The cyclic voltammogram of $Ru^{II}(OEP)(P^nBu_3)_2$ (**3**) in CH_2Cl_2 with $TBA^+ClO_4^-$ as supporting electrolyte showed two reversible oxidations at +0.03 V and +1.2 V (vs. AgCl/Ag reference electrode). Electrochemical oxidation at a potential slightly above +0.03 V gave an orange solution of $[Ru^{III}(OEP)(P^nBu_3)_2]^+ClO_4^-$ (**9**) (cf. Fig. 5). The second quasi-reversible wave is attributed to the formation of a ruthenium(III)-π-cation radical, $[Ru^{III}(OEP)^{+\bullet}(P^nBu_3)_2]^{2+}$ (**13**). The cyclic voltammogram of **9** in CH_2Cl_2 with $TBA^+ClO_4^-$ as supporting electrolyte was identical to that of **3** (due to rapid reduction of **9** to **3** in the vicinity of the working electrode at the beginning of the sweep at 0.0 V) under the same conditions. Addition of acetonitrile to the solution of **9** shifted both E_p values to less positive potentials. Addition of too much acetonitrile caused the first wave to become irreversible due to deposition of the insoluble (in CH_3CN) reduced complex $Ru(OEP)(P^nBu_3)_2$ (**3**) on the working electrode. The reductions in E_p values were particularly marked for the second wave (see figure in ref. 11) (+1.2 V in pure CH_2Cl_2 to +1.05 V in acetonitrile). We attribute this to enhanced stabilization of the positively charged species by the more polar acetonitrile; the effect is more marked for the dipositive cation radical species where the delocalized charge allows for more effective solvation. For solutions containing sufficient CH_2Cl_2 to prevent precipitation of **3**, the lack of peak broadening or new waves and an i_{pc}/i_{pa} ratio of unity indicate no ligand exchange on the time scale of the cyclic voltammetry (29).

Electrochemical oxidation of acetonitrile solutions of $[Ru^{III}(OEP)(P^nBu_3)_2]^+ClO_4^-$ (**9**) at +1.2 V gave a magenta-coloured solution of $[Ru^{III}(OEP)^{+\bullet}(P^nBu_3)_2]^{2+}2ClO_4^-$ (**13**) which was easily converted back to **9**, electrochemically or by reducing agents including methanol. Solutions of **13** at 77 K showed a broad esr signal at $g_{ave} = 2.35$ (half peak width 80 G) attributable to low spin ruthenium(III) (30), and a sharp $g_{ave} = 2.008$ cation radical-like signal (peak-to-peak width 10 G). Integration of the two peaks showed approximate equal areas. Thus there appears to be no coupling between the paramagnetic centres of the dication **13**, although on warming the solution to 200 K the broad signal was lost and the narrow signal was weakened considerably.

Solutions of **13** in acetonitrile under argon reverted after a few hours to the mono-cation (**9**) as judged by the uv/vis spectrum. Compound **9** then slowly changed over a few days to a further species, characterized by a peak at 392 nm. The spectrum closely resembled that of $[Ru^{III}(OEP)(MeCN)_2]^+ClO_4^-$ (2) and that of the mixed ligand species $[Ru^{III}(OEP)(P^nBu_3)(MeCN)]^+ClO_4^-$ (28) (Table 1); either product seems plausible. The identity of the final complex could not be determined by isolation after reduction, as this gave $Ru(OEP)(P^nBu_3)_2$ (**3**) as product due to re-coordination of the phosphine. Surprisingly, fresh samples of **9**, prepared electrochemically from **3** in dichloromethane but redissolved in acetonitrile, did not change into the "392 nm product". For this conversion to occur, species **9** had to be formed via the dication **13**. To ensure that the effect was not due to the oxidation of an impurity in the acetonitrile during electrochemical formation of the dication, the dication was prepared by electrolysis of **9** in dichloromethane. The dication **13** again reverted after a few hours to **9**; removal of solvent followed by addition of acetonitrile again gave *in situ* **9** that slowly loses phosphine ligand(s) via solvation. The data suggest that during the second oxidation a trace quantity of some species is formed that catalyzes the substitution reaction.

Samples of freshly prepared $[Ru^{III}(OEP)(P^nBu_3)_2]^+Br^-$ (**4**) slowly deteriorated while being stored as a solid. The decomposition rate depended upon the purity of the solid, cruder samples tending to deteriorate much faster. A sample a few weeks old would typically show in CH_2Cl_2 a weak 428 nm peak due to small quantities of $Ru(OEP)(P^nBu_3)_2$ (**3**). In an attempt to remove this impurity the solid was rinsed with hexane. However, instead of removing the hexane-soluble **3**, up to 50% of the solid dissolved as **3**! Repeated rinses with hexane eventually did remove all of complex **3** present, and the remaining small amount of solid (**4** and **12**, see below) could be dried and stored. The slow deterioration behaviour, however, was again observed. After weeks, the spectrum (in CH_2Cl_2) of the mixture **4** + **12** showed increasing amounts of $Ru^{III}(OEP)(P^nBu_3)Br$ (**12**), which could be very effectively purified from residual **4** by recrystallizing from a dichloromethane/hexane mixture.

Solutions of **4** in dichloromethane sealed under argon were indefinitely stable, showing no tendency to form **3**. Partly degraded samples of **4** showed peaks in the mass spectrum at $m/e = 202$ and 204 (free P^nBu_3), while a sample obtained following extraction by hexane and acetonitrile (to remove **3**) gave intense peaks at $m/e = 281$ and 283 attributable to the $[P^nBu_3Br]^+$ cation.

The slow degradation of **4** is thought to be initiated by the gradual replacement of a coordinated phosphine by a bromide ion to give two neutral molecules (**12** and P^nBu_3), the driving force being the relative instability of lattices containing ions of disparate size (31) (such as **4**). The phosphine is trapped in the crystal lattice, and dissolving such a sample in CH_2Cl_2 will give a typical Ru^{III} type spectrum — a mixture of species **4** and **12** — with little sign of $Ru(OEP)(P^nBu_3)_2$, (**3**) (recognized by a very intense Soret 428 nm). If, however, the sample is rinsed with hexane, some of the trapped phosphine will be released. In hexane both ruthenium(III) species are insoluble but **3** is soluble. Tri-*n*-butylphosphine is known to react readily with free bromine to give the species $P^nBu_3Br_2$ (32). Thus, in hexane both the equilibrium of this reaction (eq. [2]) and that shown in eq. [3] will be shifted to the right.

[2] $P^nBu_3 + Br_2 \rightleftharpoons P^nBu_3Br_2$

[3] $2[Ru^{III}(OEP)(P^nBu_3)_2]^+Br^- + P^nBu_3$

4

$$\xrightleftharpoons[CH_2Cl_2]{\text{hexane}} 2Ru^{II}(OEP)(P^nBu_3)_2 + P^nBu_3Br_2$$

3

[4] $\left[\begin{array}{l} P^nBu_3 \\ | \\ Ru^{III}(OEP) \\ | \\ P^nBu_3 \end{array}\right]^+ Br^- \xrightarrow{\text{slow}} \begin{array}{l} P^nBu_3 \\ | \\ Ru^{III}(OEP) \\ | \\ Br \end{array} + P^nBu_3$

4 **12**

The driving force for reaction [3] is probably the thermodynamic stability of complex **3** coupled with the insolubility of **4** in hexane. Repeated washing with hexane will remove more and more of **3** and eventually leave pure **12** (eq. [4]). While **4** is stable in polar solvents like CH_2Cl_2, attempted recrystallization from CH_2Cl_2/hexane is likely to speed up bromide substitution to give uncharged **12**. The free phosphine could then react rapidly by the above equilibrium (eq. [3]) to give **3**. This could explain how residual **4** is removed from **12** by recrystallization from hexane/CH_2Cl_2. All these processes would be speeded up by residual phosphine trapped in the crystal lattice of **4** from the preparation of **3**. It is very difficult to remove all the free phosphine and so the purity of **3** used to prepare the bromide complex **4** would determine how fast, and in what proportions, the reduced complex **3** and the ruthenium(III) product **12** would be formed.

Conclusions

Our continuing interest in the development of ruthenium porphyrin chemistry has led to isolation of several new tertiary phosphine complexes of ruthenium(II) and ruthenium(III). The latter ones containing bromide may be cationic or neutral and, to our knowledge, are the first well-characterized ruthenium(III) porphyrins with ligated phosphines. Studies on redox chemistry have shown: (*a*) that coordination of a ligand (bromide) to the ruthenium(II) cation-radical species $[Ru(OEP)^{\cdot+}(CO)]^+$ generates a different ground-state porphyrin radical species, (*b*) that replacement of the carbonyl ligand of these π-cation radical species by phosphine may induce an internal electron transfer from the metal to the porphyrin radical, and (*c*) the existence of a ruthenium(III) porphyrin cation-radical. Peripheral redox chemistry at the porphyrin macrocycle is known to be important in several iron enzyme systems, and more detailed studies on the internal electron transfer reactions in the ruthenium complexes are in progress.

A kinetic and nuclear magnetic resonance study of methylated pyrimidine nucleosides

B. D. ALLORE, A. QUEEN, W. J. BLONSKI, AND F. E. HRUSKA
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received April 15, 1983

B. D. ALLORE, A. QUEEN, W. J. BLONSKI, and F. E. HRUSKA. Can. J. Chem. **61**, 2397 (1983).

Alkylated pyrimidine nucleosides are of interest from the viewpoint of mutagenesis and carcinogenesis. ^1H and ^{13}C nmr data are presented for a series of 2′-deoxynucleosides methylated at the O2-, O4-, and N3-positions of the base, and discussed in terms of their physical properties. The pH dependence of the stability of the O2- and O4-methylated 2′-deoxyribosides as well as the corresponding ribosides was examined by ^1H nmr and ultraviolet (uv) spectrophotometric methods.

B. D. ALLORE, A. QUEEN, W. J. BLONSKI et F. E. HRUSKA. Can. J. Chem. **61**, 2397 (1968).

Les nucléosides du type pyrimidine alkylée sont importants du point de vue de la mutagénèse et de la carcinogénèse. On présente les données de la rmn du ^1H et du ^{13}C d'une série de déoxy-2′ nucléosides méthylés en positions O-2, O-4 et N-3 de la base et on en discute en fonction de leurs propriétés physiques. On étudie par la rmn du ^1H et par spectrophotométrie uv, l'influence du pH sur la stabilité des déoxy-2′ ribosides méthylés en positions O-2 et O-4 aussi bien que sur la stabilité des ribosides.

[Traduit par le journal]

Introduction

Alkylation of purine and pyrimidine bases is of interest from the viewpoint of mutagenesis and carcinogenesis (1–9). Following the early interest in N7-alkylation of guanine (10, 11), much attention shifted to O-alkylation when Loveless (12) suggested that the O6 of guanosine in nucleic acids could be alkylated and proposed that atypical base pairing could result. Further interest in O-alkylation was generated by the isolation of O2- and O4-alkylated pyrimidine nucleosides which were overlooked in earlier work because the acid and alkaline conditions used to release the nucleosides from polynucleotides led to their dealkylation or depyrimidination (7).

In an earlier study (13) we reported a ^1H and ^{13}C nmr study of a series of O-methylated pyrimidine ribonucleosides (Fig. 1), and commented on their conformational and hydrogen bonding properties. We have completed the synthesis of an analogous series of 2′-deoxyribosides (m^2dUrd, m^4dUrd, m^2dThd, and m^4dThd; Fig. 1) and report here a similar ^1H and ^{13}C nmr study for these molecules as well as for the N3-methylated analogs m^3dUrd and m^3dThd. In addition, using ^1H nmr and uv spectrophotometry, we have examined the pH dependence of the stability of the O-methylated molecules in both the ribose and 2′-deoxyribose series at 25°C. The pH profiles for the pseudo first-order rate constants for demethylation and depyrimidination are presented, and compared with the work of Singer *et al.* (7) on O-ethylated nucleosides carried out at mainly 100°C. Our data should be useful for appreciating the persistance of O-alkyl groups in polynucleotides (1) and the care to be exercised when handling the fragile O-alkylated nucleosides.

Experimental

Materials

The Urd, dUrd, and dThd (Sigma Chemical Co.) were used without further purification. With Urd, dUrd, or dThd as starting material, the procedure of Robins and Naik (14) was used to prepare the O4-methylated derivatives. Urd was converted to m^2Urd according to Kimura *et al.* (15, 16). The N3-methylated derivatives, m^3dUrd and m^3dThd, were prepared according to Farmer *et al.* (17). To obtain m^2dUrd and m^2dThd, dUrd and dThd were converted to their 3′-acyl derivatives by standard procedures (18) and then to the 2,5′-anhydronucleoside following Secrist (19). Reflux of the anhydronucleoside (1 mmol) in 20 mL of methanolic sodium methoxide (0.11 *M*) afforded the unprotected m^2dUrd and m^2dThd. After neutralization with IRC-50 resin, the nucleosides were purified by paper chromatography with the solvent system n-butanol–ethanol–water (9:1:2 volume ratio). Identification of the molecules was made by comparison of published uv spectral data (7, 20) and consideration of the trends in the ^1H and ^{13}C nmr data (13).

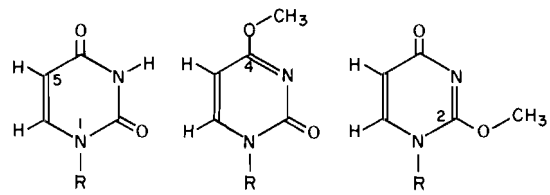

FIG. 1. Structures and abbreviations. Ribosides (R = D-ribose): uridine (Urd), O^4-methyluridine (m^4Urd), O^2-methyluridine (m^2Urd). Corresponding 2′-deoxyribosides (R = 2′-deoxy-D-ribose): dUrd, m^4dUrd, m^2dUrd. The thymine derivatives (5-CH_3): dThd, m^4dThd, m^2dThd. The free bases: uracil (Ura), thymine (Thy), O^4-methyluracil (m^4Ura), and O^2-methyluracil (m^2Ura). The N3-methyl derivatives: m^3dUrd and m^3dThd.

^1H nuclear magnetic resonance experiments

The ^1H nmr spectra were obtained on either a Nicolet NT360 (Purdue University) or a Bruker WH-270 (University of Wisconsin, Madison). All samples were examined in 5 mm (od) tubes at concentrations of 2–5 mg/mL in D_2O containing 0.1 mg/mL of sodium 3′-trimethylsilylpropionate-2,2,3,3-d_4 (TSP) as internal reference. Treatment with dithizone according to Cozzone and Jardetzky (21) removed paramagnetic metal ions. The pH was 7.0 ± 0.2 in each case (uncorrected for the deuterium isotope effect). The temperature was maintained at 25°C (360 MHz data) or at 21°C (270 MHz data). Spectral analysis was carried out using LAME (22) and computer-simulated spectra were generated as a final test of the chemical shifts (δ) and coupling constants (J) (Table 1). The uncertainties in δ and J are estimated to be about ±0.001 ppm and ±0.1 Hz, respectively. For comparison, literature data for dUrd (23) and dThd (24) are included.

^{13}C nuclear magnetic resonance experiments

Proton-decoupled ^{13}C nmr spectra were obtained on a Bruker WH-90DS spectrometer (22.63 MHz), according to described procedures (25). The nucleoside samples were contained in 10 mm (od) tubes at concentrations of 25–50 mg/mL in D_2O, containing 1% dioxane as internal reference. Paramagnetic ions were removed by shaking the

[a] Carbon data of dUrd and dThd (24°C) in ppm at 22.63 MHz measured relative to internal dioxane and converted to a TMS scale by δ(TMS) = δ(DIOXANE) +67.86 ppm. The chemical shifts of m^2-, m^4-, and m^{3}dUrd are relative to dUrd; the shifts of m^2-, m^4-, and m^{3}dThd are relative to dThd. The O(N)–CH$_3$ shifts are relative to TMS. A positive number indicates a deshielding relative to the reference molecule. dUrd$^-$ and dThd$^-$ are the anions formed by N3–H ionization (pH = 11.5).

sample with an acetylacetone–toluene mixture (equal volumes) and separating the phases (13). The pH was adjusted to 7.0 ± 0.2 (uncorrected for the deuterium isotope effect). The probe temperature was regulated at 24°C. The ^{13}C chemical shift data (Table 2) are reported in ppm downfield from external TMS by setting internal dioxane equal to 67.86 ppm. The assignments of the ^{1}H and ^{13}C spectra were facilitated by comparison with other nucleosides (13, 26). However, C1′ and C4′ can not be unambiguously assigned without further experiments because their chemical shifts are similar. In each of the 2′-deoxyribosides, C4′ was assigned to the low field resonance. With this assignment the effects of base methylation on their chemical shifts parallel the trends observed for the ribosides i.e., the effect is greater on C1′ than on C4′ (13).

Kinetic studies

We determined the products of hydrolysis for each of the six O-methylated molecules at 32°C by monitoring the time dependence of their ^{1}H nmr spectra under acidic and basic conditions on a Bruker WH-90 DS spectrometer, followed by comparison with the spectra of the parent nucleoside (Urd, etc.) and the free thymine (Thy) and uracil (Ura) bases obtained under identical conditions. Changes in chemical shifts and in the J(5, 6) proton coupling constant (13), the appearance of a methanol resonance at 3.34 ppm, and the appearance of resonances corresponding to the anomeric H1′ of the free 2-deoxyribose sugar (27) (formed in depyrimidinations) were useful diagnostic tests.

In basic solution (pH ≈ 13) the O-methylated molecules were found to undergo dealkylation to methanol and the parent nucleoside; no evidence for any depyrimidination was provided by the ^{1}H nmr spectra. Singer *et al.* (7) noted that at pH = 12.5 (100°C) the corresponding O-ethylated molecules, e^{2}Urd, e^{4}Urd, e^{4}dUrd, and e^{4}dThd also undergo dealkylation with, in the case of e^{2}Urd, some competition from depyrimidination to the 2-deoxyribose sugar and the e^{2}Ura base. However, in contrast with our observations on m^{2}dUrd and m^{2}dThd, e^{2}dUrd and e^{2}dThd were found to undergo mainly depyrimidination yielding the e^{2}Ura and e^{2}Thy bases respectively; dealkylation of e^{2}dUrd and e^{2}dThd was found to occur at a much lower rate. We cannot rationalize now this striking difference in behaviour between the O-methyl and O-ethyl derivatives because of the much higher temperatures (100°C) employed by Singer *et al.* (7).

In line with the study of O-ethylated nucleosides by Singer *et al.* (7), the m^{2}Urd, m^{4}Urd, m^{4}dUrd, and m^{4}dThd were found to dealkylate in acid solution (pH = 1.5) whereas m^{2}dUrd and m^{2}dThd were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

found to undergo an initial depyrimidination to liberate the corresponding O-methylated bases followed by a slower dealkylation of the base to yield the Ura and Thy bases. The ^{1}H nmr spectra revealed that a competitive dealkylation of m^{2}dUrd and m^{2}dThd also occurred to a small extent (≤5%).

The kinetics of the dealkylations were monitored at 25.0 ± 0.02°C in a Beckman DU spectrophotometer modified so that its output could be digitized by a voltmeter (Dana, model 5330) and stored in a Wang 600 calculator (28). Pseudo first-order rate constants (k_0) were calculated automatically by a least-squares method using eq. [1], where A represents absorbance.

$$[1] \quad \ln (A_\infty - A_t) = \ln (A_\infty - A_0) - k_0 t$$

The kinetic data for the depyrimidination of m^{2}dUrd and m^{2}dThd were obtained from the time dependence of the H6 proton nmr intensities obtained at 90 MHz (Bruker WH-90DS). (The nmr rather than spectrophotometric method was necessary because the uv spectra of the O-methylated nucleosides and the released bases are similar, and because of the complicating subsequent demethylation of the base.) The probe was maintained at a higher temperature (32 ± 0.5°C) than in the spectrophotometric experiments to lessen precipitation of the relatively insoluble bases formed in the reactions. Solutions were made up by dilution of stock 2.0 *M* HCl or 2.0 *M* NaOH, with the addition of sufficient NaCl to maintain a constant ionic strength of 2.0 *M*.

Results and discussion

^{1}H nuclear magnetic resonance data

The ^{1}H chemical shifts (δ) and coupling constants (J) of the methylated 2′-deoxyribonucleosides are given in Table 1. The striking similarity in the magnitudes of the corresponding coupling constants across the series of sugar residues indicates that the sugar conformation is little affected by O- or N-methylation of the base. (This contrasts with the shifts towards the 3′*endo* conformation effected by O-methylation in the corresponding ribonucleosides (13).) Estimates based on J(3′,4′) indicate a bias (60%) for the 2′*endo* pucker, as expected for "normal" 2′-deoxyribose sugars (29). Evaluation of the C4′–C5′ orientation according to Haasnoot *et al.* (30) gives the following narrow ranges of populations: g^+ (50 ± 2%); t (37 ± 2%); g^- (12 ± 1%). The bias towards the g^+ rotamer and the minimal contribution from g^- are standard features of normal 2′-deoxyribosides (26).

Like the coupling constants, the proton shifts of the sugar residues show only small variation. For example, δ(H2′) lies in the narrow range 2.3–2.4 ppm. Because H2′ is expected at ≈3.0 ppm in a *syn* 2′-deoxyriboside (31), a preference for the *anti* conformation is apparent. (dUrd and dThd are *anti* in the crystal state (32, 33); of the methylated derivatives only m^{4}Urd has been crystallized and shown to be *anti*.)[1] In the case of m^{2}dUrd and m^{2}dThd, methylation has converted the 2-keto oxygen to a methoxyl whose shielding effects in a *syn* pyrimidine have not been evaluated. However, the overall trends in the ^{1}H chemical shift and coupling constant data suggest the *anti* form for m^{2}dUrd and m^{2}dThd as well.

In line with observations on the ribosides (13), O2- and O4-methylation cause a 0.5 Hz decrease in J(5,6) (Table 1). This effect has been discussed in terms of the tautomeric changes in the ring (13).

^{13}C nuclear magnetic resonance data

Because the trends in the δ(C) data (Table 2) for the most part parallel those observed for the O- and N-methylated ribosides (13), only brief comment is needed here. The effects of methylation upon the sugar carbons are generally less than 1 ppm although O-methylation causes a deshielding of Cl′ of 1.4–1.8 ppm. N3-methylation has a smaller influence on δ(Cl′), in line with the smaller electronic effects associated with this modification. N3-methylation has only a small effect on the C2, C4, and C5 positions (≤1 ppm), but its shielding effect on the most distant carbon (C6) is substantial.

The most interesting observations, which reflect the strong conjugation of the O2–C2–N3–C4–O4 fragment, are that both C2 and C4 are deshielded by methylation of either of the carbonyl groups, and that C4 is more strongly affected than C2 by methylation of O2. Note further that C4 is more strongly deshielded by O4-methylation in the dUrd series than in the dThd series, suggesting some influence of the 5-CH_3 on the electronic changes associated with O4-methylation. Also interesting is that C6 is shielded by O2-methylation and deshielded by O4-methylation, whereas C5 is deshielded by O2-methylation and shielded by O4-methylation. These trends reflect a characteristic, general polarization of the O-methylated bases, but we leave for theory a more explicit discussion of electronic changes. In this regard it is interesting to note that ionization of the N3-H at basic pH to yield the anions dUrd$^-$ and dThd$^-$ has a substantial deshielding effect on C4 (≈10 ppm) and a somewhat smaller effect on C2 (≈8 ppm) (Table 2). Though somewhat larger, these changes parallel those of O-methylation, and suggest that the electronic effects of O-methylation on the O2–C2–N3–C4–O4 fragment may imitate those of base ionization. The remaining carbons are affected very little by ionization (≤0.7 ppm) except for C6 which experiences a shielding effect of 1.2–1.6 ppm.

Nuclear magnetic resonance titrations

To obtain information about the ionization behaviour of the O-methylated molecules, required for understanding their hydrolysis, we obtained the pH dependence of the H6, H5, 5-CH_3, and 2 (or 4)-OCH_3 ^{1}H chemical shifts (Fig. 2). The study focussed on the acid range because the bases have no acidic sites which could undergo ionization in basic solution. However, the ^{1}H nmr spectra reveal sugar hydroxyl ionization at pH 12, as originally noted by Fox and Shugar (34). The study could not be taken much below pH 1 where rapid decomposition occurs (see below).

For all O-methylated molecules except m^{4}dThd, the chemical shifts remain constant in the pH range 2–7 and move abruptly downfield in more acid solution. Unfortunately, a complete sigmoidal titration curve is not observed in the available pH range. Thus, the chemical shifts of the cation formed and its pK_a for ionization cannot be determined. However, the general appearance of the curves suggest pK_a values which are less than about 1.5 in all instances. In m^{4}dThd virtually no change occurs in any of the chemical shifts over the accessible pH range (0.2–7.0), suggesting that the pK_a value of its protonated form is substantially less than that of the other molecules. These trends are in rough correspondence with the pK_a data for the O-ethylated deoxyribosides obtained by Singer *et al.* using uv spectrophotometry (7): e^{2}dUrd (0.92), e^{2}dThd (0.5), e^{4}dUrd (0.66), and e^{4}dThd (−0.32).

Kusmierek and Singer (35) suggested that N3 is the primary protonation site of N1-substituted O-alkylated uracil bases, as is the case in N1-substituted cytosine. Comparison of the nmr titration behaviour of m^{4}Urd and m^{4}dUrd with that of cytidine (Cyd) (36) provides support for this suggestion. Thus, with

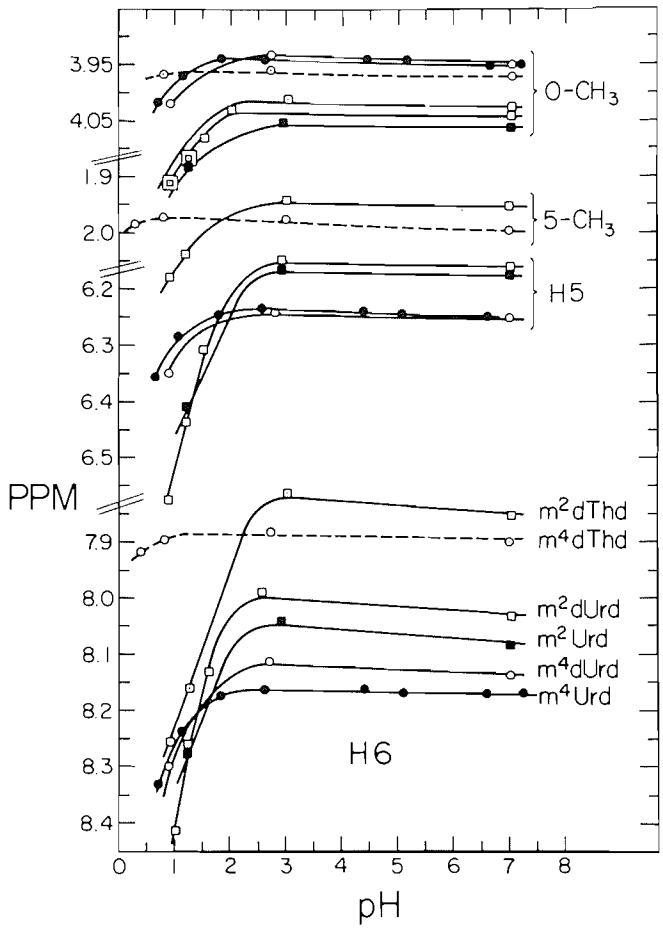

FIG. 2. The pH dependence of the proton chemical shifts of the O-methylated nucleosides. In the discontinuous vertical scale, the various ranges apply as follows: 3.95–4.05 ppm (O—CH_3), 1.9–2.0 ppm (5-CH_3 of thymine derivatives), 6.2–6.5 ppm (H5), and 7.9–8.4 ppm (H6). See Fig. 1 for numbering. The chemical shifts are relative to internal TSP. The pH is the pH-meter reading uncorrected for the deuterium isotope effect.

formation of the cytidine cation by N3 protonation, H6 and H5 move downfield by 0.33 and 0.24 ppm respectively (relative effect H6:H5 = 1.4). In our incomplete titration of m^4Urd we find downfield shifts for H6 (0.18 ppm) and H5 (0.12 ppm) in the most acidic solution (relative effect 1.5). Similarly in m^4dUrd in the most acid solution, H6 and H5 have shifted downfield by 0.19 and 0.11 ppm (relative effect 1.7). The similarity in the relative protonation effects suggests the primary protonation site is the same in Cyd, m^4Urd, and m^4dUrd. It seems likely that N3 is the primary protonation site in the other O-alkylated molecules, although we cannot entirely discount some competing protonation of the carbonyl oxygens.

Singer *et al.* (7) have noted that 5-methylation leads to a large *decrease* in the pK_a of the O4-ethylated pyrimidine base. (Compare pK_a of e^4dUrd (0.66) and of e^4dThd (−0.32)). Our titration curves for m^4dUrd and m^4dThd indicate a similar trend due to a 5-methyl group (Fig. 2). These trends are surprising in view of the finding by Borodavkin *et al.* (37) that 5-alkylation of the cytosine base leads to a small *increase* in its pK_a, suggesting an electron donating role for the 5-alkyl group. Furthermore, 5-alkylation of the uracil base leads to an increase in the pK_a of the N3-H (38, 39). Perhaps the increased acidity of cationic e^4dThd is due in part to a steric effect of the bulky 5-alkyl group which stabilizes the planar, *syn* conformation

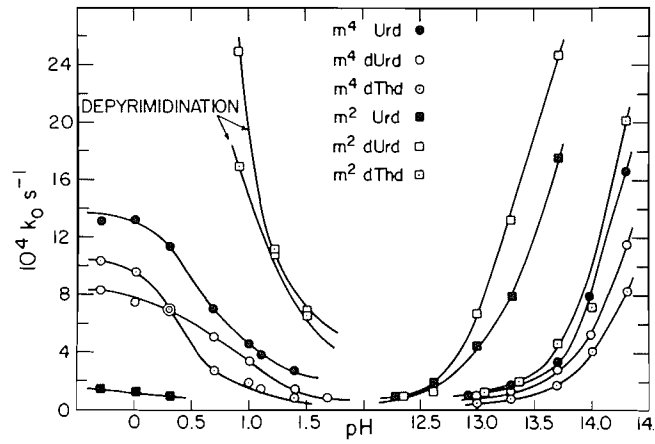

FIG. 3. Plot of the observed pseudo first-order rate constants (k_0, in 10^4 s^{-1}) versus pH, for the decomposition of O-methylated nucleosides in aqueous solution. The data for m^2dUrd and m^2dThd in *acid* solution represent the initial depyrimidination step and were obtained by ^{1}H nmr spectroscopy (32°C in D_2O). The remaining data represent demethylation processes and were obtained by uv spectrophotometry (25°C in H_2O). The pH represents −log [HCl], or 14 − log [NaOH] in basic solution.

about the C4—O4 bond. This conformation places the hydrophobic methoxyl methyl near to the N3 protonation site and should reduce its basicity.

Kinetics of alkaline demethylations

Figure 3 shows the pH dependence of the observed pseudo first-order rate constants (k_0) for the hydrolysis of the O2- and O4-methylated molecules. The m^2dUrd and m^2dThd data in *acid* solution (32°C) represent the initial depyrimidination step and were obtained from the time dependence of the H6 nmr intensities. The remaining data (25°C) represent the demethylation processes.

In the pH range 3–12 all of the nucleosides are relatively stable; at neutral pH no noticeable decomposition occurs after weeks of standing. In more basic solution, rapid demethylation ensues with k_0 increasing exponentially with pH. The plot of k_0 versus the hydroxide ion concentration is linear for each of the O-methylated molecules and passes through the origin. This indicates that the demethylation processes involve a rate determining attack of the OH^- ion, with negligible neutral hydrolysis at this temperature. One mechanism consistent with these observations involves direct S_N2 attack at the methyl group; a second mechanism involves S_NAr attack at the methoxylated ring carbon. We are considering ^{18}O isotope experiments that would provide further mechanistic information. Values of the second-order rate constants for basic hydrolysis, k_{OH}, were obtained from the slopes of the k_0 versus $[OH^-]$ plots and are listed in Table 3.

From the list of k_{OH} (Table 3), we see that the relative ease of demethylation follows the order m^2dUrd > m^2Urd ≫ m^2dThd > m^4Urd > m^4dUrd > m^4dThd. Thus the O2-methylated molecules are more labile to alkaline demethylation than the O4-methylated molecules. (This contrasts with Singer *et al.* (7) who noted at 100°C and pH = 12.5 that e^2Urd is much less readily dealkylated than e^4Urd (approximate half-lives: 4 h and <10 min, respectively).) In the O2-methylated series the deoxyriboside m^2dUrd is more labile than the riboside m^2Urd, whereas in the O4-methylated series the riboside m^4Urd is more labile than m^4dUrd. (Comparison with the work of Singer *et al.*

TABLE 3. Rate constants for the neutral (k_{H_2O}), acid (k_H), and base (k_{OH}) catalyzed hydrolysis of methylated nucleosides. Acid dissociation constants for their conjugated acids (K_a)

Compound	$10^3 k_H$ (s^{-1})	K_a	pK_a	$10^4 k_{H_2O}$ (s^{-1})	$10^4 k_{OH}$ ($1\ m^{-1}\ s^{-1}$)
m^4Urd	1.36±0.13	0.18±0.02	0.8	−0.20±0.29	8.24±0.28
m^4dUrd	0.98±0.14	0.20±0.03	0.7	0.12±0.15	5.63±0.18
m^4dThd	1.29±0.30	0.56±0.15	0.3	−0.05±0.06	4.13±0.06
m^2Urd	0.14±0.01	0.22±0.01	0.7	0.59±0.26	34.3±1.1
m^2dUrd	6.7±5.9	0.27±0.25	0.6	0.69±1.10	49.8±4.5
m^2dThd	3.3±0.3	0.11±0.01	1.0	−0.85±1.03	10.4±1.0

"The data are for demethylation processes (25°C) except k_H for m^2dUrd and m^2dThd in acid solution (32°C) which are for the initial depyrimidinations.

cannot be made because on the one hand e^2dUrd and e^2dThd primarily undergo depyrimidination and on the other hand the half-lives of e^4Urd and e^4dUrd could not be accurately measured at 100°C in basic solution (7)). Thus, our data show that sugar 2′-hydroxyl stabilizes the O2-methylated molecules and destabilizes the O4-methylated molecules to alkaline hydrolysis. Discussion of the effect of the 2′-hydroxyl is complicated because this group undergoes ionization at pH > 12, which is reflected in the ^{1}H nmr spectrum of the sugar. The greater stability of m^2Urd relative to m^2dUrd could be due in part to electron donation of the 2′-hydroxylate (which would destabilize the transition state) and to steric and electrostatic repulsion of the attacking hydroxide ion.

The 5-methyl has a stabilizing effect on both the 2- and 4-methoxyl groups in alkaline solution. This is expected for an electron donating substitutent, but it is surprising that its effect is larger on the more remote 2-methoxyl group. (Compare the m^2dUrd with m^2dThd and m^4dUrd with m^4dThd in Table 3.)

Kinetics of acidic demethylations

At pH < 3, m^2Urd, m^4Urd, m^4dUrd, and m^4dThd undergo rapid demethylation to the parent nucleoside, as was observed for the corresponding O-ethylated molecules (7). The sigmoidal k_0 versus pH profiles (Fig. 3) for m^4Urd, m^4dUrd, and m^4dThd suggest initial protonation (presumably at N3) followed by a rate determining attack by water. (Figure 2 confirms that protonation of the bases occurs at pH < 3.) The protonation could be followed by either S_N2 attack by water on the methyl group or by S_NAr attack at the methoxylated ring carbon (C2 or C4). Isotope studies might allow us to determine which mechanism prevails.

Assuming a two step model, it can be shown that

$$[2]\quad \frac{1}{k_0} = \frac{K_a}{k_H}\frac{1}{[H_3O^+]} + \frac{1}{k_H}$$

where k_H is the pseudo first-order rate constant for the attack by water on the protonated nucleoside and K_a is the acid dissociation constant of this species. In agreement with eq. [2], plots of k_0^{-1} versus $[H_3O^+]^{-1}$ are linear. The values of k_H, K_a, and pK_a obtained from the slopes and intercepts of the linear plots are listed in Table 3.

Given the combined uncertainties, the agreement is reasonable between our kinetically derived pK_a values and those given for the corresponding O-ethylated derivatives by Singer *et al.* (7). Note in particular that m^4dThd exhibits the smallest pK_a (≈0.3), a trend supported by our partial titration curves (Fig. 2).

From the list of k_H values we note that for the *base-protonated* species, m^4Urd is more labile than m^2Urd, in contrast with the situation in basic solution (compare their k_{OH} values, Table 3). The k_H values for m^4dThd and m^4dUrd suggest a small destabilizing effect of the 5-methyl substituent on the 4-methoxy group, although the trend here is not particularly clear because of the uncertainties in the k_H values. This contrasts with the statement by Singer *et al.* that in acid solution the O4-alkyl groups are more stable on dThd than on dUrd. Note, however, that their conclusion was based on pseudo first-order rate constants (expressed as half-lives) measured at pH 1.5. At this acid strength the molecules would exist partly as the neutral species and partly as the more reactive cationic form. Our full titration curves (Fig. 3) reveal that crossovers in the relative stabilities determined by k_0 can occur because of differences in the K_a values for the cationic species. (See curves for m^4dUrd and m^4dThd in Fig. 3.) Thus, some caution is required in interpreting trends if complete titration curves are not available.

Kinetics of acidic depyrimidinations

Figure 3 shows the pH dependence of k_0 for the initial depyrimidination of m^2dUrd and m^2dThd in acid solution. The rate of the reaction is very rapid at pH < 0.5 (4.6 min half-life for m^2dUrd at pH = 0.9). Thus, we could not ascertain whether the dependence of k_0 upon pH is sigmoidal. However, it is likely that the mechanism of depyrimidination is similar to that of 2′-deoxycytidine derivatives (40) in which a reversible protonation (presumably at N3) precedes a rate determining cleavage of the N-glycosyl bond.[2] In such a mechanism eq. [2] will apply. Approximate values of K_a and pK_a of the protonated nucleosides, and the value of k_H for the cleavage of the N-glycosyl bond were obtained from plots of k_0^{-1} versus $[H_3O^+]^{-1}$ (Table 3).

The uncertainties in the quantities limit the conclusions which can be made. The pK_a values for m^2dUrd and m^2dThd are not out of line with those of e^2dUrd and e^2dThd (7) and the nmr titration curves (Fig. 2). The most interesting result is the large labilization of the N-glycosyl link by O^2-methylation in the *deoxy* series; in contrast no depyrimidination of the O^4-methylated molecules was detected. This indicates that, in the cationic forms of the nucleosides, the 2-methoxylated base is the better leaving group, perhaps due to greater localization of positive charge at the N1-nitrogen of the ring.

Acid-catalyzed cleavage of 4-halonortricyclanes. Evidence that the 2-norbornyl cation is an unsymmetrical species

NICK HENRY WERSTIUK, DALJIT DHANOA, AND GEORGE TIMMINS
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received July 28, 1982[1]

NICK HENRY WERSTIUK, DALJIT DHANOA, and GEORGE TIMMINS. Can. J. Chem. **61**, 2403 (1983).

Nortricyclanes **4***a*, **4***c*, **4***d*, and **4***e* were prepared and ring opened in D_2SO_4/CD_3COOD. We found that the ratios of *endo*/*exo* deuterium at C(6) were 1.09 ± 0.02, 1.30 ± 0.03, 1.40 ± 0.04, and 1.45 ± 0.05 for cleavage of **4***a*, **4***c*, **4***d*, and **4***e*, respectively. The amount of 6,2-hydride shift decreased from 14.3 ± 1.0% in the case of nortricyclane (**4***a*) to 6.0 ± 1.1%, 6.4 ± 0.5%, and 8.1 ± 0.7% for **4***c*, **4***d*, and **4***e*, respectively. Although four distinct mechanisms involving either nonclassical or rapidly-equilibrating cations are possible, cleavage most probably occurs to generate 6,2-unsymmetrically-bridged norbornyl cations.

NICK HENRY WERSTIUK, DALJIT DHANOA et GEORGE TIMMINS. Can. J. Chem. **61**, 2403 (1983).

On a préparé les nortricyclanes **4***a*, **4***c*, **4***d* et **4***e* et on a ouvert le cycle dans du D_2SO_4/CD_3COOD. Nous avons trouvé que les rapports du deutérium *endo*/*exo* en C(6) sont de 1,09 ± 0,02, 1,30 ± 0,03, 1,40 ± 0,04 et 1,45 ± 0,05 pour le clivage respectif des composés **4***a*, **4***c*, **4***d* et **4***e*. Le taux de glissement 6,2 d'hydrure diminue de 14,3 ± 1,0% dans le cas du nortricyclane (**4***a*) à 6,0 ± 1,1%, 6,4 ± 0,5% et 8,1 ± 0,7% pour les composés **4***c*, **4***d* et **4***e* respectivement. Bien que quatre mécanismes distincts, impliquant soit des cations non classiques ou des cations qui s'équilibrent rapidement soient possibles, le clivage se produit plus probablement de façon à engendrer des cations norbonyles pontés de façon non symétrique en positions 6,2.

[Traduit par le journal]

Introduction

The norbornyl-cation controversy held the attention of physical organic chemists for two and one-half decades (1). We, along with many researchers, were drawn to contribute to the solution of the problem (2–5). The enormous effort which has been expended world-wide to solve the problem has been documented clearly by Brown (1).[2] In our view, the central issue of the controversy is stated simply in the following question. Is the symmetrical norbornonium ion (**1***a*) an intermediate or does it best represent the transition state between rapidly equilibrating unsymmetrical ions represented by **2***a* and **3***a*? By employing classical substituent effect studies to gain structural information on the norbornyl cation, researchers introduced groups on the [2.2.1]-framework and thereby destroyed the symmetry of **1***a* or rendered the equilibrating unsymmetrical ions non-degenerate. Since C(4) is the only site where a single substitution does not destroy symmetry or clutter the front-face of the cation, we reasoned that the critical question (*vide supra*) could be answered by establishing whether or not a substituent at C(4) influenced the chemistry of the 2-norbornyl cation. To that end we prepared and studied the acid-catalyzed ring opening of nortricyclane (**4***a*) and its 4-halo analogs **4***c*, **4***d*, and **4***e*. If cleavage yields symmetrical cations **1***a*–**1***e*, then the stereochemistry of the ring opening, as monitored by the *endo*/*exo* deuterium ratio at C(6), would be unaffected by the substituent. However, if cleavage yields unsymmetrical cations the rate of rearrangement could be affected by the mass of the substituent – a ponderal effect (6) – and/or a polar effect. Consequently, a change in the stereochemistry of the ring-opening would be observed because subsequent reaction of the *endo*-6-*d*-cation, formed by edge-wise attack of D^+ (7, 8), would compete more effectively with rearrangement. If the mass and/or electronegativity of the substituent at C(4) influences the stereochemistry of the ring-opening, then a change in the degree of 6,2-hydride shift would be expected also. In this publication we give a complete account of the ring cleavages of **4***a*, **4***c*, **4***d*, and **4***e* in deuterated medium. Assuming that *exo*-2-norbornyl acetate-*endo*-6-*d* is not formed by concerted termolecular addition of acetic acid, we consider four probable mechanisms for ring-opening: corner deuteronation (protonation) yielding a symmetrical nonclassical cation; edge deuteronation (protonation) yielding an edge-protonated nortricyclane which rearranges to a nonclassical species; edge-wise approach with a corner slide yielding a 6,2-unsymmetrically bridged cation which undergoes Wagner–Meerwein rearrangement; edge deuteronation (protonation) yielding an edge-deuterated nortricyclane that rearranges to a rapidly-equilibrating 6,2-unsymmetrically bridged 2-norbornyl cation. On the basis of the results of this study and our previous work (5) we prefer a route which involves edge deuteronation and yields a 6,2-unsymmetrically bridged ion.

Results

Preparation of substrates

Nortricyclanes **4***a*, **4***b*, and **4***c* were prepared by thermal decomposition of the sodium salts of the corresponding *p*-toluenesulfonylhydrazones **6***a*, **6***b*, and **6***c* as shown in Scheme 1 (9). It was established by analytical glpc analysis that the nortricyclanes were >99% pure and contained no norbornenyl impurities. Iodonortricyclane (**4***d*) was prepared by lithiating **4***c* and reacting the anion with I_2 (Scheme 2). We found that oxygen must be scavenged scrupulously from purging argon with benzophenone ketyl and that the rate of lithiation is enhanced markedly by the addition of small amounts of sodium. Attempts to prepare 4-fluoronortricyclane (**4***b*) by reacting the anion with $FClO_3$ resulted in a complex mixture of products, and only a small amount of the fluoride, as determined by ^{19}Fmr, ^{1}Hmr, and ms, was isolated in one case. Bromide **4***d* was prepared also by quenching lithium 4-nortricyclanide with CNBr, but we settled on the synthesis of **4***d* from 2-norbornanone as shown in Scheme 3 because 1-bromonorbornene (**9***a*) could be prepared on a large scale. Furthermore, we wished to use **9***a* as a starting material for the preparation of optically active 4-bromo-*exo*-2-norbornyl brosylate required for future studies of the stereochemistry of solvolysis of optically active 4-substituted norbornyl

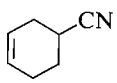
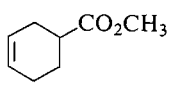
brosylates.

The ^{1}Hmr data on the nortricyclanes are summarized in Table 1. It is interesting to note that while the chemical shifts of the cyclopropyl protons are in the order **4***c* > **4***d* > **4***e* ~ **4***a*, the chemical shifts of methylene protons which are closer to the electron-withdrawing halogens remain essentially constant through the series of halides.

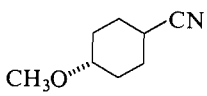
As is shown in Scheme 3, 2-norbornanone was converted into 2,2-dihalides **7***a* and **7***b* that were rearranged to the 1,2-isomers **8***a* and **8***b* by $SnCl_4$ and $ZnBr_2$, respectively. Elimination of HCl and HBr by *t*-BuOK/DMSO gave the corresponding 4-halonorbornenes **9***a* and **9***b* that were oxymercurated by $HgCl_2$/HgO in aqueous acetone (10). $NaBH_4$ reduction of the crude mercurials **10***a* and **10***b* gave the corresponding 4-halo-*exo*-2-norbornanols **11***a* and **11***b* which were oxidized by Brown's reagent to **12***a* and **12***b*, respectively. During the reduction of the mercurials we observed the formation of varying amounts – in some cases up to 70% – of **9***a* and **9***b*, but the norbornenes were recovered and recycled. While the conversion of methoxy mercurials and hydroxy mercurials to starting alkenes has been observed previously, the exact mechanism of their formation remains obscure (11). Is it possible that deoxymercuration occurs by nucleophilic attack of the oxy-anion at mercury to displace chloride, followed by elimination of HgO? That the stereochemistry and regiochemistry of the oxymercuration reactions was that indicated in Scheme 3 was established by ^{1}Hmr analysis of the mercurials and by the fact that the reduction product of **10***a* was identical to 4-chloro-*exo*-2-norbornanol prepared by the silver ion-assisted solvolysis of 1-*exo*-3-dichloronorbornane. The regiochemistry of the oxymercuration of **9***a* and **9***b* is in accord with the regiochemistry of the mercuration of **13** and **14** which yielded **15** and **16** after reduction. We attempted to use the



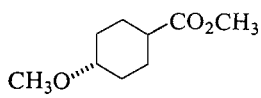
13



14



15



16

solvolysis of the 1,3-dichloride to prepare **11***a* on a large scale, but the addition of gaseous HCl to **9***a* proved to be unreliable. We also attempted to prepare **11***a* by acid-catalyzed hydration of **9***a*, but 2-norbornanone was formed, most probably via a route which involved formation and rearrangement of the 1-chloro-2-norbornyl cation to the 2-chloro-2-cation.

Ring-cleavages of nortricyclanes

Ring-cleavages were carried out in CD_3COOD/0.1 *M* D_2SO_4 rather than in CH_3COOD/D_2SO_4 to avoid dilution of the deuterium pool by exchange of the methyl group. Reduction of the deuterated acetates **17***a*–**17***d* by $LiAlH_4$ in ether gave the corresponding deuterated alcohols **18***a*–**18***d* and **18***b*, **18***c*, and **18***d* that were converted to deuterated *exo*-2-norbornanol by sodium in 2-propanol (Scheme 4). In the case of the reduction of halohydrins **18***b* and **18***c*, an additional product was observed which most likely resulted from a Grob cleavage. Analytical glpc analysis of the deuterated *exo*-norbornanols isolated by preparative glpc established that <1% of the *endo*-alcohol was present in each case. Although ^{2}Hmr showed only four resonances that were assigned to deuterons at C(1), C(2), *exo* and *endo* at C(6), the final analyses were carried out in the presence of $Pr(fod)_3$ to ensure that resonances due to deuterium which might be located at C(3) or C(7) would be shifted and would not interfere with the *endo/exo* analysis. In fact, the halohydrins were reduced to *exo*-norbornanol to insure that the analyses were identical. Figure 1 shows the 60 MHz ^{1}Hmr spectrum of *exo*-2-norbornanol complexed with $Pr(fod)_3$, along with the assignments. Clearly, only resonances due to protons (deuterons) at C(4), C(5), and C(6) appear in the region of interest. Since there are no viable mechanisms for introducing deuterium at C(5) during ring opening, and base-catalyzed deuterium scrambling during reduction should not be significant, the peaks in the region −4 to −5 ppm are due to *exo*- and *endo*-deuterons at C(6). Even if scrambling occurred to a minor extent, ^{2}Hmr analysis would yield a *minimum* C(6)-*endo/exo* deuterium ratio because the D-4 and D-5 resonances overlap with the *exo*-6-D signal. The ^{2}Hmr spectra were subjected to a computerized curve analysis using Lorentzian shapes and the results are reported in Table 2 and Table 3.[3] Figure 2 gives examples of ^{2}Hmr spectra of the deuterated *exo*-2-norbornanols obtained from ring openings of **4***a*, **4***c*, **4***d*, and **4***e* and complexed with $Pr(fod)_3$. Figure 3 provides an example of an actual spectrum, the fitted spectrum, and the resolved spectrum of the deuterated *exo*-norbornanol obtained from **4***a*. The *endo/exo* ratios obtained by averaging the results from at least six curve analyses of ^{2}Hmr spectra from at least two different ring-openings are given in Table 2. The percentages of deuterium at C(1) and C(2) obtained from at least four determinations are listed in Table 3. While there appears to be a distinct difference between the *endo/exo* ratio for **4***a*, **4***c*, and **4***d*, the difference in the ratios for **4***d* and **4***e* may not be significant.

To ensure that the deuterium was not scrambled in the acetates, ring-openings of **4***a* were run for 14 h and 48 h and, for **4***d*, reactions were run for 70 h and 240 h. Within experimental error, the deuterium distributions were identical for each pair of ring-cleavages. That the deuterated 2-norbornanols derived from the ring-openings of **4***c* and **4***d* were composites of 11.3% d_0, 87.3% d_1, 1.4% d_2 and 9.1% d_0, 90.9% d_1 and <0.1% d_2 species, respectively, established that H/D exchange did not occur to a significant extent.

Discussion and conclusions

It is clear from the data in Tables 2 and 3 that the introduction of a halogen substituent at C(4) produces a pronounced increase in the *endo/exo* deuterium ratio at C(6) and a pronounced decrease in the extent of 6,2 (6,1)-hydride shift. The *endo/exo* deuterium ratio of 1.09 ± 0.02 obtained for the ring-opening of **1***a* compares favourably with the ratio of 1.08 ± 0.05

[3]The values listed in Tables 2 and 3 differ slightly from the values reported in our initial publication and include additional analyses which were carried out.

obtained by Nickon and Hammons (12) using infrared spectroscopy. To establish that the difference in the *endo/exo* ratios observed in the cleavages of **4***a* and the 4-halonortricyclanes was not due to scrambling in the acetates, the results of two ring openings of **4***a* and **4***d* carried out for different reaction periods (*vide supra*) were compared. That the deuterium distributions for both ring-openings of each substrate were identical within experimental error established that scrambling does not occur to a significant extent. This is in accord with Nickon's findings (12) that optically active *exo*-norbornyl acetate does not racemize under the conditions used to ring open **4***a*.

Assuming that *exo*-2-norbornyl acetate-6-*endo-d* is not formed by concerted termolecular addition of acetic acid – concerted bimolecular addition would yield the *endo*-2-acetate – we envisage four probable pathways for acid-catalyzed cleavage of nortricyclanes shown in Schemes 5–8. In pathway 1 (Scheme 5), the nonclassical norbornyl cation is generated by corner deuteronation. While the protio species is symmetrical, the C(6) deuterated nonclassical cation is unsymmetrical and a larger secondary kinetic isotope effect (KIE) for formation of the *exo*-6-*d*-acetate, in principle, could result in a small excess of *endo*-6-*d*-acetate. However, that the *exo*- and *endo*-γ-KIE's for solvolysis of *exo*-norbornyl brosylate are nearly equal[4] es-

[4]The *exo*- and *endo*-6-*d*-KIE's for solvolysis in 80% CH_3CH_2OH/H_2O at 25°C are 1.09 ± 0.03 and 1.11 ± 0.01 (13). In acetic acid at 44°C the KIE's are 1.149 ± 0.016 and 1.097 ± 0.011 (14). The KIE's for solvolysis (80% CH_3CH_2OH/H_2O/25°C) of *syn*-7-chloro-*endo*-6-*d*-, *anti*-7-chloro-*endo*-6-*d*-, *syn*-7-chloro-*exo*,*exo*-5,6-d_2-, and *anti*-7-chloro-*exo*,*exo*-5,6-d_2-*exo*-norbornyl brosylates are 1.125 ± 0.007, 1.120 ± 0.005, 1.119 ± 0.011, and 1.150 ± 0.013, respectively (5).

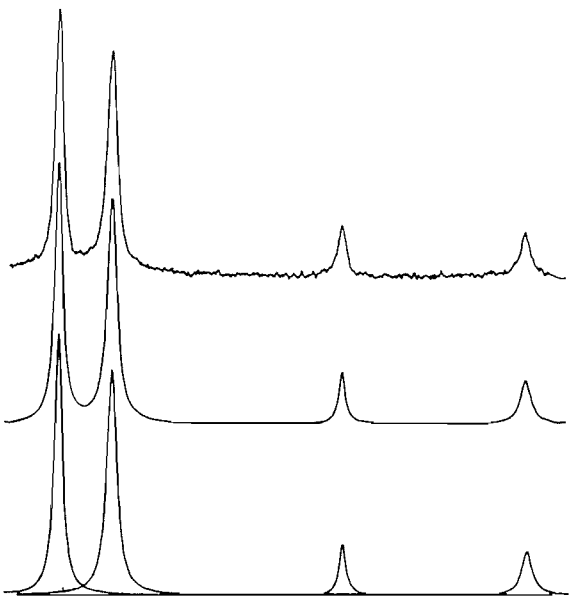

FIG. 3. (a) 13.8 MHz ^{2}Hmr spectrum of deuterated *exo*-2-norbornanol (0.0257 g) obtained from **4***a* complexed with $Pr(fod)_3$ (0.0958 g) in CCl_4; (b) computer-fitted spectrum; (c) resolved spectrum.

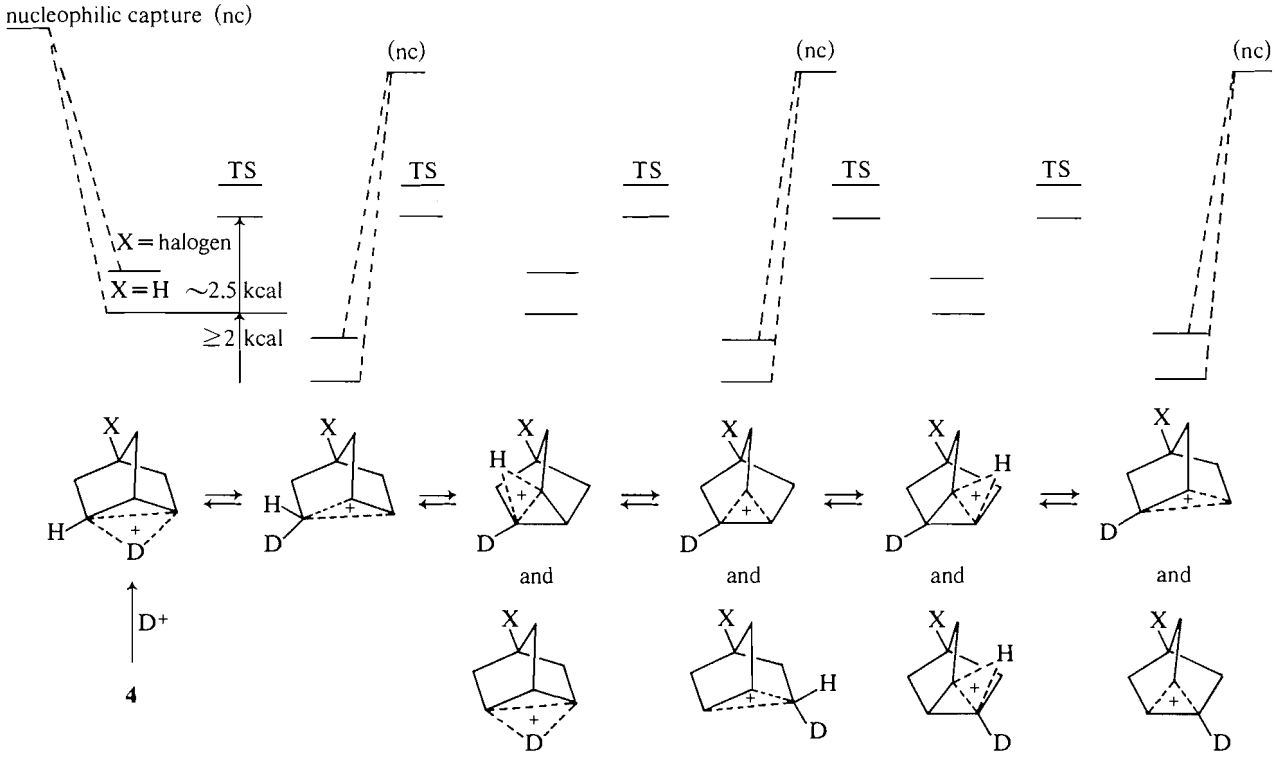
tablishes that a differential KIE cannot be invoked to account for the preferential formation of *endo*-6-*d*-acetate. That the γ-KIE's for solvolysis of *syn*- and *anti*-7-chloro-*exo*-brosylate are only slightly larger[4] than the KIE's for the parent brosylates establishes that an electron-withdrawing group at C(7) does not induce a differential in the *exo*- and *endo*-KIE's. We expect the same situation to hold for a halogen located at C(4).

In pathway 2 (Scheme 6) an edge-deuteronated nortricyclane (EDN) is considered as the initial intermediate. The EDN can react with solvent (k_s^{EDN}) or yield a nonclassical cation (NC) via an edge-to-corner deuterium shift. Other deuterated nonclassical species are formed by corner-to-edge-to-corner circumambulations. Assuming the NC's are intermediates in the ring cleavage of **4***a* and that most of the substitution occurs via the NC's (k_s^{NC}), the ratio of C(6) deuterated acetate (85%) to C(1) and C(2) deuterated acetates (15%), including a statistical factor of 2, is approximately equal to the ratio of the rates of substitution and 6,2-H shift, and

$$[1] \quad k_s^{NC}/k_{6,2H} \sim 2.8$$

The value is in good agreement, assuming there is a secondary KIE, with $k_s^{NC}/k_{6,2H}$ ratios of 1.9 ± 0.6 and 1.55 ± 0.35 obtained by Collins and Lietzke through a sophisticated analysis of ^{14}C and ^{3}H scramblings observed in the acetolysis of labelled *exo*-norbornyl brosylates (15). This analysis estab-



SCHEME 6

lishes that the intermediates, whether they are nonclassical or otherwise, generated by ring opening of norticyclane in acetic acid are the same as the species generated by acetolysis. Assuming that $k_s^{EDN} \sim k_s^{NC}$, not an unreasonable assumption since the charge on the carbon atoms should be similar[5] in both species, then [1] yields

$$[2] \quad k_s^{EDN}/k_{rearr}^{EDN\rightarrow NC} \sim 0.046$$

where 0.046 is the fractional excess (0.044/0.957) of *endo*-6-*d*-acetate formed in the ring opening of **4***a*. Thus [2] yields

$$[3] \quad k_{rearr}^{EDN\rightarrow NC} \sim 2.8 \times k_{6,2H}/0.046$$

and

$$[4] \quad k_{rearr}^{EDN\rightarrow NC} \sim 60 \times k_{6,2H}$$

Since $k_{6,2H} \sim 2.5 \times 10^8$ s^{-1} at 25°C,[6] our analysis establishes that in order for the excess *endo*-6-*d*-acetate to result from reaction of an initially formed EDN with solvent, $k_{rearr}^{EDN\rightarrow NC} \sim 1.5 \times 10^{10}$ s^{-1} and $E_a \sim 2.5$ kcal/mol. Since edge-protonated nortricyclane is not observed down to −141°C even though 6,2-hydride shifts are frozen out, this establishes that EPN (EDN) must be at least 2 kcal higher in energy than the nonclassical ion or a rapidly-equilibrating species. Recent calculations by Goddard *et al.* (18) place EDN ~12.4 kcal/mol higher in energy than classical and nonclassical norbornyl cations. Based on this analysis, E_a for conversion of NC to EPN (EDN) is ≥4.5 kcal. It is interesting to note that E_a for a 6,2-shift has been established at 5.8 kcal/mol (17). If EPN's indeed are intermediates in the ring-openings, they must be involved in solvolysis reactions and 6,2-H(D) shifts most probably occur via EPN's rather than by direct corner-to-corner shifts (19). The approximate energy profiles shown in Scheme 6 can be drawn if isotope effects are neglected. If the mechanism of ring cleavage is as outlined in Scheme 6 and NC's rather than EDN's are the major sources of acetates (*vide supra*), then the amounts of C(1)- and C(2)-deuterated acetates formed, as observed, should be similar.

Based on our previous solvolysis study (5) which pointed to the involvement of unsymmetrically-bridged cations as intermediates, two additional mechanisms can be considered. In pathway 3 (Scheme 7) – the simplest mechanism – an unsymmetrically-2,6-bridged cation (UBC) is generated directly by an edge-wise approach and corner slide of D^+ without formation of an EDN. In this case 6,2-D(H) shifts would occur corner-to-corner (19) via a transition state which resembles an EDN.

In pathway 4 (Scheme 8) edge deuteronation yields an EDN that either reacts with solvent or rearranges to a rapidly-equilibrating UBC. If W−M rearrangement is fast, then the ratio of the rates of solvent capture and 6,2-H shift can be obtained from the ratio of the amounts of acetate with deuterium at C(6) (85%) and acetates with deuterium at C(1) and C(2) (15% total), yielding

$$[5] \quad 2 \times k_s^{UBC}/k_{6,2\text{-}H} \sim 5.7$$

Consequently,

$$[6] \quad k_s^{UBC}/k_{6,2\text{-}H} \sim 2.8$$

in good agreement with $k_s/k_{6,2\text{-}H}$ obtained by Collins and Lietzke (*vide supra*). If excess *endo*-6-*d*-acetate arises from

[5]Dewar *et al.* (16) have calculated that the formal charges at C(1) and C(6) of EDN and at C(1) and C(2) of the NC are 0.176 and 0.142, respectively.

[6]Olah *et al.* (17) have established that the activation energy for a 6,2-shift at −141°C is 5.8 kcal/mol. At 25°C the rate constant is ~2.5 × 10^8 s^{-1}.

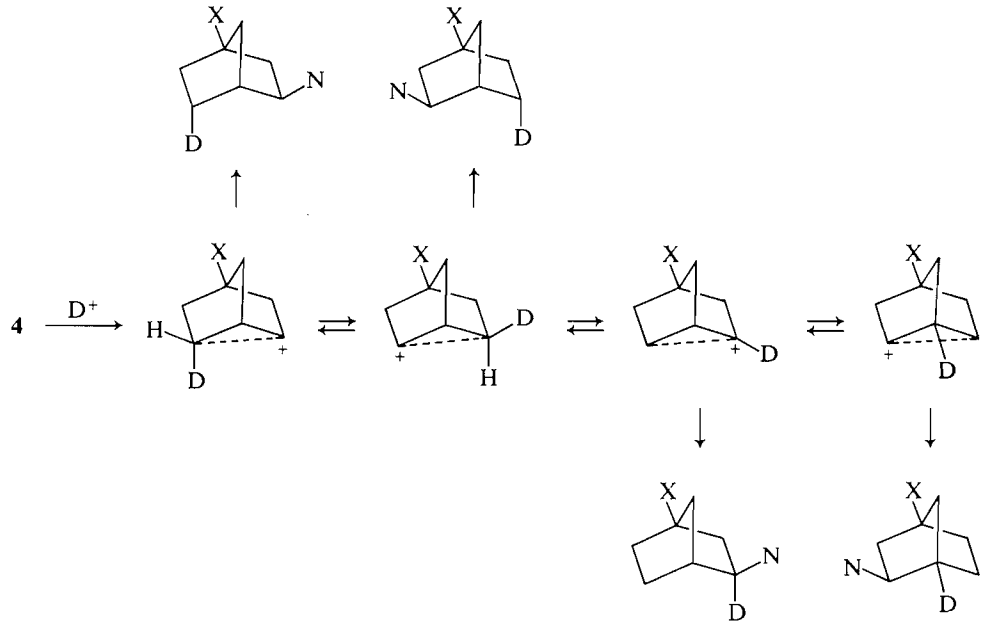

SCHEME 7

reaction of EDN with solvent, then

[7] $$2k_s^{EDN}/k_{rearr}^{EDN\rightarrow UBC} \sim 0.046$$

If the statistical factor reduces the difference in the rates of reaction of UBC and EPN (EDN) expected on the basis of their electrophilicities, then $2k_s^{EDN} \sim k_s^{UBC}$ and

[8] $$k_{rearr}^{EDN\rightarrow UBC} \leq \frac{2.8 \times 2.5 \times 10^8\ s^{-1}}{0.046}$$

since $k_{6,2\text{-H}} \sim 2.5 \times 10^8\ s^{-1}$. Consequently E_a for the rearrangement of EDN to UBC is $\geq$2.5 kcal per mol. That EPN is not observed down to -140°C, while 6,2-shifts are frozen out in the norbornyl cation, establishes that EPN (EDN) must be at least 2 kcal higher in energy than the rapidly equilibrating UBC. In this connection it is interesting to note that Dewar *et al.* (16) have calculated that EPN is 2.8 kcal higher in energy than the classical cation and that the barrier to conversion of EPN to the classical cation is 2.8 kcal/mol. However, recent calculations by Goddard *et al.* (18) place EPN ~12.4 kcal/mol higher in energy than the classical and nonclassical cations. They stated that the 2-norbornyl cation might be best viewed as an unsymmetrically-bridged species. That the acetates with deuterium located at C(1) and C(2) are formed in equivalent amounts, neglecting secondary KIE's, is expected because W–M rearrangement is fast relative to nucleophilic capture by solvent.

Effect of halogen substituents

Since steric interactions of the C(4) substituent with the reaction center are not possible, the substituent, in principle, can influence the chemistry of the 2-norbornyl cation through ponderal and polar effects and by altering solvation.

Ponderal effect

Using a theoretical study of S_N2 reactions of alkyl halides, de la Mare *et al.* (6) defined and quantified a ponderal effect as a nonpolar, nonsteric entropy effect which depends on the mass of a substituent and its position but not on its bulk or charge. Translational, rotational, and vibrational entropies which depend on the mass of a substituent and its position are components of the entropies of the reactants and the transition state and play a major role in determining the magnitude of $\Delta S^{\ddagger}$. By computing the contributions of each type, they showed that the ponderal effect in S_N2 reactions, in general, is rate retarding. While entropy change due to differences in solvation of reactants and transition states is possible also, the authors concluded that this effect would remain essentially constant for a structurally similar series of reactants and transition states, and $\Delta\Delta S^{\ddagger}_{solv} \sim 0$. We expect that the same situation holds for the ring-opening reactions as well. In their analysis of a group of S_N2 reactions (Br^- + RBr; R = methyl, *n*-propyl, isopropyl, *tert*-butyl, neo-pentyl, isobutyl) the translational entropy of activation was obtained as a difference of the terms in eq. [9].

[9] $$\Delta S^{\ddagger}_{trans} = S_t(XRX^-) - S_t(RX) - S_t(X^-)$$

where the translational entropies of the species were evaluated using eq. [10].

[10] $$S_t = 2.303R\,(1.5 \log M + 2.5 \log T) - 2.315$$

For the S_N2 process, because mass (X^-) is added in attaining the transition state, $\Delta S_t^{\ddagger}$ decreases as the mass of R is increased, i.e. $S_t(XRX^-)$ increases more slowly than $S_t(RX)$ because of the logarithm in eq. [10]. If an unsymmetrical ion **2** or **5** is generated in the ring-opening of nortricyclanes, scrambling of the *exo*- and *endo*-hydrogens at C(5) and C(6) would occur by rearrangement of **2** (XR^+) to **3**, or **5** to its enantiomer, via **1** ($XR_{\pm}^+$). Since $S_t(XR_{\pm}^+)$ and $S_t(XR^+)$ must be identical, unlike the case for the S_N2 reactions, $\Delta S^{\ddagger}_{trans} \sim 0$ for the rearrangement and for the conversion of EPN to a nonclassical ion or an unsymmetrical species.

The rotational contribution to the entropy of activation in de la Mare's analysis of S_N2 reactions was given by eq. [11] and the rotational entropies of the species were calculated using eq. [12]. A, B, and C are the principal moments of inertia and

[11] $$\Delta S^{\ddagger}_{rot} = S_r(XRX^-) - S_r(RX)$$

[12] $$S_r = 2.303R\,(0.5 \log ABC - \log \sigma + 1.5 \log T) - 5.384$$

σ is the symmetry factor. According to de la Mare's analysis,

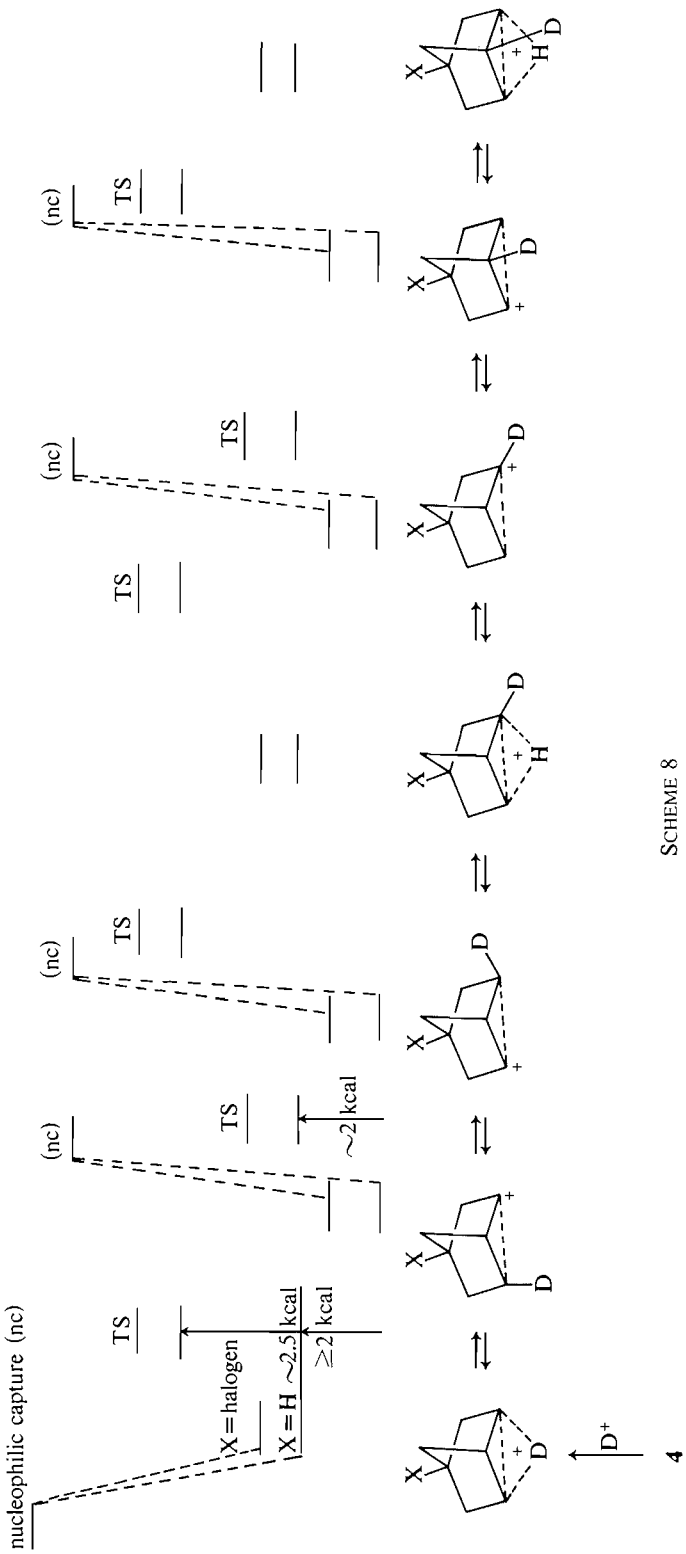


SCHEME 8

an increase in the mass of R will result in an increase or decrease in rotational entropy depending on whether the additional mass is located near or remote from the reaction centre. For the cations generated from **4***a*, **4***c*, **4***d*, and **4***e*, as the mass of X increases there will be a change in the centre of mass, i.e. a shift towards X. While an increase in the ABC term is expected for both $XR_{\pm}^{\ddagger}$ and XR^{+}, whether or not there is a significant decrease in $\Delta S_{rot}^{\ddagger}$ through the series ($\Delta\Delta S^{\ddagger} \neq 0$) is difficult to establish because $XR_{\pm}^{\ddagger}$ and XR^{+} are very similar.

The vibrational entropies of activation $\Delta S_{vib}^{\ddagger}$ for the rearrangement of XR^{+} via transition state $XR_{\pm}^{\ddagger}$ are given by eq. [13].

$$[13] \quad \Delta S_{vib}^{\ddagger} = S_v(XR^{+}) - S_v(XR^{+})$$

when the S_v's are calculated using eq. [14] and $x = 0.00483\ \omega$

$$[14] \quad S_v = \Sigma[-R \ln (1 - e^{-x}) + Rxe^{-x}/(1 - e^{-x})]$$

(ω = vibrational frequency in cm^{-1} at 298K). According to de la Mare, the general effect of added mass would be to lower frequencies and raise vibrational entropies. However, for S_N2 reactions the effect is less pronounced in the transition state than in the initial state because the mass and moments of inertia of the former are larger due to the additions of X^{-}. Thus the changes produced are proportionally smaller. Consequently, for S_N2 processes there is a reduction in $\Delta S_{vib}^{\ddagger}$ as the mass of R is increased and the reaction rate decreases due to the ponderal effect. However, in the rearrangement of cations XR^{+} there is no mass added in the transition state. While the S_v's for the 4-halocations and their corresponding transition states undoubtedly are lower than the S_v's for the unsubstituted species, whether or not $\Delta S_{vib}^{\ddagger}$ decreases or increases as the mass of X increases can only be ascertained by carrying out a complete analysis of the fundamental modes of the cations and the transition states.

Polar effects

The structural changes produced by introducing an EWG at C(4) of the nonclassical cation are difficult to predict with certainty. However, we expect that the dispersal of charge would be unaffected by a halogen at C(4) because it does not destroy the symmetry of the ion. Consequently, if **1** is the sole intermediate in the ring opening it would react as a "symmetrical" species since the γ-secondary KIE's for collapse with solvent should be similar if not identical (*vide supra*). The stereochemistry of the ring-cleavages of **4***c*, **4***d*, and **4***e* in deuterated medium should be unaffected by the halogens at C(4). Consequently, the 4-halonortricyclanes are not cleaved via the mechanism depicted in Scheme 5.

In the case where EDN's and NC's are intermediates (Scheme 6), the increase in the amount of *endo*-6-*d*-acetate obtained upon halogen substitution could result from an increase in the electrophilicity of EDN even though an EWG at C(4), in principle, can affect the rate of EDN-to-NC conversion. A reduction in the amount of "6,2-shift" products could be a consequence of the fact that a halogen-substituted NC reacts faster with solvent, but undergoes a 6,2-shift at a slower rate than the parent NC.

Recently, Grob and co-workers (20, 21) studied the solvolysis of C(6) substituted *exo*-2- and *endo*-2-norbornyl tosylates and concluded that the norbornyl cation is an unsymmetrical 2,6-bridged species **19** in keeping with our previous proposal (5). They found that solvolysis of *exo*-2-norbornyl tosylates bearing EWG's at C(6) yields substantial amounts of *endo*-2-

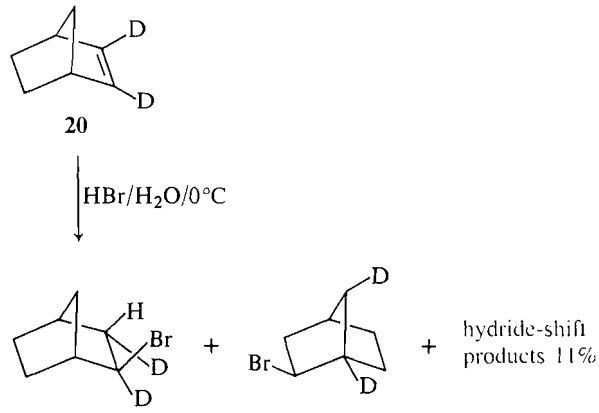
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

norbornanols. The authors concluded that EWG's at C(6) reduce 2,6-bridging and increase the barrier to interconversion of the unsymmetrical ions. If the norbornyl cation is an unsymmetrical species (Schemes 7 and 8), then EWG's at C(4) should produce the same effect as that proposed by Grob: 2,6-bridging should be reduced and the barrier to interconversion should increase. Consequently, solvent capture should compete more effectively with rearrangement and the *endo*/*exo* deuterium ratio at C(6) should increase when a halogen is substituted at C(4). Also, the 4 halogen substituted cations may be more electrophilic than the parent ion and thereby react faster with solvent. The results of our study are in accord with these hypotheses. While a difference in the stereochemistry of the ring-opening of **4***a* and **4***c* is expected on the basis of the electronegativities of H and Cl and is observed, in fact, the difference between **4***c* and the other halonortricyclanes cannot be predicted with certainty. This is so because the values of the substituent constants depend on the mode of derivation. For example, while the field effect parameters F (22) for Cl, Br, and I are 0.690, 0.727, and 0.672, respectively, the σ_I values are 0.47, 0.45, and 0.39 (23). The changes in stereochemistry of the ring-opening of **4***a*, **4***c*, and **4***d* appear to parallel the F values, but the result for iodine appears out of line. Perhaps a ponderal effect is superimposed on the polar effect.

An effect of EWG's at C(4) on 6.2-hydride shifts, E_a ~ 6 kcal/mol, in the [2.2.1]-system should also be expected. An EWG at C(4) would reduce the electron density in the C—H bonds at C(6) and thereby increase the barrier for a 6,2-shift. That a substantial decrease (~50%) in the amount of hydride shift is observed in the ring-opening of halonortricyclanes **4***c*, **4***d*, and **4***e* relative to **4***a* (Table 3) and that there is a rough parallel with substituent constants supports the hypothesis. Thus the simplest mechanism involving only rapidly-equilibrating unsymmetrical cations (Scheme 7) can be invoked to account for the results and the slight excess of *endo*-6-*d*-acetate (4.5%) observed in the cleavage of **4***a* arises from capture of *endo*-6-*d*-UBC before it equilibrates. That the *exo*-acetate obtained from the acetolysis of optically active *exo*-brosylate is racemic, runs counter to our arguments. However, it is conceivable that the brosylate anion shields the UBC and equilibration is essentially complete before solvent intervenes.[7]

In this connection it is interesting to note that addition of protio acids to 2,3-dideuterionorbornene (25) and deuterioacids to norbornene (26–28) yields labelled products which indicate capture of an unsymmetrical cation by nucleophiles. Although the interpretation has been criticized (29) because termolecular processes and 6-membered molecular additions can be involved, it is noteworthy that similar results were obtained using a variety of acids, solvents, and reaction conditions. For example, as shown in Scheme 9, addition of HBr to **20** in aqueous medium yields predominately **21** (25). In this case EPN is not an initial intermediate and a good nucleophile is present. It is difficult to understand why addition should occur via a termolecular process or by a four-centered or 6-membered addition in this case.

If EDN's and UBC's are intermediates (Scheme 8), then the increase in the amount of *endo*-6-*d*-acetate which is observed



SCHEME 9

upon halogen substitution at C(4) could be due to several factors. It is conceivable that an EWG at C(4) destabilizes the UBC, where charge is localized, more than EPN (EDN), thereby increasing E_a for the EPN(EDN)-to-UBC conversion. Moreover, a halogen at C(4) should increase the electrophilicity of EPN and enhance its rate of reaction with solvent. On this basis, the increase in the amount of *endo*-6-*d*-acetate observed upon halogen substitution could result entirely from reactions of an intermediate EDN. However, an EWG at C(4) could also increase the barrier (*vide supra*) for W—M rearrangement and increase the electrophilicity of the UBC. The net effect would be to increase the rate of capture of *endo*-6-*d*-UBC and consequently decrease the relative amount of 6,2-H shift as well.

Presently, based on the analysis of the results of this study and our previous work (5), we prefer a mechanism which involves formation of rapidly-equilibrating 6,2-bridged norbornyl cations. While edge-protonated norticyclanes can be involved as intermediates, the simplest cleavage mechanism involves edge-wise approach of D^+ to the cyclopropane bond with a corner slide to generate an unsymmetrically 6,2-bridged cation.

Experimental

General

Nuclear magnetic resonance spectra were obtained on Bruker WH-90, Varian EM 390, and Varian T 60 instruments in $CDCl_3$ or CCl_4 with TMS as an internal standard. Deuterium magnetic resonance spectra were obtained at 13.8 MHz. Deuterium analyses were carried out at low voltage (15 eV) on a CEC double-focussing mass spectrometer. Boiling points and melting points are uncorrected. Solutions of organic solvents were dried over anhydrous $MgSO_4$ or Na_2SO_4.

2,2-Dichlorobicyclo[2.2.1]heptane (7a)

2,2-Dichlorobicyclo[2.2.1]heptane (112 g) was prepared from bicyclo[2.2.1]heptan-2-one (101 g) using PCl_3 and PCl_5 according to the method of Wiberg *et al.* (30).

1,2-Dichlorobicyclo[2.2.1]heptane (8a)

1,2-Dichlorobicyclo[2.2.1]heptane (85 g) was obtained by isomerization of 2,2-dichlorobicyclo[2.2.1]heptane (112 g) catalyzed by $SnCl_4$ in toluene using a method similar to the one described by Wilt *et al.* (31).

1-Chlorobicyclo[2.2.1]hept-2-ene (9a)

1,2-Dichlorobicyclo[2.2.1]heptane (85 g, 0.52 mol) was dissolved in dry DMSO (450 mL) and added to *t*-BuOK (84 g, 0.81 mol) in a 1 L flask equipped with a $CaCl_2$ drying tube. The reaction mixture was stirred overnight, added to 1 L of water, and extracted with ether (4 × 250 mL). The combined ether extracts were washed with water (2

[7]That *exo*-brosylate racemizes during acetolysis and only 29% of products are derived from optically active substrate provides support for this possibility (24).

For personal use only.

× 100 mL) and dried. Distillation of the residue after the ether was distilled off yielded 1-chlorononbornene (51 g, bp 135–138°C/atmospheric pressure); ^{1}Hmr ($CDCl_3$) δ: 6.08 (m, 2, vinyl Hs), 2.85 (m, 1, H(4)), 2.2–1.0 (norbornyl envelope).

1,3-Dichlorobicyclo[2.2.1]heptane

1,3-Dichlorobicyclo[2.2.1]heptane (16 g, bp 71.5–73°C/10 Torr) was prepared from 1-chlorobicyclo[2.2.1]hept-2-ene by the addition of HCl in CH_2Cl_2 at −78°C according to the method of Fry and Farnham (32).

*4-Chloro-*exo*-2-bicyclo[2.2.1]heptanol (**11**a)*

To 1,3-dichlorobicyclo[2.2.1]heptane (9.2 g, 0.056 mol) in solution in dioxane (50 mL) was added with stirring $AgNO_3$ (18.6 g, 0.11 mol) in water (50 mL). The solution was refluxed for 39 h and extracted with CH_2Cl_2 (2 × 75 mL). The combined CH_2Cl_2 extracts were washed with water and dried. The solvent was distilled off and the last traces of solvent were removed under vacuum to yield 4.7 g of 4-chloro-*exo*-2-bicyclo[2.2.1]heptan-2-ol; mp 73–79°C; ^{1}Hmr ($CDCl_3$) δ: 3.90 (bd, 1, *endo*-H(2)), 2.40 (s, 1, —OH), 2.4–1.0 (norbornyl envelope).

*Large scale oxymercuration of 1-chlorobicyclo[2.2.1]hept-2-ene (**10**a)*

A solution of **9***a* (141 g, 1.1 mol), yellow mercuric oxide (120 g, 0.56 mol), and mercuric chloride (150 g, 0.56 mol) in 1200 mL of aqueous acetone (50:50) was refluxed for 72 h. Most of the solvent was distilled off and the residue was filtered and dried under vacuum to yield 423 g of organomercurial **10***a*. The dry mercurial was added to 1400 mL of ether–methanol (1:3) in a 2 L flask equipped with a condenser and $NaBH_4$ (92.4 g) was added continuously over a period of 5 h. The mixture was refluxed for 12 h, acidified with 10% aqueous HCl, and extracted with ether (6 × 500 mL). The combined ether layers were washed with saturated aqueous $NaHCO_3$ solution, water, and dried over anhydrous Na_2SO_4. The solvent was distilled off through a 30 cm glass-helices column and glpc analysis of this residue showed that the mixture was composed of ~40% **11***a* and 60% **9***a*. Continuation of the distillation gave 1-chlorononbornene and a viscous residue which crystallized. The remaining traces of alkene were removed under vacuum to yield 42 g of crude 4-chloro-*exo*-2-norbornanol (**11***a*) which was oxidized to **12***a* without further purification.

*1-Chlorobicyclo[2.2.1]heptan-3-one (**12**a)*

The crude chlorohydrin (42 g, 0.29 mol) was dissolved in 200 mL of pre-oxidized ether, 200 mL of Brown's reagent was added carefully with stirring, and the mixture was stirred vigorously for 24 h at ambient temperature. The ether layer was separated and the aqueous layer was extracted with ether (6 × 100 mL). The combined ether extracts were washed with water (150 mL), saturated aqueous sodium bicarbonate (200 mL), water (150 mL), and dried. The ether was distilled off through a 30 cm glass-helices column and the last traces of solvent were removed under vacuum to yield 41 g of **12***a* which was shown to be 90% pure by analytical glpc; ^{1}Hmr ($CDCl_3$) δ: 2.75 (bm, 1, H(1)), 2.55 (bs, 2, *exo*-H(3) and *endo*-H(3)), 2.4–1.0 (norbornyl envelope).

*4-Chlorobicyclo[2.2.1]heptan-2-one tosylhydrazone (**6**b)*

To 43 g 4-chlorobicyclo[2.2.1]heptan-2-one (**12***a*) in 800 mL of absolute ethanol was added *p*-toluenesulfonylhydrazine (56.6 g, 0.30 mol). Concentrated HCl (5 mL) was added and the mixture was heated at reflux for 72 h. The reaction mixture was cooled and the solid that crystallized was filtered off and dried under vacuum to yield 40 g of 4-chloro[2.2.1]heptan-2-one tosylhydrazone (**6***b*), mp 174–176°C.

*4-Chlorotricyclo[2.2.1.0^{2,6}]heptane (**4**c)*

Freshly prepared CH_3ONa (50 g, 0.93 mol) was dissolved in diglyme (575 mL, dried over CaH_2 and distilled), 4-chlorobicyclo-[2.2.1]heptan-2-one tosylhydrazone (35 g, 0.11 mol) was added, and the mixture was heated at reflux for 3 h until nitrogen evolution essentially stopped. The dark-brown reaetion mixture was cooled, poured into water (500 mL), and extracted with ether (6 × 300 mL); the ether extracts were washed with water, dried, and the solvent was removed by distillation through a 30 cm glass-helices column. Since glpc analysis showed that diglyme and **4***c* were present, the residue was dissolved in pentane (500 mL) and the solution was extracted with water (5 × 200 mL), dried, and the pentane was distilled off. The residue was combined with the product of a second reaction of identical scale and 10.5 g of **4***c* (97% pure) were obtained (bp 142–144°C/atmospheric pressure). A second distillation through a 30 cm glass-helices column gave **4***b* which was >99% pure; ^{1}Hmr (CCl_4) δ: 1.65 (s, 6, —CH_2—), 1.18 (s, 3, cyclopropyl H).

*2,2-Dibromobicyclo[2.2.1]heptane (**7**b)*

To norcamphor (43 g, 0.39 mol) in an ice-cooled 3-necked 1 L flask equipped with a magnetic stirrer, a reflux condenser, and drying tube were added PBr_3 (121 g, 0.45 mol) and PBr_5 (191 g, 0.44 mol) with stirring over a period of 2 h. The mixture was warmed to room temperature and stirred for 17 h. The mixture was poured onto ice (800 g), warmed to room temperature with stirring, and extracted with ether (5 × 200 mL). The combined ether extracts were dried and the solvent was distilled off through a 30 cm glass-helices column. The last traces of solvent were removed on the rotatory evaporator to yield 71.5 g of product which was shown by analytical glpc to be composed of two major products (80%) and unreacted norcamphor (15%).

*1,2-Dibromobicyclo[2.2.1]heptane (**8**b)*

The crude 2,2-dibromide (71.5 g) was dissolved in purified pentane (100 mL) and $ZnBr_2$ (40 g) was added. After 1 h the pentane solution was decanted from the sticky mass and fresh $ZnBr_2$ (20 g) was added. The process was repeated once and the solution was agitated with a magnetic stirrer for one week at ambient temperature. The glpc analysis showed that the isomerization was essentially complete and one major product (88%) was present along with ~3% of norcamphor. Distillation yielded 30 g of **8***b* (bp 78–80°C/0.1 Torr) which was shown to be 94% pure by analytical glpc.

*1-Bromobicyclo[2.2.1]heptan-2-ene (**9**b)*

Dibromide **8***b* (30 g, 0.12 mol) was dissolved in purified DMSO (150 mL, stored over NaOH, vacuum distilled, and stored over 4Å molecular sieves), and *t*-BuOK (27 g, 0.24 mol) was added. The mixture was stirred at ambient temperature for 24 h and poured into a separatory funnel containing H_2O (150 mL) and ether (150 mL). The aqueous layer was extracted with ether (6 × 100 mL) and the combined extracts were washed with water (100 mL), saturated aqueous NaCl solution (100 mL), and dried. The solvent was distilled off at atmospheric pressure through a 30 cm glass-helices column and the residue was distilled under aspirator vacuum (~20 Torr) to yield 14.2 g of **9***b*, bp 46–47°C; ^{1}Hmr (CCl_4) δ: 6.05 (m, 2, vinyl H's), 2.75 (m, 1, bridgehead H), 2.2–1.0 (norbornyl envelope).

*Oxymercuration of 1-bromobicyclo[2.2.1]hept-2-ene (**9**b)*

Bromonorbornene **9***b* (5.00 g, 0.029 mol), mercuric oxide (3.13 g, 0.0144 mol), and mercuric chloride (3.92 g, 0.0144 mol) were placed in a 100 mL round-bottomed flask, 50% v/v aqueous acetone (100 mL) was added, and the mixture was refluxed for 72 h with magnetic stirring. The solvent was removed on the rotatory evaporator and the solid was pumped under vacuum while being warmed with a hair dryer to yield 11.9 g (96.7%) of bromomercurial; mp 117–128°C; ^{1}Hmr ($CDCl_3$) δ: 4.00 (bd, 1), 3.55 (dd, 1), 2.50 (d, 1, bridgehead H), 2.4–1.0 (norbornyl evelope and —OH).

*4-Bromobicyclo[2.2.1]heptan-2-one (**12**b)*

To a solution of crude **11***b* (48 g, 0.25 mol, obtained from a large scale oxymercuration of **9***b*) in preoxidized ether (500 mL) in a 1 L flask equipped with a condenser and a magnetic stirrer was added Brown's reagent (126 mL) in small portions. The mixture was stirred vigorously for 46 h at ambient temperature, the ether layer was withdrawn, and the aqueous layer was extracted with ether (5 × 100 mL). The combined ether extracts were washed with aqueous $NaHCO_3$ (2 × 75 mL), water (2 × 100 mL), and dried. The solvent was stripped

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

by distillation and the final traces were removed under vacuum to yield 41 g of **12***b*; mp 60–62°C; ^{1}Hmr ($CDCl_3$) δ: 2.55 (m, 1, H(1)), 2.50 (s, 2, *exo*-H(3) and *endo*-H(3)), 2.4–1.4 (norbornyl envelope).

*4-Bromobicyclo[2.2.1]heptan-2-one tosylhydrazone (**6**c)*

To **12***b* (40 g, 0.21 mol) of *p*-toluenesulfonylhydrazine (39.5, 0.21 mol) in 95% ethanol (500 mL) was added concentrated HCl (5 mL) and the mixture was refluxed for 40 h. The reaction mixture was poured into water (800 mL), the solid was isolated by filtration, and the aqueous layer was extracted with CH_2Cl_2 (4 × 250 mL). The combined CH_2Cl_2 layers were washed with water (500 mL), dried, and the solvent was removed by distillation. Recrystallization of the combined solids from 95% ethanol yielded 45.5 g of **6***c*; mp 189.5–190.5°C.

*4-Bromobicyclo[2.2.1.0^{2,6}]heptane (**4**d)*

Tosylhydrazone **6***c* (36 g, 0.1 mol) was added to sodium methoxide (47.5 g, 0.88 mol) in purified diglyme (600 mL), and the mixture was refluxed for 3 h and poured into water (500 mL). The mixture was extracted with ether (10 × 250 mL); the combined ether extracts were washed with water (5 × 250 mL) and dried. The solvent was removed by distillation and the residue was dissolved in pentane (800 mL) and extracted with water (6 × 50 mL). After the pentane solution was dried and concentrated by distillation, **4***d* (7.4 g) was isolated by vacuum distillation (bp 36–37°C/1.8 Torr) and shown to be >99% pure by analytical glpc; ^{1}Hmr (CCl_4) δ: 1.70 (s, 6, —CH_2—), 1.11 (s, 3, cyclopropyl H's).

*4-Iodotricyclo[2.2.1.0^{2,6}]heptane (**4**e)*

Argon, passed through Drierite, bubbled through concentrated H_2SO_4, and passed through a trap, was bubbled through a solution of sodium (2.5 g) and benzophenone (25 g) in toluene (100 mL) in a flask equipped with a condenser and used to flush a two-necked flask equipped with a stopcock at the side and a condenser fitted with a $CaCl_2$ drying tube. The apparatus was charged with purified cyclohexane (25 mL, stored over CaH_2 and distilled), Li (1.0 g, 0.14 mol), and sodium (0.05 g) and the solution was heated at reflux under a constant flow of argon and stirred vigorously with a magnetic stirrer. After a fine Li dispersion formed, **4***c* (2.0 g, 0.016 mol) in cyclohexane (5 mL) was added and the mixture was stirred and refluxed for 7 h and cooled. Freshly sublimed iodine was added through the condenser until a purple color persisted. The solution was washed with water (3 × 25 mL) and the aqueous later was extracted with ether (2 × 20 mL). The combined organic layers were dried and filtered twice and most of the solvent was distilled through a 30 cm helices column. Additional solvent was removed by distillation through a 15 cm helices column and **4***e* (1.9 g) was isolated by preparative glpc using a 1.5 m × 6 mm 15% SE-30 on Chromosorb A column maintained at 175°C. Since the collection efficiency was 92%, the overall yield of the reaction was 58%; ^{1}Hmr (CCl_4) δ: 1.71 (s, 6, —CH_2—), 0.95 (s, 3, cyclopropyl H's).

D_2SO_4-catalyzed ring-opening of trichloro[2.2.1.0^{2,6}]heptanes (nortricyclanes)

A stock solution of D_2SO_4 (0.75 g) in CD_3COOD (75 mL) was prepared and used for the cleavage reactions.

*Tricyclo[2.2.1.0^{2,6}]heptane (**4**a)*

Nortricyclane (**4***a*) (0.23 g, 0.0025 mol) was dissolved in 10.6 mL of CD_3COOD/D_2SO_4 solution and the mixture was stirred at ambient temperature for 14 h. The mixture was added slowly in small portions to saturated aqueous $NaHCO_3$ and the aqueous layer was extracted with ether (6 × 20 mL). The glpc analysis established that the reaction was 98% complete. The combined ether extracts were washed with water, dried, and the solvent was removed by distillation through a 30 cm glass-helices column. The remaining traces of solvent were removed under vacuum to yield 0.35 g of deuterated *exo*-norbornyl acetate.

*4-Chlorotricyclo[2.2.1.0^{2,6}]heptane (**4**c)*

Chloronortricyclane **4***c* (0.36 g, 0.0028 mol) was dissolved in 12 mL of D_2SO_4/CD_3COOD solution and stirred at 49 ± 2°C for 76 h. The reaction was quenched by carefully adding it to saturated aqueous $NaHCO_3$ and extracting the aqueous layer with ether. The glpc analysis showed the reaction to be 90% complete and removal of solvent yielded 0.49 g of deuterated 4-chloronorbornyl acetate.

*4-Bromotricyclo[2.2.1.0^{2,6}]heptane (**4**d)*

Bromonortricyclane (**4***d*) (0.48 g, 0.0028 mol) was dissolved in 12 mL of D_2SO_4/CD_3COOD solution and stirred at 49 ± 2°C for 76 h. The usual work-up and glpc analysis showed that the reaction was 97% complete and evaporation of the final traces of ether under vacuum yielded 0.60 g of deuterated bromoacetate.

*4-Iodo[2.2.1.0^{2,6}]heptane (**4**e)*

Iodonortricyclane **4***e* (0.62 g, 0.0028 mol) was dissolved in 12 mL of deuterated stock acid solution and the solution was stirred at 50 ± 1°C for 90.5 h. The reaction was worked up in the usual manner and glpc analysis showed that the reaction was 97% complete and only the acetate was present. The last traces of solvent were removed under vacuum to yield 0.68 g of deuterated 4-iodonorbornyl acetate.

Lithium aluminium hydride reduction of acetates

Acetate **17***a* (0.35 g) in dry ether (5 mL) was added to a slurry of $LiAlH_4$ (0.35 g) in ether (25 mL) and the mixture was refluxed for 3 h. Water (0.5 mL), 10% aqueous NaOH (0.5 mL), and water (0.5 mL) were added slowly in sequence as the mixture was stirred vigorously. The precipitate was filtered off and washed with ether (25 mL). After the ether solution was dried, most of the solvent was removed by distillation and the deuterated *exo*-2-norbornanol (0.13 g) was isolated by preparative glpc on a 3 m × 6 mm 15% Carbowax on Chromosorb W column maintained at 170°C at a He flow rate of ~20 mL per minute. The alcohol (0.015 g) was complexed with 0.050 g of $Pr(fod)_3$ and a ^{2}Hmr was obtained at 13.8 MHz.

Acetate **17***b* (0.49 g) in dry ether (5 mL) was added to a slurry of $LiAlH_4$ (0.5 g) in dry ether (30 mL) and the mixture was refluxed for 3 h. Water (0.5 mL), 10% NaOH (0.5 mL), and water (0.5 mL) were added sequentially with vigorous stirring and the precipitate was filtered off and washed with ether (25 mL). After the ether solution was dried, the ether was distilled off and the last traces of solvent removed under vacuum to yield 0.31 g of deuterated 4-chloro-*exo*-2-norbornanol. The glpc analysis showed the chlorohydrin to be 98% pure.

Acetate **17***c* (0.60 g) in dry ether (5 mL) was added to a slurry of $LiAlH_4$ (0.5 g) in ether (30 mL) and the mixture was refluxed for 4 h. Work-up in the usual manner, followed by evaporation of the last traces of solvent under vacuum, gave 0.33 g of a solid which was shown by glpc to be comprised of 82% 4-bromo-*exo*-2-norbornanol and 17% of *exo*-2-norbornanol.

Acetate **17***d* (0.68 g) dissolved in ether (5 mL) was added to a slurry of $LiAlH_4$ (0.5 g) in ether (30 mL) and the mixture was refluxed for 3 h. Work-up in the usual manner, followed by removal of the final traces of solvent under vacuum, gave 0.33 g of 4-iodo-*exo*-2-norbornanol, shown to be 99% pure by analytical glpc.

Sodium in 2-propanol reduction of halohydrins

Chlorohydrin **18***a* (0.31 g) was dissolved in reagent-grade 2-propanol (9 mL) in a flask (25 mL) fitted with a condenser and drying tube and the solution was heated to reflux. Sodium (0.5 g) was added in small portions to the refluxing solution over a period of 0.5 h and the mixture was refluxed for 4 h. To the cooled solution was added 15 mL of saturated aqueous NaCL solution and pentane (15 mL). The pentane layer was withdrawn after shaking, the aqueous layer was extracted with additional pentane (3 × 15 mL), the combined extracts were washed with saturated aqueous NaCl solution (2 × 10 mL) and dried. Most of the solvent was removed by distillation through a 30 cm glass-helices column and the deuterated *exo*-2-norbornanol (0.076 g) was isolated by preparative glpc on a 3 mm × 6 mm 15% Carbowax on Chromosorb W column maintained at 170°C. The *exo*-norbornanol (0.013 g) was complexed with $Pr(fod)_3$ (0.113g) in CCl_4 and a 13.8 MHz ^{2}Hmr was obtained.

Bromohydrin **18***b* (0.33 g, 82% bromohydrin and 17% *exo*-norbornanol) was dissolved in 9 mL of 2-propanol, the solution was heated to reflux, 0.5 g of sodium was added in small portions over a period of 0.5 h, and the solution was refluxed for 5.5 h. The glpc analysis of the pentane solution obtained after work-up showed an additional product (~20%) of longer retention time than *exo*-norbornanol. The deuterated *exo*-norbornanol (0.040 g) that was isolated by preparative glpc was shown to be >99% *exo*-alcohol by analytical glpc. The deuterated *exo*-norbornanol (0.024 g) was complexed with $Pr(fod)_3$ (0.090 g) in CCl_4 and a 13.8 MHz ^{2}Hmr was obtained.

Iodohydrin **18***c* (0.45 g) was dissolved in 2-propanol and the solution was heated to reflux. Sodium (0.5 g) was added in small portions over a period of 0.5 h and the mixture was refluxed for 2 h. Analytical glpc analysis of a pentane solution obtained after the usual work-up showed that an additional product (~30%) of longer retention time than *exo*-norbornanol was present. Most of the solvent was removed by distillation and the deuterated *exo*-2-norbornanol (0.080 g) was isolated by preparative glpc as described above. Analytical glpc showed the *exo*-norbornanol to be >99% pure. The deuterated alcohol (0.026 g) was complexed with $Pr(fod)_3$ (0.096 g) and a 13.8 MHz ^{2}Hmr was obtained. The remainder was reinjected on the preparative glpc and the deuterated *exo*-alcohol (0.029 g) was complexed with $Pr(fod)_3$ (0.108 g) in CCl_4 and a 13.8 MHz ^{2}Hmr was obtained.

Pyrrole chemistry. XXVI. A synthesis of porphobilinogen from pyrrole

BASIL J. DEMOPOULOS, HUGH J. ANDERSON,[1] CHARLES E. LOADER, AND KURT FABER
Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received April 13, 1983

BASIL J. DEMOPOULOS, HUGH J. ANDERSON, CHARLES E. LOADER, and KURT FABER. Can. J. Chem. **61**, 2415 (1983).

A synthetic strategy has been developed which enables pyrrole to be used as the starting material for the synthesis of 2,3,4-trisubstituted pyrroles of the type used to construct porphyrins. The total synthesis of porphobilinogen has been accomplished as a demonstration of the applicability of the approach.

BASIL J. DEMOPOULOS, HUGH J. ANDERSON, CHARLES E. LOADER et KURT FABER. Can. J. Chem. **61**, 2415 (1968).

On a mis au point une méthode de synthèse qui permet d'utiliser le pyrrole comme produit de départ dans la synthèse des pyrroles trisubstitués en positions 2,3,4, analogues à ceux que l'on utilise pour synthétiser les porphyrines. On a réalisé la synthèse totale du porphobilinogène dans le but de démontrer la validité de cette méthode.

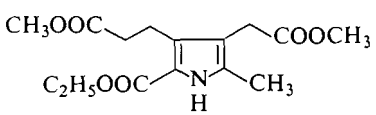
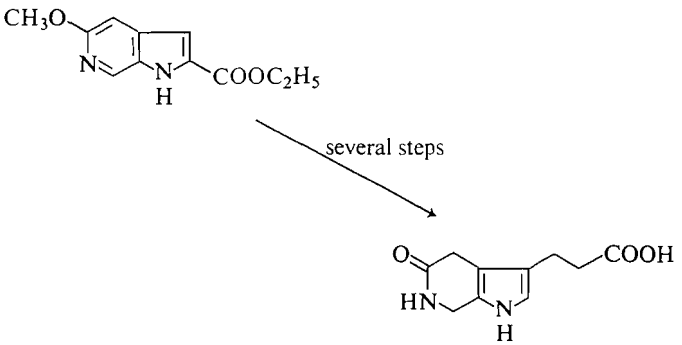
We have been struck over the years by the fact that the chemists who synthesize the tri- and tetra-substituted pyrroles which are used to assemble porphyrins have invariably chosen to prepare them by ring closure methods (1). It seemed to us that pyrrole itself should be considered as a possible starting material for these substituted pyrroles, and we proposed to demonstrate that a viable route could be developed for a typical example of this type of molecule, given the current state of pyrrole chemistry. In addition to giving an acceptable yield, the new synthetic approach should: (1) be experimentally easy to carry out on a reasonable scale; (2) not make use of large amounts of expensive reagents; (3) be capable of providing isotopically labelled elements in the side chains; (4) be capable of modification to produce related 2,3,4-trisubstituted pyrroles.

The selectivity of the electrophilic substitution reactions of pyrrole derivatives has been shown (2, 3) to be highly dependent on the presence of electron-donating or electron-withdrawing groups. Based on this premise, it was speculated that porphobilinogen, 5-(aminomethyl)-4-(carboxymethyl)-1*H*-pyrrole-3-propanoic acid, **1**, the biological precursor of the porphyrins, chlorophylls, and corrins (4), might be amenable to a total synthesis starting from pyrrole.

Following the isolation and characterization of porphobilinogen by Westall in 1952 (5), and the subsequent structure proof of Cookson and Rimington (6), the first practical synthesis by the Knorr method was carried out by Jackson and MacDonald (7) five years later. This synthesis was improved by Arsenault and MacDonald (8) to give an overall yield of about 1%. Other approaches by Plieninger *et al.* (9) and by Kenner *et al.* (10) increased the yield of the key MacDonald intermediate:



A quite different route was developed by Frydman *et al.* (11) in 1965, extending a pyridine derivative by ring closure to an azaindole which was eventually converted to the porphobilinogen lactam:



A major improvement to this approach was made by Battersby *et al.* (12), giving an overall yield of about 15% from a commercially available pyridine derivative.

Our extensive investigations of methods for the introduction of the cyano group onto pyrrole and its simple derivatives (13), as well as the behaviour of pyrrole-2-carbonitrile in substitution reactions (14), had led to a consideration of other functionalities derivable from the cyano group. One such reduction product is the aminomethyl group, an interesting grouping which occurs in porphobilinogen.

There is no easy sequence of substitution reactions that enables pyrrole to be converted directly to 2,3- or 2,3,4-substituted derivatives. While it is possible to obtain large amounts of 2-substituted pyrroles of various types, the next group enters position 4 or 5, but not position 3; except for a few special examples. In turn, 2,4-substituted compounds generally do not lead to 2,3,4-substituted products. The only general approach to the 2,3-substitution pattern starts from pyrrole with an electron donor group in position 3 (2).

As a basic synthetic plan, the sequence shown in Scheme 1 was chosen. This involves the stepwise introduction of: (a) the 3-acetate moiety, which it was hoped would behave as an electron donor, (b) the 2-aminomethyl group in the form of an electron-withdrawing functional precursor such as the cyano group, (c) the 4-propanoate moiety, and finally, (d) reduction and hydrolysis to porphobilinogen **1**. Thus pyrrole-3-acetic acid, or its ester, became the initial target molecule. Although structurally simple, no efficient syntheses for pyrrole-3-acetates on a reasonable scale are available. Ethyl pyrrole-3-acetate (**2**) has been shown (15) to form, along with the C-2 isomer, from the reaction of pyrrole with ethyl diazoacetate, but the separation of these two isomers on a preparative scale was not reported.

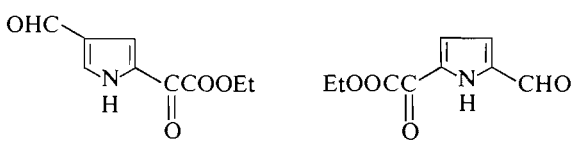
1

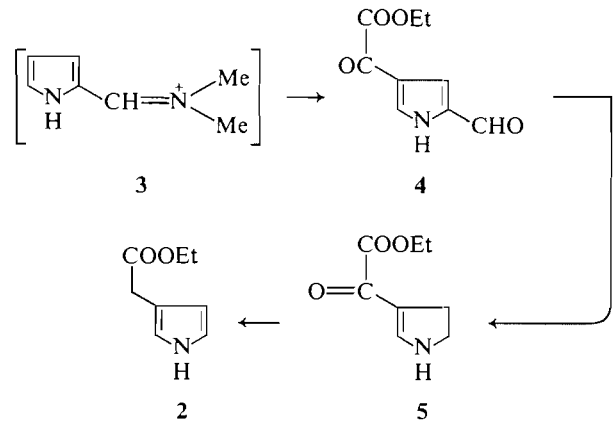
SCHEME 1

It is known (16) that the Friedel–Crafts acylation of the Vilsmeier–Haack intermediate **3** of pyrrole is selective, leading to the formation of 4-acylpyrrole-2-carboxaldehydes. In turn, the aldehyde group is easily removed to afford the 3-acylpyrrole. The same approach could be used for a 3-alkylpyrrole synthesis. It is not possible to use haloacetic acid or ester in the Friedel–Crafts synthesis to give the 4-acetic acid (or ester)-2-aldehyde (17). An attempt to use glyoxalic acid in the reductive alkylation procedure (18) on the Vilsmeier–Haack intermediate was unsuccessful. However, 4-acetylpyrrole-2carboxaldehyde was readily available from the acetylation of the Vilsmeier intermediate followed by hydrolytic work-up. It was then subjected to the thallium(III)-catalyzed rearrangement (19). Although that reaction succeeded, the yield of methyl 2-formylpyrrole-3-acetate was low and we were reluctant to proceed with the method because of (1) the large amounts of $Tl(NO_3)_3 \cdot 3H_2O$ needed at this early stage of the synthetic sequence, (2) the consequent cost, and (3) the toxicity of the reagent. On the other hand, the preparation of **4**, its decarbonylation, and the reduction of the glyoxalate **5** were anticipated to provide a facile route to the acetic ester grouping of **2**, free from the C-2 isomer, as shown in Scheme 2. Accordingly, ethyl 2-formylpyrrole-4-glyoxalate (**4**) was synthesized (69% yield) using ethyl oxalyl chloride as the acylating agent on the Vilsmeier–Haack intermediate. Two other possible isomers, **6** and **7**, were also isolated, but in yields of less than 2%.



6 **7**

We had hoped that it would be possible to decarbonylate the aldehyde group of **4** and reduce the glyoxalate to the acetic ester in a single operation through the use of Raney nickel. However, although nuclear magnetic resonance spectra showed that this succeeded to some extent, other products were also present. Milder conditions led to the presence of alcohol groups and more vigorous ones reduced some of the aldehyde function to methyl. Consequently we decided to carry out the operations individually. Compound **4** was then smoothly decarbonylated to **5** with palladium on charcoal in refluxing mesitylene (92% yield). Apparently the strong electron-withdrawing effect of the glyoxalate group present on **4** facilitates the reaction. This type of palladium catalyzed decarbonylation has been previously conducted on pyrroles (16) without a solvent at higher temperatures and, although successful here, did not give as good a yield as the solution method.



3 **4** **2** **5**

SCHEME 2

The reduction of the glyoxalate **5** to the acetate **2** was troublesome. The apparent tendency of **2** towards self-polymerization in acidic media and the ease of reduction of the pyrrole ring were major obstacles. It has been shown (20) that W-7 Raney Nickel in 50% aqueous ethanol hydrogenolyzes benzylic ketones under virtually neutral conditions. Although **2** was formed under these conditions, tarring and reduction of the pyrrole ring were still major side reactions. On the other hand, a 67% yield of **2** was attained by conducting the reduction with W-7 Raney Nickel in a two phase system consisting of toluene and 50% aqueous ethanol. Under these conditions **2** is effectively removed from the aqueous reduction medium into the toluene layer as soon as it is formed. Thus, the 3-acetic ester may be prepared easily, and on a large scale, in three steps with an overall yield of greater than 40%.

As mentioned earlier, electrophilic substitution on 3-alkylpyrroles has been shown to favor attack at position C-2 over C-5.[2] The Vilsmeier–Haack reaction is an extremely mild and selective reaction which is also very easy to carry out with pyrroles. Thus it was the reaction chosen to test the behaviour of the 3-acetic ester as a directing group. The product was a mixture of 2- and 5- substitution products **8** and **9** in which the desired 2-aldehyde-3-acetic ester was the predominant isomer. We further observed that the distribution of the two isomers

[2] See ref. 3, p. 194; ref. 2, p. 119.

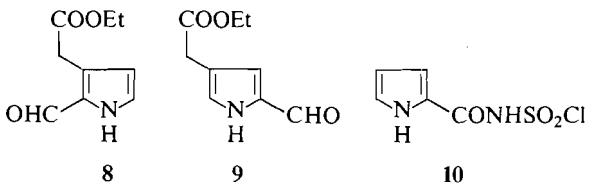
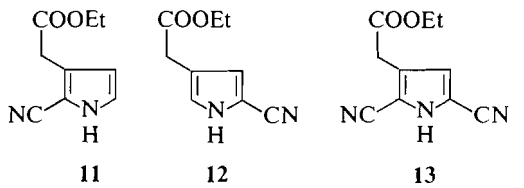
For personal use only.

(C-2 versus C-5) depended on the temperature of the reaction. For instance, lowering the reaction temperature by 20°C (0°C to −20°C) during the Vilsmeier–Haack reaction with **2** resulted in a 17% enrichment of isomer **8** (C-2 attack) over isomer **9** (C-5 attack), based on ^{1}H nmr data.





Chlorosulfonyl isocyanate (CSI) has been shown (13*b*) to react smoothly with pyrrole at low temperatures and, further, decomposition of the intermediate **10** so formed with dimethylformamide (DMF) affords pyrrole-2-carbonitrile in excellent yield. In accordance, ethyl pyrrole-3-acetate (**2**) was treated with CSI at −42°C and the intermediate was decomposed with DMF. Medium-pressure liquid chromatography (21) of the crude product afforded **11** (53%), **12** (12%), and **13** (0.8%). Lower reaction temperatures failed to change the ratio of the two monocyano isomers, while at higher reaction temperatures the amount of the disubstituted product **13** was substantially increased. That the product was a mixture, and extremely difficult to separate by column chromatography, led us to consider other pathways which might avoid this problem. One route (shown in Scheme 3) would retain the original aldehyde group, but block it as the acetal **14** formed with 2,2-dimethyl-1,3-propanediol (cf. ref. 22) until after the cyanation step, to be followed by hydrolysis and decarbonylation. Another pathway would use the readily available 2-ester as starting material, as shown in Scheme 4.

It was anticipated that one of these routes would provide an alternative, though longer, approach to the carbonitrile **11**, free from the undesired isomer **12**. Although the 2-acetal-4-glyoxalate ester **14** was readily synthesized from **4**, it resisted all attempts to reduce the keto group selectively. The 2-ester-4-glyoxalate **15** was prepared and reduced in a two-step process (23), first by Pd/charcoal to the hydroxyester **16** and then using triphenylphosphine – triphenylphosphine diiodide to give **17**. Cyanation of **17** then gave **18**, as expected. However, selective cleavage of the methyl ester in **18** under nonhydrolytic (24) conditions was not successful, so we returned to the direct cyanation of the 3-acetic ester **2** as our synthesis of **11**.

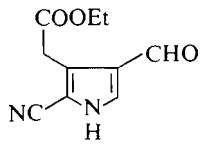
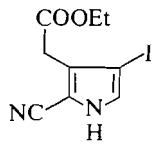
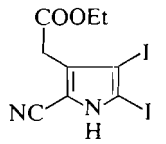
The well established (14, 25) 4-directing effect of a cyano group at the C-2 position of the pyrrole ring was expected to facilitate the introduction of electrophilic substituents at position C-4 of **11**. Aldehyde **19** or iodide **20** appeared to be suitable precursors for the construction of a 4-acrylate grouping which would be reduced subsequently to the propanoate side chain present on porphobilinogen. Formylation of **11** using a variety of methods (dichloromethyl alkyl ether – Lewis acid (14, 26), Vilsmeier–Haack, trifluoroacetic acid/triethyl orthoformate (27)) was unsuccessful; however, iodination (iodine/iodic acid (28)) proved to be specific and resulted in a



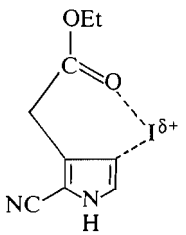
19



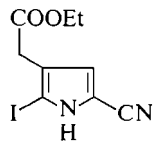
20



21



A



22

97% yield of **20** along with a very small amount (<1%) of the diiodo derivative **21**. It was thought at first that this high degree of selectivity derived from a six-membered transition state **A**, similar to that suggested for the thallium trifluoroacetate substitution (29). This was not the case because it was found that pyrrole-2-carbonitrile was converted selectively to 4-iodopyrrole-2-carbonitrile (67%) under the same reaction conditions.

On a preparative scale, it was now established that the use of liquid chromatography to separate isomers **11** and **12** could be avoided by iodination of that mixture. The desired product, **20**, can then be easily separated in pure form by flash chromatography. The overall yield of **20** from **2** was almost identical to that from the lengthier operation.

It has been shown (30) that acrylates react with aryl iodides in the presence of palladium acetate to form the corresponding cinnamates in high yield. Although **23** was formed from **20** and ethyl acrylate under these conditions, Michael type addition of ethyl acrylate on the pyrrole nitrogen and reduction of the iodo group at position C-4 to give back **11** were major side reactions. Reduction of the iodo group on electron-rich aryl iodides during the palladium acetate catalyzed vinylic arylation of olefins has been previously observed (30*a*, 31). On the other hand, as shown in Scheme 5, the *N*-benzoyl derivative of **20**, **24**, was smoothly converted to **25** (58%), along with an amount of **23**. The latter compound was immediately re-*N*-benzoylated, thus increasing the yield of **25** to 91.5%. The overall yield from pyrrole was 19% at this point.

The conversion of **25** to porphobilinogen **1** could be carried out by one of the two routes shown in Scheme 6. Hydrogenation of **25** over Adams' catalyst in acetic anhydride (32) gave the amide **26**. We had hoped that the acetylation of the aminomethyl group would provide added stability to the reduced product but the acetamide was quite unstable and could not be obtained completely pure. It was characterized by ^{1}H and ^{13}C nmr, infrared, and mass spectra. A competing reaction was the hydrogenation of the pyrrole ring of **26**. Therefore, the reaction had to be closely monitored and stopped before any substantial amount of that by-product was formed. At this point there was always some unreduced carbonitrile **27** present, as well as an unidentified by-product. A major difficulty was the need to remove the solvent and unreduced nitrile from the amide **26** as rapidly as possible. Partial decomposition during work-up could not be avoided despite the variety of techniques used.

Attempts were made to improve the hydrogenation by altering the reaction conditions. With Pd/charcoal (10%) or Pd black the reduction ceased after saturation of the double bond. While PtO_2 appeared to be the best catalyst, it afforded no real

For personal use only.

selectivity between the nitrile and the pyrrole ring. Acidic conditions greatly increased the rate of reduction but did not improve the selectivity. The use of cobalt boride catalyst (33) was unsuccessful. It is interesting to note that, where reduction of substituted pyrrole-2-carbonitriles has been successful, there was another electron-withdrawing group present on the ring (7, 34). The 1-benzoyl group does not appear to provide the required effect here.

Finally, the use of Pd black and PtO_2 in ethanol/ammonia, where the ester-amine forms the fairly stable porphobilinogen lactam-ester **28** (8, 37, 38) under the action of the weak base, almost doubled the yield from the hydrogenation. Under the conditions used, the *N*-benzoyl group was solvolytically cleaved to give the 1-*H* lactam ester.

The hydrolysis of **26** or **28** was carried out in a similar way to that of porphobilinogen lactam (11) for 96 h using 2 mol L^{-1} aqueous potassium hydroxide, followed by adjustment of the pH to precipitate porphobilinogen hydrate. It had the correct physical properties (10) and was identical to a commercial sample of authentic material isolated from natural sources. The overall yield of recrystallized porphobilinogen obtained in nine steps from pyrrole was about 6%.

While the preparation of porphobilinogen has been successfully accomplished, it is evident that the nitrile reduction step must be improved or replaced to achieve the maximum benefit from our new approach. We intend to explore the use of the aldoxime group as an alternative. Nevertheless, we feel that the flexibility of pyrrole as a starting material for the preparation of 2,3,4-substituted pyrroles possessing side-chains of interest to the porphyrin chemist has been adequately demonstrated. Most of the steps are extremely easy to carry out, even on a large scale, and yields are all very good aside from the reduction step.

Experimental

Melting points are uncorrected. Elemental analyses were by Atlantic Microlabs, GA, U.S.A. The ir spectra were recorded on a Perkin–Elmer 237B grating spectrophotometer as solutions in $CHCl_3$ unless otherwise stated. The ^1H nmr spectra (nmr) were determined using a Varian EM 360 or a Bruker WP-80 instrument and are expressed in ppm (δ values) relative to tetramethylsilane as internal reference in $CDCl_3$ unless otherwise stated. Mass spectra were recorded on a VG Micromass 7070HS spectrometer. The ^{13}C nmr spectra were determined at 20.122 MHz in $CDCl_3$ on a Bruker WP-80 Fourier transform instrument. All solvents were dried and distilled before use. Throughout, the term "petroleum" refers to the fraction of bp 30–60°C. The term "hexanes" refers to a mixture of isomers bp. 65.8–69.0°C (Fisher Scientific). Flash chromatography (35) was carried out using "Baker Analyzed" silica gel for flash chromatography.

*Ethyl 2-formylpyrrole-4-glyoxalate (**4**)*

The Vilsmeier–Haack iminium chloride **3** of pyrrole was made as previously described (16) from pyrrole (21 g, 0.313 mol), DMF (35 g, 0.48 mol), and oxalyl chloride (43.8 g, 0.34 mol) in 1,2-dichloroethane (700 mL) under nitrogen. The reaction mixture was cooled (ice bath), and $AlCl_3$ (185 g, 1.39 mol) was added. The reaction was allowed to warm to room temperature over 10 min and then nitromethane (56 mL, 1.04 mol) was added. The resulting red solution was cooled (ice bath) and ethyl oxalyl chloride (64 g, 0.47 mol) was added as rapidly as possible. The ice bath was removed and the reaction mixture was stirred vigorously under nitrogen for 4 h. The mixture was then poured into a stirred mixture of ice/water (5 L) and the stirring was continued for an additional 4 h. The aqueous and the organic layers were separated. The aqueous layer was extracted with dichloromethane (3 × 500 mL portions). The combined organic layer and the dichloromethane extracts were washed with saturated aqueous NaCl, dried ($MgSO_4$), and the solvent removed under reduced pressure. The solid residue was recrystallized from dichloromethane/petroleum to afford ethyl 2-formylpyrrole-4-glyoxalate (**4**) (41.32 g, 68%), mp 99–99.5°C. The mother liquors from the recrystallization were evaporated under reduced pressure and the residue was flash chromatographed on silica gel with petroleum – ethyl acetate (10:3 to 10:10) to afford (a) an additional 530 mg of ethyl 2-formylpyrrole-4-glyoxalate, raising the total yield to 41.85 g (69%); ir (Nujol): 1675, 1750, 1845, 3220 cm^{-1}; nmr: 1.4 (3H, t, $—CH_2—CH_3$), 4.38 (2H, q, $—CH_2—CH_3$), 7.64 (1H, m, 3-H), 8.16 (1H, m, 5-H), 9.55 (1H, s, —CHO), $J_{1,3}$ = 2.5, $J_{1,5}$ = 3.4, $J_{3,5}$ = 1.3, $J_{2\text{-CHO}}$ = 1.1 Hz; *m/e*: 195. *Anal.* calcd. for $C_9H_9NO_4$: C 55.38, H 4.64; found: C 55.32, H 4.66; (b) ethyl 2-formylpyrrole-5-glyoxalate (**7**) (639 mg, 1%), mp 57–58°C; ir: 1670, 1730, 3400 cm^{-1}; nmr: 1.4 (3H, t, CH_3, J = 7 Hz), 4.4 (2H, q, CH_2, J = 7 Hz), 6.94 (1H, dd, pyrrole H), 7.34 (1H, dd, pyrrole H), 9.68 (1H, s, —CHO), 10.6 (1H, broad s, NH), $J_{3,4}$ = 4.4, $J_{1,3}$ = 2.6 Hz; *m/e*: 195. *Anal.* calcd. for $C_9H_9NO_4$: C 55.38, H 4.64; found: C 55.43, H 4.65; (c) ethyl 3-formylpyrrole-5-glyoxalate (**6**) (234 mg, 0.4%), mp 85.5–87°C; ir: 1670, 1730, 3400 cm^{-1}; nmr: 1.4 (3H, t, CH_3, J = 7 Hz), 4.4 (2H, q, CH_2, J = 7 Hz), 7.8 (2H, m, 2-H and 4-H), 9.87 (1H, s, —CHO), 10.7 (1H, broad s, NH); *m/e*: 195. *Anal.* calcd. for $C_9H_9NO_4$: C 55.38, H 4.64; found: C 55.44, H 4.69.

*Ethyl pyrrole-3-glyoxalate (**5**)*

A mixture of ethyl 2-formylpyrrole-4-glyoxalate (**4**) (10 g, 0.051 mol) and 5% palladium on charcoal (1.5 g) in mesitylene (100 mL) was refluxed under nitrogen for 6 h. The mixture was then cooled to room temperature, diluted with dichloromethane (300 mL), filtered through Celite, and the catalyst was washed on the filter with several portions of dichloromethane. The dichloromethane solution from the combined filtrate and washings was evaporated under reduced pressure, and the residue was treated with petroleum (200 mL) and then refrigerated for 3 h. The precipitated solid was collected and recrystallized from dichloromethane/petroleum to afford ethyl pyrrole-3-glyoxalate (**5**) (7.885 g, 92%), mp 91–92°C; ir (Nujol): 1665, 1760, 3250 cm^{-1}; nmr: 1.35 (3H, t, CH_3), 4.66 (2H, q, CH_2), 6.62 (2H, m, 4-H and 5-H), 7.72 (1H, dd, 2-H), $J_{2,4}$ = 1.4, $J_{2,5}$ = 2.0, $J_{4,5}$ = 3.0 Hz; *m/e*: 167. *Anal.* calcd. for $C_8H_9NO_3$: C 57.48, H 5.43; found: C 57.30, H 5.54.

*Ethyl pyrrole-3-acetate (**2**)*

A mixture of ethyl pyrrole-3-glyoxalate (**5**) (12 g, 0.072 mol) and seven teaspoons (35 mL) of W7[3] Raney nickel (36), ethanol (200 mL), water (200 mL), and toluene (400 mL) was stirred vigorously at room temperature under nitrogen for 1.5 h. Seven more teaspoons of W7 Raney nickel were then added and the stirring was continued for an additional 3 h. Saturated aqueous NaCl (200 mL) and ether (200 mL) were then added to the mixture. The two layers that formed were separated, the aqueous layer was extracted with ether (2 × 200 mL), and the combined extracts and the organic layer were washed with saturated aqueous NaCl and then dried by filtration through a small plug of $MgSO_4$. Evaporation of the solvent under reduced pressure afforded an oil which was flash chromatographed on silica gel with ether–petroleum (1:2) as the eluent to give ethyl pyrrole-3-acetate (**2**) (7.310 g, 67%).[4] An analytical sample was prepared with some loss of material by a bulb-to-bulb distillation (0.5 Torr, 170°C); ir: 1720, 3380, 3475 cm^{-1}; nmr: 1.24 (3H, t, CH_3, J = 7 Hz), 3.48 (2H, s, CH_2COO), 4.1 (2H, q, CH_2, J = 7 Hz), 6.1 (1H, m, 4-H), 6.6 (2H,

[3] NOTE: Depending on its activity, greater or lesser amounts of the W7 Raney nickel catalyst and longer or shorter reaction times may be required. To obtain the desired activity it was necessary to double the suggested number of washings (36). The progress of the reduction was conveniently followed by thin-layer chromatography (silica gel with ether/petroleum 2:1 as the eluent) using samples taken from the toluene layer.

[4] *Storage*: The compound can be stored for long periods under nitrogen in a refrigerator without decomposition.

For personal use only.

m, 2-H and 5-H), 8.3 (1H, broad s, NH); *m/e*: 153. *Anal.* calcd. for $C_8H_{11}NO_2$: C 62.72, H 7.24, N 9.15; found: C 62.55, H 7.29, N 9.09.

*Ethyl 2-cyanopyrrole-3-acetate (**11**)*

To a well stirred and cooled (−42°C, acetone/solid CO_2 bath) solution of **2** (6 g, 0.039 mol) in acetonitrile (80 mL) and dichloromethane (20 mL), CSI (5.83 g, 3.59 mL, 0.0412 mol) was added dropwise over 30 min under nitrogen. The mixture was then stirred at the same temperature for an additional 2.5 h. DMF (15 mL) was then added rapidly and the reaction mixture was allowed to warm to room temperature over 1.5 h. The volatiles were removed under reduced pressure, the residue was taken up in toluene (400 mL) and washed successively with dilute $NaHCO_3$ solution (1 × 100 mL), water (3 × 100 mL), saturated aqueous NaCl, and then dried ($MgSO_4$). Evaporation of the toluene afforded a crude mixture of the carbonitriles **11**, **12**, and **13**. The mixture was separated using medium pressure liquid chromatography (21) on silica gel (500 g Merck Kieselgel 60, 230–400 mesh) with benzene/petroleum/ethyl acetate (10:10:1.5 rising to 10:10:3) as the eluent. The separation was monitored by a combination of ^1H nmr and tlc. The following products were eluted (in order).

(a) Ethyl 2,5-dicyanopyrrole-3-acetate (**13**) (67 mg, 0.84%), mp 73–73.5°C (from dichloromethane–petroleum); ir: 1725, 2225 cm^{-1}; nmr: 1.3 (3H, t, CH_3, J = 7 Hz), 3.64 (2H, s, CH_2COO), 4.2 (2H, q, CH_2, J = 7 Hz), 6.8 (1H, broad s, pyrrole H), 10.7 (1H, broad s, NH); *m/e*: 203. *Anal.* calcd. for $C_{10}H_9N_3O_2$: C 59.11, H 4.47, N 20.68; found: C 59.15, H 4.47, N 20.64.

(b) Ethyl 2-cyanopyrrole-3-acetate (**11**) (3.716 g, 53%) as an oil. An analytical sample was made by bulb-to-bulb distillation (200°C/0.1 Torr); ir: 1730, 2225, 3300, 3450 cm^{-1}; nmr: 1.28 (3H, t, CH_3, J = 7 Hz), 3.62 (2H, s, CH_2COO), 4.16 (2H, q, CH_2, J = 7 Hz), 6.14 (1H, dd, 4-H), 6.74 (1H, t, 5-H), 9.65 (1H, broad s, NH), $J_{4,5}$ = 2.72, $J_{1,4}$ = 2.2 Hz; *m/e*: 178. *Anal.* calcd. for $C_9H_{10}N_2O_2$: C 60.66, H 5.66, N 15.73; found: C 60.37, H 5.70, N 15.62.

(c) Ethyl 2-cyanopyrrole-4-acetate (**12**) (844 mg, 12%) as an oil. An analytical sample was made by bulb-to-bulb distillation (220°C/0.1 Torr); ir: 1725, 2225, 3300, 3450 cm^{-1}; nmr: 1.28 (3H, t, CH_3, J = 7 Hz), 3.5 (2H, s, CH_2COO), 4.14 (2H, q, CH_2, J = 7 Hz), 6.7 (2H, m, pyrrole H), 9.7 (1H, broad s, NH); *m/e*: 178. *Anal.* calcd. for $C_9H_{10}N_2O_2$: C 60.66, H 5.66, N 15.73; found: C 60.40, H 5.72, N 15.65.

*Ethyl 2-cyano-4-iodopyrrole-3-acetate (**20**)*

I. A mixture of ethyl 2-cyanopyrrole-3-acetate (**11**) (1 g, 5.62 mmol), iodic acid (198 mg, 1.123 mmol), and iodine (570 mg, 2.24 mmol) in carbon tetrachloride (40 mL), water (1.2 mL), acetic acid (2.8 mL), and concentrated sulfuric acid (0.1 mL, about 4 drops) was stirred vigorously at room temperature under nitrogen for 24 h. At this point the coloration due to the iodine had been discharged. The reaction mixture was then diluted with dichloromethane (100 mL) and the two layers formed were separated. The organic layer was washed with saturated sodium thiosulfate solution (1 × 50 mL), 5% $NaHCO_3$ (1 × 50 mL), saturated aqueous NaCl, and dried ($MgSO_4$), and the volatiles removed under reduced pressure. The solid residue was crystallized from CH_2Cl_2/petroleum to afford the product **20** (1.422 g, 83%), mp 118–118.5°C; ir: 1730, 2210, 3400 cm^{-1}; nmr: 1.3 (3H, t, CH_3, J = 7 Hz), 3.6 (2H, s, CH_2COO), 4.2 (2H, q, CH_2, J = 7 Hz), 6.84 (1H, d, 5-H, $J_{1,5}$ = 3 Hz), 9.8 (1H, broad s, NH); *m/e*: 304. *Anal.* calcd. for $C_9H_9N_2O_2I$: C 35.55, H 2.98, N 9.21; found: C 35.63, H 3.01, N 9.19.

The mother liquors from the recrystallization were concentrated and the residue was flash cromatographed on silica gel with petroleum/benzene/ethyl acetate (10:2:2) as the eluent. Thus was obtained: (a) a further 238 mg of **20**, increasing the total yield to 1.660 g (97%), and (b) ethyl 2-cyano-4,5-diiodopyrrole-3-acetate (**21**) (21 mg, 0.1%), mp 118–118.5°C; ir: 1730, 2210, 3400 cm^{-1}; nmr: 1.3 (3H, t, CH_3, J = 7 Hz), 3.64 (2H, s, CH_2COO), 4.18 (2H, q, CH_2, J = 7 Hz), 9.7 (1H, broad s, NH); *m/e*: 430. *Anal.* calcd. for $C_9H_8N_2O_2I_2$: C 25.14, H 1.88, N 6.52; found: C 25.17, H 1.93, N 6.49.

II. On a preparative scale the medium pressure chromatographic separation of **11** and **12** can be avoided by using the isomer mixture without further purification as starting material for the preparation of ethyl 2-cyano-4-iodopyrrole-3-acetate (**20**). Thus the mixture of **11** and **12** (1 g, 5.62 mmol) was treated as in I above. After removal of solvents, the residue was flash chromatographed on silica gel using hexanes/ether (4:1) as the eluent. Thus were obtained in order of elution: (a) ethyl 2-cyano-5-iodopyrrole-4-acetate (**22**). An analytical sample was prepared by bulb-to-bulb distillation (230°C/0.8 Torr) (199 mg, 11.6%), mp 81.5–82°C; ir: 1720, 2200, 3000 (broad), 3400 cm^{-1}; nmr: 1.3 (3H, t, CH_3, J = 7 Hz), 3.45 (2H, s, CH_2COO), 4.2 (2H, q, CH_2, J = 7 Hz), 6.75 (1H, d, 3-H, $J_{1,3}$ = 3 Hz), 10.0 (1H, broad s, NH); *m/e*: 304. *Anal.* calcd. for $C_9H_9N_2O_2I$: C 35.55, H 2.98, N 9.21; found: C 35.46, H 2.99, N 9.13; (b) ethyl 2-cyano-4,5-diiodopyrrole-3-acetate (**21**), (13 mg, 0.53%); (c) ethyl 2-cyano-4-iodopyrrole-3-acetate (**20**), (877 mg, 51.4%).

4-Iodopyrrole-2-carbonitrile

Pyrrole-2-carbonitrile (8.78 g, 0.095 mol) was converted to 4-iodopyrrole-2-carbonitrile according to the method used for the synthesis of **20**. The crude product was recrystallized from dichloromethane/petroleum to afford the product (13.94 g, 67%), mp 105–106°C; ir: 2210, 3400 cm^{-1}; nmr: 6.68 (2H, m, 3-H and 5-H), 9.5 (1H, broad s, NH); *m/e*: 218. *Anal.* calcd. for $C_5H_3N_2I$: C 27.55, H 1.39, N 12.85; found: C 27.51, H 1.44, N 12.83.

*Ethyl 1-benzoyl-2-cyano-4-iodopyrrole-3-acetate (**24**)*

Benzoyl chloride (844 mg, 6 mmol) in dichloromethane (10 mL) was added dropwise over 30 min to a well stirred and cooled (ice bath) mixture of **20** (1.216 g, 4 mmol), powdered NaOH (272 mg, 6.8 mmol), and tetrabutylammonium hydrogen sulfate (68 mg, 0.2 mmol) in dichloromethane (30 mL) under nitrogen. This was then stirred at the same temperature under nitrogen for an additional 2 h. The reaction mixture was filtered through Celite and the precipitate was washed on the filter with several portions of dichloromethane. The combined filtrate and washings were washed with saturated aqueous NaCl and dried ($MgSO_4$). Evaporation of the dichloromethane afforded crude **24** which was flash chromatographed on silica gel with hexanes/ether (2:1) as the eluent to give the pure product **24** (1.623 g, 99.5%), mp 116–117°C; ir: 1730, 2220 cm^{-1}; nmr: 1.34 (3H, t, CH_3, J = 7 Hz), 3.68 (2H, s, CH_2COO), 4.24 (2H, q, CH_2, J = 7 Hz), 7.28 (1H, s, 5-H), 7.6 (5H, m, phenyl H); *m/e*: 408. *Anal.* calcd. for $C_{16}H_{13}N_2O_3I$: C 47.08, H 3.21, N 6.87; found: C 47.01, H 3.23, N 6.84.

*Ethyl 1-benzoyl-2-cyano-4-carbethoxyvinylpyrrole-3-acetate (**25**)*

A mixture of ethyl 1-benzoyl-2-cyano-4-iodopyrrole-3-acetate (**24**) (2.04 g, 5 mmol), triethylamine (850 mg, 8.42 mmol), ethyl acrylate (750 mg, 7.5 mmol), CH_3CN (2 mL), and palladium(II) acetate (25 mg) was placed in a heavy walled Pyrex tube sealed at one end and fitted with a Teflon cap. The tube was flushed out with dry nitrogen. The Teflon cap was then fitted tightly and the tube was inserted into a preheated oil bath controlled within the range 99–100°C. The reaction mixture was then stirred at this temperature for 40 min. The mixture was allowed to cool to room temperature and then dissolved in dichloromethane (200 mL), washed with dilute (0.5 mol L^{-1}) HCl, saturated aqueous NaCl, and dried ($MgSO_4$). Evaporation of the volatiles afforded the crude product which was flash chromatographed on silica gel with hexanes/ether (3:2) as the eluent. Thus were obtained: (a) ethyl 1-benzoyl-2-cyano-4-carbethoxyvinylpyrrole-3-acetate (**25**) (1.103 g, 58%), mp 104–105°C (from dichloromethane/petroleum); ir: 1710, 2225 cm^{-1}; nmr: 1.3 (6H, t, CH_3, J = 7 Hz), 3.8 (2H, s, CH_2COO), 4.18 (4H, q, CH_2, J = 7 Hz), 6.1 (1H, d, CH=C*H*, J = 16 Hz), 7.38 (1H, d, 5-H), 7.4 (1H, d, C*H*=CH, J = 16 Hz), 7.6 (5H, m, phenyl H); *m/e*: 380. *Anal.* calcd. for $C_{21}H_{20}N_2O_5$: C 66.30, H 5.30, N 7.37; found: C 66.24, H 5.34, N 7.34; (b) ethyl 2-cyano-4-carbethoxyvinylpyrrole-3-acetate (**23**), (0.431 g, 31.2%), mp 107–108°C (from dichloromethane/petroleum); ir: 1635, 1710, 2200 cm^{-1}; nmr: 1.29, 1.31 (each 3H, t, CH_3, J = 7 Hz), 3.72 (2H, s, CH_2COO), 4.20 (2H, q, C*H*$_2$—CH_3, J = 7 Hz), 4.22 (2H, q,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

CH_2—CH_3, J = 7 Hz), 6.1 (1H, d, CH=C*H*, J = 16 Hz), 7.1 (1H, d, 5-H, J = 3 Hz), 7.45 (1H, d, C*H*=CH, J = 16 Hz), 10.1 (1H, broad s, N-H). *Anal.* calcd. for $C_{14}H_{16}N_2O_4$: C 60.86, H 5.84, N 10.14; found: C 61.07, H 5.85, N 10.02. The latter compound was rebenzoylated according to the procedure for **24**, raising the overall yield of **25** to 91.5%.

Ethyl 1-benzoyl-2-acetamidomethyl-4-carbethoxyethylpyrrole-3-acetate (26)

A solution of **25** (300 mg, 0.79 mmol) in acetic anhydride (3 mL) was hydrogenated over PtO_2 (100 mg) at atmospheric pressure and room temperature for 6 h.[5] The solution was taken up in ethyl acetate (50 mL) and then filtered through a Celite pad. The Celite pad was washed several times with portions of ethyl acetate and the filtrate and washings were combined and the solvent was removed under reduced pressure. The residue was flash-chromatographed on silica gel with petroleum/benzene/ethyl acetate (10:10:0 to 10:10:10) to afford the crude product (225 mg).[6]

*Ethyl 4,5,6,7-tetrahydro-5-oxo-1*H*-pyrrolo[2,3-c]pyridine-3-propanoate (28) (porphobilinogen lactam ethyl ester)*

Ethyl 1-benzoyl-2-cyano-4-carbethoxyvinylpyrrole-3-acetate (**25**) (304 mg, 0.8 mmol)[7] was dissolved in dry ethanol (30 mL) which was then saturated with dry ammonia. After the addition of Pd black (50 mg) and PtO_2 (120 mg) the mixture was hydrogenated at room temperature and pressure until H_2-takeup ceased at about 2.5 equivalents (about 24 h when thin-layer chromatography showed that all of the starting material had been consumed). The solution was then warmed to about 50°C and filtered from the catalyst through a Celite pad. The Celite pad was washed with several portions of hot dry ethanol and the combined filtrate and washings were evaporated under reduced pressure (bath temperature: 40°C) until the first cloudy precipitate appeared. The mixture was then quickly heated until the precipitate redissolved and the solution was set aside in a refrigerator overnight. The white precipitate that formed was collected and washed with dry ether to give pure **28**. A second crop was obtained by repeating the evaporation and cooling procedure to give a total yield of 102 mg (54%), mp (in a sealed, evacuated capillary, 0.05 Torr) 251°C (lit. (37) mp 261°C; (8) mp 239–244°C); ir: 1580, 1615, 1650, 1725, 2875, 3150 cm^{-1}; nmr (DMSO-d_6): 1.17 (3H, t, CH_2CH_3, J = 7 Hz), 2.50–2.55 (m, propanoate methylenes, obscured by DMSO), 3.14 (2H, t, J = 3.2 Hz, 4-H), 4.04 (2H, q, J = 7 Hz, CH_2CH_3), 4.30 (2H, m, 7-H), 6.45 (1H, d, 2-H, J = 2.3 Hz), 7.66 (1H, broad, lactam NH), 10.3 (1H, broad, pyrrole NH).

Porphobilinogen (1)

I. A mixture of the product from the foregoing reaction **26** (340 mg) in potassium hydroxide (2.5 mL, 2 mol L^{-1}) was stirred in darkness for 96 h under N_2 at room temperature. The pH of this solution was then adjusted to 6–7 with glacial acetic acid, cooled (ice bath), and the flask was scratched to initiate the precipitation of **1**. After 4 h at 0°C the precipitate was collected by filtration and washed quickly with cold water, followed by ether, and then dried for 4 h under high vacuum to give the product (106 mg, 36% from **25**), mp 174–177°C (dec., inserted at 167°C). Recrystallization from 0.7 mol L^{-1} ammonia solution/glacial acetic acid did not change the mp and gave a recovery of 55 mg (19% from **25**). Infrared and Fast Atom Bombardment mass spectra were identical to those of an authentic sample (Sigma Chemical Company) as was the ascending paper chromatogram (8). The chemical shifts in both the ^1H and ^{13}C nmr spectra matched those given in the literature (10).

II. The ethyl ester of porphobilinogen lactam (**28**) (110 mg, 0.47 mmol) was hydrolyzed in the same way to yield **1** (94 mg, 83% from **28**), identical in all respects with the product from I.

Ethyl 2-carbomethoxypyrrole-4-glyoxalate (15)

A mixture of methyl pyrrole-2-carboxylate (400 mg, 3.2 mmol), $AlCl_3$ (1.7 g, 12.8 mmol), and ethyl oxalyl chloride (0.45 g, 4.8 mmol) in dichloromethane (20 mL) containing nitromethane (0.52 mL) was stirred at room temperature under nitrogen for 15 h. This was then poured with stirring into a mixture of water and ice (200 mL) and the two layers were separated. The aqueous layer was extracted with dichloromethane (2 × 50 mL) and the combined organic layer and the extracts were washed with saturated aqueous NaCl, dried ($MgSO_4$), and the volatiles removed under reduced pressure. The residue was flash chromatographed on silica gel with ether/petroleum (2:1) as the eluent to afford the product **15** (323 mg, 45%), mp 109.5–110°C; ir: 1675, 1710, 3400 cm^{-1}; nmr: 1.44 (3H, t, CH_2CH_3, J = 7 Hz), 3.9 (3H, s, CH_3), 4.4 (2H, q, CH_2CH_3, J = 7 Hz), 7.48 (1H, m, 3-H), 7.98 (1H, m, 5-H), 10.5 (1H, broad s, NH), $J_{3,5}$ = 1.6 Hz; *m/e*: 225. *Anal.* calcd. for $C_{10}H_{11}NO_5$: C 53.33, H 4.93, N 6.22; found: C 53.33, H 4.96, N 6.21.

Ethyl 2-carbomethoxypyrrole-4-acetate (17)

Ethyl 2-carbomethoxypyrrole-4-glyoxalate (**15**) (600 mg, 2.67 mmol) in absolute ethanol (120 mL) was hydrogenated over 10% Pd/C (60 mg) in a Parr Shaker apparatus for 17 h with an initial hydrogen pressure of 40 psi. The reaction mixture was then filtered through Celite, the catalyst was washed on the filter with several portions of ethanol, and the combined washings and filtrate were evaporated under reduced pressure to leave a thick oily residue, the ^1H nmr of which indicated complete reduction of **15** to the alcohol **16**.

Triphenylphosphine (1.4 g, 5.34 mmol) was added to a stirred solution of iodine (677 mg, 2.67 mmol) in benzene (30 mL) under nitrogen. After 10 min, crude compound **16** in benzene (20 mL) was added in one portion. The mixture was then refluxed for 2 h under nitrogen. The mixture was filtered through Celite, and the precipitate was washed on the filter with several portions of benzene. The combined filtrate and washings were washed with saturated aqueous NaCl and dried ($MgSO_4$). Evaporation of the benzene under reduced pressure afforded crude material which was flash chromatographed on silica gel with ether/petroleum (1:1) as the eluent to give pure **17** (512 mg, 91%), mp 64–65°C; ir: 1700, 1725, 3420 cm^{-1}; nmr: 1.3 (3H, t, CH_2CH_3, J = 7 Hz), 3.49 (2H, s, CH_2COO), 3.8 (3H, s, CH_3), 4.15 (2H, q, CH_2CH_3, J = 7 Hz), 6.8 (2H, m, 3-H and 5-H), 9.2 (1H, broad s, NH); *m/e*: 211. *Anal.* calcd. for $C_{10}H_{13}NO_4$: C 56.86, H 6.20, N 6.63; found: C 56.79, H 6.23, N 6.60.

Ethyl 2-carbomethoxy-5-cyanopyrrole-4-acetate (18)

To a well stirred and cooled (−23°C, carbon tetrachloride – solid CO_2 bath) solution of **17** (300 mg, 1.42 mmol) in acetonitrile (30 mL), CSI (260 mg, 1.84 mmol) was added in one portion. The mixture was stirred at the same temperature under nitrogen for 2 h. DMF (1 mL) was then added rapidly and the reaction mixture was allowed to warm to room temperature over 2 h. The volatiles were removed under reduced pressure, the residue was taken up in benzene (50 mL) and washed with water (3 × 20 mL), saturated aqueous NaCl, and then dried ($MgSO_4$). Evaporation of the benzene afforded the crude material which was flash chromatographed on silica gel with ether/petroleum (1:2) as the eluent to give **18** (282 mg, 84%), mp 97–99°C; ir: 1725, 2225, 3200, 3400 cm^{-1}; nmr: 1.38 (3H, t, CH_2CH_3, J = 7 Hz), 3.6 (2H, s, CH_2COO), 3.9 (3H, s, CH_3), 4.14 (2H, q, CH_2CH_3, J = 7 Hz), 6.9 (1H, d, 3-H), 10.6 (1H, broad s, NH), $J_{1,3}$ = 1.8 Hz; *m/e*: 236. *Anal.* calcd. for $C_{11}H_{12}N_2O_4$: C 55.79, H 5.12, N 11.82; found: C 55.92, H 5.13, N 11.84.

Ethyl 2-(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole-4-glyoxalate (14)

Compound **14** was synthesized from **4** (2.0 g, 10.2 mmol) and 3.2 g (30.7 mmol) of 2,2-dimethyl-1,3-propanediol, according to the previously described method (22). The crude product was recrystallized from $CHCl_3$/petroleum to give 2.67 g (93%), mp 120–121°C; ir: 1670, 1740, 3430 cm^{-1}; nmr: 0.78 (3H, s, CH_3), 1.24 (3H, s, CH_3), 1.34 (3H, t, CH_2CH_3), 3.7 (4H, s, OCH_2), 4.3 (2H, q,

[5] The time required for the hydrogenation depended on the amount of reactants used. The reaction must be closely monitored by tlc.

[6] The chromatographed product was contaminated with a by-product which could not be distinguished from **26** by tlc.

[7] Ethyl 2-cyano-4-carbethoxyvinylpyrrole-3-acetate (**23**) (221 mg, 0.8 mmol) can be used instead of **25** without a significant change in the yield of **28**.

CH_2CH_3), 5.38 (1H, s, O—CH—O), 6.74 (1H, m, 3-H), 7.7 (1H, m, 5-H), 9.3 (1H, broad s, NH), $J_{2,3}$ = 1.6 Hz; *m/e*: 281. *Anal.* calcd. for $C_{14}H_{19}NO_5$: C 59.77, H 6.81, N 4.98; found: C 59.83, H 6.87, N 4.99.

A useful method for preparation of carboxylic acids from terminal alkynes[1]

SUZANNE R. ABRAMS

Prairie Regional Laboratory, National Research Council of Canada, Saskatoon, Sask., Canada S7N 0W9

Received April 5, 1983

SUZANNE R. ABRAMS. Can. J. Chem. **61**, 2423 (1983).

Substituted acetic acids can be prepared in good yield (50–80%) from terminal acetylenes of the same chain length. The alkyne is first converted to the thiophenyl ether, which is treated without purification with mercuric sulfate in acetic acid and 2 *N* sulfuric acid affording the carboxylic acid. The method is particularly useful in the synthesis of long chain ω-hydroxyalkanoic acids.

SUZANNE R. ABRAMS. Can. J. Chem. **61**, 2423 (1968).

On peut préparer les acides acétiques substitués avec un bon rendement (50–80%) à partir des acétylènes terminaux dont la chaîne est de la même longueur. On transforme d'abord l'alcyne en éther thiophényle que l'on traite sans aucune purification avec le sulfate mercurique dans de l'acide acétique et l'acide sulfurique 2 *N* pour obtenir l'acide carboxylique. La méthode est particulièrement utile dans la synthèse des acides ω-hydroxyalcanoiques à longue chaîne.

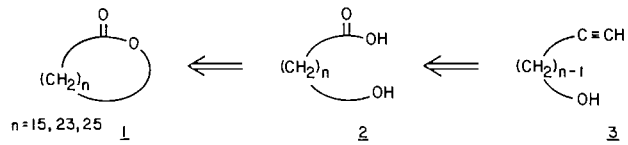
[Traduit par le journal]

In the course of a synthesis of some macrocylic lactones **1** (n = 15, 23, 25), some of which (n = 23, 25) are found in the defence secretion of a species of soldier termite (1), we encountered difficulty obtaining good yields of the substituted acetic acids **2** from the readily available ω-alkyn-1-ols **3** (2) using known methods. A sequence employing Jones oxidation of the alcohol and subsequent hydroboration of the triple bond to the primary alcohol suffered from low yields in the first step (3). The oxidation afforded poorly soluble soap-like acetylenic acids which were difficult to isolate. An alternate plan, in which the triple bond was to be converted to the carboxylic acid, met with limited success. Hydroboration of the non-polar bistrimethylsilyl derivative (4) of **3** gave the α,ω-diol as a major contaminant (50%). We sought to develop an alternative method for the preparation of alkanoic acids from terminal alkynes of the same chain length that would be suitable both for long chain alkynes and other compounds containing terminal triple bonds.

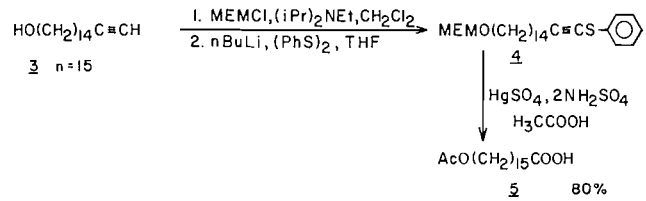
Terminal alkynes can be converted to their thioether derivatives in high yield (5) and it is known that hydration of the latter compounds with or without mercuric ion catalysis results in anti-Markovnikov attack at the terminal carbon (6). We have found that the thiophenyl derivative can be prepared in quantitative yield and treated with mercuric sulfate in 2 *N* sulfuric acid and acetic acid to give the alkanoic acid in good yield. The intermediate thiophenyl derivative does not require purification before hydrolysis.

The sequence is illustrated for 16-hydroxyhexadec-1-yne (Scheme 2). To a solution of the methoxyethoxymethyl (MEM) ether of 16-hydroxyhexadec-1-yne in THF was added n-butyllithium followed by diphenyldisulfide. The crude product **4**, was treated with a solution of mercuric sulfate, 2 *N* H_2SO_4, and acetic acid for a minimum of 4 hours at 80°C. The product. 16-acetoxyhexadecanoic acid **5**, obtained in 80% yield, is formed as the result of several processes: (1) hydration of the triple bond in the desired sense, (2) hydrolysis of the resulting thiophenyl ester, (3) removal of the MEM protecting group, and (4) acetylation of the alcohol. The product is a convenient starting material for preparation of the corresponding iodoacid (from HI and acetic acid) which can be cyclized to the macrocyclic lactone (7).

To show the generality of the procedure, a variety of alkynes



SCHEME 1



SCHEME 2

have been converted to their acetic acid derivatives (Table 1). The yields are based upon conversion from the alkyne without purification of the intermediate thioether, and are of isolated, pure products. The only exception is 1,7-octadiyne (entry 6); the intermediate monothioether was isolated before hydrolysis. The low yield of myristic acid is probably due to isolation problems.

This method for conversion of terminal alkynes to carboxylic acids of the same chain length compares favorably to those presently available (4, 10, 11). Alk-1-ynes can be converted to 1-chloroalk-1-ynes (12) which, upon treatment with base, afford carboxylic acids, but the yields are moderate (4). A direct method of preparation of carboxylic acids from acetylenes is the oxidation of 1,1-diborylalkanes with *m*-chloroperbenzoic acid, which proceeds in good yield but requires the separation of the desired acid from *m*-chlorobenzoic acid (11).

Experimental

Preparation and hydrolysis of the thiophenylacetylenic ethers was carried out under identical conditions. One experiment is described in full.

Cyclohexylacetic acid

Under a slight positive pressure of dry nitrogen, to a solution of cyclohexylacetylene (Farchan Labs., 2.16 g, 20 mmol) in THF (freshly distilled from benzophenone ketyl, 100 mL) at −70°C was added a solution of n-butyllithium (in hexane, 1.6 *M*, 15.1 mL, 24 mmol). The cooling bath was removed and the solution allowed to

TABLE 1. Carboxylic acids prepared by hydrolysis of the monothiophenyl derivative of some alkynes

Entry	Alkyne	Carboxylic acid	Yield (%)[a]
1	$MEMO(CH_2)_{14}C{\equiv}CH$	$AcO(CH_2)_{15}COOH$	80
2	$C_6H_5C{\equiv}CH$	$C_6H_5CH_2COOH$	70
3	$C_6H_{11}C{\equiv}CH$	$C_6H_{11}CH_2COOH$	64
4	$H_3C(CH_2)_5C{\equiv}CH$	$H_3C(CH_2)_6COOH$	49
5	$H_3C(CH_2)_{11}C{\equiv}CH$	$H_3C(CH_2)_{12}COOH$	32
6[b]	$HC{\equiv}C(CH_2)_4C{\equiv}CH$	$H_3CC(=O)(CH_2)_5COOH$	70

[a] Yields of isolated, pure products. The ^1H nmr and ir spectra and bp or mp were identical with literature values.
[b] The monothiophenyl derivative was isolated.

warm to 0°C, and then cooled again to −70°C prior to the dropwise addition of a solution of diphenyldisulfide (4.8 g, 22 mmol) in THF (25 mL). The solution was stirred and allowed to warm to ambient temperature overnight, then poured into ice water and extracted with ether (3X). The combined ether extracts were washed with NaCl solution, dried over Na_2SO_4, filtered, and the solvent evaporated to afford 4.46 g crude thioether which gave ir (film) ν_{max}: 3300 (absent), 3050 (w), 2910 (s), 2840 (s), 2160 (w), 2050 (absent), 1560 (m); ^1H nmr ($CDCl_3$, 90 MHz) δ: 7.1–7.5 (m, 5H), 2.5–3.0 (m, 1H), 1.1–2.0 (m, 10H).

A mixture of the crude thioether (3.46 g, 15.6 mmol in theory) mercuric sulfate (3.0 g, 10 mmol), 2 *N* sulfuric acid (60 mL), and acetic acid (180 mL) was heated at 80°C, in an oil bath overnight. The mixture was cooled, and extracted with $CHCl_3$ (3X). The combined organic extracts were washed with water, then NaCl solution, dried over Na_2SO_4, filtered, and evaporated. The crude product was taken up in ether and extracted with $NaHCO_3$ solution (3X). The combined basic extracts were acidified with HCl and extracted with $CHCl_3$ (3X). The combined extracts were washed with NaCl solution, dried over Na_2SO_4, filtered and evaporated, and distilled using a kugelrohr apparatus (140–150°C, 10 Torr), affording 1.4 g (64%) cyclohexylacetic acid which solidified on standing: ir (melt) ν_{max}: 3300–2500 (s), 1700 (s), 1440 (m), 1400 (m), and 1300 (m) cm^{-1} (9); ^1H nmr ($CDCl_3$) δ: 2.2 (d, J = 7 Hz, 2H), 0.8–1.9 (m, 11H) (8).

Optically active phosphonic analogues of alanine, valine, leucine, phenylalanine, and phenylglycine were obtained by resolution of diphenyl 1-aminoalkanephosphonates with dibenzoyl-L-tartaric acid anhydride.

PAWEŁ KAFARSKI, BARBARA LEJCZAK et JERZY SZEWCZYK. Can. J. Chem. **61**, 2425 (1983).

On a obtenu des analogues phosphoniques optiquement actifs de l'alanine, de la valine, de la leucine, de la phénylalanine et de la phénylglycine, par la résolution des dérivés diphenylamino-1-alkanephosphonates avec l'anhydride de l'acide dibenzoyl-L-tartarique.

Phosphonic analogues of important naturally occurring amino acids have received considerable attention in the past ten years in both academic and industrial laboratories.

It is now well established that 1-aminoalkanephosphonic acids act as substrates or inhibitors of several enzymes involved in the metabolism of amino acids (1).

Unfortunately, nearly all the biochemical studies were carried out using racemic 1-aminoalkanephosphonates, and evaluation of their action and of structure–activity relationships is strongly limited. Thus, for biochemical studies, the pure enantiomers of 1-aminoalkanephosphonic acids are desirable.

The optically pure 1-aminoalkanephosphonates described so far include only the analogues of alanine (2), valine (3), phenylglycine (3–5), and phenylalanine (6).

In this work the readily available diphenyl 1-aminoalkanephosphonates **1** (7) have been chosen as substrates for the preparation of the optically pure 1-aminoalkanephosphonic acids. Our attempts to separate diastereomeric salts of **1** with L-malic, L-mandelic, L-lactic, or dibenzoyl-L-tartaric acids were unsuccessful. However, we achieved successful resolution using dibenzoyl-L-tartaric anhydride **2**, which has been recently applied as a resolving agent for amines.[1]

We wish to describe here the use of this approach for the preparation of optically pure 1-aminoalkanephosphonic acids.

Optically active 1-aminealkanephosphonic acids

Reaction of dibenzoyl-L-tartaric anhydride **2** with diphenyl 1-aminoalkanephosphonate **1** leads to the corresponding am-

ides **3**, which were easily separated into diastereoisomers **3***a* and **3***b* by crystallization (Table 2).

The procedure is very effective: only one crystallization is sufficient to obtain pure diastereomeric amides **3** of sharp melting point. The purity of diastereoisomers was monitored by ^{31}P nmr and only one peak characteristic for the particular diastereomeric amide appeared in all cases.

Hydrolysis of **3***a* or **3***b* yielded the corresponding enantiomers of 1-aminoalkanephosphonic acids **4***a* and **4***b* in high yields (Table 1). In this manner we obtained enantiomeric phosphonic analogues of alanine, valine, leucine, phenylglycine, and phenylalanine. The absolute configuration of the analogues of alanine (2), valine (3), and phenylglycine (3) are given in the literature. The configurations of the phosphonic analogues of leucine and phenylalanine are tentative and are based on similar physical properties of the respective amides **3***a* and **3***b*.

Conversion of the amides 3 into imides 5

We hoped that the amides **5**, being "phthaloyl-like" molecules, could have been used for the preparation of optically active diphenyl 1-aminoalkanephosphonates. Unfortunately, the decomposition of these molecules under basic conditions (i.e. in the presence of amine, hydrazine, ammonia, or sodium hydroxide in alcohol or dioxane) yielded multicomponent mixtures without production of the desired diphenyl 1-aminoalkanephosphonates.

This part of our work, although unsuccessful in its final outcome, provided new information on the chemical properties of the amides **3** and, particularly, on chemical differences between diastereoisomers **3***a* and **3***b*.

We have noticed that the ring closure reaction rates differ significantly for diastereomeric **3***a* and **3***b*. Thus, reaction of diastereoisomeric mixtures of **3** with slight excess of thionyl chloride in benzene – methylene chloride suspension resulted, at room temperature, in formation of the soluble imide **5***b*, while unreacted amide **3***a* remained insoluble. The transformation of both stereoisomers of **3** into the imides **5** was smoothly accomplished by refluxing **3** in benzene with excess of thionyl chloride for several hours.

However, the separation of diastereomeric imides **5** was much more difficult than the separation of the corresponding amides (Table 3) and it was not recommended as a method for resolution, meaning that it is more convenient to use resolved amides **3***a* and **3***b*, instead of their mixtures, for the preparation of pure diastereoisomers of imides **5**.

*Structure of diastereomeric amides 3*a *and 3*b

Spectral data for the representative amides **3***a* and **3***b* are given in the Experimental section. Some additional comments

are in order.

The ^{1}H nmr as well as ir spectra of amides **3***a* clearly show the existence of strong hydrogen bonding in the molecule while spectra of **3***b* are tyical for amides. Thus, the spectra of amides **3***a* show N—H stretching frequencies in the range 3330–3360 cm^{-1} (3240–3250 cm^{-1} for **3***b*). It is conspicuous that two P=O stretching frequencies are found in the spectra of **3***a* while only one signal is present in the spectra of **3***b*. The splitting of P=O signals for **3***a* indicates that two non-equivalent phosphonate groups are present and suggests that **3***a* exists as dimer in the solid phase. Similar features were observed in the spectra of methyl esters **6**.

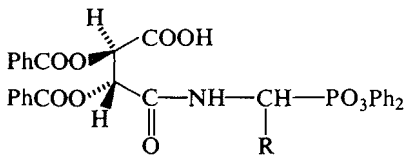
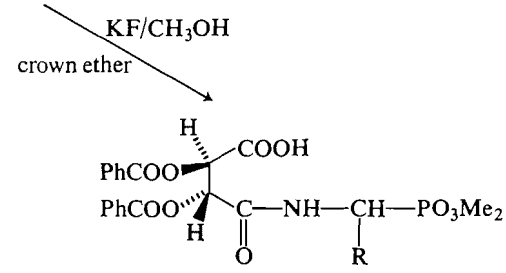
[a]By separation of diastereomeric **5***a* and **5***b* by crystallization.
[b]By ring closure of amides **3***a* or **3***b*.

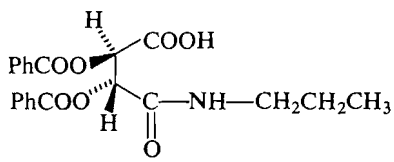


3

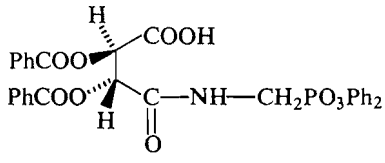


6

To confirm that the hydrogen bond in amides **3***a* is due to the participation of the phosphonic moiety, we synthesized similar amides derived from n-propylamine **7** and diphenyl aminomethanephosphonate **8**. As expected, the spectra of **8** were very close to those obtained for amides **3***a*, while spectra of n-propylamine derivative **7** were similar to those obtained for amides **3***b*.



7



8

The big difference in the structure of diastereomeric amides **3**, revealed by spectroscopy, explains the high effectiveness of the separation process, the reaction with thionyl chloride, as well as the big difference in the melting point values.

Experimental

The melting points were determined on a Koeffler apparatus and are uncorrected. Infrared spectra were taken on a Perkin–Elmer 621 instrument as KBr pellets. Absorptions are given in cm^{-1}. Nuclear magnetic resonance spectra were recorded on a Tesla BS467 instrument in DMSO-d_6 or in $CDCl_3$ solutions. The chemical shifts are reported as δ(ppm), using a capillary tube with hexamethyldisiloxane as standard. The ^{31}P nmr spectra were taken at the Centre of Molecular and Macromolecular Studies, Polish Academy of Sciences, Łódź, using 85% H_3PO_4 as internal standard.

Diphenyl 1-aminoalkanephosphonates **1**

The hydrobromide of **1** (0.06 mol) (7) was suspended in chloroform and an equal volume of 2 *N* sodium hydroxide was added. The mixture was shaken in the separatory funnel until all the solid dissolved. The chloroform layer was separated, washed with brine, and dried over anhydrous magnesium sulphate. Evaporation of the solvent yielded the desired esters in 90–98% yield.

Preparation of amides **3** *and separation of diastereoisomers – general procedure*

Diphenyl 1-aminoalkanephosphonate **1** (0.05 mol) was dissolved in 200 cc of dioxane and 17.0 g (0.05 mol) of dibenzoyl-L-tartaric anhydride **2** were added. The mixture was shaken until all the anhydride dissolved and left for 3 days at room temperature. Then the solvent was evaporated under reduced pressure, 100 cc of benzene were added (warming until all the oil dissolved) and the mixture was left in the refrigerator overnight. The product was collected by filtration and the second crop was obtained by reducing the volume of benzene to 50 cc.

The pure **3***a*, was obtained after crystallization from 75 cc of benzene or toluene.

To obtain **3***b*, the benzene was evaporated from the filtrate and the resulting oil was dissolved in 50 cc of ether. The solution was left

overnight in the refrigerator and the precipitated **3***b* was collected by filtration. The second crop of the amide **3***b* was obtained by reducing the solvent volume to 25 cc.

The analytical data for the amides obtained, **3***a* and **3***b*, are given in Table 2. Spectroscopic data of the representative pairs of isomers are given below, for those containing the phosphonic analogue of alanine.

Compound **3**a (R = CH_3)

Infrared: 3600–2400, 3340 (NH), 1745, 1715, 1690 (CO), 1530 (NH), 1265, 1236 (PO); ^{1}H nmr (DMSO): 1.33 (dd, J^3_{HH} = 7.5 Hz, J^3_{PH} = 18.5 Hz, 3H, CH_3); 4.0–5.1 (m, J^3_{HH} = 7.5 Hz, 1H, CHP), 6.11 (s, 2H, 2 × COOCH), 5.5–6.1 (m, 1H, COOH), 6.45–8.0 (m, 20H, 4 × C_6H_5), 9.13 (d, J^3_{HH} = 9.0 Hz, 1H, NH); ^{1}H nmr ($CDCl_3$): 1.21 (dd, J^3_{HH} = 7.5 Hz, J^3_{PH} = 18.5 Hz, 3H, CH_3), 4.2–5.1 (m, 1H, CHP), 5.7–6.2 (m, 3H, 2 × COOCH, NH), 6.7–8.1 (m, 21H, 4 × C_6H_5, COOH).

Compound **3**b (R = CH_3)

Infrared: 3600–2400, 3250 (NH), 1760, 1730, 1685 (CO), 1539 (NH), 1250 (PO); ^{1}H nmr (DMSO): 1.22 (dd, J^3_{HH} = 7.5 Hz, J^3_{PH} = 19.0 Hz, 3H, CH_3), 4.2–5.0 (m, 1H, CHP), 5.99 (db, J^3_{HH} = 7.5 Hz, 2H, 2 × COOCH), 5.9–6.3 (m, 1H, COOH), 6.5–8.2 (m, 20H, 4 × C_6H_5), 9.23 (d, J^3_{HH} = 9.0 Hz, 1H, NH); ^{1}H nmr ($CDCl_3$): 1.23 (dd, J^3_{HH} = 7.5 Hz, J^3_{PH} = 19.0 Hz, 3H, CH_3), 4.25–5.2 (m, 1H, CHP), 5.92 (s, 2H, 2 × COOCH), 6.93 and 6.98 (s, 5H, C_6H_5OP), 7.0–8.8 (m, 12H, 2 × C_6H_5COO, COOH, NH). Infrared data for the **3***a* and **3***b* series respectively are very close and nmr data for the fragment common for all the amides containing the defined enantiomer of aminophosphonate are analogous.

Optically active 1-aminoalkanephosphonic acids – general procedure

The amide **3** or **3***b* (0.01 mol) was dissolved in 60 mL of acetic acid and 60 cc of 40% hydrobromic acid were added. The obtained mixture was refluxed for 20 h. After cooling to room temperature, the solvents were removed under reduced pressure, the residue was mixed with 50 cc of water, benzoic acid was filtered out, the solution clarified with charcoal, and applied to the Dowex 50W X8 50–100 mesh column (15 × 300 mm). The column was washed with water and ninhydride-positive fractions were collected. Evaporation of water yielded pure, crystalline enantiomers **4***a* and **4***b* (Table 1).

Preparation of imides **5** *– general procedure*

Amide **3** (0.01 mol) was dissolved (or suspended) in 50 cc of benzene and 2 cc of thionyl chloride were added. The mixture was refluxed for 3–5 hours. The solvent was removed under reduced pressure and the residue crystallized from ether.

The analytical data and yields of the imides obtained, **5***a* and **5***b*, are collected in Table 3. Spectroscopic data of the representative pair of imides are given for those containing the phosphonic analogue of alanine.

Compound **5**a (R = CH_3)

Infrared: 1740, 1720 (CO), 1260 (PO), 1095 (POC); ^{1}H nmr (DMSO): 1.92 (dd, J^3_{HH} = 7.5 Hz, J^3_{PH} = 18.0 Hz, 3H, CH_3), 5.15 (qq, J^3_{HH} = 7.5 Hz, J^2_{PH} = 19.0 Hz, 1H, CHP), 6.43 (bs, 2H, 2 × COOCH), 7.43 and 7.46 (s, 5H, C_6H_5OP), 7.3–8.3 (m, 10H, 2 × C_6H_5COO).

Compound **5**b (R = CH_3)

Infrared: 1740, 1720 (CO), 1265, 1210 (PO), 1100 (POC); ^{1}H nmr (DMSO): 1.72 (dd, J^3_{HH} = 7.5 Hz, J^3_{PH} = 18.0 Hz, 3H, CH_3), 4.95 (qq, J^3_{HH} = 7.5 Hz, J^2_{PH} = 18.5 Hz, 1H, CHP), 6.28 and 6.30 (s, 1H, COOH), 7.27 (bs, 10H, 2 × C_6H_5OP), 7.3–8.1 (m, 10H, 2 × C_6H_5COO).

Transesterification of amides **3** *– general procedure*

Amide **3***a* or **3***b* (2.5 mmol) was dissolved in 50 cc of methanol and 2.0 g of potassium fluoride monohydrate and 10 mg of 18-crown-6 were added. The mixture was heated until all the solid material dissolved and left for two days at room temperature. Then solvent was removed on the rotatory evaporator. The residue was dissolved in 50 cc of water and acidified to about pH 3 with concentrated hydrochloric acid. The mixture was left in the refrigerator overnight and the product was filtered off. The crystallization from ethyl ether yielded the corresponding amides **6***a* and **6***b* (Table 4).

Spectroscopic data of the representative pair of isomers are given below for those containing the phosphonic analogue of phenylglycine.

Compound **6**a (R = C_6H_5)

Infrared: 3600–2200, 3300 (NH), 1735, 1725, 1695 (CO), 1545, 1525 (NH), 1270, 1240 (PO), 1060, 1030 (POC); ^{1}H nmr (DMSO): 2.46 and 2.68 (d, J^3_{PH} = 10.5 Hz, 3H, $POCH_3$), 4.76 (tt, J^3_{HH} = 5.0 Hz, J^2_{PH} = 21.5 Hz, J^3_{HH} = 8.5 Hz, 1H, CHP), 5.33 (s, 2H, 2 × COOCH), 6.5–7.6 (m, 16H, 3 × C_6H_5, COOH), 8.90 (d, J^3_{HH} = 8.5 Hz, 1H, NH).

Compound **6**b (R = C_6H_5)

Infrared: 3600–2200, 3225 (NH), 1720, 1700 (CO), 1530 (NH), 1240 (PO), 1060, 1030 (POC); ^{1}H nmr (DMSO): 2.85 and 3.01 (d, J^3_{PH} = 10.5 Hz, 3H, $POCH_3$), 4.78 (dd, J^2_{PH} = 21.5 Hz, J^3_{HH} = 9.5 Hz, 1H, CHP), 5.40 (bd, J^3_{HH} = 6.0 Hz, 2H, 2 × COOCH), 6.1–7.5 (m, 16H, 3 × C_6H_5, COOH), 9.02 (bd, J^3_{HH} = 9.5 Hz, 1H, NH).

Also, in this case, ir data for the **6***a* and **6***b* series respectively are very close and nmr data for the molecular fragment common for all the amides containing the defined enantiomer of 1-aminoalkanephosphonate are analogous.

Preparation of the amide **7**

As described for the preparation of the amides **3**, starting from n-propylamine. After crystallization from benzene, the product melting at 89–92°C and of $[\alpha]_{578}^{20}$ −82°C (*c* 1, acetone) was obtained in 74% yield; ir: 3650–2300, 3200 (NH), 1730, 1710 (CO), 1540 (NH); ^{1}H nmr (DMSO): 0.80 (t, J^3_{HH} = 6.5 Hz, 3H, CH_3), 1.46 (sex,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12

A simple point charge model has been developed for calculating the chemical shifts and line widths obtained from the ^{59}Co nmr spectra of Co(III) complexes. The chemical shift calculations assume the predominance of the paramagnetic term in the Ramsey equation and the relationship of this term to the energies of the $d-d$ electronic transitions. The line width calculations assume the predominance of quadrupolar broadening and use a point charge model to calculate electric field gradients in a manner previously used to interpret Mössbauer spectra. The model is tested by application to some fifty known Co(III) complexes. Most of the ^{59}Co spectra have been remeasured for this purpose. One chemical shift parameter and one line width parameter are required for each different type of ligand. These parameters are related to each other and to the crystal field splitting parameters of the ligands. The calculations can be readily applied to complexes of any symmetry and differentiate between different isomers of the same complex. The calculated chemical shifts cover a range of more than 14 000 ppm and the standard deviation between the calculated and experimental values is 108 ppm. Relative chemical shifts between complexes with similar ligands are calculated with considerably higher accuracy. The agreement between calculated and experimental line widths is only qualitative but the line width calculations provide valuable additional information for making assignments. The model is applied to the assignment of different isomers of cobalt dioxygen compounds and to the identification of products from oxygenation reactions.

STEVE C. F. AU-YEUNG et DONALD R. EATON. Can. J. Chem. **61**, 2431 (1983).

On a mis au point un modèle de charge ponctuelle simple pour calculer les déplacements chimiques et la largeurs des raies obtenues à partir des spectres de rmn du ^{59}Co des complexes de Co(III). Les calculs des déplacements chimiques supposent la prédominance du terme paramagnétique dans l'équation de Ramsey et la relation de ce terme avec les énergies des transitions électroniques $d-d$. Les calculs de la largeur des raies admettent la prédominance de l'élargissement quadrupolaire et utilisent le modèle de charge ponctuelle pour calculer les gradients de champ électrique comme cela a été fait antérieurement pour interpréter les spectres Mössbauer. On a vérifié l'utilité de ce modèle en l'appliquant à quelques 50 complexes connues du Co(III). Dans ce but, on a mesuré de nouveau la plupart des spectres du ^{59}Co. On a besoin d'un paramètre de déplacement chimique et d'un paramètre de largeur de raie pour chaque différent type de ligand. Ces paramètres sont reliés l'un à l'autre et au paramètre de dédoublement de champ du cristal des ligands. On peut facilement appliquer les calculs aux complexes de n'importe quelle symétrie et on peut distinguer les différents isomères du même complexe. Les déplacements chimiques calculés s'étendent sur plus de 14,000 ppm et la déviation normale entre les valeurs calculées et expérimentales est de 108 ppm. On a calculé les déplacements chimique relatifs entre les complexes ayant des ligands semblables avec une précision nettement plus grande. L'accord entre les largeur de raies calculées et expérimentales est seulement qualitatif mais les calculs de la largeur de raies fournissent une information additionnelle valable pour faire des attributions. On applique le modèle à l'identification des différents isomères des composés de cobalt dioxygénés et à l'identification des produits provenant des réactions d'oxygénation.

[Traduit par le journal]

Introduction

The ^{59}Co nmr spectra of a wide variety of Co(III) complexes have been reported (1). The chemical shifts cover a range of more than 10 000 ppm and the line widths vary from a few Hz to more than 10 kHz. Potentially, therefore, the combination of chemical shift and line width data, both of which may be readily obtained with modern multinuclear nmr spectrometers, provides a convenient method for characterizing a given complex. This potential has not been extensively exploited. It is the purpose of the present paper to develop a model which will allow facile estimation of the chemical shift and line width expected for a complex with given ligands arranged in a given geometry, using a minimal number of parameters. We will then proceed to demonstrate the utility of this model for assigning resonances and for identifying isomeric structures. The derived chemical shift and line width parameters for each type of ligand are related to the electronic structures of the ligands.

Chemical shift correlations

^{59}Co chemical shifts are dominated by the paramagnetic term in the Ramsey expression (2) for chemical shifts. The application of this theory to Co nmr was first carried out by Griffith and Orgel (3) and by Freeman, Murray, and Richards (4). Correlation of the chemical shifts with the inverse of the energy of the first spin-allowed $d-d$ transition was predicted and demonstrated to hold experimentally. The theory was further developed by Fujiwara *et al.* (5), who made allowance for variation of the orbital reduction factor k' and radial factor $\langle r^{-3}\rangle$ from complex to complex. Typically this leads to expressions such as:

$$[1]\quad \sigma_{zz} = -4\left(\frac{eh}{2mc}\right)^2\left\langle\frac{1}{r^3}\right\rangle\frac{8(k_1')^2}{\Delta E(^1A_{1g} - {}^1A_{2g})}$$

$$[2]\quad \sigma_{xx} = \sigma_{yy} = -4\left(\frac{eh}{2mc}\right)^2\left\langle\frac{1}{r^3}\right\rangle\frac{8(k_2')^2}{\Delta E(^1A_{1g} - {}^1E_{1g}(^1T_{1g}))}$$

for the components of the chemical shielding tensor for a D_{4h} complex. The nomenclature is that of ref. 5. The isotropic chemical shift can be obtained as the average of these diagonal terms. Juranic *et al.* (6, 7) have applied these results to a variety of Co(III) complexes and have pointed out the necessity of allowing for the anisotropy of the chemical shift and for variations in the orbital reduction factor from compound to compound. Yamasaki, Yajima, and Fujiwara (8) have also cor-

For personal use only.

related ^{59}Co chemical shifts with ligand electronegativities.

The objective in the present case is to derive a set of ligand parameters which will allow facile estimation of the chemical shift for a given complex. Yajima *et al.* (9) have proposed a simple linear correlation

$$\delta = 360x + \sum_{i=1}^{y} \delta_i(L)$$

for complexes of the type $Coen_x(NH_3)_{6-2x-y}L_y$ where $\delta_i(L)$ is a constant for a given ligand L. This type of correlation is not satisfactory for a wider range of complexes.

The isotropic shielding constant is given by

$$\sigma_{iso} = \frac{1}{3}(\sigma_{xx} + \sigma_{yy} + \sigma_{zz})$$

where the components of the chemical shielding tensor are given by expressions of the type of eq. [1] and [2]. It is usual to measure chemical shifts of ^{59}Co relative to the cobalticyanide anion in aqueous solution. Fujiwara *et al.* (5) have estimated the gyromagnetic ratio for ^{59}Co by plotting the chemical shifts of cobalt complexes versus the reciprocals of the energy of the first electronic transition. This estimate leads to an absolute value of 1.10% or 11 000 ppm for the shielding constant of $Co(CN)_6^{3-}$. We may therefore write the chemical shift relative to $Co(CN)_6^{3-}$ as

$$[3] \quad \delta = \frac{1}{3}\left(\frac{1}{\Delta E_x} + \frac{1}{\Delta E_y} + \frac{1}{\Delta E_z}\right) - 11\,000$$

For an octahedral complex the lowest excited state is triply degenerate but this splits into a maximum of three states with energies of E_x, E_y, and E_z as the symmetry is lowered. Ballhausen (10) has pointed out that these energies depend only on the sum of the charges produced by the ligands on the x axis, the y axis, and the z axis, respectively. We may therefore write

$$[4] \quad \delta = \frac{1}{3}\left(\frac{1}{S_1 + S_2} + \frac{1}{S_3 + S_4} + \frac{1}{S_5 + S_6}\right) - 11\,000 \text{ (in ppm)}$$

where S_1 and S_2 are parameters characteristic of the ligands on the x axis, S_3 and S_4 of ligands on the y axis, and S_5 and S_6 of ligands on the z axis. Given a set of parameters S_L for all the different ligands encountered this expression suffices to calculate the chemical shift of any cobalt complex. Yamatera (11) has applied a similar approach to the calculation of the splitting of the $d-d$ electronic bands of *cis* and *trans*, *mer* and *fac* isomers. Wentworth and Piper (12) have made similar calculations. Equation [4] is quite general and may be used for any six-coordinated Co(III) complex.

There are a number of approximations inherent in the use of eq. [4]. The major ones are: (*1*) the correct expressions for the electronic transition energies also include terms involving the inter-electronic repulsion (the Racah parameter) which may vary with the ligand in a different manner to the crystal field splitting parameter D_q; (*2*) the orbital reduction factors (k' of eqs. [1] and [2]) and radial terms $\langle r^{-3} \rangle$ will vary from complex to complex; (*3*) the crystal field splitting and hence the chemical shift parameter S, for a given ligand may depend upon the other ligands present. For these reasons we would expect only limited success in fitting experimental chemical shifts to eq. [4].

Line width correlations

The variation of line widths of Co(III) complexes has not previously been considered in detail. It has been widely recognized that complexes with low symmetry have broader lines than complexes with high symmetry and this has proved a useful generalization in assigning resonances. Yajima *et al.* (9) deduced from simple crystal field considerations that *trans* isomers should show broader lines than *cis* isomers and that for complexes of the stoichiometry CoA_3B_3 the *mer* isomer should have a broad line and the *fac* isomer a narrow line.

^{59}Co has a spin of 7/2 and therefore possesses a quadrupole moment. If quadrupolar relaxation is dominant the line width will be given by

$$[5] \quad \Delta\nu_{1/2} = \frac{\pi}{98} A^2 \tau_c$$

where

$$A^2 = \left(1 + \frac{\eta^2}{3}\right)\left(\frac{e^2qQ}{h}\right)^2$$

with

$$eq = V_{zz} \text{ and } \eta = \frac{V_{xx} - V_{yy}}{V_{zz}}$$

V_{zz}, V_{xx}, and V_{yy} are the principal components of the field gradient tensor, Q is the qudrupole moment of ^{59}Co, and τ_c is a rotational correlation time. If the correlation times for a series of complexes are approximately the same the line width will then depend only on the quadrupole coupling constants (e^2qQ/h) and the asymmetry parameters (η).

There are three approximations inherent in eq. [5]. First the instrumental contribution to the line width is neglected. Since this contribution is no more than a few Hz this is not a significant error. Secondly the contribution of relaxation mechanisms other than quadrupolar is neglected. The other mechanisms of possible importance are those arising from chemical shift anisotropy and from scalar relaxation of the second kind. We have recently shown that chemical shift anisotropy can be important for low symmetry complexes (13). However, the variation of the chemical shift tensor with geometry mathematically parallels that of the field gradient tensor. Spiess, Haas, and Hartman (14) have indeed found that for several complexes the chemical shift anisotropies measured for single crystals of cobalt complexes are directly proportional to the quadrupolar coupling constants. It seems therefore a reasonable procedure to develop line width correlations based on quadrupolar relaxation providing that it is recognized that the derived broadening parameters may contain a contribution from chemical shielding anisotropy which will be field dependent.

Scalar relaxation of the second kind involving coupling to the ^{14}N of amines is important for some complexes with high symmetry and relatively narrow lines. We must therefore expect that the model will be quantitatively poor for complexes with narrow lines. The third approximation of eq. [5] is that the extreme narrowing limit ($\omega^2\tau_c^2 \ll 1$) is assumed. This approximation is probably good for the large majority of the complexes.

A point charge model for quadrupolar coupling has been developed by Bancroft and Platt (15) and has been extensively applied to the interpretation of quadrupole coupling constants derived from Mössbauer spectra. Valiyev and Zripov (16) have presented a similar model. The latter theory has been applied to the ^{93}Nb line width of niobium halides by Tarasov *et al.* (17) and the ^{27}Al line widths of aluminum halide complexes by Wehrli and Wehrli (18). The components of the electric field

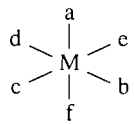
[a]The ligating atoms are arranged as indicated by the IUPAC convention (Commission on the Nomenclature of Inorganic Chemistry. Pure Appl. Chem. **28**, 1 (1971)).



gradient tensor are expressed in terms of the partial quadrupole splitting parameters for the individual ligands. Thus a single ligand gives rise to the field gradient

$$[6]\quad \begin{aligned} V_{xx} &= Zer^{-3}(3\sin^2\theta\cos^2\phi - 1)\\ V_{yy} &= Zer^{-3}(3\sin^2\theta\sin^2\phi - 1)\\ V_{zz} &= Zer^{-3}(3\cos^2\theta - 1)\end{aligned}$$

where Z is the charge on the ligand, e the charge of an electron, and r, θ, and ϕ are the polar coordinates of the ligand. The field gradient for a complex is obtained by summing the contributions to V_{xx}, V_{yy}, and V_{zz} from all six ligands with the θ and ϕ values being determined by the position of each ligand in the complex. On this model different ligands have different values of Zr^{-3}. Combination of eqs. [5] and [6] results in expressions for the line widths in terms of parameters for the individual ligands. Thus for example in the case of a *trans*-CoA_4B_2 complex:

$$\begin{aligned} V_{xx}' = V_{yy} &= [-2(Zr^{-3})_A + 2(Zr^{-3})_B]e\\ V_{zz} &= [4(Zr^{-3})_A - 4(Zr^{-3})_B]e\end{aligned}$$

where the subscripts A and B correspond to the appropriate ligands. Substitution in eq. [5] gives $\eta = 0$ and

$$\begin{aligned}\Delta\nu_{1/2} &= \frac{\pi}{98}\frac{Q^2e^4}{h}[4(Zr^{-3})_A - 4(Zr^{-3})_B]^2\tau_c\\ &= [4\gamma_A - 4\gamma_B]^2\end{aligned}$$

where

$$\gamma_A = \frac{\pi}{98}\frac{Q^2e^4}{h^2}(Zr^{-3})_A\tau_c$$

and γ_B is analogous.

In Table 1 expressions for the line widths in terms of the broadening parameters γ_A, γ_B etc. are given. The expressions of Table 1 agree with those given by Bancroft and Platt (15) for all cases where direct comparison is possible. A few of the numerical factors differ from those given by Tarasov *et al.* (17). In deriving the line broadening parameters from line width data, only the differences are obtained and there is an ambiguity in sign since they appear as squares. It will be shown that absolute values can be obtained by comparison with Mössbauer data.

Experimental

^{59}Co nmr spectra were obtained at 21.252 MHz using a Bruker WH90 FT spectrometer. The probe temperature was 24°C. A few spectra were also obtained at 94 MHz using a Bruker WH400 spectrometer. Aqueous samples were contained in 10 mm (e.d.) round bottomed tubes purchased from Wilmod Glass Co. The pH of the solutions was 5–6 except for the tetraethylene pentamine oxygen complexes which have pH values in the 6–7 range. Line widths were measured as the full width at half height of the absorption signal. Chemical shifts are reported relative to $Co(CN)_6^{3-}$ and were obtained by direct frequency measurements. Susceptibility corrections are of the order of 1–2 ppm and were neglected. ^{59}Co nmr data have been reported previously for most but not all of the complexes discussed below. Many have been remeasured since the line widths in particular vary considerably in the older literature reports. In cases where the spectra have been remeasured or are reported for the first time, appropriate synthetic references are given in the tables. Data fitting was carried out using an Osborne I microcomputer using BASIC programming. The "Supercalc" software was also used and is particularly convenient for optimizing the least-squares fit of a large amount of experimental data with variation of the chemical shift and line broad-

ening parameters. For complex spectra, a non-linear least-square program was developed. The spectrum is fitted to a sum of Lorenztians with a sixth order polynomial baseline function. The criteria for best fit is determined by the value of χ^2/df (~1.0). The standard errors were calculated in the usual way from the estimated variance-covariance matrix of the fitted parameters (19).

Results

Table 2 contains chemical shifts and line widths for 44 Co(III) complexes. The complexes reported in this table are all well characterized compounds of the types CoA_6, CoA_5B, *cis*- and *trans*-CoA_4B_2, and *mer*- and *fac*-CoA_3B_3. These data will be used to test the models for calculating chemical shifts and line widths described above. Data taken from literature sources are given in parentheses. ^{59}Co nmr spectra for eleven of these compounds have not been reported previously. Of the remainder all but five have been remeasured. Agreement with the literature chemical shift values is generally good with the ex-

ception of some of the values for the *cis*- and *trans*-CoA_4B_2 isomers. Some of the older studies using broad line nmr instruments did not distinguish between the isomers. The present results give distinct chemical shifts for the different isomers in all cases. There is considerable variation in the line widths reported in the literature. In one or two cases the present line widths do not agree with literature values obtained from broad line instruments. The ligands chosen range from the strong field CN^- to the weak field CO_3^{2-}. The total range of chemical shifts is more than 14 000 ppm which is close to the maximum observed for Co(III) complexes. These data should therefore provide a fair and adequate test for the model.

Table 3 gives chemical shift and line width data for ten low symmetry Co(III) complexes. All of these complexes have three different ligands and offer a variety of isomeric possibilities. Most, but not all, of these data have been taken from the literature. None of these data were used in the calculation of the ligand parameters and they therefore provide a further more rigorous test for the model. Table 4 gives ^{59}Co nmr data for a series of bridged cobalt complexes. Some of these data have been briefly reported in a communication (20). They will be used to provide illustrative examples of the application of the chemical shift and line width models.

Table 5 lists the chemical shift parameters (S_A, S_B, ...) and line width parameters (γ_A, γ_B, ...) which have been defined above. Tables 2, 3, and 4 include the chemical shifts and line widths calculated from these parameters.

The derivation of the chemical shift parameters of Table 5 is straightforward. For example, $S(NH_3)$ can be obtained directly from the chemical shift of $Co(NH_3)_6^{3+}$ and then used to find S(Cl) from the chemical shift of $Co(NH_3)_5Cl^{2+}$. An initial set of parameters obtained in this manner was then adjusted to optimize the fit of the data in Table 2.

The calculation of the partial broadening parameters of Table 5 is a little more complex. According to the definition proposed above the square root of the line width of a given complex, e.g., $Co(NH_3)_5Cl^{2+}$ gives the difference ($\gamma_{NH_3} - \gamma_{Cl^-}$). The signs of these differences were obtained by comparison with the analogous ^{57}Fe Mössbauer partial quadrupole coupling constants given by Bancroft and Platt (15). A plot of the differences in partial broadening constants versus the differences in ^{57}Fe partial quadrupole splitting constants is shown in Fig. 1. There is a linear relationship with a correlation coefficient of 0.988. Since the absolute values of the quadrupole splitting constants are known, the absolute values of the partial broadening constants can be obtained from the slope of this plot. This leads to a set of γ values which were then adjusted to give the best fit to the line widths of Table 2. The assumption implicit in this treatment is that since the Co(III) complexes and the Fe(II) complexes are isostructural and isoelectronic there will be proportionality between the electric field gradient produced by a given ligand at the Co nucleus and the electric field gradient produced by the same ligand at the Fe nucleus. The approximation involved in this assumption is probably less than the errors arising from assuming constant correlation times and neglecting relaxation mechanisms other than quadrupolar. For the monomeric complexes of Table 2 the variation in the correlation times may be estimated from the ionic radii to be around 20%. Bridged complexes such as those containing the peroxy ion will have significantly longer correlation times and hence the lines are likely to be significantly broader than calculated by the above simple procedure.

Discussion

A. Evaluation of the model

Of the 44 complexes in Table 2, five of the type $Co(NH_3)_5X^{2+}$ where X = F^-, I^-, NCS^-, SCN^-, and H_2O have been included to provide the corresponding *X* parameters. These ligands are only present in one compound and so the calculated shifts provide no test for the validity of the model. The remaining 39 complexes contain eight different ligands (NH_3, en, CN^-, Cl^-, Br^-, CO_3^{2-}, N_3^-, and dien). The terminal NH_2 of the dien ligand has been assigned the same parameters as the NH_2 of en. Two different parameters have been used for the central NH of dien depending on whether the three coordination positions are planar or at right angles. The same parameters will be used below for the trien and tetraen ligands. The same parameters have been used for both monodentate and bidentate CO_3^{2-}. A total of nine parameters have therefore been used to fit the 39 chemical shifts and a similar number to calculate the line widths. The standard deviation of the calculated from the experimental shifts is 108 ppm. The total range of the shifts is 14 070 ppm. As might be anticipated the fit is worst at the extreme ends of the chemical shift range. Of the four complexes for which the differences between observed and calculated are greater than 200 ppm, three are cyanide compounds (including $Co(CN)_6^{3-}$) and the fourth is the tris-carbonato complex. It is reasonable that the approximation of assuming a constant orbital reduction factor will be least applicable for these compounds. The calculations predict that *trans* isomers will have a greater shift than *cis* isomers and *mer* isomers a larger shift than *fac* isomers. The experimental data

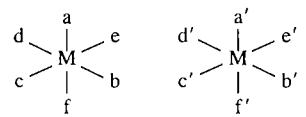
[a]Symmetric with respect to peroxo-bridge.

[b]^{1}H nmr indicated that DMSO, DMF is replaced by H_2O followed by dimerization to form *sym*-$(Co(salen))_2O_2(H_2O))_2$. Solution molecular weight studies support this assignment and the resonance is best assigned to the Cobalt center of the inner dimeric pair. The terminal Co(salen) group do not conform to $Co^{III}O_2^{2-}Co^{III}$ formalism (49). This is supported by kinetic results which will be published elsewhere.

[c]



[d]Assignment is less certain.

support these predictions in all cases.

The agreement between observed and calculated line widths is only qualitative but is nevertheless useful for making assignments as will be illustrated below. Thus it is predicted that *trans*-CoA_4B_2 isomers will be broader than *cis* by a factor of four. In all cases the *trans* lines are indeed broader but the factor is generally less than four. We attribute this mainly to broadening due to chemical shift anisotropy as has been discussed elsewhere (13). Similarly *mer* isomers always show broader lines than *fac* isomers as predicted. The calculated quadrupolar broadening for the *fac* isomers is zero and the residual width of a few hundred Hz probably arises from scalar relaxation with the nitrogen ligands. The correct prediction of trends in the line widths may be illustrated with the series of *cis*-$Coen_2X_2^+$ complexes with X = Cl^-, Br^-, CN^-, CO_3^{2-}, N_3^-, and NH_3. The experimental widths are 5126, 5420, 3700, 2968, 986, and 350 Hz, respectively and the calculated widths 2150, 1788, 2010, 1862, 793, and 103 Hz, respectively. The trend is correctly predicted but the widths of the broader lines are underestimated.

Table 3 illustrates the results of calculating chemical shifts and line widths for complexes of low symmetry. For the ten compounds in this table the standard deviation between observed and calculated chemical shifts is 66 ppm. None of these data were used in deriving the parameters. Most of the data are from the literature and were obtained on a broad line instrument which does not provide shift and line widths of the accuracy expected from a modern F.T. instrument. Nevertheless the model can clearly be used to predict the spectral parameters for complexes with several different ligands.

B. Application to cobalt dioxygen complexes

The point charge model used to calculate the line width parameters uses precisely the same assumptions as the familiar crystal field theory used to obtain the crystal field splitting parameters, D_q, from electronic spectra. Jørgensen (21) has expressed D_q in terms of ligand contributions and metal ion

ligands. There is an excellent linear correlation ($\gamma = 0.98$) with the plot passing through the origin. A plot of the shift parameters S versus the line width parameter γ is shown in Fig. 3. There is again a smooth correlation but the plot is not linear. This reflects the fact that E, and hence S, depends on both D_q and the Nephelauxetic parameter β and that, particularly for the strong field ligands, changes in the orbital reduction factor cannot be neglected. Both the line width parameter and the shift parameter are therefore indicative of the position of a ligand in the spectrochemical series. ^{59}Co nmr spectra may therefore be used to obtain this information in cases where charge transfer or other transitions complicate the interpretation of the $d-d$ electronic spectra.

The compounds formed by the reaction of molecular oxygen with Co(II) complexes (22) fall in this class. Table 4 contains the ^{59}Co nmr data for a variety of compounds with 2:1 $Co:O_2$ stoichiometries. These compounds are usually regarded as complexes of Co(III) with bridging peroxide ligands but it has been suggested on the basis of their ligand lability, that the oxidation state of the cobalt is intermediate between 2+ and 3+ (23). The nmr data indicate that they are normal Co(III) complexes. The broadening parameter (44.446 $Hz^{1/2}$) and shift parameter (2.17×10^{-5} ppm^{-1}) given in Table 5 have been used to obtain the calculated shifts and line widths of Table 4. For the shifts the agreement is good, giving a standard deviation of 9 ppm for 10 compounds. The line widths are again in qualitative agreement. For these dimeric compounds the assumption of a constant correlation time is questionable. The shift and line width parameters would place the O_2^{2-} bridging ion close to N_3^- and I^- in the spectrochemical series with an f-value of 0.95.

In many of these complexes there are extensive possibilities for isomerism. Thus in the case of the complex $(Co(dien)(en))_2O_2^{4+}$ consideration of the arrangements of the ligands bonded to the Co predicts three different isomers. The 94 MHz ^{59}Co spectra (20) clearly show three resonances for this complex. The possibility of *cis*/*trans* isomerism about the bridging oxygen is neglected. The calculated chemical shifts for these isomers are all 130–140 ppm higher than the experimental values but the relative shifts are well predicted, i.e., a low field line 77 ppm from the central line (observed 80 ppm) and a high field line 37 ppm from the central line (observed 17 ppm). The calculations also correctly predict that the highest field line will have the smallest width. On this basis the lines are given the assignments shown in Table 4. We note that application of this model has led to a change in the assignments previously given (20) which were derived by direct analogy with higher symmetry *cis* and *trans* isomers. We have some kinetic evidence that the rates of reaction of the different isomers are different so the assignments are a matter of some significance.

The complex $(Co(tetraen))_2O_2^{4+}$ has more extensive isomeric possibilities (tetraen ≡ tetraethylene pentamine). There are four possible arrangements of the pentadentate amine and the peroxide about an octahedral Co^{3+} ion. The 21 MHz and 94

MHz ^{59}Co spectra of this compound are shown in Fig. 4. This spectrum shows a minimum of seven lines and computer fitting shows that eight lines are required to obtain a satisfactory fit. A fit of the spectrum using eight lines is shown in the figure. Three of the four predicted isomers have calculated shifts of 7445, 7460, and 7550 ppm and calculated widths of 571, 408, and 985 Hz. These fit well with the observed lines at 7455, 7484, and 7569 ppm with widths of 777, 304, and 1311 Hz. The fourth isomer is predicted at 7381 ppm but not observed. Crawford *et al.* (24) have demonstrated the formation of μ-ethylenediamine-μ-peroxy complexes by the oxygenation of cobalt amine solutions. We tentatively assign the remaining resonances to complexes of this type. The calculated chemical shifts are consistent with such an assignment and are given in Table 4. The chemical shifts observed can only be associated with compounds containing five coordinated amine groups and a peroxide. Aquated species are therefore unlikely.

A final example involves an experiment in which a mixture in the ratio of 1 mol of $Co(SCN)_2$, 2 mol of ethylenediamine, and 4 mol of potassium thiocyanate was oxygenated. The initial ^{59}Co spectrum obtained is shown in Fig. 5. Parts of this spectrum were also run at 94 MHz and are shown on an expanded scale to illustrate the additional structure present. After standing for 2 h the mixture gave the ^{59}Co spectrum shown in Fig. 6. We note that it takes approximately 1 h to obtain a spectrum on the WH90 instrument. The WM400 spectrum was obtained in 15 min. The intermediate species therefore appear more strongly in the high field spectrum. Only the line at 7146 ppm (line width 97 Hz) is common to the spectra of Figs. 5 and 6. This line clearly arises from $Coen_3^{3+}$ which is formed rapidly. The remaining resonances of Fig. 5 are assigned as dioxygen complexes formed as intermediates in the oxidation of Co^{2+} to Co^{3+}. The assignments, together with those of the final Co^{3+} complexes, are given in Table 6. Most of the oxygen complexes found were of the types $(Coen_2NCS)_2O_2^{2+}$, μ-ethylenediamine-μ-O_2-$(Coen(NCS)_2)_2$, $(Coen(NCS)_3)_2O_2^{2-}$, and $(Co(NCS)_5)_2O_2^{6-}$, i.e., the ethylenediamine isothiocyanato complex series predominates and there are no thiocyanato/isothiocyanato mixed ligand complexes. The final product shows a mixture of $Coen_3^{3+}$, $Coen_2(SCN)_2$ (*cis*-isomer), and $Co(NCS)_6^{3-}$. We note that the latter complex can be assigned with some confidence to the line at 9194 ppm (line width 158 Hz) on the basis of the calculated shift of 9187 ppm (line width 0 Hz). This simple complex has apparently yet to be isolated. In addition to the above, the product mixture shows resonances at 9124 and 9101 ppm. These resonances can be assigned to the *mer* and *fac* isomers of $Coen(SCN)_3(NCS)^-$ on the basis of chemical shifts. The agreement between experimental and calculated line widths is poor, the observed line widths being too small. An alternative to these assignments involves bridged ethylenediamine complexes with four isothiocyanato and one thiocyanate ligands. These data are collected in Table 6. The assignments for the latter two resonances (i.e., 9124 and 9101 ppm) must be regarded as tentative. The occurrence of the dibridged μ-ethylenediamine, μ-O_2-$(Coen(NCS)_2)_2$ complex in the final product mixture is consistent with the known stability of μ-ligand, μ-peroxo bridged cobalt dioxygen complex (22).

The above examples are illustrative of the potential utility of the simple point charge model for calculating ^{59}Co chemical shifts and line widths. The model has clear limitations, especially in its application to line width calculations, but provides at least a reasonable starting point for assigning complex spectra of the types shown in Figs. 4, 5, and 6. With the increasing availability of high field nmr instruments, spectra of this type are likely to be encountered frequently, and to provide valuable structural and mechanistic information in the area of Co(III) chemistry.

COMMUNICATION

On the synthesis of cardioactive steroid glycosides. On cardioactive steroids. XI[1]

HAOLUN JIN, THOMAS Y. R. TSAI, AND KAREL WIESNER
Natural Products Research Centre, University of New Brunswick, Fredericton, N.B., Canada E3B 6E2

Received July 7, 1983

HAOLUN JIN, THOMAS Y. R. TSAI, and KAREL WIESNER. Can. J. Chem. **61**, 2442 (1983).

A stereoselective β-glycosidation of digitoxose and digitoxigenin involving a 1−3 participation of a urethane group is described. The conversion of digitoxin (**10**) to its furyl derivative **11** and the reoxidation of **11** to digitoxin and isodigitoxin (**12**), respectively, in high yield is reported for the first time. This is of fundamental importance for the use of the new glycosidation method in the total synthesis of digitoxin and its analogues.

HAOLUN JIN, THOMAS Y. R. TSAI et KAREL WIESNER. Can. J. Chem. **61**, 2442 (1983).

On décrit une β-glycosidation stéréosélective de la digitoxose et de la digitoxigénine qui implique une participation 1−3 d'un groupe uréthane. On rapporte pour la première fois la transformation de la digitonine (**10**) en son dérivé furyle (**11**) et la réoxydation de ce dérivé en digitonine et en isodigitonine (**12**) respectivement avec un rendement élevé. Cette réaction est très importante pour l'application de la nouvelle méthode de glycosidation dans la synthèse totale de la digitonine et de ses analogues.

[Traduit par le journal]

In previous communications of this series we have disclosed a simple and efficient methodology for the synthesis of cardenolides and bufadienolides and their analogues. As a result of this novel technique, we have succeeded in synthesizing several derivatives which, when tested in the form of glucosides, have shown a high level of inotropic activity and a margin of safety one or two orders of magnitude greater than the precariously narrow margin displayed by the natural digitalis glycosides used in therapy.[2] As our studies progressed it gradually became clear that glucosides invariably have a duration of action too short to be of practical use. Consequently, it became imperative to work out methods for the attachment of the natural glycosidic chain of digitoxin to our synthetic steroids.

A stereoselective β-glycosidation of 2-desoxyhexoses is unknown and specifically in the case of digitoxigenin and digitoxose the ß-glycoside was obtained in a yield of 4.5% in mixture with 5.4% of the corresponding α-glycoside (2). At this point we have noticed a paper by Hanessian *et al.* (3) in which 1,2,3-trideoxy-4,6-di-*O*-*p*-nitrobenzoyl-3-trifluoroacetamido-L-arabino-hex-1-enopyranose yielded on acid catalysis stereospecifically the α-glycoside with daunomicinone. It seemed to us that this process must operate via the intermediate **1** (cf. also ref. 4). We have first attempted with no success to control the glycosidation of digitoxose derivatives by 1−3 participation of a variety of esters. Finally, we decided to try a urethane group which is very similar to an acetamide by its electronic properties. We have prepared by a straightforward process starting from the known compound **2** (5) both anomers of **3** (6). (β-anomer mp 130−131°C; ir ($CHCl_3$): 3475 (NH), 1720 (C=O), 1610 cm^{-1} (aromatic); pmr ($CDCl_3$): δ = 3.87 (s, 3H, aromatic OCH_3), 3.52 (s, 3H, 1-OCH_3), 2.74 (d, J = 5 Hz, N—CH_3), 1.30 (d, J = 6 Hz, 6-CH_3); $[\alpha]_D^{22}$ = +59.18 ($CHCl_3$).)

The β-anomer **3** was hydrolysed with aqueous acetic acid at 110°C for 40 min to the foamy anomeric mixture **4**. Compound **4** was reconverted with high stereoselectivity to the β-anomer **3** with methanol under the conditions described below for a digitoxigenin derivative.

The furyl derivative of digitoxigenin (7) was coupled with 2 mol of **4** and 0.2 mol of *p*-toluenesulfonic acid in CH_2Cl_2−benzene (1:1) for 45 min at room temperature. The anomeric mixture **5** was obtained besides some starting material in a yield of 83% on the basis of starting material consumed. A small amount of the cyclic urethane **8** (mp 146−148°C; ir ($CHCl_3$): 1700 (C=O), 1610 cm^{-1} (aromatic); pmr ($CDCl_3$): δ = 3.88 (s, 3H, aromatic OCH_3), 3.12 (s, 3H, NCH_3), 1.31 (d, J = 6 Hz, 3H, 6-CH_3); $[\alpha]_D^{22}$ = +159.93 ($CHCl_3$)) was also found in this experiment. Compound **8** may be obtained quantitatively from **3** or **4** on prolonged reflux with aqueous acetic acid. Its utilization for a second method of stereospecific β-glycosidation of digitoxose is being studied. For the separation of the anomers **5**, it is necessary to deblock R_1 or both R_1 and R_2.

The anomeric mixture **5** was reduced with $LiAlH_4$ and the anomers **6** were easily separated by chromatography on silicic acid.The ratio β:α was found to be 7:1. (The α-anomer mp 173−175°C; pmr ($CDCl_3$): δ = 7.34 (br. s, 1H, 23-H), 7.24 (br. s, 1H, 21-H), 6.50 (br. s, 1H, 22-H), 5.03 (d, J = 4 Hz, 1H, 1′-H), 3.16 (m, 1H, 5′-H), 0.95 (s, 3H, 19-CH_3), 0.72 (s, 3H, 18-CH_3); $[\alpha]_D^{22}$ = +73.79 ($CHCl_3$). The major β-anomer mp 189−191°C; pmr ($CDCl_3$): δ = 7.34 (br. s, 1H, 23-H), 7.24 (br. s, 1H, 21-H), 6.49 (br. s, 1H, 22-H), 4.91 (d, J = 10 Hz, 1H, 1′-H), 3.35 (m, 1H, 5′-H), 0.92 (s, 3H, 19-CH_3), 0.72 (s, 3H, 18-CH_3); $[\alpha]_D^{22}$ = −10.51 ($CHCl_3$).)

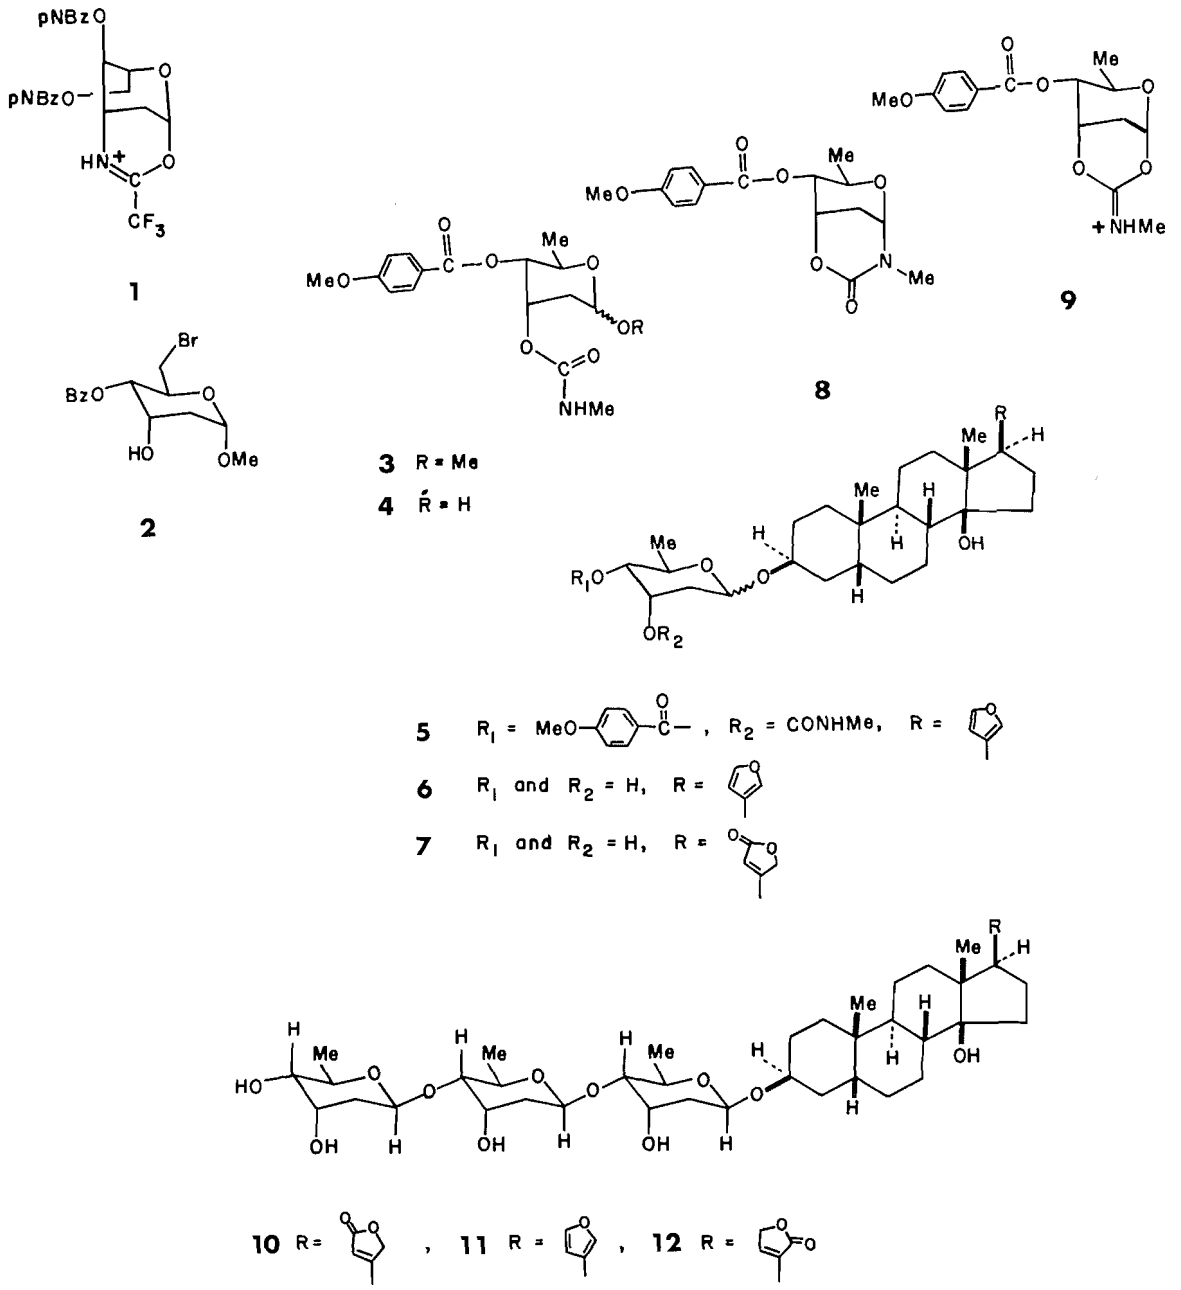
The major β-anomer **6** was oxidized as described previously (7, 8) and yielded the known β-digitoxoside **7** (2). We believe that the intermediate responsable for the steric control observed is not the urethane **8** but the charged species **9**.

In order to find out if the methodology described is of potential use for the synthesis of digitoxin and its analogues it was necessary to ascertain whether the lactone, furan, isolactone interconversions (cf. 7, 8) are possible on the level of the

[1]For Part X, see ref. 1.

[2]All the pharmacology of our compounds was performed and will gradually be reported by Professor Rafael Mendez, Departamento de Farmacologia, Instituto Nacional de Cardiologia, Juan Badiano #1, Mexico 22, D. F., Mexico and his collaborators.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.



triglycosides. We have now finally succeeded in carrying out the conversion of digitoxin (**10**) to the furan derivative **11** and the oxidation of this material back to digitoxin (**10**) and to the isolactone **12** (cf. 7, 8).

Compund **11** was obtained from digitoxin (**10**) in a yield of 86%. (mp 240–241°C; pmr ($CDCl_3$): δ: = 7.34, 7.23, 6.49 (br. s, 1H each, furan), 4.91 (m, $W_{1/2}$ = 20 Hz, 3H, 3 anomeric H, 1.31 (d, J = 6 Hz, 3H, 1 glycosidic-CH_3), 1.25 (d, J = 6 Hz, 6H, 2 glycosidic-CH_3), 0.92 (s, 3H, 19-CH_3), 0.72 (s, 3H, 18-CH_3); $[\alpha]_D^{22}$ = +12.05.) Oxidation of **11** with peracid followed by reduction with $NaBH_4$ (8) gave digitoxin (**10**) in a yield of 75%.

The conversion of **11** to isodigitoxin (**12**) was performed as described (8) and the product was obtained in a yield of 65% after chromatography on silicic acid (mp 149–150°C; ir ($CHCl_3$); 3590, 3500 (OH), 1740 cm^{-1} (C=O); pmr ($CDCl_3$): δ = 7.30 (br. s, 1H, H-22), 4.91 (m, $W_{1/2}$ = 20 Hz, 3H, 3 anomeric H), 4.81 (d, J = 2 Hz, 2H, H-23), 1.31 (d, J = 6 Hz, 3H, 1 glycosidic-CH_3), 1.25 (d, J = 6 Hz, 6H, 2 glycosidic-CH_3), 0.92 (s, 3H, 19-CH_3), 0.82 (s, 3H, 18-CH_3); $[\alpha]_D^{22}$ = +8.68 ($CHCl_3$).)

Thus a synthesis of **11** will represent not only a total synthesis of digitoxin but also a synthesis of the pharmacologically very interesting isodigitoxin (**12**) (1). Our attention has been drawn by a referee to a report in which participation in the glycosidation by a urethane group in the 2-position of a glucose derivative has been previously reported (9).

^{15}N and ^{199}Hg magnetic resonance spectral investigation of inosine protonation and diamagnetic metal ion complexation

G. W. BUCHANAN AND M. J. BELL

Ottawa–Carleton Institute for Research and Graduate Studies in Chemistry, Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received December 28, 1982

G. W. BUCHANAN and M. J. BELL. Can. J. Chem. **61**, 2445 (1983).

On the basis of complexation induced ^{15}N chemical shift changes, the nucleoside inosine is shown to protonate preferentially at the N-7 site. This nitrogen is also favoured by Zn^{+2} and Hg^{+2} ions. ^{199}Hg shifts support the notion that the binding of the first equivalent of Hg^{+2} is site selective.

G. W. BUCHANAN et M. J. BELL. Can. J. Chem. **61**, 2445 (1983).

Basé sur les changements des déplacements chimiques dan l'rmn de l'azote-15 pour le nucléoside inosine, on a montré que la protonation arrive sur N-7. Ce site est aussi favourisé par les ions Zn^{+2} et Hg^{+2}. Les déplacements chimiques dans l'rmn du ^{199}Hg sont en accord avec l'idée que la complexation du premier équivalent de l'ion metallique est selective pour un site.

Introduction

The nature of the interactions between nucleic acid components and metal ions is of intense interest because these phenomena are related to the toxic properties of some metal ion complexes (1) and the antitumour activity of others (2, 3). There appears to be a tendency for "soft" metal ions such as Pt^{2+}, Pd^{2+}, Hg^{2+}, and CH_3Hg^+ to favour nitrogenous sites for complexation, although the kinetically and thermodynamically favoured sites may not coincide (4, 5). Metals such as Zn^{2+}, which are less "soft", may prefer different nitrogenous sites of the nucleoside bases (6, 7) whereas "hard" metal ions, such as Na^+, Mg^{2+}, Ca^{2+}, Ba^{2+}, and Mn^{2+}, appear to complex preferentially at oxygenated sites.

Recent results from this laboratory (7) indicate that ^{15}N nmr chemical shift changes provide a powerful method for the study of nitrogen site-selectivity in binding of diamagnetic metal ions to the nucleosides adenosine, cytidine, and guanosine in DMSO solutions. We now wish to report on our investigation of this selectivity in the binding of Ba^{2+}, Hg^{2+}, and Zn^{2+} ions to the nucleoside inosine which contains the rare base hypoxanthine. This base occurs primarily as part of the anticodon triplet in a number of t-RNA species. For comparison with the metal ion studies, the inosine sites preferred by protons have been elucidated, whereas for the Hg^{2+} complexes, ^{199}Hg chemical shifts are reported.

As in our previous work (7), dimethyl sulfoxide has been used as solvent because relatively high concentrations of metal ions and nucleosides can be achieved in this medium. The metal ions Ba^{2+}, Zn^{2+} and Hg^{2+} were selected as examples of "hard", "intermediate", and "soft" respectively, according to the well-known classification of Lewis acid strength (8).

Although for physiological reasons water would have been a preferable solvent, work to date (9) indicates that metal binding sites on nucleosides are similar in DMSO and H_2O, except that binding sites which require deprotonation are not normally observed in DMSO solutions (4). Another factor in the choice of DMSO as solvent is the enhanced stability of metal ion – nucleoside complexes in DMSO vs. H_2O, presumably due to the lower degree of solvation of nucleoside lone pairs by DMSO than by H_2O.

Results and discussion

The structure and numbering scheme for inosine **1** is shown below. The molecule is shown in the *anti* conformation about the glycosidic bond.

TABLE 1. ^{15}N chemical shifts of inosine (δ_N from NH_3) $\pm 0.1^a$

Concn.	N-1	N-3	N-7	N-9
1.15 M^b	176.8	216.3	250.5	176.8
0.5–1.0 M^c	175.1	214.6	249.1	175.1

(a) *^{15}N nuclear magnetic resonance studies*

The ^{15}N chemical shifts of **1** in DMSO have been reported previously (10) and our results (Table 1) are in good accord with the earlier work. Results in Fig. 1 show that upon addition of $HgCl_2$, the N-7 resonance is most affected, there being a 4.8 ppm *upfield* shift upon addition of 0.75 molar equivalents of the mercuric salt. Above this concentration of $HgCl_2$, the N-7 signal cannot be observed, perhaps due to broadening caused by trace amounts of paramagnetic impurities although care was taken to remove these. (See experimental section.) The N-9 resonance of **1** moves downfield, whereas the N-1 and N-3 resonances are essentially unaffected.

Although the N-1 and N-9 resonances of **1** overlap in the absence of $HgCl_2$, they become separate when 0.2 molar equivalents of salt are added, and they can easily be distinguished via the INEPT experiment (11, 12), in which the N-1 resonance is considerably enhanced in intensity relative to N-9, due to the transfer of polarization from the directly bonded proton on N-1 to the nitrogen.

Upon addition of $Zn(NO_3)_2$ similar trends are noted in the induced ^{15}N shifts for **1** (Fig. 2) although the upfield shift for N-7 is considerably larger than in the case of $HgCl_2$ addition.

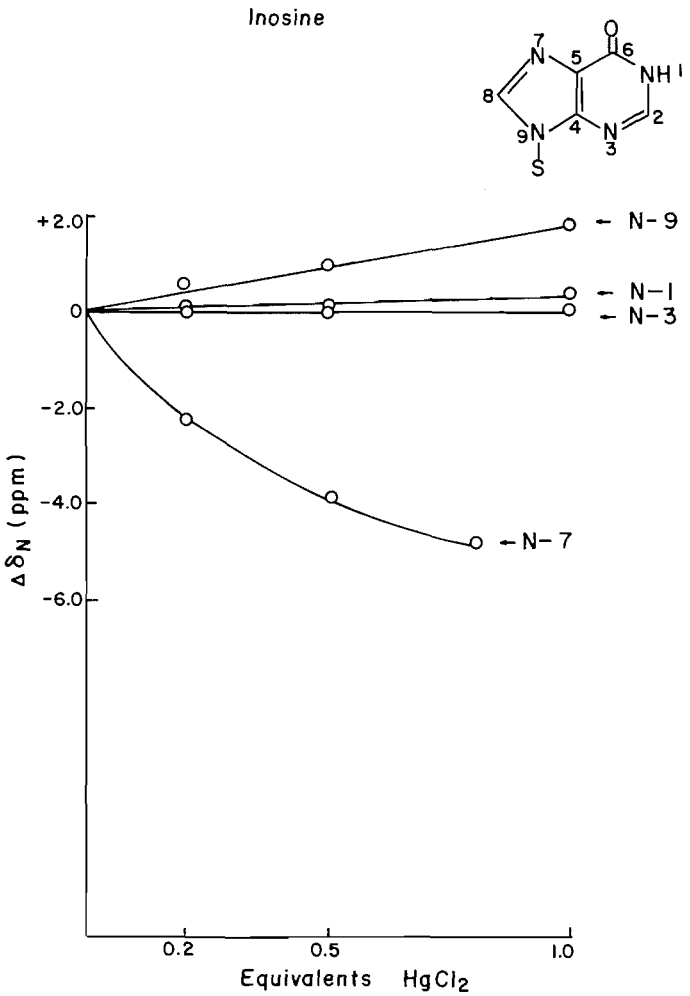

FIG. 1. ^{15}N chemical shift changes as a function of added metal ion: + sign denotes increased δ value (downfield shift); − sign denotes decreased δ value (upfield shift). **1** + $HgCl_2$.

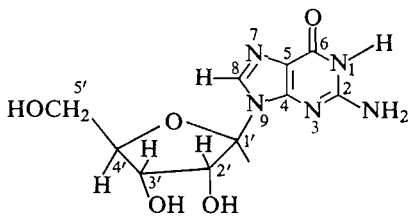
By contrast, addition of $BaNO_3$ causes no detectable changes in the ^{15}N resonance positions for any of the nitrogens of **1**, suggesting that any binding of the "hard" metal in Ba^{2+} does not involve primarily the nitrogenous sites.

It is of interest to compare the present ^{15}N results with those for the structually similar nucleoside guanosine **2** studied earlier in this laboratory (7).



2

For **2**, the N-7 resonance was also shifted considerably upfield by addition of either $HgCl_2$ or $Zn(NO_3)_2$, whereas N-9 moved downfield, but to a lesser extent. Resonances for NH_2, N-1, and N-3 were affected to a very minor extent. These results were interpreted in terms of N-7 being involved in the primary binding site for these metal ions, in agreement with predictions based on electron density calculations (13).

The similarity of the ^{15}N results for **1** and **2** support the notion

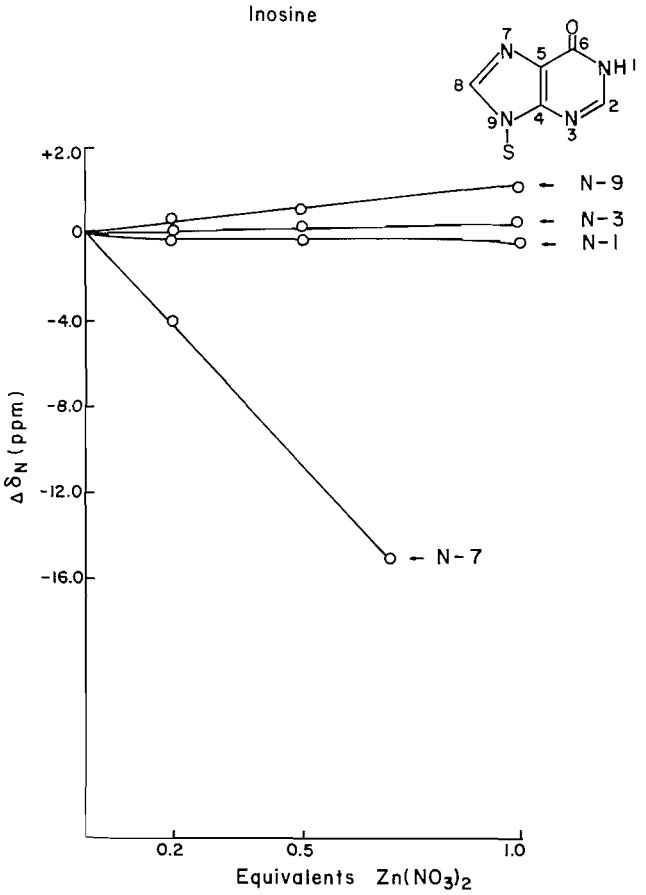


FIG. 2. **1** + $ZnNO_3$.

that N-7 is the preferred site of "soft" and "intermediate" metal ion complexation for both these nucleosides in DMSO solution. Findings of a recent ^{13}C nmr study of these interactions (4) are in accord with our conclusions.

It is useful to compare the metallation induced shifts of **1** with those caused by protonation. In their early work (10), Roberts *et al.* studied the ^{15}N spectra of protonated adenosine, cytidine, guanosine, and ATP in DMSO solutions, the protonating agent being trifluoroacetic acid (TFA).

For inosine our results are depicted in Fig. 3. The upfield shift of ca. 13 ppm for N-7 on addition of 1 molar equivalent of TFA suggests preferred protonation at this site (10). For the structurally similar guanosine nucleoside, Roberts *et al.* (10) found that N-7 was shifted upfield by ca. 40 ppm on addition of 1 molar equivalent of TFA whereas N-3 showed a minor upfield shift (ca. 1 ppm), N-9 was shifted downfield by ca. 3 ppm, and N-1 showed a very small downfield shift. Thus, the shift trends for each nitrogen resonance of inosine upon protonation are qualitatively similar to those found for guanosine. Furthermore, the directions of the protonation induced ^{15}N shift of **1** are the same as those induced by complexation with Zn^{2+} and Hg^{2+} ions. Recently, Nee and Roberts have noted the same trends for platinum complexation with nucleosides (14).

(b) *^{199}Hg nuclear magnetic resonance studies*

To study the binding of Hg^{2+} to nucleic acid components, ^{199}Hg nmr presents an interesting complement to the ^{15}N work because the range of chemical shifts for ^{199}Hg is very large and it is a relatively easy nucleus to observe experimentally (15, 16).

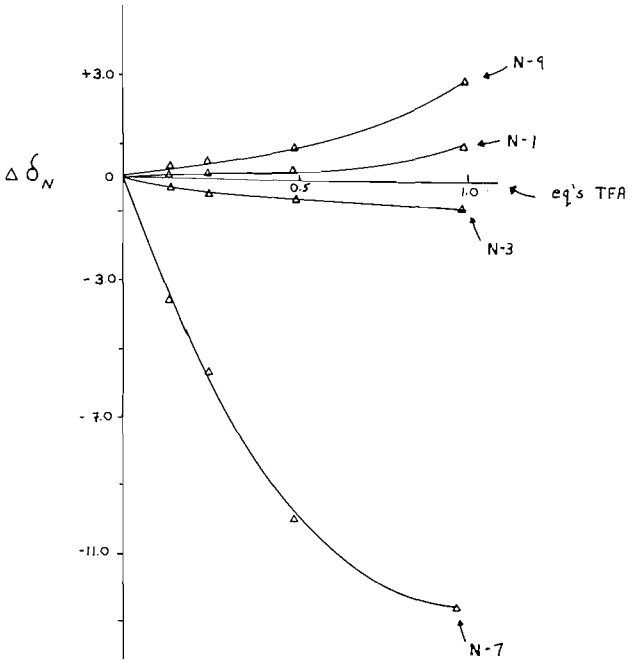

FIG. 3. ^{15}N chemical shift changes as a function of added trifluoroacetic acid (TFA).

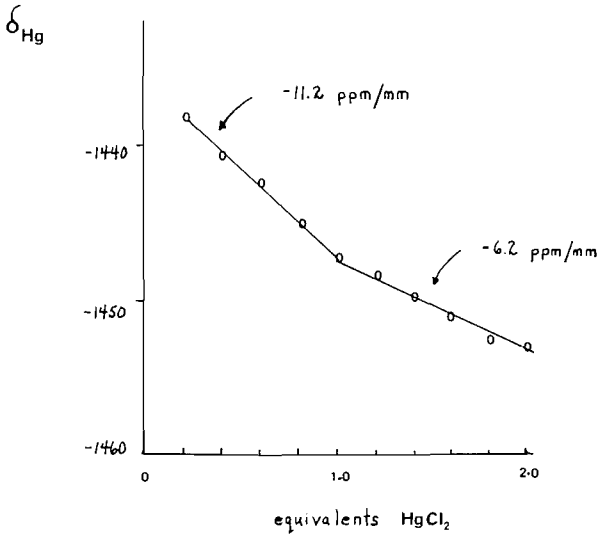

FIG. 4. ^{199}Hg chemical shifts for $HgCl_2$ as a function of added Hg^{2+} in a 0.55 *M* solution of **1** in DMSO-d_6; − sign denotes decreased δ value (upfield shift).

In the present work, we started with a fixed concentration of inosine (0.55 *M*) in DMSO-d_6 and aliquots of $HgCl_2$ were added until a ratio of 2:1 (metal/nucleoside molar equivalents) was reached. Results are shown in Fig. 4. Clearly the slope changes at 1.0 equivalents. We interpret this result in terms of selective complexation of the first metal ion equivalent (presumably at N-7) of **1**. After this site is metallated, others no doubt become complexed to varying degrees.

Unfortunately, due to solubility problems and the need for high concentrations of nucleoside for ^{15}N studies, we were not able to carry out ^{15}N studies above 1.0 equivalents of $HgCl_2$ to determine which nitrogen is metallated after N-7. It was found that $HgCl_2$ shows a marked concentration dependence (in DMSO-d_6) for the chemical shift in the absence of nucleoside, the slope being −18.7 ppm mm^{-1} $HgCl_2$ added.[1] Extrapolation to infinite dilution gives a chemical shift for $HgCl_2$ of −1464.4 ppm relative to neat $(CH_3)_2Hg$, in agreement with the literature (16).

For both ^{199}Hg and ^{15}N data, the chemical shifts of the metal–nucleoside solutions represent an average of the free and complexed shifts, the rate of metal exchange being fast on the nmr timescale. In no cases were ^{15}N–^{199}Hg couplings observed.

To conclude, this study shows the utility of ^{15}N and ^{199}Hg nmr for studying selective protonation and metallation of inosine. The N-7 site is protonated preferentially and favoured by Zn^{2+} and Hg^{2+} ions. The ^{199}Hg shifts indicate site-selective binding of the first equivalent of Hg^{2+}.

Experimental

(a) *Materials*

Inosine was obtained from the Sigma Chemical Company, St. Louis, MO 63178, U.S.A. and was used without further purification. Mercuric chloride, barium nitrate, and zinc nitrate were Fisher Certified ACS grade and were vacuum sublimed before use in an effort to remove paramagnetic impurities. Dimethylsulfoxide-d_6 was purchased from Stohler Isotope Chemicals, Montreal 101, Quebec, Canada. It was dried over molecular sieves before use and no aqueous impurity was detected by ^1H Fourier transform nmr.

(b) *Spectra*

^{15}N spectra were recorded on a Varian XL-200 spectrometer at 20.27 MHz. Routinely, the nOe. suppressed spectra were recorded using a pulse angle of 90° and a delay time of 40 s. Typical spectral width was 10 000 Hz, and satisfactory signal-to-noise ratios for 1.0 *M* inosine solutions (in 10 mm tubes) were normally obtained after ca. 1000 transients. Acquisition time was 1.6 s and 32 K data points were employed.

For the ^{15}N INEPT spectra, the refocussed sequence (11, 12) was used. Employing $^1J_{NH}$ = 90 Hz, the delays were τ = 2.78 ms (1/4*J*) and Δ = 4.17 ms (3/8*J*). The 90° pulses were 24 μs for ^{15}N and 48 μs for ^1H respectively, with a recycle time of 2 s. Chemical shifts were measured relative to external saturated aqueous NH_4Cl and then converted to the ^{15}N scale in ppm relative to NH_3 using a conversion constant of +27.3 ppm (17).

The ^{199}Hg spectra were recorded at 35.8 MHz on the Varian XL-200 spectrometer, using 10 mm sample tubes. Typical spectra width was 30 000 Hz, with a 60° pulse width, 0.53 s acquisition time (32 K data points), and a pulse repetition rate of 2 s. Chemical shifts were referenced to an external capillary of 0.5 *M* $HgCl_2$ in DMSO-d_6 and then converted to the ppm scale relative to $(CH_3)_2Hg$ (15).

SUZANNE R. ABRAMS, J. WILSON QUAIL, and LOUIS T. J. DELBAERE. Can. J. Chem. **61**, 2449 (1983).

Under the influence of the very strong base, the sodium salt of 1,2-diaminoethane in 1,2-diaminoethane, 2-tetradecynoic acid is converted to 3-tetradecynoic acid (35%) and a novel dimer **3**. Compound **3** ((*Z*)-2-(1-dodecynyl)-3-undecyl-pent-2-en-1,5-dioic diacid) is isolated as the monomethyl ester **1** after treatment of the crude product with methanolic HCl. The structures of **1** and **3** are deduced from an X-ray crystallographic analysis of the dimethyl ester **2** obtained by reaction of **1** with diazomethane. The dimer **3** is thought to arise from Michael addition of the dianion **4** of 3-tetradecynoic acid with the sodium salt of 2-tetradecynoic acid.

SUZANNE R. ABRAMS, J. WILSON QUAIL et LOUIS T. J. DELBAERE. Can. J. Chem. **61**, 2449 (1983).

Sous l'influence d'une base très forte, le sel de sodium du diamino-1,2 éthane dans le diamino-1,2 éthane transforme l'acide tétradécyne-2 oique en acide tétradécyne-3 oique (35%) et en un nouveau dimère (**3**). On a isolé le composé **3**, le diacide (*Z*)-dodécyne-1 yl-2 undécyl-3 pentène-2 dioique-1,5, sous forme de monoester méthylique (**1**) après avoir fait réagir le produit brut avec du HCl méthanolique. L'analyse par cristallographie de rayons-x de l'ester diméthylique **2**, obtenu par réaction de **1** avec le diazométhane, a permis de déterminer les structures des composés **1** et **3**. On pense que le dimère **3** provient d'une addition de Michael du dianion **4** de l'acide tétradécyne-3 oique sur le sel de sodium de l'acide tétradécyne-2 oique.

