Adduct **C9** was prepared from **A9** in 96% yield and failed to crystalize; ^{1}Hmr ($CDCl_3$, 80 MHz), δ: 1.96 (s, 3H, CH_3), 3.76, 3.82, 3.88, 3.89 (s, 3H each, 2 × CO_2CH_3, 2 × OCH_3), 5.85 (s, 1H, bridge H), 7.0, 7.07 (s, 1H each, Ar); mass spectrum, *m/z* (assignment): 334 (M^+), 192 (5,6-dimethoxy-1-methylisobenzofuran).

Compound C10

Adduct **C10** was prepared from **A10** in 96% yield. Addition of ether afforded yellow crystals, mp 87.5–89.5°C; ^{1}Hmr ($CDCl_3$, 80 MHz), δ: 1.92 (s, 3H, CH_3), 3.76, 3.82 (s, 3H each, 2 × CO_2CH_3), 5.80 (s, 1H, bridge H), 5.95 (close ABq, 2H, J = 1.1 Hz, —OCH_2O—), 6.87, 6.93 (s, 1H each, Ar); mass spectrum, *m/z* (assignment): 3.18 (M^+), 176 (1-methyl-5,6-methylenedioxyisobenzofuran). *Anal.* calcd. for $C_{16}H_{14}O_7$: C 60.38, H 4.43; found: C 61.07, H 4.52.

Compound D6

Diels–Alder reaction of the acetal alcohol **A6** (448 mg) was done with dimethyl acetylenedicarboxylate as described in the general procedure by heating at 130°C for 20 min. Usual work-up gave the naphthol **D6** (309 mg, 62%) as a crystalline solid, mp 167°C; ir (KBr): 1735 and 1640 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz), δ: 3.15 (s, 3H, OMe), 3.45 (s, 3H, OMe), 3.82, 3.87 (s, 3H each, $COOCH_3$), 5.85 (s, 2H, OCH_2O), 6.68 (m, 3H, Ar), 7.2, 8.2 (ABq, 2H, Ar), 12.4 (s, 1H, OH exchangeable with D_2O); mass spectrum, *m/z* (assignment): 440 (M^+), 408 ($M^+ - CH_3OH$), 393 ($M^+ - CH_3OH - CH_3$). *Anal.* calcd. for $C_{23}H_{20}O_9$: C 62.72, H 4.54; found: C 62.71, H 4.56.

Compound D7

The acetal alcohol **A7** heated wth dimethyl acetylenedicarboxylate at 130°C for 20 min with acetic acid, gave naphthol **D7** in 73% yield, mp 162°C; ip (KBr): 1720, 1645 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz), δ: 3.33, 3.52 (s, 3H each, 2 OMe), 3.8, 3.9 (s, 6H each, 4 OMe), 3.92, 4.05 (s, 3H each, 2 – OMe), 6.55 (s, 2H, Ar), 7.68 (s, 1H, Ar), 12.35 (s, 1H, OH exchanges with D_2O); mass spectrum, *m/z* (assignment): 516 (M^+), 485 ($M^+ - CH_3OH$), 484 ($M^+ - CH_3OH$), 453 ($M^+ - CH_3OH - CH_3O$). *Anal.* calcd. for $C_{26}H_{28}O_6$: C 60.46, H 5.42; found: C 60.40, H 5.34.

Compound C11

Adduct **C11** was prepared from the ketal alcohol **A11** in 72% yield by the general procedure described above. Crystallization from ether gave yellow prisms, mp 169°C; ir (KBr): 1705, 1720 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz), δ: 2.95 (s, 3H, Me), 3.69, 3.76 3.85, 3.90 (s, 3H each, 4 MeO), 6.0 (s, 2H, OCH_2O), 6.8–7.2 (m, 5H, Ar); mass spectrum, *m/z* (assignment): 454 (M^+), 408 ($M^+ - CH_3O - CH_3$). *Anal.* calcd. for $C_{24}H_{22}O_9$: C 63.43, H 4.84; found: C 63.43, H 4.84.

Compound C12

Adduct **C12** was prepared from the ketal alcohol **A12** in 70% yield. Crystallization from methanol gave light yellow prisms, mp 170°C; ir (KBr): 1700, 1725 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz) δ: 1.0–2.0 and 2.2–2.7 (m, 11H, C_6H_{11}), 3.75, 3.85 (s, 3H each, 2 MeO), 5.85 (s, 1H, bridge H), 5.92 (ABq, 2H, OCH_2O), 6.82, 6.87 (d, 2H, Ar); mass spectrum, *m/z* (assignment): 386 (M^+), 354 ($M^+ - CH_3OH$), 322 ($M^+ - 2CH_3OH$). *Anal.* calcd. for $C_{21}H_{22}O_7$: C 65.28, H 5.69; found C 65.26, H 5.70.

Compound D3

Diels–Alder reaction of **A3** with dimethylacetylenedicarboxylate in the presence of acetic acid of 100°C for 1 h gave naphthol **D3** in 62% yield, mp 167°C; ir (KBr): 1700, 1725 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz,) δ: 3.55, 3.85, 3.90, 3.92 (s, 3H each, 4 MeO), 6.05 (s, 2H, OCH_2O), 6.7–6.9 (m, 4H, Ar), 7.75 (s, 1H, Ar), 12.22 (s, 1H, OH); mass spectrum, *m/z* (assignment): 440 (M^+), 408 ($M^+ - CH_3OH$), 393 ($M^+ - CH_3OH - CH_3$). *Anal.* calcd. for $C_{23}H_{20}O_9$: C 62.72, H 4.54; found: C 62.66 H 4.60.

General procedure for the reaction of a variety of dienophiles with A5

The hydroxyacetal **A5**, glacial acetic acid, appropriate dienophile, and a suitable solvent were placed in a flask and refluxed to completion of the reaction. The flask was cooled and saturated bicarbonate added until the acetic acid was neutralized. The solvent was separated, dried (Na_2SO_4), and removed *in vacuo* to leave an oil.

Compound C5a

Acetal **A5** (0.55 g, 2.3 mmol), glacial acetic acid (0.2 mL) benzoquinone (2 equiv.), and CH_2Cl_2 (20 mL) were treated for 18 h as above. The addition of ether afforded a mixture (60%) of *endo/exo* (7:3) crystals which could not be separated. Analyses were done on the mixture; mp 10°C; ir ($CHCl_3$): 1675 (C=O), 1610 (C=C) cm^{-1}; mass spectrum, *m/z* (assignment): 286 (M^+), 278 (5,6-dimethoxyisobenzofuran). *Anal.* calcd. for $C_{16}H_{14}O_5$: C 67.12, H 4.93; found: C 67.01, H 5.09. The Hmr ($CDCl_3$, 80 MHz), endo adduct; δ: 3.65 (m, 2H, C(2), C(3)—H), 3.83 (s, 6H (2 × OCH_3) 5.68 (m, 2H, C(1), C(4)—H), 6.01 (s, 2H, —CH=CH—), 6.70 (s, 2H, Ar); exo adduct, δ: 2.80 (s, 2H, C(2), C(3)—H), 3.87 (s, 6H, 2 × OCH_3), 5.59 (s, 2H, C(1), C(4)—H) 6.80 (s, 2H, —CH=CH—), 6.90 (s, 2H, Ar).

Compound C5b

Acetal **A5** (0.5 g, 2 mmol), glacial acetic acid (0.2 mL), naphthaquinone (2.5 equiv.), and $CHCl_3$ (10 mL) were treated for 1 h as above. The excess naphthaquinone was removed on a column of silica gel using EtOAc/petrolum ether (1:1) as a solvent. The addition of ether to the resulting oil afforded the *endo* adduct but the *exo* adduct could not be isolated ^{1}Hmr showed the *endo/exo* ratio to be 3:1 and the yield was 86%. *Endo* Isomer: mp 215–217°C; ^{1}Hmr ($CDCl_3$, 80 MHz), δ: 3.63 (s, 6H, 2 × OCH_3), 3.8 (m, 2H, C(2), C(3)—H), 5.81 (m, 2H, C(1), C(4)—H), 6.63 (s, 2H, Ar), 7.47–7.85 (AA'BB' pattern, 4H, Ar); mass spectrum, *m/z* (assignment): 336 (M^+), 178 (5,6-dimethoxyisobenzofuran). *Anal.* calcd. for $C_{20}H_{16}O_5$: C 71,42, H 4.79; found: C 71.67, H 4.84.

Compound C5c

Acetal **A5** (4.3 g, 17.7 mmol), glacial acetic acid (1.9 mL), methyl vinyl ketone (3 equiv. freshly distilled, and 1% hydroquinone added as an inhibitor), and CCl_4 (100 mL) were heated t 60°C for 6 h. The addition of ether afforded *endo* crystals. The oil from the mother liquor was run through a gravity of column of silica gel using benzene/acetone (4:1). The faster spot (R_f = 0.52) afforded *endo*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

crystals and the slower spot (R_f = 0.50) *exo* crystals upon the addition of ether. The yield was 78% and the *endo/exo* ratio was 3:2. *Endo* Adduct: mp 129–131°C; ir ($CHCl_3$): 1710 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz), δ: 1.83 (dd, 1H, $J_{\alpha,3\beta}$ = 11.7, $J_{2,3\alpha}$ = 4.1 Hz, C(3α)—H), 1.99 (s, 3H, $COCH_3$), 2.22 (ddd, 1H, $J_{3\alpha,3\beta}$ = 11.7, $J_{2,3\beta}$ = 9.5, $J_{3\beta,4}$ = 4.6 Hz, C(3β)—H), 3.40 (ddd, 1H, $J_{1,2}$ = 5.1, $J_{2,3\alpha}$ = 4.1, $J_{2,3\beta}$ = 9.5 Hz, C(2)—H), 3.83, 3.86 (s, 3H each, 2 × OCH_3), 5.38 (d, 1H, $J_{3\beta,4}$ = 4.6 Hz, C(4)—H), 5.53 (d, 1H, $J_{1,2}$ = 5.1 Hz, C(1)—H), 6.79, 6.87 (s, 1H each, Ar); mass spectrum, *m/z* (assignment): 248 (M^+), 178 (5,6-dimethoxyisobenzofuran). *Anal.* calcd. for $C_{14}H_{16}O_4$: C 67.73, H 6.50; found: C 67.54, H 6.87. *Exo* Adduct: mp 88–90°C; ir ($CHCl_3$): 1710 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$ 80 MHz), δ: 1.66 (dd, 1H, $J_{3\alpha,3\beta}$ = 11.5, $J_{2,3\alpha}$ = 8.8 Hz, C(3α)—H), 2.88 (s, 3H, $COCH_3$), 2.29 (ddd, 1H, $J_{3\alpha,3\beta}$ = 11.5, $J_{3\beta,4}$ = 4.6, $J_{2,3\beta}$ = 4.4 Hz, C(3β)—H), 2.59 (dd, 1H, $J_{2,3\alpha}$ = 8.8, $J_{2,3\beta}$ = 4.4 Hz, (C(2)—H), 3.87 (s, 6H, 2 × OCH_3), 5.43 (d, 1H, $J_{3\beta,4}$ = 4.6 Hz, C(4)—H), 5.50 (s, 1H, C(1)—H), 6.89 (s, 2H, Ar); mass spectrum, *m/z* (assignment): 248 (M^+), 178(5,6-dimethoxyisobenzofuran): *Anal.* calcd. for $C_{14}H_{16}O_6$: C 67.73, H 6.50; found C 67.76, H 6.62.

*Compound C*5e

Acetal A5 (0.5 g, 2 mmol), glacial acetic acid (0.5 mL), acrylonitrile (6 equiv., freshly distilled, and 1% hydroquinone added as an inhibitor), and $CHCl_3$ (5 mL) were treated as above for 4 h. The addition of ether to the oil afforded *endo* crystals (64%). The ^{1}Hmr showed an *endo/exo* ratio 9:1 and the *exo* adduct could not be isolated. *Endo* Adduct: mp 184–187°C; ir ($CHCl_3$): 2200 (CN) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz), δ: 1.61 (dd, 1H, $J_{3\alpha,3\beta}$ = 11.6, $J_{2,3\alpha}$ = 4.03 Hz, C(3α)—H), 2.52 (ddd, 1H, $J_{3\alpha,3\beta}$ = 11.6, $J_{2,3\beta}$ = 10.6, $J_{3\beta,4}$ = 4.15 Hz, C(3β)—H), 3.19 (ddd, 1H, $J_{1,2}$ = 4.15, $J_{2,3\alpha}$ = 4.03, $J_{2,3\beta}$ = 10.6 Hz, C(2)—H), 3.88 (s, 6H, 2 × OCH_3), 4.57 (t, 2H, $J_{1,2}$ = $J_{3\beta,4}$ = 4.15, C(1) and C(4)—H), 6.91, 7.05 (s, 1H each, Ar); mass spectrum, *m/z* (assignment): 231 (M^+), 178 (5,6-dimethoxyisobenzofuran). *Anal.* calcd. for $C_{13}H_{13}NO_3$: C 67.52, H 5.67, N 6.06; found: C 67.35, H 5.72, N 6.12.

*Compound C*5f

Acetal A5 (0.5 g, 2.0 mmol), glacial acetic acid (0.2 mL), α-chloroacrylonitrile (0.5 mL), and CH_2Cl_2 (10 mL) were treated as above for 18 h. The oil was run through a silica gel column, but failed to crystallize upon the addition of ether (70%). There was a major and minor isomer (7:3) but the stereochemistry could not be determined; ir ($CHCl_3$): 1205 (C—O) cm^{-1}; mass spectrum, *m/z* (assignment): 265 (M^+), 178 (5,6-dimethoxyisobenzofuran). The ^{1}Hmr ($CDCl_3$, 80 MHz), minor isomer, δ: 2.39 (d, 1H, $J_{3\alpha,3\beta}$ = 12.9 Hz, C(3β)—H), 2.75 (dd, 1H, $J_{3\alpha,3\beta}$ = 12.9, $J_{3\alpha,4}$ = 4.4 Hz, C(3α)—H), 3.91, 3.94, (s, 3H each 2 × OCH_3), 5.4–5.6 (m, 2H, C(1), C(4)—H), 7.13, 7.40 (s, 1H each, Ar); major isomer, δ: 1.84 (d, 1H, $J_{3\alpha,3\beta}$ = 12.7 Hz, C(3β)—H), 3.10 (dd, 1H, $J_{3\alpha,3\beta}$ = 12.7, $J_{3\alpha,4}$ = 4.9 Hz, C(3α)—H), 3.87 (s, 6H, 2 × OCH_3), 5.4–5.6 (m, 2H, C(1) and C(4)—H), 6.90, 7.05 (s, 1H each Ar).

Compound C5h

Acetal A5 (0.5 g, 2.0 mmol), glacial acetic acid (0.5 mL), methyl acrylate (3 equiv., freshly distilled, and 1% hydroquinone added as an inhibitor), and $CHCl_3$ (10 mL) were treated as above for 10 h. Addition of ether afforded the *endo* isomer. Attempts to isolate the *exo* isomer were unsuccessful. The *endo/exo* ratio was 3:2 and the yield was 50%. *Endo* Adduct: mp 105–107°C; ir ($CHCl_3$): 1740 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz), δ: 1.74 (dd, 1H, $J_{3\alpha,3\beta}$ = 11.6, $J_{2,3\alpha}$ = 3.8 Hz, C(3α)—H), 2.31 (ddd, 1H, $J_{3\alpha,3\beta}$ = 11.6, $J_{3\beta,4}$ = 5.16, $J_{2,3\beta}$ = 10.3 Hz, C(3β)—H), 3.4 (ddd, 1H, $J_{1,2}$ = 5.16, $J_{2,3\alpha}$ = 3.8, $J_{2,3\beta}$ = 10.3 Hz, C(2)—H), 3.52 (s, 3H, —CO_2CH_3), 3.82, 3.85 (s, 3H each, 2 × OCH_3), 5.39 (d, 1H, $J_{3\beta,4}$ = 5.16 Hz, C(4)—H), 5.50 (d, 1H, $J_{1,2}$ = 5.16 Hz, C(1)—H), 6.8, 6.85 (s, 1H each, Ar); mass spectrum, *m/z* (assignment): 264 (M^+), 178 (5,6-dimethoxyisobenzofuran). *Anal.* calcd. for $C_{14}H_{16}O_5$: 63.63, H 6.10; found: C 63.24, H 6.32.

*Compound C*5i

Acetal A5 (1.02 g), glacial acetic acid (0.41 mL), acrolein (1.14 mL), and $CHCl_3$ (10 mL) were treated as above for 30 h. The addition of ether afforded *endo* crystals. The oil from the mother liquor was placed on a silica gel column. The faster spot (R_f = 0.55) gave *endo* crystals and the slower spot (R_f = 0.52) *exo* crystas upon the addition of ether (63%; *endo/exo* ratio 3:2). *endo* Adduct:: mp 103–104°C; ir (KBr): 1720 C=O), 2720 (CHO) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz), see Table 3. High resolution ms calcd. for $C_{13}H_{14}O_4$: 234.0892; found: 234.0884. *exo* Adduct: mp 73–74°C; ir (KBr):1715 (C=O), 2710 (CHO) cm^{-1}; ^{1}Hmr ($CDCl_3$, 400 MHz), see Table 3. High resolution ms calcd. for $C_{13}H_{14}O_4$: 234.0892; found: 234.0903.

*Compound C*5d

Into a refluxing solution of 2-butenolide (0.4 g, 4.75 mmol) and $CHCl_3$ (10 mL) was added a mixture of acetal A5 (0.46 g, 1.9 mmol), glacial acetic acid (0.2 mL), and $CHCl_3$ (10 mL). After 48 h at reflux, the resolution was cooled and saturated bicarbonate added until the acetic acid was neutralized. The $CHCl_3$ was separated, dried (Na_2SO_4), and removed *in vacuo* to leave an oil. The excess butenolide was removed *via* a high vacuum distillation. The remaining oil was passed through a silica gel column. The faster spot (R_f = 0.6) gave *exo* crystals and the slower (R_f = 0.53) *endo* crystals upon the addition of ether/CH_2Cl_2. The yield was 72% and the *endo/exo* ratio was 1:2 *exo* Aduct. mp 177–178°C; ir ($CHCl_3$): 1765 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz), δ: 2.6–3.0 (m, 2H, C(2) and C(3)—H), 3.85 (s, 6H, 2 × OCH_3), 4.2–4.8 (m, 2H, —CH_2O—), 5.29 (s, 1H, C(4)—H), 5.65 (s, 1H, C(1)—H), 6.87, 6.92 (s, 1H each, Ar); mass spectrum, *m/z* (assignment): 262 (M^+), 178 (5,6-dimethoxyisobenzofuran). *Anal.* calcd. for $C_{14}H_{14}O_5$: C 64.12, H 5.38; found C 63.91, H 5.33. *endo* Adduct: mp 184–185°C; ir ($CHCl_3$): 1765 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz), δ: 3.4–4.3 (m, 4H, C(2,3) and —CH_2O—), 3.85, 3.87 (s, 3H each, 2 × OCH_3), 5.4 (d, 1H, $J_{3,4}$ = 5.1 Hz, C(4)—H), 5.59 (d, 1H, $J_{1,2}$ = 5.02 Hz, C(1)—H), 6.93 (s, 2H, Ar); mass spectrum, *m/z* (assignment): 262 (M^+), 178 (5,6-dimethoxyisobenzofuran). *Anal.* calcd. for $C_{14}H_{14}O_5$: C 64.12, H 5.38; found: C 63.80, H 5.28.

*Compound C*5g

To a mixture of acetal A5 (0.5 g, 2.0 mmol) and glacial acetic acid (0.2 mL) was added acetic anhydride (0.1 mL) and maleic anhydride (0.6 g, 6.1 mmol) in CH_2Cl_2 (5 mL). The mixture was refluxed 24 h, cooled, and saturated bicarbonate added until neutral. The CH_2Cl_2 was dried (Na_2SO_4) and removed *in vacuo* to leave an oil. The addition of ether resulted in a mixture of *endo/exo* (7:3) crystals (60%) which could not be separated. Analyses were done on the mixture: mp 214–217°C; ir (KBr): 1760–1850 (C=O) cm^{-1}; mass spectrum, *m/z* (assignment): 276 (M^+), 178 (5,6-dimethoxyisobenzofuran). *Anal.* calcd. for $C_{14}H_{12}O_6$: C 60.87, H 4.38; found: C 60.53, H 4.52. The ^{1}Hmr ($CDCl_3$, 80 MHz), *endo* isomer; δ: 3.87 (s, 6H, 2 × OCH_3), 4.00 (m, 2H, C(2) and C(3)—H), 5.70 (m, 2H, C(1) and C(4)—H), 6.90 (s, 2H, Ar); *exo* isomer; δ: 3.20 (s, 2H, C(2) and C(3)—H), 3.87 (s, 6H, 2 × OCH_3), 5.85 (s, 2H, C(1) and C(4)—H), 6.96 (s, 2H, Ar).

Acknowledgements

We thank the Natural Sciences and Engineering Research Council for support of this work. The assistance of K. Hallman in the preparation of adducts B9 and B10 is also acknowledged. The 400 MHz spectra were obtained at the South-Western Ontario NMR Centre, funded by a major installation grant from NSERC Canada.

A short synthesis of (±)-2-alkylthiocarbapen-2-em-3-carboxylic acid (**2**) from sorbic acid via a key intermediate **4** is described.

YASUTSUGU UEDA, CHRISTOPHER E. DAMAS et BERNARD BELLEAU. Can. J. Chem. **61**, 1996 (1983).

On décrit une synthèse courte de l'acide (±)-alkyl-2-thiocarbapenem-2-carboxylique-3 (**2**) à partir de l'acide sorbique via l'intermédiaire-clé **4**.

[Traduit par le journal]

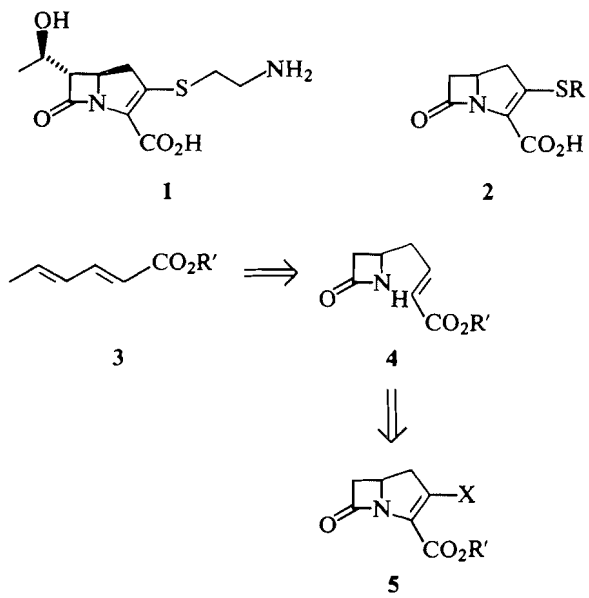
The discovery of thienamycin **1** (1), a potent and broad spectrum β-lactam antibiotic, has initiated considerable effort in the synthesis of the carbapenem ring system (2). Several methods have recently been developed for the synthesis of thienamycin (3) and its 6-unsubstituted analogs (4). Some of these methods (4) require long synthetic sequences or the starting materials are not readily available. We wish to report a short synthesis of 6-unsubstituted 2-alkylthiocarbapen-2-em-3-carboxylic acid (**2**) from an inexpensive starting material, sorbic acid (**3***a*), through a key intermediate **4**.[3] The carbon skeleton necessary for the synthesis of a carbapenem nucleus such as **5** is built-in to this intermediate.



1 **2** **3** **4** **5**

Thus, methyl sorbate (**3***b*) was converted to methyl 3,5-hexadienoate (**6***a*) in 77% yield by kinetic protonation of the enolate generated with lithium diisopropylamide at −78°C in THF–HMPA (6). *p*-Nitrobenzyl 3,5-hexadienoate (**6***b*) was prepared from sorbic acid (**3***a*) as follows: since *p*-nitrobenzyl esters generally suffer from treatment with a strong base such as LDA, sorbic acid (**3***a*) was converted to 3,5-hexadienoic acid (**6***c*) by kinetic protonation of the enolate generated at −10°C with 2 equiv. of LDA in THF (7). This acid was immediately esterified at 0–5°C with *p*-nitrobenzyl bromide and triethylamine to obtain *p*-nitrobenzyl 3,5-hexadienoate (**6***b*) in 65.7% overall yield from sorbic acid (**3***a*).

Addition of chlorosulfonyl isocyanate (8) to these conjugated dienes **6***a* and **6***b* at room temperature in CH_2Cl_2 cleanly provided azetidinone sulfonyl chlorides **7***a* and **7***b* which were, without isolation, reduced by a modification (Na_2SO_3–$NaHCO_3$) of the Durst method (9) to yield azetidinones **8***a* and **8***b* in 63% and 49% yield, respectively. Use of NaOH instead of $NaHCO_3$ caused destruction of the molecule. Isomerization of the double bond in **8***a* to the conjugated system **4***a* was studied in various base–solvent systems. Triethylamine in CH_2Cl_2 did not effect the isomerization at an appreciable rate at room temperature. Triethylamine in polar aprotic solvents, such as DMSO, DMF, or CH_3CN, gave, after weeks, the desired isomerization product **4***a* together with a white solid which consisted of β-lactam opened products.[4]

These fragmentation materials were the major products when **8***a* was treated with strong bases such as 1,5-diazabicyclo[4.3.0]non-5-ene (DBN) in CH_2Cl_2, sodium methoxide in MeOH, or potassium *tert*-butoxide in *t*-BuOH. The best result was obtained by using 1,4-diazabicyclo[2.2.2.]octane (DABCO) in CH_3CN at room temperature. Thus, **8***a* and **8***b* were treated with DABCO in CH_3CN at room temperature for 3–4 days to produce the conjugated esters **4***a* and **4***b* in 87% and 73% yield, respectively.

Although intermediates **4** could be used, after protection of

[1]For Part XVII of this series see ref. 14.

[2]Author to whom correspondence should be addressed.

[3]After a major part of this work was completed, the Smith Kline & French group described a similar approach in their recent publication (5).

[4]These by-products were tentatively characterized as a mixture of **i** and **ii** based on the ^{1}Hmr spectrum, which exhibited two different methyl signals at around 3.7 ppm, and the uv spectrum, which showed a λ_{max} at 256 nm. These were presumably formed by proton abstraction, followed by the ring opening as shown in **iii** and/or **iv**, and then isomerization to each other.

the amide, for the synthesis of carbapenems[5] by oxidation of the double bond to the aldehyde **9** (*4a*, *g*) or the carboxylic acids **10** (*3d*, *4d–f*), since they contain the carbon framework needed for the synthesis of carbapenem carboxylates, we decided to use this advantage without breaking down the molecule.

Conversion of α, β-unsaturated esters **4***a*, and **4***b* to β-keto esters **11***a* and **11***b* was readily achieved in 30% and 36% yield, respectively, by the oxypalladation method (*t*-BuOOH/$NaPdCl_4$) which was recently developed by Tsuji *et al.* (10) and employed in the synthesis of a carbapenem intermediate (*4g*). Teatment of β-keto ester **11***b* with *p*-carboxybenzenesulfonyl azide (11) gave diazo compound **12** in 88% yield, which was cyclized by $Rh_2(OAc)_4$, the Merck method (*4a*), to produce cleanly the bicyclic β-keto ester **13**. Transformation of this type of keto ester to 2-alkylthiocarbapenem was reported by the Merck group (*4a*). One example is demonstrated here. Thus **13**, treated with diphenyl chlorophosphate (diisopropylethylamine/CH_3CN, 0°C), gave enol phosphate **14** which was, without isolation, converted to 2-benzylthiocarbapenem **15** in 34% yield by reaction with benzyl mercaptan in the presence of diisopropylethylamine. Catalylic hydrogenolysis of **15** (H_2/Pd–C, $KHCO_3$) afforded carbapenem potassium salt **16**, the presence of which was confirmed by an ir absorption band at 1765 cm^{-1} and its uv spectrum (λ_{max} 299 nm). Due to the instability of this type of molecule (*4c–e*), we were unable to isolate it in a pure form.

This approach offers the following advantages over the methods previously reported. (a) The starting material is commercially available and inexpensive. (b) A variety of carboxylic acid protecting groups, particularly the *p*-nitrobenzyl group, can be easily introduced: *p*-nitrobenzyl ester is most commonly used in the penem or carbapenem synthesis since it can be cleaved to the corresponding carboxylic acid by catalytic hydrogenolysis without destruction of the labile ring system. (c) Since all the necessary carbon skeleton is constructed in one step, this is the most direct route known so far to the carbapenem ring system.

Experimental

Melting points were determined on a Gallenkamp melting point apparatus and are not corrected. The infrared spectra were recorded on a Perkin–Elmer 267 grating infrared spectrometer. The ^1H nuclear magnetic resonance spectra were taken with either the Varian EM-360 (60 MHz) or a Varian CFT-20 (80 MHz) nmr spectrometer. Tetramethylsilane (for solutions other than D_2O) and sodium 4,4-dimethyl-4-silapentane-1-sulfonate (for solutions of D_2O) were used as internal standards and chemical shifts are reported in parts per million (δ) relative to the internal standards. The ultraviolet spectra were recorded on an Unicam SP8-100 uv spectrophotometer. Tetrahydrofuran was freshly distilled from lithium aluminum hydride. Anhydrous diethyl ether (Mallinkrodt or Fisher) was used without further treatment. All other solvents were reagent grade and had been stored over molecular sieves before use. n-Butyllithium (n-BuLi) in hexane (Aldrich) was titrated periodically by the diphenylacetic acid method. Triethylamine, diisopropylamine, and diisopropylethylamine were distilled from CaH_2 and stored over NaOH. Analytical thin layer chromatography (tlc) was conducted on precoated plates (Silica Gel 60F-254, E. Merck). Visualization was effected by uv light and iodine. Preparative layer chromatography (plc) was performed on silica gel plates prepared from Silica Gel 60 GF-254 (E. Merck). For column chromatography, 70–230 mesh Silica Gel 60 (E. Merck) was

[5]The versatility of this type of intermediate **4** in the synthesis of carbapenems will be reported in a forthcoming paper.

used. The analyses were performed by Micro-Tech Laboratories, Skokie, Illinois, U.S.A. The abbreviations for ^{1}Hmr multiplicities are used as follows: s, singlet; d, doublet; dd, doublet of doublets; ddd, doublet of doublet of doublets; t, triplet, dt, doublet of triplets; td, triplet of doublets; m, multiplet; br, broad.

*Methyl 2,4-hexadienoate (methyl sorbate) (**3**b)*

Through a stirred suspension of 2,4-hexadienoic acid (**3***a*) (sorbic acid; 112 g, 1.00 mol) in methanol (0.5 L) was bubbled dry hydrogen chloride gas for 5 min, and then the mixture was heated at reflex for 4 h. After cooling, the methanol was evaporated *in vacuo* and the residual oil was diluted with CH_2Cl_2 (0.4 L), removing water which separated out. The CH_2Cl_2 solution was washed carefully with saturated $NaHCO_3$ and then brine, dried (Na_2SO_4), and evaporated. The residue was distilled under reduced pressure to obtain 98.5 g (0.782 mol, yield 78.2%) of the title compound **3***b* as a colourless liquid; bp 69°–71°C/12 Torr (lit. (12) bp 60°C/12 Torr); ir (neat) ν_{max}: 1720 (C=O), 1650 (C=C), and 1620 (C=C) cm^{-1}; R_f 0.72 (Et_2O); ^{1}Hmr ($CDCl_3$) δ: 1.87 (3H, d, J = 5 Hz, 5-Me), 3.74 (3H, s, —CO_2Me), 5.6–6.5 (3H, m, olefinic protons), and 7.05–7.5 (1H, m, 5-H) ppm.

