to act as inclusion systems in certain reactions, especially in those characteristic of natural compounds (e.g. in cyclodextrins (2) or in the antibiotic rifamycin B (3)) and for synthetic (4) multidentates.

Experimental

The nmr spectra were recorded on a Bruker 90 MHz spectrometer. Mass spectra were taken on a WSM-2 mass spectrometer; samples were introduced into the instrument via the direct insertion probe at room temperature; ion accelerating voltage: 3.0 kV, source temperature 160°C, pressure 5×10^{-7} Torr. The spectra were run at 70 eV and also at lower energy. From the mass spectrum the molecular ion was found to be at m/z 422, corresponding to $C_{20}H_{22}O_6S_2$. The main peak was at m/z 274.

A crystal suitable for single X-ray study was obtained from a saturated solution in DMF. For intensity measurements a specimen 0.8 × 0.8 × 0.7 mm was cut from a large crystal. Data were collected on a Syntex $P2_1$ four-circle diffractometer with Cu K_α radiation and graphite monochromator. The density of a few crystals was determined by flotation in a mixture of *n*-hexane/carbon tetrachloride, whose density was subsequently determined with a pycnometer. The crystal data were:

$C_{20}H_{22}O_6S_2$ $M = 422.52$

Monoclinic, $a = 5.831(3)$, $b = 37.49(2)$, $c = 9.234(4)$ Å, $\beta = 100.00(4)°$, $U = 1987.9$ Å^3, $Z = 4$, $D_c = 1.41$ g cm^{-3}, $D_{obs} = 1.42$ g cm^{-3}, Cu K_α radiation, $\lambda = 1.5418$ Å, μ(Cu K_α) = 2.65 mm^{-1}, space group $P2_1/c$.

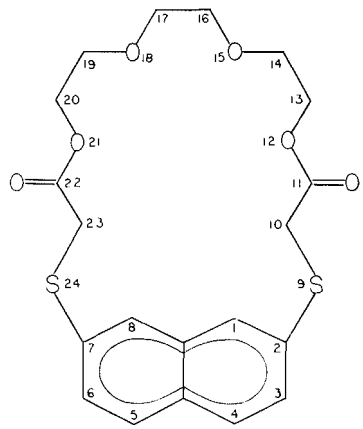

FIG. 1. The title compound. The numbering corresponds to that in Tables 1 and 2.

2672 Reflections were measured within the limits $2\theta < 115°$, 2540 with $I > 1.96\sigma(I)$ were used for the structure determination. One standard reflection was monitored after every 100 reflections; no significant change in intensity was observed. A $2\theta-\omega$ scan technique was employed. The intensities were corrected for Lorentz and polarization effects and an absorption correction was made from the φ-scan data. The scattering factors for neutral atoms employed in the calculations were those given (5). All the calculations were performed on a NOVA 1200 minicomputer with programs supplied by Syntex (6).

The crystal structure was solved by use of MULTAN (7). The solution was based on 165 reflections with $E > 1.8$. The E map corresponding to the solution with the best figure of merit revealed the positions of 21 non-hydrogen atoms. The remaining non-hydrogen atoms were located from several Fourier and difference-Fourier syntheses. Full-matrix least-squares refinement, first with isotropic, then with anisotropic thermal parameters gave $R = 0.113$ and 0.074, respectively. All H-atoms were included in geometrically calculated positions with d(C—H) = 1.0 Å and with isotropic thermal parameters of 4.5 Å^2, but were not permitted to refine. Their positions were, however, updated with respect to the subsequent refined positions of their attached carbon atoms. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$ with $w = [(\sigma^2(F) + 0.0001F_o^2]^{-1}$. The final refinement results gave a conventional R value,

16, 17	70.46	133,45
		134.34

$\Sigma||F_o| - |F_c||/\Sigma|F_o|$, of 0.042 and a weighted R value, $[\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{\frac{1}{2}}$ of 0.059 for all non-zero reflections. The goodness-of-fit, $[\Sigma w\Delta F^2/(m - s)]^{\frac{1}{2}}$, where m is the number of reflections used and s is the number of parameters refined, is 7.72. There were no significantly large positive or negative electron density peaks in a final difference Fourier synthesis; the largest positive region was 0.4 e Å^{-3} and the largest negative region was 0.3 e Å^{-3}. The final atomic positional parameters are given in Table 3, the bond lengths and angles in Tables 4 and 5, respectively.[3]

Description of the structure and discussion

The ^{1}H nmr spectrum of the compound shows that this diester is nonplanar. The structure of the diester in $CDCl_3$ solution either is symmetric or rapid conformational changes cause the protons to appear in the symmetrical positions. The CH_2 groups are influenced by the paramagnetic field resulting from the ring current of the naphthalene system. The conformation of the protons bonded with C(16) and C(17) (Fig. 1) located in the range of paramagnetic influence of the ring current may dominate. The reason for this is shown by the chemical shifts of these protons in a slightly lower field than would be present if they were located above the naphthalene ring plane (Table 1). The magnetic equivalence of chemically equivalent protons in solution implies a range of conformations whose interconversion is rapid on the nmr time-scale.

The ^{13}C nmr measurements characterize the individual C atoms (Table 2).

In the mass spectrogram the most abundant peak (m/z 274) indicates the easy splitting of ester C—O bonds.

The crystal structure of the title racemic compound is composed of discrete molecules with conformations of probably lower energy than those in the $CDCl_3$ solution (Table 1). One of the enantiomers was considered (Fig. 2). The naphthalene ring was planar to within 0.01 Å. The bond lengths were similar to those of some β-substituted (8) and 2,7-disubstituted

[3]Tables of temperature factors are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

*Estimated standard deviations are about 0.3°.

(9) naphthalenes.

The S—C_{sp^2} bond lengths are somewhat smaller (ca. 1.770(3) Å) than those of the S—C_{sp^3} bonds (ca. 1.799(3) Å) and both kinds are in the range of the known S—C lengths: 1.770(3) – 1.843(2) Å (10) for C_{sp^3} and, e.g., 1.705–1.748 Å (11), and typically 1.77 Å (12) for C_{sp^2}. The ester alkoxy C—O bonds (average 1.329(4) Å), as well as the carbonyl bonds (1.197(4) Å), are in the same expected range (ca. 1.325(2) and 1.202(2) Å, respectively) as in 2,6-diketo-18-crown-6 (13). The etheric alkoxy C—O bonds (ca. 1.449(4) Å) are of the same order of length as analogous bonds in the same crown (1.459 Å). In the ether portion the C—C bond lengths (ca. 1.485(5) Å) and the C—O distances (etheric: 1.42(1) Å) are similar to those of the mentioned crown compound (1.494(2) and 1.416(4) Å, respectively (13)).

The large distance between the 2- and 7-positions in the substituted naphthalene (Fig. 1) suggested that the two S atoms are coplanar with the naphthalene ring, similar to the methyl substituents, −0.03(1) and −0.02(1) Å, in the much more overcrowded 1,8-dibenzoyl-2,7-dimethylnaphthalene (9). Meanwhile these S atoms are displaced from the plane of the naphthalene by about 0.06 Å in the direction opposite to the main part of the chain. The angles formed by attachment of these S atoms to the *ortho* carbons are unequal, 124.9(3)° and 114.3(3)° at C(12), and 117.7(3)° and 122.6(3)° at C(18) (Fig. 2, Table 4(b)). This is further reflected in the torsional angles about the S—C bonds (Table 5, Fig. 2). Further, in the thia-oxa-alicyclic bow the angles formed by the S atoms have the usual value, ca. 103.3(2)°. The apical angles of the C(3) through C(10) atoms, e.g. C(1)—C(3)—O(1), C(2)—C(4)—O(4), and so on (Fig. 2, Table 4) are formed normally, 106.9(3)–110.2(3)°, and only those formed by the C(1) and C(2) are a little larger (ca. 114.5(3)°), similar to those of the compared (13) crown ether, ca. 113°.

The torsion angles O—C—C—O in both the alkoxide parts are of the usual synclinal value, 68.2(7)° and 63.3(7)°; compare ±70.6° (9) and ca. 60° (14). The S(2)—C(2)—C(4)—O(4) angle, 56.1(3)°, is similar; however, in contrast to this value, that of the second torsion angle S(1)—C(2)—C(3)—O(1) is −141.3(6)°, which shows the anticlinal conformation of this set of atoms. Moreover, the angle O(2)—C(7)—C(8)—O(3) of the other portion, being −176.3(7)°, corresponds to the

A series of compounds of type 2-M_a-2-M_b-1-picrylhydrazine with M_a, M_b = phenyl, *p*-bromophenyl, and *p*-nitrophenyl has been investigated. Conversion of *p*-bromophenyl into *p*-nitrophenyl caused by reaction with NO_2 has been observed in compounds of the above series. Parameters of the ^1H and ^{13}C nmr spectra for the members of the series are reported. The new compound 2-(*p*-bromophenyl)-2-(*p*-nitrophenyl)-1-picrylhydrazine has been prepared and characterized using mass spectrometry, nuclear magnetic resonance, electron paramagnetic resonance, thin-layer chromatography, and elemental analysis.

On a étudié une série de composés du type M_a-2-M_b-2 picryl-1 hydrazine avec M_a, M_b = phényle, *p*-bromophényle et *p*-nitrophényle. Dans les composés de cette série, on a observé la transformation du *p*-bromophényle en *p*-nitrophényle par suite de la réaction avec le NO_2. On rapporte les paramètres des spectres de rmn du ^1H et du ^{13}C de ces composés. On a préparé le nouveau composé (*p*-bromophényle)-2 (*p*-nitrophényle)-2 picryl-1 hydrazine et on l'a caractérisé en faisant appel à la spectrométrie de masse, à la rmn, à la rpe, à la chromatrographie en couche mince et à l'analyse élémentaire.

[Traduit par le journal]

Introduction

A series of compounds of type 2-M_a-2-M_b-1-picrylhydrazine with M_a, M_b = phenyl, *p*-bromophenyl, and *p*-nitrophenyl has been investigated. These various different molecular species will be denoted by DM_aM_b—H. The work reported here is a continuation of a project studying the reaction products resulting from reaction of bromine with the free radical 2,2-diphenyl-1-picrylhydrazyl (denoted as DH_2) (1). At ice temperatures, fast addition of bromine to DH_2 or to the corresponding hydrazine DH_2—H in solution gives the expected products DHBr—H or DBr_2—H, with bromine substitution into the *para* position(s) of the phenyl ring(s). However, substantial yields of 2-(*p*-nitrophenyl)-2-phenyl-1-picrylhydrazine ($DH(NO_2)$—H) were found at somewhat higher temperatures (60°C) and with slow addition of bromine. It was postulated that this compound was formed by reaction of DH_2 with NO_2, displaced from nitro groups in the picryl ring of DH_2 by bromine. The picryl-substituted products 2-(*p*-nitrophenyl)-2-phenyl-1-(2-bromo-4,6-dinitrophenyl)hydrazine and 2-(*p*-bromophenyl)-2-phenyl-1-(2-bromo-4,6-dinitrophenyl)-hydrazine were subsequently identified by proton nmr studies. The preparation of mono- and dinitrated diphenylpicrylhydrazines through reaction of DH_2 and NO_2 had previously been described (2). Thus a series of compounds DHBr—H, $DH(NO_2)$—H, DBr_2—H, $D(NO_2)_2$—H, and D'H(NO_2)—H, D'HBr—H (with D' denoting Br substitution for NO_2 in the *o*-position of the picryl ring) is available for study.

In the present project, replacement of Br by NO_2 was found to occur and has been investigated. No ^{13}C nmr study of the molecules listed above has yet appeared in the literature. To characterize chemical and physical variations within this series more completely and to assign unambiguously all of the peaks in the carbon nmr spectra of the compounds, it proved useful also to prepare the previously unreported compound $DBr(NO_2)$—H in which the two phenyl rings contain Br and NO_2, respectively, at the *para* positions. This hydrazine also was utilized in studying replacement of Br by NO_2 in phenyl groups.

Experimental

A. *Starting material*

1. 2-(*p*-Bromophenyl)-2-phenyl-1-picrylhydrazine (DHBr—H) was prepared by rapid addition of bromine to DH_2—H in $CHCl_3$ solution at ice temperature, as described in ref. 1. Separation from the reaction mixture was achieved by elution with chloroform from an Alcoa F-20 alumina column. Red-orange crystals, mp 182–184°C, were obtained after recrystallization from chloroform/petroleum ether.

2. $DH(NO_2)$—H was prepared as described in ref. 2. The product was separated from impurities on an alumina column using ethanol as the elutant and by recrystallization from ethanol/acetic acid.

3. The hydrazyl $DH(NO_2)$ was prepared by oxidizing $DH(NO_2)$—H with PbO_2 in chloroform (2).

B. *$DBr(NO_2)$—H synthesis*

Matheson 98% min purity NO_2 was slowly bubbled through a stirred solution of 0.5 g DHBr—H in 50 mL of chloroform cooled to 0–2°C. The reaction was monitored at two-minute intervals for formation of phenyl-nitrated product: the samples taken were spotted on Brinkmann 5538 silica gel tlc sheets with toluene developer, and the NO_2 flow was stopped (usually within 10 minutes) when samples taken indicated formation of a nitrated-phenyl species located at $R_f \sim 0.23$ (1).

The resulting solution was intensely brown in color, indicating oxidation of the hydrazine species to hydrazyls by excess NO_2. Reduction to the typical orange color of the hydrazines was effected by shaking the reaction mixture with ~0.2 g of solid sodium dithionite and 1–2 mL of 3% H_2O_2. This step simplified the product separation, done by adsorption chromatography on Alcoa alumina F-20 using 85:15 (v/v) chloroform/ethanol eluant. This first bands eluted contained low yields of unidentified brominated material. The dark red (wine-colored) band at the top of the column moved slowly, and eventually split into three sections which eluted $DH(NO_2)$—H, $DBr(NO_2)$—H, and then $D(NO_2)_2$—H, in that order.

The desired compound $DBr(NO_2)$—H could be recrystallized from a variety of solvents, including acetone, ethanol, chloroform, and acetic acid. Diarylpicrylhydrazines exhibit tenacious retention of solvent (1), so that attempts to obtain solvent-free crystals by heating at 120°C in vacuum for 24 h were unsuccessful. Elemental analyses obtained for the product recrystallized from various solvents gave the results in Table 1.

Mass spectra were recorded on an AEI MS-12 mass spectrometer operated at 70 eV. Diarylpicrylhydrazines under electron bombardment fragment via N—N bond fission, to give diarylamine ions con-

taining amine protons presumably originating from the N-picryl fragments (1). The expected doublet at m/z 292–294 ascribed to the *p*-bromophenyl-*p*-nitrophenylamine +1 ion was observed; loss of bromine (plus pick-up of a phenyl proton) led to a prominent peak at m/z 214, i.e., to the phenyl-*p*-nitrophenylamine +1 ion (1).

Oxidation with lead dioxide in benzene gives the hydrazyl $DBr(NO_2)$ which is intensely brown in solution. The hydrazyl was shown to be paramagnetic by observation of its electron paramagnetic resonance (epr) spectrum. The stability of the free radical in solution was demonstrated by the lack of change in the epr spectrum of a sealed degassed sample after standing six weeks.

Other methods of preparation of $DBr(NO_2)$—H were examined as well. A sample of $DH(NO_2)$—H prepared as described in ref. 2 was dissolved in benzene at room temperature. A 3% Br_2 (v/v) in chloroform solution was added, to attain a 2:1 mole ratio $DH(NO_2)$—H/Br_2. The precipitate recovered was substantially unreacted $DH(NO_2)$—H. Use of the hydrazyl $DH(NO_2)$ instead of the hydrazine resulted in a more complicated reaction mixture. The yield of $DBr(NO_2)$—H in these attempts was much lower than that obtained by the above method of nitrating DHBr—H with NO_2.

C. *Magnetic resonance*

Proton (^{1}H) nmr spectra were recorded on a Bruker WH-400 spectrometer at ambient temperature (ca. 295 K) and on a Bruker WP-60 at low temperatures. Chemical shifts (Tables 2a, b) were measured in ppm relative to the peak of internal tetramethylsilane (TMS) taken to be at δ = 0, and are deemed accurate to ±0.01 ppm.

Ambient (303 K) and low temperature ^{13}C nmr spectra were recorded at 15.08 MHz on a Bruker WP-60 spectrometer. Acetone-d_6 and dichloromethane-d_2 were used as solvents. Here chemical shifts (Tables 3, 4) were measured relative to the internal ^{13}C TMS peak taken to be at δ = 0, and are accurate to ±0.1 ppm.

The epr spectra of the hydrazyl free radicals obtained by oxidation of the above hydrazines are well known (2, 3), with the exception of the new radical $DBr(NO_2)$. Dilute deoxygenated solutions of this species in benzene were studied at room temperature, using our Bruker B-ER 418S epr spectrometer operating at ca. 9.4 GHz.

Results and discussion

$DBr(NO_2)$—H was reacted with NO_2 under the same conditions as in the synthesis of $DBr(NO_2)$—H. A 95% yield of $D(NO_2)_2$—H was obtained. The identity of the latter was confirmed by proton nmr. A similar experiment performed with DBr_2—H and NO_2 produced substantial yields of $D(NO_2)_2$—H, as well as some $DBr(NO_2)$—H. During initial attempts to synthesize $DBr(NO_2)$—H from DHBr—H, overnitration by NO_2 also was found to result in formation of the dinitro compound. In the DBr_2—H reaction with NO_2 the for-

mation of some $D'(NO_2)_2$—H, in which Br substitution for NO_2 in the *o*-position of the picryl ring had occurred, was confirmed by proton nmr and mass spectroscopy. This compound is analogous to $D'H(NO_2)$—H and D'HBr—H identified in our first report (1).

Thus, from the reactions studied it is clear that a bromine atom in the *p*-position of a phenyl group can be replaced by a nitro group through reaction with NO_2, in inert organic solvents. An extensive review of the reactions of NO_2 with organic compounds has been published by Riebsomer (4); however, no specific mention of such replacements was made. Another early review (5) of "anomalous" nitrations catalogues studies in which halogens, alkyl, alkoxyl, acyl, carboxyl, and sulfonic groups have been replaced by one or more nitro groups. Use of NO_2 (N_2O_4) is not cited. More modern treatises (6, 7) on the subject also do not discuss NO_2 nitration reactions of aromatic molecules in inert solvents. It thus appears that this type of nitration, as reported herein, is not well-known in organic chemistry. On the other hand, there is a growing awareness of the existence of reactions in which radicals replace other radicals in aromatic compounds; for example, see the recent review of ipso substitution (8). The reactions observed by us seem to be of this type. Detailed rate and mechanism studies now are feasible and desirable.

Characterization of $DBr(NO_2)$—H

Since unsolvated $DBr(NO_2)$—H could not be prepared, proton nmr was used to confirm the identity of this compound crystallized from various solvents (see Table 1). Despite drying the product in a vacuum oven at temperatures up to 120°C, peaks due to the solvent were always observable in the nmr spectra.

Two separate proton A_2X_2 subspectra were observed for $DBr(NO_2)$—H. One A_2X_2 subspectrum occurred with multiplets at $\delta = 7.14$ and 7.58 ppm and with a magnitude for $N_J = J_{AX} + J_{AX'}$ of 8.9 Hz. These numbers are very similar (Table 2b) to corresponding values found for the *p*-bromophenyl protons in DHBr—H and in DBr_2—H. The other subspectrum has

multiplets at $\delta = 7.17$ and 8.17 ppm with a value for N_J of 9.6 Hz. These values are almost identical (Table 2b) to the corresponding ones observed for $DH(NO_2)$—H, but somewhat displaced upfield from the values observed for $D(NO_2)_2$—H.

In addition to indicating the *p*-bromophenyl and *p*-nitrophenyl groups, the proton nmr spectrum of $DBr(NO_2)$—H also established the presence of the N—H proton and of two nonequivalent *m* protons on the picryl ring. For the latter, the low temperature observation of the AB multiplet with $J = 2.6$ Hz, resolving from the room temperature broad picryl resonances, verifies that a picryl group is indeed present (9). Thus the proton nmr spectrum confirms all the structural components of $DBr(NO_2)$—H.

Analysis of the ^{14}N hyperfine structure in the epr spectrum of $DBr(NO_2)$ was carried out as described in ref. 3 using Gaussian lineshape functions with width $\Delta = 4.97$ G. The resulting coupling parameters, $A(N_2) = 6.70(5)$ G and $A(N_1) = 10.50(5)$ G, are consistent with the similar parameters reported in ref. 3, i.e., with the known *para*-substituent effects of Br and NO_2.

^1H nuclear magnetic resonance assignments

Samples of DH_2—H, DHBr—H, $DH(NO_2)$—H, DBr_2—H, $DBr(NO_2)$—H, and $D(NO_2)_2$—H in dichloromethane-d_2 at room temperature all exhibited a broad peak at $\delta \sim 10$ ppm due to the N—H protons and two very broad peaks ($\delta_a \sim 8.6$ and $\delta_b \sim 9.2$) due to the *meta* protons on the picryl rings. Samples of DH_2—H, DHBr—H, and $DH(NO_2)$—H all showed similar patterns of three multiplets arising from the *o*, *m*, and *p* protons of the phenyl groups. DHBr—H, $DH(NO_2)$—H, DBr_2—H, $DBr(NO_2)$—H, and $D(NO_2)_2$—H all exhibited symmetric pairs of multiplets assignable as A_2X_2 spectra resulting from *para*-substituted phenyl groups. As discussed, $DBr(NO_2)$—H showed two separate symmetric A_2X_2 spectra from its *p*-bromophenyl and its *p*-nitrophenyl groups, respectively. Some 60 MHz ^1H nmr spectra of the above set of compounds were obtained at 250 K. In all cases the picryl proton peaks resolved into an AB spectrum with $J = 2.6 \pm 0.1$ Hz.

^{13}C nuclear magnetic resonance assignments

The ^{13}C nmr spectra taken of the 2,2-diaryl-1-picrylhydrazines dissolved in dichloromethane-d_2 at ca. 300 K could not be uniquely assigned due to the broadness of some lines, the averaging of the *m*-picryl carbons, the averaging of the *o*-picryl carbons, and accidental degeneracies. However, at 248.5 K, using acetone-d_6 and dichloromethane-d_2 as solvents, all carbons of all molecules in the series could be observed. The effect of lowering the temperature can be seen in the ^{13}C nmr spectrum of $DH(NO_2)$—H (Fig. 1).

In order to compare the ^{13}C nmr spectra of the six molecules, it was helpful to utilize a special numbering system (see Fig. 1). The picryl carbons were numbered 1 to 6 by the normal convention. The phenyl, *p*-bromophenyl, and *p*-nitrophenyl groups each show four carbon resonances, consistent with the proton spectra of these molecules and with free rotation about their carbon—hydrazine nitrogen (N-2) bond. The four carbon *types* for each ring have been numbered starting at the carbon attached to the hydrazine unit, followed by the carbons *ortho*, *meta*, and *para* to this unit. Thus the carbons of phenyl groups are numbered 7 to 10, the carbons of *p*-bromophenyl groups are numbered 11 to 14, and the carbons of *p*-nitrophenyl groups are numbered 15 to 18.

In the case of DBr_2—H, ^{13}C nmr spectra were obtained at 5° intervals between 275 K and 315 K, using dichloromethane-d_2 as solvent. At 275 K, the *ortho* carbons of the picryl group are

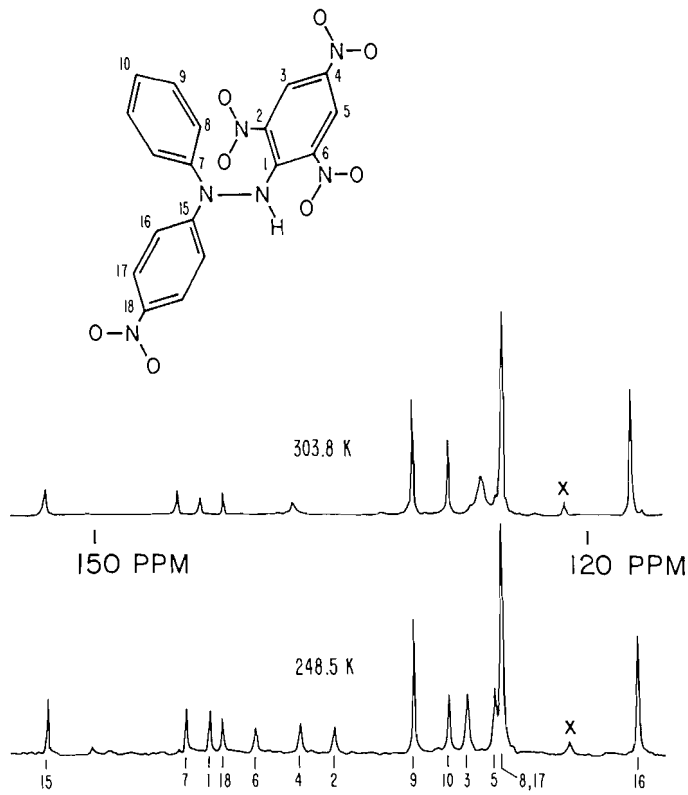

FIG. 1. The ^{13}C nmr spectra of $DH(NO_2)$—H in acetone-d_6, at temperatures 303.8 and 248.5 K. The peak labelled X arises from an impurity.

nonequivalent, as are the *meta* carbons of the picryl group. The collapse of the *meta* carbon resonances to one line and the collapse of the *ortho* carbon resonances to one line could be followed as the temperature was increased. These spectral changes are consistent with the collapse of the *meta* picryl proton resonances of DH_2—H in dichloromethane as the temperature is increased from 213 K to 309 K (9). At low temperatures there is restricted rotation of the picryl ring about the (N-1)—(C-1) bond and the two *ortho* nitro groups are inequivalent (9, 10), causing nonequivalence of the carbon atoms C-2,6 and also of C-3,5. As the temperature is increased the pairs of atoms become effectively equivalent, on our nmr time scale, due to faster rotation.

Specific proton decoupling experiments were carried out by us on the picryl protons in DHBr—H and $D(NO_2)_2$—H. In both cases the *meta* proton with its resonance at higher field was found to be attached to the (*meta*) carbon with its resonance at lower field.

Broad-band decoupled and gated decoupled spectra of all six compounds of our series in acetone-d_6 were obtained, both at ambient temperature and at 248.5 K. The splitting patterns and the coupling constants helped to decide some of the assignments. The assigned chemical shifts for all carbons in the six molecules at 248.5 K are given in Table 3. The assignments of the peaks observed at ambient temperature are given in Table 4.

The chemical shifts of the picryl carbon atoms are insensitive to the *p*-aryl substituents on the remainder of the molecule. The chemical shift for each of the six carbons on the picryl group falls into a narrow range for all six molecules. The assignments of the *ortho* pair (C-2, C-6) and the *meta* pair (C-3, C-5) require some further explanation.

*Conditions as given in Table 3.
†Abbreviations: dd, doublet of doublets; dm, doublet of multiplets.

In general, an electron-attracting substituent, such as nitro, on a phenyl ring deshields the substituted carbon, shields the carbon adjacent to the substituted carbon, and deshields the protons on the carbons adjacent to the substituent (11, 12). From a table of substituent effects on phenyl rings (11), it can be seen that the larger the carbon deshielding at the substituted position, the greater the shielding at the carbons adjacent to the substituted position.

It is believed that, because of steric interference of the diphenylamine group, one picryl nitro group *ortho* to the amine linkage is twisted out of the plane of the picryl ring (1, 9). By definition, this is the nitro group on C-2. The hydrazine proton presumably strengthens the asymmetric structure by H-bonding to an oxygen of the nitro group on C-6. The nitro group on C-2 should have less mesomeric interaction with the picryl ring and thus have a smaller electron-withdrawing effect. Thus, one would expect chemical shifts in the order

$$\delta_{C(2)}<\delta_{C(6)},\ \delta_{C(3)}>\delta_{C(5)},\ \delta_{H(3)}<\delta_{H(5)}$$

The assignments were made on this basis. The phenyl groups on N-2 could contribute either shielding or deshielding to the nearest atoms of the picryl ring, depending on the average positions of the phenyl rings. We are unable to evaluate this possibility because of the lack of structural information about the subject molecules. Solvent interactions with the nitro groups are also expected to be appreciable. The nonequivalence of the *meta* hydrogens is observed without the presence of phenyl groups, for example in various N-substituted picrylanilines (9, 13).

Turning now to the chemical shifts of the phenyl carbons, it can be seen from Tables 3 and 4 that a *p*-bromo substituent in one phenyl ring has very little effect on the other phenyl ring, whereas a *p*-nitro substituent on one ring has a substantial effect on the other. In the latter case, the *o*- and *p*-positions in the second ring are deshielded and the position of attachment to the hydrazine moiety is shielded. Only the *m*-position escapes the effect of the nitro substituent in the other ring. These long-range substituent effects imply interaction between the two phenyl groups through the joining nitrogen, probably involving the lone pair of electrons on the nitrogen.

Presumably the *p*-nitrophenyl group withdraws electron density from the remainder of the molecule, in particular from the adjacent phenyl (or *p*-bromophenyl) group, resulting in enhanced shielding of the *p*-nitrophenyl group protons. In the case of $D(NO_2)_2—H$, the two *p*-nitro groups are in opposition to each other, preventing such increased shielding of these protons.

The splitting patterns and coupling constants for the carbons with attached hydrogen atoms are tabulated in Table 5. The "doublet of doublets" splitting pattern is characteristic of carbons 3, 5, 12, 13, 16, and 17, where there is a large one-bond C—H coupling and a small three-bond coupling. The two-bond couplings are too small to be resolved. Peaks of the phenyl group carbons (C-8,9,10) are all proton-split doublets of multiplets which could not be further resolved. The one-bond coupling constants for the *meta* picryl carbons (C-3, C-5) are distinctly large ($^{1}J_{C—H} \sim 175$ Hz). At the other extreme, C-8 and C-9 have one-bond couplings in the range 160.6 to 163.4 Hz. C-12 consistently has $^{1}J_{C—H}$ of about 164.5 Hz. Carbons 13, 16, and 17 have one-bond coupling constants in the range of 166.8 to 170.8 Hz. The three-bond coupling constants included in Table 5 are seen to be insensitive to the structural variations in our molecules.

The coupling constants and splitting patterns were used to distinguish between C-8 and C-12 for DHBr—H, for which the chemical shifts are very similar. In gated decoupled spectra, the carbons (C-7, C-11, C-15) attached to N-2 of the hydrazine moiety all appear as 1:2:1 triplets with comparable splittings (7.5, 8.4, and 8.7 Hz, respectively), due to coupling through three bonds to the *meta* hydrogens. Unexpectedly, C-1 exhibits a 1:3:3:1 quartet with a splitting of ~7 Hz. As there are only two hydrogen atoms on the picryl ring, C-1 must be coupled appreciably with the N—H hydrogen. Nucleus C-14 exhibits a triplet of triplets ($^{3}J_{C—H} \sim 10$ Hz, $^{2}J_{C—H} \sim 3$ Hz). Here the attached bromine atom induces larger C—H coupling constants over two and three bonds.

In summary, the ^{13}C nmr parameters of the 2,2-diaryl-1-hydrazines are now available, and will allow future detailed study of the hindered rotations and other dynamic effects in these molecules.

Biosynthesis of antifungal stress metabolites from potato: observation of hydride shifts via the "β-hop" from incorporation of [2-$^2H_3$,2-^{13}C]acetate and ^{13}Cmr[1,2]

ALBERT STOESSL AND J. B. STOTHERS

London Research Centre, Agriculture Canada and the Chemistry Department, University of Western Ontario, London, Ont., Canada N6A 5B7

Received December 21, 1982

ALBERT STOESSL and J. B. STOTHERS. Can. J. Chem. **61**, 1766 (1983).

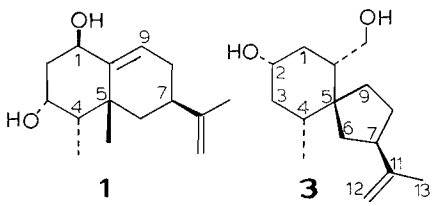
The proposed migration of hydrogen from C-5 to C-4 in the biosynthesis of the potato phytoalexins lubimin (**2**), rishitin (**5**), and 3-hydroxylubimin (**6**) has been studied by incorporation of [2-$^2H_3$,2-^{13}C]acetate. Direct observation of the predicted β-shift of the C-5 signal produced by ^{2}H at C-4 provided conclusive confirmation of the hydride (deuteride) shift. Results of some [4,4-$^2H_2$]mevalonate incorporation experiments followed by ^{2}Hmr are also described.

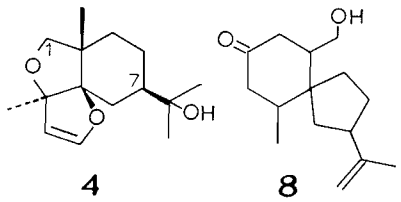
ALBERT STOESSL et J. B. STOTHERS. Can. J. Chem. **61**, 1766 (1983).

On a étudié la migration d'hydrogène du carbone en position 5 vers le carbone en position 4 lors de la biosynthèse de la phytoalexine de la pomme de terre la lubimine (**2**), de la rishitine (**5**) et de l'hydroxy-3 lubimine (**6**) en incorporant l'acétate [$^2H_3$-2, ^{13}C-2]. Les observations directes du glissement β du signal du C-5 produit par ^{2}H au niveau C-4 confirment le glissement d'hydrure (deutérure). On décrit également les résultats des expériences d'incorporation du mévalonate [$^2H_2$-4,4] que l'on a suivies en rmn du ^{2}H.

[Traduit par le journal]

Many of the sesquiterpenoid stress compounds produced by members of the *Solanaceae* (1−3) can be regarded as rearranged eudesmanoids, at least in a formal sense (4−6). Although the pathways of their biosynthesis are not always as straightforward as originally envisaged (6), there is now firm experimental evidence for postulated methyl and methylene migrations in several instances (7−10). In addition to these carbon-to-carbon migrations, some rearrangements were postulated to proceed with 1,2-hydride shifts from C-5 to C-4 of the eudesmane skeleton. The reality of such a shift was demonstrated recently for the biosynthesis of capsidiol (**1**) from sweet pepper, through direct observation with ^{2}Hmr of deuterium derived from [4,4-$^2H_2$]mevalonic acid (MVA) at C-4 in **1** (11). Despite the probable common eudesmanoid origins, **1** exhibits structural and biosynthetic features which set it apart from the vetispiranes, such as lubimin (**2**), which are the most frequently encountered stress products of the *Solanaceae*. It was therefore important to verify the proposed hydride shift in the formation of these compounds as well. We wish to describe the results of experiments which establish the existence of such shifts.





Potato tubers, which produce several compounds of interest in this context, were supplemented with [4,4-$^2H_2$]MVA after inoculation with *Alternaria solani*. This fungus was chosen as stress inducer because it converts much of the lubimin (**2**) which is formed initially into the easily crystallized 15-dihydrolubimin (**3**) (12), thus facilitating purification and, probably, also leading to increased yields. After the usual incubation period, labelled 15-dihydrolubimin (**3**), phytuberol (**4**), and rishitin (**5**) were isolated. These three compounds arise from three different major biosynthetic pathways available to stressed *Solanaceae*. The ^{2}Hmr spectrum of **4**-d_x contained two, approximately equally intense signals at 1.5 and 3.5 ppm, indicating the presence of deuterium at C-7 and -1, respectively. This is completely consistent with our biosynthetic sequence proposed previously (5, 6, 9), according to which deuterium from the third MVA unit is lost from C-5 of a hypothetical eudesmanoid intermediate.

For **3**, the ^{2}Hmr spectrum had two absorption bands in the ratio of ca. 2:1. This is consistent with incorporation of one deuterium from each of the three MVA units involved in the biosynthesis, with two nearly equivalent ^{2}H nuclei giving rise to the more intense band near 1.35 ppm. This is the region in which the 4- and axial 1-protons are known to absorb, while the second band, 2.25 ppm, coincides with the shielding expected for deuterium on C-7. These results, therefore, are compatible with the sequence outlined in Scheme 1, including a 5,4-hydride shift, but cannot confirm its validity.

In the case of **5**, the ^{2}Hmr spectrum consisted of a single broad absorption centred at 2.1 ppm showing the presence of deuterium at any or all of the three expected positions, C-1, -4, and -7. A comparison of the relative intensity of this band with respect to the natural abundance signal for the solvent ($CHCl_3$), the weight of which was accurately known, indicated an incorporation level of ca. 3%. This was comparable to the observed level for **3**, obtained in the same manner. Thus, these results appear to favor the presence of three different deuterium atoms but, as for **3**, do not confirm it. Clearly, a new approach was required.

Substitution of a proton by deuterium at a given carbon atom produces a small but readily detectable shift for the resonance signal of an immediately neighboring ^{13}C nucleus. This two-

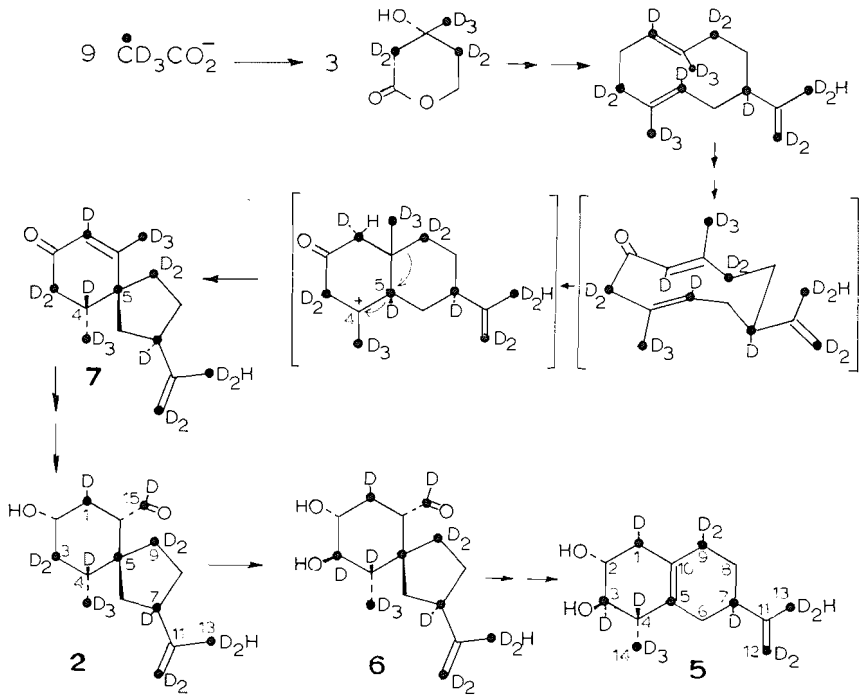

SCHEME 1

bond, isotope effect may be termed a β-shift and, for saturated systems, is ca. 0.1 ppm (13). With high ^2H incorporation, these effects are easily observed but with low ^2H incorporation the shifts may not be observable unless ^2H and β-^{13}C substitution occur simultaneously with significant probability. In practice, for biosynthetic experiments, this condition will be met only if both ^2H and ^{13}C atoms are incorporated from the same precursor molecule, for example by the intact incorporation of $^2H_3{}^{12}C\cdot{}^{13}CO_2H$ (14). It occurred to us that the condition will also be met if a "—$^2H^{13}C$—" unit is incorporated with subsequent migration of the ^2H nucleus to a contiguous carbon atom. For example, with $^2H_3{}^{13}C\cdot CO_2H$ as the precursor, migration of the deuterium either to C-1 of the same acetate residue or to another carbon which becomes attached to C-2 of this unit, will satisfy the requirement for ready detection of the β-shift. We have proposed the term "β-hop"[3] for this technique (15).

For the purpose of the present study, sodium [2-$^2H_3$,2-^{13}C]-acetate was applied to potato tubers, inoculated with *Monilinia fructicola*.[4] After the usual incubation period, lubimin (**2**) hydroxylubimin (**6**), and rishitin (**5**) were isolated and each was found to exhibit the expected β-shift for C-5 in the ^{13}Cmr spectrum. This is illustrated for **5** in Fig. 1; this spectrum contains fourteen prominent singlets whose shieldings (see Table 1) agree precisely with those previously reported for **5** (9). One at δ_C 129.0, arising from C-5, is accompanied by a singlet of comparable intensity at slightly (0.045 ppm) higher field as shown in the inset. The latter is the isotope-shifted component produced by the presence of deuterium at C-4, the deuterium having been originally bonded to C-5 at an earlier stage in the biosynthetic sequence. It is readily apparent that the intensity of the absorption at δ_C 129 is much greater than that for either of the signals at δ_C 124.9 and 148.9 (C-10 and -11, respectively) although each of the three is due to non-protonated carbons; this establishes that C-5 is ^{13}C-enriched. The singlets for C-2, -4, -6, and -8 exhibited integrated intensities significantly smaller than those for the seven remaining protonated carbons, revealing the seven additional sites of ^{13}C incorporation. In addition, these more intense singlets are each accompanied by absorption produced by the presence of directly bonded deuterium. One-bond isotope shifts are generally in the range, 0.3−0.6 ppm, towards higher field, and since $J_{CD} \sim 20$ Hz for saturated carbon, the presence of one directly bonded deuterium atom gives rise to a triplet ^{13}C pattern as is discernible for C-1, -3, and -7. More complex ^2H-coupled patterns appear with the signals for C-9, -12, -13, and -14. The methyl carbons, of course, may have from 0−3 deuterium atoms directly bonded and the absorptions for —CH_3, —CH_2D, and —CHD_2 were observable for C-13 as shown in Fig. 2. The triplet and quintet patterns for the mono- and dideuteriated carbons, respectively, are indicated in Fig. 2a and were confirmed by recording the INEPT spectrum (16) in which the phase of the CH_3 and —CHD_2 signals is opposite that for the CH_2D absorption (see Fig. 2b). In any event, the spectrum readily reveals the sites of ^{13}C and ^2H incorporation and establishes the existence of a hydride (deuteride) shift from C-5 to C-4 in the biosynthetic sequence.

Analogous results were obtained for **2** and **6**. In their ^{13}C spectra, the signal for C-5 at δ_C 46.9 and 48.3, respectively, was accompanied by a singlet of comparable intensity at higher field; in each case the isotope shift was found to be 0.085 ppm. To confirm the result for **2**, the sample was reduced to crystalline **3** with borohydride and the ^{13}C spectrum of the product exhibited a closely spaced pair of singlets for C-5 at δ_C 46.7 with an isotope shift of 0.080 ppm. The spectra for **2**, **3**, and **6** contained signals for eight carbons having somewhat enhanced singlets together with the characteristic ^2H-coupled patterns. Thus, the $^{13}C/^2H$ labelled centres were readily identified.

As may be seen in Fig. 1 for **5**, there is variation in the relative intensity of the ^2H-coupled patterns and their accom-

[3]We thank Phyllis Stoessl for suggesting this term.

[4]This fungus was used as inducer in the only partially fulfilled expectation that it would favor rishitin formation.

[a]Data obtained for $CDCl_3$ solutions in ppm from internal TMS.

panying singlets for the various labelled centres other than the methyl carbons. For example, the singlets for C-1 and -3 in **5** (Fig. 1) are significantly enhanced; this is indicative of some deuterium loss during the biosynthesis. Similar behavior was found in the spectra of **2**, **3**, and **6** for each of which the most intense signal appeared near 33 ppm. In earlier work (9), this signal had been assigned to C-6 while a signal near 42 ppm was attributed to C-1. The present results require that these assignments be reversed; the revised shieldings are listed in Table 1.

The labelling patterns which have been identified as discussed above for **2**, **3**, **5**, and **6** are consistent with the incorporation of $^{2}H_3{}^{13}CCOO^{-}Na^{+}$ as outlined in Scheme 1. This sequence incorporates the recent results of Murai and coworkers (10) which demonstrated that solavetivone (**7**) is an intermediate in the sequential biosynthesis of **2**, **6**, and **5**, while our earlier proposals (5, 6, 9) suggested possible separate pathways to **2**, **5**, and **7**. The intervention of **7** and related intermediates, either before or after its generation,[5] provides an opportunity for hydrogen exchange at C-1 and -3 which could account for somewhat lower levels of deuterium at these centres and the apparent enhancement of the C-1 signal in **2**, **5**, and **6** noted above. The C-3 signal for **2** was not significantly enhanced relative to the remaining enriched centres, presumably because this carbon can be dideuterated in the initial farnesyl pyrophosphate precursor while C-1 is monodeuterated. Qualitatively, the deuterium content at C-1 is similar in **2**, **5**, and **6**, which implies that this centre is not involved in the **6** → **5** rearrangement. It must be emphasized that, in fact, a number of differently labelled MVA species will be involved because the labelled acetate precursor undoubtedly undergoes $^{1}H/^{2}H$ exchange in the acetate pool. In addition, one can expect that kinetic isotope effects may tend to disfavor incorporation of the more heavily deuterated species into MVA. As a consequence, some deuterium loss can be anticipated to occur during the sequence. Nevertheless in each case the absorption for C-5 was a pair of closely spaced singlets, one coinciding precisely with the signal found for natural abundance material and the second at slightly higher field, 0.05−0.09 ppm, clearly establishing the presence of deuterium at the neighboring C-4 centre. Deuterium originally bonded to C-5 has, therefore, migrated via a 1,2-hydride (deuteride) shift. This intramolecular migration, or "β-hop", is clearly revealed by these incorporation results.

This "β-hop" technique should prove useful as a general and unambiguous method for the detection of 1,2-hydride mi-

[5]It has been suggested, but not confirmed, that an isolubimin (**8**) is an intermediate between **7** and **2** (17).

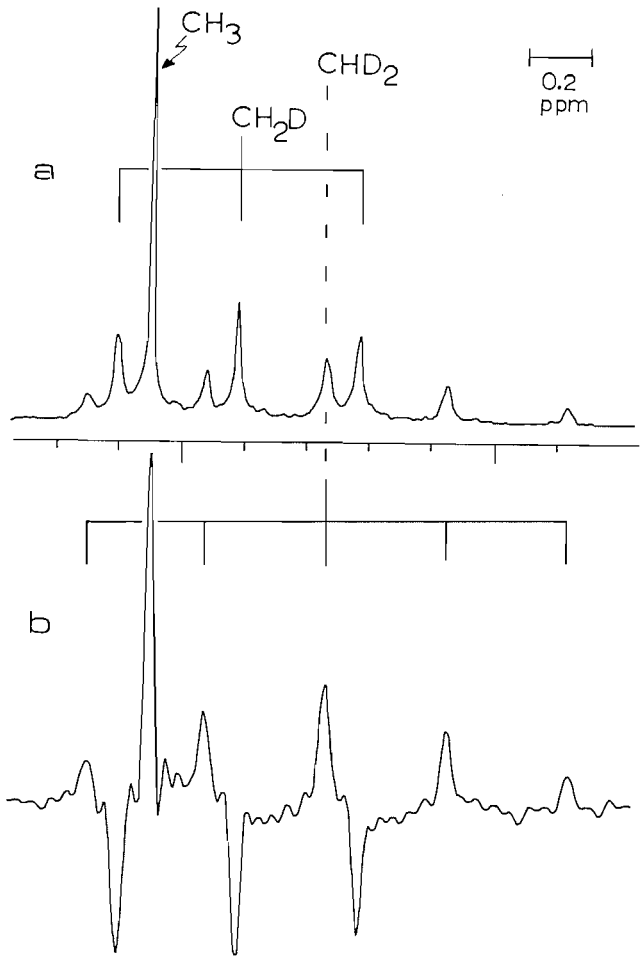

FIG. 2. The ^{13}Cmr absorption for C-13 (δ_C 21.1) in rishitin-$^2H_1$,$^{13}C_1$: (a) normal ^{1}H-decoupled spectrum, (b) the INEPT spectrum.

grations both in biosynthetic and mechanistic studies. Its applicability is by no means restricted to the incorporation of acetate; migration of deuterium from any —^{2}H^{13}C— unit to a contiguous carbon will give rise to the β-shift.

Experimental

General laboratory procedures were those described in earlier reports (9, 11, 12). The nmr spectra were obtained using a Varian XL-200 spectrometer operating at 30.7 (^{2}H) and 50.3 MHz (^{13}C) in the Fourier transform mode with 5 mm sample tubes containing 0.5 mL of solution in the solvents indicated.

Incorporation of [4,4-$^2H_2$]MVA into potato metabolites

Potatoes (25 kg; *cv.* Kennebec, aged 4 months at 4°C after harvest) were inoculated with a mycelial suspension (1.9 L) of *Alternaria solani* ATCC 44204 as described previously (9), incubated in the dark at room temperature for 24 h, and then treated with a solution (248 mL) containing (±)-[4,4-$^2H_2$]MVA (332 mg) available from an earlier study (11). After another 24 h, diffusates and loose necrotic tissue were collected and extracted with Et_2O (3 × half volume). Chromatography of the evaporated extract (330 mg) over SiO_2 (Camag DF5; 300 g) in MeOH/$CHCl_3$ (5:95 and 1:9) yielded the following compounds, identified by tlc behavior and nmr spectra.

Phytuberol (**4**), 3.9 mg after chromatography in Et_2O; ^{2}Hmr (C_6H_6): 1.5, 3.5 ppm.

Rishitin (**5**), 61 mg, before rechromatography in *i*-PrOH/EtOAc (5:95); ^{2}Hmr ($CHCl_3$): 2.15 ppm; ^{13}Cmr ($CDCl_3$): see Table 1.

15-Dihydrolubimin (**3**), 38.7 mg crude, 20.0 mg after recrystallization from Et_2O, mp 127–129°C; ^{2}Hmr ($CHCl_3$): 1.35; 2.25 ppm; ^{13}Cmr ($CDCl_3$): see Table 1.

Incorporation of [2-$^2H_3$,2-$^{13}C_1$]acetate into potato metabolites

In a similar experiment, potatoes (20 kg; *cv.* Sebago, stored at 4°C for 3 months after purchase in local market ca. 4 months after harvest) were inoculated with a spore suspension of *Monilinia fructicola* (2×10^5 spores/mL; ca. 800 mL), sodium [2-$^2H_3$-2-$^{13}C_1$]acetate (Merck Sharp & Dohme, Montreal, 98 at.% ^{2}H, 90 at.% ^{13}C-2; 413.5 mg (4.81 mmol) in H_2O (960 mL)) being added after 1 day. Incubation for a further day, extraction, and chromatography as before gave the following products.

Lubimin (**2**), 3.9 mg after rechromatography in MeOH/Et_2O (5:95); after determination of the ^{13}Cmr spectrum (see Table 1) this slightly impure sample was reduced with sodium borohydride (18) to the dihydro derivative **3**, mp 123–127°C, 1.3 mg after recrystallization from CCl_4; ^{13}Cmr ($CDCl_3$): see Table 1.

Rishitin (**5**), 20.6 mg after rechromatography in MeOH/Et_2O (5:95); ^{13}Cmr ($CDCl_3$): see Table 1.

3-Hydroxylubimin (**6**), 5.9 mg after rechromatography in *i*-PrOH/EtOAc 5:95. This product could not be crystallized but appeared chromatographically and spectroscopically pure; ^{13}Cmr ($CDCl_3$): see Table 1.

Comparative nitrosation of etintidine and cimetidine

THOMAS A. MONTZKA,[1] PETER F. JUBY, JOHN D. MATISKELLA, HENRY M. HOLAVA, AND R. R. CRENSHAW

Pharmaceutical Research and Development Division, Bristol-Myers Company, Syracuse, NY 13221–4755, U.S.A.

Received December 16, 1982

THOMAS A. MONTZKA, PETER F. JUBY, JOHN D. MATISKELLA, HENRY M. HOLAVA, and R. R. CRENSHAW. Can. J. Chem. **61**, 1771 (1983).

Etintidine (**4**), a new histamine H_2-receptor antagonist, was compared with cimetidine (**1**) for susceptibility to in vitro nitrosation at pH 1 and pH 3. Each agent formed two mono-*N*-nitrosoguanidine derivatives: *N*-cyano-*N'*-{2-[(5-methyl-1*H*-imidazol-4-yl)methylthio]ethyl}-*N''*-nitroso-*N''*-(2-propynyl)guanidine (**5**) and *N*-cyano-*N'*-{2-[(5-methyl-1*H*-imidazol-4-yl)methylthio]ethyl}-*N'*-nitroso-*N''*-(2-propynyl)guanidine (**6**) from etintidine and *N*-cyano-*N'*-methyl-*N''*-{2-[(5-methyl-1*H*-imidazol-4-yl)methylthio]ethyl}-*N'*-nitrosoguanidine (**2**) and *N*-cyano-*N'*-methyl-*N''*-{2-[(5-methyl-1*H*-imidazol-4-yl)methylthio]ethyl}-*N''*-nitrosoguanidine (**11**) from cimetidine. The *N*-nitroso derivative **5** from etintidine cyclized to 2-cyanoimino-3-{2-[(5-methyl-1*H*-imidazol-4-yl)methylthio]ethyl}-4-methylene-1-nitroso-imidazoline (**7**) at neutral or basic pH's. Both agents were nitrosated less at pH 3 than at pH 1, and at both pH's nitrosation of etintidine was considerably less than that of cimetidine. At pH 1, with a nitrite concentration about 150–500 times that expected in fasting human gastric juice, formation of **5** and **6** from etintidine was barely detectable (each <0.5%). Comments are made on the standard WHO conditions for investigating nitrosation of drugs.

THOMAS A. MONTZKA, PETER F. JUBY, JOHN D. MATISKELLA, HENRY M. HOLAVA et R. R. CRENSHAW. Can. J. Chem. **61**, 1771 (1983).

On compare l'étintidine (**4**), un nouvel antagoniste récepteur de H_2 de l'histamine, avec la cimétidine (**1**) du point de vue de la sensibilité à la nitrosation in vitro à des pH de 1 et de 3. Chaque agent donne deux dérivés de mono-*N*-nitrosoguanidine: la *N*-cyano-*N'*{[(méthyl-5 imidazol 1*H*-yl-4)méthylthio]-2 éthyl}-*N''*-nitroso-*N''* (propynyl-2) guanidine (**5**) et la *N*-cyano-*N'*{[(méthyl-5 imidazol 1*H*-yl-4)méthylthio]-2 éthyl}-*N'*-nitroso-*N''* (propynyl-2) guanidine (**6**) à partir de l'étintidine et la *N*-cyano-*N'*-méthyl-*N''* {[(méthyl-5 imidazol 1*H*-yl-4)méthylthio]-2 éthyl}-*N'*-nitrosoguanidine (**2**) et la *N*-cyano-*N'*-méthyl-*N''*{[(méthyl-5 imidazol 1*H*-yl-4)méthylthio]-2 éthyl}-*N''*-nitrosoguanidine (**11**) à partir de la cimétidine. Les dérivés nitroso **5** provenant de l'étintidine se cyclisent en cyanoimino-2{[(méthyl-5 imidazol 1*H*-yl-4)méthylthio]-2 éthyl}-3 méthylène-4 nitroso-1 imidazoline (**7**) à pH neutre ou basique. La nitrosation des deux agents est plus faible à un pH de 3 qu'à un pH de 1 et aux deux pH la nitrosation de l'étintidine est beaucoup plus faible que celle de la cimétidine. On décèle rarement la formation des produits **5** et **6** (chacun <0,5%) à partir de l'étintidine pH de 1 et pour une concentration en nitrite d'environ 150 à 500 fois plus grande que celle du suc gastrique humain à jeûn. On formule des commentaires sur les conditions normales WHO d'étude de la nitrosation des médicaments.

The question has arisen as to whether long-term treatment of disorders of the esophagus, stomach, and duodenum with cimetidine (**1**) might lead to the eventual development of gastric cancer (1). At the root of this concern are a number of factors which include the susceptibility of cimetidine to *N*-nitrosation in vitro (2, 3), the mutagenicity of *N*-nitrosocimetidine (4), the carcinogenic properties of many *N*-nitroso compounds in animals (5), the structural similarities between *N*-nitrosocimetidine (**2**) and the known animal carcinogen *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine (MNNG, **3**) (1, 2), the presence of nitrosating species in the stomach (6), and the possibility for levels of nitrosating species and total extractable gastric *N*-nitroso compounds to rise under conditions of lowered gastric acidity (7, 8). Speculation continues in spite of the findings that long-term studies of cimetidine in rats and dogs have revealed no signs of carcinogenesis (9), in vivo formation of *N*-nitrosocimetidine has not been reported, and there is no direct evidence to associate the development of cancer in man with exposure to *N*-nitroso compounds (6).

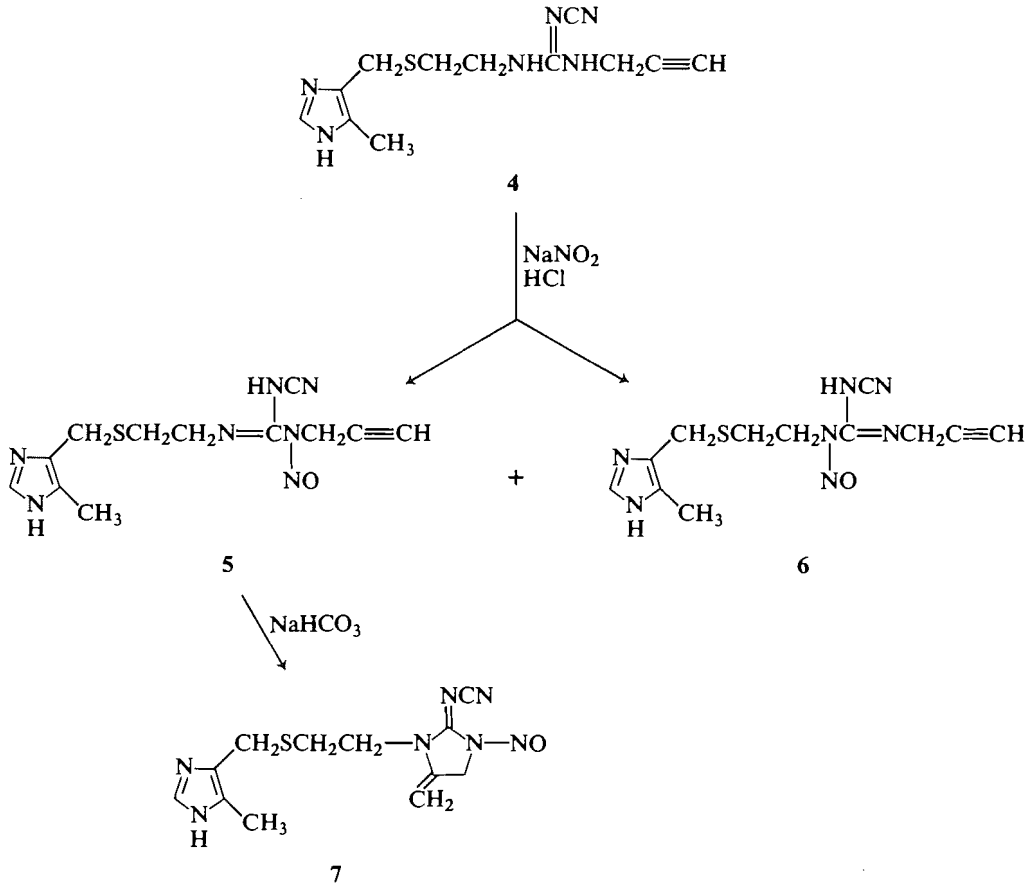
3

A new histamine H_2-receptor antagonist etintidine (BL-5641, **4**), with a potency approximately twice that of cimetidine, was recently reported from these laboratories (10). Because of the structural similarity between cimetidine (**1**) and etintidine (**4**), and because of a regulatory concern in the nitrosation issue, we have compared etintidine with cimetidine for their susceptibilities to *N*-nitrosation in vitro. This paper describes the results and our conclusions from this study.

Chemistry

The nitrosation of etintidine with excess sodium nitrite (4–10 equivalents) in 2 *N* hydrochloric acid gave three products (**5**, **6**, **7**) after neutralization and extraction as outlined in Scheme 1. The three products were separated and purified by

[1]Author to whom inquiries may be addressed.

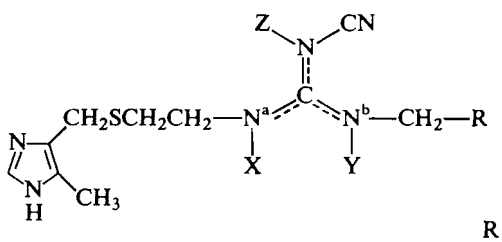


SCHEME 1. Nitrosation of etintidine

semipreparative hplc. The N^b-nitroso[2] compound **5** could not be obtained free from the imidazoline **7** except in acidic solution owing to its facile cyclization to **7** at neutral or basic pH.

The structural assignment for **6** is supported by elemental analysis, weak maxima in the 380–420 nm region of the uv spectrum (N—NO, $n \rightarrow \pi^*$) (11, 12), and consistent ^1H and ^{13}C nmr spectral data. In the ^1H nmr spectrum (see Table 1), the chemical shifts of the protons of both methylene groups adjacent to the guanidine nitrogens are shifted downfield compared to etintidine, with the methylene protons next to the N^a-NO (CH_2^a in Table 1) shifting further (0.73 ppm) than the propynyl methylene protons (CH_2^b in Table 1) (0.41 ppm). The propynyl methylene protons show as a sharp doublet resulting from coupling to the acetylenic hydrogen. No evidence of coupling to an N—H is seen, therefore we have assigned the tautomer as indicated by **6**. In the case of etintidine, both the CH_2^a and CH_2^b methylenes are coupled to adjacent NH's supporting the tautomer designated in **4**.

[2]For consistency and ease of specifying related products, we have labeled the nitrogens N, N^a, N^b as indicated below:



R = H, —C≡CH
X,Y,Z, see Table 1

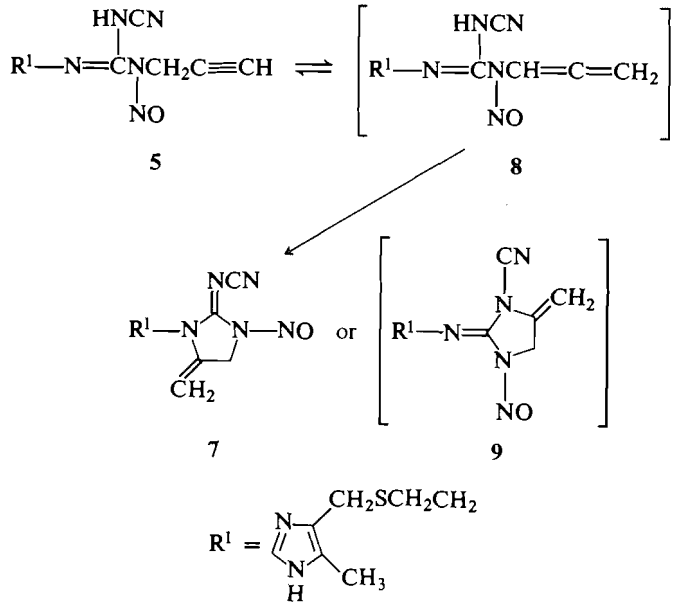
TABLE 1. ^1H nmr chemical shifts

	R	X	Y	Z	^1H nmr chemical shifts[a] CH_2^a	CH_2^b
4 (Etintidine)	C≡CH	H	H	—	3.36	4.00
5	C≡CH	—	NO	H	3.84	4.65
6	C≡CH	NO	—	H	4.09	4.41
1 (Cimetidine)	H	H	H	—	3.32	2.76
2	H	—	NO	H	3.72	3.25
11	H	NO	—	H	3.99	3.17

[a]The nmr spectra were run in DMSO-d_6. Chemical shifts are recorded in ppm relative to Me_4Si.

The structural assignment of **7** is based on ^1H nmr data (discussed below), elemental analysis, and ^{13}C nmr and uv spectra. The structure of **5** is supported by ^1H nmr data (see below) on a mixture of **5** and **7**, and by the ease of conversion of **5** to **7**. The ^1H nmr (360 MHz) spectrum of **7** in DMSO-d_6 shows the absence of the acetylenic proton (3.3–3.5 ppm region) and the presence of two exocylic olefinic protons at 4.82 ppm (1H) and 4.56 ppm (1H). On scale expansion these

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

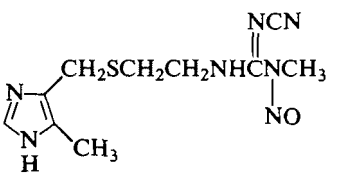


SCHEME 2

appear as narrow multiplets with small couplings to each other and very small long-range coupling to the endocyclic methylene protons. The endocyclic methylene protons appear as a singlet at 4.54 ppm (2H) which on scale expansion show as a very narrow multiplet due to long-range coupling to the olefinic protons. In the ^{1}H nmr spectrum of the mixture of **5** and **7**, the protons of both methylene groups adjacent to the guanidine group in **5** are shifted downfield compared to etintidine (see Table 1) with the methylene protons next to the N^b-NO (CH_2^b in Table 1) shifting further (0.65 ppm) than the methylene protons on the N^a-nitrogen (0.48 ppm).

The cyclization of **5** to **7** was demonstrated by hplc isolation and spiking experiments. A pure fraction of **5** in solution was obtained from reverse phase hplc using an acetonitrile–water–phosphate buffered (pH 4.0) mobile phase. In this solution (pH 4) no evidence of cyclization of **5** to **7** was observed (up to 1.5 hours). When this solution was treated with sodium bicarbonate, the conversion of **5** to **7** was complete in less than one hour. This cyclization may occur via the allene **8** (Scheme 2) (13). The nitrosation of the N^b-guanidine nitrogen activates the propynyl methylene protons so that under neutral or basic conditions the reversible isomerization of **5** to **8** occurs. Cyclization of **8** to **7** follows. Although we have indicated the cyclization to have occurred on the N^a-nitrogen (**7**), our data do not rule out the possibility of cyclization on the N—CN nitrogen to give **9**. We have not observed an analogous cyclization of either etintidine or **6**.

Previously, only one mono-*N*-nitrosated product of cimetidine, an N^b-nitroso derivative, appears to have been isolated and characterized (2, 3). This was indicated to have the tautomeric structure **10** (2). Because the nitrosation of etintidine



10

gave two mono-*N*-nitroso derivatives, we reexamined the nitrosation of cimetidine.

When cimetidine was nitrosated under similar conditions used for etintidine, two mono-*N*-nitroso products were isolated as indicated in Scheme 3. These products **2** and **11** were isolated in approximately 7:1 ratio with the major product apparently the same as the previously described N^b-nitrosated compound **10** (2). Compound **10** has been shown to be a methylating agent, as would be expected if nitrosation had occurred on the N^b-nitrogen (2). The ^{1}H nmr spectra of both **2** and **11** show a downfield shift for the protons of the methyl and methylene groups attached to the cyanoguanidine nitrogens compared to cimetidine (see Table 1). In the case of the N^b-nitroso compound **2**, the methyl protons are shifted further (0.49 ppm) than the N^a-methylene protons (CH_2^a in Table 1) (0.40 ppm), and in the N^a-nitroso compound **11** the methylene protons (CH_2^a in Table 1) are shifted further (0.67 ppm) than the methyl protons (0.41 ppm) relative to cimetidine. Again, our tautomeric assignments are based on ^{1}H nmr. In **2** the CH_2^a is a sharp triplet not coupled to an NH and in **11** the N^b-methyl is a singlet. In the ^{1}H nmr of cimetidine, both the CH_2^a and the N^b-CH_3 are coupled to NH's, which is consistent with the tautomeric structure indicated by **1**.

We have not seen any evidence of a dinitrosated product, although recently a dinitrosated product has been reported when approximately 25 equivalents of $NaNO_2$ were used (14).

Comparative nitrosation of cimetidine and etintidine

It has been reported (3) that cimetidine was nitrosated <0.5% at pH 4 and 6% at pH 3 under the experimental conditions recommended (15) by a WHO study group for comparing nitrosatable drugs (10 mmol/L compound; 40 mmol $NaNO_2$; pH 3–4; 37°C; one and 4 hour reaction times). When the nitrosation was carried out at pH 1, 39–43% nitrosation occurred (3).

Our initial comparative nitrosation experiments were done in open reaction vessels at pH 1 using WHO recommended concentrations and temperature. The products were analyzed by hplc using a variable wavelength detector set at 220 nm (see Table 2). We found cimetidine was nitrosated rapidly, with peak nitrosation occurring in less than one hour (38% at 1/2 hour). Analysis of the reaction at 4 hours showed a significant loss of the nitrosated cimetidines (4% compared to 38% at 1/2 hour) and a corresponding increase in cimetidine (96% compared to 62% at 1/2 hour). Apparently the nitrosation of cimetidine is a reversible reaction, reversal occurring as nitrosation species are lost to the atmosphere from an open vessel (16). Consequently all subsequent comparative nitrosations were carried out in closed vials.

The nitrosation of cimetidine and etintidine was compared in closed vials, first using WHO recommended concentrations (10 mmol/L drug, 40 mmol/L $NaNO_2$), temperature, and time intervals at both pH 1 and pH 3. The results are summarized in Tables 3 and 4.

At pH 1 cimetidine was nitrosated 51–54% (Table 3) to give both N-nitrosated products **2** and **11** with the N^b-nitroso compound **2** predominant by a factor of 12 at one hour and 6 after 4 hours. Etintidine at pH 1 was nitrosated 6–13% (Table 3) to give both **5** and **6**. About equal amounts of **5** and **6** were present after 4 hours. None of the cyclic material **7** was observed at this pH. The major difference was the amount of the N^b-nitrosoetintidine **5** formed (4–8%) as opposed to the amount of N^b-nitrosocimetidine **2** formed (45–48%). The N^a-nitrosated

[c]Compared to peak height of zero time hplc.

derivatives (**6**, **11**) appeared to form about equally though again etintidine may possibly form less N^a-nitroso product.

At pH 3 (Table 4) both cimetidine and etintidine were nitrosated considerably less than at pH 1. Only 4% of the major nitrosation product **2** of cimetidine was formed while the minor isomer **11** was barely detectable (0.6%) at 4 hours. Both *N*-nitroso products of etintidine were barely detectable (<0.5%).

When, however, the concentration of nitrite at pH 1 was reduced to 2 mmol/L and that of cimetidine or etintidine to 0.5 mmol/L, thus retaining the recommended 4:1 drug/nitrite molar ratio, the mononitroso products **2** and **11** of cimetidine were formed in only 4.5 and 0.9% yields, respectively (Table 3). The mononitroso products **5** and **6** of etintidine were barely detectable (each <0.5%, Table 3) at this lower concentration.

Discussion and conclusions

At pH 1 and 3 etintidine and cimetidine each formed two mono-*N*-nitrosoguanidine derivatives in vitro. Our results confirm that nitrosation of cimetidine decreases as the pH is raised (3) and show a similar effect of pH on nitrosation of etintidine.

At both pH 1 and 3 etintidine was nitrosated considerably less than cimetidine, and the extent of nitrosation of both compounds was dependent on the concentration of nitrite. Thus at pH 1, with the WHO recommended concentration of nitrite (40 mmol/L), nitrosation of etintidine was 6–13% compared to 51–54% for cimetidine. This nitrite concentration, however, is approximately 3 000–10 000 times that to be expected in fasting normal human gastric juice (17, 18) and about 140 times that after a nitrite rich meal (17). Reducing the nitrite concentration at pH 1 to a more reasonable level of 2 mmol/L, which is still about 150–500 times that to be expected in fasting normal human gastric juice (17, 18) and about 7 times that after a nitrite rich meal (17), total nitrosation of etintidine was less than 1% (barely detectable) compared to 5% for cimetidine. At pH 3 with 40 mmol/L nitrite, total nitrosation of etintidine was less than 1% compared to 1–5% cimetidine. Clearly, the extent of in vitro nitrosation of etintidine at both pH 1 and 3 under normal physiological nitrite concentrations would be small indeed and beyond our present limits of detection.

At pH 1 and 3 both etintidine and cimetidine were nitrosated on the N^a-cyanoguanidine nitrogen to a similar (small) extent, as might be predicted based on the similarity of environment. Etintidine was nitrosated on the N^b-cyanoguanidine nitrogen considerably less than cimetidine, probably the result of the greater electronic withdrawing and steric hindrance properties of the propynyl compared to the methyl group.

Standard WHO conditions for comparing nitrosatable drugs in vitro include a recommended pH range of 3–4, which, it is suggested, is optimal for most nitrosation reactions (15). This may be the case for secondary amines, but is not the case for cimetidine and etintidine, and may well not be the case for other amide, urea, or cyanoguanidine type compounds (6, 12). The pH range for testing should be extended down to 1, the lower limit being within the pH range of the human stomach (19).

Since N-nitrosation can be a readily reversible reaction (6) as has been shown for cimetidine, standardization (or statement) of reaction vessel conditions (open or closed) is important. Judging from the reasonably comparable percentage conversions of cimetidine to *N*-nitrosocimetidine attained by Bavin *et al.* (3) and ourselves, the former workers' experiments presumably were conducted in closed vessels/cells. Finally, perhaps the difficulties which have apparently been experienced in

attempts to isolate or identify *N*-nitrosocimetidine from the gastric juices of subjects receiving cimetidine (20) may have been compounded by this reversibility potential.

Experimental

Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected. Ultraviolet spectra were recorded on a Varian–Cary model 219 spectrophotometer over the range of 350–450 nm using 95% EtOH as solvent. The ^1H and ^{13}C nmr spectra were recorded on a Varian XL100 instrument or, when indicated, on a Bruker 360 MHz instrument. Chemical shifts were recorded in parts per million (δ) relative to Me_4Si as internal standard.

High pressure liquid chromatography (hplc) was performed using a Waters Associates M6000 pump and U6K loop injector and a LDC variable wavelength uv detector. The following columns, mobile phases, and wavelengths were used: (A) Alltech RSil $C_{18}HL$ (10 μ) (250 × 4.6 mm), 3:2 H_2O–MeCN, 220 nm; (B) Whatman Mag 9 Partisil-10 silica gel (500 × 9 mm), 20:1 MeCN – 95% EtOH, 254 nm; (C) Alltech RSil $C_{18}HL$ (10 μ) (250 × 4.6 mm), 2:1 H_2O–MeCN, 0.01 molar in H_3PO_4 adjusted to pH 4.0 with 20% NaOH, 220 nm; (D) Waters μ-Porasil silica gel (300 × 3.9 mm), 200:10:1 CH_2Cl_2 – 95% EtOH – conc. NH_4OH, 235 nm; (E) Waters μ-Bondapak C_{18} (10 μ) (300 × 3.9 mm), 8:1 H_2O–MeCN, 0.01 molar in H_3PO_4 adjusted to pH 4.0 with 20% NaOH, 220 nm.

For the comparative nitrosation studies, the solutions were analyzed by hplc (5.0–10.0 μL injections) using peak height comparisons to known mixtures of starting materials and products. The data in Tables 3 and 4 are the average of 3 or more hplc determinations. Because the N^b-nitrosoetintidine (**5**) was not obtained pure, the value for **5** was determined assuming a similar uv response (220 nm) for **5** and **6** and this accounts for the ranges (estimated) given in Table 3.

*Nitrosation of etintidine (BL-5641) (**4**)*

A solution of **4** (1.6 g, 5.8 mmol) in 50 mL H_2O and 10 mL concentrated HCl was treated in portions with $NaNO_2$ (3.5 g, 50 mmol) over a period of 10 min. This solution was stirred 30 min at 20°C and then added to a stirred mixture of EtOAc (100 mL), $NaHCO_3$ (15 g), and H_2O (60 mL). The two layers were separated and the aqueous layer extracted further with EtOAc (2 × 75 mL). The dried (Na_2SO_4) extracts were concentrated to leave an amorphous foam (1.8 g). The hplc (A) analysis of this material indicated three products, **5** (*k'* 4.3), **6** (*k'* 2.7), **7** (*k'* 3.6), and starting material **4** (*k'* 2.6). These materials were separated by semi-preparative hplc (B) and characterized as indicated below.

*N-Cyano-N'-{2-[(5-methyl-1H-imidazol-4-yl)methylthio]ethyl}-N'-nitroso-N''-(2-propynyl)guanidine (**6**)*

The first material off the hplc was identified as **6** and was obtained as a viscous oil containing MeCN (0.25 mol): uv λ: 390 nm (shoulder), λ_{max}: 402 (ε 155), λ 420 (shoulder); ^1H nmr (Me_2SO-d_6) δ: 7.57 (s, 1H, imidazole H), 4.41 (d, 2H, N—CH_2—C≡), 4.09 (t, 2H, CH_2—CH_2—NNO), 3.73 (s, 2H, imidazole CH_2—S), 3.44 (t, 1H, ≡CH), 2.60 (appears to be triplet for S—CH_2—CH_2 under Me_2SO peaks), 2.24 (s, 3H, imidazole CH_3), 2.17 (s, 0.75 H, CH_3CN); ^{13}C nmr (Me_2SO-d_6) δ: 155.5 (N—C(=N)—N), 133.2 (C-2 imidazole), 129.3 and 124.8 (C-4 and C-5 imidazole), 113.7 (C≡N), 78.7 (CH_2—C≡C), 74.8 (C≡CH), 42.2 (imidazole CH_2—S), 32.0, 26.8, 25.9 (N—CH_2CH_2S and N—CH_2—C≡), 9.6 (imidazole CH_3). *Anal.* calcd. for $C_{12}H_{15}N_7OS \cdot 0.25(C_2H_3N)$: C 47.46, H 5.03, N 32.18; found: C 47.13, H 5.40, N 31.89.

*N-Cyano-N'-{2-[(5-methyl-1H-imidazol-4-yl)methylthio]ethyl}-N''-nitroso-N''-(2-propynyl)guanidine (**5**)*

The second material off the hplc was identified as **5**. Very careful fraction cutting was required to separate **5** from the starting material **4** which came off the hplc immediately after **5**. Material **5** was obtained free of starting material, but was not obtained free from **7** since concentration of the hplc fractions of **5** always resulted in partial cyclization of **5** to **7** (see below); ^1H nmr (on mixture of **5** and **7**) (Me_2SO-d_6) δ: 7.47 (s, imidazole H (**5** and **7**)), 4.83 (m, one of =CH_2 (**7**)), 4.65 (d, N(NO)CH_2C≡ (**5**)), 4.55 (d, other =CH_2 and endocyclic CH_2 (**7**)), 3.84 (2 overlapping t, CH_2—CH_2—N (**5** and **7**)), 3.75 (s, imidazole CH_2—S (**7**)), 3.76 (s, imidazole CH_2S (**5**)), 3.32 (t, ≡CH (**5**)), 2.81 and 2.73 (2 overlapping t, S—CH_2—CH_2 (**5** and **7**)), 2.18 and 2.19 (ss, imidazole CH_3 (**5** and **7**)).

*2-Cyanoimino-3-{2-[(5-methyl-1H-imidazol-4-yl)methylthio]ethyl}-4-methylene-1-nitrosoimidazoline (**7**)*

The fourth material isolated from the semi-preparative hplc was an amorphous solid identified as **7**; uv λ_{max}: 400 nm (ε 252), λ_{max}: 418 (ε 178); ^1H nmr (pyridine-d_5) δ: 7.88 (s, 1H, imidazole H), 5.02 (q, 1H, one of =CH_2), 4.59 (d, 3H, other =CH_2 and endocyclic CH_2),

4.06 (s) and 4.02 (t) (4H, imidazole CH_2—S and CH_2CH_2-N), 2.98 (t, 2H, S—CH_2—CH_2), 2.38 (s, 3H, imidazole CH_3); ^{1}H nmr (Bruker; Me_2SO-d_6) δ: 7.52 (s, 1H, imidazole H), 4.82 (m, 1H, one of =CH_2), 4.56 (m, 1H, other =CH_2), 4.54 (s, 2H (narrow multiplet on scale expansion), endocyclic CH_2), 3.85 (t, 2H, CH_2CH_2N), 3.74 (s, 2H, imidazole CH_2S), 2.72 (t, 2H, S—CH_2—CH_2), 2.18 (s, 3H, imidazole CH_3); ^{13}C nmr (Bruker; Me_2SO-d_6) δ: 151.7 (s, N—C(=N)—N), 136.1 (s, N—C(=CH_2)—), 133.2 (d, C-2 imidazole), 129.7 and 126.0 (ss, C-4 and C-5 imidazole), 113.0 (C≡N), 88.0 (t, C=CH_2), 47.0 (t, endocyclic CH_2), 41.5 (t, imidazole CH_2—S), 26.7 (tt, S—CH_2CH_2—N), 9.76 (q, CH_3). *Anal.* calcd. for $C_{12}H_{15}N_7OS$: C 47.20, H 4.95, N 32.11; found: C 46.84, H 4.90, N 32.34.

Cyclization of ***5*** *and* ***7*** (analytical hplc detection)

A. The mixture of **5** and **7** from above was dissolved in Me_2SO + MeCN and treated with 2 drops of dilute $NaHCO_3$. The reaction was followed by hplc (C). The hplc indicated complete conversion of the **5** to **7** within 1 h.

B. A pure fraction (in solution) of **5** was isolated from the analytical hplc (C). Reanalysis of a portion of this solution both immediately and after 1.5 h showed only **5**. Treatment of this pure fraction with a few drops of dilute $NaHCO_3$ converted **5** completely to **7** within 1 h (identity by hplc spiking).

*Nitrosation of cimetidine (**1**)*

A solution of **1** (1.26 g, 5 mmol) in water (50 mL) and concentrated HCl (10 mL) was treated in portions with $NaNO_2$ (3.5 g, 50 mmol) over 10 min. The reaction was stirred for 0.5 h at room temperature (20°C). The reaction was diluted with water (60 mL), layered with EtOAc (100 mL), and neutralized with $NaHCO_3$ (15 g). The layers were separated and the aqueous layer was extracted with additional EtOAc (2 × 75 mL). The EtOAc extracts were dried (Na_2SO_4) and concentrated to a yellow gum (1.3 g). The hplc (D) analysis indicated two products (**2** (k' 1.0) and **11** (k' 1.43); 7:1 ratio) and some starting material (k' 3.43). These products were separated by preparative hplc (Waters Associates Prep LC 500A; one PrepPAK-500/silica column; elution with 200:2:1 CH_2Cl_2 – 95% EtOH – conc. NH_4OH; 200 mL/minute) and characterized as indicated below.

N-*Cyano*-N′-*methyl*-N″-*{2-[(5-methyl-1*H*-imidazol-4-yl)methylthio]-ethyl}*-N′-*nitrosoguanidine* (***2***)

The first material eluted was the major product, identified as **2**, mp 112–114°C dec. (from MeCN) (lit. (2) mp 112–113°C); uv λ: 385 nm (shoulder), λ_{max}: 397 (ε 200), λ: 414 (shoulder). ^{1}H nmr (Me_2SO-d_6) δ: 7.42 (s, 1H, imidazole H), 3.72 (s and t, 4H, imidazole CH_2—S and CH_2CH_2N), 3.25 (s, 3H, N—CH_3), 2.78 (t, 2H, S—CH_2—CH_2), 2.14 (s, 3H, imidazole CH_3); ^{13}C nmr (Me_2SO-d_6) δ: 156.1 (N—C(=N)—N), 133.2 (C-2 imidazole), 129.4 and 125.0 (C-4 and C-5 imidazole), 114.2 (C≡N), 42.3 (imidazole CH_2—S), 31.0 (N—CH_3), 29.7 and 26.3 (S—CH_2CH_2—N), 9.7 (imidazole CH_3). *Anal.* calcd. for $C_{10}H_{15}N_7OS$: C 42.69, H 5.37, N 34.85; found: C 42.68, H 5.36, N 34.73.

N-*Cyano*-N′-*methyl*-N″-*{2-[(5-methyl-1*H*-imidazol-4-yl)methylthio]-ethyl}*-N″-*nitrosoguanidine* (***11***)

The second material eluted was the minor product, identified as **11**, mp 128–131°C dec. (from MeCN); uv λ: 385 nm (shoulder), λ_{max}: 402 (ε 163), λ: 418 (shoulder); ^{1}H nmr (Me_2SO-d_6) δ: 7.60 (s, 1H, imidazole H), 3.99 (t, 2H, CH_2CH_2—NNO), 3.68 (s, 2H, imidazole CH_2—S), 3.17 (s, 3H, N—CH_3), 2.5 (appears to be triplet for S—CH_2—CH_2 under Me_2SO peaks), 2.18 (s, 3H, imidazole CH_3); ^{13}C nmr (Me_2SO-d_6) δ: 155.9 (N—C(=N)N), 133.2 (C-2 imidazole), 129.2 and 124.8 (C-4 and C-5 imidazole), 114.2 (C≡N), 41.9 (imidazole CH_2—S), 29.4 (N—CH_3), 26.9 and 26.0 (S—CH_2CH_2—N), 9.7 (imidazole CH_3). *Anal.* calcd. for $C_{10}H_{15}N_7OS$: C 42.69, H 5.37, N 34.85; found: C 42.86, H 5.08, N 34.95.

Nitrosation of cimetidine at pH 1 (open reaction vessel)

A suspension of **1** (139 mg, 0.55 mmol) in 50 mL H_2O was adjusted to pH 1.0 with concentrated HCl. The final volume was adjusted to 55 mL with H_2O. This solution was warmed to 36°C and 5.0 mL withdrawn for reference hplc sample. The remaining solution was treated with $NaNO_2$ (138 mg, 2.0 mmol). The temperature was held constant at 36–37°C. The pH fell to 0.93 during the first hour of reaction and was readjusted to 1.0 with 20% NaOH. No further adjustment was needed (pH range 0.98–1.0). The reaction was analyzed by hplc (E) at 0.5 h, 1 h, and 4 h (5.0 mL reaction solution diluted to 50.0 mL with H_2O for analysis). The results are summarized in Table 2.

Comparative nitrosation of etintidine and cimetidine at pH 1

*Etintidine (**4**) (40 mmol/L $NaNO_2$)*

A solution of **4** hydrochloride (172 mg, 0.55 mmol) in 50 mL H_2O was adjusted to pH 1.0 with 3 *N* HCl (about 4.5 mL required). Additional H_2O was added to obtain a volume of 55 mL. This solution was warmed to 35°C and 5.6 mL was withdrawn for reference hplc samples.[3] The remaining solution was treated with $NaNO_2$ (138 mg, 2.0 mmol). The pH remained at 1.0 so that no adjustment was necessary. Two sample vials were filled, sealed, and heated in an oil bath maintained at 37–38°C. At 1 h, 2.6 mL of one of the vials was diluted to 25.0 mL with H_2O and analyzed by hplc (C). At 4 h, 2.6 mL of the other vial was diluted to 25.0 mL with H_2O and analyzed by hplc. The results are summarized in Table 3.

*Cimetidine (**1**) (40 mmol/L $NaNO_2$)*

A suspension of **1** (141 mg, 0.55 mmol) in 50 mL H_2O was adjusted to pH 1.0 with 3 *N* HCl (about 5 mL required). This solution was warmed to 35°C and 5.6 mL was withdrawn for reference hplc samples.[3] The remaining solution was treated with $NaNO_2$ (139 mg, 2.0 mmol). The pH remained at 1.0 so that no adjustment was required. Two sample vials were filled, sealed, and heated in an oil bath maintained at 37–38°C. At 1 h, 2.6 mL of one vial was diluted to 25.0 mL with H_2O and analyzed by hplc (E). At 4 h, 2.6 mL of the other vial was diluted to 25.0 mL and analyzed by hplc. The results are summarized in Table 3.

*Etintidine (**4**) (2 mmol/L $NaNO_2$)*

A solution of **4** hydrochloride (156 mg, 0.5 mmol) in 990 mL H_2O was adjusted to pH 1.0 with concentrated HCl.[3] To this solution was added $NaNO_2$ (138 mg, 2.0 mmol). The pH remained at 1.0. Two sample vials were filled, sealed, and heated in an oil bath maintained at 37–38°C. At 1 h, the solution in one of the vials was analyzed by hplc (C). At 4 h, the solution in the other vial was analyzed by hplc. The results are summarized in Table 3.

*Cimetidine (**1**) (2 mmol/L $NaNO_2$)*

A suspension of **1** (126 mg, 0.5 mmol) in 990 mL H_2O was adjusted to pH 1.0 with concentrated HCl.[3] To this solution was added $NaNO_2$ (138 mg, 2.0 mmol). The pH remained at 1.0. Two sample vials were filled, sealed, and heated in an oil bath maintained at 37–38°C. At 1 h, the solution in one of the vials was analyzed by hplc (E). At 4 h, the solution in the other vial was analyzed. The results are summarized in Table 3.

Comparative nitrosation of etintidine and cimetidine at pH 3

*Etintidine (**4**)*

A solution of **4** hydrochloride (174 mg, 0.56 mmol) and NaCl (128 mg, 2.19 mmol) in 55 mL 0.05 *M* H_3PO_4 was adjusted to pH 3.0 with 20% NaOH. This solution was warmed to 35°C and 5.6 mL was withdrawn for reference hplc samples.[3] The remaining solution was treated with $NaNO_2$ (140 mg, 2.0 mmol). The pH was readjusted to 3.0 with 40% H_3PO_4. Two sample vials were filled, sealed, and heated in a oil bath maintained at 37–38°C. At 1 h, 2.6 mL of one of the vials was diluted to 25.0 mL with H_2O and analyzed by hplc (C). At 4 h, 2.6 mL of the other vial was diluted to 25.0 mL with H_2O and analyzed by hplc. The results are summarized in Table 4.

*Cimetidine (**1**)*

A solution of **1** (140 mg, 0.55 mmol) and NaCl (164 mg, 2.8 mmol)

[3]In all cases the starting solution was analyzed at zero time and after heating in a sealed vial at 37°C for 4 h. Cimetidine was stable at both pH 1 and pH 3. Etintidine was stable at pH 3 but decomposed slightly (~5%) after 4 h at pH 1 and 37°C.

in 55 mL 0.05 *M* H_3PO_4 was adjusted to pH 3.0 with 20% NaOH. This solution was warmed to 35°C and 5.6 mL was withdrawn for reference hplc samples.[3] The remaining solution was treated with $NaNO_2$ (140 mg, 2.0 mmol). The pH was readjusted to 3.0 with 40% H_3PO_4. Two sample vials were filled, sealed, and heated in an oil bath maintained at 37–38°C. At 1 h, 2.6 mL of one of the vials was diluted to 25.0 mL with H_2O and analyzed by hplc (E). At 4 h, 2.6 mL of the other vial was diluted to 25.0 mL with H_2O and analyzed by hplc. The results are summarized in Table 4.

Electronic spectral study of amino-acid complexes of Nd(III)

ASHOK KOTHARI AND SUDHINDRA N. MISRA
Department of Chemistry, University of Jodhpur, Jodhpur-342001, India

Received April 6, 1982[1]

ASHOK KOTHARI and SUDHINDRA N. MISRA. Can. J. Chem. **61**, 1778 (1983).

Neodymium(III) complexes with histidine and diols (ethanediol, prop-1,2-diol, but-2,3-diol, 2-butene-1,4-diol, pent-1,5-diol, and hex-1,6-diol) of the type MAB, MA_2B, and MAB_2 have been synthesized and characterised. The values of Slater–Condon (F_k), Lande' (ζ_{4f}) spin orbital interactions, oscillator strength (P), and Judd–Ofelt (T_λ) intensity parameters have been calculated. Using these parameters, energies and intensities of ten levels in all the complexes in the region 360–920 nm have been computed. The agreement between the computed and experimental values is good. Using F_2 values, the nephelauxetic ratio β, and bonding parameter $b^{1/2}$ have been calculated, these infer the incidence of some covalent character in these complexes.

ASHOK KOTHARI et SUDHINDRA N. MISRA. Can. J. Chem. **61**, 1778 (1983).

On a synthétisé et caractérisé des complexes du néodyme(III) avec l'histidine et des diols (éthanediol, propanediol-1,2, butanediol-2,3, butène-2 diol-1,4, pentadiol-1,5 et hexadiol-1,6). Ces complexes sont du type MAB, MA_2B et MAB_2. On a calculé les valeurs de Slater–Condon (F_k), les interactions d'orbitale de spin (ζ_{4f}) de Lande, la force de l'oscillateur (P) et les paramètres d'intensité de Judd–Ofelt (T_λ). A partir de ces paramètres on a calculé les énergies et les intensités de 10 niveaux pour tous les complexes dans la région de 360–920 nm. Il existe un bon accord entre les valeurs calculées et expérimentales. En utilisant les valeurs de F_2 on a calculé le rapport néphélauxétique β et le paramètre de liaison $b^{1/2}$ qui impliquent l'incidence d'un certain caractère covalent dans ces complexes.

[Traduit par le journal]

Introduction

The absorption spectra of complexed rare earth ions in the $f \leftrightarrow f$ transition region have been studied by various workers to give information regarding the structure and composition of the complexes (1–11). The present investigation was undertaken with a view to make the comparative study of various energy and intensity parameters for different energy levels of Nd(III) ternary complexes containing both oxygen and nitrogen donor ligands. Histidine, a functional amino acid, is well known as a proton donor, proton acceptor, and a nucleophilic reagent.

The values of various electronic spectral parameters like Slater–Condon (F_k), Lande' (ζ_{4f}), oscillator strength (P), Judd–Ofelt (T_λ), nephelauxetic ratio (β), and bonding ($b^{1/2}$), which give useful information regarding interelectronic repulsion, spin–orbit interaction, nephelauxetic effect, and bonding in the complexes, have been computed by using a partial multiple regression method (12).

Experimental

L-Histidine monohydrochloride and diols (ethanediol, prop-1,2-diol, but-1,3-diol, 2-butene-1,4-diol, pent-1,5-diol, and hex-1,6-diol) were obtained from Fluka A. G. and B.D.H. Ltd., and neodymium chloride (99.9%) from Indian Rare Earths Ltd.. The complexes have been synthesized in the molar ratio 1:1:1, 1:2:1, and 1:1:2 by a reported method (13) and were characterized by elemental and infrared spectral analysis.[2]

The absorption spectra of the complexes were recorded on Carl-Zeiss Spectrophotometer in the 360–920 nm region in methanol. The recorded spectra was photographically expanded to locate the energies of the transition using glass prism. The energies recorded in wavelength have been reported in wave numbers.

Results and discussion

(i) Energy parameters

The energy levels of various transitions were obtained experimentally as well as computed by using the following relationship:

$$[1]\quad E_j(F_k, \zeta_{4f}) = E_{oj}(F_k^0, \zeta_{4f}^0) + \sum_{k=2,4,6}\left(\frac{\partial E_j}{\partial F_k}\right)\Delta F_k + \left(\frac{\partial E_j}{\partial \zeta_{4f}}\right)\Delta\zeta_{4f}$$

where E_{0j} is the zero-order energy (14) of the jth level putting the observed energy value E_j and zero-order energy value and the partial derivatives for the free ion, F_2, F_4, F_6, and ζ_{4f} have been computed by using the partial multiple regression method (12).

In most of the cases of the parameters F_k and ζ_{4f} of Nd(III) complexes exhibit a decrease from the corresponding values of the Nd(III) free ion. The decrease in the interelectronic repulsion and spin–orbit interaction indicates the expansion of the central metal ion orbital on complexation and is in accordance with the theory for the origin and the intensity of $f \leftrightarrow f$ transitions reported earlier.

The average value of F_4/F_2 for Nd(III) complexes ($\simeq$ 0.152) is larger than those calculated by using the Hartree Fock method ($\simeq$ 0.13) but they are nearer to the values for the free ion (0.1531). The same trend has been observed for the ratio F_6/F_2.

A comparison of the observed and calculated values of the energy levels (Tables 6–8) shows that the rms deviation between ±45.32 to ±71.04 indicates good results even though the radial eigenfunctions have been assumed to be hydrogenic and also best fit for the partial multiple regression method. Red shift of all the energy levels from that of the free ion supports complexation.

In Table 1 the Nd(III) complexes have been arranged in the decreasing order of nephelauxetic ratio (β) and increasing order of bonding parameter ($b^{1/2}$), with the exception in case of Nd(hist)$_2$2-butene-1,4-diol. The very low value of β and very high value of $b^{1/2}$ in the series is due to the presence of π-bonding in case of 2-butene-1,4-diol which might be responsible for the greater complexation (12). The positive val-

ues of $b^{1/2}$ indicate covalent bonding in the complexes. The small value of $b^{1/2}$ and small variation of it suggests that the 4*f*-orbitals are very slightly involved in the bonding of lanthanide complexes.

Spectral intensities

The experimental value of oscillator strength is obtained from:

$$[2]\quad P_{expt} = 4.318 \times 10^{-9} \int \epsilon(\nu)d\nu$$

where $\epsilon(\nu)$ is the molar extinction coefficient corresponding to energy ν in wave number. Theoretically the oscillator strength, P_{cal}, of the induced-dipole transition of energy ν (cm^{-1}) in accordance with Judd–Ofelt relation [1] can be expressed as:

$$[3]\quad P_{cal} = \sum_{\lambda=2,4,6} T_\lambda \nu (f^n\psi|U^{(\lambda)}|f^n\psi' J)^2$$

It has been found that, in general, the oscillator strength for Nd^{3+} complexes can be expressed in terms of T_4 and T_6 parameters only. But it is important to note that the effect of solvent or ligand on the intensity of a hypersensitive transition can be explained by T_2 parameters only.

The values of T_λ-parameters have been computed from the Judd–Ofelt expression by using the partial multiple regression method where the values of reduced matrix elements have been taken from Carnall *et al.* (2). For Nd(III) complexes the Judd–Ofelt relation is applicable in the present form:

$$[4]\quad P_{obs} = [U^{(2)}]^2\nu \times T_2 + [U^{(4)}]^2\nu \times T_4 + [U^{(6)}]^2\nu \times T_6$$

The nephelauxetic ratio (β) and bonding parameter ($b^{1/2}$), along with the ratios F_4/F_2, F_6/F_2, $\%^rF_2$, and $\%^r\zeta_{4f}$ which infer some covalency due to complexation have also been reported (Table 1).

The ratio of T_4/T_6 parameter is nearly constant for these complexes indicating the same symmetry of the complexes in solution (Table 2). It is important to note that the hypersensitive transition (which is sensitive to environmental changes), $^4G_{5/2} \leftarrow {}^4I_{9/2}$ exhibits the increase in the intensity with the increase in covalency of the complexes. The hypersensitivity has been found to be proportional to the nephelauxetic ratio (β).

Choppin *et al.* (15, 16) have suggested the strong inner sphere complexation in glycinate complexes. According to them, during the formation of these complexes the hydration sphere around lanthanides is disrupted completely by the amino acid moiety. Choppin and Henrie (8) at the same time believed that increase in the degree of innersphere complexation contributes towards the enhancement of intensity of intra $f \leftrightarrow f$ transitions. Contrary to this the observed intensities of these ternary complexes are very low ($P \sim 14.922 \times 10^{-6}$ to 19.188×10^{-6}) (Tables 3–5). No doubt amino acids are expected to form inner sphere complexes by forming an ionic linkage with carboxylic oxygen and an additional linkage due to the amino group. The infrared spectra in the solid state of these compounds also indicate inner sphere complexation but on dissolution it appears that amino group participation is delinked by the solvent effect and the amino acid binds itself with the metal ion as a zwitterion (17). The proton from the carboxylic group migrates towards the amino group and the oxygen of the carboxylic group links to the metal ion while the remaining amino acid molecule hangs in space. The classical zwitterion resonance form of the acid is promoted by the highly charged lanthanide ion. This in fact contributes a significant amount of electrondensity to the lanthanide ion. This might be one of the reasons why low intensities of these bands are observed in these complexes. In spite of significant contribution from inner

sphere complexation, it has been argued earlier (18) that the increase in the intensity of the hypersensitive transition is due to the lowering of the coordination number of the lanthanide. Infrared spectral patterns and analytical data indicate the presence of a varying number of water molecules in these complexes (1:1:1 = 4, 1:2:1 = 2, and 1:1:2 = 2).

The terdentate attachment of histidine and monofunctional bidentate attachment of the diol moiety along with a varying number of coordinated water molecules yield nona-coordinated environment around neodymium. The intensities of the transitions in complexes of different series are not varied to a great extent and can be interpreted in terms of the same coordination number of neodymium.

A slightly higher value for the intensities of bands was observed in MA_2B complexes containing a larger number of nitrogen coordinating sites. The MA_2B complexes also showed the comparatively higher magnitude of the nephelauxetic effect ($1 - \beta$) yielding higher magnitude for mixing coefficients (b).

A plot of νb^2 against P has given a linear correlation with a positive slope which suggests that the increase in the incidence of covalent character brings about the intensification of the bands.

Model compounds for biodegradation studies on hydrocarbon-type dielectric fluids

WILLEM HENDRIK BAARSCHERS AND MARIA ANGELA LI

Department of Chemistry, Lakehead University, Oliver Road, Thunder Bay, Ont., Canada P7B 5E1

Received November 9, 1982

WILLEM HENDRIK BAARSCHERS and MARIA ANGELA LI. Can. J. Chem. **61**, 1784 (1983).

The hydrocarbons 7-methylpentadecane (**1**, $n = 0$) and 7-methyl-9-*n*-hexyl heptadecane (**1**, $n = 1$) have been synthesized. These compounds are suitable as model compounds for biodegradation studies on mixtures of oligomers of 1-octene and related compounds which have been proposed as dielectric fluids for the replacement of PCB's. The synthesis confirms the feasibility of isotope labelling for such biodegradation studies.

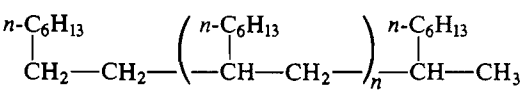
WILLEM HENDRIK BAARSCHERS et MARIA ANGELA LI. Can. J. Chem. **61**, 1784 (1983).

On a synthétisé le méthyl-7 pentadécane (**1**, $n = 0$) et le méthyl-7 *n*-hexyl-9 heptadécane (**1**, $n = 1$). Ces composés constituent des modèles convenables pour étudier la biodégradation des mélanges d'oligomères de l'octène-1 et des composés apparentés que l'on propose comme fluides diélectriques en remplacement du BPC. La synthèse confirme la possibilité de marquage isotopique dans les études de biodégradation.

[Traduit par le journal]

Introduction

A mixture of oligomers of 1-octene with average molecular weight 850 and general structure **1** ($n \approx 5.5$) has been described (1) and patented (2) as a dielectric fluid. This material, PAO-20E (Uniroyal Canada Ltd) is recommended as a suitable replacement for polychlorinated biphenyls. No study on the biodegradability of this material could be found in the literature to date. It was decided to approach such a study by means of model compounds such as the dimer (**1**, $n = 0$) and trimer



1

(**1**, $n = 1$) of 1-octene. Such an approach has some specific advantages.

Firstly, although many branched chain hydrocarbons are readily biodegradable (3), the sheer molecular size of products like PAO-20E (average $C_{60}H_{122}$) may well prevent biodegradation by microorganisms. Use of model compounds could not only determine if biodegradation of hydrocarbons with this particular branching pattern does take place, but also establish a possible limiting size in the homologous series **1**.

Secondly, the absence of functional groups prevents use of spectroscopic methods for the analysis of unchanged hydrocarbons in culture extracts and gas chromatography of compounds with this high a molecular weight is not feasible (4). The use of lower homologues **1**, which are expected to be readily eluted from conventional gas chromatography columns, would circumvent this difficulty.

Thirdly, metabolites of these branched hydrocarbons are expected to be aliphatic acids, alcohols, and esters (5), which would be difficult to distinguish from similar compounds produced by the natural metabolism of microorganisms (6). A synthetic method for model compounds **1** ($n = 0$ and $n = 1$) could be used for carbon isotope labelling, which in turn would allow for subsequent identification of metabolites by liquid scintillation counting or carbon-13 nuclear magnetic resonance.

The synthesis of compounds **1** ($n = 0$ and $n = 1$), some aspects of the characterization of compounds of this kind, and the feasibility of isotope labelling are discussed in this report.

The hydrocarbons 7-methyl-pentadecane (**1**, $n = 0$, also **5***f* in Scheme 1) and 7-methyl-9-*n*-hexyl-heptadecane (**1**, $n = 1$, also **7***d* in Scheme 1) were synthesized by repeated application of the malonic ester synthesis (7) and manipulation of functional groups as described below and summarized in Scheme 1.

Experimental

A Perkin–Elmer model 3920B dual column gas chromatograph with flame ionization detectors was used. Nitrogen was the carrier gas (25–35 mL/min) in glass columns (1.8 m, 2 mm id) packed with SE-30 silicone rubber gum (5%) or EGSS-X (10%) on Gaschrom Q, at temperatures from 120–240°C. (All column materials were from Chromatographic Specialties Ltd., Brockville, Ontario.)

Proton nmr spectra were recorded on a Bruker WP-80 spectrometer with deuterochloroform solutions containing tetramethylsilane as an internal standard at $\delta = 10$.

1-Bromohexane, 1-bromooctane, and cyclohexyl methanol (**8***a*) were used as supplied (Aldrich Chemical Co.) and diethyl malonate (**2**) was redistilled before use. Compounds **4** and **5** with R′ = *n*-C_4H_9 and **8***a* and *b* were prepared by methods similar to those used in the sequence **2** → **7***d* which is described for R′ = *n*-C_6H_{13} below.

Diethyl hexylmalonate **3**

Diethyl malonate (**2**, 16.11 g) was added to a solution of Na (2.29 g) in EtOH (50 mL) and 1-bromohexane was added to the clear solution. The mixture was refluxed (2.5 h), most of the solvent distilled off, and the residue dispersed in H_2O (40 mL). Extraction (CH_2Cl_2) and removal of the solvent gave a residue which was distilled at 16 Torr. Diethyl hexylmalonate (**3**, 20.12 g, 82%) was obtained as a colourless oil (bp 134–138°C) which was homogeneous on tlc and gc; ir: 1765 (ester) cm^{-1}; ms *m/e*: 244(M^+).

Diethyl hexyl-octylmalonate **4**a

Diethyl hexylmalonate (**3**, 17.9 g) in a solution of Na (2.93 g) in EtOH (50 mL) and 1-bromooctane (12.9 g) were allowed to react and the product was isolated as above. Diethyl hexyl-octylmalonate (**4***a*, 19.17 g, 80.6%) was obtained as a colourless oil with bp 182–186°C (12 Torr) which was homogeneous on tlc and gc; ir: 1760 cm^{-1}; ms *m/e*: 356(M^+).

Hexyl-octylmalonic acid **4**b

The diester (**4***a*, 19.17 g) was added to KOH (11.6 g) in H_2O (20 mL) and the mixture heated (90°C) for 5 h, cooled, acidified, and extracted with Et_2O. Removal of the solvent gave the diacid (**4***b*, 14.33 g, 88.4%) as white crystals, mp 73–85°C, which were characterized as the dianilide, mp 119.5°C; ir: 3495, 1700, 1540 cm^{-1}; ms *m/e*: 450(M^+). *Anal.* calcd. for $C_{29}H_{42}N_2O_2$: C 77.29, H 9.39, N 6.22; found: C 77.19, H 9.10, N 5.95.

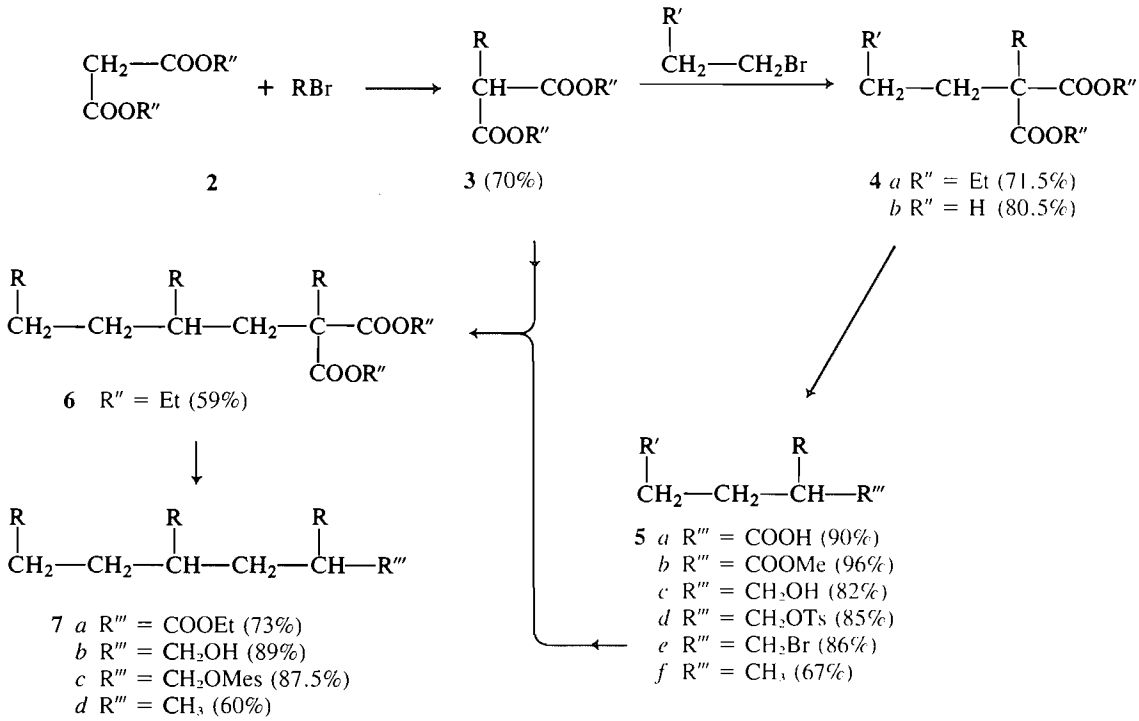

SCHEME 1. Syntheses of 7-methyl pentadecane (**5***f*) and 7-methyl-9-hexyl heptadecane (**7***d*). R = *n*-C_6H_{13}; R′ = *n*-C_6H_{13} or *n*-C_4H_9 (see discussion). Percentages in parentheses are averages of yields obtained in several trials in each reaction.

2-Hexyl-decanoic acid **5**a

The dicarboxylic acid (**4***b*) was decarboxylated in small portions by mixing 2.01 g with glass powder (1.72 g) and heating the mixture at 145°C for 3.5 h in N_2. Extraction (Et_2O) and removal of the solvent gave 2-hexyl-decanoic acid (**5***a*, 1.62 g, 95%) as a colourless oil, which was homogeneous on tlc and gc. The anilide had mp 78.0–78.5°C; ms *m/e*: 331(M^+). *Anal.* calcd. for $C_{22}H_{37}NO$: C 79.70, H 11.25, N 4.22; found: C 79.69, H 11.29, N 4.11.

Methyl 2-hexyldecanoate **5**b

Excess diazomethane in Et_2O was added to 2-hexyldecanoic acid (**5***a*, 10.8 g) in Et_2O and the mixture was stirred briefly. Evaporation of solvent and excess reagent left a residue which was filtered, in Et_2O, through silica gel to give the monoester **5***b* (9.6 g, 95%) which was homogeneous on tlc and gc; ir: 1750 cm^{-1}; ms *m/e*: 270(M^+).

2-Hexyl-1-decanol **5**c

Methyl 2-hexyldecanoate (11.44 g), dissolved in dry THF (20 mL) was added to LAH (1.36 g) in THF (30 mL), and the mixture was refluxed, with stirring, for 3 h. A saturated aqueous solution of Na_2SO_4 was added with cooling, and the resulting mixture was extracted with Et_2O. Removal of the solvent and filtration of the residue in Et_2O, through silica gel, gave 2-hexyl-1-decanol (**5***c*, 8.36 g, 82%) as a colourless oil, which was homogeneous on tlc and gc; ir: 3650 cm^{-1}; ^{1}Hmr δ: 3.55 (s, 1H) ppm; ms *m/e*: 224(M^+ − 18).

7-Methylpentadecane **5**f

To the alcohol (**5***c*, 5.30 g), in dry pyridine (30 mL), was added *p*-toluene sulfonyl chloride (5.10 g). The clear solution was kept at 0°C for 2 h and H_2O (30 mL) was added. The mixture was extracted with $CHCl_3$, the extracts washed (dilute H_2SO_4, H_2O, aqueous Na_2HCO_3, and H_2O), and the solvent removed. The residue, after filtration in $CHCl_3$ through silica gel, gave the tosyl ester **5***d* (7.34 g, 85%) as a colourless, homogeneous (tlc, gc) liquid; ir: 1190, 1200 cm^{-1}; ^{1}Hmr δ: 3.96 (s, 1H); ms *m/e*: 224(M^+ − HOTs). *Anal.* calcd. for $C_{23}H_{40}SO_3$: C 69.70, H 10.1; found: C 70.07, H 9.79. The tosylate (5.04 g) in DMSO (5 mL) was added to $NaBH_4$ (1.65 g) in DMSO (20 mL), the mixture refluxed for 2 h with stirring, diluted with H_2O, and extracted with Et_2O (3 × 25 mL). The combined extracts, after removal of the solvent, gave a residue which was chromatographed on silica gel. Elution with petroleum ether gave pure (tlc, gc) 7-methylpentadecane (1.96 g, 68.1%) as a colourless oil; ms *m/e*: 226(M^+). *Anal.* calcd. for $C_{16}H_{34}$: C 84.96, H 15.04; found: C 84.48, H 14.60.

7-(Bromomethyl)-pentadecane **5**e

2-Hexyl-1-decanol (5.07 g) was mixed with aqueous HBr (48%, 3.42 g) and the mixture was refluxed (4 h) while HBr gas was bubbled through. The mixture was extracted with benzene and the extract concentrated and filtered through silica gel. Removal of the solvent gave 7-(bromomethyl)-pentadecane (**5***e*, 6.11 g, 95.7%) as a yellow homogeneous (tlc, gc) oil; ^{1}Hmr δ: 3.39 (s, 1H) ppm; ms *m/e*: 306, 304(M^+).

Diethyl hexyl-(2-hexyldecyl)malonate **6**

Diethyl hexylmalonate (**3**, 5.49 g) was alkylated with 7-(bromomethyl)-pentadecane (6.67 g) as above. The crude product was chromatographed on silica gel. Elution with $C_6H_{12}/CHCl_3$ (1:1) gave the diester (**6**, 6.04 g, 59%) which was homogeneous on tlc and gc; ms *m/e*: 468(M^+).

Ethyl 2,4-dihexyldodecanoate **7**a

A mixture of the diester (**6**, 1.03 g), LiCl (0.18 g), DMSO (3.6 mL), and H_2O (0.4 mL) was refluxed for 4 h, poured into cold H_2O (15 mL), and extracted with hexane (8 × 25 mL). Removal of the solvent gave a residue which was chromatographed on silica gel, using $C_6H_{12}/CHCl_3$ (1:1) as eluent to give pure (tlc, gc) ethyl 2,4-dihexyldodecanoate (**7***a*, 0.63 g, 73%); ms *m/e*: 396(M^+).

2,4-Dihexyldodecanol **7**b

LAH reduction of the monoester **7***a* and work-up as described above for the ester **5***b* gave the alcohol **7***b* in 89% yield; ir: 3650 cm^{-1}; ^{1}Hmr δ: 3.50 (s, 1H) ppm; ms *m/e*: 336(M^+ − 18).

7-Methyl-9-hexyl-heptadecane **7**d

To 2,4-dihexyldodecanol (**7***b*, 0.5 g) in CH_2Cl_2 (7 mL) and trimethylamine (0.21 g) was added methanesulfonyl chloride (0.18 g) at −10°C, and the mixture stirred for 15 min. The mixture was washed successively with H_2O, cold 10% HCl, saturated Na_2CO_3 solution,

Examples of straight line plots of no. of carbon atoms/molecule vs. log retention time. 1, Diethyl esters **3**, **4**, and **6** (SE 30, 210°C). 2, Alcohols **5***c* (R′ = *n*-C_6H_{13} and R′ = *n*-C_4H_9) and **7***b* (EGSS-X, 170°C). 3, Hydrocarbons **5***f* (R′ = *n*-C_6H_{13} and R′ = *n*-C_4H_9) and **7***d* (SE 30, 190°C).

and H_2O. The organic layer was dried, the solvent removed, and the residue, in CH_2Cl_2, filtered through silica gel to give the mesylate **7***c* (0.53 g); ir: 1180, 1350 cm^{-1}. The mesylate **7***c* was reduced with LAH, as above, to give the hydrocarbon **7***d* (60%) as a colourless, homogeneous (tlc, gc) oil; ms *m/e*: 338(M^+).

8 *a* R‴ = CH_2OH
b R‴ = CH_2OTs
c R‴ = CH_2Br

The other compounds discussed (i.e. the series **5** with R′ = *n*-C_4H_9 and compounds **8***b* and *c*) were prepared and characterized by methods described above. Characteristic ^{1}Hmr data are summarized in Table 1 and gc retention characteristics are summarized in Fig. 1.

Results and discussion

7-Methyl-pentadecane (**1**, *n* = 0, also **5***f* in Scheme 1) has been described in the literature in discussions of insect chemistry (8) and photochemistry (9). An earlier synthesis (10) of this compound was based on the reaction of a Grignard compound with a ketone or a fatty acid ester. The malonic ester synthesis (11) would allow for the sequential synthesis of compounds **1** with increasing values of *n*, and is particularly attractive because of the ready availability of starting materials in view of future plans for the synthesis of isotope-labelled versions of **1**.

The manipulation of the various functional groups was achieved with standard reactions, described in the literature, with minor modifications. Thus, the three-step sequence (hydrolysis, decarboxylation, esterification) usually employed with substituted malonic esters gave good yields in the dimer series (**4***a* → **5***b*), but was unsatisfactory in the trimer series, where the conversion of **6** → **7***a* by decarbethoxylation (11) was superior. Similarly, the tosylate (**5***d*) could be prepared (12) and reduced to the dimer (**5***f*) in acceptable yields, but the use of the mesylate **7** (13) gave better yields in the trimer series.

All intermediate and final products were purified until they were homogeneous on thin-layer chromatography and on two different gas chromatography columns.

Characterization of some of the compounds had to be carried out indirectly. Traces of trapped solvent in samples too small for purification by distillation gave rise to unsatisfactory combustion analysis results. Also, the presence of a single functional group in large molecules with a predominantly hydrocarbon character greatly limited the usefulness of spectroscopic methods. While in some cases infrared spectra provided useful information (e.g. the conversion of the alcohols **5***c* and **7***b* (ν_{max} 3630 cm^{-1}) into the corresponding sulfonate esters (ν_{max} 1180, 1350, 1370 cm^{-1})), full characterization of most compounds was achieved by a combination of proton magnetic resonance spectroscopy and gas chromatography. The chemical shift of the single methine proton adjacent to the functional groups R‴ in compounds **5**, **7**, and the additional model compounds **8** is sufficiently sensitive to the nature of R‴. The δ-values, summarized in Table 1, leave no doubt to the identity of the alcohols (**5***c*, **7***b*, and **8***a*) and their conversions into the sulfonate esters (**5***d*, **7***c*, and **8***b*), which causes a downfield shift of 0.3–0.8 ppm, or conversion to the bromides (**5***e* and **8***c*) which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

causes an upfield shift of 0.15 ppm.

Additional evidence for characterization was obtained by preparing the compounds **4** and **5** with R′ = n-C_4H_9, which made available a sufficient number of compounds to utilize the linear relationship of the number of carbon atoms with the log of the gas chromatographic retention times (14). Together with the other spectroscopic evidence, the almost perfect straight-line fit of these relationships (see Fig. 1) provides for unambiguous characterization of all compounds.

Finally, with respect to planned biodegradation studies, this synthesis shows that the preparation of compounds labelled with carbon isotopes is quite feasible. From the yields obtained (see Scheme 1) it may be calculated that, starting with some 5 g of diethyl malonate, moderately enriched with either carbon-13 or carbon-14, a final yield of 0.9 g of labelled dimer (**5***f*) or 0.5 g of labelled trimer (**7***d*) may be expected. An additional 1.5 g of labelled diethyl malonate would be required for producing the trimer labelled at both tertiary carbons. Such quantities would be sufficient for conducting biodegradation studies with microorganisms so that isolated metabolites could be readily detected with liquid scintillation methods or to give significant signal enhancement in carbon-13 nuclear magnetic resonance spectra.

Preliminary biodegradation studies of unlabelled dimer **5***f* and trimer **7***d* with known hydrocarbon degraders such as *Saccharomycopsis lipolitica* (15), and carbon-13 nmr studies with some of the present compounds are in progress.

Received November 30, 1982

CHIU-MING WONG, WASIMUL HAQUE, HING-YAT LAM, KIRK MARAT, E. BOCK, and AI-QIAO MI. Can. J. Chem. **61**, 1788 (1983).

Two heteroanthracyclinones, namely 4-demethoxyxanthodaunomycinone (**29**) and its epimer 4-demethoxy-7-epixanthodaunomycinone (**30**), were synthesized using 2-acetyl-5,8-dimethoxytetralin (**12**) as starting material. Condensation of **12** with 2-methoxybenzoic acid followed by hydrolysis and oxidative cyclization gave xanthones **17** and **18** which were converted to **19** and **20** for the purpose of separation and structure assignment by dipole moment. Hydrolysis of **19** followed by alkylation with chloromethyl methyl ether and oxidation with molecular oxygen gave **26** and **27**, which on acid hydrolysis gave 4-demethoxyxanthodaunomycinone (**29**) and 4-demethoxy-7-epixanthodaunomycinone (**30**). Preliminary biological assays with MCF-7, a human breast cancer cell line, showed that both **29** and **30** were weakly active while daunomycinone, the aglycone of **2**, showed no activity under similar conditions.

CHIU-MING WONG, WASIMUL HAQUE, HING-YAT LAM, KIRK MARAT, E. BOCK et AI-QIAO MI. Can. J. Chem. **61**, 1788 (1983).

On a synthétisé deux hétéroanthracyclinones: la déméthoxy-4 xanthodaumycinone (**29**) et son épimère la déméthoxy-4 épi-7 xanthodaumycinone (**30**) en partant de l'acétyl-2 diméthoxy-5,8 tétraline (**12**). La condensation du composé **12** sur l'acide méthoxy-2 benzoïque, suivie d'une hydrolyse et d'une cyclisation oxydante conduit aux xanthones **17** et **18** que l'on transforme en composés **19** et **20** pour les besoins de séparation et d'identification de structure par le moment dipolaire. L'hydrolyse du composé **19** suivie de l'alkylation avec l'éther chlorométhyle méthyle et de l'oxydation subséquente du produit obtenu avec l'oxygène moléculaire donne les composés **26** et **27** qui par hydrolyse acide donnent accès à la déméthoxy-4 xanthodaunomycinone (**29**) et à la déméthoxy-4 épi-7 xanthodaunomycinone (**29**) et à la déméthoxy-4 épi-7 xanthodaunomycinone (**30**). Un essaie biologique préliminaire avec le MCF-7, une des cellules du cancer du sein, montre que les deux composés **29** et **30** sont faiblement actifs tandis que la daunomycinone, l'aglycone du composé **2** dans les mêmes conditions n'a aucune activité.

Introduction

The rewarding results of clinical application of some antitumor anthracyclines such as adriamycin (**1**), daunomycin (**2**), and carminomycin (**3**) and their simple derivatives are well documented (1). Efforts to improve the potency and efficacy of these first generation anthracycline antitumor drugs also met with encouraging results. Synthetic analogues such as 4-demethoxydaunomycin (**4**), 4-demethoxy-4′-deoxyadriamycin (**5**), and 4-demethoxy-11-deoxydaunomycin (**6**) are much more potent than the first generation natural anthracyclines (2, 3). However, both the synthetic and natural products are cardiotoxic and prolonged administration invariably leads to congestive heart failure (3).

Adriamycin and daunomycin bind strongly to chromosomal DNA (4), inhibiting its template function and mitotic process, causing the degeneration and destruction of cells. X-ray crystallography indicated that daunomycin molecules sit in the major groove of the DNA double helix intercalating successive base-pairs. The basic nitrogen atom of daunosamine together with the chromophore of the aglycone are involved in intercalation (5). The C-9 hydroxy and the acetyl groups are implicated to help stabilize the intercalation, possibly through hydrogen bonding, and inversion at C-7 prevents intercalation (6).

It was proposed that adriamycin stimulated the generation of superoxide in the heart cells, which have low superoxide dismutase activity. Accumulation of the highly toxic superoxide and hydrogen peroxide is responsible for the cardiotoxicity (7).

A reasonable suggestion linking the adriamycin molecule with the superoxide formation is that the quinone moiety of adriamycin may function as an electron acceptor, taking electrons from a specific site of the NADH dehydrogenase. The resulting semiquinone **7** then participates in a nonenzymatic redox reaction with molecular oxygen leading to superoxide and subsequent hydrogen peroxide formation (8). In addition, it is also possible that **7** may become an active precursor of the quinone methide (**8**) which is less likely to form when the quinone is strongly hydrogen-bonded with the C-6 phenolic function. Quinone methides are powerful alkylating and cytotoxic agents (9).

It is therefore reasonable to speculate that cardiotoxicity and intercalating and alkylating properties are three different characters of antitumor anthracycline antibiotics. Recently, adriamycin was found to exert its cytotoxic action by interaction with cell membrane (10). The mechanism of interaction is not known. Lipid peroxidation triggered by the formation of **7**, as suggested by Bachur (11), Hochstein (12), and Myres (13), could be responsible for the membrane damage. In this case, the quinone chromophore becomes responsible for the superoxide formation which in turn becomes responsible for both

cytoxicity and cardiotoxicity. Making heteroanthracyclines, such as 4-demethoxyxanthodaunomycin (**9**), 4-demethoxythioxanthodaunomycin (**10**), and 4-demethoxy-5-sulfoxodaunomycin (**11**), available could help clarify the origin of cardiotoxicity and cytotoxicity of anthracyclines.

Results and discussion

The tetracyclic xanthone skeleton of **9** was constructed using the versatile 2-acetyl-5,8-dimethoxy tetralin (**12**) (14) as starting compound. Condensation of the tetralin (**12**) with 2-methoxybenzoic acid in trifluoroacetic acid solution gave a mixture of two isomers **13** and **14**. The reaction temperature was maintained at 20–24°C. Below 15°C, the reaction was very slow and at 40°C, trifluoroacetylation of the tetralin (**12**) was a major reaction. The two isomers were separated by high performance liquid chromatography on silica and were characterized by ir, ^{1}Hmr, and ms. However, separation at this stage for preparative purposes is not practical. The isomeric mixture (**13** and **14**) was hydrolysed by aluminium chloride to the

phenols **15** and **16**; hydrolysis by trimethyl chlorosilane (15) or potassium cyanide in dimethylsulfoxide (16) gave only a mixture of partially demethylated products.

Oxidative cyclization of **15** and **16** by lead tetracetate gave the tetracyclic xanthones **17** and **18** in excellent yield. Large scale separation of **17** and **18** was accomplished easily by column chromatography of their corresponding dibenzyl ethers **19** and **20** on silica, followed by acid hydrolysis. Structure assignment to **19** and **20** based on spectroscopic data was inconclusive. However, the first isomer collected had a dipole moment of 3.5 D and was assigned structure **20**, the calculated value of which was 3.48 D. The second isomer collected from the column had a dipole moment of 4.1 D and was assigned structure **19**, the calculated value of which was 4.9 D. Dipole moments of **19** and **20** were calculated using the reported dipole moment of xanthone, 3.14 D (17), and published values for benzene solution group moments (18).

Oxidation of **19** by molecular oxygen in the presence of potassium *tert*-butoxide in *N*,*N*-dimethylformamide solution gave a good yield of the dihydroxyxanthone **21** (19). Attempts to form an isopropylidene derivative of, or to debenzylate **21** invariably led to aromatization of ring D (**23**). Oxidation of isomer **20** under similar conditions yielded the monohydroxylated xanthone (**24**) or the aromatized product (**22**) depending on the length of the oxidation process. However, methoxymethylation of **17** with chloromethyl methyl ether under proper conditions gave an excellent yield of **25** which, under similar oxidation conditions, gave **26** as the major product and **27** as the minor product. The *cis*-geometry of the C-7

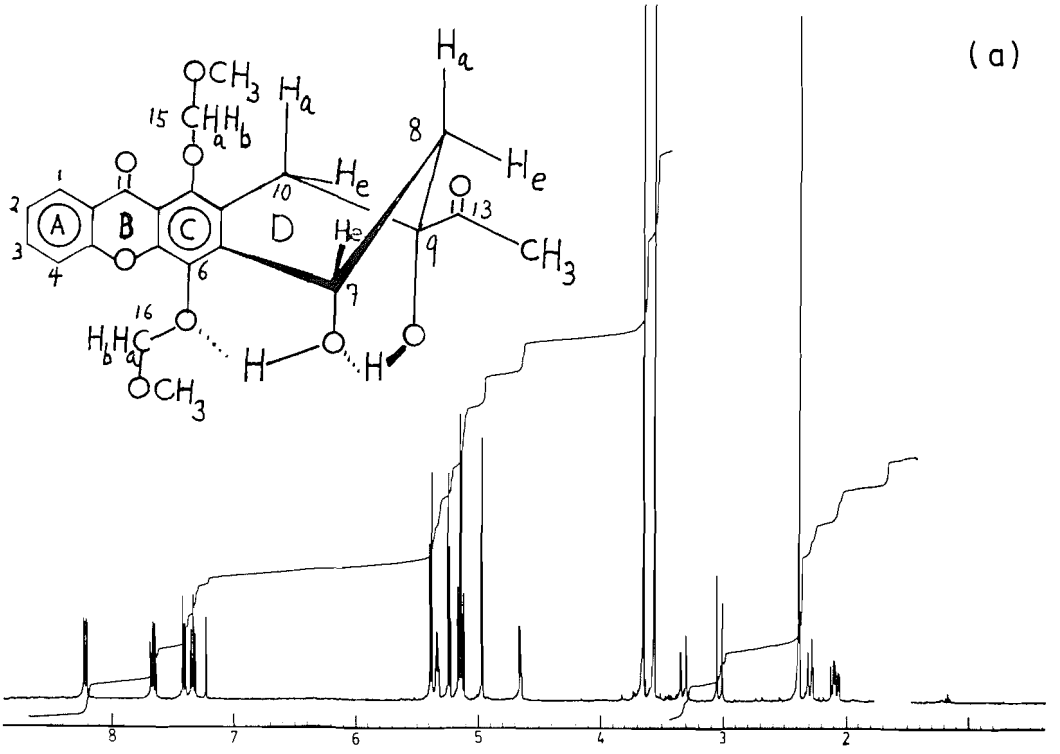

FIG. 1. (a)–(d) Bruker WH-400 ^{1}Hmr spectrum of **26** and the first order analysis of C_{15}, C_{16}, and D-ring protons. (a) Complete spectrum of **26** in $CDCl_3$.

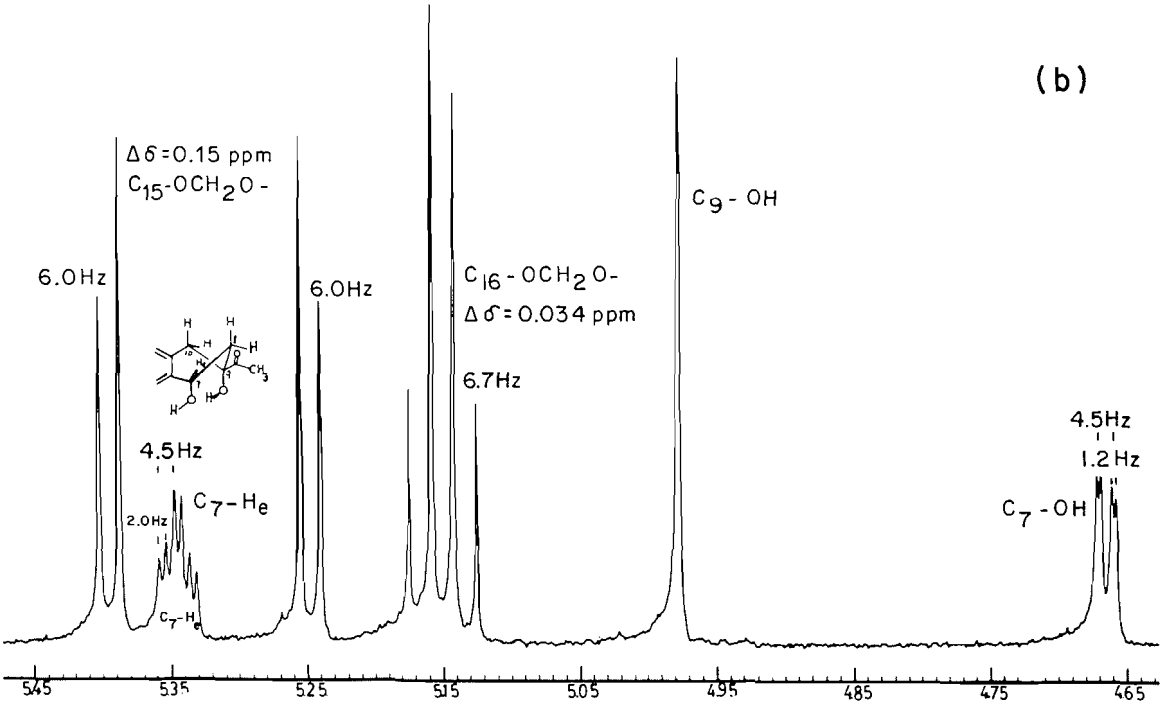

FIG. 1. (b) Expanded area between 4.65–5.45 ppm corresponding to C_7—H_e, C_7—OH, C_{15}—OCH_2O—, and C_{16}—OCH_2O—.

and C-9 hydroxy functions of **26** was established by detailed analysis of the high field ^{1}Hmr spectrum and computer simulated ^{1}Hmr spectrum of the D-ring of **26** (Figs. 1(a)–1(d) and 2).

The C_7—H_e appears as doublets of a triplet at 5.343 ppm. Its quasi-equatorial position is locked by the hydrogen-bond formation between the C_7—OH proton and the C_6-phenolic oxygen and revealed by the coupling constants. The $J_{7e,8a} = 4.5$ Hz corresponds to a dihedral angle of 45° and $J_{7e,8e} = 2.1$ Hz corresponds to a dihedral angle of 60°. The $J_{7e,7OH} = 4.6$ Hz corresponds to a dihedral angle of 40°, which agrees well with the H—O—C_7—H angle when the hydroxy proton hydrogen-bonds the C_6 oxygen. The C_7—OH appears as a quartet at 4.665 ppm due to coupling with C_7—H_e ($J_{7e,7OH} = 4.6$ Hz) and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12

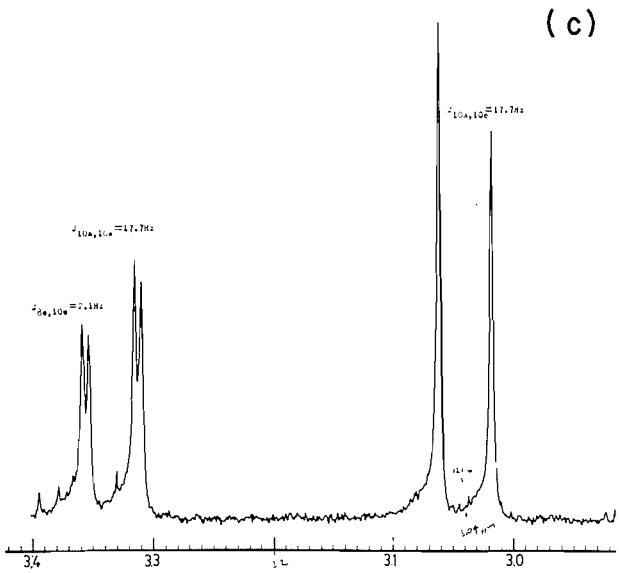

FIG. 1. (c) Expanded area between 3.0–3.4 ppm corresponding to C_{10}—H_aH_e.

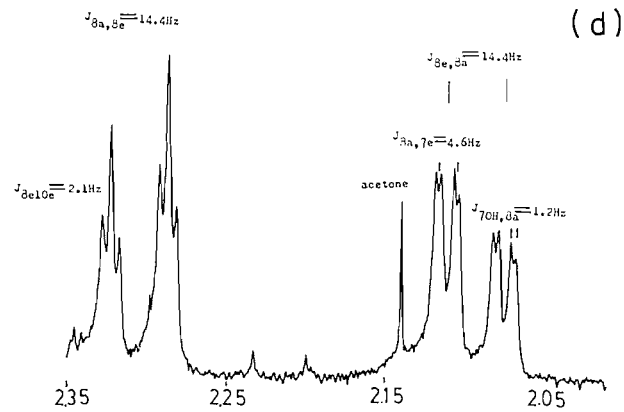

FIG. 1. (d) Expanded area between 2.05–2.35 ppm corresponding to C_8—H_aH_e.