Introduction

One of us recently reported the rearrangement of a series of isomeric tetradecynoic acid (2-, 3-, 5-, 7-, 9-, 11-) mediated by the very strong base, the sodium salt of 1,2-diaminoethane in 1,2-diaminoethane (1). The principal products were (*E,E*)- and (*E,Z*)-3,5-tetradecadienoic acids; the latter is the sex pheromone of the black carpent beetle (*Attagenus megatomia*). 2-Tetradecynoic acid was shown to be isomerized first as expected (2) to 3-tetradecynoic acid which, in turn, was rearranged to the isomeric dienoic acids. The conversion of 2- to 3-tetradecynoic acid was poor. Isolation by treatment with methanolic hydrochloric acid followed by chromatography of the crude reaction mixture afforded methyl 3-tetradecynoate in 35% yield. Unexpectedly, a polar by-product **1** (mp 104–105°C) was isolated in 24% yield. Treatment of **1** with diazomethane gave a second product **2** (mp 63–64°C) which was less polar. Spectral data indicated that the new compounds were formally methylated dimers of 2-tetradecynoic acid, but these data could not be interpreted unambiguously to permit elucidation of the structures.

We were able to find no literature precedent for a base mediated rearrangement–dimerization of a 2-alkynoic acid, and were intrigued by the apparent simplicity of the spectral data, and by the fact that the two esterification procedures gave different compounds. We thus undertook to determine the structure of these unexpected products by an X-ray analysis of the second compound **2**. The structures of the original dimeric acid **3** and the monomethylated compound **1** have been assigned by comparison of the spectral data of **1** and **2**. A mechanism is proposed to account for the transformation of 2-tetradecynoic acid to **3**.

Results and discussion

2-Tetradecynoic acid was isomerized with 4.5 equivalents of the sodium salt of 1,2-diaminoethane for 5 minutes at 60°C. Tetradecanoic acid was used as an internal standard. Analysis by glc indicated a 35% conversion to 3-tetradecynoic acid, and complete consumption of the starting material. Esterification with methanolic HCl and subsequent chromatography over silica gel gave methyl 3-tetradecynoate (34%), followed by **1** (24%, mp 104–105°C from hexane). Treatment of either the crude product followed by chromatography, or of **1**, with diazomethane afforded **2** (mp 63–64°C from methanol), upon which an X-ray crystallographic analysis was performed.

An ORTEP (3) diagram of **2**, including the numbering system which we adopted is shown in Fig. 1. Table 1 contains the positional parameters and average temperature factors for the non-hydrogen atoms of dimer **2**. Bond lengths and angles of the functionalized portion of **2** are given in Tables 2 and 3. The molecule consists of two linear fourteen-carbon chains with a double bond occurring between the second carbon atom of one chain and the third carbon atom of the other chain, and the two hydrocarbon chains are in a *cis* configuration. The IUPAC name for **2** is dimethyl (*Z*)-2-(1-dodecynyl)-3-undecylpent-2-endioate. The enyne system shows two (of the three) bonds with lengths very close to values predicted by Dewar and Schmeising (4*a*). The double bond between C(2) and C(3) is of normal length (d = 1.34(1) Å) (cf. 1.338 Å (4*a*)). A linear triple bond (d = 1.22(2) Å) joins C(6) and C(7) (cf. 1.205 Å (4*a*)). The bond between C(2) and C(6), which joins the double to triple bond, has a length of 1.37(2) Å. This length is shorter than 1.432 Å predicted by Dewar and Scheising (4*a*), but is similar to the value (1.376(6) Å) observed in a related system by Smith and Luss (4*b*). In addition, Smith and Luss also observed a triple bond length of 1.212(6) Å and a double bond

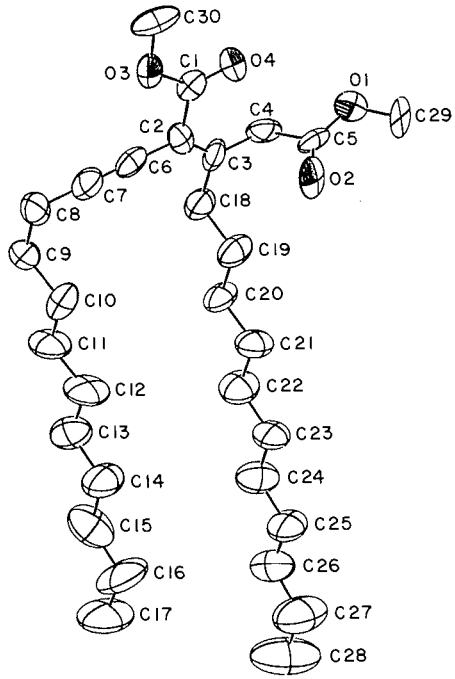

FIG. 1. ORTEP perspective drawing of dimer **2**. Hydrogens are omitted for clarity.

length of 1.386(6) Å. The enyne system (C(1), C(2), C(3), C(4), C(6), C(7), C(8), and C(18)) is planar within 0.03 Å of the least-squares plane between these atoms. The angles between the plane of the enyne system and the planes of the carboxyl groups on C(1) and C(5) are 8 and 88 degrees, respectively. The near coplanarity of the carboxyl group on C(1) and the enyne system is favorable for π electron overlap between these two groups and the ir bands at 1740 cm^{-1} and 1720 cm^{-1} (see Experimental) indicate the presence of both a saturated and an α,β-unsaturated ester. However, the bond between C(1) and C(2) (d = 1.53(2) Å) is normal in length for a single bond and shows no shortening due to conjugation between the enyne system and the carboxyl group. In addition, the 1.17(2) Å bond length of the carbonyl group on C(1) is not significantly different from the length of the C(5)—O(2) bond (1.18(2) Å) in the other carboxyl group.

An ORTEP diagram of the packing in the crystal is shown in Fig. 2. The molecules pack with the ester groups of different molecules in close proximity to each other. The hydrocarbon tails of neightboring molecules interact with each other in a manner similar to that found for the lipid hydrocarbon chains of biological membranes (5). The molecules are aligned approximately along the b axis of the unit cell. The attractive

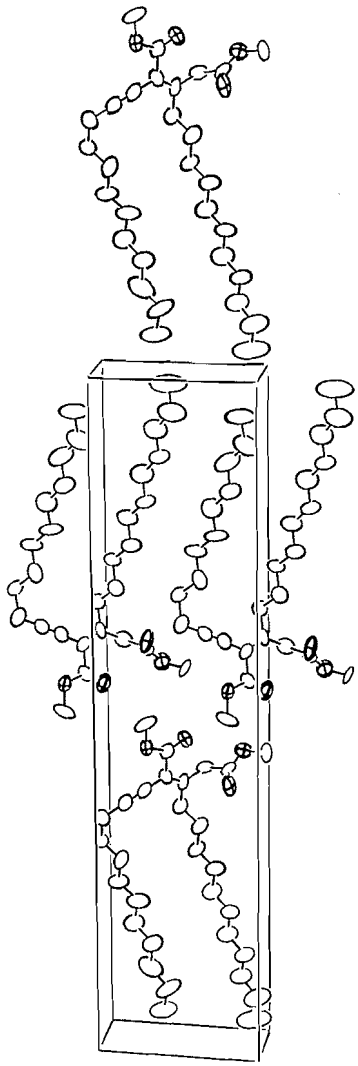

FIG. 2. Projection of the crystal structure looking approximately down the *a* axis of the unit cell of **2**.

forces between the termini of the aliphatic chains of different molecules would be very weak; consequently, the crystals grow very slowly along the *b* axis, producing soft, very thin crystal ribbons.

Detailed spectroscopic data are given in the experimental section; the highlights of the mass, ^{13}C and ^{1}H nmr spectra are presented here.

The 400 MHz ^{1}H nmr spectra of dimers **1** and **2** have the signals expected for the $COOCH_3$ and for the $=CCH_2(CH_2)_9CH_3$ and $\equiv CCH_2(CH_2)_8CH_3$ units in which only the sets of allylic and propargylic protons have different chemical shifts. The protons at C(4) of dimer **1** appear as a two proton singlet (δ 3.68), just resolved from the $COOCH_3$ singlet (δ 3.66). A similar singlet appears in the spectrum of dimer **2** at δ 3.61. Kagan *et al.* (6) reported similar shifts (δ 3.65, 3.61) for the C(4) protons of the corresponding mono- and di-esterified (Z)-2-methylpent-2-en-1,5-dioic acids.

While there have been thorough systematic studies of assignments of ^{13}C nmr signals of simple alkenoic and alkynoic acids and esters (7), data are lacking for extensively substituted conjugated systems such as those encountered here. Assignments of the ^{13}C signals of **1** and **2** (Table 4) have been made by extrapolation of available literature data and thus are tentative.

TABLE 4. ^{13}C chemical shifts of **1** and **2**[a]

Carbon	Shift		Analogs[b–e]
	Dimer **1**	Dimer **2**	
1	169.68	165.91	167.00[b]
2	114.95	115.36	119.25[b]

30	—	51.98**	

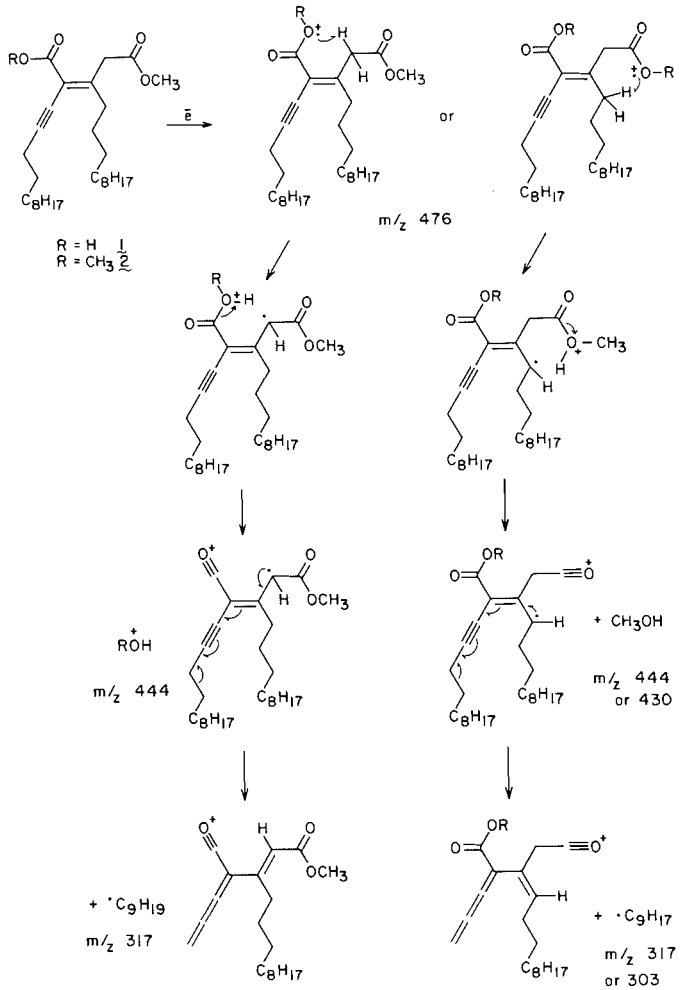
[a] In ppm relative to $(CH_3)_4Si$; in $CDCl_3$; * ambiguous pair; ** ambiguous pair.
[b] OOCC=C of methyl-2-Z-undecenoate (5).
[c] $OOCCH_2C{=}C{-}C{=}C{-}$ (1).
[d] $OOCCH_2C{\equiv}C$ of methyl 3-octadecynoate (5).
[e] $OOCC{\equiv}CCH_2CH_2$ of methyl 2-undecynoate (5).
[f] $H_3CCH_2CH_2{-}$ of methyl 2-undecynoate (5).

Particularly confusing, before the X-ray structure was obtained, were the chemical shifts of the pairs of olefinic and acetylenic carbon atoms, both of which appeared to be next to a carboxyl group. As well as the chemical shifts of the carbons, the chemical shift difference between two alkyne carbons is usually diagnostic for proximity to the carboxyl group (Δ2, 20 ppm; Δ3, 13 ppm; Δ4, 3 ppm).

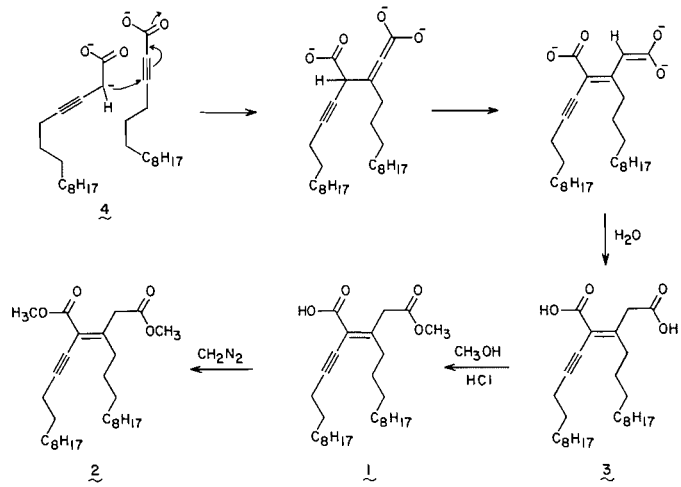
The mass spectra gave the exact masses of the molecular ions, but revealed little structural information. Dimer **2**, particularly, gave only two intense fragments with *m/z* greater than 200. With the disclaimer that multiple unsaturated long chain compounds are notorious for suffering rearrangement upon electron impact, a scheme is proposed that accounts for the two extremely stable fragments observed. The base peak (*m/z* 444, 100%) corresponds to the loss of methanol from the molecular ion (*m/z* 476, 11%). The base peak can arise by two different pathways involving an intramolecular hydrogen abstraction (Scheme 1). Both yield stabilized radicals which could lose $\cdot C_9H_{19}$ with facility to give the second large fragment (*m/z* 317, 65%). There are two lesser peaks with *m/z* greater than 200. One (*m/z* 350, 7%) probably is the product of a McLafferty rearrangement of the molecular ion ejecting C_9H_{18}; the other (*m/z* 331, 12%) may correspond to the loss of $\cdot C_8H_{17}$ from the base peak.

The fragmentation pattern of the monomethyl ester **1** is slightly more complicated. The fragmentation pattern of **2** is repeated, except that ions arise from loss of water (*m/z* 444, 93%) and from loss of methanol (*m/z* 430, 41%). The base peak (*m/z* 317, 100%) is due to expulsion of $\cdot C_9H_{19}$ from the ion with *m/z* 444. The other major fragment comes from loss of the same unit from the ion with *m/z* 430 to give an ion with *m/z* 303, 47%. While the cleavage patterns are similar in the two dimers, **1** is susceptible to more extensive fragmentation.

The carbon skeleton of the dimers is made up of two fourteen-carbon units with a double bond between C(2) of one chain and C(3) of the other. This linkage could arise from



SCHEME 1



SCHEME 2

Michael addition of a dianion **4** of 3-tetradecynoic acid (the major product isolated from the reaction) to the starting 2-tetradecynoic acid (Scheme 2). The adduct could undergo a 1,3-proton shift giving a stabilized extensively delocalized trianion. The same postulated intermediate could arise from protonation of C(4) and subsequent deprotonation of C(2). Protonation of the trianion on work-up would afford the dimeric diacid **3**.

Stabilized propargylic anions such as **4** are postulated intermediates in base mediated isomerizations of acetylenic acids (2, 8). There are a limited number of examples in the literature of reactions of dianions of acetylenic acids. The alkylation of propynoic, butynoic, and pentynoic acids has been investigated. The dianion of 2-butynoic acid affords on alkylation both 4-alkyl-2-butynoic acid (γ attack) and 2-alkyl-2,3--butadienic acid (α attack) (9, 10). The dianion of 3-butynoic acid, a special case in which the stable terminal acetylide salt is formed, is silylated exclusively at C-4 (11). Treatment of 2-pentynoic acid with three equivalents of lithium diisopropylamide followed by chlorotrimethylsilane affords a product silylated at both C-2 and C-4 (12). The authors attribute this result to isomerization during anion formation. No direct analogy to the present case, in which a longer chain acetylenic acid undergoes isomerization prior to alkylation, has been found.

There is, however, a report of a dianion of a carboxylic acid attacking the salt of an α,β-unsaturated acid. The dilithium salt of propanoic acid is found to add to lithium methacrylate in a Michael type reaction affording 2,4-dimethylglutaric acid in 67% yield (9).

The stereochemistry about the double bond may be due to several factors. Perhaps in the polar reaction medium there is a lipophilic attraction between the two methylene chains of **4** and the anion of 2-tetradecynoic acid. Perhaps a counter-ion stabilizes the intermediate trianionic diacid.

The formation of the monomethyl ester upon treatment with methanolic HCl occurs at the less hindered carboxyl group, while the carboxyl group on the double bond survives the treatment. Kagan *et al.* (6) reported that reaction of 2-methyl-Z-pent-2-en-1,5-dioic acid with concentrated sulfuric acid, followed by quenching with methanol, afforded the analogous monomethyl ester. The ir data of dimer **1** are consistent with the β,γ-unsaturated acid being esterified first.

Either the diacid **3** or dimer **1** would be expected to give dimer **2** on treatment with diazomethane.

Conclusion

Although isomerizations of alkynes have been studied extensively (8, 13), we have found no report of a rearrangement reaction such as that observed in this work.

Analogous reactions may prove useful in organic synthesis. A functionalized structure is produced that contains two carboxyl groups with different reactivities, and an unusual enyne system.

Experimental

Ultraviolet spectra were recorded on a Beckman DU-8 spectrophotometer. Infrared spectra were obtained on a Perkin–Elmer 237-B instrument. Band intensities are reported using the following abbreviations: s strong, w weak, br broad. Gas chromatographic separations were carried out on a Varian 3700 instrument with an SP2100 capillary column (J and W Scientific, 30 m) with a flame ionization detector, and were run isothermally at 160°C. Mass spectra were obtained with an MS902S instrument with VG console update at the Psychiatric Research Unit, University of Saskatchewan. Accurate masses were obtained at 1500 resolution and 3 s/decade using accurate mass – low resolution software with PFTBA internal standard. Mass spectra are reported in mass-to-charge units (m/z) with the relative intensities as percentages of the base peak. Only fragments with $m/z > 200$ are given. Proton nmr spectra were recorded on a Bruker WH 400 spectrometer using deuterochloroform with internal $(CH_3)_4Si$ as reference.

Assignments of protons are reported using the number of the carbon to which they are attached. Carbon nmr spectra were recorded on a Varian XL-100-15 instrument in the Fourier Transform mode at 25.16 MHz with proton noise decoupling. Deuterochloroform was used as solvent and also provided the internal deuterium lock. Elemental analyses were performed by Spang Microanalytical Laboratory, Eagle Harbour, Michigan, U.S.A.

The preparations of 2- and 3-tetradecynoic acids are reported in a previous paper (1).

Isomerization of 2-tetradecynoic acid

Under nitrogen, to a solution of the sodium salt of 1,2-diaminoethane at 60°C (prepared by reaction of sodium hydride, 57% in mineral oil, 380 mg, 9.2 mmol, washed free of oil with hexane, and 1,2-diaminoethane, 5.0 mL (previously distilled from BaO and stored over activated 4 Å sieves) at 60°C for 1.0 h) was added a solution of 2-tetradecynoic acid (450 mg, 2.0 mmol) and tetradecanoic acid (45 mg, 0.2 mmol) in 1,2-diaminoethane (5.0 mL). After 5 min the reaction was quenched by pouring into ice water. The mixture was acidifed with HCl and extracted with ether 3 times. The combined ethereal extracts were washed with water, then NaCl solution, dried over Na_2SO_4, filtered, and the solvent evaporated to give 533 mg of crude product. A small sample was treated with diazomethane. Analysis by glc gave peaks corresponding to methyl tetradecanoate (22%), methyl 3-tetradecynoate (69%), but no peak for methyl 2-tetradecynoate, indicating 35% conversion of 2- to 3-tetradecynoic acid. A portion of the crude product (479 mg, 90%) was dissolved in methanol (25 mL) and 3 drops of concentrated HCl added. The solution was refluxed for 2.5 h. The methanol was evaporated at reduced pressure and the residue partitioned between ether and water. The ether layer was washed successively with $NaHCO_3$ solution and NaCl solution, dried over Na_2SO_4, filtered, and the solvent removed to yield 500 mg product. This material was chromatographed over a column of silica gel (BioRad 200–400 mesh) made up in ether/hexane (20:80), eluting with 20% ether first, then 50% ether/hexane. First to elute was residual mineral oil, then methyl tetradecanoate, followed by methyl 3-tetradecynoate (140 mg, 34%). The dimer **1** was obtained last (100 mg, 24%) and gave mp 104–105°C (hexane); tlc R_f 1 (20% ether/80% hexane); uv λ_{max} 251 nm (6500) in methanol; ir ν_{max} (CCl_4): 3400–2500 (s, br), 2200 (w), 1740 (s), and 1685 (s) cm^{-1}; ^1H nmr δ: 3.68 (s, 2H, H(4)), 3.66 (s, 3H, H(29)), 2.54 (dd, J = 8.0, 7.9 Hz, 2H, H(8) or H(18)), 2.41 (t, J = 7.5 Hz, 2H, H(8) or H(18)), 1.59 (m, 2H, H(9) or H(19)), 1.46 (m, 2H, H(9) or H(19)), 1.26 (m, 34H, H(10) to H(16) and H(20) to H(27)), 0.89 (t, J = 7 Hz, 6H, H(17) and H(28)); mass spectrum: 462 (7), 445 (27), 444 (93), 431 (16), 430 (41), 385 (10), 331 (20), 319 (12), 318 (36), 317 (100), 304 (29), 303 (47), 290 (20), 277 (20), and 275 (17); molecular ion *Exact Mass* calcd.: 462.3758; found: 462.3702. *Anal.* calcd. for $C_{29}H_{50}O_4$: C 75.28, H 10.89; found: C 75.57, H 10.93.

Treatment of **1** with diazomethane gave, after work-up, dimer **2** which gave mp 63–63.5°C from methanol: tlc R_f 4 (20% ether/80% hexane); uv λ_{max} 261 (7700) in methanol; ir ν_{max} (CCl_4): 2200 (w), 1740 (s), 1720 (s) cm^{-1}; ^1H nmr δ 3.73 (s, 3H, H(30)), 3.67 (s, 3H, H(29)), 3.61 (s, 2H, H(4)), 2.50 (dd, J = 8.0, 7.9 Hz, 2H, H(8) or H(18)), 2.39 (t, J = 7.5 Hz, 2H, H(8) or H(18)), 1.57 (m, 2H, H(9) or H(19)), 1.45 (m, 2H, H(9) or H(19)), 1.26 (m, 34H, H(10) to H(16) and H(20) to H(27)), 0.88 (t, J = 7.0 Hz, 6H, H(17) and H(28)); mass spectrum: 476 (11), 445 (37), 444 (100), 350 (8), 331 (12), 318 (22), 317 (65); molecular ion *Exact Mass* calcd.: 476.3905; found 476.3884. *Anal.* calcd. for $C_{30}H_{52}O_4$: C 75.58, H 11.00; found: C 75.65, H 10.94.

Crystallographic analysis

Data collection

Dimethyl (*Z*)-2-(1-dodecynyl)-3-undecylpent-2-endioate crystallized as very thin {010} ribbons, with a tendency to curl, on slow evaporation of a methanol solution. A crystal was cut from a ribbon with a razor blade. Precession photographs showed the crystal to be monoclinic, and from the systematic absences of reflections $h0l$, l = $2n + 1$ the space group was determined to be either Pc or $P2/c$. The molecular formula was known to be $C_{30}H_{52}O_4$ from the mass spectrum. From the carbon-13 nmr it was known that all of the carbons were non-equivalent. There was sufficient space in the unit cell for only 2 molecules. Since the centrosymmetric space group $P2/c$ would require molecular symmetry, the acentric space group Pc (No. 7) (13) was chosen for the crystal, and this choice was confirmed by the successful refinement of the structure. The crystal data were the following:

$C_{30}H_{52}O_4$ mw = 476.72

Monoclinic, space group Pc, a = 4.699(2) Å, b = 37.288(12) Å, c = 8.743(2) Å, β = 92.95(2) Å, V = 1529.9 Å^3, Z = 2, ρ_o = 1.06 g cm^{-3}, ρ_c = 1.04 g cm^{-3}, $F(000)$ = 528e, radiation Ni-filtered Cu $K_{\bar{\alpha}}$, λ = 1.5418 Å, $2\theta_{max}$ = 120°, crystal dimensions (mm) 0.7 × 0.04 × 0.6, max decay correction 1.12, temp. 14°C.

The single crystal was mounted about the c^* axis on an Enraf–Nonius CAD4F diffractometer and data were collected with an $\omega/2\theta$ scan. A total of 1584 reflections (of 2282 total) had net $I > 2\sigma(I)$ and these reflections were used in the analysis. The data were corrected for Lorentz and polarization effects. Intensity data were corrected for absorption using the Gaussian integration method (14). Observational weights (15) for the reflections were derived from the formula: $W = (2I)^2/|F_o|^2\ (T + (0.02\ I)^2 + r^2B)$, where I is the net intensity, F_o is the observed structure amplitude, T is the total peak count, B is the sum of the background counts, and r is the ratio of the peak-scan time to the total background-counting time (r = 2 for this data).

MULTAN 80 (16) was used to generate starting sets of phases. Five sets of phases had similar combined figures of merit (2.6–2.2) and R_{Karle} (17) values of 0.18. The fifth best solution was selected because it showed chains of atoms (the reactant was a linear molecule) and the atoms occupied most of the volume of the repeating unit. Least-squares refinement on 26 atoms from the MULTAN solution, using unit weights, gave an R of 0.306. Additional atoms were located from difference Fourier maps. After 34 atoms had been located, the four oxygens were identified from the stereochemistry and the lower temperature factors. Refinement of atomic parameters was carried out by blocked-matrix least-squares techniques using anisotropic temperature factors and unit weights. A difference Fourier map at this point did not locate the hydrogens. Forty hydrogens (all except those on the four methyl groups) were positioned from the stereochemistry. These hydrocarbons were assigned isotropic temperature factors equal to those of the attached carbons. These forty hydrogens were not refined. Refinement was carried out using observational weights and including an extinction coefficient (18, 19).[3] The final agreement factors were $R = 0.112$ ($R = \sum_{hkl} \| |F_o| - |F_c| \| / \sum_{hkl} |F_o|$) and $R_w = 0.121$ ($R_w = (\sum_{hkl} w\Delta^2 / \sum_{hkl} w|F_o|^2)^{1/2}$). In the last least-squares cycle, the largest and average shifts in any parameter were 0.88 and 0.055 times the estimated standard deviation, respectively. Crystallographic computations were carried out using the XRAY 76 System (19) on the DEC 2060 computer at the University of Saskatchewan.[4]

Refinement based on counting statistics was chosen for the final report rather than refinement based on unit weights, because of the poor fit of about 20 intense reflections at θ values between 3 degrees and 12 degrees. When unit weights were used, these reflections dominated the refinement. Re-collection of these strong reflections some weeks after the data set was complete showed that a few of the strong reflections actually had increased in intensity (max. increase 35%).

A kinetic study of the H_2O_2-accelerated formation of *o*-nitrophenol from *o*-dinitrobenzene

RAYMOND A. HELLER, MARILYN FEWSTER,[1] AND TAYLER LAMBERT[2]
Department of Chemistry, Wilfrid Laurier University, Waterloo, Ont., Canada N2L 3C5

Received April 4, 1983

RAYMOND A. HELLER, MARILYN FEWSTER, and TAYLER LAMBERT. Can. J. Chem. **61**, 2455 (1983).

At 30°C in 50% v/v dioxane in water, the reaction of *o*-dinitrobenzene with hydroxide ion to form *o*-nitrophenolate anion is very slow but it proceeds much more rapidly when H_2O_2 is also present. Although the phenolate product absorbs strongly in the visible region, standard kinetic analysis of the spectral data fails for both the peroxide-free and the peroxide-accelerated reactions. A more thorough examination of the spectral evidence reveals that, for the peroxide-accelerated reaction, a reasonably stable intermediate is first formed so that the overall reaction is in fact a two-step sequence. We have used a computer modelling technique to determine rate constants for the two steps and we find that both rate constants are dependent on $[H_2O_2]$. Several possible structures for the intermediate are discussed, with the radical anion being preferred.

RAYMOND A. HELLER, MARILYN FEWSTER et TAYLER LAMBERT. Can. J. Chem. **61**, 2455 (1983).

A 30°C dans un mélange dioxanne-eau 50% v/v, la réaction du *o*-dinitrobenzène avec l'ion hydroxyde qui conduit à l'anion *o*-nitrophénolate est très lente mais elle est beaucoup plus rapide lorsqu'on ajoute du H_2O_2. Bien que le phénolate obtenu absorbe fortement dans la région visible, l'analyse cinétique normale des données spectrales fait défaut dans le cas des réaction sans peroxyde et des réactions accélérées par le peroxyde. Une étude soignée des preuves spectrales révèle que pour la réaction accélérée par le peroxyde, un intermédiaire raisonnablement stable se forme le premier de telle sorte que la réaction globale est en fait une séquence à deux étapes. Nous avons utilisé la technique du modèle par ordinateur pour déterminer les constantes de vitesse des deux étapes et nous avons trouvé que les deux constantes dépendent de $[H_2O_2]$. On discute des diverses structures possibles de l'intermédiaire avec une préférence pour l'anion-radicalaire.

It has long been known that appropriately substituted nitroaromatic systems are subject to attack by powerful basic species resulting in the displacement of nitrite ion. Some time ago, Tommila and Murto published (1) the results of their kinetic investigations into the reactions of *ortho*- and *para*-dinitrobenzene with hydroxide and alkoxide ions in both pure and mixed solvents. In the majority of these cases they observed clean second-order kinetic behaviour corresponding to reactions [1] and [2]:

$$[1]\quad ArNO_2 + HO^- \rightarrow ArOH + NO_2^-$$

$$[2]\quad ArNO_2 + RO^- \rightarrow ArOR + NO_2^-$$

However, as a minor part of their studies on *p*-dinitrobenzene (*p*DNB), they reported that ". . . . with dioxane–water mixtures, it was difficult to obtain a good constancy for *k*. In these runs *k* in general gradually decreased as the reaction proceeded." By a simple extension of Tommila and Murto's work, we were able to determine that *o*-dinitrobenzene (*o*DNB) exhibits similar irregular behaviour. Intrigued by the anomalous kinetics of the dinitrobenzenes in dioxane–water, we decided to attempt a thorough rate study, focussing on the *ortho* isomer. Early in the course of our investigation we happened to use some impure dioxane and thus made the surprising discovery that hydroperoxides have a strong accelerating effect on the DNB – hydroxide ion reaction. We have investigated this phenomenon in some detail and our results are presented in this paper.

While there are many literature reports describing the use of peroxides, especially hydrogen peroxide, in the production of phenols, the great majority of these deal with acidic conditions. We have found only two publications detailing the effect of H_2O_2 in aromatic substitution under basic conditions. Vainshtein *et al.* (2) have reported that the reaction between *p*-nitrobenzenesulfonic acid and hydroxide ion to give *p*-nitrophenol occurs much more rapidly in the presence of hydrogen peroxide. More recently, Ivanova and Shein (3) found that the reaction of 2,4-dinitrochlorobenzene with triethylamine in dimethylformamide is accelerated both by hydrogen peroxide and benzoyl peroxide, but it is not clear from their report whether the presence of peroxide leads to the same product mix.

Experimental

Commercial *o*-dinitrobenzene was recrystallized from benezene, mp 119–121°C (uncorrected; lit. (16) mp 118.5°C). *o*DNB stock solutions of approximately 5×10^{-4} *M* concentration were prepared by dissolving carefully weighed quantities of the crystals in peroxide-free, redistilled 1,4-dioxane. The *o*DNB concentration could be readily confirmed by diluting a measured amount of the stock solution to a specified volume with strong NaOH, sealing the mixture in a vial, and heating overnight at 70–80°C, thereby ensuring total conversion of the *o*DNB to *o*-nitrophenolate anion, the concentration of which could be measured spectrophotometrically, λ_{max} 424 nm (ϵ = 5200 M^{-1} cm^{-1}).

Hydrogen peroxide stock solutions were prepared by appropriate dilution of 30% commercial H_2O_2. Sodium hydroxide stock solutions were prepared by diluting portions of a saturated (carbonate-free) NaOH solution. For our kinetic runs, the H_2O_2 and NaOH concentrations were selected on the basis of the following considerations: (*a*) the desire to have H_2O_2 and NaOH concentrations much higher than the *o*DNB concentration so the psuedo first-order kinetics might prevail; (*b*) the observation that, when the NaOH concentration in 50% v/v dioxane in water is greater than 0.5 *M*, precipitation usually occurs; (*c*) the observation that the phenol product was not completely ionized when H_2O_2 concentration was approximately equal to, or greater than, the NaOH concentration, presumably because of competitive ionization of the H_2O_2.

For a typical kinetic run, 10 mL of *o*DNB stock solution, 40 mL of freshly distilled dioxane, and 2 mL of H_2O_2 stock solution were placed in a 100-mL volumetric flask. This mixture and a separate container of the NaOH stock solution were brought to temperature equilibrium

in a 30.0°C bath. To initiate the reaction, NaOH stock solution was added to the dioxane, bringing the total volume to 100 mL. After rapid mixing, the kinetic solution was poured into a uv cell which was placed in the thermostatted (30.0°C) cell compartment of a Beckman DB-G spectrophotometer. The reference solution was prepared similarly, substituting 10 mL of dioxane for the *o*-DNB stock solution.

All kinetic runs were carried out in duplicate. Early in each run, two aliquots of the kinetic solution were titrated with standard $KMnO_4$ to determine the hydrogen peroxide concentration, and two additional aliquots were titrated with standard acid to obtain the exact NaOH concentration.

Results

When a dilute solution of *o*DNB in dioxane is added to strong aqueous NaOH and the resulting mixture is maintained at 30.0°C, a yellow color very slowly develops. The progress of the reaction may be monitored by periodic scanning of the 250–500 nm spectral region, thus establishing that the adsorption peak originates and remains at 424 nm, which is characteristic of *o*-nitrophenolate anion. A plot of A_{424} vs. time yields a smooth, continuous line of negative curvature, asymptotically approaching a maximum value which corresponds to total conversion of the starting material to phenolate product. However, if these data are subjected to conventional first- or second-order kinetic analysis, no linear relationship is obtained.

The addition of hydrogen peroxide to the *o*DNB–NaOH reaction mixture causes the yellow color to develop much more rapidly. For example, at 30.0°C with no peroxide present and [NaOH] = 0.22 *M*, the time required for A_{424} to reach one-half of its "infinity" value is about 4500 min. If the same solution also contains 0.075 *M* H_2O_2, the corresponding time period drops to 80 min. The final absorption curves are identical in magnitude, shape, and position whether or not H_2O_2 is present, thereby indicating that the same product is formed in each case. Furthermore, if the reaction is done on a large scale with peroxide added, *o*-nitrophenol (*o*NP) may be isolated in abundance with no evidence of other products. Kinetically, the absorbance data (424 nm) for the peroxide-accelerated reaction again fail to conform to standard mathematical analysis, thus paralleling the behaviour of the peroxide-free reaction.

In the absence of NaOH, a solution containing *o*DNB and H_2O_2 is stable for many days, showing only absorbance due to *o*DNB itself; this observation establishes HO_2^- as the species responsible for the increased reaction rate.

Although we have examined only the hydrogen peroxide effect, it is worth repeating that our preliminary findings with impure dioxane strongly indicate a similar rate enhancement due to organic hydroperoxides; in contrast, we have determined that benzoyl peroxide (and presumably other organic peroxides) is not effective in this regard.

A second interesting aspect of the peroxide-accelerated system becomes apparent when the progress of the reaction is followed by regularly scanning the 300–500 nm region. In the earliest stages of the reaction, a distinct peak is observable at approximately 385 nm, but as time progresses the peak shifts to higher wavelength and increases in size until it ultimately assumes the position and magnitude corresponding to 100% formation of the *o*-nitrophenolate anion. The series of spectra shown in Fig. 1 illustrates the sequential changes for a typical reaction. Because this finding inevitably suggests the formation of an intermediate with a reasonable life-time, we are led to the conclusion that the peroxide-accelerated reaction must take place in at least two well-defined steps (see [3]) having rate

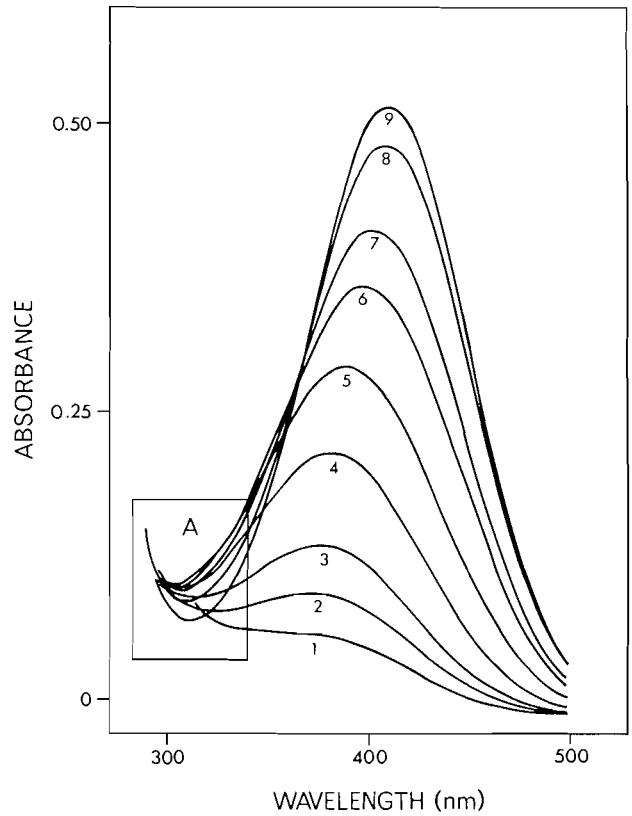

FIG. 1. Conversion of *o*-dinitrobenzene to *o*-nitrophenol anion. Spectral changes during the course of the reaction (30.0°C; 50% v/v dioxane in water; $[o\text{DNB}]_0 = 1 \times 10^{-4}$ *M*; $[\text{NaOH}]_0 = 0.449$ *M*; $[H_2O_2]_0 = 0.0805$ *M*). Spectral scans started at: 1, 8.25 min; 2, 15.5 min; 3, 25.25 min; 4, 50.5 min; 5, 84.5 min; 6, 125 min; 7, 150 min; 8, 240 min; 9, 1300 min.

$$[3] \quad o\text{DNB} \xrightarrow{k_1} (\text{intermediate}) \xrightarrow{k_2} o\text{NP anion}$$

constants of comparable magnitude, and thus we have an explanation for the nonlinear kinetic pattern.

Kinetic analysis

The elucidation of the kinetic picture for the *o*DNB–$NaOH$–H_2O_2 reaction is rather difficult, primarily because the absorbance peaks of the intermediate and the product overlap extensively and there is no direct means available for obtaining an extinction coefficient value for the intermediate. In addition, there are two other, although minor, complicating features of our reaction system. First, the initial mixing of aqueous base with dioxane produces a slight warming effect which must result in a faster reaction rate for the first few minutes. Second, there is slow but measurable decomposition of the hydrogen peroxide (typically about 5%) during the course of the *o*DNB reaction.

We have attempted to solve the kinetic problem by constructing a computer model which reproduces on a relative scale the experimental absorbance readings as a function of time. Briefly, our approach has been to assume a value for the extinction coefficient of the intermediate at 424 nm and derive from this (via an initial rate treatment) a reasonable value for k_1 which then, in conjunction with a knowledge of the time, t_{max}, corresponding to maximum concentration of the intermediate, enables k_2 to be reasonably estimated. This method

[a] Assuming reaction [3] and using $k_1 = 4.0 \times 10^{-4}$ s^{-1} and $k_2 = 3.0 \times 10^{-4}$ s^{-1}.

[b] Using $\epsilon_{424}^{INT} = 2500\ M^{-1}\ cm^{-1}$ and $\epsilon_{424}^{oNP} = 5200\ M^{-1}\ cm^{-1}$.

[c] 50% v/v dioxane in water; $[o\text{DNB}]_0 = 9.9 \times 10^{-5}\ M$; $[\text{NaOH}]_0 = 0.453\ M$; $[H_2O_2]_0 = 0.144\ M$; 30.0°C.

requires a great deal of trial-and-error computer calculation and may appear somewhat arbitrary. However, we have found that most combinations of ϵ_{424}^{INT}, k_1, and k_2 completely fail to reproduce the experimental data and we therefore have some confidence that the numerical results which produce a good match do, in fact, reflect the realities of the reacting system. At the same time it must be acknowledged that our computer analysis, while quite extensive, is not exhaustive and the results may possibly be further refined.

In more detail, we consistently find that for the first few minutes of our kinetic runs, a plot of A_{424} vs. time yields an excellent straight line. During this early time period [*o*DNB] may be taken to be the known initial concentration $[o\text{DNB}]_0$. It is similarly reasonable to assign [*o*NP] = 0.0 *M*, leaving the intermediate as the only absorbing species at 424 nm. If one then assumes a value for the extinction coefficient of the intermediate at that wavelength, it is possible to apply an "initial rate" approach and calculate k_1. Our wide-ranging attempts indicate that the value $\epsilon_{424}^{INT} = 2500\ M^{-1}\ cm^{-1}$, together with the subsequently derived k_1 and k_2, leads to the best fit between calculated and observed absorbances over the entire course of the reaction.

With a value for k_1 in hand, it is possible to evaluate k_2 by making use of the information obtainable from the 325–340 nm segments (region "A" of Fig. 1) of the spectra recorded at various time intervals during the kinetic run. In the early part of the reaction this absorption valley slowly increases in height, then reaches a maximum, and subsequently decreases. Similar behaviour has been observed for the reaction of NaOH with

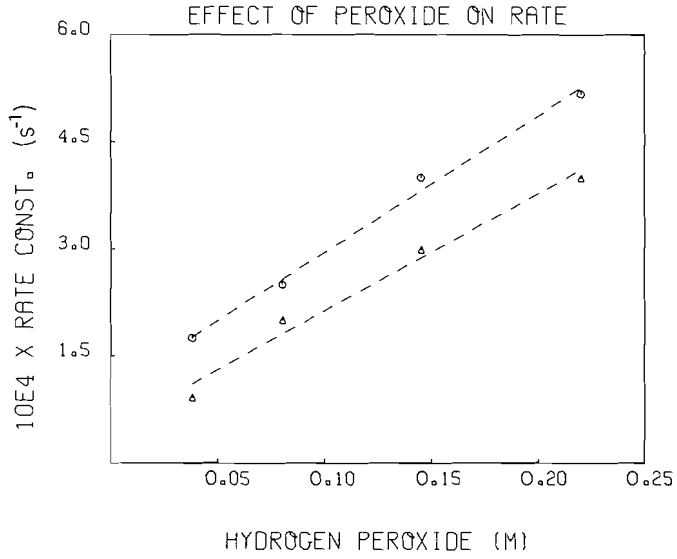

FIG. 2. Variation of rate constants with H_2O_2 concentration [NaOH] = 0.45 *M*, 30.0°C; ○ k_1, $r = 0.996$; △ k_2, $r = 0.990$.

*o*DNB in 4% v/v water in DMSO (4). Such behaviour may logically be associated with the increase of the intermediate to some maximum concentration followed by a decrease to zero. Standard equations are available (5) for relating k_1 and k_2 to the time, t_{max}, required for the concentration of the intermediate to reach a maximum, and therefore k_2 is accessible.

The derived rate constants, k_1 and k_2, may then be substituted into the appropriate integrated rate equations (ref. 5, pp. 153–154) and the relative concentrations of *o*DNB, intermediate, and *o*NP calculated as a function of time. Using the 424 nm extinction coefficients of the two absorbing species, the relative absorbances can also be evaluated and compared with the actual experimental findings. A typical set of results is shown in Table 1. (The correlation between "calculated" and "observed" absorbance is rather poor during the first 20–30 min. We believe this may be explained by the heating effect which takes place when the aqueous NaOH is mixed with the dioxane solution to begin the reaction. Thus, during the early stages, the real reaction would be somewhat faster than calculated.)

By this method we were able to obtain pairs of rate constants for a set of kinetic runs in which NaOH concentration was held constant while the hydrogen peroxide concentration was varied. The resulting k_1 and k_2 values both yield excellent linear correlations when plotted against $[H_2O_2]$, as shown in Fig. 2.

A parallel attempt to determine k_1 and k_2 as functions of NaOH concentration gave results which were less clear-cut but which unambiguously established that the two steps of the reaction are minimally affected by changes in [NaOH] so long as $[\text{NaOH}] > [H_2O_2]$.

Our overall analysis therefore indicates that k_1 is slightly greater than k_2 for any given kinetic run. We have also determined that in each case it is possible to find an alternate pair of rate constants, with $k_1 < k_2$, which also give a reasonable match. We reject these as possible solutions on the following grounds: (*a*) the alternate *k* values shown no linearity when plotted against H_2O_2 concentration; and (*b*) the t_{max} calculated from the alternate values is grossly different from the observed t_{max}.

We have not ignored the possibility that the first step of [3] is reversible, in which case a "k_{-1}" term must be introduced into our considerations. In fact, starting with a given pair of k_1 and k_2 values, we can achieve an equally good time–absorbance fit by keeping k_2 constant, increasing k_1 slightly, and setting $k_{-1} = 0.1\ k_1$. More extensive changes to k_1, k_{-1}, and k_2 result in much poorer numerical matches. Because the k_1 and k_2 values do not change appreciably when k_{-1} is included, we have opted in favour of simplicity, assuming that the first step is essentially irreversible.

Somewhat surprisingly then, our overall results establish that *both* steps of the reaction sequence are dependent on $[H_2O_2]$. Specifically, the linear plots indicate that the empirically derived psuedo first-order rate constants, k_1 and k_2, may be written as:

$$[4a] \quad k_1 = k_1^0 + k_1' [H_2O_2]$$

$$[4b] \quad k_2 = k_2^0 + k_2' [H_2O_2]$$

where the intercept, k^0, represents the rate of reaction in the absence of H_2O_2 and the slope, k^1, may be taken as the second-order rate constant for the hydrogen peroxide reaction. Equations [4*a*] and [4*b*] apply at constant $[HO^-]$ and therefore each may be rewritten in the general form:

$$[5] \quad k = k^{00} [HO^-] + k'' [HO^-] [H_2O_2]$$

Our observation that a mixture of *o*DNB and H_2O_2 undergoes no spectral change in the absence of NaOH proves that at least the first step of the reaction must be a function of $[HO_2^-]$ rather than $[H_2O_2]$. We may explicitly introduce the $[HO_2^-]$ term into the equations by taking into account the ionization of H_2O_2 in base:

$$[6] \quad H_2O_2 + HO^- \rightleftharpoons HO_2^- + H_2O$$

Reaction [6] would have an equilibrium constant $K_A = K_{H_2O_2}/K_W$ and thus we may rewrite eq. [5] in the kinetically equivalent form:

$$[7] \quad k = k^{00} [HO^-] + k'' (1/K_A) [H_2O] [HO_2^-]$$

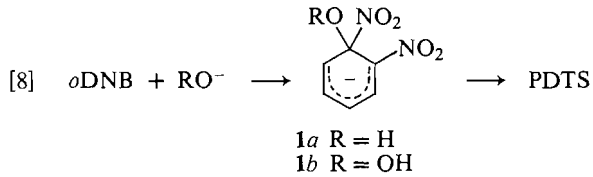
Equation [7] would have significance if the numerical value of K_A were known, but $K_{H_2O_2}$ and K_W are not available for 50% v/v dioxane in water.

Nature of the intermediate and possible mechanisms

Given our experimental findings, we are faced with the problem of identifying an intermediate which is formed through the action of hydrogen peroxide anion and which then undergoes 100% conversion to the phenol product, with the two steps occurring much more rapidly than the simple attack of HO^- on the nitroaromatic ring. A number of possibilities must be considered.

Classical $S_{N_{Ar}}2$ mechanism

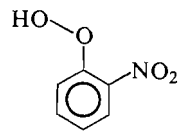
If it is assumed that the attack of HO^- on *o*DNB proceeds by the traditional sigma (σ) complex mechanism (eq. [8], R = H), it is logical to suspect that hydroperoxide ion behaves in the



1*a* R = H
1*b* R = OH

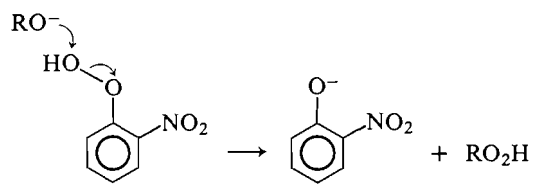
same fashion, giving structure **1***b* as the intermediate. At first glance this possibility is attractive in that it apparently constitutes another example of the well-known "alpha (α) effect" (6), a phenomenon typified by the observation that HO_2^- is about 200 times better than HO^- as a nucleophile in attack on carbonyl carbon and tetrahedral phosphorus. Furthermore, **1***b* might be expected to have an absorbance spectrum extending into the visible region (see, for example, ref. 7).

However, strong arguments against **1***b* arise from a consideration of its probable fate. Upon elimination of NO_2^-, **1***b* would be transformed into the aryl hydroperoxide, **2**, which must also be rejected as the intermediate of interest because



2

neither its ionized nor its unionized form would have the requisite spectral characteristics. More importantly, how would the aryl hydroperoxide be rapidly converted to the corresponding phenol? The only apparent pathway requires displacement by RO^- on peroxide oxygen as in eq. [9], and reactions of this type are extremely slow (ref. 6*a*, p. 20, and ref. 8). Additionally,

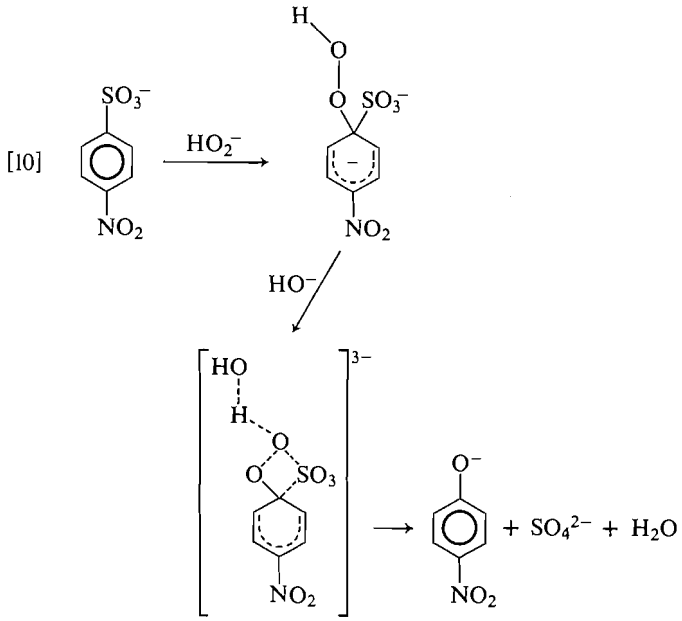


if R = H, eq. [9] fails to account for the peroxide dependence of k_2. On the other hand, if the attacking group in eq. [9] is the more powerful nucleophile, HO_2^-, the k_2 peroxide dependence is satisfied[3] although the secondary product would then be the unusual chemical species H_2O_3. Reaction [9] would also seem to demand that the aryl hydroperoxide be in the unionized form, but the anionic form would predominate under our reaction conditions. Thus, it is difficult to understand how a normal $S_{N_{Ar}}2$ mechanism could provide the explanation for our fast reaction sequence.

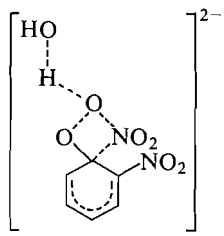
Oxidative elimination from the σ complex

Again assuming that **1***b* accumulates in detectable quantities, an alternative fate for it is suggested by the previously mentioned report (2) dealing with the conversion of *p*-nitrobenzenesulfonic acid to *p*-nitrophenol. These workers report that when the peroxide-accelerated reaction is carried out in $H_2^{18}O$, no ^{18}O is found in the phenol product. On this basis they suggest a mechanism involving the elimination of SO_4^{2-} rather than SO_3^{2-} as shown in reaction [10]:

[3] We thank one of the referees for bringing this possibility to our attention.



A parallel sequence for our reaction would proceed via intermediate **1***b* to transition state **3** and result in the formation of NO_3^- instead of NO_2^-. We have ruled out this interesting



3

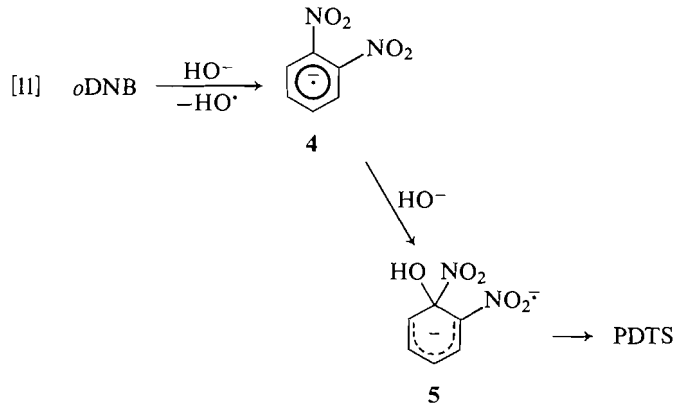
possibility by analyzing[4] for nitrite ion during the course of the reaction. Specifically, at the time when the spectral data show $[o\text{NP}] = 0.75\,[o\text{DNB}]_0$, we find that $[NO_2^-] = 0.63\,[o\text{DNB}]_0$, thus accounting for (0.63/0.75) = 84% of the theoretical amount of NO_2^-. The remaining nitrite may have been oxidized to nitrate by slow reaction with H_2O_2 (ref. 8, p. 106).

Radical anion intermediate

There is a growing school of thought which argues that many reactions which have traditionally been interpreted in terms of ionic mechanisms are, in fact, radical in nature. Eberson has recently published a comprehensive and persuasive review presenting the case for one-electron mechanisms as alternatives to two-electron processes (9). A more limited survey of radical-like intermediates in organic reactions has also been carried out by Guthrie (10).

More directly pertinent to our work are reports regarding the formation of nitroaromatic radical anions under basic conditions (ref. 7, pp. 213–214). In particular, there have been several papers claiming proof of the presence of dinitrobenzene radical anions in DMSO solutions containing hydroxide ion and *o*DNB (4) or pDNB (11, 12). Abe and Ikegami (11) believe that the radical anions are intermediates in the nucleophilic substitution sequence rather than irrelevant structures reversibly formed in side reactions. Their position has theoretical backing from Nagakura and Tanaka (13) who have suggested that nucleophilic aromatic substitution reactions in general are initiated by a one-electron transfer.

Thus, as outlined in reaction [11], Abe and Ikegami suggest



an electron transfer from hydroxide to DNB, producing hydroxyl radical and a reasonably stable DNB radical anion. They argue that HO$^\cdot$ would be rapidly destroyed by reaction with DMSO and that the DNB radical anion, **4**, undergoes attack by a second hydroxide ion to form structure **5**. For the conversion of **5** to nitrophenol they postulate two possible mechanisms, the first requiring the elimination of the radical dianion, $NO_2^{2-\cdot}$, and the other involving electron transfer from nitrophenol radical anion to unreacted DNB.

The *o*DNB radical anion identified by Abe and Ikegami is an attractive candidate for the intermediate formed in our peroxide system. A comparison of the effectiveness of HO^- and HO_2^- as electron donors (eqs. [12] and [13]) is instructive in this connection. Interestingly, the aqueous E_0 values (14) for the

[12] *o*DNB + HO^- → **4** + HO$^\cdot$

[13] *o*DNB + HO_2^- → **4** + $HO_2^\cdot$

$HO_2^\cdot/HO_2^-$ (0.8 V) and HO$^\cdot$/HO^- (1.9 V) couples lead via Marcus' Theory to the expectation[5] that [13] should be much faster than [12] even when allowance is made for the altered solvent conditions. Our confidence in the Marcus treatment is somewhat undermined by the associated prediction that [12] should be so slow as to fall into the "no reaction" category, in contrast to Abe and Ikagami's apparently firm evidence that the reaction does occur at measurable rates.

In any case, we suggest that the rapid rate of [13] accounts for the peroxide acceleration of the first step in [3].

If **4** is indeed the intermediate formed in our system, it may proceed to product via reaction with hydroxide ion as suggested by Abe and Ikegami. However, this interpretation again fails to explain the H_2O_2 dependence of k_2. A possible alternative is reaction of **4** with HO$^\cdot$, a species which might be present in relatively high concentration in the hydrogen peroxide solution, but we have no real evidence to support this view.

Additional remarks

Rather than a formal radical anion intermediate, it is possible that we are dealing with a charge transfer complex such as **6**.

[4] We thank Dr. D. Peirson of the Department of Biology, Wilfrid Laurier University, for performing these analyses.

[5] We thank one of the referees for drawing our attention both to the E_0 data and the derived rate constant values.

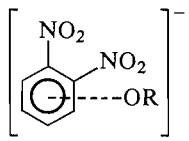
TABLE 2. Comparison of k^0 values

	Peroxide-free computer match	Figure 2 intercept
$10^5 k_1^0$ (s^{-1})	4.7	10.0
$10^5 k_2^0$ (s^{-1})	3.0	4.8

Electron spin reasonance studies (15) have indicated that the interaction between an electron donor and a nitroaromatic



6*a* R = H
6*b* R = OH

acceptor may be extremely close. Therefore, although we have assumed that there is a common intermediate, **4**, formed whether or not peroxide is present, we must admit to the possibility that there may be two distinct species, **6***a* and **6***b*, with different spectral characteristics and different rates of conversion to the phenol. We are undertaking nmr and esr studies in the hope of obtaining a more precise understanding of the structure of the intermediate.

We have also established that the parallel reaction of *p*DNB with hydroxide ion is similarly affected by the addition of hydrogen peroxide (greatly enhanced rate; spectrophotometrically detectable intermediate) and we are investigating the wider generality of this peroxide effect.

Because the peroxide-free reaction of *o*DNB with HO^- does not conform to orthodox kinetic treatment, we suspect that it also takes place in two well-defined steps although no intermediate is detectable in the spectrum. This may be explained by the presence of a different intermediate (e.g., **6***a* in place of **6***b*) with minimal absorbance in the 350–450 nm region.

We have attempted to analyze the peroxide-free reaction, assuming that the same intermediate, **4**, ($\epsilon_{424}^{INT} = 2500\ M^{-1}\ cm^{-1}$) is formed, but we have been unable to find a pair of k_1^0 and k_2^0 values which result in a good match. However, if we introduce "k_{-1}" under the assumption that the first step is reversible or that **4** decays by some equivalent process to regenerate *o*DNB, a good match can be obtained. It is particularly interesting to compare the k_1^0 and k_2^0 values derived in this way with those obtained as the intercepts of the plots shown in Fig. 2. As Table 2 shows, the k^0 values obtained by the two methods are roughly comparable.

Synthesis of coleon B tetramethyl ether

ROBERT H. BURNELL, MICHEL JEAN, AND SYLVAIN SAVARD
Département de chimie, Université Laval, Québec (Qué.), Canada G1K 7P4

Received April 25, 1983

ROBERT H. BURNELL, MICHEL JEAN, and SYLVAIN SAVARD. Can. J. Chem. **61**, 2461 (1983).

Using a simple model available from podocarpic acid, a method to synthesize the Ring A and B chromophore of coleon B (**6***b*) was elaborated. When applied to the correctly substituted starting ketone **8**, this reaction sequence afforded the first synthesis of coleon B, as the tetra-*O*-methyl ether **15***a*.

ROBERT H. BURNELL, MICHEL JEAN et SYLVAIN SAVARD. Can. J. Chem. **61**, 2461 (1983).

A partir de modèles simples obtenus de l'acide podocarpique, nous avons réussi à élaborer une méthode de synthèse des cycles A et B afin d'obtenir un chromophore analogue à celui de la coléone B (**6***b*). Mettant à profit ces résultats et en les appliquant à la cétone **8** qui a le cycle C correctement substitué, nous avons réalisé la première synthèse de la coléone B sous forme de dérivé tétra-*O*-méthylé **15***a*.

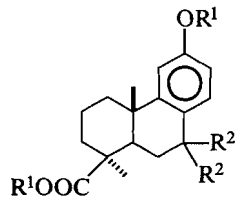
In planning synthetic approaches to several classes of diterpenes from podocarpic acid (**1***a*), we felt that the introduction of a functionality in the A ring could be a critical step. Reactions involving "remote" mechanisms might succeed but, at least as a first approach, we chose to try to extend a series of conjugated functions from the aromatic ring around the perimeter. To do this one of the two groups at C.4 must be expelled and naturally the more susceptible would be the ester function.

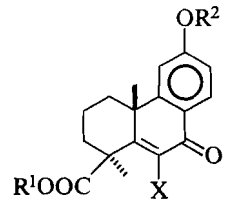
The α,β-unsaturated ketone **2***a* is available from methyl *O*-methyl podocarpate **1***b* in one step using DDQ (1) and it is also known (2*a*, *b*) that heating this enone with 3-quinuclidinol (or other bases such as DBN, DBU, or BBN) provokes demethoxycarbonylation to give **3***a*. Extending the conjugation should be easy and, in fact, when the enone **3***a* was treated with *N*-bromosuccinimide the major product (70%) isolated was the dienone **5***a*. The intermediate bromide suffers spontaneous elimination. The minor product (14%) was the less stable isomer **4***a* in which the newly introduced double bond is exocyclic to ring A but, by acid catalysis, this was quantitatively converted to the endocyclic compound **5***a*. When subjected to Ratcliffe–Rodehorst oxidation conditions (3) the latter afforded a useful yield of the diene-dione **6***a*, the chromophore of which is reminiscent of that of coleon B (4*a*) (**15***b*) with, however, the vital difference, the hydroxyl at C.6.

It was tempting to try the same sequence of reactions on the hydroxyl containing analogue **2***b* to see if the enol double bond would behave similarly to that of the enone **2***a*. The ketone **1***c* was obtained from methyl *O*-methyl podocarpate by chromic oxidation and when shaken with oxygen in the presence of strong base (*t*-BuOK in *t*-BuOH) was converted to the enolic α-diketone **2***b* (89%) along with a trace (4%) of the over-oxidized and extremely polar product **7**. The demethoxycarbonylation reaction (quinuclidinol in refluxing *o*-xylene) proved even more rewarding in this case because the isolated product had been oxidized directly to the enolic enedione **5***b*, thus shortening the sequence by one step. The enolic hydroxyl was protected as the *O*-methyl ether (**5***c*) and then oxidation led to the C.2 ketone **6***b* as in the simpler model.

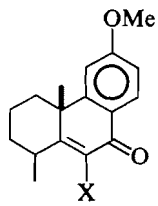
These exploratory results showed that coleon B should be accessible from the correct starting ketone **8** which happens to be one of the end products of our model experiments (5*a*) which led to the synthesis of coleon U (5*b*) and coleon C (5*c*). When ketone **8** was stirred under oxygen in strong base the C.6 position was oxidized to give the diosphenol as in numerous previous cases but, surprisingly, the ester residue was also hydrolysed and the major product was the acid **10***a*. Repeating this reaction on a larger scale confirmed this unusual result and we also isolated minor quantities of the diosphenol ester **10***b*, the enone **9**, and the lactone **11**. Both the ester **10***b* and the acid



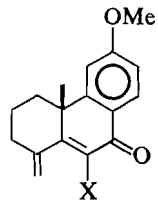
1*a* R¹ = R² = H
1*b* R¹ = Me, R² = H
1*c* R¹ = Me, R²/R² = O



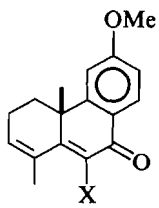
2*a* R¹ = R² = Me, X = H
2*b* R¹ = R² = Me, X = OH
2*c* R¹ = H, R² = Me, X = OH



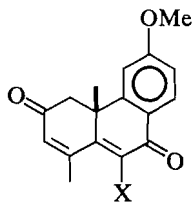
3*a* X = H
3*b* X = OH
3*c* X = OMe



4*a* X = H
4*b* X = OH



5*a* X = H
5*b* X = OH
5*c* X = OMe



6*a* X = H
6*b* X = OMe

15*a* R = Me
15*b* R = H

10*a* were converted to the enedione **13***a* by refluxing in *o*-xylene containing quinuclidinol; later we found that merely refluxing the acid **10***a* in benzene also effected the oxidative decarboxylation, but in this case the major product **12** contained an exocyclic double bond. The latter reaction involved some decarboxylation to give the enolic α-diketone **14***a* (17%) but we were unable to isolate this product in pure form except after *O*-methylation which afforded **14***b*. Since the exocyclic compound **12** readily isomerizes to the more stable transoid endocyclic system **13***a*, this milder two-step sequence proved advantageous since the product from the quinuclidinol reaction was invariably difficult to purify. In fact, the unoxidized diosphenol **14***a* was also present in the quinuclidinol reaction mixture and proved extremely difficult to separate from **13***a*, whereas it was easily removed from **12**. To complete the synthesis, the enedione **13***a* was *O*-methylated to the enol ether **13***b* and the latter afforded coleon B tetra-O-methyl ether **15***a* by chromium trioxide oxidation. Comparison with an authentic sample of this derivative, most kindly provided by Professor Eugster, Zürich, who first described coleon B in the literature (4*b*), showed our synthetic material to be identical with that obtained from nature.

Curiosity forced us to repeat the formation of the model diosphenol **2***b* several times (O_2, *t*-BuOH, *t*-BuOK) but the acid **2***c* never represented more than a minor product. Eventually we did prepare the acid by refluxing the ester **2***b* in ethanolic potassium hydroxide (1 hour). As in the more complex example, refluxing in benzene was sufficient to decarboxylate the acid to the exocyclic enedione **4***b* which also isomerized readily to the endocyclic compound **5***b*.

The assignment of structures to the compounds mentioned in the text was greatly helped by the ^{13}Cmr spectral results which are given in Table 1. The attribution of the resonances was inspired by the authoritative paper of Enzell and co-workers (6) concerning diterpenes.

A very recent synthesis of a Ring A and Ring B analog of Coleon B is described by Matsumoto *et al.* (7). The route employed is completely different from ours and the final product is comparable to **15***a* but with no methoxyl groups on the C ring.

Experimental

Unless otherwise stated the conditions and instruments used to characterize the products were: melting points, Electrothermal, uncorrected; ultraviolet spectra, ethanol solutions (log ε in parenthesis), Hewlett–Packard 8450 A; infrared spectra, carbon tetrachloride solutions, Beckman 4250 and Perkin–Elmer 457; proton magnetic resonance spectra, deuteriochloroform solutions, TMS internal standard (multiplicity, integrated peak areas, coupling constants, and assignments in parenthesis), Bruker HX 90; carbon-13 magnetic resonance spectra, deuteriochloroform solutions, TMS internal standard, Bruker WP 80; mass spectra, Hewlett Packard 5992. Elemental analyses were by Galbraith Laboratories, Knoxville. The high resolution mass spectra were recorded on an A.E.I. MS-30. Unless otherwise stated, dry column chromatography implies the use of Merck Kieselgel 60F (70–230 mesh) and elution with hexane – ethyl acetate (proportions determined by prior thin-layer chromatography using Machery–Nagel Polygram pre-coated plastic sheets).

Dienones **4***a and* **5***a*

Methyl *O*-methyl podocarpate was converted to the enone **2***a* as described by Findlay and Turner (1). The demethoxycarbonylation of **2***a* was effected following Miles' method (2*b*) which involves refluxing in *o*-xylene in the presence of 3-quinuclidinol. The product **3***a* crystallized after chromatography, mp 122–123°C (lit (2) mp 122.5–123.5°C); the spectral properties were as described. *Anal.* calcd. for $C_{17}H_{20}O_2$: C 79.65, H 7.86; found: C 79.45, H 8.07.

To a refluxing solution of the enone **3***a* (2.2 g) in CCl_4 (180 mL) was added *N*-bromosuccinimide (1.67 g). A photoflood lamp was used as a source of both light and heat. After 10 min the cooled solution was filtered from the floating succinimide and the crude product obtained by evaporation was chromatographed (dry column) over silica gel. The major product (1.52 g; 70%) was *9-oxo-6-methoxy-1,4a(β)-dimethyl-3,4,4a,9-tetrahydrophenanthrene* (**5***a*): mp 91–93°C (from hexane); uv: 233(3.87), 253(3.74), 292(3.96), and 321(3.83) nm; ir (film): 1645 cm^{-1}; ^{1}H nmr δ: 1.34 (s, CH_3—C.10), 1.96 (s, CH_3—C.4), 3.84 (s, CH_3O), 5.97 (m, C.3—H), 6.29 (s, C.6—H), 6.86 (dd, J = 8 and 2.5 Hz, C.13—H), 6.94 (d, J = 2.5 Hz, C.11—H), and 8.10 (d, J = 8 Hz, C.14—H); *m/e*: 254 (M^+).

The other product (315 mg; 14%) was *9-oxo-6-methoxy-1-methylene-4a(β)-methyl-1,2,3,4,4a,9-hexahydrophenanthrene* (**4***a*): colourless oil; uv: 238(3.62) and 310(3.63) nm; ir: 3070, 1650, and 890 cm^{-1}; ^{1}H nmr δ: 1.38 (s, CH_3—C.10), 3.89 (s, CH_3O), 5.00 and 5.13 (2t, J = 1.5 Hz, C.19—H_2), 6.33 (s, C.6—H), 6.95 (dd, J = 2.5 and 9 Hz, C.13—H), 6.98 (d, J = 2.5 Hz, C.11—H), and 8.18 (d, J = 9 Hz, C.14—H).

Refluxing a benzene solution of **4***a* containing catalytic amounts of *p*-toluene sulfonic acid effected the isomerization to **5***a* in almost quantitative yield.

Diene-dione **6**a

To pyridine (1.5 mL) in anhydrous CH_2Cl_2 (25 mL) was added CrO_3 (900 mg) in small portions. After stirring under nitrogen for 2 h the dienone **5***a* (300 mg) was added and stirring continued 70 min. The crude product was isolated in the usual manner and then dry column chromatography (silica gel; benzene – ethyl acetate 80:20) gave some starting material (90 mg; 30%) and the diene-dione **6***a* (105 mg; 33%), *3,9-dioxo-6-methoxy-1,4a(β)-dimethyl-3,4,4a,9-tetrahydrophenanthrene:* mp 116–117°C (from hexane–ether); uv: 252(4.18), 289(4.16), 301 (sh, 4.07), and 331(3.77) nm; ir: 3040 and 1645 cm^{-1}; ^1H nmr δ: 1.53 (s, CH_3—C.10), 2.27 (d, J = 1 Hz, CH_3—C.4), 3.89 (s, CH_3O), 6.18 (q, J = 1 Hz, C.3—H), 6.73 (s, C.6—H), 6.94 (d, J = 2.0 Hz, C.11—H), 7.01 (dd, J = 8.0 and 2.0 Hz, C.13—H), and 8.19 (d, J = 8.0 Hz, C.14—H); *m/e*: 268 (M^+). *Anal.* calcd. for $C_{17}H_{16}O_3$: C 76.10, H 6.01; found: C 75.96, H 6.12.

Formation of the enolic α-diketone **2**b

The aromatic ketone **1***c* (8) (1.46 g) dissolved in *t*-BuOH (30 mL) was added to the previously prepared solution resulting from dissolving potassium (1.6 g) in *t*-BuOH (40 mL). The solution was stirred vigorously for 1 h in an atmosphere of oxygen and then the product isolated in the usual manner. Dry column chromatography gave the diosphenol **2***b* (1.40 g; 89%), *1(β)-methoxycarbonyl-9-oxo-10-hydroxy-6-methoxy-1(α),4a(β)-dimethyl-1,2,3,4,4a,9-hexahydrophenanthrene:* colourless glass, ir: 3350, 1732, 1640, and 1612 cm^{-1}; ^1H nmr δ: 1.50 and 1.65 (2s, 2 × CH_3—C), 3.72 (s, $COOCH_3$), 3.91 (s, CH_3O), 6.94 (dd, J = 2.0 and 8.5 Hz, C.13—H), 7.03 (d, J = 2.0 Hz, C.11—H), 7.11 (br s, OH, D_2O !), and 8.17 (d, J = 8.5 Hz, C.14—H). *Anal.* calcd. for $C_{19}H_{22}O_5$: C 69.07, H 6.71; found: C 68.85, H 6.74.

A much more polar compound **7** (50 mg; 4%) was also obtained (*9-oxo-6-methoxy-1a-hydroxy-1(α),4a(β)dimethyl-1,1a,2,3,4,4a,9,10-octahydro-10-oxaphenanthrene*): pale yellow oil, uv: 209(4.22) and 267(4.16) nm; ir: 3370, 1680 cm^{-1}; ^1H nmr δ: 1.03 (d, J = 7 Hz, CH_3—CH), 1.28 (s, CH_3—C), 3.91 (s, CH_3O), 3.94 (br s, OH, D_2O !), 6.87 (dd, J = 2.0 and 9.0 Hz, C.13—H), 6.89 (d, J = 2 Hz, C.11—H), and 8.11 (d, J = 9 Hz, C.14—H); *m/e*: 276 (M^+).

Oxidative demethoxycarbonylation of **2**b *to* **5**b

To the enolic diketone **2***b* (500 mg) in *o*-xylene (14 mL) was added quinuclidinol (970 mg) and the mixture refluxed for 6 h. After cooling, benzene was added and the solution washed with 5% HCl and then the crude product was chromatographed (dry column) to give the enedione **5***b* (215 mg; 52%). For properties see later.

Hydrolysis of ester **2**b *(→ acid* **2**c*)*

The ester **2***b* (2.0 g) was dissolved in EtOH (40 mL), aqueous KOH (30 mL of 30%) was added, and the mixture refluxed for 1 h. Extraction gave a solid which crystallized from ether–hexane (1.70 g; 89%) *(1(β)-carboxy-9-oxo-6-methoxy-10-hydroxy-1(α),4a(β)-dimethyl-1,2,3,4,4a,9-hexahydrophenanthrene)*: mp 120°C (dec.); uv: 238(3.85), 288(3.98), and 323(3.97) nm; ir: 3400, 1700, and 1630 cm^{-1}; ^1H nmr δ: 1.54 and 1.64 (2s, 2 CH_3—C), 3.87 (s, CH_3O), 6.92 (dd, J = 2.5 and 8.5 Hz, C.13—H), 7.01 (d, J = 2.5 Hz, C.11—H), 7.18 (br s, OH, D_2O !), 8.13 (d, J = 8.5 Hz, C.14—H), and 11.07 (s, COOH); *m/e*: 316 (M^+). *Anal.* calcd. for $C_{18}H_{20}O_5$: C 68.34, H 6.89; found: C 68.93, H 6.37. (*Note:* this compound is fragile and even recrystallization causes some decarboxylation.)

Decarboxylation of the acid **2**c

The acid (1.7 g) was refluxed in benzene (200 mL) for 3 h. Evaporation of the solvent gave an oil which was purified by dry column chromatography affording the compound **4***b* as a colourless glass *(9-oxo-6-methoxy-10-hydroxy-1-methylene-4a(β)-methyl-1,2,3,4,4a,9-hexahydrophenanthrene*, 910 mg; 62%): uv: 222(4.10) and 277(4.01) nm; ir: 3390, 1625, and 890 cm^{-1}; ^1H nmr δ: 1.40 (s, CH_3—C), 3.89 (s, CH_3O), 5.30 and 5.43 (2m, exocyclic methylene), 6.95 (s, OH, D_2O !), 6.95 (dd, J = 2.5 and 9.0 Hz, C.13—H), 7.00 (d, J = 2 Hz, C.11—H), and 8.20 (d, J = 9.0 Hz, C.14—H).

The decarboxylation product **3***b* was also obtained (glass, 392 mg; 27%; *9-oxo-6-methoxy-10-hydroxy-1(β),4a(β)-dimethyl-1,2,3,4,4a,9-hexahydrophenanthrene*): uv: 245(3.82), 272(4.00), and 323(3.90) nm; ir: 3370, 1650, and 1625 cm^{-1}; ^1H nmr δ: 1.52 (s, CH_3—C), 1.56 (d, J = 7.0 Hz, CH_3—CH), 3.89 (s, CH_3O), 6.97 (dd, J = 2.0 and 8.5 Hz, C.13—H), 7.03 (d, J = 2 Hz, C.11—H), 7.07 (s, OH, D_2O !), and 8.19 (d, J = 8.5 Hz, C.14—H); *m/e*: 272 (M^+). *Anal.* calcd. for $C_{17}H_{20}O_3$: C 74.97, H 7.40; found: C 74.69, H 7.40.

Methylation of the diosphenol **3**b *to* **3**c

The enol **3***b* (500 mg) was methylated in aqueous ethanol using NaOH (10 mL of 30%) and dimethyl sulfate (6 mL) at room temp for 24 h. The pure di-*O*-methyl ether **3***c* (425 mg; 81%) was obtained by dry column chromatography as a yellow oil; uv: 239(4.02), 265(4.03), and 303(4.10) nm; ir: 1630 and 1585 cm^{-1}; ^1H nmr δ: 1.47 (d, J = 5 Hz, CH_3—CH), 1.53 (s, CH_3—C), 3.74 and 3.88 (2s, 2 CH_3O), 6.91 (dd, J = 2.0 and 9.0 Hz, C.13—H), 6.94 (d, J = 2.0 Hz, C.11—H), and 8.15 (d, J = 9.0 Hz, C.14—H); *m/e*: 286 (M^+).

Isomerization of **4**b *to* **5**b

To the enedione **4***b* (1.1 g) in benzene (100 mL) was added *p*-toluene sulfonic acid (50 mg) and the mixture was refluxed for 30 min. The cooled solution was washed with water, dried, evaporated, and the residue chromatographed (dry column) to afford the isomerized product **5***b* (glass, 850 mg; 77%; *9-oxo-6-methoxy-10-hydroxy-1,4a(β)-dimethyl-3,4,4a,9-tetrahydrophenanthrene*): uv: 279(4.17) and 326(4.11) nm; ir: 3370 and 1615 cm^{-1}; ^1H nmr δ: 1.40 (s, CH_3—C), 2.27 (m, CH_3—C.4), 3.91 (s, CH_3O), 5.78 (m, C.3—H), 6.95 (dd, J = 8.0 and 2.5 Hz, C.13—H), 7.03 (d, J = 2.5 Hz, C.11—H), 7.27 (s, OH, D_2O !), and 8.18 (d, J = 8.0 Hz, C.14—H); *m/e*: 270 (M^+).

Methylation of the enol **5**b *to* **5**c *and oxidation to* **6**b

The enol **5***b* (300 mg) was dissolved in ethanol (5 mL) and water (5 mL) and methylated by the addition of 30% NaOH (6 mL) followed by dimethyl sulfate (3.6 mL). After 24 h the product obtained by extraction was chromatographed (dry column) affording the *O*-methyl ether **5***c* (oil, 232 mg; 74%); ^1H nmr δ: 1.38 (s, CH_3—C.10), 2.18 (m, CH_3—C.4), 3.83 and 3.86 (2s, 2 CH_3O), and 5.73 (br s, H—C.3).

The ether **5***c* (200 mg) was oxidized as described above to prepare diene-dione **6***a*. Dry column chromatography gave the "dione" **6***b* (*3,9-dioxo-6,10-dimethoxy-1,4a(β)-dimethyl-3,4,4a,9-tetrahydrophenanthrene*, 84 mg; 40%): mp 102–104°C (from hexane); uv: 260(3.95) and 310(3.99) nm; ir: 1660 and 1610 cm^{-1}; ^1H nmr δ: 1.54 (s, CH_3—C.10), 2.41 (d, J = 1 Hz, CH_3—C.4), 2.74 (AB q, J = 16 Hz, —C(1)H_2—), 3.83 and 3.86 (2s, CH_3O), 5.99 (br s, C.3—H), 6.81 (d, J = 2 Hz, C.11—H); 6.89 (dd, J = 8 and 2 Hz, C.13—H), and 8.07 (d, J = 8 Hz, C.14—H; high resolution *m/e*, calcd. for $C_{18}H_{18}O_4$: 298.1205; found: 298.1208. *Anal.* calcd. for $C_{18}H_{18}O_4$: C 72.46, H 6.08; found: C 72.35, H 6.20.

Reaction of ketone **8** *with oxygen in strong base*

The ketone **8** (2.0 g, prepared as in our earlier study (4)) in *t*-BuOH (30 mL) was added to a solution prepared by dissolving potassium (1.7 g) in *t*-BuOH (40 mL). This mixture was vigorously stirred under oxygen at atmospheric pressure for 1 h. The crude oil obtained by acidification, extraction, etc. was chromatographed (dry column) to give four products.

Acid **10**a (1.5 g; 75%; *7-oxo-11,12,14-trimethoxy-6-hydroxyabieta-5,8,11,13-tetraen-19-oic acid*): mp 148–149°C (from ether); uv: 247(3.95), 278(3.92), and 332(3.96) nm; ir: 3360, 1695, and 1615 cm^{-1}; ^1H nmr δ: 1.33 and 1.36 (2d, J = 7 Hz, isoPr methyls), 1.64 and 1.72 (2s, CH_3—C), 3.60 (sept, J = 7 Hz, $CH(CH_3)_2$), 3.78, 3.87, and 3.88 (3s, CH_3O), 7.30 (br s, OH, D_2O !), and 10.90 (br, COOH); *m/e*: 418 (M^+). *Anal.* calcd. for $C_{23}H_{30}O_7$: C 66.01, H 7.23; found: C 65.88, H 7.35.

Ester **10**b (400 mg; 19%; *methyl 7-oxo-11,12,14-trimethoxy-6-hydroxyabieta-5,8,11,13-tetraen-19-oate*): mp 124–125°C (from ether–hexane); ir: 3360, 1720, and 1620 cm^{-1}; ^1H nmr δ: 1.34 and 1.36 (2d, J = 7 Hz, isoPr methyls), 1.63 and 1.68 (2s, CH_3—C), 3.60 (sept, J = 7 Hz, isoPr CH), 3.37, 3.78, 3.88, and 3.89 (4s, CH_3O), and 7.23 (s, OH, D_2O !); *m/e*: 432 (M^+). *Anal.* calcd. for $C_{24}H_{32}O_7$: C 66.50, H 7.46; found: C 66.49, H 7.62.

Enone **9** (50 mg; 2.5%; *methyl 7-oxo-11,12,14-trimethoxyabieta-5,8,11,13-tetraen-19-oate*): mp 152–153°C (from hexane); uv: 216(4.28), 248(4.19), 288(3.96), and 326(3.66) nm; ir: 1718, 1648, and 1620 cm^{-1}; ^1H nmr δ: 1.33 (d, J = 7 Hz, isoPr methyls), 1.41 and 1.46 (2s, CH_3—C), 3.58 (sept, J = 7 Hz, isoPr CH), 3.64, 3.77, and 3.83 (3s, CH_3O), and 6.46 (s, =CH—); m/e: 416 (M^+). *Anal.* calcd. for $C_{24}H_{32}O_6$: C 69.21, H 7.74; found: C 69.48, H 7.78.

Lactone **11** (glass, 60 mg; 3%); uv: 215(4.40), 280(4.12), and 327(3.59) nm; ir: 1798 (lactone), 1752, and 1712 cm^{-1}; ^1H nmr δ: 1.31 (s, CH_3—C.4), 1.33 (d, J = 7 Hz, isoPr methyls), 1.41 (s, CH_3—C.10), 3.52 (sept, J = 7 Hz, isoPr CH), 3.84 (s, CH_3O at C.14), and 3.91 (s, 6H, CH_3O at C.11 and C.12); m/e: 416 (M^+).

Decarboxylation of acid ***10****a*

The acid **10***a* (290 mg) was dissolved in benzene (100 mL) and refluxed for 3 h. Evaporation of the solvent afforded the pure diene **12** (200 mg; 77%; *11,12,14-trimethoxy-6-hydroxy-19-norabieta-4(18),5,8,11,13-pentaen-7-one*): mp 132–134°C (from hexane–ether); uv: 249(3.99), 280(3.91), and 336(4.02) nm; ir: 3350, 1670, and 1612 cm^{-1}; ^1H nmr δ: 1.36 (d, J = 7 Hz, isoPr methyls), 1.53 (s, CH_3—C), 3.62 (sept, isoPr CH), 3.79, 3.86, and 3.89 (3s, CH_3O), 5.26 (t, J = 2.0 Hz) and 5.43 (t, J = 1.5 Hz, C=CH_2), and 7.21 (s, OH, D_2O !); m/e: 372 (M^+). *Anal.* calcd. for $C_{22}H_{28}O_5$: C 70.94, H 7.58; found: C 70.81, H 7.31.

The mother liquors yielded a second product **14***a* (50 mg; 17%) which proved very difficult to rid of traces of impurities but was characterized after *O*-methylation in aqueous EtOH (15 mL of 50%), NaOH (5 mL of 30%), and dimethyl sulfate (3 mL, added after stirring for 20 min). After 36 h the product was isolated by extraction. The tetramethyl ether **14***b* (*6,11,12,14-tetramethoxy-18-norabieta-5,8,11,13-tetraen-7-one*) crystallized on standing (40 mg; 77%), mp 145–148°C; uv: 247(3.91), 268(3.87), 294(3.82), and 325(3.65) nm; ir: 1658 and 1560 cm^{-1}; ^1H nmr δ: 1.31 (d, J = 6 Hz, CH_3—C.4), 1.33 (d, 6H, J = 7 Hz, isoPr methyls), 1.59 (s, CH_3—C.10), 3.57 (sept, J = 7 Hz, isoPr CH), 3.76(3H), 3.77(3H), and 3.83(6H) (CH_3O groups at C.6, C.14, C.11, and C.12); m/e: 388 (M^+).

Isomerization of ***12*** *to* ***13****a*

A solution of the enedione **12** (450 mg) in benzene (60 mL) containing *p*-TsOH (60 mg) was refluxed for 1 h. After cooling, the solution was washed with water, dried, and evaporated to afford the endocyclic isomer **13***a* (430 mg; 96%; *11,12,14-trimethoxy-6-hydroxy-19-nor-abieta-3,5,8,11,13-pentaen-7-one*): mp 109–111°C (from hexane–ether); uv: 249(4.09), 284(3.83), and 358(4.03) nm; ir: 3320, 1610, and 1560 cm^{-1}; ^1H nmr δ: 1.36, 1.37 (2d, J = 7 Hz, isoPr methyls), 1.54 (s, CH_3—C.10), 2.26 (m, CH_3—C.4), 3.63 (sept, J = 7 Hz, isoPr CH), 3.79, 3.89, and 3.90 (CH_3O at C.14, C.12, and C.11), 5.79 (m, 1H, =CH—), and 7.54 (s, OH); m/e: 372 (M^+). *Anal.* calcd. for $C_{22}H_{28}O_5$: C 70.94, H 7.50; found: C 70.70, H 7.79.

Methylation of ***13****a* (→ ***13****b*)

Sodium hydroxide (5 mL of 30%) was added to a solution of **13***a* (130 mg) in EtOH (10 mL) and water (5 mL). After stirring for 20 min, dimethyl sulfate (3 mL) was added and stirring continued overnight. Normal extraction and washing afforded the tetra-*O*-methyl ether **13***b* (125 mg; 93%; *6,11,12,14-tetramethoxy-19-norabieta-3,5,8,11,13-pentaen-7-one*) as a pale yellow solid, mp 150–151°C; uv: 250(sh 3.94), 259(sh 3.89), 286(3.94), and 327(4.02) nm; ir: 1625 and 1550 cm^{-1}; ^1H nmr δ: 1.38 (d, J = 7 Hz, 6H, isoPr methyls), 1.56 (s, CH_3—C.10), 2.19 (m, CH_3—C.4), 3.63 (sept, J = 7 Hz, isoPr CH), 3.77(3H), 3.82(3H), and 3.89(6H) (CH_3O groups at C.14, C.6, C.11, and C.12), and 5.83 (m, =CH—); m/e: 386 (M^+). *Anal.* calcd. for $C_{23}H_{30}O_5$: C 71.48, H 7.82; found: C 71.53, H 7.88.

Allylic oxidation to coleon B tetra-O-methyl ether ***15****a*

To a solution of pyridine (1.5 mL) in dichloromethane (50 mL) was added chromium trioxide (0.9 g in small portions). After stirring for 2 h, the tetra-*O*-methyl ether **13***b* (200 mg) was added and the flask was stoppered and stirring continued at room temp for 48 h. After the usual extraction, the crude product was chromatographed (silica gel, dry column, EtOAc–benzene 1:4) to give the pure coleon B derivative **15***a* (55 mg; 27%; *6,11,12,14-tetramethoxy-19-norabieta-3,5,8,11,13-pentaen-2,7-dione*): mp 117–118°C (lit. (4*b*) mp 119–120°C); uv: 213(4.52), 283(4.16), and 326(4.02) nm; ir($CHCl_3$): 1648; ir(CCl_4): 1661 cm^{-1}; ^1H nmr δ: 1.35, 1.36 (2d, J = 7 Hz, isoPr methyls), 1.66 (s, CH_3—C.10), 2.38 (d, 1H, J = 17 Hz, C.1—H), 2.42 (d, 3H, J = 1.5 Hz, CH_3—C.4), 3.60 (sept, J = 7 Hz, isoPr CH), 3.81 (s, CH_3O at C.6), 3.84 (d, 1H, J = 17 Hz, C.1—H), 3.86, 3.87, and 3.88 (3s, CH_3O at C.14, C.12, and C.11), and 6.10 (q, 1H, J = 1.5 Hz, C.3—H); high resolution m/e, calcd. for $C_{23}H_{28}O_6$: 400.1868; found: 400.1886.

Comparison with an authentic sample (mixture mp and tlc in several solvent systems) showed this material to be identical with that described by Prof. C. H. Eugster (Zürich) (4*b*) who kindly provided the sample.

Enamines of 2,2-bis(ethylthio)ethanal: a convenient route to γ-keto crotonate derivatives[1]

GORDON S. BATES[2] AND S. RAMASWAMY

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received March 9, 1983

GORDON S. BATES and S. RAMASWAMY. Can. J. Chem. **61**, 2466 (1983).

A new α-oxoaldehyde reagent, 2,2-bis(ethylthio)ethanal **1**, has been prepared in high yield from ethanedial. Alkylation of the potassium salt of the enamines of **1** with various alkylating agents followed by *in situ* hydrolysis of the intermediate imine afforded high yields of the alkylation products of **1**. This new reagent was used in the synthesis of a chiral potential precursor of the macrocyclic fragment of cytochalasins A, B, and F, as well as in the syntheses of the physiologically active diolides pyrenophorin and norpyrenophorin.

GORDON S. BATES et S. RAMASWAMY. Can. J. Chem. **61**, 2466 (1983).

On a préparé, avec un excellent rendement, un nouveau réactif α-oxoaldéhyde, le bis(éthylthio)-2,2 éthanal (**1**) en partant de l'éthanedial. L'alkylation du sel de potassium de l'énamine du composé **1** avec divers agents alkylants, suivie de l'hydrolyse *in situ* de l'émine intermédiaire, donne avec des rendements élevés les produits d'alkylation du composé **1**. On a utilisé ce nouveau réactif dans la synthèse d'un précurseur potentiel chiral du fragment macrocyclique des cytochalasines A, B et F ainsi que dans la synthèse des diolides physiologiquement actifs: la pyrénophorine et la norpyrénophorine.

An important structural feature of many natural products (e.g. cytochalasin A, and the diolides pyrenophorin, norpyrenophorin, and vermiculin) is the presence of a γ-keto crotonate moiety. In addition, other natural products (e.g. brefeldin A, cytochalasins B and F) contain a partially reduced variation of the above structural unit, i.e. a γ-hydroxy crotonate, which is readily accessible from the above systems.

As part of a programme to develop efficient synthetic methods which are based on inexpensive and readily available reagents, it appeared that ethanedial should be a suitable precursor for **1**. This compound has synthetic potential for entry into the desired functional group array.[3]

Accordingly **1** was prepared in yields of 70−85% by shaking an aqueous ethanedial solution with two equivalents of ethanethiol in the presence of a catalytic amount of hydrochloric acid.[4]

Aldehyde **1** can in principle be elaborated to **5**, a derivative of the desired γ-keto crotonate moiety, in at least two ways. (A) Wittig−Horner or equivalent elaboration of aldehyde **1** may give either **2** or **3**. Deprotonation of either **2** or **3** will generate the same anion. Alkylation of this anion could provide **5**. (B) Alkylation of aldehyde **1** to provide **4** followed by a Wittig-Horner or equivalent elaboration could also lead to compound **5**.

The former route would require a regioselective alkylation of **2** or **3**. Considerable work on such regiocontrol in similar systems (3) has shown that the necessary control is not yet complete. Preliminary experiments in our laboratory confirmed that the anion stabilizing effect of the dithioacetal in the anion derived from **2**/**3** was not sufficient to overcome the predominant regioselectivity (α-alkylation) observed in the alkylation of these systems.

Efforts to alkylate various salts of **1** with simple alkyl halides were unsuccessful. However, the lithio derivative of the aldehyde reacted with 1-bromo-3-methyl-2-butene to provide a 70% yield of the S_N2' alkylation product **7**. This result is analogous to the observation with 2-formyl-1,3-dithiane reported by Wilson and Mathew (4). The formation of **7** may be rationalized by assuming an initial *S*-alkylation of **1** followed by a thermally allowed [2,3]-sigmatropic rearrangement of the resulting sulphonium ylide **6**.[5] It appears likely that the failure to achieve simple alkylation of the anion of **1** was due to preferential attack of the alkylating agent on sulphur rather than on carbon. The resulting stable ylide was then presumably lost in the aqueous phase upon work-up of the reaction mixture.

The pioneering work of Stork and Rowd (5) had established that, whereas aldehyde enolates themselves usually do not alkylate well, the corresponding metallo enamines undergo facile alkylation. Therefore various imine derivatives of **1** were prepared and the ease of alkylation of the corresponding salts was studied.

Various primary amines were condensed with aldehyde **1**. In every case reaction proceeded smoothly. The product was found to be exclusively the enamine tautomer and no detectable amount of the imine form was present in the product as inferred from the ^{1}H nmr spectrum of the product. The formation of the enamine tautomer in the reaction is not unusual in light of the fact that a dithioketal carbon appears to prefer to be sp^2 hydridized if possible (6).

Studies of the ease of alkylation of various salts of enamines **8***a*−*d* using bromethane showed that all of the enamines, excluding that derived from aniline, showed essentially identical reactivity. The alkylations were very regioselective. Alkylation occurred exclusively on carbon for compounds **8***a*−*c*. However, the anion of **8***d* was found to alkylate completely on nitrogen. Hydrolysis of the alkylated imines to the corresponding aldehydes was investigated (Table 1).

The results of these initial alkylation and hydrolysis studies indicated that either the cyclohexyl or 2-methyl-2-propyl enamines **8***a* or **8***b* would be suitable for further investigation. Due to its better storage properties, the cyclohexyl enamine **8***a* was used in subsequent work.

[1]Portions of this work have appeared as a preliminary communication (1).

[2]Author to whom correspondence should be addressed.

[3]For previous approaches to γ-keto crotonate derivatives, see ref. 2.

[4]Attempts to adapt this method to provide the corresponding 2-formyl-1,3-dithiane resulted in the formation of an insoluble, presumably polymeric material.

[5]γ-Alkylation of **2** also has been achieved with allylic halides, presumably via a similar rearrangement.

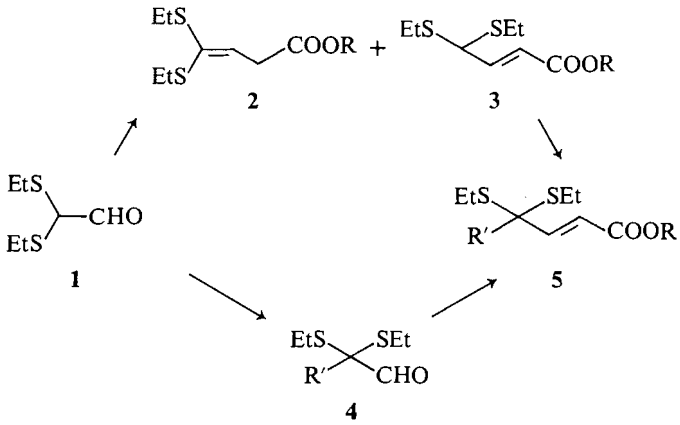

FIG. 1.

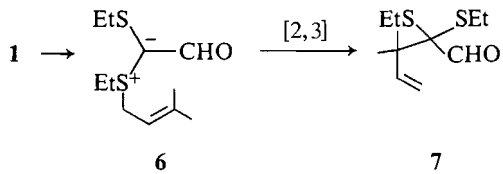

FIG. 2.

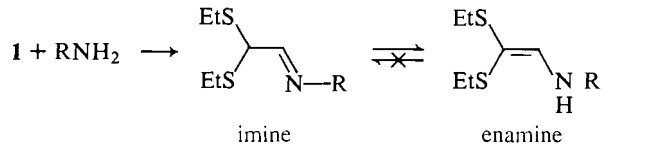
Alkylation studies using bromoethane and the cyclohexyl enamine **8***a* showed that either tetrahydrofuran or 1,2-dimethoxyethane was a suitable solvent for the alkylation reactions. However, hydrolysis of the alkylation products was much faster in tetrahydrofuran (ca. 1.5 hours) than in 1,2-dimethoxyethane (incomplete even after 6 hours). Therefore tetrahydrofuran was used as the reaction solvent in most of the subsequent alkylation studies.

A systematic study of the effect of the gegenion on the rate of the alkylation of the enamine anion then was made. The lithium salt generated by the action of lithium diisopropylamide (no significant deprotonation occurred with lithium hydride) on **8***a* was found to be unreactive towards bromoethane. Similarly the corresponding magnesium salt obtained by deprotonation of the enamine with ethyl magnesium bromide exhibited little tendency to react with either bromoethane or iodoethane even after prolonged reaction in refluxing tetrahydrofuran. Moderate yields of the desired alkylation product were obtained with bromoethane and the sodium salt of the enamine derived by deprotonation of the enamine with sodium bis(trimethylsilyl)-amide in tetrahydrofuran (attempted deprotonation with sodium hydride was unsuccessful). However, the potassium salt generated by stirring the enamine with a suspension of potassium hydride underwent smooth alkylation providing a high yield of the desired product. The results of these gegenion variation studies are summarized in Table 2.

The bright yellow potassium salt of the enamine was generated by adding the enamine to a stirred suspension of 1.1 equivalents of mineral oil-free potassium hydride in dry tetrahydrofuran. Alkylations then were carried out with a wide variety of substrates (Table 3). The reaction time for alkylation varied from 15 min at room temperature for allylic halides to 18 h at 50°C for cyclohexyl and cyclopentyl *p*-toluenesulphonates. The alkylated enamine was hydrolyzed *in situ* by stirring the product with dilute aqueous ethanedioic acid for two hours at room temperature.

The relatively low yields of alkylation products obtained



8*a* R = cyclohexyl

with the highly reactive alkylating agents, iodomethane and methyl bromoacetate, are presumably due to a competing *S*-alkylation pathway followed by hydrolysis of the sulphonium salt during work-up to regenerate water-soluble products. With 2-bromopropane, this expected β-elimination reaction appears to compete with the desired alkylation as reflected by the low yield of the alkylation product. However, a significant increase in the amount of alkylation was observed with 2-propyl *p*-toluenesulphonate. This observation is in agreement with previous observations that *p*-toluenesulphonate esters give better yields of the corresponding substitution products under conditions in which bromides predominantly undergo elimination (7). Good yields of akylation products were obtained even with the elimination-prone cyclohexyl and cyclopentyl *p*-toluenesulphonates.

Interestingly, the reaction of the enamine anion with allylic halides in which regioselective alkylation is possible (entries 13–15) yields, as the sole products, those compounds which result from a formal S_N2 alkylation. For example, the reaction with 1-bromo-3-methyl-2-butene yields compound **9**. This result is strikingly different from the corresponding reaction

†S_N2 product.
‡Reaction carried out in 1,2-dimethoxyethane. The solvent was exchanged for tetrahydrofuran prior to hydrolysis. Lithium diisopropylamide was used as the base for this reaction.

with the anion of aldehyde **1** (*vide supra*) which yielded compound **7**.

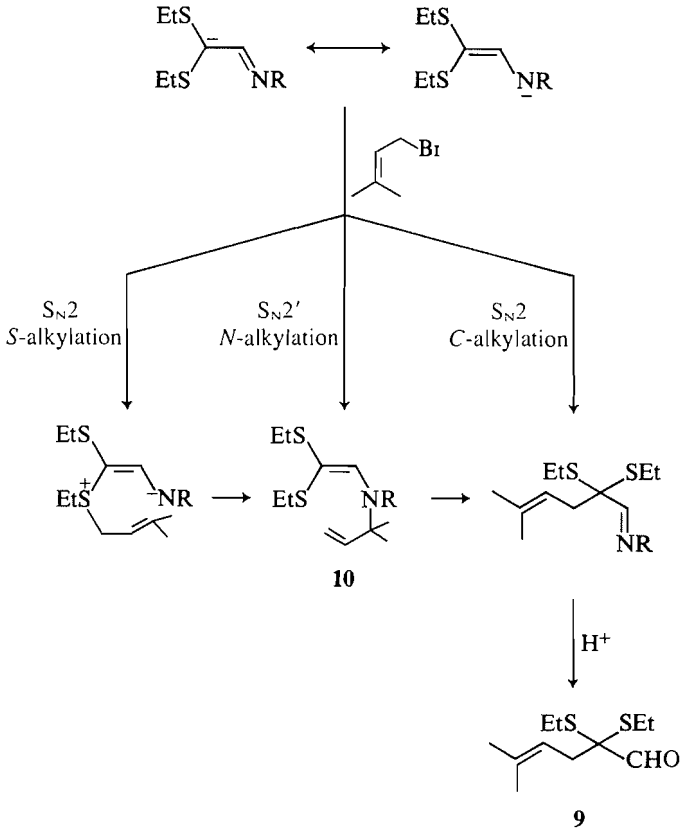
The formation of the S_N2 displacement product **9** can be visualized either as a direct displacement on the halide or via intermediacy of compound **10** arising either by an S_N2' displacement on the halide by the enamine nitrogen or by an internal displacement on an intermediate sulphonium salt (Scheme 1).

To check the validity of these possible pathways involving an aza Cope type of reaction, compound **11** was synthesized by the reaction of *N*-(2-propenyl)cyclohexanamine with aldehyde **1**. The rearrangement of **11** to yield product **12** could not be effected even at the reflux temperature of toluene. This result tends to preclude the intermediacy of compounds similar to **10** in the previous alkylation reactions. Hence it was concluded that the products of entries 12–15 result from a direct displacement on the allylic halide by the imine anion. Reaction of the lithium salt[6] of enamine **8***a* with 2-cyclohexenone afforded a 28% yield of the conjugate addition product **13**. No detectable amount of the 1,2-addition product was observed. The poor yield of the 1,4-addition product is presumably due to the reversibility of the reaction.

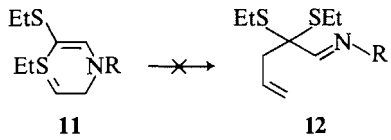
An attempted aldol condensation with benzaldehyde, an acylation with benzyl chloride, and an epoxide cleavage with the enamine anion were all unsuccessful.

The scope of a new synthetic method is best demonstrated through its use in a total synthesis. Accordingly, the diolides pyrenophorin and norpyrenophorin, as well as a chiral potential precursor of the macrocyclic fragments of cytochalasins A, B, and F were prepared using the alkylation of enamine **8***a* as a key step in each of the syntheses.

[6]The potassium salt of the enamine in tetrahydrofuran gave an even lower yield of the conjugate addition product.



SCHEME 1. Possible pathways for the formation of **9** by the reaction of the enamine anion with 1-bromo-3-methyl-2-butene.



R = cyclohexyl

FIG. 4.

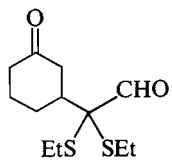


FIG. 5.

Pyrenophorin 20

This 16-membered diolide was first isolated by Ishibashi (8) from culture filtrates of *Pyrenophora avenae*, a pathogen of oats, and was found to possess antifungal and cytostatic properties.

The starting material for the present synthesis[7] of pyrenophorin was 1,3-butanediol. Compound **14** was prepared by regioselective sulphonation of the primary hydroxyl group of 1,3-butanediol, followed by silylation of the secondary alcohol group. Alkylation of the potassium salt of cyclohexyl enamine **8***a* with **14** followed by an *in situ* hydrolysis yielded aldehyde

[7]For previous syntheses, see ref. 9 and references therein.

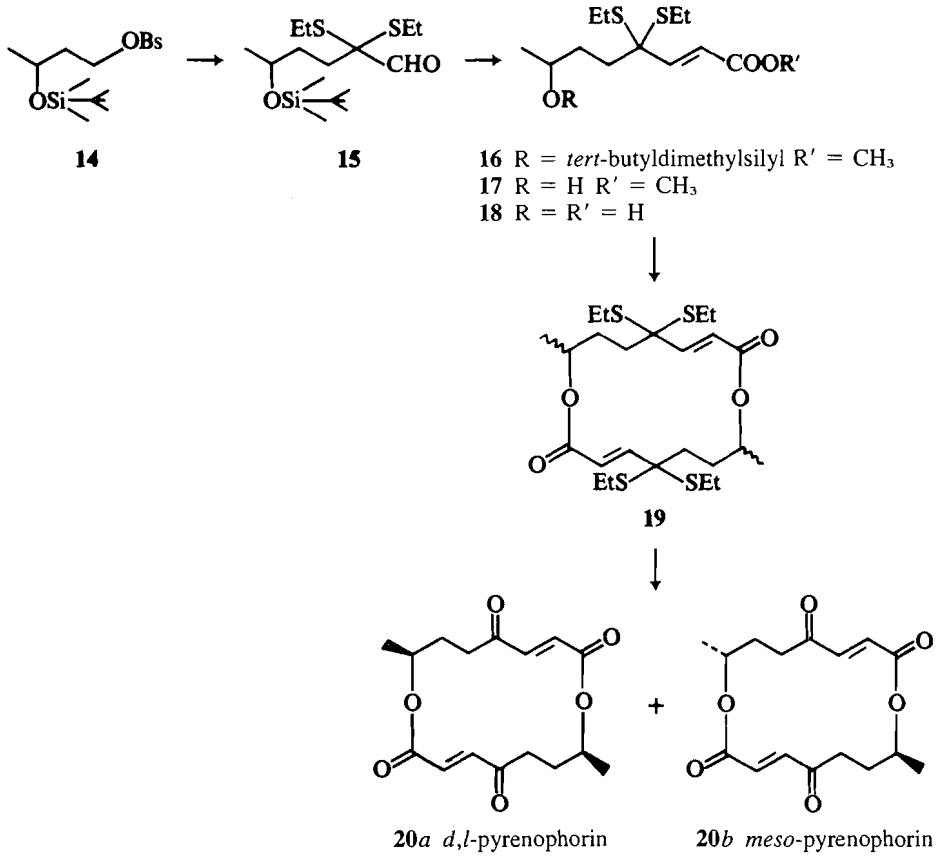

SCHEME 2. Synthesis of pyrenophorin.

15 in 82% yield from **14**. A Wittig–Horner reaction with trimethyl phosphonoacetate afforded ester **16** in 85% yield.

Attempted hydrolysis of the ester functionality in **16** prior to deprotection of the silyl ether resulted in an intractable material. Hence it was necessary to remove the silyl group before ester hydrolysis by stirring **16** with 5 *N* hydrochloric acid for two hours. The crude hydroxy ester **17** was directly saponified in 1 *M* aqueous potassium hydroxide at 60°C for three hours to provide **18** in 81% yield.

A dimerizing lactonization of hydroxy acid **18** was effected using the diethyl azodicarboxylate/triphenylphosphine method of Mitsunobu and co-workers (10) to provide a mixture of *d,l* and *meso* dimers **19** along with some cyclic trimer in ca. 20% total yield. The crude reaction mixture was purified by chromatography on a Florisil column. Although the dimeric precursor to pyrenophorin showed only one homogeneous spot by thin-layer chromatographic analysis, oxidative hydrolysis of **19** using the mercuric oxide and boron trifluoride etherate procedure (11) yielded a mixture which could be resolved into the crystalline *d,l* and *meso* isomers of pyrenophorin by thin-layer chromatography. The faster moving, less polar band was assigned as *d,l*-pyrenophorin **20***a* and the more polar band as the *meso* isomer **20***b*, by comparison with the published thin-layer chromatographic behaviour of these compounds (12).

Norpyrenophorin 26

This didemethyl derivative of pyrenophorin is not a natural product but has been shown to exhibit biological properties similar to those of pyrenophorin.

Although the synthesis of norpyrenophorin, in principle, could be accomplished by subjecting **21** to an identical sequence of reactions as described above for the synthesis of pyrenophorin, it was decided to demonstrate the compatibility of the 2,2-bis(ethylthio)ethanal enamine system to different functional group transformations. Thus, a different synthetic strategy was followed.

Alkylation of the anion of cyclohexyl enamine **8***a* with 3-bromopropene followed by hydrolysis of the resulting imine provided aldehyde **22** in 85% yield. A Wittig–Horner chain elaboration of aldehyde **22** with trimethyl phosphonoacetate afforded unsaturated ester **23** in 93% yield. The crystalline-hydroxy acid **24** was obtained in 70% yield from **23** by a sequence of hydroboration using 9-borabicyclo[3·3·1]nonane with a subsequent oxidative work-up with trimethylamine oxide (13) followed by an alkaline hydrolysis.

Dimerizing lactonization again was effected by the Mitsunobu procedure to provide compound **25**. The crude reaction mixture was chromatographed on a Florisil column to afford the pure crystalline product in 65% yield. Finally, the dithioketals present in **25** were oxidatively hydrolyzed (60%) to provide crystalline norpyrenophorin in an overall yield of over 20% from the cyclohexyl enamine **8***a*.

Cytochalasin macrocycle

The cytochalasins are a group of highly biologically active mould metabolites.[8] Cytochalasin A contains a γ-keto crotonate moiety and the related cytochalasins B and F contain the reduced γ-hydroxy crotonate.

[8]For reviews of (a) the chemistry, (b) the biological activity, and (c) the biosynthesis of the cytochalasins, see ref. 14.

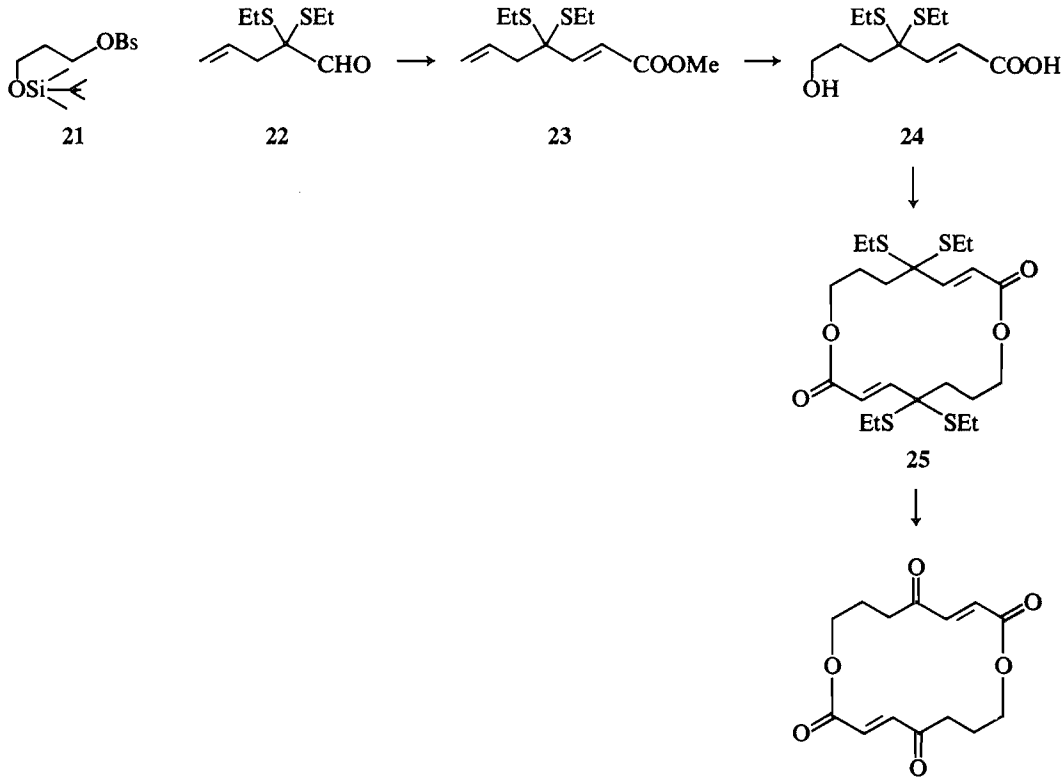
For personal use only.



SCHEME 3. Synthesis of norpyrenophorin.

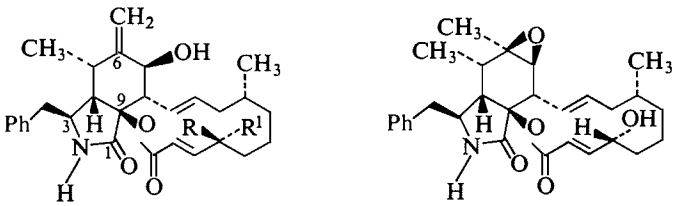


FIG. 6.

In connection with a total synthesis[9] of these microbial metabolites, an efficient preparation of a chiral precursor to the macrocylic fragment was desired. A key step in this synthesis would be the reaction of the salt of **8***a* with an alkylating agent derived from (+)-citronellol.

Initially, the acetate and benzoate esters were used to protect the hydroxyl group of (+)-citronellol. When alkylation of the enamine anion with either benzenesulphonate **27***a* or **27***b* was attempted, both sulphonates underwent a β-elimination reaction, as evidenced by the appearance of a terminal olefinic pattern in the ^{1}H nmr spectrum of the product. This result was surprising since other aliphatic benzenesulphonates clearly alkylated the same enamine anion (see Table 3). This observation may be rationalized in terms of an initial reversible attack on the carbonyl group of the ester followed by an internal alkoxide promoted elimination and a subsequent regeneration of the ester. Eventually the *tert*-butyldimethylsilyl group was found to be a suitable protecting group. Accordingly, compound **27***d* was prepared from (+)-citronellol in 78% overall yield. Alkylation of the potassium salt of **8***a* with sulphonate **27***d* was effected under the standard conditions to provide aldehyde **28** in 82% yield. A Wittig–Horner chain elaboration of **28** subsequently afforded the unsaturated ester **29** in 85% yield. This compound thus has been prepared in 54% overall yield from (+)-citronellol and is a suitable chiral precursor for the desired macrocyclic portion of the cytochalasin target molecules.

Further work on the cytochalasin synthesis is continuing and will be reported in due course.

[9]For other synthetic approaches, see ref. 15.

Experimental

General

All reactions were carried out under a nitrogen atmosphere. Stirring was accomplished using Teflon-coated magnetic stirring bars. Tetrahydrofuran and 1,2-dimethoxyethane were freshly distilled from sodium benzophenone ketyl under a nitrogen atmosphere. Potassium hydride was obtained as a 25% dispersion in mineral oil from Alpha Division, Ventron Corporation. All other reagents were obtained from the Aldrich Chemical Company, Inc. and were used without further purification. The arylsulphonate esters were prepared by reaction of an excess of the appropriate alcohol for 12 hours at 0°C with the required sulphonyl chloride in pyridine, followed by a standard work-up. All extraction and chromatography solvents were distilled before use.

All temperatures are stated in degrees Celsius. Molecular distillations were performed by means of a Buchi Kugelrohr apparatus. Proton magnetic resonance (^{1}H nmr) spectra were obtained on the following instruments: Varian Associates T-60, EM-360L, and HA-100. Spectra were run in deuterochloroform or carbon tetrachloride solution with tetramethylsilane as an internal reference. Chemical shifts are reported on the δ scale. The multiplicity, integrated peak area, and coupling constants in Hertz (Hz) (if observable) are indicated in parentheses after each signal. Infrared spectra were recorded as liquid films using a Perkin–Elmer 700 spectrometer, and were cali-

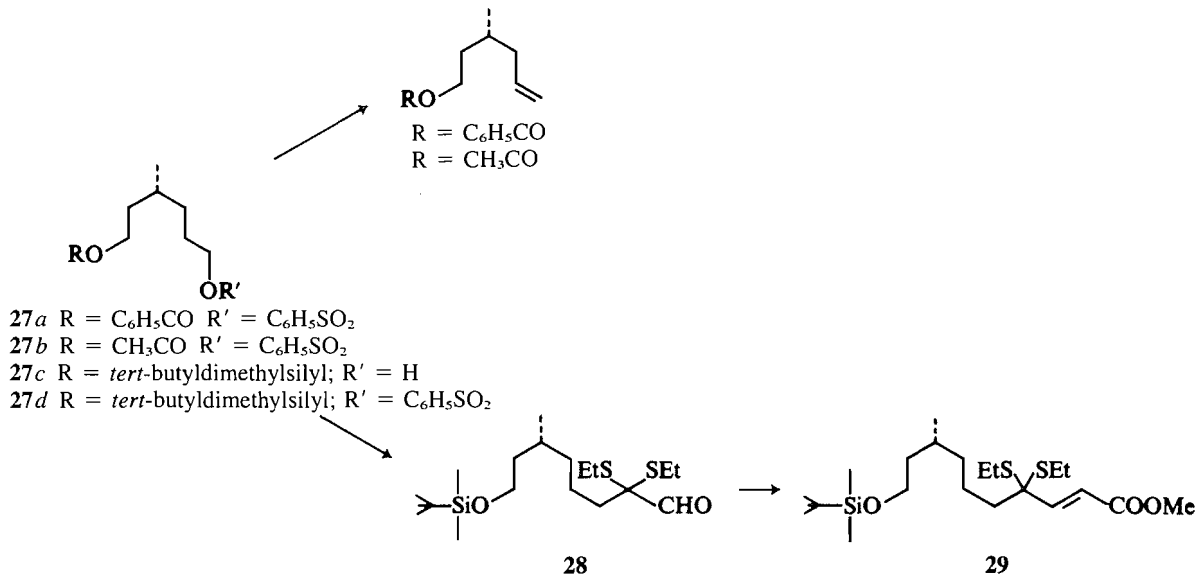

SCHEME 4. Synthesis of a precursor for the macrocyclic portion of cytochalasins A, B, and F.

brated with the 1601 cm^{-1} band of polystyrene. High resolution mass spectra were obtained using an AEI ME-50 mass spectrometer. Elemental analyses were performed at the Microanalytical Laboratory, University of British Columbia.

Merck pre-coated tlc sheets Silica Gel 60F-254 were used for analytical thin-layer chromatography. Florisil (100–200 mesh) supplied by the J. T. Baker Chemical Company and Merck Silica Gel 60 (230–400 mesh) were used for column chromatography. Analytical gas chromatography was carried out on a Hewlett–Packard Model 5830-A chromatograph equipped with 1.8 × 0.3 cm columns packed with 3% OV-101 or 5% Carbowax.

The following abbreviations are used in the description of the multiplicity of each signal in the ^1H nmr spectrum: s = singlet, d = doublet, t = triplet, q = quartet, sept = septet, m = multiplet, dd = doublet of doublets, dt = doublet of triplets, dm = doublet of multiplets, b = broad.

2,2-Bis(ethylthio)ethanal **1**

A mixture of 58 g of an aqueous 40% solution of ethanedial (ca. 400 mmol of ethanedial), 60 mL of ethanethiol (800 mmol), and 5 mL of aqueous 2 *N* HCl was shaken vigorously overnight. The reaction mixture was transferred to a separatory funnel and the heavier organic phase separated. The aqueous phase was extracted once with 50 mL of dichloromethane and the organic phases were combined. The organic phase then was washed once with aqueous dilute Na_2CO_3 and the organic layer filtered through a loose cotton plug. The bulk of the solvent was removed by distillation at atmospheric pressure. The distillation flask was allowed to cool to room temperature and then 50 mL of 30–60 petroleum ether was added to the flask and distillation resumed to ensure that the residual oil in the flask was free from noxious ethanethiol. The residual oil then was distilled under reduced pressure to afford 50.6 g (77%) of 2,2-bis(ethylthio)ethanal as a pale yellow liquid; bp 55–60°C/0.1 Torr (lit. (16) bp 67°C/0.3 Torr); ir: 2708, 1715 cm^{-1}; ^1H nmr (CCl_4) δ: 1.25 (t, 6, J = 7), 2.57 (q, 4, J = 7), 4.12 (d, 1, J = 4.5), 9.08 (d, 1, J = 4.5). *Anal.* calcd. for $C_6H_{12}OS_2$ (164.29): C 43.86, H 7.63, S 39.03; found: C 43.85, H 7.50, S 38.80. *Mol. Wt.* calcd. for $C_6H_{12}OS_2$: 164.0329; found: 164.0325.

Standard procedure for the preparation of the enamines **8**a–**8**d

To a solution of 1.64 g (10 mmol) of 2,2-bis(ethylthio)ethanal in 10 mL of dichloromethane cooled to −15°C was added 11.0 mmol of RNH_2 (R = cyclohexyl, 2-propyl, 2-methyl-2-propyl, or phenyl). The reaction mixture was maintained at −15°C for 6 h. The reaction mixture was filtered through a loose cotton plug to remove the bulk water and the solvent was evaporated under reduced pressure. Molecular distillation of the residual oil afforded the enamine as a yellow oil.

Cyclohexyl enamine **8**a: bp (molecular distillation) 90–100°C/0.1 Torr; ir: 3350, 1665, 1600 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.13 (t, 3, J = 7), 1.16 (t, 3, J = 7), 0.95–2.05 (m, 10), 2.51 (q, 2, J = 7), 2.61 (q, 2, J = 7), 2.94 (m, 1), 4.62 (m, 1), 6.83 (d, 1, J = 13). *Mol. For personal use only.

under a N_2 atmosphere. The oil-free KH was suspended in 5 mL of tetrahydrofuran and 0.245 g (1 mmol) of cyclohexyl enamine **8***a* in 0.5 mL of tetrahydrofuran was added. An immediate evolution of H_2 gas was observed and a bright yellow suspension of the potassium salt of the enamine resulted. To this suspension was added 1.05 mmol of the alkylating agent and the reaction mixture was stirred for 0.25–6 h at room temperature (18 h at 50°C for cyclopentyl and cyclohexyl *p*-toluenesulphonates). The resulting imine was hydrolyzed *in situ* by the addition of 0.126 g (1 mmol) of ethanedioic acid dihydrate in 2 mL of H_2O. After 2 h the reaction mixture was diluted with 40 mL of ethyl ether, washed with 5 mL of H_2O, and dried ($MgSO_4$). The solvent was evaporated under reduced pressure to afford the alkylated aldehyde. The trace of pale yellow colour in the product could be conveniently removed by filtration of the product through a small column of Florisil using 1–2% ethyl acetate in 30–60 petroleum ether (v/v) as the eluting solvent.

Methyl 3,3-bis(ethylthio)-4-oxobutanoate

To a stirred solution of 0.145 mL (1.05 mmol) of diisopropylamine in 2 mL of 1,2-dimethoxyethane cooled to −78°C under a N_2 atmosphere was added 0.8 mL (1 mmol) of 1.25 *M* *n*-butyllithium. After 5 min, 0.245 g (1 mmol) of cyclohexyl enamine **8***a* was added and the reaction mixture stirred for a further 15 min. To the golden yellow solution of the lithium salt of the enamine was added 0.153 g (1 mmol) of methyl bromoacetate in one portion. An immediate precipitate appeared. The reaction mixture was allowed to warm to room temperature over 1.5 h and then 0.126 g (1 mmol) of ethanedioic acid dihydrate in 2 mL of H_2O was added. The bulk of the 1,2-dimethoxyethane was evaporated under reduced pressure and then 2 mL of tetrahydrofuran was added. After 2 h, the reaction mixture was diluted with 50 mL of ethyl ether, washed with 2 × 2 mL of aqueous 2 *N* NaOH, 2 mL of H_2O, and dried ($MgSO_4$). The solvent was evaporated under reduced pressure to afford 0.228 g of crude product which was chromatographed on a 20 g column of Florisil using 2–5% ethyl acetate in 30–60 petroleum ether (v/v) as the eluting solvent. Molecular distillation of the chromatographed product yielded 0.118 g (50%) of the title compound; bp (molecular distillation) 90°C/0.1 Torr; ir: 1735, 1710 cm^{-1}; ^1H nmr (CCl_4) δ: 1.15 (t, 6, J = 7), 2.82 (s, 2), 2.55 (q, 4, J = 7), 3.68 (s, 3), 8.97 (s, 1). *Mol. d,l *and* meso-*Pyrenophorin **20**a and **20**b*

To a stirred suspension of 0.108 g (0.5 mmol) of red HgO and 0.07 g of boron trifluoride etherate in 4 mL of tetrahydrofuran and 1 mL of H_2O was added 0.040 g (0.077 mmol) of the crystalline dimeric material **19** in 0.5 mL of tetrahydrofuran. The reaction mixture was stirred for a further 0.5 h, by which time the red colour of the HgO had disappeared. The reaction mixture was diluted with ethyl ether and then centrifuged. The clear organic phase was washed with 5 mL of aqueous dilute NH_4OH and dried ($MgSO_4$). The solvent was removed under reduced pressure to afford a mixture of products which were separated by preparative thin-layer chromatography on silica using 30% ethyl acetate in 30−60 petroleum ether (v/v) as the eluting solvent.

By comparison with the literature (12) data, the more polar band (0.0075 g) and the less polar band (0.008 g) were identified as the *meso* and the *d,l* isomers of pyrenophorin, respectively

d,l-*Pyrenophorin **20**a*: mp 129−131°C (ethyl ether − 30−60 petroleum ether);[10] ir ($CHCl_3$): 1730, 1700, 1680, 1640 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.3 (d, 6, J = 6), 2.1 (m, 4), 2.63 (m, 4), 5.06 (m, 2), 6.49 (d, 2, J = 16), 6.95 (d, 2, J = 16). *Mol. Wt.* calcd. for $C_{10}H_{20}O_6$: 308.1260; found: 308.1264.

[10]Although purified by thin-layer chromatography and the product twice crystallized, the *d,l*-pyrenophorin showed a significantly lower melting point than the highest value reported in the literature (139−140°C (17)). Traces (<5%) of a structurally related impurity, observed in the ^1H nmr spectrum (400 MHz) of the compound, were undoubtedly causing the lowering of melting point. A third recrystallization was not attempted as the sample size was too small. The *meso*-pyrenophorin had a melting point significantly higher than others reported in the literature (118−119°C (12), 126−127.5°C (17*a*), 128−128.5°C (17*b*)).

To a stirred solution of 1.3 g (5 mmol) of unsaturated ester **23** in 10 mL of tetrahydrofuran was added 1.22 g (10 mmol) of 9-borabicyclo[3·3·1]nonane dimer and the reaction mixture was stirred overnight at room temperature. The solvent was evaporated under reduced pressure and the residue was dissolved in 10 mL of toluene. Then 3.3 g (30 mmol)) of trimethylamine oxide dihydrate were added and the reaction mixture was refluxed for 6 h. The reaction mixture was allowed to cool to room temperature and then was diluted with 50 mL of ethyl ether, and washed with 3 × 10 mL of aqueous saturated NaCl. The solvents were removed under reduced pressure and the crude reaction product was stirred with 10 mL of aqueous 1 *N* KOH at 60°C for 12 h. The reaction mixture was allowed to cool to room temperature and then was extracted with 2 × 10 mL of ethyl ether. The aqueous phase was acidified with aqueous 2 *N* HCl and extracted with 3 × 10 mL of chloroform. The organic phase was dried ($MgSO_4$) and the solvent evaporated under reduced pressure to afford 1.12 g of a yellow oil. The acid was purified by chromatography on a Sephadex LH-20 column (20 g). Initial elution was performed with a mixture of 50% dichloromethane in 30–60 petroleum ether (v/v). A final elution of the column with ethanol afforded 0.92 g (70%) of the desired hydroxy acid **24** as a pale yellow solid; mp 86–87°C (ethyl ether – 30–60 petroleum ether); ir ($CHCl_3$): 3300–2500, 1685, 1635 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.18 (t, 6, J = 7), 1.6–2.1 (m, 4), 2.48 (q, 4, J = 7), 3.64 (bt, 2), 5.88 (d, 1, J = 16), 6.9 (d, 1, J = 16), 6.9–7.2 (bs, 2). *Anal.* calcd. for $C_{11}H_{20}O_3S_2$ (264.408): C 49.92, H 7.62, S 24.25; found: C 50.25, H 7.71, S 24.44. *Mol. Wt.* calcd. for $C_{11}H_{20}O_3S_2$: 264.0854; found: 264.0845.

Dimerizing lactonization of ***24****: preparation of* ***25***

A 0.300 g (1.14 mmol) sample of hydroxy acid **24** was dimerized using the triphenylphosphine/diethyl azodicarboxylate method described above. The reaction product was chromatographed on 40 g of Florisil using 2–10% ethyl acetate in 30–60 petroleum ether (v/v) as the eluting solvent to afford 0.18 g (65%) of dimer **25**. The chromatographed product was pure enough to use in subsequent reactions; mp 85–86.5°C (30–60 petroleum ether); ir ($CHCl_3$): 1710, 1635 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.25 (t, 12, J = 7), 1.8 (m, 4), 2.08 (m, 4), 2.58 (q, 8), 4.18 (t, 4, J = 5), 5.96 (d, 2, J = 16), 6.82 (d, 2, J = 16). *Anal.* calcd. for $C_{22}H_{36}O_4S_4$ (492.786): C 53.62, H 7.36, S 26.03; found: C 53.87, H 7.46, S 26.12. *Mol. Wt.* calcd. for $C_{22}H_{36}O_4S_4$: 492.1496; found: 492.1492.

Norpyrenophorin ***26***

A 0.98 (0.2 mmol) sample of crystalline dimer **25** was oxidatively hydrolyzed using the HgO/boron trifluoride etherate method described above. The reaction product was recrystallized to afford 0.038 g (68%) of norpyrenophorin as a colourless solid; mp 132–133°C (ethyl ether – 30–60 petroleum ether) (lit. (18) mp 132°C); ir ($CHCl_3$): 1735, 1705, 1690, 1650 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.2 (m, 4), 2.61 (t, 4, J = 6), 4.33 (t, 4, J = 5), 6.6 (d, 2, J = 16), 7.04 (d, 2, J = 16). *Mol. Wt.* calcd. for $C_{14}H_{16}O_6$: 280.0947; found: 280.0953.

R-(+)-*4-Methyl-6-(*tert*-butyldimethylsiloxy)-1-hexanol* ***27***c

To a stirred solution of 3.12 g (20 mmol) of (+)-citronellol (19), 3.0 g (ca. 30 mmol) of triethylamine, and 0.061 g (0.5 mmol) of 4-*N*,*N*-dimethylaminopyridine in 20 mL of dichloromethane cooled to 0°C was added a solution of 3.0 g (20 mmol) of *tert*-butyldimethylchlorosilane in 2 mL of dichloromethane. The reaction mixture was stirred for 2 h at room temperature, diluted with 100 mL of ethyl ether, and washed successively with 5 mL of aqueous 2 *N* HCl, 5 mL of aqueous saturated $NaHCO_3$ and dried ($MgSO_4$). The solvent was evaporated under reduced pressure to afford 5.4 g (100%) of the silyl ether as a colourless oil which was pure enough for use in subsequent reactions. Infrared: 1100 cm^{-1}; $[\alpha]_D^{25}$ + 2.75° (*c* 0.625, $CHCl_3$); ^1H nmr ($CDCl_3$) δ: 0.01 (s, 6), 0.85 (d, 3), 0.86 (s, 9), 1.1–1.7 (m, 5), 1.57 (bs, 3), 1.65 (d, 3, J = 1), 1.94 (m, 2), 3.63 (t, 2, J = 6), 5.1 (tm, 1). *Anal.* calcd. for $C_{16}H_{34}OSi$ (270.535): C 71.04, H 12.67; found: C 71.37, H 12.66. *Mol. Wt.* calcd. for $C_{16}H_{34}OSi$: 270.2379; found: 270.2381.

An ozone stream was passed through a solution of 2.7 g (10 mmol) of the above silyl ether in 5 mL of dichloromethane and 5 mL of methanol cooled to −78°C until the solution turned blue. A solution of 0.75 g (ca. 20 mmol) of $NaBH_4$ in 10 mL of methanol was added to the ozonide at −78°C and the reaction mixture was stirred at −78°C for 1 h. Another 0.75 g (ca. 20 mmol) of $NaBH_4$ in 10 mL of methanol was added and the reaction mixture allowed to warm to room temperature over 2 h. The bulk of the solvent was evaporated under reduced pressure and then 40 mL of aqueous 2 *N* NaOH was added to the reaction mixture. The aqueous phase was extracted with 3 × 25 mL of ethyl ether and the organic extract dried ($MgSO_4$). The solvent was evaporated under reduced pressure and the residue was chromatographed on a 50 g column of Florisil using 10–30% ethyl acetate in 30–60 petroleum ether (v/v) as the eluting solvent to afford 1.92 g (78%) of alcohol **27***c* as a colourless oil; bp (molecular distillation) 70°C/0.1 Torr; ir: 3350, 1100 cm^{-1}; $[\alpha]_D^{25}$ +1.17° (*c* 0.27, $CHCl_3$); ^1H nmr ($CDCl_3$) δ: 0.00 (s, 6), 0.84 (d, 3, J = 6), 0.85 (s, 9), 1–1.7 (m, 7), 1.8 (s, 1), 3.59 (t, 2, J = 6), 3.61 (t, 2, J = 6). *Mol. Wt.* calcd. for $C_{12}H_{27}O_2Si$: (M − 15(CH_3)): 231.1780; found: 231.1807.

R-(+)-*4-Methyl-6-(*tert*-butyldimethylsiloxy)-1-hexyl benzenesulphonate* ***27***d

To a stirred solution of 1.48 g (6 mmol) of alcohol **27***c*, 1.2 g (12 mmol) of triethylamine, and 0.040 g (ca. 0.3 mmol) of 4-*N*,*N*-dimethylaminopyridine in 10 mL of dichloromethane cooled to 0°C was added 1.1 g (6.3 mmol) of benzenesulphonyl chloride over a period of 2 min. The reaction mixture was stirred for 3 h at room temperature and then diluted with 60 mL of ethyl ether, washed successively with 10 mL of aqueous 2 *N* HCl, 10 mL of aqueous saturated Na_2CO_3, 10 mL of H_2O, and dried ($MgSO_4$). The solvent was evaporated under reduced pressure to afford 2.28 g (100%) of benzenesulphonate **27***d* which was pure enough for use in subsequent reactions. Infrared: 1360, 1190, 1095 cm^{-1}; $[\alpha]_D^{25}$ +2.0° (*c* 2.45, $CHCl_3$); ^1H nmr ($CDCl_3$) δ: 0.025 (s, 6), 0.88 (s, 9), 0.89 (d, 3, J = 10), 1.48 (m, 7), 3.58 (t, 2, J = 6), 4.04 (t, 2, J = 6), 1.94 (m, 5). *Mol. Wt.* calcd. for $C_{18}H_{31}O_4SSi$ (M − 15(CH_3)): 371.1712;

found: 371.1720.

R-*(+)-2,2-Bis(ethylthio)-6-methyl-8-(*tert*-butyldimethylsiloxy) octanal* ***28***

Alkylation of the potassium salt of cyclohexyl enamine *8a* was carried out with 0.371 g (1 mmol) of benzenesulphonate **27***d* using the general procedure outlined above. Aldehyde **28** was obtained in 82% yield as a colourless oil; bp (molecular distillation) 93°C/0.2 Torr; ir: 1705, 1095 cm^{-1}; $[\alpha]_D^{25}$ +2.67° (*c* 1.0, $CHCl_3$); ^1H nmr ($CDCl_3$) δ: 0.00 (s, 6), 0.83 (d, 3, J = 6), 0.85 (s, 9), 1.18 (t, 6, J = 7), 1−1.9 (m, 9), 2.46 (q, 4, J = 7), 3.6 (t, 2, J = 6), 9.03 (s, 1). *Mol. Wt.* calcd. for $C_{18}H_{37}O_2S_2Si$ (M − 15(CH_3)): 363.2211; found: 363.2241.

R−*(+)-Methyl 4,4-bis(ethylthio)-8-methyl-10-(*tert*-butyldimethyl-siloxy)-2-decenoate* ***29***

A 0.378 g (1 mmol) sample of aldehyde **28** was reacted with the sodium salt of trimethyl phosphonoacetate using the procedure described above. Chromatography of the product yielded 85% yield of the unsaturated ester **29** as a colourless oil; bp (molecular distillation) 105°C/0.1 Torr; ir: 1730, 1640, 1090 cm^{-1}; $[\alpha]_D^{25}$ +3.38° (*c* 1.5, $CHCl_3$); ^1H nmr ($CDCl_3$) δ: 0.00 (s, 6), 0.84 (d, 3, J = 8), 0.85 (s, 9), 1.18 (t, 6, J = 7), 1.05−1.8 (m, 9), 2.48 (q, 4, J = 7), 3.6 (t, 2, J = 6), 3.71 (s, 3), 5.9 (d, 1, J = 16), 6.85 (d, 2, J = 16). *Anal.* calcd. for $C_{22}H_{44}O_3S_2Si$ (448.810): C 58.88, H 9.88, S 14.29; found: C 59.04, H 10.02, S 14.50. *Mol. Wt.* calcd. for $C_{21}H_{41}O_3S_2Si$ (M − 15(CH_3)): 433.2266; found: 433.2243.

Dérivés allyliques de la colonne IV-A, de type $R_3ECH_2CH{=}CH{-}CH_3$ et $R_3ECH(CH_3)CH{=}CH_2$. Approche des effets électroniques par résonance magnétique nucléaire ^{13}C et ^1H [1]

E. MATARASSO-TCHIROUKHINE ET P. CADIOT

Laboratoire de Recherches de Chimie Organique de l'E.N.S.C.P., 11, rue P. et M. Curie, 75231 Paris Cedex 05, France

Reçu le 16 juillet, 1982[2]

E. MATARASSO-TCHIROUKHINE et P. CADIOT. Can. J. Chem. **61**, 2476 (1983).

Un travail spectroscopique d'ensemble, de caractère comparatif a été réalisé en rmn du carbone ^{13}C et du proton ^1H sur les dérivés allyliques de type $R_3ECH_2CH{=}CH{-}CH_3$, **1***E*, *Z* et $R_3ECH(CH_3)CH{=}CH_2$, **2**; R = $-CH_3$, $-C_6H_5$; E = C, Si, Ge, Sn, Pb. La première partie de ce travail, limitée au fragment allylique, est consacrée à l'étude des déplacements chimiques du carbone, $\delta^{13}C$, du proton, δ^1H, et à l'étude des couplages homonucléaires J(H—H) et hétéronucléaires $^1J(^{13}C{-}H)$, $^nJ(^{13}C{-}E)$, n = 1 à 4 et ^nJ(E—C—H), n = 2 et 5; afin d'éclairer l'influence des effets inductifs des substituants $-ER_3$, une échelle cohérente d'électronégativité a été dressée pour les groupements G(E) = $-E(C_6H_5)_3$; il apparaît que les groupements G(E) possèdent des électronégativités intrinsèques très voisines qui satisfont au classement suivant:

$$\chi^{int}_{G(Pb)} > \chi^{int}_{G(Ge)} \approx \chi^{int}_{G(C)} \approx \chi^{int}_{G(Sn)} > \chi^{int}_{G(Si)}$$

L'étude comparative des spectres dans les séries respectives **1***E*, *Z* et **2** conduit à interpréter les déplacements chimiques des noyaux éthyléniques ainsi que les valeurs élevées des couplages hétéronucléaires ^2J(E—C—H) (CH_2), ^5J(E—C—H) et $^4J(E{-}^{13}C)$, dans le cas des dérivés de l'étain et du plomb, en termes d'hyperconjugaison $\sigma \rightarrow \pi$ de la liaison C—E et de la liaison π-allylique. Des facteurs appartenant en propre à l'élément E contrôlent les déplacements chimiques des noyaux du fragment allylique, en α de cet élément; les couplages $^1J(^{13}C_\alpha{-}H_\alpha)$ semblent dominés par le caractère *s* de la liaison $C_\alpha{-}H_\alpha$ sans que celui-ci puisse être relié de façon précise à une métallohyperconjugaison.

E. MATARASSO-TCHIROUKHINE and P. CADIOT. Can. J. Chem. **61**, 2476 (1983).

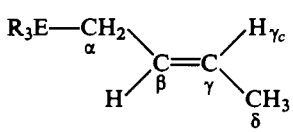
A comparative ^1H and ^{13}C nmr study of allylic derivatives of the IV-A group elements, of the type $R_3ECH_2CH{=}CH{-}CH_3$, **1***E*, *Z* and $R_3ECH(CH_3)CH{=}CH_2$, **2**, was performed (R = $-C_6H_5$, $-CH_3$, E = C, Si, Ge, Sn, Pb). The present paper dealing with the allylic moiety concerns both the chemical shifts, δ^1H and $\delta^{13}C$, and the homonuclear J(H—H) and heteronuclear couplings $^1J(^{13}C{-}H)$, $^nJ(^{13}C{-}E)$, n = 1 to 4, ^nJ(E—C—H), n = 2 and 5. The spectra are consistent with a σ-allylic structure. In order to obtain an inductive order for the groups G(E) = $-E(C_6H_5)_3$, a coherent group electronegativity scale was established. The intrinsic group electronegativities, without appreciable change, obey the following sequence:

$$\chi^{int}_{G(Pb)} > \chi^{int}_{G(Ge)} \approx \chi^{int}_{G(C)} \approx \chi^{int}_{G(Sn)} > \chi^{int}_{G(Si)}$$

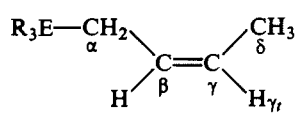
Both the changes along the series, in spectroscopic parameters, δ^1H, $\delta^{13}C$, and the unusually large heteronuclear couplings, ^2J(E—C—H), ^5J(E—C—H), $^4J(E{-}^{13}C)$ (E = Sn, Pb), are interpreted in terms of an electronic mesomeric donating effect for the substituent σ, R_3ECH_2— and $R_3ECH(CH_3)$—, by $\sigma{-}\pi$ hyperconjugation. Factors intrinsic to the main-group element control the chemical shifts δ^1H_α and $\delta^{13}C_\alpha$. The *s*-character of the bond $C_\alpha{-}H_\alpha$ appears to control the $^1J(^{13}C_\alpha{-}H_\alpha)$ couplings; no correlation with a $\sigma \rightarrow \pi$ hyperconjugation could be established.

Introduction

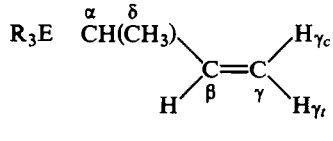
Nous nous proposons de présenter une approche physicochimique de la structure électronique des dérivés allyliques des éléments de la colonne IV-A de type $R_3ECH_2{-}CH{=}CH{-}CH_3$ **1***E*, *Z* et $R_3ECH(CH_3)CH{=}CH_2$ **2**. Elle a été réalisée en mettant en oeuvre une étude comparative des spectres de rmn ^{13}C et ^1H dans les séries respectives **1***E*, *Z* et **2**. Cette étude a permis d'interpréter les spectres de rmn en termes d'effets électroniques du substituant $-ER_3$.



1*E*



1*Z*



2

R = C_6H_5, CH_3 E = C, Si, Ge, Sn, Pb

A notre connaissance, un tel travail d'ensemble de caractère comparatif sur la totalité de la colonne IV-A n'apparaît point dans la littérature, bien que les dérivés allyliques des éléments de la colonne IV-A, aient fait l'objet de travaux plus ponctuels, notamment en spectroscopie électronique et en spectroscopie de résonance magnétique nucléaire (1 à 13).

Cette première publication portera sur des développements théoriques basés sur l'étude des déplacements chimiques $\delta^{13}C$ et δ^1H, et sur l'étude des couplages homonucléaires, J(H—H), et hétéronucléaires, $^1J(^{13}C{-}H)$, $^nJ(^{13}C{-}E)$, n = 1 à 4 et ^nJ(E—C—H), n = 2 et 5, du fragment allylique des composés **1***E*, *Z* et **2**.

Afin d'interpréter les spectres obtenus en termes d'effets électroniques, il nous a paru indispensable d'établir, en tout premier lieu, une base de comparaison des effets inductifs des groupements $-ER_3$. Dans ce but nous avons dressé une

[1] En accord avec l'usage en vigueur en Amérique du Nord, la nomenclature suivante a été adoptée dans cet article: groupe IV-A = C, Si, Ge, Sn, Pb; bien que, d'après les règles de nomenclature de Chimie Inorganique de l'UICPA les Ge, Sn, Pb constituent le groupe IV-B et les éléments de transition le groupe IV-A.

[2] Revision reçue le 4 janvier, 1983.

échelle cohérente d'électronégativité pour les groupements $-E(C_6H_5)_3$, celle des groupements $-E(CH_3)_3$ ayant été déterminée par ailleurs (14*a*).

Résultats et discussion

1. *Echelle d'électronégativité cohérente des groupements* $-ER_3$

Il convient ici d'ouvrir une parenthèse et de rappeler brièvement que l'électronégativité des éléments de la colonne IV-A a été sujette à de très nombreuses études et controverses et a suscité des discussions passionnées (15, 16).

Une échelle cohérente d'électronégativité au sens de Hinze et Jaffe (17) a été calculée pour les groupements $-E(C_6H_5)_3$ par la méthode de Huheey (14).

Il convient de rappeler (17) que l'électronégativité χ d'un atome est exprimée en fonction de la charge partielle δ, résultant de la perte ou du gain d'électrons au cours de la formation de la liaison, par la relation:

$$\chi = a + b\delta$$

a = électronégativité intrinsèque; b: coefficient de charge; a et b sont fonction du potentiel d'ionisation et de l'énergie d'affinité électronique de l'atome à l'état de valence.

L'électronégativité d'un groupe sera celle de l'atome liant perturbée par les substituants.

En appliquant le principe d'égalisation des électronégativités (17) de deux orbitales liantes, si deux groupes G_1 et G_2 sont en équilibre dans une molécule et si nous désignons par $\chi^*_{G_1}$ et $\chi^*_{G_2}$ les électronégativités des orbitales liantes à l'équilibre et par $\delta^*_{G_1}$ et $\delta^*_{G_2}$ les quantités de transfert de charge, on peut écrire:

$$\chi^*_{G_1} = \chi^*_{G_2} = a_1 + b_1\delta^*_{G_1} = a_2 + b_2\delta^*_{G_2}$$

En remarquant que pour une liaison neutre $\delta^*_{G_1} + \delta^*_{G_2} = 0$ la quantité de transfert de charge sera exprimé par:

$$\delta^*_{G_1} = -\delta^*_{G_2}\frac{a_{G2} - a_{G1}}{b_{G_1} + b_{G_2}}$$

Sur la base de ces données, l'électronégativité χ_G d'un groupe $G = -w\begin{smallmatrix}x\\y\\z\end{smallmatrix}$ peut être exprimée en fonction des électronégativités intrinsèques a et des coefficients de charge b des substituants, dans le cas général, par la formule [1] (14*a*):

$$[1]\quad \chi_G = \frac{a_w b_x b_y b_z + a_x b_w b_y b_z + a_y b_w b_x b_z + a_z b_w b_x b_y + b_w b_x b_y b_z \delta^*_G}{b_x b_y b_w + b_x b_z b_w + b_x b_y b_z + b_y b_z b_w}$$

Cette méthode, bien que mettant en jeu des approximations importantes, par ex.: assimilation d'un groupement à un atome perturbé $\chi^{int}_G = a_G$ = const., or a_G dépend, pour un groupe, du groupement antagoniste (17, 18), égalisation totale des électronégativités à l'équilibre etc. ..., permet d'obtenir pour les électronégativités de groupe des ordres de grandeur et de calculer une échelle cohérente d'électronégativité. Dans le cas présent les calculs ont été faits en appliquant la formule [2] cas particulier de la formule générale.

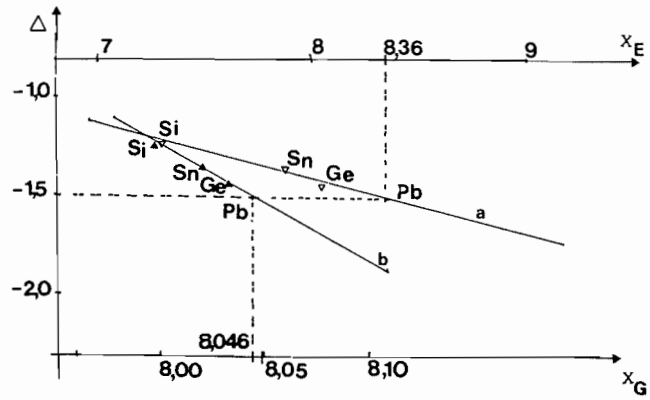

FIG. 1. Déplacement chimique interne $\Delta = \delta^1H(CH_3) - \delta^1H(CH)_\alpha$ composés **2** en fonction (a) de l'électronégativité (unités Mulliken) χ_E de l'élément E; (b) de l'électronégativité χ_G du groupe $G = -E(C_6H_5)_3$.

$$[2]\quad \chi_{G(E)} = \frac{a_E b_\phi + 3b_E a_\phi + b_E b_\phi \delta^*_G}{3b_E + b_\phi};\ G(E) = -E(C_6H_5)_3$$

où a_E et $b_E = a_{C_6H_5}$ et $b_{C_6H_5}$ (14).

Le tableau 1 donne les résultats des calculs concernant les électronégativités à l'équilibre χ^{eq}, les électronégativités intrinsèques $\chi^{int} = a$ et les coefficients de charge b pour les groupes $-E(C_6H_5)_3$, E = C, Si, Ge, Sn à l'état sp^3. L'examen de ce tableau montre que les électronégativités des groupes $-E(C_6H_5)_3$ (E = C à Si, sp^3) sont extrêmement voisines, ce qui correspond aux conclusions de Traylor et coll.: "The inductive effects of metallic groups, MR_3, in the $-CH_2MR_n$ group are negligibly small" (19) (M: élément IV-A, entre autres). Elles satisfont à l'ordre suivant:

$$\chi^{int}_{G(Ge)} \approx \chi^{int}_{G(C)} \approx \chi^{int}_{G(Sn)} > \chi^{int}_{G(Si)}$$

L'électronégativité du groupe $-Pb(C_6H_5)_3$ n'a pu être calculée par cette méthode faute de données, concernant l'électronégativité du plomb sp^3, dans la littérature. Cependant un *ordre de grandeur* pour χ_{Pb} et $\chi_{Pb(C_6H_5)_3}$ peut être obtenu, dans l'échelle d'électronégativité adoptée, en considérant le déplacement chimique interne, $\Delta = \delta^1H(CH_3) - \delta^1H(CH)$, du composé $(C_6H_5)_3PbCH(CH_3)CH{=}CH_2$ **2**; en effet, comme on peut l'observer sur la figure 1 pour les composés **2** étudiés, les déplacements chimiques internes, $\Delta = \delta^1H(CH_3) - \delta^1H(CH)_\alpha$ varient linéairement en fonction de l'électronégativité χ_E (14) de l'élément E, d'une part, et de l'électronégativité $\chi_{G(E)}$ du groupe

G = —E(C_6H_5)$_3$ de l'autre. La connaissance de Δ pour le dérivé **2** du plomb (à partir des données du Tableau 2a) permet de déduire les électronégativités χ_{Pb} et $\chi_{G(Pb)}$ et de les classer comme suit

$$\chi_{Pb(sp^3)} > \chi_{Ge(sp^3)};\ \chi_{G(Pb)} > \chi_{G(Ge)}$$

ce qui est compatible avec des résultats obtenus par ailleurs (20, 21).

II. *Déplacements chimiques* δ^1H *et* $\delta^{13}C$

1. *Spectres du proton (Tableaux 2 à 4)*

L'allure générale du spectre de protons des composés **1***E*, *Z* et **2** correspond à une structure σ-allylique et permet d'écarter un équilibre ionique ou une structure π-allylique. Dans le cas des dérivés primaires, **1***E*, *Z*, la résolution de la région éthylénique du spectre, $H_{\beta,\gamma}$, a été ramenée par double irradiation du groupement —CH_2— à la résolution de la partie AB d'un spectre ABX_3.

En toute rigueur cette partie devrait être traitée en tant que spectre du second ordre, comme on peut le déduire du tableau 4. Cependant $\delta^1H_{\beta,\gamma}$ ont pu être déterminés, comme suit, avec une approximation raisonnable, dans la plupart des cas. *Pour les composés* **1***Z et* **1***E* (E = Pb, Sn, Ge) les quadruplets correspondants aux noyaux A et B (H_β et H_γ) ne sont pas trop déformés et sont relativement aisés à attribuer; ils permettent, avec une approximation raisonnable, de déterminer en faisant leur moyenne la position du spectre pour AB et, de là, calculer

TABLEAU 2(*b*). Déplacements chimiques du proton, δ^1H; composés **1***E*, *Z*, **2**; R = CH_3; fragment allylique

		δ^1H, ppm[a]				
E		CH_3 α′	$\alpha^{b,c}$	$\delta^{b,c}$	$\beta^{b,d}$	$\gamma^{b,d}$
	1*E*	0,09$_2$	[m]: 1,8		[m]: 5,5	
Sn	**1***Z*	0,114	[m]: 1,7		[m]: 5,4	
	2	0,08	2,21	1,41	[m]: 6,0	[m]: 4,7

[a]Conditions expérimentales: Varian XL-100; liquide pur; réf.: benzène interne. Les déplacements chimiques sont donnés par rapport au TMS, en prenant pour le benzène δH_Φ = 7,27 ppm.
[b][m]: centre du multiplet.
[c]Pour les composés **1***E* et **1***Z* les protons α et δ donnent des multiplets confondus, on donne le centre du multiplet commun.
[d]Comme *c*, pour β et γ.

JAB, δAB = $\nu_A - \nu_B$, *JAB*/$\nu_A - \nu_B$ (Tableau 4). En revanche pour le dérivé **1***E* du silicium le couplage des noyaux H_β et H_γ est suffisamment important pour perturber de façon notable les parties ABX_3 du spectre (Fig. 2). De façon générale, il ressort de l'examen du tableau 4 que l'approximation est d'autant meilleure que l'on a affaire aux composés *Z* et que la période à laquelle appartient l'élément *E* est plus élevée.

Pour *les dérivés secondaires* **2**, la résolution de la région éthylénique du spectre se ramène à la résolution de celle, fortement perturbée, d'un spectre de second ordre ABCX. Seuls les centres m des multiplets correspondants aux protons H_β, d'une part, et H_γ, de l'autre, ont été déterminés (Tableau 2a). A titre d'information la partie éthylénique du spectre du dérivé deutérié (C_6H_5)$_3$SnCD$_2$CH=CH$_2$ a été résolue en la traitant, en première approximation, comme un spectre ABX (Tableau 3).

2. *Spectres du carbone* ^{13}C *(Tableau 5)*

L'identification des déplacements chimiques δ^{13}C a été faite en confrontant les spectres de rmn obtenus dans les conditions suivantes: (a) absence totale de découplage; (b) découplage sélectif et (c) découplage total des protons hors résonance. Dans le cas des dérivés de l'étain l'attribution des déplacements chimiques, faite sur la base de l'irradiation sélective des protons, a été confirmée par les valeurs des couplages hétéronucléaires à longue distance, $J(^{117,119}Sn—^{13}C)$ pour lesquels $^1J > {}^3J > {}^2J$ (11).

Pour les dérivés du plomb les attributions des déplacements chimiques des carbones éthyléniques, faites sur la base des couplages $J(^{207}Pb—^{13}C)$, par analogie avec les dérivés de l'étain, et également par comparaison dans la série, ont été confirmées par un enregistrement supplémentaire de spectres rmn à 250 MHz (dérivé **1***E*).

	Pb	67,58	10,25	$0,15_5$	6

III. *Interprétation des déplacements chimiques, $\delta^{13}C$ et δ^1H*

L'analyse, au long de la colonne IV-A, des paramètres $\delta^{13}C$ et δ^1H permet de conclure à une structure σ-allylique pour les composés **1***E*, *Z* et **2** et, en tenant compte de l'échelle d'électronégativité, de mettre au jour l'existence d'une hyperconjugaison σ−π de la liaison C—E et de la liaison π allylique, reflétée par les déplacements chimiques des noyaux sp^2, $\delta^{13}C$ $(^1H)_{\beta,\gamma}$, l'effet électronique prédominant sur les noyaux en α de l'hétéroélément étant déterminé par la *nature* même de l'hétéroélément; ces résultats se trouvent corroborés par l'examen des couplages.

Il convient de rappeler ici que, de façon générale pour un noyau A, la constante d'écran σ^A peut être exprimée (22, 23) par la formule [3]

$$[3]\quad \sigma^A = \sigma_d^{AA} + \sigma_p^{AA} + \sum_{A\neq B} [\sigma^{AB} + \sigma^{A,deloc}]$$

δ^1H sera déterminé par le terme diamagnétique σ_d^{AA} et (ou) le terme $\sum_{A\neq B} [\sigma^{AB} + \sigma^{A,deloc}]$, donc (a) par la densité électronique sur le proton ou, indirectement, par la charge portée par le carbone vicinal; (b) par la circulation des électrons sur les noyaux avoisinants; en effet, le terme paramagnétique σ_p^{AA}, est négligeable par rapport aux autres termes de l'équation [3] dans la mesure où les orbitales atomiques 2*p* n'ont pas à être prises en considération (23*b*).

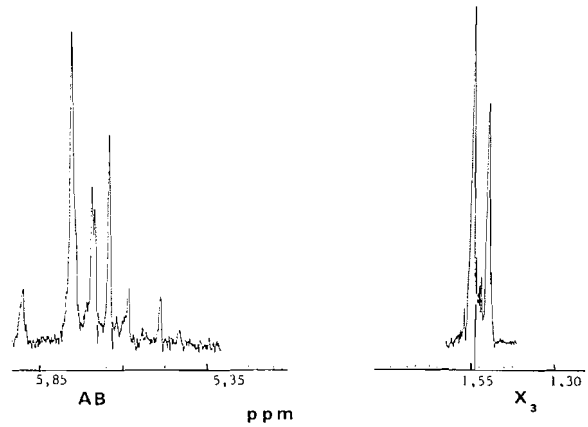

FIG. 2. Déformation d'un spectre ABX_3, par un couplage important des protons AB: partie ABX_3 du spectre de protons du composé A B X_3 $(C_6H_5)_3SiCH_2CH{=}CH{-}CH_3$, obtenue par double irradiation du groupement $-CH_2-$.

$\delta^{13}C$, du fait de l'existance d'états excités de plus basse énergie, est gouverné par le terme σ_p^{AA}; celui-ci est proportionnel à la charge effective du noyau, aux ordres de liaison et inversement proportionnel à l'énergie moyenne d'excitation de la molécule (24, 25).

De façon générale, on remarque un parallélisme entre les variations des déplacements chimiques $\delta^{13}C$ et les paramètres δ^1H des protons vicinaux correspondants, lorsqu'on se déplace le long de la colonne IV-A (Figs. 3 et 4).

Paramètres $\delta^1H_{\beta,\gamma}$ et $\delta^{13}C_{\beta,\gamma}$

Un même facteur, selon toute vraisemblance la charge portée par le carbone, dans le cas de dérivés éthyléniques alkylés, les déplacements chimiques des carbones éthyléniques sont proportionnels aux charges portées par ces atomes (26), contrôle les déplacements chimiques des carbones sp^2, et des protons correspondants; en revanche, l'effet d'anisotropie magnétique voisine, due aux groupements $-ER_3$, se manifeste de façon plus importante sur $\delta^1H_{\gamma_c}$, en position *cis* (Fig. 3). Le choix

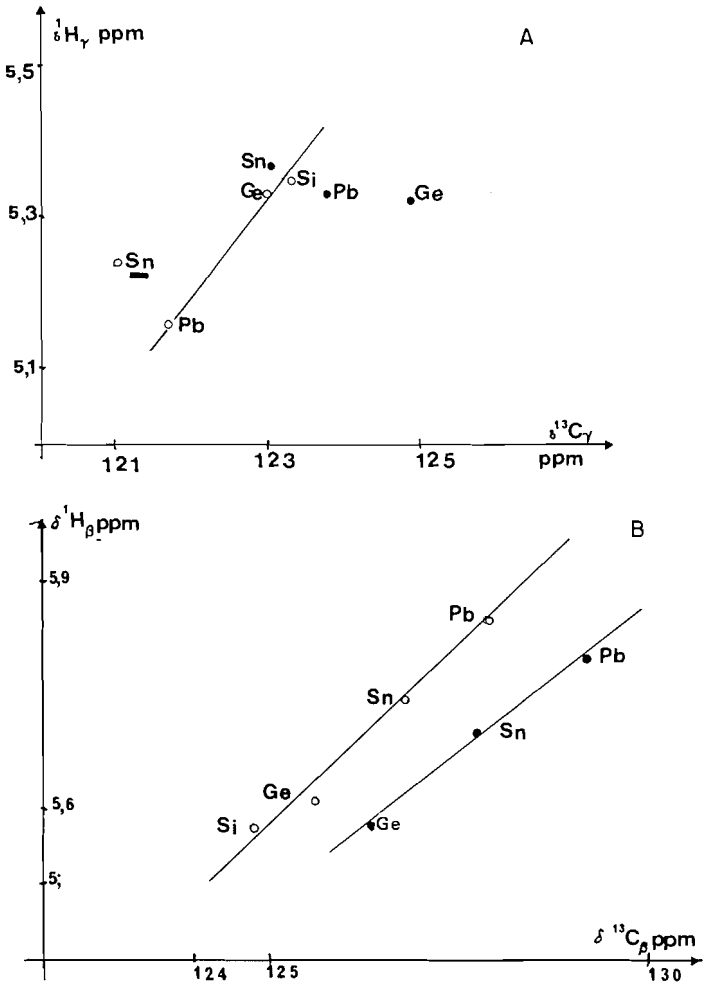

FIG. 3. Déplacement chimique du proton éthylénique ^1H en fonction du déplacement chimique du carbone ^{13}C vicinal, positions β et γ, pour les isomères $(C_6H_5)_3ECH_2CH{=}CH{-}CH_3$ **1***E*, *Z*; $\rho = \Delta\delta^{13}C/\Delta\delta^1H$; (A) position γ: **1***E* −●−; **1***Z* −○−; $\rho\mathbf{1}Z$ = 7,5; (B) position β: **1***E* −●−; **1***Z* −○−; $\rho\mathbf{1}E$ = 13,3; $\rho\mathbf{1}Z$ = 10.

de l'alignement des points pour Si, Ge et Pb, qui laisse un blindage "hors série" pour l'étain, est justifié par l'examen des figures 5 (A) et (B), qui donnent les déplacements chimiques des noyaux éthyléniques N (^{13}C et ^1H) en fonction du numéro atomique Z_E de l'élément E−IV-A.

Le tableau 5 met au jour pour les dérivés des hétéroéléments (E = Si à Pb) une polarisation de la liaison π de la façon

$$\overset{\delta^+}{R_3ECH_2CH}{=}\overset{\delta^-}{CH}{-}CH_3$$

suivante: $R_3ECH_2CH{=}CH{-}CH_3$; elle est pratiquement inexistante lorsque E appartient à la 2de période, E = C. Après avoir remarqué, (a) qu'un substituant σ agit sur la distribution des électrons d'un système π en donnant lieu (α) à une redistribution de la densité électronique du système (effet inductif Iπ, effet de champ F) liée à l'électronégativité du substituant et (ou) (β) à un transfert de charge entre le substituant σ et le système π (effet mésomère R) et (b) que, conformément aux électronégativités calculées Iπ et F, dûs aux groupements $-E(C_6H_5)_3$, doivent être extrêmement faibles, sinon négligeables (l'effet de champ ne joue pas un rôle prédominant sur la polarisation de la liaison π, car dans ce cas (27) un accroissement de l'électronégativité du substituant aurait pour conséquence un déplacement diamagnétique du carbone β, à l'opposé du phénomène observé), nous interpréterons la variation de

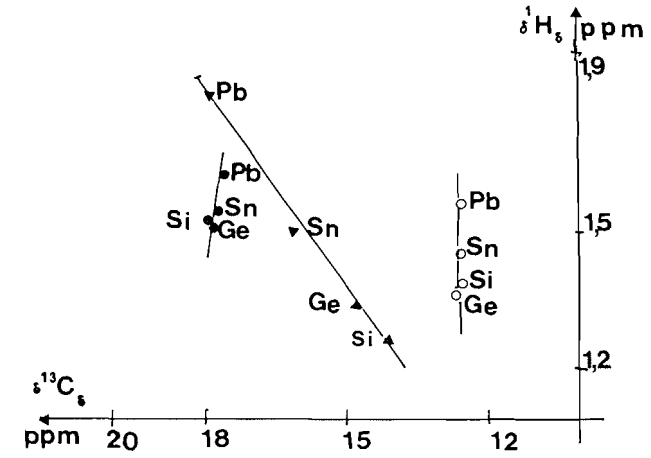

FIG. 4. Déplacement chimique du proton ^1H en fonction du déplacement chimique du carbone ^{13}C vicinal, position δ, pour les isomères $(C_6H_5)_3ECH_2CH{=}CH{-}CH_3$ **1***E* −●−, **1***Z* −○− et $(C_6H_5)_3ECH(CH_3)CH{=}CH_2$ **2** −▼−.

la polarisation de la liaison π, traduite par les spectres de rmn des composés **1***E*, *Z* et **2** (systèmes σ−π de type $R_3E\underset{\sigma}{-}CH_2\underset{\pi}{-}CH{=}CH{-}CH_3$ et $R_3E\underset{\sigma}{-}CH(CH_3)\underset{\pi}{-}CH{=}CH_2$) en termes d'effets électroniques mésomères donneurs des substituants σ (E = Si à Pb) par hyperconjugaison $\sigma \rightarrow \pi$. Des conclusions similaires, basées sur la spectroscopie électronique, ont été faites (19) à propos des dérivés benzyliques correspondants, $(C_6H_5)_3ECH_2C_6H_5$.

Le déplacement chimique interne $\Delta_E = \delta N_\beta - \delta N_\gamma$ (N = ^1H, ^{13}C) est fonction croissante (mais non pas monotone) de la (3ème à la 6ème) période à laquelle appartient l'élément E (Tableaux 3 à 5). Si l'on admet que les déplacements chimiques des carbones éthyléniques sont proportionnels aux charges portées par ces atomes, $\Delta_E = \delta C_\beta - \delta C_\gamma$ sera proportionnelle à la polarisation de la liaison éthylénique $\diagdown C{=}C \diagup$ et traduira l'effet donneur mésomère, du groupement $(C_6H_5)_3E{-}CH_2{-}$, en fonction de l'élément E. Le tableau 5 montre que $\Delta_{Ge} - \Delta_{Si}$ est de l'ordre de l'unité, $\Delta_{Pb} - \Delta_{Sn}$ de l'ordre de 0,5, en revanche $\Delta_{Sn} - \Delta_{Ge}$ est de l'ordre de 3,5, ce qui permet de classer les éléments E, dans l'ordre d'effet donneur mésomère pour les substituants $R_3ECH_2{-}$ et $R_3ECH(CH_3){-}$:

$$Pb \approx Sn \gg Ge > Si$$

Les résultats expérimentaux obtenus, ne sont pas incompatibles avec l'existence (28), d'ailleurs discutée (29), d'un effet $(p-d)\pi$ pour les dérivés du silicium et du germanium, ce qui aurait pour effet une polarisation inverse de la liaison éthylénique par effet accepteur du substituant:

$$R_3E \longleftarrow \underset{CH_2}{\diagup\diagdown} CH{=}CH{-}CH_3$$

Dans ce cas la polarisation observée expérimentalement serait la résultante de deux effets contraires.

Pour les dérivés du plomb et de l'étain les effets mésomères donneurs du substituant σ sont comparables; ce résultat s'interprète en admettant que le groupement $-Pb(C_6H_5)_3$ est plus électronégatif que $-Sn(C_6H_5)_3$. En effet, l'hyperconjugaison de deux systèmes σ et π est sous le contrôle (30) de (a) la différentielle d'énergie $E = E(\sigma) - E(\pi)$; (b) l'intégrale de perturbation $P(\sigma\pi)$; (c) la densité électronique $a^2(\sigma)$ et $a^2(\pi)$

For personal use only.

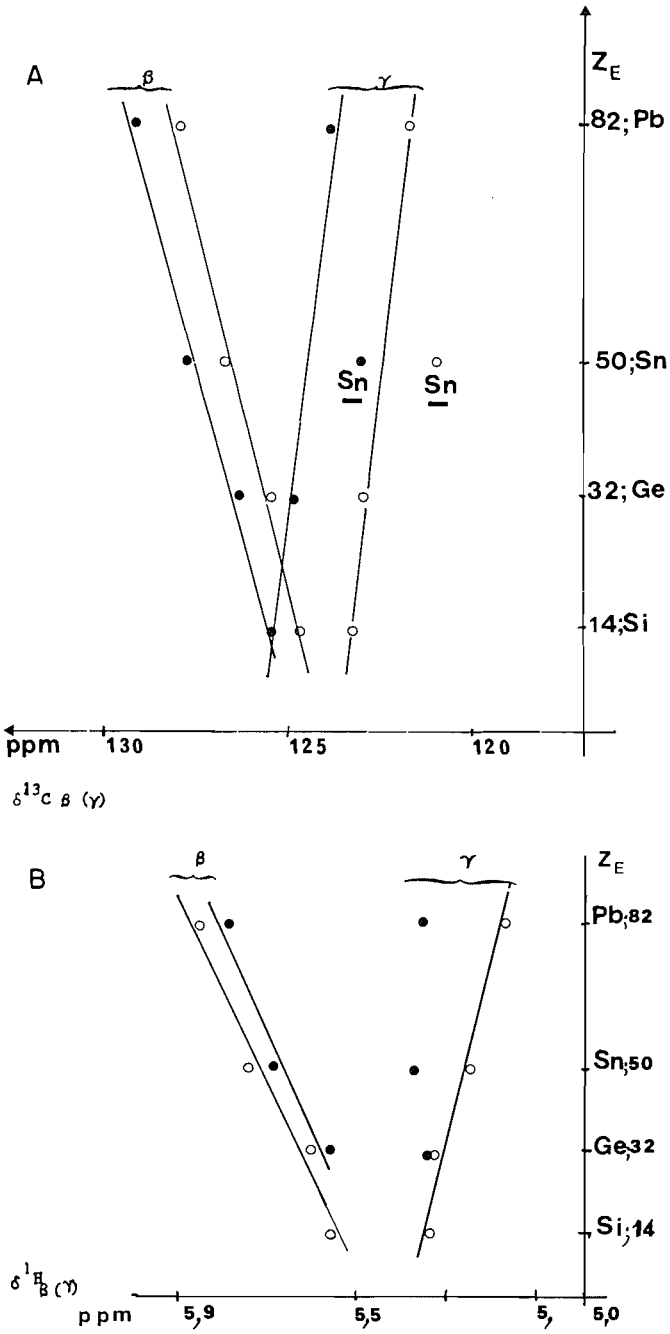

FIG. 5. Déplacements chimiques des noyaux éthyléniques N (^{13}C et ^1H), positions β et γ, en fonction du numéro atomique Z_E de l'élément E—IVA; isomères $(C_6H_5)_3ECH_2CH{=}CH{-}CH_3$, *1E* —●— et *1Z* —○—; (A) N = ^{13}C; (B) N = ^1H. On notera le blindage inattendu des carbones C_γ dans le cas des dérivés de l'étain.

dans les orbitales *p* des atomes reliant les systèmes σ et π; elle est favorisée par une différentielle d'énergie ΔE, faible, et des densités électroniques $a^2(\sigma)$, $a^2(\pi)$, élevées. Pour les systèmes envisagés $(C_6H_5)_3ECH_2CH{=}CH{-}CH_3$ *E*, *Z* et $(C_6H_5)_3ECH(CH_3)CH{=}CH_2$, l'effet donneur observé sera essentiellement sous le contrôle de $R(\sigma)$ et de $a^2(\sigma)$; en effet, $E(\pi)a^2(\pi)$, restent invariant et l'influence de $P(\sigma\pi)$ est faible (30). Comme la différentielle d'énergie, ΔE, décroît de Si à Pb (30, 31), les résultats expérimentaux obtenus impliquent que $a^2(\sigma)_{Pb} < a^2(\sigma)_{Sn}$, c'est-à-dire, que le groupement $-Pb(C_6H_5)_3$ soit plus électronégatif que $-Sn(C_6H_5)_3$, ce qui est en accord avec les résultats présentés antérieurement et comparable aux résultats obtenus par ailleurs (31) pour les systèmes benzyliques correspondants. On ne peut rien conclure quant aux électronégativités respectives des groupements $-Ge(C_6H_5)_3$ et $-Si(C_6H_5)_3$, car l'effet $(p \rightarrow d)\pi$ décroît du dérivé du silicium au dérivé du germanium. L'effet d'hyperconjugaison, traduit par la polarisation de la liaison éthylénique, proportionnelle à $\Delta_E = \delta C_\beta - \delta C_\gamma$, est nettement plus important pour $R = CH_3$ que pour $R = C_6H_5$ (Tableau 5); ce qui est en accord avec l'effet de la taille du substituant R_3E ainsi qu'avec une polarisation plus importante de la liaison $CH_2{-}Sn(CH_3)$ par rapport à $CH_2{-}Sn(C_6H_5)_3$; de plus $Sn(CH_3)_3$ possède un effet donneur par induction tandis que $Sn(C_6H_5)_3$ a une effet accepteur par induction; en effet:

$$\chi^{int}_{Sn(C_6H_5)_3} = 8{,}020 > \chi^{int}_{-CH_2CH=CH-CH_3} = 7{,}597 > \chi^{int}_{Sn(CH_3)_3} = 7{,}47$$

Nous notons, en revanche, une influence négligeable sur les déplacements chimiques δN_α et δN_β (N = ^1H, ^{13}C) du substituant à l'hétéroatome.

Il convient de souligner l'existence d'une corrélation linéaire entre les déplacements chimiques des carbones éthyléniques et le numéro atomique Z_E de l'hétéroatome (Fig. 5A). La même figure fait apparaître un blindage exceptionnel de C dans le cas des dérivés de l'étain; il peut être interprété en termes d'effet stérique γ, lequel pourrait être favorisé pour E = Sn.

Paramètres δ^1H_α, $\delta^{13}C_\alpha$

Ces paramètres sont soumis, en particulier, à l'influence de l'hétéroatome et de la double liaison allylique.

Afin d'éclairer l'influence sur ces variations de la double liaison allylique (métallohyperconjugaison, liaison $(p{-}d)\pi$...) nous avons comparé les données obtenues pour les dérivés *1E*, *Z*, **2** à celles correspondantes extraites de la littérature (32) pour les composés $E(CH_3)_4$. Cette étude comparative met au jour pour ces deux groupes de composés une similitude en ce qui concerne les paramètres δ^1H_α et $\delta^{13}C_\alpha$ (Tableau 6) et, tout particulièrement *un blindage de* $\delta^{13}C_\alpha$, *inattendu à priori, pour les dérivés de l'étain*, que l'effet inductif des groupements $-SnR_3$ (R = CH_3, C_6H_5) ne suffit pas à justifier, ce qui met au jour une solution de continuité dans la série au niveau de l'étain. Par ailleurs (33), les variations des énergies de liaison pour les composés EF_4 le long de la colonne IV-A sont similaires à celles observées pour les paramètres $\delta^{13}C_\alpha$ et δ^1H_α. De même, les courbes $\delta^{13}C_\alpha = f(\delta^1H_\alpha)$, établies pour les deux groupes de composés *1E*, *Z*, **2** et $E(CH_3)_4$ (Fig. 6*a*, *b*, *c*), présentent des analogies importantes. Ces résultats témoignent en faveur du fait que les paramètres δ^1H_α et $\delta^{13}C_\alpha$ ne se trouvent pas sous le contrôle du système π-allylique et qu'ils sont régis par des *facteurs inhérents à la nature même de l'hétéroélément*, tels que l'apparition des orbitales *d* à partir de la 3ième période (E = Si à Pb), la contraction des métaux de transition (4ème période) et la contraction des lanthanides (6^e période), ces deux derniers phénomènes ayant pour effet de rendre plus compacts le germanium et le plomb par rapport aux éléments (Si et Sn) qui les précédent respectivement; de même, dans le cas de éléments des 4ième et 6ièmes périodes, le remplissage des orbitales 3*d* et 4*f*, relativement diffuses, conduit à un blindage de la charge nucléaire moins efficace, ce qui a pour conséquence une attraction plus forte des électrons 4*s* et 6*s*.

Les remarques suivantes peuvent être faites en ce qui concerne les paramètres $\delta^{13}C_\delta$ *et* δ^1H_δ

Pour le composé **2** on observe l'existence d'une corrélation

TABLEAU 6. Données comparatives des paramètres $\delta^{13}C_\alpha$, δ^1H_α et $^1J(^{13}C—H)$ pour les composés **1***E*, *Z* ($R = C_6H_5$) et $E(CH_3)_4$

[a]Les déplacements chimiques sont donnés par rapport au TMS; un signe positif correspond à un déplacement vers les champs faibles.

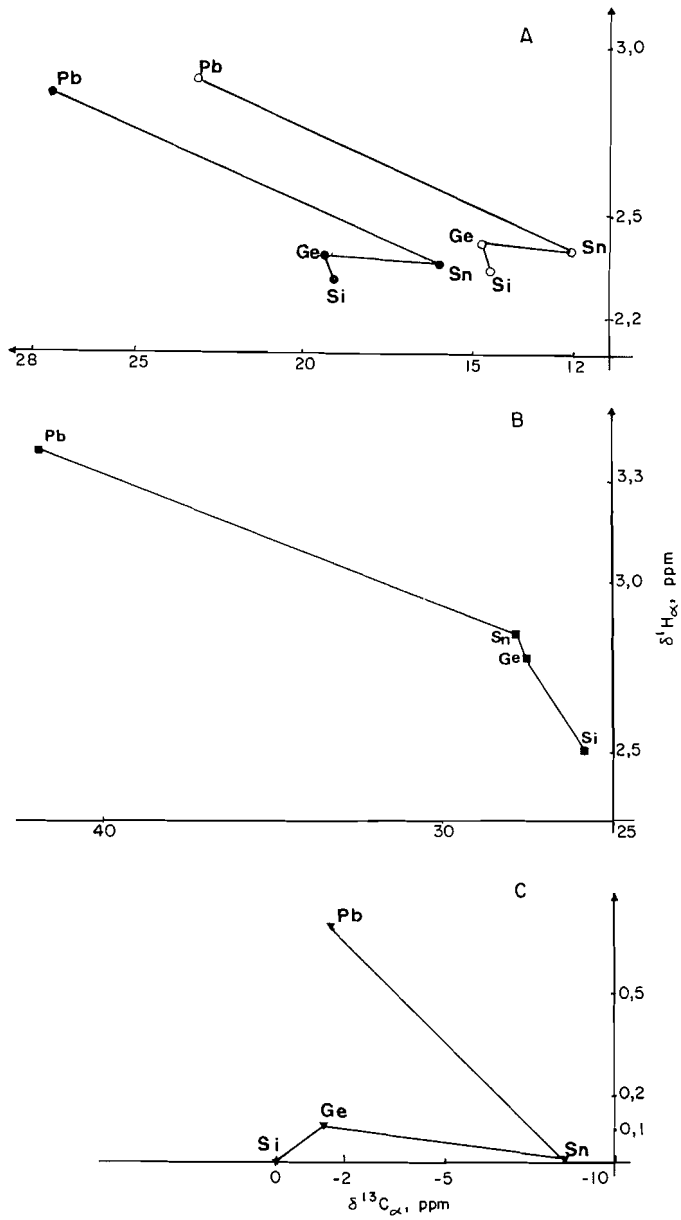

FIG. 6. Déplacement chimique du proton ^1H en fonction du déplacement chimique du carbone vicinal ^{13}C, position α, pour (A): les isomères $(C_6H_5)_3ECH_2CH=CH—CH_3$, **1***E* −●− et **1***Z* −○−; (B): l'isomère $(C_6H_5)_3ECH(CH_3)CH=CH_2$ **2** et (C): les composés $E(CH_3)_4$, données de la littérature (32).

TABLEAU 7. Couplages des protons éthyléniques H_β, H_γ; composés **1***E*, *Z*; $R = C_6H_5$

E	Composé	$J(H_\beta—H_\gamma)$ (Hz)
Si	**1***E*	—
	1*Z*	10,25
Ge	**1***E*	15
	1*Z*	10,5
Sn	**1***E*	15,25
	1*Z*	10,5
Pb	**1***E*	15
	1*Z*	10,25

linéaire entre ces deux paramètres, tandis que pour les composés **1***E*, *Z* $\delta^{13}C$ = const. (Fig. 4); ceci suggère que, dans le premier cas, un même facteur contrôle les deux paramètres tandis que, dans le second, les déplacements chimiques légèrement paramagnétiques du proton sont contrôlés par l'effet d'anisotropie magnétique voisine, dûe aux groupements $—E(C_6H_5)_3$.

IV. *Couplages*

Dans tout ce qui suit seront envisagées les *valeurs absolues* des couplages. L'étude des couplages homonucléaires $J(H—H)$ (Tableau 7), $^1J(^{13}C—H)$ (Tableau 8) $^nJ(E—C—H)$ (Tableaux 9 et 10) et $^nJ(E—^{13}C)$ (Tableau 11) corrobore les conclusions qui se dégagent de l'étude des déplacements chimiques δ^1H et $\delta^{13}C$.

1. *Couplages homonucléaires* $J(H_\beta—H_\gamma)$ *(Tableau 7)*

Les couplages $J(H_\beta—H_\gamma)$ sont de l'ordre de 15 Hz (**1***E*) et de 10 Hz (**1***Z*) (valeurs classiques pour des protons éthyléniques respectivement *trans* et *cis*); ils confirment une structure σ allylique pour les composés **1***E*, *Z*. Pour les dérivés secondaires **2** ces valeurs n'ont pu être déterminées aisément à partir des spectres, les protons H_β et H_γ étant trop fortement couplés. Cependant $J(H_\beta—H_\gamma)$ (*Z*) = 9,66 Hz et $J(H_\beta—H_\gamma)$ (*E*) = 17,33 Hz ont pu être calculés pour le dérivé deutérié $(C_6H_5)_3SnCD_2CH=CH_2$.

2. *Couplages hétéronucléaires*

Avant de discuter les résultats expérimentaux obtenus, il convient d'ouvrir une parenthèse et de rappeler que les constantes de couplage $^1J(^{13}C—H)$, $^1J(E—^{13}C)$ et $^2J(E—C—H)$ sont gouvernées par le terme de contact de Fermi (34−36) et que, si de façon générale nous désignons par N et N′ les deux noyaux couplés, les constantes de couplage envisagées seront données par l'expression [4].

Si	120,6	151,2	151,6	125,4
Sn	131,1	158,9	150,2	125,2
Pb	139,2	159	148,5	125,6

[4] $J_{NN'} = (C/\Delta E)\,\alpha_N^2\,\alpha_{N'}^2\,\psi^2(0)\mathrm{ns}(N)\,\psi^2(0)\mathrm{ns}(N')$

où α^2: caractère *s* des orbitales formant la liaison; $\psi^2(0)$: densité des électrons *s* des noyaux couplés; ΔE: énergie moyenne d'excitation singulet−triplet; C = ensemble de constantes.

$^1J(^{13}C_\alpha—H_\alpha)$ (Tableau 8)

On observe une variation non monotone du couplage $^1J(^{13}C—H)$ lorsque E varie de la seconde (n = 2) à la sixième période (n = 6) en passant par un minimum $^1J(^{13}C—H)$ = 120,6 cps, E = Si, inférieur à la valeur attribuée à un carbone sp^3, soit 125 Hz.

Conformément à l'équation [4], une interprétation possible de l'accroissement de $^1J(^{13}C—H)$ serait d'envisager un accroissement du caractère *s*, $\alpha^2(C)$, de l'orbitale hybride du carbone formant la liaison $C_\alpha—H_\alpha$ et, de façon hâtive, d'en attribuer l'origine à une hyperconjugaison σ−π. Cependant, une analyse plus poussée montre que l'hyperconjugaison, bien que compatible avec un accroissement du caractère *s* de l'orbitale du carbone formant la liaison C—H, n'est pas l'unique promoteur de celui-ci; en effet, les variations des couplages $^1J(^{13}C—H)$ observées, de même que pour les paramètres δ^1H et $\delta^{13}C_\alpha$, sont en tous points comparables à celles observées pour les dérivés tétramethylés correspondants, $E(CH_3)_4$ (32) (Tableau 6), pour lesquels un accroissement du caractère *s* de l'orbitale du carbone vers l'hydrogène et une diminution de ce caractère vers l'élément IV-A, lorsque E varie de la 3ième à la 6ième période, donc indépendemment de l'existence d'une métallohyperconjugaison, a été mis en évidence (37).

$^1J(^{13}C_\gamma—H_\gamma)$ est fonction décroissante (Tableau 8) de la période de l'élément IV-A. Ce résultat peut être interprété en termes d'une diminution du caractère *s* de l'orbitale hybride du carbone formant la liaison $C_\gamma—H_\gamma$ ou (et) en termes d'une augmentation de la charge portée par le carbone C_γ (l'énergie moyenne d'excitation ΔE, décroît de Si à Pb), ce qui témoigne en faveur de l'existence d'une hyperconjugaison σ−π de la liaison C—E et de la double liaison allylique).

Couplages $^2J(E—C—H)$ (Tableaux 9 et 10)

Si (Tableau 10) nous comparons les constantes de couplages

TABLEAU 9. Couplages $^nJ(E—C—H)$, n = 2, 3, 5; composés **1***E*, *Z*, **2**; E = Sn, Pb; fragment allylique

			$^nJ(E—C—H)$ (Hz)			
R	Composé	E	^2J	$^3J_\delta$	^5J	$^2J_{CH_3}$
C_6H_5	**1***E*	Sn	68		26	
		Pb	86		63	
	1*Z*	Sn			20	
		Pb			51	
	2	Sn		72; 75		
		Pb		158		
CH_3	**1***E*					50,8; 53,6
	1*Z*	Sn				49,6; 53,6
	2			66; 68		49,5

hétéronucléaires $^2J(E—C—H)$ des composés **1***E*, **3**, **4**, **5**, **6** et **7**, il apparait que l'on peut grouper ces composés en *2 groupes distincts: les composés **3**, **4** et **5**, d'une part*, pour lesquels $^2J(E—C—H)$ (CH_3 ou CH_2) se situe entre 50 et 55 Hz (E = Sn) ou 61 à 68,5 Hz (E = Pb) et *les composés allyliques **1** et benzyliques **6**, **7**, de l'autre*, pour lesquels $^2J(E—C—H)$ (CH_2) est nettement plus élevé: 68 Hz (E = Sn); 86 Hz (E = Pb). En outre, l'examen des couplages $^2J(E—C—H)$ (CH_3) pour les composés **1***E*, *Z*, **2** (Tableau 9) et **7** (Tableau 10) montre que celui-ci reste voisin de 50 Hz, donc de la valeur caractéristique pour la liaison $Sn(sp^3)—C(sp^3)$. Ces faits témoignent pour les dérivés allyliques **1** ainsi que pour les dérivés benzyliques **6**, **7** de l'existence d'une contribution importante d'un type particulier au mécanisme de couplage $^2J(E—C—H)$ (CH_2). En effet, la rehybridation de l'hétéroélément est insuffisante pour expliquer a elle seule une différence aussi importante des couplages observés; il paraît raisonnable d'attribuer cette valeur élevée à une contribution importante des électrons π au mécanisme de couplage, accrue par un accès direct aux électrons *s* de l'hétéroélément, ayant pour origine l'hyperconjugaison σ−π de la liaison C—E et de la liaison σ allylique; l'existence de cette dernière a été établie pour les composés **6** et **7** sur la base de la spectroscopie électronique (44) et de la rmn du carbone ^{13}C (45, 46).

$^5J(E—C—H)$ (Tableau 9) et $^nJ(E—^{13}C)$, n = 2−4 (Tableau 11)

Les valeurs élevées des *couplages hétéronucléaires à longue distance*: $^5J(E—C—H)$, $^4J(E—^{13}C)$, $^2J(E—^{13}C_\beta)$ témoignent d'une contribution importante des électrons π au mécanisme de couplage; en accord avec ce qui précède nous l'attribuons à l'hyperconjugaison σ−π.

Des valeurs de $^nJ(Sn—^{13}C)$, n = 2−4 et $^5J(Sn—C—H)$ (CH_3), en fonction du mécanisme de couplage (mécanisme σ avec plus ou moins de contribution des électrons π) sont don-

nées dans le tableau 12. On remarque, pour $^nJ(Sn—^{13}C)$, que lorsque le mécanisme est de type σ (**8**, **2**(C_δ) et **14**) l'inégalité $^2J < {}^3J$ se trouve vérifiée et que les valeurs des couplages ^2J et ^4J sont, entre autres, fonctions croissantes de la contribution des électrons π au mécanisme de couplage, en effet (Tableau 12) lorsque les électrons π participent au mécanisme de couplage $^2J > {}^3J$ (**12**, **13**) ou $^2J \approx {}^3J$ (**1***E*, *Z*, **2**(C_β), de même ^4J(**8**; σ) < ^4J(**1***E*, *Z*; σ−π) < ^4J(**9**). L'examen des constantes de couplage $^1J(^{13}C—E)$ (E = Sn, Pb) (Tableau 11) qui sont déterminées par le terme de contact de Fermi et données par l'expression [4] ne permet, dans l'état actuel des connaissances, aucune conclusion quant à l'existence d'une hyperconjugaison mettant en jeu la liaison C—E.

Nous terminerons par quelques mots sur la structure géométrique des dérivés étudiés, suggérée par les résultats obtenus au cours de cette étude.

L'hyperconjugaison σ−π entraine la coplanarité de la liaison σ et de l'axe de l'orbital π déficient en électrons. Aussi bien, nous proposons pour les composés étudiés une structure intermédiaire (Fig. 7) entre les formes *gauches* pour lesquelles ϕ = 60° et 120°.

Les conformères *cis* et *trans* sont, en général, évincés au profit des formes *gauches* lorsque la taille de X croît (48), ainsi, pour les halogénures d'allylmercure seules les formes *gauches* existent (29,49). Les valeurs élevées observées pour les couplages $^5J(E—C—H)$ et $^4J(E—^{13}C)$ E = Sn, Pb qui sont fonctions, en particulier, de l'angle dièdre ϕ des plans $SnC_\alpha C_\beta$ et $C_\alpha C_\beta C_\gamma$ (Fig. 7), s'accordent avec l'extrusion de la liaison C—E hors du plan nodal de l'orbitale π allylique favorisant le recouvrement de l'orbital π et de l'orbitale *ns* de l'élément E. Il est possible qu'en cas de demande d'électrons, la liaison σ fasse un angle voisin de 90°, avec le plan nodal de la double liaison allylique, et que, comme pour le bromure d'allymercure (29) dans la configuration d'énergie minimum, la liaison C—E soit perpendiculaire au plan nodal du système oléfinique.

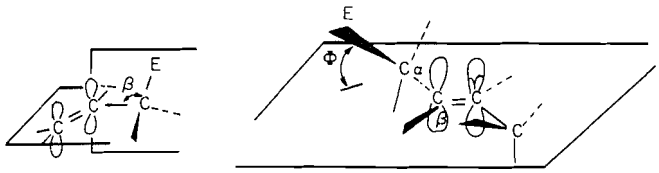

FIG. 7. Structure proposée pour les composés 1*E*, *Z* et **2**.

Partie expérimentale

I. *Synthèse des dérivés 1*E, *Z et 2*

Les synthèses des dérivés primaires $R_3ECH_2CH{=}CH{-}CH_3$ 1*E*, *Z* (E = C, Si, à Pb) (50*a*) et des dérivés secondaires $R_3ECH(CH_3)CH{=}CH_2$ **2** (E = Si à Sn) (50*b*) ont été décrites par ailleurs. Le dérivé secondaire du plomb est obtenu mélangé à du dérivé primaire (**2**: 70%; 1*E*, 1*Z*: 30%) en opérant de la même façon que pour les dérivés de l'étain, mais en effectuant toutes les opérations *rigoureusement sous argon*.

II. *Spectres de résonance magnétique nucléaire du carbone ^{13}C et du proton ^{1}H*

Les spectres de rmn ont été enregistrés sur spectrographe Varian XL-100 (100 MHz) pour le proton et Varian XL-100 (25, 15 MHz) pour le carbone-13, en utilisant la technique de transformée de Fourier; le deutérochloroforme a été utilisé comme solvant et le TMS comme étalon interne.

Remerciements

Nous remercions Madame M.-J. Pouet du laboratoire de RMN de l'E.N.S.C.P., dirigé par Madame M.-P. Simonnin pour l'enregistrement des spectres à 60 et 100 Mz; les spectres à 250 Mz ont été enregistrés au laboratoire de l'E.N.S., dirigé par Monsieur J.-Y. Lallemand, que nous remercions.

KYUNG-HOON JUNG, CHONG MOK LEE, and HEE SOO YOO. Can. J. Chem. **61**, 2486 (1983).

The vacuum ultraviolet photolysis of gas phase bromoethane at 193.1 nm (6.42 eV) was studied over the pressure range of 1.1−303.2 Torr at room temperature using a carbon atom lamp. The pressure effect with and without inert gas, i.e., He or N_2, was investigated. A scavenger effect of the reaction was also observed by adding NO as a radical scavenger. The principal reaction products were C_2H_6, C_2H_4, 1,1-$C_2H_4Br_2$, and *n*-C_4H_{10}. The quantum yields of C_2H_4 and C_2H_6 were found to increase slightly with the reactant pressure. When the pressure of He or N_2 was varied at a constant pressure of C_2H_5Br, however, the quantum yields of C_2H_4 and C_2H_6 were found to be pressure independent. Addition of NO completely suppressed the formation of C_2H_6, $C_2H_4Br_2$, and C_4H_{10}, and partially reduced that of C_2H_4. These results were interpreted in terms of two channel competition between the molecular elimination and the formation of radicals. Two different decomposition modes were 82% radical reaction and 18% molecular elimination.

KYUNG-HOON JUNG, CHONG MOK LEE et HEE SOO YOO. Can. J. Chem. **61**, 2486 (1983).

On a étudié la photolyse sous vide dans l'ultraviolet du bromoéthane gazeux à 193,1 nm (6,42 eV) dans un intervalle de pression allant de 1,1 à 303,2 Torr à la température ambiante en utilisant une lampe au carbone. On a étudié l'effet de la pression, avec ou sans gaz inerte, par exemple le He ou le N_2. On a également observé un effet de piège de la réaction en ajoutant du NO comme piège à radical. Les principaux produits de la réaction sont: le C_2H_6, le C_2H_4, le $C_2H_4Br_2$-1,1 et le *n*-C_4H_{10}. En augmentant la pression du réactif, on a trouvé que les rendements quantiques en C_2H_4 et C_2H_6 augmentent légèrement. Cependant quand on fait varier la pression de He ou de N_2 tout en maintenant la pression du C_2H_5Br constante, on a trouvé que les rendements quantiques en C_2H_4 et C_2H_6 sont indépendants de la pression. L'addition de NO ne supprime pas complètement la formation de C_2H_6, de $C_2H_4Br_2$ et de C_4H_{10}, elle réduit partiellement celle de C_2H_4. On interprète ces résultats en fonction de deux voies compétitives; l'élimination moléculaire et la formation des radicaux. Les différents modes de décomposition sont à 82% de type réaction radicalaire et à 18% de type élimination moléculaire.

[Traduit par le journal]

Introduction

In this study, the vacuum ultraviolet photochemical investigation of the gas phase unimolecular decomposition of bromoethane at 193.1 nm was carried out using a carbon atom lamp. Its objective is to elucidate the primary photodissociation process.

The photochemistry of C_2H_5Br in the 210−313 nm region (1), where only the valence shell transition is possible, proceeds mainly by radical reaction via the C−Br bond fission. On the other hand, Tschuikow-Roux and co-workers reported the molecular elimination as the major primary process in the photolyses of haloethanes at 147 nm (2). Thus it is generally accepted that the modes of photochemical decomposition of the alkyl halides are wavelength dependent (3).

Our recent studies on the photodissociation of C_2H_5Br at 104.8−106.7 nm and 123.6 nm (4) and preliminary experiments of C_2H_5Br at 147 nm, 163.3 nm, and 174.3−174.5 nm also indicate that the primary photochemical decomposition modes of bromoethane are wavelength dependent. Compared with other previous works, our studies have some interesting aspects: the sequential change with wavelength of the relative importance of the two competitive decomposition modes, i.e., radical and molecular processes. The ratios of HBr elimination to C—Br bond fission of C_2H_5Br are 4.0, 1.5, 1.0, 0.47, and 0.25 at 104.8−106.7 nm, 123.6 nm, 147 nm, 163.3 nm, and 174.3−174.5 nm, respectively. In the vacuum ultraviolet and ultraviolet regions, the electronic transition of C_2H_5Br is termed $n \rightarrow \sigma^*$ and its broad maximum appears at about 200 nm. The shorter wavelength side of this absorption frequently extends into the vacuum ultraviolet region where it may overlap the absorption associated with Rydberg type transitions, viz., B band (177 nm) (5). Therefore 193.1 nm, which is between these two strikingly different reaction modes and which lies between the A and B bands, should be the key wavelength to observe the two channel competitive reactions.

Experimental

Photolyses were carried out at room temperature in a static system using a 340 cm^3 borosilicate glass reaction vessel with a CaF_2 window and with an all-glass circulating pump. Total conversions were kept less than 0.5% of the reactant. The light source was a carbon atom lamp (6) equipped with a 1 mm thickness Suprasil quartz window (7*a*) and operated by a microwave generator, KIVA Instrument, Inc., Model MPG-4M. The purity of the light source was routinely checked with a 0.3 m GCA/McPherson 218 VUV monochromator. Without an air filter, the emission spectrum up to 210 nm showed two lines at 165.7 and 193.1 nm. However, with an air filter, only the 193.1 nm line appeared since the 165.7 nm line was absorbed by oxygen in the air (7*b*). Our measurements of the absorption spectrum in this region (Cary 17 spectrophotometer) yielded an extinction coefficient at 193.1 nm in complete agreement with that cited in ref. 3, p. 523. Since carbon deposition on the window originating from the decomposition of CH_4 could not be removed, the percent transmission of the window decreased with prolonged operation of the lamp (8). The intensity fluctuation, i.e., 2×10^{13} to 5×10^{12} photons/s, was averaged by repeating the actinometry readings twice before and after each run. Chemical actinometry was based on the production of acetylene in the photolysis of ethylene, and the quantum yield of 0.40 (9) at 193.1 nm was assumed. Product analysis was done by Hewlett-Packard 5840A GC with twin FID. 1/8″ × 3 m s.s Chromosorb 108 was used to analyze C_2H_4, C_2H_6, and C_4H_{10} and 1/8″ × 3 m Nickel 20% Silicon DC 550/Chromosorb P for $C_2H_4Br_2$ and $C_4H_8Br_2$. C_2H_5Br, Eastman Kodak, was purified until the residual impurities were not detected by gas chromatography.

Results

The principal reaction products are C_2H_6 and C_2H_4 (Table 1). In Table 1, run Nos. 1–20 represent the pressure effect of C_2H_5Br, where $\phi_{C_2H_6}$ increases from 0.53 to 0.96 and $\phi_{C_2H_4}$ also shows a small increase from 0.16 to 0.27. Run Nos. 21–26 are the results of the scavenger study, where the average $\phi_{C_2H_4}$ is 0.16 while C_2H_6 is not detected. Run Nos. 27–32 and 33–36 show the pressure effects with the addition of He and N_2, respectively, where the average quantum yield for C_2H_6 or C_2H_4 coincides in each case, i.e., $\phi_{C_2H_6}$ and $\phi_{C_2H_4}$ are 0.61 and 0.15, respectively. In addition, we observed the secondary products, $C_2H_4Br_2$ and C_4H_{10}, in a very long photolysis run for each product, i.e., $\phi_{CH_3CHBr_2} \sim 0.078$ while $\phi_{BrCH_2CH_2Br}$ is negligible at 7.2 Torr and $\phi_{C_4H_{10}}$ 0.082 at 48.5 Torr of C_2H_5Br pressure. However, these products are not detected in the presence of NO. The amounts of 2,3-dibromobutane were too small to measure.

Discussion

The discernible decrease of $\phi_{C_2H_4}$, i.e., ca. 0.05, in the presence of NO (Table 1, run Nos. 21–26), indicates the existence of some radical precursor for C_2H_4. Like the scavengeable portion of C_2H_4, the other scavengeable products, i.e., C_2H_6, $C_2H_4Br_2$, and n-C_4H_{10}, may be derived from an ethyl radical which is formed by C—Br bond fission of an electronically excited C_2H_5Br. However, the nonscavengeable portion of C_2H_4 would appear to be formed by a molecular elimination of HBr. Therefore, it is reasonable to assume that C_2H_5Br must be photolyzed by two channel competition. In the photolysis of C_2H_5Cl at 147 nm (2*b*), Tschuikow-Roux and co-workers interpret the results in terms of the initial formation of one and possibly two electronically excited states which decompose by molecular elimination and this state (or these states) is collisionally induced to cross over to an electronically excited state which decomposes by the C—Cl bond fission as the pressure is increased. In the present case, the quantum yield ratios of C_2H_4 and C_2H_6 are independent of the variation of the pressure and the product quantum yields are unaffected by the inert gases (Table 1). From these observations, it may be deduced that one electronically excited state is not converted to another by a collisionally induced process. Since the B and C bands of the Rydberg transitions are very diffuse (10), the $n \rightarrow \sigma^*$ transition absorption band and Rydberg transition absorption bands may overlap, which makes it plausible that the excitation

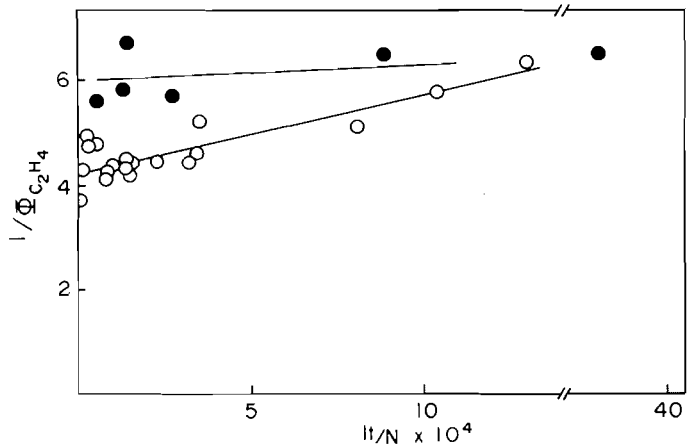

FIG. 1. Reciprocal of product quantum yields of C_2H_4 vs. It/N. ○, experiment without NO; ●, experiment with NO.

by monochromatic radiation results in two different excited states.

[1a] $C_2H_5Br + h\nu \rightarrow C_2H_5Br\dagger^{(1)}$

[1b] $\rightarrow C_2H_5Br\dagger^{(2)}$

[2] $C_2H_5Br\dagger^{(1)} \rightarrow C_2H_5 + Br$

[3] $C_2H_5Br\dagger^{(2)} \rightarrow C_2H_4 + HBr$

where the number dagger denotes an electronically excited state.

Since the photon energy at 193.1 nm is 148.1 kcal/mol and ΔH for [3] is 18.6 kcal/mol (11a), there are still 129.5 kcal/mol of energy remaining to be distributed between C_2H_4 and HBr. If the C_2H_4 molecule takes a large amount of the excess energy, it will be decomposed to C_2H_2, i.e., $C_2H_4^* \rightarrow C_2H_2 + H_2$, where the activation energy is 80 kcal/mol (12). However, the failure to observe C_2H_2 as a final product eliminates the possibility of this proposition. The number of internal degrees of freedom is larger in C_2H_4 than in HBr. Hence the C_2H_4 molecule must have a larger portion of the excess energy than the HBr molecule. Furthermore, the H—Br bond energy is 87.5 kcal/mol (11a) and the total quantum yields does not exceed unity until 100 Torr as shown in Table 1 (run Nos. 1–17). Thus it would not be likely that HBr undergo subsequent dissociation in this study.

From the tendency that $1/\phi_{C_2H_4}$ increases with increasing conversion, It/N (2), as shown in Fig. 1, one may suggest that C_2H_4 decreases by the reverse reaction of [3] and/or through some pathway to produce any other product as follows:

[4] $C_2H_4 + HBr \rightarrow C_2H_5Br$

[5] $C_2H_4 + Br \rightarrow C_2H_4Br$

[6] $C_2H_4 + C_2H_5 \rightarrow C_4H_9$

As $1/\phi_{C_2H_4}$ is almost constant with increasing It/N in the experiments with NO, the possibility of [4] can be eliminated. Since we have observed C_4H_{10} as our final product, it appears that the C_4H_9 radical formed by [6] may abstract a H atom from C_2H_5Br to produce C_4H_{10}.

[7] $C_4H_9 + C_2H_5Br \rightarrow C_4H_{10} + C_2H_4Br$

C_2H_5 radicals abstract H atoms from C_2H_5Br to produce most of the C_2H_6.

[8a] $C_2H_5 + C_2H_5Br \rightarrow C_2H_6 + CH_3CHBr$

[8b] $C_2H_6 + CH_2CH_2Br$

A possible mechanism for the scavengeable portion of the C_2H_4 can be written as:

[9] $C_2H_5 \rightarrow C_2H_4 + H$

[−5] $CH_2CH_2Br \rightarrow C_2H_4 + Br$

[10a] $2C_2H_5 \rightarrow C_2H_4 + C_2H_6$

[10b] $\rightarrow C_4H_{10}$

where the negative sign denotes the reverse reaction. ΔH of [9] is 38.1 kcal/mol (11a) whereas [8] is exothermic. Thus [9] is not plausible. Considering the ratio of [10a] to [10b] (13) and the C_2H_5 radical concentration, the contribution of [10a] is minor. Since the ΔH of [−5] is small, i.e., 8.1 kcal/mol (2c), compared with the excess energy of the bromoalkyl radical, [−5] may contribute to the major portion of scavengeable C_2H_4.

From the structural identity, the CH_3CHBr radical formed in [8a] must be the precursor of the CH_3CHBr_2. Failure to observe the 1,2-isomer (CH_2BrCH_2Br) shows that CH_3CHBr is the "wrong" radical and CH_2CH_2Br is the "right" radical which is formed in [8b] (11b)

[11] $CH_3CHBr + Br \rightarrow CH_3CHBr_2$

Since the product quantum yield of CH_3CHBr_2 is less than expected, one can propose additional termination processes as follows:

[12] $2CH_3CHBr \rightarrow C_4H_8Br_2$

[13] $2Br + M \rightarrow Br_2 + M$

The trace amount of 2,3-dibromobutane observed by GC analysis may be explained by [12].

Finally, this study makes it clear that the major mode of the primary process shifts to the radical reaction from molecular elimination sequentially with increasing wavelength of the light source in the uv/vuv region. Our ratios of $\phi_{C_2H_4}/\phi_{C_2H_6}$ extrapolate to 0.22 at zero pressure of C_2H_5Br which indicates a ratio of molecular elimination to radical decomposition of 18/82 at 193.1 nm. In addition, the importance of this study may be enhanced by the fact that the wavelength of the carbon atom lamp which has been scarcely used for photolysis work coincides with that of the ArF excimer laser and the findings of this study should be used as a key observation for a comparative study between the single photon and the multiphoton processes.

The reactions of $Pt(PPh_3)_4$ with elemental sulfur in ratios S/Pt = 3, 4, 5, and 6 give a mixture of compounds identified as $[PtS(PPh_3)_2]_2$ and $PtS_4(PPh_3)_2$; $PtS_2(PPh_3)_2$ is not detected. The dimeric complex also forms on reaction of $PtS_4(PPh_3)_2$ with 3 mol of $Pt(C_2H_4)(PPh_3)_2$. It is alkylated at one bridging sulfido ligand by CH_2Cl_2 and $CHCl_3$ to give cations $[Pt_2(\mu\text{-}S)(\mu\text{-}SR)(PPh_3)_4]^+$, R = CH_2Cl and $CHCl_2$, respectively, which are characterized as their hexafluorophosphate salts. The cations give extreme AA'BB'X ^{31}Pmr spectra since their *cis*-phosphorus atoms (A,B) have very similar chemical shifts but different coupling constants to ^{195}Pt(X); spectral features are broadened by thiolate inversion processes. Reactions of bridging sulfido ligands with other electrophiles are discussed.

RAVI R. GUKATHASAN, ROBERT H. MORRIS et ALAN WALKER. Can. J. Chem. **61**, 2490 (1983).

Le composé $Pt(PPh_3)_4$ réagit avec le soufre élémentaire dans des rapports de S/Pt = 3, 4, 5 et 6 pour donner un mélange de composés identifiés comme étant le $[PtS(PPh_3)_2]_2$ et le $PtS_4(PPh_3)_2$; on n'a pas décelé la présence du composé $PtS_2(PPh_3)_2$. Il se forme également ce complexe dimère lorsque le composé $PtS_4(PPh_3)_2$ réagit avec trois moles de $Pt(C_2H_4)(PPh_3)_2$. Ce complexe est alkylé au niveau d'un ligand sulfido en position de pont par le CH_2Cl_2 et le $CHCl_3$ pour donner les cations $[Pt_2(\mu\text{-}S)(\mu\text{-}SR)(PPh_3)_4]^+$, R = CH_2Cl et $CHCl_2$ respectivement, que l'on a caractérisés sous forme de leurs sels hexafluorophosphates. Les cations donnent des spectres en rmn du ^{31}P qui à la limite sont du type AA'BB'X puisque leurs atomes de phosphore *cis*(A,B) ont des déplacements chimiques très semblables mais les constantes de couplage avec le ^{195}Pt(X) sont différentes; les caractéristiques spectrales sont élargies par les réactions d'inversion du thiolate. On discute des réactions des ligands sulfure en position de pont avec d'autres électrophiles.

Introduction

Several recent studies have demonstrated that sulfide (S^{2-}) ligands that bridge between two electron-rich transition metal centres are reactive toward a variety of electrophiles. They undergo addition reactions with alkynes (1), isonitriles (2), transition metals (3), and alkyl halides (3). Even dihydrogen can add to sulfide ligands in certain organometallic molybdenum complexes that catalyze the reduction of acetylene to ethylene (1, 4).

Initial studies of sulfido-bridged complexes of platinum conducted by Ugo *et al.* (5) and Chatt and Mingos (6) demonstrated that these complexes also contain nucleophilic sulfido bridges and we have reinvestigated these systems, our results being the subject of this paper. The complex $[Pt(\mu\text{-}S)(PPh_3)_2]_n$, **1** (5), was reported to be dimeric in $CHCl_3$ and to react with alkyl halides RX = $PhCH_2Br$ and CH_3I to afford unstable complexes formulated on the basis of elemental analyses (5) as $[Pt_2(\mu\text{-}SR)_2(PPh_3)_4]X_2$, **2**, whereas the dimer $[Pt(\mu\text{-}S)(PMe_2Ph)_2]_2$, **3**, was reported to combine with benzyl bromide to give the monocation $[Pt_2(\mu\text{-}S)(\mu\text{-}SCH_2Ph)(PMe_2Ph)_4]Br$, **4**, and with excess methyl bromide in $CHCl_3$ to yield only $PtBr_2(PMe_2Ph)_2$ (6). We find that the sulfur ligands in complex **1** are so nucleophilic that even the very mild alkylating agents chloroform and dichloromethane react with **1** in seconds to give monocations similar in structure to **4**; no evidence of dications like **2** was found. This paper reinterprets the findings of the earlier studies in light of these observations.

Experimental

The literature method was used to prepare $[PtCl_2(PPh_3)_2]$ (7), $[Pt(PPh_3)_4]$ (7), and $[Pt(C_2H_4)(PPh_3)_2]$ (7). The ^{1}Hmr spectra were recorded on a Varian XL-200 spectrometer. The ^{31}Pmr spectra were obtained at 81 MHz on this instrument or at 32.3 MHz using a Bruker WP-80 spectrometer and were referenced to trimethylphosphite in C_6D_6 (δ140 ppm from 85% H_3PO_4) in a coaxial tube. Chemical shifts (^{31}P) are reported relative to 85% H_3PO_4. Infrared spectra from samples as KBr disks were recorded using a Beckman IR 12 spectrophotometer. Conductivity measurements were made in nitromethane at 25°C using a Beckman Model RC-18A conductivity bridge. Elemental analyses were performed by the Analytiche Laboratorien, Engelskirchen, and the Canadian Microanalytical Laboratory, Vancouver.

Reactions of sulfur with $Pt(PPh_3)_4$

The variation of product distribution for this reaction was examined for the molar ratios of sulfur to platinum given in Table 1. A representative procedure is given here for the ratio S/Pt = 4.0. To a frozen, degassed suspension of sulfur (0.21 g, 6.5 mmol) in 20 mL benzene was added $Pt(PPh_3)_4$ (2.0 g, 1.6 mmol) under nitrogen. The mixture thawed to give a clear red solution which then deposited an orange solid as it was stirred for 5 h. The solid (1.1 g) was washed with 5 mL benzene and 40 mL hexane and air dried. It analyzed as a mixture of 33% $PtS_4(PPh_3)_2$, **5** (6), and 66% $[PtS(PPh_3)_2]_n$, **1**.

Anal. calcd. for $PtS_2P_2C_{36}H_{30}$: C 55.16, H 3.86, S 8.18; found: C 54.57, H 3.97, S 8.32. This solid is only soluble in chlorinated solvents from which two components, **5** and **6** using CH_2Cl_2 and **5** and **7** using $CHCl_3$, can be separated (see below). Addition of hexane to the benzene filtrate produces in variable yield a brown material containing triphenylphosphine sulfide (^{31}Pmr δ41.5) and a mixture of platinum phosphine species (δ11 to 20, broad multiplets).

*Isolation of $PtS_4(PPh_3)_2$, **5***

Dichloromethane solutions of the orange solids from the reactions above were filtered, treated with ethanol, and vacuum concentrated until orange crystals of **5** precipitated as a CH_2Cl_2 solvate. The product was recrystallized from CH_2Cl_2/EtOH and vacuum dried.

Anal. calcd. for $PtP_2C_{36}H_{30}S_4 \cdot 0.25\ CH_2Cl_2$: C 50.09, H 3.54, S 14.76; found: C 49.73, H 3.61, S 14.78. Mp 147–150°C (lit. (6) 138–140°C). ^{31}Pmr (CH_2Cl_2) δ: 15.09, J^1(Pt—P) = 2967 Hz.

*Isolation of $[Pt_2(\mu\text{-}S)(\mu\text{-}SCH_2Cl)(PPh_3)_4](PF_6)$, **6***

After **5** is isolated, the alcoholic mother liquor is treated with a filtered solution of excess $NaPF_6$ in ethanol to yield yellow crystals which are filtered off, washed with ether, and dried *in vacuo*. Typi-

TABLE 1. Variation in product distribution with the molar ratio of the reactants — elemental sulfur to $Pt(PPh_3)_4$

Reactant ratio, S/Pt	Yield of products[a]	
	$[PtS(PPh_3)_2]_n$, **1**	$PtS_4(PPh_3)_2$, **5**
1[b]	65[b]	—
3	75–85	18–12
4	60	30
4.8	32	40
6.3	2–10	40[c]

[a] Compound **1** is taken as $PtS(PPh_3)_2$ for these calculations. Yields of $SPPh_3$ and brown soluble materials also produced could not be determined.
[b] Reference 5.
[c] We have been unable to obtain the 96% yield reported for this reaction (6).

cally, 85% of the compound **1** in the starting mixture of solids can be recovered as **6**.

Anal. calcd. for $Pt_2P_5C_{73}H_{62}S_2ClF_6$: C 51.64, H 3.68, S 3.78, Cl 2.09; found: C 50.93, H 3.79, S 3.84, Cl 2.18. Mp 188–192°C. Λ (CH_3NO_2): 74 mho cm^2 mol^{-1} at 1.0×10^{-3} *M* (1:1 electrolyte). ir (KBr) ν_{max}: 840, 560 (s, PF_6^-). ^{1}Hmr (CD_2Cl_2) δ: 6.8–8.0 (m, 60H, PPh_3), 4.1 (1:8:18:8:1 quintet of broad singlets, J^3(Pt—H) = 34 Hz, 2H, SCH_2Cl). ^{31}Pmr (CH_2Cl_2): $\delta_A \sim \delta_B$ = 22.7 (AA'BB'X, X = ^{195}Pt, J^1(A—X) = 3405, J^1(B—X) = 2631, J^2(A—B) = 20, J^4(A—B', *trans*) = J^4(A'—B, *trans*) = 20 Hz; similar parameters are obtained from the 81 and 32 MHz spectra).

Preparation of [$Pt_2(\mu$-S)(μ-SCHCl$_2$)(PPh_3)$_4$](PF$_6$), 7

Mixtures of **1** and **5** can also be separated using chloroform instead of dichloromethane as above. The yellow crystals of the product are precipitated from ethanol solutions using $NaPF_6$ and recrystallized from $CHCl_3$/ethanol.

Anal. calcd. for $Pt_2P_5C_{73}H_{61}S_2Cl_2F_6$: C 50.61, H 3.55, Cl 4.09; found: C 49.37, H 3.38, Cl 4.02. Mp 202–204°C. Λ (CH_3NO_2) 86 mho cm^2 mol^{-1} at 1.0×10^{-3} *M*. ^{31}Pmr ($CHCl_3$) δ: $\delta_A \sim \delta_B$ = 21.1 (s, br, width at base = 90 Hz, plus ^{195}Pt(X) satellites (broad multiplets) in an ABX spin system, J(A—X) = 2730, J(B—X) = 3570 Hz). Couplings J^4 were not observed.

Preparations of [$PtS(PPh_3)_2$]$_n$, 1

Method 1. According to ref. 5. A suspension of anhydrous lithium sulfide (0.93 g, 20 mmol) and $PtCl_2(PPh_3)_2$ (1.0 g, 1.3 mmol) was stirred in 20 mL benzene under N_2 for 80 h and then heated to reflux for 5 h. The orange product was filtered, washed with water and ethanol, and dried in air. The ^{31}Pmr spectrum of the orange solid (mp 246°C) in CH_2Cl_2 indicated the presence of **6** (50%) and $PtCl_2(PPh_3)_2$ (50%), ^{31}Pmr (CH_2Cl_2) δ: 13.3, J^1(Pt—P) = 3682 Hz. Sodium sulfide gave similar results.

Method 2. The mixtures of **1** and **5** obtained as above can be converted to pure **1** by reacting 3 mol of $Pt(C_2H_4)(PPh_3)_2$ per mol of **5** in the mixture: 0.09 mmol **5** and 0.17 mmol **1** (0.2 g of mixture) were reacted with 0.26 mmol $Pt(C_2H_4)(PPh_3)_2$ in 20 mL degassed benzene under nitrogen. The orange product (0.16 g, 0.21 mmol, 41%) was filtered off after 60 h stirring.

Anal. calcd. for $Pt_2S_2P_4C_{72}H_{60}$: C 57.52, H 4.02, S 4.27; found: C 56.64, H 4.41, S 3.84. Mp 245–247°C (lit. (5) 246°C). Complex **1** is also obtained in 43% yield if pure **5** (0.06 mmol) is reacted with 0.18 mmol of $Pt(C_2H_4)(PPh_3)_2$ in 20 mL benzene.

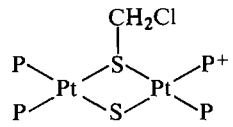
Discussion

Complex **1** was originally prepared by the reaction of *cyclo*-octasulfur with solutions of $Pt(PPh_3)_x$, x = 2 or 3 although the stoichiometry of the reaction was not precisely defined (5). We have studied the reaction of elemental sulfur with $Pt(PPh_3)_4$ in the stoichiometric ratios listed in Table 1 and find that the main product in each case is an orange, benzene-insoluble precipitate consisting of mixtures of $[PtS(PPh_3)_2]_n$, **1**, and the sulfur metallocycle $PtS_4(PPh_3)_2$, **5** (reaction [1]).

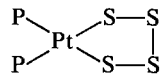
[1] $Pt(PPh_3)_4 + xS_8 \rightarrow$ **1** + **5** + $SPPh_3$

Since both compounds are sparingly soluble in common organic solvents but **1** dissolves with reaction in chlorinated solvents, the mixture can be separated using dichloromethane as in reaction [2], where **1** is converted to an ionic compound **6** whose properties are consistent with structure **I** with a chloride counterion.

[2] **1** + **5** $\xrightarrow[CH_2Cl_2]{}$ **6** + **5**



I, 6



II, 5

Complex **5** is precipitated with ethanol and then **6** is isolated as the hexafluorophosphate salt. The ^{31}Pmr spectrum of complex **5**, which is stable in CH_2Cl_2 for at least 10 h, shows a singlet at δ 15.1 ppm due to equivalent phosphorus atoms (structure **II**, the X-ray structure has been reported (8)) and a platinum-195 coupling of 2967 Hz.

Elemental analyses, conductivity, and nmr measurements indicate that **6** has the structure **I**. The central three resonances of the 1:8:18:8:1 quintet expected for the methylene protons of the alkylated sulfur are observed in the ^{1}Hmr as broad singlets. The broadening may be due to a dynamic inversion of the thiolate sulfur also noticed in the ^{1}H resonance of the benzyl group in compound **4** which also has this structure (6). A CH_2Cl_2 solution of **6** gives the remarkable ^{31}Pmr spectrum shown in Fig. 1. It can be explained by assuming that the *cis*-triphenylphosphine ligands have almost identical chemical shifts of approximately 22.7 ppm but different coupling constants J^1(Pt—P) = 3405 and 2631 Hz. The central line of the spectrum is a broad singlet composed of an AB quartet with additional J^3(P—Pt) and J^4(P—P) couplings, all of which are unresolved. A similar broad centre peak is observed in the ^{31}Pmr spectrum of $[Pt_2(\mu\text{-SMe})H_2(DPPM)_2]^+$ where inversion at the thiolate sulfur can also occur (9). The ^{195}Pt satellites can be analyzed as an AA'BB'X spin system with a *cis*-phosphine coupling constant J^2(A—B) = 20 Hz and a chemical shift difference $\delta_A - \delta_B$ which is too small to be detected. In this spin system the appearance of the ^{195}Pt satellites as pseudo triplets can be explained by invoking a coupling J^4(P—P, *trans*) ~ 20 Hz whilst J^4(P—P, *cis*) is too small to be observed. Complex **1** prepared using the sodium sulfide or lithium sulfide method (5) gives an identical spectrum apart from impurity peaks due to $PtCl_2(PPh_3)_2$. Complex **6** decomposes in CH_2Cl_2 at 30°C ($t_{1/2}$ = 10 h) to several products including $SPPh_3$. The other phosphorus-containing species have not been identified. The decomposition may be initiated by the alkylation of the bridging sulfide ligand in **6**.

A ^{31}Pmr spectrum of the amber benzene solution resulting from the reaction depicted in [1], x = 0.5, gave no evidence for the existence of $Pt(S_2)(PPh_3)_2$ which would have been signalled by a simple singlet with satellites. Such a complex might well have been formed using this stoichiometry by analogy to the reported syntheses of disulfur complexes of other group VIII

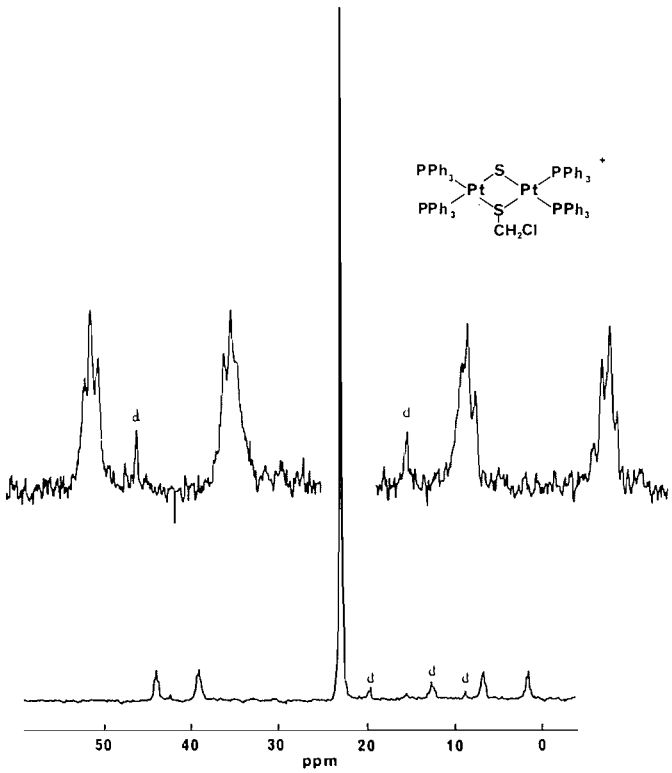

FIG. 1. The ^{31}Pmr spectrum at 81 MHz of $[Pt_2(S)(SCH_2Cl)(PPh_3)_4]PF_6$, **6**, in CH_2Cl_2. Inset are expansions of the ^{195}Pt satellites of the resonances at 22.75 ppm. The peaks labelled with d are decomposition products that formed during the hour of data collection (the probe temperature was 34°C).

metals (10, 11). This compound may form in the reaction but Ginsberg's work (10) suggests that it would be consumed rapidly as in reaction [3].

[3] $Pt(S_2)(PPh_3)_2 + Pt(PPh_3)_4 \rightarrow \mathbf{1} + 2\ PPh_3$

The disulfur ligand in rhodium and iridium complexes was abstracted by $Pt(PPh_3)_4$ to give **1** (10). We have found that even $PtS_4(PPh_3)_2$, **5**, is attacked by the zero valent platinum from $Pt(C_2H_4)(PPh_3)_2$ in benzene so that mixtures of **1** and **5** are converted to pure **1** plus unidentified benzene soluble species.

There is now strong albeit indirect evidence that **1** contains dimeric units with very nucleophilic bridging sulfur groups. Its insolubility can be explained by strong intermolecular attractions between neighbouring phenyl groups. The related ethyldiphenylphosphine derivative has been shown to be dimeric (10). The reaction products from **1** are also dimeric: the SO_2 adduct (5) and complex **6**.

The reaction of sulfur dioxide with **1** gives $[PtS(SO_2)(PPh_3)_2]_2$, **8** (5). We suggest that this Lewis acid reversibly coordinates to the basic sulfur ligands rather than the platinum atoms (5) in complex **8** since the frequencies $\nu(SO) = 1060$ and 1210 cm^{-1} fall in the ranges now recognized as characteristic of a pyramidal O_2S-S system (12). Consistent with this view, complex **8** does not react with oxygen to give sulfates (5, 8).

The "dichloroform adduct" of **1** reported by Ugo *et al.* (5) must now be formulated as $[Pt_2S(SCHCl_2)(PPh_3)_4]Cl \cdot CHCl_3$, a monoalkylated derivative of **1** with 1 mol of chloroform of solvation to explain the analytical results reported. In fact, we have isolated this complex as the hexafluorophosphate salt, **7**, and find that its properties agree with this formulation and a structure analogous to **6**. We also propose that on the basis of the conductivity data given for complexes **2**, the reactions of **1** with other alkyl halides give products alkylated at only one sulfur atom instead of two as was proposed (5). Conductivity data for complexes **2** in nitrobenzene are 22 and 16 mho cm^2 mol^{-1} (5), which match the value of 18 for the monoalkylated complex **4** reported in ref. 6. Ion pairing in solutions of these complexes could explain why these values fall below the range typical of 1:1 electrolytes: 25–30 mho cm^2 mol^{-1}; see ref. 13.

Received May 24, 1983

W. KLIEGEL, D. NANNINGA, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **61**, 2493 (1983).

The crystal structures of 2,2-diphenyl-1,3-dioxa-3*a*-azonia-2-borataindan, **6***a*, and 4-cyclohexyl-6-methyl-2,2-diphenyl-1,3-dioxa-3*a*-azonia-2-borataindan, **6***b*, reported here represent the first crystallographic examples of coordination complexes of the anionic ligand derived from 2-hydroxypyridine *N*-oxide. Crystals of **6***a* are monoclinic, a = 11.5210(13), b = 10.2860(8), c = 12.7354(15) Å, β = 101.878(5)°, Z = 4, space group $P2_1/c$; and those of **6***b* are monoclinic, a = 8.5047(8), b = 15.6603(14), c = 16.0501(18) Å, β = 104.776(5)°, Z = 4, space group $P2_1/n$. Both structures were solved by direct methods and were refined by full-matrix least-squares procedures to final R values of 0.039 and 0.042 for 1440 and 1750 reflections with $I \geq 3\sigma(I)$, respectively. Both molecules feature tetrahedrally coordinated boron atoms incorporated into five-membered OBOCN chelate rings which have B-envelope conformations. The observed molecular geometries indicate that the ligand may be classed as a hybrid of the 2-hydroxypyridine *N*-oxide and 1-hydroxy-2-pyridinone tautomers of the parent alcohol. Important bond lengths (corrected for libration) are: O—B = 1.557(3)–1.580(3), mean C—B = 1.600(4), C—O = 1.316(3), and N—O = 1.389(3) Å.

W. KLIEGEL, D. NANNINGA, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **61**, 2493 (1983).

La structure du cristal de diphényl-2,2 dioxa-1,3 azonia-3*a* borata-2 indane (**6***a*) et celle du cristal de cyclohexyl-4 méthyl-6 diphényl-2,2 dioxa-1,3 azonia-3*a* borata-2 indane (**6***b*) représentent les premiers exemples en cristallographie de complexes de coordination du ligand anionique provenant de la hydroxy-2 pyridine-*N*-oxyde. Les cristaux du composé **6***a* sont monocliniques et appartiennent au groupe d'espace $P2_1/c$ avec a = 11,5210(13), b = 10,2860(8), c = 12,7345(15) Å, β = 101,878(5)°, Z = 4; et ceux du composé **6***b* appartiennent au groupe d'espace monoclinique $P2_1/n$ avec a = 8,5047(8), b = 15,6603(14), c = 16,0501(18) Å, β = 104,776(5)°, Z = 4. On a résolu les deux structures par des méthodes directes et on les a affinées par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs respectives de R de 0,039 et 0,042 pour 1440 et 1750 réflexions avec $I \geq 3\sigma(I)$. Les deux molécules ont des atomes de bore coordonnés de façon tétraédrique et incorporés dans des noyaux chélates à cinq chainons OBOCN qui ont des conformations de type enveloppe B. Les géométries moléculaires observées indiquent que le ligand peut être classé comme un hybride des tautomères de l'hydroxy-2 pyridine *N*-oxyde et de l'hydroxy-1 pyridinone-2 de l'alcool apparenté. Les longueurs importantes de liaison (corrigées pour la libration) sont: O—B = 1,557(3)–1,580(3), C—B (moyenne) = 1,600(4), C—O = 1,316(3) et N—O = 1,389(3) Å.

Introduction

2-Hydroxypyridine *N*-oxide[2] can be classed with the cyclic hydroxamic acids or *N*-hydroxy lactams (1) which are derived from heteroaromatic compounds such as pyridine, quinoline, and related ring systems. For the structural description, different canonical forms, **1** ↔ **2** of the lactam (**1**) or **3** ↔ **4** of the lactim (**3**) tautomers can be written (2–6).

On the virtue of a strong intramolecular hydrogen bond (2, 4), one can proceed on the assumption that the proton is "chelated" as in **5** which summarizes the tautomeric equilibrium as well as the individual resonance forms **1**–**4**. Replacement of this "chelated" proton by metal ions has already been demonstrated in connection with the synthesis of 2-hydroxypyridine *N*-oxide (7), which was reported to form chelates with Cu(II) and Fe(II) ions. Many examples of such metal complexes have subsequently been reported (4, 6, 8–12). Among the ligands employed during our earlier investigations of boron chelates of hydroxamic acid derivatives (13–15) were 2-hydroxypyridine *N*-oxide (**5**, $R^1 = R^2 = H$) and a substituted derivative thereof, "ciclopirox" (**5**, $R^1 = C_6H_{11}$, $R^2 = CH_3$),[3] which is known as a very effective antimycotic (16). The exchange of the "chelated" proton in **5** for the diphenylborenium ion (Ph_2B^+) led to the diphenylboron

chelate **6** (17). In view of the *B,N*-betaine formulation **8** of open-chain hydroxamic acid boron complexes, which has been verified by X-ray crystallographic analyses of the boron chelates **8** (X = F, Ph) of *N*-methylacethydroxamic acid (13, 14), it was of special interest to determine which of the resonance structures **6**/**7** is the major contributor to the resonance hybrid. The best description for the resonance hybrid **8** ↔ **9** appeared to be the betaine form **8**, based on the analysis of the bond distances which indicate an approximate contribution of 75% by the resonance structure **8** (13, 14).

No X-ray structure analyses have yet been reported for 2-hydroxypyridine *N*-oxide or for complexes of this ligand (6). The structure of an antibiotic with a comparable ring system[4] has been reported (18), but no bond lengths or angles were

* U_{eq} = (1/3) trace U_{diag}.

given. In view of the controversy regarding the structural formulations of 2-hydroxypyridine *N*-oxide and its complexes, an X-ray crystallographic study of the diphenylboron chelate of this ligand has been undertaken. During the course of this investigation it was discovered that there was disorder between the oxygen-bearing N and C atoms of the pyridine ring of **6*a***. In order to resolve this problem (which also occurs in the case of **8** (X = Ph) (14)), the structure of the substituted derivative **6*b*** has also been determined.

Experimental

2,2-Diphenyl-1,3-dioxa-3a-azonia-2-borataindan, **6*a***

The compound was prepared by the literature method (17). Crystals suitable for X-ray analysis were obtained by recrystallization from cyclohexane/chloroform or from *n*-hexane/dioxane mixtures, mp 123–124°C. A crystal bounded by the nine faces (followed by their distances in mm from a common origin): ±(−1 1 1), 0.13, ±(1 0 0), 0.16, ±(−5 1 1), 0.15, ±(0 1 −1), 0.21, (−1 −1 1), 0.28 was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 35–42°) measured on a diffractometer with Mo-Kα$_1$ radiation (λ = 0.70930 Å). Crystal data at 22°C are:

$C_{17}H_{14}BNO_2$ fw = 275.11

Monoclinic, a = 11.5210(13), b = 10.2860(8), c = 12.7354(15) Å, β = 101.878(5)°, V = 1479.0(3) Å^3, Z = 4, ρ_c = 1.236 gcm^{-3}, $F(000)$ = 576, μ(Mo-Kα) = 0.75 cm^{-1}. Absent reflections: $h0l$, l odd, and $0k0$, k odd, uniquely indicate the space group $P2_1/c$ (C^5_{2h},

No. 14).

Intensities were measured with graphite-monochromated Mo-Kα radiation (λ = 0.71073 Å) on an Enraf-Nonius CAD4-F diffractometer. An ω-2θ scan at 0.87–10.06° min^{-1} over a range of (0.55 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 55°. The intensities of three check reflections, measured every 3600 s throughout the data collection, remained constant to within ±3%. Of the 3387 independent reflections measured and processed,[5] 1440 (42.5%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The structure was solved by direct methods, the coordinates of all non-hydrogen atoms being determined from an E-map. After full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters to $R = 0.085$, a difference map revealed the positions of all 14 hydrogen atoms which were refined with isotropic thermal parameters in subsequent cycles of refinement. It became obvious from the derived thermal parameters that the positions X(1) and X(2) were each occupied by both N and C. Refinement of the structure with either of these sites occupied by nitrogen and the other by carbon resulted in $R = 0.044$ and $R_w = 0.050$ with unbalanced thermal parameters. In the final stages of refinement the X positions were assumed to be 50% N and 50% C, this assumption being justified both by the lower residuals and by the near equality of the resulting thermal parameters. The scattering factors of ref. 19 were used for non-hydrogen atoms and those of ref. 20 for hydrogen atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and $\sin\theta/\lambda$ and was employed in the final stages of refinement. Convergence was reached at $R = 0.039$ and $R_w = 0.043$ for 1440 reflections with $I \geq 3\sigma(I)$. For all 3387 reflections $R = 0.130$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.007 and 0.08σ, respectively. The mean error in an observation of unit weight was 1.910. A final difference map was essentially featureless, the largest residual density being +0.156 e $Å^{-3}$ near oxygen. The final positional and thermal parameters appear in Tables 1 and 2[6] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[6]

4-Cyclohexyl-6-methyl-2,2-diphenyl-1,3-dioxa-3a-azonia-2-borataindan, ***6b***

Experimental details are as above except where noted. The compound was prepared according to the literature method (17). Crystals were obtained by recrystallization from ethanol, mp 150–152°C, that

employed for the data collection being bounded by the faces (followed by their distances in mm from a common origin): ±(0 1 −1), 0.15, ±(0 1 0), 0.13, ±(0 1 1), 0.16, ±(2 0 −1), 0.28. Crystal data: $C_{24}H_{26}BNO_2$ fw = 371.29 Monoclinic, a = 8.5047(8), b = 15.6603(14), c = 16.0501(18) Å, β = 104.776(5)°, V = 2066.9(4) Å^3, Z = 4, ρ_c = 1.193 g cm^{-3}, $F(000)$ = 792, μ(Mo-Kα) = 0.70 cm^{-1}. Absent reflections: $h0l$, $h + l$ odd, and $0k0$, k odd, uniquely indicate the space group $P2_1/n$ (non-standard setting of $P2_1/c$, equivalent positions: ±(x, y, z; 1/2 − x, 1/2 + y, 1/2 − z)).

An ω–2θ scan at 1.44–10.06° min^{-1} over a range of (0.65 + 0.35 tan θ)° in ω was employed. Of 3604 independent reflections measured (to 2θ = 50°), 1750 (48.6%) had intensities greater than 3σ(I) above background. The intensities of the three standard reflections (chosen to be approximately orthogonal to one another) exhibited severe and somewhat variable decay during the course of the data collection (intensities falling off by 39, 33, and 33%). A correction for anisotropic decay was made (21).

The structure was solved by direct methods, the non-hydrogen atoms being positioned from an E-map and hydrogen atoms from a difference map after refinement of the non-hydrogen atoms with anisotropic thermal parameters to R = 0.097. Hydrogen atoms were refined with isotropic thermal parameters in subsequent least-squares cycles. The structure was refined to R = 0.042 and R_w = 0.046 for 1750 observed reflections; for all 3604 reflections R = 0.119. The mean and maximum parameter shifts on the final cycle of refinement corresponded to 0.05 and 0.80σ respectively, the maximum shift being associated with the y coordinate of H(18c). The mean error in an observation of unit weight was 1.844 and the largest peak on the final difference map was +0.17 e Å^{-3} in the vicinity of oxygen.