*Methyl 3,5-hexadienoate (**6**a)*

To a stirred solution of diisopropylamine (85 mL, 0.61 mol) in THF (1.4 L) was added, at 0°–5°C under a nitrogen atmosphere, n-BuLi (396 mL, 0.61 mol; 1.54 *M* in hexane) over a period of 45 min. The resulting pale yellow solution was stirred at 0°–5°C for 15 min and then cooled to −75° to −78°C. A solution of hexamethylphosphoramide (115 mL, 0.66 mol) in THF (30 mL) was added in 30 min, and stirring continued for 30 min. To this mixture was added a solution of methyl 2,4-hexadienoate (**3***b*) (64.0 g, 0.508 mol; methyl sorbate) in THF (30 mL) during a period of 1 h at −78°C and stirred for 30 min. The dark red mixture was poured into 2 *N* HCl (900 mL) with stirring. The mixture was extracted with pentane (200 mL × 3) and these extracts combined, washed successively with H_2O (600 mL × 3), saturated $NaHCO_3$ (600 mL) and brine (600 mL), dried (Na_2SO_4), and evaporated to a yellow oil. This was distilled under reduced pressure to give 49.0 g (0.389 mol, yield 76.6%) of the title compound **6***a* as a clear liquid: bp 58°–60°C/12 Torr (lit. (6*b*) bp 73°–75°C/12 Torr); ir (neat) ν_{max}: 1735 (C=O) and 1640 (C=C) cm^{-1}; R_f 0.67 (benzene–Et_2O 4:1); ^{1}Hmr ($CDCl_3$) δ: 3.12 (2H, d, J = 6 Hz, —CH_2—), 3.69 (3H, s, —CO_2Me), 5.14 (2H, t, J = 8 Hz, olefinic protons), and 5.5–6.7 (3H, m, olefinic protons) ppm.

p-*Nitrobenzyl 3,5-hexadienoate (**6**b)*

To a stirred solution of diisopropylamine (76.5 mL, 0.55 mol) in THF (0.5 L) was added at 0°–5°C n-BuLi (344 mL, 0.55 mol; 1.6 *M* in hexane), over a period of 0.5 h under a nitrogen atmosphere, and stirred at 0°–5°C for 0.5 h. To this was added at −15° to −10°C a solution of 2,4-hexadienoic acid (**3***a*) (28.0 g, 0.25 mol) in THF (125 mL) over a period of 0.5 h. The cooling bath was removed and the mixture stirred at room temperature for 1 h. This was poured into a cold solution of concentrated HCl (125 mL) in water (500 mL). The aqueous layer was saturated with sodium chloride and extracted with EtOAc (150 mL × 3). All organic layers were combined, washed with brine (200 mL × 2), dried ($MgSO_4$), and evaporated, yielding 29.0 g of 3,5-hexadienoic acid as a crude oil: bp 61°–63°C/0.2 Torr (lit. (13) bp 102°–103°C/6 Torr); ir (neat) ν_{max}: 2500–3500 (br, CO_2H) and 1710 (CO_2H) cm^{-1}; R_f 0.57 (Et_2O); ^{1}Hmr ($CDCl_3$) δ: 3.15 (2H, d, J = 6 Hz, 2-H) and 5–6.7 (5H, m, olefinic protons) ppm. The distilled material polimerized on standing.

To a solution of this crude material (29.0 g) in DMF (250 mL) was added at 0°–5°C *p*-nitrobenzyl bromide (54.0 g, 0.25 mol) followed by triethylamine (34.75 mL, 0.25 mol). The mixture was stirred at 0°–5°C overnight (ca. 18 h). This was poured into cold water (1 L) and extracted with EtOAc (250 mL × 2), then brine (250 mL), dried ($MgSO_4$), and evaporated to yield 52.7 g of a brown oil. A major portion (30.88 g) of this crude oil was purified[6] by column chromatography (600 g, Et_2O–hexanes 1:4) to obtain 25.28 g of a yellowish oil which was crystallized from Et_2O–pentane (1:2, 15 mL) to give 23.78 g (96.3 mmol, yielded 65.7% based on 2,4-hexadienoic acid) of the title compound **6***b* as pale yellow crystals: mp 40°–41°C; ir (film) ν_{max}: 1740 (C=O), 1525 and 1350 (NO_2) cm^{-1}; R_f 0.46 (Et_2O–hex 1:1); ^{1}Hmr ($CDCl_3$) δ: 3.22 (2H, J = 6 Hz, 2-H), 5.23 (2H, s, —CO_2CH_2Ar), 5.0–6.7 (5H, m, olefinic protons), 7.48 (2H, d, J = 9 Hz, aromatic protons), and 8.16 (2H, d, J = 9 Hz, aromatic protons) ppm. *Anal.* calcd. for $C_{13}H_{13}NO_4$: C 63.15, H 5.30, N 5.67; found: C 63.02, H 5.32, N 5.56.

*Methyl 4-(2-azetidinon-4-yl)-3-butenoate (**8**a)*

To a stirred solution of methyl 3,5-hexadienoate (**6***a*) (48.85 g, 0.388 mol) in CH_2Cl_2 (1.2 L) was added, at 0°–5°C under a nitrogen atmosphere, chlorosulfonyl isocyanate (38.0 mL, 0.430 mol) in 15 min. The mixture was stirred at room temperature for 21 h. A small portion (1 mL) of the reaction mixture was added to a mixture of cold water (3 mL) and CH_2Cl_2 (3 mL), and the CH_2Cl_2 layer was dried (Na_2SO_4) and evaporated to yield methyl 4-(*N*-chlorosulfonyl-2-azetidinon-4-yl)-3-butenoate (**7***a*) as a yellowish oil: ir (neat) ν_{max}: 1815 (β-lactam) and 1730 (ester) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 3.07 (1H, dd, J_{gem} = 16 Hz, $J_{3-4\,trans}$ = 4 Hz, 3-H_b), 3.20 (2H, d, J = 6 Hz), 3.55 (1H, dd, J_{gem} = 16 Hz, $J_{3-4\,cis}$ = 6 Hz, 3-H_a), 3.70 (3H, s, —CO_2Me), 4.80 (1H, m, 4-H), 5.5–6.4 (2H, m, olefinic protons) ppm. The rest of the reaction mixture was added slowly to a mechanically stirred slurry of sodium sulfite (242 g, 1.93 mol) in water (0.5 L), ice (0.6 L), and CH_2Cl_2 (0.5 L) at 0°–5°C. During the addition, the mixture was maintained at a pH of 7–8 by addition of saturated $NaHCO_3$ (total 1.8 L). The foaming, milky reaction mixture thus obtained was warmed to room temperature during 1.5 h. The organic layer was collected and the aqueous layer saturated with NaCl and then extracted with CH_2Cl_2 (×2). The combined organic layers were washed with brine, dried ($MgSO_4$), and evaporated to yield 66.0 g of milky yellow oil, which was purified[6] by column chromatography (1.2 kg, EtOAc) to obtain 41.3 g (0.244 mol, yield 63.0%) of the title compound **8***a* as a colourless oil: bp 126°–130°/0.01 Torr; ir (neat) ν_{max}: 3280 (NH), 1760–1730 (br, β-lactam and ester), 1670 (C=C), and 970 (*trans*-disubstituted olefin) cm^{-1}; R_f 0.32 (EtOAc); ^{1}Hmr ($CDCl_3$, 80 MHz) δ: 2.70 (1H, ddd, J_{gem} = 14.9 Hz, $J_{3'-4'\,trans}$ = 2.6 Hz, $J_{3'-1'}$ = 1.3 Hz, 3'-H_b), 3.11 (2H, d, J = 5.7 Hz, —CH_2CO_2—), 3.23 (1H, ddd, J_{gem} = 14.9 Hz, $J_{3'-4'\,cis}$ = 5.1 Hz, $J_{3'-1'}$ = 2.2 Hz, 3'-Ha), 3.69 (3H, s, —CO_2Me), 4.15 (1H, m, 4'-H), 5.5–6.1 (2H, m, olefinic protons), and 5.8 (br, 1'-H) ppm. *Anal.* calcd. for $C_8H_{11}NO_3$: C 56.79, H 6.55, N 8.28; found: C 56.77, H 6.59, N 8.39.

p-*Nitrobenzyl 4-(2-azetidinon-4-yl)-3-butenoate (**8**b)*

To a stirred solution of *p*-nitrobenzyl 3,5-hexadienoate (**6***b*) (2.47 g, 10 mmol) in CH_2Cl_2 (30 mL) was added, at 0°–5°C under a nitrogen atmosphere, chlorosulfonyl isocyanate (0.98 mL, 11 mmol), and the mixture was stirred at room temperature for 3 days. A small portion (1 mL) of the reaction mixture was shaken with a mixture of water (5 mL) and CH_2Cl_2 (5 mL). The CH_2Cl_2 layer was dried (Na_2SO_4) and evaporated to yield *p*-nitronbenzyl 4-(*N*-chlorosulfonyl-2-azetidinon-4-yl)-3-butenoate as a yellowish oil: ir (neat) ν_{max}: 1825 (β-lactam), 1745 (ester), 1520, and 1350 (NO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz) δ: 3.08 (1H, dd, J_{gem} = 16.7 Hz, $J_{3'-4'\,trans}$ = 4.1 Hz, 3'-H_b), 3.28 (2H, d, J = 6.1 Hz, —CH_2CO_2—), 3.54 (1H, dd, J_{gem} = 16.7 Hz, 3'-H_a), 4.79 (1H, ddd, $J_{4'-4}$ = 7.5 Hz, $J_{4'-3'\,cis}$ = 6.5 Hz, $J_{4'-3'\,trans}$ = 4 Hz, 4-H), 5.23 (2H, s, —CO_2CH_2Ar), 5.6–6.4 (2H, m, olefinic protons), 7.50 (2H, d, J = 8.7 Hz, aromatic protons), and 8.21 (2H, d, J = 8.7 Hz, aromatic protons) ppm. The rest of the reaction mixture was added slowly at room temperature to a stirred mixture of sodium sulfite (12 g, 95 mmol), water (60 mL), and CH_2Cl_2 (60 mL). During the addition, the reaction mixture was maintained at a pH of 7–9 by simultaneous addition of saturated $NaHCO_3$ (70 mL). This was stirred for another 3 h, and the CH_2Cl_2 layer washed with brine, dried (Na_2SO_4), and evaporated *in vacuo*, yielding 1.99 g of a crude oil. This was purified by column chromatography (80 g, EtOAc) to yield 1.41 g (4.86 mmol, yield 48.6%)

[6]Distillation under reduced pressure caused serious decomposition.

of the title compound **8***b* as an oil which crystallized on standing: mp 85°–87°C (recrystallized from CH_2Cl_2–Et_2O); ir (film) ν_{max}: 1745 (β-lactam and ester), 1525, and 1350 (NO_2) cm^{-1}; R_f 0.32 (EtOAc); ^{1}Hmr ($CDCl_3$, 80 MHz) δ: 2.70 (1H, ddd, J_{gem} = 15 Hz, $J_{3'-4'trans}$ = 2.6 Hz, $J_{3'-1'}$ = 1.3 Hz, 3′-H_b), 3.19 (2H, d, J = 5.4 Hz, —CH_2CO_2—), 3.23 (1H, ddd, J_{gem} = 15 Hz, $J_{3'-4'cis}$ = 5 Hz, $J_{3'-1'}$ = 2.2 Hz, 3′-H_a), 4.16 (1H, m, 3′-H), 5.22 (2H, s, —CO_2CH_2Ar), 5.5–6.1 (2H, m, olefinic protons), 7.51 (2H, d, J = 8.7 Hz, aromatic protons), and 8.23 (2H, d, J = 8.7 Hz, aromatic protons) ppm. *Anal.* calcd. for $C_{14}H_{14}N_2O_5$: C 57.93, H 4.86, N 9.65; found: C 57.61, H 4.79, N 9.57.

*Methyl 4-(2-azetidinon-4-yl)-2-butenoate (**4**a)*

A solution of methyl 4-(2-azetidinon-4-yl)-3-butenoate (**8***a*) (16.9 g, 0.100 mol) and 1,4-diazabicyclo[2.2.2]octane (22.4 g, 0.200 mol; DABCO) in CH_3CN (100 mL) was stirred at room temperature under a nitrogen atmosphere for 4 days. The solvent was evaporated at room temperature *in vacuo*, and the residue mixed with EtOAc (20 mL). The precipitates, formed were filtered and washed with cold EtOAc (20 mL). The filtrate and the washings were combined, evaporated, and the residual oil purified by column chromatography (300 g, EtOAc) to obtain 14.68 g, (86.9 mmol, yield 86.9%) of the title compound **4***a* as an amber coloured oil. This was crystallized from Et_2O at 0°C; mp 51°–52°C; ir ($CHCl_3$) ν_{max}: 3420 (NH), 1765 (β-lactam), 1720 (ester), and 1660 (C=C) cm^{-1}; R_f 0.32 (EtOAc); ^{1}Hmr ($CDCl_3$) δ: 2.55 (2H, dt, J = 6.8 Hz, J_{4-2} = 1.4 Hz, 4-H), 2.63 (1H, ddd, J_{gem} = 14.8 Hz, $J_{3'-4'trans}$ = 2.4 Hz, $J_{3'-1'}$ = 1.2 Hz, 3′-H_b), 3.14 (1H, ddd, J_{gem} = 14.8 Hz, $J_{3'-4'cis}$ = 4.8 Hz, $J_{3'-1'}$ = 2.2 Hz, 3′-H_a), 3.74 (3H, s, —CO_2Me), 3.5–3.8 (1H, m, 4′-H), 5.90 (1H, td, J_{2-3} = 16 Hz, J_{2-4} = 1.4 Hz, 2-H), 6.87 (1H, br, 1′-H), and 6.94 (1H, td, J_{3-2} = 16 Hz, J_{3-4} = 6.8 Hz, 3-H) ppm; *Anal.* calcd. for $C_8H_{11}NO_3$: C 56.79, H 6.55, N 8.28; found: C 57.00, H 6.49, N 8.13.

*Isomerization of **8**a with Et_3N in DMSO*

A mixture of methyl 4-(2-azetidinon-4-yl)-3-butenoate (**8***a*) (4.05 g, 24.0 mmol) and triethylamine (1.50 g, 15.0 mmol) in DMSO (24 mL) was stirred at room temperature for 18 days. The rection mixture was poured into a cold mixture of 1 *N* HCl (15 mL), water (85 mL), and CH_2Cl_2 (100 mL). The aqueous layer was saturated with sodium chloride and extracted with CH_2Cl_2 (35 mL × 3). All CH_2CH_2 layers were combined, washed with brine, dried (Na_2SO_4), and evaporated, yielding 3.83 g of crude oily solid. This was purified by column chromatography (60 g, MeOH–benzene 2:98) to obtain 2.12 g (12.5 mmol, yield 52.4%) of **4***a* as a colourless oil: R_f 0.33 (MeOH–benzene 1:4), and 1.32 g (7.81 mmol, yield 32.5%) of β-lactam opened materials **i** and **ii** as a white solid: mp 127°–133°C; ir (Nujol) ν_{max}: 3390, 3190 (—$CONH_2$), 1720 (ester) and 1645 (amide) cm^{-1}; uv (EtOH) λ_{max}: 256 nm (ε 26 000); R_f 0.22 (MeOH–benzene 1:4); ^{1}Hmr ($CHCl_3$, 80 MHz) δ: 3.14 (d, J = 5.7 Hz, —CH_2—), 3.21 (d, J = 5.2 Hz, —CH_2—), 3.70 (s, —CO_2Me), 3.74 (2, —CO_2Me), 5.5 (br, —$CONH_2$), 5.87 (d, J = 15.3 Hz, olefinic proton), 6.1–7.4 (m, olefinic protons) ppm.

*p-Nitrobenzyl 4-(2-azetidinon-4-yl)-2-butenoate (**4**b)*

A solution of *p*-nitrobenzyl 4-(2-azetidinon-4-yl)-3-butenoate (**8***b*) (1.16 g, 4.00 mmol) and 1,4-diazabicyclo[2.2.2]octane (900 mg, 8.00 mmol; DABCO) in CH_3CN (8 mL) was stirred at room temperature for 3 days. After evaporation of the solvent *in vacuo*, the residue, dissolved in EtOAc (40 mL), was washed with 1 *N* HCl (10 mL), then brine, dried (Na_2SO_4), and evaporated to yield 1.05 g of yellow solid. This was purified by column chromatography (50 g, EtOAc) to obtain 850 mg (2.93 mmol, yield 73.2%) of the title compound **4***b* as white crystals: mp 126°–128°C (recrystallized from EtOAc); ir (film) ν_{max}: 3200 (NH), 1755 (β-lactam), 1720 (ester), 1655 (C=C), 1510, and 1350 (NO_2) cm^{-1}; R_f 0.31 (EtOAc); ^{1}Hmr ($CDCl_3$, 80 MHz) δ: 2.57 (2H, dt, J = 7.1 Hz, J_{4-2} = 1.3 Hz, 4-H), 2.65 (1H, ddd, J_{gem} = 15 Hz, $J_{3'-4'trans}$ = 2.4 Hz, $J_{3'-1'}$ = 1 Hz, 3′-H_b), 3.15 (1H, ddd, J_{gem} = 15 Hz, $J_{3'-4'cis}$ = 5 Hz, $J_{3'-1'}$ = 2.3 Hz, 3′-H_a), 3.74 (1H, m, 4′-H), 5.27 (2H, s, —CO_2CH_2Ar), 5.97 (1H, td, J_{2-3} = 15.7 Hz, J_{2-4} = 1.3 Hz, 2-H), 6.97 (1H, dt, J_{3-2} = 15.6 Hz, J_{3-4} = 7.1 Hz, 3-H), 7.53 (2H, d, J = 8.7 Hz, aromatic protons), and 8.23 (2H, d, J = 8.7 Hz, aromatic protons) ppm. *Anal.* calcd. for $C_{14}H_{14}N_2O_5$: C 57.93, H 4.86, N 9.65; found: C 58.01, H 4.81, N 9.59.

*Methyl 4-(2-azetidinon-4-yl)-3-oxobutanoate (**11**a)*

To a mixture of sodium tetrachloropalladate (58 mg, 0.2 mmol) and *tert*-butyl hydroperoxide (193 mg, 1.5 mmol; 70% aqueous solution) in 50% aqueous HOAc (1 mL) was added a solution of methyl 4-(2-azetidinon-4-yl)-2-butenoate (**4***a*) (169 mg, 1.0 mmol) in 50% aqueous HOAc (1 mL), and the mixture was heated at 50°C for 10 h. The solvents were evaporated by a vacuum pump at 50°C and the residue was purified by plc (EtOAc) to yield 55 mg (0.30 mmol, yield 30%) of the title compound **11***a* as a yellowish oil: ir (neat) ν_{max}: 3320 (NH), 1745 (β-lactam and ester), and 1715 (C=O) cm^{-1}; R_f 0.20 (EtOAc); ^{1}Hmr ($CDCl_3$, 80 MHz) δ: 2.59 (1H, ddd, J_{gem} = 15 Hz, $J_{3'-4'trans}$ = 2.5 Hz, $J_{3'-1'}$ = 1 Hz, 3′-H_b), 2.77 (1H, dd, J_{gem} = 18 Hz, $J_{4-4'}$ = 8 Hz, 4-H_a), 3.08 (1H, dd, J_{gem} = 18 Hz, $J_{4-4'}$ = 4.6 Hz, 4-H_b), 3.16 (1H, ddd, J_{gem} = 15 Hz, $J_{3'-4'cis}$ = 5.0 Hz, $J_{3'-1'}$ = 2.4 Hz, 3′-H_a), 3.47 (2H, s, 2-H), 3.74 (3H, s, —CO_2Me), 3.9 (1H, m, 4′-H), and 6.15 (br, NH) ppm.

*p-Nitrobenzyl 4-(2-azetidinon-4-yl)-3-oxobutanoate (**11**b)*

To a mixture of sodium tetrachloropalladate (58 mg, 0.2 mmol) and *tert*-butyl hydroperoxide (193 mg, 1.5 mmol; 70% aqueous solution) in 50% aqueous HOAc (3 mL) was added a solution of *p*-nitrobenzyl 4-(2-azetidinon-4-yl)-2-butenoate (290 mg, 1.0 mmol) in 50% aqueous HOAc (3 mL) and the mixture was heated at 60°–65°C for 6 h. The resulting reddish mixture, diluted with EtOAc (30 mL), was neutralized by careful addition of saturated $NaHCO_3$ (ca. 50 mL). The organic layer was washed with brine, dried (Na_2SO_4), and evaporated to yield 187 mg of a crude oil. This was purified by column chromatography (10 g, EtOAc) to obtain 109 mg (0.356 mmol, yield 36%) of the title compound as a clear oil. This was crystallized by trituration with i-PrOH: mp 46°–48°C; ir (film) ν_{max}: 3300 (br, NH), 1745 (β-lactam and ester), 1715 (C=O), 1520, and 1350 (NO_2) cm^{-1}; R_f 0.19 (EtOAc); ^{1}Hmr ($CDCl_3$, 80 MHz) δ: 2.59 (1H, ddd, J_{gem} = 15 Hz, $J_{3'-4'trans}$ = 2.5 Hz, $J_{3'-1'}$ = 1 Hz, 3′-H_b), 2.77 (1H, ddd, J_{gem} = 18 Hz, $J_{4-4'}$ = 8 Hz, 4-H_a), 3.08 (1H, dd, J_{gem} = 18 Hz, $J_{4-4'}$ = 5 Hz, 4-H_b), 3.18 (1H, ddd, J_{gem} = 15 Hz, $J_{3'-4'cis}$ = 5 Hz, $J_{3'-1'}$ = 2.5 Hz, 3′-H_a), 3.55 (2H, s, 2-H), 3.93 (1H, m, 4′-H), 5.27 (2H, s, —CO_2CH_2Ar), 6.0 (br, NH), 7.52 (2H, d, J = 8.7 Hz, aromatic protons), and 8.24 (2H, J = 8.7 Hz, aromatic protons) ppm. *Anal.* calcd. for $C_{14}H_{14}N_2O_6$: C 54.90, H 4.61, N 9.15; found: C 54.70, H 4.80, N 9.06.

*p-Nitrobenzyl 4-(2-azetidinon-4-yl)-3-oxo-2-diazobutanoate (**12**)*

To a mixture of *p*-nitrobenzyl 4-(2-azetidinon-4-yl)-3-oxobutanoate (**11***b*) (1.38 g, 4.51 mmol) and *p*-carboxybenzenesulfonyl azide (1.27 g, 5.59 mmol) in CH_3CN (30 mL) was added, at 0°–5°C under a nitrogen atmosphere, Et_3N (2.70 mL, 19.4 mmol), causing dissolution followed by precipitation. The mixture was diluted with CH_3CN (15 mL) and stirred at room temperature for 30 min. The precipitate was filtered and washed with EtOAc. The filtrate and washings were combined and evaporated to yield 2.0 g of a greenish oil. This was purified by column chromatography (160 g, EtOAc) to give 1.32 g (3.97 mmol, yield 88.1%) of the title compound **12** as yellowish crystals: mp 109°–110°C (recrystallized from EtOAc); ir (film) ν_{max}: 3370 (NH), 2140 (C=N_2), 1760 (β-lactam), 1720 (ester), 1650 (C=O), 1520, and 1350 (NO_2) cm^{-1}; R_f 0.41 (EtOAc); ^{1}Hmr ($CDCl_3$, 80 MHz) δ: 2.65 (1H, ddd, J_{gem} = 15 Hz, $J_{3'-4'trans}$ = 2.5 Hz, $J_{3'-1'}$ = 1 Hz, 3′-H_b), 2.99 (1H, dd, J_{gem} = 18 Hz, $J_{4-4'}$ = 8.5 Hz, 4-H_a), 3.17 (1H, ddd, J_{gem} = 15 Hz, $J_{3'-4'cis}$ = 5 Hz, $J_{3'-1'}$ = 2.4 Hz, 3′-H_a), 3.38 (1H, dd, J_{gem} = 18 Hz, $J_{4-4'}$ = 4.4 Hz, 4-H_b), 3.95 (1H, m, 4′-H), 5.35 (2H, s, —CO_2CH_2Ar), 6.07 (br, NH), 7.53 (2H, d, J = 8.8 Hz, aromatic protons), and 8.25 (2H, d, J = 8.8 Hz, aromatic protons) ppm; *Anal.* calcd. for $C_{14}H_{12}N_4O_6$: C 50.61, H 3.64, N 16.86; found: C 50.72, H 3.81, N 16.80.

*p-Nitrobenzyl 2-oxocarbapenam-3-carboxylate (**13**)*

Through a suspension of *p*-nitrobenzyl 4-(2-azetidinon-4-yl)-3-oxo-

2-diazobutanoate (49 mg, 0.15 mmol) and $Rh_2(OAc)_4$ (0.1 mg) in benzene (2 mL) was bubbled dry nitrogen for 10 min, and this mixture was heated at gentle reflux under a nitrogen atmosphere for 30 min. The catalyst was filtered and washed with EtOAc. The filtrate and washings were cobmined and evaporated to yield a crude oil which was purified by column chromatography (short column, EtOAc) to obtain 37 mg (0.12 mmol, yield 81%) of the title compound **13** as an oil: ir (film) ν_{max}: 1765 (β-lactam), 1745 (ester and ketone), 1520, and 1350 (NO_2) cm^{-1}; R_f 0.60 (EtOAc); ^{1}Hmr ($CDCl_3$, 80 MHz) δ: 2.40 (1H, dd, J_{gem} = 19 Hz, J_{1-5} = 8 Hz, 1-H_a), 2.94 (1H, dd, J_{gem} = 19 Hz, J_{1-5} = 6.2 Hz, 1-H_b), 2.96 (1H, dd, J_{gem} = 16 Hz, $J_{6-5\,trans}$ = 2 Hz, 6-H_b), 3.67 (1H, dd, J_{gem} = 16 Hz, $J_{6-5\,cis}$ = 5 Hz, 6-H_a), 4.15 (1H, m, 5-H), 4.77 (1H, s, 3-H), 5.30 (2H, s, —CO_2CH_2Ar), 7.53 (2H, d, J = 8.8 Hz, aromatic protons), and 8.24 (2H, d, J = 8.8 Hz, aromatic protons) ppm.

p-*Nitrobenzyl 2-benzylthiocarbapen-2-em-3-carboxylate (15)*

To a stirred solution of freshly prepared *p*-nitrobenzyl-2-oxo-carbapenam-3-carboxylate (**13**) (151 mg, 0.496 mmol) in CH_3CN (10 mL) was added, at 0°–5°C under a nitrogen atmosphere, diisopropylethylamine (0.095 mL, 0.55 mmol), followed by diphenyl chlorophosphate (0.11 mL, 0.55 mmol). The mixture was stirred at 0°–5°C for 30 min, by which time the tlc (EtOAc–hex 1:1) indicated that the reaction was over. The enol phosphate **14** could be isolated as an off-white solid: mp 105°–111°C (dec.); ir (film) ν_{max}: 1790 (β-lactam), 1730 (ester), and 1640 (C=C) cm^{-1}; R_f 0.20 (EtOAc–hex 1:1); ^{1}Hmr ($CDCl_3$, 80 MHz) δ: 2.96 (1H, dd, J_{gem} = 17 Hz, $J_{6-5\,trans}$ = 3 Hz, 6-H_b), 3.0–3.3 (2H, m, 1-H), 3.55 (1H, dd, J_{gem} = 17 Hz, $J_{6-5\,cis}$ = 5.5 Hz, 6-H_a), 4.15 (1H, m, 5-H), 5.20 (1H, d, J = 13.8 Hz, —CO_2CH_2Ar), 5.43 (1H, d, J = 13.8 Hz, —CO_2CH_2Ar), 7.26 (10H, s, aromatic protons), 7.54 (2H, d, = 8.8 Hz, aromatic protons), and 8.15 (2H, d, J = 8.8 Hz, aromatic protons) ppm. Without isolation of the enol phosphate **14**, to this reaction mixture was added, at 0°–5°C, diisopropylamine (0.086 mL, 0.50 mmol), and then benzyl mercaptan (0.058 mL, 0.50 mmol). The mixture was stirred at room temperature (N_2) for 1 h. The solvent was evaporated *in vacuo* at room temperature and the residue (yellowish solid), dissolved in CH_2Cl_2, was washed with diluted brine, dried (Na_2SO_4), and evaporated to yield crystalline solid. This was rinsed with a small amount of cold EtOAc to obtain 70 mg (0.17 mmol, yield 34%) of the title compound **15** as yellowish crystals: mp 124°–128°C (dec.); ir (film) ν_{max}: 1765 (β-lactam), 1690 (ester), 1515, and 1340 (NO_2) cm^{-1}; uv (EtOH) λ_{max}: 319 (ε 13 300) and 266 nm (ε 11 000); R_f 0.27 (EtOAc–hex 1:1); ^{1}Hmr ($CDCl_3$, 80 MHz) δ: 2.90 (1H, dd, J_{gem} = 16.5 Hz, $J_{6-5\,trans}$ = 3.0 Hz, 6-H_b), 2.95 (1H, dd, J_{gem} = 18 Hz, J_{1-5} = 8.5 Hz, 1-H_a), 3.29 (1H, J_{gem} = 18 Hz, J_{1-5} = 8.5 Hz, 1-H_b), 3.49 (1H, dd, J_{gem} = 16.5 Hz, $J_{6-5\,cis}$ = 5.3 Hz, 6-H_a), 4.08 (2H, s, —$SCH_2\phi$), 4.15 (1H, m, 5-H), 5.23 (1H, d, J = 13.6 Hz, —CO_2CH_2Ar), 5.50 (1H, d, J = 13.6 Hz, —CO_2CH_2Ar), 7.33 (5H, s, aromatic protons), 7.63 (2H, d, J = 8.8 Hz, aromatic protons), and 8.19 (2H, d, J = 8.8 Hz, aromatic protons) ppm. This material decomposed during preparative layer chromatography on silica gel.

Potassium 2-benzylthiocarbapen-2-em-3-carboxylate (16)

A solution of *p*-nitrobenzyl 2-benzylthiocarbapen-2-em-3-carboxylate (35 mg, 0.085 mmol) in THF (6 mL) was mixed with Et_2O (6 mL), a solution of K_2HPO_4 (15 mg, 0.085 mmol) and $KHCO_3$ (8.5 mg, 0.085 mmol) in water (6 mL), and 10% Pd–C (35 mg). This mixture was shaken in a Parr apparatus under hydrogen pressure of 30 psi at room temperature for 30 min. The aqueous layer, separated, was filtered over Celite and the filtrate washed with Et_2O. Lyophilization of the aqueous phase gave 10 mg of the title compound as greyish powder: ir (KBr disc) ν_{max}: 1765 (β-lactam) and 1630 (br, —CO_2^-) cm^{-1}; uv (H_2O) λ_{max}: 299 nm (ε 1800); ^{1}Hmr (D_2O, 80 MHz) δ: 2.7–3.5 (m, 1-H and 6-H), 3.37 (dd, J_{gem} = 16 Hz, $J_{6-5\,cis}$ = 4 Hz, 6-H_a), 4.05 (s, —$CH_2\phi$), 4.1 (m, 5-H), and 7.35 (s, aromatic protons) ppm.