C_8—H_a ($J_{7OH,8a}$ = 1.2 Hz). The latter is a four-bond coupling which is discernible only if the C_7—OH is locked by hydrogen bonding as suggested. The C_8—H_e appears as triplets of a doublet at 2.305. Its geminal coupling is $J_{8a,8e}$ = 14.4 Hz and its vicinal coupling is $J_{8e,7e}$ = 4.5 Hz and its four-bond coupling is $J_{8e,10e}$ = 2.1 Hz. The C_8—H_a appears at 2.092 as doublets of a quartet due to couplings with C_8—H_e ($J_{8a,8e}$ = 14.4 Hz), C_7—H_e ($J_{8a,7e}$ = 4.5 Hz), and C_7—OH ($J_{8a,7OH}$ = 1.2 Hz). The C_{10}—H_e appearing at 3.335 ppm as a quartet couples with C_{10}—H_a ($J_{10e,10a}$ = 17.7 Hz) and C_8—H_e ($J_{10e,8e}$ = 2.1 Hz). The C_{10}—H_a at 3.04 ppm appearing as a doublet couples to C_{10}—H_e only ($J_{10a,10e}$ = 17.7 Hz). Figures 1 and Fig. 2 show the ^{1}Hmr spectrum, including the conformation of the D-ring, and the computer simulated spectrum of the D-ring of **26**, respectively. The complete analysis of the ^{1}Hmr spectrum of **27** is difficult due to the presence of a slow equilibrium between **27** and **28**. The infrared spectrum shows a weak absorption at 1715 cm^{-1}; two methyl peaks at 2.39 ppm and 1.36 ppm integrated for 3 protons correspond to the C_{13}—CH_3 of **27** and **28**; two peaks at 3.60 ppm and 3.66 ppm integrated for 3 protons are tentatively assigned to C_{16}—O—CH_3 and two peaks at 3.703 and 3.708 ppm integrated for 3 protons are tentatively assigned to C_{15}—O—CH_3 of **27** and **28**; a quartet at

5.324 ppm ($J_{15a,15b}$ = 6.1 Hz, $\Delta\delta_{Ha,Hb}$ = 0.152 ppm) and a singlet at 5.211 ppm, together integrated for 2 protons, are assigned to the C_{15}—H_2 of **27** and **28**, respectively; a quartet at 5.159 ppm ($J_{16a,16b}$ = 6.2 Hz, $\Delta\delta_{Ha,Hb}$ = 0.034 ppm) and a singlet at 5.169 ppm, together integrated for 2 protons, are assigned to the C_{16}—H_2; a doublet at 5.475 ppm ($J_{7OH,7H}$ = 5.8 Hz) and a singlet at 4.16 ppm, together integrated for one proton, are assigned to the C_7—OH of **27** and **28**; a broad doublet of a triplet at 5.432 ppm integrated for one proton is assigned to the C_7—H which is spin–spin coupled to C_7—OH ($J_{7H,7OH}$ = 5.8 Hz), C_8—H_a ($J_{7H,8a}$ = 6.3 Hz), and C_8—H_e ($J_{7H,8e}$ = 2.0 Hz). The C_9—OH appears as two singlets at 3.0 and 3.10 ppm, integrated for one proton. Similar equilibrium also exists in the thioxanthodaunomycinone derivative (**31**) which reacts with excess 2,2-dimethoxypropane in the pres-

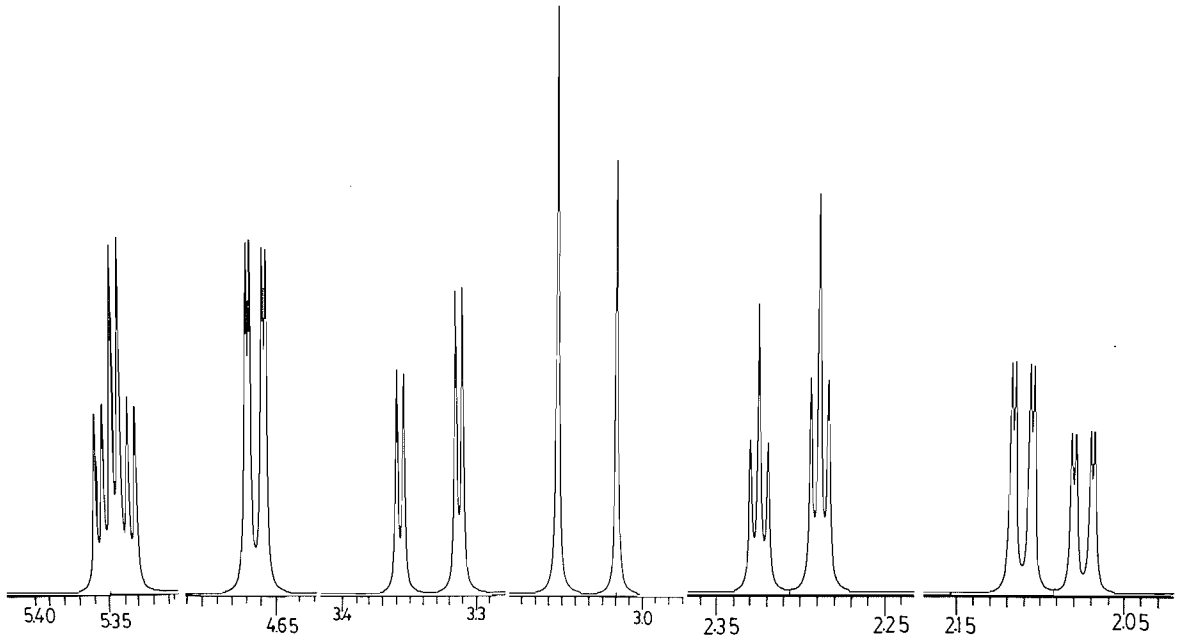

FIG. 2. Computer simulated spectrum of C_7—H_e, C_7—OH, C_8—H_aH_e, and C_{10}—H_aH_e.

ence of anhydrous *p*-toluenesulfonic acid to give exclusively **32**.[4]

Hydrolysis of **26** in dilute hydrochloric acid – acetone solution gave **29**, while **27** under similar conditions gave **30**. Both **26** and **27**, upon dissolving in trifluoroacetic acid followed by the addition of water, could be converted to a mixture of **29** and **30**. Reaction of **29** or **30** with dimethoxypropane in the presence of *p*-toluene sulfonic acid gave two isopropylidene derivatives, **33** and **34**, instead of **35**. This conclusion was arrived at solely on the basis of the coupling constants of the C_7—H of **33** and **34**. A Dreiding model of **33** shows that the H_7—C_7—C_8—H_{8a} extends a dihedral angle of about 180° and H_7—C_7—C_8—H_{8e} extends a dihedral angle of 60°, while **34** has the two corresponding dihedral angles of 160° and 40°. Thus, it is possible to come to a conclusion, according to the Karplus approximation, that the C_7—H spin–spin coupling constants of **33** and **34** will not differ greatly. However, in the case of **35**, the H_7—C_7—C_8—H_{8a} and H_7—C_7—C_8—H_{8e} can each extend a dihedral angle of about 60° and the C_7—H is likely to appear as a triplet (J = 2 Hz approximately) rather than as a quartet, in the case of **33** at 4.88 ppm ($J_{7a,8a}$ = 11 Hz, $J_{7a,8e}$ = 5.5 Hz) and in the case of **34** at 5.26 ppm ($J_{7a,8e}$ = 7 Hz). The isopropylidene methyl groups of **33** seem to be equivalent and appear as a 6-proton singlet while the isopropylidene methyl groups of **34** are nonequivalent. One methyl group appears at 1.72 ppm and the other is moved upfield to 1.63 ppm due to the shielding effect of the C-ring.

Preliminary in vitro cytotoxicity assays done in our laboratory using tumor cells MCF-7, a human breast cancer cell line, as indicator showed that both 34-demethoxyxanthodaunomycinone (**29**) and 4-demethoxy-7-epixanthodaunomycinone (**30**) were weakly cytotoxic. Daunomycinone, the aglycone of daunomycin (**2**), showed no cytotoxicity under similar conditions.

A more detailed study of the biological properties of 4-demethoxyxanthodaunomycin (**9**), 4-demethoxythioxanthodaunomycin (**10**), and 4-demethoxy-5-sulfoxodaunomycin (**11**) will be reported in later communications.

Experimental

All melting points were recorded on a Fischer–Johns apparatus and were uncorrected. Nuclear magnetic resonance spectra were recorded on a Varian spectrometer A56/60A or a HA 100, Bruker WH-90, or Bruker WH-400 spectrometer, using tetramethylsilane as internal standard unless otherwise specified. Infrared spectra were recorded on a Perkin–Elmer 710 infracord and dipole moments were taken on a DM01 Kahl dipolometer. Mass spectra were recorded on a Finnigan 1015 or a A.E.I. MS-50. Elemental analyses were performed by C. Daessle or Geller Laboratories.

*Preparation of 2-acetyl-5,8-dimethoxy-7-(2-methoxybenzoyl)tetralin (**13**) and 2-acetyl-5,8-dimethoxy-6-(2-methoxybenzoyl)tetralin (**14**)*

To a solution of trifluoracetic anhydride (38 mL) and 2-methoxybenzoic acid (40 g) was added 2-acetyl-5,8-dimethoxytetralin (12 g) followed by trifluoracetic acid (5 mL), keeping the temperature of the solution at 18–20°C. A second portion of trifluoroacetic acid (10 mL) was added after the solution was stirred for 1 h and stirring was continued for a total of 9 h. The trifluoroacetic acid was removed under reduced pressure and the residue was dissolved in chloroform (300 mL). The chloroform solution, washed with water, saturated sodium bicarbonate solution (3 × 100 mL), and dried over magnesium sulfate, was evaporated under reduced pressure to give a tinted clear residue (23 g); ir (cm^{-1}): 1710 ($COCH_3$), 1660 (phenone); ^{1}Hmr (δ): 7.6–7.35 (m, 2H, aromatic), 7.15–6.83 (m, 2H, aromatic), 6.90 (s, 1H, aromatic), 3.77 (s, 3H, —OCH_3), 3.70 (s, 3H, OCH_3), 3.46 (s, 3H, OCH_3), 2.22 (s, 3H, $COCH_3$); ms: 368 (M^+), 353, 325. *Mol. Wt.* (high resolution ms) calcd. for $C_{22}H_{24}O_5$: 368.1624; found: 368.1630.

*2-acetyl-5,8-dihydroxy-7-(2-hydroxybenzoyl)tetralin (**15**) and 2-acetyl-5,8-dihydroxy-6-(2-hydroxybenzoyl)tetralin (**16**)*

Aluminium chloride (40 g) was added to a chloroform solution (400 mL) of **13** and **14** (13 g) and stirred mechanically at room temperature for 25 h. The excess of aluminium chloride was decomposed by water and the chloroform solution washed with saturated oxalic acid solu-

tion, water, and saturated sodium bicarbonate solution and dried over magnesium sulfate, then evaporated under reduced pressure. The residue was dissolved in methylene chloride (20 mL) and ether (20 mL) from which a yellow crystalline product (3 g) was collected. The mother liquor was subjected to column chromatography on silica and an additional amount of yellow crystalline product (1.5 g) was isolated. Isomer **15** could be isolated after tedious recrystallizations (5×) from acetone, mp 224–227°C; ir(cm^{-1}): 3570 (phenol —OH), 3600–2900 (chelated phenolic H), 1705 (—$COCH_3$), 1620 (phenone), 1600, 1580 (aromatic); ^{1}Hmr (δ): 11.5 (chelated OH), 9.60 (br s, chelated OH), 8.05 (br s, nonchelated OH), 7.7–7.3 (m, 2H, aromatic), 7.15–7.85 (m, 3H, aromatic), 2.24 (s, 3H, $COCH_3$), ms: 326 (M^+), 309, 279, 232. *Mol. Wt.* (high resolution ms) calcd. for $C_{19}H_{18}O_5$: 326.1153; found: 326.1154. *Anal.* calcd. for $C_{19}H_{18}O_5$: C 69.93, H 5.52; found: C 70.11, H 5.44. The combined mother liquor was evaporated to dryness and some of the solid residue was subjected to high pressure liquid chromatographic separation on a silica column. The first isomer (**16**) collected was recrystallized from acetone, mp 208–211°C. Spectroscopic properties are similar to those of **15**. Structures were established by comparing the oxidative cyclization products with those obtained from the hydrolysis of **19** and **20** (*vide infra*).

7,8,9,10-Tetrahydro-6,11-dihydroxy-9-acetylxanthen-12-one (17) and 7,8,9,10-tetrahydro-6,11-dihydroxy-9-acetylxanthen-5-one (18)

The isomeric mixture of **15** and **16** (3 g) together with lead tetraacetate (4.4 g) in glacial acetic acid (8 mL) was ground in a mortar for 20 min at ambient temperature. The acidic slurry was washed into a separatory funnel and extracted with ethyl acetate (4 × 200 mL). The combined ethyl acetate solution was stirred with sodium thiosulfate solution (10%, 100 mL) for 2 h at room temperature, washed with water, and dried over magnesium sulfate. Evaporation of the solvent to dryness gave a yellow solid residue (2.6 g) which was purified by recrystallization from acetone, mp 219–225°C; separation could be done easily via the dibenzyl derivatives **19** and **20**.

Separation of 17 and 18

The isomeric mixture of **17** and **18** (4 g), benzyl bromide (8 mL), and pulverized anhydrous potassium carbonate (20 g) in acetone (300 mL) was heated under reflux for 14 h in a nitrogen atmosphere. The acetone solution was cooled, filtered, and evaporated to give an oily residue which was subjected to further evacuation and heating to remove the excess benzyl bromide and acetone dimer. The residue, which could be easily crystallized from ether on standing, was separated by column chromatography on silica (DSF-256 Merck) into its components (**19** and **20**) using toluene as eluent. Isomer **20** (2.6 g) was recrystallized from methylene chloride – ether, mp 119–120°C; ir (cm^{-1}): 1710 ($COCH_3$), 1660 (phenone), 1600 (aromatic); ^{1}Hmr (δ): 8.35 (dd, 1H, C_1—H, $J_{1,2}$ = 7 Hz, $J_{1,3}$ = 2 Hz, aromatic), 7.78–7.33 (m, 14H, aromatic), 5.17 (s, 2H, C_6—O—CH_2Ph), 5.09 (q, 2H, C_{12}—O—CH_2Ph, J_{gem} = 10 Hz, Δδ = 0.14 ppm), 2.18 (s, 3H, $COCH_3$); ms: 504, 413, 323. *Mol. Wt.* (high resolution ms) calcd. for $C_{33}H_{28}O_5$: 504.1937; found 504.1942; dipole moment estimated for **20**: 3.5 D; found: 3.48 D.

Heating **20** (2.2 g) in an acidic methanolic solution (concentrated hydrochloric acid 25 mL, methanol 50 mL) under reflux for 16 h gave the xanthone **18** (1.4 g) which was purified by recrystallization from acetone, mp 239–242°C; ir (cm^{-1}): 3650 (OH), 3400–2900 (chelated phenolic H), 1705 ($COCH_3$), 1650, 1630 (phenone), 1610 (aromatic); ^{1}Hmr (δ): 12.10 (s, 1H, chelated, OH), 8.26 (d,d 1H, $J_{3,4}$ = 7 Hz, $J_{2,4}$ = 1.8 Hz, aromatic), 7.30–7.80 (m, 3H, aromatic), 5.25 (br s, 1H, —OH), 2.31 (s, 3H, $COCH_3$); ms: 324 (M^+), 309, 281. *Mol. Wt.* (high resolution ms) calcd. for $C_{19}H_{16}O_5$: 324.0998; found: 324.1002.

Isomer **19** (2 g) was recrystallized from methylene chloride – ether, mp 138–140°C; estimated dipole moment for **19**: 4.9 D, found: 4.19 D. Spectroscopic data are similar ro those of **20** above. *Anal.* calcd. for $C_{33}H_{28}O_5$: C 78.57, H 5.56; found: C 78.47, H 5.65. Debenzylation as in the case of **20** gave **17** (1.2 g), which was also purified by recrystallization from acetone, mp 264–267°C; spectroscopic data are similar to those of **18**.

7,8,9,10-Tetrahydro-9-acetyl-6,11-dimethoxymethylenoxyxanthen-12-one (25)

Chloromethyl methyl ether (5 mL), freshly prepared by passing distilled chloromethyl methyl ether through an alumina column (G-1, neutral), was added dropwise under a nitrogen atmosphere to an anhydrous acetone solution (200 mL) containing freshly baked pulverized potassium carbonate (20 g) and **17** (1.2 g). The solution was heated under reflux for 4 h, cooled, filtered, and concentrated. Methylene chloride was added to the residue and the solution was filtered to remove the potassium carbonate, evaporated under reduced pressure, and finally subjected to further evacuation and heating to remove the acetone dimer. The clear residue (1.48 g), upon addition of ether, crystallized and was recrystallized from methylene chloride – ether, mp 152–154°C; ir (cm^{-1}): 1710 ($COCH_3$), 1660 (phenone), 1605 (aromatic); ^{1}Hmr (δ): 8.27 (dd, 1H, $J_{1,2}$ = 8 Hz, $J_{1,3}$ = 2 Hz, C_1—H), 8.0–7.33 (m, 3H, aromatic), 5.22 (s, 2H, —O—CH_2—O—), 5.20 (s, 2H, —OCH_2—O—), 3.70 (s, 3H, —OCH_3), 3.66 (s, 3H, OCH_3), 2.28 (s, 3H, $COCH_3$); ms: 412 (M^+), 381, 367, 337. *Mol. Wt.* (high resolution ms) calcd. for $C_{23}H_{24}O_7$: 412.1515; found: 412.1519.

*4-Demethoxy-bis-*O*-methoxymethylxanthodaunomycinone (26) and 4-demethoxy-bis-*O*-methoxymethyl-7-epixanthodaunomycinone (27)*

Potassium *tert*-butoxide (850 mg) was added to a solution of anhydrous dimethylformamide (150 mL) and *tert*-butyl alcohol (20 mL). The solution was stirred with occasional warming until the solid material was completely dissolved and then cooled in a −25°C cold bath. Trimethyl phosphite (2.7 mL) was added, followed by the xanthone (**25**) (900 mg). Dry oxygen was introduced into the solution through a gas-dispersion tube, keeping the cold bath between −25°C and −15°C for 1.5 h. Cold dilute hydrochloric acid (0.1 *M*) was added to the solution, with vigorous stirring, until the pH = 8.

Water (300 mL) was added to the solution which was exhaustively extracted with chloroform (3 × 200 mL). The combined chloroform extracts, washed with water and dried over magnesium sulfate, were concentrated under reduced pressure to give a residue which was subjected to further heating under vacuum until it was free of dimethyl formamide. The semi-solid residue was subjected to preparative thin-layer chromatographic separation and **26** (420 mg) was isolated and recrystallized from acetone–ether, mp 162–164°C; ir (cm^{-1}): 3430 (OH), 1715 ($COCH_3$), 1660 (phenone), 1605 (aromatic); ^{1}Hmr (δ): 8.236 (dd, C_1—H, $J_{1,2}$ = 7.8 Hz, $J_{1,3}$ = 2.0 Hz), 7.70–7.33 (m, 3H, aromatic), 5.324 (q, 2H, J_{gem} = 6.1 Hz, Δδ = 0.148 ppm, C_{11}—O—CH_2—O—), 5.345 (dt, 1H, C_7—He, $J_{7e,7OH}$ = 4.6 He, $J_{7e,8a}$ = 4.5 Hz, $J_{7e,8e}$ = 2.1 Hz), 5.151 (q, 2H, C_6—OCH_2O—, J_{gem} = 6.7 Hz, Δδ = 0.034 ppm), 4.98 (s, 1H, C_9—OH), 4.665 (q, 1H, C_7—OH, $J_{7e,OH}$ = 4.6 Hz, $J_{7OH,8a}$ = 1.2 Hz), 3.66 (s, 3H, OCH_3), 3.57 (s, 3H, OCH_3) 3.335 (q, 1H, C_{10}—H_e, $J_{10a,10e}$ = 17.7 Hz, $J_{10e,8e}$ = 2.1 Hz), 3.04 (d, 1H, C_{10}—H_a, $J_{10a,10e}$ = 17.7 Hz), 2.38 (s, 3H, $COCH_3$), 2.305 (td, 1H, C_8—H_e, $J_{8a,8e}$ = 14.4 Hz, $J_{8e,7e}$ = 2.1 Hz, $J_{8e,10e}$ = 2.1 Hz), 2.092 (dq, 1H, C_8—H_a, $J_{8a,8e}$ = 14.4 Hz, $J_{8a,7e}$ = 4.5 Hz, $J_{8a,7OH}$ = 1.2 Hz) (Fig. 1); ms: 444 (M^+), 414, 426, 382. *Mol. Wt.* (high resolution ms) calcd. for $C_{23}H_{24}O_9$: 444.1413; found: 444.1411.

The minor isomeric product (**27**) (140 mg) was isolated and purified by recrystallization from acetone–ether, mp. 156–158°C; ir (cm^{-1}): 3560 (OH), 3470 (OH), 1715 ($COCH_2$, weak), 1660 (phenone), 1605 (aromatic); ms: 444 (M^+), 414, 382; ^{1}Hmr: the presence of a slow equilibrium between **27** and **28** makes the complete analysis of the ^{1}Hmr spectrum difficult. Reaction of **26** and **27** with trifluoroacetic acid followed by water led to the formation of both **29** and **30** in the same ratio.

4-Demethoxyxanthodaunomycinone (29) and 4-demethoxy-7-epixanthodaunomycinone (30)

To a stirred solution of acetone (20 mL) containing **26** (180 mg) was added dropwise concentrated hydrochloric acid (1/2 mL) at room temperature and the stirring was continued for 6 h. The solution, diluted with water (50 mL), was extracted with ethyl acetate (3 × 100 mL). The combined extracts, washed with saturated sodium bicar-

The previously reported 1:1 complexes formed in $MeNO_2$ between $M(SbF_6)_2$ (M = Sn or Pb) and $Ph_2P(CH_2)_2PPh_2$, $PhP[(CH_2)_2PPh_2]_2$, $MeC(CH_2PPh_2)_3$, $P[(CH_2)_2PPh_2]_3$, and $[Ph_2P(CH_2)_2]_2P(CH_2)_2\overset{+}{P}HPh_2$ have been studied by metal (^{119}Sn or ^{207}Pb) nmr. The metal chemical shifts span the comparatively narrow range of −586 to −792 ppm and 60 to −269 ppm, relative to the resonance of MMe_4, for ^{119}Sn and ^{207}Pb nmr, respectively. The implications of these data regarding the denticity of the ligand in $M(P[(CH_2)_2PPh_2]_3)^{2+}$ are discussed, and a comparison with the metal nmr spectra of related stannous and plumbous complexes is made.

PHILIP A. W. DEAN. Can. J. Chem. **61**, 1795 (1983).

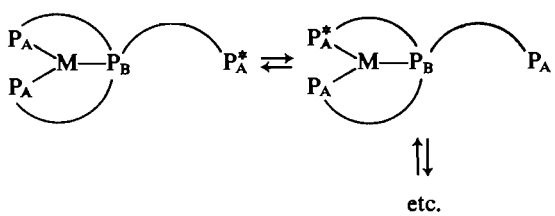
Faisant appel à la rmn du métal (^{119}Sn ou ^{207}Pb), on a étudié les complexes du type 1:1, formés dans le $MeNO_2$, entre le $M(SbF_6)_2$ (M = Sn ou Pb) et le $Ph_2P(CH_2)PPh_2$, le $PhP[(CH_2)_2PPh_2]_2$, le $MeC(CH_2PPh_2)_3$, le $P[(CH_2)_2PPh_2]_3$, et le $[Ph_2P(CH_2)_2]_2P(CH_2)_2\overset{+}{P}HPh_2$. Les déplacements chimiques du métal s'étendent sur l'intervalle comparativement étroit de −586 à −792 ppm et de 60 à −269 ppm par rapport à la résonance du MMe_4 pour le ^{119}Sn et le ^{207}Pb respectivement. On discute des implications de ces données en fonction du caractère donneur du ligand dans le $M(P[(CH_2)_2PPh_2]_3)^{2+}$ et on les comparées avec les spectres du métal des complexes stanneux et plombeux apparentés.

[Traduit par le journal]

Introduction

In recent work from this laboratory the ^{31}P nmr spectra of some new stannous and plumbous complexes with a variety of polydentate phosphines were presented (1), the complexes being prepared *in situ* from $M(SbF_6)_2$ (M = Sn or Pb) and the appropriate ligand in $MeNO_2$. For both metals, the observation of one bond metal–phosphorus couplings showed that these spectra were recorded under conditions where intermolecular ligand exchange was slow on the nmr timescale. However, the spectra of the complexes thought to be $M(PP_3)^{2+}$ (PP_3 = $P(CH_2CH_2PPh_2)_3$)[2] showed, in addition to unremarkable values for metal coupling to the unique phosphorus atom ($^1J(M—P_B)$ = 1482 and 2136 Hz for M = ^{119}Sn and ^{207}Pb, respectively), peculiarly small couplings to the nmr-equivalent terminal phosphorus atoms, P_A: 705 Hz for coupling to ^{119}Sn, compared with 1279–1665 Hz for other values of $^1J(^{119}Sn–^{31}P)$ observed; 476 Hz for coupling to ^{207}Pb, compared with 1714–2136 Hz for other values of $^1J(^{207}Pb–^{31}P)$ observed. Two possible explanations for these "anomalies" were considered: firstly the PP_3 complexes could contain the unusual (compared with the other complexes examined) MP_4 kernel, or, secondly, there could occur in these complexes one or more rapid intramolecular "end-on, end-off" exchange processes such as

[1]



which would lead to values of $^1J(M—^{31}P)$ below those expected for a static M—P bond.

If the unusual ^{31}P nmr spectra of the $M(PP_3)^{2+}$ complexes is a manifestation of an unusual coordination kernel, it seems reasonable that the metal nmr chemical shifts of the PP_3 complexes should show significant differences from the corresponding shifts of species with "normal" ^{31}P nmr spectra. To allow the necessary comparison, metal nmr spectra have now been obtained for most of the phosphine complexes reported earlier, and are described and discussed in the present paper. Quite apart from any structural implications, these data are of some intrinsic interest, as this is one of a very limited number of instances where metal nmr spectra have been reported for analogous complexes of divalent tin and lead (2).

Experimental

Preparation of samples for metal nmr

Samples with metal concentration 0.22 *m* (≡ 2.5×10^{-4} mol/mL $MeNO_2$, approximately the same concentration used for our earlier ^{31}P nmr study (1)) were prepared by the procedure reported earlier (1): under dry nitrogen, the appropriate molar ratio (M:L ≈ 1:0.8 for all of the phosphine complexes except $M(PP_2(PH))^{3+}$ for which, for best results (cleanest spectra), M:L ≈ 1:0.45) of solid $M(SbF_6)_2$ and ligand were combined in a baked out (140°C) nmr tube hand made of 8 mm od standard wall Pyrex tubing in the earlier part of this work and 9 mm od tubing in the later part; next, outside the glove box, freshly distilled $MeNO_2$ was added by standard N_2-vacuum techniques and the sample was cooled then flame sealed under vacuum, allowed to warm to room temperature and homogenized by shaking briefly (a few minutes). Thereafter the samples were stored in liquid nitrogen until used. Samples produced and stored in this way give reproducible ^{31}P and metal nmr spectra when fresh.

Phosphorus-31 nmr spectra

Prior to measurement of the metal nmr spectra, the 260 K 40.5 MHz $^{31}P-\{^1H\}$ nmr spectra were obtained to confirm the presence of the desired phosphine complexes. For ^{31}P nmr spectroscopy, 8 mm sample tubes were held concentrically in a 12 mm od nmr tube using a Teflon spacer, while the 9 mm tubes were a tight sliding fit in a conventional thin-walled 10 mm nmr tube which was held concentrically in the 12 mm nmr tube, but otherwise the spectra were recorded exactly as already described, using $(CD_3)_2CO/OP(OMe)_3$ (for reduced temperature) or $D_2O/OP(OMe)_3$ (for ambient probe tem-

perature) in the outer annulus as a deuterium lock/reference material (1).[3]

Metal nmr spectra

The 260 K and 295 K ^{119}Sn and ^{207}Pb nmr spectra were obtained using a Bruker WH-400 spectrometer operating at 149.21 and 83.71 MHz, respectively (at the resonance of the appropriate metal(IV) tetramethyl which was used as a reference),[3] without lock or proton-decoupling, with the stationary 8 mm or 9 mm od nmr tubes held in a 10 mm nmr tube by a Teflon spacer for the smaller tube and by the close fit of the two tubes for the larger tube. (The pulsed high power decoupler of this high field instrument was not used because it induces non-uniform temperature effects which, combined with the large temperature dependences of ^{119}Sn and ^{207}Pb nmr chemical shifts (see ref. 2 and later), causes unwanted line broadening. Not all of the home-made sealed tubes would spin satisfactorily, so for consistency all samples were measured stationary; with the linewidths measured here the reduction in resolution should be insignificant.) Typically, after initially locating the resonance(s) with a larger spectral window, satisfactory ^{119}Sn nmr spectra of the phosphine complexes in the 0.22 *m* solutions were obtained in several hundred transients using 65° (25 μs) pulses applied at 42 min^{-1} with a spectral window of 20 kHz and an acquisition time of 0.41 s. (In one case a sample with $Sn(SbF_6)_2:PP_3 \approx 1.6:1$, containing, initially, $Sn(PP_2(PH))^{3+}$ and $Sn(PP_3)^{2+}$, was run overnight (26000 transients) with a spectral window of 25 kHz; the spectra of decomposition products were then evident in the spectrum (see later).) Satisfactory ^{207}Pb nmr spectra were obtained in a similar length of time with similar operating conditions except that a 45° (19 μs) pulse was used.

In the interests of economy of instrument time, no attempt was made to locate any resonance from the generally small excess of metal ions that must be present in these solutions. However, such signals are clearly not in the chemical shift range of the phosphine complexes and almost certainly more shielded than this (Tables 1 and 2). The observation of one-bond metal phosphorus couplings in the ^{31}P and metal nmr spectra precludes a significant rate of intermolecular ligand exchange.

[3]Chemical shifts to higher frequency than the reference are taken as positive.

Results and discussion

Details of the 295 K ^{119}Sn nmr spectra of the various tin(II)–phosphine complexes found in fresh[4] nitromethane solutions are given in Table 1, and those of the 295 K ^{207}Pb nmr spectra of the corresponding lead(II)–phosphine complexes in Table 2. In general the linewidths of the ^{119}Sn nmr signals of the various stannous complexes were quite small (≲25 Hz), and the spectra observed for the dppe, etp, tripod, and $PP_2(PH)^+$ complexes were just the simple symmetrical splitting patterns (from $^1J(^{119}Sn-^{31}P)$) expected if the polydentate phosphines behave in a chelating (as opposed to bridging) manner, as has been deduced from the previously reported ^{31}P nmr spectra (1).[5] A representative ^{119}Sn nmr spectrum, that of $Sn(etp)^{2+}$, is shown in Fig. 1*a*. Similarly the ^{207}Pb nmr spectra of the analogous plumbous complexes were exactly as expected from the chelated structures proposed (1) on the basis of their ^{31}P nmr spectra,[5] allowing for the fact that the linewidths of the ^{207}Pb signals generally exceeded those found in the ^{119}Sn spectra of the analogous tin(II) species. In these spectra the broader lines mean that small signal separations were not resolved as can be seen, for example, in the ^{207}Pb nmr spectra of $Pb(etp)^{2+}$ (Fig. 1*b*) which is typical of those obtained in this work. The PP_3 complexes of tin(II) and lead(II) give a doublet of quartets in their respective metal nmr spectra (Tables 1 and 2), consistent with the real or time-averaged C_3 ligand symmetry implied by the published ^{31}P nmr data (1). As discussed below, the interpretation of the nmr spectra of these PP_3 complexes is not straightforward.

[4]As noted in ref. 1, both tin- and lead-containing solutions deteriorate over a period of hours at 308 K. This decomposition has not been studied in detail, and with one exception no evidence for decomposition was found in the time taken to measure the metal nmr spectra at 295 K. In one case a sample with $Sn(SbF_6)_2:PP_3 \approx 1.6:1$ was run overnight and showed not only ^{119}Sn nmr spectra from $Sn(PP_3)^{2+}$ and $Sn(PP_2(PH))^{3+}$ but also two other multiplets: one at $\delta_{Sn} = -707$ ppm with a triplet splitting of 1562 Hz and a doublet splitting of 1425 Hz, the other at $\delta_{Sn} = -734$ ppm with a triplet splitting of 956 Hz and a doublet splitting of 1654 Hz. These are evidently tin(II)–phosphine species; the origin of the first is not clear, but the 956 Hz coupling is associated with a doublet–doublet ($\delta_P = 9.4$ ppm, $J = 10$ and 38 Hz) found in the 308 K ^{31}P nmr spectrum of $Sn(PP_3)^{2+}$-containing solutions which have been allowed to stand at room temperature for ca. 12 h.

[5]In ref. 1, the small magnitude of $^3J(P—P)$ was cited in support of chelating behaviour. In addition, several conceivable bridged structures can be discarded on the basis of the symmetry implied by the slow-exchange ^{31}P spectra reported in ref. 1. For the lead complexes, the absence in the ^{31}P or metal nmr spectra of any evidence for isotopomers such as $^{207}PbPb$, $^{207}Pb_2$ etc. (expected to have significant abundance because of the relatively high natural abundance of ^{207}Pb (21.11%)) seems to rule out all other possible ligand-bridged structures. For example, the ^{207}Pb satellites in the ^{31}P nmr spectrum of the 1:1 Pb^{2+}:dppe complex are sharp singlets consistent with the occurrence of chelating dppe and show no evidence for the P—P coupling expected in the X(^{31}P) part of the AXX′X″X‴ spin system of the dimer $^{207}Pb(dppe)_2Pb$. (P—P coupling can be sizeable for bridging dppe; see, for example, ref. 3.) By extension, the close similarity between the ^{31}P and metal nmr spectra of the tin(II) and lead(II) complexes implies chelated and not ligand-bridged structures for the stannous complexes too. Also, though the natural abundances of ^{119}Sn (8.68%) and ^{117}Sn (7.67%) are too low to allow unequivocal confirmation of the absence of isotopomers in the ^{31}P spectra of tin(II)–phosphine complexes, the linewidths in the ^{119}Sn spectra are much smaller than in the ^{207}Pb spectra so that second order coupling to ^{31}P should be easier to see.

[a] See footnote *a* Table 1.
[b] Relative to the resonance of external $PbMe_4$ in toluene; shifts were measured initially relative to the signal of 1.0 *M* $Pb(NO_3)_2$(aq) by sample interchange and converted to $PbMe_4$ as reference using $\delta_{(PbMe_4(toluene))} = \delta_{(1.0\ M\ Pb(NO_3)_2(aq))} - 2961$ ppm (7); shifts to higher frequency than the reference are taken as positive; estimated error in spectral measurement ±1 ppm.
[c] See footnote *c*, Table 1.
[d] See footnote *d*, Table 1.
[e] See footnote *e*, Table 1.
[f] At 260 K; this resonance could not be observed with certainty at 295 K.
[g] Values quoted are for a solution in which $Pb/PP_3 = 1.19$ and the lead concentration is 0.22 *m* (see text).

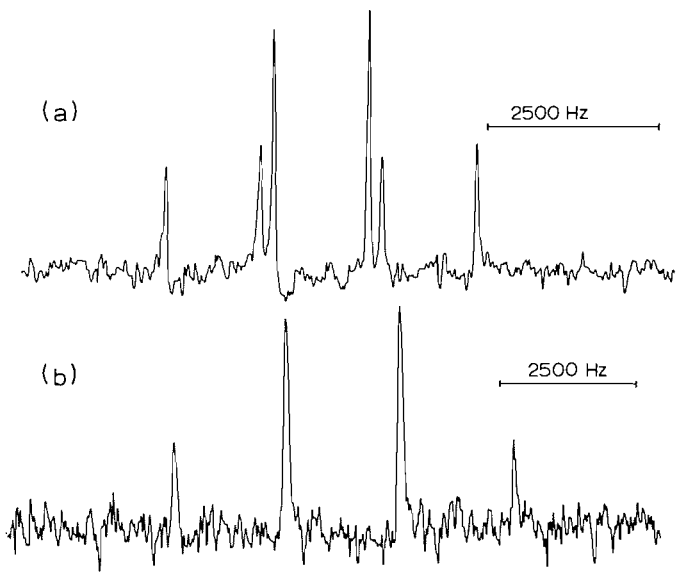

FIG. 1. (*a*) 149.2 MHz ^{119}Sn nmr spectrum of $Sn(etp)^{2+}$ at 206 K in a nitromethane solution containing $Sn(SbF_6)_2$:etp = 1.3:1 with a total tin concentration of 0.22 *m*. (Obtained using 69 90° (35 μs) pulses, acquisition and cycle times of 0.41 s and 1.41 s, respectively, and 20 kHz spectral window. 25 Hz of line broadening has been applied.) (*b*) 83.7 MHz ^{207}Pb nmr spectrum of $Pb(etp)^{2+}$ at 295 K in a nitromethane solution containing $Pb(SbF_6)_2$:etp = 1.3:1 with a total lead concentration of 0.22 *m*. (Obtained using 485 45° (19 μs) pulses, acquisition and cycle times of 0.16 s and 1.16 s, respectively, and 50 kHz spectral window. 20 Hz of line broadening has been applied.) Notes: *1*. etp = $[Ph_2P(CH_2)_2]_2PPh$; *2*. the horizonal scales in (*a*) and (*b*) are different.

It is noteworthy that, under identical conditions, the ^{119}Sn resonances of $Sn(dppe)^{2+}$ are very broad compared with those of the other tin complexes, and the analogous lead complex, in contrast to the other lead complexes, seems to give an unobservably broad resonance at 295 K. However, it is probably significant that the dppe complexes (which give ^{31}P spectra with sharp metal satellite spectra (ref. 1 and see footnote 5)) have fewer bound phosphorus atoms than species giving sharper lines, so that one site at least on the metal ion is presumably occupied by another donor (e.g. the solvent) or equilibrium mixture of donors (e.g. solvent and SbF_6^-). Some kinetic process at this site, occurring at an appropriate rate on the metal nmr timescale, might account for the observed broadening.

With the exception of $Pb(dppe)^{2+}$ (above), the splitting patterns found in the ^{119}Sn and ^{207}Pb nmr spectra of the various species are unaffected by reduction in temperature to 260 K, showing that there are no kinetic processes which can be slowed in the range 295–260 K. The most significant change is an increase in the metal nuclear shielding as the temperature is lowered, e.g. for ^{119}Sn, $\delta_{295} - \delta_{260}$, is 11, and 5 ppm for $Sn(O_2NMe)_x^{2+}$ and $Sn(etp)^{2+}$, respectively; for ^{207}Pb, $\delta_{295} - \delta_{260}$ is 17 and 39 ppm for $Pb(O_2NMe)_x^{2+}$ and $Pb(etp)^{2+}$, respectively. Such increasing shielding with decreasing temperature is normally found for temperature-dependent chemical shifts (see, for example, ref. 4); the generally larger temperature dependence of δ_{Pb} is consistent with the larger range of chemical shifts found for the lead complexes.

Dissolution of $M(SbF_6)_2$ (M = Sn or Pb) in $MeNO_2$ probably produces the solvated cations $M(O_2NMe)_x^{2+}$. On formation of the phosphine complexes from the parent cations, nmr complexation shifts of 750 to 950 ppm occur for the ^{119}Sn complexes (Table 1) and 3070 to 3400 ppm for the ^{207}Pb complexes (Table 2). For analogous compounds of lead and tin, the range of ^{207}Pb nmr chemical shifts to the range of ^{119}Sn chemical shifts has been found in earlier work to be about three or greater (e.g. refs. 2 and 5). Also, ^{119}Sn nmr complexation shifts to higher frequency have been found on formation of various $R_3P.SnCl_2$ from $(THF)_xSnCl_2$, the exact magnitude of the complexation shift being very dependent on the nature of R (6).

Compared with the magnitudes of the complexation shifts found for the various phosphine complexes examined here, the

range of ^{119}Sn or ^{207}Pb nmr chemical shifts within the series of phosphine complexes examined is quite small. Thus for the stannous complexes studied $\delta_{^{119}Sn}$ appears to be more sensitive to the presence of coordinated phosphorus atoms than to the number of phosphorus atoms coordinated. For example, the ^{119}Sn resonance of $Sn(dppe)^{2+}$ is deshielded by 100 ppm from the resonance of $Sn(etp)^{2+}$, there being a change from two to three coordinated phosphorus atoms between these species. If the effect of substituting phosphorus atoms into $Sn(O_2NMe)_4^{2+}$ approached additivity, the signal from $Sn(dppe)^{2+}$ should be shielded by ca. 300 ppm from that of $Sn(etp)^{2+}$. A similar situation holds for the analogous plumbous complexes, even allowing for the slight ambiguity introduced by an inability to observe the ^{207}Pb nmr spectrum of $Pb(dppe)^{2+}$ at 295 K coupled with the appreciable temperature sensitivity of δ_{Pb} (see above).

Within the comparatively small ^{119}Sn and ^{207}Pb nmr chemical shift ranges observed for the metal(II)–phosphine complexes (Tables 1 and 2) there is clearly some dependence on the nature of the ligand, as shown by the divergent chemical shifts of $M(etp)^{2+}$ and $M(tripod)^{2+}$, both of which contain tridentate phosphorus donor ligands. What is not evident is whether the difference reflects different geometries in the MP_3 kernel, the higher basicity of the central phosphorus atom of etp, the different number and/or size of the chelate rings, or some combination of these features. To resolve these questions study of complexes with a much wider range of ligands would be needed.

The metal chemical shifts of $M(etp)^{2+}$ and $M(PP_2(PH))^{3+}$ are close together for both M = ^{119}Sn and M = ^{207}Pb, as expected for species with essentially the same skeleton in the coordinated ligand, much closer than the metal chemical shifts of $M(etp)^{2+}$ and $M(PP_3)^{2+}$ which would also be expected to be similar if the PP_3 behaved in an etp-like manner as in [1]. In fact, the resonances of the discrete $M(PP_3)^{2+}$ complexes are probably slightly more shielded than the data given in Tables 1 and 2 suggest. It now appears that the ^{31}P nmr spectra earlier attributed to a single 1:1 complex of M^{2+} and PP_3 (1) must be a weighted average spectrum of at least two complexes, for from the wider range of ^{31}P nmr spectra now available it is evident that the ^{31}P nmr spectral parameters are sensitive to M/L in the solutions used, which contain excess M^{2+}.[6] For instance, in the 260 K ^{31}P nmr spectrum of the lead "complex", δ_{P_A}, $\nu_{1/2}(P_A)$, $^1J(^{207}Pb—P_A)$, δ_{P_B}, $^1J(^{207}Pb—P_B)$ and $^3J(P_A—P_B)$ change smoothly from 24.6 ppm, ~6 Hz, 429 Hz, 79.4 ppm, 2150 Hz, and 46 Hz when $Pb/PP_3 = 1.19 \pm 0.05/1$, to 29.3 ppm, ~60 Hz, ~504 Hz, 80.5 ppm, 2127 Hz, and 43 Hz when $Pb/PP_3 = 1.49 \pm 0.06/1$. (The P_B signal remains sharp as L/M is changed (see, for example, Fig. 1*c* of ref. 1).) The behaviour of the $Sn^{2+}–PP_3$ system is qualitatively similar. Evidently, the real $M(PP_3)^{2+}$ complex, regardless of whether it contains an MP_4 or an MP_3 kernel, is in equilibrium with a form containing $M(PP_3)^{2+}$ complexed by excess M^{2+}. Quantification of the spectral changes is complicated by the formation of $M(PP_2(PH))^{3+}$ as M/L is increased, but the occurrence of one or perhaps both, of equilibria [2] and [3] seem most likely:

[2] $M^*(PP_3) + M \rightleftarrows$ 
2

[3] $M^*(PP_3) + M \rightleftarrows$ 
3

To be consistent with the ^{31}P nmr data P_B must remain anchored to M*, as $^1J(M^*—P_B)$ is observed and of the normal magnitude for static one-bond couplings of this type (1), the equilibria must be labile, as the nmr spectra require rapid averaging of P_A environments, and probably, the equilibrium or equilibria must lie close to the right.

The illustrative data given above for "$Pb(PP_3)^{2+}$" show that $^1J(M—P_A)$ *increases* as M/L is increased. This means that the values of $^1J(M—P_A)$ reported previously (1) *exaggerate* the magnitude of this coupling, so that the already anomalously low value should, in reality, be even lower (e.g. a value of approximately 390 Hz for $^1J(^{207}Pb—P_A)$ gives a fair fit of the exchange-average data for $Pb(PP_3)^{2+}$). Similarly the metal chemical shifts given for $Sn(PP_3)^{2+}$ and $Pb(PP_3)^{2+}$ in Tables 1 and 2, respectively (which correspond to the shifts of M* in [2] and [3] above) must be approximately the population-weighted averages of the shifts of $M(PP_3)^{2+}$ and **2** and/or **3**. Now in **2**, M* is expected to have a chemical shift similar to $M(PP_2)(PH))^{3+}$, while in **3** the chemical shift will probably be close to that of $M(dppe)^{2+}$. Thus from the shifts given in Tables 1 and 2 and the stoichiometries of the solutions from which the data were obtained we can estimate that the true $Sn(PP_3)^{2+}$ and $Pb(PP_3)^{2+}$ complexes should have metal chemical shifts of approximately −780 and approximately −340 ppm, respectively.

For both ^{119}Sn and ^{207}Pb, the difference between the shifts just estimated for the discrete $M(PP_3)^{2+}$ complexes and the shifts of the corresponding etp and $PP_2(PH)^+$ complexes appear, when combined with the anomalies found in the ^{31}P nmr spectra (especially the small values of $^1J(M—P_A)$ (ref. 1 and see above)), to favour an MP_4 kernel for the $M(PP_3)^{2+}$ complexes. More definitive evidence seems to require a study of the $M(PP_3)^{2+}$ complexes in the solid state or frozen solution by techniques not available in this laboratory, for example, solid state ^{31}P nmr, or, for M = ^{119}Sn, ^{119}Sn Mössbauer spectroscopy.

Tin-119 nmr data are now available for several stannous complexes of the type SnX_3 (this work and refs. 2 and 7); nuclear shielding varies with donor atom in the sequence O > P > Cl > S > Se. Similarly, nuclear shielding of ^{207}Pb in $Pb^{II}X_3$ varies as O > P > S > Se (this work and ref. 2).

[6] I am grateful to a referee for stressing this point.

$Zn(SbF_6)_2$ in liquid SO_2 has been shown to act as an acceptor towards a variety of phosphine oxides, sulfides, and selenides, forming complexes which have been characterized in solution using ^{31}P nmr. Slow-exchange ^{31}P nmr spectra are reported for the complexes ZnL_n^{2+} (n = 6, L_2 = $Ph_2P(O)CH_2P(O)Ph_2$ or L_3 = $(Ph_2P(O)(CH_2)_2)_2P(O)Ph$; n = 4, L_2 = $Ph_2P(E)CH_2P(E)Ph_2$ (E = O, S, or Se) or *bidentate* $(Ph_2P(E)CH_2)_3CMe$ (E = S or Se), or L = $(C_6H_{11})_3PE$ (E = O, S, or Se) or R_3PE (E = S or Se, R = Ph or *o*-C_6H_4Me); n = 3, L_3 = $(Ph_2P(E)(CH_2)_2)_2P(E)Ph$ (E = S or Se) or L = R_3PE (E = S or Se, R = C_6H_{11}, Ph, or *o*-C_6H_4Me); n = 2, L = R_3PE (E = S or Se, R = *o*-C_6H_4Me or, perhaps, C_6H_{11}); n = 1 (possibly), L = (*o*-$C_6H_4Me)_3PS$), and partial spectra for $[Zn(ScP(C_6H_{11})_3)_x(SP(C_6H_{11})_3)_{n-x}]^{2+}$ (n = 3 or 4). No evidence was found for the mixed oxide-chalcogenide species $[Zn(EP(C_6H_{11})_3)_x(OP(C_6H_{11})_3)_{4-x}]^{2+}$. In most cases the ^{31}P nmr spectra are very similar to those reported earlier for the corresponding cadmium complexes. However, in most instances where comparison could be made it was found that the rate of intermolecular ligand exchange was less for the zinc complexes than for their cadmium counterparts. (Complexes with $(Ph_2P(O)(CH_2)_2)_2P(O)Ph$ and $Ph_2P(O)(CH_2)_2P(O)Ph_2$ are exceptional in being more labile for zinc than cadmium.)

PHILIP A. W. DEAN et GEETHA K. CARSON. Can. J. Chem. **61**, 1800 (1983).

On montre que le $Zn(SbF_6)_2$ dans du SO_2 liquide agit comme un accepteur envers divers oxydes de phosphine, de sulfure et de séléniure, en formant des complexes que l'on a caractérisés en solution par la rmn du ^{31}P. On rapporte les spectres de rmn du ^{31}P d'échange lent des complexes de ZnL_n^{2+} (n = 6, L_2 = $Ph_2P(O)CH_2P(O)Ph_2$ ou L_3 = $(Ph_2P(O)(CH_2)_2)_2P(O)Ph$; n = 4, L_2 = $Ph_2P(E)CH_2P(E)Ph_2$ (E = O, S ou Se) ou *bidentate*. $(Ph_2P(E)CH_2)_3CMe$ (E = S ou Se), ou L = $(C_6H_{11})_3PE$ (E = O, S ou Se) ou R_3PE (E = S ou Se, R = Ph ou *o*-C_6H_4Me); n = 3, L_3 = $(Ph_2P(E)(CH_2)_2)_2P(E)Ph$ (E = S ou Se) ou L = R_3PE (E = S ou Se, R = C_6H_{11}, Ph ou *o*-C_6H_4Me); n = 2, L = R_3PE (E = S ou Se, R = *o*-C_6H_4Me ou peut être C_6H_{11}); n = 1 (possiblement), L = (*o*-$C_6H_4Me)_3PS$) et les spectres partiels de $[Zn(ScP(C_6H_{11})_3)_x(SP(C_6H_{11})_3)_{n-x}]^{2+}$ (n = 3 ou 4). On n'a pas pu prouver l'existence d'espèces mixtes du type oxyde-chalcogéniure: $[Zn(EP(C_6H_{11})_3)_x(OP(C_6H_{11})_3)_{4-x}]^{2+}$. Dans la plupart des cas les spectres de rmn du ^{31}P sont très semblables à ceux rapportés antérieurement pour les complexes correspondants du cadmium. Cependant dans la plupart des cas, où il est possible d'établir une comparaison, on trouve que la vitesse d'échange intermoléculaire de ligand est plus faible dans le cas du zinc que dans le cas des complexes correspondants du cadmium. (Les complexes avec $(Ph_2P(O)(CH_2)_2)_2P(O)Ph$ et $Ph_2P(O)(CH_2)_2P(O)Ph_2$ sont exceptionnels en ce sens qu'ils sont plus labiles dans le cas du zinc que dans le cas du cadmium.)

[Traduit par le journal]

Introduction

In earlier work from this laboratory (1, 2), it was shown that a wide variety of new complexes of cadmium with phosphine oxides, sulfides, and selenides could be prepared from $Cd(MF_6)_2$ (M = As or Sb) with the appropriate ligand in liquid SO_2. The MF_6^- anions and the solvent SO_2 are very weak donors so that coordination by the ligand(s) of interest is facilitated in these systems. Phosphorus-31 nmr proved a useful tool to characterize the complexes, a selection of which then provided the basis for a ^{113}Cd nmr study of species containing these model Group VIA donor ligands (3). A helpful feature of both the ^{31}P and the ^{113}Cd nmr spectra of the cadmium complexes is the occurrence of two-bond $^{113}Cd—E—^{31}P$ (E = O, S, or Se) nuclear spin–spin coupling which is readily observable for E = S or Se (1, 2) and observable with ^{113}Cd enrichment for E = O (3). The splitting patterns observed in the ^{113}Cd nmr spectra both allow unambiguous assignment of these and confirm the interpretation of the ^{31}P nmr spectra.

With the ^{31}P and metal nmr spectra of the cadmium complexes in hand, we felt it would be instructive to measure analogous spectra of some related zinc complexes for comparison. As the first part of our study we have measured ^{31}P nmr spectra for a range of the title complexes, and report them here. Zinc-67 (4.1% natural abundance, spin I = 5/2) is a quadrupolar nucleus and so the ^{31}P nmr spectra of the zinc complexes contain no observable $^{67}Zn—E—^{31}P$ spin coupling. In themselves they are thus not as informative as those of their cadmium analogs. However, with a prior knowledge of the spectra of the cadmium complexes the spectra of the zinc complexes can be assigned with some confidence, as we show.

To our knowledge, there have been no previous ^{31}P nmr studies of complexes of zinc with phosphine sulfides or selenides, perhaps because of the difficulty of interpreting an isolated spectrum (see above). However, zinc complexes with phosphine selenides and, particularly, phosphine sulfides are well-established. Most involve zinc halides and are of the type $ZnX_2 . L_2$ where L represents a donor with one P=S (or Se) donor site or L_2 a donor with two such sites (eg. refs. 4–10). The complexes $2ZnX_2 . Ph_3PSe$ (X = Cl or Br) have also been reported (11), as have the species $[ZnL_4](ClO_4)_2$ (L = $SePMe_3$ (6) or L_2 = $dppmS_2$ (12)), which demonstrate the importance of the nature of the anion in maximizing the number of ligands that can be bound.[3]

Zinc complexes with phosphine oxides and related phosphoryl donor ligands have been a topic of extensive interest, though relatively few ^{31}P nmr investigations have been reported

(see below). The most important types of complexes known are: ZnL_2X_2 (L = ligand with one P=O donor site or L_2 = ligand with two P=O donor sites, X = coordinating anion) (e.g. refs. 13–17), $[ZnL_4]X_2$ (L = ligand with one P=O donor site or L_2 = ligand with two P=O donor sites; X = weakly coordinating anion) (e.g. refs. 13–15, 17–20), $[ZnL_5]X_2$ (L = ligand with one P=O donor site; X = weakly coordinating anion) (e.g. refs. 19, 21, 22), and $[ZnL_6]X_2$ (L = $(HOCH_2)_3P{=}O$, X = ClO_4^- (23); L_2 = ligand with two P=O donor sites, X = weakly coordinating anion (e.g. refs. 14, 24); L_3 = ligand with three P=O donor sites; X = weakly coordinating anion (e.g. ref. 25)).

A few ^{31}P nmr data are available for zinc complexes of phosphine oxides. In an early application of ^{31}P nmr, Walker and Li (26) used ^{31}P nmr to determine the formation constant (10 L mol^{-1}) of the (isolable) 1:1 complex $Zn(TTA)_2 \cdot OP(n\text{-}C_8H_{17})_3$ in CCl_4 at 299 K. More recently, ligand exchange with excess free ligand was found to be fast on the ^{31}P nmr timescale at ambient probe temperature for both $Zn(OPBu^n{}_3)_4^{2+}$ in DMSO and $Zn(dppmO_2)Cl_2$ in CH_2Cl_2 (15); from the position of the single exchange-averaged resonance observed in these cases, it was deduced that ligand dissociation is significant for the former system, but not for the latter. Lincoln and co-workers were able to reach the slow exchange region of the reduced temperature ^{31}P nmr spectrum for $Zn(OP(NMe_2)_3)_4^{2+}$—$OP(NMe_2)_3$ (19) and $Zn(OPPh_3)_4^{2+}$—$OPPh_3$ (20) mixtures in CD_2Cl_2, but not for ZnL_5^{2+}—L (L = $OP(OMe)_3$ or $OPMe(OMe)_2$) mixtures in the same solvent (19). In all these previous ^{31}P nmr studies of phosphoryl donor ligands sizeable positive values of the complexation shift, $\Delta\delta_P$ (= $\delta_{P,\ complex} - \delta_{P,\ free\ ligand}$) were found.

Experimental

Materials

Zinc hexafluoroantimonate, $Zn(SbF_6)_2$, was synthesized by the literature method (27). The ligands were prepared, and sulfur dioxide dried, as reported earlier (1–3, 28).

Manipulations

All transfers of the extremely moisture-sensitive $Zn(SbF_6)_2$ were carried out in a dry-nitrogen filled glovebox in which the atmosphere was maintained by circulation through liquid nitrogen cooled traps. Similarly all weighings were carried out in the glovebox. Sulfur dioxide was added to the nmr samples outside the box from a calibrated glass and Teflon vacuum line.

Phosphorus-31 nmr spectra

Nuclear magnetic resonance samples were prepared in flame-sealed hand made 10 mm od nmr tubes, and 40.54 MHz ^{31}P—{^1H} nmr spectra measured using an XL-100-12 spectrometer system, as described before (1, 2, 28). The ^{31}P nmr chemical shifts are given relative to external $OP(OMe)_3$ in $(CD_3)_2CO$, used as a reference/lock substance, in the annulus between the 10 mm tubes and a standard 12 mm od nmr tube; approximate conversion to H_3PO_4 (at 308 K) as reference is $\delta_{OP(OMe)_3(ext)} \approx \delta_{H_3PO_4(ext)} - 1.7$ ppm. Shifts to higher frequency than the reference are taken as positive. We estimate that δ_P and values of $^1J(^{31}P—^{77}Se)$ have maximum errors of ±0.1 ppm and ±2 Hz, respectively, as in ref. 2.

Results and discussion

Complexes of phosphine oxides

Samples containing $Zn(SbF_6)_2$ and $OPCy_3$ show two ^{31}P nmr resonances at ambient or reduced temperature when $OPCy_3/Zn > 4$. The more shielded of these is from excess free ligand and by studying the mixtures as a function of L/Zn the other can be attributed to $Zn(OPCy_3)_4^{2+}$. The ^{31}P chemical shift of this complex, and hence its complexation shift, both given in Table 1, are very similar to the 62.4 ppm (6.9 ppm) found for the cadmium analog (3). Evidently $Zn(OPCy_3)_4^{2+}$, like $Cd(OPCy_3)_4^{2+}$ (3), but unlike other $Zn(OPR_3)_4^{2+}$ (R = Bu" (15), NMe_2 (19), or Ph (20)), undergoes slow ligand exchange with excess free ligand at ambient probe temperature. A chemical dissimilarity between Zn^{2+}—$OPCy_3$ and Cd^{2+}—$OPCy_3$ mixtures concerns the formation of poorly soluble $M(OPCy_3)_3(SbF_6)_2$. This is formed in cadmium-rich mixtures but not in zinc-rich mixtures; in the latter case Zn^{2+} (solv.) and $Zn(OPCy_3)_4^{2+}$ seem to coexist in solution.

TABLE 1. ^{31}P nmr spectral parameters of some zinc complexes with phosphine oxides

Complex[a]	T (K)	δ_P[b] (ppm)	$\Delta\delta_P$[c] (ppm)
$Zn(OPCy_3)_4^{2+}$	209[d]	62.2	~1.8[e]
	308[d]	62.1	~4.9[e]
$Zn(dppmO_2)_3^{2+}$	209[d,f]	34.1	6.6
	308[d,f]	32.9	6.9
$Zn(dppmO_2)_2^{2+}$	209[f]	41.7	14.2
	308[f]	41.5	15.4
$Zn(triphosO_3)_2^{2+}$	204[g]	46.0(A)[h]	−1.0
		37.5(B)[h]	0.4
		35.6(C)[h]	−1.5

[a]Cy = c-C_6H_{11}; $dppmO_2$ = $Ph_2P(O)CH_2P(O)Ph_2$; $triphosO_3$ = $PhP(O)((CH_2)_2P(O)Ph_2)_2$.

[b]Measured relative to external $OP(OMe)_3$ in $(CD_3)_2CO$; $\delta_{OP(OMe)_3(ext)} \approx \delta_{H_3PO_4(ext)} - 1.7$ ppm; positive chemical shifts are to higher frequency than the reference; estimated error in measurement ±0.1 ppm or less.

[c]$\Delta\delta_P = \delta_P(complex) - \delta_P(free\ ligand)$.

[d]Slow exchange with excess free ligand at 209 and 308 K.

[e]δ_P and $\nu_{1/2}$ for free $OPCy_3$ depend markedly on temperature and solute concentration.

[f]Slow ligand exchange between 3:1 and 2:1 complexes at 209 and 308 K.

[g]Slow exchange with excess free ligand at 204 K, intermediate exchange at 308 K; the resonances B and C appear to be collapsing (intramolecular exchange) before intermolecular exchange becomes rapid (cf. ref. 1).

[h]A = non-terminal phosphorus atom, B and C = terminal phosphorus atom; $J(AB) \approx 7$ Hz; $J(AC)$ and $J(BC)$ are not observed.

Slow exchange ^{31}P nmr spectra are found at 308 K or below for $Zn(SbF_6)_2$–$dppmO_2$ mixtures over a range of L/Zn.[4] When L/Zn > 3 the spectra show two lines. The more shielded signal, attributable to excess free ligand, disappears at L/Zn ≈ 3 so that the highest complex formed is $Zn(dppmO_2)_3^{2+}$ which, by analogy with $Zn(triphosO_3)_2^{2+}$ (see below), probably contains an octahedral ZnO_6 core. When L/Zn < 3 a second species is formed which does not exchange ligands with the 3:1 complex at an nmr-detectable rate; its ^{31}P resonance is deshielded from that of $Zn(dppmO_2)_3^{2+}$ and becomes predominant at L/Zn ≈ 2. Hence the second zinc complex is $Zn(dppmO_2)_2^{2+}$. Details of the ^{31}P nmr spectra of the $dppmO_2$ complexes are included in Table 1. The ^{31}P chemical shift of the 3:1 complex is similar to that of $Cd(dppmO_2)_3^{2+}$ (34.5 ppm) which also exchanges slowly on the nmr timescale with excess free ligand at ambient probe temperature (1). However, the ^{31}P nmr chemical shift (and complexation shift) of $Zn(dppmO_2)_2^{2+}$ are significantly larger than found for

[4]The slow exchange ^{31}P nmr spectra observed for complexes of $Zn(SbF_6)_2$ and $dppmO_2$ in SO_2 at ambient probe temperature contrasts with the fast exchange spectra observed for $ZnCl_2 \cdot dppmO_2$–$dppmO_2$ mixtures in CH_2Cl_2 (15). This behaviour is consistent with the order of Lewis acidity $Zn(SbF_6)_2 > ZnCl_2$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

$Cd(dppmO_2)_2^{2+}$ (36.8 ppm (9.6 ppm) at 220 K (1)). In addition, ligand exchange in $Cd(dppmO_2)_2^{2+} - Cd(dppmO_2)_3^{2+}$ mixtures is fast at ambient probe temperature unlike the behaviour found here for the zinc complexes. A plausible explanation for these differences lies in the larger size of the cadmium ion: this should favour solvent and/or anion coordination to $Cd(dppmO_2)_2^{2+}$ (albeit short-lived to be consistent with the ^{31}P nmr spectra) and lead to a lower Lewis acidity at Cd and hence, probably, a smaller $\Delta\delta_P$; it should also favour what appears to be an S_E2 exchange process between the 2:1 and 3:1 complexes.

At 204 K, samples containing $triphosO_3/Zn > 2$ give a slow exchange ^{31}P nmr spectrum consisting of the partly superimposed spectra of excess free $triphosO_3$ and a 2:1 complex, $Zn(triphosO_3)_2^{2+}$. The spectrum of the 2:1 complex consists of three equally intense regions of resonance labelled A, B, and C in Table 1. As the temperature is raised, B and C begin collapsing together but intermolecular exchange with free ligand starts to occur before this process is complete and results in a broadened spectrum at 308 K. Nevertheless B and C can be assigned to the coordinated —$Ph_2P(O)$ groups and hence C to the coordinated —PhP(O)— group of a complexed $triphosO_3$. Overall this spectrum resembles that of $Cd(triphosO_3)_2^{2+}$ for which an *s-fac* structure has been suggested (1),[5] and so we tentatively assign the zinc complex the same structure. In these species the inequivalence of the terminal phosphoryl sites is thought to arise from the particular ligand conformation frozen out at low temperature (1). The lability of the zinc complex at ambient probe temperature is in contrast to the slow intermolecular exchange found for $Cd(triphosO_3)_2^{2+} - triphosO_3$ mixtures under the same conditions (1). The same order of lability, Zn > Cd, holds for complexes of $Ph_2P(O)(CH_2)_2P(O)Ph_2$; we could not obtain slow exchange ^{31}P nmr spectra of any $Zn^{2+} - dppeO_2$ mixtures at any accessible temperature (though $\Delta\delta_P$(ave) was significant), whereas slow exchange spectra have been measured for $Cd^{2+} - dppeO_2$ mixtures at reduced temperature (1). Possibly the bite of the seven-membered chelate ring gives a worse fit on Zn^{2+} than on the larger Cd^{2+}, resulting in labilization of the zinc complexes relative to the cadmium complexes.

Complexes with phosphine sulfides

At 199 K the ^{31}P nmr spectra of SO_2 solutions in which $dppmS_2/Zn(SbF_6)_2 > 2$ exhibit two signals. The more shielded of these is due to excess free $dppmS_2$ and variation of the L/M ratio shows that the less shielded arises from the 2:1 complex $Zn(dppmS_2)_2^{2+}$. This species has been isolated previously (12) and is now shown to exist in undissociated form in solution under the conditions of our experiment. The nmr spectral parameters of the complex are given in Table 2. As the temperature is increased from 199 K the signals from samples containing $Zn(dppmS_2)_2^{2+}$ and excess $dppmS_2$ broaden and eventually, close to ambient probe temperature, collapse to a single exchange-averaged signal. Clearly ligand exchange between free and bound $dppmS_2$ is rapid on the nmr timescale at or near 308 K. Overall, however, the zinc complex is less labile than its cadmium analog for which slow exchange ^{31}P nmr spectra could not be obtained under any conditions (1).

[5]An *s-fac* structure is also favoured for the complex $Zn(L\ L\ L)_2^{2+}$ of the tridentate phosphoryl donor ligand $(Me_2N)_2P(O)NMeP(O)(NMe_2)NMeP(O)(NMe_2)_2$ (25); this is the only other related species we are aware of.

TABLE 2. ^{31}P nmr spectral parameters of some zinc – phosphine sulfide complexes, $Zn(SPR_3)_n^{2+}$, in liquid SO_2 at 209 K

SPR_3[a]	n in $Zn(SPR_3)_n^{2+}$	δ_P[b] (ppm)	$\Delta\delta_P$[c] (ppm)

$SP(o\text{-tol})_3$	2[g,h]	41.0	2.9
$SP(o\text{-tol})_3$	1(?)[h]	40.7	2.6
$SPCy_3$	4[d,i]	64.4	−0.4
$SPCy_3$	3[i]	65.9	1.2
$SPCy_3$	2(?)	67.0	2.2
$dppmS_2/2$[j]	4	37.7	4.6

[a]o-tol = $o\text{-}C_6H_4Me$; Cy = $c\text{-}C_6H_{11}$; $dppmS_2 = Ph_2P(S)CH_2P(S)Ph_2$.

[b]Measured relative to external $OP(OMe)_3$ in $(CD_3)_2CO$; $\delta_{OP(OMe)_3(ext)} \approx \delta_{H_3PO_4(ext)} - 1.7$ ppm; positive chemical shifts are to higher frequency than the reference; estimated error in measurement ±0.1 ppm or less.

[c]$\Delta\delta_P = \delta_P$(complex) − δ_P(free ligand).

[d]Slow exchange with excess free ligand at 209 K, intermediate exchange at 308 K.

[e]Slow ligand exchange between 4:1 and 3:1 complexes at 209 K, fast exchange at 308 K.

[f]Slow ligand exchange between 4:1 and 3:1 complexes at 209 K, intermediate exchange at 308 K.

[g]Slow ligand exchange between 3:1 and 2:1 complexes at 209 K, fast exchange at 308 K.

[h]Slow ligand exchange in mixtures of 3:1, 2:1, and 1:1(?) complexes at 209 K, fast exchange at 308 K.

[i]Intermediate ligand exchange in mixtures of 4:1 and 3:1 complexes at 308 K.

[j]At 199 K; free-bound ligand exchange is slow at this temperature but fast at 308 K.

Solutions in which $SPR_3/Zn(SbF_6)_2 > 4$ (R = Ph, *o*-tol, or Cy) are readily shown by reduced temperature ^{31}P nmr spectroscopy to contain $Zn(SPR_3)_4^{2+}$, with, presumably, a tetrahedral ZnS_4 kernel. Phosphorus-31 nmr data for these complexes are included in Table 2; the values of $\Delta\delta_p$ are similar to those found for the related cadmium complexes (1, 2). Each of the zinc complexes, like $Zn(dppmS_2)_2^{2+}$ (above) is less labile than the corresponding cadmium complex, for free and bound ligand signals are incompletely collapsed at 308 K for the zinc complexes, but completely exchange-averaged for the cadmium complexes (1, 2). When SPR_3/Zn is reduced below 4, the pale yellow colour of excess SPR_3 in SO_2 disappears and the free ligand line in the reduced temperature ^{31}P nmr spectra is no longer seen. Instead, in each case a second signal attributable to bound SPR_3 is evident. From the variation of resonance intensity as a function of L/M it is clear that $Zn(SPR_3)_3^{2+}$ is formed. The ^{31}P nmr spectra of the 1:3 complexes are outlined in Table 2; again they resemble those of their cadmium analogs. As has been noted for the corresponding cadmium complexes (2), the extent of solvent or anion coordination in these $M(SPR_3)_3^{2+}$ species is not known, so it is unclear whether they contain the expectedly planar MS_3 core. When SPR_3/Zn is reduced below three, an additional signal was observed for R = Cy; this had intensity that varied as expected for $Zn(SPCy_3)_2^{2+}$ and a tentative assignment has been made accordingly (Table 2). (No evidence for $Cd(SPCy_3)_2^{2+}$ was found in earlier work (2).) Similarly, two additional signals were observed for R = *o*-tol, with an order of appearance and intensity variation suggesting the formation of first $Zn(SP(o\text{-tol})_3)_2^{2+}$ and then $Zn(SP(o\text{-tol})_3)^{2+}$. No additional signals were observed for R = Ph. However, we cannot preclude the possi-

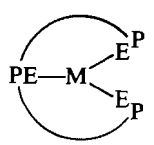
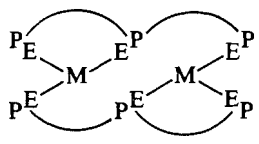
[a] o-tol = o-C_6H_4Me; Cy = c-C_6H_{11}; $dppmSe_2$ = $Ph_2P(Se)CH_2P(Se)Ph_2$.
[b] Measured relative to external $OP(OMe)_3$ in $(CD_3)_2CO$; $\delta_{OP(OMe)_3(ext)} \approx \delta_{H_3PO_4(ext)} + 1.7$ ppm; positive chemical shifts are to higher frequency than the reference; estimated error in measurement ±0.1 ppm or less.
[c] $\Delta\delta_P = \delta_P$(complex) − δ_P(free ligand).
[d] Estimated error ±2 Hz, except where noted.
[e] $\Delta J = J$(complex) − J(free ligand).
[f] Slow exchange with excess free ligand at the temperature of measurement but fast exchange at 308 K.
[g] Fast ligand exchange between 4:1 and 3:1 complexes at 308 K.
[h] Fast ligand exchange between 3:1 and 2:1 complexes at 308 K.
[i] Intermediate exchange between 4:1 and 3:1 complexes at 308 K.
[j] At 194 K.
[k] ±5 Hz.

bility that a 1:2 complex is formed in this case but gives a signal coincident with that of the 1:3 complex, as was found for $Cd(SP(o\text{-tol})_3)_{2\text{ or }3}^{2+}$ (2).

The 209 K ^{31}P nmr spectrum of an SO_2 solution in which triphosS_3/Zn = 1 showed an AMX spectrum which was assigned straightforwardly and is characterized by the parameters given in Table 4. This pattern is very similar to that observed for $Cd(triphosS_3)^{2+}$ (1), in which case it was interpreted in terms of the monomeric structure **I** (with a rigid conformation at reduced temperature causing inequivalence of the two —$P(E)Ph_2$ groups) or dimeric structure **II**, a prejudice being



I



II

expressed for **I**. The same interpretation can clearly be made here. At 209 K, mixtures in which L/M > 1 give broad ^{31}P nmr resonances indicating ligand exchange at an intermediate rate between the species present. (Although the comparative broadness of the nmr signals made assignment impossible, the spectra seem more complicated than expected for a simple mixture of $Zn(triphosS_3)^{2+}$ and excess triphosS_3.) In contrast, a fast exchange averaged AX_2 spectrum is found under the same conditions for cadmium (1).

TripodS_3, like triphosS_3, is a potentially tridentate ligand. However, the ligand has been shown to behave in a bidentate manner in $Cd(tripodS_3)_2^{2+}$ (1) and similar behaviour is found using zinc as an acceptor here. Only a 1:2 species, $Zn(tripodS_3)_2^{2+}$, could be identified with certainty in $Zn(SbF_6)_2$–tripodS_3 mixtures using ^{31}P nmr. At 308 K this complex, which, in contrast to $Cd(tripodS_3)_2^{2+}$, shows no nmr-detectable exchange with free ligand, has a ^{31}P nmr spectrum (Table 4) comprised of three equally intense lines. This is just the spectrum expected for

$$[Zn(((S)Ph_2PCH_2)_2\overset{Me}{C}CH_2PPh_2(S))_2]^{2+}$$

of time-averaged C_2 symmetry, and therefore we assign $Zn(tripodS_3)_2^{2+}$ the bis(bidentate) structure. On lowering the temperature, slight changes in chemical shift occur but the most marked change is the splitting of the least shielded resonance into two equally intense components. Similar but more extensive splitting in the resonances of the bound —$PPh_2(S)$ groups has been found for $Cd(tripodS_3)_2^{2+}$ and attributed to destruction of the C_2 symmetry by conformational effects (1). In the spectrum of the cadmium complex the resonances of the bound groups are readily apparent because of the $^{113/111}Cd$—^{31}P satellites (1). The ^{31}P nmr spectrum of $Zn(tripodS_3)_2^{2+}$ (Table 4) is assigned by analogy with that of $Cd(tripodS_3)_2^{2+}$

Complexes with phosphine selenides

Coordination is easier to show unambiguously for phosphine selenides than for phosphine sulfides because for the selenides it leads not only to a complexation shift $\Delta\delta_P$ normally, but also to a reduction in the magnitude of the $^1J(^{31}P—^{77}Se)$ satellite splitting (from ^{77}Se, 7.58% natural abundance, spin $I = 1/2$) (e.g. refs. 1, 2, 28–33).

In the system $Zn(SbF_6)_2$–$dppmSe_2$ in SO_2, the complex $Zn(dppmSe_2)_2^{2+}$ is readily detected by reduced temperature ^{31}P nmr of solutions in which L/M > 2. Details of the spectrum of this presumably tetrahedral complex are given in Table 3; both $\Delta\delta_P$ and $\Delta^1J(^{31}P—^{77}Se)$ are very similar to those found for $Cd(dppmSe_2)_2^{2+}$ (1). The major difference between the zinc and cadmium complexes is in their lability on the nmr timescale: whereas separate ^{31}P nmr signals from $Zn(dppmSe_2)_2^{2+}$ and free $dppmSe_2$ can be observed at 194 K, only an exchange-averaged spectrum is observed at this temperature for $Cd(dppmSe_2)_2^{2+}$–$dppmSe_2$ mixtures (1). At 308 K rapid exchange of free and bound ligand occurs for $Zn(dppmSe_2)_2^{2+}$–$dppmSe_2$ mixtures; the behaviour at intermediate temperatures is approximately the same as for $Zn(dppmS_2)_2^{2+}$–$dppmS_2$ mixtures (see above).

Complex formation between $Zn(SbF_6)_2$ and representative

[a]$triphosE_3$ = $PhP(E)((CH_2)_2P(E)Ph_2)_2$; $tripodE_3$ = $MeC(CH_2P(E)Ph_2)_3$.

[b]Resonances are labelled as for the corresponding cadmium complexes (1).

[c]Measured relative to external $OP(OMe)_3$ in $(CD_3)_2CO$; $\delta_{OP(OMe)_3(ext)} \approx \delta_{H_3PO_4(ext)} - 1.7$ ppm; positive chemical shifts are to higher frequency than the reference; estimated error in measurement ±0.1 ppm or less.

[d]$\Delta\delta_P = \delta_P$(complex) − δ_P(free ligand).

[e]Estimated error ±2 Hz except where noted otherwise.

[f]$\Delta J = J$(complex) − J(free ligand).

[g]Estimated error ±1 Hz.

[h]Terminal phosphorus atom.

[i]Non-terminal phosphorus atom.

[j]Could not be observed with certainty.

[k]This spectrum consists of three resonances at 308 K.

[l]At 308 K, $\delta_P(\Delta\delta_P)$ = 31.0 (−2.3), 33.1 (−0.2), and 31.5 ppm (−1.8 ppm), for P_A, P_B, and P_C respectively; by analogy with results for $Cd[(SPPh_2CH_2)_2MeCH_2PPh_2S]_2^{2+}$ (1) P_A is assigned to the unbound $\rangle$PS group.

[m]At 308 K, $\delta_P(\Delta\delta_P)$ and ^1J(P—Se) are 20.0 (−1.9) and 702, 18.9 (−3.0), and ~545, and 17.0 ppm (−4.9 ppm) and ~550 Hz for P_A, P_B, and P_C, respectively; exchange with excess free ligand is slow at both 209 and 308 K; P_A is assigned to the unbound $\rangle$PSe group.

monophosphine selenides, R_3PSe, is indicated visually by blanching of the yellow colour of the ligand−SO_2 solutions (due to $R_3PSe \cdot SO_2$ (28)). At reduced temperature, ^{31}P nmr spectra attributable to the complexes $Zn(SePR_3)_4^{2+}$ (R = Ph, *o*-tol, or Cy) can be observed; details of the spectra are given in Table 3. At 209 K intermolecular ligand exchange between the 1:4 complexes and the corresponding free R_3PSe is slow on the nmr timescale but the rate of exchange becomes rapid by 308 K. In a comparison of the ^{31}P nmr spectra of $Zn(SePR_3)_4^{2+}$ (Table 3) and $Cd(SePR_3)_4^{2+}$ (1, 2) the most striking similarity is in the values of $^1J(^{31}P—^{77}Se)$ (and hence $\Delta J(^{31}P—^{77}Se)$) which are identical within experimental error.

As R_3PSe/Zn (R = Ph, Cy, or *o*-tol) is reduced in the appropriate solutions, the complexes $Zn(SePR_3)_3^{2+}$ are formed; the ^{31}P nmr spectra of these species (Table 3) show sufficient similarity to those of their cadmium analogs (2) to support these assignments. When R = *o*-tol or Cy, entities of even lower ligation number are formed when $L/M \lesssim 2$. The ^{31}P nmr spectra of these (Table 3) have smaller ^{77}Se satellite splittings than the corresponding 1:3 complexes, and, in addition, the value of $^1J(^{31}P—^{77}Se)$ found when R = *o*-tol is close to that observed for $Cd(SeP(o\text{-tol})_3)_2^{2+}$ (504 Hz (2)). Hence it is probable that the complexes formed are $Zn(SePR_3)_2^{2+}$ (R = *o*-tol or Cy). It seems certain that $Zn(SePPh_3)_2^{2+}$ is not formed because its smaller ^{77}Se satellite splitting should have been evident even if there was no significant ^{31}P nmr chemical shift difference between the 1:3 and 1:2 complexes.

When $triphosSe_3/Zn(SbF_6)_2$ = 1, a 1:1 complex is formed giving, at 209 K, a slow-exchange ^{31}P nmr spectrum of the AMX type, an easily recognizable and interpretable pattern; the spectral parameters are given in Table 4. However, in many attempts we could not produce $Zn(triphosSe_3)^{2+}$ as cleanly as $Zn(triphosS_3)^{2+}$ (see above): the nmr spectrum invariably contained other lines varying in intensity from attempt to attempt. We can offer no simple explanation for this behaviour, but because of it, and because of overlap with the AMX centre band, not all of the ^{77}Se satellites of the spectrum of $Zn(triphosSe_3)^{2+}$ could be observed. In comparison with $Cd(triphosSe_3)^{2+}$, which undergoes rapid intermolecular ligand exchange with free $triphosSe_3$ at all temperatures (1), the zinc complex undergoes slower ligand exchange. As for the corresponding trisulfide (see above), broad ^{31}P nmr lines are found for $Zn(triphosSe_3)^{2+}$−$triphosSe_3$ mixtures at 209 K. Either of structures **I** and **II** is consistent with the slow-exchange spectrum of $Zn(triphosSe_3)^{2+}$.

A 1:2 complex, $Zn(tripodSe_3)_2^{2+}$, is formed with Zn^{2+} and $tripodSe_3$ in SO_2. At 308 K the ^{31}P nmr spectrum of this complex consists of three equally intense resonances and is not noticeably changed in the presence of excess $tripodSe_3$. The least shielded resonance (P_A in Table 4) has a ^{77}Se satellite splitting *larger* than that of uncomplexed $tripodSe_3$, while the other two resonances have smaller values of $^1J(^{31}P-^{77}Se)$ than the free ligand. Clearly only two of the three PSe groups of the ligand are coordinated, and $Zn(tripodSe_3)_2^{2+}$, like $Zn(tripodS_3)_2^{2+}$ (see above), should be formulated as a bis-(bidentate) complex of time-averaged C_2 symmetry. At re-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

duced temperatures this symmetry is apparently reduced, P_B being split (Table 4). Again we attribute this loss of symmetry to conformational effects. Both the chemical shifts and the values of $^1J(^{31}P—^{77}Se)$ found for $Zn(tripodSe_3)_2^{2+}$ (Table 4) are remarkably similar to those found earlier for $Cd(tripodSe_3)_2^{2+}$ (1). Chemically the major difference between $Zn(tripodSe_3)_2^{2+}$ and $Cd(tripodSe_3)_2^{2+}$ is in the lability of the bound ligand: whereas the zinc complex is non-labile on the nmr timescale at 308 K with or without excess $tripodSe_3$, $Cd(tripodSe_3)_2^{2+}$ undergoes intermolecular exchange at an intermediate rate under the same conditions (1).

Complexes of mixed ligands

To further strengthen our assignments for the 1:3 and 1:4 complexes with R_3PS and R_3PSe, we investigated the low temperature ^{31}P nmr spectra of solutions containing mixtures of $SPCy_3$ and $SePCy_3$ at different (total L)/Zn and $SPCy_3/SePCy_3$ ratios.

When (total L)/Zn $\gtrsim$ 4, a total of four signals was observed for coordinated $SPCy_3$ when the S/Se ratio was varied, as expected for the formation of $|Zn(SePCy_3)_x(SPCy_3)_{4-x}|^{2+}$. (At the same time we found that the sulfide and selenide compete approximately equally for coordination to the zinc.) For a typical sample at 209 K, the values of $\delta_P(SPCy_3(coord))$ were 64.4_6, 64.3_4, 64.1_9, and 64.0_2 ppm for $x = 0$, 1, 2, and 3 respectively, assignments being made from variation of the spectrum with change in S/Se ratio. Unfortunately we could not obtain the complementary information from the $SePCy_3$ region: the total variation of chemical shift and $^1J(^{31}P—^{77}Se)$ were insufficient to allow satisfactory resolution of the different centreband and ^{77}Se satellite resonances anticipated for the selenide in the various mixed ligand complexes. Nevertheless the existence of the four-coordinate complexes is confirmed.

Using (total L)/Zn < 3 (to avoid complications in the spectra from the co-existence of the four-coordinate species) a total of three signals from bound Cy_3PSe was observed in the expected region, in agreement with prediction for $|Zn(SePCy_3)_x(SPCy_3)_{3-x}|^{2+}$. Assignments were made by studying intensity as a function of the S/Se ratio, and in a typical sample $\delta_P(SePCy_3$ (coord)) and $^1J(^{31}P—^{77}Se)$ were 63.8_7 and 502, 64.0_1 and 503, and 64.1_9 ppm and 504 Hz for $x = 1$, 2, and 3, respectively. In this series the separate resonances expected for $SPCy_3$ bound in the different complexes could not be observed, but again the stoichiometry, 1:3 in these complexes, is confirmed despite this lack.

Attempts to produce species with mixtures of $SPCy_3$ and $OPCy_3$ or $SePCy_3$ and $OPCy_3$ as ligands were unsuccessful. At (total L)/Zn $\approx$ 4 (excess $OPCy_3$ displaces $EPCy_3$ (E = S or Se) completely) the major species present were identified as $Zn(EPCy_3)_4^{2+}$ (E = S or Se) and $Zn(OPCy_3)_4^{2+}$ by their reduced temperature ^{31}P nmr spectra. This is the same "antisymbiotic" (34) behaviour found earlier for divalent cadmium (3), tin (33), and lead (33) as acceptors.

Régiosélectivité d'additions de nucléophiles sur des dialkoxycarbonyle quinoxalinotropones

ALAIN TURCK, ROLAND BOUTTE ET GUY QUÉGUINER[1]

Université de Rouen, Institut National Supérieur de Chimie Industrielle de Rouen, Laboratoire de Chimie Organique Hétérocyclique, F-76130 Mont Saint Aignan, France

Reçu le 25 novembre 1982

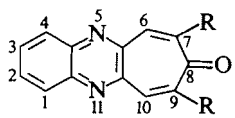
ALAIN TURCK, ROLAND BOUTTE et GUY QUÉGUINER. Can. J. Chem. **61**, 1806 (1983).

Nous avons étudié la régiosélectivité d'additions de type Michaël sur des tropones accolées à la quinoxaline: les dialkoxycarbonyle quinoxalinotropones. Nous avons utilisé des nucléophiles carbonés (malonate d'éthyle et malononitrile), oxygénés (méthylate de sodium), soufrés (méthyl et benzyl mercaptans), azotés (méthyl, phénylhydrazine et aniline). Nous avons pu montrer que ces additions conduisaient en général à des monoadditions de type 1,4 (par référence aux α énones) ou à des produits pontés provenant d'une bis-addition de type 1,4 (αα′ diénone). Nous avons pu élucider les structures complexes obtenues par référence aux travaux de B. Föhlisch et coll. en série homoaromatique. Dans le cas des hydrazines substituées nous avons pu apporter un élement de réponse au mécanisme du réarrangement proposé par ces mêmes auteurs.

ALAIN TURCK, ROLAND BOUTTE, and GUY QUÉGUINER. Can. J. Chem. **61**, 1806 (1983).

We have studied the regioselectivity of Michael type additions on tropones attached to quinoxalines, i.e. dialkoxycarbonyl quinoxalinotropones. We used carbon nucleophiles (ethyl malonate and malononitrile), oxygen nucleophiles (sodium methoxide), sulphur nucleophiles (methyl and benzyl mercaptans), and nitrogen nucleophiles (methyl and phenylhydrazine, aniline). We have shown that, in general, these reactions lead to 1,4-monoadditions or to bridged products arising from a bis-1,4-addition process. We have determined the structures of the complexes obtained by comparison to the work of Fohlisch *et al.* in the homoaromatic series. For the case of substituted hydrazines, we present some evidence on the rearrangement mechanisms proposed by these authors. [Journal translation]

L'intérêt chimique et biologique des dérivés troponiques suscite depuis quelques années de nombreuses publications. En particulier plusieurs dérivés comportant un cycle aromatique accolé au cycle troponique ont été synthétisés (1−10). Après avoir étudié la réduction par divers borohydrures alcalins de tropones de la quinoxaline **1**, nous avons entrepris une étude de



1

1*a* R = COOR′
1*b* R = phényl

la régiosélectivité d'additions de type Michaël de nucléophiles carbonés, oxygénés, soufrés, azotés sur un cycle troponique accolé à un cycle aromatique. Cette étude sur les dialkoxycarbonyl-7,9 oxo-8 (8*H*) cyclohepta[*b*]quinoxalines **1***a* s'appuie sur les résultats obtenus par B. Föhlisch et coll. à partir des benzotropones (1, 11, 12, 15).

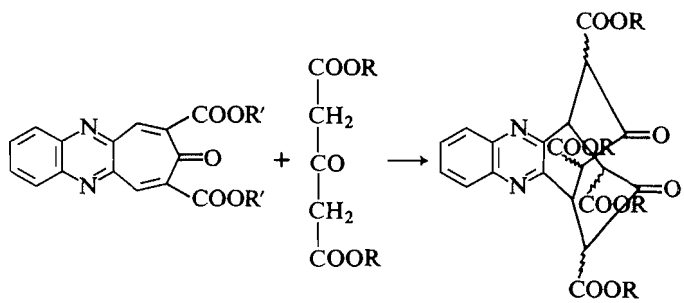
Une structure telle que **1***a* présente trois sites électrophiles principaux 6, 8, 10. Les agents nucléophiles peuvent donc conduire à des composés résultants (*i*) d'une simple attaque en 6, 10, ou 8; (*ii*) d'une double attaque 6,8 ou 6,10 avec un nucléophile monofonctionnel; une attaque de type 6,10 sur une diénone a été observée par Foster et Payne (13); (*iii*) d'une double attaque 6,8 ou 6,10 avec un nucléophile polyfonctionnel conduisant éventuellement à un produit ponté. House *et al.* (14) ont donné un exemple d'une telle attaque de type 6,8 sur une α énone;[2] (*iv*) d'une triple attaque 6,8,10 comme indiquée par Thiele et Hädicke (15) avec des hydrazines.

Il faut souligner l'intérêt de ces réactions conduisant en particulier à des analogues d'antiparkinsoniens tels que la benzotropine et à des analogues hétérocycliques de précurseurs de la tropanone et de l'atropine (parasympatholytiques) (16).

I. Addition de nucléophiles carbonés

1. *Addition de Michaël avec l'acétone dicarboxylate d'éthyle-1,3*

Nous avons obtenu les produits de bis-addition 6,10 **4***a* et **4***b* par action des acétones dicarboxylate de méthyle et d'éthyle **2***a* et **2***b* sur le composé **1***a*.



1*aa* R′ = CH_3 **2***a* R = CH_3 **4***a* R = CH_3
1*ab* R′ = C_2H_5 **2***b* R = C_2H_5 **4***b* R = C_2H_5

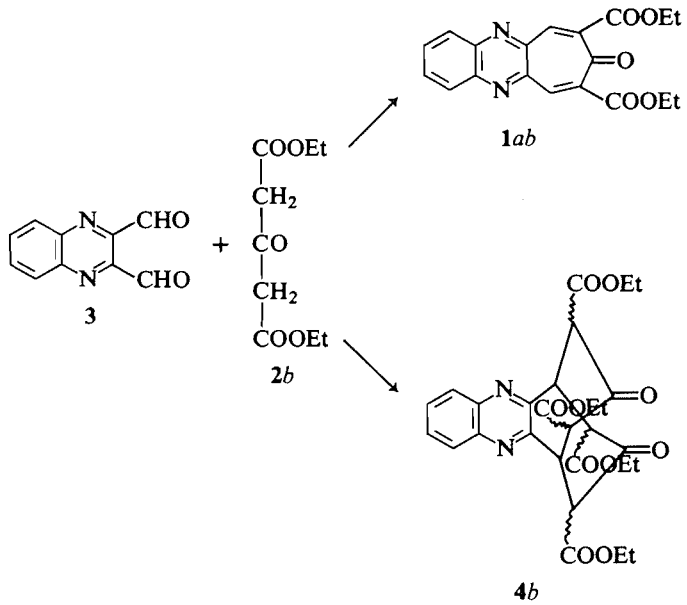
Remarquons que lors de la synthèse de la dicarbethoxy-7,9 oxo-8 (*H*) cyclohepta[*b*]quinoxaline **1***ab* nous avions constaté la formation du même produit d'addition **4***b* au cours de la réaction de l'acétone dicarboxylate d'éthyle **2***b* sur la diformyl quinoxaline **3**.

Le composé **4***b* présente un spectre de rmn complexe qui ne correspond pas à la formule développée d'un composé dicétonique. La comparaison du spectre de rmn de **4***b* avec celui du composé analogue en série benzénique dont la structure a été démontrée par Föhlisch (1) montre que le composé **4***b* est sous la forme du bisénol **6**.

Nous observons un singulet à 13,28 ppm correspondant à deux protons échangeables par D_2O. Ce signal doit correspon-

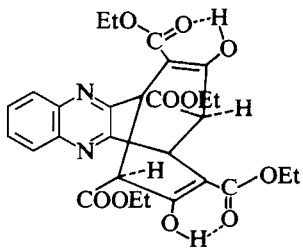
[1]Auteur à qui adresser la correspondance.

[2]On pourrait aussi envisager des réactions intermoléculaires pouvant conduire à des polymères.



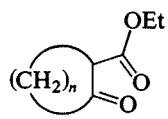
3 2b 1ab 4b

dre à des protons d'énols chélatés avec des fonctions ester voisines. Le déplacement chimique supérieur à ceux observés



6

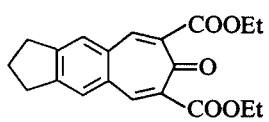
par Rhoads (17) pour la forme énol de carbethoxy-2 cyclanones **5** indique une très forte liaison hydrogène.



5

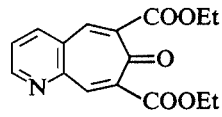
La présence de protons de type énol est confirmée par le spectre infrarouge qui montre une bande d'absorption large vers 1650 cm^{-1} et une plus étroite vers 1615 cm^{-1}; ces bandes sont caractéristiques (18) d'un groupe C=O chélaté de l'ester d'une part et du groupe C=C de l'énol d'autre part. De même le spectre ultraviolet montre une absorption dont la longueur d'onde et le coefficient d'extinction (λ = 255 nm, log ϵ 4,12) sont typiques d'une forme énol chélatée (19).

La synthèse de composés analogues a été signalée par quelques auteurs: (*i*) D. J. Bertelli (20) lors de la synthèse du composé homologue dans la série de l'indane:

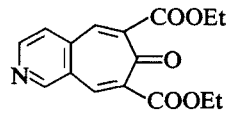


7

(*ii*) D. Letouzé (8) dans notre laboratoire, en série pyridinique:



8

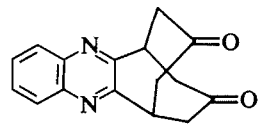


9

La dernier auteur a montré que la forme préférentielle en solution était de type **6**.

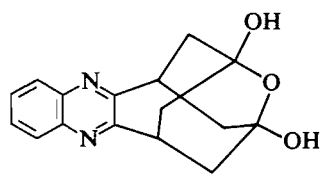
Synthèse du tétrahydro-6,7,9,10 époxy-8,13 propano-6,10 (8H) cyclohepta[b]quinoxaline diol-8,13 **11**

Le tétraester **6** présente deux fois l'élément de structure d'un β-oxoester énolisé et peut donc s'hydrolyser et se décarboxyler facilement. Nous l'avons traité par un mélange d'acides chlorhydrique et acétique et avons obtenu la dicétone **10**.



10

Ce type de composé est susceptible par des attaques nucléophiles de conduire à une cyclisation intramoléculaire (1). Par chauffage de **10** dans l'eau on obtient **11** dont la structure est confirmée par infrarouge et rmn.



11

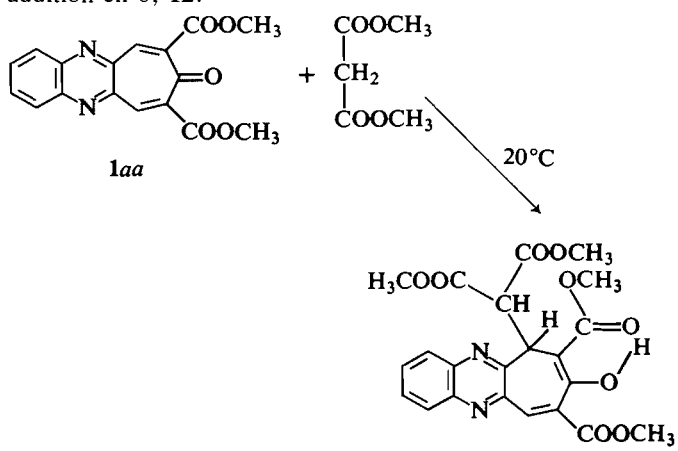
2. *Addition de Michaël avec des composés présentant un seul méthylène actif*

Nous envisageons ensuite la réaction de nucléophiles carbonés ne présentant qu'un site nucléophile pour déterminer si nous obtiendrons un produit résultant de l'addition d'une mole de nucléophile sur un site 6 ou 8 ou sur deux sites (pontage) 6,8 ou 6,10 ou de deux moles de nucléophiles sur deux sites 6,8 ou 6,10.

Nous étudions la réaction avec le malonate d'éthyle et le malononitrile.

(a) *Malonate de méthyle*

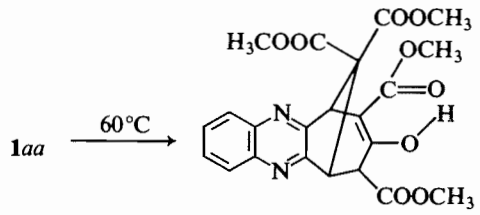
Si la réaction est conduite à 20°C dans le méthanol en présence de triéthylamine on obtient le produit de monoaddition en 6, **12**.



1aa 12

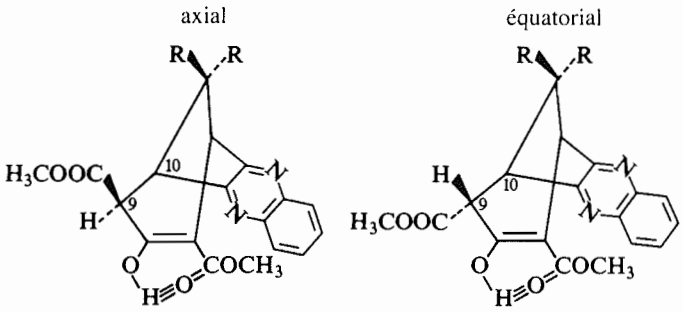
12

A 60°C l'action du malonate de méthyl sur **1***aa* conduit au composé de diaddition pontée 6,10, **13**.



13

Le produit **13** peut présenter deux isomères **14***a* et **15***a* suivant que le substituant carbométhoxylé en C(9) se trouve en position axiale ou équatoriale.



14*a* R = $COOCH_3$
b R = CN

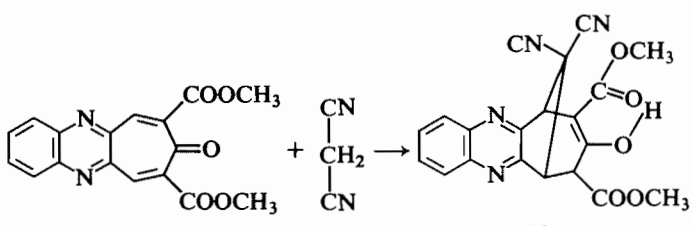
15*a* R = $COOCH_3$
b R = CN

Le composé **13** présente une constante de couplage J_{9-10} = 6 Hz qui est très proche de celle trouvée par Föhlisch sur son homologue en série benzénique $J_{8,9}$ = 5.6 Hz pour un composé sous la forme équatoriale ($J_{8,9} \leq 2$ Hz pour la forme axiale) ce qui indique comme celui-ci l'a démontré (12) que **13** est sous la forme équatoriale **15***a*.

(b) *Action du malononitrile*

Nous n'avons jamais pu isoler de composé de monoaddition. Dans le méthanol, en présence de triéthylamine, on obtient directement la dicarbométhoxy-7,9 dicyano-12,12 hydroxy-8 dihydro-9,10 méthano-6,10 (6*H*) cyclohepta[*b*]quinoxaline **16** (produit d'addition ponté en 6,10).

Notons que Föhlisch (11) a synthétisé des composés analogues à partir du dicarbométhoxy-6,8 oxo-7 (7*H*) benzocycloheptène, il n'observe qu'un isomère équatorial alors que nous avons mis en évidence la présence des 2 isomères axiaux et équatoriaux.



1*aa* **16**

Le composé **16** dont la structure est proche de celle du tétraester **13** présente un spectre de résonance magnétique nucléaire nettement différent. Nous avons en particulier constaté la présence de deux singulets correspondant à des protons de type énol (δ = 12,63 et δ = 12,4 ppm). Il y a donc un mélange de deux isomères. Nous pouvons écarter les isomères correspondant à une monoaddition. En effet de tels composés donneraient en rmn un massif fortement déblindé correspondant à cinq protons (quatre protons du cycle benzénique et le proton H(10)). Ceci se traduirait, dans le mélange, par une intégration excédentaire dans la zone des protons aromatiques, or celle-ci indique exactement quatre protons. Ce spectre ne peut donc s'expliquer que par un mélange de deux isomères **14***b* et **15***b* où les groupes carbométhoxyles en C(9) se trouvent respectivement en position axiale ou équatoriale, ce dernier composé étant majoritaire (75%).

L'encombrement stérique du groupe $-C\equiv N$, plus faible que celui d'une fonction ester, explique que l'on observe la formation de 25% de composé axial dans le cas du composé **13**.

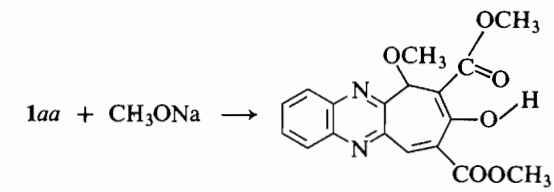
L'action des nucléophiles carbonés envisagés conduit soit à des monoadditions en 6 soit à des adduits pontés en 6,10. Ces résultats concordent avec ceux de Britten Kelly et Willis (21) dans le cas d'une αα′diénone. Dans le cas des additions avec pontage on constate la formation prépondérante du dérivé possédant une fonction ester en position équatoriale sur (C9).

Notons qu'avec les nucléophiles carbonés utilisés nous n'avons pas observé de produits résultants d'une attaque nucléophile sur le carbone C(8) (C=O) ni de bis-addition de deux moles de nucléophile à la fois en 6 et 10 ou 6 et 8 alors que House *et al.* (14) ont obtenu une addition de type 6,8 avec la cyclohéxène-2 one.

II. Nucléophiles oxygénés et soufrés

1. *Nucléophile oxygéné*

Par action du méthylate de sodium sur **1***aa* nous obtenons la dicarbométhoxy-7,9 hydroxy-8 méthoxy-6 (6*H*) cyclohepta[*b*]quinoxaline **17**.



17

Nous constatons sans ambiguité d'après le spectre rmn une monoaddition.

Foster et Payne (13) ont isolé au cours d'une réaction analogue sur la diméthoxy-4,4′ cyclohexadiène-2,5 one **18** la tétraméthoxy-3,4,4′5′ cyclohexanone-2,5 **19** avec un rendement de 17%.

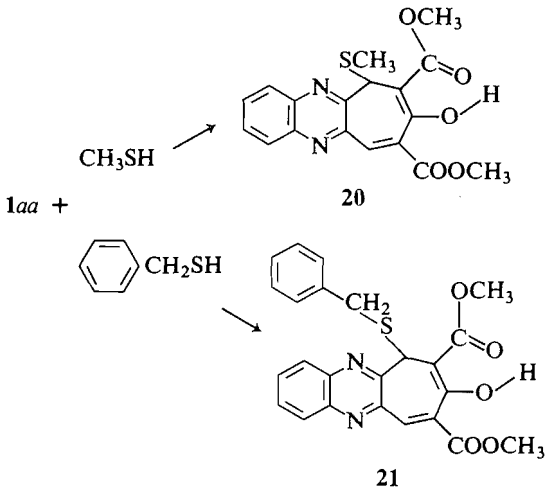
18 **19**

Dans le but d'obtenir une bis-addition nous avons fait réagir deux équivalents de méthylate de sodium sur **1***aa*; nous avons obtenu le même composé de monoaddition **17**.

2. *Nucléophiles soufrés*

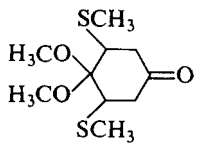
Nous avons fait réagir dans le méthanol à chaud les méthyl et benzylmercaptans. Nous avons obtenu avec de bons rendements les composés d'addition **20** et **21**.

En faisant agir CH_3SH sur le composé **18**, Foster et Payne



(13) ont obtenu une bis-addition avec un excellent rendement.

Dans le cas des nucléophiles oxygénés et soufrés utilisés



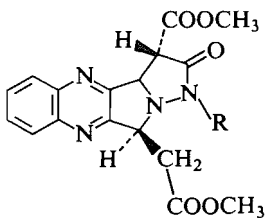
19bis

nous n'avons pas rencontré de bis-addition de deux moles de nucléophile en 6 et 10 ou 6 et 8, ni d'addition en C(8).

III. Nucléophiles azotés

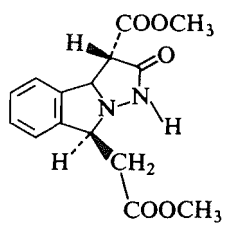
Les nucléophiles azotés tels que les méthyl, phénylhydrazines et l'aniline sont susceptibles comme les nucléophiles carbonés de donner lieu à des pontages.

Les méthyl et phénylhydrazines conduisent aux composés **22** et **23**.



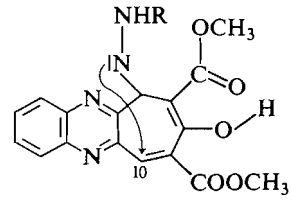
22 R = CH_3
23 R = phényl

Les produits **22** et **23** ont été identifiés grâce à leur spectre de rmn par analogie avec celui du carbométhoxy-3 oxo-2 tétrahydro-2,3,3a,8 (1H) pyrazolo[5,1-*a*]isoindole **24** dont Föhlisch et coll. (15) ont démontré la structure par RX.

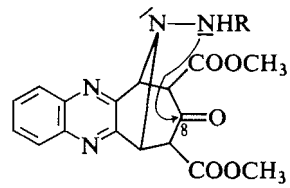


24

La formation de ce type de composé peut s'expliquer à partir du monoadduit **25** par deux mécanismes différents proposés par Föhlisch et coll. (15).



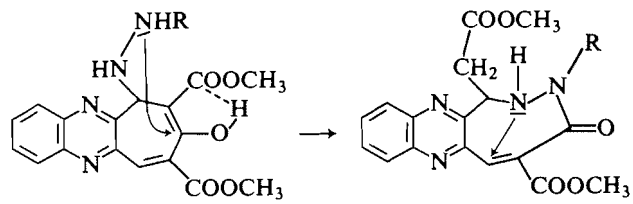
25



26

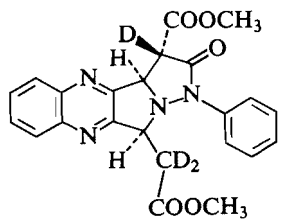
(a) Attaque nucléophile sur C(10) conduisant à un produit ponté **25** puis attaque de l'azote libre sur (C8) (carbonyle) suivie d'une ouverture du cycle en (C7)—C(8). Remarquons que l'attaque du C(8) est favorisée par la proximité géométrique de l'azote.

(b) Attaque de l'azote substitué sur le carbonyle puis attaque en (C10) après ouverture du cycle en C(8).



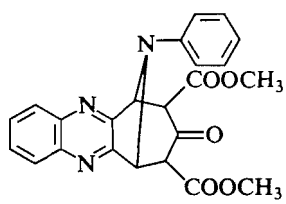
27

Pour essayer de mettre en évidence la formation d'un des intermédiaires **26** ou **27** nous avons tenté de suivre cette réaction en rmn. Nous avons fait agir à température ambiante la phénylhydrazine sur le diester **1***aa* dans le méthanol deutérié CH_3OD.[3] Nous avons observé directement l'apparition du composé deutérié **28** caractérisé par les signaux des protons H(10) et H(11).



28

Nous avons pu synthétiser **29**, un analogue de l'intermédiaire **26** par l'action de l'aniline sur le composé **1***ab*. La



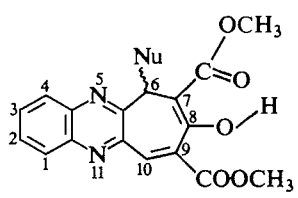
29

[3]L'utilisation de CH_3OD permet une simplification du spectre de rmn de **28** et donc une meilleure possibilité d'analyse du mélange réactionnel susceptible de contenir **28** et les espèces intermédiaires recherchées.

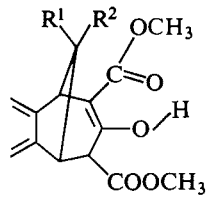
synthèse de **29** prouve la possibilité d'existence d'un intermédiaire de réaction ponté de type **26**. De plus, nous n'avons jamais rencontré avec les nucléophiles utilisés une attaque nucléophile directe sur le sommet 8. Tout ceci nous permet de proposer le premier des deux mécanismes envisagés par Föhlisch et coll. (15).

Conclusions

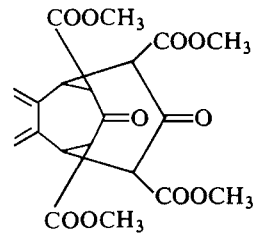
Les différentes réactions d'additions nucléophiles réalisées sur la 8*H* cyclohepta[*b*]quinoxaline dicarboxylate de méthyle-7,9 **1***a* conduisent exclusivement à des monoadditions de type I et à des produits pontés de bis-addition 6,10 de type II ou II′. Nous n'avons jamais obtenu d'addition provenant d'une



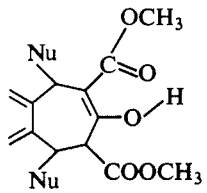
I



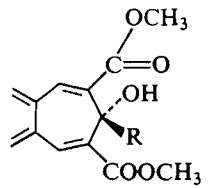
II



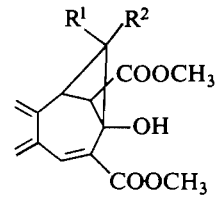
II′



III



IV



V

attaque nucléophile initiale en C(8) conduisant à une structure de type IV, de produits non pontés de bis-addition en 6 et 10 de type III ni de produits provenant d'un pontage en 6,8 de type V comme dans le cas d'une α énone (14).

Nous avons rencontré une triple attaque 6,10 puis 8 lors de l'action de dérivés de l'hydrazine. L'attaque en 8 conduit à une réarrangement complexe et nous avons pu apporter un élément au mécanisme de ce réarrangement.

Les additions de Michaël ainsi que les additions nucléophiles sur les cétones sont connues pour être réversibles. Föhlisch et coll. ont montré que pour la benzotropone le pontage 6,10 était aussi réversible dans les conditions de la réaction. Ce sont donc des réactions sous contrôle thermodynamique et le facteur déterminant est la stabilité des produits finals.

De l'étude de nos résultats il ressort que les produits de structure III, IV et V sont moins stables que ceux de structure I, II ou II′. Les structures IV et V ne possèdent plus la stabilisation apportée par la liaison hydrogène forte de l'H énolique avec l'oxygène de l'ester en α qui existe dans toutes les autres structures.

Nous n'avons pas d'hypothèse satisfaisante pour expliquer la plus faible stabilité des produits de structure III par rapport à ceux de structure I et II ou II′.

La réaction avec le malonate de méthyle montre la plus grande stabilité de la structure pontée II par rapport à la structure I.

Par action d'un nucléophile polyfonctionnel: acétone dicarboxylate de méthyl-1,3 nous observons une structure pontée de type II′ et non de type II. La structure II′ présente deux liaisons hydrogènes intramoléculaires alors que la structure II n'en présente qu'une, de plus cette forme II′ a des tensions de cycle plus faibles.

En outre ce travail nous a permis d'accéder à de nombreux composés polycycliques complexes dont nous avons pu préciser les structures.

Partie expérimentale

Les points de fusion ont été déterminés sur un banc de Kofler et n'ont pas été corrigés.

Les microanalyses ont été réalisées sur un appareil Technicon.

Les spectres ir ont été enregistrés soit avec un spectrographe Perkin–Elmer 237 soit avec un spectrographe Beckman IR 4250.

Les spectres de rmn ont été enregistrés dans le deutériochloroforme avec le TMS comme référence interne ou dans le DMSO avec le HMDS comme référence interne avec un appareil Varian T 60. Les déplacements chimiques sont exprimés en ppm par rapport au TMS.

*Dihydroxy-8,13 dihydro-9,10 propéno-10,6 (6*H*) cyclohepta(*b*)-quinoxaline tétracarboxylate d'éthyle-7,9,12,14* **4**b

Méthode (a)

Ce produit a d'abord été obtenu lors de la synthèse de la diméthoxycarbonyl-7,9 oxo-8 (8*H*) cyclohepta(*b*)quinoxaline. Après filtration du milieu réactionnel, on ajoute dans le filtrat de l'éther de pétrole jusqu'à éclaircissement de la solution. On filtre, puis on évapore à sec. Le résidu ainsi obtenu est extrait à l'éther sulfurique à chaud.

Méthode (b)

500 mg (2,69 mmol) de quinoxaline dicarboxyaldéhyde-2,3 **3** sont dissous dans 50 cm^3 de méthanol. On ajoute 1,09 g (5,4 mmol) d'acétone dicarboxylate d'éthyle-1,3 et trois gouttes de triéthylamine. On agite une heure à température ambiante. Un précipité apparait. Après filtration et lavage à l'éther on obtient 870 mg (55%) de produit d'addition. Recristallisation dans l'éthanol.

Méthode (c)

500 mg (1,42 mmol) de diéthoxycarbonyl-7,9 oxo-8 (8*H*) cyclohepta(*b*)quinoxaline **1***ab* sont mis en suspension dans 50 cm^3 de méthanol. On ajoute 290 mg (1,42 mmol) d'acétone dicarboxylate d'éthyle-1,3 et trois gouttes de triéthylamine. On agite à froid pendant une heure. Un précipité blanc apparaît. On filtre, lave à l'éther. On obtient 630 mg (80%) de composé d'addition. Recristallisation dans l'éthanol, *F*: étalé à partir de 210°C; ir (KBr, cm^{-1}): 3000, 2950 (CH), 1730, 1650 (C=O), 1615 (C=C); ^{1}H rmn ($CDCl_3$) δ: 0,76 (t, 6H, J = 7 Hz, CH_3), 1.46 (t, 6H, CH_3), 3.76 (q, 4H, CH_2), 3,90 (d, 2H, J_{9-10} = 4,5 Hz, H(9) et H(14), 4,36 (q, 4H, CH_2), 5,05 (d, 2H,

J_{6-14} = 4,5 Hz, H(6) et H(10), 7,83 (m, 4H, H(1), H(2), H(3), H(4)), 13,28 (s, 2H, H énol). *Anal.* calc. pour $C_{28}H_{28}N_2H_{10}$: C 60,86, H 5,11, N 5,07; trouvé: C 60,92, H 4,85, N 5,42.

*Dihydroxy-8,13 dihydro-9,10 propano-10,6 (6*H*) cyclohepta(*b*)-quinoxaline tétracarboxylate de méthyle-7,9,12,14* **4**a

Ce composé peut être synthétisé par l'une ou l'autre des méthodes (b) et (c); *F*: étalé à partir de 208°C; ir (KBr, cm^{-1}): 3000, 2960 (CH), 1735, 1650 (C=O), 1615 (C=C); ^{1}H rmn (CDCl3) δ: 3,33 (s, 6H, CH_3), 3,94 (s, 6H, CH_3), 3,96 (d, 2H, J_{9-10} = 4,5 Hz, H(9) et H(14)), 5,08 (d, 2H, J_{6-14} = 4,5 Hz, H(6) et H(10)), 7,85 (m, 4H, H(1), H(2), H(3), H(4)), 13,28 (s, 2H, H énol). *Anal.* calc. pour $C_{24}H_{20}N_2O_{10}$: C 58,07, H 4,06, N 5,64; trouvé: C 58,43, H 3,87, N 5,33.

*Tétrahydro-6,7,9,10 propano-6,10 (8*H*) cyclohepta(*b*)quinoxaline dione-8,13* **10**

500 mg (1,0 mmol) de dihydroxy-8,13 dihydro-9,10 propano-6,10 (6*H*) cyclohepta(*b*)quinoxaline tétracarboxylate de méthyle-7,9,12,14 **4**a sont dissous dans un mélange de 10 cm^3 d'acide acétique concentré et 2,5 cm^3 d'acide chlorhydrique concentré. On laisse à reflux 16 h. On évapore à sec. On reprend le résidu solide à chaud dans 20 cm^3 d'éther. On refroidit, on filtre. On obtient 230 mg (85%) de produit; *F* > 250°C; ir (KBr, cm^{-1}): 3040, 3000, 2920 (CH), 1690, (C=O); ^{1}H rmn (DMSO) δ: 2,87 (m, 8H, H(7), H'(7), H(9), H'(9), H(11), H'(11), H(13), H'(13)), 3,68 (m, 2H, H(6) et H(10)), 7,93 (m, 4H, H(1), H(2), H(3), H(4)). *Anal.* calc. pour $C_{16}H_{14}N_2O_2$: C 72,17, H 5,30, N 10,52; trouvé: 72,31 H 5,43, N 10,24.

*Tétrahydro-7,8,9,10 epoxy-8,13 diol-8,13 propano-6,10 (6*H*) cyclohepta(*b*)quinoxaline* **11**

200 mg (0,75 mmol) de tétrahydro-6,7,9,10 dione-8,13 propano-6,10 (8*H*) cyclohepta(*b*)quinoxaline **10** sont recristallisés dans 20 mL d'eau. Après filtration le produit est séché sur chlorure de calcium sous vide. On obtient 110 mg (55%) de dialcool; *F* > 250°C; ir (KBr, cm^{-1}): 3310(OH), 2960, 2915, 2560 (CH), 1635 (C=C); ^{1}H rmn (DMSO) δ: 1,82 (m, 8H, H(7), H'(7), H(9), H'(9), H(11), H'(11), H(12), H'(12)), 3,59 (m, 2H, H(6) et H(10)), 6,24 (s, 2H, OH), 7,81 (s, 4H, H(1), H(2), H(3), H(4)). *Anal.* calc. pour $C_{16}H_{16}N_2O_3$: C 67,59, H 5,67, N 9,85; trouvé: C 67,85, H 5,48, N 9,73.

*Hydroxy-8 [bis(methoxycarbonyl)methyl]-6 (6*H*) cyclohepta(*b*)-quinoxaline dicarboxylate de méthyle-7,9* **12**

200 mg (0,62 mmol) de diméthoxycarbonyl-7,9 oxo-8-(8*H*) cyclohepta(*b*)quinoxaline sont mis en suspension dans 10 cm^3 de méthanol. On ajoute 81 mg (0,61 mmol) de malonate de méthyle et une goutte de triéthylamine. On agite 12 heures à froid. Un précipité apparaît. Après filtration et rinçage avec deux fois 5 cm^3 d'éther, on obtient 150 mg (55%) d'un produit blanc; *F* = 185°C; ir (KBr, cm^{-1}): 3000 (OH), 2950, 2840 (CH), 1725 (C=O), 1645 (C=C); ^{1}H rmn ($CDCl_3$) δ: 3,30 (s, 3H, CH_3), 3,75 (s, 3H, CH_3), 3,97 (s, 6H, CH_3), 3,98 (d, 1H, H(11)), 5,53 (s, 1H, H(6)), 7,96 (m, 4H, H(1), H(2), H(3), H(4)), 8,2 (s, 1H, H(10)), 12,88 (s, 1H, H énol). *Anal.* calc. pour $C_{22}H_{20}N_2O_9$: C 57,90, H 4,42, N 6,14; trouvé: C 57,63, H 4,65, N 6,08.

*Hydroxy-8 dihydro-9,10 methano-6,10 (6*H*)cyclohepta(*b*)quinoxaline tétracarboxylate de méthyle-7,9,11* **13**

200 mg (0,62 mmol) de diméthoxycarbonyl-7,9 oxo-8-(8*H*) cyclohepta(*b*)quinoxaline sont mis en suspension dans 10 cm^3 de méthanol. On chauffe à environ 50°C. On ajoute trois gouttes de triéthylamine et une solution de 99 mg (0,745 mmol) de malonate de méthyle dans 10 cm^3 de méthanol jusqu'à dissolution complète du diester de départ. On agite une demi-heure à 50°C, puis on refroidit la solution. Le précipité apparu est filtré, lavé avec un peu d'éther. On obtient 190 mg (65%) d'un composé blanc. *F* = 205°C; ir (KBr, cm^{-1}): 3000 (OH), 2955, 2905, 2840 (CH), 1740, 1720 (C=O), 1640, 1615 (C=C); ^{1}H rmn ($CDCl_3$) δ: 3,58 (s, 6H, CH_3), 3,78 (s, 3H, CH_3), 3,93 (s, 3H, CH_3), 4,42 (s, 2H, H(9) et H(10)), 4,92 (s, 1H, H(6)), 7,80 (m, 4H, H(1), H(2), H(3), H(4)), 12,08 (s, 1H, H énol). *Anal.* calc. pour $C_{22}N_{20}N_2O_9$: C 57,90, H 4,42, N 6,14; trouvé C 58,13, H 4,28, N 6,39.

*Dicyano-11,11 hydroxy-8 dihydro-9,10 methano (6*H*) cyclohepta(*b*)-quinoxaline dicarboxylate de méthyle-7,9* **16**

200 mg (6,17 mmol) de diméthoxycarbonyl-7,9 oxo-8(8*H*) cyclohepta(*b*)quinoxaline sont dissous dans 5 cm^3 de méthanol. On ajoute trois gouttes de triéthylamine et du malononitrile par petites quantités jusqu'à dissolution complète du diester. On agite à température ambiante pendant une heure. On évapore à sec. On dissout dans 100 mL de chloroforme et on lave la solution obtenue avec une solution de 2,5 cm^3 d'acide chlorhydrique concentré dans 90 cm^3 d'eau. Après séparation la phase chloroformée est séchée sur sulfate de magnésium, puis évaporée à sec. Recristallisation méthanol/éther. On obtient 160 mg (65%) d'un solide jaune; F = 194°C; ir (KBr, cm^{-1}): 3000 (OH), 2960 (CH), 2255 (C≡N), 1745 (C=O), 1665, 1620, 1610 (C=C); ^{1}H rmn ($CDCl_3$) **14***b* δ: 3,96 (s, 6H, CH_3), 4,80 (d, 1H, J_{6-9} = 1,5 Hz, H(9)), 4,96 (d, 1H, H(6)), 7,95 (m, 4H, H(1), H(2), H(3), H(4)), 12,63 (s, 1H, H énol), H(10) indéterminé; ^{1}H rmn ($CDCl_3$) **15***b* δ: 3,67 (s, 3H, CH_3), 3,96 (s, 3H, CH_3), 4,28 (d, 1H, J_{9-10} = 5,5 Hz, J_{6-9} = 1,5 Hz, H(9)), 4,46 (q, 1H, H(10)), 4,96 (d, 1H, H(6)), 7,95 (m, 4H, H(1), H(2), H(3), H(4)), 12,40 (s, 1H, H énol). *Anal.* calc. pour $C_{20}H_{14}N_4O_5$: C 61,54 H 3,62, N 14,35; trouvé: C 61,78 H, 3,92, N 14,95.

*Méthoxy-6 hydroxy-8 (6*H*) cyclohepta(*b*)quinoxaline dicarboxylate de méthyle-7,9* **17**

100 mg (0,31 mmol) de diméthoxycarbonyl-7,9 oxo-8-(8*H*) cyclohepta(*b*)quinoxaline sont mis en suspension dans 10 mL de méthanol. On ajoute 30 mg de sodium et on agite pendant 20 minutes à la température de reflux. On refroidit et on filtre le précipité formé. Après rinçage avec 5 mL d'éther sulfurique et séchage sous vide on obtient 80 mg (72%) d'un solide jaune pâle; F = 222°C; ir (KBr, cm^{-1}): 3440 (OH), 3060, 3000, 2860, 2820 (CH), 1740, 1735 (C=O), 1650 (C=C); ^{1}H rmn ($CDCl_3$) δ: 3,16 (s, 3H, CH_3), 3,93 (s, 6H, CH_3), 5,88 (s, 1H, H(6)), 7,96 (m, 5H, H(1), H(2), H(3), H(4), H(10)), 13,07 (s, 1H, H énol). *Anal.* calc. pour $C_{18}H_{16}N_2O_6$: C 60,67, H 4,53, N 7,86; trouvé: C 60,89, H 4,67, N 7,95.

*Méthylthio-6 hydroxy-8 (6*H*) cyclohepta(*b*)quinoxaline dicarboxylate de méthyle-7,9* **20**

100 mg (0,31 mmol) de diméthoxycarbonyl-7,9 oxo-8-(8*H*) cyclohepta(*b*)quinoxaline sont dissous dans 5 mL de méthanol saturé en méthylthiol. On ajoute 3 gouttes de triéthylamine et on agite 10 heures à température ambiante. Le précipité formé est filtré, lavé à l'éther, séché sous vide. On obtient 70 mg (60%) d'un solide jaune; *F* = décomposition à partir de 220°C; ir (KBr, cm^{-1}): 3420 (OH), 3040, 2960, 2950, 2920, 2840 (CH), 1730 (C=O), 1645 (C=C); ^{1}H rmn ($CDCl_3$) δ: 1,90 (s, 3H, SCH_3), 3,97 (s, 3H, OCH_3), 5,65 (s, 1H, H(6)), 7,98 (m, 5H, H(1), H(2), H(3), H(4), H(10)), 13,05 (s, 1H, H énol). *Anal.* calc. pour $C_{18}H_{16}N_2O_5S$: C 58,06, H 4,33, N 7,52; trouvé: C 58,35, H 4,09, N 7,28.

*Benzylthio-6 hydroxy-8 (6*H*) cyclohepta(*b*)quinoxaline dicarboxylate de méthyle-7,9* **21**

100 mg (0,31 mmol) de diméthoxycarbonyl-7,9 oxo-8-(8*H*) cyclohepta(*b*)quinoxaline sont mis en suspension dans 20 mL de méthanol. On ajoute 3 gouttes de triéthylamine et 80 mg (0,65 mmol) de benzylthiol. On agite 2 heures à température ambiante. On filtre le précipité apparu; on le lave avec 10 mL d'éther puis on le sèche sous vide. On obtient 80 mg (55%) d'un solide jaune; *F* = décomposition à partir de 240°C; ir (KBr, cm^{-1}): 3010 (OH), 2960, 2940 (CH), 1725 (C=O), 1650, 1640 (C=C); ^{1}H rmn ($CDCl_3$) δ: 3,54 (s, 2H, CH_2), 3,77 (s, 3H, CH_3), 3,94 (s, 3H, CH_3), 5,68 (s, 1H, H(6)), 7,13 (m, 5H, H phényl), 7,93 (m, 5H, H(1), H(2), H(3), H(4), H(10)), 12,9 (s, 1H, H énol). *Anal.* calc. pour $C_{24}H_{20}N_2O_5S$: C 64,27, H 4,49, N 6,25; trouvé: C 64,57, H 4,71, N 6,22.

*Carbométhoxyméthyl-11 méthoxycarbonyl-7 tétrahydro-6,7,8,10 oxo-8 phenyl-9(9)pyrazolo(5,1-*a*)pyrrolo(3,4-*b*)quinoxaline* **23**

100 mg (0,31 mmol) de diméthoxycarbonyl-7,9 oxo-8-(8*H*) cyclo-

hepta(*b*)quinoxaline sont mis en suspension dans 5 mL de méthanol. On ajoute 65 mg de phénylhydrazine. On chauffe à reflux une demi-heure. Un précipité apparait après refroidissement. Après filtration, on reprend le solide dans 5 mL d'éther à chaud et on filtre à nouveau après refroidissement. On obtient 80 mg (60%) d'un solide blanc; F = 154°C; ir (KBr, cm^{-1}): 3050, 2940 (CH), 1720, 1700 (C=O), 1585 (C=C); ^1H rmn ($CDCl_3$) δ: 2,81 (m, 2H, $J_{12-12'}$ = 16,5 Hz, H(12) et H'(12)), 3,46 (s, 3H, CH_3), 3,9 (s, 3H, CH_3), 4,22 (d, 1H, H(7)), 5,32 (m, 1H, $J_{11-12} = J_{11-12'}$ = 5,5 Hz, H(11)), 5,88 (d, 1H, H(6b)), 7,7 (m, 9H, H(2), H(3), H(4), H(5), H'(2), H'(3), H'(4), H'(5), H'(6)). *Anal.* calc. pour $C_{23}H_{20}N_4O_5$: C 63,88, H 12,96, N 4,66; trouvé: C 63,42, H 12,91, N 4,61.

Même mode opératoire que précédemment mais en utilisant CD_3OD comme solvant: on obtient le composé trideutérié en C(12) et C(7) **28**; ^1H rmn ($CDCl_3$) δ: 3,45 (s, 3H, CH_3), 3,93 (s, 3H, CH_3), 5,35 (s, 1H, H(11)), 5,89 (s, 1H, H(6b)), 7,81 (m, 9H, H(2), H(3), H(4), H(5), H'(2), H'(3), H'(4), H'(5), H'(6).

Carbométhoxyméthyl-11 tétrahydro-6b,7,8,10 méthyl-9 méthoxycarbonyl-7 oxo-8 (9H) pyrazolo(5,1-a)pyrrolo(3,4-b)-quinoxaline
22

Même mode opératoire que précédemment avec 100 mg (0,31 mmol) de diméthoxycarbonyl-7,9 oxo-8 (8*H*) cyclohepta(*b*)-quinoxaline et 30 mg (0,65 mmol) de méthylhydrazine. On obtient 65 mg (55%) d'un solide blanc; *F* = 219°C; ir (KBr, cm^{-1}): 2940 (CH), 1735, 1720 (C=O), 1680 (C=C); ^1H rmn ($CDCl_3$) δ: 2,89 (d, 2H, $J_{12-11} = J_{12'-11}$ = 6 Hz, H(12) et H'(12)), 3,2 (s, 3H, CH_3), 3,67 (s, 3H, CH_3), 3,92 (s, 3H, CH_3), 3,95 (d, 1H, J_{7-6b} = 11 Hz, H(7)), 5,3 (t, 1H, H(11)), 5,74 (d, 1H, H(6b)), 7,95 (m, 4H, H(2), H(3), H(4), H(5)). *Anal.* calc. pour $C_{18}H_{18}N_4O_5$: C 58,37, H 4,90, N 15,13; trouvé: C 58,14, H 4,63, N 14,96.

Phénylamino-6,10 dihydro-9,10 hydroxy-8 (6H) cyclohepta(b)-quinoxaline dicarboxylate de méthyle-7,9 **29**

100 mg (0,31 mmol) de diméthoxycarbonyl-7,9 oxo-8-(8*H*) cyclohepta(*b*)quinoxaline dicarboxylate de méthyle sont mis en suspension dans 20 mL de méthanol. On ajoute 75 mg (0,69 mmol) d'aniline et 3 gouttes de triéthylamine. On porte à reflux pendant trois heures, puis on refroidit à −20°C. Un précipité apparait. Après filtration et rinçage avec 5 mL d'éther, on obtient 70 mg (50%) d'un solide jaune pâle; *F* = 173°C; ir (KBr, cm^{-1}): 3070, 3040, 3000, 2950 (CH), 1725 (C=O), 1645, 1640, 1590 (C=C); ^1H rmn ($CDCl_3$) δ: 3,65 (s, 3H, CH_3), 3,98 (s, 3H, CH_3), 4,14 (d, 1H, J_{9-10} = 5,5 Hz, H(9)), 5,58 (d, 1H, H(10)), 5,82 (s, 1H, H(6)), 7,14 (m, 5H, H'(2), H'(3), H'(4), H'(5), H'(6)), 7,88 (m, 4H, H(1), H(2), H(3), H(4)). *Anal.* calc. pour $C_{23}H_{19}N_3O_5$:C 66,18, H 4,59, N 10,07; trouvé: C 65,97, H 4,31, N 10,38.

H. A. TAJMIR-RIAHI and T. THEOPHANIDES. Can. J. Chem. **61**, 1813 (1983).

Guanosine-5′-monophosphate (5′-GMP) reacts with Pt(II) and Mg(II) metal ions to give complexes of the type $Pt(5'\text{-GMP})_n Cl_2.xH_2O$, *cis*- and *trans*-$[Pt(NH_3)_2(5'\text{-GMP})_2]Cl_2.xH_2O$ and $Mg(5'\text{-GMP}).xH_2O$, where $n = 1, 2, 3, 4$ and $x = 4-10$.

Spectroscopic and chemical evidence showed marked similarities with those of the structurally known N_7-bonded 5′-GMP complexes of Mn(II), Co(II), Ni(II), Cu(II), and Cd(II) metal ions. Therefore, Pt(II) and Mg(II) are also found to be N_7-bonded in these series of nucleotide complexes.

The direct phosphate coordination was observed in Mg(II) nucleotide complexes obtained from acidic solution, whereas Mg(II) complexes prepared from neutral solution showed no direct phosphate–Mg(II) interaction. Pt(II) complexes exhibited no direct phosphate metal bonding, while the possibility of an indirect Pt(II)–phosphate interaction through a hydrogen-bonded water molecule can be proposed here.

H. A. TAJMIR-RIAHI et T. THEOPHANIDES. Can. J. Chem. **61**, 1813 (1983).

La guanosine monophosphate-5′ (GMP-5′) réagit avec les ions métalliques du Pt(II) et du Mg(II) en donnant des complexes de $Pt(GMP\text{-}5')_n Cl_2.xH_2O$, de $[Pt(NH_3)_2(GMP\text{-}5')_2]Cl_2.xH_2O$ *cis* et *trans* et de $Mg(GMP\text{-}5').xH_2O$, où $n = 1, 2, 3, 4$ et $x = 4-10$.

Les preuves spectroscopiques et chimiques font apparaître des similitudes prononcées avec les complexes de GMP-5′, liés par l'azote en position 7, des ions métalliques du Mn(II), du Co(II), du Ni(II), du Cu(II) et du Cd(II) dont la structure est connue. Cependant, on a également trouvé du Pt(II) et du Mg(II) liés par l'azote en position 7 dans cette série de complexes de nucléotide.

On a observé la coordination directe du phosphate dans les complexes de nucléotide du Mg(II) obtenues à partir d'une solution acide, tandis que les complexes du Mg(II) préparés à partir d'une solution neutre n'ont aucune interation directe phosphate–Mg(II). Les complexes de Pt(II) n'ont aucune liaison phosphate–métal directe, cependant on propose l'existence possible d'une interaction indirecte Pt(II)–phosphate par l'intermédiaire de la liaison hydrogène de la molécule d'eau.

Introduction

Nucleotides react with alkali, alkaline earth, transition and non-transition metal ions (1–3) to give complexes of the type $M_2L.nH_2O$ and $M'L.nH_2O$, where M = Na^+, K^+, Ag^+, Hg^{2+}, M′ = Zn(II), Cd(II), Pb(II), Ca(II), Ba(II), Mn(II), Fe(II), Ni(II), Co(II), Cu(II), Al(III), n = 2–8 and L = adenosine-5′-monophosphate (5′-AMP), guanosine-5′-monophosphate (5′-GMP), inosine-5′-monophosphate (5′-IMP), uridine-5′-monophosphate (5′-UMP), citydine-5′-monophosphate (5′-CMP), and 2-deoxyguanosine-5′-monophosphate (5′-DGMP). The solid state complexes of all the said metal cations have been obtained and characterized by elemental analysis, ir and nmr spectroscopy (1–3).

Interaction of nucleotides and polynucleotides with Mg(II) and Pt(II) in solution has been the subject of numerous studies (4–11). Nuclear magnetic resonance and Raman spectroscopy were widely used to characterize the nature of the metal–ligand bonding and the coordination sites, which were used by the ligand upon complex formation.

So far, X-ray crystallographic evidence available on Pt(II) nucleotide complexes is as follows: (*a*) *cis*-$Pt(NH_3)_2(IMP)_2^{2-}$ (12) with N_7-coordination site used by IMP and (*b*) $Pt(en)(CMP)_2^{2-}$ (13), where the Pt(II) is bound to N_3 and the phosphate oxygen atom directly. Recently, the crystal structures of $Pt(tn)(IMP)_2^{2-}$ (14) and Pt(tn)(Me-5′-GMP)$_2$ (15) showed also N_7-coordination. Rich *et al.* (16) recently have determined the structure of *Z* and *B* DNA in a polymerization process in the presence of Mg(II) ions, where it has been found that GMP residues are coordinated to Mg(II) through N_7 with an indirect phosphate oxygen coordination via a water molecule. The remaining coordination sites of Mg(II) are occupied with five water molecules.

In the present work several complexes of Pt(II) and Mg(II) with 5′-GMP have been synthesized and characterized by elemental analysis, molar conductivity and FT-ir spectroscopy not reported so far. We have also prepared a series of structurally known nucleotide metal complexes (16–27), in order to compare and correlate the spectroscopic results obtained here with the corresponding known compounds, to obtain information about the coordination site and structural properties of the new Mg(II) and Pt(II) complexes studied here. The structurally known complexes with their coordination sites are given in Table I.

X-ray powder photographs were also used to find out any similarities between those of the structurally known compounds and the newly synthesized Mg(II) complexes.

Experimental

Materials

All the chemicals were reagent grade and were used without further purification. K_2PtCl_4 was purchased from Johnson Matthey and Mallory Ltd. The nucleotides in acid and sodium salt forms were purchased from Sigma Chemical Company.