Analysis of thermal motion

The thermal motion in both structures (Fig. 1) has been analysed in terms of the rigid-body modes of translation, libration, and screw-motion (22). The rms errors in the U_{ij} (derived from the least-squares analyses) are 0.0015 and 0.0020 Å^2, respectively, for **6***a* and **6***b*. In each case analysis of the entire molecules indicated significant independent motion of various molecular fragments which were then separately analysed (rms ΔU_{ij} = 0.0017–0.0038 Å^2). The appropriate bond distances have been corrected for libration (22, 23), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3 along with the uncorrected values; corrected bond

angles do not differ by more than 1σ from the uncorrected values given in Table 4. Intra-annular torsion angles defining the conformations of chelate and cyclohexane rings are listed in Table 5. Bond lengths and angles involving hydrogen and a complete listing of torsion angles (Tables 6–8) are included as supplementary material.

Results and discussion

The crystal structure of **6*a*** consists of molecules each linked to two others by a system of weak C—H···O hydrogen bonds (C(5)—H(5)···O(2) ($1 - x$, $1/2 + y$, $1/2 - z$), C···O = 3.251(3), H···O = 2.30(3) Å, C—H···O = 156(2)°) to form continuous spirals about the twofold screw axis. The structure of the substituted derivative **6*b*** consists of discrete molecules separated by normal van der Waals distances.

The central feature of each molecule is the 1,3-dioxa-3*a*-azonia-2-borataindan ring system. The pyridine rings are both slightly, but significantly, non-planar (χ^2 = 50.0 and 48.5, maximum deviation from C_5N mean planes, 0.011(3) and 0.012(2) Å, respectively, for **6*a*** and **6*b***). With the exception of the C(18) methyl substituent in **6*b*** (displacement = 0.008(7) Å), all substituents of the pyridine rings are significantly displaced from the mean plane of the ring in the same direction (displacements range from 0.013(1) Å for O(2) in **6*a*** to 0.083(2) Å for the same atom in **6*b***, mean 0.049 Å). Unlike the planar five-membered OBONC rings in the closely related molecules **8** (13, 14), the analogous rings in **6*a*** and **6*b*** both exhibit non-planar B-envelope conformations, the deviation from planarity being greater in the case of **6*b*** (see Table 5). In view of the chemical similarities between **6** and **8**, the non-planarity of the five-membered rings in the present structures is most likely a result of packing forces since intramolecular steric interactions are minimal.

The N—C(1) (X(1)—X(2)) bond lengths in **6*a*** and **6*b*** are 1.351(3) and 1.349(3) Å, respectively. These distances are significantly shorter than those observed (1.410(10) (24), 1.373(4) (25), and 1.400(5) Å (26)) and calculated (1.408 Å (27) and 1.390 Å (28)) for 2-pyridones; slightly longer than those found (1.341(3) (29) and 1.338(4) Å (25)) or calculated (1.311 Å (28)) for 2-hydroxypyridines; and similar to those observed in *N*-alkylpyridinium salts such as **10** (26) (1.358(7) Å) or in certain substituted pyridine *N*-oxides such as 2-hydroxymethylpyridine *N*-oxide (30) (1.349 and 1.358 Å). The C(1)—O(2) bond distance of 1.316(3) Å in **6*b*** is significantly longer than those observed (1.236(10) (24), 1.262(4) (25), 1.224(3) (26), and 1.250(7) Å (31)) and calculated (1.264 Å (27) and 1.221 Å (28)) for 2-pyridones; slightly shorter than those observed (1.321(3) (29) and 1.330(5) Å (25)) and calculated (1.358 Å (28)) for 2-hydroxypyridines; and equal within experimental error to that observed in **10** (26) (1.317(7) Å). The N—O(1) distance of 1.389(3) Å in **6*b*** is longer than the mean N—O distance of 1.35 Å for a number of pyridine *N*-oxides and their coordination complexes or salts (32), the only comparable distance being that of 1.39 Å reported for *N*-oxopyridinium trichloroacetate (33). Bond lengths in the pyridine ring of **6*b*** (mean[7] N—C = 1.355(6), mean C—C = 1.386(4) Å) indicate a uniform delocalization of electron density. These data indicate that both **6** and **7** (along with related canonical forms) are important contributors to the overall structures of the diphenylboron chelates, the former being dominant. In a closely related Zn(II) complex of the thio analog 2-mercaptopyridine *N*-oxide (34), where N—C(S) = 1.37(1)–1.38(2) and N—O = 1.33(1)–1.37(1) Å, a more substantial contribution of the sulphone form (analogous to **7**) to the overall structure is indicated.

The O(2)—B bond in **6*a***, 1.580(3) Å, is significantly longer than the mean, 1.560(3) Å, of the three other equivalent O—B bonds in **6*a*** and **6*b***. By analogy with a nearly identical situation observed in the structure of *rac*-bis[(salicylaldoximato(2−)) phenylboron] (35), this lengthening of the O—B bond may be ascribed to the participation of the oxygen atom in the C—H···O hydrogen bond. The B—C bonds are essentially equal in the two structures, mean B—C = 1.600(4) Å. These distances are in good agreement with those observed for other resonance-stabilized five-membered *O,O*-chelates of diphenylboron (in **8** (X = Ph) O—B = 1.548(2) and 1.552(2), B—C = 1.609(2), and in (tropolonato)diphenylboron (36) O—B = 1.544(2) and 1.565(2), B—C = 1.599(2) and 1.611(3) Å) and similar to those in the two crystalline forms of (acetylacetonato)diphenylboron (36) which contains a six-membered chelate ring (O—B = 1.530(2)–1.547(2) Å and B—C = 1.601(2)–1.610(3) Å). In the related diphenylboron chelate of *N*-hydroxymethyldimethylamine *N*-oxide (37) (one of the best known donors for the diphenylborenium cation), a saturated derivative of **8** (X = Ph), (N)O—B = 1.556(8), (C)O—B = 1.506(8), and mean B—C = 1.632(7) Å.

The equatorially substituted cyclohexane ring has a regular chair conformation and normal geometry (mean C—C = 1.529(7) Å, mean C—C—C = 111.2(7)°). Of the four B-phenyl rings in the two structures, three are slightly but significantly non-planar while the other (C(12) ring in **6*b***) is planar within experimental error (χ^2 = 32.5, 35.0, 55.4, and 5.7, maximum deviation from the mean plane 0.015(2) Å). The substituent-induced geometrical distortions of the B-substituted phenyl rings are as expected (38).

Received March 18, 1983

MILJENKO PERIĆ, SIGRID D. PEYERIMHOFF, and ROBERT J. BUENKER. Can. J. Chem. **61**, 2500 (1983).

Potential energy curves for the two lowest electronic states X^2A'' and A^2A' ($^2\Pi$ in linear geometry) of HNF are calculated employing configuration interaction. A vibrational analysis of the $A^2A'-X^2A''$ transition is undertaken; stretching and bending modes are treated separately but vibronic coupling and large-angle bending is taken into consideration explicitly. The various vibronic levels including their K-type structure are compared with measured data wherever available and the results indicate that the prediction of vibronic spectra in small molecules on the basis of purely *ab initio* data is now within reach.

MILJENKO PERIĆ, SIGRID D. PEYERIMHOFF et ROBERT J. BUENKER. Can. J. Chem. **61**, 2500 (1983).

Utilisant des interactions de configuration, on a calculé les courbes d'énergie potentielle des états électroniques les plus bas X^2A'' et A^2A' ($^2\Pi$ en géométrie linéaire) de HNF. On a effectué une analyse vibrationnelle de la transition $A^2A'-X^2A''$. On a traité séparément les modes d'élongation et de déformation, mais on prend explicitement en considération le couplage vibronique et la déformation de grand angle. On a comparé les divers niveaux vibroniques, y compris leur structure de type K, avec les mesures disponibles et les résultats indiquent que l'on peut maintenant prédire les spectres vibroniques des petites molécules en se basant purement sur des données *ab initio*.

Introduction

The absorption spectrum of the free radical HNF was first observed by Goodfriend and Woods (1) who obtained several bands in the region of 4000–5000 Å by flash photolysing difluoroamine HNF_2. They attributed the spectrum to a bending progression of the $^2A' \leftarrow {}^2A''$ transition in HNF, with an upper state vibrational frequency of about 1035 cm^{-1}. However, the resolution was not high enough to enable a detailed analysis of the K-type structure.

Jacox and Milligan (2) have produced HNF and DNF in an argon matrix by the reaction of photolytically produced atomic fluorine with NH. On the basis of the observed ir spectrum they obtained values for two vibrational fundamentals, 1432 and 1000 cm^{-1}, and attributed them to the bending and N—F stretching, respectively; no N—H stretching frequency has been found. The equilibrium geometry for the ground state of HNF has then been estimated as NH = 1.026 Å, NF = 1.400 Å and ∠HNF = 105°. Electronic transitions in HNF have also been recorded. By employing a value of 1033 cm^{-1} for the excited state (ES) bending frequency (obtained by averaging over five observed band separations) and assuming the stretching frequences to be equal in the ground and excited electronic states, one obtains T_e values of 20 431 cm^{-1} and 20 358 cm^{-1} for HNF and DNF, respectively.

A thorough high-resolution analysis of the HNF absorption spectrum has been carried out by Woodman (3). Seven members of a progression in the upper state bending mode have been observed and the K structure has been analyzed. Several perturbations in the spectrum indicate a coupling between the ν_2 and ν_3 vibrations. A progression in the stretching modes has not been found, however. The equilibrium angles and NF distances in both electronic states have been determined as ∠HNF = 125°, NF = 1.34 Å for the first excited state. The NH distances have been estimated to be 1.06 and 1.03 Å for the ground and excited state, respectively. For the excited state bending and NF stretching vibrations the values of 1070 and 1120 cm^{-1} have been obtained, while the NH stretching vibrational frequency has been estimated to be 2800 cm^{-1}. A T_e value of 20 141.3 cm^{-1} results from this analysis.

The emission spectrum of HNF has been obtained by Lindsay *et al.* (4) as a consequence of the chemiluminiscent reaction $N_2H_4 + F_2$. The transition from the vibrationless excited state to the lowest four bending levels of the ground state, as well as the (010) → (010) excitation have thus far been recorded. The value for the ground state bending vibrational frequency determined from the first electronic transition ($\nu_2'' = 1441.1$ cm^{-1}) is close to that obtained by Jacox and Milligan (2). These authors have also pointed out the large differences which exist between the spectrum of HNF and its isoelectronic analogue HOO.

To our knowledge the only theoretical (*ab initio*) study of the HNF molecule has been reported by Brotchie and Thomson (5). These authors have used the restricted Hartree–Fock scheme with three different basis sets of gaussian orbitals. With the largest set of effectively double-ζ quality, the equilibrium geometry has been calculated to be in good agreement with what has been inferred experimentally. The energy difference between the two lowest-lying electronic states has also been calculated (20 800 cm^{-1}), but altogether this study does not allow more than a rough interpretation of the main features in the HNF spectrum. It is thus the goal of the present work to obtain potential energy curves for this system by means of large-scale CI calculations and on the basis of these results to carry out a detailed vibronic analysis of the first spectral band.

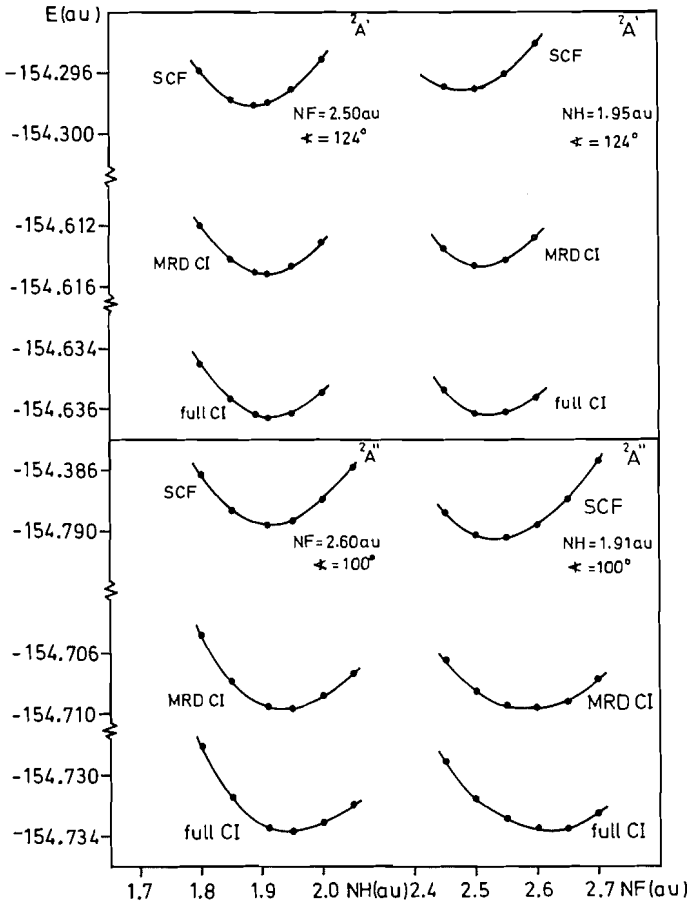

FIG. 1. Calculated potential energy curves for stretching vibrations in the lowest $^2A''$ and $^2A'$ electronic states of HNF.

Technical details of the treatment

In the present work the AO basis proposed by Huzinaga (6*a*) and Dunning (6*b*) is employed. It consists of nine *s* and five *p* functions (6*a*) in the [4*s*, 2*p*] contraction (6*b*) for the N and F atoms, respectively, and two *s* (scaling factor $\eta^2 = 2.3$ relative to the expansion given by J. L Whitten (quoted in ref. 7)) and one *p* group ($\alpha = 0.8462$) for the hydrogen atom. In addition, two sets of cartesian *d* functions are added: the first with the exponent $\alpha(d) = 0.95$ on nitrogen, the second ($\alpha(d) = 1.62$) on fluorine.

The configuration interaction treatment is of the standard MRD-CI type with configuration selection and energy extrapolation (8, 9). A core of two MO's corresponding to the 1*s* shells of N and F is kept doubly occupied in all configurations, while the corresponding two complementary MO's with highest orbital energy are excluded from consideration entirely; all other MO's are allowed variable occupation. Two reference configurations are employed for each state in order to generate the single- and double-excitation space. These are $\ldots 7a'^2\,1a''^2\,2a''$ and $\ldots 7a'^2\,1a''\,2a''^2$ for the X^2A'' ground state and $\ldots 6a'^2\,7a'\,1a''^2\,2a''^2$ and $6a'\,7a''^2\,1a''^2\,2a''^2$ for the $^2A'$ excited state. In this way a configuration space of approximately 30 000 symmetry-adapted functions is obtained, while the sizes of the secular equations actually diagonalized (corresponding to a selection threshold of $T = 10$ μhartree) is in the order of 3400–5400. For each electronic state, the respective SCF orbitals are used as the MO basis. The energy contribution of higher than double-excitation configurations is also estimated in analogy to the formula (10) $\Delta E = (1 - c_0^2) \times (E_{SCF} - E_{CI})$, which upon addition to the corresponding CI result is referred to as the full CI limit in the ensuing discussion; in the present case the SCF energy is replaced by the energy of the 2 × 2 reference set and the SCF coefficient c_0 by the respective sum of the two contributions (approximately 92%).

Since the two lowest lying states of HNF correspond at the linear geometry of the molecule to the same (orbitally) degenerate $^2\Pi$ electronic state (Renner-Teller effect), the Born–Oppenheimer approximation is not capable of yielding a suitably accurate calculation of the vibrational levels. Instead, the total wavefunction must be taken in the form of a linear combination including the electronic and nuclear coordinates of both electronic states. The vibronic energies and wavefunctions can be obtained according to the method proposed by Buenker (11), for which more details are described elsewhere (12, 13), by diagonalizing the Hamiltonian for the electronic and bending motion including rotation about the *a*-axis (coinciding at the linear geometry with the molecular axis):

$$[1]\quad H = -\frac{1}{2}\sum_i^n \Delta_i - \sum_{i,a}^{n,N}\frac{Z_a}{r_{ia}} + \sum_{i<j}^{n}\frac{1}{r_{ij}} + \sum_{a<b}^{N}\frac{Z_a Z_b}{r_{ab}}$$
$$-\frac{1}{2}\left[T_1(\rho)\frac{\partial^2}{\partial\rho^2} + T_2(\rho)\frac{\partial}{\partial\rho} + T_3(\rho)\frac{\partial^2}{\partial\phi^2} + T_4(\rho)\right]$$
$$\equiv H_e - \frac{1}{2}\left[T_1(\rho)\frac{\partial^2}{\partial\rho^2} + T_2(\rho)\frac{\partial}{\partial\rho} + T_3(\rho)\frac{\partial^2}{\partial\phi^2} + T_4(\rho)\right]$$

in a basis consisting of the products of the electronic wavefunctions Ψ^-, Ψ^+ (or linear combinations thereof (12, 13), as actually employed in the present work) calculated in the Born–Oppenheimer approximation with the nuclear functions $\Phi_i(\rho, \phi)$. The symbol ρ denotes the bending coordinate ($\rho = \pi - \angle\mathrm{HNF}$) and φ defines the rotation about the *a* axis. It is assumed that the stretching vibrations and rotations about the axes perpendicular to *a* can be treated separately (a part of the bend–stretch interaction can be included into Hamiltonian (1) (14, 15)). In order to incorporate the coupling between the electronic and bending vibrational motion exactly, the first and the second derivatives of the electronic CI functions with respect to the nuclear coordinates must be calculated (12, 16). In the present study, however, the exact dependence of these derivatives on the rotational angle φ has been replaced by their asymptotic forms $\pm\Lambda$ and $-\Lambda^2$, whereby their ρ dependence has been neglected entirely with the consequence that the secular problem becomes very similar to that in the more conventional approach (17), differing from it only in the form of the potentials (calculated pointwise by the CI method in the present case and expanded in polynomial series in ρ) and the kinetic energy operator.

The coefficients $T_i(\rho)$ ($i = 1, \ldots 4$) in the expression for the kinetic energy operator for the bending vibrations and rotations about the *a* axis are generally functions of the bending coordinate ρ (and also of the internuclear distances for some forms of the bending Hamiltonian (15)) and become constants only for infinitesimal vibrations. Their actual form depends on the Hamiltonian chosen; in the present paper the Hamiltonian developed by Hougen, Bunker, and Johns (18) is used:

$$[2]\quad T'' \equiv H_b^0 + H_{rot}^z - V_0(\rho) = -\frac{1}{2I_{\rho\rho}^0}\frac{\partial^2}{\partial\rho^2} - \frac{1}{2}$$
$$\times\left(\frac{\partial}{\partial\rho}\frac{1}{I_{\rho\rho}^0}\right)\frac{\partial}{\partial\rho} - \frac{1}{2}(\mu^0)^{1/4}\left\{\frac{\partial}{\partial\rho}\frac{1}{I_{\rho\rho}^0}(\mu^0)^{-1/2}\left[\frac{\partial}{\partial\rho}(\mu^0)^{1/4}\right]\right\}$$

[a]Assumed.
[b]The values in this column are obtained from a fit to the original data points generated, while the data in the next two columns result from the polynomial fits with the aid of additional spline points (see text).
[c]Reference number in parentheses.

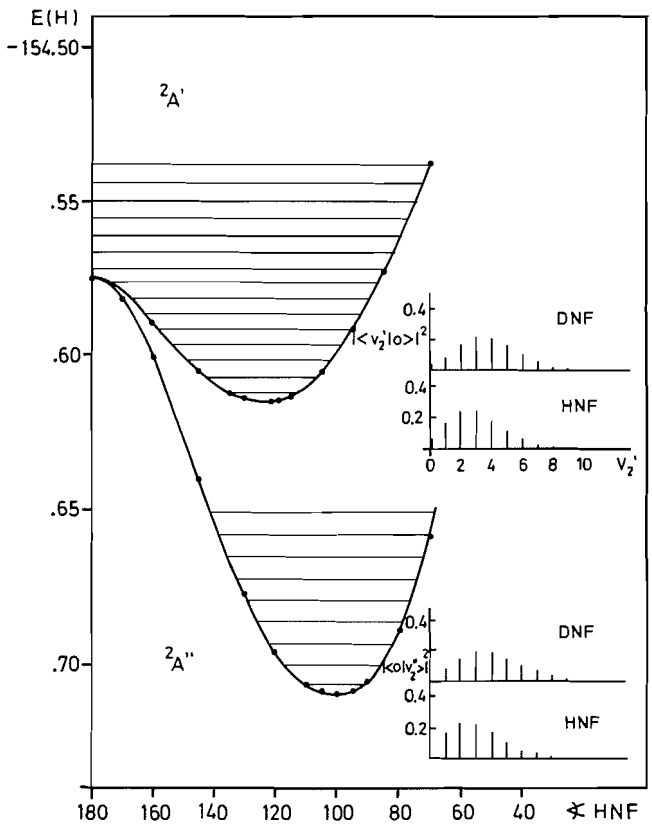

FIG. 2. Calculated MRD-CI bending potential curves and corresponding $K = 0$ vibronic levels for the two lowest electronic states of HNF. Franck–Condon factors for the transitions from $v_2'' = 0$ to various v_2' levels and from $v_2' = 0$ to v_2'' are also given.

This operator corresponds to the integration element $d\rho$. An appropriate form of the kinetic energy operator can be obtained by applying the transformation $\rho^{-1/2}\, T''\, \rho^{1/2}$ to the expression [2] and results in:

$$[3]\quad T = -\frac{1}{2I^0_{\rho\rho}}\frac{\partial^2}{\partial\rho^2} - \frac{1}{2}\left[\frac{1}{I^0_{\rho\rho}\rho} + \frac{\partial}{\partial\rho}\left(\frac{1}{I^0_{\rho\rho}}\right)\right]\frac{\partial}{\partial\rho} + \frac{1}{8I^0_{\rho\rho}\rho^2} - \frac{1}{4\rho}\frac{\partial}{\partial\rho}\left(\frac{1}{I^0_{\rho\rho}}\right) + \frac{1}{8}\mu^0\left\{\frac{\partial}{\partial\rho}\left(\frac{1}{I^0_{\rho\rho}}\right)\frac{\partial}{\partial\rho}\left(\frac{1}{\mu^0}\right) + \frac{1}{I^0_{\rho\rho}}\frac{\partial^2}{\partial\rho^2}\left(\frac{1}{\mu^0}\right) - \frac{3}{4}\frac{\mu^0}{I^0_{\rho\rho}}\left[\frac{\partial}{\partial\rho}\left(\frac{1}{\mu^0}\right)\right]^2\right\} - \frac{m[u_1\cos^2(\rho-\epsilon) + u_3\cos^2\epsilon + 2u_{13}\cos\epsilon\cos(\rho-\epsilon)]}{2(u_1u_3 - u_{13}^2)\sin^2\rho}\frac{\partial^2}{\partial\phi^2}$$

which coorresponds to the integration element $\rho d\rho d\phi$ and thus enables the use of the polar coordinate system. If the internuclear distances are assumed to be constant, it follows from eqs. [37] and [38] of ref. 18 that:

$$[4]\quad I^0_{\rho\rho} = \frac{u_1u_3 - u_{13}^2\cos^2\rho}{m(u_1 + u_3 + 2u_{13}\cos\rho)}$$

and

$$[5]\quad I^0_{yy}I^0_{zz} - I^0_{yz}I^0_{yz} = \frac{(u_1u_3 - u_{13}^2)\sin^2\rho}{m^2}$$

so that

$$[6]\quad \mu^0 = \left[\frac{\sin^2\rho}{m^4}(u_1u_3 - u_{13}^2\cos^2\rho)(u_1u_3 - u_{13}^2)\right]^{-1}$$

In explicit calculations the total Hamiltonian operator is written as

$$[7]\quad H = H_0 + H'$$

with

$$[8]\quad H_0 = \lim_{\rho\to 0} H = T_0 + \frac{1}{2}k\rho^2$$

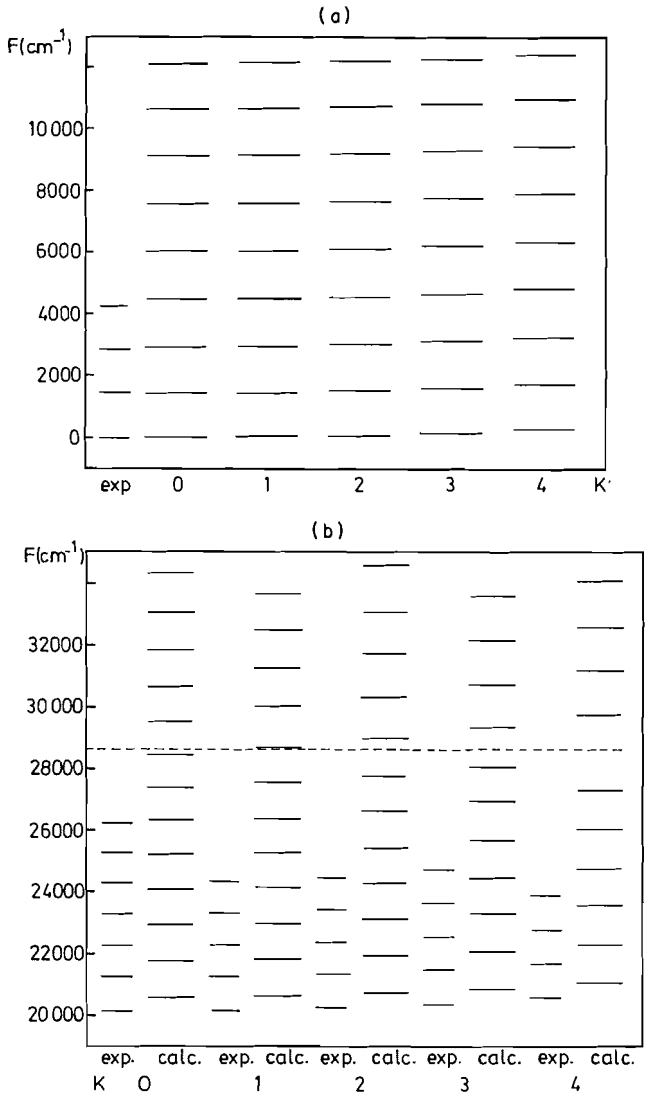

FIG. 3. Calculated $K = 0-4$ vibronic levels of the ground state X^2A'' (a) and excited state $^2A'$ (b) of HNF. Experimentally obtained term values (3, 4) are also shown.

and

$$[9] \quad T_0 = \lim_{\rho \to 0} T = -\frac{1}{2\mu}\left[\frac{\partial^2}{\partial\rho^2} + \frac{1}{\rho}\frac{\partial}{\partial\rho} - \frac{(K \pm \Lambda)^2}{\rho^2}\right]$$

whereby

$$[10] \quad \mu = \frac{u_1 u_3 - u_{13}^2}{m(u_1 + u_3 + 2u_{13})}$$

It should be noted that the force constant k in eq. [8] in general does not have any real physical meaning and can be chosen rather arbitrarily (19). The Hamiltonian [7] is diagonalized in the basis consisting of the eigenfunctions $R_{v,K\pm\Lambda}(\rho, \phi)$ of the two-dimensional harmonic oscillator H_0. The anharmonic part of the potential and the coefficients T_1', ..., T_4' ($T_i'(\rho) = T_i(\rho) - T_i^0$) are calculated for a number of ρ values ($\rho = 0°$, 1°, 2° ... 160°, for example) and the data points obtained are fitted in a power series expansion. The corresponding matrix elements are calculated in the manner described in refs. 19–21.

The Schrödinger equation for the stretching vibrations is solved with the help of the variational method, involving expansion of the vibrational wavefunctions in one-dimensional harmonic oscillator eigenfunctions and employing a polynomial fit for the electronic potential as described elsewhere (19). It has been assumed thereby that the two stretching vibrational modes are independent of one another; furthermore, the very simple form of the kinetic energy operators (diagonal elements of the G^{-1} matrix) is employed. Finally, by the calculations of rotational levels HNF have been treated as an asymmetric top, with the energies having been obtained by diagonalizing the corresponding operator in a basis of symmetric-top eigenfunctions (22).

Results and discussion

The first series of calculations were carried to determine the equilibrium geometries for the two lowest-lying states ($1^2A''$ and $1^2A'$) of HNF. A portion of the results of these calculations is presented in Fig. 1; the potential curves corresponding to the changes of the N—H and N—F distances at the H—N—F angle values of 100° (ground state GS) and 124° (excited state ES) are given. The energy values obtained at various levels of the treatment (SCF, MRD-CI, and estimated full CI) are presented and show large differences between the SCF and CI results in spite of the basically single-configuration nature of each of the two states. The calculated equilibrium data (obtained by means of a least-squares fit) are given in Table 1 and compared with the corresponding values obtained experimentally.

Having found the optimal interatomic distances for both electronic states, the calculation of the bending potential curves was carried out. For the ground state the N—H distance was kept constant at 1.935 au and N—F at 2.56 au; for the excited state the angular potential curve was calculated at N—H = 1.91 au and N—F = 2.51 au. The potential surfaces (MRD-CI values) obtained are presented in Fig. 2. The set of energy points calculated directly was augmented by a number of points generated by means of the cubic spline procedure and after that the potential surfaces have been fitted with the polynomials of the twentieth order in ρ. The $T_i(\rho)$ coefficients are thereby represented by polynomials of the sixteenth order of ρ. The vibronic energy levels are calculated with the help of the method described above, with 2×40 vibrational basis functions for each K value. The $K = 0$ levels are also indicated in Fig. 2. For the bending frequency the values of 1430 cm^{-1} for GS and 1176 cm^{-1} for ES are calculated, both results being obtained by taking the differences between the respective $v_2 = 1$ and $v_2 = 0$ term values. The computed vibronic levels for $K = 0, \ldots, 4$ are presented in Fig. 3 a and b together with the experimentally obtained term values. All calculated vibrational frequencies are collected in Table 1. For T_{00} a value of 20 600 cm^{-1} (compared to exp. 20 141 cm^{-1}) is obtained.

Very close agreement between the calculated and experimental values is not to be expected, in particular not for the stretching vibrational frequencies because of the rather unrealistic assumption of mutual independence of the various vibrational modes. It can also be noted (Fig. 3 a, b) that the agreement between the calculated and observed vibronic energy levels becomes progressively worse with higher quantum numbers, suggesting that the calculated potential curves are too steep; this effect is at least partially caused by the calculation of the bending curves at the constant internuclear distances, i.e. optimal for the equilibrium angles, but not for other values of this variable. Nevertheless, the overall vibronic structure based solely on the *ab initio* results gives a realistic picture of the spectrum.

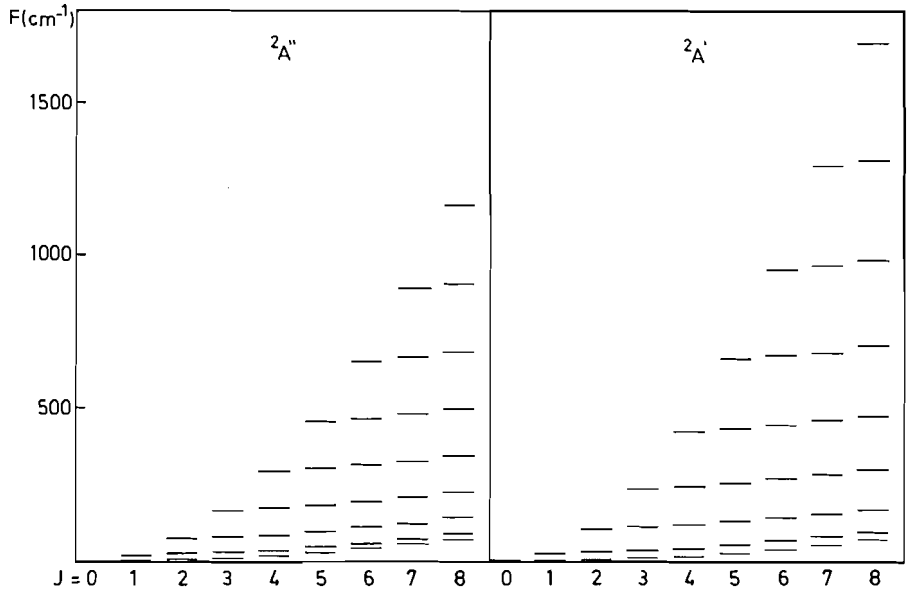

FIG. 4. Calculated rotational levels in the $^2A''$ and $^2A'$ electronic states of HNF.

The Franck–Condon factors for the transitions from the first bending vibrational level of the GS to various $K = 0$ levels of the ES are also shown in Fig. 2 for HNF and DNF. On the basis of the present calculations the strongest bands in the absorption spectrum should be those corresponding to $v_2' = 2$ and 3, whereas Woodman (3) observed the highest intensity in the second ($v_2' = 1$) and the third bands ($v_2' = 2$). The reason for this discrepancy is not clear since on the basis of the potentials themselves (Fig. 2), the vertical transition occurs to the third or fourth excited level rather than the second and direct inclusion of the electronic transition moment (zero at $\angle$HNF = 180° and increasing for smaller angles) into the intensity calculation is not likely to cause a shift relative to the Franck-Condon factors in this case.

In the emission spectrum the most intense bands should correspond to the transition from $v_2' = 0$ to $v_2'' -, 3$, again in some disagreement with the results of Lindsay *et al.* (4) who find $\Delta v_2 = 1$ transitions to be strongest and $\Delta v = 2$ bands to be appreciably weaker. The most intense bands in the stretching progression should definitely correspond to transitions between vibrationless states; the corresponding FC factors are 0.9963, 0.0003, and 0.0010 for $v_1' = 0, 1, 2$, (N—H vibrations) and 0.8538, 0.1230, and 0.0181 for $v_3' = 0, 1, 2$ (N—F vibrations) in the absorption spectrum of HNF.

In Fig. 4 the calculated rotational levels for both electronic states are presented. The corresponding rotational constants are given in Table 1. All the levels except the lowest ones appear practically in pairs; the very small J_τ splitting (which cannot be resolved in the scale used in Fig. 4) reflects the fact that HNF is nearly a symmetric top.

Summary

The present MRD-CI potential curves for the two lowest states of the HNF radical calculated in a standard AO basis (including some polarization functions) allow the geometrical parameters of the molecule to be computed within errors of less than 0.03 bohr and 4° from experimentally determined values. The calculated energy difference between the two states is $T_{00} = 20\,600$ cm^{-1}, compared to the most recent measured value of 20 141 cm^{-1}. Reduction of these discrepancies in the main requires larger AO basis sets, beyond that which has been employed in the present work.

The resulting potential energy curves have then been employed as the basis for a vibronic treatment of the $^2A'-X^2A''$ transition. The rather weak assumption of mutually independent vibrational stretching and bending modes is made. The coupling of the electronic wavefunction with the rotation and bending vibration (Renner–Teller effect) is described via a diagonalization procedure in which the coupling matrix elements (derivatives of the electronic wavefunction with respect to the azimuthal angle) are taken to be independent of the bending angle; the functional basis used thereby consists of two-dimensional harmonic oscillator functions and the corresponding Hamiltonian takes into account large-angle bending by multiplying the differential operators with bending-angle dependent coefficients represented as polynomials. The results, i.e. the K-structure of the transition, compare generally quite well with the measured data. Small discrepancies in the intensity distribution cannot be explained whereby qualitative arguments would seem to support the calculated results rather than those inferred experimentally. Deviations in the energy pattern relative to the observed data seem to result from simplifications made in the theoretical vibrational treatment. In general the present case study supports the position that standard CI calculations combined with a treatment of the Schrödinger equation for nuclear motion (employing a Hamiltonian which accounts for large-amplitude motion and vibronic coupling, if necessary) are capable of predicting to a quite useful level of accuracy the vibronic and rotational structure of electronic transitions in small molecules. These results in turn should be very helpful in interpreting and/or designing experiments from which more highly accurate details of the system under study can then be extracted.

E. COLACIO-RODRIGUEZ, J. D. LOPEZ-GONZALEZ, AND J. M. SALAS-PEREGRIN. Can. J. Chem. **61**, 2506 (1983).

New 1,3,8-trimethylxanthine complexes of Cu(II), Zn(II), Cd(II), and Hg(II) were prepared and studied by ir, H-nmr, magnetic measurements, TG, and DSC techniques. In the Cu(II), Zn(II), and Cd(II) complexes, the 1,3,8-trimethylxanthine is present in anionic form and the coordination to metal ion occurs probably through N_7 atom. In the mercury complex, coordination to metal ion is realized via the N_9 atom of neutral TMH.

E. COLACIO-RODRIGUEZ, J. D. LOPEZ-GONZALEZ et J. M. SALAS-PEREGRIN. Can. J. Chem. **61**, 2506 (1983).

On a préparé de nouveaux complexes triméthyl-1,3,8 xanthine de Cu(II), de Zn(II), de Cd(II) et de Hg(II) et on les a étudiés en faisant appel à la spectroscopie IR, la rmn du ^1H, les mesures magnétiques et les techniques de TG et de DSC. Dans les complexes de Cu(II), de Zn(II) et de Cd(II) la triméthyl-1,3,8 xanthine est sous forme anionique et la coordination à l'ion metallique s'établit probablement par l'intermédiaire de l'atome d'azote en position 7. Dans le cas du complexe de mercure la coordination à l'ion métallique s'établit par l'intermédiaire de l'atome d'azote en position 9 de la THM sous forme neutre.
[Traduit par le joural]

Introduction

The biological importance of purine bases (constituents of the nucleic acids) is well known. The interaction of metal ions with nucleic acids, nucleosides, and nucleotides has been an active area of inorganic and structural chemistry during the last few years and there exist a number of recent reviews on the subject (1, 2). Studies of the reaction of metal ions with the purine bases are important in establishing the sites of binding of the heterocyclic aromatic moiety and the stereochemistry of the compound formed. In this work the interaction of 1,3,8-trimethylxanthine with the metal ions Cu(II), Zn(II), Cd(II), and Hg(II) is studied.

Experimental

Materials

1,3,8-Trimethylxanthine (TMH) was synthesized according to the method described by Speer (3). The suitably formed isolated product was purified and characterized (melting point from its DSC curve is 329.4°C). The results obtained were in agreement with its molecular structure. All the organic salts used were of analytical reagent grade.

Methods

Infrared spectra in the region 4000−200 cm^{-1} of samples in KBr pellets were recorded using a Beckman-4250 spectrophotometer; similarly, spectra in the 600−200 cm^{-1} region of samples in polyethylene pellets were recorded.

Magnetic susceptibilities for copper complex were determined as a function of temperature (293 K, 206 K, 151 K, and 77 K) on a Bruker B-M4 apparatus. Weight changes were obtained from a Sartorius electrobalance. The temperature was controlled using an automatic temperature regulator and mercury tetrathiocyanato cobaltate was used as a standard.

The TG studies were made in static atmosphere of air (in the case of the mercury compound, a flow of 100 mL min^{-1} of pure air was used) on a Mettler TG-50 thermobalance, using a 6.5−9.4 mg sample and a heating rate of 10°C min^{-1}. On the other hand, DSC curves were obtained in a Mettler DSC-20 differential scanning calorimeter using a heating rate of 5°C min^{-1}.

The ^1H-nmr spectra were recorded of a R-600 Hitachi Perkin Elmer, FT-NMR spectrometer, using dimethyl sulfoxide-d_6 as solvent and TMS as standard reference. After which the bands of the NH_3 molecules were removed by the addition of a small amount of D_2O to the DMSO-d_6 solutions.

The microanalyses of C, H, and N were performed using a Carlo Erba 1106 microanalyzer. Metal determination were realized by atomic absorption, using a Perkin-Elmer model 290 spectrophotometer.

Preparation of the complexes

Reactions between TMH and Cu(II), Zn(II), Cd(II), and Hg(II) were carried out in neutral and basic conditions.

In neutral solution only the mercury complex is formed, whereas for Cu(II), Zn(II), and Cd(II), the reactions were not successful due to the precipitation of the ligand.

For the preparation of the complexes in basic medium, we have utilized NH_4OH solutions to preclude metal hydroxide precipitation. In this condition Hg(II) is precipitated as mercury ammine compounds.

Preparation of the $M(TM)_2(NH_3)_2$ compounds

A solution of 3 mmol of $M(NO_3)_2$ (M = Cu, Zn, or Cd), in 50 mL of 7 *M* NH_4OH was added to 6 mmol of 1,3,8-trimethylxanthine dissolved in 50 mL of 7 *M* NH_4OH. In the first hour, the clear solution was heated at 70°C with continuous stirring, and was then allowed to cool slowly to room temperature. The solid complexes precipitated in crystalline form and were filtered, washed consecutively with water, ethanol, and ether, and dried in air.

Preparation of $M(TMH)Cl_2$

A solution of 3 mmol of $HgCl_2$ in 50 mL of hot water was added to a solution of 6 mmol of 1,3,8-trimethylxanthine in 50 mL of hot water. The resulting clear solution was allowed to cool slowly to room temperature. After 1 h, colorless needles appeared, and were filtered, washed consecutively with water, ethanol, and ether, and dried in air.

The analytical data and color of the isolated compounds are: *Anal.* calcd. for $Cu(TM)_2(NH_3)_2$ (brown): C 39.71, H 4.96, N 28.96, Cu

Results and discussion

TMH may exist in two tautomeric forms, with a hydrogen atom localized in N_7 or N_9 atoms. However, in the crystal structure of theophylline (4, 5), analogous to TMH, the imidazole proton was found to be on N(7) rather than on N(9), and we believe that the N_7 tautomeric form in TMH is probably of lower energy.

From the structure of TMH, only N_7 and N_9 positions are available for coordination to metal ions.

The infrared spectrum of TMH shows characteristic absorptions at 3180 cm^{-1} $\nu(N_7—H)$ (this band has been corroborated by deuteration ($\nu(N_7—D)$ = 2380 cm^{-1}), 2940, 2820 cm^{-1} $\nu(CH_3)$, 1710 cm^{-1} $\nu(C_2=O)$ and 1630 cm^{-1} $\nu(C_6=O)$. The low frequency of $\nu(C_6=O)$ suggests the presence of a hydrogen-bond between $O_6—H_7$ atoms, which also occurs in other xanthine derivatives (6).

^{1}H-nmr spectrum of TMH in DMSO-d_6 shows three proton signals at 2.4 ppm ($C_8—CH_3$), 3.3− ppm ($N_1—CH_3$), and 3.5 ppm ($N_3—CH_3$). The corresponding signal to ($N_7—H$) has been not observed. The assignments of these signals are in accordance with the bibliographic data for other methylxanthine derivatives (7, 8).

TG studies on the compounds $Cu(TM)_2(NH_3)_2$ (**I**), $Zn(TM)_2(NH_3)_2$ (**II**), and $Cd(TM)_2(NH_3)_2$ (**III**) show that two molecules of ammonia are present in all cases. Theoretic loss weight percentages (**I** = 7.03, **II** = 7.00, and **III** = 6.39) for the elimination of ammonia molecules are in good agreement with experimental values (**I** = 7.3; **II** = 6.7; **III** = 6.8). The endothermic effects associated with the elimination of these ammonia molecules have been observed in DSC curves at the same temperature. Likewise, TG and DSC studies on the $Hg(TMH)Cl_2$ (**IV**) show the anhydrous nature of this compound.

The presence of coordinated ammonia to Cu(II), Zn(II), and Cd(II) in the corresponding complexes, can be suggested by the following bands: copper complex: 3310 cm^{-1} and 3210 cm^{-1} $\nu(N—H)$; 1125 cm^{-1} $\delta_s(H—N—H)$; 695 cm^{-1} $\rho(NH)$; 460 cm^{-1} $\nu(Cu—NH_3)$; zinc complex: 3350 and 3160 cm^{-1} $\nu(NH)$; 1170 cm^{-1} $\delta_s(H—N—H)$; 395 cm^{-1} $\nu(Zn—NH_3)$; cadmium complex: 3380 and 3250 cm^{-1} $\nu(N—H)$; 1115 cm^{-1} $\delta_s(H—N—H)$, 680 cm^{-1} $\rho(NH_3)$; 445 cm^{-1} $\nu(Cd—NH_3)$.

The second band assigned to $\nu(N—H)$, in the zinc complex (3160 cm^{-1}) is due to coordinated ammonia since under our experimental conditions (pH = 9.7), TMH will be in anionic form.

The assignment of these bands are in agreement with the bibliographic data of ammonia complexes (9).

Complexes **I**, **II**, and **III** did not show the band corresponding to $\nu(N_7—H)$, which in infrared spectrum of free TMH occurs at 3180 cm^{-1}. This observation suggests that coordination of TMH to metal ions takes place in anionic form through N_7 or N_9 atoms. Another marked difference between the TMH and its complexes is the displacement of stretching vibrations corresponding to carbonyl groups, 1680 and 1660 cm^{-1} (**I**), 1680 and 1630 cm^{-1} (**II**), 1695 and 1630 cm^{-1} (**III**), may be indicative of possible hydrogen bond interactions between oxygen atoms of TMH and ammonia molecules.

The infrared spectrum of mercury complex **IV** shows a band at 3160 cm^{-1}, corresponding to $\nu(N—H)$ (this band appears at 3180 cm^{-1} in free TMH). The presence of this band suggests that, in this case, coordination of TMH to Hg(II) takes place through the N_9 atom. In this complex $\nu(C=O)$ appears at 1702 cm^{-1} and 1645 cm^{-1}. The band at 240 cm^{-1} has been assigned to $\nu(Hg—Cl)$.

Chemical shifts and the assignment of the individual ^{1}H-resonance of the prepared compounds in DMSO-d_6 are listed in Table 1.

The upfield shifts of signals corresponding to methyl protons at C_8 in $Zn(TM)_2(NH_3)_2$ and $Cd(TM)_2(NH_3)_2$ indicates, according to the literature (10, 11), the anionic coordination of TMH through N_7 or N_9 atoms. The $N_1—CH_3$ and $N_3—CH_3$ signals practically are not shifted, since charge densities are generally affected more at the atom which is closest to the binding site. The NH_3 peaks resonances are removed when D_2O is added to DMSO-d_6 solutions of complexes **II** and **III**.

In the ^{1}H-nmr spectrum of $(TMH)HgCl_2$ there is no shift of the $C_8—CH_3$ signal. This fact could probably be explained assuming the break of metal—N_9 bonding under our experimental conditions (strong heating due to low solubility in DMSO-d_6 of the complex).

In Table 2 are summarized the found values for the molar magnetic susceptibility and μ_{eff} of $Cu(TM)_2(NH_3)_2$. The room temperature magnetic moment of the new metal complex is normal for high-spin $3d^9$ configuration (12). A small decrease of the magnetic moment (0.16 BM) was observed when the temperature was lowered from 293 K to 77 K. Plot of $1/\chi_M$ vs. T shows that the Curie−Weiss law is obeyed in 293−77 K range, and the Weiss constant corresponding to the plot is −24°. Additional magnetic studies covering the 77−4.2 K

TABLE 2. Values of the magnetic susceptibility for $Cu(TM)_2(NH_3)_2$

T (K)	$\chi_g \cdot 10^6$ (ucgs g^{-1})	$\chi_M \cdot 10^4$ (ucgs mol^{-1})	μ_{eff} (BM)
293	2.7	15.04	1.88
206	3.8	20.59	1.84
151	5.1	26.29	1.80
77	9.5	47.97	1.72

region would be necessary to reveal the possible spin–spin interactions. These studies are planned for the near future. The magnetic evidence available (μ_{eff} decreases with temperature, negative θ) is in favor of bi- or polynuclear rather than monomeric configuration for this compound (13, 14) although due to the small decrease of μ_{eff}, the type of configuration is not clear.

On the basis of experimental results for complexes **I**, **II**, and **III**, two structure assignments are possible: a distorted tetrahedral or a polymeric octahedral with purine bridging (N_7 and N_9 bonds). The second structure type (although the available magnetic data are in agreement with it) has not been found in the xanthine complexes described in the literature; in these complexes, xanthine derivatives ligands use, in anionic form only, a coordination position (normally N_7 (15, 16). Thus the tetrahedral structure is the more probable structure for these complexes (the solubility of the metal complexes in organic media also favors the tetrahedral structure over the polymeric structure).

Received March 1, 1983

JOSÉ A. BARBERO, LOREN G. HEPLER, KEITH G. MCCURDY, and PETER R. TREMAINE. Can. J. Chem. **61**, 2509 (1983).

A flow microcalorimeter and vibrating tube densimeter were used at 25°C to obtain apparent molar heat capacities and volumes of aqueous $NaHCO_3$, $KHCO_3$, $NaHSO_3$, and $KHSO_3$ from 0.1 to 1.0 mol kg^{-1}, aqueous CO_2 from 0.01 to 0.10 mol kg^{-1} and aqueous SO_2 from 0.045 to 2.0 mol kg^{-1}. The contribution of "chemical relaxation" (changes in equilibrium state and enthalpy due to change in temperature) to the experimental heat capacities of aqueous SO_2 required special attention, leading to the derivation of a new equation for calculating this effect. Standard state values for the heat capacities and volumes of aqueous CO_2, SO_2, HCO_3^-, and HSO_3^- were obtained from the apparent molar properties by extrapolation to infinite dilution. Combining these results with other thermodynamic data from the literature gave estimates of $\log K_1^b$, the equilibrium constant for the first neutralization of CO_2 and SO_2, at high temperatures. The results for CO_2 reproduce very accurate literature values to within 0.2 at 200°C. The expression for the reaction $SO_2 + OH^- \rightleftarrows HSO_3^-$, $\log K_1^b = 22.771 + 2776.0/T - 8.058 \log T$, is consistent with the sparse and limited experimental data.

JOSÉ A. BARBERO, LOREN G. HEPLER, KEITH G. MCCURDY et PETER R. TREMAINE. Can. J. Chem. **61**, 2509 (1983).

On a utilisé un microcalorimètre à écoulement et un densimètre à tube vibrant à 25°C pour obtenir les capacités calorifiques molaires apparentes et les volumes de $NaHCO_3$, de $KHCO_3$ et de $KHSO_3$ aqueux de 0,1 à 1,0 mol kg^{-1}, de CO_2 aqueux de 0,01 à 0,10 mol kg^{-1} et de SO_2 aqueux de 0,045 à 2,0 mol kg^{-1}. La contribution de la "relaxation chimique" (variations de l'état d'équilibre et d'enthalpie due à une variation de température) aux capacités calorifiques expérimentales du SO_2 aqueux requiert une attention spéciale et conduit à dériver une nouvelle équation pour calculer cet effet. On a obtenu les valeurs normales des capacités calorifiques et les volumes de CO_2, SO_2, HCO_3^- et HSO_3^- aqueux à partir des propriétés molaires apparentes par extrapolation à dilution infinie. La combinaison de ces résultats avec les autres données thermodynamiques relevées dans la littérature donne des évaluations de $\log K_1^b$, la constante d'équilibre de première neutralisation de CO_2 et de SO_2 à haute température. Les résultats relatifs à CO_2 reproduisent de façon très précise les valeurs de la littérature avec une précision de 0,2 à 200°C. L'expression $\log K_1^b = 22,771 + 2776,0/T - 8,058 \log T$ pour la réaction $SO_2 + OH^- \rightleftarrows HSO_3^-$, est en accord avec les données expérimentales peu nombreuses et limitées.

[Traduit par le journal]

Introduction

Thermodynamic properties of aqueous carbon dioxide and sulfur dioxide and their ionization products are required over a range of temperature to model steam injection and combustion processes for the *in situ* extraction of bitumen and heavy oil. These same thermodynamic properties are also important in connection with such varied problems as wet oxidation boilers, geothermal water systems, water–mineral and water–scale interactions, chemical wood-pulping processes, various pollution control problems, and certain aspects of the chemistry of seawater and blood.

Vapour pressure data and ionization constants have now been reported for aqueous CO_2 over a wide range of temperature (1–5) and for aqueous SO_2 at lower temperatures only (1, 6–12). Standard state enthalpies of solution and ionization for both acid gases (13–17), and partial molar heat capacities for the hydrogen carbonate (18–20) and hydrogen sulfite ions (21) at 25°C are also known. However, the apparent molar heat capacities of aqueous CO_2, SO_2, and indeed most other dissolved gases, have not been measured directly. The purpose of the present investigation has been to measure these heat capacities at 25°C and to use them with other thermodynamic data at 25°C to estimate various equilibrium constants over wide ranges of temperature. Comparisons of these calculated equilibrium constants with those that have been directly measured at high temperature and pressure help to establish the range of validity of the various methods for performing such extrapolations. In cases where the experimental measurements are sparse, the extrapolated equilibrium constants provide tentative values for use until accurate data are available.

Experimental

The heat capacity and density of each solution were measured relative to water using a commercial Picker flow microcalorimeter (22), vibrating tube densimeter (23), and the injection system reported in our earlier, similar study on aqueous H_2S (24). Values cited by Kell (25) for the specific heat capacity and density of pure water at 25°C, $c_{p1}^0 = 4.1793$ J K^{-1} g^{-1} and $d_1^0 = 0.997045$ g cm^{-3}, were used in the calculations. The average of the apparent molar heat capacities from the two calorimeter cells was multiplied by the mean heat leak correction factor $f = 1.009 \pm 0.003$, which we obtained by calibration with aqueous NaCl in the usual way (19).

The preparation and handling of chemicals was similar to that in our

previous study (24). Distilled water was passed through a Milli-Q reagent grade mixed bed ion exchange and activated carbon system, then vigorously purged with helium immediately before use (final conductivity 1 μS cm^{-1} or less). Fisher Certified ACS anhydrous potassium hydrogen carbonate and sodium hydrogen carbonate, B.D.H. AnalaR potassium hydrogen carbonate and Mallinckrodt Analytical Reagent sodium hydrogen carbonate were dried and then used without further purification. Stock solutions were prepared by mass, then used to prepare more dilute solutions by volumetric dilution. Some of these were also titrated with HCl using bromocresol green indicator. Fisher standardized HCl solutions were checked by titration against Fisher "primary standard" tris(hydroxymethyl)aminomethane.

Stock solutions of sodium and potassium hydrogen sulfite were initially prepared from the Baker Analyzed and Fisher Certified ACS products taken from freshly opened bottles, then standardized by adding an excess of iodine and back titrating with thiosulfate solution. Since aqueous hydrogen sulfite ion is very easily oxidized, we also prepared stock solutions *in situ* by bubbling sulphur dioxide through water in a closed, oxygen-free system, while maintaining the pH in the range 3.5 to 4.5 by dripping in aqueous NaOH or KOH that had been purged with helium. The rather irreproducible heat capacity results from solutions of the commercial crystals were more negative by 5 to 25 J K^{-1} mol^{-1} than those prepared from SO_2 and KOH, probably because of contamination by sulfate or thiosulfate, both of which have very negative heat capacities (26). The presence of sulfate was confirmed by testing with a few drops of aqueous barium hydroxide and, consequently, no data from solutions of the crystals are reported in this study. Some of the $NaHSO_3$ solutions prepared from commercial crystals reacted only slightly to the barium hydroxide test and yielded heat capacity results in good agreement with solutions prepared from SO_2 and aqueous NaOH. These results were considered to be reliable.

Anhydrous CO_2 and SO_2 were obtained from Canadian Liquid Air and Matheson, respectively. The SO_2 was analyzed by gas chromatography and contained less than 0.1% N_2 and CO_2 and no detectable amounts of H_2S, COS, or hydrocarbon impurities (<0.05%). Solutions of aqueous CO_2 and SO_2 were prepared by bubbling the gas into water in a closed pressure bottle, which allowed overpressures of up to 300 kPa. As in our previous investigation of H_2S (24), both the bottle containing the gas solution and that containing the pure water reference liquid were connected to the same cylinder of ultra high purity nitrogen so that manipulating a three-way stopcock allowed either to be pressurized. A second three-way stopcock allowed either solution to be forced into the calorimeter or densimeter by the overpressure of nitrogen and a needle valve downstream of the instruments controlled the flow rate. The CO_2 solutions were standardized by diverting the tubing from the exit so that the solutions flowed under the surface of a known weight of standardized $Ba(OH)_2$ solution, contained in a small bottle, with a few drops of carbonate-free phenolphthalein indicator added. The indicator allowed the flow of the CO_2

* $Y_\phi = Y_\phi^{\infty} + A_Y(d_1^0 m)^{1/2} + B_Y m$. Debye–Hückel limiting slopes for the electrolytes are $A_C(d_1^0)^{1/2}$ = 28.945 J kg$^{1/2}$ K^{-1} mol^{-1} and $A_V(d_1^0)^{1/2}$ = 1.865 cm^3 kg$^{1/2}$ mol^{-1}. For SO_2^0(aq) and CO_2^0(aq), A_Y = 0. Parameters for SO_2^0(aq) refer to ionic strength, αm, rather than bulk molality. The values for $NaHCO_3$ and $KHCO_3$ contain a very small contribution from disproportionation to CO_2^0(aq) + H_2O + CO_3^{2-}.

† The stated ± values are the standard deviations in Y_ϕ^{∞} and B_Y from the least squares fits, and are a measure of the precision of the fit.

solution to be stopped while excess $Ba(OH)_2$ was present, so that the concentration of CO_2 in the solution could be determined from the weight gain and a back titration of the excess hydroxide with HCl. The exact same procedure was used for handling and analyzing the aqueous SO_2, except that it was trapped in a weighed aliquot of iodine solution and the back titration of excess iodine was done using thiosulfate solution.

Experimental results and analysis of data

Aqueous salts and carbon dioxide

Apparent molar heat capacities, $C_{p\phi}$, and volumes, V_ϕ, are defined by the expression

$$[1] \quad Y_\phi = (Y - n_1 Y_1^0)/n_2$$

where Y is the extensive property of the aqueous solution, Y_1^0 is the property of one mole of pure solvent, and n_1 and n_2 are the number of moles of water and solute respectively so that, if n_1 = 55.509, n_2 is equal to the molality, m. The experimental apparent molar data for the aqueous hydrogen carbonate and hydrogen sulfite salts and aqueous carbon dioxide are tabulated in Table 1. These data are not complicated by any significant degree of ionization or association and can be analyzed in a straightforward fashion using the methods presented below. Heat capacity data for aqueous sulfur dioxide are more difficult to assess because of ionization effects. The experimental results are listed in Table 2, along with other data that will be used to treat these results later in the paper.

Following Roux *et al.* (27) we used the least squares method to fit expressions of the form

$$[2] \quad Y_\phi = Y_\phi^{\infty} + A_Y(d_1^0 m)^{1/2} + B_Y m$$

to the $C_{p\phi}$ and V_ϕ data for the aqueous electrolytes. Here, Y_ϕ^{∞} is the value of Y_ϕ at infinite dilution, $A_Y(d_1^0)^{1/2}$ is the Debye–Hückel limiting slope at the temperature in question on the molality scale, and B_Y is an adjustable parameter.

The values of $C_{p\phi}^{\infty}$, B_C, V_ϕ^{∞}, and B_V that were obtained for $NaHCO_3$, $KHCO_3$, $NaHSO_3$, and $KHSO_3$, are listed in Table 3 along with the Debye–Hückel terms (28) used in the fit. The experimental and fitted values of $C_{p\phi}$ and V_ϕ are plotted in Figs. 1 and 2. The precision can be estimated from the standard deviations of Y_ϕ^{∞} and B, which are included in Table 3. The values for $NaHCO_3$ and $KHCO_3$ include a very small contribution from the disproportionation of HCO_3^- to aqueous CO_2 and CO_3^{2-}, which is discussed in detail later in this paper.

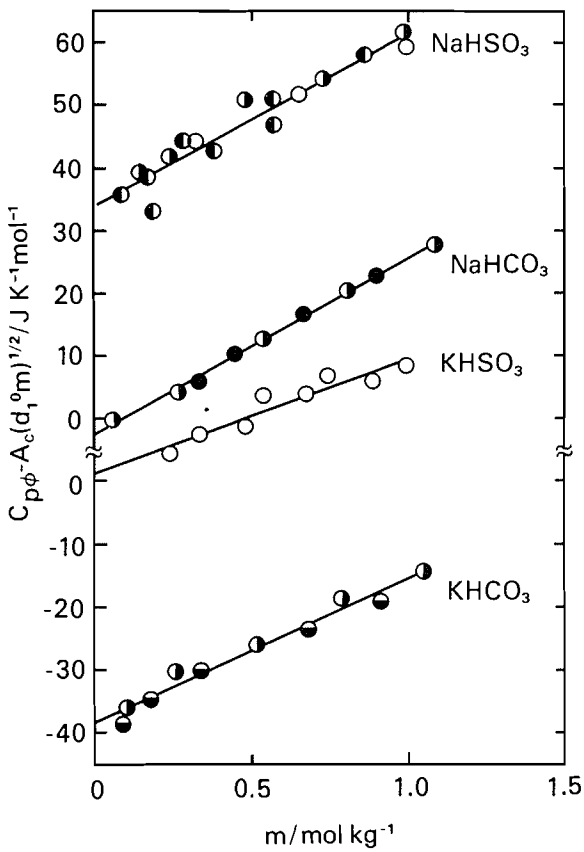

FIG. 1. Apparent molar heat capacities of aqueous hydrogen sulfite and hydrogen carbonate salts at 25°C after subtracting the Debye–Hückel limiting term: ○, synthesized *in situ* from the gas; ◑, ◐, ◒, ●, from salts. The lines are least squares fits.

The apparent molar properties for aqueous CO_2 in Table 1 were obtained at molalities below 0.1 mol kg^{-1} where CO_2 is known to be described by Henry's law (1), and are plotted in Fig. 3. Since no appreciable fraction ionizes under these conditions (3), the measured values were taken to be those at infinite dilution, $Y_\phi^{\infty} = Y^0$, corresponding to the equilibrium mixture of unhydrated CO_2 and H_2CO_3, which we define as CO_2^0 (aq). Averaging the results yields $C_p^0(CO_2^0, aq)$ = 243 J K^{-1} mol^{-1}

and $V^0(CO_2^0, aq) = 32.8\ cm^3\ mol^{-1}$, with standard deviations of 7 J K^{-1} mol^{-1} and 1.2 cm^3 mol^{-1}, respectively.

Aqueous sulfur dioxide

Aqueous solutions of sulfur dioxide are acidic because of the equilibrium represented by

[3] $$SO_2^0(aq) + H_2O(l) \rightleftarrows H^+(aq) + HSO_3^-(aq)$$

At 25°C, the neutral species $SO_2^0(aq)$ and the dissociated, ionic species $HSO_3^-(aq)$ are both present in significant amounts but equilibria involving other species such as $S_2O_5^{2-}$ and SO_3^{2-} are not important at the concentrations studied here. In the discussions that follow, we distinguish between the neutral *species* $SO_2^0(aq)$, and *stoichiometric solutions* of SO_2 which are written as $SO_2(aq)$ without the superscript, and which include the equilibrium proportions of the species $SO_2^0(aq)$ and $HSO_3^-(aq)$. The experimental apparent molar volumes and heat capacities in Table 2, $V_\phi^{exp}(SO_2, aq)$ and $C_{p\phi}^{exp}(SO_2, aq)$, refer to the stoichiometric solutions. With proper attention to detail, the apparent molar properties of each of the species can be calculated from these experimental values. We first consider the volumetric results, then the more complicated analysis of heat capacities.

The experimental apparent molar volumes in Table 2 are considered to result from an appropriate sum of contributions of the species in solution, as expressed by

[4] $$V_\phi^{exp}(SO_2, aq) = (1 - \alpha)\, V_\phi(SO_2^0, aq) + \alpha\, V_\phi(H^+ + HSO_3^-, aq) - \alpha V(H_2O)$$

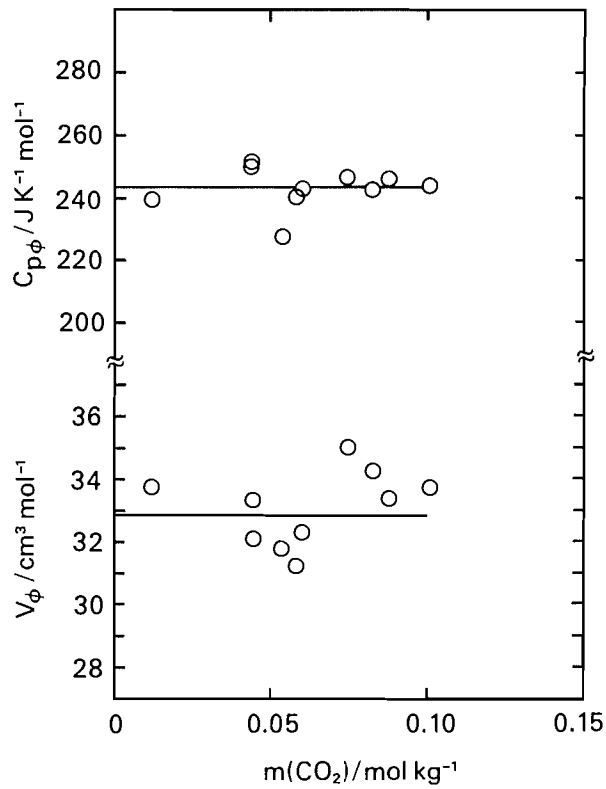

FIG. 3. Apparent molar heat capacities and volumes for aqueous CO_2.

Here, α represents the fraction of stoichiometric sulfur dioxide converted to $H^+(aq) + HSO_3^-(aq)$. For purposes of calculating $V^0(SO_2^0, aq)$, we assume that $V(H_2O) = V^0(H_2O)$ at these small molalities, and that the presence of aqueous SO_2 does not affect the ionic strength dependence of $V_\phi(H^+ + HSO_3^-, aq)$ as described by eq. [2]. Applying these assumptions yields the expression

[5] $$V_\phi(SO_2^0, aq) = \frac{1}{1-\alpha}\{V_\phi^{exp}(SO_2, aq) - \alpha\,[V^0(H^+ + HSO_3^-, aq) + A_V(d_1^0)^{1/2}\,(\alpha m)^{1/2} + B_V(H^+ + HSO_3^-, aq)\,\alpha m] + \alpha V^0(H_2O)\}$$

The degree of dissociation, α, can be calculated from the equilibrium constant for reaction [3],

[6] $$K_1 = m(H^+, aq)\, m(HSO_3^-, aq)\, \gamma_\pm^2 / m(SO_2^0, aq)\gamma_u$$

where $\gamma_\pm$ and γ_u are the activity coefficients of the ionic and undissociated, electrically neutral species, respectively. Literature values for this equilibrium constant have been reviewed by Hepler and Hopkins (29) and by Sadiq and Lindsay (30). We chose Huss and Eckert's recent results (6), $K_1 = 0.0139 \pm 0.0002$ and converted their activity coefficient expression from molarities to molalities to obtain

[7] $$\log(\gamma_\pm/\gamma_u^{1/2}) = \frac{-0.5107 m_i^{1/2}}{1 + 1.643 m_i^{1/2}} + 0.260 m_i$$

in which m_i refers to the molality of ions in a dilute aqueous solution at 25°C.

The values calculated for α are included in Table 2. Because the degree of dissociation decreases with increasing molality, the ionic strength of the solutions, αm, remains quite low. As

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12

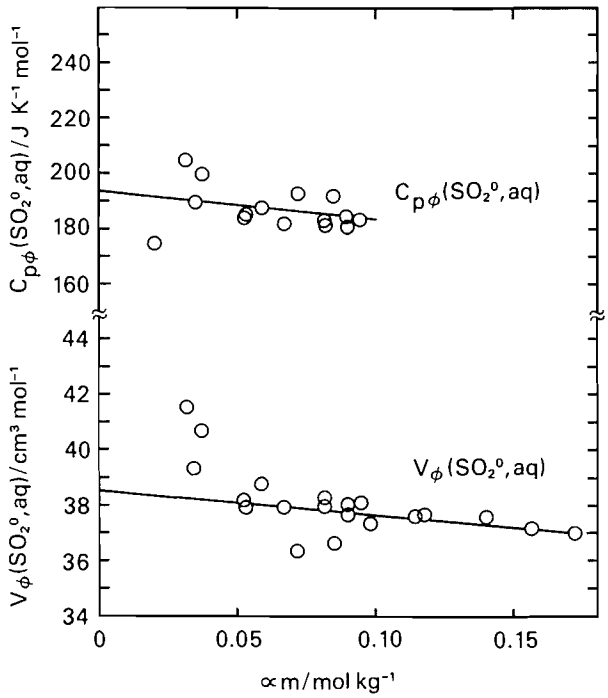

FIG. 4. Apparent molar heat capacities and volumes for the unionized aqueous species $SO_2^0(aq)$, as a function of the ionic strength due to the equilibrium concentration of HSO_3^-. The lines are least squares fits.

a result, the concentration dependence of $V_\phi(H^+ + HSO_3^-, aq)$ is described well by the Debye–Hückel limiting law, and the B_V term in eq. [5] makes only a minor contribution. An approximate value for $B_V(H^+ + HSO_3^-, aq)$ was estimated by assuming that the ionic contributions determined from pure systems are approximately additive, so that

$$B_V(H^+ + HSO_3^-, aq) \approx B_V(NaHSO_3, aq) - B_V(NaCl, aq) + B_V(HCl, aq) = 0.2 \text{ cm}^3 \text{ mol}^{-2} \text{ kg}$$

based on B_V values from ref. 31 and Table 2. The value $V^0(H^+ + HSO_3^-, aq) = 33.5$ cm^3 mol^{-1} was obtained from a similar additivity scheme, described later in the discussion of "best" standard state values.

Apparent molar volumes for undissociated SO_2 calculated from the data and equations outlined above are listed in Table 2 and plotted in Fig. 4 as a function of αm. The ionic strength dependence of $V_\phi(SO_2^0, aq)$ undoubtedly results from some combination of salting out effects (probably small), the approximations inherent in the method, and uncertainties in the degree of dissociation. We chose to calculate the infinite dilution value, $V_\phi^\infty(SO_2^0, aq) = 38.5$ cm^3 mol^{-1}, by fitting a least squares linear function in αm to the data for ionic strengths above 0.05 m. The coefficients and standard deviations are included in Table 3.

Before we can analyze the heat capacities of sulfur dioxide solutions in terms of contributions from the various species present, as in eq. [4] for volumes, it is necessary to recognize that the heat capacity is a sum of contributions from the chemical species plus a contribution due to "relaxation" of the temperature dependent equilibrium represented by [3]. This effect is caused by a shift in the degree of dissociation due to the temperature increment imposed by the calorimeter in the course of measuring the heat capacity. Thus we write

$$[8] \quad C_{p\phi}^{exp} = C_{p\phi}^{sp} + C_{p\phi}^{rel}$$

in which superscripts exp, sp, and rel refer to total experimental apparent molar heat capacity and contributions from chemical species and relaxation, respectively. It has been shown (32–34) that

$$[9] \quad C_{p\phi}^{rel} = \Delta H(\partial\alpha/\partial T)_m$$

Here, ΔH is the enthalpy of reaction at the molality of the solution and $(\partial\alpha/\partial T)_m$ is the shift in the degree of dissociation in the solution with temperature. Combining [8] and [9] gives

$$[10] \quad C_{p\phi}^{sp} = C_{p\phi}^{exp} - \Delta H(\partial\alpha/\partial T)_m$$

Analytic expressions for calculating $\Delta H(\partial\alpha/\partial T)_m$ have been derived for simple ionization or association reactions (32, 33). Some of the simplifying assumptions in these derivations cannot be used when the equilibrium concentrations of all the reactants and products are of the same order of magnitude. Peiper and Pitzer (14) have reported accurate numerical methods for making this calculation. Our method is based on an analytic equation whose derivation is described in Appendix I along with our sources for the necessary enthalpy data. Unfortunately, these enthalpy data only extend up to 0.55 m. The values for $\Delta H(\partial\alpha/\partial T)_m$ from our treatment are listed in Table 2. These were subtracted from $C_{p\phi}^{exp}(SO_2, aq)$ to yield the values for the equilibrium mixture of species in each stoichiometric solution, $C_{p\phi}^{sp}(SO_2, aq)$, also included in the table.

The apparent molar heat capacities of the neutral species $SO_2^0(aq)$ were then evaluated using an expression exactly analogous to that for the volume calculation:

$$[11] \quad C_{p\phi}(SO_2^0, aq) = \frac{1}{1-\alpha}\{C_{p\phi}^{sp}(SO_2, aq) - \alpha[C_p^0(H^+ + HSO_3^-, aq) + A_C(d_l^0)^{1/2}(\alpha m)^{1/2} + B_C(H^+ + HSO_3^-, aq)\,\alpha m] + \alpha C_p^0(H_2O)\}$$

Again, the B_C and C_p^0 terms for the salt were estimated assuming ionic additivity. From data for the sodium salts in ref. 31 and Table 3, $B_C(H^+ + HSO_3^-, aq) \approx 5$ J K^{-1} mol^{-2} kg and, from the scheme described later in this paper, $C_p^0(H^+ + HSO_3^-, aq) = -10$ J K^{-1} mol^{-1}. The resulting values for $C_{p\phi}(SO_2^0, aq)$ are included in Table 2 and plotted in Fig. 4. The infinite dilution value, $C_{p\phi}^\infty(SO_2^0, aq) = 195$ J K^{-1} mol^{-1}, was obtained by a linear least squares fit to all the data, in the manner used for the volumes. The standard deviations and other fitted parameters are listed in Table 3.

Discussion

Standard state properties

The limiting values $C_{p\phi}^\infty$ and V_ϕ^∞ can be shown to be equal to the standard state properties, C_p^0 and V^0. The purpose of this section is to critically compare the results in Table 3 with those of other workers to arrive at "best" values, then to separate these into anionic and cationic contributions according to the conventional scale $[C_p^0(H^+) \equiv 0,\ V^0(H^+) \equiv 0]$. This calculation was based on C_p^0 and V^0 values for $Na^+(aq)$, $K^+(aq)$, and $OH^-(aq)$ listed in Table 4, from Desnoyers *et al.* (19), Roux *et al.* (27), and Millero (35). A detailed examination of all recently published heat capacity values, recently carried out in our laboratories, confirmed these assignments for ionic heat capacities to within 1 J K^{-1} mol^{-1}.

Our experimental values for $C_{p\phi}(NaHCO_3, aq)$ agree well

TABLE 4. Critically evaluated standard state functions at 25°C*

Ion	C_p^0/J K^{-1} mol^{-1}	V^0/cm^3 mol^{-1}
Na^+(aq)	43	−1.26
K^+(aq)	13	9.0
Cl^-(aq)	−126	18.1
OH^-(aq)	−138	−4.2
HCO_3^-(aq)	−53±4	24.9 ±0.1
HSO_3^-(aq)	−10±4	33.5 ±0.4
CO_2^0(aq)	243±10	32.8 ±2
SO_2^0(aq)	195±10	38.5 ±2

*Ionic values are based on $C_p^0(H^+) = 0$ and $V^0(H^+) = 0$. Values for Na^+, K^+, Cl^-, and OH^- are from Desnoyers *et al.* (19), Roux *et al.* (27), and Millero (35). Here the stated ± values are our estimates of the overall accuracy of the results, as discussed in the text.

with those of Desnoyers *et al.* (18, 19) after their results were corrected for heat leaks (19). Their measurements were taken with a Picker calorimeter similar to ours and are systematically more negative by about 3 J K^{-1} mol^{-1}. As we noted above, aqueous HCO_3^- disproportionates to form CO_2 and HCO_3^-, and both sets of data must be corrected for this effect. Peiper and Pitzer (14) have calculated this correction in a rigorous way, based on the assumption that the equilibrium concentration of CO_2 gas formed during the course of each calorimetric measurement. They estimate that disproportionation caused Desnoyer's value for $C_p^0(HCO_3^-, aq)$ to be too positive by 4 J K^{-1} mol^{-1}. For the calculations in this paper, we assumed that CO_2 formed by disproportionation to the aqueous species, but did not nucleate as the gas. In this case, the degree of dissociation of HCO_3^- is nearly independent of molality, and the correction to $C_{p\phi}^{\infty}(HCO_3^-, aq)$ due to chemical relaxation can be calculated by taking $C_{p\phi}^{rel} \approx (\Delta H^0)^2\alpha/2RT^2$ (see Appendix or ref. 32). Using free energy and enthalpy data from Berg and Vanderzee (13), we calculate the degree of disproportionation to be 0.0205 in dilute solutions and the relaxation effect to be 0.43 J K^{-1} mol^{-1}. The net correction to $C_{p\phi}^{\infty}(HCO_3^-, aq)$, from equations analogous to [10] and [11], is −1.5 J K^{-1} mol^{-1}.

The corrected values for $C_{p\phi}^{\infty}(NaHCO_3, aq)$, −4.1 J K^{-1} mol^{-1} from this work, and −8.7 J K^{-1} mol^{-1} from Desnoyers *et al.* (18, 19) compare to the value −11.6 J K^{-1} mol^{-1} reported by Larson *et al.* (20). The spread between our result and Larson's is about double the usually accepted accuracy of 4 J K^{-1} mol^{-1}, for such measurements (27). Larson's result was obtained from $NaHCO_3/Na_2CO_3$ buffer solutions as part of a study to obtain data for the carbonate ion, and required a method to separate the contribution of the two mixed electrolytes, which may have slightly affected the accuracy. Our own data did not extend to the very low molalities studied by Desnoyers *et al.* and thus our limiting value may be less accurate. Combining Desnoyer's result with $C_p^0(Na^+, aq)$ from Table 4 yields $C_p^0(HCO_3^-, aq) = -52$ J K^{-1} mol^{-1}. A similar calculation based on our corrected value for the potassium salt, $C_{p\phi}^{\infty}(KHCO_3, aq) = -40.0$ J K^{-1} mol^{-1}, gives $C_p^0(HCO_3^-, aq) = -53$ J K^{-1} mol^{-1}. We propose that the value −53 J K^{-1} mol^{-1} be taken as the "best" value for $C_p^0(HCO_3^-, aq)$ and assign it an uncertainty of ±4 J K^{-1} mol^{-1} based on the scatter of the sodium results and the uncertainty in the correction for disproportionation.

Our value $V_\phi^{\infty}(NaHCO_3, aq) = 23.62$ cm^3 mol^{-1} agrees with the values 23.45 and 23.6 cm^3 mol^{-1} reported by Perron *et al.* (18) and Larson *et al.* (20), respectively. Millero (35) cited the values $V_\phi^{\infty}(KHCO_3, aq) = 32.7$ and 30.7 cm^3 mol^{-1} from reviews of work done before 1940. These are slightly less positive than our value, 33.9 cm^3 mol^{-1}. The contribution from the disporportionation reaction to all these results is less than 0.03 cm^3 mol^{-1}. Our values for the sodium and potassium salts in Table 3 lead to the identical single ion value, $V^0(HCO_3^-, aq) = 24.9$ cm^3 mol^{-1}.

The present volumetric result for $NaHSO_3$, $V_\phi^{\infty}(NaHSO_3, aq) = 32.02$ cm^3 mol^{-1}, is lower than the value 33.2 cm^3 mol^{-1}, measured by Allred, Larson, and Hepler (21). Our value and the limiting volume for the potassium salt, $V_\phi^{\infty}(KHSO_3, aq) = 42.69$ cm^3 mol^{-1}, lead to $V^0(HSO_3^-, aq) = 33.3$ and 33.7 cm^3 mol^{-1}, respectively, for the standard state volume of the hydrogen sulfite ion. Averaging these yields the result $V^0(HSO_3^-, aq) = 33.5 \pm 0.4$ cm^3 mol^{-1}. The difference between our limiting heat capacity $C_{p\phi}^{\infty}(NaHSO_3, aq) = 34.0$ J K^{-1} mol^{-1} and Allred's value of 42.2 J K^{-1} mol^{-1} lies only barely within the combined experimental uncertainty. The experimental procedures were different in that Allred *et al.* used buffer solutions prepared from the salts. Our value for the potassium salt, $C_{p\phi}^{\infty}(KHSO_3, aq) = 1.4$ J K^{-1} mol^{-1} is consistent with the sodium result in Table 3 since the derived ionic values are $C_p^0(HSO_3^-, aq) = -12$ and −9 J K^{-1} mol^{-1} respectively, and we tabulate the average, $C_p^0(HSO_3^-, aq) = -10 \pm 4$ J K^{-1} mol^{-1} in Table 4, as the best ionic value for use in calculations described later in this paper.

There are few published heat capacity or volume data for aqueous CO_2^0 and none for SO_2^0. Moore *et al.* (36) and Enns, Scholander, and Bradstreet (37) obtained $V^0(CO_2^0, aq) = 33.9 \pm 0.4$ cm^3 mol^{-1} and 34.8 ± 1.0 cm^3 mol^{-1} from density measurements and the pressure dependence of CO_2 solubility, respectively. Both are in excellent agreement with our result, 32.8 cm^3 mol^{-1}. $C_p^0(CO_2^0, aq)$ has not previously been obtained from calorimetric measurements but can be calculated by twice differentiating very accurate gas solubility data with respect to temperature. Wilhelm, Battino, and Wilcock (1) have critically evaluated literature solubility data. The parameters from their fit to the data give $[C_p^0(aq) - C_p^0(g)] = 175$ J K^{-1} mol^{-1}, probably with a large uncertainty (2). Combining this with McBride and Gordon's value $C_p^0(CO_2, g) = 37.12$ J K^{-1} mol^{-1} (38) yields $C_p^0(CO_2^0, aq) = 212$ J K^{-1} mol^{-1}, in surprisingly good agreement with the result from our direct measurement, $C_p^0(CO_2^0, aq) = 243$ J K^{-1} mol^{-1}.

Ionization equilibria versus temperature and pressure

A major objective of this work was to use the room temperature heat capacities to extrapolate the ionization constants of CO_2^0(aq) and SO_2^0(aq) to high temperatures. The relevant thermodynamic relationships are the following:

$$[12] \quad (\partial \ln K/\partial T)_p = \Delta H^0/RT^2$$

$$[13] \quad (\partial \Delta H_R^0/\partial T)_p = \Delta C_p^0$$

$$[14] \quad (\partial \ln K/\partial P)_T = -\Delta V^0/RT$$

The pressure dependence of the first ionization equilibria of both acid gases has been measured at low temperatures. Values for $\Delta V_1^0(CO_2^0, aq)$ in the range −25.4 to −27.6 cm^3 mol^{-1} have been reported by several workers (4, 39, 40) who applied eq. [14] to their pressure-dependent ionization constant data. These compare favorably with the result calculated from our direct densimetry measurements (Table 4), $\Delta V^0(CO_2^0, aq) =$

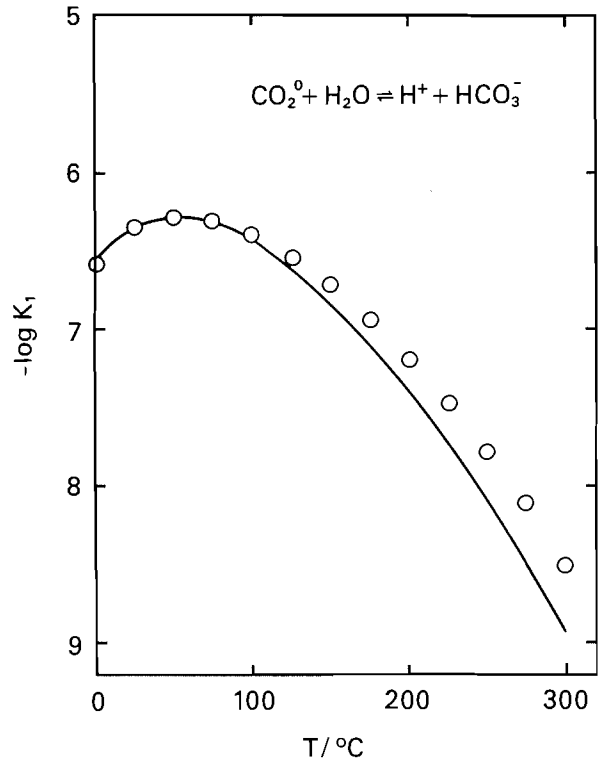

FIG. 5. The temperature dependence of the first ionization constant of aqueous CO_2. Data points are from Patterson *et al.* (3). The curve corresponds to eq. [18].

-26.0 ± 2 cm^3 mol^{-1}. Our result for $\Delta V^0(SO_2^0, aq)$, -23.1 ± 2 cm^3 mol^{-1}, is slightly more negative than Ellis and Anderson's result (12), -19.7 cm^3 mol^{-1}. Standard state volume changes of this magnitude, or even the somewhat more negative values reported at high temperatures (3, 4), would not cause ln K to be significantly affected by the saturation pressure of steam below about 300°C.

Because ΔC_p^0 is related to the second derivative of ln K with respect to temperature and because the pressure effects are so small, even a poor estimate of the temperature dependence of ΔC_p^0 can yield quite accurate values of ln K to rather high temperatures along the steam saturation curve of water, providing that ln K and ΔH^0 are known accurately at 25°C. Lindsay (41) and Murray and Cobble (42) have noted that the temperature dependence of C_p^0 for strong electrolytes is such that ΔC_p^0 changes very little over a wide range of temperatures if the reaction is "isocoulombic", that is if the products and reactants in the reactions are symmetric with respect to the number of ions in each charge type. They suggest that the temperature dependence of ln K for such reactions can therefore be estimated by assuming that ΔC_p^0 (25°C) is independent of temperature. Here, we wish to extrapolate $K_{1,b}$, the equilibrium constant for the isocoulombic neutralization reactions

[15] $CO_2^0(aq) + OH^-(aq) \rightleftarrows HCO_3^-(aq)$

and

[16] $SO_2^0(aq) + OH^-(aq) \rightleftarrows HSO_3^-(aq)$

Integrating eqs. [12] and [13] at constant pressure yields the formula:

TABLE 5. Equilibrium constants for SO_2 neutralization and dissociation from eq. [19]

t/°C	log $K_{1,b}$	log K_w*	log K_1
0	13.30 ±0.049	−14.948	−1.647±0.049
25	12.143†	−13.999	−1.856
50	11.141±0.034	−13.276	−2.135±0.034
75	10.26 ±0.08	−12.711	−2.45 ±0.08
100	9.49 ±0.12	−12.266	−2.78 ±0.12
125	8.79 ±0.18	−11.916	−3.12 ±0.18
150	8.17 ±0.23	−11.644	−3.48 ±0.23

200	7.08 ±0.35	−11.302	−4.22 ±0.35
225	6.61 ±0.41	−11.222	−4.61 ±0.41
250	6.17 ±0.48	−11.196	−5.02 ±0.48

*From Olofsson and Hepler (43).

†The ± values do not include uncertainties in log $K_{1,b}$ at 25°C, which we estimate to be ±0.01.

$$[17] \quad \ln K_{1,b}(T) \approx \ln K_{1,b}(25°C) - [\Delta H_b^0(25°C)/R - 298.15\ \Delta C_{p,b}^0(25°C)/R]\left[\frac{1}{T} - \frac{1}{298.15}\right] + [\Delta C_{p,b}^0(25°C)/R] \ln (T/298.15)$$

By combining Olofsson and Hepler's (43) compiled results for the dissociation of water with data for the ionization of aqueous CO_2 (13) and SO_2 (6, 29, 44, 48), we obtain the following values for the equilibrium constants and standard enthalpy changes of reactions [15] and [16] at 25°C: log $K_{1,b}(CO_2) = 7.649 \pm 0.005$, $\Delta H_b^0(CO_2) = -46.66 \pm 0.063$ kJ mol^{-1}, log $K_{1,b}(SO_2) = 12.143 \pm 0.010$, $\Delta H_b^0(SO_2) = -73.22 \pm 1.0$ kJ mol^{-1}. The uncertainty assigned to log $K_{1,b}(SO_2)$ includes Huss and Eckert's error estimate (6) and the results of some other workers cited in ref. 30, which are in close agreement. From Table 4, $\Delta C_{p,b}^0(CO_2) = -158 \pm 10$ J K^{-1} mol^{-1} and $\Delta C_{p,b}^0(SO_2) = -67 \pm 10$ J K^{-1} mol^{-1}. These values can be used in eq. [17] to obtain the following expressions for the temperature dependence of log $K_{1,b}$

$$[18] \quad \log K_{1,b}(CO_2, T) = 54.748 - 23/T - 19.003 \log T$$

$$[19] \quad \log K_{1,b}(SO_2, T) = 22.771 + 2776.0/T - 8.058 \log T$$

Values for the first dissociation constant of aqueous CO_2, K_1, are now quite accurately known up to 300°C and provide an excellent test for the accuracy of the extrapolation procedure. Figure 5 shows a comparison between the very detailed results of Patterson *et al.* (3) and those calculated from eq. [18] using the expression

$$\log K_1 = \log K_{1,b} - \log K_w$$

The cumulative error in the extrapolated value for log K_1 is only 0.13 at 150°C, 0.25 at 200°C, and 0.50 at 300°C, consistent with the detailed error analysis presented in our earlier study on H_2S ionization (24).

The dissociation constant of SO_2 above 50°C is much less reliably established and the extrapolated values are of considerably more practical use. These are tabulated in Table 5. The error limits were taken to be the propagated random error due to the uncertainty in ΔH_b^0 in eq. [17] plus the systematic error caused by neglecting the temperature dependence of $\Delta C_{p,b}^0$. The systematic error in the SO_2 extrapolation was simply assumed to be equal to the difference between the experimental

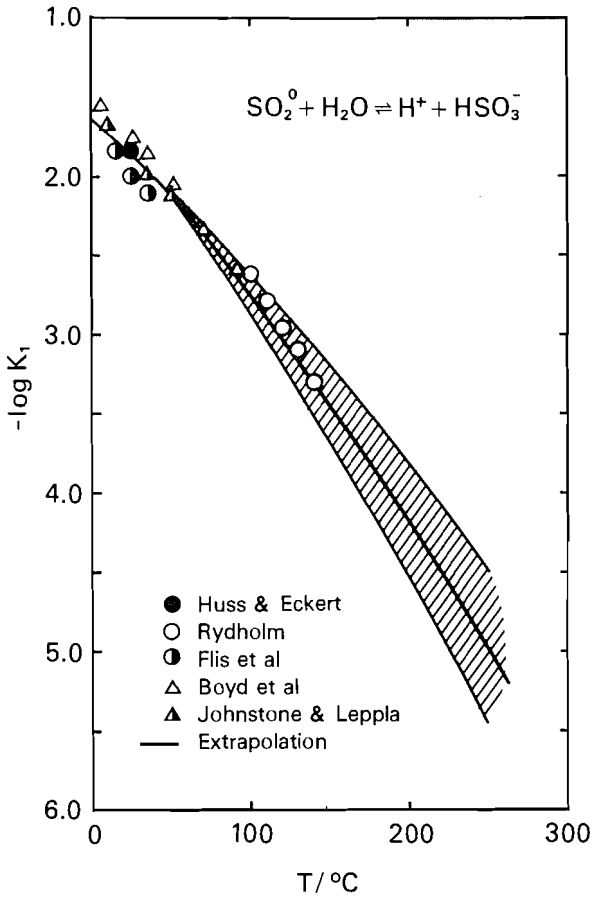

FIG. 6. The temperature dependence of the first ionization constant of aqueous SO_2. The shaded area represents the combined uncertainty in the extrapolation, from Table 5.

and extrapolated results for CO_2 (Fig. 5).

The dissociation of SO_2 has been studied by Campbell and Maass (8) from 0 to 90°C, by Flis *et al.* (7) from 10 to 35°C, and by Kaufman (9) to 130°C. Some of these results have been recalculated by Rydholm (11) and Johnstone and Leppla (10). The high temperature work was done some time ago using conductance methods and may be complicated by decomposition of the hydrogen sulfite ion, which is very easily oxidized (45, 46). These experimental data are plotted in Fig. 6 along with our estimate of the uncertainty due to the extrapolation procedure. The extrapolated results from eq. [19] agree with those of Campbell and Maass (8) and with Rydholm's tabulation of Kaufman's data to well within our estimated error. Because of the experimental problems in working with aqueous SO_2 above 100°C, the calculated K values may well be more accurate than Kaufman's measured K values.

Recently Cobble *et al.* (47) evaluated these same high temperature data using an estimated value for ΔC_p^0 and concluded that the literature values for ΔH^0 used here might be in error by more than 6 kJ mol^{-1}. The calculations outlined above suggest that the discrepancy noted in ref. 47 is due instead to the estimated value for ΔC_p^0, which is more negative than our measured value by 38 J K^{-1} mol^{-1}. Recent work at the University of Lethbridge (48) has confirmed the literature value for ΔH^0.

Appendix I

Heat capacity relaxation corrections for partially dissociated solutes

Consider an equilibrium of general type

[I-1] $MX(aq,undiss) \rightleftarrows M^+(aq) + X^-(aq)$

for which the thermodynamic equilibrium constant is

[I-2] $K = \alpha^2 m\gamma_\pm^2/(1 - \alpha)\gamma_u$

and in which symbols have the following meanings: α is the fraction of stoichiometric MX that is dissociated or ionized; m is the stoichiometric molality of MX; $\gamma_\pm$ is the mean activity coefficient of the ions in solution; and γ_u is the activity coefficient of the undissociated or un-ionized MX.

In the main part of this paper (eqs. [8] to [10]), we noted that the temperature increment imposed by any specific heat calorimeter causes a shift in α and that the contribution of this "relaxation" effect is described by the expression (32–34)

[I-3] $C_{p\phi}^{rel} = \Delta H(\partial\alpha/\partial T)_m$

where ΔH is the enthalpy of reaction at molality m.

Our first task is to evaluate $(\partial\alpha/\partial T)_m$ from eq. [I-2]. For this purpose it is convenient to define

[I-4] $F = \alpha^2/(1 - \alpha) = K\gamma_u/m\gamma_\pm^2$

Application of the quadratic equation to [I-4] gives

[I-5] $2\alpha = -F + (F^2 + 4F)^{1/2}$

Differentiation of [I-5] with respect to temperature at constant molality, followed by some algebraic manipulation, gives

[I-6] $$(\partial\alpha/\partial T)_m = \frac{(1 - \alpha)\alpha}{2 - \alpha}\left(\frac{\partial \ln F}{\partial T}\right)_m$$

from which we obtain

[I-7] $$(\partial\alpha/\partial T)_m = \frac{(1 - \alpha)\alpha}{2 - \alpha}[(\partial \ln K/\partial T)_p + (\partial \ln \gamma_u/\partial T)_m - 2(\partial \ln \gamma_\pm/\partial T)_m]$$

The first term within the brackets is easily calculated from the van't Hoff equation,

[I-8] $(\partial \ln K/\partial T)_p = \Delta H^0/RT^2$

The second term requires more care because we require the temperature dependence of $\gamma_\pm$ and γ_u in a solution of a weak electrolyte, for which the molality of ions depends on α as well as m. The temperature dependence of the activity coefficient of any non-reacting solute is given by the expression $(\partial \ln \gamma/\partial T)_m = -L/RT^2$ in which L represents the relative partial molar enthalpy of the solute. We defer, for the moment, the problem of estimating actual values $L_\pm$ and L_u in these weak electrolyte solutions and write

[I-9] $(\partial \ln \gamma_\pm/\partial T)_{\alpha m} = -L_\pm/RT^2$

and

[I-10] $(\partial \ln \gamma_u/\partial T)_{\alpha m} = -L_u/RT^2$

To relate these to [I-7], we write the total differential of $\ln \gamma_\pm$ as

[I-11] $$d \ln \gamma_\pm = (\partial \ln \gamma_\pm/\partial T)_{\alpha m}\, dT + (\partial \ln \gamma_\pm/\partial\alpha)_{T,m}\, d\alpha + (\partial \ln \gamma_\pm/\partial m)_{T,\alpha}\, dm$$

In any one experiment m is constant so that eq. [I-11] becomes

[I-12] $$(\partial \ln \gamma_\pm/\partial T)_m = (\partial \ln \gamma_\pm/\partial T)_{\alpha m} + (\partial \ln \gamma_\pm/\partial\alpha)_{T,m}(\partial\alpha/\partial T)_m$$

Combining [I-12] and the analogous equation for $(\partial \ln \gamma_u/\partial T)_m$ with eqs. [I-7] to [I-10] gives the desired equation for calculating the relaxation correction:

[I-13] $$(\partial\alpha/\partial T)_m = \frac{(1 - \alpha)\alpha}{RT^2(2 - \alpha)} \times \left\{\frac{\Delta H^0 - \bar{L}_u + 2\bar{L}_\pm}{1 + \frac{\alpha(1 - \alpha)}{2 - \alpha}\left(\frac{\partial \ln \gamma_\pm^2/\gamma_u}{\partial\alpha}\right)_{T,m}}\right\}$$

At the low ionic strengths of interest here, the activity coefficient of the undissociated species is taken to be unity and also to be temperature independent so that $\bar{L}_u = 0$. Equation [I-13] then reduces to

[I-14] $$(\partial\alpha/\partial T)_m = \frac{(1 - \alpha)\alpha}{RT^2(2 - \alpha)} \times \left\{\frac{\Delta H^0 + 2\bar{L}_\pm}{1 + \frac{2\alpha(1 - \alpha)}{2 - \alpha}\left(\frac{\partial \ln \gamma_\pm}{\partial\alpha}\right)_{T,m}}\right\}$$

To apply eq. [I-14], we calculated values of α and $(\partial \ln \gamma_\pm/$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

$\partial\alpha)_m = m(\partial \ln \gamma_\pm/\partial\alpha m)_m$ using Huss and Eckert's expression for K_1 and $\ln \gamma_\pm/\gamma_u^{1/2}$, eqs. [6] and [7] in the main text. The standard enthalpy of ionization of aqueous sulphur dioxide was taken to be $\Delta H^0 = -17.4$ kJ mol^{-1} from the National Bureau of Standards compilation by Wagman *et al.* (44). This value is consistent with several earlier investigations (7, 15–17) and with recent results obtained at the University of Lethbridge (48).

An expression for the experimental apparent relative enthalpy of the equilibrium mixture of SO_2^0 and HSO_3^- was obtained by a least squares fit to the tabulated heat of dilution data (44),

$$[\text{I-15}]\quad L_{\phi 2}/\text{J mol}^{-1} = 75224m^{1/2} - 177916m + 216208m^{3/2} - 106428m^2$$

Because the calorimetric enthalpies of dilution of aqueous sulphur dioxide include contributions from the shift in equilibrium as well as dilution of the ions, there are no model-free values of $\bar{L}_\pm$. We have therefore approximated the unknown values of $\bar{L}_\pm$ by taking them to be equal to the mean ionic values for a typical strong electrolyte, hydrochloric acid, at the same molality of ions. Fitting an expression for L_ϕ(HCl) to tabulated data from ref. 44 yielded the result

$$[\text{I-16}]\quad L_\phi(\text{HCl})/\text{J mol}^{-1} = 1972.1m_i^{1/2} - 2315.5m_i + 8139.6m_i^{3/2} - 11542.8m_i^2 + 5417.4m_i^{5/2}$$

The relative partial molal enthalpy, $\bar{L} = L_\phi + m_i(\partial L_\phi/\partial m_i)$, is therefore

$$[\text{I-17}]\quad \bar{L}(\text{HCl})/\text{J mol}^{-1} = 2958.2m_i^{1/2} - 4631.0m_i + 20348.9m_i^{3/2} - 34628.5m_i^2 + 18961.1m_i^{5/2}$$

Here, the first term is defined by the Debye–Hückel limiting slope and m_i refers to the molality of the dissociated acid. In the partially ionized SO_2 solutions m_i equals αm and, according to our assumption, $2L_{\phi\pm} = L_\phi$(HCl) and $2\bar{L}_\pm = \bar{L}$(HCl).

Finally, the enthalpy of ionization at the experimental molality, ΔH, can be calculated from the bulk heat of dilution, $-L_{\phi 2}$, and the estimated contribution of the ions. From the thermodynamic cycles used by Woolley and Hepler (32),

$$[\text{I-18}]\quad \Delta H = \Delta H^0 + 2L_{\phi\pm} - L_{\phi u}$$

and

$$[\text{I-19}]\quad L_{\phi 2} = -(1-\alpha)\Delta H_R{}^0 + (1-\alpha)L_{\phi u} + 2\alpha L_{\phi\pm}$$

Solving these expressions to eliminate the contribution of the undissociated species yields

$$[\text{I-20}]\quad \Delta H = \frac{2L_{\phi\pm} - L_{\phi 2}}{1-\alpha}$$

The enthalpy of reaction at infinite dilution calculated from this scheme agrees with the result for ΔH^0 in ref. 44 to within 0.2 kJ mol^{-1}.

Spectroscopic and electrochemical studies on linkage isomerism in iron(II) complexes of benzotriazole, a corrosion inhibitor

HENRIQUE E. TOMA, ERNESTO GIESBRECHT, AND RAMÓN L. ESPINOZA ROJAS
Instituto de Química, Universidade de São Paulo, Caixa Postal 20780, São Paulo, SP, Brazil

Received December 16, 1982

HENRIQUE E. TOMA, ERNESTO GIESBRECHT, and RAMÓN L. ESPINOZA ROJAS. Can. J. Chem. **61**, 2520 (1983).

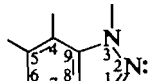
Benzotriazole reacts with the aquapentacyanoferrate(II) complex, at pH 4.5, producing a mixture of N-coordinated isomers. Characterization based on ^1H and ^{13}C nmr spectroscopy yielded an equilibrium constant $K = 1.9 \pm 0.3$, favoring the less symmetric N1-isomer. Two reversible peaks of oxidation, corresponding to the N1 and N2 isomers, were observed in the cyclic voltammograms at high scan rates, with $E_{1/2} = 0.43$ and 0.53 V versus NHE, respectively. The cyclic voltammograms at intermediate scan rates were successfully analysed in terms of an isomerization reaction preceding reversible charge-transfer. The kinetic constants of isomerization, k_f and k_b, were 1.5 and 0.65 s^{-1}, respectively. The limiting dissociative rates, $k_{-L} = 5.3 \times 10^{-3}$ s^{-1}, measured in the presence of dimethyl sulfoxide, support an intramolecular mechanism for the isomerization reaction.

HENRIQUE E. TOMA, ERNESTO GIESBRECHT et RAMÓN L. ESPINOZA ROJAS. Can. J. Chem. **61**, 2520 (1983).

Le benzotriazole réagit avec le complexe $Fe(CN)_5H_2O^{3-}$ à pH 4,5, en produçant une mélange des isomères coordonnés au Nitrogène. L'equilibre de cette réaction, avec $K = 1,9 \pm 0,3$ en faveur de le N1-isomère, a été montrée par la Spectroscopique ^1H et ^{13}C nmr, dans D_2O. Il est possible de voir deux pics correspondents a la oxydation des N1 et N2 isomères, avec $E_{1/2} = 0,43$ et 0,53 V versus ENH, dans les voltamogrammes cycliques à vélocités de balayage plus vite. L'examen théorique des voltamogrammes cycliques dans conditions de velocité de balayage intermèdes, a montrée une réaction de isomèritation précédent le transfèrement reversible des electrons. Les constants cinétiques de la isomèritation, k_f et k_b, ont été calculées comme 1,5 et 0,65 s^{-1}, respectivement. Les constants de substitution limite, $k_{-L} = 5.3 \times 10^{-3}$ s^{-1}, obtenus dans la présence de diméthyl sulfoxyde, permettent proposer un mechanisme intramoléculaire pour la réaction de isomèritation.

Introduction

Benzotriazole ($C_6H_5N_3$ or Bt) is an interesting ligand for transition metal ions, displaying remarkable efficiency as a corrosion inhibitor, particularly for copper and its alloys (1). The protective action has been associated to a compact film of a copper benzotriazole complex, produced on the metal or metal-oxide surface. The pK_a of neutral and protonated benzotriazole is 8.57 and 1.6, respectively (2). In mildly acidic or neutral solutions, there are two nitrogen atoms available for coordination with transition metal ions. Although isomeric mononuclear complexes are possible, no evidence of linkage isomerism in benzotriazole complexes has ever been published in the literature.



In this article, we report a study on the chemistry of pentacyanoferrate(II) complexes of benzotriazole in aqueous solution. The $Fe(CN)_5^{3-}$ ion can coordinate only one additional ligand, forming stable complexes with aromatic bases like pyridine (3), pyrazine (3), and imidazole (4). Therefore, in the presence of an excess of benzotriazole, two isomeric pentacyanoferrate(II) complexes can result in equilibrium, as a function of their relative stability constants. The characterization of the linkage isomerism in the pentacyanoferrate(II)–benzotriazole system constitutes the subject of this paper.

Experimental

The complex $Na_3Fe(CN)_5NH_3 \cdot 3H_2O$ was prepared from sodium nitroprusside (Carlo Erba) as described in the literature (5). Benzotriazole, dimethyl sulfoxide, and other reagent grade chemicals were used as supplied. The benzotriazole complex was prepared in aqueous solution from the amminepentacyanoferrate(II) complex, in the presence of a large excess of the free ligand at pH 4.5 (acetate buffer).

The electronic spectra of the complexes in the visible and uv region were recorded on a Cary 14 or 17 spectrophotometer fitted with thermostatted cell compartments. The measurements were carried out under argon, in the presence of an excess of benzotriazole to prevent the dissociation of the complex.

The kinetics of formation of the benzotriazole complex were investigated with a Durrum model D-110 stopped-flow apparatus, equipped with a Kel-F flow system. The aquapentacyanoferrate(II) complex was generated at concentrations smaller than 10^{-4} M, by dissolving the appropriate amount of $Na_3Fe(CN)_5NH_3 \cdot 3H_2O$ in argon saturated water. The ligand solutions containing 0.18 M potassium chloride and 0.02 M acetate buffer were always freshly prepared under argon atmosphere.

Cyclic voltammetry measurements were carried out with a Princeton Applied Research instrument, consisting of a 173 potentiostat and a 174 universal programmer. A platinum electrode was employed for the measurements, using the conventional Luggin capillary with the Ag/AgCl (1 M KCl) reference electrode in a non-isothermic arrangement. A platinum wire was used as the auxiliary electrode.

Nuclear magnetic resonance spectra were recorded on a Varian T-60 (^1H) or FT 80A (^{13}C) spectrometer, at a probe temperature of 33°C. Solutions of the pentacyanoferrate(II) complexes (0.9 M) were prepared in D_2O, under argon atmosphere, using stoichiometric amounts of $Na_3Fe(CN)_5NH_3 \cdot 3H_2O$, benzotriazole, and hydrochloric acid. The nmr spectra of benzotriazole were obtained with the sample dissolved in CD_3OD.

Results and discussion

The aquapentacyanoferrate(II) ion reacts with benzotriazole, under argon atmosphere, producing a yellow substituted complex. The electronic spectrum of the product, shown in Fig. 1, has a strong absorption band at 383 nm ($\epsilon = 4.1 \times 10^3$ M^{-1} cm^{-1}) which was assigned to a $d_\pi - p_\pi^*$ charge transfer transition, in analogy with the pentacyanoferrate(II) complexes of aromatic N-heterocycles (3). The complex can be oxidized reversibly, with mild oxidizing agents, to a violet–blue product absorbing at 570 nm ($\epsilon = 1.2 \times 10^3$ M^{-1} cm^{-1}).

TABLE 1. Observed rate constants of formation and dissociation of the benzotriazolepentacyanoferrate(II) complex

T (K)	[Bt] (M)	k_{obsd} (s^{-1})
285.7	5.0×10^{-3}	0.56[a]
289.0	5.0×10^{-3}	0.77
289.4	5.0×10^{-3}	0.82
298.2	2.5×10^{-3}	0.81
298.2	5.0×10^{-3}	1.68
298.2	7.5×10^{-3}	2.40
305.0	5.0×10^{-3}	2.65
278.2	4.8×10^{-2}	2.6×10^{-4}[b]
288.2	4.8×10^{-2}	8.3×10^{-4}
298.2	4.8×10^{-2}	5.3×10^{-3}
305.2	4.8×10^{-2}	9.2×10^{-2}

[a] k_{obsd} given by eq. [2], at $\mu = 0.100\ M$ KCl, $[Fe(CN)_5H_2O^{3-}] = 3 \times 10^{-5}\ M$.
[b] k_{obsd} given by eq. [8]; measured in the presence of 0.35 M dimethyl sulfoxide, at $\mu = 0.100\ M$ KCl, $[Fe(CN)_5Bt^{3-}] = 1.2 \times 10^{-3}\ M$.

The kinetics of formation of the benzotriazole complex (reaction [1]) were investigated by the stopped-flow technique under pseudo first order conditions. The results are shown in Table 1. A linear dependence of the observed rate constants, k_{obsd}, with respect to the concentration of the benzotriazole ligand was found according to eq. [2].

$$[1]\quad Fe(CN)_5H_2O^{3-} + Bt \xrightarrow{k_f} Fe(CN)_5Bt^{3-} + H_2O$$

$$[2]\quad k_{obsd} = k_f[Bt], \text{ where } k_f = 330\ M^{-1}\ s^{-1}$$

The specific rates and the activation parameters, $\Delta H^{\ddagger} = 60$ kJ mol^{-1}, $\Delta S^{\ddagger} = 6$ J mol^{-1} deg^{-1}, are consistent with the substitution kinetics previously reported in the literature (4, 6) for the $Fe(CN)_5H_2O^{3-}$ ion. It has been shown that the kinetics are practically independent on the nature of the attacking ligand, in agreement with a dissociative D, or D–IP mechanism. According to these mechanisms, two isomeric forms of the benzotriazole complex, N1 and N2, should be formed simultaneously. However, the stopped-flow kinetics monitored at several wavelengths, and the electronic spectra of the products recorded at several temperatures (Fig. 1) provided little evidence for the isomers in solution.

In the ^{13}C nmr spectrum of benzotriazole there are three peaks at 139.96, 126.93, and 115.93 ppm, which can be assigned to the C8,9, C5,6, and C4,7 atoms, respectively, in comparison with the literature assignment for benzoimidazole (10). Seven intense peaks and two shoulders are observed in the ^{13}C nmr spectra of the benzotriazolepentacyanoferrate(II) complexes (Fig. 2), in addition to broad peaks at 175 ppm, associated to the cyanide ligands.

For symmetry reasons, three ^{13}C nmr peaks are expected for the N2-isomer, and six for the N1-isomer. Therefore, one can see that the ^{13}C nmr spectrum of the complexes is consistent with a mixture of isomers (reaction [3]).

[3] 
(N2) (N1)

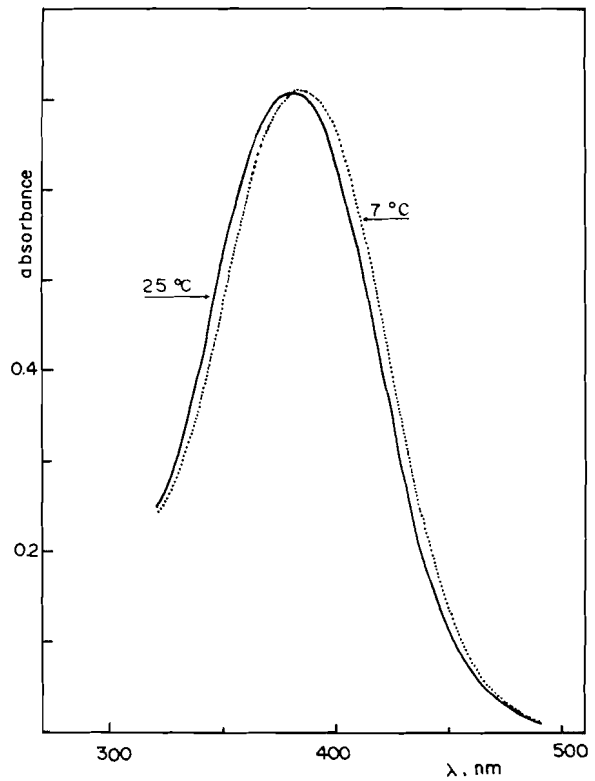

FIG. 1. Electronic spectra of the $Fe(CN)_5$ (benzotriazole)$^{3-}$ complex, $1.5 \times 10^{-4}\ M$, recorded in the presence of free ligand, $5 \times 10^{-3}\ M$, pH 4.5 (acetate buffer).

Previous studies on the ^{13}C nmr spectra of pentacyanoferrate(II) complexes of aromatic N-heterocycles have shown that the $Fe(CN)_5^{3-}$ moiety produces upfield shifts on the remote and carbon atoms, and downfield shifts on the carbon atoms close to the coordinating site. Therefore, in the less symmetric isomer B, the C6, C7, and C8 peaks are shifted downfield with respect to the corresponding C5, C4, and C9 peaks. Based on this argument, we have tentatively assigned the peaks at 126.09, 121.47, and 114.15 ppm to the C8,9, C5,6, and C4,7 atoms, respectively, of the N2-isomer. The corresponding peaks for the N1-isomer are observed at 126.30 (sh, C8), 123.76 (C9), 122.08 (C6), 121.3 (sh, C5), 115.39 (C7), and 113.34 ppm (C4), respectively. Because of strong overlap in the C5,6 and C8,9 peaks, the relative amounts of the isomers were evaluated from the intensities of the C4,7 peaks. The calculated value of K was 1.8 ± 0.4 at 33°C.

As one can see in Fig. 2, there are two groups of peaks at 8.92 and 7.57 ppm in the ^1H nmr spectrum of the benzotriazole complex, shifted downfield and upfield, respectively, from the resonance peaks of the free ligand. Their relative intensities (1.3/6.7) are indicative of a mixture of isomers. The typical A_2B_2 pattern observed for the free ligand is expected to be preserved in the case of the N2-isomer; however, a more complicated pattern is predicted for the less symmetric N1-isomer.

According to several systematic studies on ^1H nmr spectra of pentacyanoferrate(II) complexes of aromatic N-heterocyclic ligands (7–9), the signals of the protons close to the $Fe(CN)_5^{3-}$ group are shifted downfield by the magnetic anisotropy of the metal ion and of the cyanide ligands. In contrast, the peaks of remote protons in the ligand are shifted upfield by π-backbonding interactions with the metal ion. Based on molecular models, we assigned the peaks at 8.92 ppm to the

proton at C7 in the N1-isomer. This atom is located perpendicularly to the cyanide ligands, in a region where the deshielding effect is maximum. The splittings are similar to those observed for the C2-proton of quinoline, and consistent with an ABX system. Analogous assignment can be excluded for the N2-isomer, since the protons are quite remote from the

[c] Dissociation rate constants expressed by eq. [8], at $\mu = 0.100$ *M* KCl, in the presence of 0.35 *M* dimethyl sulfoxide.

$Fe(CN)_5^{3-}$ group.

The several peaks around 7.57 ppm were ascribed to the other protons in the mixture of isomers. Assuming that the contribution of the N1-isomer to the integrated intensity at 7.57 ppm is three times the value measured at 8.92 ppm, the calculated value for the isomerization constant K is 1.9 ± 0.3 at 33°C, in agreement with the results from ^{13}C nmr.

The electrochemical behavior of the benzotriazole complexes was investigated using cyclic voltammetry. The measurements were carried out in aqueous solutions at pH 4.5 (10^{-2} *M* acetate buffer) in the presence of 0.100 *M* KCl, and at least ten times excess of free ligand to prevent the dissociation of the complexes. Typical cyclic voltammograms of the benzotriazole complexes are shown in Fig. 3.

At low scan rates, e.g., 10 mV s^{-1}, a single peak is observed, exhibiting reversible characteristics, with $E_{1/2}$ = 0.434 V versus NHE and $D = 4.3 \times 10^{-6}$ cm^2 s^{-1}. These voltammograms can be fitted by eq. [4], using the work functions χ previously described in the literature (11),

$$[4] \quad i = nFAC\,(\chi Da)^{1/2}$$

where $a = nFv/RT$, v = scan rate (V s^{-1}), and the other terms have the conventional meaning.

Two peaks of oxidation, separated by 100 mV, were detected in the cyclic voltammograms at high potential scan rates. Theoretical analysis in terms of eq. [4] provided very good fittings, as shown in Fig. 3, indicating that the two oxidation waves are electrochemically reversible. Based on their relative intensities, the oxidation waves with $E_{1/2}$ = 0.43 and 0.53 V versus NHE were assigned to the N1 and N2 isomers, respectively. The equilibrium constants of isomerization evaluated from the cyclic voltammograms at 200, 300, 400, and 500 mV s^{-1}, were respectively, 2.39, 2.40, 2.44, and 2.35 at 25°C. These results are practically identical. Therefore, we conclude that the equilibrium measurements are not affected by the potential scan rates above 200 mV s^{-1}.

The pattern observed at intermediate scan rates, e.g. 50 mV s^{-1}, is characteristic of a reversible electrochemical process preceded by a reversible chemical reaction, as in reaction [5]. In this case, the relaxation time of the chemical system is close to the potential scan rates, and the measurements become dependent on these two variables. At very low potential scan rates, as the N1 isomer is oxidized, the equilibrium is reestablished rapidly enough, so that a single wave is observed.

$$[5] \quad (CN)_5FeBt^{3-}\ (N2) \underset{k_{12}}{\overset{k_{21}}{\rightleftharpoons}} (CN)_5FeBt^{3-}\ (N1)$$

$$(CN)_5FeBt^{3-}\ (N1) \xrightarrow{\text{fast}} (CN)_5FeBt^{2-} + e^-$$

In order to evaluate the kinetic constants of isomerization we have employed eq. [6], previously proposed by Shain and Nicholson (11) for the case of a reversible electrochemical process preceded by a chemical reaction.

$$[6] \quad \frac{i_d}{i} = 1.02 + \frac{0.471}{K}\left[\frac{a}{(k_{12} + k_{21})}\right]^{1/2}$$

In eq. [6], i is the observed current, and i_d is the diffusion controlled current calculated from the data in the absence of chemical reactions, or at low scan rates.

Because the N2-isomer is electrochemically active, the calculations were carried out at the half wave potential of the N1-isomer. Theoretical analysis has shown that the contribution of the N2-isomer to the currents measured at 0.43 V versus NHE is practically zero. Typical results for $k_{12} + k_{21}$, obtained at 20, 30, 40, 50, 60, 70, 80, 90, 100, 110, and 120 mV s^{-1}, were 2.20, 1.99, 2.46, 2.49, 1.95, 1.98, 2.00, 2.15, 2.08, 2.21, and 2.03 s^{-1}, respectively, with an average of 2.14 ± 0.18 s^{-1}. Similar calculations were carried out at several concentrations of the complexes, with identical results. From the values of $k_{21} + k_{12}$ and $K = k_{21}/k_{12}$, we obtained the isomerization constants shown in Table 2.

In order to elucidate the mechanisms involved in the isomerization reaction, we investigated the substitution processes in the benzotriazole complexes. For convenience, the kinetics were carried out using cyclic voltammetry, under identical conditions of the electrochemical study. Dimethyl sulfoxide was chosen as the attacking ligand because it forms a very stable complex with the pentacyanoferrate(II) ion (12), having $E_{1/2}$ = 0.89 V. Thus it does not interfere in the cyclic voltammograms of the starting complex.

The decay of the benzotriazole complexes in the presence of dimethyl sulfoxide is illustrated in Fig. 4. The logarithmic plots of peak currents against time were linear for at least three half lives. The first order rate constants are shown in Table 1. At 25°C, $k_{obsd} = 5.3 \times 10^{-3}$ s^{-1}.

It has been shown (3, 5) that the typical mechanism of substitution in pentacyanoferrate(II) complexes is given by eqs. [7]–[9].

$$[7] \quad Fe(CN)_5L^{3-} \underset{k_L}{\overset{k_{-L}}{\rightleftharpoons}} Fe(CN)_5^{3-} + L$$

$$[8] \quad Fe(CN)_5^{3-} + H_2O \overset{K}{\rightleftharpoons} Fe(CN)_5H_2O^{3-}$$

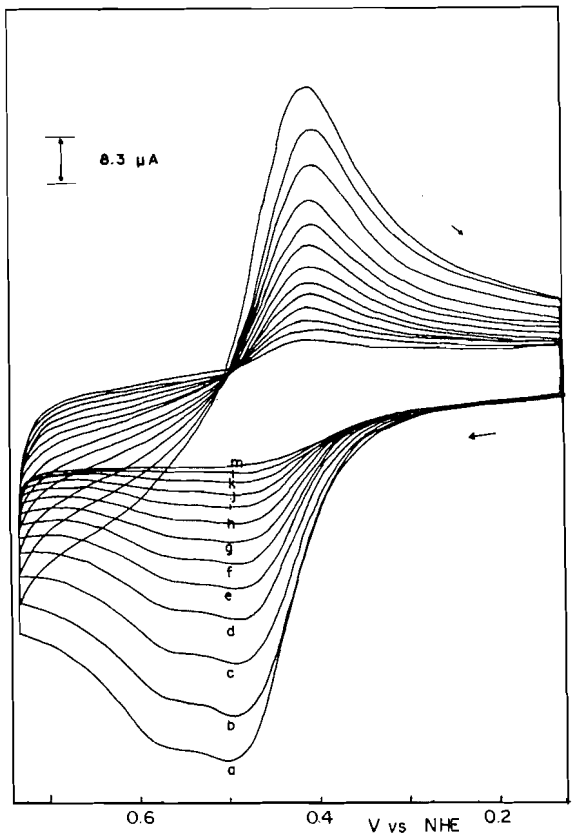

FIG. 4. Decay of the $Fe(CN)_5$ (benzotriazole)$^{3-}$ complexes, 1.2×10^{-3} *M*, followed by cyclic voltammetry, in the presence of 0.35 *M* dmso, 0.048 *M* Bt, 0.100 *M* KCl, at 25°C, 100 mV s^{-1}, from zero time (*a*) to 630 s (m).

$$[9]\quad Fe(CN)_5^{3-} + X \xrightarrow{k_X} Fe(CN)_5X^{3-}$$

In this mechanism, the dissociation of the ligand L constitutes the rate determining step. The observed rate constant follows a saturation behavior with respect to the concentration of the attacking ligand, so that, in the presence of a high excess of X, $k_{obsd} = k_{-L}$.

Because of the isomerization equilibrium, the substitution reactions can take place in two parallel ways, represented by k_{-N1} and k_{-N2}, respectively, in reactions [10]–[12].

$$[10]\quad Fe(CN)_5Bt^{3-}\ (N2) \overset{K}{\rightleftharpoons} Fe(CN)_5Bt^{3-}\ (N1)$$

$$[11]\quad Fe(CN)_5Bt^{3-}\ (N2) \xrightarrow{k_{-N2}} Fe(CN)_5dmso^{3-} + Bt$$

$$[12]\quad Fe(CN)_5Bt^{3-}\ (N1) \xrightarrow{k_{-N1}} Fe(CN)_5dmso^{3-} + Bt$$

In the presence of a high excess of dimethyl sulfoxide, the limiting rate constant is given by eq. [13].

$$[13]\quad k_{obsd} = \frac{k_{-N2} + k_{-N1}K}{1 + K}$$

From the isomerization constants K (Table 2), and k_{obsd} (Table 1), it is possible to calculate the dissociation rate constants k_{-N1} and k_{-N2}. The results at 25°C were 3.7×10^{-3} and 9.0×10^{-3} s^{-1}, respectively. In comparison with the isomerization rates shown in Table 2, one can see that the dissociation of the benzotriazole ligand from the complex is slower by a factor of two orders of magnitude. *Therefore, we conclude that the isomerization mechanism is essentially intramolecular.* Possibly, the mechanism involves π-intermediate complexes, with the $Fe(CN)_5^{3-}$ moiety coordinated to the N=N group.

TABLE 3. Kinetic and thermodynamic parameters for the pentacyanoferrate–benzotriazole system[a]

Parameter	Value	
	N2-isomer	N1-isomer
k_f (M^{-1} s^{-1})	330	330
$\Delta H_f^{\ddagger}$ (kJ mol^{-1})	60	60
$\Delta S_f^{\ddagger}$ (J mol^{-1} deg^{-1})	6	6
k_{-L} (s^{-1})	9.0×10^{-3}	3.7×10^{-3}
$\Delta H_{-L}^{\ddagger}$ (kJ mol^{-1})	89	93
$\Delta S_{-L}^{\ddagger}$ (J mol^{-1} deg^{-1})	11	19
$K_{II} = k_f/k_{-L}$ (M^{-1})	3.7×10^4	8.8×10^4
ΔH_{II} (kJ mol^{-1})	−29	−33
ΔS_{II} (J mol^{-1} deg^{-1})	−5	−13
K_{III} (M^{-1})	67	7.8×10^3

[a] 25°C, μ = 0.100 *M* KCl, pH 4.5 acetate buffer (10^{-2} *M*).

The activation and thermodynamic parameters calculated for the two isomers, based on temperature variation studies, can be seen in Table 3.

In spite of some possible steric hindrance at the N1 atom of benzotriazole, this isomer is more stable thermodynamically than the N2-isomer. The difference is essentially enthalpic, indicating a stronger $d_\pi - p_\pi^*$ interaction in the N1-isomer, in agreement with previous CNDO calculations for the benzotriazole molecule (13).

Because the diffusion coefficients of the oxidized and reduced complexes are similar, the half wave potentials can be considered identical to the formal redox potentials, E^0. Therefore, starting from the E^0 values and the equilibrium constants for the iron(II) complexes, K_{II}, one can calculate the corresponding constants for the oxidized complexes, using eq. [14].

$$[14]\quad K_{III} = K_{II} \exp\left[(E^0_{H_2O} - E^0_{Bt})/RT\right]$$

$E^0_{H_2O}$ is the reduction potential of the $Fe(CN)_5H_2O^{2-}$ complex, equal 0.368 V versus NHE at μ = 0.100 and 25°C.

The calculated value of K_{III} are shown in Table 3. It should be noted that the oxidized form of the N1-isomer is much more stable than the oxidized form of the N2 analog. The ratio of the stability constants defines an isomerization constant $K' = 115$, favoring the N1-isomer.

Returning to the cyclic voltammograms of Fig. 3, one can see that the cathodic response at high or intermediate scan rates has a much greater contribution of the isomer N1 than it would be expected if the relative ratio of the two isomers were constant, i.e., $K = 2.4$. Analysing the cathodic part of the cyclic voltammograms, we observed that the plots of peak currents versus $v^{1/2}$ are linear up to $v = 100$ mV s^{-1}. The peak currents are consistent with a complete conversion of the N2-isomer to the N1-isomer. Above 200 mV s^{-1}, we noted increasing negative deviations from the linear behavior, indicating incomplete relaxation of the oxidized system in the time scale of the cyclic

voltammetry. At the same time, the cathodic wave corresponding to the N2-isomer became more evident in the cyclic voltammograms (see Fig. 3).

In order to estimate the kinetic constants for the oxidized complexes, we considered that the relative distribution of the N1 and N2 isomers at zero time was 71% over 29%, based on $K = 2.4$. The time interval from the oxidation to the reduction of the two isomers was measured directly from the cyclic voltammograms. If the differences from the expected peak currents for the N1-isomer correspond to the amounts of the N2-isomer in solution, then the calculated distribution of the N1 and N2 isomers becomes 86/14, 87/13, 89/11, and 94/6, after 1.4, 1.7, 2.3, and 3.5 s, respectively. These results are consistent with a relaxation constant of $0.45 \pm 0.08\ s^{-1}$, for the oxidized complexes. The elementary constants, k'_{21} and k'_{12} are 0.44 and $0.004\ s^{-1}$, respectively, at 25°C.

The results obtained in this work are summarized in reaction [15].

$$[15]\quad (CN)_5FeBt^{2-}\ (N2) \underset{4\times10^{-3}\ s^{-1}}{\overset{0.44\ s^{-1}}{\rightleftharpoons}} (CN)_5FeBt^{2-}\ (N1)$$

$$\Big\Uparrow\Big\Downarrow 0.53\ V \qquad\qquad \Big\Uparrow\Big\Downarrow 0.43\ V$$

$$(CN)_5FeBt^{3-}\ (N2) \underset{0.65\ s^{-1}}{\overset{1.55\ s^{-1}}{\rightleftharpoons}} (CN)_5FeBt^{3-}\ (N1)$$

$$330\ M^{-1}\ s^{-1} \Big\Uparrow\Big\Downarrow 9.0\times10^{-3}\ s^{-1} \quad 3.7\times10^{-3}\ s^{-1} \Big\Uparrow\Big\Downarrow 330\ M^{-1}\ s^{-1}$$

$$\searrow \qquad Fe(CN)_5H_2O^{3-} + Bt$$

These data provide definite evidence of coordination mobility in a typical benzotriazole complex. A similar case of intramolecular isomerization has been reported by Armor and Taube (14) in the $Ru(NH_3)_5N_2^{2+}$ complex. This kind of mechanism is particularly important in catalytic processes involving π-systems. Following this line, we are investigating the fluxional properties of several ruthenium(II)–benzotriazole complexes.

The alkaloids of *Senecio triangularis* Hook.

H. RÜEGER AND M. H. BENN
Department of Chemistry, The University, Calgary, Alta., Canada T2N 1N4

Received May 2, 1983

H. RÜEGER and M. H. BENN. Can. J. Chem. **61**, 2526 (1983).

Pyrrolizidine alkaloids were isolated from *Senecio triangularis* Hook. growing in Alberta, and identified as 7-angelylretronecine, 7-senecioylretronecine, 7-angelyl-9-sarracinylretronecine, and 7-senecioyl-9-sarracinylretronecine, the last three of which appear to be new natural products.

H. RÜEGER et M. H. BENN. Can. J. Chem. **61**, 2526 (1983).

On a isolé les alcaloides du type pyrrolizidine du *Senecio triangularis* de Hook croissant en Alberta et que l'on a identifiés comme étant l'angélyl-7 rétronécine, la sénécioyl-7 rétronécine, l'angélyl-7 sarracinyl-9 rétronécine et la sénécioyl-7 sarracinyl-9 rétronécine; les trois derniers composés semblent être des nouveaux produits naturels.

Senecio triangularis Hook. is often found growing in cool wet habitats throughout the Rocky Mountains; the Cheyenne Indians are said to have used the plant as a medicinal: to prepare a tea used as a sedative, and to treat chest-pains (1).

In connection with another project, we were faced with the need of a specimen of senecionine (**1**), and knowing that this was the major alkaloid of *S. triangularis* collected around the Arrowhead – Big Bear Lake region of the San Bernadino mountains in S. California (2),[1] we decided to isolate the compound from Albertan plants. To our surprise, *S. triangularis* collected in Kananaskis Country yielded no senecionine, but instead a mixture of four other alkaloids: A – D. We report here the results of our investigations of the structures of these alkaloids.

An initial gc–ms analysis of the mixture of bases suggested that alkaloids A (ca. 60%) and B (ca. 5%), and C (ca. 20%) and D (ca. 15%) were isomeric, with molecular weights of 237 and 335 respectively. Given that the *Senecio* are a rich source of pyrrolizidine alkaloids (2), it seemed very probable that our alkaloids belonged to this class of natural products, and were therefore likely to be ester derivatives of the C_8N skeleton characteristic of most of those compounds. Plausible possibilities for the molecular compositions were then $C_{13}H_{19}NO_3$ (A and B) and $C_{18}H_{25}NO_5$ (C and D).

Alkaloids A, C, and D were individually isolated by chromatographic procedures, detailed in the Experimental, and characterized spectroscopically. The ^1H and ^{13}C nmr data for these compounds are summarized in Tables 1 and 2, and it is apparent that the carbon and proton counts are in accord with the tentative molecular formulae deduced from the gc–ms results.

If alkaloid A is a $C_{13}H_{19}NO_3$ compound, the structure must contain the equivalent of 5 rings/double bonds. Inspection of its ^{13}C nmr spectrum revealed four olefinic carbons and an ester carbonyl carbon. The remaining two units of unsaturation therefore correspond to two rings as expected for a pyrrolizidine. Since the ir spectrum of A contained strong absorptions attributable to hydroxyl as well as ester functions, we suspected that we were dealing with a C_5-monoester of the commonly encountered necine system **2**. The location of the ester followed from a scrutiny of the ^1H nmr spectrum of the alkaloid: the chemical shifts of the almost magnetically equivalent H-9 protons (δ 4.18), as well as of the H-7 proton (δ 5.42), are consistent with the esterified hydroxyl being that at C-7, and not at C-9 (2, 3).

The identity of the C_5-acid component, which must be one of the mono-olefinic $C_5H_8O_2$ possibilities, also followed from the ^1H nmr spectrum of A: the absorptions at δ 1.81, 1.96, and 6.08 define an angelate (*Z*-2-methyl-2-butenoate) unit (2, 4, 5). (These shifts unambiguously exclude the tiglate (*E*-2-methyl-2-butenoate) and senecioate (3-methyl-2-butenoate) alternatives.)

There remained the stereochemistry of the necine moiety: whether the C-7 functionality is *exo*, as in a 7β,8α retronecine system, or *endo*, as in a 7α,8α heliotridine situation. Fortunately, both 7-O-angelylretronecine and 7-O-angelylheliotridine are known compounds, and their cd spectra have been recorded and found to be very different (6). The cd spectrum of alkaloid A corresponded with that reported for 7-O-angelylretronecine, and the mp of the picrate salt of our base was also the same as that given for that compound. Thus alkaloid A is **3**.

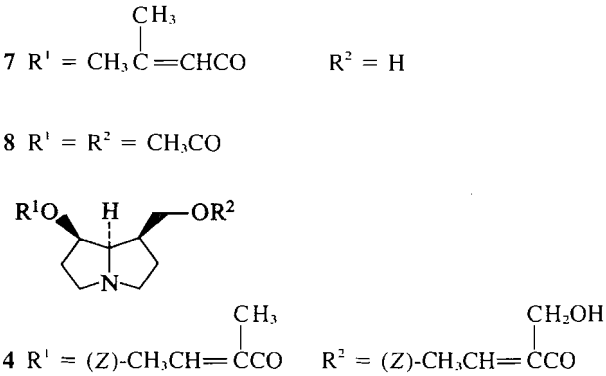
5 R^1 = (*Z*)-$CH_3CH{=}C(CH_3)CO$ (5′-CH_3) R^2 = (*Z*)-$CH_3CH{=}C(CH_2OH)CO$ (5″-CH_2OH)

6 R^1 = $CH_3C{=}CHCO$ (5′-CH_3) R^2 = (*Z*)-$CH_3CH{=}C(CH_2OH)CO$ (5″-CH_2OH)

[1]One of us (M.H.B.) collected *S. triangularis*, in blossom, in the San Bernadino Mountains, with Prof. T. A. Geissman, in Sept. 1960, and isolated senecionine from these plants.

FOR ERRATA SEE
v.62 #12 1984 p.2948



The identities of the other alkaloids proved to be more interesting. By an analysis of the spectroscopic data similar to that described for alkaloid A, C was recognized to be an acyclic diester of **2**. In particular, note that the ^{13}C nmr spectrum of C contained signals due to six olefinic carbons and two ester carbonyl carbons. Comparison of the data with that for alkaloid A revealed the presence of one angelyl unit, and another C_5-alkenoic acid. This second acid differed from angelic acid in having one of the methyl groups converted to hydroxymethyl. That this acid was in fact sarracinic acid (*Z*-2-(hydroxymethyl)-2-butenoic acid) was deduced from the ^1H nmr spectra: the CH_2OH signal contained no vicinal coupling, whereas the methyl signal did, and the *Z*-stereochemistry could be inferred, with reasonable confidence, from the shift of the vinylic proton (δ 6.38) (5). Further comparison of the ^{13}C nmr data wth that for the alkaloid sarracine (**4**) showed an excellent agreement between the signals for its sarracinic acid moiety and these ascribed to that unit in the spectra of alkaloid C (see Table 1).

The close correspondence of the ^{13}C nmr signals for the pyrrolizidine portion of alkaloid C with those recorded for 7,9-diesters of retronecine (as contrasted with 7,9-diesters of heliotridine) (7–9) indicated the nature of the necine. The location of the individual esterifying acids was originally deduced from the ms. Alkaloid C had a base-peak ion at *m/z* 220 corresponding to the loss of 115 mass units, which we ascribed to the typical fragmentation at the allylic site. The loss corresponds to $C_5H_7O_3$, i.e., the loss of the sarracinyl unit. Other independent evidence supporting this conclusion followed from the controlled-hydrolysis studies described later. We therefore formulated our base C as 7-*O*-angelyl-9-*O*-sarracinylretronecine (1,2-didehydrosarracine) (**5**), an apparently previously undescribed alkaloid. The ord/cd data were in accord (6) with the absolute stereochemistry shown in **5**.

Similar inspection of the data collected from alkaloid D revealed that it differed from C only in the nature of the esterifying acid at position 7, this now being senecioic acid (note the absence of a $J^{vic}_{H,H}$ coupling in the methyl signals for this C_5-unit, and the shift of the vinylic proton), i.e. alkaloid D is 7-senecionyl-9-sarracinylretronecine (**6**). Esterification with senecioic acid has rarely been reported in the pyrrolizidine akaloids,[2] and, like C, alkaloid D appears to be a new alkaloid.

We were unable to isolate enough of alkaloid B to characterize it completely. However its ms was consistent with this alkaloid being 7-*O*-senecioylretronecine (**7**), a compound which also does not apear to have been described before, as a natural product.

It will be observed that alkaloids A and C, and B and D are related as pairs of 7,9-diester and 7-ester derivaties of retronecine, in which the 9-ester was sarracinyl. This prompts the thought that the monoesters may be arising from the diesters during the isolation procedures. Controlled saponification of a mixture of alkaloids C and D did generate a mixture of A and B (as determined by gc–ms). But, under the conditions employed for their isolation, alkaloids C and D seemed to be quite stable. Since relatively large amounts of alkaloid A were obtained from the plant, we conclude that it cannot all be an artefact of the isolation procedure, i.e. that A, like C and D, is a genuine alkaloid of Albertan *S. triangularis*. We cannot be as confident about alkaloid B, since it was only present in very small amounts. However, given the authenticity of the monoester A as a natural product, it appears reasonable to accept B as one too.

Apart from the novelty of 7-*O*-angelyl-9-*O*-sarracinylretronecine, 7-senecioyl-9-*O*-sarracinylretronecine, and 7-senecioylretronecine as additions to the already long list of pyrrolizidine alkaloids, their isolation, together with 7-*O*-angelylretronecine, from a plant elsewhere known to produce senecionine is noteworthy. Qualitative, as well as quantitative, intraspecific variations in alkaloid production by plants are well established, and a fairly recent essay has discussed possible genetic control mechanisms (11). In the particular case of *S. triangularis*, our findings recall an apparently unpublished idea of the late Professor Geissman: that macrocylic diester pyrrolizidine alkaloids may be biosynthesized from acylic diesters, i.e. the appearance of 7-*O*-angelyl-9-*O*-sarracinylretronecine in the Albertan plants might reflect the absence of an ability possessed by those in S. California to effect a $C_5 + C_5$ cyclization needed to construct senecionine.

As a final comment, the reputed medicinal use of *S. triangularis*, to which we alluded at the start, would seem to have been hazardous: the toxicological properties of 9-*O*-esters of retronecine and the macrocyclic diesters are well established (2, 12).

[2]See ref. 10 for a recent list of more than 200 pyrrolizidine alkaloids, of which fewer than 2% were esters of senecioic acid.

Experimental

The gc–ms analyses were carried out on an HP 5992A instrument using a 2 m × 4 mm glass column packed with 3% OV-1™ on Chromosorb W (80–100 mesh), programmed from 220–250°C at 16°/min, and a He flow of ca. 20 mL/min; hplc separations were done on a Varian Vista instrument.

Other instrumental methods were as described previously (13). Sarracine was obtained from a sample of the hydrogen tartrate salt originally provided by Professor T. A. Geissman.

Isolation of the alkaloids

Blossoming *S. triangularis* plants, incuding the roots, were collected along side-stream banks to the East of Elbow Lake, Kananaskis Country. A voucher specimen of these plants is deposited in the Herbarium, Biology Department, University of Calgary. The air-dried plant material (1.05 kg) was macerated in two portions (Waring Blendor) in ethanol (96%, 4 L) and then filtered. This process was repeated (5×) until the filtrates were pale yellow in colour. The combined filtrates were then concentrated (t < 40°C) to ca. 300 mL, 0.5 M aqueous H_2SO_4 (600 mL) was added, and the mixture was then extracted with $CHCl_3$ (4 × 400 mL). The brownish aqueous phase was brought to ca. 1 M with concentrated H_2SO_4 and then stirred, at room temperature, for 3.5 h with zinc dust (10 g) in order to reduce any N-oxides to the free bases (2). The mixture was filtered, ice added, and then brought to pH ca. 9 (indicator paper) with concentrated NH_4OH. After extraction with $CHCl_3$ (5 × 150 mL), the aqueous phase was made strongly alkaline (pH ca. 14) with aqueous NaOH and reextracted with $CHCl_3$ (5 × 100 mL). Evaporation of these two sets of $CHCl_3$ extracts (dried over $MgSO_4$) gave 2.25 g and 0.45 g of brown oils, respectively. A tlc analysis ($CHCL_3$–MeOH, 4:1) revealed these oils to be similar in composition, showing four Dragendorff-positive components. They were therefore combined and partitioned between $CHCl_3$ (50 mL) and 1 M aqueous H_2SO_4 (20 mL). The aqueous phase was washed with more $CHCl_3$ (2 × 50 mL), and the combined $CHCl_3$ extracts were then backwashed with H_2O (20 mL). The aqueous acid phase and the H_2O-wash were then combined, basified with saturated aqueous K_2CO_3 while kept at ca. 0°C with ice, and extracted with $CHCl_3$ (4 × 50 mL). The combined $CHCl_3$ extracts were then dried ($MgSO_4$) and the solvent removed under reduced pressure to leave the alkaloids as a pale brown oil (2.21 g, 0.21% wt./dry wt. plant).

Thin-layer chromatographic analysis of the alkaloids, as before, revealed 4 components: R_f 0.32, 0.28, 0.13, 0.11. Under the same conditions senecionine had R_f 0.40.

A preliminary fractionation of the mixture was achieved by chromatography on silicic acid (200 g, first washed with $CHCl_3$–MeOH–NH_4OH 9:1:0.3 v/v until the eluate was basic to indicator paper, and then equilibrated with $CHCl_3$–MeOH 95:5 v/v). The alkaloid mixture (2.2 g) was applied to the column in $CHCl_3$–MeOH (95:5 v/v) and then eluted with $CHCl_3$–MeOH–NH_4OH (95:5:0), 500 mL; 90:9:1, 500 mL; 80:18:2, 500 mL; 3:2:1, 300 mL; and 0:10:1, 300 mL), fractions of ca. 50 mL being collected. Fractions 4–11 very largely contained the alkaloids of R_f 0.32 (C) and 0.28 (D), while fractions 12–27 were similarly enriched in the slow-moving pair (A and B). The recovery of alkaloids was ca. 80%.

The gc–ms of 4–11 revealed the following 4 components: A, R_T 2.2 min (ca. 5%), m/z: 237 (17), 219 (24), 218 (10), 193 (17), 154 (43), 138 (66), 137 (100), 136 (62), 126 (17), 124 (38), 117 (15), 111 (42), 108 (10), 107 (11), 106 (41), 94 (49), 93 (70), 83 (12), 81 (10), 80 (73), 55 (32), 53 (18), and 41 (16); B, R_T 2.4 min (ca. 3%), m/z: 237 (22), 219 (4), 193 (37), 155 (37), 154 (39), 138 (37), 137 (100), 136 (60), 126 (17), 124 (47), 117 (32), 111 (50), 106 (46), 94 (41), 93 (65), 83 (29), 80 (73), 55 (22), 53 (16), 43 (10), and 41 (15); C, R_T 9.0 min (ca. 45%), m/z: 335 (3), 237 (46), 236 (15), 221 (15), 220 (100), 219 (58), 136 (72), 121 (17), 120 (44), 119 (20), 94 (32), 93 (34), 83 (21), 80 (11), 55 (26), 53 (16), and 41 (16); and D, R_T 9.9 min (ca. 40%), m/z: 335 (3), 237 (35), 220 (54), 219 (23), 154 (12), 137 (12), 136 (100), 121 (17), 120 (38), 119 (27), 118 (11), 94 (33), 93 (38), 83 (38), 55 (15), 53 (14), and 41 (14).

Similar analysis of fractions 12–27 revealed components with the same R_T and ms as A (ca. 90%), and B (ca. 10%).

A portion (100 mg) of fractions 4–11 was then fractionated by hplc (Varian Micropak MCH-10-N-cap, 24 cm × 8 mm ϕ) using CH_3CN–MeOH 7:3 → 3:7 v/v as eluant, and monitoring the uv absorption of the eluant at 254 nm. By these means we were able to isolate samples of C (39 mg) and D (19 mg) that were homogeneous by tlc analysis (the balance of the alkaloids (32 mg) was recovered as an unresolved mixture). Similar fractionation of part (100 mg) of fractions 12–27 yielded alkaloid A (69 mg) and a mixture of A and B (ca. 30 mg).

Properties of the individual alkaloids (See Tables 1 and 2 for nmr data)

The controlled saponification of alkaloids C and D

A mixture of alklaoids C and D (11 mg, 33 μmol) was dissolved in aqueous 1,4-dioxane (1:1 v/v, 0.6 mL) containing K_2CO_3 (4.5 mg, 33 μmol). After this reaction mixture had been kept at 20°C for 30 min, gc–ms analysis showed no significant saponification had occurred. The mixture was therefore warmed, first to 50°C for 30 min, and then to 70°C, at which temperature it was held for a further 2.5 h Both gc–ms and tlc revealed that saponification was already appreciable after the 30 min at 50°C, and that it increased further at 70°C. At the end of the experiment similar analyses showed that small amounts of C and D remained, and some retronecine was also detected, but the major products were alkaloids A and B, present in about the same ratio (ca. 5:4) as that of C/D in the starting material.

Acknowledgements

Financial assistance from the Natural Sciences and Engineering Research Council of Canada (grant-in-aid to M.H.B.) and the Alberta Heritage Foundation for Medical Research (scholarship to H.R.) is acknowledged with gratitude. We thank Ms. N. Duke for assistance with the plant collection, and Drs. R. Yamdagni and W.-S Lin for help with instrumental analyses. This paper is dedicated to the memory of the late Professor Ted Geissman, from whom one of us (M.H.B.) learned much during a post-doctoral year (1960–61).

Synthesis of (±)-trixagol by an electrophilic cyclization of an allylsilane

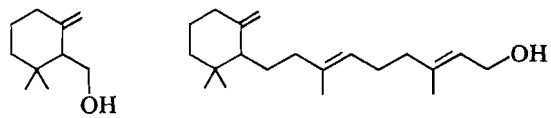
ROSEMARY J. ARMSTRONG AND LARRY WEILER[1]

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received April 18, 1983

ROSEMARY J. ARMSTRONG and LARRY WEILER. Can. J. Chem. **61**, 2530 (1983).

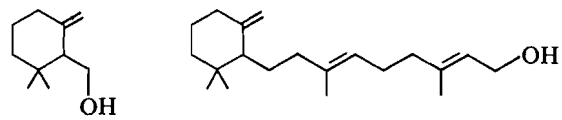
1,5-Dienes containing an allylsilane are cyclized by Lewis acids to methylenecyclohexanes. The trimethylsilyl group exerts a strong activating and directing influence on the regioselectivity of this cyclization. The monocyclic compound **10** was converted into the diterpene, (±)-trixagol (**3**).



10 **3**

ROSEMARY J. ARMSTRONG et LARRY WEILER. Can. J. Chem. **61**, 2530 (1983).

Les acides de Lewis permettent de cycliser les diènes-1,5 contenant un silane allylique en méthylènecyclohexanes. Le groupe triméthylsilyle agit fortement et influence la régiosélectivité de cette cyclisation. On transforme le composé monocyclique **10** en diterpène, le (±)-trixagol (**3**).



10 **3**

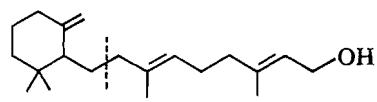
[Traduit par le journal]

In 1955 Stork and Burgstahler (1) and Eschenmoser *et al.* (2) independently proposed the hypothesis that many isoprenoid natural products are biosynthesized via a polyolefinic electrophilic cyclization. Since then this concept has been applied in many natural product syntheses, and has been expanded to include a variety of initiating and terminating groups which yield specific functionalities in the cyclized product. In 1976 Fleming *et al.* (3) showed that the trimethylsilyl moiety in **1** controlled the cyclization (eq. [1]) to regioselectively yield the exocyclic olefin **2**. The allyl silane has been used as an effective terminating unit in electrophilic cyclizations by a number of groups since that time (4). We recently demonstrated the use of allylsilanes in polyolefinic cyclizations of esters and acids (5) and here we report a synthesis of (±)-trixagol (**3**) using an electrophilic cyclization of a polyolefin allylsilane.

[1] 
1 **2**

Recently de Pascual Teresa *et al.* isolated a hydroxylated diterpene from the hemiparasite plant *Bellardia trixago* (6). The diterpene was named trixagol and was shown to have the structure **3**, which contains a cyclohexane moiety with an exocyclic methylene and an olefinic side chain. We envisioned a synthesis of **3** via a convergent route which involved joining the two appropriately functionalized subunits A and B.

The sulphone **14** served as the synthetic equivalent of subunit A and a synthesis of **14** is shown in Scheme 1. The dianion of



A B

3

methyl acetoacetate (**4**) was alkylated (7) with γ,γ-dimethylallyl bromide to give the β-keto ester **5**, which was then converted to the *Z*-enol phosphate **6** in 82% yield from methyl acetoacetate (7*b*). The enol phosphate was coupled with trimethylsilylmethylmagnesium chloride in the presence of nickel(II) bisacetylacetonate (5, 8) to give the *Z*-allylsilane **7** in 75% yield. No *E*-isomer was detected in either the enol phosphate **6** or the allylsilane **7**. Cyclization of **7** was performed with a series of reagents under a number of different reaction conditions, and the results of this study are shown in Table 1. The ratio of the regioisomers **8**/**9** was determined by 80 MHz ^{1}H nmr. The olefinic protons of **8** resonate at δ 4.75 and 4.86 whereas the olefinic proton of **9** resonates at δ 5.70. First it can be seen that cyclization is only achieved in the presence of a Lewis acid (runs 1–3). Either stannic chloride or boron trifluoride etherate will effect cyclization, but in the latter case at least one equivalent of acetic acid must be used in order to obtain **8** and **9** uncontaminated with by-products (runs 4–6). Interestingly, the presence of acetic acid reduces the amount of exocyclic isomer obtained when stannic chloride is used (runs 7–9). In fact, the *endo* isomer was the sole product obtained (70% yield) with the reaction conditions listed in run 9. The effect of solvent was examined with both boron trifluoride etherate/ acetic acid (runs 6 and 10) and with stannic chloride (runs 7, 11, and 12). There was no change in isomer ratio with either methylene chloride or toluene, but when the solvent was changed to methylene chloride which had been saturated with

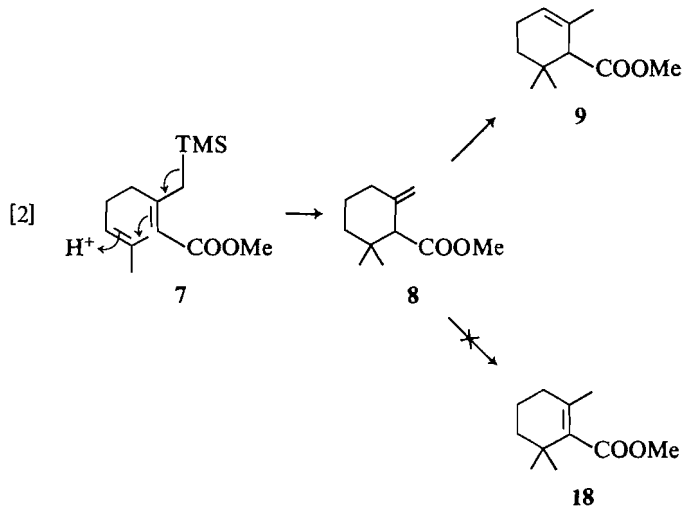
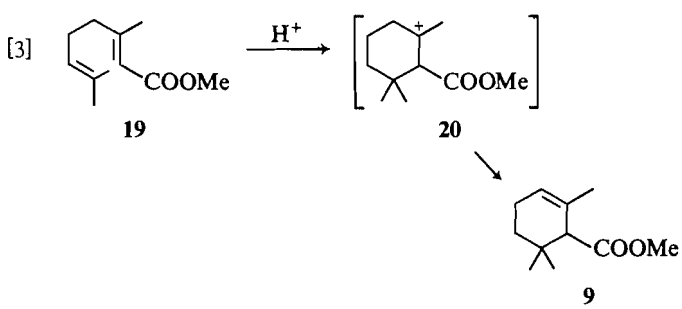
SCHEME 1. Synthesis of sulphone **14**

water (run 12) a significant improvement in the ratio of **8**/**9** was observed. Finally a study was performed on the quantity of Lewis acid, the temperature, and the reaction time. At low temperature (run 13) a mixture of endocyclic product, exocyclic product, and also an acyclic chloride **17** was obtained; the yield of the latter was 15%. A similar ratio of **8**/**9** could be obtained by treatment of the allylsilane in wet methylene chloride at 0°C for 2 hours, or at room temperature for 1 hour (runs 14, 15). Higher reaction temperatures gave increasing amounts of the endocyclic isomer and polymeric material. The reaction time could be shortened to 30 min by increasing the amount of stannic chloride (run 16), but the optimum reaction conditions were found to be 5 equivalents of stannic chloride in wet methylene chloride at 0°C for 1 hour (run 12, **8**/**9** = 7:1, 70% yield). It should be noted that the reaction must be performed under dilute conditions (0.08 *M*) in order to obtain this regioselectivity. In addition, it was found that the reaction gave a poorer regioselectivity when it was scaled up to more than 10 mmol of allylsilane. The crude yield of the cyclization step invariably was nearly quantitative.

It is interesting to speculate on the mechanism of the cyclization, but at this stage we merely note that at least one equivalent of Lewis acid is necessary to achieve conversion (run 17). The efficiency of the reaction in the presence of a proton source such as water or acetic acid suggests that the cyclization is initiated by a proton attack on the terminal olefin of **7** (eq. [2]) to give **8** which is subsequently isomerized to **9**.



No α,β-unsaturated ester **18** was observed in any cyclization, presumably because of the severe steric hindrance encountered around the tetrasubstituted olefin. The ability of the trimethylsilyl group to control the regioselectivity of the olefin is seen very clearly when one compares the cyclization of **7** with that of methyl geranate (**19**) (eq. [3]). Kurbanov *et al.* (9) were able to cyclize **19** with either sulphuric acid or fluorosulphonic acid, both very strong protonic acid sources. In each case the endocyclic isomer **9** was the major product obtained, presumably via the carbocyclic carbonium ion **20**.



We were unsuccessful in isomerizing the endocyclic isomer **9** to the exocyclic olefin. The mixture of esters **8** and **9** was converted without separation into the alcohols **10** and **11**, and then to the corresponding tosylates in near quantitative yield

17

using standard procedures. At this point it is pertinent to mention the severe steric hindrance of the hydroxymethyl group in the exocyclic isomer **10**. All attempts to convert the alcohol to a halide were unsuccessful, and this is undoubtedly due to the severe steric crowding around the hydroxymethyl in **10** flanked by the quaternary carbon and the exocyclic double bond (A (1, 3) strain (ref. 10)). Consistent with this analysis was the observation that conversion of the cyclohexenyl alcohol **11** to the tosylate could be performed in 24 h, whereas the alcohol in **10** required 72 h for complete conversion to the tosylate. The sulphides **12** and **13** were obtained in 74% yield from their respective tosylates using the highly nucleophilic thiophenolate anion (11) in ethanol under reflux for 16 h. Sulphides **12** and **13** were separated by flash chromatography (12). Sulphone **14** was readily obtained from **12** in 96% yield via oxidation using *m*-chloroperoxybenzoic acid.

A second approach to subunit A was studied using the carbocyclic acid **24** as shown in Scheme 2. Diketene (**21**) was treated with trimethylsilylmethylmagnesium chloride via the method of Itoh and co-workers (13, 14) but with some modifications. Alkenoic acid **22** was then alkylated in the γ-position (13, 15) with γ,γ-dimethylallyl bromide to give the silyl acid **23** in 70% yield. No α-alkylation was observed. Although this alkylation is regioselective, it is not stereoselective, and a mixture of *E* and *Z* isomers of **23** was obtained (*E*/*Z* = 7:3). A variety of reaction conditions and reagents were studied in the cyclization of the silyl acid **23**, and these results are shown in Table 2. Similarly to the ester cyclizations, the ratio of the regioisomers **24**/**25** was determined by integration of the resonances due to the olefinic protons in the ^1H nmr (**24**, δ 4.85, δ 4.91; and **25**, δ 5.65). It was found that titanium tetrachloride gave a very poor isomer ratio regardless of the temperature employed (runs 1 and 2). However, both stannic chloride and boron trifluoride etherate gave similar product ratios. The addition of acetic acid with boron trifluoride etherate had no effect on the ratio of **24**/**25**, but the yield of the reaction was improved (runs 3–5). Toluene was found to be the solvent of choice over both methylene chloride and benzene when using boron trifluoride etherate as the Lewis acid. However, when stannic chloride was employed the cyclization seemed to be solvent independent (runs 3, and 6–9). The optimum temperature with stannic chloride appeared to be quite low (−50°C), but higher temperatures were required for cyclization to proceed when using boron trifluoride etherate/acetic acid (runs 5, 10, and 11). However, increasing the temperature above ambient temperature did not improve the isomer ratio. Run 12 shows that a very poor ratio of **24**/**25** was obtained with wet methylene chloride under the conditions found to be the best for the

[a] Ratios were determined by ^1H nmr.
[b] Crude yields of all runs were nearly quantitative.
[c] Some acyclic product with no trimethylsilyl residue was also obtained.
[d] 40% purified yield of **24** and **25**.
[e] 76% purified yield of **24** and **25** after conversion to alcohols **10** and **11**.
[f] Methylene chloride saturated with water.

cyclization of the silyl ester **7**.

The optimum cyclization conditions for the silyl acid **23** are those shown in run 5 (**24**/**25** = 4:1) and, after reduction to the alcohols **10** and **11**, the yield for the two steps was 76%, or 61% for the conversion of **23** into pure exocyclic alcohol **10**. However, the cyclization of ester **7** was the preferred route because of the higher ratio of the exocyclic to endocyclic products.

The protected hydroxy bromide **30** is the synthetic equivalent of unit B, and a synthesis of **30** is shown in Scheme 3. Geraniol (**26**) was protected as its benzoate ester **27** in quantitative yield. Oxidation of **27** was performed with selenium dioxide and 70% *tert*-butyl hydroperoxide using a modification (*7b*) of the method of Umbreit and Sharpless (16). The desired alcohol **28** was isolated in 50% yield, in additon to recovered starting material **27** (40%) and aldehyde **29** (5%). It was found that if the reaction temperature was allowed to warm above 10°C a higher proportion of the undesired aldehyde was obtained. Conversion of alcohol **28** to the bromide **30** was performed in 97% yield using phosphorus tribromide and pyridine.

With subunits A and B in hand, the synthesis of trixagol was effected as shown in Scheme 4. Sulphone **14** was deprotonated, using *n*-butyllithium, and coupled to bromide **30** in the presence of hexamethylphosphoramide to give a mixture of diastereomers **31** in a nine-to-one ratio (as determined by ^1H nmr). The alcohol was deprotected by removal of the benzoate ester using diisobutylaluminium hydride to give hydroxy sulphone **32** in 64% yield from the coupling reaction. Unreacted

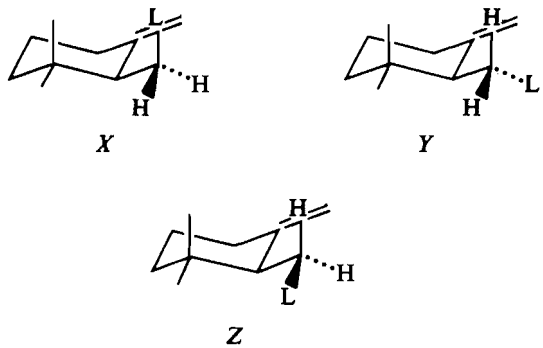
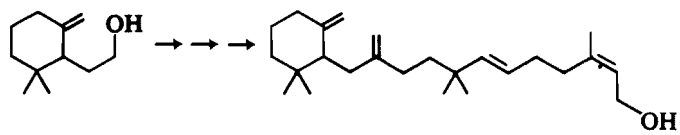
SCHEME 4. Synthesis of (±)-trixagol

sulphone **14** (36%) was also recovered during purification. We had attempted several other methods without success to form the C—C bond between subunits A and B. The hydroxymethyl group in **10** and related derivatives is severely hindered towards nucleophilic substitution. We were unable to add any carbon nucleophiles to this centre. There are three possible conformations for such a nucleophilic substitution, *X*, *Y*, and *Z*.



The conformation *X* has a serious 1,3-interaction between a methyl and the leaving group L, making this conformation rather inaccessible. In conformations *Y* and *Z* the backside of the C—L bond is effectively blocked by the *gem* dimethyl group or the exocyclic methylene, respectively. Kocienski (17*a*) has reported similar problems and in his synthesis of diumycinol (**34**) the next higher homologue of **10**, namely the alcohol **33**, was used to overcome the problems associated with the lack of reactivity in **10** and its derivatives (17*b*).



33 34

The final step in our synthesis was achieved by hydrogenolysis of the sulphone moiety with 6% sodium amalgam in a method analogous to that of Trost *et al.* (18). Once again some difficulties were encountered in this reaction due to the steric hindrance of functionalities attached to the carbon α to the ring. Trost *et al.* achieved cleavage of model sulphones with temperatures from −20°C to room temperature, and reaction times ranging from 7 min to 1 hour. However it was necessary to heat sulphone **32** in boiling ethanol for 16 h before cleavage could be effected (68% yield). The ir, ^1H nmr, and gas chromatographic data of the synthetic racemic trixagol were identical with that of the natural compound (6).

From these results and others (3–5) it is clear that the trimethylsilyl group is exceedingly effective in activating an alkene in an electrophilic cyclization and in controlling the regiochemistry of the resulting alkene. This methodology is particularly useful in generating exocyclic alkenes which are

isomerized to the endocyclic isomers under more vigorous conditions.

Experimental

General

Unless otherwise stated the following are implied.

Melting points (mp) were determined on a Kofler micro heating stage and are uncorrected. Kugelrohr distillations were performed by means of a Büchi Kugelrohr thermostat. The 80 MHz nuclear magnetic resonance spectra were recorded on a Bruker WP 80. Chemical shifts in ppm are reported using the δ scale with tetramethylsilane (TMS) as internal reference. Signal multiplicity, coupling constants, and integrated areas are indicated in parentheses. Infrared spectra were recorded on a Perkin–Elmer model 710B spectrophotometer. Solution spectra were performed using a sodium chloride solution cell of 0.2 mm thickness. Absorption positions are given in cm^{-1} and are calibrated by means of the 1601 cm^{-1} band of polystyrene. Low resolution mass spectra were determined on either a Varian MAT model CH4B or a Kratos-AEI model MS50 mass spectrometer. Spectra are quoted as *m/e* values. The major ion fragmentations are reported as percentages of the base peak. High resolution mass measurements were determined using a Kratos-AEI model MS50 mass spectrometer. Gas–liquid chromatography was performed on a Hewlett–Packard Model 5830A gas chromatograph using a 6 ft × 1/8 in. column of 10% Carbowax C-20M and nitrogen as the carrier gas. The flow rate was 30 mL/min. Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia, Vancouver.

Silica gel $PF_{254+366}$ supplied by E. Merck Co. was used for preparative thin layer chromatography (tlc). The plates were approximately 1 mm in thickness and were visualized under long and short wavelength ultraviolet radiation, iodine vapour staining and/or 3 *M* sulphuric acid spray, then heating. Flash chromatography (12) was performed using silica gel 60, 230–400 mesh ASTM, supplied by E. Merck Co.

The petroleum ether used was of boiling range ca. 30–60°C. Dry ethyl ether (ether) and tetrahydrofuran (THF) were obtained by distillation from lithium aluminium hydride. Methylene chloride (CH_2Cl_2) was dried by distilling from phosphorus pentoxide. Wet methylene chloride was obtained by shaking with water and using the saturated methylene chloride layer. Anhydrous hexamethylphosphoramide (HMPA), pyridine (py), toluene, and diisopropylamine were obtained by distillation from calcium hydride. Ethanol was dried by distillation from magnesium ethoxide. Sodium hydride was weighed as a 50% or 60% dispersion in mineral oil and was washed with dry ether to remove the oil prior to use.

Diisobutylaluminium hydride (in hexane) (DIBAL) and *n*-butyllithium (in hexane) were obtained from Aldrich Chemical Company, Inc. The alkyllithium solution was standardized by titration against 1.0 *M* *tert*-butanol in benzene using 1,10-phenanthroline as indicator.

All reactions involving air or moisture sensitive reagents were performed under an atmosphere of dry nitrogen using either oven or flame-dried glassware.

Methyl 7-methyl-3-oxo-6-octenoate (5)

This compound was prepared using a method analogous to that of Sum and Weiler (7).

Methyl Z-3-(diethylphosphoryloxy)-7-methyl-2,6-octadienoate (6)

To a stirred suspension of 10.6 g (0.22 mol) of sodium hydride (50% in oil) in ether at 0°C was slowly added 39.5 g of the crude β-keto ester **5** as a solution in ether. After 10 min at 0°C, 31.7 mL (0.22 mol) of diethyl chorophosphate was quickly added and the reaction mixture was stirred for 2 h while allowing it to warm to room temperature. The reaction was quenched with 1 *M* HCl and diluted with ether. The ethereal layer was washed twice with saturated $NaHCO_3$, twice with saturated NaCl, dried ($MgSO_4$), and concentrated. The orange oil was then distilled (bp 144–148°C/0.25 Torr) to give 52.7 g (82% from methyl acetoacetate) of enol phosphate **6** as a yellow oil. Preparative tlc of a small amount of this material using petroleum ether – ethyl acetate (2:1) gave **6** as a colourless liquid; ir ($CHCl_3$): 1730, 1670, 1280, and 1030 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.35 (dt, $J_{CH_2CH_3}$ = 7 Hz, $J_{POCH_2CH_3}$ = 1 Hz, 6H), 1.60 (s, 3H), 1.70 (s, 3H), 2.15–2.60 (m, 4H), 3.68 (s, 3H), 4.30 (dq, $J_{CH_2CH_3}$ = 7 Hz, J_{POCH_2} = 8 Hz, 4H), 5.00–5.20 (m, 1H), and 5.35 (s, 1H); mass spectrum, *m/e*: 320(18), 289(11), 252(23), 220(31), 192(23), 176(17), 174(19), 155(100), 150(10), 135(18), 134(63), 127(41), 119(13), 107(26), 106(28), 105(15), 98(57), 91(25), 81(18), 79(12), and 69(31). *Anal.* calcd. for $C_{14}H_{25}O_6P$: C 52.50, H 7.87; found: C 52.49, H 7.92.

Methyl Z-3-(trimethylsilylmethyl)-7-methyl-2,6-octadienoate (7)

The Grignard reagent was prepared from 1.82 g (0.075 mol) of magnesium turnings and 11.8 mL (0.085 mol) of trimethylsilylmethyl chloride in ether at room temperature, and to this stirred solution was added 0.32–0.64 g (2.5–5.0 mmol) of anhydrous nickel(II) bis-acetylacetonate (8). The dark-brown mixture which resulted was stirred for 5 min at room temperature and a solution of 16.0 g (0.050 mol) of enol phosphate **6** in ether was slowly added (exothermic reaction). The reaction mixture was heated to reflux for 16 h and further portions of 0.32–0.64 g (2.5–5.0 mmol) of nickel(II) bis-acetylacetonate were added after ½ h, 1½ h, 2½ h, and 4 h. The reaction mixture was cooled to room temperature, quenched by the careful addition of 1 *M* HCl (until acidic to litmus paper), and diluted with ether. The organic layer was washed once with saturated $NaHCO_3$, twice with saturated NaCl, dried ($MgSO_4$), and concentrated to give 12.7 g of crude product. Purification by flash chromatography using petroleum ether – ethyl acetate (40:1) as eluant gave 9.5 g (75%) of **7** as a yellow oil. Preparative tlc of a small amount of this material using petroleum ether – ethyl acetate (20:1) gave **7** as a colourless liquid; bp (Kugelrohr distillation) 90°C/0.1 Torr; ir ($CHCl_3$): 1705, 1620, 1435, 1250, 1155, and 850 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.05 (s, 9H), 1.60 (s, 3H), 1.70 (s, 3H), 2.05–2.20 (m, 4H), 2.43 (s, 2H), 3.65 (s, 3H), 4.95–5.25 (m, 1H), and 5.55 (s, 1H); mass spectrum, *m/e*: 255(4), 254(18), 239(32), 223(13), 186(19), 150(30), 135(22), 107(63), 89(28), 82(60), 80(20), 73(100), 69(33), and 59(22). *Anal.* calcd. for $C_{14}H_{26}O_2Si$: C 66.07, H 10.32; found: C 65.89, H 10.24.

Methyl 2,2-dimethyl-6-methylenecyclohexanecarboxylate (8)

To a solution of 2.54 g (0.010 mol) of the trimethylsilyl ester **7** in 110 mL of CH_2Cl_2 saturated with water at 0°C was slowly added a solution of 5.85 mL (0.050 mol) of $SnCl_4$ in 15 mL of wet CH_2Cl_2. The reaction mixture was stirred for 1 h at 0°C, then quenched with an aqueous solution of KF at 0°C. The organic layer was diluted with ether, washed four times with aqueous KF, twice with saturated $NaHCO_3$, once with saturated NaCl, dried ($MgSO_4$), and the solvent removed to give 2.0 g of a mixture of **8** and the *endo* isomer **9** (**8**/**9** = 7:1, as determined by ^1H nmr and gc (*T* = 100°C)). Purification by flash chromatography using petroleum ether – ethyl acetate (40:1) as eluant gave 1.27 g (70%) of **8** and **9** (7:1), and this mixture was used without further purification in the preparation of alcohol **10**. Preparative tlc of a small amount of this material using petroleum ether – ethyl acetate (10:1) gave **8** as a colourless liquid; bp 130°C/760 Torr; ir ($CHCl_3$): 1730, 1645, and 1155 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.95 (s, 3H), 1.02 (s, 3H), 1.10–2.55 (m, 6H), 2.90 (s, 1H), 3.67 (s, 3H), 4.75 (bs, 1H), and 4.86 (bs, 1H); mass spectrum, *m/e*: 182(46), 167(29), 125(31), 123(65), 122(77), 114(42), 107(41), 83(22), 82(31), 81(31), 79(20), 59(100), and 57(21). *Anal.* calcd. for $C_{11}H_{18}O_2$: C 72.49, H 9.95; found: C 72.36, H 10.05. The *endo* isomer **9** was prepared as shown below.

Methyl 2,6,6-trimethylcyclohex-2-enecarboxylate (9)

To a solution of 2.54 g (0.010 mol) of the trimethylsilyl ester **7** in 110 mL of CH_2Cl_2 saturated with water was added a solution of 0.58 mL (0.010 mol) of acetic acid at room temperature. A solution of 5.85 mL (0.050 mol) of $SnCl_4$ in 20 mL of wet CH_2Cl_2 was added slowly, and the reaction mixture was stirred at room temperature for 2 h. The solution was quenched with an aqueous solution of KF, diluted with ether, and the organic layer washed four times with aqueous KF and

For personal use only.

once with saturated NaCl. The solution was dried ($MgSO_4$) and the solvent removed to give 1.64 g of crude ester **9**. Purification by flash chromatography using petroleum ether – ethyl acetate (19:1) as eluant gave 1.28 g (70%) of **9**[2] as a colourless liquid; bp (Kugelrohr distillation) 80°C/0.8 Torr; ir ($CHCl_3$): 1730, 1440, and 1160 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.97 (s, 6H), 1.10–2.25 (m, 4H), 1.67 (s, 3H), 2.64 (s, 1H), 3.71 (s, 3H), and 5.70 (bs, 1H).

*2,2-Dimethyl-6-methylenecyclohexanemethanol (**10**)*

A slurry of 0.59 g (0.015 mol) of $LiAlH_4$ in dry ether was stirred at 0°C, and 2.81 g (0.015 mol) of a mixture of esters **8** and **9** in dry ether was slowly added to the slurry. The reaction mixture was heated to reflux for 2 h, then cooled to room temperature and quenched with 1 *M* HCl. The ethereal layer was washed once with 1 *M* HCl, twice with saturated NaCl, dried ($MgSO_4$), and concentrated to give 2.22 g (96%) of alcohol **10** and 2,6,6-trimethylcyclohex-2-ene methanol **11** (**10**/**11** = 7:1) as determined by ^1H nmr and gc (T = 130°C). This material was used without further purification in the preparation of the corresponding tosylates. Purification of a small amount of this material by flash chromatography using petroleum ether – ethyl acetate (9:1) as eluant gave **10**[3] as a colourless liquid; bp (Kugelrohr distillation) 80–86°C/2.0 Torr; ir ($CHCl_3$): 3600, 3400, 1245, and 850 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.88 (s, 3H), 0.97 (s, 3H), 1.20–1.80 (m, 4H), 1.70 (bs, 1H, exchangeable with D_2O), 1.90–2.25 (m, 3H), 3.58–3.80 (m, 2H), 4.75 (bs, 1H), and 4.95 (bs, 1H).

The *endo* isomer **11** was prepared in a similar manner using 0.19 g (0.005 mol) of $LiAlH_4$ and 0.91 g (0.005 mol) of ester **9**. Work-up of the reaction mixture as above gave 0.76 g (99%) of crude **11** which was purified by flash chromatography using petroleum ether – ethyl acetate (9:1) as eluant to give **11** as a colourless liquid; bp (Kugelrohr distillation) 95°C/0.8 Torr. The spectral data are in good agreement with the literature values (21); ir ($CHCl_3$): 3450, 1450, 1390, 1370, and 1025 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.92 (s, 3H), 1.06 (s, 3H), 1.25–2.10 (m, 5H), 1.40 (bs, 1H, exchangeable with D_2O), 1.78 (bs, 3H), 3.86 (d, 2H), and 5.62 (bs, 1H).

p-*Toluenesulphonyloxy-2,2-dimethyl-6-methylenecyclohexanemethanol*

To a solution of 2.22 g (0.014 mol) of a mixture of alcohols **10** and **11** in ether at 0°C was added 4.85 mL (0.060 mol) of pyridine. The reaction mixture was stirred at 0°C for 5 min, then 2.86 g (0.015 mol) of *p*-toluenesulphonyl chloride (22*a*) was added and the mixture was refrigerated at 0°C for 72 h. The reaction was quenched with iced water, diluted with ether, and the organic phase washed twice with 1 *M* HCl, twice with saturated $NaHCO_3$, once with saturated NaCl, and dried ($MgSO_4$). The solvent was removed to yield 4.30 g (97%) of a mixture of two tosylates which was used without purification in the preparation of sulphide **12**. Flash chromatography of a small amount of this material using petroleum ether – ethyl acetate (15:1) gave pure exocyclic tosylate from **10** as a colourless oil; ir ($CHCl_3$): 1650, 1600, 1360, 1175, 1100, and 960 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.84 (s, 3H), 0.98 (s, 3H), 1.25–2.30 (m, 7H), 2.50 (s, 3H), 4.00–4.40 (eight-line ABX, J_{AB} = 9 Hz, J_{AX} = 6 Hz, J_{BX} = 5 Hz, 2H), 4.58 (bs, 1H), 4.84 (bs, 1H), and 7.30–7.90 (AA′XX′, $\delta_A = \delta_{A'}$ = 7.38, $\delta_X = \delta_{X'}$ = 7.82; J_{AX} = 8 Hz, 4H); mass spectrum, *m/e*: 308(0.1), 173(2), 155(11), 137(17), 136(100), 122(54), 108(16), 107(30), 81(20), 80(16), 79(18), 69(22), 68(20), 57(17), 55(74), 53(46), and 41(65).

*2,2-Dimethyl-6-methylene-1-phenylthiomethylcyclohexane (**12**)*

A slurry of 4.96 g (0.031 mol) of KH (25% in oil) in dry ethanol was stirred at room temperature and 3.14 mL (0.031 mol) of thiophenol (11) was added to the slurry. After 10 min a solution of 4.71 g (0.015 mol) of the above tosylates in ethanol was added to the mixture and the reaction was heated to reflux for 16 h. The ethanol was removed under reduced pressure and the residue was dissolved in ether and saturated NaCl. The two phases were acidified with 1 *M* HCl, and the organic layer was washed twice with saturated NaCl, dried ($MgSO_4$), and concentrated. The crude product was purified by flash chromatography using petroleum ether as eluant, and performing three successive chromatographic separations on the mixture of isomers. The following compounds were obtained in order of elution: (a) diphenyl disulphide: R_f 0.7; ir ($CHCl_3$): 3050, 2950, 1580, 1480, 1440, and 1025 cm^{-1}; ^1H nmr ($CDCl_3$) δ 7.25–7.60; (b) 0.35 g (9%) of 2,6,6-trimethyl-1-phenylthiomethylcyclohex-2-ene (**13**) as a colourless oil; R_f 0.6; bp (Kugelrohr distillation) 110°C/0.5 Torr; ir ($CHCl_3$): 1585, 1480, and 1440 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.88 (s, 6H), 1.20–2.40 (m, 5H), 1.62 (bs, 3H), 2.79–3.12 (m, 2H), 5.45 (bs, 1H), and 7.15–7.40 (bm, 5H); mass spectrum, *m/e*: 247(12), 246(62), 231(7), 137(32), 136(30), 123(100), 121(36), 109(13), 107(20), 95(27), 93(20), 91(12), 81(57), 79(20), 77(17), 69(14), 67(16), and 55(17). *Exact Mass* calcd. for $C_{16}H_{22}S$: 246.1443; found (ms): 246.1438; (c) 2.40 g (65%) of thioether **12** as a colourless oil: R_f 0.5; bp (Kugelrohr distillation) 100°C/0.5 Torr; ir ($CHCl_3$): 3180, 1640, 1580, 1480, 1440, 1390, 1370, 1095, 1025, and 900 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.92 (s, 3H), 1.01 (s, 3H), 1.25–1.75 (m, 4H), 1.98–2.27 (m, 3H), 2.86–3.34 (eight-line ABX, J_{AB} = 11 Hz, J_{AX} = 10 Hz, J_{BX} = 5 Hz, 2H), 4.70 (bs, 1H), 4.90 (bs, 1H), and 7.15–7.42 (bm, 5H); mass spectrum, *m/e*: 247(7), 246(29), 137(25), 136(61), 124(15), 123(100), 121(21), 107(16), 95(18), 93(30), 92(15), 81(47), 79(20), 77(16), 69(24), 67(22), 55(18), 45(16), 41(36), and 37(79). *Anal.* calcd. for $C_{16}H_{22}S$: C 77.99, H 9.00, S 13.01; found: C 77.83, H 8.94, S 12.80.

*2,2-Dimethyl-6-methylene-1-phenylsulphonylmethylcyclohexane (**14**)*

To a solution of 1.01 g (4.1 mmol) of thioether **12** in CH_2Cl_2 at 0°C was slowly added 1.78 g (0.010 mol) of MCPBA (22*b*). The ice bath was removed from the reaction mixture and the reaction was stirred for 3 h and allowed to warm to room temperature. The reaction was quenched with saturated $NaHCO_3$ and diluted with ether. The organic phase was washed three times with saturated $NaHCO_3$, once with saturated NaCl, dried ($MgSO_4$), and concentrated to give 1.2 g of crude **14**. Purification by flash chromatography using petroleum ether – ethyl acetate (9:2) as eluant gave 1.09 g (96%) of sulphone **14** as a viscous oil. Preparative tlc of a small amount of this material using petroleum ether – ethyl acetate (9:2) gave **14** as a colourless oil; bp (Kugelrohr distillation) 150°C/0.5 Torr; ir ($CHCl_3$): 1445, 1300, 1140, and 1080 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.80 (s, 3H), 0.91 (s, 3H), 1.20–1.60 (m, 4H), 1.90–2.12 (m, 2H), 2.45 (dd, J = 7 Hz, 4 Hz, 1H), 3.25–3.40 (m, 2H), 4.58 (bs, 1H), 4.74 (bs, 1H), and 7.40–8.00 (m, 5H); mass spectrum, *m/e*: 278(0.05), 143(17), 138(26), 137(81), 136(100), 121(36), 95(31), 94(30), 93(54), 82(22), 81(66), 79(23), 77(29), 69(70), 67(21), 55(25), and 41(58). *Anal.* calcd. for $C_{16}H_{22}O_2S$: C 69.03, H 7.97, S 11.52; found: C 68.90, H 8.06, S 11.33.

*3-Trimethylsilylmethyl-3-butenoic acid (**22**)*

This compound was prepared using a method analogous to that of Itoh and co-workers (13, 14). The Grignard reagent was prepared from 5.35 g (0.22 mol) of magnesium turnings and 27.8 mL (0.20 mol) of trimethylsilylmethyl chloride in dry THF, and to this stirred suspension was added 0.48 g (2.0 mmol) of nickel(II) chloride (8) at 0°C. The brown mixture was stirred for 10 min at room temperature, cooled to 0°C, and a solution of 15.6 mL (0.20 mol) of diketene in THF was added. The resulting green reaction mixture was stirred for 5 h and allowed to warm to room temperature. The reaction mixture was quenched with 1 *M* HCl and diluted with ether. The aqueous layer was separated, extracted twice with ether, and the combined organic layers washed twice with saturated NaCl, dried ($MgSO_4$), and concentrated. The crude material was diluted with 200 mL of hexane, stirred for 10 min, decanted from an insoluble gum, and the solvent was removed under reduced pressure to give 29.7 g of **22** (86%) as an orange oil. Preparative tlc of a small amount of this material using petroleum ether – ethyl acetate – acetic acid (93:5:2) gave **22** as a colourless liquid; R_f 0.4; bp (Kugelrohr distillation) 53°C/0.01 Torr. The spec-

[2] Spectral information on compound **9** was kindly provided by Professor Joseph Wolinsky, Purdue University (19).

[3] A ^1H nmr spectrum of alcohol **10** was kindly provided by Professor Paul A. Grieco, Indiana University (20).

tral data are in good agreement with the literature values (13); ir ($CHCl_3$): 1710, 1635, and 850 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.10 (s, 9H), 1.62 (d, J = 1 Hz, 2H), 2.98 (d, J = 1 Hz, 2H), 4.70–4.80 (m, 2H), and 11.35 (bs, 1H); mass spectrum, *m/e*: 172(0.5), 157(5), 117(5), 82(5), 75(30), 74(10), 73(100), and 53(14). *Anal.* calcd. for $C_8H_{16}O_2Si$: C 55.77, H 9.36; found: C 56.00, H 9.44.

*3-Trimethylsilylmethyl-7-methyl-2,6-octadienoic acid (**23**)*

This compound was prepared using a method analogous to that of Itoh and co-workers (13) and Katzenellenbogen and Crumrine (15). To 9.23 mL (0.066 mol) of a solution of diisopropylamine in dry THF at 0°C was added 42.6 mL (0.066 mol) of a 1.55 *M* solution of *n*-butyllithium in hexane. The pale yellow solution was stirred for 30 min and a solution of 5.16 g (0.030 mol) of **22** in dry THF was added slowly. The mixture was stirred for 30 min at 0°C, forming an orange solution, cooled to −78°C, and 5.72 g (0.030 mol) of freshly purified cuprous iodide (23) was added. The slurry was stirred for 1 h at −78°C and 3.49 mL (0.030 mol) of freshly distilled 1-bromo-3-methyl-2-butene was quickly added to the bright yellow slurry. The reaction was stirred overnight while allowing it to warm to room temperature. The reaction mixture was quenched with 1 *M* HCl, diluted with ether, and filtered through a Celite pad. The aqueous layer was extracted four times with ethyl acetate, and the combined organic layers were washed twice with saturated NaCl, dried ($MgSO_4$), and concentrated. The crude material was diluted with hexane, stirred for 10 min, decanted from an insoluble gum, and the solvent was removed under reduced pressure to give 23 as a yellow oil. Purification by flash chromatography using chloroform as eluant gave 5.05 g (70%) of **23** as a pale yellow oil. Preparative tlc of a small amount of this material using petroleum ether – ethyl acetate – acetic acid (93:5:2) gave a mixture of *E*- and *Z*-isomers of **23** as a colourless liquid (*E*/*Z* = 7:3); R_f 0.6; bp (Kugelrohr distillation) 105°C/0.20 Torr; ir ($CHCl_3$): 2960, 1680, 1608, and 850 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.05 (s, 9H), 1.60 (s, 3H), 1.67 (s, 3H), 1.80 (s, 1.4H), 2.05–2.75 (m, 4H), 2.45 (s, 0.6H), 4.90–5.30 (m, 1H), 5.48 and 5.58 (2s, 0.7H and 0.3H), and 12.85 (bs, 1H); mass spectrum, *m/e*: 240(3), 225(7), 157(14), 156(11), 122(13), 107(17), 82(36), 75(40), 73(100), 69(59), and 45(20). *Anal.* calcd. for $C_{13}H_{24}O_2Si$: C 64.95, H 10.06; found: C 65.23, H 10.17.

*2,2-Dimethyl-6-methylenecyclohexanecarboxylic acid (**24**)*

To a solution of 4.80 g (0.020 mol) of the trimethylsilyl acid **23** in 150 mL of toluene was added 1.15 mL (0.020 mol) of acetic acid at 0°C. A solution of 12.3 mL (0.10 mol) of $BF_3 \cdot Et_2O$ in 25 mL of toluene was added slowly, and the reaction mixture was stirred for 2.5 h while allowing it to warm to room temperature. The solution was quenched with saturated NaCl, diluted with ether, and washed four times with saturated NaCl. The organic layer was dried ($MgSO_4$) and concentrated to give 4.30 g of a mixture of **24** and the *endo* isomer **25** (**24**/**25** = 4:1, as determined by ^1H nmr). The crude mixture was used without further purification in the preparation of alcohol **10**. Preparative tlc of 310 mg of acids **24** and **25** using petroleum ether – ethyl acetate – acetic acid (93:5:2) gave the following components: (a) 140 mg of **24** as a colourless oil (bp 75°C/0.20 Torr, Kugelrohr distillation) which crystallized on standing; R_f 0.3; mp 43–48°C; ir ($CHCl_3$): 2950, 1705, 1645, and 900 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.96 (s, 3H), 1.07 (s, 3H), 1.10–2.70 (m, 6H), 2.90 (s, 1H), 4.85 (bs, 1H), 4.91 (bs, 1H), and 10.50 (bs, 1H); mass spectrum, *m/e*: 169(4), 168(38), 153(21), 125(19), 123(22), 111(19), 100(24), 82(18), 81(15), and 69(100). *Anal.* calcd. for $C_{10}H_{16}O_2$: C 71.39, H 9.59; found: C 71.60, H 9.66; (b) 40 mg of 2,6,6-trimethylcyclohex-2-enecarboxylic acid (**25**) as a colourless oil (bp 90°C/0.10 Torr, Kugelrohr distillation) which crystallized on standing; R_f 0.15; mp 101–103°C (lit. (24) mp 104°C); ir ($CHCl_3$): 2950, 1705 cm^{-1}; ^1H nmr δ: 1.00 (s, 3H), 1.07 (s, 3H), 1.20–2.30 (m, 4H), 1.75 (d, J = 1 Hz, 1H), 2.64 (bs, 1H), 5.65 (bs, 1H), and 9.50 (bs, 1H).

*2,2-Dimethyl-6-methylenecyclohexanemethanol (**10**)*

A mixture of 4.30 g of the crude acids **24** and **25** in dry ether was slowly added to a slurry of 0.76 g (0.02 mol) of $LiAlH_4$ in dry ether at 0°C. The reaction mixture was heated to reflux for 2.5 h, then cooled to room temperature. The reaction mixture was quenched with 1 *M* HCl, diluted with ether, and the organic phase was washed once with 1 *M* HCl, twice with saturated NaCl, dried ($MgSO_4$), and concentrated to give a mixture of alcohols **10** and **11**. Purification by flash chromatography using petroleum ether – ethyl acetate (9:1) as eluant gave 2.34 g of **10** and **11** (**10**/**11** = 4:1; 76% from **23**). The spectral data of the mixture of alcohols was in good agreement with that obtained previously.

*(E)-3,7-Dimethyl-2,6-octadienyl benzoate (**27**)*

A mixture of 17.3 mL (0.10 mol) of geraniol, 16.2 mL (0.20 mol) of pyridine, and a catalytic amount of 4-dimethylaminopyridine was stirred in dry ether at room temperature. A solution of 12.8 mL (0.11 mol) of benzoyl chloride in ether was added to the mixture and the reaction was stirred for 2 h at room temperature. The reaction mixture was washed three times with saturated $NaHCO_3$, three times with 1 *M* HCl, twice with saturated NaCl, dried ($MgSO_4$), and concentrated to give 27.4 g (quantitative yield) of ester **27**. This material was used without purification in the preparation of alcohol **28**: ir ($CHCl_3$): 1710, 1450, 1270, and 1010 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.64 (s, 3H), 1.71 (s, 3H), 1.80 (s, 3H), 2.07–2.25 (m, 4H), 4.86 (d, J = 7 Hz, 2H), 5.14 (bs, 1H), 5.52 (t, J = 7 Hz, 1H), 7.25–7.66 (m, 3H), and 8.00–8.20 (m, 2H).

*(E,E)-8-Hydroxy-3,7-dimethyl-2,6-octadienyl benzoate (**28**)*

A suspension of 1.90 g (0.017 mol) of freshly sublimed selenium dioxide and 9.4 mL (0.069 mol) of 70% *tert*-butylhydroperoxide (Aldrich) in CH_2Cl_2 was stirred for 30 min at room temperature in the dark (7, 16). To the resulting solution was added 8.90 g (0.034 mol) of diene **27** at 10°C and the mixture was stirred for 5 h at 10°C, then quenched with saturated $NaHCO_3$. The organic phase was diluted with ether, washed three times with saturated $NaHCO_3$, once with saturated NaCl, dried ($MgSO_4$), and concentrated. The crude material was purified by flash chromatography using petroleum ether – ethyl acetate (4:1) as eluant to give the following compounds in order of elution: (a) starting material **27** (3.50 g, 40%); R_f 0.85; (b) 0.46 g (5%) of (*E,E*)-3,7-dimethyl-8-oxo-2,6-octadienyl benzoate (**29**) as a colourless oil: R_f 0.6; bp (Kugelrohr distillation) 112°C/0.15 Torr; ir ($CHCl_3$): 1710, 1460, 1280, and 1110 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.78 (s, 3H), 1.83 (s, 3H), 2.20–2.65 (m, 4H), 4.87 (d, J = 7 Hz, 2H), 5.55 (t, J = 7 Hz, 1H), 6.50 (t, J = 7 Hz, 1H), 7.30–7.70 (m, 3H), 8.00–8.17 (m, 2H), and 9.42 (s, 1H); mass spectrum, *m/e*: 272(0.1), 214(1), 150(25), 121(15), 106(11), 105(100), 96(12), 95(12), 94(12), 93(12), 84(20), 82(19), 81(10), 77(25), 68(13), 67(13), 55(23), 53(14), and 51(16). *Anal.* calcd. for $C_{17}H_{20}O_3$: C 74.97, H. 7.40; found: C 75.05, H 7.41; (c) 4.66 g (50%) of alcohol **28** as a viscous oil; R_f 0.4; bp (Kugelrohr distillation) 140°C/0.15 Torr; ir ($CHCl_3$): 3600, 3450, 1715, 1455, 1280, and 1115 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.67 (s, 3H), 1.78 (s, 3H), 2.05–2.26 (m, 4H), 2.55 (s, 1H, exchangeable with D_2O), 3.99 (s, 2H), 4.85 (d, J = 6 Hz, 2H), 5.25–5.60 (m, 2H), 7.27–7.70 (m, 3H), and 7.98–8.19 (m, 2H); mass spectrum, *m/e*: 274(0.01), 257(0.1), 152(5), 134(24), 121(6), 119(7), 106(9), 105(100), 95(5), 94(13), 93(8), 84(31), 81(5), 80(7), 79(7), 77(32), 69(5), 68(22), and 67(7). *Exact Mass* calcd. for $C_{17}H_{22}O_3$: 274.1569; found (ms): 274.1564.

*(E,E)-8-Bromo-3,7-dimethyl-2,6-octadienyl benzoate (**30**)*

To a stirred solution of 1.10 g (4.0 mmol) of alcohol **28** and 0.016 mL (0.20 mmol) of pyridine in dry ether at 0°C was slowly added 0.15 mL (1.6 mmol) of phosphorus tribromide in ether. The reaction mixture was stirred at 0°C for 5 h, then quenched with iced water. The organic phase was diluted with ether, washed 3 times with saturated $NaHCO_3$, once with saturated NaCl, dried ($MgSO_4$), and concentrated to give 1.31 g (97%) of bromide **30** which was used without further purification in the preparation of compound **31**. Preparative tlc of a small amount of this material using petroleum ether – ethyl acetate (10:1) gave **30** as a colourless oil which decomposed upon distillation; ir ($CHCl_3$): 1710, 1455, 1275, and 1105 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.79 (s, 6H), 2.12–2.40 (m, 4H), 3.97 (s, 2H), 4.86 (d, J = 7 Hz,

2H), 5.39–5.71 (m, 2H), 7.27–7.70 (m, 3H), and 8.00–8.20 (m, 2H); mass spectrum, *m/e*: 257(8), 136(8), 135(62), 134(6), 107(24), 106(30), 105(100), 93(34), 91(10), 81(10), 79(13), 77(47), 68(39), 67(38), 55(13), 53(20), 51(14), and 41(29). *Anal.* calcd. for $C_{17}H_{21}BrO_2$: C 60.54, H 6.28, Br 23.69; found: C 60.67, H 6.48, Br 23.50.

(E,E)-9-(2',2'-Dimethyl-6'-methylenecyclohexanyl)-3,7-dimethyl-9-phenylsulphonyl-2-6-nonadienyl benzoate (31)

To a stirred solution of 0.22 g (0.80 mmol) of sulphone **14** in 8 mL of THF and 0.8 mL of HMPA at 0°C was added 0.70 mL (1.2 mmol) of a 1.7 *M* solution of *n*-butyllithium in hexane. After 1 h a solution of 0.30 g (0.88 mmol) of halide **30** in 3 mL of THF (pre-dried by stirring over CaH_2) was added at 0°C and the reaction mixture was stirred overnight, while allowing it to warm to room temperature. The reaction mixture was quenched with 1 *M* HCl, diluted with ether and petroleum ether, the organic phase washed once with 1 *M* HCl, and four times with saturated NaCl. It was dried ($MgSO_4$) and the solvent removed to give 0.44 g of crude coupled product **31** which was used without further purification in the preparation of alcohol **32**. Preparative tlc of a small amount of this material using petroleum ether – ethyl acetate (6:1) gave both diastereomers of **31** (≈9:1 as determined by ^{1}H nmr) as a viscous oil which decomposed upon distillation; ir ($CHCl_3$): 1705, 1445, 1300, 1275, and 1145 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 0.76 (s, 0.3H), 0.87 (s, 0.3H), 0.96 (s, 2.7H), 1.10 (s, 2.7H), 1.30–2.75 (m, 13H), 1.76 (s, 6H), 3.40–3.70 (m, 1H), 4.79 (bs, 1H), 4.82 (d, J = 6 Hz, 2H), 5.05 (bs, 1H), 5.25–5.40 (m, 1H), 5.47 (t, J = 6 Hz, 1H), and 7.38–8.17 (m, 10H); mass spectrum, *m/e*: 534(0.5), 413(2), 412(5), 272(17), 271(65), 270(31), 255(12), 215(12), 203(21), 202(12), 201(14), 187(13), 177(17), 175(22), 163(11), 161(15), 159(16), 149(19), 148(18), 147(66), 146(23), 145(16), 135(25), 133(32), 123(38), 122(59), 121(40), 120(35), 119(38), 109(42), 107(42), 105(100), 95(39), 93(52), 91(30), 81(67), 79(33), 77(59), 69(48), 67(24), and 55(37). *Exact Mass* calcd. for $C_{33}H_{42}O_4S$: 534.2804; found (ms): 534.2789.

(E,E)-9-(2',2'-Dimethyl-6'-methylenecyclohexanyl)-3,7-dimethyl-9-phenylsulphonyl-2-6-nonadien-1-ol (32)

To a stirred solution of 0.44 g of crude benzoic ester **31** in dry ether at 0°C was added 2.4 mL (2.4 mmol) of a 1 *M* solution of DIBAL in hexane. The reaction was stirred for 2 h and allowed to warm to room temperature, then cooled to 0°C and quenched with 1 *M* HCl until both layers were clear. The mixture was stirred for 15 min, then diluted with ether, the organic phase washed twice with saturated $NaCl_3$, dried ($MgSO_4$), and the solvent removed. The crude product was purified by flash chromatography using petroleum ether – ethyl acetate (7:2) as eluant to give the following compounds in order of elution: (a) sulphone **14** (0.083 g, 36% from coupling reaction); R_f 0.80; (b) 0.219 g (64% from coupling reaction) of both diastereomers of alcohol **32** (≈9:1 as determined by ^{1}H nmr), as an extremely viscous oil which rearranged upon distillation; R_f 0.40; ir ($CHCl_3$): 3600, 3500, 1450, 1305, 1150, and 1090 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 0.98 (s, 2.7H), 1.10 (s, 2.7H), 1.19 (s, 0.3H), 1.24 (s, 0.3H), 1.30–2.80 (m, 13H), 1.65 (s, 6H), 1.90 (bs, 1H, exchangeable with D_2O), 3.45–3.90 (m, 1H), 4.12 (d, J = 7 Hz, 2H), 4.76 (bs, ~0.9H), 5.04 (bs, ~1.1H), 5.10–5.25 (m, 1H), 5.40 (t, J = 7 Hz, 1H), and 7.40–7.95 (m, 5H); mass spectrum, *m/e*: 430(1.5), 289(14), 288(17), 272(12), 271(43), 270(21), 255(13), 203(34), 162(20), 149(25), 147(54), 135(30), 133(32), 123(55), 122(36), 121(45), 120(20), 119(33), 109(55), 107(52), 105(52), 95(52), 93(60), 91(38), 81(100), 80(20), 79(52), 77(34), 69(92), 67(39), 57(26), 55(78), and 53(22). *Anal.* calcd. for $C_{26}H_{38}O_3S$: C 72.52, H 8.89, S 7.45; found: C 72.26, H 8.80, S 7.31.

(E,E)-9-(2',2'-Dimethyl-6'-methylenecyclohexanyl)-3,7-dimethyl-2,6-nonadien-1-ol (trixagol) (3)

To a stirred solution of 0.151 g (0.35 mmol) of sulphone **32** in dry ethanol was added 0.20 g (1.4 mmol) of disodium hydrogen phosphate, then 0.54 g (1.4 mmol) of freshly ground 6% sodium amalgam (18, 25). The reaction mixture was heated to reflux for 16 h, then cooled to room temperature, quenched with 1 *M* HCl, diluted with ether, and decanted from the mercury. The organic phase was washed once with 1 *M* HCl, twice with saturated $NaHCO_3$, twice with saturated NaCl, dried ($MgSO_4$), and the solvent removed. The crude product was purified by flash chromatography using petroleum ether – ethyl acetate (5:1) as eluant to give 0.069 g (68%) of alcohol **3**[4] as a colourless oil whose spectral data are in good agreement with the literature values (6*a*); ir ($CHCl_3$): 3600, 3450, 1645, 1450, 1385, 990, and 800 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 0.85 (s, 3H), 0.91 (s, 3H), 1.15–2.20 (m, 15H), 1.20 (bs, 1H, exchangeable with D_2O), 1.60 (s, 3H), 1.70 (s, 3H), 4.17 (d, J = 7 Hz, 2H), 4.54 (m, 1H), 4.75 (m, 1H), 4.95–5.20 (m, 1H), and 5.45 (t, J = 7 Hz, 1H), mass spectrum, *m/e*: 290(1.5), 288(3), 257(6), 204(7), 203(6), 177(20), 175(26), 137(28), 136(42), 135(23), 123(29), 121(36), 109(45), 107(36), 105(24), 95(45), 93(57), 81(100), 79(27), 69(71), 67(28), and 55(37). *Exact Mass* calcd. for $C_{20}H_{34}O$: 290.2610; found (ms): 290.2610.

Synthesis of spin-labeled analogues of drug molecules with potential action on neuroreceptors

H. DUGAS, C. SPINO, AND M. OUELLETTE

Department of Chemistry, Université de Montréal, C.P. 6210, Montreal, P.Q., Canada H3C 3V1

Received February 17, 1983

H. DUGAS, C. SPINO, and M. OUELLETTE. Can. J. Chem. **61**, 2540 (1983).

The syntheses of novel spin-labeled analogues of butaclamol, a spin-labeled phenylaziridinium and two amino derivatives of butaclamol, are presented. Preliminary results of in vitro activity of these compounds on dopaminergic, serotoninergic, and adrenergic receptors correlate with the importance of the previously proposed lipophilic accessory binding site in CNS dopamine receptor.

H. DUGAS, C. SPINO et M. OUELLETTE. Can. J. Chem. **61**, 2540 (1983).

L'article présente la synthèse de nouveaux analogues marqueurs de spin de butaclamol, d'un marqueur de spin du type phénylaziridinium et de deux dérivés aminés du butaclamol. Les résultats préliminaires d'activité in vitro de ces produits sur les récepteurs dopaminergique, sérotoninergique et adrénergique sont en accord avec l'hypothèse d'un site auxiliaire lipophilique pour le récepteur de dopamine au système nerveux central.

Introduction

Spin-labeled (SL) drugs have become in the past ten years important molecular probes in studies of drug mechanisms at a molecular level. For example, a large number of drug analogues containing the nitroxide moiety have been synthesized and used to study the topography of specific binding sites in receptor macromolecules. The most representative efforts toward this goal include the preparation of SL-analogues of acetylcholine (1–3), SL-quaternary ammonium ligands (4, 5), SL-propranolol (6, 7), SL-narcotics (8), SL-steroids (9–11), SL-phenytoin (12), SL-penicillin (13), and a SL-analogue of *N*,*N*-dimethyl-2-phenylaziridinium (14).

The antipsychotic agent butaclamol **1** and related compounds are rigid dopamine antagonists and may thus be very helpful probes in receptor mapping. Furthermore, the fact that the dopamine receptor is highly stereoselective for the (+)-isomer of butaclamol derivatives (15–17), in both in vivo and in vitro experiments, renders the preparation of SL-analogues even more attractive as molecular monitors for the mapping of the dopamine receptor.

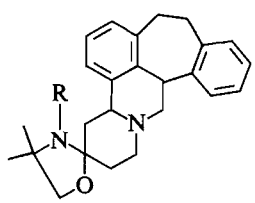
3



4*a* R = H
b R = O

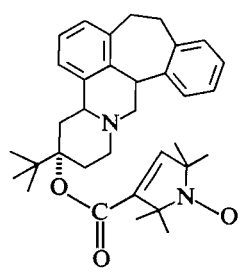
In this report, we describe for the first time the synthesis of such SL-analogues, a new SL-analogue of phenylaziridinium as well as two amino derivatives of butaclamol. Preliminary biochemical tests on these compounds are also disclosed.

Results and discussion

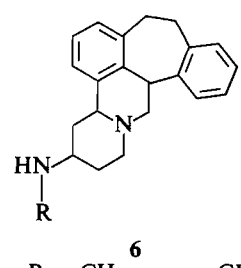
Chemistry

The ketone precursor **2** (15) was treated with 4-amino-2,2,6,6,-tetramethylpiperidinyl-1-oxyl in the presence of $NaBH_3CN$ to give **3** in 53% yield. In the presence of 2-methyl-2-amino-1-propanol and *p*-TsOH, **2** was converted to the oxazolidine **4***a* in 65% yield. Unfortunately, all attempts to obtain the corresponding nitroxide **4***b* using the procedure of Waggoner *et al.* (18), or variations thereof, were unsuccessful. This is probably due to the presence in the molecule of another nitrogen atom which may also be partially oxidized during the process, resulting only in decomposition products.

The SL-ester **5** was obtained in 17% yield by heating (+)-butaclamol with the acid chloride of 2,2,5,5-tetramethylpyrrolidinyl-1-oxyl-3-carboxylic acid in the presence of AgCN (19). The methylamino compound **6***a* and the isobutylamino compound **6***b* were prepared by treatment of the ketone **2** with the corresponding amine in the presence of $NaBH_3CN$ and were obtained in 32% and 57% yield respectively.



5



6
a R = CH_3
b R = CH_2—$CH(CH_3)_2$

The preparation of the 2-phenylaziridinium precursor **10***b* is illustrated in Scheme 1. Epoxystyrene **9** and *N*-methyl-4-amino-2,2,6,6-tetramethylpiperidinyl-1-oxyl **8**, prepared from tampone **7** according to the procedure of Rosen (20), were used as starting materials. The compounds were coupled in the pres-

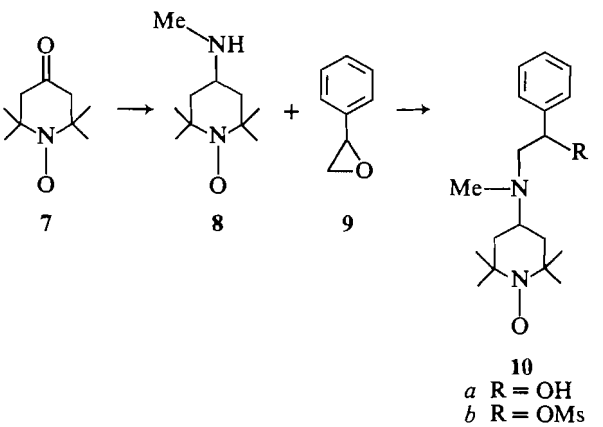
[a] The in vitro tests were performed on rat striatum (23) (dopamine), cortex (24) (serotonin), and forebrain (25) (α_1-adrenergic). Although at Ayerst spiroperidol is used routinely, Lazareno and Nahorski (26) have shown recently that ^{3}H-domperidone would be a much better ligand to label dopamine receptors.

[b] The concentration corresponds to the amount of drug-analogue used in the test and the percentage represents the amount of radioactive tracer displaced.

[c] These standards are included for comparative purposes.

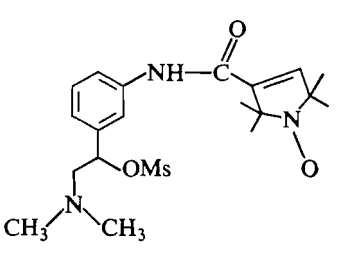
[d] With the exception of **5**, all compounds are racemic mixtures.



SCHEME 1

ence of water to give **10***a* as the ring-opening product in 98% yield. Treatment of **10***a* with mesyl chloride in dry benzene followed by a trace of HCl gave the expected hydrochloride salt of the SL-mesyl amine **10***b* in 49% yield. The compound gives a typical three-line epr signal with a_N = 17.2 G in water. This salt is expected to cyclize instantaneously to the aziridinium chloride salt in aqueous buffer above pH 7 (21).

The synthesis of a similar molecule **11**, but with the nitroxide function in a different position, has already been reported (14). Originally the synthesis of the SL-amine **11** was developed with the objective of probing the geometry of the anionic site of acetylcholinesterase since the corresponding *N*,*N*-dimethyl-2-phenylaziridinium chloride has been shown to be a potent anionic-site-directed irreversible inhibitor (21, 22).



11

However, the product turned out to be only a poor competitive inhibitor (K_i = 2.1 × 10^{-3} *M*) of bovine erythocyte acetylcholinesterase (14). The reason probably lies in the presence of a bulky spin label group on the aromatic ring. To overcome this problem, the synthesis of the *N*-SL analogue **10***b* was envisaged.

Biochemistry

The compounds cited in this article were tested on rat striatal membranes for dopaminergic activity (23), as well as rat cortex for serotoninergic (24) and rat forebrain for α_1-adrenergic (25) activities, for compounds **10***b* and **11**. The results are presented in Table 1. Generally, binding studies are not sufficient on their own to demonstrate the interaction of compounds with receptors, especially if only one concentration is used. Nevertheless, a general trend can be observed from these preliminary results even though the dopaminergic activity, represented in percentage of inhibition of ^{3}H-spiroperidol binding, is low. It seems that a bulky substituent at position 3 of butaclamol enhances the activity since the activity found is **6***b* ≈ **3** > **6***a*. On the other hand, the presence of a chemical group in the axial orientation reduces considerably the activity, as in **4***a* and **5**. This observation is in agreement with the hypothesis of a lipophilic accessory binding site for the *tert*-butyl group of butaclamol, as proposed previously by Humber and co-workers (16).

As for compounds **10***b* and **11**, both are inactive in all three assays and thus further investigations of the covalent binding of these compounds to receptor macromolecules, using the present spin-labeling approach, is unwarranted.

In conclusion, only the spin-label analogue **3** shows some promise for the study of its interaction with membrane systems in an attempt to ascertain the mode of action of this class of drugs. In particular, the molecule should allow monitoring of both dynamical and structural perturbations of the dopamine receptor macromolecules by neuroleptic agents at specific binding sites. Work is also in progress to bind covalently **6***a* and **6***b* to Sepharose gel for the eventual purification of solubilized dopaminergic D_2 receptor by affinity chromatography.

Experimental

Melting points were obtained with a Reichert micro hotstage apparatus and are uncorrected. Elemental analytical results were performed

by H. Seguin of the National Research Council of Canada, Ottawa and at the Microanalysis Center, Université Louis Pasteur, Strasbourg. Infrared (ir) spectra were recorded on a Perkin–Elmer 710A spectrometer as films on NaCl or in solution in $CHCl_3$. The ^1H nmr spectra were recorded using a Varian Associates EM-360A or a Bruker-WH90 spectrometer in $CDCl_3$, using Me_4Si as the internal standard. Mass spectra (ms) were obtained using a Hitachi–Perkin–Elmer model RMU 6-D. For tlc, commercial plates of silica gel (Eastman or Mancherey–Nagel) were used. Nitroxide group gives white spots on a blue background with molybdenum (Zinzadze) reagent. Nitroxide starting materials were purchased from Aldrich and Frinton Laboratories.

(4a,13b-trans*)-2,3,4,4a,8,9,13b,14-Octahydro-1*H*-benzo[6,7]-cyclohepta[1,2,3,*d,e*]-pyrido[2,1,*a*]-isoquinolin-3-[4'-amino-2',2',6',6'-tetramethylpiperidinyloxyl] (**3**)*

The ketone **2** (Ayerst) (300 mg, 0.99 mmol) was dissolved in tetrahydrofuran (15 mL) and added to a solution of 4-amino-2,2,6,6-tetramethylpiperidinyloxyl (168 mg, 0.99 mmol) and sodium cyanoborohydride (Aldrich) (62 mg, 0.99 mmol) in methanol (30 mL). The reaction mixture was stirred at room temperature in the dark for 48 h. The solution was then evaporated to dryness under reduced pressure, dissolved in chloroform, and washed four times with cold water. The chloroformic solution was dried over magnesium sulfate and evaporated under reduced pressure to give a crude orange oil. The crude product was chromatographed on an alumina (activity 1) column and the desired product was eluted with a mixture of benzene and acetone to give 167 mg (53%) of **3** as salmon colored crystalline needles; mp 75°–76°C; ir cm^{-1}: 3600–3400 (N—H), 2950–2850 (Boltzman's band), 1600, 1475 (aromatic); epr ($CHCl_3$) 3 lines, a_N = 14.5 G; ms *m/e*: 459 (M^+), 304, 287. *Anal.* calcd. for $C_{30}H_{40}N_3O$: C 78.57, H 8.89, N 9.16; found: C 77.42, H 8.81, N 8.35.

(4a,13b-trans*)-2,3,4,4a,8,9,13b,14-Octahydro-1*H*-benzo[6,7]-cyclohepta[1,2,3,*d,e*]-pyrido[2,1,*a*]-isoquinolin-3-[2',2'-dimethyloxazolidine] (**4**a)*

Toluene (80 mL), *p*-toluenesulfonic acid (25 mg), and 2-methyl-2-amino-1-propanol (Aldrich) (724 mg, 8.1 mmol) were refluxed for 15 min with a Dean–Stark trap to remove the water. Then the ketone **2** (400 mg, 1.3 mmol) was added and the mixture left under reflux for 48 h in the dark. The solution was filtered, washed four times with a saturated solution of $NaHCO_3$ (15 mL), once with cold water, dried over $MgSO_4$, and evaporated to dryness to give 324 mg (65%) of the crystalline yellow product **4***a*, mp 61°–62°C; ir cm^{-1}: 3600–3400 (N—H), 2950–2850 (Boltzman's band), 1600, 1475 (aromatic); ^1H nmr ($CDCl_3$) δ: 1.35 (s, 6H), 3.70 (s, 2H), 4.5 (s, 1H), 7.4 to 6.9 (m, 7H). *Anal.* calcd. for $C_{24}H_{30}NO_2$: C 79.51, H 8.34, N 7.73; found: C 78.55, H 7.99, N 7.41.

(4a,13b-trans*)-2,3,4,4a,8,9,13b,14-Octahydro-1*H*-benzo[6,7]-cyclohepta[1,2,3,*d,e*]-pyrido[2,1,*a*]-isoquinolin-3-*tert*-butyl-3-[2',2',5',5'-tetramethylpyrrolidinyloxyl-3'-carboxyl]ester (**5**)*

(+)-Butaclamol·HCl (Ayerst) was converted to the free base by passing a methanolic solution on an ion exchange resin AG1-X8, OH^- form (Bio-Rad). Butaclamol (200 mg, 0.552 mmol) was dissolved in 4 mL of anhydrous benzene and freshly prepared AgCN (19) (268 mg, 0.552 mmol) was added with vigorous stirring. To this was added the acid chloride (108 mg) of 2,2,5,5-tetramethylpyrrolidinyloxyl-3-carboxylic acid (from $SOCl_2$ in $CHCl_3$) and the mixture was refluxed for 18 h. The reaction mixture was diluted with 20 mL of pentane, filtered over Fuller's earth, washed with 10% $NaHCO_3$, water, then dried (Na_2SO_4) and evaporated to dryness to give 73 mg of a yellow oily crude product. Preparative tlc (Macherey–Nagel) silica gel G-100, UV_{254} with benzene–$CHCl_3$ (1:1) was used to purify the product and gave 42 mg (17%) of a yellow oil, homogenous on tlc; ir cm^{-1}: 1715 (ester), 1600 (aromatic), 1290 (C—O); epr ($CHCl_3$) 3 lines, a_N = 14.0 G. The ^1H nmr ($CDCl_3$) was taken on 7 mg of material in the presence of a microdroplet of phenylhydrazine to reduce the nitroxide function; δ: 0.9 (s, 9H, *tert*-butyl), 1.15 (d, 12H, tetramethyl), 6.8 to 7.3 (m, 7H, aromatic).

N-*methyl-(4a,13b*-trans*)-2,3,4,4a,8,9,13b,14-octahydro-1*H*-benzo[6,7]cyclohepta[1,2,3,*d,e*]pyrido[2,1,*a*]isoquinolin-3-amine (**6**a)*

To a solution of the ketone **2** (300 mg, 0.99 mmol) in 15 mL anhydrous THF were added an excess of methylamine·HCl (Anachemia) (100 mg) and 61 mg (0.99 mmol) of $NaBH_3CN$ (Aldrich) dissolved in 40 mL MeOH.

The mixture was stirred at ambiant temperature for 48 h. The solution was evaporated and the residue redissolved in $CHCl_3$, washed four times with 10 mL water, dried (Na_2SO_4), filtered, and evaporated to dryness. The resulting oil was chromatographed on an alumina column (activity 1) with $CHCl_3$ as eluant and 105 mg (32%) of a pale yellow crystalline material was obtained, mp 65°–66°C; ^1H nmr ($CDCl_3$) δ: 2.43 (s, 3H), 6.8 to 7.4 (m, 7H). For analysis, the compound was converted to its hydrochloride salt (HCl–Et_2O). *Anal.* calcd. for $C_{22}H_{28}N_2Cl_2$: C 67.51, H 7.21, N 7.16, Cl 18.12; found: C 67.98, H 7.46, N 7.45, Cl 17.11.

N-*isobutyl-(4a,13b*-trans*)-2,3,4,4a,8,9,13b,14-octahydro-1*H*-benzo[6,7]cyclohepta[1,2,3,*d,e*]pyrido[2,1,*a*]isoquinolin-3-amine (**6**b)*

The methodology was the same as above. From 100 mg (0.33 mmol) of ketone **2**, 68 mg (57%) of the desired product was obtained, after preparative tlc (silica gel), as an oil; ^1H nmr ($CDCl_3$) δ: 0.8 (d, 6H), 2.0 to 3.5 (m, 2H), 6.7 to 7.4 (m, 7H).

N-*methyl*-N'-*4'-(2',2',6',6'-tetramethylpiperidinyloxyl)-2-hydroxy-1-aminoethylbenzene (**10**a)*

N-methyl-4-amino-(2,2,6,6-tetramethylpiperidinyloxyl) **8** (20) (254 mg, 1.39 mmol) was dissolved in 3 mL of distilled water (33 % by weight) and epoxystyrene **3** (Eastman) (166 mg, 1.39 mmol) was added. The reaction mixture was left at room temperature in the dark for five days. At the end of this period, more than 95% of the products were coupled as judged by tlc. The solution was evaporated under reduced pressure to give 418 mg (98%) of an orange oil which was directly used for the next step; ir cm^{-1}: 3600–3200 (OH), 1240–1200 (C—O).

N-*methyl*-N'-*4'-(2',2',6',6'-tetramethylpiperidinyloxyl)-2-methylsulfonyloxy-1-aminoethylbenzene hydrochloride salt (**10**b)*

The alcohol nitroxide **10***a* (418 mg, 1.38 mmol) was dissolved in 6 mL of dry benzene and mesyl chloride (157 mg, 1.38 mmol) was added dropwise over a period of 10 min at room temperature under argon atmosphere in the dark. After 2 h of stirring, 2 drops of concentrated HCl were added to precipitate the product in its hydrochloride form. The solvent was removed to yield 257 mg (49%) of the yellow crystalline compound **10***b* and 168 mg of an orange oily substance that can easily be separated. The compound is rather hygroscopic and melts at 145°–153°C; ^1H nmr ($CDCl_3$), in the presence of phenylhydrazine to reduce the nitroxide group, δ: 1.4 (s, 12H), 2.35 (s, 3H, N—CH_3), 3.0 (s, 3H, CH_3SO_2—), 7.5 (bs, 5H); ms *m/e*: 419. *Anal.* calcd. for $C_{19}H_{32}N_2O_4Cl\cdot 2H_2O$: C 50.48, H 8.02, N 6.21; found: C 50.48, H 8.22, N 6.84.

Acknowledgments

The authors would like to express their gratitude to Dr. L. Humber and Ayerst Research Laboratories for a generous supply of (+)-butaclamol·HCl and the ketone precursor **2** and to Dr. M. Stern, Ayerst Research Laboratories, for conducting the receptor binding studies. Financial support from the Natural Sciences and Engineering Research Council of Canada (NSERC) is also acknowledged.

Hydride transfer reactions. Substituent effects in oxidation of *N*-benzylacridans by π acceptors

ALLAN K. COLTER, CHARLES C. LAI, TERRY W. WILLIAMSON, AND RAYMOND E. BERRY
Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received January 6, 1983

ALLAN K. COLTER, CHARLES C. LAI, TERRY W. WILLIAMSON, and RAYMOND E. BERRY. Can. J. Chem. **61**, 2544 (1983).

The kinetics of oxidation of a series of eight *N*-(substituted benzyl)acridans (**3**, NBA's) by 1,4-benzoquinone (BQ), *p*-chloranil (CA), 2,3-dicyano-1,4-benzoquinone (DCBQ), 7,7,8,8-tetracyanoquinodimethane (TCNQ), and tetracyanoethylene (TCNE) in acetonitrile (AN) and by BQ in 50:50 (v/v) AN-water were measured at 25°C. Equilibrium constants for pseudobase formation, K_{R^+}, from the corresponding acridinium ions (**4**) were measured in water at 25°C. Hammett correlations of the second-order rate constants for reaction of the NBA's without *ortho* substitutents (**3***a*–*e*) led to ρ values of −0.29 (BQ, AN), −0.55 (CA), −0.56 (DCBQ), −0.64 (TCNQ), −0.41 (TCNE), and −0.47 (BQ, 50:50 AN–water). The second-order rate constants for **3***a*–*e* also give good linear free energy correlations with the pK_{R^+} values of **4***a*–*e*. These correlations and the pK_{R^+} values for the *ortho*-substituted acridinium ions (**4***f*, *g*, *h*) are used to calculate rate constants for oxidation of the corresponding *ortho*-substituted NBA's (**3***f*, *g*, *h*). The rate constants calculated in this way are 4.7 to 6.6 times and 6.4 to 12 times larger, respectively, than the observed rate constants for *N*-(2,4,6-trimethylbenzyl) and *N*-(2,6-dichlorobenzyl)acridan (**3***g* and *h*). The variations in ρ values are attributed mainly to differences in the amount of electrostatic stabilization in the transition state resulting from differences in the separation of donor and acceptor and the degree of delocalization of the negative charge. The rate retarding effect of a pair of *ortho* substituents is attributed to steric effects in a preferred face-to-face transition state.

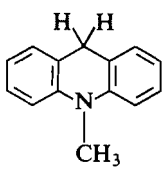
ALLAN K. COLTER, CHARLES C. LAI, TERRY W. WILLIAMSON et RAYMOND E. BERRY. Can. J. Chem. **61**, 2544 (1983).

On a étudié les cinétiques d'oxydation d'une série de 8 acridanes ayant un substituant benzyle sur l'azote (**3**, NBA) par la benzoquinone-1,4 (BQ), par le *p*-chloranil (CA), par la dicyano-2,3 benzoquinone-1,4 (DCBQ), par le tétracyano-7,7,8,8 quinodiméthane (TCNQ) et par le tétracyanoéthylène (TCNE) dans l'acétonitrile (AN) et par la BQ dans un mélange 50:50 (v/v) de AN–eau, à 25°C. On a mesuré, dans l'eau à 25°C, la constante d'équilibre de formation de la pseudobase pK_{R^+} à partir des ions acridinium (**4**). Les corrélations de Hammett relatives à la constante de vitesse d'ordre deux de la réaction des NBA sans substituant en position *ortho* (**3***a*–*e*) conduisent à des valeurs de ρ de: −0,29 (BQ, AN), de −0,55 (CA), de −0,56 (DCBQ), de −0,64 (TCNQ), de −0,41 (TCNE) et de −0,47 (BQ, 50:50 AN–eau). La constante de vitesse du deuxième ordre des composés **3***a*–*e* donne également de bonnes corrélations linéaires de l'énergie libre avec les valeurs de pK_{R^+} des composés **4***a*–*e*. On a utilisé ces corrélations et les valeurs du pK_{R^+} des ions acridinium substitués en position *ortho* (**4***f*, *g*, *h*) pour calculer la constante de vitesse d'oxydation des composés NBA (**3***f*, *g*, *h*) correspondants substitués en position *ortho*. Les constantes de vitesse calculées de la sorte sont respectivement de 4,7 à 6,6 fois et de 6,4 à 12 fois plus grandes que les constantes de vitesse observées pour les *N*-(trimethyl-2,4,6 benzyl) et *N(dichloro-2,6)benzylacridane* (**3***g* et *h*). On attribue les variations des valeurs de ρ principalement aux différences dans le taux de stabilisation électrostatique de l'état transition résultant des différences de séparation du donneur et de l'accepteur ainsi qu'au degré de délocalisation de la charge négative. On attribue l'effet retardant de vitesse d'une paire de substituants en position *ortho* aux effets stériques dans une conformation face à face privilégiée de l'état de transition.

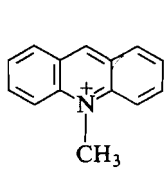
[Traduit par le journal]

Introduction

Oxidation of *N*-methylacridan (**1**, NMA) to *N*-methylacridinium ion (**2**) by π acceptors has been investigated (1, 2) as a model for biological redox reactions involving the nicotinamide coenzymes (3, 4) and as a common type of reaction between π donors and π acceptors (5). The net result of this and similar oxidations of dihydropyridines and dihydropyridine benzologues is transfer of a hydride ion from a hydride donor



1, NMA



2

such as **1** to a suitable hydride acceptor. In theory, the formal transfer of hydride could occur in a single step or by any of several mechanisms involving transfer of an electron and a hydrogen atom in two steps or two electrons and a proton in three steps. Stepwise mechanisms with an electron transfer as the first step have been suggested for particular hydride transfer reactions on the basis of spin-trapping experiments (2), hydrogen/deuterium isotope effects (6–11), detection of radical products (12), isotopic exchange with solvent (13–15), and substituent effects on the degree of asymmetric induction in reductions by chiral dihydronicotinamides (16). However, there remains considerable disagreement about the interpretation of many of these results. Recently, for example, it has been shown that some of the discrepancies between deuterium isotope effects measured by product and kinetic studies are due to the formation of a covalent adduct intermediate rather than an intermediate formed by electron transfer (17). For most hydride transfers it remains difficult to specify the mechanism with any certainty.

We have previously reported the kinetics and kinetic isotope effects in oxidation of NMA by a series of quinone and cyanomethylene acceptors spanning a greater than 10^7-fold range of reactivity. The present study was initiated with the hope that a change in mechanism or significant changes in transition state structure might be revealed by kinetic substituent effects if studied for a sufficiently wide range of acceptor strengths.

We report here an investigation of substituent effects in the oxidation of a series of *N*-(substituted benzyl)acridans (**3**, NBA's) with a series of 3 benzoquinone and 2 cyanomethylene acceptors (**5**–**9**), eq. [1]. The substituents in compounds **3***a*–*e*

5, BQ **6**, CA **7**, DCBQ **8**, TCNQ **9**, TCNE

are sufficiently remote and insulated from the reaction site so that they are not likely to have any significant effect on the mechanism as compared to that for NMA. Compounds **3***f*, *g*, *h* were included with the hope of learning something about transition state geometry through steric effects of *ortho* substituents.

Results

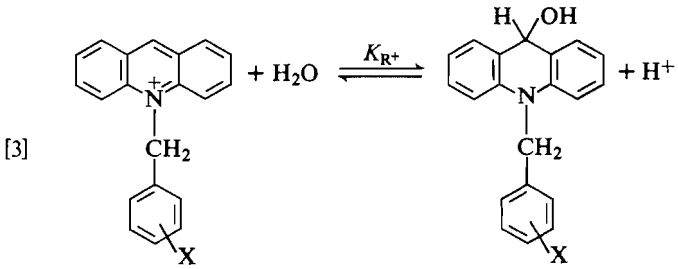
The product of oxidation of **3** by the five acceptors **5**–**9** is in every case the corresponding *n*-benzylacridinium ion **4**, identified by spectral examination of reaction mixtures and, in selected reactions, by isolation as the perchlorate or chloride salt. The corresponding reduction product of each acceptor, A, is identical to that produced in oxidation of NMA (1, 18), namely AH_2 from BQ + acetic acid, $A^{\cdot-}$ + 0.5 AH_2 from DCBQ, TCNQ, and TCNE, and a mixture of $A^{\cdot-}$, AH^-, and AH_2 from CA. As emphasized earlier (1), the radical anions of **6**–**9** are known to form very rapidly by reaction of AH^- (the product of hydride transfer) with unreacted acceptor ($2AH + A \rightarrow 2A^{\cdot-} + AH_2$), consequently the formation of $A^{\cdot-}$ in these reactions sheds no light on the mechanism of hydride transfer.

All rate measurements were carried out under pseudo first-order conditions using a 30-fold or greater excess of acceptor and following the progress of the reaction as previously described (1). The kinetics followed a first-order rate law through more than 3 half-lives, with pseudo first-order rate constants proportional to acceptor concentration within experimental error. The kinetic results for the NBA's without *ortho* substituents are summarized in Table 1, together with rate constants for NMA included for comparison.

The second-order rate constants in Table 1 are well-correlated by eq. [2] using normal σ values. Best fit slopes (ρ) and intercepts are listed in Table 2.

$$[2] \quad \log k = \rho\sigma + A$$

In order to obtain a measure of the electronic effects of substitution in the *ortho*-substituted NBA's, **3***f*, *g*, and *h*, equilibrium constants for pseudobase formation (20), eq. [3] were measured for all of the *N*-benzylacridium salts (**4**). The results



[3]

are summarized in Table 3. The pK_{R^+} values for **4***a*–*e* are also well correlated by Hammett σ values (eq. [4]).

$$[4] \quad pK_{R^+} = -0.794(\text{s.d. } 0.010)\sigma + 8.925(\text{s.d. } 0.005)$$

(corr. coeff. = 0.9996)

The correlations [2] and [4] require a correlation between log *k* for **3***a*–*e* and pK_{R^+} for **4***a*–*e*. This relationship (eq. [5]) is obtained by combination of [2] and [4] with elimination of σ.

$$[5] \quad \log k = \rho \frac{(8.925 - pK_{R^+})}{0.794} + A$$

Lacking appropriate σ values for the *ortho* substituents, the pK_{R^+} values for **4***f*, *g*, and *h* can now be used with eq. [5] to calculate the second-order rate constants for oxidation of **3***f*, *g*, and *h* under the 5 sets of conditions studied. These values are listed in Table 4, together with the observed rate constants for **3***f*, *g*, and *h*, and the ratio of the two values. This comparison is just a way of examining how well the rate constants for oxidation of the *N*-benzylacridans with one or two *ortho* substituents fit the correlation [5] between log *k* and pK_{R^+} defined by the NBA's without *ortho* substituents.

Discussion

Because of the similarity in the reactivities of the NBA's and

NMA under the same conditions (Table 1), we assume in the discussion which follows that earlier mechanistic conclusions based on solvent effects (1), deuterium labelling experiments (1), and spin-trapping experiments (2) are equally valid for oxidation of an NBA under the same conditions.

Before discussing the substantial differences in ρ values we note first that the results are consistent with a transition state having a partial positive charge on the hydride donor (NBA) for all of the reactions studied. The ρ value for the pK_{R^+} correlation (−0.79) can be taken as a measure of the sensitivity to substitution in the phenyl ring expected for development of a full positive charge, well separated from the negative charge on the acceptor, in aqueous solution. In AN the absolute value of ρ, i.e., |ρ|, is expected to be somewhat larger than 0.79. Bunting *et al.* (22) have compared ρ values for oxidation of *N*-(substituted benzyl)dihydronicotinamides by three quaternary heterocyclic cations in 20% AN − 80% water, with ρ values for dissociation of the cyanide adduct of the corresponding pyridinium ion oxidation product in the same solvent. Based on the assumption that |ρ| is proportional to charge development, these comparisons led to estimates of 0.7 to 0.8 of a full positive charge on the hydride donor in the transition state. If valid, these estimates exclude a mechanism involving reversible electron transfer followed by rate-determining hydrogen atom transfer in which the donor would bear a full positive charge in the rate-determining transition state. Our results strongly point to a similar conclusion for the hydride transfers studied in this work. However, as discussed later, in reaction of an uncharged donor with an uncharged acceptor the |ρ| value could be significantly reduced if the developing positive and negative charges are in close proximity.

[b]Averages of 7 or more values measured over a range of 1.0−1.3 pH units.
[c]Literature (21) 9.86 ± 0.06 (uncorrected for ionic strength).

In considering possible reasons for the substantial differences in the |ρ| values in Table 2 it is instructive to first consider the changes in transition state structure expected on changing from a relatively unreactive hydride acceptor and weak electron acceptor such as BQ (E^0_{red} in AN = −0.51 V vs. SCE (23)) to DCBQ, which is 10^7 times as reactive in oxidation of NMA and which is a much stronger electron acceptor (E^0_{red} in AN = 0.31 V vs. SCE (24)). The results of our earlier studies with NMA (1, 2) as well as those of the present studies with NBA's are equally compatible with a one-step hydride transfer mechanism [6] or with a three-step electron−proton−electron mechanism [7] in which the proton transfer step is rate-determining.

[6] $DH + A \rightarrow D^+ + AH^-$

[7] $DH + A \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} DH^+ A^- \xrightarrow[k_2]{\text{slow}} D\,AH^{\cdot} \xrightarrow{\text{fast}} D^+ + AH^-$

(DH represents hydride donor (NMA or NBA) and A the hydride (or π) acceptor.)

Following an argument first presented by Verhoeven and co-workers (25), we can now ask whether the radical cation − radical anion pair intermediate, DH^+A^-, of [7] is energetically accessible in the reactions investigated in this work. The standard free energy change accompanying formation of DH^+A^- from DH + A in AN is given by (25, 26):

[8] $\Delta G^0 = E^0_{ox}(DH/DH^+) - E^0_{red}(A/A^-) - C$

where $E^0_{ox}(DH/DH^+)$ is the standard one-electron oxidation

potential of the donor, $E^0_{red}(A/A^{\cdot-})$ the standard reduction potential of A (vs. the same reference), and C is the coulombic stabilization of the $DH^{+}A^{\cdot-}$ ion pair (about 0.06 eV in AN (26)). For strongly endothermic electron transfer the standard free energy of activation, $\Delta G^{\ddagger}$, can be approximated by ΔG^0, and the rate constant for electron transfer calculated from eq. [9] (27).

$$[9] \quad k_{ET} = 10^{11}\, e^{-\Delta G^{\ddagger}/RT}\, M^{-1}\, s^{-1}$$

The value of E^0 (DH/DH^{+}) cannot be measured precisely electrochemically because of the irreversibility of the one-electron oxidation on the time scale of the electrochemical measurements. However, from CV measurements on a series of acridans (28) a value of about 0.78 V (vs. SCE) can be estimated for NMA. Using this value, eqs. [8] and [9] lead to a value of 1.2×10^{-10} M^{-1} s^{-1} for k_{ET} from NMA to BQ. This value is 3×10^6 times smaller than the observed rate constant for oxidation of NMA by BQ, hence the radical ion pair $NMA^{+}BQ^{\cdot-}$ would appear to be an unlikely reaction intermediate. However, this discrepancy decreases with increasing reduction potential among the quinone oxidants studied and with DCBQ the calculated k_{ET} is 1.3 times the observed rate of oxidation of NMA by DCBQ. Successful trapping of the *N*-methyl-9-acridanyl radical (D˙) in this hydride transfer is evidence that a three-step mechanism is followed at least in part. With the cyanomethylene acceptors TCNQ (E^0_{red} vs. SCE = 0.19 V (29)) and TCNE (E^0_{red} vs. SCE = 0.24 V (29)) the calculated values of k_{ET} are 6×10^2 and 9 times larger, respectively, than their measured rate constants for oxidation of NMA, suggesting that mechanism [7] is at least possible in these reactions.

Application of the Hammond postulate to either of the mechanisms [6] or [7] leads to the prediction that |ρ| for a series of structurally-related acceptors should decrease with increasing acceptor reactivity. With the one-step mechanism [6], increasing acceptor reactivity is predicted to result in a more reactant-like transition state with less charge development. In the e^-, H^+, e^- mechanism [7] the charges in the radical ion pair intermediate are partially neutralized in the slow proton transfer (k_2) step. For the quinone acceptors the basicity of $A^{\cdot-}$ decreases with increasing acceptor reduction potential (30), hence k_2 should decrease at the same time, leading to a more product-like transition state with more complete charge neutralization. The same conclusion concerning the k_2 step in [7] is required by the observation (1)[1] that the observed rate constant for oxidation of NMA with quinones increases more slowly with increasing reduction potential than would the ratio k_1/k_{-1}.

Clearly, the observed ρ values, except those for TCNQ (−0.64) and TCNE (−0.41) are not in accord with these predictions. Furthermore, the two cyanomethylene acceptors are the most likely to react via a stepwise mechanism, yet their |ρ| values are the highest and second lowest, respectively. The ρ values alone therefore do not provide any clear evidence for a change in mechanism.

The observation that the rates of oxidation by BQ, the least reactive acceptor, are the least sensitive to substitution was unexpected. It is possible that the substituents in CA and TCNQ, as well as the greater delocalization of negative charge with these acceptors results in a transition state with greater charge separation and consequently less electrostatic stabilization of the developing positive charge.

The increase in |ρ| accompanying the change from AN to AN–water solvent is also unexpected. If the most important effect of water cosolvent is more effective solvation of the

developing negative charge on the acceptor, an increased separation of charge in the transition state with consequent decreased stabilization of the developing positive charge, and a larger $|\rho|$ value, could result.

The ρ value for pseudobase formation (−0.79) is to be compared with values of −1.32 and −1.14 for pseudobase formation from *N*-(substituted benzyl)-5-nitroquinolinium and 5-nitroisoquinolinium ions, respectively (31). The difference must reflect more extensive charge delocalization in the acridinium ions.

A single *ortho* methyl group in the *N*-benzylacridinium ions has an acidifying effect of 0.045 pK_a units, while the acidifying effect of two *ortho* methyl groups (**4***g* vs. **4***b*) is 0.181 pK units. No earlier examples of reversal of the normal effect of methyl substitution are known in pseudobase formation; however, numerous analogies are known with Brönsted acids. For example, the pK_a's of substituted benzylammonium ions fall in the order 4-methyl- > unsubstituted > 2-methyl (32). The usual explanation is steric inhibition of solvation (33).

As noted above, the rate constants for oxidation of **3***g* and *h* are 4.7 to 6.6 and 6.4 to 12 times smaller, respectively, than predicted by [5] from the pK_{R^+} values of **4***g* and *h*. Molecular models indicate that NBA's having two *ortho* substituents are forced to adopt a conformation in which the phenyl and heterocyclic rings are perpendicular and in which the nitrogen atom is shielded from both sides by the two *ortho* substituents. The perpendicular conformation is supported by nmr studies on *ortho*-substituted *N*-benzylpyridinium ions (34) and by nmr and dipole moment measurements and force field calculations on substituted diphenylmethanes (35). The *ortho* substituents in a conformation of this kind prevent an ideal face-to-face transition state in which electrostatic attraction between the positive and negative charges and π−π charge transfer interaction are maximized. The discrepancies between the calculated and observed rate constants for **3***g* and *h* therefore provide strong evidence for a face-to-face relationship between the donor and acceptor in the transition state. Given the differing steric requirements of the different acceptors and the differing degrees of charge delocalization, both of which will affect the degree of stabilization to be gained from an ideal face-to-face arrangement, it is perhaps surprising that the discrepancies between the calculated and observed rate constants for **3***g* and *h* are so similar.

Using eq. [5] and the pK_R- value for **2** it is also possible to predict a rate constant for NMA in each of the oxidations studied in this work. The rate constants calculated in this way are uniformly greater than the measured rate constants for NMA, the discrepancies varying from a factor of 2.6 (BQ in AN) to 6.4 (TCNQ). Speculation on the origin of these differences must await a more extensive investigation of substituent effects.

Experimental

Melting points were measured in open capillary tubes and are uncorrected. Proton nmr spectra were measured using Varian T60 or A60 spectrometers. Chemical shifts are reported in δ units, with tetramethylsilane as internal standard. Ultraviolet–visible spectra were obtained using Unicam SP800, Beckman 24, or Cary 118C spectrophotometers. Mass spectra were measured with a Varian Mat CH7 mass spectrometer. Elemental microanalyses were performed by Guelph Chemical Laboratories, Guelph, Ontario, or by MHW Laboratories, Phoenix, Arizona.