Received July 15, 1982[2]

C. FAERMAN, H. NEGRI, G. PUNTE, A. A. VITALE, and N. S. NUDELMAN. Can. J. Chem. **61**, 2001 (1983).

Di-*o*-anisylcarbinol crystallizes in the triclinic system, space group $P\bar{1}$ with a = 7.50 (4), b = 10.89 (4), c = 7.98 (3) Å, α = 101.9 (1), β = 94.1 (1), γ = 94.6 (1)°, Z = 2, V = 633.11 Å^3, D_c = 1.28 mg m^{-3}, D_m = 1.26 (1) mg m^{-3}, CuK$_\alpha$ radiation, λ = 1.54178 Å, μ(CuK$_\alpha$) = 0.633 mm^{-1}, F(000) = 260. The structure has been determined by direct methods using single crystal X-ray data and refined by least-squares to the final R factors R = 5.89% and R_w = 5.35%. The molecule has a twist-skewed conformation with the phenyl rings on nearly orthogonal planes. The crystal structure shows a hydrogen-bonded dimer and a peculiar arrangement of the methoxy and phenyl groups.

C. FAERMAN, H. NEGRI, G. PUNTE, A. A. VITALE et N. S. NUDELMAN. Can. J. Chem. **61**, 2001 (1983).

Le di-*o*-anisylcarbinol cristallise dans le système triclinique et appartient au groupe d'espace $P\bar{1}$, avec a = 7,50 (4), b = 10,89 (4), c = 7,98 (3) Å, α = 101,9 (1), β = 94,1 (1), γ = 94,6 (1)°, Z = 2, V = 633,11 Å^3, D_c = 1,28 mg m^{-3}, D_m = 1,26 (1) mg m^{-3}, radiation CuK$_\alpha$, λ = 1,54178 Å, μ(CuK$_\alpha$) = 0,633 mm^{-1}, F(000) = 260. On a déterminé la structure par des méthodes directes en utilisant les données de rayons-X sur un monocristal et on l'a affinée par la méthode des moindres carrés jusqu'à des valeurs de R = 5,89% et de R_w = 5,35%. La molécule a une conformation *gauche* croisée avec les noyaux phényles dans des plans quasi orthogonaux. La structure du cristal montre un dimère lié par une liaison hydrogène et un arrangement particulier des groupes méthoxy et phényle.

[Traduit par le journal]

Introduction

As part of a study on the reaction of aryl-lithiums with carbon monoxide, initiated several years ago (1) and reviewed very recently (2), we have investigated the carbonylation reaction of *o*-anisyllithium. In this reaction di-*o*-anisylcarbinol (**1**), Fig. 1, and di-*o*-anisylketone are the only isolable reaction products (ca. 40% each) (2, 3).

Our interest in compound **1** arose by the observation of two different nmr signals for the hydrogen atoms of the methoxy groups of **1** in CCl_4 solution, suggesting a partially restricted rotation of the aryl rings.

A considerable number of molecular structure determinations, theoretical calculations, and nmr spectra on bridged diphenyl compounds have been performed by several authors (4–12). A common purpose of these works was to study the effects of different bridging atoms and phenyl substituents on the bridged diphenyl conformation. The special efforts devoted to these compounds were to some extent due to the biological importance of disclosing the relationship between conformation and activity in thyroid hormone. Some of these reported works provide theoretical as well as experimental evidence for intermolecular and intramolecular hydrogen bonding (5–9, 11, 12).

In this paper we present an X-ray single crystal molecular structure determination of **1** which supplies experimental data that may contribute to the understanding of conformation in bridged diphenyl compounds.

Experimental

Preparation of compound

Compound **1** was prepared in excellent yield (88%) by adding *o*-methoxybenzaldehyde to *o*-anisyllithium (prepared by the method described for phenyllithium (13)), in THF at room temperature. Hydrolysis and standard work-up (14) of the reaction mixture, rendered **1** (mp 82–83°C, lit. (15) mp 83°C). Compound **1** may also be obtained from the reaction of *o*-anisyllithium with carbon monoxide (2, 3). Infrared (KBr, cm^{-1}): 3300 (st O—H), 2800 (st C—H), 1580 (st C=C), 1450 (def C—H), 1220 (st C—O), 750 (def C—H ar); nmr (CCl_4) δ:3.55 (s, 3H, —OC*H*$_3$, 3.80 (s, 3H, —OC*H*$_3$), 6.35 (d, 1H, —C*H*), 7.2 (m, 9H, ar *H* and —O*H*; this signal integrates to 8H in D_2O); nmr (acetone-d_6) δ: 3.80 (s, 6H, —OC*H*$_3$), 4.26 (d, 1H, —O*H*), 6.44 (d, 1H, —C*H*), 7.1 (m, 8H, ar *H*). Colourless single crystals were grown by controlled slow evaporation from methanol solution at room temperature.

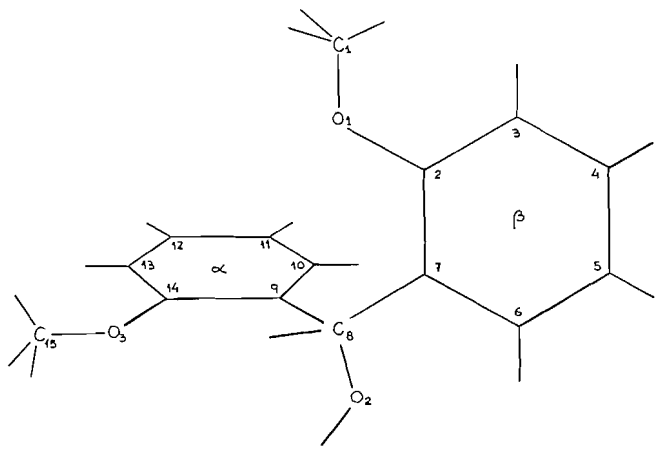

FIG. 1. Atom labelling of di-*o*-anisylcarbinol (**1**).

Structure determination and refinement

Crystal data are as stated in the abstract. An irregular specimen, mounted along ***a***, with approximate dimensions 0.55 × 0.73 × 0.91 mm was used to collect the data. Precession and Weissenberg photographs showed the crystallographic system is triclinic and were

used to determine the preliminary cell dimensions. Single crystal diffraction data were obtained using the equi-inclination multiple film Weissenberg technique; 1431 reflections, with intensities above background, were measured on the layers (0–5, k, l) by the S.R.C. Daresbury Laboratory microdensitometer service, England.

All measurable intensities were treated as observed. The intensities from different layers were scaled according to the number of oscillations, and corrected for Lorentz and polarization factors. No extinction and absorption corrections were performed. Acurate cell dimensions were obtained from least-squares fitting of Weissenberg film coordinates.

From 798 unique measured reflections the structure was solved with the aid of the MULTAN 78 program (16), assuming the space group to be $P1$.

The solution obtained with this program not only showed all the non-hydrogen atoms but also the center of symmetry corresponding to the space group $P1$. The positions of these atoms were then refined in the latter group using the SHELX program (17), by isotropic full-matrix least-squares methods up to an R value of 13%.

A difference Fourier map phased on the refined positions of all the previously located atoms showed all the hydrogen atoms. An anisotropic refinement performed on the non-hydrogen atoms lowered the R value to 10.36%. At this stage it was necessary to refine the inter-layer scale factors. After doing this, the agreement clearly improved, the final R value being 7.52%. The methyl hydrogen atoms that had been constrained to a primary sp^3 group conformation during the initial cycles of refinement were gradually freed. Non-hydrogen and hydrogen atoms were refined respectively by anisotropic and isotropic blocked diagonal matrix least-squares methods to convergence, yielding final R values of $R = 5.89\%$ and $R_w = 5.35\%$. The weighting scheme used was $w = 1.0/0.028855F^2$.

The final refined positional and thermal parameters are given in Tables 1 and 2. Bond lengths and angles are given in the schematic drawing of the title compound shown in Fig. 2.[3]

Results and discussion

Description of the structure

The molecular conformation of the title compound is illustrated in Fig. 1. In the crystalline state the two phenyl rings adopt a twist-skewed conformation (C(7)—C(8)—C(9)—C(10) = 16.64° and C(2)—C(7)—C(8)—C(9) = 79.73°). This conformation is similar to those observed in other C-bridged diphenyl compounds (9*b*, 18–21).[4] The dihedral angle between least-squares planes for rings α and β is 88.36°, as can be seen in Table 3. A lack of planarity of ring β is observed. Each methoxy group is coplanar with its ring (Table 3) and distal to the other one. The C(7)—C(8)—C(9) angle is 112.9(4)°, which compares fairly well with the bridge angle observed in 4-(α-hydroxy-4-methoxybenzyl)-3,5-diiodobenzyl alcohol (bridge angle = 113.5(4)°) (9*b*).

The molecules related by the symmetry operation $\bar{x}, \bar{y}-1, \bar{z}$ are linked by two hydrogen bonds, bond lengths and angle being 2.99(1) Å and 169(2)°, respectively. Although the donor–acceptor distance could suggest a weak interaction, the observed directionality of the bridge, and the H-acceptor distance, 2.11 Å, allows the assumption that the molecules build

[3]Tables of the structure factors may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Reasearch Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[4]The active twist-skewed conformation adopted by the molecules of thyronine and its derivatives has been associated with the presence of iodine or other bulky substituents in the two *ortho* positions of the inner ring (9*b*, 9*d*, 11).

centrosymmetric dimers through O(2)—H(02)··· O′(3) (the prime indicates symmetry operation: $(\bar{x}, \bar{y}-1, \bar{z})$). The distance of 2.11 Å is shorter than the 2.4 Å that can be taken as a criterion for hydrogen bonding (22) and shorter, as well, than the Rahim and Barman van der Waals criterion (23). Furthermore, the observed bond length is in good agreement with theoretical calculations (24) and statistical mechanical treatment (25) of water dimers, which give a value of $R = 3.0$ Å and 5 kcal stabilization energy.

Dimers are additionally stabilized through the dipole–dipole interaction between OH groups (the distance between dipole centers is 2.73(5) Å).

A stereoscopic view of the structure (Fig. 3) shows an unusually oriented packing of the dimers along *b*. In that direction, dimers related by the symmetry operation $(x, y, n-z)$ present the α ring of one dimer opposite to the methyl hydrogens of the α ring of the other one, and vice versa. The distance between gravity centers of facing groups is 4.47 Å. The particular reason for this special packing is not yet clear. No other signifiant short intermolecular distance was detected. Interaction between dimers in other directions seems to be through van der Waals contacts.

Comparison of experimental results

The different chemical shifts observed for the hydrogen atoms of the methoxy groups in the CCl_4 solution can be interpreted as a result of the partially restricted rotation of the aryl rings that could be, in part, due to the existence of an intramolecular hydrogen bond between the hydrogen of the OH group and one of the oxygen atoms of the methoxy groups located at the *o*-position of the phenyl rings.

Although the formation of an intermolecular hydrogen bond in solution cannot be excluded only on the basis of the nmr data, it can be assumed that at the low concentration used to run the spectra an intramolecular hydrogen bond should be preferred to an intermolecular one. When the solvent has hydrogen bond acceptor capabilities (case of acetone), the formation of stronger hydrogen bonds between the molecules of **1** and the solvent prevents the intramolecular H-bond. The rotation is no longer restricted and both methoxy groups are equivalent in the nmr spectra.

On the other hand, the crystallographic determination provides structural evidence which shows general agreement with the existence of an intermolecular hydrogen bond, since each molecule contributes with a hydrogen bond to the building of a centrosymmetric dimeric unit which is stabilized by the energy decrease produced by two hydrogen bonds and the additional dipole–dipole interaction.

Crystallographic studies of di-*o*-anisylketone, where a hydrogen bond is not expected, are in progress, since out of the present results it is not possible to establish fully whether the above-mentioned interactions may contribute to the twist-skewed conformation adopted by **1** in the crystal.

2,2-Bis(ethylthio)ethanenitrile: preparation and use as a one or two carbon nucleophile

GORDON S. BATES[1] AND S. RAMASWAMY
Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received January 31, 1983

GORDON S. BATES and S. RAMASWAMY. Can. J. Chem. **61**, 2006 (1983).

2,2-Bis(ethylthio)ethanenitrile **1** was prepared in high yield from 2,2-bis(ethylthio)ethanal **2**. Alkylation of the potassium salt of **1** with various alkylating agents and conjugate addition to cyclic α,β-unsaturated ketones provided high yields of the alkylation products of **1**. The potential one and two carbon chain extension capability of this new reagent has been demonstrated.

GORDON S. BATES et S. RAMASWAMY. Can. J. Chem. **61**, 2006 (1983).

On a préparé, avec un bon rendement, le bis(éthylthio)-2,2 éthanenitrile **1** à partir du bis(éthylthio)-2,2 éthanal **2**. L'alkylation du sel de potassium du composé **1** avec divers agents alkylants et l'addition conjuguée sur des cétones cycliques α,β insaturées donnent les produits d'alkylation du composé **1** avec d'excellents rendements. On démontre la possibilité d'ajouter à ce nouveau réactif une à deux chaines carbonées.

[Traduit par le journal]

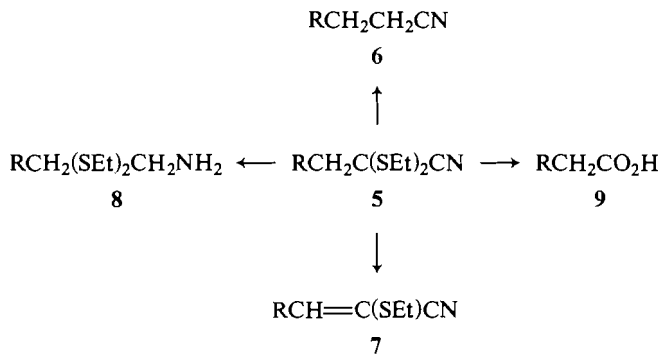
A reagent that can serve as a one or two carbon nucleophile would be of great applicability in organic synthesis. An investigation of the literature revealed that with the exception of diazoacetic esters there did not appear to be any reagents of *demonstrated* one and two carbon nucleophilic capability. However, there are a few reagents that are *potential* one or two carbon chain extending agents but which have been used only as single carbon reagents. These reagents fall into two categories: those in which a carbon is lost as carbon dioxide (1) and those in which a carbon is lost as a nitrile group during hydrolysis (or alcoholysis) of a transient acyl nitrile intermediate (2) or in the process of regeneration of a ketone from a cyanohydrin (3).

2,2-Bis(ethylthio)ethanenitrile **1**, which can be prepared readily from aldehyde **2** (4), appeared to be a potential one or

$(EtS)_2CHCN$ **1** $(EtS)_2CHCHO$ **2**

$(EtS)_2C{=}CHNHR$ **3** $(EtS)_2CHCO_2H$ **4**

two carbon nucleophile.[2] Alkylation of **1** should yield the two carbon chain extension product **5**.[3] Both newly added carbons can be maintained in the product during several subsequent transformations. For example, a Raney nickel desulphurization would lead to product **6**. Elimination of the elements of ethanethiol from **5** would produce the alkene **7** which has recently been shown to be an excellent dienophile in Diels–Alder reactions (8). In addition, **7** could act as an acceptor molecule in a conjugate addition reaction. The nitrile group in **5** could also be reduced to yield **8**, a precursor to an α-amino ketone.[4] All of these processes lead to products in which both carbons of the nucleophile derived from **1** have been conserved. Conversely, oxidative cleavage of the thioketal group in **5** would generate an acyl nitrile intermediate which could be



intercepted by a nucleophile such as water to provide the one carbon chain extended product **9**.

These numerous potential synthetic possibilities associated with nitrile **1** prompted an investigation of the chemistry of this compound.

The conversion of **2** into **1** was accomplished readily by stirring a dichloromethane solution of aldehyde **2** with hydroxylamine hydrochloride in the presence of three equivalents of triethylamine followed by the slow addition of two equivalents of methanesulphonyl chloride. This procedure provided an overall yield of 75–80% of **1** starting from aldehyde **2**.

Our previous experience with the enamine **3** (4) and acid **4** (10) suggested that alkylation of **1** would be best accomplished using the potassium salt of the nitrile in tetrahydrofuran. A preliminary experiment confirmed that the expected difference in reactivity of various salts of **1** was again present. For example, complete alkylation of the lithium salt of **1** with bromoethane required almost seven hours, whereas alkylation of the potassium salt was complete within 45 minutes.

The potassium salt of nitrile **1** was generated by the addition of the nitrile to one equivalent of mineral oil-free potassium hydride in tetrahydrofuran at 0°C. Deprotonation of **1** occurred essentially instantaneously to yield a yellow solution of the potassium salt which could be alkylated cleanly by a variety of halides and sulphonate esters[5] (Table 1). However, the anion apparently fails to react with carboxylate esters and aldehydes,

[1]Author to whom correspondence should be addressed.

[2]The *S*-methyl (5) and 1,3-dithiane (6) analogues of **1** have been reported.

[3]Compounds of this type have been prepared in poor yield by the reaction of various nitriles with sulphur in the presence of alkyl halides (7).

[4]Thioacetal derivatives of 2-aminoethanal have been reported (9).

[5]Benzene sulphonate esters are superior to *p*-methyl benzenesulphonates when alkylation is sluggish and elevated temperatures or prolonged reaction times are required to bring the reaction to completion.

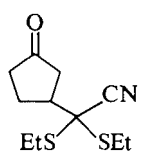
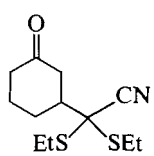
‡Alkylation at −78°C.

presumably due to a ready reversal of the initial addition step (cf. conjugate additions below).

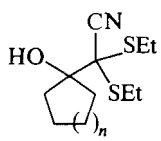
Conjugate addition reactions of the anion of **1** were also investigated. Metallated dithioacetals, in general, show a high preference for direct addition to α, β-unsaturated ketones (11). However, substitution of carbanion stabilizing groups on the nucleophilic reagent enhances the ability of conjugate addition to occur (12). It was found that **10** and **11** were formed in virtually quantitative yield when the anion of **1** was allowed to react with 2-cyclopentenone and 2-cyclohexenone, respectively, at −78°C. No detectable amount of the direct addition product **12** was observed in these reactions.



10



11



12

The conjugate addition reaction showed an interesting temperature dependence. When the reaction between 2-cyclopentenone and the anion of **1** was quenched at higher temperatures an increasing amount of nitrile **1** was reisolated (Table 2). On the basis of the temperature dependence study on the conjugate addition reaction of the anion of **1** with 2-cyclopentenone, it appears that an equilibrium exists between the starting materials and the product. Indeed, when the conjugate addition product **10** was deprotonated at 0°C with potassium bis(trimethyl)silylamide and the reaction mixture was allowed to warm to room temperature and was quenched with aqueous ammonium chloride, nitrile **1** could be isolated in high yield from the reaction mixture.

As the ability to alkylate **1** had been established, several functional group transformations on the alkylation products of

1 were subsequently examined in order to demonstrate the one or two carbon extension capabilities of the reagent. 2,2-Bis(ethylthio)decanenitrile **5** (R = *n*-C_7H_{15}), prepared by reaction of the nitrile anion with 1-bromooctane, was chosen as a suitable substrate. Partial hydrolysis of this compound using pyridinium hydrobromide perbromide (13) in a two phase solvent system yielded the desired unsaturated nitrile **7** (R = *n*-C_7H_{15}) in 86% yield. Reduction of the decanenitrile derivative with lithium aluminum hydride produced the masked α-amino ketone **8** (R = *n*-C_7H_{15}) in 81% yield and a P-2 Raney nickel (14) desulphurization proceeded smoothly to yield decanenitrile in 76% yield. In each of the above procedures both carbons of the nucleophile derived from **1** have been retained in the product. In contrast, oxidative hydrolysis of the dithioketal group of **5** (R = *n*-C_7H_{15}) using *N*-chlorosuccinimide − silver nitrate (15) afforded the one carbon chain extension product, nonanoic acid, in 75% yield.

Thus, the readily available and inexpensive reagent **1** represents a nucleophilic reagent which may be used as a one *or* two carbon chain extension synthon. The further synthetic utility of this reagent in natural products synthesis is currently under investigation.

Experimental

General

All reactions were carried out under a nitrogen atmosphere. Stirring was accomplished using Teflon-coated magnetic stirring bars. Tetrahydrofuran was freshly distilled from sodium benzophenone ketyl under a nitrogen atmosphere. Potassium hydride was obtained as a 25% dispersion in mineral oil from Alpha Division, Ventron Corporation. All other reagents were obtained from the Aldrich Chemical Company, Inc. and were used without further purification. Methyl, ethyl, 2-propyl, and cyclohexyl arylsulphonate esters were prepared by reaction of an excess of the appropriate alcohol for 12 hours at 0°C with the appropriate sulphonyl chloride in pyridine, followed by a standard work-up. All extraction and chromatography solvents were distilled before use.

All temperatures are stated in degrees Celsius. Molecular distillations were performed by means of a Buchi Kugelrohr apparatus. Proton magnetic resonance (^{1}H nmr) spectra were obtained on the following instruments: Varian Associates T-60, EM-360L, and HA-100. Spectra were run in deuterochloroform or carbon tetrachloride solution with tetramethylsilane as an internal reference. Chemical shifts are reported on the δ scale. The multiplicity, integrated peak area, and coupling constants in Hertz (Hz) (if observable) are indicated in parentheses after each signal. Infrared spectra were recorded as liquid films using a Perkin−Elmer 700 spectrometer, and were calibrated with the 1601 cm^{-1} band of polystyrene. High resolution mass spectra were obtained using an AEI MS-50 mass spectrometer. Elemental analyses were performed at the Microanalytical Laboratory, University of British Columbia.

Merck pre-coated tlc sheets Silica Gel 60F-254 were used for analytical thin-layer chromatography. Florisil 100−200 mesh supplied by the J. T. Baker Chemical Company and Merck Silica Gel 60

(230–400 mesh) were used for column chromatography. Analytical gas chromatography was carried out on a Hewlett–Packard Model 5830-A chromatograph equipped with 1.8 m × 0.3 cm columns packed with 3% OV-101 or 5% Carbowax.

The following abbreviations are used in the description of the multiplicity of each signal in the ^{1}H nmr spectrum: s = singlet, d = doublet, t = triplet, q = quartet, sept = septet, m = multiplet, dd = doublet of doublets, dt = doublet of triplets, dm = doublet of multiplets, b = broad.

2,2-Bis(ethylthio)ethanenitrile ***1***

To a stirred solution of 12.32 g (75 mmol) of 2,2-bis(ethylthio)-ethanal (4) in 300 mL of dichloromethane was added 5.45 g (78.25 mmol) of hydroxylamine hydrochloride, followed by 45 mL (330 mmol) of triethylamine. The reaction mixture was stirred overnight at room temperature, and then was cooled to 0°C and 12.5 mL (162 mmol) of methanesulphonyl chloride in 25 mL of dichloromethane was added over 0.5 h. Stirring was continued for a further 3 h, during which time the reaction mixture was allowed to warm to room temperature. The solvent was evaporated under reduced pressure and the residue was dissolved in 300 mL of ethyl ether, washed successively with 50 mL of H_2O, 2 × 50 mL of aqueous 2 *N* HCl, 4 × 25 mL of aqueous saturated Na_2CO_3, 25 mL of H_2O, and dried ($MgSO_4$). The solvent was evaporated under reduced pressure and the crude product was distilled to afford 9.2 g (76%) of **1** as a pale yellow liquid; bp 68°C/0.2 Torr; infrared: 2230 cm^{-1}; ^{1}H nmr (CCl_4) δ: 1.31 (t, 6, *J* = 7), 2.79 (q, 4, *J* = 7), 4.55 (s, 1). *Anal.* calcd. for $C_6H_{11}NS_2$ (161.29): C 44.68, H 6.87, N 8.68; found: C 44.76, H 6.97, N 8.58. *Mol. Wt.* calcd. for $C_6H_{11}NS_2$: 161.0333; found: 161.0335.

Standard procedure for the alkylation of 2,2-bis(ethylthio)ethanenitrile

A suspension of 0.160 g (1 mmol) of 25% KH in mineral oil was washed free of oil by stirring with 3 × 5 mL portions of pentane under a N_2 atmosphere. The oil-free KH was suspended in 5 mL of tetrahydrofuran and 0.161 g (1 mmol) of **1** in 0.5 mL of tetrahydrofuran was added. An immediate evolution of H_2 gas was observed and a yellow solution of the potassium salt of the nitrile resulted. To this solution was added 1.05 mmol of the alkylating agent and the reaction mixture was stirred for 0.25–4 h at room temperature (at 50°C for cyclohexyl benzenesulphonate and at −78°C for methyl bromoacetate). The reaction mixture was diluted with 40 mL of ethyl ether, washed with 5 mL of H_2O, and dried ($MgSO_4$). The solvent was evaporated under reduced pressure to afford the alkylated nitrile. The trace of pale yellow colour in the product could be conveniently removed by filtration of the product through a small column of Florisil using 1–2% ethyl acetate in 30–60 petroleum ether (v/v) as the eluting solvent.

For the conjugate addition reactions with 2-cyclohexenone and 2-cyclopentenone, the solution of the nitrile salt was cooled to −78°C. The ketone (1 equivalent) was added in one portion and the reaction mixture was stirred at −78°C for 30 min. The reaction was quenched at −78°C with aqueous saturated NH_4Cl and worked up as above.

2,2-Bis(ethylthio)propanenitrile

Boiling point (molecular distillation) 60°C/0.1 Torr; infrared: 2240 cm^{-1}; ^{1}H nmr (CCl_4) δ: 1.28 (t, 6, *J* = 7), 1.85 (s, 3), 2.83 (q, 4, *J* = 7). *Anal.* calcd. for $C_7H_{13}NS_2$ (175.32): C 47.96, H 7.47, N 7.99; found: C 48.05, H 7.49, N 8.09. *Mol. Temperature dependence on the addition of the anion of ***1*** *to 2-cyclopentenone*

Generation of the anion of nitrile **1** and the addition of 2-cyclopentenone at −78°C was carried out as described above. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

reaction mixture was allowed to warm to the indicated temperatures (−64°C, −23°C, 0°C, 20°C) and allowed to stir for 30 min to reach equilibrium. The reaction mixture was quenched with aqueous saturated NH_4Cl and worked up as described earlier. The relative amounts of the nitrile **1** and the conjugate addition product **10** were established by the relative integration of the methine singlet of **1** at δ 4.55 with respect to the ethyl triplet at δ 1.34 (corrected for **1**) in the ^1H nmr spectrum of the product mixture.

Reverse conjugate addition of ***1***

A suspension of 0.160 g (1 mmol) of 25% KH in mineral oil was washed free of oil by stirring with 3 × 5 mL portions of pentane under a N_2 atmosphere. The oil-free KH was suspended in 5 mL of tetrahydrofuran and 0.210 mL (1 mmol) of *N,N*-bis(trimethyl)-silylamine was added. The mixture was stirred until evolution of H_2 gas ceased. The resulting solution was cooled to 0°C and 0.100 g (0.41 mmol) of the conjugate adduct **10** in 0.5 mL of tetrahydrofuran was added in one portion. The reaction mixture was allowed to warm to room temperature and was stirred at room temperature for a further 30 min. The reaction mixture was quenched with aqueous saturated NH_4Cl and diluted with ethyl ether, washed with 5 mL of H_2O, and dried ($MgSO_4$). The solvent was evaporated under reduced pressure to afford a yellow oil which upon molecular distillation gave 0.055 g (83%) of nitrile **1**.

Preparation of decanenitrile

To 2.4 g (10 mmol) of $NiCl_2 \cdot 6H_2O$ dissolved in 8 mL of ethanol was added 0.75 g (20 mmol) of $NaBH_4$ in small portions over 5 min with vigorous stirring. After 0.5 h, 0.273 g (1 mmol) of 2,2-bis-(ethylthio)decanenitrile was added and the reaction mixture refluxed for 12 h. The reaction mixture was cooled to room temperature and the solvent was evaporated under reduced pressure. The residue was triturated with 5 × 10 mL of ethyl ether and the combined washings dried ($MgSO_4$) and then filtered through 20 g of Florisil using 5% ethyl acetate in 30−60 petroleum ether (v/v) as the eluting solvent. The eluent was evaporated under reduced pressure and the oily residue was subjected to molecular distillation (70°C/0.1 Torr) to afford 0.116 g (76%) of a product whose spectral data were in agreement with those of authentic decanenitrile.

2-Ethylthio-2-decenenitrile

A mixture of 0.273 g (1 mmol) of 2,2-bis(ethylthio)decanenitrile, 0.400 g (1.25 mmol) of pyridinium hydrobromide perbromide, and 0.01 g of tetra-*n*-butylammonium bromide in 4 mL of dichloromethane and 4 mL of H_2O was stirred vigorously for 6 h. The reaction mixture was diluted with ethyl ether, washed with 2 × 5 mL of H_2O, and dried ($MgSO_4$). The solvent was evaporated under reduced pressure and the residue subjected to molecular distillation to afford 0.181 g (86%) of the desired product as a mixture of *E* and *Z* isomers; bp (molecular distillation) 90°C/0.1 Torr; infrared: 2240, 1705 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.88 (t, 3, J = 7), 1.25, 1.28 (t, 3, J = 7), 1.1−2.5 (m, 10), 2.38 (m, 2), 2.8 (m, 2), 6.59, 6.63 (t, 1, J = 7.75). *Anal.* calcd. for $C_{12}H_{21}NS$ (211.37): C 68.19, H 10.01, N 6.63; found: C 68.04, H 10.00, N 6.60. *Mol. Wt.* calcd. for $C_{12}H_{21}NS$: 211.1395; found: 211.1398.

2,2-Bis(ethylthio)decanamine

A mixture of 0.273 g (1 mmol) of 2,2-bis(ethylthio)decanenitrile and 0.114 g (3 mmol) of $LiAlH_4$ in 10 mL of tetrahydrofuran was stirred vigorously for 12 h. The excess $LiAlH_4$ was decomposed by the cautious addition of $Na_2SO_4 \cdot 10H_2O$. The mixture was filtered and the solvent evaporated under reduced pressure. The residue was chromatographed on silica using 5% ethanol in 30−60 petroleum ether (v/v) as the eluting solvent to afford 0.214 g (77%) of the desired product. Infrared: 3600−3200 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.85 (t, 3, J = 7), 1.0−1.4 (m, 20), 1.4−1.8 (m, 4), 2.6 (q, 4, J = 7). *Anal.* calcd. for $C_{14}H_{31}NS_2$ (277.54): C 60.59, H 11.26, N 5.05; found: C 60.42, H 11.11, N 5.13. *Mol. Wt.* calcd. for $C_{14}H_{31}NS_2$: 277.1898; found: 277.1901.