Preparation of Mg(II) complexes

Magnesium(II) complexes were synthesized at two different pH ranges, namely 4–6 and 7–9. 5′-GMP (1 mmol) was dissolved in 30 mL of H_2O and added to the solution of $MgCl_2.6H_2O$ (1 mmol) in 20 mL of H_2O. The pH of the solution was adjusted at the pH values mentioned above with 0.1 *N* HNO_3 or 0.1 *N* NaOH and was heated at 60°C for 30 min. After cooling down at room temperature, a white precipitate appeared; this was filtered off and washed with cold water

TABLE 1. Structurally known nucleotide complexes of some metal ions

Compound	Coordination site	Reference
$Cu_3(GMP)_3.8H_2O$	N_7 and O atom of PO_3^{2-} and $2H_2O$	17
$Ni(GMP).8H_2O$	N_7 and 5 H_2O	18
$Co(GMP).8H_2O$	N_7 and 5 H_2O	19
$Mn(GMP).8H_2O$	N_7 and 5 H_2O	20
$Cd(GMP).8H_2O$	N_6 and 5 H_2O	21
$Co_2(UMP)_2.4H_2O$	O atoms of H_2O and PO_3^{2-}	22
$Cd(IMP).3H_2O$	N_7, O atoms of OH groups and PO_3^{2-}	23
$Ni(AMP).6H_2O$	N_7 and 5 H_2O	24
$Zn(IMP).3H_2O$	N_7 and O atoms of PO_3^{2-}	25
$Cu(IMP).3H_2O$	N_7 and O atoms of PO_3^{2-}	26
$Cd(CMP).H_2O$	N_3 and O atoms of PO_3^{2-}	27
$Co(CMP).H_2O$	N_3 and O atoms of PO_3^{2-}	27
$Pt(tn)(Me\text{-}5'\text{-}GMP)_2$	N_7 of the purine ring only	15
$Pt(IMP)_2(NH_3)_2^{2-}$	N_7 of the purine ring only	12
$Pt(IMP)_2(tn)^{2-}$	N_7 of the purine ring only	14
$Pt(CMP)_2(en)^{2-}$	N_3 and O atoms of PO_3^{2-}	13

and air dried. Mg(II) complexes of the nucleotides are soluble in hot water and slightly in hot alcohol, and they can be recrystallized from 0.1 *N* HCl or HNO_3 solution. The complexes show a conductivity value of 120–180 Ω^{-1} cm^2 mol^{-1}, corresponding to 1:1 electrolytes. The analytical data and millimolar conductances are given in Table 2.

Synthesis of Pt(II) complexes

The Pt(II) complexes of 5′-GMP were prepared by addition of the stoichiometric amount of K_2PtCl_4 or *cis*- and *trans*-$Pt(NH_3)_2Cl_2$ to the solution of the nucleotides in 200 mL of water in the presence of appropriate amount of NaCl at room temperature. The solutions were kept in the dark for one week and then the amount of water was reduced to 40 mL under low pressure at 50°C. The mixture of ethanol–ether (50 mL) was then used to bring down the precipitate. The precipitate (yellowish white) was redissolved in a small amount of water and reprecipitated by the addition of ethanol–ether, then dried in a desiccator over $CaCl_2$ and analyzed to give the empirical formula of $Pt(5'\text{-}GMP)_nCl_2.xH_2O$, where $n = 1, 2, 3, 4$ and $x = 4–6$. The complexes are soluble in H_2O and acidic solution only and not in the common organic solvents. Their colour varies from yellow for the 1:1 to white for the 4:1 complexes. They show high values of molar conductivity and this is mainly due to the presence of Na^+ ions associated with 5′-GMP molecule in these Pt(II)–GMP complexes. The analysis and millimolar conductances are shown in Table 2. The structurally known complexes were prepared by routine methods (1–4) and were analyzed for metal ion.

Physical measurements

FT-ir have been recorded on a DIGILAB FTS-15/C Fourier Transform Michelson infrared interferometer equipped with a high-sensitivity HgCdTe detector and a KBr beam splitter with a spectral resolution of 2 to 4 cm^{-1}.

Conductance measurements were carried out on a conductoscope, E365B METROHM.

X-ray powder pattern photographs were taken by using a powder camera (Philips, Debye-Scherre) with Copper K_α-radiation and nickel filters.

Elemental analysis

Pt(II) content has been analyzed by atomic absorption. Mg(II) content was determined complexometrically. C, H, N were analyzed at Schwarzkops Microanalytical Laboratory (U.S.A.). Halide was determined as silver halide.

Results and discussion

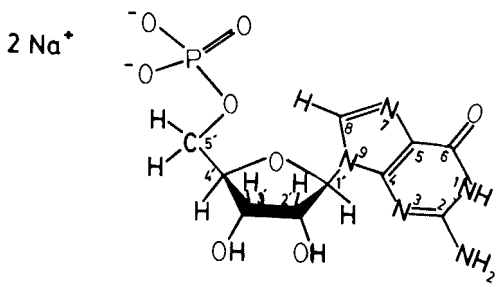
Raman and nmr techniques have been widely used to distinguish between complexation sites in nucleotides (4, 5, 7–11); with nucleotides reliable correlation between structures and spectral information is still missing. Infrared spectroscopy has been the least used technique to demonstrate the coordination mode of the nucleotide–metal complexes in solid state.

Since we had unambiguous X-ray structural information on a series of transition and non-transition metal nucleotide complexes (6, 17–27), we carefully examined their FT-ir spectra hoping to detect characteristic features for each structural type of the complexes synthesized in this work for Mg(II) and Pt(II) nucleotide complexes and to establish a correlation between the spectral changes and the N_7-coordination site in nucleotides.

It should be noted that our ir spectra for 5′-GMP are in good agreement with the vibrational studies previously reported by Lord and Thomas (28), Lautie and Novak (29), and Chinsky *et al.* (30) and our discussion is largely based on the normal coordinate analysis carried out by Tsuboi *et al.* (31–33).

5′-GMP complexes

X-ray analysis shows that Cu(II) is directly bonded to N_7 of the base and to the oxygen atom of the phosphate group as well as to water molecules in the $Cu_3(GMP)_3(H_2O)_8$ compound (17), whereas the divalent metals Mn, Co, Ni, and Cd are bonded to N_7 and to the oxygen atom of H_2O (which are hydrogen-bonded to PO_3^{2-} group in the corresponding 5′-GMP complexes (18–21). Here the FT-ir spectra of these two types of complexes are analyzed and compared with those of Mg(II) and Pt(II) complexes. The main features of the spectra will be discussed in two different parts, namely, 4000–2700 cm^{-1} and 1800–400 cm^{-1}. The 5′-$GMPNa_2$ molecule with numbering of the atoms is illustrated in **1**.



1

4000–2700 cm^{-1}. In this region, due to the presence of the strong intramolecular hydrogen-bonding of the free 5′-GMP (34) and its metal derivatives (21), very little information can be obtained on the nature of metal–ligand interaction, since there have not been considerable changes in the position of hydrogen-bonded NH_2, NH, and OH vibration frequencies of the free 5′-GMP upon complexation. A small shift of the bands at about 3500–3300 cm^{-1} in the spectra of the free base related to the asymmetric and symmetric stretching vibrations of NH_2, NH, and OH to higher frequencies in the spectra of the metal complexes would be due to the general weakening and the rearrangement of the strong hydrogen-bonding network of the ligand on complexation.

1800–400 cm^{-1}. In this region, the ir spectra of 5′-GMP showed considerable changes upon complexation. Spectral changes observed in this region will be discussed below: (*a*) The pyrimidine and purine vibration frequencies (1800–1180 cm^{-1}) and (*b*) the PO_3^{2-} stretching vibration frequencies (1180–900 cm^{-1}). Structurally known N_7-coordinated complexes of Co, Ni, and Cu (17–20) showed marked similarities in the pyrimidine and purine region of the spectra (Fig. 1), meanwhile Cu showed marked differences in the PO_3^{2-} region of the spectra, and this is mainly due to the direct Cu–phosphate bonding compared to the indirect metal–phosphate interaction of the Co and Ni cations (Fig. 1). *cis*-, *trans*-$Pt(NH_3)_2(GMP)_2Cl_2$ and other K_2PtCl_4 complexes of 5′-GMP showed similarities with those of the structurally known complexes mentioned above in both regions of the spectra (Fig. 2), whereas Mg(II) complexes show marked similarities with the structurally known N_7-bonded Cd(II) compound (21) (Fig. 3). The ir spectra of the structurally known compounds and those of Pt(II) and Mg(II) are shown in Figs. 1, 2, and 3. The possible assignments are given in Table 3.

(a) The pyrimidine and purine vibration frequencies (1800–1180 cm^{-1}). In the spectrum of the free 5′-GMP there are five absorption bands at 1692 cm^{-1} (bs), 1662 cm^{-1} (sh), 1597 cm^{-1} (s), 1575 cm^{-1} (sh), and 1535 cm^{-1} (m) assignable mainly to the stretching of $C_6{=}O$, the scissoring mode of NH_2, $C_4{-}N_3$, $C_4{-}C_5$, and the $C_4{-}N_9$ stretching vibrations, respectively (28–33). These absorption bands showed considerable changes upon N_7-coordination in the structurally known metal complexes (Fig. 1 and Table 3). The $C_6{=}O$ stretching vibration of the free base at 1692 cm^{-1} lost intensity, but did not show any considerable displacement ($\Delta\nu = \pm 6$ cm^{-1}), and this would be mainly due to the participation of the O_6 atom of 5′-GMP in hydrogen bonding upon complexation. In the free 5′-GMP acid (34) the O_6 atom is not hydrogen bonded, whereas in the metal complexes (20, 21) the O_6 is hydrogen bonded to a water molecule coordinated to the metal ion. The crystal structure of Pt(tn)(Me-5′-$GMP)_2$ showed a strong hydrogen bonding of the O_6 atom via a water molecule connected to a phosphate oxygen atom (P—O···H—O—H···O_6) (15). This hydrogen-bonding network causes the broadening of the $C_6{=}O$ stretching which shifts to a lower frequency. The bending (scissoring) motion of NH_2 of the free ligand at 1662 cm^{-1} gained intensity, and in some cases split into two components in the spectra of metal complexes (Fig. 1). The crystal structure of 5′-GMP acid (34) shows strong O···H—N—H···O hydrogen-bonding to the phosphate group, whereas such a hydrogen-bonding system would be weakened in the crystal structures of the metal complexes (17–20). Releasing or weakening of the NH_2 group from hydrogen-bonding causes the sharpening and shifting of the NH_2 stretching vibration at 3400 cm^{-1} to a higher frequency, and the bending mode of NH_2 group at 1662 cm^{-1} to a lower frequency. It should be noted that metalation or deprotonation of the NH_2 group brings considerable changes to the said absorption frequencies. The band at 1597 cm^{-1} in the spectrum of 5′-GMP mainly due to the skeletal vibrations, gained intensity, and shifted to 1600–1610 cm^{-1}. This shift is due to the inductive effect of the metal ion electrophile bound to N_7, which causes less electron delocalization, and finally less contribution to the skeletal vibrations of the ring system. Similar effects were observed in the spectra of Mg(II) and Pt(II) complexes.

A band with medium intensity at 1479 cm^{-1} of the free base, assignable to the vibration involving primarily the five-

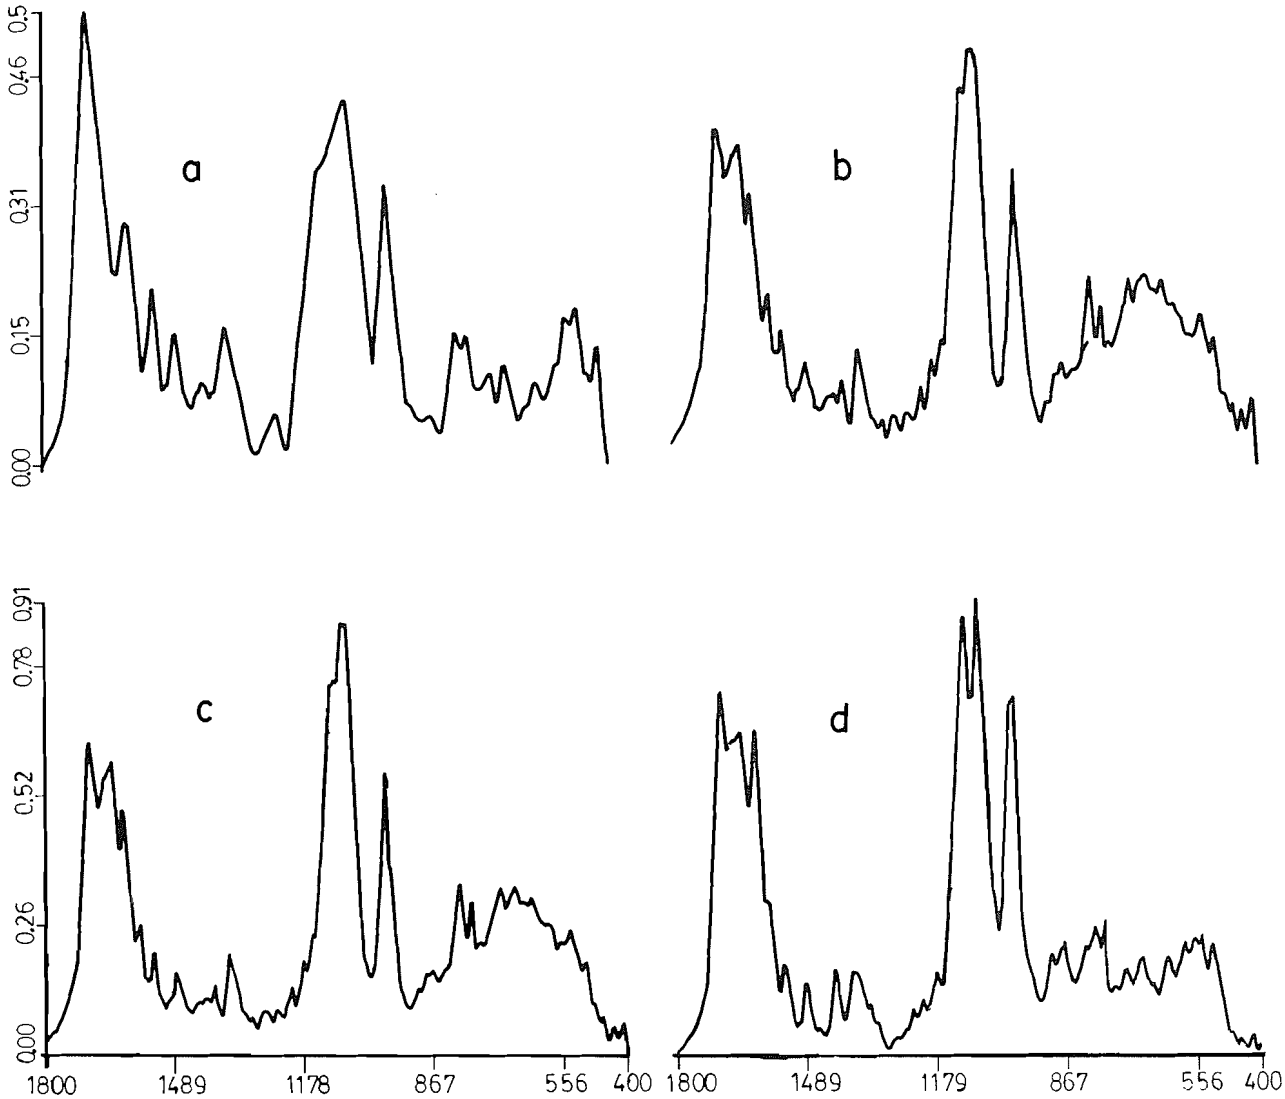

FIG. 1. FT-ir spectra of 5′-GMP and its structurally known N_7-bonded metal complexes in the region 1800–400 cm^{-1} for *a*, 5′-$GMPNa_2$; *b*, $CoGMP.8H_2O$; *c*, $NiGMP.8H_2O$; and *d*, $Cu_3(GMP)_3.8H_2O$.

membered ring C_8—H bending and the N_7—C_8 stretching frequencies (35), split into two absorption bands at 1476 cm^{-1} (m) and 1465 cm^{-1} (sh) in the spectra of N_7–metal complexes. The said absorption band also shifted to 1500 cm^{-1} in the spectra of Pt(II) complexes (Fig. 2 and Table 3). It has been found (35) that the Raman line corresponding to the said absorption at 1480 cm^{-1} disappeared upon protonation and methylation and it shifted on deuteration of H_8, whereas heavy metalation and particularly platination do not affect the Raman line of the said absorption to the same extent (9, 11, 36). It has been experimentally found (37) that the $C{=}N^+$ groups have in general higher frequencies than the parent C=N groups; therefore protonation (38) or metalation (39) could bring an increase to the infrared absorption and of the C=N stretching frequency of the purine ring system in these series of metal nucleotide complexes.

Three absorption bands with medium intensities at 1333, 1254, and 1204 cm^{-1} in the spectrum of 5′-GMP were mainly assigned to N_7—C_8, C_8—N_9, and N_7—C_5 stretching frequencies (30–33), each one appeared as a doublet at about *1350–1290 cm^{-1}*, *1280–1240 cm^{-1}*, and *1205–1210 cm^{-1}* in the spectra of the structurally known N_7–GMP complexes, respectively. A medium absorption band at 1180 cm^{-1} in the spectrum of the free base related to N_7–C_8 (31) showed intensity changes in the spectra of the said metal complexes. These observed shifts upon N_7-coordination can be explained by a distortion of the imidazol ring, where the vibrations are mostly localized and therefore N_7-metalation could change the electron distribution in the ring system. The shift of each component of the N_7—C_8 stretching vibration to a higher frequency upon N_7 metal bonding was explained above.

The shoulder absorption band at 1125 cm^{-1} in the infrared spectrum of 5′-GMP was attributed to the C—O stretching vibration of the sugar ring (35) shifted to lower frequency (1110 cm^{-1}) in the spectra of metal complexes. This shift would be either due to the rearrangement of the strong intramolecular hydrogen-bonding of O_2'—H···N_3 and O_3'—H···O_4' system found in the crystal structure of the free ligand (34), or to the conformational changes around the phosphate–ribose bond upon indirect (via H_2O) or direct coordination of the phosphate group in these series of metal–GMP complexes.

Cd–GMP complexes

The Cd(II) ion forms two complexes with the 5′-GMP mol-

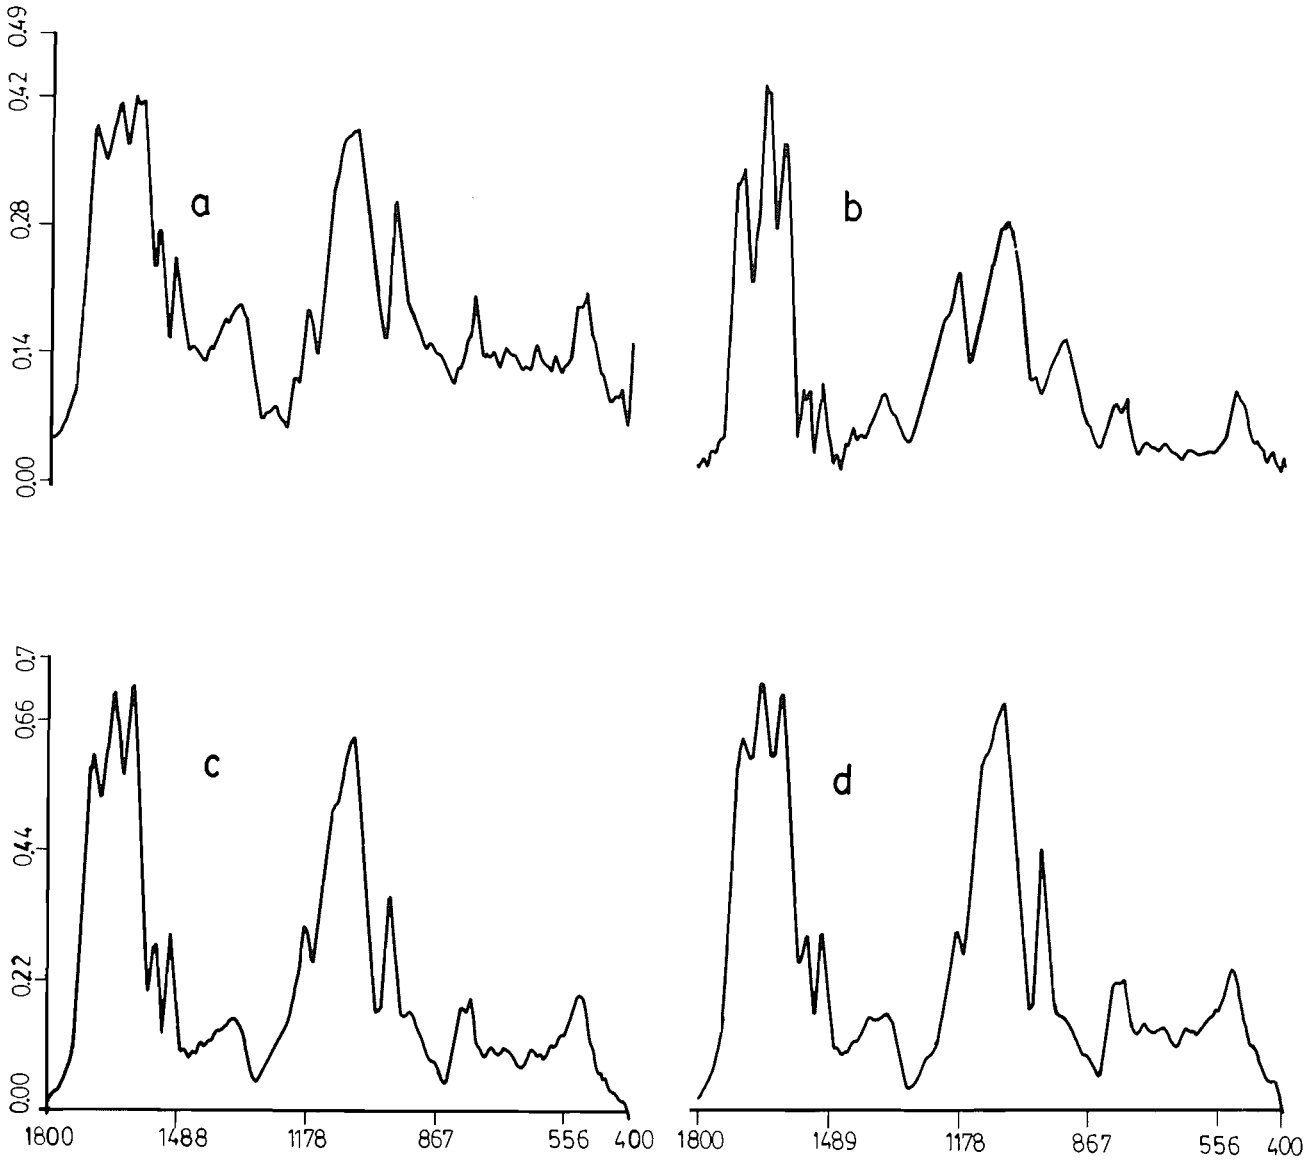

FIG. 2. FT-ir spectra of Pt(II)–GMP complexes in the region 1800–400 cm^{-1} for *a*, $[Pt(GMP)_4]Cl_2$; *b*, $K[Pt(GMP)Cl_3].4H_2O$; *c*, *cis*-$[Pt(GMP)_2(NH_3)_2]Cl_2.6H_2O$; and *d*, *trans*-$Pt(GMP)_2(NH_3)_2]Cl_2.6H_2O$.

ecule, one was obtained at pH = 6–7 which shows similarity with those of the structurally known N_7-bonded transition metal complexes (Figs. 1 and 3) and the other was recrystallized at pH = 4–5, which is structurally known (21) to be N_7-bonded and showed dissimilarities with those of the corresponding transition metal complexes in the region 1700–1600 cm^{-1} (Figs. 1 and 3). The dissimilarities observed in this region of the spectra are reflected in the crystal structures of these complexes. The Cd(II) ion is bonded to the N_7-atom of the 5′-GMP molecule as well as to five water molecules and shows indirect Cd–carbonyl interaction via a hydrogen-bonded water molecule containing also a hydrogen-bonded NH_2 group. In the corresponding copper complexes the Cu(II) ion is N_7-bonded and exhibits direct Cu–OPO_3 interaction as well as coordination to two water molecules (17), but it contains no indirect Cu–carbonyl interaction via a hydrogen-bonded water molecule. In addition, it does not show any strong hydrogen-bonded NH_2 group. Therefore, the dissimilarities observed in the region 1700–1600 cm^{-1} are due to the different hydrogen-bonding networks of carbonyl and NH_2 groups in these cadmium complexes.

It is worth noting that the ir spectra of Mg(II) complexes synthesized in this work showed marked similarities to the structurally known cadmium compound (Fig. 3). Therefore, these complexes are structurally related in terms of N_7-bonding and the possibility of the indirect Mg–carbonyl interaction through a hydrogen-bonded water molecule can not be ruled out.

(b) The phosphate vibrations of mononucleotides (1100–900 cm^{-1}). The mononucleotides, 5′-GMP, 5′-AMP, 5′-IMP, 5′-UMP, and 5′-CMP have a phosphate group at C-5′ of the ribose ring. The disodium salts of these bases contain a phosphate group capable of acting as a polydentate ligand or hydrogen-bonding agent.

The Raman spectra of the phosphate group in mononucleotides, polynucleotides, and DNA have been extensively studied (40–43). There are also some calculations on the normal vibrational modes of the phosphate group and the ribose in DNA (41, 43), but the ir spectra of the nucleotide phosphate group has not yet been fully investigated (33, 42).

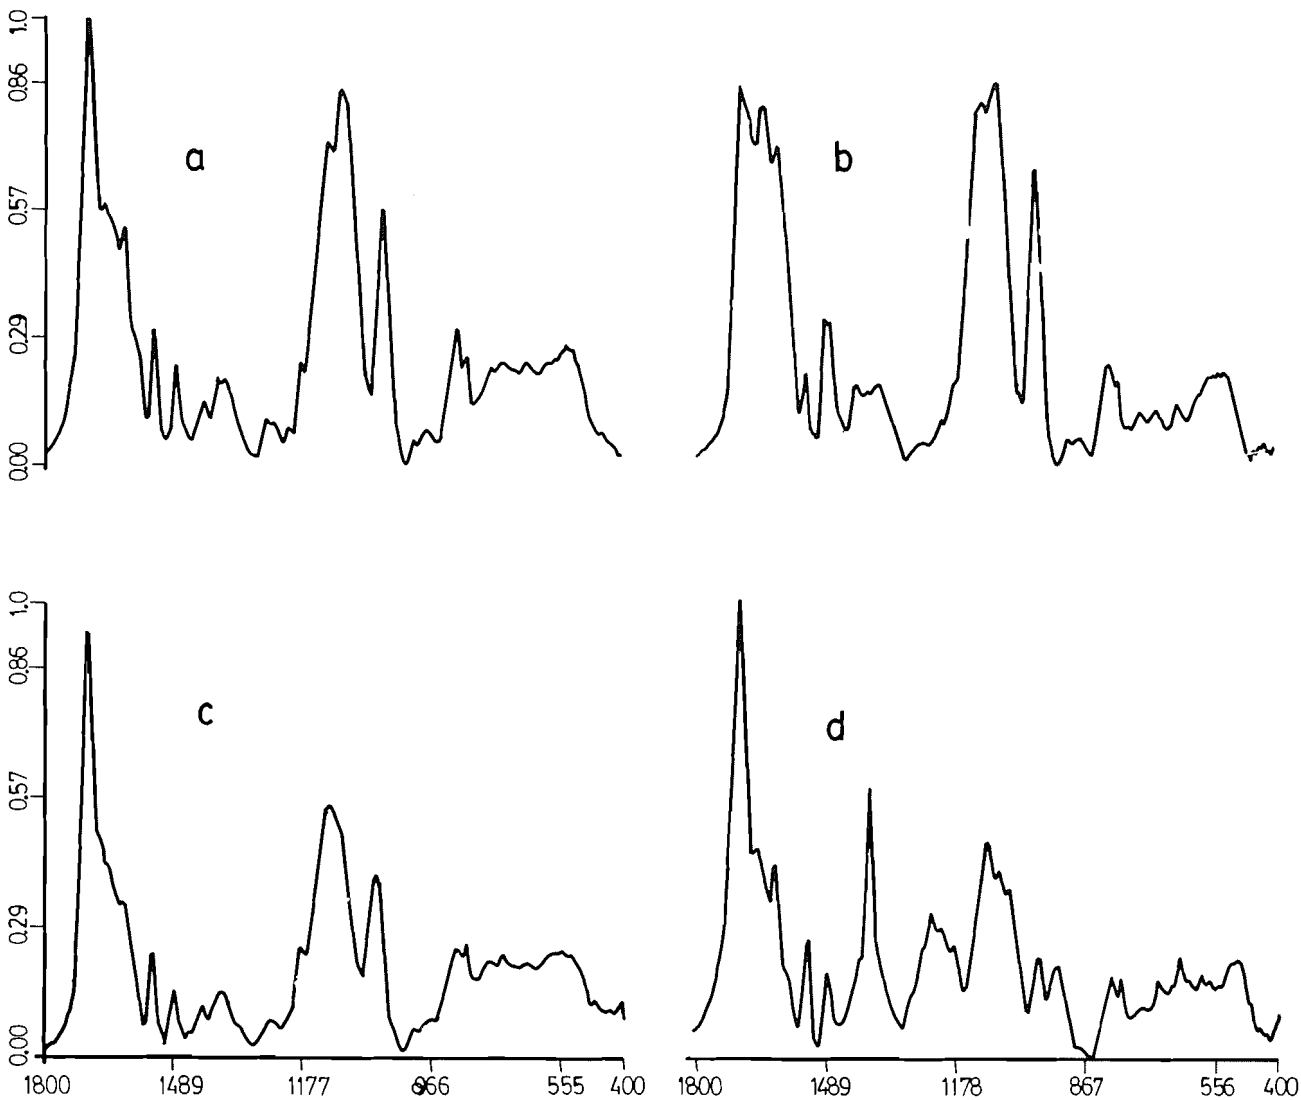

FIG. 3. FT-ir spectra of Mg(II) and Cd(II)–GMP complexes in the region 1800–400 cm^{-1} for *a*, $CdGMP.8H_2O$ (pH = 4–5); *b*, $CdGMP.8H_2O$ (pH = 5–6); *c*, $MgGMP.10H_2O$ (pH = 7); and *d*, $MgGMP.6H_2O$ (pH = 4).

The monoalkyl phosphate anion (CH_3—OPO_3^{2-}) shows infrared absorption bands in the region 1115–750 cm^{-1} (42), which can be compared with those of the already mentioned mononucleotides in this region of the spectra, and the results are given in Table 4. There are also two other absorption bands with medium intensities in the ir spectra of the PO_3^{2-} group (42) at 600–400 cm^{-1}, which are assigned to the PO_3^{2-} symmetric deformation (550 cm^{-1}) and the PO_3^{2-} degenerate deformation (460 cm^{-1}) (Table 4). Six fundamental frequencies are expected for the PO_3^{2-} ion of C_{3v} symmetry, three of these belong to the symmetric vibrations of A_1 type and the other three are related to the doubly degenerate vibrations of the *E* type. The CH_3–OPO_3^{2-} no longer has C_{3v} symmetry due to the lack of a C_3 axis and possesses a lower C_s symmetry. Therefore, the degeneracy of the absorption at 1100 cm^{-1} has been removed and split into a doublet at 1115 and 1090 cm^{-1} (Table 4). In the FT-ir spectra of the solid mononucleotides studied here such splitting has not been observed (see Table 4), but most likely it was overlapped by the strong and broad absorption at 1090 cm^{-1}. Upon coordination of the PO_3^{2-} group the degeneracy of the vibration frequencies is removed (in CH_3—OPO_3^{2-} it has been partially removed) and the three of the six vibrational modes are split, each one into a doublet due to the lowering of the symmetry (Table 3).

The Raman spectra of mononucleotides (40) containing PO_3^{2-}, such as 5′-AMP and 5′-GMP, showed lines at 850, 882, and 980 cm^{-1} assignable to the PO_3^{2-} symmetric stretchings and at 1123 and 1170 cm^{-1} related to asymmetric stretchings. Protonation and metalation caused large perturbation in the intensity of the said frequency changes (44). The Cu(II) ion is coordinated directly to the phosphate group, as well as to the N_7-atom in $Cu(GMP)_3.8H_2O$ (17), whereas the corresponding complexes of Co(II), Ni(II), Mn(II), and Cd(II) ions are indirectly bonded to the phosphate group via two hydrogen-bonded water molecules, in addition to the linkage through the N_7-atom of the base (18–21). The crystal structure of the 5′-GMP acid shows (34) that PO_3^{2-} is involved in a strong intramolecular hydrogen-bonding, as well as the protonation of N_7 in a zwitterionic type, but the crystal structure of 5′-$GMPNa_2$ salt has not yet been determined. Comparing the ir spectra of 5′-GMP with the corresponding Mn(II), Co(II), Ni(II), Cu(II), and Cd(II) complexes in the region of 1070–970 cm^{-1} and the absorption band at 805 cm^{-1}, the spectra of the free ligand shows drastic changes in the Cu(II) complex, upon phosphate

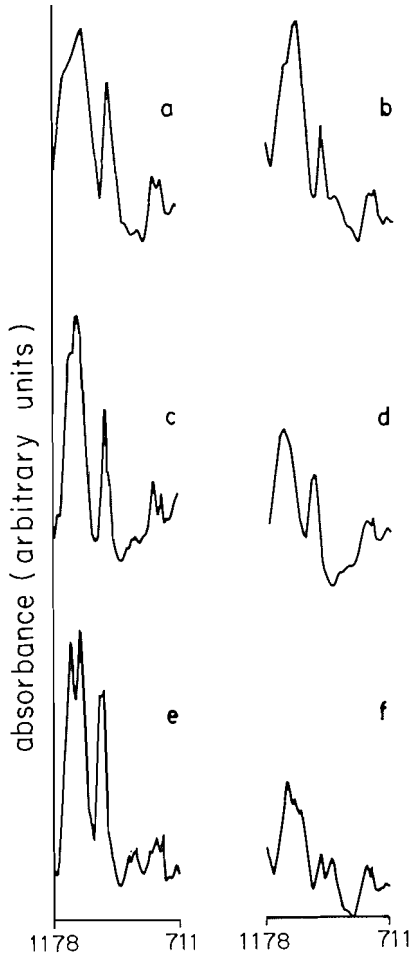

FIG. 4. FT-ir spectra of 5′-GMPNa$_2$ and its metal complexes in the phosphate region 1178–711 cm^{-1} for *a*, 5′-GMPNa$_2$; *b*, *cis*-[Pt(GMP)$_2$(NH$_3$)$_2$]Cl$_2$.6H$_2$O; *c*, NiGMP.8H$_2$O; *d*, MgGMP.10H$_2$O (pH = 7); *e*, Cu$_3$(GMP)$_3$.8H$_2$O; and *f*, MgGMP.6H$_2$O (pH = 4).

coordination (Fig. 4). The bands at 1070, 972, and 805 cm^{-1} split each one into two components, whereas in the analogous Mn(II), Ni(II), Co(II), and Cd(II) complexes, where the phosphate is not directly bound to these metal cations (18–21), there has been no significant changes in this region of the spectra (Fig. 4 and Table 3).

Cu(II) and Zn(II) are also directly bonded to the PO_3^{2-} group of the 5′-IMP molecule (25, 26), as well as to the N_7 of the purine base residue, whereas in the corresponding Ni(II) and Co(II) complexes the phosphate group is not directly bonded to these metal ions (45). On comparing the ir spectra of these nucleotide complexes, the absorption bands at 1092 and 976 cm^{-1} in the spectra of the free 5′-IMPNa$_2$ showed splitting and shifting in the Cu(II) and Zn(II) complexes, whereas the corresponding Co(II) and Ni(II) complexes did not show appreciable changes in this region of the spectra.

The Co(II) ion is coordinated to the phosphate group of the 5′-UMPNa$_2$ molecule only in Co$_2$(UMP)$_2$.4H$_2$O (22). On comparing the ir spectra of free 5′-UMPNa$_2$ with that of Co(II) complexes, each of the bands at 1086, 979, and 816 cm^{-1} has been split into a doublet in the spectrum of Co$_2$(UMP)$_2$.4H$_2$O.

Co(II) and Cd(II) are directly bonded to the phosphate group of the 5′-CMP molecule, as well as to the N_3 of the pyrimidine base residue (27). The ir spectra of the Co(II) and Cd(II) complexes showed splitting of the bands at 1080, 984, and 812 cm^{-1} by comparison with that of the free ligand in the same region of the spectra.

In NiAMP.6H$_2$O, the only crystal structure known (24) for the 5′-AMP nucleotide, the Ni(II) ion is bonded to N_7 of the base moiety and to five water molecules (two of these water molecules are hydrogen-bonded to a phosphate group). The ir spectrum of 5′-AMP in the phosphate absorption region showed no considerable changes upon complexation in the NiAMP.6H$_2$O complex.

It could be conlcuded from the observations made on the ir spectra of all the structurally known (17–27) examples discussed here that (*a*) the absorption bands at about 1100, 970, and 800 cm^{-1} in the spectra of mononucleotides are certainly due to the PO_3^{2-} vibrational frequencies, as assigned in Table 4. They show large perturbations upon phosphate coordination. Due to the skeletal and the breathing modes of the pyrimidine and purine vibrational frequencies together with the NH_2 out-of-plane wagging (30) vibrations in the region 700–400 cm^{-1} of the spectra of the nucleotide complexes, it is very difficult to distinguish any changes which occurred for the sym. def. (*A*) and the deg. def. (*E*) (Table 4), upon metal coordination or hydrogen-bonding. The ir spectra of the Pt(II) and the Mg(II) complexes of the 5′-GMP molecule studied here show great similarities with those of the corresponding hydrogen-bonded phosphate group (indirect coodination through water molecules) in the Ni(II) complex (Fig. 4 and Table 3), and no marked similarities with the directly coordinated PO_3^{2-} group as in the Cu–GMP complex (due to the lack of splitting or considerable changes in the region 1100–900 cm^{-1}). Therefore, it can be suggested that the phosphate group of 5′-GMP is indirectly linked to Pt(II) and Mg(II) via hydrogen-bonded water mole-

cules, similar to those of the known Co(II), Ni(II), Cd(II), and Mn(II) 5′-GMP complexes. It should be noted that the ir spectra of the Mg(GMP).$6H_2O$ compound synthesized at pH = 4 showed a direct phosphate–Mg interaction by exhibiting the splitting and shifting of the absorption bands at 1070, 972, and 805 cm^{-1} which are related to the phosphate vibrational frequencies upon metal coordination, whereas the spectra of the Mg(GMP).$10H_2O$ complex obtained at pH = 7–9 showed marked similarities with that of Ni(GMP).$8H_2O$ compound containing hydrogen-bonded phosphate groups (Fig. 4).

Sugar ribose stretching vibrations and other vibrational frequencies

The ribose vibrational frequencies appear almost as sharp bands (28) with medium intensities in the region of 1400–400 cm^{-1} of the spectra. Most of these absorptions are obscured by the strong and broad absorptions of the phosphate group in the region of 1100–800 cm^{-1} and the base vibrational frequencies in the other regions of the spectra. The phosphate–ribose stretching vibration shows two weak absorption bands at 870 and 777 cm^{-1} in the spectra of the 5′-GMP molecule. The one at 870 cm^{-1} shows considerable changes upon direct or indirect metal–phosphate coordination in the spectra of structurally known metal complexes (Fig. 1). These changes can be explained by the inductive effect of the PO_3^{2-} electron distribution on the ribose–phosphate bond or by conformational changes about the phosphodiester bond upon PO_3^{2-} complexation (9). The other ribose ring vibrational frequencies at about 900, 770, and 710 cm^{-1}, which are very weak in the spectra of the free ligand, do not show changes in the spectra of the metal complexes (Fig. 1).

The ring breathing mode at 680 cm^{-1} (31) in the spectra of 5′-GMP shifted to 700 cm^{-1} in the spectra of the N_7–metal complexes (Fig. 1). The bending vibration and the out-of-plane deformation modes of NH_2 and NH (28, 31) at 700–500 cm^{-1} in the ligand spectra do not shift considerably upon N_7-complex formation.

The metal–nitrogen stretching vibrations of all the 5′-GMP complexes studied here occurred in the lower region (400–200 cm^{-1}) of the spectra and will be reported elsewhere.

Conclusions

On the basis of spectroscopic studies of some structurally known metal complexes compared to the unknown Pt(II) and Mg(II) complexes synthesized here, the following conclusions can be drawn.

Metalation at the N_7-site of 5′-GMP brings drastic spectral changes which are often difficult to be rationalized, mainly due to the vibrations of the purine ring system which are strongly coupled. Coordination can also change the electron distribution within the ring system and further complicates the vibrational problem. However, some of the most meaningful and common changes observed in the vibrational spectra of 5′-GMP on complexation with different metal cations are summarized below.

The characteristic features of the N_7-bonding of guanine are: (*1*) modification of the band at 1480 cm^{-1}; (*2*) splitting of the bands at 1333, 1254, and 1204 cm^{-1}, and (*3*) shift of the band at 680 cm^{-1}, assigned to breathing mode of the ring system, to 700 cm^{-1} in the spectra of metal–GMP complexes.

The characteristic features of metal–phosphate bonding are: (*1*) splitting and shifting of the broad and strong absorption bands at 1090 and 970 cm^{-1}, upon direct metal–phosphate bonding and (*2*) the lack of splitting indicative of an indirect phosphate–metal bonding via a hydrogen-bonded water molecule.

It is interesting that the reaction between the Mg(II) ion and 5′-GMP at pH = 9–6 produces complexes with no direct Mg–OPO_3 interaction, whereas at pH = 5 and lower the direct phosphate–Mg bonding is prevailing.

The Pt(II) ion is N_7-bonded in all the GMP synthesized complexes and exhibits no direct Pt–OPO_3 interaction. Due to the lack of crystallographic evidence and the absence of any considerable infrared absorption band changes at 1690 cm^{-1} (C_6=O stretching), the possibility of direct or indirect Pt–carbonyl interaction does not occur for these solid state Pt(II) complexes studied here.

Synthesis and crystal structure analysis of trichloro(dimethylformamide)bis(dimethylsulfoxide)rhodium(III)

F. D. ROCHON, P. C. KONG, AND R. MELANSON

Département de chimie, Université du Québec à Montréal, C.P. 8888, Succ. A, Montréal (Qué.), Canada H3C 3P8

Received August 16, 1982[1]

F. D. ROCHON, P. C. KONG, and R. MELANSON. Can. J. Chem. **61**, 1823 (1983).

mer-[Rh(DMSO)$_2$(DMF)Cl$_3$] was prepared by dissolving [Rh(DMSO)$_3$Cl$_3$] in dimethylformamide (DMF). It forms monoclinic crystals, a = 11.530(3), b = 8.971(2), c = 15.912(3) Å, β = 107.88(2)°, Z = 4, and space group $P2_1/c$. The structure was refined by full-matrix least-squares analysis to a conventional R factor of 0.038 (3495 observed reflections).

The coordination around the Rh atom is octahedral. The compound is the peripheral or the 1,2,6-isomer. The DMF molecule is in *trans* position to a DMSO ligand and bonded to rhodium through the oxygen atom. The two molecules of DMSO are bonded to rhodium through sulfur. The Rh—Cl(1) bond (2.366(1) Å) *trans* to a DMSO molecule seems slightly longer than the two Rh—Cl bonds *trans* to each other (2.329(1) and 2.343(1) Å).

F. D. ROCHON, P. C. KONG et R. MELANSON. Can. J. Chem. **61**, 1823 (1983).

mer-[Rh(DMSO)$_2$(DMF)Cl$_3$] a été synthétisé en dissolvant [Rh(DMSO)$_3$Cl$_3$] dans le diméthylformamide (DMF). Le composé cristallise dans le système monoclinique, a = 11,530(3), b = 8,971(2), c = 15,912(3) Å, β = 107,88(2)°, Z = 4 et le groupe d'espace $P2_1/c$. La structure a été affinée par moindres-carrés à matrice entière jusqu'à un facteur R = 0,038 (3495 réflexions observées).

La coordination autour de l'atome de rhodium est octaédrique. Le composé est l'isomère 1,2,6. La molécule de DMF est en position *trans* d'un ligand DMSO et liée au rhodium par l'atome d'oxygène. Les deux molécules de DMSO sont liées au rhodium par le soufre. Le lien Rh—Cl(1) (2,366(1) Å) en position *trans* d'un ligand DMSO, semble légèrement plus long que les deux liens Rh—Cl en *trans* de chacun d'eux (2,329(1) et 2,343(1) Å).

In the early 1970's, interest in rhodium compounds was greatly enhanced when their potential as anticancer agents was discovered (1). Chemotherapeutic studies on rhodium compounds are encouraged by the fact that contrary to *cis*-[Pt(NH$_3$)$_2$Cl$_2$] and other antitumor agents, they produce only slight chromosome damage in treated cells (2). We have been studying platinum compounds for many years, partly with a view of synthesizing better antitumor agents than *cis*-[Pt(NH$_3$)$_2$Cl$_2$]. Recently, we have decided to study a few rhodium compounds to compare their chemical behavior with platinum compounds.

Many years ago, Kukushkin and Rubtsova (3) synthesized [Rh(DMSO)$_3$Cl$_3$]. The authors suggested that two molecules of DMSO were bonded to Rh through the sulfur atoms, while the third molecule was coordinated through the oxygen atom. The latter is more labile and more easily displaced by other nucleophiles, even by the weak chloro ligand, to form [Rh(DMSO)$_2$Cl$_4$]$^-$. One chloro ligand in [Rh(DMSO)$_2$Cl$_4$]$^-$ can be easily displaced by NH$_3$ or pyridine (py) to form [Rh(DMSO)$_2$(NH$_3$)Cl$_3$] or [Rh(DMSO)$_2$(py)Cl$_3$]. These reactions show that the oxygen-coordinated DMSO is a weaker ligand than NH$_3$ or pyridine (4).

When [Rh(DMSO)$_3$Cl$_3$] was dissolved in dimethylformamide (DMF) and recrystallized in the presence of a small quantity of ether, bright orange crystals were isolated. Infrared spectroscopy showed that the product contained some DMF. Since then, no Rd−DMF compound has yet been reported in the literature, we therefore decided to determine the crystal structure of the orange compound. The results of the structure analysis have shown that the oxygen-bonded DMSO had been replaced by DMF during the recrystallization process. The compound was identified as [Rh(DMSO)$_2$(DMF)Cl$_3$].

DMF is an oxygen-coordinated ligand and cannot displace chloro ligands from K[Pt(py)Cl$_3$] (5). We have done a comparative study of the two oxygen-coordinated ligands (DMF and DMSO) in the following reaction

$$[Rh(DMSO)_3Cl_3] \rightleftarrows [Rh(DMSO)_2(DMF)Cl_3]$$

This reaction will be briefly discussed in this paper.

Experimental

[Rh(DMSO)$_3$Cl$_3$] was synthesized by the method described by Kukushkin and Rubtsova (4). The compound was dissolved in dimethylformamide. A small quantity of diethylether was added to the solution which was set aside. Bright orange crystals were slowly formed which were later found to be [Rh(DMSO)$_2$(DMF)Cl$_3$].

A set of precession photographs indicated the monoclinic $P2_1/c$ space group. The cell parameters were calculated by least-squares refinement of the setting angles of 15 independent peaks centered on a Syntex P$\bar{1}$ diffractometer using graphite monochromatized MoKα radiation.

Crystal data

$RhCl_3C_7H_{19}NS_2O_3$ mw = 438.63

Monoclinic, $P2_1/c$, a = 11.530(3), b = 8.971(2), c = 15.912(3) Å, β = 107.88(2)°, Z = 4, V = 1566.3(6) Å^3, D_x = 1.859 g cm^{-3}, D_m = 1.86(2) g cm^{-3} (flotation), λMoKα = 0.71069 Å, μMoKα = 18.17 mm^{-1}, and T = 22°C.

The intensity data were collected from a crystal having 9 faces with approximate dimensions of 0.23 × 0.25 × 0.48 mm. A total of 4621 independent reflections were measured in the region of $2\theta < 60°$ by the $2\theta/\theta$ scan technique using MoKα radiation. During the data collection, three standard reflections were measured after every 47 reflections. Their variations were less than 3% from their respective means. The reflections (3495) for which the intensity was greater than $2.5\sigma(I)$ were considered as observed. The standard deviation $\sigma(I)$ was calculated as already described (6). An absorption correction based on the equations of the crystal faces was applied to all the reflections. The transmission factors varied from 0.659 to 0.697. The data were then corrected for the Lorentz and polarization effects. The scattering factors of Cromer and Waber (7) were used for rhodium, chlorine, sulphur, oxygen, nitrogen, and carbon, those of Stewart, Davidson, and Simpson (8) were used for hydrogen. The anomalous dispersion terms (9) of rhodium, chlorine, and sulphur were included in the calculations.

[1]Revision received March 9, 1983.

For personal use only.

The position of the rhodium atom was easily located from the three-dimensional Patterson map. The positions of all the other atoms, except the hydrogen atoms, were obtained by structure factor and Fourier map calculations. The refinement of the parameters was done by full-matrix least-squares calculations. In the early stages of refinement, unit weight was assigned to all the reflections. Later individual weights $w = 1/\sigma^2(F)$ were applied. The hydrogen atom in the DMF molecule was fixed at the calculated position, assuming a sp^2 hybridization of the C atom and a C—H distance of 0.95 Å. It was assigned an isotropic thermal parameter of 6.0 Å^2. The hydrogen atoms on the $-CH_3$ groups could not be located. The refinement of the scale factor, the coordinates and anisotropic temperature factors of all the non-hydrogen atoms converged to $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.038$ and $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.050$. The final difference Fourier map did not show peaks higher than ± 0.4 e Å^{-3}.

The calculations were carried out with a Cyber 73 computer and the programs used have already been described (6). A table of observed and calculated structure factors is available from the Depository of Unpublished Data.[2]

Results and discussion

The refined atomic parameters are listed in Table 1. A list of the anisotropic temperature factors is available.[2] A labelled diagram of the molecule is shown in Fig. 1. The bond lengths and the bond angles are shown in Table 2.

The coordination around the Rh atom is octahedral. The angles are close to the expected 90 and 180°, but there are some slight distorsions from the ideal octahedron (Table 2). These deviations are probably caused by the smaller size of the oxygen atom compared to chlorine or sulfur atoms.

The compound $[Rh(DMSO)_2(DMF)Cl_3]$ is the peripheral or the 1,2,6-isomer. The three chlorine atoms are meridional. The two DMSO molecules are in *cis* position and the DMF ligand is *trans* to one of the DMSO molecule. The crystal structure of $[Rh(DMSO)_3Cl_3]$ has been determined by Sokol and Porai-Koshits (10) and Sokol, Rubtsova, Gribenyuk, and Porai-Koshits (11) with low accuracy ($R = 0.125$ and 0.14 respectively). The results have shown that $[Rh(DMSO)_3Cl_3]$ is also the peripheral isomer. Two DMSO ligands (in *cis* positions) are bonded to Rh through the sulfur atom, while the third one, which is in *trans* position to a DMSO, is bonded to Rh through the oxygen atom. In our compound *mer*-$[Rh(DMSO)_2(DMF)Cl_3]$ the DMSO bonded to Rh through the O atom in $[Rh(DMSO)_3Cl_3]$ has been replaced by a DMF molecule, also bonded through O.

The Rh—Cl bond distances are 2.329(1), 2.343(1), and 2.366(1). The latter bond in *trans* position to a DMSO molecule seems significantly longer than the two Rh—Cl bonds *trans* to each other. In $[Rh(DMSO)_3Cl_3]$ the Rh—Cl bonds are 2.33 to 2.34 Å. In *trans*-$Na[Rh(DMSO)_2Cl_4]$, the Rh—Cl bonds range from 2.32 to 2.34 Å (12). In $[RhCl_3(DMSO)(py)_2]$ in which two Cl atoms are *trans* to each other and the third one *trans* to a pyridine ligand, the six Rh—Cl bonds range from 2.314 to 2.348 Å (13). Pt—Cl bonds in *trans* position to DMSO are also longer (~0.02 Å) than normal bonds (14–16).

The Rh—S distances are 2.242(1) and 2.290(1) Å. The bond in the position *trans* to DMF is shorter than the bond *trans* to Cl(1). In $[RhCl_3(DMSO)(py)_2]$ the Rh—S bond is 2.28 Å. The DMSO ligands in $[Rh(DMSO)_2(DMF)Cl_3]$ have approximate tetrahedral geometry about S, the angles ranging from 102 to 116°. The S—O distances are 1.461(4) and 1.467(4) Å and the S—C distances vary from 1.774(5) to 1.800(6) Å. The structure of the coordinated DMSO molecules is very similar to the structure of free DMSO (17, 18) and to the structure of coordinated DMSO in the Rh and Pt complexes mentioned above.

DMF is bonded to Rh through the O atom as in *trans*-$[Pt(DMF)(2,6\text{-lutidine})Cl_2]$ (19). The Rh—O bond of 2.112(3) Å is probably normal. To our knowledge, this study is the first structure determination of a rhodium–DMF complex. In the above Pt compound, the Pt—O distance is 2.051(6) Å. Rhodium, like platinum, being a soft metal, does not usually form bonds with the oxygen atom. DMF exists as a resonance structure of the two mesomeric forms $(CH_3)_2NCHO$ and $(CH_3)_2N^+CHO^-$. Because of the ionic form, rhodium will form bonds more easily with the oxygen atom than with the nitrogen atom. The decrease in multiplicity of the C—O bond and the increased multiplicity of the C—N bond resulting from the ionic resonance structure have been observed in all published crystal structures involving DMF molecules (19). It is inter-

		C(5)—N—C(6)	121.6(5)
		C(5)—N—C(7)	120.5(4)
		C(6)—N—C(7)	117.9(5)

esting to observe that DMF has the same structure, whether it is free (20), coordinated to a metal, or uncomplexed as a molecule of crystallization (19). In our Rh compound, the C—O bond is 1.241(6) Å and the C—N bond is 1.304(6) Å. In *trans*-[Pt(DMF)(2,6-lutidine)Cl_2], the C—O bond was 1.253 Å and the C—N bond 1.326 Å. All the published structures containing DMF have shown that DMF is planar. In $[Rh(DMSO)_2(DMF)Cl_2]$ the DMF ligand is also planar. The angles around the N atom are close to 120° and the angle at the carbonyl C is 124°.

The packing of the molecules in the crystal is shown in Fig. 2. There is no hydrogen bonding. It appears that the normal van der Waals attractions are the only packing forces in the crystal.

The infrared spectrum of $[Rh(DMSO)_2(DMF)Cl_3]$ in a Nujol mull showed that the carbonyl stretching of DMF is lowered by 38 cm^{-1} (from 1668 cm^{-1} in free DMF to 1630 cm^{-1} in $[Rd(DMSO)_2(DMF)Cl_3]$ indicating that the oxygen atom is the donor atom. The far infrared spectrum of the complex showed bands at 438(sh), 426(sh), 412(m), 379(s), 355(s), 328(s), and at 295(vw) cm^{-1}. The nmr spectrum of the rhodium compound in chloroform was also measured. The aldehyde proton is shifted downfield upon coordination by 0.23 ppm (from 8.10 (δ) to 8.33 ppm) while the CH_3—N protons are shifted by about 0.2 ppm (DMF: 2.87 and 2.95 ppm; $[Rd(DMSO)_2(DMF)Cl_3]$: 3.08 and 3.11 ppm). There are two peaks for the methyl protons of the DMSO molecules indicating two different environments of the methyl groups (3.44 and 3.64 ppm).

$[Rh(DMSO)_2(DMF)Cl_2]$ was prepared by dissolving $[Rh(DMSO)_3Cl_3]$ in DMF. In $[Rh(DMSO)_3Cl_3]$ two DMSO ligands are bonded to Rh through the S atom. These bonds are quite strong. The third DMSO molecule is bonded to Rh through the O atom. This bond should be quite weak and this DMSO ligand can be easily replaced by other ligands like DMF.

$$[Rh(DMSO)_3Cl_3] \underset{\text{DMSO}}{\overset{\text{DMF}}{\rightleftharpoons}} [Rh(DMSO)_2(DMF)Cl_3]$$

When $[Rh(DMSO)_2(DMF)Cl_3]$ is dissolved in DMSO and some ether is added to the solution, crystals of $[Rh(DMSO)_3Cl_3]$ can be isolated. Therefore the above reaction is reversible.

Introduction

The plant *Adina cordifolia* has been used in oriental medicine since ancient times as a very important component of various prescriptions acting as antiseptic and febrifuge (1). This communication records the isolation and structure of two known compounds, α-amyrin and octacosanol, and two new compounds, stigmasta-5,22-diene-3β-*O*-α-L-rhamnopyranosyl-(1→4)-β-D-xylopyranoside (**1**) and naringenin-7-methylether-4′-*O*-α-L-rhamnopyranoside (**2**), which are reported for the first time in nature. Previous chemical investigations by Srivastava *et al.* (2, 3) show that the stem of *A. cordifolia* yields a number of flavonoids.

Results and discussion

Four compounds were isolated from the stem of *A. cordifolia* (for details see Experimental) which were designated as compound A (stigmasta-5,22-diene-3β-*O*-α-L-rhamnopyranosyl-(1→4)-β-D-xylopyranoside) (**1**), B (α-amyrin), C (octacosanol), and D (naringenin-7-methylether-4′-*O*-α-L-rhamnopyranoside) (**2**). The known compounds B and C were identified as α-amyrin and octacosanol by the agreement of their mp, mmp, ir, ms, derivatives, and chromatographies with authentic samples. The isolation and identification of two new compounds A and D are described in detail.

Compound A

Repeated column chromatography of the petroleum ether (bp 40−60°C) soluble part of the rectified spirit extract of the stem of *A. cordifolia* on an Al_2O_3 column (C_6H_6−MeOH, 1:9) and crystallization yielded a pure brown amorphous substance, $C_{40}H_{66}O_9$ (M^+ at *m/z* 690), mp 130°C (dec.); $[\alpha]_D^{30}$ +58.5° ($CHCl_3$). It gave characteristic saponin reactions, copious lather with H_2O, and haemolysed red blood cells. Acid hydrolysis (7% H_2SO_4) of the saponin afforded a genin, L-rhamnose, and D-xylose (identical paper chromatographies and glc (alditol acetates)) (4) as the sugar components. The genin had mp 155−157°C; $[\alpha]_D^{25}$ −48° ($CHCl_3$); and molecular formula $C_{29}H_{48}O$ (M^+ at *m/z* 412) by mass spectrometry. From the detailed study of the ir, ^1H nmr, ms spectra, acetate derivative, oxidation (5), reduction (H_2−Pt), Oppenhauer oxidation ($(Me_3CO)_3Al$ + C_6H_{12} + Ph·Me under reflux) (6, 7), and ozonolysis (8) the genin was shown to be stigmasta-5,22-diene-3β-ol (poriferasterol or the C_{24} epimer of stigmasterol) which was confirmed by co-chromatography with an authentic sample (9, 10). When A was subjected to periodate oxidation (11), it consumed 3.00 moles of periodate and liberated 2.00 moles of HCO_2H per 1 mole of the saponin, thus indicating the presence of two units of monosaccharide in the pyranose form. Quantitative estimation of the genin (gravimetric) and the sugars by the Dubois method (12) showed that the genin, L-rhamnose, and D-xylose were present in the molar ratio of 1:1:1. A glc analysis of the alditol acetates of the sugars obtained from the acid hydrolysate (freed from the genin) further showed the presence of L-rhamnose and D-xylose in the ratio 1:1. When saponin A was methylated (13), then subjected to acid hydrolysis, it afforded an aglycone poriferasterol (mp, mmp, and co-thin-layer chromatography) and two methylated sugars 2,3-di-*O*-methyl-D-xylose and 2,3,4-tri-*O*-methyl-L-rhamnose (paper chromatrographies and glc of alditol acetates). The sequence of the sugars in the saponin was established as follows. Partial acid hydrolysis of A resulted in the formation of L-rhamnose (co-paper chromatography, as an end sugar) and prosaponin (**3**). This prosaponin, on complete acid hydrolysis, yielded D-xylose (co-paper chromatography) and an aglycone, poriferasterol (mp, mmp, and co-thin layer chromatography). Hence the structure of the saponin can be represented as stigmasta-5,22-diene-3β-*O*-α-L-rhamnopyranosyl-(1→4)-β-D-xylopyranoside. The configurations of the anomeric carbon atoms of the sugars in the methylated saponin were deduced by the application of Klyne's rule of molecular rotation (14, 15) and were found to be α for L-rhamnose and β for D-xylose. Thus the structure of saponin A was assigned as **1**.

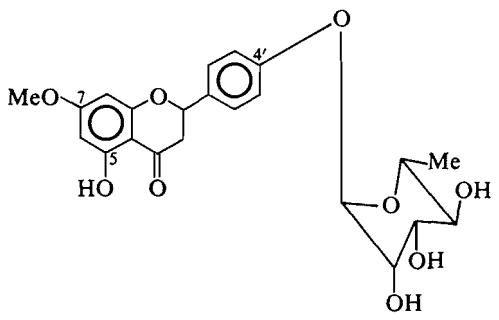
Compound D

This compound was purified over a magnesol column (EtOH) and crystallized as pale yellow needles from EtOAc – petroleum ether (1:9), mp 80–84°C, $C_{22}H_{24}O_9$ (M^+ at m/z 432). It gave characteristic flavanone colour reactions: purplish brown with $FeCl_3$, yellow with NaOH, reddish colour with Mg–HCl, Na–Hg/HCl, and 2,4-DNP. Acid hydrolysis of glycoside D gave an aglycone, mp 152–154°C, $[\alpha]_D^{30}$ +30° (MeOH), which was identical with an authentic sample of naringenin-7-methylether (16) (sakuranetin) (mp, mmp, uv, ir, ^{1}H nmr; and co-thin-layer chromatography). In the hydrolysate, freed from the aglycone, L-rhamnose was detected by thin-layer, paper, and co-chromatographies and also with glc (alditol acetate). When D was subjected to periodate oxidation, the glycoside consumed 2.00 moles of periodate with the liberation of 1.00 mole of HCO_2H per 1 mole of the glycoside, thus indicating that the monosaccharide is in pyranose form. KOH degradation (17) of glycoside D yielded phloroglucinol monomethylether, mp 74°C (lit. (16) mp 75°C), and co-thin-layer chromatography suggested that the site of rhamnosidation is the C-4′ OH. Glycoside D was permethylated (13), then subjected to acid hydrolysis, affording naringenin-5,7-dimethylether (18) (mp, mmp, uv, ir, ^{1}H nmr, and co-thin layer chromatography) and 2,3,4,-tri-*O*-methyl-L-rhamnose (R_G value and glc of alditol acetate). This provides further confirmation that the rhamnosidation occurs at C-4′. The nature of the sugar linkage was deduced by Klyne's generalization rule (14) and was found to be α. Thus it may be concluded that compound D was naringenin-7-methylether-4′-*O*-α-L-rhamnopyranoside (**2**).



2

Experimental

Melting points are uncorrected; column, thin-layer, and paper chromatographic analyses were performed at room temperature. Sugars were characterized spectrophotometrically by the PhOH–H_2SO_4 method (12), using a Klett–Summerson photoelectric colorimeter and also by Whatmann filter paper No. 1, descending paper chromatography technique, using *n*-butanol – acetic acid – water (4:1:5) as a developing solvent and aniline hydrogen phthalate for revealing the spot.

Plant material

The stem was obtained from the local city Sagar, and was identified by the Botanical Survey of India, Allahabad.

Isolation and purification

The air-dried and powdered stem of *A. cordifolia* (2 kg) was extracted with triple-distilled ethanol under reflux. The total ethanolic extract (1.5 L) was concentrated (100 mL) and shaken separately with petroleum ether and absolute EtOH (99.5%). The petroleum ether extract (500 mL) gave a mixture of three compounds (thin layer chromatographic examination) which were separated on Al_2O_3 using different gradients of C_6H_6–MeOH to yield compounds A (2 g, C_6H_6–MeOH, 1:9); B (200 mg, C_6H_6–MeOH, 3:7), and C (220 mg, C_6H_6–MeOH, 5:5). The absolute EtOH extract deposited a single compound, D (thin-layer chromatographic examination) (800 mg).

Compound A (stigmasta-5,22-diene-3β-O-α-L-rhamnopyranosyl-(1→4)-β-D-xylopyranoside

Melting point 130°C (dec.); $[\alpha]_D^{30}$ +58.5° ($CHCl_3$); $C_{40}H_{66}O_9$ (M^+ at m/z 690); thin-layer chromatography (Si gel): R_f 0.40 ($CHCl_3$–MeOH, 8:2). *Anal.* calcd. for $C_{40}H_{66}O_9$: C 69.56, H 9.56; found: C 69.57, H 9.55%.

Acid hydrolysis of the saponin

The saponin (1 g) was dissolved in a minimum amount of absolute alcohol (99.5%) (25 mL) and was refluxed with 7% H_2SO_4 (100 mL) for 6 hours, concentrated, diluted with H_2O (100 mL), and cooled to yield genin as a white amorphous solid which was crystallized as microcrystalline colourless needles ($CHCl_3$–MeOH), mp 156–157°C; $[\alpha]_D^{30}$ −49.00 ($CHCl_3$); $C_{29}H_{48}O$ (M^+ at m/z 412). *Anal.* calcd. for $C_{29}H_{48}O$: C 84.46, H 11.65; found C 84.48, H 11.65%. Monoacetate (100 mg of the genin + 8 mL C_5H_5N + 5 mL Ac_2O): mp 145–146°C; $[\alpha]_D^{30}$ −53.00° ($CHCl_3$). *Anal.* calcd. for $C_{31}H_{50}O_2$: C 81.93, H 11.01; found: C 81.90, H 11.00%. The aqueous solution after neutralization ($BaCO_3$) gave D-xylose and L-rhamnose (R_f 0.28 and 0.37, respectively, in the solvent *n*-butanol – acetic acid – water, 4:1:5, finally confirmed with co-paper chromatographies).

Reduction of the genin

The genin (100 mg) and Pt catalyst (100 mg) in the glacial acetic acid (20 mL) were shaken with H_2 for 10 hours, worked up as usual, and crystallized (Et_2O), mp 142–144°C; $[\alpha]_D^{30}$ +25.00° ($CHCl_3$). *Anal.* calcd. for $C_{29}H_{52}O$: C 83.63, H 12.50; found: C 83.62, H 12.50%. The reduced product did not give the tests for unsaturation (tetranitromethane and Br_2 water test).

Oppenhauer oxidation of the genin

The genin (100 mg) in dry C_6H_{12} (5 mL) was mixed with $(Me_2CHO)_3Al$ (120 mg) in Ph·Me (10 mL) and refluxed for 23 h. The reaction mixture was washed in turn with 2 *N* H_2SO_4, H_2O, and aqueous $NaHCO_3$. The product was crystallized as colourless needles (MeOH), mp 75–80°C; $[\alpha]_D^{30}$ +58.5° ($CHCl_3$). *Anal.* calcd. for $C_{29}H_{46}O$: C 84.87, H 11.21; found: C 84.88, H 11.20%. It was identical with poriferast-5,22-diene-3-one (poriferastadienone) (mp, mmp, and co-thin-layer chromatography).

Ozonolysis of the genin

The genin (100 mg) in glacial acetic acid (10 mL) was ozonized for 2 hours at an O_3 concentration of about 2%, the exit gases being led through 20 mL H_2O. The reaction mixture passed through a Si column. The distillate (20 mL) was collected, a solution of 100 mg crystallized *p*-NO_2—Ph—NH—NH_2 in 10 mL glacial acetic acid was gradually added, and hydrazone crystallized out immediately (MeOH), mp 85–88°C (dec.), identical with α-ethylisovaleraldehyde (co-thin-layer chromatography). *Anal.* calcd. for $C_{13}H_{20}N_3O_2$: C 62.40, H 8.00, N 16.80; found: C 62.40, H 8.00, N 16.82%.

Catalytic hydrogenation of the genin acetate

The genin acetate (100 mg) was treated with PtO_2 (100 mg) in glacial acetic acid (15 mL) and worked up usual. The product was crystallized (MeOH–Me_2CO) and identified as poriferastanyl acetate *Anal.* calcd. for $C_{31}H_{54}O_2$: C 84.22, H 11.83; found: C 84.23, H 11.84%.

Quantitative estimation of the sugars of the saponin by gas–liquid chromatography

The saponin (100 mg) was hydrolysed with acid as was done earlier. The filtrate was neutralized with $BaCO_3$ and filtered. The filtrate containing the sugar mixtures was evaporated to dryness *in vacuo*. This was then dissolved in H_2O (20 mL) and reduced with $NaBH_4$ (750 mg) for 4 hours. The reduced product was treated with Dowex 50 (H^+) and the solution was concentrated. The H_3BO_3 was removed by co-distillation with MeOH and the product was acetylated with Ac_2O–Py (5:5) at 100°C for 40 min, diluted with H_2O, evaporated to dryness, dissolved in $CHCl_3$, and glc was performed. From the areas

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

of peaks corresponding to alditol acetates, D-xylose and L-rhamnose were found in 1:1 molar ratio.

Permethylation and hydrolysis of the saponin

Permethylation of the saponin was carried out by Hakomori's method (13) (15% NaH dispersed in oil (180 mg) with DMSO (20 mL) kept on an oil bath at 80°C for 1 hour). A solution of the saponin (100 mg) in DMSO (4 mL) was added dropwise to the contents of the same oil bath with constant stirring and the mixture was kept again at 80°C for 3 hours until the olive-green colour appeared. The olive-green solution was cooled in ice and MeI (2.5 mL) was slowly added with shaking. It was then left overnight at room temperature. The fully methylated product was isolated in the usual way (syrup) (120 mg) and showed no absorption band for hydroxyl group in the ir spectrum. The fully methylated product was hydrolysed with $N-H_2SO_4$ under reflux for 5 hours. The hydrolysate was neutralized with $BaCO_3$, filtered, deionized, and evaporated to a syrup (80 mg).

Identification of the methylated sugars by paper chromatography and gas–liquid chromatography

The syrup (obtained as above) was divided into two portions. The first portion was examined by paper chromatography with the solvent system butanol–ethanol–water (5:1:4) (upper layer). Two spots were observed with R_G values 0.74 and 1.01, corresponding to 2,3-di-*O*-methyl-D-xylose and 2,3,4-tri-*O*-methyl-L-rhamnose (19–21), respectively.

The second portion was reduced with $NaBH_4$ and acetylated as described earlier. The partially methylated alditol acetates were identified by glc from their relative retention times (22) with respect to 2,3,4,6-tetra-*O*-methyl-D-glucitol diacetate. Two peaks were observed with relative retention times 0.94 and 2.20, which corresponded to 2,3-di-*O*-methyl-D-xylitol triacetate and 2,3,4-tri-*O*-methyl-L-rhamnitol diacetate, respectively.

Periodate oxidation of the saponin

A solution of the saponin (30 mg) in ethanol (20 mL) was treated with an equal volume of 0.1 *M* $NaIO_4$. After 48 h the uptake of periodate and liberated HCO_2H were estimated by the standard titration method as corresponding to 3.00 and 2.00 moles, respectively.

Partial hydrolysis of the saponin

The saponin (200 mg) was dissolved in ethanol (20 mL) and hydrolysed with 7% H_2SO_4 (50 mL) at 90°C for 20 min and worked up in the usual way. Prosaponin (**3**) was separated out and the aqueous hydrolysate yielded only L-rhamnose (co-paper chromotagraphy) as an end sugar. The prosaponin (**3**) on further acid hydrolysis (4 hours) gave poriferasterol (mp, mmp, and co-thin-layer chromatography) and D-xylose (which was attached to the genin part) by co-paper chromatography.

Compound B (α-amyrin)

This compound was purified over the column of Al_2O_3 (C_6H_6–MeOH, 3:7) as a white amorphous solid which crystallized as white needles (ethanol), mp 185–186°C (lit. (16, 23) mp 186°C); $[\alpha]_D^{25}$ +83.00° ($CHCl_3$); molecular formula $C_{30}H_{50}O$ (M^+ at *m/z* 426); thin-layer chromatography (Si gel): R_f 0.52 ($CHCl_3$–MeOH, 8:2) and 0.68 (butanol – acetic acid – water, 4:1:5); ir ν_{max} (KBr) cm^{-1}: 3350 (br, OH), 3000, 2950, 2895, 1649, 1425, 1382, 1210, 1060, 1028, 880, and 725; ms: 426 (M^+), 411 (M^+-Me), 408 (M^+-H_2O), 393 ($M^+-(Me + H_2O)$), 189, 187, 149, and 147. *Anal.* calcd. for $C_{30}H_{50}O$: C 84.50, H 11.73; found: C 84.51, H 11.72%. Acetate (50 mg of the compound + 5 mL C_5H_5N + 4 mL Ac_2O): mp 220–223°C; $C_{32}H_{52}O_2$ (M^+ at *m/z* 468). *Anal.* calcd. for $C_{32}H_{52}O_2$: C 79.91, H 11.11; found: C 80.00, H 11.10%. Benzoate (50 mg of the compound + 5 mL C_5H_5N + 5 mL $PhCO\cdot Cl$): mp 190–191°C; $C_{37}H_{54}O_2$ (M^+ at *m/z* 530). *Anal.* calcd. for $C_{37}H_{54}O_2$: C 83.77, H 10.18; found: C 83.75, H 10.20%.

Compound C (octacosanol)

This compound was purified over the column of Al_2O_3 (C_6H_6–MeOH, 5:5) as a white amorphous compound, mp 82–85°C (lit. (16, 24) mp 83.2–83.4°C); $C_{28}H_{58}O$ (M^+ at *m/z* 410); thin-layer chromatography (Si gel): R_f 0.72 ($CHCl_3$–MeOH, 8.2); ir ν_{max} (KBr) cm^{-1}: 3345 (br, OH), 2920, 2840, 1460, 1410, 1378, 1366, 1330, 1174, 730–725. Acetate (Ac_2O/Py): mp 66–67°C; $C_{30}H_{60}O_2$ (M^+ at *m/z* 452). *Anal.* calcd. for $C_{30}H_{60}O_2$: C 79.64, H 13.27; found: C 79.65, H 13.25%. Iodide: mp 64°C.

Compound D (naringenin-7-methylether-4′-O-α-L-rhamnopyranoside

This compound was purified over the column of magnesol (EtOH) and crystallized (EtOAc – petroleum ether mixture, 1:9), mp 80–84°C; $C_{22}H_{24}O_9$ (M^+ at *m/z* 432); thin-layer chromatography (Si gel): R_f 0.63 ($CHCl_3$–MeOH, 7:3) and paper chromatography (Whatmann No. 1 filter paper, descending technique): R_f 0.92 (butanol – acetic acid – water, 4:1:5) and 0.28 (15% glacial acetic acid); uv λ_{max} (MeOH) nm: 290, 330 (sh); +$AlCl_3$: 315, 335 (sh); +NaOAc: 290, 332 (sh); ir ν_{max} (KBr) cm^{-1}: 3400 (br, OH), 2930, 2870, 1680, 1600, 1480, 1400, 1365, 1210, 1175, 1160, 825, 810, and 720; ^1H nmr (DMSO-d_6, TMS, 90 MHz), δ: 7.20 (d, 2H, *J* = 8.5 Hz, H-2′ and H-6′), 6.80 (d, 2H, *J* = 8.5 Hz, H-3′ and H-5′), 6.45 (d, 2H, *J* = 2.5 Hz, H-6 and H-8), 3.78 (s, 3H, 1 × MeO), 5.40 (1H, H-2), 2.80 (2H, H-3), 1.32 (d, 3H, *J* = 12 Hz, rhamnose Me), 5.00–4.00 (m, sugar protons). *Anal.* calcd. for $C_{22}H_{24}O_9$: C 61.11, H 5.55; found: C 61.12, H 5.53%. The glycoside (500 mg) was dissolved in ethanol (25 mL) and to it 40 mL of 7% H_2SO_4 was added. The mixture was refluxed on a water bath for 4 hours and worked up as usual, which gave naringenin-7-methylether (mp, mmp, uv, ir, ^1H nmr, and co-thin-layer chromatography) and L-rhamnose (co-paper chromatography and alditol acetates). Methylation followd by acid hydrolysis afforded naringenin-5,7-dimethylether (mp, mmp, uv, ir, ^1H nmr, and co-thin-layer chromatography) and 2,3,4,-tri-*O*-methyl-L-rhamnose (R_G 1.01 in butanol–ethanol–water, 5:1:5 and alditol acetates).

The stationary-state approximation in the photolysis of acetone

A. J. C. NICHOLSON
CSIRO Division of Chemical Physics, P.O. Box 160, Clayton, Victoria, Australia 3168

Received October 25, 1982

A. J. C. NICHOLSON. Can. J. Chem. **61**, 1831 (1983).

A mechanism has been written for the photolysis of acetone at 313 nm and 253.7 nm and the differential equations involved solved rigorously. Testing this mechanism has revealed inconsistencies between different sets of experiments that were not previously obvious. The stationary-state approximation is valid up to ca. 0.5% decomposition but its practical usefulness is minimal. Graphs are given showing the variation of all significant quantum yields with temperature, pressure, and light intensity.

A. J. C. NICHOLSON. Can. J. Chem. **61**, 1831 (1983).

On propose un mécanisme pour la photolyse de l'acétone à 313 et 253,7 nm et on a résolu de façon rigoureuse les équations différentielles qui y sont impliquées. La vérification de ce mécanisme révèle, entre les différents groupes d'expérience, des contradictions qui n'étaient pas évidentes. L'approximation de l'état stationnaire est valable jusqu'à une décomposition de 0,5% envirion mais son utilité pratique est très faible. On présente des graphiques qui illustrent la variation de tous les rendements quantiques appréciables en fonction de la température, de la pression et de l'intensité de la lumière.

In 1913 Bodenstein (1) first postulated that the very low concentrations of intermediates present in photolytic reactions could be taken as constant in the early stages of reaction. This "stationary-state approximation" can be used to convert the series of coupled differential equations describing the reactions occurring, into an equivalent series of simultaneous equations. These can sometimes be solved but more often require further approximations to obtain relationships between experimental conditions and final products in which the concentrations of intermediates have been eliminated. Recently developed mathematical techniques (2) for computer solution of such differential equations have made the approximation unnecessary. Farrow and Edelson (3) have shown that the approximation can give erroneous results in some circumstances and recommend that it should be abandoned or at least never used without checking whether it is applicable to a particular case.

The photolysis of acetone has probably been studied as extensively as that of any single molecule. The present paper is an attempt to write a complete mechanism for the acetone photolysis, to solve the differential equations rigorously, and to determine the limits of validity of the stationary-state approximation. A common mechanism could not be found to cover two different sets of experimental results that appeared, at first glance, to be "in good agreement". This reveals where further experimental work is required.

Selection of experimental data

(A) Quantum yield of carbon monoxide production, Φ_{CO}

All workers agree that Φ_{CO} tends to one with increase in temperature. Calvert and Pitts (4) recommend acetone as an actinometer stating that $\Phi_{CO} = 1$ for all wavelengths and intensities at pressures <50 Torr and temperatures >125°C. The experimental evidence on which this is based is surprisingly limited and there is disagreement over the value of the temperature at which $\Phi_{CO} = 1$. Leermakers (5) places this temperature between 148°C and 163°C, while Herr and Noyes (6) place it around 115°C. Pitts, Margerum, Taylor, and Brim (7) give a measurement at 125°C as "1 within experimental error" although their figures would suggest 0.95 ± 0.05. Shaw and Toby (8) give 0.86 at 122°C and 1 at 210°C, and state that Φ_{CO} is independent of pressure over the range 3–219 Torr: Cundall and Davies, CD (9), assume $\Phi_{CO} = 1$ at 135°C and 50 Torr: Pearson (10) chooses 131°C and 145 Torr. Caldwell and Hoare (11) at 120°C, and Boyd, Carter, and Kutschke (12) at 145°C, are in agreement that Φ_{CO} is constant to within 2% over the pressure range from 60–130 Torr. Yet any mechanism involving collisional deactivation of excited states would suggest Φ_{CO} should decrease with increasing pressure at temperatures where the concentration of acetyl radicals is small. No data on this pressure effect are available in the crucial temperature range between 75°C and 100°C.

In view of these uncertainties, an author's quantum yields were only used uncorrected when light intensities were measured directly. When acetone was used as an actinometer and Φ_{CO} assumed to be one at a stated temperature, the value of Φ_{CO} at this temperature was calculated by the mechanism given below and used to correct the quoted intensities and quantum yields of other products. This correction only amounted to a few percent. It will be suggested that there is a small variation in Φ_{CO} with pressure and light intensity.

(B) Quantum yields of ethane and methane

A wider range of experimental data is available on the rates of formation of ethane, $R_{C_2H_6}$, and methane, R_{CH_4}. The results of different experimenters are easier to compare than those on carbon monoxide formation because of the relationship discovered by Dorfman and Noyes (13) that $R_{CH_4}/[A]R_{C_2H_6}^{1/2} =$ constant, where [A] is the concentration of acetone. This relationship has been extensively checked for acetone (14, 15); its particular merit is that the constant is independent of pressure, light wavelength, and light intensity. Results from seven experimental papers are used in Fig. 1 to establish a very reliable value of this constant and of its variation with temperature.

(C) Quantum yields of other products

Few quantitative measurements have been made on products other than the above. Estimates have frequently been made from the conditions for material balance.

Mechanism

The reactions chosen to describe the photolysis are set out in Table 1. This mechanism is an expanded version of the schemes given by Heicklen and Noyes (16) and by CD (9). The former authors showed from fluorescence and phosphor-

escence measurements and the latter, from measurements of the *cis–trans* isomerization of olefins in the presence of photolysing acetone, that both singlet and triplet excited states are involved in the photolysis. The transitions giving fluorescence and phosphorescence have a total quantum yield of 0.02 only (9) at 50°C and have not been included in the mechanism. The reaction producing ethylene which occurs above 200°C (17) has also been ignored.

A represents the acetone molecule in its ground state, ${}^1A_m$ and ${}^1A_0$ the first excited singlet of acetone in its mth and zeroth levels, ${}^3A_n$ and ${}^3A_0$ levels of the lowest triplet state; concentrations, in molecules cm^{-3}, are indicated by square brackets; pressure, p, is in Torr; the intensity, I, is the rate of light absorption in quanta (q) cm^{-3} s^{-1}. Rate constants, k, are in the form $k = A' \exp(-E/RT)$ with A' in s^{-1} or cm^3 molecule^{-1} s^{-1}; activation energy, E, in J mol^{-1}, T, the temperature in K and R = 8.314 J K^{-1} mol^{-1}.

(*a*) For reasons given below under Results, k_2 and k_6 were fitted to the Φ_{CO} values of Pearson (10) rather than those of CD (9). A'_3, A'_4, A'_7, A'_8 are the estimates of CD.

(*b*) This value for k_5 is that of Shortridge, Yang, and Lee (22). The reaction is believed to be first-order (9).

(*c*) Values of k_9 cover a range of thousands! The latest was measured by Watkins and Word (23) who give a unimolecular value $k_{9\infty} = 2.5 \times 10^{13} \exp(-72\,000/RT)$ and calculate a correction factor for pressures between 1 and 1000 Torr. The half pressure between uni- and bimolecular rates is at around 500 Torr at 0°C. The bimolecular constant chosen here gives the same value of rate constant at 25°C and 50 Torr as that given by Watkins and Word. Φ_{CO} is not sensitive to the value chosen.

(*d*) Figure 1 gives a plot of $\log R_{CH_4}/[A]R_{C_2H_6}^{1/2}$ vs. $1/T$ from many experimenters (8, 10, 13–15, 17, 18). Where this is a straight line it is taken that reactions [10] and [11] are the only

For personal use only.

ones producing CH_4 and C_2H_6 respectively; hence this line gives $k_{10}/k_{11}^{1/2}$. Ausloos and Steacie (19) showed that the low temperature deviation from the straight line can be partially accounted for by reaction [18]. This is arbitrarily assigned a rate constant one tenth of that of reaction [12]. This gives the curved portion of Fig. 1 in reasonable agreement with experiment. Johnston (34) has suggested that this curvature can be accounted for by quantum mechanical tunnelling but this possibility is not considered in the mechanism given here.

(*e*) The value for k_{11} is very reliable (20) for pressures above 50 Torr. For lower pressures (18, 21) the reaction moves towards the region of 3rd order kinetics.

(*f*) Reactions [12], [13], [15], [16], [17]. Few quantitative rate constants are available. Reactions of CH_3CO are not important except at low temperatures. For the most important, reaction [13], $k = 5 \times 10^{-12}$ is chosen intermediate between the estimates of Avery, Hayes, and Phillips (24), 1.32×10^{-11}, and Szirovica and Walsh (25), 4.15×10^{-13}. The same value is chosen for k_{15}. Reactions of CH_2COCH_3 are important whenever CH_4 is formed but not enough experimental data are available to test this estimate.

(*g*) It seems necessary to postulate that biacetyl can be formed both by homogeneous (26) and heterogeneous (27) combination of acetyl radicals. The latter is covered by reaction [14]. This can only be a very approximate representation since its rate will be sensitive both to the nature of the walls and the distance of the light beam from the walls. It can be regarded as an arbitrary parameter to reproduce the experimental observation that Φ_{CO} increases with increasing pressure at low temperatures; reaction [9] alone is not fast enough to provide such a result.

(*h*) Reactions [19] and [20] are relatively unimportant. One or both may account for the formation of acetaldehyde at low temperatures.

Results

The reactions and rate constants of Table 1 were used in a computer program devised by Davies (28). For a nominated acetone concentration, light intensity, and temperature the program calculates the concentrations of all intermediates and products as a function of time. Quantum yields are calculated from these as required.

For Φ_{CO} and its variation with temperature CD (9) (their Fig. 1) consider their results "agree closely" with those of Pearson (10). This is not so when allowance is made for the different pressures at which Φ_{CO} was measured. CD measured rates at two temperatures to give $k_2 = 2.5 \times 10^{16} \exp(-70\,700/RT)$ and $k_6 = 2.5 \times 10^{10} \exp(-26\,800/RT)$ and get a good fit to their data using reactions [1]–[8]. If the additional reactions of CH_3CO are included, reactions [9], [12], [13], [14], [17], [18], [19], and [20], a best fit is obtained with $k_2 = 1.8 \times 10^{16} \exp(-71\,000/RT)$ and $k_6 = 1.25 \times 10^{10} \exp(-24\,000/RT)$. However, the rate constants used by CD result in a sharp decrease in Φ_{CO} with acetone pressure such that calculation for the experimental conditions of Pearson give values of both Φ_{CO} and $\Phi_{C_2H_6}$ that are 50% too low. Accordingly the value of $k_2 = 2.5 \times 10^{16} \exp(-66\,000/RT)$ was used which gives a best fit to Pearson's value of Φ_{CO} as shown in Fig. 2 and also a fair fit to his $\Phi_{C_2H_6}$ and Φ_{CH_4} values.

A difficulty arises in applying this mechanism to CD's results because these authors only specify their intensities as between 10^{12} and 5×10^{12} q cm^{-3} s^{-1}. Figure 3 shows that for both intensities the calculated curves lie appreciably above the

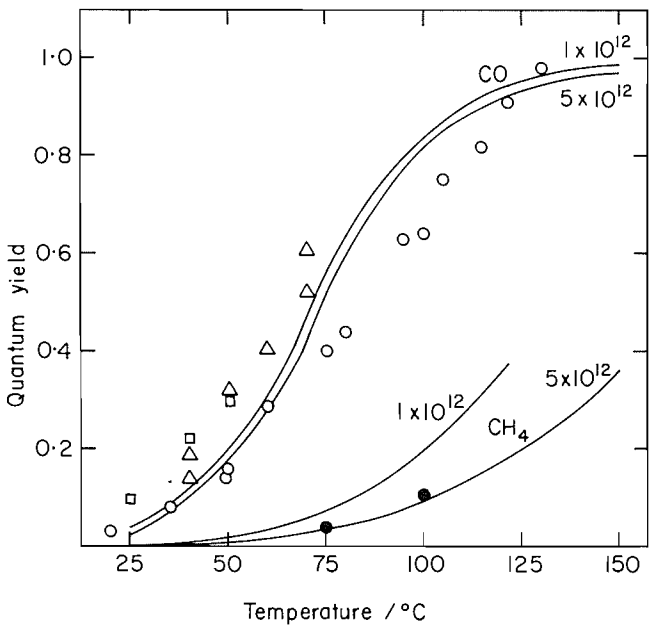

FIG. 3. Calculated quantum yields as a function of temperature at $\lambda = 313$ nm, $I = 10^{12}$ and 5×10^{12} q cm^{-3} s^{-1}, $p = 50$ Torr CO, ○ CD (9), □ Herr and Noyes (6), △ Heicklen and Noyes (16). CH_4, ● CD (9).

experimental values obtained by CD at 50 Torr. It seems more plausible that CD's results are low rather than that Pearson's are high. In Fig. 3 the results of Heicklen and Noyes (16) and the low temperature results of Herr and Noyes (6) are included. Both support high values of Φ_{CO}. The measurements of Heicklen and Noyes were made at very low conversions and they showed that, as products accumulate, biacetyl reduces Φ_{CO} by reacting with the triplet acetone. The results of Herr and

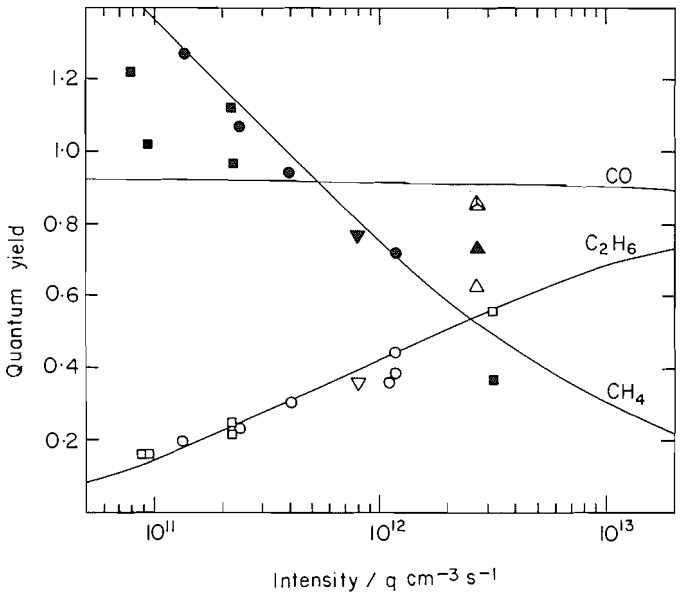

FIG. 4. Calculated quantum yields as a function of intensity. λ = 313 nm, T = 122°C, p = 125 Torr; □ ref 13, ○ ref. 15, △ ref. 8, ▽ ref. 18. C_2H_6 open symbols, CH_4 filled, CO ◬.

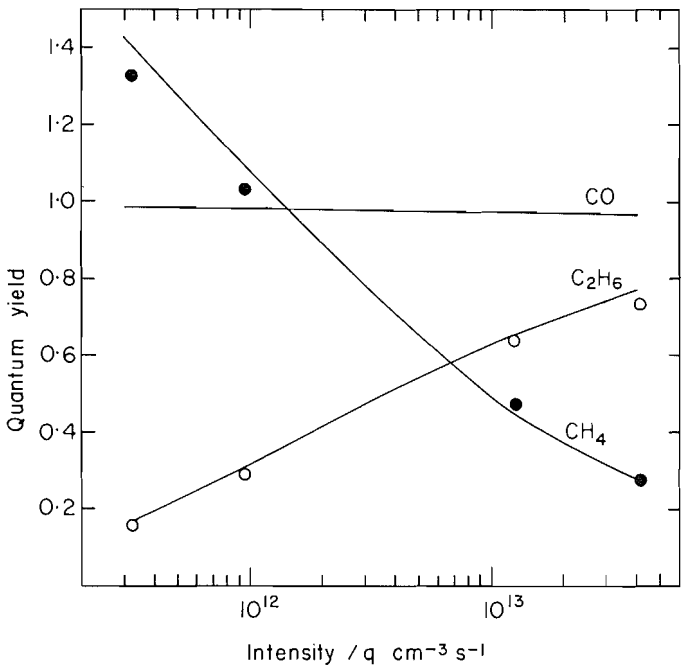

FIG. 5. Calculated quantum yields as a function of intensity. λ = 313 nm, T = 150°C, p = 100 Torr; ref. 15; C_2H_6 open symbols, CH_4 filled.

Noyes at high temperatures have been omitted because they failed to detect methane in conditions where it is now known that it should have been found.

The rate constant ratio, $k_{10}/k_{11}^{1/2}$, was deduced from the data in Fig. 1 which are independent of intensity and pressure. Accordingly, a sensitive test of this value is obtained by seeing how the individual values of $\Phi_{C_2H_6}$ and Φ_{CH_4} vary with intensity and pressure. Figures 4 and 5 for intensity and Fig. 6 for pressure illustrate this; the temperature, pressure, and intensities have been chosen to cover conditions where a reasonable number of measurements by different experimenters are available.

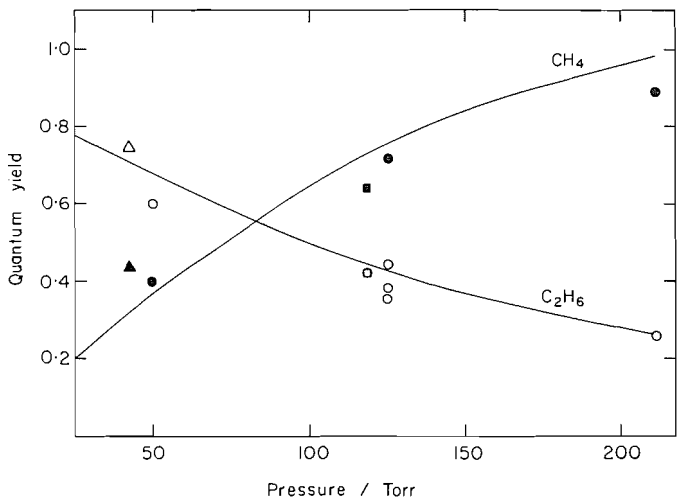

FIG. 6. Calculated quantum yields as a function of pressure; λ = 313 nm, T = 122°C, I = 10^{12} q cm^{-3} s^{-1}; △ ref. 8, □ ref. 13, ○ ref. 15. C_2H_6 open symbols, CH_4 filled.

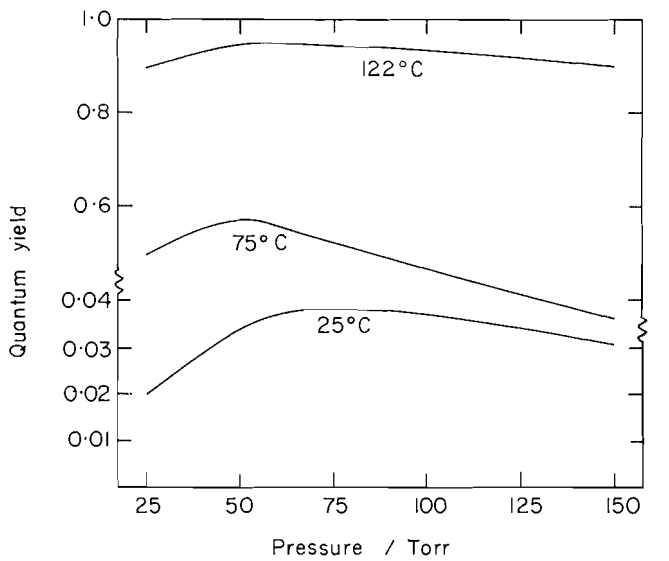

FIG. 7. Calculated quantum yield of CO as a function of pressure at 25°C, 75°C, and 122°C. I = 10^{12} q cm^{-3} s^{-1}, λ = 313 nm.

Figure 7 gives a plot of the variation of Φ_{CO} with pressure at I = 10^{12} q cm^{-3} s^{-1} for three temperatures. At 25°C, Φ_{CO} increases with pressure up to about 100 Torr in agreement with experiment (6, 30) although the absolute values given in these early papers are about three times those given in more recent papers (9, 10). The gentle curvature of the calculated values at 122°C would explain why measurements at this temperature have been taken to indicate that Φ_{CO} does not vary with pressure.

Over the range of conditions covered by Figs. 2–6 agreement between experiment and calculation is sufficiently good to suggest that the mechanism should have a reasonable predictive value for conditions where no experimental data exist. Figures 8, 9, and 10 cover such regions; with Fig. 2 they provide a latin square for I = 2 × 10^{10} and 7.17 × 10^{13} q cm^{-3} s^{-1} and p = 50 and 145 Torr all at λ = 313 nm.

Only a few experiments are available for λ = 253.7 nm. CD showed that at this wavelength the maximum value of Φ_{CO} for decomposition via the triplet is about 0.09, i.e., decomposition

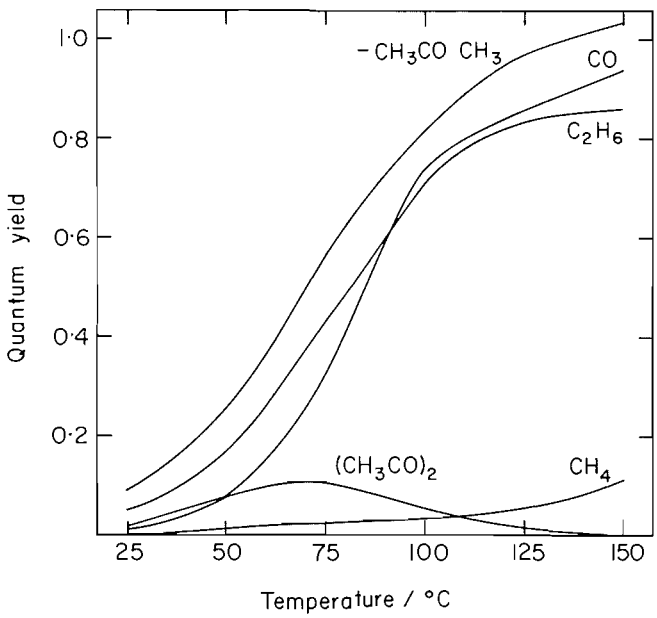

FIG. 9. Calculated quantum yields as a function of temperature. λ = 313 nm, p = 50 Torr, $I = 7.17 \times 10^{13}$ q cm^{-3} s^{-1}.

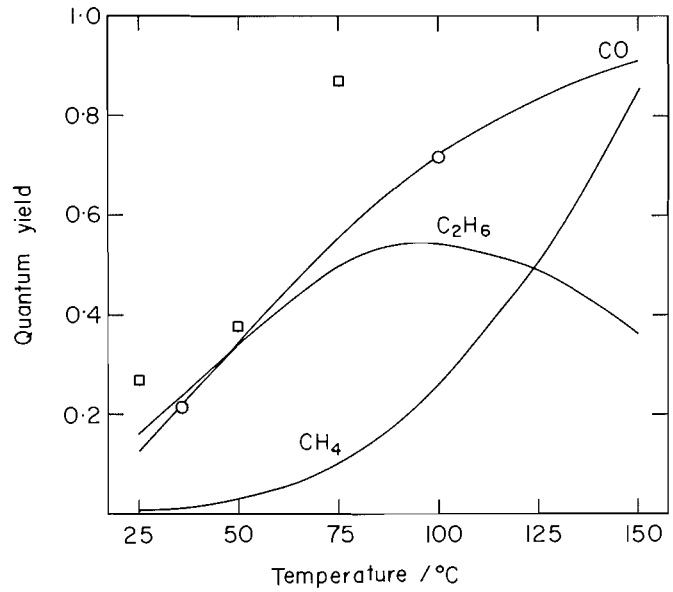

FIG. 11. Calculated quantum yields as a function of temperature. λ = 253.7 nm, p = 145 Torr, $I = 4 \times 10^{12}$ q cm^{-3} s^{-1}. ○, Pearson (10), □ Herr and Noyes (6) for CO.

is largely via the singlet state which is excited to higher vibrational levels by the more energetic quantum. It was found that the single change of k_2 to $1.5 \times 10^{10} \exp(-21\,500/RT)$ gave a fit to Pearson's measurements as shown in Fig. 11. The calculated triplet contribution to Φ_{CO} is 0.016 at 25°C and 0.086 at 150°C. The variation of $\Phi_{C_2H_6}$ and Φ_{CH_4} with intensity for this λ = 253.7 nm mechanism is given in Fig. 12 and compared with experimental values. Figure 12 for λ = 253.7 nm is almost but not quite the same as Fig. 5 for λ = 313 nm.

Minor products

Quantum yields of minor products are shown in Figs. 2, 8, 9, and 10 when they are greater than 0.01. Biacetonyl ranks as a major product at high temperatures and low intensities. The quantum yield of acetone disappearance can be calculated from any of the equations derived from the conditions for material balance — the most convenient is

$$-\Phi_{CH_3COCH_3} = \Phi_{CO} + \Phi_{CH_4} + \Phi_{(CH_3CO)_2} + 2\Phi_{CH_3CHO} + \Phi_{CH_3COCH_2COCH_3}$$

for which the last three terms are negligible except at low temperatures.

Figure 13 shows that for this photolysis the steady-state approximation is an excellent one. For a representative set of conditions, λ = 313 nm, p = 100 Torr, T = 100°C, and $I = 10^{12}$ q cm^{-3} s^{-1} all three free radicals have reached a steady state after 1 s reaction time. This is maintained for 10^4 s at

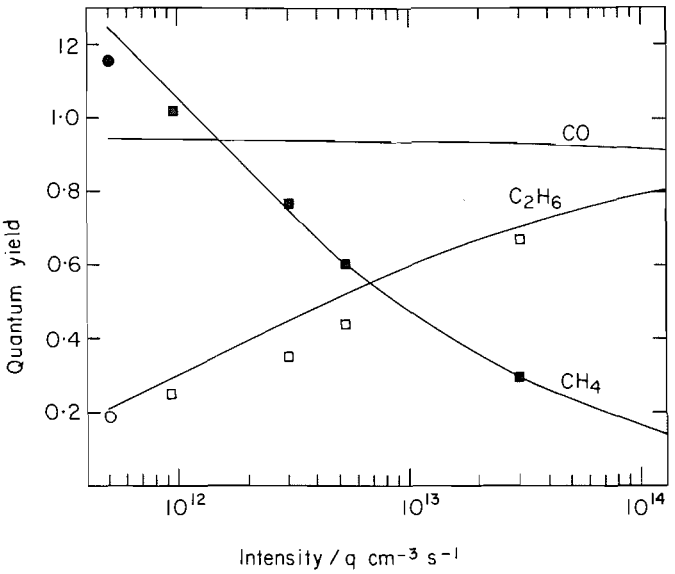

FIG. 12. Calculated quantum yields as a function of intensity. λ = 253.7 nm, T = 150°C, p = 100 Torr, □ ref. 14, ○ ref. 15, C_2H_6 open symbols, CH_4 filled.

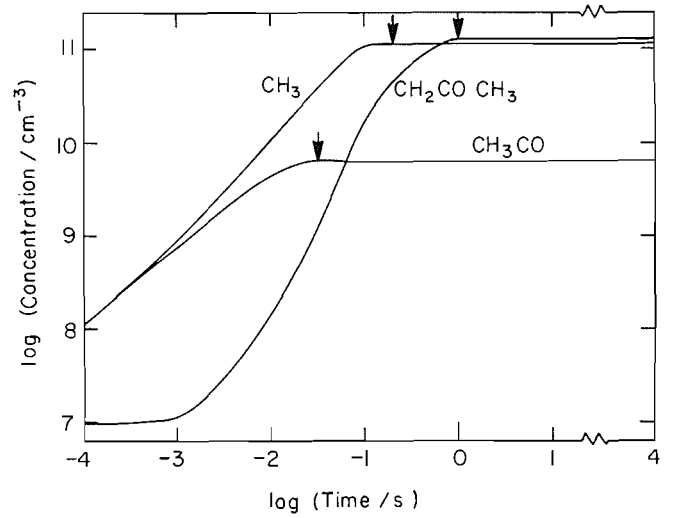

FIG. 13. Log–log plot of concentration of free radicals vs. time. p = 100 Torr, T = 100°C, $I = 10^{12}$ q cm^{-3} s^{-1}.

which time the concentrations begin to drop. The decrease is not visible on the scale of the diagram but amounts to a fall of 0.3% from the maximum. The concentrations of the excited states, $^1A_n = 5 \times 10^4$ cm^{-3}, $^3A_0 = 3 \times 10^4$ cm^{-3}, $^3A_m = 1.5 \times 10^4$ cm^{-3}, and $^1A_0 = 2.5 \times 10^3$ cm^{-3} have reached steady states in less than 10^{-4} s and also remain constant to 10^4 s. The time at which departure from the steady state is noticeable to this extent corresponds to about 0.5% of acetone decomposed. For other conditions of temperature and intensity the same limit of 0.5% decomposition holds.

Discussion

At p = 100 Torr and T = 100°C (Fig. 13), the lifetimes of the excited states range from 10^{-8} to 2×10^{-7} s while those of the free radicals lie between 0.2 and 0.7 s. At times between 1 s and 10^4 s which correspond to 5×10^{-5} and 0.5% decomposition the steady-state approximation is an excellent one.

For practical use the equations derived from the steady-state approximation usually require further approximation by elimination of reactions judged to be unimportant. For example, CD ignore reactions [12]–[20] in order to obtain an equation linear in [CH_3CO] and calculate

$$[i] \quad \Phi_{CO} = \frac{k_2}{k_2 + k_3[A]} + \frac{k_3[A]}{k_2 + k_3[A]} \cdot \frac{k_5}{k_5 + k_4[A]} \cdot \frac{k_6}{k_6 + k_7[A]}$$

They also assume $k_5/(k_5 + k_4[A]) \sim 1$. This effectively gives a 4-parameter (E_2, E_6, A'_2/A'_3, and A'_6/A'_7) equation which gives a reasonable fit to their experimental results. It may be noted that their equation is independent of the value of k_9. However, a dilemma arises when eq. [i] is used: k_2 and k_6 are the only constants which vary with temperature and the S-shaped curve of Φ_{CO} vs. T results from competition between them and the deactivation reactions [3] and [7]; yet such a scheme must give a Φ_{CO} which decreases with increasing pressure. This does not seem to be in agreement with the limited experimental evidence available and as outlined above, Fig. 3, makes the experiments of CD and Pearson difficult to reconcile. The difficulty can be overcome by introducing reaction [14] when the steady-state solution becomes

$$[ii] \quad \Phi_{CO} = \Phi_{CO}[i] \times k_9[A]^2/(k_9[A]^2 + k_{14})$$

By suitable choice of k_9 and k_{14} this gives a Φ_{CO} that increases with pressure at low temperatures and only decreases slowly at high temperatures, Fig. 7. Values of both k_9 and k_{14} are uncertain as is knowledge of the experimental variation of Φ_{CO} with pressure. The values chosen here give Φ_{CO} at 25°C increasing with pressure (25–100 Torr) at 313 nm as required by the experiments of Herr and Noyes (6) and Howland and Noyes (29).

At 25°C, p = 50 Torr and $I = 2 \times 10^{10}$ q cm^{-3} s^{-1} it can be calculated from the mechanism of the present paper that the reactions omitted by CD only contribute 1.5% to the removal of acetyl radicals: Φ_{CO} calculated by the steady-state approximation [ii] is 95% of the value obtained from the full calculation. On the other hand, at 36°C, p = 145 Torr, and $I = 7.17 \times 10^{13}$ q cm^{-3} s^{-1} these reactions contribute 40% and Φ_{CO} calculated by [ii] is 170% of the value obtained from the full calculation.

For calculation of any other quantum yields the steady-state equations for [CH_3], and [CH_2COCH_3] are complex under all conditions. Thus although the steady-state approximation is true for appreciable times in the acetone photolysis its usefulness is minimal.

As is always the case it is impossible to prove that a complex mechanism that fits the known facts is unique. More detailed mechanism involving further vibrational states of ^1A and ^3A could undoubtedly be written that would fit the experiments as adequately as the one given here. Nevertheless this mechanism is claimed as the most comprehensive available and it is suggested that the graphs of Figs. 2, 3, 7, 8, 9, 10, 11 could well replace those given by Herr and Noyes (6). These latter have been republished in so many monographs (30, 31) and reviews (32, 33) that they have gained an authority never claimed by the authors (who suggested their quantum yields were accurate to ±10%). Only Fig. 9 of this paper looks like the figures obtained by Herr and Noyes. It is understandable from their Figs. 3, 4, and 7 that they believed $\Phi_{CO} = \Phi_{C_2H_6} = -\Phi_{CH_3COCH_3} = 1$ above 75°C. In reality, the temperature at which Φ_{CO} tends

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

to 1 is much higher than 75°C, Φ_{CH_4} tends to 2, $\Phi_{C_2H_6} + \Phi_{(CH_2COCH_3)_2} + \Phi_{C_2H_5COCH_3}$ tends to 1, and $-\Phi_{CH_3COCH_3}$ tends to 3. The mechanism given here predicts that Φ_{CO} is not truly independent of pressure and intensity and that while Φ_{CO} (253.7) is $>\Phi_{CO}$ (313) at low temperatures, at higher temperatures the reverse holds.

It would particularly test this mechanism if the variation of Φ_{CO} with pressure were measured at around 75–100°C. More accurate measurements of Φ_{CO} at low temperatures and with minimal percentage decompositions are also needed.

Received January 6, 1983

CHOI CHUCK LEE, ERIC C. F. KO, CRAIG A. OBAFEMI, and J. WILSON QUAIL. Can. J. Chem. **61**, 1838 (1983).

Tri-*p*-tolyl[2-^{13}C]vinyl bromide (**3**-Br-2-^{13}C) was solvolyzed in 70% HOAc − 30% H_2O and the scrambling of the label from C-2 to C-1 in the reaction product was found to decrease with increasing concentrations of added NaOAc. For example, the 18.5% scrambling found for the solvolysis of **3**-Br-2-^{13}C in 70% HOAc in the absence of any NaOAc was decreased to 7.7% when the reaction was carried out in the presence of 4770 m*M* NaOAc. Common-ion rate depression as well as isotopic exchange between [^{82}Br]Et_4NBr and the organic substrate, **3**-Br, were observed, indicating the formation of the dissociated tri-*p*-tolylvinyl cation. Apparently, the tri-*p*-tolylvinyl cation, similar to the trianisylvinyl cation, is of sufficient stability to allow it to discriminate between different nucleophiles.Thus the presence of increasing concentrations of the acetate ion would favor the product-forming capture of the tri-*p*-tolylvinyl cation at the expense of the 1,2-shift process, resulting in a decrease in the extent of scrambling. From the observed scrambling data, selectivity ratios such as k_{OAc}/k_{SOH} and $k_{OAc}/k_{t(Tol)}$ were calculated.

CHOI CHUCK LEE, ERIC C. F. KO, CRAIG A. OBAFEMI et J. WILSON QUAIL. Can. J. Chem. **61**, 1838 (1983).

On a effectué la solvolyse du bromure (Br-**3**-^{13}C-2) de tri-*p*-tolyl[^{13}C-2]vinyle dans une solution de HAcO−H_2O à 70:30 en pourcentage et on a trouvé que, dans les produits de la réaction, le taux de mélange de C-2 à C-1 diminue lorsqu'on augmente la concentration en NaAcO ajouté. Par exemple, le taux de mélange de 18,5% trouvé dans la solvolyse du Br-**3**-^{13}C-2 dans du HAcO à 70% en l'absence de NaAcO tombe à 7,7% en présence de NaAcO à 4770 m*M*. On a observé la diminution de la vitesse de l'ion commun aussi bien que l'échange isotopique entre le [^{82}Br]Et_4NBr et le substrat organique, Br-**3**, ce qui indique la formation du cation tri-*p*-tolylvinyle dissocié. Apparemment, le cation tri-*p*-tolylvinyle, identique au cation trianisylvinyle, est suffisamment stable pour permettre de distinguer les différents nucléophiles. Ainsi la présence d'une concentration croissante de l'ion acétate favorise le produit de capture du cation tri-*p*-tolylvinyle aux dépens du glissement 1−2 résultant d'une diminution du taux de mélange. A partir des données de mélange observées, on a calculé les rapports de sélectivité tels que: k_{AcO}/k_{SOH} et $k_{AcO}/k_{t(Tol)}$.

[Traduit par le journal]

Since the first demonstration by Grob and Cseh (1) of the involvement of vinyl cations in the solvolysis of α-bromostyrenes, much work has been done and a book was published in 1979 on vinyl cations (2). More recently, Apeloig *et al.* (3) have reported on the experimental and computational evidence for the formation of α-arylvinyl cations in the gas phase, and numerous references on vinyl cations were cited by these authors (3). Our studies in this area chiefly involved investigations on degenerate rearrangements arising from 1,2-aryl shifts in isotopically labeled triarylvinyl cations, and a review on such degenerate rearrangements appeared in 1980 (4). Among the interesting findings from the degenerate rearrangement studies was the observation that in the solvolysis of triphenyl[2-^{14}C]vinyl bromide (**1**-Br-2-^{14}C) in 70% HOAc − 30% H_2O (to be designated as 70% HOAc, which was used as solvent since the solvolysis of **1**-Br in pure HOAc was too slow), the extent of scrambling of the isotopic label from C-2 to C-1 in the reaction product showed no significant variations when the reaction was carried out in the presence of up to 30 molar equivalents of added NaOAc (5). On the other hand, in the solvolysis of trianisyl[2-^{14}C]vinyl bromide (**2**-Br-2-^{14}C) in 70% HOAc, the scrambling of the label in the product was found to decrease with increasing amounts of added NaOAc (5).

In an attempt to explain the different effects of NaOAc on the solvolysis of **1**-Br-2-^{14}C and **2**-Br-2-^{14}C, the possibility was considered that in the solvolysis of **2**-Br-2-^{14}C, the dissociated "free" trianisylvinyl cation was formed and the extent of scrambling arising from 1,2-anisyl shifts in the trianisylvinyl cation would be decreased by the presence of the more nucleophilic acetate ion, while in the solvolysis of **1**-Br-2-^{14}C, ionization might have proceeded only to the ion-pair stage and the degenerate rearrangement resulting from 1,2-phenyl shifts in the ion-pair could be insensitive to externally added nucleophiles (5, 6). However, recent work in this laboratory has shown that in the solvolysis of **1**-Br or **2**-Br in 70% HOAc, a common-ion rate depression was observed for the reaction of either **1**-Br or **2**-Br carried out in the presence of added Et_4NBr and that there was incorporation of ^{82}Br into the **1**-Br or **2**-Br due to exchange with added ^{82}Br-labeled bromide ion (7). Since both common-ion rate depression and ^{82}Br exchange would be diagnostic for the formation of dissociated ions (8), it was concluded that the solvolysis of **1**-Br and **2**-Br in 70% HOAc both would proceed to the dissociated ion, and the insensitivity of the extent of scrambling towards added NaOAc in the solvolysis of **1**-Br-2-^{14}C could be attributed to a lack of ability of the less stable triphenylvinyl cation to discriminate between different nucleophiles (7). Since the stability of the tri-*p*-tolylvinyl cation is intermediate between the stabilities of the triphenylvinyl and trianisylvinyl cations, it would be of interest to ascertain whether the tri-*p*-tolylvinyl cation could discriminate between different nucleophiles in the reaction medium. Thus, in the present work, the effect of added NaOAc on the extent of scrambling in the solvolysis of tri-*p*-tolyl[2-^{13}C]vinyl bromide (**3**-Br-2-^{13}C) in 70% HOAc was investigated. ^{13}C instead of ^{14}C was used as the label so that the necessity of oxidative degradations required in the determination of ^{14}C scrambling may be avoided, since such oxidations would also oxidize the *p*-methyl substituent of the *p*-tolyl group. In conjunction with the isotopic scrambling work, common-ion rate depression and ^{82}Br exchange were also studied.

Tri-*p*-tolyl[2-^{13}C]vinyl bromide (**3**-Br-2-^{13}C) has been synthesized and its acetolysis in the presence of AgOAc resulted in 13−14% scrambling of the ^{13}C-label from C-2 to C-1 in the reaction product (9). This scrambling was attributed to 1,2-tolyl shifts in the tri-*p*-tolylvinyl cation and was determined

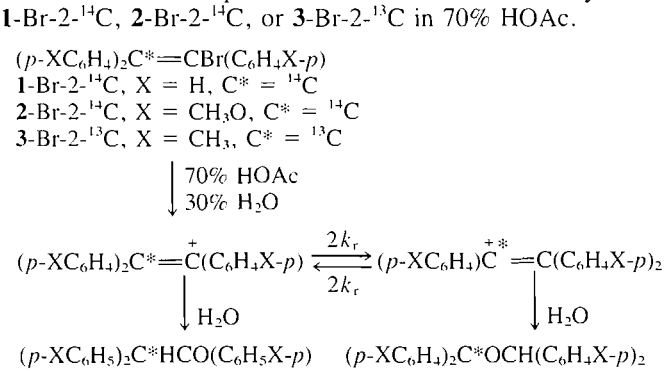
by the conversion of the reaction product, tri-*p*-tolyl[1,2-^{13}C]vinyl acetate (**3**-OAc-1,2-^{13}C), to 1,2,2-tri-*p*-tolyl-[1,2-^{13}C]ethanol (**4**-1, 2-^{13}C) followed by ^{13}C nmr analysis of the ^{13}C distribution in the C-1 and C-2 positions of **4**-1,2-^{13}C (9). In conjunction with a study on the migratory aptitudes of some aryl groups in triarylvinyl cations, **3**-Br-2-^{13}C has also been solvolyzed in 70% HOAc without the presence of any added salt and about 18.5% scrambling of the label was observed in the product, tri-*p*-tolyl[1,2-^{13}C]ethanone (**5**-1,2-^{13}C) (10). In the present work, **3**-Br-2-^{13}C was solvolyzed in 70% HOAc in the presence of various amounts of added NaOAc. The product was found to be **5**-1,2-^{13}C, any **3**-OAc-1,2-^{13}C that might have been formed apparently was hydrolyzed under the conditions of the reaction. The **5**-1,2-^{13}C product was reduced to 1,2,2,-tri-*p*-tolyl[1,2-^{13}C]ethanol (**4**-1,2-^{13}C) and then analyzed by ^{13}C nmr to give the scrambling results summarized in Table 1. As an illustration of the 1,2-shift mechanism for the scrambling of the ^{14}C- or ^{13}C-label in the triarylvinyl cation, given in Scheme 1 are the processes leading to the formation of isotopically unrearranged and rearranged triarylethanones obtained after complete reaction from the solvolysis of **1**-Br-2-^{14}C, **2**-Br-2-^{14}C, or **3**-Br-2-^{13}C in 70% HOAc.



SCHEME 1

In the studies on ^{82}Br exchange, ordinary **3**-Br was solvolyzed in 70% HOAc in the presence of 1, 10, or 30 molar equivalents of added [^{82}Br]Et_4NBr and the incorporation of ^{82}Br into the recovered unconsumed **3**-Br was determined. Assuming that 100% exchange would correspond to a complete mixing of the ^{82}Br in the added Et_4NBr and in the substrate **3**-Br, from the observed incorporation of ^{82}Br in the recovered **3**-Br, the % exchange could be calculated, an illustration of the calculation being given in the Experimental section. The results, given in Table 2, definitely showed the occurrence of exchange between the added Br^- ion and the substrate, **3**-Br. Moreover, as might be expected, the further the reaction has proceeded, the greater extent of exchange was observed in the recovered **3**-Br. From Table 2, it might also be pointed out that the single point measurements of % reaction would indicate that the rate of solvolysis of **3**-Br in 70% HOAc was lowered with an increase in the concentration of the added Br^- ion. This common-ion rate depression was confirmed as the rate of solvolysis of 20 m*M* **3**-Br in 70% HOAc in the presence of 0, 60, or 180 m*M* Et_4NBr at 150 ± 0.2°C was found to be 2.17×10^{-4}, 1.90×10^{-4}, or 1.20×10^{-4} s^{-1}, respectively.

The observed ^{82}Br exchange and common-ion rate depression in the solvolysis of **3**-Br in 70% HOAc are similar in behavior to triphenylvinyl bromide (**1**-Br) and trianisylvinyl bromide (**2**-Br) (7), and are indicative of the formation of the dissociated tri-*p*-tolylvinyl cation. As already discussed previously (5, 7), the generalized mechanism involving 1,2-shifts to give rise to isotopic scrambling may be depicted by Scheme 2, where R^+ and R'^+ are the isotopically unrearranged and rearranged tri-*p*-tolyl[2-^{13}C]vinyl and tri-*p*-tolyl[1-^{13}C]vinyl cations, respectively. The effect of added NaOAc, as recorded in Table 1, showed that the scrambling in the product was decreased with an increase in the concentration of added OAc^- ion, a behavior similar to that found for **2**-Br-2-^{14}C (5) but different from that observed for **1**-Br-2-^{14}C, the scrambling in

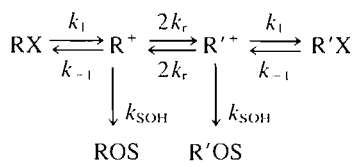

SCHEME 2

the solvolysis with **1**-Br-2-^{14}C being unaffected by NaOAc (5). Apparently the tri-*p*-tolylvinyl cation, like the trianisylvinyl cation, is of sufficient stability and with a sufficiently long lifetime to allow for the discrimination between different nucleophiles in the product-forming capture of the cation by the different nucleophiles (7). With the presence of increasing concentrations of the more nucleophilic OAc^- ion, formation of the unrearranged product is favored at the expense of the 1,2-shift process, thus giving rise to a decrease in the extent of scrambling.

It may be noted from Table 1 that, for a series of experiments with a given concentration of added NaOAc, the scrambling observed was independent of the concentration of the substrate and independent of the extent of reaction. This behavior is also similar to that observed for **2**-Br-2-^{14}C (5). For the scrambling processes as depicted in Scheme 2, it has been shown that, at complete reaction, eq. [1] holds (5, 10, 11). Since eq. [1]

[1] $[ROS]/[R'OS] = 1 + (k_{SOH}/2k_r)$

does not involve the concentration of the substrate, the extent of scrambling would be independent of substrate concentration, as was observed (cf., for example, Expts. 3 and 4, and Expts. 12 and 13, Table 1). Again as discussed in the treatment of the scrambling data from **2**-Br-2-^{14}C (5), the independence of the extent of scrambling with changes in the extent of reaction is consistent with the finding that in Expts. 1 and 2, Table 1, recovered unconsumed reactant showed essentially no scrambling (negligibly small amount of R'X in Scheme 2) (10). The observations of ^{82}Br exchange and the lack of any significant amount of scrambling in the recovered substrate are again similar to the behaviour of **1**-Br-2-^{14}C and **2**-Br-2-^{14}C in their solvolysis in 70% HOAc, suggesting that the capture of the triarylvinyl cation to return to RX is much faster than the internal rearrangement in the cation through 1,2-shifts (7).

From the effects of added NaOAc on the extent of scrambling, a number of selectivity ratios have been calculated for the solvolysis of **2**-Br-2-^{14}C in 70% HOAc (5). Similar treatments of the data can be made using the scrambling results in Table 1. For the product-forming processes as depicted in Scheme 2, k_{SOH} is the pseudo first order rate constant for the bimolecular capture of the cation by all the nucleophiles present. To separate the effects of added OAc^- ion, k_{SOH} and $k_{SOH'}$ for the product-forming processes in 70% HOAc − 30% H_2O with no added NaOAc and with added NaOAc, respectively, may be defined by eqs. [2] and [3]

[2] $k_{SOH} = k_{HOAc}[HOAc] + k_{H_2O}[H_2O]$

[3] $k_{SOH'} = k_{OAc}[OAc^-] + k_{HOAc}[HOAc] + k_{H_2O}[H_2O]$
$= k_{OAc}[OAc^-] + k_{SOH}$

Using eq. [4], which is a modification of eq. [1], and the mean scrambling values in Table 1, $k_{SOH'}/k_{r(Tol)}$ can be calculated and the results are included in Table 1. It is seen that

[4] $(100 - \%\text{scrambling}/\%\text{scrambling})$
$= 1 + (k_{SOH'}/2k_{r(Tol)})$

$k_{SOH'}/k_{r(Tol)}$ increases with increasing concentrations of added OAc^- ion, as is expected, since the addition of OAc^- ion favors product formation, the $k_{SOH'}$ process, at the expense of scrambling, the $k_{r(Tol)}$ process.

For Expts. 1−4, Table 1, with a mean scrambling of 18.5%, $k_{SOH'}/k_{r(Tol)}$ was calculated to be 6.8. Since no NaOAc was present in these experiments, $k_{SOH'}$ would be the same as k_{SOH}, thus giving rise to eq. [5]

[5] $k_{SOH}/k_{r(Tol)} = 6.8$

For Expt. 5, Table 1, with 59 m*M* added NaOAc and a scrambling of 16.8%, eq. [6] can be written:

[6] $k_{SOH'}/k_{r(Tol)} = (0.059\ k_{OAc} + k_{SOH})/k_{r(Tol)} = 7.9$

From eqs. [5] and [6], the selectivity ratios, k_{OAc}/k_{SOH} and $k_{OAc}/k_{r(Tol)}$ for Expt. 5 can be obtained:

[7] (From [6]/[5]) $k_{OAc}/k_{SOH} = 2.7\ M^{-1}$

[8] (From [7] × [5]) $k_{OAc}/k_{r(Tol)} = 2.7 \times 6.8 = 18.4\ M^{-1}$

The ratios k_{OAc}/k_{SOH} and $k_{OAc}/k_{r(Tol)}$ have a unit of M^{-1} because k_{SOH} is a pseudo first order rate constant and no composite concentration for the HOAc − H_2O solvent system was used in the calculations. These selectivity ratios, calculated for the various mean scrambling values, are also included in Table 1. It may be noted that these ratios as recorded in Table 1 are not constant, and their magnitude decreases as the concentration of the added NaOAc increases. A major factor that may be responsible for this trend could be due to the use of concentrations in the calculations. Since the activities of the acetate

For personal use only.

ion rather than its concentrations are involved in the rates of reaction and corrections for such effects would be more drastic at higher concentrations, there should be a decrease in the calculated selectivity ratios with increasing concentrations of added NaOAc, as was obtained. In Expts. 5 and 6, Table 1, with relatively lower concentrations of added acetate ion and thus involving less drastic corrections, the observed k_{OAc}/k_{SOH} were greater than unity, indicating that the capture of the tri-*p*-tolylvinyl cation was indeed faster for the acetate ion than for 70% HOAc.

Experimental

Solvolysis reactions

The synthesis of **3**-Br-2-^{13}C, its solvolysis in 70% HOAc, and the ^{13}C nmr analysis of the extent of scrambling in the reaction product have already been described in the literature (9, 10). In the present work, the solvolyses were carried out in the presence of various concentrations of added NaOAc as given in Table 1. In Expts. 7, 8, or 9, Table 1, for example, a solution of 712 mg (1.9 mmol) of **3**-Br-2-^{13}C and 1600 mg (19.5 mmol) of NaOAc in 40 mL of 70% HOAc was placed in a sealed tube and heated in an oil bath at 150 ± 1°C for 50, 90, or 240 min. The reaction mixture was then worked up as described previously (10) to give 1,2,2-tri-*p*-tolyl-[1,2-^{13}C) ethanol for ^{13}C nmr analysis, again according to procedures already described (9).

^{82}Br exchange reactions

The procedure used for the study of exchange between ^{82}Br-labeled bromide and **3**-Br is similar to that employed in analogous exchange studies with **1**-Br and **2**-Br (7). The individual experiments as given in Table 2 were carried out in sealed tubes. After the desired reaction time, each tube was cooled in an ice bath before it was opened and, if necessary, an appropriate amount of **3**-Br was added as carrier. The mixture was then extracted with $CHCl_3$ and from the extract the unconsumed **3**-Br was recovered and purified by passage through an alumina column. The ^{82}Br activity incorporated into the recovered **3**-Br was then measured using a γ-ray counter. The added [^{82}Br]Et_4NBr and the recovered **3**-Br were counted as solutions in 70% HOAc. A sample containing a known amount of ^{82}Br was used as a reference standard and the standard was counted immediately before and after the counting of a sample to provide the correction for the decay of the ^{82}Br.

As an illustration of the experimental data, the details for Expt. 1, Table 2, are described. In this experiment, a solution of 712 mg (1.9 mmol) of **3**-Br and 399 mg (1.9 mmol) of [^{82}Br]Et_4NBr in 40 mL of 70% HOAc in a sealed tube was heated at 150 ± 1°C for 50 min. Upon work-up of the reaction mixture, and without the use of any additional **3**-Br carrier, 95.6 mg of **3**-Br was recovered.

From a parallel experiment under the same conditions, except that ordinary Et_4NBr without the label was utilized, titration of the liberated bromide ion showed that the extent of reaction was 46%. Thus, after the reaction, the original substrate remaining was $0.54 \times 712 = 384$ mg. The ^{82}Br activity in the 95.6 mg of recovered **3**-Br was 9.05×10^5 dpm. The total ^{82}Br activity in the unconsumed **3**-Br would be $(384/95.6) \times 9.05 \times 10^5 = 3.64 \times 10^6$ dpm. The total ^{82}Br activity introduced as [^{82}Br]Et_4NBr was 5.36×10^7 dpm. Therefore, the incorporation of ^{82}Br into the recovered unconsumed reactant was $[3.64 \times 10^6)/(5.36 \times 10^7)] \times 100 = 6.8\%$.

For 100% exchange, there would be a complete mixing of 100% of the ^{82}Br in the 1.9 mmol of substrate and 1.9 mmol of Et_4NBr, and the ^{82}Br incorporation in the recovered reactant would be $100/(1.9 + 1.9) = 26.3\%$ ^{82}Br/mmol **3**-Br. The observed incorporation in the recovered reactant was 6.8% of the ^{82}Br in (0.54×1.9) mmol of **3**-Br, or $6.8/(0.54 \times 1.9) = 6.6\%$ ^{82}Br/mmol **3**-Br. Therefore, the extent of exchange in the recovered reactant was $(6.6/26.3) \times 100 = 25\%$.

Kinetics and thermodynamics of dissociation of nickel(II)–isoquinoline complexes in tetrahydrofuran. Effect of trace water on ligand substitution kinetics

P. K. CHATTOPADHYAY[1] AND B. KRATOCHVIL[2]

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received November 5, 1982

P. K. CHATTOPADHYAY and B. KRATOCHVIL. Can. J. Chem. **61**, 1842 (1983).

Rate constants and associated activation parameters for the dissociation of $(solv)_5Ni(isoquin)^{2+}$ (solv = solvent, isoquin = isoquinoline) were determined in tetrahydrofuran (THF) over the range 15 to 35°C by stopped-flow spectrophotometry. Comparison of the enthalpy of activation $\Delta H_b^{\ddagger}$ for the dissociation of $(solv)_5Ni(isoquin)^{2+}$ in THF with previous results in other solvents reveals that the linear relation between $\Delta H_b^{\ddagger}$ for the dissociation of this ion in the various solvents and the Gutmann donicity can be extended to THF. From this relation the donor number of THF is found to be 18.8 ± 0.5, in agreement with the value 19.3 reported from other methods. Dissociation of $(solv)_5Ni(isoquin)^{2+}$ in THF is controlled by an I_d-type mechanism, as was previously observed in other protic and aprotic solvents. The rate of dissociation in THF is strongly affected by the free-water concentration in the medium.

P. K. CHATTOPADHYAY et B. KRATOCHVIL. Can. J. Chem. **61**, 1842 (1983).

Faisant appel à la spectrophotométrie du flux stoppé, on a déterminé les constantes de vitesse et les paramètres d'activation de la dissociation du $(solv)_5Ni(isoquin)^{2+}$ avec (solv = solvant, isoquin = isoquinoléine) dans le tétrahydrofuranne (THF) dans un intervalle de température allant de 15 à 35°C. La comparaison de l'enthalpie d'activation $\Delta H_b^{\ddagger}$ de la dissociation du $(solv)_5Ni(isoquin)^{2+}$ dans le THF avec les résultats antérieurs obtenus pour d'autres solvants, révèle qu'on peut étendre au THF, la relation linéaire entre $\Delta H_b^{\ddagger}$ de la dissociation de cet ion dans divers solvants et le caractère donneur de Gutmann. A partir de cette relation on trouve que le nombre donneur du THF est de 18,8 ± 0,5 en accord avec la valeur de 19,3 rapportée à partir d'autres méthodes. La dissociation du $(solv)_5Ni(isoquin)^{2+}$ dans le THF est contrôlée par un mécanisme de type I_d tel qu'observé antérieurement dans d'autres solvants protiques et aprotiques. La vitesse de dissociation dans le THF est fortement affectée par la concentration en eau libre du milieu.

Introduction

The Lewis basicity of solvents toward metal ions as Lewis acids is an important parameter in the intrinsic solvating capacities of the solvents. Values for the donicities of alcohols relative to nickel(II) as a Lewis acid can be obtained by extrapolating the linear relation between the enthalpy of activation $\Delta H_b^{\ddagger}$ for the dissociation of $(solv)_5Ni(isoquin)^{2+}$ (solv = solvent, isoquin = isoquinoline) or $(solv)_5Ni(SCN)^+$ and the Gutmann donor number for solvents to the corresponding values of $\Delta H_b^{\ddagger}$ in alcohols as solvents. These donicities have been observed to be unexpectedly low for methanol, ethanol, and *n*-propanol (1). The significance of these low values is unclear. A similarly low value for the donor number of methanol has also been reported from nmr studies (2). Accordingly, it was of interest to see whether the relation holds for additional solvents whose donor numbers can be estimated independently.

Tetrahydrofuran (THF) is frequently employed as a reaction medium for organic synthesis. It is stable to powerful reductants and can be prepared very dry. The donor number of THF has been determined coulometrically with $SbCl_5$ as a reference Lewis acid (3). THF is of interest also because it is a convenient solvent for the study of the effect of trace water on the rate of dissociation of metal–ligand complexes.

The Lewis basicity of most organic solvents, especially dipolar aprotic solvents, is sharply affected when even traces of water are present. The effect of water on solvent basicity is generally linear up to a concentration of a few millimolar and then levels off gradually as the concentration is further increased. It is not yet possible to define unambiguously the state of aggregation of water in many organic solvents. Since in ligand-substitution kinetics the microscopic molecular properties of the medium, especially in the immediate vicinity of the dissociating ion, are more important than the macroscopic characteristics of the bulk solvent (4), the effect of trace water on the dissociation of $(solv)_5Ni(isoquin)^{2+}$ should be significant in a solvent of low dielectric constant such as THF, and investigation of the magnitude of this effect should provide useful information on the water distribution.

Experimental

Chemicals

THF (J. T. Baker, ACS grade) was distilled fractionally under nitrogen. The middle fraction was refluxed with $LiAlH_4$ (Alpha Ventron) powder for 2 days in an atmosphere of dry nitrogen. This portion was then distilled fractionally over nitrogen under reduced pressure. The middle fraction was collected in a glass-stoppered bottle and stored in the dark in an atmosphere of dry nitrogen in a dry box (Kewaunee Scientific). All THF was used within 6 to 12 h of the final distillation. Deionized water was distilled twice from alkaline $KMnO_4$ in a closed all-glass distillation apparatus.

Nickel(II) was introduced as either hexakisacetonitrile nickel(II) perchlorate or monohydrated nickel(II) perchlorate. Both salts gave the same results. Methods of preparation of the salts were as previously reported (5, 6). The analytical procedure for determining the concentrations of the nickel(II) solutions (1) and the method for purification of isoquinoline (7) (Aldrich, mp 26 to 28°C, bp 242°C) have also been described previously. $LiAlH_4$ and perchloric acid (70 to 72%, Fisher Chemical Co., analytical grade) were used as obtained.

Instrumentation and experimental procedure

All solutions were prepared with oven-dried glassware in a dry box filled with dry nitrogen gas. Standard procedures for handling nonaqueous solutions so as to minimize water contamination were followed. In order to observe the effect of acid and nickel(II) concentrations on the rate of dissociation of $(solv)_5Ni(isoquin)^{2+}$, a series of solutions were prepared in which the nickel(II) concentration was varied from 1.25×10^{-3} *M* to 5.0×10^{-3} *M* in four increments while

the ligand concentration was held constant at 7.0×10^{-5} *M*. This procedure ensured the formation of only the 1 : 1 complex in all solutions (4, 8). Acid solutions were prepared by adding weighed quantities of 70 to 72% perchloric acid to measured volumes of solvent and calculating the molar concentrations of acid from the weights. The concentrations ranged from 0.0576 to 0.0125 *M*. For measurement of the thermodynamic parameters associated with the dissociation of the complex, solutions of $(solv)_5Ni(isoquin)^{2+}$ were prepared in which the concentration of nickel(II) was held at 5.0×10^{-4} *M* and that of isoquinoline at 5.0×10^{-5} *M*, while the acid solutions were varied from 4.27×10^{-3} *M* to 36.2×10^{-3} *M*. All concentrations refer to final values after mixing during the kinetic experiments.