Reagents and solvents

BQ, CA, DCBQ, TCNE, and TCNQ were obtained and purified as previously described (1). Borax buffers (pH 8.00–9.40) were prepared from Fisher Scientific sodium hydroxide and hydrochloric acid solutions, and sodium tetraborate (Fisher, reagent) following Bates (36). Reagent grade acetonitrile was purified as described previously (1).

N-*Benzylacridinium salts* (**4**)

Six of the *N*-benzylacridinium bromides (all except **4***g* and *h*) were prepared by alkylation of acridine. Acridine (1.79 g, 0.010 mol) was heated with 0.015 mol of the appropriate benzyl bromide at 120°C (oil bath) for 24 h in a stoppered flask. (All of the bromides were commercially available except for *p*-methoxybenzyl bromide, which was prepared from the corresponding alcohol (37).) The resulting black solids were washed with large portions of ether until the washings were

almost colourless. The crude products were dissolved in the minimum amount of hot ethanol and precipitated by addition of ether at 0°C. The greenish powders were vacuum dried for 12 h at 78°C. Yields of salts prepared in this way were around 40%, and they were often contaminated by varying amounts of acridinium bromide. All attempts to obtain **4***g* and *h* in this way were unsuccessful.

Higher purity *N*-benzylacridinium salts were obtained by oxidation of the corresponding NBA's (below) with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) and isolation as the chloride or perchlorate. In a typical oxidation a solution of 0.85 g (3.7×10^{-3} mol) of DDQ in 125 mL of ether was added dropwise to a stirred solution of 3.5×10^{-3} mol of the NBA in 25 mL of ether at room temperature. Hydrogen chloride gas was passed through the black suspension until the solution turned clear, and the precipitated chloride salt isolated in essentially quantitative yield by filtration. Alternatively, the perchlorate salt could be isolated by addition of 3.0 mL of 70% $HClO_4$, instead of HCl gas, to the initial ether suspension. The crude product was purified by repeated solution in 10 mL of methanol followed by precipitation by addition of 50 mL of ether. The *N*-benzylacridinium salts melted with decomposition with darkening around 150°C. Their uv–visible spectra were all similar to that of *N*-methylacridinium cation (38) with characteristic maxima at 342, 358, 400, 420, and 440 nm in 0.01 mol dm^{-3} aqueous HCl solution. The *N*-benzylacridinium salts were further characterized by their ^{1}H nmr and mass spectra (Table 5) as well as by reduction to the corresponding NBA's (below). The mass spectra showed characteristic peaks at *m/e* corresponding to the cation of the salt (M^+) and often $M^+ + 1$, 179 and/or 180 (acridine and acridine + H) and (except for **4***e*) $M^+ - 179$, corresponding to a substituted benzyl cation. Similar results with quaternary pyridinium salts have been interpreted as arising from thermal reduction to the corresponding dihydro derivative (in this work, NBA's) prior to evaporation (39).

*N-Benzylacridans (**3**, NBA's)*

The NBA's were prepared by sodium borohydride reduction of the corresponding *N*-benzylacridinium salts as described earlier for *N*-methylacridinium salts (1). Yields were quantitative. All of the NBA's except **4***e* were also prepared by reaction of the lithium salt of acridan with the appropriate benzyl bromide. The following procedure for **4***d* is typical. To a stirred solution of 1.5 g (8.3×10^{-3} mol) of acridan in dry tetrahydrofuran (THF) under a nitrogen atmosphere and connected to a mercury bubbler was added 10 mL of 1.6 *M* butyllithium in hexane. The solution immediately turned purple with evolution of butane. After addition of gas stopped (ca. 5 min), a solution of 1.7 g (8.7×10^{-3} mol) of 4-cyanobenzyl bromide in 25 mL of THF was added. The solution turned a clear straw color after a few seconds. The THF was distilled off to a volume of about 15 mL and 85 mL of ether added. The ether solution was washed with water, dried over $MgSO_4$, filtered, and evaporated to yield a pale yellow solid which was crystallized from ethanol to yield 1.0 g (41% of theory) of white needles, mp 163–163.5°C. The NBA's were characterized by their ^{1}H nmr and mass spectra and by elemental analysis (Tables 6 and 7).

Kinetic measurements

Kinetic measurements were carried out spectrophotometrically as previously described for NMA (1). Measurements were carried out under pseudo first-order conditions using a 30-fold or greater excess of acceptor. The progress of the reaction was followed at the acridinium ion absorption maxima at 357.5–359 nm (BQ, CA, TCNE) or 420 nm (DCBQ), or the acceptor radical anion absorption at 680 or 725 nm (TCNQ). First-order plots were linear through at least 3 half-lives.

Final absorbances were constant for at least 20 half-lives in all rates except those involving oxidation of **3***a–f* with BQ in AN, where optical densities decreased very slowly after 7 to 10 half-lives. The uv–visible spectra of solutions of the *N*-benzylacridinium perchlorates, **4** ClO_4^-, in AN or 50:50 AN–water showed no detectable change over the periods of time involved in the rate measurements.

With BQ in 50:50 AN–water, CA, TCNE, and DCBQ infinite time absorbances (after subtraction of the absorbance due to the radical anion reduction products) agreed within ±5% of the values predicted from independently measured absorbances of **4** ClO_4^- in AN or AN–water. The final absorbances in the rates with BQ in AN were approximately 75% of the expected value with all donors. The reason for this discrepancy is not clear; however no product other than the *N*-benzylacridinium ion could be detected by uv–visible spectroscopy and **4***c* ClO_4^- was isolated in 88% yield in oxidation of **3***c* with BQ in AN (below). The absorbance due to **4** is masked in the TCNQ rates; however, uv–visible spectroscopy showed that the theoretical amount of $TCNQ^-$ was produced.

To further confirm that the NBA's are cleanly oxidized to the corresponding *N*-benzylacridinium ion, the products of oxidation of **3***c* and/or **3***d* by all acceptors in AN and by BQ in 50:50 AN–water

were isolated as the perchlorate salt. The following procedure is typical. A mixture of 0.0970 g (3.57×10^{-4} mol) of **3***c* and 0.0470 g (4.35×10^{-4} mol) of BQ was dissolved in 2 mL of AN containing 20 μL of anhydrous acetic acid. After 40 h at room temperature (correspondingly shorter times with 50:50 AN–water solvent and with the more reactive acceptors), the mixture was transferred to 50 mL of ether and 1 mL of 60% aqueous $HClO_4$ added. Filtration yielded 0.1165 g (88.1%) of **4** ClO_4^-, shown to be pure by quantitative uv–visible spectroscopy. Yields of 80–90% were obtained in the other product isolations.

pK_a measurements

The pK_a values were determined as described by Albert and Serjeant (40). Optical densities were measurd using a Guilford model 200 spectrophotometer with the cell compartment maintained at 25.00 ± 0.05°C, and were reproducible to ±0.002. pH measurements were carried out with a Beckman Research model pH meter equipped with a Sargent model DS-30072-15 combination glass–thallium amalgam electrode, in a jacketted cell mainained at 25.00 ± 0.05°C. A 0.01 *M* sodium tetraborate solution (pH = 9.180 at 25.0°C) was used as the primary pH standard. The pH readings were stable for at least 1 h and were reproducible to ±0.002 pH units. Solutions were prepared by dilution of 5.00 mL aliquots of a 10^{-4} *M* stock solution of the chloride or bromide salt to 50.00 mL with 0.01 *M* hydrochloric acid and 0.01 *M* sodium hydroxide solutions. Spectra were recorded from 300–500 nm in order to ensure stability of the acridinium ion and pseudobase. All of the salts had an adsorption maximum near 358 nm ($\epsilon \sim 2.6 \times 10^4$) where the pseudobase had no measurable absorbance at these concentrations. The position of this maximum was chosen as the analytical wavelength. A series of 7 or 8 solutions covering a pH range of at least 1.0 between 10% and 90% pseudobase formation was then prepared by dilution of the stock solution with borax buffers, and the pH and optical density (1 cm cell) at the analytical wavelength measured for each solution. With **4***h*, precipitation of pseudobase occured at 10^{-5} *M* concentrations necessitating further dilution to about 2×10^{-6} *M* and use of a 10-cm cell. Following each pH measurement the pH meter was rechecked with standard buffer to confirm instrumental stability during the measurements.

The aqueous stock solutions and the solutions of salts in 0.01 *M* hydrochloric acid showed no detectable change in absorbance after 48 h. The more basic buffer solutions faded slowly, particularly those of **4***a* and **4***g* which showed a detectable decrease after about 20 min. Absorbance readings were taken between 5 and 15 min of preparation of the solutions, during which no detectable change in absorbance occurred. The reaction responsible for the decrease in absorbance was not investigated.

A "mixed" pK_a value, pK_a^M (40) was calculated from each set of measurements using the equation

$$[10] \quad pK_a^M = pH + \log\frac{[OD - OD_{base}]}{OD_{acid} - OD}$$

where OD, OD_{base}, and OD_{acid} are the optical densities of the solution prepared from buffer, NaOH, and HCl solutions. Each "mixed" constant so obtained was corrected to zero ionic strength by means of the expression (40)

$$[11] \quad pK_a = pK_a^M - \frac{0.507\, I^{1/2}}{1 + 1.6\, I^{1/2}}$$

where I is the ionic strength for the particular buffer (36). Corrections varied from −0.048 to −0.067.

A constrained configuration interaction method

G. D. ZEISS and M. A. WHITEHEAD

Chemistry Department, McGill University, 801 Sherbrooke Street West, Montreal, P.Q., Canada H3A 2K6

Received February 21, 1983

G. D. ZEISS and M. A. WHITEHEAD. Can. J. Chem. **61**, 2552 (1983).

Constrained configuration interaction (CI) wavefunctions (CVM-CI) were determined using the modified perturbation–iteration (MPI) method, two approximate versions of the MPI method, and the secant-parameterization method. The results of constrained CI calculations on CO using a 25 configuration wavefunction showed that the MPI method converged rapidly, and that the secant-parameterization method was computationally more economical.

G. D. ZEISS et M. A. WHITEHEAD. Can. J. Chem. **61**, 2552 (1983).

On a déterminé les fonctions d'onde (CVN-IC) d'interaction de configuration (IC) contrainte en utilisant la méthode modifiée de perturbation–itération (MPI), deux versions approximatives de la méthode MPI ainsi que la méthode de paramétrisation séquentielle. Les résultats des calculs de IC contrainte, effectués sur le CO en utilisant une fonction d'onde à 25 configurations, montrent que la méthode MPI converge rapidement et que la méthode de paramétrisation séquentielle est, du point de vue du temps de calcul, plus économique.

Introduction

The variational problem of minimizing the energy of the trial wavefunction which is constrained to give a known theoretical or experimental expectation value of an operator is well known, and becomes even more difficult when the trial wavefunction is a configuration interaction expansion.

An earlier attempt (1, 4*a*) to solve constrained secular equations for configuration interaction calculations, the modified perturbation–iteration method, MPI, needed an initially fully diagonalized Hamiltonian matrix, which is a serious computational disadvantage, because for large CI expansions, the time required to fully diagonalize the Hamiltonian is formidable. Therefore two approximate MPI methods which use a partially diagonalized Hamiltonian matrix and the secant-parameterization procedure which does not require the Hamiltonian matrix to be diagonal will be developed and their results compared to those from the MPI method using a diagonalized Hamiltonian matrix. The test molecule is CO with a 25 configuration CI wavefunction on which the constrained calculations are performed. The relative accuracies and computational efficiencies of the methods will be compared.

The constrained configuration interaction equations

The general form of a CI wavefunction (2, 3) is

$$[1] \quad \psi_{CI} = \sum_i c_i \Phi_i$$

The Φ_i are orthogonal, symmetry-adapted linear combinations of Slater determinants D_k,

$$[2] \quad \Phi_i = \sum_k a_k D_k$$

the a_k are determined by requiring each configuration Φ_i to have the correct spatial and spin symmetry. The constrained CI equations are suitable to solve by the parameterization (4*b*) or iterative–perturbation procedures (4*b*) and the variational principle (5) to give

$$[3] \quad \sum_j (H'_{ij} - E\,\delta_{ij})\, c_j = 0$$

where

$$H' = H + \lambda[M - \mu]$$

and

$$[4] \quad \sum_{ij} c_i (M_{ij} - \mu\delta_{ij})\, c_j = 0$$

where H'_{ij} and M_{ij} are matrix elements of the Hamiltonian H' and the property operator, M', is the known expectation value of the operator M which constrains the Hamiltonian

$$[5a] \quad H'_{ij} = \langle \phi_i | H' | \phi_j \rangle = \langle \phi_i | H + \lambda[M - \mu] | \phi_j \rangle$$

and

$$[5b] \quad M_{ij} = \langle \phi_i | M | \phi_j \rangle$$

Only single constraints μ are explicitly considered. Generalization of [3] and [4] to multiple constraints μ, ν etc. is straightforward.

Procedures for solving the constrained CI equations

The secant-parameterization (6) and a modified perturbation–iteration method are considered (6).

The secant-parameterization procedure is easily adapted to constrained CI calculations. Instead of solving the constrained RHF equation (6)

$$\sum_j^m F'_{ij} C_{iv} = \sum_j^m S_{ij} C_{jv} \epsilon'_v$$

for each new estimate of λ, the constrained CI equation [3] is solved. The ground state CI wavefunction for each new estimate of λ is found; they are very rapid procedures to calculate one or more eigenvectors of large matrices (7–11).

The perturbation–iteration method (12, 13) is iterative; a new λ is obtained in each iteration using the perturbation expression (1, 4). The perturbation energy coefficients $E^{(n)}$ are evaluated using sum-over-states expressions involving eigenvalues and matrix elements between eigenfunctions of a zeroeth order Hamiltonian (14). The zeroeth order eigenvalues and eigenfunctions are chosen to be the eigenvalues and eigenfunctions of H' from the previous iteration; thus, H' is diagonalized completely for each new λ. When the CI expansion eq. [1] involves more than a few terms, the time to repeatedly fully diagonalize H' becomes prohibitive.

The modified perturbation–iteration (MPI) method (1) diagonalizes the unperturbed Hamiltonian H, uses the eigenvalues and eigenfunctions to calculate a set of perturbation energies

[a]Diamagnetic contribution to the diamagnetic susceptibility, au; au = $N_0 a_0^3$ (Avogadros Number and Bohr radius from ref. 26) = 8.92394×10^{-2} cm mol^{-1}.

$E^{(n)}$ that are used throughout the iterative procedure. After the first iteration only the eigenfunction corresponding to the lowest eigenvalue is needed; this is a very rapid process (7−11).

For elaborate CI wavefunctions it is computationally unfeasible to fully diagonalize the Hamiltonian matrix, and *approximate* zeroeth order eigenfunctions and eigenvalues are used to evaluate the perturbation energies $E^{(n)}$ by partially diagonalizing the Hamiltonian. This is equivalent to solving the CI eq. [3] for a truncated CI expansion eq. [1] obtained by including only the most important configurations, depending on the particular constraint, and the method to construct the configurations Φ_i. If one configuration, Φ_0, is expected to be the dominant term, i.e. $c_0 \gg c_i$ for $i > 0$, then one criterion for choosing the configurations to be included in the truncated expansion is that $|M_{0j}|^2/|H_{00} - H_{jj}|$ be large.

For a closed shell system the configuraion Φ_i in eq. [1] is the RHF wavefunction and the excited RHF symmetry adapted configurations are obtained by exciting one or more electrons into virtual RHF orbitals (15). The RHF wavefunction is the dominant term in the CI expansion for the ground state wave-

function (16). For a one-electron operator M, the matrix element M_{0j} remains only for the singly excited configurations. Therefore an appropriate choice of configurations in the truncated expansion is the ground state and singly excited RHF configurations: the eigenvalues and eigenfunctions[1] from solving the CI eq. [3] are the singly excited state energies and wavefunctions in the Tamm–Dancoff approximation (20) and represent reasonable approximations to the eigenvalues and eigenfunctions of the full Hamiltonian matrix, which make the largest contributions to $E^{(n)}$.

Another choice of approximate zeroeth order wavefunctions and energies is the RHF ground and singly excited configurations and the corresponding diagonal elements of the Hamiltonian matrix, which is equivalent to the uncoupled RHF, UCRHF, method I approximate RHF perturbation theory (4, 6).

Constrained CI calculations on CO: comparison of the secant-parameterization and modified perturbation–iteration methods

Singly constrained calculations using the dipole moment, x_n, molecular quadrupole moment $-\theta_n^e$, and the diamagnetic contribution to the diamagnetic susceptibility, r_n^2, as constraints were performed on CO using a minimum basis set of STO-4G (21) functions with Slater exponents (22). The CI wavefunction was expanded in $25\,^1\Sigma^+$ configurations (78 Slater determinants), including the RHF ground state and all singly and doubly excited RHF configurations (SDECI) except doubly excited configurations involving excitations from the 1σ and 2σ core orbitals and a small number of doubly excited configurations that contributed negligibly to the unperturbed ground state CI wavefunction. Eigenfunctions of the S^2 spin operator were obtained by the diagonalization method (23–25). The lowest eigenvalue of the unperturbed CI Hamiltonian matrix was calculated to be −134.6760 hartree, 0.1282 hartree below the minimum basis set RHF energy. The increase in the total energy due to each constraint was x_n, 0.0193, $-\theta_n^e$, 0.0257, and T_n^2, 0.1314 hartree. The results of the constrained CI calculations are reported in Tables 1 through 3. The MPI procedure converges very rapidly, requiring from one to three iterations. The SEMPI and RHFMPI procedures converge to the correct value much more slowly. Comparing the perturbation–iteration and secant-parameterization procedure results, Table 4 shows the latter procedure requires a few more iterations for convergence than the MPI method. However, the computation time to fully diagonalize the initial unperturbed Hamiltonian matrix outweighs the advantages of the better rate of conver-

[1]Brillouin's theorem (17–19) requires that Hamiltonian matrix elements between the ground state RHF wavefunction and singly excited RHF configurations vanish. Therefore the ground state wavefunction in the single excitation CI approximation is just the RHF ground state wavefunction.

gence using the MPI procedure. The secant-parameterization procedure usually converges much more rapidly than the approximate MPI procedures.

Values of the perturbation energies $E^{(n)}$ and perturbation estimates of λ calculated using the SDECI, SECI, and UCRHF I ground and excited wavefunctions are reported in Tables 5 thorough 7. Except the values of $E^{(2)}$ through $E^{(4)}$ obtained when $-\theta_n^c$ is the constrained property, the SECI and UCRHF I values of the $E^{(n)}$ agree poorly with the SDECI results, accounting for the poor rate of convergence obtained with the approximate MPI procedures. The SECI and UCRHF I results agree well. The difference between the SECI and UCRHF I second and seventh order estimates of λ, $\lambda^{(2)}$, and $\lambda^{(7)}$ respectively is small compared to the error in the quantities due to the choice of zeroeth-order eigenvalues and eigenfunctions. Therefore there appears to be little value in carrying the perturbation expansion beyond second order.

Conclusion

The results of the constrained CI calculations on CO show that the secant-parameterization procedure is computationally a more economical constraint procedure than the MPI or approximate MPI methods because, in contrast to the MPI methods, *it is not necessary* to fully diagonalize the Hamiltonian matrix initially, a very important advantage in large CI calculations. The secant-parameterization procedure is easily extended to multiple constraint calculations, whereas for multiple constraints the MPI method is unwieldly.

Kinetics and mechanism of the bromination of 4-pyridone and related derivatives in aqueous solution

OSWALD S. TEE[1] AND MARTINO PAVENTI

Received May 9, 1983

OSWALD S. TEE and MARTINO PAVENTI. Can. J. Chem. **61**, 2556 (1983).

The kinetics of bromination of 4-pyridone and selected derivatives have been measured in aqueous solutions in the pH range 0–9, at 25°C. The tautomerie system 4-pyridone ⇄ 4-hydroxypyridine (**1***a* ⇄ **2***a*) reaets with bromine via the predominant (pyridone) tautomer at pH < 6 and via the conjugate anion at pH > 6. 3-Bromo-4-pyridone behaves similarly. The kinetics also reveal that the facile dibromination of 4-pyridone occurs because at most pH's the monobromo derivative is actually more reactive towards bromine by virtue of its lower pK_a values. From the point of view of reactivity the 4-pyridones and their anions behave as substituted phenoxide ions. 4-Methoxypyridine does not undergo bromination under comparable conditions, but rather forms a complex with bromine.

OSWALD S. TEE et MARTINO PAVENTI. Can. J. Chem. **61**, 2556 (1983).

On a mesuré les cinétiques de la bromation de la pyridone-4 et de quelques dérivés en solutions aqueuses et dans un intervalle de pH allant de 0 à 9, à 25°C. Le système tautomère pyridone-4 ⇄ hydroxy-4 pyridine (**1***a* ⇄ **2***a*) réagit avec le brome par l'intermédiaire du tautomère prédominant (pyridone) à un pH < 6 et par l'intermédiaire de l'anion conjugué à un pH > 6. La bromo-3 pyridone-4 se comporte de la même façon. La cinétique révèle également que la débromation facile de la pyridone-4 se produit parce qu'à plusieurs pH le dérivé monobromé est actuellement plus réactif vis-à-vis du brome en raison de ses pK_a's plus faibles. Du point de vue de la réactivité, les pyridones-4 et leurs anions se comportent comme des ions phénoxydes substitués. La méthoxy-4 pyridine, dans des conditions comparables, n'est pas bromé, mais elle forme de préférence un complexe avec le brome.

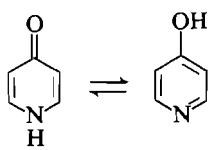
Introduction

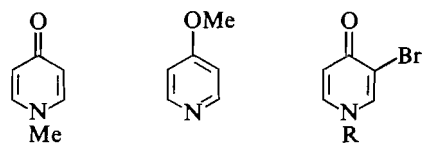
Pyridones react readily with halogens or halogenating agents in various media (1). The reactions are so facile that 3,5-disubstitution is almost always observed, and useful clean monohalogenation has rarely been reported (1, 2). We recently showed that monobromination of 2-pyridone can be achieved in aqueous solution by controlling the pH of the medium (3). This was made possible by a kinetic study of the bromination of 2-pyridone and selected derivatives over a wide range of pH. We ascertained the reactive forms of 2-pyridone and the relative reactivities of its monobromo derivatives and their reactive forms. This information enables the choice of conditions such that the second bromination is slow relative to the first (3).

The present paper reports an analogous study of the aqueous bromination of 4-pyridone (**1***a*). In it we likewise ascertain the reactive forms of the substrate and probe the origins of its facile dihalogenation. As a result, we show how its monobromination can be carried out relatively easily. In contrast, other routes to 3-bromo-4-pyridone are long and give poor overall yields.



1*a* **2***a*

In the vapour phase and in dilute nonpolar solution the tautomeric equilibrium **1***a* ⇄ **2***a* favours 4-hydroxypyridine (**2***a*). However, in aqueous solution the pyridone tautomer **1***a* predominates by a factor of ~2000:1 (4). Nevertheless, in principle the aqueous bromination of 4-pyridone could take place upon the minor tautomer if this was sufficiently reactive. Therefore, in order to find out which of the tautomers is the reactive form we have studied the bromination of the tautomeric system **1***a* ⇄ **2***a*, and of the methyl derivatives, 1-methyl-4-pyridone (**1***b*) and 4-methoxypyridine (**2***b*).



1*b* **2***b* **3***a*, R = H
3*b*, R = Me

To gain insight into the facile dihalogenation of 4-pyridone we have also studied the bromination of 3-bromo-4-pyridones **3***a* and **3***b*. As with our previous study, the speed of the reactions rules out conventional means of following the kinetics, and so we have used stopped-flow uv spectrophotometry (3, 5).

Results

All of the substrates studied react fairly quickly with bromine in water and undergo bromination, with the exception of 4-methoxypyridine, **2***b*. This substrate reacts to form a 1:1 complex with bromine which impedes normal electrophilic bromination of **2***b* (see Experimental).

Kinetic studies

The four remaining substrates (**1***a*, **1***b*, **3***a*, **3***b*) were studied in reaction with bromine in aqueous media in the pH range 0–9 using the same methods as earlier (3, 5). For the most part a large excess of substrate over bromine was employed, and under these conditions the disappearance of bromine was cleanly first-order. Rate constants (k_1^{obs}) obtained from analysis of the absorbance data increased linearly with substrate concentration, but were independent of the initial bromine concentration. Thus we conclude that at any given pH the reaction of

[a]Introduced as HNO_3 salt.
[b]Introduced as sodium salt dihydrate.
[c]Introduced as HBr salt.
[d]Correction for Br^- includes contribution from KBr + HBr.

bromine with the substrates follows a second-order rate law. Accordingly, the observed values of k_1^{obs} were converted to

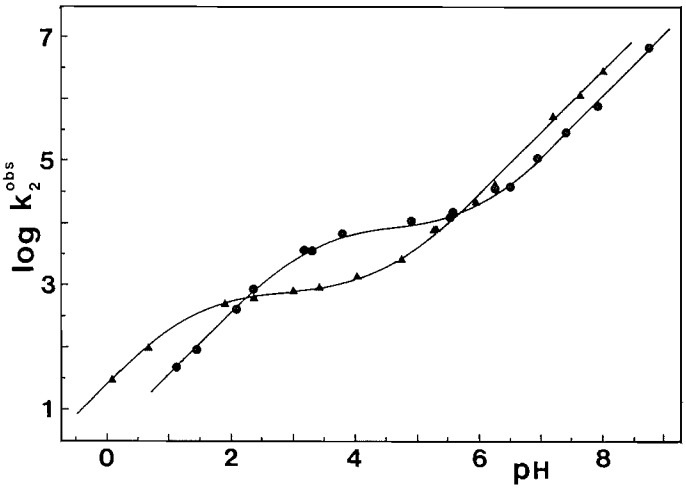

FIG. 1. pH–rate profiles for reaction of aqueous bromine with 4-pyridone **1***a* (circles) and 3-bromo-4-pyridone **3***a* (triangles) at 25°C, I = 1.0 *M* (KBr).

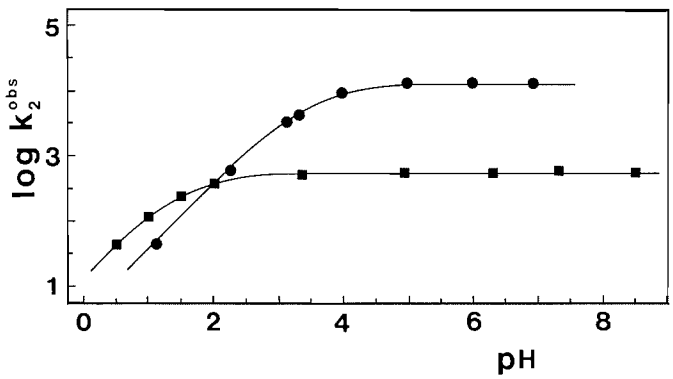

FIG. 2. pH–rate profiles for reaction of aqueous bromine with 1-methyl-4-pyridone **1***b* (circles) and 3-bromo-1-methyl-4-pyridone **3***b* (squares) at 25°C, I = 1.0 *M* (KBr).

second-order rate constants (k_2^{obs}), taking into account the substrate concentration and the depletion of free bromine due to the formation of tribromide ion, hypobromous acid, and its anion (see Experimental).

The observed rate constants are collected in Table 1, and displayed in Figs. 1 and 2. In many cases the absorbance data were also analyzed directly for second-order behaviour (5*c*). The rate constants (k_2^{obs}, after correction for the free bromine concentration) thus obtained were generally in good agreement with those derived from k_1^{obs} values. In Table 1, where no entry is given for k_1^{obs}, the value of k_2^{obs} was obtained solely from second-order analysis (5*c*).

The observed pH–rate profiles (Figs. 1 and 2) are very similar to those obtained earlier for the analogous 2-pyridones (3). The *N*-methyl derivatives **1***b* and **3***b* show profiles (Fig. 2) appropriate for reaction upon their free base forms, since the literature protonation pK for **1***b* is 3.33 (6) and that for **3***b* we have measured to be 1.52. For such behaviour (eq. [1]) the appropriate form of the observed rate constant is given by

$$[1]\quad SH^+ \overset{K_1}{\rightleftharpoons} S \xrightarrow[Br_2]{k_2} \text{products}$$

$$[2]\quad k_2^{obs} = k_2K_1/(K_1 + [H^+])$$

eq. [2]. The calculated curves in Fig. 2 were generated from eq. [2] using the values of k_2 and K_1 (expressed as pK_1) given

TABLE 2. Constants for reaction of bromine with 4-pyridones in aqueous solution (25°C, I = 1.0 M (KBr))

Substrate	pK_1 meas.	pK_1 fitted	pK_2	k_2 (M^{-1} s^{-1})	$k_2'K_2$ (s^{-1})	k_2' (M^{-1} s^{-1})

1*b*	3.33[a]	3.58	—	12800	—	—
3*a*	1.37[b]	1.53	9.46[c]	791	0.0287	8.28×10^7
3*b*	1.52[b]	1.58	—	549	—	—

[a]At 20°C, from ref. 6.
[b]This work, at 25°C, and I = 0.15 M ($HClO_4$ + $NaClO_4$).
[c]This work, at 25°C, and I = 0.1 M (KBr).

in Table 2. The fitted values of pK_1 (3.58 and 1.58) are in good agreement with the measured values (3.33 and 1.52).

The data for 4-pyridone **1***a* and its 3-bromo derivative **3***a*, which are shown in Fig. 1, cannot be solely explained by eqs. [1] and [2]. Clearly in each case another process takes over at the higher pH's which we believe to be reaction upon the conjugate anions of the substrates. Such behaviour was observed earlier for 2-pyridones (3). For this situation (eq. [3]) the expected variation of k_2^{obs} with acidity is given by eq. [4].

[3] $$SH_2^+ \overset{K_1}{\rightleftharpoons} SH \overset{K_2}{\rightleftharpoons} S^-$$
$$k_2 \downarrow Br_2 \qquad k_2' \downarrow Br_2$$
$$\rightarrow \text{products} \leftarrow$$

[4] $$k_2^{obs} = \frac{k_2K_1}{(K_1 + [H^+])} + \frac{k_2'K_2}{[H^+]}$$

The simplicity of the second term in this equation is warranted at the pH's employed, since for 4-pyridone pK_2 = 11.09 (6) and for 3-bromo-4-pyridone we have measured pK_2 = 9.46.

From Fig. 1 and the calculated curves shown therein, it is clear that eq. [4] gives an excellent representation of the data for the substrates **1***a* and **3***a*. The appropriate parameters are again collected in Table 2.

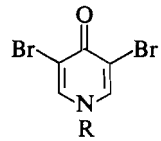
In summary, the reaction of bromine with the 4-pyridones **1***a*, **1***b*, **3***a*, and **3***b* over the pH range 0–9 apparently involves attack upon the free base form and upon the conjugate anions of **1***a* and **3***a* at higher pH (see Fig. 1).

Product studies

As noted above, and detailed in the experimental section, 4-methoxypyridine **2***b* does not undergo normal electrophilic bromination, but rather forms a relatively stable complex with bromine. This complex is obtained whether the solvent is water, ethanol, or chloroform. It brominates acetone in chloroform and **2***b* is recoverable as its hydrobromide salt.

Attempted bromination of 4-pyridone **1***a* in concentrated hydrobromic acid gave a 73% yield (based on bromine) of 3,5-dibromo-4-pyridone **4***a*. Proton magnetic resonance analysis of the mother liquor revealed a 2:5 ratio of **3***a*/**1***a*. Likewise, bromination of **1***a* in unbuffered 1 M aqueous KBr gave a 67% yield of **4***a*. When this reaction was repeated in the presence of one equivalent (to **1***a*) of KOH the yield of **4***a* was 86%. In all cases, 3-bromo-4-pyridone **3***a* was only a minor product of reaction.

We also carried out various other bromination reactions employing different reagents and solvents. In all cases the dibromo derivative **4***a* was the major product, with yields of 60–72% (see Experimental).



4*a*, R = H
4*b*, R = Me

After we had obtained the kinetic data shown in Fig. 1 it seemed likely that the best chance of monobrominating 4-pyridone was in aqueous solution buffered in the region pH 3–5, the only region where the rate profile of **1***a* rises above that of **3***a*. Accordingly, bromine in aqueous KBr was slowly added to an equivalent amount of 4-pyridone in water buffered with sodium acetate/acetic acid to pH 4.2–4.4. From solution there precipitated a 26.2% yield of the dibromo compound **4***a*, but the mother liquor contained **3***a* (73.8%) and the appropriate amount of **1***a* (26.2%). After purification and recrystallization we obtained a 28% yield of the desired 3-bromo-4-pyridone, **3***a*. No optimization was attempted, but probably with stronger buffering and improved separation of the product mixture a higher isolated yield of **3***a* could be obtained.

Other routes to **3**a

At the outset various attempts were made to synthesize **3***a* unambiguously using routes based directly or indirectly on literature precedents. With one exception they were unsuccessful due to reactions giving no product or an undesired product. The successful exception involves a multistep route in which the last step gave a very poor yield of the desired product. 3-Bromopyridine (7) was converted to its *N*-oxide (8) which was then nitrated to 3-bromo-4-nitropyridine-*N*-oxide by a modification of literature procedures (9, 10). Simultaneous reduction of the nitro group and the *N*-oxide moiety by iron and acetic acid (11) gave 3-bromo-4-aminopyridine. After several attempts, hydrolysis of this product by diazotization (12) produced only 3% of the desired 3-bromo-4-pyridone, **3***a*.

3-Bromo-4-nitropyridine was made by deoxygenation (13) of its *N*-oxide (*vide supra*). An attempt to hydrolyse it to **3***a* with aqueous barium hydroxide (14) failed. Hydrolysis in refluxing aqueous sulphuric acid gave material which had some of the characteristics of **3***a*, but the melting point was 125° too low!

Bromination of 4-hydroxypyridine-*N*-oxide, according to the procedure of Hayashi (15), gave the 3,5-dibromo derivative and not the desired 3-bromo product, as reported (15). Likewise, attempted monobromination of chelidamic acid (4-pyridone-2,6-dicarboxylic acid) gave the undesired dibromo derivative.

Monobrominations of 4-aminopyridine and of 4-dimethylaminopyridine were also not successful due to the formation of complexes with the halogen (16).

Clearly, on the basis of our experience, the best approach to 3-bromo-4-pyridone **3***a* is to use direct bromination of 4-pyridone in an aqueous medium strongly buffered at pH 4.

Discussion

Reactive forms

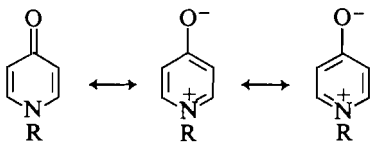
Over the pH range 0–5 the rate profiles of 4-pyridone **1***a* and its *N*-methyl derivative **1***b* are virtually superimposable. This is reflected in Table 2 by their very similar values of k_2. In contrast, the *O*-methyl derivative **2***b* shows quite different behaviour towards bromine. Given that the pyridone tautomer **1***a* greatly predominates in aqueous solution (4), our results provide compelling evidence that 4-pyridone **1***a* reacts with bromine as its major tautomer and not via the minor hydroxy tautomer **2***a*, at pH < 6. At higher pH the rate of bromination of **1***a* increases in a manner appropriate for reaction upon its conjugate anion (eq. [4], Fig. 1).

In the same way, the reactivity of the monobromo derivatives **3***a* and **3***b* are very similar at low pH, consistent with **3***a* reacting as such. Above pH > 3.5, **3***a* apparently reacts with bromine via its anion.

Our results complement those of Katritzky and co-workers for the nitration in strong acid and the deuterium exchange of 4-pyridone at high temperatures (17, 18). Nitration takes place upon the free base pyridone tautomer except at higher acidities where the conjugate acid reacts (17). Hydrogen isotope exchange apparently only involves the free base form (18).

Reactivities

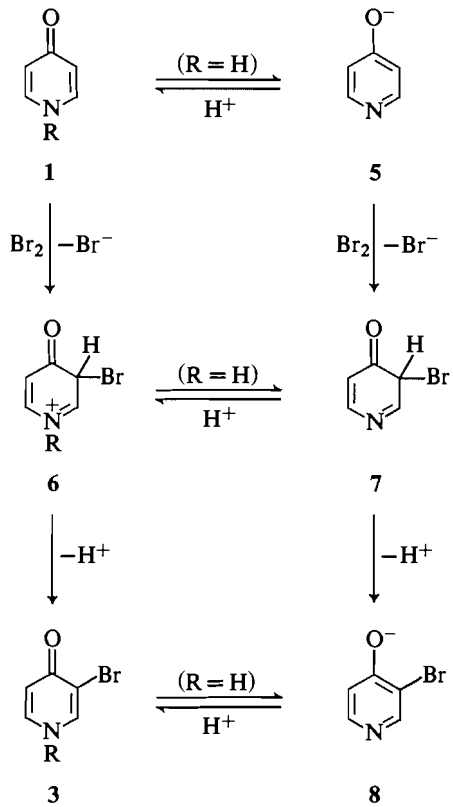
For 2-pyridones and their anions we showed that they react with bromine at rates expected for substituted phenoxide ions (3). This correlation is rationalized by consideration of the dipolar valence-bond structures which contribute to a pyridone. In the case of the 4-pyridones **1**, there must be significant contributions from the structures **1′** and **1″**, as Acheson emphasizes (19). They can account for various properties of **1***a* (19),



1 **1′** **1″**

including the solvent dependence of its tautomerism (4) and its reactivity in deuterium exchange (18). The structures **1′** and **1″** suggest that 4-pyridone can be considered as phenoxide ion bearing a *para* azonium nitrogen (=$\overset{+}{N}$H—) as substituent. Of course, the anion of **1***a* is phenoxide ion with a *para* aza nitrogen (=N—).

Using literature values of σ_m^+ for azonium nitrogen (2.00), aza nitrogen (0.54), and bromine (0.41) (3, 20, 21) the rate data for **1***a*, **3***a*, and their respective anions give a good correlation (r = 0.9987) with $\rho^+ = -3.43$. This is similar to the value of −3.83 for 2-pyridones and their anions (3) and the value of −3.5 for phenoxide ions estimated by Kulic and Vecera (22). It adds further weight to the idea that, with respect to reactivity, pyridones and their anions behave as substituted phenoxides.



SCHEME 1

Mechanism

Our data can be explained by the simple pathways set out in Scheme 1. In acidic solution **1** (*a* or *b*), in equilibrium with its protonated form, is attacked by bromine to give the transient cation **6** which is deprotonated to form the product **3**. In the case where R = H the cation **6***a* may also deprotonate to the neutral azacyclohexadienone **7**. However, we see no evidence of the build-up of any intermediates during the reaction.[2] Therefore we surmise that acid- or base-catalyzed tautomerization of **7** to **3***a* is relatively fast.[3]

At higher pH 4-pyridone **1***a* reacts via its anion **5** to give directly the azacyclohexadienone **7**. Again, tautomerization of this intermediate (**7** → **8** → **3**) is presumed to be fast.[3] This pathway is analogous to that followed by phenols which react via their anions, except at high acidities (22, 23).

The brominations of **3***a* and **3***b* show similar rate profiles to those of **1***a* and **1***b*. Therefore we propose that they occur by mechanisms analogous to those set out in Scheme 1.

[2]We have observed the formation of relatively long-lived intermediates during the bromination of pyrimidones, uracils, and cytosines (5).

[3]Available evidence in the literature suggests that cyclohexadienones are not observable in the aqueous bromination of phenols. Kulic and Vecera found that bromine decrease and product increase occur at the same rate for various *para* substituted phenols (22). However, we have recently shown that 4-bromo-2,5-cyclohexadienones are observable in the aqueous bromination of simple phenols. On the other hand, we cannot detect any intermediates from phenols bearing electron-withdrawing groups or the cyclohexadienones derived from *ortho* bromine attack. In these cases tautomerization to the aromatic product is almost certainly too fast (39).

For personal use only.

The principal active electrophile in the brominations of **1** and **3** is almost certainly molecular bromine, as depicted in Scheme 1. Tribromide ion is present in significant concentration under the conditions used. However, it is a much weaker electrophile in general (24), and for highly reactive phenoxide ions its reactivity is only about 1% of that of bromine (23). It is probable, therefore, that Br_3^- only makes a contribution where 4-pyridone is reacting via its anion **5**.

Other potential electrophiles are hypobromous acid (HOBr) and its protonated form (H_2OBr^+) (24). The former is much less reactive than bromine and its concentration is very low under our conditions, excepts at the higher pH's. Moreover, the observed pH dependences are inconsistent with its involvement. The concentration of the much more reactive electrophile H_2OBr^+ must be extremely low, given the low concentration of HOBr. For it to be involved in the reaction of the anions of **1***a* and **3***a* would required rate constants above diffusion-controlled (25).

Disubstitution

The reasons behind the facile dibromination of 4-pyridone **1***a* are easily seen by referring to Fig. 1 and Table 2. Except for the relatively small range of pH 2.5−5.5, 3-bromo-4-pyridone **3***a* is effectively more reactive than **1***a* (Fig. 1). This apparently anomalous situation arises because of the relationships between the values of k_2K_1 and k_2K_2 for the two substrates.

At pH < 2, where both **1***a* and **3***a* are significantly protonated, the difference in reactivity of **1***a* and **3***a* (factor of 12) is more than offset by the difference in K_1 values (factor of 85). Likewise at pH > 5.5, where reaction upon the conjugate anions predominates, the higher reactivity of the anion of 4-pyridone is more than compensated for by the larger value of K_2 for **3***a*.

Even at pH 4, where the rate profile for **1***a* is significantly above that for **3***a*, reaction upon **1***a* is only favored by a factor of about 6.3 (Fig. 1). Therefore, in a 1:1 reaction of bromine with 4-pyridone **1***a*, by the time of 86% reaction the product **3***a* effectively competes with **1***a* for bromine, and a significant amount of dibromo product **4***a* will result. Seen in this light, our 26% yield of **4***a* from a reaction buffered around pH 4.3 is not surprising.

The literature contains a preparative iodination of 4-pyridone, carried out with iodine in aqueous potassium iodide (26). This procedure leads to a 50% yield of the 3-iodo derivative, as well as 21% of the 3,5-diiodo compound. Presumably similar factors are involved here as in the bromination reaction, and so one can anticipate similar rate profiles. A higher yield of the monoiodo product might be obtained by using a medium buffered around pH 4.

Experimental

Kinetic methods

The stopped-flow apparatus, data acquisition, and data analysis were as in other recent work (3, 5). All kinetics solutions were 1.0 *M* in potassium bromide and, except for the highest acidities, I = 1.0 *M*. For pH > 1 a "universal buffer" was used as before (3). Reactions were followed as bromine disappearance by monitoring the tribromide ion band near 265 nm. Temperature control was obtained by circulation of water from a Lauda constant temperature bath kept at 25.0 ± 0.1°C.

The second-order rate constants (k_2^{obs}) given in the main text have been corrected for the actual free concentration of bromine. This is less than the total concentration of bromine due to the formation of tribromide ion and, at higher pH, of hypobromous acid (5*a*). In the present work, since higher pH's were employed than earlier, it was also necessary to correct for the ionization of HOBr.

The relevant equilibria are:

$$Br_3^- \overset{K_1}{\rightleftharpoons} Br^- + Br_2$$

$$Br_2 + H_2O \overset{K_2}{\rightleftharpoons} H^+ + Br^- + HOBr$$

$$HOBr \overset{K_3}{\rightleftharpoons} H^+ + {}^-OBr$$

From $[Br_2]_t = [Br_2] + [Br_3^-] + [HOBr] + [{}^-OBr]$ and the definition of K_1, K_2, and K_3 one can easily derive the equation for the correction factor, as given below in eq. [5].

$$[5] \quad \frac{[Br_2]_t}{[Br_2]} = 1 + \frac{[Br^-]}{K_1} + \frac{K_2}{[H^+][Br^-]} + \frac{K_2K_3}{[H^+]^2[Br^-]}$$

The appropriate values of the constants are K_1 = 0.0625 *M* (27), $K_2 = 9.6 \times 10^{-9}$ M^2 (28), and $K_3 = 2.06 \times 10^{-9}$ *M* (29). Apparent second-order rate constants, either from direct analysis or from pseudo first-order rate constants, were multiplied by the factor in eq. [5] to give values of k_2^{obs}. Those given in the text are averages of 3−5 runs. The validity of the corrections for HOBr and OBr^- is supported by the lack of systematic deviations in the rate profiles at the higher pH's.

*p*K *measurements*

These were made by the normal spectrophotometric method (30), at 25°C. For **3***a* we obtained pK_1 = 1.37 ± 0.01, pK_2 = 9.46 ± 0.02, and for **3***b* we found pK_1 = 1.52 ± 0.02. Ionic strength was 0.1 *M* or 0.15 *M*, as given in Table 2. For future use we also measured pK_1 = 7.14 ± 0.02 (I = 0.1 *M*) for 4-amino-3-bromopyridine.

Substrates and products

The compounds used in this study are known from the literature. Accordingly, in the following we provide details only for those procedures which differed from the literature either in execution or in outcome. Elemental analyses were performed by Galbraith Labs. Inc., Knoxville, Tennessee.

*4-Pyridone (1*a*)*

This substance is difficult to purify and to keep pure. Therefore we made use of salts, since this approach worked well in earlier work (3).

Compound **1***a* (Aldrich, technical grade) was dissolved in ethanol and decolourized with charcoal. To the clear filtrate was added one equivalent of sodium ethoxide, and the *sodium salt* was precipitated with acetone. Three recrystallizations from 10:1 CH_3CN/EtOH gave white needles, mp 96−97°C. Spinner and White (31, 32) reported this compound but gave no melting point. Proton magnetic resonance in D_2O and in DMSO-d_6 suggested two waters of crystallization, but the elemental analysis was poor. *Anal.* calcd. for $C_5H_4NONa \cdot 1.25\ H_2O$: C 43.14, H 4.71, N 10.06; found: C 43.42, H 5.76, N 10.15.

Initial kinetic studies were carried out with the above material. However, the *nitrate salt* proved to be a superior alternative which was used for the remainder of the kinetic work. It was initially produced by accident during an attempted nitration following Albert and Barlin (33). 4-Hydroxypyridinium nitrate was extracted from the salts with ethanol, decolourized with charcoal, and twice recrystallized from water, mp 198−200°C (dec). *Anal.* calcd. for $C_5H_6N_2O_4$: C 37.98, H 3.82, N 17.72; found: C 37.94, H 3.95, N 17.58. The same nitrate salt was more conveniently prepared by acidifying a concentrated aqueous solution of **1***a* with nitric acid to pH 1. After standing, the material which crystallized out was treated as above. It gave an identical ir spectrum and mp.

*1-Methyl-4-pyridone (1*b*) hydrobromide salt*

Compound **1***a* (practical grade) was partially dehydrated and purified by heating with two equivalents of hexamethyldisilazane in chloroform. Solid material was filtered off and the filtrate was reduced to half its original volume. Addition of ether gave white flakes of a hydrate of **1***a*, mp 66−67°C (sublimed **1***a* has mp 148−149°C) (18).

To this hydrate (7.6 g, 68 mmol) and sodium methoxide (3.7 g, 68.5 mmol) in 10 mL methanol was added, with stirring, dimethyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

sulphate (8.83 g, 70 mmol) in 10 mL methanol. The solution was heated for 15 min and then the pH was adjusted to 7–8 with sodium bicarbonate. Repeated addition and evaporation with 1:1 acetone/chloroform precipitated the salts which were filtered off. The filtrate was reduced to give an oil which was dissolved in acetone containing a slight excess of concentrated hydrobromic acid. Evaporation of the solvent gave the hydrobromide salt (6 g, 46%), recrystallized from methanol/ether, mp 175–177°C (when dried at 110°C for 1 hour). *Anal.* calcd. for C_6H_8BrNO: C 37.92, H 4.24, N 7.37, Br 42.05; found: C 37.80, H 4.16, N 7.22, Br 41.95.

*4-Methoxypyridine (2*b*)*

To 4-methoxypyridine-*N*-oxide (Aldrich) was slowly added 2 equivalents of phosphorus trichloride and a vigorous reaction ensued. The solution was stirred for 20 min and then made slightly alkaline with concentrated aqueous ammonia. The resultant solution was extracted 3 × 100 mL of chloroform and the dried extracts (Na_2SO_4) were evaporated to give an 85% yield of **2***b*. The proton nmr agreed with the literature (34).

4-Methoxypyridine: bromine complex

Addition of bromine to **2***b* in water, ethanol, or in chloroform precipitated a complex. From water the complex was yellow, mp 120–121°C; from chloroform it was red, mp 117–119°C. The proton nmr spectra of these materials were similar to that of **2***b*.

The complex brominated acetone in chloroform and gave back **2***b* as its HBr salt. Its ir spectrum was identical to that of the hydrochloride salt (34). Upon heating the bromine complex in water, bromine vapour was evolved and no bromination of **2***b* was detected.

*3-Bromo-4-pyridone (3*a*)*

(a) *From 4-amino-3-bromopyridine* (see below)

Diazotization of this compound employing the procedure of Talik (12) gave only a 3% yield after several attempts.

(b) *From bromination of 4-pyridone (1*a*)*

4-Pyridone (0.95 g, 10 mmol) was dissolved in 50 mL water containing sodium acetate (1 g, 12 mmol) and the pH was adjusted to 4.2–4.4 with acetic acid. This solution was cooled in ice, and bromine (1.6 g, 10 mmol) in 50 mL 1 *M* aqueous KBr was added, with stirring, over 45 min. A precipitate of dibromo compound **4***a* (0.33 g, 26.2% based on bromine) was filtered off and the filtrate was evaporated to dryness. The residue, containing inorganic salts and organics, was extracted with ethanol and the extract was evaporated. The solid residue contained a 4:1 mixture of **3***a* and **1***a*, from its ^{1}Hmr spectrum. To effect further separation from salts the residue was treated with boiling acetone. The hot solution was filtered and reduced to dryness to give 1.55 g of solid which contained 80% 3-bromo-4-pyridone **3***a* (73.8%, based on bromine) and 20% unreacted 4-pyridone **1***a*. Decolourization with charcoal and recrystallization from boiling water gave **3***a* (0.48 g, 28% isolated yield), mp 229–231°C (lit. (9) mp 228–230°C).

No optimization was attempted. Doubling the concentrations of the reactants caused a 1.6-fold increase in the percent formation of the undesired dibromo product **4***a*.

Attempted brominations of 4-pyridone

(a) *In acid*

To 4-pyridone (0.95 g, 10 mmol) in 25 mL of concentrated HBr was added, with stirring, an equivalent amount of bromine in 25 mL of the same acid, over 30 min. Ice was added and the pH brought to 3 with sodium carbonate. The solution was reduced in volume on a water bath and, upon cooling, 0.923 g of 3,5-dibromo-4-pyridone (**4***a*) crystallized out (73% yield, based on bromine). Its ir spectrum matched that in the literature (35). The ^{1}Hmr analysis of the solid from evaporating the filtrate showed a 2:5 mixture of **3***a* and unreacted **1***a*.

(b) *In 1* M *aqueous KBr*

The above procedure again yielded **4***a* (0.842 g, 67%).

(c) *In base*

The same procedure in 1 *M* aqueous KBr containing 1 equivalent of KOH precipitated **4***a* (1.08 g, 86%). Both here and in (b) **3***a* was a minor product.

(d) *In dioxane*

"Dioxane dibromide" is considered a mild brominating agent (36). However, mixing equimolar quantities of bromine and **1***a*, each in dioxane, slowly precipitated **4***a* (60% yield).

(e) *Pyridinium hydrobromide perbromide* (37) and **1***a* in $CHCl_3$ gave **4***a* (72%).

(f) *2,4,4,6-Tetrabromo-2,5-cyclohexadienone* is another mild brominating agent (38). From a 1:1 reaction with **1***a* in $CHCl_3$ at 0°C we again obtained **4***a* (65%).

*Other routes to 3*a

Various other attempts to make **3***a* were unsuccessful, as outlined in the text. These failed either because of a recalcitrant hydrolysis step, or due to attempted monobromination again giving undesired dibromination.

4-Amino-3-bromopyridine

3-Bromopyridine was obtained from Aldrich and by diazotization of 3-aminopyridine (74% yield) (7). It was oxidized in 90–93% yield (8), and the *N*-oxide was nitrated as follows.

3-Bromopyridine-*N*-oxide hydrochloride (8) (35 g, 0.166 mmol) dissolved in 35 mL concentrated H_2SO_4 was poured into a mixture of KNO_3 (32 g), concentrated HNO_3 (54 mL), concentrated H_2SO_4 (42 mL), and 20% oleum (28 mL). The solution was heated slowly to 100°C and held there for 21 h. The cooled solution was treated with ice and sodium carbonate, and finally brought to pH 7–8 with aqueous ammonia. After cooling in ice for 20 min the solid from the mixture was filtered off and dried in air. The desired 3-bromo-4-nitropyridine-*N*-oxide (25.1 g, 70%) was extracted from the solid with boiling $CHCl_3$ and was recrystallized from benzene, mp 150–152°C (lit. (8) mp 152–152.5°C, 58%).

The above product was reduced by a procedure modified from the literature (11). 3-Bromo-4-nitropyridine-*N*-oxide (5.0 g, 22.8 mmol) was dissolved in 100 mL acetic acid containing iron powder (8.33 g) in apparatus fitted with fast mechanical stirring. Gentle heat was applied to bring the temperature to 80°C. After 10 min the exothermic reaction brought the temperature to 110°C and the heat source was temporarily removed until it fell back to 80°C. After 90 min at this temperature the solution was cooled and brought to pH 8 with sodium bicarbonate and then ammonium hydroxide. Extraction with ether (3 × 300 mL) and evaporation of the extract gave 4-amino-3-bromopyridine (3.42 g, 86.7%), mp 66–68°C from light petroleum (lit. (11) mp 66–68°C),

This compound has a protonation p*K* of 7.14 ± 0.02 (*vide supra*).

*3-Bromo-1-methyl-4-pyridone (3*b*)*

To **3***a* (1.5 g, 8.6 mmol) in 30 mL MeOH containing KOH (0.48 g) was added dimethyl sulphate (1.6 mL, 18 mmol), and the mixture was refluxed for 2 h. The cooled solution was made basic with sodium methoxide. Addition of acetone (200 mL) and ether (10 mL) precipitated salts. Further removal of salts was achieved by repeated treatment with chloroform/acetone. After solvent removal the residual oil was dissolved in $CHCl_3$, filtered, and the filtrate was evaporated. The resulting oil was dissolved in acetone and addition of a slight excess of concentrated HBr precipitated **3***b*, as *the hydrobromide salt* (1.57 g, 68%). Recrystallization from acetonitrile (1 g/300 mL) gave transparent needles, mp 253–255°C; ^{1}Hmr (D_2O/DSS) δ: 4.23 (s, 3), 7.13 (d, 1, $J_{5,6}$ = 7.0 Hz), 8.23 (q, 1, $J_{2,6}$ = 2.4 Hz), 8.64 (d, 1). *Anal.* calcd. for $C_6H_7NOBr_2$: C 26.80, H 2.62, N 5.21, Br 59.42; found: C 27.08, H 2.69, N 5.23, Br 59.48.

Reçu le 21 avril 1981[1]

MARTINE BELJEAN-LEYMARIE, MICHEL PAYS et JEAN-CLAUDE RICHER. Can. J. Chem. **61**, 2563 (1983).

On rapporte les synthèses d'alkyl ou d'aryl-5 dihydro-3,5 (ou 1,5) imidazo-[4,5-*d*] pyridazinones-4 effectuées à partir des diaminopyridazinones correspondantes. La méthylation d'alkyl ou d'aryl-5 mercapto-2 dihydro-3,5 (ou 1,5) imidazo-[4,5-*d*] pyridazinones-4 conduit à des mélanges d'alkyl ou d'aryl-5 méthyl-1 méthylthio-2 dihydro-3,5 (ou 1,5) imidazo-[4,5-*d*] pyridazinones-4 et d'alkyl ou d'aryl-5 méthyl-3 méthylthio-2 dihydro-3,5 (ou 1,5) imidazo-[4,5-*d*] pyridazinones-4 dont les structures ont pu être établies par effet Overhauser. Ces imidazo-[4,5-*d*] pyridazinones-4 sont utilisées pour les synthèses d'hydrazines et d'hydrazones. Les spectres de masse de quelques intermédiaires clés sont rapportés et discutés.

MARTINE BELJEAN-LEYMARIE, MICHEL PAYS, and JEAN-CLAUDE RICHER. Can. J. Chem. **61**, 2563 (1983).

We report the syntheses of 5-alkyl or 5-aryl-3,5-dihydro[4,5-*d*]imidazo-4-pyridazinones (or the 1,5-dihydro derivatives) from the corresponding diaminopyridazinones. The methylation of 5-alkyl or 5-aryl-2-mercapto-3,5 (or 1,5)-dihydro [4,5-*d*]imidazo-4-pyridazinones leads to mixtures of 5-alkyl or 5-aryl-1methyl-2-methylthio-3,5 (1,5)-dihydro[4,5-*d*]imidazo-4-pyridazinones and 5-alkyl or 5-aryl-3-methyl-2-methylthio-3,5 (or 1,5)-dihydro[4,5-*d*]imidazo-4-pyridazinones whose structures have been established by the Overhauser effect. These [4,5-*d*]imidazo-4-pyridazinones are used for the syntheses of hydrazines and hydrozones. The mass spectra of several key intermediates are presented and discussed.

[Journal translation]

Introduction

Dans le cadre de nos études sur les propriétés, en chimie analytique, d'hydrazines et d'hydrazones de composés hétérocycliques, nous avons entrepris la synthèse et la caractérisation d'alkyl ou d'aryl-5 dihydro-3,5 (ou 1,5) imidazo-[4,5-*d*] pyridazinones-4 isostères d'alkyl ou d'aryl-6 dihydro-2,3 6*H*-thiazolo[4,5-*d*] pyridazinones-7 précédemment décrites (1). Ce sont les résultats obtenus au cours de ces études qui font l'objet du présent travail.

En raison de leur analogie de structure avec les bases puriques, les imidazo-[4,5-*d*] pyridazines sont fait l'objet d'études nombreuses de la part de différents auteurs (2−7). Par contre, les alkyl ou les aryl-5 dihydro-3,5 (ou 1,5) imidazo-[4,5-*d*] pyridazinones-4 n'avaient pas été synthétisées à l'exception de la mercapto-2 phényl-5 dihydro-3,5 imidazo-[4,5-*d*] pyridazinone-4 qui a été signalée comme produit secondaire d'une réaction (8) avant d'être synthétisée pour fins d'identification par condensation de la thiourée sur la diamino-4,5 phényl-1 pyridazinone-6.

Résultats et discussion

Les synthèses que nous avons mises en oeuvre utilisent les diaminopyridazinones (**4**) correspondantes, soit la diamino-4,5 méthyl-1 pyridazinone-6 (**4***a*) et la diamino-4,5 phényl-1 pyridazinone-6 (**4***b*). Les essais d'utilisation des dihydro-3,5 imidazo-[4,5-*d*] pyridazinones-4 n'ont pas abouti. Dans le but d'obtenir des composés substitués en 2, les diaminopyridazinones (**4**) ont été condensées avec le sulfure de carbone. Les alkyl ou les aryl-5 mercapto-2 dihydro-3,5 (ou 1,5) imidazo-[4,5-*d*] pyridazinones-4 (**5**) ainsi obtenues conduisent ensuite à des thioéthers méthyliques (**6** et **7**), puis à des hydrazines (**10** et **11**) ou à l'hydrazone (14).

I. *Méthodes de synthèse*

Les alkyl ou les aryl-2 diamino-4,5 pyridazinones-3 (**4**) sont synthétisées à partir des composés dichlorés-4,5 correspondants (**1**) selon les procédés de Reicheneder et Dury (9−11) par l'intermédiaire de dérivés nitroaminés (**3**) (cf. Schéma 1). A la méthode classique de réduction de **3** par hydrogénation catalytique en présence de platine utilisée par ces auteurs (11) et même plus récemment par Yanai *et al.* (12), nous avons préféré le procédé de Kuhn (13), plus simple et plus rapide, qui consiste en un reflux dans l'éthanol en présence d'hydrazine et de charbon palladié.

La synthèse d'alkyl ou d'aryl-5 mercapto-2 dihydro-3,5 (ou 1,5) imidazo-[4,5-*d*] pyridazinones-4 (**5**) à partir d'alkyl ou d'aryl-2 diamino-4,5 pyridazinones-3 correspondantes (**4**) peut s'effectuer selon les deux procédés habituels: cyclisation avec le sulfure de carbone en milieu pyridinique ou condensation à sec avec la thiourée en utilisant la technique décrite par Elion (14). Contrairement aux résultats rapportés par Itai et Suzuki (5) avec la diamino-4,5 diméthoxy-3,6 pyridazine, la condensation à sec avec la thiourée ne conduit aux mercapto-2 imidazo-[4,5-*d*] pyridazinones désirées qu'avec des rendements variables. Le rendement de la cyclisation de nos dérivés diaminés avec le sulfure de carbone s'est révélé constant et supérieur aux 30% décrit(5); nous avons donc préféré ce procédé.

Mis en solution aqueuse de soude à 10%, à température ambiante et en présence d'iodure de méthyle, les composés **5** conduisent aux composés mono S-méthylés (**8**). Dans des conditions plus drastiques, soit une solution aqueuse de soude à 10% en présence d'iodure de méthyle à 80°C ou une solution de sodium dans le méthoxy-2 éthanol à froid en présence d'un excès de CH_3I, les dérivés **5** conduisent à des mélanges des composés N et S-méthylés **6** et **7**, en proportions variables selon les séries *a* et *b*: environ 5% de **6***a* et 95% de **7***a*; environ 25% de **6***b* et 75% de **7***b*. Facilement mis en évidence par chromatographie en couche mince, les composés ont pu être

[1]Revision reçue le 3 juin 1983.

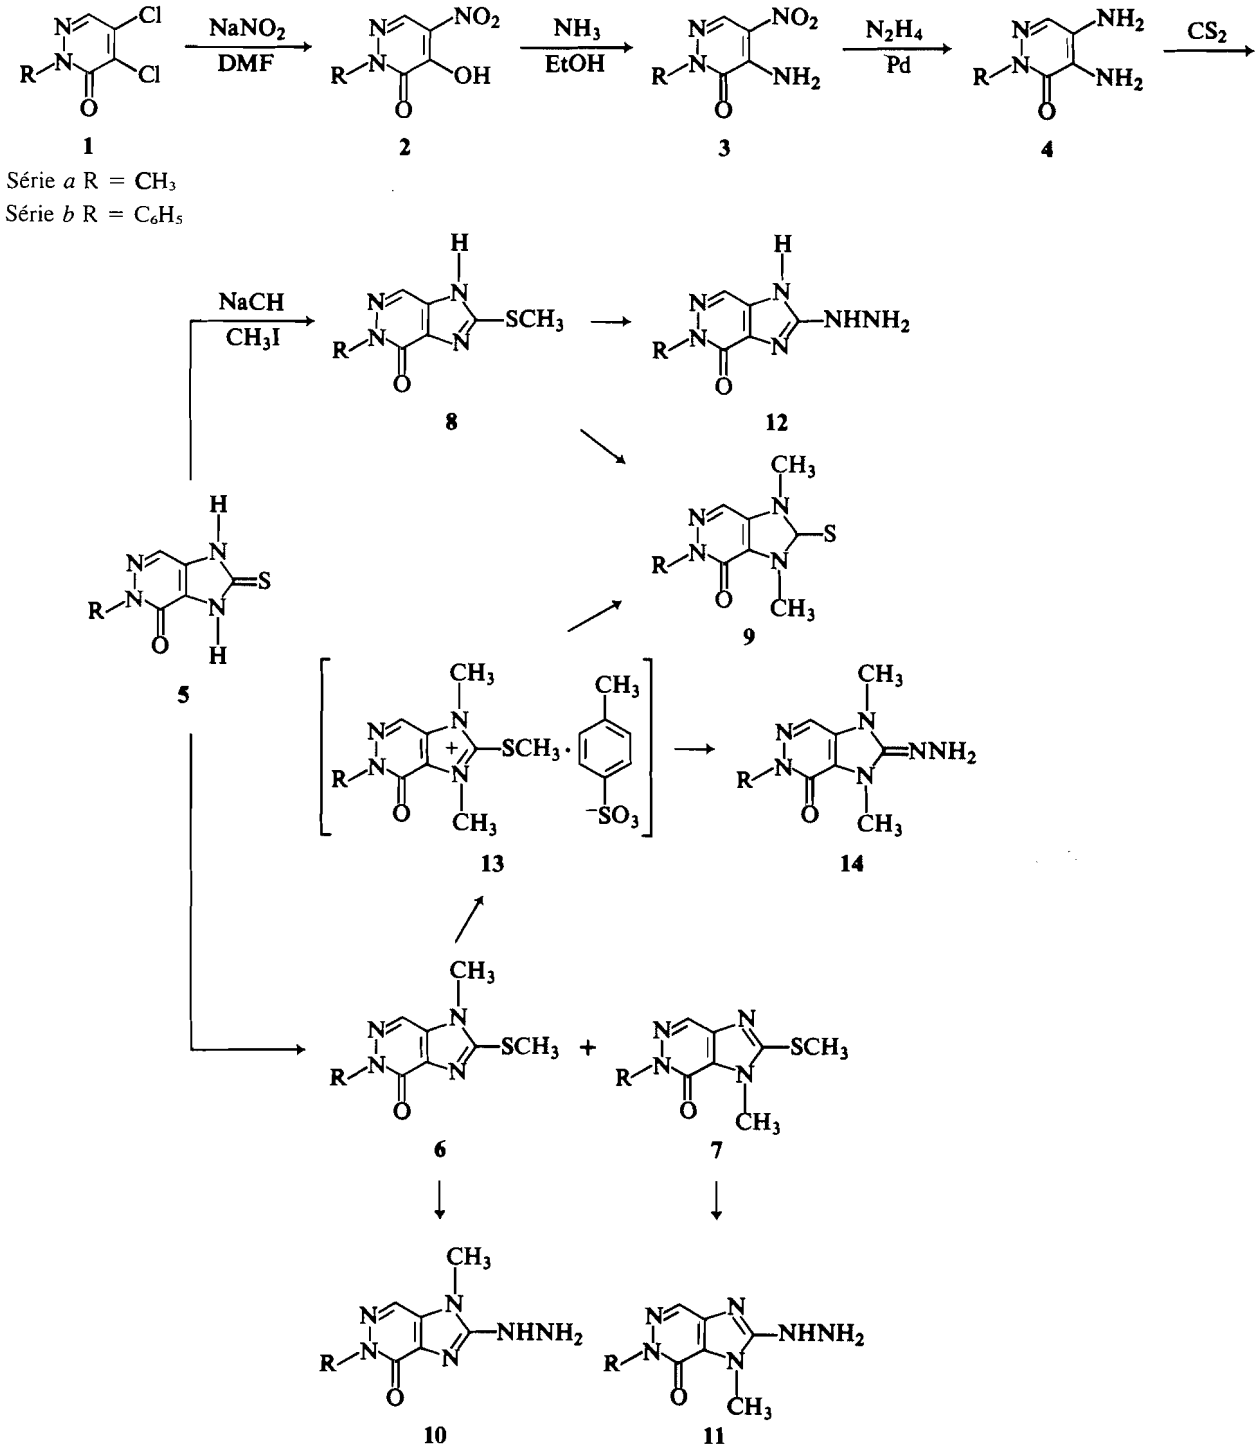

SCHÉMA 1. Synthèses d'hydrazino-2 ou hydrazono-2 alkyl- ou aryl-5 dihydro-3,5 (ou 1,5) imidazo 4,5-*d* pyridazinones-4.

isolés par chromatographie sur colonne de gel de silice. Dans des conditions encore plus fortes (méthoxy-2 éthanol et sodium à chaud en présence d'un excès de CH_3I, **5***b* conduit encore au même mélange 25:75 de **6***b* et **7***b*. Par contre, **5***a* conduit à un nouveau composé, soit le dérivé N_1, N_3 diméthylé (**9***a*). Ce composé **9***a* ne se forme qu'à chaud en solution dans le méthoxyéthanolate de sodium et en présence d'un grand excès d'iodure de méthyle. En effet, **5***a* porté au reflux dans ce milieu en présence de 2 équivalents d'iodure de méthyle conduit au mélange de **6***a* et de **7***a*; par contre, en présence d'une quantité d'iodure de méthyle supérieure à 3 équivalents **5***a* donne **9***a*.

De plus, **9***a* porté à reflux dans le méthoxy-2 d'éthanolate de sodium avec une quantité d'iodure de méthyle légèrement supérieure à 2 équivalents conduit également à **8***a*. Par contre, le composé **9***b* mis dans les mêmes conditions conduit au mélange de **6***b* et de **7***b*. Il semble donc possible d'envisager un mécanisme de formation de **8***a* impliquant la formation d'un dérivé quaternaire intermédiaire instable à la chaleur et représenté dans le schéma 2.

D'ailleurs ce phénomène de déquaternisation par la chaleur

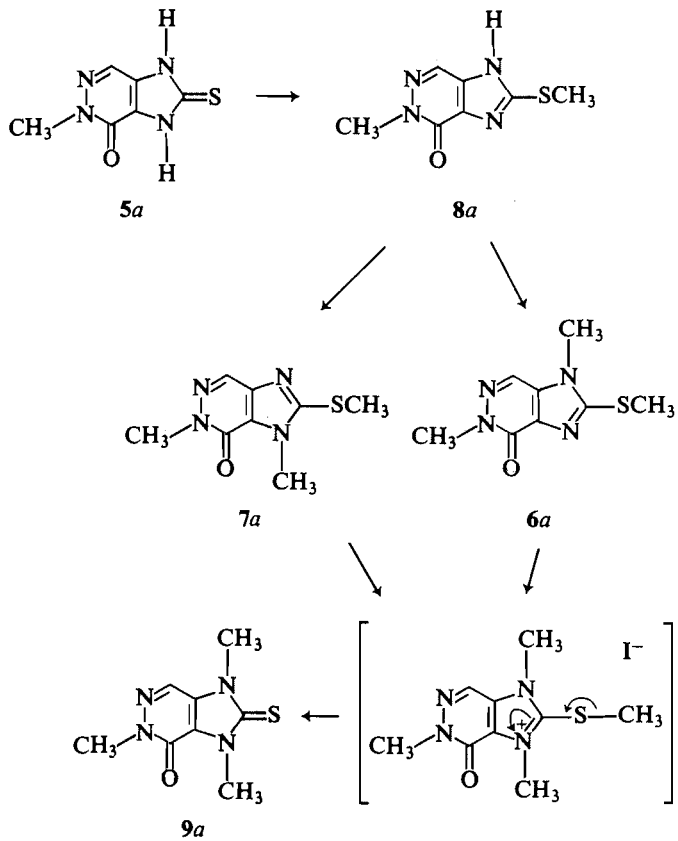

SCHÉMA 2. Rationalisation de la formation de **9***a* à partir de **5***a*, **6***a*, **7***a* ou **8***a*.

a été également décrit auparavant pour les sels de benzimidazolium (15). Les synthèses des dérivés hydrazino-2 (**10**, **11**, et **12**) ont été effectuées à partir des dérivés méthylthio-2 correspondants (**6**, **7** et **8**) alors que la synthèse des hydrazino-2 diméthyl-1,3 alkyl ou aryl-5 dihydro-3,5 imidazo-[4,5-*d*] pyridazinone-4 (**14**) peut être effectuée à partir des composés **6** et **7** selon le procédé classique décrit en la série thiazolique (1, 16), soit la formation d'un sel immonium par réaction à chaud avec le *p*-toluènesulfonate de méthyle suivi d'une décomposition par l'hydrazine; la synthèse de l'hydrazino-2 triméthyl-1,3,5 dihydro-3,5 imidazo-[4,5-*d*] pyridazinone-4 (**14**) doit toutefois être menée avec précaution car un chauffage trop prolongé de **13***a* entraine sa déquaternisation en **9***a* (voir plus haut).

II. *Détermination des structures des composés 6 et 7*

L'attribution des structures des composés **6** et **7** dans les séries *a* ainsi que *b* est basée sur des mesures en rmn du ^1H, d'effet Overhauser obtenu par irradiation de la fréquence de résonance des groupes N—CH_3. On a enregistré l'intensité du signal du proton pyridazinique situé à 8,3 ppm pour les composés *b*, en appliquant successivement une irradiation de puissance modérée à la fréquence de résonance du N—CH_3 (4,1 ppm) et à 500 Hz de cette fréquence. Dans le cas du composé **7***b* (F = 150°C), l'irradiation provoque une augmentation relative de l'intensité du signal qui est inférieure à 5% pour les dix intégrations effectuées tandis que l'on note une augmentation moyenne de 32% pour les dix mesures dans le cas du composé **6***b* (F = 230°C). Ce composé possède donc la structure pour laquelle le proton pyridazinique se trouve dans l'environnement du N—CH_3 (cf. Schéma 1).

III. *Spectres de masse des produits et de quelques-uns de leurs intermédiaires*

Les principales fragmentations observées lors de la spectrométrie de masse sous impact électronique, des dérivés **5***a* et **5***b*, **6***a* et **6***b*, **7***a* et **7***b*, **8***a* et **8***b* ainsi que **9***a* sont rapportées dans la partie expérimentale. Une comparaison des résultats obtenus permet de réaliser que les substituants R qui différencient les séries *a* et *b* n'ont qu'une influence négligeable sur le cours des fragmentations; on n'a pas observé de fragmentations importantes de la liaison N—R.

Par ailleurs, les groupements méthyles attachés au soufre sous forme de S—CH_3 n'ont pas tendance à se dissocier; on observe plutôt des pertes de SCH_3. Dans les séries examinées, l'expulsion d'un groupe méthyle est une caractéristique des composés portant au moins un CH_3 attaché aux azotes de l'imidazo. Cette propriété pourrait s'avérer utile au point de vue analytique.

Dans les composés isomères **6** et **7**, les groupes méthyles des composés **7** qui sont soumis à des interactions stériques plus grandes que ceux des composés **6** sont expulsés plus facilement que ceux des composés **6** (35 vs. 15 et 23 vs. 13%). Il est peut-être possible de relier cette sélectivité accrue dans un processus primaire de fragmentation des composés **7** avec le fait que l'on observe un plus grand nombre de pics d'intensité > 5% dans les composés **6** par rapport aux composés **7**.

Finalement, on doit noter la stabilité remarquable des composés **5** sous impact électronique; leur fragmentation est minimale.

Partie expérimentale

Les points de fusion ont été mesurés sur un banc Kofler. Les spectres ir ont été enregistrés à l'aide d'un spectrophotomètre Perkin–Elmer.

Les spectres de résonance magnétique nucléaire ont été déterminés sur un spectromètre modèle T-60 de la compagnie Varian pour des solutions dans le DMSO-d_6 (à moins d'indication contraire).

Les spectres de masse à haute résolution ont été déterminés à l'aide d'un spectromètre AEI MS–902 relié à un ordinateur PDP-8; toutes les masses moléculaires expérimentales déterminées correspondent à ±0,0015 unités de masse aux valeurs calculées.

L'effet Overhauser nucléaire à été mesuré à 302 K sur des échantillons rigoureusement dégazés, par plusieurs cycles de pompage sous vide et de refroidissement à l'azote liquide, au moyen du spectrographe Varian XL 100-12 du Centre Régional de Mesures Physico-Chimique de l'Ouest (Nantes).

Synthèse des alkyl-1 ou aryl-1 diamino-4,5 pyridazinones-6 (4)

Une solution de 50 g d'alkyl ou aryl-1 amino-4 nitro-5 pyridazinone-6 (**3**) obtenue selon Reicheneder et Dury (10) dans 500 mL d'éthanol contenant 50 mL d'hydrate d'hydrazine et 1 g de charbon palladié à 10% est portée au reflux pendant 4 heures. Par refroidissement, les dérivés diaminés précipitent et on les obtient sous forme de poudre blanche avec un rendement de 80% après recristallisation dans l'éthanol.

Composé **4***a*: pf = 212°C; spectres ir et rmn rapportés antérieurement (1). *Anal.* calc. pour $C_5H_8N_4O$: C 42,85, H 5,75, N 39,98; trouvé: C = 43,05, H = 6,0, N = 39,77.

Composé **4***b*: pf = 200°C *Anal.* calc. pour $C_{10}H_{10}N_4O$: C 59,39, H 4,98, N 27,71; trouvé: C 59,07, H 4,95; N 27,84.

Synthèse des méthyl ou phényl-5 mercapto-2 dihydro-3,5 imidazo-[4,5-d] pyridazinones-4 (5)

On porte 0,075 mol de **4** à reflux 2 heures dans 200 mL de pyridine en présence de 0,15 mol (6 g) de soude caustique et de 150 mL de CS_2. Par concentration, les composés **5** précipitent avec un rendement de 70%.

Composé **5***a*: pf > 260°C; ir (KBR cm^{-1}): 3410 f, 1670 f, 1592 tf,

1510 f, 1210 f, 975 f, 827 f; rmn: 3,92 (N—CH_3), 8,00 (H-7). Masse, *m/e* (intensité): 182 (100), 154 (12, −H, −HCN), 111 (12, $C_4H_3N_2S$). *Anal.* calc. pour $C_6H_6N_4OS$: C 39,56, H 3,30, N 30,75; trouvé: C 39,42, H 3,29, N 30,62.

Composé **5***b*: pf > 260°C ir (KBR cm^{-1}): 1672 f, 1658 tf, 1480 f, 1450 f, 1190 f, 690 f, 635 f; rmn: 7,56 (C_6H_5) et 8,25 (H-7). Masse: 244 (100), 243 (31), 111 (6, $C_4H_3N_2S$). *Anal.* calc. pour $C_{11}H_8N_4OS$: C 54,10, H 3,30, N 22,94; trouvé: C 54,24, H 3,26, N 22,80.

Synthèse des composés ***6*** *et* ***7***

A 2,5 g de sodium dissous dans 80 mL de carbitol, on ajoute 15 g de **5** et 10 mL d'iodure de méthyle. On agite une heure. On isole un produit blanc formé par un mélange de deux isomères **6** et **7**. Par chromatographie sur colonne de gel de silice, on sépare les deux isomères à l'aide d'un mélange éluant benzène−méthanol (95:5 v/v).

Composé **6***a*: pf = 230°C; ir (KBr cm^{-1}): 1648 tf, 1550 f, 1039 f, 960 f, 698 f, rmn ($CDCl_3$): 2,79 (s, CH_3), 3,84 et 4,02 (N—CH_3), et 8,19 (H-7). Masse: 210 (100), 209 (12), 195 (15, $-CH_3$), 182 (6, −HCN), 177 (14, −SH), 163 (12, $-SCH_3$). *Anal.* calc. pour $C_8H_{10}N_4OS$: C 45,71, H 4,80, N 26,66, S 15,47; trouvé: C 46,02, H 4,75, N 26,45, S 15,60.

Composé **6***b*: pf = 230°C; ir (KBr cm^{-1}): 1660 tf, 1555 f, 1120 f, 755 f, 685 f. rmn: 2,78 (SCH_3), 3,62 (N—CH_3), 8,0 (H-7). Masse: 272 (100), 271 (44), 257 (13, $-CH_3$), 225 (13, $-SCH_3$), 180 (14, $-C_6H_5NH$), 179 (8, $-C_6H_5NH_2$). *Anal.* calc. pour $C_{13}H_{12}N_4OS$: C 57,35, H 4,44, N 20,58; trouvé: C 57,36, H 4,40, N 20,52.

Composé **7***a*: pf = 150°C; ir (KBr cm^{-1}): (1680−1650) tf, 1370 f, 948 f, 870 f, 830 f, 660 f, 560 f. Masse 210 (100), 209 (11), 195 (35, $-CH_3$), 182 (5, −H, −HCN), 177 (25, −SH), 163 (5, $-SCH_3$). *Anal.* calc. pour $C_8H_{10}N_4OS$: C 45,71, H 4,80, N 26,66, S 15,41; trouvé: C 45,83, H 5,00, N 26,66, S 15,22.

Composé **7***b*: pf = 150°C; ir (KBr cm^{-1}): 1665 tf, 1545 f, 1370 f, 1310 f, 925 f, 748 f, 685 f; rmn: 2,68 (SCH_3), 3,89 (NCH_3), 7,32 (C_6H_5), 8,18 (H-7). Masse: 272 (100), 271 (22), 257 (23, $-CH_3$), 225 (11, $-SCH_3$), 180 (7, $-C_6H_5$ − NH), 179 (23, $-C_6H_5NH_2$). *Anal.* calc. pour $C_{13}H_{12}N_4OS$: C 57,35, H 4,44, N 20,58; trouvé: C 57,32, H 4,46, N 20,43.

Synthèse des composés ***8***

A une solution alcaline saturée du composé **5**, on ajoute 1,5 équivalent de CH_3I. On maintient le mélange à la température ambiante. Les composés **8** précipitent et on les obtient avec un rendement de 90% après les avoir essorés et recristallisés.

Composé **8***a*: pf > 260°C; ir (KBr cm^{-1}): 1650 tf, 1540 f, 1430 f, 1375 f, 827 f; rmn: 2,70 (SCH_3), 3,74 (NCH_3), 8,34 (H−7). Masse: 196 (100), 195 (16), 168 (6, −H, −HCN), 167 (6, −H, −CO), 163 (12, −SH). *Anal.* calc. pour $C_7H_8N_4OS$: C 42,86, H 4,1, N 28,56, S 16,31; trouvé: C 42,71, H 4,09, N 28,32, S 16,15.

Composé **8***b*: pf = 280°C; ir (KBr cm^{-1}): 1650 tf, 1545 f, 1490 f, 1420 f, 1390 f, 1300 f, 675 f; rmn: 2,73 (SCH_3), 7,55 (C_6H_5), 8,68 (H-7). Masse: 258 (100), 257 (32), 229 (5, −H, −CO), 225 (8, −SH). *Anal.* calc. pour $C_{12}H_{10}N_4OS$: C 55,81; H 3,90, N 21,70, S 12,39; trouvé: C 55,41, H 3,99 N 21,67, S 12,55.

Synthèse du composé ***9***a

A une solution de 3 g de sodium dans 100 mL de méthoxyéthanol, on ajoute 9 g de **5***a* et 12 mL de CH_3I. On maintient ce mélange au reflux pendant 4 heures alors que le produit **9***a* précipite. Le produit filtré et recristallisé dans l'éthanol présente les caractéristiques suivantes: pf = 238°C; ir (KBr cm^{-1}): 1670 tf, 1580 f, 1350 tf, 1025 f, 982 f, 888 f, 782 f; rmn: 3,70, 3,74 et 3,89 (N—CH_3) et 8,60 (H-7). Masse: 210 (100), 209 (6), 195 (37, $-CH_3$), 182 (10), −H, −HCN). *Anal.* calc. pour $C_8H_{10}N_4OS$: C 45,71, H 4,8, N 26,66, S 15,41; trouvé: C 45,92, H 5,0, N 26,24, S 15,27.

Synthèse des composés ***10***, ***11*** *ou* ***12***

On porte respectivement à reflux pendant 6 heures des solutions de **6**, **7** ou **8** dans le méthoxyéthanol en présence de 1,5 équivalents d'hydrate d'hydrazine. Après concentration, on obtient avec des rendements de 90% les composés **10**, **11** ou **12** que l'on purifie par recristallisation dans le méthoxy-2 éthanol (à moins d'indication contraire).

Composé **10***b*: pf > 260°C; (recristallisation dans l'éthanol); ir (KBr cm^{-1}): (1680−1660) tf, 1480 f, 1392 f, 1345 f, 1034 f, 760 f, 700 f; rmn: 3,68 (N—CH_3), 7,53 (C_6H_5), 8,57 (H-7). *Anal.* calc. pour $C_{12}H_{12}N_6O$: C 56,24, H 4,72, N 32,80; trouvé: C 56.13, H 5,03, N 32,55.

Composé **11***a*: pf = 244°C; ir (KBr cm^{-1}): 3300 f, 1640 tf, 1570 f; rmn: 3,69 et 3,75 (N—CH_3), 8,1 (H-7). *Anal.* calc. pour $C_7H_{10}N_6O$: C 43,29, H 5,19, N 43,28; trouvé: C 43,29, H 5,16, N 43,07.

Composé **11***b*: pf = 242°C (recristallisation dans l'éthanol); ir (KBr cm^{-1}): 3295 f, (1660−1650 tf), 1563 f, 1385 f, 755 f, 690 f; rmn: 3,75 (N—CH_3), 7,47 (C_6H_5), 8,28 (H-7). *Anal.* calc. pour $C_{12}H_{12}N_6O$: C 56,24, H 4,72, N 32,82; trouvé: C 56,00, H 5,00 N 32,43.

Composé **12***a*: pf > 260°C. *Anal.* calc. pour $C_6H_8N_6O$: C 40,00, H 4,48, N 46,65; trouvé: C 40,15, H 4,43, N 46,51.

Composé **12***b*: pf > 260°C; rmn: 7,48 (C_6H_5), 8,15 (H-7). *Anal.* calc. pour $C_{11}H_{10}N_6O$: C 54,54, H 4,16, N 34,70; trouvé: C 54,40, H 4,25, N 34,55.

Synthèse des composés ***14***

On porte respectivement les composés **6** ou **7** (isolés ou en mélange) au bain d'huile à 180°C en présence d'une quantité équivalente de *p*-toluènesulfonate de méthyle, pendant 5 min; on refroidit et isole le sel grâce à un mélange d'éthanol et d'éther. Après avoir dissous le sel dans l'eau, on ajoute deux équivalents d'hydrate d'hydrazine à la température ambiante. Après avoir laissé le mélange au repos pour une heure, on extrait au chloroforme. Les produits sont obtenus avec un rendement de 60% après recristallisation dans l'acétate d'éthyle.

Composé ***14b***: pf = 174°C (recristallisation dans l'éthanol); ir (KBr cm^{-1}): 3380 f, (1680−1650) tf, 1555 f, 995, 760 f, 685 f. *Anal.* calc. pour $C_{13}H_{14}N_6O$: C 57,76, H 5,22, N 31,10, trouvé: C 57,92, H 5,12, N 31,18.

Remerciements

J. M. CAMPELO, A. GARCIA, J. M. GUTIERREZ, D. LUNA, and J. M. MARINAS. Can. J. Chem. **61**, 2567 (1983).

The skeletal isomerization of cyclohexene, in a microcatalytic pulse reactor, was investigated by using aluminium orthophosphates (Al/P = 1) as catalysts. An attempt has been made to correlate the isomerization activity with the acid properties of the solids, measured by means of the irreversible adsorption of different organic bases in cyclohexane, at 298 K, using a spectrophotometric method.

Apparent rate constants were calculated in terms of the kinetic model of Bassett and Habgood. Selectivity studies led to the conclusion that 1-MCP and 3-MCP were competitive products. Correlation between the kinetic selectivity factor, σ, and the number of strong acid sites has been sought.

A possible parallel reaction pathway is proposed, which agrees with both the observed rates and selectivities.

J. M. CAMPELO, A. GARCIA, J. M. GUTIERREZ, D. LUNA et J. M. MARINAS. Can. J. Chem. **61**, 2567 (1983).

On a étudié l'isomérisation du cyclohexène dans un réacteur microcatalytique à impulsion en utilisant les orthophosphates d'aluminium (Al/P = 1) comme catalyseur. On a essayé d'établir une corrélation entre l'activité d'isomérisation et les propriétés acides du solide mesurées au moyen de l'adsorption irréversible des différentes bases organiques dans le cyclohexane à 298 K en faisant appel à la méthode spectrophotométrique.

On a calculé les constantes de vitesse apparentes en fonction du modèle cinétique de Bassett et Habgood. Des études sélectives portent à conclure que le MPC-1 et le MPC-3 sont des produits de compétition. On a établi une corrélation entre le facteur de sélectivité σ et le nombre de sites d'acide fort.

On propose un chemin réactionnel possible qui est en accord avec les vitesses et les sélectivités observées.

[Traduit par le journal]

Introduction

The catalytic activity of many surfaces has been linked strongly with the presence of acid sites. Not only the number of acid sites, but also their strength, is important in many catalytic conversions. Thus, it is well known that the isomerization of olefins readily proceeds in the presence of acidic catalysts and that, for skeletal isomerization, acidic sites of high strength are necessary (1–3). Isomerization of CH to 1- and 3-MCP is sometimes even used as a model reaction for testing catalyst acidity.

The use of amorphous aluminium orthophosphates as catalysts in various organic reactions, viz. dehydration, isomerization, alkylation, cracking, etc., has been summarized in a recent review (4). The fact that the $AlPO_4$ surface possesses acid sites capable of taking part in the catalytic process has been shown in several ways (3, 5). Thus, the catalytic activity of $AlPO_4$ is affected by two main factors: the chemical nature of the surface (number and strength of acid sites) and the texture of the solid.

In previous papers (6, 7) we have shown the applicability of a spectrophotometric method in determing the acid properties of $AlPO_4$, $AlPO_4-Al_2O_3$, and $AlPO_4-SiO_2$ catalysts by means of the adsorption of different organic bases. The use of compounds with different pK_a enables us to obtain information on the strength distribution of acid sites.

The present paper deals with the study of the catalytic properties of several aluminium orthophosphates (Al/P = 1) in comparison to their surface acidity, measured by a spectrophotometric method developed by Marinas *et al.* (6) in the skeletal isomerization of CH, carried out in a microcatalytic pulse reactor using the Bassett–Habgood kinetic model (8). This model is applied to the first order processes in which the surface reaction is the controlling step and the partial pressure of the reactant is low.

[2]Revision received May 19, 1983.

Experimental

Catalysts

Three $AlPO_4$ samples were studied in this investigation: sample F was prepared by precipitation from aluminium chloride and phosphoric acid (aqueous solutions), using ammonium hydroxide solution. Samples B and BP were precipitated using ethylene and propylene oxide, respectively. The three parent $AlPO_4$ samples received the same thermal treatment, namely, drying at 393 K for 24 h and calcination at 923 K for 3 h in a muffle furnace. In all cases, the composition was Al/P = 1.

Physico-chemical properties

The physico-chemical properties of the solids have already been researched. Thus, the surface area, accumulated pore volume, and main pore diameter were determined by the BET method (9) from the adsorption–desorption nitrogen isotherms at liquid nitrogen temperature (10, 11). The porosity detection was carried out by means of the Lecloux method (12) using n_3 due to the monolayer value. Pore size analysis was made using the "corrected modelless" method developed for the analysis of mesopores (13) using cylindrical idealization.

The surface acidity was determined by titration with cyclohexylamine (pK_a = 10.6), pyridine (pK_a = 5.3), and aniline (pK_a = 4.6) from cyclohexane solutions (spectroscopic grade, Merck) at 298 K using a spectrophotometric method described elsewhere (6).

In each experiment, a freshly prepared titrant agent solution (10 mL) is pipetted into a cylindrical glass tube that previously was loaded with the solid (about 0.1 g). The tube is fitted with a ground glass stopper, shaken for 1 h at constant temperature, 298 K, and the concentration of the organic base is determined spectrophotometrically.

Sorption experiments are developed at the wavelength of the maximum absorption (λ_{max}, nm) and between the titrant concentration were the Lambert–Beer law is fitted. The time required for the system to reach the equilibrium at constant temperature was checked for each solid and it was never more than 45 minutes.

The chemical interaction adsorbate–surface may be accomplished by applying the linear transformed Langmuir adsorption isotherm:

$$[1] \quad c/x = 1\,b\,x_m + c/x_m$$

The monolayer coverage, which corresponds to the theoretical

TABLE 1. Textural properties and surface acidity of $AlPO_4$ catalysts

Catalyst	S (m^2/g)	V (mL/g)	D (nm)	Surface acidity (μmol/g) CY	PY	AN
BP	210	0.42	2.5	732	380	125
B	256	0.60	4.5	789	320	86
F	181	0.40	3.6	1042	260	75

amount of solute adsorbed by 1.0 g of solid system if all sites are covered, must be assumed as a measure of the acid sites corresponding to a pK_a equal to or greater than that of the base.

Thus, the irreversible adsorption of bases with different pK_a's allows us to obtain the strength distribution of acid sites.

This method lets us determine the surface acidity of white, as well as deeply coloured, porous solids. The bases used as titrants were high purity materials from various commercial suppliers and were used without additional purification.

Apparatus and procedure

The CH isomerization was carried out in a microcatalytic pulse reactor. The pulse system consisted of a 5830 Hewlett–Packard gas chromatograph modified by the introduction of a microreactor between the sample inlet and the analytical column. The catalyst (100–150 mg, ≤0.07 mm) was held by small plugs of Pyrex glass wool in the 4 mm diameter reactor tube. The carrier gas was ultrapure nitrogen (40–60 mL min^{-1}). The experiments were conducted at temperatures between 573 and 673 K, and the hydrocarbon pulse was in the range 0.2–1.0 L.

Before each run, samples of the catalyst were standardized in a stream of 40 mL min^{-1} of dehydrated and deoxygenated nitrogen at 573 K for 1 h. The reproducibility for different samples was checked experimentally, and the measurements were repeated 2–3 times. The relative error was approximately 7%.

The products were analyzed on a 3 m stainless-steel column of 2 mm diameter, filled with 5% squalane on Chromosorb G AW-DMCS 80/100. A Hewlett–Packard electronic digital integrator was connected to the gas chromatograph. The temperature of the column was 338 K. Response factors were equal for all alkenes (CH, 1-MCP, and 3-MCP). The column gave the following order of elution: 3-MCP, 1-MCP, CH.

Results and discussion

Textural and acid properties

The adsorption isotherms are type II of Brunauer's classification, and pronounced hysteresis loops are exhibited for the three parent $AlPO_4$. The hysteresis loops close at some intermediate relative pressure.

For the pore size analysis, using the "corrected modelless" method developed for the analysis of mesopores, the cylindrical idealization could fit the criteria of corrected analysis, including the agreement between the total pore volume (the saturation point of the isotherm) and the cumulative pore volume.

The surface area, pore volume, and the main pore diameter for the $AlPO_4$ samples are collected in Table 1. Also, in Table 1, the surface acidity values are presented.

The reproducibility of the spectrophotometric method was checked experimentally, and the measurements were repeated 2–3 times. The relative error was approximately 6%.

Since the amount required to cover the surface of the solid with a monolayer was assumed as the acidity of the sample, corresponding to a specific pK_a of the titrant used, the chemisorption of CY was greater than that of the any other base. Thus, because of its high pK_a, by definition, CY measures the total acidity of these surfaces. The sequence obtained, in all cases, is:

TABLE 2. Catalytic isomerization in the CH isomerization on BP

Catalyst	W (mg)	Q (mL/min)	Total conversion 573 K	623 K	673 K
BP	100	40	0.019	0.043	0.060

		60	0.012	0.029	0.043
	148	40	0.021	0.057	0.082
		50	0.017	0.042	0.078
		60	0.014	0.036	0.059
	183	40	0.028	0.081	0.099
		50	0.022	0.054	0.082
		60	0.020	0.049	0.072

$$CY > PY > AN$$

On the other hand, the differences between the values for CY and the other bases (PY and AN) are a measure of the number of weaker acid sites. Thus, sample F has the highest number of acid sites, though of moderate strength. B and BP samples exhibit a lower number of acid sites, although their strength is greater.

Aluminium orthophosphate BP shows the highest concentration of strong acid sites (vs. PY and AN) of all phosphates studied. The sequence obtained for the number of stronger acid sites (vs. AN) is:

$$BP > B > F$$

Thus, the number and strength of acid sites of phosphates depend on the method of precipitation, independent of the identical value of Al/P ratio and the results provide strong evidence for the existence of a heterogeneous distribution of surface acid sites of different acid strengths.

Catalytic activity

The operating variables, space velocity and particle size, were so chosen as to eliminate diffusion control on the reaction rate. On the other had, the thermal process without catalyst is negligible.

In the catalytic studies, CH isomerization was maintained at low conversion levels, ranging approximately from 0.1 to 8–10%.

The skeletal isomerization process of CH yields a mixture of 1- and 3-MCP. The 4-MCP isomer was not detected among the reaction products as a result of the short contact time in the reaction process.

The isomerization activity was expressed by the total conversion to 1-MCP and 3-MCP at different flow rates of the carrier gas in the reaction (mL min^{-1}), which only is exact for conversions below 10–20%, where the equilibrium reaction can be neglected.

In Table 2 the conversion values are listed at different temperatures and catalyst weights on BP catalyst. All values were reproducible to within about 7%.

The experimental results are adjusted to the Bassett–Habgood eq. [2] (8) as may be seen in Fig. 1.

$$[2] \quad \ln (1/1 - X) = RT \cdot kK (W/Q)$$

Thus, the skeletal isomerization of CH is a first order kinetic process, where the fractional conversion of reactants to products is independent of the pressure, and the rate of adsorption is faster than the rate of surface reaction, the latter being the

rate determining step.

[3] $r = kP_{CH}$

In our experimental conditions the catalytic activity of sample F is negligible and, therefore, more data are reported on B and BP samples, especially the latter.

From eq. [2] it is possible to obtain the apparent rate constant, kK, at a fixed temperature, by plotting $\ln (1/1 - X)$ vs. $1/Q$. The apparent activation energy is obtained in each case by plotting $\ln [\ln (1/1 - X)]$ vs. $1/T$. The results are summarized in Table 3.

The apparent activation energies are practically constant for all $AlPO_4$ studied. This, together with the fact that we are dealing with first order kinetics, seems to indicate that the transition state is of the same type for all catalysts.

On the other hand, the total conversion of CH increases with both temperature and catalyst charges and the concentration of 1-MCP was always higher than of 3-MCP, as may be seen in Tables 4 and 5.

To determine if the above mentioned products are really competitors, we employ the kinetic selectivity factor (σ) of

Wheeler (14), viz., that for a process such as is outlined:

[4] $\mathrm{CH} \xrightarrow{k_1} \text{1-MCP}$, $\mathrm{CH} \xrightarrow{k_3} \text{3-MCP}$

when a first order kinetics is followed, can be written

[5] $\sigma = k_1/k_3 = X_1/X_3$

The application of this criterion allows us to draw the conclusion that 1-MCP and 3-MCP are competitive products with a first order kinetics (Fig. 2). This also occurs when the isomerization is carried out with traditional solid acids as catalysts (1, 15).

A least-squares regression analysis shows correlation coefficients above 0.99. A "t-test" of significance, performed on the coefficients of regression, shows that these are significant at a level better than 1%. This is a measure of accuracy of fit of the data, in all experimental conditions, by the linear plots of Fig. 2.

Since Fig. 2 contains points at all temperatures, the apparent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

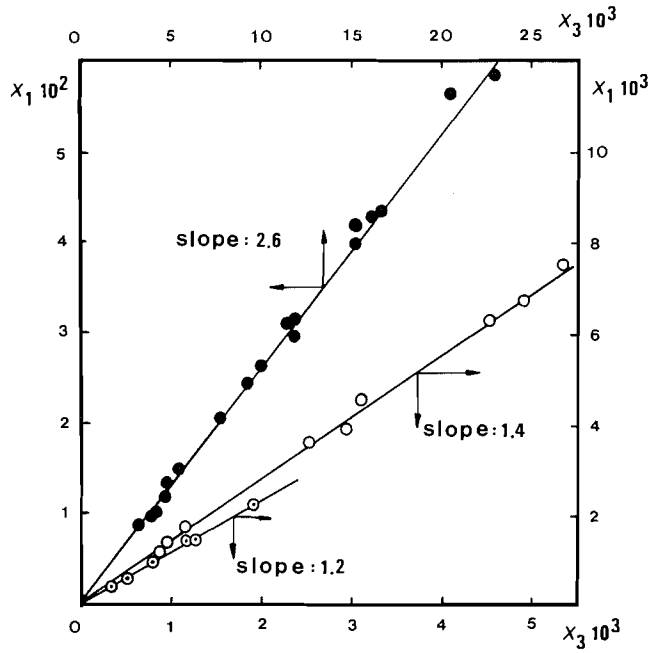

FIG. 2. Selectivity factors X_1 vs. X_3 on BP (●), B (○), and F (⊙) catalysts (data at every temperature).

activation energies for K_1 and K_3 are identical on each catalyst.

On the other hand, the selectivity to 1-MCP clearly increases in the order:

$$BP > B > F$$

This sequence is the same as that which was found for the number of strongest acid sites. Thus, if on each catalyst K_1 and K_3 have identical apparent activation energies, σ can be expressed by

$$[6] \quad \sigma = \frac{A_1 \exp(-E_{a_1}/RT)}{A_3 \exp(-E_{a_3}/RT)} = \frac{A_1}{A_3}$$

and, since the preexponential factor is a function of the number of active sites that is different on each catalyst, the selectivities on the three $AlPO_4$ samples are different. Therefore, the different σ values on each catalyst are due to different A_1/A_3 ratios.

Furthermore, by plotting the selectivity factors, σ, vs. the acidity of the catalysts (vs. AN, Fig. 3) it can be seen that the selectivity of 1-MCp formation increases with an increase of the catalyst acidity, and that its variation is linear.

Thus, it seems that the sites with higher acid strength (vs. AN) are those mainly responsible for the skeletal isomerization of CH, the sample BP being the most active catalyst in this series of samples. As well, the apparent rate constant, Kk, also increases when the number of strongest acid sites is increased, and this variation is linear (vs. AN) with a correlation coefficient of 0.99.

Conclusions

From the results obtained, it seems that the acidity of the catalyst is the main variable to be considered, and that the stronger acid sites are necessary for the CH isomerization to 1- and 3-MCP on $AlPO_4$ catalyst. Thus, the $AlPO_4$ obtained by precipitation with propylene oxide has the highest number of acid sites of high strength and, therefore, exhibits the highest isomerization activity and selectivity to 1-MCP.

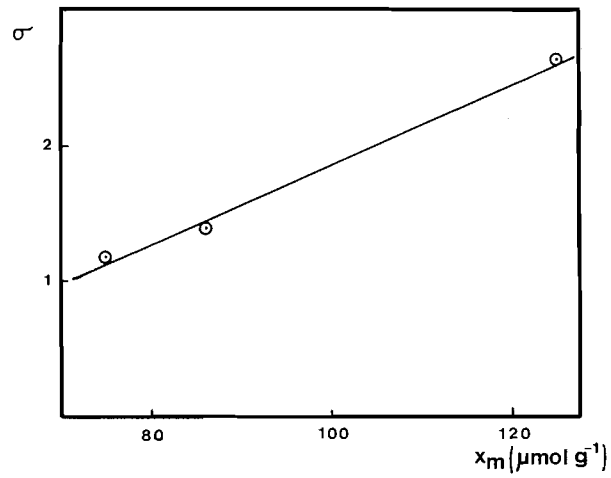

FIG. 3. Selectivity factors, σ, vs. acidity measured by titration with aniline.

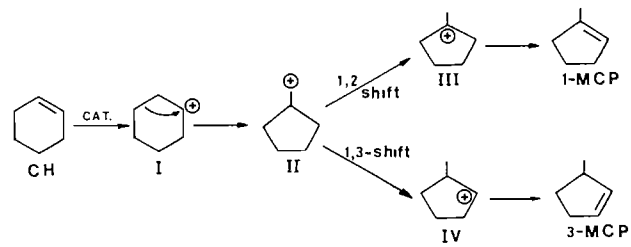

SCHEME 1

The isomerization products are obtained by parallel reactions according to a carbocationic mechanism with rearrangement of intermediates (3, 11, 15–19).

The mechanism proposed below agrees with the experimental results and is an attempt to explain how both reaction products could be formed. The first step would imply the chemisorption of CH on the acid sites of the catalyst resulting in the formation of a carbenium ion (I), which suffers skeletal isomerization (Wagner–Meerwein rearrangement) involving a less stable primary carbenium ion (II), which rearranges to a more stable tertiary carbenium ion (III) by 1,2-hydride shift. This then desorbs as 1-MCP. A 1,3-hydride shift changes the carbenium ion I to a secondary ion (IV). The desorption of this intermediate gives rise to 3-MCP.

The fact that the 1,3-hydride shift is not so easy as the 1,2-hydride shift, and that the stability of intermediate III is greater than II, accounts for the lower concentration of 3-MCP. Thus, an increase in the acid strength of catalyst produces intermediates with a more developed carbocationic character and, therefore, increases the conversion of both substrates (1- and 3-MCP) with a rise in the selectivity factor, σ, since a 1,2-hydride shift is easier.

Furthermore, the results seem to confirm the applicability of the spectrophotometric method in determining the acid site distribution of heterogeneous catalysts by the adsorption of bases with different pK_a.

Nomenclature

A: preexponential factor of Arrhenius equation
AN: aniline (λ_{max}: 232 nm)
b: constant of Langmuir (L mol^{-1})
c: concentration of titrant agent in solution at equilibrium with the adsorbate on the surface acid sites (mol L^{-1}).
CH: cyclohexene
CY: cyclohexylamine (λ_{max}: 225 nm)
E_a: apparent activation energy (kJ mol^{-1})
k: rate constant of the surface process (s^{-1})
K: adsorption constant of the CH on the catalyst (mol atm^{-1} g^{-1})
MCP: methylcyclopentene
P_{CH}: cyclohexene pressure (atm)
PY: pyridine (λ_{max}: 252 nm)
Q: flow rate of the carrier gas (mL s^{-1})
r: reaction rate
R: gas constant (atm 1 mol^{-1} K^{-1})
S: surface area (BET method, m^2g^{-1})
T: reaction temperature (K)
V: pore volume (mL g^{-1})
x: amount of titrant agent adsorbed on the acid sites (mol g^{-1})
x_m: saturation concentration; the theoretical amount of titrant agent that may be chemically adsorbed by 1.0 g of solid system (mol g^{-1})
X: molar fractionary conversion
σ: kinetic selectivity factor
λ: wavelength of the maximum absorption (nm)

Subscripts: 1: 1-MCP; 3: 3-MCP

Received April 29, 1983

ARVI RAUK, DONALD F. TAVARES, MOHSIN A. KHAN, AMY J. BORKENT, and JOHN F. OLSON. Can. J. Chem. **61**, 2572 (1983).

The static and dynamic structures of the amide derivatives of racemic and (*R*)-(+)-2-methoxy-2-phenyl-3,3,3-trifluoropropanoic acid (MPTA) with diisopropyl amine (**1**), *meso*-2,6-dimethylpiperidine (**2**), (*R*)-(−)- and (*S*)-(+)-2-methylpiperidine (**3** and **4**, respectively) were investigated by proton nmr spectroscopy. The piperidine rings adopt a single dominant conformation in which the substituent methyl groups occupy axial positions. One of the isopropyl groups of **1** is oriented in the same way as the corresponding side of the piperidine ring of **2**−**4** but the other (*syn* to carbonyl oxygen) is turned so that the methyl groups are toward the carbonyl oxygen and the oxygen lies in the plane bisecting the C—C—C angle. Rotation about the amide C(O)—N bond of **1** is accompanied by concurrent rotation about each of the N—*i*Pr single bonds. The free energies of activation of the hindered rotation about the C(O)—N bond in **1**−**4**, 81 kJ/mol, 77 kJ/mol, 77kJ/mol, and 79kJ/mol, respectively, are higher than found in most other hindered amides, suggesting that buttressing due to the steric crowding around the amide functionality is felt throughout the rotational pathway.

ARVI RAUK, DONALD F. TAVARES, MOHSIN A. KHAN, AMY J. BORKENT et JOHN F. OLSON. Can. J. Chem. **61**, 2572 (1983).

Faisant appel à la spectroscopie de rmn du proton, on a étudié les structures statique et dynamique des amides provenant de la réaction des acides racémique et (*R*)-(+) méthoxy-2 phényl-2 trifluoro-3,3,3 propanoiques (MPTA) avec la diisopropylamine (**1**), la *méso*-diméthyl-2,6 pipéridine (**2**), les (*R*)-(−) et (*S*)-(+) méthyl-2 pipéridine (**3** et **4** respectivement). Le cycle pipéridine adopte une conformation simple dominante dans laquelle les groupes méthyles occupent des positions axiales. L'un des groupes isopropyle du composé **1** s'oriente de la même manière que le côté correspondant du cycle pipéridine des composés **2**−**4** mais l'autre face (*syn* par rapport à l'oxygène du carbonyle) se tourne de telle sorte que les groupes méthyles soient vis-à-vis de l'oxygène du carbonyle et l'oxygène se trouve dans le plan bisecteur de l'angle C—C—C. La rotation autour de la liaison C(O)—N de l'amide s'accompagne d'une rotation de même sens autour de chaque liaison simple N—*i*Pr. Les énergies libres d'activation de la rotation empêchée autour de la liaison C(O)—N dans les composés **1** à **4** sont respectivement de 81, de 77, de 77 et de 79 kJ/mol. Elles sont plus élevées que celles de la plupart des autres amides encombrées, ce qui suggère un effet de compression, du à l'encombrement stérique autour de la liaison amide, qui se manifeste entièrement dans la rotation.

[Traduit par le journal]

Introduction

In a previous communication, we reported the results of an investigation by ^{19}F nmr spectroscopy, on hindered rotation about a carbon−carbon single bond to a trifluoromethyl group in a series of derivatives of 2-methoxy-2-phenyl-3,3,3-trifluoropropanoic acid (MPTA), including several hindered chiral amides (1). As an extension of that work, we wish to report the observations on the static and dynamic stereochemistry associated with severe steric crowding about the nitrogen atom of the amide functionality. The presence in our system of a chiral centre of known absolute configuration enables the unambiguous assignment of the stereochemistry associated with groups on the nitrogen atom. The large magnetic anisotropy of the phenyl group as well as of the carbonyl bond in the amide group greatly assists in the assignments. All of the molecules involved in the present study are amide derivatives of racemic or (*R*)-(+)-MPTA (2) with the amines diisopropyl amine, *cis*-2,6-dimethylpiperidine, and (*R*)-(−)- and (*S*)-(+)-2-methylpiperidine (3), i.e. compounds **1**−**4**, respectively.

Crystallographic (4−7) and nmr (6−14) investigations of 2-methyl- and 2,6-dimethylpiperidyl derivatives have established that steric constraints force the methyl groups to adopt axial positions when the substituent on nitrogen conjugates sufficiently well with the nitrogen lone pair to impose a planar or near planar geometry (Structure A). This is the case with amides (X=Y = RCO) and *N*-nitroso (X=Y = N=O)

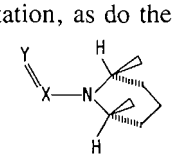
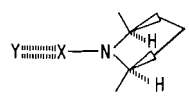
4

compounds. The structurally related hydrazones (X=Y = N=CR_1R_2) adopt a conformation in which the average plane of the ring is perpendicular to the plane of the N substituents (15) (Structure B). Amidines (X=Y = RC=NR) represent an intermediate case and both structures have been found by Lunazzi *et al.* (6). Even with bulky acyl substituents, amides (X=Y = CO*t*Bu) adopt the planar A ground state structure, the equilibrium structure being destabilized by buttressing effects by an amount roughly equivalent to the $A^{(1,3)}$ strain (11). The results presented below on **2**, **3**, and **4** require a different interpretation, as do the results for **1**.



A X=Y = COR
= N=O
= N=NR



B X=Y = N=CC_1C_2

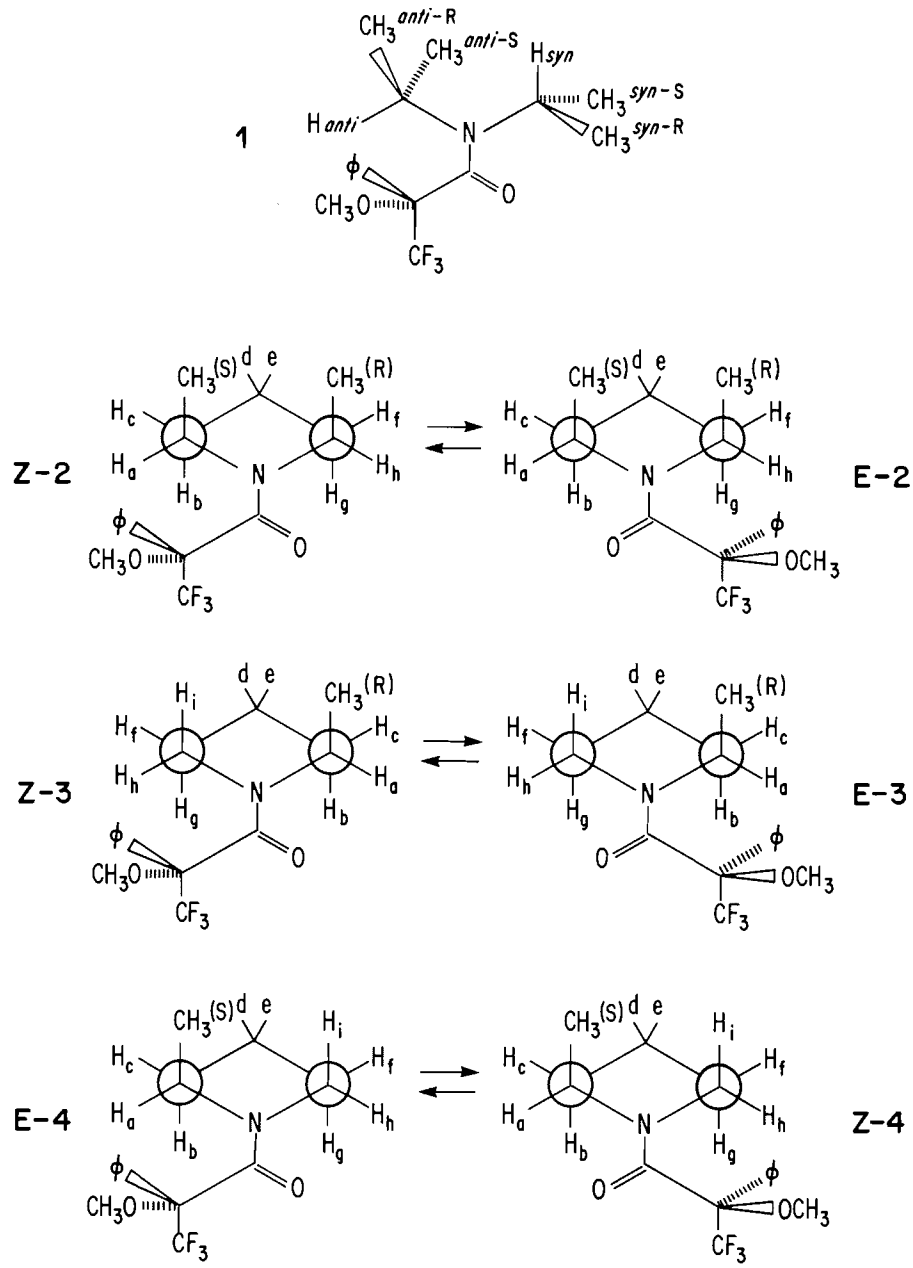

FIG. 1. Structures **1**–**4**, identifying protons discussed in the text.

The structures of the systems of the present study are shown in Fig. 1. Amides **2**–**4** are capable of rotational isomerism about the C(O)—N bond. The resulting structures are distinguished by the stereochemical labels, *Z* and *E*, and are defined in Fig. 1. Each of **2**–**4** is presented as having axial methyl groups. For clarity, the structures are drawn as Newman projections and all the protons which could be assigned by decoupling experiments are explicitly labelled. The α-methyl groups of **2**–**4** are labelled *R* or *S* according to the absolute configuration of the carbon atom to which they are attached. The methyl groups of **1** are labelled in a similar manner according to whether the isopropyl group (*syn* or *anti* to carbonyl oxygen) would gain the *R* or *S* configuration, respectively, if the priority of the methyl carbon were increased by isotopic substitution.

Rotation about the C(O)—N bond in most amides is hindered by barriers in the range 67–92 kJ/mol (4, 11, 16). The higher values are found for relatively unhindered amides (for example, $HC(O)N(CH_3)_2$: 88 kJ/mol (4)). Since the six-atom amide unit is essentially coplanar, increasing the steric size of either the acyl moiety or the nitrogen substituents is expected to destabilize the crowded planar ground state configuration (Structure A) compared to the relatively less crowded perpendicular geometry (4) (Structure B) which should resemble the transition state for C(O)—N bond rotation. Thus the rotation barrier for the highly crowded benzamide of 2,6-dimethylpiperidine (A, X=Y = $C(O)C_6H_5$) is abnormally low, namely 52 kJ/mol (11). If the acyl group is sufficiently large to "lock" the substituents on nitrogen into a planar configuration, much higher values are found (4). For example, a barrier of 125 kJ/mol has been estimated for 2,4,6-(tBu)$_3C_6H_2C(O)NMe_2$ (17). Electronic effects also influence the magnitudes of barriers to rotation about the C(O)—N bond, electron withdrawing substituents on the acyl moiety tending to increase the height of the barrier (18). The latter two effects will be seen to contribute to the magnitudes of the rotation barriers of amides **1**–**4**.

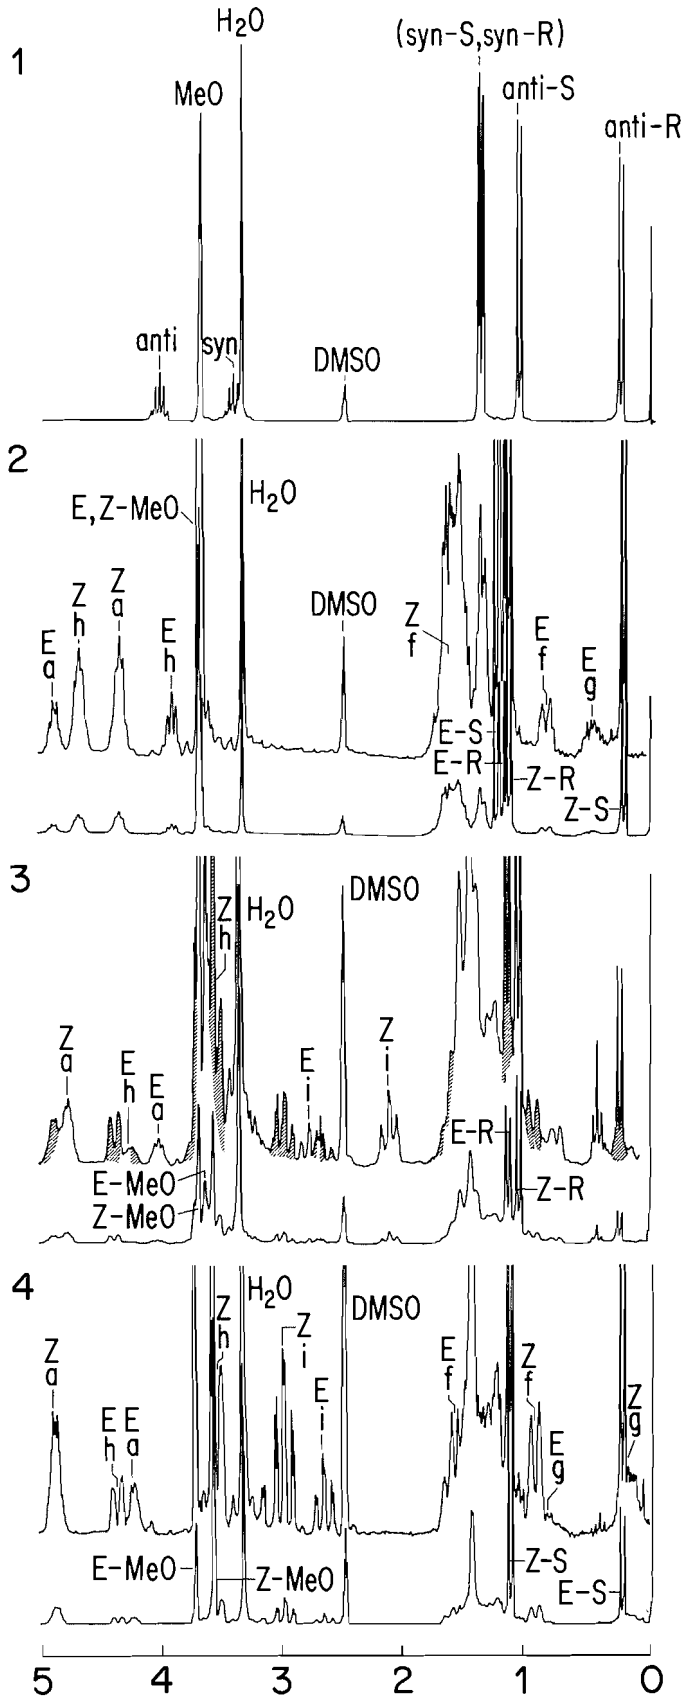

FIG. 2. Proton nmr spectra of **1**–**4** in DMSO-d_6 at 22°C. The sample of **3** is contaminated by 43% admixture of **4** (shaded peaks). All of the spectra have absorptions due to water and incompletely deuterated DMSO. Prominent proton absorptions are identified according to the convention adopted (refer to Figs. 1 and 3).

Results

Ambient temperature nuclear magnetic resonance spectra of 1–4

The ^{1}H nmr spectra of amides **1**–**4** in DMSO-d_6 at 22°C are shown in Fig. 2.[4] Chemical shift data are presented in Table 1. As discussed in the Introduction, compounds **2**–**4** are capable of geometric isomerism due to hindered rotation about the C(O)—N bond. The spectra of **1**, **2**, and **4** exhibit unusually high field methyl absorptions. at 0.30 ppm, 0.21 ppm, and 0.25 ppm, respectively. The positions of the remaining methyl absorptions of the four amides fall into the narrow range 1.07–1.17 ppm downfield from TMS. The only exceptions are the absorptions due to two of the methyl groups of **1**, which occur at 1.45 and 1.46 ppm. The significance of this result is discussed below.

Variable temperature nuclear magnetic resonance spectra of 1–4

The nmr spectra of **1**–**4** were determined in the temperature range −90°C to 180°C. For the low temperature study, the samples were dissolved in $CDCl_3$/acetone-d_6 (50:50). The high temperature spectra were determined for solutions in DMSO-d_6. At low temperatures, all of the samples showed general line broadening which seems most likely to be due to viscosity broadening. Only one dynamic intramolecular process is slowed in this temperature range, rotation about the C—CF_3 bond, which manifests itself in the collapse of the methoxy methyl quartet and its recovery as a doublet. Previous work has demonstrated a stereospecific long range H—F coupling of the methyl to a single fluorine atom of the trifluoromethyl group (1).

All of the compounds **1**–**4** exhibit temperature dependent phenomena at elevated temperatures. The temperature dependent proton nmr spectrum of **1** is shown in Fig. 4. The variation of the nmr spectra of **2** and **4** with temperature is shown in Figs. 5 and 6, respectively. The corresponding spectra for **3** are not shown since this compound was not prepared free of **4**.

Activation parameters for rotation about the C(O)—N bond were estimated as described below. The results are shown in Table 2 and Fig. 7.

Discussion

Equilibrium geometries of 1–4

Structures **1**–**4** have a number of conformational options available as a consequence of rotation about the single bonds to the chiral centre of the MPTA moiety, rotation about the amide C(O)—N bond, and chair–chair inversion of the six-membered piperidine ring. In fact, we will argue that the results of the present study are consistent with a very limited subset of the possible conformations. Inspection of the nmr spectra shown in Fig. 2 reveals that **1** appears to have only a single dominant conformation, and **2**, **3**, and **4** seem to exist as a mixture of only two conformations present in unequal proportions. Although an X-ray structure of MPTA or any of its derivatives has not been reported, numerous applications of chiral amide and ester derivatives of MPTA for the determination of absolute configurations and optical purities by nmr spectroscopy after the work of Mosher and co-workers (19), as well as CD studies (20), are consistent with the CF_3 group

[4]The ^{1}H nmr spectrum of **3** is contaminated by 43% admixture of **4**.

TABLE 1. Chemical shifts (ppm in DMSO-d_6 at 22°C)[a]

Compound	MeO	Me (*R*)	Me (*S*)	H (a)	H (f)	H (g)	H (h)	H (i)
1	3.75	1.45 or 1.46[b]	0.30[c]	4.01[d]	1.14[e]	1.46 or 1.45[f]	3.48[g]	—
(*Z*)-**2**[h]	3.72	1.07	0.21	4.35	1.68	[i]	4.68	—

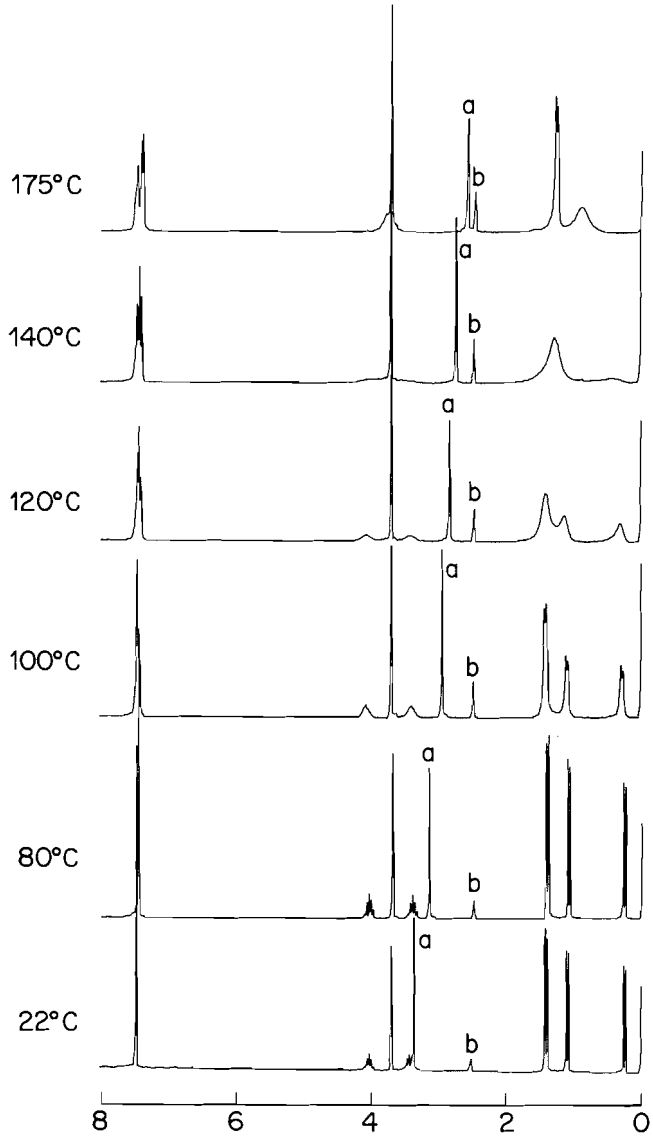

FIG. 4. Temperature dependent nmr spectrum of **1** in DMSO-d_6. The water (a) and incompletely deuterated DMSO (b) peaks are marked.

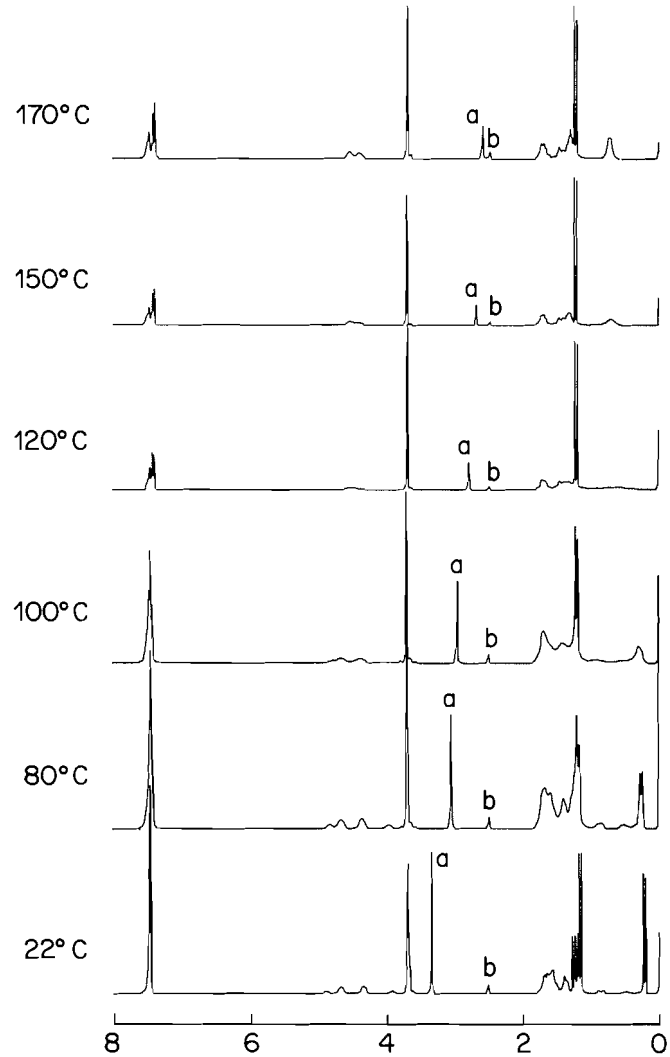

FIG. 5. Temperature dependent nmr spectrum of **2** in DMSO-d_6. The water (a) and incompletely deuterated DMSO (b) peaks are marked.

being eclipsed to the carbonyl double bond. Limited geometry optimization of the structure of the dimethylamide of MPTA by MNDO calculations also showed that the C—CF_3 and C=O bonds are eclipsed (1).[5] As a result, the position of the phenyl group on one side of the mean plane of the amide functionality serves as an internal probe for the positions of other groups in the molecule, on the nitrogen atom in the present case.

It has previously been shown by nmr (6–8, 11) studies that amides of 2-methylpiperidine and 2,6-dimethylpiperidine adopt the chair form of the piperidyl ring which has the α-methyl substituents in the axial positions. The structures in solution are deduced from chemical shifts and coupling constants, as well as thermodynamic activation parameters for the hindered rotation about the C(O)—N bond (11). The spectra of compounds **3** and **4** (Fig. 2) are consistent with axial methyl groups in each of the diastereomeric rotamers. Inspection of molecular models, in which the CF_3 group is eclipsed to the carbonyl bond, reveals that in each of compounds **1**, **2**, and **4** there is a methyl group positioned directly over the phenyl ring, in the shielding region of the ring magnetic anisotropy. This is not the case for amide **3**. Assuming a distance of 3.7 Å (measured from Dreiding models) between the plane of the phenyl group and the methyl carbon atom, and using an average value of 1.17 ppm for the chemical shift of an axial α-methyl group, one sees that *a methyl group situated 3.7 Å above a phenyl ring is shifted upfield by about 0.92 ppm*. This value is in accord with that predicted by the free electron model of long range shielding associated with the benzene ring, as proposed by Johnson and Bovey (21).

The low field positions of the α methine proton absorptions, H_h in *Z*-**2** (4.68 ppm), H_a in *E*-**2** (4.89 ppm), H_a in *Z*-**3** (4.78 ppm), and H_a in *Z*-**4** (4.88 ppm) can be taken as representative of the position of an equatorial methine proton approximately in the plane of the amide carbonyl. The average value is 4.81 ppm. The other equatorial α methine protons, H_a of *Z*-**2** (4.35 ppm), H_h of *E*-**2** (3.92 ppm), H_a of *E*-**3** (4.04 ppm) and H_a of *E*-**4** (4.24 ppm) yield an average value 4.14 ppm as reference. While this may not be typical of equatorial

[5]One cannot determine from the present results whether or not rotation about the C(O)—C bond is slow on the nmr time scale. However, the results strongly suggest a single dominant conformation in which C—CF_3 is eclipsed to C=O.

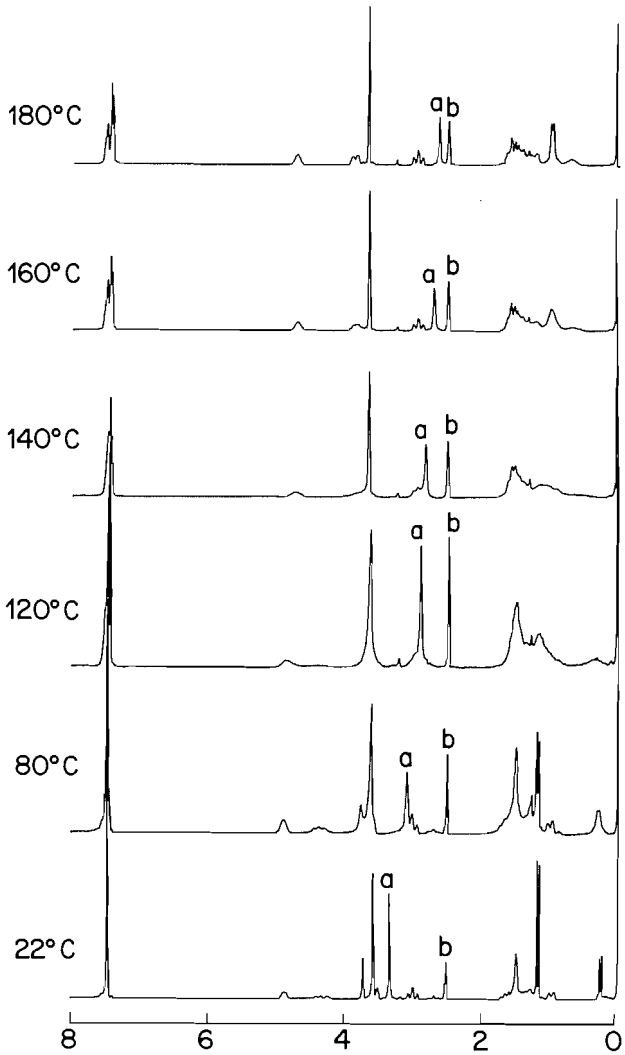

FIG. 6. Temperature dependent nmr spectrum of **4** in DMSO-d_6. The water (a) and incompletely deuterated DMSO (b) peaks are marked.

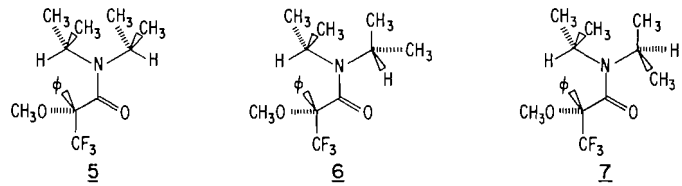
α-methine protons because of the atypical grouping of substituents on the saturated carbon atom, the difference, 0.67 ppm, serves as a measure of the deshielding effect of the amide carbonyl at a distance of 2.9 Å (measured from Dreiding models). A similar comparison of the equatorial α-methylene protons deshielded by carbonyl (H_h of *E*-**3** (4.38 ppm) and H_h of *E*-**4** (4.38 ppm)) and not deshielded by the carbonyl (H_h of *Z*-**3** (3.6 ppm) and H_h of *Z*-**4** (3.55 ppm)) yields a somewhat higher value of 0.80 ppm for the deshielding effect of the amide carbonyl at about the same distance.

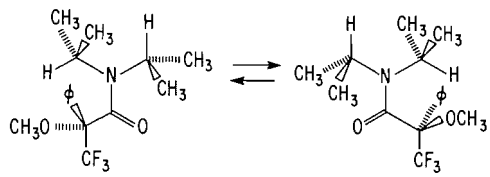
It is apparent from the nmr spectrum of **1** (see Figs. 1 and 2 and Table 1) that the isopropyl group which is *syn* to the chiral centre is oriented in the same way as the corresponding side of the six membered ring in **2** and **4**. The *anti*-(*R*) methyl group is highly shielded (0.30 ppm), the other has a normal chemical shift (1.14 ppm), and the methine proton has a chemical shift (4.01 ppm) close to the average value (4.14 ppm) for corresponding equatorial methine protons of **2**–**4**. On the other hand, the isopropyl group *syn* to oxygen must be oriented differently from the corresponding side of the six membered ring in **2** and **3**. The two methyl groups are nearly isochronous and are deshielded by 0.3 ppm relative to all of the other methyl groups which are not in the shielding region of the phenyl group. In addition, the chemical shift of the methine proton (3.48 ppm) suggests that this proton is oriented in a different fashion than any of the others. Thus structure **5** cannot correspond to the most stable conformation of **1**.



5 **6** **7**

Mechanism of conformational interchange

Although the diisopropyl amide, **1**, could exist in many conformations that can be generated by torsional motions about the single bonds, in actuality very few of the possible structures are available to it because of steric interactions. As discussed above, the amide unit is essentially planar and the chiral centre is oriented so that the trifluoromethyl group is eclipsed with the carbonyl group. The group attached to the nitrogen which is *syn* to the chiral centre must be oriented in such a way as to present a hydrogen atom toward the chiral centre. The isopropyl group *syn* to the chiral centre thus has no rotational flexibility. At first glance, there does not appear to be as great an impediment preventing the isopropyl group *anti* to the chiral centre from adopting any of several staggered conformations, such as **6**, **7**,



8a **8b**

or **8**. Indeed, the small difference in the chemical shift, 0.01 ppm, may be due to residual diastereotopism after rapid rotational averaging among structures **6**, **7**, and **8** (for example). Evidence that this is unlikely to be the case for **1** is the observation that the nmr spectrum of **1** remains unchanged as the temperature of a solution of **1** in $CDCl_3$/acetone-d_6 is lowered to −90°C with the exception that the methoxy peak becomes a doublet (as a result of slowing the CF_3 rotation (1)) and there is a general broadening of all of the signals, probably due to increased viscosity of the medium. The positions of the absorptions remain at 1.45 and 1.46 ppm. Raising the temperature of a solution of **1** in DMSO-d_6, Fig. 4, brings about exchange coalescence of the (*S*)-methyls (at 1.14 and 1.45/6 ppm), of the (*R*)-methyls (at 0.30 and 1.46/5 ppm), and of the methine septets. The temperatures of maximum broadening of the signals occur at approximately 130°C, 145°C, and 140°C, respectively. Rates of exchange, k, at these temperatures were determined by comparison of computed lineshapes[6] with the experimentally obtained nmr spectra. Application of the Eyring equation [1]

$$[1] \quad k = \left(\frac{k_B}{h}T\right)e^{-\Delta G^*/RT}$$

[6]Lineshapes were calculated for various rates of exchange from equation [15] of Binsch (22*a*). Linewidths in the absence of exchange were assumed to be 1 Hz, measured from the room temperature spectrum. A full lineshape analysis could not be performed to extract enthalpies and entropies of activation for amides **2**–**4** because of the complexity of the spectra.

	H(g)	0.20−0.86	140[f]	590	80
	H(h)	3.55−4.38	140[f]	660	80
	H(i)	3.01−2.69	110[f]	250	77

[a]Refer to Figs. 1−3 for assignment of protons.
[b]Temperature at which maximum broadening is judged to occur.
[c]Reference 23.
[d]$\Delta G^{\ddagger}$, estimated using eq. [1].
[e]Z and E refer to the isopropyl groups which are *syn* and *anti* to the carbonyl oxygen, respectively. From lineshape analysis, $\Delta H^{\ddagger} = 83 \pm 2$ kJ/mol, $\Delta S^{\ddagger} = 5 \pm 4$ J/mol deg, $\Delta G^{\ddagger} = 80.56 \pm 0.04$ kJ/mol.
[f]Approximate values; see text for discussion.

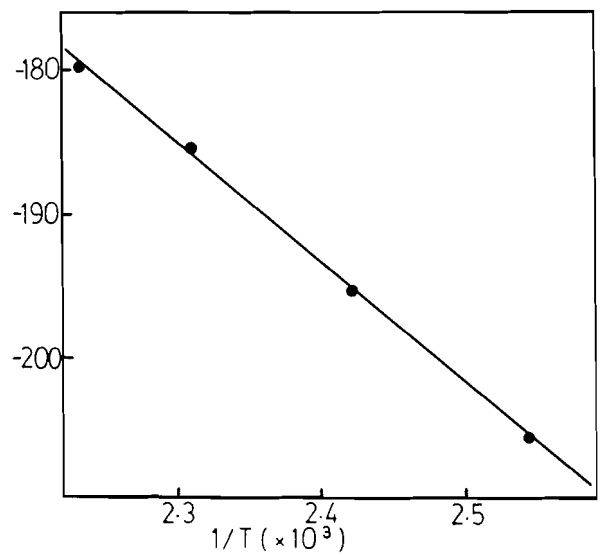

FIG. 7. Plot of ln (k/T) vs. T^{-1} for **1** from lineshape fitting of the 0−2 ppm region of the nmr spectrum (see Fig. 4). The ordinate is R ln (hk/k_BT) in units of J/deg mol. The data are: 155 s^{-1}, 120°C; 550 s^{-1}, 140°C; 1900 s^{-1}, 160°C; 3800 s^{-1}, 175°C.

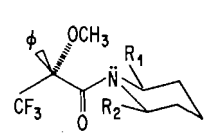
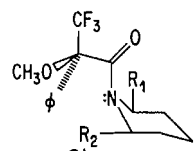
yields three independent estimates of the free energy of activation, $\Delta G^{\ddagger}$, for the conformational process, 81 kJ/mol, 79 kJ/mol, and 81 kJ/mol, respectively, at the above-mentioned temperatures. Details are given in Table 2. Rate constants at four temperatures spanning the range 120°C−175°C were obtained by lineshape analysis of the methyl region of **1**. A plot of ln (k/T) vs. T^{-1} (Fig. 7) yields the results: $\Delta H^{\ddagger} = 83 \pm 2$ kJ/mol; $\Delta S^{\ddagger} = 5 \pm 4$ J/mol deg. From the values for $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$, a more accurate value for $\Delta G^{\ddagger}$ may be calculated: $\Delta G^{\ddagger} = 80.6 \pm 0.04$ kJ/mol (22*b*) at 145°C. The error in $\Delta G^{\ddagger}$ was computed from the least-squares errors for $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ by the method of Binsch and Kessler (22*b*).

The insensitivity of the chemical shifts of the two methyls of the isopropyl group *syn* to the carbonyl oxygen over a wide temperature range (−90°C to +120°C) renders it probable that only a single conformation of **1** is significantly populated. We shall assume that that conformation is **8**. The data in Table 2 are interpreted as corresponding to the conformational exchange process **8***a* ⇌ **8***b*. Rotation through 180° about the C(O)—N bond involves simultaneous rotations about both N—*i*Pr single bonds. Thus, the methyl groups which exchange their environments are on the same side of the amide plane.

Amides **2**, **3**, and **4** exist as equilibrating mixtures of Z and E diastereomeric forms. The free energy differences, estimated (by integration) from the populations at 22°C are 1.7 kJ/mol, 2.6 kJ/mol, and 2.7 kJ/mol, respectively. The process which interconnects the Z and E forms may be regarded as simple rotation about the C(O)—N bond. While the piperidine ring may undergo chair−chair inversion during the course of the rotation, thus placing the methyl group(s) into equatorial position(s), the population of such forms as **9***a* and **9***b* must be too



9a



9b

small to have consequences to the temperature dependence of the nmr spectra in the accessible temperature range. Thus the interpretation of the temperature dependent nmr spectra of **2** (Fig. 5), **3**, and **4** (Fig. 6) is most appropriate in terms of the equilibrium between Z and E pairs as shown in Figs. 1 or 3 in which rotation through 180° has taken place about the C(O)—N bond and the piperidine ring remains in the same chair form with the substituents in the axial positions.

Free energies of activation for the rotation about the C(O)—N bond of **2**, **3**, and **4** were determined in the same way as described above for **1** (22), taking into account the variation of population with temperature, and assuming that entropy differences between the conformers are zero. The data are

collected in Table 2. As can be seen in Figs. 2, 5, or 6, the spectra are more complicated and, in the instances noted in Table 2, it was not possible to determine very accurately the temperature of maximum line broadening for some of the exchanging protons. We believe the values of $\Delta G^{\ddagger}$ obtained, though approximate, for the independently observed exchange processes are similar enough to reinforce the hypothesis that the piperidine rings of **3** and **4** are "frozen" into a single chair conformation. That this also appears to be true for **2** is somewhat surprising since the $A^{(1,3)}$ strain for diaxial methyls, 20 kJ/mol (11) is close to the energy of a "twist boat" conformation, 23 kJ/mol for cyclohexane (23). From inspection of models, it does not appear that the chemical shifts of the methyl and methine protons of **2** in the chair and "twist boat" forms should differ appreciably. As the expected barrier to interconversion of the two forms, 24 kJ/mol, is too low to have been detected in the present study, the question of the dynamics of the 2,6-dimethylpiperidine ring system remains unresolved.

The observed magnitudes of the rotation barriers are larger than barriers found in a previous investigation on related systems (11). We attribute this result to a combination of two factors, both of which have the effect of raising the barrier to rotation about an amide bond. An electron withdrawing group on the acyl carbon atom has the effect of increasing the electronic demand of that centre and thus of increasing the involvement of the nitrogen lone pair in bonding to it (18). In the present case, the acyl carbon is substituted by a carbon containing a trifluoromethyl and a methoxy group. Second, and probably more important in view of the above discussion, is the very large steric bulk of the acyl group. It is evident that buttressing effects due to the acyl group are manifest throughout the rotational motion, the transition state being destabilized approximately as much as the ground state (4).

Finally, we note that the phenyl absorptions of all of the present systems also undergo significant changes in appearance as the temperature is raised (see Figs. 4, 5, and 6). In all cases the phenyl absorption is sharp at ambient temperature and broadens, revealing considerable structure, as the temperature is changed. The nature of the temperature dependence is not suggestive of an exchange process, but rather of a differential temperature dependence of the chemical shifts of the aromatic protons, probably due to changing solvation.[7]

Experimental

Materials

Diisopropyl amine, 2,6-dimethylpiperidine, and 2-methylpiperidine were commercial reagent grade (Aldrich Chemical Co.) and were redistilled before use, and their purity was checked by glc (Porapak Q). The 2,6-dimethylpiperidine was shown to be exlusively the *cis*- or (*R*,*S*)-isomer by ^{13}C nmr spectroscopy (24). The 2-methylpiperidine was resolved as described below.

(R)-(−)- and (S)-(+)-2-methylpiperidine

2-Methylpiperidine was resolved as reported by Craig and Pinder (25), using (*R*)-(−)-mandelic acid (Sigma Chemical Co.). After two recrystallizations from anhydrous methanol−ether (1:4), the mandelate salt, $[\alpha]_D$ −59.8° (*c* 2.5%, methanol) was converted to the free base, to give (*S*)-(+)-2-methylpiperidine, $[\alpha]_D$ +33.1° (neat), after distillation; lit (26) $[\alpha]_D$ +31.2° (neat). This material was shown to be optically pure (*S*)-(+)-isomer (3) by preparation of the amide, **4**, from (*R*)-(+)-MPTA (see below). No trace of the other diastereomer, **3**, could be detected by ^{19}F nmr spectroscopy (18). Concentration of the solvent from which the aforementioned mandelate salt was isolated gave a syrupy residue. Conversion of this residue to the free base gave material enriched in the (*R*)-(−)-enantiomer, $[\alpha]_D$ −5.75° (neat), after distillation. From the optical rotation, it can be estimated that the composition was 58.7% (*R*)-(−)-2-methylpiperidine mixed with 41.3% of the (*S*)-(+)-enantiomer. The composition estimated by integration of the ^{19}F absorptions due to amides **3** and **4** from this material confirmed this (19*a* and footnote 4).

Racemic and (R)-(+)-2-methoxy-2-phenyl-3,3,3-trifluoropropanoyl chloride

These acid chlorides were prepared from racemic or (+)-α-methoxy-α-trifluoromethylphenylacetic acid (Aldrich Chemical Co.) by a modification of the published procedure (19), using a catalytic amount of dimethylformamide (27).

Preparation of racemic and optically active 2-methoxy-2-phenyl-3,3,3-trifluoropropanamides

Racemic or (*R*)-(+)-2-methoxy-2-phenyl-3,3,3-trifluoropropanoyl chloride (2) was heated (reflux) for about 12 h with a four- to eightfold excess of amine, followed by standing at room temperature for 18−20 h. Acidification with concentrated hydrochloric acid, followed by extraction with ether, gave the crude amides, after evaporation of the ether.

N,N-*Diisopropyl-(R,S)-2-methoxy-2-phenyl-3,3,3-trifluoropropanamide* **1**, recrystallized from hexane. Sublimation *in vacuo* afforded an analytical sample, mp 94−96°C (uncorrected). *Anal.* calcd. for $C_{16}H_{22}O_2NF_3$: C 60.56, H 6.99, N 4.41; found: C 60.74, H 6.83, N 4.74. Specific details concerning the ^1H nmr spectrum of **1** are given in Table 1.

(R,S)-2,6-Dimethylpiperidinyl-(R,S)-2-methoxy-2-phenyl-3,3,3-trifluoropropanamide **2**, recrystallized from hexane. Sublimation *in vacuo* afforded an analytical sample, mp 83−87°C (uncorrected). *Anal.* calcd. for $C_{17}H_{22}O_2NF_3$: C 61.99, H 6.73, N 4.25; found: C 62.10, H 6.65, N 4.17. Specific details concerning the ^1H nmr spectrum of **2** are given in Table 1.

(R,S)-2-Methylpiperidinyl-(R,S)-2-methoxy-2-phenyl-3,3,3-trifluoropropanamide **3/4**, recrystallized from cyclohexane.[8] Sublimation *in vacuo* afforded an analytical sample, mp 61−64°C (uncorrected). *Anal.* calcd. for $C_{16}H_{20}O_2NF_3$: C 60.99, H 6.39, N 4.44; found: C 60.83, H 6.41, N 4.62. Specific details concerning the ^1H nmr spectra of **3** and **4** are given in Table 1.

(+)-(S)-2-Methylpiperidyl-(R)-2-methoxy-2-phenyl-3,3,3-trifluoropropanamide **4**

(*S*)-(+)-2-Methylpiperidine (see above), dissolved in triethylamine, was added to an equimolar amount of (*R*)-(+)-2-methoxy-2-phenyl-3,3,3-trifluoropropanoyl chloride and heated at reflux for 7 h. The crude amide was recrystallized from methanol−water,[8] mp 80−84°C (uncorrected), $[\alpha]_D$ +92.4 (*c* 2.4%, methanol). Specific details of the ^1H nmr spectrum of **4** are given in Table 1.

(59% 3/41% 4) **3**

The mixture of amines enriched in the (*R*)-(−)-enantiomer (see above) was added to (*R*)-(+)-2-methoxy-2-phenyl-3,3,3,-trifluoropropanoyl chloride, as described above. The crude product was subjected to ^{19}F and ^1H nmr analysis without further purification by recrystallization.[8] The composition of the mixture was confirmed by integration of the CF_3 signals in DMSO-d_6 at 80°C; found: 57% **3**, 43% **4**. Specific details of the ^1H nmr spectrum are given in Table 1.[4]

Recrystallization from methanol−water[8] afforded a sample of composition 47.3% **3**/52.7% **4**, $[\alpha]_D$ +75.5 (*c* 1.0%, methanol), from which the specific rotation of optically pure **3** could be calculated; $[\alpha]_D$ +57°.

[7]Solvent dependence of aromatic protons is well established (ref. 28). This is observed in the present systems as well. As an example, the nmr spectrum of a solution of **1** in $CDCl_3$ shows the phenyl absorption to be split into two groups of peaks, at 7.49 ppm (2H) and 7.34 ppm (3H), respectively.

[8]Recrystallization of **3** (*RR* and/or *SS*)/**4** (*RS* and/or *SR*) from methanol−water leads to enrichment of the sample in **4** (*RS* and/or *SR*).

^{1}H nuclear magnetic resonance experiments

The ^{1}H nmr spectra were obtained on a Varian XL-200 spectrometer, equipped with a variable temperature controller (accurate to ± 1°C). For the high temperature measurements (22°C to 180°C), samples were dissolved in DMSO-d_6; for the low temperature measurements (−90°C to 22°C), samples were dissolved in $CDCl_3$/acetone-d_6 (50:50). Chemical shift data (δ) are presented in Table 1, relative to tetramethylsilane (δ = 0) as internal reference.

Acknowledgments

We wish to thank R. Yamdagni for running the nmr spectra and T. S. Sorensen for valuable discussions. The financial support of the Natural Sciences and Engineering Research Council of Canada is gratefully appreciated.

Reçu le 8 avril 1983

CHANTAL DEGRAND, GERARD BELOT, PAUL-LOUIS COMPAGNON et FRANÇOISE GASQUEZ. Can. J. Chem. **61**, 2581 (1983).

Dans l'acétonitrile, les anions $^-CH_2CN$ électrogénérés provoquent la régression de divers composés de réduction–acylation de la fluorènone **1***a* et de son anil **1***b* vers **1***a* et **1***b*; cette évolution est contrôlée par l'introduction fortuite d'oxygène moléculaire. Les anions $^-CH_2CN$ catalysent alors la transformation de **1***a* et **1***b* en fluorènylidèneacétonitrile FlC=CHCN **17**, dont dérivent les nitriles FlC=CHC(CN)=C(NH$_2$)CH$_3$ **8**, FlC=C(CN)CHFl **10** et FlC=C(CN)CH$_2$CN **11**. Ces résultats permettent d'interpréter l'évolution de la nature des produits apparus pendant l'électrolyse de la fluorènone dans l'acétonitrile, en présence d'un équivalent de chlorure ou d'anhydride d'acide ω-chloré. Apparaissent successivement les dérivés de réduction–acylation, puis les nitriles FlC(OH)CH$_2$CH$_2$CN **3***a*, **10**, FlC(OH)CH$_2$CN **24** et des polymères. Grâce à sa basicité, le radical-anion de la fluorènone est le promoteur des réactions avec le solvant, l'oléfine **17** étant un intermédiaire privilégié. Le bis-fluorènol, le fluorènol, enfin le fluorène accompagnent **1***a* et les produits ci-dessus.

CHANTAL DEGRAND, GERARD BELOT, PAUL-LOUIS COMPAGNON, and FRANÇOISE GASQUEZ. Can. J. Chem. **61**, 2581 (1983).

The electrogenerated anions $^-CH_2CN$ induce the conversion of the various reduction–acylation products of fluorenone **1***a* and its anil **1***b* in acetonitrile into **1***a* and **1***b*; this phenomenon is controlled by the fortuitous introduction of molecular oxygen. The $^-CH_2CN$ anions catalyse the transformation of **1***a* and **1***b* into fluorenylideneacetonitrile (FlC=CHCN) **17**, convertible into the nitriles FlC=CHC(CN)=C(NH$_2$)CH$_3$ **8**, FlC=C(CN)CHFl **10**, and FlC=C(CN)CH$_2$CN **11**. These observations allow us to interpret the formation of the products appearing during the electrolysis of fluorenone in acetonitrile in the presence of an equivalent of chloride or anhydride of ω-chloro acid. The products of reduction–acylation appear successively, followed by the nitriles, FlC(OH)CH$_2$CH$_2$CN **3***a*, **10**, FlC(OH)CH$_2$CN **24**, and polymers. Because of its basicity the fluorenone radical anion promotes reactions with the solvent, olefin **17** being a preferred intermediate. Bis-fluorenol, fluorenol, and finally fluorene are found with **1***a* and the above products.

[Journal translation]

Introduction

Au cours d'électroréductions effectuées dans l'acétonitrile, divers exemples de cyanométhylation ont été signalés (1–11). L'acidité de ce solvant est telle que de nombreuses formes réduites (dianions, monoanions, voire même radicaux-anions) sont suffisamment basiques pour le déprotoner. Les anions $^-CH_2CN$ ainsi formés réagissent avec diverses espèces présentes au sein du catholyte pour livrer une grande variété de nitriles.

Nous avons pour notre part (12) observé que la réduction acylante de la fluorènone **1***a* et de sa base de Schiff **1***b* dans l'acétonitrile en présence du chlorure d'acide **2***a* conduit, entre autres, à la formation de produits mineurs inattendus, les propionitriles **3***a* et **3***b*. En cours d'électrolyse, nous avions observé une évolution des formes réduites acylées **4***a*, *b* et **5***a*, *b* de la fluorènone; la nature de cette évolution n'avait pas été établie, celle-ci fait l'objet de ce travail.

Dans la partie A, nous étudions le comportement des composés **4***a–c*, **5***b*, **6***a*, *b*, **7***a*, *b* vis-à-vis des anions $^-CH_2CN$ électrogénérés par réduction de l'azobenzène en son dianion au sein de l'acétonitrile (2, 6, 13). Ces composés sont obtenus par électroréduction–acylation de la fluorènone **1***a* ou de son anil

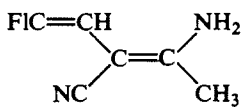
1*b*, les agents acylants étant le chlorure et l'anhydride d'acide ω-chloré **2***a* et **2***b* (12) et l'anhydride acétique **2***c*.

Dans la partie B, nous examinerons en détail l'électroréduction de la fluorènone conduite dans l'acétonitrile, en présence d'un équivalent d'agent acylant **2***a* ou **2***b*. L'évolution de la nature des produits en fonction du degré d'avancement de l'électrolyse est interprétée compte tenu des résultats de la première partie.

Résultats et discussion

A. *Stabilité des formes réduites acylées de la fluorènone ou de sa base de Schiff vis-à-vis d'anions $^-CH_2CN$ électrogénérés*

L'addition de deux équivalents de $^-CH_2CN$ aux diverses formes réduites acylées étudiées conduit à l'obtention des nitriles **8**, **9***a*, **10** et **11**. Les rendements obtenus après purification par chromatographie sont indiqués dans le Tableau 1 (expériences 1 à 8).



8

$RCOC(CN)=C(NH_2)CH_3$

9*a*: R = cycloPr
9*b*: R = $(CH_2)_3Cl$
9*c*: R = CH_3

$FlC=C(CN)CHFl$

10

$FlC=C(CN)CH_2CN$

11

Les résultats des expériences 1 à 8 du Tableau 1 conduisent aux conclusions suivantes.

(*i*) Dans la moitié des expériences, la fluorènone ou sa base de Schiff est isolée en faible quantité.

(*ii*) Dans toutes les expériences, on obtient le dièmaminonitrile **8**. Nous avons montré récemment (14) que l'attaque par $^-CH_2CN$ de la fluorènone et de ses bases de Schiff conduit également à **8**, à l'abri de l'air. En présence de traces d'oxygène, la formation de **8** est en compétition avec celle de **11** (15).

(*iii*) L'attaque par $^-CH_2CN$ des formes réduites N-acylées **7***a* et **7***b* est lente puisque le substrat est en grande partie récupéré après les temps de contact choisis (expériences 7 et 8).

(*iv*) L'énaminonitrile cyclopropylé **9***a* est isolé dans toutes les expériences où le substrat possède un reste cyclopropyle préexistant ou potentiel ($CO(CH_2)_3Cl$) sauf dans l'expérience 7 pour la raison précédente.

(*v*) A partir des dérivés de la fluorènone, on obtient le produit de couplage **10** (16*a*), exception faite de l'expérience 3 où, en revanche, le rendement en **8** est élevé.

La formation de fluorènone ou de son anil se conçoit comme résultat de l'action conjointe des anions $^-CH_2CN$ électrogénérés dans un premier temps et de traces d'oxygène qui peuvent s'introduire de façon aléatoire dans la seconde phase non-électrochimique.

TABLEAU 2. Valeurs des pK_a dans le DMSO de divers composés à H mobile

	CH_3CN	$FlCH_2$	FlCHOH	$FlCHOCH_3$
pK_a	31,3[a]	22,6[b]	16[c]	16[c]
	$PhCOCH_2CN$	H_2O	$CH_3CHOHCH_3$	$PhNH_2$
pK_a	10,2[a]	31,4[d]	30,2[d]	30,7[e]

[a] Voir réf. 31.
[b] Voir réf. 32.
[c] Voir réf. 33.
[d] Voir réf. 34.
[e] Voir réf. 35.

Le tableau 2 rassemble les pK_a dans le DMSO de quelques molécules afin de montrer que $^-CH_2CN$ peut générer leurs anions et provoquer les réarrangements évoqués ci-dessous. Le DMSO est retenu comme solvant de référence pour son caractère dipolaire non-hydroxylé ("aprotique") qui est celui de MeCN.

Esters de fluorènol **4**a–c

Ils doivent se cliver en premier lieu selon [1].

L'alcoolate libéré se réarrange spontanément en carbanion **12** (17). Ce carbanion est très sensible aux traces d'oxygène puisque par voltamétrie cyclique dans le DMF, on observe son potentiel de pic d'oxydation E_{pa} à −1,21 V/ECS (17) tandis que l'oxygène se réduit vers −0,7 V. La fluorènone est régénérée dans le milieu basique selon le processus catalytique [3]–[6]: la formation de la fluorènone provient de la rupture du bis-fluorènol intermédiaire par une base B^- telle que l'anion **12** (21). L'ion superoxyde constitue éventuellement une autre base; il évolue probablement vers la formation d'eau oxygénée. L'ènol de la réaction [1] conduit à l'anion correspondant **13** selon [7].

[1] 
[2] 
[3] 
[4] 
[5] 
[6] 
[7] 
Dérivé diacylé **5**b

Il conduit aussi à la fluorènone puisque le dérivé acylé **4***b* se forme intermédiairement.

[8] 
[9] 
Dérivés C-acylés **6**a, b

Après libération de l'anion **15**, un processus d'oxydation par O_2 conduit à la base de Schiff **1***b* selon [11]–[13]. Le mécanisme proposé tient compte des observations suivantes. L'anion **15** est facilement oxydable par l'oxygène [11] puisqu'on observe son oxydation à $E_{pa} = -0{,}93$ V/ECS par voltamétrie cyclique dans le DMF (18). Les bases fortes B^- déprotonent le radical apparu (18). Le radical-anion de la base de Schiff s'oxyde, lui aussi très facilement, à $-1{,}4$ V (12); en conséquence, il réduit instantanément les traces d'oxygène. On peut également envisager[2] que le radical apparu dans [11] se dimérise selon [13] avant de livrer la base de Schiff **1***b*.

[10] 
[11] 
[12] 
[13] 
Dérivés N-acylés **7**a, b

La déprotonation de **7***a, b* est certainement plus rapide que l'addition nucléophile au carbonyle de **6***a, b*. On observe cependant que l'anion **16** ainsi formé [14] évolue difficilement: le produit principal est le produit initial. L'anion **16** est plus stable et moins facilement oxydable que l'anion **15**; ceci justifie la lenteur d'évolution des composés **7***a, b*.

[2] Suggestion de l'un des examinateurs.

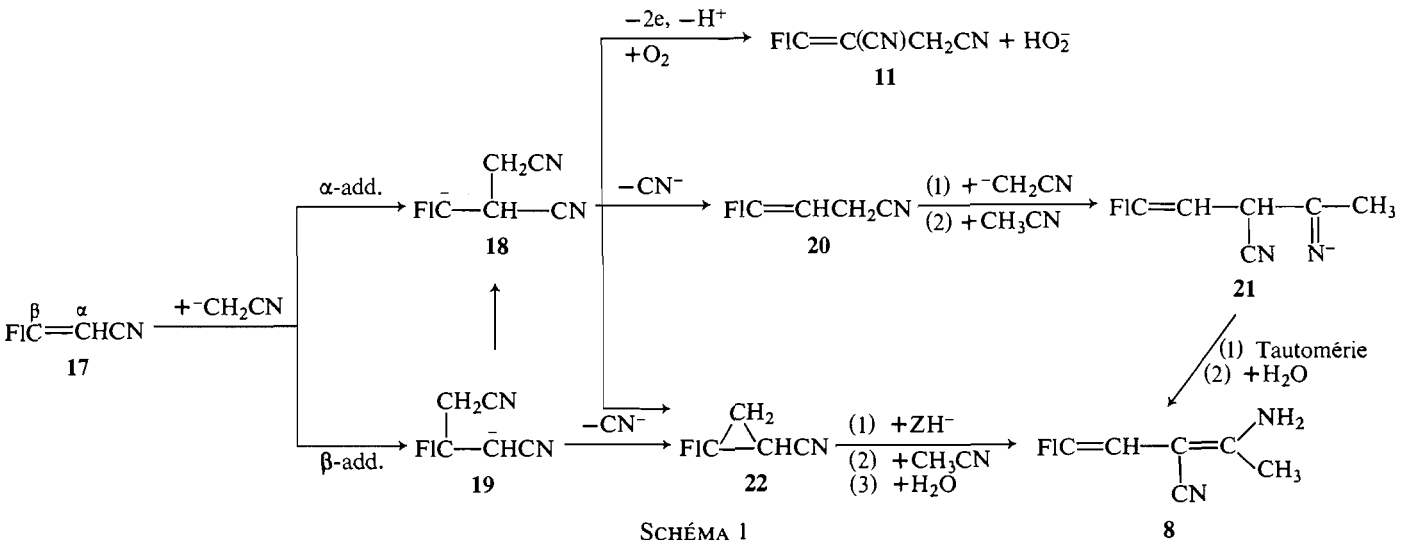

SCHÉMA 1

[14] $FlCH{-}NPh \xrightarrow{+{}^-CH_2CN} Fl\bar{C}{-}NPh$ (RC=O)

7*a*,*b* 16

Les anions **13**, issus des β-cétonitriles $RCOCH_2CN$, se comportent comme de bons nucléophiles. Leur condensation avec l'acétonitrile-solvant conduit aux ènaminonitriles **9***a*–*c*. Que

[15] $RCO\bar{C}HCN \xrightarrow{+CH_3CN} RCOCH{-}C(CN){=}N^-$ (CN, CH_3)

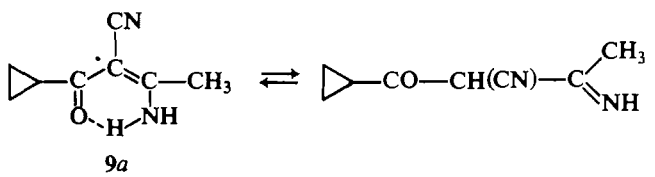
13

$RCO\bar{C}{-}C{=}NH \leftrightarrow RCOC(CN){=}C(NH^-)CH_3$

$\xrightarrow{+H_2O}$ $RCOC(CN){=}C(NH_2)CH_3$

9*a*–*c*

l'on parte de **4***a*, **6***a*, ou de **4***b*, **5***b*, seul **9***a* est isolé; dans le cas de **4***b*, **5***b*, la basicité du milieu induit la cyclisation de **9***b* en **9***a*. En revanche, l'homologue méthylé **9***c* n'a pu être isolé à partir de **4***c*, **6***b*, et **7***c*. L'étude spectroscopique de **9**a montre un équilibre tautomère entre les formes ènamine et imine.



9*a*

La fluorènone **1***a* et son anil **1***b* régénérés à partir des divers substrats sont eux-mêmes sensibles à l'attaque nucléophile des anions $^-CH_2CN$ (14): il en résulte un nitrile α,β-éthylénique **17** très électrophile [16]. En quelques étapes (Schéma 1), on accède aux nitriles **8** et **11** à partir du promoteur **17** (14, 15). Les résultats de l'expérience 9 (Tableau 1) confirment que ces deux nitriles dérivent bien de **17**. Le dinitrile **11** résulte de l'oxydation de l'anion **18** par l'oxygène moléculaire (15). Le potentiel d'oxydation de **18** n'est pas connu, mais il est voisin de celui des anions fluorènyles $FlCH^-$, $E_0 = -0{,}67$ V/ECS dans le DMF (19) et $Fl\bar{C}CH_3$, $E_0 = -0{,}78$ V/ECS dans le DMF (17). Le dièneaminonitrile **8** provient de l'oléfine **20** et/ou du dérivé cyclopropylé **22** (14), dont l'ouverture résulte de l'attaque de bases telles HO^-, $PhNH^-$ (ZH^- accompagne la formation de **17**). L'attaque du dérivé cyclopropyle **22** par les bases HO^- et $PhNH^-$ permet également d'accéder aux propionitriles **3***a*, *b* [17] qui sont apparus lors de l'électroréduction–acylation de la fluorènone (12).

22

(ZH^-: HO^-, $PhNH^-$)

$\xrightarrow{+H^+}$ **3***a*,*b*

L'attaque nucléophile du nitrile α,β-éthylènique **17** par les anions $^-CH_2CN$ implique une régiosélectivité particulière. L'attaque du C-β conduirait à un produit classique d'addition-1,4, avec formation de l'anion intermédiaire **19**. La protonation de **19** par le solvant ou lors du traitement final par l'eau livrerait le dinitrile $FlC(CH_2CN)_2$ que nous n'avons pas isolé. Des nitriles analogues, les glutaronitriles $PhRC(CH_2CN)_2$ ont été obtenus par électroréduction de PhCOR et d'oléfines activées $PhRC{=}CHCN$ dans l'acétonitrile; seule intervient alors la β-addition d'anions $^-CH_2CN$ électrogénérés (1, 2, 6, 9–11). Dans notre cas, l'attaque du C-α livre l'anion fluorènyle **18** beaucoup plus stable. L'anion **19** est donc peu compétitif vis-à-vis de **18**; s'il apparaît, il s'isomérise plutôt en anion **18**.

L'attaque du C-α du nitrile **17** est aussi sensible à d'autres nucléophiles tels les anions **14** $Fl\bar{C}OCOR$ issus de **5***b* [8] ou de **4***a*–*c*. On obtient alors un anion très délocalisé **23** dont le traitement final par l'eau livre le nitrile **10**. Le pK_a dans le DMSO du fluorènylidèneméthyl-9 fluorène est évalué à 14,2

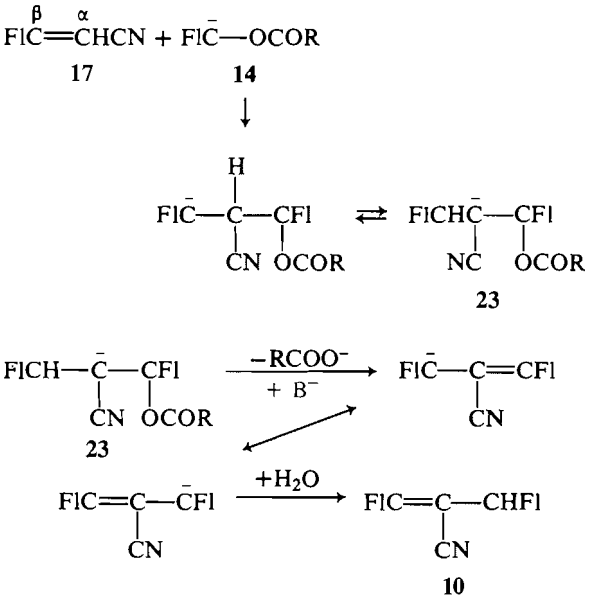
TABLEAU 3. Potentiel de demi-vague $E_{1/2}$ ou de pic E_{pc} de formes réduites acylées de **1***a* et de **1***b* et des nitriles insaturés **8**, **10**, **11** et **17**

		Substrats				Nitriles insaturés			
	Solvant	**4***a*	**4***b*	**5***a*	**6***a*	**8**	**10**	**11**	**17**
$E_{1/2}$ ou E_{pc}* (V)	MeCN	−2,30	−2,30	−2,12		−1,86*	−1,42*	−1,22*	−1,35*
	DMF	−2,21		−2,06	−2,25	−1,90		−1,18	

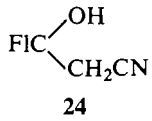
(16*b*), celui de **10** est inférieur à 14 grâce à l'effet −I du groupe cyano.

[18]



Une grande dispersion caractérise les rendements exposés au tableau 1. Le taux de récupération du noyau fluorène varie de 44 à 66% (en moyenne 55%) car la formation de polymères est fréquente. En ce qui concerne l'acyl-ènaminonitrile **9***a*, son instabilité lors de l'hydrolyse est sans doute cause des variations de rendement observées. Par ailleurs, si la formation d'un composé dépend de la concentration aléatoire en oxygène moléculaire résiduel, il faut s'attendre à des fluctuations de son rendement. Ainsi le nitrile **11**, résultat du processus oxydatif de l'anion **18** (Schéma 1), a un rendement variant de 0 à 30% selon l'électrolyse. Si ce processus est limité, la formation de **8** est favorisée. Enfin, les nitriles **8** et **10** sont en compétition à partir de l'oléfine **17** (Schéma 1 et [18]). Dans le meilleur cas, **10** atteint un rendement de 45% au lieu des 1 à 5% de la référence 16*a*; la méthode électrochimique constitue donc une bonne voie d'accès à cette molécule.

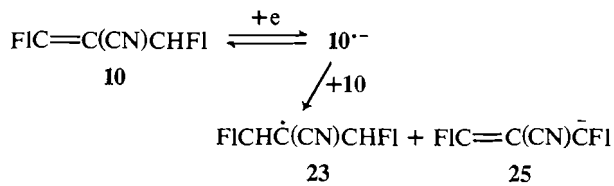
Pour aborder la deuxième partie de notre étude, il est nécessaire de déterminer les propriétés électroréductrices (potentiel de demi-vague $E_{1/2}$ sur électrode à gouttes de mercure ou potentiel de pic E_{pc} sur électrode stationnaire de carbone vitreux) de quelques dérivés acylés des types **4**, **5** et **6** et des divers nitriles insaturés préparés. Ces données sont rassemblées dans le tableau 3. La réduction de tous les dérivés acylés survient au-delà de −2 V. Elle provoque la rupture des composés **4***a*, *c* libérant l'anion fluorènyle $FlCH^-$ rouge intense qui, après traitement, livre du fluorène et de la fluorènone. L'anion $Fl\bar{C}H$ est, en effet, très sensible aux traces d'oxygène, et donne de la fluorènone (20). Par exemple, une électroréduction préparative à partir de **4***c*, à −2,2 V dans l'acétonitrile conduit à un mélange de fluorène, de fluorènone **1***a* et d'alcool **24** en proportions relatives de 24, 40 et 36%. Ce dernier apparaît également lors de la réduction de **1***a* (voir partie B). Les nitriles insaturés



24

8, **10**, **11** et **17** sont plus faciles à réduire. Le premier stade de réduction correspond à la fixation d'un électron. La voltamétrie cyclique indique que les radicaux-anions obtenus ont des stabilités différentes: le plus stable est issu de **10**. Dans ce cas, le catholyte devient bleu intense; de plus cette coloration persiste malgré un barbotage d'oxygène. Nous suggérons que le radical-anion conduit à deux espèces très stables: l'anion délocalisé bleu **23** et le radical encombré **25**. Le mécanisme [19] fera l'objet d'une étude ultérieure.

[19]



Une électroréduction préparative de **17** conduit à une solution vert bronze. Après passage de 1 F, on note à côté d'oléfine résiduelle **17**, la présence principale de polymères.

B. *Electroréduction acylante de la fluorènone dans l'acétonitrile liée à la présence d'un équivalent de chlorure ou d'anhydride d'acide* **2**a *ou* **2**b

Une série d'électrolyses préparatives sur nappe de mercure a été effectuée à des potentiels contrôlés E_c qui correspondent à la formation initiale du radical-anion de la fluorènone (E_c = −1,35 ± 0,15 V); un équivalent de **2***a* ou **2***b* est initialement présent. Ces expériences sont résumées dans le Tableau 4 (électrolyses 1–4). Elles correspondent à divers degrés d'avancement de l'électrolyse, le nombre *n* de faradays consommés variant de 1,7 à 3,2. Les rendements indiqués sont calculés après purification par chromatographie sur colonne.

Le degré d'avancement de l'électrolyse se traduit par une évolution de la couleur du catholyte, ce qui permet de distinguer six étapes successives. Le Tableau 5 rassemble ces données ainsi que la nature des produits identifiés à chaque étape par chromatographie en couche mince. Ces deux tableaux révèlent la complexité des réactions qui se produisent au sein du catholyte. Cette complexité se retrouve dans l'évolution du courant faradaïque présentée par la Fig. 1. Après une décroissance normale, on note deux reprises successives de l'électrolyse quand *n* = 1,6 F et *n* = 2,4 F.

[a] L'étape est définie en fonction de *n* et de la couleur du catholyte dans le Tableau 5.
[b] Voir la référence 12.
[c] Des substances polymériques non identifiées sont également isolées.

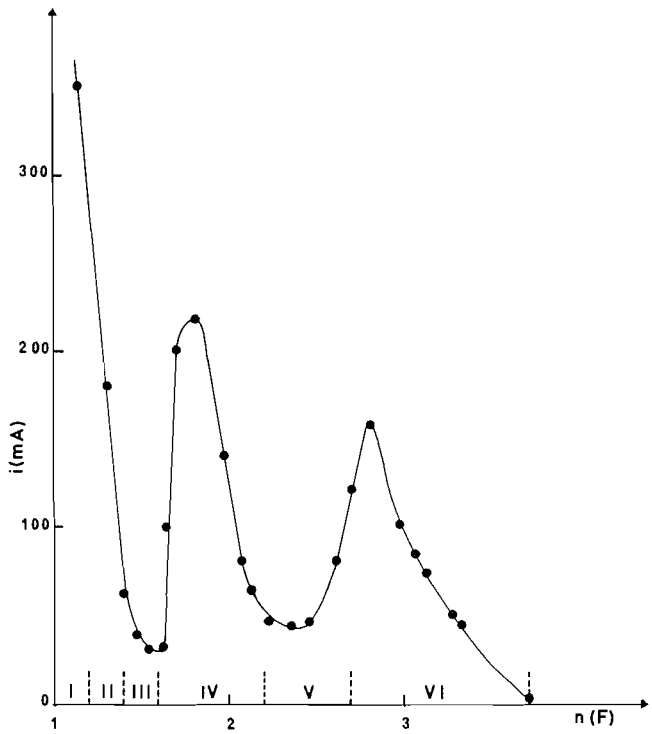

FIG. 1. Electroréduction préparative à −1,4 V de **1***a* en présence d'un équivalent de **2***a*. Les conditions sont celles du Tableau 5. Influence du nombre *n* de F consommés sur l'intensité du courant faradaïque. Les nombres romains indiquent les étapes successives définies dans le Tableau 5, à partir de la couleur du catholyte.

Les électrolyses conduisent aux remarques suivantes.

(*i*) La présence de fluorènone est constante. Son taux oscille autour de 20% de façon aléatoire: lorsque l'électrolyse progresse, il peut augmenter ou diminuer.

(*ii*) L'évolution de l'électrolyse ne semble pas corrélée à la nature de l'agent acylant. L'utilisation du chlorure d'acide **2***a* favorise cependant la formation des formes réduites diacylées aux dépens des formes monoacylées.

(*iii*) Le bis-fluorènol et le fluorènol se forment dès l'origine, mais le premier disparaît plus précocement que le second.

(*iv*) Le fluorène apparaît tardivement avec l'étape V.

(*v*) Les dérivés acylés disparaissent en fin d'électrolyse.

(*vi*) Les étapes finales se caractérisent surtout par l'apparition des nitriles **3***a*, **10** et **24**.

Etape I

Elle correspond à la réduction acylante de la fluorènone; l'excès originel d'agent acylant autorise à partir de l'anion **14**, la formation du diacylé **5***c*. La rapidité des acylations cause la disparition immédiate du radical-anion **26** rouge et de l'anion **14**. Le catholyte reste jaune même au voisinage immédiat de la nappe de mercure. Le dérivé diacylé **5***c* disparaît dès cette étape en détruisant **26**. La chromatographie sur couche mince (Tableau 5) révèle déjà **5***b*, à côté du bisfluorènol, de l'ester **4***b* et du fluorènol qui proviennent du traitement par l'eau des anions **14** et **12** respectivement.

[20] $\underset{\mathbf{1}a}{FlC{=}O} \overset{+e}{\rightleftharpoons} \underset{\mathbf{26}}{Fl\dot{C}{-}O^-}$

$\underset{\mathbf{26}}{Fl\dot{C}{-}O^-} \xrightarrow{+2a,b,\ +e} \underset{\mathbf{14}}{Fl\bar{C}{-}OCOR} \xrightarrow{+2a,b} \underset{\mathbf{5}c}{FlC(COR)OCOR}$

[21] $\underset{\mathbf{5}c}{5c} + \underset{\mathbf{26}}{Fl\dot{C}{-}O^-} \rightarrow 5b + Cl^- + Fl\dot{C}{-}OH \xrightarrow{+e} \underset{\mathbf{12}}{Fl\bar{C}{-}OH}$

$Fl\dot{C}{-}OH \rightarrow \tfrac{1}{2}FlC(OH)C(OH)CFl$

Etape II

Avec la progression de l'électrolyse, les concentrations relatives de **2***a*, *b* diminuent: le radical-anion **26** réagit avec le dérivé diacylé **5***c* dont la cyclisation progresse de **5***b* vers **5***a*. La coloration rouge du catholyte au voisinage de la nappe de mercure montre l'accumulation du radical-anion **26**. En conséquence, la cyclisation **5***b* → **5***a*, sous l'influence de **26**, est relativement lente.

Etape III

Elle s'achève avec la réduction totale de la fluorènone et la formation des esters **4***b*, **5***a*, *b*, de fluorènol et de bis-fluorènol. Le courant faradaïque devient négligeable et le catholyte incolore.

Etape IV

Elle correspond à la reprise du courant faradaïque et à une nouvelle coloration en rouge du catholyte; des radicaux anions **26** réapparaissent tandis que le bis-fluorènol disparaît. Les esters **4***b* et **5***a*, *b* n'étant pas réductibles au potentiel utilisé (Tableau 3), la formation de radicaux-anions **26** est liée à la réapparition de fluorènone au sein du catholyte. La régénéra-

For personal use only.

tion de la cétone est provoquée par la présence de bases telles que FlC̄OH qui catalysent la transformation du bis-fluorènol en fluorènone (21) (voir partie A, [4] à [6]).

Les radicaux-anions **26** à nouveau apparus sont suffisamment basiques pour déprotoner le solvant. Ceci est démontré par l'électrolyse 5 du tableau 4, effectuée *sans agent acylant*. Les résultats de cette électrolyse annexe sont intéressants car, nous le verrons, ils entrent en ligne de compte dans l'interprétation du cours de cette étape et des suivantes. L'électrolyse 5 montre une intervention des anions $^{-}CH_2CN$ puisqu'elle conduit à la formation des nitriles **17** et **24** selon [22] à [26]. La transformation de la fluorènone en oléfine **17** est un processus catalytique (séquence [23]–[25]) en raison de la basicité de l'ion HO^{-} dans l'acétonitrile (cf. les pK_a du tableau 2).

[22] $FlC{=}O \underset{}{\overset{+e}{\rightleftharpoons}} Fl\dot{C}{-}O^{-}$ (**26**)

$Fl\dot{C}{-}O^{-} + CH_3CN \rightarrow Fl\dot{C}{-}OH + {}^{-}CH_2CN$

[23] ${}^{-}CH_2CN + FlC{=}O \rightarrow FlC(O^{-}){-}CH_2CN \rightleftharpoons FlC(OH)\bar{C}HCN$

[24] $FlC(OH)\bar{C}HCN \rightarrow HO^{-} + FlC{=}CHCN$ (**17**)

[25] $HO^{-} + CH_3CN \rightleftarrows HOH + \bar{C}H_2CN$

[26] $FlC(OH)\bar{C}HCN \xrightarrow{+H_3O^{+}} FlC(OH)CH_2CN$ (**24**)

Compte tenu des résultats de cette électrolyse, on conçoit que dans l'étape IV, les radicaux anions **26** à nouveau apparus, livrent l'oléfine **17** selon [22] à [24]. Dans cette étape, la formation de polymères est induite à partir de **17** selon [27] et celle du nitrile **3***a* s'effectue probablement selon [28] (cf. partie A, Schéma 1 et [17]). La consommation continuelle et rapide de la fluorènone provoque la chute du courant faradaïque.

[27] $FlC{=}CHCN$ (**17**) $\xrightarrow{+Fl\dot{C}OH}$ polymères

[28] $FlC{=}CHCN$ (**17**) $\xrightarrow{\text{Schéma 1}}$ $FlC(CH_2){-}CHCN$

$FlC(CH_2){-}CHCN \xrightarrow{+HO^{-}} FlC(OH)CH_2\bar{C}HCN \xrightarrow{\text{hydrolyse}} \mathbf{3}a$

Etape V

Elle débute quand **5***b* est totalement cyclisé en **5***a*. Les bases fortes présentes ($Fl\dot{C}{-}O^{-}$, HO^{-}, $^{-}CH_2CN$) entraînent la cyclisation de **4***b* en **4***a*. L'oléfine activée **17** formée dès l'étape IV constitue toujours un piège pour d'éventuels radicaux $Fl\dot{C}OH$, d'où l'apparition de polymères [27]. Par ailleurs, **17** est elle-même réductible en polymères au potentiel appliqué (Tableau 3).

TABLEAU 5. Electroréduction préparative de **1***a* en présence d'un équivalent de **2***a*. Au total, 3,72 F sont consommés (cf. Fig. 1). Influence du degré d'avancement de l'électrolyse sur la couleur du catholyte et sur la nature des produits apparus en cours d'expérience. Ces produits sont identifiés par chromatographie sur couche mince

			Temps d'électrolyse[a]					Dérivés acylés				Dérivés nitriles

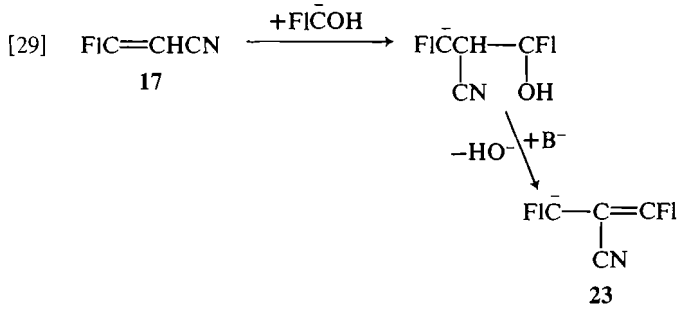
[a] Fin de l'étape.

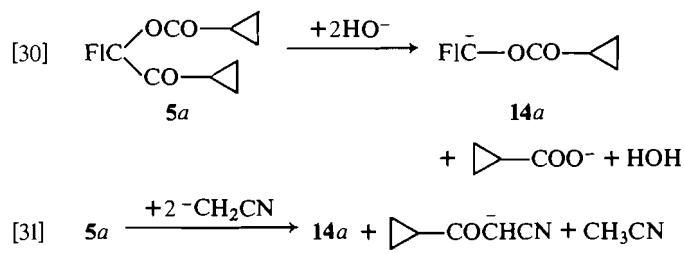
Le nitrile **24** se forme, lors de l'extraction, selon [23] et [26]. Le nitrile insaturé **10** FlC=C(CN)CHFl dérive de **17** à la suite de deux types d'addition. Nous avons montré dans la partie A, que l'addition à **17** des anions **14** issus du dérivé monoacylé **4***a*, conduit à **10** [18]; on note en conséquence une disparition progressive de **4***a*. L'anion du fluorènol FlC̄OH peut lui aussi se condenser avec **17** [29] entraînant la disparition du fluorènol à cette étape. La présence de l'anion **23** issu de **10** provoque la coloration bleu foncé du catholyte. Du fluorène est identifié dont l'origine est discutée ci-dessous.



Etape VI

Elle est caractérisée par la reprise d'un courant faradaïque de faible intensité, suggérant la réapparition de traces de fluorènone. La couleur violette du catholyte résulte du mélange d'anions bleus **23** du nitrile **10** et du radical-anion **26** de la fluorènone. Du fluorène et de la fluorènone sont encore identifiés dans cette étape. Enfin, le dérivé diacylé **5***a* disparaît à son tour. Dans la partie A, nous avons montré que la présence de traces d'oxygène est favorable à une décomposition de **4***a*, *b* et **5***a*, *b* en fluorènone; nous avons aussi rappelé que l'anion fluorènyle livre de la fluorènone en présence de O_2 (20).

Les bases fortes présentes (HO^- et $^-CH_2CN$) provoquent également la rupture de **5***a* selon [30] et [31]. L'anion **14***a* libéré est piégé par **17**, donnant l'anion bleu **23** [18]. Le



fluorène, déjà trouvé à l'étape V, est le stade final de réduction de **1***a*. Plusieurs composés formés pendant l'électrolyse se réduisent en fluorène, mais au-delà de −2 V: le fluorènol et ses éthers se rompent entre C et O (17, 22–24); de même, les esters **4***a*, *b* se réduisent avec coupure à −2,3 V (Tableau 3). Le bis-fluorènol dont le stade final de réduction est aussi le fluorène, est réduit dans une première étape en fluorènol (réfs. 17 et 22). Ici, le potentiel d'électrolyse ne dépasse pas −1,5 V. La réduction d'un intermédiaire instable non identifié peut conduire au fluorène; mais nous émettons également l'hypothèse suivante, en raison de la nature hyperbasique du catholyte (25). Le pouvoir réducteur des électrons serait exalté par le milieu hyperbasique, à l'image de l'accroissement considérable du pouvoir réducteur de HNa par les alcoolates RONa (26) découverts par Caubère et coll. Selon Bordwell et Clemens (27), plus un carbanion est basique, plus grande est la probabilité qu'il réagisse selon un processus de transfert (mono) électronique plutôt que par un processus S_N2. Cet accroissement du pouvoir de transfert expliquerait la réduction finale en fluorène.

Conclusion

Nos résultats montrent que l'évolution de l'électroréduction–acylation de la fluorènone est orientée par la réaction du solvant, l'acétonitrile, avec les intermédiaires apparus, en particulier le radical-anion de la fluorènone.

Partie expérimentale

Un potentiostat Amel-552 et un intégrateur Tacussel IG5-N sont utilisés pour l'électrosynthèse; une unité Tacussel UAP 4 et un générateur de fonctions Tacussel GST pour les expériences en voltamétrie. Les voltamogrammes sont enregistrés sur un appareil Ifelec 2025 CX-Y. Les spectres de rmn ^1H sont tracés sur un spectromètre Perkin–Elmer R-24, les spectres de masse sur un spectromètre Finnigan 3003 (introduction directe; 70 eV), les spectres ir sur un spectromètre Beckman IR-8. Les points de fusion sont déterminés sur un banc de Köfler. Les chromatographies sur colonne sont conduites sur gel de silice Kieselgel 70, 70–230 mesh, Merck 7734 et celles en couche mince sur plaques de Kieselgel 60F 254 Merck 5554 (éluant: acétone/hexane 3:7).

Les solvants (MeCN et DMF) de pureté analytique sont soigneusement séchés sur tamis moléculaire 4 Å, puis sur alumine neutre.

Tous les potentiels indiqués se réfèrent à l'électrode au calomel saturé (ECS).

L'électrosynthèse des dérivés acylés **4***a*, **4***b*, **5***a*, **5***b*, **6***a* et **7***a* est déjà décrite (12). L'électroréduction de la fluorènone dans l'acétonitrile en présence d'un équivalent d'anhydride acétique, a permis l'obtention de **4***c*. Les composés **6***b* et **7***b* sont obtenus électrochimiquement à partir de l'anil **1***b*. Ils sont identiques à ceux décrits dans la littérature: **4***c* (28), **6***b* (29) et **7***b* (30).

Les anions $^-CH_2CN$ (2 équivalents) sont électrogénérés par réduction de l'azobenzène dans l'acétonitrile selon la procédure décrite dans la référence 14. L'électroréduction de la fluorènone en présence d'un équivalent de **2***a* ou **2***b* est effectuée selon la méthode B de la référence 12.

Les nitriles sont séparés par chromatographie dans l'ordre d'élution suivant: **10** (16*b*), **11** (15), **9***a* et **8** (14).

Amino-3 cyano-2 cyclopropyl-1 butène-2 one-1 **9***a*

Cristaux beiges, F = 141°C (éther diéthylique – hexane); ir (KBr) cm^{-1}, ν_{NH_2} et ν_{NH}: 3320 (épaulements à 3400, 3300, 3250) et 3140, $\nu_{C=C-C\equiv N}$: 2230, $\nu_{C=C-C=O}$: 1700, $\nu_{C=C}$ ou $\nu_{C=N}$: 1645, 1530, 1400, 1320, 1200, 940; rmn ^1H ($CDCl_3$, référence interne TMS) δ ppm: 0,7–1,2 (m, 4H, cyclopropyle), 1,3–1,7 (m, 1H, cyclopropyle), 2,20 (s, 3H, CH_3), 6,40 (s, 1H, H—C-2), 7,85 (large s, 1H, NH); spectre de masse *m/e* (intensité relative %): 151 (11), 150 ($M^{\cdot+}$, 100), 149 (4), 122 (M − 1 − HCN, 12), 82 (16), 70 (15). En raison de son instabilité, l'analyse centésimale de **9***a* n'a pu être effectuée.

5-Methylthienylacryloyl chymotrypsin has been prepared with ^{13}C at the carbonyl and, separately, at the α carbon atoms of the acyl moiety. The isotopically labelled species confirm the assignments of several of the bands in the resonance Raman (RR) spectrum of the acyl-enzyme and show that the feature occurring near 1260 cm^{-1} involves the motion of the carbonyl carbon atom. It is likely that the 1260 cm^{-1} band is associated with the stretching vibration of the C—O bond in the =C—C(=O)—O— chymotrypsin moiety, i.e. the vibration of the bond being cleaved in the active site. A moderately intense 1260 cm^{-1} feature occurs only in the RR spectrum of the native acyl-enzyme and possible reasons are given for its appearance. The labelled species also confirm that the bands appearing near 1715 cm^{-1} in the RR spectrum of the acyl-enzyme are associated with the stretching mode of the acyl carbonyl, $\nu_{C=O}$. This frequency is that expected for an unperturbed α,β-unsaturated ester. Additionally, RR data are presented for 5-methylthienylacrylic acid in its —COOH and —COO^- forms labelled with ^{13}C at the C=O and α carbon positions.

P. R. CAREY et D. J. PHELPS. Can. J. Chem. **61**, 2590 (1983).

On a préparé la méthyl-5 thiénylacryloyl chymotrypsine avec un ^{13}C au niveau du carbonyl et séparément avec un ^{13}C au niveau des atomes de carbone en α du groupe acyle. Les espèces marquées confirment les attributions de plusieurs bandes qui apparaissent dans le spectre de résonance Raman (RR) de l'enzyme acylé et montrent que la particularité observé près de 1260 cm^{-1} implique le mouvement de l'atome de carbone du carbonyle. Il est probable que la bande à 1260 cm^{-1} est communément associée à la vibration d'élongation de la liaison C—O de l'unité =C—C(=O)—O— chymotropsine, c'est-à-dire de la vibration de la liaison qui se clive dans le site actif. Une caractéristique modérément intense à 1260 cm^{-1} apparaît uniquement dans le spectre de RR de l'enzyme acylé naturel et on donne les raisons possibles de son aspect. Les espèces marquées confirment également que les bandes qui apparaissent près de 1715 cm^{-1} dans le spectre de RR de l'enzyme acylé sont associées avec le mode d'élongation du carbonyle de l'acyle, $\nu_{C=O}$. Cette fréquence est celle attendue pour un ester α,β insaturé non perturbé. On présente de plus des données de RR pour l'acide méthyl-5 thiényl-acrylique dans ses formes —COOH et —COO^- marqués au ^{13}C au niveau du C=O et au niveau des carbones en α.

Introduction

A detailed description of the chemical events occurring in an enzyme's active site during the catalytic process is a major goal of enzymological studies. Although no single technique can provide a complete picture of the process at the molecular level it is becoming increasingly apparent that resonance Raman (RR) spectroscopy is capable of delineating structural and conformational events in an enzyme-bound substrate (1, 2). The spectroscopic data obtained is a property of the vibrational motions of the molecules and since these are sensitive to effects, such as hydrogen bonding, the disposition of charges and dipoles and conformational strain, which are of interest in mechanistic analysis, the RR spectrum provides an ideal probe of the catalytic process (3). There are, moreover, two other factors which strengthen the RR approach. Firstly, joint Raman and X-ray crystallographic studies on single crystals of suitable model compounds permit us to set up precise spectra–structure correlations which go a long way towards eliminating the problems of spectral interpretation. Secondly, using multiplex detection (4) it is possible to obtain the RR data for the enzyme substrate complex in a short time span, which, of course, renders the technique suitable for the characterisation of transient species.

Due to the availability of suitable laser excitation wavelengths the first RR studies of enzyme–substrate complexes (5) utilised substrates which were derivatives of cinnamic acid esters and which gave rise to an electronic absorption band in the 450 nm region. As reliable laser sources became available in the 350 nm spectral range it was possible to extend the work to include substrates based on furylacryloyl and thienylacryloyl derivatives undergoing transformation by chymotrypsin (6, 7), papain (8), and glyceraldehyde-3-phosphate dehydrogenase (9). Some of the intermediates in these reactions have been the subject of pioneering studies principally by Bernhard and coworkers (10, and references therein). These workers characterised the intermediates by absorption spectroscopy and with the higher information content of RR spectroscopy it is now possible to build on and refine their findings.

The impetus for the present work came from two sources. In recent papers concerning some furylacryloyl- and thienylacryloyl chymotrypsins (6, 7) we observed a feature which occurred only in the RR spectra of the native acyl-enzymes. To investigate further the origins of this curious, and possibly important, band we have synthesised two ^{13}C substituted derivatives of 5-methylthienylacryloyl chymotrypsin. The second stimulus for synthesising the isotopically substituted derivatives relates to the absorption studies on substrates with extended π-electron system mentioned above. The absorption maximum, λ_{max}, of the enzyme-bound acyl group shows a characteristic red shift compared to λ_{max} of various model compounds (10). A possible explanation of the red shift seen for the

acyl group in an acyl chymotrypsin such as furylacryloyl chymotrypsin is that the ester group linking the acyl group to the enzyme moiety becomes ketone-like due to the alkoxy oxygen atom being forced out of the plane defined by the C=C—C=O atoms (10). Since the RR spectral signatures of $\nu_{C=O}$ from α,β-unsaturated esters and ketones are characteristic and different, we may use the RR spectrum to test the "ketone" hypothesis. Previously, we assigned bands near 1720 cm^{-1} in the RR spectra of the acyl enzymes to $\nu_{C=O}$ of an ester function (6) and now it is necessary to confirm this assignment by ^{13}C substitution to either support or refute the analysis based on the early absorption studies.

Experimental procedures

Synthesis

The ^{13}C-labelled substrates were synthesized in two steps from malonic acid-2 ^{13}C or malonic acid-1,3 $^{13}C_2$ (Merck, Sharp and Dohme) and 5-methyl-2-thiophenecarboxaldehyde (Aldrich) as reported by MacClement *et al.* (6). Products were crystallized and identified by comparison to authentic unlabelled samples.

Preparation of acyl-enzymes and Raman measurements

The acyl-enzymes were prepared and the RR spectra recorded in the manner described in MacClement *et al.* (6).

Results and discussion

The acyl-enzyme 5-methylthienylacryloyl chymotrypsin is formed by reacting an excess of the corresponding acylimidazole with the enzyme near neutral pH. After approximately half a minute the pH of the reaction mixture is reduced to 3.0 by adding 1 *N* HCl. At this pH the acyl-enzyme is completely stable and may be purified by dialysis or column chromatography (6). The pure stable acyl-enzyme is the subject of discussion here. The 350.7 nm excited RR spectra of the 5-methylthienylacryloyl chromophore, unlabelled and substituted in the C=^{13}C—C=O and C=C—^{13}C=O positions are shown in Figs. 1–3. The spectra in Fig. 1 are for the acyl-enzymes at pH 3.0, while the spectra in Figs. 2 and 3 are of the ionised and unionised acid derivatives, respectively. In every instance the solvent is water, with, in the case of the acids, a small amount of CH_3CN being present to aid solubility. Before proceeding to a discussion of the isotope shifts and related assignments in Figs. 1–3 it is necessary to briefly summarise the state of our knowledge regarding the conformations of thienylacryloyl-like molecules in solution and bound to the active site of chymotrypsin.

For the acids in solution it is likely that the thienylacryloyl skeleton is essentially planar and predominantly *s-trans* about the single bond linking the ring and the ethylenic double bond. However, the enthalpy difference of the *s-cis* and *s-trans* forms is probably <1 kcal/mol (11, 12) and it is likely that there are significant amounts of both forms in solution. Furthermore, the position of the proton in the —COOH group is another source of conformational heterogeneity. Therefore, the ethylenic stretch, $\nu_{C=C}$, probably contains unresolved components, with each component due to one of two or several rotamers and reflecting the spectral signature and population of that rotamer. In recognition of the composite nature of such features we call the measured value $\langle\nu_{C=C}\rangle$, the fences standing for weighted mean. Support for this concept comes from the spectrum of the =^{13}C—COOH molecule obtained at higher resolution (~4 cm^{-1} spectral slit) where the 1599 cm^{-1} band seen in Fig. 3 (bottom) could be partially resolved into two features (data not shown). For the unlabelled acyl-chymotrypsin the appearance of two features in the carbonyl stretching region between 1700 and 1725 cm^{-1} is taken as evidence for the presence of two conformational states for the enzyme-bound acyl group (6). This finding is consistent with kinetic (13) and nmr (14) studies on other acyl-chymotrypsins. In the RR spectrum the sharp feature occurring near 1725 cm^{-1} is assigned to a carbonyl in a hydrophobic environment and for which the acryloyl moiety is essentially planar and possibly *s-cis* about the =C—C=O single bond. The broader $\nu_{C=O}$ occurring near 1700 cm^{-1} in the RR spectrum is assigned to a strongly H-bonded carbonyl attached to an essentially planar acryloyl moiety which is *s-trans* about the =C—C=O single bond. Again, the intense ethylenic feature near 1612 cm^{-1} is made up of contributions from both conformers.

Isotope shifts and band assignments

In general, for either the acids or the acyl-chymotrypsin the effects of isotopic substitution are seen only in a few features. For the unionised acid, the band at 1617 cm^{-1} moves to 1610 and 1599 cm^{-1} in the =C—^{13}C=O and =^{13}C—C=O derivatives, respectively (Fig. 3). In the ionised acid the corresponding band shifts from 1627 cm^{-1} to 1625 and 1606.5 cm^{-1} (Fig. 2). For the acyl-enzyme, the intense band at 1612.5 cm^{-1} is unshifted in the =C—^{13}C=O derivative but moves to 1594.5 cm^{-1} in the =^{13}C—C=O compound (Fig. 1). In each case the results support the assignment of the intense band in the 1615 cm^{-1} region to $\langle\nu_{C=C}\rangle$. The shift of $\langle\nu_{C=C}\rangle$ by only ~20 cm^{-1} in the —C=^{13}C—C=O compounds is not unexpected for a conjugated ethylenic linkage and emphasises the fact that the —C=C— group cannot be regarded as a simple diatomic oscillator. The differences in position of $\langle\nu_{C=C}\rangle$ for the acids and the acyl-enzyme can be understood in terms of the electron polarisation theory (3, 15). According to this theory, the RR and absorption spectral properties are explained by changes in the distribution of the electrons in the chromophore's extended π-electron chain. The changes may be caused intramolecularly by factors such as the addition of electron donating or accepting groups, or caused intermolecularly by, for example, protein H-bonds or charges when the chromophore is enzyme bound.

The ^{13}C derivatives also confirm the assignment of the weak bands near 1700 cm^{-1} to $\nu_{C=O}$. The broad band near 1680 cm^{-1} in the unlabelled and ^{13}C=C—COOH form of the acid is not resolved in the —^{13}COOH derivative (Fig. 3, although it may appear as a shoulder on the 1610 cm^{-1} feature) and thus the 1680 cm^{-1} feature is assigned to $\nu_{C=O}$ for the —COOH acid, which is broadened by hydrogen bonding to solvent. For the —COO^- acid the band at 1342.5 cm^{-1}, which appears to shift to 1323 and 1339 cm^{-1} in the =C—$^{13}COO^-$ and =^{13}C—COO^- molecules, respectively (Fig. 2), is assigned to the symmetric stretching motion of the —COO^- moiety. For the acyl-chymotrypsin the ^{13}C results confirm the important assignment of the profile centred about 1710 cm^{-1} to $\nu_{C=O}$ modes (6). In the case of the =C—^{13}C=O derivative, both the broad band at 1700 cm^{-1} and the sharper feature at 1725 cm^{-1} shift to lower wavenumbers, while for the =^{13}C—C=O derivative the 1710 cm^{-1} region appears to be unchanged (Fig. 1). The normal mode origins of the bands seen in the unlabelled —COO^- molecule at 1428 and 1546 cm^{-1}, and which are sensitive to isotopic substitution are not understood. However, the isotopic substitutions do cast light on the nature of the band appearing near 1260 cm^{-1} in the acyl-enzyme. This feature is unusual in that it appears only in the native 5-methyl-

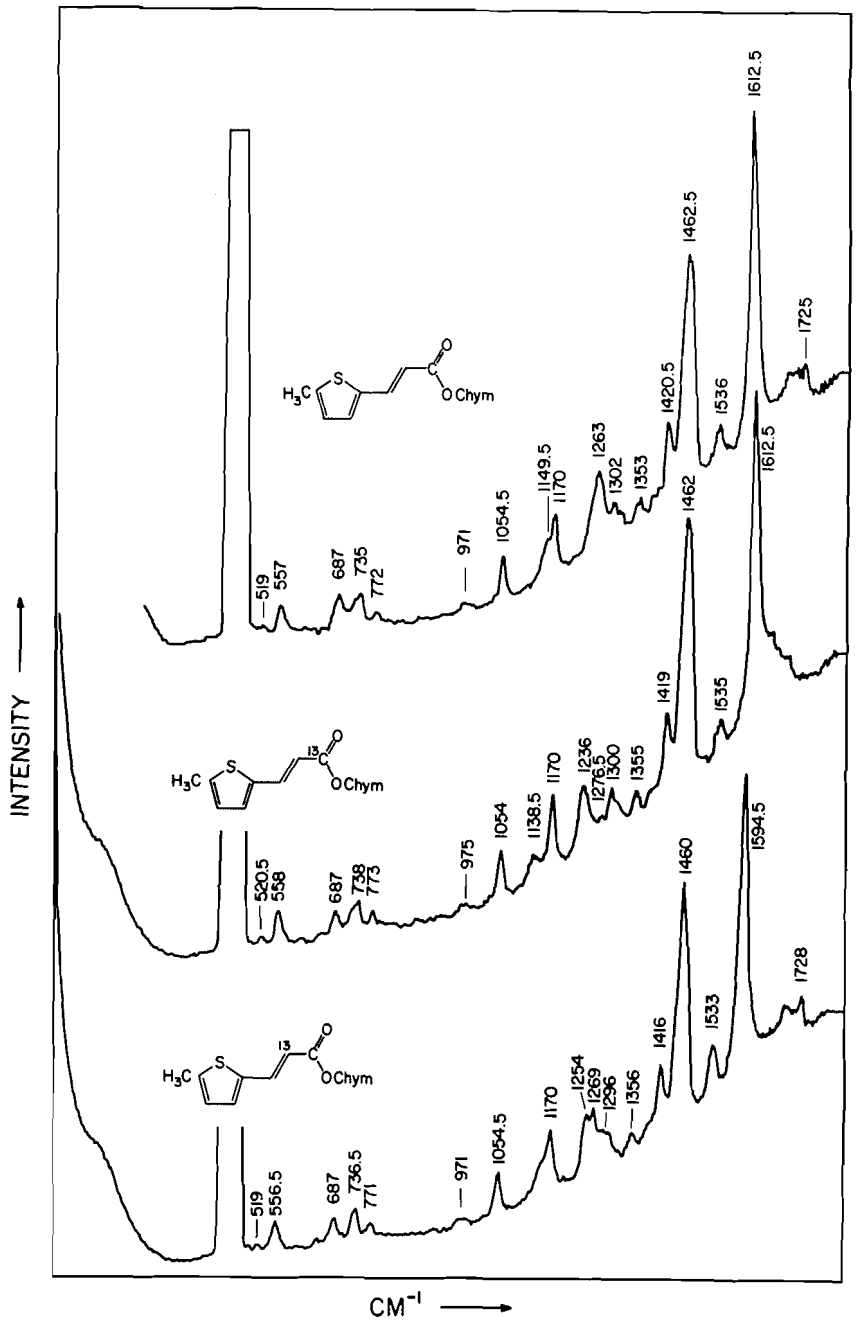

FIG. 1. Resonance Raman spectra of unlabelled and ^{13}C substituted 5-methylthienylacryloyl chymotrypsin. Enzyme ~4×10^{-4} M, approximately 75% acylated. Laser excitation ~100 mW, 350.7 nm; 8 cm^{-1} spectral slit.

thienylacryloyl chymotrypsin. A band of comparable intensity is absent in the SDS denatured complex (6) and in the RR spectra of any of the other 5-methylthienylacryloyl derivatives examined. Substitution in the $=^{13}C-C=O$ position seems to have little effect on the 1260 cm^{-1} mode (Fig. 1) but upon substitution in the $=C-^{13}C=O$ position the band shifts to 1236 cm^{-1}. At the same time the shoulder at 1149.5 cm^{-1} is unshifted in the $=^{13}C-C=O$ form but moves to 1138.5 cm^{-1} in the $=C-^{13}C=O$ derivative (Fig. 1). It is believed that both the 1260 and 1150 cm^{-1} features are associated with C—O stretching motions. The infrared studies of Thompson and coworkers (16) drew attention to two fairly intense bands in the 1000–1200 cm^{-1} range which are associated with the C—O and O—C bonds. Later investigations (17) found that α,β-unsaturated esters show two strong IR bands in the 1300–1100 cm^{-1} region. These findings, taken with the present ^{13}C substitutions, strongly favour the assignment of the 1260 and 1150 cm^{-1} bands to motions involving the C—O atoms. The large shift of the 1260 cm^{-1} peak, in particular, upon $=C-^{13}C=O$ substitution suggests a major contribution of the C—O stretching motion to this feature.

Consequences for the structure of the enzyme-bound acyl group

For the acyl-enzyme, the results of ^{13}C substitution presented here confirm the assignments made earlier (6) of the intense RR band at 1612.5 cm^{-1} and the profile around 1710 cm^{-1} to modes associated with the C=C and C=O moieties (Fig. 1), respectively. There does not appear to be extensive vibrational coupling between the two, since substitution at $=C-^{13}C=O$ does not perturb $\langle \nu_{C=C} \rangle$ and substitution at $=^{13}C-C=O$ does

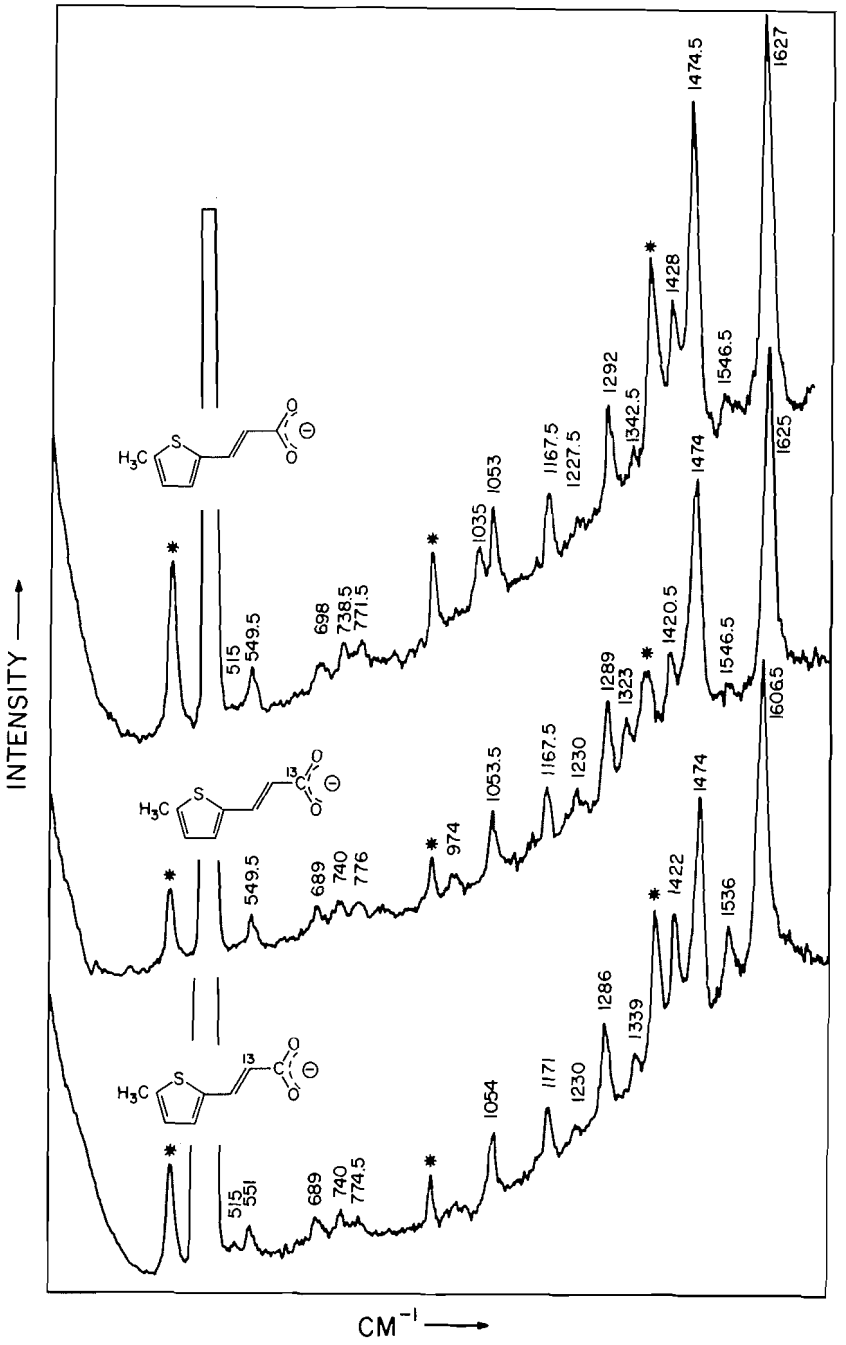

FIG. 2. Resonance Raman spectra of $\sim 2 \times 10^{-4}$ *M* unlabelled and ^{13}C substituted 5-methylthienylacrylic acid near neutral pH and thus in the ionised form. Approximately 15% of CH_3CN is present to aid solubility, CH_3CN peaks marked with an asterisk. Laser excitation ~100 mW, 350.7 nm; 8 cm^{-1} spectral slit.

not perturb the $\nu_{C=O}$ profile. Thus, the model given earlier (6) for the bound acyl group still holds. There are two conformers in the active site, neither of which is grossly distorted from planarity. One form has strong, sterically well-defined hydrogen bonds to the carbonyl and is *s-trans* about the =C—C=O single bond, while the second conformer probably binds *s-cis* about this linkage and has its carbonyl in a hydrophobic non-hydrogen bonding environment. The presence of the first conformer is consistent with crystallographic (18) and chemical evidence (19) for the formation of a strong hydrogen bond to the ester carbonyl.

Confirmation by the present studies of the $\nu_{C=O}$ assignments enables us to eliminate certain mechanisms which have been proposed to account for the absorption spectral properties of acyl-enzymes such as cinnamoyl- and furylacryloyl-chymotrypsins (10). In one of these mechanisms, the alkoxy oxygen atom (contributed by Ser-195) of the acyl-enzyme is brought out of the plane of the —C=C—C=O group. The resulting loss of conjugation renders the carbonyl aldehyde- or ketone-like and Bernhard and co-workers (10) have noted the striking similarity between the absorption spectra of the chromophoric acyl-enzymes and their corresponding aldehydes and ketones. However, $\nu_{C=O}$ for α,β-unsaturated ketones or aldehydes occurs near 1680 cm^{-1} (e.g. at 1679 cm^{-1} in the RR spectrum of 3-(2-furyl)acrolein in CH_3CN, unpublished work from this laboratory). The 1700 and 1725 cm^{-1} $\nu_{C=O}$ features

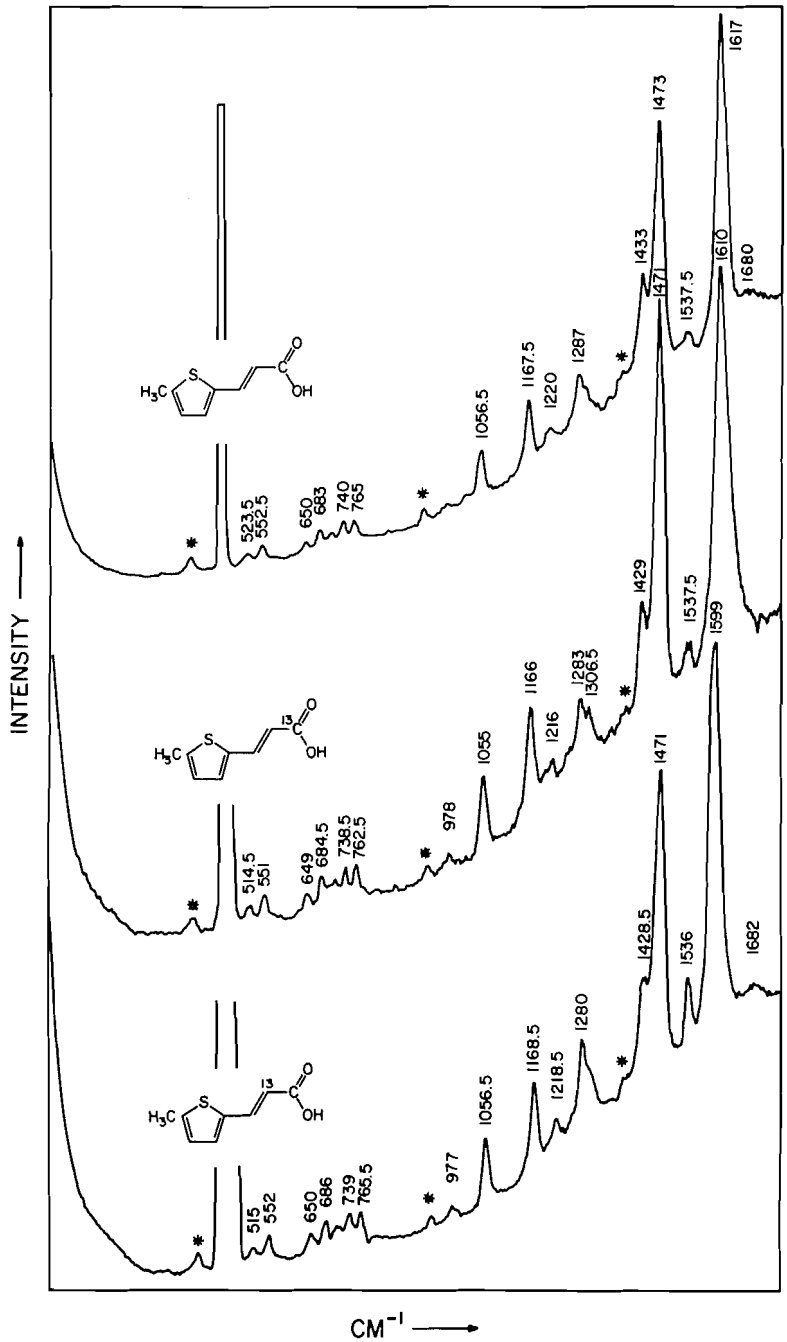

FIG. 3. Resonance Raman spectra of $\sim 2 \times 10^{-4}$ *M* unlabelled and ^{13}C substituted 5-methylthienylacrylic acid in the —COOH form, pH ~2.5. Approximately 5% of CH_3CN is present to aid solubility, CH_3CN peaks marked with an asterisk. Laser excitation ~100 mW, 350.7 nm; 8 cm^{-1} spectral slit.

seen for the acyl-enzymes are characteristic of α,β-unsaturated esters. Indeed, a $\nu_{C=O}$ feature is seen near 1720 cm^{-1} for the esters of 5-methyl- and 5-ethyl furylacrylic acid in CCl_4 (6). The observation of the $\nu_{C=O}$'s near 1715 cm^{-1} also rules out the possibility that the carbonyl group has become protonated. The cause of the spectral red shift seen in chromophoric acyl-chymotrypsins has been discussed in detail before (3, 6, 15). The red shift is due to the polarisation of the π electrons throughout the entire π-electron chain. In turn, the polarisation is caused by one or more of a number of possible effects such as well-defined hydrogen bonding to the ester C=O group, the conformation about the =C—C=O single bond and local protein dipoles (6). The correspondence between the absorption maxima of an acyl-enzyme and its aldehyde or ketone analog is, in all likelihood, coincidental.

The assignment of the 1260 cm^{-1} band in the RR spectrum of the acyl-enzyme (Fig. 1) raises several interesting questions. The mode involves the carbonyl carbon atom and is probably ascribable, in part, to the stretching motion of the C—O single bond. Since this is the bond being cleaved during the hydrolysis of the acyl-enzyme, it might be expected to offer insight into the special chemical nature, if any, of this linkage in the enzyme's active site. However, the appearance of the 1260 cm^{-1} band appears to be related to subtle stereochemical factors which are not correlated with chemical reactivity. The important observations regarding the 1260 cm^{-1} feature are as

For personal use only.

follows: (*1*), it is observed for only certain furylacryloyl- or thienylacryloyl-based acyl-enzymes (6); (*2*), there appears to be no correlation between the appearance of the 1260 cm^{-1} band and the appearance of the $\nu_{C=O}$ profile or the deacylation rate (6, 7); (*3*), a band of comparable intensity has not been observed in the RR spectra of any model compounds or the SDS denatured acyl-enzymes; (*4*), it is unaffected by raising pH and forming the catalytically active acyl-enzyme (7); and (*5*), it is unchanged in D_2O solvent compared to H_2O.

In connection with (*3*) above we have examined the 647.1 nm excited Raman spectra of the methyl esters of furylacrylic acid and its 5-methyl- and 5-ethyl-derivatives in CH_3CN solution and as solids. The rationale for these experiments was to search for a Raman mode which occurs in the 1200 cm^{-1} region in the spectra of the solid forms but which might appear with reduced intensity or disappear altogether in the solvated species. The appearance in the solid would then have been ascribed to the formation of a single "locked" conformation, and its disappearance in solution to the formation of a population of rotamers and their non-planar, torsionally excited states. However, for the three esters studied, the Raman spectra of the solution and solid forms appeared to be identical in the 1000–1350 cm^{-1} region. In an additional experiment, we synthesised and examined the RR spectra of the ethyl ester of 5-methylthienylacrylic acid. This was to investigate the effect on the RR spectrum of attaching a C—C moiety to the alkoxy atom and thereby producing a heavy atom skeleton more closely resembling that seen in the acyl-serine moiety. The ethyl ester was examined in H_2O (containing 5% CH_3CN) and in CCl_4 with 324 and 350.6 nm excitation. In CCl_4 solution a band was detected at 1269 cm^{-1} but it was of low relative intensity; it could not be associated with reasonable probability with the 1260 cm^{-1} band seen in the RR spectrum of the native acyl-enzyme.

Taking these data together it seems that the appearance of the 1260 cm^{-1} C—O stretch in the RR spectrum of a thienyl- or furylacryloyl based acyl-enzyme occurs by chance. It probably relies on the active site of the enzyme selecting out a particular, but presently unknown, conformation about the ester bonds. This selection is determined, in turn, by enzyme contacts about the furyl or thienyl ring and, given the variation among the substituted rings, the process must be subtle. Additionally, the 1260 cm^{-1} feature may require the process of electron polarisation producing, within the selected conformer, a higher degree of RR intensity enhancement for modes associated with the C—O linkage. Acyl groups such as thienylacryloyl and furylacryloyl are, of course, quite far removed from natural, specific substrates. The former do provide good probes for the physical forces operating in the active site and one can obtain detailed data on the structure of the non-specific acyl group bound to the active site. But facts such that 5-methylthienylacryloyl chymotrypsin gives a fairly intense 1260 cm^{-1} band, whereas the 5-methylfurylacryloyl analog does not, suggest that considerable care must be exercised in drawing conclusions on the catalytic mechanisms for specific substrates from the spectroscopic results on non-specific substrates. This situation is not without its positive aspects, since, by using non-specific substrates, we may be able to probe key processes which would not be observable using specific substrates. For example, the phenomenon of electron polarisation is now well established for non-specific substrates with delocalised π-electron systems (3, 5–9, 15). We may speculate that the forces that give rise to these effects in the ground state of the non-specific acyl-enzymes would not be observed at all for the specific intermediates. Instead, for the latter, precise stereochemical factors might ensure that the electrical forces are used solely in the transition state to stabilise the build up of charge (20).

Ab initio molecular orbital studies on thiirene and its isomeric structures

RATNAKAR K. GOSAVI AND OTTO P. STRAUSZ
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received March 3, 1983

This article is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

RATNAKAR K. GOSAVI and OTTO P. STRAUSZ. Can. J. Chem. **61**, 2596 (1983).

Ab initio molecular orbital calculations have been carried out on the lowest closed shell singlet states of six isomeric forms of C_2H_2S at the SCF and CI levels using STO-3G and 6-31G* basis sets. Molecular geometries of the isomers and the activated complexes for their isomerization reactions were optimized by the energy gradient method at the SCF level and the CI calculations were performed at these geometries. In addition, the lowest singlet and triplet states of the ·SCHĊH diradical were also studied and their geometries optimized by the Restricted Hartree Fock method.

The computed stabilities follow the order

$$H_2C{=}C{=}S\ (S_0) > HC{\equiv}CSH\ (S_0) > \text{  }\ (S_0) > \cdot SCH\dot{C}H\ (T_0) \approx \cdot SCH\dot{C}H\ (S_1) > \text{}\ (S_0) >$$

$$\text{  }\ (S_0) > H\ddot{C}{-}\text{  }\ (S_2)$$

The pseudo antiaromatic character of the 4n-π electron thiirene is manifested by its drastically reduced C—S bond energy, ~15 kcal mol^{-1} as compared to the value of >40 kcal mol^{-1} estimated for its 2n-π electron analog, thiirane. This explains why thiirenes can be stabilized in inert matrices at 8 K but decompose readily at higher temperatures. In agreement with experimental results the lowest energy path for the unimolecular decomposition of thiirene leads to thioketene via the lowest singlet (or triplet) state of thioformylmethylene.

The ir frequencies calculated for thiirene from *ab initio* mo theory using 6-31G + polarization functions on the sulfur show reasonably good agreement with the experimental frequencies, confirming the earlier assignments of the ir spectrum of thiirene.

RATNAKAR K. GOSAVI et OTTO P. STRAUSZ. Can. J. Chem. **61**, 2596 (1983).

On a effectué des calculs *ab initio* d'orbitales moléculaires sur l'état singulet ayant la couche électronique complète de plus bas niveau d'énergie de six formes isomères du C_2H_2S aux niveaux SCF et CI en utilisant les ensembles de bases STO-3G et 6-31G*. On a optimisé les géométries moléculaires des isomères et des complèxes activés de leurs réactions d'isomérisation, en utilisant la méthode de gradient d'énergie au niveau SCF et on a effectué les calculs de CI sur ces géométries. De plus on a étudié les états singulets et triplets de plus bas niveau d'énergie de diradical ·SCHĊH et on a optimisé leurs géométries par le méthode restreinte de Hartree–Fock.

Les stabilités calculées sont dans l'ordre suivant:

$$H_2C{=}C{=}S\ (S_0) > HC{\equiv}CSH\ (S_0) > \text{  }\ (S_0) > \cdot SCH\dot{C}H\ (T_0) \approx \cdot SCH\dot{C}H\ (S_1) > \text{}\ (S_0) >$$

$$\text{  }\ (S_0) > H\ddot{C}{-}\text{  }\ (S_2)$$

Le caractère pseudo antiaromatique de l'électron 4n-π du thiirène se manifeste par la réduction drastique de son énergie de liaison C—S de ≃ 15 kcal mol^{-1} telle que comparée à la valeur supérieure à 40 kcal mol^{-1} évaluée pour l'électron 2n-π analogue du thiirane. Ceci explique pourquoi on peut stabiliser les thiirènes dans des matrices inertes à 8 K mais ils se décomposent rapidement à des températures plus élevées. En accord avec les résultats expérimentaux, la voie de plus faible énergie pour la décomposition unimoléculaire du thiirène conduit au thiocétène via l'état singulet (ou triplet) le plus bas du thioformylène.

Les fréquences ir calculées pour le thiirène à partir de la théorie *ab initio* des OM utilisant la base 6-31G + les fonctions de polarisation du soufre montrent un accord raisonnablement bon avec les fréquences expérimentales confirmant ainsi les attributions antérieures du spectre ir du thiirène.

[Traduit par le journal]

Introduction

The intervention of thiirene, **1**, as a reactive intermediate in a reaction mechanism was first suggested for the $S(^1D_2) + C_2H_2$ system and the photochemical decomposition of 1,2,3-thiadiazole, **2**, in 1967 (1) and since then a series of thiirenes, including the parent compound, have been isolated and characterized in the low temperature argon-matrix photolysis of **2** and its derivatives (2, 3), and of vinylene trithiocarbonate (4). In the Pyrex filter photolysis of **2** only two principal products, the thioketene, **3**, and the ethynylthiol, **4**, have been isolated and identified by ir spectroscopy (2). Isotopic labelling studies, however, indicated that ethynylthiol was formed mainly via the intermediacy of thiirene (2). In the λ = 215 or 265 nm photolysis, however, in addition to **3** and **4** another product appeared which was identified by ir spectroscopy as being the thiirene (2, 3). On further photolysis of

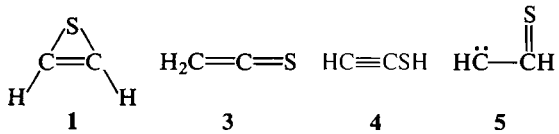
the photolyzate with λ = 330–370 nm light, thiirene could readily be converted to **3** and **4**. Spectral assignments of the vibrational frequencies of **1** have been made (5–8) and several substituted thiirenes have subsequently been synthesized (2–4, 9, 10).

Of the six valence isomers of formula C_2H_2S, all of which may be implicated in the photodecomposition sequence of 1,2,3-thiadiazole, three (**1**, **3**, **4**) have bond order of six and the other three (**5**–**7**) five:

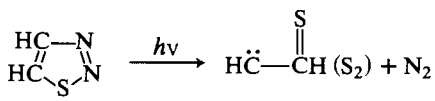


1 **3** **4** **5**

6 **7**

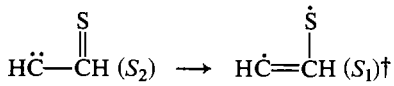
Of these, only the molecular species thiirene, **1**, thioketene, **3**, and ethynylthiol, **4**, have been isolated to date. *Ab initio* molecular orbital calculations on the relative stabilities of these isomers at the SCF level using the STO-4G basis set predicted the following order and energy separations (kcal mol^{-1}) (10, 11) for the lowest singlet state:

In the photolysis of 1,2,3-thiadiazole, **2**, thioformylmethylene, **5**, is generated, probably in a higher excited singlet state:



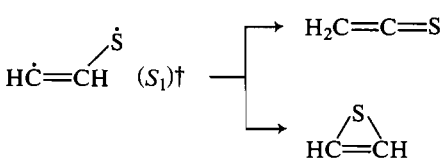
2 **5**

and undergoes rapid internal conversion to give the vibrationally excited S_1 state.

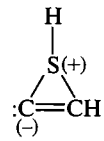


Earlier theoretical calculations also predicted a triplet ground state for **5** with a small T_0–S_1 energy separation of the order of −9 kcal mol^{-1} (11). The isolation of thioformylmethylene has not been achieved to date, but its diphenyl derivative, thiobenzoylphenylmethylene, has recently been isolated in the low temperature photolysis of 4,5-diphenyl-1,2,3-thiadiazole and identified by esr spectroscopy (12).

On the basis of experimental observations and in analogy with the well documented Wolff rearrangement of ketocarbenes (10, 13–15) the subsequent reactions of the vibrationally hot S_1 state **5** would be:



Photolysis of ^2H and ^{13}C labelled **2** affords completely randomized ethynylthiol, but the bulk (~80%) of the thioketene retains the original skeleton of the precursor (2). This requires the intermediacy in the conversion of thiirene to ethynylthiol of some structure(s) which features complete carbon and hydrogen equivalences. For this, thiiranylidine, **6**, (16) and the zwitter ion (9, 10)



have been considered.

In order to get a better understanding of the thermodynamic stabilities of the C_2H_2S isomers and their interconnecting reaction surfaces we have carried out a more detailed molecular orbital computational study of these systems.

Method

It is known that SCF geometry predictions using split valence or double ζ basis sets for molecules containing H, C, N, and O usually yield bond lengths within ~0.02 Å and bond angles within 2° of the experimental values (17); however, for molecules containing heavier atoms such as S, little is known concerning the effects of the basis set size on SCF structural predictions (18–21).

Therefore, for comparison purposes, we carried out SCF geometry optimizations of the ground state singlet using STO-3G (for S, ref. 22*a*; for C and H, ref. 22*b*), STO-3G* (18), 6-31G (21)[1], and 6-31G* basis sets for the molecules: hydrogen sulfide, methanethiol, thiirane, thioformaldehyde, and thioketene, for which the experimental geometries are known (23–25).

On the basis of these results, we then reoptimized the geometries of all six C_2H_2S isomers at the SCF level and studied the reaction paths for their interconversions at the CI level to include the correlation energy.

All the molecular calculations were performed with the MONSTERGAUSS Program (26). Five 3*d* polarization functions (on S, α = 0.5874) for the 6-31G* basis set were optimized for the thioketene molecule at the experimental geometry (25) using the Davidon (27, 28) method, and used in all the subsequent 6-31G* calculations. All geometries were fully optimized at the SCF level by the energy gradient method (29, 30). STO-3G, STO-3G*, 6-31G, and 6-31G* basis sets were used for the geometry optimization of the six C_2H_2S isomers. Reaction path transition states were optimized with STO-3G and 6-31G* basis sets using the VAO5AD optimization method (31). Configuration interaction calculations include all singly and doubly excited configurations (CISD) with respect to the closed shell SCF configuration, and were done using the direct CI method (32) at the SCF level optimized geometry. Davidson's formula (33) was applied to the CI results to estimate the correction for the quadruple excitations (CISDQ). The lowest seven orbitals, corresponding to carbon 1*s* and sulfur 1*s*, 2*s*, 2*p* core orbitals, were kept doubly occupied and frozen, and the top ten virtual orbitals in the 6-31G* basis set calculations were kept frozen in the CI calculations. All calculations were carried out on an AMDAHL 470 V/7 computer at the University of Alberta.

Results

The optimized and experimental geometries of the model molecules H_2S, CH_3SH, C_2H_4S, CH_2S, and C_2H_2S are summarized in Table 1. For the five molecules the geometries optimized by the minimal STO-3G basis set are in better agreement with the experimental values than the significantly extended (s,p) basis set (6-31G). Addition of polarization functions ($3d$) on the sulfur atom to the extended 6-31G basis (6-31G*) improved the geometry and the optimized geometries are in very good agreement with the experimental values.

For the C_2H_2S isomers the optimized geometries and total SCF energies with STO-3G, STO-3G*, 6-31G, and 6-31G* basis sets are summarized in Table 2. CI calculations were performed at the optimized geometries with STO-3G and 6-31G* basis sets and the total energies for the lowest closed shell singlet states are tabulated in Table 3, while the relative energies with respect to thioketene are given in Table 4.

Experimental values of the geometrical parameters are known only for thioketene (25) and the optimized values of the STO-3G and 6-31G* basis sets are in good agreement. The C—S bond distance in thiirene (1.812 Å, STO-3G and 1.861 Å, 6-31G*) appears to be reasonable, in comparison with the experimental value of the C—S bond distance in thiirane (1.819 Å) (23). The C=C distance (1.266 Å) is similar to the experimental value of 1.300 Å for cyclopropene (23) and the calculated values for oxirene (1.270 Å) (14) and 2-azirine (1.265 Å) (34). The effect of polarization functions and correlation energy on the relative energies varies with structure. Inclusion of polarization functions decreases the relative energies for all the isomers with the exception of thioformylmethylene and thiirene (Fig. 1). The inclusion of correlation energy increases the relative energies of thioformylmethylene and thiovinylidene, and decreases them in thiirene and ethynylthiol (Fig. 1).

The present results (Table 4) predict thioketene **3** to be the most stable C_2H_2S isomer, closely followed (7.8 kcal mol^{-1}) by ethynylthiol **4**. Thiirene **1** is 35.1 kcal mol^{-1} higher in energy than thioketene. All three carbenoid structures **5**, **6**, **7**, have higher energies than the molecular species **1**, **3**, **4**. Of the three carbenes thioformylmethylene **5** is the least stable and the cyclic thiiranylidene **6** is the most stable.

Thioformylmethylene lies 31.6 kcal mol^{-1} higher in energy than thiirene.

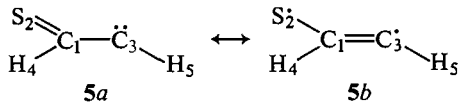
Thioformylmethylene

Thioformylmethylene **5** can also be written as a 1,3-diradical structure:



5*a* **5***b*

In the earlier report by Strausz *et al.* (11), the energy for the optimized geometry of the 1,3-diradical structure was calculated by using the UHF-SCF method with STO-4G basis set. We have now optimized the geometries for the *cis*, *trans*, and linear configurations of the $^1A''$, $^1A'$, $^3A''$, and $^3A'$ states of the diradical structure (**5***b*) with the open shell Restricted Hartree Fock (RHF) SCF method using both STO-3G and 6-31G* basis

sets. The results are presented in Table 5. Due to technical difficulties, CI calculations on the open shell singlet were not performed. SCF and CI energies for the triplet states and SCF energy for the singlet states of the 1,3-diradical are summarized in Table 6. The C—C bond distance in the 1,3-diradical is close to the C—C double bond distance and the C—S bond distance is close to the single bond C—S distance.

The energy difference for the $^1A''$ and $^1A'$ states is about 2–3 kcal mol^{-1} at the SCF level with 6-31G* basis and ~5–7 kcal mol^{-1} at the SCF level and ~8–10 kcal mol^{-1} at the CISDQ level for the $^3A''$ and $^3A'$ states. The *trans* and *cis* structures have almost the same stability; slightly favouring the trans configuration in $^1A''$, $^3A''$, and $^3A'$, and the *cis* in $^1A'$. The barrier for the *trans* → *cis* in plane isomerization in the $^1A''$ state and *cis* → *trans* in the $^1A'$ state, both are 7.8 kcal mol^{-1}. The barrier for the *trans*–*cis* in plane isomerization in the $^3A''$ and $^3A'$ states are 8.7 and 6.8 kcal mol^{-1} at the SCF level and 5.9 and 3.7 kcal mol^{-1} at the CISDQ level, respectively. The triplet singlet separation (ΔT_0–S_1) at the SCF level is very small (−5.7 kcal mol^{-1} for the *trans* A'' state) (Table 5) and the singlet ($^1A''$) 1,3-diradical has almost the same total energy as thiirene.

The complications in geometry optimizations for 3-center, 3-electron π networks have recently been discussed by Baird *et al.* (35). They and others (36, 37) have shown that the RHF SCF geometry optimization for open shell molecules containing multiple bond(s) tends to over-estimate the stability of the extreme, localized structures. SCF-CI optimization gives a completely delocalized structure with a global minimum lying below either of the local minima in the SCF hypersurface. On this basis it would be expected that both the singlet and triplet state energies of 1,3-diradicals would decrease somewhat in energy on reoptimization with inclusion of CI. The main consequence of this in the present context would be a decrease in the computed bond dissociation energy of thiirene (*vide infra*).