Nonanoic acid

To a stirred solution of 0.400 g (3 mmol) of *N*-chlorosuccinimide and 0.519 g (3 mmol) of $AgNO_3$ in 4 mL of acetonitrile and 1 mL of H_2O was added 0.273 g (1 mmol) of 2,2-bis(ethylthio)decanenitrile in 1 mL of acetonitrile. The reaction mixture was stirred for 0.5 h and then 0.5 g of Na_2SO_3 was added and stirring continued for a further 10 min. The reaction mixture was diluted with 20 mL of ethyl ether and the organic phase decanted. The residue was washed with a further 2 × 10 mL portion of ethyl ether. The combined organic phase was washed with 5 × 5 mL of H_2O and then extracted with 1 mL of aqueous 2 *N* NaOH. The basic aqueous phase was washed with 10 mL of ethyl ether, acidified with aqueous 2 *N* HCl, and extracted with 2 × 20 mL of ethyl ether. The organic extract was dried ($MgSO_4$) and then evaporated under reduced pressure to afford 0.118 g (75%) of a product whose spectral data were identical to those of authentic nonanoic acid.

RICHARD L. EAGER, JAMES M. PEPPER, JIBEN C. ROY, and JOSEPH F. MATHEWS. Can. J. Chem. **61**, 2010 (1983).

An initial study has been made of the chemical nature of the oil phase resulting from the the conversion of aspen poplar wood, cellulose, and an isolated lignin from the aspen poplar as a result of their interactions with water and carbon monoxide in the presence of sodium carbonate at 360°C. Gas chromatographic analysis of the sodium hydroxide soluble fractions from each substrate revealed similar spectra of alkyl-substituted phenols. The relative abundance of identified low molecular weight phenolic compounds decreased from lignin to wood to cellulose. This was in agreement with the known phenolic nature of lignin. As well, it confirmed the synthesis during reaction of such compounds from a carbohydrate substrate. Gas chromatographic analysis of the whole oils also revealed the presence in each case of several alkyl-substituted cyclopentanones whose relative abundance decreased from cellulose to wood to lignin. Silica gel column separation of the oils, after a charcoal treatment, followed by capillary gas chromatographic – mass spectrometric analyses of the resulting fractions indicated the presence of other higher molecular weight phenols, napthols, cycloalkanols, cycloalkanones, and polycyclic and long chain alkanes and alkenes.

RICHARD L. EAGER, JAMES M. PEPPER, JIBEN C. ROY et JOSEPH F. MATHEWS. Can. J. Chem. **61**, 2010 (1983).

On a fait une étude préliminaire sur la nature chimique de la phase huileuse résultant de la transformation du bois de peuplier, de la cellulose et de la lignine isolée du peuplier par suite de leurs interactions avec l'eau, et le monoxyde de carbone en présence du carbonate de sodium à 360°C. L'analyse chromatographique en phase gazeuse des fractions de ces substrats, solubles dans l'hydroxyde de sodium, révèle des spectres identiques de phénols portant des substituants alkyles. L'abondance relative des composés phénoliques de faible masse molaire que l'on a identifiés, diminue lorsqu'on passe de la lignine, au bois et à la cellulose. Ce fait s'accorde très bien avec la nature phénolique connue de la lignine. Ce fait est également confirmé lors de la synthèse de tels composés à partir d'un carbohydrate. L'analyse chromatographique de toutes les huiles révèle également dans chaque cas la présence de plusieurs cyclopentanones portant un substituant alkyle dont l'abondance relative diminue lorsqu'on passe de la cellulose, au bois et à la lignine. La séparation des huiles sur gel de silice, après traitement au charbon, suivie d'une analyse par cpg sur colonne capillaire couplée à un spectromètre de masse indique la présence d'autres composés de poids moléculaires plus élevés: des phénols, des naphtols, des cycloalcanols, des cycloalcanones et des alcanes et des alcènes polycycliques et à longues chaines.

[Traduit par le journal]

Introduction

Considerable attention has been given lately to studies on the conversion of biomass to a fuel oil to function as an alternative energy source. Some of these reported studies (1–5) have been based on the early work of Appell *et al.* (6) who reported that a variety of lignocellulosic materials (wood products, agricultural and civic wastes) could be converted, in part, into a fuel oil by reaction with carbon monoxide and water at elevated temperatures in the presence of sodium carbonate as a catalyst. Other studies (7, 8) involved the use of metallic catalysts in the presence of either hydrogen or mixtures of hydrogen and carbon monoxide. In each case complete conversion of the lignocellulosic material occurred to produce an oil fraction, a water-soluble fraction, and a residual gaseous fraction. In this laboratory attention has been directed (9) towards the use of local aspen poplar as the lignocellulosic raw material. Factorial design experiments were made to determine the optimum reaction conditions in the batch process (temperature, reaction time, water-to-wood ratio, nature of and amount of catalyst, and initial gas (carbon monoxide and/or nitrogen) pressure). The black, moderately viscous oil, obtainable in yields of 35–45 percent of the wood, was, to a first approximation, qualitatively similar to that reported by other workers using varied raw materials. The residual oxygen content was 15–20 percent and, of the 70–75 percent carbon content, 36 percent was unsaturated and/or aromatic in nature as revealed by ^{13}C nmr. As an initial step to learn more about the chemical composition of the conversion products which, in turn, would lead to a better understanding of the mechanisms of the reactions involved, a study was made of the apparently less complex water-soluble products. Several highly oxygenated products were identified (10), including a mixture of low-molecular weight (C_1–C_7) aliphatic alcohols, ketones, and acids. This paper reports on the initial study of the chemical nature of the components comprising the oil fraction. A similar study was made using separately the cellulose and lignin components of the aspen wood as reaction substrates in order that some conclusions may be drawn with respect to the origin of the identified compounds.

The oil samples were prepared, according to the procedure reported previously (10), from aspen poplar wood (*Populus tremuloides* Michx), cellulose, and an isolated aspen poplar lignin (11, 12). All such samples subsequently referred to as total oil were air-dried in a fumehood at room temperature for

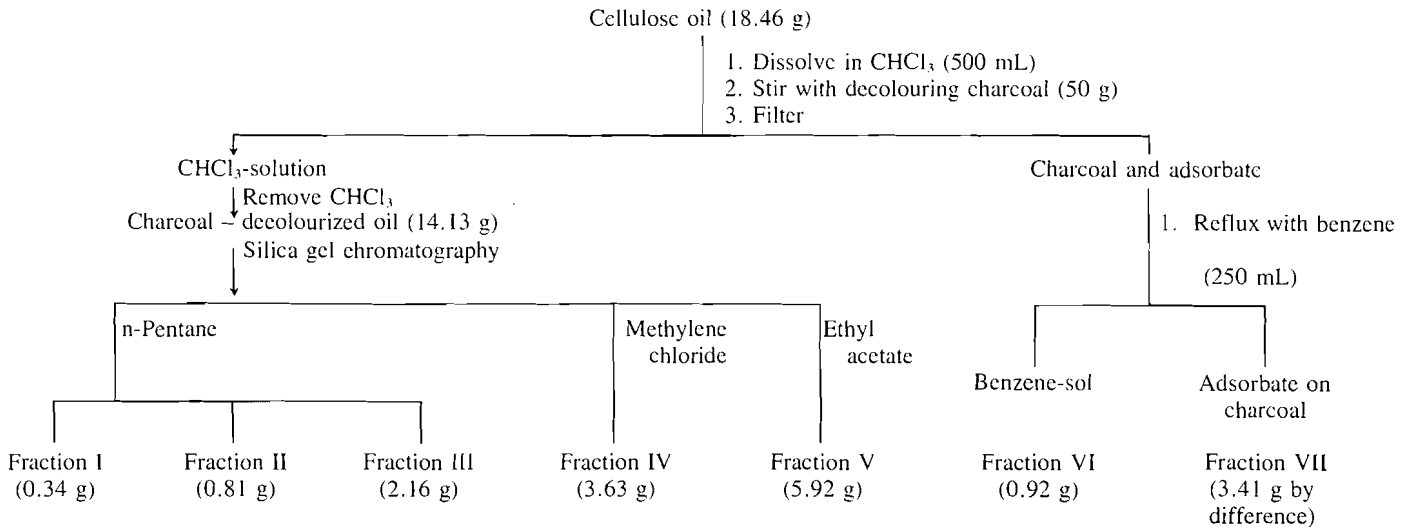

FIG. 1. Fractionation of oil from cellulose.

2–3 days, until the moisture content as determined by Karl Fischer titration was less than one percent. A preliminary examination of these oils indicated a similar carbon, hydrogen, and oxygen analysis (C 74%, H 7.5%, and O (by difference) 18.5%) for wood and cellulose and a slightly different analysis (C 66%, H 6.5%, and O (by difference) 27.5%) for the isolated lignin. There were strong infrared absorption bands for hydroxyl and carbonyl functional groups, and evidence by ^1H and ^{13}C nmr for the presence of unsaturated and/or aromatic ring structures. The ^{13}C analysis indicated that 36, 32, and 49 percent of the total carbon present in the oils obtained from the wood, cellulose, and lignin, respectively, was of an aromatic and/or unsaturated nature.

A preliminary study of the oil obtained from the wood by column chromatographic separation, using silica gel and elution with n-hexane – acetone (1:1), toluene – dioxane (6:1), toluene – ethyl formate – formic acid (4:5:1), showed that separation, as monitored by thin-layer chromatography, was not effected. Similarly, solvent extraction in a Soxhlet extractor, using solvents of increasing polarity (n-hexane, benzene, diethyl ether, acetone) gave rise to black viscous fractions representing approximately 7, 67, 8, and 12 percent respectively of the oil and char-like residue of 9 percent. Neither procedure was suitable to produce fractions that were amenable for further identification studies.

A useful chemical separation was achieved by extraction of acidic (later shown to be essentially phenolic) components using five percent sodium hydroxide solution. Acidification of these alkaline extracts from the oils obtained from wood, cellulose, and lignin and the subsequent examination of the ether-soluble fractions by gas chromatography indicated a similarity of composition. Mass spectrometry, along with a comparison with authentic compounds, permitted the identification of several mononuclear alkyl-substituted phenols. In earlier work, extractions of these oils had been made with five percent sodium bicarbonate in an attempt to isolate any strong acidic compounds. Such extracts were found to be similar to those later made using sodium hydroxide. This similarity was presumably the result of the water solubility of the phenolic products.

A similar gas chromatographic analysis of the whole oils from wood, cellulose, and lignin permitted the identification of several alkyl-substituted cyclopentanones.

With recognition that phenolic compounds were being derived not only from the initially phenolic lignin but from all the carbohydrate sources examined, attention was directed to a detailed study of the oil obtained from the cellulose component only. Such a product would be free of whatever different compounds may arise from the hemicellulose and lignin components. Treatment of a chloroform solution of the originally black oil with decolourizing charcoal and subsequent silica gel column separation (Fig. 1) was useful in obtaining fractions amenable for further study. No compounds were detected in a chloroform extract of the charcoal alone. Each Fraction (I to VI) was examined by gas chromatography and/or gas chromatography – mass spectrometry. Invidual compounds were identified by analysis of their mass spectra and, in some cases, also by comparison with authentic reference samples.

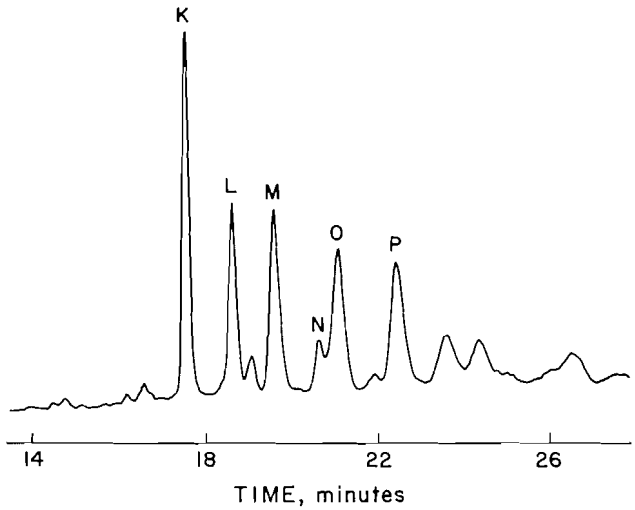

FIG. 2. Typical gas chromatogram of sodium hydroxide extract of oil from aspen wood (see Table 1 for compound identification).

Experimental results

Extraction with five percent sodium hydroxide of the product oils from wood, cellulose, and the isolated lignin led to fractions which were examined by gas chromatography using a SP-1200/1% H_3PO_4 on Chromosorb column. A typical chromatogram (from wood) serves to represent each of these fractions and is shown as Fig. 2. Identifications of the compounds

represented by the various peaks were made on samples collected using a column splitter and were analysed by ultraviolet absorption spectroscopy and mass spectrometry and by comparison with authentic samples. The nature of these compounds and their relative abundance are given in Table 1.

Subsequently a more detailed qualitative analysis of the alkali-soluble fractions with boiling points and retention times higher than those reported in Table 1 was obtained using capillary gas chromatography – mass spectrometry. The presence of several other mono- and dinuclear phenols was confirmed. These are given in Table 2.

The product oils produced earlier (10) as a result of treating each of cellobiose, glucose, fructose, xylose, and glycerol under the same conditions as used for the cellulose were available in the laboratory. Extraction of these oils with sodium bicarbonate and gas chromatographic examination of the recovered acidic products showed that very similar profiles were obtained in each case and were similar to that derived from the oil from cellulose. Three other model substances, formaldehyde, acetaldehyde, and glycolaldehyde, were also treated under the same reaction conditions. In each case an oil was obtained which contained an alkali-soluble fraction which gave a gas-chromatographic profile indicating the presence of phenolic compounds.

Furthermore, samples of the whole oils from wood, cellulose, and lignin were gas-chromatographed using the same column as that used for the phenolic fractions. A typical chromatogram (from wood) serves to represent each of these fractions and is shown as Fig. 3. Identifications of the compounds represented by the labelled peaks were made on samples collected using a column splitter and analyses by infrared spectrophotometry, mass spectrometry, and comparison with authentic reference samples. The nature of these compounds and their relative abundance is given in Table 3. Data from several runs agreed closely. Table 3 shows a typical analysis.

Since it was now apparent that cellulose could be a precur-

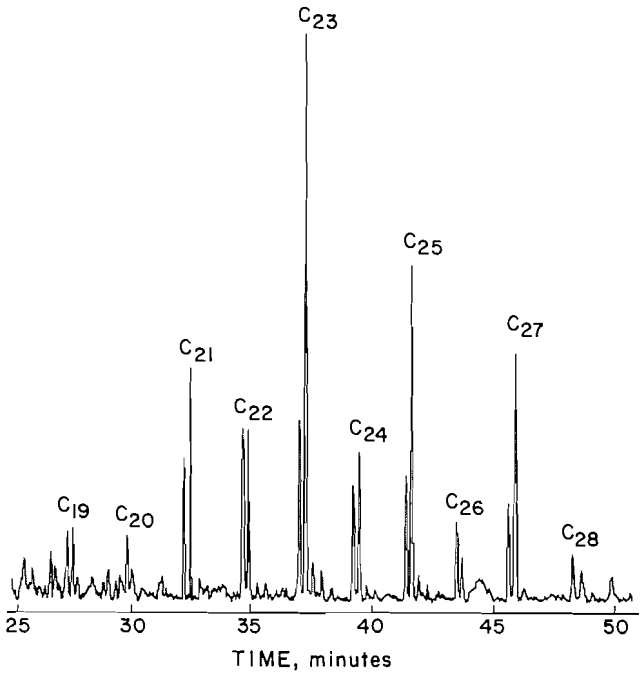

FIG. 4. Capillary gas chromatogram of alkane/alkene components of Fraction I of oil from cellulose.

sor, although not the only precursor, of the majority of the various types of products comprising the oil produced from wood, it alone was used as the raw material for further studies. The black, moderately viscous oil produced in 28% yield was examined as illustrated in Fig. 1, with the disposition of the original amount of oil among the separated fractions as shown. An examination of Fractions I through VI by capillary gas chromatography – mass spectrometry revealed the following.

Fraction I

The presence of the following compounds was confirmed:[4] methylindan, ethylindan, dimethylindan, trimethylindan, ethyltetralin, diphenyl ether, and a series of both long chain alkanes and alkenes (C_nH_{2n+2} and C_nH_{2n} where n = 19 to 28). The chromatograms (Fig. 4) representing the alkane/alkenes exhibited a characteristic series of doublet peaks with the peak of shorter retention time corresponding to the alkane. The mass spectra of the alkanes displayed the characteristic fragmentation pattern with groups of peaks spaced 14 mass units apart and each group having, as the most abundant species, the C_nH_{2n+1} ion which occurred with gradually decreasing abundance with increasing mass. On the other hand, mass spectra of the alkenes were dominated by ions of the general formula C_nH_{2n-1}, which also gradually declined in abundance with increasing mass.

Fraction II

Some of the indans found in Fraction I were also found here but the poor resolution of peaks prevented further identification.

Fraction III

This fraction contained the ketonic derivatives. Those listed in Table 3 were identified, along with 2-pentylcyclopentanone, 2-cyclopentylcyclopentanone, 2-ethylcyclohexanone, β-hydrindanone, methyl-β-hydrindanone, methylindanone, dimethylindanone, and methyltetralone.

Fractions IV and V

The chromatograms of these fractions were very similar and represented primarily the phenolic compounds listed in Tables 1 and 2. Also identified was a series of alcohols including cyclopentanol, 2-methylcyclopentanol, 2,5-dimethylcyclopentanol, 5-methylcyclohexanol, and 3-cyclohexen-1-ol. Mass fragmentation patterns of two sizable peaks at higher retention times gave a strong indication for the presence of hexadecanoic acid and a C_{18} or C_{19} alcohol.

Fraction VI

The chromatogram of this fraction was very similar to that shown in Fig. 3 indicating that some of the phenols and cyclopentanones originally present in the oil had been adsorbed and removed by the charcoal.

Discussion

It is now abundantly evident from this research and from

[4]All possible sources of contaminants (grease, pump oil) were checked as potential precursors of these compounds. No evidence was found.

earlier reports (3–5) that the alkaline degradation of whole biomass or of its separate constitutent components leads to a very complex mixture of chemical products. In turn, these compounds, due to their greater variance in structure, must involve extensive and complex mechanistic pathways for their production. Clarification of these mechanisms should lead to a better understanding of the conversion process and ultimately to the recognition of those reaction conditions whereby potentially valuable chemical products may be obtained in economically acceptable yields. This complexity has been supported herein by the identification of several distinctly different classes of compounds including mono- and dinuclear phenols, cycloalkanones and cycloalkanols, and polycyclic and long-chain alkanes and alkenes. Sufficient specific examples of each such group have been identified to characterize the group.

The identification of the alkyl-substituted phenols obtained by the sodium hydroxide extraction of the oil from wood, cellulose, and isolated lignin (Table 1) strongly suggests, as expected, that the aromatic nature of lignin results in significantly more phenolic degradation products (although of the same type) than are observed from wood or cellulose. Under these reaction conditions carbohydrates function as precursors for phenolic substances and, in the case of wood, the net result of converting both the carbohydrate and the lignin is the larger percentage yield of phenolic compounds over that from cellulose alone. On the other hand, the origin of the cyclopentanones (Table 2) would appear to be primarily the hexose-based cellulose, with lesser yields from wood with only 50% cellulose and much less from the lignin preparation which is primarily aromatic but most likely contains carbohydrate impurities.

Little can yet be said about the mechanism of formation of any of these varied products. The alkaline conversion of carbohydrates to aromatic materials, including phenols, has been recognized for a long time and recently has been studied extensively by Theander and Westerlund (13). The current study emphasizes the apparent role of smaller (1-, 2-, or 3-carbon) fragments being involved in the synthetic pathways. In particular, the multiple methyl-substituted phenols and cyclopentanones suggest the involvement of a one-carbon reactant. As well, in the homologous series of higher molecular weight alkanes and alkenes (Fig. 4), there are indications of either one- or two-carbon fragments being involved. The predominance of the odd numbered carbon units may be synthetically significant but is as yet not understood. It must be recognized that the relatively long times of reaction at an elevated temperature, due to the extended heating-up and cooling-off periods, contribute to the complexity of the rections involved. Currently studies are underway to examine the nature of the oil produced in short periods of time using a small-scale semicontinuous reactor (14). These studies, together with concurrent ones using model substances, may provide more useful information about the overall mechanism of the reactions involved and will be reported at a later date.

Experimental

The apparatus and the standard experimental conditions used to prepare oil fractions by the high temperature (360°C), alkaline (Na_2CO_3) catalyzed degradation of aspen wood (*Populus tremuloides* Michx) (100 g), cellulose (MN-Cellulose Powder for Column Chromatography) (100 g), and an isolated aspen poplar lignin (11, 12) (25 g) were described earlier (10). The time of extraction of the lignin was 1.5 h.

The lignin sample analyzed for C 57.7%, H 5.76%, suggesting the presence of some carbohydrate impurity since similarly isolated samples (15) analyzed for C 59.3%, H 6.0% (average).

Sodium hydroxide extraction

A solution of oil (1 g) dissolved in $CHCl_3$ (75 mL) was extracted with 5% NaOH (10 × 40 mL). The combined extracts, after acidifying with HCl, were extracted with diethyl ether, the extract dried over anhydrous Na_2SO_4, and excess solvent removed. The residue weights from wood, cellulose, and lignin were 28, 22, and 32.5% of original oil respectively.

Gas chromatographic analysis for relative abundance studies

The sodium hydroxide soluble fractions (Fig. 2) and the whole oil fractions (Fig. 3) were chromatographed on a HP Model 5750 instrument using a 6 ft × 1/8 in. od stainless steel column packed with 10% SP-1200/1% H_3PO_4 on Chromosorb W (80–100 mesh, AW). The detector temperature was maintained at 310 ± 10°C and the injector temperature at 250 ± 10°C. Hydrogen was passed at 40 mL/min and the air flow rate at 500 mL/min. To produce Fig. 2, the temperature was held constant at 50°C for one minute, then programmed from 50°C to 180°C at 10°/min and held at 180°C, using nitrogen as the carrier gas, at 15 mL/min until no further peaks appeared. To produce Fig. 3, similar conditions were used except that the initial temperature was 55°C and the carrier gas flow rate was 25 mL/min. Calibration curves for each of the standards were prepared by injecting varying amounts to cover the expected range in the sample for analysis.

Capillary gas chromatographic analyses

Gas chromatographic – mass spectrometric analyses of Fractions I through V and the alkaline extracts were made using a Finnigan Model 4000 system interfaced to an INCOS Model 2300 data acquisition system. The column was fused silica (25 m × 0.25 mm id) coated with OV-17. The initial temperature of 30°C was raised rapidly to 60°C and programmed from 60°C to 200°C (hold) at 4°/min. Electron impact mass spectra were obtained respectively every 1.5 s by scanning from m/z 41 to m/z 650 at 70 eV.

Sources of reference compounds

All the alkyl-substituted cyclopentanones were synthesized, using the general procedure reported by Stork *et al.* (16) starting from cyclopentanone or previously prepared 2-methylcyclopentanone or 3-ethylcyclopentanone, synthesized from β-ethyladipic acid using the method of Thorpe and Kon (17). All structures were confirmed by an examination of their mass spectral fragmentation patterns.

Distillation of ω-carboxyalkyl lactams from soda-lime leads to the formation of bicyclic enamines or imines with concomitant loss of carbon dioxide and water. Monoamides of dicarboxylic acids afford cyclic ketones. A mechanistic rationale is presented and it is concluded that the reaction is a variant of the classical Ruzicka cyclization of dicarboxylic acids. The method allows the regiospecific formation of iminium salts of bicyclic nitrogen heterocycles.

JOHN M. MCINTOSH, LILIANNA Z. PILLON, SAMUEL O. ACQUAAH, JAMES R. GREEN et GRAHAM S. WHITE. Can. J. Chem. **61**, 2016 (1983).

La distillation des lactames ω-carboxyalkyles sur de la chaux sodée conduit à la formation d'énamines bicycliques ou d'imines avec une perte concomittante de bioxyde de carbone et d'eau. Les monamides d'acides dicarboxyliques conduisent à des cétones cycliques. On propose un mécanisme réactionnel et on conclut que la réaction est une variante de la cyclisation des acides dicarboxyliques selon la méthode classique de Ruzicka. La méthode permet la formation régiospécifique des sels d'iminium des hétérocycles azotés bicycliques.

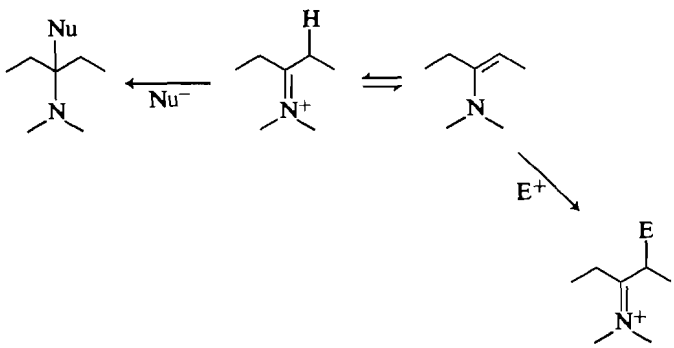
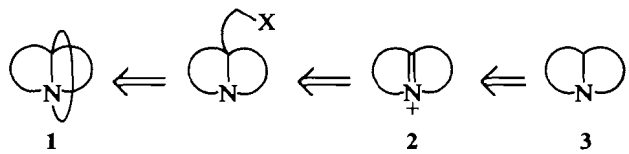
The enamine functionality is one of the most versatile in the array of processes available to the synthetic chemist (1). The interconversion between the iminium and enamine forms, a process which can frequently be controlled and which is of central importance in the synthetic and biosynthetic elaboration of many alkaloids (1), allows the manipulation of electrophilic and nucleophilic sites with remarkable ease. Reactions can then be effected with nucleophilic (e.g. Grignard reagents) or electrophilic reagents (e.g. acyl or alkyl halides) (Scheme 1).



SCHEME 1

. Enamines are most frequently prepared (1) by interaction of secondary amines with aldehydes or ketones (i.e. a C—N bond-forming process). Another process used, particularly in bicyclic materials, is the mercuric acetate oxidation of tertiary amines, a method pioneered by Leonard *et al.* (2) and used to great advantage in alkaloid synthesis. Another very useful process, which has been described recently by Rapoport and coworkers (3), involves decarboxylation of α-amino acids. The iminium salts so obtained can be isomerized to the enamine form under the usual conditions.

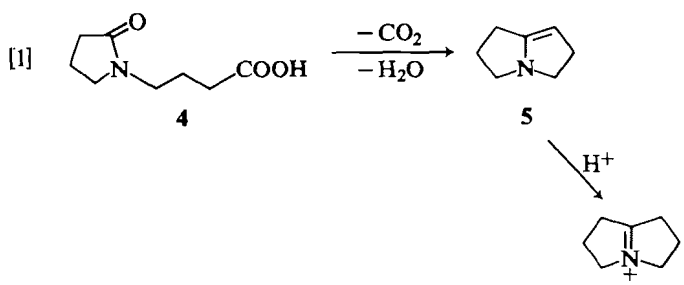
An ongoing project in our laboratories is directed toward the synthesis of substituted tricyclic ammonium salts of type **1**. Antithetical analysis suggested that appropriate precursors would be the bicyclic salts **2** (Scheme 2). Results already



SCHEME 2

reported (4) have verified the proposed route for **2** → **1**. However, the project demanded the synthesis of **1** with varying ring sizes and substituents present in the rings. For Leonard's oxidative procedure to be useful, the synthesis of the saturated bicyclic amines **3** with these points satisfied was required. Such syntheses appeared to be long and the regiospecific oxidation of several of these was problematical.

Our attention was attracted by a report by Miyano *et al.* (5) of the preparation of dehydropyrrolizidine (**5**) by the simple expedient of distilling the carboxy-lactam **4** from soda-lime (eq. [1]). Such an operation, if generally applicable, would be



highly attractive in that the lactams are relatively easily prepared and the overall sequence from commercially available materials would be quite short. In addition, it represents a method of enamine formation by a C—C bond-forming process.

A literature review showed that this reaction had been investigated by Murakoshi *et al.* in the late 1960's (6, 7). This work, which appeared largely in Japanese, does not seem to have been widely recognized. From these reports it can be seen that 5-, 6-, and 7-membered rings can be formed, the stereochemistry at the C—N center is retained, and that the presence of N—H bonds does not interfere with the cyclization. Further-

more, both Murakoshi and Alder[3] have shown that esters can be used in place of the acids. In view of the importance of this method to our research, we undertook to explore its limits more fully and our results are the subject of this report.

One can envisage several different types of amido-acids which might undergo this reaction. Both *C*- and *N*-(ω-carboxyalkyl)lactams, as well as ω-acylaminocarboxylic acids, are potential substrates for the reaction. In each of these, the effect of ring size (both of the existing and cyclizing rings) and substituents on nitrogen and/or the chains are possible variables.

Results

Our first investigations centered on the use of *N*-(ω-carboxyalkyl)lactams. We have already reported, in the context of the synthesis of **1** (4), the preparation of **6***a* and **6***b* and their conversion to **7***a* and **7***b* respectively. An improved procedure for the preparations of **6***a*,*b* is included in the experimental section of this paper. The procedure is simple and easily carried out. In addition, Miyano *et al.* have recently reported the formation of **7***c* (8) as well as **5** (5). To investigate the application

d $n = 4$, $m = 4$, R = H
e $n = 5$, $m = 2$, R = H

to the annulation of larger rings, the homologous lactam **6***d* was prepared. Pyrolysis afforded a complex mixture of products, as was evidenced by glc analysis. A crystalline perchlorate salt (**7***d*) could be isolated, but the yield was only 14%. An unidentified side-product was also obtained which was clearly ketonic in nature (ir, ms). The difficulty in forming seven-membered rings is well-known and has recently been encountered by Rapoport (3). It appears that this situation applied also to the pyrolysis reaction, although the formation of the seven-membered imine from 6-acetamidohexanoic acid is successful (7).

Annulated seven-membered rings can be approached from the other direction as is evidenced by the formation of **7***e*. In this case, the previously described (9) strategy for assembling the *N*-alkylated piperidones was not applicable. However, *N*-alkylation of caprolactam with 5-chloro-1-pentene (10) under phase-transfer (PT) conditions (11) followed by permanganate oxidation, also using PT methodology (12), gave **6***e* in acceptable amounts.

Simple alkyl substituents do not interfere with the reaction whether they are at the reacting center or elsewhere. This is shown by the formation of **7***c* (8) as well as the two new transformations leading to **10** and **14**. Two points of interest regarding **10** and **14** can be noted.

The cyanide addition products **11** and **15** appear to be stereochemically homogeneous, based primarily on ^{13}C evidence. However, in both cases, we were unable to effect replacement

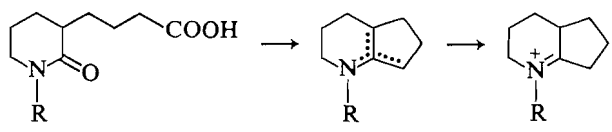
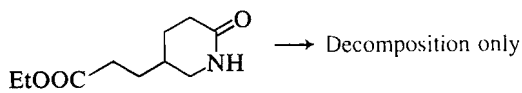
of the cyano group with Grignard reagents. Prolonged reaction times with large excess of 4-phenoxybutylmagnesium bromide led to only 10% conversion of starting material.