The first-order rate constant for the dissociation of $(solv)_5Ni(isoquin)^{2+}$ was determined from the rate of formation of protonated isoquinoline (H^+isoquin). This rate was measured by monitoring the absorbance at 332 nm with time after mixing equal volumes of $(solv)_5Ni(isoquin)^{2+}$ and acid solutions. In all experiments the concentration of acid was at least 100 times that of $(solv)_5Ni(isoquin)^{2+}$ to ensure that the observed first-order dissociation rate constant would be independent of acid concentration. Kinetic measurements were made on a stopped-flow spectrophotometer (Durrum Instrument Co., Model D-110). A description of the instrument, including modifications for better temperature control, has been given (8, 9). The temperature of the thermostated waterbath and cell was controlled within ±0.3°C, the value being measured with a calibrated quartz thermometer (Hewlett Packard, Model 2801A). Changes in absorbance with time were recorded on a storage oscilloscope (Tektronix, Model R 564B) and an oscilloscope Polaroid Land camera (Tektronix, Model C-12). All measurements were repeated several times with different batches of solvent and reagents; all results agreed within at least ±1 to 2%.

Results and discussion

Results of the kinetic measurements are displayed in Table 1. The major conclusions are the following.

(*a*) The rate of dissociation of the complex is independent of nickel(II) concentration when the concentrations of acid (H_3O^+), free water (H_2O^*), and ligand are all held constant. During these measurements the concentration of nickel(II) was 15 to 70 times higher than that of the ligand, and the concentration of acid about 10 times higher than that of the nickel(II) (Table 1, Set A). From this result we conclude that the dissociation of $(solv)_5Ni(isoquin)^{2+}$ in THF produced by addition of H_3O^+ can be represented by relations similar to those observed in other solvents (1, 6):

$$[1] \quad (solv)_5Ni(isoquin)^{2+} \underset{k_f}{\overset{k_b}{\rightleftharpoons}} (solv)_5Ni(solv)^{2+} + isoquin$$

$$[2] \quad isoquin + H_3O^+ \overset{k_1}{\rightleftharpoons} (H_3O^+isoquin)$$

From eqs. [1] and [2] it can be shown that, when $[H_3O^+] \gg$ [isoquin], as in this work, the experimentally determined pseudo-first-order rate constant k_{obs} is given by

$$[3] \quad k_{obs} = \frac{k_b k_1 [H_3O^+]}{k_1[H_3O^+] + k_f[Ni(solv)_6]^{2+}}$$

If $k_1[H_3O^+] \gg k_f[Ni(solv)_6]^{2+}$, $k_{obs} = k_b$. Previous work in water and alcohols (1) showed that, when $[Ni]^{2+}$ is 10 to 100 times higher than the ligand concentration, and $[H_3O^+] \geq [Ni]^{2+}$, k_{obs} is the true dissociation constant of $(solv)_5Ni(isoquin)^{2+}$. The independence of k_{obs} of nickel(II) concentrations suggests a dissociation process corresponding to eqs. [1], [2], and [3]. The value of k_b can be taken to be the true value of the dissociation rate constant in THF if the small amount of water introduced into the dry THF by the perchloric acid dihydrate is assumed not to change the true dissociation constant of $(solv)_5Ni(isoquin)^{2+}$ in the rate-determining step of the dissociation process.

[a](solv) = solvent, (isoquin) = isoquinoline.
[b]Isoquinoline concentration held constant throughout at 7.0×10^{-5} *M*.

(*b*) k_{obs} increases when both $[H_3O^+]$ and $[H_2O^*]$ are increased at a constant concentration of $(solv)_5Ni(isoquin)^{2+}$ (Table 1, Set B). However, k_{obs} decreases with an increase in acid concentration when both the complex and H_2O^* concentrations are held constant along with the nickel(II) and ligand concentrations (Table 1, Set C).

The study of temperature effects summarized in Table 2 shows that k_{obs} increases when $[H_3O^+]$ and $[H_2O^*]$ are increased at a constant concentration of the complex over the range 15 to 35°C.

All the results in Tables 1 and 2 can be explained by the dissociation process represented by eqs. [1] and [2] through consideration of the following points: (*1*) trace amounts of water in THF influence the rate-determining step in the dissociation process and increase k_b; (*2*) acid has no direct influence on k_b until $k_1[H_3O^+] \gg k_f[Ni(solv_6)]^{2+}$. As $[H_3O^+]$ and $[H_2O^*]$ are simultaneously increased, however, the effective concentration of H_2O^* in the medium, and accordingly its effect on k_b, is decreased. Consequently, as $[H_3O^+]$ increases at a fixed concentration of free water, k_{obs} decreases. This effect may be explained as follows.

When trace levels of perchloric acid dihydrate (commercial 72% material) are added to anhydrous THF, a solvent of low dielectric constant, the proton is likely present principally as the $H(H_2O)_2^+$ species. As the concentration of perchloric acid dihydrate is increased, aggregation of the solvated hydronium ions into clusters containing $[H^+(H_2O)_2]_2$ and higher species may result in concentrations of free water that are lower than the calculated values. Under these conditions a plot of k_{obs} against theoretical free-water concentration would give a curve of the same type as that observed experimentally in Fig. 1. The true first-order dissociation rate constant can be evaluated by extrapolating the curve to zero free-water concentration. True rate constants for the dissociation of $(solv)_5Ni(isoquin)^{2+}$ in THF evaluated in this way at different temperatures are given

TABLE 2. Dissociation rate constants (k_b) of $(solv)_5Ni(isoquin)^{2+}$ in tetrahydrofuran at several temperatures with various concentrations of acid $[H_3O^+]$ and free water $[H_2O^*]$ in the medium[a]

[a]Concentrations of nickel(II) and isoquinoline held constant at 5.0×10^{-4} M and 5.0×10^{-5} M.

[b]I represents concentration of acid in molarity satisfying $I \geq 4.0\times10^{-3}$ M. Values of k_b at $[H_2O^*] = 0$ at different temperatures were calculated from Fig. 1 (see text). Using the temperature coefficient of k_b at $[H_2O^*] = 0$ (k_b being independent of $C_{H_3O^+}$, $C_{Ni^{2+}}$, and C_{ligand}), $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ for dissociation of $(solv)_5Ni(isoquin)^{2+}$ in THF were calculated to be $16.2_6 \pm 0.1$ kcal and -1.1 ± 0.4 eu.

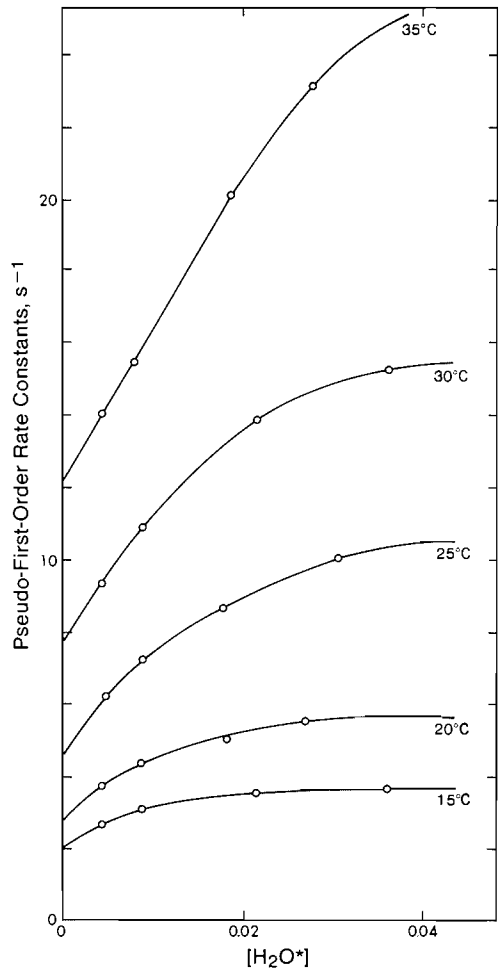

FIG. 1. Pseudo-first-order rate constants for the dissociation of the monocomplex of nickel(II) with isoquinoline in THF as a function of the calculated concentration of free water present.

in Table 2. As the temperature of the solution is increased, $[H_3O^+]$ will decrease and $[H_2O^*]$ will increase and approach the theoretical value. Therefore, k_{obs} will be linear with respect to the theoretically calculated free-water concentration in the medium. This observation explains why the deviations from linearity for plots of k_{obs} against $[H_2O^*]$ are least at 35°C and greatest at 15°C (Fig. 1).

Trace water clearly has a profound effect on the rates of many reactions in aprotic organic solvents, especially of low dielectric constant. The effect generally levels off with increasing water concentration. Whether the water molecules are uniformly distributed throughout the organic medium or are present as hydrogen-bonded clusters or aggregates is uncertain. In contrast to the behavior of hydrogen-bonding solvents of high dielectric constant such as the lower alcohols, THF may facilitate the formation of water clusters by intensifying dipole–dipole and induced ion – dipole interactions among the water molecules. Both the number and size of such clusters would likely decrease with increasing temperature.

The mechanistic pathways for the dissociation of $(solv)_5Ni(isoquin)^{2+}$ induced by H_3O^+ in THF fit an I_d-type mechanism similar to that observed for other systems (10). The pathways can be represented by

[8] $(isoquin)Ni(solv)_5^{2+} + (solv) \underset{k_b}{\rightleftarrows} (isoquin)Ni(solv)_5^{2+}, (solv)$

[9] $(isoquin)Ni(solv)_5^{2+}, (solv) \underset{k_f}{\rightleftharpoons} (solv)Ni(solv)_5^{2+}, (isoquin)$

Any condition that influences the rate-controlling step, represented by eq. [9], will affect k_b. When a small amount of water is added to anhydrous THF, at least one of the THF solvent molecules in $(solv)_5Ni(isoquin)^{2+}$ is likely replaced by a water molecule. The stronger interaction of H_2O^* with Ni^{2+} and isoquinoline thereby increases the value of k_b. Contrary to previous results in alcoholic solvents, the addition of even a small amount of water to anhydrous THF influences the rate-controlling step by changing the structure of the dissociating $(solv)_5Ni(isoquin)^{2+}$ ion to $(solv)_4(H_2O^*)Ni(isoquin)^{2+}$ ion. The H_2O^* in the latter ion is attached to Ni^{2+} by a coordinate bond, the strength of which depends on the intrinsic properties of H_2O^* relative to Ni^{2+}, and by ion–dipole interaction forces. In THF this interaction between Ni^{2+} and H_2O^* will be higher than the corresponding values in alcohols, owing to the lower dielectric constant of THF. Consequently, less water is required to form $(solv)_4(H_2O^*)Ni(isoquin)^{2+}$ from $(solv)_5Ni(isoquin)^{2+}$ in THF than in alcohols. This fact may explain why, contrary to the observation of this study, a small amount of water introduced into dry alcoholic solvents along with H_3O^+ has no effect on the dissociation of $(solv)_5Ni(isoquin)^{2+}$ at a particular temperature, whereas an equivalent amount of water in dry THF increases the dissociation rate constant at the same temperature. Also, the difference in size and polarity of water relative to the lower alcohols is small compared to the difference between water and THF.

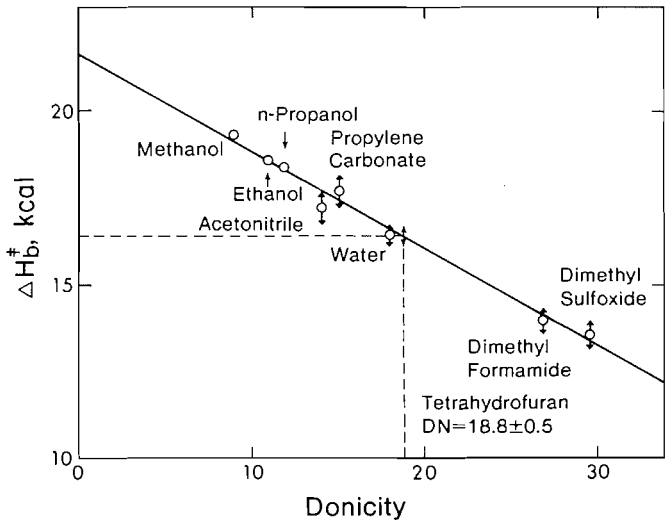

FIG. 2. Relation between the enthalpy of activation for the dissociation of the monocomplex of nickel(II) with isoquinoline against solvent donicity. From the plot the donicity of THF is predicted to be 18.8 ± 0.5.

Enthalpies and entropies of activation associated with the dissociation of $(solv)_5Ni(isoquin)^{2+}$ in THF were calculated from the true dissociation rate constants at different temperatures with the standard thermodynamic equations (Table 2). Plotting $\Delta H_b^{\ddagger}$ for the dissociation of $(solv)_5Ni(isoquin)^{2+}$ in different solvents against the Gutmann donor numbers for those solvents (1) gives a value for THF on the Gutmann donicity scale of 18.8 ± 0.5 (Fig. 2). Gutmann reported 19.3 for the donor number of THF (3), in agreement with the value reported in this work. Thus the linear relation between $\Delta H_b^{\ddagger}$ in different solvents and the donor numbers of the solvents for the dissociation of $(solv)_5Ni(isoquin)^{2+}$ can be extended to anhydrous THF.

It would be useful to extend the relation between $\Delta H_b^{\ddagger}$ and Gutmann donor numbers for the dissociation of $(solv)_5Ni(isoquin)^{2+}$ to other solvents, protic as well as dipolar aprotic. Also, Lewis acids other than nickel(II) and differently charged ionic as well as neutral ligands other than isoquinoline should be investigated to assess the generality of the approach.

In summary, dissociation of $(solv)_5Ni(isoquin)^{2+}$ in THF induced by H_3O^+ is controlled by the same I_d-type mechanism as observed for this and similar nickel complexes in many solvents, and the linear relation between $\Delta H_b^{\ddagger}$ and the Gutmann donor number of various solvents can be extended to THF. The existence of solvated hydronium ions associated with clusters of water molecules is postulated in THF containing trace concentrations of water at low temperature. Low concentrations of free water in anhydrous THF increase appreciably the true dissociation rate constant of $(solv)_5Ni(isoquin)^{2+}$, especially at 35°C. From kinetic measurements of the dissociation constant of the complex at 35°C, the presence of water in dry THF can be detected at concentrations as low as 1 ppm.

Intramolecular participation by the thiol group in amide hydrolysis: the general acid-catalyzed pathway[1]

ROBERT S. MCDONALD,[2] PATRICIA PATTERSON,[3] AND ANN STEVENS-WHALLEY[3]
Department of Chemistry, Mount Saint Vincent University, Halifax, N.S., Canada B3M 2J6

Received March 31, 1982[4]

ROBERT S. MCDONALD, PATRICIA PATTERSON, and ANN STEVENS-WHALLEY. Can. J. Chem. **61**, 1846 (1983).

The hydrolysis of *N*-n-propyl-2-mercaptomethylbenzamide has been investigated in HCl and a series of buffers over the pH region 0–8.5 at 40.0°C, μ = 1.0. Nucleophilic participation by the thiol group during amide hydrolysis produces 2-thiophthalide as the stable product. The second-order rate constant for the acid-catalyzed reaction is 10^7 times greater than that for the hydrolysis of *N*-propylbenzamide.

The pH–rate profile and buffer catalysis data are indicative of a change in rate-determining step near pH 3–3.5 from the uncatalyzed formation of neutral tetrahedral intermediate at low pH to its general acid-catalyzed breakdown (or a kinetic equivalent) at high pH. The Brønsted catalysis plot for this latter process is most consistent with rate-determining general base-catalyzed breakdown of the cationic tetrahedral intermediate directly to product.

ROBERT S. MCDONALD, PATRICIA PATTERSON et ANN STEVENS-WHALLEY. Can. J. Chem. **61**, 1846 (1983).

On a étudié l'hydrolyse du *N*-n-propylmercapto-2 méthylbenzamide dans du HCl et dans diverses solutions tampon dans l'intervalle de pH allant de 0 à 8,5 à 40,0°C, μ = 1,0. La participation nucléophile du groupe thiol à l'hydrolyse de l'amide conduit au thio-2 phtalide comme produit stable. La constante de vitesse d'ordre deux de la réaction catalysée par un acide est de 10^7 fois supérieure à celle de l'hydrolyse du *N*-propylbenzamide. La courbe de la vitesse en fonction du pH et les données de la catalyse par les solutions tampon indiquent un changement dans l'étape déterminante à un pH voisin de 3 à 3,5 à partir de la formation non catalysée de l'intermédiaire tétraédrique neutre à faible pH jusquà sa rupture générale catalysée par un acide (ou un équivalent cinétique) à fort pH. La courbe de catalyse de Brønsted de ce dernier processus s'accorde d'avantage avec une étape déterminante de rupture générale, catalysée par une base, de l'intermédiaire tétraédrique cationique donnant directement le produit.

[Traduit par le journal]

A thiol group has been implicated in the catalytic activity of a number of enzymes either through the coenzyme (1, 2)[5] or as an integral part of the enzyme active site (3–6). Members of the family of cysteine proteases possess a thiol group which has been assigned a nucleophilic role during peptide (amide) hydrolysis (4–6).

Considerable information may be gained on the mechanism of enzyme-catalyzed reactions by the study of appropriate model compounds which react by an intramolecular pathway (7). However, a survey of recent reviews (8, 9) reveals that reports of the thiolysis of an amide (either intermolecular or intramolecular) are conspicuous by their absence (see, however, refs. 10 and 11).

In order to obtain direct evidence for thiol group participation during amide hydrolysis, the *N*-alkyl-2-mercaptomethylbenzamides (**1**) were synthesized and their hydrolytic behaviour studied in buffered aqueous solution over a range of pH. Nucleophilic participation by sulfur would lead to 2-thiophthalide (**2**), or its basic hydrolysis product, and amine.

b, R = —$CH_2CH_2OCH_3$

Experimental

General

Melting points were taken on a Gallenkamp apparatus and are uncorrected. An Orion 601A pH meter with a research grade combination electrode was used for all pH measurements. The meter was calibrated with two Fisher-certified buffers selected to bracket the pH of the solutions. Nuclear magnetic resonance (nmr) spectra were recorded at 60 MHz or 80 MHz on either a Varian EM360A or a Bruker WP-80 spectrometer. Chemical shifts are given in ppm (δ) relative to internal TMS in $CDCl_3$ solution. Infrared (ir) spectra were recorded on a Beckman Acculab 6 spectrometer; solid samples were run in KBr pellets, the liquids as thin films between NaCl plates. Peak positions are quoted in cm^{-1}.

Ultraviolet (uv) spectra were recorded on a Beckman 24 spectrophotometer equipped with a dedicated 10-inch flat bed recorder, four-position manual sample changer, electronic temperature controller, and temperature readout accessory. This machine was also used to monitor the kinetic runs. Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, Department of Chemistry, University of British Columbia.

Materials

Liquid amines were dried overnight over KOH pellets, distilled from zinc dust at atmospheric pressure, and stored under N_2 until ready to use. Imidazole was recrystallized from benzene using decolorizing charcoal until colorless crystals were obtained; mp, after drying *in vacuo*, 89–90.5°C (lit. (12) mp 90–91°C). All other buffer components were reagent grade and used without further purification. The purification of water and dioxane and the preparation of buffer solutions has been described (13).

2-Thiophthalide, **2** (14), was prepared by a modification of literature procedures. The 2-(benzylmercaptomethyl)benzoic acid was obtained in 66% yield by the method described by Storm and Koshland (15). The cyclization–debenzylation was accomplished with refluxing trifluoroacetic anhydride according to Lumma *et al.* (16). Crude **2**, produced in 86% yield, was purified initially by chromatography on silica gel (80–200 mesh). Elution with pentane gave a trace of dibenzyl disulfide and considerable benzyl trifluoroacetate in the early

fractions. Pentane–ether (15:1) eluted **2** as a pale yellow solid, mp 53–55°C. Repeated recrystallization from pentane–ether afforded colorless needles, mp 58.5–60°C (lit. (14) mp 58–60°C). Spectroscopic data are as follows: ir: 1685 (γ-thiolactone carbonyl); uv (H_2O) λ_{max} (log ε): 213 (4.02), 243 (4.04), 269 (3.92); nmr δ: 4.48[6] (s, 2H), 7.2–8.0 (m, 4H). *Anal.* calcd. for C_8H_6OS: C 63.97, H 4.03, S 21.35; found: C 64.02, H 4.00, S 21.30.

The *N*-alkyl-2-mercaptomethylbenzamides (**1**) proved to be remarkably sensitive to aerial oxidation during prepration and isolation, and special precautions had to be taken to minimize disulfide formation during the kinetic runs. This instability presumably results from the method of preparation which is outlined below.

Thiolactone **2** (20–250 mg) was dissolved in large excess (2–3 mL) of neat liquid amine and sealed off with Parafilm under N_2 in a small round-bottom flask. Reaction was allowed to proceed at room temperature in the dark until nmr revealed less than 5% of **2** remained. This required 20–30 min for the n-propylamine and 10 h for the 2-methoxyethylamine (prolonged reaction times are to be avoided). No ring opening of **2** could be detected after treatment with isopropylamine for 24 h or with *tert*-butylamine for 8 months. Excess amine was then removed under reduced pressure at 30–35°C and the residual colorless liquid used without further purification. All attempts to isolate analytically pure **1** resulted in contamination with **2** or disulfide. However, the following spectral data are consistent with the proposed structure for **1***a*: ir: 2530 (v w, SH), 1626 (amide I), 1551 (amide II), 1315 (amide III); uv (H_2O) no λ_{max} above 215 nm; nmr,[7] δ: 0.98 (t, 3H), 1.2–1.8 (m, 2H), 3.39 (q, 2H), 3.88 (s, 2H), 6.5–8 (v broad s, 1H), 7.2–7.5 (m, 4H). Further evidence to support the structure for **1***a* comes from spectral and microanalytical data collected for the disulfide which must have **1***a* as its precursor.

The disulfide separated out in 95% yield when **2** and a 3-fold excess of n-propylamine were refluxed together in ether solution for one hour. The colorless solid was purified by crystallization from dioxane–water and after drying *in vacuo* had mp 175–176°C; nmr, δ: 0.97 (t, 6H), 1.35–1.85 (m, 4H), 3.37 (q, 4H), 3.87 (s, 4H), 6.3–6.6 (v broad s, 2H), 7.2–7.6 (m, 8H). *Anal.* calcd. for $C_{22}H_{28}N_2S_2O_2$: C 63.43, H 6.77, N 6.72, S 15.39; found: C 63.54, H 6.59, N 6.60, S 15.56.

Kinetics

Stock solutions of the thiol amides **1** were prepared by taking up the product from 22.5 mg of **2** in 5.0 mL dioxane as described above. The resulting 0.03 *M* solution when stored under N_2 proved to be stable for periods of up to one week. Kinetic runs were initiated by injecting 15 μL of this stock solution into 2.50 mL of aqueous buffer which had been temperature-equilibrated for at least 30 min in the thermostatted sample compartment of the spectrophotometer. Reacting solutions were maintained at 40.0 (±0.1)°C unless otherwise noted and the ionic strength (μ) was kept constant at 1.0 with KCl. The initial concentration of **1** was 1.8×10^{-4} *M* in the solution which also contained 0.6% dioxane. Quartz cuvettes equipped with tight-fitting Teflon stoppers were used throughout. Successive scans of the uv spectrum of a reaction mixture containing **1** clearly revealed the appearance of absorption maxima near 240 and 265 nm due to **2**. An isosbestic point is found near 231 nm. Reactions were monitored by taking absorbance readings at 265 nm over 75–90% reaction; an "infinity" value (A_∞) was taken after at least 10 half-lives. Rate-constants (k_{obs}) were calculated from the linear plots of ln ($A_\infty - A$) vs. *t* in the usual way. Runs having kinetic plots with correlation coefficients (*r*) <0.999 over at least two half-lives were rejected. The very slow runs in 1.0 *M* KCl ($\tau_{1/2} \simeq 17$ h) were followed to about 30% reaction and the A_∞ value estimated to be the same as that obtained from a reaction mixture containing an identical injection of the same stock solution which was followed to completion. Three independent runs using different stock solutions gave excellent plots, the resulting k_{obs} values agreeing to within 4%. The pH of all solutions was taken before and after the kinetic runs; agreement was within 0.02 pH units except for the very dilute HCl solutions and in 1.0 *M* KCl where the amine produced during the reaction caused appreciable pH changes. In these cases, the average a_{H^+} during the runs was calculated from the initial and final pH values. After the kinetic run, the solution was carefully examined for turbidity (a fine white precipitate of disulfide). While the presence of trace amounts of precipitate appeared to have little effect on the linearity of the kinetic plots or the derived k_{obs} values, appreciable amounts were invariably accompanied by erratic absorbance readings, A_∞ values which were too low, and curved kinetic plots. Such runs were routinely rejected. The formation of disulfide concurrent with thiolactonization hampered many of our early kinetic trials. The problem was overcome for the acidic and weakly basic solutions by using only freshly prepared stock solutions of **1**, degassing all solutions before use, carrying out the reactions under N_2 in cuvettes sealed off with Parafilm, and maintaining all kinetic solutions at 1.0×10^{-4} *M* in EDTA (17). However, even these precautions could not prevent disulfide formation during the very slow runs at pH ≥ 8.5 and these trials were abandoned. Quoted k_{obs} values are the average of at least duplicate runs; agreement between replicate runs was always within 10% and normally within 5–6%.

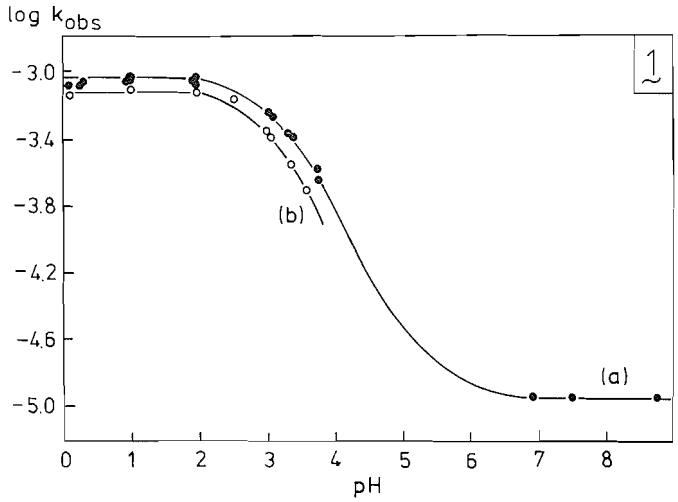

FIG. 1. The pH–log rate constant (k_{obs}) profiles for thiolactonization of (a) **1***a* and (b) **1***b* at 40.0°C, μ = 1.0.

Product

The appearance of absorption maxima near 240 and 265 nm gives clear evidence for the formation of **2** during the hydrolysis of thiol amides **1**. The final absorbances at these wavelengths typically were 80–90% of those of an equal concentration of **2** under identical conditions. The product is invariably contaminated by a small amount of disulfide which remains in solution and has no appreciable effect on the kinetics under investigation.

Product isolation was carried out as follows. Thiol n-propylamide **1***a* prepared from 75 mg of **2** was taken up in 5.0 mL dioxane and added slowly to 1.75 L of degassed 0.10 *M* HCl at 25°C. The solution was stirred vigorously under N_2 in the dark for 18 h. A fine suspension of disulfide (10 mg, 13%) was removed by filtration and the resulting solution extracted with three 250-mL portions of ether. The combined ether extracts were dried ($MgSO_4$) and concentrated to dryness to yield 53 mg (71%) of **2** (identified by nmr), contaminated by a trace (<5%) of disulfide.

Results

The hydrolysis of thiol amides **1** provides clear evidence for nucleophilic participation by the thiol group during amide hydrolysis. The characteristic uv absorptions of **2** appear during the reaction and this product can be isolated in good yield from

[6]Chemical shift incorrect in ref. 15.

[7]After shaking with D_2O, the variable broad NH signal near δ 6.5–8 was removed and the δ 3.39 resonance became a triplet (—CH_2CH_2ND—).

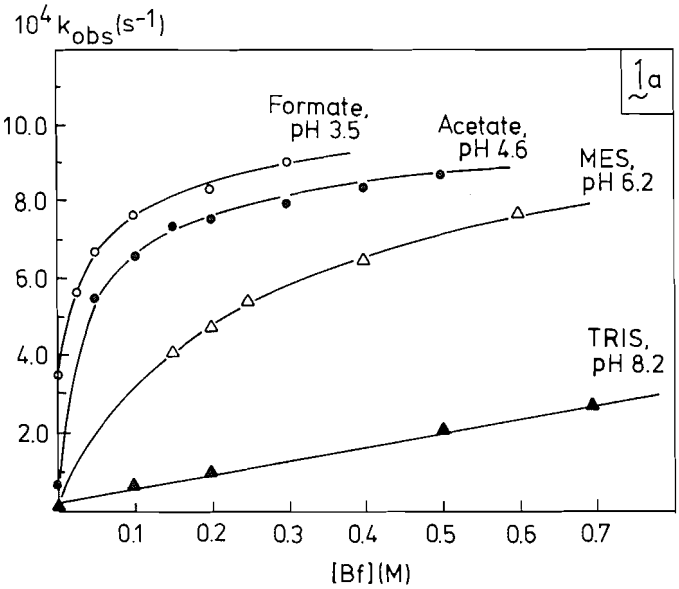

FIG. 2. Buffer catalysis plots for the thiolactonization of **1***a* at 40.0°C, μ = 1.0 (the fraction of the buffer in its basic form is 0.5 in each case).

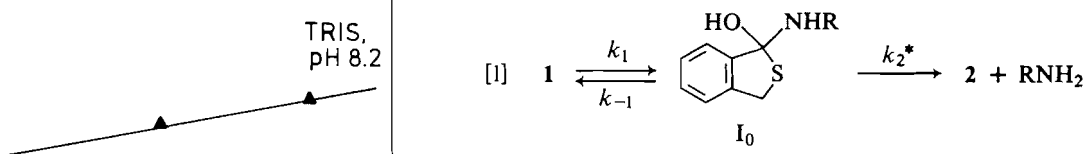
the reaction mixture. No base-catalyzed hydrolysis pathway (with or without sulfur participation) could be detected for **1***a* up to pH 8.7, and the subsequent basic hydrolysis of **2** did not interfere with our measurements.[8]

The pH–log rate constant (k_{obs}) profiles for appearance of **2** from **1***a* and **1***b* at 40.0°C are illustrated in Fig. 1. Both amides exhibit a rate plateau from pH 0–2 which then falls off with decreasing acidity to a slow spontaneous (water-catalyzed) process above pH 6. The average value of k_{obs} on the low pH plateau is 8.5 (±0.5) × 10^{-4} s^{-1} for **1***a* and 7.3 (±0.4) × 10^{-4} s^{-1} for **1***b*. The inflection points in both curves in Fig. 1 occur at a pH of 3.3 and, since there is no group in either **1** which has a pK near this value,[9] this behavior must be indicative of a change in rate-determining step from one which is uncatalyzed at low pH to one which is acid-catalyzed at pH >3.5.

Although buffer catalysis was examined only for **1***a*, it is clear that the thiolactonization is strongly catalyzed by the carboxylate, amine, and phosphate buffers used to maintain constant pH over the pH range 3.5–8.3. Some typical buffer catalysis plots are illustrated in Fig. 2. The saturation behavior observed for buffer catalysis is again consistent with a change in rate-determining step. The maximum value of k_{obs} at high concentration of buffer or HCl varied randomly with pH over the pH range 0–7 within the limits 8.0–9.8 × 10^{-4} s^{-1}. Catalytic effectiveness of the buffers decreases as the pK_a of the conjugate acid of the buffer increases (Fig. 2) and, for a given buffer, as the pH increases.

The minimum mechanistic pathway required to account for the results above is the two-step, one-intermediate (I_0), scheme below.



Under our reaction conditions (low [RNH_2], pH < 9), the reverse of the second reaction can be neglected.[10] In analogy with mechanisms proposed for the reverse reaction, thiolester aminolysis (17, 23–26), and thioimidate ester hydrolysis (27), we propose that formation of I_0 from **1** is uncatalyzed and that its breakdown is subject to acid and buffer catalysis. Making the steady-state assumption for I_0 (repetitive scans of the uv spectrum of reacting **1** gave no evidence for the accumulation of an intermediate), solution of the rate equation gives:

$$[2] \quad k_{obs} = k_1 \cdot k_2^*/(k_{-1} + k_2^*)$$

where, in general, k_2^* is given by

$$[3] \quad k_2^* = k_{H_2O} + k_H \cdot a_{H^+} + k_{Bf} \cdot [Bf]$$

Rearranging eq. [2] gives, after substitution of eq. [3],

$$[4] \quad k_{obs}/(1 - k_{obs}/k_1) = k'_{H_2O} + k'_H \cdot a_{H^+} + k'_{Bf} \cdot [Bf]$$

where

$$k'_{H_2O} = k_1 \cdot k_{H_2O}/k_{-1}, \; k'_H = k_1 \cdot k_H/k_{-1}$$

and

$$k'_{Bf} = k_1 \cdot k_{Bf}/k_{-1}$$

Kinetic data were analyzed as follows. At low pH or high [Bf], $k_2^* \gg k_{-1}$ and eq. [2] becomes: $k_{obs} = k_1$, independent of pH and [Bf]. The low pH rate plateau and the limiting rate constant extrapolated from buffer catalysis data (*vide infra*) give values for k_1 in the range 9.8 (±1.8) × 10^{-4} s^{-1} (pH 0–7.5).

Three runs in 1.0 *M* KCl at pH 6.9–8.7 gave an average value of k_{obs} = 1.11 (±0.02) × 10^{-5} s^{-1}. Clearly the last two terms in eq. [3] can be neglected in this range and eq. [4] becomes

$$k'_{H_2O} = k_1 - k'_{obs}(k_1 - k_{obs})$$

[8]We have measured the rate of basic hydrolysis of **2** in dilute NaOH solution at 40°C, μ = 1.0 (k_{OH} = 7.7 × 10^{-2} M^{-1} s^{-1}). Thus at pH 8.7, hydrolysis of **2** occurs at a rate only 6% of that of its rate of formation in 1.0 *M* KCl and none of the k_{obs} values have been corrected for this effect.

[9]The acidity constants of the amide carbonyl and the thiol group in **1***a* are estimated as follows. Yates and co-workers (18) recently determined the pK_{BH^+} values of a large number of *N*-substituted benzamides and although the n-propyl derivative was not reported, its value must be close to −1.5. Since the —CH_2OH and —CH_2SH have very similar electronic and steric effects (19), we assume that the *o*-CH_2SH group will have the same effect on this pK_{BH^+} as an *o*-CH_2OH group has on the pK_a of benzoic acid, i.e. acid strengthening by 0.3 ± 0.1 pK units (20). Similarly, we assume that the *o*-carbamido substituent will have the same effect on the pK of the thiol group in benzylmercaptan (pK_{SH} = 9.43 (21)) as it does on the pK_a of benzoic acid, acid-strengthening by 0.4 ± 0.2 pK units (22). Thus, our estimates for pK_{BH^+} and pK_{SH} of **1***a* are −1.8 ± 0.1 and 9.0 ± 0.2, respectively.

[10]Kinetics of the aminolysis of thiolactone **2** with n-propylamine and 2-methoxyethylamine have been studied in aqueous solution at 40°C, μ = 1.0 (unpublished results from this laboratory). Partially acidified amine solutions at high concentrations (0.25–1.0 *M*) served as their own buffers (pH 9.7–11.3). The kinetic data were analyzed in terms of the general rate law used previously (23). Under thiolactonization conditions (low [RNH_2], pH < 9) only the term first-order in amine contributes significantly to the thiolester aminolysis rate. This allows calculation of the maximum value of the [**2**]/[**1**] ratio under thiolactonization conditions to be in the range 1–2 × 10^3 for **1***a* or **1***b* at pH 8.5. Since this ratio increases as pH decreases, we conclude that the thiolactonization reaction **1** → **2** proceeds essentially to completion at pH ≤ 8.5 and $k_{-2} \simeq 0$.

2-Methoxyethylamine (10; 0.50−1.0)	8.25	3	0.0177(±0.0007)	[d]

[a]Measurements of pH were made at 25°C.
[b]n = number of runs.
[c]The errors quoted are standard deviations.
[d]The buffer catalysis plots were essentially linear up to [Bf] = 1.0 *M*.

Taking $k_1 = 9.8 \times 10^{-4}$ s^{-1} yields $k'_{H_2O} = 1.12 \times 10^{-5}$ s^{-1}.

In the dilute HCl solutions over the pH region 1−3.4, the contribution of k_{H_2O} to k_2* can be neglected and eq. [2] becomes, after substitution,

$$k_{obs} = k_1 \cdot k_H \cdot a_{H^+}/(k_{-1} + k_H \cdot a_{H^+})$$

Now, a double reciprocal plot (of k_{obs}^{-1} vs. $a_{H^+}^{-1}$) should be linear, yielding values for k'_H and k_1 from the slope and intercept, respectively. The plot for **1***a* gave $k'_H = 1.66\ (\pm 0.06)\ M^{-1}$ s^{-1} and $k_1 = 8.9\ (\pm 0.2) \times 10^{-4}$ s^{-1} ($r = 0.998$). An alternative analysis of the HCl data involves eq. [4] in the form

$$k'_H = [k_{obs}/(1 - k_{obs}/k_1) - k_{H_2O}]a_{H^+}^{-1}$$

Now, using values for k_1 and k'_{H_2O} obtained above allows calculation of an average value of k'_H of 1.65 (±0.15) M^{-1} s^{-1} for the eight runs on **1***a* over the pH range 3−3.8. A similar analysis of the kinetic data for **1***b* using values for k_1 of 7.5×10^{-4} s^{-1} and k'_{H_2O} of 9.7×10^{-6} s^{-1} (lower by 15% than the value observed for **1***a*) gave $k'_H = 1.03\ (\pm 0.12)\ M^{-1}$ s^{-1}.

The distinct curvature in most of the buffer catalysis plots (Fig. 2) over the pH range 3.5−8 indicated that, in general, solution of eq. [4] was necessary to evaluate k'_{Bf}. However, we found that the buffers studied at pH > 8 gave linear plots of k_{obs} vs. [Bf] up to 1.0 *M*. Under these conditions then, $k_2^* \ll k_{-1}$ and eq. [2] becomes, after substitution,

$$k_{obs} = k'_{H_2O} + k'_H \cdot a_{H^+} + k'_{Bf} \cdot [Bf]$$

Thus k'_{Bf} is obtained from the slope of these plots (see the Tris plot in Fig. 2 and the last two entries in Table 1).

In the pH region 5.5−8, neglecting the contribution of k_{H_2O} and $k_H \cdot a_{H^+}$ to k_2*, eq. [2] becomes, after substitution,

$$k_{obs} = k_1 \cdot k_{Bf}\,[Bf]/(k_{-1} + k_{Bf} \cdot [Bf])$$

Plots of k_{obs}^{-1} vs. $[Bf]^{-1}$ were reasonably linear, yielding values for k'_{Bf} and k_1 from the slope and intercept, respectively. The value of k_1 so determined was then used in eq. [4] to calculate another value for k'_{Bf} where now the k'_{H_2O} and k'_H contributions were considered. The values of k'_{Bf} calculated by these two methods agreed to within 5%.

Over the pH range 3.5−5.5 now the general form of eq. [4] was used to calculate k'_{Bf}, using 8.9×10^{-4} s^{-1} as an initial estimate for k_1. Only data where $k_{obs} \leq 0.75k_1$ were used in these calculations (see form of eq. [4]). We found it necessary to use an iterative procedure, making small adjustments in the value of k_1 to achieve constant values for k'_{Bf}. The values of k'_{H_2O} and k'_H were those calculated above. The values of k'_H and k'_{Bf} and the optimized values for k_1 are collected in Table 1.

Changing the pK_a[11] of the amine leaving group in **1** from 10.43 (n-propylamine) to 9.31 (2-methoxyethylamine) decreases the rate of formation of I_0 by 15% and also decreases the rate of its subsequent acid-catalyzed breakdown (*vide supra*).

Activation parameters for the thiolactonization of **1***a* were determined in 0.10 *M* HCl where formation of I_0 is solely rate-determining. The kinetic data are collected in Table 2 and the linear plot of $\ln kT^{-1}$ vs. T^{-1} gave $\Delta H^{\ddagger} = 18.5\ (\pm 0.6)$ kcal mol^{-1} (77.7 kJ mol^{-1}) and $\Delta S^{\ddagger} = -14\ (\pm 2)$ cal K^{-1} mol^{-1} (−59 J K^{-1} mol^{-1}), $r = 0.997$.

Where buffer catalysis was examined at more than one buffer ratio, plots of k'_{Bf} vs. f_B (the fraction of the buffer in its basic form) are linear with intercepts, at $f_B = 1$, of essentially zero. Intercepts of these plots at $f_B = 0$ gave k'_{HA}, the second-order rate constants for apparent general acid catalysis. The k'_{HA} values for all general acids including H_3O^+ and H_2O are collected

[11]See footnote *a* in Table 3.

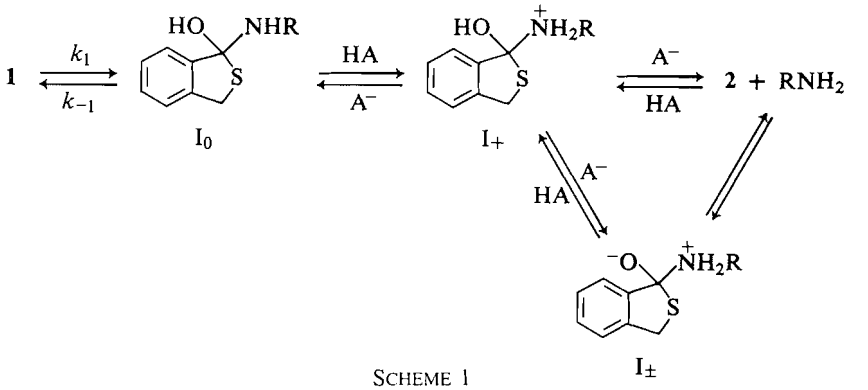
in Table 3 along with values for k'_B, the corresponding rate constants for general base-catalyzed breakdown of the cationic tetrahedral intermediate ($k'_B = k'_{HA} \cdot K_{I+}/K_{HA}$). The statistically corrected Brønsted plot for such general base catalysis is illustrated in Fig. 3.

Our kinetic results in the imidazole buffers have been omitted from the analysis above since they differ in several important respects from those observed in the other buffers studied. For example, the buffer catalysis plots over the [Bf] range 0.20–1.0 *M* are essentially linear, such that there appears to be no upper limit to the value of k_{obs}. The maximum catalytic effect is observed in the buffer at f_B = 0.5 (pH 7.1). Presentation and discussion of these results will be deferred until our continuing investigation of this behaviour is completed. However, it should be pointed out that these results may be particularly relevant to the mechanism of action of papain in which an imidazole group has been assigned a general acid–base role in acylation by amide substrates (5, 6).

Discussion

The neighbouring thiol group has a very dramatic effect on the rate of hydrolysis of amides **1**. In the pH region 3–4 where the H_3O^+-catalyzed thiolactonization dominates, the rate constant k_H for **1***a* is 1.65 M^{-1} s^{-1} at 40°C, roughly 10^7 times that calculated for the H_3O^+-catalyzed hydrolysis of *N*-propylbenzamide.[12] Calculation of the effective concentration of the thiol group in **1***a* is not possible since the bimolecular thiolysis of an unactivated amide has not been reported.

The following general mechanism (an expansion of eq. [1]) is proposed to account for the observed kinetic results:



SCHEME 1

The two alternative pathways for breakdown of I_+ will be discussed later. The intermediates involved in Scheme 1 are analogous to those proposed by Jencks and Barnett (17) for the intramolecular sulfur-to-nitrogen acetyl transfer in *S*-acetyl-2-aminoethanethiol. There appears to be no need to invoke any significant reaction via an anionic tetrahedral intermediate (I_-) or the O-protonated form of the substrate.

The uncatalyzed pathway

At low pH or high buffer concentration, we propose the rate-determining step on the thiolactonization pathway to be the uncatalyzed ring-closure of **1** to form I_0. The values of k_1 extrapolated from HCl- and buffer-catalyzed data in Table 1 give an average value for k_1 of 9.7 (±1.1) × 10^{-4} s^{-1} at 40°C up to pH 7. The fact that k_{obs} in 1.0 *M* HCl is roughly 10% lower than that observed in 0.10 *M* HCl may be attributed to a lowering of water activity in the more concentrated acid (27).

However, there does appear to be a systematic (although somewhat erratic) upward trend in the extrapolated values of k_1 at higher pH. Due to the rather long extrapolations involved and the difficulty of obtaining reliable kinetic data for the very slow reactions above pH 8, we have not pursued this matter and simply ascribe this behaviour to a small medium, or pH, effect on k_1. The $\Delta S^{\ddagger}$ associated with the cyclization step (−14 cal $K^{-1}mol^{-1}$) is consistent with the loss of rotational freedom on forming the five-membered ring.

Further support for this assignment comes from studies by Schmir and co-workers (27) on the pH-dependence of products formed in thioimidate ester hydrolysis. This reaction provides an independent method of generating the same type of intermediates as those involved in thiolester aminolysis and amide thiolysis. In every case studied, Schmir found that, at low pH, the products were thiolester and amine exclusively, implying that the rate-determining step in amide thiolysis under these conditions would be formation of neutral tetrahedral intermediate, I_0.

However, conclusions drawn from the results of kinetic studies on thiolester aminolysis (26) and product studies of the hydrolysis of 2-methyl-Δ^2-thiazoline (17, 25) introduce the kinetically equivalent possibility that breakdown of $I_\pm$ to **2** and amine (Scheme 1) may be solely or partially rate-determining at low pH. In order to investigate this possibility in our case, the rate of hydrolysis of the 2-methoxyethylamide (**1***b*), which has a considerably better leaving group than the propylamide

[12]The acid-catalyzed hydrolysis rate constant (k_H) for *N*-methylbenzamide in HCl solution at 100.4°C is 6.13 × 10^{-5} M^{-1} s^{-1} (29). Using $\Delta H^{\ddagger}$ = 21.2 kcal mol^{-1} (30), we calculate k_H = 2.07 × 10^{-7} M^{-1} s^{-1} at 40°C. Making a correction of 1.35-fold for the lower reactivity of the *N*-propyl derivative (31) gives k_H = 1.54 × 10^{-7} M^{-1} s^{-1} at 40°C.

TABLE 3. Rate constants for catalysis of the thiolactonization of **1***a* at 40.0°C, $\mu = 1.0$

	Acid	pK_a[a]	k'_{HA} (M^{-1} s^{-1})[b]	k'_B (M^{-1} s^{-1})[c]
1.	H_3O^+	−1.74	1.65(±0.15)	1.20×10^{-7}
2.	HCO_2H	3.47	$7.82(\pm0.46) \times 10^{-2}$	9.2×10^{-4}
3.	$ClCH_2CH_2CO_2H$	3.88	$7.83(\pm0.27) \times 10^{-2}$	2.36×10^{-3}
4.	CH_3CO_2H	4.57	$5.27(\pm0.23) \times 10^{-2}$	7.79×10^{-3}
5.	$CHF_3CH_2NH_3^+$	5.32	$2.82(\pm0.10) \times 10^{-2}$	2.35×10^{-2}
6.	MES (H^+)	6.21	$9.2\ (\pm0.8) \times 10^{-3}$	5.94×10^{-2}
7.	$H_2PO_4^-$	6.48	$2.27(\pm0.29) \times 10^{-2}$	2.73×10^{-1}
8.	Tris (H^+)	7.85	$7.5\ (\pm0.5) \times 10^{-4}$	2.11×10^{-1}
9.	$CH_3OCH_2CH_2NH_3^+$	9.31	$1.97(\pm0.08) \times 10^{-4}$	1.60
10.	H_2O	15.27	$2.03(\pm0.04) \times 10^{-7}$[d]	1.50×10^3

[a]Except for H_3O^+ and H_2O, the pK_a values were calculated from the pH values of half-neutralized solutions at 25°C, $\mu = 1.0$, and corrected to 40°C (28).
[b]The errors quoted are standard deviations.
[c]Calculated from $k'_B = k'_{HA} \cdot K_{I+}/K_{HA}$ where $pK_{I+} = 5.4$ (see text).
[d]The value of k'_{H_2O} has been converted to a second-order rate constant by dividing by 55.1.

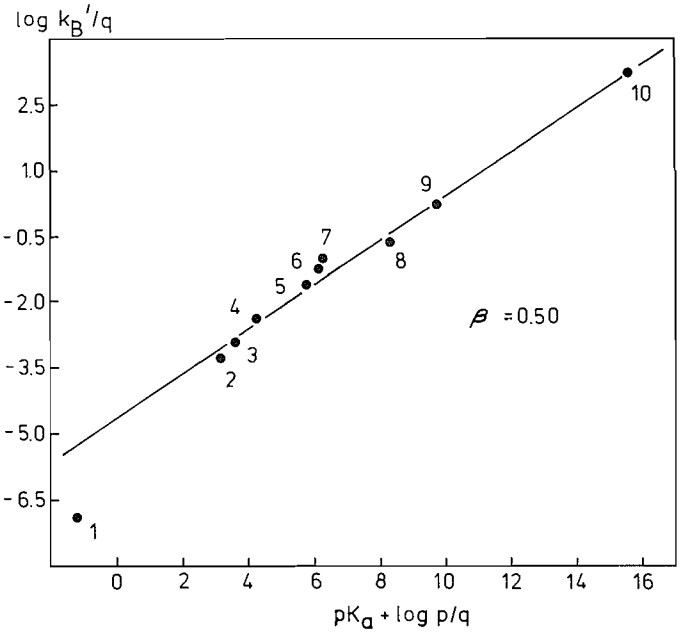

FIG. 3. The statistically-corrected Brønsted plot for the general base-catalyzed step in the thiolactonization of **1***a* at 40.0°C, $\mu = 1.0$ (the numbers refer to the conjugate base of the species in Table 3).

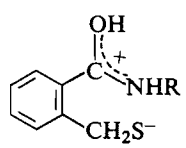
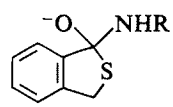
(**1***a*), was investigated. We anticipated that if breakdown of $I_\pm$ were rate-limiting, **1***b* should hydrolyze more rapidly than **1***a* at low pH. In fact, **1***b* reacts more slowly than **1***a* over the pH range 0−4 (Fig. 1), a result more in accord with formation of I_0 being rate-determining.

It should be pointed out that the formation of I_0 from **1** may also proceed via one or more intermediates which cannot be detected kinetically. For example, I_0 may be formed by the cyclization of zwitterion **3** formed in a highly unfavorable equilibrium from **1** (31, 32) or by way of H_3O^+-catalyzed conversion of I_- formed by the cyclization of the thiolate ion of **1** (26).



3



I_-

The general acid-catalyzed pathway

At pH ≥3.5 and low buffer concentration, the thiolactonization of **1***a* exhibits apparent general acid catalysis in terms of neutral substrate (or neutral tetrahedral intermediate) and we propose that breakdown of I_0 becomes rate-determining under these conditions. For general acid catalysis to be observed, this breakdown must proceed via I_+ rather than I_- (see Scheme 1). The $I_0 \rightarrow$ **2** conversion requires two proton transfers and a carbon−nitrogen bond breaking. Presumably loss of amine can occur only in a step following or concerted with *N*-protonation and will occur in the last step of the reaction.[13] This then requires the formation of I_+ or $I_\pm$ or both of these intermediates on the breakdown pathway. Now if either proton transfer in Scheme 1 were solely rate-determining, the Brønsted plot for acid catalysis should show all the characteristics of rate-determining diffusion-controlled proton transfer which have been summarized by Barnett and Jencks (17) and Kirby and co-workers (33). One characteristic of such a plot is a slope of zero or unity or curvature of the type discussed by Eigen (34) with limiting slopes of zero (at low pK_a) and unity (at high pK_a). The Brønsted plot of the k'_{HA} data in Table 3 (not shown) does exhibit some curvature for acids having a $pK_a < 4$ but the limiting slope for weaker acid catalysts is only 0.5. Thus we conclude that the proton transfer is occurring in a step concerted with loss of amine and, referring to Scheme 1, that the rate-determining step in the breakdown of I_0 is the general base-catalyzed conversion of I_+ to **2**, thus avoiding formation of $I_\pm$ as a discrete intermediate. The proposed specific acid−general base catalysis is kinetically equivalent to the general acid catalysis observed. The pK_a values of the two potentially acidic sites in I_+ have been estimated by the method of Fox and Jencks (35) to be 5.4 (ammonium group) and 8.3 (hydroxyl group).[14] Clearly then, over much of the pH range used in this study, a significant proportion of I_0 is converted to I_+ and $I_\pm$ would be the highest energy intermediate at pH ≤ 8. The above estimate of the pK_a of I_+ (to form I_0) allows calculation of the rate constants for general base-catalyzed breakdown of I_+, k'_B ($= k'_{HA} \cdot K_{I+}/K_{HA}$), which are collected in

[13]This follows from the fact that the initial step in the aminolysis of a thiolester is believed to involve attack by amine on the neutral thiolester (24).

[14]The pK_a of I_0 (to form I_-) is similarly estimated to be 11.0. The error in these pK_a values is estimated to be ±1 unit.

Table 3 and the Brønsted plot is illustrated in Fig. 3. If the point for H_2O is omitted, the correlation is good ($r = 0.993$) with a Brønsted coefficient, β, of 0.50 ± 0.02, consistent with the mechanism proposed.

The interconversion of a neutral tetrahedral intermediate and thiolester (and amine) has been previously proposed to be rate-determining at high pH in the hydrolysis of thioimidate esters (27), in the aminolysis of thiolesters (17, 26), and in the hydrolysis of 2-methyl-Δ^2-thiazoline (17, 25). Further, in each case where buffer catalysis was examined (17, 26, 27), the reaction showed general acid catalysis (or a kinetic equivalent) with a Brønsted plot indicative of rate-determining diffusion-controlled proton transfer. Specifically, these authors proposed that the slow step involves the protonic interconversion of tetrahedral intermediates analogous to I_+ and $I_\pm$. The Brønsted plot in Fig. 3 provides clear evidence that this is not the case for our reaction.

The pK_a estimates described above allow calculation of the equilibrium constant for the conversion I_0 into $I_\pm$ to be $\sim 1 \times 10^{-3}$ (17, 33). Thus $I_\pm$ is roughly 4 kcal mol^{-1} (17 kJ mol^{-1}) higher in energy than I_0 and the concerted pathway proposed must provide a lower energy pathway to product.

Kinetics of carbon monoxide oxidation over Co_3O_4 containing catalysts studied by the reversed-flow technique

GEORGE KARAISKAKIS, NICHOLAS A. KATSANOS, AND ALEXIS LYCOURGHIOTIS
Physical Chemistry Laboratory, University of Patras, Patras, Greece

Received October 19, 1982

GEORGE KARAISKAKIS, NICHOLAS A. KATSANOS, and ALEXIS LYCOURGHIOTIS. Can. J. Chem. **61**, 1853 (1983).

The reversed-flow technique, used previously to measure gas diffusion coefficients, heterogeneous catalysis of simple first-order reactions, and other processes, is now extended to the study of the kinetics of a more complicated reaction, namely, the oxidation of carbon monoxide over solid catalysts containing Co_3O_4. The reactants are allowed to diffuse slowly onto the catalyst bed and the reaction is sampled at various times by repeatedly reversing the direction of flow of a gas chromatographic carrier gas passing perpendicularly to the diffusion current.

Rate constants, calculated under steady-state conditions with a second-and first-order rate law, conform to the latter, and this is explained by assuming a reaction between adsorbed carbon monoxide and surface lattice oxygen. Activation energies, calculated from the variation of rate constants with temperature, show a minimum of 14 kJ mol^{-1} for 0.984 mmol of Ca^{2+} per g of the catalyst support. This value is lower than that found by others for pure Co_3O_4 over a similar temperature range.

GEORGE KARAISKAKIS, NICHOLAS A. KATSANOS et ALEXIS LYCOURGHIOTIS. Can. J. Chem. **61**, 1853 (1983).

On a déjà utilisé la technique de l'écoulement inversé pour mesurer les coefficients de diffusion des gaz, la catalyse hétérogène des réactions simples d'ordre un et d'autres processus. On étend maintenant cette technique à l'étude de la cinétique d'une réaction plus compliquée à savoir l'oxydation du monoxyde de carbone sur un catalyseur solide contenant du Co_3O_4. On permet aux réactifs de diffuser lentement dans le lit catalytique et on prélève des échantillons à différents intervalles en inversant de façon répétée la direction d'écoulement du gaz vecteur d'un chromatographe qui passe perpendiculairement à la direction du courant de diffusion.

Les constantes de vitesse, calculées dans les conditions d'état stationnaire avec une loi de vitesse d'ordre deux et d'ordre un, sont en accord avec cette dernière, et on l'explique en supposant qu'il se produit une réaction entre le monoxyde de carbone adsorbé et l'oxygène du réseau de la surface. Les énergies d'activation calculées à partir de la variation des constantes de vitesse avec la température passent par un minimum de 14 kJ mol^{-1} pour 0,984 mmol de Ca^{2+} par gramme de catalyseur. Cette valeur est plus faible que celle trouvée par d'autres chercheurs pour le Co_3O_4 pur dans des intervalles identiques de température.

[Traduit par le journal]

Introduction

Gas chromatography offers many possibilities for physicochemical measurements and some of them are based on perturbations imposed on the carrier gas flow. One such perturbation is to *reverse* the direction of flow of the carrier gas from time to time. Each reversal creates perturbations on the chromatographic elution curve, having the form of extra peaks recorded by the detector system. These peaks constitute a kind of "chromatographic sampling" technique, the rate process taking place within the chromatographic column being the phenomenon sampled.

In its simplest form the above technique was used to measure mutual diffusion coefficients in binary gas mixtures (1), and their temperature variation (2). The diffusion cell consists of an empty chromatographic column $l' + l$ and a diffusion column L connected perpendicularly to the first, around its midpoint (cf. Fig. 1 of ref. 1). The one gas component A (solute) is injected as a pulse at the closed end of the diffusion column, while the other component B (carrier gas) flows continuously through $l' + l$, filling also L. At known times the direction in the flow of B is reversed by means of a suitable valve (cf. Fig. 2 of ref. 1), thus creating sample peaks of A in the detector trace. When the time elapsing between any two successive reversals of the flow is greater than the total gas hold-up time $t'_M + t_M$ in column $l' + l$, a sample peak follows *every* reversal (1). But when the time passing between two successive reversals is less than both t'_M and t_M, only one (symmetrical) sample peak appears after the two successive reversals (2). The dependence of the heights of the sample peaks on the time when the last reversal was made has been derived in an analytical mathematical form and used to calculate the diffusion coefficient of A into B.

A second application of the reversed-flow method was to measure adsorption equilibrium constants of gaseous hydrocarbons on γ-aluminium oxide (3). The adsorbent in this case filled the lower part of the diffusion column L (cf. Fig. 1 of ref. 3), and the hydrocarbon was injected on the top of this column, while carrier gas helium was passing through the empty chromatographic column.

A variation of this method (4) relating to catalysis was to study the kinetics of the drying of a catalytic support impregnated with an organic solvent.

In another series of papers (5–8) the reversed-flow technique was applied to real heterogeneous catalysis. After a general theoretical analysis (6) in which the relevant mathematical equations were derived, the method was used to study the kinetics of alcohols dehydration and of some deaminations over 13X molecular sieve and γ-aluminium oxide (6–8).

In these catalytic studies only the chromatographic column $l' + l$ was employed, filled with the catalyst, and the reactant was injected as a pulse at a middle position of the column, which was also used to separate the products from the reactants (cf. Fig. 3 of ref. 6). However, the theoretical analysis (6) was made only for the case of a reactant A more strongly adsorbed on the catalyst surface than the product(s). Only the latter are eluted from the column, while the reactant, owing to its high adsorption equilibrium constant and to the repeated flow reversals, never is eluted from the column, and also it approximately retains its original space distribution along the column.

In the present paper the reversed-flow technique was applied to a quite different case of heterogeneous catalysis, with *two* gaseous reactants, namely, carbon monoxide and oxygen, neither of which could be retained in the catalytic bed for a long time. Both reactants, together with the product carbon dioxide,

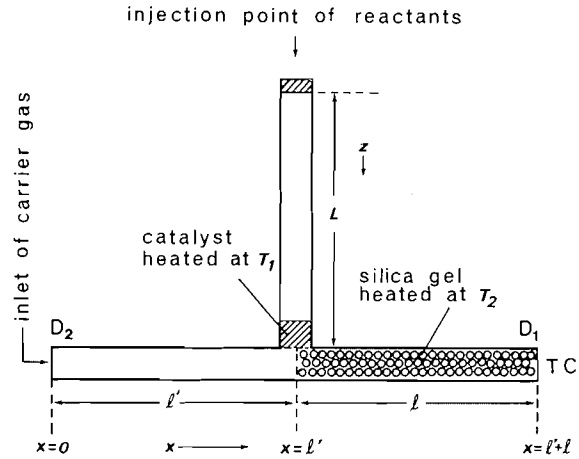

FIG. 1. Schematic representation of the cell used to study heterogeneous catalysis, feeding the catalyst bed by diffusion of the reactants from a remote point of injection.

were rapidly eluted from the catalytic column. In order to extend the reversed-flow method to this type of reactions, we combined the experimental arrangements used to study diffusion coefficients on the one hand (1) and heterogeneous catalysis on the other (6), with the result shown schematically in Fig. 1. A mixture of the reactants is introduced as a pulse at the top of the column L and is allowed to diffuse slowly onto the catalyst retained within a short section at the lower part of the column, and heated to a temperature T_1. The concentration of the reactants at the junction $x = l'$ depends on: (*a*) the time, (*b*) their diffusion coefficient, modified to an effective value because of possible adsorption inside the catalyst bed (3), (*c*) the rate of the chemical reaction on the catalyst, (*d*) the mass of the catalyst, and (*e*) the volume flow-rate of the carrier gas. The concentration of the product at the same point $x = l'$ is determined by: (*a*) the reaction rate which in turn depends on the concentration(s) of reactants, (*b*) the catalyst mass, and (*c*) the carrier gas flow-rate.

A sampling of all concentrations issuing from L can be made by reversing the direction of the carrier gas flow for a short time, and then restoring it in its original direction from D_2 to D_1. Following this flow perturbation, fairly symmetrical sample peaks are recorded by the thermal conductivity detector (TC). These peaks appear separate for the reactants and products, since the chromatographic material (silica gel), filling the column section l and heated at a different temperature (T_2) from that of the catalyst (T_1), causes separation of the various substances.

The above are an obvious extension of the technique reported earlier (6). They continuously sample the catalytic reactor by repeatedly reversing the gas flow direction and measuring the sample signals produced in a chromatographic detector. If the reactants have considerably bigger adsorption equilibrium constants on the catalyst surface than the products, only column $l' + l$, filled with catalyst, is necessary. This acts both as a catalytic reactor and a chromatographic column, and the reactants are injected directly onto it, at some intermediate position along the column (6). Then only the products are eluted and recorded, whereas the reactants approximately retain their original space distribution in the column. If, on the other hand, the adsorption equilibrium constants of the reactants are comparable to those of the products, so that no separation can be effected by the catalytic bed itself, the arrangement of Fig. 1 is employed, i.e. a separate chromatographic material is placed within the system to cause separation of the various substances. Moreover, the catalyst is restricted to a small column length and is fed with reactants by their diffusion from a remote point of injection. This arrangement ensures the presence of reactants over the catalyst for a long time period, and also that the space within which reaction takes place is confined near the junction of the two columns and is not spread with time along the column $l' + l$.

The reversed-flow method is a differential technique for studying heterogeneous catalysis, not suffering from a possible disadvantage of the stopped-flow method (9), consisting in continuously switching the system under study from a flow dynamic one to a static system and vice versa. This permits diffusion and other related phenomena to come into play when the flow is stopped. Compared to the sample vacancy chromatography (10), it is simpler experimentally, since it is not necessary to pass the reactants, mixed with the carrier gas, continuously through the catalyst. Moreover, a whole range of reactants composition is possible within one single experiment, by feeding the catalyst through the diffusion column L.

The oxidation of carbon monoxide was chosen because of the well known interest in this reaction in connection with control of automotive emissions (11) and in order to study the activity for the above reaction of some catalysts newly synthesized in this laboratory (12).

Experimental

Materials

The carrier gas helium and the oxygen were of gas chromatographic grade (Linde, ≥ 99.99% purity). Carbon monoxide and carbon dioxide were obtained from Matheson Gas Products.

The catalysts, designated as Ca-X-Co-420, contained X mmol Ca^{2+} per g of γ-Al_2O_3, and 2.8 g of Co_3O_4 per 100 g of the modified support. They were calcined at 420°C and prepared as already reported (12).

Silica gel 100–120 mesh from Matheson Coleman and Bell was used for gas chromatography.

Apparatus

The apparatus is shown diagrammatically in Fig. 2 and was a variation of that used to measure diffusion coefficients (1). It consisted of a simple gas chromatograph (Pye series 104) with a thermal conductivity detector (TC), incorporating the cell of Fig. 1 and a suitable valve S (four-port or six-port with two alternate ports connected through a small piece of 1/16 in. tube).

The three arms of the cell had lengths L = 70.5 cm (stainless steel), $l = l'$ = 40 cm (glass), and a common i.d. 4 mm. The catalytic bed was 2.8 cm long and contained 0.35 g of catalyst each time.

The flow reversals were made by switching the gas valve S from one position (solid lines) to the other position (dotted lines) and vice versa.

The column length l' was an open tube, while the column length l was filled with silica gel effecting the separation of the reactants CO + O_2 from the product CO_2. Both column sections l' and l were kept at 323 K by means of the chromatograph oven. The catalyst bed always was heated to a higher temperature by means of a heated injector block, incorporating a thermocouple and regulated through the electrical control unit of the chromatograph. Temperature variations along the bed were smaller than 3 K.

Procedure

Before measurements, the whole system was conditioned by heating *in situ* the catalyst at 673 K and the silica gel column at 473 K, both for 20 h, under helium flow. The reactants were premixed at room temperature and atmospheric pressure in a proportion by volume 3:1 $CO:O_2$. Some preliminary injections of this mixture were made

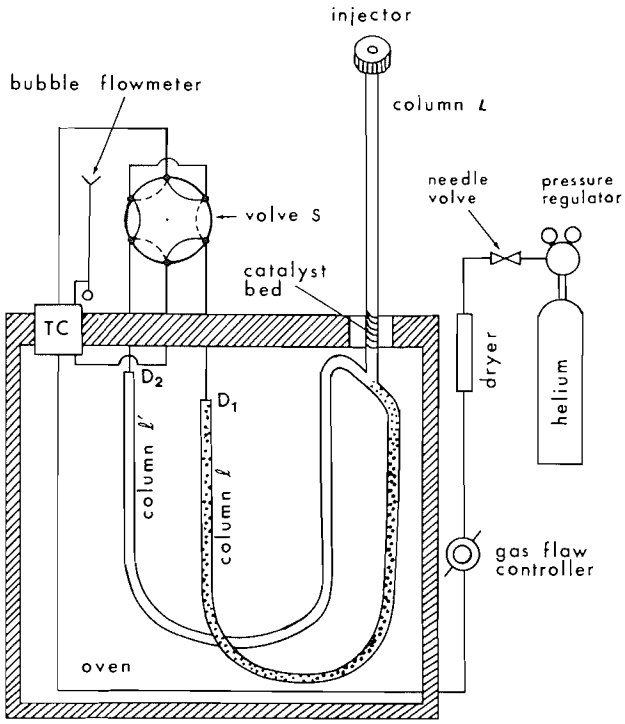

FIG. 2. Experimental set-up to study heterogeneous catalysis by the reversed-flow method.

to stabilise the catalyst, and then, with the carrier gas flowing in direction from D_2 towards D_1 (cf. Figs. 1 and 2) with a flow rate 0.281 $cm^3 s^{-1}$, 2 cm^3 of the reacting mixture were rapidly introduced with a gas-tight syringe at the top of the diffusion column L.

After some time (usually about 15 min or more), a detectable continuous signal appeared in the chromatographic trace, being obviously due to both reactants and products. Then, the direction of the carrier gas flow was reversed by switching valve S to its dotted position, the exact time of the reversal being noted. This reversed flowing was maintained for a period of 12 s, which was less than the gas hold-up time in the empty column section l'. Then the flow was restored to its original direction by valve S. After a dead time of about 12 s, the continuous chromatographic signal is reestablished and on it appear two fairly symmetrical and relatively narrow *sample* peaks, as Fig. 3 shows. The first of these peaks is due to a mixture of CO and O_2, while the second to CO_2. Both constitute what was called in the Introduction "chromatographic sampling" of the chemical reaction at the time of the flow reversal. This sampling is repeated several times with always the same duration (12 s) of reverse flow, giving a series of pair peaks, corresponding to various times from the injection of the reactants. The pressure at the injection point was 1.2 atm. The pressure change in tube L at each flow reversal was small because of the small pressure drop along the filled column l (about 0.2 atm), and also because of the short reversal duration (12 s). In cases of large pressure drops along l, the column section l' should also be filled with the same material as l to minimize pressure changes at the exit of L.

It was not found possible to separate all the three substances CO, O_2, and CO_2 after each flow reversal, since this would require a rather long time compared to the time of the reaction. Thus, we confined ouselves to the separation of the product CO_2 from the reaction mixture CO + O_2. The relative sensitivity of the thermal conductivity detector for CO and O_2 was determined by injecting a mixture of known composition in these two gases at the top of a column L which did not contain any catalyst, while the separation column l contained molecular sieve 5A 80–100 mesh. By applying the same reversed-flow technique, a series of pair peaks was obtained. Plotting the height of CO peaks and the height of O_2 peaks separately as described elsewhere (2), the effective diffusion coefficients of the two gases in

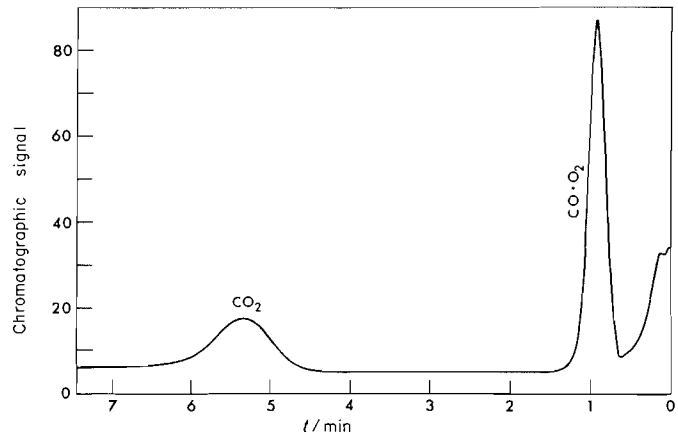

FIG. 3. Chromatographic sampling of the reaction CO + $\frac{1}{2}O_2 \rightarrow CO_2$ at 552.2 K, 44 min after injection of the reactants.

helium were determined. They were found 0.578 and 0.604 $cm^2 s^{-1}$ for CO and O_2, respectively, reduced to 1.2 atm. These differ by about 5% from the theoretically calculated values at the same pressure and temperature. The relative sensitivity for the detector used, found from the ratio of the intercepts of ln $(ht_0^{1/2})$ against $1/t_0$ plots, gave a response of O_2 to that of CO 1.05, when the response was measured as the height of the peak maximum above the continuous signal. The relative sensitivity of CO and CO_2 was found in a similar way without catalyst, but with silica gel in column l. Measured in peak heights to the maximum it was CO_2:CO = 1:5.37, while in peak areas CO_2:CO = 1:1.62.

Results and discussion

The chromatographic sampling equation has been derived in special forms (1, 6), as well as in a general form (2):

$$\begin{aligned} c_x = {} & c_{x,1}(l', t_0 + t' + \tau)\cdot u(\tau) + c_{x,2}(l', t_0 + t' - \tau) \\ & \cdot[1 - u(\tau - t')]\cdot[u(\tau) - u(\tau - t'_M)] \\ & + c_{x,3}(l', t_0 - t' + \tau)\cdot u(t_0 + \tau - t') \\ & \cdot\{u(t - t')[1 - u(\tau - t'_M)] \\ & - u(\tau - t')[u(\tau) - u(\tau - t'_M)]\} \end{aligned} \quad [1]$$

where c_x is the concentration of the various substances at the detector, $c_{x,1}(l',\ldots)$, $c_{x,2}(l',\ldots)$, $c_{x,3}(l',\ldots)$ are concentrations at the point $x = l'$ (cf. Fig. 1) for the times shown, the various u's are unit step functions for the arguments shown in parentheses, and τ was taken to mean $t - t_M$, i.e. the time from the last restoration of the carrier gas flow diminished by the gas hold-up time in section l of the column. Now that this section is filled with a solid adsorbent, the retention time t_R of the various substances for linear ideal chromatography on column l must be substituted for t_M. This can easily be proved by starting from eq. [5] of ref. 2 which now must be written as:

$$(1 + k_A)\frac{\partial c_x}{\partial t} = -v\frac{\partial c_x}{\partial x} + v(c_x)_{x=l'}\delta(x - l')$$

k_A being the partition ratio of each substance A on column l. This amounts to a substitution of v by $v/(1 + k_A)$, or $l/v = t_M$ by $(1 + k_A)l/v = (1 + k_A)t_M = t_R$. Thus, for the present situation

$$\tau = t - t_R \quad [2]$$

and since t_R is different for the reactants CO + O_2 and the product CO_2, eq. [1] predicts a separation for two out of the three terms $c_{x,1}^{(r)}$, $c_{x,2}^{(r)}$, $c_{x,3}^{(r)}$ of the reactants, from two out of the three $c_{x,1}^{(p)}$, $c_{x,2}^{(p)}$, $c_{x,3}^{(p)}$ terms of the product, as depicted in

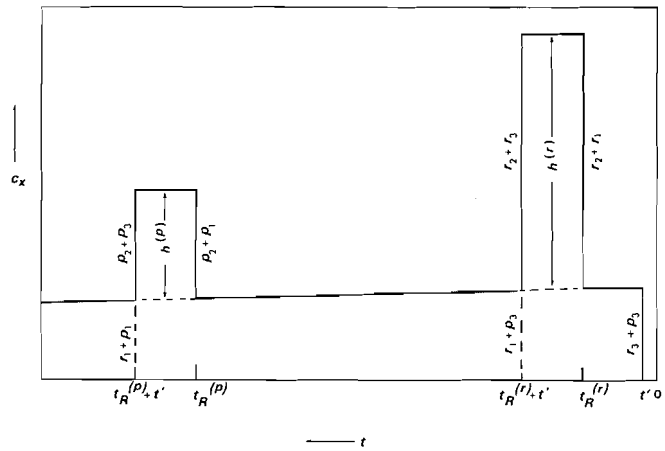

FIG. 4. Values of the time variable t, at which the various terms of eq. [1] for the reactants and the product appear and cut down, for linear ideal chromatography in column l. r_1, r_2, r_3, p_1, p_2, p_3 stand for $c_{x,1}^{(r)}$, $c_{x,2}^{(r)}$, $c_{x,3}^{(r)}$, $c_{x,1}^{(p)}$, $c_{x,2}^{(p)}$, $c_{x,3}^{(p)}$, respectively.

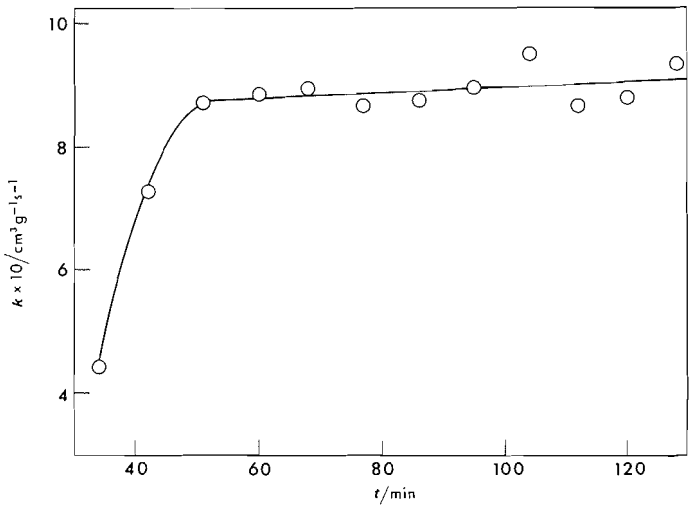

FIG. 5. An example of attainment of a steady-state condition in the reaction rate for the catalyst containing 0.392 mmol Ca^{2+} per g γ-Al_2O_3 at 526.2 K.

Fig. 4. Comparison of this figure with the experimental Fig. 3 shows that eq. [1] correctly predicts the elution curve after each flow reversal, apart from a different normal spreading of the two peaks. This is due to non-ideality (axial diffusion in column l, mass transfer resistance in the stationary phase, non-equivalent flow paths in the packed bed), and also to the fact that there is a small volume between the tube l' and the bottom of the catalyst bed in L which, on restoring the original gas flow direction, is "drained" by an exponential dilution phenomenon.

The height h of the maximum of the peaks, measured from the steady continuous signal, is equal to the sum $c_{x,2} + c_{x,3}$ and corresponds to time $t_R + t'/2$ or $\tau = t'/2$ (cf. Fig. 4). From eq. [1], by putting $\tau = t'/2$ in these two terms, we obtain

$$[3] \quad h = c_{x,2}(l', t_0 + t'/2) + c_{x,3}(l', t_0 - t'/2)$$

for both reactants and product. Since the times in the two terms on the r.h.s. differ only by t' (= 12 s), both terms can be taken at a mean time t_0. Then eq. [3] reduces to

$$[4] \quad h^{(r)} \simeq 2c_x^{(r)}(l', t_0) \qquad \text{and} \qquad h^{(p)} \simeq 2c_x^{(p)}(l', t_0)$$

for reactans and product, respectively.

There remains to be seen what the two concentrations $c_x^{(r)}$ and $c_x^{(p)}$, measured by the respective heights $h^{(r)}$ and $h^{(p)}$, represent. If $r(t_0)$ is a mean reaction rate at time t_0 for the whole catalyst bed in mol CO_2 s^{-1} g^{-1} catalyst, the concentration of CO_2, at $z = L$, $x = l'$ is given by

$$[5] \quad c_x^{(p)}(l', t_0) = \frac{r(t_0)M}{\dot{V}}$$

and thus $h^{(p)}$ is a measure of the mean reaction rate at the time of each flow reversal. The height $h^{(r)}$ of the other peak clearly measures the sum of the concentrations of the non reacted CO + O_2 diffusing out of the catalyst bed at $x = l'$ and time t_0.

In steady-state conditions, assumed to be established after a certain time, the relative concentrations of the three substances will depend on the concentrations of reactants reaching the catalyst bed by diffusion and the stoichiometry of the reaction, $CO + \frac{1}{2}O_2 \rightarrow CO_2$, since no accumulation of reactants or product occurs in the catalyst bed. Then, if $3a$ is the concentration of CO diffusing into the bed at any time, the respective O_2 concentration will be a, since the two reactants were introduced at the top of the diffusion column in a volume ratio 3:1 and their effective diffusion coefficients in the inert helium were found approximately equal. Thus, at any time after steady state the three concentrations detected will be $[CO_2] = y$, $[CO] = 3a - y$, $[O_2] = a - y/2$. Since $h^{(r)} = 2[CO] + 2[O_2] = 8a - 3y$ and $h^{(p)} = 2[CO_2] = 2y$, the two concentrations [CO] and $[O_2]$ can be expressed in terms of $h^{(r)}$ and $h^{(p)}$, the measured $h^{(p)}$ being multiplied by 5.37 to correct it for relative sensitivities of the detector (cf. Experimental section):

$$[6] \quad [CO] = \frac{3}{8}h^{(r)} + \frac{1}{16}h^{(p)} \qquad \text{and} \qquad [O_2] = \frac{1}{8}h^{(r)} - \frac{1}{16}h^{(p)}$$

Because of the small concentrations of both reactants over the catalyst surface, linear Henry-type adsorption isotherms can be assumed. Therefore, if the reaction follows a simple Langmuir–Hinshelwood or Rideal mechanism, a second-order rate law is expected, $r = k[CO][O_2]$, where k is an apparent rate constant. Combining this rate law with eqs. [4], [5], and [6], one obtains

$$[7] \quad k = \frac{32\dot{V}}{M} \cdot \frac{h^{(p)}}{(3h^{(r)} + h^{(p)}/2)(h^{(r)} - h^{(p)}/2)}$$

However, the experimental data do not conform to this equation, since the k values calculated using eq. [7] increase with time continuously without limit. Thus, a mechanism involving a reaction between adsorbed carbon monoxide and adsorbed or gaseous oxygen or vice versa does not seem to be supported by the present experimental evidence.

Another mechanism, pointed out by Mehandjien and Nikolova-Zhecheva (13), namely, a reaction between adsorbed carbon monoxide and surface lattice oxygen, would follow a phenomenological rate law $r = k[CO]$, if the mass of the catalyst is big enough. Then, instead of eq. [7], we would have

$$[8] \quad k = \frac{4\dot{V}}{M} \cdot \frac{h^{(p)}}{3h^{(r)} + h^{(p)}/2}$$

Rate constants calculated from the experimental $h^{(r)}$ and $h^{(p)}$ values, using eq. [8] for all catalysts studied and at all temperatures, initially increase but then reach a limiting value and remain constant, within the limits of experimental error, after a certain time. An example is shown in Fig. 5, while Table 1 lists the mean limiting values of this rate constant. It is seen

*Each k value is a mean of a number of k's shown in parentheses, measured in the time interval under t_0. The ± values are standard errors of the mean.

†Each final entry in the intervals given corresponds to the time of the last flow reversal, but does not include the final elution time of the product CO_2 (ca. 8 min).

TABLE 2. Activation energies for the oxidation of carbon monoxide over Co_3O_4 supported on γ-Al_2O_3 doped with Ca^{2+}, for various support compositions; the ± values are standard errors from the regression analysis

Ca^{2+} content (mmol per g γ-Al_2O_3)	E_a (kJ mol^{-1})
0.392	33±5
0.621	24±7
0.984	14±1
1.560	26±1
2.470	44±6

from this table that there exists a variation in the time required for attainment of the steady state (initial entries under t_0). This is probably due to the pure repeatability of introducing the gaseous reacting mixture of CO and O_2, since the time required for the model to apply (and the rate coefficients to become constant) depends mainly on the time required for a steady-state situation to be attained in the diffusion tube and catalyst bed. Anyhow, the constancy of k after some time is consistent with the mechanism implied by eq. [8] in agreement with the findings of Mehandjiev and Nikolova-Zhecheva (13), who established that at temperatures between 250 and 350°C the catalyst (Co_3O_4) stoichiometry changes under the effect of the reactants.

The relevant activation energies, calculated from conventional Arrhenius plots, are collected in Table 2. A remarkable fact is immediately apparent from this table, namely that the activation energy decreases almost linearly with increasing Ca^{2+} content of the catalyst support, until a minimum value at 0.984 mmol Ca^{2+} per g γ-Al_2O_3, and then increases again linearly with Ca^{2+} content. The minimum value (3.2 ± 0.3 kcal mol^{-1}) is rather smaller than that found by others (13) for pure Co_3O_4 (4.6 ± 0.5 kcal mol^{-1}) at a comparable temperature range, but discussion of this behaviour is beyond the scope of this article.

Appendix

c_x = concentration of the reactants and products at the detector (mol cm^{-3})
h = height of the maximum of extra peaks above the continuous signal (mol cm^{-3})
l, l' = lengths of the two sections of the chromatographic column (cm)
L = length of diffusion column (cm)
k = apparent rate constant for the reaction
M = catalyst mass (g)
$r(t_0)$ = mean reaction rate at time t_0 (mol $g^{-1}\ s^{-1}$)
t_0 = time measured from the injection of reactants to the last backward reversal of gas flow (min)
t' = time interval of backward flow of carrier gas (s)
t = time measured from the last restoration to forward direction of the gas flow (s)
t_M, t'_M = gas hold-up time of column section l or l', respectively (s)
t_R = ideal retention time on column section l (s)
$\dot{V}$ = volume flow-rate of carrier gas ($cm^3\ s^{-1}$)
x, z = distance coordinates along the chromatographic and the diffusion column, respectively (cm)
τ = time defined by eq. [2]

Modified Curtius rearrangements in the selective cleavage of β-D-glucosiduronic acid and β-D-glucosiduronamide linkages[1]

The selective cleavage of β-D-glucosiduronic acid linkages in permethylated carbohydrates is achieved by modified Curtius rearrangements involving (a) reaction of glycosiduronic acids with diphenylphosphoroazidate or (b) treatment of glycosiduronamides with lead tetraacetate, each in the presence of *tert*-butanol or benzyl alcohol to give 5-*tert*-butyloxycarbonylamino- or 5-benzyloxycarbonylaminopentopyranosides, followed by mild acid hydrolysis (for *tert*-butyl) or hydrogenolysis (for benzyl) of the carbamates to give pentodialdoses (from uronic acids) with retention of substituents, and with exposure of aglyconic hydroxyl groups. The liberated functional groups are available for derivative formation. These reaction sequences have been performed on permethylated derivatives of D-glucuronic acid, gentiobiouronic acid, 2-*O*-β-D-glucopyranosyl-D-galacturonic acid, and gum arabic.

GERALD OLIVER ASPINALL, HANY KAMAL FANOUS, NIMAL SAVITRI KUMAR et VELUPILLAI PUVANESARAJAH. Can. J. Chem. **61**, 1858 (1983).

On a clivé sélectivement la liaison reliant l'acide β-D-glucosiduronique aux carbohydrates perméthylés en utilisant une transposition de Curtius modifiée qui implique les étapes suivantes: (a) la réaction de l'acide glycosiduronique avec la phosphoroazidate de diphényle ou (b) la réaction des glycosiduronamides avec le tétraacétate de plomb. La réaction dans les deux cas a lieu en présence de l'alcool *tert*-butylique ou de l'alcool benzylique et conduit aux *tert*-butyloxycarbonylamino-5 ou aux benzyloxycarbonylamino-5 pentopyranosides. L'hydrolyse acide douce (du *tert*-butyle) ou l'hydrogénolyse (du benzyle) des carbamates donne les pentoaldioses (à partir de l'acide uronique) avec rétention des substituants et avec exposition des groupes hydroxyles de l'aglyconique. On peut utiliser les groupes fonctionnelles ainsi libérés pour préparer des dérivés. On a réalisé cette suite de réactions sur les dérivés perméthylés de l'acide D-glucuronique, de l'acide gentiobiouronique, de l'acide *O*-2-β-D-glucopyranosyl-D-galacturonique et de la gomme arabique.

[Traduit par le journal]

The selective cleavage of glucosiduronamide linkages in polysaccharides by the Hofmann degradation was first performed by Kochetkov *et al.* (1) with the net liberation, after mild acid treatment of the reaction mixture, of a pentodialdose and an aglycone. We have previously shown (2) that this degradation (see Scheme 1) may be carried out on permethylated polysaccharides containing nonterminal glucuronic acid residues so that (*i*) pentodialdoses (B″) derived from the uronic acid residues (B) are reduced to pentitols (B‴) with glycosyl substituents (A) still attached, and (*ii*) the sites of former attachment of glycosyluronic acid residues may be ascertained by further reactions of the exposed hydroxyl groups (in C′). The reaction sequence, however, suffers from disadvantages in that (a) it is carried out under strongly basic conditions, and (b) that the isolation and characterization of products only at the end of a lengthy series of operations does not permit the detection of incomplete reaction in the early steps of the sequence. We now describe two modified Curtius rearrangements, carried out under neutral conditions in nonaqueous solvents, in which the intermediate isocyanates (B*), common to Hofmann and Curtius rearrangements, are converted into isolable *tert*-butyl or benzyl carbamates (B′) without rupture of glycosidic linkages. Cleavage of glycosidic linkages in the structurally modified methylated oligo- or polysaccharides may then be effected by decomposition of the carbamates with the same net formation of pentodialdoses from hexuronic acid units and liberation of aglycones as in the Hofmann degradation. Fragmentations leading to the same products have been achieved by oxidative decarboxylation with lead tetraacetate (3) via 5-acetoxypentopyranosides (B^+).

Methyl 2,3,4-tri-*O*-methyl-β-D-glucopyranosiduronic acid (**1**) and the permethylated derivative (**5**) of methyl β-gentiobiosiduronic acid (3) were used as substrates for the modified Curtius rearrangement described by Yamada and coworkers (4, 5). Treatment of the glycosiduronic acids with diphenylphosphorazidate in *tert*-butanol in the presence of 1 molar equivalent of triethylamine furnished *tert*-butyl carbamates **3** and **8** as crystalline rearrangement products in high yield. The available nmr data did not define the stereochemistry at C-5 of the modified sugar residues but retention of configuration is assumed as with other Curtius rearrangements (5). Alternatively, *tert*-butyl carbamates **3** and **8** were prepared in similar yield by reaction of the corresponding glycosiduronamides **2** and **7** with lead tetraacetate in *tert*-butanol (6, 7). For polysaccharide substrates we have found this latter procedure to be superior in degree of structural modification and in ease of product isolation. The same two procedures have been used for the preparation of the analogous benzyl carbamates **4** and **9**, reactions being performed in benzene solution with only a small excess of benzyl alchol.

Controlled cleavage of the *tert*-butyl carbamates was achieved with formic acid at room temperature, intermediate pentodialdoses were reduced with sodium borohydride, and the products were acetylated to give the corresponding pentitol diacetates. Thus carbamate **3** afforded 2,3,4-tri-*O*-methylxylitol diacetate which was characterized by glc – mass spectrometry. With 1,6-anhydro-2,3,4-tri-*O*-methyl-β-D-galactopyranose as internal standard, analysis of the products similarly

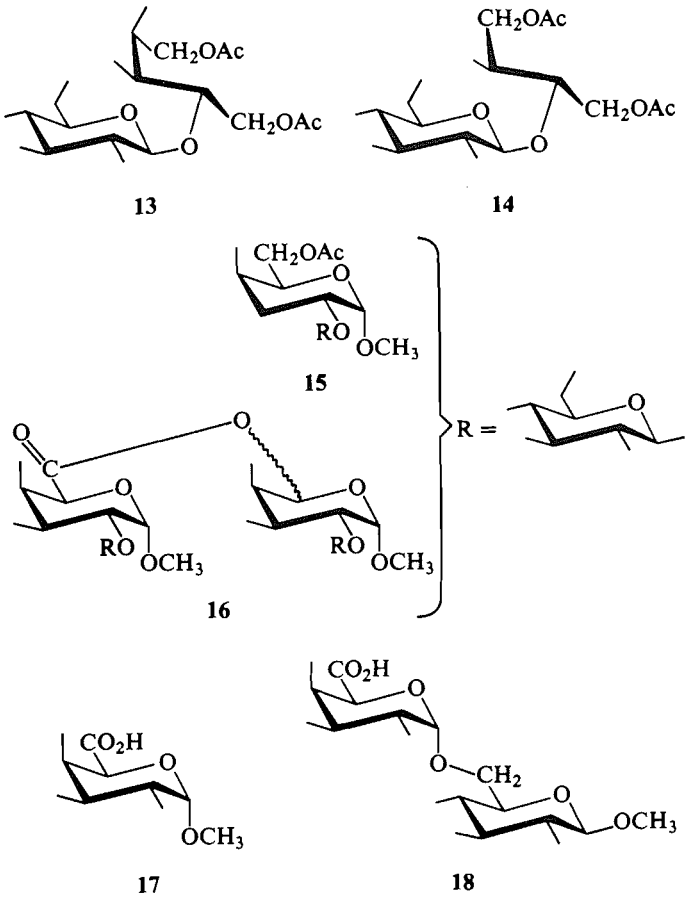
generated from the disaccharide carbamate **8** showed liberation of aglycone as methyl 6-*O*-acetyl-2,3,4-tri-*O*-methyl-β-D-glucopyranoside, in 95% yield, but only 35% of the above pentitol derivative was detected, probably due to inadvertent loss of this substance or its precursors during the various concentration steps. Degradations of benzyl carbamates **4** and **9** were carried out by hydrogenolysis over palladium–charcoal, followed by mild treatment with aqueous acid to ensure complete hydrolysis of intermediate 5-aminopentopyranosides to pentodialdose, and then reduction with sodium borohydride and acetylation as for the products from the *tert*-butyl carbamates. Again, product analysis by glc – mass spectrometry indicated liberation of aglycone in greater than 90% yield but overall formation of uronic acid-derived pentitol derivative in only 35–40% yield.

In order to furnish substrates yielding relatively nonvolatile products, and also to provide a basis for comparison of the new procedure with the lead tetraacetate degradation (3) and related reactions, samples of the permethylated pseudoaldobiouronic ester, methyl [methyl 2-*O*-(2,3,4,6-tetra-*O*-methyl-β-D-glucopyranosyl)-3,4-di-*O*-methyl-α-D-galactopyranosid]uronate (8), were converted into the amide (**10**) and thence to the *tert*-butyl carbamate (**11**) and, by saponification, to the acid (**12**). Hydrolysis of the carbamate **11**, followed by reduction and acetylation, gave products which were examined by glc – mass spectrometry. Using 1,6-anhydro-hexa-*O*-methyl-β-maltose as internal standard, the results indicated the formation of the disaccharide alditol, 1,5-di-*O*-acetyl-2-*O*-(2,3,4,6-tetra-*O*-methyl-β-D-glucopyranosyl)-3,4-di-*O*-methyl-L-arabinitol (**13**), as the major product in 67% yield. Side-reactions resulted in the liberation of some 2,3,4,6-tetra-*O*-methyl-D-glucose



from nonreducing units, as shown by the detection of the derived partially methylated alditol acetate, and a third component, whose mass spectrum showed the presence of an intact nonreducing end group but did not define the nature of the modified unit as aglycone.

In a separate series of reactions the permethylated pseudoaldobiouronic acid **12** was treated with lead tetraacetate in boiling benzene, as described previously (3), and reaction of the products with sodium borohydride followed by acetylation afforded the same disaccharide alditol derivative **13** in 45% yield. Side-reactions resulted in the formation of two other disaccharide derivatives. The mass spectrum of the product of lower retention time pointed to the formation of a tetritol-terminated derivative **14** from more extensive oxidative degradation of the uronic acid **12**. The mass spectrum of the second by-product indicated the formation of a mono-*O*-acetyl-hexa-*O*-methyl disaccharide methyl glycoside, probably **15**. Such a compound could arise from the reduction of the uronic acid residue of a dimeric ester (**16**) formed during the lead tetraacetate reaction, cf. Kitagawa *et al.* (9). These investigators also observed that methyl 2,3,4-tri-*O*-methyl-α-D-galactopyranosiduronic acid (**17**) reacted with lead tetraacetate much more slowly than the corresponding β-D-glucopyranosiduronic acids. In our hands, examination of the products of reaction of this compound (**17**) with lead tetraacetate, followed by reduction and acetylation, showed the formation of 2,3,4-tri-*O*-methylarabinitol diacetate (85%), a di-*O*-methyltetritol diacetate (8%), and methyl 6-*O*-acetyl-2,3,4-tri-*O*-methyl-α-D-galactopyranoside (5%) from reduction of dimeric ester. In the degradation of methyl hexa-*O*-methyl-β-melibiosiduronic acid (**18**) previously reported (3), complete liberation of aglycone was observed but the pentitol derivative was formed in slightly lower yield (~80%). Re-examination of these products has shown that ~12% of the corresponding tetritol was formed from further degradation of the uronic acid residue, but no reduced disaccharide was detected. In the case of the permethylated pseudoaldobiouronic acid **12**, larger amounts of reagent and extended reaction time were required to effect complete disappearance of starting material. In the lead tetraacetate reaction sequence, the products from these side-reactions are apparently formed in significant proportions only when the main reaction takes place slowly. The corresponding by-products have not been detected in reactions of β-D-glucopyranosiduronic acid derivatives, either in model compounds or in more complex polysaccharides.

Kitagawa *et al.* (10) have shown that uronic acid glycosides may be decarboxylated by anodic oxidation in acetic acid solution to give the same 5-acetoxypentopyranosides that are formed in the lead tetraacetate reaction (9). The permethylated pseudoaldobiouronic acid **12** was submitted to anodic oxidation, the reaction mixture was treated directly with sodium borohydride and then acetylated, and the products were examined by glc – mass spectrometry. The disaccharide alditol derivative **13** was formed in ~75% yield, and the tetritol-terminated derivative **14** was detected as a by-product together with traces of the reduced disaccharide methyl glycoside **15**. Although this degradation effected a more satisfactory conversion of this uronic acid glycoside into disaccharide alditol, other experiments showed that no detectable reaction occurred at the electrode surface with methylated polysaccharide substrates.

As for the lead tetraacetate degradation (3), permethylated gum arabic was used as a substrate for the modified Curtius rearrangement and subsequent carbamate degradation. The methylated polysaccharide was converted into the corresponding amide, completeness of reaction being checked by ir spectroscopy. *tert*-Butyl and benzyl carbamates were formed separately by reaction of polysaccharide amide with lead tetraacetate in the presence of the appropriate alcohol. Completeness of the desired structural modification was checked (a) by disappearance of amide carbonyl absorption at 1700 cm^{-1}, and (b) by glc examination of methyl glycosides formed on methanolysis which showed, within the limits of detection, that reaction had resulted in complete modification of methylated glucuronic acid residues. Quantitative analysis of the constituent sugars in the methylated polysaccharide carbamates by glc of the partially methylated alditol acetates formed on hydrolysis, reduction, and acetylation showed that structural modification had been effected without change in neutral sugar composition (Table 1). The modified methylated polysaccharides containing *tert*-butyl and benzyl carbamate residues were degraded by controlled formic acid hydrolysis, and by hydrogenolysis followed by mild acid treatment, respectively, and the reaction mixtures were treated with sodium borohydride and then acetylated. In each case products of low molecular weight were separated by fractional precipitation and/or chromatography on Sephadex LH-20. Further separation of the fractions of low molecular weight gave two main components, which were shown by glc – mass spectrometry to be indistinguishable from the previously characterized (3) 1,5-di-*O*-acetyl-2,3,4-tri-*O*-methylxylitol and 1,5-di-*O*-acetyl-2,3-di-*O*-methyl-4-*O*-(2,3,4-tri-*O*-methyl-α-L-rhamnopyranosyl)-D-xylitol (**19**). For the sample of disaccharide alditol (**19**) formed from the *tert*-butyl carbamate, the ^{13}C nmr spectrum

20

showed a value of $^1J_{^{13}C_1,^1H_1}$ = 167.5 Hz and thus confirmed (11) the previously assigned α-L-rhamnopyranosyl configuration (2) for this compound, and hence for terminal units in methylated gum arabic (**20**). Methylated sugar analysis for the degraded methylated polysaccharides showed that the reaction sequences had resulted in the removal of at least 90% of the terminal rhamnose residues external to the modified uronic acid residues without alteration in the proportions of arabinose and galactose methyl ethers (Table 1).

The Curtius rearrangement of permethylated glycosiduronamides followed by controlled cleavage of carbamates and the associated modified glycosidic linkages provides a satisfactory alternative procedure to the lead tetraacetate decarboxylation–acetoxylation reaction sequence for the selective cleavage of β-D-glucopyranosiduronic acid derivatives with formation of the same final products. The formation of *tert*-butyl carbamates is experimentally more satisfactory than that of benzyl carbamates, and no inadvertent hydrolysis of other glycosidic linkages has yet been detected in the cleavage of the *tert*-butyl carbamates with formic acid. The undefined side-reactions in the degradations of these carbamates do not detract from the value of the degradations for glucuronic acid-containing polysaccharide substrates which are described in this and the following paper (12). In the following paper we show that both reaction procedures may be used to generate oligosaccharide fragments of structural significance from the cleavage of interior glucosiduronic acid linkages. In the lead tetraacetate degradation, side-reactions of the types shown in the fragmentation of α-D-galactopyranosiduronic acid linkages in mono- and disaccharide derivatives have not been detected in the cleavage of β-D-glucopyranosiduronic acid linkages in methylated polysaccharide substrates. Neither procedure, however, has yet proved suitable for the corresponding depolymerization of polysaccharides containing α-D-galactopyranosyluronic acid residues, and an entirely different approach to this problem is now being explored.

Experimental

Evaporations were carried out under diminished pressure at temperatures of 40°C or less. Optical rotations were measured in chloroform solution with a Perkin–Elmer model 141 polarimeter at 20 ± 2°C. The ir spectra were measured on a Unicam SP 200 spectrophotometer. The ^{1}H nmr spectra were recorded on a Varian EM 360 spectrophotometer in deuteriochloroform with tetramethylsilane as internal standard. The ^{13}C nmr spectrum was measured on a Bruker WH 400 spectrophotometer. Gas–liquid chromatography was performed on a Perkin–Elmer Sigma 3B chromatograph using a S.C.O.T. column coated with silicone gum OV-225. For glc – mass spectrometry, the column in a Pye 204 chromatograph was attached by a jet separator to a VG Micromass 16F mass spectrometer operated with an inlet temperature of 250°C, an ionization potential of 70 eV, and an ion-source temperature of ~250°C.

Preparation of tert-*butyl and benzyl carbamates*

Method A

An equimolar (0.5–1.0 mmol each) mixture of glycosiduronic acid, diphenyl phosphorazidate, and triethylamine was heated under reflux overnight in (*i*) anhydrous *tert*-butanol (15 mL) or (*ii*) benzyl alcohol (1.2 molar proportions) in benzene (15 mL). The reaction mixture was concentrated, the residue in benzene was washed successively with aqueous 5% citric acid, water, aqueous sodium hydrogen carbonate, and water, and the dried solution was concentrated. The product was chromatographed on silica gel with ether–hexane (4:1) and the resulting carbamate was recrystallized from ether – light petroleum.

Starting materials were methyl 2,3,4-tri-*O*-methyl-β-D-glucopyranosiduronic acid (**1**) (13) and methyl hexa-*O*-methyl-β-gentiobiosiduronic acid (**5**) (3).

Method B

Methyl permethylated glycosiduronates were converted into the corresponding glycosiduronamides by treatment with methanolic ammonia. A mixture of permethylated glycosiduronamide (1 mmol), pyridine (1 mmol), and lead tetraacetate (4.5 mmol) in (*i*) *tert*-butanol (15 mL) or (*ii*) benzene (15 mL) containing benzyl alcohol (1.2 mmol) was heated under reflux for 4 h. A further quantity (4. 5 mmol) of lead tetraacetate was added and the mixture was heated under reflux overnight. The reaction mixture was concentrated, the residue was extracted with ether or ethyl acetate, and the extract was washed with water, dried, and concentrated. The product was chromatographed as above and the carbamate was recrystallized.

Starting materials were methyl 2,3,4-tri-*O*-methyl-β-D-glucopyranosiduronamide (**2**) (14), methyl hexa-*O*-methyl-β-gentiobiosiduronamide (**7**), and methyl 3,4-di-*O*-methyl-2-*O*-(2,3,4,6-tetra-

O-methyl-β-D-glucopyranosyl)-α-D-galactopyranosiduronamide (**10**). Amide **7** had mp 199–200°C, $[\alpha]_D$ −62°. *Anal.* calcd. for $C_{19}H_{35}NO_{11}$: C 50.32, H 7.78, N 3.09; found: C 50.19, H 8.07 N 3.40. Amide **10** had mp 189–190°C, $[\alpha]_D$ +52.7°. *Anal.* calcd. for $C_{19}H_{35}NO_{11}$: C 50.32, H 7.78, N 3.09; found: C 50.34, H 7.83, N 3.00.

The following carbamates were prepared: methyl (5*S*)-5-*tert*-butyloxycarbonylamino-2,3,4-tri-*O*-methyl-β-D-xylopyranoside (**3**), methyl (5*S*)-5-benzyloxycarbonylamino-2,3,4-tri-*O*-methyl-β-D-xylopyranoside (**4**), methyl 2,3,4-tri-*O*-methyl-6-*O*-[(5*S*)-5-*tert*-butyloxycarbonylamino-2,3,4-tri-*O*-methyl-β-D-xylopyranosyl]-β-D-glucopyranoside (**8**), methyl 6-*O*-[(5*S*)-5-benzyloxycarbonylamino-2,3,4-tri-*O*-methyl-β-D-xylopyranosyl]-2,3,4-tri-*O*-methyl-β-D-glucopyranoside (**9**), and methyl 3,4-di-*O*-methyl-2-*O*-(2,3,4,6-tetra-*O*-methyl-β-D-glucopyranosyl)-5-(5*S*)-*tert*-butyloxycarbonylamino-β-L-arabinopyranoside (**11**). Methods of preparation, yields, physical constants, and elemental analyses for these compounds are given in Table 1. The ir spectra of all carbamates showed absorption at 3330–3350 (NH), 1710–1730 (CO), and 1550 cm^{-1} (NH), and the ^{1}Hmr spectra gave signals for the correct ratios of OCH_3 (δ 3.4–3.6) and *Ph*—CH_2 (δ 7.3) or *tert*-Bu (δ 1.45) groups.

Degradations of tert-*butyl carbamates*

Weighed quantities (10–20 mg) of *tert*-butyl carbamate and internal standard (1,6-anhydro-2,3,4-tri-*O*-methyl-β-D-galactopyranose (15) for carbamates **3** and **8** and 1,6-anhydro-2,2′,3,3′,4′,6′-hexa-*O*-methyl-β-maltose (16) for carbamate **11**) in approximately equimolar proportions were treated with 98% formic acid (2 mL) at room temperature for 2 h. Formic acid was removed by codistillation with toluene under diminished pressure without increase in temperature, the residue in water (1 mL) was treated with sodium borohydride (50 mg) for 5 h, excess hydride was destroyed and sodium ions were removed with Amberlite resin IR-120(H), and the filtered solution was concentrated by codistillation with toluene and then methanol. The residue was acetylated in acetic anhydride – pyridine (1:1) (1 mL), the products were examined by glc (at 150°C for monosaccharide derivatives or 210°C for disaccharide derivatives) for quantitative analysis, and their identities were confirmed by glc – mass spectrometry using authentic samples, when available, for comparison.

Carbamate **3** afforded 2,3,4-tri-*O*-methylxylitol diacetate (*m/e* 117, 161). Carbamate **8** furnished 2,3,4-tri-*O*-methylxylitol diacetate (40%) and methyl 6-*O*-acetyl-2,3,4-tri-*O*-methyl-β-D-glucopyranoside (95%) (*m/e* 187, 247). Carbamate **11** afforded a major product (67%), $T_{1,6\text{-anhydro-hexamethylmaltose}}$ 1.57, which showed prominent fragment ions at *m/e* 307, 247, 219, 187, 161 and was assigned the structure **13**. Other products in the mixture were 2,3,4,6-tetra-*O*-methylglucitol diacetate (*m/e* 205, 161, 145, 129, 117, 101) (~10%), and two incompletely identified disaccharide derivatives at $T_{1,6\text{-anhydro-hexamethylmaltose}}$ 0.85 and 2.10, both of whose mass spectra showed ions at *m/e* 219 and 187 arising from tetra-*O*-methylglucopyranosyl residues.

Degradations of benzyl carbamates

Weighed quantities (10–20 mg each) of benzyl carbamate and 1,6-anhydro-2,3,4-tri-*O*-methyl-β-D-galactopyranose in approximately equimolar proportions in ethanol (10 mL) were hydrogenolysed at atmospheric pressure over 10% palladium–charcoal overnight, the filtered solutions were concentrated, and the products in water (5 mL), brought to pH 5 by the addition of acetic acid, were kept overnight. The resulting solutions were treated with sodium borohydride (50 mg) for 4 h, and the reduction products were worked up and acetylated as described above for analysis by glc – mass spectrometry.

Carbamate **4** afforded 2,3,4-tri-*O*-methylxylitol diacetate (40%). Carbamate **9** furnished 2,3,4-tri-*O*-methylxylitol diacetate (35%) and methyl 6-*O*-acetyl-2,3,4-tri-*O*-methyl-β-D-glucopyranoside (95%).

Degradations of permethylated galactopyranosiduronic acids with lead tetraacetate

Degradations were performed as described earlier (3) with the addition of one or other of the above-mentioned internal standards, but for longer reaction times (up to 48 h) than for the corresponding glucopyranosiduronic acids, to ensure complete disappearance of starting material. The products were treated with sodium borohydride and then acetylated for examination by glc – mass spectrometry.

Methyl 2,3,4-tri-*O*-methyl-α-D-galactopyranosiduronic acid (**17**) from the corresponding methyl ester (17) afforded 2,3,4-tri-*O*-methylarabinitol diacetate (85%), $T_{1,6\text{-anhydro-tri-}O\text{-methylgalactose}}$ 3.38, an incompletely identified product (8%), $T_{1,6\text{-anhydro-tri-}O\text{-methylgalactose}}$ 1.19, whose mass spectrum with fragment ions at *m/e* 161, 143, 129, 117, and 101 was consistent with that of a di-*O*-methyltetritol diacetate, and a compound (5%), $T_{1,6\text{-anhydro-tri-}O\text{-methylgalactose}}$ 3.69, which was indistinguishable from methyl 6-*O*-acetyl-2,3,4-tri-*O*-methyl-α-D-galactopyranoside and showed fragment ions at *m/e* 247, 215, 187. Re-examination of the products from methyl hexa-*O*-methyl-β-melibiosiduronic acid (**18**) (3) showed, in addition to the major products, a minor product (12%) which was indistinguishable from the above-mentioned di-*O*-methyltetritol diacetate. Methyl 3,4-di-*O*-methyl-2-*O*-(2,3,4,6-tetra-*O*-methyl-β-D-glucopyranosyl)-α-D-galactopyranosiduronic acid (**12**) furnished as the major product the disaccharide alditol (**13**) (45%), which was identical (glc – ms) to the previously characterized compound, together with two minor disaccharide derivatives (each 15%) and 2,3,4,6-tetra-*O*-methylglucitol diacetate (12%). The first disaccharide derivative, $T_{1,6\text{-anhydrohexamethylmaltose}}$ 0.90, showed fragment ions at *m/e* 263, 219, 203, 161, 155, 143, and 117 and was assigned structure **14**. The second disaccharide derivative, $T_{1,6\text{-anhydro-hexa-}O\text{-methylmaltose}}$ 2.10, showed fragment ions at *m/e* 307, 247, 219, 215, 187, 161, and 155, and was indistinguishable (glc – ms) from methyl 6-*O*-acetyl-3,4-di-*O*-methyl-2-*O*-(2,3,4,6-tetra-*O*-methyl-β-D-glucopyranosyl)-α-D-galactopyranoside (**15**) prepared from the methyl ester (8) by reduction with lithium aluminum hydride followed by acetylation.

Anodic oxidation of permethylated pseudoaldobiouronic acid **12**

Permethylated pseudoaldobiouronic acid (**12**) (14.6 mg) and 1,6-anhydro-hexa-*O*-methyl-β-maltose (9.9 mg) in acetic acid (20 mL) containing triethylamine (0.5 mL) were electrolyzed at 20°C for 24 h (50 V, 120 mA). After work-up, the reaction products were treated with sodium borohydride and acetylated as in the lead tetraacetate degradations, and the resulting compounds were examined by glc – mass spectrometry. The major product was the disaccharide alditol **13** (75%); the tetritol-terminated derivative **14** (10%) was a minor product, but only traces (~1%) of the reduced disaccharide methyl glycoside **15** could be detected.

Preparation and degradation of tert-*butyl carbamate from methylated gum arabic*

Methylated gum arabic was converted into the methylated polysaccharide amide as described previously (2) and completeness of reaction was checked by disappearance of ester carbonyl absorption in the ir spectrum at 1740 cm^{-1}. Methylated gum arabic amide (150 mg) in benzene (5 mL) and *tert*-butanol (5 mL) containing pyridine (0.2 mL) and lead tetraacetate (500 mg) were heated under reflux for 4 h, a further quantity (500 mg) of lead tetraacetate was added, and heating under reflux was continued overnight. The cooled reaction mixture was diluted with benzene, filtered, and the filtrate was washed with water, dried, and concentrated. The residue was purified by chromatography on Sephadex LH-20 with dichloromethane–acetone (1:1) to give the polysaccharide *tert*-butyl carbamate (135 mg). Completeness of reaction was shown (a) by ir absorption at 1740 cm^{-1} (carbamate C=O) but none at 1700 cm^{-1} (amide C=O), and (b) by the absence of peaks with the retention times of methyl ester methyl glycosides of 2,3,4-tri- and 2,3-di-*O*-methylglucuronic acid on glc examination of the methanolysis products.

Methylated gum arabic *tert*-butyl carbamate (150 mg) was kept in 98% formic acid for 4 h at room temperature. The formic acid was removed by codistillation with toluene under reduced pressure. The residue in water–methanol (3:2) (5 mL) was treated with sodium borohydride (50 mg) for 4 h. The solution was treated with Amberlite resin IR-120(H) to destroy excess of hydride and remove sodium ions,

TABLE 2. Methylation analyses of neutral sugar components of methylated gum arabic and derived methylated polysaccharides

		Derived alditol acetates[b] (mol% of neutral sugar components)			
	T^a	A	B	C	D
2,3,4-Me_3 Rha[c]	0.44	8	8	1	1
2,3,5-Me_3 Ara[c]	0.44	17	17	18	17
2,3,4-Me_3 Ara	0.55	2	2	3	3

[b]A, Neutral sugar constituents only from methylated gum arabic; B, neutral sugar constituents from methylated gum arabic *tert*-butyl and benzyl carbamates; C, neutral sugar constituents from degraded methylated polysaccharides formed from both *tert*-butyl and benzyl carbamates; D, calculated from C allowing for loss of ~7% of rhamnose residues.

[c]The relative proportions of these two sugars were estimated separately by glc of the methyl glycosides formed on methanolysis of the methylated polysaccharides.

and the filtrate was concentrated by codistillation with toluene and then methanol. The product showed a weak ir absorption at 1740 cm^{-1}, and the whole procedure was repeated (treatment with formic acid for 2 h) to give material with no residual ir absorption at 1740 cm^{-1}. The residue was acetylated with acetic anhydride – pyridine (1:1) (1 mL) and, after normal work-up, addition of light petroleum to the products in ether afforded degraded methylated gum arabic (110 mg), which was washed thoroughly to remove products of low molecular weight (detected on tlc) and then chromatographed on Sephadex LH-20 using dichloromethane as eluant.

The supernatant liquid from the above precipitation was chromatographed on silica gel using dichloromethane–acetone (4:1) as eluant to give three fractions. Fraction (*i*) (5 mg) was identified as 2,3,4-tri-*O*-methylxylitol diacetate by glc – mass spectrometry. Fraction (*ii*) (15 mg) was indistinguishable by glc – mass spectrometry from 1,5-di-*O*-acetyl-2,3-di-*O*-methyl-4-*O*-(2,3,4-tri-*O*-methyl-α-L-rhamnopyranosyl)-D-xylitol (**19**) (*1*); ^{1}H nmr ($CDCl_3$) δ: 1.28 (d, 3H, $J_{5,6}$ = 6 Hz, H-6 of Me_3 rhamnopyranose residue), 2.09, 2.10 (2s, 2 × 3H, 2 × OAc), 3.44, 3.50, 3.51, 3.52, 3.55 (5s, 5 × 3H, 5 × OCH_3); ^{13}C nmr ($CDCl_3$) δ: 97.10 (C1′, $^1J_{^{13}C_1,^1H_1}$ = 167.5 Hz). Fraction (*iii*) (3 mg) was shown by glc–ms to contain a main component, $T_{\text{fraction}(ii)}$ 0.56, whose mass spectrum included fragment ions at *m/e* 189 and 157 indicating the presence of a tri-*O*-methylrhamnopyranosyl residue.

Preparation and degradation of benzyl carbamate from methylated gum arabic

Methylated gum arabic amide (150 mg) in benzene (10 mL) containing pyridine (0.2 mL), benzyl alcohol (27 mg), and lead tetraacetate (500 mg) was heated under reflux for 4 h, further lead tetraacetate (500 mg) was added, and refluxing was continued overnight. The cooled solution was diluted with benzene, filtered, and concentrated. The residue in water was dialysed against distilled water, the solution was concentrated, and the product was extracted with dichloromethane and then purified by chromatography on Sephadex LH-20 with dichloromethane–acetone (1:1) as eluant to give the polysaccharide benzyl carbamate (120 mg). Completeness of reaction was checked as for the methylated polysaccharide *tert*-butyl carbamate.

Methylated gum arabic benzyl carbamate (150 mg) in ethanol (10 mL) was hydrogenolysed at atmospheric pressure over 10% palladium–charcoal overnight. The filtered solution was concentrated, the residue in water (5 mL) was acidified to pH 5 with acetic acid and kept overnight, and the products were treated with sodium borohydride (50 mg) for 4 h. The reaction mixture was worked up as described for that from the *tert*-butyl carbamate, the products were acetylated, and fractional precipitation of the polysaccharide component and chromatographic separations furnished (*i*) degraded methylated gum arabic (110 mg), (*ii*) 1,5-di-*O*-acetyl-2,3,4-tri-*O*-methylxylitol (5 mg), and (*iii*) 1,5-di-*O*-acetyl-2,3-di-*O*-methyl-4-*O*-(2,3,4-tri-*O*-methyl-α-L-rhamnopyranosyl)-D-xylitol (13 mg). Fractions (*ii*) and (*iii*) were characterized by glc – mass spectrometry.

Compositional analysis of methylated polysaccharides

The sugar components of methylated gum arabic, methylated polysaccharide *tert*-butyl and benzyl carbamates, and the degraded methylated polysaccharides after carbamate cleavage were analyzed as partially methylated alditol acetates formed on hydrolysis, followed by reduction with sodium borohydride and acetylation, by glc (170°C). Average values for two determinations are shown in Table 2. For separations of derivatives of 2,3,4-tri-*O*-methylrhamnose and 2,3,5-tri-*O*-methylarabinose, methylated polysaccharides were heated under reflux with methanolic 5% hydrogen chloride and the resulting methyl glycosides were examined by glc (130°C, 5°/min to 180°C). The results are shown in Table 2.

The selective fragmentation of methylated leiocarpan A by β-D-glucosiduronic acid and β-D-glucosiduronamide cleavage[1]

GERALD OLIVER ASPINALL[2] AND VELUPILLAI PUVANESARAJAH
Department of Chemistry, York University, Downsview, Toronto, Ont., Canada M3J 1P3

Received January 27, 1983

GERALD OLIVER ASPINALL and VELUPILLAI PUVANESARAJAH. Can. J. Chem. **61**, 1864 (1983).

Selective cleavage of internal β-D-glucopyranosiduronic acid linkages in permethylated leiocarpan A has been achieved by two procedures for structural modification involving (a) decarboxylation–acetoxylation using lead tetraacetate or (b) *tert*-butyl carbamate formation by a modified Curtius rearrangement, followed by controlled fragmentation of the modified polysaccharides to yield the same two main partially methylated pentitol-terminated oligosaccharides. Chemical and spectroscopic characterization of these oligosaccharides and their substitution products has shown them to be derivatives of *O*-β-D-xylopyranosyl-(1 → 6)-*O*-α-D-mannopyranosyl-(1 → 4)-D-xylitol and *O*-β-L-arabinofuranosyl-(1 → 3)-[*O*-β-D-xylopyranosyl-(1 → 6)]-*O*-α-D-mannopyranosyl-(1 → 4)-D-xylitol. These observations provide new information on the anomeric configuration and mode of attachment of side-chains in the polysaccharide.

GERALD OLIVER ASPINALL et VELUPILLAI PUVANESARAJAH. Can. J. Chem. **61**, 1864 (1983).

On a clivé sélectivement des liaisons internes de l'acide β-D-glucopyranosiduronique des leiocarpanes perméthylés, selon deux méthodes dans le but d'apporter des modifications structurales impliquant: (a) une décarboxylation–acétoxylation par le tétraacétate de plomb ou (b) la formation du *tert*-butylcarbamate selon une transposition modifiée de Curtius suivie de la fragmentation contrôlée des polysaccharides modifiés pour aboutir à deux oligosaccharides principaux terminés par un pentitol partiellement méthylé. La caractérisation chimique et spectroscopique de ces oligosaccharides et de leurs produits de substitutions révèlent qu'ils sont des dérivés du *O*-β-D-xylopyranosyl-(1 → 6) *O*-α-D-mannopyranosyl-(1 → 4)-D-xylitol et du *O*-β-L-arabinofuranosyl-(1 → 3) [*O*-β-D-xylopyranosyl-(1 → 6)] *O*-α-D-mannopyranosyl-(1 → 4)-D-xylitol. Ces observations fournissent de nouvelles informations sur la configuration de l'anomère et sur le mode de liaison des chaines latérales du polysaccharide.

[Traduit par le journal]

We have recently described two procedures for the selective cleavage of glycosiduronic acid or glycosiduronamide linkages in permethylated polysaccharides (1, 2). Each procedure involves modification of uronic acid residues prior to depolymerization, followed by selective glycoside cleavage at the altered sugar residues. In the first method (1), reaction of permethylated uronic acid residues with lead tetraacetate results in decarboxylation and acetoxylation giving epimeric 5-acetoxypentopyranose units. Reductive cleavage of these units with sodium borohydride affords pentitol-terminated fragments with exposure of aglyconic hydroxyl groups at the former sites of attachment of uronic acid residues. In the second method (2), the same net transformation is achieved by Curtius rearrangement of glycosiduronic acid or glycosiduronamide residues to 5-*tert*-butyloxycarbonyl (or benzyloxycarbonyl) aminopentopyranose residues, followed by carbamate cleavage and reduction of liberated pentodialdoses. These methods, developed for monosaccharide and disaccharide model compounds, have been used also for the cleavage of glucosiduronic acid linkages in the outer chains of methylated gum arabic. Polysaccharides containing a high proportion of uronic acid residues in interior chains present a more stringent test of the general applicability of these methods since fragmentation to the desired neutral oligosaccharide alditols will only occur if (*i*) a high degree of structural modification of uronic acid residues is achieved, and (*ii*) selective cleavage of the modified polysaccharide proceeds to completion with minimum formation of by-products. We describe here the application of both methods to methylated leiocarpan A (3). Leiocarpan A, the major polysaccharide component of *Anogeissus leiocarpus* gum (4), contains a backbone with alternating 4-*O*-substituted β-D-glucuronic acid and 2-*O*-substituted α-D-mannopyranose residues (5) with terminal D-xylopyranose and L-arabinofuranose residues attached variously to mannose residues (**1**). A base-catalyzed degradation of the methylated polysaccharide has provided direct evidence for the site of attachment and anomeric configuration of the terminal

FIG. 1. Mass spectral fragmentation of peralkylated oligosaccharide alditol **2**; unless otherwise specified substituents are OCH_3.

β-D-xylopuranose residues (6). The provisionally assigned site of attachment of L-arabinofuranose residues at O-3 mannose units was inferred from methylation studies on the parent gum and on the arabinose-free degraded gum (4, 5), but no information was available on the anomeric configuration of these residues.

Methylated leiocarpan A was treated with aqueous alkali at pH 12 and 0°C to ensure complete ester hydrolysis with no detectable accompanying β-elimination. As shown previously (1), the methylated polysaccharide underwent decarboxylation and accompanying acetoxylation on heating with lead tetraacetate in benzene. Completeness of reaction was ascertained by withdrawal of aliquot samples for ir spectroscopic examination which showed disappearance of ionizable carboxyl groups. Samples of modified methylated polysaccharide were also methanolyzed and examination of the products by glc showed, within the limits of detection, the absence of methyl ester methyl glycosides of uronic acids. Treatment of the modified methylated polysaccharide with sodium borohydride, followed by methanolysis and acetylation, and glc examination showed the formation of units of 2,3-di-*O*-methylxylitol (from the corresponding residues of 2,3-di-*O*-methylglucuronic acid) together with those of the unaltered neutral sugars, 2,3,5-tri-*O*-methylarabinose, 2,3,4-tri-*O*-methylxylose, and 3,4-di- and 4-*O*-methylmannose. The suitably modified methylated polysaccharide containing epimeric 5-acetoxypentopyranose residues was then treated with sodium borohydride to effect deacetylation and reduction of exposed pentodialdose to pentitol residues.

The partially methylated oligosaccharides thus generated were separated most satisfactorily by preparative hplc of their *O*-benzoyl derivatives. Although a small degree of mutual contamination was observed, the results of the following experiments left no doubt as to the identities of the major component in each fraction. The oligosaccharide fractions were de-*O*-benzoylated and samples were withdrawn for hydrolysis, followed by reaction with hydroxylamine and acetylation to form partially methylated alditol acetates and partially methylated aldononitriles which were examined by glc – mass spectrometry. The partially methylated oligosaccharides were further alkylated with trideuteriomethyl iodide, and the fully alkylated oligosaccharides were characterized by ^1H and ^{13}C nmr spectroscopy, mass spectrometry, and methylated sugar analysis.

Hydrolysis of oligosaccharide fraction I gave, as major components, 2,3,4-tri-*O*-methylxylose, 3,4-di-*O*-methylmannose, and 2,3-di-*O*-methylxylitol. After trideuteriomethylation, hydrolysis of the fully alkylated oligosaccharide furnished 2,3,4-tri-*O*-methylxylose, 2-*O*-[$^2H_3$]methyl-3,4-di-*O*-methylmannose, and 1,5-di-*O*-[$^2H_3$]methyl-2,3-di-*O*-methylxylitol whose derivatives were identified by glc – mass spectrometry. The mass spectrum of the peralkylated oligosaccharide fraction gave fragment ions at *m/e* values shown in Fig. 1 and was consistent with proposed structure **2**. The ^1H nmr spectrum showed signals for two anomeric protons at δ 5.15 (broad singlet) and 4.26 (doublet, $J_{1,2}$ = 7.3 Hz), in accord with previous evidence for β-D-xylopyranose and α-D-mannopyranose residues in the polysaccharide. Signals in the Cmr spectrum for anomeric carbon atoms at δ_C 102.3 and 96.2 in the corresponding residues further supported the conclusions.

Hydrolysis of oligosaccharide fraction II gave, as major components, 2,3,5-tri-*O*-methylarabinose, 2,3,4-tri-*O*-methylxylose, 4-*O*-methylmannose, and 2,3-di-*O*-methylxylitol. After trideuteriomethylation, hydrolysis of the fully alkylated oligosaccharide afforded 2,3,5-tri-*O*-methylarabinose, 2,3,4-tri-*O*-methylxylose, 2-*O*-[$^2H_3$]methyl-4-*O*-methylmannose, and 1,5-di-*O*-[$^2H_3$]methyl-2,3-di-*O*-methylxylitol. The mass spectrum of the peralkylated oligosaccharide gave fragment ions at the *m/e* values shown in Fig. 2 for the proposed structue **3**. The ^1Hmr spectrum showed the same two signals for anomeric protons at δ 5.12 (broad singlet) and 4.27 (doublet, $J_{1,2}$ = 7.3 Hz), together with a third signal at δ 5.19 (doublet, $J_{1,2}$ = 4.3 Hz). Similarly, the Cmr spectrum showed a signal for a third anomeric carbon atom at δ_C 104.1, in addition to those assigned to anomeric centres in β-D-xylopyranose and α-D-mannopyranose residues at δ_C 102.7 and 97.9. The additional anomeric signals are in agreement with other assignments for β-L-arabinofuranose residues (7, 8). These observations provide direct confirmation that O-3 of D-mannose residues is the site of attachment of L-arabinofuranose residues in leiocarpan A and show that these units have the β-L-configuration.

The methylated oligosaccharide fraction II contained a small proportion (~10%) of contaminating trisaccharide alditol from fraction I, as shown by the formation of 3,4-di-*O*-methylmannose on hydrolysis. However, after trideuteriomethylation, hydrolysis of the peralkylated oligosaccharide fraction gave a rather higher proportion (~20%) of the corresponding 2,3,4-tri-*O*-methylmannose and the mass spectrum of the derived partially methylated alditol acetate showed the presence of

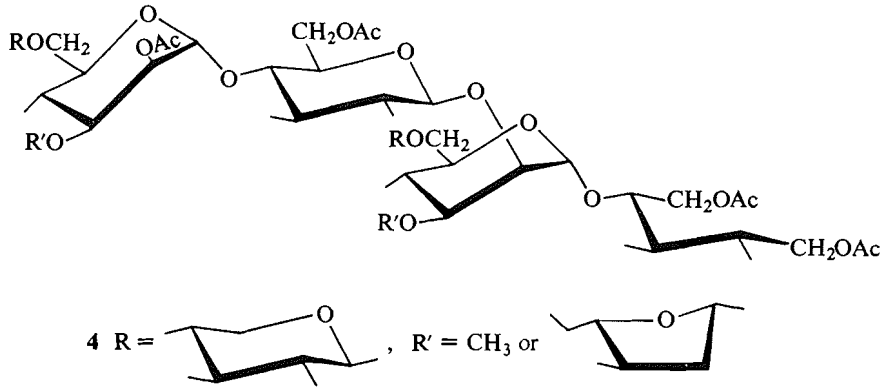
FIG. 2. Mass spectral fragmentation of peralkylated oligosaccharide alditol **3**.

some trideuteriomethyl substituent at O-3 in addition to that expected at O-2. Such a substituent probably arose from a trisaccharide fragment originating from a less than fully methylated region of the polysaccharide. However, in view of the detection of only one site of incomplete methylation, we consider it more likely that the exposed hydroxyl group arose from the inadvertent loss of an arabinofuranosyl residue during the preparation of the original sample of methylated leiocarpan A rather than from incomplete alkylation.

The importance of achieving complete structural modification of uronic acid residues prior to depolymerization was shown in an earlier series of experiments. Saponification of methylated leiocarpan A for a period sufficient for complete reaction of mono- and disaccharide derivatives resulted in less than complete (but still >80%) de-esterification. Since uronic esters are stable to reaction with lead tetraacetate (1), subsequent treatment of the modified polysaccharide with sodium borohydride resulted in less than complete depolymerization, but was accompanied by reduction of esterified 2,3-di-*O*-methylglucuronic acid to the corresponding 2,3-di-*O*-methylglucose units. Separation of the reaction products led to the isolation and characterization in terms of sugar composition of a higher oligosaccharide (or possibly a mixture of closely related species). The proposed structure **4** for this oligosaccharide fraction indicates the presence of a tetrasaccharide al-



ditol segment derived from the glucuronomannan main chain with three or four attached pentose residues in side-chains.

A further sample of methylated leiocarpan A was treated with methanolic ammonia, care being taken to ensure completeness of amidation. Reaction of the polysaccharide amide with lead tetraacetate in *tert*-butanol furnished (5*S*)-5-*tert*-butyloxycarbonylamino-2,3-di-*O*-methyl-β-D-xylopyranose in place of 2,3-di-*O*-methyl-β-D-glucuronic acid residues. Completeness of reaction was ascertained by (a) disappearance of amide carbonyl absorption at 1700 cm^{-1}, and (b) by glc analysis of methyl glycoside acetates formed on methanolysis followed by acetylation, which showed that all 2,3-di-*O*-methylglucuronic acid units had been modified. The modified polysaccharide was selectively hydrolyzed with formic acid at room temperature and the hydrolyzate was treated with sodium borohydride. The resulting mixture of partially methylated oligosaccharides was fractionated, as for the products of the lead tetraacetate degradation, by preparative hplc of the *O*-benzoyl derivatives. The two main oligosaccharide fractions were shown to be identical to those formed in the lead tetraacetate degradation. On trideuteriomethylation they gave the same fully alkylated oligosaccharides as shown by their mass spectra and by glc – mass spectrometry of the sugar derivatives formed on hydrolysis.

These experiments have shown that both the lead tetraacetate decarboxylation–acetoxylation procedure (1) and the Curtius rearrangement to furnish *tert*-butyl carbamate-containing derivatives (2) may be used to effect structural modification of internal glucuronic acid residues in methylated polysaccharides, and that selective glycoside cleavage at the altered sugar residues, followed by reduction, results in the formation of pentitol-terminated oligosaccharides. The oligosaccharides thus generated retain all the structural information of the corre-

sponding segments of the parent polysaccharide other than that on configuration at C-5 and the anomeric centre of the uronic acid residues. Completeness of reaction at each modification step is essential if the desired depolymerization is to be achieved.

Experimental

Unless otherwise stated, general experimental methods were as described in the preceding paper (2). Most ^{1}H and all ^{13}C nmr spectra were measured on a Bruker WH 400 spectrophotometer. High-pressure liquid chromatography (hplc) was performed on a Waters Associates μ-Porasil column (3.9 × 300 mm, 10 μ silica), the solvent gradient was delivered by two model 6000A pumps controlled by a Waters Associates model 660 programmer, and a model 440 uv absorbance detector set at 254 nm was used. Elution at a flow rate of 2 mL/min was performed with chloroform for 5 min, followed by a linear gradient over 20 min to a final solvent composition of chloroform–acetonitrile (70:30), and isocratic elution at that solvent composition for a further 10 min.

Lead tetraacetate degradation of methylated leiocarpan A

Methylated leiocarpan A (200 mg) was saponified at 0°C and at pH 12 as described previously (1) but for a period of 6 h to ensure complete de-esterification. The resulting methylated polysaccharide acid (180 mg) in benzene (10 mL) containing pyridine (0.2 mL) and lead tetraacetate (1 g) was heated under reflux for 15 h.[3] A sample from the reaction mixture was methanolyzed, the products were acetylated, and glc analysis (120°C, 5°/min to 180°C and hold) showed the presence of acetylated (if possible) methyl glycosides of 2,3,4-tri-*O*-methylxylose, 2,3,5-tri-*O*-methylarabinose, 3,4-di- and 4-*O*-methylmannose, but the absence of derivatives of 2,3-di-*O*-methylglucuronic acid. The remainder of the reaction solution was filtered, the precipitate was washed with benzene, and the combined filtrate and washings were washed several times with water, dried, and concentrated to give modified methylated leiocarpan A (150 mg), ν_{max} 1750 cm^{-1} but no absorption at 1600 cm^{-1} on treatment with triethylamine. The modified methylated polysaccharide (150 mg) in tetrahydrofuran–water (1:1, 3 mL) was treated with sodium borohydride (100 mg) for 15 h. Excess of hydride was destroyed, the pH of the solution was brought to 5 by the addition of Dowex-50 (H) resin, and the filtered solution was repeatedly concentrated with methanol to a mixture of partially methylated oligosaccharide alditols (140 mg). A portion of the mixture was methanolyzed, the products were acetylated, and glc (as above) showed the formation of derivatives of 2,3,4-tri-*O*-methylxylose and 2,3,5-tri-*O*-methylarabinose (incompletely separated), and 3,4-di- and 4-*O*-methylmannose, together with 2,3-di-*O*-methylxylitol triacetate.

The mixture of partially methylated oligosaccharide alditols (140 mg) in pyridine (2 mL) was treated with benzoyl chloride (0.25 mL) at 0°C and then kept at room temperature for 24 h. Ice was added to destroy excess benzoyl chloride, and the mixture was poured into water and then extracted with dichloromethane. The extract was washed with aqueous sodium hydrogen carbonate and then with water, dried, and concentrated to a syrup (250 mg). Thin-layer chromatography (dichloromethane–acetone, 8:1) of the syrup showed the presence of two major components. A portion of the mixture was separated in batches by hplc (flow rate, 2 mL/min) with initial elution with chloroform for 5 min, followed by gradient elution over 20 min to a final solvent composition of chloroform–acetonitrile (70:30), and isocratic elution for a further 10 min. The *O*-benzoyl derivatives of partially methylated oligosaccharide alditols I and II (~30 mg each) were eluted at 22.5 and 26 min, and the collected fractions contained less than 10% of cross-contamination. The benzoylated oligosaccharide fractions were each de-*O*-benzoylated with catalytic quantities of sodium methoxide in methanol, the solutions were treated with Amberlite resin IR-120(H) to remove sodium ions, and the filtrates were concentrated to give the respective partially methylated oligosaccharide alditols.

Partially methylated oligosaccharide alditol I

A sample of the oligosaccharide was hydrolyzed and the resulting mixture of sugars was heated with hydroxylamine hydrochloride in pyridine, and again after addition of acetic anhydride (9). Analysis of the products by glc – mass spectrometry (column temperature 180°C, 1°/min to 220°C) showed the presence of 2,3-di-*O*-methylxylitol triacetate and of partially methylated aldononitrile acetates from 2,3,4-tri-*O*-methylxylose and 3,4-di-*O*-methylmannose in approximately equimolar proportions, and from 2,3,5-tri-*O*-methylarabinose and 4-*O*-methylmannose in much smaller proportions. The oligosaccharide was further alkylated with trideuteriomethyl iodide by the Hakomori procedure (10). The fully alkylated oligosaccharide alditol gave significant fragment ions in the mass spectrum at *m/e* values shown with formula **2**; ^{1}H nmr ($CDCl_3$) δ: 5.15 (broad s, 1H, H-1 of α-D-mannopyranose residue), 4.26 (d, 1H, $J_{1,2}$ = 7.3 Hz, H-1 of β-D-xylopyranose residue); ^{13}C nmr ($CDCl_3$) δ_C: 102.3 (C-1 of β-D-xylopyranose residue), 96.2 (C-1 of α-D-mannopyranose residue). Hydrolysis of the fully alkylated oligosaccharide alditol, followed by treatment with sodium borohydride and acetylation, gave the following partially alkylated alditols, the identities of whose acetates were established by glc – mass spectrometry: 1,5-di-*O*-[$^2H_3$]methyl-2,3-di-*O*-methylxylitol, 2,3,4-tri-*O*-methylxylitol, 2-*O*-[$^2H_3$]methyl-3,4-di-*O*-methylmannitol, and, in trace amount, 2,3,5-tri-*O*-methylarabinitol.