Although the correlation energy for the singlet diradical structure could not be calculated, a reasonably close estimate of it can be made from the averages of the computed correlation energies, Table 7, which have the values of 0.1696 hartree for the various isomers of the triplet state diradical, 0.1809 hartree for the closed shell singlet carbenoid structures (**5**, **6**, **7**) and 0.1952 hartree for the singlet state molecular species (**1**, **3**, **4**). The variation is small and the trend lies in the direction expected. The correlation energy for the singlet diradical should lie between the values for the triplet diradical and closed shell singlet carbenoids. These differ by only 0.0114 hartree and their mean value is 0.1752 hartree. The CISDQ energy of the *trans*, $^1A''$, singlet diradical is then computed to be −474.2604 + −0.1752 = −474.4356 hartree and the T_0–S_1 splitting ($^3A''$–$^1A''$) for the *trans*-1,3-diradical is ca. −1.5 kcal mol^{-1}.

Geometry optimizations for the lowest closed shell singlet state of the carbene structure (**5***a*) were carried out for the planar *cis*, *trans*, and linear configurations and the results with the total energies are summarized in Table 8. The *cis* and *trans* configurations have almost the same stability although the *trans* configuration is slightly favoured. Both configurations appear as first order saddle points on the energy hypersurface with critical point order of 1. The optimized C—C bond distance is close to the normal C—C single bond, and the C—S bond distance is close to the C—S double bond distance. In contrast, the linear configuration has a C—C bond distance which is much shorter than the normal single bond and slightly longer than the double bond distance. The C—S bond distance is slightly longer than the normal C=S distance, probably due to the contribution from the open shell, 1,3-diradical singlet configuration (**5***b*). On relaxing the planarity, the hydrogen (H_5) on the carbene carbon (C_3) moves out of the plane and converges to the thioformylmethylene structure (**5**). Both the linear (**5***a*) and perpendicular (**5**) structures have a critical point order of 0 corresponding to minima on the potential energy surface. The linear structure is only 5.4 kcal mol^{-1} higher in energy than the thioformylmethylene perpendicular (**5**) structure. Thus, the present optimized geometry (Table 2) for the lowest closed shell singlet state of the carbene structure **5** predicts that the hydrogen (H_5) on the carbene carbon (C_3) is in the plane perpendicular to the CCS plane, similar to the case of formylmethylene (13–15).

These results are in agreement with the small value of the zero field splitting parameter, D = 0.0318 cm^{-1}, obtained for thiobenzoyl phenylmethylene (12) which points to a high degree of delocalization of the unpaired electron on sulfur. Also the decay of the triplet spectrum followed a first order kinetics in the temperature range of 77–106 K with an activation energy of 5.4 kcal mol^{-1} which may correspond to the triplet–singlet energy separation.

Reaction path for the isomerization of C_2H_2S isomers

Transition state geometries for the isomerization reactions were optimized at the SCF level by the VA05AD gradient optimization method (31) for the closed shell singlet with both

STO-3G and 6-31G* basis sets. Optimized geometries are shown in Fig. 2 and total energies are summarized in Table 9. All possible reaction paths for the isomerization reactions were studied by STO-3G basis set and the important ones were repeated with the 6-31G* basis set, mainly due to economical reasons. The activation energies calculated for the various possible interconversions are summarized in Table 10 and illustrated schematically in Figs. 3, 4, and 5.

Thioformylmethylene **5** can isomerize to thioketene **3** with no activation energy (with STO-3G) or with a very small activation energy of 1.8 kcal mol^{-1} (with 6-31G*) (Figs. 3 and 5). Direct isomerization to thiirene **1** is predicted to have no activation energy. STO-3G basis set geometry optimization of transition state **8** (Fig. 2) at SCF level predicts a very small (3.5 kcal mol^{-1}) activation energy; however, 6-31G* basis set geometry optimization did not predict any transition state. If we assume the *cis* configuration of thioformylmethylene to be the transition state between thioformylmethylene **5** and thiirene **1**, then the activation energy is 20.9 kcal mol^{-1} with 6-31G* basis set and 5.4 kcal mol^{-1} with STO-3G basis set. The ring closure of *cis* thioformylmethylene to thiirene does not show any activation energy. All the other possible rearrangements, i.e., to ethynylthiol **4**, thiiranylidene **6**, or thiolvinylidene **7**, feature substantial energy requirements (Table 10 and Figs. 3 and 5) and are not likely to occur thermally in low temperature matrices.

The lowest energy reaction path on the lowest closed shell singlet surface for the isomerization of thiirene **1** is to thiolvinylidene **7** with E_a = 43.5 kcal mol^{-1} (Figs. 4 and 5, Table 10). The next lowest energy reaction path is the C—S ring cleavage of **1** to produce thioformylmethylene **5** via the *cis* thioformylmethylene intermediate with 52.5 kcal mol^{-1} activation energy. Thus, the transformation of thiirene to thioketene is more favorable via the sequence **1** → **5** → **3** than via the direct route **1** → **3** involving the activated complex **13** for which E_a = 68.7 kcal mol^{-1}. In spite of the fact that thiiranylidene **6** is thermodynamically more stable than **5** or **7**, the rearrangement **1** → **6** appears to have prohibitively high energy requirements. Similarly, interconversion of **1** to **3** and **4** via the activated complexes **13** and **14**, respectively, are extremely high energy processes (Fig. 4 and Table 10).

Isomerization of thiiranylidene **6** to thioketene **3** requires an activation energy of 21.3 kcal mol^{-1}, to ethynylthiol **4** via migration of one H from C_1 to S_2 and opening of the $C_1—S_2$ bond (**18***a*, Fig. 2); and via simultaneous migration of both hydrogens from C_1: one to S_2 and the other to C_3, and opening of the $S_2—C_3$ bond (**18***b*, Fig. 2), both requiring 70–75 kcal mol^{-1} (Fig. 5, and Table 10). Similarly, isomerization to **7** also requires about 79 kcal mol^{-1} (Fig. 4 and Table 10).

Two reaction paths were also considered for the isomerization of thiolvinylidene **7** to ethynylthiol **4**: (*1*) migration of H_4 from C_1 to C_3 with accompanying changes in the $S_2C_1C_3$ angle (**20***a*, Fig. 2); and (*2*) maintaining H_4 on C_1 and varying the $S_2C_3C_1$ angle (**20***b*, Fig. 2), i.e., the migration of SH from C_1 to C_3. In both cases, the computed activation energies are low, 8.5 and 7.3 kcal mol^{-1}, respectively.

The thioketene ethynylthiol rearrangement in the singlet ground state possesses an intrinsic energy barrier of about 94.7 kcal mol^{-1} (Fig. 4).

Next the isomerization reactions of the 1,3-diradicals were explored in some detail. Geometry optimized total energies were calculated at various CCS bond angles en route to the

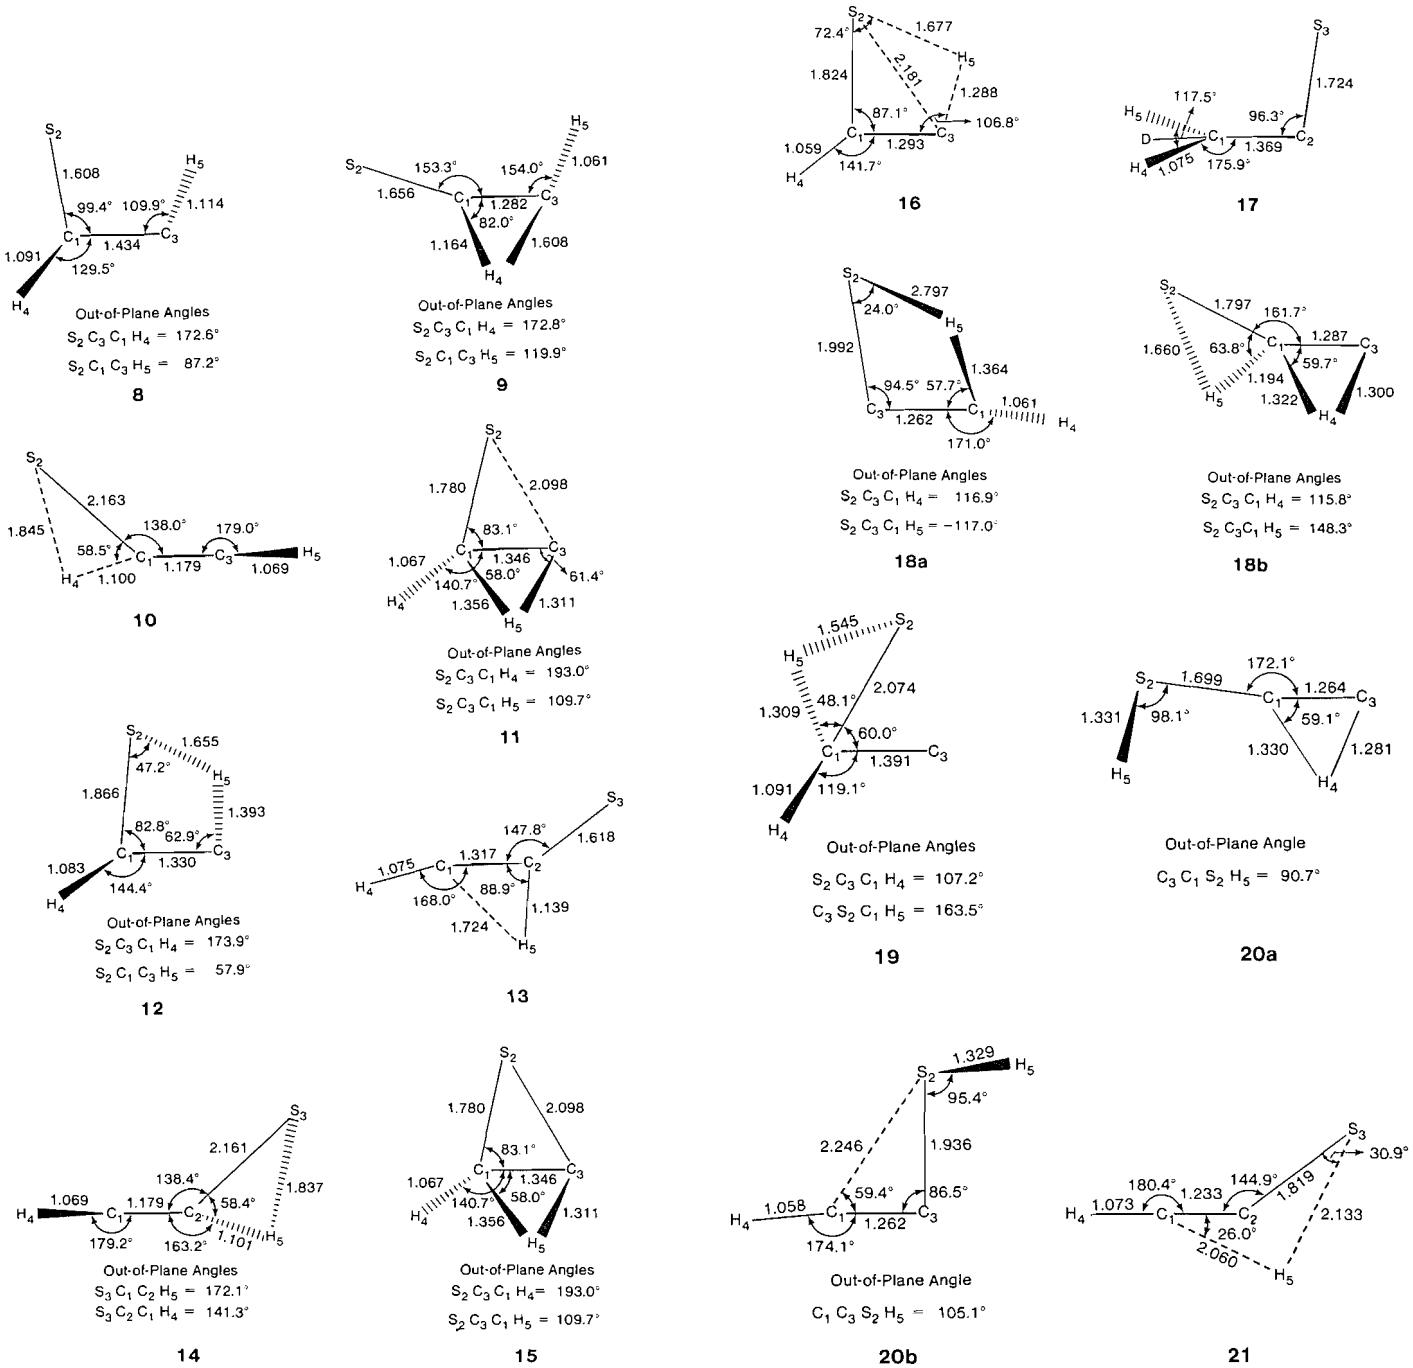

FIG. 2. Optimized geometries of the lowest closed shell singlet transition states for the C_2H_2S isomerizations with 6-31G* basis set except for **8**, **10**, **12**, **13**, **14**, **19**, and **21** for which values are of STO-3G basis set. Bond lengths are in Å and bond angles in deg.

thiirene geometry for the triplet and singlet *cis* $^3A''$, $^3A'$, $^1A''$, and $^1A'$ diradicals at the SCF level using the 6-31G* basis. Similarly, total energies were calculated for the ring opening of thiirene en route to the diradical structures (Fig. 6). The crossing points are assumed to represent the transition states with activation energies for the 1,3-diradical → thiirene rearrangement ranging between 14.8 and 17.3 kcal mol^{-1} (Table 11). For the lowest lying crossing point ($^3A''$) the geometry was reoptimized keeping the CCS angle fixed at 95.5°, at the SCF level and the CI calculation was then performed at the SCF optimized geometry. This gave E_a = 12.7 kcal mol^{-1} (at CISDQ) for the *cis*-1,3-diradical ($^3A''$) → thiirene step which may be viewed as an upper limit (and may be a factor of three too high) because CI calculations on the entire curve would have had the effect of lowering the thiirene curve relative to the curves of the diradicals (cf. Table 7).

The results of analogous calculations for the triplet ($^3A''$) and singlet ($^1A''$) *trans*-1,3-diradical ↔ thiolvinylidene (Fig. 7 and Table 12), and the singlet ($^1A'$) *cis*-1,3-diradical ↔ ethynylthiol rearrangement (Fig. 8 and Table 13) yielded intrinsic activation energies of 17.1 and 17.9 kcal mol^{-1} and 39.9 kcal mol^{-1}, respectively.

Finally we computed the ir frequencies of the thiirene molecule using the 6-31G* basis set on the 6-31G* optimized geometry of the molecule. HONDO 76 (IBM version) (38) program was used for vibrational frequencies calculations. The results

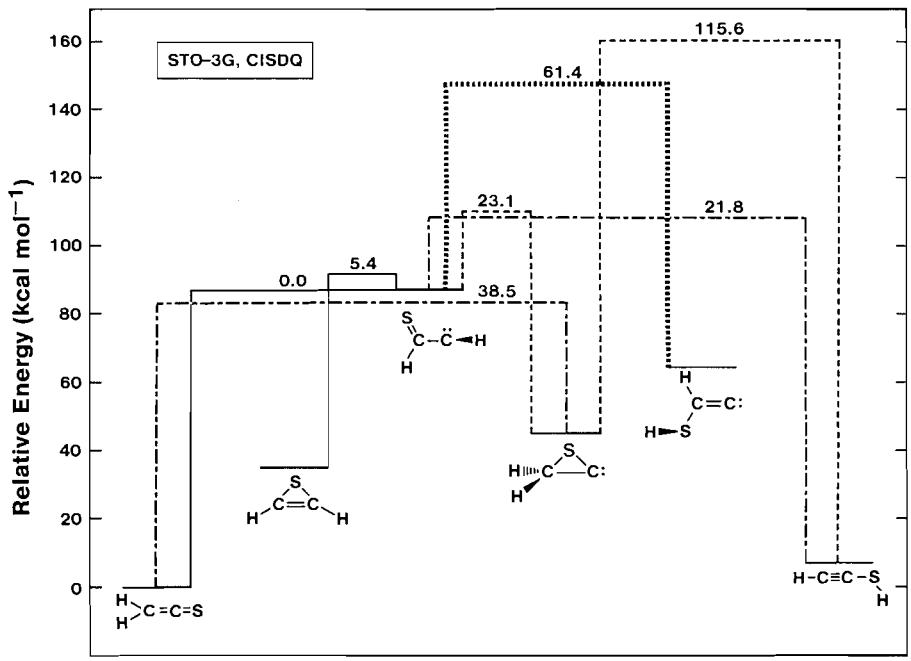

FIG. 3. Activation energies (kcal mol^{-1}) at CISDQ level for the possible isomerization reactions of thioformylmethylene (**5**) in the lowest singlet state with STO-3G basis set.

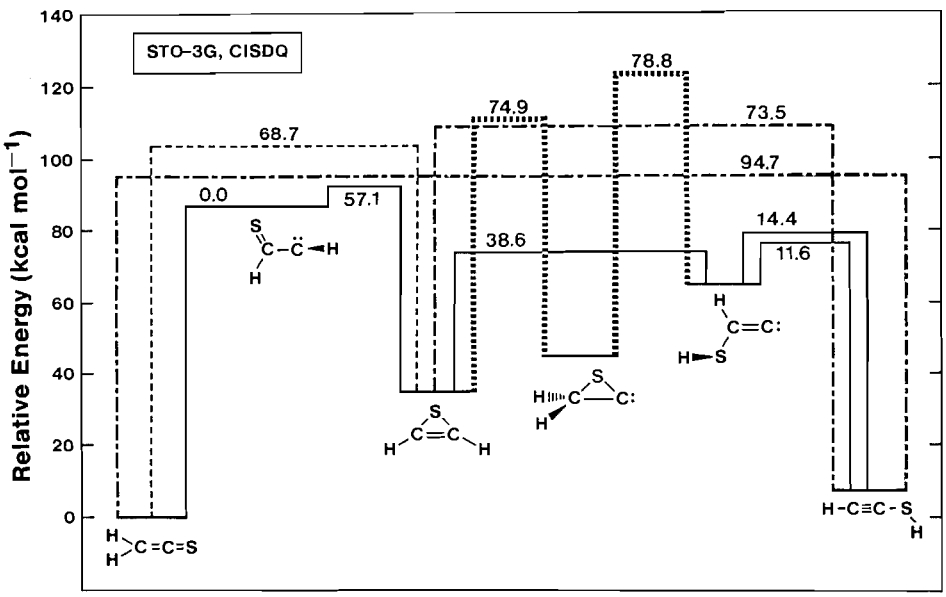

FIG. 4. Activation energies (kcal mol^{-1}) at CISDQ level for the possible isomerization reactions of thiirene in the ground singlet state with STO-3G basis set.

Discussion

The great theoretical interest in the stability, structure, and chemistry of thiirene is partly related to its 4n-π electron system which by definition implies an antiaromatic character for this molecule.

The low thermal stability of thiirene and its derivatives along with the results of an earlier *ab initio* mo calculation with STO-4G basis set and the unrestricted Hartree Fock method for the calculation of its ring opened structure, the 1,3-diradical form of thioformylmethylene predicting a lower thermodynamic stability of the ring structure (9–11) appeared to lend support to the antiaromaticity of thiirene. The results of the present, more refined calculations, however, appear to suggest otherwise.

At all levels of calculation the ground state of thioformylmethylene is the triplet ($^3A''$) 1,3-diradical which is nearly isoenergetic with the lowest singlet ($^1A''$) state, also corresponding to the 1,3-diradical structure. The T_0–S_1 (*trans* A'') energy separation at the 6-31G* CISDQ level is estimated to be ca. -1.5 kcal mol^{-1}. The S_2 state corresponds to the closed shell thioformylmethylene carbene with $E(T_0$ — *trans* $^3A'') - E(S_2)$ = 19.0 kcal mol^{-1} and 16.7 kcal mol^{-1} with *cis* $^3A''$ (6-31G* CISDQ). The T_0(*trans* $^3A''$) diradical at the SCF level lies 5.9 kcal mol^{-1} and *cis* $^3A''$, 4.5 kcal mol^{-1} below thiirene, however, when the correlation energy is included at CI level, it has the effect of lowering the energy of thiirene below that of the $T_0(^3A'')$ state of the diradical. At the 6-31G* CISDQ level $E(T_0(^3A''$ *cis*) − diradical) − $E(S_0$ − thiirene ($^1A_1$)) = 14.9 kcal

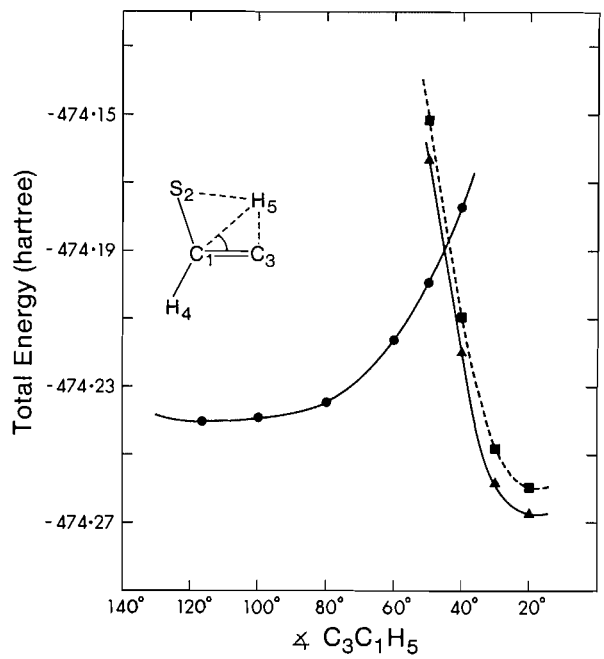

FIG. 7. Potential energy surface of lowest triplet and singlet state *trans*-1,3-diradical-thioformylmethylene ↔ lowest singlet thiolvinylidene at SCF level with 6-31G* basis set. ● lowest singlet thiolvinylidene, ▲ lowest triplet $^3A''$, 1,3-diradical, ■ lowest singlet $^1A''$, 1,3-diradical.

mol^{-1} and consequently, in spite of its low thermal stability, thiirene is not strictly antiaromatic. On the other hand, the cyclic electron delocalization in thiirene has a marked lowering effect on its C—S bond energy ~15 kcal mol^{-1} as compared to its 2n-π electron analog, the thiirane molecule, where the corresponding value is >40 kcal mol^{-1} (39). Thus, while the effect of electron destabilization is clearly evident, it is not sufficient to thermodynamically destabilize the ring structure with respect to the open structure. The phenomenon may be termed "pseudo" antiaromaticity and the thiirene molecule a pseudo antiaromatic molecule. It should be noted at this point that the decrease in stability of the thiirene versus the thiirane ring may be partly due to increased angular strain (as in the case of the cyclopropene versus cyclopropane ring) which, however, may be offset by the relief of the eclipsing strain present in thiirane as in cyclopropane (40).

Thiirene is also thermodynamically more stable than its other two closed shell carbenoid isomers, the thiiranylidene and thiolvinylidene (Tables 3 and 4) and its rearrangement on the lowest closed shell singlet surface appears to be prohibited by large energy barriers (Figs. 4 and 5). The lowest energy reaction channel which may be accessible at low thermal energies is isomerization to the thioketene via the T_0 or S_1 diradical

[a] With closed shell singlet optimized geometry, E_{SCF} = −474.187674, E_{CISD} = −474.365993, E_{CISDQ} = −474.385303, E_a for thiolvinylidene → triplet ($^3A''$) 1,3-diradical (*trans*) = 33.07 kcal mol^{-1} at SCF and 17.12 kcal mol^{-1} at CISDQ.
[b] With closed shell singlet optimized geometry, E_{SCF} = −474.184679, E_{CISD} = −474.364429, E_{CISDQ} = −474.384042, E_a for thiolvinylidene → singlet ($^1A''$) 1,3-diradical (*trans*) = 34.95 kcal mol^{-1} at SCF and 17.92 kcal mol^{-1} at CISDQ.

intermediate with computed activation energies of E_a (via T_0 (*cis* $^3A''$)) ≈ 28 and E_a (via S_1) ≈ 29 kcal mol^{-1}. These values, were they correct, should endow the thiirene molecule with considerable stability even at room temperature where the lifetime for unimolecular isomerization would be in the order of tens of minutes. The actual activation energies are the sum of the enthalpy changes and intrinsic activation energies. The computed values of the latter, $E_a(T_0) \approx 12.7$ and $E_a(S_1) \approx 14.8$ kcal mol^{-1}, are probably too high by as much as a factor of three because of the inadequate representation of correlation energies (*vide supra*). An overall activation energy of about 20 kcal mol^{-1} would be more realistic and in better agreement with the observed stability of thiirene and its derivatives in low temperature inert matrices, although no quantitative kinetic measurements have been reported to date on the thermal isomerization of thiirene. The only relevant piece of information that exists comes from the low temperature kinetic study of triplet ground state diphenyl substituted thioketocarbene, thiobenzoylphenylmethylene (12), which isomerizes to the thioketene structure in a first order process with an activation

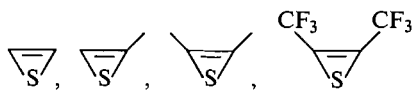
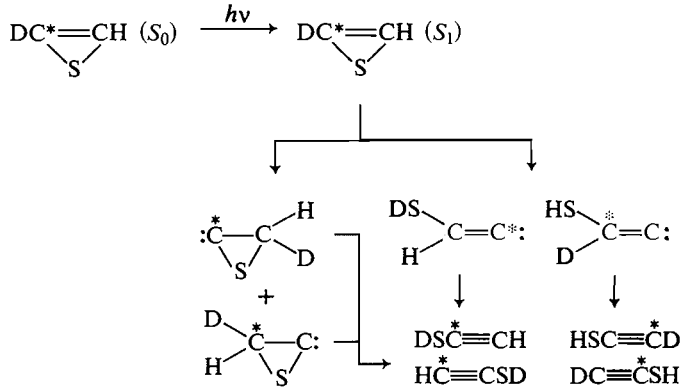
gas phase studies (1). The lifetime of thiirenes



produced in the gas phase addition of $S(^1D_2)$ atoms to acetylenes have been estimated to lie in the tenths to few seconds range at low pressures. Also the ready scavengability of thiirene in the gas phase by perfluorobutyne-2 requires a substantial lifetime for these molecules.

In contrast, the oxygen analog of thiirene, oxirene computed to be antiaromatic even at *ab initio* double ζ basis SCF level (13–15): it lies higher in energy than any of its ring opened diradical or carbenoid isomers and its ring opening reaction features a small activation energy, 2–6 kcal mol^{-1}. In line with the computed low stability of oxirene all previous attempts for its isolation have failed, although recently we have succeeded in isolating an intermediate, in low yields, to which the structure of bis(trifluoromethyl)oxirene has been assigned (41). The chemical scavenging of oxirenes has not been achieved on account of its short lifetime, in spite of the fact that its intermediacy in the reactions of many diazoketones and diazoesters have been known for over fifteen years (10).

The present computational result that the lowest energy reaction channel for thiirene is conversion to the thioketene is in agreement with the experimental observation that thiirene thermally converts only to thioketene (42–44). The appearance of ethynylthiol among the low temperature argon-matrix photolysis products of 1,2,3-thiadiazoles can be ascribed to the secondary photolysis of thiirene. This has been demonstrated experimentally: photolysis of matrix isolated thiirene at 10 K with λ > 330 nm radiation resulted in its conversion to ethynylthiol, and to thioketene in smaller yields. The photochemical path involves the lowest excited singlet state of thiirene with an excitation energy of about 85 kcal mol^{-1} which could then energetically readily convert to ethynylthiol via the intermediacy of thiiranylidene, or vinylidenethiol which can result in isotopic scrambling when isotopically labelled thiirene is used:



The computed relatively high stability of thiirene is also in accord with its computed geometry, in particular, with the magnitude of the C—S bond length which at the 6-31G* SCF level is only 0.04 Å larger than the experimental value in the 2n-π electron analog, thiirane. Calculations using the 6-31G basis set without the polarization function tend to give about 0.1 Å larger bond length (Tables 1 and 2).

The ir spectra of argon-matrix isolated thiirene, d_1- and d_2-thiirenes have been analyzed previously with the aid of normal coordinate calculations (5, 6) and *ab initio* SCF mo calculations using the 4-31G basis set (8). From the data summarized in Table 14 it is seen that the present 6-31G* basis set calculations gave ir frequencies which are from 2% to 31% larger than the experimental values. In comparing them to the frequencies computed with the 4-31G basis set we note that, with one exception, the 6-31G* computed frequencies are closer to the experimental values. The most notable discrepancies exist for the ring deformation frequencies, the values of which are underestimated by the 4-31G calculation probably because this basis set gives incorrect molecular geometries and too large C—S bond lengths.

After submission of the present article we came across a paper by Siegbahn, Yoshimine, and Pacansky (45) dealing with the *ab initio* theoretical study of the lowest singlet and triplet states of the C_2H_2S isomers. Our results are in good agreement with their findings.

Further studies are in progress.

Received March 10, 1983

F. W. B. EINSTEIN, C. H. W. JONES, T. JONES, and R. D. SHARMA. Can. J. Chem. **61**, 2611 (1983).

The structure of $(Ph_3Sn)_2Te$ has been determined by X-ray crystallography. The compound crystallizes in the space group $C2/c$ with a = 18.578(3) Å, b = 7.731(1) Å, c = 25.272(4) Å, β = 117.17(1)°, ρ_c = 1.702 g cm^{-3}, $\rho_o(CHCl_3/CH_2I_2)$ = 1.69 g cm^{-3}, and Z = 4. Intensities were measured for 2853 independent reflections ($2\theta \leq 50°$) of which 2044 were observed ($I \leq 2.3\sigma(I)$) and used in subsequent refinement (final R values were R = 0.034 and R_w = 0.045). The $(Ph_3Sn)_2Te$ molecule exhibits a "bent" structure in which Sn—Te—Sn = 103.68(2)° and Te—Sn = 2.7266(6) Å and in which the Te atom lies on a crystallographic two-fold axis. Comparison of the present structure with corresponding selenide and sulphide analogues indicates that in all three cases the environment about tin corresponds to that of sp^3 hybridisation. The ^{119}Sn Mössbauer quadrupole splittings of $(Ph_3Sn)_3E$ and $(Me_3Sn)_2E$, where E = S, Se, or Te, show a correlation with the ^{119}Sn solution nmr chemical shifts and this correlation is discussed.

F. W. B. EINSTEIN, C. H. W. JONES, T. JONES et R. D. SHARMA. Can. J. Chem. **61**, 2611 (1983).

On a déterminé, par cristallographie de rayons X, la structure du cristal de $(Ph_3Sn)_2Te$. Le composé cristallise dans le groupe d'espace C_2/c avec a = 18,578(3) Å, b = 7,731(1) Å, c = 25,272(4) Å, β = 117,17(1)°, ρ_c = 1,702 g cm^{-3}, $\rho_o(CHCl_3/CH_2I_2)$ = 1,69 g cm^{-3} et Z = 4. On a mesuré les intensités pour 2853 réflexions indépendantes ($2\theta \leq 50°$) et 2044 de ces réflexions sont observées ($I \leq 2{,}3\sigma(I)$); on les a utilisées dans les améliorations subséquentes jusqu'à des valeurs de R = 0,034 et de R_w = 0,045. La molécule de $(Ph_3Sn)_2Te$ a une structure déformée dans laquelle l'angle Sn—Te—Sn = 103,68(2)° et la liaison Te—Sn = 2,7266(6) Å et où l'atome de Te se trouve sur un axe cristallographique binaire. La comparaison de cette structure avec celle de séleniure correspondant et des sulfures analogues indique que dans les trois cas, l'environnement autour de l'étain correspond à celui d'une hybridation sp^3. Les découplages quadrupolaires de Mössbauer du ^{119}Sn des composés $(Ph_3Sn)_3E$ et $(Me_3Sn)_2E$ où E = S, Se ou Te montrent une corrélation avec les déplacements chimiques dans la rmn du ^{119}Sn en solution. On discute de cette corrélation.

Introduction

As part of a detailed ^{119}Sn and ^{125}Te Mössbauer and nmr study of the compounds $(R_3M)_2E$ where M = C, Si, Ge, Sn, and Pb, E = S, Se, and Te, it was relevant to determine the crystal structure of $(Ph_3Sn)_2Te$. The crystal structures of the compounds $(Ph_3Sn)_2S$ and $(Ph_3Sn)_2Se$ have previously been reported and it was of interest to establish how the coordination about the tin in $(Ph_3Sn)_2Te$ compared with the sulphur and selenium derivatives, since this might allow conclusions to be drawn about the ^{119}Sn Mössbauer and ^{119}Sn solution nmr data.

The X-ray crystal structure of $(Ph_3Sn)_2Te$ has been determined and the ^{119}Sn Mössbauer and solution nmr spectra of $(Ph_3Sn)_2E$, E = Se and Te, and $(Me_3Sn)_2E$, E = S, Se, Te, measured. The Mössbauer (1) and nmr (2) data for $(Ph_3Sn)_2S$ have previously been reported. The trends in the Mössbauer and nmr data for $(Ph_3Sn)_2E$ and $(Me_3Sn)_2E$ are discussed briefly.

Experimental

The preparation of compounds

The compounds $(Ph_3Sn)_2E$, E = Se and Te, were synthesised in 80–85% yield in the following way. Sodium hydrogen selenide (telluride) was prepared by reacting selenium (tellurium) with $NaBH_4$ in a water/ethanol mixture. A benzene solution of Ph_3SnCl was then added drop-wise. The benzene layer containing $(Ph_3Sn)_2E$ was separated off and evaporated to dryness and the resulting residue was then recrystallised several times from a diethyl ether/hexane mixture. *Anal.* calcd. for $(Ph_3Sn)_2Se$: C 55.51, H 3.88; found: C 55.40, H 3.86; mp 150°C (lit. (3) 148°C). *Anal.* calcd. for $(Ph_3Sn)_2Te$: C 52.25, H 3.65; found: C 52.40, H 3.62; mp 150°C (lit. (3) 149–150°C).

This one-pot synthesis proved a much more direct way of preparing $(Ph_3Sn)_2E$ than the literature method (3) and gave much better yields. The latter is a multi-step synthesis involving the preparation $Ph_3Sn^-Li^+$, its reaction with selenium (tellurium) to give Ph_3SnELi and finally the reaction of Ph_3SnELi with Ph_3SnCl to yield $(Ph_3Sn)_2E$.

The bis(trimethyltin) selenide and telluride were synthesised using the method of ref. 4, appropriately adapted to tin rather than silicon chemistry. Bis(trimethyltin) sulphide was prepared by reacting trimethyltin chloride with sodium sulphide in water. These three compounds are all liquids at room temperature and it was not possible to obtain consistent chemical analyses for them. They were characterised by their proton nmr spectra and by their ^{119}Sn nmr spectra, which were in agreement with the literature values.

Spectroscopic studies

The ^{119}Sn Mössbauer spectra were recorded with the source and absorbers at liquid nitrogen temperature using a conventional constant acceleration drive. A $Ba^{119m}SnO_3$ (New England Nuclear) source was used and the Mössbauer γ-ray monitored using a NaI(Tl) scintillation counter. The spectra were computer fitted to Lorentzians.

^{119}Sn nmr spectra were obtained on a Bruker WM400 spectrometer at 149 MHz operating at ambient temperature. Resonances were found by utilizing 100–150 kHz sweep widths, 10 μs (25°) pulse widths, and a 0.05 s delay between acquisitions. Final spectra were obtained at the appropriate frequency generally using a 5 kHz sweep width and 90° pulse widths with no delay. No broadband decoupling was employed. Data acquisitions consisted of 16K data points which were zero filled to 32K data points for the Fourier transform. Linewidths were in the range of 5 to 15 Hz. Samples were prepared in $CDCl_3$ for field shimming. Where the deuterium lock was insensitive to the shim coils, the homogeneity was adjusted by monitoring the FID.

Structure determination

Crystal data are

$C_{36}H_{30}Sn_2Te$ fw = 827.62

Monoclinic, a = 18.578(3) Å, b = 7.731(1) Å, c = 25.272(4) Å, β = 117.17(1)°, V = 3229.21 Å^3, ρ_c = 1.702 g cm^{-3},

[a]Estimated standard deviations refer to the last digit printed.
[b]For anisotropic atoms (all non-hydrogen atoms) $B_{iso} = 8\pi^2(U_{11} + U_{22} + U_{33})/3$.

$\rho_o(CHCl_3/CH_2I_2)$ = 1.69 g cm^{-3}, Z = 4, μ = 24.96 cm^{-1}, λ(Mo-K$_{\alpha 1}$) = 0.70926 Å, $F(000)$ = 1591.8.

A crystal suitable for data collection (0.25 × 0.25 × 0.13 mm) was mounted in a Lindemann glass capillary tube. Weissenberg and precession photographs were used to determine approximate cell dimensions and to define the space group as Cc or $C2/c$ (systematic absences: hkl, $h + k = 2n$; $h0l$, $l = 2n$). Accurate cell dimensions were determined by least-squares refinement of 20 accurately centred reflections (2θ = 27−36°). Data were collected using an automatic Picker FACS-I four-circle diffractometer with a graphite monochromator and a scintillation counter with pulse height discrimination. The take-off angle was 3° and a symmetrical θ−2θ scan (2°/min) of (1.3 + 0.692 tan θ)° was used. Stationary-crystal, stationary-counter background counts of 10% of the scan time were taken at each side of the scan. The peak profile of each reflection was analysed and used to derive its intensity and associated error (5). Intensity measurement of two standards every 40 reflections showed no evidence of crystal deterioration, however, there did appear to be a cyclical variation in their intensity (±5%) during data collection which was corrected appropriately.

Intensities were measured for 2853 independent reflections (2θ ≤ 50°), of which 2044 were classed observed ($I \leq 2.3\sigma(I)$). The data have been corrected for Lorentz, polarisation, and absorption effects (transmission coefficients varied from 0.536−0.738). The structure was solved using conventional Patterson and Fourier methods. The Te atom was found to lie on a crystallographic two-fold axis. Hydrogen atoms were included as fixed contributions in their calculated positions and given isotropic temperature factors derived from their parent carbon atoms. Block diagonal least-squares refinement with anisotropic temperature factors for all non-hydrogen atoms gave final agreement factors of $R = 0.034$ ($R = \Sigma||F_o| - |F_c||\Sigma|F_o|$) and $R_w = 0.045$ ($R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$) for 177 variables. A weighting scheme of the form $w = 1/\sigma^2(F_o) + (kF_o)^2$ has been applied (where $k = 0.03$) (Table 1).

The final difference map was very clean (<0.3 e/Å^3) apart from five positive peaks (0.4−0.7 e/Å^3) and two negative peaks (1.2 e/Å^3) close to the Te and Sn atoms. To account for this electron density the possibility of alternative models involving (*a*) disorder or (*b*) an asymmetric Ph_3Sn—Te—$SnPh_3$ unit with approximate two-fold symmetry in space group Cc were considered. However, in view of the good agreement achieved with the present model and the well behaved nature of the phenyl rings, pursuit of these other alternatives was not deemed worthwhile.

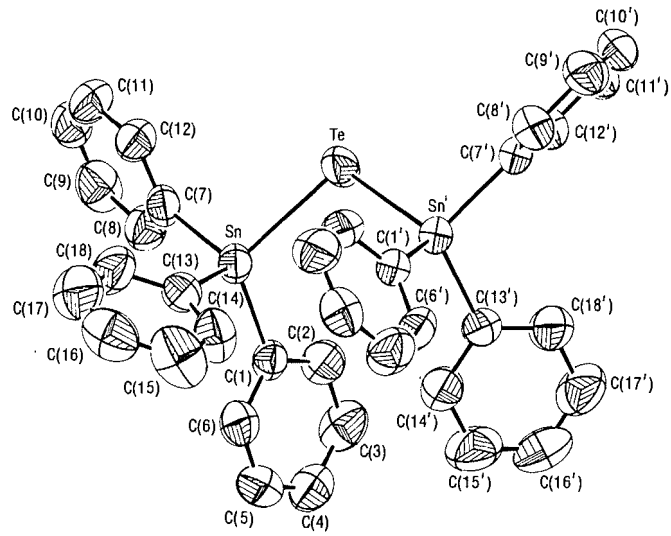

FIG. 1. ORTEP[8] diagram and numbering scheme for the $(Ph_3Sn)_2Te$ molecule. Atoms are represented by 50% thermal ellipsoids. (Hydrogen atoms have not been included for clarity.)

Atomic scattering factors including anomalous dispersion were taken from ref. 6. The computer programs used are those from ref. 7. Final positional parameters are listed in Table 2.[1]

Discussion

An ORTEP (8) diagram and numbering scheme for the $(Ph_3Sn)_2Te$ molecule is given in Fig. 1. Bond parameters are given in Table 2. The molecule possesses a crystallographic two-fold symmetry axis which runs through the central Te

[1]Complete set of structure factor listings, anisotropic temperature factors, and hydrogen atom parameters are available at a nominal charge, upon request, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[e]The Te atom lies on a crystallographic two-fold axis; consequently both halves of the molecule are equivalent.

atom. As expected the "bent" structure found for the present compound, $(Ph_3Sn)_2E$, where E = Te, is very similar to those found for the analogous compounds where E = S (9) and Se (10). Important bond parameters for all three compounds are summarized in Table 3. The coordination about tin is essentially tetrahedral in each case. Indeed, while a range of bond angles is observed about tin in each compound, the average E—Sn—C and C—Sn—C bond angles all approach the tetrahedral value of 109.5°. As might have been predicted, the Sn—E—Sn angle contracts on moving from S → Se → Te, corresponding to an increase in Te—E distance in the same order. There were no unusual intermolecular distances found for $(Ph_3Sn)_2Te$.

The fact that the coordination about the tin is essentially tetrahedral in all the triphenyltin chalcogenides is of some importance in interpreting the Mössbauer and nmr spectroscopic data for these compounds.

The ^{119}Sn Mössbauer quadrupole splittings (Table 4) for $(Ph_3Sn)_2E$ and for $(Me_3Sn)_2E$ show a trend to smaller values as the electronegativity of the chalcogen decreases. This is readily understood in terms of an increased donation of electron density from the chalcogen to the tin as the chalcogen electronegativity decreases, since this would lead to a decrease in the *p*-orbital imbalance about the tin and hence a smaller quadrupole splitting. The very small increase in the Mössbauer isomer shifts with decreasing electronegativity of the chalcogen corre-

sponds to the increased donation from the chalcogen into an sp^3 hybrid orbital on the tin and a small net increase in the *s*-electron density at the nucleus.

It can also be seen that the quadrupole splittings for the trimethyltin compounds are consistently greater than those of the triphenyltin analogues. This is consistent with the phenyl group having a greater electronegativity than the methyl group in these compounds.

In contrast with the ^{119}Sn Mössbauer data in the solid state, the ^{119}Sn solution nmr chemical shifts exhibit a wide range of values (Table 4). The chemical shifts of the heavier nuclei, such as tin, are generally assumed to be dominated by the Ramsey paramagnetic term (11−14) which may be written approximately as:

$$\sigma^p \propto \frac{-1}{\Delta E}\left(\langle r^{-3}\rangle_{5p}P + \langle r^{-3}\rangle_{5d}D\right)$$

where ΔE is the mean electronic excitation term, the $\langle r^{-3}\rangle$ terms are the mean inverse cubes of the $5p$ and $5d$ electron−nuclear distances, and the P and D terms reflect the imbalance of the $5p$ and $5d$ orbitals. Within a closely related series of compounds the ΔE terms may be taken as comparable and, if the D term can be neglected, then the chemical shifts should show a dependence on the P term. As the electronegativity of the chalcogen bonded to tin decreases in the $(R_3Sn)_2E$ compounds, then P should decrease, the nucleus should become increasingly shielded, and the chemical shift should become more negative, as is indeed observed, both for the triphenyl and the trimethyl compounds. While there are many other factors which may also influence the nmr chemical shifts (12), the above argument provides a qualitative explanation for the observed trends.

The preceding discussion suggests that in these compounds, assuming that the chemical environment about the tin in these molecules is similar in solution to that in the solid state, the ^{119}Sn Mössbauer quadrupole splitting and the ^{119}Sn nmr chemical shift should be correlated. As is illustrated in Fig. 2 this would appear to be the case. The fact that in Fig. 2 the triphenyltin and trimethyltin compounds all appear to lie on a straight line may be fortuitous since the parent species, Ph_4Sn and Me_4Sn, do not themselves have the same chemical shift. It should also be noted that for selenium, and more particularly for tellurium, the so-called (12) "bulky atom effect" may also influence the chemical shifts. Nevertheless, it can be seen the correlation between the nmr chemical shifts and Mössbauer quadrupole splittings is the same for both the triphenyltin and the trimethyltin compounds.

It must be emphasised that such correlations between the Mössbauer and nmr data can only be anticipated within a series of compounds of similar structure and where the environment about the tin is similar throughout the series in both the solid state and in solution. The present crystal structure data confirms that the environment about the tin in the telluride is indeed similar to that in the selenide and sulphide. Moreover, since this environment is very close to tetrahedral in the solid state, with the absence of any significant intermolecular inter-

actions, it would be expected that a similar geometry would prevail in solution. Crystal structure data for the $(Me_3Sn)_2E$ compounds are not currently available.

The effects of the shift reagents $Eu(dpm)_3$ and $Eu(fod)_3$ on the ^1H and ^{13}C nmr spectra of twelve oximes of diverse structure were examined. The proton data show that the use of proton shifts to assign oxime stereochemistry, as has been done in the past, is unreliable. In contrast, $Eu(dpm)_3$ causes LIS values for the ^{13}C signals of α carbons which are strongly dependent on stereochemistry. Signals for all α carbons *anti* to the oxime oxygen experience large downfield shifts while all *syn* carbons are either unaffected or shifted upfield. Thus the effects of $Eu(dpm)_3$ on these ^{13}C signals provides an unambiguous method of configurational assignment to oximes. The effects of $Eu(fod)_3$, though similar to $Eu(dpm)_3$, were less consistent and thus less promising for making configurational assignments.

ROBERT R. FRASER, RAJ CAPOOR, JOHN W. BOVENKAMP, BENOIT V. LACROIX et JACK PAGOTTO. Can. J. Chem. **61**, 2616 (1984).

On a étudié les effets des réactifs de contact $Eu(dpm)_3$ et $Eu(fod)_3$ sur les spectres de rmn du ^1H et du ^{13}C de douze oximes ayant diverses structures. Les données de la rmn du proton révèlent que l'utilisation des réactifs de contact pour attribuer la stéréochimie d'oximes n'est pas rigoureuse. Le $Eu(dpm)_3$ au contraire provoque des déplacements des signaux du ^{13}C des carbones en position α qui dépendent beaucoup de la stéréochimie. Les signaux de tous les carbones α en position *anti* par rapport à l'oxime-oxygène subissent de forts déplacements vers les champs faibles tandis que tous les carbones en position *syn* ou bien ne bougent pas ou alors se déplacent vers les champs forts. Ainsi l'effet du $Eu(dpm)_3$ sur ces signaux du ^{13}C fournit une méthode non équivoque d'attribution de configuration des oximes. Les effets du $Eu(fod)_3$, quoiqu'identiques à ceux du $Eu(dpm)_3$, sont moins cohérents et par conséquent peu sûrs pour faire des attributions de configuration.

The effect of the addition of the shift reagent, $Eu(dpm)_3$[2] on the proton spectra of oximes has been the subject of some controversy and of considerable misunderstanding. The first study by Wolkowski (1) described the observation of a dependence of the observed downfield shifts on the proton to oxime oxygen distance. In the same year, a paper by Berlin and Rengaraju (2) described a study of the effect of adding $Eu(dpm)_3$ to a mixture of *E* and *Z* 2-butanone oximes. The conclusion of this paper, based on the observation of larger lanthanide induced shifts (LIS values) for all of the protons in the *Z* isomer, was that complexation occurred at the nitrogen atom. Concurrently, a third paper by Tronchet *et al.* (3) described a study of LIS values for pairs of isomeric aldoximes. For this class of oximes the *Z* isomers were also observed to give much larger downfield shifts, indicative of coordination at nitrogen. Subsequently, the proposed distance relation of Wolkowski was employed in assigning configuration to pairs of oximes. In one paper the assignment on this basis (4) turned out to be in error (5), while a second utilization of the dependence on distance from oxygen actually gave the correct assignment as it was unambiguously confirmed by subsequent Beckmann rearrangements (6). Interestingly, a comparable number of later papers chose to interpret Berlin's data as indicating that protons closer to the lone pair on nitrogen should show larger LIS values (by assuming a distance dependent correlation). Both of these papers (5, 7) in fact, gave correct assignments as subsequently validated by Beckmann rearrangements. In view of such conflicting results, we hesitated in using any shift reagent data to aid us in assessing the configurations of oximes of unknown stereochemistry. We therefore decided to undertake a more thorough examination of the effects of stereochemistry on proton LIS values obtained using both $Eu(dpm)_3$ and the more popular $Eu(fod)_3$ with a variety of ketoximes. We have extended the study to include the comparison of all ^{13}C spectral changes as well. The results clearly show ^1H nmr to be an unreliable probe for the correlation of LIS values with configurational assignments. In contrast, ^{13}C nmr provides a strikingly clear relationship between LIS values and the stereochemistry of oximes.

Scope of studies

We have examined the effects of the addition of the two most commonly used shift reagents, $Eu(dpm)_3$ and $Eu(fod)_3$, on both the ^1H and ^{13}C spectra of twelve ketoximes, including four symmetrical oximes, and four pairs of *E* and *Z* stereoisomers. The resultant proton data are reported in Fig. 1, and the ^{13}C data appear in Fig. 2.

Results of proton spectral studies

The first observation of interest is the very good agreement (<5% difference in all LIS) between our proton data for **2** and **3** and that reported earlier under identical conditions (in $CDCl_3$) by Berlin and Rengaraju (2). In contrast, the values reported by Wolkowski (1) differ widely (in one case, three-fold) from the results obtained by us under his conditions (in CCl_4). His

[1]DREO Report No. 879.

[2]$Eu(dpm)_3$ is the abbreviation for tris(2,2,6,6-tetramethylheptane-3,5-dionato)europium, $Eu(fod)_3$ for tris(1,1,1,2,2,3,3-heptafluoro-7,7-dimethyloctane-4,6-dionato)europium.

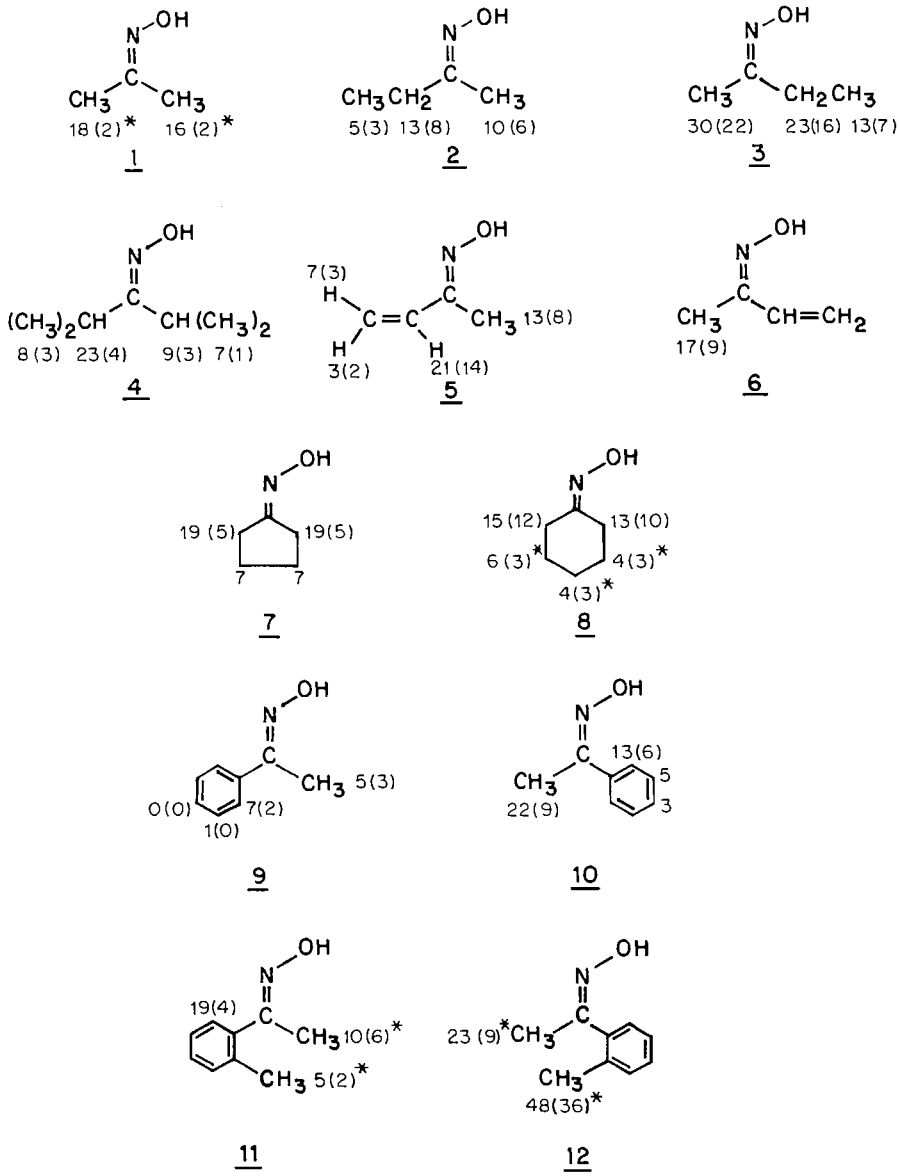

FIG. 1. The downfield shifts (LIS values) are given for individual protons, as induced by the addition of 0.1 equivalent of shift reagent to 0.5 *M* solutions, in $CDCl_3$, of oximes **1** to **12**. The figures represent the effects of $Eu(dpm)_3$ and (in brackets) $Eu(fod)_3$ after extrapolation to one equivalent. Those shifts which might reasonably be interchanged are indicated with an asterisk.

reported LIS values for acetone oxime and methyl vinyl ketoxime also differ from those we report in Fig. 1. Furthermore, Wolkowski's values for the *Z* and *E* isomers of acetaldoxime were reported to be in error in the paper by Tronchet *et al.* (3). It is therefore clear, though for reasons not apparent, that the data reported in ref. 1 are not reliable. The other results in Fig. 1 further support this contention in that the purported relationship between the magnitude of the LIS value of a proton and its distance from the oxime oxygen cannot be seen.

For all pairs of oximes, **2** and **3**, **5** and **6**, **9** and **10**, and **11** and **12** there is a consistent pattern in that the *Z* isomer having the methyl *syn* to the lone pair on nitrogen always exhibits larger LIS values for all its proton signals than for those of the *E* isomer, a result consistent with greater binding of the *Z* isomer at nitrogen.[3] Another feature of the ^1H data is the complete lack of any relationship between the LIS values and distance between the proton and the nitrogen binding site (see, for example, data on **1**, **7**, and **8**). The lack of any distance dependence may arise from a number of factors including a variation in binding site. The most likely complication is a significant contribution from the angular term (8) which would cause protons *syn* to the binding site at nitrogen to be much less influenced by the shift reagent than those *anti* but further away. The presence of a contact shift which can occur with both aliphatic and aromatic amines (8) would further obscure any distance dependence. A recent review (9) discusses these and several other factors which are widely recognized contributors to the complication of LIS data. The net result is the failure of the data in Fig. 1 to provide a general method of configurational assignment. However, it can be said that for a pair of ketoximes of recognizable differences in steric access to the oxime nitrogen an assignment could be made on the basis of relative binding strengths, as was seen for aldoximes (7). Finally, it should be pointed out that the LIS data for $Eu(fod)_3$

[3]This does not preclude the possibility of some binding of the *Z* isomer at oxygen, or of a larger amount of binding at oxygen by the *E* isomer.

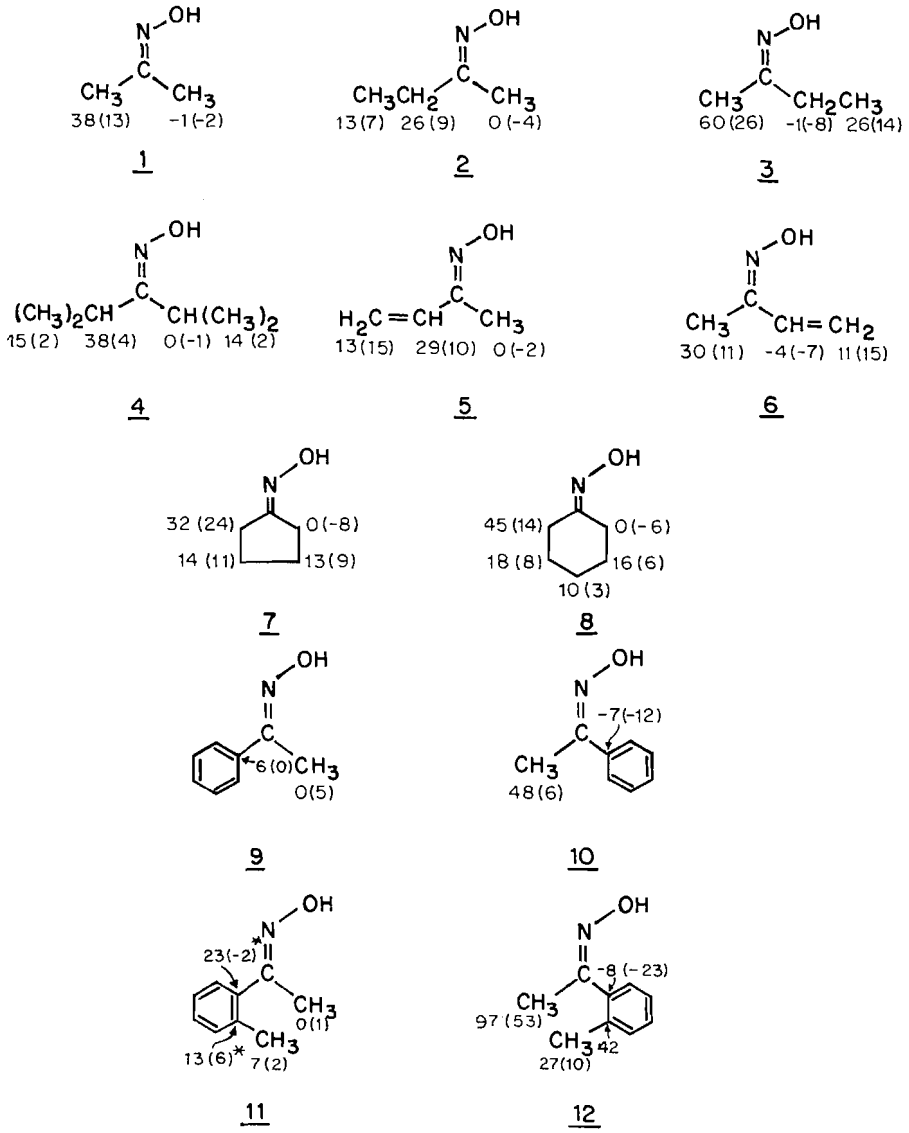

FIG. 2. The LIS values are given for the ^{13}C nuclei, induced by the addition of 0.1 equivalent of shift reagent to 0.5 *M* solutions, in $CDCl_3$ of oximes **1** to **12**. The figures, extrapolated to 1 equivalent, represent the effects of $Eu(dpm)_3$ and (in brackets) $Eu(fod)_3$. Negative values indicate upfield shifts.

is notable only in the sense that the induced shifts are consistently much smaller. This is an effect opposite to that normally seen (8) although there is precedent in the literature (10).

A special comment is required regarding some of the data in Fig. 1 and also Fig. 2. The data for **2** and **3**, for **5** and **6**, and for **11** and **12** were obtained from a mixture of both components (see Experimental for compositions). As a result of the greater binding ability of the *Z* isomer, there is a bias to larger LIS values for each *Z* isomer and concomitantly a depression of the figures for the *E* isomers. The data for **9** and **10** were obtained using the pure compounds.

Results of ^{13}C spectral studies

(a) *Effects of Eu(dpm)$_3$*

The ^{13}C data in Fig. 2 show a remarkably clear pattern of stereochemical influence on the shifts caused by the addition of this shift reagent. The α carbon *syn* to the lone pair on nitrogen is always shifted downfield more than any other carbon and the carbon *anti* to the lone pair on nitrogen is either shifted upfield or unaffected. Such a marked difference in LIS behaviour provides an unmistakable method for the assignment of configuration to ketoximes. The compounds studied include α carbons which are aliphatic, olefinic, and aromatic and so structural variation has not affected their LIS values. The reason for the strikingly different results for *syn* and *anti* α carbons is undoubtedly the intrusion of a stereochemically dependent contact shift. Studies of the effect of nickel(II) acetylacetonate have clearly shown that its complex formation with amines causes contact shifts of the ^{13}C nuclei whose magnitudes depend on both stereochemistry and the number of intervening bonds. A β carbon *trans* to the lone pair site of complexation experiences a two to threefold larger contact shift than when *gauche* or *cis* (11, 12). There is also ample evidence that ^{13}C shifts are much more susceptible than protons to contact shifts when complexed to a europium tris diketonate (13, 14). In one study, the proportion of contact to pseudo-contact (normal) mechanism contributing to the LIS of ^{13}C nuclei using $Eu(fod)_3$ has been shown to be of approximately the same magnitude for picoline and for octylamine (15). Thus, the LIS values in Fig. 2 for $Eu(dpm)_3$ reflect a downfield shift

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

resulting from dominance of the pseudocontact mechanism for all carbons except those *anti* to the lone pair on nitrogen. In the latter case, the contact mechanism causes an upfield shift equal to or greater than the pseudocontact contribution and the resultant zero or upfield movement of the carbon signal. Shifts for the other carbons can, in principle, receive finite but smaller contact contributions whose signs sometimes alternate with distance. The magnitude of such contributions to the observed carbon shifts cannot be properly assessed.

Regardless of the limitations to our rationalization of these results, as we also must bear in mind the caveats of ref. 9, the ^{13}C LIS values induced by $Eu(dpm)_3$ provide an unambiguous method for the assignment of configuration to oximes. Indeed the differences in behaviour of *E* and *Z* isomers is sufficiently great that a reliable assignment should be possible even in a case where only one isomer is available. The same does not appear to apply to previous methods involving proton shifts (16–18). Additionally, $Eu(dpm)_3$ provides a method of signal assignment in symmetrical ketoximes.

(b) *Effects of $Eu(fod)_3$*

There are several notable features seen in the effects of $Eu(fod)_3$ on the ^{13}C spectra of **1** to **12**. In general, the induced shifts are algebraically more negative than those produced by $Eu(dpm)_3$. This very likely reflects a weaker binding of $Eu(fod)_3$ as is evident by the much smaller LIS values at the β carbons. There also appears to be a larger contact shift at the α carbons *anti* to the lone pair on nitrogen. The striking exception, **9**, shows a significantly more positive LIS caused by $Eu(fod)_3$ at the carbon *anti* to the lone pair on nitrogen. A possible explanation for this deviant behaviour is a decrease in the strength of binding at nitrogen due to interference by the bulky phenyl group, which thereby decreases the contact shift and allows the effect of binding at oxygen to be seen. As a consequence of this lesser consistency in the effects of $Eu(fod)_3$ on ^{13}C shifts, we recommend that only $Eu(dpm)_3$ be used, in conjunction with ^{13}C, as a reliable method of making configurational assignments to oximes.

Spectral assignments

Most of the oximes in this paper have been the subject of earlier ^{13}C studies (19–22). One of the signal assignments, specifically that made for the α carbon *syn* to the oxime function in **8**, (19, 20) must be altered. The signal appearing at δ 24.4, previously assigned to C–4, is the peak whose LIS in the presence of $Eu(dpm)_3$ is zero and thus represents C-2 (*syn* to the oxime oxygen). The low field peaks at δ 25.6, 25.8, and 26.9 are best assigned to C-3, C-4, and C-5 respectively, also on the basis of the LIS data.

Those oximes whose ^{13}C spectra have not yet been described, **6**, **11**, and **12**, presented little difficulty in signal assignment. For **6**, present as a minor component with **5** in a mixture of stereoisomers, the configurations were assigned utilizing the general rule that the upfield methyl signal belongs to the *E* isomer (19, 20, 23). In **11** and **12**, it was first necessary to establish the methyl assignments by measuring the fully coupled spectrum of each isomer. The signal for the α methyl in the *Z* isomer (δ 21.9) appeared as a sharp quartet while the *ortho* methyl (δ 19.4) gave a quartet consisting of four peaks broadened substantially by unresolved coupling with the *ortho* (and *para*) protons on the aromatic ring. The methyl assignments for the *E* isomer were similarly determined. The complete shift data for **6**, **11**, and **12** appears in the Experimental.

The proton data given in Fig. 1 are ambiguous in certain cases due to uncertain proton assignments. Specifically, in **1** and **7** the LIS shifts for the α protons were so similar that there was no need to make a rigorous assignment. To indicate where the possibility of a reversal of assignment exists, as in **1**, the LIS value is given an asterisk. For **4**, the proton assignments were proven by selective decoupling of the peaks for the α ^{13}C signals and are given in the Experimental. For **8**, the previous literature assignments (24) were confirmed by selective decoupling.

Experimental

The oximes **1**, **7**, **8**, and **9** were obtained commercially. The oximes of 2-butanone (**2** and **3**), synthesized by the method of Pearson and Bruton (25), were produced in a 76:24 ratio respectively (determined from the proton nmr spectrum of 50 mg of the oxime mixture and 60 mg of $Eu(fod)_3$ in 0.5 mL carbon tetrachloride). Berlin and Rengaraju (2) reported a similar ratio of 72:28. Ketoxime **4**, obtained by the method of Pearson and Bruton (25), had a bp of 89°C/20 Torr (lit. (26) bp 91°C/21 Torr); nmr in $CDCl_3$, δ: 1.13, 1.16 (CH_3's), 2.5 (CH *anti* to oxime), 3.2 (CH *syn* to oxime). Oximes **5** and **6** were obtained as an 85:15 mixture by reacting methyl vinyl ketone with hydroxylamine hydrochloride in the presence of sodium acetate (27). An identical ratio was obtained by Buczkowski and Plenkiewicz (28). The pure *Z*-isomer of α bromoacetophenone oxime was prepared using the method Blumbergs *et al.* (29) and then converted to **10** as described by Smith and Kaiser (30) (mp 82–83°C (lit. (30) mp 81–83°C).

A mixture of **11** and **12** was obtained by the oximation of 2-methylacetophenone (31). The ratio of **11** to **12** in the semi-solid product was shown to be 67:33, as determined by hplc (Waters Associates model ALC/GPC 201, uBondapak C18 column (7.8 mm × 30 cm), water/methanol 50:50).

All ^1H nmr spectra were measured on a Varian T-60 nmr spectrometer. The LIS values reported in Fig. 1 were obtained from spectra run in the presence of 0.05 and 0.1 mmol of shift reagent added to 0.5 mL of 0.5 *M* solution of the oxime in $CDCl_3$. The LIS values for **2** and **3** in CCl_4 under the conditions of Wolkowski (1) were for **2**: 12(C-1), 16(C-3), and 6(C-4), and for **3**: 40(C-1), 35(C-3), and 17(C-4). All ^{13}C spectra were measured on a Varian FT-80 nmr spectrometer. The LIS values reported in Fig. 2 were obtained from spectra run in the presence of 0.05 and 0.1 mmol of shift reagent added to 2.0 mL of 0.5 *M* solution of the oxime in $CDCl_3$. Selective decoupling of the α protons in **4** and **8** during measurement of the ^{13}C spectra were performed on a Varian XL-200.

^{13}C chemical shifts

The ^{13}C spectra of oximes **6**, **11**, and **12** have not been reported previously. For the major isomer of methyl vinyl ketoxime, **5**, shifts were measured on the neat liquid (22). Our shifts (δ in ppm from TMS) measured on 0.5 *M* solutions of **5**, **6**, **11**, and **12** and assigned as discussed earlier are, for *E*-1-buten-3-one oxime, C-1 (118.7), C-2(134.2), C-3(156.6), C-4(9.0), and *Z*-1-buten-3-one oxime, C-1(122.2), C-2(125.9), C-3(163.9), C-4(16.2); and for *E-ortho*-methylacetophenone oxime, C_α(15.9), C=N(157.9), *o*-CH_3(20.0), C-1—C-6(137.4 and 135.7, quaternary carbons; 125.8, 128.2, 128.6, 130.7, tertiary carbons) and *Z-ortho*-methylacetophenone oxime, C_α(21.9), C=N(156.5), *o*-CH_3(19.4), C-1 and C-2(135.5 and 134.6), C-3—C-6 unidentified.

The retroaldol reaction of chalcone

J. Peter Guthrie,[1] John Cossar, Patricia A. Cullimore, Nayyer Monshizadeh Kamkar, and Kathleen F. Taylor

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received April 7, 1983

J. Peter Guthrie, John Cossar, Patricia A. Cullimore, Nayyer Monshizadeh Kamkar, and Kathleen F. Taylor. Can. J. Chem. **61**, 2621 (1983).

All four rate constants required to describe the hydration and aldolization/dealdolization reactions of chalcone (1,3-diphenyl-2-propen-1-one) have been determined in aqueous sodium hydroxide solutions. Kinetics were studied starting with chalcone, with its hydrate, 1,3-diphenyl-3-hydroxy-1-propanone, and with benzaldehyde in the presence of excess acetophenone. The rate constants for hydroxide catalyzed reactions, defined in terms of eq. [1] are: $k_{12} = 10.5 \pm 0.5 \times 10^{-4}\ M^{-1}\ s^{-1}$; $k_{21} = 0.026 \pm 0.002\ M^{-1}\ s^{-1}$; $k_{23} = 0.194 \pm 0.017\ M^{-1}\ s^{-1}$; and $k_{32} = 0.84 \pm 0.12\ M^{-2}\ s^{-1}$ (all at ionic strength 0.1). The corresponding equilibrium constants for aldol adduct formation and dehydration are 4.3 M^{-1} and 25.

J. Peter Guthrie, John Cossar, Patricia A. Cullimore, Nayyer Monshizadeh Kamkar et Kathleen F. Taylor. Can. J. Chem. **61**, 2621 (1983).

On a déterminé, dans des solutions aqueuses d'hydroxyde de sodium, les quatre constantes de vitesse requises pour décrire l'hydratation et les réactions d'aldolisation/désaldolisation de la chalcone (diphényl-1,3 propène-2 one-1). On a étudié les cinétiques en partant de la chalcone, de son hydrate, la diphényl-1,3 hydroxy-3 propanone-1 et du benzaldéhyde en présence d'un excès d'acétophénone. Les constantes de vitesse des réactions catalysées par l'hydroxyde, définies selon l'équation [1], sont de $k_{12} = 10{,}5 \pm 0{,}5 \times 10^{-4}\ M^{-1}\ s^{-1}$, $k_{21} = 0{,}026 \pm 0{,}002\ M^{-1}\ s^{-1}$, $k_{23} = 0{,}194 \pm 0{,}017\ M^{-1}\ s^{-1}$ et $k_{32} = 0{,}84 \pm 0{,}12\ M^{-2}\ s^{-1}$ (le tout à une force ionique de 0,1). Les constantes d'équilibre correspondantes de la formation de l'adduit aldolique et de la déshydratation sont de 4,3 M^{-1} et de 25.

[Traduit par le journal]

Introduction

We have reported a study (1) of the equilibrium constants for aldol condensation reactions. Since we consider it important to have a reliable set of rate and equilibrium constants for a set of simple aldol reactions and need such data for an examination of rate–equilibrum correlations for the aldol reaction, we have undertaken the investigation of the kinetics of various aldol reactions (2–4), studying them in the reverse sense to avoid the difficulties of side reactions which often plague the kinetics of aldol reactions in the forward sense. Very few other aldol reactions had been subjected to kinetic study when we began this investigation (5–21). The case of chalcone is of interest because, despite a number of studies by various research groups, no detailed kinetic analysis for reactions in aqueous solution has been reported. There have been previous studies of the formation and breakdown of chalcone in alcohol (16, 18, 19) and in acetic acid (17, 18), and there has been a qualitative kinetic study using polarographic analysis in aqueous ethanol (21). More recently there has been an investigation of the cleavage of a series of substituted chalcones in aqueous alkali (20). Although three of the four rate constants have been reported for alcoholic solution (18), there was no consideration of the possible addition of ethanol to chalcone as a confusing side reaction. There are literature methods for preparing the ketol corresponding to chalcone, i.e. 3-hydroxy-1,3-diphenyl-1-propanone (18, 22). This compound proved essential to the investigation, because the equilibrium constant for dehydration to chalcone is quite large and cannot be measured directly by studying the hydration of chalcone, yet must be known to sort out the kinetics. By measuring the rates of formation of chalcone from benzaldehyde in the presence of excess acetophenone we have been able to determine the overall equilibrium constant for chalcone formation in aqueous solution.

Results and discussion

The retroaldol reaction of chalcone can be followed spectrophotometrically; when chalcone, as a solution in acetonitrile, is injected into aqueous sodium hydroxide solution there is a smooth disappearance of the absorbance at 312 nm, which follows a simple first order rate law. Thus one can see no sign of the two stages which are believed to be essential for this reaction as shown in eq. [1].

$$[1]\quad \mathrm{Ph{-}Ch{=}CH{-}CO{-}Ph} \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} \mathrm{Ph{-}CHOH{-}CH_2{-}CO{-}Ph}$$

$$\mathrm{Ph{-}CHOH{-}CH_2{-}CO{-}Ph} \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} \mathrm{Ph{-}CHO + CH_3{-}CO{-}Ph}$$

The two phases of the reaction are quite apparent when the ketol, 3-hydroxy-1,3-diphenyl-1-propanone, is injected into aqueous sodium hydroxide solution; the absorbance at 312 nm first rises and then, about 250 times more slowly, falls again; see Fig. 1. The rate of the slow fall in absorbance is essentially identical to the rate of disappearance of the absorbance of chalcone when the latter is used to initiate reaction. Analysis of the two-phase kinetics data permits evaluation of the rate constants. For the system of interest, where a low concentration of ketol product undergoes retroaldol cleavage, the rate of the second order ketol formation process, k_{32}, is negligible. A rigorous solution of the kinetics equations is possible following the procedure described in Moore and Pearson (23), but leads to a cumbersome equation of the form [2]:

$$[2]\quad A = A_B + \alpha \exp(-\lambda_2 t) + \beta \exp(-\lambda_3 t)$$

where A = absorbance and $\lambda_{2,3}$ = the apparent rate constants. In the present case, the two exponential terms correspond to

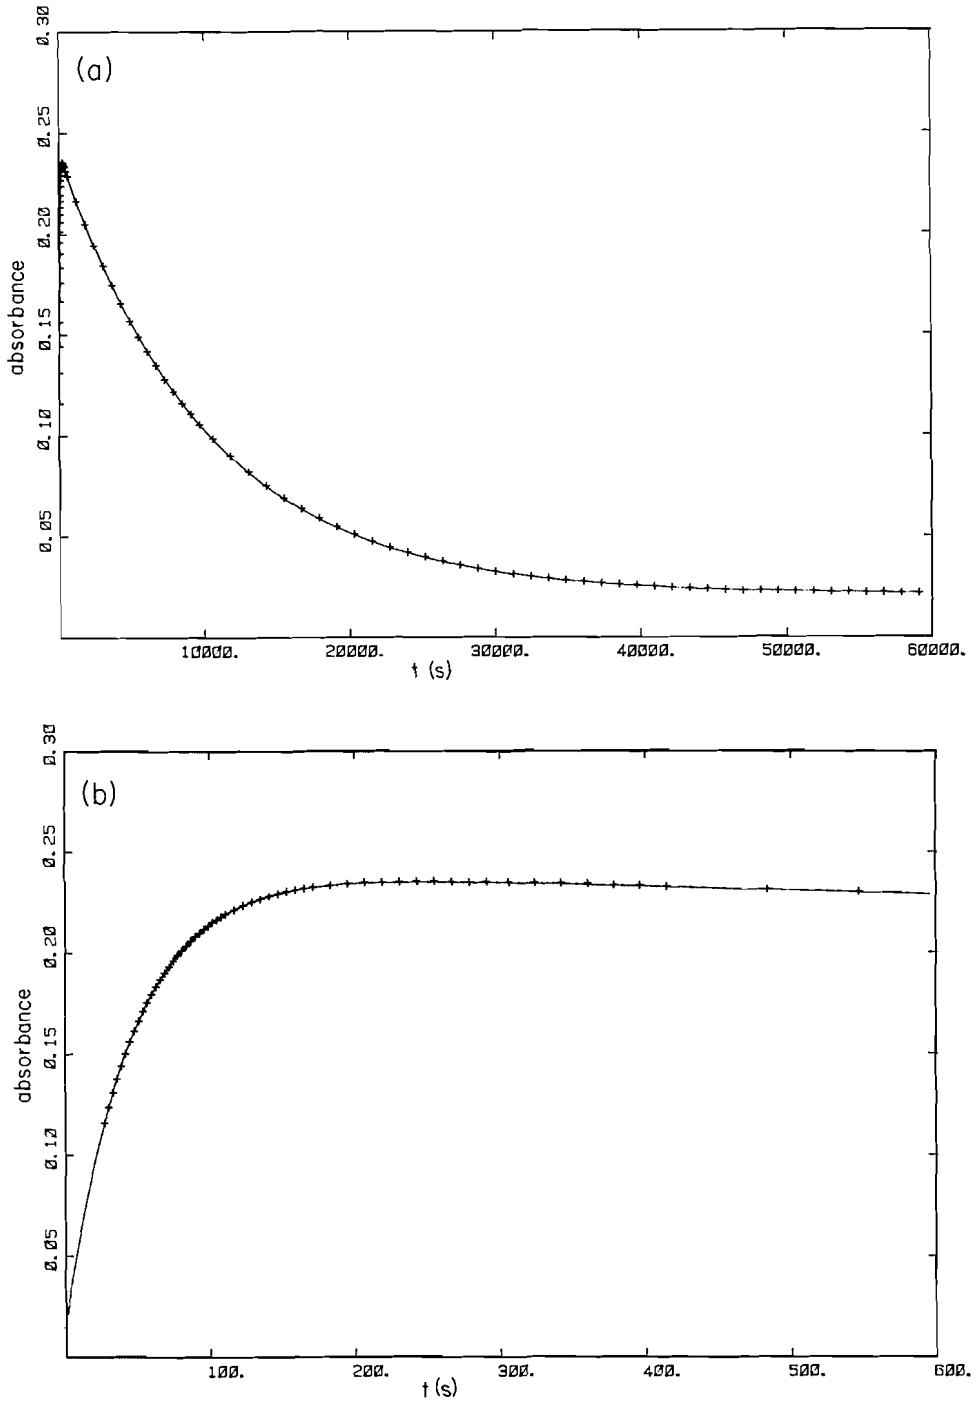

FIG. 1. Biphasic kinetics for the reaction of 3-hydroxy-1,3-diphenyl-1-propanone. Initial concentrations of starting materials was 8.5×10^{-6} *M*, in 0.1 *N* NaOH at 25°C.

very different time scales, so that it is practical to use an approximation treating the two stages separately. The fast reaction, breakdown of the ketol to enone or benzaldehyde plus acetophenone, has rate constant $\lambda_2 \simeq k_{21} + k_{23}$, and an absorbance change governed by the fraction of the ketol which goes to enone, i.e.

$$|\alpha| \simeq C_2^0 \epsilon_1 k_{21}/(k_{21} + k_{23})$$

where C_2^0 is the initial concentration of ketol, and the extinction coefficients are ϵ_i: i = 1, chalcone; 2, ketol; 3, acetophenone + benzaldehyde. The slow reaction is the hydrolysis of the enone so formed, with the ketol as a steady state intermediate, with $\lambda_3 \simeq k_{12}/(1 + k_{21}/k_{23})$. These equations may also be derived from the rigorously correct general solution, by imposing the conditions $\epsilon_1 \gg \epsilon_2$, ϵ_3 and $\lambda_2 \gg \lambda_3$.

The equations used to calculate the rate constants are:

$$k_{21} = |\alpha|\lambda_2/C_2^0\epsilon_1$$

[3] $$k_{23} = \lambda_2 - k_{21}$$

$$k_{12} = \lambda_3(1 + k_{21}/k_{23})$$

Table 1 shows the results of applying this analysis to the experimental data for chalcone and the corresponding ketol. We used $\epsilon_1 = 2.1 \pm 0.02 \times 10^4$; see Experimental. The

individual rate constants show the expected first order dependence upon the hydroxide concentration; see Fig. 2. For reactions starting with the ketol, the maximum absorbance corresponds to about 12% conversion to chalcone, which then undergoes slow cleavage.

Table 2 shows the second order rate constants for the individual steps evaluated in this work, and compares them with literature values for aqueous ethanol, and the results of studies of the overall retroaldol reaction in aqueous solution. It is interesting that k_{21} and k_{23} are quite similar in water and 90% aqueous ethanol, whereas k_{12} in constant boiling aqueous ethanol is different by a factor of about 60 from the value in water. This difference is in large measure attributable to the lowered concentration of water in the mixed solvent; constant boiling aqueous ethanol is 4.4% or 1.96 *M* water. If the concentration of hydroxide ion in aqueous ethanol containing a fixed concen-

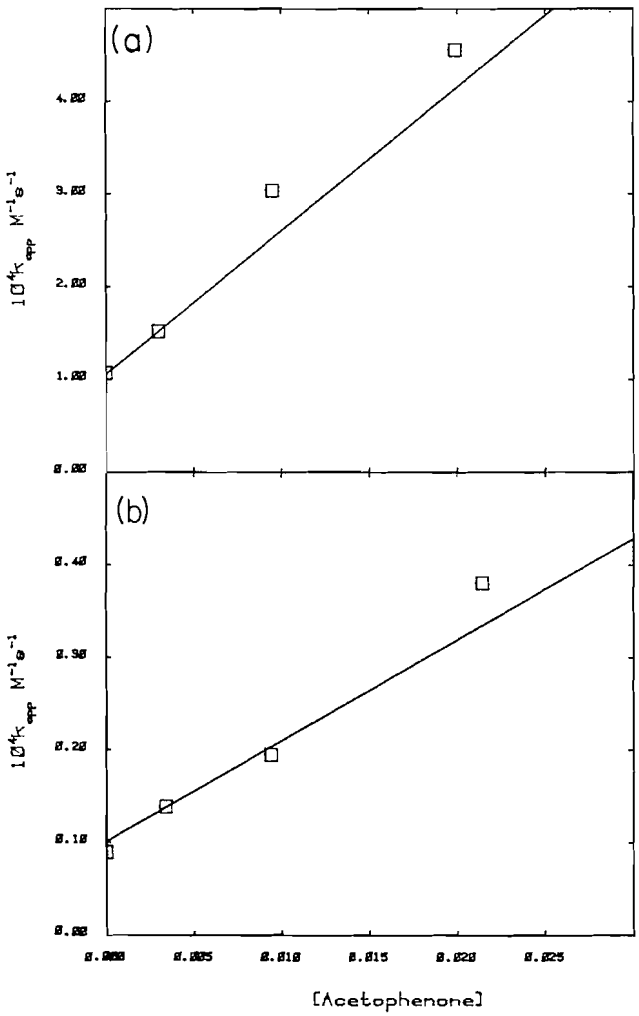

FIG. 3. Dependence of the apparent second order rate constants for chalcone formation on the acetophenone concentration. (a) [NaOH] = 1.0 M; (b) [NaOH] = 0.1 M.

tration of sodium hydroxide/ethoxide is proportional to the water concentration (which will not be exactly true, but should be a rough approximation) then the rate of productive lyate ion additions to chalcone will be decreased by 55.5/1.96 or 28-fold in constant boiling aqueous ethanol. Applying this correction to the k_{12} value estimated from the data in ref. 16 leads to a value within a factor of two of that observed in this work for water. The remaining difference can reasonably be ascribed to solvent effects upon the rate constant, and/or imperfections in our approximation. It should be noted that the unknown amount of addition of ethoxide ion to chalcone leads to an unproductive adduct which cannot react further, and will not accumulate because the equilibrium constant for addition is unfavorable.

The equilibrium constant for aldol dehydration (k_{21}/k_{12}) calculated from the rate constants determined in this work is 25, which differs significantly from the value of 87 which we estimated previously (1) from the rate constants in aqueous ethanol. The previous estimate was indirect, requiring the overall equilibrium constant and the equilibrium constant for the aldol addition, both in aqueous ethanol. We had, therefore, to consider the possibility that this estimated value for the overall equilibrium constant was in error, and accordingly studied the kinetics of the formation of chalcone in order to determine the equilibrium constant in water.

These experiments were done with excess acetophenone to give pseudo first order conditions; acetophenone does not react in the presence of base at rates which would give difficulties, either with itself or with oxygen. Since the equilibrium constant is not strongly favorable it was necessary to use acetophenone concentrations of 0.003−0.02 M in order to get satisfactory amounts of conversion. This has as an unavoidable consequence a large background absorption due to the acetophenone, and necessarily limits the precision of our kinetics. Furthermore, cloudiness was noticeable for the final solutions from the runs at the two highest concentrations of acetophenone in 1.0 M NaOH, and for the run at the highest concentration of acetophenone in 0.1 M NaOH. At either ionic strength good first order behavior was seen for 2−3 half-lives at the two highest acetophenone concentrations and for 7 half-lives at the lowest concentration. We are clearly at the solubility limit for chalcone, yet to lower the benzaldehyde concentration would result in a small change in absorbance superimposed on the unavoidable high background absorbance from the acetophenone. The acetophenone concentrations could not be lowered if the forward reaction were to make a major contribution to the observed rate of approach to equilibrium. Our kinetics results are given in Table 3. When the apparent second order rate constants for approach to equilibrium (first order in benzaldehyde, first order in hydroxide) were plotted as a function of acetophenone concentration, Fig. 3, the data at either ionic strength could be fitted to a straight line, and the intercepts matched the apparent rate constants obtained starting with chalcone cleavage under the same conditions.

In these experiments, the observed rate constants reflect the rate of approach to equilibrium, and will be the sum of the rate constants for chalcone formation and cleavage. From the previous experiments studying cleavage we know that no intermediates will accumulate. Necessarily, the rate of cleavage of chalcone must be the same for a given set of conditions, wheth-

er it is measured in the cleavage for formation direction.

$$[4]\quad PhCHO + PhCOCH_3 \underset{k_r[OH^-]}{\overset{k_f[OH^-]}{\rightleftharpoons}} Ph—CH=CH—CO—Ph$$

$$k_{obs}/[OH^-] = k_f[PhCOCH_3] + k_r$$

Thus we expect k_r, the intercept of a plot of $k_{obs}/[OH^-]$, to be identical to $\lambda_3/[OH^-]$ from cleavage experiments. In fact, when the appropriate values of $\lambda_3/[OH^-]$ were included in the plots of $k_{obs}/[OH^-]$ vs. $[PhCOCH_3]$ they were in excellent agreement. Figure 3 shows these plots; the fit is by weighted least squares, using weights based on the errors estimated by the least-squares fit to the kinetic data (24). The rate constants for runs at high acetophenone concentration, which are known to be less reliable because the final solutions were turbid, had larger errors, and so were allowed to deviate more by the least-squares calculations. Using the slopes and intercepts of these lines we obtain overall equilibrium constants $K = 148 \pm 4\ M^{-1}$ at 1 M ionic strength, and $K = 108 \pm 20\ M^{-1}$ at 0.1 M ionic strength. These values are very similar, as one would expect for an equilibrium involving neutral moelcules. These values are disturbingly different from the value of $K = 66\ M^{-1}$ which we estimated (1) on the basis of data in aqueous ethanol (16, 18). Clearly our attempts to correct for the change in solvent were imperfect, although the difference in free energy terms is still small enough (0.5 kcal/mol) that it makes little difference to the overall arguments in ref. 1.

We may calculate a value for k_{32} from the apparent third order rate constant for chalcone formation, noting that

$$k_{app} = k_{32}/(1 + k_{23}/k_{21})$$

and consequently that $k_{32} = k_{app}(1 + k_{23}/k_{21})$. In this way we obtain $k_{32} = 1.20 \pm 0.09\ M^{-2}\ s^{-1}$ at 1.0 M ionic strength and $0.84 \pm 0.12\ M^{-2}\ s^{-1}$ at 0.1 M ionic strength.

These values differ by a factor of 5 or more from the values estimated from data in aqueous ethanol. No obvious rationalization for what is, after all, a rather small solvent effect has presented itself.

With directly measured values now in hand we can compare the equilibrium constants for condensation of acetone and acetophenone with benzaldehyde. The equilibrium constants are much more similar than previously estimated: for the aldol addition to benzaldehyde, $K_1 = 8.5\ M^{-1}$ for acetone and 4.3 M^{-1} for acetophenone, while $K_2 = 31$ for acetone and 25 for acetophenone. This agreement is in fact quite reasonable because the varying substituent, methyl or phenyl, is isolated from the reaction center by the carbonyl.

Experimental

Materials

3-Hydroxy-1,3-diphenyl-1-propanone was prepared by directed aldol condensation. To a reaction flask containing 20 mL dry tetrahydrofuran (THF) (distilled from $LiAlH_4$) at −70°C under a nitrogen atmosphere was added 6 mL n-butyllithium solution (2.2 M in hexane) and then 1.7 mL diisopropylamine dissolved in 10 mL dry THF; the solution was stirred for 10 min. Acetophenone (1.3 mL) in dry THF (10 mL) was added and the solution stirred for 20 min. Benzaldehyde (1.3 mL) in dry THF (10 mL) was added and the solution was stirred for 30 min. Acetic acid (0.7 mL) in water (10 mL) was added to quench the reaction and the entire solution was poured into 60 mL ice water and then extracted using ethyl acetate (3 × 30 mL); the combined organic layers were washed with saturated $NaHCO_3$, water, and saturated NaCl, dried over anhydrous Na_2SO_4, and evaporated. The resulting oil was purified by medium pressure chromatography on silica (Merck PF 254) using Glenco apparatus with a continuous gradient from petroleum ether (30−60) to 60% ethyl acetate − 40% petroleum ether to elute the product. Crystallization from petroleum ether gave material of mp 51.7−52.3°C (lit. (18) mp 49.7−50.7°C). Chalcone (Aldrich) was purified by recrystallization from petroleum ether; mp 55.5−56.5°C (lit. (25) mp 57−58°C). Acetophenone and benzaldehyde were redistilled immediately before use in kinetics.

Methods

We had immense difficulty in this project because of irreproducible kinetic behavior which was finally ascribed to impurities in the tetrahydrofuran which we used for stock solutions of the substrates. The THF was always purified, starting from reagent or spectrophotometric grade solvent or even Caledon "distilled in glass" grade, at least by passage through alumina, and sometimes by distillation from sodium benzophenone ketyl. In all cases there were impurity peaks at about 313 nm (smaller in the solvent from Caledon), and rate constants were not accurately reproducible. These problems ceased when we began to use spectrophotometric grade acetonitrile to make up the stock solutions. Calculations showed that consumption of OH^- by hydrolysis of the acetonitrile would be negligible over the course of a kinetics experiment.

Weighed amounts of acetophenone were dissolved in aqueous sodium hydroxide solutions. A stock solution of benzaldehyde in spectrophotometric grade acetonitrile was used; reaction was initiated by adding 30 μL of a 0.0104 M solution to 3.0 mL of acetophenone − sodium hydroxide solution. Stock solutions of chalcone and ketol were prepared in spectrophotometric grade acetonitrile and were used to initiate kinetics; all reactions were followed at 310 nm. The procedure for kinetics was as previously described (4). All reactions were carried out in 10 cm cells holding 25 mL of solution. The extinction coefficient of chalcone was measured by adding measured amounts (Hamilton syringe) of a stock solution in acetonitrile (two different stock solutions were used) to 25 mL of pH 10 carbonate buffer, μ = 1.0 (KCl). The value so obtained was $2.10 \pm 0.02 \times 10^4\ M^{-1}\ cm^{-1}$. This is in good agreement with the value calculated from the absorbance changes for reactions where chalcone was injected into sodium hydroxide solutions: $\epsilon = 2.13 \pm 0.04 \times 10^4\ M^{-1}\ cm^{-1}$.

Hydrogen isotope exchange between fluoroform (CF_3H) and water. 4. Catalysis by NaOH and anionic resin above 100°C as an alternative to DMSO addition for rate enhancement[1]

E. Allan Symons, J. Douglas Bonnett, and M. de Lurdes Martins

Physical Chemistry Branch, Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Research Company, Chalk River, Ont., Canada K0J 1J0

Received March 18, 1983

E. Allan Symons, J. Douglas Bonnett, and M. de Lurdes Martins. Can. J. Chem. **61**, 2627 (1983).

Measurement of rate constants for NaOH-catalyzed CF_3D/H_2O isotopic exchange has been extended from 80 to 140°C. Corresponding CF_3H solubility data were obtained for water and 1.0 mol/L NaOH solution up to 120°C. Above 120°C, the NaOH solution provides sufficient catalytic activity to be considered as a simple alternative to the use of aqueous DMSO systems containing NaOH for a CF_3H redeuteration process.

Tests done with both Ionac A-935 and regular types of anion exchange resin in the hydroxide ion form indicate that these resins, although initially quite effective for deuterium exchange catalysis, lose their reactivity when employed above 100°C. The thermal instability of this type of supported ^-OH catalyst makes it unsuitable for use (as a substitute for NaOH) at elevated temperatures in packed towers in a commercial process.

E. Allan Symons, J. Douglas Bonnett et M. de Lurdes Martins. Can. J. Chem. **61**, 2627 (1983).

On a mesuré les constantes de vitesse de l'échange isotopique CF_3D/H_2O catalysé par du NaOH dans un intervalle de température allant de 80 à 140°C. On a obtenu les données relatives à la solubilité du CF_3H dans l'eau et dans une solution de NaOH 1 mol/L jusqu'à 120°C. Au-dessus de 120°C, la solution de NaOH a suffisamment d'activité catalytique pour être considérée comme une alternative à l'utilisation du système DMSO aqueux contenant du NaOH dans le processus de redeutération du CF_3H.

Des essais effectués sur une résine échangeuse d'anion, sous forme d'ions hydroxydes, de type Ionac A-935 et de type régulier, indiquent que ces résines, au départ tout à fait efficaces pour catalyser l'échange de deutérium, perdent leur activité au-dessus de 100°C. L'instabilité thermique de ce type de catalyseur empêche de l'utiliser (comme substitut au NaOH) à des températures élevées dans les colonnes à remplissage des procédés industriels.

[Traduit par le journal]

Introduction

Efficient catalysis of deuterium transfer to gaseous fluoroform from a natural deuterium source like liquid water will be a vital part of any heavy water production process based on laser-induced multiphoton dissociation of CF_3D in the presence of excess CF_3H (1, 2). The effectiveness of a variety of both homogeneous and heterogeneous catalysts for exchange with water has been studied (3–5). Although none were found to be very active in the temperature range 25 to 80°C, hydroxide ion, when used in the presence of dimethyl sulfoxide (DMSO) as co-solvent with water, provided in-solution deuterium exchange rates that would be suitably fast for an industrial process at 60–70°C (1, 4).[2] Unfortunately, the cost of DMSO addition to and recovery from large process water streams is likely to be prohibitive.[2]

The Arrhenius activation energy for NaOH catalysis of CF_3D-H_2O exchange is quite large over the temperature range 50 to 80°C, being 125 kJ/mol (29.9 kcal/mol) (corrected value, slightly lower than that given in ref. 3). Kinetic measurements have now been extended up to 140°C, to determine how high a reaction temperature would be needed to achieve rates comparable to the fastest values possible for the DMSO–water system at 70°C. In addition, as an extension of a parallel study based on catalysis by anion exchange resins (5), the exchange reactivity and thermal stability of a "high temperature" resin, Ionac A-935, have been examined at temperatures from 90 to 140°C. These results obtained for both NaOH and A-935 catalysis are given in this paper.

Experimental

CF_3D was prepared in batches by NaOD-catalyzed reaction of CF_3H with D_2O as already described (4). Stock NaOH solutions were prepared by diluting Fisher Scientific concentrates with deionized distilled water. The Ionac Chemical Company's A-935 resin (Aquacare Services Ltd., Huntsville, Ontario) was converted to the hydroxide form and analyzed for base strength by standard column techniques (6). This strong base resin is recommended for continuous use up to 100°C (Ionac literature). Analysis of two separate preparative batches (treated only with NaOH) gave loadings of 1.53 and 1.57 mmol $^-OH/g$ dried resin. However, the values are well below the Ionac specification of 3.5 (for Cl^-). With a recommended Na_2SO_4 solution rinse of the Cl^- form resin prior to NaOH treatment, only a slight increase to 1.69 mmol $^-OH/g$ was achieved. Even if the remaining Cl^- sites could be converted to ^-OH, these ions would probably be in locations less accessible for catalysis.

For deuterium exchange kinetic runs at up to 90°C one of our glass, stirred gas/liquid reactors (3) was employed. Because of high water vapour pressure above 90°C, a metal shell reactor of similar design (nickel bottom half for corrosion resistance and aluminum top half for magnetic stirring from above) was constructed for these runs. Fluoroform sample analysis and data treatment methods were the same as used previously (3).

For calculation of in-solution exchange rate constants from the measured rate constant data, the solubility of fluoroform in the catalyst solutions as a function of temperature is required. Measurements of CF_3H solubility in water, 1.0 mol L^{-1} NaOH solution, and A-935 resin slurry between 80 and 120°C were carried out with the same gas chromatographic method used to obtain the solubility data at lower temperature (3, 5). The metal stirred reactor, modified to take a long syringe needle mounted along the inside wall, was substituted for the glass flask system to permit gas–liquid equilibration and solution sampling at the higher total pressures.

The rate of CF_3H hydrolysis below 80°C had been determined to be low (3). The extent of such reaction at higher temperatures was studied by analyzing solutions for $[F^-]$ after exchange runs, using the same specific fluoride ion electrode technique (3).

Results

CF_3H solubility in H_2O and NaOH solution

In both water and 1 mol/L NaOH solution the solubility of CF_3H decreases, but progressively more slowly, over the temperature range 20 to 70°C (3). Between 90 and 130°C the solubility has become practically independent of temperature; the values are $0.89 \pm 0.03 \times 10^{-4}$ and $0.55 \pm 0.03 \times 10^{-4}$ mol fraction for the water and NaOH solution, respectively. There may be a shallow minimum in this region; such behaviour has been observed for other inert gases like H_2 dissolved in water (7).

CF_3D-H_2O exchange

The temperature dependence of the calculated in-solution/slurry rate constants is shown in Fig. 1. The deviation from linearity seen for both solid-line ln k versus $1/T$ plots at higher temperatures arises most likely from mass transfer limitation. Data could not be obtained independent of stirring rate above ~100°C (max. ~800 r/min) in the sealed metal reactor, so that points on the curved sections are minimum values. From the linear sections, Arrhenius activation energies of 129 and 112 ± 4 kJ/mol (30.8 and 26.7 ± 1 kcal/mol) were calculated for NaOH and A-935 resin catalysis, respectively.

Even the "high temperature" Ionac A-935 resin was found to be thermally unstable above 100°C, where its initial ^-OH activity would be acceptable. For example, catalytic reactivity declined by 30% after 19 h at 108°C and by a factor of seven after 22 h at 136°C. A slight curvature was seen in most kinetic plots for the resin runs, an indication of the gradual loss of ^-OH groups.

The greater catalytic activity for resin-bound ^-OH groups compared to solution NaOH and the temperature dependence of this effect, seen in Fig. 1, were also noted for Rexyn 201 (OH) resin (5). In each case E_a (NaOH) is larger than E_a (resin ^-OH) by ~10–15 kJ/mol. Possible reasons for this behaviour, including changes in fluoroform solubility and ^-OH ion solvation, have been discussed elsewhere (5).

Fluoroform hydrolysis

As expected, hydrolysis of the fluoroform in 1 mol/L hydroxide solution becomes more significant with increasing temperature. Although variation in fluoride ion concentration for identical or similar reaction conditions was sometimes as great as a factor of five (measured $[F^-]$ range 1×10^{-5} to 4×10^{-2} mol/L), the trend is clear. After 24 h in the stirred reactor the following approximate percentages of the fluoroform charge had been hydrolyzed: 0.008% at 98°C, 0.2% at 108°C, 4% at 117°C, and 15% at 126°C.

Discussion

Recorded in Table 1 are the calculated in-solution half-lives for CF_3D exchange in 1.0 mol/L NaOH solution from 100 to 140°C. The two sets of data are derived from the experimental curved plot in this region and the extrapolated straight line plot in Fig. 1; the latter set will be valid if the mass transfer effect can be eliminated by more efficient gas/liquid mixing. For comparison, some data are included for representative aqueous DMSO systems near the solubility-limited, maximum NaOH concentrations (4). Because the exchange reaction is first order in ^-OH (3), the higher [NaOH] possible in pure water will give shorter reaction half-lives (3). However, proportionately higher *rates* of deuterium exchange would not be fully realized, because of greater salting out of solution of the fluoroform gas with increasing NaOH concentration (3).

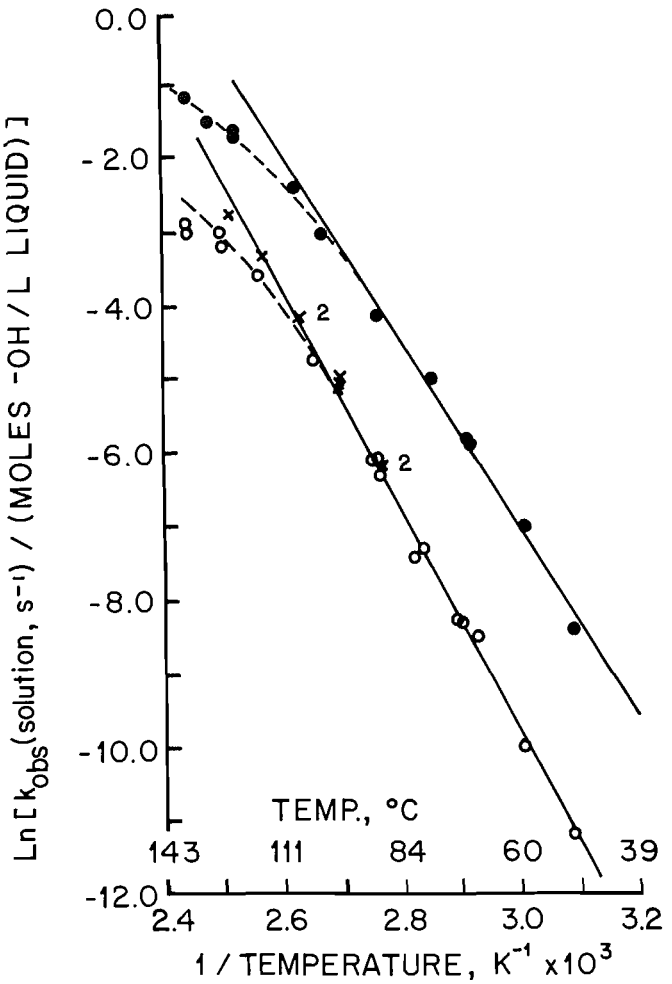

FIG. 1. Temperature dependence of CF_3D/H_2O isotope exchange rate constant for catalysis by (○) 60 mL 1.0 mol/L NaOH solution, and (●) 5 g dried Ionac A-935 resin slurried in 50 mL H_2O, 1.53 mmol ^-OH/g; molar NaOH/resin ^-OH ratio = 7.8. (Points (×) added in press, obtained for 8000 r/min runs in high speed stirred reactor equipped with ferrofluidic rotary feedthrough; mass transfer limitation suppressed.)

TABLE 1. Temperature dependence of in-solution reaction half-life for CF_3D-H_2O exchange in 1.0 mol L/NaOH[a]

Temperature °C	$t_{1/2}$, s (exper.)[b]	$t_{1/2}$, s (extrap.)[c]
100	106	90
110	43	30
120	21	11
130	13	4.1
140	9	1.6

[a]For comparison, the following aqueous DMSO solutions produce similar exchange reactivities: 25 mol% DMSO with 1.0 mol/L NaOH at 68°C, 40 s; 50 mol% DMSO with 0.1 mol/L NaOH at 68°C, 7 s. DMSO thermal stability in alkaline solution may be a problem at higher temperature.

[b]Experimental NaOH line in Fig. 1, including curved section.

[c]Extrapolated straight line for NaOH data in Fig. 1.

We have confirmed that by simply raising the temperature of aqueous solution to about 120°C, fluoroform–water exchange

rate constants comparable to those measured for, e.g., 50 mol% (80 vol%!) DMSO in water at 70°C (4) can be achieved. From an industrial point of view, the expense of handling large volumes of DMSO and of recovering this co-solvent from the effluent water stream can thus be avoided. However, the advantage of higher fluoroform solubility in the aqueous DMSO systems (4) would be lost.

In general, the results of this study look encouraging for the use of aqueous NaOH solution (no DMSO) above ~120°C for a CF_3H redeuteration step.[2] The physical advantage of utilizing *supported* ^-OH groups under packed tower conditions is offset, unfortunately, by the poor thermal stability of commercial anion exchange resins at the temperatures necessary for effective deuterium exchange catalysis. Alternative types of supported basic catalysts are under investigation. Hydrolysis of fluoroform should not be a significant problem.

Structure of the principal antineoplastic glycosides of *Phyllanthus acuminatus* Vahl[1]

GEORGE R. PETTIT, GORDON M. CRAGG, MARGARET L. NIVEN,[2] AND LUIGI R. NASSIMBENI[3]
Cancer Research Institute and Department of Chemistry, Arizona State University, Tempe, AZ 85287, U.S.A.

Received June 20, 1983

GEORGE R. PETTIT, GORDON M. CRAGG, MARGARET L. NIVEN, and LUIGI R. NASSIMBENI. Can. J. Chem. **61**, 2630 (1983).

A series of degradative and X-ray crystallographic studies has led to unequivocal evidence for the structure (**3***a*) assigned to the unique disaccharide phyllanthose. In turn, the X-ray crystal structure of phyllanthose confirms structures previously assigned to the potentially important antineoplastic plant glycosides phyllanthostatins 1 and 2 (**1***a*, *c*) and phyllanthoside (**1***b*). The chemical degradation and crystallographic analyses allowed assignment of structure **2***a* to phyllanthostatin 3.

GEORGE R. PETTIT, GORDON M. CRAGG, MARGARET L. NIVEN et LUIGI R. NASSIMBENI. Can. J. Chem. **61**, 2630 (1983).

Une série d'études impliquant des dégradations et des diffractions de rayons-X a permis d'établir la structure du disaccharide phyllanthose (**3***a*). Cette démonstration de la structure du phyllanthose permet de confirmer les structures attribuées antérieurement aux glycosides phyllanthostatines 1 et 2 (**1***a* et **1***c*) et phyllanthoside (**1***b*), des produits antinéoplastiques potentiellement importants extraits de plantes. Les dégradations chimiques et les analyses cristallographiques permettent d'attribuer la structure **2***a* à la phyllanthostatine 3.

While only a relatively small number (<5%) of higher plants have received even a superficial examination for anticancer constituents, a series of such promising candidates bearing novel structures is beginning to reach clinical trial in the U.S. National Cancer Institutes (NCI) programs. Several are already established drugs for human cancer treatment (1). Analogous chemical and medical progress continues to be made with lower plant biosynthetic products for cancer chemotherapy. New advances in the chemistry of both higher (2) and lower (3) plant antineoplastic components combined with increasing successes in the total syntheses (4, 5) of these very important substances provide an instructive overview.

Recently we summarized the isolation and antineoplastic activity of phyllanthostatins 1–3 (**1***a*, *c*, **2***a*) and phyllanthoside (**1***b*) from roots of the Central American tree *Phyllanthus acuminatus* Vahl (2*a*, *b*). Glycosides **1***a* and **1***b* are two of the higher plant constituents presently being considered by the NCI for eventual clinical trial. The structural assignments for these principal *P. acuminatus* glycosides were based upon detailed interpretation of their high resolution (400 MHz) ^{1}H nmr, ^{13}C nmr, and mass spectra. Assignment (2*a*) of the aglycone unit of glycosides **1***a*–*c* resided upon an earlier X-ray crystallographic study of phyllanthocin (**1***d*) (6), but the unique

evidence for the structure (**3***a*) previously assigned phyllanthose and thereby for the very important glycosides **1***a*–*c*. We also report completion of the phyllanthostatin 3 (**2***a*) assignments by determining the crystal structure of an aglycone segment termed phyllanthocindiol methyl ester (**2***b*).

Selective methanolysis (0.1 *N* sodium methoxide in methanol, 30 min, room temperature) of phyllanthostatin 3 (**2***a*) afforded the aglycone methyl ester **2***b*: crystals from acetone–hexane, mp 127–128°C; $[\alpha]_D^{25}$ +2.45° (*c* 1.63, chloroform).[4] The neutralized (1 *N* hydrochloric acid) aqueous fraction from isolation of ester **2***b* was treated with Amberlite MB-3 and lyophilized to yield phyllanthose (**3***a*) (6); mp 225–229°C; $[\alpha]_D^{26}$ −3.3°; FAB ms *m/e*: 333 $(M + Na)^+$.[4] Phyllanthose (**3***a*) was found identical (ir in KBr, tlc) with the disaccharide (**3***a*) obtained by methanolysis of phyllanthostatin 1 (**1***a*) and phyllanthoside (**1***b*). Peracetylation (acetic anhydride – pyridine, 1:1, room temperature, 2 days) of phyllanthose yielded 2-*O*-(6-deoxy-β-D-glucopyranosyl)-6-deoxy-α-D-glucopyranose hexaacetate (**3***b*) as crystals from acetone–hexane; mp 224–226°C; $[\alpha]_D^{26}$ +71.1° (*c* 0.83, chloroform); and EI ms *m/e*: 562 (M^+), 561 $(M^+ - H)$ and 503 $(M^+ - O_2CCH_3)$.[4]

A single crystal (0.75 × 0.5 × 0.5 mm) of phyllanthocindiol methyl ester (**2***b*) recrystallized from acetone–hexane was analyzed using a Philips PW1100 four-circle diffractometer with CuKα radiation (λ = 1.5418 Å). The crystals were found to exhibit monoclinic space group $P2_1$ with cell constants a = 9.891 (5), b = 24.84 (1), and c = 9.687 (5) Å; β = 94.82 (2) Å by least squares from the setting of 25 high-order reflections. Intensities were collected in the range $8 < 2\theta < 136$ by the $\omega-2\theta$ scan technique and were corrected for Lorentz polarization but not for absorption. Of the 4011 reflections obtained, 3692 (with $I_{rel} > 2\sigma I_{rel}$) were employed in the solution. The crystal density (ρ = 1.21 Mg m^{-3}) gave $Z = 4$ corresponding to two molecules of $C_{25}H_{32}O_8$, M_r = 460.52, per asymetric unit.

The structure (**2***b*) was solved by direct methods using the multisolution tangent refinement procedures of the program SHELX (7). A starting set of eight reflections (with three used for origin definition) generated 256 permutation. Twelve *E*-maps were obtained and the first (reliability index $R_A = 0.138$), which gave 36 of the 66 non-hydrogen atoms, yielded sufficient phase information to locate all the non-hydrogen atoms in subsequent weighted difference syntheses. The hydrogens of CH_2 and CH units were placed at 1.00 Å from their parent carbons and their positions were dictated by the geometry of the molecule. Methyl hydrogens were treated as rigid groups. Hydroxyl hydrogens (on 07 and 014) were not revealed in the final difference maps, and are not included in the final model. However, there is strong evidence for both intra- and intermolecular H-bonding involving the 07 and 014 atoms. Because of the large number of independent atoms, final refinements were accomplished using the blocked-matrix technique with the non-hydrogen atoms treated anisotropically and the hydrogen atoms isotropically to provide a final $R = 0.072$ (R_w = 0.085, $w = (\sigma^2 F + 0.002F^2)^{-1}$.

By the same general X-ray crystallographic techniques, a single crystal (0.15 × 0.25 × 0.50 mm) of phyllanthose peracetate (**3***b*) led to the following summary data: space group $P2_1$ with a = 13.077 (7), b = 9.306 (5), and c = 12.009 (6) Å with β = 92.33 (2) Å. As above, intensities were collected in the range $10° < 2\theta < 120°$ by the $\omega-2\theta$ scan technique. A total of 2299 reflections was obtained and 1930 (with $I_{rel} > 2\sigma I_{rel}$) were employed in the solution. Density (ρ = 1.24 Mg m^{-3}) of the crystal gave $Z = 2$, allowing one molecule of $C_{24}H_{34}O_{15}$ with M_r = 562.52 for each asymmetric unit.

The program SHELX (7) was employed as outlined above, using a starting set of eleven reflections to generate 256 permutations. Of the twelve *E*-maps obtained, the fifth (reliability index $R_A = 0.129$) gave, as a recognizable molecular fragment, 21 of the 39 non-hydrogen atoms in the asymmetric unit. Weighted difference syntheses yielded the remaining non-hydrogen atoms. Hydrogen atoms were placed at 1.00 Å from their respective carbon atoms and their positions were based on the geometry of the molecule. Again, methyl hydrogens were handled as rigid groups. Because of the large number of independent atoms, final refinements were performed using the blocked-matrix technique with the non-hydrogen atoms treated anisotropically and the hydrogen atoms isotropically to yield $R = 0.053$ (unit weights).

Completion of the X-ray crystal structure determinations of phyllanthocindiol methyl ester (**2***b*) and phyllanthose acetate (**3***b*) clearly substantiates the assignment of structure **2***a* to phyllanthostatin 3 and confirms the previous (**2***a*, *b*) assignments of phyllanthostatins 1 and 2 (**1***a*, *c*) and of phyllanthoside (**1***b*). Presently, the results of these structural elucidations are being employed in establishing structures for related glycosides in this potentially important series of biosynthetic products.

Glycosides from *Muscari comosum*. 4.[1] Structure of muscaroside A[2]

M. ADINOLFI, G. BARONE, R. LANZETTA, G. LAONIGRO, L. MANGONI, AND M. PARRILLI[3]

Istituto di Chimica Organica e Biologica della Università di Napoli, Via Mezzocannone 16, 80134 Napoli, Italy

Received March 9, 1983

M. ADINOLFI, G. BARONE, R. LANZETTA, G. LAONIGRO, L. MANGONI, and M. PARRILLI. Can. J. Chem. **61**, 2633 (1983).

The less polar component of the glycoside mixture extracted from the bulbs of *Muscari comosum* has been completely characterized. This glycoside, **5**, possesses an α-L-rhamnopyranosyl(1→2)-β-D-glucopyranosyl(1→2)-α-L-arabinopyranosyl-(1→6)-β-D-glucopyranosyl chain linked at the C-3 position of eucosterol **1**.

M. ADINOLFI, G. BARONE, R. LANZETTA, G. LAONIGRO, L. MANGONI et M. PARRILLI. Can. J. Chem. **61**, 2633 (1983).

On a identifié complètement le composé le moins polaire du mélange de glycosides extrait des bulbes du *Muscari comosum*. Ce glycoside, **5**, possède une chaîne de α-L-rhamnopyrannosyl(1→2)-β-D glucopyrannosyl(1→2)-α-L-arabinopyrannosyl-(1→6)-β-D glucopyrannosyle, liée au carbone en position 3 de l'eucostérol (**1**).

[Traduit par le journal]

Muscari comosum Mill. is a plant widely distributed in the Mediterranean area. Its aqueous extracts have been reported (1) to display antitumoral activity. Recently we have isolated from the bulbs of the plant a complex glycoside mixture and identified aglycone moieties **1**−**4** (2−4). Compounds **1**−**4** possess a 27-norlanostane skeleton and are characterized by the unique structural feature constituted by a tetrahydrofuran ring spirofused at the C-17 position. In continuation of our study on this subject, we report now the isolation and the structural elucidation of muscaroside A, **5**, the less polar component of the glycoside mixture. It possesses an α-L-rhamnopyranosyl-(1→2)-β-D-glucopyranosyl(1→2)-α-L-arabinopyranosyl(1→6)-β-D-glucopyranosyl chain as its sugar moiety linked at the C-3 position of eucosterol **1**.

Column chromatography (silica gel) of the crude glycoside mixture extracted (4) from the bulbs afforded four main fractions. High performance liquid chromatography (hplc) of the less polar one yielded muscaroside A. This was shown to be homogeneous by spectroscopy (^{13}C and ^{1}H nmr, Tables 1 and 2, respectively) and by degradative experiments (see below). Muscaroside A is levorotatory, $[\alpha]_D$ −20°, and melts at ca. 205°C with decomposition. Chemical analysis gave $C_{52}H_{82}O_{23}$, according to the pseudo-molecular ion peak (MH^+ 1075) in the FAB mass spectrum. On enzymatic hydrolysis, it yielded eucosterol **1** as aglycone, identified by comparison (tlc, mp, ^{13}C and ^{1}H nmr) with an authentic sample.

The acid hydrolysis (7% H_2SO_4) of muscaroside A gave rhamnose, arabinose, and glucose, identified by tlc. In the ^{1}H nmr spectrum (DMSO-d_6) of this monose mixture the signals of the anomeric protons of rhamnopyranose, glucopyranose, arabinopyranose, and arabinofuranose were identified through a comparison with the signals displayed by equilibrated authentic samples of the monoses and attributed on the basis of the displayed shifts and coupling constants (5). The integration of the anomeric proton signals established the 1:2:1 molar ratio of rhamnose, glucose, and arabinose. The monoses were identified also by hplc analysis of the hydrolysate, and calibration of the peak integrated areas against known concentrations confirmed that molar ratio. Isolation of the three monoses from the hydrolysate by hplc and determination of their rotations established the absolute D-configuration of glucose and the L-configuration of arabinose and rhamnose. The L-configuration of arabinose was confirmed by the positive response of a D-galactose dehydrogenase test (6, 7).

Permethylation (DMF/NaH/MeI) (8) of muscaroside A and subsequent acid hydrolysis (2 *N* HCl/dioxane) afforded, after column chromatography, 2,3,4-tri-*O*-methyl-L-rhamnopyranose, 3,4,6-tri-*O*-methyl-D-glucopyranose, 2,3,4-tri-*O*-methyl-D-glucopyranose, and 3,4-di-*O*-methyl-L-arabinopyranose, identified by comparison (tlc, ^{1}H nmr) with authentic samples. Methanolysis (anhydrous HCl/MeOH) of the permethylated muscaroside A followed by column chromatography gave methyl 3,4,6-tri-*O*-methyl-α-D-glucopyranoside, methyl 2,3,4-tri-*O*-methyl-α-D-glucopyranoside, and methyl 3,4-di-*O*-methyl-α-L-arabinopyranoside, identified by comparison (tlc, ^{1}H nmr) with authentic samples. We were not able to isolate the permethylation−methanolysis product of the rhamnose unit in a pure form. However, all these data safely establish the interglycosidic linkages in muscaroside A and the sugar-ring size; more precisely, L-rhamnopyranose is the terminal sugar unit, L-arabinopyranose is linked at position 2, one D-glucopyranose is linked at position 2, and the other at position 6.

The configuration at the anomeric centres of the monose units of muscaroside A was suggested by consideration of molecular rotation values in the light of Klyne's rule (9). Calculation (Table 3) led to the conclusion that α-configuration of the anomeric centres of the rhamnose and arabinose units and β-configuration of the anomeric centres of the two glucose units may be assumed.

The ^{13}C and ^{1}H nmr spectra of muscaroside A agreed with all above conclusions and also indicated the attachment position of the sugar chain to the aglycone moiety.

The significant (+9.0) downfield shift observed for the C-3 of the aglycone unit clearly indicates (10−13) that this carbon bears the sugar chain. Furthermore, deshielding of G′-6 and G″-2 and shielding of the adjacent carbons G′-5, G″-1, and G″-3 fully accord (10−13) with the above established interglycosidic linkages involving the glucose units. Given the size of the coupling constants (14) (Table 1), the signals at δ 102.0 and δ 101.2 in the ^{13}C-spectrum in Py-d_6 may be attributed to R-1 and A-1 respectively. However, the unchanged shifts of the other carbons of the rhamnose unit, as compared to those of methyl α-L-rhamnopyranoside, agreed with the terminal location of rhamnose. Furthermore, the line of A-1 is shifted

upfield as compared to that of the reference compound and this, besides the downfield shift of A-2, indicates that arabinose is linked at this latter position.

TABLE 3. Calculated and observed contribution of the sugar chain to the $[M]_D$ of muscaroside A, **5**[a]

Chain	$[M]_D$
Methyl α-D-glucopyranoside	+309°
Methyl β-D-glucopyranoside	−66°
Methyl α-L-arabinopyranoside	+17°
Methyl β-L-arabinopyranoside	+245°
Methyl α-L-rhamnopyranoside	−111°
Methyl β-L-rhamnopyranoside	+170°
β-D-glu*p* + α-L-ara*p* + β-D-glu*p* + α-L-rha*p*	−225°[b]
$[M]_{D_{muscaroside\ A}} - [M]_{D_{eucosterol\ 1}}$	−304°

[a]$[M]_D$ values of methyl glycosides are taken from ref. 23.
[b]All other possible combinations give much more positive values.

The anomeric proton signals (methanol-d_4) at δ 4.42 and 4.69 may be attributed to G′-1-H and G″-1-H, respectively, as they were correlated to the signals (methanol-d_4) of G′-1 and G″-1, respectively, by pertinent heteronuclear selective decoupling experiments. The $J^{3}_{H\text{-}1,H\text{-}2}$ coupling constant values (~7 Hz) are compatible only with β-configuration at these centres (5). Accordingly (14), the values 158 and 154 Hz were observed for the $J^{1}_{C\text{-}1,H\text{-}1}$ of G′-1 and G″-1 in the spectrum in Py-d_5. The α-configuration of the L-rhamnose anomeric centre

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

was confirmed by the good agreement in the R-3 and R-5 peaks (δ 72.7 and δ 69.5, respectively, in Py-d_5) with the values given for methyl α-L-rhamnopyranoside (δ 72.5 and δ 69.4, respectively), the values for the β-anomer being instead δ 75.3 and δ 73.4, respectively (15).

No further support for the α-configuration of the L-arabinose unit could be drawn from the nmr data. In the ^{1}H nmr spectrum of muscaroside A in methanol-d_4 the signal at δ 4.63, J = 4.4 Hz, may be attributed to the anomeric proton of the arabinose unit, as the remaining anomeric signal (δ 5.25, J = 1.5 Hz) fits the R-1-H proton well (15, 16). The 4.4 Hz value for $J^3_{H\text{-}1,H\text{-}2}$ of the arabinose unit falls in a range which has often been taken as an indication of α-configuration (17, 18). More recently, however, the value of this coupling constant, as well as $J^1_{C\text{-}1,H\text{-}1}$, has been reported (19) not to be diagnostic on its own, owing to the high conformational mobility of arabinopyranosides ($^4C_1 \rightleftarrows {}^1C_4$) (20). Finally, shift values (δ 66.5 and δ 64.2) attributed (Table 1, Py-d_5) to A-4 and A-5, respectively, accorded neither with the corresponding values (δ 69.1 and δ 66.6, respectively) given for reference methyl α-L-arabinopyranoside nor with the values (δ 70.8 and δ 63.9, respectively) given (21) for methyl β-L-arabinopyranoside. However, we have found shifts similar to those reported (19) for carbons 4 and 5 of the 2-linked α-arabinopyranose units of a series of glycosides. In conclusion, α-configuration of the arabinose unit in muscaroside A rests only on the evidence afforded by the application of Klyne's rule. This indication, however, appears to be particularly sound, as the alternative combination β-D-glu*p* + β-L-ara*p* + β-D-glu*p* + α-L-rha*p* implies (Table 3) a contribution of +2° to the $[M]_D$ of **5**, much further indeed from the observed value (−304°).

Sequence of the monose units in muscaroside A was readily arrived at as follows. Rhamnose having been established as the terminal unit, the small value (+4.5) of the glycosylation shift of G″-2 indicates (22) that the glucose unit linked at position 2 is glycosylated by rhamnose. Furthermore, a significant Overhauser effect was measured for the signal at δ 4.42 (in methanol-d_4) of the anomeric G′-1-H of the other glucose unit upon irradiation of the 30-H_3 protons of muscaroside A. This result indicates spatial proximity between the G′-1-H and the 30-H_3 protons and established that the glucose unit substituted at position 6 is directly linked to the C-3 carbon of the aglycone moiety. The location of the arabinose unit between the two glucose units necessarily follows.

Experimental[4]

General

Melting points were determined with a Kofler block. The ^{1}H (270 MHz) and ^{13}C nmr (67.88 MHz) spectra were taken on a Fourier transform Bruker instrument WH 270 (TMS as internal reference) with an Aspect 2000 computer with 48 K memory (32 K data). Nuclear Overhauser enhancement effects were obtained in the difference mode as reported in ref. 3. Mass spectra were recorded with a Kratos 902 instrument equipped with a FAB source. Rotations were determined on a Perkin–Elmer 141 polarimeter. The hplc was performed with a Varian 5020 instrument using a differential refractometer Waters R 401 as the detector. The tlc was carried out on precoated silica gel layers (0.25 mm, Merck F_{254}). Silica gel 0.05–0.20 (Merck) was used for column chromatography. Sugars and methylated sugars were detected with aniline phtalate or *p*-anisaldehyde, glycosides and aglycone with chromium oxide/sulphuric acid.

[4]With the assistance of Italo Giudicianni.

Reference methylated sugars

These were obtained by permethylation (NaH/DMF/MeI, see below) followed by acid hydrolysis (1:1 2 *N* HCl/dioxane, 4 h, reflux) or methanolysis (anhydrous 3% HCl/MeOH, 3 h, 90°C) from starting material indicated below and were purified by preparative tlc (97:3 or 9:1 chloroform–methanol).

Methyl 2,3,4-tri-*O*-methyl-β-L-rhamnopyranoside was obtained by permethylation of L-rhamnose. Acid hydrolysis of the former gave 2,3,4-tri-*O*-methyl-L-rhamnopyranose. 3,4,6-Tri-*O*-methyl-D-glucopyranose was prepared by permethylation and acid hydrolysis from naringin (Fluka AG). Methyl 3,4,6-tri-*O*-methyl-α-D-glucopyranose was prepared by permethylation and acid methanolysis from naringin. 2,3,4-Tri-*O*-methyl-D-glucopyranose was prepared by permethylation and acid hydrolysis from rutin (Fluka AG). Methyl 2,3,4-tri-*O*-methyl-α-D-glucopyranoside was prepared by permethylation and acid methanolysis from rutin. Methyl 3,4-di-*O*-methyl-L-arabinopyranosides were prepared as in ref. 24. Their acid hydrolysis gave 3,4-di-*O*-methyl-L-arabinopyranose.

The ^{1}H nmr data of methylated sugars are summarized in Table 4.

Isolation of muscaroside A

The glycoside mixture (9 g), extracted from sliced fresh bulbs (1 kg) of the plant as reported in ref. 4, was chromatographed on a silica gel (200 g) column with a Chromatospac Prep. 10 apparatus (Jobin Yvon). Elution with 3:2 chloroform–methanol afforded four main fractions: *a* (1.4 g), *b* (2 g), *c* (1.5 g), and *d* (1 g) (decreasing R_f order).

Fraction *a* was subjected to semi-preparative hplc (Lichrosorb RP-18 (7 μm) column, 75:25 methanol–water, 5 mL min^{-1}, 75 mg in 1 mL of 75:25 methanol–water) to give muscaroside A (215 mg); mp (from ethanol) 205°C dec.; $[\alpha]_D$ −20° (methanol, *c* 0.6); FAB-ms: 1074 *m/e*. Elemental analysis: C 57.9, H 7.6 ($C_{52}H_{82}O_{23}$ requires C 58.1, H 7.7%). The ^{1}H and ^{13}C nmr data are given in Tables 2 and 1, respectively.

Enzymatic hydrolysis of muscaroside A

To a solution of muscaroside A (30 mg) in water (10 mL), digestive juice of *Helix pomatia* (0.1 mL, Industrie Biologique Française) was added. The solution was stirred for 40 days at room temperature and then extracted with chloroform. Evaporation of the chloroform extract gave a solid (8 mg). Preparative tlc (4:1 chloroform – ethyl acetate, 2 runs) yielded eucosterol **1** (6 mg), identical (mp, ms, ^{1}H nmr) to an authentic sample (4, 25).

Acid hydrolysis of muscaroside A

A solution of muscaroside A (50 mg) in 7% H_2SO_4 (5 mL) was heated at 90°C for 3 h. The solution was cooled and washed with chloroform. The aqueous layer was filtered through an Amberlite IR-4B (OH) (2 g) column and the eluate was freeze-dried to give a solid (28 mg, monose mixture).

A sample was dissolved in water and analyzed by tlc (silica gel layers, 14:6:1 chloroform–methanol–water and silica gel layers treated with 0.2 *N* sodium acetate, 24:12:64 isopropanol–water – ethyl acetate); the presence of rhamnose, glucose, and arabinose was established by comparison with authentic samples.

Anomeric proton signals in the ^{1}H nmr spectrum (DMSO-d_6) δ: 4.84 d, J = 1.7 Hz and 4.56 bs (α- and β-anomer, respectively, of rhamnopyranose); 4.23 d, J = 7.7 Hz and 4.92 d, J = 3.4 Hz (β- and α-anomer, respectively, of glucopyranose); 4.23 d, J = 6.5 Hz and 4.87 d, J = 3.0 Hz (α- and β-anomer, respectively, arabinopyranose); 4.92 d, J = 3.0 Hz and 5.01 d, J = 3.9 Hz (α- and β-anomer, resp. of arabinofuranose). The integration of these signals established the molar ratio 1:2:1 rhamnose/glucose/arabinose.

A sample of the monose mixture was analyzed at hplc (Lichrosorb NH_2 (10 μm); 4:1 acetonitrile–water; 0.5 mL min^{-1}). Glucose (t_r 18.3 min), arabinose (t_r 13.7 min), and rhamnose (t_r 10.4 min) were identified by comparison with authentic samples. The areas of the peaks were in the same ratio as those of a 2:1:1 mixture of authentic glucose, rhamnose, and arabinose.

Semi-preparative hplc with the same column (1.5 mg per 200 μL, 4:1 acetonitrile–water) allowed separation of D-glucose ($[\alpha]_D$ +58°

TABLE 4. ^{1}H nuclear magnetic resonance ($CDCl_3$) shifts (δ) of reference methylated sugars

	Anomeric protons		Methoxyl protons	
	α	β	α	β
2,3,4-Tri-*O*-methyl-L-rhamnopyranose[a]	5.26 bs	4.64 bs	3.51 (6H), 3.56	3.54 3.56, 3.67
Methyl 2,3,4-tri-*O*-methyl-β-L-rhamnopyranoside[b]		4.27 s		3.49 3.51 3.56 3.64
3,4-Di-*O*-methyl-L-arabinopyranose	4.62 d *J* = 7.4 Hz	5.29 d *J* = 3.7 Hz	3.47, 3.47, 3.51, 3.54,	
Methyl 3,4-di-*O*-methyl-L-arabinopyranoside	4.13 d *J* = 7.4 Hz	4.80 d *J* = 3.7 Hz	3.47, 3.51 3.55	3.50, 3.47 3.45
3,4,6-Tri-*O*-methyl-D-glucopyranose	5.26 d *J* = 4.0 Hz	4.57 d *J* = 7.7 Hz	3.49, 3.54 (6H), 3.56, 3.66, 3.67	
Methyl 3,4,6-tri-*O*-methyl-α-D-glucopyranoside	4.76 d *J* = 4.5 Hz		3.42 (6H), 3.53, 3.66	
2,3,4-Tri-*O*-methyl-D-glucopyranose	5.32 d *J* = 3.7 Hz	4.61 d *J* = 7.4 Hz	3.53, 3.54, 3.56, 3.63, 3.63 (6H)	
Methyl 2,3,4-tri-*O*-methyl-α-D-glucopyranoside	4.81 d *J* = 3.3 Hz		3.41, 3.52, 3.58, 3.63,	

[a]Chemical shifts of —CH_3 at C-5: 1.29 (d, *J* = 6.6 Hz, α-anomer), 1.33 (d, *J* = 6.6 Hz, β-anomer).
[b]Chemical shift of —CH_3 at C-5: 1.36 (d, *J* = 6.6 Hz).

(final, H_2O), lit. (26*a*) +53° (final)); L-arabinose ($[\alpha]_D$ +102° (final, H_2O), lit. (26*b*) +105° (final)); and L-rhamnose ($[\alpha]_D$ +10° (final, H_2O), lit. (26*c*) +8° (final)). The L-arabinose sample obtained produced the expected response with the D-galactose dehydrogenase system in an assay for determination of L-arabinose as described in ref. 7 and in the information sheet from Boehringer Mannheim GMBH.

Permethylation of muscaroside A

To a solution of **5** (100 mg) in anhydrous dimethylformamide (20 mL), NaH (400 mg) was added and the mixture was stirred in an ice bath for 15 min. Methyl iodide (15 mL) was added and the mixture was stirred for 10 min in the ice bath and for 12 h at room temperature. The excess of sodium hydride was destroyed by adding methanol (2 mL). After evaporation at reduced pressure, the residue was treated with water and chloroform. The chloroform layer was evaporated. The residue (120 mg) is a complex mixture since the aglycone moiety undergoes changes in the alkaline medium of reaction (25). However, the occurrence of a complete permethylation was confirmed by the ir spectrum which showed no —OH absorption. Conclusive evidence was furnished by the fact that attempts at further methylation (with $NaH/CH_3I/DMF$) or acetylation (Ac_2O/Py) left the sample totally unchanged (tlc, ir, nmr).

Acid hydrolysis of permethylated muscaroside A

Permethylated muscaroside A (60 mg) was hydrolyzed with 1:1 dioxane − 2 *N* HCl (10 mL) by refluxing for 6 h. The cooled mixture was neutralized with solid Na_2CO_3 and evaporated. The residue was extracted with chloroform and the chloroform extract was evaporated. The residue (60 mg) was chromatographed on a column of silica gel (8 g). Elution with chloroform containing increasing percentages of ethyl acetate afforded pure 2,3,4-tri-*O*-methyl-L-rhamnopyranose (9 mg), 3,4,6-tri-*O*-methyl-D-glucopyranose (10 mg), 2,3,4-tri-*O*-methyl-D-glucopyranose (10 mg), and 3,4-di-*O*-methyl-L-arabinose (8 mg) which were identified by comparison (tlc, 1:9 methanol−water, 1 run; ^{1}H nmr: see Table 4) with authentic samples.

Acid methanolysis of permethylated muscaroside A

Permethylated muscaroside A (60 mg) was heated in anhydrous HCl/methanol (3%, 5 mL) at 90°C for 3 h. After cooling, the mixture was neutralized with Ag_2CO_3, filtered, and evaporated. The residue (60 mg) was chromatographed on a column of silica gel (12 g). Elution with chloroform containing increasing percentages of ethyl acetate yielded pure methyl 3,4,6-tri-*O*-methyl-α-D-glucopyranoside, methyl 2,3,4-tri-*O*-methyl-α-D-glucopyranoside, and methyl 3,4-di-*O*-methyl-α-L-arabinopyranoside which were identified by comparison (tlc, 3:97 methanol−chloroform, 1 run; ^{1}H nmr: see Table 4) with authentic samples.

The intercalation of bromine fluorosulfates into graphite

S. KARUNANITHY and F. AUBKE

Department of Chemistry, The University of British Columbia, Vancounver, B.C., Canada, V6T 1Y6

Received April 8, 1983

S. KARUNANITHY and F. AUBKE. Can. J. Chem. **61**, 2638 (1983).

The action of bromine(I)fluorosulfate on graphite has led to the synthesis of several novel intercalation compounds. The intercalation of bromine(I)fluorosulfate at room temperature results in a first stage compound, $C_{12}BrSO_3F$, while at higher temperatures (~110°C) $C_{20}BrF(SO_3F)_2$ forms instead. Oxidation of $C_{12}BrSO_3F$ with $S_2O_6F_2$ yields $C_{16}Br(SO_3F)_3$ and this reaction can be reversed by reacting the latter with an excess of Br_2.

Graphite trifluoromethylsulfate $C_{12}SO_3CF_3$ is formed in the solvolysis of $C_{12}BrSO_3F$ with an excess of trifluoromethylsulfuric acid. First stage nature of these compounds has been confirmed by the X-ray identity period along *C* axis and $\nu_{E_{2g}}$ vibrational lattice mode in the Raman spectra. The use of ^{19}F nmr in identifying the chemical species in the inter-lamellar space has been demonstrated. The planar electrical conductivity of these compounds has been observed to be three to six times higher than that of graphite.

S. KARUNANITHY et F. AUBKE. Can. J. Chem. **61**, 2638 (1983).

L'action du fluorosulfate de brome(I) sur le graphite conduit à la synthèse de plusieurs noveaux composés d'insertion. L'insertion du fluorosulfate de brome(I) à la température ambiante conduit dans un premier temps au composé $C_{12}BrSO_3F$ tandis qu'à des températures plus élevées (~110°C) il se forme de préférence le composé $C_{20}BrF(SO_3F)_2$. L'oxydation du composé $C_{12}BrSO_3F$ par le $S_2O_6F_2$ donne le composé $C_{16}Br(SO_3F)_3$ et on peut inverser cette réaction en faisant réagir le produit obtenu avec un excès de Br_2.

La solvolyse du $C_{12}BrSO_3F$ dans de l'acide trifluorométhylsulfurique en excès conduit à la formation du trifluorométhylsulfate de graphite $C_{12}SO_3CF_3$. On a confirmé la nature du premier stade de ces composés, par la période d'identité aux rayons X le long de l'axe *C* et par le mode de réseau vibrationnel $\nu_{E_{2g}}$ des spectres Raman. On met en évidence l'utilisation de la rmn du ^{19}F pour identifier les espèces chimiques dans l'espace interlamellaire. On a observé que la conductivité électrique planaire de ces composés est de 3 à 6 fois plus élevées que celle du graphite.

[Traduit par le journal]

1. Introduction

The intercalation of a rather wide range of elements and molecular compounds into the layer lattice of graphite is well documented and a large number of lamellar compounds of graphite have been synthesized and extensively studied over the years (1, 2). Recent interest in intercalation compounds of graphite has focussed in particular on those compounds where molecular intercalants are capable of acting as electron acceptors, giving rise to intriguing electronic properties and reactivities (3), with a wide range of possible applications (4).

Two examples, both germane to our study, may serve as illustrations. Intercalation of bromine was first observed in 1933 (5), with the highest degree of saturation found for a second stage compound of the stoichiometry C_8Br (6). The mechanism of intercalation by Br_2 and the nature of the resulting materials, in particular the extent of electron transfer from graphite to intercalant, have all been the subject of numerous studies (1, 2).

The oxidative intercalation of bis(fluorosulfuryl)peroxide, $S_2O_6F_2$, on the other hand, was first reported in 1978 (7) with the highest saturation found in first stage compounds of the stoichiometry C_nSO_3F with *n* between 7 and 8 (8, 9). The electron transfer appeared to be complete and formulation of the product as graphite salt $C_n^+SO_3F^-$ seemed justified in this case.

We became interested in attempting the intercalation of bromine(I)fluorosulfate for a number of reasons.

(*i*) $BrSO_3F$ is obtained by the reaction of Br_2 with $S_2O_6F_2$ according to reaction [1] (10,11):

$$[1]\quad Br_2(l) + S_2O_6F_2(l) \rightarrow 2\ BrSO_3F(l)$$

Since both "parent molecules" Br_2 and $S_2O_6F_2$ intercalate, the chance that $BrSO_3F$ would intercalate as well appeared rather high, even though no previous intercalation by any halogen oxyacid derivative (12) seemed to have been undertaken.

(*ii*) The physical properties of bromine(I)fluorosulfate (11) suggested possible intercalation with $BrSO_3F$ either in the gas or the liquid phase. Its chemical behavior as "pseudohalogen" with positively polarized bromine should facilitate charge transfer and formation of an acceptor intercalation compound.

(*iii*) Two typical chemical reactions of $BrSO_3F$, the further oxidation of bromine(I)fluorosulfate (10):

$$[2]\quad BrSO_3F + S_2O_6F_2 \rightarrow Br(SO_3F)_3$$

and its complex formation with metal fluorosulfates (13), e.g.

$$[3]\quad CsSO_3F + BrSO_3F \rightarrow Cs[Br(SO_3F)_2]$$

could possibly be extended to intercalated systems. Again very little reaction chemistry of intercalants in the graphite lattice seemed to have been studied so far and it became a challenge to see to what extent reactivity is affected by intercalation.

2. Experimental

(a) Chemicals

One type of natural graphite (Ticonderoga mines, New York) and two synthetic Graphites, powdereus SP 1 (Union Carbide) and HOPG (highly oriented pyrolytic graphite) in plate and powder form were used in this study. All graphite samples were dried *in vacuo* at 150°C over a period of 24 h, immediately prior to use. Bis-(fluorosulfuryl)peroxide, $S_2O_6F_2$ (14), and bromine(I)fluorosulfate, $BrSO_3F$ (11), were synthesized according to published methods. All other chemicals were obtained from commercial sources in the highest grade of purity available.

(b) Instrumentation

A Spex Ramalog 5 Spectrometer, equipped with an Ar^+ laser (Spectra Physics 164) with the 514.5 nm line was used for excitation. A back scattering geometry was used similar to the one described in the literature (15). The sample was contained in a Teflon sample holder,

fitted with circular quartz windows. Spectra were recorded on low laser output power to prevent de-intercalation. X-ray powder photographs were obtained using a Phillips powder camera of 57 mm radius and a Cu source. Samples were sealed in 0.5 mm od Lindemann glass capillaries.

Room temperature ^{19}F solid state nmr spectra were taken at 188 MHz with a Brucker CXP-200 Fourier Transform-NMR spectrometer using a high power ^{19}F probe. Samples were contained in nmr tubes of 30 mm length with a 5 mm od. Electrical conductivity measurements were made at room temperature, employing a contactless radio frequency technique (16). The ferrite core system was used at an induction frequency of 16.8 kHz. Samples of a thickness of 0.2 to 0.4 mm were used for both calibration and measurements.

The conductivity σ was evaluated from the relationship $\Delta V = Kts^2\sigma$, where ΔV = voltage change observed in the sensory coil (using a Keithley 148 Nano voltmeter), t = thickness of the sample (measured with a tool makers micrometer), and s = area of plate (measured with a travelling microscope). The system was calibrated with samples of known resistivity (e.g. Cu, Al, brass, and Pb) in order to obtain K. The resistivity of these samples was checked by means of the four point method (17).

Microanalysis for sulfur bromine and fluorine contents was performed by Analytische Laboratorien, Gummersbach, West Germany. Chemical analysis for carbon and hydrogen was carried out by Mr. P. Borda of this department. A Carbo Erba Model 1106 analyser employing a flash oxidation technique was used and CuO was added to samples. Details of the method were similar to those given in a recently published report (18).

Standard vacuumline techniques were used for the transfer of volatile materials. Solids were manipulated in a Vacuum Atmosphere Corp. "Dri lab", Model HE-43-2, filled with purified dry nitrogen and equipped with a "Dri-Train" Model No. He-93-B circulating unit. Reactions, oxidative intercalation, as well as solvolysis were performed in Pyrex reaction vials fitted with Teflon stem valves (Kontes Glasware). All reactions were followed by recording weight changes.

(c) Synthesis and chemical analysis

(i) The reaction of $BrSO_3F$ with graphite at ambient temperature

In a typical reaction 0.5237 g of vacuum dried graphite powder (SP-1) was allowed to react with ~20 mL of freshly prepared $BrSO_3F$ for a period of 48 h, with the suspension vigorously stirred magnetically. The reddish-brown colour of pure $BrSO_3F$ persisted in the liquid phase throughout the reaction and no evidence for bromine formation could be detected.

Excess $BrSO_3F$ was removed in a dynamic vacuum. Since intercalated $BrSO_3F$ gives a ^{19}F nmr signal at 9.3 ppm relative to $CFCl_3$ and surface adsorbed material resonates at about 35 ppm, ^{19}F nmr could be used to monitor the evaporation process. The signal at 9.3 ppm was found to persist even after prolonged pumping, while the 35 ppm signal eventually disappeared. The resulting solid showed a deep blue luster. Gravimetry gave slightly varying compositions depending on the type of graphite used. Natural graphite flakes: $C_{12.14}BrSO_3F$, HOPG plates: $C_{12.6}BrSO_3F$ and SP-1 powder: $C_{12.03}BrSO_3F$. The SP-1 sample had an interlayer separation $I_c = 7.75 \pm 0.03$ Å. *Anal.* calcd. for $C_{12}BrSO_3F$: C 44.59, S 9.91, Br 24.74, F 5.88; found: C 44.47, S 10.22, Br 24.48, F 5.75. Higher stage compounds used for electrical conductance studies are more conveniently prepared inside the conductance cell by gas phase intercalation. The composition of these samples was determined gravimetrically after prolonged pumping.

(ii) The reaction of $BrSO_3F$ with graphite at 105 to 110°C

In a typical reaction 0.1776 g of graphite powder was heated to 105 to 110°C together with about 20 mL of freshly prepared $BrSO_3F$ for a period of about 48 h. Bromine released during the reaction was evident in the gas phase. Volatile materials were removed *in vacuo* until constant weight of 0.4038 g was reached and a black–blue solid was obtained. *Anal.* calcd. for $C_{20}BrF(SO_3F)_2$: C 44.71, Br 14.87, S 11.93, F 10.61; found: C 44.50, Br 14.90, S 12.08, F 10.55. Interlayer separation. $I_c = 7.76 \pm 0.03$ Å.

(iii) The reaction of $C_{12}BrSO_3F$ with $S_2O_6F_2$

In a typical reaction 0.2785 g of graphite powder were converted quantitatively into $C_{12}BrSO_3F$ following the procedure described above. The composition of the product was determined gravimetrically and an excess of $S_2O_6F_2$ was distilled onto the black–blue solid and the suspension was stirred magnetically for 48 h at room temperature. Removal of all volatiles over several days in a dynamic vacuum to constant weight yielded 0.8291 g of final product. Gravimetry suggested a composition $C_{15.9}Br(SO_3F)_3$, while microanalysis agrees well with $C_{16.5}Br(SO_3F)_3$. *Anal.* calcd.: C 34.43, Br 13.91, F 9.91; found: C 34.48, Br 14.04, F 10.01. Interlayer separation = 7.92 Å.

(iv) The reactionof C_7SO_3F with $BrSO_3F$

In a typical reaction 0.3045 g of C_7SO_3F, prepared from the interaction of SP-1 graphite powder with an excess of $S_2O_6F_2$, was allowed to react with an excess of $BrSO_3F$ for 48 h. The excess of $BrSO_3F$ was subsequently removed *in vacuo*. Initially samples exhibiting two broad ^{19}F nmr signals at 11 and 32 ppm respectively were obtained but continued pumping produced a sample with a single line at 10.16 ppm and small shoulders at 22.4 and 25.3 ppm respectively. The interlayer separation of the product was 7.86 ± 0.03 Å and microanalysis gave C 45.45, Br 1.88.

(v) The reaction of $C_{16}Br(SO_3F)_3$ with Br_2

In a typical reaction 0.1550 g of graphite were first converted to $C_{12}BrSO_3F$ and then to $C_{16}Br(SO_3F)_3$ as described above. Reaction of $C_{16}Br(SO_3F)_3$ with an excess of bromine at room temperature for 24 h and removal of all volatiles yielded 0.3481 g of $C_{12}BrSO_3F$. *Anal.* calcd. for $C_{11.98}BrSO_3F$: C 44.52; found C 44.77.

(vi) The reaction of $C_{12}BrSO_3F$ with HSO_3CF_3

As described before 0.2749 g of graphite was converted to 0.6166 g of $C_{12}BrSO_3F$, which was subsequently reacted with about 10 mL of freshly distilled HSO_3CF_3 for 48 h. Evolution of Br_2 was noted during the reaction and 0.5873 g of the composition ~$C_{12}SO_3CF_3$ were obtained and identified by an interlayer separation of 8.08 ± 0.03 Å, in good agreement with the published value (9). *Anal.* calcd.: C 51.24; found C 51.01.

Results and discussion

The intercalation of bromine(I)fluorosulfate into graphite proceeds smoothly and efficiently at room temperature over a period of 48 h to give a deep blue intercalation compound of the limiting composition $C_{12}BrSO_3F$, according to:

[4] $12C + BrSO_3F \rightarrow C_{12}BrSO_3F$

Small variations in the composition of the final product depend on the type of graphite used and may be due to differences in flake size and the degree of order found in the lattice. No Br_2 seems to be formed during the reaction, which argues against a mere fluorosulfonation reaction of the type:

[5] $14C + 2BrSO_3F \rightarrow 2C_7SO_3F + Br_2$

Microanalysis and the observed ratio of Br:F:S of 1:1.012:1.04 are very consistent with our formulation as $C_{12}BrSO_3F$.

Identification of $C_{12}BrSO_3F$ as a first stage intercalation compound is based on the observed interlayer separation of 7.75 ± 0.03 Å and the shift of the Raman active E_{2g} lattice vibration of graphite to 1641 cm^{-1} in agreement with published observations for other first stage compounds (19, 20).

That the intercalant is packed rather tightly may be deduced in the following manner: the interlayer separation of 7.75 Å, allowing 3.35 Å for the carbon layer, suggests a gallery volume of 11.4 $Å^3$ per C atom. The reported density of $BrSO_3F$ (11) at 25°C is 2.238 g/cm^3 which leads to a molecular volume

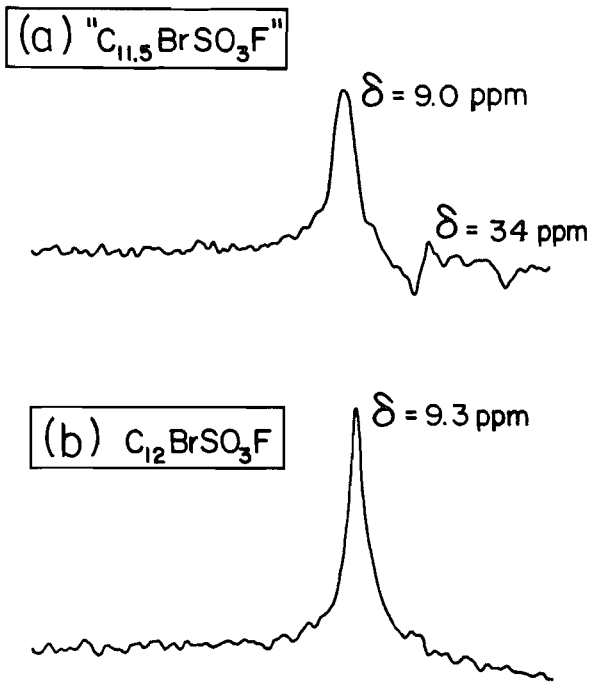

FIG. 1. The ^{19}F nmr spectrum of C_nBrSO_3F.

of about 133 Å^3. This would then suggest an "ideal" composition of $C_{11.67}BrSO_3F$, in reasonable agreement with our experimental finding, with molecular association found in the liquid to persist on intercalation.

While no vibrational modes due to the intercalant are observable in the Raman spectrum, the ^{19}F nmr spectrum shows a single resonance at 9.3 ppm relative to $CFCl_3$ shifted upfield from 34.6 ppm in liquid $BrSO_3F$ (see Fig. 1*a*). ^{19}F nmr spectra are also rather useful in testing for the complete removal of non intercalated $BrSO_3F$. As illustrated in Fig. 1, a weak signal at 34 ppm found in a product of the composition $C_{11.5}BrSO_3F$ appears to be due to surface adsorbed $BrSO_3F$. This signal will disappear on prolonged pumping, the resulting composition will then be close to $C_{12}BrSO_3F$ and the single resonance shown in Fig. 1*b* is observed.

Even though $C_{12}BrSO_3F$ is stable at 25°C *in vacuo*, heating to 100°C results in some decomposition. Both Br_2 and $BrSO_3F$ are detected in the volatile fraction by Raman spectroscopy. Since $BrSO_3F$ is reported to be thermally stable up to 150°C (11), the formation of bromine at 100°C prompted us to study the intercalation at about this temperature using an excess of $BrSO_3F$. Evolution of Br_2 is instantaneous and after a reaction time of 48 h and removal of all volatiles *in vacuo*, a product of the composition $C_{20}BrF(SO_3F)_2$ is obtained. Microanalysis indicates a ratio of Br:S:F of 1:2.02:2.98. Again an interlayer separation of 7.76 ± 0.03 Å and a frequency shift of the E_{2g} band to 1645 cm^{-1} suggest a first stage intercalation compound with the composition indicative of the large size of the intercalant.

^{19}F nmr provides information on the nature of the intercalant: two single, broad resonances at +9.7 ppm (assigned to fluorine attached to sulfur) and at −84.1 ppm are observed of the approximate intensity ratio of 2:1 (see Fig. 2). This second resonance is attributed to fluorine attached to bromine.

The proposed assignment is aided by a ^{19}F nmr study of the system BrF_3–$Br(SO_3F)_3$ (21). It appears that both BrF_3 and $Br(SO_3F)_3$ are miscible over the entire composition range to

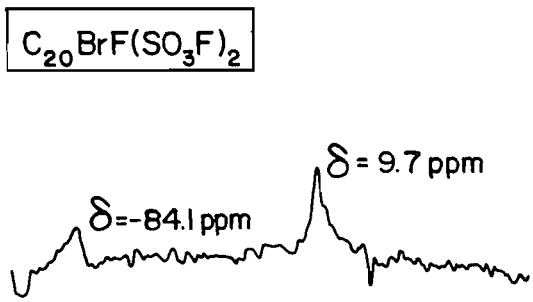

FIG. 2. The ^{19}F nmr spectrum of $C_{20}BrF(SO_3F)_2$.

give viscous liquids of the general composition $BrF_x(SO_3F)_{3-x}$, with x ranging from 0 to 3. Rapid ligand exchange produces two single broad resonances with the chemical shift depending on the composition. For $BrF(SO_3F)_2$ resonances at −46.5 ppm (Br−F group) and about 40 ppm (F attached to S) would be expected. A substantial upfield shift of both resonances appears to occur on intercalation, similar to the one found for $C_{12}BrSO_3F$.

Formation of $BrF(SO_3F)_2$ on intercalation of $BrSO_3F$ at elevated temperature may be rationalized in the following manner: Initial disproportionation of $BrSO_3F$ according to

[6] $3\ BrSO_3F \rightarrow Br_2 + Br(SO_3F)_3$

is followed by partial decomposition

[7] $Br(SO_3F)_3 \rightarrow BrF(SO_3F)_2 + SO_3$

during the intercalation process. It must be emphasized, however, that the proposed disproportionation is well known for BrF (22), but hitherto not observed for $BrSO_3F$ in its pure state (12). Likewise the proposed decomposition is a very plausible reaction for fluorosulfates (23), but again has not been observed for $Br(SO_3F)_3$ (12).

The oxidation of $C_{12}BrSO_3F$ with an excess of $S_2O_6F_2$ leads to a black–blue product of the composition $C_{16.5}Br(SO_3F)_3$. The interlayer separation of 7.92 Å and a Raman band at 1646 cm^{-1} agree well with expectations for a first stage intercalation compound, however, it is very unlikely that all $Br(SO_3F)_3$ is intercalated for the following reason:

Since all three graphite intercalation compounds of bromine fluorosulfate derivatives discussed so far are first stage compounds with all galleries filled, their overall composition should reflect the intercalant size, with the highest carbon:bromine ratio expected for $Br(SO_3F)_3$ as intercalant. It is therefore not unexpected that the ^{19}F nmr spectrum of $C_{16.5}Br(SO_3F)_3$ has two rather broad resonances (see Fig. 3): one of these at 38.3 ppm is quite close to the literature value of free $Br(SO_3F)_3$ of 39.0 ppm (21), while a second, approximately three times more intense line at 10.6 ppm is attributed to intercalated $Br(SO_3F)_3$. It appears then that oxidation of $C_{12}BrSO_3F$ occurs under extrusion of some $BrSO_3F$ from the lattice, followed by oxidation to give "free" $Br(SO_3F)_3$. While some of this material is removed with the excess $S_2O_6F_2$, some of the bromine(III)fluorosulfate, a solid at room temperature, remains mixed in with the intercalation compound. We have so far failed to affect a complete separation of the two reaction products. Nevertheless, the experiment confirms that intercalant oxidation is possible, leading to a first stage compound. Supporting evidence for the formulation of intercalated $Br(SO_3F)_3$ in the previous reaction may also be obtained from the successful reduction with an excess of Br_2 according to

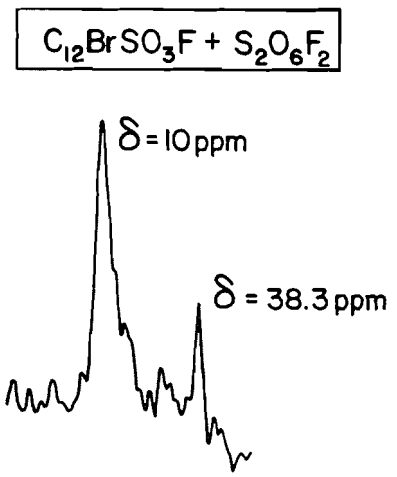

FIG. 3. The ^{19}F nmr spectrum of the product of the reaction of $C_{12}BrSO_3F$ with $S_2O_6F_2$.

[8] $3C_{16}Br(SO_3F)_3 + 3Br_2 \rightarrow 4C_{12}BrSO_3F + 5BrSO_3F$

with the resulting product identified by gravimetry and microanalysis.

The attempted complex formation of C_7SO_3F with $BrSO_3F$ to form intercalated $[Br(SO_3F)_2]^-$ was, however, less successful. There appears to be a small change in the interlayer separation, but the bromine contents of 1.88% and the ^{19}F nmr resonance at 32 ppm suggest rather surface adsorption than intercalation to occur.

Another attempted reaction also did not yield the expected product. We reacted $C_{12}BrSO_3F$ with an excess of trifluoromethyl sulfuric acid in the hope to produce $C_nBrSO_3CF_3$, in analogy to the previously reported (9) successful conversion of C_7SO_3F into $C_{12}SO_3CF_3$. Evolution of Br_2 from the reaction mixture indicated a reaction. The isolated solid, however,was free of bromine and analysed as $C_{12}SO_3CF_3$, suggesting the overall reaction:

[9] $2C_{12}BrSO_3F + 2HSO_3CF_3 \rightarrow 2C_{12}SO_3CF_3 + Br_2 + 2HSO_3F$

with HSO_3F reacting further with HSO_3CF_3 (9). Our inability to convert intercalated bromine(I)fluorosulfate into the trifluoromethyl sulfate analogue is not unexpected since $BrSO_3CF_3$ is not thermally stable above 0°C (24).

The reactions described here allow a few, general conclusions, concerning the reaction chemistry of graphite intercalation compounds. Where the initial intercalant is attacked and, during the course of the reaction, consumed, as in the reaction of $C_{12}BrSO_3F$ with HSO_3CF_3, oxidized, as in the reaction of $C_{12}BrSO_3F$ with $S_2O_6F_2$, or reduced as in reaction [8], conversion of one intercalation compound into another one is observed. The previously reported conversions of C_7SO_3F into $C_{12}SO_3CF_3$ (9) or into C_8SbF_6 (25) by solvolysis in HSO_3CF_3 or SbF_5 respectively belong to the same reaction type.

On the other hand, the attempted complexation of C_7SO_3F, where all galleries in the graphite layer lattice are completely filled, with an excess of $BrSO_3F$ would require an extrusion of some SO_3F^- to enable complexation to take place. Our evidence suggests surface adsorbtion rather than a complexation takes place. We have noted a similar lack of reactivity of C_7SO_3F towards HSO_3F, where previously known (26) acid salts of the type $C_n(SO_3F)_x(HSO_3F)_y$ had been expected (9).

The high temperature intercalation reaction with $BrSO_3F$ illustrates a third point. Here the presence of graphite leads to a disproportionation of $BrSO_3F$, which, though not totally unexpected, had not been observed before for neat $BrSO_3F$. There appear to be no precedents for this reaction, when interhalogen compounds are intercalated (1, 27).

The identification of all new graphite intercalation compounds as first stage compounds had been based on the interlayer separation I_c, the shift in frequency for the Raman active E_{2g} lattice vibration, the ^{19}F nmr spectra and last but not least the chemical analysis.The physical data for the new intercalation compounds as well as pertinent data for C_7SO_3F and $C_{12}SO_3CF_3$ (9) are summarized in Table 1. The measured ^{19}F nmr chemical shift data are compared to literature data for the pure intercalants. Also tabulated are the results of our electrical conductance studies for first stage compounds only.

All interlayer separations for the fluorosulfates fall well below 8.0 Å, suggesting tightly packed structures with electron transfer from graphite to intercalant causing Coulomb attraction between the carbon and the intercalant layer. Considering the rather large size of $Br(SO_3F)_3$ the small value of 7.92 Å seems surprising, but if one assumes that the planar coordination around bromine suggested for $Br(SO_3F)_3$ (26) is retained on intercalation the observed separation becomes plausible. Unfortunately we were unable to observe any vibrational

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

bands, due to the intercalants, which would have provided more definitive information on the structure of the various intercalants in these compounds.

Additional evidence for the intercalants acting as electron acceptors may be found in the other data tabulated. The strong shift of the Raman active E_{2g} lattice vibration is consistent with reports (19, 20) for other first stage acceptor compounds of graphite. The ^{19}F nmr chemical shifts appear all shifted to higher fields relative to the position for the neat intercalants. Fluorine attached to sulfur in the fluorosulfates studied here appears to be shifted by about 25 ppm upon intercalation, while an even larger shift is found for fluorine attached to bromine.

Because of this shift it is possible, as demonstrated in the preparation of $C_{12}BrSO_3F$, to differentiate between intercalated and surface adsorbed $BrSO_3F$.

The increased electrical conductivities for all compounds studied, with σ/σ_g values of approximately 3, point again to extensive electron transfer from graphite to the intercalant. Even greater enhancements of basal plane electrical conductivities are found in the higher stage intercalation compounds formed by $BrSO_3F$, and details of our conductance studies on this and related systems will be published shortly (27).

While sufficient evidence has been presented for the action of $BrSO_3F$ and $Br(SO_3F)_3$ as acceptors of electronic charge, two points still remain unsolved: (*a*) the exact extent of charge transfer, commonly expressed in terms of f, the carrier density parameter (28), and (*b*) the anions formed in the intercalant layer on charge transfer. Both $Br(SO_3F)_2^-$ (13) and $Br(SO_3F)_4^-$ (26) are well established in the form of alkali salts but others like $Br_2SO_3F^-$ may be possible as well.

Détermination cinétique de la nature du conformère réactif dans l'hydrolyse des orthoesters[1]

GÉRARD LAMATY, CLAUDE MOREAU ET ZÉPHIRIN MOULOUNGUI
Laboratoire de Chimie Organique Physique, Université des Sciences et Techniques du Languedoc, Place Eugène Bataillon, 34060 Montpellier Cédex, France

Reçu le 17 mars 1983

GÉRARD LAMATY, CLAUDE MOREAU et ZÉPHIRIN MOULOUNGUI. Can. J. Chem. **61**, 2643 (1983).

Les vitesses d'hydrolyse des orthoesters diéthoxy-1,1 dihydro-3,4 benzopyrannes-2 substitués en position 6 ou 7 (R = 6-MeO, H, 7-MeO, 7-NO_2 et 6-NO_2) ont été déterminées à 27°C dans le solvant eau/dioxanne 2:1 en volumes. Les constantes de vitesse et les constantes ρ de Hammett montrent que l'étape limitante est la formation d'un ion carboxonium cyclique. Ces résultats constituent une preuve cinétique quant à la nature du conformère réactif dans l'hydrolyse des orthoesters dialkoxy-2,2 tétrahydropyrannes.

GÉRARD LAMATY, CLAUDE MOREAU, and ZÉPHIRIN MOULOUNGUI. Can. J. Chem. **61**, 2643 (1983).

The rates of hydrolysis of the following orthoesters, 6 or 7-substituted 1,1-diethoxy 3,4-dihydrobenzo-2-pyrans (R = 6-MeO, H, 7-MeO, 7-NO_2 and 6-NO_2) were determined at 27°C in water/dioxan (2:1 by volume). The catalytic rate constants as well as the Hammett ρ constants show that the rate-determining step is the formation of a cyclic carboxonium ion intermediate and constitute a kinetic piece of evidence for the determination of the nature of the reactive conformer in hydrolysis of 2,2-dialkoxy tetrahydropyran orthoesters.

Introduction

Les intermédiaires tétraédriques, dans lesquels un atome de carbone est lié à trois hétéroatomes, jouent un rôle de premier plan dans un grand nombre de réactions tant organiques que bioorganiques, catalysées ou non par les enzymes. L'étude de la réactivité de systèmes mettant en jeu ce type d'intermédiaires est donc nécessaire pour contribuer à l'élucidation des mécanismes biologiques.

Un progrès très important a été réalisé dans ce sens avec l'élaboration d'une théorie stéréoélectronique qui implique une relation très étroite entre la conformation et la réactivité d'un intermédiaire tétraédrique (2).

Les orthoesters constituent un modèle chimique de ce type d'intermédiaires et il nous a paru intéressant de revenir sur un point particulier concernant la nature du conformère réactif dans l'hydrolyse des orthoesters diéthoxy-2,2 tétrahydropyrannes.

Ce problème a déjà été abordé par Deslongchamps *et al.* (3) en utilisant une méthode analytique basée sur l'analyse des produits de la réaction. Une telle méthode implique que l'intermédiaire hémiorthoester conserve la configuration et la conformation du produit de départ et, par conséquent, ne constitue pas une preuve absolue quant à la conformation de ce produit de départ; en effet, si l'on considère le mécanisme de l'hydrolyse des dialkoxy-2,2 tétrahydropyrannes (4), il existe deux étapes faisant intervenir la coupure d'une liaison C—O tout en respectant les règles stéréoélectroniques (schéma 1): (1) la formation de l'ion carboxonium intermédiaire, étape cinétique de la réaction (eq. [1]); (2) la décomposition de l'intermédiaire tétraédrique hémiorthoester, laquelle décomposition détermine la nature du ou des produit(s) de la réaction (eq. [3]).

Nous souhaitons rapporter dans le présent travail les résultats cinétiques obtenus au cours de la première étape du processus d'hydrolyse, résultats qui permettent de trancher définitivement sur la nature du conformère réactif.

Parmi les neuf conformères possibles représentant un orthoester diéthoxy-2,2 tétrahydropyranne, Deslongchamps *et al.* avaient retenu deux conformères réactifs seulement, équivalents du point de vue stéréoélectronique de surcroît: *A* et *F* (Fig. 1).

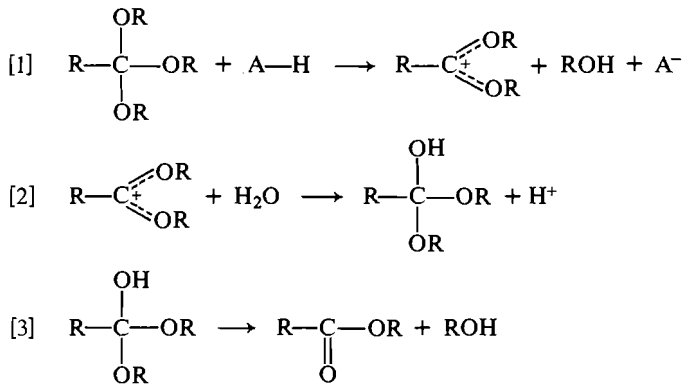

SCHÉMA 1

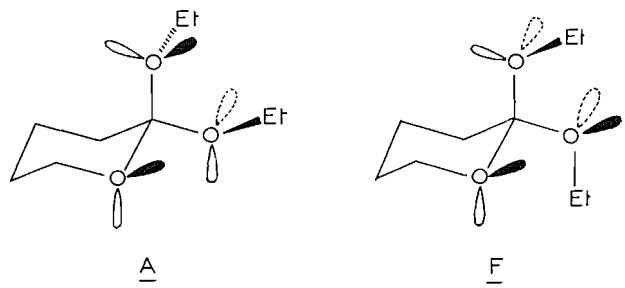

A F

FIG. 1.

En se basant sur l'analyse des produits de la réaction d'hydrolyse, les auteurs avaient conclu que le conformère *A*, plutôt que *F*, était le conformère réagissant (2, 3).

On pouvait espérer obtenir d'autres arguments, en particulier cinétiques, puisque l'hydrolyse des conformères *A* et *F* fait intervenir deux sortes d'ions carboxoniums intermédiaires, un ion cyclique dans le cas de *A* et un ion non cyclique dans le cas de *F* (Schéma 2).

La différenciation entre les deux modes de rupture de la liaison C—O, exocyclique (*A*) ou endocylique (*F*), nous apparaissait possible a priori. En effet, Kresge et coll. ont montré

[1]Ce travail a été présenté à la VI° Conférence I.U.P.A.C. de Chimie Organique Physique, Louvain la Neuve, Belgique, Juillet 1982 (1).

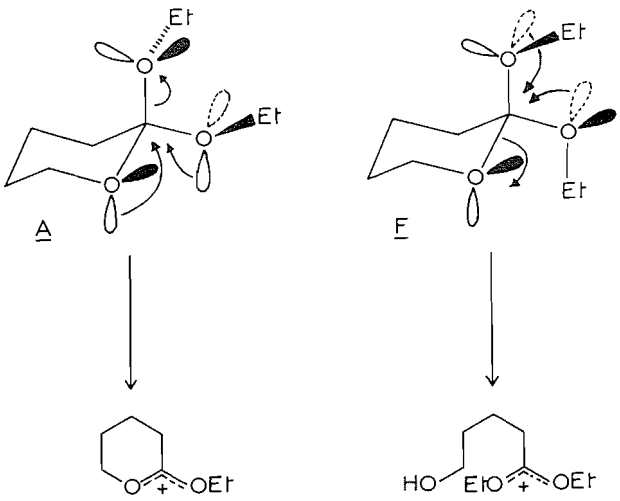

SCHÉMA 2

qu'il existait un empêchement stérique à la conjugaison dans l'ion carboxonium issu de l'hydrolyse de l'orthobenzoate de méthyle, empêchement stérique qui n'existe plus dans l'ion carboxonium issu de l'hydrolyse du méthoxy-2 phényl-2 dioxolanne-1,3 (5); dans le premier cas, l'ion carboxonium n'est pas cyclique alors que cet ion est cyclique dans le second cas. Cet empêchement stérique à la conjugaison se traduit par des différences à la fois dans les vitesses d'hydrolyse ($k_{cycle}/k_{non\ cycle} \simeq 100$) et dans les constantes ρ de Hammett ($\rho_{cycle} = -1{,}60$; $\rho_{non\ cycle} = -1{,}12$) (6); ces deux points seront repris dans la discussion.

Pour concilier dans une même molécule la réactivité d'un système orthobenzoate et la conformation d'un diéthoxy-2,2 tétrahydropyranne, nous avons, dans un premier temps, synthétisé une série d'orthoesters dérivés de la dihydro-3,4 isocoumarine (Fig. 2) et, dans un deuxième temps, nous avons étudié l'hydrolyse acido-catalysée de ces produits.

Résultats expérimentaux

I. *Synthèse*

Les orthoesters **1** à **5** ont été préparés à partir des lactones convenablement substituées selon la procédure générale décrite par Deslongchamps *et al.* (3). Les propriétés physicochimiques des nouveaux produits sont données en détail dans la partie expérimentale.

II. *Analyse des produits de la réaction*

L'analyse des produits de la réaction d'hydrolyse peut apporter des renseignements utiles sur le sens d'ouverture des orthoesters: l'hydrolyse des composés **1** à **5** peut conduire à deux couples de produits suivant la rupture, endocyclique ou exocyclique, de la liaison C—O tout en respectant les règles stéréoélectroniques: lactone + 2EtOH ou bien hydroxyester + EtOH (Schéma 3). Expérimentalement, l'hydrolyse des orthoesters **1** à **5** conduit à des mélanges lactone + hydroxyester. Cet aspect sera développé plus en détail dans la partie discussion.

III. *Résultats cinétiques*

L'hydrolyse acido-catalysée des diéthoxy-1,1 dihydro-3,4 benzopyrannes-2 substitués en position 6 ou 7 a été effectuée dans le solvant eau/dioxanne 2:1 en volumes à 27°C. Les couples acide/base utilisés pour tamponner le milieu sont acide formique/formiate de sodium, acide acétique/acétate de

[a]Les constantes k_{H_2O} ont été évaluées à partir des ordonnées à l'origine des graphes k_{obs} en fonction de AH; l'erreur sur ces constantes est de l'ordre de 50%.

diéthoxy-1,1 dihydro-3,4 benzopyrannes-2 substitués en position 6 ou 7 est soumise à une catalyse acide générale; ce type de catalyse est courant dans l'hydrolyse des orthoesters et nous avons montré par ailleurs qu'il était compatible avec le concept de contrôle stéréoélectronique qui implique que la rupture d'une liaison C—O est favorisée si les deux autres atomes d'oxygène ont chacun une paire d'électrons libres orientée de manière antipériplanaire par rapport à la liaison C—O qui se coupe (4).

Par ailleurs, les résultats expérimentaux sont en accord avec un mécanisme dans lequel l'étape déterminant la vitesse de réaction est la formation d'un ion carboxonium (7, 8). Les constantes ρ de Hammett, mesurant l'influence des substituants polaires en position 6 ou 7 sur le mécanisme de la réaction, sont obtenues en portant log k_{AH} en fonction des constantes de substituants σ (Fig. 3). Les constantes ρ ont été calculées ainsi que les écart-types correspondants et sont rassemblés dans le tableau 5.

Les constantes ρ sont négatives quel que soit le catalyseur et sont compatibles avec l'apparition d'une charge positive dans l'état de transition, la diminution de la densité électronique sur le carbone réactionnel étant favorisée par des groupements donneurs d'électrons et, à l'inverse, défavorisée par des groupements attracteurs d'électrons.

Si l'on associe les constantes ρ de Hammett à la position de l'état de transition le long du chemin réactionnel, les valeurs trouvées (−1,62 à −2,02) indiquent que l'état de transition possède un caractère ion carboxonium peu accentué comparativement à la valeur de ρ = −3,3 déterminée dans l'hydrolyse des acétals où l'état de transition est proche de l'ion carboxonium (9). Le faible avancement de la réaction a été démontré par ailleurs (7, 8).

Discussion

Trois points importants se dégagent des résultats expérimentaux en vue de discuter de la nature des conformères réac-

HCOOH	−2,02	0,997	0,08
CH_3COOH	−1,77	0,996	0,07
$(CH_3)_2AsOOH$	−1,86	0,998	0,06
H_2O	−1,78[a]	0,998	0,08

[a]Etant donné l'erreur importante sur les constantes k_{H_2O}, la valeur de ρ_{H_2O} n'est pas absolument significative.

tifs, *A* ou *F*: (1) l'analyse des produits de la réaction, (2) l'examen des constantes de vitesse d'hydrolyse et (3) l'influence des substituants polaires sur la réactivité.

Analyse des produits de la réaction

Nous avons déjà mentionné que la nature des produits de la réaction d'hydrolyse ne constituait pas une preuve formelle quant à la conformation du produit de départ; il est cependant intéressant de considérer le chemin suivi par chacun des deux conformères *A* et *F* (Schéma 4)[3] puisque l'hydrolyse des orthoesters **1** à **5** peut s'effectuer par rupture d'une liaison C—O exocyclique (conformère *A*) ou bien par rupture d'un liaison C—O endocyclique (conformère *F*), tout en respectant les règles stéréoélectroniques.

(a) *Rupture d'une liaison C—O exocyclique (conformère A)*

La rupture d'une liaison C—OEt exocyclique conduit à l'ion carboxonium cyclique A^+; l'addition de l'eau sur cet ion conduit préférentiellement à l'intermédiaire tétraédrique IT_1 qui, s'il ne subit pas de mouvements conformationnels, se décompose avec assistance stéréoélectronique par rupture de la liaison C—O endocyclique pour donner l'hydroxyester.

S'il existe une possibilité d'inversion de cycle, c'est-à-dire si le temps de demi-vie de l'intermédiaire IT_1 est suffisamment long, le nouvel intermédiaire résultant de l'inversion du cycle, IT_2, pourra se décomposer avec assistance stéréoélectronique par rupture d'une liaison C—O exocyclique ou endocyclique pour donner la lactone ou (et) l'hydroxy-ester.

(b) *Rupture de la liaison C—O endocyclique (conformère F)*

La rupture de la liaison C—O endocyclique conduit à l'ion carboxonium non cyclique F^+; l'addition de l'eau sur l'une ou l'autre face de cet ion conduit à deux intermédiaires tétraédriques lesquels se décomposent avec assistance stéréoélectronique pour donner uniquement l'hydroxy-ester.

En suivant la cinétique de disparition de l'orthoester par rmn ^1H on observe des quantités variables d'hydroxy-ester et de lactone selon le substituant X (Tableau 6).

La lactone observée au cours de l'hydrolyse peut être soit le résultat cinétique de la réaction, soit le résultat de la transestérification de l'hydroxy-ester. La vitesse de transestérification a été obtenue avec le dérivé non substitué; dans les conditions expérimentales utilisées (D_2O/acétone-d_6 20:80, pD = 1,74) la constante de vitesse bimoléculaire de transestérification est voisine de $10^{-4}\ M^{-1}\ s^{-1}$; cette constante est du même ordre de grandeur que celle reportée dans la littérature par McClelland dans le cas d'un système similaire au nôtre, le diéthoxy-1,1 dihydro-1,3 isobenzofuranne ($1{,}4 \times 10^{-3}\ M^{-1}\ s^{-1}$) (10) et bien inférieure à la constante de vitesse d'hydrolyse ($7{,}7 \times 10^{3}\ M^{-1}\ s^{-1}$). La lactone ne peut donc pas provenir de la transestérification de l'hydroxy-ester; elle provient par conséquent du chemin réactionnel qui met en jeu l'ion carboxonium cyclique, l'intermédiaire IT_1 ayant un temps de demi-vie suffisamment long pour que l'équilibre $IT_1 \rightleftarrows IT_2$ puisse s'établir; cette hypothèse est vraisemblable au vu des travaux récents de McClelland et Alibhai (10).

[3]Par souci de clarté dans le schéma 4, les cycles aromatiques n'ont pas été représentés sur les dessins en trois dimensions; l'examen des modèles moléculaires montre cependant que l'orientation relative des liaisons C—O et des paires d'électrons libres est la même dans les orthoesters **1** à **5** que dans le diéthoxy-2,2 tétrahydropyranne.

SCHÉMA 4

TABLEAU 6. Pourcentage des produits formés au cours de l'hydrolyse des orthoesters **1** à **5** en suivant la disparition de l'orthoester par rmn ^1H

Orthoesters	% Lactone	%Hydroxyester
1 X = 6-MeO	50	50
2 X = H	60	40
3 X = 7-MeO	75	25
4 X = 7-NO_2	100	Non détectable
5 X = 6-NO_2	100	Non détectable

La variation du pourcentage de produits d'hydrolyse en fonction du substituant X peut résulter d'une compétition entre la voie cinétique (formation de lactone + alcool) et la voie thermodynamique (formation de l'hydroxy-ester, ester transoïde plus stable que la lactone, ester cisoïde (2)), les substituants donneurs d'électrons orientant la décomposition de l'intermédiaire tétraédrique vers le produit le plus stable et inversement avec des substituants attracteurs.

Même si la nature des produits d'hydrolyse ne se détermine qu'après l'étape cinétique du processus réactionnel, la présence de lactone est une bonne indication en faveur du conformère *A*.

Analyse des constantes de vitesse d'hydrolyse

Les constantes de vitesse d'hydrolyse peuvent apporter les éléments cinétiques permettant de déterminer la nature du conformère réactif. Kresge et coll. (11) ont montré qu'il existait un empêchement stérique à la conjugaison dans l'ion carboxonium issu de l'hydrolyse de l'orthobenzoate de méthyle, empêchement stérique qui n'existe plus dans l'ion carboxonium issu de l'hydrolyse du méthoxy-2 phényl-2 dioxolanne-1,3; cet empêchement stérique se traduit par une vitesse d'hydrolyse beaucoup plus faible dans le cas d'un ion carboxonium non cyclique comparativement à un ion carboxonium cyclique (Tableau 7).

Si l'on compare nos résultats expérimentaux avec ceux de la littérature (Tableau 7), on s'aperçoit que les trois systèmes qui conduisent au cours de l'étape cinétique à un ion carboxonium

TABLEAU 7. Tableau comparatif des constantes de vitesse $k_{H_3O^+}$ obtenues dans l'hydrolyse des différents systèmes orthobenzoates

Produits	$k_{H_3O^+}(M^{-1}\ s^{-1})$	Réf.
	69,7 à 25°C	5
	$7{,}37 \cdot 10^3$ à 25°C	5
	$5{,}4 \cdot 10^3$ à 25°C	11
	$3{,}1 \cdot 10^3$ à 25°C	10
	$7{,}72 \cdot 10^3$ à 27°C	Ce travail

cyclique ont des vitesses d'hydrolyse du même ordre de grandeur et très différentes, par un facteur 50 à 100, de celles d'une système non cyclique.

Effets de substituants

Nous avons montré dans un précédent travail que la substitution d'un groupe phényle par un groupe méthyle se traduisait, dans l'hydrolyse d'orthoesters cycliques, par un rapport $k_{C_6H_5}/k_{CH_3} \simeq 0{,}4$ à 1,4 (12). En comparant la réactivité de l'orthoester non substitué **2** à celle du diéthoxy-2,2 tétrahydropyranne (Schéma 5) (4) on obtient un rapport $k_{C_6H_5}/k_{CH_3}$ égal à 0,35.

Donc aussi bien l'analyse des constantes de vitesse proprement dites que les effets de substituants constituent un premier argument cinétique en faveur du conformère *A*.

Influence des substituants polaires sur le réactivité

L'empêchement stérique à la résonance invoqué lors de la

	H_2O	−1,78 (0,08)	0,998	

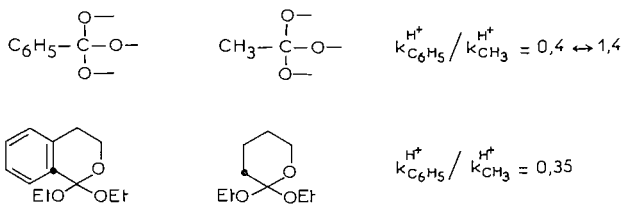

SCHÉMA 5

discussion des constantes de vitesse a également des conséquences sur les constantes ρ de Hammett: plus l'état de transition sera conjugué (systèmes cycliques), plus la constante ρ sera négative et réciproquement pour les systèmes non cycliques. C'est en effet ce qu'il ressort de l'examen du tableau 8; il existe un parallélisme assez fidèle entre les constantes ρ déterminées dans l'hydrolyse de nos composés et l'hydrolyse des méthoxy-2 phényl-2 dioxolannes-1,3: les constantes $\rho_{H_3O^+}$ sont sensiblement les mêmes et légèrement inférieures aux constantes ρ déterminées pour les autres catalyseurs acides. Si l'on tient compte des écart-types associés aux constantes ρ, cette tendance ne paraît pas absolument significative (14). Par contre, dans la réaction catalysée par H_3O^+, les différences dans les constantes ρ entre le système non cyclique (ρ = −1,12) et les deux systèmes cycliques (ρ = −1,60 et −1,62) sont, elles, significatives.

Donc, dans le cas des systèmes que nous avons étudiés, la détermination des constantes ρ de Hammett constitue un deuxième argument cinétique en faveur du conformère *A*.

Conclusion

Dans le travail que nous avons présenté, nous avons voulu reconsidérer d'un point de vue quantitatif la nature du conformère réactif dans l'hydrolyse des orthoesters diéthoxy-2,2 tétrahydropyrannes, aspect qui avait été abordé antérieurement par Deslongchamps d'un point de vue qualitatif.

En faisant appel à des composés ayant la réactivité d'un système orthobenzoate et la conformation d'un diéthoxy-2,2 tétrahydropyranne, nous avons pu apporter les éléments cinétiques qui manquaient; ces éléments cinétiques confirment ce qui avait été observé à partir de l'analyse des produits de la réaction d'hydrolyse, à savoir que le conformère réactif, dans l'hydrolyse des orthoesters diéthoxy-2,2 tétrahydropyrannes, est le conformère *A*.

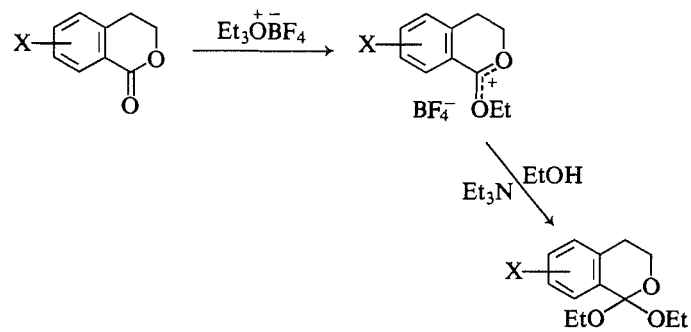

SCHÉMA 6

Partie expérimentale

Produits

Les orthoesters **1** à **5** ont été préparés à partir des lactones convenablement substitués selon le schéma 6.

(1) *Synthèse des lactones*

Les dihydro-3,4 isocoumarines substituées en position 6 ou 7 ont été synthétisées par les voies décrites dans la littérature: méthoxy-6 (15, 16), non substituée (17), méthoxy-7 (18) et nitro-7 (19); la nitro-6 dihydro-3,4 isocoumarine a été synthétisée à partir de l'acide nitro-4 homophtalique (20) en adaptant la procédure décrite dans la littérature pour le composé méthoxy-6 (15, 16) (Schéma 7).

Nitro-6 dihydro-3,4 isocoumarine: F: 162−164°C (MeOH); rendement à partir de l'acide nitro-4 homophtalique: 47%; ir ($CHCl_3$) $\nu_{c=o}$: 1725 cm^{-1}; rmn ^1H ($CDCl_3$) 3,22 δ: (2H, triplet, *J* = 6 Hz, méthylène sur C_4), 4,62 (2H, triplet, *J* = 6 Hz, méthylène sur C_3), 8,22 (3H, multiplet, protons aromatiques). *Anal.* ($C_9H_7NO_4$): calc. (%): C 55,96, H 3,65, N 7,25; tr. (%): C 55,84, H 3,81, N 7,07.

(2) *Mise au point de la synthèse des ions lactonium (X = H)*

Les sels de lactonium sont extrêment hygroscopiques et la synthèse s'effectue en boîte à gants sous atmosphère anhydre.

552 mg (3,73 mmol) de dihydro-3,4 isocoumarine sont ajoutés à une solution de 850 mg (4,47 mmol) de tétrafluoroborate de triéthyloxonium dans 10 mL de dichlorométhane séché sur tamis moléculaire

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12

SCHÉMA 7

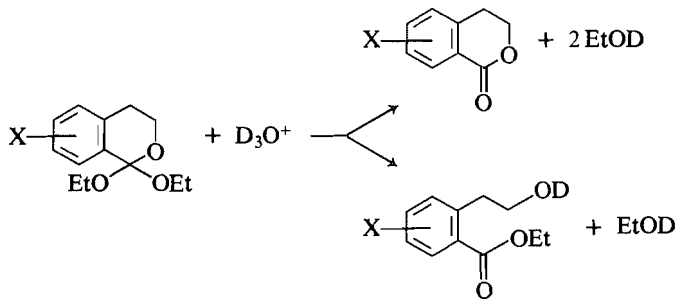

SCHÉMA 8

4 Å. Après 24 h à température ambiante, l'ion lactonium précipite sous forme d'un solide marron. Le solide est rapidement filtré et dissous dans du nitrométhane deutérié (1 mL); la fin de la réaction est contrôlée par rmn ^{1}H δ: 1,66 (3H, triplet, J = 7,5 Hz, $\overset{+}{O}CH_2CH_3$), 3,50 (2H, triplet, J = 6 Hz, méthylène sur C_4), 5,07 (2H, quadruplet, $\overset{+}{O}CH_2CH_3$), 5,31 (2H, triplet, J = 6 Hz, méthylène sur C_3), 7,20 à 8,60 (4H, protons aromatiques).

La même procédure expérimentale a été suivie pour les autres substituants au facteur temps de réaction près: 48 h pour les méthoxy-6 et méthoxy-7, 96 h pour les nitro-6 et nitro-7.

(3) *Préparation* in situ *des orthoesters 1 à 5 (procédure générale)*

La suspension d'ion lactonium est ajoutée lentement, sous atmosphère d'azote, à une solution refroidie à −64°C. (chloroforme − azote liquide) de deux équivalents d'éthanol anhydre et trois équivalents de triéthylamine dans 20 mL de dichlorométhane anhydre. L'agitation est maintenue pendant 2 heures à −64°C. Après avoir laissé le mélange réactionnel revenir à température ambiante, on ajoute 20 mL d'une solution aqueuse saturée de carbonate de sodium. Après décantation et réextraction de la phase aqueuse avec du dichlorométhane, la phase organique est séchée sur carbonate de potassium anhydre et évaporée.

Par rmn ^{1}H, on observe la présence de traces de lactone. Les orthoesters bruts sont repris avec de la soude 4 *N* pendant 24 h à température ambiante et extraits comme précédemment.

Identification des orthoesters

1 (6-MeO): résidu cristallin blanchâtre; rendement: 97%; rmn ^{1}H ($CDCl_3$) δ: 1,17 (6H, triplet, J = 7,5 Hz, O—CH_2—CH_3), 2,83 (2H, triplet, J = 6 Hz, méthylène sur C_4), 3,26 à 3,96 (4H, 2 octuplets,[4] O—CH_2—CH_3), 3,80 (3H, singulet, —OCH_3), 4,12 (2H, triplet, J = 6 Hz, méthylène sur C_3), 6,66 (1H, quadruplet, $J_{méta}$ = 3 Hz, H_5), 6,87 (1H, quadruplet, J_{ortho} = 9 Hz, $J_{méta}$ = 9 Hz, H_8).

2 (H): résidu cristallin blanchâtre; rendement: 74%; rmn ^{1}H ($CDCl_3$) δ: 1,17 (6H, triplet, J = 7,5 Hz, O—CH_2—CH_3), 2,78 (2H, triplet, J = 6 Hz, méthylène sur C_4), 3,23 à 3,93 (4H, deux octuplets,[4] O—CH_2—CH_3), 4,08 (2H, triplet, J = 6 Hz, méthylène sur C_3), 6,93 à 7,60 (4H, massif, protons aromatiques).

3 (7-MeO): huile jaune; rendement: 41%; rmn ^{1}H ($CDCl_3$) δ: 1,13 (6H, triplet, J = 7,5 Hz, O—CH_2—CH_3), 2,78 (2H, triplet, J = 6 Hz, méthylène sur C_4), 3,13 à 3,93 (4H, deux octuplets,[4] O—CH_2—CH_3), 3,77 (3H, singulet, O—CH_3), 4,07 (2H, triplet, J = 6 Hz, méthylène sur C_3); 6,67 à 7,20 (3H, massif, protons aromatiques).

4 (7-NO_2): liquide qui cristallise; rendement: 69%; rmn ^{1}H ($CDCl_3$) δ: 1,17 (6H, triplet, J = 6 Hz, O—CH_2—CH_3), 2,93 (2H, triplet, J = 6 Hz, méthylène sur C_4), 3,23 à 3,97 (4H, deux octuplets,[5] O—CH_2—CH_3), 4,15 (2H, triplet, J = 6 Hz, méthylène sur C_3), 7,3 (1H, doublet, J_{ortho} = 9 Hz, H_5), 8,10 (1H, quadruplet, J_{ortho} = 9 Hz, $J_{méta}$ = 3 Hz, H_6), 8,33 (1H, doublet, $J_{méta}$ = 3 Hz, H_8).

5 (6-NO_2): liquide qui cristallise; rendement: 60%; rmn ^{1}H ($CDCl_3$) δ: 1,13 (6H, triplet, J = 7 Hz, O—CH_2—CH_3), 2,93 (2H, triplet, J = 6 Hz, méthylène sur C_4), 3,25 à 3,95 (4H, deux octuplets,[5] O—CH_2—CH_3), 4,13 (2H, triplet, J = 6 Hz, méthylène sur C_3), 7,55 à 8,13 (3H, massif, protons aromatiques).

Analyse des produits d'hydrolyse

Les produits de la réaction d'hydrolyse des orthoesters **1** à **5** ont été analysés par rmn ^{1}H de la façon suivante: 50 mg d'orthoester sont dissous dans 600 μL d'acétone-d_6 et 100 μL de D_2O; 2 à 5 μL d'une solution de DCl dans D_2O (≈0,1 *M*) sont ajoutés dans le tube rmn; dans ces conditions, on peut suivre la disparition de l'orthoester ainsi que l'apparition du ou des produits d'hydrolyse (Schéma 8).

Les intensités relatives des protons méthyléniques sur le carbone C_3 de la lactone (triplet, J = 6 Hz, δ ≃ 4,6 ppm) et des protons méthyléniques de la fonction ester de l'hydroxy-ester (quadruplet, J = 7 Hz, δ ≃ 4,40 ppm) permettent de déterminer la proportion des produits formés dans les conditions cinétiques (cf. Tableau 6).

Lactonisation de l'hydroxy-ester

Une estimation de la vitesse de la lactonisation en milieu acide de l'hydroxy-ester a été obtenue avec le composé non substitué (X = H) de la façon suivante: après disparition de l'orthoester dans les conditions cinétiques (cf. ci-dessus) la composition des produits de la réaction est 60% de lactone et 40% d'hydroxy-ester; on ajoute dans le tube rmn 2 μL de DCl 20% dans D_2O et on enregistre les spectres rmn à des intervalles de temps réguliers; au bout de 3 jours, la composition des produits est 80% de lactone et 20% d'hydroxy-ester, ce qui confirme l'extrême lenteur de la réaction de lactonisation déjà observée par McClelland sur un composé voisin de ceux que nous avons étudiés (10).

Méthodes cinétiques

Les réactions d'hydrolyse sont suivies par spectrophotométrie uv (Gilford 250 équipé d'un passeur automatique de cuves) en mesurant l'augmentation de la densité optique due à l'apparition des produits. Les longueurs d'onde utilisées sont les suivantes: 240 nm (**1**), 235 nm (**2**), 235 nm (**3**), 232 nm (**4**) et 267 nm (**5**). Les cuves en quartz contiennent 2 mL de solution tampon à la température désirée et 20 μL de solutions 10^{-2} *M* d'orthoester dans le dioxanne pur.

Après agitation, la densité optique est enregistrée en fonction du temps. Les constantes de vitesse k_{obs} sont obtenues en traitant l'exponentielle $D = D_\infty + (D_\infty - D_0)e^{-kt}$ par la méthode des moindres carrés ou bien en portant $\ln (D_\infty - D)/(D_\infty - D_0)$ en fonction du temps. Les concentrations en orthoester sont choisies de façon à avoir une variation convenable de densité optique (0,2 à 0,8).

Influence de la composition du solvant et de l'activité du milieu sur les pK_a des acides catalyseurs et sur le calcul des constantes catalytiques

(1) *pH réels, pK_a réels*

Les valeurs des pH et des pK_a dans un solvant mixte peuvent être déterminées directement en utilisant un pH-mètre conventionnel qui a

[4]Les protons méthyléniques ne sont pas équivalents; ils sont diastéréotopes et se présentent sous la forme d'un système ABX: $J_{AX} = J_{BX} \simeq 7$ Hz, $J_{AB} \simeq 10 - 11$ Hz.

TABLEAU 9. Variation des pK_a des acides formique, acétique et cacodylique en fonction de la composition du solvant

Acides	pK_a réels $\mu = 0{,}1\ M$ Eau/dioxanne 2:1	pK_a $\mu = 0$ H_2O	ΔpK_a	Correction
Formique	4,48	3,75	0,73	0,9
Acétique	5,58	4,76	0,82	1,0
Cacodylique	6,96	6,19	0,77	(0,95)

été standardisé à l'aide de tampons dans le même solvant (21).

Une méthode approchée de détermination des pH réels est également possible si le pH-mètre est standardisé à l'aide de tampons aqueux; la lecture (pH lu), obtenue dans un solvant mixte, diffère par une quantité δ de la lecture (pH réel) qui est obtenue lorsque le pH-mètre est standardisé à l'aide de tampons dans ce solvant mixte.

$$\text{pH réel} = \text{pH lu} - \delta \qquad pK_a \text{ réel} = pK_a \text{ lu} - \delta$$

Ainsi, une valeur approchée de pH peut être obtenue si les valeurs de δ sont connues. Dans le cas du solvant que nous avons utilisé, eau/dioxanne 2:1 en volumes, le terme δ est égal à $-0{,}08$ (22).

(2) *pK_a des acides formique, acétique et cacoadylique dans le solvant eau/dioxanne 2:1 en volumes*

L'influence de la composition du solvant sur le pK_a des acides catalyseurs est connue pour les acides formique et acétique (23):

$$\text{HCOOH: } pK_a \text{ (eau/dioxanne 2:1)} = pK_a \text{ (eau)} + 0{,}9 = 4{,}65$$

$$CH_3COOH: pK_a \text{ (eau/dioxanne 2:1)} = pK_a \text{ (eau)} + 1{,}0 = 5{,}76$$

Le pK_a de l'acide cacodylique dans l'eau/dioxanne 2:1 à force ionique nulle peut être estimé à partir des différences ΔpK_a observées entre les pK_a réels (égaux aux pH réels lorsque $[AH] = [A^-]$) déterminés dans l'eau/dioxanne 2:1 à force ionique égale à 0,1 *M* et les pK_a correspondants connus dans l'eau à force ionique nulle (Tableau 9).

La valeur ΔpK_a obtenue pour l'acide cacodylique est intermédiaire entre celles calculées pour les acides acétique et formique. Nous pouvons donc raisonnablement penser que la correction de pK_a à apporter sera, selle aussi, comprise entre les corrections apportées aux acides formique et acétique à force ionique nulle.

Le pK_a de l'acide cacodylique dans l'eau/dioxanne 2:1 en volumes et à force ionique nulle peut donc être estimé à 6,19 + 0,95 = 7,14.

(3) *pK_a de H_3O^+ et H_2O dans le solvant eau/dioxanne 2:1 en volumes*

Les values de pK_a de H_3O^+ et H_2O peuvent être calculées à partir des données de la littérature (23):

$$H_3O^+: pK_a = -1{,}57 \qquad H_2O: pK_a = 16{,}67$$

(4) *Calcul des constantes catalytiques* k_{AH}, $k_{H_3O^+}$ et k_{H_2O}

Le calcul des différentes constantes catalytiques nécessite la connaissance de la concentration en proton pour chaque acide dans le milieu eau/dioxanne 2:1 en volumes et à force ionique égale à 0,1 *M*. La concentration en proton est calculée au moyen de la formule ci-dessous (24):

$$[H^+] = K_a \frac{[AH]}{[A^-]} \times \frac{1}{\gamma_\pm^2} \quad \text{avec} \quad \begin{matrix} [AH] = [AH]_0 - [H^+] \\ [A^-] = [A^-]_0 - [H^+] \end{matrix}$$

Le coefficient d'activité $\gamma_\pm$ peut être déterminé par extrapolation des valeurs de $\gamma_\pm$ reportées dans la littérature (ref. 23, p. 717); pour un mélange eau/dioxanne 2:1 en volumes et à force ionique égale à 0,1 *M*, $\gamma_\pm = 0{,}66$.

La résolution du système d'équation ci-dessus conduit aux concentrations en proton suivantes.

Acide formique $[AH]_0/[A^-]_0 = 0{,}25$ $[H^+] = 1{,}28 \times 10^{-5}\ M$

Acide formique $[AH]_0/[A^-]_0 = 1$ $[H^+] = 5{,}13 \times 10^{-5}\ M$

Acide acétique $[AH]_0/[A^-]_0 = 1$ $[H^+] = 3{,}99 \times 10^{-6}\ M$

Acide cacodylique $[AH]_0/[A^-]_0 = 1$ $[H^+] = 1{,}28 \times 10^{-5}\ M$

La concentration en proton est négligeable devant la concentration en acide non dissocié [AH]; on peut donc assimiler [AH] et $[AH]_0$. En portant k_{obs} en fonction de $[AH]_0$ # [AH], on obtient ainsi les constantes catalytiques k_{AH}.

Les constantes catalytiques $k_{H_3O^+}$ et k_{H_2O}, difficiles à déterminer directement, sont obtenues en résolvant le système d'équations des ordonnées à l'origine des graphe $k_{obs} = f([AH])$ pour les acides acétique et cacodylique.

Effet de groupe partant dans l'hydrolyse d'orthoesters cycliques: changement de conformère réactif dans l'hydrolyse des diéthoxy-2,2 tétrahydropyrannes[1]

GÉRARD LAMATY, PHILIPPE LORENTE ET CLAUDE MOREAU

Laboratoire de Chimie Organique Physique, Université des Sciences et Techniques du Languedoc, Place Eugène Bataillon, 34060 Montpellier Cédex, France

Reçu le 17 mars 1983

GÉRARD LAMATY, PHILIPPE LORENTE et CLAUDE MOREAU. Can. J. Chem. **61**, 2651 (1983).

Les vitesses d'hydrolyse des orthoesters diéthoxy-2,2 dihydro-3,4 benzopyrannes-1 substitués en position 6 (X = OMe, Me, H et Cl) ont été déterminées à deux températures dans le solvant eau/dioxanne 2:1 en volumes. Le changement de signe observé dans les constantes ρ de Hammett ($\rho_{H_3O^+} = -0{,}8$; $\rho_{AH} = +0{,}7$) est caractéristique du départ d'un groupe phénolate, c'est-à-dire de la rupture de la liaison C—O endocyclique dans les systèmes étudiés ici; ces résultats indiquent un changement du conformère réactif dans l'hydrolyse des diéthoxy-2,2 tétrahydropyrannes.

GÉRARD LAMATY, PHILIPPE LORENTE, and CLAUDE MOREAU. Can. J. Chem. **61**, 2651 (1983).

The rates of hydrolysis of 6-substituted 2,2-diethoxy 3,4-dihydro benzo-1-pyrans (X = MeO, Me, H and Cl) were determined at two temperatures in water/dioxane 2:1 by volume. The observed change of sign of the Hammett ρ constants ($\rho_{H_3O^+} = -0.8$; $\rho_{AH} = +0.7$) is characteristic of a phenolate leaving group, i.e. of the rate-determining cleavage of the endocyclic C—O bond in the systems here studied; these results clearly indicate a change in the nature of the reactive conformer in hydrolysis of 2,2-diethoxy tetrahydropyrans.

Introduction

De nombreuses réactions rencontrées en biochimie font intervenir des intermédiaires tétraédriques dans lesquels trois hétéroatomes sont fixés sur l'atome de carbone siège de la réaction.

L'étude de ces intermédiaires a connu un regain d'intérêt avec l'élaboration d'une théorie stéréoélectronique qui permet d'expliquer et de prévoir la formation et la décomposition d'intermédiaires tétraédriques et qui s'énonce comme suit (2): "la coupure spécifique d'une liaison carbone−hétéroatome n'intervient que si les deux autres hétéroatomes ont chacun une paire d'électrons libres anticoplanaire à la liaison carbone−hétéroatome qui va se couper".

Pour étayer cette théorie, de nombreuses réactions chimiques ont été étudiées, en particulier la réaction d'hydrolyse des orthoesters qui fait intervenir des intermédiaires tétraédriques hémiorthoesters. Les travaux effectués ont clairement montré, qu'au cours de la réaction d'hydrolyse, interviennent des coupures spécifiques de liaisons C—OR en accord avec la théorie stéréoélectronique.

La spécificité observée ne peut être expliquée qu'en postulant une différence entre les énergies libres d'activation pour les réactions de coupure des différentes liaisons C—OR; c'est ainsi que dans un précédent travail (3), nous avons montré à partir de résultats cinétiques que l'hydrolyse des diéthoxy-2,2 tétrahydropyrannes s'effectuait par l'intermédiaire du conformère *A* et non par l'intermédiaire du conformère *F* (Schéma 1), hypothèse déjà retenue à partir de l'analyse des produits de réactions (4).

L'hydrolyse préférentielle par l'intermédiaire du conformère *A* réside très vraisemblablement dans le facteur entropique qui défavorise l'ouverture du cycle tétrahydropyranne dans le conformère *F*. Pour essayer de déterminer la réactivité du conformère *F*, il faut favoriser la rupture de la liaison C—O endocyclique; en adjoignant un cycle benzénique au cycle tétrahydropyranne, on obtient l'équivalent d'un groupement phénolate connu pour être un meilleur groupe partant qu'un groupement alcoolate (5), situation que l'on rencontre dans les orthoesters dérivés de la dihydro-3,4 coumarine (Fig. 1).

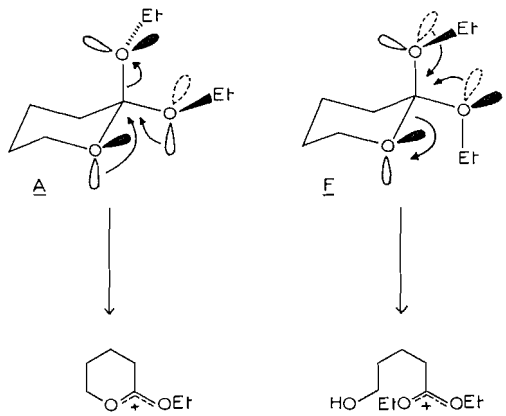

SCHÉMA 1

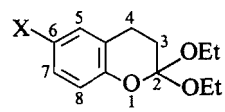

1 X = OMe
2 X = Me
3 X = H
4 X = Cl

FIG. 1

La synthèse des orthoesters **1** à **4** a donc été effectuée dans un premier temps; dans un deuxième temps, nous avons étudié l'hydrolyse de ces composés, du point de vue qualitatif (analyse des produits d'hydrolyse) et du point de vue quantitatif (constantes de vitesse d'hydrolyse, type de catalyse, grandeurs d'activation).

Résultats expérimentaux

I. *Synthèse*

Les composés étudiés ont été synthétisés à partir des lactones convenablement substituées selon la procédure générale décrite par Deslongchamps *et al.* (2, 4). Les propriétés physicochimiques des nouveaux produits sont donnés en détail dans la partie expérimentale.

II. *Analyse des produits de la réaction*

L'analyse des produits de la réaction d'hydrolyse peut ap-

SCHÉMA 2

porter des renseignements utiles sur le sens d'ouverture des orthoesters: l'hydrolyse des composés **1** à **4** peut conduire à deux couples de produits suivant la rupture – endocyclique ou exocyclique – de la liaison C—O, tout en respectant les règles stéréoélectroniques: lactone + 2EtOH ou hydroxy-ester + EtOH (Schéma 2). Expérimentalement, l'hydrolyse des orthoesters **1** à **4** conduit essentiellement à l'hydroxy-ester. Ce point sera repris plus en détail dans la partie discussion.

III. *Résultats cinétiques*

L'hydrolyse acido-catalysée des diéthoxy-2,2 benzopyrannes-1 substitués en position 6 a été effectuée dans le solvant eau/dioxanne 2:1 en volumes. Les couples acide/base utilisés pour tamponner le milieu sont acide monochloracétique/monochloracétate de sodium, acide formique/formiate de sodium et acide acétique/acétate de sodium. La force ionique a été maintenue constante à 0,0686 *M* par addition de chlorure de potassium. Les résultats cinétiques obtenus dans l'eau/dioxanne 2:1 en volumes sont rassemblés dans les tableaux 1 à 4. Les constantes catalytiques k_{H^+}, k_{ClCH_2COOH}, k_{HCOOH} et k_{CH_3COOH} (corrections faites de l'effet de solvant et de l'activité du milieu)[2] ont été obtenues en exploitant les résultats des tableaux 1 à 4;[3] ces constantes sont rassemblées dans le tableau 5.

[2]L'influence de la composition du solvant et de l'activité du milieu sur les pK_a des acides catalyseurs et sur le calcul des constantes catalytiques est donnée en détail dans l'article précédant directement celui-ci (3).

[3]Le graphe obtenu en portant la constante de vitesse observée en fonction de la concentration en acide faible, pour un pH donné, n'est pas linéaire. Un comportement semblable a déjà été observé par d'autres auteurs (5, 6) et aucune analyse approfondie du phénomène n'a été faite jusqu'à présent. Les constantes catalytiques reportées dans le tableau 5 ont été déterminées en effectuant les régressions linéaires pour les valeurs de k_{obs} aux trois plus faibles concentrations.

TABLEAU 3. Hydrolyse du diéthoxy-2,2 benzopyranne-1 (**3**) dans l'eau/dioxanne 2:1 en volumes, à force ionique égale à 0,0686 *M* (KCl) et à 25,2°C

Interprétation des résultats expérimentaux et discussion

Les composés que nous avons étudiés peuvent théoriquement s'hydrolyser par rupture d'une liaison C—OEt exocyclique ou bien par rupture de la liaison C—O endocyclique (Schéma 3)[4] au cours de l'étape limitante. Deux points importants sont donc à élucider: le premier est de savoir quelle est la nature de la liaison C—O qui se coupe au cours de l'étape cinétique et le second point est de savoir quelle est la nature du conformère réactif. Ces deux points seront abordés successivement.

I. *Nature de la liaison C—O qui se coupe*

La nature de la liaison C—O qui se coupe peut être déterminée à partir des résultats obtenus dans le solvant eau/dioxanne 2:1 en volumes: l'examen des tableaux 1 à 4 montre que l'hydrolyse des composés étudiés est soumise à une catalyse acide générale; ce type de catalyse est généralement celui qui est observé dans l'hydrolyse des orthoesters (7, 8) et est compatible avec le concept de contrôle stéréoélectronique (9).

Analyse des produits d'hydrolyse

Dans le cas d'une rupture de la liaison C—O endocyclique (Schéma 3, conformère *F*) le produit d'hydrolyse normalement attendu est l'hydroxy-ester. Par contre dans le cas d'une rupture

[4]Par souci de clarté dans le schéma 3, les cycles aromatiques n'ont pas été représentés sur les dessins en trois dimensions; l'examen des modèles moléculaires montre que l'orientation relative des liaisons C—O et des paires d'électrons libres est la même dans les orthoesters **1** à **4** que dans le diéthoxy-2,2 tétrahydropyranne lui-même. La position du groupe phényle est symbolisée par la liaison en trait épais.

SCHÉMA 3

TABLEAU 6. Hydrolyse des orthoesters **1** à **4**: constantes catalytiques k_{H^+} (M^{-1} s^{-1}) à deux températures et paramètres d'activation donnés à 25,0°C

X	k_{H^+} à 12,0°C	k_{H^+} à 25,2°C	$\Delta H^{\neq}$ kcal/mol	$\Delta S^{\neq}$ ue
OMe	74	166	9,7	−16
Me	70	160	9,9	−15
H	56	126	9,7	−16
Cl	32	71	9,5	−18

de la liaison C—O exocyclique (Schéma 3, conformère *A*) deux produits peuvent être présents, la lactone et l'hydroxy-ester, tout en respectant les règles stéréoélectroniques. La lactone ne peut se former que si le temps de demi-vie de l'intermédiaire tétraédrique est suffisamment long pour permettre l'équilibre $IT_1 \leftrightarrows IT_2$ (Schéma 3). Capon et Grieve (10) ont montré que l'hydrolyse du diéthoxy-2,2 tétrahydropyranne lui-même conduisait à 30% de lactone. La présence d'un caractère double liaison dans le cycle tétrahydropyrannyle des systèmes que nous avons étudiés devrait donc favoriser l'équilibre $IT_1 \leftrightarrows IT_2$, et par conséquent, accroître le pourcentage de lactone. Expérimentalement, nous n'observons qu'un faible pourcentage de lactone, environ 4%, ce qui laisse penser que le chemin *F* serait favorisé, en l'occurrence la rupture de la liaison C—O serait endocyclique.

Analyse des constantes ρ de Hammett

L'examen des constantes ρ de Hammett calculées pour l'hydrolyse de nos composés (Tableau 5) amène deux remarques intéressantes: (1) la constante ρ, en valeur absolue, est de faible amplitude et (2) la constante ρ change de signe lorsque le catalyseur passe d'un acide fort ($\rho_{H_3O^+} < 0$) à un acide faible ($\rho_{AH} > 0$).

Ces résultats montrent que l'étape cinétique est la rupture de la liaison C—O endocyclique:

(1) Le pouvoir électroattracteur du groupe phénolate a pour conséquence deux effets d'influence contraire: d'une part il favorise la coupure de la liaison C—O et d'autre part il défavorise la protonation. La superposition de ces deux effets entraîne un nivellement de la différence de réactivité en fonction du substituant, et donc, des valeurs de la constante ρ de faible amplitude. Ce résultat a déjà été observé dans l'hydrolyse d'acétals faisant intervenir le départ d'un groupe phénolate (5, 11, 12).

(2) Le changement de signe de la constante ρ lorsque le catalyseur passe d'un acide faible à un acide fort a également été observé dans l'hydrolyse d'acétals faisant intervenir le départ d'un groupe phénolate (7, 12) et est donc caractéristique d'un effet de groupe partant, c'est-à-dire dans le cas des orthoesters étudiés dans ce travail, d'une rupture de la liaision C—O endocyclique, équivalente à une liaison C—Oϕ. Ce changement de signe de la constante ρ de Hammett a été interprété de la façon suivante: en milieu acide faible, l'élongation de la liaison C—O est plus importante que la protonation du groupe phénolate, ce qui entraîne une augmentation de la densité électronique sur l'atome réactionnel, dans ce cas l'atome d'oxygène, donc une valeur de ρ positive.

En milieu acide fort, à l'inverse, la protonation du groupe phénolate est plus importante que l'élongation de la liaison C—O. L'atome d'oxygène réactionnel voit donc sa densité électronique diminuer, conduisant ainsi à une constante ρ négative.

Analyse des entropies d'activation

Les grandeurs d'activation déterminées pour les composés **1** à **4** font apparaître des valeurs fortement négatives pour les entropies d'activation dans l'hydrolyse catalysée par le proton (Tableau 6). Ces valeurs négatives peuvent résulter de deux choses: (1) du remplacement d'un groupe éthylate par un groupe phénolate (Tableau 7) comme cela a été montré dans l'hydrolyse des éthoxy-2 et phénoxy-2 tétrahydropyrannes (11); (2) du passage d'un système non cyclique à un système cyclique comme on peut le voir dans le tableau 8 à partie des résultats obtenus dans l'hydrolyse des acétals dérivés de l'éthanol ou de l'éthylèneglycol et du formaldéhyde ou du benzaldéhyde (13, 14).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

TABLEAU 7. Hydrolyse des éthoxy-2 et phénoxy-2 tétrahydropyrannes: grandeurs d'activation dans la réaction catalysée par le proton (11)

	R	$\Delta H^{\neq}$ (kcal/mol)	$\Delta S^{\neq}$ (ue)
	C_2H_5	22,2	+8
	C_6H_5	17,9	−3

TABLEAU 8. Hydrolyse des acétals dérivés de l'éthanol et de l'éthylèneglycol avec le formaldéhyde et le benzaldéhyde: grandeurs d'activation dans la réaction catalysée par le proton (13, 14)

	R	$\Delta H^{\neq}$ (kcal/mol)	$\Delta S^{\neq}$ (ue)
	C_2H_5	24,9	+7
	Dioxolanne-1,3	24,9	−1
	C_2H_5	16,5	+1
	Dioxolanne-1,3	15,5	−9

Que ce soit donc l'analyse des produits d'hydrolyse, l'analyse des constantes ρ de Hammett ou bien l'analyse des entropies d'activation, ces trois points permettent de conclure sans ambiguité que l'étape cinétique de la réaction d'hydrolyse des orthoesters étudiés ici est la rupture de la liaison C—O endocyclique.

II. *Nature du conformère réactif*

Il a été montré que dans l'hydrolyse des orthoesters diéthoxy-2,2 tétrahydropyrannes, aussi bien à partir de la nature des produits d'hydrolyse (2, 4) qu'à partir de résultats cinétiques (3) le conformère réactif était, dans le cas d'une rupture de liaison C—O exocyclique, le conformère *A* et non *F* (Schéma 1).

Dans le cas de nos composés, nous venons de montrer que c'est la liaison C—O endocyclique qui se coupe au cours du processus cinétique. Si l'on considère les orientations relatives des liaisons C—O et des paires d'électrons libres dans chacun des conformères, le conformère réactif serait le conformère *F*.

La réactivité du conformère *F* peut être évaluée d'une façon approchée à partir des valeurs des grandeurs d'activation obtenues pour le conformère *A* qui s'hydrolyse par rupture de la liaison C—OEt axiale. Il suffit, ensuite, d'ajouter algébriquement les incréments spécifiques à nos produits, incréments qui rendent compte de l'ouverture d'un cycle et du remplacement d'un groupe éthylate par un groupe phénolate; le système d'équations suivant peut donc être posé:

$$\Delta H_F^{\neq} = \Delta H_A^{\neq} + \Delta H^{\neq}_{\text{groupe partant}} + \Delta H^{\neq}_{\text{cycle}}$$

$$\Delta S_F^{\neq} = \Delta S_A^{\neq} + \Delta S^{\neq}_{\text{groupe partant}} + \Delta S^{\neq}_{\text{cycle}}$$

D'après les tableaux 7 et 8, les grandeurs d'activation pour le groupe partant sont:

$$\Delta H^{\neq}_{\text{groupe partant}} = -4{,}3 \text{ kcal/mol et } \Delta S^{\neq}_{\text{groupe partant}} = -11 \text{ ue;}$$

pour l'ouverture d'un cycle, les valeurs sont:

$$\Delta H^{\neq}_{\text{cycle}} = -0{,}5 \text{ kcal/mol et } \Delta S^{\neq}_{\text{cycle}} = -9 \text{ ue.}$$

Ces valeurs peuvent être considérées comme extrêmes puisqu'empruntées à l'hydrolyse des acétals où l'état de transition est très avancé le long du chemin réactionnel. Pour tenir compte de l'avancement moindre de l'état de transition dans l'hydrolyse des orthoesters ces valeurs peuvent être raisonnablement réduites de moitié. Sachant que $\Delta H_A^{\neq} = 11$ kcal/mol et $\Delta S_A^{\neq} = -3$ ue (15) il est possible de calculer les grandeurs d'activation pour le conformère *F*: $\Delta H_F^{\neq} = 11{,}1 - 4{,}3/2 - 0{,}5/2 = 8{,}7$ kcal/mol et $\Delta S_F^{\neq} = -3 - 11/2 - 9/2 = -13$ ue, valeurs très proches des valeurs expérimentales (9,7 kcal/mol et −16 ue).

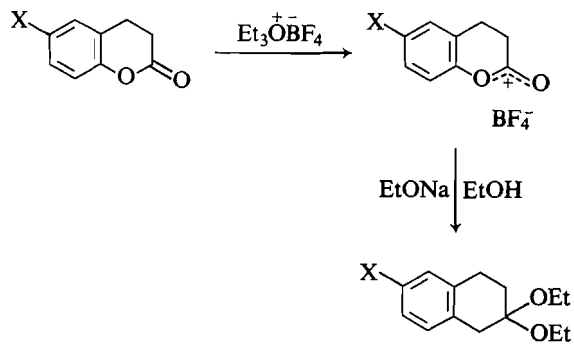

SCHÉMA 4

Conclusion

Dans le travail que nous avons présenté ici, il a donc été possible de montrer, par des mesures cinétiques, que des changements conformationnels peuvent s'opérer afin de respecter les règles stéréoélectroniques.

Il a été également possible d'évaluer la différence d'énergie d'activation entre les conformères *A* et *F*, différence égale à 2,5 kcal/mol qui favorise largement le conformère *A* sur le conformère *F* en l'absence d'effets particuliers.

Partie expérimentale

I. *Synthèse*

Les orthoesters ont été préparés à partir des lactones correspondantes, selon la procédure décrite par Deslongchamps *et al.* (4) (Schéma 4).

La lactone non substituée (X = H) est un produit commercial. La synthèse des lactones substituées (X = OMe, X = Me et X = Cl) a été effectuée selon la procédure décrite dans la littérature (16). Les rendements indiqués n'ont cependant jamais été atteints. Avant d'effectuer la synthèse des orthoesters, une vérification de la formation de l'ion lactonium a été faite pour les composés **2** (X = Me) et **3** (X = Cl).

Formation de l'ion lactonium

0,5 mmol de lactone et 0,5 mmol de tétrafluoroborate de triéthyloxonium sont dissous dans 1 mL de dichlorométhane deutérié. Le mélange est agité à température ambiante. La quantité approximative des produits présents dans le milieu est déterminée à partir des intensités relatives des différents signaux rmn observés.

X = H t = 5 h: lactonium
X = Me t = 24 h: lactonium (34%) + lactone (49%) + hydroxyester (17%)
t = 48 h: lactonium (29%) + lactone (55%) + hydroxyester (22%)

Le temps de réaction utilisé pour la formation des ions lactonium est de 24 h.

Les spectrres rmn ^{1}H ont été enregistrés sur un appareil Varian EM 390 (solvant: CD_2Cl_2; référence interne: TMS).

X = H; rmn, ^{1}H δ: 1,60 (3H, triplet, J = 7 Hz, OCH_2CH_3), 2,60 à 3,10 (4H, massif, méthylène sur C3 et C4), 4,80 (2H, quadruplet, J = 7 Hz, $\overset{+}{O}CH_2CH_3$), 6,90 à 7,40 (4H, massif, H aromatiques).

X = Me: rmn, ^{1}H δ: 1,60 (3H, triplet, J = 7 Hz, OCH_2CH_3), 2,35

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

(3H, singulet, CH_3 sur C6), 3,10 à 3,50 (4H, multiplet, méthylènes sur C3 et C4), 5,20 (2H, quadruplet, J = 7 Hz, $\overset{+}{O}CH_2CH_3$), 7,10 à 7,40 (3H, massif, H aromatiques).

Pour la suite de la synthèse des orthoesters, nous avons reproduit la procédure décrite dans la littérature (4).

Caractérisation des orthoesters

Une première caractérisation des produits formés est donnée par les spectres rmn ^1H (solvant: $CDCl_3$, référence interne: TMS).

Des analyses élémentaires, constituant une seconde caractérisation, ont ensuite été effectués pour les produits distillés, par le Service Central de Microanalyse de Vernaison.

1 – Rendement brut: 35%; rmn ^1H δ: 1,15 (6H, triplet, J = 7 Hz, OCH_2CH_3), 2,02 (2H, triplet, J = 6,5 Hz, méthylène sur C3), 2,80 (2H, triplet, J = 6,5 Hz, méthylène sur C4), 3,68 (4H, quadruplet, J = 7 Hz, OCH_2CH_3), 3,70 (3H, singulet, OCH_3), 6,50 à 6,88 (3H, massif, H aromatiques).

2 – Rendement brut: 27%; Eb. = 99°C/0,28 Torr; rmn ^1H δ: 1,15 (6H, triplet, J = 7 Hz, OCH_2CH_3), 2,08 (2H, triplet, J = 6,5 Hz, méthylène sur C3), 2,25 (3H, singulet, CH_3 sur C6), 2,82 (2H, triplet, J = 6,5, méthylène sur C4), 3,70 (4H, quadruplet, J = 7 Hz, OCH_2CH_3), 6,70 à 7,10 (3H, massif, H aromatiques). *Anal.* calc. (%) pour $C_{14}H_{20}O_3$: C 71,19, H 8,47, O 20,34; tr. (%): C 71,86, H 7,70, O 19,33.

3 – Rendement brut: 23%; Eb. = 66°C/0,1 Torr; rmn ^1H δ: 1,16 (6H, triplet, J = 7 Hz, OCH_2CH_3), 2,08 (2H, triplet, J = 6,5 Hz, méthylène sur C3), 2,82 (2H, triplet, J = 6,5 Hz, méthylène sur C4), 3,70 (4H, quadruplet, J = 7 Hz, OCH_2CH_3), 6,70 à 7,20 (4H, massif, H aromatiques). *Anal.* calc. (%) pour $C_{13}H_{18}O_3$: C 70,25, H 8,16, O 21,59; tr. (%): C 70,30, H 8,25, O 21,40.

4 – Rendement brut: 6%; rmn ^1H δ: 1,15 (6H, triplet, J = 7 Hz, OCH_2CH_3), 2,04 (2H, triplet, J = 6,5 Hz, méthylène sur C3), 2,80 (2H, triplet, J = 6,5 Hz, méthylène sur C4), 3,70 (4H, quadruplet, J = 7 Hz, OCH_2CH_3), 6,76 (1H, doublet, J = 9 Hz, H8), 6,90 à 7,20 (2H, massif, H5, H7).

II. *Identification des produits d'hydrolyse*

Cette identification a été faite avec le composé non substitué **3**. La procédure employée est la suivante: 20 μL de solution d'HCl 0,1 *N* sont ajoutés à 400 mg d'orthoester (1,8 mmol) dissous dans 2 mL de solvant MeOH/H_2O 80:20 en volumes. Le mélange est agité à température ambiante pendant 5 min, puis versé en refroidissant dans un mélange contenant 10 mL d'anhydride acétique et 10 mL de pyridine anhydre.

L'agitation à température ambiante est maintenue pendant 24 h, le mélange est ensuite évaporé à sec.

Le spectre rmn ^1H ($CDCl_3$) permet de connaître la composition du produit, par comparaison des intensités des différents signaux: lactone: 4%, acétoxyester: 96%.

III. *Cinétiques*

Les cinétiques d'hydrolyse ont été suivies par spectrophotométrie uv (Gilford 250). Une procédure détaillée concernant la mise en oeuvre des cinétiques ainsi que le mode de calcul des constantes catalytiques a été décrite par ailleurs (3). Les longueurs d'onde permettant de faire notre étude sont les suivantes: λ = 240 nm (**1**), 234 nm (**2**), 274 nm (**3**) et 290 nm (**4**). La reproductibilité sur les constantes de vitesse observées est de ±3%.

Received February 17, 1983

RENATO CAPASSO, GIACOMINO RANDAZZO, and LAURA PECCI. Can. J. Chem. **61**, 2657 (1983).

The DL-γ-carboxyglutamic acid (Gla) reacts quantitatively with formaldehyde to give 4,4-dicarboxyproline and with other aldehydes to give the racemic diastereoisomers of the 5-substituted 4,4-dicarboxyprolines. The pH-dependent reaction rate and the stereochemical behaviour suggest an intramolecular Mannich mechanism.

After heating at 100°C for 30 min, the 4,4-dicarboxyproline and the 5-substituted 4,4-dicarboxyprolines lose a carboxyl group from C4 to give the racemic diastereoisomers of the cyclic analogs of glutamic acid.

RENATO CAPASSO, GIACOMINO RANDAZZO et LAURA PECCI. Can. J. Chem. **61**, 2657 (1983).

L'acide DL-γ-carboxyglutamique (Gla) réagit quantitativement avec le formaldéhyde pour donner la dicarboxy-4,4 proline tandis qu'avec d'autres aldéhydes, on obtient les diastéréoisomères racémiques des dicarboxy-4,4 prolines substitués en position 5. La vitesse de la réaction qui dépend du pH et le comportement stéréochimique fait penser à un mécanisme de Mannich intramoléculaire.

Par chauffage à 100°C pendant 30 minutes, la dicarboxy-4,4 proline et les dicarboxy-4,4 prolines substituées en position 5 perdent le groupe carboxyle du carbone en position 4 en donnant les diastéréoisomères des analogues cycliques de l'acide glutamique.

Introduction

γ-Carboxyglutamic acid (Gla) was found in the N-terminal calcium binding region of vitamin K-dependent coagulation factors II, VII, IX, and X (1, 2). Gla-containing proteins were identified also in calcified tissues such as the organic matrix of bone (3), renal stones (4), and atherosclerotic plaque (5). Free Gla was found in human urine (6) as a metabolite of the catabolism of Gla-containing proteins (6, 7). In pharmacological therapy with warfarin (8) and in pathological cases such as osteoporosis (9), abnormal levels of Gla were found in urine. The determination of Gla levels in urine may assume an important role as a diagnostic parameter.

In a recent paper (10), a method for the quantitative determination of Gla, based on the reaction with acetaldehyde, has been described. Here, we discuss the mechanism (Scheme 1) and products **1**–**7** (Fig. 1) obtained by the reaction of Gla with aldehydes. We also report the nature of the derivatives produced by heating compounds **1**–**7** at 100°C.

Experimental

The DL-γ-carboxyglutamic acid was a gift of Dr. S. Dupré, University of L'Aquila, Italy. The aldehydes were provided by commercial sources. The amino acid analysis was performed on a LKB 4400 Amino Acid Analyzer. The proton ^{1}H nmr spectra were run on a Bruker 270 spectrometer, using (unless otherwise noted) deuterated water as solvent and *tert*-butyl alcohol as internal reference (1.23 ppm); all the chemical shifts are reported in ppm from TMS. The mass spectrum was recorded on an AEI-902 spectrometer at 70 eV. The uv spectra were recorded in water on a Cary-118 spectrophotomer and the ir spectra were run in chloroform or in Nujol. Electrophoresis was run on a silica gel plate (20 × 20 cm, Kieselgel Merck 0.25 mm) in 0.5% pyridine and 5% acetic acid buffer, pH 3.5, at 500 volt for one hour. Thin-layer chromatography (tlc) was performed on silica gel plates (Kieselgel 60 F_{254} 0.25 mm, chloroform–isopropanol, 90:10, as eluent) and on cellulose plates (F 0.1 mm, n-butanol – acetic acid – water 60:15:25, as eluent); the spots were developed by spraying with ninhydrin and heating at 110°C for 10 min. Dowex-50 (Fluka AG) and DEAE-cellulose (Whatman DE 52) were used for chromatographic separations.

The reaction rate of Gla with aldehydes as a function of pH was monitored by tlc of 10^{-2} *M* Gla and 5 *M* aldehyde solutions in 0.3 *M* pyridine acetate buffers of pH values ranging from 2 to 8.

4,4-Dicarboxyproline ***1***

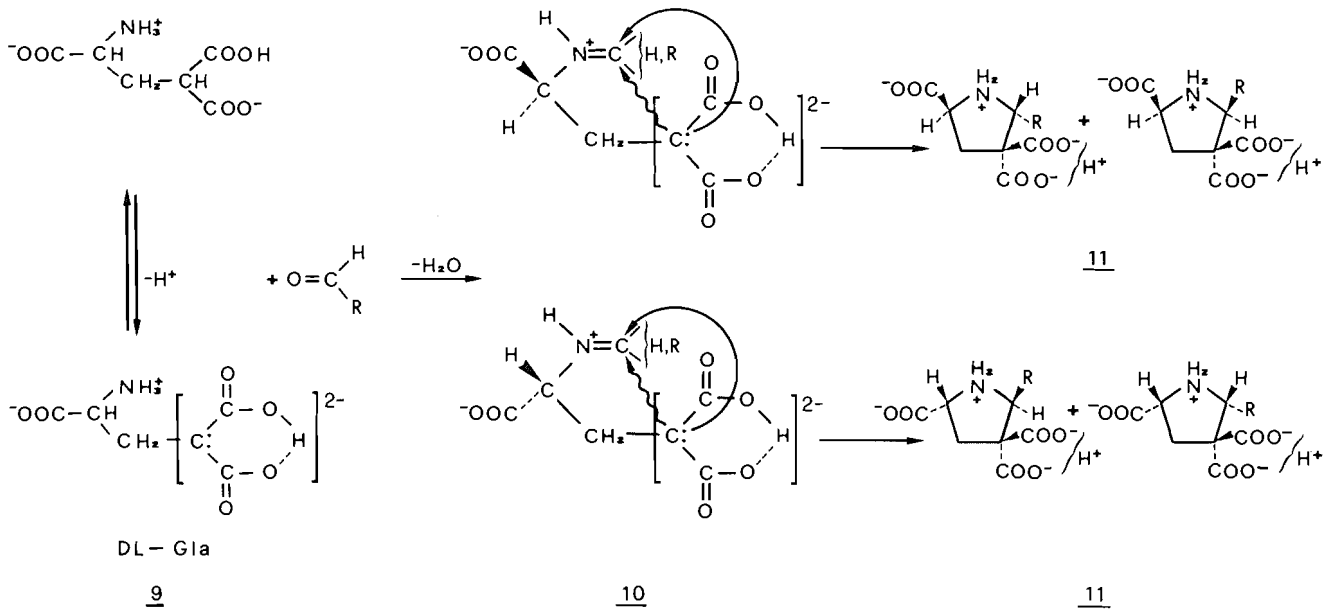
DL-Gla (35 mg) is dissolved in 4.5 mL of 35% aqueous formaldehyde. The reaction is completed after 16 h, as shown on tlc by the appearance of a new yellow spot with R_f higher than Gla. The mixture is chromatographed on a DEAE-cellulose column (1.2 × 55 cm) equilibrated and eluted with 0.3 *M* pyridine acetate buffer, pH 4.75. The fractions are analyzed by tlc and those giving the yellow spot with ninhydrin are pooled and lyophilized. The residue, redissolved and lyophilized at least three times, is a white crystalline solid (25 mg); mp 120–130°C, with full transformation to **8**, as shown by tlc control; electrophoresis: at pH 3.5, **1** shows a yellow spot with a higher anodic mobility than glutamic acid and aspartic acid; automatic aminoacid analysis: **1** shows a single peak eluted 5 min after sample loading or 16.5 min before proline; ir (Nujol) ν_{max}: 3500, 3150, 1730, and 1630 cm^{-1}; ^{1}H nmr and uv data are summarized in Table 1 and Fig. 2.

Trimethylester of 4,4-dicarboxyproline ***1***a

Compound **1** (5 mg) is dissolved in methanol (2 mL) and treated with diazomethane in an ice bath under stirring until the yellow colour of mixture persists. After tlc control (chloroform–isopropanol, 90:10, ninhydrin), which shows a single yellow spot, the solution is evaporated under reduced pressure; the residue is an amorphous solid (5 mg); ir($CHCl_3$), ν_{max}: 3400 and 1730 cm^{-1}; ^{1}H nmr ($CDCl_3$): 3.71, 3.72, and 3.73 (3s, 3 × 3H, 3-COOMe); ms, m/z: 244(M^+ – H), 214 (M^+ – OMe), 186(M^+ – COOMe), 68(M^+ – 3COOMe).

4,4-Dicarboxy-5-methylproline ***2*** *and -5-ethylproline* ***3***

To a solution of DL-Gla (5.7 mg) in water (0.6 mL) freshly distilled acetaldehyde (150 μL) (propionaldehyde, 150 μL) is added. The reaction is carried out at room temperature and monitored by tlc as for **1**. After two hours, the acetaldehyde (propionaldehyde) in excess is carried off under a nitrogen stream and the solution is lyophilized. The residue is crystalline (6.7 mg for **2**, 7 mg for **3**). The ^{1}H nmr and uv



SCHEME. 1. Mannich reaction mechanism of Gla with aldehydes.

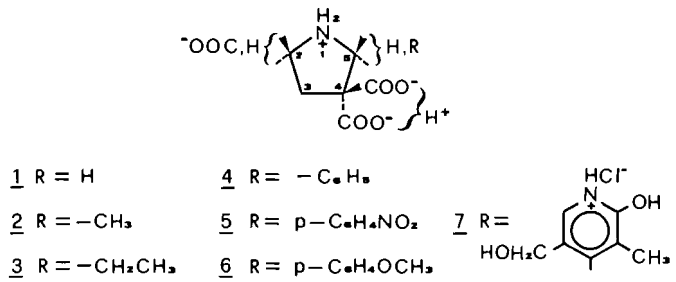


FIG. 1. Reaction products of Gla with aldehydes.

data are summarized in Table 1. As an example, the nmr spectrum of **2** is reported in Fig. 3(*a*).

4,4-Dicarboxy-5-phenylproline **4**, *-5-(*p*-NO_2-phenyl)proline* **5**, *and -5-(*p*-OCH_3-phenyl)proline* **6**

DL-Gla (6 mg) is dissolved in a mixture of water (3 mL) and methanol (3 mL). To this solution, benzaldehyde (0.6 mL) (*p*-NO_2-benzaldehyde, 300 mg, for **5**, *p*-OCH_3-benzaldehyde, 0.7 mL, for **6**) is added. The reaction is left overnight at room temperature and monitored as described above. Methanol is evaporated from the mixture under reduced pressure. The remaining aqueous phase is washed with methylene chloride (3 × 3 mL). When the solid *p*-NO_2-benzaldehyde is used, the mixture is filtered before washing. The lyophilized residue is crystalline (8 mg for **4**, 8.6 mg for **5**, and 8.3 mg for **6**). The ^{1}H nmr and uv data are summarized in Table 1. As an example, the nmr spectrum of **4** is reported in Fig. 3(*b*).

4,4-Dicarboxy-5-pyridoxylproline hydrochloride **7**

DL-Gla (10 mg) is dissolved in water (5 mL). To the solution, three aliquots of pyridoxal hydrochloride (50 mg) are added every two hours. After the last addition, the solution is left overnight at room temperature, then monitored by tlc. A yellow spot with R_f 0.5 appears after spraying with ninhydrin in the usual chromatographic system. The solution is then chromatographed on a Dowex-50 column (2 × 10 cm), equilibrated, and eluted with ammonium formate buffer 0.1 *M*, pH 4. The fractions which give yellow spots with ninhdydrin are pooled and lyophilized. The residue, redissolved and lyophilized at least three times, is a white crystalline solid (16 mg). The ^{1}H nmr and uv data are summarized in Table 1.

4-Carboxy-4-deuteroproline **8**

Compound **1** (5 mg) is dissolved in D_2O (0.5 mL) in an ^{1}H nmr tube. The solution is heated for 30 min at 100°C and cooled to room temperature. The solution is analyzed by ^{1}H nmr (Fig. 4 and Table 1). The amino acid analysis of **8** shows two peaks with elution times 12 min and 13.2 min respectively (9.9 min and 8.7 min before proline).

4-Carboxy-4-deuteroprolines, 5-substituted

Compounds **2**–**7** are treated as **8** and analyzed by ^{1}H nmr.

Results and discussion

The structure **1** has been suggested for the product of reaction between Gla and formaldehyde (11). We have confirmed the structure **1** mainly by ^{1}H nmr spectrum (Fig. 2 and Table 1) and by the spectroscopic analysis of its trimethylester derivative **1***a*. The ^{1}H nmr spectrum (Fig. 2) displays a typical ABX system, where the AB part consists of H_A— and H_B—C3, each resonating as a quartet centred at 3.08 δ and 2.80 δ respectively (J_{AB} = 15 Hz, J_{AX} = J_{BX} = 7.5 Hz), while the X part consists of H_X—C2, resonating as a triplet centered at 4.70 δ (J_{AX} = J_{BX} = 7.5 Hz). Finally, two doublets centered at 4.22 δ and 4.12 δ (J_{AB} = 12.75 Hz) appear, corresponding to H_A— and H_B—C5, respectively.