We next turned our attention to *C*-(ω-carboxyalkyl)lactams. It was of interest to determine if cyclization would occur to give fused bicyclic systems in which nitrogen was not at the bridgehead position. To this end, lactams **16***ab* and **19** were prepared and subjected to the pyrolysis reaction. Lactam **16***a* afforded **17***a* in 61% crude yield. The perchlorate **18***a* was not crystalline but a low yield of a hygroscopic hexachloroplatinate could be isolated. Lactam **16***b* gave 78% of enamine **17***b* which was pure according to glc analysis. The hexachloroplatinate was extremely hygroscopic and could not be isolated in a crystalline form. The nmr of **17***a* showed that it existed primarily



16*a* R = H **17** **18**

[5] **16***b* R = Me



19

in the imine form, while that of **17***b* showed the two possible enamine forms in approximately equal amounts. As expected, **19** gave a complex mixture of products which remain unidentified.

Cyclization of monoamides of α,ω-dicarboxylic acids would be expected to lead to enamines of cycloalkanones. In the event, reaction of **20***a* or **20***b* led to the formation of the cycloalkanone directly. That these products were not formed

by hydrolysis of the enamine was shown by including authentic samples of these in a pyrolysis reaction and isolating them unchanged.

Murakoshi's work (6) has delineated the cyclization of ω-acylaminocarboxylic acids to cyclic imines and iminium salts (6, 7). We repeated his work using the commercially available **22**. In this case the cyclization occurred in two ways to afford **23** and **24**, the latter being obtained in 74% yield.

[7] $AcNH(CH_2)_5COOH \longrightarrow$ 
22 **23** **24**

Finally the possibility of intermolecular reactions was investigated briefly. Attempts to condense hexanoic acid with hexanamide or phenylacetic acid with *N,N*-dimethyl hexanamide were unsuccessful. The use of the primary amide led to the precedented (13) formation of hexanonitrile plus 6-undecanone, while the reaction involving the tertiary amide led to a mixture of 1,3-diphenylacetone and 1-phenyl-2-heptanone in low yield.

Discussion

Speculation on the mechanism of reactions occurring under the heterogeneous and high-temperature conditions employed is unproductive. However, a rationale has been developed based on the observations of the ketone-forming reactions. Such products are reminiscent of the classical Ruzicka reaction (14) which involves the pyrolysis of dicarboxylic acid salts over barium, calcium, or thorium oxide. Both radicals and anionic routes have been postulated (15), although it is difficult to explain the reported (16) formation of 2,2,5,5-tetramethylcyclopentanone from 2,2,5,5-tetramethylsuccinnic acid using an anionic mechanism. Nevertheless, our results allow the use of the pathway shown in Scheme 3 to be used as a predictive tool. The formation of ketonic products from the monoamides **20** would be expected if the nitrogen atom is not "tied" to the rest of the molecule. Similarly, the cyclization of **19** would involve a very strained intermediate and failure to cyclize is predictable. Finally, the observation of ketonic material from **6***d* can be viewed as support for this rationale, as such molecules might be expected to be more resistant to intramolecular enamine formation than would the related ten- and nine-membered ring analogs. The intervention of an aminoketone intermediate would, of course, obviate the attractive possibility of a regiospecific enamine synthesis.

The formation of bicyclic enamines by a C—C bond-forming process is a very useful adjunct to the usual methodology. Particularly important for our purposes is that it allows the regiospecific preparation of substituted bicyclic iminium salts. It is worthy of note that hydrolysis of the iminium salts (e.g. **18**, **24**) provides molecules which are related to the amino acids by apparent N → C acyl transfer and results in the effective transformation of an acid to a ketone. While we feel that hetero substituents are unlikely to survive the conditions, the point remains to be tested. In any case, the method allows the synthesis of enamines without the necessity of prior preparation of amino ketones and thus provides a rapid formation of these materials from precursors which are easily prepared and stable to many common reaction conditions.

Experimental

Melting points are corrected; boiling points are uncorrected. Infrared spectra were run on a Beckman IR-12 instrument. The ^{1}Hmr spectra were run at 60 MHz and are reported in the following format: chemical shift (δ) (multiplicity, number of protons, coupling constant). The Cmr spectra were run at 22.64 MHz in the FT mode using a flip angle of 45° on a Bruker CXP-100 instrument. Mass spectra were obtained on a Varian MATCH5-DF instrument in one of two modes coded FDMS (field desorption mode) or FIMS (field ionization mode). Gas chromatographic analyses were performed using either 10% or 20% SE30 on Chromosorb W columns, solvents were removed at reduced pressure, and the drying agent used was anhydrous magnesium sulfate.

Syntheses of amidoacids

Improved preparation of N-*(3-carboxypropyl)-2-piperidinone (**6**a) and* N-*(4-carboxybutyl)-2-piperidinone (**6**b)*

The reaction between 2-methoxypyridine and either ethyl 4-bromobutyrate or ethyl 5-bromovalerate was carried out as previously described (9). The mixture was distilled to a head temperature of ca. 120°C (0.15 Torr) to remove *N*-methylpyridone and other low-boiling impurities. The brown residue was then hydrogenated at 60 psi initial pressure over a 10%Pd/C catalyst and the hydrogenated material was hydrolyzed as previously described (9). The method avoids the difficult distillation of the pyridone esters, a procedure which causes significant decomposition and consequent loss of material.

N-*(5-carboxypentyl)-2-piperidinone (**6**d)*

Ethyl 6-bromohexanoate was prepared from ϵ-caprolactone by saturating an ice-cold ethanolic solution of the lactone with hydrogen bromide, allowing the mixture to stir at ambient temperature overnight, pouring onto ice, and extracting with dichloromethane. Dis-

tillation afforded a 44% yield of the bromoester, bp 69–72°C (0.13 Torr) (20). Alternatively, the bromoester could be purified using silica gel chromatography and 3:1 petroleum ether/ether as eluant. Using this procedure, the yield of pure product was 56%; ir ($CHCl_3$): 2950, 2880, 1730, 1465, 1380 cm^{-1}; ^{1}Hmr ($CDCl_3$): 4.2 (q, 2H, J = 8 Hz), 3.5 (t, 2H, J = 7 Hz), 2.6–1.1 (m, 8H), 1.25 (t, 3H, J = 8 Hz); Cmr ($CDCl_3$): 173.1, 60.1, 34.0, 33.2, 32.6, 27.7, 24.2, 14.3. The bromoester (6.5 g, 0.06 mol) was heated to 195°C under a nitrogen atmosphere and 10 g (0.045 mol) of 2-methoxypyridine was added dropwise by a syringe over 4 h. Methyl bromide was evolved. The mixture was heated at 195°C for 3 h and then stirred at ambient temperature overnight.

Distillation gave a large forerun consisting largely of *N*-methylpyridone (bp 66–67°C (0.15 Torr)). The desired product, *N*-(5-carbethoxypentyl)-2-pyridone, remained as the residue after removal of this fraction. The crude yield was 6.9 g (64%) and the material was used directly in the succeeding step; ^{1}Hmr ($CDCl_3$): 7.6 (m, 2H), 6.8 (dd, 1H, J = 1, 8 Hz), 6.45 (dt, 1H, J = 1, 6 Hz), 4.15 (m, 4H), 2.5–1.2 (m, 8H), 1.25 (t, 3H, J = 7 Hz).

The crude ester (6.0 g, 0.025 mol) was dissolved in 30 mL of ethanol and hydrogenated over platinum oxide. Hydrogen absorption was complete in 6 h. Filtration and evaporation afforded 6.0 g (100%) of *N*-(5-carbethoxypentyl)-2-piperidinone as a clear liquid which was pure according to glc analysis; ^{1}Hmr ($CDCl_3$): 4.2 (q, 2H, J = 7 Hz), 3.7–3.2 (m, 4H), 2.6–2.1 (m, 4H), 2.1–1.1 (m, 10H), 1.25 (t, 3H, J = 7 Hz).

The amidoester (5.5 g, 0.023 mol) was dissolved in 25 mL of ethanol and a solution of 1.85 g (0.033 mol) of KOH in 10 mL of water was added. The mixture was stirred at ambient temperature overnight, evaporated, diluted with water, and extracted with ether. The aqueous phase was acidified and extracted with chloroform (4 × 75 mL). The extracts were dried and evaporated, the last traces of solvent being removed at 0.05 Torr. The white solid remaining (**6***d*) (3.5 g, 71%) had mp 72–74°C; ir ($CHCl_3$): 3500–2400, 1715, 1630, 1510, 670 cm^{-1}; ^{1}Hmr ($CDCl_3$): 10.7 (s, 1H), 3.6–3.2 (m, 4H), 2.5–2.0 (m, 4H), 2.0–1.2 (m, 10H); Cmr ($CDCl_3$): 177.2, 170.5, 48.0, 47.3, 34.1, 32.0, 26.7, 26.4, 24.7, 23.6, 21.2. *Anal.* calcd. ($C_{11}H_{19}NO_3$): C 61.95, H 8.98, N 6.57; found: C 62.16, H 9.37, N 6.36.

N-*(3-carboxy-2-methylpropyl)-2-piperidinone (**9**b)*

A stereoisomeric mixture of methyl 4-bromo-3-methylbut-2-enoate (17) (10 g, 0.052 mol) was heated to 160°C under nitrogen. 2-Methoxypyridine (10 g, 0.092 mol) was added in the usual manner. After heating at 165°C for 3 h, the mixture was distilled. The product **8** (4.2 g, 31%) was obtained, bp 130–140°C (0.15 Torr). The ^{1}Hmr and glc analyses showed this material to be a 60:40 mixture of the *E* and *Z* isomers. *Anal.* calcd. ($C_{11}H_{17}NO_3$): C 63.56, H 6.37, N 6.76; found: C 63.41, H 6.42, N 6.79.

Ester **8** (3.5 g, 0.017 mol) was hydrogenated in methanol solution over a 5% Rh/Al_2O_3 catalyst at one atmosphere pressure. Three equivalents of hydrogen were absorbed in 3 h. Filtration and evaporation gave **9***a* as a yellow liquid which required no further purification; ^{1}Hmr ($CDCl_3$): 3.70 (s, 3H), 3.34 (m, 4H), 2.30 (m, 5H), 1.80 (m, 4H), 0.95 (d, 3H, J = 6 Hz).

Ester **9***a* (3.3 g, 0.015 mol) was added to a solution of 1.0 g KOH in 80 mL of ethanol and 10 mL of water. The mixture was stirred at ambient temperature overnight and then evaporated to remove the alcohol. Water (30 mL) was added and the solution was washed with ether. The aqueous phase was acidified to pH 3 and extracted thoroughly with chloroform (5 × 50 mL). The dried extracts were evaporated to give a clear oil which solidified when final traces of solvents were removed at 0.1 Torr pressure. There was obtained 2.4 g (78%) of **9***b*, mp 94–96°C; ir ($CHCl_3$): 3600–2400, 1715, 1630, 1510 cm^{-1}; ^{1}Hmr ($CDCl_3$): 12.2 (s, 1H), 3.35 (m, 4H), 2.38 (m, 5H), 1.82 (m, 4H), 1.00 (d, 3H, J = 8 Hz); Cmr ($CDCl_3$): 175.5, 171.4, 52.4, 48.3, 39.2, 31.9, 28.6, 23.1, 21.0, 17.8. *Anal.* calcd. ($C_{10}H_{17}NO_3$): C 60.28, H 8.70, N 7.03; found: C 60.70, H 9.02, N 7.00.

N-*(4-carboxy-3-methylbutyl)-2-piperidinone (**13**b)*

3-Methyl-δ-valerolactone (Aldrich) (7 g, 0.06 mol) was converted to ethyl-5-bromo-3-methylvalerate (9.7 g, 88%) according to a published procedure (18). The ester (9 g, 0.04 mol) was heated to 180°C under nitrogen. 2-Methoxypyridine (10 g, 0.09 mol) was added dropwise with stirring via syringe in the usual manner and then the liquid was distilled. Ester **12** (3.68 g, 38.5%) was obtained (bp 139–150°C (0.2 Torr)) as a clear liquid; ir (film): 2980, 1730, 1660, 1590, 1540 cm^{-1}; ^{1}Hmr ($CDCl_3$): 7.63 (d, 1H, J = 6 Hz), 7.42 (dd, 1H, J = 2, 4 Hz), 6.73 (d, 1H, J = 9 Hz), 6.38 (td, 1H, J = 6, 1 Hz), 4.07 (m, 4H), 2.4–1.45 (m, 5H), 1.23 (t, 3H, J = 7 Hz), 1.02 (d, 3H, J = 6 Hz); Cmr ($CDCl_3$): 172.3, 162.5, 140.3, 138.2, 120.2, 107.6, 60.2, 48.3, 41.4, 36.0, 28.1, 19.7, 14.3.

Hydrogenation over platinum oxide, followed by hydrolysis as described for **9***b*, afforded **13***b* (83%) as a white solid after trituration with petroleum ether, mp 91–93°C; ^{1}Hmr ($CDCl_3$): 11.6 (s, 1H), 3.33 (m, 4H), 2.65–1.20 (m, 11H), 1.00 (d, 3H, J = 8 Hz); Cmr ($CDCl_3$): 176.4, 170.6, 47.8, 45.3, 41.5, 33.5, 32.0, 28.1, 21.2, 19.8. *Anal.* calcd. ($C_{11}H_{19}NO_3$): C 61.95, H 8.98, N 6.57; found: C 61.93, H 9.15, N 6.82.

N-*(3-carboxypropyl)caprolactam (**6**e)*

A solution of 2.8 g (0.025 mol) of caprolactam and 2.6 g (0.025 mol) of 5-chloro-1-pentene (10) in 20 mL of dry THF was added to a suspension of 1.3 g (0.023 mol) of finely ground KOH and 5 mmol of tetrabutylammonium bromide in 50 mL of dry THF. The addition required 1 h and vigorous stirring was used. The mixture was then refluxed for 8 h, the precipitate removed by filtration, and the filtrate evaporated. The residue was diluted with methylene chloride and the solution was washed with water, saturated brine, and dried. Evaporation gave an oil which upon distillation gave 2.8 g (62%) of *N*-(4-pentenyl)carpolactam, bp 95–98°C (0.7 Torr); ir (film): 3080, 2950, 2855, 1660, 1635, 1470, 1350, 975, 900 cm^{-1}; ^{1}Hmr ($CDCl_3$): 6.00–5.33 (m, 1H), 5.05–4.55 (m, 2H), 3.30–3.08 (m, 4H), 2.48–2.13 (m, 2H), 2.10–1.80 (bt, 2H, J = 6 Hz), 1.78–1.20 (m, 8H); Cmr ($CDCl_3$): 175.6, 138.0, 114.9, 49.7, 48.0, 37.4, 31.2, 30.1, 28.9, 27.5, 23.6.

To a vigorously stirred cold solution of 9.8 g (0.062 mol) of potassium permanganate in 100 mL of water was added a solution of 3.6 g (0.02 mol) of the olefinic lactam in 15 mL of acetic acid over 30 min. Stirring was continued for 12 h at ambient temperature. Sodium bisulfite (3 g) was added slowly to the cooled solution, followed by enough 6 *N* hydrochloric acid to bring the pH to 1. The solution was extracted with methylene chloride (4 × 25 mL), and the organic extracts washed with cold water and dried. Evaporation and trituration with ether gave **6***e* (48%) as a white solid, mp 73–75°C; ir ($CHCl_3$): 3600–2400, 1730, 1600, 1500, 1450, 1400, 1210, 1010, 890, 750, 620 cm^{-1}; ^{1}Hmr ($CDCl_3$): 9.3 (s, 1H), 3.5 (m, 2H), 2.5 (m, 4H), 2.0 (m, 8H); Cmr ($CDCl_3$): 176.8, 176.4, 49.9, 47.8, 36.9, 31.5, 28.5, 23.3. *Anal.* calcd. ($C_{10}H_{17}NO_3$): C 60.28, H 8.60, N 7.03; found: C 60.17, H 8.60, N 7.16.

*3-(3-Carboxypropyl)-2-piperidinone (**16**a)*

To a mixture of 6.9 g of potassium *tert*-butoxide (0.061 mol) in 50 mL of *tert*-butyl alcohol was added 10.5 g (0.061 mol) of 3-carbethoxy-2-piperidinone. The solution was stirred at ambient temperature for 40 min and then ethyl 4-bromobutyrate (11.9 g, 0.061 mol) was added dropwise. After stirring overnight the solution was refluxed for 30 min, evaporated, diluted with chloroform, washed once with water, dried, and evaporated. The residue was treated with petroleum ether and filtered to remove residual starting material. Evaporation of the filtrate gave 9.4 g (54%) of a colorless oil (3-carbethoxy-3-(3-carbethoxypropyl)-2-piperidinone) which was purified using silica gel chromatography (ether); ir ($CHCl_3$): 3420, 3015, 1730, 1670, 1470, 1380, 1360, 1250, 1200 cm^{-1}; ^{1}Hmr ($CDCl_3$): 7.7 (s, 1H), 4.2 (qq, 4H, J = 7, 7 Hz), 3.6–3.2 (m, 2H), 2.5–1.7 (m, 10H), 1.25 (t, 3H, J = 7 Hz); Cmr ($CDCl_3$): 172.2, 171.9, 170.1, 60.2, 59.2, 52.6, 41.1, 33.9, 33.5, 28.7, 19.1, 18.8, 13.1; FDMS m/z = 285. *Anal.* calcd. ($C_{14}H_{23}NO_5$): C 58.96, H 8.06, N 4.91; found: C 58.61, H 8.00, N 4.90.

The diester (7.35 g, 0.025 mol) was heated at reflux with 30 mL of 50% sodium hydroxide for 2 h. The cooled solution was diluted with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

water, washed with chloroform, acidified, and evaporated to dryness. The residue was slurried with absolute ethanol and filtered. The filtrate was evaporated to give 3-carboxy-3-(3-carboxypropyl)-2-piperidinone (5.4 g, 95%) as white crystals, mp 181–183°C; ir (KBr): 3400–2600, 1720, 1650, 1620, 1470, 1440, 1300, 810 cm^{-1}; ^{1}Hmr (DMSO): 8.2 (bs, 1H), 2.7 (m, 2H), 2.3–1.2 (m, 10H).

The diacid (5.0 g, 0.021 mol) was heated at 180–190°C for 5 h. Carbon dioxide was evolved. The yellow oil was purified by silica gel chromatography (ethanol/methylene chloride) to give 3.6 g (97%) of acid **16***a*; ir (film): 3500–2500, 1740, 1630, 1510, 1455, 1400, 1280, 1200, 1060, 880 cm^{-1}; ^{1}Hmr (D_2O): 3.4 (m, 2H), 2.9 (m, 3H), 2.6–1.9 (m, 8H).

*3-(3-Carboxypropyl)-1-methyl-2-piperidionone (**16**b)*

Sodium hydride (0.021 mol) which had been washed three times with hexane was added to a solution of 2.37 g (0.021 mol) of *N*-methyl-2-piperidinone in toluene (40 mL) and the mixture was refluxed overnight. To the cooled mixture was added dropwise 4.3 g (0.022 mol) of ethyl 4-bromobutyrate and the mixture was refluxed overnight. The cooled solution was filtered and the residue washed with chloroform. The filtrates were evaporated to give 3.8 g (80%) of the ethyl ester of **16***b* as a colorless oil which was pure according to glc analysis; ^{1}Hmr ($CDCl_3$): 4.15 (q, 2H, J = 7 Hz), 3.7 (t, 1H, J = 6 Hz), 3.3 (m, 2H), 2.95 (s, 3H), 2.7–1.5 (m, 10H), 1.25 (t, 3H, J = 7 Hz).

The ester (3.4 g, 0.017 mol) was hydrolyzed using 25 mL of 50% sodium hydroxide at ambient temperature for 3 days. The basic solution was washed once with chloroform, acidified, evaporated to dryness and worked up as described for **16***a* to give 3.1 g (92%) of **16***b* as a colorless oil which crystallized on standing to give oily crystals, mp 40–43°C; ir (KBr): 3300–2500, 1735, 1470, 1435, 1230, 1200, 1100, 950 cm^{-1}; ^{1}Hmr (D_2O): 3.6 (m, 3H), 3.3 (s, 3H), 3.2–2.0 (m, 10H).

*Ethyl 2-piperidinone-5-propionate (**19**)*

Compound **19** was prepared from diethyl 4-cyanopimelate (19) by hydrogenation over platinum oxide and heating the resulting aminodiester to achieve cyclization. The crude product (90% by glc analysis) was used directly in the pyrolysis experiment; ir ($CHCl_3$): 3425, 3000–2880, 1720, 1655 cm^{-1}; ^{1}Hmr ($CDCl_3$): 4.10 (q, 2H, J = 7 Hz), 3.20 (m, 2H), 2.30 (m, 3H), 1.70 (m, 4H), 1.23 (t, 3H, J = 7 Hz).

General procedure for soda-lime pyrolyses

The procedure was the same in all cases. The acid was thoroughly mixed with twice its weight of finely ground soda-lime. The soda-lime used contained an indicator which turned blue in the presence of carbon dioxide. Frequently the mixture became sticky and turned blue as soon as mixing began. The pasty mass was transferred to a flask which was fitted with a short-path distillation apparatus, purged with nitrogen, and the flask was heated with a free flame. The contents of the flask turned blue, evolved carbon dioxide, and then turned white again. Water distilled, followed by organic material (head temperature 140–200°C). After all the material had distilled, the two-phase distillate was diluted with ether, the phases were separated, and the aqueous phase extracted with ether. The combined ethereal extracts were dried and evaporated to give the crude enamine which was treated with either 70% perchloric acid in ethanol (1:1) or 10% hexachloroplatinic acid hydrate in absolute ethanol as outlined below for each individual case. It is noteworthy that many of the enamines appear to react with chloroform over a period of several hours, leading to discolored solutions. Fresh samples were used for all spectral investigations.

From **6***a* and **6***b*, salts **7***a* and **7***b* were obtained in 71% and 78% yields respectively. The physical and spectroscopic data for these compounds have been reported previously (1, 9).

From **6***d*, the enamine was obtained in 49% crude yield. Gas-liquid chromatographic analysis showed the enamine to constitute approx. 70% of the mixture; ir ($CHCl_3$): 2960, 1640 cm^{-1}; ^{1}Hmr ($CDCl_3$): 4.55 (bs, 1H), 3.3 (m, 4H), 2.5–2.1 (m, 12H); Cmr ($CDCl_3$): 115.7, 65.7, 49.6, 48.0, 37.1, 33.6, 29.8, 26.0, 23.1. The perchlorate **7***d* was obtained in 30% yield from this mixture, mp 150–152°C (from ethanol after precipitation from ether with ethanolic perchloric acid); ir ($CHCl_3$): 2950, 1680, 1470, 1450, 1100 cm^{-1}; ^{1}Hmr ($CDCl_3$): 3.6 (m, 4H), 2.55 (m, 4H), 1.55 (m, 10H); Cmr ($CDCl_3$): 193.7, 59.7, 55.6, 37.2, 34.8, 29.1, 23.9, 21.3, 20.8, 16.7; FDMS m/z = 152. *Anal.* calcd. ($C_{10}H_{18}NClO_4$): C 47.72, H 7.16, N 5.56; found: C 48.28, H 6.44, N 4.72. (The hygroscopic nature of the crystals made better analyses impossible.)

From the distillation of **6***e* there was obtained a 95% yield of a clear oil which rapidly turned brown on contact with air. Gas-liquid chromatographic analysis showed this material to be 95% pure; ir ($CHCl_3$): 2920, 2850, 1650, 1425 cm^{-1}; ^{1}Hmr ($CDCl_3$): 3.15 (t, 1H, J = 6 Hz), 2.88 (m, 4H), 2.68–1.1 (m, 10H). Acidification of an ethanolic solution of this enamine with perchloric acid, followed immediately by treatment with saturated sodium cyanide solution in the usual manner (9), gave a clear oil whose ^{1}Hmr was featureless but whose Cmr was entirely consistent with the expected cyano adduct of **7***e*; Cmr ($CDCl_3$): 120.1, 65.5, 55.0, 51.1, 40.4, 38.1, 27.0, 25.9, 23.8, 21.3; FIMS m/z = 164.

From **9***b*, the perchlorate **10** was obtained in 75% overall yield, mp 210–212°C (from acetone/ethanol) (hygroscopic white crystals); ^{1}Hmr: 4.4–3.5 (m, 4H), 3.4–2.4 (m, 5H), 2.3–1.7 (m, 4H), 1.28 (d, 3H, J = 6 Hz); Cmr ($CDCl_3$): 190.4, 66.8, 48.0, 45.9, 27.5, 20.1, 18.4, 16.4. *Anal.* calcd. ($C_9H_{16}NClO_4$): C 45.48, H 6.79, N 5.89; found: C 45.47, H 6.69, N 6.23. Treatment of this salt with saturated aqueous sodium cyanide (1) gave the cyano derivative **11** (90%) as a colorless liquid; Cmr ($CDCl_3$): 118.9, 60.4, 59.0, 48.0, 46.0, 45.2, 34.4, 28.4, 24.6, 21.6.

From **13***b* salt **14** (as the perchlorate) was obtained in 61% yield, mp 208–209°C (from ethanol); ^{1}Hmr ($CDCl_3$): 3.80 (m, 4H), 2.78 (m, 5H), 2.02 (m, 6H), 1.10 (d, 3H, J = 5 Hz); Cmr ($CDCl_3$): 186.7, 54.6, 53.9, 40.5, 32.6, 28.5, 23.4, 20.5, 16.6. *Anal.* calcd. ($C_{10}H_{18}NClO_4$): C 47.71, H 7.21, N 5.59; found: C 48.17, 7.13, 5.32.

Treatment of this salt with sodium cyanide as described above gave the cyano derivative **15** in 92% yield as a clear oil which solidified in the freezer; Cmr ($CDCl_3$): 118.0, 60.9, 52.4, 52.1, 45.1, 37.0, 33.7, 28.1, 25.1, 21.4.

From **16***a*, the crude organic material was obtained in 61% yield. From this mixture, the hexachloroplatinate **18***a* was obtained in 15% yield as a yellow solid, mp 162–163°C; ir (KBr): 3190, 2990, 1630, 1500, 1100 cm^{-1}; ^{1}Hmr (DMSO): 7.4 (s, 2H), 3.6 (m, 4H), 2.9 (m, 4H), 2.3–1.3 (m, 18H); FDMS m/z = 124. Correct analytical data could not be obtained because of the highly hygroscopic nature of this salt.

From **16***b*, the enamine(s) **17***b* were obtained in 78% yield. Gas-liquid chromatographic analysis showed this material to be ca. 90% pure, but attempts to isolate salts **18***b* were unsuccessful because of their extremely hygroscopic nature; ir ($CHCl_3$): 2990, 2900, 1640, 1520, 1475, 1370, 1110 cm^{-1}; ^{1}Hmr ($CDCl_3$): 3.4 (m, 2H), 3.05 (s, 3H), 2.7–1.5 (m, 11H); ms m/z = 137 (M^+).

From **20***a*, a distillate was obtained which was shown by glc to consist mainly of cycloheptanone (**21***a*). The melting point of the 2,4-DNP derivative (147°C) was undepressed by admixture of an authentic sample. The yield was 47%.

From **20***b*, a distillate was obtained which was shown by glc to consist mainly of piperidine and cyclopentanone (**21***b*). Distillation of an authentic sample of the piperidine enamine of **21***b* from soda-lime led to its recovery in 70% yield.

From **22** was obtained a mixture of a solid and liquid product. The solid was removed by filtration of an ether solution and shown to be **23** by mixture melting point and spectral comparison with an authentic sample. The remaining material was imine **24** (74%). The hexachloroplatinate had mp 160–162°C (absolute ethanol); ir (KBr): 3480, 3230, 2960, 1720, 1485, 1390 cm^{-1}; ^{1}Hmr (DMSO): 7.5 (bs, 2H), 3.0–2.2 (m, 4H), 2.1 (s, 6H), 1.8–0.9 (m, 12H); Cmr (DMSO): 43.3, 39.5, 39.3, 30.5, 27.5, 26.1, 23.5. *Anal.* calcd. ($C_{14}H_{28}N_2PtCl_6$): C 26.68, H 4.16, N 4.44; found: C 26.11, H 4.87, N 4.56.

NOTE ADDED IN PROOF:

It has recently come to our attention that a similar type of reaction has been reported by Mundy (21). Alkali ring-opening of the acyl lactams described would lead to the same intermediates invoked to rationalize our results.

La dissolution de l'anode de cuivre dans les solutions faiblement chlorurées

ROBERT-LOUIS BROSSARD

Institut de recherche d'Hydro-Québec, C.P. 1000, 1800 Montée Ste-Julie, Varennes (Qué.), Canada J0L 2P0

Reçu le 21 décembre 1982

ROBERT-LOUIS BROSSARD. Can. J. Chem. **61**, 2022 (1983).

La dissolution de l'anode de cuivre a été étudiée en solution aqueuse de pH égal à 4 et dont la concentration en LiCl dissous a été variée de 0,005 *M* à 0,1 *M*. Dans la zone de dissolution active, la valence de dissolution est égale à 1 entre 0,03 *M* et 0,1 *M* pour être comprise entre 1 et 2 en-dessous de 0,03 *M*. Entre 0,03 *M* et 0,1 *M*, l'étape qui contrôle la vitesse de dissolution est presque entièrement attribuable à la diffusion des ions $CuCl_2^-$ dans la solution pour les tensions les plus faibles. La mesure de l'ordre de la réaction par rapport aux ions Cl^- qui est proche de un pour des tensions voisines de la tension réversible ($E_{Cu/CuCl}$) de la réaction $Cu + Cl^- = CuCl + 1e$, suggère que la diffusion des ions Cl^- dans la solution tend aussi à devenir une étape contrôlante lorsque la tension devient voisine de $E_{Cu/CuCl}$.

Pour sa part, le CuCl fait son apparition dès que la tension atteint $E_{Cu/CuCl}$ alors que les courbes en balayage linéaire de tension présentent deux sommets. Ces deux pics ont comme étape limitante la diffusion des ions dans la solution. La hauteur des deux pics est entièrement explicable à partir de la diffusion des ions Cl^- dans la solution comme étape la plus lente. Par ailleurs, le rapport entre le sommet de la deuxième vague et le sommet de la première vague est de 2,14. Ce comportement est en harmonie avec le fait que la valence de dissolution du cuivre augmente depuis le premier pic jusqu'au deuxième.

ROBERT-LOUIS BROSSARD. Can. J. Chem. **61**, 2022 (1983).

The dissolution of a copper anode has been studied in aqueous solution at pH 4 and in which the dissolved LiCl was varied between 0.005 *M* and 0.1 *M*. In the dissolution zone, the dissolution valence is unity between 0.03 *M* and 0.1 *M* and the step controlling the speed of dissolution is almost entirely attributable to the diffusion of $CuCl_2^-$ ion in solution for the weakest voltage. The order of reaction with respect to the chloride ion (Cl^-) is close to unity for voltage close to the reversible voltage ($E_{Cu/CuCl}$) of the reaction $Cu + Cl^- = CuCl + 1e$, suggesting that diffusion of Cl^- ions in solution tends also to become a controlling step when the voltage is close to $E_{Cu/CuCl}$.