Partially methylated oligosaccharide alditol II

Hydrolysis of the oligosaccharide, followed by analysis of the liberated sugars as for oligosaccharide I, showed the formation of derivatives of 2,3-di-*O*-methylxylitol, 2,3,5-tri-*O*-methylarabinose, 2,3,4-tri-*O*-methylxylose, and 4-*O*-methylmannose in approximately equimolar proportions, with a much smaller proportion of 3,4-di-*O*-methylmannose. Further alkylation with trideuteriomethyl iodide gave fully alkylated oligosaccharide alditol II, whose mass spectrum gave significant fragment ions at *m/e* values shown with formula **3**; ^{1}H nmr ($CDCl_3$) δ: 5.19 (d, 1H, $J_{1,2}$ = 4.3 Hz, H-1 of β-L-arabinofuranose residue), 5.12 (broad s, 1H, H-1 of α-D-mannopyranose residue), 4.27 (d, 1H, $J_{1,2}$ = 7.3 Hz, H-1 of β-D-xylopyranose residue); ^{13}C nmr ($CDCl_3$) δ_C: 104.1 (C-1) of β-L-arabinofuranose residue), 102.7 (C-1 of β-D-xylopyranose residue), 97.9 (C-1 of α-D-mannopyranose residue). Hydrolysis of the fully alkylated oligosaccharide alditol II, followed by reduction and acetylation, gave derivatives of the following partially alkylated alditols, whose identities were established by glc – mass spectrometry as 1,5-di-*O*-[$^2H_3$]methyl-2,3-di-*O*-methylxylitol, 2,3,5-tri-*O*-methylarabinitol, 2,3,4-tri-*O*-methylxylitol, and 2-*O*-[$^2H_3$]methyl-4-*O*-methylmannitol. A further compound formed in much smaller amount was 2-*O*-[$^2H_3$]methyl-3,4-di-*O*-methylmannitol, in which ~50% of OCH_3 groups at C-3 carried deuterium labelling.

*Lead tetraacetate degradation of methylated leiocarpan A and partial characterization of a higher oligosaccharide (**4**)*

Methylated leiocarpan A (200 mg) was saponified at 0°C and at pH 12 for 2 h as described previously (1), and the ir spectrum of the methylated polysaccharide acid showed that more than 80% of uronic esters groups had been saponified. Methylated polysaccharide acid (175 mg) in benzene (8 mL) containing pyridine (0.5 mL) and lead tetraacetate (1 g) was heated under reflux for 15 h, the reaction mixture was worked up as described above, and the products were treated with sodium borohydride and then acetylated to give partially methylated oligosaccharide alditol acetates (100 mg). The mixture was chromatographed on a column of Sephadex LH-20 with dichloro-

[3]This reaction may also be carried out in *N*,*N*-dimethylformamide at *room temperature* for 20 h. The advantage of lower reaction temperature with less decomposition of lead tetraacetate is more than offset by the much less clean work-up procedure. The reaction at lower temperature achieves no more satisfactory modification of polysaccharides containing α-D-galactopyranosyluronic acid residues (cf. refs. 1 and 2).

methane as eluant to give fractions A (28 mg), B (40 mg), and C (22 mg). Thin-layer chromatographic examination with dichloromethane–acetone mixtures as eluant and analysis of sugar composition of fractions B and C showed that they were partially separated mixtures of acetylated derivatives of partially methylated oligosaccharide alditols I and II. Fraction A had much lower tlc mobility and the ^{1}H nmr spectrum showed O—CH_3 and O—$COCH_3$ protons in a ratio to be expected for a hepta- or octasaccharide derivative (**4**). The sugar composition of the fraction was determined by (*i*) methanolysis and acetylation of the resulting mixture of alditol and methyl glycosides, and (*ii*) hydrolysis, reduction, and acetylation of the resulting mixture of partially methylated alditols, followed by glc analysis. The results showed the presence of the following constituents: 2,3,4-trimethylxylose, 2,3,5-tri-*O*-methylarabinose, 3,4-di- and 4-*O*-methylmannose, 2,3-di-*O*-methylglucose, and 2,3-di-*O*-methylxylitol, the last two in approximately equimolar proportions.

Preparation and degradation of tert*-butyl carbamate from methylated leiocarpan A*

Methylated leiocarpan A (3) (150 mg) in methanol (10 mL) and liquid ammonia (20 mL) was kept under pressure at room temperature for 24 h, and removal of solvent furnished methylated leiocarpan A amide (130 mg), ν_{max} 1700 cm^{-1}. Methylated leiocarpan A amide (130 mg) in *tert*-butanol (8 mL) containing pyridine (0.2 mL) and lead tetraacetate (700 mg) was heated under reflux for 15 h. The reaction mixture was diluted with *tert*-butanol and filtered, the insoluble residue was washed several times with *tert*-butanol, and the combined filtrate and washings were concentrated. The product was chromatographed on Sephadex LH-20 with dichloromethane as eluant to give methylated leiocarpan A *tert*-butyl carbamate (110 mg), ν_{max} 1740 cm^{-1} with no absorption at 1700 cm^{-1}. A portion of the methylated polysaccharide carbamate was methanolyzed and the products were acetylated, and glc showed the formation of derivatives of 2,3,4-tri-*O*-methylxylose, 2,3,5-tri-*O*-methylarabinose, and 3,4-di- and 4-*O*-methylmannose, but not of 2,3-di-*O*-methylglucuronic acid. The methylated leiocarpan A carbamate (110 mg) was kept in 98% formic acid (2 mL) for 4 h at room temperature. The solution was poured into water, the diluted solution was extracted with dichloromethane, and the extract was dried and concentrated to a syrup. Since the ir spectrum showed residual absorption at 1740 cm^{-1}, the formic acid treatment was repeated to yield a syrup (90 mg) with no absorption at 1740 cm^{-1}. The syrup was reacted with sodium borohydride (75 mg) in water (2 mL) for 15 h, and normal work-up afforded a mixture of partially methylated alditol acetates. Methanolysis of a sample of this mixture, followed by acetylation and glc analysis, showed the formation of derivatives of the same sugars as derived from the corresponding oligosaccharide fraction generated by the lead tetraacetate procedure. As above, the partially methylated oligosaccharide alditols were fractionated by hplc of the *O*-benzoyl derivatives to give two main fractions which were de-*O*-benzoylated to furnish partially methylated oligosaccharide alditols I and II. The oligosaccharide alditols were shown to be identical to those formed by the lead tetraacetate method by (a) characterization of hydrolysis products, (b) the mass spectrum of the fully alkylated derivatives formed on further trideuteriomethylation, and (c) characterization of the hydrolysis products from the fully alkylated derivatives.

Methyl substituted thioxanthones and thioxanthone-10,10-dioxides

IAN D. BRINDLE[1] AND PAUL P. DOYLE
Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received December 10, 1982

IAN D. BRINDLE and PAUL P. DOYLE. Can. J. Chem. **61**, 1869 (1983).

The preparation of all four monomethylthioxanthones and their corresponding dioxides is described. A previously published synthesis of the 2- and 3-methylthioxanthones by Gilman and Diehl has been shown to produce the 2- and 4-methyl isomers.

IAN D. BRINDLE et PAUL P. DOYLE. Can. J. Chem. **61**, 1869 (1983).

On décrit la préparation des quatre monométhylthioxanthones et de leurs dioxydes correspondants. On montre qu'une synthèse des méthyl-2 et méthyl-3 thioxanthones, publiée antérieurement par Gilman et Diehl donne les isomères méthyl-2 et méthyl-4.

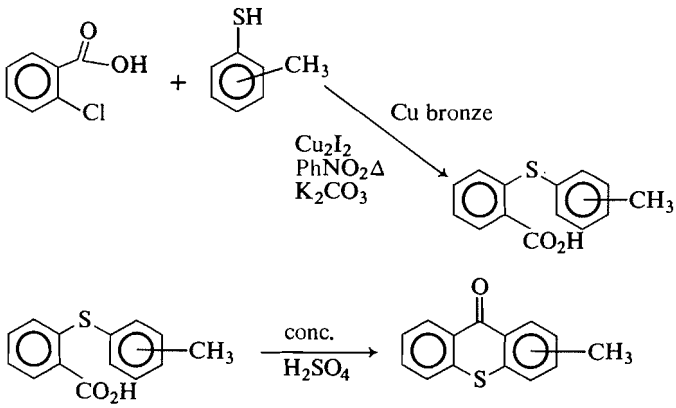
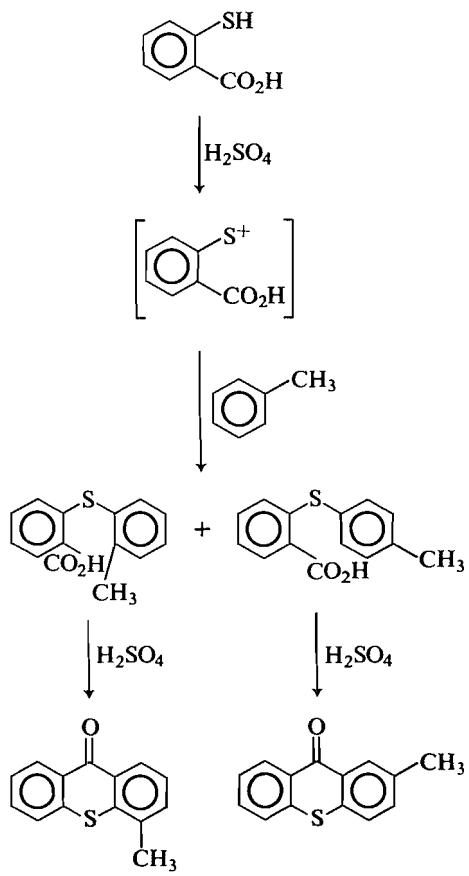
The methyl substituted thioxanthones and corresponding dioxides have not been well studied. Although the 2-methylthioxanthone and the 2- and 4-methylthioxanthone-10,10-dioxides were known before 1910 (1, 2), of the remaining five compounds only the 3-methylthioxanthone-10,10-dioxide has been reported (3). We required methyl substituted thioxanthones and their dioxides for long range nmr coupling experiments, the results of which will be published elsewhere, thus we undertook the synthesis of the title compounds.



The Ullman reaction has been used to prepare 2-carboxyl diphenyl sulfides (4). These sulfides were readily cyclized by concentrated sulfuric acid to thioxanthones in about 60% yield by the procedure of Mayer (2). 2-Carboxy-3′-methyldiphenyl sulfide cyclized to the 1- and 3-methylthioxanthones in almost equal yields and the two isomers were readily separated by column chromatography. The identity of the two isomers was readily established by comparison of the nmr spectra of the two isomers with the known xanthones.[2] The thioxanthones were readily oxidized to the dioxides, using 30% hydrogen peroxide in glacial acetic acid, in 90% yield.

The large discrepancy between the reported melting point of 3-methylthioxanthone-10,10-dioxide and our compound led us to investigate the work of Gilman and Diehl (3). In their work, 2-mercaptobenzoic acid was condensed with toluene in the presence of sulfuric acid to give a mixture of isomers which could not be separated. Subsequent treatment of the mixture with 30% hydrogen peroxide gave a mixture which was separable by fractional crystallization into 2-methylthioxanthone-10,10-dioxide and a lower-melting material tentatively identified as the 3-methyl isomer on the basis of infrared evidence.



SCHEME 1

We have repeated this experiment under the same conditions used by Gilman and Diehl. After the disulfide by-product was removed, the remaining yellow product was subjected to hplc analysis which showed two components which were identified, on the basis of retention time and addition of the known isomers, as the 2- and 4-methylthioxanthones in the ratio 3:1.[3]

The products and the product ratio suggest an attack by an electrophilic sulfur on toluene on the *o*- and (preferred) *p*-positions, followed by sulfuric acid mediated ring closure to the observed products (Scheme 1). The sulfenium ion equivalent

could be derived from sulfenic acid, as suggested by Gilman and Diehl. The product distribution is, in fact, what would be predicted by the mechanism suggested by Gilman and Diehl. The low melting point obtained by Gilman and Diehl for the compound isolated probably resulted from the cocrystallization of both the 2- and 4-methylthioxanthone-10,10-dioxides.

Experimental

The series of reactions to make the thioxanthone-10,10-dioxides was similar in each case, so the preparation from *m*-thiocresol will be illustrative of the method.

Analyses were performed by Dr. Franz Pascher Microanalytisches Laboratorium, Buchstr., 45, 5300 Bonn, West Germany. Melting points are uncorrected.

2-Carboxy-3'-methyldiphenyl sulfide

o-Chlorobenzoic acid (5.0 g; 0.032 mol), *m*-thiocresol (4.0 g; 0.032 mol), dry potassium carbonate (13.2 g; 0.096 mol), copper I iodide (0.2 g), and copper bronze (93.3% Cu, 4.98% Sn, 1.55% Zn, and 0.08% Pb; 0.2 g) were stirred together in dry nitrobenzene (40 mL). The reaction mixture was heated to reflux and maintained, with stirring, for 10 min.

The nitrobenzene was removed by steam distillation and the tars were removed by filtering with charcoal. The filtrate was treated with hydrochloric acid to pH 1 and the solid was filtered off and dried to give the crude product (3.1 g, 80%) as a tan powder melting at 170–174°C. Crystallization from methanol gave *2-carboxy-3'-methyldiphenyl sulfide* as white needles, mp 180–182°C (microanalysis given in Table 1).

1- and 3-Methylthioxanthone

2-Carboxy-3'-methyldiphenyl sulfide (14.6 g; 0.060 mol) was stirred in sulfuric acid (146 mL) under nitrogen for 1.5 h at 100°C. The cooled mixture was poured onto ice and the crude product was filtered off and taken up in chloroform. Unreacted starting material was removed by shaking with 10% sodium carbonate. The chloroform was washed with water, dried ($MgSO_4$), and evaporated to dryness. The resultant yellow oil solidified on standing (9.00 g, 66%), mp 55–90°C; ^{1}Hmr ($CDCl_3$) showed two methyl singlets at δ 2.46 (54%) and δ 2.91 (46%).

The yellow oil was dissolved in a minimum volume of toluene and chromatographed on 60–100 mesh Florisil. Elution with hexane, and hexane–ether, 9:1, 8:2, 7:3 gave two bands which were examined by tlc (silica gel, CCl_4). The first fraction (R_f 0.81) gave 1-methylthioxanthone (3.75 g; 28%) as pale yellow blades after crystallization from hexane, mp 93–95°C. The second fraction (R_f 0.58) yielded *3-methylthioxanthone* (3.87; 29%) as pale yellow needles from hexane, mp 115–116°C (microanalysis given in Table 2).

1-Methylthioxanthone-10,10-dioxide

1-Methylthioxanthone (3.0 g; 0.13mol) was dissolved in 50 mL of hot glacial acetic acid. The solution was heated to reflux and 30%

For personal use only.

hydrogen peroxide (18 mL) was added in 6-mL portions at half hour intervals. The reaction mixture was maintained at reflux, with stirring, for 3 hours. A pale yellow crystalline solid separated upon cooling and was filtered off (3.0 g; 88%). An additional 0.07 g precipitated when the filtrate was poured over ice. The product was dissolved in chloroform and passed through a short column of acid-washed alumina with 200 mL of chloroform. A small amount of unidentified material remained at the top of the column. *1-Methylthioxanthone-10,10-dioxide* (2.6 g) was obtained as pale yellow rods from glacial acetic acid, mp 201–203°C (microanalysis given in Table 3).

Reaction of o-*mercaptobenzoic acid and toluene*

The reaction was carried out under the same conditions used by Gilman and Diehl (3). The yellow solid recovered after the removal of the disulfide was subjected to hple analysis on a Partisil PSX 10–25 column and eluted with 50% hexane in chloroform at 2 mL/min. Retention times for the two components were 3.3 min and 3.8 min corresponding to the 2- and 4-methylthioxanthones; these were in the ratio 3:1.

2-Mercaptoaldehyde dimers and 2,5-dihydrothiophenes from 1,3-oxathiolan-5-ones[1,2]

JOHN M. MCINTOSH AND MAQBOOL A. SIDDIQUI
Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received December 16, 1982

JOHN M. MCINTOSH and MAQBOOL A. SIDDIQUI. Can. J. Chem. **61**, 1872 (1983).

Representative 1,3-oxathiolan-5-ones (**6**), prepared from 2-mercaptoacids, have been reduced to 2-mercaptoaldehydes **1** with diisobutylaluminum hydride. The aldehydes **1**, which appear to exist in several dimeric forms, react with vinyltriphenylphosphonium bromide to give 2,5-dihydrothiophenes.

JOHN M. MCINTOSH et MAQBOOL A. SIDDIQUI. Can. J. Chem. **61**, 1872 (1983).

On a réduit les oxa-1,3 thiolanones-5 (**6**) typiques obtenues à partir des mercapto-2 acides, en mercapto-2 aldéhydes **1** avec l'hydrure de diisobutylaluminium. Les aldéhydes **1** qui semblent exister sous plusieurs formes dimères réagissent avec le bromure de vinyltriphénylphosphonium en donnant les dihydro-2,5 thiophènes.

For a number of years we have been interested in the formation and synthetic applications of substituted and functionalized 2,5-dihydrothiophenes (**2**) (Scheme 1). We have shown that these molecules can be prepared simply and in high yield by the reaction of 2-mercaptocarbonyl compounds (**1**) with vinylphosphonium salts (1) or vinylphosphonates (2) and that they are efficient precursors of conjugated dienes (1, 2) and substituted thiophenes (3). In order to use this methodology in the synthesis of more complex systems, it became imperative to develop ways of introducing the 2-mercaptoaldehyde or ketone into a molecule which also contained other functional groups or, conversely, carrying this combination of reactive functionalities in some protected or latent form from which they could be generated under mild and specific conditions.

2-Mercaptoaldehydes and ketones have usually been prepared from the parent carbonyl compounds by bromination (which must be regiospecific in the case of ketones), followed by reaction with a salt of hydrogen sulfide. The conditions for the latter reaction are necessarily strongly basic, conditions which are normally avoided with molecules containing an aldehyde group. Compounds **1** exist largely in dimeric forms. Several different structural types have been identified (Scheme 1), two of which are represented by **3** and **4** (4). Form **3***a* is

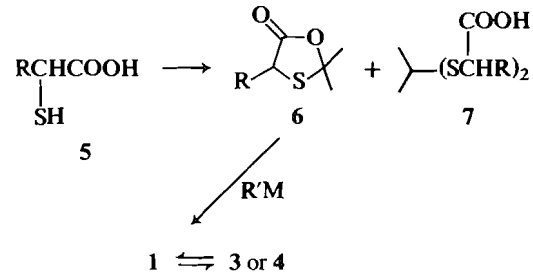

SCHEME 2

sensitive to acid-catalyzed dehydration (4*a*) but these revert to **1** under basic conditions. The liberated groups are sensitive to acid, base, and oxidizing conditions. A suitable solution to the problem would involve the use of a heterocyclic species which would be easily formed from readily available precursors, stable to a variety of reaction conditions, and which would generate the desired 2-mercaptocarbonyl compound in a chemospecific and regiospecific way.

We chose the 1,3-oxathiolane-5-one system (**6**) (5) as an ideal point to begin our investigation. It possesses the following advantages: (1) it is easily prepared from 2-mercaptoacids; (2) it offers the possibility of being alkylated at the 4-position, thus allowing the direct introduction of the desired functionalities into a larger molecule in the protected form; (3) the reaction of the ester carbonyl with either hydride or organometallic reagents should lead to the mercaptoaldehydes or ketones (Scheme 2). Our results on the hydride reduction reaction are the subject of this report.

Preparation of 1,3-oxathiolan-5-ones

Acetone was chosen as the blocking group for the mercaptoacids in order to give the simplest possible nmr spectra in a compound which had no potentially troublesome protons at C2. Also, the presence of the *gem*-dimethyl substituents should materially reduce difficulties arising from reactions at the nucleophilic sulfur atom. Compounds **6***a*–*e* (Table 1) were prepared from the corresponding mercaptoacids **5** by condensation either with acetone (6) or 2-methoxypropene (7). In some cases one of these methods was superior and in other cases the reverse situation occurred. The spectroscopic data for compounds **6** are contained in Table 2.

stable, further reduction to the alcohol is to be expected. Therefore the reduction conditions must allow the lactol intermediate to survive until all the hydride has been consumed. Initial investigations using LAH at −78°C were not encouraging. Significant overreduction to mercaptoalcohols was observed, even when the consumption of **6** was incomplete. The known (8) ability of diisobutylaluminum hydride (DIBAL) to reduce lactones and nitriles to the aldehyde stage led us to consider this reagent. It should be noted that potentially troublesome Lewis acid–base interactions can occur in this combination of reagents. However, when the reduction was carried out in toluene at −78°C, the 2-mercaptoaldehydes were obtained in their dimeric forms **3** and **4**. In several cases more than one dimeric form was isolated. Some were crystalline, others were not. In at least one case (**3***d*), significant portions of the product showed a carbonyl absorption in the infrared spectrum suggesting the presence of monomeric species. In all cases, either the separated forms or the mixture reacted equally well in the formation of 2,5-dihydrothiophenes mentioned below. Thus the overall yields of **3** are calculated on the basis of the combined yields of all forms. In most cases, the major dimeric form appeared to be **3**, but most of these can exist in diastereomeric forms and the nmr spectra of such materials indicate such mixtures. In addition, **3** are only very sparingly soluble in organic solvents and resort had to be made to either DMSO or pyridine. In these solvents, the dimer(s) and monomer are in equilibrium and, for this reason, the nmr spectra of **3** are difficult to interpret and thus are omitted from this paper.

The yields (Table 3) of **3** range from 14 to 70%. In general, our experience in preparing these compounds via the reaction of 2-haloaldehydes with sodium hydrosulfide (9, 1*d*) suggests that the described method is superior in all respects. The 2-haloaldehydes, prepared by the chlorination (sulfuryl chloride) or bromination of aldehydes, are extemely fragile molecules which polymerize readily and cannot be purified. The reaction of these with sodium hydrosulfide gives the dimers **3** in a maximum yield of 50% and many are formed in much lower amounts (cf. 6% yield of **3***b*) (1*d*)). In contrast, the present method starts with either the much more stable haloacids or with commercially available mercaptoacids (**5***a*, *b*).

Each of the dimers **3** and **4** was used to prepare the dihydrothiophenes **2** by reaction with vinyltriphenylphosphonium bromide (1). The yields and spectroscopic data for **2** are given in Table 4.

Further work is in progress on the reaction of **6** with alkylating and organometallic reagents as potential routes to homologated and functionalized mercaptoaldehydes and ketones and the results will be reported in due course.

Experimental

Melting points are corrected; boiling points are uncorrected. Infrared spectra were run on a Beckman IR-12 instrument in chloroform solution. The ^{1}Hmr spectra were run at 60 MHz in deuterochloroform and are reported in the following format: chemical shift (δ) (multiplicity, number of protons, coupling constant). The Cmr spectra were run in deuterochloroform at 22.64 MHz in the FT mode using a flip angle of 45° on a Bruker CXP-100 instrument and are reported in ppm relative to internal TMS as standard. The aquisition time was 0.7 s and 8K data points were collected. Gas chromatographic analyses were performed using either 10% or 20% SE30 on Chromosorb W columns as previously described (1), solvents were removed at reduced pressure, and the drying agent used was anhydrous magnesium sulfate. Satisfactory C, H, and S analyses were obtained on all new compounds (Table 5) except **3***d* which gave a mass spectrum (molecular weight and fragmentation pattern) consistent with the assigned structure.

Mercaptoacids **5***a* and **5***b* are commercially available. Acids **5***c*, *d*, and *e* were prepared from the corresponding 2-bromoacids by treatment with potassium *O*-ethyl xanthate, followed by alkaline hydrolysis according to literature precedents (10).

Preparation of 1,3-oxathiolan-5-ones

Two methods (A and B) were used.

Method A (7)

To the appropriate mercaptoacid (0.2 mol) was added 2-methoxypropene (0.8 mol), dropwise with stirring at 0°C. After the addition was complete, the mixture was refluxed for 24 h, cooled, diluted with ether, and the mixture successively washed with 1 *N* sodium carbonate solution (3 × 50 mL), water (3 × 50 mL), and dried. Removal of the solvent gave **6**, which was purified by distillation or crystallization. Physical constants and spectroscopic data are given in Tables 1 and 2. In the case of **6***a*, a solid product sometimes formed which was shown to be **7** (11) by its melting point and spectral features.

Method B (6)

To a solution of mercaptoacid (0.4 mol) in 100 mL of benzene in a 250-mL flask fitted with a Dean–Stark water separator was added 3 equiv. of acetone and a catalytic amount of toluene sulfonic acid. The mixture was refluxed for 24 h, at which point no more water was separating. The cooled solution was diluted with ether (200 mL) and washed and dried as described under Method A. The products obtained are described in Tables 1 and 2.

Preparation of 2-mercaptoaldehyde dimers **3** *and* **4**

To a solution of the lactone **6** (0.02 mol) in 5 mL of dry toluene which had been cooled to −78°C was added 4 equiv. of DIBAL-H (25% in toluene), dropwise with stirring under a nitrogen atmosphere. Stirring was continued at −78°C for 2 h after the final addition and then the mixture was poured slowly into 200 mL of 50% aqueous acetic acid and 100 g of ice. The mixture was stirred vigorously for 15 min and extracted with chloroform (3 × 100 mL). The extracts were washed successively with saturated sodium bicarbonate solution (until the extracts were basic) and water and dried. Evaporation gave a semi-solid product which was treated with ether and then filtered. The filtrate was evaporated, treated again with ether, and refiltered. In this manner, the solid form (**3**) of **1** was obtained, which appeared from ir and ^{1}Hmr data to be a diastereomeric mixture of dimers **3**. The ^{1}Hmr spectra of the liquid material obtained from the ether filtrate showed many absorptions which, taken in conjunction with the infrared spectra, suggested mixtures of **3**, **4**, and in the case of **6***d*, **1**. These spectra were strongly solvent dependent. On the basis of their subsequent reaction with vinyltriphenylphosphonium bromide, the liquid portions are considered to be equivalent to the solids and the yields reported in Table 3 are calculated on this basis.

Dihydrothiophene formation

Each of the DIBAL-H products **3** and **4** were converted to the 2,5-dihydrothiophenes **2** in the following manner (1). To a solution of vinyltriphenylphosphonium bromide (4 g, 0.01 mol) in 50 mL of dry pyridine containing 0.015 mol of triethylamine was added a pyridine solution of 5 mmol of **3** or **4**, dropwise with stirring under a nitrogen atmosphere. After addition was complete, the solution was refluxed for the time indicated in Table 4, cooled, poured into water (500 mL), and extracted with ether (2 × 100 mL) and pentane (2 × 100 mL). The combined extracts were washed with 10% hydrochloric acid, water, and dried. Evaporation to ca. 10 mL, followed by filtration through a short column of acidic alumina using pentane as eluant, afforded **2**, free of colored or phosphorus-containing impurities. Gas–liquid chromatographic analysis showed them to be >95% pure. The yields and spectral data are given in Table 4.

Excess enthalpies, heat capacities, and volumes of trialkylamine and cyclohexane systems: NR_3 + NR'_3 and c-C_6 + NR_3. Effect of correlations of molecular orientations and steric hindrance

BERNARD RIEDL AND GENEVIÈVE DELMAS[1]

Département de chimie, Université du Québec à Montréal, C.P. 8888, Succ. A, Montréal (Qué.), Canada H3C 3P8

Received July 6, 1982

BERNARD RIEDL and GENEVIÈVE DELMAS. Can. J. Chem. **61**, 1876 (1983).

A Picker flow calorimeter has been used to obtain molar excess heat capacities, c_p^E, through the concentration range at 25°C for the NR_3 + NR'_3 systems where R = C_nH_{2n+1} and n = 2, 3, 4, 5, 6, 8, 12. Excess heats, h^E and c_p^E are also given for the mixtures of four trialkylamines with cyclohexane. Excess volumes V^E have been also measured on the same systems. Two contributions to the three thermodynamic functions were investigated, namely, that of disordering the long chains and that called steric hindrance. The steric hindrance has been found to occur with molecules having a highly substituted central atom. The corresponding contribution has an unexpected sign for non-polar systems, i.e., negative for h^E and positive for c_p^E, indicative of a loss of molecular mobility on passing from the pure liquid to the solution. The mixtures of the globular NR_3 give small negative c_p^E (≥ -0.7 J K^{-1} mol^{-1}) except for one. For the systems involving globular + linear molecules, the c_p^E are also negative but larger (down to -3.7 J K^{-1} mol^{-1}) due principally to the disordering contribution. The c_p^E confirm the small steric hindrance contribution seen on the h^E. The cyclohexane + NR_3 systems have positive h^E (varying between 275 and 660 J mol^{-1}) and negative c_p^E (varying between -1.6 and -5.2 J K^{-1} mol^{-1}) typical of a disordering effect and/or of a small force field difference. The parameter characteristic of the disappearance of order with temperature, obtained from the slope of h^E versus c_p^E, is found to be 90 K, understandably in between the value for the linear alkanes (50 K) and the SnR_4 (140 K). The V^E are well predicted by the Prigogine–Patterson–Flory equation of state theory, in particular, the contrast between the all positive values for the cyclohexane systems and the negative ones for the NR_3 mixtures due to the much higher cohesive energy of cyclohexane compared to that of the trialkylamines.

BERNARD RIEDL et GENEVIÈVE DELMAS. Can. J. Chem. **61**, 1876 (1983).

Nous avons utilisé le calorimètre à flux Picker pour mesurer à 25°C les capacités calorifiques d'excès, c_p^E, en fonction de la concentration pour les systèmes NR_3 + NR'_3 avec R = C_nH_{2n+1} et n = 2, 3, 4, 5, 6, 8, 12. Les enthalpies d'excès h^E et c_p^E sont données aussi pour les mélanges de quatre trialkylamines avec le cyclohexane. Pour les mêmes systèmes, nous avons mesuré aussi les volumes de mélange V^E. Deux contributions à ces trois fonctions thermodynamiques étaient l'objet de ce travail, la contribution de désordre des longues chaines et la contribution d'empêchement stérique. Cette dernière se retrouve avec des molécules qui ont un atome central très substitué. Le signe de la contribution correspondante est plutôt inattendu pour les systèmes non-polaires puisqu'il est négatif pour h^E et positif pour c_p^E révélant une diminution de mobilité moléculaire en solution. Les mélanges de NR_3 globulaires (sauf un) ont des c_p^E négatives (≥ -0.7 J K^{-1} mol^{-1}). Pour les mélanges de molécules globulaires et linéaires, les c_p^E sont aussi négatives mais la plus grande valeur absolue (qui atteint -3.7 J K^{-1} mol^{-1}) est due à la contribution de désordre. Les valeurs de c_p^E confirment la modeste contribution d'empêchement stérique vue sur les h^E. Les systèmes cyclohexane + NR_3 ont des valeurs positives de h^E (variant entre 275 et 660 J mol^{-1}) et négatives de c_p^E (variant entre -1.6 et -5.2 J K^{-1} mol^{-1}) typiques d'une contribution de désordre et d'une petite différence d'énergie de cohésion. Le paramètre caractéristique de la disparition de l'ordre avec la température τ obtenu par la pente de h^E en fonction de c_p^E a une valeur de 90 K intermédiaire entre celle pour les alcanes linéaires (50 K) et les SnR_4 (140 K). Les V^E sont bien prédits par la théorie de Prigogine, Patterson et Flory et en particulier le contraste entre les valeurs positives pour les systèmes SnR_4 et négatives pour les NR_3, différence due à la valeur élevée de l'énergie de cohésion du cyclohexane comparée à celle des trialkylamines.

Introduction

This work is part of an investigation of the effect of molecular shape on the thermodynamic properties of mixtures. The NR_3 series (R = C_nH_{2n+1}) is convenient for this purpose since in the passage from n = 2 for the first member of the series to n = 12 for the longest studied here, the molecular shape changes from globular to linear without too much modification of the component chemical nature. The aim of the present paper is to confirm by c_p^E and V^E measurements, the information previously (1) obtained from the h^E of the NR_3 + NR'_3 systems and of the NR_3 + linear and branched alkane (2) systems on two contributions to the thermodynamic functions, namely, the disordering contribution and the steric hindrance contribution.

The disordering contribution h^E(dis) occurs when an ordered liquid (A) is mixed with a non-ordered one (B). Most of the ordered, non-polar liquids studied have been made of long-chain anisotropic molecules and the non-ordered ones are made of globular isotropic molecules. Rayleigh scattering data on pure components and solutions (3) confirm and complete the information on orientational order obtained by thermodynamic methods. The effect of molecular size, free volume, and temperature on h^E(dis) have been discussed in previous work on small molecule systems (1–4) and on polymeric solutions (5). An enthalpy–entropy compensation reduces the effect of disordering on the free energy of mixing (6, 7) when the solution is made of small molecules but, in polymeric systems, correlations of molecular orientations stabilize the solution (8, 9). In binary systems, the label of steric hindrance effect has been given to systems having an unexpected value of the heat which could be either exothermic or less endothermic than forecast and containing a molecule with a highly substituted atom. The presence of two neighbouring substituted atoms or of a substituted atom situated in the center of the molecule appears to be a favorable factor for the steric hindrance effect (10, 11) since 2,3-dimethylpentane gives the steric hindrance effect, but 2,4-dimethylpentane does not. Surprisingly 3-methylhexane gives a more exothermic contribution than 2-methylhexane (8). The

SnR_4 (21, 22) (with R = ethyl and propyl) and 3,3-diethylpentane (4) (which can be written C(ethyl)$_4$ or 3,3-DEP), which show an important effect, have been studied extensively (2, 11). The sign of the heat indicates that there is less mobility in the solution than in the pure components. This contribution, also called "condensation contribution" by Patterson (11) and "coupling of torsionnal oscillations" by de Ligny (12), may be correlated with the mean number of *gauche* configurations Z_g (13) in the case of the branched alkanes.

The h^E data on mixtures of NR_3 with normal and branched alkanes (2) and with other trisubstituted amines have shown a small steric hindrance effect in the triethylamine and tripropylamine systems (1). The present measurements aim at confirming the characteristic features of the NR_3 + NR'_3 mixtures seen for the h^E data. The c_p^E data have been obtained on the following systems: five type-A systems made of all the binary combinations of the globular NR_3 (triethyl-, tripropyl-, tributyl-, and tri-(methyl-2-butyl)-) except one and nine type-B binary systems containing a long chain trialkylamine (hexyl, octyl, and dodecyl) with the three lower amines compounds (triethyl, tripropyl, and tributyl amines).

V^E values have been also measured for these systems to follow the effect of the cohesive energy difference on V^E and to compare it with the predicted values. The investigation of steric hindrance using *c*-C_6 as second component is reported in Part 2 of this work (19). In the course of this study, h^E, c_p^E, and V^E have been measured for *c*-C_6 for four long chain compounds: the trihexyl-, trioctyl-, tridodecyl-, and dimethyl dodecyl amines. However, as the data are interpreted mainly in terms of correlations of orientations destructions, the presentation and discussion of the results, more fitted to the present paper, will be given here.

In the following text, the names of the NR_3 compounds will be shortened to NEt_3, NPr_3, etc, as listed in the tables. *N*-(methyl-2-butyl)$_3$ has been written $NIsopent_3$.

Experimental

Materials

The amines come from the same source as in previous work (1, 2, 14), namely, Eastman (Rochester), Aldrich (Milwaukee), and the Chemical Procurement Laboratories (College Point, NY) and cyclohexane from the Chemical Samples Co. (Colombus, OH). Their physicochemical properties, density (d), expansion coefficient (α), thermal pressure coefficient (γ), and molecular (V^*, P^*) and shape (s) parameters are given in Table 1. (See Appendix for their interrelationships and the definitions of the surface-to-volume ratios (s).)

The lower amines which adsorb readily water are kept on molecular sieves. For each new batch of compound, the known heat of mixing with *c*-C_6 is re-measured as well as the refractive index and the density in order to test the quality of the compound.

Apparatus

The excess heat capacities c_p^E have been obtained at 25°C throughout the concentration range using the Picker flow calorimeter (Technorep, Montreal and Setaram, Lyon) which has been used (15, 21) and described (16) previously. The precision and accuracy of the present measurements for the reference system, *c*-C_6 + *n*-C_{16} are within 0.02 J K^{-1} mol^{-1} of the published data (−6.67 J K^{-1} mol^{-1} compared to −6.69 (16) at the maximum). For a given system, the reproducibility of the measurements of solution density and heat capacity data are about the same. For the $NDodec_3$ systems, the reproducibility is poorer (0.05 to 0.1 J K^{-1} mol^{-1}) due to the viscosity of this compound (17). The enthalpies of mixing are obtained with a tilting Tian Calvet calorimeter with the usual two compartment cells. The h^E of a reference system, CCl_4 + benzene, are obtained within 1−2% of the published results. The excess volumes are calculated from densities determined with an Anton Paar precision densitometer (Fisher Co.).

Results and discussion

The c_p^E, V^E, and h^E have been fitted through the concentration range to the Redlich−Kister equations:

$$c_p^E = x_1x_2 \sum_{i=0}^{i=2} B_i(x_1 - x_2)^i$$

[1] $$V^E = x_1x_2 \sum_{i=0}^{i=2} C_i(x_1 - x_2)^i$$

$$h^E = x_1x_2 \sum_{i=0}^{i=2} A_i(x_1 - x_2)^i$$

The concentration and values at the maximum have been listed in Tables 2, 3, and 5 as well as the A_i, B_i, and C_i parameters.

For analysing the data more easily, the heats of mixing have been written in previous work as the sum of different contributions:

[2] $$h^E_{exp} = h^E(\text{chem}) + h^E(\text{free volume}) + h^E(\text{disorder}) + h^E(\text{steric hindrance})$$

even if their independence and additivity have not been proven. h^E(chem) and h^E(free volume) correspond, respectively, to the terms having their origin in the force field and the free volume difference. h^E(chem) should be small in mixtures of alkane-like systems as the present ones (except possibly for NEt_3) and h^E(f.v.) can be calculated from an equation of state term. By analogy, c_p^E may be written under the same format:

[3] $$c_p^E = c_p^E(\text{chem}) + c_p^E(\text{f.v.}) + c_p^E(\text{dis}) + c_p^E(\text{steric hindrance})$$

The expected temperature dependence of the h^E contributions will permit the prediction of the sign of c_p^E for the corresponding contribution. As reported in Table 4, the steric hindrance and disordering contributions diminish when the temperature is raised, so the corresponding c_p^E is positive for the first (h^E being negative) and negative for the second (h^E being positive). The free volume contribution increases with T so that c_p^E is negative (h^E being negative). The different signs of c_p^E for the contributions investigated in this work are an advantage for the separation of the different terms in h^E and c_p^E. Since h^E(chem) does not vary much with temperature the corresponding contribution to c_p^E is negligible. In systems containing only globular or short chain amines, or A-type mixtures, the disordering contribution prevalent in the long-chain B-type mixtures is negligible so that eq. [3] becomes:

[4] $$c_p^E(\text{exp}) - c_p^E(\text{f.v.}) = c_p^E(\text{steric hindrance}) \text{ for the A-type mixtures}$$

and

[5] $$c_p^E(\text{exp}) - c_p^E(\text{f.v.}) = c_p^E(\text{dis}) + c_p^E(\text{steric hindrance}) \text{ for the B-type mixtures}$$

The free volume contributions (see Appendix) to c_p^E have been listed in the last but one column of the tables. $(c_p^E)_v$ is the experimental c_p^E divided by $x_1V_1^* + x_2V_2^*$ where V_1^* and V_2^* are the core volumes of the two components.

Mixtures of globular NR_3: type-A systems

The small values of h^E found on these systems (<32 J mol^{-1})

[e]Used in Part 2 (19).

indicate that these solutions are almost ideal. The small negative c_p^E are due in part only to the free volume difference since $c_p^E(\text{exp}) - c_p^E(\text{f.v.})$ is still negative. The sign of the difference would correspond to a larger decrease of h^E at higher temperature than expected from the free volume term. The molecular origin of this exothermic heat or better cohesion in solution is not easy to guess. It could be of the dipole–dipole type which would be more stable in solution than in the pure components.

$NIsopent_3$ + $NBut_3$ system is interesting since h^E and c_p^E are both positive. Contrary to the four other systems, h^E is predicted to increase with increasing temperature. An indication of the existence of subtle effects in these systems is given by the two different signs of c_p^E for the apparently quite similar systems $NIsopent_3$ + $NBut_3$(0.125) and $NIsopent_3$ + NPr_3-(−0.50) systems which are likely to have similar shape and equation of state parameters. Perhaps the investigation of other systems where the effects would be larger may help to see the origin of these differences.

Mixtures of globular + linear NR_3 (type-B systems)

In order to compare the experimental values for the different systems, $c_p^E(\text{exp})$ per cm^3 at the maximum of the concentration have been plotted in the bottom part of Fig. 1 versus the molar volume of the second component. Lines are drawn through the systems containing $NDodec_3$, $NOct_3$, and $NHex_3$. The same plot is made in the top part of Fig. 1 with the h_v^E the heats per cm^3 for the same systems. The characteristic features of these NR_3 mixtures given by this figure are the following: (*1*) the c_p^E are large and negative and their absolute values increase between $NHex_3$ and $NDodec_3$; (*2*) the irregularities observed in h_v^E with NEt_3 and NPr_3 are seen on the c_p^E; (*3*) the c_p^E are mirror images of the h^E indicating probably the dominance of one contribution or of two contributions which are not independent.

Quantitative evaluation of the disordering contribution on c_p^E

Temperature variation of the order in long-chain liquids

The temperature variation of the heats of mixing (15) or of other thermodynamic property such as the excess viscosity of mixtures (18), of a globular molecule with an ordered liquid, is indicative of the fast decrease of orientational order when the

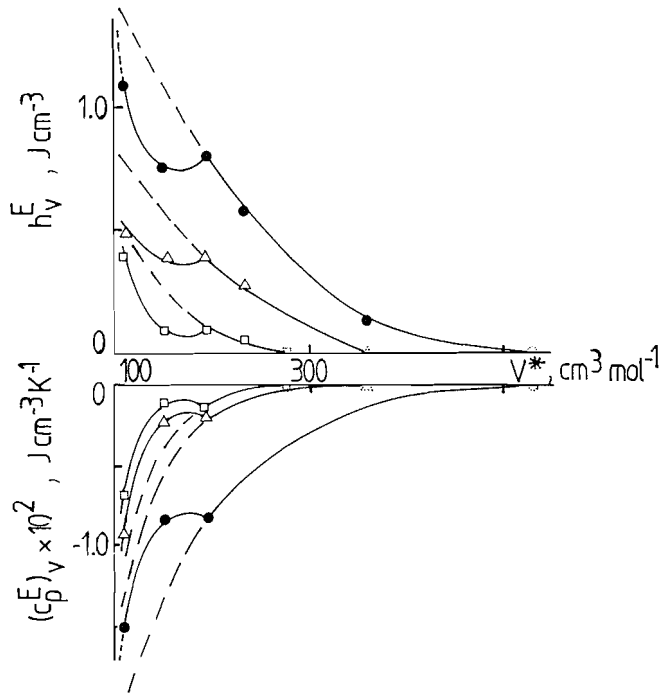

FIG. 1. Excess heats h_v^E in J cm^{-3} (upper part) and excess heat capacities, $(c_p^E)_v$ in J cm^{-3} K^{-1} (lower part) for $NHex_3$ (□), $NOct_3$ (△), and $NDodec_3$ (●) mixed with NEt_3, NPr_3, $NBut_3$ plotted against the core volume V^* of the smaller NR_3. The main contribution comes from the disordering of the long chains, bringing about h^E positive and c_p^E negative. The difference between the curves and the dotted lines corresponds to the extra steric hindrance contribution with NEt_3 and NPr_3 ($h^E < 0$ and $c_p^E > 0$).

temperature is raised. If the order is assumed to diminish exponentially with temperature with a characteristic temperature, τ, the disordering contribution to h^E and c_p^E can be written (15) as

$$h^E(\text{dis}) = h_0 e^{-T/\tau}$$

$$[6]\quad c_p^E(\text{dis}) = -(h_0/\tau)e^{-T/\tau}$$

$$h^E(\text{dis})/c_p^E(\text{dis}) = -\tau$$

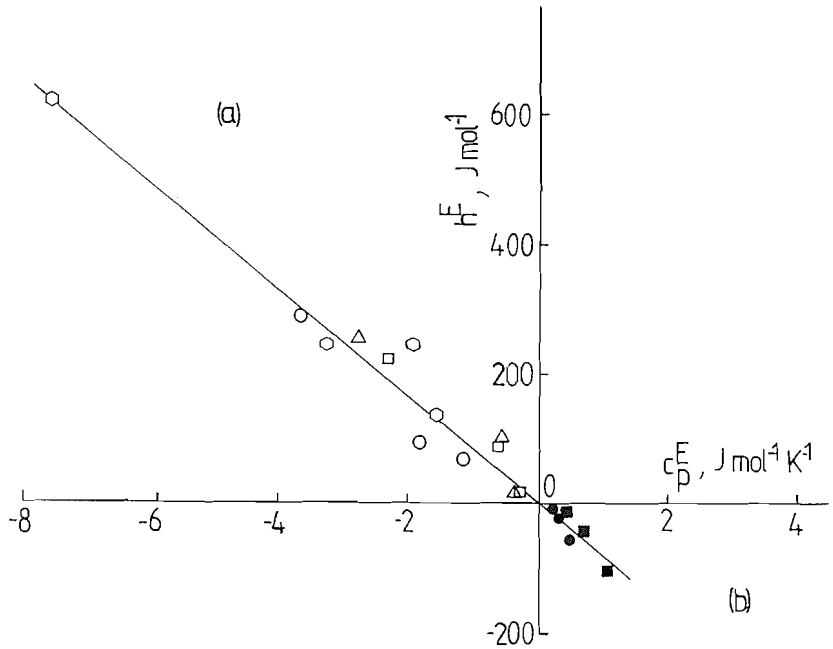

FIG. 2. Correlation between the h^E and c_p^E for the disordering contribution (curve *a*) of the long chain NR_3 mixed with NEt_3 (○), NPr_3 (□), NBut (△), and *c*-C_6 (⬡) and for the steric hindrance contribution (curve *b*). From eq. [6], the characteristic temperature is found to be 90 K for the disordering and about 100 K for the steric hindrance effect.

TABLE 4. Expected signs of h^E, V^E, and c_p^E for the different contributions

	Sign			
Parameter	Force field difference	Free volume difference	Disordering	Steric hindrance
h^E	+[a]	−[b,d]	+	−
Change of h^E when T increases	Little change	More −	Less +	Less −
c_p^E	About 0	−[b,d]	−	+
V^E	+	−[b,c,d]	+	−

[a]In non-polar systems.
[b]Depends mostly on the difference in expansion coefficients.
[c]Depends also on the relative cohesive energy of the two components.
[d]Values have been calculated in ref. 1 and Table 5 for h^E in Tables 2, 3, and 5 for c_p^E and V^E.

Equation [6] predicts a linear relationship between h^E(dis) and c_p^E(dis).

In the upper part of Fig. 2, one can see such a relationship for the nine B-type systems. The experimental h^E and c_p^E have been used instead of eq. [5] for the sake of simplicity. A similar line would be obtained by subtracting the free volume terms. The systems involving NEt_3 and NPr_3 for which steric hindrance has been found from the heats are also in the graph because of the relatively small part of the total heat due to steric hindrance. The characteristic temperature τ is found to be about 90 K, which is higher than the value (50 K) found for the linear alkanes. A greater stability with temperature of the correlations of molecular orientations between the NR_3 molecules could be expected since the branched character of the NR_3 more than two molecules can be involved in the correlations and also because of the lower free volume of these compounds compared to the linear alkanes of the same carbon atom number in the chain.

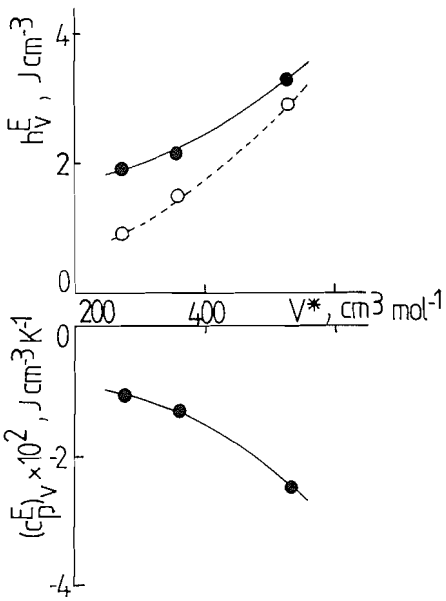

FIG. 3. h_v^E and $(c_p^E)_v$ for the mixtures of three long chain trialkyl amines with *c*-C_6 plotted against the volume V^* of the NR_3. The dotted line represents the disordering contribution (values used for the *c*-C_6 points in Fig. 2 (⬡)). The force field contribution or "rotation" contribution needed to make the separation is described in Part 2.

The results of theories developed for order in the linear alkanes or for liquid crystals which do not predict a linear temperature-independent relation between h^E(dis) and c_p^E(dis) are discussed in ref. 14.

Evaluation of the steric hindrance contribution to c_p^E

In the SnR_4 + SnR'_4 systems, the irregularities (21) of the h^E and of the c_p^E indicated a steric hindrance contribution more important for the $SnEt_4$ and $SnPr_4$ than for the $SnMe_4$ and $SnBut_4$ systems. By analogy, one can extend this property to the NR_3 compounds. The steric hindrance contribution will be

obtained from the difference between the expected value of the h^E and c_p^E (dotted line in Fig. 1) at the abscissa of $V^*(NEt_3)$ and $V^*(NPr_3)$, and the experimental value. The lack of data for h^E and c_p^E data for the volatile NMe_3 system diminishes greatly the reliability of the c_p^E(steric hindrance) values since the position of the dotted line is ambiguous. The more positive values of c_p^E(exp) in Fig. 1 for the six points corresponding to the NEt_3 and NPr_3 systems are in agreement with a positive contribution coming from c_p^E(steric hindrance). On the lower part of Fig. 2, the estimated c_p^E(steric hindrance) have been plotted against the h^E(steric hindrance) found previously. The value of the characteristic temperature is found to be 100 K compared to 70–80 K for the steric hindrance contribution for the $SnPr_4$ and $SnEt_4$ derivatives, but it should be considered as an approximate value because of the method of separation of the contribution used.

Excess volumes

Table 3 gives the experimental V^E at the concentration of the maximum, the parameters of eq. [1], and the different contributions to V^E for the two series. The seventh column lists V^E(exp) − V^E(calcd) and the last, the interchange energy parameter $X_{12}s_1^{-1}$ (see Appendix). The Prigogine–Patterson–Flory theory, using the Van der Waals model for energy, can predict V^E usually quite successfully. In this calculation, the steric hindrance and disorder contributions are included in $V^E(h^E)$ or $V^E(X_{12})$, the contribution calculated from the experimental heats of mixing. The free volume term V^E(f.v.) depends on $\tilde{v}_1 - \tilde{v}_2$ and is always negative (third term in the table). The second term $V^E(P^*)$, proportional to $(\tilde{v}_1 - \tilde{v}_2)(P_1^* - P_2^*)$, can change sign depending on the relative cohesive energy of the expanded and less expanded component. It gives a quantitative expression to the fact that an expanded but cohesive (high P^*) component will contract less in solution with a non-expanded second component than a less cohesive liquid would do and vice versa. For the A-type systems, $V^E_{exp} - V^E_{calcd}$ is less than 0.04 $cm^3\ mol^{-1}$ except for one system (0.058). For the B-type systems, the three contributions are large since the h^E can reach 300 J mol^{-1}, the difference in free volume is important between NEt_3 and $NDodec_3$ and the difference in P^* varies from 20 to 65 J cm^{-3} between the members of the series. A perfect prediction of the V^E in these systems would be somewhat surprising with such a simple model, the van der Waals model (see Appendix), for the energy. For six systems out of nine, $V^E_{exp} - V^E_{calcd}$ is less than 0.10 $cm^3\ mol^{-1}$. With the NPr_3 systems, the large difference in P^* with the long-chain component (32 to 64 J cm^{-3}) produces a large $V^E(P^*)$ contribution which is probably overestimated in the case of the NPr_3 + $NDodec_3$ for which $V^E_{exp} - V^E_{calcd}$ reaches 0.28. In the NEt_3 systems, the $(\tilde{v}_1 - \tilde{v}_2)(P_1^* - P_2^*)$ is now positive which, in these cases, does not improve the agreement between V^E_{calcd} and V^E_{exp} although one can find other cases where the $V^E(P^*)$ term is quite instrumental in giving a good theoretical prediction of V^E_{exp}.

Long-chain trialkylamines + c-C_6 systems: h^E, c_p^E, *and* V^E

One can expect that the dominant contribution for these systems will be the disordering of the long chains of the NR_3 molecules by the globular *c*-C_6. h^E will be positive and since orientational order in the pure components diminishes at higher temperature, c_p^E is expected to be negative and to increase with the size of the ordered component. In Fig. 3, one can see the familiar occurrence, that h_v^E and $(c_p^E)_v$ are mirror images of each other with respect to the *x* axis. In Figs. 1 and 3, the lines have different slopes because in one case (Fig. 1) the points with the same long chain compounds and in the other (Fig. 3) the points with the same globular molecule are joined. Comparing Table 5 with Table 2 (last column), one cannot miss the fact that the h^E values are systematically larger when *c*-C_6 replaces NR_3 as the order-breaker. One of the sources of this difference is the force field contribution to h^E in the case of the *c*-C_6 mixtures. The method developed in Part 2 (19) has been used here to obtain h^E(chem) for these systems and calculate h^E(dis) (--- in Fig. 3) by subtraction from h^E_{exp}. The corresponding heat capacity contribution was not subtracted in the lower part of Fig. 3 because the available data on several systems did not permit to ascertain a special contribution to c_p^E coming from the difference in the force field. After the subtraction of the force field contribution, h^E(dis) is still consistently much larger with *c*-C_6 than with the NR_3 molecules. For instance, h^E(dis) of $NDodec_3$ is found to be 2.90 J cm^{-3} with *c*-C_6 and 1.1 J cm^{-3} with NEt_3, both having about the same expansion coefficient. The reason for this effect may come from the method of separation of the contribution, or of a lack of additivity of the contributions due to a cross term, depending on a large force field difference as it is the case here. The molecular shape and cohesive energy of the order breaker may have an effect on the magnitude of the disorder in solution (1, 2). However, the characteristic temperature of the orientational order in the NR_3 molecules which is a property of the pure component is found the same if the order breaker is a globular NR_3 or *c*-C_6 as can be seen in Fig. 2 in which the points representing the *c*-C_6 + NR_3 mixtures, except one, fall on the same h^E, c_p^E, correlation line as the NR_3 + NR'_3 systems.

The experimental values of V^E are given in the bottom part of Table 5. The different columns give the same parameters as Table 3 for the NR_3 + NR'_3 systems. Although the three contributions to V^E have comparable magnitude and different signs, the value of $V^E_{exp} - V^E_{calcd}$ is smaller than 0.02 $cm^3\ mol^{-1}$ for two systems out of four. On the other hand, for the two systems containing the dodecyl chain the excess volume is much more positive than calculated. This may correspond to a real physical effect, i.e., the uneasy packing of molecules of quite different shape like *c*-C_6 and the long NR_3 molecules. Such a large value for $V^E_{exp} - V^E_{calcd}$ (0.28 $cm^3\ mol^{-1}$) is found for only one system (NPr_3 + $NDodec_3$) in the NR_3 + NR'_3 series. It is difficult to decide between the packing effect and the overestimation of $V^E(P^*)$ as given above. In a qualitative analysis, it is interesting to compare the two series of systems NR_3 + NR'_3 and *c*-C_6 + NR'_3 viewed from their excess volumes (here R′ stands for a long chain). A rapid guess would make one predict similar V^E since a long chain amine (NR'_3) is mixed in each case with a globular, volatile component, NR_3 or *c*-C_6 but the experiments show that the V^E are all negative in the amine mixtures and all positive in the *c*-C_6 ones. Two of the present systems, NEt_3 + $NDodec_3$ and *c*-C_6 + $NDodec_3$, illustrate the difficulty of guessing V^E, since one is −0.64 $cm^3\ mol^{-1}$ and the other is +0.65 $cm^3\ mol^{-1}$. This constitutes a striking case of the resistance to the contraction in solution of a volatile but highly cohesive molecule like cyclohexane, when mixed with a low free volume second component. This effect is well predicted by the Prigogine–Patterson–Flory theory with a Van der Waals model for the energy.

Appendix

List of symbols

The density (d), expansion coefficient (α), and thermal pressure coefficient (γ) are measurable parameters from which the volume at 0 K or "core volume", V^*, can be calculated as well as P^*, the cohesive energy per cm^3. The surface-to-volume ratio (s) can be calculated from a model (sphere, cylinder etc...). c_p^E is an experimental quantity defined as the difference between the experimental c_p of the solution and the c_p obtained by a molar fraction average of the c_p for the two pure components. The values of v, U, c_p, and T with a tilde are dimensionless reduced values used in the theory. They can be obtained from an equation and experimental data (d, α, and γ). The interchange energy parameter X_{12} is obtained essentially from the heat of mixing of 1 and 2 after subtracting the free volume term. ψ and θ are respectively energy and surface fraction averages defined as below.

Calculation of the free volume terms

$h^E(f.v.)$ *and* $X_{12}s_1^{-1}$

The free volume term depends only on the difference between the reduced volume of the pure components. We apply an approximate (19) form of the Prigogine–Flory theory which separates the interactional and free volume contributions. The free volume contribution h^E(f.v.) is defined as:

$$[1]\quad h^E(\text{f.v.})/(x_1U_1^* + x_2U_2^*) = \tilde{c}_p(\tilde{T}_u)(\psi_1\tilde{T}_1 + \psi_2\tilde{T}_2 - \tilde{T}_u)$$

Here $\tilde{T}_u$ is the average reduced temperature for the solution appropriate to the energy $\tilde{U}$ and is defined by:

$$\tilde{U}(\tilde{T}_u) = \psi_1\tilde{U}(\tilde{T}_1) + \psi_2\tilde{U}(\tilde{T}_2)$$

With the Van der Waals model, $\tilde{U}(\tilde{T}_u) = -1/\tilde{v}$, so that the volume corresponding to $\tilde{T}_u$ is $1/\tilde{v}_u = \psi_1/\tilde{v}_1 + \psi_1/v_1$, where $\psi_1 = x_1U_1^*/(x_1U_1^* + x_2U_2^*)$. In this model, the reduced volume of a pure component is obtained from its expansion coefficient, α, and $\tilde{v}^{1/3} = ((\frac{4}{3}\alpha T) + 1)/(\alpha T + 1)$. The reduced temperature is calculated from the reduced volume and $\tilde{T} = \tilde{v}^{-1}(1 - \tilde{v}^{-1/3})$. Also, $\tilde{c}_p(\tilde{T}_u) = (\frac{4}{3}\tilde{v}_u^{-1/3} - 1)^{-1}$, $U^* = P^*V^*$ and $P^* = \gamma\tilde{v}^2T$ where γ is the thermal pressure coefficient. Equation [1] does not depend on the surface-to-volume ratio. In the Flory terminology, the interactional contribution, which is the difference between the experimental value of the heat and the free volume contribution, is expressed through the X_{12} parameter. In the present form, X_{12} is obtained by eq. [2]:

$$[2]\quad h^E(\text{exp}) - h^E(\text{f.v.})/(x_1U_1^* + x_2U_2^*) = (X_{12}/P_1^*)\theta_2\psi_1 f(\tilde{v})$$

$f(\tilde{v})$ is defined as $(\tilde{v}^{-1} + \tilde{T}\tilde{c}_p)$ and is not very different from 1. ψ_1 and θ_2 ($\theta_2 = x_2V_2^*s_2/(x_1V_1^*s_1 + x_2V_2^*s_2)$) are used rather than the mole fractions. The units of X_{12} are energy per cm^3. The parameter $X_{12}s_1^{-1}$ is independent of the choice of 1 or 2 as a second component, i.e. $X_{12}s_1^{-1} = X_{21}s_2^{-1}$. The left side of eq. [2] does not depend on the surface-to-volume ratios s_1 and s_2 while X_{12} and θ_2 do to some extent. $X_{12}s_1^{-1}$ also relies very little on the s's. The core volume, V^*, is obtained from the molar volume V and $\tilde{v} = V/V^*$.

$c_p^E(f.v.)$

It is given by the equation:

$$[3]\quad c_p^E = \tilde{c}_{p,s}[x_1U_1^*/T_1^*) + x_2(U_2^*/T_2^*)] - x_1\tilde{c}_{p_1}(U_1^*/T_1^*) - x_2\tilde{c}_{p_2}(U_2^*/T_2^*)$$

The reduced volume of the solution $\tilde{v}_s$ used to calculate $\tilde{c}_{p,s}$ is obtained from the solution reduced temperature $\tilde{T}_s$ defined as an energy average.

$$\tilde{T}_s = (\psi_1\tilde{T}_1 + \psi_2\tilde{T}_2)(1 - X_{12}\psi\theta_2/P_1^*)$$

The X_{12} term does not have a large effect on $\tilde{T}_s$ in the present systems.

V^E

According to ref. 20, the excess volume can be written using the Van der Waals model:

$$[4]\quad \frac{V^E}{x_1V_1^* + x_2V_2^*} = \tilde{T}_v\frac{\partial\tilde{v}}{\partial\tilde{T}_v}\psi_1\theta_2(X_{12}/P_1^*) + (\tilde{v}_1 - \tilde{v}_2) \times (\psi_1 - \phi_1) - \frac{1}{2}\left(\frac{\tilde{v}_1 - \tilde{v}_2}{\partial\tilde{v}/\partial\tilde{T}_v}\right)^2\frac{\partial^2\tilde{v}}{\partial\tilde{T}_v^2}\{\psi_1\psi_2 + (\psi_1 - \phi_1)^2\}$$

here $\tilde{v}_v = \phi_1\tilde{v}_1 + \phi_2\tilde{v}_2$ and $\tilde{T}_v$ corresponds to $\tilde{v}_v$ so defined. By developing the second term of eq. [4], we can show that $\psi_1 - \phi_1$ varies as $P_1^* - P_2^*$. The first term of eq. [4] is $V^E(h^E)$, the second $V^E(P^*)$, and the last V^E(f.v.) as listed in Tables 3 to 5.

Surface-to-volume ratios

In order to compare the cohesive energies of molecules of different shapes, models have been detailed in ref. 14. For the globular molecules, assimilated to a sphere of a radius R, $s = (4/3)\pi R^3(\pi R^2)^{-1} = 4.083(V^*)^{-1/3}$. For linear- and branched-alkanes, the model used is that of a right cylinder with a 4.98 Å and 6.98 Å diameter. The NR_3 and SnR_4 molecules are assimilated to a group of three and four cylinders if the chain is longer than two carbons. Probably, for the ethyl derivatives, neither model is very realistic.

Excess heats, heat capacities, and volumes of globular non-polar molecules: mixtures of trialkylamine and tetraalkyltin compounds with cyclohexane

H. PHUONG-NGUYEN, BERNARD RIEDL, AND GENEVIÈVE DELMAS[1]

Département de chimie, Université du Québec à Montréal, C.P. 8888, Succ. A, Montréal, (Qué.), Canada H3C 3P8

Received July 6, 1982

H. PHUONG-NGUYEN, BERNARD RIEDL, and GENEVIÈVE DELMAS. Can. J. Chem. **61**, 1885 (1983).

h^E, c_p^E, and V^E have been measured at 25°C over the whole composition range for eight mixtures of cyclohexane (c-C_6) with $N(C_nH_{2n+1})_3$ (n = 2, 3, 4, 5) and with $Sn(C_nH_{2n+1})_4$ (n = 1, 2, 3, 4). The effect of sterically hindered molecules on the thermodynamic functions of mixtures containing a globular second component like c-C_6 was investigated. For the $Sn(C_nH_{2n+1})_4$ + c-C_6 systems, the c_p^E values are positive; this is quite unusual for non-polar systems. It is found that the sterically hindered molecules do not lower h^E as is the case with long chain alkanes or the NR_3 or SnR_4 molecules. On the other hand, h^E for these systems and for others of the type c-C_6 + A (A being a globular molecule) when plotted versus α_A, the expansion coefficient of A, fall on a smooth curve which increases with α_A. This is interpreted as an increase of the mobility or/and rotation of c-C_6 in high free volume solvents. A maximum of 1.8 J K^{-1} mol^{-1} in c_p^E for the c-C_6 + Sn(propyl)$_4$ system is in agreement with the rapid change of h^E around $\alpha_A = 0.9 \times 10^{-3}$ K^{-1}. The negative values of c_p^E for the NR_3 systems probably indicate a weak association between the NR_3 molecules. The V^E values follow quite well the predictions made using h^E and the Prigogine–Patterson–Flory equation of state theory.

H. PHUONG-NGUYEN, BERNARD RIEDL et GENEVIÈVE DELMAS. Can. J. Chem. **61**, 1885 (1983).

h^E, c_p^E et V^E ont été mesurés à 25°C en fonction de la concentration pour huit mélanges de c-C_6 avec $N(C_nH_{2n+1})_3$ (n = 2, 3, 4, 5) et avec $Sn(C_nH_{2n+1})_4$ (n = 1, 2, 3, 4). On étudie l'effet d'empêchement stérique dans le cas de mélanges dont le deuxième composant est une molécule globulaire comme c-C_6. Pour les mélanges c-C_6 + $Sn(C_nH_{2n+1})_4$, les c_p^E sont positifs ce qui est inhabituel dans les systèmes non-polaires. On trouve que les composés empêchés stériquement ne diminuent pas les h^E comme c'était le cas avec des deuxièmes constituants en chaine. De plus, h^E pour ces systèmes et pour d'autres du type c-C_6 + A (A étant une molécule globulaire) quand portés en fonction de α_A, le coefficient d'expansion de A, se retrouvent sur une courbe régulière qui augmente avec α. Cet effet est interprété comme indiquant une augmentation de mobilité ou/et de rotation du c-C_6 dans les solvants de volume libre élevé. Un maximum de 1.8 J K^{-1} mol^{-1} pour le c_p^E du système c-C_6 + Sn(propyl)$_4$ est consistant avec la variation rapide de h^E autour de $\alpha = 0.9 \times 10^{-3}$ K^{-1}. Les valeurs négatives de c_p^E pour les systèmes contenant les trialkylamines sont probablement dues à une faible association entre les molécules NR_3. Les V^E suivent bien les prédictions faites par la théorie développée par Prigogine, Patterson et Flory.

Introduction

In the preceding paper (1) the information given by h^E, c_p^E, and V^E for mixtures of trialkyl amines (NR_3 + NR_3') and long chain amines mixed with c-C_6 have been interpreted in terms of two contributions, associated with disorder and steric hindrance. The disordering contribution occurs when a globular molecule is mixed with a long-chain ordered liquid. The decrease of the cohesive energy in solution due to the loss of the correlation of molecular orientations present in the pure liquid corresponds to a positive contribution to h^E. The steric contribution is associated with the presence of a crowded central atom in a molecule. The resulting effect in solution, since the excess heat is exothermic, is to diminish the overall mobility or to improve the packing. More details about non-thermodynamic methods used to study orientational order or about the effect of temperature, free volume, or molecular shape can be found in references 1 and 2 for the disordering contribution and in references 1 to 3 for steric hindrance. In several instances, both contributions are met in the same system and understandably so, because in mixtures of long-chain molecules the heats are larger and irregularities in the thermodynamic functions can be seen and interpreted with less ambiguity than in mixtures of globular non-polar molecules in which the effects are usually small. This is illustrated by the h^E values of the SnR_4 + SnR_4' (3*a*, *e*) (R = C_nH_{2n+1}, and $n \leq 4$) system which do not exceed 65 J mol^{-1}.

In systems where a steric hindrance effect is expected, an indication of the importance of the molecular shape of the second component is given by the results of h^E of n-C_{16}, on one hand, and c-C_6 on the other hand, with two branched nonanes. At the equimolar concentration, the h^E of n-C_{16} with the highly sterically hindered 3,3-diethylpentane (3,3-DEP) is 18 J mol^{-1}, i.e. 300 J lower than the value with the non-sterically hindered 2,2,5-trimethylhexane (317 J mol^{-1}) (4). On the other hand, the corresponding h^E of the same branched nonanes with c-C_6 are, respectively, 179 and 192 J mol^{-1} (3*d*), showing that the steric hindrance contribution, familiar with the 3,3-DEP systems, is almost zero when c-C_6 is the second component. Similar results are found for other cycoalkanes such as methylcyclohexane, cycloheptane, and cyclooctane for which the sterically hindered component gives even higher h^E (3*d*).

The aim of the present paper is to investigate the steric hindrance effect of the NR_3 and SnR_4 molecules in solution with c-C_6. The relatively large h^E found systematically in systems containing c-C_6 (5–7) even when no force field difference contribution or no disordering contribution occurs, should facilitate the analysis of the results. The c_p^E and V^E data will be obtained on the same systems to see if these functions may detect, better than h^E, the steric hindrance effect in c-C_6 mixtures. Furthermore, the c-C_6 + NR_3 and c-C_6 + SnR_4 systems promise to be a good series to test the effect on V^E of the difference in cohesive energy as predicted by the equation of state theories (8, 9), since the pressure reduction parameter P^* which reflects the cohesive energy is high (530 J cm^{-3}) for c-C_6 compared to those of the NR_3 and SnR_4 compounds (ref. 1, Table 1). The present paper reports the h^E, c_p^E, and V^E data of four globular amines N(ethyl)$_3$, N(propyl)$_3$, N(butyl)$_3$, N(2-methylbutyl)$_3$ with c-C_6 and four tetraalkyltin compounds Sn(methyl)$_4$, Sn(ethyl)$_4$, Sn(propyl)$_4$, Sn(butyl)$_4$ with c-C_6 at

25°C over the whole concentration range. The names of the compounds are abbreviated as shown in the tables, NEt_3 for N(ethyl)$_3$, $SnMe_4$ for Sn(methyl)$_4$, and so on.

Experimental

Materials

Cyclohexane was purchased from the Chemical Samples Co. (Columbus, OH). The amines came from the same sources as in Part 1 (Eastman, Aldrich, and Chemical Procurement), the SnR_4 from the Organisch Chemisch Instituut (Utrecht) or the K and K company. Their physicochemical characteristics are given in Table 1 of the preceding paper (Part 1).

Apparatus

The c_p^E and V^E values are obtained as in Part 1 with a Picker Flow calorimeter (Sodev, Sherbrooke, Canada) and an Anton-Paar precision densitometer (Fisher Co.). The heats of mixing were obtained with an adiabatic Calvet calorimeter (10).

Equation of state contributions

The contributions to h^E, h^E (f.v.), c_p^E, c_p^E (f.v.), and V^E, V^E (f.v.) coming from the difference in state of expansion of the two components have been calculated from the equations given in the Appendix of Part 1 and are listed in Tables 1–3. The contribution to V^E coming from h^E and the difference of P^* are added in Table 3. $X_{12}s_1^{-1}$ corresponds to the part of h^E not associated with the free volume difference.

Results and discussion

The h^E, c_p^E, and V^E have been fitted through the concentration range to the Redlich–Kister equations:

$$h^E = x_1x_2 \sum_{i=0}^{i=2} A_i(x_1 - x_2)^i$$

$$[1] \quad c_p^E = x_1x_2 \sum_{i=0}^{i=2} B_i(x_1 - x_2)^i$$

$$V^E = x_1x_2 \sum_{i=0}^{i=2} C_i(x_1 - x_2)^i$$

Heats of mixing

Table 1 gives h^E at the maximum, the concentration of the maximum, the parameters of eq. [1], the heat per cm^3 h_v^E, and two calculated parameters h^E (f.v.), and $X_{12}s_1^{-1} \cdot h_v^E$ is obtained through

$$h_v^E = h^E/(x_1V_1^* + x_2V_2^*)$$

V_1^* and V_2^* are the core volumes (or volumes at 0 K) of the two components (see Appendix of Part 1).

In previous work (2*a*) with long-chain alkanes as the second component, the steric hindrance contribution was seen in the following way: h^E or h_v^E was plotted against $V^*(SnR_4)$ and the points joined by a line. It was found that the points for $SnEt_4$ (1.71) and $SnPr_4$ (1.16) were situated well below the expected value between the $SnMe_4$ (3.08) and $SnBut_4$ (1.38) values. The figures in parentheses correspond to h_v^E with n-C_{16}. The difference between the expected value and the experimental ones was assumed to correspond to the negative steric hindrance contribution which could amount to −200 J mol^{-1}. A similar plot of the present data will not show a special lower h^E for the $SnEt_4$ and $SnPr_4$ derivatives so that it is concluded that the steric hindrance contribution does not occur, in its usual form, with a globular second component like c-C_6, a feature already seen with 3,3-DEP as the sterically hindered molecule. On the other hand, the jump towards more positive h^E between $SnPr_4$ and $SnEt_4$ is similar to that obtained (13) with *trans*-decalin or three highly branched alkanes as a second component.

In order to see some trend in the h^E with c-C_6, the h_v^E have been plotted in Fig. 1*a* versus α, the expansion coefficient of the NR_3 (□) or SnR_4 (○) compounds. On the same curve, h_v^E of other globular molecules such as the very branched alkanes 2,2,4-trimethylpentane, 2,2,4,6,6-pentamethylheptane, and 2,2,4,4,6,8,8,-heptamethylnonane have been added (△). The h_v^E values of two branched nonanes, (▲) 3,3-DEP and 2,2,5-dimethylpentane (11), of n-C_6 (●) and CCl_4 (■) have been joined to complete the present data. The free volume term would be represented by a curve going from 0 for $\alpha = 1.22 \times 10^{-3}$ (that of c-C_6) to −0.4 J cm^{-3} for $\alpha = 0.8 \times 10^{-3}$. If $h_v^E - h_v^E$ (f.v.) were plotted instead of h_v^E, the points would be displaced towards more positive values by the corresponding amount. However, it is preferable to plot just the experimental data for the sake of simplicity and also because the theory overestimates the free volume contribution to h^E when the difference of expansion coefficients of the two components increases.

The large h_v^E values found in non-polar systems when one of the components is c-C_6 have always been puzzling, particularly in mixtures with branched alkanes whose chemical groups CH_2 and CH_3 are rather similar to those of c-C_6. The explanation is given in terms of the larger cohesive energy of c-C_6 compared to the branched alkanes. The curve shown in Fig. 1*a* may help to obtain a more molecular picture of the origin of these relatively large heats. The variation of h^E with the expansion coefficient of the second component indicates that the perturbation or loss of cohesion or disorder introduced in c-C_6 is very dependent on the free volume of the second component. The mixing may have changed a particularly good and cohesive packing between the c-C_6 molecules. This hypothesis is not too satisfactory because one would then expect that if there were

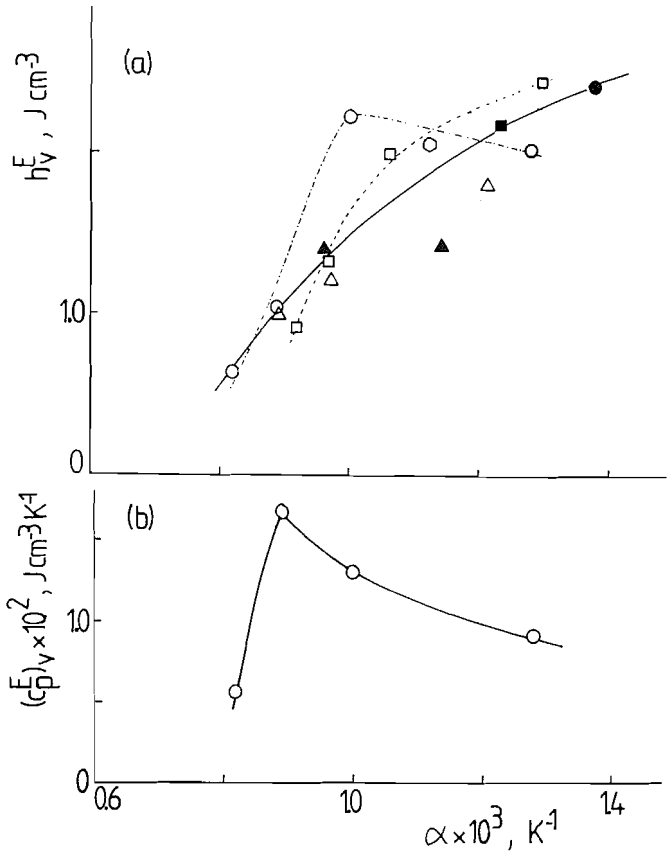

FIG. 1. (*a*) h_v^E, the excess heat per cm^3 at the maximum at 25°C, for the (□) NR_3 + *c*-C_6 and (○) SnR_4 + *c*-C_6 systems plotted against the expansion coefficient of the NR_3 or SnR_4 compounds. Seven other systems have been added: (△) the three highly branched alkanes 2,2,4-trimethylpentane, 2,2,4,6,6-pentamethylheptane, and 2,2,4,4,6,8,8-heptamethylnonane, (●) *n*-hexane, (■) CCl_4, (▲) two branched nonanes, and (⬡) *cis*-1,3-dimethylcyclohexane. Full curve through all the points. Dotted lines with inflexion points for the NR_3 and SnR_4 sytems. (*b*) $(c_p^E)_v$ for the SnR_4 + *c*-C_6 systems in J K^{-1} cm^{-3} plotted against α, the expansion coefficient of the SnR_4 compound.

really a random mixing, this packing is destroyed whatever the free volume of the second component. A change which could be related more to the free volume than the molecular shape of the neighbours would be the rotations of the symmetrical *c*-C_6. A more extensive rotation in a large free volume solution could explain the large variation of the heats with the free volume. If this is so, one would expect a smaller variation of h^E if a less symmetrical molecule like methylcyclohexane were mixed with the same series of globular compounds.

Other systems containing c-C_6

h^E data have been obtained recently (12) for *c*-C_6 with methylcyclohexane and six dimethylcyclohexane, the methyl conformation being either equatorial–axial or equatorial–equatorial. For all systems except one, h^E is very small so that the representative points for h_v^E situated between 0.20 and 0.95 J cm^{-3} for $\alpha = 1.13 \times 10^{-3}$ K^{-1} are quite outside the main curve. h_v^E is almost zero (<0.1 J cm^{-3}) (11) for *c*-C_6 mixed with *c*-C_7 and *c*-C_8. This means that the other cycloalkanes keep the cohesive energy of *c*-C_6 unchanged. Surprisingly, the *cis*-1,3-dimethylcyclohexane with its two equatorial methyl groups has a large h^E value and produces apparently the same effect as the branched alkanes, or the NR_3 or SnR_4 compounds of loosening the *c*-C_6 "structure". ((⬡) in Fig. 1).

Excess heat capacities

SnR_4 systems

In Table 4 of Part 1 the expected temperature dependence of the known contributions to h^E is given and consequently the expected c_p^E for each contribution. The total c_p^E may either be the balance of the different c_p^E or it may reflect the dominance of one contribution as is often the case for h^E (disorder) or h^E (free volume). The occurrence of $h^E > 0$ and $c_p^E > 0$, which means that the heat of mixing becomes more endothermic at higher temperature, is not listed because it does not correspond to any of the usual contributions described for non-polar systems in the present work. However, the experimental curve of Fig. 1*b* would provide an obvious reason for having in *c*-C_6 mixtures a positive c_p^E. When *T* increases, the h^E for systems with a free volume lower than that of *c*-C_6 should be moving towards higher values corresponding to systems with larger α. Furthermore, one would expect that the fastest changes in h^E would occur for systems situated in the lower part of the $h^E(\alpha)$ curve. The *c*-C_6 + SnR_4 systems fall in this category of $h^E > 0$ and $c_p^E > 0$ systems with c_p^E ranging from 0.8 to 2.8 J K^{-1} mol^{-1}. A confirmation of the hypothesis that, in the SnR_4 + *c*-C_6 systems, the main contribution to h^E comes from the change of cohesion or order in *c*-C_6 induced by a change in the free volume of the solution, can be seen in Fig. 1*b*, where $(c_p^E)_v$ has been plotted against α. $(c_p^E)_v$ is seen to go through a maximum for $SnPr_4$. This maximum of $(c_p^E)_v$ with $SnPr_4$ is due to this system approaching the domain of free volume (or of α) corresponding to the fastest change in the state of rotation of *c*-C_6. With $SnEt_4$ and $SnBut_4$, the $(c_p^E)_v$ are smaller because the change of rotation has reached its peak at 25°C in $SnEt_4$ mixtures and is on the contrary too far away in temperature for the $SnBut_4$ solutions.

Other systems

c_p^E have been obtained for several branched nonanes (such as 2,2,4,4-tetramethylpentane, 3,3-diethylpentane) mixed with *c*-C_6 (Huu Tra Van and D. Patterson, to be published). The fact that the $c_p^E(x)$ have an *S*-shaped curve with maxima around +0.3 and −0.3 J K^{-1} mol^{-1} makes it difficult to predict the change of h^E with *T*. The c_p^E obtained for three highly branched alkanes (2,2,4-trimethylpentane, 2,2,4,6,6-pentamethylheptane, and 2,2,4,4,6,8,8,-heptamethylnonane are negative and small (−0.12, −0.22, −0.55 J K^{-1} mol^{-1}) (7). It is possible that the temperature dependence of the effect of the branched alkanes on *c*-C_6 is different from that of the SnR_4 compounds due to their quite different shape. An indication of this fact can be seen in Fig. 1*a* where a line going only through the branched alkanes (△) would increase more gently with α than the main curve.

NR_3 systems

Table 2 lists the c_p^E of the NR_3 + *c*-C_6 systems which are all negative, in contrast to those for the SnR_4 + *c*-C_6 mixtures. The free volume contribution (varying between −0.07 and −0.15 J mol^{-1} K^{-1}) represents only a small part of the experimental value. The decrease of h^E with *T* predicted for the NR_3 + *c*-C_6 systems is encountered in ordered pure components whose order diminishes through thermal agitation with temperature. It is possible that a small contribution in the total h^E comes from a disordering type contribution to h^E. The structure or order in the pure NR_3 compounds may be due to the non-symmetrical character of these molecules whose arrangement in the liquid at 25°C may involve some kind of order among the molecules, in order to avoid the electron pair of the nitrogen atom of two NR_3

molecules being next neighbours. In the more isotropic SnR_4 molecules such structure would not be necessary. The sign of c_p^E for the above system does not put in question the interpretation of the data given in Fig. 1*b*. Due to the moderate magnitude of the positive and negative c_p^E, a $h^E(\alpha)$ curve with the same overall trend is likely to be found even at temperatures higher than 25°C.

Excess volumes

Table 3 gives the V^E values at the maximum and the concentration of the maximum, the Redlich–Kister parameters, and the calculated V^E obtained from the sum of the usual three contributions $V^E(h^E)$, $V^E(P^*)$, and V^E(f.v.). As said more explicitly in Part 1, $V^E(h^E)$ has the sign of h^E, V^E(f.v.) is always negative, and $V^E(P^*)$ is proportional to $(\tilde{v}_1 - \tilde{v}_2)(P_1^* - P_2^*)$. This last term goes from negative to positive in the two series because $\tilde{v}_1 - \tilde{v}_2$ changes sign in the series, but not $P_1^* - P_2^*$ which is always > 0 due to the higher P^* value of c-C_6. The sixth column gives $V^E - V^E$(calcd). The agreement between the experimental and calculated values is very good. Possibly, the more positive values obtained with volatile second components may have a physical significance, that reveals that an increase of volume is needed to accommodate the increase of motion in c-C_6.

The electrochemical behavior and structure of silver salts of imides and carboxamides[1,2]

JEAN-YVES HUOT,[3] DENIS SERVE,[4] AND JEAN LESSARD[5]

Département de chimie, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received September 30, 1982

JEAN-YVES HUOT, DENIS SERVE, and JEAN LESSARD. Can. J. Chem. **61**, 1890 (1983).

Silver salts of amides (imides and carboxamides), containing silver cations and amide anions in a one-to-one ratio, have been studied by electrochemical, potentiometric, and spectroscopic means. They have the structure [Amide–Ag–Amide]Ag with a linear nitrogen–silver–nitrogen bond and a silver cation loosely bound to the oxygens of the amide moieties. For instance, (*i*) the electrochemical data show that half of the silver ions are tightly bound (more difficult to reduce); (*ii*) only the loosely bound half can be titrated with chloride ions; (*iii*) according to ^{1}H and ^{13}C nmr spectroscopy, the silver salt of succinimide (**1**) is symmetric. The selective reduction of the loosely bound silver ions in acetonitrile containing tetraethylammonium tetrafluoroborate consumes 0.5 F/mol and leads to the mixed salt [Amide–Ag–Amide]Et_4N; further reduction at a more negative potential leads to the formation of the tetraethylammonium salt, Et_4NAmide. The latter two salts derived from succinimide have been prepared by a chemical route. The silver, mixed silver–tetracthylammonium, and tetraethylammonium salts are electroactive in oxidation.

JEAN-YVES HUOT, DENIS SERVE et JEAN LESSARD. Can. J. Chem. **61**, 1890 (1983).

Nous avons étudié, par des méthodes électrochimiques, potentiométriques et spectroscopiques, quelques sels d'argent d'amides (imides et carboxamides) formés par une mélange équimolaire de cations argent et d'anions d'amides. Les résultats permettent de déduire la structure [Amide–Ag–Amide]Ag comportant une liaison azote–argent–azote linéaire et un cation argent faiblement lié aux oxygènes des groupements amides. Par exemple, (*i*) les études électrochimiques montrent que la moitié des ions argent sont fortement liés (plus difficle à réduire); (*ii*) uniquement les cations argent faiblement liés peuvent être titrés par les ions chlorures; (*iii*) selon les spectres rmn de proton et du carbone-13, le sel d'argent du succinimide (**1**) est symétrique. La réduction sélective des ions argent faiblement liés, dans l'acétonitrile contenant du tétrafluoroborate de tétraéthylammonium, donne le sel mixte [Amide–Ag–Amide]Et_4N; une réduction plus poussée à un potentiel plus négatif conduit au sel de tétraéthylammonium, Et_4NAmide. Ces deux derniers sels ont été préparés par voie chimique dans le cas du succinimide. Les sels d'argent, les sels mixtes d'argent et de tétraéthylammonium et les sels de tétracthylammonium sont électroactifs en oxydation.

Introduction

Our interest in the oxidation of imide and amide anions in a nonaqueous medium led us to prepare their silver salts which are more soluble in acetonitrile than the alkali metal salts. Furthermore, the silver salts should be readily converted to tetraalkylammonium salts by deposition of silver on a cathode in a medium containing a tetraalkylammonium salt as supporting electrolyte.

The silver salt of formanilide was prepared by Comstock and Kleeberg (1) in 1890 and those of benzamide, proprionamide, and acetamide by Titherley (2) in 1897. Conductometric (3) and electrochemical (4) studies of the silver salt of acetamide in melted acetamide led to the identification of a soluble 2:1 (amide anion – silver ion) complex, $[(CH_3CONH)_2Ag]Na$, and an insoluble 1:1 complex, $CH_3CONHAg$. From studies on the site of alkylation of ambident anions, Stein and Tan (5) concluded that, in the silver salts of carboxamides, the silver ion (a soft acid) is bound to the nitrogen (the softer site of the amide anion).

Thermodynamic analysis of the silver salt of succinimide in water revealed the existence of a 1:1 and a 2:1 complex (6); the small contribution from entropy would be characteristic of a soft–soft (nitrogen–silver ion) interaction. According to potentiometric and thermodynamic data on silver complexes of uracil, the monoanion forms a 2:1 complex and the dianion, a 1:1 complex (7). In the dianion salt, one silver ion would be attached to the more basic nitrogen and the other to the neighboring carbonyl group (7). Recently, Guay and Beauchamp (8) have reported the X-Ray crystallographic structure of the silver salt of 1-methyl thymine: two imide anions are bound to one silver ion through the nitrogens and in a linear fashion.[6]

This paper deals with the structure of some silver salts of imides and carboxamides determined from electrochemical, potentiometric, and spectroscopic data.

Results and discussion

The stoichiometry of the silver salts of imides and carboxamides corresponds to a one-to-one ratio of amide anion and silver cation according to the method of preparation and to the analytical data (see the Experimental). The electrochemical behavior of the silver salt of succinimide, AgSucc (**1**), on a platinum electrode and in acetonitrile containing tetraethylammonium tetrafluoroborate (TEAFB) as supporting electrolyte, is summarized in Table 1 and is representative of the behavior of the other silver salts.

The linear voltammogram of **1** (Fig. 1, A) shows three diffusion controlled waves having the same amplitude (I_l/C): one

[6]The X-ray structure of gold(I) salt of *N*-methyl hydantoin also shows a nitrogen–gold(I)–nitrogen linear bond with two amide anions (9). A 2:1 structure has been accepted since 1940 for the mercuric complexes of succinimide and acetamide (10). Like the Ag^+ ion, the Au^+ and Hg^{2+} ions have a d^{10} configuration.

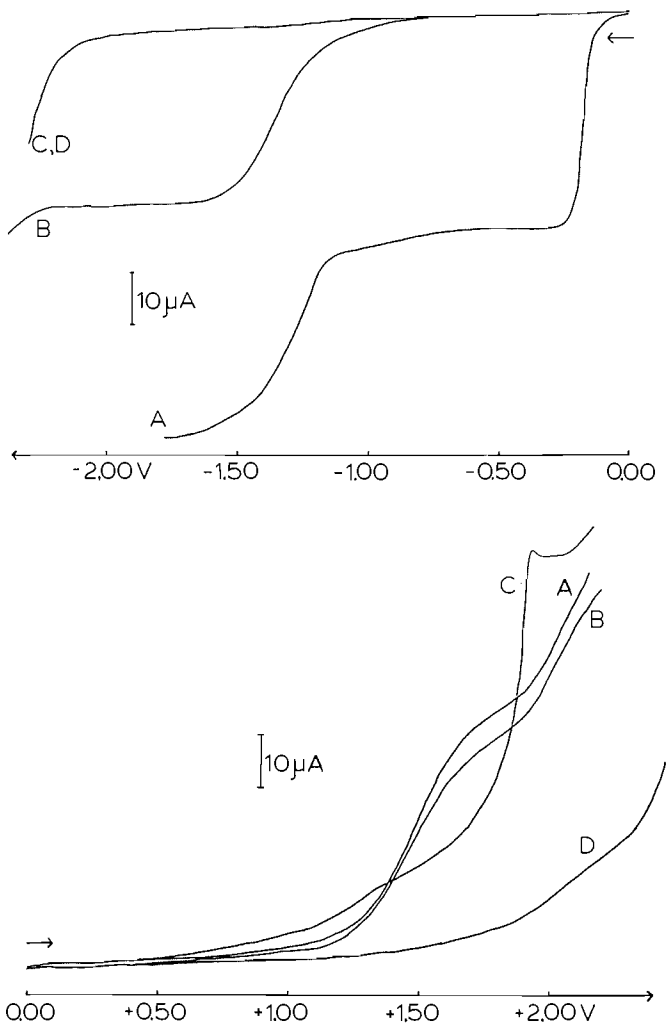

FIG. 1. Linear voltammetry of [Succ–Ag–Succ]Ag (**1**) in acetonitrile–TEAFB (0.1 *M*) on a Pt electrode (ω = 600 rpm, sweep rate = 16 mV/s): A, before reduction; B, after reduction at −0.50 V; C, after reduction at −1.50 V; D, residual current.

anodic wave and *two cathodic waves*.[7] The corresponding cathodic peaks of the cyclic voltammogram are shown in Fig. 2, A; the large anodic peak at 0 V is due to the oxidation of Ag^0 deposited on the electrode during the cathodic sweep. Upon reduction at −0.50 V, 50% of the silver present in **1** is deposited. The first cathodic wave disappears while the second cathodic wave and the anodic wave remain unchanged (Fig. 1, B). The cyclic voltammogram (Fig. 2, B) shows the second cathodic peak only and a new anodic peak at −0.29 V. There is no change in the uv spectrum (Table 1). Further reduction at −1.50 V leads to the deposition of the remaining 50% of the silver initially present in **1**. In the uv spectrum, there is a small bathochromic shift and an hyperchromic effect. The linear voltammogram (Fig. 1, C) shows the anodic wave only, which now appears at a more anodic potential; its amplitude has increased by a factor of two (Table 1).

The above results can only be accounted for if salt **1** has the structure [Succ–Ag–Succ]Ag in which there are two different types of silver ions in a one-to-one ratio. The silver ion tightly bound to two succinimide anions should be more difficult to reduce than the other. Therefore, the first cathodic wave ($E_{1/2}$ = −0.2 V) corresponds to process [1] and the second cathodic wave ($E_{1/2} \simeq -1.35$ V), to process [2].

[1] [Succ–Ag–Succ]Ag + Et_4NBF_4 + $e^- \xrightarrow{-0.2\ V}$ **1** [Succ–Ag–Succ]Et_4N + Ag^0 + BF_4^- **1***a*

[2] [Succ–Ag–Succ]Et_4N + Et_4NBF_4 + $e^- \xrightarrow{-1.35\ V}$ **1***a* 2 Et_4NSucc + Ag^0 + BF_4^- **1***b*

[7]The fact that the αn value for the first cathodic wave is larger than 1.0 can probably be ascribed to the modification of the nature and surface of the electrode with the deposition of Ag^0. The same phenomenon was observed when reducing silver nitrate on platinum in acetonitrile–TEAFB (0.1 *M*) (see Table 3, last entry). The αn values have been obtained by plotting log $[(i_l - i)/i]$ versus potential according to the relationship given in ref. 11 for irreversible processes.

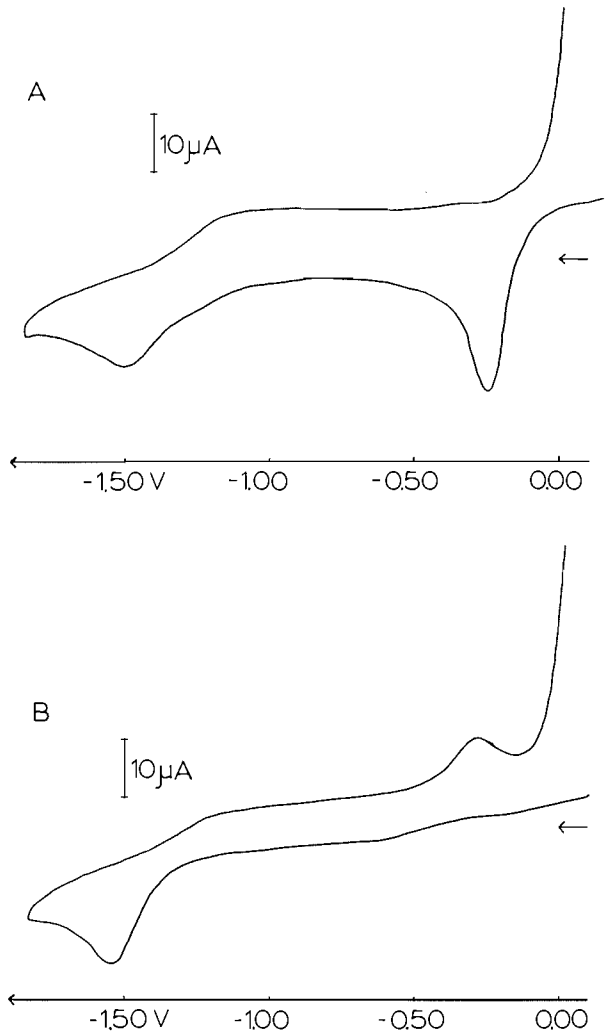

FIG. 2. Cyclic voltammetry of [Succ–Ag–Succ]Ag (**1**) in acetonitrile–TEABF (0.1 *M*) on a Pt electrode (sweep rate = 200 mV/s): A, before reduction; B, after reduction at −0.50 V.

The mixed silver tetraethylammonium salt **1***a* and the tetraethylammonium salt **1***b* have been prepared chemically (see the Experimental) and their electrochemical and uv spectroscopic behavior were identical to those of the species obtained from the electrochemical reduction of AgSucc (**1**) after passing 0.49 F/mol at −0.50 V, then 0.52 F/mol at −1.50 V, respectively. The mixed salt **1***a* is oxidized at the same potential and gives a uv spectrum practically identical to that of the silver salt **1** in agreement with the conclusion that the same species, the Succ–Ag–Succ anion, is involved in both salt **1** and salt **1***a*. Reduction of **1***a* at −1.50 V liberates two succinimide anions (eq. [2]), which accounts for the two-fold increase of the amplitude of the anodic wave.[8] The succinimide anion (see **1***b*) is more difficult to oxidize ($E_{1/2}$ = +1.90 V) and absorbs at a longer wavelength (λ_{max} = 227 nm) than the Succ–Ag–Succ anion (see **1** or **1***a*, $E_{1/2}$ = +1.48 V, λ_{max} = 223 nm). The extinction coefficient of 4500 L mol^{-1} cm^{-1} reported for **1** and **1***a* (Table 1) is based on the concentration of succinimide anions; it becomes 9000 (as compared to 11 000 for **1***b*) when based on the concentration of Succ–Ag–Succ anions.

Further confirmation of structure [Succ–Ag–Succ]Ag for **1** is provided by the following potentiometric and amperometric titrations. First, as shown in Table 3, only half of the silver ions present in **1**, the loosely bound ones, can be titrated with tetraethylammonium chloride (eq. [3]). The protonolysis of **1** with nitric acid (eq. [4]) liberates the tightly bound silver ions

[3] $\underset{\mathbf{1}}{[Succ-Ag-Succ]Ag} + Et_4NCl \rightarrow \underset{\mathbf{1}a}{[Succ-Ag-Succ]Et_4N} + AgCl$

[4] $\underset{\mathbf{1}}{[Succ-Ag-Succ]Ag} + 2HNO_3 \rightarrow 2HSucc + 2AgNO_3$

which can then be titrated with chloride ions (Table 3). Secondly, the potentiometric titration of silver nitrate with the sodium salt of succinimide in 50% ethanol gives one end point at 2.0 equivalents (Fig. 3) and is thus described by reaction [5]. Thirdly, the amperometric titration of the tetraethylammonium

[5] $AgNO_3 + 2NaSucc \rightarrow [Succ-Ag-Succ]Na + NaNO_3$

salt of succinimide (**1***b*) with silver nitrate (Fig. 4) shows clearly that the mixed silver–tetraethylammonium salt **1***a*, where only the tightly bound silver ions are present, is formed first (eq. [6]). Indeed when about 0.4 equivalent of silver nitrate has been added, the cyclic voltammogram shows a

[6] $\underset{\mathbf{1}b}{2Et_4NSucc} + AgNO_3 \rightarrow \underset{\mathbf{1}a}{[Succ-Ag-Succ]Et_4N} + Et_4NNO_3$

[7] $\underset{\mathbf{1}a}{[Succ-Ag-Succ]Et_4N} + AgNO_3 \rightarrow \underset{\mathbf{1}}{[Succ-Ag-Succ]Ag} + Et_4NNO_3$

cathodic peak at −1.45 V, an anodic peak at −0.20 V, and the large anodic peak at 0 V; thus, this voltammogram corresponds to the cyclic voltammogram of **1***a* (see Fig. 2, B). As more silver nitrate is added, the cathodic peak at −0.20 V due to the reduction of the loosely bound silver ions in **1** first appears, then increases in intensity,[9] while the intensity of the cathodic peak at −1.45 V remains more or less constant (Fig. 4). The anodic peak at −0.30 V decreases in intensity and disappears when **1***a* has been completely converted to **1** (eq. [7]). Finally, the amperometric titration of the silver salt **1** with the tetraethylammonium salt **1***b* followed by cyclic voltammetry (Fig. 5) shows clearly the formation of the mixed silver–tetraethylammonium salt **1***a*, according to eq. [8]. As salt **1** is converted to salt **1***a*, the amount of loosely bound silver ions

[8] $\underset{\mathbf{1}}{[Succ-Ag-Succ]Ag} + \underset{\mathbf{1}b}{2Et_4NSucc} \rightarrow 2\underset{\mathbf{1}a}{[Succ-Ag-Succ]Et_4N}$

(limiting current of the cathodic peak at −0.20 V) decreases while that of the tightly bound silver ions (limiting current of the cathodic peak at −1.45 V) increases. Surprisingly, when the loosely bound silver ions (salt **1**) have completely disappeared, further addition of succinimide anions leads to a steeper increase of the limiting current at −1.45 V; a plateau is reached when about 2 equivalents of **1***b* have been added, as if the effective concentration of tightly bound silver ions (of **1***a*) was

[8]The *n* value for the oxidation of the Succ–Ag–Succ anion is ≤1.2 and that for the oxidation of the succinimide anion is 0.97 (see footnote 11).

[9]Since the peak potentials for the reduction of $AgNO_3$ and the reduction of the loosely bound silver ion of **1** are quite close, a single peak at ca. −0.2 V is observed when the two species are present, that is, when there is an excess of $AgNO_3$.

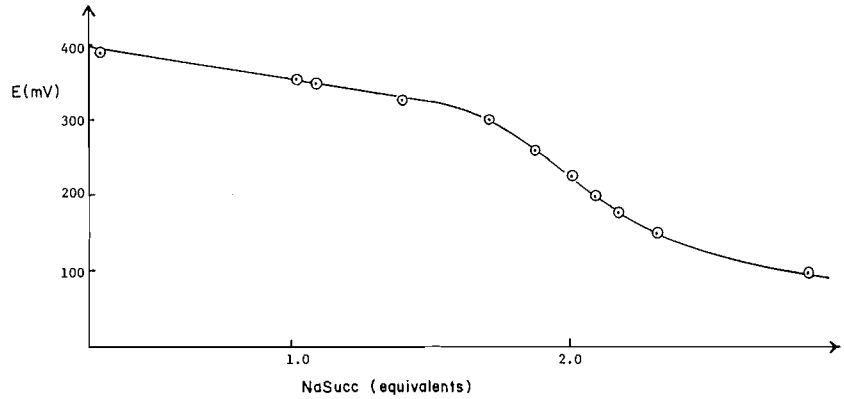

FIG. 3. Potentiometric titration of silver nitrate by the sodium salt of succinimide in 50% ethanol.

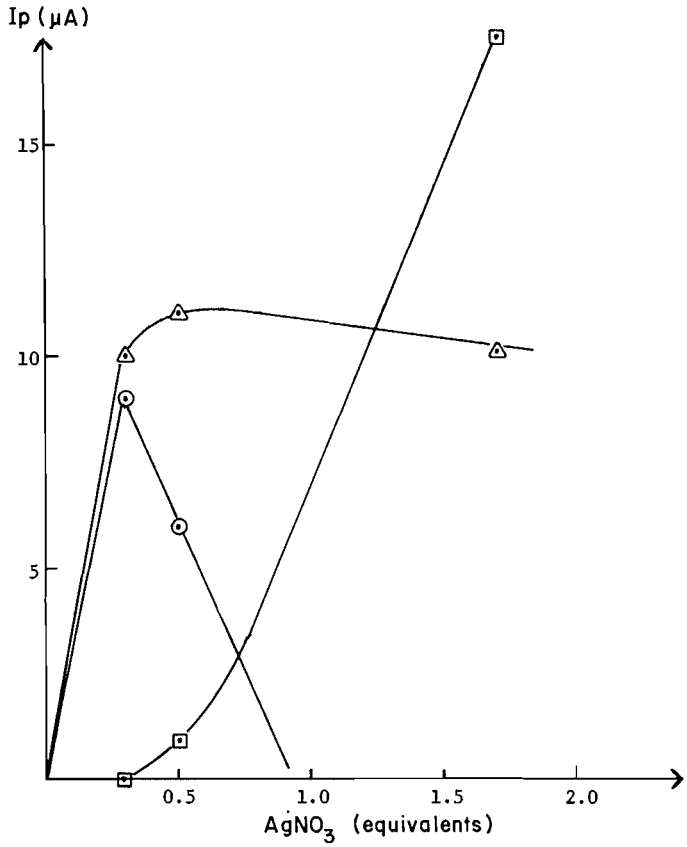

FIG. 4. Amperometric titration (cyclic voltammetry) of Et_4NSucc (**1***b*) (prepared by reduction of AgSucc (**1**) (3.40 m*M*) at −1.70 V in acetonitrile–TEAFB (0.1 *M*)) by silver nitrate: △, current of the cathodic peak at −1.48 V; ⊡, current of the cathodic peak at −0.20 V; ⊙, current of the anodic peak at −0.30 V.

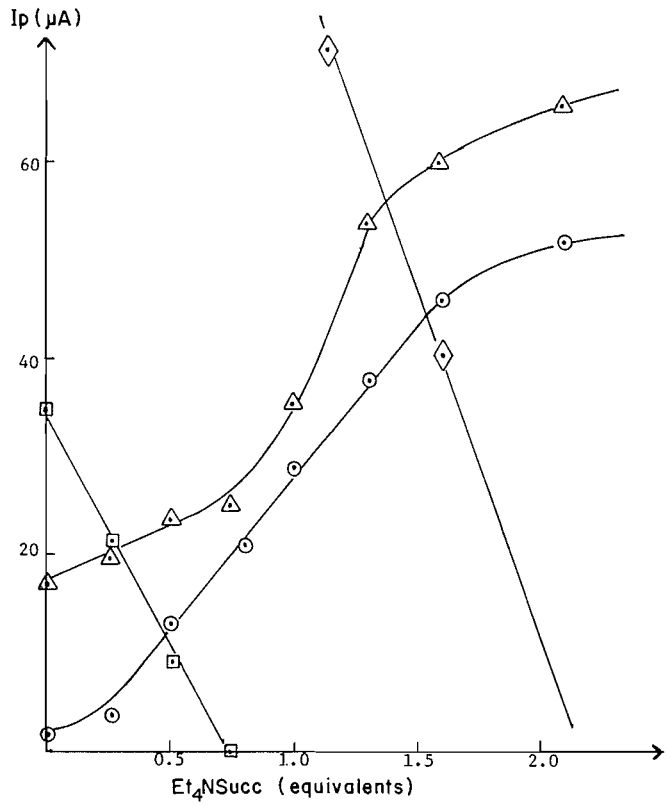

FIG. 5. Amperometric titration (cyclic voltammetry) of [Succ–Ag–Succ]Ag (**1**) (4.39 m*M*) by Et_4NSucc (**1***b*) (the equivalents of **1***b* are calculated using the formula AgSucc for **1**) in acetonitrile–TEAFB (0.1 *M*): △, current of the cathodic peak at −1.45 V; ⊡, current of the cathodic peak at −0.20 V; ⊙, current of the anodic peak at −0.30 V; ◇, current of the anodic peak at 0 V.

twice as large in the presence of a 100% excess of succinimide anions. We have no satisfactory explanation for that phenomenon.

The origin of the anodic peak at −0.30 V in the cyclic voltammogram of the mixed salt **1***a* (Fig. 2, B) can be ascribed to the oxidation of electrodeposited silver to a tightly bound silver ion in the presence of succinimide anions at the surface of the electrode (eq. [9]). Succinimide anions are liberated by

$$[9]\quad Ag^0 + 2Succ^- \xrightarrow{-0.30\ V} [Succ{-}Ag{-}Succ]^- + e^-$$

$$[10]\quad Ag^0 + BF_4^- \xrightarrow{0\ V} Ag^+BF_4^- + e^-$$

the reduction of tightly bound silver ions (reduction of **1***a*, eq. [2]) during the cathodic sweep. However, because reaction [8] is rapid, succinimide anions cannot be present at the electrode, during the anodic sweep, as long as there is still some salt **1** left. Indeed, as shown in Figs. 4 and 5, the anodic peak at −0.30 V appears only when there are no more loosely bound silver ions left. Furthermore, its limiting current increases with the concentration of succinimide anions. In Fig. 4, the maximum value of the limiting current at −0.30 V corresponds to the highest concentration of mixed salt **1***a*, as expected. In Fig. 5, however, the limiting current reaches a plateau when there is a 100% excess of succinimide anions with respect to salt **1**, a phenomenon which is also observed for the cathodic wave at

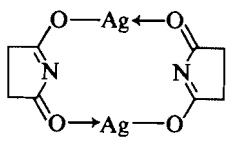
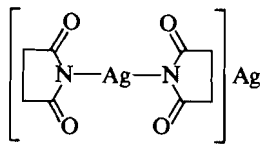
−1.45 V and for which we cannot provide a satisfactory explanation as stated above. In the absence of succinimide anions, all the electrodeposited silver is oxidized according to eq. [10]. Since there is a large excess of tetrafluoroborate anions, the rate of this process is limited by the diffusion of silver ions into the solution and the current of the anodic peak at 0 V is large; this current decreases as the peak at −0.30 V (the amount of succinimide anions) increases, as expected (see Fig. 4).

The fact that there are two types of silver ions in silver salt **1** derived from succinimide eliminates structure A in which the two silver ions would be equivalent. The ^1H and ^{13}C nmr data recorded in Table 2 show clearly that the [Succ–Ag–Succ]Ag complex (**1**) must be symmetric and have structure B in which the tightly bound silver ion is linked linearly to each nitrogen of the two succinimide anions. Indeed, the eight protons of the two succinimide moieties give rise to a singlet; the four carbons



A



B

of the carbonyl groups give a single signal, as do the four carbons of the methylene groups. The loosely bound silver ions, which are more difficult to reduce ($E_{1/2}$ = −0.20 V) than silver nitrate ($E_{1/2}$ = −0.10 V), probably interact with the carbonyl groups of the two succinimide anions. In solution, this interaction is not strong enough to make the rotation around the N—Ag—N bond a slow process on the nmr time scale. Structure B is in agreement with the classical theory according to which an Ag—N bond should be stronger than an Ag—O bond (12). It also agrees perfectly with the X-ray crystallographic structure of the silver salt of 1-methyl thymine determined by Guay and Beauchamp (8): half of the silver ions are bound linearly to the nitrogens of two imide anions and the other half interact with four carbonyl groups. The nmr and ir data for the mixed silver–tetraethylammonium salt **1***a* (Table 2) are very similar to those for the silver salt **1** since the same species, the Succ–Ag–Succ anion, is responsible for the absorptions. We have already pointed out the similarity of the uv spectra (Table 1).

As shown in Table 3, the electrochemical and potentiometric behavior of all the silver salts studied is perfectly analogous to that of salt **1**. Reduction at a potential ($-E_{appl} \simeq -E_{1/2}$ + 200 mV) corresponding to the first cathodic wave leads to the deposition of only 50% of the silver ions and the remaining 50% are deposited upon reduction at a potential corresponding to the second cathodic wave. Thus, all the silver salts must have the same [Amide–Ag–Amide]Ag structure. The silver salts and the corresponding mixed tetraethylammonium salts are oxidized at nearly the same potentials as in the case of salts **1** and **1***b* derived from succinimide (see Fig. 6 for salts **5** and **5***a* derived from benzoylimide). The tetraethylammonium salts of glutarimide (**2***b*) and phthalamide (**4***b*) are more difficult to oxidize than the corresponding silver (**2** and **4**) and mixed silver–tetraethylammonium (**2***a* and **4***a*) salts as in the succinimide case (see Table 1 and Fig. 1, C), whereas the reverse situation is found for the tetraethylammonium salts of tetramethylsuccinimide (**3***b*), benzoylimide (**5***b*) (see Fig. 6), and formanilide (**6***b*). The oxidation of the silver salt of formanilide (**6**), a carboxamide, is much easier than that of silver salts of imides because the energy of the HOMO of the Amide–

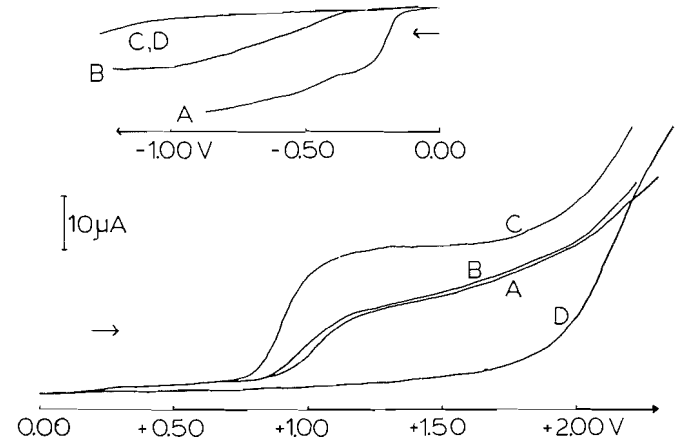


FIG. 6. Linear voltammetry of the silver salt of benzoylimide (**5**) (2.15 m*M*) in acetonitrile–TEAFB (0.1 *M*) on a Pt electrode (ω = 600 rpm, sweep rate = 16 mV/s): A, before reduction; B, after reduction at −0.25 V; C, after reduction at −0.90 V; D, residual current.

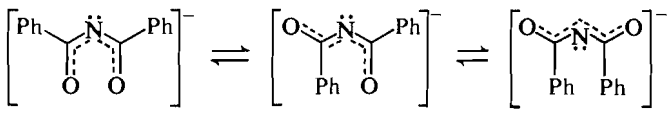


trans–trans *cis–trans* *cis–cis*

SCHEME 1

Ag–Amide anion must be lower when the anionic ligands are derived from an imide (two carbonyl groups) than when they are derived from a carboxamide (one carbonyl group) (13). We could not obtain a satisfactory oxidation wave for the silver salt of benzamide (**7**).[10]

The silver salt of benzoylimide (**5**) is the sole salt derived from an acyclic imide and is less stable than the other salts. We also tried to prepare $[(CH_3\overset{O}{\overset{\|}{C}})_2N—Ag—N(\overset{O}{\overset{\|}{C}}CH_3)_2]Ag$ but this salt was still less stable and was too sensitive to hydrolysis to be isolated and studied under the standard conditions. The electrochemical behavior of salt **5** is somewhat different from that of the other silver salts since the two cathodic waves are separated by about 0.3 V as compared to 1.1–1.3 V for the other salts. Furthermore, as shown in Fig. 6, the second cathodic wave is not very well defined, being spread over a 0.5 V range. In salt **5**, the ligands (the benzoylimide anions) could *a priori* exist under the three planar conformations shown (Scheme 1). For the free anion, the *cis–cis* conformation should be much less stable than the two others because of steric interactions between the two phenyl rings which would tend to orient themselves into the OCNCO plane to allow some delocalization of the electrons of the imide anion onto the aromatic rings. However, if the *cis–cis* benzoylimide ((*cis–cis*)Bzmide) anion is a better ligand to Ag^+ than the two other conformers, the [(*cis–cis*)Bzmide–Ag–(*cis–cis*)Bzmide]$^-$ anion could be present in significant amount together with the other complex anions: [(*cis–trans*)Bzmide–Ag–(*cis–trans*)Bzmide]$^-$, [(*trans–trans*)Bzmide–Ag–(*trans–*

[10]Further work on the oxidation of the silver salts of imides and carboxamides is in progress and will be reported in a forthcoming paper.

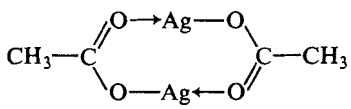
TABLE 4. Ultraviolet spectral data of the salts of imides and carboxamides in acetonitrile–TEABF (0.01 *M*)[a]

Silver salt of	Concentration[b] (10^{-4} *M*)	$\lambda_{max}(\epsilon)$(nm) Before reduction	After reduction 0.5 F/mol	After reduction 1 F/mol	Parent amide[c]
Succinimide (**1**)	3.35	223(4500)[d]	223(4500)[d]	227(11 000)[d]	224(100), 230 (93), 245(73)
Glutarimide (**2**)	1.02	231(9000)	213(9300)	237(9900)	233(215), shoulder
Tetramethyl-succinimide (**3**)	2.34	227(4000)	227(4150)	230(5750)	233(150), 251(130)
Phthalimide (**4**)	1.58	230(15 600) 236(15 500) 226(9100)	230(15 700) 236(15 600) 226(9100)	230(17 850) 238(17 200) 246(10 400)	230(9600), 238(9200), 234(8400)
Benzoylimide (**5**)	0.28	241(28 000)	—	237(21 000)	243(22 400)
Formanilide (**6**)	0.95	242(10 500) 209(8900)	242(11 000) 209(9500)	242(11 000)	243(12 900)

[a]0.5 mL of the electrochemical solution was diluted to 5 mL with dry acetonitrile.
[b]Based on the concentration of amide anions.
[c]In dry CH_3CN without any supporting electrolyte.
[d]Taken from Table 1.

trans)Bzmide]$^-$, [(*cis*–*cis*)Bzmide–Ag–(*cis*–*trans*)Bzmide]$^-$, etc. The fact (*i*) that salt **5** is less stable than the other silver salts, and (*ii*) that the reduction of the tightly bound silver ion in **5** and **5***a* occurs at potentials lower than those observed with the other silver and mixed silver–tetraethylammonium salts, shows that the benzoylimide anion binds Ag^+ less tightly than a carboxamide anion or a cyclic imide anion. The presence of a mixture of benzoylimide–Ag–benzoylimide complexes, which differ from one another by the conformation of the benzoylimide anions and which have different reduction potentials, could explain the spreading of the cathodic wave due to the reduction of [Bzmide–Ag–Bzmide]$^-$ in **5** and **5***a*.

We have included silver acetate in Table 3 for comparison purposes. The low cathodic half-wave potential as well as the precipitation of 100% of the silver ions by tetraethylammonium chloride shows that Ag—O bonds are weaker than Ag—N bonds and thus confirms the conclusions of the classical theory (12). The structure of silver carboxylates has been determined by potentiometry (14), linear voltammetry (15), and X-ray diffraction (16–18) and corresponds to:



The one cathodic wave and the one cathodic peak observed in the voltammograms for silver acetate show that the silver ions are all equivalent, in agreement with the structure shown above.

Table 4 summarizes the uv spectral data, in acetonitrile, of the various salts studied. The parent amides (imides and carboxamides) are included for comparison. As in the case of succinimide, the uv spectra before any reduction and after reduction of the loosely bound silver ions (0.5 F/mol) are identical because the same species, the amide–Ag–amide anion, is responsible for the absorption. The salts derived from imides bearing no aromatic ring(s) show a large hyperchromic effect when compared to the parent imide. However, since succinimide shows a strong band at 190 nm (ϵ = 15 000) in acetonitrile (19), the formation of the imide anion must be accompanied by a ca. 35 nm bathochromic shift of the 190 nm band.[11] As for salt **1***a* (0.5 F/mol), further reduction of salts **2***a* and **3***a* to give the corresponding tetraethylammonium salts **2***b* and **3***b* (1 F/mol) is accompanied by a small bathochromic shift. However, the hyperchromic effect was observed only in the case of salt **1***a*.

Experimental

General

Melting points were determined on a Buchi apparatus and are uncorrected. Infrared (ir) spectra were obtained using a Perkin–Elmer 257 spectrophotometer. Ultraviolet (uv) spectra were recorded with a Varian–Techtron 635 spectrophotometer. Proton magnetic resonance (^{1}H nmr) spectra were measured using Bruker WP-60 and Varian A-60 instruments. Carbon magnetic resonance (^{13}C nmr) spectra were recorded on a Bruker HX-90 spectrometer. Mass spectra were taken on Hitachi RMU-6E instrument. Microanalysis were carried out by Mr. H. Seguin, National Research Council of Canada, Ottawa.

Solvent and electrolyte

Technical grade acetonitrile was purified as reported in ref. 21. Tetraethylammonium tetrafluoroborate (TEAFB), prepared from tetrafluoroboric acid and tetraethylammonium bromide (22), was recrystallized from 95% ethanol until the silver ion test was negative. It was then dried in a vacuum oven for 2 days at 80°C.

Electrochemical instrumentation and methods

Solutions were deoxygenated with dry and oxygen-free nitrogen saturated with acetonitrile. A nitrogen atmosphere was maintained over the solutions throughout the experiments. A three-electrode system and a PAR cell (type K0060) were used for the voltammetric analyses and the electrodepositions of silver. The auxiliary electrode was a platinum wire. Potentials were measured with respect to an Ag^0/Ag^+ (0.01 *M*) electrode (23).

The voltammetric analyses were carried out with a homemade potentiostat. A Tacussel rotating electrode type ED1 (with Controvit speed controller) having a platinum 20 mm^2 disc was used at rotation rates of 500 to 5000 rpm for the linear voltammograms; the sweep rate was 16 mv/s. The same electrode served as a stationary electrode for the cyclic voltammograms; the sweep rate was 200 mV/s. The plat-

[11]The ionization of phenol to phenolate causes a 25 nm bathochromic shift of the 210 nm band (20).

inum disc was washed with nitric acid, rinsed with water, dried, then polished on a Carbimet-600A paper (Buehler) before each use.

The electrodepositions of silver were performed with a Tacussel type ASA-100 potentiostat having both a Tacussel type IG-5 integrator and an ammeter connected in series within the auxiliary circuit. The working electrode was a 18 cm^2 platinum plate. After the deposition of silver, the electrode was washed with acetonitrile, dried, and the amount of silver deposited was determined by weight.

Amides and imides

Succinimide, glutarimide, phthalamide, and benzanilide were obtained from commercial sources.

Tetramethylsuccinimide

It was prepared according to the method described by Bickel and Waters (24) in a 22% yield, mp 186°C (lit. (23) mp 187–188°C); ν_{max} ($CHCl_3$): 3510, 3220, 1790 and 1740 cm^{-1}; δ ($CDCl_3$): 1.18 and 1.21 (not resolved, 12 H) and 8.56 ppm (m, NH).

Benzoylimide

It was obtained as described by Titherley (25) in a 10% yield; mp 144–145°C (lit. (24) mp 144°C); ν_{max} ($CHCl_3$): 3440, 3380, 1750, 1690, 1600, and 1580 cm^{-1}; δ ($CDCl_3$): 7.40 (m, 6H) and 7.75 ppm (m, 4H), the NH absorption could not be seen.

Formanilide

It was prepared in a 72% yield by refluxing equimolar quantities of aniline and formic acid for 5 h while removing water with a Dean–Stark separator, mp 47°C (lit. (26) mp 50°C); ν_{max} ($CHCl_3$): 3420, 3380, 1690, and 1600 cm^{-1}; δ ($CDCl_3$): 7.15–7.48 (5H), 8.32 (d, J = 1.7 Hz, 0.7H), and 8.66 ppm (d, J = 11.4 Hz, 0.3H). Thus the conformer with C—H and N—H in a *cis* relationship predominates.

Silver salts

Silver acetate is commercially available. The silver salts of imides and amides were prepared according to the following general procedure (27). Equimolar amounts of silver nitrate and imide or carboxamide were dissolved in 50% ethanol (between 1 and 2 mL per mol of amide except in the case of benzoylimide where 6 mL per mol of imide was used). The solution was heated to reflux and an equimolar quantity of sodium hydroxide (a 1.00 *M* or a 5.00 *M* aqueous solution) was then added dropwise and slowly. The precipitate formed was filtered, washed with 95% ethanol, then with ether. It was dried at room temperature and in the dark in a vacuum desiccator containing phosphorus pentoxide.

The ir spectra of all the silver salts in KBr show a broad band in the 1600 cm^{-1} region for the C=O stretching vibration and a broad absorption around 3400–3500 cm^{-1} due to the presence of water in the crystals. Except for the silver salt of succinimide (**1**), the silver salts of imides and carboxamides were generally not soluble enough in acetonitrile to yield satisfactory ir (dry CH_3CN) and nmr (CD_3CN–D_2O) spectra.

Salt 1 (succinimide)

It was isolated as a greyish solid, dec. at 250°C (72% yield); ν_{max} (CH_3CN): 3640 and 3540 (water), 1650 (C=O) cm^{-1}; δ (CH_3CN, 20% D_2O): 2.56 ppm (s). *Anal.* calcd. for $C_4H_4NO_2Ag \cdot \frac{1}{2}H_2O$: C 22.34, H 2.37, N 6.51, Ag 50.18; found: C 22.72, H 2.27, N 6.68, Ag 49.30.

Salt 2 (glutarimide)

It was isolated as a brown solid, dec. at 220°C (81% yield). *Anal.* calcd. for $C_6H_6NO_2Ag$: C 27.29, H 2.75, N 6.37, Ag 49.04; found: C 27.04, H 2.79, N 6.52, Ag 48.88.

Salt 3 (tetramethylsuccinimide)

It was isolated as a brown solid which melted above 280°C (69% yield). *Anal.* calcd. for $C_8H_{12}NO_2Ag$: C 36.64, H 4.58, N 5.34, Ag 41.20; found: C 36.17, H 4.43, N 5.17, Ag 40.70.

Salt 4 (phthalimide)

It was isolated as a beige solid melting above 345°C (92% yield). *Anal.* calcd. for $C_8H_4NO_2Ag \cdot \frac{1}{2}H_2O$: C 36.53, H 1.92, N 5.33, Ag 41.02; found: C 37.01, H 1.89, N 5.40, Ag 40.39.

Salt 5 (benzoylimide)

It was isolated as a brownish solid, mp 265°C (91% yield). *Anal.* calcd. for $C_{14}H_{10}NO_2Ag \cdot \frac{1}{2}H_2O$: C 49.46, H 3.27, N 4.12, Ag 31.73; found: C 49.67, H 3.22, N 4.04, Ag 31.48.

Salt 6 (formanilide)

It was isolated as a greyish solid, mp 182–185°C (90% yield). *Anal.* calcd. for $C_7H_6NOAg \cdot \frac{1}{2}H_2O$: C 35.47, H 2.98, N 5.91, Ag 45.51; found: C 35.97, H 2.75, N 6.02, Ag 47.01.

Salt 7 (benzamide)

The orange-brown solid obtained was not pure according to the elemental analysis and was most probably contaminated with silver oxide. *Anal.* calcd. for $C_7H_6NOAg \cdot \frac{1}{2}H_2O + \frac{1}{6}Ag_2O$: C 30.50, H 2.20, N 5.08, Ag 52.18; found: C 30.06, H 2.18, N 5.36, Ag 53.73.

Mixed silver–tetraethylammonium salt of succinimide (1a)

To a stirred mixture of succinimide (2.00 g, 20.2 mmol), tetraethylammonium hydroxide (14.4 mL of 1.40 *M* aqueous solution, 20.2 mmol), and water (15 mL) was added dropwise to a solution of silver nitrate (1.72 g, 10.1 mmol) in water (30 mL). No precipitation occurred. The reaction mixture took a greyish-blue color. The solvent was removed in a rotatory evaporator and the resulting greyish-blue solid was washed with methylene chloride, mp 190–192°C (3.26 g, 69%); ν_{max} (CH_3CN): 3620, 3540, and 3420 (water), 1640 (C=O) cm^{-1}; δ (CD_3CN, 20% D_2O): 1.20 (t of t, J = 8 and 2 Hz, 12H), 2.59 (s, 8H), and 3.16 ppm (q, J = 8 Hz, 8H). *Anal.* calcd. for $C_{16}H_{28}N_3O_4Ag \cdot 2H_2O$: C 40.85, H 6.87, N 8.94; found: 40.35, H 6.82, N 8.85.

Tetraethylammonium salt of succinimide (1b)

Tetraethylammonium bromide (42.0 g, 0.20 mol) was dissolved in the minimum amount of hot 95% ethanol. Silver sulfate (31.2 g, 0.10 mol) was added. Silver bromide was removed by filtration and the solvent was removed with a rotatory evaporator. The residue was recrystallized from ethanol–acetone to afford tetraethylammonium sulfate, mp 164–165°C (5.5 g, 15%). The sodium salt of succinimide was then prepared from succinimide (0.458 g, 4.6 mmol) and sodium ethoxide (30 mL of 0.15 *M* solution in absolute ethanol, 4.5 mmol). Tetraethylammonium sulfate (0.800 g, 2.25 mmol) in absolute ethanol (4 mL) was added to the previous solution which became clouded. Part of the solvent was removed in a rotatory evaporator. The addition of acetonitrile caused the quantitative precipitation of sodium sulfate which was removed by filtration. The solvent was stripped off in a rotatory evaporator, then the residue was dried in a vacuum desiccator over phosphorous pentoxide to afford salt **1***b* as a white solid, mp 72–73°C (sealed tube) (0.806 g, 76%); ν_{max} (CH_3CN): 3600 (b, water), 1650 and 1600 (C=O) cm^{-1}; δ (CD_3CN): 1.22 (t of t, J = 7 and 2 Hz, 12 H), 2.33 (s, 4H), and 3.20 ppm (q, J = Hz, 8H).

Sodium salt of succinimide

The salt was prepared from succinimide and sodium ethoxide (see above). It was also obtained *in situ* for the amperometric titration of silver nitrate by adding sodium hydroxide (1.30 mL of a 1.0 *N* solution, 1.30 mmol) to a solution of succinimide (0.127 g, 1.28 mmol) in 50% ethanol (250 mL).

Nuclear analogs of β-lactam antibiotics. XVII.[1] Stereospecific synthesis of penem and carbapenem precursors

ALAIN MARTEL,[2] JEAN-PAUL DARIS, CAROL BACHAND, MARCEL MÉNARD, TONY DURST,[3] AND BERNARD BELLEAU[4]
Bristol Laboratories of Canada, 100 Industrial Boulevard, Candiac, P.Q., Canada J5R 1J1

Received February 9, 1983

ALAIN MARTEL, JEAN-PAUL DARIS, CAROL BACHAND, MARCEL MÉNARD, TONY DURST, and BERNARD BELLEAU. Can. J. Chem. **61**, 1899 (1983).

The transformation of methyl 6-α-bromopenicillanate (**6**) to *N*-methoxalyl-(3*S*)-bromo-(4*R*)-chloro-2-azetidinone (**8**) is described. Azetidinone **8** was converted, in a stereoselective manner, to (3*S*)-bromo-(4*R*)-tritylthio-2-azetidinone (**9**). Subsequent reduction of the 4-bromo substituent with zinc afforded the chiral (4*R*)-tritylthio-2-azetidinone (**10**), a useful intermediate for the synthesis of penems. Azetidinone **8** was also converted to the reactive (3*S*)-bromo-(4*R*)-chloro-2-azetidinone (**11**). Treatment of the (4*R*)-chloroderivative **11** with *n*-butyl or allylcuprate afforded the (4*R*)-butyl and (4*R*)-allylazetidinones **12** and **13** as the predominant diastereomers. Finally, an improved synthesis of **11** to **13** using tetraallyltin is also described.

ALAIN MARTEL, JEAN-PAUL DARIS, CAROL BACHAND, MARCEL MÉNARD, TONY DURST et BERNARD BELLEAU. Can. J. Chem. **61**, 1899 (1983).

On décrit la transformation de l'α-bromo-6 pénicillanate de méthyle (**6**) en *N*-méthoxalyl-bromo (3*S*) chloro (4*R*) azétidinone-2 (**8**). On transforme l'azétidinone (**8**) d'une façon stéréosélective en bromo (3*S*) tritylthio (4*R*) azétidinone-2 (**9**). La réduction subséquente du brome en position 4, par le zinc, permet d'obtenir le composé chiral: la tritylthio (4*R*) azétidinone-2 (**10**), un intermédiaire utile pour la synthèse des pénems. On a également transformé l'azétidinone (**8**) en bromo (3*S*) chloro (4*R*) azétidinone-2 (**11**). La réaction du dérivé chloré (4*R*) (**11**) avec le *n*-butyle ou l'allylcuprate donne les butyles (4*R*) et les allyl (4*R*) azétidinones **12** et **13** comme diastéréoisomères majoritaires. On décrit également une synthèse améliorée des composés **11** à **13** qui fait appel au tétraallylétain.

[Traduit par le journal]

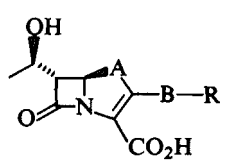
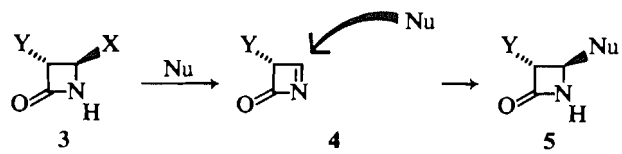
The discovery of thienamycin (**1**) (2) and the subsequent disclosure of the penem system (**2**) by Woodward (3) opened new synthetic challenges to organic chemists. The accessibility to both nuclei via a common chiral intermediate became highly desirable in terms of synthetic strategy. An enormous amount of work has already been documented for the manipulation and transformation of penicillins to various azetidinone nuclei (for a recent review, see ref. 4). The pioneering work of Kukolja (5) on the chlorinolysis of penicillins and the subsequent work by Wolfe *et al.* (6) and Sheehan *et al.* (7) first demonstrated the potential of a 3-substituted 4-chloro-2-azetidinone. The penicillin nucleus, because of its low cost and chirality, remains the substrate of choice for degradation to a precursor giving access to both chiral penems (8) and carbapenems.

Our approach was based on the conversion of a penicillin to a chiral azetidinone derivative, such as **3**, having (a) a leaving group (X) at position 4 and (b) a 3-α substituent (Y) that would be bulky enough to induce a stereoselective β-face entry of the incoming nucleophile (Scheme 1).



1, A = CH_2, B = S
2, A = S, B = CH_2

We found that the α-bromine substituent in the readily available methyl 6-α-bromopenicillanate (**6**) (9) was indeed capable of inducing complete chiralty when SNi displacement reactions (10) were performed at the adjacent position. Consequently we now report (1) the transformation of **6** to *N*-methoxalyl-(3*S*)-bromo-(4*R*)-chloro-2-azetidinone (**8**) and (3*S*)-bromo-(4*R*)-chloro-2-azetidinone (**11**), (2) the conversion of **8** or **11** to (4*R*)-tritylthio-2-azetidinone (**10**), and (3) the synthesis of (3*S*)-bromo-(4*R*)-allyl-2-azetidinone (**13**) from **11**.



SCHEME I

Treatment of methyl 6-α-bromopenicillanate (**6**) (obtained in 93% yield from the corresponding acid (MeI, DMF)) with chlorine (2.6 equiv., CH_2Cl_2) at low temperature gave the *trans* 4-chloroazetidinone **7**[5] in excellent yield (86%). The ^{1}Hmr spectrum of derivative **7** (see Table 1) showed, for H-3 and H-4 respectively, two doublets centered at 4.90 and 5.84 with a small coupling constant (ref. 11) ($J_{3,4}$ = 1.0 Hz). Interestingly, the corresponding *cis* isomer was not observed in the reaction mixture. Ozonolysis of methyl α-[(3*S*)-bromo-(4*R*)-chloro-2-azetidinon-1-yl]-β-methylcrotonate (**7**) (12) in CH_2Cl_2 (−78°C) with subsequent reduction of the ozonide with $(CH_3)_2S$ (13) gave, after careful work-up, the labile *N*-methoxalyl derivative **8** (yield 94%). Azetidinone **8** revealed a carbonyl absorption at remarkably high frequency in the infrared (ν_{max} (CH_2Cl_2): 1840 (s), 1805 (sh), 1760 (s), and 1730 (s) cm^{-1}).

When treated with 2,4-dinitrophenylhydrazine (THF, room temperature, 18 h) compound **8** gave the labile (3*S*)-bromo-(4*R*)-chloro-2-azetidinone **11** (yield 71%) that could be isolated from the reaction residue by extraction and crystallization from hexane. Although unstable at room temperature in the presence of moisture, the crystalline[6] **11** could be kept in an

air-tight container at low temperature (Dry Ice) for months without serious degradation.

Addition of azetidinone **11** to a solution of sodium triphenylmethyl mercaptide (1.5 equiv.) in isopropanol–water gave the chiral *trans* azetidinone **9** ($J_{3,4}$ = 2 Hz, mp 130–131°C, $[\alpha]_D^{25}$ +48.2° (c 0.305, MeOH)) in 25% yield. As observed for 4-acetoxazetidinone (10) and other *N*-unsubstituted azetidinones (14*a*), conversion of **11** to **9** presumably proceeds

For personal use only.

through intermediate **4** (Y = Br). None of the possible *cis*-diastereomers of **9** could be detected in the reaction mixture, which indicated the high stereocontrol (10, 14) exerted by the 3-α-bromine atom on the nucleophilic attack at position 4. Removal of bromine with zinc in methanol afforded the pure (4*R*)-tritylthio-2-azetidinone (**10**) (mp 119−119.5°C, $[\alpha]_D^{25}$ +70.5° (*c* 0.112, MeOH)) in 76% yield. Racemic **10** has already been described as a key intermediate in the synthesis of 6-unsubstituted and substituted penems (8, 15).

Alternatively, the azetidinone **9** could be obtained in one step from **8** by using an excess (2 equiv., MeOH) of triphenylmethyl mercaptide. Presumably the nucleophile first cleaved the *N*-methoxalyl group to liberate **11** *in situ*, which then reacted with a second molecule of the nucleophile as described above. Thus addition of **8** to sodium triphenylmethyl mercaptide gave, after filtration on silica gel, the desired azetidinone **9** (yield 49%) which was identical with the sample described above.

Onoue *et al.* (16) have reported the coupling of allylcopper with *N*-substituted 4-chloroazetidinone to give mixtures of the corresponding 4-α and 4-β-allylazetidinones. Due to the facile formation of reactive intermediates such as **4**, *N*-unsubstituted azetidinones usually undergo nucleophilic substitution at position 4 more readily than their *N*-substituted counterparts. Accordingly, the coupling of cuprates with azetidinone **11** was attempted. Treatment of **11** with lithium di-*n*-butylcuprate (17) gave a 57% yield of the corresponding (4*R*)-*n*-butyl-(3*S*)-bromo-2-azetidinone (**12**, $J_{3,4}$ = 1.9 Hz).