When the Gla is left to react with other aldehydes, the products are 5-substituted 4,4-dicarboxyprolines **2**–**7** (Fig. 1), as shown mainly by ^{1}H nmr data (Table 1). The ^{1}H nmr spectra of **2** and **4** (Figs. 3(*a*) and (*b*)), reported as examples, display the same characteristic signals of an ABX system as **1**, but doubled, while the signals related to C5 are modified as compared to **1**. The double signals, which are of similar intensity, are attributed to racemic diastereoisomers formed by the introduction of a new racemic center (C5) in the pyrrolidinic ring (Scheme 1). The reaction rate has been studied as a function of pH. The reaction takes place at pH values ranging from 3 to 6.5; its rate depends on pH and on the solubility of the aldehydes in water. Our data are consistent with the curve reported for the reaction of Gla with pyridoxal phosphate (11); in this case it has been shown that the proline derivative is formed only when the iminium ion is present as intermediate. In the above pH range Gla is present as polyanion as the C-γ proton is able to dissociate at slightly acidic pH values giving rise to the exocyclic planar carbanion **9** (13). In fact, as shown

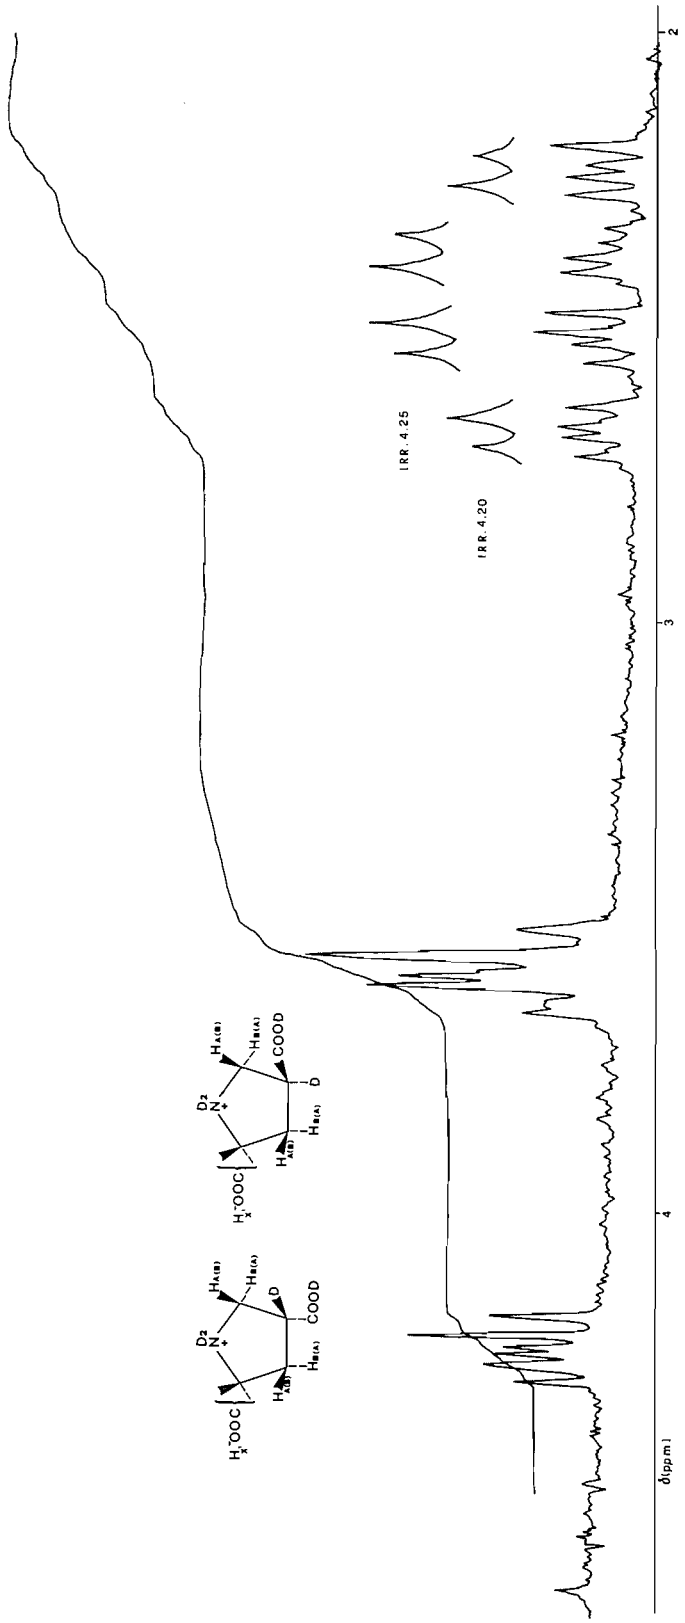

FIG. 4. The ^1H nmr spectrum of **8** in D_2O, using as internal reference *tert*-butyl alcohol (1.23 ppm).

by Price *et al.* (13), the C-γ proton of Gla easily exchanges in the acidic pH range with maximal rate at about pH 3.1 and the nmr spectrum of Gla in D_2O does not show any C-γ proton chemical shift. Therefore, these data allow us to formulate the Mannich mechanism in Scheme 1 for the reaction of Gla with aldehydes and to exclude three alternative possibilities (12): (a) formation of the Mannich base at alkaline pH by a S_N2 mechanism between the methylol derivative and the carbanion; (b) reaction at acidic pH, by a S_E2 mechanism, between the Schiff base and the compound containing the activated hydrogen; (c) formation, from the activated-hydrogen compound and the aldehyde, of an intermediate adduct which, in turn, reacts with the amino group. In fact, the iminium ion in **10** (the protonated Schiff base (11), Scheme 1) gives an intramolecular ion−ion reaction with the C-γ carbanion of amino acid **9** (Scheme 1); at pH > 6.5, the formation of the prolinic ring is not observed, because the C-γ hydrogen does not dissociate; the two carboxyl groups of the side chain of **9** are fully ionized ($pK_1 = 2.03$ and $pK = 4.37$) (13) and the Schiff base in **10** deprotonates. At pH < 3, the reaction is not observed, due to loss of nucleophilicity of the ammonium ion of Gla (Scheme 1). Finally, the attack of C-γ of the adduct **10** on both faces of the iminium ion of **10** occurs statistically to give both possible stereoisomers **11** (Scheme 1). According to the Curtin−Hammett principle (14), this result means that the relative energy levels of the transition states by which the stereoisomers are formed are very similar.

We will now discuss the behaviour of **1**−**7** upon heating in D_2O for 30 min at 100°C. In particular, the ^1H nmr spectrum of the product of heating **1**−**8**, (Fig. 4 and Table 1) shows double signals with the same intensity, shifted upfield, in comparison to the ^1H nmr spectrum of **1**. These signals are attributed to the racemic diastereoisomers of **8** (Fig. 4), produced by the introduction of a new chiral racemic center in C4 of **1**, as a consequence of the statistical replacement of one carboxyl group with deuterium. The appearance of two peaks in the amino acid chromatogram indicates that the two diastereoisomers have different acid properties, due to the possibility of hydrogen bonding between the two *syn* carboxyl groups. A similar behaviour is shown by the **2**−**7** derivatives, whose ^1H nmr spectra are not reported here. The described treatment leads to the formation of many different cyclic analogs of glutamic acid which could possess biological activity (15).

In conclusion, the quantitative and rapid reaction of Gla with aldehydes suggests the possibility of applying this reaction for analytical purposes, by using a coloured or fluorescent aldehyde for quantitative determination of Gla in the serum.

Received January 7, 1983

ORAZIO ATTANASI, PAOLO BATTISTONI, and GABRIELE FAVA. Can. J. Chem. **61**, 2665 (1983).

The reaction of (phenylazo) stilbene and copper(II) chloride wih some dienophiles produced benzaldehyde and *N*-(α-chlorobenzylidene)-*N'*-phenylhydrazine, instead of the expected (4+2)-cycloaddition products. By reaction of some (arylazo) alkenes and copper(II) chloride in acetone at 0°C, the relative *N*-(α-chlorobenzylidene)-*N'*-arylhydrazine derivatives were successfully obtained in high yields.

ORAZIO ATTANASI, PAOLO BATTISTONI et GABRIELE FAVA. Can. J. Chem. **61**, 2665 (1983).

Le (phénylazo) stilbène et le chlorure de cuivre(II) réagissent avec quelques diénophiles en donnant le benzaldéhyde et le *N*-(α-chlorobenzylidène)*N'*-phénylhydrazine au lieu des produits de cycloaddition (4+2) attendus. On a obtenu, avec des rendements élevés, les dérivés *N*-(α-chlorobenzylidène)*N'*-arylhydrazine apparentés en faisant réagir quelques (arylazo)alcènes et le chlorure de cuivre(II) dans l'acétone, à 0°C.

It is known that the conjugated azo-ene system of aliphatic and aromatic azoalkenes, with or without electron-withdrawing groups on the azo group, frequently have a reactivity analogous to that of other conjugated double bonds. In fact, several of these compounds are known to undergo (2+2)- and (4+2)-type cycloadditions with some carbon–carbon dienophiles and heterodienophiles, providing interesting heterocyclic compounds (1). Furthermore, some azoalkene derivatives are known to give 1,4-additions (Michael-type) with a variety of nucleophiles, producing the respective hydrazone derivatives and simultaneous C-functionalization which may be of great usefulness in organic synthesis (2–6). In particular, some (arylazo) alkenes are demonstrated to undergo 1,4 conjugate addition of activated methylene compounds (3, 6). However, several of the above-mentioned reactions cannot always be so immediately extended and generalized to all azoalkene derivatives known, mainly because of their different degree of stability and reactivity. In fact, some of these compounds may not be sufficiently stable and may be difficult to preserve, while others are fairly stable and easily available products (2–7). Furthermore, a lot of these compounds are in general rather reactive, while others are much less reactive. For these reasons, the activation by metal ions of some azoalkenes in certain 1,4-addition reactions was studied and reported in our previous papers (2, 3). On the basis of these investigations and considering that several (4+2)-type cycloadditions may be promoted by metal ions, and especially by copper ions (8), we undertook the study of the reaction between some (arylazo) alkenes (**1**) and copper(II) chloride dihydrate (**3**) in the presence of some dienophiles (**2**).

Results and discussion

While in the absence of **3** no reaction was observed, in the presence of this inorganic salt (phenylazo) stilbene **1***a* in tetrahydrofuran (THF) and **2** (acrylonitrile, tetracyanoethylene, *N*-phenylmaleimide) react, sometimes completely, providing benzaldehyde (**4**), *N*-(α-chlorobenzylidene)-*N'*-phenylhydrazine (**5***a*), and traces of benzoic acid, instead of the expected (4+2)-cycloaddition products (Scheme 1).

In Table 1 are reported the percentages of unreacted **1***a*, and **4** and **5***a* produced (detected by hplc).

The results (Table 1) do not allow elucidation of the reaction pathway or the role played by copper(II) chloride and dienophiles. For this reason, we examined the reaction of **1***a* with **2** in THF and tetracyanoethylene **6** in particular (Table 2).

This investigation demonstrated that **6** did not behave as a dienophile with **1***a* and suggested **3** to have a reactive rather than a catalytic role, as suggested in our previous papers (2, 3). All the experimental evidence supports the hypothesis that two different and concomitant pathways for reaction of **1***a* may be operative. Route A: probable adduct between **1***a*, **6**, and **3** would promote the 1,4-addition of water to **1***a*, producing the benzoin phenylhydrazone intermediate that provides at first **4** and benzaldehyde phenylhydrazone **7**. This latter compound affords a further molecule of **4** by copper(II) ion-promoted hydrolysis, in accordance with previous investigations (2).

1:0.1:4		130	30	

[a]Yields of **4** produced were calculated assuming that one molecule arises from each molecule of **1***a*.

Route B: the same adduct would also activate the chlorination of **1***a*, producing **4** and **5***a*. This hypothesis is supported by some previous findings on this matter (9). On the other hand, **7**, **3**, and excess **6** provide only **4**, but not **5***a* (Scheme 2), in spite of its good stability in the reaction medium.

This compound **5***a* represents a very important intermediate in the chemistry of the 1,3-dipolar cycloadditions, where its basic treatment (generally triethylamine) easily generates, by 1,3-elimination of hydrogen chloride, diphenylnitrilimine ($Ph—\overset{+}{C}=N—\bar{N}—Ph \leftrightarrow Ph—C\equiv\overset{+}{N}—\bar{N}—Ph$). Furthermore, if produced *in situ*, it readily reacts with several 1,3-dipolarophile reagents, providing very interesting heterocyclic compounds (10, 11). Our attention was then focused on finding the best reaction conditions for synthesis of **5***a*. Considering that this compound arises from chlorination of **1***a*, and since under several reaction conditions no substantial increase of **5***a* to more than 30% yields was observed, a tentative experiment using acetone instead of dienophile was performed. In fact, it is known that acetone, as well as several other ketones, promotes the chlorine transfer from copper(II) chloride by chloro-acetone intermediate formation, coming from chlorocopper(II) – acetone precursor complexes (9, 12).

By a detailed experiment it was found that formation of **5***a*, due to the chlorination of **1***a* by **3**, occurs faster and with highest yields in pure acetone and when the molecular ratio between **1***a* and **3** is 1:2, respectively. Under the same reaction conditions **7** gave **4** as the main reaction product, while **5***a* was detected only in traces. This observation is in accordance with the reaction pathway shown in Scheme 2.

In view of the synthetic usefulness of *N*-(α-chlorobenzylidene)-*N'*- arylhydrazine derivatives, the reaction discussed above was successfully extended to [(*p*-chlorophenyl)azo] stilbene **1***b* and (*p*-tolylazo)stilbene **1***c* (Scheme 3). According to our preliminary paper (11), treatment of these compounds with **3** in acetone at 0°C readily affords **5***a–c* in high yields (90–95% by hplc, 80–85% after column chromatography and crystallization).

These derivatives appear not to be easily synthesizable by other known methods (10, 11, 13). Furthermore, **5***a–c* prepared with our method can be utilized without complicated procedures for their isolation and purification. In fact, the reaction mixture, after extraction with benzene and aqueous hydrogen chloride, affords **5***a–c* in good purity. These latter products, without further purification, were successfully utilized by us in some typical 1,3-dipolar cycloadditions. This possibility is also noteworthy in consideration of the fact that these compounds are seriously irritant and the occasional contact with contaminated articles causes severe dermatitis.

For these reasons, the procedure reported here represents a mild, simple, and convenient method for the synthesis and use in organic synthesis of the mentioned *N*-(α-chlorobenzylidene)-*N'*-arylhydrazine derivatives.

In order to make the present method even more convenient, the procedure previously reported (11) for the synthesis in high yields of (phenylazo) stilbene **1***a* was successfully applied to the synthesis of the other unknown (arylazo) alkene derivatives **1***b–c* considered in this work (see Experimental section).

Experimental

(Arylazo) alkenes **1**a–c

These compounds were synthesized according to the procedure previously reported in detail for the synthesis of (phenylazo) stilbene,

and were used as mixtures of two isomers (*EE* and *ZE*) (11). The analytical data of compound **1***a* were described in detail by Bonini *et al.* (1) and Brodka and Simon (5).

*[(*p*-Chlorophenyl)azo] stilbene* **1**b: yield 83%; red crystals from n-pentane (or petroleum ether 40–60°C); mp 100–104°C with decomposition (uncorrected); ir (Nujol) and ^{1}H nmr ($CDCl_3$, Me_4Si) spectra show no particular features. *Anal.* calcd. for $C_{20}H_{15}N_2Cl$: C 75.35, H 4.74, N 8.79; found: C 75.71, H 4.69, N 8.85.

*(*p*-Tolylazo) stilbene* **1**c: yield 78%; red crystals from n-petane (or petroleum ether 40–60°C); mp 112–116°C with decomposition (uncorrected); ir (Nujol) spectrum shows no particular features; ^{1}H nmr ($CDCl_3$, Me_4Si) δ: 2.25 (3H, s), 7–8 (15H, m). *Anal.* calcd. for $C_{21}H_{18}N_2$: C 84.53, H 6.08, N 9.39; found: C 85.02, H 5.99, N 9.43.

Reaction of **1**a *and* **3** *in* **2**. *General procedure*

A solution of an appropriate amount of **2** (see Tables 1 and 2) in THF (20 mL) was added dropwise at room temperature to a stirred solution of **1***a* (0.70 mmol) and an appropriate amount of **3** (see Tables 1 and 2) in THF (20 mL). The mixture was stirred magnetically at room temperature during 21 or 48 h. THF was then evaporated under reduced pressure, the residue was dissolved in ether and washed several times with water. The organic layer was dried with anhydrous sodium sulphate and concentrated under reduced pressure. The reaction mixtures were examined by hplc. Alternatively, the reaction components were isolated by chromatography on a silica gel column (at first elution with cyclohexane and then with cyclohexane–benzene mixtures, gradually increasing the amount of benzene to a 60:40 (v/v) ratio).

Reaction of (arylazo) alkenes **1**a–c *and* **3** *in acetone. General procedure for the synthesis of* **5**a–c *derivatives*

A solution of (arylazo) alkenes **1***a*–*c* (0.07 mmol) in acetone (50 mL) was added dropwise to a stirred solution of **3** (1.4 mmol) in acetone (50 mL), cooled in an ice bath. The mixture was stirred magnetically at 0°C during 1 h until the reaction was completed (monitored by silica gel tlc). Acetone was then evaporated under reduced pressure, the residue was dissolved in benzene and washed several times with 5% aqueous hydrogen chloride and then with water. The organic layer was dried with anhydrous magnesium sulphate and concentrated under reduced pressure. The crude **5***a*–*c* derivatives obtained in good purity can be further purified by chromatography on a silica gel column (at first elution with cyclohexane and then with cyclohexane–benzene mixtures, gradually increasing the amount of benzene to a 60:40 (v/v) ratio). Alternatively, the crude products may be successfully used for 1,3-cycloaddition reactions, without further purification.

N-(α-Chlorobenzylidene)-N′-phenylhydrazine **5**a: yield 95% by hplc, yield 85% of isolated product by chromatography on a silica gel column; white crystals from acetonitrile–acetone; mp 129–131°C (uncorrected) (lit. (11) mp 129.5–130.5 or 128–131°C); ir (Nujol): 3305 (NH), 1600 (aromatic) cm^{-1}; ^{1}H nmr (CCl_4, Me_4Si) spectrum shows no particular features. *Anal.* calcd. for $C_{13}H_{11}N_2Cl$: C 67.68, H 4.81, N 12.14; found: C 67.79, H 4.85, N 12.09.

N-(α-Chlorobenzylidene)-N′-p-chlorophenylhydrazine **5**b: yield 92% by hplc, yield 83% of isolated product by chromatography on a silica gel column; white crystals from acetonitrile–acetone; mp 105–107°C (uncorrected); ir (Nujol): 3320 (NH), 1600 (aromatic) cm^{-1}; ^{1}H nmr (CCl_4, Me_4Si) spectrum shows no particular features. *Anal.* calcd. for $C_{13}H_{10}N_2Cl_2$: C 58.89, H 3.80, N 10.57; found: C 58.99, H 3.76, N 10.62.

N-(α-Chlorobenzylidene)-N′-p-tolylhydrazine **5**c: yield 90% by hplc, yield 80% of isolated product by chromatography on a silica gel column; white crystals from acetonitrile–acetone; mp 118–121°C (uncorrected); ir (Nujol): 3320 (NH), 1610 (aromatic) cm^{-1}; ^{1}H nmr (CCl_4, Me_4Si) δ: 2.30 (3H, s), 7–8 (10H, m). *Anal.* calcd. for $C_{14}H_{13}N_2Cl$: C 68.71, H 5.35, N 11.45; found: C 68.85, H 5.29, N 11.52.

High resolution HeI and HeII photoelectron spectra of the thallium halides: valence bands and Tl 5*d* ligand field splittings

G. M. BANCROFT[1] AND D. J. BRISTOW[2]

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received January 17, 1983

G. M. BANCROFT and D. J. BRISTOW. Can. J. Chem. **61**, 2669 (1983).

We report high resolution photoelectron spectra of both the valence bands and Tl 5*d* levels of the thallium halides (TlX; X = Cl, Br, I) in the gas phase. A transition state Xα-SW calculation on TlCl agrees with previous valence band assignments, although our calculated orbital characters are quite different from those reported previously. The calculated spin–orbit splitting of the $2^2\Pi$ state in TlI is in good agreement with the observed value of 0.83 eV. Line width variations are rationalized considering the increase in covalency from TlCl to TlI, and variations in the slope of the excited state potential curve.

Ligand field splitting of the Tl 5*d* level has been resolved in all three compounds. The observed values of the non-cubic part of the crystal field (C_2^0) are: −0.0210 eV (TlCl), −0.0233 eV (TlBr), and −0.0258 eV (TlI). The above trend is due to the increasing covalency from TlCl to TlI, with a concomitant increase in the Tl 6*p* orbital population. Calculated C_2^0 values are in good agreement with those observed. The configuration interaction structure in the Tl 5*d* region is explained qualitatively using Xα-SW calculations of two-hole valence band energies in TlCl.

G. M. BANCROFT et D. J. BRISTOW. Can. J. Chem. **61**, 2669 (1983).

Nous rapportons les spectres photoélectroniques à haute résolution des bandes de valence ainsi que des niveaux de 5*d* du Tl des halogènures de thallium (TlX; X = Cl, Br, I) en phase gazeuse. Un calcul de l'état de transition Xα-SW du TlCl s'accorde avec les attributions antérieures des bandes de valence, quoique notre calcul des caractères d'orbitale soit tout à fait différent de ceux rapportés antérieurement. Le découplage spin–orbite calculé de l'état $2^2\Pi$ du TlI est en accord avec la valeur de 0,83 eV observée. On rationalise les variations de la largeur des raies en considérant l'augmentation de la covalence à partir du TlCl au TlI et les variations de la pente de la courbe d'énergie potentielle de l'état excité.

On a résolu le découplage de champ du ligand du niveau 5*d* du Tl dans les trois composés. Les valeurs observées pour la partie non cubique du champ du cristal (C_2^0) sont de: −0,0210 eV (TlCl), −0,0233 eV (TlBr) et de −0,0258 eV (TlI). Cette tendance est due à l'augmentation de la covalence de TlCl à TlI avec une augmentation concomitante de la population de l'orbitale 6*p* du Tl. Les valeurs de C_2^0 calculées sont en bon accord avec celles observées. On explique de façon qualitative la structure de l'interaction de configuration dans la région 5*d* du Tl en utilisant les calculs Xα-SW des énergies de la bande de valence à deux trous du TlCl.

[Traduit par le journal]

Introduction

During the last ten years, there has been a number of uv photoelectron studies on the thallium halides in the gas phase (1–5). In fact, the pioneering work with high temperature vapours involved these compounds (1). The focus of these previous studies has centred both on the assignment of the valence bonds (1, 2, 4), and the interpretation of the Tl 5*d* spectra (2–5). Like the Zn 3*d* and Cd 4*d* spectra of the Zn and Cd dihalides (ref. 6 and references therein), the Tl 5*d* spectra exhibit final state effects such as ligand field splitting and configuration interaction. However, in the previous studies, the resolution of the Tl 5*d* spectra was not sufficient to resolve and characterize the ligand field splittings and configuration interaction. As a result, derived ligand field parameters in two studies (3, 4) were not in good agreement; and in one study (4), the unexpected increase in ligand field splitting from TlI to TlCl and TlBr was rationalized using the spectrochemical series (7).

In this paper, we report high resolution HeI valence band and HeII Tl 5*d* photoelectron spectra of the thallium halides. With the aid of our higher resolution and an Xα-SW calculation on TlCl, we are able to characterize further the valence band spectra. Of greater interest, we have been able to resolve more fully the ligand field splitting and configuration interaction peaks on the Tl 5*d* levels. Our calculations of the major crystal field parameter C_2^0 are in surprisingly good agreement with the values obtained from the spectra.

Experimental

The experimental details for our high temperature spectra have been reported in two previous papers (8, 9). All spectra were obtained on our McPherson ESCA-36 photoelectron spectrometer using a hollow cathode He lamp (10). The spectra have been computer fitted to Lorentzian–Gaussian line shapes (11). The compounds were heated up to within about 30°C of their literature melting points (≥400°C) to obtain sufficient vapour pressure.

Results and discussion

(a) Valence bands

The HeI spectra of the valence bands of the thallium halides are presented in Fig. 1. The general features are similar to those published previously (1–4). However, higher resolution in the present work has enabled further analysis. Our assignments binding energies, relative areas, and half widths are given in Table 1.

For the assignment of these spectra, we follow the original assignment (1). The results of extended Hückel calculations were used to determine the orbital character associated with each band (1). Taking TlCl as an example, the highest occupied orbital was found to be predominantly Tl 6*s* (62%) in character. This fact was used to explain the sharpness of the low binding energy peak (A, Fig. 1) in the photoelectron spectrum. It was rationalized that removal of an electron from a predominantly metal centre should increase the Coulombic attraction only slightly between the metal and halogen (12). Conversely, the broadness of the second band (B) results from a significant disruption of the ionic bond via removal of an electron from a lone pair *p* orbital centred on the negative halogen. The 3σ orbital (C) was found to be about 65% Cl $3p_\sigma$ and 20% Tl 6*s* (1).

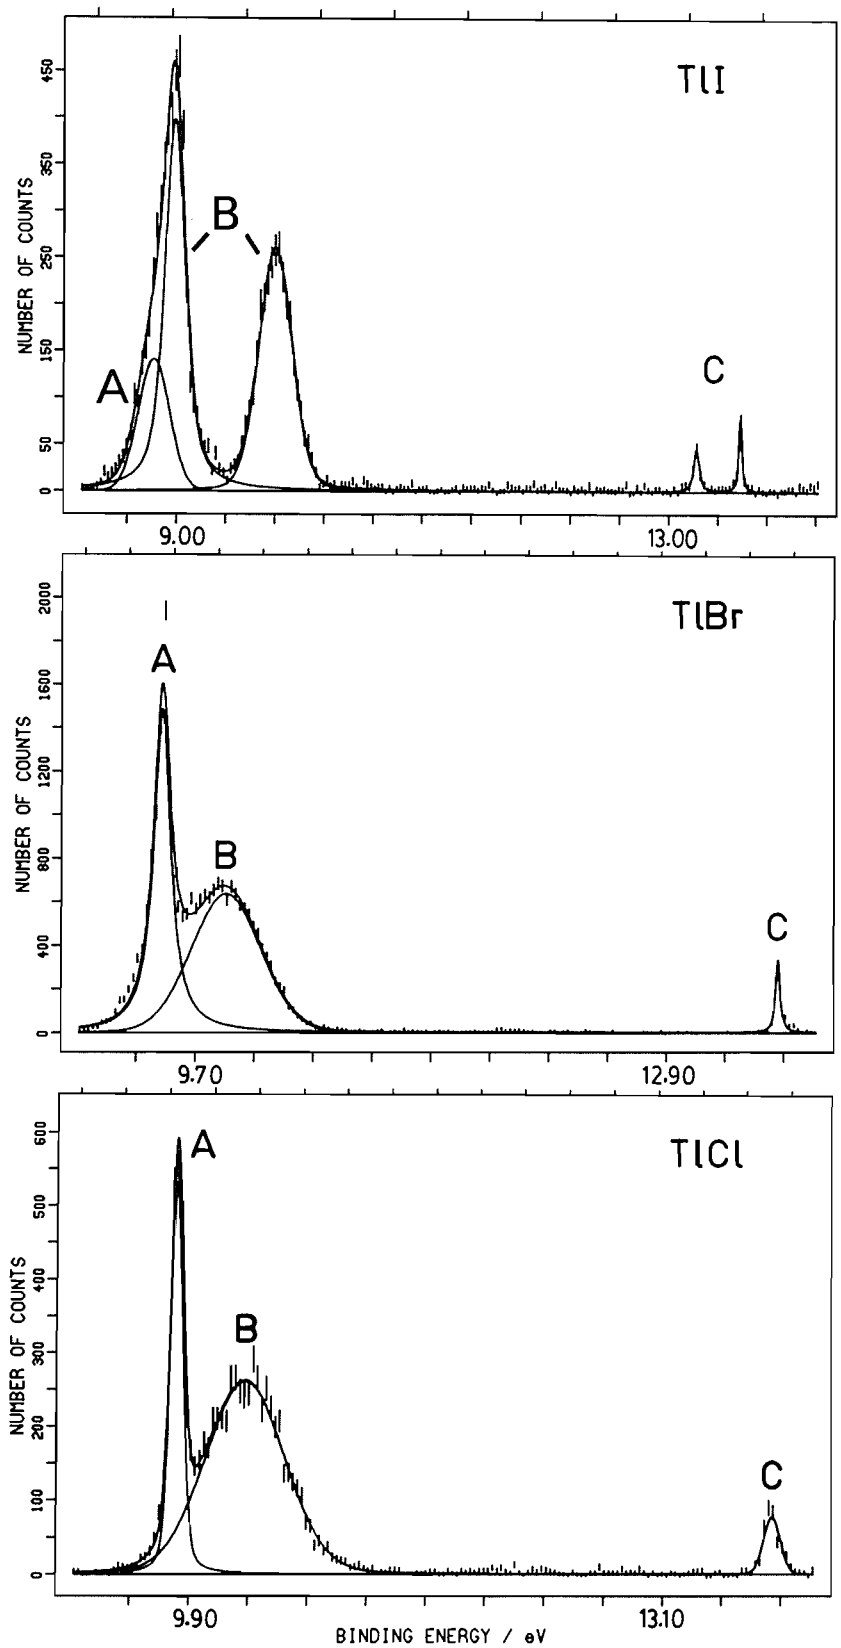

FIG. 1. HeI valence band spectra of the Tl halides.

We have undertaken a non-relativistic Xα-SW calculation on TlCl and the Xα parameters appear in Table 4. The calculated binding energies based on the HOMO transition state and the percentage orbital character for the ground state are presented in Table 5. By use of Stater's transition state concept (13), quantitative agreement has been obtained between observed and calculated optical transition energies in many molecules. Schwarz's α_{HF} values (14) were used for the atomic exchange parameters. For the extramolecular and intersphere regions, a weighted average (weighting factors proportional to the num-

[a]The values for peaks A, B, and C are from the Xα-SW calculation; while the other values are calculated using the derived C_2^0 and C_4^0 values (Table 6) and the crystal field Hamiltonian, refs. 17–19.

ber of valence electrons in Cl(7) and Tl(3)) of the values in the atomic region was used. Norman's nonempirical procedure (15) was used to obtain the ratio of sphere radii. The intersphere charge, which in the valence region comprises ~20% of the total, has not been assigned specific character. Partitioning of the intersphere charges into atomic spheres is proportional to the percentage atomic character (16).

It is immediately evident that the Xα-SW calculation implies considerably more mixing between the Tl 6*s* and Cl 3*p* orbitals in both the 4σ and 3σ molecular levels than was the case with the extended Hückel calculation. These results imply that the first photoelectron peak (A) results from ionization of a slightly antibonding Tl—Cl level rather than a predominantly Tl 6*s* orbital. The 3σ orbital represents the bonding part of this combination while the 2π orbital is essentially 100% lone pair Cl 3*p* in character. Removal of an electron from a slightly antibonding (4σ) level should not disrupt the bond greatly. Hence the experimentally observed narrow peak (A) is consistent with the present calculation.

This conclusion is substantiated by a recent DV-Xα calculation on TlCl (17). The DV-Xα calculation indicates 25% and 67% Tl 6*s* participation in the 4σ and 3σ orbitals, respectively. This division of bond character is essentially the reverse of the extended Hückel calculations.

As with the Zn and Cd dibromide and diodide spectra (9), we expect to be able to resolve the spin–orbit splitting in the 2π state for TlBr and TlI. In the TlBr spectrum, peak B is too broad to resolve the expected spin–orbit splitting of about 0.3 eV (9). However, in the TlI spectrum, a distinct asymmetry is seen on the low binding energy band, and the band is readily resolved into two peaks (Fig. 1). Previous spectra (1, 3, 4) were not of sufficient resolution to allow determination of accurate binding energies for these two peaks. We assign the low binding energy peak (peak A) to the $4\Sigma_{1/2}$ state. This leaves us with a $2^2\Pi$ spin–orbit splitting of 0.82 eV, considerably larger than the expected two thirds of the atomic splitting (9, 18). This increase in spin–orbit splitting results from mixing and repulsion between the $2^2\Pi_{1/2}$ and $4^2\Sigma_{1/2}$ states. Using the method (18) outlined in our previous paper (9), the predicted splitting is 0.83 eV, in good agreement with that observed. The $2^2\Pi_{1/2}$ peak is broader and less intense than the $2^2\Pi_{3/2}$ peak, presumably because of mixing between the $2^2\Pi_{1/2}$ and $4^2\Sigma_{1/2}$ states.

The variation in peak widths from TlCl to TlI is also of some interest. For example, for peaks A and B, the linewidths increase and decrease respectively on going from TlCl to TlI. Both trends can be rationalized by the increasing importance of covalency from TlCl to TlI as suggested by Berkowitz for peak A (1). In the more covalent TlI, peaks B are much narrower than in TlCl and TlBr, as expected for ionization from a nonbonding halogen orbital in a covalent molecule.

The width of the $3^2\Sigma_{1/2}$ peak(s) decreases markedly in going from TlCl to TlBr and TlI. Indeed, these peak widths for TlBr and TlI are rather close to our instrumental resolution of ≤30 meV, and appear as very sharp spikes. These narrow widths for the TlI doublet make it possible to comment further on the origin of this splitting. It was originally proposed (1) that the splitting arose from Franck–Condon transitions from higher vibrational levels of the ground state. In a subsequent publication on the indium halides (12) it was pointed out that the splitting could be due to a double minimum in the hole state curve in the Franck–Condon region. It has been shown that the width of a photoelectron peak can be related to the slope of the hole state potential energy (19). This correlation arises from the fact that a steep slope in the Franck–Condon region provides overlap with a large number of vibrational states, leading to a broad peak (e.g. peaks B in our spectra). The large reduction in half width of the $3^2\Sigma_{1/2}$ peak on going from TlCl to TlBr and TlI implies a corresponding reduction in the slope of the hole state potential energy curve. For TlI, the double minimum explanation is reasonable, because such a phenomenon is more easily envisioned in a potential region exhibiting little slope. Also, as was pointed out previously (1), the ground vibrational frequency in TlBr (192 cm^{-1}) is not a great deal larger than that in TlI (~152 cm^{-1}), and a bimodal ground state distribution should split the $3^2\Sigma_{1/2}$ peak in TlBr as well as in TlI.

*(b) Ligand field splitting on the Tl 5*d *orbitals*

Our primary interest in this work was the investigation of the ligand field splitting of the Tl 5*d* level. The HeII spectra of these levels are presented in Figs. 2 to 4. A broader scan of the TlCl $5d_{5/2}$ region has been included (Fig. 4) because of additional structure at the low binding energy end of the spectrum. Due to the relatively large spin–orbit coupling value in this orbital we collected the $5d_{5/2}$ and $5d_{3/2}$ regions in separate spectra. This was done in order to maintain high resolution during the short scans of each region. Individual scans were later added together on a computer with a provision for shifting spectra to eliminate differential charging effects. Since the two regions were of necessity collected for different periods of time and on different days it is not possible to obtain $^2D_{5/2}/^2D_{3/2}$ ratios.

The binding energies, relative areas, and widths are summarized in Tables 1–3. Many of the widths are ~100 meV — probably very close to the lifetime values for the Tl 5*d* level. As a result, we have been able to resolve a number of additional peaks in these spectra from those reported previously, and in all three cases, we have resolved the five Tl 5*d* peaks due to ligand field splitting. The peaks due to configuration interaction are labelled with letters (D, E, F, etc) and will be discussed later. The additional peaks are crucial to the assignment, interpretation, and trends. However, our assignment of the *ordering*

of the ligand field states is the electrostatic order assumed previously (3, 4):

$$^2\Sigma_{1/2} < {}^2\Pi_{3/2} < {}^2\Delta_{5/2} < {}^2\Pi_{1/2} < {}^2\Delta_{3/2}$$

Also, where peaks were resolved in the previous studies, previous binding energies are in good agreement with ours.

The rich structure in the Tl $5d_{5/2}$ region in the TlCl spectrum presented an initial problem, which is readily clarified when the

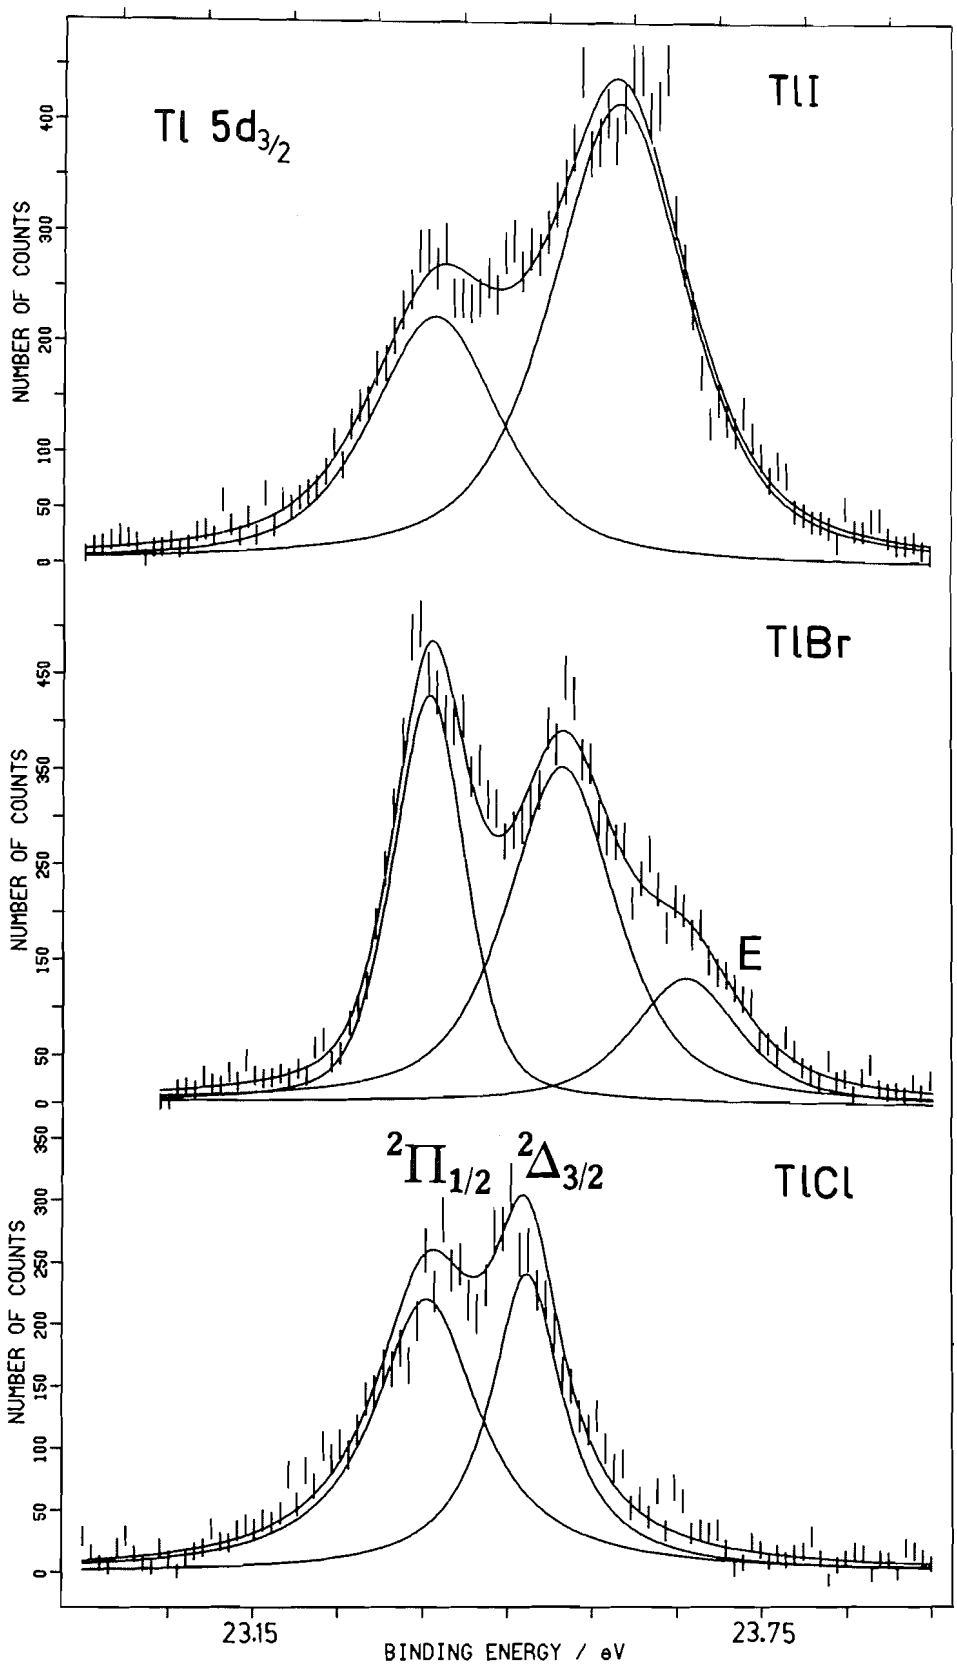

FIG. 3. HeII spectra of the Tl $5d_{3/2}$ region in the Tl halides. The $1^2\Pi_{1/2}$ peaks at low binding energy are at the same apparent binding energy.

$5d_{5/2}$ spectra for all three compounds are directly compared (Fig. 2). The third and fourth peaks from the left in TlCl are most logically assigned to the $^2\Pi_{3/2}$ and $^2\Delta_{5/2}$ levels respectively, since they line up rather well with the corresponding peaks in the bromide and iodide. In both the Tl $5d_{5/2}$ and $5d_{3/2}$ regions, the splitting increases in the order Cl < Br < I, although the increase in splitting is much more pronounced in the $5d_{3/2}$ region. In previous spectra (2–4), peaks

due to $^2\Pi_{3/2}$ and $^2\Delta_{5/2}$ levels were not resolved in any of the spectra, and in one case (4), peak G in TlCl was assigned to the $\Delta_{5/2}$ state.

As in our previous papers (6, 20–22), we use the crystal field Hamiltonian for a d^9 state in a $D_{\infty h}$ or $C_{\infty v}$ crystal field to analyze the ligand field splitting. The five energies for the d levels yield the chemical shifts, spin–orbit splittings, and axial and cubic components (C_2^0 and C_4^0 respectively) of the crystal field. These are summarized in Table 6. Using these values, the peak positions are generally reproduced to within 0.02 eV (Tables 1–3). The parameter of greatest interest — the C_2^0 value — increases steadily from TlCl to TlI. This is the same trend as in the zinc and cadmium halide series (6), and corresponds to an increasing $6p$ orbital population on Tl from chloride to iodide expected from covalency considerations. The order is not that of the spectrochemical series (4). The chemical shifts are in good agreement with those reported earlier (3, 4). The spin–orbit coupling values are all fairly close to the atomic value (2.25 eV), implying that the $5d$ level is essentially atomic in nature. The fact that the TlCl value (2.28 eV) is within 2% of the atomic splitting is more evidence that our assignment of the $5d_{5/2}$ levels is correct.

In order to determine the relative magnitudes of the crystal field and valence contributions to the observed C_2^0 term, we have calculated C_2^0 values using our previous theoretical approach (6, 22) (Table 6). It is immediately obvious that the crystal field contribution ($C_2^0{}_{C.F.}$) is considerably smaller than the valence contribution ($C_2^0{}_{Val}$), and that $C_2^0{}_{Val}$ is in remarkably good agreement with the derived experimental values. In the Zn and Cd halides, $C_2^0{}_{C.F.}$ was larger than $C_2^0{}_{Val}$, although $C_2^0{}_{Val}$ was probably underestimated (6). There are at least two reasons for this difference between Tl and Zn, Cd compounds. First, there is only one negatively charged ligand in the Tl compounds which, assuming the same ligand charge as in the Zn and Cd analogs, would immediately halve $C_2^0{}_{C.F.}$. In fact, the ligand charges calculated from the chemical shifts using the normal treatment (23) are smaller than in the Zn and Cd series, leading to an expected C_2^0 value for Tl of well under one half that for the Zn and Cd analogs. Using Pauling's electro-

[c]$\Delta\rho = 1 - q$.
[d]Calculated using the following values: $F^2(dp)$ = 0.0977 Ryd; $G^1(dp)$ = 0.0310 Ryd; $G^3(dp)$ = 0.0274 Ryd.

negativity expression (24, 25):

$$q \times 100 = |\chi_A - \chi_B| + 3.5|\chi_A - \chi_B|^2$$

where χ_A and χ_B are the electronegativities of the two atoms, we obtain q values which are in qualitative agreement with those obtained from the chemical shifts in Table 6: 0.223, 0.177, and 0.113 for TlCl, TlBr, and TlI, respectively. Second, $C_2^0{}_{val}$ for the Tl compounds is much larger for the Zn and Cd analogs, because Δρ (Δρ = $n_{pz} - (1/2)(n_{px} + n_{py})$) is much larger for Tl than for Zn or Cd. This difference can be related, at least to a first approximation, to the electronic structure of these atoms. Zinc and cadmium both have two valence electrons (ns^2) and thallium has three ($6s^26p$). In the ionic limit, zinc and cadmium lose both outer *s* electrons while thallium loses the 6*p* electron. As these atoms form covalent bonds, the halide ligands donate charge to the outer *s* and *p* orbitals of zinc and cadmium, but primarily to the 6*p* orbital in Tl. In fact, the Xα calculation in our previous paper (9) indicates that the majority of charge in Zn and Cd compounds is located in the outer *s* orbital which does not contribute to Δρ. If we consider that Tl^+ has the electronic configuration $6s^2$, donation of charge in the halides will be to the Tl 6*p* orbital, and we can take Δρ = 1 − *q*. Our Xα calculation (Table 5) shows that this simple approximation will undoubtedly lead to an overestimate of Δρ.

To test our theory further, we use the combined crystal field and valence matrix elements (6, 22) to calculate the relative positions of the Tl 5*d* levels. These results appear in Table 7, and show that the agreement between experiment and theory is relatively good. It is interesting to note that the separation of the $2^2\Sigma_{1/2}$ level from the $1^2\Delta_{5/2}$ is consistently underestimated throughout the series. This may be indicative of a slight interaction with the halogen localized *s* orbital as was observed in the Zn and Cd series (6). The steady reduction in relative intensity of the $^2\Sigma_{1/2}$ level from TlCl to TlI (Fig. 2) may suggest that such an interaction exists, although other effects may be responsible for these changes (6).

[a]Calculated using the parameters in Table 6, and the matrix elements in refs. 6 and 19.

A good correlation between $C_2^0{}_{Exp.}$ and the chemical shift of the Tl 5*d* orbital has been obtained and is presented in Fig. 5. The chemical shifts have been taken relative to the metal (4). The $C_2^0{}_{Val}$ term is essentially colinear with the experimental values while the crystal field term is considerably smaller and of course has the opposite slope. These results again indicate a

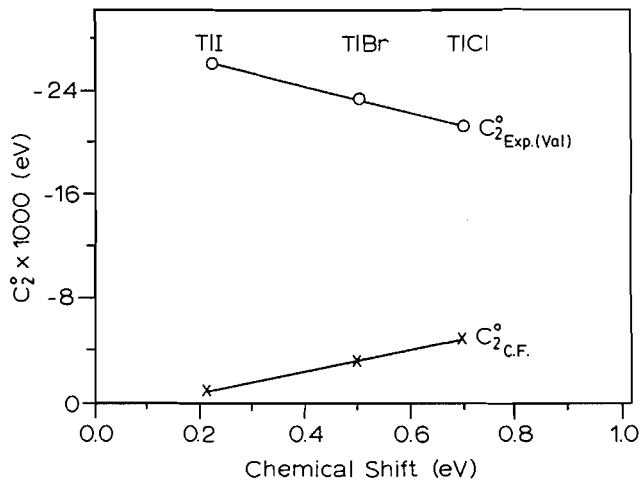

FIG. 5. Plot of C_2^0 versus the Tl $5d$ chemical shift for the Tl halides. The chemical shifts are given relative to Tl metal (4).

predominantly valence contribution to the C_2^0 asymmetric potential felt by the Tl $5d$ orbital.

(c) Configuration interaction

The additional structure in the Tl $5d$ region of TlCl and TlBr is of some interest. The structure in TlCl is associated with the $5d_{5/2}$ level (Fig. 4, peaks D, E, F, G), while that in TlBr can be seen in both the $5d_{5/2}$ (Fig. 2, peak D) and $5d_{3/2}$ (Fig. 3, peak E) regions. We also observed the additional weak peak observed by other workers (3, 4) at an ionization potential of 18.55 eV. The two primary effects which could be responsible for this additional structure are initial state configuration interaction (ISCI) and final ionized state configuration interaction (FISCI). Since the additional peaks are associated with the localized Tl $5d$ orbital, it would seem reasonable to investigate initially the atomic Tl $5d$ spectrum (26–29) which has rich CI structure. This system is immediately complicated, of course, by the unpaired electron in the Tl atom ground state ($5d^{10}6s^26p^1$). Ignoring further effects, this will produce a doublet for both the $5d_{5/2}$ and $5d_{3/2}$ components of the spin–orbit pair due to coupling to the unpaired $6p$ electron. Two peaks are in fact observed for the $5d_{5/2}$ ionization, but six peaks arise with $5d_{3/2}$ ionization (27). There are fundamentally two different types of processes responsible for the structure, both of which are attributed to FISCI. An example of the first of these can be illustrated schematically as (27):

$$(5d_{3/2})^3(5d_{5/2})^6(6s)^2(6p_{1/2})^1(6p_{3/2})^0 \leftrightarrow (5d_{3/2})^4(5d_{5/2})^5(6s)^2(6p_{1/2})^0(6p_{3/2})^1$$

This then is a two electron process in which an electron has fallen from the $5d_{5/2}$ manifold into the $5d_{3/2}$ at the same time as the $6p_{1/2}$ electron jumps up to the $6p_{3/2}$ level. This process (one electron up, one electron down) is only available for the deeper lying $5d_{3/2}$ level. The other type of two electron process contributing to the structure but which maintains the full complement of $5d$ electrons derives from final states such as $5d^{10}6s^17p^1_{3/2,1/2}$ (26, 27). It seems clear that the first type of process involving the $5d^9$ hole and $6p$ electron is not possible for the halides: all the valence orbitals are full and electrons paired. The second type is possible, the only restriction being that the final state have the same designation as the one electron $5d$ ionization and close to the same total energy. In general, it has been found that this type of CI occurs where there is an appropriate orbital at approximately half the binding energy of the primary hole (30–32).

Looking at TlCl first, this prerequisite is met by the $4^2\Sigma_{1/2}$ and $1^2\Pi_{3/2,1/2}$ states (Table 1). We see from the Xα calculation that the majority of the Tl $6s$ character (47%) is located in the 4σ orbital, and this could be viewed as a prime candidate for CI. One possibility for interacting configurations is

$$1\sigma^21\delta^41\pi^42\sigma^13\sigma^22\pi^44\sigma^2 \leftrightarrow 1\sigma^21\delta^41\pi^42\sigma^23\sigma^22\pi^44\sigma^0n\sigma^{*1}$$

where the orbital numbering begins with Cl $3s$ level. The left hand side is the one electron 2σ ($5d$) ionization while that on the right is a two electron process involving simultaneous photo ejection and excitation from the 4σ (HOMO) orbital. The designation of both final states would be $^2\Sigma_{1/2}$.

We have used our Xα calculation on TlCl to obtain the "binding" energies for two electron processes such as the one just described and present the results in Table 8. The results included in this table are for monopole transitions only such as $\sigma \rightarrow \sigma^*$ and $\pi \rightarrow \pi^*$. The various final states possible have been included in the left hand column of the table. These calculations have been performed by initially removing one electron from the valence orbital involved (4σ, 2π, or 3σ) and obtaining the corresponding converged potential. Using this potential then, a second electron from the same orbital is transferred to one of the virtual levels and the final converged potential is obtained. The total energy involved in this process is simply the difference between the total ground state molecular energy. These values have been listed in the column labelled energy of Table 8. It is immediately clear that a number of the final states represent energies in the range of the Tl $5d$ ionizations (~20 eV). The calculation itself, however, provides no indication of the relative probability associated with the various transitions. Since the $5d$ orbital is localized on thallium, valence and virtual orbitals exhibiting a significant population on thallium and close to the same final state energy as the $5d$ ionization might be expected to be the most likely for configuration interaction. Both the 4σ and 3σ valence orbitals possess a considerable thallium contribution. The $5\sigma^*$ virtual level is also predominantly thallium in character, but the higher virtual levels are associated primarily with the outer sphere region. In these cases, transitions to virtual orbitals with a high percentage of s-character in the outer sphere region such as the $6\sigma^*$ and $8\sigma^*$ are likely as the valence character of the 4σ and 3σ levels on thallium is primarily Tl $6s$. Based on these arguments then, the $4\sigma \rightarrow n\sigma^*$ (n = 5, 6, 8) and $3\sigma \rightarrow 5\sigma^*$ transitions would all appear to be possible candidates for final state configuration interaction. Of these possibilities the $4\sigma \rightarrow 8\sigma^*$ and $3\sigma \rightarrow 5\sigma^*$ at 19.63 eV and 23.18 eV, respectively, are energetically the most favourable as their final energies are closest to the $5d$ ionization energies. The $2\pi \rightarrow n\pi^*$ are not as likely since the valence 2π orbital is localized almost entirely on chlorine. It is not possible to unequivocally assign the CI structure because of the numerous transitions available (Table 8) and the lack of information concerning their cross-sections.

It is interesting to note that simple monopole transitions cannot give rise to $^2\Delta$ type final states. The $^2\Delta$ final state is strictly inaccessible from valence σ-orbitals because of the selection rule $\Delta\lambda = 0, \pm 1$. However, if we assume that conjugate shakeup (33, 34) represents a significant configuration interaction mechanism, then a transition such as $2\pi \rightarrow n\sigma^*$ involving the excited electron would produce a $^2\Delta$ final state. In support of this conjecture, work on Ne (33) concludes that at low photon energies, up to 25% of the shakeup intensity

could be due to "conjugate" shakeup. Also, 20% of the $^2P_{3/2,1/2}$ intensity observed in the spectra of atomic mercury (34) is due to the "conjugate" shakeup mechanism.

We have calculated a number of transitions in which the dipole process now involves the electron undergoing excitation ("conjugate" shakeup) and present the results in Table 9. The percent orbital character of all the levels appears in Table 8. While this calculation has been performed on TlCl, the small difference in binding energies for the TlBr orbitals (Table 2) suggests that the energy involved in TlBr CI will be quite similar to TlCl. Thus a transition such as

$$2\pi^4 \rightarrow 2\pi^2 6\sigma^{1*}\ (^2\Delta) + e$$

which requires 23.8 eV (Table 9) could be responsible for peak E in the $5d_{3/2}$ region of TlBr (Fig. 2) which has an ionization energy of 23.4 eV (Table 2). This peak (E) is apparently associated with the $1^2\Delta_{3/2}$ state as was the case for the $3d$ orbital of $ZnBr_2$.

Conclusion

Tl $5d$ core level ligand field splittings have been completely resolved in the photoelectron spectra of the main group thallium halides. The splitting is mainly due to the non-cubic (C_2^0)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

part of the crystal field. For the first time, our calculated C_2^0 values are in very good agreement with the observed values, and we show that the valence part of the C_2^0 term, $C_2^0{}_{val}$, is the dominating contribution to C_2^0. We have also advanced the understanding of the Tl $5d$ configuration interaction structure and the valence bonds with the aid of our higher resolution and transition state Xα-SW calculation.

Charge distributions and chemical effects. XXXII. Energies of multiple carbon–carbon bonds

S. FLISZÁR

Department of Chemistry, University of Montreal, Montreal, P.Q., Canada H3C 3V1

Received April 11, 1983

S. FLISZÁR. Can. J. Chem. **61**, 2679 (1983).

Bond energies are derived from total (nuclear–electronic and nuclear–nuclear) potential energies involving the individual nuclei of a molecule. It appears that the carbon–carbon bond energies in ethane, ethylene, allene, acetylene, and benzene are in a ratio of 1:2:1.9:2.9:1.6. This result enables a rapid estimate of approximate atomization energies of unsaturated hydrocarbons from those of their corresponding saturated parent compounds and, more importantly, shows the links relating to one another the various classes of saturated and unsaturated hydrocarbons in a unifying fashion.

S. FLISZÁR. Can. J. Chem. **61**, 2679 (1983).

Les énergies de liens sont déduites à partir des énergies potentielles noyau–électron et noyau–noyau impliquant les noyaux individuels d'une molécule. Les énergies de liens carbone–carbone de l'éthane, de l'éthylène, de l'allène, de l'acétylène et du benzène sont dans un rapport de 1:2:1.9:2.9:1.6. Cette information permet une évaluation rapide des énergies d'atomisation de composés insaturés à partir de leurs précurseurs saturés et, primordialement, illustre les liens de parenté reliant entre elles les différentes classes d'hydrocarbures saturés et insaturés.

Introduction

The concept of a chemical bond is central in the understanding of many aspects of molecular structure and thermochemical stability. The present study considers the problem for molecules taken in their hypothetical vibrationless state, at 0 K. Attention is primarily directed toward the conceptual aspects surrounding the energy partitioning among chemical bonds, in order to put in a clear perspective what type of approximations are involved in the derivation of theoretical bond energies and what causes them to differ from the usual ones, retrieved from empirical correlations. Unlike empirical bond energies, the present theoretical results create a clear link between the different types (single, double, etc.) of carbon–carbon bonding and offer a simple unifying view encompassing both saturated and unsaturated hydrocarbons.

Atoms in a molecule

The difference between a molecule as we know it and the corresponding collection of isolated atoms is a relatively minor one, from the energetic point of view. In this sense, it is fair to say that the largest part, by far, of the molecular energy is already partitioned in a quite natural way, in terms of atomic contributions. What really remains to be partitioned is the difference

$$[1]\quad \Delta E_a^* = \Sigma_i E_i^{\text{atom}} - E^{\text{molecule}}$$

between the energy of the isolated atoms making up a molecule and that of the molecule itself. Viewing the latter as a collection of "atoms" with energies E_i^{mol} differing from those of their isolated counterparts, let

$$[2]\quad \Delta E_i = E_i^{\text{atom}} - E_i^{\text{mol}}$$

describe this energy difference for atom i. The atomization energy ΔE_a^*, which measures chemical binding, is then $\Delta E_a^* = \Sigma_i \Delta E_i$. The advantage offered by this type of description resides in the fact that nonrelativistic atomic and molecular ground-state energies can be expressed in terms of the electrostatic potentials at the nuclei, the molecular energy thus being given as a sum of atomiclike terms (1).

For the isolated, viz. bonded, atom i, we can write (2–4)

$$[3]\quad E_i^{\text{atom}} = K_i^{\text{at}} V_{\text{ne}}(\text{atom } i)$$

$$[4]\quad E_i^{\text{mol}} = K_i^{\text{mol}} V(i, \text{mol})$$

where (in conventional notation)

$$V_{\text{ne}}(\text{atom } i) = -Z_i \int \frac{\rho(\boldsymbol{r})}{|\boldsymbol{r} - \boldsymbol{r}_i|}\, d\boldsymbol{r}$$

is the nuclear–electronic potential energy of the isolated atom i and

$$V(i, \text{mol}) = -Z_i \int \frac{\rho(\boldsymbol{r})}{|\boldsymbol{r} - \boldsymbol{r}_i|}\, d\boldsymbol{r} + Z_i \sum_{k \neq i} Z_k / r_{ki}$$

is the total potential energy involving nucleus i, due to all the electrons and nuclei other than i in the molecule. In eq. [3], K_i^{at} is necessarily a constant for each individual atom. For hydrogen, $K_{\text{H}}^{\text{at}} = 1/2$ (because of the virial theorem); $K_i^{\text{at}} \simeq 3/7$ for atoms other than H is predicted by the Thomas–Fermi model (5–7) as well as by approaches (1, 8) rooted in density functional theory (9). Selected K_i^{at} values, deduced from SCF calculations, are (2–4) 0.4276 (C), 0.4239 (N), and 0.4201 (O). The K_i^{mol} coefficient introduced by Politzer (2) in writing eq. [4] appears to behave as a constant for each atomic species, as indicated by a host of SCF calculations (2–4), but this is not an exact result. Selected K_i^{mol} values are: 1/2 (H), 0.4287 (C), 0.4260 (N), and 0.4213 (O). Constancy of these K_i^{mol} coefficients is assumed in the present work. In this approximation, the binding contributed by atom i is

$$[5]\quad \Delta E_i = K_i^{\text{at}} V_{\text{ne}}(\text{atom } i) - K_i^{\text{mol}} V(i, \text{mol})$$

This energy partitioning involves no distinction between bonded and nonbonded atoms in a molecule. Unfortunately, ΔE_i is not what one is usually looking for, as important arguments in the understanding of chemistry still remain linked to the concept of chemical bonds. This concept shall now be examined, taking eq. [5] as a starting point.

The chemical bond

Before entering the world of chemical bonds, let us briefly consider atom pairs (in a molecule) which are not bonded in the usual chemical sense. In σ systems, their interactions can be estimated using Del Re's approximation (10)

$$E(\text{nonbonded}) = \tfrac{1}{2} \sum_{k,l} q_k q_l / r_{kl}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

which is simply the Coulomb energy between net (i.e., nuclear minus electronic) charges of nonbonded atoms at a distance r_{kl}. These interactions are not only minor (typically 0.02−0.05% of ΔE_a^*) but often exhibit the wrong trend in comparisons between structural isomers (3). (For example, the difference in nonbonded energy between normal pentane and neopentane is only ~0.1 kcal mol^{-1} favoring, as expected, the normal isomer, whereas neopentane is actually the more stable form by ~4 kcal mol^{-1} (3)). Temporarily neglecting nonbonded contributions, it is therefore defendable to assimilate the bonded part of ΔE_a^* to ΔE_a^* itself, i.e.,

$$[6] \quad \Delta E_a^{*\text{bonded}} \simeq \Delta E_a^*$$

In this approximation, we write

$$[7] \quad \Delta E_a^* \simeq \Sigma \epsilon_{ij}$$

where ϵ_{ij} is the contribution of the bond formed by atoms i and j to the total atomization energy. Note that for any bonded atom pair we speak in all cases of *one* bond only, whether this bond is a single one (in conventional language), like the CC bond in ethane, or a multiple bond (like the CC bonds in ethylene, acetylene, benzene, etc.). Also note that the ϵ_{ij} bond contributions under scrutiny are dictated by the actual bond properties in the molecule (internuclear distance and local charge density): they should not be mistaken for the energy required for breaking these bonds. Indeed, bond dissociation energies depend also on electronic rearrangements (like making sure that a neutral H atom is formed during the cleavage of a CH bond in methane, in which hydrogen carries a partial charge) and on structural changes in the fragments (like that of a CH_3 radical formed during a CH bond cleavage in methane).

The derivation of the equation describing ϵ_{ij} involves the following steps. From eq. [1], written (in conventional notation) as

$$\Delta E_a^* = \Sigma_i \langle \psi_i^{at} | H_i^{at} | \psi_i^{at} \rangle - \langle \psi^{mol} | H^{mol} | \psi^{mol} \rangle$$

one obtains by means of the Hellmann−Feynman theorem that (3)

$$Z_i(\partial \Delta E_a^*/\partial Z_i) = V_{ne}(\text{atom } i) - V(i, \text{mol})$$

which is an exact equation for molecules at equilibrium. On the other hand, it follows from eq. [7] that

$$\partial \Delta E_a^*/\partial Z_i \simeq \Sigma_j(\partial \epsilon_{ij}/\partial Z_i)$$

where the j atoms are bonded to atom i. Consequently, it results that

$$[8] \quad Z_i \Sigma_j(\partial \epsilon_{ij}/\partial Z_i) \simeq V_{ne}(\text{atom } i) - V(i, \text{mol})$$

and, from eq. [5],

$$[9] \quad \Delta E_i \simeq K_i^{mol} Z_i \Sigma_j(\partial \epsilon_{ij}/\partial Z_i) + (K_i^{at} - K_i^{mol}) V_{ne}(\text{atom } i)$$

What has happened here can be described as follows. With the calculation of $Z_i(\partial \Delta E_a^*/\partial Z_i)$ from eq. [1], we have reduced the quantum chemical problem to a purely electrostatic one, with a solution for each individual atom i. Then, introducing the concept of chemical bonds by means of eq. [7], we have obtained an energy formula, eq. [9], for the binding of each atom in the molecule, featuring the role of the bonds it forms. The point is that eq. [9] expresses most appropriately that part of the "true" ΔE_i which depends specifically on bond formation, i.e., precisely what is required for deducing ϵ_{ij}. Indeed, the "extraction" from the host molecule of an atom i forming v_i bonds requires an energy $(K_i^{at} - K_i^{mol}) V_{ne}(\text{atom } i)/v_i$ for each bond, meaning that this type of contribution must be counted once for both the i and j atoms of the ij bond. In addition, this "atomization" requires an energy $K_i^{mol} Z_i(\partial \epsilon_{ij}/\partial Z_i)$ for each bond formed by i, meaning that the suppression of an ij bond involves this type of contribution for each bonded partner. Consequently, it follows from this partitioning that (3)

$$[10] \quad \epsilon_{ij} = K_i^{mol} Z_i(\partial \epsilon_{ij}/\partial Z_i) + K_j^{mol} Z_j(\partial \epsilon_{ij}/\partial Z_j) + (K_i^{at} - K_i^{mol}) V_{ne}(\text{atom } i)/v_i + (K_j^{at} - K_j^{mol}) V_{ne}(\text{atom } j)/v_j$$

Numerical applications of eq. [10] are presented below. These calculations involve two assumptions. Firstly, the K_i^{mol}'s are treated as constants — an assumption which is supported by Hartree-Fock results (2−4). Secondly, it is regarded that nonbonded interactions are sufficiently small as to permit a reasonable evaluation of $\Sigma_j(\partial \epsilon_{ij}/\partial Z_i)$ from Hartree−Fock applications of eq. [8]. These working hypotheses are tested in comparisons involving experimental energies, which is a severe way of assessing their validity. Unfortunately, it is by no means an easy task to estimate the $\partial \epsilon_{ij}/\partial Z_i$ derivatives at the level of experimental accuracy. It has been done in a few cases (3, 11), e.g., for the ethane CC and CH bonds and for the ethylene CC double bond. However, this type of calculation needs to be done only once for each type of chemical bond, for reasons given below. Selecting ethane as the reference compound for the definition of reference bond energies ϵ_{ij}^0, it is found (3) from eq. [10] that $\epsilon_{CC}^0 = 69.633$ and $\epsilon_{CH}^0 = 106.806$ kcal mol^{-1}. (For ethylene (11), $\epsilon_{C=C}^0 = 139.27$ kcal mol^{-1}). Here we wish to show that the reference bond energies ϵ_{CC}^0 and ϵ_{CH}^0 indicated above for ethane and the use of eqs. [8] and [10] suffice for describing both saturated and unsaturated hydrocarbons (e.g., benzene) at a level reasonably close to experimental accuracy. In this manner, it becomes possible to show that eq. [10] provides a unifying picture for the thermochemical stability of hydrocarbons belonging to well diversified classes as regards their molecular and electronic structure. This approach is thus markedly different from the usual bond additivity schemes which require separate parametrizations for single, double, etc. bonds, developed on an empirical basis for satisfying observed thermochemical properties.

There is a point of utmost importance which requires immediate attention. The derivatives $\partial \epsilon_{ij}/\partial Z_i$ are bound to the conditions set by the present use of the Hellmann−Feynman theorem in that they are carried out leaving the internuclear distances and number of electrons unchanged, as they are in the molecule under study. A transfer of the corresponding ϵ_{ij}'s (like the ϵ_{CC}^0 and ϵ_{CH}^0 energies deduced for ethane) from one molecule to another implies the transfer of the bond-forming atoms as they are in the molecule for which they were derived. Such a transfer, involving invariant "local" electron populations, cannot (as a rule) describe an electroneutral molecule (3). For example, if the ethane C and H net charges are 0.0351 and −0.0117 e (3), respectively, a methane "molecule" constructed from these "atoms" would carry a negative charge of −0.0117 e. Clearly, the simple transfer of selected "reference" bond energies ϵ_{ij}^0 would not satisfy the requirement for molecular electroneutrality. The appropriate charge renormalization accompanying the use of "reference" bond energies ϵ_{ij}^0 leads to a description of ϵ_{ij}, eq. [11], featuring the effects due to changes in net atomic charges (Δq_i and Δq_j) with respect to the charges of the atoms forming the reference bonds (3).

For personal use only.

$$[11] \quad \epsilon_{ij} = \epsilon^0_{ij} + a_{ij}\Delta q_i + a_{ji}\Delta q_j$$

The a_{ij} parameters are derived from theory (3). Typical values are, for alkanes, $a_{CC} = -0.777$, $a_{CH} = -0.394$, and $a_{HC} = -1.007$ au. Note that the sum of all the ϵ_{ij}'s yields the bonded part of ΔE^*_a, i.e.,

$$[12] \quad \Delta E^*_a \simeq \Sigma\epsilon^0_{ij} + \Sigma_i\Sigma_j a_{ij}\Delta q_i$$

Equation [12] offers a detailed insight into charge effects governing bond energies and has been applied to a body of over 120 molecules, with an accuracy which is well within experimental uncertainties (3, 11, 12). The point made here is that only a few ϵ^0_{ij}'s need now be calculated by means of eq. [10]. (The new problem, of course, is one of calculating charges — a task which is aided by correlations involving nuclear magnetic resonance shifts (3, 13)).

So far we have dealt with theoretical energies defined by eqs. [10] and [11]. Let us briefly examine the nature of their empirical counterparts. Saturated hydrocarbons $C_nH_{2n+2-2m}$ containing m (≥ 0) cycles serve as a simple typical example. For these compounds, the expansion of eq. [12] yields (3)

$$[13] \quad \Sigma\epsilon_{ij} = (n + m - 1)(\epsilon^0_{CC} - a_{HC}q^0_C/2) + (2n + 2 - 2m)(\epsilon^0_{CH} - a_{HC}q^0_H/4) + \lambda_1\Sigma N_{CC}\Delta q_C + \lambda_2\Sigma\Delta q_C$$

where the Δq_C's are the increments in net charge at the carbon atoms, relative to that of ethane, whose net charge is q^0_C (= 0.0351 e), with $q^0_H = -q^0_C/3$ = hydrogen net charge. $\lambda_1 = a_{CC} - a_{CH}$, $\lambda_2 = 4a_{CH} - a_{HC}$; N_{CC} = number of CC bonds a C atom is engaged in. Note that $(n + m - 1)$ and $(2n + 2 - 2m)$ are the numbers of CC and CH bonds in the molecule, respectively. If all Δq_C's are set equal to 0, eq. [13] reduces formally to a simple bond additivity scheme with no explicit charge effects. Indeed, in this manner we achieve a token charge renormalization by assuming constant atomic charges for the carbon atoms and letting the hydrogen atoms pick up whatever is necessary to ensure electroneutrality. The "apparent" CC and CH bond contributions are then

$$\epsilon^{apparent}_{CC} = \epsilon^0_{CC} - a_{HC}q^0_C/2 = 80.723 \text{ kcal mol}^{-1}$$

$$\epsilon^{apparent}_{CH} = \epsilon^0_{CH} - a_{HC}q^0_H/4 = 104.958 \text{ kcal mol}^{-1}$$

Clearly, these quantities are not true CC and CH bond energies. This aspect is important because it explains the origin of this sort of numerical values obtained from empirical correlations and the fallacy underlying them. Of course, empirical schemes also incorporate part of the $\lambda_1\Sigma N_{CC}\Delta q_C + \lambda_2\Sigma\Delta q_C$ term in "apparent" bond energies and account, in one way or another, for the remaining part in terms of "steric effects". (For example, Allen's scheme (14), which is successful in its own right, gives 82.31 and 104.73 kcal mol^{-1} for the CC and CH bonds of ethane, respectively.) The fact remains that "apparent" bond energies, like those retrieved from empirical correlations, should not be mistaken for true bond properties.

We can now proceed with an examination of the merits of bond energies expressed by eq. [10].

A unifying description of hydrocarbons

Detailed charge analyses are not yet available for a number of classes of compounds (e.g., dienes, allenes, alkynes, and benzene), thus precluding temporarily the evaluation of the $\Sigma_i\Sigma_j a_{ij}\Delta q_i$ terms which are required in any accurate calculation of atomization energies. However, it is still possible to gain some insight into the major factors governing their thermochemical stabilities by taking advantage of an approximation as regards the role of the $\Sigma_i\Sigma_j a_{ij}\Delta q_i$ part. In doing so, we lose the fine-tuning offered by this term which differentiates isomers from one another and introduce an uncertainty of a few kcal mol^{-1} in ΔE^*_a, but this is a small price to pay for the possibility of presenting a general view on the thermochemical stabilities of hydrocarbons in terms of eq. [10].

TABLE 1. Selected $\Sigma_i\Sigma_j a_{ij}\Delta q_i$ values of saturated hydrocarbons and monoolefins (kcal mol^{-1})[a]

Alkane	$\Sigma_i\Sigma_j a_{ij}\Delta q_i$	Alkene	$\Sigma_i\Sigma_j a_{ij}\Delta q_i$
Ethane	0	Ethene	−4.27
Propane	10.38	Propene	8.90
Butane	20.82	1-Butene	19.57
		(Z)2-Butene	20.84
		(E)2-Butene	22.01
Pentane	31.25	1-Pentene	30.18
		(Z)2-Pentene	31.65
		(E)2-Pentene	32.49
Hexane	41.69	1-Hexene	40.28
		(Z)2-Hexene	42.12
		(E)2-Hexene	43.09
		(Z)3-Hexene	42.38
		(E)3-Hexene	43.10

[a]Results extracted from refs. 3 and 11 for the saturated and unsaturated compounds, respectively. A systematic error in Table 3 of ref. 11 indicates $\Sigma_i\Sigma_j a_{ij}\Delta q_i$ values which are too low by 2.13 kcal mol^{-1} and $\Sigma\epsilon^0_{ij}$'s too large by the same amount — an error which is of no consequence as regards the final ΔE^*_a results given for the olefins.

This approach is rooted in two conclusions derived from the detailed energy analyses of alkanes (3) and simple olefins C_nH_{2n} (11). Firstly, it has appeared from eq. [10] that the energy contribution of the carbon−carbon double bond in ethylene (139.27 kcal mol^{-1}) is virtually twice that of the simple bond in ethane (69.633 kcal mol^{-1}) although, admittedly, minor uncertainties subsist as regards the precision of the $\epsilon^0_{C=C}$ term. It is clear that this result departs markedly from the usual understanding of a double vs. a single CC bond which is based on empirical bond energies. In the following, we shall assume that, indeed, $\epsilon^0_{C=C} = 2\epsilon^0_{CC}$ and see what happens. Secondly, it is observed that the $\Sigma_i\Sigma_j a_{ij}\Delta q_i$ terms are quite similar for the alkanes and the alkenes having the same number of carbon atoms. (This information is easily extracted from the results given in Table 1.) Hence, the argument focusses now on the $\Sigma\epsilon^0_{ij}$ part of ΔE^*_a: if we decide not to be too critical about discrepancies of a few kcal mol^{-1} when examining the major trends in hydrocarbon chemistry, it appears that the difference in ΔE^*_a energy between a C_nH_{2n+2} and a C_nH_{2n} hydrocarbon is roughly due to the removal of two CH bonds (2 × 106.81 kcal mol^{-1}) and their replacement by a CC bond (69.63 kcal mol^{-1}), representing a decrease of ~144.0 kcal mol^{-1} in chemical binding energy. Table 2 offers this type of rough estimates using, where appropriate, the averages of the various alkene isomers (e.g., the average ΔE^*_a of *cis*- and *trans*-2-butene, in the comparison with butane). These estimates, whose theoretical validity rests on the similarity in the $\Sigma_i\Sigma_j a_{ij}\Delta q_i$ values for alkanes and alkenes with the same number of carbon atoms, certainly support the result that $\epsilon^0_{C=C} = 2\epsilon^0_{CC}$ given by eq. [10]. No traditional (empirical) bond energies could provide this sort of simple link between saturated and unsaturated hydro-

TABLE 2. Alkene atomization energies estimated from the parent alkanes (kcal mol^{-1})[a]

Alkane/alkene	ΔE_a^*, alkene Estd.	Exptl.
1 Ethane/ethylene	566.5	562.2
2 Propane/propene	860.1	858.6
3 Butane/butene	1154.2	1154.5
4 Pentane/pentene	1448.2	1447.6
5 Hexane/hexene	1742.0	1741.9
6 Butane/1,3-butadiene	1010.2	1010.2
7 Cyclohexane/cyclohexene	1616.8	1616.1
8 Methylcyclohexane/1-methylcyclohexene	1913.1	1913.2
9 Ethylcyclohexane/1-ethylcyclohexene	2206.3	2207.6
10 Cyclohexane/1,4-cyclohexadiene	1472.8	1472.8

[a]The experimental ΔE_a^* values are from refs. 3 and 12 for the saturated hydrocarbons and ref. 11 for the olefins **1**–**5**. The ΔE_a^* of cyclohexene was deduced from ΔH_f^0(298.15, gas) = −0.84 (15) and ZPE + $H_T - H_0$ = 92.70 kcal mol^{-1}, from data given in ref. 16. For 1-methylcyclohexene, ΔH_f^0(298.15, gas) = −10.0 (15) and ZPE + $H_T - H_0$ = 110.57 kcal mol^{-1} were used, following the rules given by Fliszár and Cantara (12). For 1-ethylcyclohexene, ΔH_f^0(298.15, gas) = −15.0 (15) and ZPE + $H_T - H_0$ = 128.8 kcal mol^{-1} (estimated from 1 methylcyclohexene, using the rules indicated in ref. 12) were used. For 1,4-cyclohexadiene, ΔH_f^0(298.15, gas) = 26.3 (15) and ZPE + $H_T - H_0$ = 77.8 kcal mol^{-1} were used (estimated from the difference between cyclohexane and cyclohexene (14.84 kcal mol^{-1}) which is subtracted from the value of cyclohexene). The ΔE_a^* of butadiene was deduced from ΔH_f^0(298.15, gas) = 26.33 (15), $H_T - H_0$ = 3.63 (17) and ZPE = 51.56 kcal mol^{-1}, from data given in ref. 18.

carbons.

Of course, these results trigger the question about allenic double bonds, triple bonds, and the CC bonding in benzene. In order to gain an insight into these problems, we go back to the fundamental equations [8] and [10] and calculate the appropriate bond energies from the total potential energies $V(i, \text{mol})$ at the atomic nuclei. The following results (Table 3) are derived from SCF calculations at the $(9s5p/6s) \rightarrow [5s3p/3s]$ level. Although this basis cannot match experimental accuracy, it remains that comparisons on a relative scale can be reasonably regarded as being meaningful.

While the result $\epsilon_{C=C}^0 \simeq 2\epsilon_{CC}^0$ is clearly confirmed, it also appears that the carbon–carbon triple bond in acetylene is not far from being the triple of a single bond contribution. It remains, however, that the 2.9 factor (instead of 3) is significant. Indeed, by subtracting four CH bond contributions from butane and adding $1.9\epsilon_{CC}^0$ (i.e., by subtracting ~295 kcal mol^{-1} from the ΔE_a^* of butane) we obtain, in this rough estimate, ΔE_a^* (2–butyne) ≃ 1003.1 kcal mol^{-1}. Under these circumstances, the agreement with the experimental value,[1] ΔE_a^* = 1001.5 kcal mol^{-1}, is certainly satisfactory. On the other hand, taking now propane as model compound in order to evaluate allene, we replace four CH bonds by two CC bonds using the 128.5/66.7 ratio given by *ab initio* calculations (Table 3). The value estimated for allene, $\Delta E_a^* \simeq$ 705.9 kcal mol^{-1}, is reasonably close to its thermochemical counterpart,[2] ~701.9 kcal mol^{-1}. Similarly, the atomization energy of 2,3-pentadiene, 1294.0 kcal mol^{-1}, deduced from normal pentane compares favorably with its experimental counterpart,[3] 1293.3 kcal mol^{-1}. Finally, using now the 1.6 factor deduced from benzene, we estimate its atomization energy from that of cyclohexane by removing six CH bonds and adding six times $0.6\epsilon_{CC}^0$. This estimate leads to ΔE_a^*(benzene) ≃ 1370.6 kcal mol^{-1}, still in acceptable agreement with its experimental value,[4] ΔE_a^* = 1366.51 kcal mol^{-1}. Obviously, it is not everyday chemistry to deduce the energy of benzene from that of cyclohexane in a simple way, with the aid of eq. [10]. Needless to say, conventional empirical bond energies would not have permitted us to see the simple link between these molecules. There is another point worth mentioning. Had we taken the benzene CC bond contribution as the average of single and double bond energies (i.e., the factor 1.5 instead of 1.6) as if there were 3 single and 3 double bonds in the cycle, the estimated energy would be 1328.9 kcal mol^{-1}, leaving us with the problem of explaining why benzene is 37.6 kcal mol^{-1} more stable than the prediction based on this model. The traditional answer, of course, is "resonance energy." This question now seems somewhat artificial since eq. [10] (and the SCF results which are used in its application) clearly lead to a result which, under the present circumstances, is sufficiently close to the experimental value as to kill the problem before it arises.

TABLE 3. SCF calculations of selected bond energy contributions, eqs. [8] and [10], using the contracted $[5s3p/3s]$ basis set[a]

Molecule	V(C, mol), au	ϵ_{CC}, kcal mol^{-1}	Ratio relative to 66.7
Ethane	−88.4670	66.7	1.00
Ethylene	−88.4168	133.7	2.00
Acetylene	−88.3345	193.6	2.90
Benzene	−88.3391	108.1	1.62
Allene	−88.3582 (C-1) −88.2815 (C-2)	128.5	1.93

[a]The following SCF values were used for atomic carbon: E(C, at) = −37.5995 and V_{ne}(C, at) = −87.9315 au, as well as $\partial\epsilon_{CH}/\partial Z_C \simeq 0.026$ au.

Conclusions

The chemical binding of a molecule is conveniently expressed by a sum, $\sum\epsilon_{ij}^0$, of appropriately selected reference bond energies plus a term, $\sum_i\sum_j a_{ij}\Delta q_i$, which ensures molecular electroneutrality, on one hand, and provides an accurate fine-tuning of molecular energies, on the other. The dehydrogenation of a saturated hydrocarbon to give a monoolefin is shown (in a first approximation) not to affect the $\sum_i\sum_j a_{ij}\Delta q_i$ term, thus suggesting the reasonable expectation that, in similar manner, the dehydrogenation of a monoolefin to give a diolefin also leaves $\sum_i\sum_j a_{ij}\Delta q_i$ practically unchanged, an uncertainty of a few (say, 5) kcal mol^{-1} being regarded acceptable in this approximation. It turns out that this rough approach is also valid when dehydrogenation is carried further, e.g., in the series cyclohexane, cyclohexene, cyclohexadiene and, finally,

[1]This value was deduced from ΔH_f^0(298.15, gas) = 34.97 (15), $H_T - H_0$ = 3.96 (17), and ZPE = 51.21 kcal mol^{-1}, from data given in ref. 19.

[2]Deduced from ΔH_f^0(298.15, gas) = 45.92 kcal mol^{-1} (15). The ZPE + $H_T - H_0$ = 37.2 kcal mol^{-1} value is estimated from the difference between propane (20) and propene (11) (i.e. 14.38 kcal mol^{-1}) which is subtracted from the value of propene.

[3]ΔH_f^0(298.15, gas) = 31.79 kcal mol^{-1} (15). The value for ZPE + $H_T - H_0$ = 73.15 kcal mol^{-1} is estimated from the difference between *n*-pentane (20) and pentene (11) (i.e., 14.84 kcal mol^{-1}) which is subtracted from the value of pentene.

[4]ΔH_f^0(298.15, gas) = 19.82 kcal mol^{-1} (15). ZPE + $H_T - H_0$ = 66.22 kcal mol^{-1}, from data given in ref. 19.

benzene, as well as in the formation of allenic and triple CC bonds.

The $\sum_i \sum_j a_{ij} \Delta q_i$ term being practically invariant in dehydrogenations, the change in energy is primarily reflected in the $\sum \epsilon_{ij}^0$ sum. Equation [10] and the appropriate Hartree–Fock potential energies yield (on the basis of $\epsilon_{CC}^0 = 69.633$ for the CC single bond) the following results for CC bonds: 139.27 (ethylene), 201.9 (triple bond), 134.2 (allenic double bond), and 111.4 kcal mol^{-1} (benzene). These theoretical energies enable a simple description of energy changes in dehydrogenations, quite unlike their empirical counterparts which already include part of the $\sum_i \sum_j a_{ij} \Delta q_i$ term. No claim for accuracy can be made for this sort of brute force approach. It remains, however, that a clear link is created in this manner between typical saturated, olefinic, acetylenic, and aromatic compounds. Of course, a host of details has to be worked out, a task which looks promising. The present results should certainly encourage us to do some more thinking about possible further applications of eq. [10].

Deuterium isotope effects on the partial molal volumes of cyclohexane, acetone, and acetonitrile in carbon tetrachloride

G. RONALD BROWN, JULIAN K. EDWARD, AND JOHN T. EDWARD

Department of Chemistry, McGill University, 801 Sherbrooke St. W., Montreal, (P.Q.), Canada H3A 2K6

Received March 2, 1983

G. RONALD BROWN, JULIAN K. EDWARD, and JOHN T. EDWARD. Can. J. Chem. **61**, 2684 (1983).

At 25°C both molar volumes V and partial molal volumes $\bar{V}^0_{CCl_4}$ in carbon tetrachloride of cyclohexane-d_{12} and of acetone-d_6 are smaller than V and $\bar{V}^0_{CCl_4}$ of the corresponding protio compounds. However, both V and $\bar{V}^0_{CCl_4}$ of acetonitrile-d_3 are larger than V and $\bar{V}^0_{CCl_4}$ of acetonitrile-h_3, and in solvent cyclohexane $\bar{V}^0_{C_6H_{12}}$ of acetone-d_6 and of acetone-h_6 are approximately equal. Apparently deuteration has not only a steric effect, but (in polar compounds) a counter-balancing effect, which may be polar.

G. RONALD BROWN, JULIAN K. EDWARD et JOHN T. EDWARD. Can. J. Chem. **61**, 2684 (1983).

A 25°C, les volumes molaires V et les volumes molaires partiels $\bar{V}^0_{CCl_4}$ du cyclohexane-d_{12} et de l'acétone-d_6 dans le tétrachlorure de carbone sont plus faibles que V et $\bar{V}^0_{CCl_4}$ des composés non deutérés correspondants. Cependant, les valeurs de V et de $\bar{V}^0_{CCl_4}$ de l'acétonitrile-d_3 sont plus grandes que les valeurs correspondantes pour l'acétonitrile non deutéré; dans le cyclohexane comme solvant, les valeurs de $\bar{V}^0_{C_6H_{12}}$ de l'acétone-d_6 et de l'acétone-h_6 sont à peu près égales. Apparemment, la deutération n'a pas seulement un effet stérique, mais (dans les composés polaires) un effet contre balançant qui peut être polaire.

[Traduit par le journal]

A large number of examples of secondary deuterium isotope effects on reaction rates (reviewed in refs. 1–3) has been observed. One explanation which accounts for many results depends on the idea that protio-alkyl groups (such as CH_3) occupy a slightly larger volume than the corresponding deuteroalkyl groups (such as CD_3), because of the greater amplitude of the zero-point vibration of the C—H as compared with the C—D bond. This idea finds support in the studies of Baldry and Robinson (4) on the conformational equilibrium of *trans*-1-methyl-d_3-3-methylcyclohexane, which showed the conformation having CD_3 axial favoured by 11 cal mol^{-1} over the conformation having CH_3 axial; in optical rotatory dispersion studies of Djerassi and co-workers (5); and in studies of steric effects of H and D on ^1H and ^{13}C chemical shifts by Anet and Dekmezian (6).

However, the most direct indication of this volume difference might be expected to come from measurements of molar volumes. Indeed, at the triple point (7) and at the critical temperature (8) the molar volume V of CH_4 is greater than that of CD_4. Similarly, at ordinary temperatures the molar volumes of benzene (9–11), cyclohexane (16), and toluene (11) are greater than the volumes of their deuterated forms. However, Rabinovich (11) reported that the molar volumes of $CDCl_3$, CD_3NO_2, $PhND_2$, CH_3OD, CH_3CH_2OD, $CH_3CH_2CH_2OD$, $(CH_3)_2CHOD$, $CH_3CH_2CH_2CH_2OD$, $CH_2OD—CH_2OD$, $CH_2OD—CHOD—CH_2OD$, and $(CH_3)_3CCO_2D$ were greater than the volumes of the corresponding protio compounds.

This last result pointed to a curious difference between hydrocarbons and more polar organic molecules which we thought worth confirming, particularly since it was based on density measurements made with pyknometers, which are probably less accurate than the direct-reading density meters now available. Furthermore, measurements of partial molal volumes $\bar{V}^0$ in a single solvent should be preferable to measurements of molar volumes of the neat liquids in revealing differences in intrinsic volumes of molecules. Liquids differ in internal pressure (12) and cohesive energy density (13), factors which might be expected to change on deuteration and to affect V. We have chosen carbon tetrachloride as our solvent for $\bar{V}$; it is probably the favoured solvent for partial molal volume determinations because it is reasonably non-polar and yet has fairly good solvent properties. We have also made a few measurements using cyclohexane as solvent.

Experimental

Materials

Perdeuterated solvents were obtained from Merck, Sharp and Dohme Inc., and are reported to be >99% isotopically pure. They were used without further purification. Cyclohexane, acetone, and acetonitrile were spectrograde solvents and were also used without purification. All of these solvents showed only one peak in vapour phase chromatography. Carbon tetrachloride was purified as reported previously (14), but results using this purified material did not differ appreciably from results using Fisher Scientific Company spectrograde material, and so the latter was used as solvent in later experiments.

Measurements

Density measurements were carried out at 25.0°C using a Paar digital precision density meter, Model DMA 02C. A water bath thermostat (12 L) was used to control the temperature of the density meter. The temperature was monitored continuously using an HP Quartz Thermometer (Model 2804A) and was kept constant at 25.00 ± 0.01°C. Apparent molar volumes ϕ_v of solutes were calculated from

$$\phi_v = M \frac{1/d - w_1/d^0}{w_2}$$

where M is the molecular weight of the solute, w_2 its concentration expressed as a weight fraction, w_1 the weight fraction of the solvent (carbon tetrachloride or cyclohexane), and d and d^0 the density of solution and of solvent, respectively. Solutions were made up by weight. The chief source of error in w_2 was found to be the loss of solvent when a flask was unstoppered to allow the addition of very small amounts of solute; this was prevented by the use of serum caps impermeable to the vapors of carbon tetrachloride or cyclohexane.

Results

Results are given in Table 1 and shown graphically in Figs. 1 and 2. Agreement with data in the literature, where available, is good, as shown by footnotes in Table 1 and, more convincingly, by the points from literature data for cyclohexane and acetone plotted in Fig. 1.

Values of apparent molal volumes in carbon tetrachloride ϕ_v plotted against concentration expressed as mole fraction fitted

TABLE 1. Molar volumes, V, and partial molal volumes in carbon tetrachloride $\bar{V}^0_{CCl_4}$ (both at 25.00°C)

Compound	V (mL mol^{-1})	Δ_1* (mL mol^{-1})	$\bar{V}^0_{CCl_4}$ (mL mol^{-1})	Δ_2† (mL mol^{-1})
Cyclohexane	108.995‡	0.463	109.63	0.52
Cyclohexane-d_{12}	108.532§		109.11	
Acetonitrile	52.796	−0.082	52.54	−0.15
Acetonitrile-d_3	52.878		52.69	
Acetone	73.987	0.132	74.15	0.15
Acetone-d_6	73.865		74.00	

* $\Delta_1 = V$ (protio compound) − V (deutero compound).
† $\Delta_2 = \bar{V}^0_{CCl_4}$ (protio compound) − $\bar{V}^0_{CCl_4}$ (deutero compound).
‡ From the data of Dixon and Schiessler (10), it may be calculated that at 25.0°C, V = 108.75 mL mol^{-1}.
§ V = 108.42 from the data in ref. 10.

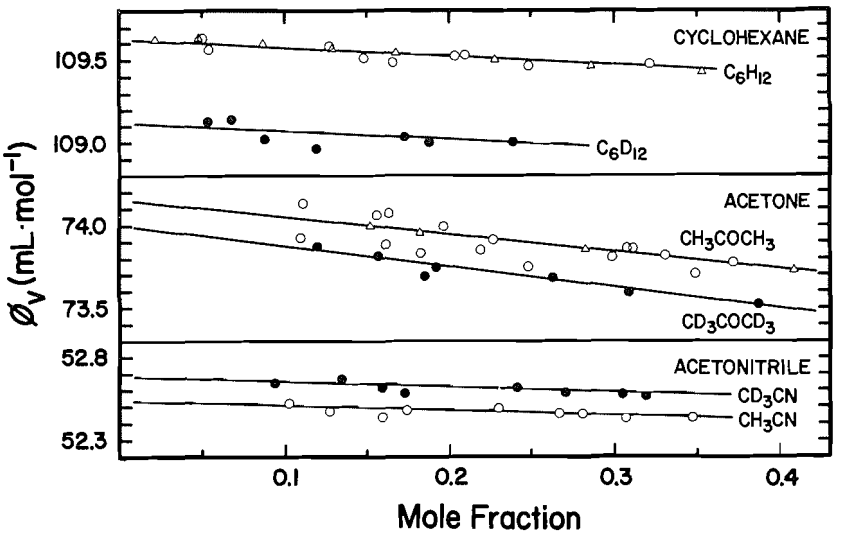

FIG. 1. Plots of apparent molal volume ϕ_v of cyclohexane, acetone, and acetonitrile (open circles), and of cyclohexane-d_{12}, acetone-d_6, and acetonitrile-d_3 (filled circles) against concentration of solute in carbon tetrachloride. Straight lines show least-squares fit to data. Values calculated from excess volumes of cyclohexane + carbon tetrachloride (ref. 15) and of acetone + carbon tetrachloride (ref. 16) in the literature are shown as triangles, and not included in least-squares calculations.

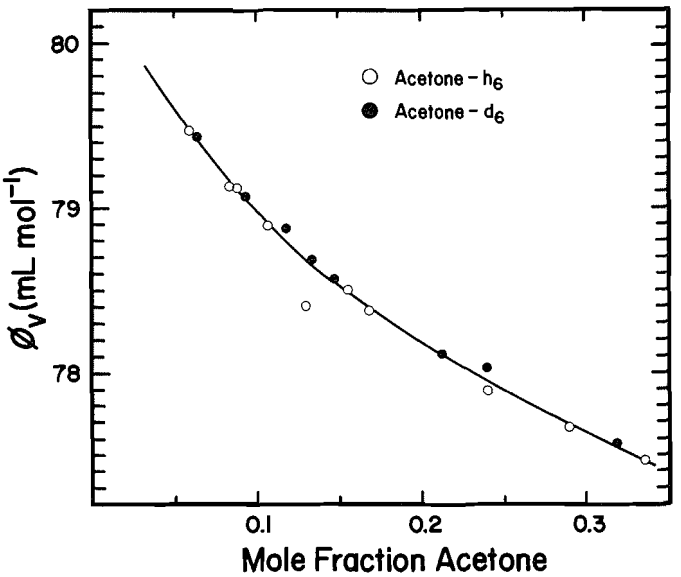

FIG. 2. Plots of apparent molal volumes ϕ_v of acetone (open circles) and of acetone-d_6 (filled circles) in cyclohexane as solvent. (Notice that scale for y-axis is the same as in Fig. 1.)

straight lines of negative slope, as is generally found for solutions in this solvent, and $\bar{V}^0_{CCl_4}$ values were obtained by extrapolation to zero concentration. Although the points show some scatter, the differences between $\bar{V}^0_{CCl_4}$ of protio- and deutero-compounds are too great to be dismissed as experimental error. Furthermore, as seen in Table 1, the differences Δ_2 between $\bar{V}^0_{CCl_4}$ values are not greatly different from the differences Δ_1 between V values. The latter are obtained from densities of the neat liquids, without the errors introduced by making up solutions of known concentration, and hence V values are likely to be very accurate.

Discussion

Cyclohexane and cyclohexane-d_{12}

It is evident from Table 1 that replacing the protium atoms of C_6H_{12} by deuterium to give C_6D_{12} results in a contraction of about 0.5 mL mol^{-1} in both V and $\bar{V}^0_{CCl_4}$.

The volume occupied by a mole of cyclohexane, either as the neat liquid (V), or at infinite dilution in carbon tetrachloride ($\bar{V}^0_{CCl_4}$), is made up of the van der Waals volume V_w ($\equiv Nv_w$) of Avogadro's number N of molecules, each having a van der Waals volume v_w (17, 18), plus the empty volume V_e ($\equiv Nv_e$) require to pack the molecules into the pure liquid or into the

carbon tetrachloride solvent (18, 19).

Cyclohexane C_6H_{12} has $V_w = 61.4$ mL mol^{-1}, and hence V_e makes a contribution of 47.6 mL mol^{-1} to V and 48.2 mL mol^{-1} to $\bar{V}^0_{CCl_4}$, i.e. about 44% to each volume. V_e decreases with decreasing V_w (20). We shall consider first the decrease in V_w, and then the decrease in V_e, to be expected on replacing H by D.

In ethane the bond length of C—H is 1.112 ± 0.001 Å, as determined by electron diffraction; this is reduced to 1.107 ± 0.001 Å for C—D (ref. 2, p. 59). This shortening of the bond will (according to the method of calculation described in ref. 22) result in v_w of D attached to aliphatic carbon being smaller by 0.021 Å^3 than H attached to aliphatic carbon, or v_w of C_6D_{12} being 0.25 Å^3 smaller than v_w of C_6H_{12}, i.e. in V_w for C_6D_{12} being 0.15 mL mol^{-1} smaller than V_w for C_6H_{12}.

Going along with a smaller V_w will be a smaller V_e. While $v_w \propto r_w^3$, very roughly $v_e \propto r_w^2$ (20, 23), and so one may expect V_e for C_6D_{12} to be about 0.16% smaller than V_e for C_6H_{12}, or 48.1 mL mol^{-1} in $\bar{V}^0_{CCl_4}$. Consequently, a total reduction of 0.15 + 0.10 = 0.25 mL mol^{-1} is to be expected in $\bar{V}^0_{CCl_4}$ in going from C_6H_{12} to C_6D_{12}.

This is about half the reduction observed. It seems likely that because of the closer approach of solvent CCl_4 molecules to the skeletal carbon atoms of C_6D_{12}, the time-averaged attraction will be greater and the empty volume will be reduced more than calculated above. (The calculations above assume V_e to be determined solely by geometric factors, and attractive forces to be the same for protio- and deutero-compounds). More accurate data (e.g. by excess volume measurements by dilatometry) would be desirable to check this idea.

Acetone and acetone-d_6

A molecule of acetone has half the number of hydrogen atoms of a molecule of cyclohexane, and so the reduction in V and $\bar{V}^0_{CCl_4}$ of acetone on replacing H by D might be expected to be half as great as the reduction in V and $\bar{V}^0_{CCl_4}$ of cyclohexane for this change. In fact, it was only about one-third as great in both cases. It has been shown that the proportion of empty volume in $\bar{V}^0_{CCl_4}$ of acetone is smaller than in $\bar{V}^0_{CCl_4}$ of a hydrocarbon of equal v_w (23), presumably because of the attractive effect of the dipolar carbonyl group on the polarizable CCl_4 molecule. If, indeed, deuteration affects volume largely by changes in v_e surrounding the solute molecules, then its effect might be expected to be diminished as v_e is diminished.

Similar considerations might be expected to apply to V of acetone, v_e being diminished by the dipole–dipole attractions of the molecules of the liquid. Consequently, it was thought that greater volume differences would show up if the solvent were changed from carbon tetrachloride to the less polarizable cyclohexane, in which v_e surrounding the solute acetone molecules should become greater (24).

These expectations were not realized, as shown by the ϕ_v values of acetone-h_6 and acetone-d_6 plotted in Fig. 2: although there is some indication that ϕ_v of the deutero compound at a given mole fraction is slightly *greater* than ϕ_v of the protio compound, the differences are within experimental error. The plots are no longer straight lines, making extrapolation to zero concentration to get $\bar{V}^0_{C_6H_{12}}$ difficult, but it is apparent that $\bar{V}^0_{C_6H_{12}}$ is essentially the same for the two compounds.

The curvature of the plots and the steepness of the slopes in Fig. 2 probably result from solute–solute interactions, which can be expected to be much greater in cyclohexane than in carbon tetrachloride. A comparison of the results for acetone in CCl_4 in Fig. 1 and in cyclohexane in Fig. 2 shows why carbon tetrachloride is preferred as solvent in volumetric studies of polar organic molecules.

Acetonitrile and acetonitrile-d_3

The same arguments which led us to expect a small reduction in $\bar{V}^0_{CCl_4}$ of acetone in carbon tetrachloride on replacing H by D lead us to expect a yet smaller decrease in $\bar{V}^0_{CCl_4}$ of acetonitrile on replacing H by D. However, an increase and not a decrease in $\bar{V}^0_{CCl_4}$ is now observed.[1] This, like the abolition of the expected decrease in volume in $\bar{V}^0_{C_6H_{12}}$ on going from acetone to acetone-d_6, indicates that some second effect is at work in polar compounds which can more than offset the simple steric effect observed with hydrocarbon solutes. The nature of this second effect remains unclear. The smaller polarizability of C—D bonds (10) might be expected to cause polar molecules such as CD_3CN to have slightly lower dipole moments that their protio analogues and hence to attract solvent CCl_4 molecules less strongly, leading to larger $\bar{V}^0_{CCl_4}$ values. This agrees with the view of Buckingham (25), who has asserted that deuterium compounds have lower dipole moments than the corresponding protium compounds. However, majority opinion at present supports the opposite viewpoint (21), and further investigations are required.

A reversal in the order of H-6$_R$ and H-6$_S$ chemical shifts of some aldohexopyranose derivatives, associated with the acetylation of OH-4 and OH-6 groups. A distinction between 3- and 4-linked D-glucose residues in disaccharides

Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2A7

Received April 11, 1983

VANGA S. RAO and ARTHUR S. PERLIN. Can. J. Chem. **61**, 2688 (1983).

On peracetylation of methyl α- or β-D-glucopyranoside, there is a reversal in the order of the chemical shifts of the 6,6′-methylene protons, i.e., whereas the H-6$_S$ signal appears downfield of H-6$_R$ in the spectra of the glucosides, their relative locations in the spectra of the tetraacetates are interchanged. Evidence is presented from comparative data for a wide range of regioselectively acetylated D-glucose derivatives, showing that the reversal in chemical shifts of the methylene protons occurs only when *both* O-4 and O-6 are acetylated. Consequently, in the disaccharide series, shift reversal is *not* observed with glucose residues that are bonded glycosidically through O-4, whereas the reversal occurs when the linkage is through O-3. A conformational model offered to account for these effects suggests that the 4- and 6-*O*-acetyl substituents are oriented by means of a weak, mutual, interaction in such a way that the magnetic anisotropy of the carbonyl group of the 6-*O*-acetyl substituent can induce selective deshielding of H-6$_R$. The comparable influences of *O*-benzoyl and *O*-(4-nitro)benzoyl substituents on chemical shift are consistent with this proposal. D-Mannopyranosides exhibit characteristics analogous to those of their D-*gluco* epimers, whereas D-galactopyranosides give a different, more complex, chemical shift pattern.

VANGA S. RAO et ARTHUR S. PERLIN. Can. J. Chem. **61**, 2688 (1983).

La peracétylation de l'α ou du β-D-glucopyrannoside de méthyle provoque une inversion dans l'ordre des déplacements chimiques des protons du méthylène en 6,6′; par exemple, alors que le signal du H-6$_S$ sort à champ faible par rapport à celui du H-6$_R$ dans les spectres des glucosides, leurs positions relatives sont interchangées dans les spectres des tétraacétates. A partir de données comparatives se rapportant à un grand nombre de dérivés du D-glucose acétylé de façon régiosélective, on montre que l'inversion des déplacements chimiques des protons du méthylène se produit uniquement lorsque les deux oxygènes en positions 4 et 6 sont acétylés. Par conséquent, dans la série des disaccharides, on n'observe pas d'inversion dans les déplacements chimiques lorsque les unités de glucose sont liées de façon glycosidique par l'intermédiaire de l'oxygène en position 4 cependant l'inversion se produit lorsque cette liaison s'établit par l'intermédiaire de l'oxygène en position 3. Un modèle conformationnel utilisé pour tenir compte de ces effets suggère que les substituants O-4 et O-6 acétylés sont orientés par une interaction mutuelle faible de telle sorte que l'anisotropie magnétique du groupe carbonyle du substituant acétyle peut induire un déblindage sélectif de H-6$_R$. Les influences comparables des substituants *O*-benzoyle et *O*-(nitro-4)benzoyle sur les déplacements chimiques sont en accord avec cette suggestion. Les D-mannopyrannosides présentent des caractéristiques semblables à celle de leurs épimères D-gluco, tandis que les D-galactopyrannosides ont des déplacements chimiques différents et plus complexes.

Introduction

Of the two anisochronous 6,6′-methylene proton nmr signals of methyl 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranoside (**2**), that at lower field (δ 4.25, $J_{H\text{-}5,H\text{-}6}$ = 4.6 Hz) has been unambiguously assigned (1) to the *pro-R* hydrogen, and the higher field resonance (δ 4.08, $J_{H\text{-}5,H\text{-}6}$ = 2.4 Hz) to the *pro-S* nucleus. From the magnitude of proton coupling, it has been estimated (1) that *RHS* and *RCS* represent the major rotamers about the C-5,C-6 bond; little or no contribution would be expected from the *ROS* rotamer, because of an unfavorable *quasi-syn-axial* interaction between the 4- and 6-*O*-acetyl group. The corresponding data (2) for the methylene protons of methyl α-D-glucopyranoside (**1**) differ from those of **2** in that the smaller coupling (2.2 Hz) is exhibited by the downfield H-6 resonance of **1** (δ 3.85), and the larger value (5.4 Hz) by that at higher field (δ 3.75). Consequently, when compound **1** is peracetylated there appears to be a reversal either in the order of the chemical shifts of H-6$_R$ and H-6$_S$, or else in the magnitude of their couplings with H-5. Although a change in coupling appeared to be less likely, because it would entail a major contribution from the *contra* thermodynamic rotamer (*ROS*) as well as from the *RHS* rotamer, a more definitive answer to the question was warranted.

Results and discussion

A choice between the two possibilities represented by the apparent change in the coupling or chemical shift pattern was readily provided by reference to the ^{1}H nmr spectra of methyl α-D-glucopyranoside, partially monodeuterated at C-6 (**3**), and its tetraacetate (**4**) (3). This showed that *chemical shift reversal* occurs: i.e., the more downfield of the methylene resonances was produced by H-6$_S$ of **3**, and by H-6$_R$ of **4** (Fig. 1).[1] Clearly, also, the rotamer population about the C-5,C-6 bond of methyl α-D-glucopyranoside (**1**) must be closely similar to that in tetraacetate **2**, because the appropriate couplings are of virtually the same size in both spectra.

Considering the orientations of the methylene protons in major rotamers *RHS* and *RCS* leads to the expectation that H-6$_R$ should resonate at higher field than H-6$_S$, according to the "*syn*-up" rule (2). That is, H-6$_R$ is *syn* with respect to C-4 in both rotamers and also to O-5 in *RCS*, whereas H-6$_S$ experiences only two *syn* relationships – with respect to O-5 in *RHS* and to C-4 in *RCS*. Consequently, although the "*syn*-up" rule is applicable with **1**, it fails with **2**.[2] As shown later, this difference can be attributed to the replacement of OH-4 and

[1] Each spectrum consists (3) of overlapping signals produced by a mixture of molecules in which either H-6$_R$ or H-6$_S$ is replaced by deuterium, together with molecules in which C-6 is not deuterated. Consequently, the upfield values of δ correspond to deuterium isotope shielding increments of 0.014–0.02 ppm.

[2] However, the data used in formulating the "*syn*-up" rule (2) did not include those for *O*-acyl derivatives.

RCS

R′ = H, Ac

Analogous reversals in the order of methylene ^1H-chemical shifts were inferred for a number of glucopyranoside derivatives assuming, on the basis of the observed coupling patterns, that the population of rotamers is essentially the same in these instances as in **1** and **2**. Thus, in the spectra of methyl 2-*O*-benzyl- (**5**), 3-*O*-benzyl- (**7**), 2,3-di-*O*-benzyl- (**9**), and 2,3,4-tri-*O*-benzyl- (**11**) β-D-glucopyranosides, available from a previous study (4), the lower field signal consistently showed weaker coupling with H-5 (2.7–3.6 Hz) than did the upfield multiplet (4.6–5.0 Hz) (Table 1). For acetylated compounds **6**, **8**, and **10**, as well as for their α-anomers (**15**, **17**, and **19**), the order was reversed, as the downfield signal always was characterized by the larger coupling with H-5 (4.4–5.0 Hz vs. 2.0–2.4 Hz) (Table 1). By analogy with monodeuterated **3** and **4**, H-6_S is taken to be the less shielded proton within the non-acetylated series, and the more shielded nucleus within the series of *O*-acetyl derivatives.

An exception was found, nevertheless, in the relationship between methyl 2,3,4-tri-*O*-benzyl-β-D-glucoside (**11**) and its 6-acetate (**12**). Hence, the downfield H-6 signal for both compounds exhibited the smaller coupling with H-5, suggesting that there was no reversal in the methylene chemical shifts when OH-6 was converted into OAc-6. The most obvious way in which **11** and **12** differ from the other pairs of compounds is in having an ether substituent at O-4, which prevents the introduction of an *O*-acetyl group at that position. This indicated that a 4-*O*-acetyl substituent must be present if the order of the chemical shifts is to be reversed, although it was not clear that a 6-*O*-acetyl group is a prerequisite as well. Consequently, several other derivatives were chosen to examine systematically the effect of different combinations of substitution at O-4 and O-6. The data they afforded (Table 2) clearly indicate that both a 4-*O*-acetyl and a 6-*O*-acetyl group, as in **23** (or **24**), are essential for the interchange in the methylene chemical shifts to be observed. Hence, **23** and **24** exhibited an interchange, whereas when there was an acetyl group solely at O-4 (**22**, **25**), or only at O-6 (**12** (Table 1), **21**), or when other types of substituents were present at position-6 (**26**–**28**), the combined pattern of chemical shifts and couplings paralleled that of the unsubstituted glycoside (**20**): i.e., the smaller of the H-5,H-6 couplings (1.6–2.8 Hz vs. 3.6–6.7 Hz), was consistently observed in the downfield multiplet.

O-*Acetyl derivatives of* D-*glucose disaccharides*

If the phenomenon just described is a general one, it should also be evident with more complex types of structures. For example, the methylene protons of the reducing end residue of a D-glucose disaccharide linked through O-4 or O-6 should, upon acetylation, exhibit neither a reversal in chemical shift nor a change in coupling pattern. Accordingly, H-6_S would be expected to show a smaller coupling than H-6_R with H-5, in both the free sugar and its peracetate. However, if the glycosidic bond were (1 → 3) or/and (1 → 2), then the signal position of the methylene protons of the acetate should be interchanged and, by analogy with **2**, the signal at lower field should exhibit the larger coupling with H-5.

A comparison of the appropriate data for the β-(1 → 4) linked disaccharide, cellobiose (**33**) (5), and acetylated cellobioside **34** (6) (Table 3) shows that the chemical shifts of H-6_R and H-6_S of the reducing end residue retain the same relative order (based on the observed couplings with H-5) whether *O*-acetyl groups are present, or not. By contrast, the two C-6 protons of the non-reducing group do exhibit the expected shift reversal (Table 3), as the broader signal (J = 4.4 Hz) is located more upfield in the spectrum of **33**, and downfield in that of **34**. Strictly analogous results were found (Table 3) with the α-(1 → 4) linked isomer, i.e., in comparing maltose (**35**) with heptaacetate **36**. Consequently, although unequivocal assignments for the methylene protons of **36** were not available (whereas those of **34** were (6)), we propose that they are now established by the present findings. Noteworthy also is the

(**38**) and its octaacetate (**39**) amount to an interchange in the order of H-6_R and H-6_S chemical shifts for both the reducing and non-reducing moieties. Consequently, with OH-4 and OH-6 of each residue accessible to acetylation, chemical shift reversal must occur as the coupling patterns observed for the two pairs of methylene protons are analogous to those of **1** and **2**, respectively.

A departure from this consistent series of observations is found with 6-*O*-α-D-glucopyranosyl-D-glucose (isomaltose, **40**). That is, the more downfield H-6 signal of the reducing end residue is broader (J = 4.0 Hz) than the upfield one (J = 2.0 Hz) (Table 3), which is the converse of what is observed when O-6 is not glycosidically bonded. According to Rees and Scott (7), the average orientation of the C-1′—O′—C-6—C-5 sequence of bonds in **40** is approximately *anti*, and the rotamer population about the C-6—C-5 bond contains major contributors analogous to *RHS* and *RCS*. Within this conformation of **40**, as depicted for the *RCS* rotamer in Fig. 2, H-6_R (reducing end) appears to be much nearer to O-5 and O-6 than is H-6_S, and hence could experience additional deshielding by the oxygen atoms.[3] As this possibility does not apply for any of the other compounds mentioned, it may account for the apparent discrepancy in chemical shifts exhibited by the methylene protons of **40**. With peracetylated isomaltose (**41**), nevertheless, the chemical shift and coupling pattern are consistent with expectation (Table 3), in that H-6 and H-6′ of the non-reducing end unit undergo chemical shift reversal whereas those of the reducing end residue do not.

Inasmuch as both a 4-*O*-acetyl and 6-*O*-acetyl group are essential for these alterations in signal position to occur, it appears probable that the orientations of the two substituents are strongly interdependent. Moreover, their net conformational preferences, determined by the interaction between them, must lead to disparate shielding influences on H-6_R and H-6_S of the acetylated D-glucose residue. One conformational possibility is depicted in Fig. 3 for the *RHS* rotamer; under these circumstances, the C=O functions are positioned so that minimum energy orientations of the *O*-acetyl groups are favored by a weak polar interaction or, perhaps, a π-stacking type of interaction between the two π bonds. The carbonyl oxygen of the 6-*O*-acetyl group may then be close enough to H-6_R to induce deshielding in the acetylated species sufficient for a reversal in chemical shift.

O-*Benzoyl derivatives of* D-*glucopyranosides*

The reversal in chemical shift observed for 6,6′-methylenic protons upon acetylation of O-4 and O-6 does not occur when these oxygen atoms are benzoylated. Hence, the patterns of chemical shift and coupling with H-5 are analogous for both methyl β-D-glucopyranoside (**20**) and its 2,3,4,6-tetrabenzoate (**29**), in that the more downfield H-6 resonance (attributed accordingly to H-6_S) exhibits the smaller coupling in each instance (Table 2). As envisaged in Fig. 3*a*, selective deshielding of H-6_R is attributed to the magnetic anisotropy of the carbonyl function of the 6-*O*-acetyl substituent, which is appropriately oriented through a weak interaction between the latter and the 4-*O*-acetyl substituent. By analogy, the fact that the deshielding is not observed in the presence of *O*-benzoyl substituents implies a reduction in the anisotropy effect of the 6-benzoate, or of the interaction between the 4- and 6-substituents, or both. Charge delocalization by the phenyl group, in contrast to methyl, may account for these differences by altering the polarization of the C=O bond and its effect on the anisotropy of the carbonyl group.

Consistent with these possibilities are the ^{1}H nmr characteristics of other derivatives, chosen specifically in order to examine the influence of various combinations of *O*-acyl substituents at the 4- and 6-positions (Table 2). Thus, in the spectrum of methyl 2,3,4-tri-*O*-acetyl-6-*O*-benzoyl-β-D-gluco-

[3] However, we are unable to assess the magnitude of deshielding by neighboring oxygen atoms in a mobile system of this kind.

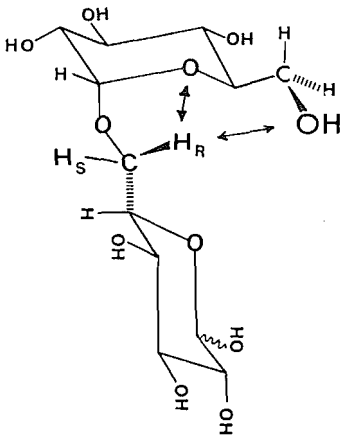

FIG. 2. Representation of 6-*O*-α-D-glucopyranosyl-D-glucose (isomaltose, **40**) in a favored conformation (7), showing the close proximity of H-6_R of the reducing end residue to oxygen atoms of the non-reducing end group.

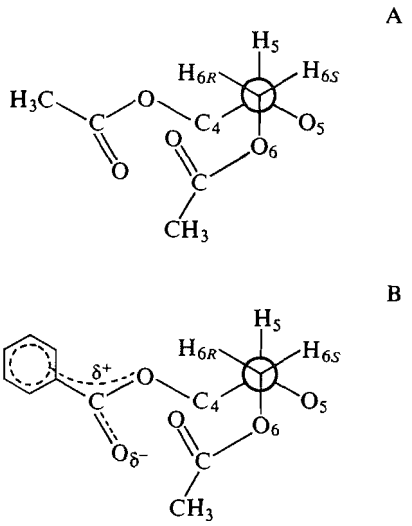

FIG. 3. Conformational representation of the C-4,C-5,C-6 segment of (A): a 4,6-di-*O*-acetyl aldopyranose derivative, or (B): a 6-*O*-acetyl-4-*O*-benzoyl aldopyranose derivative, showing possible orientations of the *O*-acyl substituents.

pyranoside (**30**) the 6,6′-protons display a pattern closely similar to that of the tetrabenzoate (**29**). By contrast, a chemical shift reversal is indeed observed for the methylene protons of methyl 2,3,4-tri-*O*-benzoyl-6-*O*-acetyl-β-D-glucopyranoside (**31**). Consequently, irrespective of the nature of the 4-*O*-acyl substituent, a 6-*O*-benzoyl group (in **29** or **30**) does not deshield H-6_R sufficiently to cause it to resonate downfield of H-6_S, whereas a 6-*O*-acetyl group does. When, as in **31**, there is a combination of 4-*O*-benzoyl and 6-*O*-acetyl substituents, it appears that the former substituent is adequate for the maintenance of an (presumably, essential) anchoring interaction between the two carbonyl groups, so as to enable the acetyl group on O-6 to exert its anisotropic effect on H-6_R. Nevertheless, the chemical shift difference between the methylene protons of **31** is only about one-half (0.06 ppm) of that observed (0.14 ppm) with the peracetylated derivative, which may reflect a lower degree of interaction between the 4-*O*-benzoyl and 6-*O*-acetyl substituents, and the extent to which they influence each other's conformational preference.

The *O*-(4-nitro)benzoyl substituent also was introduced to see if the change expected in the polarization of the C=O group, as compared with that of *O*-benzoyl, would alter the anisotropic influence upon H-6_R. For methyl 2,3,4,6-tetra-*O*-(4-nitro)benzoyl-β-D-glucopyranoside (**32**), no chemical shift reversal was observed, as the downfield H-6 signal (δ 4.74) had the smaller coupling (2.5 Hz) (Table 2). Moreover, the chemical shifts of H-6 and H-6′ of **32** differed by about the same amount (0.08 ppm) as found with the tetrabenzoate (**29**). This close similarity suggested that in neither of these two compounds does the 6-*O*-acyl substituent exert an appreciable anisotropic deshielding effect, because the C=O bond polarization[4] difference should then be evident. Consequently, as already implied for **29** and **30**, the 4- and 6-*O*-acyl substituents of **32** may not interact sufficiently to ensure that the C-6 carbonyl function is oriented suitably for inducing enhanced deshielding of H-6_R. These findings are taken as additional support, therefore, for the present proposals about the orientations favored by the 4- and 6-*O*-acetyl substituents of D-glucopyranosides.

Derivatives of D-*mannopyranose and* D-*galactopyranose*

The resonance characteristics of the C-6 protons of methyl α-D-mannopyranoside (**42**) and its tetraacetate (**43**) are only slightly different from those described for their *gluco* (C-2) epimers. As shown in Table 4, the more downfield H-6 signal has the smaller spacing (J = 1.7 Hz) in the spectrum of **42**, whereas in the spectrum of **43** it is the broader signal (J = 5.4 Hz). Assuming that the rotamer population about the C-5,C-6 bond is essentially the same in both compounds (and similar to that in the *gluco* series), these data represent an additional example of an interchange in the order of the H-6_R and H-6_S chemical shifts upon acetylation of both OH-4 and OH-6.

The presence of an axial 4-hydroxyl group in compounds of the D-*galacto* configuration is regarded (2) as the source of a rotamer population about the C-5—C-6 bond differing from those of the *gluco* and *manno* diastereomers, based on coupling between H-5 and the 6,6′-methylene protons. Rotamer ROS has been designated (2) as a major contributor in methyl β-D-galactopyranoside (**44**), and this has been confirmed by the examination of a specimen of **44** stereoselectively deuterated at C-6 (9). That is, the observed values (Table 4) of $J_{5,6_S}$ = 8.00 Hz and $J_{5,6_R}$ = 4.3 Hz, while consistent with a high population of rotamer ROS, show that the contribution of rotamer RCS must be minimal. As to chemical shift, the H-6_S signal of **44** is slightly downfield of that of H-6_R (Table 4), which is opposite to that found in the spectrum of the 2,3,4,6-tetraacetate (**45**) (9). However, the two couplings with H-5 in **45** are almost equal (Table 4). Consequently, the acetylation of **44** does not induce a reversal in chemical shift, although there is an accompanying change in the rotamer population. Both of these characteristics add to the distinctiveness of the *galacto* isomer, when compared with the *gluco* and *manno* isomers.

Experimental

General methods

Solutions were evaporated below 40°C under diminished pressure.

[4] For a detailed study of "localized" and "extended" π-polarization effects on carbonyl ^{13}C chemical shifts in a wide range of *meta*- and *para*-substituted benzoyl derivatives of the type XC_6H_4COZ, see ref. 8.

TABLE 4. Chemical shift and coupling data[a] for the 6,6′-methylene protons of D-manno- and D-galactopyranosides, and their tetraacetates

Compound	H-6 δ	H-6′ δ	$J_{5,6}$	$J_{5,6'}$	$J_{6,6'}$	OCH_3	$OCOCH_3$
Methyl α-D-mannopyranoside (D_2O) (**42**)	3.70	3.54	1.7	5.6	12.0	3.20	
-2,3,4,6-tetraacetate ($CDCl_3$) (**43**)	4.30	4.12	4.5	2.4	12.2	3.41	2.16, 2.11, 2.05, 2.00
Methyl β-D-galactopyranoside (D_2O) (**44**)	3.53	3.49	8.00	4.3	11.5	3.33	
-2,3,4,6-tetraacetate ($CDCl_3$) (**45**)	4.20	4.14	6.5	7.2	11.5	3.53	2.17, 2.08, 2.07, 2.00

[a] In solvent indicated (in parenthesis).

Eastman Chromagram sheets of silica gel with fluorescent indicator were used for thin-layer chromatography. Proton magnetic resonance spectra were recorded with a Varian XL-200, or a Bruker WH-400, with the aid of homonuclear decoupling. Chemical shifts (δ) are reported with reference to tetramethylsilane with $CDCl_3$ as solvent, and *HOD* (δ 4.61) with D_2O as solvent. Elemental analyses were obtained from Guelph Chemical Laboratories, Guelph, Ont. Compounds **5** to **19** were available from an earlier study (4) although the complete proton nmr data for **12** were not given therein.

Methyl 6-O-acetyl-β-D-glucopyranoside (21)

The title compound was obtained, as a 3:1 mixture with its 4-*O*-acetyl isomer, by catalytic transfer hydrogenolysis of the *O*-benzyl groups of methyl 2,3,4-tri-*O*-benzyl-6-*O*-acetyl-β-D-glucopyranoside (**12**) using 10% Pd–C/formic acid/ methanol, as described earlier (10). The ^1H nmr data for **12** ($CDCl_3$, δ: 7.5–7.2 (m, 15H, $3C_6H_5$), 4.94 and 4.81 (AB, 2H, OCH_2, J_{gem} = 10.9 Hz), 4.90 and 4.72 (AB, 2H, OCH_2, J_{gem} = 11.0 Hz), 4.85 and 4.56 (AB, 2H, OCH_2, J_{gem} = 10.8 Hz), 4.31 (d, H-1, $J_{1,2}$ = 7.7 Hz), 3.74–3.38 (m, H-3, 4, 5), 3.56 (s, 3H, OCH_3), 3.43 (dd, H-2, $J_{2,3}$ = 8.8 Hz), 2.03 (s, 3H, CH_3); other data are given in Table 2. The ^1H nmr data for **21** (D_2O), δ: 4.22 (d, H-1, $J_{1,2}$ = 7.9 Hz), 3.09 (dd, H-2, $J_{2,3}$ = 9.4 Hz), 3.37 (s, 3H, OCH_3), 3.30 (m, overlapping, H-3), ~3.5 (m, overlapping, H-5), 1.95 (s, 3H, CH_3); other data are given in Table 2.

Methyl 4-O-acetyl-β-D-glucopyranoside (22)

Methyl 2,3-di-*O*-benzyl-β-D-glucopyranoside was tritylated with trityl chloride in dry pyridine. The reaction mixture,[5] after work-up, was chromatographed on silica gel (packed in chloroform under pressure) by gradient elution with chloroform – ethyl acetate which readily separated the unreacted material (R_f 0.63, EtOAc) from the product, methyl 2,3-di-*O*-benzyl-6-*O*-trityl-β-D-glucopyranoside (R_f 0.34, EtOAc). The ^1H nmr data ($CDCl_3$; D_2O exchanged), δ: 7.5–7.2 (m, 25H, phenyl), 4.93 and 4.71 (AB, 2H, OCH_2, J_{gem} = 11.0 Hz), 4.90 and 4.74 (AB, 2H, OCH_2, J_{gem} = 11.0 Hz), 4.34 (d, H-1, $J_{1,2}$ = 7.3 Hz), 3.64 (t, H-4, $J_{3,4} = J_{4,5}$ = 9.0 Hz), 3.60 (s, 3H, OCH_3), 3.45 (t, H-3, $J_{2,3}$ = 9.0 Hz), 3.42 (H-2), 3.35–3.44 (m, overlapping, 3H, H-5, 6 and 6′). *Anal.* calcd. for $C_{40}H_{40}O_6$: C 77.92, H 6.49; found: C 78.02, H 6.61.

The product was acetylated with Ac_2O/pyridine to give methyl 2,3-di-*O*-benzyl-4-*O*-acetyl-6-*O*-trityl-β-D-glucopyranoside (**27**). The ^1H nmr data for **27** ($CDCl_3$), δ: 7.5–7.2 (m, 25H, phenyl), 5.07 (m, combination transition, H-4), 4.94 and 4.71 (AB, 2H, OCH_2, J_{gem} = 11.0 Hz), 4.80 and 4.58 (AB, 2H, OCH_2, J_{gem} = 11.6 Hz), 4.37 (m, combination transition, H-1, $J_{1,2}$ = 7.6 Hz), 3.66 (s, 3H, OCH_3), 3.59–3.52 (m, overlapping, H-2 and 3), 3.42 (m, H-5), 1.63 (s, 3H, CH_3); other data are given in Table 2. *Anal.* calcd. for $C_{42}H_{42}O_7$: C 76.59; H 6.38; found: C 76.58, H 6.28.

A solution of **27** (0.17 g) in a mixture of formic acid (98%, 1 mL), methanol (9 mL), and tetrahydrofuran (5 mL) was added to a stirred suspension of 10% Pd–C (1 g) in formic acid (98%, 1 mL) and methanol (9 mL), under nitrogen. After 20 h, when tlc showed that the reaction was complete, the catalyst was filtered off, washed with chloroform, tetrahydrofuran, and water, and the combined filtrate was evaporated, affording methyl 4-*O*-acetyl-6-*O*-trityl-β-D-glucopyranoside (**26**) (0.1 g; R_f 0.33 (EtOAc)). The ^1H nmr data for **26** ($CDCl_3$), δ: 7.5–7.2 (m, 15H, C_6H_5), 4.98 (t, H-4, $J_{3,4} = J_{4,5}$ = 9.4 Hz), 4.25 (d, H-1, $J_{1,2}$ = 7.4 Hz), 3.63 (s, 3H, OCH_3), 3.60 (t, H-3), 3.50 (dd, H-2), ~3.5 (m, H-5), 1.81 (s, 3H, CH_3); other data are given in Table 2.

Removal of the 6-*O*-trityl group from 26 under catalytic transfer hydrogenolysis conditions with 10% Pd–C/formic acid/methanol (10) gave a 1:3 mixture of methyl 4-*O*-acetyl (**22**) and 6-*O*-acetyl (**21**)-β-D-glucopyranosides, consistent with the reported (11) acyl migration from O-4 to O-6 under acid catalysis conditions. The ^1H nmr data for **22** ($CDCl_3$, sparingly soluble), δ: 4.89 (t, H-4, $J_{3,4} = J_{4,5}$ = 9.3 Hz), 4.25 (d, H-1, $J_{1,2}$ = 7.8 Hz), 3.75 (dd, H-6, $J_{5,6}$ = 2.1, $J_{6,6'}$ = 12.5 Hz), 3.7 (t, H-3, $J_{2,3} = J_{3,4}$ = 9.3 Hz), 3.59 (dd, H-6′, $J_{5,6'}$ = 3.6 Hz), 3.56 (s, 3H, OCH_3), 3.45 (dd, H-2), ~3.45 (m, H-5), 2.13 (s, 3H, CH_3); other data, obtained with D_2O as solvent, are given in Table 2.

Methyl 4,6-di-O-acetyl-β-D-glucopyranoside (23)

Methyl 2,3-di-*O*-benzyl-β-D-glucopyranoside was acetylated with acetic anhydride in pyridine to the corresponding 4,6-di-*O*-acetyl derivative which was then de-*O*-benzylated under catalytic transfer hydrogenation conditions, as already described, to afford the title compound. The ^1H nmr data for **23** (D_2O), δ: 4.68 (dd, H-4, $J_{3,4}$ = 9.3 Hz, $J_{4,5}$ = 9.5 Hz), 4.27 (d, H-1, $J_{1,2}$ = 7.8 Hz), 3.69 (m, H-5), 3.55 (t, H-3, $J_{2,3} = J_{3,4}$ = 9.3 Hz), 3.38 (s, 3H, OCH_3), 1.97, 1.94 (s, 2 × 3H, CH_3); other data are given in Table 2.

Methyl 2,3,4-tri-O-acetyl-β-D-glucopyranoside (25)

Methyl β-D-glucopyranoside was 6-*O*-tritylated with trityl chloride in pyridine, followed by acetylation with acetic anhydride – pyridine. Subsequent de-*O*-tritylation under catalytic transfer hydrogenation conditions, as above, gave the title compound as the sole product. The ^1H nmr data for **25** ($CDCl_3$), δ: 5.26 (t, H-3, $J_{2,3} = J_{3,4}$ = 9.6 Hz), 5.04 (t, H-4, $J_{4,5}$ = 9.6 Hz), 4.97 (dd, H-2, $J_{1,2}$ = 8.0 Hz), 4.46 (d, H-1), ~3.54 (m, H-5), 3.52 (s, 3H, OCH_3), 2.05 (s, 2 × 3H, CH_3), 2.01 (s, 3H, CH_3); other data are given in Table 2.

Methyl 2,3,4-tri-O-benzoyl-6-O-acetyl-β-D-glucopyranoside (31)

Methyl β-D-glucopyranoside was 6-*O*-tritylated, as above, followed by benzoylation with benzoyl chloride in pyridine, the progress

[5] The tlc examination (ethyl acetate) showed that, even after 8 days, the reaction was incomplete. In a separate experiment, the addition of the trityl chloride over a period of several days did not improve the yield of product.

of the reaction being monitored by tlc. (R_f 0.55, 7:4 petroleum ether – EtOAc). The ^{1}H nmr data ($CDCl_3$), δ: 8.2–7.1 (phenyl), 5.81 (t, H-3, $J_{2,3} = J_{3,4} = 9.6$ Hz), 5.65 (t, H-4, $J_{4,5} = 9.6$ Hz), 5.55 (dd, H-2, $J_{1,2} = 7.7$ Hz), 4.74 (d, H-1), 3.86 (m, H-5), 3.62 (s, 3H, OCH_3), 3.37 (dd, H-6, $J_{5,6} = 2.5$ Hz, $J_{6,6'} = 10.5$ Hz), 3.28 (dd, H-6′, $J_{5,6'} = 4.7$ Hz).

The product was de-*O*-tritylated by catalytic transfer hydrogenation, as above, to give methyl 2,3,4-tri-*O*-benzoyl-β-D-glucopyranoside after chromatography on silica gel (packed in petroleum ether under pressure) by gradient elution with petroleum ether and ethylacetate (R_f 0.13, 7:4 petroleum ether – EtOAc). The ^{1}H nmr data ($CDCl_3$), δ: 8.15 – 7.24 (phenyl), 5.95 (t, H-3, $J_{2,3} = J_{3,4} = 9.7$ Hz), 5.51 (dd, H-2, $J_{1,2} = 7.9$ Hz), 5.50 (t, H-4, $J_{4,5} = 9.7$ Hz), 3.93–3.72 (m, 3H, H-5, 6 and 6′, $J_{5,6'} = 4.0$ Hz), 3.57 (s, 3H, OCH_3). Acetylation of the product with acetic anhydride – pyridine gave the title compound as a syrup. The ^{1}H nmr data for **31** ($CDCl_3$), δ: 8.00–7.80 (m, 6H, phenyl-*ortho*), 7.6–7.2 (m, 9H, phenyl-*meta, para*), 5.88 (t, H-3, $J_{2,3} = J_{3,4} = 9.7$ Hz), 5.60 (t, H-4, $J_{4,5} = 9.7$ Hz), 5.50 (dd, H-2, $J_{1,2} = 7.8$ Hz), 4.74 (d, H-1), 4.02 (m, H-5); the other data are given in Table 2.

Methyl 2,3,4,6-tetra-O-(4-nitro)benzoyl-β-D-glucopyranoside (32)

A solution of methyl β-D-glucopyranoside (0.25 g) and 4-nitrobenzoyl chloride (3.0 g, 12 equiv.) in pyridine was stirred for 48 h, and then poured onto ice. The precipitated material was recovered, suspended in chloroform (50 mL), and the chloroform extract was washed with sodium hydrogen carbonate solution and water, dried over anhydrous sodium sulfate, and evaporated. The ^{1}H nmr data for **32** ($CDCl_3$), δ: 8.44–7.98 (phenyl), 5.93 (t, H-3, $J_{2,3} = J_{3,4} = 9.6$ Hz), 5.74 (t, H-4, $J_{4,5} = 9.6$ Hz), 5.57 (dd, H-2, $J_{1,2} = 7.8$ Hz), 4.84 (d, H-1), 4.24 (m, H-5); the other data are given in Table 2.

Hydrogen bonded interactions of methanol and water with purines and pyrimidines

J. N. SPENCER, S. W. BARTON, K. A. SMITH, W. S. WOLBACH, J. F. POWELL, M. R. KIRSHENBAUM, D. W. FIRTH, E. M. HARRIS, AND T. A. JUDGE

Department of Chemistry, Franklin and Marshall College, Lancaster, PA, 17604, U.S.A.

Received October 13, 1982[1]

J. N. SPENCER, S. W. BARTON, K. A. SMITH, W. S. WOLBACH, J. F. POWELL, M. R. KIRSHENBAUM, D. W. FIRTH, E. M. HARRIS, and T. A. JUDGE. Can. J. Chem. **61**, 2695 (1983).

The solvation of benzimidazole, 4-azabenzimidazole, purine, adenine, uracil, thymine, and cytosine in water and methanol was determined by a combination of calorimetric and spectral analysis. Specific enthalpies have been assigned to each interaction site in the first solvation shell. Calculations, based on the enthalpies of hydrogen bond formation with water, and estimates for intermolecular hydrogen bond enthalpies, show that the self-association of purine and adenine in water through hydrogen bonded interactions is enthalpically possible.

J. N. SPENCER, S. W. BARTON, K. A. SMITH, W. S. WOLBACH, J. F. POWELL, M. R. KIRSHENBAUM, D. W. FIRTH, E. M. HARRIS et T. A. JUDGE. Can. J. Chem. **61**, 2695 (1983).

Faisant appel à l'analyse spectrale combinée à l'analyse calorimétrique, on a déterminé le solvatation du benzimidazole, de l'aza-4 benzimidazole, de la purine, de l'adénine, de l'uracile, de la thymine et de la cytosine dans l'eau et dans le méthanol. On a attribué les enthalpies spécifiques à chaque site d'interaction dans la première couche de solvatation. Les calculs, basés sur les enthalpies de formation de la liaison hydrogène avec l'eau et les évaluations des enthalpies de liaison hydrogène intermoléculaire, montrent que l'autoassociation de la purine et de l'adénine dans l'eau par l'intermédiaire des interactions liées d'hydrogène est possible du point de vue de l'enthalpie.

Introduction

The calculation of hydration schemes for the bases of the nucleic acids have been the object of several theoretical studies (1–3). These studies have generally been concerned with the first hydration shell and have dealt with preferred orientations of water molecules for hydrogen bonded interactions. Teplitsky *et al.* (4) have used enthalpies of sublimation and solution to calculate the overall hydration of uracil, thymine, and their derivatives. From a study of the temperature dependence of the enthalpy of solution of thymine in water and ethanol, Alvarez and Biltonen (5) have concluded that nucleic acid bases do not make all possible hydrogen bonds in the vicinity of room temperature. Gill, Downing, and Sheats (6) determined the enthalpy of self association of purine derivatives in water and attributed the association to base stacking interactions. D'Albis, Wickens, and Gratzer (7) investigated the association of derivatives of uracil and adenine in $CHCl_3$ in the presence of dissolved water. They conclude that the extent of association is unchanged by the presence of water and that little or no competition occurs between the formation of base pairs through hydrogen bonds and bonding of water to the bases.

The object of the present study was to make reasonable estimates of the hydrogen bonding of water to purines and pyrimidines in the first hydration shell and to estimate the overall hydration enthalpy. Solvation schemes in methanol were also determined and transfer enthalpies were used to assess the relative hydrogen bonded interactions in water and methanol.

Experimental

The calorimetric methods used have been previously described as have the purifications of water and methanol (8). Aldrich tech. grade benzimidazole and Aldrich 98% 4-azabenzimidazole were vacuum sublimed. Aldrich 99% purine was vacuum dried and used without further purification. 1-Methyl-2-pyridone and 4(3*H*)-pyrimidone were supplied by Aldrich and were distilled under nitrogen atmosphere. Successive injections of solute were used to identify any concentration dependence of the enthalpy of solution. Concentrations of solutes ranged from 0.003 to 0.015 *M*.

Calculation and discussion

The assignment of enthalpies due to interactions at each site of the first solvation shell made use of calorimetric and near ir spectroscopic data. For adenine, the interaction at the amino group was considered to be the formation of two hydrogen bonds by the solvent, either methanol or water, to the N6 protons. These interactions were taken to be the same as those found from pure base calorimetric analysis for the amino group interaction of 2-aminopyridine with methanol and water, −3.5 and −2.8 kcal mol^{-1}, respectively (8). Previous studies of pyrrole, imidazole, the diazines (9), and the aminopyridines showed that an interaction by methanol at the nitrogen of amino groups and at the nitrogen of N—H ring groups was responsible for the greater enthalpic stability of the aminopyridines, pyrrole, and imidazole in methanol relative to water (Table 1). The methanol interaction at N6 of adenine was assumed to be that previously assigned to the interaction between methanol and the amino group nitrogen of 2-aminopyridine, −1.7 kcal mol^{-1}. No similar interaction was found for water at these nitrogen sites for pyrrole, imidazole, or the aminopyridines.

The interaction at the imidazole moiety of benzimidazole, 4-azabenzimidazole, purine, and adenine was taken to be the same as that for the corresponding nitrogen in imidazole. The aza nitrogen of 4-azabenzimidazole was modeled by the pyridine nitrogen interaction (9).

The interactions at N1 and N3 of purine and adenine were determined from a plot of pK versus enthalpies of interaction for the diazines (9). pK values at N3 for purine and adenine were obtained from a relationship between pK and the sum of particular coulomb integrals for the purine and pyrimidine bases (10).

Interactions by the N—H of the imidazole moiety of these compounds were calculated from a two-parameter equation

[1]Revision received June 16, 1983.

TABLE 1. Enthalpies of solution (kcal mol^{-1}, 298 K)

Solute	Enthalpy of solution in H_2O	Enthalpy of solution in CH_3OH	ΔH_{tr} $H_2O \rightarrow CH_3OH$
Benzimidazole	+4.85±0.21	+2.53±0.20	−2.32
4-Azabenzimidazole	+4.14±0.13	+2.89±0.18	−1.25
Purine	+4.48±0.23	+4.85±0.10	+0.37

developed by Rider (11):

$$\Delta H = bxc$$

b is a measure of the relative proton donating abilities of a series of acids with a given base and is considered to be related to the corresponding frequency shifts. The parameter c represents the proton accepting abilities of the base, which is constant, if the base remains the same. Rider (11) has determined these constants for methanol and water. By using enthalpy changes found for pyrrole and imidazole with water and methanol (9) along with Rider's values for c, the parameter b was calculated for imidazole and pyrrole. Then, frequency shifts for imidazole and pyrrole with *N*,*N*-dimethylformamide (DMF) in CCl_4 solvent were used to establish a relation between b and these frequency shifts. The b value for benzimidazole was then determined from the derived relation between b and the frequency shift. The frequency shift for benzimidazole is 192 cm^{-1}, compared to 176 cm^{-1} for imidazole, and 135 cm^{-1} for pyrrole. Thus benzimidazole is a better proton donor than either imidazole or pyrrole. The previously determined enthalpies of hydrogen bond formation of pyrrole and imidazole with methanol were −3.0 and −3.8 kcal mol^{-1}, respectively (9). The assigned interaction enthalpy of the N—H of benzimidazole with methanol is −4.1 kcal mol^{-1}. In water, the corresponding N—H interaction enthalpies for pyrrole (9), imidazole (9), and benzimidazole are −2.3, −2.7, and −2.9 kcal mol^{-1}, respectively.

Due to low solubility, frequency shifts for purine could not be determined in CCl_4 solvent. Mixtures of DMF and CCl_4 were used as a solvent and the frequency shift data were extrapolated to infinite dilution in DMF. The frequency shift found for purine was nearly the same as that found for benzimidazole. Thus the enthalpies due to interactions at the purine N9—H were taken to be the same as for benzimidazole. It was also assumed that the same interactions occurred with 4-azabenzimidazole and adenine. The last interaction remaining to be assigned is that of the nitrogen of the imidazole N—H group with methanol.

The enthalpy of N—H hydrogen bonding for pyrrole to methanol is −3.0 kcal mol^{-1} (9). The interaction enthalpy at the nitrogen is −0.4 kcal mol^{-1} (8). The N_1—H hydrogen bond enthalpy of imidazole hydrogen bonding to methanol is −3.8 kcal mol^{-1} and the N_1 interaction enthalpy is −1.2 kcal mol^{-1} (8). The interaction enthalpy at the nitrogen thus increases directly with the N—H bond enthalpy in almost a one-to-one correspondence. Similar results are found for corresponding interactions with 2- and 3-aminopyridine (8). The N—H_2 enthalpies for these two compounds are −3.5 and −3.7 kcal mol^{-1}, respectively, and the amino nitrogen–methanol interactions are −1.7 and −1.9 kcal mol^{-1}, respectively. This allowed the assignment of the interactions at the imidazole nitrogen given in Table 2.

Gonnella and Roberts (12) report that in water solvent, the purine N7H and N9H tautomers are present in nearly equal amounts. Similar observations were made for adenine. Thus the tautomers of purine and those of adenine must undergo similar interactions with water since neither is preferred. It was assumed that the same would be true for methanol solvent.

The transfer enthalpies from water to methanol given in Table 1 indicate that benzimidazole, 4-azabenzimidazole, and adenine are enthalpically stabilized by methanol relative to water. Only purine is more strongly solvated by water than by methanol. In addition to the hydrogen bonding to the ring nitrogens and amino group by water and methanol, interactions at the π clouds are possible. The factors which contribute to the enthalpic stability of these solutes in methanol and water can be determined from an analysis of the transfer enthalpies.

That part of the transfer enthalpy due to the making and breaking of hydrogen bonds to the ring nitrogens and amino group can be estimated from the enthalpies given in Table 2. The cavity and interaction terms of the remainder of the molecule can be estimated by choosing an appropriate model compound. Benzimidazole was chosen to model 4-azabenzimidazole, purine, and adenine. The transfer enthalpy from water to methanol for benzimidazole is −2.3 kcal mol^{-1}. The N_1—H and N_3 hyrogen bonded interactions in methanol and water contribute −1.4 kcal mol^{-1} to the transfer enthalpy. Thus −0.9 kcal mol^{-1} must be due to differences in cavity and interaction terms for the ring system in methanol and water.

By using the interaction enthalpies given in Table 2 and the transfer enthalpy just found for the cavity and interaction terms, the transfer enthalpies for 4-azabenzimidazole, purine, and adenine may be calculated. The results of this calculation are given in Table 3.

The transfer enthalpy for benzene from water to methanol is −0.1 kcal mol^{-1} (9) and that for the imidazole ring, when hydrogen bonded interactions by N1H and N3 are taken into account, is −0.4 kcal mol^{-1}. Previous studies of the amino-

[a]Thymine interaction enthalpies are taken to be the same as those for uracil. The contribution of the methyl group is added to the uracil interaction terms.

pyridines have shown that the transfer enthalpy from water to methanol could be accounted for if only the making and breaking of hydrogen bonds in the two solvents were considered. Thus, any cavity or interactions terms due to the benzene ring or imidazole ring are not of overriding significance in determining the transfer enthalpy. The sum of the transfers of the appropriate six-member ring and imidazole compounds should give the transfer enthalpy for the compound formed from the fusion of these two compounds if only the making and breaking of hydrogen bonds is important. The sum of the transfer enthalpies for pyrimidine and imidazole should approximate the transfer enthalpy of purine; benzene and imidazole transfers should approximate that of benzimidazole; pyridine and imidazole serve as models for the transfer of 4-azabenzimidazole; and the sum of transfers of imidazole, 2-aminopyridine, and pyridine should give the transfer enthalpy of adenine. The sums

[f]Calculated from the appropriate sum of the transfer enthalpies of pyridine, pyrimidine, 2-aminopyridine, and imidazole.

of these transfers are given in Table 3. These summed transfers agree very closely with the transfers calculated on the basis of the assigned interaction enthalpies (column 2, Table 3). If only making and breaking of hydrogen bonds are significant for the transfer enthalpies, exactly such an agreement would be expected. However, the experimental transfer enthalpies for the solutes of this work are all about 1 kcal mol^{-1} more negative than the summed transfer enthalpies or those transfer enthalpies calculated from assigned specific interactions. It would appear that when ring systems such as pyrimidine and imidazole are fused, the cavity and interaction terms for the fused compound may be quite different than for the separate components. The transfer enthalpy of benzene from water to methanol is −0.1 kcal mol^{-1}, the same transfer for biphenyl is −3.0 kcal mol^{-1} and that for naphthalene is −2.5 kcal mol^{-1} (13, 14).

D'Albis *et al.* (7) have suggested that nucleic acid bases in water solvent may self-associate through hydrogen bonding. An estimate of the enthalpy change for the formation of a hydrogen bonded self-association complex of purine in water may be made by using the enthalpies given in Table 2. If a cyclic dimer is formed by hydrogen bonding from N9H of one purine molecule to N_3 of another, water molecules must be cleared from both sites; this requires 6.1 kcal mol^{-1}. The resulting N—H···N hydrogen bond releases about 4.3 kcal mol^{-1} (15). The water molecules cleared from N9H and N_3 reform hydrogen bonds to other water molecules. The water−water hydrogen bond is estimated to be 5.1 kcal mol^{-1}. For the dimerization,

$$2w - \text{pur-2} = (\text{pur})_2 + 2ww$$

the enthalpy change is +12.2 − 8.6 − 10.2 = −6.6 kcal mol^{-1}.

A similar analysis allows the assignment of the first solvation shell hydrogen bond enthalpies for uracil, thymine, and cytosine. The model compound 1-methyl-2-pyridone and previously determined interaction enthalpies were used to make these assignments (8, 9).

The transfer enthalpy from water to methanol, +2.9 kcal mol^{-1}, for 1-methylpyridone was considered to be the sum of the transfers of the methyl group, the carbonyl group, and the nitrogen atom. The cavity and interaction terms for the benzene moiety are insignificant. The transfer enthalpy, water to methanol, is +0.8 kcal mol^{-1} for the methyl group (9) and −0.4 kcal mol^{-1} for the nitrogen (8, 9). Thus the transfer enthalpy for the carbonyl group is +2.5 kcal mol^{-1}. If DMA is used as a model for the carbonyl group, the interaction enthalpy previously determined (16) for the carbonyl−water hydrogen

[f]Reference 24.

bond, −5.9 kcal mol^{-1}, may be used to assign the hydrogen bond enthalpy for the carbonyl−methanol hydrogen bond as −3.4 kcal mol^{-1}.

The transfer enthalpy of 4(3*H*)-pyrimidone is then considered to involve the transfer of the ring nitrogen (pyridine is the model compound) (9), the carbonyl group, and the N—H group. The N—H enthalpies are taken to be the same as those determined for adenine.

For uracil and thymine O_2 and O_4 are not equivalent (15) and consequently previously determined interactions for these groups hydrogen bonding to water have been used (16). The hydrogen bonded interactions with methanol were taken to be less than those to water by the transfer enthalpy of 2.5 kcal mol^{-1}. For cytosine, 4-aminopyridine was used to model the amino group interactions (8). These interaction enthalpies, given in Table 2, may be used to calculate the transfer enthalpies. The results of these calculations are given in Table 4.

The transfer enthalpies given in Table 4 show that 4(3*H*)-pyrimidone and 1-methyl-2-pyridone are enthalpically more stable in water than in methanol. The interaction enthalpies indicate that water stabilizes these two compounds relative to methanol because the proton donating ability of water is greater than that for methanol. The order of enthalpic stability is reversed for uracil and cytosine with methanol being the better solvent. This is due to the two proton donating groups on these compounds and the superior proton accepting ability of methanol over water. Thymine is slightly more stable in water than in methanol. The methyl group of thymine is 0.8 kcal mol^{-1} more stabilized by water than methanol due to the structuring of water molecules about this non-polar group. Hydrophobic hydration of the methyl group is thus seen to be the reason for the greater enthalpic stability of thymine in water relative to methanol.

Étude polarographique du niobium dans les mélanges eau − fluorure d'hydrogène

H. MÉNARD et R. BEAUDOIN

Département de chimie, Faculté des sciences, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Récu le 8 mars 1983

H. MÉNARD et R. BEAUDOIN. Can. J. Chem. **61**, 2699 (1983).

L'analyse de certains minerais requiert leur solubilisation dans le fluorure d'hydrogène. Nous avons élaboré une méthode d'analyse directement applicable aux mélanges eau − fluorure d'hydrogène.

Cependant, dans l'acide fluorhydrique 50% le niobium est soluble sous la forme du complexe NbF_6^- qui est réductible à l'électrode polarographique à un potentiel de −0,880 volt vs. ECS. Pour des concentrations inférieures à 45% en HF, le complexe du niobium s'hydrate pour donner l'ion $NbOF_5^{-2}$ non réductible.

H. MÉNARD and R. BEAUDOIN. Can. J. Chem. **61**, 2699 (1983).

Solubilization in hydrogen fluoride is required for the analysis of some minerals. A method of analysis directly applicable to water − hydrogen fluoride mixtures was worked out.

However, in 50% hydrofluoric acid niobium is soluble as NbF_6^- complex, which can be reduced with a polarographic electrode at a potential of −0.880 V vs. E.C.S. For concentrations lower than 45% in HF, the niobium complex is hydrated and exists as a non-reducible ion $NbOF_5^{-2}$.

Introduction

La polarographie du niobium peut s'effectuer dans un grand nombre de milieux (1), pour autant que les éléments interférents soient absents au facilement éliminables. Le minerai de niobium contient généralement du tantale. Il est donc important de pouvoir analyser le mélange de ces deux métaux doués de propriétés similaires. Quoique le tantale ne donne que rarement une vague polarographique (2), il peut toutefois interférer dans certains milieux en formant un complexe contenant à la fois le tantale et le niobium. Ces complexes diffusent plus lentement à cause de leur taille accrue, ce qui contribue à la diminution du courant de diffusion lié à la réduction du niobium. Il existe quelques études polarographiques de la réduction du niobium dans divers solvants et électrolytes supports (1, 3−6).

Les solutions sont généralement préparées par fusion de l'oxyde de niobium dans le carbonate de potassium, suivie de la dissolution du mélange dans le milieu choisi.

La réduction dans l'acide chlorhydrique dilué est impossible à cause de l'instabilité de la solution. Selon Henrion et Alder (7) et Elving et Olson (8), la vague présente son amplitude maximale pour une concentration de 11 mol/L en HCl. Aux concentrations plus faibles, il y a formation hydrolytique d'acide niobique. McCullough et Meites (9, 10) ont étudié en détail le mécanisme du transfert d'électrons. Ils arrivent à la conclusion que le transfert monoélectronique est suivi par une disproportion du type suivant:

$$[1] \quad Nb^{+5} + é \rightarrow Nb^{+4}$$

$$[2] \quad 2Nb^{+4} \rightarrow Nb^{+5} + Nb^{+3}$$

la contribution de la réaction [2] étant relativement négligeable.

L'oxyde de niobium est très soluble dans les mélanges eau − fluorure d'hydrogène à partir de faibles concentrations en HF. La polarographie dans ce milieu permet donc d'éliminer l'étape de la fusion alcaline suivie de la redissolution dans le milieu désiré. De plus le tantale ne donne pas de vague de réduction et n'interfère pas sur celle du niobium dans ce milieu; il n'est donc pas nécessaire d'éliminer le tantale de la solution avant la détermination du niobium. La présence des complexes NbF_6^- et $NbOF_5^{-2}$ peut aussi être mise en évidence, l'ion $NbOF_5^{-2}$ n'étant pas électroactif. Plusieurs auteurs (11−14) ont étudié les complexes du niobium dans les mélanges eau − fluorure d'hydrogène. Pour des solutions contenant plus de 35% en HF, le complexe prédominant est NbF_6^-, alors que pour une concentration inférieure à 25% en HF, l'espèce prépondérante devient $NbOF_5^{-2}$.

Partie expérimentale

La cellule polarographique est constitutée d'un bécher en polyméthylpentane d'une capacité de 50 mL surmonté d'un couvercle de Teflon qui sert à maintenir les électrodes. L'électrode de référence au calomel saturé est munie d'une double jonction séparée de la solution par une gaine de Teflon et un disque de polyéthylène poreux. L'électrode auxiliaire est un fil de platine. L'électrode de travail est un capillaire polarographique Sargent−Welch S-2418 recouvert de polyéthylène (15) et dont la période de chute est contrôlée par un dispositif électronique réalisé dans nos ateliers. Tous les potentiels se réfèrent à l'électrode de calomel saturé. L'analyseur polarographique PAR est le modèle 364. La table traçante est une techneurop, Sefram T.G.M. 101.

Les produits utilisés sont: niobium métallique en poudre de Pfaltz and Bauer; Nb_2O_5 99,9% de Alfa Product et HF 49% de Baker.

Le niobium métallique n'est soluble que dans un mélange d'acide nitrique et fluorhydrique. Pour faire une mesure polarographique, il suffit d'évaporer à sec pour éliminer l'acide nitrique et redissoudre dans l'acide fluorhydrique. Le résidu obtenu après évaporation dans un bain d'huile est un fluorure de niobium qui peut être redissous en un temps très court.

La mise en solution du minerai s'effectue en pesant environ 0,25 g dans un erlenmeyer de polyéthylène auquel au ajoute 10 mL d'acide fluorhydrique à 49% puis 5 mL d'acide nitrique concentré. Le mélange est agité et évaporé à sec sur bain d'huile. Le résidu est redissous dans HF 49% et jaugé à 100 mL. Le polarogramme peut être pris directement ou en diluant à la concentration requise.

Pour l'analyse des minerais bruts dont la teneur en niobium se situe entre 0 et 1%, il est préférable d'utiliser la méthode des ajouts dosés. La technique consiste à peser des échantillons du minerai (soit un gramme) auxquels on additionne des quantités croissantes de Nb_2O_5. Après resolubilisation, les polarogrammes sont enregistrés et la concentration de niobium dans le minerai est déduite par extrapolation.

Résultats

Dans l'acide fluorhydrique, on observe une vague de réduction de niobium. La figure 1 montre la vague obtenue par rapport au courant résiduel du HF 49%. Quoiqu'assez près du

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

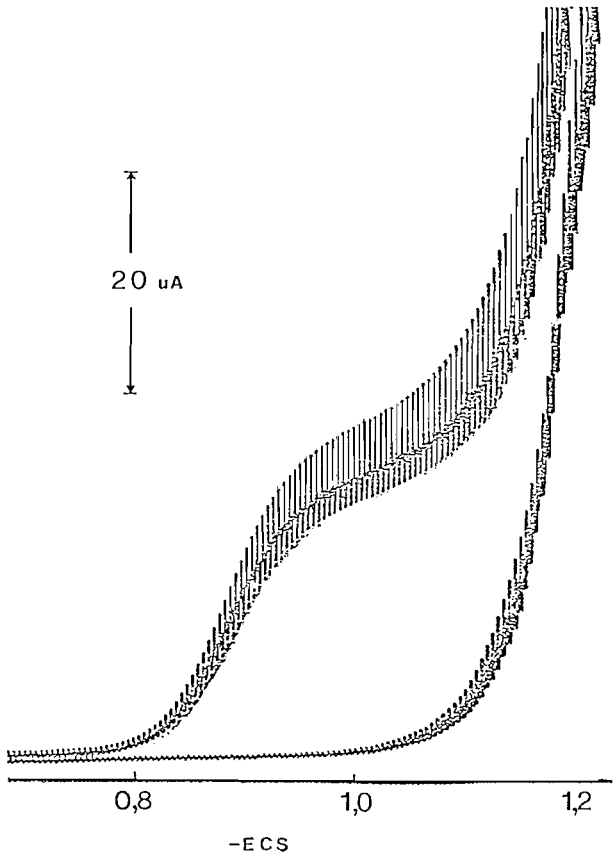

FIG. 1. Polarogramme du niobium dans HF 49,1%.

mur de réduction de l'hydrogène la vague est suffisamment bien résolue. Le potentiel de demi-vague est de −0,880 V.

La réversibilité de la vague a été vérifiée à partir de différentes techniques polarographiques: le graphique du potentiel en fonction du log $i/(id-i)$ présente une droite dont la pente est de 59 mV; le potentiel de demi-vague obtenu par polarographie impulsionnelle est le même que celui obtenu par polarographie classique; le pic que l'on obtient par polarographie impulsionnelle différentielle est situé à la valeur de potentiel prévue par Parry et Osteryoung (16), plus positive de 25 mV que la valeur obtenue par polarographie classique, dans le cas d'une impulsion de 50 mV.

A partir de l'équation du courant en polarographie impulsionnelle différentielle:

$$[3] \quad \delta i = \frac{nFAD^{1/2}C_0^*}{\Pi^{1/2}(\tau - \tau')^{1/2}} \left| \frac{P_A(1-\sigma^2)}{(\sigma + P_A)(1 + P_A\sigma)} \right|$$

où τ' est le temps immédiatement avant l'impulsion et τ est le temps juste avant la fin de l'impulsion,

$$[4] \quad P_A = \left(\frac{D_0}{D_R}\right) \exp\left[\frac{nF}{RT}\left(E + \frac{\Delta E}{2} - E^{0\prime}\right)\right]$$

et

$$[5] \quad \sigma = \exp\frac{nF}{RT}\frac{\Delta E}{2}$$

où ΔE est le saut de potentiel.

On démontre facilement par dérivation $d(\delta i)/dP_A$ que δi est maximum pour $P_A = 1$.

Dès lors:

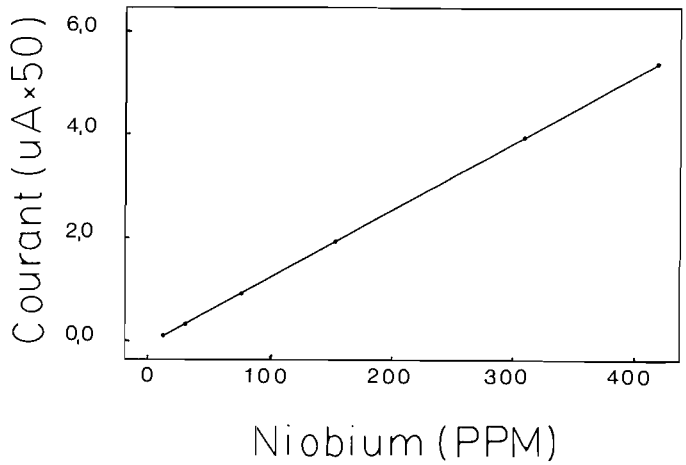

FIG. 2. Courbe d'étalonnage pour la détermination quantitative du niobium en milieu HF 49%, en régime polarographie impulsionnelle différentielle.

$$[6] \quad E_{max} = E_{1/2} - \frac{\Delta E}{2}$$

La largeur du pic à mi-hauteur augmente avec l'amplitude de l'impulsion imposée (17); elle est de 100 mV pour une amplitude de 50 mV.

Ces mesures confirment le caractère réversible et monoélectronique de la réaction.

$$[7] \quad Nb^{+5} + e^- \rightleftarrows Nb^{+4}$$

Cette conclusion peut être correlée au fait que Senderoff et Mellors (17) ont établi que la réduction du niobium V au niobium IV est également une réaction réversible en milieu fluorure fondu.

Les résultats polarographiques permettent de calculer le coefficient de diffusion du niobium dans HF commercial à 49% à partir de l'équation d'Ilkovic. La valeur est de $9{,}1 \times 10^{-6}$ cm^2/s.

Du point de vue analytique, il est préférable d'utiliser la polarographie impulsionnelle différentielle. Le niobium présente un pic à un potentiel de −0,855 V pour une hauteur d'impulsion de 50 mV et une vitesse de balayage de 2 mV par seconde, le temps de chute de la goutte de mercure étant de 1.00 s.

La hauteur du pic est proportionnelle à la concentration. La figure 2 montre une courbe d'étalonnage à laquelle correspond une limite de détection de l'ordre de 15 ppm. Cette valeur est essentiellement déterminée par l'interférence entre le mur de réduction de l'hydrogène et le pic de réduction du niobium.

Il est à remarquer que la concentration minimale détectable ne varie pas en fonction du vieillissement des solutions de niobium dans le fluorure d'hydrogène.

Le tableau 1 montre les résultats obtenus pour des échantillons de minerais concentrés ayant une teneur en niobium de l'ordre de 60%. Ces résultats sont reproductibles à environ 1%.

Lorsque l'on diminue la concentration en HF, la hauteur de la vague de niobium décroît et finit par disparaître complètement pour un pourcentage en HF de 22% (Fig. 3). Le potentiel de demi-vague n'étant pas déplacé, on peut conclure à la simple disparition de l'espèce électroactive. L'observation de la solution ne montre aucun signe de précipitation, la décroissance de l'onde polarographique étant due à la formation d'un nouveau complexe, selon

[8] $HNbF_6 + H_2O \rightleftarrows H_2NbOF_5 + HF$

Les espèces $HNbF_6$ et H_2NbOF_5 étant les espèces ioniques fortement solvatées, l'équilibre est essentiellement contrôlé par l'activé du HF et de H_2O en solution. Les activités sont calculées selon Vaillant (18) à partir des valeurs de pression partielle de l'eau, P_{H_2O} et de HF, P_{HF} publiés par Munter *et al.* (19). L'activité de l'eau est calculée à l'aide de la loi de Raoult (état de référence: eau pure):

[9] $P_{H_2O} = a_{H_2O} P^0_{H_2O}$

L'activité du fluorure d'hydrogène est calculée à partir de la

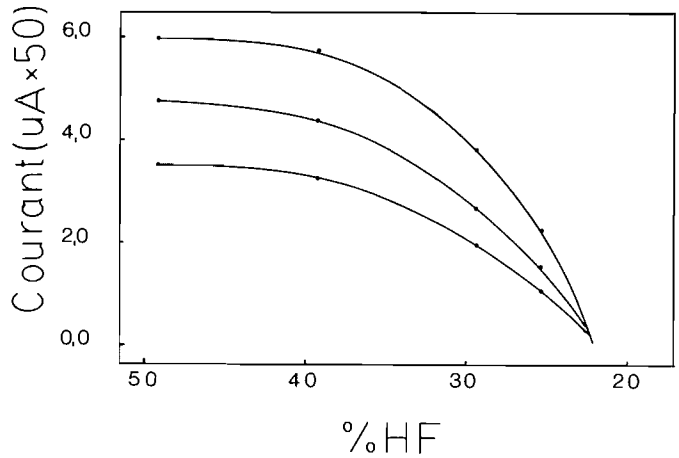

FIG. 4. Influence de la concentration en HF sur le courant de pic aux concentrations suivantes en niobium: (1) $2{,}21 \times 10^{-3}$ mol/L; (2) $1{,}67 \times 10^{-3}$ mol/L; (3) $1{,}23 \times 10^{-3}$ mol/L.

loi de Henry (référence: solution infiniment diluée de HF dans l'eau):

[10] $\text{fugacité}_{HF} = a_{HF} K_{HF}$

Le coefficient de Henry, K_{HF}, est déterminé à partir de la courbe de variation de P_{HF} en fonction de la concentration (en molarité).

La constante d'équilibre peut être calculée si on fait l'approximation que l'activité des complexes du niobium est égale à leur concentration. A la concentration en HF où le courant est la moitié de sa valeur maximale (HF à 50%), la valeur est de $0{,}7 \times 10^2$.

[11] $$K = \frac{[NbF_6^-]\, a_{HF}}{[NbOF_5^{-2}]\, a_{H_2O}}$$

Le complexe $NbOF_5^{-2}$ n'est pas réductible à l'électrode polarographique et il est responsable de la disparition de la vague de réduction. La figure 4 montre les courbes obtenues pour trois concentrations de niobium en fonction de la concentration en HF. Le point de convergence pour la disparition complète de la vague du niobium est le même dans les trois cas, soit 22% en HF.

Keller (13) puis Howell et Moss (15) ont démontré par spectroscopie que la totalité du niobium se retrouve sous la forme de NbF_6^- dans HF 50% et sous forme $NbOF_5^{-2}$ dans une solution contenant moins de 20% en HF. A partir des données polarographiques, confirmées par spectroscopie, il est aisé de calculer le pourcentage de chacun des deux complexes en fonction de la concentration en HF (Tableau 2). L'accord entre les données spectroscopiques et électrochimiques démontre que la réaction d'interconversion est très lente, à l'échelle de la période de chute de l'électrode à goutte.

Keller et Chetham-Strode (20) ont comparé le comportement du niobium et du tantale dans les mélanges eau − fluorure d'hydrogène. Le niobium a tendance à s'hydrater lorsque la concentration en HF diminue (11). En milieu chlorhydrique, on observe la précipitation d'acide niobique à acidité décroissante (7). Dans l'acide fluorhydrique, le complexe $NbOF_5^{-2}$ très stable s'observe pour des concentrations inférieures à 40% en HF. Le tantale forme également un complexe oxyfluorure mais celui-ci disparaît à une concentration de 0,1 mol/L en HF pour faire place au complexe heptafluoré (18). Les complexes heptafluorés étant généralement instables, le niobium ne donne le

complexe NbF_7^{-2} qu'en sel fondu (21) où la concentration en fluorure libre est très élevée par rapport aux mélanges eau − fluorure d'hydrogène.

Conclusions

Nous avons étudié le comportement polarographique du niobium dans les mélanges eau − fluorure d'hydrogène jusqu'à 50%. Dans les mélanges à 50%, on observe une réduction monoélectronique réversible dont le potentiel de demi-vague est de −0,880 V.

Du point de vue analytique, il est possible de déterminer la concentration de niobium contenue dans un minerai avec une limite de détection de 15 ppm, même en présence de tantale.

Pour des concentrations en HF inférieures à 45% il y a formation du complexe $NbOF_5^{-2}$ non réductible, qui devient prépondérant aux concentrations en HF inférieures à 25%.

Remerciements

Nous remercions le Ministère de l'Education du Québec et le Conseil de Recherches en Sciences naturelles et en Génie du Canada pour leur support financier. Nous remercions aussi la compagnie NIOBEC pour nous avoir fourni des échantillons de minerais analysés par fluorescence des rayons X.

State-resolved quantum yields of the reactions of metastable Ca(^3P, ^1D) with NO_2 and N_2O

HUI WANG[1] AND MICHAEL MENZINGER

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received January 4, 1983

HUI WANG and MICHAEL MENZINGER. Can. J. Chem. **61**, 2703 (1983).

Absolute chemiluminescence and quenching (beam attenuation) cross sections were measured for the title reactions in a beam/gas experiment. In the Ca* + NO_2 system, both quantities are about twice as large as in the N_2O reaction. The chemiluminescence quantum yields, corrected for infrared emission from the $A\,^1\Sigma^+$ and $A'\,^1\Pi$ states, are of similar magnitude $Y_{CL}(Ca^* + N_2O) = 7.2 \pm 1.1\%$ and $Y_{CL}(Ca^* + N_2O) = 8.0 \pm 0.9\%$. The quenching cross sections are $\sigma_T(Ca^* + N_2O) = 153 \pm 32$ Å^2 and $\sigma_T(Ca^* + N_2O) = 73.2 \pm 5.7$ Å^2, consistent with a long-range harpooning process in the former and an electron transfer at closer range for the latter system. The partial resolution of CL spectra was aided by lifetime-separated spectroscopy. The principal emitter in both systems is the long-lived CaO($A'\,^1\Pi$), next to minor yields of CaO in the short-lived $A\,^1\Sigma^+$, $B\,^1\Pi$, and "orange and green arc band" states. The results are discussed in light of adiabatic correlations. The arc states are argued to arise in nearly coplanar collisions from the rearrangement of an excited intermediate. An information theoretical analysis reveals considerable dynamical bias in the form of non-linear surprisal plots.

HUI WANG et MICHAEL MENZINGER. Can. J. Chem. **61**, 2703 (1983).

On a mesuré les sections droites de chimiluminescence et d'extinction (attenuation de faisceau) des réactions mentionnées dans le titre dans une expérience de faiseau/gas. Dans le système Ca* + NO_2 les deux quantités sont environ deux fois plus élevées que dans la réaction du N_2O. Les rendements quantiques de chimiluminescence, corrigés pour l'émission infrarouge à partir des états $A\,^1\Sigma^+$ et $A'\,^1\Pi$, sont du même ordre de grandeur $Y_{CL}(Ca^* + N_2O) = 7{,}2 \pm 1{,}1\%$ et $Y_{CL}(Ca^* + N_2O) = 8{,}0 \pm 0{,}9\%$. Les sections droites d'extinction sont de: $\sigma_T(Ca^* + N_2O) = 153 \pm 32$ Å^2 et $\sigma_T(Ca^* + N_2O) = 73{,}2 \pm 5{,}7$ Å^2 et elles sont en accord avec un processus d'harponnage à longue distance dans le premier transfert d'électron à un intervalle plus rapproché que celui du dernier système. La spectroscopie de temps de vie séparé aide à résoudre partiellement les spectres du CL. Le principal émetteur dans les deux systèmes est le CaO ($A'\,^1\Pi$) de longue période de vie après $B\,^1\Pi$ et "la bande d'arc orange et vert". On discute des résultats en fonction des corrélations adiabatiques. On pense que les états d'arc proviennent de collisions quasi coplanaires à partir de la transposition d'un intermédiaire excité. Une information d'analyse théorique révèle une déviation dynamique considérable dans la forme non linéaire surprenante des courbes.

[Traduit par le journal]

Introduction

Since the first studies, more than a decade ago (1), on the chemiluminescence from alkaline earth metal atoms M with oxidizers N_2O and NO_2, much progress has been made in understanding their rich spectroscopy and dynamics (2). The complexity of these seemingly innocuous reactions becomes first evident in the spectroscopy of the metal oxides (3), which has made the determination of the primary product state distribution a non-trivial and still ongoing task (4). The dramatic rise of photon yield with pressure (5) and the entire issue of dark (or reservoir) states have made the Ba + N_2O system a cause celèbre (2) and a paradigm for similar systems reflecting the importance of energy transfer following the primary reaction step. The involvement and the high quantum yields of the metastable M(^3P, ^1D) metal atoms reacting with N_2O were first noted in ternary flames (6) in the presence of CO. It was subsequently shown (7) that the metastable reactions lend themselves readily to measuring absolute chemiluminescence and quenching cross sections σ_{CL}, σ_T, without the need for tedious and inherently inaccurate absolute calibrations (5). The present work was undertaken to shed light on the multi-potential energy surface dynamics through its key-witness, the partitioning of electronic energy. We concern ourselves only with the primary reaction yields and hence have confined the measurements to gas pressures below 1.4 mTorr. Dagdigian and co-workers have already studied the Ca* + N_2O system both under single collision (8) and multiple collision conditions (8) and have reported state-resolved quantum yields. The purpose of the present work is to study comparatively the NO_2 as well as the N_2O reactions under single collision conditions and to further develop the resolution of product states (8).

The assignment and "carving up" of the CL spectra relies greatly on indirect inference based on lifetime-separated spectroscopy (9). By this technique the long-lived CaO($A'\,^1\Pi$) state can be shown to be the principal emitter, while ($A\,^1\Sigma^+$), ($B\,^1\Pi$), and the "orange and green arc band" emitters are relatively minor products for the NO_2 and N_2O reactions alike. Possible dark products are CaO($X\,^1\Sigma^+$, $^3\Sigma^+$, $a^3\Pi$, $b^3\Pi$) (26).

This paper concludes with an interpretation of the observed distributions in terms of two limiting points of view: adiabatic correlations (10) provide a classification of the observed channels into diabatic and adiabatic, as well as an appreciation of the high degree of departure of the present reactions from simple expectations based on the Born–Oppenheimer approximation (the conservation of spin and symmetry). An opposite, statistical viewpoint is taken in an information theoretical analysis. Given the failure of state correlations in providing a reliable predictive tool, one may ask whether and to what extent dynamics matters at all. Again we find substantial departures from prior expectation and conspicuously non-linear surprisal plots, indicating electronic energy partitioning that cannot be explained by presently available simplified models.

The experiments

Standard metastable metal chemiluminescence measurements (7, 8) were modified to obtain lifetime-separated spectral information. To this end two types of detection geometry were employed: the first type (mode V) saw only those short-lived emitters radiating directly from the collision zone. The second type (mode H) viewed a bigger detection volume that includes those long-lived products that had drifted

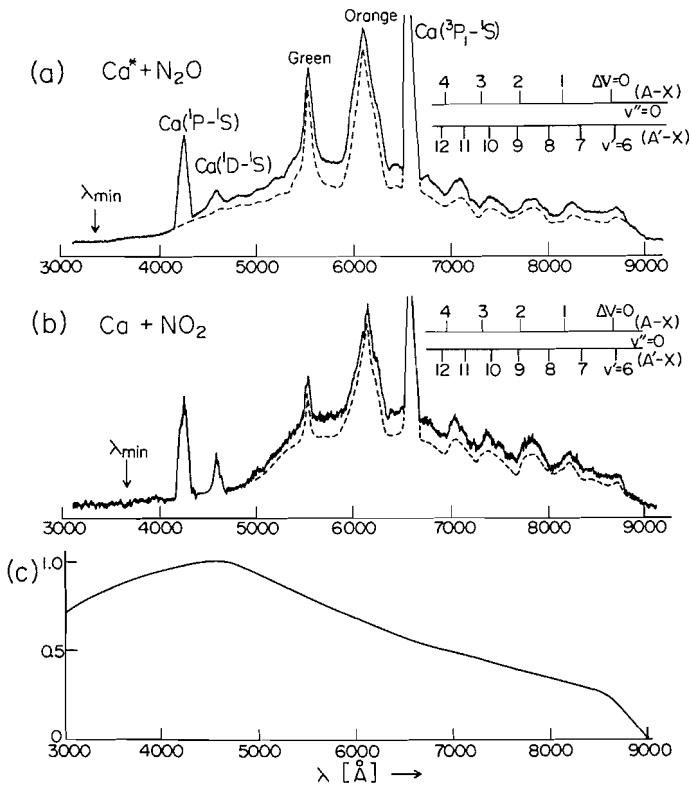

FIG. 1. Chemiluminescence spectra $S(\lambda)$ for (a) Ca* + N_2O and (b) Ca* + NO_2. The solid line S_H represents measurements in the H-mode and the dashed line in the V-mode. Both are normalized to equal arc band intensity. (c) Spectral response $D(\lambda)$ of the detection system.

out of the collision volume prior to radiative decay.

A metastable $Ca(^3P,^1D)$ beam, generated by a low-voltage discharge at the exit orifice of an effusive beam oven (8, 12) was, after deflection of charged particles, shot into a 4 × 4 × 6 cm scattering chamber. The latter was blackened with soot and carried a Wood's horn at the beam-exit orifice for reducing stray light from the discharge. The pressure in the scattering chamber was directly measured by a capacitance manometer (MKS Baratron 77H3) connected to the chamber by a 25 cm long, 2 cm diameter tube. The pressure dependence of the metastable decay lines $Ca(^3P_1-{}^1S_0$, $^1D_2-{}^1S_0)$ and of the chemiluminescence were monitored by a 30 cm monochromator and an RCA C31034 multiplier, and analyzed as described below (7, 8). The wavelength response $D(\lambda)$ of the detector (Fig. 1c) was obtained with a standard tungsten lamp. The observation zone was confined by a mask on the scattering chamber window to a horizontal slit (mask: 0.36 cm high, 3 cm wide; both the mask and the viewing direction are at right angles to the metal beam), located at a distance $l = 2.2 \pm 0.18$ cm (the scattering path length) downstream from the (0.25 cm diameter) beam entrance orifice. Two quartz lenses (overall magnification $M = 0.51$) sharply focussed the reaction zone onto the 2.0 × 0.2 cm monochromator slit.

The monochromator was operated with its slit either vertical (normal, mode V) or horizontal (mode H). In mode V the detection volume was 0.36 × 0.4 cm, formed by the intersection of the horizontal mask with the vertical slit. Short-lived emitters are seen preferentially in this mode. In mode H the 0.36 × 3.0 cm detection volume coexistent with the horizontal mask contained those long-lived emitters (with radiative lifetime $\tau_R = 10^{-5}-10^{-6}$ s) that had drifted out of the metal beam prior to their decay and also the elastically scattered metastable atoms.

From the fluorescence spectra of the pure metal beam and the known radiative lifetimes $\tau_R(Ca^3P) = 5.0 \pm 0.4 \times 10^{-4}$ s (13, 14) and $\tau_R(Ca^1D_2) = 2.3 \pm 0.5 \times 10^{-3}$ s (14), the $^1D/^3P$ density ratio was found (14b) to be 0.03 ± 0.005 under typical discharge conditions.

Results and discussion

1. Chemiluminescence spectra and assignment

Chemiluminescence overview spectra $S(\lambda)$ are presented in Fig. 1a, b for Ca* + N_2O and NO_2, respectively. Their independence from pressure ($p < 1.4$ mTorr) indicates that single collision conditions prevail. Measurements with vertical and horizontal monochromator slits (V- and H-modes) are represented by dotted and full curves, respectively. They are normalized to equal arc band intensity since the short-lived arc band emitters ($\tau_R = 42 \pm 2$ and 33 ± 3 ns for the green and orange systems) (8) are considered a measure of the rate of formation of nascent products.

Both systems yield qualitatively similar spectra in either of the (H, V) detection modes. Superimposed on a broad quasi-continuum extending from 3250 Å and 3650 Å for N_2O and NO_2 respectively to the detection limit at 9000 Å, one discerns the atomic lines $Ca(^1P_1-{}^1S_0)$ at 4228 Å, $(^1D_1-{}^1S_0)$ at 4577 Å, and $(^3P_1-{}^1S_0)$ at 6575 Å; the following clearly structured molecular band systems: the green and the orange "arc band" systems at 5440−5670 Å and 5913−6345 Å, respectively (32); and to the red side of the orange band where one expects the $CaO(A'^1\Pi-X^1\Sigma^+)$ and $(A^1\Sigma^+-X^1\Sigma^+)$ emission to occur, a series of bands peaking at 6040, 6450, 6900, 7400, 7780, 8220, and 8720 Å. Since the detector cuts off at 9000 Å (see Fig. 1c), the emission continues most likely into the infrared, as discussed below. None of the latter bands could be unambiguously assigned to the $A'-X$ and $A-X$ systems, respectively, due to their inherent complexity (overlapping sequences) and to low spectral resolution, but their relative contributions were determined by lifetime-separated spectroscopy.

The principal differences of the N_2O and NO_2 spectra are (*1*) the more rapid fall-off of the continuum in the less exothermic NO_2 reaction (short wavelength limits $\lambda_{min}(N_2O) = 3250$ Å and $\lambda_{min}(NO_2) = 3650$ Å, corresponding to the exothermicities $\Delta E(N_2O) = -429$ kJ/mol and $\Delta E(NO_2) = -292$ kJ/mol), (*2*) the decreased relative intensities of both arc bands in the NO_2 reaction, and (*3*) the decreased (green/orange) arc band ratio in the NO_2 system. The shapes and the intensities of the $A-X$ and $A'-X$ bands in the 6700−9000 Å range are surprisingly similar in both cases. The two detection modes have qualitatively similar effects in both systems: the continuum emission and the "red" bands are reduced by ca. 30% in the V-mode, relative to the H-mode. The loss of continuum and "red" band emitters from the V-mode detection volume due to drift constitutes proof of their long radiative lifetime. The $CaO(A'^1\Pi)$ state has both a suitably long radiative lifetime[2] $\tau_R = 10^{-5}$s and an assigned emission spectrum in the 5490−7520 Å range (unassigned bands at $\lambda > 4864$ Å) resembling closely our unresolved "continuum" emission (19). In agreement with Irvin *et al.* (8) we therefore ascribe this feature primarily to the $A'^1\Pi-X^1\Sigma^+$ band system although other contributors cannot be excluded. A similar analysis has led to the assignment of $BaO(A'^1\Pi-X^1\Sigma^+)$ as the primary emitter in the Ba + N_2O reaction (3a, 9).

To analyze more closely the V- and H-mode spectra (Fig. 1a, b), we have plotted the ratios of the normalized signals:

[2]The radiative lifetime $\tau(A'^1\Pi)$ was estimated analogously to $BaO(A'^1\Pi)$ in ref. 8.

[1] $R(\lambda) = S_V(\lambda)/S_H(\lambda)$

as a function of wavelength in Fig. 2*a*, *b*.

For N_2O (Fig. 2*a*), the constant and low value of $R = 0.7$ at $5200 < \lambda < 7200$ Å is taken as evidence for CaO($A'-X$) emission alone. The rise of R at either side of this range reflects the participation of shorter lifetime emitters. The CaO($B\,^1\Pi-X\,^1\Sigma^+$) system (20) appears as the most obvious, *known* source of the R-enhancement at $\lambda < 5200$ Å, since most higher states emitting to $X\,^1\Sigma^+$ in this region (see Table 4) are expected to be long-lived with respect to emission to $X\,^1\Sigma^+$ on the basis of spin and symmetry restrictions. The absence of an identifiable ($B-X$) structure is not surprising, considering the known (20*b*) complexity of the $B-X$ spectrum and the low resolution and population. The enhanced collection efficiency R in the $7250 < \lambda < 8200$ Å range is ascribed to the ($A\,^1\Sigma^+-X\,^1\Sigma^+$) band system (20). Quantitative estimates of the $B\,^1\Pi$ and $A\,^1\Sigma^+$ contributions are obtained by taking the areas above the $R = 0.7$ asymptote relative to the total area under the curve as the fractions of the $B\,^1\Pi$ and $A\,^1\Sigma^+$ states emitting in the corresponding spectral regions. The formation of the short-lived emitter of blue light which we assign here to CaO($B\,^1\Pi$) has escaped the attention of previous workers (8).

The NO_2 system (Fig. 2*b*) exhibits similar $R(\lambda)$ structure as N_2O: the flat portion occurs at $R = 0.75$, probably reflecting the lower exothermicity and lower recoil velocity of the emitter and hence its enhanced collection efficiency. The short wavelength feature in $R(\lambda)$ is much less pronounced than in N_2O, reflecting a lower $B\,^1\Pi$ population, while the $A\,^1\Sigma^+$ feature is of about equal integrated intensity.

2. *Chemiluminescence branching ratios*

Having assigned the $A'\,^1\Pi$, $A\,^1\Sigma^+$, $B\,^1\Pi$, "green and orange arc band" emitters, their relative populations are obtained from the wavelength-corrected spectra $S(\lambda)/D(\lambda)$ as the relative areas under the corresponding spectral features. The A and B state contributions were obtained as described above. These fractions for visible emission f_i^{vis} are listed in Tables 2 and 3 for

N_2O and NO_2, respectively.

To obtain the total CL emission one has to correct for the loss of the long-lived and rapidly recoiling $A'^1\Pi$ emitters from the observation zone, and for emission of $A'^1\Pi$ and $A^1\Sigma^+$ in the infrared $\lambda > 9000$ Å, beyond the detector cutoff. The former effect can be shown to be small (<10%), assuming a forward peaked angular distribution with 25% translational energy release, and a radiative lifetime of $\tau(A'^1\Pi) = 10^{-5}$ s (8, 18), particularly since losses from the observation zone are nearly balanced by a corresponding gain of emitters formed upstream.

The correction for emission in the infrared is obtained as follows. The fraction $F(v')$ emitted in the visible ($\lambda < 9000$ Å) from the vibrational level v' is taken to be the ratio of the Einstein emission coefficients

$$[2] \quad F^{vis}(v') = \sum_{v''=0}^{v''_{max}} q_{v',v''}\nu^3 \Big/ \sum_{v''=0}^{v''} q_{v',v''}\nu^3$$

where $q_{v',v''}$ is the Franck–Condon Factor, ν is the wavenumber of the v',v'' band origin, and v_{max}'' is the highest vibrational level of the $X^1\Sigma^+$ state for which emission still occurs below 9000 Å. Rotational broadening of the vibrational bands has been neglected. Franck–Condon factors for the $(A-X)$ and $(A'-X)$ band systems were kindly calculated for us by Telle (21) from literature spectroscopic constants (20) for $v',v'' < 50$. To assess the influence of molecular rotation on $F^{vis}(v')$, the FCF calculations were performed both for rotationless as well as for $J' = J'' = 75$ molecules. Although some *FCF*'s depend markedly on J', the total fractions F^{vis} (eq. [3]) are independent of J' within 1%.

The fraction of the total chemiluminescence in the visible F^{vis}, regardless of the upper vibrational state is

$$[3] \quad F^{vis} = \sum_{v'} F^{vis}(v')P(v')$$

where $P(v')$ is the (unknown) normalized vibrational distribution in the upper state. It is approximated by

$$[4] \quad F^{vis} = \sum_{v'} F^{vis}(v')/v_{max}'$$

assuming for simplicity a uniform vibrational distribution for both NO_2 and N_2O systems, and is proportional to the area under the $F^{vis}(v')$ curves, Fig. 3. According to this analysis,

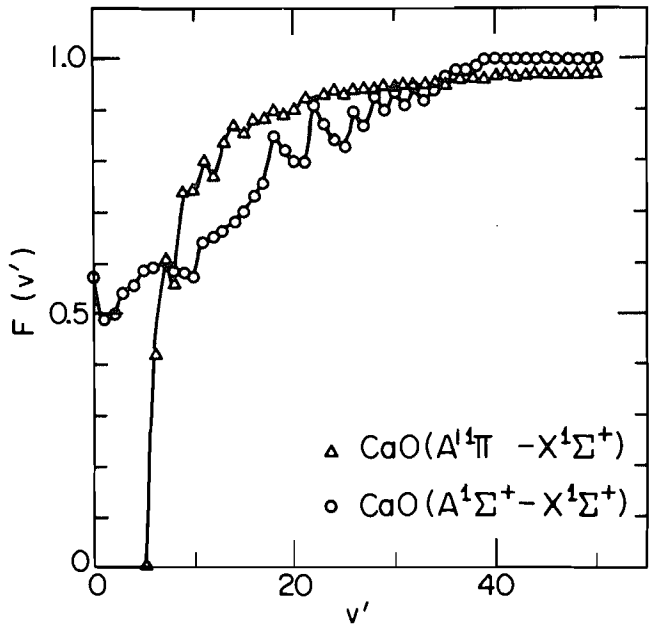

FIG. 3. Fractions $F^{vis}(v')$ of CaO($A\,^1\Sigma^+$) and ($A'\,^1\Pi$) that radiate in the part of the spectrum visible to the detector ($\lambda < 9000$ Å) as a function of vibrational state v' (eq. [2]). The areas under the curves are the total relative fractions F^{vis} emitting in the visible for a uniform distribution $P(v')$.

our experiments "see" only $F^{vis} = 79.7\%$ and 82.6% of the $A'-X$ and $A-X$ emission, respectively. The cross sections for total emitter production

$$[5] \quad \sigma_{CL}{}^{tot} = \sigma_{CL}{}^{vis}/F^{vis}$$

are summarized in Tables 2 and 3.

3. $Ca(^3P_J)$ and $Ca(^1D_J)$ attenuation cross sections σ_T

These were determined from Beer's law attenuation of the metastable emission signal as a function of scattering gas density (7, 8):

$$[6] \quad \ln (I_{Ca^*}) = \text{constant} - nl\,\sigma_T{}^{Ca^*}$$

via linear least square fits of the $\ln (I_{Ca^*})$ vs. n data. This yielded well reproducible results for $Ca(^3P_1)$, while the $Ca(^1D_1)$ results are of poorer quality, due to the much weaker $Ca(^1D_1)$ line and the relatively intense CL background (see Table 1).

The alternate chemiluminescence attenuation cross sections $\sigma^{CL}{}_T$, obtained from a linear plot of the CL signal (7*b*)

$$[7] \quad \ln (I_{CL}/n) = \text{constant} - nl\,\sigma_T{}^{CL}$$

against the scattering gas number density n is given in the second column. Its agreement with the metastable attenuation cross section $\sigma_T{}^{Ca^*}$ shows that the bulk of the chemiluminescence arises from the $Ca(^3P_1)$ state. For $Ca(^3P) + N_2O$, the first and second entries in Table 1 were taken with horizontal and vertical detector slits. The increased V-mode cross section with its higher angular resolution reflects a 22% contribution from elastic scattering. Hence the H-mode attenuation cross sections represent a more realistic upper limit of the total reaction cross section. In the N_2O reaction the attenuation cross sections for $Ca(^3P)$ and (^1D) are practically equal, while for NO_2 the (^1D) value is significantly higher. In the NO_2 reaction the agreement of $\sigma_T{}^{CL}$ with $\sigma_T{}^{Ca(^3P)}$ rather than with $\sigma_T{}^{Ca(^1D)}$ confirms $Ca(^3P)$ as the principal CL precursor. The high attenuation cross sections in the NO_2 system compared with N_2O are evidence for a long-range electron transfer as the rate determining step. Harpooning cross sections calculated for NO_2 are included in Table 1. Although they reproduce the general trend, they overestimate the experimental data, particularly for the (^1D) state. The failings of the simple harpoon model due to "reactive" electron affinities, diabatic effects, dynamical constraints, and lastly due to the fact that not all states that correlate with the metastable reactants do harpoon due to symmetry constraints, are well known (23). The Ca* + N_2O reaction is likewise thought to be initiated by an electron transfer, albeit at closer range than in the NO_2 case due to the negative electron affinity (15, 33) of the target molecule, as has been established elsewhere (15) for the Ba + N_2O system.

4. Absolute chemiluminescence cross sections σ_{CL} and quantum yields γ_{CL}

The theory and practice of absolute σ_{CL} measurements has been amply discussed (7, 8). We first present the cross section $\sigma_{CL}{}^{vis}$ for total CL production in the visible and compare them with published values (7). In applying the working formula (7)

$$[8] \quad I_{CL}/I_{Ca^3P} = \sigma_{CL}{}^{vis}\,\langle v\rangle\,\tau_R\,[n]/f_{J=1}$$

where $\langle v\rangle$ is the average relative velocity (15), τ_R the radiative lifetime of the ^3P state, $f_{J=1}$ the fraction in the emitting $^3P_1$ state, and $[n]$ the gas density. The measurement reduces to determining $[n]$ at the point where the ratio of the carefully normalized intensities is unity: $I_{CL}/I_{Ca^3P} = 1$. The results, given in Tables 2, 3 along with the corresponding quantum yields $Y_{CL} = 100(\sigma_{CL}/\sigma_T{}^{Ca^*})$, represent averages over five runs. It was implicitly assumed that all CL stems from Ca^3P and that the ^1D contribution was negligible. The N_2O cross section $\sigma_{CL}{}^{vis} = 4.75 \pm 0.45$ Å^2 agrees excellently with published data (8). The NO_2 cross section $\sigma_{CL}{}^{vis} = 9.11 \pm 1.2$ Å^2 is nearly twice this value, but due to the likewise enhanced σ_T, the NO_2 quantum yield is of the same order and slightly less than that for N_2O.

5. State-resolved (visible + ir) CL cross sections $\sigma_{CL}{}^{tot}$ (i)

These were obtained by partitioning the total visible $\sigma_{CL}{}^{vis}$ (Table 1) into the contributions from the individual emitters i, using the relative contributions f_i^{vis} to the visible spectra (Fig. 1, Tables 2, 3), and subsequently correcting the cross sections for ir emission from the $A'\,^1\Pi$ and $A\,^1\Sigma^+$ states by $(1/F^{vis})$. The resulting cross sections and quantum yields are summarized in Tables 2, 3. Compared to the data on the Ca* $+N_2O$ reaction reported elsewhere (8), the $B-X$ emission has been assigned tentatively and the total CL yield $Y_{CL}{}^{tot}$ is enhanced through the ir contribution.

6. Discussion

To interpret the results of Tables 2 and 3 we have at our disposal simple classification schemes such as spin- and symmetry-correlation rules (10) as well as statistical and information theoretical methods (11). The conceptual machinery of full dynamical calculations on more than one potential energy surface (24) is too complex to be of practical use, and there is little middle ground between these extremes. In using state correlation diagrams as devices for rationalizing the observed distributions and as a means for classifying processes, one searches for the point group of lowest symmetry which is statistically acceptable, and for an angular momentum coupling scheme that is appropriate to both reagents and products, for which adiabatic pathways in favour of the major products (24) exist. In the absence of such correlations, an observed channel

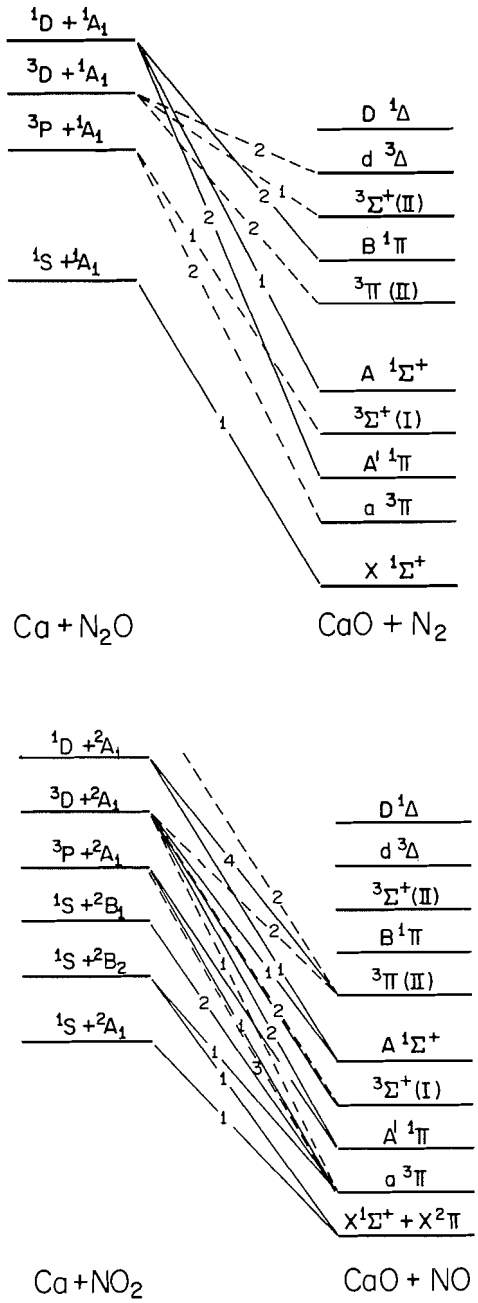

FIG. 4. Adiabatic state correlation diagrams in C_1 point group. Energies are not to scale. The numbers represent the degeneracies of the surfaces; top, Ca* + N_2O. Solid lines: singlet states, dashed lines: triplet states; bottom, Ca + NO_2. Solid lines: doublets, dashed lines: quartets.

is classified as diabatic. Furthermore, one expects correlation rules to provide some guidance regarding the distribution of the dark states (in our cases $X\,^1\Sigma^+$, $^3\Sigma^+$, and $a\,^3\Pi$) which account for the bulk (>90%) of the products.

The *adiabatic state correlation diagrams* shown in Figs. 4*a*, *b* are drawn for the point group C_1, assuming $L-S$ coupling. Going to C_s, C_{2v}, and $C_{\infty v}$ point groups does not change the following conclusions: in the *Ca* + N_2O system* there is no adiabatic pathway to the principal $A'\,^1\Pi$ product. Instead, the reactants correlate with the lowest $a\,^3\Pi$ and $^3\Sigma^+$ states (25). For this reason this reaction is a good candidate for the search for this $b\,^3\Pi^+$ state which has so far not been observed. In BaO it has been identified by laser-induced fluorescence (25). In the J-coupling representation (10), the intersection of the latter triplet surface correlating with CaO($^3\Sigma^+$) with the singlet surface connecting Ca(^3P) with CaO($A'\,^1\Pi$) provides an adiabatic avenue to the main product. Hence CaO($A'\,^1\Pi$) formation can be explained by a spin–orbit mechanism similar to the one responsible for the quenching of O(^1D) by N_2 via a long-lived complex and the multiple passage through the coupling region (27). While none of the minor products are adiabatically accessible from Ca(^3P), the $A'\,^1\Pi$, $A\,^1\Sigma^+$, and $B\,^1\Pi$ states correlate with the minor beam constituent Ca(^1D). Indeed the yields of A and B states are not inconsistent with ^1D as the parent. According to Irvin *et al.* (8), ^1D produces the arc band emitters ca. 10 times more efficiently than Ca(^3P), a reasonable finding if one considers the great number of surface-hops required for their formation from Ca(^3P).

An electron jump, albeit at closer range than in the NO_2 system, has been shown to be the initial rate determining step in the Ba(^1S) + N_2O reaction (15), and is thought to operate also in the present metastable Ca(^3P) + N_2O reaction. It is accompanied and facilitated by N_2O bending which lowers the energy of the accepting (10*a*) LUMO (15).

The *Ca + NO_2 correlation diagram* (Fig. 4*b*) is more complex than that for N_2O due to the radical character of both NO_2 and NO and the low lying NO_2 ($^2B_2$ and $^2B_1$) states. The reactants give rise to three doublet and quartet surfaces of which the former correlate adiabatically with the principal product CaO($A'\,^1\Pi$) and with CaO($a\,^3\Pi$). The statistical weights would favor the triplet over the singlet state 3:1. A long-range electron transfer (harpooning) in the entrance channel is a virtual certainty for the NO_2 reaction, considering the Ca(^3P) ionization potential (4.22 eV) and the NO_2 electron affinity (ca. 2.5 eV (22)). This is confirmed by the agreement of attenuation and calculated harpooning cross sections (Table 1).

In both reactions, the ion-pair intermediates appear to rearrange with equal ease into the principal $A'\,^1\Pi$ product, regardless of the absence (NO_2) or presence (N_2O) of spin restrictions. Arguments based on adiabatic correlations appear to be of little predictive value in these systems.

Formation of the high-lying (arc band and $B\,^1\Pi$) emitters can be understood by a mechanism which emphasizes the transitions between electron configurations, similar to that discussed by Brinkmann *et al.* (17, 29): For nearly coplanar (C_s) collisions in which the $p(a'')$ orbital of Ca*(^3P) is oriented perpendicular to the molecular plane, transfer of the electron from this orbital into the LUMO's of both NO_2 (a') and N_2O(a') (30, 31) is symmetry forbidden. Consequently the subjacent Ca($4s(a')$) electron is transferred, resulting in an excited ionic intermediate which eventually rearranges smoothly into products with Ca($4p\pi$)O($2p\sigma^1 2p\pi^4$) configuration, from which the $B\,^1\Pi$ state and the arc states derive (8, 16, 17, 26, 32). The decreased yield of arc state emitters in the NO_2 reaction relative to the N_2O system is consistent with the decreased probability of such coplanar collisions due to the non-linearity of the NO_2 molecule.

An information theoretic analysis has been performed as follows (11, 17). The surprisal I_i of product state i is

$$[9] \quad I_i = \ln (p_i{}^0/p_i)$$

in terms of the branching ratio $p_i = Y_{CL}(i)/100$. The prior branching ratio is normalized to unity

$$[10] \quad P_i{}^0 = g_i\rho_i(E_i')/\sum_j g_j\rho_j(E_j')$$

where g_j is the statistical weight (spin multiplicity times orbital

[a–i] See footnotes in Table 4.

degeneracy) of the product state j. It was calculated from the rigid rotor harmonic oscillator (RRHO) approximation of the diatomic product state densities (28):

$$[11] \quad \rho_j(E_j') = k\,\mu'^{3/2}\,(\omega_{\gamma j}\omega_\delta B_{\gamma j};\, B_\delta)^{-1}(E_i')^{4.5}$$

Here k is a collection of constants, μ' is the product reduced mass, ω and B are the vibrational and rotational constants of the products $\gamma = CaO(j)$, and $\delta = N_2$, NO, and E_j' is the total energy excluding the electronic excitation of product j. Although this simplest form of the prior disregards the cutoff angular momentum for complex formation, and treats all degrees of freedom classically, it is known to agree quite well with more detailed treatments (11*b*, 30). For non-reactive (elastic and electronic quenching) scattering the atom-triatom state density is

$$[12] \quad \rho_j(E_j') = k\mu'^{3/2}A(E_j')^n$$

where $n = 5$ and 5.5 for non-linear (NO_2) and linear (N_2O) reactants, respectively, and $A^{-1} = (\omega_1\omega_2\omega_3(A_0B_0C_0)^{1/2})$ for nonlinear and $A^{-1} = B(\omega_1\omega_2^2\omega_3)$ for linear (N_2O) reactants. The ω_1, ω_2, ω_3 are vibrational constants (10). The translational−vibrational−rotational product energies E_j' are given by energy conservation

$$[13] \quad E_j' = E_{trans} + E_{v,J} + \Delta D_0 + E_{el}(Ca^*) - E_{el}'(CaO(j))$$

The reactant energies E_{trans} and $E_{v,J}$ are thermal averages appropriate to the experimental conditions (15), dissociation energies were taken from Irvin *et al.* (8) and from standard tables (20*a*), and the electronic term energies of CaO were the observed (20*a*) and *ab initio* calculated (26) values for observed and hitherto unobserved states respectively.

Since the dark state distribution is unknown, we computed the surprisals for the two assumptions of exclusive $X^1\Sigma^+$ and of exclusive $a^3\Pi$ formation. The results for both reactions are summarized in Tables 4, 5. They include also the energetics of the elastic and electronic quenching channels, for which experimental data are however lacking.

In neither of the two reactions do the branching ratios decrease monotonically with excitation energy, suggesting already qualitatively some measure of non-statistical behaviour. While the primary products (dark products and $A'^1\Pi$) are formed mainly from $Ca(^3P)$, since the reaction probability P_i calculated for ^1D exclusively would exceed unity for these products, there is some ambiguity regarding the precursor of the minor products. Surprisals were therefore calculated under the assumptions that they are formed from either reactant state. The surprisals are all non-zero, non-linear, and erratic, indicating definite dynamical bias.

In the $Ca(^3P) + NO_2$ case the high energy channels comprising the $B^1\Pi$ and arc states are energetically inaccessible: hence $Ca(^1D)$ is necessarily their precursor. A similar conclusion has been reached by Irvin *et al.* (8) for the $Ca + N_2O$ system, where the corresponding ($Ca(^3P) + N_2O \rightarrow$ arc state) reaction, in spite of being energetically feasible, appears to be dynamically disfavoured relative to the $Ca(^1D)$ reaction. This finding is in agreement with the correlation diagrams, Figs. 4*a*, *b*, which demonstrate that the diabatic formation of arc states from $Ca(^1D)$ requires fewer surface-hops than if $Ca(^3P)$ were the reactant.

In both reactions, the principal CL channel $A'^1\Pi$ is characterized by relatively low surprisal. Phase space theory serves as a reasonable first approximation to their dynamics. The $A^1\Sigma^+$ channels, on the other hand, exhibit substantial surprisals (underpopulation) if $Ca(^3P)$ is assumed to be the reactant, but a nearly statistical population if $Ca(^1D)$ is the precursor. In the N_2O reaction the surprisal of the high energy channels, particularly those of the $B^1\Pi$ and "orange arc states" are moderate but non-negligible. The surprisals of the corresponding states in the NO_2 reaction are very substantial and correspond to overpopulations from 90 (for $B^1\Pi$) to 757 (for the "orange arc state").

Conclusion

Some comments are in order regarding the information theoretical analysis. The surprisals are erratic albeit small and within the accuracy of the analysis non-linear in the state energy E_i'. This is in contrast to what has become an established amenity in many examples of reactive and non-reactive vibrational and rotational energy disposal (11). Monotonic (e.g. linear) surprisal plots are prevalent in systems where the product levels form a smooth sequence of hierarchically equivalent states: in vibrational disposal, for instance, there is no qual-

itative difference between the formation of products in states v' and in $v' + 1$.

In contrast, the present systems as well as the better documented Mg, Ca(^3P) + X_2 reactions (34) are characterized by conspicuously non-monotonic surprisals, which probably reflect the specific nature of the electronic transitions between pairs of potential energy surfaces that are generally localized in different regions of configuration space. This and the coupling mechanisms and strengths that may differ greatly between pairs of surfaces due to symmetry, spin, energy, and geometric restrictions, lend a high degree of individuality to each transition. Indeed, it is puzzling that these reactions exhibit as little surprisal as they do: product phase space considerations seem to take care of the bulk of electronic energy disposal. A well documented and even more striking example for this behaviour are the well-known reactions between alkali dimers and halogen atoms, the source of luminescence in alkali diffusion flames (35). They have yielded a puzzlingly statistical product M*-state distribution.

Is statistics then all, or most of what there is to electronic energy disposal? The results of the present study and previous ones (34) show clearly that this is not the case. Yet it is the tendency toward statisticity which has prevented specific energy disposal and electronic inversions from occurring in the great number of chemiluminescent reactions that have been studied during the past decade (36) in the course of searches for electronic transition lasers (18).

Received April 14, 1983

JOHN E. DRAKE, ANKIN VAHRADIAN, and BORIS M. GLAVINCEVSKI. Can. J. Chem. **61**, 2712 (1983).

Symmetrically substituted 1,3-divinyltetramethyldisilyl chalcogenides $(CH_2{=}CHSiMe_2)_2E$, where E = O, S, Se, and Te have been prepared and characterized by their ir, Raman, ^1H and ^{13}C nmr spectra. Reactions of the sulfide and selenide with anhydrous H_2S and H_2Se, respectively, are discussed.

JOHN E. DRAKE, ANKIN VAHRADIAN et BORIS M. GLAVINCEVSKI. Can. J. Chem. **61**, 2712 (1983).

On a préparé des divinyl-1,3 tétraméthyldiselylchalcogénures $(CH_2{=}CHSiMe_2)_2$ E, où E = O, S, Se et Te, et on les a caractérisé à partir de leurs spectres ir, Raman et de rmn du ^1H et du ^{13}C. On discute des réactions respectives du sulfure et du séléniure avec le H_2S et le H_2Se anhydres.

[Traduit par le journal]

Introduction

The effect of substituents on the spectroscopic features and structure–reactivity relationships of silyl species has been a concern for many years, particularly the substituent effects of halogens, chalcogens, hydrogen, phenyl and methyl groups (1). However, the effect of the vinyl group on the ^1H, ^{13}C, and ^{29}Si nmr (2–8, 13), vibrational (9–11), photoelectron (12, 13), and mass (13–15) spectra of various silyl compounds has been the subject of much discussion. We report on the synthesis and characterization of some new 1,3-divinyltetramethyldisilyl chalcogenides, $(CH_2{=}CHSiMe_2)_2E$ where E = O, S, Se, and Te and draw comparisons with the related species $(Me_nH_{3-n}Si)_2E$ (16, 17).

Experimental

All preparative manipulations were conducted using a conventional high-vacuum system fitted with greaseless stopcocks. The allied spectroscopic techniques were as described previously (16, 17). Details of the preparation of Li_2E (E = S, Se, Te) have been given elsewhere (18). Hydrogen sulfide and selenide were obtained by hydrolysis of the respective Al_2E_3 (19) and were dried by passing through $CaCl_2$ and P_4O_{10}. Peroxide-free diethyl ether was distilled in a vacuum system from fresh $Li[AlH_4]$ and stored *in vacuo*. Chlorovinyldimethylsilane was obtained commercially (Petrarch Systems) and the purity was confirmed by its ir/Raman (20) and nmr (6) spectra. The new compounds, $(CH_2{=}CHSiMe_2)_2E$, were synthesised in essentially the same manner as in the published procedures (16) for related compounds.

Reactions of 1,3-divinyltetramethyldisilyl chalcogenides with hydrogen halides

Typically, $(CH_2{=}CHSiMe_2)_2S$ (0.16 mmol), anhydrous HCl (0.38 mmol), and traces of TMS were condensed into a semi-micro nmr tube which was then sealed and allowed to warm to room temperature. After ca. 30 min the ^1H nmr spectrum showed the resonances expected for $CH_2{=}CHSiMe_2Cl$ (6) and H_2S (δ(SH) 0.82 ppm).

Reactions of $(CH_2{=}CHSiMe_2)_2E$ with H_2E where E = S and Se

The sulfide, $(CH_2{=}CHSiMe_2)_2S$ (0.0306 g, 0.15 mmol), and an excess of anhydrous H_2S (0.5 mmol) were sealed in a semi-micro nmr tube with some TMS. The ^1H nmr spectrum of the reaction was recorded after 10 min and disclosed only the resonances of the starting materials $(CH_2{=}CHSiMe_2)_2S$ (δ(Me) 0.38 ppm and δ(H_2S) 0.82 ppm). After a longer reaction time (ca. 14 days) there was still essentially no change in the ^1H nmr spectrum.

In an analogous manner, the selenide $(CH_2{=}CHSiMe_2)_2Se$ (0.083 g, 0.39 mmol) and an excess of H_2Se (1.13 mmol) were sealed in a semi-micro nmr tube. The ^1H nmr spectrum of the reaction was recorded after 16 h and revealed resonances centred at ca. 2.68, ca. 1.50, ca. 1.29, ca. 0.48, ca. −0.83, and a very weak peak at ca. −2.82 ppm. assignable to $(HSeCH_2CH_2SiMe_2)_2Se$ and presumably traces of $HSeCH_2CH_2SiMe_2SeH$.

Results and discussion

Metathesis reactions between Group IV halides and dilithium salts have been demonstrated previously for the synthesis of a number of disilyl and digermyl chalcogenides (16, 18, 21). In this study the method was extended to the synthesis of otherwise inaccessible vinyl-containing species, i.e.

$$[1]\quad 2CH_2{=}CHSiMe_2Cl + Li_2E \xrightarrow{Et_2O} (CH_2{=}CHSiMe_2)_2E + 2LiCl \quad (E = S, Se, Te)$$

The yields are high (ca. 80–90%) and the only significant loss of material arose because of the susceptible nature of the Si—Cl and Si—E bond to hydrolysis. The formation of disilazane $(CH_2{=}CHSiMe_2)_2NH$ was often observed in cases where the dilithium salt contained ammonia, $Li_2E \cdot nNH_3$. The use of a slight excess of chalcogen and removal of the solvated ammonia from Li_2E resulted in complete conversion of the chloride into the corresponding Si—E species. The oxide, $(CH_2{=}CHSiMe_2)_2O$, was readily obtained by the hydrolysis of the chloride. The other Si—E (E = S, Se, Te) species are all unstable to air and moisture. With the exception of the siloxane linkage Si—O—Si, these bonds are readily cleaved by HCl with formation of $CH_2{=}CHSiMe_2Cl$ and the corresponding H_2E, i.e.

$$[2]\quad (CH_2{=}CHSiMe_2)_2Se + 2HCl \rightarrow 2CH_2{=}CHSiMe_2Cl + H_2Se$$

TABLE 1. Chemical shifts and coupling constants of $(CH_2{=}CHSiMe_2)_2E$ species

	$(CH_2{=}CHSiMe_2)_2E$				
E	$^1H\delta$(Me)	$^{13}C\delta$(Me)	$^{13}C\delta(CH_2)$	$^{13}C\delta$(CH)	$\lvert J_{^{13}CH}\rvert$ (Me)
O	0.12	−0.44	130.85	138.83	118.0
S	0.36	2.28	131.92	139.09	119.6
Se	0.45	2.67	132.12	139.16	120.7
Te	0.60	3.58	132.14	139.35	121.5

Analogous reactions with H_2Se gave addition across the double bond with anti-Markownikoff orientation, i.e.

[3] $(CH_2{=}CHSiMe_2)_2Se + H_2Se$ (excess)
$\rightarrow (HSeCH_2CH_2SiMe_2)_2Se$

The reaction of the sulfide, $(CH_2{=}CHSiMe_2)_2S$, with hydrogen sulfide did not lead to the addition of H_2S to the vinyl group or cleavage of the Si—S—Si linkage. These reactions demonstrate the resistance of the Si—E—Si linkage (where E = S, Se, Te) to attack in these compounds in contrast to the species $(H_{n-3}SiMe_n)_2E$ (16).

(i) The ^1H and ^{13}C nmr spectra

The observed methyl proton and carbon-13 parameters are given in Table 1. The values of the proton chemical shifts of the methyl group $^1H\delta$(Me) fall generally between the values of those obtained for $(HSiMe_2)_2E$ and $(SiMe_3)_2E$ (16).

The largest deviation in the magnitude of $^1H\delta$(Me) is shown between the selenides ($(CH_2{=}CHSiMe_2)_2Se$ (0.45 ppm) and $(HSiMe_2)_2Se$ (0.51 ppm)) and oxides ($(CH_2{=}CHSiMe_2)_2O$ (0.12 ppm) and $(SiMe_3)_2O$ (0.06 ppm)) with chemical shift differences of 0.06 ppm. While the shift of $^1H\delta$(Me) values from 0.06 → 0.12 → 0.14 ppm in the series

$$(SiMe_3)_2O \rightarrow (CH_2{=}CHSiMe_2)_2O \rightarrow (HSiMe_2)_2O$$

implies weakening of the oxygen–silicon ($p \rightarrow d$) π bonding, the magnitude of $^1H\delta$(Me) values for the selenides

$$(SiMe_3)_2Se\ (0.42) \rightarrow (CH_2{=}CHSiMe_2)_2Se\ (0.45) \rightarrow (HSiMe_2)_2Se\ (0.51)\ \text{ppm}$$

suggest that the vinyl group has a similar effect as does a methyl group even though the electro-negativity of the vinyl group has been inferred to be comparable to that of a hydridic hydrogen atom (22). However, the effect of the introduction of the vinyl group on the carbon-13 chemical shifts is large, so that the trend of shielding parallels only that of $(SiMe_3)_2E$ (17). The magnitude of the values indicates that the methyl carbons in the vinyl-containing species are more shielded and the shielding increases as it does for the protons in the series

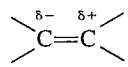
$$Te(3.58) \rightarrow Se(2.67) \rightarrow S(2.28) \rightarrow O(-0.44)\ \text{ppm}$$

Apparently, there is a linear relationship between the ^{13}C and ^1H chemical shifts which suggests that similar factors are responsible for the observed trends.

The carbon-13 resonances of the sp^2 carbons appear considerably down-field relative to those of the sp^3 carbon. The shielding of the sp^3 carbons is much more sensitive to substituent changes than the sp^2 carbons. Thus as the chalcogen changes from oxygen to tellurium there is a slight successive down-field shift in the ^{13}C (sp^2) resonances matching a larger similar shift in the sp^3 resonances. The effect of chalcogen change is markedly attenuated on $\delta^{13}C(sp^2)$ such that the values of $\delta(C_\beta)$ and $\delta(C_\alpha)$ are relatively small between the selenide and telluride (Δ = 0.02 ppm), and the sulfide and selenide (0.07 ppm), respectively. In contrast to the successive down-field shift of the $^{13}C(sp^2)$ resonances from oxygen to tellurium, the internal chemical shift $\Delta = \delta(C_\alpha) - \delta(C_\beta)$ increases from

$$Se\ (7.04) \rightarrow S\ (7.17) \rightarrow Te\ (7.21) \rightarrow O\ (7.98)\ \text{ppm}$$

It has been suggested (23) that the internal chemical shift is a measure of a double bond polarization



and if other effects remain constant, increased polarization should increase the Δ value. Nevertheless, the deshielding or the chemical shift of the C_β is presumably controlled by the π-electron density and that of the C_α by σ-electron density, though other effects may also contribute.

The trends in the values of the ^{13}CH coupling constants parallel those for $^1H\delta$(Me), in that they fall between those for $(SiMe_3)_2E$ and $(HSiMe_2)_2E$ (16). The effect of the chalcogen is substantial and leads to an increase in the ^{13}CH coupling constants along the series

$$O(118.0) \rightarrow S(119.6) \rightarrow Se(120.7) \rightarrow Te(121.5)\ \text{Hz}$$

This increase suggests that the *s*-hypothesis (the Fermi contract term) might not dominate the coupling mechanism between carbon and hydrogen.

(ii) Vibrational spectra

The assignment of spectral features (Table 2) is based on comparisons within the $(CH_2{=}CHSiMe_2)_2E$ series (E = O → S → Se → Te) and on the spectra of the known species $(CH_2{=}CHSiMe_2)_2O$ (24), $CH_2{=}CHSiMe_2Cl$ (11), $(CH_2{=}CH)_4Si$ and $(CH_2{=}CH)SiH_3$ (9, 10). The three Raman bands at ca. 3053 ($\nu_a(CH_2)$), ca. 3008 (ν(CH)), and ca. 2969 cm^{-1} ($\nu_s(CH_2)$) with corresponding ir absorptions can be assigned to the vinyl CH and CH_2 stretches. Except for the oxide, the $\nu_s(CH_2)$ stretching frequency is indistinguishable from the $\nu_a(CH_3)$ mode. The latter mode is observed as a very strong polarized band at ca. 2902 cm^{-1} with a weak ir counterpart. The C=C stretching vibration gives rise to the band at ca. 1592 cm^{-1}.

The CH_2 scissors and δ(CH) vibrations are obscured by $\delta_a(CH_3)$ at 1404 cm^{-1} and the ν(Si—O) mode at 510 cm^{-1}, respectively. The $\delta(CH_2)$ vibration is assigned at somewhat higher frequency at ca. 1440 cm^{-1} as a very weak absorption. The remaining bands appearing at ca. 1264, 1000, 947, and 1242 cm^{-1} are assigned to ρ(CH), δ_{tw}(CH), $\delta_{wag}(CH_2)$, and $\delta_s(CH_3)$ in agreement with previous reports (9, 11, 12, 25), as are the C_3Si skeletal vibrations between ca. 787 and ca. 574 cm^{-1}. The Si—E—Si stretching vibrations at 1049 and 542 (O), 448 (S), 398 (Se), and 297 cm^{-1} (Te) are the most characteristic of the new chalcogenides. The large splitting between the asymmetric and symmetric mode for the oxide is as expected for a Si—O—Si angle greater than 120°, whereas the negligible splitting for the other species is as expected if the Si—E—Si angles are close to 90°. The marked decrease in the values of (Si—E) are greater than that expected purely on the

basis of the increasing reduced mass. Similar trends of decreasing Si—E stretching frequencies have been observed in related silyl species (16). The remaining vibrational degrees of freedom involve only the deformations of the

C=C—Si—E—Si—C=C

skeletal frame and they appear in the low-frequency region. The frequency of the Si—E—Si deformations decreases as expected, but less rapidly than the frequency of the skeletal stretching.

The force constants (26) of the Si—E bonds were calculated by making the naive assumption that in the 1,3-divinyltetramethyldisilyl chalcogenides the Si—E bond can be treated as a diatomic molecule, the average values of the ν_a(Si—E) and ν_s(Si—E) stretches were taken as the stretching vibrations of the assumed diatomics. The Si—E bond "force constants" so calculated give the values 3.8, 1.9, and 1.2×10^5 dyn/cm^{-1} for Si—O, Si—S, Si—Se, and Si—Te, respectively. Despite the exaggerated approximation these values disclose the expected trend where the force constant of Si—O is very much greater than that of the other Si–chalcogen bonds, which suggests a much greater rigidity for the Si—O bond. This is, of course, in keeping with the general stability of compounds containing Si—O bonds where a degree of Si—O π-bonding has been invoked. Given the gross approximation, the calculated values still suggest a bond of similar rigidity in the case of Si—S and Si—Se but a weaker one for Si—Te.

The reactions of $O(^3P)$ with the butanols

JOHN M. ROSCOE
Department of Chemistry, Acadia University, Wolfville, N.S., Canada B0P 1X0

Received April 26, 1983

JOHN M. ROSCOE. Can. J. Chem. **61**, 2716 (1983).

The reactions of $O(^3P)$ with the butanols were studied kinetically as a function of temperature and substrate concentration. The absolute rate constants for the gas phase reactions, in the units M^{-1} s^{-1}, obey the following relations.

O + 1-butanol: $\ln k = 24.12 \pm 0.16 - (1.78 \pm 0.19) \times 10^3/T$
O + 2-butanol: $\ln k = 22.22 \pm 0.16 - (1.19 \pm 0.19) \times 10^3/T$
O + 2-methyl-1-propranol: $\ln k = 22.02 \pm 0.13 - (1.10 \pm 0.15) \times 10^3/T$
O + 2-methyl-2-propranol: $\ln k = 22.33 \pm 0.20 - (2.19 \pm 0.27) \times 10^3/T$

The results suggest that although the α-CH bond in these alcohols is the most reactive one, reaction of $O(^3P)$ with other CH bonds in the alcohols is also appreciable. The kinetic data for these and other alcohols are separated into contributions from the different types of CH bonds and the results are discussed in terms of linear free energy relations.

JOHN M. ROSCOE. Can. J. Chem. **61**, 2716 (1983).

On a étudié la cinétique en fonction de la température et de la concentration de substrat, des réactions de $O(^3P)$ avec les butanols. Les constantes absolues de vitesse des réactions en phase gazeuse ayant pour unités M^{-1} s^{-1} obéissent aux relations suivantes:

O + butanol-1: $\ln k = 24.12 \pm 0.16 - (1.78 \pm 0.19) \times 10^3/T$
O + butanol-2: $\ln k = 22.22 \pm 0.16 - (1.19 \pm 0.19) \times 10^3/T$
O + methyl-2 propanol-1: $\ln k = 22.02 \pm 0.13 - (1.10 \pm 0.15) \times 10^3/T$
O + methyl-2 propanol-2: $\ln k = 22.33 \pm 0.20 - (2.19 \pm 0.27) \times 10^3/T$

Ces résultats suggèrent qu'en dépit du fait que la liaison CH-α de ces alcools soit la plus réactive, $O(^3P)$ réagit avec les autres liaisons de façon appréciable. On a séparé les données cinétiques de ces alcools et celles relatives à d'autres alcools en des contributions provenant de différents types de liaison CH et on discute des résultats en fonction des relations linéaires d'énergie libre.

Introduction

The general features of the reactions of $O(^3P)$ with alcohols have been thoroughly documented (1–4). The primary reaction path is thought to be abstraction of the hydrogen atom α- to the OH, although the reactivity of other CH bonds in the alcohols does not seem to have been evaluated directly. The overall reaction is generally discussed in terms of the following general mechanism under conditions of large excess of the alcohol.

[1] $O + R{-}\underset{\displaystyle R'}{\underset{|}{C}}HOH \rightarrow R{-}\underset{\displaystyle R'}{\underset{|}{C}}OH + OH$ (R and R′ = H or alkyl)

[2] $OH + R{-}\underset{\displaystyle R}{\underset{|}{C}}HOH \rightarrow R{-}\underset{\displaystyle R'}{\underset{|}{C}}OH + H_2O$

[3] $2R{-}\underset{\displaystyle R'}{\underset{|}{C}}OH \rightarrow R{-}\overset{\displaystyle OH}{\overset{|}{\underset{\displaystyle R'}{\underset{|}{C}}}}{-}\overset{\displaystyle OH}{\overset{|}{\underset{\displaystyle R'}{\underset{|}{C}}}}{-}R$

[4] $2R{-}\underset{\displaystyle R'}{\underset{|}{C}}OH \rightarrow R{-}\underset{\displaystyle R'}{\underset{|}{C}}HOH + RC\overset{\displaystyle O}{\overset{\|}{}}R'$

When $O(^3P)$ is in excess, or when the alcohol is not in sufficient excess, reactions [2] to [4] become less important and one must include reactions such as (4, 5)

[5] $O + OH \rightarrow O_2 + H$

[6] $O + R{-}\underset{\displaystyle R'}{\underset{|}{C}}OH \rightarrow RC\overset{\displaystyle O}{\overset{\|}{}}{-}R' + OH$

The reactions of $O(^3P)$ with the butanols were studied for several reasons. 2-Methyl-2-propanol is the simplest alcohol lacking α-CH bonds. Its reactivity toward $O(^3P)$ would indicate whether corrections should be applied in the reactions of $O(^3P)$ with other alcohols to compensate for the reactivity of CH bonds that are not α- to OH. The other butanols include two primary alcohols, one of which is branched, as well as a secondary alcohol. Kinetic data for their reactions with $O(^3P)$ might be combined with other work in the literature to assess correlations of reactivity with structure. This might be useful in predicting the reactivity of other alcohols with $O(^3P)$.

Experimental

The experimental methods and apparatus used in this work have been described in detail elsewhere (4, 6). The reactions were studied in a conventional flow system at pressures from 0.7 to 1.2 Torr. Oxygen atoms were formed by titrating $N(^4S)$ atoms with NO in order to prevent interference from O_2 (4, 5). $N(^4S)$ was produced by dissociating purified N_2 with a microwave discharge. The concentration of $O(^3P)$ produced in this way was kept small by passing only a small part of the total nitrogen flow through the discharge, the remainder of the nitrogen mixing with the products of the discharge upstream from the NO inlet. This arrangement made it possible to achieve as much as 500-fold excess of alcohol, thereby avoiding interference from the

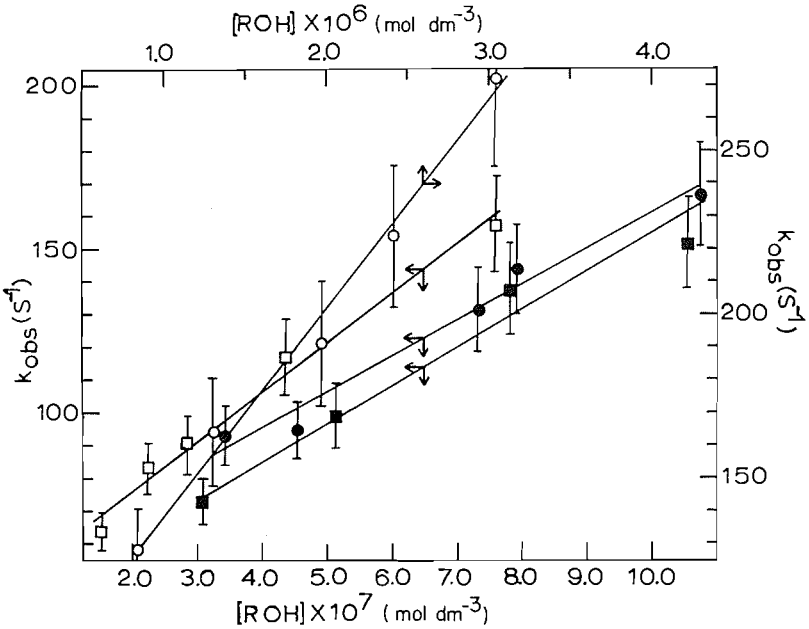

FIG. 1. Dependence of pseudo first order rate constant on alcohol concentration ○, O + 2-methyl-2-propanol, 461 K; □, O + 1-butanol, 320 K; ●, O + 2-methyl-1-propanol, 357 K; ■, O + 2-butanol, 303 K.

secondary reactions of $O(^3P)$ referred to in the Introduction. The concentration of $O(^3P)$ was determined by measuring the intensity of the emission from electronically excited NO_2 produced by adding a small amount of NO in excess of that required to completely consume the $N(^4S)$. The rate constants obtained in this way were independent of the amount of excess NO used.

The alcohols (Fisher, Certified) were purified by repeated fractional distillation until no impurities could be detected by gas chromatography. Their purity was estimated on this basis to be better than 99.999%. Gas chromatographic analysis of both starting materials and reaction products was done on an 8-foot column packed with Porapak Q, using a F and M model 700 gas chromatograph equipped with both a flame ionization detector and a thermal conductivity detector. The former detector was used for analysis of starting materials while the latter was used for analysis of reaction products because of the need to detect water. The reaction products were trapped at liquid nitrogen temperature, warmed to room temperature, and then removed from the flow system for injection into the gas chromatograph. Because of the large excess of alcohol used in these experiments, the alcohol could be used as an internal standard for the determination of other products.

The method of data analysis differed somewhat from that used in earlier work (4, 6). This was necessary because of a complicating first order loss route for $O(^3P)$ which was independent of both the alcohol and NO concentrations, was insensitive to temperature, and was only observed after the alcohol had been admitted to the reaction vessel. It seems probable that this loss route represents a heterogeneous process due to efficient adsorption of a reactant or product on the walls of the reactor. As indicated in Fig. 1, this behaviour is adequately represented by

$$[7] \quad k_{obs} = k_0 + k_R[ROH]$$

At each temperature, first order rate constants (k_{obs}) were plotted as in Fig. 1 to yield a straight line whose slope was k_R at that temperature. It is assumed that k_R is the rate constant for the homogeneous reaction between $O(^3P)$ and the alcohol and that k_0 refers to the extraneous first order loss route for $O(^3P)$. Both the first order rate constants (k_{obs}) and the Arrhenius parameters obtained from them were calculated by weighted least squares with weights $y^2/\sigma^2(y)$ where $y = k_R$ in the Arrhenius expression and $y = O(^3P)$ signal in the pseudo first order analysis of $O(^3P)$ decay. Data for both the rate constant determinations and the Arrhenius expressions were within two standard deviations of the regression line.

Results and discussion[1]

Gas chromatographic analysis of the reaction products indicated that the yield of water was equivalent to the consumption of O atoms. This suggests that the mechanism outlined in the Introduction adequately describes the reactions of the primary and secondary butanols with $O(^3P)$ under our experimental conditions. The reaction of $O(^3P)$ with 2-methyl-2-propanol would then be described by reactions analogous to [1], [2], and [3] but involving β-CH bonds. This would be consistent with other work (1, 2, 4–6) and would mean that k_R is the absolute rate constant for reaction [1].

No products other than water could be detected by gas chromatography. This could result if the organic radical formed in reactions [1] and [2] underwent recombination in preference to disproportionation. The glycols that would be formed would be expected to adhere to the glass tubing between the reaction vessel and the cold trap and would be lost to analysis. Moreover, the chromatographic column used gives poor results for high molecular weight glycols. Similar behaviour was experienced in our earlier work with the propanols (6) in which pinacol was detected, but could not be quantified and the glycol produced by the reaction of $O(^3P)$ with 1-propanol could not be detected. This is also consistent with our experience that recombination products predominated over disproportionation products in the reactions of $O(^3P)$ with methanol and ethanol under similar experimental conditions (4). These results suggest that reaction [6] does not occur to any appreciable extent with the large alcohol/$O(^3P)$ ratios used in this work.

Pseudo first order loss of $O(^3P)$ was observed for alcohol/atom concentration ratios ranging from about 50 to nearly 500 and for temperatures ranging from 300 K to 600 K. The temperature dependence of the homogeneous rate constants for the reactions of $O(^3P)$ with the butanols is summarized in Table 1 and Fig. 2. As anticipated, the rate

[a]Several kinetic studies have given values which deviate markedly from the results tabulated here and from the predictions of correlations such as those of ref. 12. These values have been omitted from this table but may be found in refs. 13 to 16 inclusive.

[b]While the preexponential factors for these reactions are evidently too small and calculation of the components due to the α-CH bonds is not possible, these values are included because the activation energies correlate well with the other reactions.

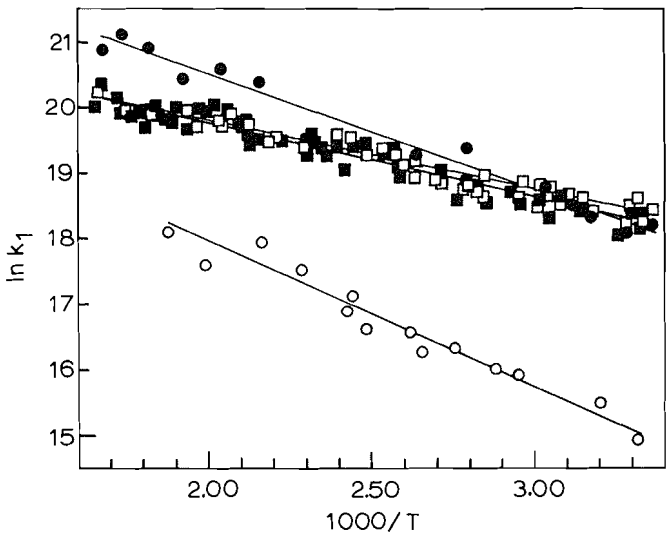

FIG. 2. Arrhenius plots for the reaction of O atoms with the butanols. Absolute uncertainty in ln k is 0.16. ○, O + 2-methyl-2-propanol; ●, O + 1-butanol; □, O + 2-methyl-1-propanol; ■, O + 2-butanol.

constants for the reaction of O atoms with 2-methyl-2-propanol were much smaller, at a given temperature, than those for the corresponding reactions of the other alcohols. This is primarily due to the relatively large activation energy for the reaction with 2-methyl-2-propanol and confirms the earlier suggestion (1−3, 6) that $O(^3P)$ reacts with alcohols primarily by abstracting the H atom α- to the OH group.

While good Arrhenius behaviour was observed for all the reactions studied, it is evident that abstraction of hydrogens that are not α- to OH can be a significant reaction path for $O(^3P)$. Moreover, the comparatively large activation energy for this path makes it increasingly important as the temperature increases. This situation may be described by

$$[8]\quad k = k_\alpha + k' = n_\alpha A_\alpha \exp(-\Delta E_\alpha/RT) + n'A' \exp(-\Delta E'/RT)$$

where n_α and n' are the number of CH bonds α- and not α- to OH, A_α and A' are the corresponding Arrhenius preexponential factors per CH bond, and ΔE_α and $\Delta E'$ are the activation energies characteristic of abstraction of the two kinds of hydrogen atom. Equation [8] could be further refined by writing the last term on the right as a sum of contributions by primary, secondary, and tertiary CH bonds that are not α- to OH. This approach has been applied to the reactions of $O(^3P)$ with alkanes (7), but the smaller activation energies for the reactions of $O(^3P)$ with the alcohols made this impractical. It has also been assumed that abstraction of the OH hydrogen is of negligible importance. While there is no direct proof that this is valid, it seems reasonable in view of the relatively small reactivity of CH bonds which are not α- to OH. It is also relevant that product analysis in reactions of $O(^3P)$ with alcohols has not detected products which could be unambiguously attributed to radicals formed by abstracting the OH hydrogen from the alcohol (1−3, 6).

If eq. [8] is to be applied to existing data, it is necessary to assume that all CH hydrogens not α- to OH have the same Arrhenius parameters and that these may be estimated from the data for the reaction of $O(^3P)$ with 2-methyl-2-propanol. This is likely to be an oversimplification since, by analogy with the reactions of $O(^3P)$ with the alkanes, the activation energy should decrease in the order primary CH > secondary CH > tertiary CH (7). However, since 2-methyl-2-propanol contains only primary CH hydrogens and the contribution per CH is small in our temperature range, this approximation will at worst underestimate the contribution of hydrogens not α- to OH. The availability of kinetic data for a more extensive range of tertiary alcohols would clearly improve the accuracy of this analysis, particularly at the high temperatures typical of combustion where such contributions would be substantial.

The Arrhenius parameters for abstraction of the α-hydrogen atoms, calculated from eq. [8], are given in Table 1. In making these calculations, the contribution of non-α CH bonds ($n'A' \exp(-\Delta E'/RT)$) was calculated from the data for 2-methyl-2-propanol and subtracted from the measured absolute rate constant for each set of experimental conditions. The resulting rate constants (k_α) were then fitted to the Arrhenius equation by y-weighted least squares as described in the Experimental section. The resulting slope and intercept gave values of $-\Delta E_\alpha$ and $n_\alpha A_\alpha$ in the usual way. Also found in Table 1 are Arrhenius

parameters for other alcohols as reported in the literature and the corresponding values of the parameters for abstraction of the α-CH hydrogens calculated as above. As with the lower alcohols, the preexponential factors are some 10 to 100 times smaller than those obtained for the reactions of $O(^3P)$ with the alkanes (3, 4, 7). However, no clear relation between the preexponential factor and molecular structure is evident other than a purely statistical dependence on the number of α-CH bonds. Our earlier results for the reactions of the propanols with $O(^3P)$ (6) give preexponential factors which are much too small in comparison with the results for the other alcohols. This problem was referred to in our earlier work although no explanation could be offered.

The activation energy for abstraction of the α-hydrogen by $O(^3P)$ also shows little variation among the alcohols. The value for ethanol seems smaller than for the other primary alcohols, but this may be accidental as a result of the limited temperature range used in that work and the relatively large uncertainty reported for the activation energy. The activation energies for the reactions of $O(^3P)$ with 2-propanol and 2-butanol are similar and are smaller than the values obtained with the primary alcohols, as might be expected due to the somewhat weakened α-CH bond in the secondary alcohols.

It is useful to compare the activation energies for the reactions of $O(^3P)$ with alcohols to those for the corresponding reactions of alkanes. In so doing, one must allow for the differences in reactivity of primary, secondary, and tertiary CH bonds referred to earlier. Since primary alcohols except methanol have secondary CH bonds, primary alcohols should be compared with alkane secondary CH bonds and secondary alcohols should be compared with alkane tertiary CH bonds. With this in mind, the ratio of activation energies for α-hydrogen abstraction from primary and secondary alcohols is about the same as the ratio of activation energies for abstraction of secondary and tertiary hydrogens in the alkanes. However, the activation energies for the reactions of $O(^3P)$ with the alcohols are some two to four times smaller than those for the alkane reactions as a result of the inductive effect of the alcohol oxygen atom. This makes differences in activation energy for different kinds of CH bonds in the alcohols more difficult to measure than in the alkane reactions. It is also of interest that the activation energy for the reaction of $O(^3P)$ with 2-methyl-2-propanol is comparable to that for abstraction of a secondary CH hydrogen from an alkane. Since 2-methyl-2-propanol contains only primary CH bonds this implies that the inductive effect of OH is significant more than one carbon atom into the aliphatic chain.