CuCl appears when the voltage reaches $E_{Cu/CuCl}$, that is when the linear sweep voltage curves show two peaks. These two peaks have the diffusion of ions in the solution as their limiting step. The height of these two peaks is explicable by the diffusion of Cl^- ions in solution as the slowest step. On the other hand, the ratio between the peak of the second wave and that of the first is 2.14. This behaviour is in agreement with the fact that the valence of dissolution of copper increases from the first peak to the second.

1. Introduction

L'usage de solutions qui contiennent des ions Cl^- tend à se répandre dans les procédés d'usinage et de polissage du cuivre par voie électrochimique. Il est aussi reconnu que les ions Cl^- jouent un rôle prédominant dans le processus de corrosion de ce métal (1 à 8). Ainsi, de nombreuses recherches se sont penchées sur l'étude des mécanismes de dissolution du cuivre en présence des ions chlorures (1 à 20).

Dans les solutions acides ou voisines de la neutralité, l'étape déterminante de la dissolution active du cuivre est imputée à la diffusion d'une espèce ionique dans la solution. Les espèces envisagées sont le Cl^- (1), le Cu^+ (13, 14) ou, plus généralement, un chlorocomplexe de cuivre (2–8, 18–20). L'anode a cependant tendance à se recouvrir de CuCl (16) lorsque la tension devient suffisamment anodique. Dans ces conditions, les auteurs (5, 13, 14, 18) pensent que l'étape limitante est la diffusion des ions Cl^- dans la solution. Ces études ont été conduites pour des concentrations en Cl^- supérieures à 0,1 *M* soit en milieu de pH 3 (1, 5, 13, 14, 16), soit dans une gamme de pH comprise entre 4 et 7 (8, 19, 21, 22), alors que Braun et Nobe (1) prévoient un changement de mécanisme en-dessous de 0,1 *M* en Cl^-.

Le présent travail se propose d'approfondir l'étude de la dissolution anodique du cuivre en solution aqueuse de pH = 4 dont la concentration en Cl^- est comprise entre 0,005 *M* et 0,1 *M*.

2. Partie expérimentale

2.1 *La cellule et ses accessoires*

Les détails relatifs à la cellule et ses accessoires ainsi qu'aux électrodes de travail sont donnés dans un article précédent (20).

2.2 *La préparation des essais*

Un barbotage d'azote de 6 h précédait l'immersion de l'électrode de cuivre dans la solution. Les solutions contenaient entre 0,05 et 0,1 *M* de LiCl dissous. Un tampon à base de phtalate de potassium a été utilisé pour stabiliser le pH à 4.

La méthode employée par Shoesmith *et al.* (23, 24) a été retenue pour le polissage du cuivre: l'échantillon était poli mécaniquement par abrasion avec du papier au carbure de silicium pour se terminer par un polissage avec l'alumine de 1 μ. L'échantillon était alors rincé à l'alcool, à l'acétone puis à l'eau distillée avant son immersion.

2.3 *Les techniques expérimentales utilisées*

Les courbes en balayage linéaire de la tension ont été obtenues par les méthodes courantes. Un bain thermostatique a servi au contrôle de la température. La valence de dissolution a été déterminée dans la zone de dissolution active avec 0,1 *M* en LiCl dissous. Elle a été mesurée par perte de poids (11, 21) après que l'électrode de cuivre, soumise à une tension constante, ait été traversée par une charge de 50 C.

3. Résultats expérimentaux

3.1 *Apparition du produit de corrosion*

L'enregistrement obtenu en balayage linéaire de la tension, reproduit à la fig. 1, et qui correspond à une vitesse de balayage en tension de 1 mV/s, est représentatif du comportement de l'anode de cuivre. La courbe montre deux vagues d'oxydation. La vague "1" est bien définie et son maximum a comme coordonnées 0 mV_{ecs} et 5,3 mA/cm^2. La vague "2", plus diffuse, a un maximum en courant voisin de 12 mA/cm^2. D'après les travaux réalisés dans les solutions chlorurées acides (14), la valence de dissolution est proche de un dans la région de la première vague pour être voisine de deux dans la région de la deuxième vague.

Par ailleurs, la relation E vs. $\log_{10} i$ est linéaire dans la partie

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

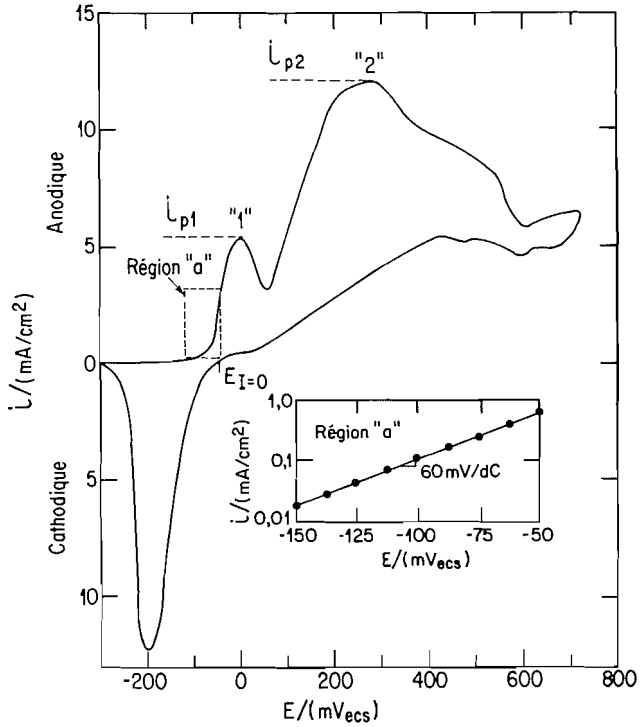

FIG. 1. Courbe de polarisation en balayage linéaire de la tension sur un fil de cuivre. Balayage à 1 mV/s. LiCl: 0,1 *M*. La solution est non agitée et l'électrode est en position stationnaire. $E_{I=0}$: tension à courant nul. La région "a" en médaillon correspond à la première portion de la partie ascendante de la première vague d'oxydation.

ascendante de la vague "1" alors que l'examen de la surface de l'anode par le microscope a permis d'observer que le cuivre reste à nu jusqu'au voisinage de la tension réversible ($E_{Cu/CuCl}$) de la réaction:

[1] $\quad Cu + Cl^- = CuCl + e$

qui est donné par (25):

[2] $\quad E_{Cu/CuCl} = 0{,}109 - 0{,}0591 \log_{10} (Cl^-)$

où $E_{Cu/CuCl}$ est en volt par rapport à l'électrode au calomel saturé.

Le produit de corrosion s'accumule sur l'électrode dès que la tension imposée dépasse de quelques mV la tension réversible $E_{Cu/CuCl}$ (Fig. 2). Dans le cas reproduit à la fig. 2, $E_{Cu/CuCl}$ est de -50 mV$_{ecs}$ (25) alors que l'échantillon a été polarisé jusqu'à -25 mV$_{ecs}$. On remarque que la surface est non uniformément recouverte par le produit de corrosion.

Pour sa part, la relation E vs. $\log_{10} i$ cesse d'être linéaire lorsque le produit de corrosion fait son apparition et le sommet de la première vague de passivation est atteint lorsque E dépasse $E_{Cu/CuCl}$ de 50 mV environ. Ce comportement laisse entrevoir un changement au niveau du mécanisme de dissolution avec l'apparition du produit de corrosion.

3.2 *Comportement du cuivre dans la zone de dissolution active* ($E \leq E_{Cu/CuCl}$)

Les valeurs expérimentales de la valence de dissolution sont rassemblées au tableau 1 pour des concentrations en ions Cl^- comprises entre 0,005 et 0,1 *M*. On remarque que la valence de dissolution dépend de la concentration en ions Cl^-. Elle est de 1,0 entre 0,1 et 0,03 *M* pour augmenter avec une concentration

FIG. 2. Aspect de la surface de l'anode en présence du produit de corrosion. Retrait de l'électrode: -25 mV$_{ecs}$. Conditions expérimentales données à la fig. 1.

TABLEAU 1. Valeurs expérimentales de la valence de dissolution à différentes concentrations en ions Cl^-

Cl^- (*M*)	n^a
0,005	1,65
0,01	1,65
0,02	1,35
0,03	1,0

[a] Valeurs calculées à partir de la pente $(\partial E/\partial \log_{10} i)$ à 22°C.

[b] Valeur confirmée expérimentalement par perte de poids.

décroissante en Cl^- et atteindre 1,65 à 0,005 *M*. Ce comportement tend à confirmer les prévisions faites à partir des calculs théoriques de Braun et Nobe (1) qui suggèrent, notamment, qu'une portion non négligeable du cuivre se dissous sous forme de Cu^{2+} lorsque la concentration en ions Cl^- est en dessous d'une valeur voisine de 0,05 *M*.

Les particularités de l'anode de cuivre, polarisée à des tensions inférieures à $E_{Cu/CuCl}$, et dans la gamme de concentration comprise entre 0,03 et 0,1 *M*, sont:

(a) la relation E vs. $\log_{10} i$ est linéaire avec une pente voisine de 60 mV/décade (Fig. 3). $(\partial E/\partial \log_{10} i)_{Cl^-} = 60$ mV/décade;

(b) la relation i vs. $\omega^{1/2}$ est linéaire pour $\omega \leq 375$ rad/s et l'ordonnée à l'origine passe près de zéro (Fig. 4), i.e. $(\partial i/\partial \omega^{1/2})_{E,Cl^-}$ est constante;

(c) la relation E vs. $\log_{10} i\omega^{-1/2}$ donne une droite avec une

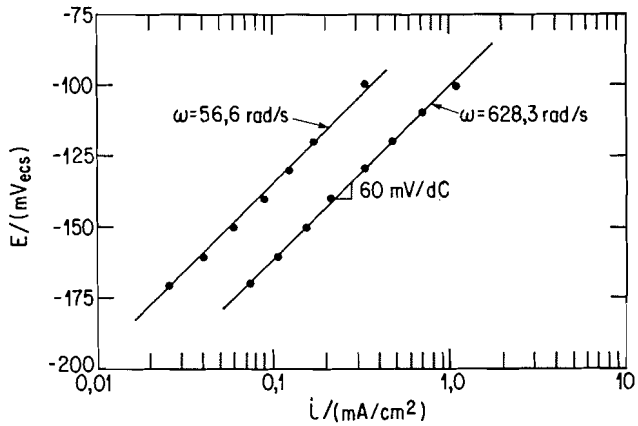

FIG. 3. Relations E vs. $\log_{10} i$ à différentes valeurs de ω. Balayage à 0,5 mV/s; LiCl: 0,1 M. $E \leq E_{Cu/CuCl}$.

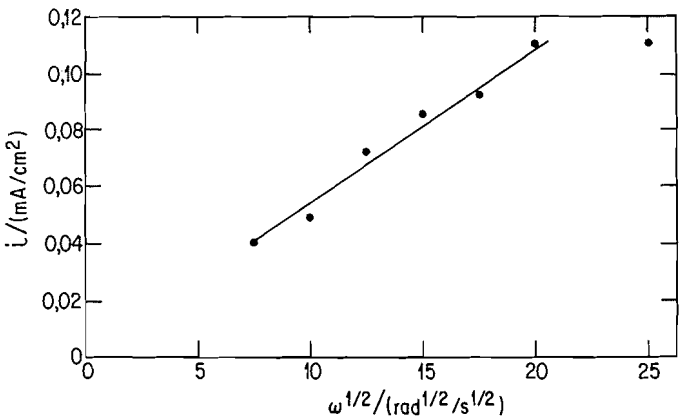

FIG. 4. Courant de dissolution anodique en fonction de $\omega^{1/2}$ avec E et Cl^- fixes. $E = -160$ mV_{ecs} ($E \leq E_{Cu/CuCl}$); LiCl: 0,1 M.

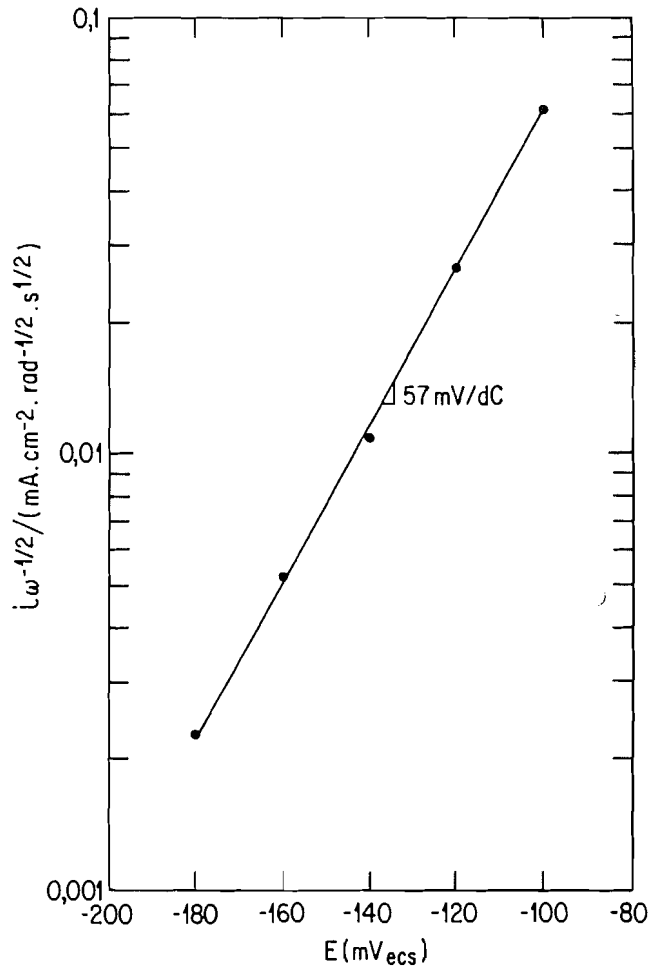

FIG. 5. $i\omega^{-1/2}$ en fonction de la tension imposée. LiCl = 0,1 M; $E \leq E_{Cu/CuCl}$.

pente de 60 mV/décade approximativement (Fig. 5), i.e. $(\partial E/\partial \log_{10} i\omega^{-1/2})_{Cl^-,T} = 60$ mV/décade. Le produit $i \cdot \omega^{-1/2}$ représente la pente de la relation i vs. $\omega^{1/2}$ dans la zone où cette relation est linéaire et où l'ordonnée à l'origine passe par 0 (Fig. 4). Une valeur de $i \cdot \omega^{-1/2}$ correspond à une tension et une concentration en Cl^- fixées;

(d) l'ordre de la réaction par rapport aux ions Cl^- dépend de la tension (Fig. 6). Il est proche de 1 lorsque la tension est élevée i.e. −20 mV pour tendre vers 2 lorsque la tension va décroissant. Ainsi, il atteint 1,83 pour une tension de −140 mV;

(e) la valence de dissolution est égale à 1 (Tableau 1).

De plus, lorsque l'échantillon est soumis à un balayage de retour rapide, une vague de réduction est observée (Fig. 7). Le courant qui correspond au sommet de la vague de réduction (i_p) est proportionnel au courant d'oxydation (i_{ox}). Dans l'exemple choisi ici, le balayage est dix fois plus rapide lors du retour. Enfin, la quantité d'électricité mise en jeu lors du balayage de retour (Q_{cat}) est inférieure à celle mise en jeu lors de l'aller (Q_{an}).

3.3 *Comportement du cuivre en présence du produit de corrosion*

3.3.1 *Nature et caractéristiques du film formé*

L'utilisation du microscope à balayage a permis d'observer la surface de l'électrode durant l'oxydation anodique (Figs. 2, 8). Rappelons que la présence du produit de corrosion est perceptible dès que E dépasse $E_{Cu/CuCl}$ (Fig. 2) alors que le sommet de la première vague d'oxydation coïncide avec le recouvrement complet de l'électrode (Fig. 8). Pour sa part, le courant de dissolution demeure élevé malgré la présence du produit de corrosion sur toute la surface. Après un balayage anodique de 1 mV/s, l'examen de l'électrode révèle un dépôt de plusieurs microns d'épaisseur (à l'oeil nu) dans la partie descendante de la deuxième vague.

Par ailleurs, la diffraction aux rayons-X a permis l'identification d'un seul composé, le chlorure cuivreux, jusqu'à une tension de +800 mV_{ecs}. La présence du CuCl sur l'électrode est associée: (a) à la vague cathodique qui est la signature de la réduction du CuCl (20) formé par voie électrochimique; (b) au fait que la tension à courant nul ($E_{I=0}$), lors du balayage de retour, est de quelques mV inférieure à la tension réversible $E_{Cu/CuCl}$ (Fig. 9).

L'ensemble de ces observations autorise à penser que le CuCl formé est peu protecteur et que le cuivre en présence de CuCl se conduit comme une électrode de second genre où le métal est en équilibre avec un de ses sels insolubles.

3.3.2 *Etape déterminante de la dissolution*

La présence d'une légère agitation dans la solution se traduit par une augmentation considérable du courant de dissolution. La diffusion d'une espèce ionique dans la solution est donc susceptible de contrôler la dissolution du cuivre.

Les courbes $i(E)$, obtenues en balayage linéaire de la tension (Figs. 1, 10), montrent qu'une augmentation de la vitesse de balayage se traduit par une augmentation de courant. Le phé-

nomène de diffusion a été mis en évidence à partir des relations entre le sommet de la vague d'oxydation (i_{p1} et i_{p2}) et la vitesse de balayage dE/dt sur un fil de cuivre (Fig. 11). La relation qui lie i_{p1} et i_{p2} à la racine carrée de la vitesse de balayage est bien représentée par une droite dont l'ordonnée à l'origine passe par

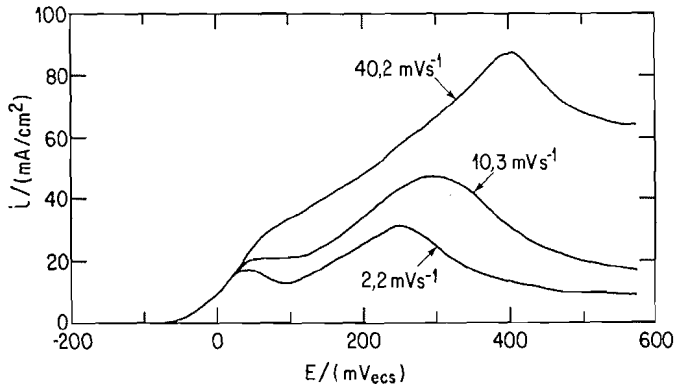

FIG. 10, Influence de la vitesse de balayage sur les courbes $i(E)$ obtenues en balayage linéaire de la tension sur un fil de cuivre. LiCl: 0,1 *M*. La solution est non agitée et l'électrode est en position stationnaire.

zéro. Ce comportement est la signature d'un processus contrôlé par la diffusion en phase liquide (26). Pour les solutions 0,1 *M* LiCl, les relations trouvées sont:

$$[3] \quad i_{p1} = 0{,}21 \left(\frac{dE}{dt}\right)^{1/2}$$

$$[4] \quad i_{p2} = 0{,}45 \left(\frac{dE}{dt}\right)^{1/2}$$

où i_{p1} et i_{p2} sont exprimées en A cm^{-2} et dE/dt en V s^{-1}.

4. Discussion

Dans un premier temps, la dissolution active du cuivre est discutée. La tension imposée est alors inférieure à la tension réversible $E_{Cu/CuCl}$ et le cuivre reste à nu durant la dissolution. Dans un second temps, on discute de la dissolution du cuivre lorsqu'il y a présence de CuCl sur la surface; la tension imposée est alors supérieure à la tension réversible $E_{Cu/CuCl}$.

4.1 *Dissolution active du cuivre*

Les relations i vs. $\omega^{1/2}$ (Fig. 4) suggèrent que la diffusion d'une espèce ionique en solution est l'étape lente de la dissolution du cuivre. Par ailleurs, l'espèce la plus stable pour le cuivre dissous est le $CuCl_2^-$ (1, 25, 27) dans la gamme de concentration en Cl^- comprise entre 0,05 et 0,1 *M* (1). Lorsque la dissolution du cuivre sous forme de $CuCl_2^-$ est envisagée, les étapes les plus probables sont (2, 28):

$$[5] \quad Cu + 2Cl^- = (CuCl_2^-)_i + 1e \text{ (étape rapide)}$$

qui est suivie de:

$$[6] \quad (CuCl_2^-)_i \rightarrow (CuCl_2^-)_s \text{ (étape lente)}$$

les indices i et s indiquent la concentration à la surface de l'électrode et au sein de la solution, respectivement. La deuxième étape, qui est l'étape lente, correspond à la diffusion du $CuCl_2^-$ depuis la surface de l'anode jusqu'au coeur de la solution. La première étape, qui est l'oxydation du cuivre en $CuCl_2^-$, est susceptible d'être dans un état très voisin de l'équilibre, ce qui autorise à utiliser l'équation de Nernst:

$$[7] \quad E = E^0_{Cu/CuCl_2^-} + \frac{RT}{F} \ln \frac{(CuCl_2^-)_i}{(Cl^-)^2}$$

Le réarrangement des termes donne:

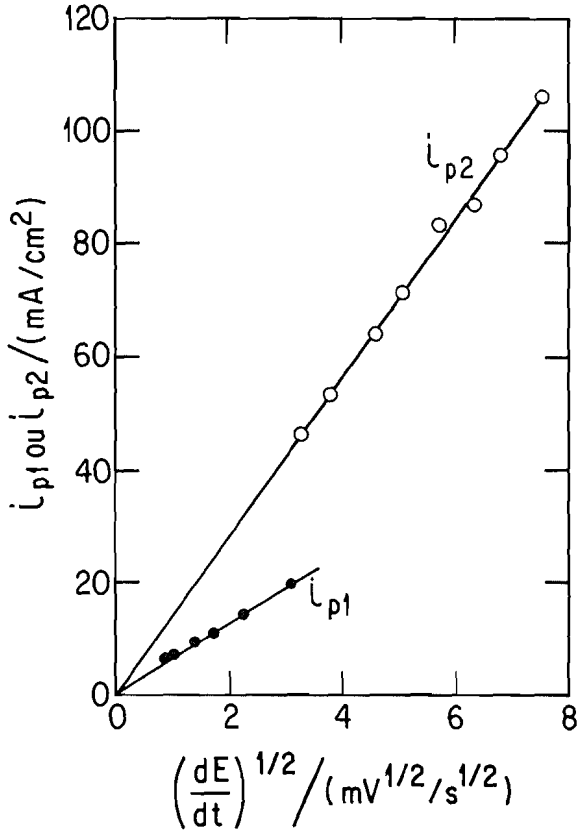

FIG. 11. Influence de la vitesse de balayage sur le sommet des vagues d'oxydation. LiCl: 0,1 *M*.

$$[8] \quad (CuCl_2^-)_i = (Cl^-)^2 \exp \frac{F}{RT} (E - E^0_{Cu/CuCl_2^-})$$

On suppose que la concentration en ions (Cl^-) demeure la même à l'interface, (Cl_i^-), que dans la solution (Cl_s^-). Par ailleurs, l'étape lente en est une de diffusion et la vitesse de la réaction est donnée par la première loi de Fick, dont la forme simplifiée est:

$$[9] \quad i = ZFD \frac{(CuCl_2^-)_i - (CuCl_2^-)_s}{\delta}$$

La relation [9] devient:

$$[10] \quad i = ZFD \frac{(CuCl_2)_i}{\delta}$$

lorsque $(CuCl_2)_i \gg (CuCl_2^-)_s$.

La combinaison des relations [7], [8] et [10] donne:

$$[11] \quad i = \frac{ZFD}{\delta} (Cl^-)^2 \exp \frac{F}{RT} (E - E^0_{Cu/CuCl_2^-})$$

L'utilisation de l'électrode à disque tournant permet d'écrire (29):

$$[12] \quad \delta = 1{,}63\, D^{1/3}_{(CuCl_2^-)}\, \nu^{1/6}\, \omega^{-1/2}$$

La substitution de δ dans la relation [11] donne:

$$[13] \quad i = 0{,}62\, ZF\, \nu^{-1/6}\, D^{2/3}_{(CuCl_2^-)}\, \omega^{1/2}\, (Cl^-)^2 \times \exp \frac{F}{RT} (E - E^0_{CuCl_2^-})$$

où Z, la charge de l'espèce qui diffuse, est égale à 1; ν, la viscosité cinématique, est voisine de $0{,}96 \times 10^{-2}$ cm^2/s (30);

$D_{(CuCl_2^-)}$ est le coefficient de diffusion de l'espèce $CuCl_2^-$; ω est la vitesse de rotation de l'électrode en radians par seconde; E est la tension d'électrode alors que $E^0_{Cu/CuCl_2^-}$ est la tension d'équilibre standard pour la réaction [4].

Les dérivées partielles de la relation [13] sont:

[14] $\left(\frac{\partial E}{\partial \log_{10} i}\right)_{298\,K,Cl^-} = 59$ mV/décade (Fig. 3)

[15] $\left(\frac{\partial i}{\partial \omega^{1/2}}\right)_{E,Cl^-} =$ constante (Fig. 4)

[16] $\left(\frac{\partial E}{\partial \log_{10} (i\omega^{-1/2})}\right)_{298\,K,Cl^-} = 59$ mV/décade (Fig. 5)

Les équations [14], [15] et [16] sont semblables aux particularités (a), (b) et (c) trouvées pour la dissolution active du cuivre (Figs. 3–5) entre 0,03 et 0,1 *M* en LiCl dissous. La valeur expérimentale de l'ordre de la réaction par rapport aux ions Cl^-, qui tend vers 2 lorsque la tension va décroissant (Fig. 6), est conforme avec la relation [13]. On est alors conduit à penser que l'espèce ionique qui diffuse dans la solution est le $CuCl_2^-$ plutôt qu'une autre espèce comme le Cl^-, dans la gamme de tension et de concentration considérées. L'existence du $CuCl_2^-$ est d'ailleurs en harmonie avec le fait que le cuivre dissous a une forte tendance à être associé aux ions Cl^- pour former des complexes (25, 27) lorsque la concentration en ions Cl^- dépasse 0,05 *M* (1).

Le coefficient de diffusion du $CuCl_2^-$ est calculable à partir de l'équation [13].

Les termes Z, F, V et F/RT ont été remplacés par leur valeur respective. Pour sa part, $E^0_{Cu/CuCl_2^-}$ est égal à $+208$ mV_{enh} ou -38 mV_{ecs} (25). Il suffit de connaître $i\omega^{-1/2}$ pour des valeurs de Cl^- et de E données (Fig. 5). C'est ainsi que les coefficients de diffusion donnés au tableau 2 ont été calculés. Ils sont voisins de 1×10^{-5} cm^2/s et dépendent peu de la tension imposée. Ils sont tout à fait conformes aux valeurs de $D_{CuCl_2^-}$ données dans la littérature (18, 26).

Enfin, dans le cas où l'étape déterminante est entièrement imputée à la diffusion des ions Cl^- dans la solution, le courant doit être indépendant de la tension imposée et l'ordre de la réaction par rapport aux ions Cl^- doit être égale à 1 (5). Ces particularités sont incompatibles avec les caractéristiques (a), (c) et (d) trouvées pour l'anode de cuivre aux tensions les plus faibles. Néanmoins, l'ordre de la réaction est compris entre 1 et 2 lorsque la tension s'élève pour atteindre 1 à -20 mV (Fig. 6). La tension de -20 mV est proche de la tension réversible $E_{Cu/CuCl}$ donnée par la relation [2]. Ce comportement laisse croire que la diffusion des ions Cl^- tend aussi à devenir une étape contrôlante à mesure que la tension devient voisine de $E_{Cu/CuCl}$.

Les caractéristiques de la vague de réduction, observée durant le balayage de retour (Fig. 7), sont aussi tout à fait compatibles avec le mécanisme de dissolution formé par les étapes [5] et [6].

En effet, l'équation [10] est équivalente à:

[17] $(CuCl_2^-)_i = (ZFD)^{-1}\,\delta\, i$

Pour un fil de cuivre en l'absence d'agitation imposée, l'écriture de la relation [17] se simplifie:

[18] $(CuCl_2^-)_i = k_1\, i$

où k_1 est une constante de proportionnalité.

TABLEAU 2. Valeurs expérimentales du coefficient de diffusion déterminé à partir de la relation [13]

E (mV_{ecs})	$Cl^- = 0{,}1$ *M*	$Cl^- = 0{,}04$ *M*
-180	$0{,}91 \times 10^{-5}$ cm^2/s	$1{,}3 \times 10^{-5}$ cm^2/s
-160	$1{,}0 \times 10^{-5}$ cm^2/s	$1{,}3 \times 10^{-5}$ cm^2/s
-140	$1{,}0 \times 10^{-5}$ cm^2/s	$1{,}2 \times 10^{-5}$ cm^2/s
-120	$1{,}1 \times 10^{-5}$ cm^2/s	$1{,}2 \times 10^{-5}$ cm^2/s

Pour sa part, le sommet de la vague de réduction (i_p), lors du balayage de retour, est susceptible d'être d'autant plus élevé que la concentration en $CuCl_2^-$ au voisinage de la surface de l'électrode est grande. Ce qui autorise à écrire:

[19] $i_p \propto (CuCl_2^-)_i$

Les relations [18] et [19] donnent:

[20] $i_p \propto i$

C'est à dire que i_p doit augmenter avec l'intensité du courant d'oxydation. Cette prévision est conforme aux résultats expérimentaux (Fig. 7).

Enfin, les courbes voltamétriques de la fig. 7 présentent une particularité supplémentaire. La tension à courant nul, durant le balayage de retour ($E_{i=0}$), est très voisine de la tension où le sens du balayage est inversé (E_{inv}). D'après le modèle envisagé, il est prévisible que la concentration en $CuCl_2^-$ à la surface de l'électrode, $(CuCl_2^-)_i$, change peu entre les instants où $E = E_{inv}$ et où $E = E_{i=0}$ si la vitesse de balayage en retour est suffisamment élevée. Puisque $(CuCl_2^-)_i$ change peu et que E est fixé par $(CuCl_2^-)_i$, à une concentration en Cl^- donnée (relation [7]), il est envisageable que E change peu, i.e. que E_{inv} soit très voisin de $E_{i=0}$.

4.2 *Dissolution du cuivre dans la zone des vagues d'oxydation*

4.2.1 *Pic de la première vague d'oxydation*

On a vu que la première vague d'oxydation est contrôlée par la diffusion d'une espèce dans la solution (Fig. 11). Pour un procédé d'électrode contrôlé par la diffusion, le sommet de la vague est relié à la vitesse de balayage selon (26):

[21] $i_{pi} = (3{,}76 \times 10^5)\, n^{3/2}\, D_i^{1/2} \left(\frac{dE}{dt}\right)^{1/2} C_i$

où i_{pi} est le sommet de la vague en A cm^{-2}, D_i le coefficient de diffusion en $cm^2\ s^{-1}$, dE/dt la vitesse de balayage en V s^{-1}, C_i la concentration de l'espèce qui diffuse en mol cm^{-3} et n le nombre d'électrons.