Since 4-allylazetidinones have been reported as useful intermediates for carbapenems (16, 18), the coupling of lithium diallylcuprate (generated from tetraallyltin or triphenylallyltin) (19) with azetidinone **11** was carried out. In this way a good yield (75%) of the allylazetidinone **13** was obtained, with the desired *trans* diastereomer as the major component (95:5, *trans*/*cis*, estimated by ^{1}Hmr). The pure *trans* isomer **13** ($J_{3,4}$ = 1.8 Hz $[\alpha]_D^{25}$ +38.6° (*c* 0.78, MeOH)) could be isolated by column chromatography (silica gel, 2−8% ether/CH_2Cl_2). Since tin derivatives are reported to react with acid chlorides (20), it was speculated that azetidinone **11**, via **4** (Y = Br), might react with tetraallyltin directly. Indeed, treatment of **11** with tetraallyltin in CH_2Cl_2 also gave a high yield (86%) of **13** as a mixture of *trans* (82%) and *cis* (18%) diastereomers.[7] This reaction was also found to be solvent dependent, with the ratio being greatly improved in favor of the *trans* isomer **13** (*trans*/*cis*, 92.5:7.5)[7] when THF was used as solvent. To our knowledge, this is the first report of a C4—C azetidinone coupling reaction of this type.

In summary, (3*S*)-bromo-(4*R*)-chloro-2-azetidinone (**11**) was prepared in high overall yield (53%) from 6-α-bromopenicillanic acid. Azetidinones **11** and **8** are key intermediates for the preparation of chiral penem and carbapenem precursors (**10**, **13**). The preparation of allylazetidinone **13** was greatly improved by using tetraallyltin instead of allylcuprate.

Thermodynamics of H^+/Na^+ exchange on amorphous zirconium phosphate in mixed solvents

N. Z. MISAK AND E. M. MIKHAIL

Nuclear Chemistry Department, Atomic Energy Establishment, Cairo, Egypt

Received June 9, 1982[1]

N. Z. MISAK and E. M. MIKHAIL. Can. J. Chem. **61**, 1902 (1983).

ΔG^0 of the H^+/Na^+ exchange on zirconium phosphate is positive and changes a little on addition of up to 90% methanol. On addition of isopropanol and acetone, ΔG^0 becomes less positive. Both ΔH^0 and ΔS^0 become progressively less negative on adding increasing amounts of the organic solvents. The decrease of ΔG^0 on addition of isopropanol and acetone is at least partly due to effects on the ion–solvent interactions in the liquid phase. In the case of methanol, these effects lead to a decrease of ΔG^0 but the decrease is mostly balanced by an increase due to effects on the interactions in solid phase. The latter effects involve an increase of enthalpy and a decrease of entropy, these changes are larger the higher the methanol content. Possible reasons for these enthalpy and entropy changes are discussed.

N. Z. MISAK et E. M. MIKHAIL. Can. J. Chem. **61**, 1902 (1983).

Le ΔG^0 d'échange de H^+/Na^+ sur le phosphate de zirconium est positif et varie légèrement lorsqu'on ajoute du méthanol à une concentration allant jusqu'à 90%. L'addition d'isopropanol et d'acétone rend le ΔG^0 moins positif. Les ΔH^0 et le ΔS^0 deviennent progressivement moins négatifs lorsqu'on ajoute des quantités croissantes de solvants organiques. La diminution de ΔG^0 lors de l'addition d'isopropanol et d'acétone est due partiellement aux effets des interactions ion–solvant dans la phase liquide. Dans le cas du méthanol, ces effets provoquent une diminution de ΔG^0, mais la diminution est contre-balancée par une augmentation due aux effets des interactions dans la phase solide. Les derniers effets impliquent une augmentation d'enthalpie et une diminution d'entropie qui sont plus fortes lorsque la teneur en méthanol est très élevée. On discute des causes possibles de ces variations d'enthalpie et d'entropie.

[Traduit par le journal]

Introduction

In a previous paper (1), we reported on tracer equilibria, capacity and kinetics of exchange on amorphous zirconium phosphate (ZrP) in mixed solvents. It was established that in mixed solvents of up to 90% methanol and acetone and 60% isopropanol, Na^+ is sorbed by ZrP by an ion exchange mechanism. With the exception of 90% methanol, the Na-capacity increases with the increase of the concentration of added organic solvent. The diffusion of Na^+ in ZrP is slackened in the presence of methanol and acetone. These results were tentatively discussed in terms of the possible effects of organic solvents on the hydration and solvation of Na^+, the basicity of the organic solvents, and the decrease of the dielectric constant inside the exchanger.

The present paper reports on the thermodynamics of H^+/Na^+ exchange on amorphous ZrP in solutions containing up to 90% methanol and 60% isopropanol and acetone. The study of the thermodynamics of ion exchange in mixed solvents is important in revealing, through the examination of the role of solvent, the various phenomena underlying the selectivity behaviour of the exchanger. Amorphous ZrP was used because ion exchange on the crystalline material has been shown to be thermodynamically irreversible (2–4). On the crystalline material, the isotherms for the forward and reverse processes do not coincide and considerable hysteresis is observed.

Experimental

Zirconium phosphate

ZrP was prepared by addition at about 60°C of equal volumes of 0.8 *M* zirconyl chloride and 2 *M* H_3PO_4 to the same volume of distilled water. After washing with water till a pH of about 4 of the washings, the solid was air-dried at 50°C, soaked in 1 *M* HCl, washed with distilled water, and redried at 50°C. It was then sieved to different sizes and stored over saturated NH_4Cl in a nitrogen atmosphere. The prepared exchanger is a partially hydrolysed $Zr(HPO_4)_2$ having a PO_4/Zr ratio of 1.33 and a weight loss at 1000°C of 24.8%, which corresponds to the empirical formula $ZrO_2.0.67\ P_2O_5.4H_2O$. The Na-capacity of the exchanger in water, 30% methanol, 60% methanol, 90% methanol, 30% isopropanol, 60% isopropanol, 30% acetone, and 60% acetone (weight percents of the organic solvents), determined by equilibration with 0.1 *m* NaCl solutions tagged with ^{22}Na, is 1.35, 1.51, 1.58, 1.21, 1.46, 1.72, 1.61, and 1.72 mequiv./g, respectively (1). These values are practically independent of temperature in the 25–65°C range studied.

Ion exchange isotherms

Precalculated amounts of standard NaCl and HCl, and of water, organic solvent, and tracer ^{22}Na were added to weighed amounts of the H-form of ZrP. The concentration of NaCl + HCl was kept constant at a total molality of 0.1 and the initial concentration of Na^+ in solution was varied from 0.01 to 0.1 *m*. All samples were shaken for 48 h (sufficient to attain equilibrium) in a shaker thermostat adjusted at 25, 45, and 65 ± 0.5°C. The solution was separated from the solid and analysed for Na^+ and Cl^- ions. The solid was washed with a small amount of alcohol and analysed for Na^+. In all the media, Cl^- was found to retain its initial concentration, indicating the absence of electrolyte invasion and that only ion exchange took place. The reversibility of the isotherms was tested and proved in all media at 25°C by making isotherms in the same conditions but starting with the Na-form of the exchanger and excluding ^{22}Na. The Na^+ ion concentration was also determined in both solution and solid. Isopropanol and acetone concentrations higher than 60% were not used due to the precipitation of NaCl.

Analyses

In the forward isotherms (starting with the H-form of ZrP), Na^+ was determined by γ-counting of the solution and the solid, using a NaI scintillation head connected to a scaler of the type Nuclear Chicago, Model 186A, USA. The γ-activity of the solid was measured either directly or after elution with 1 *N* HCl. In the reverse isotherms (starting with the Na-form of ZrP), the Na^+ content of the solution and of the solid, after elution with HCl, was determined by atomic absorption, using a Pye Unicam SP 90A atomic absorption spectrophotometer.

Results and discussion

The selectivity coefficient K is given by the equation:

$$[1] \quad K = \frac{q/q_0(1 - m/m_0)}{m/m_0(1 - q/q_0)}$$

q_0 is the Na-capacity in the respective medium in mequiv./g, m_0 is the total molality of solution and is constant and equal to 0.1. q is the concentration at equilibrium of Na^+ in ZrP in mequiv./g and m is its respective molality in solution. q and m are obtained from the analysis of the solid and weighed aliquots of the solution. Higher values of q/q_0 are obtained by increasing the relative concentration of Na^+ in solution, and the values of K at the different values of q/q_0 are calculated by the use of eq. [1] and the respective values of m/m_0. The ion exchange isotherms (not given here to save space) which are drawn as q/q_0 versus m/m_0 have shown that the forward and reverse exchanges coincide.

The corrected selectivity coefficient K' is given by:

$$[2] \quad K' = K\frac{\gamma_{\pm}^2(\mathrm{HCl})}{\gamma_{\pm}^2(\mathrm{NaCl})}$$

where $\gamma_{\pm}$ is the mean activity coefficient in the respective medium. Once K' is known, the thermodynamic equilibrium constant K_a can be obtained from the well-known Gaines–Thomas equation (5). This equation applies at total molalities ≤ 0.1 for both aqueous and mixed media (6, 7) provided that the solvent composition remains the same (7), which is the case with ZrP displaying no swelling (1). The equation has the following form:

$$[3] \quad \log K_a = \int_0^1 \log K' \mathrm{d}(q/q_0)$$

With regard to the values of $\gamma_{\pm}^2(\mathrm{HCl})/\gamma_{\pm}^2(\mathrm{NaCl})$, this ratio can be considered equal to unity in the aqueous medium (8). In the mixed solvents, many authors assume this ratio to be equal to unity (7, 9–11). This is based on Harned's rule (12) stating that the ratio of the mean molal activity coefficients of two electrolytes at a given concentration and temperature is independent of solvent composition. However, the examination of many data in the literature (13–15) shows that Harned's rule is not always applicable. The above mentioned ratio can be far from unity and is actually dependent on solvent composition.

Data on the activity coefficients of HCl and NaCl in mixed solvents are available only in methanolic solutions (13–18). We have plotted $\gamma_{\pm}(\mathrm{HCl})$ and $\gamma_{\pm}(\mathrm{NaCl})$ against the weight percent of methanol and from these plots we obtained the required values at 30, 60, and 90% methanol. As to the other mixed solvent solutions, we used the following approximate equation (8) to obtain the values of $\gamma_{\pm}(\mathrm{HCl})$ (or $\gamma_{\pm}(\mathrm{NaCl})$) in 30 or 60% isopropanol and acetone from the values of $\gamma_{\pm}(\mathrm{HCl})$ (or $\gamma_{\pm}(\mathrm{NaCl})$) in 30% or 60% methanol:

$$[4] \quad \frac{\log \gamma_{\pm}}{\log \gamma'_{\pm}} = \left(\frac{D'}{D}\right)^{3/2}$$

$\gamma_{\pm}$ and $\gamma'_{\pm}$ are the mean activity coefficients in solvents of dielectric constants D and D', respectively. The application of eq. [4] to obtain activity coefficient values for HCl in the various mixed media from values in aqueous methanol gave figures which are in reasonable agreement with the experimental figures given in the literature for these systems (13, 19). Agreement to better than 10% for 60% organic solvent contents and 5% for 30% organic solvent contents was obtained. Unfortunately, there are no experimental values for NaCl in solvents other than methanol, but it may be anticipated that the agreement will be as good.

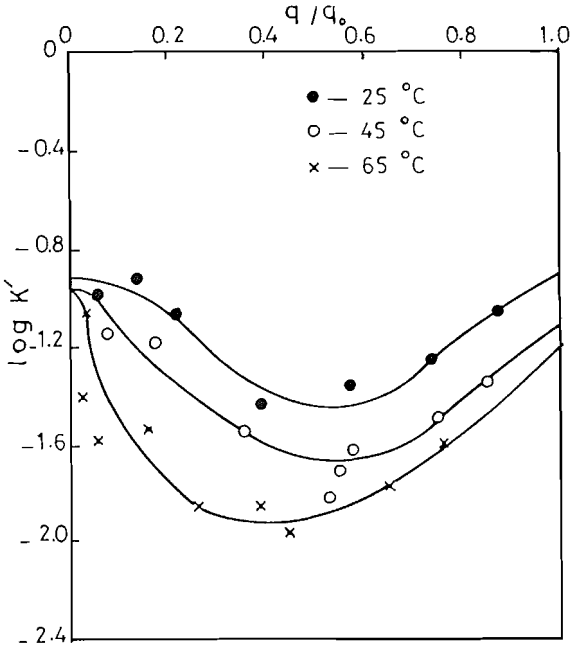

FIG. 1. Variation of log K' with q/q_0 for exchange from the aqueous medium at different temperatures.

The mean activity coefficients of HCl and NaCl in presence of each other are obtained from the values for the single electrolytes by the use of the Glueckauf equation (20). The calculated values of $\gamma_{\pm}(\mathrm{HCl})/\gamma_{\pm}(\mathrm{NaCl})$ were found to be constant regardless of the relative amounts of the two electrolytes in solution. The values of $\gamma_{\pm}^2(\mathrm{HCl})/\gamma_{\pm}^2(\mathrm{NaCl})$, necessary for the calculation of K' (eq. [2]), are 1.06, 1.12, and 1.49 in 30%, 60%, and 90% methanol, respectively, 1.08 and 1.19 in 30% and 60% isopropanol, respectively, and 1.06 and 1.14 in 30% and 60% acetone, respectively. It is seen, therefore, that this ratio cannot be put equal to unity at the relatively high organic solvent concentrations.

The variation of log K' with q/q_0 is exemplified by Fig. 1 for the aqueous medium, Fig. 2 for 60% methanol, and Fig. 3 for 60% isopropanol. The figures not given here are similar in shape to those for the aqueous medium. Considering this variation, it can be said that except in 60% isopropanol, log K' first decreases with increase of loading and then increases with a minimum at values of q/q_0 around 0.5. In 60% isopropanol, log K' first decreases with loading and then tends to be more or less constant. Such a complex nature of the log K' – loading plots may be related to the proportions and properties of energetically different exchange sites in the exchanger (21).

Having obtained the values of K_a by integration under the curves in the log K' – q/q_0 plots, standard thermodynamic equations are used for the calculation of ΔG^0, ΔH^0, and ΔS^0. ΔH^0 is calculated from the slopes of the straight lines given in Fig. 4.

The various thermodynamic data are given in Table I for the different conditions. ΔS^0 is split in the case of the aqueous medium into two terms (22), one belonging to the solution phase, ΔS^h, and the other belonging to the exchanger phase, ΔS^e. ΔS^h is equal to the difference in the hydration entropies of the two ions (H^+ and Na^+) and is obtained from the data of Rosseinsky (23). ΔS^e is obtained by subtraction of ΔS^h from

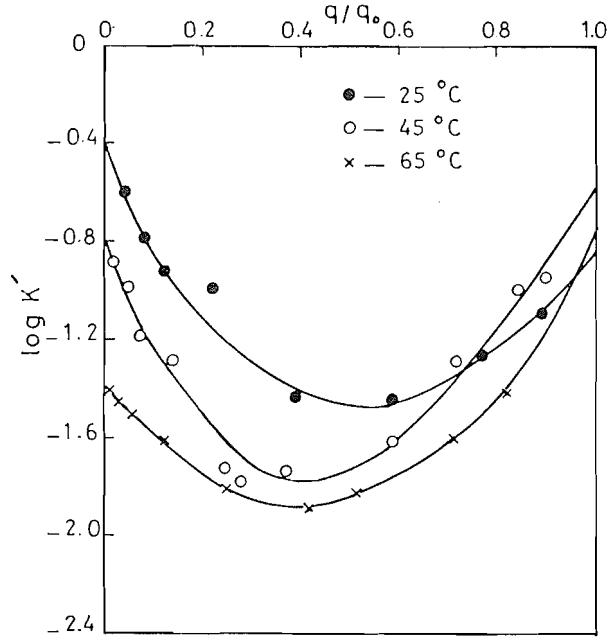

FIG. 2. Variation of log K' with q/q_0 for exchange from 60% methanol at different temperatures.

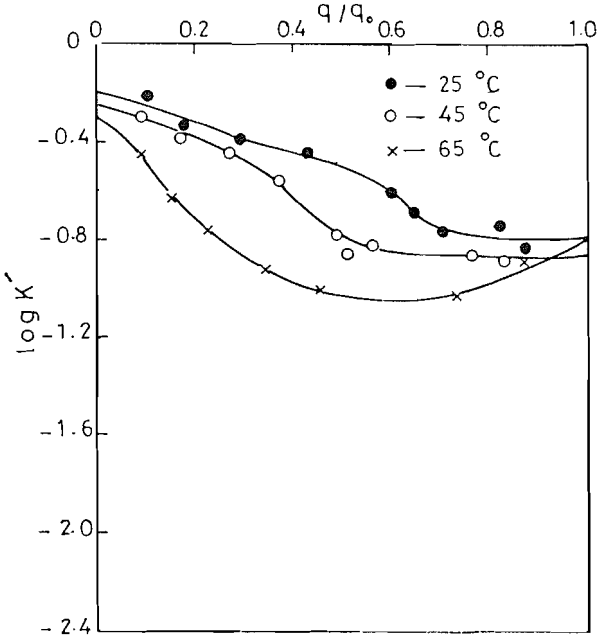

FIG. 3. Variation of log K' with q/q_0 for exchange from 60% isopropanol at different temperatures.

ΔS^0. The estimated accuracy for the ΔG^0 values is generally ± 0.1 kJ/mol, for the ΔH^0 values, ± 1.0 kJ/mol, and for the ΔS^0 values, ± 4 J/mol deg.

Table 1 shows that in all media, H^+/Na^+ exchange is an entropy-directed reaction. In the aqueous medium, this is in qualitative agreement with previous studies (24, 25). In this medium, $\overline{\Delta S}^e$ is negative, showing a decrease of entropy when H^+ in ZrP is replaced by Na^+. Since the alkali ions are retained in a hydrated state inside ZrP (26), such an entropy decrease is presumably due to a water transfer from the aqueous solution to the solid phase. Such a transfer results in the decrease of the entropy of the whole system because the water molecules have less degrees of freedom in the solid phase than in the liquid phase (22). In the methanolic solutions, Table 1 shows that ΔG^0 is only little changed, while in the other media ΔG^0 decreases (becomes less positive) in the presence of the organic solvents. The decrease is progressive in the case of isopropanol while a small decrease is observed when going from 30 to 60% acetone. ΔH^0 and ΔS^0 increase (become less negative) with increasing additions of the organic solvents. However, in the methanolic solutions, this increase is appreciable only in 90% methanol. In acetone, little change is observed, as in the case of ΔG^0, on going from 30 to 60% of the organic solvent.

Changes in the values of ΔG^0, ΔH^0, and ΔS^0, obtained in the aqueous medium, due to addition of organic solvents should be sought in the effect of this addition on the ion–solvent interactions in solution and on the various interactions in the solid exchanger. Effects on ion–solvent interactions are related to the thermodynamics of transfer of the exchanging ions from water to the respective mixed-solvent solution, while the effects on the interactions in the solid phase are related to the thermodynamics of similar transfer of the Na- and H-forms of ZrP. The latter transfer depends on the solvent composition of liquid and solid phases and on the extent of solvent imbibition by the solid (6, 7, 27). Changes in ΔG^0, ΔH^0, and ΔS^0 due to effects on the interactions in the solid phase may be obtained by subtraction of changes due to effects on ion–solvent interactions (which may be estimated in many cases) from the values of ΔG^0, ΔH^0, and ΔS^0, obtained experimentally.

With regard to ΔG^0, it is seen from the data given in the literature and involving the free energies of transfer ΔG_t^0 or the medium effect ${}_m\gamma$ ($\Delta G_t^0 = RT \ln {}_m\gamma$) for H^+ and the alkali ions (28–37) that for transfer from water to mixtures of water and methanol, ethanol, or acetone, ΔG_t^0 for H^+ is more negative than for any of the alkali ions. Besides, this trend is generally more profound the higher the crystallographic radius of the alkali ion and the higher the organic solvent content. Changes on addition of organic solvents in the value of ΔG^0, obtained in the aqueous medium, due to effects on ion–solvent interactions in the liquid phase may be put equal to $\Delta G_t^0(H^+) - \Delta G_t^0(Na^+)$ (7, 27). Hence, it can be deduced that the addition of methanol, acetone, and presumably also isopropanol should lead to a lower ΔG^0, i.e., to the increase of the selectivity constant.

The decrease (Table 1) of ΔG^0 on addition of isopropanol and acetone should be therefore, at least partly, attributed to effects on ion–solvent interactions in the liquid phase. The very little changes in the presence of methanol mean that the effects on interactions in the solid exchanger mostly balance the effects in the liquid phase. Quantitative evaluation is possible only with methanol, since the transfer free energy data in acetone (37) do not include the Na^+ ion and there are no data at all in isopropanol. Even in the case of methanol, a strictly quantitative evaluation is possible only for the interrelation of the results in 30% and 60% methanol. This is due to the fact that at these methanol concentrations, the Na-capacity is almost the same (see Experimental). Hence the standard states of the solid phase, involving the pure cationic form in equilibrium with an infinitely dilute solution of the respective electrolyte in the respective solvent (5), can be considered as consistent.

One can write the following equality in the case of ion–solvent interaction effects in the liquid-phase being the only factor responsible for change of ΔG^0 on increase of the methanol content from 30 to 60%:

[5] $\Delta G^0(60\%) = \Delta G^0(30\%) + \Delta G_t^0(H^+) - \Delta G_t^0(Na^+)$

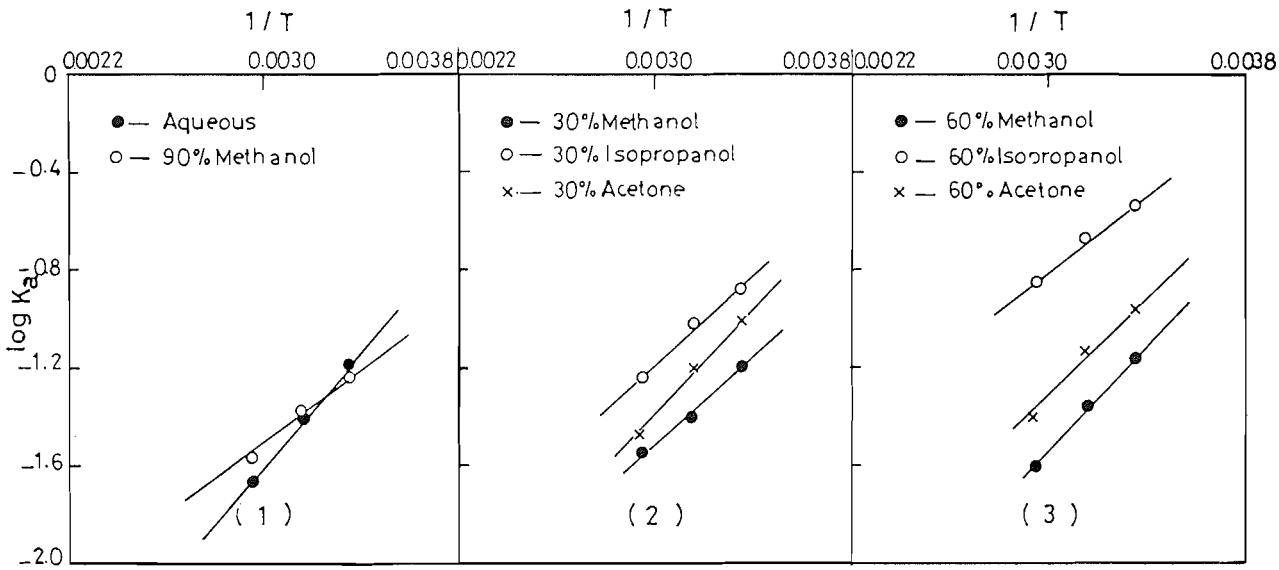

FIG. 4. Variation of log K_a with $1/T$ for exchange from: (*1*) aqueous and 90% methanol solutions; (*2*) 30% methanol, isopropanol, and acetone; and (*3*) 60% methanol, isopropanol, and acetone.

TABLE 1. Thermodynamic data for H^+/Na^+ exchange at 25°C on ZrP in aqueous and mixed-solvent solutions

Medium	ΔG^0 (kJ/mol)	ΔH^0 (kJ/mol)	ΔS^0 (J/mol deg)	ΔS^h	$\overline{\Delta S^e}$
Aqueous	6.91	−8.30	−51.1	−21.4	−29.7
30%Methanol	6.96	−8.17	−50.8	—	—
60%Methanol	6.70	−7.75	−48.5	—	—
90%Methanol	7.12	−5.24	−41.5	—	—
30% Isopropanol	5.07	−5.87	−36.7	—	—
60% Isopropanol	3.10	−5.03	−27.3	—	—
30% Acetone	5.87	−7.21	−43.9	—	—
60%Acetone	5.53	−6.83	−41.5	—	—

$\Delta G^0(30\%)$ and $\Delta G^0(60\%)$ are the free energies of exchange obtained experimentally in 30 and 60% methanol, respectively. $\Delta G_t^0(H^+)$ and $\Delta G_t^0(Na^+)$ are the free energies of transfer of H^+ and Na^+ ions from 30 to 60% methanol. Using for the calculation of $\Delta G_t^0(H^+) - \Delta G_t^0(Na^+)$ the most recent and accurate data of Bax *et al.* (35), the value −3.52 kJ/mol is obtained. Thus, $\Delta G^0(60\%)$ should be less than $\Delta G^0(30\%)$ by 3.52 kJ/mol if ion–solvent interactions are the only factor. The fact that $\Delta G^0(60\%)$ is almost equal to $\Delta G^0(30\%)$ (Table 1) shows that major changes in ZrP occur on the increase of methanol concentration from 30 to 60%. These changes involve an increase of ΔG^0 by about 3.52 kJ/mol on going from 30 to 60% methanol, probably due to more sorption of methanol by ZrP.

The evaluation of the changes in ΔH^0 and ΔS^0, occurring on addition of organic solvents, due to solid phase interactions is of interest. It may allow to make a semiquantitative judgement about the changes occurring in the solid phase and leading to changes in ΔG^0, and consequently to a modification of the selectivity of the exchanger in presence of organic solvents. However, such an evaluation is possible only in the case of methanol where values for ΔH_t^0 and ΔG_t^0 of both HCl and NaCl are available (29, 32). From these values ΔS_t^0 is obtained and the changes in ΔH^0 and ΔS^0 on addition of the organic solvent due to effects on ion–solvent interactions in solution can be taken equal to $\Delta H_t^0(HCl) - \Delta H_t^0(NaCl)$ and $\Delta S_t^0(HCl) - \Delta S_t^0(NaCl)$. From the values obtained either directly or by interpolation, it can be readily deduced that ΔH^0 may decrease due to these effects by values of 84 and 335 J/mol on addition of 30 and 60% methanol, respectively. At 90% methanol, an increase of 84 J/mol is expected. With regard to ΔS^0, increases of 11.3, 26, and 36.9 J/mol deg at 30, 60, and 90% methanol, respectively, are expected due to these effects. From these values and the differences between the values of ΔH^0 and ΔS^0 in the aqueous and mixed-solvent solutions (representing overall changes due to ion–solvent and solid phase interactions), the effects of methanol addition on solid phase interactions are evaluated. These effects give rise to an increase in ΔH^0 of 214, 885, and 2976 J/mol at 30, 60, and 90% methanol, respectively, and a decrease in ΔS^0 of 11, 23.4, and 27.3 J/mol deg, respectively, at these same methanol concentrations. Thus, the rather significant increase of ΔH^0 on addition of 90% methanol (Table 1) comes almost exclusively from the effects of this addition on the solid phase. The increase of ΔS^0 is the outcome of effects on the liquid phase outweighing those on the solid phase.

The expected major effects of addition of methanol on the solid phase are connected with sorption–desorption processes of the two components of solvent (H_2O and CH_3OH) and dehydration of ingoing Na^+ with its subsequent stronger, relative to the aqueous medium, interaction with the exchange sites.

Methanol has been reported to be chemisorbed by ZrP and an indication has been found for an esterification reaction between the alcohol and the P—OH groups of ZrP (38). Water in ZrP is either interstitially sorbed water or water weakly sorbed by hydrogen bonds to the P—OH of ZrP (39, 40). The dehydration of Na^+ ions with their subsequent stronger interaction with the exchange sites is expected to give rise to positive enthalpy and entropy changes (41, 42). It seems therefore possible that the decrease of entropy on addition of methanol due to effects on the solid is mainly connected with the chemisorption of methanol. The increase of enthalpy is probably connected with the sorption of Na^+ in a less hydrated state from the mixed solvent than from the aqueous medium. This seems to be particularly true at relatively high methanol concentrations where the increase of enthalpy is rather significant.

The existence of binuclear species in the nickel(II)/azide system

M. E. V. SUÁREZ, E. A. NEVES, AND R. TOKORO

Instituto de Química da Universidade de São Paulo, Cx. Postal 20780, São Paulo, Brazil

Received July 5, 1982[1]

M. E. V. SUÁREZ, E. A. NEVES, and R. TOKORO. Can. J. Chem. **61**, 1907 (1983).

The binuclear species $Ni_2N_3^{3+}$ has been found by potentiometric and spectrophotometric measurements to coexist with the monoazide species NiN_3^+ at $C_{Ni(II)} \gg C_{N_3^-}$ conditions. The formation constants β_{11} and β_{21} are 7.5 M^{-1} and 4.3 M^{-2} respectively, as determined potentiometrically at 25.0°C, with a glass electrode at an ionic strength of 2.00 M held with $NaClO_4$. The molar absorptivities ϵ_{11} and ϵ_{21} have been determined in the 302−290 nm wavelength range.

M. E. V. SUÁREZ, E. A. NEVES et R. TOKORO. Can. J. Chem. **61**, 1907 (1983).

Les mesures potentiométriques et spectrophotométriques ont permis de découvrir l'existence d'espèce binucléaires du type $Ni_2N_3^{3+}$ à côté du monoazothydrure NiN_3^+ dans des conditions où $C_{Ni(II)} \gg C_{N_3^-}$. Par potentiométrie à 25°C en utilisant une électrode de verre avec une force ionique de 2,0 M dans du $NaClO_4$, on trouve des constantes de formation β_{11} et β_{21} de 7,5 M^{-1} et de 4,3 M^{-2} respectivement. On a déterminé les absortivités ϵ_{11} et ϵ_{21} dans l'intervalle de longueur d'onde de 302−290 nm.

Knowledge of the overall stepwise formation constants of the nickel(II)/azide complexes is desirable in order to better interpret the electrochemical behaviour of nickel(II) in an azide supporting electrolyte without hydrazoic acid (1, 2) or in the N_3^-/HN_3 buffer, where two catalytic waves occur (3). An earlier equilibrium study of the cobalt(II)/azide/hydrazoic acid system (4) was very helpful in the interpretation of these catalytic waves (5), which present many different characteristics when compared with the analogous nickel(II) system. There have been reports of spectrophotometric studies of the monoazide specie (1, 6, 7), NiN_3^+, and of potentiometric studies of the monoazide and successive complexes of up to three ligands (8, 9), $Ni(N_3)_3^-$.

There is disagreement as to the magnitude of the β_1 formation constant. In one of these studies, a dispersion of the $\bar{n}$ data (average ligand number) with the free ligand concentration can be observed at several metal cation concentrations, which could be the evidence for the existence of polynuclear species (8). However, the presence of polynuclear species was not considered.

A potentiometric study of the nickel(II)/azide system was undertaken and it was found that polynuclear species were present whereas in the corresponding cobalt(II) system none was detectable. The former system is so complicated that it will be described separately.

The present paper deals with spectrophotometric and potentiometric studies in which the ratio $C_{Ni(II)}/C_{N_3^-} \gg 1$, the main purpose being to check the possibility of the existence of species like $Ni_mN_3^{(2m-1)}$ where m could be 1 and 2.

Experimental

Reagents and solutions

All reagents were of chemically pure or analytical grade.

Sodium perchlorate (Merck) was used to prepare 6.5 M solutions. Standardization was performed gravimetrically by drying 3−4 mL of the solution in an oven at 110°C to constant weight.

Nickel perchlorate was prepared by treating cobalt-free nickel carbonate (Baker Analyzed) with 4.0 M perchloric acid at room temperature, stirring for three days, and filtering. Standard perchloric acid was added to give a solution with an excess of 0.01000 M hydrogen ion concentration, $C_{H^+,M}$. Standardization was performed electrogravimetrically in the presence of hydrazine sulfate to avoid anodic oxidation of the ammonia buffer.

Sodium azide (Fischer) was washed with pure alcohol, vacuum dried, and oven dried at 110°C; after this it was used as a primary standard.

Instruments and methods

An Orion Research model 801 A digital potentiometer, adapted to a Metrohm EA 121 glass electrode, combined with an Ag/AgCl reference electrode filled with 3.0 M sodium chloride, was used in the pH measurements. The glass electrode was maintained in thermostated 2.0 M sodium perchlorate for at least 30 min prior to all measurements. A 1.99 M $NaClO_4$ solution with a free hydrogen concentration of 0.01000 M was used to standardize the glass electrode to a conditional pH = 2.000, refering to the hydrogen ion concentration instead of activity. The calibrated electrode was then employed for the pH measurements on the azide buffer solutions at the same ionic strength. All solutions were gently stirred during measurements and a small constant flux of reference electrode solution (1 drop per hour) was maintained to provide a reproducible electrolyte junction.

The standard nickel(II) solution was added to 5.000 mL of the N_3^-/HN_3 buffer, where a change from pH_1 to pH_2 was observed. The data treatment was carried out using a HP-97 calculator as described previously (4). The original program was slightly modified in order to provide only ΔN_3^- data instead of $\bar{n}$ (see Results and discussion).

The spectrophotometric measurements were taken with 1.000 cm quartz cells in a Carl Zeiss PM-QII instrument. The same azide concentration in the blank solution, without nickel(II), was used.

All measurements were done at 2.00 M ionic strength, maintained with $NaClO_4$, at (25.0 ± 0.2)°C.

Results and discussion

Spectrophotometric measurements

Evidence of species other than NiN_3^+ was obtained from the application of the McConnell and Davidson spectrophotometric method (10), modified for the conditions in which the ligand forms a weak acid (11, 12). This method is applied at different $C_{Ni(II)}$ levels and it is expected to provide constant values for β_1 in each set of results, independent of the nickel(II) concentration.

The basis of the method in its final form (12) results in the application of the following equation, when only NiN_3^+ exists,

$$[1]\qquad \underbrace{\underbrace{\frac{C_{Ni(II)}C_{N_3^-}}{A\left(1+\frac{|H^+|}{K_{HN_3}}\right)}}_{y}+\frac{A}{\epsilon_1^2\left(1+\frac{|H^+|}{K_{HN_3}}\right)}}_{y'}=\underbrace{\frac{1}{\epsilon_1\beta_1}+\frac{1}{\epsilon_1}\times\underbrace{\frac{C_{Ni(II)}+C_{N_3^-}}{\left(1+\frac{|H^+|}{K_{HN_3}}\right)}}_{x}}_{y'}$$

where A, ϵ_1, K_{HN_3}, $C_{Ni(II)}$ and $C_{N_3^-}$ are the absorbance, molar absorptivity of the first complex, the stoichiometric ionization constant of the HN_3 acid, and the analytical concentration of the metal cation and ligand, respectively.

This is not an exact equation when considering only "y" and "x". The term containing ϵ_1^2 is normally neglected, but it can be introduced iteratively to convert "y" into "y'", after previous estimation of β_1 and ϵ_1 until these parameters converge to constant values.

If there is more than one species, instead of NiN_3^+, as $Ni_2N_3^{3+}$ or $Ni_2(N_3)_2^{2+}$, an apparent β_1' "constant" will be obtained as well as an average ϵ_1', which changes in magnitude with the metal cation concentration.

Table 1 presents a typical set of experimental data of absorbance measured at six different wave lengths to give the apparent formation constant in a particular $C_{Ni(II)}$, β_1'. There are three other series like this one. The final β_1' and ϵ_1' after the iterative procedure are also presented. The K_{HN_3} value was potentiometrically determined at 2.00 *M* ionic strength and at 25°C to be 2.46×10^{-5} *M* by a similar procedure which has been used previously (12).

We observed that β_1' determined as above changes with nickel(II) concentration over the range $(2.0-6.1) \times 10^{-2}$ *M*. This is a clear evidence that β_1' does not remain constant with nickel(II) concentration as would happen if only the monoazide species were formed. All results for different concentrations of nickel(II) at six wave lengths and also the average $\overline{\beta}_1'$ are presented in Table 2.

If the β_1' data are extrapolated to zero concentration of nickel(II) an almost linear plot results from which the true β_{11}, related to NiN_3^+, may be obtained. However, a much better extrapolation was obtained through a least-squares fit of the data to a parabolic equation with the following interception:

$$\beta_{11} = 6.90\ M^{-1}$$

This extrapolated value is coincident with the one found by Senise and Godinho (6) (Table 3). They worked at varying nickel(II) concentration. This procedure probably results in compensation for the formation of the binuclear species during extrapolation of the "y" term in eq. [1] to the zero value of "x". They were unable to detect the $Ni_2N_3^{3+}$ complex formation by their procedure.

More reliable results are expected from potentiometric measurements at comparable conditions of $C_{Ni(II)}/C_{N_3^-}$ than in the spectrophotometric study. The basis of this method has been described earlier (4). It depends on the change of a conditional pH in N_3^-/HN_3 buffers by the introduction of an analytical concentration of the metal cation.

It is expected that at least species like NiN_3^+, $Ni_2N_3^{3+}$, $Ni_2(N_3)_2^{2+}$ can coexist under the working conditions. Thus, the original program, slightly changed, can provide $\Delta|N_3^-|$ data, which are related with the bonded nickel(II) concentration by:

$$[2\text{-A}] \quad \Delta|N_3^-| = |NiN_3^+| + |Ni_2N_3^{3+}| + 2|Ni_2(N_3)_2^{2+}| + \ldots\ldots$$

The combination of this with the formation constants β_{ml} refering to $Ni_m(N_3)_l^{2m-l}$ complexes gives

$$[2\text{-B}] \quad \Delta|N_3^-| = \beta_{11}|Ni^{2+}||N_3^-| + \beta_{21}|Ni^{2+}|^2|N_3^-| + 2\beta_{22}|Ni^{2+}|^2|N_3^-|^2 + \ldots\ldots\ldots\ldots$$

A subsidiary F_1 function can be derived:

$$[3\text{-A}] \quad F_1 = \frac{\Delta|N_3^-|}{|Ni^{2+}||N_3^-|} = \beta_{11} + \beta_{21}|Ni^{2+}| + 2\beta_{22}|Ni^{2+}||N_3^+| + \ldots\ldots\ldots\ldots$$

These F_1 data can be easily calculated because the calculator program also provides $|N_3^-|$ data. As $C_{Ni(II)} \gg C_{N_3^-}$, the $|Ni^{2+}|$ data can be obtained as a first approximation by:

$$|Ni^{2+}| \cong C_{Ni(II)} - \Delta|N_3^-|$$

If only NiN_3^+ exists several terms in eq. [3-A] will disappear and is reduced to

$$[3\text{-B}] \quad F_1 = \text{constant} = \beta_{11}$$

This was not actually found when different values of $C_{Ni(II)}$ were added to solutions with the $|N_3^-|/|HN_3|$ ratio equal to 10:10, 14:14, and 20:20 (m*M*). Table 4 shows that F_1 changes linearly with $|Ni^{2+}|$ which suggests that:

$$[3\text{-C}] \quad F_1 \cong \beta_{11} + \beta_{21}|Ni^{2+}|$$

The linear regression with the three series of data leads to values of β_{11} and β_{21} which are approximately equal. The $|Ni^{2+}|$ data were then corrected again by solving the second degree equation obtained by

$$[4\text{-A}] \quad C_{Ni(II)} = |Ni^{2+}| + \beta_{11}|Ni^{2+}||N_3^-| + 2\beta_{21}|Ni^{2+}|^2|N_3^-|$$

$$[4\text{-B}] \quad 2\beta_{21}|Ni^{2+}|^2|N_3^-| + (1 + \beta_{11}|N_3^-|)|Ni^{2+}| - C_{Ni(II)} = 0$$

The final values of the formation constants are:

$$\beta_{11} = \frac{|NiN_3^+|}{|Ni^{2+}||N_3^-|} = 7.5 \pm 0.1\ M^{-1}$$

$$\beta_{21} = \frac{|Ni_2N_3^{3+}|}{|Ni^{2+}|^2|N_3^-|} = 4.3 \pm 0.1\ M^{-2}$$

This β_{11} value is doubtless more reliable than the value 6.9 M^{-1} obtained from spectrophotometric data.

However, another explanation for this higher stoichiometric β_{11} constant can be proposed on the basis of the reasonable assumption that two monoazide species exist in equilibrium: a true complex and an ion pair. Thus, the spectrophotometric measurements at the ultraviolet region would provide a lower constant value because it brings up spectral differences between the outer-sphere complex and the inner one. Such a situation has been described by Posey and Taube (13) and Bell and Panckhurst (14).

Other attempts to solve a 3 × 3 matrix from simultaneous equations with the data of Table 4 by including in [2-B] the terms corresponding to $Ni_2(N_3)_2^{2+}$ or $Ni(N_3)_2$ were unsuccessful. This result is expected because the $C_{N_3^-}$ is maintained at a very low level and the formation of those two species requires the addition of a quadratic term, $|N_3^-|^2$, which is very low (see eq. [2-B]). However, solution of the 2 × 2 matrix confirmed the values for β_{11} and β_{21}.

These constants are expected to describe in a better way the system at high $C_{Ni^{2+}}/C_{N_3^-}$ ratio. They can also be used in the calculation of the individual values of ϵ_{11} and ϵ_{21} from the spectrophotometric measurements, where the following equation can be derived:

$$[5\text{-A}] \quad A = A_{NiN_3^+} + A_{Ni_2N_3^{3+}}$$

$$[5\text{-B}] \quad A = \epsilon_{11}|NiN_3^+| + \epsilon_{21}|Ni_2N_3^{3+}|$$

$$[5\text{-C}] \quad A = \epsilon_{11}\beta_{11}|Ni^{2+}||N_3^+| + \epsilon_{21}\beta_{21}|Ni^{2+}|^2|N_3^-|$$

Table 5 presents the absorbance values and the ϵ_{11} and ϵ_{21} data from the matrix solution of simultaneous equations such as [5-C], from the absorbance measured at known $|Ni^{2+}|$ and $|N_3^-|$ calculated by iteration from eq. [4-B] and:

$$[6\text{-A}] \quad C_{N_3^-} = |N_3^-| + |HN_3| + \beta_{11}|Ni^{2+}||N_3^-| + \beta_{21}|Ni^{2+}|^2|N_3^-|$$

$$[6\text{-B}] \quad |N_3^-| = (C_{N_3^-} - |HN_3|)/(1 + \beta_{11}|Ni^{2+}| + \beta_{21}|Ni^{2+}|^2)$$

$$[7] \quad |HN_3| = C_{HClO_4} + C_{H^+,Ni^{2+}}$$

We can observe that ϵ_{11} reaches a maximum value at 293 nm while ϵ_{21} shows a regular increase toward lower wave lengths. These different tendencies may explain why the apparent constant, β_1', increases at lower wave lengths where the species $Ni_2N_3^{3+}$ absorbs preferentially.

These spectrophotometric and potentiometric measurements confirm that azide ion can behave as a bridge ligand to nickel(II) cations, which is not the case with a similar cobalt(II) system. Thus it is expected that at higher azide concentrations many other polynuclear species can be formed with more than one ligand, due to a more favorable exponential factor. These results will be reported later.

Finally, it should be pointed out that the effect of hydrolysis on the present measurements should be negligible because the pH of the majority of the working solutions was lower than 5.

TABLE 4. Data obtained from potentiometric measurements

Nucleic acid related compounds. 41. Restricted furanose conformations of 3′,5′-*O*-(1,1,3,3-tetraisopropyldisilox-1,3-diyl)nucleosides provide a convenient evaluation of anomeric configuration[1,2]

Received November 16, 1982

MORRIS J. ROBINS, JOHN S. WILSON, LINDSAY SAWYER, and MICHAEL N. G. JAMES. Can. J. Chem. **61**, 1911 (1983).

Treatment of ribonucleosides (and related furanosyl compounds) with 1,3-dichloro-1,1,3,3-tetraisopropyldisiloxane in pyridine gave high yields of 3′,5′-*O*-(1,1,3,3-tetraisopropyldisilox-1,3-diyl)nucleosides (3′,5′-*O*-TPDS-nucleosides). The ^{1}H nmr coupling parameters of the sugar backbone of the β-D-ribofuranosyl anomers of these *trans*(1,2)-fused 8 to 5 membered ring TPDS compounds indicated a remarkably consistent range of furanose conformations. The data are compatible with a predominant population of conformers in the general ^3E (C3′-*endo*) range found for a large series of rigidly *trans*-fused 6 to 5 membered ring nucleoside cyclic 3′,5′-monophosphates. X-ray crystallographic analysis of 3′,5′-*O*-TPDS-cytidine revealed an almost perfect ^3E sugar envelope conformation (P = 19.7°, τ_m = 41.9°) in agreement with the ^{1}H nmr solution data. Attachment of two bulky isopropyl groups to each silicon atom and expansion of the Si—O—Si bond angle to 155° gives an essentially planar six atom segment of the 8-membered ring. Apparently this demands a distinctly preferred conformation for the fused ring system. The readily prepared 3′,5′-*O*-TPDS-β-D-ribofuranosyl derivatives have $J_{1'-2'} \leq 1.5$ Hz in most cases. This provides a rapid and convenient evaluation of the H1′—H2′ *trans* configuration in these structures.

MORRIS J. ROBINS, JOHN S. WILSON, LINDSAY SAWYER et MICHAEL N. G. JAMES. Can. J. Chem. **61**, 1911 (1983).

Les ribonucléosides (et les composés furannosyles apparentés) réagissent avec le dichloro-1,3 tétraisopropyl-1,1,3,3 disiloxane dans la pyridine en donnant les *O*-(tétraisopropyl-1,1,3,3 disiloxydiyl-1,3)-3′,5′ nucléosides (*O*-TPDS-3′,5′ nucléosides) avec de forts rendements. Les paramètres de couplage en rmn du ^{1}H, de l'unité sucre des anomères du β-D-ribofurannosyle de ces composés TPDS à noyaux condensés de 5 à 8 chainons en position *trans*(1,2) indiquent un nombre très important de conformations du furannose. Les données sont en accord avec une population prédominante de conformères dans le domaine général ^3E (C′3-*endo*) trouvés pour un très grand nombre de nucléosides monophosphates-3′,5′ cycliques à noyaux condensés de 6 à 5 chainons en position *trans*. L'analyse par cristallographie de rayons X de la *O*-TPDS-3′,5′ cytidine révèle une conformation enveloppe presque parfaite de sucre du type ^3E (P = 19,7°, τ_m = 41,9°) en accord avec les données de la rmn du ^{1}H en solution. La fixation de deux groupes isopropyles encombrants sur chaque atome de silicium et l'expansion de l'angle de liaison Si—O—Si à 155°C donne essentiellement un segment plan de 6 atomes dans le cycle à 8 chainons. Apparemment ceci requiert une conformation préférée distincte du système cyclique condensé. Les dérivés du *O*-TPDS-3′,5′ β-D-ribofurannosyle ont un $J_{1'-2} \leq 1,5$ Hz dans la plupart des cas. Cette donnée fournit une évaluation rapide et convenable de la configuration *trans* H1′—H2′ de ces structures.

[Traduit par le journal]

A variety of chemical, chiroptical, and nmr methods have been used to determine the anomeric configuration of ribonucleosides (for a critical survey of the major methods see ref. 1). However, many of these criteria are based on unique and/or empirical properties of specific nucleoside structures and the majority require both anomers for comparison. We have described a general and unequivocal method for the independent assignment of β or α anomers based on ^{1}H nmr analysis of the rigid geometric orientation of the anomeric proton (H1′) and H2′ on the *trans*(1,2)-fused 6 to 5 membered ring system of nucleoside cyclic 3′,5′-monophosphates (1). However, this procedure suffers from the experimental involvement required to synthesize and purify these cyclic nucleotides. We now wish to report application of the easily prepared 3′,5′-*O*-(1,1,3,3-tetraisopropyldisilox-1,3-diyl)nucleoside (3′,5′-*O*-TPDS-nucleoside) derivatives for the convenient anomeric configuration assignment of applicable β-ribofuranosyl structures.

Markiewicz and Wiewiorowski described the synthesis of 1,3-dichloro-1,1,3,3-tetraisopropyldisiloxane (TPDS dichloride) and its reaction with ribonucleosides to give their 3′,5′-*O*-TPDS derivatives (2). Others (3) and ourselves (4) have used this novel protecting group with related furanosyl compounds. Most ribo- and arabinofuranosyl compounds were converted smoothly into their 3′,5′-*O*-TPDS derivatives upon treatment with TPDS dichloride in pyridine (4, 5). Guanosine required a cosolvent and by-product formation (3) occurred when *N*,*N*-dimethylformamide (DMF) was used (4*b*). Extended heating of 3′,5′-*O*-TPDS derivatives in protic solvents and acid treatment (3) should be avoided. The 3′,5′-*O*-TPDS-guanosine derivative was obtained in ~70% yield, but no difficulties were encountered with the other products in our studies and high yields were easily obtained (4*b*).

It is noteworthy that the arabinofuranosyl nucleosides of adenine (4*b*) and cytosine (4*b*, 5) gave the 3′,5′-*O*-TPDS derivatives exclusively. Cyclization of ribonucleoside 5′-monophosphates was known to proceed at O3′ to give the cyclic 3′,5′-monophosphates (6), whereas analogous treatment of the 2′-epimeric arabinonucleoside 5′-monophosphates gave

the cyclic 2′,5′-monophosphates (7) uniquely. Verification of the O3′ linkage of the present 3′,5′-*O*-TPDS structures was provided by acylation of the 2′-hydroxyl group and observation of the marked downfield shift of the nmr signal for H2′ ($\Delta\delta$ = 1.1 to 1.5 ppm for 2′-OH → 2′-OAc; and $\Delta\delta \sim 2$ ppm for 2′-OH → 2′-OCSOPh).

It has been concluded that vicinal proton–proton coupling values of $J \lesssim 1$ Hz on a 5-membered ring provide definitive verification of their *trans* orientation (8) since *cis* coupling values of $\lesssim 2$ Hz are precluded geometrically. The anomeric proton nmr signal in over 200 examples of various types of β-D-ribonucleoside cyclic 3′,5′-monophosphates appeared as a sharp singlet without a reported exception (1). Coupling values of $J_{1'-2'} < 0.7$ Hz were found in all cases examined by double resonance (1, 9).

Experimental

The ^1H nmr spectra were recorded in the Fourier transform mode using Bruker WH-200 and WH-400 spectrometers by the High-Field NMR Laboratory of the Department of Chemistry. Spectra were determined in Me_2SO-d_6 solutions with Me_4Si as internal standard. Poorly resolved spectra were improved by dilution of the sample with Me_2SO-d_6 or other solvents as indicated. Additional spectra were determined in the other solvents indicated, with Me_4Si as internal standard. First order spectral analysis was performed with the aid of double resonance decoupling. No coupling values are given when resolution or spectral complexity was prohibitive at 400 MHz. Ambient spectrometer temperatures were employed. Insignificant effects on coupling parameters were observed over a 10°C range and major effects were not apparent over a 30°C range with compound **1**.

X-ray crystallographic analysis was performed on a crystal of 3′,5′-*O*-TPDS-cytidine (**8**) that measured 0.7 × 0.55 × 0.25 mm. A final *R*-factor of 0.059 (R_w = 0.070) was obtained.[5] The description of an independent structure determination of **8** was published subsequent to the completion of our analysis (10). A comparison of temperature effects on this molecular structure at 116 K (10) and 289 K[5] was thereby afforded.

Synthesis of the 3′,5′-O-(1,1,3,3-tetraisopropyldisilox-1,3-diyl) compounds was effected by a general procedure illustrated by the following preparation.

3′,5′-O-TPDS-adenosine (1)

To 267 mg (1 mmol) of dried adenosine suspended in 10 mL of dry pyridine was added 320 μL (316 mg, 1 mmol) of 1,3-dichloro-1,1,3,3-tetraisopropyldisiloxane and the mixture was stirred at room temperature for 3 h. Pyridine was evaporated and the residue was partitioned between EtOAc and H_2O. The organic phase was washed with 2 × 20 mL of cold 1 *N* HCl/H_2O, H_2O, saturated $NaHCO_3$/H_2O, saturated NaCl/H_2O, dried (Na_2SO_4), filtered, and evaporated. The resulting amorphous product contained only minor impurities (tlc).

For characterization, this material was chromatographed on a column of silica gel (2 × 10 cm, 10 g) using $CHCl_3$ followed by 2% MeOH/$CHCl_3$ for elution. Appropriately pooled fractions were evaporated and the residue was crystallized from CH_3CN to give 433 mg (85%) of **1** with mp 98–99.5°C; uv (0.1 *N* HCl) max 257 nm (ε 14 900), (0.1 *N* NaOH) max 259 nm (ε 15 100). *Anal.* calcd. for $C_{22}H_{39}N_5O_5Si_2$: C 51.84, H 7.71, N 13.74; found: C 51.65, H 7.92, N 13.73.

Isolation methods and characterization data for compounds **1***a*, **4**, **4***a*, **5**, **5***a*, **6**, **6***a*, **7**, **7***a*, **8***b*, **8***c*, **11** will be published separately (11) with details of our 2′-deoxygenation procedures (4*a*). Isolation, yields, and data for compounds **3**, **8**, **8***a*, **13** may be found in ref. 4*b*. Compounds **2**, **4***b*, **4***c*, **9**, **10**, **12**, **12***a*, **14**, **15**, **16**, **17**, **19**, **20**, **21**, **22**, **23** were prepared by treatment of a 0.1 mmol sample of the precursor nucleoside with 2.5 mL of dry pyridine and 32 μL (0.1 mmol) of 1,3-dichloro-1,1,3,3-tetraisopropyldisiloxane according to the general procedure. The standard processing was followed by chromatography of the residue on preparative silica gel plates (5 × 20 cm) using 5% MeOH/$CHCl_3$. The product zone was scraped from the plate and the compound was eluted with 7% MeOH/$CHCl_3$. The filtered eluate was evaporated and the tlc homogeneous oils had the spectral properties listed in Tables 2–6.

Compound **18** was prepared by the procedure used for **11** (4*b*).

Compounds **19***a* and **23***a* were prepared by the general procedure using 0.1 mmol samples of the precursor nucleosides and 32 μL of the bifunctional silylating reagent in 5 mL of dry pyridine. After stirring for 3 h, 20 μL (2 mmol) of acetic anhydride was added and stirring was continued for 4 h. Volatile materials were evaporated and the residues were chromatographed on columns (1.5 × 7 cm, 6 g) of silica gel using $CHCl_3$. Evaporation of appropriate fractions gave **19***a* (76%) and **23***a* (77%) as tlc homogeneous oils with the spectral properties listed in Tables 4–6.

Results and discussion

Table 1 presents the 36 structures of the 3′,5′-*O*-TPDS-furanosyl derivatives examined in this study. Table 2 contains the chemical shift data and Table 3 the first order spin–spin coupling parameters for 25 β-D-ribofuranosyl compounds. Table 4 contains the chemical shift data and Table 5 the coupling parameters for α-D-ribo-, β-D-arabino-, and α-D-arabino-furanosyl derivatives. Table 6 contains the high resolution mass spectral data and uv absorbance maxima for characterization of the 3′,5′-*O*-TPDS derivatives prepared for this study. The X-ray crystallographic positional and equivalent isotropic thermal parameters for the non-hydrogen atoms of 3′,5′-*O*-TPDS-cytidine (**8**) are given in Table 7.

A. Determination of anomeric configuration

As seen in Table 3, the coupling of H1′ with H2′ was less than the limit of resolution ($J_{1'-2'} < 0.5$ Hz) resulting in the appearance of a sharp singlet for the anomeric proton signal for 13 β-D-ribofuranosyl derivatives (**5**, **6**, **7**–**12***a*). The anomeric proton signal for 9 additional compounds (**1**–**4**, **4***b*, **4***c*, **5***a*, **6***a*) appeared as a narrowly split doublet with $J_{1'-2'} \leq 1.5$ Hz. Exceptions to this $J_{1'-2'} \leq 1.5$ Hz limit were observed with the 3′,5′-*O*-TPDS derivatives of the C-nucleoside antibiotics formycin (**13**, $J_{1'-2'}$ = 2.0 Hz) and pyrazofurin (**14**, $J_{1'-2'}$ = 2.7 Hz) as well as with the 2′-*O*-phenoxythiocarbonyl derivative (**4***a*, $J_{1'-2'}$ = 2.6 Hz) of 3′,5′-*O*-TPDS-guanosine.

Examination of the types of compounds reveals that all ten pyrimidine-type derivatives gave anomeric proton singlets. This includes three pyrimidine *N*-nucleosides with free 2′-hydroxyl functions (**7**, **8**, **8***b*), three with 2′-*O*-phenoxythiocarbonyl groups (**7***a*, **8***a*, *c*), two 3-deazapyrimidine *N*-nucleosides (**9**, **10**), and two pyrimidine C-nucleosides (pseudouridine, **12**, and the antibiotic oxazinomycin, **12***a*) each with free 2′-hydroxyl functions. Additional examples of related pyrimidine C-nucleoside derivatives have been reported very recently.[6] Anomeric proton singlets were also observed for the 3′,5′-*O*-TPDS derivatives of methyl β-D-ribofuranoside (**11**), and the two pyrrolo[2,3-*d*]pyrimidine antibiotics tuber-

[5]A discussion of the crystal data and detailed structure features as well as tables of anisotropic thermal factors, hydrogen parameters, and calculated and observed structure factor amplitudes (19 pages) have been placed in the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2, and may be obtained from that depository at a nominal cost.

[6]Four pyrimidine C-nucleosides with a free 2′-hydroxyl and two with 2′-*O*-imidazolylthiocarbonyl groups were reported by Pankiewicz *et al.* (12) to have anomeric proton singlets.

[a]The indicated hydroxy-purine and pyrimidine compounds occur as their keto tautomers in solution.

cidin (**5**) and toyocamycin (**6**), each with a free 2′-hydroxyl group. The purine nucleoside derivatives with free 2′-hydroxyl functions (**1**, **2**, **3**, **4**, **4***b*, **4***c*) had narrow anomeric proton doublets with $J_{1'-2'}$ = 0.9–1.5 Hz. The 2′-*O*-phenoxythiocarbonyl derivatives of the purine and pyrrolo[2,3-*d*]-pyrimidine compounds (**1***a*, **4***c*, **5***a*, **6***a*) exhibited anomeric proton doublets with $J_{1'-2'}$ = 1.2–1.5 Hz with the exception of the above noted $J_{1'-2'}$ = 2.6 Hz for **4***a*.

A minor increase in the anomeric proton coupling constant of **1** was observed with an ~80°C increase in temperature in dimethylsulfoxide (DMSO) solution. However, solvent effects were more substantial. The spectrum of **1** in DMSO had $J_{1'-2'}$

[j]Singlet —OCH_3.

= 0.9 Hz, but in chloroform it increased to $J_{1'-2'}$ = 1.4 Hz. Compound **5** in DMSO had an anomeric proton singlet, but in chloroform $J_{1'-2'}$ = 1.5 Hz was observed. The anomeric proton coupling of **13** was reduced to $J_{1'-2'}$ = 2.0 Hz in acetone, but increased to $J_{1'-2'}$ = 3.2 Hz in chloroform.

It is apparent that the conformations of these *trans*(1,2)-fused 8 to 5 membered ring 3′,5′-*O*-TPDS-β-compounds reside in a *preferred range* rather than the rigidly fixed geometry of the *trans*(1,2)-fused 6 to 5 membered cyclic 3′,5′-monophosphates (1). The purine-type 3′,5′-*O*-TPDS derivatives exhibit larger anomeric proton couplings and are subject to temperature and solvent effects. Significant increases in the H1′ coupling constant occur with several of the present derivatives upon acylation of O2′ to give phenyl thionocarbonate esters in contrast with negligible effects observed upon substitution of O2′ with the cyclic 3′,5′-monophosphates (1).

Four α-D-ribofuranosyl 3′,5′-*O*-TPDS derivatives (**15–18**) were examined. As seen in Table 5, their anomeric proton coupling values ($J_{1'-2'}$ = 3.5–4.0 Hz) are closely similar to those observed with the cyclic α-D-3′,5′-monophosphates (1, 13). Likewise, five β-D-arabinofuranosyl 3′,5′-*O*-TPDS derivatives (**19–22**) had *cis* $J_{1'-2'}$ = 6.0–6.7 Hz couplings in harmony with the cyclic 3′,5′-monophosphate analogues (1).

With the evidence at hand we consider that an anomeric proton coupling of $J_{1'-2'} \leq 1.5$ Hz provides a safe criterion for assignment of the β configuration to a ribofuranosyl 3′,5′-*O*-TPDS derivative. It would appear that the corresponding α anomers have $J_{1'-2'} \geq 3.5$ Hz. However, owing to the exceptions noted, couplings of $J_{1'-2'} \gtrsim 2$ Hz could be ambiguous and corroborative methods (1) should be employed.

B. X-ray crystal structure of 3′,5′-O-TPDS-cytidine (8)

Final positional and isotropic thermal parameters for the atoms of compound **8** are listed in Table 7.[5] Figure 1 shows a stereo ORTEP (14) diagram of the molecule with identification of the atomic numbering scheme used for the crystallographic analysis. Bond lengths (no corrections were made for riding motion) and bond angles are given in Fig. 2. A stereoscopic diagram of the crystal packing of **8** is presented in Fig. 3.

1. *General structure features*

The endocyclic bond lengths and angles in the sugar moiety of **8** are compatible with those found in nucleoside cyclic 3′,5′-monophosphates (15). However, they deviate from certain trends noted in "free" nucleoside furanosyl structures (16). The expanded Si—O—Si bond angle of 155.1° allows formation of a "flattened" disiloxane ring with Si1, Si2, O12, O3′, O5′, and C4′ coplanar within a mean deviation of 0.037 Å. The C3′ and C5′ atoms lie 0.81 Å and 0.78 Å, respectively, on opposite sides of the plane, resulting in an overall "twist" conformation for the 8-membered ring. Large variations in

[a]See footnotes *a–j* of Table 2 which apply also to this table.

Si—O—Si bond angles have been reported (17). The glycosyl torsion angle χ_{CN} (O4′-C1′—N1-C6) is 16.9°, in the normal *anti* range. The C4′—C5′ rotamer is *gauche*$^+$ (gg) with a torsion angle of 45.9°. The nearly perfect ^3E (C3′-*endo* envelope) conformation of the furanose ring has a pseudorotation angle of $P = 19.7°$ with a maximum puckering amplitude of $\tau_m = 41.9°$, in harmony with the normal *N*-hemisphere ranges (18) and our ^{1}H nmr solution results (see section C.2.).

2. *Temperature effects*

Crystals of 3′,5′-*O*-TPDS-cytidine (**8**) decrease in their unit cell volume by 3.7% on cooling from 289 K[5] to 116 K (10). This decrease is due completely to a 1.07 Å shrinkage in the *c* unit cell dimension (the *a* and *b* cell axes lengths increase slightly). In spite of the large change in unit cell dimension, the molecular dimensions of 3′,5′-*O*-TPDS-cytidine are very similar. Bond lengths C2—N3, C2′—C3′, and C4′—O4′ differ by 3σ to 4σ between the two determinations. However, the largest discrepancies of up to 0.07 Å are in the disordered region of the four isopropyl groups. In our room temperature structure determination the equivalent isotropic B factors are in the range 9–18 Å^2 (Table 7)[5] whereas the liquid nitrogen temperature has reduced these values by a factor of approximately three to 3.1–8.7 Å^2 (10).

The two structures have been compared by a rigid body rotation and translation least-squares minimization program. The rms difference in positional coordinates after the refinement is 0.081 Å for the 32 non-hydrogen atoms. The largest atomic position differences are in the isopropyl groups (0.10–0.16 Å) and for the amino-nitrogen atom of the cytosine

agree more closely.

It can be seen in Fig. 3 that there are 4 molecules stacked parallel to the *c* axis. Thus, the large shrinkage of 1.07 Å in the *c* dimension can occur by relatively small movements of ~0.25 Å between the layers relative to one another. This movement is probably a result of the reduced amplitude of thermal motion of the isopropyl groups in the hydrophobic layer. Also contributing is an apparent change in the intermolecular hydrogen bonding involving O2′ and N3 on 2_1 related molecules. The low temperature structure has a bifurcated hydrogen bond for the hydrogen atom on atom O2′ (to N3 and O2 respectively) whereas in our room temperature structure the O2′—H···O2 interaction is not consistent with hydrogen bonding even though the O2′···O2 distance is short (O---O: 2.99 Å, O---H: 2.41 Å). Theoretical analysis of these two structures should contribute to an understanding of the molecular dynamics involved in the structural changes.

C. ^{1}H nuclear magnetic resonance solution studies

1. *General considerations*

Conversion of the 2′-hydroxyl groups of 3′,5′-*O*-TPDS-ribonucleosides to their phenyl thionocarbonate esters resulted in downfield shifts of $\Delta\delta$ = 1.94–2.16 ppm for the H2′, 0.44–0.80 ppm for the H3′, and 0.22–0.50 ppm for the H1′ signals (see Table 2). The $J_{1'-2'}$ values increased upon thioacylation of O2′ for the purine-type compounds (**1**, **4**, **5**, **6** → **1***a*, **4***a*, **5***a*, **6***a*), but remained at $J_{1'-2'} < 0.5$ Hz for the pyrimidine derivatives (**7**, **8**, **8***b* → **7***a*, **8***a*, **8***c*). The $J_{2'-3'}$ values increased significantly upon thioacylation of O2′ for both purine and pyrimidine compounds (**1**, **4**, **7**, **8** → **1***a*, **4***a*, **7***a*, **8***a*), but remained essentially constant for tubercidin and toyocamycin (**5**, **6** → **5***a*, **6***a*) (see Table 3).

A remarkably consistent environment in the C4′—C5′ region of these 3′,5′-*O*-TPDS derivatives is indicated by the chemical shift and coupling data for H4′, H5′, and H5″ in Tables 2–5. Only minor perturbations in these parameters occur upon changing the base substituent at C1′ or upon thioacylation of O2′. A nearly symmetrical *gauche*$^+$ equilibrium for the C4′—C5′ orientation in harmony with the crystal data (see section B.1.) is suggested from the $J_{4'-5'}$ and $J_{4'-5''}$ values. The absence of trends relating minor changes in $J_{3'-4'}$ with changes in $J_{1'-2'}$, base substituent type at C1′, or thioacylation of O2′ argues for restricted conformational mobility and/or a consistent equilibrium population in the C3′—C4′—C5′ molecular fragment.

Reliable conformational analysis of these 3′,5′-*O*-TPDS derivatives in solution by ^{1}H nmr is complicated by several factors. (1) Karplus equation constants are sensitive to the electronegativity of substituents as well as to bond length and angle distortions. The disiloxane bridge represents a new substituent and furanose ring distortions similar to those seen in cyclic 3′,5′-monophosphates (15) are present. (2) Nucleosides, nucleotides, and nucleoside cyclic 2′,3′-monophosphates have been treated as pseudorotating equilibrium mixtures (19–21) whereas nucleoside cyclic 3′,5′-monophosphates have been regarded as rigid single conformers in solution (1, 9, 13, 22). Crystallographic thermal parameters of **8** are high for the isopropyl groups. Temperature and solvent effects on the coupling parameters of certain 3′,5′-*O*-TPDS compounds also would suggest conformational flexibility for the fused ring system. However, the X-ray structure of **8** as well as consistency in coupling values in the C3′—C4′—C5′ region are more compatible with the restricted cyclic 3′,5′-monophosphate features. (3) The two-state *N* ⇄ *S* (C3′-*endo* C2′-*exo* ⇄ C3′-*exo* C2′-*endo*) pseudorotational model of Altona and Sundaralingam (18*a*, 19) assumes a small rotation barrier about C2′—C3′ on a "symmetrical" furanose ring and is in harmony with a large data base of crystal structures for nucleosides and "open" nucleotides. However, in the present 3′,5′-*O*-TPDS-ribonucleosides, there are no clear reciprocal trends relating $J_{1'-2'}$ and $J_{3'-4'}$ or ($J_{1'-2'}$ + $J_{3'-4'}$) and $J_{2'-3'}$. Therefore, flattening of the molecule and fluctuations of the pucker in the O4′—C1′—C2′ region might add further complexity.

First-order analysis of the 400 MHz ^{1}H nmr spectrum of **8** gave coupling parameters that were not altered significantly by computer simulation. No attempt was made to further refine the data for the other compounds since first-order values were similar for a sizeable number of resolved spectral peaks. The pseudorotational model involves major assumptions (19, 23) and the resulting analyses, while providing very useful results, must be recognized as somewhat uncertain approximations.

2. *3′,5′-O-TPDS-β-D-ribofuranosyl compounds*

Mean average coupling parameters for nine 3′,5′-*O*-TPDS ribonucleoside derivatives (**1**, **1***a*, **2**–**4**, **4***b*, **4***c*, **5***a*, **6***a*) from Table 3 are $J_{1'-2'}$ = 1.4 ± 0.2 Hz, $J_{2'-3'}$ = 5.1 ± 0.2 Hz, $J_{3'-4'}$ = 8.2 ± 0.3 Hz, and ($J_{1'-2'}$ + $J_{3'-4'}$) = 9.6 ± 0.4 Hz. The Altona–Sundaralingam numerical treatment (19) gives a "best fit" for an 85% *N* (15% *S*) equilibrium composition (K_{eq} = 0.18) with pseudorotational parameters of P_N = 4.3°, $^N\tau_m$ =

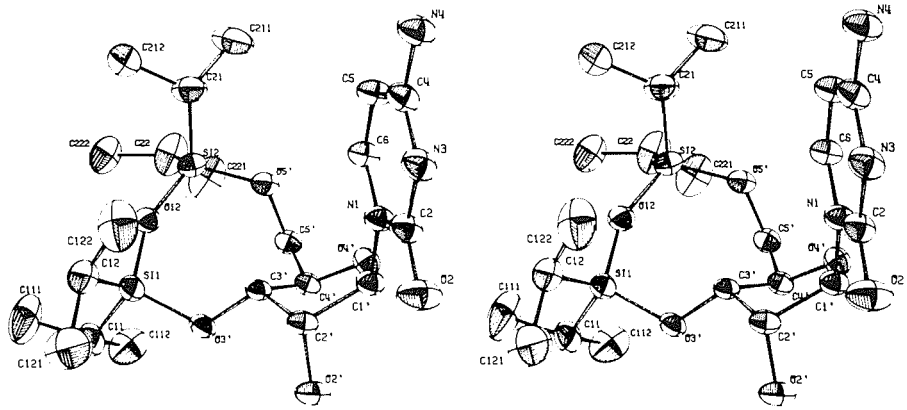

FIG. 1. ORTEP stereodrawing of 3′,5′-*O*-TPDS-cytidine showing the atom numbering used in this analysis. The thermal ellipsiods enclose 20% probability. The glycosyl torsion angle χ_{CN} (O4′-C1′—N1-C6) is 16.9°. The β-D-ribose ring has the ^3E conformation. The fused 8-membered trioxadisilacyclooctane is flattened with six atoms approximately coplanar (mean Δ = 0.037 Å). Atoms C3′ and C5′ deviate by −0.81 Å and 0.78 Å on opposite sides of this plane.

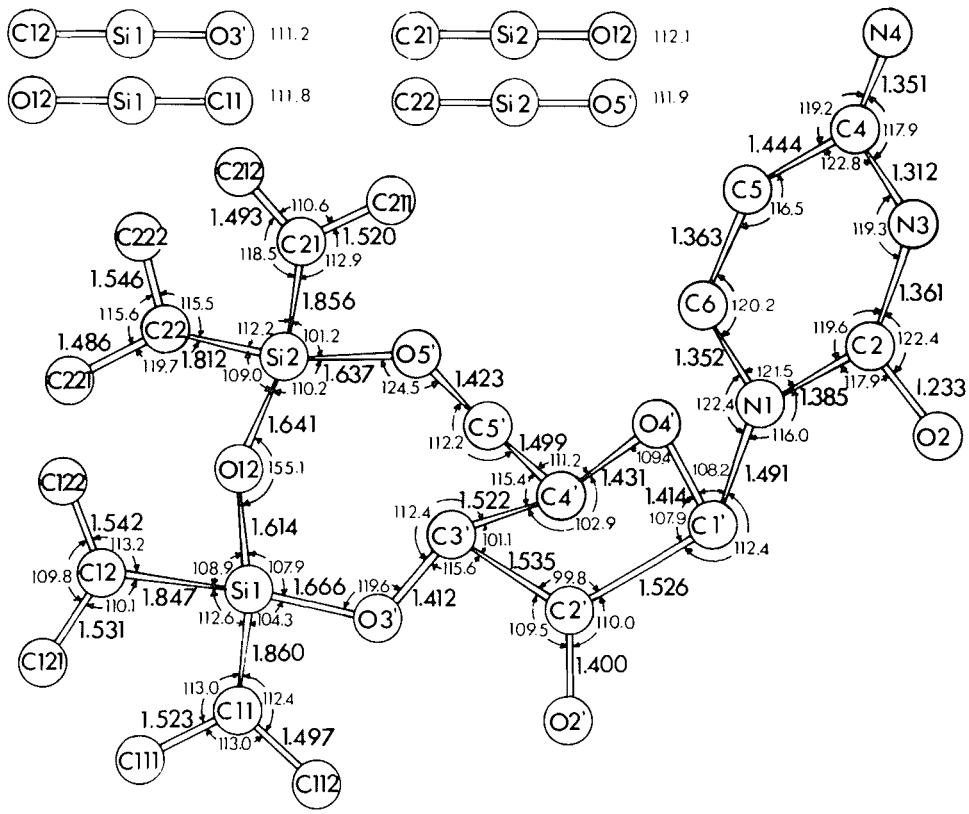

FIG. 2. Bond distances and interbond angles for 3′,5′-*O*-TPDS-cytidine at $R = 0.059$. The average esd's in bond lengths are 0.006 Å, in bond angles 0.4°.

35.6°; $P_S = 170.4°$, $^S\tau_m = 36°$; $^NJ_{1'-2'} = 0$ Hz, $^NJ_{3'-4'} = 9.6$ Hz; $^SJ_{1'-2'} = 9.5$ Hz, $^SJ_{3'-4'} = 0.1$ Hz. A modified Karplus vicinal proton coupling equation ($J_{H-H} = A\cos^2\phi_{H-H} - B\cos\phi_{H-H}$) with $A = 10.5$ and $B = 1.2$ was used (19). The related graphical analysis of Davies and Danyluk with Karplus constants of $A = 9.8$ and $B = 0.9$ calculated for ribonucleotides (20*a*) gave an 87% *N* (13% *S*, $K_{eq} = 0.15$) composition with $P_N = 21°$, $^N\tau_m = 37°$; $P_S = 163°$, $^S\tau_m = 39.5°$.

These parallel pseudorotational treatments indicate an $N \rightleftarrows S$ equilibrium with ~85% population in the ^3E–$^3T_2$ sector of *N*-pseudorotamers and ~15% in the ^2E–$^2T_3$ *S*-range (19). The calculated parameters fall within the most highly populated ranges found for β-D-ribofuranosyl compounds in the solid state (18*a*) and those indicated for the *N*-conformer average are compatible with the crystallographic structure of **8** (see section B.1.). It is noteworthy that the averaged coupling values are in harmony with the Case D pseudorotational composition of Altona and Sundaralingam,[7] but not with any single "ideal" conformation derived directly.

The derivatives (**5**, **6**, **7**–**8***a*, **8***c*, **10**–**12***a*) with vanishingly small anomeric proton coupling constants ($J_{1'-2'} < 0.5$ Hz) have a slightly smaller $J_{2'-3'} = 4.9 \pm 0.4$ Hz mean coupling

and a slightly larger $J_{3'-4'} = 8.5 \pm 0.4$ Hz mean than the above group of nine compounds. However, the variation in these couplings is greater and the mean limits overlap the former series. The sum ($J_{1'-2'} + J_{3'-4'}$) is smaller in the latter group owing to the decrease in $J_{1'-2'}$. This would suggest a more flattened ring, but no significant increase in $J_{2'-3'}$ is observed as would be expected from an "ideal" pseudorotating furanose system (19). By comparison, mean coupling values for four nucleoside cyclic 3′,5′-monophosphates (*c*AMP, *c*GMP, *c*UMP, *c*CMP) were reported to be $J_{1'-2'} < 0.7$ Hz, $J_{2'-3'} = 5.4 \pm 0.2$ Hz, and $J_{3'-4'} = 9.9 \pm 0.2$ Hz (1, 22*c*). *Both* $J_{2'-3'}$ and $J_{3'-4'}$ are significantly larger than in the present series of 3′,5′-*O*-TPDS derivatives. The cyclic 3′,5′-monophosphates have been assumed to exist in an essentially rigid $^3T_4$ to ^3E conformation range. Distortions resulting from the strained fused ring system have been assumed to cause deviations in coupling values from those expected for an ideal ^3E conformer.

A "relaxed" C3′—C4′ region with a more flattened furanose ring in the *N* (^3E–$^3T_2$) range distorted by fusion with the hindered disiloxane fragment (in pseudorotational equilibrium with a minor population of *S*-forms) probably represents the best estimation of the solution conformation of these 3′,5′-*O*-TPDS-β-D-ribofuranosyl compounds. The series with $J_{1'-2'} < 0.5$ Hz appears to shift toward a more nearly pure *N*-type population with additional furanose distortions. However, a more nearly rigid conformation with significant angle distortions cannot be exluded completely.

3. *3′,5′-O-TPDS-α-D-ribofuranosyl compounds*

Mean coupling values for the four α-D-ribofuranosyl anomers (**15**–**18**) in Table 5 are $J_{1'-2'} = 3.8 \pm 0.2$ Hz, $J_{2'-3'} = 4.5 \pm 0.5$ Hz, and $J_{3'-4'} = 8.5 \pm 0.5$ Hz. These parameters compare favorably with those found for four α-D-ribofuranosyl cyclic 3′,5′-monophosphates ($J_{1'-2'} = 3.9 \pm 0.6$ Hz, $J_{2'-3'} = 4.2 \pm 0.4$ Hz, and $J_{3'-4'} = 10.0 \pm 0.2$ Hz) (13) except, again, for the more "relaxed" H3′—H4′ coupling. The slightly increased $J_{2'-3'}$ mean and sizeably reduced $J_{3'-4'}$ couplings in the 3′,5′-*O*-TPDS compounds are compatible with flattening of the furanose ring in the *N*-range (19) relative to the "maximally puckered" cyclic 3′,5′-monophosphates (13).

4. *3′,5′-O-TPDS-arabinofuranosyl compounds*

Mean coupling values for the five β-D-arabinofuranosyl derivatives (**19**,. **19***a*, **20**–**22**) in Table 5 are $J_{1'-2'} = 6.4 \pm 0.2$ Hz, $J_{2'-3'} = 7.8 \pm 0.4$ Hz, and $J_{3'-4'} = 8.1 \pm 0.2$ Hz. Directly derived mean angles from $J_{H-H} = 10.5 \cos^2 \phi_{H-H} - 1.2 \cos \phi_{H-H}$ are $\phi_{1'-2'} = 33°$, $\phi_{2'-3'} = 144°$, and $\phi_{3'-4'} = 145°$. This clearly, indicates a conformer population in the *N* ($_2T^3$–$_2E$) range in harmony with partial coupling data for β-D-arabinofuranosyl cyclic 3′,5′-monophosphates (1) and in constrast with the "pure" *S* (^2E) conformers observed for arabinofuranosyl cyclic 2′,5′-monophosphates (9, 24, 25). This also provides corroboration of the 3′,5′-*O*-TPDS (vs. the possible 2′,5′-*O*-linkage) structure for these arabino derivatives.

Two 3′,5′-*O*-TPDS-α-D-arabinofuranosyl anomers (**23** and **23***a*) were prepared. The $J_{1'-2'} = 5.7$ Hz, $J_{2'-3'} = 8.1$ Hz, and $J_{3'-4'} = 8.7$ Hz values for **23** and $J_{1'-2'} = 5.8$ Hz and $J_{2'-3'} = 7.5$ Hz for **23***a* are again compatible with an *N*-type conformation population.

Conclusions

A strong preponderance of *N*-type conformers with a remarkably consistent range of $J_{3'-4'}$ values is seen throughout the 3′,5′-*O*-TPDS nucleosides in the present study irrespective of the type of base substituent at C1′, the anomeric configuration at C1′, and the epimeric configuration or substituent at C2′. This indicates a rather demanding conformational preference for the tetraisopropyl-substituted *trans*(1,2) 1,3,5-trioxa-2,4-disilacyclooctane to furanose ring fusion. The powerful bias for the *N*-range of conformers is responsible for the small anomeric proton (H1′) to H2′ coupling values observed in the 3′,5′-*O*-TPDS-β-D-ribofuranosyl derivatives. An apparent low limit of $J_{1'-2'} \geq 3.5$ Hz exists for α-D-ribofuranosyl 3′,5′-*O*-TPDS compounds in agreement with their cyclic 3′,5′-monophosphate analogues (1). Larger anomeric proton coupling values occur with both α-D- and β-D-arabinofuranosyl 3′,5′-*O*-TPDS derivatives.

The β configuration of a ribofuranosyl 3′,5′-*O*-TPDS derivative can be assigned with confidence when $J_{1'-2'} \lesssim 1.5$ Hz. It should be recognized that *this is not an empirical criterion*, but is dependent on the geometrical constraints of the fused ring system. It is *definitive for the β anomeric assignment* whenever $J_{1'-2'} \lesssim 1.5$ Hz is observed directly, or is realized by alteration of solvent or temperature. Alternative methods (1) should be employed to corroborate β assignments in cases of $J_{1'-2'} \gtrsim 1.6$ Hz and to verify α assignments ($J_{1'-2'} \geq 3.5$ Hz). The latter ranges of couplings might be found to overlap with certain anomeric pairs owing to the potential flexibility of the 8 to 5 fused ring system.

The commercial availability of 1,3-dichloro-1,1,3,3-tetraisopropyldisiloxane[8] makes this determination readily applicable.

A mixed micellar cholesteric mesophase has been prepared using sodium L-lauroylalaninate (L-LAK) and sodium D-lauroylserinate (D-LSK). The cholesteric mesophase can be synthesized with all mixtures of these amphiphiles from 100% L-LAK to 100% D-LSK in the micelle. The measurement of the pitch length at constant temperature has been accomplished for the whole range of relative composition of the two different single chiral centre amphiphiles at constant water content and with all other components unchanged in composition. The inverse pitch length is not a simple function of composition as has been found in thermotropic cholesterics. The sign of the helix is the same for L-LAK and D-LSK. Temperature dependence of the pitch in both the single chiral amphiphile and mixed chiral amphiphile mesophases gives longer pitches as the temperature is raised in all cases.

D. D. LASIČ, M. E. MARCONDES HELENE et L. W. REEVES. Can. J. Chem. **61**, 1921 (1983).

On a préparé une mésophase cholestérique micellaire mixte en utilisant le L-lauroylalaninate de sodium (L-LAK) et le D-lauroylsérinate de sodium (D-LSK). On peut synthétiser la mésophase cholestérique avec tous les mélanges possibles de ces amphiphiles en partant de 100% de L-LAK jusqu'à 100% de D-LSK dans la micelle. On a mesuré la longueur du pas à température constante pour tout le domaine de composition relative des deux différents amphiphiles de centre chiral simple pour une teneur constante en eau sans changer la composition des autres composants. La longueur du pas inverse n'est pas une fonction simple de la composition comme on l'a trouvé dans les cholestériques thermotropiques. L'hélice a le même signe dans le L-LAK et dans le D-LSK. L'effet de la température sur le pas de l'hélice dans le cas de l'amphiphile simple et dans le cas des mésophases amphiphiles chiraux mixtes, se traduit dans tous les cas par une augmentation du pas lorsque la température s'élève.

Introduction

A type II cholesteric liquid crystal based on finite micelles, containing a single centre resolved optically active amphiphile, was recently prepared for the first time (1). The negative diamagnetic anisotropy, perpendicular to the helix axis, requires that the latter axis aligns parallel to a magnetic field (2). The procedure of locating a type II DM nematic phase, and then at the same composition unbalancing the mixture of *d* and *l* forms of the amphiphile, was successful in creating three more type II cholesterics based on potassium lauroyl alaninate, serinate, and valinate (3). The pitch length of the aligned mesophases was determined as a function of the mole fraction of D and L forms, the water content, the concentration of some highly dissymmetric solutes, and the presence of such solutes at a fixed concentration in the bilayers (3). In the simplest case of mixtures of D and L forms the inverse pitch obeyed the equation

$$[1] \quad \frac{1}{2p} = \beta(2x_L - 1)$$

where p = the helical pitch length, β is the twisting power of the single centre amphiphile, and x_L = mole fraction of the L form of this amphiphile in the bilayer of the mesophase. The mole fractions of all components in the mesophases made from potassium lauroylalaninate (LAK) and potassium lauroyl serinate (LSK) were the same and, consequently, mixed phases using the L form of one and the D form of the other are accessible. The cholesteric behaviour in these micellar liquid crystals is a secondary consequence of the dissymmetric amphiphile, which resides in a micelle bilayer (3). The agreement with eq. [1] gives no information that the twist is a secondary consequence of interactions between molecules. The present article is devoted to a study of the cholesteric pitch resulting from the use of two different amphiphiles where the cross term in the interaction model is not zero (4). In addition, the opportunity has been afforded to study the pitch length as a function of temperature.

Experimental

Sodium D-*N*-lauroylserinate(D-LSK) and sodium L-*N*-lauroylalaninate (L-LAK) were synthesized according to published procedures for acylation of amino acids (5). Mesophases which were type II cholesteric were prepared using mixtures of D-LSK and L-LAK, in which the mole fractions of all components, amphiphiles, electrolyte, and water, were maintained constant. The mesophase compositions in terms of moles were: 1.175 mol of L-LAK + D-LSK, 0.337 mol of Na_2SO_4, 0.446 mol of decanol, and 38.9 mol of $H_2O(D_2O)$. The ratio of moles of the L-LAK and D-LSK used in the mixture of chiral amphiphiles were 1:0, 0.8:0.2, 0.6:0.4, 0.4:0.6, 0.2:0.8, and 0:1. The pitch lengths were measured by laser diffraction in aligned or unaligned samples with the wavelength 632.8 nm at room temperature.

Results

The inverse pitch versus mole fraction of D-LSK in the mixture of optically active amphiphiles is plotted in Fig. 1. Unlike mesophases prepared from single optically active amphiphiles, the dependence is not linear (3). The mixture produces a nematic mesophase at 0.72 mole fraction D-LSK in the mixture at 30°C.

The inverse pitch versus temperature for the mesophases

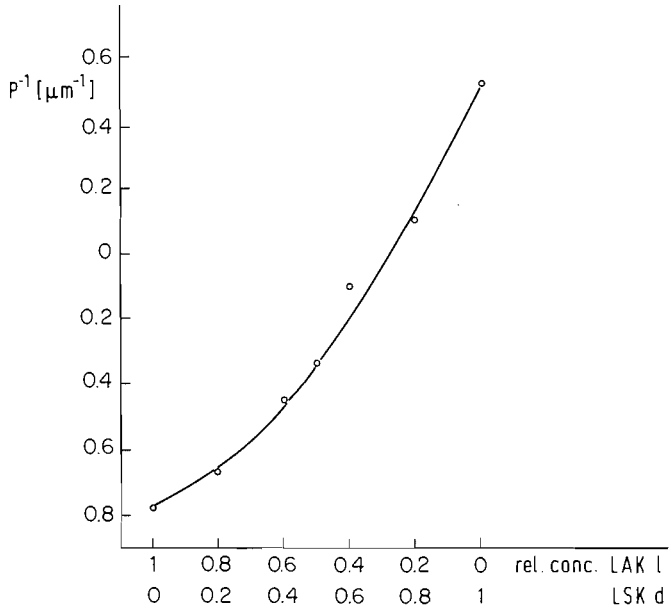

FIG. 1. Variation of the inverse pitch versus composition.

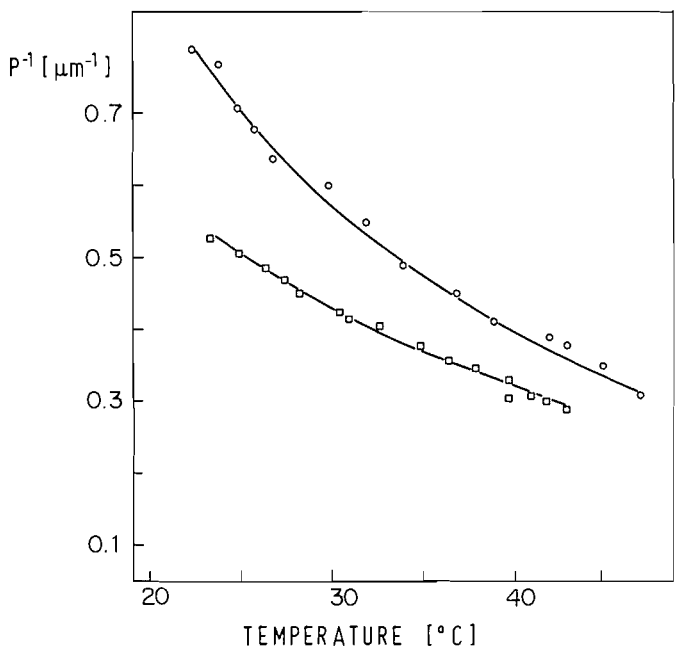

FIG. 2. Temperature dependence of the inverse pitch of pure L-LAK (circles) and pure D-LSK (squares).

containing pure D-LSK and pure L-LAK is plotted in Fig. 2. In both cases the pitch length increases with temperature and the inverse pitch is not a linear function. In Fig. 3 the inverse pitch of two mixtures of the two amphiphiles is represented as a function of temperature. A similar nonlinear dependence is found with the pitch lengthening with temperature rise.

Discussion

Cholesteric liquid crystals derived from orientationally ordered finite micelles (6) are fundamentally different from thermotropic liquid crystals from a molecular viewpoint. The system is compartmentalized into nonmixing regions, the finite micelles, and the aqueous compartment. In this and prior cases (1, 3) the optically active components are contained within the

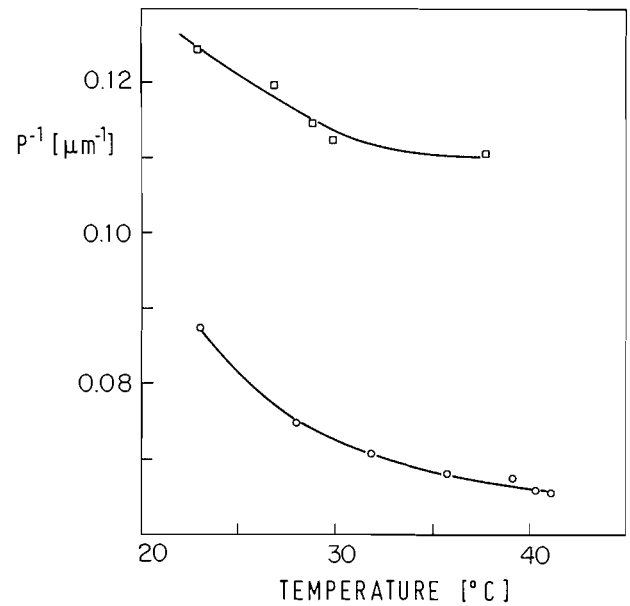

FIG. 3. Temperature dependence of the inverse pitch of sample with 0.4 L-LAK and 0.6 D-LSK (squares) and of sample with 0.2 L-LAK and 0.8 D-LSK (circles).

micelles, being amphiphilic compounds. The nematic phase is obtained from equimolar concentrations of D and L forms of the same amphiphile, in which case the micelles are known to be bilayer disks which are planar. The micellar liquid crystals have, in the present case, no chiral components in the aqueous compartment. The twisting action at short range between dissymmetric components can only proceed within the micelle to the extent of its major dimension distance. The micelle is then isolated from the next neighbour by components such as water and simple spherical ions which have no chiral aspect. It was suggested in two prior publications (1, 3) that the long range helical orientational order of the cholesteric phase derives from a partial twisting of individual micelles which then pack more efficiently with helical rather than nematic order. However, there are other explanations of the reduction of asymmetric micelles.[2] The same chiral amphiphiles in lower concentrations of water form *lamellar* phases, which can have no helical axis formed from a transmission of chiral information across the intervening water barrier between infinite micelles.

It is known (6) that the finite micelle nematics have different mean micelle sizes over the range of water content of the nematic system. At the highest water content the planar disk micelles are smaller. Correspondingly, because the cholesteric phase is derived from the nematic phase merely by preparing it with an unbalanced mixture of D and L forms, the micelle size in the cholesteric phase decreases as water content increases. Since the pairwise interaction over long range between amphiphiles may proceed only as far as the major dimension of the micelle, then this factor must enter into the equations affecting the pitch length. For this reason it was shown (3) that the pitch length depends in a complex manner on water content.

[2]D. D. Lasič, unpublished results. The chiral molecules dissolved in the micelle may induce tilted bilayers in the disklike micelles. In the rodlike micelles the lipid micelles may also not be perpendicular to the water surface. The same effect may also have chiral amphiphiles. Such asymmetric micelles can be packed into a helical order rather than in nematic order.

The equation of Bak and Labes (4) for thermotropic cholesteric mixtures, applies to D and L mixtures of the same amphiphile in the finite micelle case for fixed water content. The mole fraction taken for the D or L form is that in the micelle, and the number of moles of water and other nonchiral components are kept constant. The twist coefficients β are much smaller for the lyotropic case. The equation for a mixture of two optically active compounds (4) is

$$[2] \quad \frac{1}{2p} = \frac{1}{n_A + n_B} \{\beta_A n_A^2 + 2\beta_{AB} n_A n_B + \beta_B n_B^2\}$$

where β_A and β_B are twist coefficients for compound A and compound B and β_{AB} is a mutual twisting coefficient for the pairwise interaction of A with B. n_A and n_B are the number of moles of A and B. p is the helical pitch length. This equation is based on a model for the thermotropic case, where intermolecular pairwise interactions are continuous throughout the mesophase with no interruptions. In the lyotropic case, the water compartment interrupts the transmission of chiral information. In the form where β_A and β_B are obtained from the pitch in pure L-LAK and pure D-LSK mesophases, the equation is *not* obeyed in the present experiments. A much more complex theory is first required, which can account for such events as the change in micelle size with water content for the related nematic phases.

Figure 1 reveals that the sign of the helix in mesophases prepared from L-LAK is opposite to those prepared from D-LSK, because the pitch passes to infinity at an intermediate composition, to give a nematic phase.

The pitch length increases as the temperature is raised in all cases and this is unusual for thermotropic cholesterics; nevertheless an increase was previously observed in some thermotropic mixtures and induced cholesteric phases (7).

Cyclohexanones: evidence of chair inversion and estimate for barriers to planarity from the far-infrared spectra

TRACY L. SMITHSON, NAN IBRAHIM, AND HAL WIESER[1]

Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received February 23, 1983

TRACY L. SMITHSON, NAN IBRAHIM, and HAL WIESER. Can. J. Chem. **61**, 1924 (1983).

The far-infrared spectra in the region of 50–450 cm^{-1} are reported for the vapours of cyclohexanone and the structurally related compounds tetrahydro-4*H*-pyran-4-one, tetrahydro-4*H*-thiopyran-4-one, tetrahydro-4*H*-pyran-3-one, 1,3-dioxan-5-one, and 4*H*-pyran-4-one. Except for the last mentioned, the spectra are characterized by two or in some cases three sequences of Q branches which are assigned to the out-of-plane deformations of the cyclohexanone ring. The lowest wavenumber sequence in each compound is believed to arise from a vibration which, if completely executed, would take the chair conformation to its equivalent via an inversion through the planar form. Each sequence is amenable to solution by a one-dimensional Hamiltonian incorporating a quadratic–quartic potential function, providing estimates for the magnitudes of the barriers to planarity.

TRACY L. SMITHSON, NAN IBRAHIM et HAL WIESER. Can. J. Chem. **61**, 1924 (1983).

On rapporte les spectres dans l'infrarouge lointain (région de 50 à 450 cm^{-1}) des vapeurs de cyclohexanone et des composés structurellement apparentés: la tétrahydro-4*H*-pyranone-4, la tétrahydro 4*H*-thiopyranone-4, la tétrahydro 4*H*-pyranone-3, la dioxane-1,3 one-5 et la 4*H*-pyranone-4. A l'exception du dernier composé, les spectres sont caractérisés par deux ou, dans certain cas, trois séquences de Q raies que l'on attribue aux déformations hors plan du cycle de la cyclohexanone. On pense que la séquence ayant la plus faible longueur d'onde dans chaque composé, provient d'une vibration qui si elle est complète transformerait la conformation chaise en son équivalent via une inversion en passant par la forme plane. Chaque séquence peut être résolue par un Hamiltonien unidimensionnel impliquant une fonction de potentiel quadratique–quartique et fournit ainsi des évaluations de l'ordre de grandeur des barrières à la planéarité.

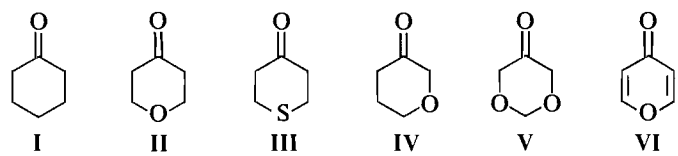
Introduction

In its ground state, cyclohexanone is believed to exist in a chair conformation that is somewhat flattened at the carbonyl end (1). In a fashion similar to cyclohexane, the ketone will pass from one chair conformation to its equivalent via several higher energy flexible forms. The inversion process is thought to reach a position of maximum energy with a transition state that is partially on its way to a symmetric boat form, and an intermediate metastable state with a symmetric twist form. Enthalpy differences between these two and the chair are estimated to be of the order of 26 and 13 kJ/mol (2140 and 1120 cm^{-1}), respectively (1). A corresponding experimental number quoted in terms of the free energy of activation of the transition state is 21 kJ/mol at −170°C (2). To our knowledge, no estimates of the barrier to planarity are available at this time.

The cyclohexanone ring gives rise to three out-of-plane deformation vibrations, at least one of which should exhibit a fair degree of anharmonicity. Carreira and Lord (3) some years ago have searched for evidence of these anharmonic motions in the far-infrared spectrum of the vapour without success. They reported a relatively strong B band at 182.0 cm^{-1}, and a much weaker and unresolved C band at 92.1 cm^{-1}, concluding harmonic behaviour from these observations. A hint that the situation may be more complicated comes from the microwave spectrum (4) which apparently was difficult to assign because of its richness, as indeed one would expect if a number of vibrational states were accessible at ambient temperature.

We have recorded recently the far-infrared spectra in the region of 50–450 cm^{-1} of cyclohexanone (**I**) and the structurally related compounds tetrahydro-4*H*-pyran-4-one (**II**), tetrahydro-4*H*-thiopyran-4-one (**III**), tetrahydro-4*H*-pyran-3-one (**IV**), 1,3-dioxan-5-one (**V**), and 4*H*-pyran-4-one (**VI**):



I **II** **III** **IV** **V** **VI**

All of these compounds but one (**VI**) show absorptions with the fine structure that is characteristic of anharmonic skeletal deformations. In the following the spectra and their interpretations are reported, together with estimates for the barriers to planarity where appropriate.

Experimental

The compounds **II**, **III**, and **VI** were purchased from Aldrich Chemicals and **I** from Matheson, with quoted purities of at least 99%. After verifying by nmr we used these materials without further purification. Drying was necessary only for **I** and was achieved by storing it over KOH. The compounds **IV** and **V** were synthesized as follows.

Tetrahydro-4*H*-pyran-3-one (**IV**): The 3-hydroxy precursor was first prepared by hydroboration of dihydropyran with sodium borohydride and borontrifluoride-etherate (5) in 21% yield, followed by oxidation (in 19% yield) with Jones' reagent (6, 7) to give the desired compound, bp 76–80°C/23 mm (lit. bp 57–58°C/9 mm (8)). NMR (60 MHz, $CDCl_3$): δ 3.91 (singlet, 2H, CH_2—O); 3.75 (triplet, 2H, CH_2—O); 2.60–2.30 (multiplet, 2H, CH_2); 2.26–1.81 (multiplet, 2H, CH_2). After fractional distillation the compound was about 91% pure, the impurity being the alcohol precursor. No attempt was made at further purification since the alcohol has a much lower vapour pressure and therefore did not cause any interference in the vapour phase far-infrared spectra.

1,3-Dioxan-5-one (**V**): In the first step, glycerol was acetalated with paraformaldehyde in an acidic medium following the method of Hibbert and Trister (9). The mixed acetals were equilibrated with a trace of acid to give the 5-hydroxy precursor in 36% yield. Subsequent oxidation with CrO_3–pyridine–CH_2Cl_2 complex (10) gave the target compound in 12% yield, bp 51–52°C/20 mm (semi-solid at room temperature). NMR (60 MHz, $CDCl_3$): δ 4.88 (singlet, 2H,

[1]To whom all correspondence should be addressed.

For personal use only.

O—CH_2—O); 4.23 (singlet, 4H, CH_2). Purification was achieved by fractional distillation. The final product was 90% pure, pyridine being the impurity. Interference in the far-infrared spectra from the latter material was removed by computer subtraction.

All the spectra were obtained with a Nicolet 8000 Fourier Transform Interferometer. The samples were contained in either a matched 60 m variable path gas cell manufactured by the same company, or a commercial Wilks 20 m variable path cell. The spectra were taken with 45 or 18.75 m, respectively, with sample pressures adjusted to give reasonable absorbancies for the features of interest. In most instances this meant near saturated vapour pressures. The resolution was set at 0.12 or 0.24 cm^{-1} with boxcar apodization. We used a liquid nitrogen cooled MCT-B detector above 400 cm^{-1}, and below that a liquid helium cooled bolometer operating at 4.2 K, equipped with the appropriate cut-on filters. The mirror velocity was adjusted for optimum signal-to-noise in the specific regions under study. Either a KBr beamsplitter, or a 3, 6, or 12 μm Mylar beamsplitter was used as appropriate. Between 200–500 scans were accumulated as required to achieve good signal-to-noise. The spectrometer was calibrated against standard water absorptions, and the reported positions of the sharp lines are believed to be accurate to at least 0.02 cm^{-1}.

The spectra and their interpretation

The three out-of-plane deformation modes of the cyclohexanone ring span $2A' + A''$ in the C_s symmetry point group. For the present purposes we will label them at $\nu_1(A')$, $\nu_2(A'')$, and $\nu_3(A')$ in increasing energy. In the liquid phase they have been assigned to the lowest three absorptions at 106, 188, and 312 cm^{-1}, respectively (11). The moments of inertia are such that the A' modes should display C-type contours and the A'' mode a B-type (4). Based on an extensive valence force field analysis (11), ν_1 is described as a ring distortion in which all the CCC angles change and the CC torsions and the C=O out-of-plane wag also participate, ν_2 is described essentially as a ring twisting deformation involving the β-CC bonds (a "partial flipping toward a chair–boat conformation inversion" (11)), and ν_3 as mostly a twisting of the γ-CC bonds. In addition, we may expect some involvement from the "in-plane" and "out-of-plane" wagging of the carbonyl group the latter of which we designate here by ν_{op}, not meaning to imply, however, that these vibrations are so localized.

The survey spectra of the six compounds in the region of 75–435 cm^{-1} are displayed in Fig. 1. Clearly, the most prominent common feature is ν_1 with its distinct C-type contour. The position is remarkably uniform, excepting **III** for which it is shifted to lower wavenumber due possibly to the increased reduced mass, and **VI** for which in any case one would expect a shift to higher wavenumbers. These findings agree with the description of ν_1 as involving the ring as a whole, with perhaps a greater contribution from the C=O end. The second mode is characterized by B contours at nearly the same position for **I**, **II**, and **III**. With the introduction of the oxygen atoms, the band contour changes for **IV** and **V**. In **VI** this vibration is infrared forbidden. These observations are in keeping with the notion that ν_2 represents primarily a twisting of the middle part of the chair. Finally, the C band of ν_3 shows little intensity in **I** and **III**, is prominent in **II** and **IV**, and weaker again in **V** and **VI**. The relative intensity of this mode in **I** as compared to **II**, **IV**, and **V** would suggest that the vibration involves a significant amount of that end of the ring which is diagonally opposite to the C=O group, also agreeing with the earlier assignment (11). The positions are summarized in Table 1.

The ν_1 mode of all compounds except for **VI** clearly exhibits the characteristic sequences of Q branches. This structure is not so apparent for the parent, although there too it can be seen distinctly upon expansion. The bands for **I** and **II** are shown on an enlarged scale in Fig. 2. The assignment for **I** is not immediately obvious, but can be made with confidence by comparing with **II**. For the latter, ν_3 also shows combination structure (Fig. 3), as well as a much weaker difference series near 240 cm^{-1} (Fig. 4). These sequences together provide an unambiguous assignment of all the transitions involved, yielding the unique energy level diagram depicted in Fig. 5. Accordingly, the structure of the ν_1 band in **I** and **II** must arise from the sequence of transitions in the ground state of all other modes and in the first excited state of ν_3. The ground state separations of ν_1 in **II** are confirmed by combination series based on ν_{op}, namely ν_{op} in several excited state of ν_1 starting at 504.57 cm^{-1}, and the corresponding sum bands $\nu_1 + \nu_{op}$, starting at 599.89 cm^{-1}, both progressing to lower wavenumbers (see Fig. 6). The ν_1 sequences of **IV** and **V** are expanded in Fig. 7. While for **III** the Q branches are so closely spaced as to be poorly resolved even with 0.06 cm^{-1} resolution (spectrum not shown), those of **IV** and **V** are widely separated as evident already in the survey spectra (cf. Fig. 1). There is some indication of ν_1 in the excited state of another mode for both **IV** and **V**, but in the absence of any sum or difference bands no clear assignment can be made. The modes ν_2 and ν_3 of the same molecules also show the distinctive multiplet structure (see Fig. 1), but again no unambiguous correlations are possible. For **V** the sequence of ν_2 appears to be that of a purely quartic oscillator for which reason it is reproduced on an expanded scale in Fig. 8.

The positions of ν_1 in the ground state of all other modes for compounds **I** to **V** are summarized in Table 2. In Table 3 are given the ν_1 separations in several excited states of ν_3 for **I** and **II**, as well as the separations of ν_2 for **V**. The positions of the other sequences in **II** are tabulated in Table 4.

Inversion of the cyclohexanone ring

For cyclohexane Pickett and Strauss pictured the three out-of-plane coordinates as deforming the planar ring to a boat-like, to a twist-like, and to a chair-like form (13). The corresponding vibrations, designated ω_1, ω_2, and ω_3, respectively, are assigned to absorptions at 243 cm^{-1} for the degenerate pair of ω_1 and ω_2, and 384 cm^{-1} for ω_3 (14). Hendrickson classified the same modes of inversion as symmetrical and pseudorotation (15). There are two of the former, namely the transition from chair to boat to chair maintaining a plane of symmetry, and from chair to "twist-boat" and back to chair maintaining an axis of symmetry. The pseudorotation mode is said to describe the passage from the boat to the twist forms.

Following the discussion in the preceding section, we visualize the coordinates of cyclohexanone as follows. While the twist, ν_2, is essentially equivalent to its cyclohexane counterpart ω_2, the other two modes may be viewed as "weighted" out-of-phase (ν_1) and in-phase (ν_3) combinations of a simultaneous folding about the C2—C6 and C3—C5 diagonals. The word "weighted" is meant to imply that the folding about the two diagonals may not be taking place to the same extent, but rather would be quite different for the two modes. In terms of these three coordinates the potential energy forms a four dimensional surface with the origin at the central maximum corresponding to the planar conformation. Any one of the coordinates in zero displacement of the other two may follow a double minimum potential function. The extent of coupling between them would depend on the energies of the three conformers relative to one another, to the barriers to interconversion, and

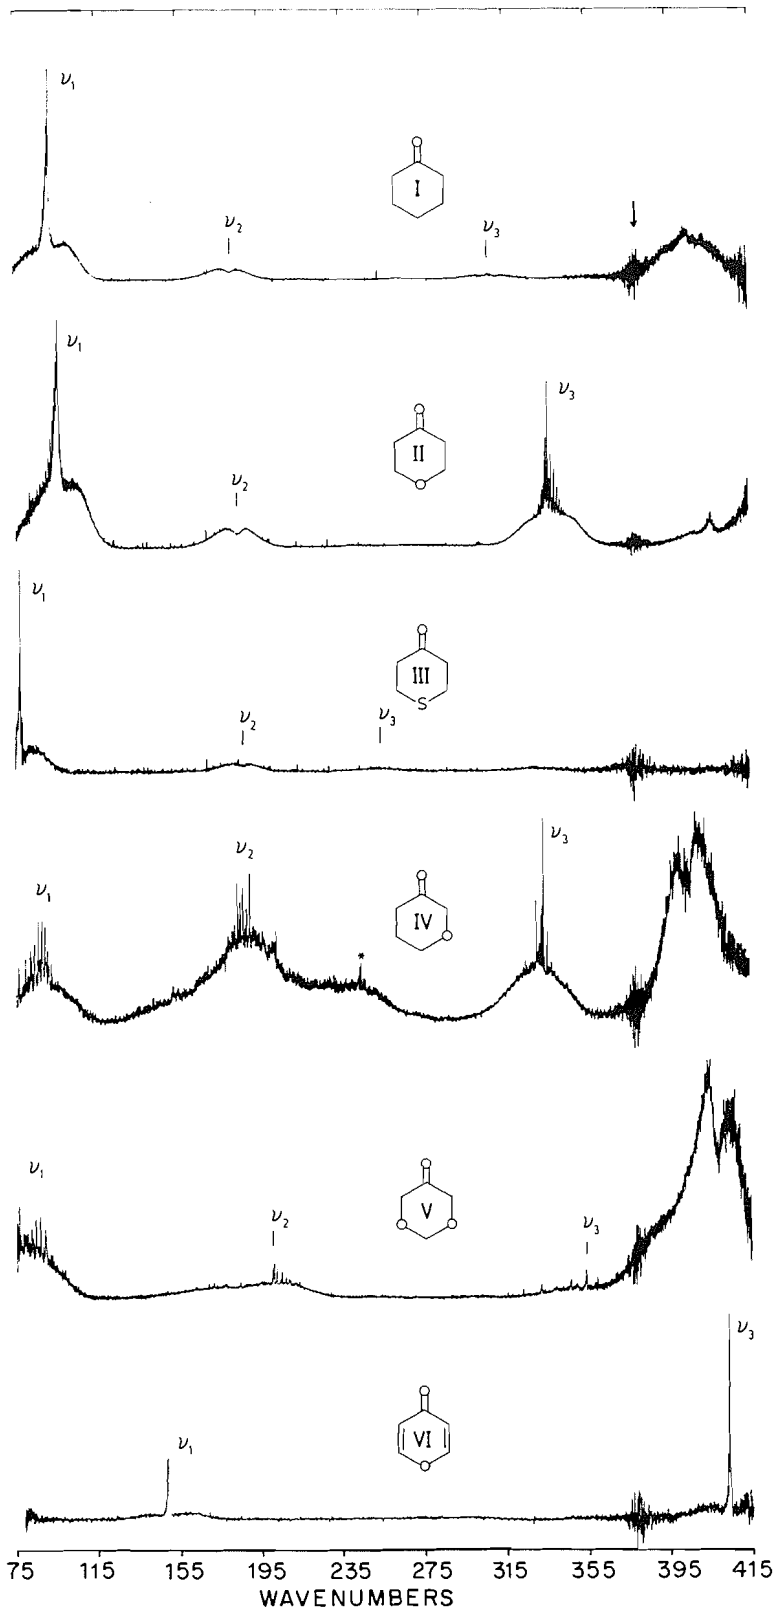

FIG. 1. Survey spectra of cyclohexanone and related compounds. Near saturated vapour pressures, 45 m path, 0.12 cm^{-1} resolution, 3 μm Mylar beamsplitter, 300 scans. Band marked with an asterisk in **IV** is residual pyridine impurity. The noise in the region of 380 cm^{-1} in all the spectra, marked with an arrow in **I**, is due to the strong absorption of the Mylar cut-on filter.

to the central barrier to planarity. The actual interconversion between the conformers, of course, would follow the path of minimum energy.

Since the ground state conformation of the ring is the chair form, we expect ν_1 to be the dominant vibration. If, therefore, that mode gives rise to a diminishing sequence of absorptions we might attempt in the first instance to model these transitions by a one-dimensional Hamiltonian incorporating a quadratic–

quartic potential function. This is tantamount to saying that the coupling between the ν_1 mode and the other two is not too severe so as not to affect seriously its vibrational spacings. Such an assumption is not unreasonable in view of the considerable energy difference between the chair and the other two conformers. In that case, ν_2 and ν_3 would resemble near-harmonic vibrations in the deep potential well of the chair. The situation is similar to the bend/twist coupling in cyclohexene-type molecules, although there the twist, which is the higher energy mode, is the dominant one and the lower energy bend is a near-harmonic vibration constrained in the well of the twisted ground state conformation (16). It is important to note that in these molecules both the twist and the bend vibration exhibit diminishing absorption sequences, reflecting some coupling between the two.

For the one-dimensional calculations we used the standard Hamiltonian in a computer program described elsewhere (12). As mentioned earlier, the assignments of all the ν_1 sequences

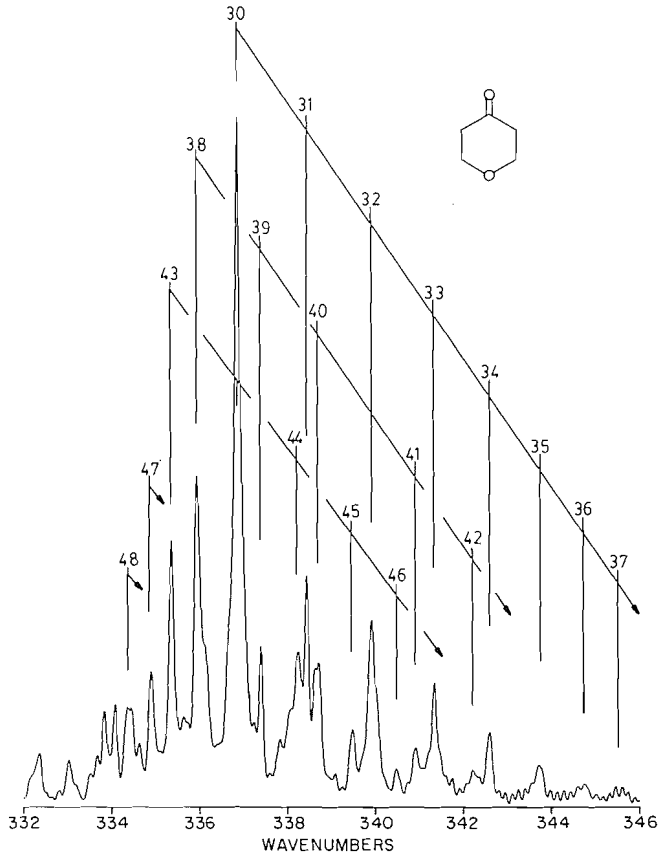

FIG. 3. Sequences of ν_3. Reduced vapour pressure, 45 m path, 0.12 cm^{-1} resolution, 6 μm Mylar beamsplitter, 400 scans. Numbered peak positions are tabulated in Table 4.

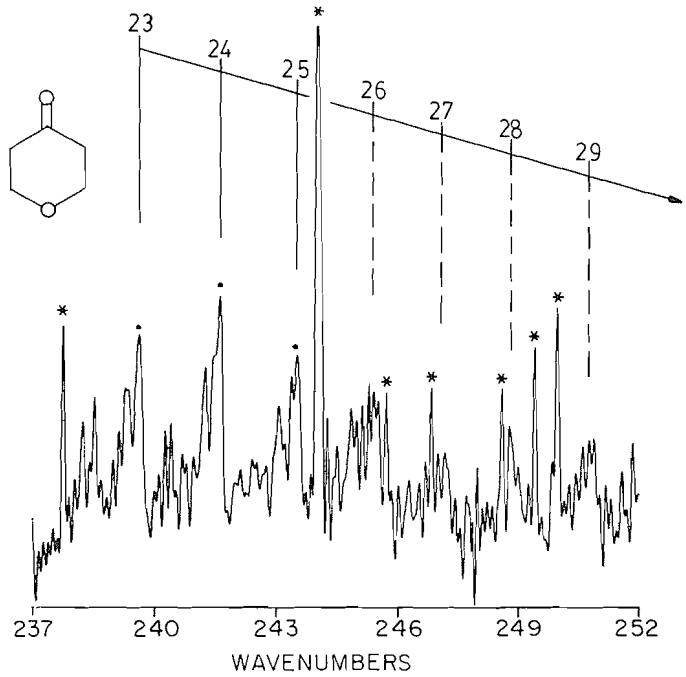

FIG. 4. Difference sequence, $\nu_3 - \nu_1$. Saturated vapour pressure, 45 m path, 0.12 cm^{-1} resolution, 6 μm Mylar beamsplitter, 600 scans. Lines marked with an asterisk are D_2O and HOD absorptions. Numbered peak positions are tabulated in Table 4.

are based on those of **II**. For compound **V** we used only the first three absorptions (labelled 1 to 3 in Fig. 7) in the initial calculation which then predicted the next three positions (peaks 4 to 6 in Fig. 7). The results of all the calculations are listed in Table 2 in terms of the observed − calculated values for the transitions. The best fitting dimensionless quadratic and quartic potential constants and the corresponding barriers (equal to $V_2^2/4V_4$) are also given.

Since compound **II** yielded the most complete information not only for ν_1 but also for ν_3 (see Fig. 5), we used its data for several tests. We first confirmed that the double minimum barrier for ν_1 is well determined by the observed transitions and is not affected by extrapolation errors. In order to establish the role of ν_3 we then attempted to fit its sequence, which also progresses to lower wavenumbers, with the one-dimensional quadratic–quartic potential. While the fit was very good, it suggested an unrealistic barrier height of about 16 000 cm^{-1}. We therefore concluded that the diminishing sequence for ν_3 could result from coupling with one or both of the two other modes. It is of interest to note that the ν_1 separations in the excited state of ν_3 in **I** and **II**, as they are either observed in the spectra or determined from the combination principle, are also amenable to modelling with the quadratic–quartic Hamiltonian (see Table 3). The effective excited state barriers are clearly different from those in the ground state, confirming that some degree of coupling must exist between at least these two modes. If the coupling were taking place preferentially between ν_1 and ν_3, a coupled oscillator approach might be successful. We therefore tried to determine a best fitting two-dimensional potential surface described by a function of the form

$$V(x_1, x_3) = V_{21}x_1^2 + V_{23}x_3^2 + V_{41}x_1^4 + V_{43}x_3^4 + V_{\text{mix}}x_1^2x_3^2$$

in the appropriate Hamiltonian, x_1 and x_3 being the dimensioned coordinates corresponding to ν_1 and ν_3, using a computer program outlined elsewhere (17). Taking ν_3 as a harmonic oscillator with the appropriate scaling coefficient, constraining V_{21} and V_{41} to the one-dimensional values, and using all the data for ν_1 and ν_3, we first allowed V_{mix} to seek its own value. The least-squares refinement forced V_{mix} to zero. Including a small quartic anharmonicity in ν_3 did not assist in determining the coupling constant. Allowing V_{23} to vary simultaneously with V_{mix} also did not improve the results. When all constants were allowed to float the calculation became ill-conditioned as the estimated standard deviation on V_{mix} was consistently larger than the computed value. While the spectra indicate that some coupling must exist, this two-dimensional analysis clearly is not possible. One reason could be that the extent of coupling is too small for a meaningful determination of V_{mix}. Another reason could be that the current method, containing only the fourth power mixing term which is quadratic in both coordinates, is insensitive to coupling in this case when the conformers are so different in energy and the barrier between them is that large, and that perhaps other coupling terms would be more effective. Indeed, ν_3 in the ground state of the ν_1 mode (i.e. ν_3 in the chair conformer) may resemble more a vibration with cubic anharmonicity than follow a quadratic dependence. Still another possibility is that the projection of the four-dimensional potential surface into three dimensions simply is inappropriate in this case.

At this stage we are left with the conclusion that the one-dimensional double minimum potential function which suc-

ring. The trend in the barrier heights displayed by the various compounds (see Table 2) is consistent with what one would expect for the successive replacement of methylene groups by oxygen atoms. For the sulfur compound the unresolved ν_1 transitions indicate a higher barrier than for any of the other molecules. Comparing **II** and **IV** it appears that an oxygen atom in the 3 position of the cyclohexanone ring more effectively reduces the barrier than when it occupies the 4 position.

The barrier is lowest for **V** where the methylene groups have been isolated so that the driving force towards an aplanar form is mainly the steric requirement of the bond angles. As a consequence, the twist in the zero displacements of the other two modes would be a single minimum vibration. Indeed, the ν_2 sequence of **V** (Fig. 8) is reproduced remarkably well by a one-dimensional quartic oscillator (see last columns in Table 3). If the twist in this case were a relatively independent single minimum vibration, we would not expect to find a twisted conformation either as a metastable or as a transition state. The most stable conformer most likely still is a chair. It is not certain, however, whether the inversion takes place via a boat-like form or the planar conformation.

Summary[2]

The far-infrared spectra in the region of 50–450 cm^{-1} of gaseous cyclohexanone (**I**) and the related compounds tetrahydro-4*H*-pyran-4-one (**II**), tetrahydro-4*H*-thiopyran-4-one (**III**), tetrahydro-4*H*-pyran-3-one (**IV**), and 1,3-dioxan-5-one (**V**), reveal distinctive absorptions several of which exhibit characteristic sequences of Q branches. Based on the relative band positions, intensities, and contours these absorptions are assigned to the three out-of-plane deformations of the cyclohexanone ring skeleton. In all five compounds the lowest energy vibration, designated ν_1, gives rise to a prominent di-

[2]NOTE ADDED IN PROOF

A recent microwave study of tetrahydro-4*H*-pyran-4-one (**II**) (18) confirmed the chair conformation as the most stable form. The microwave spectrum also showed evidence of the four excited states of ν_1 and the first excited state of ν_2 (referred to by the author as ring bending and twisting modes, respectively). The far-infrared positions of the fundamentals were reported as very broad lines at about 100 and 185 cm^{-1}. The rotational constants when plotted against the "bending" quantum number deviated slightly from linearity, indicating an anharmonic potential function. For tetrahydro-4*H*-thiopyran-4-one (**III**) the ground state chair conformation was confirmed by electron diffraction (19).

[a]Quantum numbers of the upper (u) and lower (l) levels, designated with double labels if degenerate.
[b]The numbers correspond to observed peak positions marked in Figs. 3, 4, and 6, and the numbered transitions in the energy level diagram in Fig. 5.
[c]Determined by combination principle from Fig. 5.

minishing series of Q branches below 100 cm^{-1}. The other two modes, ν_2 and ν_3 near 180 and 300 cm^{-1}, respectively, vary in intensity and band contour for the different molecules. Supported by earlier force field calculations on the parent the ν_1 and ν_3 modes are described, respectively, as an out-of-phase and in-phase combination of an unequal though simultaneous folding about the C2—C6 and C3—C5 diagonals, whereas ν_2 is described as a twisting of the central part of the skeleton.

The spectrum of **II** provides the most comprehensive information about the ν_1 and ν_3 modes, leading to an extensive energy level diagram. The ν_1 sequences in the ground state of all other modes and in several excited states of ν_3 are amenable to solution with a one-dimensional Hamiltonian containing a quadratic–quartic potential function. Combined solution with a corresponding two-dimensional Hamiltonian was not possible. It is concluded, therefore, that the double minimum potential function for ν_1 represents a section along that coordinate in the potential energy surface at zero displacement of the other two modes. The inversion barrier resulting from that function is thought to give a reasonable estimate of the barrier to planarity for the six-membered ring skeleton.

In **I**, **IV**, and **V** only the ν_1 mode can be dealt with in a similar fashion. For **III** the fine structure though clearly present could not be resolved. The barriers to planarity so derived are 2940, 2772, 1068, and 806 cm^{-1}, respectively, for **I**, **II**, **IV**, and **V**. For the sulfur compound the barrier is expected to be higher than that for the parent. The present analysis yields no information about the relative stabilities of the various possible conformers nor about the barriers to interconversion between them. For **V** there are reasons to suggest that the symmetric twist conformation does not exist as either a metastable or a transition state, and that the energetically favoured chair–chair inversion may pass through the planar form.

Department of Chemistry, University of Michigan, Ann Arbor, MI 48109, U.S.A.

Received July 6, 1982[1]

SUNNY J. LO and MILTON TAMRES. Can. J. Chem. **61**, 1933 (1983).

The spectral and thermodynamic properties of the ethyl methyl sulfide – iodine complex were determined in the vapor phase by both a modified Benesi–Hildebrand method and the constant activity method. The former method also was used to study this complex in *n*-heptane solution. The results in both phases are compared with those for diethyl sulfide – iodine and dimethyl sulfide – iodine. Since solution data were lacking for the latter complex, it was studied in *n*-heptane in the present work. Trends in the homologous series and solvent effects are noted.

SUNNY J. LO et MILTON TAMRES. Can. J. Chem. **61**, 1933 (1983).

Faisant appel à la méthode modifiée de Bénési–Hildebrand et à la méthode d'activité constante, on a déterminé les propriétés spectrales et thermodynamiques du complexe de: iode–sulfure d'éthyle méthyle en phase gazeuse. On également utilisé la première méthode pour étudier ce complexe en solution dans le *n*-heptane. On a comparé les résultats relatifs aux deux phases avec ceux des complexes de: iode–sulfure de diéthyle et iode–sulfure de diméthyle. En l'absence de données relatives au deuxième complexe en solution, on a choisi de l'étudier en solution dans le *n*-heptane. On a relevé les tendances des séries homologues et les effets de solvant.

Introduction

Thermodynamic and spectral properties of iodine complexes with homologous series of donors have been studied extensively in solution (1–4), but relatively few comparable studies have been made in the vapor phase (5). In the special case of sulfide–iodine complexes, only the following donors have been studied in the vapor phase: diethyl sulfide (6–10), dimethyl sulfide (8–10), and tetramethylene sulfide (8). For the last donor, except for establishing the position of the charge-transfer (CT) band maximum, the remaining data are suspect due to a slow reaction (9). Also, of these three sulfide complexes, the dimethyl sulfide – iodine has been studied primarily in the visible region in solution (in CCl_4) (11). Very little has been reported for the CT band in solution (8).

To further enhance the comparison between vapor and solution studies, the ethyl methyl sulfide – I_2 complex was investigated in the vapor phase using both the conventional (modified Benesi–Hildebrand) method (2, 12, 13) and the constant activity method (14–16). It was studied as well in *n*-heptane solution by the conventional method, as was also the dimethyl sulfide – I_2 complex.

Experimental section

Material

Ethyl methyl sulfide and dimethyl sulfide (Eastman Kodak Co.) were distilled through a 27-cm insulated Vigreux column packed with glass helices, and a middle cut was taken. Vapor phase chromatography showed the absence of impurities.

The purification of iodine and the synthesis of tetramethylammonium pentaiodide followed procedures described elsewhere (17–19).

Apparatus and procedures

A Cary 14 spectrophotometer was used for all spectral measurements. Details regarding the apparatus and the procedures used for studies in the vapor phase and in solution have been described in earlier papers (8–10, 20, 21, and in the thesis of Lo (22)).

Calculations

The spectrophotometric equation which applies to the conventional method of studying the interaction of donor (D) with an acceptor (A) to form complex (C) is given by eq. [1]. D_0 and A_0 are the initial concentrations of donor and acceptor, respectively, K_c is the equilibrium constant, l is the cell path, ϵ_c is the molar absorptivity, and

$$[1]\quad \frac{D_0 l A_0}{\mathrm{ABS}'} = \frac{D_0 + A_0}{\epsilon_c'} + \frac{1}{K_c \epsilon_c'} - \frac{\mathrm{ABS}'}{l(\epsilon_c')^2}$$

ABS is the absorbance. The primes on ABS and ϵ_c signify values corrected for the contributions of free donor and free acceptor. Equation [1] is quadratic in ϵ_c. For rather weak complexes, the last term may be dropped with very little effect on K_c and ϵ_c (23, 24). The resulting equation, of Scott type (13), is linear in ϵ_c.

In the constant activity method, the iodine content was controlled by the equilibrium between tetramethylammonium polyiodides, e.g.,

$$[2]\quad \mathrm{TMAI_5(solid)} \rightleftarrows \mathrm{TMAI_3(solid)} + \mathrm{I_2(vapor)}$$

In this method the spectrophotometric equation which applies, for the condition $D_0 \gg C$, is

$$[3]\quad \mathrm{ABS} = K_c \epsilon_c l D_0 [\mathrm{I_2}]_{0,T}$$

where $[\mathrm{I_2}]_{0,T}$ is the fixed iodine concentration for the polyiodide mixture at a specified temperature T.

The change in internal energy of complexation (ΔE_c^0) in the vapor phase, or in the heat of complexation (ΔH_c^0) in solution, was determined and checked by several methods: (*1*) from the temperature dependence of log K_c; (*2*) from the temperature dependence of log $K_c\epsilon_c$ (for those cases where the complex is too weak to get good separation of K_c and ϵ_c from the $K_c\epsilon_c$ product); and (*3*) from the temperature dependence of log ABS for a single donor–acceptor mixture. The last applies to the constant activity study (10, 25) provided data are available for the temperature dependence of the equilibrium in eq. [2]. It is readily shown for the vapor phase that eq. [3] becomes

$$[4]\quad \frac{-\Delta E_c^0}{2.303R} = \frac{\mathrm{d}\log K_c\epsilon_c}{\mathrm{d}(1/T)} = \frac{\mathrm{d}\log \mathrm{ABS}}{\mathrm{d}(1/T)} - \frac{\mathrm{d}\log [\mathrm{I_2}]_{0,T}}{\mathrm{d}(1/T)}$$

This technique holds approximately in the conventional study if the change in concentration of the lesser component is small over the temperature range (e.g., for weak complexes) (5).

Results

Ethyl methyl sulfide – I_2

For the vapor phase conventional study, four experiments were performed with varying donor and acceptor concen-

[1]Revision received February 9, 1983.

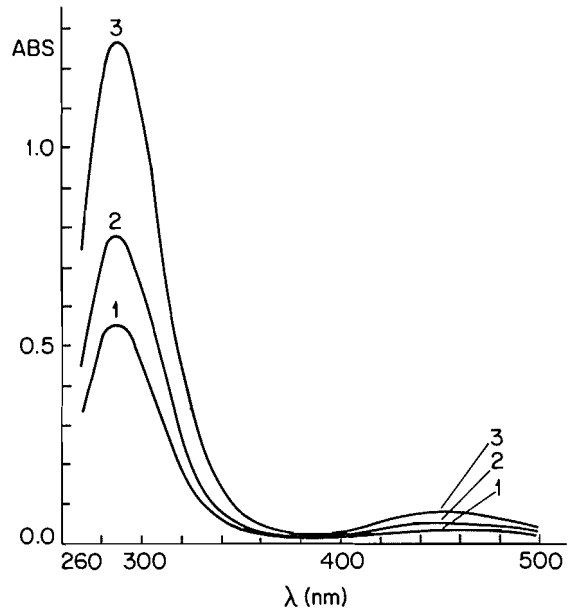

FIG. 1. The charge-transfer band and complexed visible iodine band for the ethyl methyl sulfide – iodine complex in the vapor phase: cell path = 75 cm; $[(CH_3)(C_2H_5)S] = 7.587 \times 10^{-3}$ M; (*1*) 70.0°C, $[I_2] = 2.790 \times 10^{-6}$ M; (*2*) 80.0°C, $[I_2] = 5.470 \times 10^{-6}$ M; (*3*) 95.8°C, $[I_2] = 1.466 \times 10^{-5}$ M. These are difference spectra with $TMAI_5/TMAI_3$ in the sample and reference cells.

trations and cell paths.[2] A charge-transfer band with a maximum at 289 nm was observed. The peak decreased in intensity with increasing temperature.[2] A regression analysis of log ABS vs. $1/T$ was made for each of the four mixtures. The average internal energy change (ΔE_c^0) was -7.1 ± 0.4 kcal mol^{-1} (correlation constant 0.998).

K_c and the molar absorptivity of the charge-transfer band, ϵ_{max}^{CT}, were determined by the usual regression analysis of eq. [1]. For this particular system, absorbance corrections due to contributions from the donor and acceptor species were small because of their low molar absorptivities in the region of the charge-transfer band maximum. The results of the analysis are listed in Table 1.

The rather large decrease in ϵ_{max}^{CT} with increase in temperature indicates that the separation of K_c and ϵ_{max}^{CT} from the $K_c\epsilon_{max}^{CT}$ product is poor. This may be due to a slow reaction. It was found for experiments where the sulfide concentration was high (>0.008 M) that it was not possible to return to the same absorbance at a fixed temperature at the end of a run. Therefore, a calculation of ΔE_c^0 was made based on a plot of log $K_c\epsilon_{max}^{CT}$ vs. $1/T$. This gave a value of -7.4 ± 0.8 kcal mol^{-1} which is in good agreement with that cited from the plot of the log ABS vs. $1/T$. (It is estimated (9) that the difference in ΔE_c^0 in the two methods for sulfide–I_2 complexes at elevated temperatures is ~0.3 kcal mol^{-1}.)

For the vapor phase constant activity method, $TMAI_5/TMAI_3$ was used as the iodine source. The spectrum of the charge-transfer band and the complexed visible iodine band is shown in Fig. 1 at 70.0°C, 80.0°C, and 95.8°C. (The spectrum also was recorded, although not shown in the figure, at 74.9°C, 85.2°C, and 89.2°C.) The charge-transfer band is well defined with a maximum at 289 nm. The complexed visible iodine band is less well defined due to the low absorbance in this region. The maximum does seem to occur at approximately 450 nm. The iodine spectrum cannot be studied in the vapor phase above 498 nm due to the onset of iodine's vibrational structure.

The experimental absorbance values and the $K_c\epsilon_{max}^{CT}$ values, calculated using eq. [3], are shown in Table 2, along with the $\epsilon_{max}^{CT}/\epsilon_{max}^{BS}$ ratio. The small variation in the ratio is probably due to small baseline shifts. A change of only 0.005 absorbance can change the ratio significantly. The average value of the ratio from this run and from a duplicate experiment is 17.1.

As derived in eq. [4], from the known temperature dependence of log ABS, and also, the saturation pressure curve for the $TMAI_5/TMAI_3$ equilibrium, the internal energy of complex formation can be calculated. The internal energy of vaporization, ΔE_{sat}, for this polyiodide system is 16.14 ± 0.76 kcal mol^{-1} (10). A regression analysis of the data at 289 nm in Table 2 gave a ΔE_c^0 of -8.19 ± 0.32 kcal mol^{-1}. This is slightly more negative than the value of -7.4 ± 0.8 kcal mol^{-1} obtained by the conventional method.

For the *n*-heptane solution study by the conventional method, the same solutions were used in both the uv and visible regions.[2] Matched far-uv glass-stoppered silica cells 0.100 cm in length were used in the ultraviolet spectral region. In the visible region, 1.000 cm cells were used. The charge-transfer band maximum[2] is at 301 nm. The visible absorbance data at 24.5°C are shown in Fig. 2. There is a well-defined isosbestic point at 492 nm. A slight temperature dependence of the isosbestic point was observed. At 4.7°C the crossing occurred at 490.5 nm. No shift in the maximum of the complexed visible iodine band or of the charge-transfer band was observed over the concentration range studied. The complexed visible iodine band[2] was obtained by subtracting the absorbance due to free

[2]Tables of concentration and spectral data in the vapor phase and in solution, and figures of spectra of the charge-transfer and blue-shifted visible iodine bands in the vapor phase and in solution, are available as supplementary material, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

iodine from the total visible absorbance at each wavelength. This requires a knowledge of the equilibrium constant, which was determined from the data in the ultraviolet region. The complexed visible iodine band maximum is at 438 nm.

K_c, ϵ_{max}^{CT}, and ϵ_{max}^{BS} were determined by the usual regression analysis of eq. [1]. While corrections in the ultraviolet region are small because the free donor and free acceptor contribute very little to the absorbance near the charge-transfer band maximum, in the region of the complexed visible iodine band maximum they are significant because of the free iodine absorption.