Useful qualitative information may often be obtained by correlating relative rate constants with functional group parameters through a linear free energy relation. An appropriate correlation of this type is the Taft equation (8) which estimates the sensitivity of a reaction to inductive donation of electron density at the reactive site. A comparison of some abstraction reactions of $O(^3P)$ and of OH radicals is provided in Table 2 and in Fig. 3.

The Taft polar reaction coefficient, ρ*, is negative for all the reactions tested, indicating that $O(^3P)$ is an electrophile as expected (12). The steric sensitivity parameter, δ, is negligibly small for all the reactions, suggesting that structural variation within a given class of compound does not significantly alter the steric constraints on oxygen atom attack at the reactive site. This would not preclude the existence of some constant steric feature such as the postulated preferential collision of the elec-

[a]In all cases the reference compound is the one for which $\sigma^* = E_s = 0.00$ by definition.

[b]Rate constants for the reactions of $O(^3P)$ with the alcohols were calculated for abstraction of hydrogen from a single α-C—H bond.

[c]Calculated in ref. 12 from linear free energy correlations with other reactions.

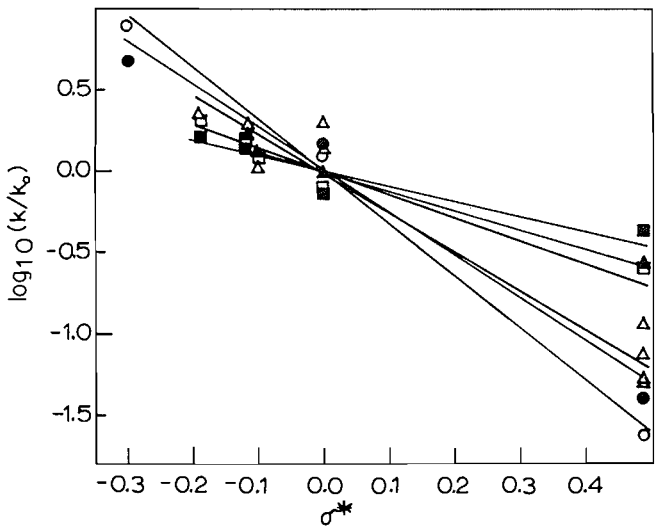

FIG. 3. Taft plots for ○, O + alkanes containing only primary C—H bonds; ●, OH + alkanes containing only primary C—H bonds; □, O + aldehydes; ■, OH + aldehydes; △, O + primary alcohols; ▲, OH + primary alcohols.

trophyllic $O(^3P)$ with the OH group of an alcohol (3), which is unreactive and could lead to an unusually small Arrhenius preexponential factor for all the reactions in an homologous series of alcohols.

The values of ρ* become less negative as the strength of the reactive CH bond decreases. This is in agreement with the theoretical result (18) that the absolute value of the selectivity parameter (ρ* in the Taft equation) should become smaller as the general reactivity increases. The sensitivity to polar effects also appears somewhat greater for reactions of $O(^3P)$ than for the corresponding reactions of OH. This is consistent with the linear free energy correlation of Gaffney and Levine (12) in which the slope (1.364) of their correlation of log $k_{(O(^3P))}$ with log $k_{(OH)}$ for hydrogen atom abstraction can be identified as $\rho^*_{(O(^3P))}/\rho^*_{(OH)}$ in the Taft analysis.

Several novel *C*-nucleosides have been prepared by Pictet–Spengler condensations between biogenic amines and carbohydrates. Dopamine hydrochloride reacted with D-glucose to give 6,7-dihydroxy-1(*R*)- and -1(*S*)-(D-*gluco*-pentitol-1′-yl)-1,2,3,4-tetrahydroisoquinoline hydrochlorides, and with 2,5-anhydro-D-mannose to give 1(*R*)- and 1(*S*)-(α-D-arabinofuranosyl)-6,7-dihydroxy-1,2,3,4-tetrahydroisoquinoline hydrochlorides. Tryptamine hydrochloride and histamine did not react with D-glucose, but with 2,5-anhydro-D-mannose gave 1(*R*)- and 1(*S*)-(α-D-arabinofuranosyl)-1,2,3,4-tetrahydro-β-carboline and 4-(α-D-arabinofuranosyl)-imidazo[4,5-*c*]-4,5,6,7-tetrahydropyridine, respectively. The structures of the compounds have been established by nmr experiments and by mass spectrometry.

IAN M. PIPER, DAVID B. MACLEAN, INGEMAR KVARNSTRÖM et WALTER B. SZAREK. Can. J. Chem. **61**, 2721 (1983).

On a préparé plusieurs nouveaux *C*-nucléosides par des condensations de Pictet–Spengler entre des amines biogènes et des hydrates de carbone. Le chlorhydrate de dopamine réagit avec D-glucose pour conduire aux chlorhydrates des dihydroxy-6,7 (D-*gluco* pentitolyl-1)-1(*R*) et -1(*S*) tétrahydro-1,2,3,4 isoquinoléines et avec l'anhydro-2,5 D-mannose pour conduire aux (α-D-arabinofurannosyl)-1(*R*) et -1(*S*) dihydroxy-6,7 tétrahydro-1,2,3,4 isoquinoléines. Le chlorohydrate de tryptamine et l'histamine ne réagissent pas avec le D-glucose, mais avec l'anhydro-2,5 D-mannose, ils donnent respectivement les (α-D-arabinofurannosyl)-1(*R*) et -1(*S*) tétrahydro-1,2,3,4 β-carbolines et la (α-D-arabinofurannosyl)-4 imidazo[4,5-*c*] tétrahydro-4,5,6,7 pyridine. On a déterminé les structures par spectroscopie rmn et par spectrométrie de masse.

[Traduit par le journal]

Introduction

The Pictet–Spengler reaction has been widely employed in the synthesis of isoquinolines and related heterocyclic systems (1–3). However, to our knowledge, reactions of this type have not been reported between biogenic amines and sugars or sugar derivatives. The synthesis of pyridindolol by Cook and co-workers (4), by the condensation of tryptophan with glyceraldehyde, represents a related example. In an earlier report, Severin and Heidenhain (5) obtained 1-(1,2-dihydroxyethyl)-1,2,3,4-tetrahydro-β-carboline-3-carboxylic acid and 1-(1,2,-dihydroxyethyl)-1,2,3,4-tetrahydro-β-carboline from the reaction of glyceraldehyde with tryptophan and tryptamine respectively. Severin and Bräutigam (6) have also reported the production, in low yields, of a variety of compounds containing the β-carboline skeleton from the reaction of tryptophan or tryptamine with xylose or glucose. However, the condensation reactions in each case were accompanied by extensive elimination and rearrangement processes. Almost all reported reactions involving the amino group of the amines and the carbonyl function of sugars have dealt with the Amadori rearrangement (7) or the Maillard (browning) reaction (8). It seemed likely to us that a Pictet–Spengler reaction, between a biogenic amine and a sugar, (or sugar derivative containing a carbonyl group), might be used to prepare *C*-glycosides, or to provide useful intermediates for isoquinoline alkaloid synthesis. Furthermore, it was hoped that use of the asymmetric sugar moieties would encourage stereoselectivity in the formation of the new chiral centre of the product heterocycle.

Results and discussion

Heating at reflux temperature of dopamine hydrochloride (**1**) with D-glucose in aqueous solution gave, after work-up and chromatography, 6,7-dihydroxy-1(*R*)- and -1(*S*)-(D-*gluco*-pentitol-1′-yl)-1,2,3,4-tetrahydroisoquinoline hydrochlorides (**2**), in excellent yield (Scheme 1). In a similar fashion, dopamine hydrochloride (**1**) reacted with 2,5-anhydro-D-mannose (**3**), prepared from 2-amino-2-deoxy-D-glucose by a modification of the method of Horton and Philips (9), to give a mixture of 1(*R*)- and 1(*S*)-(α-D-arabinofuranosyl)-6,7-dihydroxy-1,2,3,4-tetrahydroisoquinoline hydrochlorides (**4**), and tryptamine hydrochloride (**5**) reacted with **3** to give 1(*R*)- and 1(*S*)-(α-D-arabinofuranosyl)-1,2,3,4-tetrahydro-β-carboline (**6**). 3,4-Dimethoxyphenylethylamine hydrochloride gave no appreciable reaction with either D-glucose or **3**, presumably because of the known (10) lower activation of *para*-methoxyl groups compared with hydroxyl groups in electrophilic substitution reactions. Additionally, no products could be detected in the reaction between tryptamine hydrochloride and D-glucose after heating at reflux temperature in water or ethanol for 48 hours; the starting materials were recovered in each case.

Histamine dihydrochloride gave no observable reaction with **3**, probably because protonation of the imidazole ring discourages electrophilic attack at the C-4 of imidazole. However, reaction of histamine (**7**) with **3** in slightly alkaline aqueous solution (see ref. 11) gave 4-(α-D-arabinofuranosyl)-imidazo[4,5-*c*]-4,5,6,7-tetrahydropyridine (**8**) in moderate yield and high purity (Scheme 2). No reaction was obtained with D-glucose.

With the exception of the product of condensation between histamine (**7**) and **3**, all of the products were obtained as mixtures of isomers at C-1. In the case of **6** the mixture of isomers

SCHEME 2

was resolved by column chromatography, but in the cases of **2** and **4** conversion into their peracetyl derivatives was necessary to effect separation. One interesting point is that while **2** and **4** were isolated as the hydrochlorides, **6** (prepared by the same method) was found to be a free base. The titration curve confirmed this observation, and showed that the product had $pK_a \sim 6.7$, but the result was still rather surprising. One possibility is that internal hydrogen bonding may lessen the availability of the lone pair on N-2 of the tetrahydro-β-carboline ring, thus reducing basicity.

The structures assigned to the compounds were supported by their ^1H- and ^{13}C-spectra. The assignments of the signals in the spectra were made by comparison with those of model compounds, and by off-resonance ^{13}C and homonuclear ^1H decoupling experiments. For the products derived from dopamine, the model compounds for the amine portion were dopamine hydro-

[c]No attempt is made to assign carbons C_a and C_b separately.

chloride (**1**) and 6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline (**9**) (12). For the product **6**, derived from tryptamine, comparison was made with tryptamine hydrochloride and with 2-methyl-1,2,3,4-tetrahydro-β-carboline (**10**) (13), while for compound **8** the model compound was histamine (**7**). For the sugar portions of the compounds derived from 2,5-anhydro-D-mannose, assignments in the cases of **6** and **8** were confirmed by ^1H homonuclear decoupling experiments, and in the case of **4** assignment was by analogy with these results. For compound **2**, derived from D-glucose, the model compound was D-glucitol (**11**) (14). It was important to establish that cyclization had occurred and to demonstrate that the product was not a Schiff base. For each compound (**2**, **4**, **6**, and **8**) this aspect was apparent from both ^1H- and ^{13}C-spectra. In each of the compounds examined there was one fewer aromatic proton signal than in the spectrum of the corresponding amine. Secondly, no signal was visible in the ^1H nmr spectrum corresponding to an iminium proton ($CH{=}\overset{+}{N}$, ~9−10 ppm), expected of a Schiff base. Finally, in the ^{13}C nmr spectrum, off-resonance decoupling clearly showed that the carbon atom to which cyclization should occur did not bear any hydrogen (Table 1).

Mass spectral analysis of the condensation products (**2**, **4**, **6**, and **8**) gave unsatisfactory spectra because of their involatility. The use of a variety of protecting groups was examined, the most satisfactory one being the acetyl group.

Under electron impact conditions the molecular ions of the peracetylated compounds were either very weak or not observable. Instead, the base peak of the spectrum in each case corresponded to a fragment arising from C-1—C-1′ fission (or C-4—C-1′ fission in the case of the imidazo[4,5-*c*]tetrahydropyridine derivative (**15**)) (Schemes 3−6), thus confirming that cyclization had taken place. Other major peaks observed were those due to successive losses of ketene (15) from this fragment. As a result, little evidence was obtained for the existence of the sugar portion of the compounds. Various other derivatives, in particular alkyl silyl ethers, were prepared in the hope of obtaining prominent ions containing the sugar portion (16), but with little success. More satisfactory results were obtained by use of chemical ionization on the peracetylated compounds. In each case, the expected $(M + 1)^+$ ion was observed as the base peak; additionally, the peak corresponding to C-1—C-1′ (or C-4—C-1′) fission was observable. In several cases, other peaks could be assigned to successive losses of acetic acid from the sugar portions of the molecules (15) (Schemes 3−6). High resolution mass spectrometry was used (under electron impact conditions) to measure masses of major ions; accurate mass measurement of the molecular ion was possible only in two cases (**14** and **15**) since the molecular ion was not observable in other cases. Likely fragmentation patterns for the compounds prepared are summarized in Schemes 3−6. Ions whose compositions were confirmed by high resolution measurements are indicated by a dagger symbol (†). These data are shown in Table 2.

The compounds above represent a new group of organic compounds of potential value as pharmaceuticals and as synthons in enantioselective synthesis of alkaloids and other natural products. It is well known that the tetrahydroisoquinolines, tetrahydro-β-carbolines, and imidazo[4,5-*c*]tetrahydropyridines resulting from analogous condensations involving simple aldehydes show a variety of pharmacological activities (17). The condensation products can also be viewed as a novel class of *C*-nucleosides; such compounds are of great interest because of their demonstrated antibiotic and antitumor activities (8). A biological evaluation of the new compounds is in progress and the results will be reported separately.

Experimental

The nmr spectra were run on a Varian EM390 (90 MHz), a Bruker WP80 (80 MHz), or a Bruker WM250 (250 MHz) spectrometer. Chemical shifts are reported in ppm (δ) from tetramethylsilane. The symbols, s (singlet), d (doublet), t (triplet), q (quartet), and b (broad) are used to report the multiplicity and shape of signals. Coupling constants are accurate within ±0.5 Hz. Mass spectra were recorded on a VG Micromass 7070F mass spectrometer at an ionizing voltage of 70 eV and a source temperature of 120°C (for C.I. (CH_4)) or 200°C (for E.I.), and are reported as m/z values with relative intensities in brackets. Natural abundance ^{13}C nmr spectra were recorded on a Bruker WP80 Fourier transform spectrometer at 20.1 MHz, or on a Bruker WM250 spectrometer at 62.9 MHz. Melting points are uncorrected. Silica gel G/UV-254 (Merck) was used for tlc analysis,

silica gel 60 (Merck, 70–230 mesh) for column chromatography, and silica gel 60 (Merck, 230-400 mesh) for flash chromatography (19).

Acetylation of condensation products: general procedure

The compound to be acetylated (5 mg) was taken up in dry pyridine (0.3 mL) and acetic anhydride (0.3 mL) was added. The mixture was stirred for 24 h at room temperature. The resulting solution was analysed directly by probe ms. Alternatively, on a preparative scale, the compound (~0.5 g) was treated for 24 h with dry pyridine (5 mL) and acetic anhydride (5 mL). The resulting solution was poured into chloroform (75 mL) and washed with water (3 × 25 mL). The chloroform solution was dried over $MgSO_4$ and the solvents removed, finally under high vacuum, to yield a yellow-brown foam (70%–85%). The product was purified by column chromatography or flash chromatography on silica gel, using a variety of solvents.

2,5-Anhydro-D-mannose

2-Amino-2-deoxy-D-glucose hydrochloride (1.08 g, 5 mmol) was dissolved in water (10 mL), and the solution was cooled to 0°C. Sodium nitrite (0.69 g, 10 mmol) was added in one batch, followed by cation-exchange resin (Amberlite IR-120, (H^+), 7 g) in portions with stirring, the temperature being maintained at 0°C–5°C during the addition. The mixture was stirred vigorously for 1 h while it warmed to room temperature. The resin was filtered, and the filtrate was neutralized by addition of anion-exchange resin (Amberlite IRA-400, (−OH)). The mixture was filtered and the filtrate concentrated to a small volume by rotary evaporation without heating. The solution was used directly in the condensation reactions described below. In a separate experiment, complete removal of solvent gave a hygroscopic, yellow-white solid (0.77 g, 95%); $[\alpha]_D^{20}$ +30.2 (*c* 1.26, H_2O); ^1H nmr (D_2O): 4.04–4.24 (3H, m, H's at C-5 and C-6),4.27–4.39 (1H, m, H at C-2), 4.46 (1H, t, H at C-3, J = 5 Hz), 4.59 (1H, t, H at C-4, J = 5 Hz), 5.50 (1H, d, H at C-1, J = 5 Hz) ppm; ^{13}C nmr (D_2O): 62.1 (C-6), 77.9, 78.4, 84.1, 85.4 (C-2, C-3, C-4, and C-5), 90.6 (C-1) ppm; ms: 133 ($(M - 28)^+$, 24), 126 (18), 113 (38), 97 (100).

Reaction of dopamine hydrochloride with D-glucose

Dopamine hydrochloride (1.33 g, 7 mmol) and D-glucose (5.05 g, 28 mmol) were dissolved in water (30 mL), and the solution was boiled under reflux for 48 h, then cooled and filtered. The resulting dark brown solution was stirred for 1 h with cation-exchange resin (Amberlite IR-120, (H^+), 15 g), and filtered. The resin was washed with water to remove non-basic impurities (150 mL), and then with HCl solution (2 *M*, 500 mL). The acidic filtrate was evaporated to give a yellow-brown powder (3.0 g). This was purified on a short column of silica gel (25 g) using acetonitrile/water (9:1), to give the product

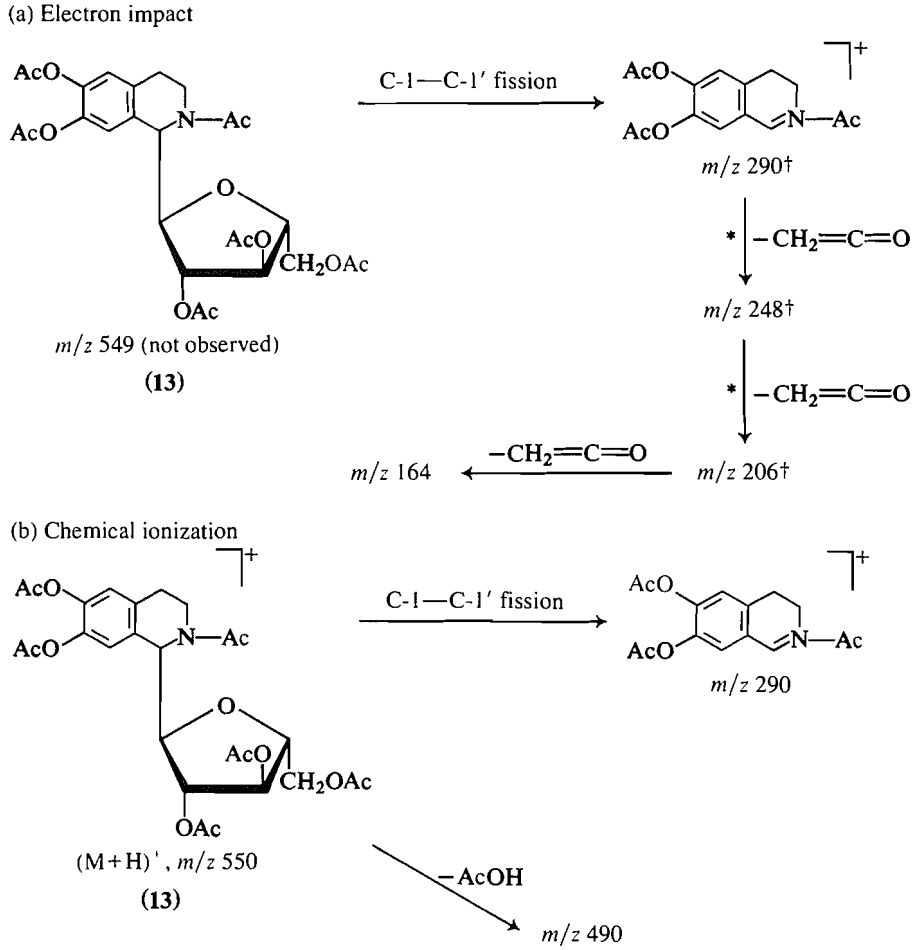

SCHEME 4. Likely mass spectral fragmentations for **13**.

as a yellow hygroscopic solid (2.3 g, 92%). The ^{1}H and ^{13}C nmr spectra indicated that the product was a mixture of two isomers, in the approximate ratio of 4:1. The chemical shifts for the minor isomer are given in square brackets where observed; ^{1}H nmr (D_2O): 2.88–3.13 (2H, m, H's at C-4), 3.60–3.93 (6H, m, H's at C-3, C-3′, C-4′, and C-5′), 4.16 (1H, t, H at C-2′, J = 2 Hz), 4.37 (1H, dd, H at C-1′, J = 4.5 Hz and J = 2 Hz), 4.71 (1H, d, H at C-1, J = 4.5 Hz) [4.61 (1H, d, J = 4.5 Hz)], 6.80 (1H, s) [6.77 (1H, s)], and 6.87 (1H, s) [6.84 (1H, s)] (H's at C-5 and C-8) ppm; ^{13}C nmr (D_2O): 24.7 [25.6] (C-4), 40.4 [42.1] (C-3), 57.9 [59.9] (C-1), 63.6 (C-5′), 70.5 [69.9], 72.3, 73.4 (C-1′, C-2′, C-3′, and C-4′), 115.3 [114.5] and 117.0 (C-5 and C-8), 121.7 [120.8] and 126.4 (C-4a and C-8a), 144.0 and 145.3 (C-6 and C-7) ppm.

The condensation product was peracetylated by the method described and a partial separation of the isomers effected by column chromatography using ethyl acetate (R_f (major isomer) = 0.23, R_f (minor isomer) = 0.25). The major isomer was obtained pure, as a pale yellow syrup; $[\alpha]_D^{20}$ +12.8, (c 1.71, $CHCl_3$); ^{1}H nmr ($CDCl_3$): 1.83 (3H, s, $(CO)CH_3$), 2.08, (9H, s, 3 × $(CO)CH_3$), 2.23, 2.24, 2.27, 2.30 (12H, 4 × s, 4 × $(CO)CH_3$), 2.78–3.02 (2H, m, C-4), 3.80–4.01 (2H, m, C-3), 4.22–4.37 (2H, m, H's at C-5′), 4.89–5.53 (4H, m, H's at C-1′, C-2′, C-3′, and C-4′), 5.80 (1H, d, C-1, J = 9 Hz), 7.03 (1H, s) and 7.07 (1H, s) (H's at C-5 and C-8) ppm; ^{13}C nmr ($CDCl_3$): 20.5 ($(CO)CH_3$), 21.5 ($(CO)CH_3$), 28.2 (C-4), 42.1 (C-3), 50.8 (C-1), 62.0 (C-5′), 68.8 (C-2′, C-3′, and C-4′), 73.9 (C-1′), 122.4 and 123.2 (C-5 and C-8), 131.1 and 133.7 (C-4a and C-8a), 140.8 and 141.4 (C-6 and C-7), 167.8 and 170.1 ($CO CH_3$) ppm; ms (C.I.): 652 ($(M + 1)^+$, 100), 592 (37), 290 (59); ms (E.I.): 290 (96), 248 (100), 206 (30), 164 (27).

Reaction of dopamine hydrochloride with 2,5-anhydro-D-mannose

Dopamine hydrochloride (1.33 g, 7.0 mmol) was added to an aqueous solution (ca. 10 mL) containing 2,5-anhydro-D-mannose (prepared as described above from 2-amino-2-deoxy-D-glucose hydrochloride (3.23 g, 15 mmol)). The resulting solution was kept at room temperature for 48 h, then evaporated to dryness, to give a brown solid (3.5 g). Chromatography on a short column of silica gel (25 g), using acetonitrile/water (9:1), gave the product as a pale yellow hygroscopic powder, (2.30 g, 98%); ^{1}H nmr (D_2O): 2.99–3.17 (2H, m, H's at C-4), 3.58–3.91 (4H, H's at C-3 and C-5′), 4.13 (1H, m, H at C-4′), 4.19 (1H, t, H at C-2′, J = 5 Hz), 4.28 (1H, dd, H at C-1′, J = 5 Hz, J = 7.5 Hz), 4.41 (1H, t, H at C-3′, J = 5 Hz), 4.71 (1H, d, H at C-1, J = 7.5 Hz), 6.83 (1H, s) and 6.89 (1H, s) (H's at C-5 and C-8) ppm. The ^{13}C nmr spectrum showed 2 isomers to be present, in the approximate ratio of 4:1. The chemical shifts for the minor isomer are shown in square brackets where observed; ^{13}C nmr (D_2O): 24.6 [25.0] (C-4), 39.9 [41.5] (C-3), 56.5 (C-1), 62.4 (C-5′), 78.5 [77.2], 79.2, 83.2 [84.0], 84.9 [85.6] (C-1′, C-2′, C-3′, and C-4′), 115.5 and 117.1 (C-5 and C-8), 120.9 [120.2] and 126.1 (C-4a and C-8a), 143.9 and 145.5 (C-6 and C-7) ppm.

The compound was peracetylated and a partial separation of the isomers effected by chromatography as described above, using ethyl acetate (R_f (major isomer) = 0.19, R_f (minor isomer) = 0.24). For the major isomer, the following data were obtained: $[\alpha]_D^{20}$ −19.6 (c 2.56, $CHCl_3$); ^{1}H nmr ($CDCl_3$): 2.08, (6H, s, 2 × $(CO)CH_3$), 2.11, 2.20, 2.30, 2.31 (12H, 4 × s, 4 × $(CO)CH_3$), 2.96 (2H, m, H's at C-4), 3.87 (2H, m, H's at C-3), 4.19–4.35 (3H, m, H's at C-4′ and C-5′), 4.46 (1H, t, H at C-1′, J = 5 Hz), 5.17 (1H, t, H at C-3′, J = 3 Hz), 5.37 (1H, dd, H at C-2′, J = 5 Hz, J = 3 Hz), 5.95 (1H, d, H at C-1,

J = 5 Hz), 7.09 (1H, s) and 7.17 (1H, s) (H's at C-5 and C-8) ppm; ^{13}C nmr ($CDCl_3$): 20.6 ((CO)CH_3), 21.7 ((CO)CH_3), 28.4 (C-4), 42.1 (C-3), 52.0 (C-1), 62.9 (C-5′), 78.7, 80.9, 85.5 (C-1′, C-2′, C-3′, and C-4′), 122.5 and 123.4 (C-5 and C-8), 132.3 and 133.2 (C-4a and C-8a), 141.0 and 141.6 (C-6 and C-7), 168.0 and 170.3 (COCH$_3$) ppm; ms (C.I.): 550 ((M + 1)$^+$, 100), 490 (14), 290 (28), 248 (8); ms (E.I.): 290 (100), 248 (95), 206 (29), 164 (36).

Reaction of tryptamine hydrochloride with 2,5-anhydro-D-mannose

Tryptamine hydrochloride (1.38 g, 7.0 mmol) was added to an aqueous solution (ca. 20 mL) containing 2,5-anhydro-D-mannose (prepared as described above from 2-amino-2-deoxy-D-glucose hydrochloride (3.23 g, 15 mmol)). The mixture was warmed gently (to ~40°C) until all material had dissolved, and the solution was kept at room temperature for 7 days. Evaporation gave an amorphous brown solid (3.5 g), which was purified on a short column of silica gel (25 g) using acetonitrile/water (9:1), giving the product as a yellow-brown powder (2.35 g, 98%). The product was found to be a mixture of two isomers in the approximate ratio of 40:60. These were partly separated by chromatography on silica gel using ethyl acetate/methanol/water (85:10:5) (R_f (major isomer) = 0.07, R_f (minor isomer) = 0.12). Each isomer crystallized as fine white needles from methanol, mp 228°C–230°C (dec.) for each isomer. Mixture mp 216°C–218°C (dec.); $[\alpha]_D^{20}$ (major isomer) +51.0 (c 0.6, 0.1 M HCl); $[\alpha]_D^{20}$ (minor isomer) +21.9 (c 0.54, 0.1 M HCl). *Anal.* calcd. for $C_{16}H_{20}N_2O_4$: C 63.15, H 6.62, N 9.20; found (major isomer): C 63.18, H 6.66, N 9.39%; found (minor isomer): C 63.11, H 6.71, N 9.04%.

Minor isomer

^{1}H nmr (DMSO-d_6 + D_2O): 2.95 (2H, m, H's at C-4), 3.26 (2H, m, H's at C-3), 3.57 (2H, dd, H's at C-5′, J = 5.1 Hz, J = 6.8 Hz), 3.78 (1H, t, H at C-2′, J = 3.5 Hz), 3.90 (1H, t, H at C-3′, J = 3.1 Hz), *3.96 (1H, m, H at C-4′), 4.18 (2H, s, H's at C-1 and C-1′), 6.99 (1H, t, J = 7.5 Hz) and 7.08 (1H, t, J = 7.5 Hz) (H's at C-6 and C-7), 7.38 (1H, d, J = 7.9 Hz) and 7.44 (1H, d, J = 7.9 Hz) (H's at C-5 and C-8) ppm; ^{13}C nmr (DMSO-d_6 + D_2O): 22.0 (C-4), 42.0 (C-3), 54.2 (C-1), 62.2 (C-5′), 77.8, 79.2, 86.8 (C-1′, C-2′, C-3′, and

ROBERT R. FRASER, MONIQUE BRESSE, NOEMI CHUAQUI-OFFERMANNS, K. N. HOUK, and N. G. RONDAN. Can. J. Chem. **61**, 2729 (1983).

The relative acidities of fiteen aldimines and ketimines have been measured in THF using either ^{13}C nmr spectroscopy or trapping experiments with methyl iodide. The pK_A's are found to vary over a range of more than four pK units. The effects of structure on acidity indicate the acid-weakening effect of alkyl substitution in ketimines to be due to steric effects. This interpretation is supported by the results of *ab initio* calculations. The data also permit a quantitative estimation of the preference for the *syn* configuration of lithiated imines to be at least four kcal/mol. The *anti* selectivity previously reported for the lithiation of endocyclic imines can be accounted for by angular constraints, as indicated by both *ab initio* calculations and pK_a data on this class of imine.

ROBERT R. FRASER, MONIQUE BRESSE, NOEMI CHUAQUI-OFFERMANNS, K. N. HOUK et N. G. RONDAN. Can. J. Chem. **61**, 2729 (1983).

On a mesuré les acidités relatives de quinze aldimines et cétimines dans le THF en faisant appel soit à la spectroscopie rmn du ^{13}C ou à des expériences de trappage avec l'iodure de méthyle. On a trouvé que les pK_a varient sur plus de quatre unités de pK. Les effets de structure sur l'acidité indiquent que l'abaissement de l'acidité lors de la substitution alkyle dans les cétémines serait dû à des effets stériques. Cette interprétation est en accord avec les résultats de calculs *ab initio*. Les données permettent aussi d'évaluer quantitativement, à au moins 4 kcal/mol, la préférence pour la configuration *syn* des imines lithiés. On peut expliquer la sélectivité *anti* rapportée antérieurement lors de la lithiation d'imines endocycliques en faisant appel à des contraintes angulaires qui sont suggérées à la fois par les calculs *ab initio* et les données de pK_a sur cette classe de composés.

For personal use only.

During the course of our investigations on the chemistry of lithiated aldimines (1) and ketimines (2) a number of unusual results were encountered for which satisfactory explanations required further experimental support. For example, with but two exceptions the lithiation of aldimines and ketimines gave exclusively anions having the *syn* configuration, the main exception being the endocyclic imines **9** to **12** which formed *anti* lithio derivatives only (3).[2] A second striking feature of the lithiation of ketimines concerns the regioselectivity of the reaction. Just as had been observed earlier for ketone oximes (4), oxime ethers (5), and hydrazones (6), lithiation is markedly favored at a primary vs. secondary carbon atom (7) or at a secondary vs. a tertiary one (2, 8). This is anomalous too, in the sense that the stability differences at primary, secondary, and tertiary carbons are normally small and in the reverse order when a change of sp^3 to sp^2 hybridization is involved (9, 10).

As a potential aid to our understanding these results, we set out to obtain quantitative information on the deprotonation reaction, that is, to measure the relative acidities of a variety of imines on a common scale of pK's. As will be shown later, the pK's obtained not only fulfilled our original aim, but provided information on the magnitude of steric effects in aldimine lithiation which permits us to estimate more acurately the magnitude of the "*syn* effect" (11) in imine lithiations.

Measurements of pK's

The development of an acidity scale for weak carbon acids has been a continuously evolving area of research. The MSAD scale was assembled by Cram (12) from the works of many chemists, mainly W. K. McEwen, A. Streitwieser, Jr., D. E. Applequist, and R. E. Dessy and covered a total range in pK's of 18.5 (9-phenylfluorene was chosen as the standard having this pK) to 40 in a variety of solvents.

Two newer scales have been developed which extend the coverage to include much weaker acids. One scale, developed and expanded by Bordwell and co-workers (13) uses pure DMSO as solvent and, from rates of proton abstractions, uses Brønsted correlations to estimate acidities. The second one, developed by Streitwieser and co-workers, has been termed an "ion-pair acidity scale" to indicate the nature of the ionic solutes in his chosen solvent, cyclohexylamine (14). Two special techniques have also provided additional useful data on pK's. Breslow and co-workers have been able to determine the pK's of extremely weak acids using an electrochemical technique (15) and Arnett and Venkatasubramanian have recently described estimates of pK's from measurements on the enthalpies of deprotonation (16). Remarkably good agreement has been achieved for those measurements common to the three different solvents in spite of the known dependence of pK on solvent (17). For example, the pK_a of toluene is assessed at 41.2 (18) in cyclohexylamine, 42 (19) in DMSO, and 45 (15) in THF containing hexamethylphosphoramide.

Most recently, we have initiated studies of pK_a's in THF using lithium diisopropylamide (LDA) as the proton abstraction reagent. We have found that there is a sufficiently slow rate of proton transfer between LDA and diisopropylamine, as well as between both of these and weak carbon acids and their anions, to allow direct observation of an equilibrium mixture of two anions and their conjugate acids using ^{13}C nmr at room

[1]This is the third in a series of papers describing acidity measurements in tetrahydrofuran (THF). Parts I and II are ascribed to the refs. 20 and 21 respectively.

[2]The other exception recently reported a striking solvent effect of HMPA on lithiated propionaldimine (25).

TABLE 1. Relative pK's from alkylation reactions[a]

Entry	Compound	Reference compound	K (eq. [1])	ΔpK	Assigned pK[b,c]
1	$CH_3CH_2(CH_3)C{=}NCH_2\phi$ (**2**)	**1**	2	0.3	0.3
2	$CH_3CH_2(CH_3)C{=}NCH_2\phi$ (**2**)	**2** (CH_3 protons)	81	1.9	2.0
3	$(CH_3CH_2)_2C{=}NCH_2\phi$ (**3**)	**2** (CH_3 protons)	182	2.3	2.4
4	$(CH_3CH_2)_2C{=}NCH(CH_3)_2$ (**4**)	**3**	67	1.8	4.2
5	$(CH_3CH_2)_2C{=}NCH(CH_3)\phi$ (**5**)	**4**	0.62	−0.2	4.0

temperature. This provides a value for K for the equilibrium [1]

[1] $HA_1 + A_2^- \rightarrow A_1^- + HA_2$

where $K = K_1/K_2$ and thus yields a $\Delta pK = -\log K = pK_1 - pK_2$.[3] Using this technique we have determined an increasing order of acidities for tetramethylpiperidine, diisopropylamine, and *cis*-2,6-dimethylpiperidine (20) (relative pK_a's being 2.1, 0.5, and 0). We have subsequently utilized the lithio derivatives of these amines to measure the relative pK's of fifteen weak carbon acids (21). One of the most notable facts emerging from these preliminary studies is a very different order of acidities in THF compared to cyclohexylamine. Since the most common synthetic method for the generation of anions utilizes LDA in THF, additional quantitative data in this medium should prove of widespread use in furthering our understanding of anion reactions. Towards our goal of elucidation of the chemical properties of lithiated imines in THF, we have employed this method in conjunction with a second to measure their relative acidities. The latter involves the trapping of a mixture of anions by alkylation with methyl iodide at −78°C. This approach is somewhat more complex to use, since all the alkylation products are formed initially in the *syn* configuration, but isomerize at varying rates to the *anti* form in the case of aldimines or to a *syn*−*anti* mixture in the case of ketimines. In some cases, spectra could be obtained before isomerization intervened, and in other alkylations, spectra were measured only after equilibrium had been reached. The observation of each of the four species in eq. [1] at equilibrium at room temperature is quite remarkable in the sense that the lithium−hydrogen interchange is sufficiently slow, on the nmr time scale, to permit the direct measurement of signal intensities for all species. For this to be possible, the barrier to interconversion can be calculated to have a minimum value of 16 kcal/mol.[4] There is, however, a limitation to the use of either method, particularly the direct method at room temperature. On certain occasions, reaction of an anion and an imine can occur, usually with compounds of low molecular weight. For example, we were unable to measure the pK_a of $CH_3CH{=}NCH_2\phi$ vs. **7** due to a destructive reaction even at −78°C.

A total of fifteen imines have been subjected to pK measurements using the two methods. Table 1 presents the results of competitive alkylation studies and Table 2 gives the results of direct measurements of ΔpK. All of the data are presented in the Summary of results using acetone *N*-benzylimine as the reference (pK = 0) since it is the strongest acid of all the imines studied herein. It would be desirable to anchor the scale to a known standard and work is proceeding to this end. We can put some estimates on the pK of the least acidic imine; since it is completely deprotonated by LDA (pK_a = 35.7) (21) it must have a maximum for its pK_a of 33. The fact that DMSO-d_6

[3]Reference 10, Chapt. 1. In converting our data into pK units, we adopt the common assumption that activity coefficients may be assumed to have unit value.

[4]We have determined the barrier to lithium−hydrogen exchange between LDA and tetramethylpiperidine to be 16.8 kcal/mol. (20).

exchanges its deuterium with acetone imine in the presence of *tert*-butoxide (2) allows an estimate for its minimum to be around 30 on the DMSO scale, near enough to the pK of DMSO, (35 on Bordwell's scale (13)) to permit facile exchange.

There is some risk in comparing the pK's from method (a) measured at −78°C with those obtained at room temperature by method (b), as it requires the assumption of a constant ΔS for all equilibria. This assumption has previously been tested and found valid by Jaun *et al.* (15) for acids in THF containing 20% HMPA. Furthermore, there is an established internal consistency in our results which indicates the assumption to be valid for our imines. For example, using method (b), the acidity of **13** was established in relation to both **3** and **5** as being 2.8 and 2.7 respectively on the chosen scale. This agreement is particularly satisfying when one considers the acidities of **3** and **5** were each established relative to **4** using method (a). Method (a) was also proven consistent in the determinations of the pK for **6** by comparison with **3** (pK = 2.6) and with **4** (pK = 2.2). The former value will be the more accurate since K for the pair **6** and **3** is close to unity, in which instance a 5% error in peak intensities gives the smallest error in pK (<0.1 units). Thus we have assigned a weighted average pK values of 2.5 to **6**.

The accuracy of both our methods is limited primarily by the accuracy of the intensity measurements. While we have adopted operating conditions for spectral acquisition which nullify the effects of differing relaxation times on peak intensities (see Experimental), there is nevertheless a limit in accuracy of ±5% for each peak intensity measurement. This alone introduces an uncertainty in K of 20% and in each ΔpK of ±0.1. Including all operational and systematic errors, we estimate a maximum error in pK's of ±0.3 units.

Results and discussion

The data in Table 1 provide a value for the ΔpK between various pairs of imines. Since we have assigned a pK = 0 to the imine **1**, we must make a statistical correction for each ΔpK measurement in which a different number of acidic hydrogens in the two imines is involved. Since $\Delta pK = \log K = \Delta G/2.3RT$ and this statistical contribution to ΔG will be a $T\Delta S$ term equal to $2.3RT \log (N_1/N_2)$, the correction term for ΔpK will be $\log (N_1/N_2)$, i.e., log 3/2, log 3/1, or log 2 as the case

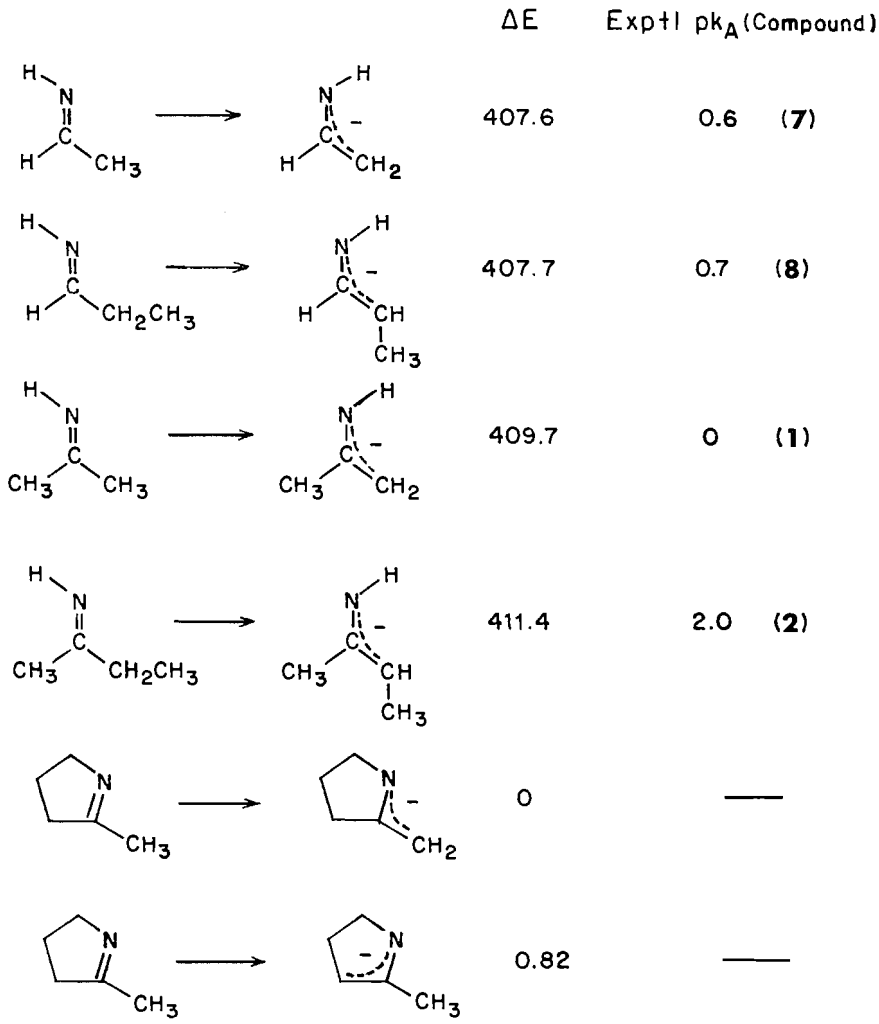

FIG. 1. A comparison of the deprotonation energies obtained by *ab initio* calculations with the experimental values for pK_a.

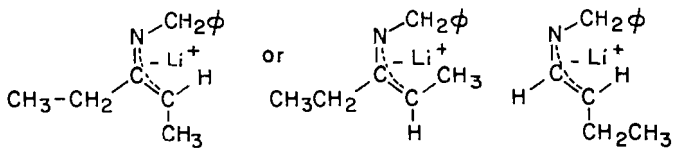
may be.

Several interesting effects of structure on acidity are revealed by the pK's in the Summary. A most informative feature is the relative insensitivity of pK to a change from a primary to a secondary α carbon as in **7** vs. **8**. This contrasts with 2 pK unit increase for the same structural change in ketimines **2** (at the CH_2) or **3** vs. **1**. The latter change is completely consistent with the well-documented behaviour observed for the lithiation of ketimines (2, 7, 8).[5] A comparison of **7** with **8** shows that the electronic effect of an alkyl substituent is negligible as expected (9, 10). It would seem likely that the large effect of the methyl substituent in ketimines **2** (or **3**) versus **1** arises from another source, most probably steric in origin. Specifically, lithiation of **8** produces **8**-Li which possesses no steric problems in the *E* configuration (see the structure (*E*) **8**-Li); in contrast, **3**-Li will suffer a destabilizing influence at the methyl on the lithiation site in either the *E* or *Z* configurations. Further support for this explanation is seen in the pK value for **15**.

The data for the endocyclic ketimines, **9** to **12**, support our earlier contention that the lithiation occurs in the *anti* position effectively by default, since *syn* lithiation would produce an anion whose internal C═C═N bond angle is highly strained when unable to attain the optimum value of 133°. Comparison of **9** with **1** shows that the endocyclic imine is considerably less acidic, though not as much as anticipated on the basis of the completely selective *syn* deprotonation of **1** versus *anti* deprotonation of **9**. Perhaps there is also a stabilizing effect of the cyclic structure on **9**-Li, conceivably in making the optimum C—C—N bond angle of 127° easier to achieve than in **1**.



(E) **3**-Li (Z) **3**-Li (E) **8**-Li

Since we have been continuing our theoretical studies (3) on imines and their lithio derivatives, we have available the results of our *ab initio* calculations for the effect of a methyl group on the deprotonation of aldimines versus ketimines for comparison with experiments. The deprotonation energies, obtained from optimization of all structures at the 4-31G level (23), appear in Fig. 1. Since the calculations refer to the free anions in the gas

[5]Very recently, a complete reversal of regioselectivity was reported to be attainable by changing the lithiation agent from LDA to an alkyllithium; see ref. 22. There is additional evidence (D. E. Bergbreiter, private communication) that the reason for the reversal is that totally *anti* deprotonation yields the high proportion of most substituted carbanion which reflects the ratio of *syn*—*anti* isomeric imines.

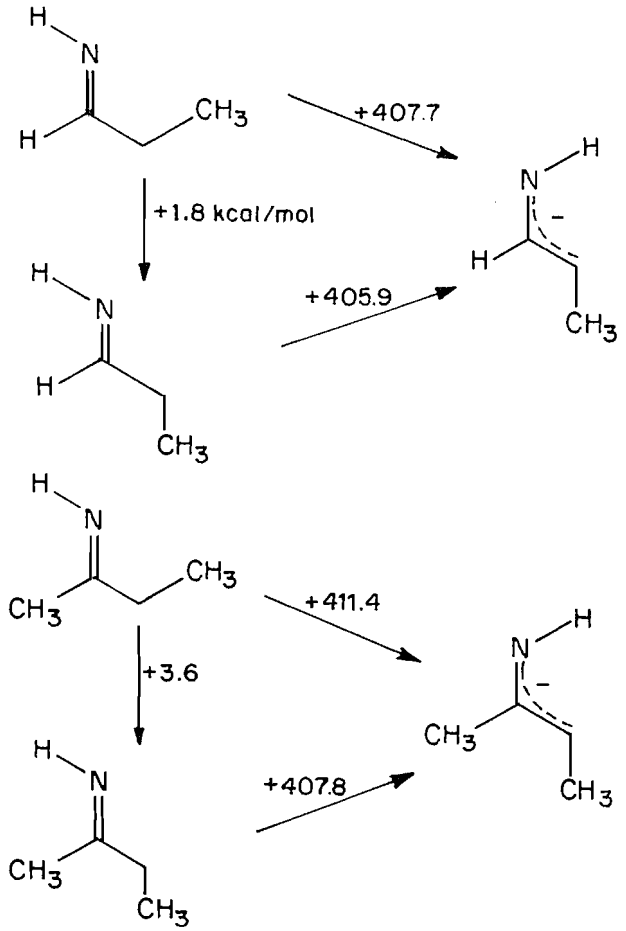


FIG. 2. A comparison of the calculated deprotonation energies of propionaldimine and 2-butanone imine with the inclusion of conformational effects in the neutral imine.

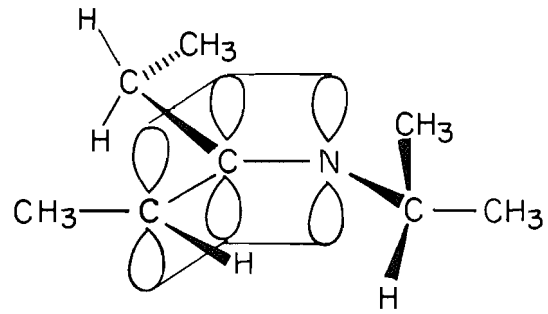
phase, the close agreement between computations and experiment suggests that lithium coordination of the anions, and aggregation and solvation of the resulting ion pairs, must occur with equal exothermicity, or with exothermicity approximately linearly related to anion stabilities. Figure 1 also presents the difference in deprotonation energies for abstraction of the endocyclic versus exocyclic proton in 2-methylpyrroline. Here there is a qualitative accord with experiment, the observed exclusivity in *exo* abstraction being much more than that suggested by either the calculations (done at the STO-3G level for these two reactions) or the pK_a data.

The large difference in the acidity of **4** and **15**, and the similarity between the acidities of **15** and **6** can be understood with the aid of calculations. The preferred conformations of propionaldimine and of methyl ethyl ketimine, each having the allylic methyl group eclipsed with the CN double bond, are shown in Fig. 2. Also shown are higher energy conformations of each in which the N—C—C—C fragment has the same planar arrangement as in the most stable (*E*) conformations of their corresponding anions (25).[6] The energy for deprotonation of the ketimine is calculated to be 3.7 kcal/mol more endothermic than for the aldimine and appears to be due, in part, to the energetically more demanding change in conformation of the ketimine. Compound **15**, which is already constrained to the same conformation as that of the most stable anion, is therefore more easily deprotonated than **4** (by an amount which the calculations for methyl ethyl ketimine indicate to be 3.6 kcal/mol).



4-Li

The pK value for the isobutyraldimine **13** provides valuable information regarding the magnitude of the "*syn* effect" (11), that factor responsible for complete *syn* lithiation. We had earlier estimated it to be in excess of 4 kcal/mol (1). We have established the stereochemistry of the anion **13**-Li to be entirely *syn* in THF through variable-temperature ^{13}C studies (26), indicating the *syn* **13**-Li anion to be at least 2 kcal/mol more stable than its *anti* form (assuming we would be capable of detecting 4% of *anti*). Since *syn* **13**-Li is strained by 2 kcal/mol as indicated by the pK value for **13** being 2.1 units higher than for **8**, yet exists solely in the *syn* configuration, we can assess a minimum value of 4 kcal/mol to the "*syn* effect."

Experimental

All ^{13}C spectra were recorded on a Varian TF-80 nmr spectrometer. In order to obtain accurate quantitative results, it was necessary to ensure that effects due to differential T_1's were negligible. For this reason the signals chosen to measure $[HA_1]$ versus $[HA_2]$ and $[A_1^-]$ versus $[A_2^-]$ or their alkylation products had similar structures. For example, a pair of methyl, methylene, or methine groups would be selected and quarternary carbons were not used. Furthermore, the repetition rate and pulse angle were varied to test for a variation in intensity ratios. It was found that use of a pulse angle of 26° and a one-second repetition rate gave intensity ratios which were not altered (±5%) by a further decrease in pulse angle or increase in delay time between acquisitions.

All alkylation reactions were carried out under the atmosphere of nitrogen and all reagents added by syringe.

Method (a): measurement of ΔpK by competitive alkylation

A typical procedure is as follows: to a septum-capped flask under an atmosphere of nitrogen was added 0.46 mL (3 mmol) of diisopropylamine in 4 mL of dry THF. To this stirred solution at −20°C was added 1.4 mL (3 mmol) of n-butyllithium in hexane. After 10 min, 3 mmol of **4** and 3 mmol of **6** were added. The flask was then warmed to 0°C and stirring continued for 1 hour. After cooling the mixture to −78°C, 0.39 mL (3.1 mmol) of benzyl bromide was added and stirring continued for 1 hour. The solution was concentrated at −20°C and 3 mL of deuterochloroform was added. The solution gave a ^{13}C nmr spectrum which indicated the presence of **4** and **6** and their alkylation products. By recording the spectrum immediately over a 17 minute period it was possible to obtain a spectrum in which only the presence of *syn* benzyl derivatives could be detected. Even in the case

[6]In this paper, the *E* configuration has been observed for lithiated *N*-cyclohexyl propionaldimine and lithiated *N*-*tert*-butyl propionaldimine (as indicated by J_{H-H} = 15 Hz for the attached vicinal protons). The extra ethyl group in **4**-Li would not affect the stability of this configuration on the basis of previously observed *cis* preference in butenyllithiums (27). The same paper reports partial isomerization of the *E* to *Z* isomer when hexamethylphosphoramide is added.

For personal use only.

of the alkylations of aldimines **7** and **8** this rapid work-up and spectral acquisition avoided complication by the presence of *anti* isomers.

Method (b): direct measurement of equilibrium position

In a typical experiment, 2 mmol of lithium diisopropylamide were prepared by the addition of 0.95 mL (2 mmol) of butyllithium in hexane to 0.28 mL (2 mmol) of diisopropylamine in 2 mL THF. A mixture of two imines (2 mmol of each) was then added and the solution stirred for 30 min. The solution was then transferred under argon to an nmr tube filled with argon. The tube was capped, wrapped with Parafilm, and subjected to ^{13}C nmr analysis. Typically, 3 to 5 thousand transients gave a spectrum having sufficiently low signal-to-noise to allow accurate intensity measurements.

Theoretical calculations

The *ab initio* calculations were performed using the GAUSSIAN 80 program by J. S. Binkley, R. A. Whiteside, R. Krishnan, R. Seeger, D. J. DeFrees, H. B. Schlegel, S. Topiol, L. R. Kahn, and J. A. Pople, QCPE 406, Quantum Chemistry Program Exchange, Indiana University, Bloomington, IN. The program was modified for Harris 800 and DEC 1099 computers by Dr. John H. Yates.

Received March 9, 1983

RAMANATHAN GOPAL, BEVERLY E. ROBERTSON, and JOHN A. WEIL. Can. J. Chem. **61**, 2735 (1983).

Crystals of potassium 1-(*N*,*N*-diphenylhydrazono)-2,4,6-trinitrobenzenide, $C_{18}H_{12}N_5O_6K$, are monoclinic, $P2_1/c$, a = 9.871(2), b = 12.940(3), c = 16.754(4) Å, β = 118.31(1)°, Z = 4, T = 22°C. Diffraction data were collected on a modified Picker FASC-1 diffractometer. The structure was solved by direct methods and refined by full-matrix least-squares to $R = R_w = 0.056$ using the 2627 independent reflections with $|F_o| > \sigma(|F_o|)$. The benzenide ring shows a significant puckering toward the boat conformation. Some important canonical structures contributing to the average geometry of the molecule are discussed. The bonding sphere of the K^+ cation contains all of the oxygen atoms and the hydrazine nitrogen atom bonded to the trinitrobenzenide group. Two phenyl carbon atoms also have short contact distances to the cation.

RAMANATHAN GOPAL, BEVERLY E. ROBERTSON et JOHN A. WEIL. Can. J. Chem. **61**, 2735 (1983).

Les cristaux du (*N*,*N*-diphénylhydrazono)-1 trinitro-2,4,6 benzéniure de potassium, $C_{18}H_{12}N_5O_6K$, sont monocliniques et appartiennent au groupe d'espace $P2_1/c$ avec a = 9,871(2), b = 12,940(3), c = 16,754(4) Å, β = 118,31(1)°, Z = 4, T = 22°C. On a recueilli les données de diffraction à l'aide d'un diffractomètre modifié de Picker FASC-1. On a résolu la structure par des méthodes directes et on l'a affiné par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de $R = R_w$ = 0,056 pour 2627 réflexions indépendantes avec $|F_o| > \sigma(|F_o|)$. Le cycle benzéniure montre un gauchissement significatif vers la conformation bateau. On discute de quelques structures canoniques importantes qui contribuent à la géométrie moyenne de la molécule. La sphère de liaison du cation K^+ contient tous les atomes d'oxygène et l'atome d'azote de l'hydrazine liés au groupe trinitrobenzéniure. Deux atomes de carbone du phényle sont également très près du cation.

[Traduit par le journal]

Introduction

It has long been known that the addition of bases to solutions of 2,2-diphenyl-1-picrylhydrazine produces a dark colour and the reaction has been assumed to involve the removal of the hydrazine proton (1). Isolation and characterization of salts produced by the reaction was reported by Weil and Janusonis (2) in 1962. Their nmr results indicated that the 1-(*N*,*N*-diphenylhydrazono)-2,4,6-trinitrobenzenide ion was indeed formed. Optical spectroscopic studies showed that the primary peak responsible for the intense colour occurs at 424 nm and is independent of the cationic species present (2). The transitions giving rise to the colour were therefore assumed to be internal to the anion, probably involving quinoid and nitronic canonical structures. A knowledge of the important canonical structures contributing to the ground state of the anion is therefore of interest. This might be inferred both from the precise geometry of the molecule and from the nature of the association between it and the cation.

The present structure determination was therefore undertaken to (*i*) establish unambiguously the existence of the 1-(*N*,*N*-diphenylhydrazono)-2,4,6-trinitrobenzenide ion, (*ii*) determine the nature of the association between the anion and the cation, (*iii*) determine the exact geometry of the anion, and therefore (*iv*) provide information which might lead to a better understanding of the optical transition.

Experimental

$C_{18}H_{12}N_5O_6K$ fw = 433.42
Monoclinic, $P2_1/c$, a = 9.871(2), b = 12.940(3), c = 16.754(4) Å, β = 118.31(2)°, Z = 4, V = 1884.0 Å^3, T = 22(1)°, D_x = 1.528 g cm^{-3}, μ(MoKα) = 3.33 cm^{-1}, F(000) = 867, λ(MoK$\bar{\alpha}$) = 0.71069 Å.

Black crystals of the title compound were prepared by the method described previously by Weil and Janusonis (2), with crystallization from an acetone/petroleum ether mixed solvent. A crystal with dimensions 0.06 × 0.06 × 0.04 cm was selected for data collection. Lattice constants were determined and the Laue group and systematic absences ($h0l$, $l = 2n + 1$; $0k0$, $k = 2n + 1$) indicated space group $P2_1/c$. Data were collected using MoKα radiation in $\theta-2\theta$ scan mode, 2.65° minimum base width, 40 s background counts at the limits of the scan, a scan rate of 1° min^{-1} and a graphite monochromator, up to 2θ values of 50°. Data were collected in the hkl and $\bar{h}kl$ octants. The intensities of three standard reflections were collected after each set of 51 reflections were recorded and were observed to decrease by 7% over the period of the data collection. The intensities of the 3340 independent reflections were compensated for this variation and reduced to observed structure factors using standard procedures. The standard deviation was calculated as $1.0 + 0.01|F| + \sigma$ where σ represents counting statistics. No corrections were made for absorption or extinction effects. Scattering factors for the potassium ion, and carbon, oxygen, and nitrogen atoms were taken from those given by Cromer and Mann and for hydrogen from Stewart *et al.* (3). Corrections for anomalous absorption were not made. The 300 reflections with $E > 1.8$ were used in the multiple solution, logical symbolic addition method of Germain and Woolfson (4). The E map calculated from the best non-trivial solution gave the positions of all of the non-hydrogen atoms. After anisotropic refinement hydrogen atoms were found from a difference map. The largest peaks in the difference map used to locate the hydrogen atoms were those corresponding to the hydrogen atoms themselves.

The structure was refined by the full-matrix least-squares method using isotropic temperature factors for the hydrogen atoms, with the Busing, Martin, and Levy program ORFLS (5). The weighting scheme used in the final cycles of least-squares was given by $w^{-1/2} = 1.065 - 0.0183|F_o| + 0.00032|F_o|^2$. This weighting scheme is based on the assumption that the best estimate of $\sigma(|F_o|)$ in a range of $|F_o|$

[1]These results were reported in partial form, Program and Abstracts, American Crystallographic Association, Series 2, Vol. 6, 72 (1979).

is the average value of $||F_o| - |F_c||$. The final values of $R = [\Sigma||F_o| - |F_c||]/\Sigma|F_o|$ and $R_w = \{[\Sigma w(|F_o| - |F_c|)^2]/\Sigma w|F_o|^2\}^{1/2}$ for 2627 reflections with $|F_o| > \sigma(|F_o|)$ were both 0.056. Using all reflections, the corresponding values were 0.083 and 0.057, respectively. Observed and calculated structure factors, individual anisotropic temperature factors, and equations of the planes of the molecule have been placed in the Depository of Unpublished Data.[3]

Results and discussion

Final atomic positional parameters and U or U_{eq} for non-hydrogen atoms or hydrogen atoms respectively are given in Table 1. The atom numbering scheme as well as the bond lengths and bond angles, with esd's are given in Fig. 1 for the anion, whose existence is confirmed by the results of this structural study.

There are seven oxygen atoms lying within 2.875(3)–3.174(3) Å of the potassium ion; all six independent oxygen atoms are involved at least once and one, O(1), is involved twice. These distances are within the expected range for ionic bonds. The atom N(4) of the hydrazine linkage is also ionically bonded to potassium. As is shown in Fig. 2, these atoms occupy roughly one half of a sphere about the K^+ ion. The other half of the sphere contains a phenyl ring with two short K—C distances.

This unusual coordination about potassium and the short K—C distances are not solely a consequence of the need to coordinate to the atom N(4), because N(4) can be approached without bringing the potassium ion so near one of the phenyl rings. More general packing considerations might explain the geometry of the coordination sphere, but the nature of the short K—C interactions remains of interest. The relevant contact distances to the K^+ ion are given in Table 2. The angles between the planes of the molecule, as defined in Fig. 3, are given in Table 3. The torsional angles of rotation about the C—N bonds to the nitro groups are also given in Fig. 3.

In Fig. 3, plane *10* contains atoms C(7) to C(12) and is closest to the nitro group containing N(2). The dihedral angle between the planes of these groups is forced by steric requirements to be relatively small, at 34.7°. Atoms O(3) and O(1) are only 3.004(4) and 2.709(4) Å from atom N(4). Atom O(1) not only enters into the coordination sphere of two cations but it also forms the two shortest K—O distances. Its N—O distance is also the longest, at 1.242(3) Å. We note that the K^+ ion contains in its coordination sphere atoms N(4) and O(1) of the same anion, forming the equivalent intramolecular linkage as that which might be formed by an intramolecular hydrogen bond in 2,2-diphenyl-1-picrylhydrazyl.

Various important canonical structures contributing to the average geometry of the molecule are shown in Fig. 4. Forms **1**, **2**, and **4** have a multiplicity of 2, to give a total of eight. The 0.067(6) Å shortening of [C(4)—C(5)] over [C(2)—C(3)] and of [C(5)—C(6)] over [C(2)—C(1)] is contributed by some combination of one each of **2** and **4**. The additional 0.030(6) Å shortening of [C(3)—C(4)] over [C(2)—C(3)], and of [C(1)—C(6)] over [C(2)—C(1)], is contributed by **3** and **5** and one of **2** and **4**. We assume that a combination of **2** and **4** is an important contributor to the average structure of the molecule

TABLE 1. Fractional atomic coordinates (× 10^4) and isotropic or equivalent isotropic temperature factors (× 10^3) for potassium 1-(*N*,*N*-diphenylhydrazono)-2,4,6-trinitrobenzenide (esd's in parentheses)

H(18)	−1811(64)	5594(48)	−3922(39)	86(23)

but that a combination of **3** and **5** is less important. However, **5** also decreases [N(3)—C(5)] over [N(2)—C(3)] and [N(1)—C(1)] by 0.022 Å which suggests that **5** is important. These observations and the nature of the coordination sphere of the cation suggest that all forms in Fig. 4 play an appreciable role.

The contribution of canonical structures involving the substituents allows significant puckering of the trinitrobenzenide ring. The least-squares plane fitted to the six atoms of the ring shows the atoms C(1) and C(3) to be approximately 0.10 Å below the plane, the atoms C(4) and C(6) also to be 0.03 Å below, and the atoms C(2) and C(5) are 0.15 and 0.10 Å respectively above the plane. The conformation is clearly *boat*. However, in order to describe the ring in quantitative terms we use the analysis of Cremer and Pople (6). We find for the benzenide ring, in terms of their pseudorotation parameters for six-membered rings, $\theta = 71.9°$, $\phi = 62.3°$, and $Q = 0.23$

[3]Tables of observed and calculated structure factor amplitudes, anisotropic temperature factors and the equations of the planes of this anion are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

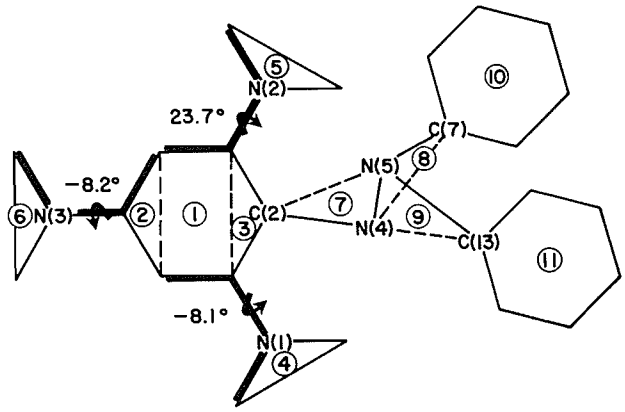

FIG. 3. Designation of the molecular planes of the anion.

(Q is a measure of the magnitude of the puckering). The ϕ angle is nearly an even multiple of 30° which indicates that the ring would have the *boat* conformation if θ were 90°. However, the two folds of the molecule, which correspond to the dihedral angles between planes *1* and *2* and between planes *1* and *3*, are 8.5° and 20.0°, respectively. If these dihedral angles were equal, the parameters describing the conformation of the molecule would approach much more closely to those of the *boat* conformation.

The hydrazine linkage to the trinitrobenzenide group (plane *7*) is nearly coplanar with that part of the trinitrobenzenide group to which it is bonded (plane *3*). The nitro group at C(3) is rotated 25.7° from the plane of the central part of the benzenide ring (plane *1*) and 44.8° from plane *3*. This rotation is much greater than that of the other nitro groups but it has not significantly affected the C—N bond length relative to the other C—N bonds to nitro groups although all show evidence of some double bond character.

We now compare the geometry of the 1-(*N*,*N*-diphenyl-

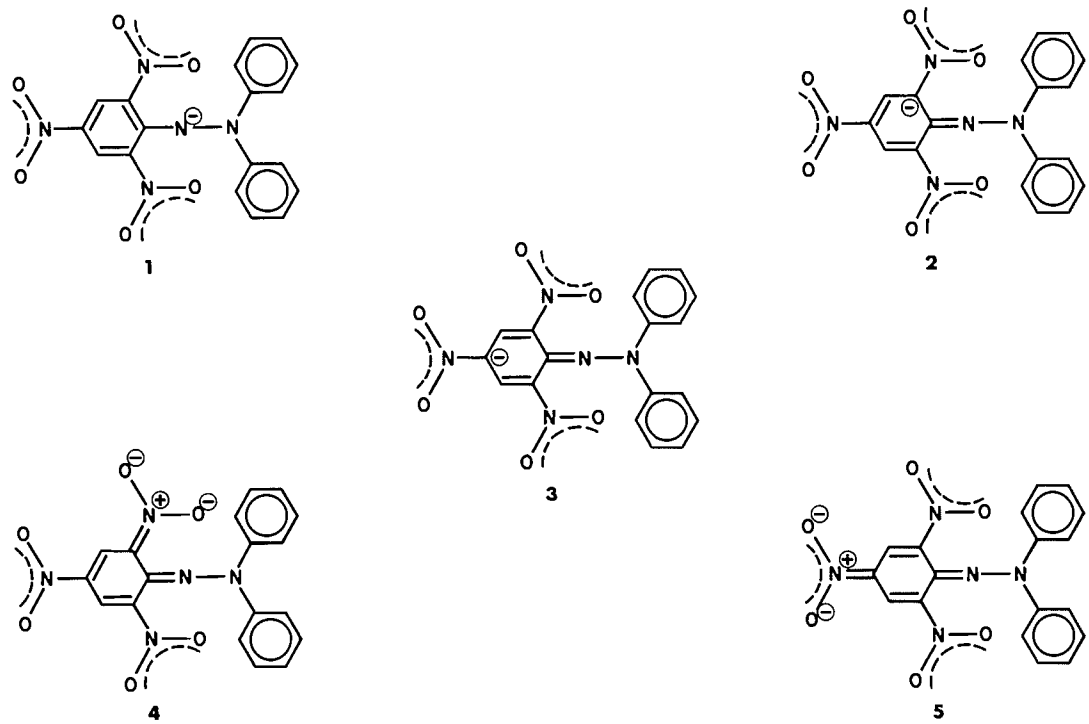

FIG. 4. Important canonical structures of the trinitrobenzenide ring contributing to the anion in its ground state.

hydrazone)−2,4,6-trinitrobenzenide with that of the related free radical 2,2-diphenyl-1-picrylhydrazyl. The molecule exists in several crystalline forms but the more precise structural determination is that of Kiers *et al.* (7). The N—N bond length in the anion, 1.412(3) Å, is 0.076 longer than the average value for the N—N bonds in the two independent molecules of the free radical, as found in the aforementioned structure determination. Similarly, the C(2)—N(4) bond length, 1.303(4) Å, is 0.061 Å shorter than in the free radical, clearly demonstrating the influence of the canonical structures shown in Fig. 4. The N—N bond length found here compares with the single N—N bond length of 1.390(8) Å in the room temperature structures of tetraphenylhydrazine (8) (the value at −160°C is 1.406(4) Å). The C(2)—N(4) bond length compares with the C—N double bond length of 1.287(4) Å, as determined in *N*-(diphenylmethane) aniline at −160°C (9).

The trinitrobenzenide ring in the free radical is nearly planar. As a result, the two *ortho nitro* groups are rotated through large angles to avoid close contacts between nitro oxygen atoms and N(4). In particular, the nitro groups analogous to O(1)—N(1)—O(2) in the ion are rotated 60.6 and 57.1° from coplanarity with the trinitrobenzenide ring in the two independent molecules of the free radical. The *boat* conformation in the ion obviates the need for much of this rotation.

The two phenyl rings are oriented similarly in the ion and in the free radical. The dihedral angle between the planes of the two rings in the anion is 70.6°, compared to 62° and 65° in the free radical. However, the geometry of the central moiety of the molecule containing the hydrazine linkage and the atoms C(7) and C(13) are quite dissimilar. In the free radical these four atoms are nearly coplanar. In the ion, atoms C(7) and C(13) are 0.71 and 0.76 Å removed from planes *9* and *8* respectively.

New multidentate ligands. XXI. Synthesis, proton, and metal ion binding affinities of *N,N′,N″*-tris[2-(*N*-hydroxycarbamoyl)ethyl]-1,3,5-benzenetricarboxamide (BAMTPH)

ISAO YOSHIDA, ICHIRO MURASE, RAMUNAS J. MOTEKAITIS, AND ARTHUR E. MARTELL[1]
Department of Chemistry, Texas A&M University, College Station, TX 77843, U.S.A.

Received February 22, 1983

ISAO YOSHIDA, ICHIRO MURASE, RAMUNAS J. MOTEKAITIS, and ARTHUR E. MARTELL. Can. J. Chem. **61**, 2740 (1983).

Synthesis of a new tris-bidentate multidentate ligand, *N, N′, N″*-tris[2-(*N*-hydroxycarbamoyl)ethyl]-1,3,5-benzenetricarboxamide (BAMTPH), designed for the binding of trivalent metal ions such as Fe(III), Ga(III), and Al(III), is described. Its cation binding affinities for hydrogen ion and for Fe(III), Co(II), Ni(II), Cu(II), Zn(II), Ga(III), and Al(III) ions are described, and the equilibrium data are compared with those of analogous ligands. The binding constants of trivalent metal ions with the ligand do not show a chelate effect relative to the binding to individual bidentate hydroxamic acids.

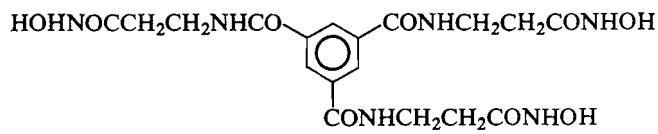
ISAO YOSHIDA, ICHIRO MURASE, RAMUNAS J. MOTEKAITIS et ARTHUR E. MARTELL. Can. J. Chem. **61**, 2740 (1983).

On décrit la synthèse d'un nouveau ligand bis tridentate multidentate, *N,N′,N″*-tris[(*N*-hydroxycarbamoyl)-2 éthyl]benzène-tricarboxamide-1,3,5 (BAMTPH) conçu pour se lier aux ions métalliques trivalents comme le Fe(III), le Ga(III) et le Al(III). On décrit les affinités de liaison de ce ligand pour les ions hydrogènes et pour les ions Fe(III), Co(II), Ni(II), Cu(II), Zn(II), Ga(III) et Al(III) et on compare les données d'équilibre avec celle de ligands analogues. Les constantes de liaison des ions métalliques trivalents avec le ligand ne montrent aucun effet de chélation par rapport à la liaison avec des acides hydroxamiques qui sont des bidentates individuels.

[Traduit par le journal]

Introduction

A major group of the numerous microbial ligands for the complexation of iron(III) are hydroxamic acids such as the ligands in ferrichromes and the ferrioxamines (1). Ferrichrome in particular has a large polypeptide macrocyclic structure holding three side chains, each containing a hydroxamate group in sterically favorable configuration for formation of a stable macrocyclic complex of iron(III), gallium(III), and other trivalent ions. The ligand described in the present paper is analogous to the natural iron(III) carriers in that it contains three hydroxamic acid groups bound to the 1,3,5-positions of a benzene ring. These donor groups are sterically arranged in positions that allow facile binding to a single metal ion. This paper describes the synthesis of this ligand, *N,N′,N″*-tris-[2-(*N*-hydroxycarbamoyl)ethyl]-1,3,5-benzenetricarboxamide (BAMTPH), **1**, and a potentiometric and spectrophotometric study of its affinity for iron(III) and representative trivalent and divalent metal ions.



1

Experimental

N,N′,N″-Tris(2-carboxyethyl)-1,3,5-benzenetricarboxamide

An ether solution (200 mL) of 1,3,5-benzenetricarbonyl chloride (27 g, 0.1 mol) was added dropwise at 5–10°C with vigorous stirring to an aqueous solution (250 mL) of β-alanine (36 g, 0.4 mol) and potassium hydroxide (46 g, 0.8 mol). The mixture was stirred further at room temperature for 2 h. The aqueous layer was acidified with 3 *M* sulfuric acid and the resulting precipitate was collected by filtration. Yield 36 g (86%). The sample was recrystallized from boiling water and dried at 60°C under vacuum, mp 257–258°C (decomp). ^{1}H nmr (D_2O + NaOD) δ 2.6 (t, J = 7.5 Hz, 6, CH_2), 3.66 (t, J = 7 Hz, 6, CH_2), 8.25 (s, 3, ArH). Ir (KBr) 1722 (s, COOH), 1640 (s, amide I), 1540 (s, amide II). *Anal.* calcd. for $C_{18}H_{21}N_3O_9$: C 51.06, H 5.01, N 9.93; found: C 50.91, H 5.08, N 9.89.

[1]To whom all correspondence should be addressed.

N,N′,N″-Tris(2-ethoxycarbonylethyl)-1,3,5-benzenetricarboxamide

A suspension of the acid (18 g, 0.043 mol) in absolute ethanol (200 mL) containing 0.50 g of *p*-toluenesulfonic acid was refluxed for 48 h and a clear solution was obtained. Ethanol (100 mL) was removed by distillation, absolute ethanol (100 mL) was added, and the solution was refluxed further for 24 h. The solvent was removed by distillation under reduced pressure to give an oily residue which solidified upon standing. It was treated with ether, filtered, and dried under vacuum. Yield 21 g (96%). The sample was recrystallized from dilute ethanol, mp 110–111°C. Ir (KBr) 1727, 1710 (s, ester C=O), 1670, 1638 (s, amide I), 1522 (s, amide II). *Anal.* calcd. for $C_{24}H_{33}N_3O_9$: C 56.78, H 6.57, N 8.28; found: C 56.24, H 6.49, N 8.17.

N,N′,N″-Tris[2-(N-hydroxycarbamoyl)ethyl]-1,3,5-benzenetricarboxamide

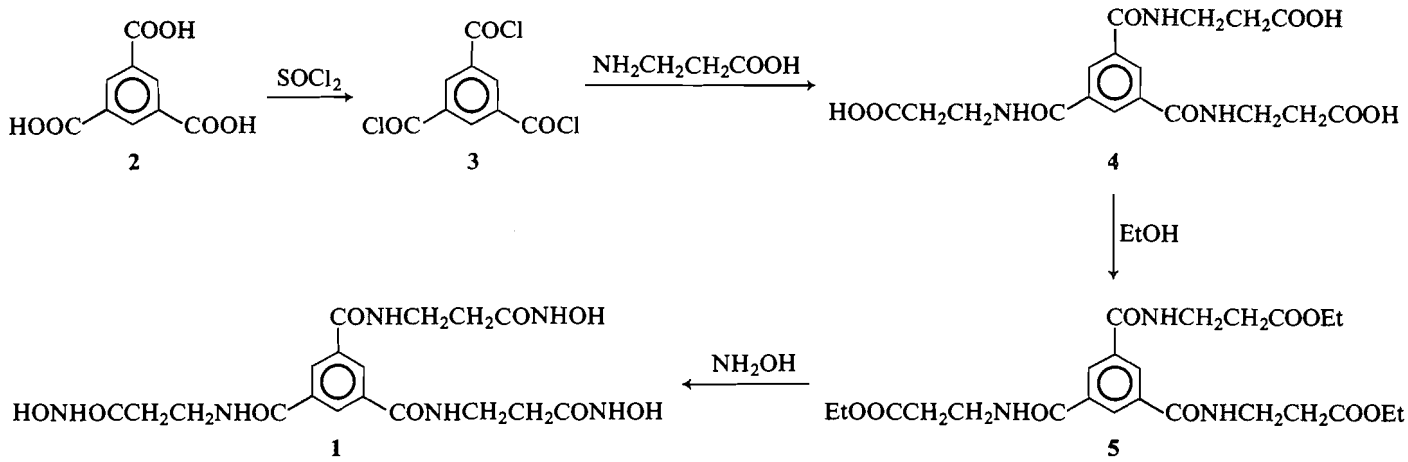
An alkaline solution of hydroxylamine was prepared by mixing hydroxylamine hydrochloride (8.4 g, 0.12 mol) in methanol (50 mL) and potassium hydroxide (11.8 g, 0.20 mol) in methanol (30 mL) at a temperature below 30°C, followed by filtration of the resulting potassium chloride. To the filtrate was added a methanol solution (30 mL) of the ester (10.1 g, 0.02 mol) and the mixture was stirred for 3 days at room temperature. A potassium salt of the hydroxamic acid was obtained as an insoluble precipitate. It was suspended in methanol (150 mL) and an excess of acetic acid was added to give a clear solution. It soon became turbid and a colorless precipitate was obtained after standing 1 h in a refrigerator. The product was collected by filtration and recrystallized from 90% methanol. Yield 5.2 g (55%), mp 139–140°C. Ir (KBr) 1650, 1638 (s, amide I), 1543, 1530 (s, amide II). *Anal.* calcd. for $C_{18}H_{24}N_6O_9$: C 46.14, H 5.17, N 17.94; found: C 46.13, H 5.27, N 17.76.

Apparatus

The equipment employed consisted of a Cary Model 14 vis–uv spectrophotometer, a Corning Model 130 pH meter equipped with extension calomel reference and high pH glass electrodes, a Metrohm 10-mL piston burette, a Haake refrigerated constant temperature bath set at 25.0°C, an all-glass jacketed, stirred, and sealed 50 mL reaction vessel, and a Varian EM 390 NMR spectrophotometer.

Reagents

The ferric salt, $Fe(NO_3)_3 \cdot 9H_2O$, was obtained as reagent grade material from Baker Chemical Co. The gallium employed was the pure metal. Other materials used were: $Al(NO_3)_3 \cdot 9H_2O$ (Baker); $Co(NO_3)_2 \cdot 6H_2O$, $Ni(NO_3)_2 \cdot 6H_2O$, $Zn(NO_3)_2 \cdot 6H_2O$ (MCB); KOH, 0.100 *M*, CO_2-free Dilut-It^R (Baker); and doubly distilled water.



Experimental solutions

Stock solutions of metal salts were prepared by dissolving the appropriate compound and determining the metal ion concentrations by EDTA titration procedures found in Welcher (2) or Schwarzenbach (3). Standard gallium chloride solution was prepared by dissolving a weighed amount of gallium metal in 1 mL of concentrated HCl with heating followed by quantitative dilution. Excess mineral acid in the iron(III) solutions was determined potentiometrically, taking into account the hydrolysis constant for the ferric ion (4). For the gallium solution, Gran's method (5) was employed.

Experimental procedures

Potentiometric equilibrium measurements were made with a Corning research pH meter calibrated to read $-\log [H^+]$ directly by using solutions containing standard 0.01–0.0001 *M* HCl with KNO_3 added to maintain $\mu = 0.100$ *M* at 25.0°C. The basic region was standardized in a similar manner with standard KOH solution. The calibration was checked after each experiment. For each metal ion – ligand system, as well as for the ligand alone, the pH profile was determined from pH 2 to pH 11. The detailed procedure has been described in previous publications (6, 7). Care was taken to exclude carbon dioxide and other contaminants and to obtain the best quality data possible.

Computations

Protonation constants were computed with the FORTRAN program PKAS (8) while the stability constants were in general computed using the FORTRAN program BEST (9). The Fe(III) binding constant was computed from spectrophotometric data taken over a moderately to strongly acid pH range by treating ϵ_{FeL} as an adjustable parameter to minimize the discrepancies between the constants computed as the ratio of iron/ligand was varied. The computers employed were a PDP 11/44 and a VAX 11/780.

Results

Synthesis and characterization

The new ligand **1** was synthesized from commercially available benzene-1,3,5-tricarboxylic acid **2**. This compound was converted to the acid chloride **3**, which upon treatment with β-alanine was converted to **4**. **4** was then converted to the ester **5** which on treatment with hydroxylamine gave the crystalline ligand **1**. With space-filling CPK molecular models it was shown that the three hydroxamic acid groups may simultaneously coordinate to a central metal ion. This property is made possible by the length of the chains and their inherent flexibility. The purity of the compound was determined by elemental analysis and nmr spectra as shown in the Experimental section and by potentiometric titration.

Proton – metal ion – ligand interactions

Protonation reactions. The trihydroxamic acid, **1**, is an

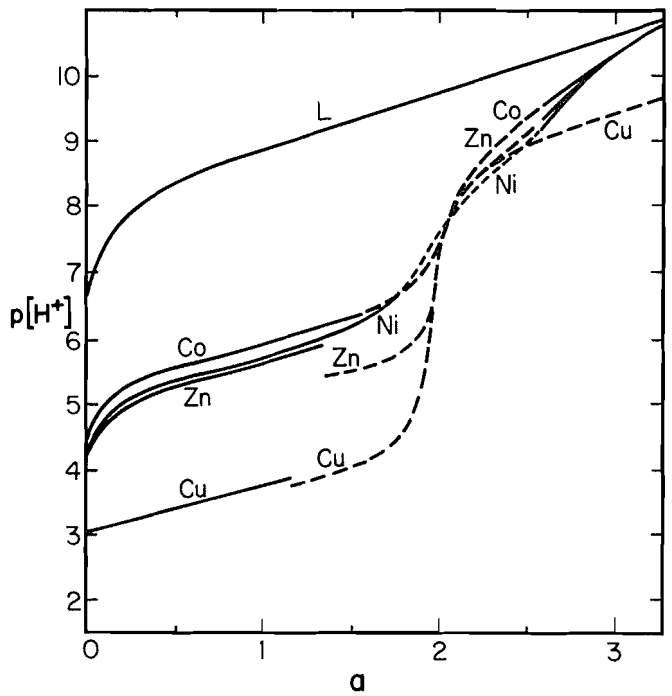


FIG. 1. Potentiometric equilibrium curves for BAMTPH, H_3L, in terms of $-\log [H^+]$ as a function of added base (a = mol KOH/mol ligand) for ligand alone, and for 1:1 molar ratios of ligand to metal ion. In all cases $T_L = 1.058 \times 10^{-3}$ *M*, $T_M = 1.028 \times 10^{-3}$ *M*, $t = 25.0$°C, $\mu = 0.100$ *M* KNO_3.

H_3L-type compound, implying that it has three dissociable hydrogen ions per molecule. The potentiometric equilibrium profile of pH vs. a (a = mol of KOH added/mol ligand present), shown as the upper curve in Fig. 1, has a long high pH buffer zone starting at $a = 0$, and with no break at $a = 3$ because of the high pH of the system. The successive protonation constants calculated for these equilibria are 10.04, 9.33, and 8.48 log units respectively. These values were rounded to two decimals, but the computer-refined constants provided an excellent recalculation of the entire titration curve with a value of $\sigma = 0.0012$ log $[H^+]$. A discussion of the nature and significance of σ values has been published (8). The differences (0.71, 0.85) between the successive protonation constants indicate essentially statistical behavior with negligible intergroup interaction in the absence of metal ions. These values also compare well with acetohydroxamic acid which has

a protonation constant of 9.36 (10). This comparison indicates the absence of inductive interactions through the connecting amide groups because of the insulating methylene groups on each side chain.

Divalent metal ion interactions. The potentiometric behavior of the divalent ions investigated was found to be similar near neutral pH, but markedly different for Cu(II) at pH ~7–10. As shown in Fig. 1, each divalent ion produces a two-proton displacement buffer region, part of which is obscured by precipitation. In the cases of Co(II), Ni(II), Cu(II), and Zn(II) these precipitates are the neutral MHL species, and form at a values of 1.5, 1.8, 1.1, and 1.5 respectively. Accurate stability constant computations were found to be possible in each soluble region and the calculated results are listed in Table 1. The formation equilibria at low pH were therefore found to be:

$$[1]\quad M^{2+} + H_3L \rightleftharpoons MH_2L^+ + H^+$$

$$[2]\quad MH_2L^+ \rightleftharpoons MHL^0 + H^+$$

Beyond $a = 2$ the highly insoluble MHL^0 species dissolved in proportion to the amount of base added, and with the exception of Cu(II), each system cleared up when the neutralization value reached $a \cong 2.5$ to give a completely clear solution. Equation [3] expresses the reaction that occurs in this buffer region.

$$[3]\quad MHL \rightleftharpoons ML^- + H^+$$

The corresponding chelate protonation constants are listed in Table 1. It should be borne in mind that they were computed at pH values near those at which precipitation occurred. The high pH curve at $a > 2$ for Cu(II) indicates that $Cu(OH)_2$ forms and that the ligand is not able to keep divalent copper ion in solution at these pH values, perhaps because the ligand is not able to conform sterically to the well-known square planar coordination tendency of the metal ion.

Trivalent ions. When Fe(III) and H_3L solutions were mixed

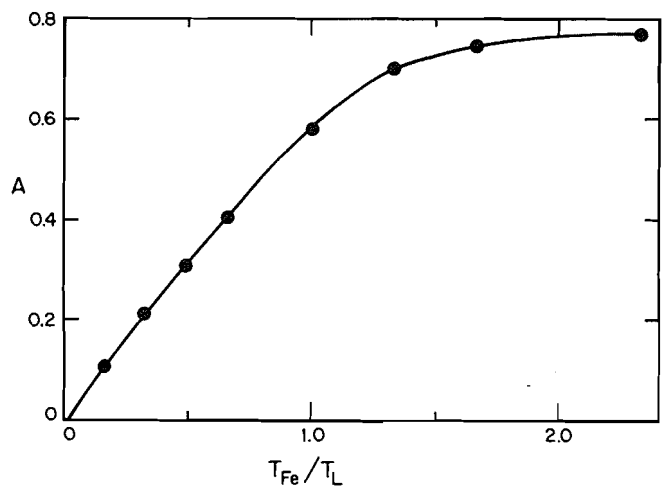

FIG. 2. Absorbance vs. molar ratio of total iron(III)/total ligand measured at 463 nm. $T_L = 3.00 \times 10^{-4}\ M$; $T_{Fe} = 5.00 \times 10^{-5}$ to $7.00 \times 10^{-4}\ M$, $t = 25.0°C$, $\mu = 0.100\ M\ KNO_3$, $-\log [H^+] = 1.80$.

a red precipitate formed immediately from a red solution. Addition of base revealed a strong acid behavior with a break from the acid to the alkaline region at $a = 3$. The total conversion to the products indicated in reaction [4] apparently took place

$$[4]\quad Fe^{3+} + H_3L \rightleftharpoons FeL^0\downarrow + 3H^+$$

at the beginning of the potentiometric determination. In the presence of excess acid, however, achieved by lowering the pH to 1.80 and dilution of the reaction mixture, it was found to be possible to compute the equilibrium constant corresponding to reaction [4] from spectrophotometric data. Figure 2 shows the variation of absorbance with the ratio of a T_{Fe}/T_{H_3L} where T represents the total analytical concentrations of the species involved. The non-limiting slope and the curvature of the plot

indicate the presence of an equilibrium situation. From the data in Fig. 2, the value of log K_{ML} was then computed to be 26.32 ± 0.08 (ϵ_{FeL} = 3324 at 463 nm).

The titration curve of the 1:1 Ga(III)/H_3L solution also provided a strong acid titration, indicating very strong metal ion coordination. After the break at a = 3, there is an indication that Ga(III) may be converted to $Ga(OH)_4^-$, but this matter was not pursued further since equilibrium analysis in the presence of solid phases is difficult. Since Ga(III) is colorless, the stability constant could not be obtained from spectrophotometric measurements.

The equilibrium measurements made on aluminum(III) resulted in the formation of a white precipitate (probably ML) at a = 0.5, beyond which the measurement of useful potentiometric data was not possible. However, an approximate formation constant was calculated directly and was found to be log K_{ML} = 21.85 ± 0.01.

Discussion

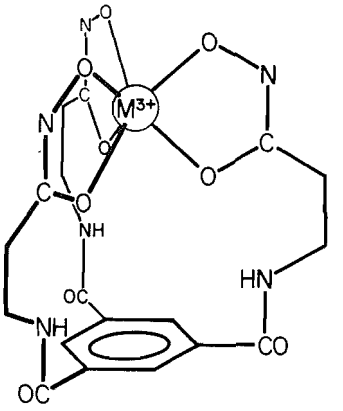
The results demonstrate that it is possible to utilize basic principles for the design and synthesis of chelating agents possessing desirable properties. It is disappointing in this particular case, however, that the neutral species CoHL, NiHL, ZnHL, CuHL, and GaL, FeL, and AlL are insoluble. On the other hand, it is obvious now that the use of appropriate solubilizing groups would convert the ligand and its chelates to more soluble compounds without the loss of metal ion affinity, and that such compounds should be the subject for further investigations.

Both internal comparisons and comparisons with published data reveal interesting structural information for the probable arrangements of coordination linkages around each metal ion.

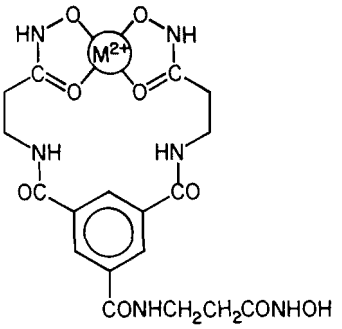
The most obvious difference between the metal chelates investigated is the approximately ten orders of magnitude between the stabilities of the di- and trivalent metal chelates. Also, the absence of protonated complexes of the Fe(III), Ga(III), and Al(III) chelates indicates the participation of all three hydroxamate groups in complex formation even at very low pH when these trivalent metal ions combine with the ligand.

The fact that the protonation constant of the ML species for the Ni(II), Co(II), and Zn(II) complexes is 8.8−9.2 strongly supports the conclusion that in the divalent systems, only two arms of the ligand are utilized for coordination while the third probably is extended away from the metal center, and exhibits little or no apparent interaction with the metal ion. In dramatic contrast, the log $K^{H}_{MH_2L}$ values for these metals range from 5.2−4.8 (values much smaller than ~9) indicating a strong tendency for the participation of two hydroxamic acid moieties in complex formation. Thus divalent metal chelates can be represented schematically by the general formula **7** while the trivalent metal chelates are given by **6**.

The stability constant for the formation of a 1:1 chelate between Fe^{3+} and acetohydroxamic acid is $10^{11.42}$ (12). Comparison of this value with the results of this work (26.32) indicates that more than two hydroxamates are bound in the complex formed from the trishydroxamate ligand. In addition, when one compares the overall reactions of 3-acetohydroxamates with Fe^{3+} (log β_3 = 28.3) (12), it is seen that the stability of the latter is just ~2 log units higher than the iron binding constant found in the present work. This comparison shows a substantial lack of any additional stabilization resulting from the fact that the hydroxamate groups are bound to the benzene ring. In fact, it was pointed out by Schwarzenbach (13) that the Fe^{3+} binding constant to desferrichrome (log K_{ML} = 29.1) does not indicate the presence of a chelate effect, or of stabilization through the attachment of the hydroxamate groups to a macrocycle.



6, BAMTPH complex of a trivalent metal ion (formal charges and some H atoms omitted for clarity)



7, BAMTPH complex of a divalent metal ion (formal charges and some H atoms omitted for clarity)

Similar comparisons can be made for tris-acetohydroxamate of Al^{3+} (log β_3 = 21.47) (12) with the value found for K_{ML} in this work (log β = 21.85). This result points to the same conclusion concerning the lack of a chelate effect as was reached in the case of Fe(III), discussed above. A similar conclusion had been reached for a "rhodotorulate" determination of the Fe(III) binding constant (14). Rhodotorulate is a natural bis-hydroxamic acid of bacterial origin.

The log K_{ML} values for the Ni(II), Co(II), and Zn(II) chelates of BAMTPH are only 1.0 log unit larger than that of the bis-acetohydroxamates (12) of these metals. Thus the divalent ions also indicate negligible additional stabilization resulting from attachment of the bidentate moieties of BAMTPH to a benzene ring. The lack of appreciable chelate effects in these systems, previously pointed out by Schwarzenbach (13) and Raymond (14), is reaffirmed by the results of the present paper. This result is no doubt due to the long bridges between the bidentate pairs in the sexadentate and quadridentate ligands, which therefore function essentially independently, and result in the formation of very large chelate rings.

Evans and Wright (1) have shown that a sharp and weak absorption band X, falling within the energy range of a strong and broad band Y, may create a transmission window (hole) in its position due to Fermi interactions. Such holes have been observed in the ir spectra of crystal hydrates by Othen *et al.* (2) and are important in interpreting the shape of the OH stretching profiles (3). In the present paper the presence of Evans holes in the OH stretching region of water is shown in eight samples of formates $M(HCOO)_2.2X_2O$ (M = Mn, Co, Ni and Zn; X = H, D).

The methods of preparation of samples and recording of ir and Raman spectra have been described elsewhere (4). The accuracy in the measurement of band positions is ± 4 cm^{-1}, while the estimated half-widths and relative intensities are dependable within 20% for the OH stretching region.

The isomorphous compounds $M(HCOO)_2.2H_2O$ belong to the monoclinic space group C_{2h}^5 ($Z = 4$) with two inequivalent C_1 sites for each of the species M^{2+}, $HCOO^-$, and H_2O (5). The structural data (6) of $Zn(HCOO)_2.2H_2O$, a representative of the series, indicate that the hydrogen bonding effects are stronger in H_2O(I) than in H_2O(II).

The ir spectra of the samples in the OH and OD stretching regions at 300 K and 93 K are shown in Fig. 1(*A*).The corresponding Raman spectra at 300 K are shown in Fig. 2. The observed band positions along with their relative intensities and half-widths are given in Table 1.

In general the ν_1 mode is stronger than ν_3 mode in the Raman spectra, therefore two very weak bands (e.g. at 3420 and 3120 cm^{-1} in Mn salt) and two very strong bands (e.g. at 3360 and 3268 cm^{-1} in the same salt) in Raman spectra (cf. Table 1) are assigned to the ν_3 and ν_1 modes of water, respectively. A fifth band (at 3218 cm^{-1} in Mn salt) is assigned to the combination mode of different factor group components of ν_2 modes of water ($\nu_2^u + \nu_2^g$). The bands pertaining to H_2O(I) and H_2O(II) are distinguished considering the relative strengths of hydrogen bonding in the two types of water molecules. The lower and higher set of ν_3 and ν_1 bands are obviously assignable to H_2O(I) and H_2O(II), respectively (6).

The ν_2 bands of water are identified by their shifts on deuteration, and are assigned to H_2O(I) and H_2O(II) such that the $\nu_2^u + \nu_2^g$ falls close to the corresponding ν_1 mode of water. Interpretation of the low temperature spectra justifies these choices.

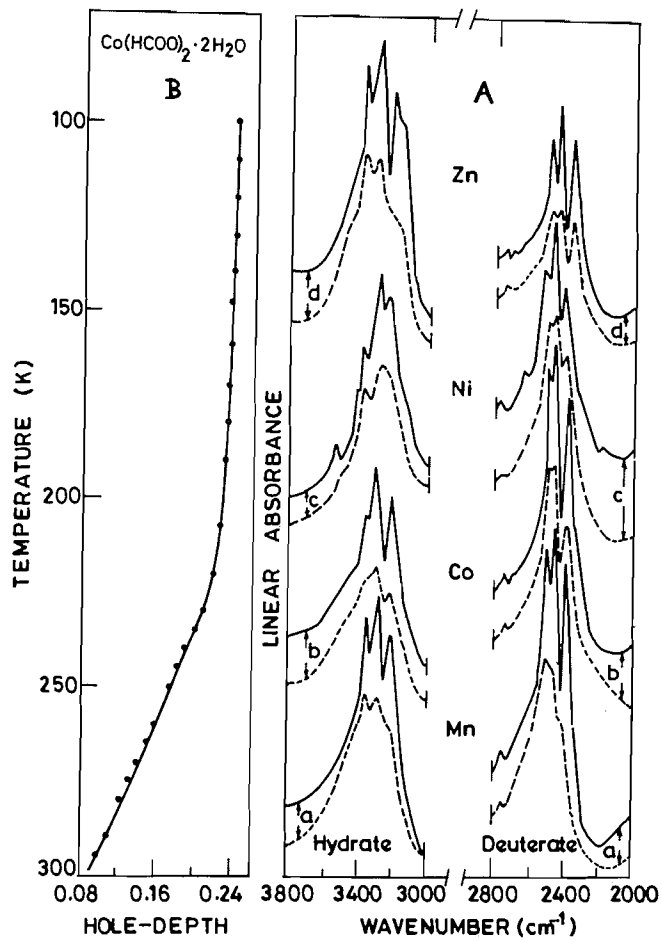

FIG. 1.(*A*) IR spectra of the hydrated and the deuterated formate dihydrates of (*a*) Mn, (*b*) Co, (*c*) Ni, and (*d*) Zn, recorded in linear absorbance mode. The continuous and broken curves in each case represent the spectra at 93 K and 300 K respectively. (*B*) Temperature dependence of hole-depth in $Co(HCOO)_2.2H_2O$. The depth is given in absorbance unit.

In going to 93 K a sharp dip appears between the ν_1 and $\nu_2^u + \nu_2^g$ modes of H_2O(I). This feature is common to all the compounds of the two isotopic series studied, and gets satisfactory explanation on the basis of Evans holes. In the deu-

93	1630	1213	1632	1216	1640	1220	1625	1208	ν_2
	+8	+3	+4	+2	+6	+5	+5	+3	$\Delta\nu_2$

terated salts the hole appears weakly even at 300 K, and gets considerably enhanced in going to 93 K. To study the temperature dependence of the depth of the holes, Co salt was chosen which shows the hole at 300 K in the ir spectrum of its hydrate (cf. Fig. 1(*B*)). The hole-depth increases linearly till the temperature falls to 220 K and thereafter becomes almost constant. In contrast, the hydrated Ni salt shows a weak hole even at 93 K (cf. Fig. 1*A*(*c*)).

The positions of the dip of Evans holes and ν_2 peaks are given in Table 2 along with their shifts ($\Delta\nu_h$ and $\Delta\nu_2$ respectively) in going from 300 K to 93 K. It is observed that the effect of the temperature on the peak of the bending fundamental (shifts towards higher frequencies) broadly agrees in direction and magnitude with the effect of the temperature on the position of the holes (the shifts $\Delta\nu_h$ are approximately twice of $\Delta\nu_2$ within the experimental errors).

The ir-active components of the ν_1 mode of H_2O(I) belong to A_u, B_u species. Suitable combinations of ν_2 mode such as $\nu_2^u + \nu_2^g$ also belong to A_u, B_u species and may thus show strong Fermi interaction with ν_1. Assuming such interactions, the unperturbed frequencies of the interacting bands are obtained from the relation (1, 3):

$$[1] \quad \frac{I_1}{I_2} = \frac{\Delta - \delta}{\Delta + \delta}$$

where I_1 and I_2 are the observed intensities of the weak and the strong bands respectively, Δ is their perturbed (observed) separation, and δ is the unperturbed separation. In the Zn salt the unperturbed position of $\nu_2^u + \nu_2^g$ comes to 3224 cm^{-1}, and we note that this is in close agreement with the position of the hole (3222 cm^{-1}). Such close agreement is an essential characteristic of Evans holes. The observed and the calculated data on Evans holes are given in Table 3, which shows that such agreement holds in all the eight samples studied.

Since the ν_2^g mode expected in Raman spectrum does not show up in our spectra, we use $2\nu_2^u$ as a close approximation to the expected $\nu_2^u + \nu_2^g$, and get 3250 cm^{-1} for H_2O(I) as compared to 3224 cm^{-1} deduced from Fermi interaction formula. Anharmonicity of this order (26 cm^{-1}) is reasonable. Considerable enhancement of the interaction on lowering of temperature is because the downward shift of ν_1 and upward shift of $\nu_2^u + \nu_2^g$ brings them closer at 93 K than at 300 K.

The strength of the interaction between the two levels can be determined by the magnitude of the Fermi-interaction energy,

Studies of the dihedral angle of a crowded diselenide by X-ray crystallography and ultraviolet spectroscopy

THOMAS G. BACK[1] AND PENELOPE W. CODDING
Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received April 25, 1983

THOMAS G. BACK and PENELOPE W. CODDING. Can. J. Chem. **61**, 2749 (1983).

Bis(di-*tert*-butylmethyl) diselenide (**4**) is the first example of a diselenide with an abnormal obtuse dihedral angle resulting from steric crowding. Its value was determined to be 112.1(3)° by X-ray crystallography, as compared with typical dihedral angles of 74–87° for other diselenides. The uv spectrum of **4** supports a similar conformation in solution.

THOMAS G. BACK et PENELOPE W. CODDING. Can. J. Chem. **61**, 2749 (1983).

Le diséléniure **4** est le premier exemple d'un tel composé qui possède un angle dièdre abnormalment étendu à cause de la congestion stérique. Sa valeur de 112.1(3)° était determinée par la crystallographie à rayons X. Par comparaison, les diséléniures typiques ont les angles dièdres entre 74° et 87°. Le spectre uv de **4** est en accord avec une conformation similaire en solution.

The crystal structures of a considerable number of organoselenium compounds have been determined (1). The range of observed values for parameters such as bond angles and bond lengths is well defined for many selenium-containing functionalities and often shows relatively little variation between members of that class. In the case of diselenides **1** (2–6), the C—Se bond lengths typically fall within the range of 1.91–1.97 Å, while the diselenide linkage (Se—Se) has values of 2.285–2.33 Å. These compounds show a consistent preference for conformations where the dihedral angle (C—Se—Se/Se—Se—C) (Fig. 1) is acute and lies within the range of 74°–87°, except when constrained by the imposition of a cyclic structure. Thus, the cyclic diselenide **2** displays a dihedral angle of only 56° (7).

The effects of very bulky substituents on the conformations of diselenides have not been investigated by crystallographic methods. To our knowledge, even the most hindered diselenide with a known crystal structure, bis(diphenylmethyl) diselenide (**3**), exhibits a normal, acute dihedral angle of 82° (2). More recently, Barton and co-workers (8) reported the preparation of bis(di-*tert*-butylmethyl) diselenide (**4**), a stable, crystalline substance. An examination of a model of this compound indicated that steric interactions might be severe enough to result in significant departure from the usual preferred diselenide geometry. Steric congestion could be relieved either through an increase in the dihedral angle or by lengthening of the bonds in the C—Se—Se—C moiety. It is also interesting to note that the analogous triselenide **5**, whose crystal structure has been reported (9), displays normal C—Se and Se—Se bond lengths and moderate extension of the two C—Se—Se/Se—Se—Se dihedral angles to 100.6° and 86.9°. It is evident, however, that any steric effects resulting from the interaction of the bulky terminal substituents are greatly reduced in the triselenide by

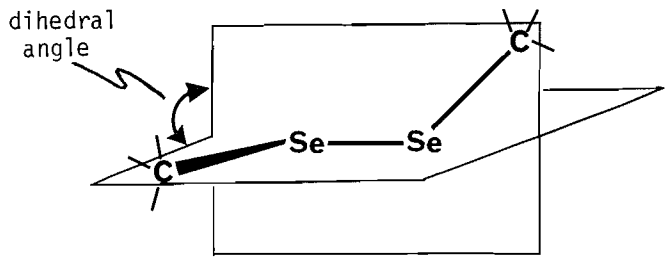

FIG. 1. Conformation of a typical diselenide.

the interposition of the third contiguous selenium atom. To ascertain the extent of such effects in diselenide **4**, we undertook its X-ray crystallographic structure determination. We now report the first example of a diselenide with an obtuse dihedral angle.

Since molecular conformations may differ in the solid state and in solution, we also endeavoured to confirm that diselenide **4** has an abnormal dihedral angle in solution. Compression of the dihedral angle from the preferred value of 74–87° raises the energy of the ground state of a diselenide but has little effect on the excited state (10). Thus, cyclic diselenides such as **2** exhibit strong bathochromic shifts as a result of the lowered excitation energy (11). A similar phenomenon might be expected in the case of a diselenide in which destabilization of the ground state results from the enlargement rather than the compression of the dihedral angle, although such an effect has not yet been documented. We believe that diselenide **4** constitutes the first such example, as it displays a marked bathochromic shift compared to other, less crowded acyclic diselenides.

Experimental

Bis(di-*tert*-butylmethyl) diselenide (**4**) was prepared by the method of Barton and co-workers (8) and was crystallized from hexane–methanol by slow evaporation of the solvent at room temperature. The uv spectrum was recorded on a Varian–Cary 219 Spectrometer in 95% ethanol solution and had λ_{max} = 324 nm (ϵ = 310).

Crystal structure analysis

A yellow plate-like crystal was used for the data collection on an Enraf Nonius CAD4F diffractometer. The crystal data are in Table 1. The procedures for the alignment, space group determination, and intensity data measurements were as described previously (12). Systematic absences of (hkl), $h + k = 2n + 1$; ($h0l$), $l = 2n + 1$; and the symmetry of the diffracted intensities identified the space group as $C2/c$. The intensities were converted to structure factors by the appli-

cation of Lorentz and polarization corrections; no absorption correction was applied. E-values were calculated by applying a K-curve.

The structure was solved using the program MULTAN 78 (13). All of the Se and C atoms were located in the first E-map. After nonlinear least-squares refinement of the atomic positions and thermal parameters (isotropic parameters for the carbon atoms and anisotropic parameters for the Se atoms), a difference Fourier synthesis revealed the positions of at least one hydrogen atom on each methyl carbon atom. This allowed calculation of the position of all the hydrogen atoms; they were included in the model at ideal positions, were assigned an isotropic thermal parameter which was 20% greater than that of the appropriate methyl carbon atom, and were not refined. The positions and anisotropic thermal parameters of the carbon and selenium atoms were refined along with an isotropic extinction correction using the 1444 reflections with $I > 3\sigma(I)$ and the 356 reflections with $I_{calc} > 3 \times \sigma(I_{obs})$. The final cycle had a maximum shift/error of 0.021 and the standard deviation of an observation of unit weight was 0.87. A final difference Fourier synthesis contained four peaks of 0.6 e/Å^3 which were diffraction ripples near the two Se positions; all other peaks were

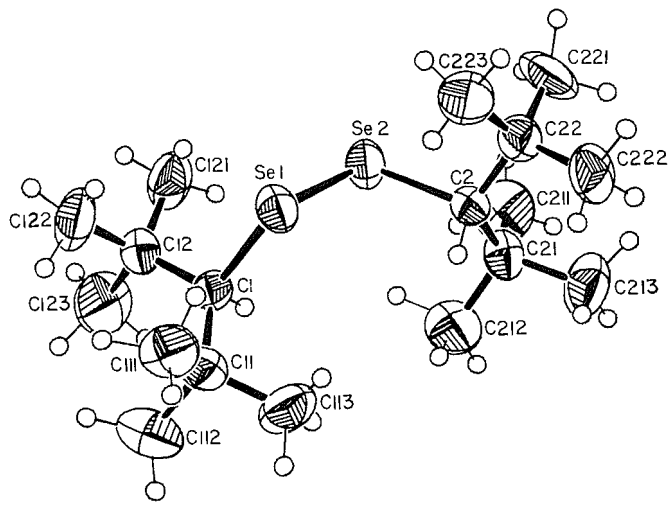

FIG. 2. The conformation and atomic labeling scheme for bis(di-*tert*-butylmethyl) diselenide. The drawing was made with the computer program ORTEP (19), the thermal ellipsoids are drawn at the 50% probability level for Se and C, while the H atoms are represented as spheroids of radius 0.1 Å.

less than 0.3 e/Å^3. The weights were defined as $\omega = 1/(\sigma^2(F_o) + 0.005\ F_o^2)$. The value of g, the isotropic extinction factor, was 4.0(1) × 10^{-3} where the treatment of g followed that of Larson (14). Atomic coordinates[2] for Se and C are given in Table 2 with the atoms labeled as shown in Fig. 2.

All computations were done using the XRAY 76 system of programs (15) on a Honeywell computer with a Multics operating system. The scattering factors were those of Cromer and Mann (16).

Results and discussion

The bond lengths and bond angles in diselenide **4** are shown in Table 3 and an illustration of the structure, including the labeling scheme employed, is shown in Fig. 2. The average C—Se and the Se—Se bond lengths of 2.010(6) Å and

[2] The anisotropic thermal parameters, hydrogen atom parameters, and the observed and calculated structure factor amplitudes are available at a nominal charge from the Depository of Unpublished Data. CISTI, National Research Council of Canada, Ottawa, Ont., Canada, K1A 0S2.

2.315(1) Å, respectively, are only slightly longer than normal values for an aliphatic diselenide. The corresponding values for diselenide **3** are 1.97(1) Å and 2.285(5) Å (2). The bond angles C(1)—Se(1)—Se(2) and C(2)—Se(2)—Se(1) are 102.3(2)° and 101.6(2)°, respectively, and show little variation from those in triselenide **5** (9). Similarly, bond lengths and bond angles in the di-*tert*-butylmethyl residues resemble those of the triselenide, as expected.

The chief steric interactions in **4** involve the selenium atoms and the nearest methyl groups on both the distant and adjacent alkyl residues. The Se2 to C121 distance is 3.472(8) Å and Se1 to C223 is 3.657(9) Å (see Fig. 2); the sum of the van der Waals radii for a selenium atom and a methyl group is 4.0 Å (17). Also, C223 is closest to Se2 at 3.129(9) Å and C121 is closest to Se1 at 3.164(9) Å. All other intramolecular selenium-to-methyl group distances are greater than 4.2 Å when the methyl groups are part of the distant alkyl residue, and greater than 3.4 Å when they are in the adjacent alkyl moiety. The contact between the methyl groups at C212 and C113 is 3.88 Å, again slightly shorter than the sum of the van der Waals radii. The most striking feature in **4** is the abnormally large dihedral angle C1—Se1—Se2—C2 of 112.1(3)°. The crystal structure clearly demonstrates that the principal means for relieving congestion in this crowded molecule is by torsion about the Se1—Se2 bond rather than through the lengthening of bonds C1—Se1, Se1—Se2, or Se2—C2.

The closest intermolecular contacts are between methyl groups; C123 to C222 at $(x, -y, z - 1/2)$ is 3.93(1) Å and C122 to C111 at $(1 - x, -y, -z)$ is 3.99(1) Å. The shortest Se atom to methyl group intermolecular contact is between Se2 and C212 at $(3/2 - x, 1/2 + y, 1/2 - z)$ and is 4.090(9) Å. All other intermolecular contacts are greater than 4.2 Å.

Typical acyclic dialkyl diselenides have uv absorption maxima in the range 286–316 nm, the precise wavelength being determined by three effects: inductive, hyperconjugative, and torsional (or steric) (10–11, 18). Since inductive effects are comparable for different alkyl groups, they will play a relatively minor role in the absence of polar substituents. Hyperconjugation lowers the energy of the electronic transition. Hence, diselenides which contain more α-hydrogens display bathochromic shifts relative to those with fewer or none (18). For example, this phenomenon is chiefly responsible for the difference in the uv spectra of di-*tert*-butyl diselenide, which has no α-hydrogens (λ_{max} = 286 nm), and dimethyl diselenide which has six (λ_{max} = 316 nm). A valid comparison can be made between diisopropyl diselenide and compound **4**, as each has two α-hydrogens. The former compound has λ_{max} = 305 nm (18) whereas we observed λ_{max} of diselenide **4** at 324 nm. If we rule out differences in inductive and hyperconjugative effects, the bathochromic shift of 19 nm for the more hindered diselenide must be attributed to the torsional effect. We therefore conclude that bis(di-*tert*-butylmethyl) diselenide (**4**) exhibits an abnormally large dihedral angle in solution as well as in the solid state.[3,4]

[3] The study of conformational effects in hindered diselenides in solution by nmr spectroscopy may provide an interesting subject for future work.

[4] In response to a referee's suggestion, we attempted to obtain a solid state diffuse reflectance spectrum of diselenide **4** in Nujol and observed the same λ_{max} = 324 nm. However, we suspect that a significant amount of the diselenide dissolves in Nujol under these conditions. A KBr disc transmission absorption spectrum of **4** produced a very broad, flat absorption from which a reliable value of λ_{max} could not be determined.

The reaction products of chrysotile asbestos with titanium trichloride in organic and aqueous media are described. The titanium(III) acidity in H_2O solution is sufficiently strong to cause fiber lixiviation and unrollment. The reaction product of the water reacted fiber is an amorphous titanium containing silicate. A series of reactions with $TiCl_3$ in THF were carried out. The results show that the titanium bonded species is a $Ti^{III}Cl_n$ group with $n \leq 2$. In some experiments as much as 3 wt% titanium was fixed to the fiber without destroying the fiber structure of chrysotile. All the reaction products discussed were characterized by sem X-ray analysis, ir, esr, dta, and elemental microanalysis.

Nous avons fait réagir l'amiante chrysotile avec le trichlorure de titane. Les produits de réaction en milieu organique et en milieu aqueux sont ici caractérisés. En milieu aqueux on constate que l'acidité du titane(III) est suffisamment forte pour causer la lixiviation du chrysotile. Le produit de réaction est un silicate amorphe contenant du titane. Pour les réactions en milieu tetrahydrofurane, la structure fibreuse du chrysotile est préservée. Les essais que nous avons fait en milieu organique indiquent que l'espèce $Ti^{III}Cl_n$, $n \leq 2$ se trouve chimiquement lié à la fibre. Dans les cas extrêmes nous avons réussis a fixer jusqu'à 3% (p/p) de titane à la fibre sans détruire la structure fibreuse. Les produits de réactions ont été caractérisés par analyse thermogravimétrique différentielle, microscopie électronique (morphologie et rayon-X), infrarouge, résonance paramagnétique électronique et microanalyse élémentaire.

Introduction

Asbestos fibers are used as filler in the industrial fabrication of several materials having widespread fields of application such as concrete cement, plastics, paper, etc. (1). For these applications the most important fiber property is its good mechanical performance, which makes it an interesting filling material, for example, in the reinforcement of plastics or for the armature of concrete cement. Studies have shown that the mechanical characteristics of these new composites are related to the physico-chemical interaction at the fiber–matrix interface (2, 3). Hence, in the chemical treatment of fibers, conditioning is an important step aimed at improving chemical interaction between the silicate mineral and the host material without changing the fibers' mechanical properties.

The exact composition of asbestos varies significantly, depending on its origin and history (4, 5). The Quebec 4-T-30 asbestos samples used in this work are known to contain 80–90% chrysotile fibers (5, 6). Chrysotile has the formula $Mg_3(Si_2O_5)(OH)_4$ and is the only known member of its type with a cylindrical structure (7). A detailed atomic structure is given in Fig. 1*A*, showing the hexagonal close packing arrangement of the oxygen and hydroxyl groups forming the $(SiO_4)^{2-}$ tetrahedrons of the silicate layer and the brucite –Mg(OH) octahedrons. The fiber can also be represented, Fig. 1*B*, as a hollow tube with its external surface covered with hydroxyl groups (brucite layer) and the inner hollow center made up of bridging oxygen atoms (silicate layer).

In aqueous media chrysotile has a positively charged surface (55 $\mu C/cm^2$ at pH 7 (8)] and gradually dissociates water until an acid–base equilibrium is reached. To explain this behaviour, chemical and thermodynamical considerations led Ahmed (8) to propose, among others, a reaction scheme in which the freed protons coagulate on the fibers' surface between ca. pH 6 and 10, while the released hydroxyl groups contribute to the solution's basicity. Depending on the fibers' condition, the zero point charge is reached between pH = 10–12. Furthermore, under acidic conditions (pH < 6), rapid decomposition of the fiber is observed due to acidic attack of the brucite layer, Fig. 1*B*. Similarly, in highly basic media (pH > 10) dissolution of the silicate also causes unrollment of the fiber.

Moreover, chemical treatment of asbestos is an important avenue currently being explored for the development of less pathogenic chrysotile fibers (9). Work on the chemical properties of asbestos will give, we believe, more insight into the physiological interaction of silicate minerals in living organisms (10). The biological tests performed on short fiber chrysotile asbestos show a net decrease in the cytotoxic and hemolytic properties for the titanium modified fibers (11). Furthermore, binding of the known carcinogen benzopyrene drops significantly for the titanium treated fibers (in THF) discussed in this work (12). The property of chrysotile to concentrate carcinogenic agents has been linked with the unusually high lung cancer incidence observed in asbestos workers who smoked (10).

In the following sections, the products of reaction of short fiber chrysotile asbestos with $TiCl_3$ in water and in tetrahydrofuran are described. Our main concern in this work was to verify the fibers' condition after reaction and to characterize the resulting titanium species. Titanium treated fibers have in the

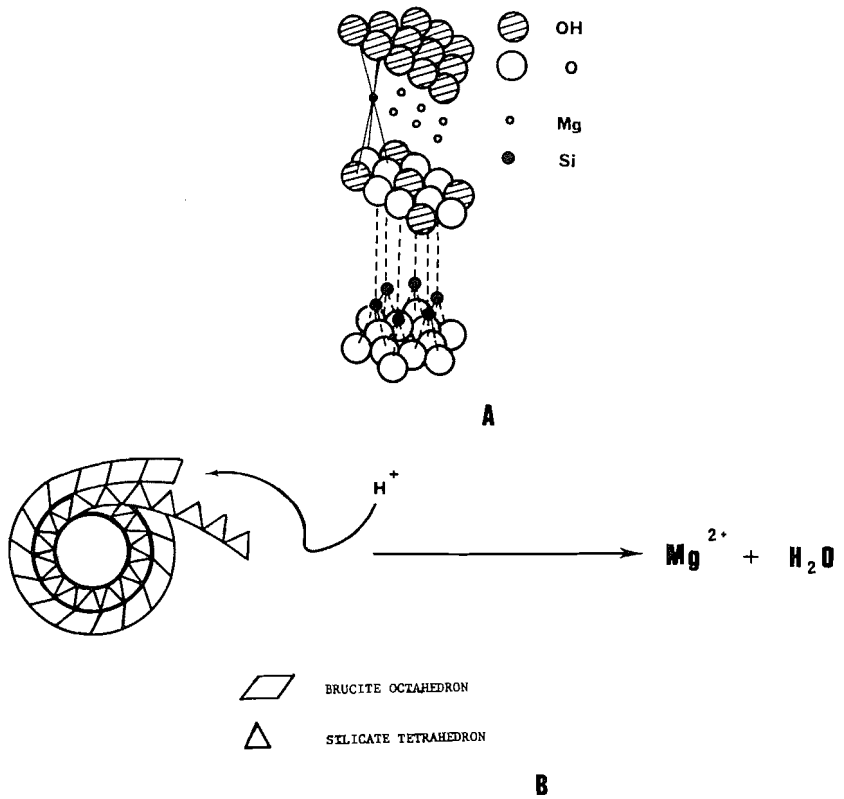

FIG. 1. *A*, Blown-up view of the chrysotile mineral structure, $Mg_3(Si_2O_5)(OH)_4$. *B*, acid lixiviation reaction showing unrollment of the chrysotile fiber.

past been used as paint pigment (13) and filling material in Ziegler-Natta prepared polymers (14). In the latter case, repeated reaction with the pure $TiCl_4$ liquid yielded a maximum titanium concentration in the fiber of 0.28 wt%. To the best of our knowledge no attempts as yet have been made to isolate and identify reaction products of chrysotile asbestos with titanium(III) or (IV) compounds.

Experimental

All the chemical reactions, together with microanalytical analyses, ir, nmr, and esr spectroscopy, were done under anaerobic conditions using Schlenk type vessels and argon filled glove bags. Exceptions are sample preparation for scanning electron microscopy (sem), differential thermogravimetric analysis (dta) experiments, and certain titanium analysis, which were carried out in the open air. Also chemical reactions were repeated at least twice to insure reproducibility of the results.

The argon gas used was first circulated through a copper catalyst, BASF-R3-11 (Badische Anilin und Soda-Fabrik AG, 6700 Ludwigshafen, W. Germany), at 200°C and then on molecular sieve, type 4A, to remove oxygen and water contained in the commercial argon. Titanium trichloride, $TiCl_3$ 98%, purchased from Ventron-Thiokol-Alfa, was stocked under argon and used without any further purification. Tetrahydrofuran (THF) was distilled under argon after refluxing for 30 min over a benzophenone–sodium drying mixture. Aqueous solutions were deoxygenated by distillation under argon. Asbestos fibers classified 4-T-30 from Johns Manville Ltd. (Thetford mines, Quebec) were generously supplied to us by the Asbestos Mining Association of Quebec (AMAQ).[2]

The elemental Mg, Si, and Ti microanalyses were done by atomic flame absorption using a Perkin Elmer model 305 spectrometer (λ = 285.2, 251.6, and 276.8 nm, respectively). Because of the methodology followed, the Mg analysis is reproducible only to ±1 wt% due to dilution factors of the mother solution prepared for all three elements analysed. The C, H, N, and Cl analyses were carried out by Schwarzkopf Microanalytical Laboratory, New York, U.S.A. and by us on a Hewlett Packard 185 CHN analyser. Electron spin resonance (esr) spectra were recorded on a Varian E-9 (9.3 GHz) spectrometer and proton nuclear magnetic resonance (^{1}H-nmr) on a Bruker WP-80-FT spectrometer. Infrared (ir) spectra were recorded in KBr pellets on a Beckman IR-4250 spectrometer and calibrated against a polystyrene film (±3 cm^{-1}) or on a Digilab FTS-11 Fourier transform ir spectrometer. Fiber morphology was checked using an Itec Auto Scan scanning electron microscope (sem) equipped with a Quantex-7000 Kevex energy dispersive (ed) X-ray analyser with which the spectra were recorded. Samples for sem-ed analysis were prepared in the following manner. A thick layer of fibers is formed by syringing through a millipore filter (0.4 μm pores,13 mm diameter), 1 mL containing ca. 0.6 mg fiber from an aqueous solution. The samples were then mounted on a metal stub, dried over night in a vacuum desiccator, and sputtered with gold. Sem morphology verifications were performed on more dilute samples and using Nuclepore filters. Reproducibility of the elemental peak intensity ratios for a given fiber was found to be satisfactory. Variations from one sample preparation to another for the same reacted fibers did not exceed ±5% for $Si/Mg(K_\alpha)$ and $Ti/Mg(K_\alpha)$ ratios under the same spectroscopic conditions. Also, irregular distribution of the fibers on the filter and possibly composition heterogeneity in the fibers themselves is believed to be the prime source of error for the intensity ratios, especially in fibers with more than 2 wt% titanium. Therefore, in all cases discussed hereafter reproducibility of the sem-ed analysis results are compatible with the mean ratio variation averaged for three spectra (covering 1 μm^2 area) taken from the same experiment, i.e., maximum observed variation ±3% and ±12% for Si/Mg and Ti/Mg respectively as indicated in Table 2. Differential thermogravimetric

[2]The designation 4-T-30 is a commercial grading code for medium length asbestos. The fibers of this category are mainly (~80%) 1–4 mm long.

[a]The standard deviations are given in parentheses and are calculated from three different spectra of the same experiment (area = 1 μm^2; acquisition time = 300 s).
[b]Fe/Mg = 0.046 (0.001) for the reaction [A] fibers. This value decreased monotonously with increase titanium ratio in reactions [B]–[I].
[c]In parentheses is the magnesium content found in the reaction filtrates expressed as the wt% fiber loss.
[d]Analyses from other experiments gave lower values, e.g. Mg = 23.20 wt%.
[e]Analysis performed on a different sample of the same experiment gave Ti = 1.73 wt% and Mg = 23.01 wt%.
[f]Analysis performed on a different sample of the same experiment.

experiments were carried out in a nitrogen atmosphere on ca. 20 mg oxidized fiber samples using a Perkin Elmer thermal data system model TGS-2 equipped with a TADS computer. During the experiments the temperature was varied from 50 to 1000°C at a rate of 20°/min.

Sedimentation of short fiber chrysotile

Short fiber chrysotile can be separated from the commercial product in the following way. A glass column measuring 120 cm long and 9 cm wide was filled with 6 L of distilled water to which 60 to 80 g of 4-T-30 asbestos fibers were added in loose bundles. The column was then turned over several times until the fibers were well suspended in the tube. On standing for 1 h, the longer fibers deposited at the bottom and the milky white solution was transferred to a second identical column equipped with a 6 mm stop-cock at the bottom. Coagulation of the short fibers was then triggered by adding 5 g NaBr (ca. 10 m*M*) to the white suspension.[3] Within 10 min the sedimentation was over and the product was recovered through the stop-cock, filtered, and washed with distilled water until the washings were free of bromide (AgBr test). Following this the fibers were predried over P_4O_{10} in a vacuum desiccator, transferred to a Schlenk tube, and further dried for 20 h at 250°C, 10^{-2} Torr. The fibers were stored under argon.

Using this method, two successive separations on a 60.90 g batch of asbestos yielded, respectively, 4.40 and 1.73 g of short fiber chrysotile asbestos for a total yield of 10%. Since chrysotile is very sensitive to pH conditions (5, 8) care was taken to avoid exposing the fibers needlessly to water for long periods.

Reaction of short fiber chrysotile with $TiCl_3$ in THF (method A)

In a typical reaction 0.493 g (3.19 mmol) $TiCl_3$ were mixed together with 1.821 g (6.58 mmol) fibers in a 250 mL Schlenk tube. Freshly distilled THF, 150 mL, was added and the suspension was refluxed under a positive argon pressure. After 20 h, the solution was cooled and the fibers were collected on a fritted disk while the blue THF filtrate was discarded. The fibers were then rinsed with two 50 mL portions of THF and dried on the fritted disk under vacuum for 2 h at ambient temperature. Weight of the dry fibers, 1.647 g. The microanalytical data are given in Table 1. Analyses of the reaction filtrate indicated only slight amounts of magnesium, cf. Table 2.

[3]When NaCl was used as coagulating electrolyte instead of NaBr, a significant amount of halogen (e.g. 2 wt%) was detected in the fiber. Care was taken to make sure that no halogen was left in order to avoid false Cl/Ti atomic ratios in the microanalytic data of the reacted fibers.

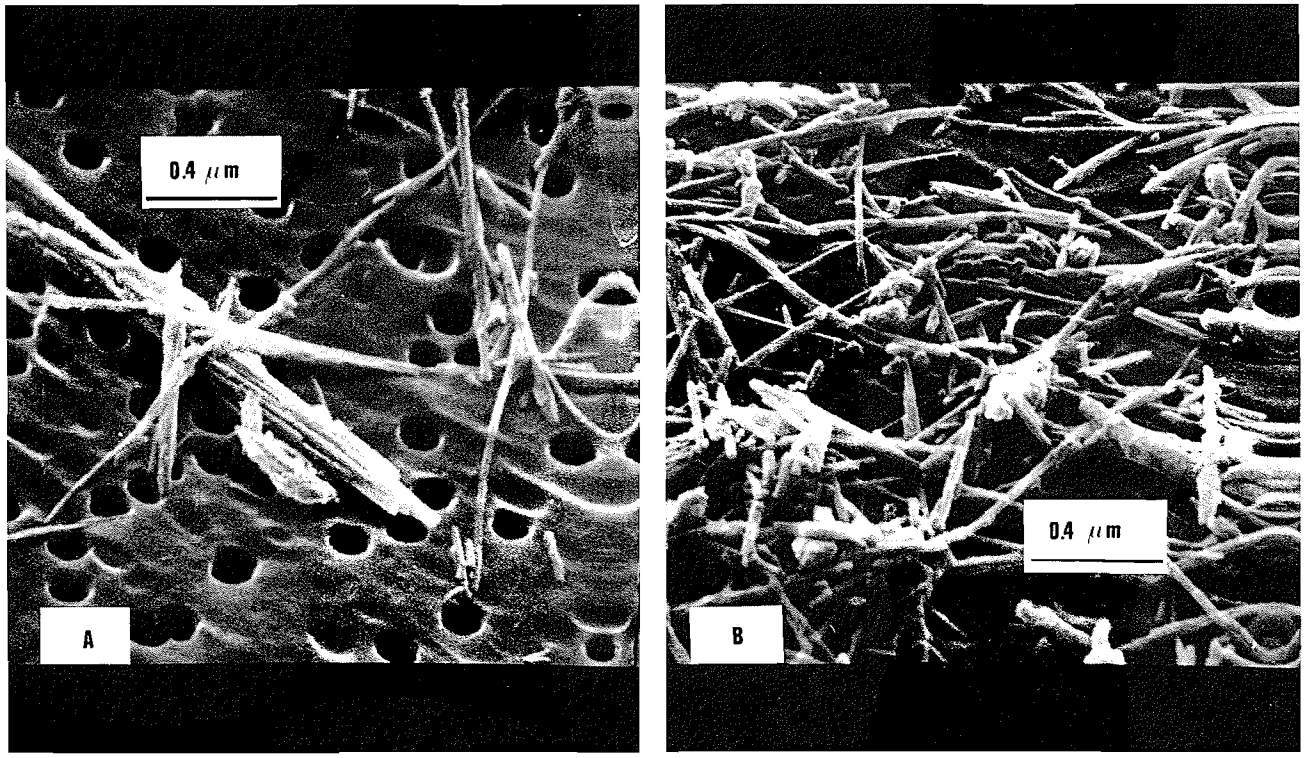

FIG. 2. Scanning electron micrographs (20 000×) of *A*, 4-T-30 asbestos chrysotile showing long fibers and fiber bundles; *B*, $TiCl_3$–THF reacted short fiber chrysotile (reaction [I], Table 2). This micrograph is representative of the monofibril morphology observed after reaction of the sedimented short fibers.

In some reactions a pale blue prismatic air sensitive compound crystallized from the solution upon cooling.This compound analyzed as $TiCl_2(OH)\cdot 2(C_4H_8O)$. *Anal.* calcd.: C 34.31, H 6.12, Ti 17.11, Cl 25.31; found: C 33.46, H 6.15, Ti 17.36, Cl 25.06. Furthermore, ^{1}H-nmr of this compound in D_2O shows two broad featureless resonances at 1.48 and −0.48 ppm (half height width, $H_{1/2}$ = 23 Hz), in acetone-d_6 the resonances are at 1.41 and −0.17 ppm ($H_{1/2}$ = 40 Hz). These values are significantly upfield from those of the free uncomplexed THF, 3.71 and 1.83 ppm (AA′BB′ spin coupled multiplets). No proton nmr signal for the hydroxyl group was observed in the spectra. Nuclei adjacent to a paramagnetic transition metal center such as that found here for Ti—OH are generally hard to detect due to excessive signal broadening.

Reaction of short fiber chrysotile with $TiCl_3$ in H_2O (method B)

The same procedure as in method A was followed using this time 0.890 g (5.76 mmol) $TiCl_3$, 1.060 g (3.82 mmol) fibers, and 100 mL H_2O instead of THF. The mixture was then refluxed for 2 h. From this reaction 0.790 g of air sensitive blue solid was recovered. Microanalysis data of the reaction product are given in Table 1.

Results and discussion

The short fibers reported in our work were separated from the commercial asbestos by the sedimentation–flocculation method (15). Short monofibril chrysotile isolated, as described in the Experimental section, are highly homogeneous in size and are relatively free of amorphous material. For example, the corrected stoichiometry found for these fibers, $2.94MgO\cdot 1.94SiO_2\cdot 2.42H_2O$, is very close to the ideal formula for chrysotile asbestos, $3MgO\cdot 2SiO_2\cdot 2H_2O$.[4] The sem micrographs (20 000×) of the separated fibers show monofibrils which are in most part 1.5–2.0 μm in length, cf. Fig. 2. These results are in good agreement with a more detailed characterization reported by Jolicoeur *et al.* in which they report 90% of the separated short fibers to be less than or equal to 2 μm long. Moreover, the X-ray sem-ed spectrum, Fig. 3A ($Si(K_\alpha)$ = 1.7 keV, $Mg(K_\alpha)$ = 1.3 keV, and Si/Mg(intensity) = 1.3) is in good agreement with the previously reported data for chrysotile (16, 17).

Aqueous reaction of the fibers

The reaction of chrysotile with $TiCl_3$ in H_2O affords a blue solid product. The sem reveals that this product has neither the morphology nor the chemical composition of chrysotile. In addition, analysis of the reaction filtrate for different reactions indicates that 80 to 100% of the chrysotiles magnesium is leached out of the fiber during reaction, depending on the reaction times. Accordingly, the ν(Mg—OH) bands usually visible at 3685 and 3640 cm^{-1} in the ir spectrum are absent. Also, the ir spectra for all the $TiCl_3$—H_2O reacted chrysotile experiments showed changes in the ν(Si—O) vibration intensities at 1075, 1015, and 950 cm^{-1}, and the appearance of a new absorption at 795 cm^{-1}. This is characteristic of acid lixiviated and unrolled fibers (5, 11).

Lixiviation or leaching of chrysotile by organic and mineral acids is well known (5). The present results indicate that the Lewis acid property of $TiCl_3$ is responsible for the observed reaction of chrysotile in water. The following hydrolysis equilibrium is known to be the main chemical process for titanium(III) ions in H_2O (18–20),

$$[Ti(H_2O)_6]^{3+} \rightleftharpoons [Ti(H_2O)_5(OH)]^{2+} + H^+$$

The resulting decrease in pH when $TiCl_3$ dissolves is sufficient

[4]A correction of 4 wt% was made on the total weighed analytical mass due to impurities; iron (3.58 wt%), carbon (0.25 wt%) and other undetermined but small quantities of; sodium, potassium, calcium, manganese, chrome, nickel, and aluminium, usually found in Quebec asbestos. See refs. 1, 5, and 6.

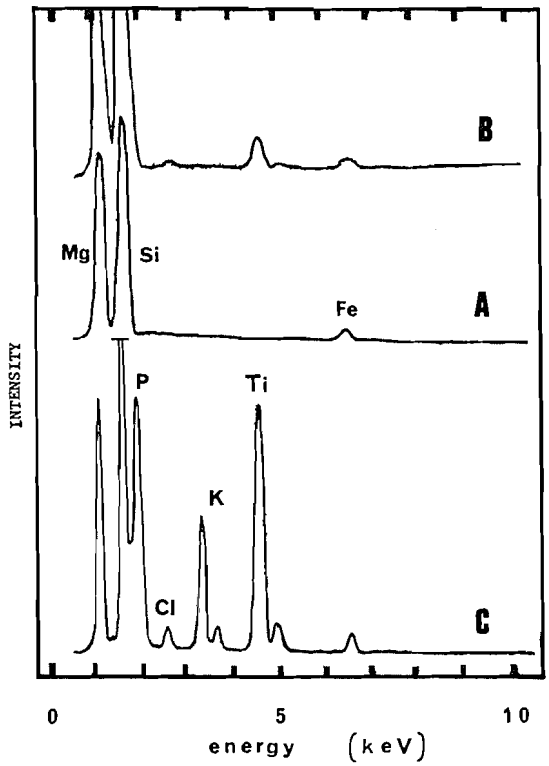

FIG. 3. Scanning electron microscope X-ray spectra of *A*, short fiber chrysotile asbestos; *B*, $TiCl_3$–THF reacted fibers (method A); and *C*, $TiCl_3$–H_2O reacted fibers (method B) with phosphate buffer (pH = 7).

to cause acid lixiviation of the chrysotiles –MgOH layer.[5]

In an attempt to control the pH a phosphate buffer (KH_2PO_4) solution was used as reaction media. Microanalysis (cf. Table 1), ir and sem-ed X-ray spectroscopy (cf. Fig. 3*C*) were used to characterize the blue solid reaction product. The analytical data confirm the previously reported chemical reactivity of chrysotile towards phosphate compounds (e.g. NaH_2PO_4, Cl_3PO, etc.) (22). Invariably most buffers have good coordinating anions capable of complexation with either titanium or magnesium.[6] Hence, the use of an aprotic solvent seemed to be a more convenient way of loading significant amounts of titanium on to the fiber without destroying it.

Tetrahydrofuran reacted fibers

The reactivity of the chrysotile–$TiCl_3$–THF system is very different from the aqueous analogue. Titanium(III) chlorides are in general good Lewis acids. In the presence of THF the following acid-base pair is formed (18)

$$TiCl_3 + nC_4H_8O \rightarrow TiCl_3 \cdot n(C_4H_8O) \qquad n = 3$$

When the $TiCl_3$ reaction concentration exceeded 0.04 *M*, a blue crystalline solid was observed in addition to the fibers. Microanalysis of these crystals is consistent with the formulation of the THF addition compound, $TiCl_2(OH) \cdot 2(C_4H_8O)$. This result is in agreement with the above reaction assuming $n = 2$ and that one chlorine atom has been replaced by one hydroxyl group from the fiber.

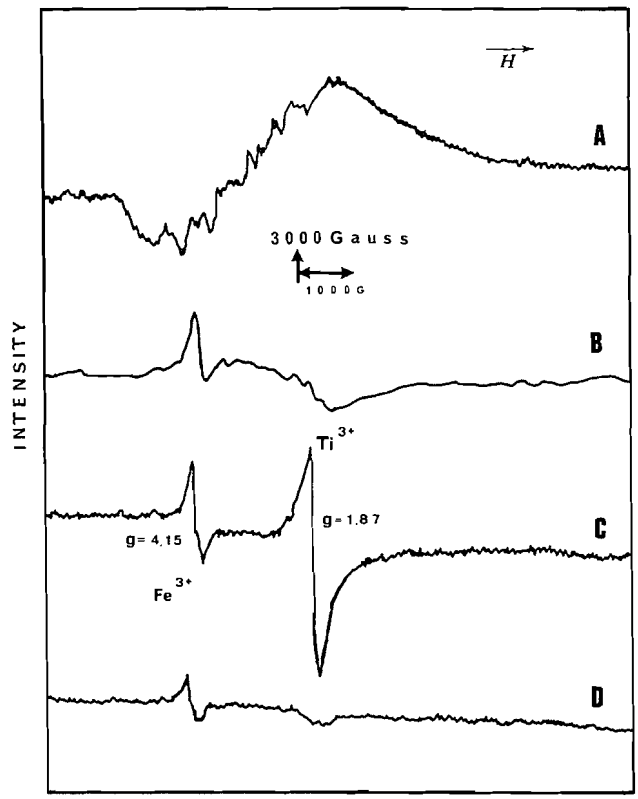

FIG. 4. Room temperature esr spectra of *A*, short fiber chrysotile; *B*, $TiCl_3$–THF reacted fibers (method A); *C*, $TiCl_3$–H_2O reacted fibers (method B); and *D*, same sample as *C* but 20 min after opening the cell to air.

In a series of experiments short fiber chrysotile was reacted under the same conditions. In order to study the influence of the reactants concentration on the titanium fixation to the fiber, the $TiCl_3$ to chrysotile ratio was varied. Moreover, since 7% of the total brucite is estimated to be at the fiber surface (2), the concentrations in Table 2 are expressed as the titanium to surface-magnesium ratio, Ti/Mg(surf.). The solvent volume was kept constant throughout the experiments.

The blue reacted fibers obtained were characterized by dta, elemental microanalysis, sem, esr, and ir spectroscopy. The esr spectrum of the THF reacted chrysotile is somewhat different from that of the product obtained from the reaction in water, Fig. 4. Nevertheless, a broad resonance at $g = 1.87$ indicates the presence of Ti(III). The possible interference from Mn(II) impurities ($g = 2.05$, sextet), contained in the fibers, is improbable due to the experimental conditions used here (i.e. T = 25°C) (23). The signal observed in all spectra at $g = 4.15$ is attributable to the presence of Fe(III) impurities. Identical spectra, for the reacted fibers, were observed at lower temperatures, 25 to –196°C.

The presence of titanium and chloride in the fibers was confirmed by microanalysis, Tables 1 and 2, and by sem-ed analysis, Fig. 3. The X-ray emission at 2.6 keV indicates only slight amounts of chlorine in the air exposed fibers. Under these conditions, oxidation of the titanium(III) chloride is expected to give a titanium(IV) product and HCl (18). In accord with this is the color change from blue to white when the reacted fibers are exposed to air. Moreover, the transformation of paramagnetic titanium(III) to diamagnetic titanium(IV) was followed by esr. Figure 4*D* shows the final spectrum of the

[5]In this case the acidity of $TiCl_3$, $pK_a = 3.9$, is comparable to that of acetic acid, $pK_a = 4.8$. This acid is a well known leaching agent for chrysotile.

[6]In the latter case solubilisation of the brucite layer through uncontrolled complexation rather than acid attack will also cause fiber unrollment.

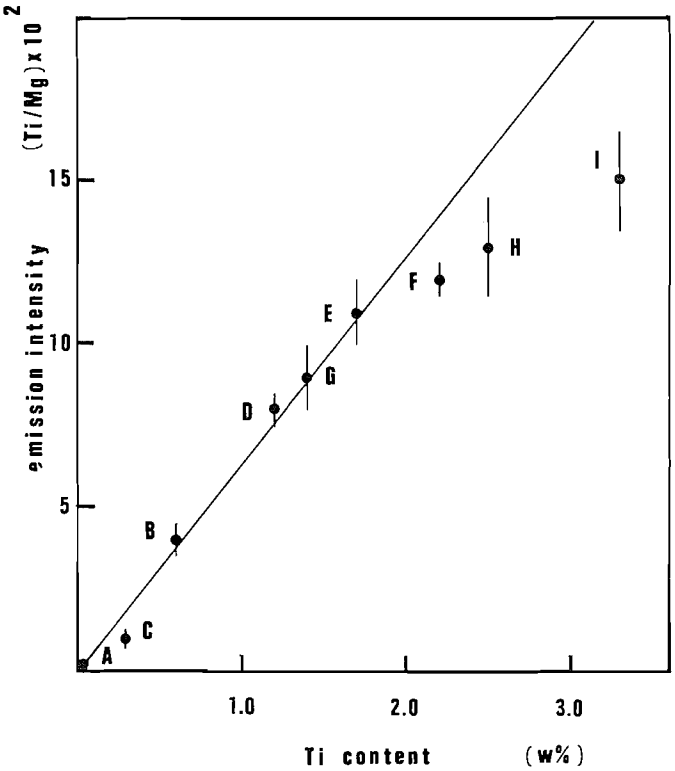

FIG. 5. Graph showing the titanium sem-ed X-ray emission intensity, Ti/Mg(K_α) versus the total titanium content (microanalysis) for a series of reacted fibers. The letters correspond to the reactions in Table 2. The vertical lines show the mean standard deviation for three spectra.

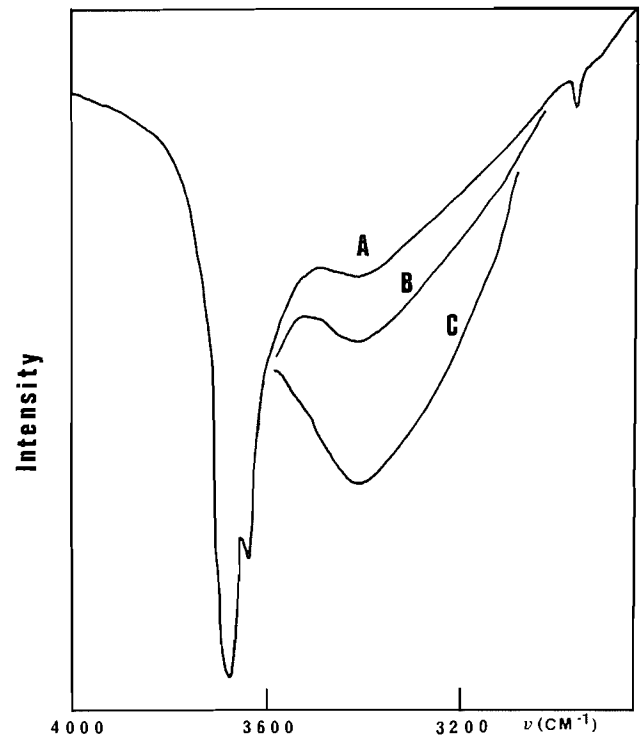

FIG. 6. Infrared spectra of the ν(OH) region of $TiCl_3$–THF reacted chrysotile; *A*, before heating (solvent evaporated, 25°C/10^{-2} Torr), and fibers heated in vacuum for (125°C, 10^{-2} Torr) *B*, 2 h; *C*, 14 h.

$TiCl_3$–H_2O reacted fiber when the seal of the esr cell is broken and air slowly diffuses in. The main change observed is the disappearance of the $g = 1.87$ resonance assigned to titanium(III). This oxidation was also observed for the THF reacted fibers, but oxidation is not as rapid.

Varying the reactants Ti/Mg (surf.) ratio over a 100-fold concentration does not affect significantly the Si/Mg ratio of the sem-ed spectra, Table 2. Also, microanalytical data for the series of reaction products in this table show no appreciable changes in the magnesium and silicon composition of the reacted fibers (for reactions [C] and [G] in Table 2, the offset Mg wt% analysis is given for coherency with the sem-ed results. A more complete analysis, also given, is more consistent with this affirmation). Furthermore, unlike the water reacted fibers the sem micrographs (20 000×) show a cylindrical monofibril morphology for the THF reacted fibers, identical to the original fibers, Fig. 2*B*.

Figure 5 gives the plot of the sem-ed X-ray intensity for titanium, Ti/Mg, as a function of the total microanalytical concentration of this element in the treated fibers. This relation is linear for concentrations below ca. 2 wt%. The weaker emission observed for the concentrations above this value can be due to either sample absorption or to binding of the titanium elsewhere than on the surface of the fiber. Moreover, the graph shows that there is a good correlation between the two analytical methods and as expected the amount of reacted titanium increases with the reactants Ti/Mg(surf.) ratio. However, this increase is not regular. For example, the amount of titanium found in the fibers of reaction [B] is greater than in reaction [C], though the titanium chloride concentration used in the latter reaction is greater. Hence, in Fig. 5, points B and C are inverted on the graph, as well as points corresponding to reactions [E], [F], and [G]. As we will see further, the amount of reacted titanium depends on the heating rate of the reaction.

All the elemental analyses for the THF reacted fibers invariably gave Cl/Ti ratios equal to or smaller than 2, depending on the experiment. For example, the fibers from reactions [B] and [I] give atomic ratios of 1.86 and 0.88, respectively. Thus it seems that the titanium attached species, (fiber)–$TiCl_n$, is a mixture of $n \leq 2$ species.

Moreover, the ir spectrum of the $TiCl_3$–THF treated fiber contained more water after reaction judging from the stronger H_2O bands at ca. 3400 and 1625 cm^{-1}. Figure 6 shows the high frequency ν(OH) water band for THF reacted fibers (reaction [H], Table 2). After reaction the intensity of this band is already stronger relative to the chrysotile spectrum when compared to the original unreacted fibers. Heating the treated fibers under vacuum caused the set of water bands to grow as shown for the ν(OH) band at 3400 cm^{-1} in spectra [B] and [C]. Concomitantly, new bands at 2960, 1260, and 795 cm^{-1} for the reacted fibers were also affected in the same way. Goni *et al.* (21) have studied the ir spectra of acid lixiviated chrysotile. Especially interesting is the absorption band, here at 795 cm^{-1}, which they assign to the presence of amorphous silicate and is taken to be symptomatic for open or unrolled fibers. Early thermal decomposition of the chrysotile can be ruled out to explain the observed ir changes on the basis of previously reported ir results on the thermal degradation of asbestos (24). The thermally induced lixiviation observed here is consistent with the proposed reaction scheme in Fig. 7.

The differential thermogravimetric analysis curves for the reacted and unreacted fibers were found to be identical. Both curves show weight loss caused by residual water at 100 and

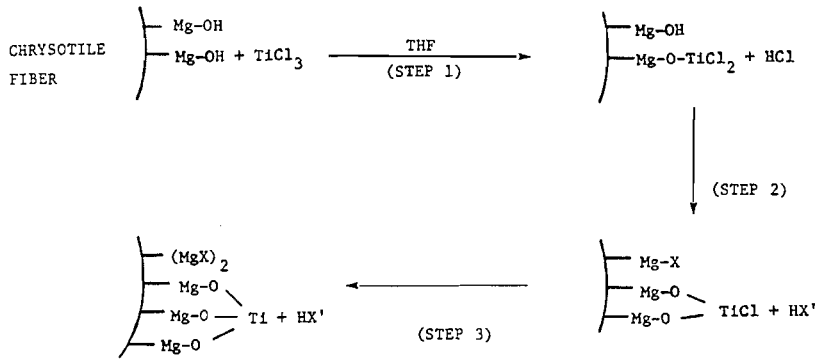

FIG. 7. Proposed reaction scheme for chrysotile asbestos with $TiCl_3$ in THF; X = OH or Cl, X′ = Cl or OH.

111°C, and dehydroxylation of chrysotile at 658 (−11.7 wt%) and 676°C (−11.4 wt%), respectively. From the recorded weight loss, the amount of water contained in the reacted fibers is 2.1 wt% compared to less than 0.1 wt% before reaction. Furthermore, the weight loss usually observed at 370−400°C(1) due to dehydroxylation of amorphous brucite, often present with asbestos minerals, was negligible (<0.1 wt%) for the short fibers and was not observed for the reacted fibers.

In one experiment, THF reacted fibers were washed for 24 h with THF in a soxhlet under positive argon pressure. The only change in the composition of the resulting white chrysotile, cf. microanalysis in Table 1, is the disappearance of chlorine. Furthermore, the sem spectroscopic results corroborate the presence of titanium and the fibrous structure of the product. The absence of chloride in these fibers can be accounted for by the reaction scheme discussed below.

The reaction scheme in Fig. 7 summarizes the observed chemical behavior of $TiCl_3$−THF treated asbestos chrysotile. For example, the analytical data for the soxhlet extracted fiber are consistent with the reaction product of step 3, X = OH and X′ = Cl. In summary, this scheme is applicable in any case where reacted fibers are either directly or indirectly submitted to heat treatment such as in a reaction or soxhlet extraction. Therefore, when X′ = Cl the freed hydrogen chloride can, in the presence of trace amounts of H_2O, lixiviate the fiber, steps 1, 2 and 3. On the other hand, if X′ = OH water is directly produced. In either case, the reaction scheme accounts well for the observed experimental data of $TiCl_3$−THF reacted fibers; i.e. increased water and decreased chloride content of the fibers as $TiCl_3$ reacts with chrysotile.

These results lend support to our belief that the titanium chloride is chemically bonded to chrysotile and not chemisorbed. Attempts to isolate characteristic titanium vibrations (e.g. ν (Ti—O), ν(Ti—Cl), etc.) between 1000 and 200 cm^{-1} in the ir were unsuccessful owing to strong silicate and brucite vibration modes in this region. We are currently seeking more information on the titanium binding mode to the fiber using Auger, esca, and uv spectroscopic techniques.

Received May 19, 1983

R. LE SAGE, K. L. SALA, R. W. YIP, and C. H. LANGFORD. Can. J. Chem. **61**, 2761 (1983).

The spectra and risetimes for the doublet excited state absorption (ESA) of *t*-$[Cr(NH_3)_2(NCS)_4]^-$ (Reineckate ion), $[Cr(NCS)_6]^{3-}$, and *t*-$[Cr(en)_2(NCS)_2]^+$ have been measured at picosecond times in several solvents. The ESA spectra observed after approximately one half the risetimes showed no measurable change with time. The result is consistent with vibrational relaxation times which are comparable to or faster than the risetimes. The ESA risetimes for Reineckate ion and *t*-$[Cr(en)_2(NCS)_2]^+$ were found to be fastest in hydroxylic solvents and slowest in non-hydroxylic solvents. No such solvent trend was found for $[Cr(NCS)_6]^{3-}$. Possible photophysical models to account for the observed solvent-dependent risetimes are discussed. Kinetic simulations based on a quasi four-level model which explicitly includes the pump pulse function are reported.

R. LE SAGE, K. L. SALA, R. W. YIP et C. H. LANGFORD. Can. J. Chem. **61**, 2761 (1983).

On a mesuré les spectres et les temps d'apparition de l'absorption de l'état excité du doublet (AEE) de *t*-$[Cr(NH_3)_2(NCS)_4]^-$ (ion de Reineckate), de $[Cr(NCS)_6]^{3-}$ et de *t*-$[Cr(en)_2(NCS)_2]$ dans des temps de l'ordre de la picoseconde et dans plusieurs solvants. Les spectres observés pour l'AEE après approximativement la moitié du temps d'apparition ne révèlent pas de changements mesurables avec le temps. Le résultat est en accord avec des temps de relaxation vibrationnelle qui sont comparables ou plus élevés que les temps d'apparition. On a trouvé que les temps d'apparition de l'AEE de l'ion de Reineckate et du *t*-$[Cr(en)_2(NCS)_2]$ sont plus rapides dans les solvants hydroxyliques et plus lents dans les solvants non hydroxyliques. On n'a pas trouvé une telle tendance avec le $[Cr(NCS)_6]^{3-}$. On discute des modèles photophysiques susceptibles d'expliquer l'influence du solvant sur les temps d'apparition. On rapporte les simulations cinétiques basées sur le quasi modèle à 4 niveaux qui comprend explicitement la fonction de pompe à pulsation.

1. Introduction

In O_h symmetry Cr(III) complexes, the photochemistry and photophysics are associated with two close-lying states: a $^4T_{2g}$ and a ^2E_g state, the former being "distorted" with respect to the ground state. The spin-forbidden ^2E_g state, which is usually the lowest energy and the emitting state, has been extensively studied (1–4). However, owing to the close but unquantified proximity of the two excited states, the respective roles of the quartet and doublet states in photoreactions and in the decay of the doublet state has not yet been unambiquously delineated for most systems (3–8).

Although the vibrationally relaxed doublet state of Cr(III) complexes is well characterized, data at early times leading to the formation of the relaxed doublet are sparse. Notable exceptions are the picosecond excited state absorption (ESA) studies by Windsor and co-workers (9, 10). Doublet risetimes of 16–22 ps for three Cr(III) isothiocyanato complexes in H_2O were reported. It was suggested that the risetime may reflect a combination of intersystem crossing and relaxation within the doublet manifold.

The influence of solvent on the primary photophysical/photochemical rates following population of the Franck–Condon quartet state is unclear. Provided that intersystem crossing occurs after substantial quartet relaxation, significant change from the Franck–Condon geometry and solvent reorganization can occur. The role of solvent in the relaxation process might involve a non-specific property such as viscosity or a specific solvent–ligand interaction such as hydrogen bonding.

To gain further understanding of the primary processes involved in Cr(III) complexes, we have measured the doublet ESA spectra and risetimes of $[Cr(NCS)_6]^{3-}$, *t*-$[Cr(NH_3)_2(NCS)_4]^-$ (Reineckate ion, R^-), and *t*-$[Cr(en)_2(NCS)_2]^+$ in a variety of solvents and analyzed these results in terms of the rate constants associated with the quartet and doublet states. Kinetic simulations in terms of a quasi four-level model are reported.

2. Experimental

The Nd/glass picosecond absorption apparatus used (11) was similar to that reported earlier (12) but has been significantly improved. The 5 cm D_2O cell used to produce the 1.06 u superbroadened picosecond probe beam (13, 14) was reduced to 2.0 cm. This reduction in cell length resulted in a probe beam with a reduced chirp (measured 6 ps) (15) and which was spectrally more uniform and reproducible across the echelon. The equally stepped echelon used previously was replaced with a quartz 5-step echelon having relative step differentials of 50, 5, 5, 20, and 50 mm (= 81.3, 8.13, 8.13, 32.5, and 81.3 ps at 5300 Å). The first step provided a "$-\infty$" time spectrum in advance of the 5300 Å pump pulse and the last step a "$+\infty$" long time continuum reference spectrum. The spectra were recorded on Royal Pan-X sheet film which was pushed-developed (in HC-110B) to yield an effective ASA of 3000, with a measured γ of 0.64 and a linear density range of 0.4–1.4. The film containing a set of six spectra was scanned by a microprocessor-controlled sampling microdensitometer (16). The data were smoothed by a series of Fast Fourier transform based algorithms (11) to yield a sequence of related density spectra. A selected

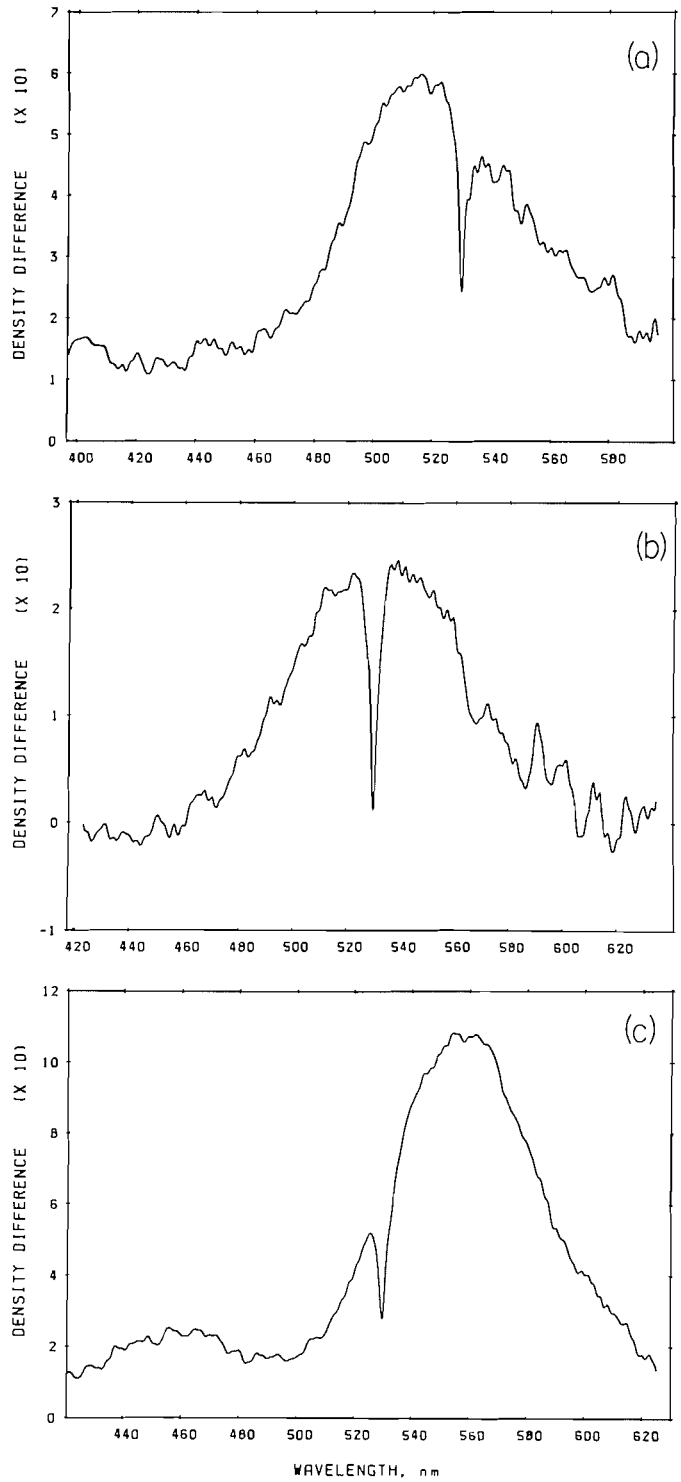

FIG. 2. Transient absorption spectra of some isothiocyanato Cr(III) complexes in acetonitrile solution. (*a*) $[Cr(NCS)_6]^{3-}$ at 47 ps; (*b*) R^- at 71 ps; and (*c*) $[Cr(en)_2(NCS)_2]^+$ at 43 ps.

wavelength range of the transient absorption spectra was integrated and used for kinetics. The relative timing of the excitation and probe pulse was determined to within 3 ps by a sensitive zero-background null method based on the Kerr gating of the continuum pulse (15).

3. Results

Transient absorption spectra were observed when $[Cr(NCS)_6]^{3-}$, R^-, and *t*-$[Cr(en)_2(NCS)_2]^+$ in various solvents were excited by picosecond laser pulses at 530 nm. Typical spectra recorded at probe delay times of less than 100 ps are shown in Figs. 1 and 2, and the transient absorption maxima recorded in Table 1. The transient absorption band observed for both R^- and *t*-$[Cr(en)_2(NCS)_2]^+$ showed a noticeable solvent dependence (shifted towards the blue in water), whereas the symmetric complex $[Cr(NCS)_6]^{3-}$ did not. The intensities of the transient absorption bands for R^- and $[Cr(NCS)_6]^{3-}$ were comparable, independent of solvent, and approximately two times less intense than that for *t*-$[Cr(en)_2(NCS)_2]^+$. We were

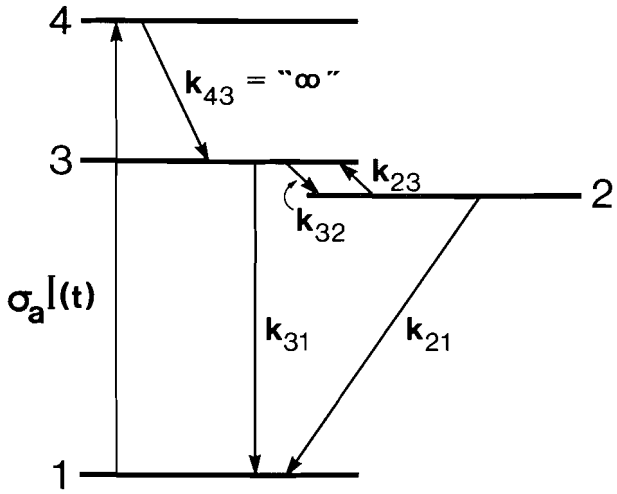

FIG. 3. Schematic of a quasi four-level system.

unable to detect a change in any of the transient absorption spectra with time. Any change was therefore either small or very rapid ($t < 1/2$ risetime), or both.

Buildup of the transient absorption for the complexes varied from a few picoseconds to tens of picosecond depending upon the complex and solvent. During the excitation pulse, formation of the transient population will be integral functions of the excitation pulse. Therefore, for those transients rising within one or two laser pulse widths (6–12 ps), the pump pulse function cannot be ignored in any kinetic analysis. For a quasi four-level system (Fig. 3), we have for the populations of the three states:

$$[1] \quad \dot{n}_1 = -\sigma_a I(t) n_1 + k_{31} n_3 + k_{21} n_2$$

$$[2] \quad \dot{n}_2 = k_{32} n_3 - (k_{23} + k_{21}) n_2$$

$$[3] \quad \dot{n}_3 = \sigma_a I(t) n_1 + k_{23} n_2 - (k_{31} + k_{32}) n_3$$

where σ_a is the absorption cross section (see Fig. 3). Empirically, a satisfactory fit of the data was obtained with the function

$$[4] \quad n_2(t) = 1/2(T\sqrt{\pi} I_0 \sigma_a n_1) \{\exp(-k_{32}t + k_{32}^2 T^2/4) \times [1 + \text{erf}(t/T - k_{32}T/2)] - [1 + \text{erf}(t/T)]\}$$

which can also be derived from the three coupled differential equations for the conditions in which $\dot{n}_1 = 0$; $k_{31} = k_{21} = k_{23} = 0$; and for the Gaussian pulse

$$[5] \quad I(t) = I_0[\exp(-t^2/T^2)]$$

where I_0 is the peak photon flux of the pump pulse. The data were fitted to eq. [4] by trial values of the parameter T and k_{32} to find the smallest value of the sum of squares of the residuals between the calculated and observed values of n_2 for the set of data. The parameter T in the Gaussian pulse is related to τ, the full-width at half-maximum (FWHM) by $T = \tau/2\sqrt{\ln 2}$. The kinetics for formation of the transient from R^- in D_2O and acetone are shown in Figs. 4 and 5. The solid curves are calculated from eq. [4]. Risetime results are recorded in Table 2. The most significant variations in the risetimes were found for R^- which varied from less than 6 ps in H_2O to 29 ps in DMF. The risetimes of R^- in H_2O appeared to be faster than

D_2O but both risetimes are fast and close to the temporal width of the laser pulse. While it is possible to obtain reliable risetimes to within a fraction of the laser pulse width using our data fitting procedure, the requirement of low jitter in the width of the pulse from shot to shot is presently one of the main, though not insurmountable, difficulty towards realizing a shorter time resolution.

4. Discussion

The transients observed for the three chromium complexes have been assigned to excited state absorption from the doublet state on the basis of the agreement between the transient absorption and phosphorescence lifetimes (7−10, 17−21). The ESA risetime for R^- and *t*-$[Cr(en)_2(NCS)_2]^+$ were found to be fastest in hydroxylic solvents and slowest in non-hydroxylic less polar solvents. No such solvent trend was found for the symmetric $[Cr(NCS)_6]^{3-}$. The risetime in glycerol/water was not significantly different from the less viscous solvents. This observation could be interpreted in two ways: either (*1*) bulk viscosity does not correlate with the difficulty of solvation shell rearrangement because of the presence of few glycerol molecules in the solvent sphere of the complex ion, or (*2*) solvent-restricted quartet relaxation for $[Cr(NCS)_6]^{3-}$ is unimportant in the photophysics.

The absence of observable time dependent changes in the ESA spectra after approximately one half the risetimes is consistent with vibrational relaxation times which are comparable to or faster than the risetimes. Absorption from vibrationally unrelaxed states of the doublet appears as "hot band" absorption. In the case of very fast crossing the unrelaxed doublet followed by slow vibrational relaxation to the zero level of the doublet, the shift is given by the difference in energy between the pump wavelength and 0−0 transition between the doublet and the ground state. The shift is substantial for the present complexes. In the case of reduced hot band population due to substantial vibrational relaxation, the shift is less evident. Another caveat to the above conclusion is the remote possibility of the effects of vibrational relaxation being masked by compensating time-dependent solvation effects.

The simplest interpretation of the observed solvent-dependent ESA risetimes is to assume that the risetime is governed by the rate of intersystem crossing from the quartet manifold. An intersystem crossing model involving "prompt" crossing from the unrelaxed quartet levels and a slower crossing rate is expected to give a risetime with a slow and fast regime. We found no kinetic evidence for this. In the case of R^- in water, buildup of the doublet was complete after less than 20 ps; a slower component, which would be noticeable, was not observed.

A possible explanation for a solvent-dependent intersystem crossing in non-symmetrically substituted complexes such as the R^- ion (D_{4h} symmetry) was suggested by Orlandi and Siebrand (22). The model assumes rapid vibrational relaxation and redistribution and that the solvent dependent electrostatic field of the ligand influences the energies of the quartet states. Because of a lowering in symmetry for O_h to D_{4h} because of the unequal ligands, $^4T_{2g}$ splits into $^4E + {}^4B_{2g}$. The splitting, ϵ, is assumed to be solvent dependent. On the basis of symmetry arguments, the coupling between the ^4E and ^2E is zero but coupling between the $^4B_{2g}$ and ^2E is non-zero. For the case in which the ^4E is lower in energy than the ^4B state, the relative population of the $^4B_2$ and ^4E states differ by the Boltzmann factor $\exp(-\epsilon/kT)$, so that the rate of intersystem crossing

$$[6] \quad k_{isc} = 2\pi/\hbar|\langle {}^2E|H_{so}|{}^4B_2\rangle|^2 \exp(-\epsilon/kT)\rho_E$$

is solvent dependent through ϵ. For R^-, owing to solvation of the charged NCS groups, ϵ is expected to be smaller in polar than non-polar solvents. For the symmetric $[Cr(NCS)_6]^{3-}$ complex, no solvent effect is predicted. For the cationic *t*-$[Cr(en)_2(NCS)_2]^+$ complex where the relative energies of the $^4B_{2g}$ and ^4E states would be the opposite that of R^-, no solvent effect is predicted. The Orlandi−Siebrand model correctly predicts the trend of the results for R^- and $[Cr(NCS)_6]^{3-}$ but not for *t*-$[Cr(en)_2(NCS)_2]^+$, where a small solvent effect is observed. In the case of the *t*-$[Cr(en)_2NCSF]^+$, differential quenching and quantum yield evidence does indeed suggest the participation of two quartet states (23).

Hollebone and co-workers (24) have described a model in which photochemistry and intersystem crossing competes with vibrational relaxation and redistribution. In this model, population and decay on a specific nuclear coordinate governs the photophysical and photochemical behaviour. Solvents which hydrogen bond to the ligands could couple to vibrational coordinates active in intersystem crossing. The present data are consistent with the view that hydrogen-bonding is an important influence on the rate of intersystem crossing.

Thus far, we have assumed that the risetime is governed only by the rate constant for intersystem crossing, k_{32}. To investigate the sensitivity of the *form* of the normalized risetime function to other rate constants, numerical simulations were carried out based on the quasi four-level system (Fig. 3). The system can be characterized by the equations:

$$[7a] \quad \dot{n}_2(x) = R_5[n_3 - (R_2 + R_3)n_2]$$

$$[7b] \quad \dot{n}_3(x) = R_5[R_4F(x)(1 - n_2 - n_3) + R_3n_2 - (1 + R_1)n_3]$$

$$[8] \quad n_1 + n_2 + n_3 = 1$$

and the five dimensionless parameters:

$$[9a] \quad R_1 = k_{31}/k_{32}$$

$$[9b] \quad R_2 = k_{21}/k_{32}$$

$$[9c] \quad R_3 = k_{23}/k_{32}$$

$$[9d] \quad R_4 = \sigma_a I_0/k_{32}$$

$$[9e] \quad R_5 = \tau k_{32}$$

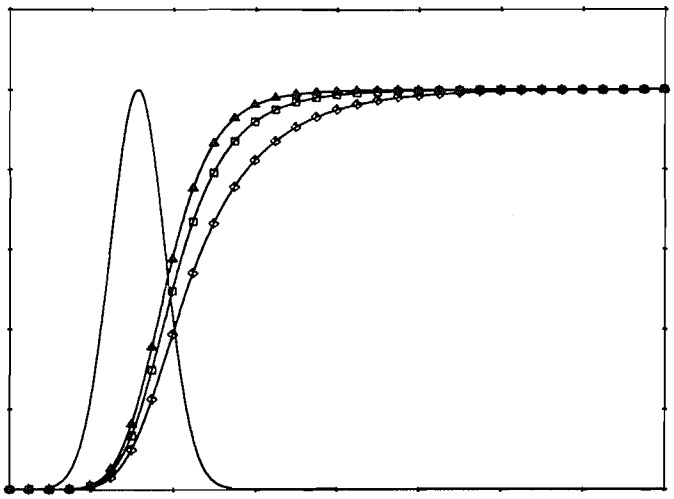

FIG. 6. Calculated normalized $n_2(x)$ vs. x from numerical simulation (see text). $R_2 = 0, R_3 = 0, R_4 = 0, R_5 = 1.0$. (△) $R_1 = 0$; (□) $R_1 = 0.5$; (◇) $R_1 = 1.0$. The curve without symbol is the Gaussian pump function $F(x)$ vs x.

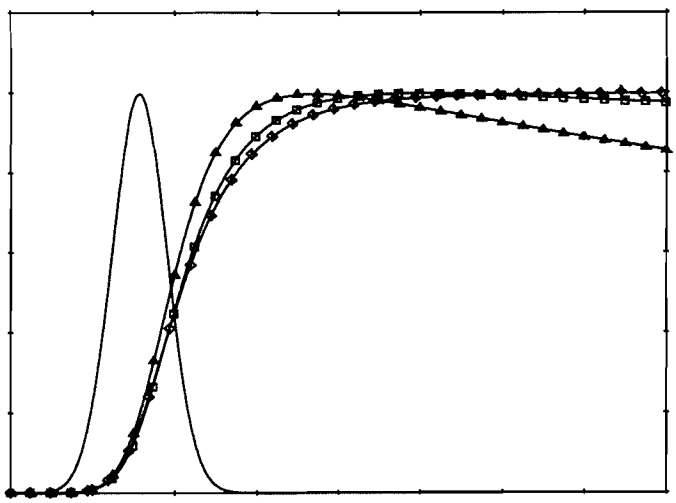

FIG. 7. Calculated normalized $n_2(x)$ vs. x from numerical simulation (see text). $R_2 = 0, R_3 = 0.1, R_4 = 0, R_5 = 1.0$. (△) $R_1 = 0$; (□) $R_1 = 0.1$; (◇) $R_1 = 0.5$. The curve without symbol is the pump pulse function $F(x)$ vs. x.

where τ is the full-width at half-maximum of the pump pulse, and I_0 is the maximum intensity of the pump pulse $I(t) = I_0F(x)$, $(0 < F(x) < 1$ for $\tau > 0)$, and $x = t/\tau$. The coupled first-order differential equations, [7*a*] and [7*b*], which explicitly include the pump function, were solved using Hamming's modified predictor-corrector method (25). The time-dependent population of level 2, $n_2(t)$, was calculated for a Gaussian pump pulse and for the parameter $R_2 = 0$, since decay of the doublet state is known to be negligible over the range of the dimensionless time variable $x = t/\tau$ of the simulation. Details of a general treatment of the quasi four-level system, driven by an arbitrary laser pulse, will be reported in a future publication. The normalized population of level 2 together with the laser pulse function is shown in Figs. 6–8. The simulation shows that: (*1*) For no reverse reaction ($k_{23}/k_{32} = 0$), level 2 builds up more rapidly as k_{31} is increased. (*2*) The rate of buildup of level 2 is also increased when the reverse reaction is included ($k_{23}/k_{32} > 0$). In this case, the effect of k_{31} is to cause a decay in the population of level 2 after the maximum population is reached.

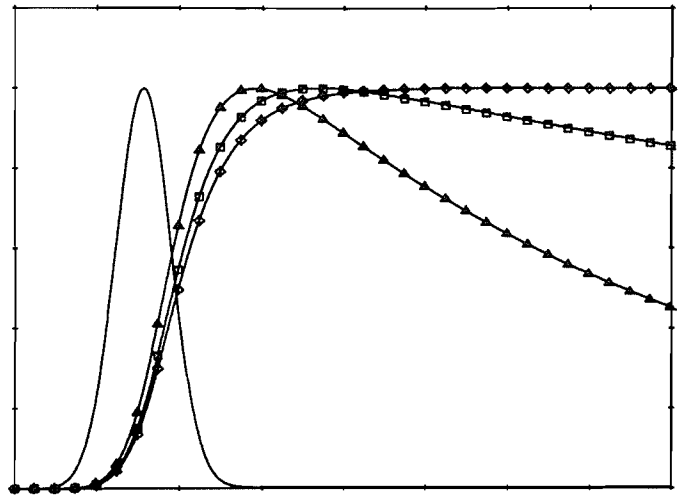

FIG. 8. Calculated normalized $n_2(x)$ vs. x from numerical simulation. $R_2 = 0, R_3 = 0.5, R_4 = 0, R_5 = 1.0$. (△) $R_1 = 0$; (□) $R_1 = 0.1$; and (◇) $R_1 = 0.5$. The curve without symbol is the pump pulse function $F(x)$ vs. x.

In the present study, no doublet state decay has been observed over the range of time studied. Therefore the rate of back intersystem crossing from the initially formed vibrationally excited doublet state appears to be significantly slower than the rate of intersystem crossing or vibrational relaxation. The simulation suggests that the conditions $k_{23}/k_{32} > 0.1$ and $k_{31}/k_{32} > 0.1$ cannot be both true. Less can be said about the relative rates of decay and intersystem crossing of the quartet state. There are two consequences of quartet decay in competition with intersystem crossing: the yield of doublet, and the form of the doublet population vs. time function (especially in the rising part) are affected. If the rate constant for intersystem crossing (k_{isc}) is much greater than other quartet decay channels (k_Q), then the doublet yield will not be very sensitive to changes in k_Q. Current data on the relative doublet yield in various solvents are consistent with this condition, although we cannot exclude the possibility on the basis of doublet yield alone, that both k_Q and k_{isc} are affected by solvent.

As the simulation shows, the precise form of the doublet population function is sensitive to five kinetic parameters R_1–R_5. Of the five, R_4 is constant and R_5 can be controlled. The parameter R_2, which measures decay directly from the doublet state, is known to be small compared with R_1 and R_3. With sufficiently accurate data, it is thus possible to obtain the rate constants for quartet decay and back intersystem crossing relative to that for intersystem crossing by fitting the data with the exact form of the population function. The realization of this goal awaits the obtention of highly accurate kinetic data which requires close control of the laser parameters and possibly signal averaging.

Nitric oxide and oxygen reactions with 1-butene over manganese(III) oxide

ROBERT ANDERSON ROSS[1] AND CRAIG FAIRBRIDGE[2]

Department of Chemistry, Lakehead University, Thunder Bay, Ont., Canada P7B 5E1

Received April 15, 1983

ROBERT ANDERSON ROSS and CRAIG FAIRBRIDGE. Can. J. Chem. **61**, 2767 (1983).

Reactions of 1-butene with nitric oxide from 623 to 723 K and with oxygen from 433 to 573 K have been studied in a differential flow system over manganese(III) oxide. Nitrous oxide was formed in the reaction of the hydrocarbon with nitric oxide along with products of complete combustion. The apparent activation energies were respectively 69 ± 4, 78 ± 4, and 30 ± 4 kJ mol^{-1} for nitrogen, carbon dioxide, and nitrous oxide reaction rates. The corresponding pre-exponential factors were 1.72×10^{-1} and 1.16 $mol^{0.5}\ L^{-0.5}\ m^2\ g^{-1}$, and 1.99×10^{-2} $mol^{-0.35}\ L^{0.35}\ m^2\ g^{-1}$. In the reaction with oxygen, apparent activation energies of 183 ± 4, 523 to 503 K, and 88 ± 4 kJ mol^{-1}, 503 to 433 K, were determined with pre-exponential factors 1.74×10^{15} and 2.94×10^5 $mol^{0.3}\ m^{-2}\ g^{-1}$. During catalysis the oxide underwent a partial phase change from α to γ in both reactions. Additionally, nitrate species were present on the surface after oxidation with nitric oxide. Kinetic expressions have been derived and mechanisms proposed for both reactions which may occur in emission control systems requiring the removal of NO_x and unburned hydrocarbons.

ROBERT ANDERSON ROSS et CRAIG FAIRBRIDGE. Can. J. Chem. **61**, 2767 (1983).

On a étudié les réactions du butène-1 avec l'oxyde nitrique à des températures allant de 623 à 723 K et avec l'oxygène dans l'intervalle de température allant de 433 à 573 K, dans un système à écoulement différentiel sur l'oxyde de manganèse(III). Il se forme de l'oxyde nitreux ainsi que des produits de combustion complète dans la réaction avec l'oxyde nitrique. Les énergies apparentes d'activation sont respectivement de 69 ± 4, 78 ± 4 et de 30 ± 4 kJ mol^{-1} pour les vitesses de réaction de l'azote, du dioxyde de carbone et de l'oxyde nitreux. Les facteurs pré exponentiels correspondants sont respectivement 1,72 $\times 10^{-1}$ et 1,16 $mol^{-0.5}\ L^{-0.5}\ m^2\ g^{-1}$ et $1{,}99 \times 10^{-2}$ $mol^{-0.35}\ L^{0.35}\ m^2\ g^{-1}$. Dans le cas de la réaction avec l'oxygène les énergies apparentes d'activation sont: 183 ± 4 de 523 à 503 K et de 88 ± 4 de 503 à 433 K avec des facteurs pré exponentiels de 1,74 $\times 10^{15}$ et de $2{,}94 \times 10^5$ $mol^{0.3}\ m^{-2}\ g^{-1}$. Au cours de la réaction, l'oxyde subit un changement partiel de phase d'α à γ dans les deux réactions. De plus, on constate la présence d'espèces nitrates sur la surface après l'oxydation par l'oxyde nitrique. On a déduit des expressions cinétiques et on propose des mécanismes pour les deux réactions qui peuvent se produire dans les systèmes de contrôle d'émission nécessitant l'élimination de NO_x et des hydrocarbures qui n'ont pas brûlés.

[Traduit par le journal]

Introduction

Currently the combination of the reduction of oxides of nitrogen and the complete oxidation of hydrocarbons is of practical significance because of the impact of such gases on urban environments. A major source is the automobile exhaust where components from both groups of compounds occur along with oxygen and several pollutants. Catalytic processes may be applied as one way of removing the noxious gases and these processes continue to receive acute attention.

The main problem in finding a suitable catalyst (1) lies probably in obtaining a high activity for hydrocarbon oxidation at low temperatures in tandem with high stability and, thus, an acceptable lifetime. Generally, unsaturated hydrocarbons are more reactive towards oxygen than are saturated hydrocarbons and therefore they react over "milder" catalysts with better selectivity. The reaction rates and selectivities vary with the position of the double bond and the nature of substituent groups (2).

The present work considers the catalysed reaction of 1-butene with nitric oxide and with oxygen in a link to recent studies of the oxidation of ethane by nitrous (3) and nitric oxides (4) over Mn_2O_3.

Experimental

Materials

Oxygen (99.99%), nitric oxide (99.0%), and 1-butene (99.0%) were supplied by Matheson of Canada Limited. All other gases were at least 99.5% pure and were obtained from Canadian Liquid Air Limited. Manganese(III) oxide was prepared and analysed as described elsewhere (5).

Procedure and apparatus

Helium was the carrier gas in the quartz reactor flow system (6) and in the Hewlett–Packard Research Chromatograph, Model 5754B. Gases were analysed by a thermal conductivity bridge from stainless steel analytical columns packed with "Poropak Q" (4). A Beckman 951 NO/NO_x analyser was used in series with the gas chromatograph.

Kinetic measurements were conducted at a total flow rate of 350 mL min^{-1} (NTP) on 1 g catalyst samples, <37 μm maximum diameter with surface area 15.5 $m^2\ g^{-1}$, and were recorded as the rate of carbon dioxide, nitrous oxide, or nitrogen production after attaining the steady level at less than 15% total conversion to products. The temperature regions were defined by the maximum of 15% conversion at the high end and at the low end by the reasonable limits of detection of nitrogen and carbon dioxide, $>10^{-4}$ mol L^{-1}. The experimental conditions were chosen after the usual preliminary tests to ascertain the regime in which reaction rates were not influenced by external or internal diffusion (3).

Infrared spectra were measured with a Beckman IR-12 spectrophotometer (3). A Vacuum Generator ESCA-3 instrument was used for XPS determinations.

Results

The nitric oxide/1-butene reaction

When the catalyst was exposed to 3.06 kPa nitric oxide and 2.32 kPa 1-butene at 673 K, the initial rates of nitrogen (r_1) and carbon dioxide (r_2) formation were very high, Fig. 1. These rates quickly decreased to steady values in approximately 5 h. The rate of nitrous oxide production (r_3) increased in the first hour then decreased to reach a constant value after 5 h. Under these experimental conditions, the rate of reaction remained

constant for up to 48 h and the conversion of 1-butene reached 13% at 723 K.

Rate orders were determined at 673 K after catalyst pretreatment under standard conditions of 2.89 kPa nitric oxide and 2.35 kPa 1-butene for 12 h.

Nitric oxide

The partial pressure of nitric oxide was adjusted from 0.17 to 8.17 kPa with 1-butene maintained at 2.60 kPa. A reaction rate order of 0.5 with respect to nitric oxide partial pressure was found from logarithmic plots of nitrogen and carbon dioxide experimental rates, Fig. 2. For the rate of nitrous oxide formation, a rate order of 1.35 with respect to nitric oxide partial pressure was calculated.

1-Butene

A zero order rate dependency with respect to 1-butene partial pressure variations from 0.92 to 7.49 kPa was observed, Table 1, with the partial pressure of nitric oxide constant at 3.05 kPa.

TABLE 1. The effects of component partial pressures on the NO/C_4H_8 reaction over Mn_2O_3

$P_{C_4H_8}$ (kPa)	$r_1 \times 10^{-8}$ (mol m^{-2} s^{-1})	$r_2 \times 10^{-8}$ (mol m^{-2} s^{-1})	$r_3 \times 10^{-8}$ (mol m^{-2} s^{-1})
0.92	3.39	3.00	2.55
1.32	3.26	2.68	2.93
1.44	3.39	2.48	3.19
1.63	3.39	2.74	2.90
2.77	3.26	3.16	3.16
2.84	3.29	3.55	2.81
3.22	2.87	2.80	3.19
3.72	3.10	2.81	2.90
5.50	3.26	2.81	2.58

4.15	3.00	5.23	7.54
5.75	3.78	6.30	11.25
8.17	5.26	7.54	18.55

Nitrogen

With the partial pressures of nitric oxide and 1-butene maintained at 2.41 and 2.57 kPa, respectively, the nitrogen partial pressure was altered from 0.55 to 6.94 kPa. This had no effect on the rate of reaction, r_2 or r_3, and therefore the rate order was zero with respect to nitrogen concentration.

Carbon dioxide

Variations in the carbon dioxide partial pressure from 0.82 to 7.15 kPa had no effect on the rate of nitrogen or nitrous oxide formation. The reaction was zero order with respect to carbon dioxide concentration wih nitric oxide and 1-butene partial pressures maintained at 2.41 and 2.57 kPa, respectively.

Water vapour

The reactant partial pressures were held constant as described above while the water vapour concentration was altered from 0.07 to 2.41 kPa. This had no effect on the experimental

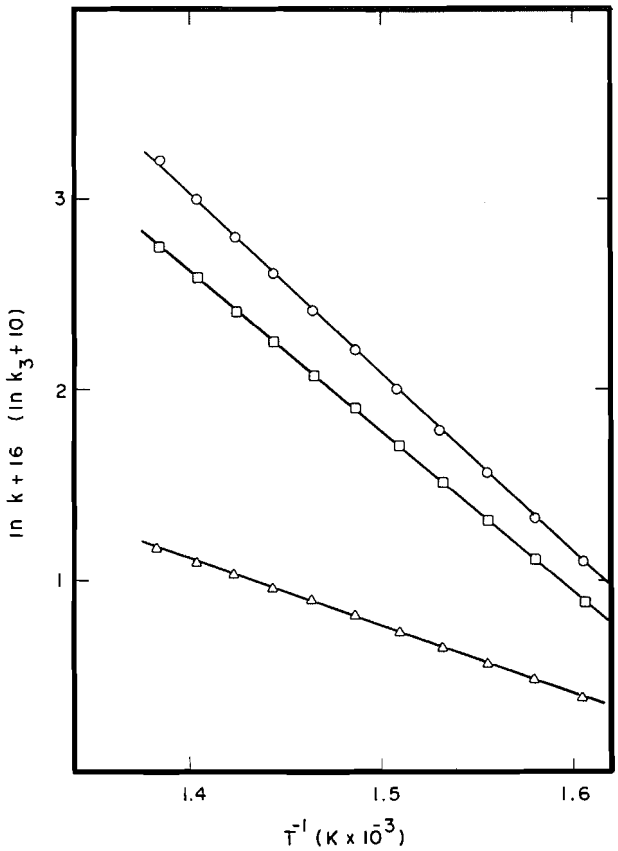

FIG. 3. Arrhenius plots for the NO/C_4H_8 reaction; □, k_1; ○, k_2; △, k_3.

rates of reaction and thus the reaction was zero order with respect to water vapour partial pressure.

From the preceding results, the experimental rate of reaction was given by:

[1] $r = kP_{NO}^{0.5}$

for r_1 and r_2 and

[2] $r_3 = k_3 P_{NO}^{1.35}$

Temperature/time effects

Specific rate constants were calculated from the integrated forms of eqs. [1] and [2] with respect to concentration at temperatures from 723 to 623 K. The catalyst was pretreated with 2.89 kPa nitric oxide and 2.35 kPa 1-butene for 12 h. Apparent activation energies, determined from Arrhenius plots, Fig. 3, were 69 ± 4, 78 ± 4, and 30 ± 4 kJ mol^{-1} from nitrogen, carbon dioxide, and nitrous oxide rates, respectively. The corresponding pre-exponential factors were 1.72×10^{-1} and 1.16 $mol^{0.5}\ L^{-0.5}\ m^2\ g^{-1}$, and $1.99 \times 10^{-2}\ mol^{-0.35}\ L^{0.35}\ m^2\ g^{-1}$.

After 48 h exposure to 3.06 kPa nitric oxide and 2.32 kPa 1-butene at 673 K, the catalyst surface area remained 15.5 $m^2\ g^{-1}$. Under the scanning electron microscope, catalyst particles exhibited a separate crystalline phase on parts of the surface similar to that previously observed in studies of the reaction of ethane with nitric oxide over manganese(III) oxide (4). The infrared spectrum of the oxide after catalysis was also similar to that obtained after the C_2H_6/NO reaction and included absorption bands at 1630, 1390, and 845 cm^{-1} indicative of a nitrate species, along with bands at 615, 490, 425, and 350 cm^{-1}.

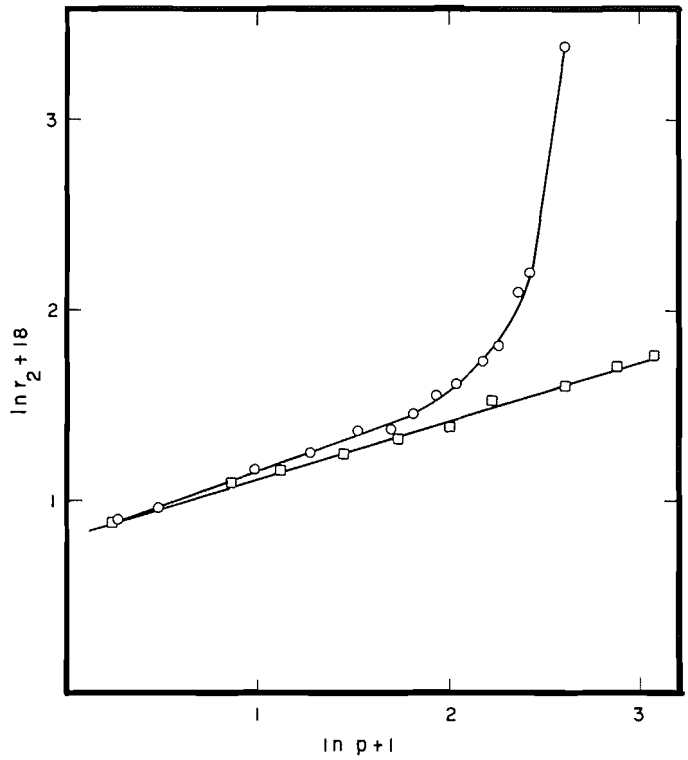

FIG. 4. Effect of component partial pressures on the rate of the O_2/C_4H_8 reaction; P_{O_2}, ○, r_2; $P_{C_4H_8}$, □, r_2.

Chemical analysis indicated 69.0% w/w manganese in the used catalyst which remained black in colour. X-ray powder diffraction produced *d*-spacings corresponding to γ manganese(III) oxide; 2.48, 2.74, 3.08, 1.54, 1.56, 1.81, and 2.06 Å.

The oxygen/1-butene reaction

With 2.12 kPa oxygen and 2.35 kPa 1-butene, the catalytic reaction rate increased slightly for the first 30 min of reaction and then remained constant for at least 24 h at 523 K where the conversion of 1-butene was 13%. Prior to subsequent experiments the catalyst was pretreated under these conditions for 3 h.

Reaction rate orders were evaluated at 473 K.

Oxygen

The partial pressure of oxygen was altered from 0.48 to 4.95 kPa with that of 1-butene maintained at 2.77 kPa. For oxygen partial pressures <2.20 kPa, the rate order with respect to oxygen was 0.4, Fig. 4. The rate order increased with an increase in partial pressure above this point.

1-Butene

With oxygen partial pressure maintained at 2.18 kPa, the rate order was 0.3 with respect to 1-butene from 0.46 to 7.88 kPa, Fig. 4.

Carbon dioxide

Variations in the partial pressure of carbon dioxide from 0.55 to 6.45 kPa had no effect on experimental reaction rates with oxygen and 1-butene partial pressures held constant at 2.16 and 2.71 kPa, respectively. Hence the rate order with respect to carbon dioxide concentration was zero.

Water vapour

With the partial pressures of oxygen and 1-butene main-

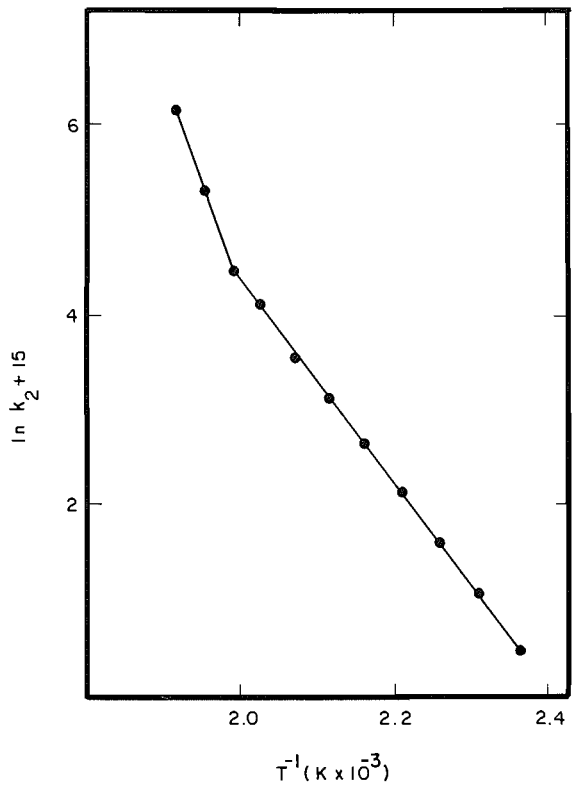

FIG. 5. Arrhenius plot for the O_2/C_4H_8 reaction.

tained at 2.16 and 2.71 kPa, respectively, the rate order was zero with respect to water vapour partial pressure from 0.08 to 2.33 kPa.

On the basis of these results, the catalytic rate of reaction was expressed as:

$$[3] \quad r_2 = kP_{O_2}^{0.4} P_{C_4H_8}^{0.4}$$

for $0.48 < P_{O_2} < 2.20$ kPa.

The effects of temperature and reaction conditions

Rate constants were calculated from the integrated form of eq. [3] from 523 to 433 K. When plotted as ln k versus T^{-1}, Fig. 5, two linear regions were observed which gave apparent activation energies of 183 ± 4 and 88 ± 4 kJ mol^{-1} for the ranges 523 to 503 K and 503 to 433 K. The corresponding pre-exponential factors were 1.74×10^{15} and 2.94×10^5 $mol^{0.3}$ $L^{-0.3}$ m^2 g^{-1}.

The oxide surface area remained 15.5 m^2 g^{-1} after reaction at 523 K for 24 h and the infrared spectrum, with absorption bands at 615, 490, 425, and 350 cm^{-1}, was similar to that described above. Chemical analyses yielded 69.3% w/w manganese and the *d*-spacings were 2.48, 2.74, 3.08, 1.54, 1.56, 1.80, and 2.08 Å as determined by X-ray diffraction.

X-ray photoelectron spectra of the catalysts used in both reactions were corrected for charging by reference to the C(1*s*) line at 285.0 eV. The Mn($2p_{3/2}$) spectrum gave a binding energy of 642.0 eV for all samples in comparison with 640.7 eV for unreacted managanese(III) oxide. The O(1*s*) spectrum of the latter gave a binding energy of 528.7 eV which became 528.8 eV after the O_2/C_4H_8 reaction and split to 530.0 and 533.0 eV after the NO/C_4H_8 reaction. Catalysts used in the nitric oxide work gave a N(1*s*) spectrum with a binding energy 406.2 eV.

The atomic percentages were 26.4 carbon, 18.1 and 37.3 oxygen, 8.7 manganese, and 9.5 nitrogen for catalysts from the nitric oxide/1-butene reaction and 19.3 carbon, 60.1 oxygen, and 20.6 manganese for those from the oxygen/1-butene reaction.

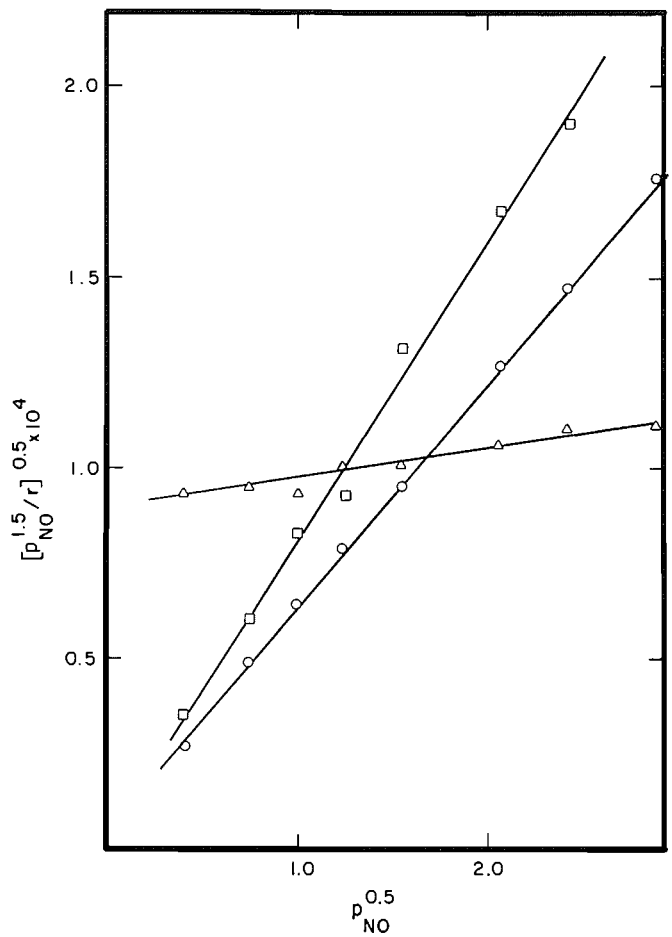

FIG. 6. Reduced plots corresponding to eq. [4] for the NO/C_4H_8 reaction at 673 K; □, r_1; ○, r_2; △, r_3.

Discussion

The nitric oxide/1-butene reaction

Various kinetic expressions mainly of the Langmuir–Hinshelwood type (7–10) were surveyed and tested. The equation which gave the best statistical correlation coefficient for all of the rate order data was then adopted. As shown by the linear plots of $P_{NO}^{0.5}$ against $(P_{NO}^{1.5}/r)^{0.5}$, Fig. 6, only one expression accommodated the nitric oxide rate order results:

$$[4] \quad r = \frac{kaP_{NO}^{0.5}}{(1 + aP_{NO}^{0.5})^2} \times P_{NO}$$

The square-root relationship with the partial pressure of nitric oxide suggests that this species adsorbs and reacts on two surface sites while the zero order rate dependency on 1-butene concentration indicates that adsorption and reaction of 1-butene is very rapid compared to the reactions of nitric oxide.

A surface mechanism consistent with the experimental results may be formulated:

$$[5] \quad C_4H_{8(g)} \rightleftharpoons C_4H_{8(ads)}$$

$$[6] \quad NO + S + C_4H_{8(ads)} \rightarrow C_4H_{7(ads)} + HNO_{(ads)}$$

$$[7] \quad 2HNO_{(ads)} \rightarrow N_2O_{(ads)} + H_2O_{(ads)}$$

where S is a surface site. These reactions account for the formation of nitrous oxide. Further reactions involve nitric oxide as indicated by the P_{NO} term in eq. [4] and, overall, these might be represented by:

[8] $2C_4H_{7(ads)} + 22NO + [O] \rightarrow 8CO_2 + 7H_2O + 11N_2$

As was observed in the nitric oxide/ethane reaction (4), the rate of nitrogen production was less than that of carbon dioxide which suggests that disproportionation may occur between two nitric oxide molecules to give nitrous oxide and an oxygen ion (11, 12) as previously suggested for the nitric oxide/methane reaction over platinum (13).

The apparent activation energies were similar to those found in the nitric oxide/ethane reaction over the same catalyst (4) and to the nitric oxide/propane (14, 15) and nitric oxide/propylene (16) reactions over various catalysts. In the propane reaction (15) over bismuth phosphomolybdate, the activation energy was 92 kJ mol^{-1} for nitrogen formation and 55 kJ mol^{-1} for nitrous oxide while the corresponding values in the present work were 69 and 30 kJ mol^{-1}.

Infrared spectra showed the presence of a nitrate species with absorption bands at 1630, 1390, and 845 cm^{-1}. The catalyst appeared to have undergone a phase change from α to γ manganese(III) oxide. The extent of this change is not known, although the fact that it occurs indicates that surface oxygen ions are actively involved in reaction.

Nitric oxide has been shown to exist as $(NO)_2$ or as a nitro species on different surfaces (17–19) and this species may be involved in the disproportionation reaction. The nitrous oxide thus produced may also take part in the oxidation of 1-butene, although in the nitric oxide/methane reaction in a static system (13), methane oxidation by nitrous oxide only occurred when all of the nitric oxide was consumed. It seems more likely that the oxygen ion produced by disproportionation would be involved in 1-butene oxidation.

The oxygen/1-butene reaction

A number of kinetic expressions were examined and the best correlations were obtained with the equation:

$$[9] \quad r = \frac{kaP_{O_2}^{0.5} bP_{C_4H_8}^{0.5}}{(1 + aP_{O_2}^{0.5} + bP_{C_4H_8}^{0.5})^2} \times (P_{O_2} P_{C_4H_8})$$

The reduced plots are shown in Fig. 7.

The equation suggests that an irreversible bimolecular reaction occurs between adsorbed species (20), and each species is adsorbed on two surface sites as indicated by the one-half order exponents. Additional reactions involve both oxygen and 1-butene as indicated by the $(P_{O_2} P_{C_4H_8})$ term. With eq. [9] as a general guide, a plausible surface mechanism was developed:

[10] $C_4H_{8(g)} + 2S \rightleftharpoons C_4H_{8(ads)}$

[11] $O_2 + [\ ] + C_4H_{8(ads)} \rightarrow C_4H_{7(ads)} + [OOH]$

[12] $C_4H_8 + S + [OOH] \rightarrow C_4H_{7(ads)} + [O] + H_2O$

and additional reactions summarized by:

[13] $2C_4H_{7(ads)} + 11O_2 + [O] \rightarrow 8CO_2 + 7H_2O + [\ ] + 4S$

The square-root relationships in eq. [9] with respect to 1-butene and oxygen are rationalized in steps [10] and [11], respectively.

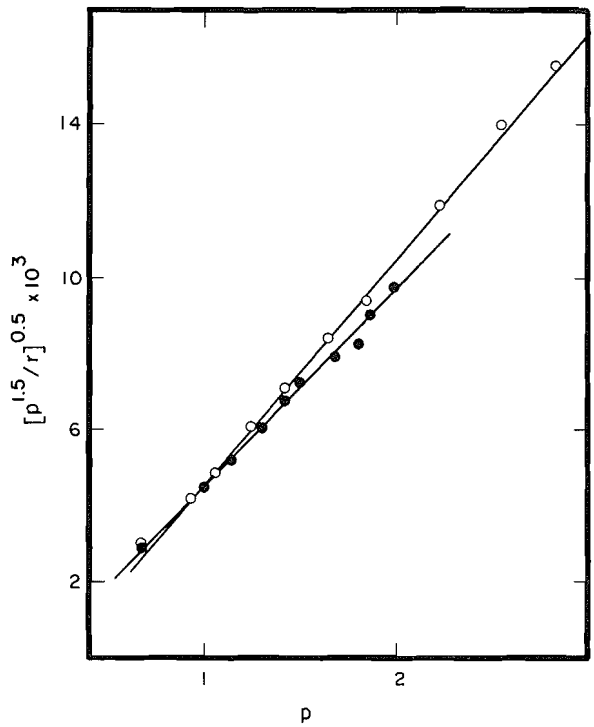

FIG. 7. Reduced plots corresponding to eq. [9] for the O_2/C_4H_8 reaction at 473 K; ○, r_2 for $P_{C_4H_8}$; ●, r_2 for P_{O_2}.

The change in apparent activation energy from 88 kJ mol^{-1}, 433 to 503 K, to 183 kJ mol^{-1}, 503 to 523 K, occurs at the temperature at which the conversion of oxygen exceeds 15%. As the temperature is increased above 503 K, the conversion of oxygen increases rapidly compared to 1-butene as expected from the overall stoichiometry:

[14] $2C_4H_8 + 12O_2 \rightarrow 8CO_2 + 8H_2O$

The lower value for activation energy corresponds closely to that found in the complete oxidation of ethane on palladium (21) or nickel(II) oxide and to that for propane oxidation on manganese(IV) oxide (22). The rate-determining step may involve C—H bond rupture as in eqs. [11] and [12].

Although the kinetic parameters for the oxygen/1-butene reaction correspond closely to those for the reaction of nitric oxide with ethane (3), the rate with respect to the oxidizing gas increased with partial pressures >2.6 kPa for the unsaturated hydrocarbon. The rate-limiting step would then be the adsorption and reaction of the oxidizing gas, eq. [11].

XPS showed two O(1*s*) binding energy values in catalysts used in the NO/C_4H_8 reaction. This indicates that two surface oxygen species are present. The lower energy of 530.0 eV is close to that expected for chemisorbed oxygen in metal oxides while the higher value of 533.0 eV characterizes the presence of a molecular oxygen species (23). Elsewhere, it has been proposed that in hydrocarbon oxidation reactions, oxygen is activated and adsorbed on the catalyst surface as O^- or O_2^- species which may result in the formation of epoxy or peroxy intermediates (24).

Conclusions

Products of complete oxidation only were observed in the reaction of 1-butene with oxygen over manganese(III) oxide. When nitric oxide was the oxidant, nitrous oxide was also

present in the effluent. These reactions may all occur in emission control systems which require the removal of NO_x and unburned hydrocarbons.

Manganese(III) oxide underwent a partial phase change from α to γ during catalysis indicating that the involvement of active surface centres in the reactions had some effect on lattice stability. Nitrate species were present on the surface after oxidation of 1-butene by nitric oxide.

Both reactions appear to initiate via an irreversible bimolecular reaction between adsorbed species on the catalyst surface which may involve C—H bond rupture.

The spin–spin coupling mechanism for ^5J(C-4, CH_α) in toluene derivatives and its conformational applications

TED SCHAEFER, JAMES PEELING,[1] AND GLENN H. PENNER
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received May 10, 1982

TED SCHAEFER, JAMES PEELING, and GLENN H. PENNER. Can. J. Chem. **61**, 2773 (1983).

It is shown that the spin–spin coupling over five formal bonds between carbon 4 and the α protons in toluene and its ring or sidechain substituted derivatives is transmitted by a σ–π mechanism. As such it varies as $\sin^2\theta$, where θ is the angle by which the α C—H bond twists out of the benzene plane, and can be used to determine the conformational preference and the barrier to internal rotation about the exocyclic sp^2–sp^3 carbon–carbon bond. The coupling is remarkably insensitive to ring substituents, even to those at carbon 4. Two measurements suggest that the coupling over six formal bonds between a β carbon nucleus and a *para* proton also represents a σ–π interaction

TED SCHAEFER, JAMES PEELING et GLENN H. PENNER. Can. J. Chem. **61**, 2773 (1983).

On démontre que le couplage spin–spin à travers cinq liaisons formelles entre les protons du carbone 4 et ceux en α du toluène se transmet par un mécanisme σ–π; cette conclusion est aussi vraie pour les dérivés du toluène substitués que le cycle ou sur la chaîne latérale. L'intensité de ce couplage varie donc en fonction de $\sin^2\theta$, où θ est l'angle formé par la α liaison C—H et le plan du noyau benzénique; elle peut donc être utilisée pour déterminer la préférence conformationnelle et la barrière à la rotation interne autour de la liaison carbone–carbone sp^2–sp^3 exocyclique. Cette constante de couplage est peu sensible aux substituants du cycle, même ceux en position 4. Deux mesures suggèrent que le couplage à travers six liaison formelles entre un noyau de carbone en β et un proton en *para* représente aussi une interaction σ–π.

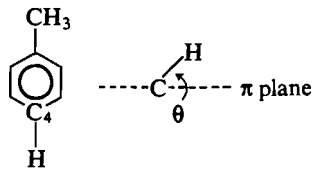
Introduction

The σ–π electron coupling mechanism of $^6J_p^{H,CH_3}$ in toluene is well established, entails a $\sin^2\theta$ dependence (1, 2) in **1**, and



1

via an appropriate averaging procedure can be used to determine the preferred conformations and barriers to internal rotation about the C_{sp^2}—C_{sp^3} bonds in toluene derivatives (3). One simply uses eq. [1], in which $^6J_{90}$ is the H,H coupling constant

$$[1]\quad {}^6J_p^{H,CH} = {}^6J_{90}\,\langle\sin^2\theta\rangle$$

over six bonds between the sidechain and ring protons at θ = 90° and $\langle\sin^2\theta\rangle$ is the expectation value of $\sin^2\theta$ as determined by the preferred conformation, the magnitude of the internal rotational barrier, and the temperature. The latter determines the populations of the hindered rotor states.

It has been suggested (4, 5) that $^5J_p^{C,CH}$ in toluene is also dominated by a π electron mechanism. In this paper its coupling mechanism is investigated and its use in conformational applications is indicated.

Experimental

Most of the compounds were available commercially. The 3,5-dibromo derivatives of ethyl and isopropylbenzene were prepared in the obvious way from the 4-amino derivatives. The 2,6-dichloro derivative of ethyl benzene was obtained by hydrogenation of the corresponding styrene (6).

The ^{13}C nmr spectra were recorded at 22.63 MHz on a WH90 Bruker spectrometer. For reasons of sensitivity, the INEPT sequence was used (7). For C-4 in 4-fluorotoluene this sequence involved transfer of polarization from ^{19}F to ^{13}C. The 90° pulse for ^{19}F was of 50 μs duration while that for ^{13}C was 12 μs. A spectral width of 400 Hz was studied, 2600 acquisitions into 32 K being summed during a time of 20.48 s for each free induction decay.

Samples were prepared in solvents as indicated in Table 1 and were transferred to 10-mm od nmr sample tubes. The solutions were degassed by a number of freeze–pump–thaw cycles and the tubes were flame-sealed.

INDO MO FPT calculations (8) were performed on an Amdahl 470/V7 system.

Results and discussion

1. *Spectral analysis*

The proton-coupled spectra of C-4 were analyzed with the computer program LAME (9, 10). The initial assignments were facilitated by knowledge of the proton chemical shifts and of the proton–proton coupling constants. The C,H couplings could be estimated from data for toluene (4) and the monosubstituted benzenes (5). Iteration then yielded the data in Table 1. An example of the analysis is that for *p*-fluorotoluene. Of the 205 calculated transitions in the C-4 region, 166 transitions were assigned to 92 observed peaks. The calculated and observed spectra are shown in Fig. 1. The important parameters, ^5J(C-4, H) ≡ $^5J_p^{C,CH}$ ≡ ^5J is 0.948 ± 0.009 Hz, where the standard deviation from the analysis is multiplied by three.

Substantial data sets were also obtained for C,H couplings involving C-2, C-3, C-α, and C-β. Most of them (but see below) do not contribute to the point of this paper nor are they properly understood in terms of coupling mechanisms or their conformational or substituent dependence. These data sets are not reproduced here, but will be published if and when their conformational behaviour becomes clear.

2. *The mechanism for* ^{5}J *in toluene*

(i) *INDO MO FPT calculations*

Calculations of ^5J(C-4, H) ≡ ^5J have been performed previously (5). So as to obtain some hints as to the perturbations of ^5J caused by ring or sidechain substituents, INDO MO FPT

[1]On sabbatical leave from the University of Petroleum and Minerals, Saudi Arabia.

[f]40% v/v in benzene-d_6.
[g]This is ^1J(C,F).

calculations were done for toluene, ethylbenzene, *p*-fluorotoluene, benzyl fluoride, *p*-fluorobenzyl fluoride, 2,3,5,6-tetrafluorobenzyl fluoride, benzal fluoride, *p*-fluorobenzal fluoride, and 2,3,5,6-tetrafluorobenzal fluoride. Some of the calculated couplings are given in Table 2.

For toluene the numbers agree well with previous data (5) and can be reproduced by the equation $^5J = 0.20 + 3.89 \sin^2 \theta$ where θ is the angle by which the C—H bond of the methyl group twists out of the ring plane. For reasons given below the value of 0.20 Hz at $\theta = 0$ is most likely an artefact of the calculation. Substraction of 0.20 Hz from each calculated number in Table 2 gives a set related by $^5J = 3.89 \sin^2 \theta$. Consequently, these calculations can be taken (1, 3) to imply a σ−π electron mechanism for ^5J(C-4, H) in toluene.

Very similar numbers are computed for ethyl benzene in Table 2 and suggest a similar equation for ^5J. In *p*-fluorotoluene the same computed behaviour appears with the proviso that $^5J_{90}$ increases slightly to 4.02 Hz from the 3.89 Hz in toluene.

Substitution of fluorine into the sidechain reduces the calculated couplings by about 15%. An asymmetry is introduced into the θ dependence of ^5J in that the values at 30° and 150° are no longer equal (see Table 2). However, the averages of the values at θ and 180° − θ still follow closely a $\sin^2 \theta$ relationship. Of course, an observed ^5J involves both methylene protons and is the average of the couplings at θ and 180° − θ.

Substitution of a second flourine into the methyl group causes a further reduction of about 20% in the calculated ^5J numbers (about 30% relative to toluene), but does not change the θ dependence of ^5J.

In summary, the INDO MO FPT computations are consistent with a $\sin^2 \theta$ dependence of $^5J_p^{C,CH}$ in toluene, a small increase caused by ring substituents more electronegative than hydrogen, and a somewhat larger decrease entailed by electronegative α-substituents.

(ii) *Experimental verification of the σ−π mechanism for* $^5J_p^{C,CH}$

In toluene, $^5J_p = 0.84 \pm 0.03$ Hz (3). In 2,6-dichlorotoluene it is 0.893 ± 0.015 Hz, where the error is taken as three times the standard deviation (Table 1). In 3,5-dichlorotoluene the coupling is 0.883 ± 0.015 Hz (the analysis for C-4 in these two compounds is rather less complex than for toluene itself). It appears that substitution at sites along the coupling path does not perturb ^5J significantly, just as for $^6J_p^{H,CH}$ (3, 11). The expectation value of $\sin^2 \theta$ is 0.5 for 3,5-dichlorotoluene. Therefore write

$$[2] \quad {}^5J = {}^5J_{90} \langle \sin^2 \theta \rangle = 1.77 \langle \sin^2 \theta \rangle$$

In *p*-fluorotoluene, $^5J = 0.948 \pm 0.009$ Hz, implying a 7% increase in $^5J_{90}$ when the highly electronegative fluorine substituent is introduced at one end of the coupling path. This rather small increase is in qualitative agreement with the computed numbers in Table 2.

If eq. [2] represents ^5J correctly, then in 3,5-dibromoethylbenzene $\langle \sin^2 \theta \rangle$ should be 0.385 as deduced originally (3, 12) from $^6J_p^{H,CH}$. Indeed, ^5J in this compound is 0.680 ± 0.006 Hz (Table 1) yielding $\langle \sin^2 \theta \rangle$ as 0.680/1.77 = 0.384. In view of the possible measurement errors, the agreement is probably too good. It does imply that eq. [2] is good and that ^5J is dominated by a σ−π mechanism. Furthermore, the computed numbers in Table 2 are clearly overestimated and the nonvanishing values at $\theta = 0$ should very likely be ignored.

Another test of eq. [2] is provided by the value of 0.368 ± 0.006 Hz in 3,5-dibromoisopropylbenzene in Table 1. Hence, $\langle \sin^2 \theta \rangle$ is 0.368/1.77 or 0.208, again as deduced (13) from the σ−π coupling, $^6J_p^{H,CH}$, which yielded 0.204. In both of these examples it is assumed that the CH_3 substituents do not appreciably perturb ^5J, as is also suggested by the theoretical numbers in Table 2.

In Table 2 the computed ^5J values for benzal fluoride indicate a substantial decrease relative to toluene. In 2,6-dichlorobenzal chloride, in which the C_α—H bond prefers the ring plane to the extent of about 57 kJ/mol (14), ^5J was too small to observe. Because the calculated value at $\theta = 0°$ is now also smaller (fluorine simulates chlorine) than in toluene, this experiment does not prove that ^5J vanishes, although it is consistent with this condition implied by an equation of type [2].

3. *The 2,6-dichloro derivatives*

As discussed above, ^5J is 0.89 Hz in 2,6-dichlorotoluene, in line with a rather small perturbation of the coupling mechanism by the chlorine substituents. In the corresponding ethyl benzene, $^6J_p^{H,CH}$ is −0.29 ± 0.02 Hz (6), approximating to the

45	2.15	2.18	2.21	1.46(2.35)	1.48
60	3.12	3.15	3.20	2.37(3.13)	2.20
75	3.83	3.88	3.94	3.15(3.58)	2.72
90	4.09	4.14	4.23	3.59	2.89

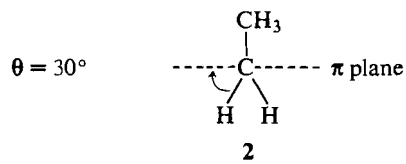
[a]The angle θ is zero when the C—H bond of the methyl group lies in the benzene plane.

[b]These numbers for ^5J(C-4, H) ≡ $^5J^{C,CH}$ ≡ ^5J in Hz may be compared with those given in ref. 5.

[c]The calculations did not converge for θ = 0° and 90°. Therefore 5° should be added to the θ value tabulated as 0° and subtracted at θ = 90°. The value at θ = 90° must be very near 2.91 Hz.

[d]The asymmetry introduced by the highly electronegative α-substituent entails values tabulated for θ between 0 and 180°. For a given pair of numbers the one in parentheses corresponds to 180° − θ.

−0.31 Hz expected for a *very* large twofold barrier to rotation about the C_{sp^2}—C_{sp^3} bond. Consequently, the lower limit of $^5J_p^{C,CH}$ in 2,6-dichloroethyl benzene, in which θ = 30° as in **2**,



2

should be 1.77 $\langle \sin^2 \theta \rangle$ = 0.44 Hz. The observed value is 0.353(15) Hz, corresponding to a θ value of 27°. A similar discrepancy exists for the benzyl halide and benzyl alcohol derivatives in Table 1, where the numbers would suggest a θ value of 23°. These are numbers for a *rigid* conformation of structure type **2**. Now, the σ−π parameter[2] for the methylene protons depends somewhat on the electronegativity of the substituent (3), decreasing as the electronegativity increases. Part of the discrepancy arises from this perturbation. The theoretical numbers in Table 1 indicate a reduction in ^5J in the presence of an electronegative α substituent, but not to the extent suggested by the experimental data for the 2,6-disubstituted derivatives in Table 2. However, the methyl group is not very much more electronegative than a hydrogen substituent. The possibility of a distortion of the sidechain geometry has been previously discussed in detail (15) and it is possible that an effective $\langle \theta \rangle$ of less than 30° can occur for the 2,6-dichoro derivatives. Yet the molecular orbital calculations in ref. 15 gave ambiguous support to this hypothesis (depending on the level of the calculations).[3] Again, a cosine potential might suffer a distortion in these *ortho*-substituted compounds and could possibly account for the anomalous observations. Nevertheless, it should be noted that the V_2 value derived from the *J* method for ethyl benzene agrees exactly with the latest thermodynamic results

[2]In 2,6-dichloro-4-methylbenzyl bromide $^7J_p^{H,H}$ is +0.204 Hz (unpublished work in this laboratory), compared to a value of −0.21(2) Hz for $^6J_p^{H,H}$ in 2,6-dichlorobenzyl bromide (6). The anomalous numbers are therefore still σ−π couplings.

[3]A detailed structure determination would be of interest for compounds of this kind.

(16) and is possibly more precise than conclusions based on electron diffraction data (17).

$^6J_p^{H,C\text{-}\beta}$ in 2,6-dichloroethyl benzene

This coupling changes the relevant preferred θ value to 90° (see structure **2**). Its magnitude is 0.618 ± 0.016 Hz (the coupled spectra are rather complex, causing a substantial error). In the 3,5-dibromo derivative this coupling between the *para* proton and the methyl ^{13}C nucleus is 0.432 ± 0.005 Hz (standard deviations being given in both instances). If 0.618 Hz represents the magnitude of $^6J_p^{H,C}$ at θ = 90°, then $\langle \sin^2 \theta \rangle$ becomes (0.432 ± 0.005)/(0.618 ± 0.016) or 0.699 ± 0.027 for the 3,5-dibromo compound. The relationship between $\langle \sin^2 \theta \rangle$ for the methyl carbon data and $\langle \sin^2 \theta \rangle$ for the methylene protons is $\langle \sin^2 \theta \rangle^C = 1.5 - 2\langle \sin^2 \theta \rangle^H$. When V_2 is zero both expectations are 0.5, whereas they are unity and 0.25 when V_2 is infinite. Thus one has (see previous sections) 0.699 ± 0.027 = 1.5 − 2 (0.384 ± 0.010) = 0.732 ± 0.020. This agreement is taken as confirmation of the σ−π mechanism[4] for $^6J_p^{H,C}$.

4. *Conformational analysis*

The σ−π mechanism for $^5J_p^{C,CH}$ and its $\sin^2 \theta$ dependence implies its use in the determination of preferred conformations and barriers to internal rotation. An advantage of $^5J_p^{C,CH}$ over $^6J_p^{H,CH}$ is that substituents other than hydrogen are allowed at C-4. Note that even a polar fluorine substituent at this position causes only a small change in ^5J. Of course, a substituent which gives rise to very short T_1 or T_2 values for C-4 would cause line broadening and would interfere with the measurement of ^5J; although if it shortened T_2 only, then enrichment of ^{13}C at C-4 would circumvent the difficulty because the coupling would be obtainable from the ^1H nmr spectrum. A wider variety of molecules has therefore become amenable to studies by the *J* method (3). A sensible procedure would involve the measurement of $^5J_p^{C,CH}$ in the toluene substituted at C-4 followed by study of the corresponding benzyl or benzal compound.

[4]The sign of $^6J_p^{H,C}$ is most likely negative, by analogy to the σ−π coupling, $^6J_p^{H,CH_3}$ in toluene; its sign could not be determined because the INEPT sequences were necessary for reasons of sensitivity.

Acknowledgments

We are grateful to Kirk Marat for setting up the INEPT sequences for the transfer of polarization to ^{13}C from ^1H and ^{19}F and to the Natural Sciences and Engineering Research Council of Canada and the University of Petroleum and Minerals for financial assistance.

A relationship between some long-range $^2H/^1H$ isotope shifts in ^{13}C nuclear magnetic resonance and long-range spin–spin coupling constants for toluene, ethylbenzene, and isopropylbenzene

TED SCHAEFER, JAMES PEELING,[1] AND TIMOTHY A. WILDMAN
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received May 25, 1983

TED SCHAEFER, JAMES PEELING, and TIMOTHY A. WILDMAN. Can. J. Chem. **61**, 2777 (1983).

A very good correlation exists between long-range spin–spin coupling constants involving the α-protons in toluene, ethylbenzene, and cumene, and the changes in the chemical shifts of the *para* and α carbons caused by deuterium substitution at the α carbon. The coupling constants depend on $\sin^2\theta$, where θ is the angle by which the α C—H bond twists out of the ring plane, and can be used to find the expectation value of $\sin^2\theta$. Consequently the observed correlation provides quantitative support for the hyperconjugative model employed by Wesener and Günther.

TED SCHAEFER, JAMES PEELING et TIMOTHY A. WILDMAN. Can. J. Chem. **61**, 2777 (1983).

Il existe une très bonne corrélation entre les constantes de couplage à longue distance impliquant les protons en α du toluène, de l'éthylebenzène et du cumène et les variations, provoquées par l'introduction d'un deutérium sur le carbone α, des déplacements chimiques des carbones en position *para* et α. Les constantes de couplage dépendent de $\sin^2\theta$, où θ est l'angle de déformation hors du plan de la liaison C—H en position a; elles peuvent être utilisées pour trouver la valeur probable de $\sin^2\theta$. Par conséquent, les corrélations observées appuient de façon quantitative le modèle d'hyperconjugaison utilisé par Wesener et Günther.

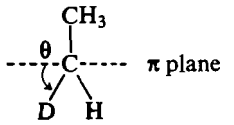
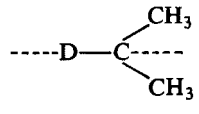
Introduction

Although all $^2H/^1H$ isotope effects, $^n\Delta$, on ^{13}C chemical shifts originate in vibrational/rotational perturbations (1, 2), a simple hyperconjugative model (3) has had some success (4) in the rationalization of some observed $^n\Delta$ values (*n* counts the number of formal bonds between ^2H and ^{13}C sites). In particular, Wesener and Günther (5) indicate that in the title compounds the lesser hyperconjugative electron-donating ability of an α C—D bond relative to a C—H bond, combined with the preferred conformations **1** and **2**, accounts for the magnitudes



1



2

of the negative $^5\Delta$ at C-4 (downfield shifts caused by ^2H substitution). These authors suggest further investigations as to whether these isotope shifts can serve as probes for hyperconjugation.

A quantitative hyperconjugative model for $^5\Delta$

Indeed, if the hyperconjugative interaction has a $\sin^2\theta$ dependence (6, 7), where θ is measured from the π plane as in **1**, then a quantitative test of such a model becomes possible. The *J* method (8), as applied to the title molecules, relates $^6J_p^{H,CH}$, the spin–spin coupling constant between the *para* proton and the α-protons, to the preferred conformations and to the internal barrier to rotation about the C_{sp^2}—C_{sp^3} bond. In other words, the observed ^6J_p allows a derivation of $\langle\sin^2\theta\rangle$ (angular brackets indicate the expectation value), which in turn is related via a hindered rotor model to the internal barrier, taken as twofold for ethylbenzene and isopropylbenzene. One has eq. [1]

$$[1]\quad {}^6J_p^{H,CH}\,(\text{Hz}) = {}^6J_{90}\,\langle\sin^2\theta\rangle$$

in which $^6J_{90}$ is the coupling when θ is 90° (see **1**).

Therefore, hypothesize eq. [2],

$$[2]\quad {}^n\Delta(\text{ppb}) = a\langle\sin^2\theta\rangle + b$$

implying a linear relationship between ^6J_p and $^5\Delta$, where $^5\Delta$ is the value observed for C-4 in these compounds. In fact, the data in Table 1 yield eq. [3] in which, because $^6J_p^{H,CH}$ is negative, the magnitude of the latter is employed. In this way the

$$[3]\quad {}^5\Delta(\text{ppb}) = -10.6|{}^6J_p^{H,CH}| + 2.69, \qquad r = -1.0000$$

negative $^5\Delta$ is emphasized. Furthermore, *a* and *b* in eq. [2] are found as in eq. [4]. For toluene, $\langle\sin^2\theta\rangle$ is 0.5 because the

$$[4]\quad {}^5\Delta(\text{ppb}) = -13.5\,\langle\sin^2\theta\rangle + 2.9$$

barrier to internal rotation is only 59 J/mol (9). Because successive deuteration of the methyl group in toluene produces additive changes in $^5\Delta$, the present treatment is consistent with the assumption that any conformational preferences introduced by C—D bonds are insignificant. The $\langle\sin^2\theta\rangle$ values in Table 1 for ethylbenzene and cumene are those derived by the *J* method (8) and correspond to twofold internal barriers of 5.0 and 8.2 kJ/mol, respectively.

In as yet unpublished work, we show that $^5J_p^{C,CH}$, the coupling between C-4 and α-protons, is transmitted by the same kind of mechanism as $^6J_p^{H,CH}$ and therefore also depends on $\langle\sin^2\theta\rangle$. The data in Table 1 follow eq. [5]. It is interesting that

$$[5]\quad {}^5\Delta(\text{ppb}) = -7.50\,{}^5J_p^{C,CH} + 2.83, \qquad r = 0.9970$$

the constants of 2.8 ± 0.1 ppb in eqs. [3] to [5] are positive. Presumably this number does not have a hyperconjugative origin and is plausibly assigned to an angle-independent inductive shift (7), it being known that C—D bond is *more* inductively electron-donating than a C—H bond.

If the model is adequate, then two predictions are possible. First, in the presence of *ortho* substituents which raise the internal barrier substantially and therefore tend to stabilize conformations **1** and **2**, $^5\Delta$ should approach −0.4 ppb in the ethylbenzene derivative ($\langle\sin^2\theta\rangle \sim 0.25$). Second, $^5\Delta$ should be as

[1]On sabbatical leave from the University of Petroleum and Minerals, Saudia Arabia.

TABLE 1. Some long-range spin–spin coupling constants and changes in ^{13}C chemical shifts caused by deuteration in toluene, ethylbenzene, and cumene

	$^6J_p^{H,CH}$(Hz)	$^5J_p^{C,CH}$(Hz)	$^5\Delta$(ppb)[f]	$^1\Delta$(ppb)[f]	$\langle\sin^2\theta\rangle$[g]
Toluene-α-d_1	−0.62[a]	0.88_3[d]	−3.9	275.5	0.500
Ethylbenzene-α-d_1	−0.45[b]	0.68_0[e]	−2.1	349.1	0.385
Cumene-α-d_1	-0.25_3[c]	0.36_8[e]	0	434.4	0.204

[a]See ref. 13. All these couplings are for undeuterated compounds, ±0.01 to 0.02 Hz.
[b]W. E. Hull, to be published; for a $CDCl_3$ solution.

[e]For the 3,5-dibromo derivative and as in [b].
[f]From ref. 5, ±0.4 ppb (parts per billion).
[g]From ref. 8. These are H values (see text).

large as 2.9 ppb for the cumene derivative ($\langle\sin^2\theta\rangle \sim 0$). These measurements cannot be made in this laboratory.

Concerning $^1\Delta$

While the discussion above supports the suggestions of Wesener and Günther (5), it is notable that $^1\Delta$ also correlates with $^6J_p^{H,CH}$ and $^5J_p^{C,CH}$ as in eqs. [6] and [7]. These *upfield* shifts

$$[6] \quad {}^1\Delta(\text{ppb}) = 433.0\ {}^6J_p^{H,CH} + 543.9 \qquad r = 1.000$$

$$[7] \quad {}^1\Delta(\text{ppb}) = -305.6\ {}^5J_p^{C,CH} + 549.7 \qquad r = 0.9969$$

increase as the hyperconjugative release to the π system decreases. Thus, if $^6J_p^{H,CH}$ were zero – no hyperconjugation – then $^1\Delta$ would be 543.9 ppb or, alternatively, would be 549.7 ppb if $^5J_p^{C,CH}$ were to vanish. Again, if the barrier to internal rotational in toluene-α-d_1 is negligibly different from 59 J/mol, as in toluene, then $\langle\sin^2\theta\rangle$ is 0.5, so that 275.5 × 2 = 551 ppb would represent $^1\Delta$ in the absence of hyperconjugation, where 275.5 ppb is the shift observed in toluene-α-d_1. In other words, the three different estimates suggest 548 ± 4 ppb for $^1\Delta$ in the absence of hyperconjugation. This value contrasts with a $^1\Delta$ of only 187 ppb in CH_3D (10). In the latter one expects a rather different potential energy surface than in toluene, of course. In any event, we take eqs. [6] and [7] as confirmation that both $^1\Delta$ and $^5\Delta$ originate in isotopic perturbations of the vibrational/rotational potential energy surface.

Other $^n\Delta$ values

An insignificant correlation, $r = 0.964$, exists between $^3\Delta$ at C-2 and $^4J_4^{H,CH}$ for these three compounds. The data are therefore not reproduced here, although it should be noted that an angle-dependence of $^3\Delta$ can occur in saturated systems (11). No $^4\Delta$ at C-3 is observed in the title compounds, perhaps because substituents in benzene perturb only slightly the shielding of *meta* carbon nuclei.

In ethylbenzene-β-d_3, $^6\Delta$ at C-4 is +12.6 ppb (5). A tentative observation holds that the C—C bond hyperconjugates, perhaps better than a C—H bond (12), and that deuteration of the group enhances this interaction, being an inductive donor to the C—C bond region. This line of argument implies two consequences. The $^6\Delta$ value should increase as substitution at the *ortho* positions stabilizes **1**. Furthermore, a single CD_3 group in cumene should cause a smaller $^6\Delta$ than in ethylbenzene. This result follows from the $\langle\sin^2\theta\rangle$ numbers in Table 1 because $\langle\sin^2\theta\rangle^C = 1.5 - 2\langle\sin^2\theta\rangle^H$ for ethylbenzene and for cumene one has $\langle\sin^2\theta\rangle^C = 0.75 - 0.5\langle\sin^2\theta\rangle^H$.

In summary, the present discussion provides evidence in favour of the approach used by Wesener and Günther and suggests further quantitative tests of $^2H/^1H$ isotope shifts of ^{13}C as a hyperconjugative probe.

Signs and mechanisms of ^{13}C, ^{19}F spin–spin coupling constants in benzotrifluoride and its derivatives

TED SCHAEFER, KIRK MARAT, JAMES PEELING,[1] and RICHARD P. VEREGIN
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received May 2, 1983

TED SCHAEFER, KIRK MARAT, JAMES PEELING, and RICHARD P. VEREGIN. Can. J. Chem. **61**, 2779 (1983).

The magnitudes of ^nJ(C, F) for n = 3, 4, 5 bonds are remeasured for benzotrifluoride. The signs of ^2J(C, F) and ^3J(C, F) are determined for 4-chloro-3,5-dinitrobenzotrifluoride and that of ^5J(C, F) for 2-amino-3,5-dibromobenzotrifluoride. ^4J(C, F) is not observable in these compounds. The contact contributions to ^nJ(C, F) are calculated for benzotrifluoride by INDO MO FPT. The long-range coupling constants are discussed in terms of the mechanisms which transmit nuclear spin state information. It seems that ^5J(C, F) is a $\sigma-\pi$ coupling, ^4J(C, F) is a composite of σ and $\sigma-\pi$ components of opposite sign, and that ^3J(C, F) has a Karplus behaviour modified by a $\sigma-\pi$ contribution.

TED SCHAEFER, KIRK MARAT, JAMES PEELING et RICHARD P. VEREGIN. Can. J. Chem. **61**, 2779 (1983).

On a mesuré de nouveau les valeurs ^nJ(C, F) pour n = 3, 4, 5 liaisons du benzotrifluorure. On a déterminé les signes de ^2J(C, F) et de ^3J(C, F) du chloro-4 dinitro-3,5 benzotrifluorure et ceux de ^5J(C, F) de l'amino-2 dibromo-3,5 benzotrifluorure. Dans ces composés, on n'a pas observé de ^4J(C, F). On a calculé les contributions de contact à ^nJ(C, F) du benzotrifluorure en faisant appel aux méthodes INDO OM FTP. On discute des constantes de couplage à longue distance en fonction du mécanisme qui transmet l'information de l'état de spin nucléaire. Il semble que ^5J(C, F) est un couplage $\sigma-\pi$, ^4J(C, F) est un mélange de contributions α et $\sigma-\pi$ de signes opposés et que ^3J(C, F) a un comportement de Karplus modifié par une contribution $\sigma-\pi$.

Introduction

INDO MO FPT calculations give a decent account of the signs and magnitudes of the long-range spin–spin coupling constants, $^nJ(H, CH_3)$, between methyl and ring protons in toluene (1). Similar calculations (2) for couplings (3) between methyl protons and ring carbon nuclei in toluene agree rather less well with experiment, yet they do provide information about the conformational dependence of these coupling parameters.

The electronic interactions of the CF_3 group with the phenyl moiety in benzotrifluoride are rather different (4) from the analogous interactions in toluene. Nevertheless, the magnitudes and signs of $^nJ(H, CF_3)$ in benzotrifluoride are not strikingly different from $^nJ(H, CH_3)$ in toluene (5). $^nJ(F, CH_3)$ and $^nJ(F, CF_3)$ in fluorine derivatives of toluene and benzotrifluoride, respectively, have also been discussed in some detail in terms of composite coupling mechanisms (6, 7).

The magnitudes of ^nJ(C, F) are available for many benzotrifluoride derivatives (8–10). In 2-fluorobenzotrifluoride $^1J(C, F_3)$ is negative and $^3J(C\text{-}2, F)$ is positive (11). Sign determinations for all ^nJ(C, F) in benzotrifluoride itself, as was done for toluene (3), would be ideal but would also require much more effort than is necessary. The magnitudes of ^nJ(C, F) are not very sensitive to substitution. Accordingly we remeasured the magnitudes of ^nJ(C, F), for n = 3, 4, 5, in benzotrifluoride, **1**, and determined the signs of ^nJ(C, F), for n = 2, 3, 5 employing 4-chloro-3,5-dinitrobenzotrifluoride, **2**, and 2-amino-3,5-dibromobenzotrifluoride, **3**, in double resonance experiments. These results are reported here, as are INDO MO FPT calculations for **1**, and ^nJ(C, F) for n = 3, 4, 5 are discussed in terms of coupling mechanisms.

Experimental

Compounds **1** and **2** came from Pierce Chemical Company and **3** was prepared from 2-aminobenzotrifluoride (Aldrich) by bromination. A 7.8 mol% solution of **2** in acetone-d_6 (nearly saturated) and a 38 mol% solution of **3** in the same solvent were degassed by a number of freeze–pump–thaw cycles and were flame-sealed into 10-mm od nmr sample tubes. A 50% v/v solution of **1** in acetone-d_6 was not degassed but simply transferred to a 10-mm od nmr tube.

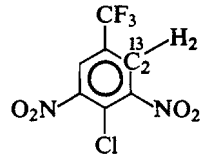
The ^{13}C, ^{19}F, and ^1H nmr spectra were accumulated on a WH-90 spectrometer at a probe temperature of 305 K and at transmitter frequencies of 22.63, 84.70, and 90.02 MHz, respectively. The spectrometer employs a Bruker magnet and console, except that it uses a 293 A′ pulse programmer and an 1180 data system and associated software from Nicolet Technology Corporation. The B_1 fields for multiple resonance experiments were calibrated with off-resonance techniques and could be controlled in 1-dB steps. Details of the instrumental modifications for such experiments have been mentioned (12, 13). A typical experiment on **3** involved 256 scans over a period of 96 minutes with 32 K data points devoted to a spectral width of 800 Hz, yielding ^{13}C multiplets of the kind displayed in Fig. 1. Experiments on the dilute solution of **2** involved as many as 3152 transients to obtain a coupled ^{13}C nmr spectrum. The proton-decoupled ^{13}C nmr spectrum of **1** could be obtained relatively easily and displayed linewidths at half-height of ≤0.2 Hz.