Dans les solutions acides de LiCl, la valeur élevée du courant de dissolution fait penser selon Kozin *et al.* (13, 14) que la première vague d'oxydation est limitée par la diffusion des ions Cl^-, depuis le coeur de la solution jusqu'à la surface de l'électrode. Le courant qui correspond au maximum de la première vague d'oxydation est aussi de plusieurs mA cm^{-2} pour le cuivre immergé en solution 0,1 *M* LiCl (Fig. 1). Par ailleurs, on a vu que la diffusion des ions Cl^- tend à devenir une étape contrôlante de la dissolution active du cuivre lorsque la tension devient voisine de $E_{Cu/CuCl}$. Il semble donc raisonnable d'envisager la diffusion des ions Cl^- comme étape contrôlante. Pour une solution 0,1 *M* en Cl^- i.e. pour C_i de $0{,}1 \times 10^{-3}$ mol cm^{-3}, $D_{Cl^-} \simeq 1{,}94 \times 10^{-5}$ $cm^2\ s^{-1}$ (31), alors que $n \simeq 1{,}2$ (21). La substitution de ces valeurs dans la relation [21] conduit à:

[22] $i_{pl} = 0{,}21 \left(\frac{dE}{dt}\right)^{1/2}$

où i_{p1} est exprimé en A cm^{-2} et correspond au sommet de la vague lorsque la diffusion des ions Cl^- est considérée; (dE/dt) est en V s^{-1}. i_{p1} donné par la relation [22] est donc en bon accord avec i_{p1} trouvé expérimentalement, i.e. la relation [3].

4.2.2 *Deuxième vague d'oxydation*

Dans le cas où l'étape déterminante est attribuée à la diffusion des ions Cl^- dans la solution, les valeurs de D_{Cl^-} et de (Cl^-) sont identiques à celles utilisées dans la relation [22]. Pour sa part, $n \simeq 2$ (25). On obtient alors:

$$[23] \quad i_{p2} = 0{,}45 \left(\frac{dE}{dt}\right)^{1/2}$$

Ainsi, i_{p2} donné par la relation [23] est en harmonie avec i_{p2} trouvé expérimentalement i.e. la relation [4]. On envisage donc la formation d'intermédiaire comme le $CuCl^+$ ou le Cu^{2+} (25) dans la région de la 2e vague alors que l'étape déterminante de la dissolution est entièrement imputable à la diffusion des ions Cl^- dans la solution.

Conclusion

La surface de cuivre reste complètement à nu durant la dissolution anodique de ce métal à des tensions inférieures à $E_{Cu/CuCl}$. La valence de dissolution est égale à 1 entre 0,03 *M* et 0,1 *M* en LiCl dissous pour être comprise entre 1 et 2 en dessous de 0,03 *M*. Entre 0,03 *M* et 0,1 *M*, la vitesse de dissolution est presque entièrement expliquable à partir de la diffusion du $CuCl_2^-$ dans la solution pour les tensions les plus faibles. La diffusion des ions Cl^- tend aussi à devenir une étape contrôlante à mesure que la tension devient voisine de $E_{Cu/CuCl}$.

Il y a apparition de chlorure cuivreux à la surface de l'anode de cuivre en position stationnaire et en contact avec une solution non agitée lorsque la tension imposée est voisine de la tension réversible $E_{Cu/CuCl}$.

Les courbes en balayage linéaire de tension présentent deux vagues de dissolution. La hauteur de la 2e vague est environ 2,2 fois la hauteur de la première.

Dans le cas de la première vague, son sommet (i_{p1}) augmente de façon linéaire avec la racine carrée de la vitesse de balayage. Les valeurs expérimentales de i_{p1} sont en harmonie avec les valeurs théoriques du sommet de la vague qui sont calculées en considérant la diffusion des ions Cl^- comme étape déterminante.

Dans le cas de la deuxième vague, son sommet (i_{p2}) augmente de façon linéaire avec la racine carrée de la vitesse de balayage. Les valeurs expérimentales de i_{p2} sont en accord avec les valeurs théoriques du sommet de la vague qui sont calculées en considérant la diffusion des ions Cl^- comme étape déterminante.

Remerciements

Received February 2, 1983

ARNOLD JARCZEWSKI, PRZEMYSLAW PRUSZYNSKI, and KENNETH T. LEFFEK. Can. J. Chem. **61**, 2029 (1983).

The kinetic deuterium isotope effect for the proton transfer reaction between 4-nitrophenylphenylcyanomethane and tetramethylguanidine, k_H/k_D, at 25°C, is 10.7 in acetonitrile solvent and 12.5 in benzonitrile. The enthalpy of activation difference, $(\Delta H^{\ddagger}_D - \Delta H^{\ddagger}_H)$, in both solvents is large, 2.2 kcal mol^{-1}, and 2.4 kcal mol^{-1}; respectively, indicating a significant contribution from proton tunnelling to the reaction. The equilibrium constants, K, measured spectrophotometrically are large, 6000 dm^3 mol^{-1} in acetonitrile and 2000 dm^3 mol^{-1} in benzonitrile and in good agreement with the values calculated from the kinetic measurements.

ARNOLD JARCZEWSKI, PRZEMYSLAW PRUSZYNSKI et KENNETH T. LEFFEK. Can. J. Chem. **61**, 2029 (1983).

L'effet isotopique cinétique du deutérium dans la réaction de transfert de proton entre le nitrophényl-4 phénylcyanométhane et la tétraméthylguanidine k_H/k_D à 25°C est de 10,7 dans l'acétonitrile et de 12,5 dans le benzonitrile. Il y a une grande différence d'enthalpie d'activation $(\Delta H^{\ddagger}_D - \Delta H^{\ddagger}_H)$ dans les deux solvants. Elle est respectivement de 2,2 kcal mol^{-1} et de 2,4 kcal mol^{-1} ce qui indique une contribution importante de l'effet tunnel du proton à la réaction. Les constantes d'équilibre mesurées par spectrophotométrie sont élevées, 6000 dm^3 mol^{-1} dans l'acétonitrile et 2000 dm^3 mol^{-1} dans le benzonitrile et s'accordent bien avec les valeurs calculées à partir des mesures cinétiques.

[Traduit par le journal]

Introduction

Primary deuterium isotope effects can vary over a wide range, from $k_H/k_D \sim 2$ up to more than 20 at 25°C, depending on a number of factors. It has been known for a long time (1–3) that reactions involving extensive steric hindrance may have high narrow potential energy barriers which give rise to large isotope effects, $k_H/k_D > 7$, as a result of proton tunnelling. A significant contribution to the isotope effect from proton tunnelling has been noted in reactions with symmetrical transition states (4–6) and also in reactions in solvents of low polarity (7). In such solvents the proton transfer takes place independently of solvent reorganization which allows the tunnel effect to exert a maximum influence on the rate.

Caldin and Mateo (7) found very high isotope effects up to $k_H/k_D \sim 50$ at 25°C, for proton transfer reactions to tetramethylguanidine base. However, Rogne and co-workers (8, 9) have suggested that these extremely large values in nonpolar solvents are artefacts of deuterium scrambling during the reaction. Melander and Saunders (10) have given a kinetic treatment of this case and demonstrated that the standard equation [1] for a reversible deuteron transfer reaction, where k_{obs} is the

$$[1] \quad k_{obs} = k_f b + k_b$$

observed pseudo-first order rate constant when the base concentration b is in large excess and k_f and k_b are the rate constants for the forward and backward reactions respectively, is changed to [2] when the equilibrium constant k_f/k_b is small and deuterium exchange is rapid. Thus, fitting the deuteron transfer

$$[2] \quad k_{obs} = k_f b$$

reaction to eq. [1] instead of eq. [2] would yield a k_{fD} value lower than its true value and hence an abnormally large k_H/k_D isotopic ratio.

One manifestation of deuterium scrambling is that the equilibrium constant, determined from optical density measurements on reaction solutions which have reached equilibrium, does not agree with that calculated from k_f/k_b (9). This may be used as a test that deuterium scrambling is not significant when it can be shown that the two determinations of the equilibrium constant are the same within experimental error. However, the rate constant k_f is always determined correctly whether or not deuterium scrambling takes place, i.e. whether eq. [1] or eq. [2] is appropriate.

The present work extends the range of the experimental observations for systems where a large isotope effect due to proton tunnelling may be expected. A carbon acid with increased steric hindrance relative to *p*-nitrophenylnitromethane studied by Caldin and Mateo (7), and which could show no secondary isotope effect, was selected, *p*-nitrophenylphenylcyanomethane. This reacts with tetramethylguanidine (TMG) but the reaction could be followed only in fairly polar solvents where the equilibrium constants for proton transfer were large.

Results and discussion

The reaction of 4-nitrophenylphenylcyanomethane with TMG base gives a violet-blue product, $\lambda_{max} = 590$ nm in both acetonitrile and benzonitrile solvents. The absorbance measurements of the product gave good linear plots of a/A versus $1/b$ as required by eq. [3], where a and b are the initial concentrations of the acid and base respectively, A is the absorbance

$$[3] \quad a/A = \frac{1}{Kb\epsilon} + \frac{1}{\epsilon}$$

at equilibrium, ϵ the molar extinction coefficient of the product, and K is the equilibrium constant. Equation [3] is derived on the assumption that the product is an ion-pair, so the reaction is represented by eq. [4].

[4] $NO_2C_6H_4\underset{\underset{C_6H_5}{|}}{C}HCN + HN{=}C(N(CH_3)_2)_2 \underset{k_b}{\overset{k_f}{\rightleftharpoons}}$

$$NO_2C_6H_4\underset{\underset{C_6H_5}{|}}{\bar{C}}CN\cdots H_2\overset{+}{N}{=}C(N(CH_3)_2)_2$$

The data did not fit the analogous equation derived on the assumption that the product consists of separate ions (11).

The equilibrium constant for both reactions is high, K = 6000 dm^3 mol^{-1} and 2000 dm^3 mol^{-1} for acetonitrile and benzonitrile respectively, at 20°C. The molar extinction coefficient in both solvents is equal to 4000 dm^3 mol^{-1} cm^{-1}.

The value of the equilibrium constant depends on the polarity of the solvent and, in the case of a reaction with more polar products than reactants, should be higher for the more polar solvent, as is the case for this reaction.

Pseudo-first order rate constants were determined using an acid concentration of 8×10^{-6} M in acetonitrile solvent and 4×10^{-5} M in benzonitrile solvent, with varying base concentrations always in large excess. The rate constants for the forward and backward reactions of eq. [4] were calculated using eq. [1] and are collated in Table 1. The errors quoted for k_f and k_b are the standard deviations.

It may be noted that the rate constants for the backward reaction are small. Thus, this cyano-carbon acid does not show the very rapid reaction of its carbanion with acids which was observed by Hibbert *et al.* (12, 13) for malononitriles. Rather, it reacts very much like the acid studied by Caldin *et al.* (14, 15), 4-nitrobenzyl cyanide. This suggests that, as expected (16), the negative charge in the carbanion is delocalized into the nitrophenyl ring.

The values of the equilibrium constants for the normal acid, calculated from k_f/k_b, are 5700 dm^3 mol^{-1} and 2000 dm^3 mol^{-1} in acetonitrile and benzonitrile respectively, at 20°C, in good agreement with the results obtained from equilibrium measurements, showing that the proton transfer is free from side reactions, such as decomposition of the ion-pair to products other than the original substrate and base. This confirms that eq. [4] is the correct description of the reaction, the kinetic equation for which gives eq. [1] as the expression for the observed first-order rate constant.

The equilibrium constants, calculated from k_f/k_b, for the deuterated substrate at 20°C are 2700 dm^3 mol^{-1} and 1800 dm^3 mol^{-1} in acetonitrile and benzonitrile respectively. The isotope effect on the equilibrium constant should be approximately unity, as is the case in benzonitrile. The apparent equilibrium isotope effect of about 3 in acetonitrile shows that some deuterium exchange is taking place and that the results do not fit

eq. [1] exactly. If exchange were complete and eq. [2] were followed, the apparent isotope effect on the equilibrium constant would be infinity. Thus, the reaction in acetonitrile falls between eq. [1] and eq. [2], leading to k_b values which are in error. The k_f values, however, are valid. Thus, the k_b values in acetonitrile cannot be used to interpret the reaction.

It has been suggested (17) that traces of water, which always remain in TMG after drying and purification, could give rise to $\bar{O}H$ ion which might be the proton abstracting base rather than the TMG. To test this possibility, experiments were carried out in which the solvent benzonitrile was saturated with D_2O before purification by the Coetzee and McGuire method (18). Previously dried and purified TMG was also equilibrated with about 1% D_2O and then redried and distilled. Observed pseudo-first order rate constants for the deuterated substrate at 20°C for the same TMG concentrations in line 3 of Table 1 (b) (ii) were 1.7 to 3.0 s^{-1} yielding $k_f = 1.32$ dm^3 mol^{-1} s^{-1} and $k_b = 0.76$ s^{-1}, in excellent agreement with the values in the table. If $\bar{O}H$ had been replaced by $\bar{O}D$ as the reagent base, an isotope effect from about 50% up to 80% (19) should have been observed. The influence of $\bar{O}H$ or the ion-pair $TMGH^+\bar{O}H$ on the reaction rates and isotope effects, therefore, appears to be negligible.

The k_f rate constants for the reaction in Table 1 are about 3 times smaller in acetonitrile than in benzonitrile. This is not expected from the dielectric constants for these solvents. However, Caldin and Mateo (7) found a similar rate reversal for 4-nitrophenylnitromethane, although it was not as large. From Caldin's study of ten solvents, the rate constants in acetonitrile seem to be abnormally small. For such a rate reversal to occur in a reaction in which the transition state is more polar than the initial state, the transition state must come early along the reaction coordinate, before much charge development has taken place.

The activation parameters, together with their standard deviations, for the proton and deuteron transfer reactions are shown in Table 2. The forward reaction shows rather small enthalpy of activation values and negative entropy of activation values, typical of proton transfer reactions. It may be seen that the enthalpy of activation is smaller in acetonitrile than in benzonitrile, as would be expected from the dielectric constants of the solvents, and that the rate reversal is brought about by the much larger negative entropy of activation in acetonitrile.

The activation parameters for the reverse reaction are determined with considerably less precision, but this reaction also shows a large negative entropy of activation.

The values of the primary deuterium isotope effect (Table 1) are large, and larger in the less polar benzonitrile ($k_H/k_D = 12.5$ at 25°C) than in the more polar acetonitrile (10.7 at 25°C). These values are larger than can be explained by the loss of the zero-point energy of the C—H stretching vibration, although not beyond the limits of a zero-point energy effect involving the loss of the C—H stretch and changes in the two C—H bending modes. However, the large isotopic difference in the enthalpies of activation for the forward reaction ($\Delta H_D^{\ddagger} - \Delta H_H^{\ddagger}$) = 2.2 to 2.4 kcal mol^{-1} indicates a significant contribution from the tunnelling effect to the proton transfer reaction.

TABLE 2. Activation parameters for the reaction of 4-nitrophenylphenylcyanomethane with tetramethylguanidine

Parameter	Proton transfer	Deuteron transfer
(a) Acetonitrile solvent		
$\Delta H_f^{\ddagger}$ (kcal mol^{-1})	3.7±0.2	5.9±0.2
$\Delta S_f^{\ddagger}$ (cal mol^{-1} deg^{-1})	−28.3±0.7	−25.6±0.8
$\Delta H_b^{\ddagger}$ (kcal mol^{-1})	9.9±0.9	—
$\Delta S_b^{\ddagger}$ (cal mol^{-1} deg^{-1})	−24±3	—
(b) Benzonitrile solvent		
$\Delta H_f^{\ddagger}$ (kcal mol^{-1})	7.3±0.2	9.7±0.2
$\Delta S_f^{\ddagger}$ (cal mol^{-1} deg^{-1})	−14.0±0.6	−11.1±0.7
$\Delta H_b^{\ddagger}$ (kcal mol^{-1})	8.2±0.4	9.9±0.9
$\Delta S_b^{\ddagger}$ (cal mol^{-1} deg^{-1})	−26±1.3	−25±3

Experimental

Materials

p-Nitrophenylphenylacetonitrile was prepared by the procedure of Neresheimer and Rupple (20) for the condensation of phenylacetonitrile with *p*-nitrochlorobenzene. A mixture of *p*-nitrochlorobenzene (10 g), pyridine (100 g), and a paste obtained by grinding pyridine (21 g) and potassium hydroxide (21 g) in a ball mill under a nitrogen atmosphere, was cooled to −5°C. Phenylacetonitrile (7.5 g) was added, with stirring, during a period of 10 minutes. This mixture was maintained at 0°C and stirred for 10 hours, then benzene (100 mL) was added with stirring and the blue-violet mixture was suction-filtered. The solid material was washed with benzene, then with diethyl ether, and then with cold water. The solid was then placed in water (1 L) and acetic acid (50 g) was added slowly. The precipitated product was filtered, washed with water, and vacuum dried. After recrystallization from 95% ethanol, the product had a mp of 70–72°C; nmr, aliphatic proton, δ 5.6 ppm; ratio of aromatic to aliphatic hydrogen, 9.2:1.

The deuterated carbon acid was obtained by exchanging 0.2 g of the above product with dioxan/D_2O (5:1) in which a small amount of sodium had been dissolved. After 1 or 2 minutes the mixture was neutralized with DCl in D_2O and the solvent evaporated. The carbon acid was extracted with dioxan and the exchange procedure was repeated four times. After the fourth exchange the deuterated substrate was recovered by extracting the sediment with dry chloroform and pouring this solution into an excess of dry petroleum ether. The nmr spectrum showed that the signal from the aliphatic proton was reduced to the background. Therefore, the carbon acid was at least 98% deuterated in the aliphatic position.

Reagent grade acetonitrile was purified by the method of O'Donnell *et al.* (21), with a final fractional distillation from P_2O_5.

Reagent grade benzonitrile was purified by the method of Coetzee and McGuire (18) by drying with CaH_2, followed by fractional distillation at reduced pressure over a small amount of P_2O_5.

Tetramethylguanidine was dried with KOH and then fractionally distilled under reduced pressure. The middle fraction, about 25% of the total, was used.

Equilibrium and kinetic measurements

The optical density measurements were made on Specord UV-VIS and VSU-2P spectrophotometers fitted with a constant temperature bath to control the temperature of the cell block within 0.1°C.

The kinetic runs were performed under pseudo-first order conditions with the base always in at least 50-fold excess. The solvents were always freshly distilled and the deuterated carbon acid stock solutions were always freshly prepared to avoid the possibility of a slow exchange of the deuterium atom with the solvent. The kinetic measurements for the normal and deuterated carbon acids were made in a stopped-flow spectrophotometer and the pseudo-first order rate constants were calculated using the Guggenheim method. The second-order rate constants were calculated from eq. [1] and the activation parameters were evaluated from these by means of a least-squares fit to the transition state theory equation.

Induction periods in the formation of ethane from the pyrolysis of ethylene

ALLAN L. MACKENZIE, PHILIP D. PACEY,[1] AND JAYANTHA H. WIMALASENA[2]
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received February 2, 1983

ALLAN L. MACKENZIE, PHILIP D. PACEY, and JAYANTHA H. WIMALASENA. Can. J. Chem. **61**, 2033 (1983).

Induction periods have been observed in the formation of C_2H_6 from C_2H_4 pyrolysis at 895 K and 23 to 78 Torr. The induction periods were interpreted as evidence of the approach to the steady-state concentration of radicals. The observed inverse pressure dependence of the induction periods was an indication that both chain initiation and termination were bimolecular. Taking the termination rate constant as 1.3×10^{10} L mol^{-1} s^{-1} and neglecting autocatalysis, for the most likely initiation reaction,

$$2C_2H_4 \rightarrow C_2H_3 + C_2H_5$$

the rate constant was found to be 2.3×10^{-4} L mol^{-1} s^{-1}. Assuming further that termination is dominated by recombination and disproportionation of C_2H_5, the rate constant for

$$C_2H_5 + C_2H_4 \rightarrow C_2H_6 + C_2H_3$$

was found to be 8×10^4 L mol^{-1} s^{-1}.

ALLAN L. MACKENZIE, PHILIP D. PACEY et JAYANTHA H. WIMALASENA. Can. J. Chem. **61**, 2033 (1983).

On a observé des périodes d'induction lors de la formation du C_2H_6 à partir de la pyrolyse du C_2H_4 à 895 K et à des pression entre 23 et 78 Torr. On considère que ces périodes d'induction soient une preuve de l'évolution des radicaux vers la concentration de l'état stationnaire. L'influence inverse de la pression sur la période d'induction indique que l'amorçage et la rupture des chaînes sont bimoléculaires. En utilisant la constante de vitesse de $1{,}3 \times 10^{10}$ L mol^{-1} s^{-1} pour la rupture des chaînes et en négligeant l'autocatalyse on trouve une constante de vitesse de $2{,}3 \times 10^{-4}$ L mol^{-1} s^{-1} pour la réaction d'amorçage la plus courante:

$$2C_2H_4 \rightarrow C_2H_3 + C_2H_5$$

De plus, en supposant que la combinaison et la dismutation du C_2H_5 sont responsables de la rupture des chaînes, on trouve une constante de vitesse de 8×10^4 L mol^{-1} s^{-1} pour la réaction:

$$C_2H_5 + C_2H_4 \rightarrow C_2H_6 + C_2H_3$$

[Traduit par le journal]

Introduction

The pyrolysis of ethylene at 750–900 K has proved to be difficult to study (1–7) for the following reasons: (*i*) rates have been found to increase with increasing reaction times, a phenomenon attributed to autocatalysis; (*ii*) some products may be formed by several pathways, making it impossible to determine the rate of any one of these paths; and (*iii*) several radicals are believed to participate in the reaction and it has not been possible to demonstrate conclusively which radical is dominant.

In the present work, these difficulties have been addressed in the following ways: (*i*) a flow system has been used to study the system at short reaction times, before autocatalysis becomes dominant; (*ii*) the product, ethane, has been studied, as this product is formed mainly by one path; and (*iii*) temperatures and pressures have been chosen so that reactor residence times would be similar to the times necessary to establish the steady state concentrations of the radicals. Experiments satisfying the latter criterion are capable of providing information about chain initiation and termination processes (8, 9).

The mechanism for the formation of ethane in ethylene pyrolysis has been proposed to be as follows (6):

[1] $2C_2H_4 \rightarrow C_2H_3 + C_2H_5$

[2] $C_2H_5 + C_2H_4 \rightarrow C_2H_6 + C_2H_3$

. . . . . .

[3*a*] $2C_2H_5 \rightarrow n\text{-}C_4H_{10}$

[3*b*] $2C_2H_5 \rightarrow C_2H_4 + C_2H_6$

Here the dots stand for various omitted addition, abstraction, isomerization, and decomposition reactions of the radicals.

The chain lengths are believed to be long (6), so the propagation reaction, [2], occurs many times more often than the termination, [3*b*], and the rate of formation of C_2H_6 can be identified with the rate of reaction [2].

The rate constant, k_1, has previously been estimated by comparing rates of formation of products in the presence and absence of additional initiation processes (5–7). These studies agree that initiation in pure C_2H_4 is second order, but do not agree on the absolute initiation rate.

During the establishment of the steady-state concentration of C_2H_5, it may be shown (8, 10) that the chordal rate of formation of C_2H_6 should be given by the following expression:

$$[4] \quad [C_2H_6]/t = (b/t) \ln [1 + \exp(at)]/2 - ab/2$$

Here it has been assumed that the above mechanism is correct, that autocatalysis has not begun, that chains are long, and that the pseudo-stationary state approximation (11) is valid for all radical species except C_2H_5. The parameters a and b in eq. [4] may be shown by the methods of ref. 8 to be given by:

$$[5] \quad a = 4[C_2H_4](k_1k_3)^{1/2}$$

and

$$[6] \quad ab = 2k_2(k_1/k_3)^{1/2}[C_2H_4]^2$$

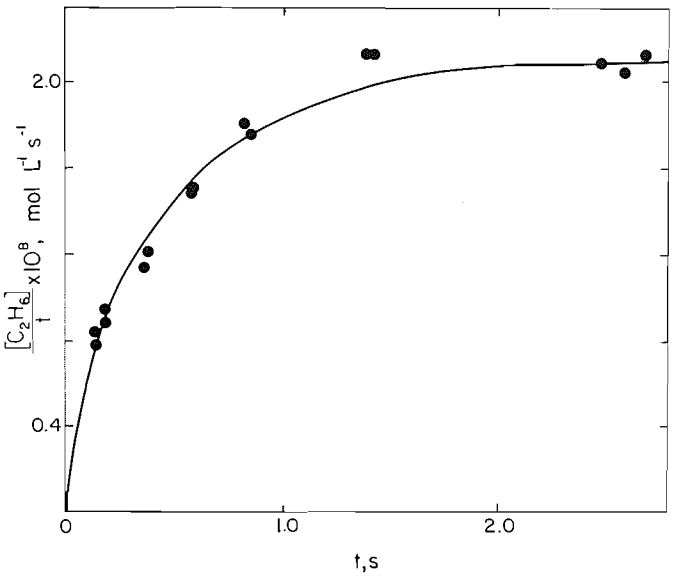

FIG. 1. Dependence of the chordal rate of formation of C_2H_6 on the reactor residence time at 73 Torr and 896 K: (●) experimental; (—) least-squares fit to eq. [4].

where $k_3 = k_{3a} + k_{3b}$. The parameter a has the units, s^{-1}, and is related to the inverse of the induction period, the time during which radical concentrations build up toward their steady-state values. This induction period should occur much earlier in the course of the reaction than the induction period for establishment of a steady-state concentration of 1-C_4H_8, investigated in ref. 1. The product, ab, is twice the steady rate of formation of C_2H_6.

The experimental temperature, 895 K, has been chosen so that C_2H_6 yields are great enough to be measured and induction periods long enough to be accessible with the equipment available (10).

Experimental section

The apparatus and experimental technique were similar to those used in refs. 8 and 10. Three cylindrical quartz reactors were used, with internal diameters and surface-to-volume ratios (S/V) of, respectively, (*i*) 1.7 cm, 3.1 cm^{-1}, (*ii*) 0.8 cm, 9.9 cm^{-1}, and (*iii*) 0.4 cm, 8.8 cm^{-1}. Along the axes of reactors i and ii were placed 0.4 cm o.d. quartz thermocouple wells. Reactor iii was placed along the axis of a 1.1 cm i.d. quartz tube, which held a moveable platinum – platinum – 13% rhodium thermocouple. The temperature profile was used in a computer program (12) to calculate the length of the reaction zone.

Reactant and product concentrations were analyzed in a gas chromatograph with a 1-m, 10% NaOH on alumina column at 23°C. The chromatograph was calibrated each day with mixtures containing small concentrations of ethane diluted with nitrogen. Ethylene (Matheson, research purity, 99.98%) was degassed at the melting temperature of isopentane. The principal impurities remaining were CH_4 (1–1.5 ppm), C_2H_6 (1–2 ppm), 1,3-C_4H_6 (<0.4 ppm), and C_4H_{10} (<0.3 ppm).

Results

Experiments[3] have been performed at reactor temperatures of 892–900 K, reactant pressures from 23 to 78 Torr, and residence times from 0.136 to 5.7 s.

[3]Tables of experimental results are available from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

TABLE 1. Parameters at 895 K determined by least-squares fits to eq. [4] as in Fig. 1

P, Torr	Reactor diameter, cm	$10^{-6}a^2/(4[C_2H_4])^2$ (L^2 mol^{-2} s^{-2})	$10^2ab/(2[C_2H_4]^2)$ (L mol^{-1} s^{-1})
23	1.7	2.9	1.01
35	0.8	3.3	0.97
35	0.8	3.5	0.80
42	0.8	3.1	0.94
47	0.8	2.8	1.08
52	0.4	3.5	1.15
58	0.4	2.5	1.03
61	0.8	2.0	0.97
73	0.4	2.9	1.25
78	0.4	3.7	1.03
Ave.		3.0±0.5	1.02±0.12

Results of a series of experiments at 896 K and 73 Torr are shown in Fig. 1. The points are experimental; the solid curve is a non-linear least-squares fit to eq. [4], representing the establishment of the steady state.

The results of this and other least-squares fits at other pressures are summarized in Table 1. Parameters determined at experimental temperatures other than 895 K have been adjusted slightly to 895 K by multiplying by exp $[-E_a((R895\ \mathrm{K})^{-1} - (RT)^{-1}))$. For the third column in Table 1, equal to $10^{-6}k_1k_3$ by eq. [5], E_a was taken as 269 kJ mol^{-1} from ref. 7. For the final column, equal to $10^2k_2(k_1/k_3)^{1/2}$ by eq. [6], E_a was taken as 176 kJ mol^{-1}, from ref. 2. The quoted uncertainties in the averages are standard deviations of the tabulated values.

It can be seen from the table that parameters obtained in different reactors and at different pressures are in satisfactory agreement. When the logarithms of the parameters were plotted against the logarithm of the pressure, it was possible to find the orders for these parameters. The orders were found to be 1.93 ± 0.17 for a^2 and 2.16 ± 0.10 for ab, in agreement with eqs. [5] and [6], within experimental uncertainty.

Taking $k_3 = 1.3 \times 10^{10}$ L mol^{-1} s^{-1} from ref. 8 and assuming eqs. [5] and [6] are correct, one obtains from the average values in Table 1, $k_1 = 2.3 \times 10^{-4}$ L mol^{-1} s^{-1} and $k_2 = 8 \times 10^4$ L mol^{-1} s^{-1}.

Discussion

Possible competing processes

For an alternative initiation reaction,

[7] $C_2H_4 + M \rightarrow C_2H_3 + H + M$

k_7, when M = Ar, is calculated (13) to be five orders of magnitude slower than k_1 at this temperature. Although C_2H_4 is likely to be more efficient at energy exchange than Ar, reaction [1] should still be much faster than [7].

Similarly, the rate of decomposition (8) of the major impurity, C_2H_6, is calculated to be three orders of magnitude slower than reaction [1] and the concentration of C_4H_{10} impurity was much less than that which was found to have an effect on the rate in ref. 6. Other possible initiation reactions have been shown not to be significant in ref. 5.

Using the rate constants from the previous section, one can calculate that the chain length is about 50. Following the argument in the Introduction, 99% or more of the C_2H_6 should be formed by reaction [2].

We now consider whether reactions [3*a*] and [3*b*] are the

For personal use only.

principal termination reactions. The yield of CH_4, probably formed by

[8] $CH_3 + C_2H_4 \rightarrow CH_4 + C_2H_3$

was found in this work to be 10% of the yield of C_2H_6 from reaction [2]. Similarly, the yield of C_4H_{10}, formed partly by reaction [3*a*] and partly, perhaps, by the reaction

[9] $C_4H_9 + C_2H_4 \rightarrow C_4H_{10} + C_2H_3$

has been shown (2) to be 7% of the rate of formation of C_2H_6. Since the rate constants of reactions [8] and [9] are probably similar to that for reaction [2], it may be concluded that the concentration of C_2H_5 is greater than that of CH_3 or C_4H_9 and that C_2H_5 is the dominant alkyl radical.

If a first-order termination, with rate constant k_w, were dominant, then the induction period would be k_w^{-1}, independent of pressure (14, 15). If this termination were a kinetically controlled surface process, the induction period would be inversely proportional to S/V. Instead, the induction period, related to a^{-1}, was found to be inversely proportional to pressure and independent of S/V in accord with eq. [5] and with the hypothesis that second-order homogeneous terminations are dominant.