The results of the analysis are shown in Table 3. The ultraviolet and visible molar absorptivities, ϵ_{max}^{CT} and ϵ_{max}^{BS}, respectively, show small variations over the limited temperature range. The average of the five ϵ_{max}^{CT} and ϵ_{max}^{BS} values is 28 660 M^{-1} cm^{-1} and 1 922 M^{-1} cm^{-1}, respectively. The $\epsilon_{max}^{CT}/\epsilon_{max}^{BS}$

The visible spectra of the ethyl methyl sulfide – iodine complex at 24.5°C in *n*-heptane; isosbestic point at 492 nm; cell path = 1.000 cm; (*1*) $[I_2] = 1.190 \times 10^{-3}$ *M*; (*2*) $[I_2] = 1.189 \times 10^{-3}$ *M*, $[(CH_3)(C_2H_5)S] = 1.001 \times 10^{-3}$ *M*; (*3*) $[I_2] = 1.188 \times 10^{-3}$ *M*, $[(CH_3)(C_2H_5)S] = 2.996 \times 10^{-3}$ *M*; (*4*) $[I_2] = 1.184 \times 10^{-3}$ *M*, $[(CH_3)(C_2H_5)S] = 5.990 \times 10^{-3}$ *M*; (*5*) $[I_2] = 1.185 \times 10^{-3}$ *M*, $[(CH_3)(C_2H_5)S] = 1.004 \times 10^{-2}$ *M*.

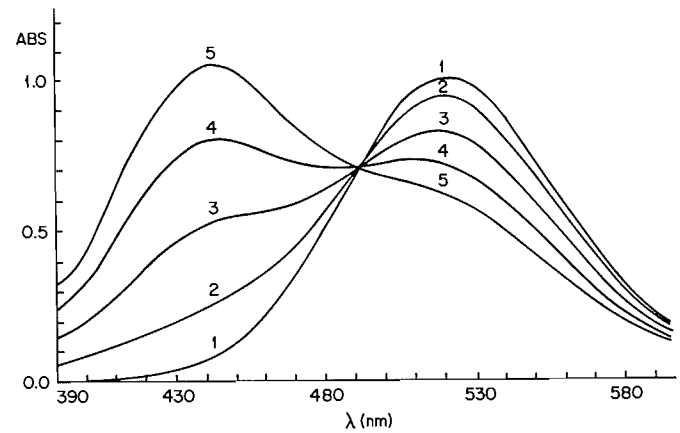

FIG. 3. The visible spectra of the dimethyl sulfide – iodine complex at 19.4°C in *n*-heptane; isosbestic point at 492.3 nm; cell path = 1.000 cm; (*1*) $[I_2] = 1.087 \times 10^{-3}$ *M*; (*2*) $[I_2] = 1.091 \times 10^{-3}$ *M*, $[(CH_3)_2S] = 1.051 \times 10^{-3}$ *M*; (*3*) $[I_2] = 1.090 \times 10^{-3}$ *M*, $[(CH_3)_2S] = 3.190 \times 10^{-3}$ *M*; (*4*) $[I_2] = 1.086 \times 10^{-3}$ *M*, $[(CH_3)_2S] = 6.365 \times 10^{-3}$ *M*; (*5*) $[I_2] = 1.091 \times 10^{-3}$ *M*, $[(CH_3)_2S] = 1.055 \times 10^{-2}$ *M*.

ratio is 14.8. At 24.5°C the equilibrium constant is 124.2 ± 3.4 M^{-1}. This agrees well with a previously reported equilibrium constant of 136.2 ± 15.8 M^{-1} at 25°C via an nmr study in CCl_4 (26).

A plot of D_0lA_0/ABS versus $(D_0 + A_0)$ at different temperatures for both the ultraviolet and visible data gave parallel slopes which is indicative of the small variation in the molar absorptivity with temperature.

The enthalpy of complexation, ΔH_c^0, was determined via a regression analysis of $\log K_c\epsilon_{max}^{CT}$ versus $1/T$ and also of $\log K_c$ versus $1/T$. ΔH_c^0 values of −7.8 ± 0.8 kcal mol^{-1} (correlation constant 0.998) and −7.6 ± 1.0 kcal mol^{-1} (correlation constant 0.998), respectively, were obtained. The two ΔH_c^0 values are the same within experimental error, indicating good $K_c\epsilon_{max}^{CT}$ separation. The thermodynamic data for K_c obtained in the visible spectral region are within experimental error of the data obtained in the ultraviolet region as Table 3 shows.

Dimethyl sulfide – I_2

The ultraviolet and visible spectral characteristics of the dimethyl sulfide – iodine complex were investigated via the conventional method in *n*-heptane. The temperature dependence of the complex was studied in the range 4.8–19.4°C at approximately 5° intervals. The volatility of the donor made it difficult to study this complex at higher temperatures. Again, 0.100-cm cells were used in the ultraviolet spectral region, and 1.000-cm cells were used in the visible spectral region. The charge-transfer band maximum[2] is at 300 nm. The visible absorbance data at 19.4°C are shown in Fig. 3. The isosbestic point occurs at 492.3 nm and shows a slight temperature dependence (490.5 nm at 4.8°C, 491.3 nm at 9.7°C, and 491.6 nm at 14.3°C). The complexed visible iodine band[2] has a maximum at 441 nm. From the absorbance data[2] of the charge-transfer and complexed visible iodine bands, K_c, ϵ_{max}^{CT}, and ϵ_{max}^{BS} were determined by the usual regression analysis of eq. [1], and the results are given in Table 4. The average molar absorptivity for the charge-transfer and complexed visible iodine bands, 27 850 and 1 813 M^{-1} cm^{-1}, respectively, shows no significant variation over this limited temperature range. The $\epsilon_{max}^{CT}/\epsilon_{max}^{BS}$ was calculated at each of the four temperatures studied. The average of the four ratios was 15.4.

A regression analysis of $\log K_c\epsilon_{max}^{CT}$ versus $1/T$ and, also, of $\log K_c$ versus $1/T$ gave ΔH_c^0 values of −8.29 ± 1.22 kcal mol^{-1} (correlation constant 0.999), and −8.24 ± 1.58 kcal mol^{-1} (correlation constant 0.998), respectively, based on the absorbance data at the charge-transfer band maximum. The agreement in the ΔH_c^0 values again is indicative of good separation of the $K_c\epsilon_{max}^{CT}$ product. The determination of ΔH_c^0 from only four temperatures probably accounts for the higher error limits compared to the ethyl methyl sulfide – iodine case.

The ΔH_c^0 results from the ultraviolet absorbance data are expected to be more accurate than those based on the visible data. Analysis of the visible data gave $\Delta H_c^0 = -7.68 \pm 2.74$ kcal mol^{-1} (correlation constant 0.992) from the $\log K_c\epsilon_{max}^{CT}$ versus $1/T$ plot, and −7.45 ± 3.81 kcal mol^{-1} (correlation constant 0.986) from the $\log K_c$ versus $1/T$ plot.

Discussion

The complete spectral and thermodynamic properties of the three sulfide–I_2 complexes in the vapor phase and in *n*-heptane solution are summarized in Table 5. It would be expected that these properties would show a systematic trend within each phase for a homologous series of donors with a common acceptor. However, the error limits in the determination of ϵ_{max}^{CT}, of ϵ_{max}^{BS}, of K_c, and of ΔE_c^0 (or ΔH_c^0) generally mask any correlation of these properties with strength of complexation. Only in two instances is it clear that the sequence of donor strength is Et_2S > EtMeS > Me_2S: (*1*) the solution values of K_c (at 25°C), where the error limits are relatively small, and (*2*) the $K_c\epsilon_c$ product in both phases. In the latter case, the precision in determining the $K_c\epsilon_c$ product is better than that obtained when this product is separated into its components, especially for weak complexes. Further, if K_c and ϵ_c follow a similar trend, then the $K_c\epsilon_c$ product should magnify that trend.

Band intensities are measured by the transition dipole (27*a*) μ ($\simeq 0.0958(\epsilon_{max}\Delta\bar{\nu}_{1/2}/\bar{\nu})^{1/2}$), and the oscillator strength (27*a*), f ($= 4.704 \times 10^{-7}\bar{\nu}_{max}\mu^2$). Here, $\Delta\bar{\nu}_{1/2}$ is the half-width of the band in cm^{-1}, and $\bar{\nu}$ is the average wave number in cm^{-1} (usually approximated as the wave number at the absorption maximum, $\bar{\nu}_{max}$). The values of $\Delta\bar{\nu}_{1/2}$ for the CT bands are

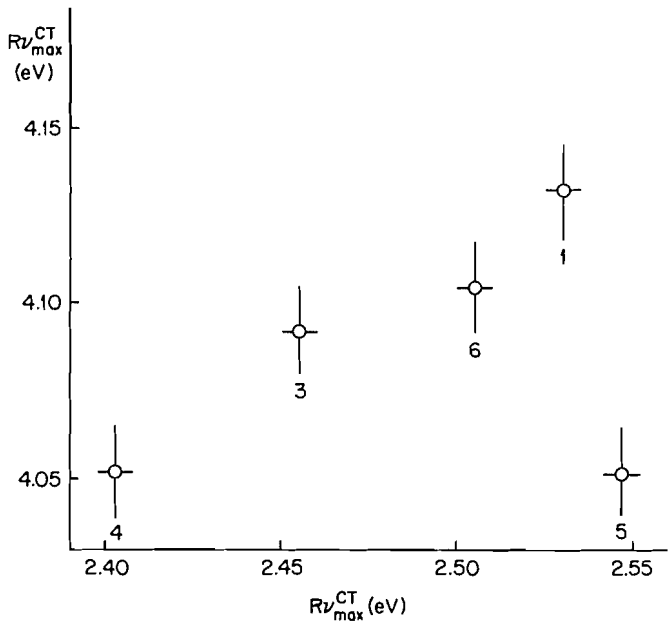

FIG. 4. Correlation between the charge-transfer band position of sulfide–iodine complexes in *n*-heptane (*Y*-axis) vs. that of sulfide–TCNE complexes in methylene chloride (*X*-axis); numbering corresponds to that in Table 6.

rather comparable for all the complexes, as is also the case for the blue-shifted iodine bands. Further, the variation in $\bar{\nu}_{max}$ for the three complexes, both for the charge-transfer and blue-shifted iodine bands, is very small. Consequently, the trends in the magnitude of μ and of f follow essentially those for ϵ.

The solvent effect on the thermodynamic properties of the sulfide–I_2 complexes is relatively small. Taken as a whole, the values for ΔH_c^0 in the vapor phase and in solution are comparable. Further, extrapolation of the solution data to 100°C, or the vapor phase data to 25°C, shows that K_c is about the same in the two phases (9, 22).

It is of interest to compare the spectral properties of the complexes between the two phases. ϵ_{max} is an order of magnitude greater for the charge-transfer band than for the blue-shifted iodine band, as seen in the $\epsilon_{max}^{CT}/\epsilon_{max}^{BS}$ (or f^{CT}/f^{BS}) ratio. This ratio is larger in the vapor phase than in solution. Analysis of the data shows that both the charge-transfer band and the blue-shifted iodine band are increased in intensity in going from the vapor phase to solution. However, the solvent effect on the band intensity is *relatively greater* for the blue-shifted iodine band than for the charge-transfer band, thereby decreasing the $\epsilon_{max}^{CT}/\epsilon_{max}^{BS}$ ratio.

Several of the theories which have been proposed to account for the solvent influence on the properties of complexes have been discussed earlier (5, 22, 25). However, one model bears special mention in the light of some recent experimental results, namely, the solvent cage effect (28). Creation of a solvent cavity requires energy and, therefore, the cavity will tend to be of minimum size, causing the complex within the cavity to be compressed. This compression in going from the vapor phase to solution has been proposed to account for (*a*) the red shift in the CT band of weak complexes (28), (*b*) the blue shift in the iodine visible band (5, 29), and (*c*) an increase in band intensity due to greater orbital overlap (27*d*).

The solvent cage effect has been compared to pressure effects on these complexes (28, 30). A study by Suzuki *et al.* of the effect of pressure on the CT band (31, 32) and on the visible I_2 band (33) of the diethyl sulfide–I_2 complex in *n*-heptane solution supports the solvent cage model. These authors noted the following changes as the pressure increased from 1 to 3300 bar: (*1*) initial increase in pressure caused red shifts in the CT band (but increasing the pressure still further reversed the trend and caused blue shifts); (*2*) ϵ_{max}^{CT} was enhanced; (*3*) there was a blue shift in the visible iodine band; (*4*) ϵ_{max}^{BS} was enhanced; (*5*) the enhancement was greater for ϵ_{max}^{BS} than for ϵ_{max}^{CT}, so that the $\epsilon_{max}^{CT}/\epsilon_{max}^{BS}$ ratio decreased from 11.9 at 1 bar to 10.7 at 3300 bar.

Further support for a solvent cage model stems from a recent study (34) of iodine complexes formed with donors in supersonic molecular beams. A typical system is dimethyl sulfide – iodine in He as a diluent gas. The fluorescence excitation spectra of the "cold clusters" are attributed to a blue-shifted absorption of the complexed I_2, followed by emission from free I_2 when the complex dissociates. Comparison of these spectra with the absorption spectra of donor–iodine complexes in the vapor phase and in *n*-heptane solution shows they resemble more closely the spectra in solution.

It has been found for iodine complexes that a relation exists, although with much scatter, between the blue shift of the visible iodine band and the strength of complexation (as, say, measured by ΔH_c^0) (27*c*). Paetzold (35–37) has found, for a homologous series of donor–iodine complexes, that quite a good linear correlation exists between the blue-shifted visible iodine band and several parameters which are a measure of bond strength (e.g., ΔH_c^0, ΔG_c^0, force constants). Comparison

For personal use only.

of the solution data in Table 5 shows a consistent decrease in λ_{max}^{BS} with increased donor strength. However, in the vapor phase, λ_{max}^{BS} for EtMeS–I_2 was not sufficiently resolved for quantitative comparison.

For a homologous series of donors with a common acceptor, theory (27*b*) predicts a correlation between the charge-transfer band position, $h\nu_{max}^{CT}$, and the vertical ionization energy of the donor, I_D^v. Table 6 lists data for the sulfide–I_2 complexes in the vapor phase and in *n*-heptane solution. Corresponding data are given for these sulfides complexed with TCNE in methylene chloride (38). The range in values of I_D^v and of $h\nu_{max}^{CT}$ is rather small, and makes their correlation seem more scattered. When $h\nu_{max}^{CT}$ data for sulfides complexed with iodine in *n*-heptane are plotted versus comparable data for the same sulfides complexed with TCNE in methylene chloride the correlation is improved (Fig. 4), except the point for $(CH_2)_3S$ which is significantly out of line. The value for $h\nu_{max}^{CT}$ for the iodine complex in *n*-heptane was rechecked by the constant activity method, using $TMAI_5$, and the result was the same.

VILAS KASHINATH CHITALE and KRISHNA SADASHIV PITRE. Can. J. Chem. **61**, 1941 (1983).

Polarographic measurements have been used to evaluate the overall formation constants of simple and mixed complexes of Pb(II) with itaconic acid and nicotinic acid at (25 ± 0.1) °C (abbreviated as ICA and NA). It is observed that Pb(II) forms 1:1, 1:2, and 1:3 binary complexes with ICA, whereas 1:1 and 1:2 binary complex species are formed with NA. The reduction of binary as well as ternary complexes is found to be reversible and diffusion controlled, involving two electrons at constant ionic strength $I = 1.0$ adjusted with the necessary addition of potassium nitrate.

For ternary system the reduction of Pb(II) has been carried out at two fixed concentrations of nicotinic acid, whereas itaconic acid concentration is varied. Schaap and McMaster's treatment reveals the formation of $[Pb(ICA)(NA)]^-$, $[Pb(ICA)(NA)_2]^{2-}$, and $[Pb(ICA)_2(NA)]^{3-}$ with $\log \beta_{11} = 3.00 \pm 0.03$, $\log \beta_{12} = 5.35 \pm 0.028$, and $\log \beta_{21} = 5.52 \pm 0.032$, respectively. The numbers after the ± signs stand for the standard deviation.

Addition and substitution of the ligand species in the ternary complexes have also been discussed.

VILAS KASHINATH CHITALE et KRISHNA SADASHIV PITRE. Can. J. Chem. **61**, 1941 (1983).

On a utilisé des mesures polarographiques pour évaluer la constante de formation globale des complexes simples et mixtes du Pb(II) avec l'acide itaconique et avec l'acide nicotinique à (25 ± 0,1)°C (AIC et AN). On a observé que le Pb(II) forme des complexes binaires du type 1:1, 1:2 et 1:3 avec le AIC tandis qu'il forme des complexes binaires du type 1:1 et 1:2 avec le AN. On a trouvé que la réduction des complexes binaires aussi bien que celle des complexes ternaires est réversible et contrôlée par la diffusion. Elle implique deux électrons à une force ionique constante de $I = 1,0$ que l'on ajuste en ajoutant nécessairement du nitrate de potassium.

Dans le cas des systèmes ternaires on effectue la réduction du Pb(II) pour deux concentrations fixes d'acide nicotinique tandis qu'on fait varier la concentration de l'acide itaconique. Le traitement de Schaap et McMaster révèle la formation du $[Pb(AIC)(AN)]^-$, du $[Pb(AIC)(AN)_2]^{2-}$ et du $[Pb(AIC)_2(AN)]^{3-}$ avec $\log \beta_{11} = 3,00 \pm 0,03$, $\log \beta_{12} = 5,35 \pm 0,028$ et $\log \beta_{21} = 5,52 \pm 0,032$ respectivement. Les nombres entre parenthèses indiquent la déviation normale.

On discute également de l'addition et de la substitution des ligands dans les complexes ternaires.

[Traduit par le journal]

Introduction

In continuation of our previous work on the polarographic study of mixed complexes of Pb(II) with some organic ligands (1, 2), the present paper deals with the ternary complexes of Pb(II) with itaconic acid and nicotinic acid. This system has not been reported so far polarographically.

Experimental

All the chemicals used were of analytical reagent grade and their solutions were prepared in doubly distilled water. The ionic strength was adjusted at $I = 1.0$ by necessary addition of KNO_3, used as supporting electrolyte (0.01%). Gelatin was used as maxima suppressor, sodium itaconate and sodium nicotinate were used as ligands. The concentration of Pb(II) was maintained at 1×10^{-3} *M*.

Polarograms were recorded on a CIC (Baroda, India) automatic pen recording polarograph. The characteristics of the DME used were $m = 2.37$ mg, $s = 3.0$ s at 35 cm, the effective height of the mercury column, open circuit, when measured in air-free 1.0 *M* KNO_3 ($m^{2/3} t^{1/6} = 2.136\ mg^{2/3} s^{-1/2}$). The pH of the test solution was adjusted at pH 6.5 ± 0.1 by necessary addition of nitric acid/sodium hydroxide solutions. For pH measurements, an Elico digital pH meter (model LI-120) was used. Pure nitrogen gas was passed through test solutions before recording the polarograms. All the measurement were made at room temperature 25 ± 0.1°C.

Results and discussion

Pb(II) gives a single, well-defined reversible reduction wave in potassium nitrate. The reduction of Pb(II) as well as its binary and ternary complexes with itaconic acid and nicotinic acid are diffusion controlled, as revealed from the straight line plots of i_d vs. $\sqrt{h}$ passing through the origin. The plot of $\log i/i_d - i$ vs. E_{dc} for each polarogram was found to be linear with a slope of 30 ± 2 mV indicating the reversibility of the electrode process involving two electrons.

(A) Binary systems

The stability constants of simple binary complexes of Pb(II) with itaconic acid and nicotinic acid were evaluated separately prior to the study of ternary system. Identical conditions were maintained in both the simple as well as mixed systems.

(i) Pb(II)–itaconate system

A plot of $-E_{1/2}$ vs. $\log C_x$ (logarithm of the concentration of itaconate) was a smooth curve (Fig. 1*a*), thereby suggesting the formation of successive complexes. The Deford and Hume method (3) was applied to determine the formation constants of the successive complexes. Three complexes were formed (4):

$[Pb(ICA)]$	$\log \beta_{10} = 2.17;$	$\beta_{10} = 150$
$[Pb(ICA)_2]^{2-}$	$\log \beta_{20} = 3.30;$	$\beta_{20} = 2000$
$[Pb(ICA)_3]^{4-}$	$\log \beta_{30} = 5.30;$	$\beta_{30} = 200000$

$F_j(X)$ functions of simple complexes of Pb(II) with itaconate are presented in Table 1.

(ii) Pb(II)–nicotinate system

In this case the plot of $-E_{1/2}$ vs. $\log [NA]$ was again a smooth curve, thereby showing the formation of successive complexes (Fig. 1*b*). The stability constants of the successive complexes were evaluated by the Deford and Hume method (3). Two successive complexes were formed:

$[Pb(NA)]^+$	$\log \beta_{01} = 1.24;$	$\beta_{01} = 17.5$
$[Pb(NA)_2]$	$\log \beta_{02} = 2.32;$	$\beta_{02} = 210$

0.20	0.420	72	11.55	52.75	176.35
0.25	0.428	70	22.19	84.76	269.04
0.35	0.436	68	26.71	73.45	159.79

$\beta_{00} = 1.0$, $\beta_{01} = 17.5$, and $\beta_{02} = 210$

$F_j(X)$ functions of simple complexes of Pb(II) with NA are tabulated in Table 2. The shift in $E_{1/2}$ and the reduction of i_d values is exactly according to the scheme of complexation satisfying polarographic requirements. This also rules out any adsorption of the charged and neutral species formed. Polarographic studies of Pb(II)–nicotinate system as carried out by Gaur *et al.* (5) also supports the above observation.

(B) Ternary system

In this case the concentration of sodium itaconate was varied and that of sodium nicotinate was kept constant at 0.1 *M* and 0.25 *M*, respectively. It was noted that $E_{1/2}$ values were greater as compared to those observed in binary systems, thereby showing the formation of mixed complexes.

The method of Schaap and McMasters (6) was used to evaluate the overall formation constants of the ternary system. The polarographic measurements and $F_{ij}(X)$ functions of mixed complexes of Pb(II) with itaconic and nicotinic acids at fixed concentrations of the latter at 0.1 *M* and 0.25 *M* have been listed in Tables 3 and 4 respectively.

The overall formation constants calculated from the functions *A*, *B*, *C*, and *D* were:

$[Pb(ICA)(NA)]^-$	$\log \beta_{11} = 3.00$;	± 0.030
$[Pb(ICA)(NA)_2]^{2-}$	$\log \beta_{12} = 5.35$;	± 0.028
$[Pb(ICA)_2(NA)]^{3-}$	$\log \beta_{21} = 5.52$;	± 0.032

The numbers after the ± signs stand for the standard deviation.

The mixing constant K_M (equilibrium constant) for reaction

$$\tfrac{1}{2}[Pb(ICA)_2]^{2-} + \tfrac{1}{2}[Pb(NA)_2] \rightleftharpoons [Pb(ICA)(NA)]^-$$

is a measure of relative stability of mixed complexes in solution as compared to simple binary complexes. This is expressed (7, 8) as

$$K_M = \frac{\beta_{11}}{\sqrt{\beta_{02}\,\beta_{20}}}$$

In the present case the value of log K_M comes to be 0.1883 and that of stabilization constant K_S expressed as

$$\log K_S = \log K_M - \log 2$$

and it comes to be −0.1127.

The positive value of log K_M and the negative value of log K_S thus show that mixed complexation is preferred over simple bis-complexation.

Pb(II) is hexa-coordinated. Three mixed complexes existing

TABLE 5. Equilibria involved in three mixed complexes and equilibrium constants (K) values

No.	Equilibria	log K at 25°C
[1]	$Pb^{2+} + ICA^{2-} + NA^- \rightleftarrows [Pb(ICA)(NA)]^-$	3.0
[2]	$Pb^{2+} + ICA^{2-} + 2NA^- \rightleftarrows [Pb(ICA)(NA)_2]^{2-}$	5.35
[3]	$Pb^{2+} + 2ICA^{2-} + NA^- \rightleftarrows [Pb(ICA)_2(NA)]^{3-}$	5.52
[4]	$[Pb(ICA)(NA)]^- + NA^- \rightleftarrows [Pb(ICA)(NA)_2]^{2-}$	2.35
[5]	$[Pb(ICA)(NA)]^- + ICA^{2-} \rightleftarrows [Pb(ICA)_2(NA)]^{3-}$	2.52
[6]	$[Pb(NA)_2] + ICA^{2-} \rightleftarrows [Pb(ICA)(NA)_2]^{2-}$	3.03
[7]	$[Pb(ICA)]^{2-} + NA^- \rightleftarrows [Pb(ICA)(NA)]^-$	0.83
[8]	$[Pb(ICA)_2]^{2-} + NA^- \rightleftarrows [Pb(ICA)_2(NA)]^{3-}$	2.22
[9]	$[Pb(ICA)_3]^{4-} + NA^- \rightleftarrows [Pb(ICA)_2(NA)]^{3-} + ICA^{2-}$	0.22
[10]	$[Pb(ICA)(NA)_2]^{2-} + ICA^{2-} \rightleftarrows [Pb(ICA)_2(NA)]^{3-} + NA^-$	0.17

in solution have the equilibria as listed in Table 5. The equilibrium constants (log values) have been calculated and written in front of each equilibrium as also reported earlier by Shivhare and Singh (9).

From the equilibrium constants the tendency of a ligand to add to a complex and to substitute another ligand may be compared. It is seen that ICA^{2-} adds readily to $[Pb(ICA)(NA)]^-$ as compared to NA^- (equilibria [4], [5]). It is also observed that the complexing tendency of ICA^{2-} is much more than NA^- (equilibria [6], [7]). The stability of three complexes as seen from their overall formation constants follow the order:

$$Pb(ICA)(NA)]^- < [Pb(ICA)(NA)_2]^{2-} < [Pb(ICA)_2(NA)]^{3-}$$

Comment: Temperature profiles for reactions with self-heating: thermal explosion in the sphere

TERRY BODDINGTON, PETER GRAY, AND STEPHEN SCOTT
School of Chemistry, University of Leeds, Leeds LS2 9JT, U.K.

Received January 4, 1983
(Ref.: Can. J. Chem. **60**, 2012 (1982))

TERRY BODDINGTON, PETER GRAY, and STEPHEN SCOTT. Can. J. Chem. **61**, 1944 (1983).

Attention is drawn to two unifying treatments of self-heating and self-cooling in chemical systems. They lead to simple but accurate expressions not only for temperature–position "profiles" but also for all the other important aspects of non-isothermal behaviour, up to and including the point of critical ignition.

TERRY BODDINGTON, PETER GRAY et STEPHEN SCOTT. Can. J. Chem. **61**, 1944 (1983).

On met l'accent sur deux études unifiées de l'autochauffage et de l'autorefroidissement dans les systèmes chimiques. Ces études conduisent à des expressions simples et précises non seulement pour les profils de température vs la position mais aussi pour tous les autres aspects importants du comportement non isotherme, jusqu'à inclure le point d'inflammation critique.

In a recent article, Moise and Pritchard (1) offer an approximate alternative to the tabulated solutions of Chandrasekhar and Wares (2) for temperature–position profiles in an exothermic reactant of spherical geometry, and for the connection between the dimensionless centre temperature θ_0 and the value of Frank–Kamenetskii's parameter δ. Their approach is said to require no more than a hand-held, programmable calculator to yield profiles that are nowhere in error by more than 1% for $\delta \leqq 3$ nor by more than 5% for $\delta = 3.3$. The purpose of the present note is to point out that precision of this level and better is attainable with more illumination and less effort. It can also be got with greater generality, since the treatment copes easily both with general boundary conditions (arbitrary Biot number) from the Frank–Kamenetskii to the Semenov extremes, and also with endothermic reactions. It also requires a minimum of manipulation to lead to other important properties of the system, such as the corrections that are to be made to Arrhenius parameters when kinetic measurements are made without regard for self-heating.

Although our earliest accounts (3) of this work go back to 1970 and routes to temperature–position profiles are given (4) in full in 1971, the most complete studies (5, 6) overlap in time with Moise and Pritchard, appearing in 1981 whilst their work was being printed. Only the main points need to be made here. We focus these comments on spherical geometry.

(*1*) Two independent, analytical routes (6) are now available. One proceeds via a quintic approximation (7) to the Arrhenius temperature-dependence; the other uses a second-order reversion (3, 4) of a series solution, invoking the exponential approximation to the Arrhenius term. (Moise and Pritchard use the exponential approximation also.)

(*2*) Although these analytical treatments are not exact, they yield algebraic solutions of kinds that are rarely in error by more than 1 or 2%, and that apply without difficulty right up to criticality.

(*3*) Explicit (and fairly simple) algebraic equations can be set out for:

(*a*) temperature–position profiles, central excess temperatures, and temperature gradients at the surface for stable stationary states;

(*b*) the same quantities for unstable states and for criticality;

(*c*) rate-constant correction factors f;

(*d*) errors in kinetic parameters (e.g. E_{act}) from criticality to limiting forms for very small self-heating;

(*e*) generalized heat-transfer conditions at the boundary where the algebra is heavier, but quite manageable;

(*f*) endothermic systems, which can be treated easily and yield parallel expressions. These often differ by no more than the sign of a single coefficient.

All this is not to deny the possible value in other contexts of approaches like Moise and Pritchard's, but so far as the topic of thermal explosion in the sphere is concerned, it seems an arduous, lonely, and obscure path to results that can be reached more easily and by routes that offer clearer views.

Homoenolization of 3,3,6,6-tetramethylbicyclo[2.2.1]heptan-2-one and 1,3,3-trimethylbicyclo[2.2.1]heptan-2-one. Preferential *syn* exchange at C-7

NICK HENRY WERSTIUK, SHAHIN YEROUSHALMI, AND GEORGE TIMMINS
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received March 29, 1983

NICK HENRY WERSTIUK, SHAHIN YEROUSHALMI, and GEORGE TIMMINS. Can. J. Chem. **61**, 1945 (1983).

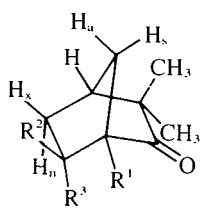
Preliminary studies of the KO*t*Bu-catalyzed H−D exchange of 3,3,6,6-tetramethylbicyclo[2.2.1]heptan-2-one (**1***b*) and 1,3,3-trimethylbicyclo[2.2.1]heptan-2-one(fenchone, **1***c*) in *t*-BuOD at elevated temperatures have been carried out. We find that **1***b* undergoes H−D exchange at the bridgehead α to the carbonyl group and at C-7 with a *syn*/*anti* preference of 5:1, establishing that C-7 of a bicyclo[2.2.1]heptan-2-one is an homoenolizable site. A similar preference was observed for exchange at C-7 of fenchone. These exchange studies also indicate that significant dilution of the deuterium pool occurs when a solution of KO*t*Bu/*t*-BuOD is heated at elevated temperatures for extended periods.

NICK HENRY WERSTIUK, SHAHIN YEROUSHALMI et GEORGE TIMMINS. Can. J. Chem. **61**, 1945 (1983).

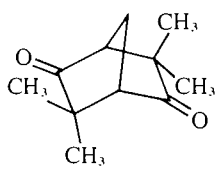
On a effectué des études préliminaires sur l'échange H−D de la tétraméthyl-3,3,6,6 bicyclo[2.2.1] heptanone-2 (**1***b*) et la tétraméthyl-1,3,3 bicyclo[2.2.1] heptanone-2 (fenchone, **1***c*) catalysée par le KO*t*-Bu dans le *t*-BuOD à des températures élevées. Nous avons trouvé que le composé **1***b* subit un échange H−D au niveau de la tête de pont en α du carbonyle et au niveau du C-7 avec une préférence *syn*/*anti* de 5:1 qui permet d'établir que le carbone en position 7 du bicyclo[2.2.1] heptanone-2 est un site homoénolisable. On a noté une préférence analogue pour l'échange au niveau C-7 de la fenchone. Ces études d'échange indiquent également qu'il se produit une dilution significative du deutérium lorsqu'on chauffe une solution KO*t*-Bu/*t*-BuOD à des températures élevées pendant des périodes assez longues.

[Traduit par le journal]

Following the report of Nickon and Lambert (1) on the base-catalyzed homoenolization of 3,3-dimethylbicyclo-[2.2.1]heptan-2-one (camphenilone, **1***a*), a number of ketones have been studied and information has been obtained regarding the factors which determine the rates and stereochemistry of H−D exchange and the propensity for skeletal rearrangement. Reviews (2−5) of the subject have been published. While Nickon and Lambert established that **1***a* incorporated three deuterium atoms at C-1 and C-6 quite readily in KO*t*Bu/*t*BuOD at 185°C and racemized at essentially the same rate, they were unable to quantify the rate of bridgehead H−D exchange because C-1 and C-6 become equivalent in the homoenolate anion. Subsequently, Nickon *et al.* (6) studied the



1



2

a, $R^1 = R^2 = R^3 = H$
b, $R^1 = H$; $R^2 = R^3 = CH_3$
c, $R^1 = CH_3$; $R^2 = R^3 = H$

exchange of 7-D-**1***a* in KO*t*Bu/*t*-BuOH, detected no loss of deuterium when the deuterated ketone was heated for 98 h at 185°C, then recycled at 185°C for 200 h, and stated that C-7 was not an homoenolizable site. The lack of reactivity at C-7 was noteworthy because the hydrogens, like those at C-6, are β to the carbonyl group. Ring strain and poor orbital alignment were invoked to account for the lack of reactivity at C-7 (6). Stothers and co-workers, in an apparently complete study of the homoenolization of 1,3,3-trimethylbicyclo[2.2.1]heptan-2-one (fenchone, **1***c*), established that the *exo*/*endo* rate ratio for exchange at C-6 was ~3.5, but did not observe exchange at C-7 (7). In contrast, studies in this laboratory showed that 3,3,6,6-tetramethylbicyclo[2.2.1]heptane-2,5-dione (**2**) undergoes relatively rapid exchange at the bridgeheads ($k \sim 1.5 \times 10^{-5}$ s^{-1}) and at C-7 ($k \sim 9 \times 10^{-6}$ s^{-1}) (8).

In this communication we provide evidence that monoketone **1***b* undergoes exchange *at C-1 and C-7* as well as the methyls. In contrast to the *exo* preference observed for exchange at C-6 of **1***c*, exchange at C-7 of **1***b* occurs preferentially *syn* to the carbonyl group. We have reexamined the homoenolization of fenchone (**1***c*) that was studied by Stothers and find that slow exchange also occurs at C-7, again with a *syn* preference. Table 1 lists the data on the homoenolizations of **1***b* and **1***c*. The crucial assignments of the $^1H(^2H)$ resonances used in determining the deuterium distributions were accomplished using double irradiation experiments.[1]

From entries 1, 2, and 4 it is clear that exchange at C-7 of **1***b* and **1***c* is slower than exchange at C-1 of **1***b* and the *exo*-3-methyls of **1***b* and **1***c*. Significant deuterium incorporation at C-7 occurs above 200°C. The approximate pseudo-first-order rate constants for exchange of *syn*-7-H, *anti*-7-H, and H-1 of **1***b* at 185°C are estimated to be $\sim 1.5 \times 10^{-8}$, $\sim 3 \times 10^{-9}$, and

[1]Irradiation of H-4 (δ 2.13) of **1***b* resulted in loss of a 4.4 Hz coupling in a high-field component (centered at δ 1.4) of an AB quartet and thereby identified H-5x, and also H-5n. Irradiation of H-5n resulted in a loss of coupling (2.6 Hz, W-type) in a low-field component (centered at δ 1.95) of an AB quartet and thereby identified H-7s, and H-7a (δ 1.85) as well. Even at 400 MHz, all the resonances of **1***c* are not resolved. From double irradiation experiments and by analogy to **1***b*, a complex multiplet centered at δ 1.7 was assigned to H-7s, H-5x, and H-5n. Our assignment of H-6x, which according to our analysis overlaps with H-7a, and the other resonances, H-6n and the methyls, agreed with Stothers' assignments (7).

[a]The base solutions were prepared in a dry-box or glove bag.
[b]Determined mass spectrometrically at low voltage. Recoveries of the ketone usually were ~70%.
[c]Determined by ^{2}Hmr at 38.4 MHz. Incorporations were determined by computerized curve-fitting of the spectra to Lorentzian line shapes and are averages of at least three fittings. The average error is in the order of ±10%.
[d]Determined by ^{2}Hmr at 61.4 MHz using Eu(fod)$_3$.
[e]Not determined.
[f]The deuterated ketone was isolated from the first exchange and recycled.
[g]A very weak signal (<0.020) which overlapped partially with D-1 was assigned to D-4, indicating that very slow exchange was occurring at C-4 as well.
[h]From ^{1}Hmr it was deduced that one of the methyls, most likely the *exo*-C-3-methyl, had exchanged preferentially.
[i]The signal due to H-7a overlaps H-6x.

~3×10^{-7} s^{-1}, respectively, by a one-point kinetic analysis of the data in entries 1, 2, and 3. Thus, α exchange is ~20 times faster than *syn* exchange at C-7 and ~100 times faster than *anti* exchange. While the *syn*/*anti* preference is ~5:1 for **1***b*, it is difficult to establish the ratio exactly for **1***c* because the *anti*-7-D resonance overlaps with the *exo*-6-D resonance (*vide supra*). Since the deuterium incorporation in the *syn*-7-position of **1***c* is essentially the same as the incorporation in **1***b* and the *exo* and *endo* incorporations at C-6 of **1***c* are identical within experimental error, a comparable *syn* preference is indicated for **1***c*. From entry 6 it is seen that the rate of exchange of *syn*-7-H of **1***c* is approximately equal to the rate of exchange of the bridgehead methyl on a per hydrogen basis. Since the *syn*- and *anti*-hydrogens of **1***b* are in nearly identical steric environments and *syn* exchange is preferred, the interpretation of the *exo* preference observed for exchange at C-6 of **1***c* on the basis of a homoconjugative effect must be reconsidered because *exo* approach to **1***c* is less hindered than the *endo* approach. Perhaps electrostatic stabilization (5, 9) of the inside anions at C-7 of **1***b* and **1***c* is greater than stabilization of the outside anions. Additional studies are planned to probe this possibility.

Since the rate of *exo* ($k \sim 7 \times 10^{-6}$ s^{-1}) H−D exchange at C-6 of fenchone (**1***c*) (7) should be a good measure of *exo* exchange of camphenilone (**1***a*) at C-6, our studies establish, using the bridgehead exchange of **1***b*, that *exo* exchange at C-6 of camphenilone should be ~25 times as fast as bridgehead exchange. This analysis is in keeping with the observation that the rates of H−D exchange and racemization of camphenilone are equal within experimental errors (6).

As is indicated in entries 3 and 6, an attempt was made to increase the deuterium incorporation by heating **1***b* and **1***c* at 220°C for 300 h and then recycling the deuterated ketones. While more deuterium was incorporated into the ketones, the reactive positions − C-1 and the *exo*-3-methyl of **1***b* and C-6 and the *exo*-3-methyl of **1***c* − did not contain the expected amounts of deuterium. In fact, more deuterium is incorporated at C-6 of **1***c* in shorter reaction periods (entry 4). The data in entry 6 also indicate that the *exo*- and *endo*- positions at C-6, and most likely the *exo*-2-methyl as well, were equilibrated with the deuterium pool. The low deuterium incorporations at C-6 and the *exo*-methyl which equilibrate rapidly with the deuterium pool clearly indicate that the pool is being diluted by a process other than exchange of the ketone, that we calculate to be not greater than 10% after two cycles. While the mode of the dilution is not known, *tert*-butyl alcohol must be the source of the protons. It is conceivable that *tert*-butoxide promotes $\overline{O}D$ elimination at elevated temperatures, forming *t*-BuOH and isobutene that can undergo H−D exchange as well. A substantial dilution of the deuterium pool would result and a decrease in the basicity of the medium would occur, which appears to be the case when homoenolizations are run at elevated temperatures or for long periods. This interesting possibility will be probed by carrying out the homoenolization of **1***c* in perdeuterated *tert*-butyl alcohol. Deuterium incorporation should increase and the activity of the base should be maintained for a longer period. The study of exchange at fairly unreactive positions, a necessity if the exact role of the carbonyl group in stabilizing remote anions is to be detailed, will be facilitated.

The determination of technetium-99 in urine[1]

GARY H. KRAMER

Biomedical Research Branch, Health Sciences Division, Atomic Energy of Canada Limited, Research Company, Chalk River Nuclear Laboratories, Chalk River, Ont., Canada K0J 1J0

Received December 21, 1982

GARY H. KRAMER. Can. J. Chem. **61**, 1949 (1983).

A method has been developed for the routine radiochemical analysis of technetium-99 in human urine. The excreted technetium is coprecipitated from a 200 mL urine sample with CuS. Valence state adjustments are performed with $K_2S_2O_8$. The precipitate is dissolved in ammoniacal peroxide and, after the Cu(II) is removed by ion exchange, the Tc-99 is extracted with 2-butanone (MEK). Subsequent evaporation of the organic solvent gives an essentially weightless source that if counted with a gas proportional counter will give a better limit of detection than liquid scintillation methods. The recovery of Tc-99 using this procedure is 80% (σ = 4%) and the limit of detection is 20 mBq (0.6 pCi) at the 95% confidence level for a routine sample – counting time 20 minutes, counting efficiency 24%, ambient background 1.3 counts per minute (cpm).

GARY H. KRAMER. Can. J. Chem. **61**, 1949 (1983).

On a mis au point une méthode d'analyse radiochimique courante du technétium-99 dans l'urine humaine. A partir d'un échantillon de 200 mL d'urine, on fait coprécipiter le technétium excrété avec du CuS. On réalise des ajustements de la valence avec du $K_2S_2O_8$. On dissout le précipité dans du peroxyde ammoniacal et on extrait le Tc-99 avec la butanone-2 (MEK) après avoir enlevé le Cu(II) par échange d'ions. L'évaporation subséquente du solvant organique donne essentiellement une source impondérable qui si elle est comptée avec un compteur proportionnelle de gaz donnera une meilleure limite de détection que les méthodes de scintillation liquide. Par cette méthode on récupère le Tc-99 à 80% (σ = 4%) et la limite de détection est de 20 mBq (0,6 pCi) avec une certitude de 95% pour un echantillon courant. Le temps de comptage est de 20 minutes, l'efficacité de comptage est de 24%, le bruit de fond est de 1,3 compte par minute (cpm).

Introduction

Technetium-99 is produced either as a fission product in nuclear reactors or by the thermal neutron bombardment of Mo-98. In both cases, the initial product is Tc-99m that decays by internal transfer with the emission of 140 keV γ-rays to Tc-99. The half-life of Tc-99m is 6.0 hours. This metastable state of Tc-99 is one of the most widely used clinical radionuclides; however, Tc-99 finds virtually no commercial use except for investigations into the physical and chemical properties of technetium. Technetium-99 is the longest lived of all the technetium isotopes (half-life = 2.1×10^5 a) and decays by beta particle emission (E_{max} = 0.292 MeV). There are no accompanying gamma emissions.

To design an effective analysis method for Tc-99 it is necessary to estimate the level of activity in urine for the most conservative case. Assuming the ALI (annual limit on intake) to be 2×10^{-9} Sv/Bq and that personnel are sampled monthly, then the activity in a 24 hour urine sample is estimated to be 1.3 kBq. Typically, 200 mL of urine is collected and analysed so that the estimate of activity becomes 186 Bq. These figures are estimated for a Class W inhalation incident as described elsewhere (1). Similar calculations performed for a Class D inhalation case give a level of activity in a urine sample of 235 Bq and for an ingestion incident the level of activity in urine would be 224 Bq. Hence, the DIL (derived investigation limit) should be 186 Bq and the analytical method should be capable of estimating a value less than the DIL.

There are many methods in the literature for radiochemical analysis of technetium, but most of them are not designed to deal with low levels of activity that are usually found in bioassay and environmental samples. Typical of these are the methods of Anders (2) and Embleton and Foreman (3). Technetium urinalysis has received very little attention except by Fairman and Sedlet (4) and Walker *et al.* (5). The former procedure does not provide adequate separation from some interfering activities and does not have adequate sensitivity (6). The latter procedure can only deal with a small sample size and also suffers from inadequate sensitivity. Pacer (7) has recently described the counting efficiency and quenching characteristics of liquid scintillation counting of Tc-99, and Zodda *et al.* (8) have described an analysis method for pertechnetate using hplc; however, neither method is suitable for bioassay. Foti *et al.* (9) have described a method for measuring Tc-99 in environmental samples using neutron activation that gives good recovery of Tc-99 and a low detection limit.

It has often been stated that any analytical scheme for technetium must avoid heating because of the high vapour pressure of Tc_2O_7 and $HTcO_4$. Indeed, Boyd and co-workers (10) have shown the vapour pressures to be considerable at 100°C; Tc_2O_7, 13.3 Pa; $HTcO_4$ (saturated aqueous solution), 9.3 Pa. The results given in this work indicate that loss of technetium by evaporation is not a problem because the results obtained under reflux conditions are identical to those obtained under "open-beaker" conditions.

This paper describes a method (that is designed for routine personnel monitoring) for the determination of small amounts of inorganic or weakly bound Tc-99 in urine. Analysis time is approximately 6 hours prior to radioactive counting.

Experimental

Reagents

2-Butanone (MEK): a "Baker analysed" reagent was obtained from the J. T. Baker Chemical Company and used without further purification.

Tracers

Technetium-99 was obtained from New England Nuclear Canada Limited as an aqueous solution of ammonium pertechnetate. The activity was determined to 98% precision by 4π beta counting. Appropriate dilutions of the initial solution in 1 *M* NH_4OH were prepared for routine use.

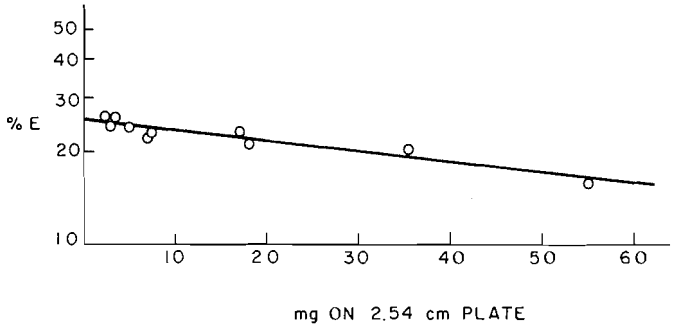

FIG. 1. Calibration curve for technetium-99.

Equipment

Beta counting was performed with a gas proportional (GP) counter. The average background for the 5.6 cm (diameter) detector was 1.3 counts per minute (cpm). The instrument calibration curve is shown in Fig. 1.

Procedure

The urine sample (200 mL) is acidified with 6 mL concentrated H_2SO_4. Ten grams of $K_2S_2O_8$ are added and the solution is heated with stirring. The heating is continued until the pale yellow solution begins to turn orange again. Two milliliters of the Cu(II) carrier solution (5 mg Cu(II)/mL) are added to the cooled solution. A thioacetamide solution is also added (200 mg/10 mL). The solution is heated with stirring to 70°C ± 5°C for 30 min and then allowed to cool to room temperature. The CuS precipitate is removed by vacuum filtration through a sintered glass frit (fine) and washed with 30 mL of 0.1 *M* H_2SO_4. The CuS precipitate is also washed with 30 mL of methanol to remove the coprecipitated organics which appear as a dark brown impurity in the methanol wash. The precipitate is dissolved by adding NH_4OH – 30% H_2O_2 (5–10 mL) (5:1, v:v) in small amounts (1–2 mL). After the dissolution is complete the solution is drawn through the frit into the collection vessel and the procedure repeated until all the precipitate is dissolved. If all the organics have not been washed out with methanol the solution will appear green, otherwise it will be predominately blue. The solution is transferred to a covered beaker and heated on a hot plate to destroy any residual H_2O_2 and to convert all the sulfo salts of technetium to TcO_4^-. After the completion of this step the solution will be blue. The solution is cooled and the pH adjusted to 10, or greater. The Cu(II) ions are removed by adding sufficient cation exchange resin (Bio-Rad AG 50W) in the NH_4^+ form until the solution is either colourless or *very* pale yellow. The resin is removed by passing the solution through a glass wool filter. The resin is washed with a dilute NH_4OH wash solution (5 mL). The filtrate is transferred to a round bottom flask and treated with 3–5 drops of 30% H_2O_2. Sufficient Na_2CO_3 is added to make the solution 0.25 *M* and an equal volume of MEK is added. The flask is shaken for 10 min. The organic layer is removed and retained. Another extraction is performed and the two organic layers are combined in a beaker and evaporated to a small volume (5–10 mL) under a heat lamp in a fume cupboard. Finally, the remaining MEK is transferred to a weighed aluminum counting dish (2.5 cm diameter) and evaporated to dryness. The beaker is rinsed with a few mL of MEK and this is also added to the counting dish and evaporated.The dish is counted for Tc-99.

Results and Discussion

Gerlit (11) has shown that Tc(VII) is quantitatively carried by CuS coprecipitation but that other valence states are not. It was, therefore, necessary to preadjust the technetium valence state in urine by oxidation. Although an intake of technetium would probably be originally a pertechnetate intake, the chemical environment in the body and, certainly, in the urine could reduce a significant portion to the lower valence states. To simulate this, all spiked urine samples were allowed 24 h to equilibrate prior to analysis.

TABLE 1. Some typical experimental data for Tc-99 recovery

Sample[a]	Recovered (cpm)	Counting efficiency (%)	% Recovered
1	188	24	84
2	158	22	77
3	189	24	83
4	172	23	81

[a]Sample volume 200 mL; added activity 15.4 Bq; counting time 20 min; ambient background ~1.3 cpm.

A sulphate medium was selected for the following reasons. Copper sulphide will dissolve in hot 2 *M* nitric acid and also at lower acidities if large quantities of ammonium nitrate are present. The sulphide ion is oxidized to elemental sulphur under these conditions. Hydrochloric acid was rejected because it will rapidly reduce Tc(VII) to lower valence states (12). Some attempts have been made to utilize this fact to design a radiochemical separation procedure (12–14). Therefore, sulphuric acid was chosen as the acidic medium and $K_2S_2O_8$ was chosen as the oxidizing agent because its decomposition product, SO_4^{2-}, does not interfere with the subsequent CuS coprecipitation. Other oxidizing agents were tried, but only H_2O_2 was potentially suitable in leaving no interfering products. Unfortunately, H_2O_2 is not completely decomposed during the oxidation step and the residual peroxide reacts with the thioacetamide to form elemental sulphur. Interferences from sulphate precipitates were not found to be a problem.

The dissolution of CuS by ammoniacal hydrogen peroxide is a well known method (4, 15, 16) and, provided that it is carried out carefully, is quite satisfactory. It is important to add small amounts of the dissolving solution, otherwise the reaction will become very violent and a significant portion of the sample may be lost. Other workers have used acidic peroxide dissolution solutions (6) but this method cannot be conveniently interfaced with the MEK extraction.

The MEK extraction from a basic 0.25 *M* Na_2CO_3 solution has a distribution coefficient of about 16 (17). The two extractions should recover 99.5% of the technetium that is maintained as Tc(VII) by the addition of peroxide. A further advantage is the ease of evaporation of MEK to give essentially weightless sources for beta counting. In practice, between 3 and 6 mg residues were found on the counting dishes and the counting efficiency was approximately 24%; however, the limit of detection is still improved over liquid scintillation methods. To obtain the same detection limit given below, a liquid scintillation sample would have to be counted for approximately 50 min. The evaporation of MEK on the counting dish was tested for volatilization of technetium. No noticeable decrease in activity was observed between samples that were counted, exposed to the heat lamp for six hours, and then recounted.

The method has been tested on 14 spiked (15 Bq) urine samples that were analysed under reflux conditions. The amount of added activity was chosen to be an order of magnitude less than the DIL (see Table 1). The mean recovery was 81% (σ = 6%). A further five samples were analysed under "open-beaker" conditions and the mean recovery was 79% (σ = 4%). Obviously volatilization is not a problem. To check the efficiency of the oxidation step, three urine samples were spiked with Tc(IV), prepared by reducing Tc(VII) with hydrazine (2), and the mean recovery was 85% (σ = 5%). The amount of oxidant was also optimized by studying the mean

For personal use only.

recovery as a function of weight of added $K_2S_2O_8$/200 mL urine. At 10 g and above, the recovery of Tc-99 remained constant at 82% (σ = 5%) whereas at lower weights there was a significant drop in recovery, i.e., at 5 g, recovery was 59%.

Further investigations were carried out using Tc-95m (78 kBq) to find where the major source of loss of technetium was occurring. No activity was found in the trap above the reflux condenser. The major source of loss was found to be at the CuS precipitation step. The results of six experiments showed that 16 ± 5% Tc-95m remained in solution after CuS had precipitated. The balance of the activity (84%) was found in the redissolved CuS fraction. The source of this loss was thought to be incomplete oxidation but the earlier results, where the recovery of Tc-99 was investigated as a function of the amount of oxidant, refutes this hypothesis; nevertheless, if the oxidation step is removed, and Tc-95m is prereduced, then the recovery and loss are both 50%, indicating that oxygen is converting much of the Tc(IV) to Tc(VII). Similarly, experiments have shown that prereduced Tc-95m can be recovered to the extent of 85% when the oxidation step is included in the analysis. Clearly some component of urine is acting as a holdback carrier because a second CuS precipitation does not recover any further activity.

This method compares favourably with the results found by Foti *et al.* (9). Their quoted recoveries were 80% and the detection limit for vegetation varied from 9×10^{-12} to 3×10^{-11} g Tc-99 (i.e., 6 to 19 mBq/25 g sample). The mean recovery of the method described in this paper was 81% but the detection limits are poorer than those of Foti *et al.*. It is estimated that the detection limit (18) for this procedure at the 95% confidence level is 20 mBq (0.6 pCi) for a routine sample that would have a counting efficiency of approximately 24%, a counting time of 20 min, and a chemical recovery of 80%; however, if the counting time is extended to 200 min, then the detection limit falls to 6.5 mBq.

Quenching of the fluorescence of substituted benzenes by halomethanes

H. A. KHWAJA, G. P. SEMELUK, AND I. UNGER

Department of Chemistry, University of New Brunswick, Fredericton, NB., Canada E3B 6E2

Received November 25, 1982

H. A. KHWAJA, G. P. SEMELUK, and I. UNGER. Can. J. Chem. **61**, 1952 (1983).

Rate constants, k_q, for the quenching of the singlet state of benzene, toluene, *p*-xylene, fluorobenzene, trifluoromethyl benzene, *p*-bis(trifluoromethyl)benzene, and aniline by CCl_4, CH_3CCl_3, $CHCl_3$, and $CFCl_3$ in the gas phase have been determined. In each instance the quenching is via a charge-transfer complex with the aromatic acting as donor. There is a linear dependence between ln k_q and IP (ionization potential) of the aromatics which supports Klein's model for exciplex formation. The most effective quencher is CCl_4 while the least effective is $CFCl_3$. The most effective donor was aniline while the least effective one was *p*-bis(trifluoromethyl)benzene. In general, fluorinated aromatics are less effective donors than the corresponding protonated molecules.

H. A. KHWAJA, G. P. SEMELUK et I. UNGER. Can. J. Chem. **61**, 1952 (1983).

On a déterminé la constante de vitesse, k_q, de rupture de l'état triplet du benzène, du toluène, du *p*-xylène, du fluorobenzène, du trifluorométhylbenzène, du *p*-bis(trifluorométhyl) benzène et de l'aniline par le CCl_4, le CH_3CCl_3, le $CHCl_3$ et le $CFCl_3$ en phase gazeuse. Dans chaque cas la rupture se fait par l'intermédiaire d'un complexe de transfert de charge où le noyau aromatique joue le rôle de donneur. Il y a une relation linéaire entre ln k_q et le PI (potentiel d'ionisation) des composés aromatiques qui vient à l'appui du modèle de Klein relatif à la formation d'un exciplexe. Le CCl_4 est le meilleur agent de rupture tandis que le $CFCl_3$ est le moins efficace. L'aniline est le meilleur donneur tandis que le *p*-bis(trifluorométhyl) benzène est le moins efficace. En général les composés aromatiques fluorés sont des donneurs moins efficaces que les molécules protonées correspondantes.

Introduction

Exciplex and excimer formation has been shown to be responsible for the quenching of the excited states of a large variety of molecules in solid, liquid, and vapor phases (see, for example, ref. 1). Exciplex formation may be due to charge transfer or to hydrogen bonding, or to a combination of both (2). In the case of charge-transfer (CT) complex formation, a model proposed by Klein (3) based on the absolute rate theory of Eyring has been tested by various authors (4, 5) and found to hold. Klein's model requires that there be a linear dependence of the overall second-order quenching rate constant, k_q, on the exponential of some measure of the free energy change associated with the formation of the complex. The two most important factors in CT exciplex formation are the ionization potential (IP) of the donor and the electron affinity (EA) of the acceptor. Thus the common method of investigating for the formation of CT exciplexes, when no spectral change in the emission of the excited state of the monomer is observed, is to vary either the EA of a number of acceptors while holding the IP of the donor constant, or the IP of a number of donors while holding the EA of the acceptor constant. The excited molecule may act either as donor or acceptor. If the resulting plot of ln k_q vs. EA or IP is linear it is considered likely that a CT exciplex is responsible for quenching. Recently we reported (6) on the quenching of benzene fluorescence by a number of halocarbons in the gas phase. In that study a good Klein correlation between k_q and EA of the halocarbons was established, thus suggesting a CT exciplex and charge transfer from benzene to halocarbon. In order to complete the study we have examined the fluorescence quenching of a number of aromatics by several halocarbons, thus allowing for an examination of the variation of k_q with IP as well as the influence of benzene ring charge density on charge transfer. The study was carried out in gas phase in order to eliminate solvent effects.

Experimental

Materials

Toluene was obtained from J. T. Baker Chemical Company as GC spectrophotometric quality and was used without any further purifications. Benzotrifluoride was obtained from PCR Research Chemicals Inc. with a stated minimum purity of 99.5%. Fluorobenzene and *p*-xylene were from Aldrich Chemical Company and 1,4-bistrifluoromethylbenzene was from Pfaltz and Bauer Inc. The research grade aniline (Anachemia Chemical Company) was purified by a conventional fractional distillation procedure, in which only the middle fraction was collected. None of the aromatics exhibited detectable impurity emission under the conditions of excitation and detection utilized here.

CCl_4 (GC spectrophotometric quality) was obtained from J. T. Baker Chemical Co., 1,1,1-trichloroethane (analytical reagent grade, 99.5%) was from BDH Chemicals Ltd., and $CHCl_3$ (spectrograde) was from Caledon Laboratories. These halogenated methanes were further purified by gas–liquid chromatography using an HP Model 7620 A chromatograph attached to a 5797A collecting unit, with He as the carrier gas; detection was by flame ionization. The chromatographic procedure gave a purity of >99.9% for each of the materials. $CClF_3$ was obtained from Matheson Company with a stated purity of >99% and was used as received.

Apparatus and procedures

Absorption spectra were obtained with a Perkin-Elmer 330 spectrophotometer. Fluorescence spectra were recorded with a modified Aminco-Bowman spectrophotofluorométer (SPF) using a quartz cuvette with inside dimensions 1 cm × 1 cm × 4.5 cm.

Samples were admitted to the working manifold from sample reservoirs attached to the vacuum line and were degassed by the freeze–pump–thaw method with a minimum of three cycles at better than 5×10^{-6} Torr. The pressures of aromatics in the quenching experiments were: benzene, 20 Torr; toluene, 3.5 Torr; *p*-xylene, 3 Torr; fluorobenzene, 1.0 Torr; trifluoromethyl benzene, 2.0 Torr; *p*-bis(trifluoromethyl)benzene, 2.0 Torr; aniline, 0.3 Torr. The pressures of halocarbon quencher ranged from 20 to 80 Torr.

For each point to be determined, a freshly prepared mixture of quencher and aromatic was admitted to the cell. Fluorescence spectra of aromatic were measured as a function of quencher concentration (up to 80 Torr). Details of pressure measurements, quantum yield determination, etc. have been given in ref. 6.

A full description of the apparatus, data collection, and processing used in this study has been given elsewhere (6, 7).

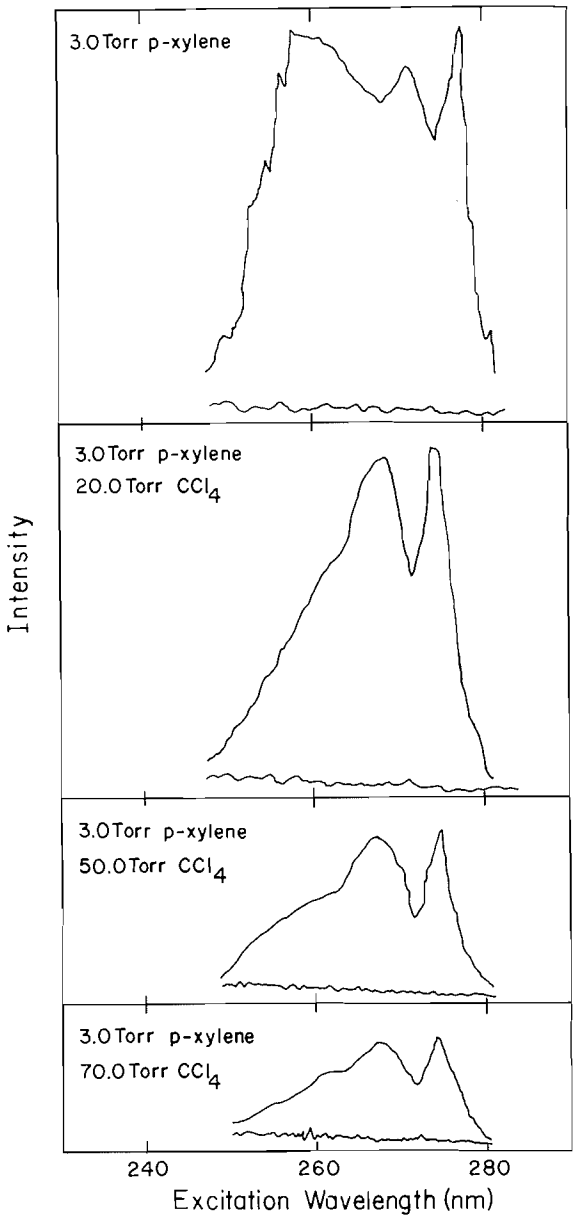

FIG. 1. Fluorescence excitation spectra of *p*-xylene in the presence of CCl_4, λ_{em} = 296 nm.

Results and discussion

Absorption, fluorescence emission, and excitation spectra of each of the aromatics in the absence and presence of each of the quenchers at the highest pressures used were recorded. The absorption and emission spectra were identical to that reported previously (8) and have therefore not been reproduced here. The absorption spectra of the aromatics with and without quencher were identical, thus ruling out the possibility of ground state complexation. Moreover, mixtures of aromatic and halocarbon that had been left in the cell in the dark for periods of up to 24 h showed no change in absorptivity.

With the exception of 1,4-$C_6H_4(CH_3)_2$ the excitation spectra of the aromatics exhibit the same maxima as do the absorption spectra and they are unaltered by the addition of halocarbons. The fluorescence excitation spectrum of 1,4-$C_6H_4(CH_3)_2$ is changed by the addition of CCl_4. Figure 1 demonstrates this effect for CCl_4, showing that the addition of CCl_4 strongly quenches the fluorescence of 1,4-$C_6H_4(CH_3)_2$ by preferential

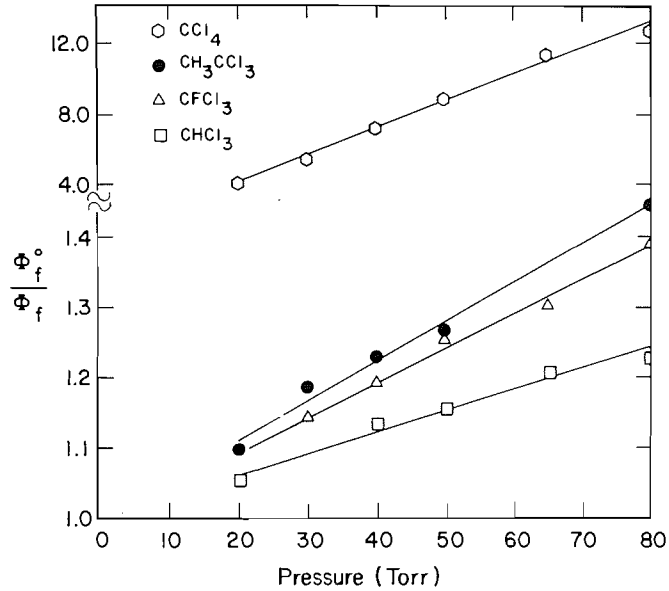

FIG. 2. Stern–Volmer plots for the quenching of *p*-xylene fluorescence by CCl_4, CH_3CCl_3, $CHCl_3$, and $CFCl_3$ (P(1,4-$C_6H_4(CH_3)_2$) = 3.0 Torr, λ_{ex} = 272 nm, T = 297.9 ± 0.2 K).

quenching of the shortest wavelength excitation sub-band; at 70 Torr of CCl_4 the yield from excitation into this sub-band is almost zero and there is simultaneously a shift of the longer wavelength excitation sub-bands to higher energies (CH_3CCl_3 and $CFCl_3$ also alter the excitation spectrum of 1,4-$C_6H_4(CH_3)_2$ but not as dramatically with the middle sub-band least affected). However, the shape of the fluorescence emission spectrum is unaffected by the addition of CCl_4. These observations indicate that the fluorescence observed in 1,4-$C_6H_4(CH_3)_2$ originates solely from the vibrationally relaxed excited singlet state and that there is a vibronic interaction between the excited state of the aromatic and some vibrational motion in CCl_4.

Fluorescence yields, Φ_f, of each of the aromatics were determined as a function of halocarbon pressure and are based on Φ of benzene being 0.183 (9). For every aromatic halocarbon pair, Φ_f was found to decrease with increasing quencher pressure. Plots of Φ_f^0/Φ_f vs. the quencher pressure obeyed the Stern–Volmer expression

$$[1] \quad \Phi_f^0/\Phi_f = 1 + k_q\tau[Q]$$

where Φ_f^0 and Φ_f refer to fluorescence yields of aromatics in absence and presence of halogenated methane, k_q is the bimolecular quenching rate constant, and τ is the lifetime of the excited singlet aromatic. A typical plot is given in Fig. 2. k_q was evaluated from the slopes of the plots and literature values of τ taken under similar conditions of excitation wavelength, aromatic pressure, etc. as those used in this study. The results are summarized in Table 1. It is evident from Table 1 that quenching by CCl_4, CH_3CCl_3, $CHCl_3$, and $CFCl_3$ of the excited singlet states of most of the aromatic molecules studied is a highly efficient process. k_q ranges from 5.2×10^8 L mol^{-1} s^{-1} for the $C_6H_5CH_3$–$CFCl_3$ pair to 9.4×10^{11} L mol^{-1} s^{-1} in the $C_6H_5NH_2$–CCl_4 system. Comparison of the quenching rate constants for aromatics by CCl_4 and $CHCl_3$ reveals a dramatic difference in quenching efficiency, see Table 1. The greater quenching efficiency of CCl_4 as compared with $CHCl_3$ is related to their difference in electron affinity. Similarly, for any single quencher, the magnitude of k_q increases with the

electron-donating power of the substituents in the aromatics.

In the benzene – halogenated methane systems π-bonding is possible between the electron cloud of the benzene ring and the empty 3*d* levels of the Cl atoms in the chloralkane. One would expect therefore that formation of the complex would be enhanced by substituents on the benzene ring that increase the electron density of the ring, and would be hindered by groups that withdraw electrons from the ring. If, on the other hand, the interaction is between the electron-deficient carbon atom on the halocarbon and the π ring electrons, changing electron density of the latter will have the same effect as above. Methyl substitution leads to increasing effectiveness. For example, the magnitude of k_q is increased by a factor of 5 in going from the benzene–CCl_4 pair (31.8×10^8 L mol^{-1} s^{-1}) to the toluene–CCl_4 pair. Similarly the higher quenching constants observed for 1,4-$C_6H_4(CH_3)_2$ compared to those for $C_6H_5CH_3$ must be due to the inductive effect of two such substituents. This concurs with the trends seen in fluorescence quenching of pyrazoline derivatives by halomethanes (10), where the formation of a donor–acceptor complex has been postulated. The same behavior has been observed in the quenching of aliphatic ketones (4), where successive substitution of methyl groups around the carbonyl chromophore promotes quenching by CCl_4. When an amino donor group is introduced into the benzene chromophore, k_q increases by nearly two orders of magnitude (see Table 1). In contrast, electrophilic fluorine atoms would be expected to effectively deactivate the aromatic ring and reduce the donor ability. Comparison of the quenching rate constants of the C_6H_5F–CCl_4 pair and C_6H_6–CCl_4 pair confirms this point. k_q for the $C_6H_5CF_3$–CCl_4 pair is found to be smaller than k_q for the C_6H_5F–CCl_4 pair, as expected for such an electron-withdrawing substituent. Further, the second trifluoromethyl group increases the electron affinity over that of the monosubstituted molecule by ~1 eV (11), which should make donor–acceptor complex formation less favourable and k_q smaller; this is indeed observed here.

The fluorescence quenching observed here cannot be due to ground state complexation or to chemical reaction since samples exposed for prolonged periods showed no evidence of product formation. In the case of $C_6H_5NH_2$, quenching with $CHCl_3$ and CH_3CCl_3 could be due to hydrogen bonding, but the literature suggests that this is unlikely (12).

The charge transfer exciplex model of quenching is based on eq. [2]

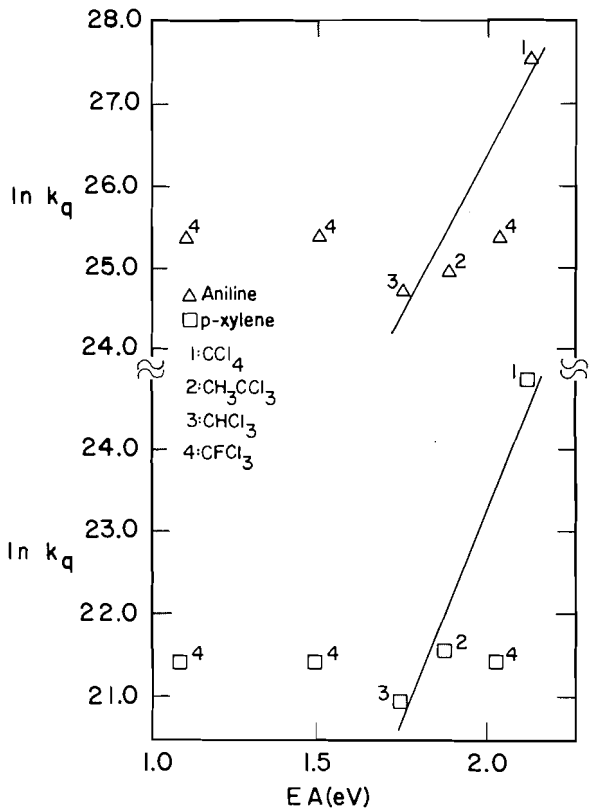

FIG. 3. Plot of ln k_q vs. EA for aniline and *p*-xylene singlet quenching by CCl_4, CH_3CCl_3, $CHCl_3$, and $CFCl_3$ in the vapor phase. Three different values for EA ($CFCl_3$) are given in the literature (5, 14, 15).

$$[2]\quad {}^1D^* + Q \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} {}^1(\delta+\ \ \delta-)^* \xrightarrow{k_2} D + Q \text{ or products}$$

where D* represents the fluorescent donor aromatic; Q, the ground state halogenated methanes; and $(D^{\delta+}.....Q^{\delta-})^*$, an exciplex. Applying the steady-state approximation gives

$$[3]\quad k_q = \frac{k_1 k_2}{k_{-1} + k_2}$$

and if $k_{-1} \gg k_2$,

$$[4]\quad k_q = Kk_2$$

$$[5]\quad \ln k_q = -\frac{\Delta G}{RT} + \ln k_2$$

$$[6]\quad \ln k_q \propto |-(IP_D - EA_A - E_{S^1} - C - P)|/RT$$

where k_q is the overall quenching rate constant, IP_D is the ionization potential of the donor, EA_A is the electron affinity of the acceptor, C is the Coulomb energy, P is the polarization energy of the separated charges, and E_{S^1} represents the energy of the first excited state.

In the case of benzene and a large number of halocarbons it has been shown that ln k_q does indeed vary linearly with EA_A, all the other terms of eq. [6] being constant. In the present case the dependency of ln k_q vs. EA_A was examined for each aromatic and a reasonably linear relationship holds. Typical plots are given in Fig. 3. That the point for $CFCl_3$ falls far off the line is not surprising since widely divergent values for E_A of this molecule are given in the literature (5, 13, 14). It is also possible to test eq. [6] by plotting ln k_q vs. IP_D; the results of this plot are shown in Fig. 4. A combination of all the free energy parameters allows one to plot ln k_q vs. ΔG^* ($\Delta G^* = \Delta G + C + P$ where $C + P$ are constant throughout), the results are given in Fig. 5. The deviation from linearity is undoubtedly due to the assumption $k_{-1} \gg k_2$ not being equally valid for all fluorophore quencher pairs.

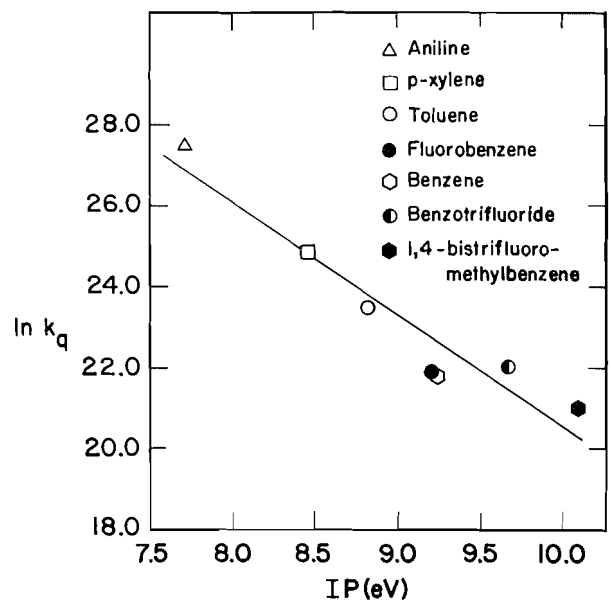

FIG. 4. Variation of ln k_q with IP(aromatic) for quenching by CCl_4.

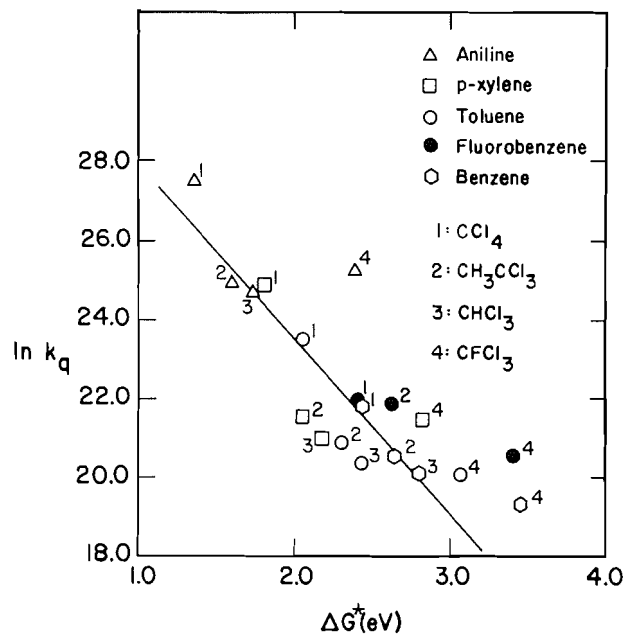

FIG. 5. Variation of ln k_q with free energy change for various quenchers.

Finally, if full electron-transfer from excited aromatic to quencher occurs, the maximum slope should be $1/RT \simeq 39$ eV^{-1}. From Fig. 4, a gradient of 2.72 eV^{-1} is obtained. The degree of charge transfer is therefore relatively small (~7%) and is comparable with the value of ~4 eV^{-1} quoted by Loutfy *et al.* (15) for the quenching of triplet acetone by olefins and ~6 eV^{-1} given by Saperstein and Levin (5) for the quenching of singlet aromatics by chloroform.

Reactions of the trisulfur trinitride anion, $S_3N_3^-$, with halogens and other electrophilic substrates

TRISTRAM CHIVERS AND M. N. SUDHEENDRA RAO
Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received December 16, 1982

TRISTRAM CHIVERS and M. N. SUDHEENDRA RAO. Can. J. Chem. **61**, 1957 (1983).

The reactions of the trisulfur trinitride anion, $S_3N_3^-$, with halogens (Cl_2, Br_2, I_2), AsF_5, $SOCl_2$, SO_2Cl_2, S_2Cl_2, $COCl_2$, CS_2, Me_3SiCl, and Ph_2PCl have been investigated. In all cases these reactions gave mixtures of known sulfur–nitrogen compounds. Thus the halogens react with $S_3N_3^-$ to give mainly S_4N_4, $S_4N_3^+X^-$ (X = Br, Cl), $(SN)_x$, and $S_3N_3X_3$ (X = Cl), while AsF_5 oxidizes $S_3N_3^-$ to $S_4N_4 \cdot AsF_5$. The major products of the reaction of $S_3N_3^-$ with $SOCl_2$ or SO_2Cl_2 were S_4N_4, $S_4N_3^+Cl^-$, and (for $SOCl_2$ only) $S_3N_2O_2$. S_3N_2Cl was the main product of the reaction of $S_3N_3^-$ with S_2Cl_2, whereas $COCl_2$ yielded $(SN)_x$ in addition to S_3N_2Cl and S_4N_4. Carbon disulfide reacts with $S_3N_3^-$ to give S_4N_2, S_4N_4, and CNS^-. The cyclophosphathiazenes, $(Ph_2PN)(SN)_2$, 1,3- and 1,5-$(Ph_2PN)_2(SN)_2$, in addition to $(Ph_2PN)_x$ (x = 3, 4), $(Ph_2PN)_3 \cdot HCl$ and $(Ph_2PN)_2NSCl$ were isolated from the reactions of Ph_2PCl with $S_3N_3^-$ in various molar ratios. The latter reaction represents a useful alternative synthesis of the 1,5-isomer of the eight-membered ring $(Ph_2PN)_2(SN)_2$.

TRISTRAM CHIVERS et M. N. SUDHEENDRA RAO. Can. J. Chem. **61**, 1957 (1983).

On étudie les réactions de l'anion trinitrure de soufre $S_3N_3^-$ avec les halogènes (Cl_2, Br_2, I_2), le AsF_5, le $SOCl_2$, le S_2Cl_2, le $COCl_2$, le CS_2, le Me_3SiCl et le Ph_2PCl. Dans tous les cas ces réactions donnent des mélanges de composés connus de l'azote avec le soufre. Ainsi les halogènes réagissent avec le $S_3N_3^-$ en donnant principalement le S_4N_4, le $S_4N_3^+X^-$ (X = Br, Cl), le $(SN)_x$ et le $S_3N_3X_3$ (X = Cl), tandis que le AsF_5 oxyde le $S_3N_3^-$ en $S_4N_4 \cdot AsF_5$. Le $S_3N_3^-$ réagit avec le $SOCl_2$ ou le SO_2Cl_2 en donnant comme produits majoritaires le S_4N_4, le $S_4N_3^+Cl^-$ et (dans le cas du SO_2Cl_2 seulement) le $S_3N_2O_2$. La réaction avec le S_2Cl_2 donne le S_3N_2Cl comme produit principal tandis qu'avec le $COCl_2$ on obtient surtout du $(SN)_x$ en plus du S_3N_2Cl et du S_4N_4. Le bisulfure de carbone réagit avec le $S_3N_3^-$ en donnant du S_4N_2, du S_4N_4 et du CNS^-. En faisant réagir le Ph_2PCl avec le $S_3N_3^-$ et en faisant varier les rapports molaires on obtient les cyclophosphathiazènes $(Ph_2PN)(SN)_2$, les $(Ph_2PN)_2(SN)_2$-1,3 et -1,5 en plus du $(Ph_2PN)_x$ (x = 3, 4), du $(Ph_2PN)_3 \cdot HCl$ et du $(Ph_2PN)_2NSCl$. La dernière réaction représente une autre synthèse utile de l'isomère-1,5 du cycle à 8 chainons: $(Ph_2PN)_2(SN)_2$.

[Traduit par le journal]

Introduction

The trisulfur trinitride anion, $S_3N_3^-$, has been thoroughly characterized both structurally (1) and spectroscopically (ir and Raman (1), uv–visible (1, 2), MCD (2), and ^{15}N nmr (3)). This thermally unstable and oxygen-sensitive anion is a planar six-membered ring (1). *Ab initio* Hartree–Fock–Slater SCF calculations show that it is a six orbital 10π-electron system in which the degenerate π* levels are fully occupied (1, 4) and this view of the electronic structure has been confirmed by experiment (2).

Some aspects of the chemical behaviour of $S_3N_3^-$ have been investigated and a variety of transformations including oxidation ($S_3N_3O^-$, ref. 5), ring contraction ($CCl_3CON{-}S_3N_2$, ref. 6), cage formation ($S_4N_5^-$, ref. 6), and ring opening (S_4N^-, ref. 7) have been observed (see Fig. 1). Of particular interest to us is the preparation of monosubstituted derivatives, S_3N_3X,[1] and the cation $S_3N_3^+$.[2] We have, therefore, conducted a study of the reactions of $S_3N_3^-$ with halogens, AsF_5, and other electrophilic substrates and we report the details of our findings here.

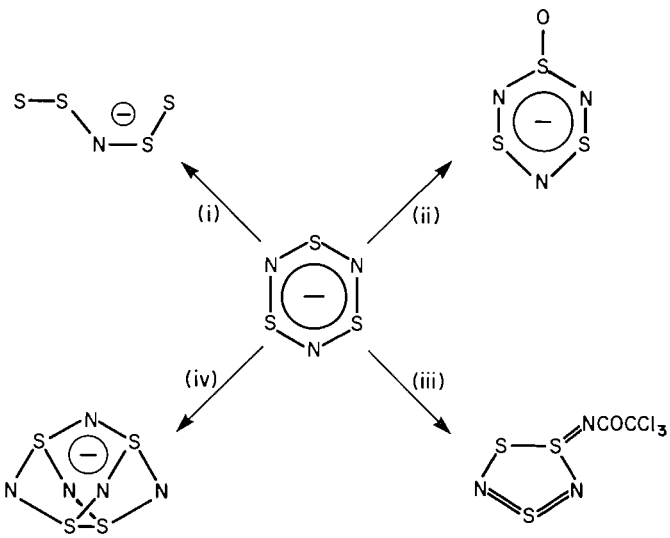

FIG. 1. Some reactions of the trisulfur trinitride anion, $S_3N_3^-$. (*i*) In CH_3CN at reflux (7), (*ii*) O_2 in CH_3CN (5), (*iii*) CCl_3COCl in CH_2Cl_2 (6), (*iv*) S_4N_4 in C_2H_5OH (6).

Experimental

Reagents and general procedures

$Cs^+S_3N_3^-$ (6) and $PPN^+S_3N_3^-$ (7) (PPN = Ph_3PNPPh_3) were prepared by the literature procedures. The following chemicals were obtained commercially and used as received: chlorine (Matheson), bromine (Fisher Scientific Co.), iodine (J.T. Baker Chemical Co.), arsenic pentafluoride (Ozark-Mahoning), chlorotrimethylsilane (Pen-

[1]Reference 8*a*. There are conflicting literature reports on the preparation of S_3N_3Cl from the reaction of $S_3N_3Cl_3$ and S_4N_4 and, recently, this reaction has been shown to produce $S_5N_5^+Cl^-$ (8*b*). A report of the formation of S_3N_3Br by bromination of S_4N_4 in CS_2 (8*c*) must be viewed with caution in view of more recent work which identified $S_4N_3^+Br^-$, $S_4N_3^+Br_3^-$, and $CS_3N_2Br_2$ as the products of this reaction (8*d*).

It has been claimed that the dark red amorphous solid which precipitates when S_4N_4 reacts with I_2 in boiling inert solvents is S_3N_3I (8*c*). However, the characterization is based entirely on analytical data. We were unable to repeat this synthesis.

[2]Planar $S_3N_3^+$ is expected to be a diradical (see ref. 1). However, if the symmetry of the ring is lower than D_{3h}, the degeneracy of the antibonding levels would be removed and a stable 8 π-electron system might result (cf. $Ph_2PS_2N_3$, ref. 9).

TABLE 1 *(Concluded)*

Reactants[a]		Reaction conditions[b]	Products isolated[c,d]	Comments
$Cs^+S_3N_3^-$ (2.00 g; 7.38 mmol)	+ Ph_2PCl (14.8 mmol)	CH_2Cl_2 (70 mL), 0°C, 20 h	$(Ph_2PN)_3$ $(Ph_2PN)(SN)_2$ (trace) 1,5-$(Ph_2PN)_2(SN)_2$ S_8 S_4N_4 $Ph_2P(S)Cl$ CsCl	As above
$Cs^+S_3N_3^-$ (0.93 g; 3.93 mmol)	+ Ph_2PCl (13.7 mmol)	CH_3CN (25 mL), 23°C, 38 h	1,3-$(Ph_2PN)_2(SN)_2$ 1,5-$(Ph_2PN)_2(SN)_2$ $(Ph_2PN)_4$ (trace) S_8 $Ph_2P(S)Cl$ $(Ph_2PN)_3 \cdot HCl$ CsCl	Products were isolated by fractional crystallization. A small amount of the hydrolysis product $[H_2NPPh_2NPPh_2NH_2]^+Cl^-$ was also isolated
$Cs^+S_3N_3^-$ (5.42 g; 20.0 mmol)	+ Ph_2PCl (49.9 mmol)	CH_3CN (100 mL), 0°C, 15 h	$(Ph_2PN)_3$ 1,5-$(Ph_2PN)_2(SN)_2$ $(Ph_2PN)_2NSCl$ S_8 S_4N_4 $Ph_2P(S)Cl$ $(Ph_2PN)_3 \cdot HCl$ CsCl	Products were separated by chromatography. $[H_2NPPh_2NPPh_2NH_2]^+Cl^-$ was also isolated

[a]The stoichiometry is indicated except for gaseous reagents (see Experimental section).
[b]The identity and volume of the solvent, the temperature, and the time of reaction are indicated in that order.
[c]Products were isolated from both the precipitate and filtrate portions of the reaction mixture. Only the S—N products are shown with yields of pure products based on sulfur in parentheses. The products in the precipitate were usually mixed with PPN^+ or Cs^+ halides and were not always obtained pure, in which case no yield is indicated.
[d]The structures of $(Ph_2PN)(SN)_2$ (**1**), 1,3-$(Ph_2PN)_2(SN)_2$ (**2**), and 1,5-$(Ph_2PN)_2(SN)_2$ (**3**) are illustrated in Fig. 2.
[e]Identifed by comparison of infrared and mass spectra and the X-ray powder diffraction pattern with the literature values (13).

insular Chem Research), chlorodiphenylphosphine (Alfa Products), and phosgene (Matheson). Sulfur monochloride (Fisher Scientific Co.), thionyl chloride (Fisher Scientific Co.), and sulfuryl chloride (Aldrich Chemical Co.) were distilled prior to use.

Methylene chloride and carbon disulfide were dried over P_2O_5 and distilled from P_2O_5 before use. Acetonitrile (reagent grade) was dried by distillation from P_2O_5 followed by distillation from CaH_2. All reactions and distillations were carried out under an atmosphere of nitrogen (99.99% purity) passed through Ridox and silica gel. Air-sensitive materials were manipulated under an atmosphere of dry nitrogen in a Vacuum Atmospheres Dri-Lab fitted with a Dri-Train.

Instrumentation

Routine infrared spectra (CsI windows) were recorded as Nujol mulls on a Perkin-Elmer 467 grating spectrometer. Ultraviolet–visible spectra were obtained by using a Cary 219 spectrophotometer. ^{31}P nmr spectra were recorded on a Varian XL-200 NMR spectrometer. Routine EI (70 eV) mass spectra were run on a Varian CH5 mass spectrometer. Chemical analyses were performed at the Department of Chemistry, University of Calgary (C, H, N) and at M.H.W. Laboratories, Phoenix, AZ (C, H, N, S, P, and halogens).

Reactions of $PPN^+S_3N_3^-$ with halogens and other electrophilic reagents

The experimental details for the reactions of $S_3N_3^-$ salts with various reagents are summarized in Table 1. The reactions were carried out by adding the stoichiometric amount of the reagent to a stirred solution of the $S_3N_3^-$ salt at the temperature indicated. For gaseous reagents (Cl_2, $COCl_2$, AsF_5), a moderate flow of gas was passed into the solution for 2–4 min. In the case of the low temperature reactions, the reaction mixture was allowed to reach ambient temperature slowly. At the conclusion of each reaction solid products were filtered off and solvent was removed from the filtrate *in vacuo*. The products from the precipitate and filtrate portions of the reaction mixture were treated separately and pure components were isolated by solvent extraction and fractional crystallization. This was particularly difficult in the case of the precipitates due to the presence of large amounts of PPN^+ or Cs^+ halides. All the products isolated were known compounds which were identified by ir and mass spectra and, in some cases, by uv–visible and ^{31}P nmr spectra. Good agreement with spectroscopic data quoted in the literature was found for the following products: $S_3N_3Cl_3$ (10), S_4N_4 (11), S_4N_3Cl and S_4N_3Br (12), S_3N_2Cl (12), $(SN)_x$ (13), $S_4N_4 \cdot AsF_5$ (14), S_4N_2 (15), $S_3N_2O_2$ (16), $(Ph_2PN)_3$ and $(Ph_2PN)_4$ (17), $(Ph_2PN)(SN)_2$ (18), 1,3- and 1-5,$(Ph_2PN)_2(SN)_2$ (19), and $(Ph_2PN)_2NSCl$ (20).

Characterization of $(Ph_2PN)_3 \cdot HCl$

In the reaction of Ph_2PCl with $Cs^+S_3N_3^-$ (2.5:1 and 4:1 molar ratios) an air-stable, white crystalline solid (ca. 200 mg) was isolated and identified as $(Ph_2PN)_3 \cdot HCl$. *Anal.* calcd. for $C_{36}H_{31}ClN_3P_3$: C 68.19, H 4.94, Cl 5.59, N 4.94, P 14.65; found: C 68.25, H 5.03, Cl 5.86, N 5.03, P 14.27. The major bands in the infrared spectrum (Nujol mull) were at 3080 (sh)w, 3057 w, 1440 s, 1242 vs, 1235 (sh), vs, 1205 s, 1200 (sh)s, 1186 s, 1130 m, 955 s, 734 s, 728 (sh)m, 702 m, 550 vs, 523 m, 516 (sh)m, 509 m cm^{-1}.

The mass spectrum showed major peaks at m/e 597 ($Ph_6P_3N_3^+$, 19%), 520 ($Ph_5P_3N_3^+$, 15%), 38 ($H^{37}Cl$, 33%), and 36 ($H^{35}Cl$, 100%). The ^{31}P nmr spectrum (in $CDCl_3$) showed a broad singlet at $\delta = +21.9$ (ref. external 85% H_3PO_4). The reaction of the adduct $(Ph_2PN)_3 \cdot HCl$ with triethylamine in boiling benzene gave $(Ph_2PN)_3$, identified by comparing its infrared spectrum with that of an authentic sample, and $Et_3N \cdot HCl$.

Results and discussion

Reactions of $S_3N_3^-$ with halogens and AsF_5

The products of the reactions of S_4N_4 with halogens are dependent on the reaction conditions. Thus the final product of the chlorination of S_4N_4 at ambient temperature is $S_3N_3Cl_3$ (10), but at −60°C the thermally unstable $S_4N_4Cl_2$ is formed (21).

With an excess of *liquid* bromine S_4N_4 forms the salt $S_4N_3^+Br_3^-$ quantitatively (22), whereas the reaction of bromine *vapour* with *solid* S_4N_4 gives the conducting polymer $(SNBr_{0.4})_x$ (23). We have, therefore, carried out the reactions of $S_3N_3^-$ with halogens (Cl_2, Br_2, and I_2) under a variety of conditions.

With all three halogens the major reaction product was S_4N_4 and there was no evidence for the formation of monosubstituted products S_3N_3X. Differences were observed, however, in the identities of the minor products obtained when the reactions were carried out under different conditions. Thus Cl_2 reacted with $PPN^+S_3N_3^-$ *in solution* to give $S_4N_3^+Cl^-$ (in addition to S_4N_4) whereas with *solid* $PPN^+S_3N_3^-$ the only S—N product was $S_3N_3Cl_3$. The latter is probably formed by the reaction of excess chlorine with S_4N_4 (10). The minor products of the reactions of $PPN^+S_3N_3^-$ with bromine were $(SN)_x$ (CH_2Cl_2 solvent) and $S_4N_3^+Br^-$ (solid state reaction). The reaction of I_2 with $PPN^+S_3N_3^-$ in CH_2Cl_2 gave S_4N_4 as the only identifiable S—N product.

The formation of $S_4N_3^+X^-$ (X = Cl, Br) probably occurs by the known reaction of S_4N_4 with S_2X_2 (24), the latter being formed by the reaction of halogen with sulfur produced in the reaction.

$$3S_4N_4 + 2S_2X_2 \rightarrow 4S_4N_3^+X^-$$

The absence of $S_4N_3^+I^-$, a thermally unstable salt (25), is accounted for by the instability of S_2I_2 (26).

The oxidation of $Cs^+S_3N_3^-$ by AsF_5 in CH_2Cl_2 gave three S—N products: S_4N_4, $S_4N_4 \cdot AsF_5$, and $(SN)_x$. It should be noted that the oxidation of S_4N_4 with excess AsF_5 in SO_2 produces the cation $S_4N_4^{2+}$ directly (27), but the adduct $S_4N_4 \cdot AsF_5$ is obtained when the reaction is conducted in CCl_4 (14*a*).

Reactions of $S_3N_3^-$ with $SOCl_2$, SO_2Cl_2, S_2Cl_2, $COCl_2$, and Me_3SiCl

The reactions of $SOCl_2$ and SO_2Cl_2 with $Cs^+S_3N_3^-$ produced an interesting sequence of colour changes (see Table 1) suggesting the formation of unstable intermediates. S_4N_4 was a major product in both reactions and, in the case of $SOCl_2$, $S_3N_2O_2$ was also isolated in ca. 50% yield. It should be mentioned that the related anion $S_4N_5^-$ also produces $S_3N_2O_2$ on reaction with $SOCl_2$ (28), as does S_4N_4 (29). The latter reaction also yields $S_4N_3^+Cl^-$ (29), but this cannot be the only source of $S_3N_2O_2$ in the $S_3N_3^-/SOCl_2$ reaction since only a small amount of $S_4N_3^+Cl^-$ was obtained. The main product of the reaction of S_2Cl_2 with $S_3N_3^-$ was S_3N_2Cl.

When $COCl_2$ gas was passed into a solution of $Cs^+S_3N_3^-$ in acetonitrile at −78°C a substantial amount of good quality $(SN)_x$ was obtained in addition to S_4N_4. The reaction of $PPN^+S_3N_3^-$ with Me_3SiCl in CH_2Cl_2 produced S_4N_4 in 56% yield.

Comments on the mechanism of the reactions of $S_3N_3^-$ with halogens and other electrophilic substrates

The ready oxidation of $S_3N_3^-$ is expected in view of its electronic structure (*vide supra*) and the initial oxidation product is expected to be the $S_3N_3^{\bullet}$ radical, which has been identified as one of the products of the pyrolysis of S_4N_4 over quartz or silver wool (30). However, there is disagreement over its structure. An open chain structure has been suggested on the basis of LCAO-SCF (minimal basis set) calculations (31), while more recent studies by photoelectron spectroscopy have led to the conclusion that $S_3N_3^{\bullet}$ is cyclic (32). It seems reasonable to rationalize the formation of S_4N_4 and, in some cases, smaller amounts of $(SN)_x$ from the oxidation of $S_3N_3^-$ with halogens or other electrophilic substrates by the initial formation of $S_3N_3^{\bullet}$ which rearranges quickly to give the observed products before further oxidation can take place. It is worth noting that the reaction of $S_3N_3Cl_3$, $S_3N_2Cl_2$, or S_3N_2Cl with Me_3SiN_3 also produces $(SN)_x$ and S_4N_4. The $S_3N_3^{\bullet}$ radical has been proposed as an intermediate in the formation of $(SN)_x$ in these reductions (13), and it is conceivable that the reduction of $S_3N_3Cl_3$ and the oxidation of $S_3N_3^-$ to $(SN)_x$ and S_4N_4 proceed via the same intermediate.

Reaction of $S_3N_3^-$ with CS_2

During the attempted removal of elemental sulfur from $PPN^+S_3N_3^-$ by washing with CS_2, a blood-red solution was observed. Tetrasulfur dinitride, S_4N_2, was isolated from the reaction mixture in addition to S_4N_4 and PPN^+CNS^-. Since the yield of S_4N_2 is only ca. 15%, this reaction does not represent an improvement over existing syntheses (15*b*, 33). It is clear, however, that CS_2 should be avoided as a solvent for reactions of $S_3N_3^-$.

Reaction of $S_3N_3^-$ with Ph_2PCl

The reaction of $Cs^+S_3N_3^-$ with Ph_2PCl in CH_2Cl_2 or acetonitrile yielded a complex mixture of products whose composition was dependent on the molar ratio of the reactants. The known cyclophosphathiazenes (**1**, ref. 18), (**2** and **3**, ref. 19) (see Fig. 2) and $(Ph_2PN)_2NSCl$ (20), in addition to small amounts of the cyclophosphazenes $(Ph_2PN)_x$ (x = 3, 4) and the adduct $(Ph_2PN)_3 \cdot HCl$ were isolated and identified (see Table 1 and Experimental section). A stoichiometry of 1:1 favours the formation of the six-membered ring (**1**), but an increase in the molar ratio $Ph_2PCl:S_3N_3^-$ leads to preferential formation of the eight-membered rings (**2** and **3**, see Table 1). The cyclophosphathiazenes can be separated by gel permeation chromatography but the pure products are obtained in fairly low yields. Consequently, this synthesis is not superior to the reaction of Ph_2PH (or Ph_2PPPh_2) with S_4N_4 for the preparation of these inorganic heterocycles with the exception of **3** which is only obtained in very low yields (ca. 1%) by the latter route (19).

In attempting to rationalize the formation of the cyclophosphathiazenes (**1**–**3**), we propose that the reaction of Ph_2PCl with $S_3N_3^-$ proceeds via the formation of an open-chain intermediate $Ph_2P—N=S=N—S—N=S$, **4**, which cyclizes with loss of S, to give **1** (cf. the formation of $Ph_3P=N—S_3N_3$ via an open-chain intermediate in the reaction of Ph_3P with S_4N_4 (34)). The formation of the isomers **2** and **3** can then be explained by a head-to-tail dimerization of **4** with loss of $(SN)_xS$ units (x = 0 and 2, **2**; x = 1, **3**). In support of this proposal S_8 and S_4N_4 (in the case of the 1:1 reaction) were isolated as reaction products. In the presence of excess Ph_2PCl, S_4N_4 would undergo the following sequence of known reactions (20), thus accounting for the formation of $(Ph_2PN)_2NSCl$ and its hydrolysis product $[H_2NPPh_2NPh_2PNH_2]^+Cl^-$ in reactions in which the molar ratio $Ph_2PCl:S_4N_4$ exceeded 2:1.

$$S_4N_4 \xrightarrow{Ph_2PCl} (Ph_2PN)_2NSCl \xrightarrow{2H_2O} [H_2NPPh_2NPh_2PNH_2]^+Cl^- + SO_2$$

The isolation of the adduct $(Ph_2PN)_3 \cdot HCl$ was unexpected since HCl adducts of cyclophosphazenes are formed readily only when the substituents on phosphorus are alkyl or dialkylamino groups (17). However, it has been suggested that the adduct $(Ph_2PN)_3 \cdot HICl_2$, formed by the reaction of $(Ph_2PN)_3$

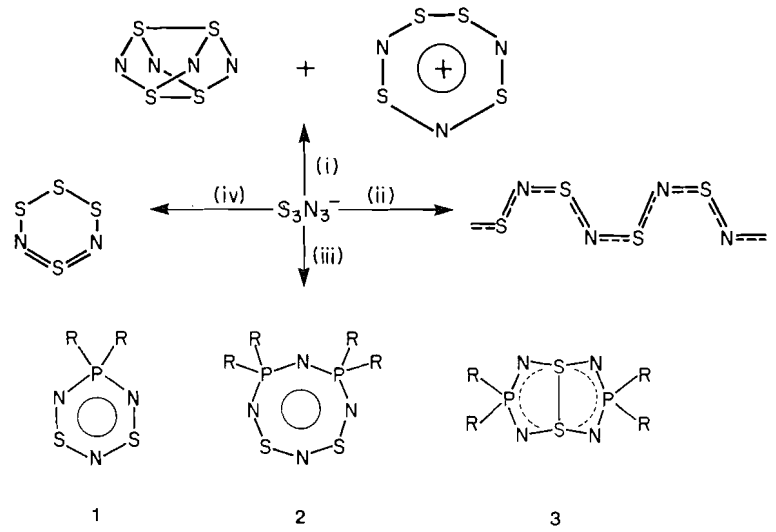

FIG. 2. Major products from the reactions of $S_3N_3^-$ with (*i*) halogens, (*ii*) $COCl_2$, (*iii*) Ph_2PCl, and (*iv*) CS_2.

with ICl in the presence of moisture, contains the cation $Ph_6P_3N_3H^+$ but no spectroscopic data were given (35). In the infrared spectrum of $(Ph_2PN)_3 \cdot HCl$ the degenerate ring stretching vibration, $\nu(P{=}N)$, is shifted to higher wavenumbers by ca. 50 cm^{-1} compared to the free base, $(Ph_2PN)_3$, as expected for protonation at a ring nitrogen atom (17).

Summary and conclusions

The reactions of $S_3N_3^-$ with halogens and other electrophilic substrates gave a complex mixture of products in which S_4N_4 is the major component. In some cases, smaller amounts of $(SN)_x$ were also isolated. These results are best rationalized in terms of initial oxidation of the electron-rich $S_3N_3^-$ ion to the $S_3N_3^{\cdot}$ radical, which rearranges quickly to S_4N_4 or $(SN)_x$ before further oxidation can take place. It is conceivable that the electrochemical oxidation of $S_3N_3^-$ will produce the corresponding cation, $S_3N_3^+$, and this possibility is under investigation. The reaction of $S_3N_3^-$ with Ph_2PCl yields the cyclophosphathiazenes **1**–**3**, but it is only synthetically useful for the preparation of the 1,5-isomer, **3**.

GEORGE M. STRUNZ, DENIS BRILLON, and PIERRE GIGUÈRE. Can. J. Chem. **61**, 1963 (1983).

An improved method for transforming certain coumarins to 2,2-dimethylchromenes has been developed. Umbelliferone (**1***b*) was efficiently converted to precocene I (**2***b*) (73%) by etherification to herniarin (**1***c*) with tetramethylorthocarbonate, followed by reaction with methyllithium and cyclization of the resulting phenolic alcohol on silica gel.

GEORGE M. STRUNZ, DENIS BRILLON et PIERRE GIGUÈRE. Can. J. Chem. **61**, 1963 (1983).

On a amélioré la methode de la conversion de quelques coumarines au diméthyles-2,2-chromènes. L'umbelliférone (**1***b*) était transformé efficacement en précocène I (**2***b*) (73%) par préparation de l'éther méthylique herniarin (**1***c*), utilisant le tetraméthylorthocarbonate, suivi de la réaction avec le méthyllithium et cyclisation de l'alcool phénolique résultant avec le gel de silice.

The methoxy-2,2-dimethylchromenes **2***b* and **2***c* (1) were observed by Bowers to exhibit antiallatotropic activity in several hemimetabolous insect species (2), i.e. they disrupt juvenile hormone production, and cause precocious metamorphosis and sterility when administered to these insects. The compounds, designated precocenes 1 and 2 respectively (2), appear to be metabolized to the cytotoxic 3,4-epoxides in the corpus allatum, accounting for their selective effects against this endocrine organ (3).

The precocenes have been synthesized via 4-chromanones produced by condensation of appropriately substituted phenols or phenol derivatives with dimethylacrylic acid or its chloride (2, 4).

An alternative approach, which has been employed with variable success in the synthesis of substituted 2,2-dimethylchromenes, involves reaction of appropriate coumarins with methyl magnesium halides and cyclization of the product by acid treatment and/or distillation (5).

We have confirmed the previous observation (5*d*) that application of the Grignard procedure to 7-methoxycoumarin (herniarin) (**1***c*) (prepared, *vide infra*, by methylation of umbelliferone (**1***b*)) gives, at best, modest yields of the corresponding

c	OCH_3	OCH_3

2,2-dimethylchromene, precocene 1 (**2***b*). (Livingstone and coworkers (5*d*,*e*) reported yields of 44%, 42%, and 52% respectively for the conversion of 7-, 5-, and 8-methoxycoumarins to the corresponding 2,2-dimethylchromenes by the action of methyl magnesium iodide.) This paper reports our observation that the desired transformation to precocene 1 can be accomplished with substantially improved yield (~73%) by treatment of herniarin with methyllithium and, after careful work-up, cyclization of the phenolic alcohol product under mild conditions on silica gel.

The initial step, methylation of the phenolic hydroxyl group of umbelliferone, was executed virtually quantitatively by refluxing the latter with tetramethylorthocarbonate (6) in the presence of a catalytic amount of *p*-toluenesulfonic acid.

The methyllithium – silica gel procedure applied to coumarin itself afforded 2,2-dimethylchromene in 83% yield (cf. 59% by the Grignard method (5*b*)).

Experimental

Commercial umbelliferone (95+%) was purified prior to use by elution with acetone successively through columns of silica gel and of neutral alumina. The crystalline material obtained on removal of solvent melted at 234–237°C (hot-stage apparatus, uncorrected) (lit. (7) mp 230–231°C).

*7-Methoxycoumarin (herniarin) (***1***c)*

A solution of umbelliferone (**1***b*) (925 mg, 5.70 mmol; purified as above) in anhydrous tetrahydrofuran (12.0 mL) and tetramethylorthocarbonate (11.0 mL) containing *p*-toluenesulfonic acid (3 mg), was heated under reflux for 18 h. Distillation at atmospheric pressure until the temperature began to rise above ca. 90°C removed tetrahydrofuran and volatile products (dimethylcarbonate and methanol (6)). Additional tetramethylorthocarbonate (2–6 mL) was then added until solid material redissolved, and the resulting solution was refluxed for a further 65 h, when tlc analysis revealed that the reaction was complete. After the mixture had returned to ambient temperature, volatile material was removed by vacuum distillation (water pump). Subsequent application of high vacuum for several hours ensured that no volatile material remained. Nuclear magnetic resonance and tlc analysis demonstrated that the conversion to herniarin was virtually quantitative, and the product was sufficiently pure to be used directly in the subsequent step.[2]

*7-Methoxy-2,2-dimethylchromene (precocene I) (*2b)

Herniarin (~5.70 mmol), from the previous step, was dissolved by gentle warming in a mixture of anhydrous ether (27.0 mL) and toluene (18.0 mL). In a nitrogen atmosphere, and with a bath temperature of 38–40°C, a solution of methyllithium in ether (14.8 mmol of ca. 1.3 *M* solution) was added steadily by syringe during 1 min (it was found that if the addition of methyllithium was too slow, production of by-products increased). Vigorous agitation was necessary throughout this and the following step. After a further minute, the reaction

[1] Undergraduate cooperative program participant from University of Sherbrooke.

[2] Herniarin was also prepared in excellent yield from umbelliferone using excess methyl iodide and potassium carbonate in acetone (5*a*).

For personal use only.

flask was cooled in a Dry Ice – ethanol bath, and a mixture of water (1.0 mL) and tetrahydrofuran (10.0 mL) was added by syringe during 3 min. The temperature was allowed to rise to ca. 0°C and 10% aqueous KH_2PO_4 solution (~11 mL) was added to bring the pH below 7.0. The mixture was poured into water (total volume ca. 100 mL), and NaCl was added to saturation. The mixture was extracted five times with ethyl acetate (total volume ~300 mL), and the extracts were dried over $MgSO_4$ and filtered. The resulting solution of phenolic alcohol was refrigerated if not used immediately.

For cyclization to the chromene, the solvent was removed *in vacuo*, and the residue in hexane (75 mL) was refluxed with stirring under nitrogen in the presence of silica gel[3] (30 g) for 6 h. The silica gel was then removed by filtration and washed with hexane. Evaporation of the filtrates under reduced pressure afforded crude precocene I. The hope that the silica gel would retain by-products produced during the sequence was only partially realized, and it was necessary to effect a final purification by flash chromatography (8) using hexane–EtOAC (96:4) as eluent.

Precocene I (pure by nmr, tlc, and glc) was obtained in an overall yield of 73% from umbelliferone, and was characterized by comparison of its spectroscopic and chromatographic characteristics with those of a commercial sample (Aldrich Chemical Co.).

2,2-Dimethylchromene (2a)

The title compound was prepared from coumarin (**1***a*) in a manner analogous to that used for the preparation of precocene I. The procedure was identical as far as the phenolic alcohol which, in the absence of the electron-donating methoxyl group on the aromatic ring, required somewhat more vigorous conditions for cyclization (toluene in lieu of hexane, 98°C, 8.5 h). The yield of pure 2,2-dimethylchromene obtained after flash chromatography (85% hexane, 15% chloroform) was 83%.

Received October 7, 1982

A. Douglas Broadbent and John M. Stewart. Can. J. Chem. **61**, 1965 (1983).

Irradiation of a sulfuric acid solution of 9,10-anthracenedione with near-uv light generated 2-hydroxy-9,10-anthracenedione as the major product. In addition, the 1-hydroxy and polyhydroxy derivatives and the reduction products anthrone and bianthronyl were also formed. The yields of these minor products were markedly influenced by the concentrations of water and oxygen in the sulfuric acid. At low light intensities, oxygen quenched the efficient formation of the hydroxyanthracenediones and also oxidised the initial quinone reduction products. Photoreduction of the anthracenedione and photooxidation of anthrone occurred simultaneously in the solution. The reaction mechanism is more complex than previous studies indicated.

A. Douglas Broadbent et John M. Stewart. Can. J. Chem. **61**, 1965 (1983).

L'irradiation de l'anthracènedione-9,10, en solution dans l'acide sulfurique avec une lumière du proche uv conduit à la formation de l'hydroxy-2 anthracènedione-9,10 comme produit majoritaire. De plus, il se forme également l'hydroxy-1, les dérivés polyhydroxy et les produits de la réduction de l'anthrone et du bianthronyle. Les rendements de ces produits secondaires sont fortement influencés par la concentration en eau et en oxygène dans l'acide sulfurique. Lorsqu'on utilise une lumière de faible intensité, l'oxygène bloque la formation efficace des hydroxyanthracènediones et oxyde également les produits initiaux de la réduction de la quinone. La photoréduction de l'anthracènedione et la photoxydation de l'anthrone se produisent simultanément en solution. Le mécanisme de la réaction est plus complexe que ne l'indiquent les études antérieures.

Introduction

Although sulfuric acid is a widely used and excellent solvent for 9,10-anthracenedione and its derivatives (1), little is known about photochemical reactions of these compounds in this solvent. Irradiation of a 100% sulfuric acid solution of 9,10-anthracenedione-2-sulfonate, with near-uv light, has been reported to produce only 2-hydroxy-9,10-anthracenedione sulfonates, with no 1-hydroxy derivatives (2). Total regioselectivity was also found in the similar photochemical reaction of the unsubstituted 9,10-anthracenedione (OAO), which was claimed to yield 2-hydroxy-9,10-anthracenedione (2-HO—OAO) as the sole product (3). Observation of well-defined isosbestic points in a series of uv spectra of a progressively irradiated solution indicated a clean, efficient reaction. No differences in reaction rate were noted between preparative experiments using nitrogen or air bubbling. The lack of oxygen influence on the photochemical reaction of OAO in sulfuric acid was apparently confirmed by subsequent studies (4), in which 1-hydroxy- (1-HO—OAO) and 1,4-dihydroxy-9,10-anthracenedione (quinizarin) were also isolated in addition to the major 2-HO—OAO. Changes in the product distribution during the reaction suggested that the initially formed 1-HO—OAO underwent a subsequent photochemical hydroxylation reaction yielding quinizarin.

We have recently established (5) that the photochemical reaction of OAO in sulfuric acid is more complex than the earlier studies indicated. The rate of formation of 2- and 1-HO—OAO, and the yields of the minor products, are markedly affected by the concentrations of oxygen and water in the sulfuric acid solution. This paper reports our results on product isolation and identification and the dependence of product yields on the reaction conditions. In addition, since oxygen has been found to effectively quench the reaction at low light intensities, some preliminary photochemical kinetic data are included.

Results

Product yields

Irradiation of OAO in 96% sulfuric acid solution, stirred by nitrogen bubbling, gave 2-HO—OAO as the major isolated product, along with low yields of 1-HO—OAO, and the quinone reduction products 9(10*H*)-anthracenone (anthrone) and 9,9′(9*H*,9′*H*)-bianthracene-10,10′-dione (bianthronyl). Traces of polyhydroxyanthracenediones were also observed on TLC analysis, but the quantities were insufficient for identification. An identical reaction performed with oxygen bubbling yielded more 2- and 1-HO—OAO, but only a trace of bianthronyl and no detectable anthrone. Although the yields of polyhydroxyanthracenediones were always low (<1%), their formation was sufficiently enhanced by the presence of oxygen that isolation and identification of quinizarin (minor) and 1,2-dihydroxy-9,10-anthracenedione (alizarin, major) were possible. Product yields for photochemical reactions in nitrogen- and oxygen-stirred sulfuric acid solutions are given in Table 1.

In preparative experiments, the initial rate of conversion of OAO was less in solutions containing oxygen, but rapidly increased, so that the overall yields of 2- and 1-HO—OAO were larger than in the nitrogen-stirred reactions. In 100% sulfuric acid, the rate was much less than in solutions containing water.

Dark reactions

Sulfuric acid solutions of OAO and its monohydroxy derivatives were stored in the dark for one week and the quinones recovered unchanged. Since the photochemical reaction of OAO in sulfuric acid resembled that with peroxydisulfate (6), dark reactions, comparable to the photolyses, were performed with added ammonium peroxydisulfate and similarly analysed. The yields of products are given in Table 1 in parentheses. No reduction products of the OAO were detected in these dark reactions. The only polyhydroxy product found was quinizarin, which was only detected in 100% sulfuric acid reactions with a yield of 3% for either oxygen or nitrogen bubbling.

Time-lapse spectrophotometry

Because of the obvious change in product distribution in the reaction on switching from nitrogen to oxygen bubbling, and

the report that irradiation of a dilute sulfuric acid solution of OAO gave a series of uv spectra with well-defined isosbestic points, unaffected by the stirring gas (3), this experiment was re-examined. The series of recorded spectra resembled those already published (3), but they did depend upon the nature of the gas used for stirring. In the photochemical reaction of OAO in 96% sulfuric acid saturated with air, enhanced absorption at 547 nm was observed during the later stages of the irradiation. In a subsequent reaction performed with oxygen bubbling, this absorption was noticed much earlier and became more intense. No such absorption was seen in a nitrogen-saturated solution, even on prolonged irradiation. The spectrophotometric data in Table 2 indicate that the 547 nm absorption is characteristic of quinizarin, which is the only hydroxyanthracenedione with such long-wave absorption in sulfuric acid solution.

On irradiation of an OAO solution in 96% sulfuric acid saturated with nitrogen, an additional maximum absorption was observed at 354 nm. Furthermore, such solutions displayed a more intense absorption in the 320–370 nm range, which was not observed in aerated reaction solutions. These additional absorptions, observed only in the absence of oxygen, are typical of the OAO reduction products anthrone and bianthronyl.

The repetition of the time-lapse spectrophotometry was thus useful in confirming the conditions under which the newly established minor products were formed. In addition, a pronounced influence of the nature of the stirring gas on the rate of reaction was noted. The rate of conversion of OAO and of appearance of 2-HO—OAO was much lower in the presence of oxygen. In fact, if the sulfuric acid solution was effectively oxygen saturated prior to and during the irradiation, it was possible to almost totally inhibit all product formation in the dilute solution.

Product photostability

Both 2- and 1-HO—OAO were shown to be stable to irradiation in 96 and 100% sulfuric acid saturated with nitrogen or oxygen. No polyhydroxyanthracenedione formation was detected by TLC or uv analysis. In control experiments using NaOH solutions of hydroxy compounds, the spectrophotometric detection limit for quinizarin was found to be about 0.1% of the amount of monohydroxy compound present. The possibility of a photosensitized reaction involving OAO was eliminated when no increase in the rate of formation of polyhydroxyanthracenediones was found on irradiation of 1- and 2-HO—OAO in the presence of OAO, where the latter absorbed a considerable fraction of the incident light.

Formation of anthrone and bianthronyl

TLC analysis of samples removed during irradiation of a 96% sulfuric acid solution of OAO under nitrogen established an initial rapid increase in the amount of anthrone produced, followed by its gradual disappearance and the simultaneous formation of bianthronyl. The occurrence of such reduction products of OAO under these conditions, and their absence in solutions containing oxygen or in the more strongly oxidising 100% acid, suggested that OAO underwent solvent-induced photoreduction to 9,10-anthracenediol (HOAOH). The reaction of this oxygen-sensitive compound in sulfuric acid was therefore examined. Within 1 min, reaction in the dark gave a stable solution containing OAO, anthrone, and a trace of bianthronyl. Because of the extreme ease of oxidation of HOAOH, similar reactions of the more stable tautomeric

*Determined by uv spectrophotometry in 96% sulfuric acid by comparison with the known spectra of OAO and anthrone.

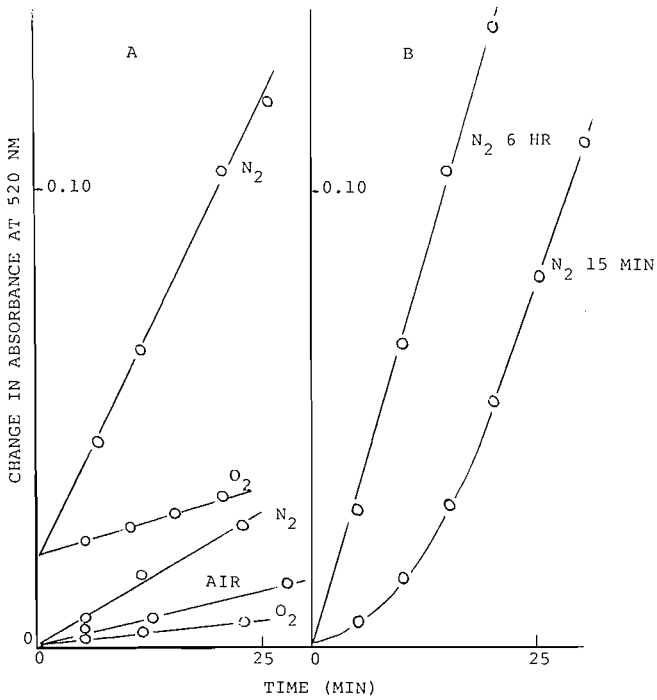

FIG. 1. Rates of product formation (change of absorbance at 520 nm) on irradiation of OAO in 96% sulfuric acid solution in a 5 cm cell. *A*: At 366 nm with gas stirring; 5.6 m*M* (upper plots offset 0.02) and 0.52 m*M*. *B*: With unfiltered radiation $\lambda > 300$ nm and manual agitation after pre-bubbling with nitrogen for stated times; 1.25 m*M*.

10-hydroxy-9(10*H*)-anthracenone (oxanthrone) and of 9,10-diacetoxyanthracene (AcOAOAc) were studied with similar results. The yields in Table 3 were determined by uv spectrophotometric analysis of the OAO/anthrone mixtures. The presence of OAO and anthrone was confirmed by TLC analysis, which also detected traces of bianthronyl.

On irradiation of OAO in 96% sulfuric acid under nitrogen, anthrone might arise by disproportionation of initially generated HOAOH. The formation of bianthronyl could then occur by the previously established photo-oxidation of anthrone (7). This photo-oxidation reaction is little affected by the presence of OAO and its hydroxy derivatives in the irradiated acid solution, because anthrone absorbs in the 350 nm region, where the other compounds are relatively transparent. On photolysis in 100% sulfuric acid, no anthrone and only a trace of bianthronyl were found. In 100% sulfuric acid, HOAOH is rapidly oxidised to OAO with little formation of anthrone, which itself is oxidised in the dark yielding OAO and bianthronyl (8).

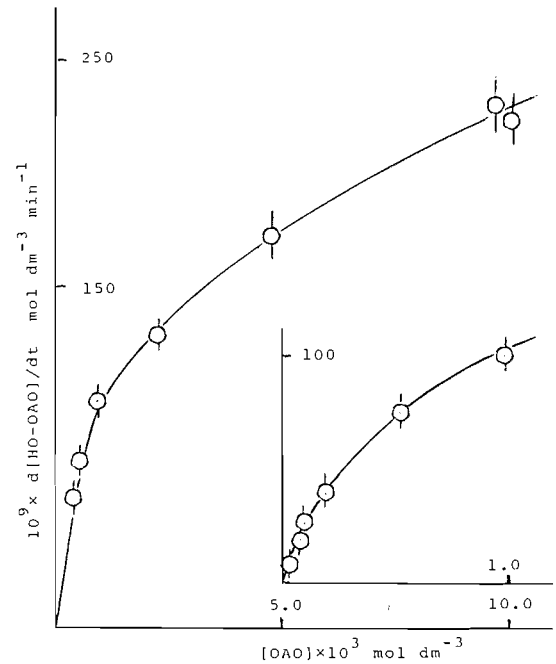

FIG. 2. The dependence of the rate of formation of HO—OAO, determined from linear plots of absorbance at 490 or 520 nm versus time, on the initial OAO concentration for irradiation at 366 nm. Solutions with initial OAO concentrations above 1×10^{-4} *M* absorbed >99% of the incident radiation. The low end of the concentration range is expanded in the box.

Photochemical kinetics

In addition to product identification, the rate of consumption of OAO and of formation of hydroxy products was examined using incident radiation at 366 nm on an optical bench. Product formation was monitored at 490 nm, or at 520 nm, if the initial concentration of OAO was sufficiently high to result in initial absorption at the shorter wavelength. The irradiated solutions were constantly stirred by gas bubbling. In reactions on the optical bench, the absorbance of the products (mainly 2-HO—OAO) was directly proportional to the irradiation time, i.e., plots of absorbance versus time were linear. Figure 1*A* illustrates the influence of the stirring gas on the initial rate of formation of the HO—OAO. The initial rate continued to increase as the starting concentration of OAO increased beyond that where more than 99% of the incident radiation was absorbed. This is shown in Fig. 2. In reactions performed with short irradiation times and intermediate manual agitation of the solution, the quantum yield was found to be 0.5. This was the maximum value recorded but solution homogeneity was not certain.

The rate measurements using different gases demonstrated that oxygen was an effective quencher of the overall reaction. Irradiation of thoroughly oxygen-saturated solutions resulted in a low rate of consumption of OAO and formation of meagre amounts of products, particularly at the low light intensities used on the optical bench. As the light intensity was increased, the low rate of reaction in the oxygen-saturated solution also increased, until it approached the rate in a nitrogen-stirred reaction at the same high light intensity. Initial inhibition in the presence of oxygen was a useful criterion of inadequate nitrogen bubbling (Figure 1*B*), but the effect of residual oxygen was less pronounced at high light intensities and OAO concentrations.

Removal of dissolved oxygen from sulfuric acid solutions, as indicated by no initial rate inhibition, required bubbling with nitrogen over several hours, and preferably overnight. Although nitrogen and oxygen are slightly soluble in this solvent, 6.8×10^{-4} and 1.3×10^{-3} M, respectively (9), the rate of exchange on bubbling was slow. The influence of oxygen on the initial rate of consumption of OAO, or of formation of HO—OAO, suggested that oxygen has a dual role in the overall reaction. Oxygen not only inhibits the photochemical reaction by quenching the excited state, but is also consumed by oxidation of OAO reduction products such as HOAOH. In relation to the quenching of the excited state by oxygen, a dull red emission was observed (by dark adapted eye) just inside the front window of an irradiated oxygen-saturated solution of OAO in 96% sulfuric acid. This emission was absent in the presence of nitrogen, was not the weak fluorescence emission of OAO or 2-HO—OAO (3), but was like the red emission of excited singlet oxygen. At low incident light intensities, quenching is most evident because the rate of formation of HOAOH, and of oxygen consumption, is low. At high intensities, the high rate of formation of HOAOH and its subsequent oxidation depletes the oxygen in the acid solution so that quenching is minimized, even though the solution is continuously bubbled with oxygen. No consumption of oxygen was detected in an experiment using a gas burette to measure the volume of oxygen absorbed by the irradiated solution. This result, and the low yields of OAO reduction products, indicated that the solvent can function as oxidising agent in place of the oxygen when the latter is absent or its concentration is low.

Discussion

The parent OAO, having $pK = -8.27$ (10), is essentially fully monoprotonated in 100% sulfuric acid. This is not the case in the 96% acid. The H_0 acidity functions for these solutions are -11.94 and -9.88, respectively (10). The various products will be present as their protonated, conjugate acids or as sulfate esters, if they have hydroxy groups. These compounds dissociate or hydrolyse on addition of water.

The results do not support the proposal of a reaction mechanism involving nucleophilic addition of bisulfate ion to the photo-excited conjugate acid of OAO (3). Although such a mechanism can be modified to account for the occurrence of reduction products, it is not consistent with the influence of the initial OAO concentration on the initial rate of formation of HO—OAO, in solutions which absorb >99% of the incident light (Fig. 2). Our observations indicate that polyhydroxyanthracenediones arise from the intervention of oxygen in the reaction, rather than from the proposed secondary photochemical process of the monohydroxy products (4). This result suggested that the reaction might proceed by an electron transfer mechanism analogous to that proposed for photochemical hydroxylation of anthracenediones in aqueous solution (11). Electron transfer from bisulfate ion to the excited state of OAO or its conjugate acid would give HOAOH, by disproportionation of the semiquinone so produced, and a sulfate radical. The hydroxy products would arise by oxidation of the sulfate radical – OAO adduct, and polyhydroxy derivatives by interception of the sulfate radical adduct by oxygen. Unfortunately, the attempt to confirm the sulfate radical mechanism by dark reactions with peroxydisulfate was not totally successful, despite the similarity of these reactions to the photochemical hydroxylations.

We have established that HOAOH in sulfuric acid undergoes rapid oxidation by oxygen, or the solvent, or disproportionates to OAO and anthrone. Such disproportionation is known in other solvents (12). Disproportionation of HOAOH or its derivatives in sulfuric acid did not give the expected equal yields of OAO and anthrone but an excess of OAO, because of oxidation by the solvent. Photochemical reduction and oxidation, involving the solvent, occur simultaneously in the same solution. The photoreduction of OAO to anthrone is favoured by the presence of water, bisulfate ion being a likely electron donor for the initial reduction of the OAO. The photo-oxidation of anthrone, or more probably the tautomeric 9-anthracenol, is diminished in the presence of water, and oxidation even occurs in the dark in 100% sulfuric acid solution (8). Sulfur trioxide, or sulfuric acid itself, could function as the oxidising agent in these reactions.

Our studies have established that the photochemical reaction of OAO in sulfuric acid solution produces 2-HO—OAO, 1-HO—OAO, and several minor products, whose yields were markedly dependent upon the concentrations of water and oxygen in the acid solution. No definitive conclusions regarding the mechanism of the overall reaction were reached, and alternatives to the proposed electron transfer process are possible. The influence of concentration on the rate of reaction could also be rationalized by a bimolecular primary photochemical step involving ground and excited state OAO molecules. Such a mechanism has been proposed for photochemical reactions of OAO derivatives in aqueous solutions but was not confirmed by triplet state lifetime measurements (13).

Experimental

Materials

The various anthracenediones were commercial samples purified by column chromatography and/or recrystallization. Column chromatography of both 1- and 2-HO—OAO was necessary (SiO_2/$CHCl_3$) to remove polyhydroxy derivatives. Anthrone (14), bianthronyl (15), oxanthrone (16), HOAOH (17), AcOAOAc (18), and hystazarin (19) were prepared by published procedures. The sulfuric acid was reagent grade 95.5–96.5%. The 100% sulfuric acid was prepared by addition of redistilled sulfur trioxide to 96% sulfuric acid to give an initial freezing temperature of 10.3°C (20) and the strength checked by volumetric analysis.

Reaction conditions

For photochemical reactions, the solutions were prepared by addition of the anthracenedione to the sulfuric acid, bubbled with the appropriate gas for at least 4 h and then irradiated with a water-cooled Hanovia 450 W mercury lamp at 15–18°C. In most cases, the solutions were saturated with the gas by bubbling overnight. The oxygen and nitrogen were passed through 96% sulfuric acid prior to passage through the reaction solution. For reactions of HOAOH and its derivatives, the solutions were prepared by addition of the appropriate solid to nitrogen-saturated sulfuric acid. These were immediately mixed under nitrogen and the uv spectra recorded.

Products were isolated by pouring the solution onto ice and extracting with $CHCl_3$. For TLC analysis, Eastman Chromagram SiO_2 plates 13181 were used with *p*-xylene as the developing solvent. The following R_f values were found: OAO, 0.60; 1-HO—OAO, 0.70; 2-HO—OAO, 0.03; anthrone, 0.52; bianthronyl, 0.09; quinizarin, 0.75; alizarin, 0.01; hystazarin, 0.01. For column chromatography $SiO_2/CHCl_3$ and Al_2O_3/ethanol were used. The % yields were determined by TLC, followed by extraction of the various zones with $CHCl_3$ and uv analysis in sulfuric acid solution with the Cary 219 UV Spectrophotometer. The uv spectrum of the isolated alizarin indicated possible contamination by hystazarin (19).

Optical bench studies

For time-lapse spectrophotometric studies, light from the Hanovia

450 W mercury lamp was passed through a glass lens ($\lambda > 300$ nm) and into the solution cell. For kinetic and quantum yield studies, an Ealing 366 nm interference filter was placed in the optical train. Light intensities were measured by ferrioxalate actinometry (21) and were in the range $1.10 \pm 0.06 \times 10^{15}$ photon cm^{-3} min^{-1}. For quantum yield measurements, the following molar absorptivities were used: $\epsilon_{490} = 8.0 \times 10^3$, $\epsilon_{520} = 5.2 \times 10^3$ dm^3 mol^{-1} cm^{-1}. These values were calculated from the absorption spectra of 1- and 2-HO—OAO in 96% sulfuric acid solution and the determined ratio of these products. For reactions involving 15 s irradiation periods with 2 min intermediate manual agitation of the solution, the maximum quantum yield was 0.5 for an OAO concentration of 1×10^{-2} *M* in sulfuric acid under nitrogen. It may be higher with optimum mixing, a situation not easily achieved with sulfuric acid solutions.

La photolyse du cyclohexène gazeux à 184,9 nm

GUY J. COLLIN ET HÉLÈNE DESLAURIERS
Département des Sciences Fondamentales, Université du Québec à Chicoutimi, Chicoutimi (Qué.), Canada G7H 2B1

Reçu le 10 janvier 1983

GUY J. COLLIN et HÉLÈNE DESLAURIERS. Can. J. Chem. **61**, 1970 (1983).

La photolyse du cyclohexène gazeux a été systématiquement étudiée à 184,9 nm en l'absence ou en présence d'intercepteur radicalaire tel que O_2, NO, H_2S ou HI entre 1 et 70 Torr. En outre, le propane ou le soufre hexafluoré a été utilisé comme agent stabilisant. L'éthylène et le butadiène-1,3 ont été les seuls produits majeurs observés avec des rendements quantiques supérieurs à 0,5 quelles que soient les conditions expérimentales. Les analyses isotopiques de l'éthylène formé dans la photolyse du cyclohexène-3,3,6,6-d_4 montrent la présence prépondérante de la variété perhydrogénée. Ces résultats, avec d'autres observations tirées de la littérature, favorisent un mécanisme de fragmentation de la molécule excitée en une étape ou en deux étapes, mais dans ce cas via un intermédiaire dont le temps de vie est plus court que celui de la molécule photoexcitée.

GUY J. COLLIN and HÉLÈNE DESLAURIERS. Can. J. Chem. **61**, 1970 (1983).

We have studied the 184.9 nm photolysis of gaseous cyclohexene either in the absence or in the presence of radical scavengers such as O_2, NO, H_2S, or HI at pressures between 1 and 70 Torr. Propane or sulfur hexafluoride has also been used as stabilizing agent. In all cases, ethylene and 1,3-butadiene have rather high quantum yields ($\Phi \geq 0.5$). The isotopic analysis of the ethylene formed in the photolysis of cyclohexene-3,3,6,6-d_4 shows the high importance of the perhydrogenated species. These results, together with others taken from the literature, favor a one-step fragmentation mechanism or a double-step mechanism involving an intermediate which has a lifetime shorter than that of the photoexcited molecule.

Introduction

La photochimie du cyclohexène est relativement bien connue. Déjà en 1965, DeMaré *et al.* ont étudié la mercurisensibilisation de cet hydrocarbure à 254 nm (1). L'éthylène et le butadiène-1,3, en rendements similaires, sont les produits majeurs avec toutefois des quantités fort appréciables de vinylcyclobutane et de cyclohexane. L'augmentation de la pression a un effet négatif sur les rendements des deux hydrocarbures insaturés tandis que celui du vinylcyclobutane atteint un maximum à une pression de 5–10 Torr (665–1 330 N m^{-2}). Plus tard, Lesclaux *et al.* ont étudié la photolyse directe de cet hydrocarbure cyclique à 147, 123,6 et vers 105 nm en présence ou en l'absence de divers intercepteurs radicalaires (2). A 147 nm (8,4 eV) le système est relativement simple: hormis la formation de petites quantités d'hydrogène et de pentadiènes ($\Phi \leq 0{,}04$), les produits majeurs sont l'éthylène ($\Phi = 0{,}83$) et le butadiène-1,3 ($\Phi = 0{,}71$). Il ne semble pas que des radicaux stables soient formés en quantités appréciables sauf l'atome d'hydrogène qui a un rendement de l'ordre de 0,2 (2). Finalement, il apparaît que la photolyse du tétradeutérocyclohexène-3,3,6,6-d_4 forme principalement l'éthylène-d_0 et le butadiène-1,1,4,4-d_4.

[1] $\text{cyclo-}C_6H_{10} + h\nu \longrightarrow \text{cyclo-}C_6H_{10}^{**}$

[2]  $\longrightarrow C_2H_4 + CD_2{=}CHCH{=}CD_2$

A plus courtes longueurs d'onde, 123,6 nm (10,0 eV) et 106,7–104,8 nm (11,6–11,8 eV) les mêmes processus semblent actifs, de façon prépondérante. Cependant l'augmentation de l'énergie du photon, et donc de celle de la molécule photoexcitée, favorise la fragmentation secondaire de l'éthylène et du butadiène, de telle sorte que le rapport $\Phi(C_2H_4)/\Phi(C_4H_6)$, qui est voisin de 1,2 à 147 nm, passe à 2,1 et à presque 4 à 123,6 et à 106,7–104,8 nm, respectivement (2). Il faut ajouter que l'apparition de paires d'ions – le potentiel d'ionisation du cyclohexène est de 8,94 eV (3) – vient compliquer l'interprétation quantitative relative à la fragmentation de la molécule photoexcitée.

A plus longue longueur d'onde, soit à 184,9 nm (6,4 eV), Inoue *et al.* ont également montré que les produits majeurs sont toujours l'éthylène et le butadiène-1,3 avec un rapport $\Phi'(C_2H_4)/\Phi'(C_4H_6)$ voisin de 1,05–1,10 (4). Bien que les rendements quantiques n'aient pas été mesurés, ils sont fortement affectés par l'augmentation de la pression: ils décroissent de moitié entre 5 et 30 Torr (650 et 4 000 N m^{-2}). Ces auteurs ont aussi observé la formation de mini-quantités de méthylènecyclopentane et de bicyclohexane[3.1.0] dont les rendements ne semblent pas affectés par l'augmentation de la pression (4). En phase liquide, ces deux isomères sont formés chacun avec des rendements quantiques de l'ordre de 0,06 (5).

Nous avons repris ce dernier travail avec bien entendu l'intention de le compléter en orientant nos efforts vers l'identification d'indices permettant d'apprécier à leur juste valeur, et s'ils existent, les processus d'isomérisation et de façon plus générale les comportements de la molécule photoexcitée.

Méthode expérimentale

Le cyclohexène est un produit "A.P.I." dont le contenu affiché en impuretés est de 0,023 ± 0,020 mol%. Aucune impureté couramment analysée par chromatographie en phase gazeuse à l'aide d'un double détecteur à ionisation de flamme, n'y est décelée. L'oxygène (99,99%) et l'oxyde nitrique (99,0%) sont des produits achetés chez Matheson du Canada. Le cyclohexène-3,3,6,6-d_4 a déjà été décrit (2). Les techniques photolytiques utilisées à 184,9 (6) et vers 163 nm (7), les actinométries (6, 8), les analyses chromatographiques (6, 8) de même que celles réalisées par spectrométrie de masse (2) ont toutes été décrites. Des analyses ont aussi été effectuées à l'aide d'une colonne de SE-30 afin de confirmer l'absence d'une éventuelle formation de vinylcyclobutane (1).