INDO MO FPT calculations (14) of ^nJ(C, F) in benzotrifluoride employed an Amdahl 470/V7 system and were based on the recent electron diffraction geometry (15).

Results and discussion

1. *Signs of* $^nJ(C, F)$ *in 2 and 3*

The coupling data for **2**, relevant to the present discussion, are given in Table 1. The sign of $^3J(C\text{-}2, F)$ in **2** was determined by double resonance experiments (16) on the nmr spectra of the isotopomer, **4**. Irradiation of the appropriate ^{19}F peaks



4

and observation of the connected transitions in the H-2 nmr spectrum showed that $^3J(C\text{-}2, F)/^1J(C, H) > 0$. Therefore (17)

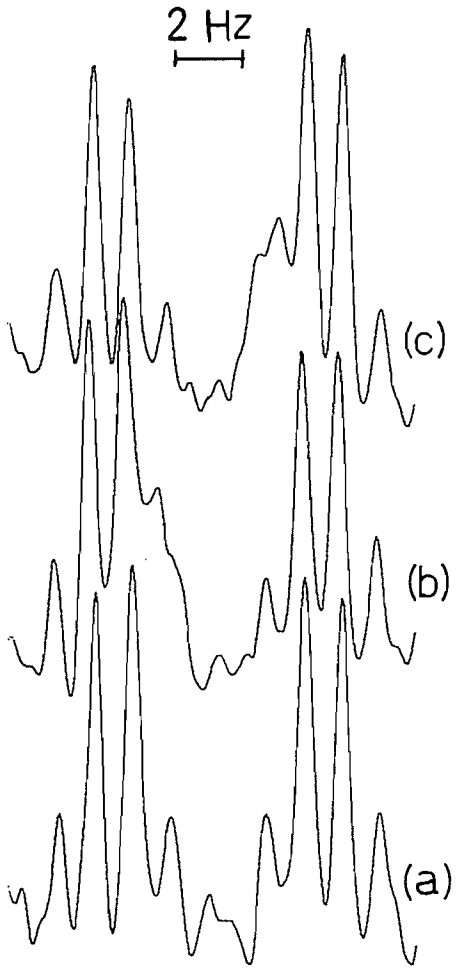

FIG. 1. In (a), the C-4 resonance at 22.63 MHz of 2-amino-3,5-dibromobenzotrifluoride, **3**, in acetone-d_6 solution is shown for one spin state of H-4 and both spin states of H-6. The pair of quartets is separated by ^3J(H-6, C-4). The quartet splitting represents ^5J(F, C-4). In (b), the same quartets are displayed under conditions where one peak in an H-4 quartet is irradiated corresponding to selected spin states of H-6 and CF_3. In (c), a peak of H-4 is irradiated with spin states of H-6 and CF_3 opposite to those in (b). The experiments show that ^5J(F, C-4)/^6J(F, H-4) < 0. Therefore ^5J(F, C-4) is positive. In these experiments it is useful to remember that one finds the ratio of the signs of the coupling constants to a third nucleus from the observed nucleus-one and irradiated nucleus-two. For example, half of the H-4 signal consists of a pair of quartets, separated by ^3J(H-6, H-4). This coupling is small enough so that the quartets due to ^6J(F, H-4) overlap. However, the lowest field peak corresponds to a single spin state of each of H-6 and of the F nuclei. Irradiation of only this peak causes the high-field peak of the low-field quartet in (b) to be split. This shows that the ^{19}F nuclei couple to C-4 with an interaction of opposite sign to their coupling to H-4. The latter is negative. Furthermore, this experiment also shows that ^3J(H-3, H-4) and ^3J(C-4, H-6) have the same sign.

^3J(C-2, F) = +3.75 Hz in **2** and no doubt +3.9 Hz in **1** (10). This sign agrees with the +2.6 Hz found by ^{19}F {^{19}F} double resonance experiments in 2-fluorobenzotrifluoride (11).

That ^2J(C-1, F)/^2J(C-1, H) < 0 was ascertained from irradiation of the appropriate transitions of H-2,6 in the molecule **5** and observation of the ^{19}F nmr peaks. The sequence of ^2J(C-1, H) in C_6H_5X compounds is +1.1, +0.5, −2.5, −3.4, −3.6, −4.9 Hz for X = H, CH_3, I, Cl, NO_2, F, respectively (2, 3, 18), and shows a very rough correlation with the electronegativity of X. The electronegativity of the CF_3 group is at least as large as that of the iodine substituent (19), so that ^2J(C-1, H) is no doubt negative in benzotrifluoride itself. Furthermore, a chlorine substituent on benzene causes a decrease in ^2J(C-4, H) of 0.25 Hz, whereas a nitro group increases ^2J(C-3, H-4) by 0.35 Hz and decreases ^2J(C-3, H-2) by 1.4 Hz. Accordingly, it seems certain that ^2J(C-1, H-2) is −1.9 Hz in **5** (see Table 1). Therefore ^2J(C-1, F) is +36.0 Hz in **2** and no doubt +32.2 Hz in **1** (20).

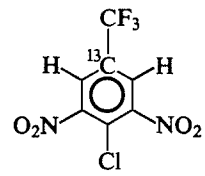
^3J(C_α, H)	4.53(4)	^5J(C-4, F)	+1.11(5)[c]
^3J(C-2, F)	+3.75(1)[d]	^4J(C-3, F) ^4J(C-5, F)	not seen[e]

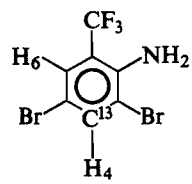
[a]For a 7.8 mol% solution in acetone-d_6 and 305 K, values in Hz.
[b]If ^2J(C-1, H) is negative, as is almost certain, then ^2J(C-1, F) is positive. See text.
[c]Assumed to be of the same sign as the +1.10(2) Hz determined for ^5J(C-4, F) in 2-amino-3,5-dibromobenzotrifluoride (see text and Fig. 1).
[d]Sign is relative to ^1J(C, H) and is the same as the +2.6 Hz determined for ^3J(C-2, F) in 2-fluorobenzotrifluoride (11).
[e]For the 50% v/v solution of benzotrifluoride in acetone-d_6, repeated measurements gave ^4J(C-3, F) < 0.1 Hz, the linewidth at half height being 0.2 Hz for C-4 and other carbons; ^3J(C-2, F) = 3.92 ± 0.05 Hz, ^5J(C-4, F) = 1.39 + 0.03 Hz.



5

Multiple resonance experiments designed to determine the sign of ^5J(C-4, F) in **2** were unsuccessful. Even weak irradiation of ^{1}H nmr peaks caused large polarizations of the C-4 populations, leading to large negative and positive enhancements of those C-4 peaks corresponding to +1 and −1 spin states of the H-2,6 triplet. These phenomena can be traced back to the rather long relaxation time of C-4 and are interesting here only insofar as they obscured the relative sign information inherent in the experiment.

Consequently, the sign of ^5J(C-4, F) was determined for structure **6** of compound **3**.



6

This molecule also gives rise to spectra for which double resonance experiments are unequivocal in that the spectra do not deviate greatly from first order. Figure 1 displays one-half of the C-4 multiplets of **6** and shows how they are perturbed by

[a]For a 38 mol% solution in acetone-d_6 at 305 K.
[b]In ppm corrected to internal TMS by adding 29.8 ppm to the shifts, which were measured relative to acetone solvent. The C-3 and C-5 shifts are assigned on the basis of additivity of substituent induced shifts and could possibly be reversed.

irradiation of peaks from H-4 which correspond to selected spin states of H-6 and ^{19}F. The experiment gives ^5J(C-4, F)/^6J(F, H-4) < 0 and therefore (5) ^5J(C-4, F) = +1.10 Hz. Undoubtedly this coupling is then +1.11 Hz in **2** and +1.39 Hz in **1**. Because ^{13}C nmr data are not documented for **3**, Table 2 collects our spectral data for this compound.

2. *The C, F, spin–spin coupling mechanisms*

(i) *Preliminary considerations*

In toluene, $^6J(H, CH)$ is −0.62 Hz (21) and is transmitted via a σ−π electron spin polarization mechanism (1, 22). As such, it is expected and calculated to follow the relationship $^6J = {}^6J_{90} \sin^2 \theta$, where θ is the angle by which the C—H bond of the methyl group twists out of the benzene plane (1). $^6J_{90}$ is the value of ^6J when θ is 90°. The INDO MO FPT calculations agree quantitatively with experiment, indicating that the σ−π parameters for the methyl group and the ring C—H bond are correctly reproduced by the INDO parameterization.

Similarly, $^6J(H, CF)$ in benzotrifluoride is −0.64 Hz (5), suggesting that the σ−π parameters for the CH_3 and CF_3 groups are nearly the same, in line with the hyperfine parameters for the neutral $CF_3CH_2\cdot$ and $CH_3CH_2\cdot$ radicals (23, 24). In contrast to $^6J(H, CH)$ in toluene derivatives (7), $^6J(H, CF)$ is somewhat substituent dependent ranging from −0.58 to −0.68 Hz (6, 25). It has been suggested that this coupling contains a σ electron contribution of 0.15 ± 0.05 Hz (6), although it seems reasonable that the σ−π parameter of the CF_3 group be somewhat more sensitive to the presence of ring substituents than is the CH_3 moiety, so that a σ electron contribution is not certain.[2] Certainly, INDO MO FPT computations of $^6J(H, CF)$ indicate (26) a precise $\sin^2 \theta$ dependence, i.e., a σ−π mechanism (1), but yield $^6J_{90}$ as −2.40 Hz instead of the −1.28 Hz expected from experiment. The barrier to internal rotation in benzotrifluoride (27) is only 40 J/mol; hence the average value of $\sin^2 \theta$ is 0.5. Therefore $^6J(H, CF)$ should be $-1.28 \langle \sin^2 \theta \rangle$ or −0.64 Hz. It appears that the INDO calculations overestimate the σ−π parameter for the CF_3 group by a factor of 1.87_5. Note that the toluene data indicate a correct INDO value for the σ−π parameter of the *para* C—H bond.

[a]Using the electron diffraction geometry (15).
[b]The value of θ is zero degrees when the C—F bond lies in the benzene plane and is *cis* to the carbon atom for ^3J and ^4J. See, for example, Fig. 2.

Of course, the present discussion imples that a discussion of the coupling mechanism in terms of σ and of π electrons is useful. As developed below, such a model can rationalize ^4J(C-3, F) in benzotrifluoride.

(ii) $^5J(C\text{-}4, F)$ *in benzotrifluoride as a* σ−π *coupling*

The INDO values for this coupling in Table 3 closely follow a $\sin^2 \theta$ relationship if the value at θ = 0°, 0.15 Hz, is subtracted from each entry. The theoretical coupling obeys eq. [1]

[1] $^5J(C\text{-}4, F) = 0.15 + 7.46 \sin^2 \theta$

to within an average deviation of 0.01_5 Hz. The number, 0.15 Hz, can be considered as an angle independent (σ) term or as an artifact of the calculation.

However, $7.46 = {}^5J_{90}$ is clearly much too large. In benzotrifluoride, ^5J(C-4, F) is 1.39(3) Hz (Table 1). The present study finds it as +1.11(5) Hz in 4-chloro-3,5-dinitrobenzotrifluoride and as +1.10(2) Hz in 2-amino-3,5-dibromobenzotrifluoride. Assuming 1.3_9 Hz as the proper value, and remembering the overestimate of the σ−π parameter for the CF_3 group above (1.87_5), one has $7.46/(1.87_5 \times 2 \times 1.39)$ or 1.43 as the overestimate of the σ−π parameter for the *para* carbon atom. In other words, *if* ^5J(C-4, F) is indeed a σ−π coupling, then it can be written as eq. [2]

[2] $^5J(C\text{-}4, F) = A + (2.78 - A) \sin^2 \theta$

This discussion describes ^5J(C-4, F) as predominantly a σ−π coupling. Then the substituent-induced variations in this coupling arise from a perturbation of one or both of the σ−π parameters at the ends of the coupling fragment.[3] If the present approach has value, then it should rationalize the unobservably small ^4J(C-3, F) in benzotrifluoride and its derivatives.

[2]Such a contribution can only be established by a lengthy and systematic study of a large number of benzotrifluoride derivatives, similar to the one recently described for 2-fluorotoluene and its derivatives (7), and is in progress.

[3]The σ−π parameter at C-4, which might be writtten as Q^C_{CX}(28), no doubt consists of a number of terms (29) and would need to be established for each type of sidechain at C-1. The σ−π parameter will be sensitive to the spin densities at the neighbouring carbon atoms, for example.

(iii) *^4J(C-3, F) as a composite σ and σ−π coupling*

It has been suggested (8) that this coupling apparently vanishes because of σ and σ−π electron contributions of opposite sign. INDO calculations of $^5J(F, CF_3)$ in 3-fluorotoluene are indeed compatible with such a situation for the very small *substituent-independent* coupling of ca. +0.25 Hz (7, 30). Furthermore, $^5J(H, SH)$ and $^5J(H, CH_3)$ in thiophenol (31) and toluene (1) can be rationalized as additive contributions of σ and σ−π mechanisms of the same sign. Indeed, in thiophenol and some of its derivatives, $^5J(H, SH)$ can be written as (31) eq. [3],

$$[3] \quad {}^5J = A \sin^2(\theta/2) + B \sin^2\theta$$

where the first term represents the σ electron part of ^5J.

Now, the INDO numbers of ^4J(C-3, F) in Table 3 are approximately reproduced by a closely related eq.[4]

$$[4] \quad {}^4J(\text{C-3, F}) = -0.20 + 3.10 \sin^2(\theta/2) - 6.88 \sin^2\theta$$

with an average absolute deviation of 0.07 Hz. It can be argued that the constant term is contrary to the implied coupling mechanism and that it should be eliminated. It is small, however, and any adjustment to eq. [4] would be somewhat arbitrary. Because the rotational averages of $\sin^2\theta$ and of $\sin^2(\theta/2)$ are both 0.5 (31), the calculated value of ^4J(C-3, F) becomes −2.89 Hz. Of course, the composite σ−π parameters are incorrect and, as estimated above for ^5J(C-4, F), should be reduced by a factor of 2.67 = 1.43 × 1.87. Therefore, the rotationally averaged ^4J(C-3, F) becomes +0.06 Hz, indeed compatible with an experimentally vanishing coupling.

This argument implies that the σ electron contribution to ^4J(C-3, F) is calculated correctly by the theory. The σ−π contribution is negative because of electron correlation. The spin correlation function for atoms belonging to different classes is negative (28), so that if positive σ−π components occur at C-2 and C-4, the component at C-3 is expected to be negative.

(iv) *The vicinal coupling, ^{3}J(C-2, F)*

The vicinal coupling ^3J(C-2, F), calculated in Table 3, displays a distorted Karplus behaviour in that the minimum lies nearer 60° than 90°. A reasonable fit to an equation of the form $^3J = A + B\cos\theta + C\cos 2\theta$ is not possible. Furthermore, the value of 10.72 Hz at θ = 0° is very small relative to that of 17.60 Hz at θ = 180° when compared to other theoretical and experimental vicinal couplings (32), e.g. ^3J(H, C). The reason for the small $^3J(\theta = 0°)$ is very likely related to large negative couplings to ^{19}F, calculated by INDO MO FPT when the other nucleus lies near ^{19}F. For example, in benzotrifluoride large negative ^4J(F, H-2) numbers are computed for θ < 45° (26). Again in 2-fluorotoluene similar negative $^4J(F, CH_3)$ values arise for θ values which bring the methyl hydrogen atoms and the fluorine atom into proximity (26). In fact, $^4J(F, CH_3)$ is +0.5 Hz for θ ~ 0° (7), not −3.2 Hz, as calculated (26). Similar remarks apply to $^5J(CHO, CF_3)$ in 2-trifluoromethylbenzaldehyde (33).

We suggest that the calculated ^3J(C-2, F) parameters in Table 3 suffer from such distortions. The normal Karplus curve displays a minimum nearer 90°. The calculated data in Table 3 are easily adjusted to meet these requirements and yield the Karplus eq. [5]. This equation gives 11.51 Hz as the average

$$[5] \quad {}^3J = 11.51 - 2.28\cos\theta + 3.81\cos 2\theta$$

^3J, whereas the observed average is 3.92 ± 0.05 Hz. Of course, a positive σ−π contribution to ^3J of the form $D \sin^2\theta$ is also expected. Because $2\sin^2\theta = 1 - \cos 2\theta$, eq. [5] contains this contribution. It enters as $A + D/2$ and $C - D/2$, where A and C are the σ electron terms. Available data (1, 26) indicate that its *calculated* magnitude will be comparable to the σ−π contribution to the *para* position (cf. eqs. [1] and [4]). A brief speculation then proposes eq. [6]

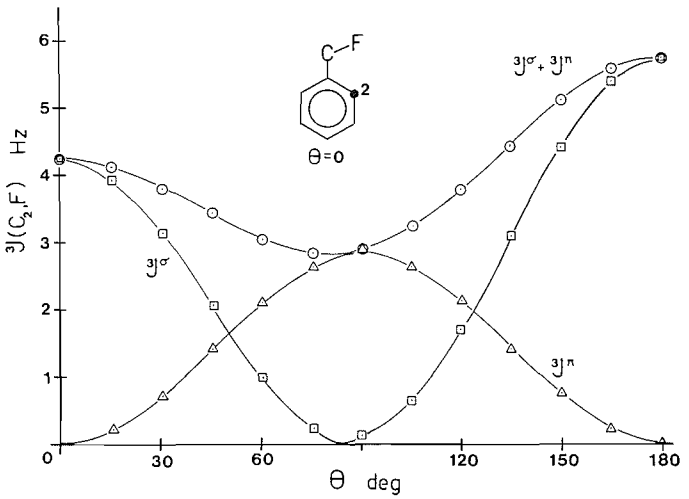

FIG. 2. ^3J(C-2, F) in benzotrifluoride is plotted versus the dihedral angle θ. The circles represent the equation $^3J(\text{C-2, F}) = 2.52 - 0.74\cos\theta + 2.44\cos^2\theta + 2.79\sin^2\theta$. The π electron contribution is given by the last term of this equation and is also plotted in the figure, as is the σ electron component given by the first three terms of the equation. See text for a discussion.

$$[6] \quad {}^3J = 7.78 - 2.28\cos\theta + 7.54\cos 2\theta + 7.46\sin^2\theta$$

where the σ−π contribution is written explicitly. Now, 7.46 $\sin^2\theta$, the σ−π term, is too large by a factor of 2.67 (see above). Furthermore, to obtain agreement with experiment, divide the σ terms in eq. [6] by an arbitrary factor of 3.08 and obtain eq. [7].

$$[7] \quad {}^3J(\text{C-2, F}) = 2.52 - 0.74\cos\theta + 2.44\cos 2\theta + 2.79\sin^2\theta$$

In eq. [7] the average over essentially free rotation is now 3.92 Hz, as observed (note that $\langle\cos\theta\rangle = \langle\cos 2\theta\rangle = 0$ and $\langle\sin^2\theta\rangle = 0.5$). This equation is plotted in Fig. 2 and may represent the experiment in a reasonable way. Of course, for a CF_3 group with its threefold local symmetry, this equation predicts the same *average* ^3J(C-2, F) value for any θ, so that it could be tested only for a situation where reorientation about the C_{sp^2}—C_{sp^3} bond were slow enough to cause the differences in observable chemical shifts among the ^{19}F nuclei of the CF_3 group. Note that *meta* or *para* substitution with up to three substituents in benzotrifluoride causes very little change (9) in ^3J(C-2, F). A 2-X substituent decreases ^3J(C-2, F) and increases ^3J(C-6, F), as can be seen for **3**. In view of the properties of eq. [7], such changes reflect intrinsic substituent perturbations of ^3J(C, F) and not conformational preferences of the CF_3 group. Some support for the presence of a σ−π contribution to ^3J(C, F) can be garnered from the data on 2-trifluoromethylnaphthalene (8). In this compound, ^3J(C-3, F) is 3.2 Hz and ^3J(C-1, F) is 4.5 Hz, whereas ^3J(C-2, F) in benzotrifluoride is 3.9 Hz. The double-bond character of the C-1, C-2 bond in naphthalene is larger than that in benzene, while that of the C-2, C-3 bond is smaller. The σ−π contribu-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

tion should therefore be larger to ^3J(C-1, F) in the naphthalene derivative than to ^3J(C, F) in benzotrifluoride and should be less to ^5J(C-3, F), as is observed.

(v) ^2J(C-1, F) *and* ^1J(C, F)

The discussions of ^nJ(C, F) for $n = 3$, 4, 5 above are couched in terms of σ and $\sigma-\pi$ components, and are based on experiment and on hints from the INDO computations. The latter are based on the contact term only. Neglect of other than contact terms for ^1J(C, F) is not justified and ^2J(C, F) very likely also contains such terms. It may be noted that the θ dependence of ^2J(C-1, F) in Table 3 is qualitatively similar to that computed for ^2J(C-1, CH_3) in toluene (3), but is too *small* (compare ^nJ(C, F) for $n = 3$, 4, 5 in Table 3 where the calculated values are too *large*) by a factor of about seven. This result can be taken as a hint that other than contact terms are significant.

(vi) *Concerning non-contact contributions to* ^{n}J(C, F)

As a referee points out, the possible presence of non-contact mechanisms for ^nJ(C, F) must be considered. Beginning with ^1J(C, F) early calculations (34) noted the disagreement between the INDO MO FPT contact contributions and experiment. Non-contact contributions to ^1J(C, F) were mentioned as one possible reason for the disagreement. Indeed, their presence was confirmed by Blizzard and Santry (35). Other calculations have been reviewed (36–39). Computations of ^2J(C, F) are more equivocal as to the relative contributions of non-contact mechanisms (37–40), but their presence seems likely, particularly in fluorobenzene (39–43). In the latter compound ^3J(C, F) and ^4J(C, F) are also calculated to have non-contact contributions.

However, it has been shown experimentally and theoretically, as reviewed by Wray (44), that ^3J(C, F) in saturated acyclic and cyclic fluorine derivatives is dominated by the contact mechanism and that other mechanisms are not important in determining its conformational behaviour. The CF_3 group in benzotrifluoride is to first order a saturated group and the C—F bonds interact only in a second order manner with the aromatic ring. In that sense, the approach taken in this paper to ^3J(C, F) may have validity.

Turning to ^5J(C-4, F), the contact contributions in Table 3 yield a $\sigma-\pi$ mechanism, but are too large by a factor of 2.7. Similar calculations (45) for ^5J(C-4, H) in toluene suggest a $\sigma-\pi$ mechanism, yet are again too large by a factor of 2.4. In a recent extensive theoretical and experimental investigation, we have shown that ^5J(C-4, H) is indeed a $\sigma-\pi$ coupling (46). The overestimate of its magnitude and that of ^nJ(C-4, F) by INDO MO FPT methods is very likely traceable to the theoretical, effective $\sigma-\pi$ parameter at C-4 in these compounds. It seems unlikely that the theoretical overestimates are an indication of other than contact mechanisms for ^5J(C-4, F) and ^5J(C-4, H).

As to ^4J(C, F) we have presented a rationalization of its absence in benzotrifluoride but cannot prove that non-contact mechanisms are negligible. A full theoretical approach is indicated, now that all the signs of ^nJ(C, F) in benzotrifluoride are known.

Conclusions

The long-range coupling ^5J(C-4, F), in benzotrifluoride can be interpreted as a π electron-mediated interaction, while ^4J(C-3, F) is a composite of mutually cancelling σ and π electron components of opposite sign. Any substituent perturbations of these components must also compensate one another. ^3J(C-2, F) very likely consists of a σ electron contribution, obeying a Karplus dependence on the conformational angle θ, and a π electron contribution which, obeying a $\sin^2\theta$ law, can be absorbed into a Karplus equation.

Concerning the mechanism of $^5J_m^{H,CH_3}$ in toluene and its derivatives

TED SCHAEFER AND REINO LAATIKAINEN[1]

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba, Canada R3T 2N2

Received June 7, 1983

TED SCHAEFER and REINO LAATIKAINEN. Can. J. Chem. **61**, 2785 (1983).

On the basis of the observed five-bond spin–spin coupling constants between the α protons and the *meta* ring protons in the 2,6-difluoro derivatives of toluene, ethylbenzene, and cumene, it is argued that $^5J_m^{H,CH_3}$ in toluene can be written as $A\langle\sin^2\theta\rangle + B\langle\sin^2(\theta/2)\rangle$. A and B are of the same sign and of very similar magnitude. In consequence, $^5J_m^{H,CH_3}$ cannot be used to measure the conformational preference of the methyl group. However, $^5J_m^{H,CH_2}$ and $^5J_m^{H,CH}$ in α-substituted toluene derivatives will be useful in conformational studies. $^5J_m^{H,CH_3}$ in toluene derivatives varies between 0.30 and 0.46 Hz and some patterns in its ring substituent dependence can be gleaned from some fifty precise values.

TED SCHAEFER et REINO LAATIKAINEN. Can. J. Chem. **61**, 2785 (1983).

En se basant sur les constantes de couplage spin–spin à travers cinq liaisons que l'on a observées entre les protons α et les protons en position *meta* du cycle dans les difluoro-2,6 toluène, ethylbenzène et cumène, on suggère que $^5J_m^{H,CH_3}$ dans le toluène peut être représentée par l'équation $A\langle\sin^2\theta\rangle + B\langle\sin^2(\theta/2)\rangle$. Les constantes A et B ont le même signe et sont de valeurs semblables. En conséquence, on ne peut pas utiliser $^5J_m^{H,CH_3}$ pour mesurer la préférence conformationnelle du groupe methyle. Toutefois, $^5J_m^{H,CH_2}$ et $^5J_m^{H,CH}$ dans les dérivés du toluène substitués en α peuvent être utiles dans des études conformationnelles. Les valeurs de $^5J_m^{H,CH_3}$ dans les dérivés du toluène varient entre 0.30 et 0.46 Hz et quelques patrons de leur dépendance avec les substituants du cycles peuvent être glanés à partir de cinquante valeurs précises.

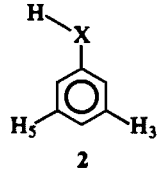
Introduction

The long-range spin–spin coupling constants between nuclei in the benzene ring and those in sidechains are of interest in the theory of the transmission of nuclear spin state information via electronic interactions, as well as in their applications to conformational problems. For example, the coupling over six bonds between α and ring protons, $^6J_p^{H,CH_3}$, in toluene is proportional to $\sin^2\theta$ (see **1**). $^6J_p^{H,CH_3}$ is therefore understood as a

1

σ–π coupling mechanism (1), in which the π electrons transmit the spin information and a σ–π spin polarization acts at both ends of the coupling path to complete the interaction between the protons in the σ electron framework. The θ dependence implies the use of $^6J_p^{H,CH_3}$ in conformational studies which, in fact, can yield quantitative information about the orientational preferences and the small internal barriers to rotation about the exocyclic bonds in molecules such as ethylbenzene (1, 2). The somewhat more complex angle dependence of $^4J_o^{H,CH_3}$ has recently been discussed in detail (3), and discussions of $^5J_{o,m,p}^{F,CH_3}$ are also available (4–7).

For couplings over five formal bonds, two mechanisms must be considered. A σ–π contribution no doubt exists. It is very likely that a σ contribution is also present. The latter will have its largest magnitude when the nucleus in the sidechain lies in the plane of the benzene ring, as in **2**. When the sidechains are



2

aldehydic or hydroxyl groups, for which the stereochemistry of **2** is strongly preferred, many studies have shown the coupling to H-3 to be large (θ = 180°) and that to H-5 (θ = 0°) to be very small or, more often, undetectable (8–14).

The behaviour of ^5J for θ values other than 0° or 180°, that is for nonplanar conformations, has received much less attention. A detailed INDO MO FPT approach to toluene and the xylenes suggested that $^5J_m^{H,CH_3}$ was a composite of σ–π and σ electron interactions (15). The former varied as $\sin^2\theta$ and the latter perhaps as $\sin^2(\theta/2)$. There exists some evidence for the σ–π component (16–19) from the methyl group replacement technique (20), in which the coupling over six formal bonds between the methyl groups in *m*-xylene is taken as the negative of the σ–π component of $^5J_m^{H,CH_3}$.

More recently, a σ component of $^5J_m^{H,SH}$ varying as $\sin^2(\theta/2)$ was plausibly deduced for thiophenol and its *para*-substituted derivatives (21). In such molecules $\langle\sin^2(\theta/2)\rangle$ (brackets indicate expectation values) is necessarily 0.5 whatever the twofold barrier to rotation about the C—S bond, whereas $\langle\sin^2\theta\rangle$ varies with the twofold barrier, allowing a decomposition of the observed couplings into their two components.

For methyl groups, with their local threefold symmetry, the properties of $\sin^2\theta$ and $\sin^2(\theta/2)$ make such a decomposition rather more difficult. In addition, substituents placed along the coupling path may alter the magnitudes of the two components. Nevertheless, a sizeable number of $^5J_m^{H,CH}$ values are available in this laboratory and the most precise of these allow a test of the hypothesis in eq. [1]. In this equation, $^5J_{90}^{\pi} \equiv {}^5J^{\pi}$ is the magnitude of the σ–π component for θ = 90° and $^5J_{180}^{\sigma} \equiv {}^5J^{\sigma}$

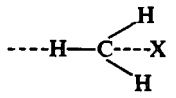
$$[1]\quad {}^5J_m^{H,CH_3} = {}^5J_{90}^{\pi}\langle\sin^2\theta\rangle + {}^5J_{180}^{\sigma}\langle\sin^2(\theta/2)\rangle$$

is the magnitude of the σ component for θ = 180°, or planar zig-zag bond arrangement. $^5J^{\pi}$ vanishes for conformations in which the α C—H bond lies in the molecular plane and $^5J^{\sigma}$ vanishes only at θ = 0°.

Discussion

Whatever the preferred orientation of the methyl group, for example as in **3** for an *ortho* substituted toluene, both $\sin^2\theta$ and

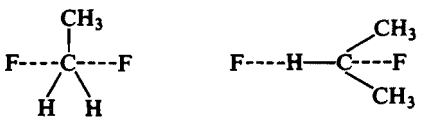
[1] Present address: Department of Chemistry, University of Kuopio, Kuopio 10, Finland.



3

$\sin^2(\theta/2)$ yield 0.5 when averaged over the three protons. Of course, a rigid conformation **3** does not exist. Thus, in 2-fluorotoluene the microwave spectra demonstrate **3** as the most stable and that the threefold rotation barrier lies near 3 kJ/mol (22). Nevertheless, the implied torsional motions will still leave $\langle\sin^2\theta\rangle$ and $\langle\sin^2(\theta/2)\rangle$ as 0.5. In other words, any orientation of the methyl group yields the same value of these quantities, simply because of the threefold symmetry of the methyl group (this is not true for sidechains like SH or CHO, for example).

A disentanglement of the σ and $\sigma-\pi$ components of $^5J_m^{H,CH_3}$ requires a lower symmetry in the sidechain. This situation is achieved by substitution at the methyl site, preferably with substituents which do not significantly alter the coupling mechanisms nor their magnitude. Such substituents may well be methyl groups (1). Furthermore, a range of $\langle\sin^2\theta\rangle$ and $\langle\sin^2(\theta/2)\rangle$ values is needed in order to have a set of well-conditioned equations of type [1]. This need is met by the introduction of *ortho* substituents to give conformations as in **4** and **5**. In the 2,6-difluoro derivatives of toluene, ethylbenzene,



4 5

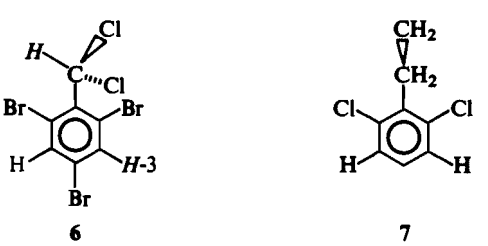
4, and cumene, **5**, one has (4, 23) $^5J_m^{H,CH}$ as 0.438(2), 0.363(2), and 0.292(3) Hz, respectively. Also, the values of $\langle\sin^2\theta\rangle$ are 0.5, 0.277, and 0.074 in the same order (23), as deduced from $^6J^{H,CH}$, whereas $\langle\sin^2(\theta/2)\rangle$ is 0.5 for each molecule because of the twofold nature of the barriers involved (21). Hence one has eq. [2] to [4], which yield $^5J_{90}^{\pi}$ as 0.336 Hz and $^5J_{180}^{\sigma}$ as

$$[2]\quad 0.438 = 0.5\,J_{90}^{\pi} + 0.5\,J_{180}^{\sigma}$$

$$[3]\quad 0.363 = 0.277\,J_{90}^{\pi} + 0.5\,J_{180}^{\sigma}$$

$$[4]\quad 0.292 = 0.074\,J_{90}^{\pi} + 0.5\,J_{180}^{\sigma}$$

0.540 Hz. In view of the possible errors, the exact agreement among the three equations is surprising. Nevertheless, they are consistent with a composite of σ and $\sigma-\pi$ mechanisms. The $^5J_{90}^{\pi}$ value of 0.336 Hz compares with the 0.38 ± 0.04 Hz implied by $^6J_m^{CH_3,CH_3}$ in a *m*-xylene derivative (16). The $^5J_{180}^{\sigma}$ number of 0.540 Hz can be compared with the 0.54 ± 0.02 Hz measured (24) in rigid **6** (no coupling to H-5),



6 7

and similar compounds (25).

In **7** the ^5J numbers from eqs. [2] to [4] predict $^5J_m^{H,CH_2}$ as 0.354 Hz if $\langle\sin^2\theta\rangle$ is taken as 0.25, approximately correct for a very large twofold barrier. In ethylbenzene itself one has a twofold barrier of 5 kJ/mol (2) and in **4** it is ca. 25 kJ/mol (23), corresponding to a $\langle\sin^2\theta\rangle$ of 0.277. In **7**, $^5J_m^{H,CH_2}$ is 0.36(3) Hz (26).

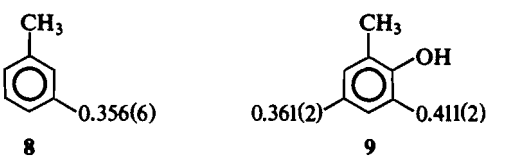
Intrinsic perturbations of $^5J_m^{H,CH_3}$ *by ring substituents*

In toluene, $^5J_m^{H,CH_3}$ is 0.356(6) Hz (27) and is 0.438(2) Hz in 2,6-difluorotoluene (see Table 1). From the discussion above it appears that the major part of the increase on *ortho* substitution arises from an increase in the σ electron contribution, that is, in $^5J^{\sigma}$. The relative insensitivity of $^5J^{\pi}$ to ring substitution (16, 17, 28) as measured by $^5J_m^{CH_3,CH_3}$ and, indeed, to replacement of a ring carbon by nitrogen as in some dimethyl pyridine derivatives (19), is consistent with the invariance of $^6J_p^{H,CH_3}$ in toluene derivatives (1, 4). The latter is a pure $\sigma-\pi$ coupling, as far as can be discovered.

If $^5J^{\pi}$ is 0.336 Hz, then in toluene itself $^5J_{180}^{\sigma}$ follows as 0.376 Hz, yielding $^5J_m^{H,CH_3}$ as 0.5(0.336) + 0.5(0.376) = 0.356 Hz. Allowing for experimental error, it seems that the σ and $\sigma-\pi$ components of $^5J_m^{H,CH_3}$ in toluene are roughly equal in magnitude and of the same sign.

In the following paragraphs, 52 precise values of $^5J_m^{H,CH_3} \equiv {}^5J$ are surveyed and are given in Table 1. Most of these numbers are unpublished results from this laboratory. Their standard deviations as determined from least-squares analyses are typically less than 0.005 Hz, so that an error of rather less than 0.02 Hz may probably be assumed. The values range from 0.300(1) to 0.464(4) Hz. At the very least, this data set provides hints as to the initial guess at ^5J in an interative analysis of the spectrum of a toluene derivative.

There exist some patterns in the substituent perturbations of ^5J in Table 1. For example, examine ^5J(Hz) in the sequence **8**



8 9

10 11

to **11**, in which the numbers in parentheses are standard deviations and were obtained for solutions in CCl_4 at the same concentrations, at the same temperature, and by experienced analysts employing the same calibration and spectral analytical procedures. The 2-OH substituent increases $^5J_3$ (to H-3) by 0.05_5 Hz, but does not alter $^5J_5$ (to H-5) significantly, suggesting that the perturbation occurs, not in the methyl group orbitals but in the orbitals involved in the coupling path in the ring (see **2**). Now, addition of a chlorine substituent at position 3 to give **10** causes a decrease of 0.03_9 Hz in $^5J_5$, whereas a remote chlorine substituent at position 5, giving **11**, decreases $^5J_3$ by 0.03_5 Hz. This pattern is general. A substituent *meta* to the methyl group in toluene derivatives decreases the (single) ^5J (a possible exception is 2-fluoro-*m*-xylene in Table 1, where the 3-CH_3 substituent does not appear to cause a decrease in $^5J_5$ from its value in 2-fluorotoluene). Whether these decreases in ^5J arise from a perturbation at the CH_3 site or in the ring path cannot be said, although it is interesting that a *meta* fluorine

[q] Reference 41, in CS_2 solution.

substituent causes only a slight change (0.8 ± 0.6 Hz) in ^1J (^{13}C, H) of CH_3, whereas ^1J (^{13}C, H) increases by 1.7_5 ± 0.6 Hz in the presence of a *meta* nitro group (29–31). In Table 1, nitro and amino groups in the *meta* position cause the same (small) reduction of ^5J.

A lone *para* substituent apparently causes a very small reduction in ^5J (F, SO_2F, SH, NH_2, CH_2, Br). Two *ortho* substituents induce relatively large increases in ^5J (although a single *ortho* CHO group does not). Thus, for 2-F-6-Y toluenes one has $^5J_5 + {}^5J_3$ as 0.753, 0.808, 0.853, 0.854, 0.876, 0.895 Hz for Y = H, NO_2, NH_2 Cl, F, CH_3, respectively. For toluene this sum is 0.712 Hz. For 2-F-4-Y toluene derivatives, the sum is 0.753, 0.807, 0.729, 0.816, 0.802 Hz for Y = H, NO_2, NH_2, CFO, I, respectively. In more heavily substituted toluene derivatives, ^5J is largest.

As stated above, eqs. [2] to [4] and the methyl group replacement technique suggest that $^5J^{\pi}$ is relatively insensitive to ring substitution. INDO MO FPT calculations of $^5J_{180}$ for toluene yield 0.831 Hz, an overestimate as has been discussed (15). For 3-fluorotoluene, this number is computed as 0.758 Hz, in *qualitative* agreement with the observed reduction of 0.05_6 Hz in $^5J_m^{H,CH_3}$. The theoretical value is (0.831 − 0.758)/2 (average of $\sin^2(\theta/2)$ is 0.5) or 0.037 Hz. For 4-fluorotoluene, $^5J_{180}$ is calculated as 0.798 Hz, indicating a decrease of 0.033/2 Hz, again in qualitative agreement with the *apparent* experimental decrease of 0.015 Hz. In 2-fluorotoluene INDO MO FPT finds $^5J_{180}$ to H-3 as 0.858 Hz and to H-5 as 0.819 Hz, the changes from toluene being also in very rough agreement with experiment. Similar calculations on nitro and amino derivatives of 2-fluorotoluene gave mixed results, only $^5J_{180}$ for the 5-nitro derivative agreeing with experimental trends.

Furthermore, although in 3-fluorotoluene the average of $^5J_m^{H,CH_3}$ over 13 values of θ (15° intervals) is indeed computed to be 0.03 lower than in toluene (observed reduction is 0.05_6 Hz), and can reasonably be attributed to a change in the σ component, similar averages for the two couplings in 2-fluorotoluene yield changes which are the reverse of the observed ones. It must be concluded that the theoretical computations provide ambiguous evidence as to the nature of the small perturbations induced in $^5J_m^{H,CH_3}$ by ring substituents. Accordingly the large theoretical data set is not reproduced here.

A more systematic and extensive experimental study of $^5J_m^{H,CH_3}$ would be necessary in order to establish a clear separation between σ and σ−π substituent perturbations. However, because the changes in ^5J are so small and because the first section of this paper suggests the infeasibility of $^5J_m^{H,CH_3}$ as a conformational indicator, such an expenditure of effort is not recommended. Note, however, that this recommendation does *not* apply to α-substituted toluenes, for which $^5J_m^{H,CH_2}$ and $^5J_m^{H,CH}$ can provide detailed conformational information.

Conclusions

In toluene the coupling over five bonds between the methyl and ring protons consists of roughly equal σ−π and σ electron contributions. The former varies as $\sin^2\theta$, where θ is the angle by which the α C—H bond twists out of the nodal plane of the π electrons. The latter is proportional to $\sin^2(\theta/2)$. The same

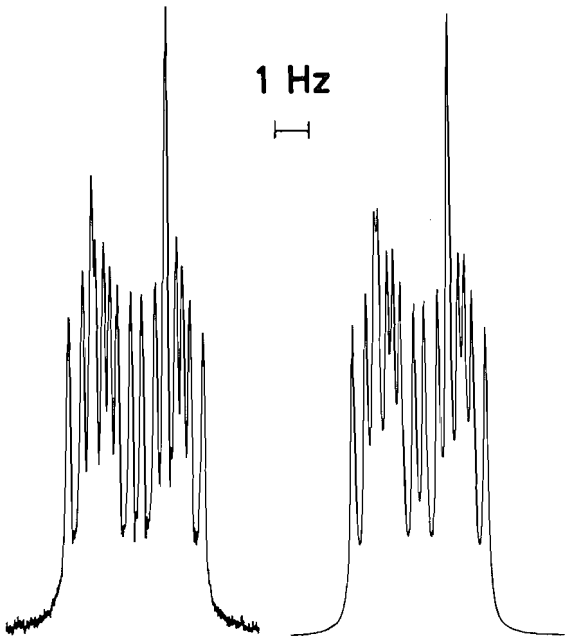

FIG. 1. The observed and calculated ^{1}H nmr spectra of the methyl protons for a 4.5 mol% solution of 2-fluoro-5-aminotoluene in CCl_4 at 305 K and 100.001 MHz (centerband). The calculated spectrum assumes a linewidth at half-height of 0.14 Hz and the parameters from a full analysis of the experimental spectrum from seven spins. It should be noted that the analysis is one of the *least* satisfactory for the molecules in Table 1, the rms deviation between calculated and observed transtions amounting to 0.024 Hz. Of 220 calculated transitions in the proton region, 201 were assigned. The ^{19}F nmr spectrum was not analyzed. $^5J_m^{H,CH_3}$ is 0.387(3) Hz.

behaviour has been previously noted for $^5J_m^{H,SH}$ in thiophenol, suggesting a similar dependence for ^5J in other molecules like benzaldehyde and phenol.

An important consequence for toluene derivatives is that $^5J_m^{H,CH_3}$ *cannot* be used as a indicator of the conformational preferences of the methyl group. However, in the presence of substituents on the methyl group this restriction is lifted and encourages the use of $^5J^{H,CH_2}$ and $^5J^{H,CH}$ in conformational analysis.

The ring-substituent dependence of $^5J_m^{H,CH_3}$ is generally such that a *meta* substituent causes a decrease, while *ortho* substituents cause an increase, in its magnitude.

Finally, it may be noted that partially restricted molecular orbitals, designed to estimate the $\sigma-\pi$ component of $^5J_m^{H,CH_3}$, appear to overestimate its magnitude substantially (32).

Experimental

The data in Table 1 (except for toluene) were accumulated in this laboratory during the last dozen years and are the results of careful analyses and spectral calibrations (33) using an HA100 nmr spectrometer at a probe temperature of 305 K. The solvents were usually CCl_4 or CS_2 but acetone-d_6, chloroform-d, or benzene-d_6 were employed for a few of the analyses. The footnotes to Table 1 may be consulted for further information, particularly footnote *o* where analyses for two different solvents are compared. Some 16 of the 52 values of $^5J_m^{H,CH_3}$ in Table 1 have been published previously, but not discussed.

In Fig. 1 the calculated and observed spectra of the methyl protons in 2-fluoro-5-aminotoluene are depicted. The figure caption points out that the analysis of the seven-spin spectrum was among the least satisfactory obtained for the examples in Table 1. Indeed, small deviations between the observed and calculated spectra are noticeable, parts of which arise from the finite sweep rate of the spectrometer.

INDO MO FPT computations (34) of $^5J_m^{H,CH_3}$ were performed on an Amdahl 470/V7 system, employing standard geometries (35) for the most part, but for 2-fluorotoluene some partially optimized (4) geometries were also used for purposes of comparison. No alteration in relative trends of $^5J_m^{H,CH_3}$ were found.

Acknowledgements

We are grateful to a number of co-workers, named in the references, for the spin–spin coupling data. The Natural Sciences and Engineering Research Council of Canada and the Research Council for the Natural Sciences of the Academy of Finland are thanked for financial support.

The thermal and photochemical decompositions of succinic anhydride and 2,3-dimethyl succinic anhydride in the gas phase[1]

S. YAMAMOTO[2] AND R. A. BACK

Division of Chemistry, National Research Council of Canada, 100 Sussex Drive, Ottawa, Ont., Canada K1A 0R6

Received March 4, 1983

S. YAMAMOTO and R. A. BACK. Can. J. Chem. **61**, 2790 (1983).

The absorption spectrum of succinic anhydride shows a broad maximum near 220 nm, attributed to the lowest π^*-n^- transition. Photolysis in this region (220–270 nm) gives CO_2, CO, and C_2H_4, but not in the equimolar quantities expected from a simple molecular dissociation. Production of CO also shows a time dependence, increasing with time, and a free-radical mechanism is tentatively suggested to account for this. The thermal decomposition of succinic anhydride at 625–775 K yields the same products, but is more complex, with larger deviations from the simple stoichiometry, and product formation non-linear with time and pressure. At short times, production of CO, the most abundant product, is described by first-order Arrhenius parameters of log A (s^{-1}) = 11.6 and E = 53 kcal/mol, apparently independent of surface.

The photolysis of the *cis* and *trans* isomers of 2,3-dimethylsuccinic anhydride at 250 and 230 nm is simpler than that of succinic anhydride, giving equimolar CO and CO_2, but with butene-2 still falling short of a stoichiometric yield by from 10 to 40%. Both *cis*- and *trans*-butene-2 were produced, with the latter always in excess and with no retention of the configuration of the original anhydride. The thermal decomposition of 2,3-dimethylsuccinic anhydride is more complex than the photolysis, with much less butene-2 produced (again with no retention of *cis–trans* configuration) and methane an important product. Activation energies for CO formation were about 48 and 45 kcal/mol and log A (s^{-1}) was 10.4 and 9.5 for the *cis* and *trans* isomers, respectively.

S. YAMAMOTO et R. A. BACK. Can. J. Chem. **61**, 2790 (1983).

Le spectre d'absorption de l'anhydride succinique révèle un large maximum près de 220 nm que l'on attribue à la plus faible transition π^*-n^-. La photolyse à cette longueur d'onde (220–270 nm) donne du CO_2, du CO et du C_2H_4 mais pas selon les quantités équimoléculaires attendues pour une simple dissociation moléculaire. La formation de CO montre également une influence du temps augmentant avec le temps et on essaie d'expliquer ce fait en faisant intervenir un mécanisme par radical libre. La décomposition thermique de l'anhydride succinique donne les mêmes produits, mais elle est plus complexe avec de plus grandes différences par rapport aux quantités stoechiométriques et la formation des produits ne varie pas de façon linéraire avec le temps et la pression. A des temps courts, on décrit la production de CO le produit le plus abondant avec les paramètres d'Arrhenius de premier ordre: log A (s^{-1}) = 11,6 et E = 53 kcal/mol qui sont apparemment indépendants des surfaces.

La photolyse des isomères *cis* et *trans* de l'anhydride diméthyl-2,3 succinique à 250 et 230 nm est plus simple que celle de l'anhydride succinique et donne des quantités équimolaires de CO et de CO_2 mais avec le butène-2, là encore l'on s'écarte des rendements stoechiométriques de 10 à 40%. On obtient les butènes-2 *cis* et *trans* avec le produit *trans* toujours en excès et sans rétention de la configuration de l'anhydride original. La décomposition thermique de l'anhydride diméthyl-2,3 succinique est plus complexe que la photolyse avec beaucoup moins de butène-2 produit (encore sans rétention de la configuration *cis–trans*) et le méthane comme produit majoritaires. Les énergies d'activation de la formation du CO sont de 48 et de 45 kcal/mol environ et les valeurs de log A (s^{-1}) sont respectivement 10,4 et 9,5 pour les isomères *cis* et *trans*.

Introduction

There have been few quantitative studies of the decomposition of simple cyclic anhydrides in the gas phase. Recent work in this laboratory on maleic anhydride showed a simple unimolecular decomposition into C_2H_2, CO_2, and CO in both the thermal and photochemical reactions, with the former at least apparently following a concerted path rather than a biradical one (1). Watkins and Whittle found a similar simple decomposition in the photolysis of perfluorosuccinic anhydride (2). The present study was undertaken to see whether other simple cyclic anhydrides show similar behaviour.

Experimental

Apparatus and techniques were similar to those used earlier (1). The light source was a 1000 W Hg–Xe arc with matching monochromator. Analysis of products was by simple fractionation at 77, 195, and 273 K, measurement by gas burette, and by gas chromatography.

Succinic anhydride was obtained from Aldrich and used after simple degassing and sublimation. The *cis* and *trans* isomers of 2,3-dimethylsuccinic anhydride were prepared by dehydration of the appropriate acids from Aldrich, by treatment with excess acetic anhydride or acetyl chloride. *Meso*-2,3-dimethylsuccinic acid yielded *meso-cis*-2,3-dimethyl-succinic anhydride (mp 37°C), while a racemic mixture of the D- and L-acids gave the mixed D- and L-*trans*-anhydride.

Absorption spectra were measured in a double-beam spectrophotometer fitted with a 4 m heated absorption cell.

Results and discussion

Succinic anhydride

The absorption spectrum (Fig. 1) shows a broad maximum at about 220 nm, with absorption on the long-wavelength side extending to at least 300 nm. Weak vibrational features are evident on the long-wavelength shoulder, with an average separation of about 1200 cm^{-1}, probably corresponding to excitation of a carbonyl stertching vibration in the excited state. The photoelectron spectrum of succinic anhydride, supported by calculations (3, 4), indicates that the n^-, the out-of-phase combination of the two carbonyl lone-pair orbitals, is the highest occupied orbital. The extinction coefficient of about 25 M^{-1} cm^{-1} estimated at 220 nm is reasonable for a weakly allowed π^*-n^- transition.

The photolysis was studied at wavelengths of 220, 230, 252, and 270 nm, and pressures of anhydride from about 3 to

[1]NRCC No. 22589.

[2]NRCC Research Associate, 1981–1983.

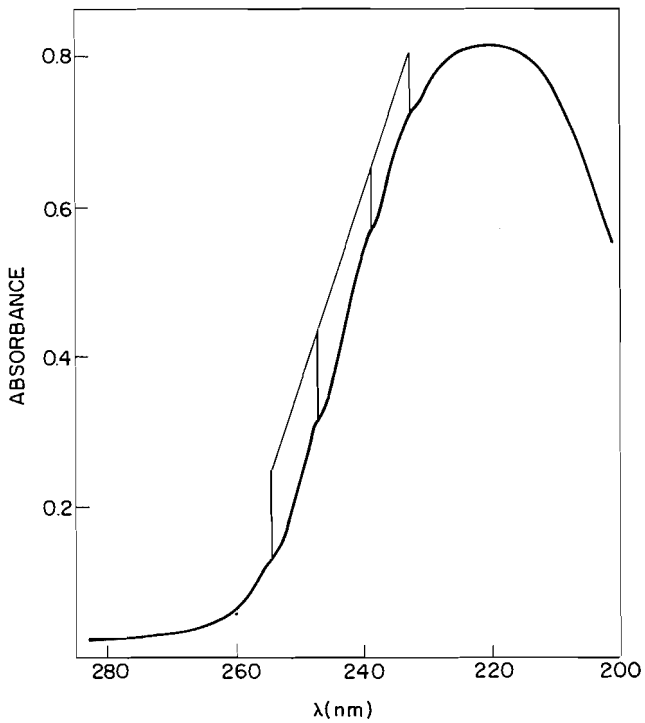

FIG. 1. Absorption spectrum of succinic anhydride measured at pressures of about 2 Torr.

15 Torr, all at a temperature of about 400 K. The major volatile products of the photolysis were CO_2, C_2H_4, and CO, but these were not produced in the equimolar quantities expected from a simple fragmentation as observed with maleic anhydride (1). Production of CO_2 and of C_2H_4 were linear with time, and the ratio C_2H_4/CO_2 was consistently about 0.9 (±0.05), independent of reaction time, wavelength, and pressure of succinic anhydride. The formation of CO was not linear with time, and the ratio CO/CO_2 increased from about 0.5 at the shortest times observed to about 1.0 at the longest. This time dependence varied with pressure and wavelength, but when variation in light intensity and absorption were taken into account by plotting CO/CO_2 against CO_2 (Fig. 2), a common simple dependence on the amount of reaction (measured by CO_2), independent of pressure and wavelength, was shown.

It is clear from these observations that the photolysis of succinic anhydride does not proceed simply by a direct fragmentation into CO_2, C_2H_4, and CO, although as much as about half of the products *may* have been formed in this way. The delayed appearance of at least half of the CO, but not of the other products is difficult to explain by any simple mechanism; one that can be suggested involves the initial formation of CO_2 and acrolein, perhaps following ring opening,

[1] $C_4H_4O_3 + h\nu \rightarrow C_4H_4O_3^* \rightarrow CO.CH_2CH_2CO.O \rightarrow CO_2 + CH_2{=}CH{-}CH.O^{\ddagger}$

This reaction releases 98 kcal/mol at 270 nm and 122 kcal/mol at 220 nm, and the acrolein could be formed with enough energy to dissociate[3]

[2] $CH_2{=}CH{-}CH.O^{\ddagger} \rightarrow C_2H_3 + HCO$

Abstractions by vinyl and formyl radicals would follow,

[3] $C_2H_3 + C_4H_4O_3 \rightarrow C_2H_4 + C_4H_3O_3$

[4] $HCO + C_4H_4O_3 \rightarrow H_2CO + C_4H_3O_3$

These reactions account for the initial formation of CO_2 and C_2H_4, and as formaldehyde built up in the system, attack by free radicals such as vinyl, HCO, and $C_4H_3O_3$ on the weakly bound hydrogen could lead to formation of CO;

[5] $R + H_2CO \rightarrow RH + HCO$

[6] $R + HCO \rightarrow RH + CO$

Some loss of C_2H_3 by combination or disproportionation with other radicals could account for the observed deficit of C_2H_4 relative to CO_2, and the detection of small amounts of C_2H_2, 1,3-butadiene, and acrolein, products of such reactions, lends some support to this mechanism. Formaldehyde, which should have been present as an intermediate in amounts equal to the CO deficit, could not be detected, but the small amounts may well have been lost in the analysis. In one experiment, 260 Torr of N_2 was added to the photolysis at 230 nm, with no effect on the C_2H_4/CO_2 ratio. This suggests that the excited acrolein formed in reaction [1] must have decomposed quantitatively even under these conditions, not unreasonable considering the excess energy at this wavelength. An alternative, probably less likely, mechanism for the photolysis involves formation of a CO – succinic anhydride adduct, of unspecified structure,

[7] $C_4H_4O_3 + h\nu \rightarrow C_4H_4O_3^* \xrightarrow{+C_4H_4O_3} CO_2 + C_2H_4 + C_5H_4O_4$

which subsequently decomposes to CO and succinic anhydride.

The thermal decomposition of succinic anhydride was studied at pressures from about 4 to 20 Torr and temperatures from 625 to 775 K. The main products observed were CO, CO_2, and C_2H_4, and again these products expected from simple fragmentation were not produced in equimolar quantities, with the reaction apparently even more complex than the photolysis. While CO_2 and C_2H_4 production were approximately linear with time (with perhaps some upward curvature in CO_2), the production of CO was strongly time dependent, with the yield increasing sharply to a value more than ten times that of CO_2 (Fig. 3). As in the photolysis, trace quantities of C_2H_2, 1,3-butadiene, and acrolein were detected. The CO yield also rose sharply, with respect to CO_2 and C_2H_4, with increasing anhydride pressure (Fig. 4).

In the early stages of the reaction, CO production is approximately described by a first-order rate constant given by $\log k\ (s^{-1}) = 11.6 - 53000/4.58T$, which was found to be unchanged when the surface/volume ratio was increased by a factor of 4 by packing the reaction vessel with tubing. Production of CO_2, on the other hand, while again approximately first order, showed much lower Arrhenius parameters ($\log A\ (s^{-1}) = 5.5$, $E = 34$ kcal/mol) and was markedly increased in the packed vessel.

The mechanism of the thermal decomposition is clearly complex, and no quantitative conclusions can be drawn about its thermochemistry. There may be some simple unimolecular decomposition into CO, CO_2, and C_2H_4, but the activation energy for CO formation is much too low for biradical formation by opening of the almost strain-free anhydride ring. The sharply accelerating production of CO in amounts greatly exceeding CO_2 and C_2H_4, and its sharp increase with pressure, suggest an autocatalytic free-radical chain reaction, or perhaps formation of an unstable intermediate that begins to eliminate CO thermally as it accumulates. In either case, CO_2 and C_2H_4 must

[3]Based on ΔH_f^0 of −125 and −23 kcal/mol for succinic anhydride and acrolein, respectively, calculated from heats of combustion (5).

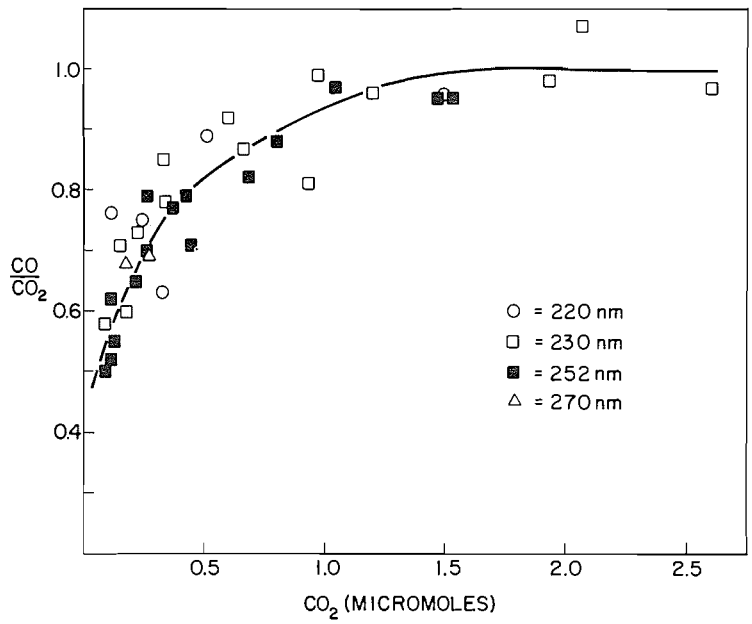

FIG. 2. The product ratio, CO/CO_2, for the photolysis of succinic anhydride, vs. yield of CO_2.

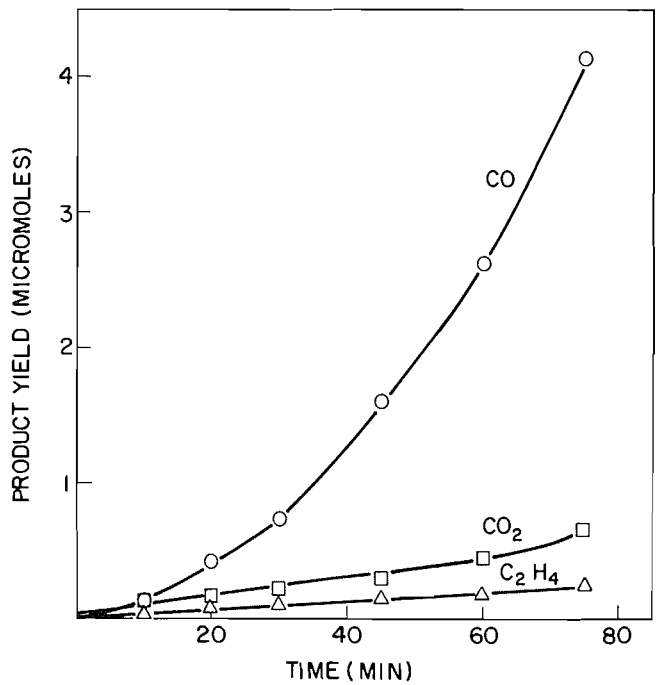

FIG. 3. Time dependence of products in the thermal decomposition of succinic anhydride at 722 K and a pressure of 10 Torr.

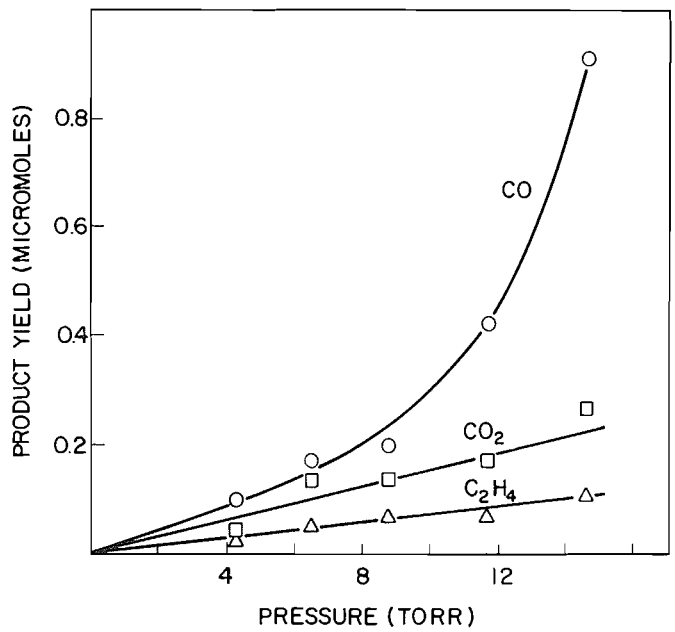

FIG. 4. Pressure dependence of products in the thermal decomposition of succinic anhydride at 722 K and a reaction time of 20 min.

remain tied up in non-volatile products. Brown and Ritchie (6) proposed a ketene acid, O=C=CH—CH_2CO.OH as an intermediate in the "hot tube" pyrolysis of succinic anhydride at 773 K, and its decomposition to CO and acrylic acid (which they observed as a product) could account for our CO formation if the acrylic acid were lost by polymerization or other reaction. Rice and Murphy (7), on the other hand, observed almost stoichiometric formation of CO, CO_2, and C_2H_4 in a single experiment at much higher temperature (1170 K). This could indicate that a simple fragmentation, having a high activation energy, becomes predominant at high temperature. In the present experiments, the decomposition is certainly not simple, and further speculation about mechanism is unwarranted.

2,3-Dimethylsuccinic anhydride

The spectra of *cis*- and *trans*-dimethylsuccinic anhydride were similar to that of succinic anhydride, with similar extinction coefficients, but with the maxima red-shifted to about 230 and 225 nm, respectively. No vibrational structure was evident.

The photolysis of both *cis* and *trans* isomers was studied at 250 and 230 nm, at pressures of about 10 Torr and a temperature of 400 K. Products volatile at room temperature were CO_2 and CO, formed in equal amounts in all experiments, and butene-2, which was always appreciably less than stoichiometric. With the *trans* isomer at both wavelengths and the *cis* isomer at 250 nm, the amounts of these products were always proportional to the photolysis time. With the *cis* isomer at 230 nm, formation of all products showed a distinct acceler-

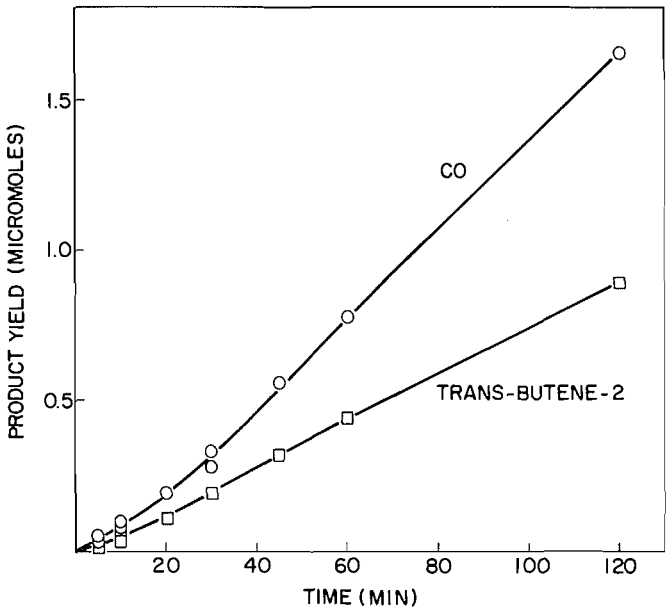

FIG. 5. Time dependence of products from the photolysis of *cis*-dimethylsuccinic anhydride at 230 nm.

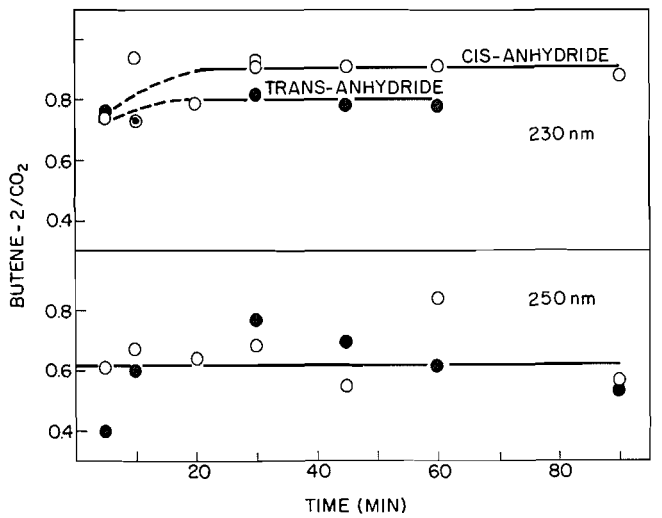

FIG. 6. Time dependence of product ratios from the photolysis of *cis*-dimethylsuccinic anhydride (○) and *trans*-dimethylsuccinic anhydride (●).

ation with increasing time, reaching a constant rate after about 20 min (Fig. 5). The ratio butene-2/CO_2, (Fig. 6) and CO/CO_2 were effectively independent of photolysis time. Both *cis*- and *trans*-butene-2 were produced in the photolysis, and ratios of the two isomers are shown in Fig. 7.

The photolysis of 2,3-dimethylsuccinic anhydride appears to be a much cleaner and simpler decomposition than that of succinic anhydride itself. Yields of CO and CO_2 are always equal, with stoichiometric deficits of butene-2 of 40% at 250 nm and about 10% at 230 nm. No other C_4 or lighter hydrocarbons were detected, and the missing butene-2 must be accounted for by higher, non-volatile products or polymer.

There appears to be a complete loss of *cis*–*trans* configuration of the methyl groups in the photolysis. At 250 nm, the *cis*-anhydride in fact gave a slightly higher ratio of *trans*-butene-2/*cis*-butene-2 than does the *trans* anhydride (Fig. 7), while at 230 nm, the ratio of butene isomers from the two

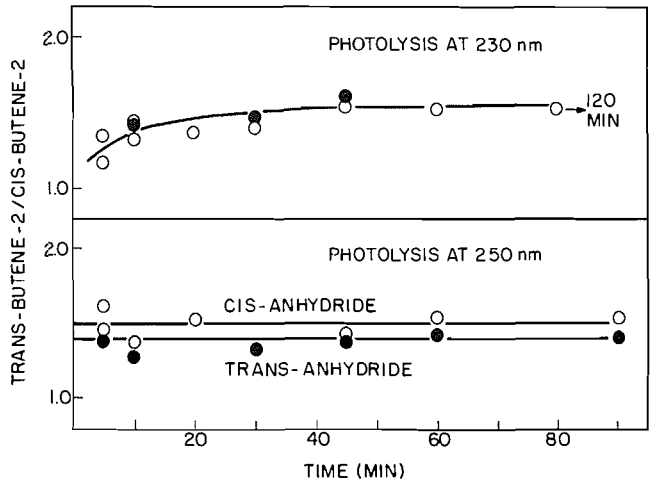

FIG. 7. Ratio of *trans*-butene-2/*cis*-butene-2 from the photolysis of the *cis* (○) and *trans* (●) isomers of dimethylsuccinic anhydride.

anhydrides was the same. The lack of retention of the *cis*–*trans* configuration, and the deficit of butene-2, both argue strongly against a direct molecular dissociation into CO_2, CO, and butene, and suggest instead ring-opening to form a biradical which successively loses CO_2 and CO, leaving a C_4H_8 biradical that can be stabilized as butene-2 by hydrogen transfer or can react to form higher products. Rotation about the C—C bond leading to loss of the *cis*–*trans* configuration may occur in the primary biradical or in those formed by successive loss of CO_2 and CO. The preferred formation of *trans*–butene-2 is not surprising, and can be attributed to repulsion of the methyl groups in the transition state finally leading to butene formation.

While this simple picture of the photolysis is attractive, there is clear evidence that at least at 230 nm, the system is more complex. The partial induction period observed with the *cis*-anhydride (Fig. 5) suggests that there is an intermediate which is decomposed by secondary photolysis to form the final products. The time dependence of the product yields is paralleled by a change in the *trans*-butene-2/*cis*-butene-2 ratio (Fig. 7) and perhaps by a change in the butene-2/CO_2 ratio (Fig. 6). The fact that the ratio of butene-2 isomers at long reaction times from the *cis*-anhydride rises to the same value observed with the *trans*-anhydride suggests that the same intermediate may be present in the photolysis of the latter, but is decomposed more rapidly (perhaps because of a shift in the absorption spectrum) so that its presence was not evident at the shortest times used in the present experiments.

The thermal decomposition of *cis*- and *trans*-dimethylsuccinic anhydride was studied from about 630 to 770 K at pressures from 4 to 13 Torr. Products observed were CO, CO_2, butene-2, and CH_4, all formed linearly with time (conversions were below 10%). The product with the highest yield was CO; CO_2 was less, with CO_2/CO ratios varying from about 0.25 at the highest temperature to 0.75 at the lowest. The ratio CH_4/CO varied from about 0.15 at the highest temperature to almost unity at the lowest. Yields of butene-2 were about 10% of the CO, independent of temperature, and all product ratios were about the same for the two anhydride isomers.

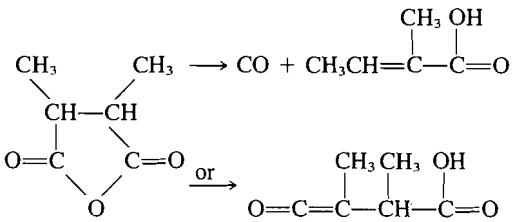
First-order rate constants for production of CO gave reasonable Arrhenius plots (Fig. 8) with values for the *cis* isomer consistently higher than for the *trans*. Arrhenius parameters were E = 47.6 kcal/mol and log A (s^{-1}) = 10.4 for the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

cis-anhydride, and $E = 45.3$ and $\log A = 9.55$ in the same units for the *trans*-anhydride. Packing the reaction vessel with tubing to increase the surface/volume ratio by a factor of 4 had no significant effect, and the production of CO is apparently a gas-phase process. Production of CO_2, on the other hand, had an appreciably lower activation energy and *A*-factor for both isomers (E = ~42 kcal/mol, log A (s^{-1}) = ~8.2), and was much higher in the packed vessel, while the formation of CH_4 was also enhanced by the increase in surface.

Both *cis*- and *trans*-butene-2 were formed in the decompositions, with a *trans*/*cis* ratio of about 2.6 for both anhydride isomers, independent of reaction temperature, time, and S/V ratio. Blank experiments with butene-2 showed that there was negligible thermal *cis-trans* isomerization. Thus, as in the photolysis, there is complete loss of configuration of the methyl groups in the decomposition to form butene-2. The observed activation energies, however, are much too low to permit direct opening of the anhydride ring to form a biradical, so that rotation of the methyl groups must occur in some other way. (This raises the possibility that biradicals are not necessarily involved in the photolysis either, although there is more than enough energy for their formation).

The Arrhenius parameters for CO formation may correspond to a simple unimolecular process, perhaps elimination of CO concerted with H-atom transfer, or perhaps an isomerization to a ketene acid as suggested by Brown and Ritchie (6).



The linear rate of formation of all products with time indicates that, whatever the intermediate, it must have decomposed or reacted rapidly to yield the ultimate products observed. The surface dependence of CO_2 and CH_4 formation must then arise from some surface-dependent stoichiometry in this decomposition. The system is obviously complicated and further discussion of mechanism is not justified.

Conclusions

Neither the photochemical nor the thermal decomposition of succinic anhydride and its 2,3-dimethyl derivative follows a simple unimolecular dissociation as apparently observed with maleic anhydride (1) and perfluorosuccinic anhydride (2). The main products in all cases were those expected from such a dissociation, CO_2, CO, and an olefin, and *part* of each decomposition may proceed in a simple way, but products are not formed in stoichiometric ratios. The photolyses were simpler than the thermal reactions, probably reflecting the higher energy content of the decomposing molecules in the former, but in both systems there was evidence for unstable intermediates and higher, non-volatile products, and complex mechanisms are indicated. Complete loss of *cis*–*trans* configuration of the methyl groups in the photolysis of 2,3-dimethylsuccinic anhydride suggests a biradical intermediate, but this also occurred in the thermal decomposition in which the activation energy is too low to permit biradical formation. The more complex behaviour of these anhydrides compared with maleic anhydride may reflect a more easy intramolecular transfer of hydrogen atoms in the saturated ring than in the stiffer conjugated structure of maleic anhydride with the hydrogens in the molecular plane. It is interesting that the photolysis and the thermal decomposition of succinimide vapor, studied in this laboratory (8), showed a similar behaviour, with both a simple decomposition into HNCO, CO, and C_2H_4, together with several more complex channels involving internal hydrogen transfer.

Thallimetric oxidations. Part II. Titrimetric and spectrophotometric methods for the determination of oxalate

S. R. SAGI, K. APPA RAO, AND M. S. PRASADA RAO
Inorganic Chemistry Laboratories, Andhra University, Waltair-530 003, India

Received January 13, 1983

S. R. SAGI, K. APPA RAO, and M. S. PRASADA RAO. Can. J. Chem. **61**, 2795 (1983).

Titrimetric and spectrophotometric methods are developed for the estimation of oxalate at mmole and micromole ranges, respectively. In these methods thallium(III) is used as the oxidant and the reduced thallium(I) is determined oxidimetrically by potassium bromate in the titrimetric method and by measuring the optical density of thallium(III) at 260 nm in the presence of 0.1 *M* HCl and 1 *M* $HClO_4$ in the spectrophotometric method. A series of photochemical and thermal redox methods are described for the estimation of oxalate in the presence of a number of carboxylic acids.

S. R. SAGI, K. APPA RAO et M. S. PRASADA RAO. Can. J. Chem. **61**, 2795 (1983).

On a mis au point des méthodes titrimétriques et spectrophotométriques pour évaluer l'oxalate en mmole et en micromole respectivement. Dans ces méthodes, on utilise le thallium(III) comme oxydant et on détermine le thallium réduit(I) par oxydimétrie à l'aide du bromate de potassium dans la méthode titrimétrique et en mesurant la densité optique du thallium(III) à 260 nm en présence de HCl 0,1 *M* et de $HClO_4$ 1 *M* dans la méthode spectrophotométrique. On décrit une série de méthodes photochimiques et redox pour évaluer l'oxalate en présence d'un certain nombre d'acides carboxyliques.

Introduction

The unique properties like acidity, reducing capacity, and chelating ability of oxalic acid and oxalates made them a very useful class of compounds in industry as well as in analytical chemistry. Oxalates occur widely in many biological systems. The various spectrophotometric, solubility, kinetic, ion exchange, solvent extraction, potentiometric, polarographic, and other methods for the determination of oxalates were reviewed by Murty and Harris (1). Rao and Aravamudan (2) have surveyed the available methods for the determination of oxalic acid and described a new method utilising the photochemical reaction between iron(III) and oxalic acid, titrating the iron(II) formed by sodium vanadate. The advantages claimed by the authors over other methods are (*i*) no heating is required and (*ii*) formic acid will not interfere in the method. Riggs and Bricker (3) have extended the same idea and estimated oxalic acid at mg level by titrating the iron(II) formed using potassium dichromate stating that its interference with organic substances is tolerable. However, they pointed out that an inert atmosphere is necessary to avoid the air oxidation of iron(II) formed during the reaction; about this Rao and Aravamudan have not mentioned anything. Rao *et al.* (4) avoided the use of dichromate because of the induced oxidation of oxalic acid in the presence of iron(II), they preferred sodium vanadate as the oxidant.

Riggs and Bricker followed the progress of the reaction with the time of irradiation by estimating iron(II) formed with dichromate. If the view expressed by Rao *et al.* regarding the induced oxidation of oxalic acid by dichromate was correct the values reported by these authors were prone to error especially in reporting the interferences.

Using the same photochemical reaction Cooley and Kratochvil (5) have described a method for the determination of oxalate using a CO_2 electrode detector. Later using the same reaction they described another method (6) using a gas chromatographic technique for measuring CO_2, and claimed that this method is less expensive and rapid and also subject to fewer interferences compared to their first method. They reported obtaining values with an accuracy of about 2%.

In the light of the above reports the present authors have attempted to suggest simple and convenient methods for the estimation of oxalic acid in the presence of other organic acids both at mg and μg levels.

A consideration of the redox potentials of the thallium(III)/thallium(I) couple in perchloric and sulphuric acid media, and the special photochemical properties associated with the thallium species have led the present authors to investigate the use of thallium(III) for the estimation of oxalic acid.

Experimental

Thallium(III) solution was prepared and standardised as reported earlier (7, 8). All the other reagents are of AR grade. Though the photochemical reactions described take place much faster under direct sun light, in view of its variable intensity all the investigative work described here was done using a Phillips high pressure mercury vapour lamp (200/250 V − 125 W) as the light source. The photochemical reactions were carried out by exposing the solutions in colourless glass containers, kept a constant distance of 6 in. from the light source.

A Shimadzu, U.V. 140 double beam spectrophotometer is used for the optical density measurements.

Results and discussion

The photochemical reduction of thallium(III) with oxalic acid in the presence of halides as catalysts has been reported (8). Studies on photochemical oxidation of oxalic acid with thallium(III) show that the stoichiometry of the reaction may be represented by the equation

$$Tl(III) + H_2C_2O_4 \rightarrow Tl(I) + 2CO_2 + 2H^+$$

A minimum of double the amount of thallium(III) with respect to oxalic acid is necessary for a rapid reaction to take place and any ratio of thallium(III) to oxalate above 2:1 will not very much increase the rate of the reaction. Hence, keeping the concentration of thallium(III) double that of oxalic acid, the effect of acid, chloride, and bromide concentration on the speed of the reaction is studied in perchloric acid medium and the results are represented in Figs. 1 and 2. The relative mean deviation of the values recorded is 2%. The progress of the reaction is followed by monitoring the thallium(I) formed by oxidimetric titration with potassium bromate.

From Figs. 1 and 2 it is clear that the time required for completion of the reaction is minimum when the chloride concentration is double or the bromide concentration is half that of

thallium(III). The reaction is fast even when the Tl(III)-to-Cl^- ratio is in the range of 10:1 to 1:10 and Tl(III)-to-Br^- ratio is in the range of 10:1 to 1:1. Under these conditions thallium(III) is known to exist as $TlCl^{2+}$, $TlCl_2^+$, $TlBr^{2+}$ (9, 10), which are likely to be photochemically active and hence give the fast rate of the reaction.

An increase in acid concentration has a retarding effect on the rate of the reaction. The acid concentration has less effect on the chloride ion catalysis than on the bromide ion catalysis.

* / = do not interfere, × = interfere, RRR = reaction rate reduced (this drawback can be avoided by suitably increasing the time of exposure to light).

Recommended procedure (photochemical method, mmol range)

To an aliquot containing 0.05 to 0.5 mmol of sodium oxalate in a 200 mL beaker add 20 mL of 1 *M* perchloric acid, 2 mmol of chloride (or 0.5 mmol of bromide), 1 mmol of thallium(III), and dilute to 100 mL. Stir the solution and expose to the light from a high pressure mercury vapour lamp for 10 min. Add 25 mL of concentrated hydrochloric acid, 0.1 mL of 0.1% methyl orange or brilliant ponceaux 5R indicator, heat to 60°C, and titrate with 0.05 *N* potassium bromate (1.392 g/L) until the indicator is destroyed. The method is applicable in sulphuric acid medium also.

Thermal method

The thermal reaction between thallium(III) and oxalic acid is quantitative even in the presence of stoichiometrically equal amounts of oxalic acid and thallium(III). To an aliquot containing 0.05 to 0.5 mmol of sodium oxalate in a 200 mL beaker add 10 mL of perchloric acid (or 10 mL of 5 *M* sulphuric acid), 1 mmol of thallium(III), dilute to 100 mL, and heat on a boiling water bath for 5 min (or heat just to boiling). The reduced thallium(I) is titrated with potassium bromate under the conditions already described.

In the thermal method chloride or bromide will not interfere if the concentration is half or one fourth that of thallium(III) respectively. But further increase in chloride concentration decreases the rate of the reaction, and bromide gives erroneous results. Typical results are summarized in Table 1.

Spectrophotometric method for the estimation of microquantities of oxalate

The absorption spectra (11) of thallium(I) and thallium(III) separately in a medium containing 1 *M* perchloric acid and 0.1 *M* hydrochloric acid show that at 260 nm thallium(III) has considerable molar absorptivity ($\epsilon \approx 9150$) while thallium(I) has no absorbance. At 260 nm thallium(III) species obey Beers law under the above conditions. In this method excess of thallium(III) is allowed to react with oxalic acid either photochemically (using chloride as catalyst) or thermally. The amount of oxalate corresponds to the amount of thallium(III) reduced to thallium(I), which can be computed from a calibration curve (Table 2).

Recommended procedures

1. Photochemical: To an aliquot containing 0.01 to 0.12 μmol of sodium oxalate add 1 mL of 5 *M* perchloric acid, 0.5 μmol of sodium chloride, 5 mL of 5×10^{-4} *M* thallium(III), and expose it to the light of mercury vapour lamp for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

10 min. Transfer the solution to a 50 mL volumetric flask, add 8 mL of 5 *M* perchloric acid, and 5 mL of 1 *M* hydrochloric acid, and dilute to volume (I). Prepare another solution in a 50 mL flask by mixing all the above solutions except oxalate (II). Shake well and wait 60 min. Adjusting the optical density of I to zero measure the optical density of II (which corresponds to the thallium(III) reacted). The concentration of thallium thus reacted is read from a calibration curve. The oxalate concentration corresponds to the thallium(III) reacted.

2. Thermal method: To an aliquot containing 0.01 to 0.13 μmol of sodium oxalate add 9 mL of 5 *M* perchloric acid, 5 mL of 5×10^{-4} *M* of thallium(III) in 1.0 *M* perchloric acid, and boil for 2 min. Cool and transfer to a 50 mL volumetric flask. Add 5 mL of 1 *M* hydrochloric acid and dilute to volume (I). Adopting the same procedure in the absence of oxalate prepare another solution and dilute to volume (II). The amount of oxalate is computed as before.

Interferences: Sodium oxalate (0.125 mmol) is used for the study of interferences in the titrimetric method; while 0.05 μmol is used in the spectrophotometric method. The results of the study of the interferences of some organic acids is given in Table 3.

From the data in Table 3 it is clear that by suitably selecting the method, oxalate in the mmole to micromole range can be determined even in the presence of other carboxylic acids (except in the presence of malic, tartaric, and citric acids).

If the sample contains Cl^- or Br^-, their content has to be taken into account in maintaining the proper ratio of thallium(III) to halide in the photochemical determination. In these methods the use of an inert atmosphere is not necessary, the possibility of induced reactions is completely excluded and the methods do not need cumbersome apparatus. Of the common reagents used in these methods, potassium bromate is a primary standard and thallium(III) perchlorate is very stable.

A photoconductivity study of trapped electrons in γ-irradiated hydrocarbon glasses at 77 K

NAOTO OKABE, TOYOAKI KIMURA,[1] AND KENJI FUEKI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464, Japan

Received May 3, 1983

NAOTO OKABE, TOYOAKI KIMURA, and KENJI FUEKI. Can. J. Chem. **61**, 2799 (1983).

Photoconductivity spectra of trapped electrons in γ-irradiated 3-methylpentane, 2-methylpentane, 3-methylheptane, and 3-methylpentane–methylcyclohexane (1:9 volume ratio) glasses at 77 K were measured. From the comparison of photoconductivity and optical absorption spectra in these systems we have obtained relative values of quantum efficiencies for a trapped electron in the ground state to be excited to the conduction band by photo-induced transition. For electrons stably trapped, we have measured the ranges of trap depths from the shallowest to the deepest in these systems.

NAOTO OKABE, TOYOAKI KIMURA et KENJI FUEKI. Can. J. Chem. **61**, 2799 (1983).

On a mesuré à 77 K les spectres de photoconductivité des électrons piégés dans des verres de méthyl-3 pentène, de méthyl-2 pentène, de méthyl-3 heptane et de méthyl-3 pentane-méthylcyclohexane (rapport de volume 1:9) irradiés aux rayons γ. A partir de la comparaison des spectres de photoconductivité et d'absorption optique de ces systèmes, on a obtenu les valeurs relatives des efficacités quantiques de l'électron piégé dans l'état fondamental et qui doit être excité à la bande de conduction par une transition photoinduite. Par rapport à la profondeur des pièges à électron dans lesquels les électrons sont piégés de façon stable, on a trouvé que la profondeur des pièges va du piège le moins profond au piège le plus profond dans ces systèmes.

Introduction

Ionizing radiations produce trapped electrons in various frozen matrices and many studies of these trapped electrons have been reported (1). Light irradiation to trapped electrons under an applied field gives photocurrents when the photon energy is higher than the binding energy of trapped electrons. Thus comparison of optical absorption and photoconductivity spectra is expected to provide information on the energy level structure of trapped electrons. For trapped electrons in polar glasses several photoconductivity studies have been made (2–9) and theoretical approaches have been attempted to interpret these experimental results (10, 11). On the other hand, only a few photoconductivity studies have been done for trapped electrons in nonpolar organic glasses (12, 13).

In the present work we have measured optical absorption and photoconductivity spectra of trapped electrons in γ-irradiated 3-methylpentane (3MP), 2-methylpentane (2MP), 3-methylheptane (3MHp), and a mixture of 3MP and methylcyclohexane (3MP–MCH) in 1:9 volume ratio. We have set up an apparatus for the photoconductivity measurement with a time constant of 30 ms for a current rise (0 ~ 90%) in order to observe photocurrents induced by monochromatic light at shorter times than in the previously reported work (12). Using this apparatus we have investigated in some detail the wavelength and light intensity dependence of photocurrents in the γ-irradiated hydrocarbon glass at 77 K. From comparison of photoconductivity spectra with optical absorption spectra we have deduced some significant information on the energy level structure of trapped electrons in these hydrocarbon matrices.

Experimental

3-Methylpentane and 2-methylpentane were standard pure (99% up) from Tokyo Kagaku Seiki. 3-Methylheptane was of special grade from Wako Pure Chemicals. Methylcyclohexane was standard pure (99.9%) from Tokyo Kagaku Seiki. The hydrocarbons were degassed on a vacuum line, vacuum-distilled into glass bulbs containing molecular sieves 13X pellets, heated at 280–300°C for 10 h *in vacuo* before use, and stored overnight in the dark. The purification with molecular sieves 13X was repeated three times. The purified hydrocarbons were then vacuum-distilled into photoconductivity cells and sealed off from the vacuum line. The photoconductivity cell was made of Supracil quartz and consisted of a Teflon spacer and electrodes (whose spacing was 0.6 and 1.1 mm) made of Supracil quartz coated with In–Sn. The design of the photoconductivity cell was described previously (14). In the case of 3MP, the conductivity cell with stainless mesh electrodes (whose spacing was 1 mm) was used. Both types of cells were also used for optical absorption measurements.

^{60}Co γ-rays were used for irradiation and the dose was 9.4×10^4 rad. Samples were kept in the dark at 77 K during γ-irradiations and photoconductivity or optical absorption measurements. When the samples were transferred from the γ-irradiation to the measuring Dewar, a bucket made of copper foil was used in order to keep the main part of the cell immersing in liquid nitrogen during the transfer.

The scheme of the photoconductivity measurement was given in ref. 14. A dc voltage (8 kV/cm) was supplied to the electrodes with a Watanabe PH-8A power supply. By opening a mechanical shutter, light from a xenon lamp (Xebex UXL-1000D-0) passed through a Ritsu MC-10N monochromator and an optical filter, generating a photocurrent in a γ-irradiated sample, which was amplified by a Keithley 427 current amplifier and stored in a Nicolet 2090-204 digital oscilloscope. In order to eliminate electrical noise, both the photoconductivity cell in a liquid nitrogen Dewar and the amplifier were set in a copper box which was connected to the ground. BNC connectors and coaxial cables were used and they were further shielded by mesh wires when necessary. The window through which the light passed was made of Supracil quartz coated with In–Sn which was stuck to a copper box with an electrical conductive paint.

In addition to electrical noise, there was also noise generated by mechanical vibrations. To avoid the latter the copper box was set on a polystyrene foam.

Toshiba glass filters UV-39, VR-69, and IR-D1A, which cut off the light shorter than 390, 690, and 900 nm, respectively, were used for the monochromatic light irradiation over the wavelength region of 500 ~ 700, 700 ~ 1000, and 1000 ~1600 nm, respectively. A silicone filter was used for the light of 1600 ~ 2200 nm. The actual band widths were <30 nm and ~60 nm for the visible and ir light, respectively. The intensity of monochromatic light was measured by a YSI Model 65A radiometer.

Optical absorption spectra were measured on a Hitachi model 323 spectrophotometer.

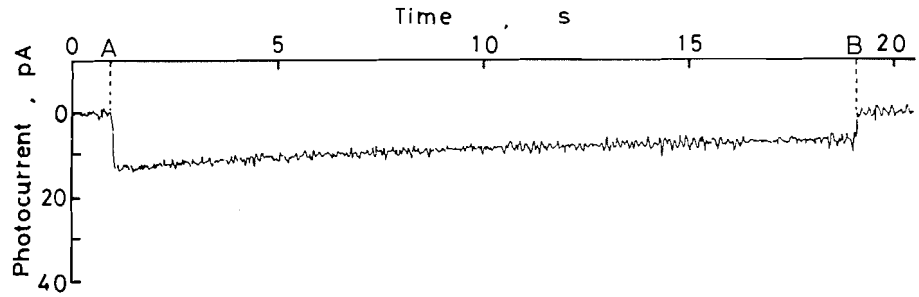

FIG. 1. Time profile of photocurrent in 3MP–MCH system. *A*: shutter opened; *B*: shutter closed.

Results and discussion

1. Time profile of photocurrents

The time constant (30 ms) in the present work is fast enough to make measurements on a time scale of second. In every case throughout this work, photocurrent was generated instantaneously when the shutter was opened; it then decayed very slowly during the light irradiation and fell to zero instantaneously when the shutter was closed. A typical example is shown in Fig. 1. A large decrease in photocurrent such as that reported in ref. 12 for the case of 3-methylhexane (3MHx) was not observed for 3MP, 2MP, 3MHp, and 3MP–MCH systems studied here. However, we have reconfirmed the large decrease in photocurrent, irrespective of the incident photon energy, for the 3MHx systems.[2] Except in the case of 3MHx, a flat time profile such as that shown in Fig. 1 appears to be a general feature of photocurrents in hydrocarbon glasses at 77 K. Trapped electrons cannot be considerably bleached out on a time scale of seconds by monochromatic light, intensity of which is at most 10^{15} photon/s. Thus, the time profile of such flat shape as shown in Fig. 1 is readily understandable because the concentration of trapped electrons remaining changes only slightly with irradiation time.

Photocurrents are related to the drift mobility of mobile electrons along the direction of the applied electric field. The mobile electron alternates between the conduction state in which the mobility is high and the localized state in which the mobility is negligibly small (15). This localized state corresponds to very shallow trapping sites and should be differentiated from deep trapping sites in which electrons can be stably trapped to form the so-called trapped electrons. Deeply trapped electrons cannot be detrapped unless photoexcited.

The magnitude of photocurrents depends on the equilibrium between the rates of production and depletion of mobile electrons. The depletion of mobile electrons results from their retrapping in the matrix or reactions with radicals, positive ions, and impurities, etc. The fact that time profiles of photocurrents are flat indicates that the major process for depletion of mobile electrons is retrapping on the time scale studied, otherwise such flat profiles would not be observable. Therefore, photocurrents are observed as a result of repetition of the production and depletion of mobile electrons in the matrix: trapped electrons are mobilized by absorbing photons, retrapped in the matrix, mobilized again, and so on.

2. Photoconductivity and optical absorption spectra of trapped electrons

As was described already we have obtained the relationship between the magnitude of photocurrent and the intensity of incident photon for each photon energy and for each system. Examples of a linear or nonlinear relation between the magnitude of photocurrent and the intensity of incident photon are shown for 3MP in Fig. 2. Nonlinear relationship, as shown in Fig. 2(*b*), was frequently observed in the experiments on 3MHx.[2] However, this nonlinear relationship was not observed for 2MP, 3MHp, and 3MP–MCH systems. Thus 3MP is in between 3MHx and the group of 2MP, 3MHp, and 3MP–MCH in the photocurrent – light intensity relationship.

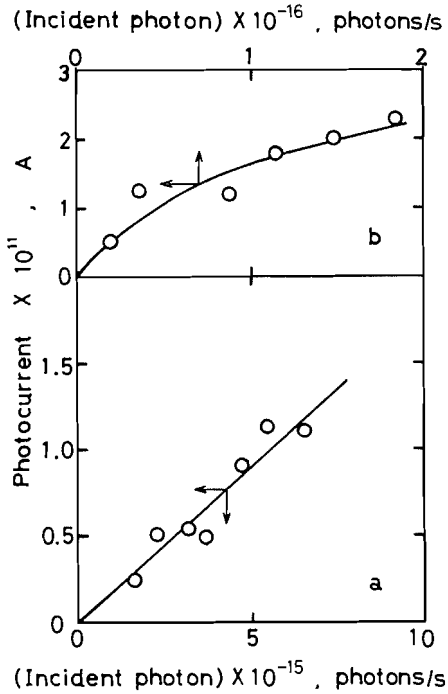

FIG. 2. Photocurrent vs. intensity of incident photon in 3MP system. *a*: wavelength of incident light, 1300 nm; *b*: wavelength of incident light, 1000 nm.

Photocurrents per incident photon for the 3MP, 2MP, 3MHp, and 3MP–MCH systems are plotted, together with the optical densities of trapped electrons, in Figs. 3, 4, 5, and 6, respectively. When the photocurrent is nonlinearly dependent on the incident photon intensity as shown in Fig. 2(*b*), the initial slope is taken as the value of photocurrent per incident photon. The unit of the ordinate in the photoconductivity spectra is expressed as A/(photon per s) which is equal to C/photon. Thus we will use C/photon for the ordinate of the photoconductivity spectra. Optical absorption spectra shown in Figs. 3–6 are normalized so that the magnitude of their maxima is equal to that of the maxima of the corresponding photoconductivity spectra. The tails of the optical absorption spectra on the low energy side cannot be fully given because of the high

absorbance of the matrix itself.

There is no doubt that the photoconductivity spectra represent the transition probabilities from the ground state to the conduction state (bound–free transitions) vs. incident photon energy. However, the optical absorption spectra represent the transition probabilities from the ground state to the bound excited states (bound–bound transitions) and/or the conduction state vs. incident photon energy. Some experimental evidence by which optical absorption spectra can be assigned to bound–bound and bound–free transitions has been reported (2–5, 7, 12), but this is not conclusive because the photoconductivity thresholds are not given in these studies. Recent work has determined the photoconductivity thresholds for trapped electrons in amine and alcohol glasses at 77 K (16). On the other hand, some workers have assigned the entire spectrum of trapped electrons in a hydrocarbon glass to the bound–free transition alone (17). However, we have shown from the measurement of photoconductivity threshold that the optical absorption spectrum of trapped electrons in 3MP can be assigned to the bound–bound and bound–free transitions (13). The present results on 2MP, 3MHp, and 3MP–MCH systems also support the conclusion given in ref. 13. In all of Figs. 3–6, the photoconductivity thresholds appear at the photon energies at which the corresponding optical absorption is still finite. This indicates that optical absorption at photon energies less than the photoconductivity threshold, E_{th}^{ph}, must be attributed to bound–bound transitions alone. In the photon energy range between E_{th}^{ph} and the energy, E_{max}^{ab}, at which the optical absorption spectrum is maximum, bound–bound, and bound–free transition coexist but the former is predominant. In the photon energy range between E_{max}^{ab} and the energy, E_{max}^{ph}, at which the photoconductivity spectrum is maximum, both bound–bound and bound–free transitions exist to a significant extent. At photon energies higher than E_{max}^{ph} the bound–free transition is predominant.

The results in Figs. 3–6 are similar to each other, but the photoconductivity spectra on the high energy side differ slightly among each other. The photoconductivity spectrum for 3MP is the lowest in its intensity on the high energy side. The energy separation between E_{max}^{ab} and E_{max}^{ph} is similar among 3MP, 2MP, and 3MHp. However, in the 3MP–MCH system the photoconductivity maximum is closer to the optical absorption maximum.

3. Relative quantum efficiency for the bound–free transition

Photocurrent, i, can be given by eq. [1].

$$[1] \quad i = \frac{e\mu V}{d} 10^{-3} [e_m^-] N_0 S$$

where e is the charge on an electron, μ is the drift mobility of the mobile electron, V is the applied voltage, $[e_m^-]$ is the concentration of mobile electrons in units of M, N_0 is Avogadro's number, S is the surface area of electrodes, and d is the separation distance between electrodes. Since the time profiles of photocurrents observed are nearly flat as was already described, we can assume a steady-state for the production and depletion of mobile electrons:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

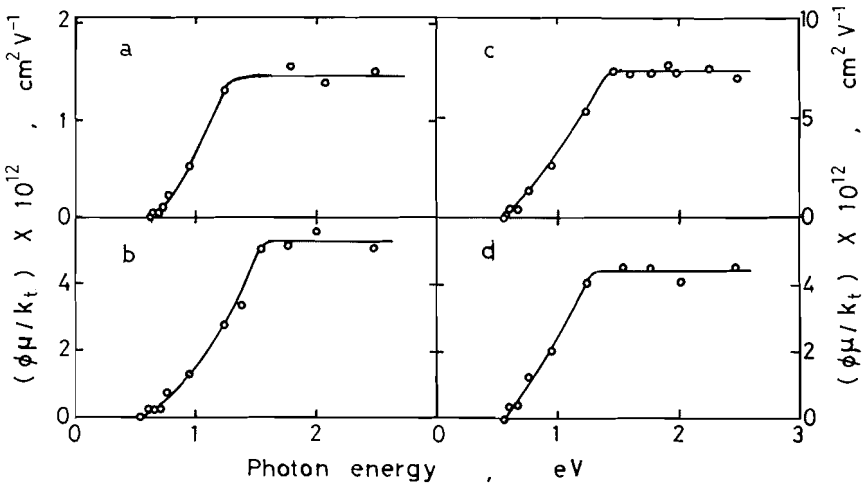

FIG. 7. $\phi\mu/k_t$ vs. photon energy. *a*: 3MP; *b*: 2MP; *c*: 3MHp; *d*: 3MP–MCH.

$$[2]\quad \frac{d[e_m^-]}{dt} = \phi I_0(1-10^{-OD})/(10^{-3}N_0 d) - k_t[e_m^-] = 0$$

where I_0 is the number of incident photons per unit time (s) per unit area (cm^2), OD is the optical density of trapped electrons at a specified photon energy, and ϕ and k_t are the quantum efficiency for the bound–free transition and the rate constant for the depletion of mobile electrons by trapping, respectively. Then the steady-state concentration of mobile electrons are derived as eq. [3] from eq. [2].

$$[3]\quad [e_m^-] = \frac{10^3 \phi I_0}{N_0 d k_t}(1-10^{-OD})$$

From eqs. [1] and [3] we obtain,

$$[4]\quad \frac{\phi\mu}{k_t} = \frac{id^2}{I_0(1-10^{-OD})SeV}$$

It should be noted that all the quantities on the right hand side of eq. [4] are observable or known. We assume here that μ/k_t is independent of the photon energy. This assumption is valid when the hot electron relaxation time is short compared with the measurement time. This condition is satisfied under our experimental conditions. If this assumption is accepted, the value of the right-hand side of eq. [4] gives the relative value of ϕ. The values of $\phi\mu/k_t$ for 3MP, 2MP, 3MHp, and 3MP–MCH systems are plotted as a function of photon energy in Fig. 7. It should be noted that for all four systems, the values of $\phi\mu/k_t$ are constant when the photon energy is greater than a certain value, E_c^{ph}. These critical photon energies, E_c^{ph}, are slightly different for the four systems. The values of $\phi\mu/k_t$ decrease monotonically with decreasing photon energy below E_c^{ph} and fall to zero at the photon energies which correspond to the photoconductivity thresholds, E_{th}^{ph}. Based upon the above assumption, all the results in Fig. 7 are satisfactorily explained as follows. We consider that electrons are stably localized in matrix traps whose depths have a certain distribution. Here we define the trap depth as the difference in energy between the bottom of the conduction state and the ground state. When the photon energy is lower than the value corresponding to the depth of the shallowest trap,[3] no bound–free transition occurs

[3] This is the shallowest trap relevant to stably trapped electrons, but not to mobile electrons.

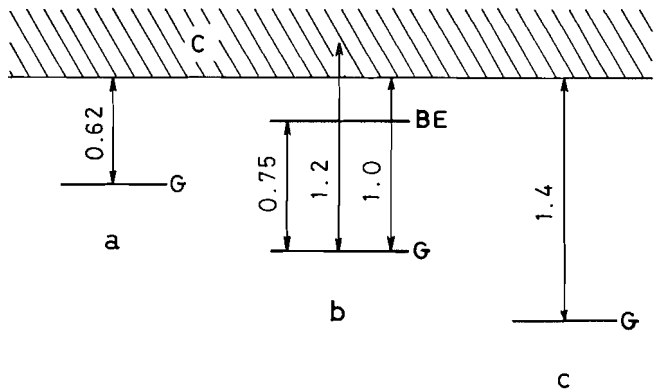

FIG. 8. Energy diagram for trapped electrons in 3MP at 77 K. G, BE, and C denote the ground, bound-excited, and conduction states, respectively, and arrows show the difference between the two energy levels in units of eV. *a*: the shallowest trap; *b*: the average trap, *c*: the deepest trap.

and ϕ is zero. In the photon energy range between those corresponding to the shallowest and deepest traps, photon absorption by trapped electrons, whose trap depths are less than the photon energy, results in bound–free transitions, but photon absorption by trapped electrons, whose trap depths are greater than the photon energy, does not. Thus it is expected that a fraction of the bound–free transition, i.e., ϕ, increases with increasing photon energy in this range. When the photon energy exceeds the energy value corresponding to the deepest trap, photon absorption results in only bound–free transitions, i.e., $\phi = 1$, independent of photon energy. Assuming that the depths of the shallowest and deepest traps correspond to E_{th}^{ph} and E_c^{ph}, respectively, we see that the experimental results shown in Fig. 7 can be well accounted for: the relative values of ϕ are zero for the photon energy $< E_{th}^{ph}$, increase with increasing photon energy between E_{th}^{ph} and E_c^{ph} and are constant when the photon energy $> E_c^{ph}$.

The values of the shallowest and deepest trap depths obtained as E_{th}^{ph} and E_c^{ph} from Fig. 7 are listed in Table 1 together with the energies, E_{max}^{ab} and E_{max}^{ph}, corresponding to the optical absorption and photoconductivity maxima, respectively. Taking 3MP as an example, the shallowest and deepest trap depths are 0.6 and 1.4 eV, respectively. If it is assumed that the optical absorption and photoconductivity maxima correspond to the

3MP–MCH	0.71	0.95	0.56	1.3

most probable excitation energies for bound–bound and bound–free transitions, the average energy level of the bound excited state lies above that of the ground state by 0.75 eV and the most probable bound–free transition occurs at 1.2 eV above the average energy level of the ground state. The energy level to which the most probable bound–free transition occurs is higher by 0.2 eV than the bottom of the conduction state. The energy level diagram for trapped electrons in 3MP is schematically shown in Fig. 8.

Since two types of conductivity cells were used in the present work, we do not intend to compare the absolute values of $\phi\mu/k_t$ among the hydrocarbon systems studied here. $\phi\mu/k_t$ in the present work corresponds to $\langle\phi\mu\tau\rangle$ in refs. 5 and 6. The reported values of $\langle\phi\mu\tau\rangle$ in polar aqueous and alcoholic glasses and aqueous LiCl glass are $10^{-15} \sim 10^{-13}$ and 10^{-12} cm^2 V^{-1}, respectively. The constant values of $\phi\mu/k_t$ for the photon energy $> E^{ph}_c$ are of the order of 10^{-12} cm^2 V^{-1}. If we use a $(1/k_t)$ value of $\sim 10^{-10}$ s (18) and a μ value of $\sim 10^{-2}$ cm^2 V^{-1} s^{-1} (19–21),[4] then ϕ becomes the order of 1.

Steen and Moan have stated that photobleaching of trapped electrons occurs by photoexcitation from the ground to a superexcited state which lies above the bottom of the conduction state and then the superexcited state autoionizes to give conduction electrons (22). The present results do not discriminate whether trapped electrons are mobilized by direct transitions from the ground to conduction states or by transitions to superexcited states and subsequent autoionization. If we take the latter process into consideration, the depths of the shallowest and deepest traps may be somewhat lower than the values listed in Table 1, since it is stated that the probability of autoionization relative to deactivation of superexcited states increases rapidly with increasing excitation energy (22).

As described above, we have shown the existence of the range of trap depths based on the assumption that μ/k_t is independent of photon energy. Figure 7 shows that the values of $\phi\mu/k_t$ are constant in the higher photon energy region. Since it is expected that ϕ is constant when photon energy exceeds a certain value, μ/k_t could be constant in the higher photon energy region. In the lower photon energy region, however, we might suppose that μ/k_t may not be independent of photon energy. If a bound–free transition takes place at an energy only slightly above the threshold, the electron formed may have so little energy that it can be thermalized and be attracted back to the trap very quickly without ever being able to escape from the locale of the trap. If so, this would be reflected as a decrease in ϕ in the present experimental system, because we have observed photocurrents in the time scale of seconds. Then, ϕ would increase from zero (photon energy = threshold) with increasing photon energy. An alternative explanation for the increase in $\phi\mu/k_t$ with increasing photon energy in Fig. 7 may be as follows: depth of electron traps is uniform and ϕ increases from zero (photon energy = threshold) with increasing photon energy (uniform trap depth model). However, the fact that the most probable bound–bound transition occurs at a photon energy higher than E^{ph}_{th} cannot be explained by the uniform trap depth model. Even if there exists a range of trap depths, ϕ may increase with increasing photon energy for electrons trapped in a specified depth of trap. If this is true, the depths of the deepest traps would be somewhat lower than those listed in Table 1.

[4] The reported electron mobilities in organic glasses at 77 K are 0.1 (19) and 0.055 (20) cm^2 V^{-1} s^{-1} for 3MP and MTHF, respectively. However, Kevan and Rice have suggested later that the lower limit of electron mobility in MTHF at 77 K is 0.005 cm^2 V^{-1} s^{-1} (21). Thus we may say that electron mobility in organic glasses at 77 K is of the order of 10^{-2} V^{-1} s^{-1}.

III. Order–disorder transitions and electrical conductivity studies in Na_2SO_4 – Ag_2SO_4 system

M. SUNITHA KUMARI and ETALO A. SECCO[1]

Chemistry Department, St. Francis Xavier University, Antigonish, N.S. Canada B2G 1C0

Received May 20, 1983

M. SUNITHA KUMARI and ETALO A. SECCO. Can. J. Chem. **61**, 2804 (1983).

The physico-chemical aspects of the order–disorder phase transitions occurring in the Na_2SO_4–Ag_2SO_4 system were investigated by thermal analyses, X-ray diffraction, and electrical conductivity techniques. Electrical conductivity data on pure and doped compositions reveal high conductivity values in the high temperature phase.

The lower conductivity of Ag_2SO_4 with Na^+ presence relative to pure Ag_2SO_4 is attributed to lattice contraction effecting lower mobility of ions.

M. SUNITHA KUMARI et ETALO A. SECCO. Can. J. Chem. **61**, 2804 (1983).

On a étudié les aspects physico-chimiques de l'ordre et du désordre des transitions de phase qui se produisent dans le système Na_2SO_4–Ag_2SO_4 en faisant appel à l'analyse thermique, aux techniques de diffraction des rayons-X et à la conductivité électrique. Les données de conductivité électrique des compositions à l'état pur et à l'état dopé révèlent des valeurs élevées de conductivité dans la phase à haute température.

On attribue la plus faible conductivité du Ag_2SO_4 en présence de Na^+ par rapport à celle du Ag_2SO_4 à l'état pur à une contraction du réseau qui provoque une plus faible mobilité des ions.

[Traduit par le journal]

Introduction

Recently, we reported on the order–disorder phase transitions occurring in the Na_2SO_4–K_2SO_4 system (1) and on the high ionic conductivity values observed in the high temperature phase of undoped and doped $KNaSO_4$ and $K_3Na(SO_4)_2$ (2). Binary sulfates containing monovalent cations are members of a group of compounds which exhibit fast-ion or super-ionic conductivity in the high-temperature phase (3). The mechanism of fast-ion conduction is not completely understood although proposed models involve basically two structural types, viz. (*i*) layer structure as in β-alumina and (*ii*) channel structure as in NASICON where an open network or skeleton framework of anions facilitate cation mobility (3).

The low temperature form of Ag_2SO_4, I-Ag_2SO_4 (β), orthorhombic and space group *Fddd* with unit cell dimensions a_0 = 5.82 Å, b_0 = 12.70 Å, c_0 = 10.27 Å, is isomorphic with the low temperature form of Na_2SO_4, V-$NaSO_4$, with unit cell dimensions a_0 = 5.80 Å, b_0 = 12.30 Å, c_0 = 9.82 Å (4). Furthermore, the high temperature forms of Ag_2SO_4, II-Ag_2SO_4(α), and of Na_2SO_4, I-Na_2SO_4, are isostructural hexagonal with space groups $P6_3/mmc$ and $P6_3/mc$, respectively. With their lattice constants differing by <4%, Ag_2SO_4 and Na_2SO_4 are expected to form a continuous solid solution over the entire composition range with only one single solid phase present.

The early paper of Nacken (5) reporting on the Na_2SO_4–Ag_2SO_4 phase diagram was followed by the study of Burmistrova *et al.* (6) wherein solid solutions and solid–solid phase transitions are shown to exist over the complete composition range. Since Ag_2SO_4 exhibited high cationic conductivity in the high temperature phase (7, 8), the prospect of higher cationic conductivity with smaller radius and lower mass Na^+, r_{Na^+} = 96 pm versus r_{Ag^+} = 126 pm, in the Ag_2SO_4 structure prompted us to probe the nature of the solid–solid phase transitions in the Na_2SO_4–Ag_2SO_4 system and to explore its potential for enhanced fast-ion conduction using thermal analyses, DSC, electroconductivity, and X-ray diffractometry techniques.

[1]To whom all correspondence should be addressed.

Experimental

Anhydrous Na_2SO_4 was from two sources, Fisher Certified and Alfa Products ultrapure grade. Anhydrous Ag_2SO_4 was Alfa Products ultrapure grade. Although there was no discernible difference in the measured physico-chemical and thermal properties of Na_2SO_4–Ag_2SO_4 samples using Na_2SO_4 from both sources, the electrical conductivity measurements revealed parallel but distinct plots. Only ultrapure Na_2SO_4–Ag_2SO_4 results are reported here. The $CdSO_4$ was Fisher Certified grade and $Gd_2(SO_4)_3$ was Alfa Ventron Corp. of stated purity 99.9%.

Na_2SO_4–Ag_2SO_4 samples, undoped and doped (Cd^{2+}, Gd^{3+}), were prepared by fusing the requisite composition mixture, previously well ground manually, of the respective sulfates in a Pt crucible.

DTA traces were recorded on a duPont 990 Thermal Analyzer in a flowing N_2 (ultrapure) atmosphere using ignited Al_2O_3 as reference material. The precision of a melting temperature measurement was ±5°C whereas the transition temperature measurement was within ±2°C. The enthalpies and heat capacities of transformation were evaluated with the DSC accessory to the 990 DTA module using the heats of fusion for In, Sn, and Zn as references; samples were encapsulated in Al containers — identical results within experimental error were obtained using Au containers.

X-ray diffraction patterns were obtained using a Norelco diffractometer with CuK_α radiation. Diffraction patterns at elevated temperatures were recorded with a Model X-86-N high temperature accessory (Materials Research Corp.) attached to the Norelco unit (9).

Electrical conductivity measurements were made on compressed polycrystalline sample in a stainless steel conductivity cell following the procedure described earlier (2, 10). The sample was in the form of a disc, 1 mm thick and 100 mm^2 in surface area, for Na_2SO_4 and Ag_2SO_4. All other compositions were 1 mm thick and ~30–50 mm^2 in surface area whose shape ranged from a semi-circle to a sector — it was the crack-free portion recovered from the compressed disc.

Results and discussion

Phase diagram

The transition temperatures recorded on DTA traces and plotted versus composition in Fig. 1. Figure 1*a* represents the solid–solid phase diagram and Fig. 1*b* represents the solid–liquid phase diagram. The cool mode plot, filled circles, in Fig. 1*a* and *b* are in general agreement with the reports of Nacken (5) and Burmistrova *et al.* (6). Figure 2 gives the enthalpy change, ΔH_t, dependence on composition for the solid–solid

ior expected for isomorphic binary systems with conspicuous absence of the solidus curve. Reisman (11) has done theoretical analyses of solid solutions using computer-derived models incorporating the ΔH_f^0, heat of fusion, and T_0, the melting temperature for each component. The Na_2SO_4–Ag_2SO_4 binary system with ΔH_f^0 = 5.8 kcal/mol, T_0 = 1153 K and ΔH_f^0 = 4.3 kcal/mol, T_0 = 954 K, respectively is expected to show a linear liquidus curve with a slightly convex solidus separation. No solidus curve was discernible in our data but there is evidence of slight concavity among the data although we chose a straight line plot.

(ii) Solid–solid

The solid phase diagram displays a simple linear dependence of the transition temperature on composition from 10 mol% to pure Ag_2SO_4 in the heat mode. The higher transition temperature at 10 mol% represents the shoulder of the endotherm, Fig. 5*a*. Figure 5 presents traces *a*, *b*, and *c* in the heat mode for 10, 20, and 30 mol% Ag_2SO_4. The upper trace is for the sample within 24 h after fusion and cooled abruptly by sample withdrawal from furnace to room temperature. The lower trace is for the same sample after 15–21 days storage at room temperature in open air or on second heating after slow cooling in the DTA cell. The DTA cool traces of these compositions

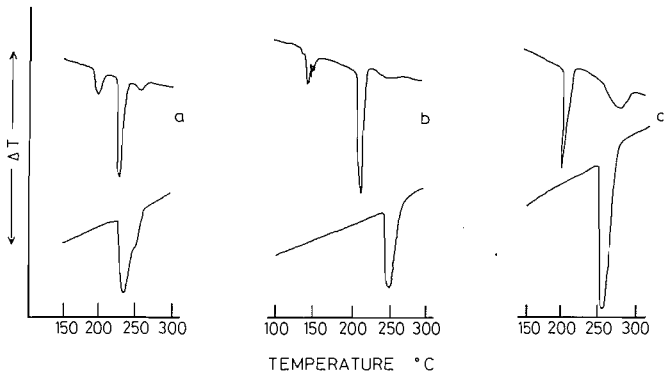

FIG. 5. DTA heat mode traces of fused $Na_2SO_4-Ag_2SO_4$ samples: upper trace, cooled abruptly to room temperature and 24 h after fusion; lower trace, after 15–21 days storage at room temperature or on second heating after slow cooling in DTA cell. (*a*) 10 mol% Ag_2SO_4; (*b*) 20 mol% Ag_2SO_4; (*c*) 30 mol% Ag_2SO_4.

showed only one exotherm, indicating the stabilization to a single phase after slow cooling or storage. Figures 1*a* and 1*b* and Figs. 2, 3, and 4 are for samples after 15–21 days storage.

The irregular behavior of the 10 mol% composition throughout the study most likely originates with the polymorphism of Na_2SO_4 where four phases have been confirmed (12). That is, two kinds of $Ag_2SO_4-Na_2SO_4$ solid solutions exist where Ag_2SO_4 is distributed between two structural forms of Na_2SO_4 – a novel effect where a solute is distributed between two immiscible solid phases of the same compound.

The cool mode data display appreciable hysteresis effects relative to the heat mode data, with the minimum at 40 mol%, which are consistent with the diagram from Nacken (5). Our T_t of 422°C for Ag_2SO_4 is closer to value of 420°C from Burmistrova *et al.* (6) than the values of 412°C and 430°C of Nacken (5) and Hedvall *et al.* (13) respectively. Thermal hysteresis effect, $\Delta T = T_p^f - T_p^r$, where T_p^f refers to the peak temperature on heating and T_p^r the peak temperature on cooling, has been linked (14) to a necessary consequence of the coexistence mechanism of continuous transformations with the main factor controlling the hysteresis being the strain energy E_s. Thermodynamic considerations relate strain energy to $\Delta T\Delta S$, i.e. $E_s \propto \Delta T\Delta S$ where ΔS is the entropy change for the transformation. Figure 4 shows a maximum strain energy at 40 mol% whereas the pure components, Na_2SO_4 and Ag_2SO_4, possess the same strain energy. Another basis for the hysteresis effect may be the disorder → order direction which imposes a configurational requirement of "long-range" order with the ordered migration of ions from one set of sites to another. The largest hysteresis may imply the highest order-to-disorder ratio resulting from the existence of predetermined and specifically crystallographically identified sites for each ionic species. Guthrie and McCullough (15) expressed this approach by the relation $\Delta S = R \ln Q$, where Q is the ratio of the numbers of disordered states in the two phases, and ΔS is the entropy of transformation. Using this equation for the 40 mol% ΔS_t of 20.5 J mol^{-1} K^{-1} and subtracting a correction for the librational entropy of 3 J mol^{-1} K^{-1} and assuming no cation disorder, a disorder ratio of $Q = 11$ is found in good agreement with the value of $Q = 10$ for model substances of pure compounds. However, Fig. 2 reveals an essentially constant ΔH_t or ΔS_t value up to 60 mol%, excepting 10 mol%, suggesting that the order-to-disorder ratio is also constant. But this inference ignores the binding energy between like pairs and unlike pairs,

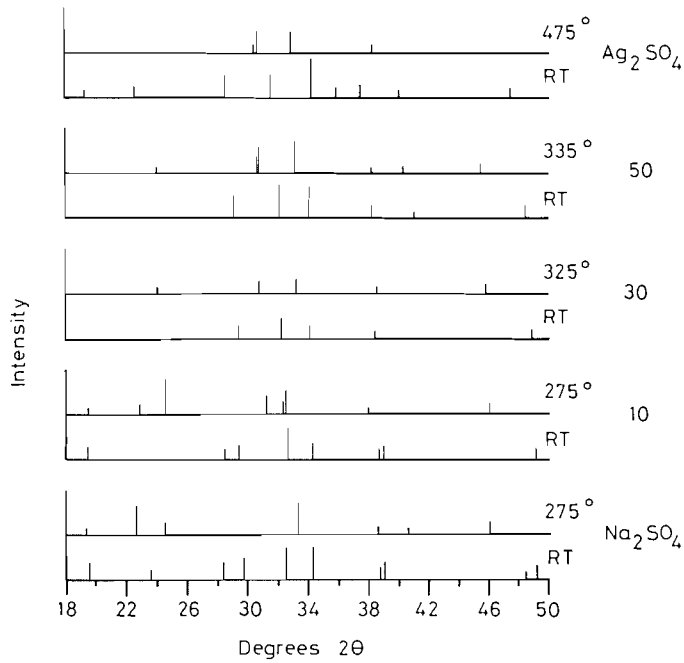

FIG. 6. X-ray diffraction line patterns, converted from diffractogram peaks, of relative intensity versus angle 2θ for Na_2SO_4, 10, 30, 50 mol% Ag_2SO_4, and Ag_2SO_4 at room temperature (RT) and transition temperatures in °C.

i.e. Na^+ and Ag^+, in the lattice where a change in binding energy may be compensated by the enthalpy of mixing. The dashed linear relation in Fig. 2 represents the physical mixture of Na_2SO_4 and Ag_2SO_4 where the difference between this value and the observed solid solution value is taken as the net binding energy – enthalpy of mixing contribution. This latter topic is planned as a further study.

X-ray diffraction

X-ray diffraction patterns at room temperature and above the transition temperature for Na_2SO_4, Ag_2SO_4, 10 mol% Ag_2SO_4, 30 mol% Ag_2SO_4, and 50 mol% Ag_2SO_4 are presented in Fig. 6. The patterns confirm the solid phase structural transformation. Na_2SO_4 and Ag_2SO_4 correlate with their reported patterns (4). The room temperature 10 mol% pattern, except for minor displacements and intensity differences, resembles the Na_2SO_4 pattern at room temperature; distinct differences appear, however, above the transition temperature (275°C) for the two samples. While the room temperature patterns of 30 and 50 mol% Ag_2SO_4 show strong resemblance to each other and are simpler than the room temperature patterns of Na_2SO_4 and Ag_2SO_4, their high temperature patterns closely resemble the Ag_2SO_4 high temperature pattern. These patterns imply that the low temperature structure of a $Na_2SO_4-Ag_2SO_4$ solid solution undergoes a phase transformation resembling the II-Ag_2SO_4 (α) form at high temperature with ΔH_t equal to that value for Na_2SO_4.

Electrical conductivity

The temperature dependence of the ionic conductivity, σ, is interpreted in terms of the Arrhenius-type equation.

$$\sigma = (\sigma_0/T) \exp(-Q_c/RT)$$

where σ_0 represents a composite constant $(ne^2\lambda^2\nu/k)$; n, the number of ions per unit volume; e, the ionic charge; λ, the distance between two jump positions; ν, the jump frequency; k,

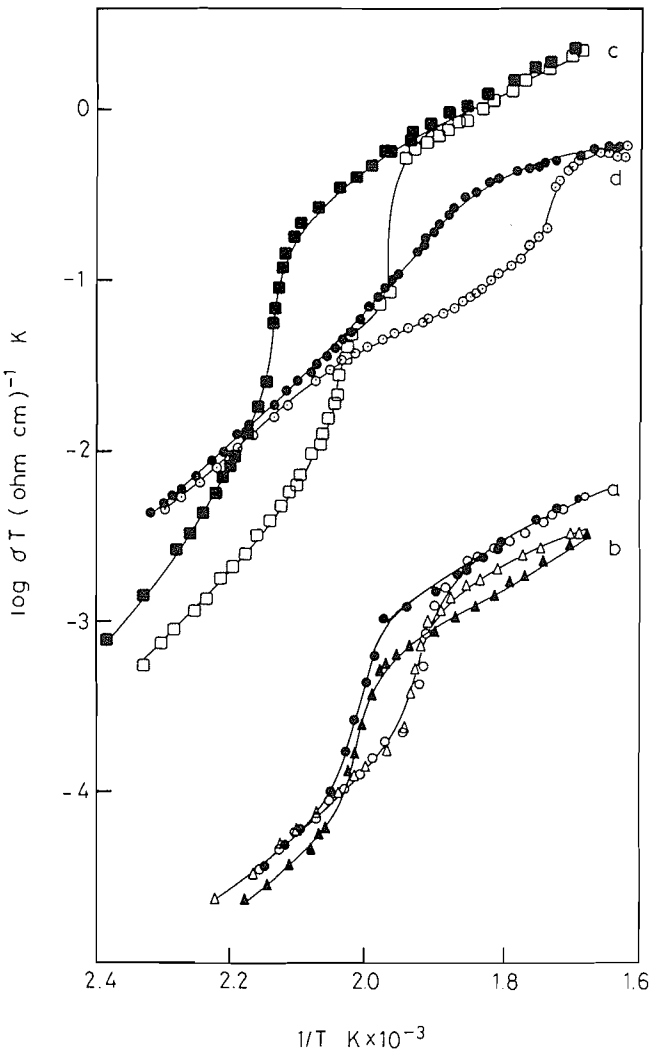

FIG. 7. Plots of log σT versus $1/T$: (*a*) Na_2SO_4, Fisher Certified, ○, ● heat and cool modes, respectively; (*b*) Na_2SO_4, Alfa ultrapure, △, ▲ heat and cool modes, respectively; (*c*) 5 mol% Cd^{2+} in Na_2SO_4, □, ■ heat and cool modes, respectively; (*d*) 5 mol% Gd^{3+} in Na_2SO_4, ○, ● heat and cool modes, respectively.

the Boltzmann constant; and Q_c is the activation energy for ionic motion, assuming the conductivity to be effectively ionic with negligible electronic or hole conductivity.

Plots of log (σT) vs. $1/T$ K for pure and doped Na_2SO_4, pure Ag_2SO_4, and doped and undoped 40 mol% Ag_2SO_4 are presented in Figs. 7 and 8, respectively. The two samples of undoped Na_2SO_4, curves *a* and *b* in Fig. 7, from different sources display the same behavior on the heat mode within limits of experimental error, but show a distinct difference on the cool mode. The doped samples, curves *c* and *d* in Fig. 7, were with Alfa Products Na_2SO_4. Na_2SO_4 doped with 5 mol% $CdSO_4$ showed higher σ values above the transition temperature than Na_2SO_4 doped with 5 mol% $Gd_2(SO_4)_3$. The reduced transition effect, temperature dependence and σ value for 5 mol% $Gd_2(SO_4)_3$ is consistent with vacancy-cation cluster formation analogous to that proposed for anion conductors (16). These plots show the expected phase transition and hysteresis effects consistent with DTA traces.

The conductivity plots in Fig. 8 reveal pronounced hysteresis effects for the 40 mol% Ag_2SO_4 composition consistent with the DTA result, Fig. 1*a*, whereas a minor hysteresis effect

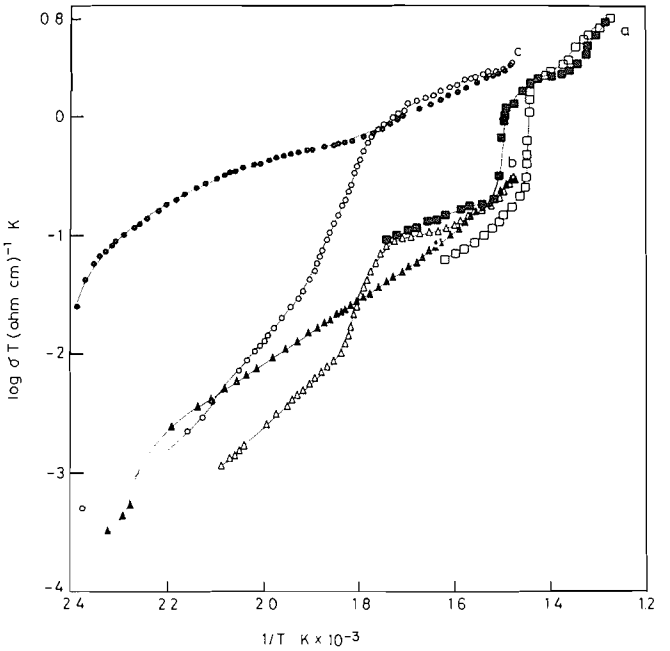

FIG. 8. Plots of log σT versus $1/T$: (*a*) Ag_2SO_4, □, ■ heat and cool modes, respectively; (*b*) 40 mol% Ag_2SO_4, △, ▲ heat and cool modes, respectively; (*c*) 4 mol% Cd^{2+} in 40 mol% Ag_2SO_4, ○, ● heat and cool modes, respectively.

appears for Ag_2SO_4. While the 4 mol% $CdSO_4$ doped sample possesses a higher conductivity than the undoped sample, the undoped sample conductivity is lower than the Ag_2SO_4 value and furthermore the sharper transition of Ag_2SO_4 is evident. The predicted enhanced conductivity of Na^+ incorporated in the Ag_2SO_4 structure did not materialize. A lattice contraction with Na^+ in the Ag_2SO_4 structure, as suggested by X-ray diffraction patterns, would effect a lower mobility of Na^+ and Ag^+ ions. The presence of 4 mol% $CdSO_4$ in the lattice provides vacant sites, on the basis of electroneutrality requirement, and greater freedom for mobility of Na^+ and Ag^+ ions.

The activation energy Q_c for the phase transition of the undoped 40 mol% Ag_2SO_4 of 163 ± 15 kJ/mol and 177 ± 20 kJ/mol for the 4 mol% $CdSO_4$ doped sample indicates a common conductivity mechanism. However, the higher conductivity of the doped sample must originate with the higher number of mobile charge carriers. That is, the kinetic mechanism remains the same but the concentration factor, *n*, is increased by Cd^{2+} presence. The Q_c values for the post transition region of the 4 mol% doped 40 mol% Ag_2SO_4, the 5 mol% doped Na_2SO_4, and pure Na_2SO_4 are 37 ± 5, 45 ± 5, and 50 ± 5 kJ/mol, respectively. The Q_c values suggest the major charge carrier to be Na^+ ion and the number of mobile ions per unit volume to be approximately the same in the first two samples whereas a much lower *n* appears in pure Na_2SO_4.

The crystal and molecular structure of di-μ-phenylthiolatobis[trichloro(dimethyl sulfide) tungsten(IV) (W—W)]

P. MICHAEL BOORMAN,[1] JOANNE M. BALL, KELLY J. MOYNIHAN, VIKRAM D. PATEL, AND JOHN F. RICHARDSON
Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received May 30, 1983

P. MICHAEL BOORMAN, JOANNE M. BALL, KELLY J. MOYNIHAN, VIKRAM D. PATEL, and JOHN F. RICHARDSON. Can. J. Chem. **61**, 2809 (1983).

The complex $(Me_2S)Cl_3W(\mu\text{-}SPh)_2WCl_3(SMe_2)$, **1**, has been isolated as one product of the 1:1 reaction between $WCl_4(Me_2S)_2$ and $SiMe_3(SPh)$ in CH_2Cl_2 solution. A single crystal X-ray diffraction study shows that the molecule has the relatively unusual edge-shared bioctahedral structure, with a W—W bond length of 2.759(1) Å. The dimethyl sulfide ligands occupy positions *trans* to one another in the equatorial mean plane of the molecule, which has two-fold symmetry imposed on it. The structure was solved by the heavy atom method and refined to $R = 0.044$ and $R_w = 0.058$ for 2001 reflections. Crystals of **1** are monoclinic, space group $C2/c$, with $a = 17.445(4)$, $b = 12.594(2)$, $c = 11.509(3)$ Å, $\beta = 91.22(1)°$, and $Z = 4$.

P. MICHAEL BOORMAN, JOANNE M. BALL, KELLY J. MOYNIHAN, VIKRAM D. PATEL et JOHN F. RICHARDSON. Can. J. Chem. **61**, 2809 (1983).

On a isolé le complexe $(Me_2S)Cl_3W(\mu\text{-}SPh)_2WCl_3(SMe_2)$, **1**, lors de la réaction 1:1 entre le $WCl_4(Me_2S)_2$ et le $SiMe_3(SPh)$ dans une solution de CH_2Cl_2. Une étude de diffraction sur un monocristal indique que la molécule a une structure inhabituelle bioctaédrique à arête séparée avec une longueur de liaison W—W de 2,759(1) Å. Les ligands sulfure de diméthyle sont en position *trans* l'un par rapport à l'autre dans le plans équatorial moyen de la molécule qui a un axe de symétrie binaire. On a résolu la structure par la méthode de l'atome lourd et on l'a affinée jusqu'à des valeurs de $R = 0{,}044$ et de $R_w = 0{,}058$ pour 2001 réflexions. Les cristaux du composé **1** sont monocliniques et appartiennent au groupe d'espace $C2/c$ avec $a = 17{,}445(4)$, $b = 12{,}594(2)$, $c = 11{,}509(3)$ Å, $\beta = 91{,}22(1)°$ et $Z = 4$.

There is intense current interest in the chemistry of metal thiolates, due largely, no doubt, to the biological importance of such complexes (see for example, ref. 1). Recent studies in our laboratory have shown that the W—SR group in complexes of tungsten(IV) is unstable as a terminal entity (2–5). By metathesis of WCl_4L_2 (L = Me_2S; C_4H_8S) with $SiMe_3(SR)$ (R = alkyl, aryl), the intermediates $WCl_{4-n}(SR)_nL_2$, **2**, have been prepared via the equation:

$$WCl_4L_2 + nSiMe_3(SR) \rightarrow WCl_{4-n}(SR)_nL_2 + nSiMe_3Cl$$

2 can undergo degradation by one of two observed pathways, depending on the stoichiometry (i.e. the value of n) and the nature of R. When $n > 1$, reductive elimination of R_2S_2 is predominant, yielding complexes with lower oxidation state metal centres. On the other hand, monothiolato-complexes of the type $WCl_3(SR)L_2$ are prone to degrade via the elimination of RCl. In both instances we have observed a pronounced tendency for the dimerization of the intermediates to yield confacial bioctahedral complexes such as $LCl_2W(\mu\text{-}S)(\mu\text{-}SR)_2WCl_2L$ (W—W), **3** (3, 5), and $LCl_2W(\mu\text{-}SR)_3WCl_2L$ (W—W), **4** (4). The inherent stability of thiolato-bridged, metal–metal bonded confacial bioctahedral complexes of tungsten(III)/(IV) has been a prominent feature of this synthetic program, along with the apparent instability of complexes of the type $WCl_3(SR)L_2$ or any species containing terminal thiolate groups.

Recently, we have been studying the reaction between $WCl_4(Me_2S)_2$ and $SiMe_3(SPh)$. In the light of earlier work (2) we anticipated that the loss of PhCl would be unlikely and that the reductive elimination of Ph_2S_2 would probably occur. So it transpired (6), since the major product isolated was the mixed oxidation state confacial bioctahedral dimer, $(Me_2S)Cl_2W(\mu\text{-}Cl)(\mu\text{-}SPh)_2WCl_2(SMe_2)$, **5**. Since **4** is also a compound of this type, this seems to be a useful synthetic route to these relatively unusual mixed oxidation state dimers.

We have subsequently isolated and characterized a second species from the 1:1 reaction between $WCl_4(Me_2S)_2$ and $SiMe_3(SPh)$, namely, the title compound, $(Me_2S)Cl_3W(\mu\text{-}SPh)_2WCl_3(SMe_2)$, **1**. This compound contains the hitherto elusive species "$WCl_3(SR)$", but in a dimeric, thiolato-bridged edge-sharing bioctahedron rather than in a monomeric molecule containing a terminal thiolate.

Experimental

Synthesis of **1** was achieved by the reaction of $WCl_4(Me_2S)_2$ with $SiMe_3(SPh)$ as follows. A one molar equivalent of $SiMe_3(SPh)$ in dry CH_2Cl_2 was added to a stirred solution of 2.56 g (56.9 mmol) of $WCl_4(Me_2S)_2$ in ~40 mL of CH_2Cl_2 under an atmosphere of dry nitrogen. The solution color changed from orange–brown to red–brown immediately upon the addition of the $SiMe_3(SPh)$. After stirring for 20 h at room temperature a brown precipitate was filtered off, which we have recently reported as the mixed oxidation state W(III)/W(IV) dimer, $(Me_2S)Cl_2W(\mu\text{-}Cl)(\mu\text{-}SPh)_2WCl_2(SMe_2)$. Concentration of the red–brown filtrate by removal of ~10 mL of solvent *in vacuo* allowed the growth of small red crystals of $(Me_2S)Cl_3W(\mu\text{-}SPh)_2WCl_3(SMe_2)$, **1**. Yield: 13%, based on $WCl_4(Me_2S)_2$. *Anal.* calcd. for $W_2Cl_6(SPh)_2(Me_2S)_2$: C 20.8, H 2.40; found: C 20.9, H 2.38. The starting materials were obtained as previously described (5).

X-ray analysis

A needle-shaped crystal of the title complex, **1**, which had been coated with epoxy resin to minimize aerial decomposition, was mounted on an Enraf Nonius CAD4F automated diffractometer. The unit cell was identified as C-centred monoclinic using the indexing routines of the instrument. Examination of the intensities measured during the data collection confirmed this lattice assignment and systematic absences of (hkl), $h + k = 2n + 1$; $(h0l)$, $l = 2n + 1$ identified the space group as either Cc or $C2/c$. $C2/c$ was the final choice based on the centric distribution of E values and the successful solution of the structure. With four formula units per unit cell, site

symmetry 2 is imposed on the molecule. The crystal data and crystallographic experimental conditions are summarized in Table 1.

Data were collected at room temperature using an ω/2θ scan of 96 steps, of which the central 64 steps were taken as the peak, P, and the first and last 16 steps were taken as backgrounds, $B1$ and $B2$, so that $I = [P - 2(B1 + B2)]Q$, where Q was the scan rate. The standard deviation of the intensity was defined as $\sigma(I) = [P + 4(B1 + B2)]^{1/2}Q$. Lorentz and polarization corrections were applied and E values were calculated using a K-curve. After the data collection was complete, the crystal was measured for an absorption correction. Eight faces of the forms {111} and {11−1} were identified. The data were corrected for absorption effects using the Gaussian method[2] with a 16 × 10 × 10 grid. Transmission coefficients were found to vary from 0.213 to 0.439.

The coordinates of the unique W atom were located from a three-dimensional Patterson synthesis. Structure factor and difference Fourier calculations revealed the positions of the remaining unique non-hydrogen atoms. Refinement of atomic parameters was carried out by full-matrix least-squares techniques based on F, minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, where the weight w was defined as $[\sigma^2(F_o) + 0.002(F_o^2)]^{-1}$ in the final cycles. All computations were done using the XRAY 76 system of programs[3] implemented on a Honeywell computer with a Multics operating system. Scattering factors were those of Cromer and Mann (9).

The 11 unique hydrogen atoms were readily located from a difference Fourier map and were included in idealized positions (sp^2 or sp^3 hybridization at C, C—H, 0.95 and 1.00 Å, respectively), but not refined. For the final cycles, positional and anisotropic thermal parameters were refined for all non-hydrogen atoms, an isotropic extinction correction was refined, and the H atom positions were recalculated after each cycle. The model converged for 2001 reflections (observed reflections plus those for which $I_c > 3\sigma(I_o)$) and 128 variables with the agreement factors $R = \Sigma(||F_o| - |F_c||)/\Sigma|F_o| = 0.044$ and $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.058$. In the final cycle, the maximum shift/error was 0.04, the goodness of fit value was 0.85, and the isotropic extinction parameter was 2.4(9) × 10^{-4}. The highest peak in the final difference Fourier map was approximately 2.5 e Å^{-3}, and this peak was associated with the W atom. Final atomic positional parameters for the non-hydrogen atoms are presented in Table 2. Anisotropic thermal parameters, H atom parameters, and a table of observed and calculated structure amplitudes have been deposited.[4]

TABLE 2. Atomic coordinates (W, S, Cl × 10^4; C × 10^3) and U_{eq} (× 10^3) for the non-hydrogen atoms of $(Me_2S)Cl_3W(\mu\text{-}SPh)_2WCl_3(SMe_2)$; standard deviations are given in parentheses

Results and discussion

The structure of **1** is shown in Fig. 1, with only the unique atoms labelled and hydrogen atoms omitted for clarity. The packing diagram (Fig. 2) displays the molecule as viewed approximately down the metal−metal vector. It can be seen that

[2]The absorption correction was performed using the program CADABS, a local modification of ref. 7.

[3]Computing was performed at the University of Calgary using the XRAY-76 package of crystallographic programs (8).

[4]Anisotropic thermal parameters, H atom parameters, and observed and calculated structure amplitudes are available at a nominal charge from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ontario, Canada, K1A 0S2.

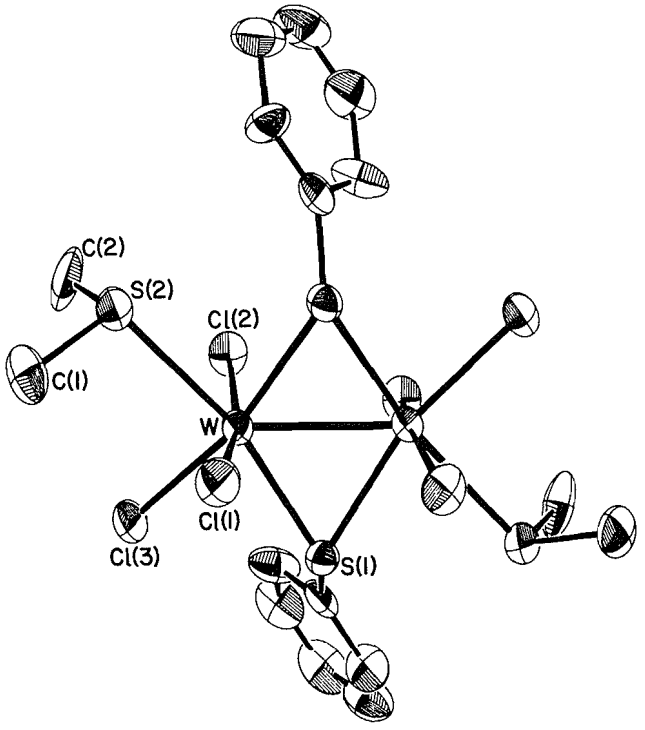

FIG. 1. ORTEP view of the structure of $(Me_2S)Cl_3W(\mu\text{-}SPh)_2WCl_3(SMe_2)$ showing the atomic numbering scheme. Thermal ellipsoids are drawn at the 50% probability level.

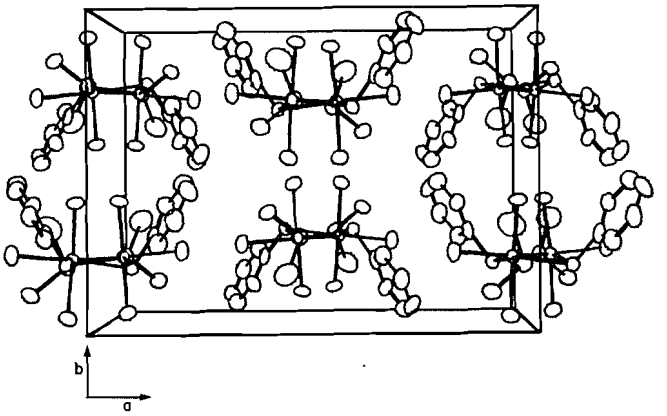

FIG. 2. Crystal packing of the compound $(Me_2S)Cl_3W(\mu\text{-}SPh)_2WCl_3(SMe_2)$.

the molecule possesses an edge-sharing bioctahedral structure, with the phenylthiolato groups occupying the bridging positions. The phenyl groups lie in *syn*–*syn* configurations. A crystallographic two-fold axis perpendicular to the mean $W—S_{br}—W—S_{br}$ plane imposes the observed symmetry on the molecule. Thus the two terminal Me_2S ligands are *trans* to one another, in the equatorial plane.

The structural data for **1** are presented in Table 3. There is strong evidence for the presence of metal–metal bonding in this diamagnetic d^2–d^2 species, in which a formal double bond could occur (**10**). A search for related structures contained in the literature reveals a surprising dearth of edge-sharing bioctahedral molecules of tungsten(IV) which contain formal metal–metal double bonds (10). Furthermore, there seems to be no precedent for such bonds to be longer than ca. 2.55 Å. The alkoxo-bridged ditungsten(IV,IV) complexes $W_2Cl_4(OR)_4(ROH)_2$ (R = Me, Et) possess W—W bond lengths of 2.481–2.483(1) Å (11), for which calculations showed the existence of a σ- and a π-bond. Similarly, in

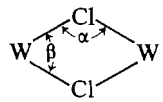
For personal use only.

comparing the complexes $W_2(\mu\text{-}S)_2(Et_2NCS_2)_2(\mu\text{-}Et_2NCS_2)_2$, (W(IV),W(IV)), and $W_2(\mu\text{-}S)_2(Et_2NCS_2)_2(CH_3O)_4$, (W(V), W(V)), bond lengths of 2.530(2) and 2.791(1) Å were concluded to be consistent with the presence of double and single bonds respectively (12). Only rarely have pairs of related structures such as these been available to justify such conclusions. Thus in the case of **1**, on the basis of bond length alone a single W—W bond might have been diagnosed. However, the nature of the bridging ligands has been shown both theoretically (13, 14) and experimentally (15) to have a profound influence on the metal–metal separation in dinuclear complexes. The terminal ligands can also play a role in this matter (14). Previous work in our laboratory has indicated some similarity in the structures of thiolato-bridged and chloro-bridged confacial bioctahedral structures. We have therefore extended the present comparison to chloro-bridged, edge-sharing bioctahedral structures of ditungsten(III), (IV), and (V), and ditantalum(III) complexes, since the latter are isoelectronic with ditungsten(IV).

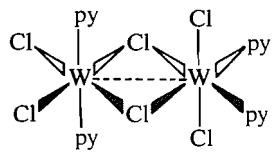
The structure of W_2Cl_{10} is a classical case of a molecule in which no metal–metal bond exists, even though the two d^1 centres are potentially capable of forming a single bond (16). The W···W separation, 3.813(1) Å, and the related distortions of the entity **I**,



I

all indicate repulsion between the metal atoms. The angles α, 98.5(1)°, have opened up from the 90° required for a pure edge-shared bioctahedron while β undergoes a contraction from 90° to 81.5(1)° (16).

Jackson and Streib (17) described the structure of $W_2Cl_6py_4$, which is shown schematically as **II**:

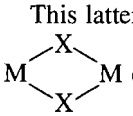


II

This ditungsten(III) complex has been interpreted as containing a single W—W bond, since the 6*d* electrons are believed to adopt a $\sigma^2\pi^2\delta^{*2}$ configuration (10, 13).

The structure **II** appears to be particularly stable for $M_2Cl_6L_4$ complexes. For example, the ditantalum(III) species, $Ta_2Cl_6(R_3P)_4$ (R = Me, Et), have been reported by Sattelberger and co-workers. The formal Ta=Ta double bond in $Ta_2Cl_6(Me_3P)_4$ is 2.721(1) Å in length, and the angles subtended at the μ-Cl atom (equivalent to α in **I**) are very acute (67.4(1)°) (18).

This latter structure is very similar to that of **1** as far as the



entity is concerned. In **1**, the formal W=W bond length (2.759(1) Å) and the W—(μ-S)—W angles (70.5(1)° ≡ α in **I**) and the (μ-S)—W—(μ-S) angles (107.4(1)° ≡ β in **I**) strongly support the existence of metal–metal bonding, rather than repulsion as in W_2Cl_{10}. Also, as can be seen in Fig. 1, the axial ligands are tipped away from the metal–metal vector. The terminal thioether ligands possess very long W—S bonds while the μ-S atoms to which they are *trans* have relatively short W—S bonds. This, of course, introduces a further distortion from the pure bioctahedral stereochemistry.

Thus the structure of **1** possesses a number of interesting features which will enhance the available data on ditungsten(IV) species.

The synthesis of Nauclea indole-pyridine alkaloids. 3,4-Disubstituted and 3,4,5-trisubstituted pyridines as synthetic intermediates; a total synthesis of (±)-decarbomethoxy-3α- and -3β-nauclechine

AZIM SHARIFF[1] AND STEWART MCLEAN

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received April 29, 1983

AZIM SHARIFF and STEWART MCLEAN. Can. J. Chem. **61**, 2813 (1983).

Synthetic routes to a number of 3,4-disubstituted and 3,4,5-trisubstituted pyridines have been explored. These pyridines, designed to be used in the synthesis of Nauclea indole-pyridine alkaloids, are potentially useful intermediates in a number of syntheses. Particular attention has been paid to more highly substituted derivatives of 4-pyridineacetic acid, and the experimental limitations associated with their synthesis and use in subsequent reactions such as the Bischler–Napieralski cyclization have been described and explained. A synthesis of decarbomethoxynauclechine from 4-methylnicotinaldehyde avoiding these difficulties was then designed and executed. Both diastereoisomers, (±)-decarbomethoxy-3α-nauclechine and (±)-decarbomethoxy-3β-nauclechine, were obtained; the structure and stereochemistry of each was rigorously established, but it was not possible to demonstrate which corresponded to the natural alkaloid, decarbomethoxynauclechine, reported previously.

AZIM SHARIFF et STEWART MCLEAN. Can. J. Chem. **61**, 2813 (1983).

On a exploré diverses voies de synthèse de pyridines disubstituées en 3,4 ou trisubstituées en 3,4,5. Ces pyridines, qui pourraient être utilisées dans la synthèse d'alcaloïdes indole-pyridine de la famille Nauclea, sont des intermédiaires qui pourraient s'avérer utiles dans plusieurs synthèses. On a fait particulièrement attention aux dérivés plus substitués de l'acide pyridineacétique-4 et aux limitations expérimentales associées avec leur synthèse; de plus, on décrit et on explique leur utilisation dans des réactions subséquentes comme les cyclisations de Bischler–Napieralski. On a proposé et réalisé une synthèse de la décarbométhoxynaucléchine à partir de la méthyl-4 nicotinaldéhyde qui évite ces difficultés. On a obtenu les deux diastéréoisomères, les (±)-décarbométhoxy-3α (et -3β) nauclechine; on a établi d'une façon rigoureuse la structure et la stéréochimie de chacun des composés mais il n'a pas été possible de démontrer lequel correspond à l'alcaloïde naturel, decarbomethoxynaucléchin, rapportée antérieurement.

As part of our program concerned with the synthesis of Nauclea alkaloids we have turned our attention to those such as nauclechine (**1***a*) (2) and decarbomethoxynauclechine (**1***b*) (3) that can, in a retrosynthetic manner, be readily dissected into a tryptamine unit and a 3,4-disubstituted or 3,4,5-trisubstituted pyridine (**2**), but have not been synthesized previously. The nature of the substituents on the precursor **2** can be specified more precisely: the nature of R obviously depends on whether the target is **1***a* or **1***b*; in principle, X could be any substituent that would allow **2** to be used in a Pictet–Spengler or Bischler–Napieralski reaction with tryptamine, but the nature of X is very much more restricted in practice by the requirement that **2** should not undergo ready decarboxylation or decarbonylation; Y is a hydroxyl group, actual or latent, and Z is a function that can be used in the formation of the C—N bond with the tryptamine unit. Our first task was the synthesis of suitable intermediates corresponding to **2**.

3,4,5-Trisubstituted pyridines

Compound **3** was an attractive sub-target for the synthesis of **2** (R = COOMe); a useful synthesis of precursor **4** has been reported (4), there is ample precedent for the carboalkoxylation of a γ-picoline, and the vinyl side chain could be used to incorporate several variations of the functionality (Y, Z) required for **2**. Consequently, **4** was prepared from 2-acetylbutyrolactone and cyanoacetamide in seven steps, and then subjected to reaction conditions normally used for carbomethoxylation. In related studies we have generally found that the most satisfactory procedure for carboalkoxylating a γ-picoline has been that described by Uskoković *et al.* (5), in which the picolyl anion is formed at low temperature (−78°C)

[1]Taken from the Ph.D. thesis of A.S. (University of Toronto, 1982). Part of this work has appeared in preliminary form (1).

For personal use only.

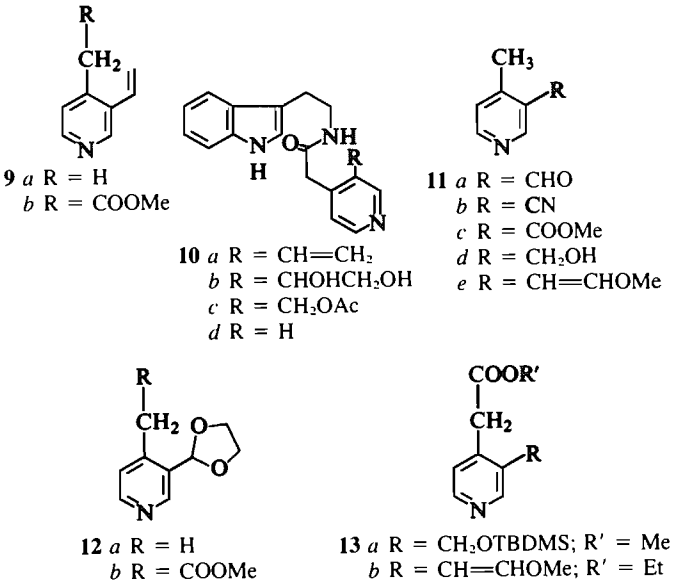
by the action of lithium diisopropylamide (LDA); the dialkyl carbonate is then introduced, and the temperature is kept low until the reaction is complete. However, **4** did not undergo carbomethoxylation by this method, and was recovered unchanged. That the picolyl anion had formed was clear from the deep color of the reaction mixture and from the demonstration that deuterium was incorporated into recovered **4** when the reaction mixture was treated with D_2O. Attempts were made to carry out the carbomethoxylation step at higher temperatures, but even at −15°C there was no significant improvement, and raising the temperature further led to intractable products, probably polymeric. In the best case, a 4% yield of **3** was isolated, and 7% of **4** was recovered. Numerous variations of the carboalkoxylation process were attempted, using other strong bases and other acylating agents (simple esters, oxalates, chloroformates, dimethylformamide, etc.), but only the method described by Wenkert *et al.* (6), using potassium *tert*-butoxide as base and dimethyl oxalate as acylating agent, gave a satisfactory yield of product. The product isolated (in 72% yield) was the lactone **5**, the analog of Wenkert's product; very similar results have been reported by Kametani *et al.* (4). However, the vinyl side chain made **5** unsuitable for conversion to **3** by a continuation of Wenkert's procedure, which required hydrolysis and peroxide-induced decarbonylation of the intermediate.

The reluctance of the picolyl anion derived from **4** to undergo acylation can be attributed to the additional stabilizing effect of the carbomethoxyl group, resulting from charge delocalization and from chelation, especially when the counter ion is lithium. In order to mask the carbomethoxyl group, **4** was reduced to the alcohol **6***a* by lithium aluminum hydride; the reaction was clean and the yield was high (93%). The alcohol was protected as its *tert*-butyldimethylsilyl (TBDMS) ether (**6***b*), which now underwent carbomethoxylation by the Uskoković procedure without difficulty, and the ester **7** was isolated in 68% yield.

In a brief investigation of selective oxidations of the vinyl group of **7**, it was found that, although dihydroxylation could not be effected using catalytic osmium tetraoxide systems, osmylation was successful when stoichiometric amounts of the reagent were used, and the lactonized product **8** was isolated in 47% yield after treatment of the osmylated intermediate with aqueous sodium bisulfite. This product comes close to meeting the requirements specified for the intermediate **2** in the proposed synthesis of **1***a*. However, a considerable amount of exploration of the remaining steps of the proposed route was still needed, and the preparation of the intermediate **8** had already involved a lengthy sequence of reactions. Consequently, we decided to investigate first the remainder of the route with a simpler intermediate, **2** (R = H), the precursor of **1***b*.

3,4-Disubstituted pyridines

Two known 3,4-disubstituted pyridines appeared to be especially promising starting materials, and the conversion of each to useful synthetic intermediates was investigated. The first, 4-methyl-3-vinylpyridine (**9***a*), the analog of **4**, was prepared by established procedures (4, 7) and converted to the ester **9***b* in 57% yield by Uskoković's carbomethoxylation procedure (5). The reaction of **9***b* with tryptamine provided the amide **10***a* in 77% yield. Dihydroxylation of **10***a* produced the glycol **10***b* in 50% yield; as was the case with **7**, the method employing a stoichiometric amount of osmium tetraoxide had to be used for this conversion. This intermediate satisfied the criteria defined for **2** (R = H).



The aldehyde **11***a* is another known 3,4-disubstituted pyridine that is an attractive starting material for the projected synthesis. We prepared **11***a* by the method of Bobbitt and Scola (8) with a few minor modifications: the conversion of the nitrile intermediate **11***b* to the ester **11***c* was carried out in 84% yield by the action of methanolic sulfuric acid (9), and the alcohol **11***d*, obtained on reduction of **11***c*, was cleanly and efficiently oxidized to the aldehyde **11***a* (85% yield) by activated manganese dioxide at room temperature (10). The aldehyde was then protected as its acetal **12***a*, a conversion that Bobbitt and Scola (8) had been unable to take to completion; we found that when **11***a* was treated with ethylene glycol and *p*-toluenesulfonic acid in refluxing benzene for 48 hours, no aldehyde remained, and **12***a* was isolated in 65% yield. Carbomethoxylation of **12***a* by the Uskoković procedure provided **12***b* in a very disappointing yield (19%); the poor yield in this case appears to be caused by degradation of the product during isolation and purification. The attractiveness of this route was further diminished when we discovered that we could not regenerate the aldehyde function from **12***b* by the usual acid-catalyzed hydrolysis, and more vigorous conditions caused the ester to undergo hydrolysis and decarboxylation. The resistance of this acetal to hydrolysis is attributed to the difficulty of cleaving a carbon–oxygen bond after O-protonation since this would lead to the development of positive charge at the picolyl position of a pryidine that is also N-protonated. The difficulty observed in preparing the acetal **12***a* from the aldehyde **11***a* provides support for this explanation.

Under these circumstances we decided to explore an approach which retained the C-3 substituent at the oxidation level of an alcohol, leaving the oxidation and further elaboration of the side chain to a later stage in the synthesis, and carry out the carbomethoxylation on **11***d* after it had been protected as its TBDMS ether. This sequence worked well, and the carbomethoxylation step, using the Uskoković procedure, provided ester **13***a* in 48% yield. Deprotection of the alcohol, either by acid or by tetrabutylammonium fluoride, led to lactonization. Consequently, **13***a* was converted to an amide by reaction with tryptamine in methanol containing sodium methoxide; the silyl

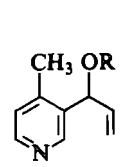
ether was cleaved in this process, so the crude product was treated with acetic anhydride and isolated as the acetate **10***c* in 73% yield from **13***a*.

The most serious defect in compound **13***a* with respect to the criteria defined for a key intermediate of form **2** (R = H) is that it carries a one-carbon substituent in place of the bifunctional two-carbon substituent required. The aldehyde **11***a* remained the most promising intermediate for development of all of the required functionality. Its homologation through the Wittig product **11***e* appeared to offer a useful route that also had the advantages that carboalkoxylation of **11***e* should take place without difficulty and procedures for converting the methoxyvinyl substituent of **11***e* to the required bifunctional side chain are easily recognized. In practice, the Wittig reaction converted **11***a* to **11***e* (88% yield of a 3:2 mixture of *E* and *Z* isomers) and carboethoxylation converted **11***e* to **13***b* (62% yield) without difficulty. Unfortunately, attempts to oxidize **13***b* with osmium tetraoxide failed to give recognizable products, and simple acidic hydrolysis led to a product that was extremely unstable; the ^{1}Hmr spectrum of freshly isolated product showed signals corresponding to the required aldehyde, but the spectrum rapidly became more complex. It appeared, therefore, that this type of aldehyde is inherently unstable.

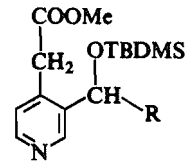
We turned, therefore, to a strategy that converted **11***a* to a derivative having, in effect, a masked α-hydroxy aldehyde as the C-3 substituent. The aldehyde **11***a* was converted by treatment with vinylmagnesium bromide to the allyl alcohol **14***a*, which was then protected as its TBDMS ether, **14***b* (54% yield from **11***a*). Carbomethoxylation of **14***b* by the Uskoković procedure provided the ester **15***a* in 64% yield. The vinyl substituent served as a masked aldehyde which could be revealed by ozonolysis; treatment of a solution of **15***a* in a dichloromethane–methanol mixture with ozone at −40°C and then dimethyl sulfuide (11) generated **15***b* which, although unstable, showed the expected signals in the ^{1}Hmr spectrum, of which the doublet, J = 2 Hz, at δ 9.53 was the most significant. This aldehyde was normally not isolated; instead the reaction mixture, after treatment with dimethyl sulfide, was washed with brine and dried with anhydrous sodium sulfate; tryptamine was added to couple with the aldehyde and the product was subsequently reduced with sodium borohydride. By this sequence, **15***a* was converted to the amino ester **16** in 50% yield. Conversion of **16** to the lactam **17** was carried out by heating **16** for 20 hours in refluxing methanol containing anhydrous potassium carbonate; the yield was disappointing (40%), but the alternative methods tried either failed to cause lactamization or else led to a considerable amount of degradation.

Decarbomethoxynauclechine

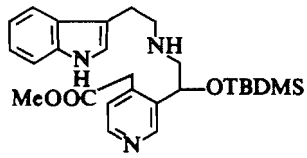
Among the intermediates we have described are tryptamides (**10***a*–*c*) that appeared to provide access through a Bischler–Napieralski cyclization to the corresponding dihydro-β-carbolines. We have previously used this process to cyclize tryptamides derived from pyridinecarboxylic acids (12) and a 3-pyridineacetic acid (13), but we found, in accord with earlier reports, that yields are variable and it is critically important to find the optimal reaction conditions in order to obtain acceptable yields. However, with tryptamides of general formula **10** no such conditions could be found; the simplest member of the series, **10***d*, was prepared for model studies, but no reaction conditions were found that gave more than an unacceptably low yield of a dihydro-β-carboline. We are led,



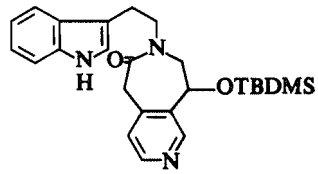
14 *a* R = H
b R = TBDMS



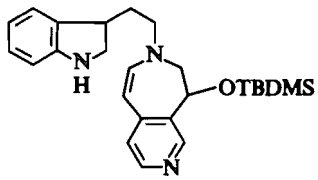
15 *a* R = CH=CH$_2$
b R = CHO



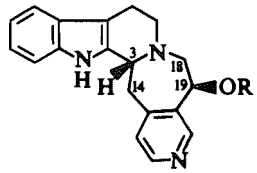
16



17



18



19 *a* R = TBDMS
b R = H
c R = Ac

consequently, to the conclusion that tryptamides **10** are inherently unsuitable for Bischler–Napieralski cyclization, and we feel that an explanation can be found by recognizing that a 4-picolyl unit, especially when N-protonated, can act as a good leaving group (as in the facile decarboxylation of 4-pyridineacetic acid). The detailed mechanism of the Bischler–Napieralski reaction continues to be a subject of discussion (14), but it is clear that at an early stage the tryptamide is converted into an intermediate that normally undergoes an elimination to form an iminium species, and we suggest that it is at this stage that the intermediate derived from **10** can eliminate a 4-picolyl unit, leading to a destructive fragmentation in competition with the desired reaction. In the case of the 3-pyridineacetic acid derivative previously cited (13), we obtained the dihydro-β-carboline in 38% yield, and we note the analogy that 3-pyridineacetic acid undergoes decarboxylation much less readily than 4-pyridineacetic acid.

Under these circumstances it was deemed unwise to subject our most advanced intermediate, the tryptamide **17**, to Bischler–Napieralski conditions. However, as a tertiary amide, **17** appears ideally suited to the procedure described by Takano *et al.* (15) which transforms the cyclization into a Pictet–Spengler process. We reduced **17** by the action of excess diisobutylaluminum hydride at −78°C; the best results were obtained with four equivalents of the hydride, but even then nearly half of the starting material (**17**) was recovered and could be recycled. It appears that, in a competitive reaction, a proton is removed from the unusually acidic 4-picolyl site, preventing reduction but allowing **17** to be recovered on work-up. The reduction product, obtained in 84% yield based on unrecovered **17**, was shown to be the enamine **18**; the material could not be completely characterized because of its instability, but it provided a ^{1}Hmr spectrum completely in accord with the assigned structure, the one-proton doublets, J = 10 Hz, at δ 6.23 and 4.88 assigned to vinyl protons being of special significance since they show that the reduction product in this case is

an enamine rather than a hemiaminal (15). Since we had previously found 90% formic acid to be a particularly effective reagent in a Pictet–Spengler cyclization (16), a solution of **18** in 90% formic acid was stirred overnight at room temperature. A mixture of two main components was obtained, and the major product, shown subsequently to be **19***a*, was isolated in 63% yield by chromatography; the second component could not be obtained free from a contaminant by this procedure, but its spectroscopic characteristics indicated it to be a diastereoisomer of **19***a*. The TBDMS group of **19***a* proved to be unusually resistant to acidic hydrolysis and the best experimental procedure for isolating the deprotected materials was to treat the mixture of cyclized products obtained from the Pictet–Spengler reaction with tetrabutylammonium fluoride in tetrahydrofuran at room temperature. Chromatography then provided both diastereoisomers, **19***b* and **1***b*, in pure form in a ratio of about 3:1 (yield > 95%). When the Pictet–Spengler cyclization was carried out by treating **18** with methanolic hydrogen chloride at room temperature overnight, a mixture of cyclized products was again obtained; in this case most of the product had been desilylated, but some retained the TBDMS substituent. On work-up, both **19***b* and **1***b* were obtained (65% yield), but in this case, **1***b* was the dominant isomer by a factor of 5:1. Both isomers were obtained crystalline, both darkened on standing in air, and neither was appreciably soluble in chloroform; each formed a chloroform-soluble acetate, but neither acetate was obtained crystalline.

The diastereoisomers **1***b* and **19***b* showed, predictably, very similar spectroscopic characteristics, as did their acetates **1***c* and **19***c*. Only the 400 MHz ^{1}Hmr spectra of **1***c* and **19***c* showed significant differences (see Table 1), and these were essentially confined to the characteristics associated with protons on the seven-membered ring; even here the chemical shifts of the protons at C-3 and C-14 showed only small differences between the two compounds and the coupling constants $J_{3,14a} = 10$, $J_{3,14b} = 0$, $J_{14a,14b} = 15$ Hz were the same in both compounds, indicating that the conformational relationships on this side of the ring are the same in both isomers. Only the protons on the other side of the ring led to distinctive differences in the spectra; in **1***c*, the chemical shifts of the protons designated H-19, H-18a, and H-18b were δ 5.91, 3.55, and 3.17 respectively, and the coupling constants were $J_{18a,19} = 6$, $J_{18b,19} = 2$, and $J_{18a,18b} = 14$ Hz, while the corresponding values for the protons of **19***c* were δ 6.34, 3.33, and 3.12 and 1.5, 9, and 13 Hz. These differences are clearly of stereochemical origin, but we could not use them with confidence to make configurational assignments to the flexible seven-membered rings incorporating a pyramidal nitrogen atom and two sp^2 carbon atoms. Consequently, the structure and stereochemistry of the synthetic alcohols **1***b* and **19***b* were determined to be as shown

by single-crystal X-ray crystal structure analysis;[2] the configurational assignments for all of the cyclized products obtained from **18** were made on the basis of their chemical relationship to **1***b* and **19***b*.

The synthesis has thus provided both diastereoisomers, **1***b* and **19***b*. Why the Pictet–Spengler cyclization of **18** by the action of methanolic hydrogen chloride gave **1***b* as the dominant isomer while formic acid led to the other isomer remains an intriguing question. It is tempting to suggest that it is the nature of the substituent at C-19 that governs the stereochemistry of the process: in formic acid the silyl ether survives the reaction and the substituent is undoubtedly OTBDMS while the C-3 stereochemistry is being established, while it is possible that the substituent has already become OH by this stage in methanolic hydrogen chloride. However, the chronology of the latter process is by no means certain, and further study is required to establish it; we note that some silyl ether survives the conditions used, and the silyl ether in **19***a* is unusually difficult to hydrolyze in acid, but we have no direct information concerning its ease of hydrolysis in the precursor **18**.

Even with both **1***b* and **19***b* in hand in racemic form we were unable to complete the task of establishing which corresponded to the *Nauclea latifolia* alkaloid described by Pousset and coworkers (3). Only a very small quantity (1 mg) of the natural alkaloid was isolated, and very few physical data were determined. Crystals, mp 222°C, were obtained from ethyl acetate; the alkaloid can be expected to be optically active, but this was not established. When recrystallized from ethyl acetate, synthetic **1***b* formed crystals, mp 218–221°C (prior phase change at 213°C), and **19***b* formed crystals mp 219–220°C (dec.). Only the mass spectrum of the natural alkaloid was available for spectroscopic comparison. The mass spectra of **1***b* and **19***b*, obtained on our spectrometer, were virtually identical; the mass spectrum of the natural material, obtained previously on a different spectrometer and kindly provided by Professor Pousset, resembled our spectra, the main points of difference being in the relative intensities of the strongest peaks. Consequently, it is not possible to identify either of the synthetic products as the racemic form of a natural alkaloid. In order to avoid possible confusion in the future, and because of the obvious analogy with the dihydrocadambines (13, 16, 17), we shall refer to **1***b* as decarbomethoxy-3α-nauclechine and to **19***b* as decarbomethoxy-3β-nauclechine, anticipating that both may eventually be isolated from natural sources.

Experimental

Melting points were determined on a calibrated Thomas–Kofler micro hot stage. Infrared spectra were measured on a Perkin–Elmer 137 spectrometer; the wavelengths (μ) of selected absorptions of solutions in chloroform are reported. Unless otherwise indicated, ^{1}Hmr spectra of solutions in $CDCl_3$ were recorded at 60 MHz on a Varian T-60 spectrometer, and chemical shifts (δ scale) are reported followed in parentheses with a description of the multiplicity (initial letter), coupling constants, if measurable, and number of protons associated with the signal; a Bruker WH-400 spectrometer was used for spectra at 400 MHz. Mass spectra were measured at 70 eV on a Bell and Howell CEC 21-490 mass spectrometer, and *m/z* values for significant ions are reported followed in parentheses by the relative peak height; exact mass measurements were made on an AEI MS 902 mass spectrometer.

[2] The X-ray analyses were carried out by Dr. Jeffery F. Sawyer of this Department, whom we thank. A detailed account of this work will be published.

*3-Hydroxymethyl-4-methyl-5-vinylpyridine (**6**a) and its derivatives*

A solution of 3-carbomethoxy-4-methyl-5-vinylpyridine (4) (9.30 g; 52.5 mmol) in 250 mL of dry ether was added over 50 min to a stirred suspension of lithium aluminum hydride (2.40 g; 63.2 mmol) in 100 mL of ether under nitrogen, and stirring was continued for a further 30 min. After the reaction mixture had been treated with sodium sulfate decahydrate and worked up, the alcohol **6***a* was isolated as an oil (7.30 g; 50.0 mmol); recrystallization from ether provided white crystals, mp 50–51°C; ir: 2.78, 6.20, 6.30; ^{1}Hmr: 8.33 (s, 1), 8.20 (s, 1), 6.81 (dd, *J* = 11, 17; 1), 5.56 (dd, *J* = 2, 17; 1), 5.36 (dd, *J* = 2, 11; 1), 4.92 (s, 1, D_2O removed), 4.67 (s, 2), 2.33 (s, 3); ms: 149 (100), 131 (53), 130 (49), 120 (57). *Anal.* calcd. for $C_9H_{11}NO$: C 72.45, H 7.43, N 9.39; found: C 72.13, H 7.48, N 9.40.

The tert*-butyldimethylsilyl ether **6***b* was prepared by treating a solution of **6***a* (6.74 g; 45.2 mmol) in 35 mL of dry dimethylformamide under nitrogen with imidazole (8.1 g; 120 mmol) and *tert*-butyldimethylsilyl chloride (8.9 g; 60 mmol). The reaction mixture was stirred for 18 h at room temperature, the solvent was removed under reduced pressure, and the residue was treated with 100 mL of water and extracted with chloroform. The extract afforded a dark oil that was distilled under vacuum, and **6***b* was obtained as a clear liquid (8.88 g; 33.8 mmol), bp 84–86°C (0.01 Torr); ir: 6.10, 6.30; ^{1}Hmr: 8.48 (s, 1), 8.38 (s, 1), 6.87 (dd, *J* = 11, 17; 1), 5.61 (dd, *J* = 2, 17; 1), 5.36 (dd, *J* = 2, 11;1), 4.71 (s, 2), 2.28 (s, 3), 0.98 (s, 9), 0.10 (s, 6); ms: 264 (3), 206 (100), 176 (26), 132 (35). *Anal.* calcd. for $C_{15}H_{25}NOSi$: C 68.39, H 9.56, N 5.32; found: C 68.71, H 9.52, N 5.73.

Carbomethoxylation product 7

A solution of **6***b* (8.0 g; 30.4 mmol) in 80 mL of dry tetrahydrofuran was added dropwise over 20 min to a stirred solution in 80 mL of tetrahydrofuran, under nitrogen and cooled in an acetone – Dry Ice bath, of lithium diisopropylamide prepared from butyllithium (90 mmol in hexane) and diisopropylamine (110 mmol). The red solution was stirred for 15 min further, and dimethyl carbonate (110 mmol) in 30 mL of tetrahydrofuran was added over 10 min. The solution was stirred at −78°C for 30 min, and then the cooling bath was removed. When the reaction mixture had reached room temperature, it was treated with 50 mL of saturated aqueous sodium bicarbonate; the aqueous layer was separated and extracted with dichloromethane, and the extract was combined with the organic layer. The organic solvents were removed by evaporation and the dark oil that remained was chromatographed (silica gel; 2:8 ethyl acetate – hexane); a small amount of **6***b* (0.67 g; 2.5 mmol) was recovered unchanged, and **7** (6.11 g; 19.0 mmol) was isolated as an oil, bp 90–95°C (0.005 Torr); ir: 5.77, 6.14, 6.31; ^{1}Hmr: 8.55 (s, 1), 8.41 (s, 1), 6.85 (dd, *J* = 11, 17; 1), 5.62 (dd, *J* = 2, 17;1), 5.41 (dd, *J* = 2, 11; 1), 4.73 (s, 2), 3.83 (s, 2), 3.67 (s, 3), 0.93 (s, 9), 0.10 (s, 6); ms: 265 (57), 264 (100), 232 (21), 131 (45), 130 (77), 103 (35). *Anal.* calcd. for $C_{17}H_{27}NO_3Si$: C 63.51, H 8.47, N 4.36; found: C 63.17, H 8.52, N 4.44.

Dihydroxylation product 8

A solution of **7** (1.26 g; 3.9 mmol) and osmium tetraoxide (1.0 g; 3.9 mmol) in 15 mL of distilled pyridine was stirred at room temperature for 3 h. A solution of sodium bisulfite (1.8 g) in 30 mL of water and 20 mL of pyridine was added and stirring was continued overnight. Extraction with dichloromethane provided the product which was purified by chromatography (silica gel; 9:1 ethyl acetate – hexane) and isolated as a white amorphous solid (0.61 g; 1.9 mmol); ir: 2.77, 5.73, 6.29; ^{1}Hmr: 8.55 (s, 1), 8.38 (s, 1), 5.50 (m, 1), 4.72 (s, 2), 4.10 (m, 2), 3.81 (s, 2), 2.93 (broad, 1, D_2O removed), 0.93 (s, 9), 0.10 (s, 6); ms: 266 (64), 146 (80), 108 (57), 75 (100), 73 (33). *Exact Mass* calcd. for $C_{12}H_{16}NO_4Si$ (M − *t*-Bu): 266.0848; found: 266.0852.

*4-Methoxycarbonylmethyl-3-vinylpyridine (**9**b) and its derivatives*

4-Methyl-3-vinylpyridine (**9***a*) was prepared by the method of Stevens *et al.* (7), except that Kametani's procedure (4) was used in the final step to effect quantitative dehydrochlorination. A solution of **9***a* (5.80 g; 48.7 mmol) was carbomethoxylated by the Uskoković pro-

For personal use only.

cedure (5) described above for **7**. When the reaction mixture had reached room temperature, 80 mL of benzene and 80 mL of saturated aqueous sodium sulfate were added and, after a short period, excess anhydrous sodium sulfate was added. After filtration, the solvent was removed by distillation, the residue was dissolved in benzene, and the solution was extracted with 5% hydrochloric acid. The acidic solution was made basic with aqueous ammonia and extracted with dichloromethane. This extract afforded the product, which was purified by Kugelrohr distillation at 70°C (0.01 Torr), and **9***b* (4.90 g; 27.6 mmol) was isolated as a clear oil; ir: 5.75, 6.13, 6.27; ^{1}Hmr: 8.60 (s, 1), 8.38 (d, J = 5; 1), 7.09 (d, J = 5; 1), 6.83 (dd, J = 11, 17; 1), 5.66 (dd, J = 2, 17; 1), 5.40 (dd, J = 2, 11; 1), 3.71 (s, 5); ms: 177 (85), 162 (22), 120 (23), 119 (37), 118 (89), 117 (100), 91 (43), 85 (42), 83 (69), 65 (24), 59 (29), 51 (21) *Exact Mass* calcd. for $C_{10}H_{11}NO_2$: 177.0790; found: 177.0794; also characterized as its dihydro derivative (catalytic hydrogenation) described previously by Uskoković (5): ir and ^{1}Hmr data identical, hydrochloride mp 163–164°C (lit. (5) mp 167–168°C).

The tryptamide **10***a* was prepared by refluxing a solution of **9***b* (5.00 g; 28.2 mmol), tryptamine (4.55 g; 28.4 mmol), and sodium methoxide (30 mmol) in 100 mL of dry methanol under argon for 17 h. The solution was cooled, 100 mL of water and 100 mL of brine were added sequentially, and the mixture was extracted with dichloromethane. The material (7.85 g) obtained from the extract was purified by flash chromatography (18) (93:7 chloroform–methanol) to provide **10***a* (6.59 g; 21.61 mmol) as an amorphous solid; ir: 2.91, 5.98, 6.28; ^{1}Hmr: 8.53 (s, 1), 8.5 (broad, 1, D_2O removed), 8.28 (d, J = 5; 1), 7.55–6.67 (complex, 7), 5.6 (broad, 1, D_2O removed), 5.52 (dd, J = 2, 17; 1), 5.29 (dd, J = 2, 11; 1), 3.52 (s, 2), 3.52 (m, 2), 2.88 (m, 2); ms: 305 (10), 143 (100), 130 (53). *Exact Mass* calcd. for $C_{19}H_{19}N_3O$: 305.1528; found 305.1518.

Dihydroxylation product **10***b* was prepared by treatment of **10***a* (487 mg; 1.60 mmol) with osmium tetraoxide (411 mg; 1.62 mmol) in 6 mL of pyridine in the manner described for **8** above. The product (385 mg) was purified by flash chromatography (18) (8:2 dichloromethane–methanol) and **10***b* (272 mg; 0.80 mmol) was isolated as a white amorphous solid, insoluble in chloroform. This material was treated with acetic anhydride in pyridine to obtain its diacetate as an amorphous solid; ir: 2.84, 5.73, 5.96, 6.24; ^{1}Hmr: 8.55 (s, 1), 8.39 (d, J = 5, 1), 8.1 (broad, 1, D_2O removed), 7.57–6.80 (complex, 6), 6.12 (m, J = 6; 1) 6.1 (broad, 1, D_2O removed), 4.15 (d, J = 5; 2), 3.60 (s, 2), 3.55 (m, 2), 2.95 (m, 2), 2.03 (s, 3), 2.00 (s, 3); ms: 423 (5), 281 (15), 144 (18), 143 (100), 130 (44). *Exact Mass* calcd. for $C_{23}H_{25}N_3O_5$; 423.1794; found: 423.1796.

*4-Methylnicotinaldehyde (**11**a) and its derivatives*

The preparation of **11***a* followed the procedures described by Bobbitt and Scola (8) with the following modifications. The nitrile **11***b* was heated to 130°C with 75% sulfuric acid (20 mL/g of **11***b*) under nitrogen for 20 h; the mixture was allowed to cool, methanol (40 mL) was added, and the solution was heated to reflux for 4 h. The ester **11***c* (84%) was isolated by standard procedures (9). Reduction of **11***c* by lithium aluminum hydride (8) provided the alcohol **11***d* nearly quantitatively. The alcohol was stirred with freshly activated manganese dioxide (10) (6.7 g/g of **11***d*) in dichloromethane (100 mL) under argon for 24 h. After filtration, evaporation of the solvent, and distillation under reduced pressure, **11***a* (8) was isolated as a clear liquid (85% yield). The acetal (**12***a*) was prepared in 65% yield by the method described previously (8), except that reflux in benzene was continued for 48 h.

*3-(β-Methoxyvinyl)-4-methylpyridine (**11**e)*

A solution of **11***a* (300 mg; 3.3 mmol) in 4 mL of dry dimethyl sulfoxide was added over 2 min to the Wittig reagent prepared (19) from (methoxymethyl)triphenylphosphonium chloride (2.82 g; 8.2 mmol) in 10 mL of dimethyl sulfoxide and sodium hydride (8.4 mmol) in 4 mL of dimethyl sulfoxide under nitrogen. The reaction mixture was stirred at room temperature for 14 h, treated with excess saturated aqueous sodium bicarbonate, and extracted with ether. The extract afforded a solid which was subjected to Kugelrohr distillation at 95°C (0.005 Torr) and **11***e* (433 mg; 2.91 mmol) was obtained as an oily mixture of stereoisomers; ir: 6.1, 6.27; ^{1}Hmr (combined areas for E and Z isomers shown as 1H, etc.): 8.97 (s) and 8.40 (s) (1H), 8.23 (d, J = 5) and 8.19 (d, J = 5) (1H), 7.00 (d, J = 5; 1H), 6.85 (d, J = 13) and 6.22 (d, J = 7) (1H), 5.75 (d, J = 13) and 5.22 (d, J = 7) (1H), 3.75 (s) and 3.72 (s) (3H), 2.27 (s, 3H); ms: 149 (100), 134 (40), 117 (22), 106 (33), 77 (20). *Exact Mass* calcd. for $C_9H_{11}NO$: 149.0841; found 149.0824.

*Carbomethoxylation product **12**b*

The procedure described above for the carbomethoxylation of **9***a* was employed, using acetal **12***a* (1.0 g; 6.2 mmol) in 5 mL of tetrahydrofuran, lithium diisopropylamide (13 mmol) in 10 mL of tetrahydrofuran, and dimethyl carbonate (15 mmol) in 5 mL of tetrahydrofuran, with the modification that stirring at −78°C was continued for 2 h. The oily product (930 mg) was purified by bulb-to-bulb distillation at 130°C (0.05 Torr), and **12***b* (266 mg; 1.2 mmol) was isolated as a yellow oil; ir: 5.76, 6.25; ^{1}Hmr: 8.70 (s, 1), 8.57 (d, J = 5; 1), 7.20 (d, J = 5; 1), 5.93 (s, 1), 4.08 (broad, 4), 3.82 (s, 2), 3.70 (s, 3); ms: 223 (1), 222 (5), 150 (100), 120 (22), 92 (20), 73 (49). *Exact Mass* calcd. for $C_{11}H_{13}NO_4$: 223.0845; found: 223.0855.

*Carbomethoxylation product **13**a*

The alcohol **11***d* (6.10 g; 49.2 mmol) in 30 mL of dry dimethylformamide at 35°C under nitrogen was treated with imidazole (8.8 g; 130 mmol) and *tert*-butyldimethylsilyl chloride (9.4 g; 62 mmol) and the mixture was stirred for 1.5 h. Volatile materials were removed under vacuum at room temperature, the oily residue was treated with 200 mL of water and thoroughly extracted with ether. The extract afforded the TBDMS ether of **11***d* which was distilled and obtained as a colorless oil (10.5 g; 44.2 mmol), bp 84–85°C (0.05 Torr); ir: 6.23; ^{1}Hmr: 8.47 (s, 1), 8.33 (d, J = 5; 1), 6.99 (d, J = 5; 1), 4.70 (s, 2), 2.28 (s, 3), 0.93 (s, 9), 0.10 (s, 6); ms: 180 (100), 150 (26), 106 (52), 75 (22). *Anal.* calcd. for $C_{13}H_{23}NOSi$: C 65.77, H 9.76, N 5.90; found: C 65.71, H 9.66, N 5.64.

The TBDMS ether (8.0 g; 33.8 mmol) in 80 mL of dry tetrahydrofuran was added to lithium diisopropylamide (72 mmol) and treated with dimethyl carbonate (95 mmol) in the manner described above for **7**; in the work-up, 100 mL of saturated aqueous ammonium chloride was used (in place of sodium bicarbonate). The oily product was chromatographed (silica gel; 4:5 ethyl acetate – hexane) to provide **13***a* (4.80 g; 16.3 mmol), bp 95°C (0.005 Torr); ir: 5.76, 6.25; ^{1}Hmr: 8.52 (s, 1), 8.41 (d, J = 5; 1), 7.11 (d, J = 5; 1), 4.73 (s, 2), 3.72 (s, 2), 3.67 (s, 3), 0.92 (s, 9), 0.08 (s, 6); ms: 239 (100), 207 (20), 132 (75), 104 (45), 89 (44). *Anal.* calcd. for $C_{15}H_{25}NO_3Si$: C 60.97, H 8.52, N 4.74; found: C 61.18, H 8.93, N 4.89.

*The carboethoxylation product **13**b*

The mixture of stereoisomers **11***e* (355 mg; 2.38 mmol) was treated with lithium diisopropylamide (5.6 mmol) and diethyl carbonate (5.9 mmol) by the procedure described above for **7**. The crude product was dissolved in benzene and extracted with cold 10% hydrochloric acid; the acidic extract was made basic with ammonia and extracted with dichloromethane. This extract afforded **13***b* which was obtained as an oily mixture of stereoisomers (329 mg; 1.49 mmol) after Kugelrohr distillation at 110°C (0.025 Torr); ir: 5.77, 6.10, 6.29; ^{1}Hmr (combined areas for E and Z isomers shown as 1H, etc.): 8.97 (s) and 8.48 (s) (1H), 8.34 (d, J = 5) and 8.29 (d, J = 5) (1H), 7.09 (d, J = 5; 1H), 6.88 (d, J = 13) and 6.24 (d, J = 7) (1H), 5.80 (d, J = 13) and 5.24 (d, J = 7) (1H), 4.16 (q, J = 7; 2H), 3.76 (s) and 3.73 (s) (3H), 3.47 (s, 2H), 1.23 (t, J = 7, 3H); ms: 221 (100), 176 (22), 148 (26), 133 (53), 132 (22), 118 (27), 117 (63), 105 (24), 104 (20). *Exact Mass* calcd. for $C_{12}H_{15}NO_3$: 221.1052; found: 221.1050.

The tryptamide **10***c* was prepared by refluxing a solution of the ester **13***a* (3.50 g; 11.8 mmol), tryptamine (2.0 g; 12.5 mmol), and sodium methoxide (12.4 mmol) in 50 mL of dry methanol under nitrogen for 13 h. The methanol was removed under reduced pressure, and the residual oil was treated with brine and extracted with chloroform. The extract afforded a product (3.27 g) that was acetylated with acetic anhydride in pyridine. The crude product was purified by chromatography (silica gel; 9:1 chloroform–methanol) and **10***c* (3.04 g;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

8.7 mmol) was isolated as a pale yellow amorphous solid; ir: 5.74, 5.99, 6.24; ^{1}Hmr: 8.88 (broad, 1, D_2O removed), 8.42 (broad, 2), 7.56–6.73 (complex, 6), 6.13 (m, 1, D_2O removed), 5.03 (s, 2), 3.55 (m, 2), 3.50 (s, 2), 2.90 (m, 2), 1.93 (s, 3); ms: 351 (7), 143 (100), 130 (98). *Exact Mass* calcd. for $C_{20}H_{21}N_3O_3$: 351.1583; found: 351.1584.

*3-(3-Hydroxy-3-propenyl)-4-methylpyridine (**14**a) and its derivatives*

A solution of the aldehyde **11***a* (1.22 g; 10.0 mmol) in 5 mL of dry tetrahydrofuran was added over 20 min to a solution of vinylmagnesium bromide (12 mmol) in 6 mL of tetrahydrofuran (20), and the mixture was refluxed for 30 min. The mixture was cooled, treated with 2 mL of saturated aqueous ammonium chloride, and worked up by standard procedures. The product was isolated as a viscous oil (1.10 g; 7.4 mmol); a sample of **14***a* was purified by molecular distillation at 80°C (0.005 Torr) and isolated as a clear colorless oil; ir: 2.85, 6.10, 6.23; ^{1}Hmr: 8.47 (s, 1), 8.22 (d, J = 5; 1), 7.00 (d, J = 5; 1), 6.0 (m, 1), 5.4–5.1 (complex, 3), 4.35 (broad, 1, D_2O removed), 2.33 (s, 3); ms: 149 (28), 148 (37), 132 (21), 131 (70), 130 (28), 122 (40), 120 (100), 106 (20), 94 (51), 93 (40), 92 (60), 65 (30). *Exact Mass* calcd. for $C_9H_{11}NO$: 149.0841; found: 149.0853.

Undistilled **14***a* (2.95 g; 19.8 mmol) in 12 mL of dry dimethylformamide under argon was treated with imidazole (3.24 g; 47.6 mmol) and *tert*-butyldimethylsilyl chloride (3.58 g; 23.8 mmol), and the mixture was stirred for 15 h at room temperature. Volatile materials were removed under vacuum at room temperature, the residue was treated with 100 mL of water, and extracted with ether. The extract afforded **14***b* as an oil (4.64 g), which was purified by Kugelrohr distillation at 100°C (0.005 Torr) and obtained as a clear colorless liquid (3.28 g; 14.5 mmol); ir: 6.23; ^{1}Hmr: 8.53 (s, 1), 8.32 (d, J = 5; 1), 6.97 (d, J = 5; 1), 6.0 (m, 1), 5.4–5.0 (complex, 3), 2.33 (s, 3), 0.95 (s, 9), 0.10 (s, 3), 0.03 (s, 3); ms: 263 (1), 206 (100), 132 (71), 75 (35). *Exact Mass* calcd. for $C_{11}H_{16}NOSi$ (M − *t*-Bu): 206.1001; found: 206.1002.

The carbomethoxylation product **15***a* was prepared from **14***b* (3.5 g, 13.3 mmol) by the procedure used to prepare **13***a*. The product was purified by chromatography (silica gel; 7:3 hexane – ethyl acetate) and **15***a* was obtained as a pale yellow oil (2.71 g; 8.4 mmol); a sample, purified by molecular distillation at 90°C (0.005 Torr), was obtained as a colorless oil; ir: 5.75, 6.24; ^{1}Hmr: 8.52 (s, 1), 8.37 (d, J = 5; 1), 7.07 (d, J = 5; 1), 6.0 (m, 1), 5.4–5.0 (complex, 3), 3.75 (s, 2), 3.65 (s, 3), 0.90 (s, 9), 0.08 (s, 3), 0.00 (s, 3); ms: 264 (100), 232 (29), 158 (22), 130 (66), 93 (40), 89 (33), 85 (39), 83 (60), 77 (37), 75 (91), 73 (27). *Exact Mass* calcd. for $C_{13}H_{18}NO_3Si$ (M − *t*-Bu): 264.1055; found: 264.1055.

*The tryptamine derivative **16***

A solution of **15***a* (548 mg; 1.7 mmol) in 15 mL of 95:5 dichloromethane–methanol was cooled to −40°C and saturated with ozonized oxygen. The system was flushed with argon and 1 mL of dimethyl sulfide was added to the stirred reaction mixture which was then allowed to warm slowly (3 h) to room temperature. The solution was diluted with 50 mL of dichloromethane and washed with brine. The organic solution was stirred with an excess of anhydrous sulfate while tryptamine (546 mg; 3.4 mmol) was added. After 1.5 h the solution was filtered, the solvent was removed under reduced pressure and replaced with 50 mL of dry benzene, which was then removed in the same way; the residue was dried further in a vacuum system and then dissolved in 20 mL of dry methanol. To the stirred solution, placed under argon and cooled in an ice bath, sodium borohydride (137 mg; 2.6 mmol) was added in small portions. The ice bath was removed, stirring was continued for 17 h, and 25 mL of brine and 5 drops of acetic acid were then added. The mixture was thoroughly extracted with dichloromethane, and the material (966 mg) recovered from the extract was chromatographed (silica gel; 95:5 dichloromethane–methanol). The product **16** (365 mg; 0.78 mmol) was isolated as a white amorphous solid that darkened on standing; ir: 2.86, 2.99, 5.71, 5.90, 6.24; ^{1}Hmr: 8.55 (s, 1), 8.32 (d, J = 5; 1), 8.03 (broad, 1, D_2O removed), 7.7–7.0 (complex, 5), 6.99 (d, J = 5; 1), 4.97 (m, 1), 3.8–3.6 (complex, 5), 2.92 (s, 4), 2.9 (m, 2), 2.02 (broad, 1, D_2O removed), 0.77 (s, 9), 0.00 (s, 3), −0.15 (s, 3); ms: 467 (1), 452 (1), 410 (5), 337 (6), 297 (7), 296 (24), 295 (100), 237 (4), 223 (9), 205 (10), 173 (7), 144 (29), 130 (29). *Exact Mass* calcd. for $C_{22}H_{28}N_3O_3Si$ (M − *t*-Bu): 410.1900; found: 410.1891.

*The lactam **17***

A solution of the amino ester **16** (322 mg; 0.69 mmol) in 15 mL of dry methanol under argon was stirred with anhydrous potassium carbonate (103 mg; 0.75 mmol) and refluxed for 20 h. The methanol was removed under reduced pressure, the residue was dissolved in dichloromethane, and the solution was washed with brine. The product (283 mg) isolated from the organic solution was purified by flash chromatography (96:4 dichloromethane–methanol) (18), and **17** (111 mg; 0.26 mmol) was isolated as a white amorphous solid; ir: 2.87, 6.00, 6.25; ^{1}Hmr: 8.62 (broad, 1, D_2O removed), 8.4–8.2 (complex, 2), 7.7–6.8 (complex, 5), 6.75 (d, J = 2; 1), 4.4 (m, 1), 4.1–2.9 (complex, 8), 0.83 (s, 9), 0.03 (s, 3), −0.07 (s, 3); ms: 436 (2), 435 (6), 296 (4), 293 (15), 145 (6), 144 (19), 143 (100), 130 (16), 117 (5). *Exact Mass* calcd. for $C_{25}H_{33}N_3O_2Si$: 435.2342; found: 435.2359.

*The enamine **18***

Diisobutylaluminum hydride (0.84 mmol; 25% solution in toluene) was added over 7 min to a stirred solution of lactam **17** (93 mg; 0.21 mmol) in 2 mL of dry tetrahydrofuran at −65°C under argon. Stirring was continued for 1 h further, and saturated aqueous ammonium chloride (250 μL) was then added. The reaction mixture was allowed to warm to room temperature, the solvent was removed under reduced pressure, replaced with toluene, which was then removed in the same way, and then the residue was stirred in chloroform with anhydrous sodium sulfate. The chloroform solution, after filtration, was evaporated and the residue (92 mg) was subjected to flash chromatography (9:1 dichloromethane–methanol). Unchanged **17** (40 mg; 0.092 mmol) was recovered, and **18** (43 mg; 0.10 mmol) was isolated as an unstable amorphous solid; ir: 2.86, 6.13, 6.29; ^{1}Hmr: 8.73 (broad, 1, D_2O removed), 8.37 (s, 1), 8.18 (d, J = 5; 1), 7.7–7.0 (complex, 4), 6.95 (d, J = 2; 1), 6.84 (d, J = 5; 1), 6.23 (d, J = 10; 1), 4.9 (m, 1), 4.88 (d, J = 10; 1), 3.8–2.9 (complex, 6), 0.92 (s, 9), 0.13 (s, 3), −0.03 (s, 3).

The decarbomethoxynauclechines

Formic acid procedure

A solution of enamine **18** (71 mg; 0.17 mmol) in 1.5 mL of 90% formic acid was stirred at room temperature under argon for 18 h. The resulting solution was added dropwise to 20 mL of aqueous sodium carbonate, and the mixture was thoroughly extracted with chloroform. Drying (Na_2SO_4) and evaporation of the extract provided a yellow residue (73 mg) that was subjected to flash chromatography (18) (93:7 dichloromethane–methanol). The major component, **19***a* (45 mg; 0.11 mmol), was isolated as an amorphous yellow solid; ir: 2.89, 3.55, 3.61, 6.25; ^{1}Hmr: 9.00 (s, 1, D_2O removed), 8.77 (s, 1), 8.37 (d, J = 5; 1), 7.5–6.9 (complex, 5), 5.22 (d, J = 8; 1), 3.8–2.6 (complex, 9), 0.98 (s, 9), 0.20 (s, 3), 0.03 (s, 3); ms: 421 (8), 420 (34), 419 (100), 418 (55), 286 (21), 272 (12), 250 (23), 245 (26), 184 (41), 183 (69), 170 (38), 169 (36), 156 (20), 143 (25). Another fraction (14 mg) appeared to be a mixture of at least two components, but these could not be separated by further chromatography.

When the mixture of products before flash chromatography was stirred with 2 equivalents of tetrabutylammonium fluoride in dry tetrahydrofuran at room temperature under argon for 1 h, desilylated products were obtained. A minimum of water was added, solvent was removed under reduced pressure, and the residue was dried. By flash chromatography (9:1 dichloromethane–methanol) of the residue, **1***b* (see below) was isolated (25% yield for the desilylation step) in early fractions, and decarbomethoxy-3β-nauchlechine (**19***b*) was isolated (73%) as a white amorphous solid that rapidly became yellow; recrystallization from ethyl acetate provided pale yellow crystals, mp 219–220°C (dec.); ms: 306 (21), 305 (100), 304 (76), 288 (33), 274 (23), 245 (16), 184 (44), 183 (33), 170 (32), 169 (44), 156 (26), 144 (22), 143 (23). *Exact Mass* calcd. for $C_{19}H_{19}N_3O$: 305.1528; found: 305.1524. Acetylation of **19***b* with acetic anhydride in pyridine pro-

vided a product that was purified by flash chromatography (95:5 dichloromethane–methanol) and **19***c* was isolated as an amorphous solid; ir: 2.88, 5.75, 6.25; ^{1}Hmr: see Table 1 (400 MHz spectrum).

Hydrogen chloride procedure

A solution of enamine **18** (188 mg; 0.45 mmol) in 6 mL of 10% methanolic hydrogen chloride was allowed to stand under argon for 14 h. The solution was neutralized with anhydrous sodium carbonate added in small portions, filtered, and evaporated to dryness. The residue was thoroughly triturated with acetone, and the solution obtained was evaporated to dryness. The residue (117 mg) was subjected to flash chromatography (as described above), and **1***b* (38 mg; 0.12 mmol) was isolated as a white amorphous solid that turned yellow on standing; recrystallization from ethyl acetate provided colorless crystals, mp 218–221°C (prior phase change at 213°C); ms: 306 (21), 305 (100), 304 (77), 288 (33), 274 (16), 245 (13), 184 (25), 170 (17), 169 (26), 156 (11), 144 (10), 143 (15). *Exact Mass* calcd. for $C_{19}H_{19}N_3O$: 305.1528; found: 305.1530. Acetate **1***c* was prepared (see preparation of **19***c*) and obtained as an amorphous solid; ir: 2.89, 5.74, 6.25; ^{1}Hmr: see Table 1 (400 MHz spectrum). Later fractions provided **19***b* (8 mg; 0.026 mmol) and a middle fraction contained both **1***b* and **19***b* (25 mg; 0.08 mmol); one fraction afforded undesilylated cyclized material (see **19***a*) (37 mg; 0.09 mmol).

Discreteness-of-charge effects in electrode kinetics. II. The electroreduction of hexamminocobalt(III) cation in the presence of specifically adsorbed nitrate anions

W. RONALD FAWCETT AND KVETA MARKUŠOVÁ[1]

Guelph–Waterloo Centre for Graduate Work in Chemistry (Guelph Campus), Department of Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received February 28, 1983

W. RONALD FAWCETT and KVETA MARKUŠOVÁ. Can. J. Chem. **61**, 2821 (1983).

The kinetics of electroreduction of the hexamminocobalt(III) cation have been studied at a Hg electrode in aqueous solutions of $NaNO_3$ + NaF and KNO_3 + KF with an ionic strength of 0.2 *M*. The rate of reaction was observed to increase with increasing nitrate ion concentration but was independent of the cation nature. Analysis of the double layer effect for this system indicates that ion pairs formed between the reacting cation and anions of the base electrolyte also participate in the electrode reaction, and that attractive interactions between the reactant and adsorbed anions have a significant influence on the interfacial kinetics.

W. RONALD FAWCETT et KVETA MARKUŠOVÁ. Can. J. Chem. **61**, 2821 (1983).

On a étudié la cinétique de l'électroréduction du cation hexamminocobalt(III) utilisant une électrode au Hg dans des solutions aqueuses de $NaNO_3$ + NaF et de KNO_3 + KF avec une force ionique de 0,2 *M*. On a noté que la vitesse de la réaction augmente avec la concentration en ions nitrates, mais elle ne dépend pas de la nature du cation. L'analyse de l'effet de couche double dans ce système, indique que les paires d'ions formées entre le cation réagissant et les anions de l'électrolyte de base participent également à la réaction d'électrode et que les interactions attractives entre le réactif et les anions absorbés ont une influence significative sur la cinétique à l'interface.

[Traduit par le journal]

Introduction

In reviewing the literature concerned with discreteness-of-charge effects in interfacial electrochemistry, one finds considerable interest in the effects of specifically adsorbed ions on the kinetics of simple electrode reactions (1–4). A large fraction of the experimental work has been directed to studies of the effects of specifically adsorbed non-reacting anions on the electroreduction of a second anion; an example of such a system, which has been studied in some detail (5–7), is the electroreduction of tetrathionate anion at mercury in the presence of specifically adsorbed iodide anions. In this case, significant deceleration of the reaction rate is observed due to the increase in the electric field at the interface in the negative direction with increasing anion adsorption. The opposite occurs in the case of the electroreduction of a cation; the reaction rate increases with increasing anion adsorption. However, because of the attractive interactions between the reacting cation and adsorbed anion, local ion pairing effects involving the adsorbed species are also possible in the latter system (8–10).

Double layer effects on the electroreduction of a variety of Co(III) ammine complexes were recently studied by Satterberg and Weaver (11). They showed that the increase in the logarithm of the apparent rate constant at constant potential is a linear function of adsorbed anionic charge density for a variety of anions including Cl^-, Br^-, ClO_4^-, NO_3^-, and N_3^-. They concluded, on the basis of the magnitude of the double layer effects, that the reaction site is in the inner layer. They also discussed discreteness-of-charge effects for these reactions but did not give a detailed analysis of the kinetic data. In the present paper, the hexamminocobalt(III) system is reexamined for nitrate anions adsorbed on the electrode in order to determine more carefully the extent of discreteness-of-charge effects.

Experimental and method of data analysis

The kinetic data were obtained by dc polarography as described previously (7). The drop time of the mercury electrode was controlled at 5 s and the flow rate was 0.26 mg s^{-1}. Sodium and potassium nitrate were twice recrystallized from triply distilled water and dried *in vacuo*. Sodium fluoride was twice recrystallized from purified methanol and dried *in vacuo* at 100°C in a platinum dish. A similar procedure was used for potassium fluoride, the drying being carried out at 300°C. The diffusion coefficient of the dipolarizer, $Co(NH_3)_6^{3+}$ in solutions of ionic strength = 0.2 *M* was 7.35×10^{-6} cm^2 s^{-1}; its concentration was kept constant for all experiments at 5×10^{-4} *M*. The rate constant was calculated from the ratio of the observed current to its diffusion limited value according to the theory of Koutecky for an irreversible electrode process with inclusion of the correction for electrode sphericity (12). The reference electrode was a saturated calomel electrode, and the counter electrode a Pt cylinder. All experiments were carried out at 25°C.

The potential drop across the diffuse layer, ϕ^d was estimated on the basis of the equation

$$[1] \quad (\sigma_m + \sigma_a)^2 = \theta^2 \sum_i c_i[\exp(-z_i f \phi^d) - 1]$$

where σ_m is the charge density on the electrode, σ_a, that due to adsorbed anions, c_i, the concentration of ion i with valence z_i, and $f = F/RT$. θ^2 is equal to $2RT\epsilon\epsilon_0$ where ϵ is the dielectric constant of the solvent and ϵ_0, the permittivity of free space. The necessary double layer data for the system

$$x\ M\ NaNO_3 + (0.2 - x)\ M\ NaF$$

were obtained earlier (13). In the present case, the kinetic data are obtained close to the point of zero charge in the 0.2 *M* NaF system. As a result, the concentrations of the reactant and product in the diffuse layer are significant and must be taken into account in the estimation of ϕ^d. Setting $\Phi = \exp(-f\phi^d)$ and $\Sigma = (\sigma_m + \sigma_a)^2/\theta^2$, eq. [1] may be written as

$$[2] \quad \Sigma = c_s\Phi + c_2\Phi^2 + c_3\Phi^3 + (c_s + 3c_d)/\Phi - 2c_s - 4c_d$$

where c_s is the base electrolyte concentration (c_s = 0.2 *M*), c_d,

the depolarizer concentration in the bulk ($c_d = 5 \times 10^{-4}$ *M*), c_2, the concentration of divalent (product) cations at the boundary of the diffusion layer diffusing away from the electrode, and c_3, the concentration of trivalent cations at the boundary of the diffusion layer close to the electrode ($c_2 + c_3 = c_d$). In general, c_2 and c_3 vary with variation in current density, and therefore, with electrode potential. In the present case, it was assumed that $c_2 = c_d i/i_d$ where i is the current at the end of drop life and i_d its diffusion limited value. When $\Phi > 1$, eq. [2] is most easily solved by neglecting the term in $1/\Phi$ and obtaining an analytical solution of the resulting cubic equation; the estimate of Φ and thus ϕ^d is improved with the inclusion of the term in $1/\Phi$ by iteration. When $\Phi < 1$, eq. [2] can be solved by neglecting the terms in Φ, Φ^2, and Φ^3 and solving the resulting linear equation in $1/\Phi$; improved estimates are obtained by iteration with inclusion of the terms in Φ, Φ^2, and Φ^3 as constants calculated on the basis of the previous estimate. It should be noted that when both reactant and product concentrations are considered in the estimation of ϕ^d, the result is very little different than the result obtained when the concentration of multivalent cations in the diffuse layer is assumed to be determined only by the concentration of depolarizer in the bulk ($c_3 = c_d$ and $c_2 = 0$). Therefore, it is concluded that the above method of estimating ϕ^d using the Gouy–Chapman model is reasonable even though one recognizes that the estimates of c_2 and c_3 are approximate.

If ion pairing of the reactant $Co(NH_3)_6^{3+}$ with the anion of the supporting electrolyte is significant, as suggested previously for the case of F^- (11), then the charge on the reactant is 2+. The product cation which is substitutionally labile has the same charge. In this case, eq. [1] becomes

$$[3] \quad \Sigma = c_s\Phi + c_d + (c_s + 2c_d)/\Phi - 2c_s - 3c_d$$

The techniques outlined above are used to solve this equation for Φ, and thus, ϕ^d. When $\Phi > 1$, the term in $1/\Phi$ is initially neglected and the resulting quadratic equation in Φ solved. The initial estimate is improved by iteration with inclusion of the term in $1/\Phi$ calculated on the basis of the previous estimate. Similarly, when $\Phi < 1$, the linear equation in $1/\Phi$ is solved initially neglecting the terms in Φ and Φ^2, and subsequently by iteration.

Results

Kinetic data were obtained in eighteen different electrolyte solutions of composition

$$x\ M\ NaNO_3 + (0.2 - x)\ M\ NaF$$

and

$$x\ M\ KNO_3 + (0.2 - x)\ M\ KF$$

where $x = 0$, 0.01, 0.016, 0.025, 0.04, 0.063, 0.10, 0.14, and 0.2. Data obtained in 0.2 *M* solutions of NaF, $NaNO_3$, KF, and KNO_3 are shown in Fig. 1. As one would anticipate, the rate constant increases with increase in NO_3^- concentration at constant electrode potential and ionic strength for solutions containing a given cation. The acceleration is attributed to the shift in the potential drop across the diffuse layer in the negative direction with increase in the extent of NO_3^- ion adsorption, and the corresponding increase in the rate of reduction of the positively charged reactant. No significant difference between the data obtained in the Na^+ and K^+ systems was observed. The experimental transfer coefficients obtained in 0.2 *M* NaF and KF are 0.98 and 1.00, respectively. These results agree well with those obtained by Satterberg and Weaver (11), namely, 0.88 in 1.0 *M* KF and 0.98 in 0.1 *M* NaF; as the ionic strength increases, the double layer effect is reduced and its influence on the transfer coefficient becomes smaller. In 0.2 *M* $NaNO_3$ and KNO_3, the experimental transfer coefficient is 0.67. As a result of adsorption of the nitrate anion, the potential drop across the diffuse layer changes much less with electrode potential so that the transfer coefficient is less than that in the fluoride systems.

Satterberg and Weaver (11) argued that $Co(NH_3)_6^{3+}$ is predominantly present in fluoride solutions as the outersphere ion pair $Co(NH_3)_6^{3+} \cdots F^-$, and presented convincing evidence that the ion pair is the predominant reacting species when the potential drop across the diffuse layer is positive. Since ϕ^d is approximately a linear function of electrode potential in the present systems, the method proposed earlier (14) to estimate the charge on the reactant cannot be used. This method was introduced in order to avoid estimating the reactant charge on the basis of kinetic data obtained in different electrolyte solutions, either with a constant electrolyte at varying ionic strength as was common in early work (15, 16), or at constant ionic strength with variation in the nature of the ions as in the present investigation. When the methods developed by Frumkin (15) and Gierst (16) are used to determine the charge on the reactant, the change in the local activity coefficient of the reactant at the reaction site due to changes in ionic strength and composition is ignored. If it is assumed that the reaction site is on the outer Helmholtz plane (o.H.p.), then the experimental transfer coefficient is given by

$$[4] \quad \alpha_{ex} = \alpha_a - (\alpha_a - z)\frac{d\phi^d}{d\phi^m}$$

where α_a is the apparent transfer coefficient, z, the charge on the reactant, and ϕ^m, the electrode potential on the rational potential scale. In the case of 0.2 *M* NaF and KF, ϕ^d is positive over most of the available potential range, and therefore, independent of whether one assumes the charge on the reactant is 2+ or 3+ when this quantity is estimated on the basis of the Gouy–Chapman model. The value of $d\phi^d/d\phi^m$ in this potential range is 0.22. If z is assumed to be 3+, the corresponding value of α_a is 0.42; on the other hand, assuming $z = 2+$, the estimated value of α_a is 0.71. In the case of 0.2 *M* $NaNO_3$ and KNO_3, ϕ^d is negative. The magnitude of ϕ^d is slightly higher when z is assumed to be 2 rather than 3 but the coefficient $d\phi^d/d\phi^m$ is independent of this assumption and equal to 0.028. When z is set equal to 3+, the value of α_a from eq. [4] is 0.60, whereas it is 0.63 when z is assumed to be 2+. Keeping in mind that the contributions of discreteness-of-charge and coverage effects are neglected on the basis of eq. [4], the best agreement between estimated values of α_a in the presence and absence of adsorption occurs when the charge on the reactant is set equal to 2+. In the absence of discreteness-of-charge effects, attractive ion–ion interactions and surface coverage effects, the apparent transfer coefficient is related to the true or intrinsic transfer coefficient α by the equation (17, 18)

$$[5] \quad \alpha_a = \alpha - \lambda(\alpha - z)$$

where λ is a dimensionless fraction determined by the distance between the reaction plane (r.p.) and o.H.p., and the dielectric permittivity of the medium between these planes. When the reaction site is in the inner layer, λ is positive and α_a is greater than α in the case of cationic reactants. In previous studies of

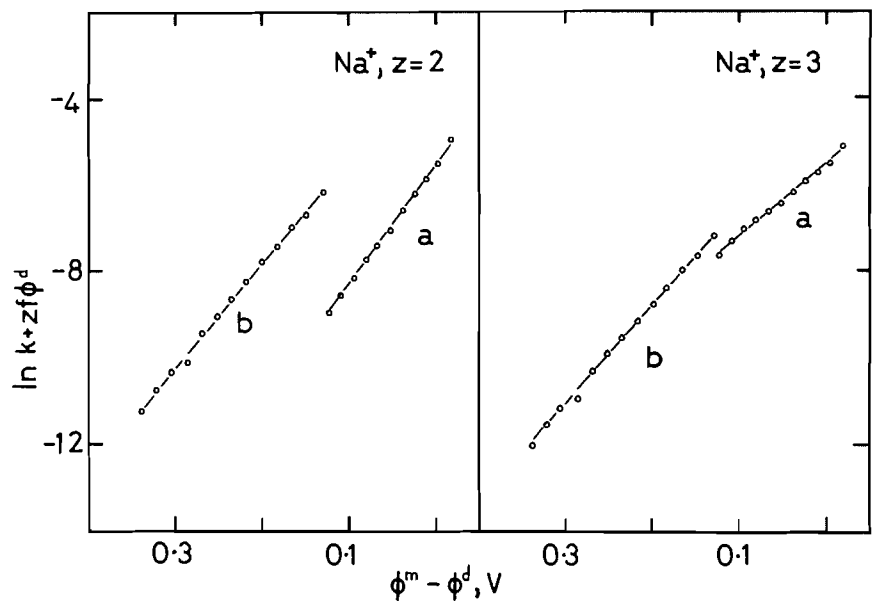

FIG. 2. Plots of the logarithm of the corrected rate constant, $\ln k + zf\phi^d$ for reduction of $Co(NH_3)_6^{3+}$ at mercury against the potential drop across the inner layer, $\phi^m - \phi^d$ in solutions of 0.2 *M* NaF (*a*) and 0.2 *M* $NaNO_3$ (*b*). The corrected rate constants for the plots on the left hand side were calculated assuming a reactant charge, $z = 2+$, whereas those on the right hand side were calculated assuming $z = 3+$.

the ammine complexes of both Co(III) (11) and Cr(III) (19), it was concluded that the reaction site for reactants not adsorbed on the electrode is in the inner layer in aqueous solutions. In this case, α_a is anticipated to be greater than 0.5, and the effect of the adsorbed anions rather large. These conclusions are consistent with the present results if the charge on the reactant is assumed to be 2+.

Corrected Tafel plots (cTp) for the data obtained in the Na^+ systems are shown in Fig. 2 for the cases that z is set equal to 2+ and 3+. Neglecting discreteness-of-charge effects, the corrected rate of reaction is given by

$$[6] \quad \ln k + zf\phi^d = \ln k_0 - \alpha_a f(\phi^m - \phi^d)$$

where k is the rate constant for the reduction reaction, and k_0, its value when both ϕ^m and ϕ^d are zero. The cTp were constructed using values of ϕ^d estimated as described above with consideration of the presence of the reactant and product in the double layer. When z is assumed to be 2+, the corrected rate constant in the presence of 0.2 *M* $NaNO_3$ is an order of magnitude greater than that in the presence of 0.2 *M* NaF. A large acceleration of the reaction rate above that predicted by the classical theory is expected when the reaction site is in the inner layer and attractive interaction between the reactant and adsorbed anions is strong. On the other hand, if z is set equal to 3+, the corrected rate constant in $NaNO_3$ is only slightly greater than that in NaF, but the slope of the c.T.p. in the former system is significantly higher. This analysis demonstrates that determination of z by the classical methods (15, 16) would have

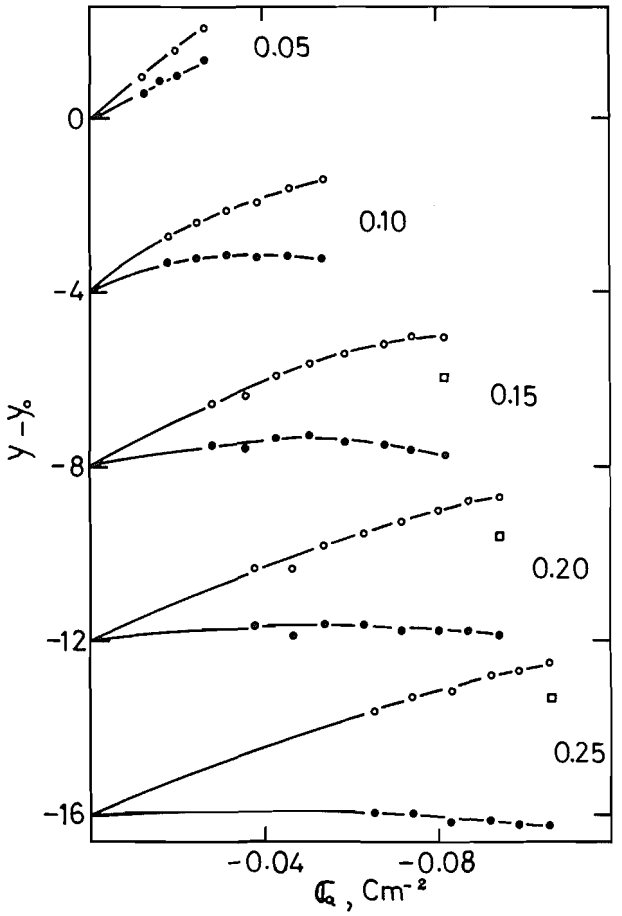

FIG. 3. Plots of the logarithm of the corrected rate constant, $y = \ln k + zf\phi^d$ for reduction of $Co(NH_3)_6^{3+}$ at mercury in mixed $NaNO_3$–NaF solutions with respect to that in pure NaF, y_0 against adsorbed charge density due to nitrate anions, σ_a for constant potential drop across the inner layer, $\phi^m - \phi^d$. The points (●) were calculated assuming $z = 3+$ whereas those marked (○) were calculated assuming $z = 2+$. The single points (□) give the values of y for $z = 3+$ with respect to y_0 for $z = 2+$. The values of $\phi^m - \phi^d$ in volts are indicated adjacent to each group of curves. The ordinate scale is correct for the data at $\phi^m - \phi^d = 0.05$ V whereas the data at 0.10, 0.15, 0.20, and 0.25 V have been shifted down by 4, 8, 12, and 16 units, respectively.

given a value of 3+ when discreteness-of-charge effects are neglected, and the reaction site assumed to be the o.H.p. However, the classical analysis ignores possible variation in α_a with change in solution composition; in the present case, α_a changes significantly with solution composition when z is set equal to 3+ (Fig. 2). Furthermore, if discreteness-of-charge effects are truly negligible, the r.p. must be sufficiently far from the inner Helmholtz plane (i.H.p.) that attractive interaction between adsorbed nitrate ions and the reactant is not possible. In the analysis of the adsorption data for NO_3^- at Hg (13), it was concluded that i.H.p. is very close to the o.H.p., so that interactions with the reactant even when it is on the o.H.p. or slightly further away in the diffuse layer are highly probable. Thus, the present analysis of the kinetic data indicates strongly that the average charge on the reactant is less than 3+. The c.T.p. obtained for the K^+ system are qualitatively similar when z is assumed to be 2+. However, when z is set equal to 3+, the corrected rate constant in the KF system is greater than that in KNO_3 for more positive values of $\phi^m - \phi^d$. The latter result is entirely unexpected and lends further support to the assumption that ion pairs play a role in the electrode reaction.

The change in the corrected rate constant, $y = \ln k + zf\phi^d$ with solution composition at constant $\phi^m - \phi^d$ is illustrated in Fig. 3 for the Na^+ system with z set equal to 2+ or 3+. When $z = 3+$, y increases with the extent of NO_3^- adsorption for $\phi^m - \phi^d = 0.05$ V, but the change in y with σ_a at more positive potentials is negligible. On the other hand, when z is assumed to be 2+, y increases smoothly with the amount of NO_3^- adsorbed and a significant discreteness-of-charge effect is observed at all potentials where data were obtained. When the results for the Na^+ system presented in Figs. 1 and 2 are examined, it is clear that approximately one half of the double layer effect due to adsorbed nitrate ions is accounted for by the classical Frumkin theory when it is assumed that only ion pairs react. Accordingly, the reaction site is assumed to be the o.H.p., and the local potential at this site to be the average potential on the o.H.p., ϕ^d. The portion of the double layer effect not accounted for by the classical model is attributed to non-coincidence of the r.p. and o.H.p., non-equality of the local potential at the reaction site and the average potential on the r.p., local ion pairing due to attractive ion–ion interactions, and coverage of the electrode by adsorbed nitrate ions.

In order to assess further the double layer effects and the role of ion pairs in the reaction, the magnitude of the discreteness-of-charge effects are now considered. On the basis of the theory presented earlier (18), the change in y with respect to its value in the absence of adsorbed nitrate ions, y_0, is given by

$$[7] \quad y - y_0 = \frac{(\alpha - z)f(1-\lambda)(1-g)\sigma_a}{K_2} + \frac{(a_{\neq}\sigma_d)_0}{RT} - \frac{a_{\neq}\sigma_r}{RT} + p_{\neq}\ln(1 - \sigma_a/\sigma_{am})$$

The first term accounts for the departure of the local potential at the reaction site from its average value; the dimensionless parameter g is related to the degree that repulsive interactions between adsorbed anions are screened by their electrostatic environment and is given by

$$[8] \quad g = (C_d + K_2)/(C_d + K_i)$$

where C_d is the differential capacity of the diffuse layer, K_i, the integral capacity of the inner layer, and K_2, the integral capacity of the region between the i.H.p. and o.H.p. The second and third terms account for attractive interactions between the cationic reactant and anions on the r.p., and in the vicinity of the reaction site in the diffuse layer. The first of these refers to interaction in pure NaF; σ_d is anionic charge density in the diffuse layer and $a_{\neq}$, the interaction parameter in the activated state (18). When nitrate ion adsorption is present, attractive ion–ion interactions are possible with both the adsorbed anions and anions in the vicinity of the o.H.p. in the diffuse layer when the potential drop across the region is positive, or when the same potential drop is negative but the anion concentration in the vicinity of the o.H.p. is still significant. σ_r refers to the anionic charge density in the vicinity of the reaction site and includes contributions from both the inner and diffuse layers; on the other hand, σ_d refers to the corresponding anionic charge density in the diffuse layer only (18). The last term accounts for surface coverage by adsorbed nitrate ions, σ_{am} being the maximum adsorbed charge density and $p_{\neq}$, the number of solvent molecules displaced by the reactant at the surface in the transition state.

The quantitative contribution of two of the effects discussed above may be estimated on the basis of the double layer data obtained earlier for the nitrate system (13). From the value of α_a obtained in 0.2 *M* NaF (0.71), $(\alpha - z)(1 - \lambda)$ is equal to -1.29 when $z = 2+$. In the case of $NaNO_3$ – NaF systems, g was found to be 1.3 and $K_2 \simeq 2.0$ F m^{-2} (13). It follows that $(\alpha - z)f(1 - \lambda)(1 - g)/K_2$ is equal to 7.5 m C^{-1}, and that $y - y_0$ should decrease with increasing $|\sigma_a|$. This result reflects the fact that the accelerating effect of adsorbed nitrate is overestimated when the discrete nature of these anions is ignored (18). The coverage term also leads to a decrease in $y - y_0$ with increase in $|\sigma_a|$. Setting σ_{am} equal to -0.25 C m^{-2} (13) and assuming $p_\neq$ is unity, $p_\neq \ln (1 - \sigma_a/\sigma_{am})$ is equal to -0.51 when $\sigma_a = -0.1$ C m^{-2}. Considering these two terms only, $y - y_0$ is expected to decrease by 1.26 when σ_a reaches -0.1 C m^{-2}. However, experimentally, $y - y_0$ increases by at least 2.4 units under these conditions for the case $z = 2+$. It follows that the influence of attractive interaction between the reactant and adsorbed anions, accounted for by the term $-a_\neq \sigma_r/RT$, would have to be very large and positive to account for the discreteness-of-charge effect estimated when $z = 2+$. Although attempts have been made to calculate $a_\neq$ (8–10), the models proposed are not very sophisticated, and therefore no attempt is made here to estimate $a_\neq$. Alternatively, when z is assumed to be 3+, α_a is 0.42 and $(\alpha - z)f(1 - \lambda)(1 - g)/K_2$ is approximately equal to 15.1 m^2 C^{-1}. With consideration of coverage, $y - y_0$ is expected to decrease by 2.02 when σ_a reaches -0.1 C m^{-2}. In this case, the attractive interaction on the reaction plane is approximately equal and opposite to the effects of ion shielding and coverage. Whether z is assumed to be 2+ or 3+, there is considerable variation in the magnitude of the non-classical contribution to y with the potential drop $\phi^m - \phi^d$. This can be attributed to the large variation in the inner layer parameters for the NaF – $NaNO_3$ system (13) which results in a corresponding variation in the degree of ion screening and interaction.

Discussion

Analysis of the double layer effects in the present case is complicated by the fact that the nature of the ionic atmosphere in the diffuse layer changes from an anionic environment to a cationic one when the electrolyte is changed from fluoride to nitrate. For example, in the presence of 0.2 *M* NaF, the kinetic data are obtained positive of the point of zero charge (p.z.c.) where the predominant ion at the o.H.p. is the flouride anion. On the other hand, in the presence of 0.2 *M* $NaNO_3$, the potential drop across the diffuse layer is negative and the reaction occurs in an ionic atmosphere composed chiefly of sodium cations in the diffuse layer together with adsorbed nitrate ions in the inner layer. Thus, the nature of the double layer effects undoubtedly changes with the change in solution composition. The analysis is further complicated by the fact that the reactant is expected to pair with anions in the bulk of the solution. The influence of the ion pair on the electrode kinetics is expected to change with the nature of the anion in the bulk and with the potential drop across the diffuse layer. On the basis of existing data (20, 21), $Co(NH_3)_6^{+}$ is expected to ion pair relatively strongly with the F^- anion and to a somewhat lesser extent with the NO_3^- ion (13). Thus, in 0.2 *M* NaF, the reactant is predominantly the ion pair $Co(NH_3)_6^{3+} \cdots F^-$, the unpaired species being more strongly repelled from the r.p. when the value of ϕ^r, the average potential on that plane, is positive. The double layer effect under these circumstances is classified as Type II (18), some attractive interaction between the reactant and the F^- anions on the o.H.p. being expected. Neglecting the effect of these interactions on α_a, the value of λ in eq. [5] is 0.14; accordingly, the r.p. is slightly closer to the electrode than the o.H.p. In 0.2 *M* $NaNO_3$, the reactant is predominantly the trivalent cation. This conclusion is based on the facts that ion pairing is weaker in the nitrate solution, and that the trivalent species is predominant on the r.p. because the potential drop across the diffuse layer is negative in the range where the kinetic data are obtained. Under these circumstances, the kinetics are very strongly influenced by attractive interactions between the reactant and the nitrate ions adsorbed on the i.H.p. In fact, on the basis of the previous analysis of the equilibrium data for the NO_3^- – F^- system (13), the i.H.p. is estimated to be quite close to the o.H.p., and thus, also to the r.p. The lower value of α_a in 0.2 *M* $NaNO_3$ (0.60) is assumed to reflect the decrease in attractive ion–ion interactions with change in electrode potential in the negative direction, and the corresponding decrease in the value of σ_a. It follows that the kinetic data in mixed electrolyte solutions are for a parallel reaction involving both unpaired and paired reactants. The apparent rate constant is then given by (22)

$$[9] \quad k = k_M \rho_M \exp(-3f\phi^d) + k_{MA}(1 - \rho_M) \exp(-2f\phi^d)$$

when discreteness-of-charge effects are neglected and the classical model assumed. k_M and k_{MA} are the rate constants for the unpaired and ion paired species, respectively, and ρ_M, the fraction of unpaired cobalt cations in the bulk. The rate constant for either species may be written

$$[10] \quad k_i = k_{0i} \exp[\alpha_{ai} f(\phi^d - \phi^m)]$$

where k_{0i} and α_{ai} are quantities analogous to those defined in eq. [6]. No attempt is made to analyze the present data with respect to a parallel reaction mechanism but such an analysis could be carried out if equilibrium data for the bulk of the solution were available.

If the above assumptions regarding the charge on the reactant in 0.2 *M* NaF and $NaNO_3$ are correct, then the analysis of discreteness-of-charge effects presented in Fig. 3 should be modified. More specifically, the value of y with $z = 3+$ in 0.2 *M* $NaNO_3$ should be compared with y_0 using $z = 2+$ in 0.2 *M* NaF. Values of $y - y_0$ for three higher values of $\phi^m - \phi^d$ are also shown in Fig. 3. It is apparent that the discreteness-of-charge effect is still very large when the data are examined in this fashion. The calculation of y when a parallel reaction is involved is not a simple matter and would require separate estimates of k_M and k_{MA} (eq. [9]). In this case, y is given by

$$[11] \quad y = \rho_M(\ln k_M + 3f\phi^d) + (1 - \rho_M)(\ln k_{MA} + 2f\phi^d)$$

Although our data are not sufficiently detailed to estimate y in this case, it seems clear that it would vary smoothly with σ_a and indicate a strong influence of local ion pairing on the reaction plane.

As pointed out above, there are no great differences in the results obtained in the Na^+ and K^+ systems. A small increase in $\ln k$ (0.12) is observed in going from 0.2 *M* KF to 0.2 *M* NaF. This may reflect a small double layer effect caused by the potential at the reaction site being more positive at the Hg/aqueous KF interface but it could also be due to a change in the activity of the reactant in the bulk of the solution. In the case of pure nitrate solutions, $\ln k$ is slightly higher in KNO_3 (0.01). Although the above factors must also be considered, in the case of the nitrate systems, the anion is more strongly

adsorbed from KNO_3 solutions (13) so that the effects observed with NaF and KF are reversed. Because the inner layer parameters differ in KNO_3 and $NaNO_3$, the magnitude of the discreteness-of-charge contribution is also expected to change but the magnitude of this change is not very large.

The analysis of discreteness-of-charge effects presented here relies heavily on the Gouy–Chapman theory of the diffuse layer and its estimate of the potential drop ϕ^d. Deficiencies in this model with respect to the analysis of kinetic data for reactions involving highly charged species which are attracted into the double layer have been discussed in detail in the literature (11, 19, 23, 24). The present data were obtained at a lower ionic strength than most of those presented earlier, where less severe problems with the Gouy–Chapman model are expected. In addition, the effect of the presence of the reactant and product on the value of ϕ^d, which is not negligible, was taken into consideration. The influence of the highly charged species is even more important on estimates of $d\phi^d/d\phi^m$, a quantity which plays an important role in the analysis used in previous work (11, 19, 23, 24). In fact estimates of this quantity given by Satterberg and Weaver (11) are significantly higher than those calculated here. In view of the complex nature of the double layer effect for the present system it is not possible to comment further on the reliability of the Gouy–Chapman results. However, recent estimates of ϕ^d based on more sophisticated models (25, 26) are in serious disagreement with the classical results when multivalent ions are involved. In conclusion, double layer effects for highly charged reactants must be examined in more detail in the absence of ion pairing in order to elucidate the problem further.

SHINICHI YAMABE, TSUTOMU MINATO, and KIMIHIKO HIRAO. Can. J. Chem. **61**, 2827 (1983).

An *ab initio* MO calculation is made for the $H^+(acetone)_n$ and $H^+(DMSO)_n$ gas-phase clusters. In the "shells" of $n = 2$, the cationic nature for the attack of the third solvent molecule is dispersed to the methyl hydrogens and the S atom (in DMSO) as well as to the proton. This leads to the small difference of stability for several geometries of $n = 3$. A noticeable disagreement between experimental and calculated energies for $n = 1 \rightarrow 2$ in $H^+(DMSO)_n$ is discussed.

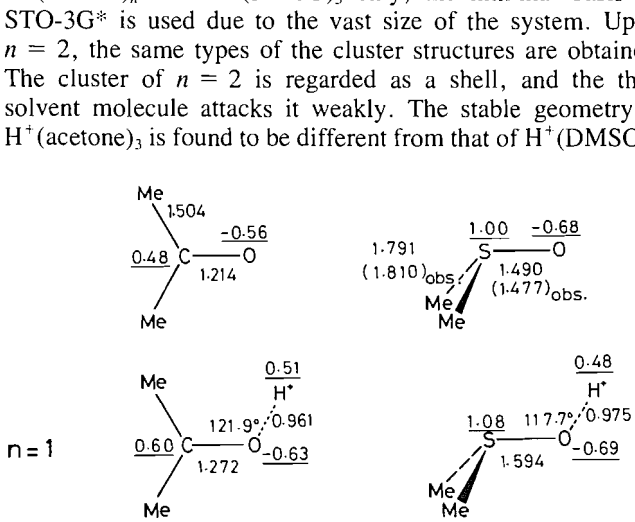
SHINICHI YAMABE, TSUTOMU MINATO et KIMIHIKO HIRAO. Can. J. Chem. **61**, 2827 (1983).

On a effectué des calculs "*ab initio*" des OM pour des aggrégats de H^+(acétone)$_n$ et de $H^+(DMSO)_n$ en phase gazeuse. Dans les "couches" de $n = 2$, la nature cationique pour l'attaque de la troisième molécule de solvant se répartit sur les hydrogènes du méthyle et sur l'atome de S (dans le DMSO) ainsi que sur le proton. Ceci conduit à une légère différence de stabilité pour les géométries de $n = 3$. On discute d'une différence assez significative qui existe entre les énergies calculées et expérimentales pour $n = 1 \rightarrow 2$ du $H^+(DMSO)_n$.

[Traduit par le journal]

High ion source pressure mass spectrometer measurements can provide thermochemical data for gas-phase clustering of ions through measurements of the temperature variation of the equilibrium constant of the clustering reaction (1). Also we have established that satisfactory agreement can be obtained between the observed enthalpy change ($\Delta H^0_{n-1,n}$) and the calculated stabilizing energy ($\Delta E_{n-1,n}$) (2). Here we present a theoretical analysis of the protonated clusters of two dipolar aprotic solvents, acetone and dimethylsulfoxide (DMSO). Experimental measurements have been reported for these two clusters which led to the suggestion of some interesting structural differences (3).

In Fig. 1, the optimized geometries are displayed together with the net electronic charges. The basis sets used for the MO calculation are 4-31G for $H^+(acetone)_n$ and 3-21G(*) (4) for $H^+(DMSO)_n$. For $H^+(DMSO)_3$ only, the minimal basis set STO-3G* is used due to the vast size of the system. Up to $n = 2$, the same types of the cluster structures are obtained. The cluster of $n = 2$ is regarded as a shell, and the third solvent molecule attacks it weakly. The stable geometry of $H^+(acetone)_3$ is found to be different from that of $H^+(DMSO)_3$.



[1]To whom all correspondence should be addressed.

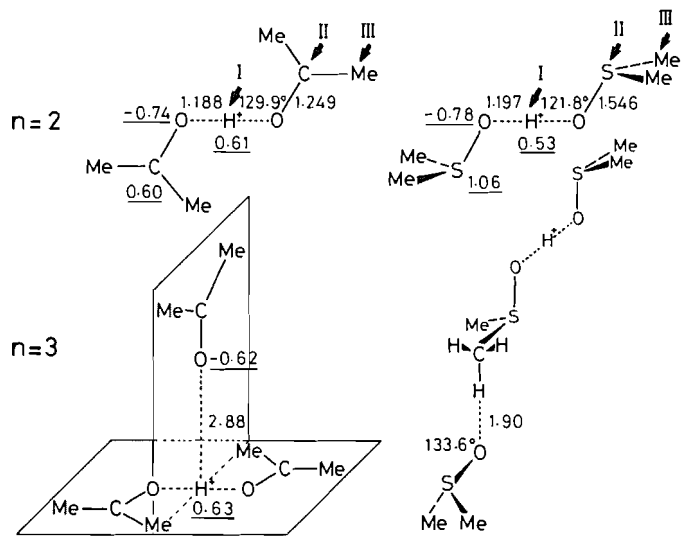


FIG. 1. Geometries of $H^+(acetone)_n$ and $H^+(DMSO)_n$ clusters optimized with the 4-31G and 3-21G(*) basis sets, respectively. The geometries of acetone and DMSO are fully optimized. For $n = 1$ and 2, the internal freedoms are optimized except the methyl part taken from the neutral molecules. For $n = 3$, only the orientation and the distance between the $n = 2$ cluster and the neutral molecule are optimized. For $n = 2$, another model of the "head-to-tail" type is examined and is found to be less stable than that shown in the figure. The bond length is in Å. Underlined numbers denote the net charges where negative values correspond to the electron-rich atoms. The geometry of $H^+(DMSO)_3$ is obtained by the STO-3G* basis set. The bold arrows indicated in $n = 2$ mean the cationic sites for the attack of the third solvent molecule.

In the former system, the proton is attacked by the third molecule in the direction perpendicular to the shell plane. Due to the large distance ($R_{H^+\cdots O} = 2.88$ Å), the third acetone can rotate freely around the $H^+\cdots O{=}C$ axis. In the latter system, type III

is the best among three possible stable geometries shown by three bold arrows in Fig. 1 (III > II > I). Apparently, type II is favorable in view of the cationic character of the S atom, but the exchange repulsion between the lone-pair electrons on the sulfur atom and that on the oxygen atom of the third DMSO decreases the stability of II. The larger stability of III arises both from the protonic net atomic charges on the methyl hydrogen (*0.22* in the neutral molecule and *0.25* in $n = 2$) of DMSO and from the absence of the exchange repulsion. However, the energy differences between the three types are only a few kcal/mol, and it is seen that H^+, S, and methyl H are all favorable sites for the third DMSO. Similarly, type III in $H^+(acetone)_3$ is only slightly less stable (~2 kcal/mol) than type I shown in Fig. 1. In this respect, the cluster size would be enlarged readily through the attachment of solvent molecules toward various moderately cationic sites in the shells of $n = 2$. Comparison between the energies, $\Delta E_{n-1,n}$ and $\Delta H^0_{n-1,n}$ is given in Table 1. While good agreement is obtained for $H^+(acetone)_n$, a somewhat noticeable discrepancy is observed for $H^+(DMSO)_n$. The 3-21G(*) MO calculation is found to overestimate $\Delta E_{n-1,n}$ by 1~6 kcal/mol relative to that of 4-31G(*). The latter may yet overestimate $\Delta E_{n-1,n}$ to some extent (4~5 kcal/mol at most), according to our experience. On the other hand, $\Delta H^0_{1,2}$ for $H^+(DMSO)_n$ seems to be too small in view of $\Delta H^0_{0,1}$ and $\Delta H^0_{1,2}$ for $H^+(acetone)_n$ and $H^+(acetonitrile)_n$. The $\Delta H^0_{1,2}$ values for the three clusters have been reported to be almost the same (~−30 kcal/mol) (3). The electron-rich oxygen of DMSO would result in a larger $\Delta H^0_{1,2}$ (probably −34~35 kcal/mol) than those of the latter systems. In proton bound dimers of n-donor oxygens, the systems with a hypervalent bond, $=S \rightarrow O$ and $\equiv N \rightarrow O$, would give the larger hydrogen bond energies. Further experiment on $H^+(DMSO)_n$ seems to be desirable.