Résultats

a. *La formation des produits*

La photolyse à 184,9 nm du monomère pur, ou en présence

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

d'oxygène, d'oxyde nitrique, d'hydrogène sulfuré, d'isoprène ou d'iodure d'hydrogène, montre la présence d'éthylène et de butadiène-1,3 avec des rendements supérieurs à 0,5 quelle que soit la pression du cyclohexène entre 1 et 60 Torr (133–8 000 N m^{-2}). On observe en outre quelques produits supplémentaires avec des rendements mineurs. Il faut mentionner en présence d'iodure d'hydrogène: le méthane (Φ = 0,02), le propène (Φ = 0,01). En présence d'hydrogène sulfuré on observe, en outre, du cyclohexane: Φ = 0,12 et 0,07 à 2,5 et 30 Torr. Il faut enfin ajouter que tous les efforts réalisés en vue de mettre en évidence la formation éventuelle de composés isomères acycliques ou du vinylcyclobutane ont été vains, que ce soit en présence du cyclohexène pur ou en présence du propane ou de soufre hexafluoré à des pression de 400–500 Torr.

b. *L'effet de la pression à 184,9 nm*

La figure 1 montre la variation du rendement quantique de l'éthylène entre 10 et 70 Torr (1 330 et 9 300 N m^{-2}). Il faut tout de suite remarquer l'importance du rendement quantique un peu inférieur à l'unité à faible pression. Hormis une erreur systématique toujours possible, il est clair que la fragmentation de la molécule photoexcitée à cette longueur d'onde produit essentiellement de l'éthylène avec en contre partie du butadiène-1,3 (Fig. 2). Là encore existe un léger déficit en butadiène. L'addition de l'atome d'hydrogène sur la double liaison du monomère a déjà été signalée comme pouvant ajouter de l'éthylène (9). L'effet de la pression sur le rapport $\Phi(C_2H_4)/\Phi(C_4H_6)$ pourrait être alors expliqué sur la base de la stabilisation d'un intermédiaire:

$$[3]\quad H\cdot + \text{cyclo-}C_6H_{10} \xrightarrow{\text{cyclo-}C_6H_{11}^{\#}} C_2H_4 + C_4H_7' \qquad \Delta H = -15 \text{ kcal mol}^{-1}$$

$$[4]\quad C_4H_7' \rightarrow H\cdot + C_4H_6 \qquad \Delta H \cong 41 \text{ kcal mol}^{-1}$$

$$[5]\quad C_4H_7' \xrightarrow{(M)} C_4H_7\cdot$$

La réaction [4] étant endothermique, il est assuré que la réaction de stabilisation par collision, processus [5], lui fait une concurrence d'autant plus vive que la pression s'accroît. Il faut aussi ajouter que le butadiène-1,3 est plus sensible, réactif que l'éthylène vis-à-vis les radicaux usuels, de telle sorte qu'il peut aussi être consommé dans des réactions secondaires. Il faut finalement ajouter que la présence de quantités minimes de radicaux est révélée par la formation de méthane, de propène et de cyclohexane lorsque le monomère est photolysé en présence d'iodure d'hydrogène ou de sulfure d'hydrogène: (R = H·, CH_3·, ou C_3H_5')

$$[6]\quad R\cdot + HX \rightarrow RH + X \qquad (\text{où X = I ou HS})$$

c. *La photolyse du cyclohexène-3,3,6,6-d_4*

Le tableau 1 montre les analyses isotopiques de l'éthylène obtenu à diverses longueurs d'onde. Au fur et à mesure que celle-ci croît, l'éthylène perhydrogéné croît en importance en même temps que diminue celle de l'éthylène-d_2. Par contre, entre 147 et 184,9 nm, il semble y avoir un peu plus de C_2D_4 et de C_2D_3H. Il faut ajouter que l'addition signalée plus haut d'un atome d'hydrogène sur ce cyclohexène partiellement deutérié libère normalement une molécule d'éthylène-1,1-d_2 (9). Dans ce cas, la tendance observée dans ce tableau montre sans ambiguité possible la diminution de l'importance de ce produit avec l'allongement de la longueur d'onde.

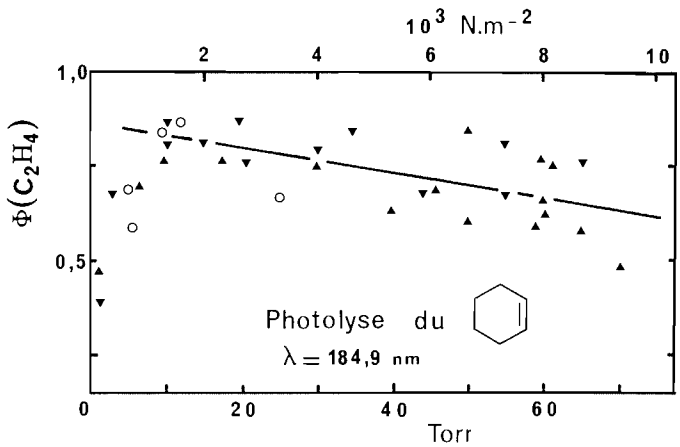

FIG. 1. Rendement quantique de l'éthylène en fonction de la pression du cyclohexène. ○: aucun additif; ▲: 10% O_2; ▼: 10% NO. Note: la décroissance du rendement quantique à des pressions inférieures à 10 Torr est liée à l'absorption partielle du faisceau photonique.

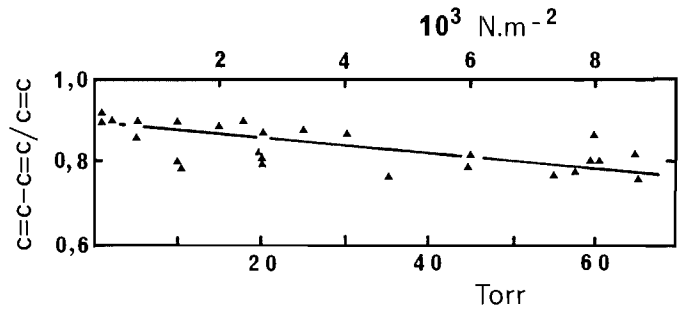

FIG. 2. Variation du rapport $\Phi(C_4H_6)/\Phi(C_2H_4)$ en fonction de la pression du cyclohexène.

Puisque le monomère contient 40% d'atomes d'hydrogène lourds, et sur la base où tous les atomes d'hydrogène seraient équivalents, l'éthylène formé devrait être constitué principalement des variétés -d_2 (43%) et -d_1 (38%). Il est évident que ce n'est pas le cas.

Discussion

La molécule, en absorbant un photon, est portée dans un état électronique, S_n. Le spectre d'absorption de la molécule n'est pas trop bavard et la nature de l'état électronique excité n'est pas évidente. La vibration d'élongation de la liaison C—C est cependant visible et le spectre présente certaines similarités avec celui du tétraméthyléthylène (10). La photochimie des alcènes acycliques en phase gazeuse a été, en général, expliquée sur la base de la rupture primaire de la liaison β(C—C) (11) et ce probablement à partir de l'état fondamental électronique vibrationnellement excité. Le mécanisme déjà proposé par ailleurs pour le cyclohexène met plus directement en cause les états électroniques S_1 et Rydberg (4, 5).

Mécanisme réactionnel

L'effet de pression est évidemment intéressant. S'il permet une estimation grossière du temps de vie d'un intermédiaire impliqué dans la formation de l'éthylène, il n'en indique pas la nature. Tous les efforts faits en vue de stabiliser un hydrocarbure acyclique en C_6 ou le vinylcyclobutane ont été vains. Cet échec est peut-être le résultat d'une pression de stabilisation insuffisante de la chambre expérimentale bien que d'autres études ont montré par ailleurs que, vers 60 Torr, la moitié des

TABLEAU 1. Photolyse du cyclohexène-3,3,6,6-d_4. Analyses isotopiques de l'éthylène

λ (nm)	Pression (Torr)	C_2D_4	C_2D_3H	$C_2D_2H_2$	C_2DH_3	C_2H_4
106,7–104,8[a]	1	4,1	5,4	29,3	0,5	54,0
	28	2,0	3,0	28,3	5,3	61,5

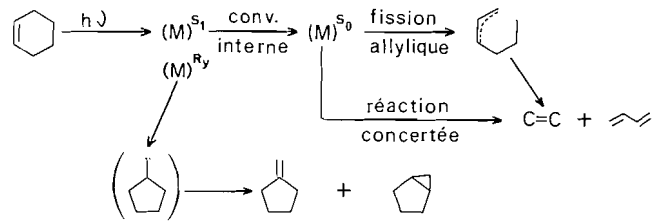
[b]Non déterminé.

molécules hexène-1 (C_6H_{12}), dans l'état fondamental vibrationnellement excité à 184,9 nm, devraient être stabilisées par collision.[1] Cette pression est de l'ordre de 1 500 Torr dans le cas du pentène-1 (C_5H_{10}). Cet échec peut être aussi le résultat des propriétés physiques associées du ou des états électroniques de la molécule photoexcitées.



Mécanisme Réactionnel

La décomposition thermique du cyclohexène a été, elle aussi, étudiée par plusieurs laboratoires. La constante de vitesse du processus 2 – en système thermique – est telle que log $k_2 = 15{,}3 - 66900/RT$ (9) ou $14{,}93 - 65200/RT$ (12). L'énergie d'activation et le facteur de fréquence sont plus faibles que ceux observés dans le cas des ruptures de liaisons β(C—C) (13). Cette remarque a déjà été faite ailleurs (14) de telle sorte que l'éthylène et le butadiène-1,3 sont le résultat d'une fragmentation concertée du cyclohexène telle que cela a été calculé théoriquement (15) plutôt qu'en deux étapes. C'est donc une fragmentation de type rétro-Diels–Alder (16) permise selon les règles de conservation de symétrie des orbitales de Woodward et Hoffmann (17). Il est pertinent de rappeler ici que la mercurisensibilisation semble générer plutôt un mécanisme en deux étapes puisque vinylcyclobutane, qui y est observé, est le résultat de la cyclisation de l'intermédiaire radicalaire n-propylallyle.

Lanostane-to-cucurbitane transformation[1,2]

O. E. EDWARDS AND Z. PARYZEK[3]

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received February 22, 1983

O. E. EDWARDS and Z. PARYZEK. Can. J. Chem. **61**, 1973 (1983).

Westphalen-type rearrangement of a 9α-hydroxy-11-ketone derived from lanosterol resulted in formation of two 19(10 → 9β)*abeo*-lanostenes representing the first lanostane-to-cucurbitane transformation. A novel ring A aromatic 9,10-seco derivative was formed as an acid catalysed cleavage product of 11-keto cucurbitenes. A cine 9 → 12 substitution led to the first 12-substituted lanostane derivatives and the first C-nor-D-homolanostane derivatives.

O. E. EDWARDS et Z. PARYZEK. Can. J. Chem. **61**, 1973 (1983).

Une transposition du type Westphalen de l'hydroxy-9α cétone-11 provenant du lanostérol conduit à la formation de deux *abeo*-lanostènes 19(10 → 9β) qui représentent la première transformation du lanostane en cucurbitane. Le clivage, catalysé par un acide, des céto-11 curcurbitènes permet d'obtenir un nouveau cycle aromatique A le dérivé séco-9,10. Une substitution du type cine 9 → 12 conduit au premier dérivé du lanostane substitué en position 12 et au premier dérivé du C-nor-D homolanostane.

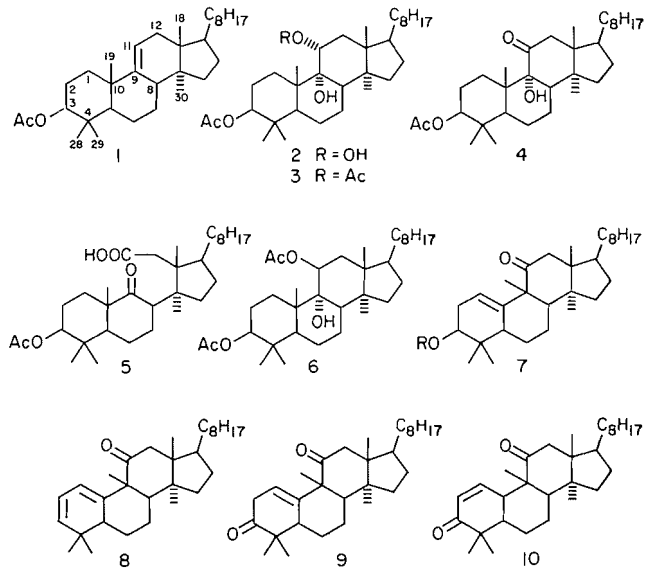
Our long-standing interest in the behaviour of α-keto carbenium ions (1–3) led us to study the deamination of steroidal α-aminoketones (4). However, attempts to prepare 9α-amino-11-keto lanostane derivatives failed (5). An alternative method of generating tertiary α-keto carbenium ions appeared to be the Westphalen-type (6) dehydration (sulfuric acid in acetic acid – acetic anhydride) of the tertiary α-ketols. (Numerous studies have been made of the steric and electronic factors influencing the molecular rearrangements that usually accompany the dehydrations resulting from the use of these reagents (*7a–d*).)

Because of our hope of efficiently preparing cucurbitanes (19(10 → 9 β)*abeo*-lanostanes) and/or cycloartanes (9,19-cyclo-lanostanes) we chose to examine the behaviour under Westphalen conditions of 3β-acetoxy-9α-hydroxylanostanes with either a carbonyl or acetoxy group on C-11. A preliminary account of this work has been published (8).

The desired substrates were prepared from dihydrolanosterol by way of 3β-acetoxy-5α-lanost-9(11)-ene (**1**) (9). Hydroxylation of the double bond of **1** using osmium tetroxide in pyridine afforded the 3β-acetoxy-9α,11α-diol **2**. Acetylation of **2** gave 3β,11β-diacetoxy-5α-lanostan-9α-ol (**3**). Dehydration of **3** using thionyl chloride – collidine in chloroform gave the known 3β-acetoxy-5α-lanostan-7,9(11)-diene (10).

Oxidation of **2** using Jones' reagent gave only 32% of the desired ketol **4**. However, oxidation of **2** under Pfitzner–Moffatt conditions (11) as modified by Turnbull *et al.* (12) gave **4** (3β-acetoxy-9α-hydroxy-5α-lanostan-11-one) in 69% yield. Its structure was confirmed by dehydration using thionyl chloride – pyridine to the known 3β-acetoxy-5α-lanost-8-en-11-one (13). Since our preliminary report (8), Lawrie *et al.* have described compounds **2** and **4** with spectra corresponding to those of our specimens (14).

In contrast to the above oxidations of **2**, chromium trioxide in acetic acid converted it into an acid in 89% yield. This gave a methyl ester with ν_{max}: 1728 and 1708 cm^{-1}. The ^{13}C nmr spectrum of the acid confirmed the presence of a ketone carbonyl (215.5 ppm) as well as the carboxyl group (178.6 ppm)



and 3-acetoxy group (171.8 ppm). This evidence, and its analysis and mass spectrum, confirmed that it was 3β-acetoxy-9-oxo-9,11-seco-5α-lanostan-11-oic acid (**5**).

Reduction of the ketone carbonyl of **4** with sodium borohydride, followed by acetylation using acetyl chloride-*N*,*N*-dimethylaniline in dichloromethane (15) gave 3β,11β-diacetoxy-5α-lanostan-9α-ol (**6**).

Westphalen dehydration of ketol **4** gave a complex mixture containing some sulfur. Three products, designated for discussion as A, B, and C, were isolated in a pure state by repeated chromatography in yields of 21, 14 and 39%, respectively.

Compound A analysed for $C_{32}H_{53}O_3$ and had ν_{max}: 1225 and 1685 cm^{-1}. Its ^{1}H nmr spectrum had signals due to an olefinic proton at δ 5.14 and the 3-hydrogen at δ 4.54. Hydrolysis of A gave the 3-hydroxy compound, which was converted to the tosylate. Elimination of *p*-toluene sulfonic acid was effected using potassium *tert*-butoxide in dimethyl sulfoxide at 75°C under argon. The resultant diene still contained the isolated carbonyl group (λ_{max}: 1695 cm^{-1}) and had ultraviolet absorption (ν_{max}: 270 nm, ε 6450) showing it to be a homoannular diene. Its ^{1}H nmr spectrum had a 3-hydrogen multiplet at δ 5.5. Thus structure **7** (R = Ac) (3β-acetoxy-19(10 → 9β)*abeo*-

11-oxo-lanost-1,(10)-ene) seemed certain for A and 19(10 → 9β)*abeo*-11-oxo-lanosta-1(10),2-diene (**8**) for the diene. Confirmation of the structure came from the action of potassium hydroxide in ethanol on the 3-ketone (**9**) derived from A. A mixture rich in the conjugated ketone **10** with λ_{max}: 229 nm (ε 7000) was formed. However, pure **10** could not be obtained by chromatography. Oxidation of ketone **9** with selenium dioxide in dioxane gave a crystalline yellow selenium-containing compound with ν_{max}: 1690 and 1646 cm^{-1}

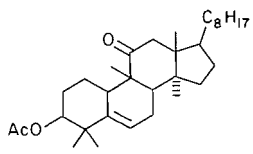
18 R = -C(=N-NHTs)-CH(CH3)2



19

and λ_{max}: 270 nm (ε 12 000). It gave a one-hydrogen signal at δ 7.15. Its analysis and molecular weight were consistent with structure **11**. However, its mass spectrum gave only ions resulting from loss of selenium. Comparable diselenides have been reported previously (16). Finally, a double irradiation experiment showed that the vinyl hydrogen of **9** was coupled with a methylene group resonating at δ 2.82.

Compound B was also an unsaturated ketone isomeric with A. Alkaline hydrolysis of B gave a hydroxy ketone which was still unconjugated. Jones' oxidation of this gave a non-conjugated diketone (ν_{max}: 1713 and 1693 cm^{-1}). Its rather intense $n-\pi^*$ absorption (λ_{max}: 293 nm, ε 150) was consistent with it being the β,γ unsaturated ketone **14** (17). Thus B appeared to be 3β-acetoxy-19(10 → 9β)*abeo*-11-oxolanostan-5(10)ene (**12**) and the corresponding alcohol was **13**. Interrelation of A and B was achieved by selenium dioxide oxidation of the derived diketone **14**. A minor product was the diselenide **11** previously obtained from A. The major product was an amorphous dienone. This had ν_{max}: 1690, 1660, and 1625 cm^{-1}, and λ_{max}: 325 nm (ε 4800). The ultraviolet absorption was consistent with structure **15**, 3,11-dioxo-19(10 → 9β)-*abeo*-5α-lanosta-1,5(10)-diene (18), as was the presence of two low field ^1H nmr signals at δ 7.00 and 5.96 (doublets, J = 11 Hz). The intense cd maxima at 300 nm (ε 4.65 and 7.5, respectively) shown by A and B were also characteristic of 11-keto cucurbitanes (19), reinforcing the above structural conclusions.

Final proof of structure of A and B came from interrelation with the cucurbitacins bryodulcosigenin **16** (20) and bryogenin **17** (19) from *Bryonia alba* (20).[4] The 24-carbonyl of bryogenin was removed in two ways, by cyanoborohydride reduction (21) of its 24-tosylhydrazone (**18**) or by Wolff–Kishner reduction of the 24-semicarbazone. The resulting 24-deoxybryogenin was purified as its beautifully crystalline acetate **19** but the alcohol could not be obtained crystalline. The acetate **19** was heated with a solution of anhydrous *p*-toluenesulfonic acid in benzene. A minor product was a conjugated diene (see Discussion). The main product (60% yield) had intense end absorption in the ultraviolet, λ_{max}: 263 (ε 110) and 271 nm (ε 70) and ν_{max}: 1692 cm^{-1}. It thus appeared to be an aromatic compound with the 11-ketone intact. Its ^1H nmr spectrum contained a three hydrogen signal at δ 7.05, a two hydrogen triplet at δ 2.71 (benzylic hydrogens), and two methyl singlets at δ 2.30 and 2.24. Successive additions of $Eu(dpm)_3$ caused a methyl doublet and a broad 1H singlet to move rapidly downfield. In addition, a two hydrogen singlet attributable to the 12-hydrogens moved rapidly downfield and became a quartet with J = 16 Hz. Its ^{13}C nmr spectrum showed the presence of three substituted and three unsubstituted aromatic carbons. Thus the aromatic compound unequivocally had structure **20**.

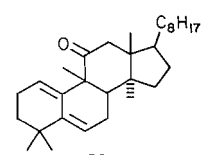
27



28

The same treatment of compound B gave a 19% yield of the identical aromatic compound, confirming the structures **12** and **7** assigned to it and to A.

Product C proved to be the known 3β,-11-diacetoxy-5α-lanosta-7,9(11)-diene (13*b*) which could be hydrolysed with alkali to 3β-hydroxy-5α-lanost-8-ene-11-one.

The action of sulfuric acid in acetic anhydride on ketol **4** gave similar results to those using the acetic acid–anhydride mixture. Compounds A, B, and C were isolated in 19, 13, and 27% yields, respectively.

Treatment of the 11α-acetoxy-9α-hydroxy compound **3** under Westphalen conditions gave a crude product containing 6% sulfur. From the mixture, 11% of starting material, 25% of 3β-acetoxy-5α-lanosta-7,9(11)-diene, and 14% of an unknown product were obtained. The spectral characteristics of the unknown suggested that it had structure **21**, 3β,11α-

[4]Roots supplied as *Bryonia Alba* by the S. B. Penick Co. contained glyosides yielding these two aglycones. Unpublished work with J. P. Devlin and J. W. Elder.

diacetoxy-19(10 → 9β)*abeo*-lanost-5(10)-ene. This was confirmed by hydrolysis to the diol, then Jones' oxidation to a dione which had ir and nmr spectra identical to those of dione **14** prepared earlier from compound B (**12**).

The attempted Westphalen dehydration of the 3β,11β-diacetoxy-9α-hydroxy compound **6** gave a complex mixture which was not further investigated.

In the course of studying other conditions for dehydrating ketol **4**, it was heated in benzene with *p*-toluenesulfonic acid hydrate. Neither simple elimination of water nor dehydration with migration of C-19 ensued. Instead, a mixture was produced which, after hydrolysis, could be separated into two main products. The major product (43%) had infrared absorption at 1695 and 1620 cm^{-1} and an ultraviolet maximum at 255 nm (ε 14 000). Its ^1H nmr spectrum had a 3H singlet at δ 2.08 consistent with the presence of a β-methyl group on an α,β-unsaturated ketone. Jones' reagent oxidized the compound to a diketone with ν_{max}: 1695 cm^{-1} (increased intensity) and 1620 cm^{-1}. This evidence indicates the structure of the diketone to be 3,11-dioxo-C-nor-D-homolanostan-12-ene (**22**) and hence that of the original hydrolysis product to be **23**. The minor product was a keto alcohol (ν_{max}: 3615, 3435, and 1705 cm^{-1}). A 12-hydroxy-11-ketone system was indicated by a ^1H nmr doublet at δ 4.27 (J = 8 Hz) and ^{13}C nmr signals at 214 and 72.4 ppm, in addition to the signals at δ 3.25 and 78.5 ppm due to C-3. The equatorial nature of the 12-hydroxyl group of the ketol was probable since its ultraviolet maximum was at 277 nm with ε 87 (22). The compound could be oxidized to a trione which enolized in alkali (λ_{max}: 283 nm, ε 290, shifted to λ_{max}: 330 nm, ε 3600 at high pH). Thus the structure of the ketol was 3β,12β-dihydroxy-5α-lanostane-11-one (**24**).

Discussion

Although prior to the present work, methyl migration to give 19(10 → 9β)*abeo* steroids had been observed during deamination of 9α-amino compounds (4, 23) and Lewis acid catalysed opening of 9α,11α-epoxides (24, 25), attempts to obtain the same migration in lanosterol analogues had failed (24*b*, 26). Thus the formation of **7** and **12** was the first successful production of cucurbitanes from lanostanes. Since then, superior yields of cucurbitanes were obtained by methyl migration following boron trifluoride catalysed opening of 3β-acetoxy-9β,11β-epoxylanostan-7-one by Paryzek and co-workers (27) and by Baddeley and Simes and their co-workers (28). This led to the first preparation of a true cucurbitacin (24-deoxybryogenin) (27).

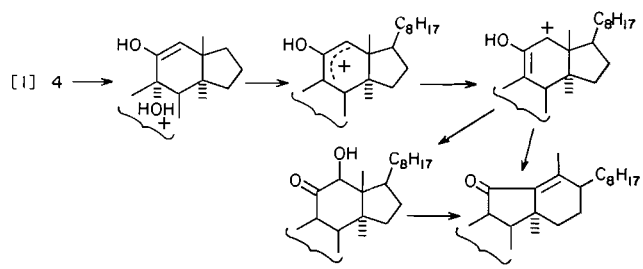
Evidence for the nature of the carbocations involved in these rearrangements exists. At one extreme, the deamination of α-amino ketones and diazo ketones (2), and probably Westphalen dehydration of β-fluoro alcohols (29), the cation formation is slow and there is high retention of steric identity. This is consistent with σ-bond involvement during, or very rapidly after, cation formation. The Westphalen dehydration of tertiary alcohols with less electronegative β groups (e.g. acetoxy) has been shown to lead to tight ion pairs (30). The counter-ion location determines the stereochemistry of resulting steps. However, the epoxide opening in acetic anhydride catalysed by boron trifluoride seems to lead to a nearly planar cation, since migration of methyl groups *cis* to the epoxide can be a major event (27, 28).

Of the reactions open to a cationic center at C-9 with an 11-carbonyl, the migration of the 10-methyl group and loss or migration of the 8β-hydrogen are the most probable events. In the case of the 11α-acetoxy compound **3**, the additional possibility of loss of the 11β-hydrogen exists. The methyl migration is competitive with these hydrogen involvements, partly because of repulsive interaction between the 4β-methyl group and the 10-methyl group which is relieved as migration starts, and partly because proton loss from carbon carrying an acetoxy group appears to be disfavored (29–31).

Although the 10-methyl migration must pass through a transition state or intermediate resembling a corner-protonated cyclopropane, no evidence has been found for the formation of 9,19-cyclo compounds (cycloartanes) in the deamination or Westphalen dehydration studies. However, in the prolonged reaction at 10°C in the epoxide opening work of Baddeley *et al.* (28), the ring B expanded compound **25** was formed. This probably arose from a cycloartane (see **26**) formed by acid catalysed cyclization of the 19(10 → 9 β)*abeo* olefins.

Although they were probably formed, no products of backbone migration of the 9-hydrogen and 13- and 14-methyl groups were identified in this work.

In interesting contrast to the Westphalen-type dehydration of ketol **4**, the action of *p*-toluenesulfonic acid hydrate in hot benzene resulted in formal migration of the cationic center from C-9 to C-12. The products arising from this were the C-nor-D-homo compound **23** and the 12β-hydroxy-11-ketone **24**. A likely mechanism for the ciné substitution (32) is shown in eq. [1]. The C-nor-D-homo rearrangement is characteristic of a 12β leaving group (4, 33), suggesting that the 12β-hydroxy compound is an intermediate in the formation of **23**. This appears to be the first report of formation of a C-nor-D-homo compound in the lanostane series.



The selenium dioxide oxidation of **9** and **14** has its parallel in steroid chemistry (16). It seems likely that a seleno-ketone **27** is an intermediate. Air oxidation of its enol could give the dimer (eq. [2]).

One of the most interesting reactions encountered in this work was the aromatization of ring A resulting when olefin **12** or 24-deoxybryogenin acetate were treated with anhydrous *p*-toluenesulfonic acid in refluxing benzene. The main product **20** probably arose by the sequence shown in eq. [3]. The forma-

For personal use only.

tion of an alkylic cation from an isolated carbocation, and the aromatization, provide obvious driving force for the sequence of events. A second product from 24-deoxybryogenin was a conjugated diene with λ_{max}: 242 nm. This, the absence of the 3-acetoxy group, and the presence of the 11-carbonyl and two vinyl hydrogens, make it probable that its structure was **28**, formed by elimination of acetic acid followed by double bond migration. This diene position seems specially favored for the cucurbitane skeleton (34).

The failure of the 11β-acetoxy-9α-ol **6** to give appreciable quantities of the C-19 migrated products can be attributed to the bulk of the 11-acetoxy group which opposes the movement of the methyl group toward C-9. If this is correct, the complexed 11β oxygen in the probably more planar cation arising by opening of the 9β,11β-oxide (27, 28) must have much less repulsive interaction with C-19. The methyl migration in the α-ketols is probably closer to a synchronous process because of the higher energy required to ionize the C—O bond (2, 7*c*).

Experimental

Unless otherwise stated, infrared spectra and rotations were for chloroform solutions, ultraviolet spectra for 95% ethanol solutions, and nmr spectra for deuteriochloroform solutions. Preparative tlc was done on 1000 μ SiO_2 plates with fluorescent indicator. Proton nmr spectra were obtained on a Varian EM-360 spectrometer (60 MHz) and ^{13}C spectra on Varian CFT-20 and Brüker WP-80 spectrometers. Mass spectra were produced by electron impact unless otherwise stated.

3β-Acetoxy-9α,11α-dihydroxy-5α-lanostane 2

A solution of 3.5 g of the 9,11 olefin **1** (9) and 1.5 g of osmium tetroxide in 50 mL of pyridine was stirred under nitrogen at room temperature for 15 h. An additional 0.5 g of osmium tetroxide was added, then the mixture left for 50 h. Saturated sodium hydrosulfite solution was added, then the products extracted into benzene. The benzene layers were washed with dilute hydrochloric acid, water, dilute sodium carbonate solution, water, then dried over magnesium sulfate. The 3.98 g of product recovered from the benzene crystallized from n-heptane, giving 3.45 g (92%) of the 9α,11α-diol **2**. This was recrystallized from methanol giving needles, mp 162−164°C. Since our communication (8), this has also been described by Lawrie *et al.* (14) as having mp 164.5−165.5°C. Our ir and ^1H nmr spectra accord with those reported.

3β,11α-Diacetoxy-9α-hydroxy-5α-lanostane 3

A solution of 601 mg of 9α,11α-diol **2** in 5 mL of pyridine and 2 mL of acetic anhydride was left at room temperature for two days. The reagents were removed under reduced pressure, the product dissolved in benzene, then this solution was washed with dilute acid and sodium carbonate solution. The 702 mg of crude product crystallized from methanol giving 642 mg of 3,11-diacetate **3** with mp 76−78°C. It had ν_{max}: 3580, 1725, 1260, and 1025 cm^{-1}. Its ^1H nmr spectrum gave signals at δ: 5.40 (1H, dd, J = 10 and 6.5 Hz), 4.47 (1H br t), and 2.04 (6H, singlet). *Anal.* calcd. for $C_{34}H_{58}O_5$: C 74.68, H 10.69; found: C 74.84, H 10.72.

Reaction of 3 with thionyl chloride − collidine

An ice-cold solution of 78 mg of 3β,11α-diacetoxy-9α-hydroxylanostane **3** and 0.3 mL of s-collidine in 0.3 mL of dry, ethanol-free chloroform was prepared. After addition of 0.1 mL of thionyl chloride the mixture was left at 0°C for 25 min. Ice water was then added, the products extracted into benzene, the benzene layers washed with water, dilute hydrochloric acid, then dilute sodium carbonate solution. The benzene contained 63 mg of crystalline product, which was purified on a 1000 μ silica gel plate using 5:1 benzene − ethyl acetate for development. The main zone gave 44 mg of 3β-acetoxy-5α-lanosta-7,9(11)-diene. After crystallization from acetone−dichloromethane, it had mp 163−166°C (lit. (10) mp 167−169°C). Its ir, uv, and ^1H nmr spectra were in accord with those reported.

3β-Acetoxy-9α-hydroxy-5α-lanostan-11-one 4

(a) *With DCC−DMSO − dichloroacetic acid (12)*

A solution containing 2.32 g of the diol **2**, 2.85 g of dicyclohexylcarbodiimide, 0.313 mL of dichloroacetic acid, and 10 mL of dimethylsulfoxide (added last) was left at room temperature for 5.5 h. A solution of 2.5 g of oxalic acid dihydrate in 2 mL of methanol was added. After a further 6 h, 20 mL of water was added, then the product extracted into benzene. The organic layers were washed with 5% potassium carbonate solution, then water, and dried over magnesium sulfate. The benzene solutions gave an oil which crystallized from aqueous acetone giving 1.61 g of ketol **4** which had mp 183−185°C. This has since been described by Lawrie *et al.* (14). Its ir and ^1H nmr spectra accord with those reported. Its ^{13}C nmr spectrum had signals at δ: 210.4, 171.0, 80.5, and 80.2, and its mass spectrum gave ions with m/e: 502 (M^+), 484, 442, 424, 319, 306, 293, and 137.

(b) *With Jones' reagent*

One mL of Jones' reagent (35) was added dropwise to a stirred solution of 504 mg of acetoxy diol **2** in 30 mL of acetone. Excess reagent was destroyed using 2-propanol. The acetone solution was decanted, then evaporated. The products were distributed between benzene−ether mixture and water. The organic layers gave 422 mg of light green oil. A hexane solution of this was filtered through 5.5 g of alumina (Act. III). The eluate was chromatographed on 20 g of neutral alumina (Act. III). Benzene eluted 151 mg of ketol **4** whose physical properties were the same as those described above.

The structure of the ketol **4** was firmly established by dehydration using thionyl chloride in pyridine at room temperature to give 3β-acetoxy-5α-lanost-8-en-11-one, mp 127−130°C (lit. (13) mp 130−132°C). Its ir and uv spectra agreed with the literature. Its ^1H nmr spectrum had signals at δ: 4.62 (1H, t), 2.09 (1H, s), 1.17, 1.15, 0.93, and 0.84 (methyl signals).

3β,11β-Diacetoxy-5α-lanostan-9α-ol (6)

Sodium borohydride (392 mg) was added gradually over 45 min to a refluxing solution of 512 mg of acetoxy ketol **4** in 20 mL of methanol under nitrogen. The products were distributed between benzene and water, giving 521 mg of crystalline reduction products. This was dissolved in 5 mL of dichloromethane and 2.15 mL of dimethylaniline. The solution was cooled to 0°C, then 1 mL of acetyl chloride in 5 mL of dichloromethane was added dropwise. After 21 h the mixture was added to an ethyl ether − water mixture. The organic layer was washed successively with sodium carbonate solution, dilute hydrochloric acid, then sodium bicarbonate solution. The crude product crystallized from ethanol giving the diacetate **6** with mp 178.5 − 180.5°C. It had ν_{max}: 3640, 3500, 1730, 1260, and 1030 cm^{-1} and gave ^1H nmr signals at δ: 4.96 (1H, br s), 4.56 (1H, m), 2.07 (6H, s), 1.26, 0.97, 0.93, and 0.83 (methyl signals). *Anal.* calcd. for $C_{34}H_{58}O_5$: C 74.68, H 10.69; found: C 74.62, H 10.95.

3β-Acetoxy-9-oxo-9,11-seco-5α-lanostan-12-oic acid (5)

The diol **2** (204 mg) was added to a solution of 210 mg of chromium trioxide in 10 mL of 95% acetic acid. After 25 min at room temperature, the mixture was diluted with water and the product extracted into benzene. Although the benzene layers were washed with sodium carbonate solution, the 187 mg of crude product was rich in acid, crystallizing from aqueous ethanol to give 141 mg of keto acid **5**, mp 159−162°C. It had ν_{max}: 3510, 3400−2400, 1725, 1705, and 1253 cm^{-1}. It gave ^1H nmr signals (100 MHz) at δ: 4.46 (1H, m), 2.84 and 2.48 (two 1H doublets, J = 14 Hz), 2.02 (3H, s), 1.21, 1.0, 0.95, 0.88, and 0.81 (methyl signals) and ^{13}C nmr signals at δ: 215.5, 178.6, 171.8, and 81.0 ppm. Its mass spectrum had peaks at m/e: 518 (M^+), 472, 440, 387, 363, 319, 252, and 207. *Anal.* calcd. for $C_{32}H_{54}O_5$: C 74.09, H 10.49; found: C 74.19, H 10.49.

A comparable yield of the keto acid was obtained by oxidation of the diol **2** using chromium trioxide − pyridine in dichloromethane at room temperature.

Methyl 3β-acetoxy-9-oxo-9,11-seco-5α-lanostan-12-oic acid

An ether solution of 100 mg of the keto acid **5** was treated with excess diazomethane in ether. After 10 min, the excess reagent was destroyed with acetic acid. The crude ester crystallized from aqueous ethanol, giving 73 mg with mp 89–91°C. It had ν_{max}: (CH_2Cl_2): 1728, 1708, and 1243 cm^{-1} and gave ^1H nmr signals at δ: 4.56 (1H, m), 3.70 (3H, s), 2.92 and 2.54 (pair of 1H doublets, J = 14 Hz superimposed on a broad 1H singlet), 1.29, 1.13, 0.99, 0.93, 0.88, and 0.83 (methyl signals) and ^{13}C nmr signals at δ: 214.6, 174.3, 170.5, 79.9, and 54.8. It gave *m/e*: 532 (M^+), 517, 500, 472, 387, 377, and 279. *Anal.* calcd. for $C_{33}H_{56}O_5$: C 74.39, H 10.59; found: C 74.18, H 10.32.

Westphalen dehydration of ketol (4) in acetic acid – acetic anhydride

A solution of 41 mg of concentrated sulfuric acid in 9 mL of acetic anhydride and 18 mL of acetic acid was added at room temperature to 911 mg of ketol (**4**). The mixture was agitated until the solid had dissolved (1 min), then left at room temperature for 2 h. The solution was then poured onto crushed ice. After one hour the products were extracted into pentane. The pentane layer and washings were extracted with water, then with dilute aqueous sodium hydroxide, giving 822 mg of gum. This still contained 1.58% of sulfur.

The product was absorbed from dichloromethane onto 60 g of tlc silica gel, and eluted with the same solvent. Following 20 mg of unidentified material, fractions yielding 192 mg of pure compound A or mixtures rich in this compound were eluted. The next 107 mg of eluate also contained considerable A. This was followed by mixtures of B with compound C, then C alone. Methanol in dichloromethane eluted more C. The early fractions crystallized from methanol. The mother liquors were repeatedly separated on silica gel plates using dichloromethane or 10% ethyl acetate in benzene for development. In this way 183 mg (21%) of compound A with structure (**7**) was obtained.

Compound B was separated from C by repeated purification on silica gel plates using 10% ethyl acetate in benzene as developing solvent. Finally 124 mg (14%) of compound B, to which structure (**12**) was assigned, was obtained pure. Compound C was the major product (39%). Its ir and uv spectra were in accord with the data reported for 3β,11-diacetoxy-5α-lanosta-7,9(11)-diene (13*b*) and its ^1H nmr spectrum showed signals at δ: 5.60 (1H, br t, J = 5 Hz), 4.51 (1H, br t, J = 7 Hz), 2.12, and 2.03 (2–3H, s). Alkaline hydrolysis of this compound in methanolic potassium hydroxide gave 3β-hydroxy-5α-lanost-8-en-11-one with mp 163–164°C, whose spectral properties were in accord with those reported (13).

Action of acetic anhydride – sulfuric acid on ketol 4

To a stirred solution of 222 mg of ketol **4** in 12 mL of acetic anhydride at 80°C was added dropwise a solution of 0.1 g of sulfuric acid in 0.45 mL of acetic anhydride. The reaction mixture was allowed to cool. After 15 min, water was added, then the products extracted into a 1:1 benzene–ether mixture. The organic layers were washed with sodium carbonate solution, then with water, dried with magnesium sulfate, and evaporated to give 236 mg of oil. Separation similar to that described for the preceding experiment gave compound A (19% yield), compound B (13%), and 3β,11-diacetoxy-lanosta-7,9(11)-diene (27%).

3β-Acetoxy-19(10 → 9β)abeo-5α-lanost-1(10)-en-11-one (7, R = Ac)

This crystallized as plates from methanol, mp 85°C. It had ν_{max}: 1725 and 1685 cm^{-1}. Its ^1H nmr spectrum had signals at δ: 5.14 (1H, br s), 4.54 (1H, dd, J_1 = 10.5, J_2 = 7 Hz), 2.80 and 2.40 (two-1H, d, J = 15 Hz), 2.06 (3H, s), 1.25, 1.08, 0.92, 0.82, and 0.76 (methyl signals). *Anal.* calcd. for $C_{32}H_{52}O_3$: C 79.28, H 10.81; found: C 79.45, H 10.85.

3β-Hydroxy-19(10 → 9β)abeo-5α-lanost-1(10)-en-11-one (7, R = H)

The 3-acetoxy unsaturated ketone **7**, (R = Ac) (41 mg), was hydrolysed by refluxing a solution in 3 mL of methanol containing 90 mg of potassium hydroxide under argon for 1 h. The solvent was removed under reduced pressure, then the products distributed between water and dichloromethane. The dichloromethane layer and washings gave 39 mg of amorphous keto alcohol **7** (R = H). It had λ_{max}: 296 (ε 88), cd peaks at 300 nm (ε 4.65) and 207 nm (ε 4.4); ν_{max}: 3600, 3480, and 1690 cm^{-1}; and gave ^1H nmr signals at δ: 5.2 (1H, m, $W_{1/2}$ = 8 Hz), 3.52 (1H, dd, J_1 = 9 and J_2 = 6 Hz), 2.82 and 2.41 (two 1H doublets, J = 15 Hz), 1.28, 1.11, 1.06, 0.92, 0.82, 0.73, and 0.67 (methyl signals). Its ^{13}C nmr spectrum had signals at δ: 213.9, 139.0, and 119.5 ppm. It gave *m/e*: 442 (M^+), 427, 424, 409, 250, 192, 173, and 149.

3β-Acetoxy-19(10 → 9β)abeo-lanost-5(10)-en-11-one (12)

This formed plates from methanol, mp 149°C. It had ν_{max}: 1719 and 1690 cm^{-1} and Δε +7.5 (at 300 nm). It gave ^1H nmr signals at δ 4.72 (1H, m), 2.57 (2H, br s), 2.05 (3H, s), 1.18, 1.13, 1.00, 0.98, 0.93, 0.83, and 0.72 (methyl signals). It gave ^{13}C nmr signals at δ: 216.4, 171.0, 134.4, 128.2, and 77.9 ppm and *m/e*: 482 (M^+), 469, 424, 409, 174, 145, 131, 101, and 95. *Anal.* calcd. for $C_{32}H_{52}O_3$: C 79.28, H 10.81; found: C 79.10, H 10.81.

Ring A diene 8

Fifty mg of *p*-toluenesulfonyl chloride was added to a solution of 55 mg of hydroxyketone, **7** (R = H), in 0.5 mL of dry pyridine. After three days at room temperature, benzene was added, then the solution washed with dilute hydrochloric acid, water, and sodium bicarbonate solution. The dried benzene layers yielded a thick oil which was chromatographed on 18 g of tlc silica gel using dichloromethane for elution. The main eluate gave 38 mg of tosylate which would not crystallize. Its ^1H nmr spectrum had two 1H doublets at δ 7.83 and 7.35 (J = 8 Hz), a broad singlet at δ 5.10, a 1H triplet at 4.49, a 3H singlet at δ 2.37, and methyl signals at 1.24, 1.06, 0.92, 0.81, and 0.71.

The tosylate was dissolved in 0.5 mL of dry dimethyl sulfoxide under argon at 75°C, then 37 mg of potassium *tert*-butoxide in 0.6 mL of dimethyl sulfoxide added dropwise. The mixture was stirred under argon at 75°C for 1.75 h, cooled, then diluted with benzene. The benzene solution was washed with water, dried, and distilled, giving 27 mg of oil. A benzene solution of this was filtered through a column of 1 g of neutral alumina, Act I. The eluted product (20 mg) crystallized readily. After recrystallization from methanol, 19(10 → 9β)-*abeo*-lanosta-1(10),2-diene had mp 116–117°C; ν_{max} ($CHCl_3$): 1695 cm^{-1}; and λ_{max}: 270 nm (ε 6450). Its ^1H nmr spectrum gave signals at δ: 5.5 (br 3H, m), 2.67 and 2.54 (two apparent 1H singlets) 1.42, 1.27, 1.13, 1.09, 0.98 and 0.87, and 0.82 (methyl signals). It gave *m/e*: 424 (M^+), 409, 406, 392, and 294. *Anal.* calcd. for $C_{30}H_{48}O$: C 84.84, H 11.39; found: C 83.31, H 10.92.

19(10 → 9β)abeo-5α-Lanost-1(10)-en-3,11-dione (9)

One drop of Jones' reagent (35) was added to a solution of 50 mg of hydroxy-ketone **7** (R = H) in 5 mL of acetone. After 5 min the excess reagent was reduced with methanol, then the solution evaporated to dryness. The product was distributed between water and dichloromethane, then the organic layer and washings extracted with dilute sodium carbonate solution. The gum recovered from the dichloromethane was purified on a 1000 μ silica gel plate using 0.75% ethanol in chloroform for development. A dark front zone was followed by the desired diketone **9** (R_f approx 0.6). Yield 29 mg (58%). The amorphous diketone had ν_{max}: 1710 and 1690 cm^{-1} and gave ^1H nmr (100 MHz) signals at δ: 5.26 (1H, dd, J_1 = 8 Hz, J_2 = 3 Hz), 2.61 and 2.47 (two 1H doublets, J = 14 Hz), 2.82 (2 H, m), 1.36, 1.09, 1.00, 0.92, 0.88, 0.82, and 0.77 (methyl signals). The multiplet at δ: 5.26 was coupled with one centered at δ 2.82, collapsing to a broad singlet when the latter was irradiated. Its mass spectrum had peaks at *m/e*: 440 (M^+), 425, 356, 250, 217, 190, 165, 147, and 142.

The diketone **9**, when dissolved in 15% ethanol containing potassium hydroxide under argon, rapidly gave a maximum at 229 nm, rising in intensity to an ϵ_{max} over 7000. The crude product isolated from this reaction had ν_{max}: 1695 and 1647 cm^{-1}. However, attempted purification on silica gel plates gave no pure enone **10**.

*Bis(3,11-dioxo-19(10 → 9β)abeo-lanosta-1,5(10)-dien-2-yl) diselenide (**11**)*

Thirty-three mg of diketone **9** in 3 mL of dry dioxane containing 0.15 mL of water and 10 mg of sublimed selenium dioxide was heated under reflux in an argon atmosphere for 2 h. The mixture was left overnight at room temperature, filtered, then evaporated to dryness. The residue was dissolved in dichloromethane and the solution filtered through a short bed of Act. I neutral alumina. Dichloromethane eluted 17 mg of yellow product, while 0.75% ethanol in chloroform eluted 13 mg of more polar products.

The dichloromethane eluates crystallized from 95% ethanol giving 7 mg of **11** as yellow needles, mp 205°C. This had ν_{max}: 1690, 1646, and 1623 cm^{-1} and λ_{max}: 370 nm, ϵ 12 000. It gave ^1H nmr signals at δ: 7.15 (1H, s), 2.52 (2H, s), 1.33, 1.27, 1.20, 1.06, 0.91 and 0.80, and 0.72 (methyl signals). Its mass spectrum (chemical ionization) had peaks at 518, 516, 439, 438, 437, 436, 409, and 408. *Anal.* calcd. for $C_{60}H_{90}O_4Se_2$ (1033): C 69.74, H 8.78; found: C 69.19, H 8.86; *Mol. Wt* (thermistor drop method) 1012.

*3β-Hydroxy-19(10 → 9β)abeo-lanosta-5(10)-ene-11-one (**13**)*

The acetate of the Westphalen product B (**12**) (32 mg) was dissolved in 3 mL of methanol containing 223 mg of potassium hydroxide. The solution was refluxed under argon for 2 h, then the solvent evaporated. The product was distributed between water and dichloromethane, giving 26 mg of colorless oil in the organic phase. This had ν_{max}: 3600, 3350 (broad), and 1692 cm^{-1}, λ_{max}: 296, ϵ 88; and gave ^1H nmr signals at δ: 3.4 (1H, t, J = 5 Hz), 2.51 (2H, s) 1.18, 1.14, 1.04, 0.97, 0.90, 0.80, and 0.70 (methyl signals). Its cd spectrum had $\Delta\epsilon$ +8.0 (300 nm).

*19[10 → 9β]abeo-Lanosta-5(10)-ene-3,11-dione (**14**)*

A solution of 20 mg of **13** in 3 mL of acetone was titrated with a dilute solution of Jones' reagent in acetone. The acetone solution was decanted from the precipitate, then evaporated under reduced pressure. The product was taken up in dichloromethane, the solution washed with aqueous sodium carbonate, dried, and distilled. The 19 mg of product was purified on a 10 × 20 cm 500 μ SiO_2 plate using 0.75% ethanol in chloroform for elution. Zone 1 (R_f 0.55) gave 11 mg of diketone **14** as an oil. This had ν_{max}: 1713 and 1693 cm^{-1} and λ_{max}: 293 nm, ϵ 150. It gave ^1H nmr signals at δ: 2.50 (2H, s) 1.22, 1.17, 1.12, 0.90, 0.80, and 0.72 (methyl signals).

*Action of selenium dioxide on diketone **14***

A solution of 25 mg of diketone **14** and 11 mg of selenium dioxide in 4 mL of pure dioxane and 200 μL of water was heated at 100°C under argon for 6 h. The mixture was taken to dryness on a rotating evaporator, then the product taken up in hexane. This solution was washed with dilute sodium hydroxide solution, dried, and distilled, giving 25 mg of yellow gum. This was separated on a 500 μ fluorescent silica gel plate using 2% methanol in chloroform. The fastest moving compound (R_f 0.9) gave a yellow band with strong fluorescence quenching. It yielded 4 mg of crystalline solid (needles mp 205°C from ethanol) with λ_{max}: 370 nm. Its spectral properties were identical with those of compound **11** obtained from **9**. The next zone did not strongly quench fluorescence. It gave 6 mg with a weak uv maximum at 324 nm. This was followed by a strongly quenching zone containing 9 mg of an amorphous dienone (**15**) which had ν_{max}: 1690, 1660 and 1625 cm^{-1}; λ_{max}: 325 nm (ϵ 4800). It gave ^1H nmr signals at δ: 7.00 (1H, d, J = 11 Hz), 5.96 (1H, d, J = 11 Hz), 2.58 (2H, s), 1.30, 1.23, 1.08, 0.92, 0.80, and 0.78 (methyl signals). Its mass spectrum had peaks at m/e: 438 (M^+), 423, 410 and 395. M^+ calcd. for $C_{30}H_{46}O_2$: 438.

*Action of p-toluenesulfonic acid on B (**13**)*

A solution of 47 mg of the acetoxy keto olefin B (**13**) and 184 mg of anhydrous *p*-toluenesulfonic acid in 4 mL of dry benzene was refluxed under argon for 4.5 h. A pink color developed rapidly. The red solution was cooled, washed with dilute sodium carbonate solution, dried, and evaporated. The 44 mg of residue was separated on a 1000 μ silica gel plate, developing with 0.75% ethanol in chloroform. The weakly fluorescent band with R_f approx 0.5 gave 9 mg (19%) of essentially pure aromatic ketone **20** with spectra identical to that derived from 24-deoxybryogenin acetate (see below).

*Bryogenin (**17**)*

This was prepared by the action of acid on bryodulcosigenin (**16**) from *Bryonia alba* (20). After crystallization from acetone–hexane it had mp 157–158°C. This proved homogeneous by hplc. Its ^1H nmr spectrum had signals at δ: 5.7 (1H, br d), 3.49 (1H, br s), 1.13, and 1.15 (methyl signals). Half the expected doublet of doublets for the 12-hydrogens was visible at δ 2.96 (J = 14 Hz).

*Bryogenin 24-tosylhydrazone (**18**)*

Bryogenin (350 mg) and 400 mg of *p*-toluenesulfonylhydrazine in 6 mL of ethanol containing 50 mg of acetic acid was refluxed for 5 h. The solvent was removed on a rotating evaporator. A solution of the residue in dichloromethane was washed with dilute sulfuric acid, then sodium carbonate solution, dried, and distilled, leaving 526 mg of neutral product. This was adsorbed on 11 g of neutral alumina, activity III. Elution with 1:1 ether–hexane gave 41 mg of byrogenin, followed by 392 mg of the tosylhydrazone. This was never obtained crystalline. It had ν_{max}: 3500, 3280, 3210, 1694, 1600, and 1168 cm^{-1} and gave ^1H nmr signals at δ: 7.9 and 7.32 (two 2H doublets, J = 8 Hz), 7.7 (br s, 1H, NH), 5.7 (br d, 1H, J = 6 Hz), 3.50 (1H, s), 2.50 (3H, s), 1.15, 1.03, 0.95, and 0.70 (methyl signals).

Reduction of bryogenin 24-p-toluenesulfonylhydrazone

A solution of 410 mg of the tosylhydrazone in 4 mL of methanol was prepared. To this was added 106 mg of sodium cyanoborohydride, followed by slow addition of 79 mg of *p*-toluenesulfonic acid (during 2.75 h). Finally, another 80 mg of the acid was added, leading to rapid gas evolution. The methanol was evaporated. A dichloromethane solution of the products was washed with sodium carbonate solution, then dried. The 293 mg of product was purified on four 1000 μ silica plates using 5% methanol in chloroform for development. A front zone R_f 0.7 (86 mg of unknown) was followed by 151 mg rich in the desired 24-deoxybryogenin. This was acetylated by heating for 2 h at 60°C with a 1:1 mixture of acetic anhydride – pyridine. A methanol solution of the product gave 86 mg of crystals, mp 89–94°C, which, on recrystallization, had mp 133–135°C. The mother liquors were purified on preparative tlc plates, then crystallization from methanol, giving 80 mg, mp 108–109°C. Recrystallization of this gave 40 mg, mp 116–125°C, with similar spectra to the product with mp 135°C.

Bryogenin 24-semicarbazone

Bryogenin (411 mg, mp 153–155°C), semicarbazide hydrochloride (440 mg), and sodium acetate (504 mg) in 10 mL of methanol was heated to the boiling point for 10 min, then left for 22 h at room temperature. The solvent was removed under reduced pressure. A dichloromethane solution of the product was washed with dilute sulfuric acid, then dilute sodium carbonate solution. The neutral product was absorbed from chloroform onto 50 g of tlc silica gel, then eluted with 5% methanol in chloroform, giving 500 mg of quite pure semicarbazone.

A sample was purified for analysis by recrystallization from methanol, giving mp 156–164°C. It had ν_{max}: 3520, 3460, 3380, 1686, and 1560 cm^{-1} and gave ^1H nmr signals at δ: 8.35 (1H, s), 5.75 (3H, br), 1.16, 1.05, and 0.76. *Anal.* calcd. for $C_{31}H_{51}N_3O_3$: C 72.47, H 10.01; found: C 72.60, H 10.12.

Action of alkali on bryogenin semicarbazone

Bryogenin 24-semicarbazone (1.04 g) was mixed with 20 mL of diethylene glycol and 4 g of potassium hydroxide. This was heated to 190°C in an oil bath under a gentle stream of argon. As the vigorous boiling subsided, the temperature of the bath was raised to 205°C (total heating time 2 h). The mixture was cooled, then diluted with water, and extracted with dichloromethane. The dichloromethane extracts were washed with water, dried, then freed of solvent. The 832 mg of product was acetylated in 1:1 acetic anhydride – pyridine overnight. The acetate crystallized from methanol, giving 480 mg, mp 131°C and

277 mg, mp below 90°C. The first crop was nearly pure 24-deoxybryogenin acetate **19**. The second crop was a mixture of **19** with another product, giving very similar ir and ^{1}H nmr spectra. This was not further investigated.

24-Deoxybryogenin

This was not obtained crystalline. Product from reduction of the tosylhydrazone was purified by chromatography on silica gel plates using 5% methanol in chloroform for elution. Material giving a single spot on tlc (same solvent) gave ν_{max}: 3610, 3520 and 1690 cm^{-1} and ^{1}H nmr signals at δ: 5.60 (1H, br), 3.50 (1H, s), 2.97, 2.42 (two 1H doublets, J = 14 Hz), 1.15, 1.10, 1.02, 0.92, 0.85, and 0.73. It gave ^{13}C nmr signals at δ: 214.9 (s), 139.6 (s), 120.6 (d), and 76.15 (d).

24-Deoxybryogenin acetate **19**

Product with mp 135°C from reduction of tosylhydrazone **18** and Wolff–Kishner reduction of the semicarbazone **17** was further purified using silica gel plates under argon, with development using 2% methanol in chloroform. Recrystallization from methanol gave a product with mp 137–138°C. A final purification by flash chromatography on 40 times its weight of silica gel, eluting with benzene – ethyl acetate (95:5), followed by recrystallization from methanol, gave 24-deoxybrogenin acetate as laths, mp 143.5–145°C. It had ν_{max}: 1726 and 1690 cm^{-1} and gave ^{1}H nmr signals at δ: 5.67 (1H, br), 4.73 (1H, br s), 3.0, 2.46 (two 1H doublets, J = 14 Hz), 2.05 (3H, s), 1.10, 1.06, 0.92, 0.82, and 0.73. Its ^{13}C nmr spectrum had signals at δ: 214.6 (s), 170.6 (s), 139.7 (s), 119.1 (d), 78.2 (d), 49.6 (t), 48.9 (s) 43.9 (d), 40.0 (s), 39.5 (t), 36.4, 35.9, 35.6, 34.5, 28.0, 26.2, 25.0, 24.0, 22.9, 22.7, 21.3, 19.9, 18.6, 18.3, and 16.8. *Anal.* calcd. for $C_{32}H_{52}O_3$: C 79.28, H 10.81; found: C 79.36, H 10.26.

Action of p-*toluenesulfonic acid on* ***19***

A solution of 101 mg of dry 24-deoxybryogenin acetate (**19**) and 239 mg of anhydrous *p*-toluenesulfonic acid in 7 mL of dry benzene under argon was refluxed gently for 4.5 h. It was then cooled, extracted with sodium carbonate solution, dried, and distilled. The 90 mg of neutral product was put on a 1000 μ SiO_2 plate and developed with 0.75% ethanol in chloroform. A dark zone (uv light with R_f 0.8) contained 19 mg of a mixture of diene **28** with ca. 3 mg of aromatic compound **20**. A weaker fluorescent band with R_f 0.7 gave 51 mg of fairly pure amorphous aromatic compound **20**. (Estimated total yield 56%).

19(10 → 9β)abeo-Lanostan-1(10),5-diene-11-one (28)

The less polar product from the action of *p*-toluenesulfonic acid on deoxybyrogenin was further purified on a silica gel plate using 1:1 dichloromethane–benzene for development. The oil so obtained (ca. 17%) had λ_{max}: 242 nm (ε 10 500) and ν_{max}: 1690 cm^{-1}. Its ^{1}H nmr spectrum gave signals at δ: 5.43 (1H, m), 5.0 (1H, m) and methyl signals at 0.90, 0.82, and 0.74. Its mass spectrum gave ions at *m/e*: 424.3712 (M^+), 409, 278, 151, and 95. *Mol. Wt.* calcd. for $C_{30}H_{48}O$: 424.3705.

9,10-Seco-28(4 → 3)abeo-cucurbita-1,3,5(10)-triene-11-one (20)

After a second purification on silica gel plates, using 20:1 benzene – ethyl acetate for development, this crystallized and had mp 41–45°C. It had intense absorption below 225 nm and λ_{max}: 263 nm (ε 110) and 271 nm (ε 70). It had ν_{max}: 1692 cm^{-1}. Its ^{1}H nmr spectrum had signals at δ: 7.06 (3H, s), 2.71 (2H, t, J = 8 Hz), 2.54 (2H, s), 2.30 (3H, s), 2.24(3H, s), 1.28, 1.18, 1.03, 0.92, 0.83, and 0.77 (methyl signals). The signals for the aromatic protons, the low-field methyl protons (2.30, 2.24), and the benzylic hydrogens (2.71) hardly moved as Eu(dpm)$_3$ was added to the solution, although the aromatic proton signal changed from a singlet to a multiplet. The singlet at 2.54 attributable to the 12-hydrogens moved rapidly downfield as the shift reagent was added, becoming a doublet of doublets with J = 16 Hz. A broad one-hydrogen signal attributable to the 9-hydrogen and a methyl doublet (1.23, J = 6 Hz) also moved rapidly, indicating proximity of these groups to the carbonyl. Its ^{13}C nmr spectrum had signals at δ: 214.3, 140.8 (s), 136.9 (s), 134.1 (s), 127.8 (d), 127.0 (d), and 125.5 (d) and its mass spectrum gave peaks at *m/e*: 424.3700 (M^+), 304, 291, 254, 151, and 119. *Mol. Wt.* calcd. for $C_{30}H_{48}O$: 424.3705.

Westphalen dehydration of 3β,11α-diacetoxy-5α-lanostan-9α-ol

A solution of 125 mg of sulfuric acid in 2.5 mL of acetic acid was added dropwise at room temperature to a solution of 506 mg of **2** in 12.5 mL of acetic acid and 10 mL of acetic anhydride. After 3 h, a precipitate which had formed was removed by filtration. After crystallization from acetone–dichloromethane, this had mp 162–164°C and spectral properties characteristic of 3β-acetoxy-5α-lanosta-7,9(11)-diene. The filtrate was poured into water, then the products extracted into benzene. The benzene layers were washed free of acid using sodium carbonate solution, dried, and evaporated, giving 325 mg of yellow oil (at least 4 components). This was chromatographed on Act. III alumina, eluting with hexane and hexane–benzene mixtures. A further 28 mg of 3β-acetoxy-5α-lanosta-7,9(11)-diene and 57 mg of starting material were obtained. Fractions with medium polarity contained 68 mg of olefin **21** which gave ^{1}H nmr signals at δ: 5.20 (1H, m), 4.74 (1H, m) 2.08 (3H, s), and 2.05 (3H, s). This was hydrolysed using refluxing potassium hydroxide in 95% ethanol. The tlc separation of the products gave 30 mg of dihydroxy olefin with ^{1}H nmr signals at δ: 3.73 (1H, dd, J_1 = 9 Hz, J_2 = 7 Hz), 3.40 (1H, t, J = 4 Hz), 1.20, 1.02, 0.93, 0.80, and 0.70 (methyl signals). Finally, oxidation of this compound with Jones' reagent in acetone gave 28 mg of diketone. Its ir and nmr spectra were identical with those of diketone **14**.

Action of p-*toluenesulfonic acid hydrate on* ***4***

The ketol (**4**) (327 mg), mp 181°C, and 291 mg of powdered *p*-toluenesulfonic acid monohydrate was suspended in 8 mL of dry benzene. This was refluxed under argon for 2.5 h, giving a dark red solution. This was cooled, then washed with sodium carbonate solution. The dried benzene layers (Na_2SO_4) were distilled, leaving a crystalline residue. This was dissolved in 10 mL of absolute ethanol containing 230 mg of potassium hydroxide, then the solution refluxed under argon for 1 h. The ethanol was removed on a rotating evaporator, then the residue distributed between water and dichloromethane. The 317 mg of product recovered from the dichloromethane was put on two 1000 μ 20 cm × 20 cm SiO_2 plates, then developed with 20% ethyl acetate in benzene. Band 4 (R_f 0.5) gave 135 mg, which crystallized from methanol to yield 92 mg of enone **23**. Band 5 (R_f 0.4) gave 63 mg, which crystallized from methanol to yield 38 mg of ketol **24**.

3β-Hydroxy-11-oxo-C-nor-D-homo-5α-lanost-12-ene (23)

This had mp 159°C; ν_{max}: (CH_2Cl_2): 3500, 3489, 1695, and 1620 cm^{-1}; and λ_{max}: 255 nm (ε 14 000) and 356 nm (ε 100). It gave ^{1}H nmr signals at δ: 3.31 (1H, m), 2.08, 3H, s), 1.01, 0.93, 0.90, 0.85, and 0.80 (methyl signals). *Anal.* calcd. for $C_{30}H_{50}O_2$: C 81.39, H 11.38; found: C 81.28, H 11.12.

3β,12β-Dihydroxy-5α-lanostan-11-one (24)

This had mp 146°C, ν_{max} (CH_2Cl_2): 3615, 3435, and 1705 cm^{-1}; and λ_{max}: 277 nm, (ε 87). It gave ^{1}H nmr signals at δ: 4.27 (1H, br d, J = 8 Hz) and 3.25 (1H, m) and ^{13}C nmr signals at δ: 214.2, 78.5, and 72.4 ppm. *Anal.* calcd. for $C_{30}H_{52}O_3$: C 78.20, H 11.38; found: C 77.94, H 11.57.

C-nor-D-homolanost-12-en-3,11-dione (22)

Compound **23** (24 mg) in 2 mL of acetone was titrated with a dilute solution of Jones' reagent (35) in acetone. The product was purified using a 500 μ silica gel plate with 0.75% ethanol in chloroform for development. The main zone gave 12 mg of pure diketone (**22**) with mp 133°C; ν_{max}: 1695 and 1620 cm^{-1}; and λ_{max}: 255 nm (ε 15 300). It gave ^{1}H nmr signals at δ: 2.13 (3H, s), 1.30, 1.14, 1.07, 0.96, and 0.86 (methyl signals). Its mass spectrum had peaks at *m/e*: 440 (M^+), 425, 355. 327, 312, 295, 189, 175, 149, and 141.

5-α-Lanostan-3,11,12-trione

Ketol **24** (17 mg) in 2 mL of acetone was titrated with dilute solution of Jones' reagent (35) in acetone. The product crystallized from

methanol giving 13 mg of triketone **11** with mp 154–156°C. It had ν_{max}: 1722, 1705, and 1695 cm^{-1} and λ_{max}: 283 nm (ϵ 290) shifting to λ_{max}: 330 nm (ϵ 3600) in ethanol containing potassium hydroxide. Its ^1H nmr spectrum had signals at δ: 2.9 to 2.1 (3H, multiplet), 1.29, 1.09, 1.03, 0.94, and 0.83 (methyl signals).

Lewis acid complexes of 1,2-diketones and their derivatives. The synthesis of seven-membered rings

CHRISTOPHER BLACKBURN, RONALD F. CHILDS,[1] AND ROGER A. KENNEDY
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received February 24, 1983

CHRISTOPHER BLACKBURN, RONALD F. CHILDS, and ROGER A. KENNEDY. Can. J. Chem. **61**, 1981 (1983).

The structures and charge distributions of Lewis acid complexes of butane-2,3-dione, **1**, cyclohexane-1,2-dione, **2**, and 2-methoxycyclohex-2-en-1-one, **5**, have been investigated by ^{1}H nmr spectroscopy. A 1:1 complex was formed between **1** and $SnCl_4$ which appeared to have a bridged structure. In the case of **2** and **5** both oxygens were again involved in complex formation with $TiCl_4$ or $SnCl_4$. In each case the large downfield shift of the vinyl proton resonance, H3, indicated extensive charge delocalization within the complexes and that these systems can be regarded as complexed α,β-unsaturated enones. The reactions of Lewis acid complexes of **2**, **5**, and the silyl ethers 2-(trimethylsiloxy)cyclohex-2-en-1-one, and 3-(trimethylsiloxy)-but-3-en-2-one, **11**, with butadiene have been investigated. The acyclic enol ether **11** reacted with butadiene in the presence of either $TiCl_4$ or $SnCl_4$ to give products corresponding to both 4C + 3C and 4C + 2C cycloaddition reactions; in all other cases 4C + 2C products only could be isolated.

CHRISTOPHER BLACKBURN, RONALD F. CHILDS et ROGER A. KENNEDY. Can. J. Chem. **61**, 1981 (1983).

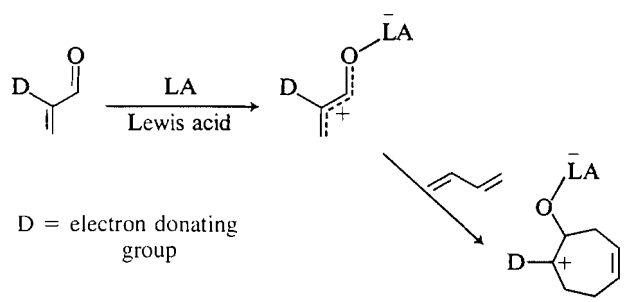
Faisant appel à la spectroscopie de rmn du ^{1}H, on a étudié les structures et les distributions de charges des complexes d'acide de Lewis de la butanedione-2,3 (**1**), de la cyclohexanedione-1,2 (**2**) et de la méthoxy-2 cyclohexène-2 one-1 (**5**). Il se forme un complexe 1:1 entre le composé **1** et le $SnCl_4$ qui semble posséder une structure pontée. Dans le cas des composés **2** et **5** les deux oxygènes sont encore impliqués dans la formation d'un complexe avec le $TiCl_4$ ou le $SnCl_4$. Dans chaque cas, le grand déplacement de la résonance du proton vinylique, H3, vers les champs faibles indique une forte délocalisation de charge à l'intérieur de ces complexes et on peut considérer ces systèmes comme des énones-α,β insaturées complexées. On a étudié les réactions des complexes d'acide de Lewis des composés **2** et **5**, et des éthers silylés: (triméthylsiloxy)-2 cyclohexène-2 one-1 et (triméthylsiloxy)-3 butène-3 one-2, **11**, avec le butadiène. L'éther énol acyclique **11** réagit avec le butadiène en présence du $TiCl_4$ ou du $SnCl_4$ en donnant des produits correspondants aux deux réactions de cycloaddition 4C + 3C et 4C + 2C. Dans tous les autres cas on obtient uniquement des produits 4C + 2C.

[Traduit par le journal]

The synthesis of carbocyclic seven-membered rings by 3C + 4C cycloaddition reactions has received much attention (1). These reactions normally involve a thermal $4\pi + 2\pi$ cycloaddition with an allyl cation adding to a 1,3-diene (2). The allyl cations are generated as transient species and the addition to the diene is but one of several competing reactions. For example, proton loss or nucleophilic capture of the allyl cation can readily occur and this leads to low yields of the desired seven-membered rings with less reactive dienes.

An attractive alternative approach would be to generate the allyl cations as long-lived species. One potential way of doing this is to react a suitably substituted α,β-unsaturated carbonyl compound with a Lewis acid. Lewis acid complexes of enones are well characterized compounds that are involved in a large variety of reactions (3) including the catalysed Diels–Alder reaction to form cyclohexenones (4). If the enone were to contain a good electron-donating group at the α-carbon, it might be possible to divert this reaction to form a cycloheptenone, eq. [1]. Indeed, as this work was underway, Sasaki *et al.* reported that such a reaction occurs with the $SnCl_4$-catalysed reaction of 1,3-butadiene with trimethylsilyl ether of pyruvaldehyde (5).

[1]

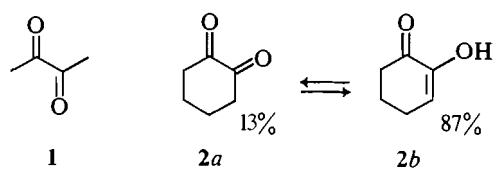


Potentially, complexation of a 1,2-diketone with a Lewis acid and subsequent removal of a proton from an adjacent carbon could give an allyl cation with an oxygen substituent at C2. We have explored this type of reaction of diketones and their derivatives and have found that, in certain cases, the resulting complexes undergo cycloadditions with dienes to form seven-membered rings (6).

Results and discussion

Complexations of 1,2-diketones

The 1,2-diketones used in this study were butane-2,3-dione, **1**, and cyclohexane-1,2-dione, **2**. The former material exists mainly in the diketo form, whereas **2***a* is present mainly as its enol tautomer **2***b*.



1 **2***a* **2***b*

Treatment of CH_2Cl_2 solutions of **1** with $SnCl_4$ or $TiCl_4$ at room temperature led to fairly rapid decomposition ($t_{1/2}$ ca. 1 h at 34°C). To minimize these decompositions, the reactions were studied at lower temperatures. Solubility problems made work with $TiCl_4$ difficult but a detailed examination of the $SnCl_4$ system was undertaken.

The ^{1}H nmr spectra of **1** and $SnCl_4$ mixtures in CD_2Cl_2 displayed both a concentration and temperature dependence, Table 1. At −18°C a single methyl resonance was seen irre-

spective of the ratio of **1**/$SnCl_4$ used. However, the position of this resonance was shifted progressively further downfield as the ratio of Lewis acid was increased. This behavior indicates that at least one complex is being formed between **1** and $SnCl_4$ in this solvent and that at −18°C there is rapid equilibrium between free and complexed **1** which leads to an averaging of the ^{1}H nmr spectrum.

The equilibrium constant for the reaction of $SnCl_4$ with **1** was estimated from a modified Benisi–Hildebrand plot, Fig. 1, as 31.5 (7). The linearity of this plot indicates that only one equilibrium is important at −18°C.

The ^{1}H nmr spectra of **1**/$SnCl_4$ mixtures exhibited a reversible temperature dependence, Table 1. As the temperature was lowered, two different types of behavior were noted, depending on whether the ratio of $SnCl_4$ to **1** was greater or less than 1. In cases where a molar excess of $SnCl_4$ was present, a downfield shift of the methyl resonance was observed as the temperature was lowered. In each case a limiting chemical shift was reached at δ 3.28, indicating essentially complete formation of the complex at the lower temperatures. With less than one molar equivalent of Lewis acid, two methyl group resonances were observed in the nmr spectra at low temperatures. For example, with a **1** to $SnCl_4$ ratio of 1:0.33 at −100°C, resonances at δ 3.31 and 2.39 were observed with a relative area of 1:2.5, respectively. The former resonance is very close to that observed above with more than a one molar equivalent of $SnCl_4$, whereas the latter resonance is attributable to free **1**. The area ratio of these two resonances corresponded to the formation of a 1:1 complex between biacetyl and $SnCl_4$. Clearly, at −100°C, exchange between free and complexed biacetyl is slow on the nmr time scale.

Taken together, these results strongly indicate that a 1:1 complex is formed between **1** and $SnCl_4$. The question arises as to the structure of this complex. Only one methyl group resonance is observed for the complex in its nmr spectrum at low temperatures. This could be taken to mean that a symmetrical bridged structure is formed or that there is a rapid equilibration between two mono-coordinated structures, eq. [2]. This exchange could be intramolecular, eq. [2], or proceed by an intermolecular process involving a nondissociative mechanism. The limiting downfield shift of the methyl resonances seen in the ^{1}H nmr spectrum of **1** on complexation with $SnCl_4$ in 0.98 ppm. This is a considerably greater shift than normally encountered on complexation of a methyl-substituted ketone with $SnCl_4$ and would possibly indicate that the bridged structure **3** is preferred.

[2] 
3

Attempts were made to remove a proton from the $SnCl_4$ complex of **1** by adding 2,6-di-*tert*-butylpyridine to the solutions. This base does not react with a Lewis acid such as $SnCl_4$ (8), but can form a salt with protic acids. From the ^{1}H nmr spectra of solutions of **1**/$SnCl_4$ containing 2,6-di-*tert*-butylpyridine, it was clear that some complex reaction(s) had taken place. It was not possible to identify any of the products of these reactions.

Cyclohexane-1,2-dione

It was again found necessary to use low temperatures in order to retard decomposition of the complexes of **2** and either $SnCl_4$ or $TiCl_4$. The ^{1}H nmr spectra of solutions of **2** and $TiCl_4$ were both concentration and temperature independent when the ratio of $TiCl_4$/**2** was equal to or greater than 1, Table 2. This suggests the formation of a 1:1 complex between **2** and $TiCl_4$, with a large equilibrium constant in favour of formation of the complex.

As cyclohexane-1,2-dione exists predominantly in its enol form **2***b*, there are two nonequivalent Lewis base sites available for complexation. From the changes in the ^{1}H nmr spectrum, it would appear that complexation has taken place at both the keto and enol oxygen atoms. Evidence for reaction at the former site comes from the large downfield shift of the vinyl proton reso-

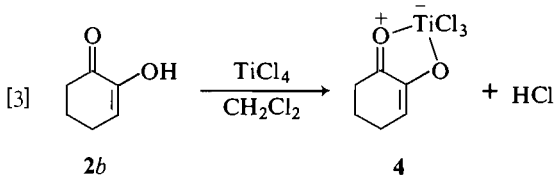
[a]Solvent CD_2Cl_2 for all complexes; $CDCl_3$ for **2** and **5** in absence of any Lewis acid. Reference for complexes $CHDCl_2$ taken as 5.30 ppm.

nance of **2***b* on complexation. The magnitude of this shift is that which would be expected for complexation of a normal enone with $TiCl_4$ (9).

The hydroxy proton signal that is present in the ^{1}H nmr spectrum of **2** disappeared when the dione was complexed with $TiCl_4$. A new peak was observed at much higher field (δ 1.2). The chemical shift of this signal was shifted downfield as the temperature was lowered. The disappearance of the OH resonance of the hydroxy group and the appearance of this new signal suggested that HCl had been evolved as the complex was formed. Further evidence for the presence of HCl was obtained by the addition of the hindered base 2,6-di-*tert*-butylpyridine to the nmr tube and the formation of the 2,6-di-*tert*-butylpyridinium cation. Addition of gaseous HCl to the nmr tube enhanced the intensity of the peak at δ 1.2, confirming that it was indeed attributable to HCl. Thus the reaction of 2*b* with $TiCl_4$ may occur as shown in eq. [3], although comparable intermolecular complexes involving bonding of the titanium to oxygens of two diketones cannot be ruled out. It is likely that the small amount of **2***a* in equilibrium with **2***b* is also converted to **4**.



2*b* **4**

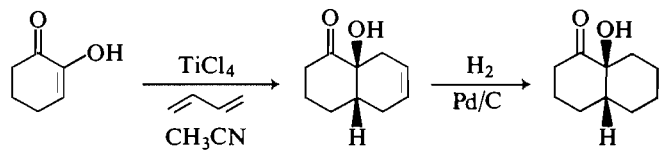
The reaction of **2** with $SnCl_4$ appears to be similar to that with $TiCl_4$ except that the loss of HCl is not complete. The complexation of the tin to the keto oxygen is indicated by the large downfield shift of the vinyl proton resonance. In addition, a broad concentration and temperature dependent signal at ca. δ 8.0 was observed, which was attributed to an OH resonance. This signal was absent at very low temperatures or in the presence of 2,6-di-*tert*-butylpyridine.

2-Methoxycyclohex-2-en-1-one, 5

The reaction of **5** with $SnCl_4$ and $TiCl_4$ was examined at −18°C. A considerable downfield shift of the vinyl proton resonance was observed with each Lewis acid, indicating that complexation had taken place at the keto oxygen, Table 2. In addition, the resonance associated with the methoxy group was also shifted downfield. This is suggestive that further complexation of the Lewis acid to the ether oxygen is occurring to some extent. No signals which could be attributed to the formation of HCl could be detected.

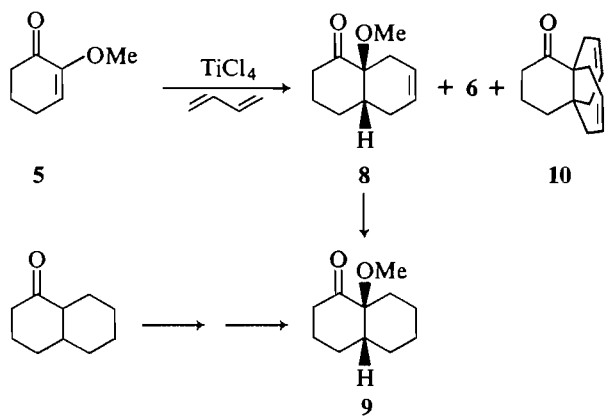
Addition reactions of complexes

Reactions of solutions of the above complexes with 1,3-butadiene were examined. Treatment of the $TiCl_4$ complex of **2** with butadiene and subsequent work-up gave a single product which appeared to have the structure **6** on the basis of its spectroscopic properties. This structural assignment was confirmed by catalytic hydrogenation of **6** to give **7**, a compound which has been previously described in the literature (10).



2 **6** **7**

The enol ether **5** reacted in a similar manner to **2** to give **8**. In addition to **8**, small amounts of **6** and a compound containing two butadiene residues were also isolated. Structural proof for **8** rests in its reduction to **9** and comparison of its properties to those of authentic material prepared by chlorination and methoxide displacement of 1-decalone and separation of the corresponding *cis* and *trans* isomers (10). The third component isolated from this reaction had a M^+ peak in its mass spectrum at *m/e* 202 and an elemental analysis corresponding to $C_{14}H_{18}O$. The ^{1}H nmr and ir spectra were consistent with the structure **10**, in which methanol has been lost from the original adduct **8** and a further butadiene added.



5 **8** **10**

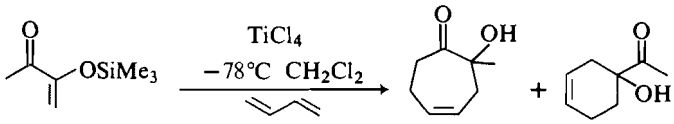
The trimethylsilyl ether of **2** also reacted with $TiCl_4$ and butadiene to give **6** in 40% yield. Sasaki *et al.* have reported a similar result (5).

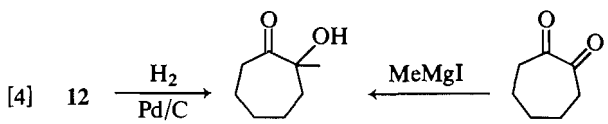
It would seem that all the products isolated in these reactions of **2** and its enol ethers with butadiene result from 4C + 2C cycloadditions. It should be noted that these 4 + 2 adducts would be expected to be more thermodynamically stable than the corresponding 4C + 3C adducts and that the two types of adduct can be formally interconverted by an acyloin rearrangement (11). In the absence of any materials corresponding to 4 + 3 adducts, it was not possible to test whether they would have survived the somewhat acidic reaction and work-up conditions.

As 2,3-butanedione did not form complexes which had an enol type structure, the reactions of the trimethylsilyl ether **11** with butadiene were investigated. With $TiCl_4$ as the Lewis acid, **11** reacted with butadiene to give the two isomeric products **12** and **13**, plus some uncharacterized high boiling material.

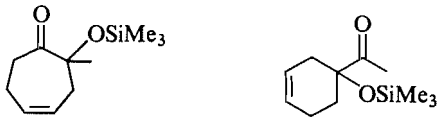


11 **12** **13**

Some difficulty was experienced in separating **12** and **13**, as **12** was relatively unstable and was converted to **13** when adsorbed on silica gel or at high temperatures on a glc column. Initial structural assignments for these materials were based on their spectroscopic properties. Infrared spectra indicated that both **12** and **13** were hydroxyketones; the ^1H nmr spectra showed that each compound had two vinyl protons, methylene protons and a methyl group. The signals of the latter protons were a singlet in each case and in characteristic positions for a methyl group on a saturated carbon, compound **12**, and adjacent to a carbonyl group, compound **13**. The structural assignment of **12** was confirmed by its reduction to **14** and subsequent independent synthesis of **14** from cycloheptan-1,2-dione, eq. [4].



In an attempt to improve the yield of **12** and **13**, a smaller excess of butadiene was used and moisture carefully excluded from the system. Under these conditions two additional products were detected. From both the ^1H nmr and ms of these products, it was clear that they were silyl ethers. Reaction of a mixture of **12** and **13** with trimethylsilylchloride and triethylamine gave two silyl ethers which were identical to the extra materials produced in the cycloaddition reaction. On this basis these additional products were identified as **15** and **16**.



15 **16**

With limited amounts of butadiene and using $SnCl_4$ as a catalyst, **11** reacted to give **15** and **16** together with dimers of **11**. Acid hydrolysis of the mixture afforded **12** and **13** in a 1 : 1.5 ratio. This latter result contrasts with the report of Sasaki *et al.* who reported **13** as the sole product. It is possible that, during the chromatography used by these workers, **12** rearranged to **13**.

It is interesting to note that Sasaki *et al.* observed the formation of a 7-membered ring compound in the reaction of the trimethylsilyl ether of the enol of pyruvaldehyde. It might well be that the acyloin rearrangement of these seven-membered ring hydroxyketones occurs less readily with the secondary alcohol resulting from this latter reaction than the tertiary alcohols produced in the reaction of biacetyl.

In conclusion, it should be emphasized that the Lewis acid catalysed cycloaddition reactions of α,β-unsaturated carbonyl compounds, observed here to form seven-membered rings, proceed by a 4C + 3C route. The seven-membered ring products have been shown to be thermodynamically less stable than the related six-membered ring products. This means that these seven-membered ring products can only be produced directly in the reaction and not by an initial formation of the six-membered ring and subsequent ring expansion. It is not known whether the formation of the seven-membered ring is a concerted reaction; however, it is clear that the presence of a strong electron-donating group at the α-carbon of an enone can divert the normal pattern of Lewis acid catalysed cycloadditions to a 4C + 3C cycloaddition.

Experimental

General

The ^1H nmr spectra were obtained on Varian EM 390 and Bruker WP 80 instruments. CD_2Cl_2 and $CDCl_3$ were dried over freshly activated 4 Å molecular sieves before use. CH_2Cl_2 and CH_3CN were distilled from P_2O_5 and stored over molecular sieves. The Lewis acids, $SnCl_4$ and $TiCl_4$, were distilled and stored in sealed glass ampules.

The following compounds were prepared by literature procedures: 3-(trimethylsiloxy)-but-3-en-2-one, **11**, (12); cycloheptan-1,2-dione (13); 2-methoxycyclohex-2-en-1-one, **5** (14). 2-(Trimethylsiloxy)-cyclohex-2-en-1-one was prepared by silylation of **2** in acetonitrile using a similar procedure to that given above for **11**. The ^1H nmr spectrum was identical to that given in the literature (15).

Preparation of nuclear magnetic resonance samples

These were prepared under dry nitrogen. The appropriate Lewis base was weighed into a dry nmr tube, solvent added, and the tube capped with a rubber septum cap. A measured volume of a Lewis acid was added to the cooled tube (−78°C) using a 10 μL syringe. The contents of the tube were mixed by tilting the tube. Samples were kept at −78°C until their nmr spectra were obtained.

Reaction of 2 with butadiene

Compound **2** (1.6 g) in CH_3CN (1 mL) was placed in a thick-walled glass tube. The tube was blanketed with argon, cooled to −78°C, and $TiCl_4$ (1.8 mL, 1.65×10^{-2} mol) added. The solution was warmed to 0°C, further CH_3CN (6 mL) added, and the tube cooled to −78°C before 1,3-butadiene (4 mL) was condensed into the tube. The tube was sealed and allowed to warm to 25°C for 14 h. The contents of the tube were added to a 1 : 1 mixture of ether and water (20 mL) and the acid neutralized with solid $NaHCO_3$. After removal of the solids by filtration through Celite, the organic material was extracted into ether (2 × 15 mL), the ether layer dried ($MgSO_4$), and ether removed *in vacuo* to give an oil. Vacuum transfer of the oil gave **6** (0.78 g, 35%); ir (film): 3490, 3030, 1715, 1070 cm^{-1}; ^1H nmr (CCl_4), δ: 1.5–2.7 (m, 11H), 3.8 (s, 1H), 5.7 (m, 2H); ms M^+: 166. *Anal.* calcd. for $C_{10}H_{14}O_2$: C 72.26, H 8.49; found: C 72.24, H 8.55%.

*Reaction of **5** with butadiene*

An exactly comparable procedure to that given above for **2** was used. The resulting oil (0.7 g) was separated by preparative glc (15% Carbowax on Chromosorb A) at 200°C to give three compounds, **8**, 58%; **6**, 12%; **10**, (12%), plus other unidentifed minor components. Properties of **8** (10): ir (film): 3020, 1720, 1080 cm^{-1}; ^1H nmr (CCl_4), δ: 1.6–2.6 (m, 11H), 3.4 (s, 3H), 5.8 (m, 2H); ms M^+ 180. Properties of **10**: ir: 3025, 1710 cm^{-1}; ^1H nmr (CCl_4), δ: 1.15–2.8 (m, 14H), 5.3–6.0 (m, 4H); ms M^+: 202. *Anal.* calcd. for $C_{14}H_{10}O$: C 83.12, H 8.97; found: C 83.26, H 9.03%.

*Reaction of 2-(trimethylsiloxy)-but-1-en-3-one **11** with butadiene*

(a) *Excess butadiene*

A solution of **11** (2 g) in dry CH_2Cl_2 (15 mL) was cooled to −78°C under a nitrogen atmosphere and 1,3-butadiene (ca 10 mL) condensed into the reaction flask. $TiCl_4$ (1.4 mL) was added and the reaction mixture stirred for 1 h at −78°C. The reaction mixture was poured into a 1:1 mixture of ether/ice water (150 mL) and neutralized by the addition of $NaHCO_3$. The crude product was isolated as described above and the resulting oil distilled (70–75°C, 4 Torr) to give a mixture of **12** and **13** (0.42 g, 24%) in a 1.1:1 ratio. The products were separated by preparative glc (5% OV-17 on Chromosorb W) at 75°C, to give **12**; ir (film): 3490, 3040, 1710, 1095 cm^{-1}; ^1H nmr (CCl_4), δ: 1.25 (s, 3H), 2.10–2.47 (m, 4H), 2.5–2.93 (m, 2H), 3.8 (s, 1H), 5.85 (m, 2H); ms M^+: 140. *Anal.* calcd. for $C_8H_{12}O_2$: C 68.55, H 8.63; found: C 68.56, H 8.60%.

The properties of **13** were: ir (film): 3480, 3035, 1710, 1090 cm^{-1}; ^1H nmr (CCl_4), δ: 1.5–2.7 (m, 6H), 2.2 (s, 3H), 3.2 (s, 1H), 5.65 (m, 2H); ms *m/e*: 122 ($M^+ - H_2O$). *Anal.* calcd. for $C_8H_{12}O_2$: C 68.55, H 8.63; found: C 68.83, H 8.66%.

(b) *Limited butadiene*

1,3-Butadiene (0.27 g) was transferred into a 100-mL round bottom flask, the flask cooled to −78°C under N_2, and dry CH_2Cl_2 (10 mL), **11** (0.52 g), and $TiCl_4$ (0.36 mL) added successively using dry syringes. The reaction was stirred at −78°C for 6 h and worked up as above. Analysis of the resulting mixture by glc–ms indicated four major components, **12**, **13**, and the silyl derivatives **15** (ms *m/e*: 197, 169, 143, 73) and **16** (ms *m/e*: 212, 197, 169, 143, 73) (16). The ^1H nmr of the mixture indicated the presence of trimethylsilyl groups (δ 0.09 and 0.07).

The above mixture (0.2 g) was treated with chlorotrimethylsilane (1.3 mL) and triethylamine (1.4 mL) in dry CH_2Cl_2 (5 mL) for 20 h. The resulting suspension was treated with pentane (5 mL) and the precipitate removed by filtration in a nitrogen atmosphere. The residue obtained after removing the solvent was distilled (100°C, 5 Torr) to give a mixture of **15** and **16** (0.236 g; 34% based on **11**). The products were separated by preparative glc (5% OV-17 on Chromosorb W) at 105°C, to give **15** (retention time 11.5 min); ^1H nmr (CCl_4), δ: 0.09 (s, 9H), 1.6–2.3 (m, 6H), 2.15 (s, 3H), 5.60 (m, 2H). Compound **16** (retention time 13.5 min), ^1H nmr (CCl_4), δ: 0.07 (s, 9H), 1.30 (s, 3H), 2.25–2.9 (m, 6H), 5.72 (m, 2H).

(c) *$SnCl_4$ catalyst*

The procedure (b) above was employed using $SnCl_4$ (0.38 mL) as the Lewis acid. The crude product was distilled (120°C, 3 Torr) to give an oil (0.19 g). The major components were identified as **15** and **16** by ^1H nmr and glc comparison with authentic materials, and (two) dimers of **11** by glc–ms analysis; each showed *m/e*: 316, 273, 231, 143, 73; M^+ calcd. for $C_{14}H_{28}O_4Si_2$: 316 (12).

The mixture obtained above was treated with 1 *N* HCl (1 mL) in methanol (5 mL) for 30 min at 25°C and poured onto ice-water containing $NaHCO_3$. The organic material was extracted into ether and the extracts were dried ($MgSO_4$). The ^1H nmr analysis of the oil obtained on removing the solvent indicated a mixture containing **12** and **13** in a 1:1.5 ratio according to the peak heights of the methyl resonances.

Reaction of 2-(trimethylsiloxy)-cyclohex-2-en-1-one with butadiene

A solution of butadiene (0.27 g) and 2-(trimethylsiloxy)-cyclohex-2-en-1-one (0.60 g, 3.3 mmol) in dry CH_2Cl_2 (10 mL) was treated with $TiCl_4$ (0.36 mL) as described in (b) above. The reaction mixture was allowed to warm up to room temperature, stirred for a further 20 h, and worked up as described above. The oil obtained after removing the solvent was distilled (3 Torr; Kugelrohr temperature 130°C) to give **6** (220 mg, 40%); ir and ^1H nmr spectra identical to those of authentic **6** described earlier.

*Hydrogenation of **6***

A solution of **6** (44 mg) in ethanol (1 mL) was hydrogenated (1 atm) over Pd/C at room temperature. After 18 h the catalyst was removed by filtration and the solvent was evaporated under reduced pressure. The crude product was vacuum transferred to give **6** (37 mg, 83%), mp 56–60°C (lit. (10) mp 61–64°C); ir: 3490 (br), 1710 cm^{-1}; ^1H nmr (CCl_4), δ: 0.9–2.0 (m, 13H), 2.4 (m, 2H), 3.6 (s, 1H).

*Hydrogenation of **12***

Compound **12** (114 mg, 0.8 mmol) was hydrogenated as described above for compound **6**. The crude product was distilled (120°C, 4 Torr) to give **14** (60 mg, 53%). Preparative glc (5% OV-17 on Chromosorb W) at 130°C afforded the analytical sample (retention time 2.5 min); ir (CCl_4): 3520, 3220, 2980, 2940, 2870, 1715, 1460, 1370, 1340, 1185, 1050, 950 cm^{-1}; ^1H nmr (CCl_4), δ: 1.25 (s, 3H), 1.25–2.22 (m, 8H), 2.37–2.70 (m, 2H), 3.50 (s, 1H) exchanges with D_2O; ms M^+ calcd. for $C_8H_{14}O_2$: 142.0094; found: 142.0964.

Reaction of cycloheptan-1,2-dione with methylmagnesium iodide

A solution of methylmagnesium iodide (2.32 mmol) in ether (7 mL) was added dropwise to a solution of crude cycloheptan-1,2-dione (0.59 g, ca 50% dione) in dry ether (5 mL) at 0°C. The reaction mixture was stirred at the same temperature under dry nitrogen for 1.5 h and poured into ice-cold ammonium chloride solution. The organic material was extracted into ether and the extracts were washed with brine and dried ($MgSO_4$). The residue obtained after removing the solvent under reduced pressure was distilled (4 Torr; Kugelrohr temperature 140°C) and the resultant oil was subjected to preparative glc (5% OV-17 on Chromosorb W) at 125°C. Collection of the fraction with retention time 3.7 min afforded **14**; properties (retention time, ir spectrum, ^1H nmr spectrum) identical to those of the hydrogenation product of compound **12**.

Hydroxyacetals, phthalans, and isobenzofurans therefrom

BRIAN A. KEAY, HEINZ P. PLAUMANN, DAYANANDA RAJAPAKSA, AND RUSSELL RODRIGO
Guelph–Waterloo Centre for Graduate Work in Chemistry, Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received January 31, 1983

BRIAN A. KEAY, HEINZ P. PLAUMANN, DAYANANDA RAJAPAKSA, and RUSSELL RODRIGO. Can. J. Chem. **61**, 1987 (1983).

A general method for the generation of isobenzofuran intermediates is described. Lithiated aromatic acetals are converted to hydroxyacetals (A) which may be cyclized to isobenzofurans by mild acid treatment through the 1-hydroxyphthalans (B). The isobenzofurans generated *in situ* are trapped by a variety of dienophiles to provide the expected oxo-bicyclo adducts (C). The mass and ^{1}Hmr spectra of B and C are discussed.

BRIAN A. KEAY, HEINZ P. PLAUMANN, DAYANANDA RAJAPAKSA et RUSSELL RODRIGO. Can. J. Chem. **61**, 1987 (1983).

On décrit une méthode générale de production des intermédiaires de l'isobenzofuranne. On transforme les acétals aromatiques lithiés en hydroxyacétals (A) que l'on peut cycliser en isobenzofurannes via les hydroxy-1 phtalanes (B) en présence d'un acide dans des conditions douces. On piège les isobenzofurannes générés *in situ* avec divers diénophiles pour obtenir les adduits oxo-bicyclo attendus (C). On discute des spectres de masse et de rmn du ^{1}H des composés B et C.

The benzo[*c*]furan system, trivially called isobenzofuran (ISB), has been known (1) since 1964. In the following years, many methods were developed for the production of isobenzofurans, most of them involving retro Diels–Alder reactions of various precursors (2) and culminating in the isolation (3) of the parent benzo[*c*]furan as an unstable solid very prone to polymerization. Several theoretical calculations (2) suggest that the molecule is nonaromatic but the appearance of furanoid protons at δ 8.40 in the ^{1}Hmr spectrum of ISB implies (3) the presence of a significant ring current. The reactivity of isobenzofurans as dienes in the Diels–Alder reaction, however, is extremely well documented (2) and their widespread application[1] to the construction of aromatic and hydroaromatic natural products has hitherto been limited only by the lack of versatile methods of ISB synthesis. Syntheses not entailing Diels–Alder reversions have been reported (5) in recent years and the consequent enhancement in synthetic versatility has led to many applications of inter (6) and intramolecular (7) Diels–Alder reactions of ISB's in natural product synthesis. In this report we discuss some of our recent work on the generation of a variety of ISB's and their reactions with many common dienophiles.

The aromatic acetal route we have employed is generalized in Scheme 1. It is a "one-pot" process, although phthalans (B) and even isobenzofurans[2] may be isolated in some instances.

Preparation of hydroxyacetals (A)

Many acetals (and ketals), incorporating a variety of substituents differing in number, type, and position, were prepared. The most convenient route, also the simplest, begins with a bromoaldehyde which is converted to its dimethyl acetal (with trimethylorthoformate and Dowex 50 W-X2 resin in refluxing methanol), lithiated by halogen–lithium exchange, and reacted with formaldehyde or an aromatic aldehyde (A**1**–A**5**).

Alternatively, direct *ortho*-deprotonation (8) of aromatic acetals, followed by treatment of the ensuing *ortho*-lithio species with nonenolizable aldehydes, provides a series of contiguously substituted hydroxyacetals (A**6**–A**8**). A major shortcoming of these preparations is that the aryl lithium species is readily protonated by enolizable aldehydes or ketones, thus precluding the use of most aliphatic aldehydes and limiting the R^1 substituent to H or aryl.

One solution to this problem is to start with a bromoketal instead, and to carry out the same sequence of reactions. Thus, hydroxyketals A**9**–A**11** are obtained by halogen–lithium exchange from the corresponding bromoketal and reaction with formaldehyde (A**9**, A**10**) or piperonal (A**11**). Compounds A**9** and A**10** are precursors of 1-methyl isobenzofurans and in general this route will provide 1,3-dialkyl (or 1,3-alkyl aryl)

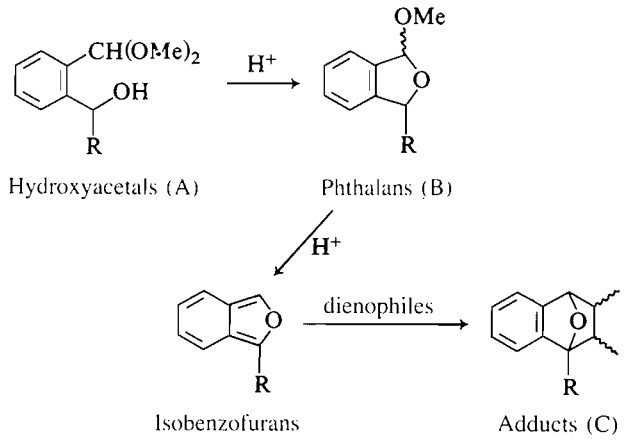
[1]One exception has been the use of an isobenzofuran intermediate in the synthesis of an anthracyclinone (see ref. 4).
[2]D. Rajapaksa and R. Rodrigo. Unpublished results.



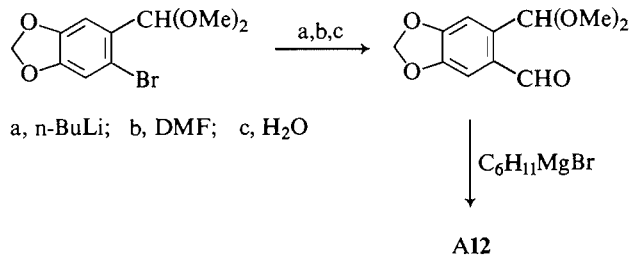
SCHEME 1

isobenzofurans.

In the course of our work we have made the fortuitous discovery that carbinolamines arising from the capture of lithiated acetals by dimethyl formamide can be selectively hydrolysed without affecting the acetal moiety to provide *ortho* formyl acetals. Thus hydroxyacetal A**12** was prepared from the 6-bromo dimethyl acetal of piperonal as illustrated in Scheme 2.

The success of this Grignard route provides another avenue of access to such hydroxyacetals (R^1 = alkyl) previously prepared by the ketal method. Furthermore, the potential of the Grignard and bromoketal technologies for assembling complex fragments, in preparation for intramolecular Diels–Alder reactions, is obvious. Investigations concerned with the synthesis of condensed hydroaromatic systems by these methods are in progress.

All but two (A**4** and A**8**) of these hydroxyacetals are oils that



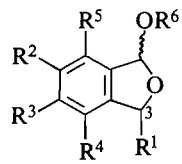
SCHEME 2

provided spectroscopic data consistent with their structures but resisted crystallization. They were used without further purification for the generation of isobenzofurans according to Scheme 1.

The mass spectra of these compounds are characterized by the presence of prominent ions resulting from sequential elimination of two molecules of methanol from the parent ion ($M - 32$, $M - 64$); an ion corresponding to loss of methanol and a methoxy radical ($M - 63$) is also found in the spectra.

Phthalans (B)

The 1-methoxy (or hydroxy) phthalans formed by mild acid treatment of the hydroxyacetals are easily detectable by ^{1}Hmr spectroscopy. Some were isolated and characterized (B**2**, B**5**, B**6**, B**7**, B**8**, B**13**, and B**14**). The known 1-hydroxyphthalan B**14** was prepared by reduction of the corresponding phthalide as previously reported (9). This is not a general route to hydroxyphthalans, however; its success depends on the presence of "peri" substituents (R4, R5 ≠ H) in the benzene ring. They prevent the ring opening and thereby forestall the further reduction of the masked aldehyde initially formed. A similar explanation has been advanced (10) for reactions where one mole of a Grignard reagent adds to certain peri-substituted phthalides to form hydroxyphthalans. The related 1-methoxyphthalan



B**2** $R^2 + R^3 = OCH_2O$, R^1 = 3,4-methylenedioxyphenyl, $R^4 = R^5 = R^6 = H$
B**5** $R^2 = R^3 = OCH_3$, $R^1 = R^4 = R^5 = H$, R^6 = Me
B**6** $R^3 + R^4 = OCH_2O$, R^1 = 3,4-methylenedioxyphenyl, $R^2 = R^5 = H$, R^6 = Me
B**7** $R^2 = R^3 = R^4$ = OMe, R^1 = 3,4,5-trimethoxyphenyl, $R^5 = H$, R^6 = Me
B**8** $R^3 = R^4$ = OMe, $R^1 = R^2 = R^5 = H$, R^6 = Me
B**13** $R^4 = R^5$ = OMe, $R^1 = R^2 = R^3 = H$, R^6 = Me
B**14** $R^4 = R^5$ = OMe, $R^1 = R^2 = R^3 = R^6 = H$

B**13** was also prepared by a more direct route from 2,5-dimethoxybenzyl alcohol. Lithiation (11) of its vinyl ether and treatment and dimethylformamide provided a hydroxyacetal equivalent A**13** which, upon successive treatment with methanolic mercuric acetate and methanolic *p*-toluene sulfonic acid, gave B**13**.

Phthalans show substantial long-range coupling between protons at C-1 and C-3. It has been suggested that this is a "dual pathway" interaction ($^4J + {}^3J$) and its magnitude in several variants of 2,5-dihydrofurans has been related (12) to conformational factors. Our phthalans all possess a C-1 oxygen substituent and in every instance we have observed that $J_{1,3}$ (*trans*) is ≈2.4 Hz while $J_{1,3}$ (*cis*) ≈ 0 Hz. Although such a distinct stereochemical dependence of 1,3 coupling has not been previously reported for oxygen-substituted phthalans, similar drastic decreases in the 1,3 *cis* coupling constants of 2,5-dihydrofurans have been noted and correlated (12) with the electronic effects of a 2-oxygen substituent in the latter compounds. It thus appears that in 1- or 3-oxygenated phthalans the magnitude of the long-range ($J_{1,3}$) coupling is stereochemically diagnostic. In all our phthalans where *cis* and *trans* stereoisomers can exist we find that ring closure of the acyclic precursors takes place approximately equally in either direction to produce a 1:1 mixture of *cis* and *trans* isomers. Signals of H-1 and H-3 of both isomers are visible in the ^{1}Hmr spectrum in approximately equal intensities. The isomers must be of about

equal stability because the 1 : 1 proportion is unaffected by the duration of acid exposure in the cyclization.

The Diels–Alder reaction and formation of adducts (C)

The Diels–Alder reactions of ISB precursors A and B were studied in two ways. In the first instance almost all precursors were reacted with dimethyl acetylenedicarboxylate in the presence of a catalytic quantity of glacial acetic acid at steam bath temperatures. With this combination of reactants both regiochemical and stereochemical problems were avoided for the time being. The bridged adducts were isolated in good yields after crystallization from ether. In a few cases care had to be taken to prevent aromatization to the naphthol. Thus adducts **C1**, **C2**, and **C4** (Table 1) were very prone to aromatization and careful control of time (25–30 min) and temperature (95–100°C) was necessary. Under these conditions the Diels–Alder reaction remains incomplete and acceptable yields of these compounds were only obtained after recycling mother liquors remaining from crystallization of the adducts. Adducts **C3** and **C10** resisted crystallization but could be converted to the crystalline naphthols D**3** and D**10** by further acid treatment. Adduct **C7** could not be obtained under any conditions. It appears that the peri-methoxy group (R_4 = OMe) hinders ISB formation below 130°C. At this temperature **C7** is rapidly isomerized to D**7**, the isolated product.

In a second study, a symmetrical ISB precursor A**5** (or B**5**) was subjected to Diels–Alder additions with a variety of dienophiles (Table 2). Regiochemical complications were thus circumvented but in every case mixtures of *endo–exo* products were isolated in good to excellent yields. *endo* Isomers generally predominated except in the case of the 2-butenolide adduct (entry 4). *endo* Isomers were crystallized from the mixture in some cases (entries 2, 5, and 8) while in others the adducts were separated by a combination of chromatography and fractional crystallization. *endo–exo* Ratios were easily estimated by ^{1}Hmr spectroscopy, aided by spectra of pure isomers where available. To illustrate the use of ^{1}Hmr spectroscopy for this purpose, a tabulation and brief discussion of the spectra of pure *exo* and *endo* C**5***i* (entry 9, Table 2) is presented below (Table 3).

Differences between the spectra of *exo* and *endo* isomers observed here are typical of all the adducts and are easily detected and explained. In the *exo* isomers bridgehead protons (H-1) are singlets; H-4 is coupled only to the β-proton at C-3 and thus appears as a doublet in both isomers. These protons are rigidly held in a plane approximating that of the adjacent benzene ring and are consequently subject to its deshielding influence. Thus H-1 and H-4 signals are both around δ 5.5 but with differing coupling patterns in the two isomers. No "phthalan-type" long range coupling was found between these two protons, however, even though the rigidity of the molecule ensures a favourable "W" pathway. Further differences between the two spectra can also be associated with the disposition of the C-2 substituent. A significant variation is found in H-9 (aldehyde proton) and H-2 resonances, an obvious consequence of differential shielding by the benzene ring. Such shielding also affects the 3α protons in both isomers making $\Delta\nu(3\alpha,3\beta)$ relatively large and thus simplifying the spectra. Slight, but consistent, differences in the absorptions of aromatic protons and substituents between *exo* and *endo* isomers are seen in all adducts. Again, it is the C-2 substituent in the *endo* configuration only that is responsible for the nonequivalence of the observed chemical shifts. All assignments and coupling constants were secured by decoupling experiments and 400 MHz spectra where necessary.

The mass spectra of all adducts were characterized by the presence of a very intense ion corresponding to a retro Diels–Alder fission of the molecular ion. This ion, the base peak in all spectra, corresponds to 5,6-dimethoxy isobenzofuran. Charge localization on the "dienophile" is also observed in many cases. The ISB ion (common at *m/z* 178 in all examples of **C5**) shows subsequent extrusions of CO, CH_3, CO, and CH_2O represented by ions at 150, 135, 107, and 77 mass units respectively. A minor decomposition pathway in all **C5** cases (except **C5***f*) involves dehydration to a naphthalene represented by an ion at $M - 18$ ($M - 19$ in 2-deutero examples).

Adducts substituted at a bridgehead position by an aryl group (e.g. **C1**–**C4**, **C6**, **C7**) were easily aromatized to the corresponding naphthols (6, 7).

Experimental

General methods

Melting point determinations were made using a Buchi SMP-20 apparatus and are uncorrected. Infrared spectra were obtained on Beckman Model IR-10 or on Acculab 10 spectrophotometers. Nuclear magnetic resonance spectra were obtained on either a Varian T-60, Perkin–Elmer R12-B, Bruker WP-80, or Bruker WH-400 spectrophotometer. Samples were run in $CDCl_3$ solutions containing tetramethylsilane as an internal standard. Low and high resolution mass spectra were measured on a Varian VG Organic 7070F mass spectrometer. Flash column chromatography was performed using Merck 0.063–0.200 mm (70–230 mesh) silica gel 60 which was packed dry into glass columns and eluted with benzene–acetone (4:1) unless otherwise noted. Combustion analyses were performed by Guelph Chemical Laboratories, Guelph, Ontario and/or Canadian Microanalytical Service Ltd, Vancouver, British Columbia.

General method for preparing benzaldehydedimethyl acetals

A stirred mixture of the benzaldehyde (0.1 mol), trimethylorthoformate (0.3 mol), absolute methanol (150 mL), and Dowex 50W-X8 acid exchange resin was refluxed for 20 h. The solution was cooled, filtered, and evporated *in vacuo*. The residual oil was distilled *in vacuo* providing the acetal in pure form.

General lithium–halogen exchange procedure (A1–A5, A9–A11)

A stirred solution of the bromoacetal and dry diethyl ether (15 mL) was cooled to −78°C under N_2. n-BuLi (1.1 equiv./ mol of acetal) was added dropwise and the resulting precipitate stirred for 0.5 h before being treated with the appropriate electrophilic reagent. Increasing the scale of the reaction to 30 mmol did not noticeably affect the yields.

6-Formyl piperonal dimethyl acetal

6-Bromopiperonal dimethyl acetal (6.08 g, 22.1 mmol) was lithiated as previously described and treated with excess of dry dimethylformamide (10 g, 137 mmol) at −78°C. The reaction mixture was allowed to warm up to room temperature during 2 h and quenched with H_2O. The ether layer was separated, the aqueous layer extracted with ether (2 × 50 mL), and the combined ether extracts washed with

For personal use only.

a saturated solution of NaCl and dried (Na_2SO_4). Evaporation of solvent gave crystalline 6-formyl piperonal dimethylacetal (4.05 g, 82%) which was recrystallized from ether–hexane, mp 80°C; ir ($CHCl_3$): 1670 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz), δ 3.40 (s, 6H, 2 OMe), 5.85 (s, 1H, C*H*$(OMe)_2$), 6.08 (s, 2H, OCH_2O), 7.18, 7.40 (s, 1H each, Ar), 10.30 (s, 1H, CHO); mass spectrum, *m/z* (assignment): 224 (M^+), 209 ($M^+ - CH_3$) 194 ($M^+ - 2\ CH_3$), 193 ($M^+ - OCH_3$). *Anal.* calcd. for $C_{11}H_{12}O_5$: C 58.92, H 5.35; found: C 58.96, H 5.26.

*Compound A***1**

6-Bromo-3,4-dimethoxybenzaldehyde dimethyl acetal (5.0 g, 17.2 mmol) was lithiated as previously described. To the stirred suspension was added a solution of piperonal (2.8 g, 18.7 mmol) and dry diethyl ether (50 mL) via a pressure-equalizing dropping funnel. The mixture was stirred for 0.5 h, poured into H_2O (50 mL), and extracted with ether (2 × 50 mL). The extract was dried (Na_2SO_4) and evaporated *in vacuo*. This afforded a light oil (16.6 g, 95%) which was not purified further; ir (neat): 3450 (OH) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz), δ: 3.23 (s, 6H, —CH$(OCH_3)_2$), 3.37 (d, 1H, —OH, J = 4 Hz, exchangeable with D_2O), 3.85, 4.18 (s, 3H each, 2 × OCH_3), 5.40 (s, 1H, C*H*$(OCH_3)_2$), 5.87 (s, 2H, —OCH_2O—), 5.97 (d, 1H, —C*H*OH, J = 4 Hz, collapses to a singlet after D_2O), 6.63–6.90 (m, 4H, Ar), 7.05 (s, 1H, Ar); mass spectrum, *m/z* (assignment): 362 (M^+), 330 ($M^+ - CH_3OH$), 299 ($M^+ - CH_3OH - CH_3O$), 298 ($M^+ - 2CH_3OH$).

*Compound A***2**

6-Bromo-3,4-methylenedioxybenzaldehydedimethyl acetal (5.0 g, 18.2 mmol) was lithiated and treated with piperonal (2.87 g, 19.1 mmol) as previously described. Work-up was similar to that of A**1** and afforded an oil (6.0 g, 95%) which was not purified further; ir (neat): 3420 (OH) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz) δ: 3.21 (s, 6H, 2 × OCH_3), 3.45 (br, 1H, OH, exchangeable with D_2O), 5.37 (s, 1H, C*H*$(OCH_3)_2$), 5.87 (s, 4H, 2 × —OCH_2O—), 5.96 (br, 1H, —C*H*OH, sharpens with D_2O,) 6.66–6.95 (m, 3H, Ar), 6.75, 7.02 (s, 1H, each, Ar); mass spectrum, *m/z* (assignment): 346 (M^+), 314 ($M^+ - CH_3OH$), 283 ($M^+ - CH_3OH - CH_3O$), 282 ($M^+ - 2CH_3OH$).

*Compound A***3**

6-Bromo-3,4-methylenedioxybenzaldehydedimethyl acetal (5.0 g, 18.2 mmol) was lithiated and treated with veratraldehyde (3.15 g, 1.90 mmol). Work-up as described gave A**3** as an oil (6.0 g, 91%) which was not purified further; ir (neat): 3520 (OH) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz), δ: 3.25 (s, 6H, CH$(OCH_3)_2$), 3.50 (d, 1H, OH, J = 4.2 Hz, disappears with D_2O), 3.91 (s, 6H, 2 × OCH_3), 5.42 (s, 1H, C*H*$(OCH_3)_2$, 5.95 (s, 2H, —OCH_2O—), 6.1 (d, 1H, J = 4.2 Hz, collapses to a singlet with D_2O), 6.7–7.2 (m, 5H, Ar); mass spectrum, *m/z* (assignment): 362 (M^+), 330 ($M^+ - CH_3OH$), 299 ($M^+ - CH_3OH - CH_3O$), 298 ($M^+ - 2CH_3OH$).

*Compound A***4**

Treatment of lithiated 6-bromo-3,4-methylenedioxybenzaldehydedimethyl acetal (3.0 g, 10.9 mmol) with 3,4,5-trimethoxybenzaldehyde (2.3 g, 11.7 mmol) gave A**4** as an oil (4.0 g, 93%) which later crystallized from diethyl ether; mp 111–112.5°C; ^{1}Hmr ($CDCl_3$, 60 MHz), δ: 3.22, 3.30 (s, 3H each, CH$(OCH_3)_2$), 3.77 (s, 9H, —OCH_3), 3.6 (d, 1H, OH, disappears with D_2O), 5.41 (s, 1H, —C*H*$(OCH_3)_2$), 5.80 (s, 2H, —OCH_2O—), 6.01 (d, 1H, —C*H*OH, collapses to a singlet with D_2O), 6.55 (s, 2H, Ar), 6.63, 6.95 (s, 1H each, Ar); mass spectrum, *m/z* (assignment): 392 (M^+), 360 ($M^+ - CH_3OH$), 329 ($M^+ - CH_3OH - CH_3O$), 328 ($M^+ - 2CH_3OH$); hrms calcd. for $C_{20}H_{24}O_8$: 392.1471; found: 392.1414. *Anal.* calcd. for $C_{20}H_{24}O_8$: C 61.21, H 6.17; found: C 61.01, H 6.41.

*Compound A***5**

6-Bromo-3,4-dimethoxybenzaldehydedimethyl acetal (5.4 g) was lithiated and treated with anhydrous formaldehyde gas. The latter was generated by pyrolyzing paraformaldehyde (6 g) with a hot air gun and the resulting gas passed, in a stream of drynitrogen, over a boat of anhydrous $CaCl_2$ and into the lithiated solution. The mixture was stirred for 1 h at room temperature and poured into H_2O (50 mL). The ether layer was separated, dried (Na_2SO_4), and the ether removed *in vacuo* to leave an oil (95%) which resisted crystallization; ^{1}Hmr ($CDCl_3$, 80 MHz) δ: 3.01 (t, 1, OH, disappears with D_2O), 3.35 (s, 6H, —CH$(OCH_3)_2$, 3.85 (s, 6H, 2 × OCH_3), 4.59 (d, 2H, O—C*H*$_2$OH, collapses to a singlet in D_2O), 5.41 (s, 1H, —C*H*$(OCH_3)_2$), 6.82, 7.00 (s, 1H each, Ar); mass spectrum, *m/z* (assignment): 242 (M^+), 210 ($M^+ - CH_3OH$).

*Compound A***7**

2-Bromo-3,4,5-trimethoxybenzaldehydedimethyl acetal (1.46 g, 4.5 mmol) was lithiated and previously described. To the stirred suspension was added a solution of 3,4,5-trimethoxybenzaldehyde (0.891 g, 4.56 mmol) in dry ether (50 mL). Work-up as previously described gave A**7** as an oil (1.9 g, 95.6%), ir (neat): 3450 (OH) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz), δ: 3.27, 3.29, 3.50, 3.74, 3.79, 3.80, 3.81, 3.83 (all s, 3H each, 8 OMe groups), 3.98 (d, 1H, OH, exchangeable with D_2O), 5.30 (s, 1H, C*H*$(OMe)_2$), 6.1 (d, 1H, C*H*OH, J = 10.7 Hz), 6.55, 6.56, 6.96 (all s, 1H each, Ar), mass spectrum, *m/z* (assignment): 438 (M^+), 406 ($M^+ - CH_3OH$), 375 ($M^+ - CH_3OH - CH_3O$), 374 ($M^+ - 2CH_3OH$).

General lithiation procedure for piperonal and veratraldehyde dimethyl acetals

A stirred solution of the acetal and dry diethyl ether (15 mL), under N_2, was cooled to 0°C and treated with n-BuLi (1.1 equiv./mole of acetal). After 1 h the mixture was treated with the appropriate electrophilic reagent.

*Compound A***6**

Veratraldehyde dimethyl acetal (2.07 g; 9.76 mmol) was lithiated and treated dropwise with an ethereal solution of piperonal (1.46 g, 9.8 mmol in 50 mL) at −78°C. It was allowed to warm up to room temperature. Work-up similar to that of A**1** afforded an oil (3.35 g, 95%) which was used in the Diels–Alder reaction without further purification; ir (neat): 3450 (OH) cm^{-1}; Hmr ($CDCl_3$, 80 MHz), δ: 3.23 (s, 6H, 2 acetal OCH_3), 3.52 (s, 3H, OCH_3), 3.80 (s, 3H, OCH_3), 4.2 (d, 1H, OH, J = 10 Hz, exchangeable with D_2O), 5.2 (s, 1H, C*H*$(OMe)_2$), 5.85 (s, 2H, —OCH_2O), 6.13 (d, 1H, C*H*OH, J = 10 Hz), 6.65–7.35 (m, 5H, Ar); mass spectrum, *m/z* (assignment): 362 (M^+), 331 ($M^+ - CH_3O$), 330 ($M^+ - CH_3OH$), 299 ($M^+ - CH_3OH - CH_3O$), 298 ($M^+ - 2CH_3OH$).

*Compound A***8**

Veratraldehyde dimethyl acetal (2.5 g) was lithiated and treated with gaseous formaldehyde as per A**5**. Similar work-up gave a white amorphous solid which later crystallized from ether (2.7 g, 95%); mp 54–56°C; ir ($CHCl_3$): 3420 (OH) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz), δ: 3.0 (t, 1H, OH, disappears with D_2O), 3.35 (s, 6H, —CH$(OCH_3)_2$), 3.81 (s, 6H, 2 × OCH_3), 4.70 (d, 2H, C*H*$_2$OH), collapses to a singlet with D_2O), 5.32 (s, 1H, —CH$(OCH_3)_2$), 6.65 and 7.07 (ABq, 1H each, J_{ortho} = 8.1 Hz, Ar); mass spectrum, *m/z* (assignment): 242 (M^+), 210 ($M^+ - CH_3OH$). *Anal.* calcd. for $C_{12}H_{18}O_5$: C 59.49, H 7.49; found: C 59.22, H 7.78.

*Compound A***9**

6-Bromo-3,4-dimethoxyacetophenonedimethyl ketal (2.0 g) was lithiated and treated with formaldehyde gas (6 g of paraformaldehyde) as previously described. Similar work-up afforded an oil (86%) which resisted crystallization; ir (neat): 3450 (OH) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz), δ: 1.60 (s, 3H,—CH_3), 3.2 (s, 1 1H, OH, disappears with D_2O), 3.29 (s, 6H, —C$(OCH_3)_2$)CH_3), 3.90 (s, 6H, 2 × OCH_3), 4.61 (s, 2H, —C*H*$_2$O), 6.93, 7.07 (s, 1H each, Ar); mass spectrum, *m/z* (assignment): 256 (M^+), 225 ($M^+ - CH_3O$).

*Compound A***10**

6-Bromo-3,4-methylenedioxyacetophenonedimethyl ketal (1 g) was lithiated and treated with formaldehyde gas (3 g of paraformaldehyde) as previously described. Similar work-up gave an oil (72%) which resisted crystallization; ir (neat): 3460 (OH) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz), δ: 1.58 (s, 3H,—CH_3), 3.0 (t, 1H, —OH, disappears with D_2O), 3.29 (s, 6H, —C$(OCH_3)CH_3$), 4.56 (d, 2H, —CH_2OH, collapses to a singlet with D_2O), 5.96 (s, 2H, —OCH_2O—), 6.88, 7.01 (s, 1H each, Ar); mass spectrum, *m/z* (assignment): 240 (M^+), 209 ($M^+ - CH_3O$).

Compound A**11**

6-Bromo-3,4-dimethoxyacetophenonedimethyl ketal (0.434 g, 1.42 mmol) was lithiated and treated with a solution of piperonal (0.213 g, 1.42 mmol) in dry ether at −78°C. The reaction mixture was allowed to warm up to room temperature, and worked up as in A**7** to give A**11** as an oil (0.485 g, 91%); ir (neat): 3450 (OH) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz), δ: 1.52 (s, 3H, Me), 3.15 3.28, 3.76 (s, 3H each, 3MeO), 3,9 (s and overlapping m, 4H, MeO and OH), 5.94 (s, 2H, OCH_2O), 6.27 (d, 1H, C*H*OH, J = 4.49 Hz, collapses to a singlet with D_20), 6.79−6.89 (m, 4H, Ar), 7.06 (s, 1H, Ar); mass spectrum, m/z (assignment): 312 ($M^+ - 2CH_3OH$).

*Compound A***12**

Bromocyclohexane (2.04 g, 10 mmol) was added dropwise under N_2 from a syringe, while stirring, to Mg turnings (0.31 g, 12.5 mmol) in dry ether (50 mL) so that the ether refluxes gently. Stirring continued for 1 h at room temperature. A solution of 6-formylpiperonal dimethyl acetal (2.24 g, 10 mmol) in ether (50 mL) was added from a dropping funnel to the ice-cold solution. The ice bath was removed and stirring at room temperature continued for 2 hours. The resulting solution was decanted from Mg and a saturated NH_4Cl solution added. It was extracted with ether (3 × 50 mL) and the combined ether extracts washed with water (50 mL) and dried (Na_2SO_4). Removal of solvent afforded A**12** as an oil (2.98 g, 97%) which was used without further purification, ir: 3450 (OH) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz) δ: 0.9−2.5 (m, 11H, C_6H_{11}) 3.3 (s, 6H, 2 MeO) 4.58 (d, 1, C*H*—OH, collapses to a singlet with D_2O), 5.5 (s, 1H, C*H*$(OMe)_2$), 5.95 (s, 2H, OCH_2O) 6.95, 7.06 (s, 1H each, Ar); mass spectrum, m/z (assignment): 277 ($M^+ - CH_3OH$), 276 ($M^+ - CH_3OH$), 245 ($M^+ - CH_3OH - CH_3O$), 244 ($M^+ - 2CH_3OH$), 193 ($M^+ - CH_3OH - C_6H_{11}$).

*Compound A***13**

2,5-Dimethoxybenzyl vinyl ether (5.0 g, 25.7 mmol) was lithiated with n-BuLi (2 equiv.) at 0°C in anhydrous pentane (150 mL, distilled over CaH_2) for 6 h, under nitrogen. The flask was placed in the freezer for 6 h to allow the solid lithio derivative to sediment. The pentane was then syringed out and dry diethyl ether (100 mL) added at 0°C. Once the anion dissolved, dry DMF (5 mL, distilled *in vacuo* from CaH_2 into NaH) was added slowly, not allowing the temperature to rise above 0°C. After 12 h at room temperature, the solution was poured in H_2O (50 mL) and washed with saturated brine solution (3 × 50 mL). The ether was dried (Na_2SO_4) and removed *in vacuo* to leave an oil. Repeated crystallizations from ether afforded 0.8 g of A**13**. Final distillation of the mother liquor (120−140°C/0.01 Torr) afforded another 0.8 g (total yield: 30%), mp 82−83°C; bp 120−124°C/0.01 Torr; ir (KBr): 1695(CHO), 1625 (C=C) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz), δ: 3.83, 3.87 (s, 3H each, 2 × OCH_3), 4.04 (dd, 1H, J_{gem} = 2.0, J_{cis} = 6.8 Hz, vinyl H), 4.30 (dd, 1H, J_{gem} = 2.0, J_{trans} = 14.1 Hz, vinyl H), 5.12 (s, 2H, —CH_2O—), 6.55 (dd, 1H, J_{cis} 6.8, J_{trans} = 14.1 Hz,—OC*H*CH_2), 7.12 and 6.95 (ABq, 1H each, J_{ortho} = 8.2 Hz, Ar), 10.55 (s, 1H, —CHO); mass spectrum, m/z: 222 (M^+), 179 ($M^+ - OCHCH_2$): *Anal.* calcd. for $C_{12}H_{14}O_4$: C 64.86, H 6.35; found: C 64.64, H 6.09.

*Compound B***2**

The hydroxyacetal A**2** (7.0 g) was dissolved in degassed 1,2-dimethoxyethane (70 mL) and H_2O (50 mL) was added. The mixture was stirred for 24 h under N_2. The resulting white precipitate (a mixture of *cis* and *trans*, a mixture of steroisomers) was filtered and washed with diethyl ether (72%); mp 151−152°C (scaled tube); ^{1}Hmr ($CDCl_3$, 60 MHZ), δ: 5.8−6.11 (m, 5H, 2 × OCH_2O—, C(3)H), 6.35, 6.50 (s, 1H each, *cis* and *trans* C(1)H), 6.8−7.1 (m, 5H, Ar); hrms calcd. for $C_{16}H_{12}O_6$: 300.0634; found: 300.0598. *Anal.* calcd. for $C_{16}H_{12}O_6$: C 64.00, H 4.03; found: C 64.17, H 3.99.

*Compound B***5**

The hydroxyacetal A**5** (1.0 g) was placed in methanol (5 mL) and 2 *N* HCl (3 mL) added. After stirring for 8 h at room temperature, the methanol was removed *in vacuo* and the resulting oil extracted with $CHCl_3$ (3 × 10 mL). Drying (Na_2SO_4) and removal of $CHCl_3$ afforded an oil (92%) which resisted crystallization; ^{1}Hmr ($CDCl_3$, 80 MHz), δ: 3.38 (s, 3H, C(1)—OCH_3), 3.86, 3.87 (s, 3H each, 2 × OCH_3), 4.93 (d, 1H, J_{gem} = 12.0 Hz, C(3)H), 5.16 (dd, 1H, J_{gem} = 12.0, $J_{1,3\,trans}$ = 2.2 Hz, C(3)H), 6.13 (d, 1H, $J_{1,3\,trans}$ = 2.2 Hz, C(1)H), 6.75, 6.88 (s, 1H each, Ar); mass spectrum, m/z (assignment): 210 (M^+), 179 ($M^+ - CH_3O$); hrms calcd. for $C_{11}H_{14}O_4$: 210.0892; found: 210.0889.

*Compound B***8**

Several recrystallizations of A**8** from boiling methanol gave B**8** (88%), mp 60−61.5°C; ^{1}Hmr ($CDCl_3$, 60 MHz), δ: 3.31 (s, 3H, C(1)—OCH_3), 3.80 (s, 6H, 2 × OCH_3), 4.98 (br s, 2H, C(3)H's), 5.86 (br s, 1H, C(1)H), 6.66 and 6.82 (ABq, 1H each, J_{ortho} = 8.2 Hz, Ar): *Anal.* calcd. for $C_{11}H_{14}O_4$: C 62.84, H 6.71; found: C 62.74, H 6.80.

*Compound B***13**

Aldehyde A**13** (1.5 g) was dissolved in methanol (20 mL) and treated with $Hg(OAc)_2$ (83 mg). After 1 h, *p*-toluenesulfonic acid (21 mg) was added and 0.5 h later solid sodium bicarbonate (0.2 g) was added. The mixture was filtered and the methanol removed *in vacuo* to leave an oil. This oil was extracted into ether (2 × 10 mL), washed with H_2O (10 mL), dried (Na_2SO_4), and the ether removed to leave an oil which later crystallized from ether (90%); mp 75−76°C; ^{1}Hmr ($CDCl_3$, 80 MHz), δ: 3.44 (s, 3H, C(1)—OCH_3), 3.78, 3.82 (s, 3H each, 2 × OCH_3), 4.95 (d, 1H, J_{gem} = 13.1 Hz, C(3)H), 5.15 (dd, 1H, $J_{1,3\,trans}$ = 2.0, J_{gem} = 13.1 Hz, C(3)H), 6.23 (d, 1H, $J_{1,3\,trans}$ = 2.0 Hz, C(1)H), 6.75 (s, 2H, Ar); mass spectrum, m/z (assignment): 210 (M^+), 179 ($M^+ - OCH_3$). *Anal.* calcd. for $C_{11}H_{14}O_4$: C 62.85, H 6.71; found: C 62.62, H 6.43.

*Compound B***14**

Method A. Aldehyde A**13** (1.5 g) was dissolved in dioxane−water (20 mL, 7:3) and treated with $Hg(OAc)_2$ (03 g). After 3 h at room temperature, the dioxane was removed *in vacuo* and the resulting oil extracted into the $CHCl_3$ (3 × 10 mL). Drying (Na_2SO_4) and removal of $CHCl_3$ afforded a solid which was filtered and recrystallized from CH_2Cl_2 (91%), mp 155−157°C (lit (9) mp 156−158°C); ir (KBr): 3450 (OH) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz), δ: 2.97 (d, 1H, —OH, $J_{1,OH}$ = 7.0 Hz, disappears with D_2O), 3.80, 3.85 (s, 3H each, 2 × OCH_3), 4.97 (d, 1H, J_{gem} = 13.3 Hz, C(3)H), 5.27 (dd, 1H, $J_{1,3\,trans}$ = 2.15, J_{gem} = 13.3 Hz, C(3)H), 6.57 (dd, 1H, $J_{1,3\,trans}$ = 2.15, $J_{1,OH}$ = 7.0 Hz, collapses to a doublet in D_2O, C(1)H), 6.77 (s, 2H, Ar); mass spectrum, m/z (assignment): 196 (M^+), 179 (M^+—OH).

Method B. 4,7-Dimethoxyphthalide (1.94 g, 9.97 mmol) was dissolved in dry CH_2Cl_2 (from CaH_2, 163 mL) and cooled to −60 ± 5°C. Dibal-H (15 mL of 1.52 *M* in toluene, 22.8 mmol) was added over 0.25 h and the solution stirred a further 70 min. Methanol (5 mL) was added slowly and the mixture warmed to room temperature. The mixture was poured into $CHCl_3$ (200 mL), shaken with saturated NaCl (200 mL), and filtered through Celite. The $CHCl_3$ was dried (Na_2SO_4) and removed *in vacuo*, leaving a white solid. This was slurried in hexane and filtered, leaving 1.8 g (93%) of B**14**.

General procedure for dimethyl acetylenedicarboxylate (DMAD) adduct formation

The hydroxyacetal or phthalan (1 g) was dissolved in excess DMAD (5 mL). Glacial acetic acid (0.3 mL) was added and the mixture heated on a steam bath with swirling for 20−30 min. The excess DMAD was distilled *in vacuo* leaving a thick oil. Crystals formed upon the addition of ether were filtered, and examination of the mother liquor revealed unreacted phthalan. This could be recycled to optimize the yield.

*Compound C***1**

Adduct C**1** was prepared from A**1** by the above method in 65% yield. Crystals were obtained from ether; mp 178−180°C; ir ($CHCl_3$): 1725 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz) δ: 3.75, 3.78 (s, 3H each, 2 × CO_2CH_3), 3.83, 3.84 (s, 3H each, 2 × OCH_3), 6.00 (s, 3H, —OCH_2O— and bridge H), 6.8−7.2 (m, 5H, Ar); mass spectrum, m/z (assignment): 440 (M^+), 408 ($M^+ - CH_3OH$), 298 (5,6-dimethoxyisobenzofuran). *Anal.* calcd. for $C_{23}H_{20}O_9$. C 62.71,

H 4.59; found: C 62.99, H 4.59.

Compound C2

Adduct **C2** was prepared from **A2** by the above method in 65% yield. Crystals were obtained from ether; mp 129–130°C; ir ($CHCl_3$): 1725 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz), δ: 3.68, 3.72 (s, 3H each, 2 × OCH_3), 5.93 (m, 5H, 2 × —OCH_2—O, bridge H), 6.8–7.2 (m, 5H, Ar); mass spectrum, *m/z* (assignment): 424 (M^+), 282 (5,6-methylenedioxyisobenzofuran). *Anal.* calcd. for $C_{22}H_{16}O_9$: C 62.23, H 3.81; found: C 62.31, H 3.85.

Compound C4

Adduct **C4** was prepared from **A4** by the above procedure in 65% yield, mp 159°C; ir ($CHCl_3$); 1720 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz), δ: 3.73, 3.77 (s, 3H each, 2 × CO_2CH_3), 3.87 (s, 9H, 3 × OCH_3), 5.90 (close ABq, 2H, —OCH_2O—), 5.95 (s, 1H, bridge), 6.77 (s, 2H, Ar), 6.90 (s, 2H); hrms calcd. for $C_{24}H_{22}O_{10}$: 470.1213; found: 470.1241. *Anal.* calcd. for $C_{24}H_{22}O_{10}$: C 61.28, H 4.71; found: C 61.03, H 4.68.

Compound C5

Compound **A5** was treated as above and provided yellow crystals upon the addition of ether (95%); mp 139–139.5°C; ir ($CHCl_3$): 1710, 1730 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz), δ: 3.80 (s, 6H, 2 × CO_2CH_3), 3.80 (s, 6H, 2 × OCH_3), 5.93 (s, 2H, 2 bridge H), 7.10 (s, 2H, Ar); mass spectrum, *m/z* (assignment): 320 (M^+).

Compound C8

Adduct **A8** was treated as above and provided **C8** in 34% yield, mp 104–105°C; ir ($CHCl_3$): 1736, 1714 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz), δ: 3.71 (s, 9H, 2 × CO_2CH_3, 1 × OCH_3), 3.98 (s, 3H, —OCH_3), 5.78 and 6.21 (ABq, 1H each, J = 1.7 Hz, 2 bridge H), 6.4 and 6.91 (ABq, 1H each, J_{ortho} = 8.7 Hz, Ar); mass spectrum, *m/z* (assignment): 320 (M^+). *Anal.* calcd. for $C_{16}H_{16}O_7$: C 60.00, H 5.04; found: C 59.97, H 5.13.

Compound C9