The observed pressure dependence of a could also be explained by an alternative bimolecular termination, for example,

[10] $2C_2H_3 \rightarrow C_4H_6$

Delliste *et al.* (6) have shown that the ratio $[C_2H_3]/[C_2H_5]$ is approximately equal to k_2/k_{11}, where reaction [11] is

[11] $C_2H_3 + C_2H_4 \rightarrow C_4H_7$

Based on Arrhenius parameters (16) for other radical additions to C_2H_4 and on the value of k_2 from the Results section, it may be estimated that $[C_2H_3]$ is 1 or 2% of $[C_2H_5]$ and hence that reaction [10] may be neglected.

A possible alternative cause of induction periods in pyrolysis reactions is the delay in warming the reactant after it enters the reactor. The steady-state rates in the cylindrical reactor, iii, would be reduced (17) by a fraction approximately equal to $r^2/\kappa t$, where r is the reactor radius, t the residence time, and κ the thermal diffusivity, which equals $\lambda/([C_2H_4]C_p)$. Here λ, the thermal conductivity, has been calculated by the method of ref. 18 and C_p, the heat capacity, has been obtained from ref. 19. The maximum reduction in apparent rate from this source in the present work would be 4% and would occur for the shortest times in Fig. 1. Any errors from this source will be neglected in this work.

In deriving eqs. [4] to [6] it was assumed that autocatalysis does not affect the results under the present experimental conditions. Boyd, Wu, and Back (2) found that there was a period of steady formation of C_2H_6 before the onset of catalysis. Other workers (1, 6) did not observe this steady period, and Delliste *et al.* (6) fitted their results to the following expression:

$$[12] \quad \frac{[C_2H_6]}{t} = k_2\left(\frac{k_1}{k_3}\right)^{1/2}[C_2H_4]^2(1 + ct)$$

Here the parameter c is a combination of rate constants important in the formation and decomposition of 1-C_4H_8. The possibility of autocatalysis during the establishment of the steady state may be approximately taken into account by multiplying eq. [4] by the factor $(1 + ct)$ from eq. [12]:

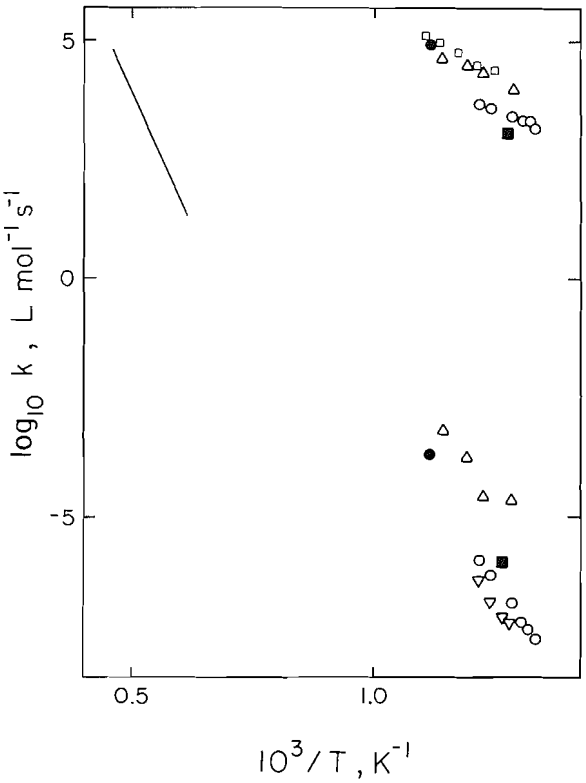

FIG. 2. Arrhenius plots for reactions [1] (lower right), [2] (upper right), and [7] (upper left); □, ref. 1; △, ref. 2; ■, ref. 6; ○, ref. 7, $C(CH_3)_4$ addition; ▽, ref. 7, C_2H_6 addition; —, ref. 13; ●, this work.

$$[13] \quad \frac{[C_2H_6]}{t} = \left[\frac{b}{t}\ln\{[1 + \exp(at)]/2\} - \frac{ab}{2}\right](1 + ct)$$

This equation may be justified in the same way as the use of the factor $(1 - ct)$ to account for self-inhibition in ref. 10.

Equations [12] and [13] have been fitted to the data in Fig. 1 by least squares. Equation [12], the equation of a straight line, has a sum of squares of residuals five times as large as for eq. [4] and does not fit the data well. For eq. [13], a is increased by 18%, b is decreased by 23%, and the sum of squares of residuals is decreased by 6% compared to the fit to eq. [4]. By the method of analysis of variance (20), it is found that the third parameter, c, is significant only at the 50% confidence level. Henceforth, we will adopt the values of a and b from fits to eq. [4], but recognize that the possibility of autocatalysis introduces an uncertainty in these parameters.

Comparison with other work

Values of k_1 are shown in the form of an Arrhenius plot in the lower part of Fig. 2. Values based on acceleration by 1-butene, whether added initially (5) or formed as a product (6), have been omitted, because of a ten-fold uncertainty in the rate constant of the reference reaction

[14] 1-$C_4H_8 \rightarrow CH_3 + C_3H_5$

Instead, k_1 has been estimated, using the following equation (6, 21), from initial rates of formation of n-C_4H_{10} reported in refs. 2 and 6:

$$[15] \quad 1.14R^0_{C_4H_{10}} = k_1[C_2H_4]^2$$

Use of this equation is supported by the observation that C_4H_{10} formation is second order and has an activation energy of 290

kJ mol^{-1} (2), similar to values for reaction [1] obtained by other techniques.

The values of k_1 obtained by the different techniques do not agree well. Each technique has its own weaknesses. The present technique assumes that autocatalysis does not affect the induction period and assumes a value for the termination rate constant. The acceleration technique assumes a mechanism for acceleration and a value for the reference rate constant. Equation [15] is based on the assumption that reactions [3*a*] and [3*b*] are the only termination steps and that there are no other sources of C_4H_{10}. Preparations are being made to use the latter technique in this laboratory for comparison with the present results. Values of the rate constant for the high temperature initiation reaction, [7], are shown at the left in Fig. 2.

In the upper right hand corner of Fig. 2 are shown values for the abstraction rate constant, k_2. In most cases, values of $k_2 k_1^{1/2} k_3^{-1/2}$ have been taken from the steady-state rate of formation of C_2H_6, k_3 has been taken from ref. 8, and k_1 has been taken as the corresponding value from the lower part of Fig. 2. Values of k_2 calculated from observed C_2H_6 and C_4H_{10} yields in ref. 1 have been adjusted to take into account the more recent value of k_3 (8). Again there are differences between the results of different techniques.

In conclusion, we note that there are still aspects of C_2H_4 pyrolysis that are not completely understood. Studies of induction periods do introduce a new perspective on the problem. The observed pressure dependence of the induction periods can be simply explained only if the initiation and termination reactions are both bimolecular. The observed pressure dependence of the product *ab* is in agreement with the hypothesis that reactions [3*a*] and [3*b*] are the main termination reactions. Values of the parameters, *a* and *b*, would be somewhat affected if autocatalysis occurs, but there is no evidence that autocatalysis is significant at these early reaction times. Subject to the above assumptions and limitations, it has been possible to estimate values of k_1 and k_2.

Absolute rate constants for hydrocarbon autoxidation. 33. A product study of the self-reaction of α-tetralylperoxyls in solution[1]

A. BAIGNÉE,[2] J. H. B. CHENIER, AND J. A. HOWARD[3]

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received January 28, 1983

A. BAIGNÉE, J. H. B. CHENIER, and J. A. HOWARD. Can. J. Chem. **61**, 2037 (1983).

The major initial products of the self-reaction of α-tetralylperoxyls ($C_{10}H_{11}O_2^{\cdot}$) in chlorobenzene at 303–353 K are equal concentrations of α-tetralol and α-tetralone in ~90% yield based on the number of initiating radicals. These yields are consistent with the non-radical (Russell) mechanism for self-reaction. Low concentrations of bis(α-tetralyl) peroxide are produced, indicating that there is a small but detectable free-radical contribution towards termination. $C_{10}H_{11}O_2^{\cdot}$ undergoes β-scission in this temperature range but steady-state concentrations of $C_{10}H_{11}^{\cdot}$ are too low to influence the termination rate constant $2k_t$, or react with $C_{10}H_{11}O_2^{\cdot}$ to give $(C_{10}H_{11})_2O_2$. α-Tetralol to α-tetralone ratios and total yields of these products are significantly less than 1 and 100%, respectively, in methanol and acetonitrile. Formaldehyde is produced in methanol indicating the involvement of α-hydroxymethylperoxyls, derived from the solvent, in termination. There is no evidence for a chain reaction or a zwitterion intermediate for self-reaction of $C_{10}H_{11}O_2^{\cdot}$ in solution.

A. BAIGNÉE, J. H. B. CHENIER et J. A. HOWARD. Can. J. Chem. **61**, 2037 (1983).

Les produits initiaux majoritaires de l'autoréaction des α-tétralylpéroxyles ($C_{10}H_{11}O_2^{\cdot}$) dans le chlorobenzène à 303–353 K correspondent à des concentrations égales d'α-tétralol et d'α-tétralone avec un rendement approximatif de 90% basé sur le nombre de radicaux initiateurs. Ces rendements sont en accord avec le mécanisme d'autoréaction non radicalaire (Russell). Les faibles concentrations de bis(α-tétralyl) peroxyde obtenues indiquent que la contribution du radical libre à la rupture est faible mais décelable. Le composé $C_{10}H_{11}O_2^{\cdot}$ subit une scission β dans cet intervalle de température mais les concentrations de l'état stationnaire du $C_{10}H_{11}^{\cdot}$ sont trop faibles pour influencer la constante de vitesse de rupture $2k_t$, ou pour réagir avec le radical $C_{10}H_{11}O_2^{\cdot}$ pour donner le $(C_{10}H_{11})_2O_2$. Les rapports α-tétralol/α-tétralone et les rendements totaux de ces produits sont de façon significative inférieures à 1 et à 100% respectivement dans le méthanol et l'acétonitrile. Dans le méthanol, il se forme de la formaldéhyde, ce qui indique que des α-hydroxyméthylpéroxyles provenant du solvant sont impliqués dans la rupture. Il n'y a pas de preuve d'une réaction en chaine ou de la présence d'une paire d'ions intermédiaires dans l'autoréaction du $C_{10}H_{11}O_2^{\cdot}$ en solution.

[Traduit par le journal]

Introduction

Kinetic studies of the self-reaction of alkylperoxyls ($RO_2^{\cdot}$) in solution below 403 K have revealed that absolute rate constants for self-reaction ($2k_t$) of primary ($R^1CH_2O_2^{\cdot}$) and secondary alkylperoxyls ($R^1R^2CHO_2^{\cdot}$) are several orders of magnitude larger than rate constants for tertiary alkylperoxyls ($R^1R^2R^3CO_2^{\cdot}$) (1). Self-reactions of peroxyls with and without a hydrogen atom on the α-carbon atom would, therefore, appear to involve different mechanisms. Product studies have, in general, supported this conclusion, since primary and secondary alkylperoxyls give products indicative of a non-radical mechanism (Russell mechanism) while tertiary alkylperoxyls give products consistent with the intermediacy of tertiary alkoxyls.

The mechanism for self-reaction of tertiary alkylperoxyls has been well estabished (2–4). These radicals exist in dynamic equilibrium with a tetroxide which decomposes to give two caged alkoxyls and oxygen. A fraction (~10%) of these alkoxyls combine to give di-*tert*-alkyl peroxide while the remainder escape the solvent cage and undergo H-atom abstraction, β-scission, or rearrangement (3, 4).

Secondary alkylperoxyls (and probably $R^1CH_2O_2^{\cdot}$) also exist in equilibrium with tetroxide at low temperatures and values of the thermodynamic parameters ΔH^0 and ΔS^0 appear identical, within experimental error, to values for $R^1R^2R^3CO_2^{\cdot}$ (5). This suggests that $2k_t$ (primary and secondary) are $>2k_t$ (tertiary) because primary and secondary alkyl tetroxides decompose faster than tertiary alkyl tetroxides, either because of a change in mechanism or because primary and secondary alkyl tetroxides homolyze much faster than tertiary alkyl tetroxides.

Russell (6) over 20 years ago suggested that $R^1R^2CHO_2^{\cdot}$ and $R^1CH_2O_2^{\cdot}$ undergo self-reaction via a cyclic intermediate which decomposes by a non-radical mechanism to give alcohol, ketone (or aldehyde), and oxygen in equal yields.

[1] $2R^1R^2CHO_2^{\cdot} \rightleftharpoons$ 
$R^1R^2C{=}O + O_2 + R^1R^2CHOH$

This mechanism has received experimental support from the observation of a primary kinetic isotope effect on $2k_t$ when the H attached to the α carbon is replaced by deuterium (7), the evolution of $^1\Sigma_g^+$ and $^1\Delta_g$ oxygen (8, 9), and the production of equal yields of alcohol and ketone (10–14). Product yields are, however, not always compatible with this mechanism. For instance, Bennett and Summers (15) reported high ketone-to-alcohol ratios from self-reaction of several secondary alkylperoxyls at low temperatures. Furthermore, at ambient temperatures, a considerable fraction of 1-ethoxyethylperoxyls and 1,2-diphenylethylperoxyls give free alkoxyls (16).

It has been argued (17), with the aid of thermochemical calculations, that the activation energy for non-radical tetroxide decomposition would have to be very small or even negative to compensate for the entropy loss in the formation of the cyclic transition state. In actual fact, overall pre-exponential factors

of $10^8-10^9\ M^{-1}\ s^{-1}$ and overall activation averages of 1–2 kcal mol^{-1} have been determined by kinetic electron spin resonance studies of the decay of secondary alkylperoxyls (18).

In an attempt to account for the kinetics and products of self-reaction of $R^1CH_2O_2^{\cdot}$ and $R^1R^2CHO_2^{\cdot}$, Nangia and Benson (19) have proposed the following chain mechanism which involves the intermediacy of a diradical, $R\dot{C}HO\dot{O}$, or zwitterion, $R\overset{+}{C}HO\bar{O}$.

[2] $2RCH_2O_2^{\cdot} \longrightarrow RCH_2OOH + R\dot{C}HO\dot{O}$

[3] $R\dot{C}HO\dot{O} + RCH_2O_2^{\cdot} \longrightarrow RCHO + RCH_2O_3^{\cdot}$

[4] $RCH_2O_3^{\cdot} \longrightarrow RCH_2O^{\cdot} + O_2$

[5] $RCH_2O^{\cdot} + RCH_2O_2^{\cdot} \longrightarrow RCH_2OH + R\dot{C}HO\dot{O}$

[6] $RCH_2O^{\cdot} + RCH_2O_2^{\cdot} \longrightarrow RCHO + RCH_2OOH$

[7] $RCH_2O^{\cdot} + RCH_2O_2^{\cdot} \rightleftharpoons RCH_2OOOCH_2R$

[8] $RCH_2O^{\cdot} + RCH_2OOH \longrightarrow RCH_2OH + RCH_2O_2^{\cdot}$

[9] $R\dot{C}HO\dot{O} + RCHO \longrightarrow$  $\longrightarrow RCHO + R\dot{C}H\text{–}O^{\cdot} \longrightarrow RCOOH$

Reaction [2] is a disproportionation reaction which would be expected to have a small activation energy and an A-factor of $\sim 10^9\ M^{-1}\ s^{-1}$. Reactions [3] to [5] constitute a chain cycle with aldehyde (or ketone) and alcohol as the reaction products, and chain lengths of 2–10. In solution, in the presence of a good H-atom donor such as an aralkane or aralkyl hydroperoxide, the diradical should react to give an α-hydroperoxyalkyl which would undergo β-scission to give ketone or aldehyde and hydroxyl

[10] $R\dot{C}HO\dot{O} + RH \longrightarrow R\dot{C}HOOH + R^{\cdot}$

[11] $R\dot{C}HOOH \longrightarrow RCHO + HO^{\cdot}$

There have been several careful kinetic and product studies of the self-reactions of alkylperoxyls ($CH_3O_2^{\cdot}$, $C_2H_5O_2^{\cdot}$, $(CH_3)_2CHO_2^{\cdot}$, and $(CH_3)_3CO_2^{\cdot}$) in the gas phase (20–26) and absolute termination rate constants are very similar in the gas and liquid phases. It has been concluded that $CH_3O_2^{\cdot}$, for example, interact by terminating and non-terminating mechanisms with the ratio of rate constants k_{12b}/k_{12a}, falling in the range 1.3 to 2 at ambient temperatures.

[12] $2CH_3O_2^{\cdot} \xrightarrow{a} CH_3OH + CH_2O + O_2$

$2CH_3O_2^{\cdot} \xrightarrow{b} 2CH_3O^{\cdot} + O_2$

$2CH_3O_2^{\cdot} \xrightarrow{c} CH_3OOCH_3 + O_2$

In several of these studies, in marked contrast to solution studies (27), dialkyl peroxide has been tentatively identified and a value of the rate constant ratio $k_{12c}/k_{12} \leq 0.14$ has been calculated.

Apart from H-atom abstraction and β-scission, the alkoxyls formed in reaction [12b] are believed to undergo self-reaction to give carbonyl and alcohol (reaction [13]), react with oxygen to give carbonyl and hydroperoxyl (reaction [14]), and react with alkylperoxyl to give carbonyl and hydroperoxide (reaction [15]).

[13] $2CH_3O^{\cdot} \longrightarrow CH_3OH + CH_2O$

[14] $CH_3O^{\cdot} + O_2 \longrightarrow CH_2O + HO_2^{\cdot}$

[15] $CH_3O^{\cdot} + CH_3O_2^{\cdot} \longrightarrow CH_2O + CH_3OOH$

Clearly there are some quite marked differences in the behaviour of primary and secondary alkylperoxyls in the gas phase and in solution. In an attempt to study the self-reaction of secondary alkylperoxyls more thoroughly in solution, we have determined the products of the autoxidation of tetralin, the induced decomposition of α-tetralin hydroperoxide, the thermolysis of azotetralin in the presence of oxygen, and the metal-catalyzed decomposition of α-$C_{10}H_{11}OOH$ by high performance liquid chromatography under a wide variety of reaction conditions. The results of this study are reported here.

Experimental

Materials

α-Tetralol and α-tetralone were obtained from Aldrich and were used as received. Tetralin was purified by washing with concentrated sulfuric acid, sodium bicarbonate solution, and water, then dried, distilled, and chromatographed on alumina under argon. α-Tetralin hydroperoxide was prepared by the cobalt naphthanate-initiated autoxidation of tetralin at 50°C. The crude hydroperoxide, obtained by removal of the excess hydrocarbon, was recrystallized from toluene.

2,2,3,3-Tetraphenylbutane and di-*tert*-butyl hyponitrite had been prepared previously in our laboratory. Azo-bis-isobutyronitrile was recrystallized from methanol below 40°C. Methanol, chlorobenzene, and acetonitrile were carefully dried and distilled. Lead oxide (Anachemia) and cobalt acetylacetonate (Ventron) were used as received. Cobalt stearate and naphthanate were prepared by standard procedures.

Bis(α-tetralyl) peroxide was prepared from α-tetralin hydroperoxide by the method of Triebs and Pellman (28). The product, after having been recrystallized from hexane, had a mp 90–91°C.

Azo-bis-α-tetralin was prepared from α-tetralone and hydrazine by the method of Cohen and Wang (29, 30). The final product gave one peak in the hplc chromatogram. The ultraviolet spectrum (Hewlett–Packard 8450A) gave $\lambda_{max} = 364$ mμ (the azo linkage) and $\epsilon = 90\ M^{-1}\ cm^{-1}$. Complete decomposition in chlorobenzene at 323 K gave 1 mole of N_2 per mole of azotetralin. A 9.6 mM solution in C_6H_5Cl at 323 K evolved N_2 with a rate of $2.3 \times 10^{-8}\ M\ s^{-1}$; giving $k_d = 2.4 \times 10^{-6}\ s^{-1}$ where k_d is the first-order rate constant for decomposition of $(C_{10}H_{11})_2N_2$.

Product studies

Oxidation and decomposition products were identified and quantified by high performance liquid phase chromatography using a Varian 5000 liquid chromatograph in conjunction with a Vista 401 chromatography data system. The chromatograph was equipped with a reverse phase column and the eluting solvent was a mixture of acetonitrile and water. Formaldehyde was converted to the formylhydrazone by reaction with a slight excess of 2,4-dinitrophenylhydrazine after trap-to-trap distillation (31). Autoxidations were performed at O_2 pressures of 1 to 100 atm as described previously (3). Yields, unless stated otherwise, were based on the total number of radicals produced in the initiation reaction and were accurate to ~5%.

Results

Products of autoxidation of tetralin

The initial rate of autoxidation of tetralin (1 M) in chlorobenzene, intitiated by di-*tert*-butyl hyponitrite (10.8 mM), under oxygen (1 atm) at 303 K was $5.4 \times 10^{-7}\ M\ s^{-1}$ and the kinetic chain length was 9–10. The major reaction products

were α-tetralin hydroperoxide, α-tetralone, and α-tetralol in the yields given in Table 1. The initial ratio of α-tetralol to α-tetralone, [A]/[K], was 0.9 and decreased gradually as the reaction proceeded. The total yield of alcohol plus ketone was initially ~90% per chain initiated. Clearly α-tetralol and α-tetralone were the major termination products and they were formed in almost equal yields. As the reaction proceeded, the yield of ketone became greater than the yield of alcohol, the latter being close to the yield expected from the toal number of termination reactions. At high conversions (1–2%) there was a minor peak in the hplc with a retention time identical to that for bis(α-tetralyl) peroxide. The maximum yield of this termination product was ~0.7% per initiation radical.

Autoxidation of tetralin under 100 atm of O_2 at 303 K gave the same products as were formed at 1 atm; there was, however, some perturbation of the product yields (Table 2). The yield of alcohol was reduced slightly while the yield of ketone was increased slightly, although the total initial yield was close to 100%. The high pressure of O_2 had no noticeable effect on the rate of decomposition of BON_2OB, very little influence on the rate of autoxidation, and no effect on the yield of $(C_{10}H_{11})_2O_2$.

The AIBN initiated autoxidation of tetralin in chlorobenzene at 353 K gave [A]/[K] = 1.4 after 1 h and 0.7 after 23 h. $(C_{10}H_{11})_2O_2$ was produced with a maximum yield of 2% based on the alcohol yield after 23 h (Table 3).

Autoxidation of tetralin in methanol at 303 K gave the products listed in Table 4. Values of [A]/[K] were much lower than in chlorobenzene and were of the order of 0.1 or less. In addition, the total yield of [A] + [K] was initially only 35–40% and $(C_{10}H_{11})_2O_2$ was not produced. The low yield of tetralol was not due to autoxidation of this product, because the concentration of initially added tetralol (2.7 m*M*) did not decrease in autoxidizing tetralin under standard conditions for 48 h. Separate experiments showed that formaldehyde was formed in this solvent in yields ~ [K] − [A].

Inclusion of benzaldehyde into this system did not influence the yields of alcohol, ketone, and peroxide or [A]/[K] to any appreciable extent. Very little benzoic acid was produced and there was no additional peak in the peroxide region of the chromatogram which could be attributed to ozonide formation.

Induced decomposition of α-tetralin hydroperoxide

The major products of the induced decomposition of $C_{10}H_{11}OOH$ in chlorobenzene, methanol, methanol containing LiCl, and acetonitrile under argon at 303 K were α-tetralol and α-tetralone in the yields summarized in Table 5.

The initial [A]/[K] in chlorobenzene was ~0.9 and decreased to ~0.6 when all the initiator had decomposed. The stoichiometry of the reaction, *n*, ($\Delta[ROOH]/\Delta[BO^{\cdot}]$) was 1 and most of the hydroperoxide decomposed could be accounted for as alcohol and ketone. Bis(α-tetralyl) peroxide was formed with a maximum yield of 0.023 m*M* or 0.3%. [A]/[K] was not influenced to any appreciable extent by an increase in tem-

perature to 353 K, whereas there was a small increase in the yield of $(C_{10}H_{11})_2O_2$. Again, almost all of the hydroperoxide decomposed could be accounted for as $C_{10}H_{10}O$ and $C_{10}H_{11}OH$.

In methanol, [A]/[K] was about 1/20 of the ratio in chlorobenzene and most of the hydroperoxide decomposed gave $C_{10}H_{10}O$ and $C_{10}H_{11}OH$. Formaldehyde was produced in yields ~ [K] − [A]. Initial stoichiometric factors fell between 1 and 2, suggesting some induced decomposition. At higher conversions, where yields could be measured more accurately, *n* values were 1. $(C_{10}H_{11})_2O_2$ was not produced in this solvent and there was no evidence for the formation of methyl α-hydroperoxytetralyl ether. Replacing the argon with 5 atm of O_2 and increasing the temperature to 353 K had no effect on [A]/[K], and $(C_{10}H_{11})_2O_2$ was not produced in either of these experiments. In methanol containing LiCl, [A]/[K] was low, $(C_{10}H_{11})_2O_2$ was not detected, and there was no significant peak in the chromatogram which could be assigned to α-chloro-α-hydroperoxytetralin. The hydroperoxide was, however, decomposed much more rapidly in this system.

[A]/[K] in acetonitrile was less than the value in chlorobenzene but greater than the value in methanol. In this solvent there was no evidence for induced hydroperoxide decomposition since *n* was ~1 throughout the reaction. The yields of alcohol and ketone were, however, consistently just less than 1. The yield of $(C_{10}H_{11})_2O_2$ in CH_3CN was ~0.1%.

It is conceivable that β-scission of $C_{10}H_{11}O_2^{\cdot}$ to give $C_{10}H_{11}^{\cdot}$ and O_2 could play an important role in the chemistry of this peroxyl at ambient temperatures. Decompositions of $C_{10}H_{11}OOH$ were, therefore, conducted under an atmosphere of $^{36}O_2$ at 303, 343, and 353 K. $C_{10}H_{11}{}^{18}OH$ and $C_{10}H_{10}{}^{18}O$ were definitely formed under these conditions but their yields were extremely low (Table 6).

Decomposition of azotetralin in the presence of oxygen

Azotetralin decomposed slowly in solution at 303 K to give α-tetralyls which, in the presence of O_2, were rapidly converted to α-tetralylperoxyls. The major products in chlorobenzene, acetonitrile, and methanol were $C_{10}H_{10}O$, $C_{10}H_{11}OH$, and $C_{10}H_{11}OOH$ in the yields given in Table 7. $C_{10}H_{11}OH$ only appeared after prolonged oxidation and [A]/[K] < 1. $C_{10}H_{11}OOH$ was almost certainly produced by reaction of $C_{10}H_{11}O_2^{\cdot}$ with $(C_{10}H_{11})_2N_2$ and/or the solvent.

Decomposition of azotetralin was faster at 323 K and a 9.6 m*M* solution in C_6H_5Cl absorbed O_2 (1 atm) with a rate of 2.9

$\times 10^{-8}$ M s^{-1}, suggesting very little induced decomposition of the azo compound. $C_{10}H_{10}O$ and $C_{10}H_{11}OH$ were formed in equal yields and $[C_{10}H_{11}OOH]/([A] + [K])$ was ~1.9.

Induced decomposition of α-$C_{10}H_{11}OOH$ by metal catalysts

The behaviour of $C_{10}H_{11}O_2^{\cdot}$ in solution, at higher steady-state radical concentrations than are encountered in autoxidation and in systems where alkoxyls as well as alkylperoxyls are produced, has been investigated by product studies of the induced decomposition of $C_{10}H_{11}OOH$ by metal catalysts. The results of these studies are summarized in Table 8.

Lead dioxide, which oxidizes a hydroperoxide to its peroxyl, gave $([A] + [K])/\Delta[C_{10}H_{11}OOH] \sim 1$, $[A]/[K] \sim 1$, and $[(C_{10}H_{11})_2O_2]/\Delta[C_{10}H_{11}OOH] = 0.004-0.007$ in chlorobenzene and methanol.

Decomposition of $C_{10}H_{11}OOH$ by $Co(acac)_2$, which gives alkoxyls as well as peroxyls, in chlorobenzene was fast, and ~80% of the hydroperoxide gave $[A]/[K] \sim 0.4$ and $[(C_{10}H_{11})_2O_2]/\Delta[C_{10}H_{11}OOH] \sim 0.003$. Decomposition by $Co(acac)_2$ was much slower in methanol and $([A] + [K])/\Delta[C_{10}H_{11}OOH] \sim 0.62$, $[A]/[K] \sim 1.6$, and $[(C_{10}H_{11})_2O_2]/\Delta[C_{10}H_{11}OOH] \sim 0.004$. Cobalt stearate is less reactive than $Co(acac)_2$ and in chlorobenzene $([A] + [K])/\Delta[C_{10}H_{11}OOH] \sim 0.87$, $[A]/[K] = 0.3$, and no $(C_{10}H_{11})_2O_2$ could be detected. Clearly, in systems which give alkoxyls as well as peroxyls, $[A]/[K]$ is <1 in chlorobenzene and >1 in methanol.

Discussion

Self-reaction of $C_{10}H_{11}O_2^{\cdot}$, prepared by autoxidation of tetralin, induced decomposition of $C_{10}H_{11}OOH$, and autoxidation of azotetralin in chlorobenzene in the temperature range 303–353 K, initially gives equal yields of α-tetralone and α-tetralol with a total yield of ~90%. Low yields of $(C_{10}H_{11})_2O_2$ are, however, definitely produced. These results are contrary to those of Fukuzumi and Ono (32) who found $(C_{10}H_{11}OH]/[C_{10}H_{10}O] = 1.72$ at 291 K for the PbO_2–$C_{10}H_{11}OOH$ initiated autoxidation of tetralin. As the autoxidation of tetralin proceeds, $[A]/[K]$ decreases because of the formation of excess α-tetralone which is almost certainly produced by autoxidation of accumulated α-tetralin hydroperoxide. Thus, at 5–10% conversion, $C_{10}H_{11}O_2^{\cdot}$ has about the same probability of abstracting the α-tertiary hydrogen atom from $C_{10}H_{11}OOH$ as it does reacting with $C_{10}H_{12}$. The resulting α-hydroperoxytetralyl undergoes very rapid β-scission, even in the presence of O_2, to give α-tetralone (reaction [16]).

[16] 
In chlorobenzene, there is no evidence for the involvement of a chain process in the self-reaction of $C_{10}H_{11}O_2^{\cdot}$ and the free-radical induced decomposition of $C_{10}H_{11}OOH$. Furthermore, experiments performed in methanol and in the presence of lithium chloride and benzaldehyde give no evidence for the intermediacy of a zwitterion, which would be expected to give methyl α-hydroperoxytetralyl ether in methanol, α-chloro-α-hydroperoxytetralin in the presence of LiCl, and the ozonide **1** in the presence of benzaldehyde.

For personal use only.

The low yields of bis(α-tetralyl) peroxide and the fact that [A]/[K] in C_6H_5Cl is initially >1 at 323 K do suggest a minor contribution from the free-radical mechanism,

[18] $2C_{10}H_{11}O_2^{\bullet} \rightleftarrows C_{10}H_{11}OOOOC_{10}H_{11} \rightarrow 2C_{10}H_{11}O^{\bullet} + O_2$

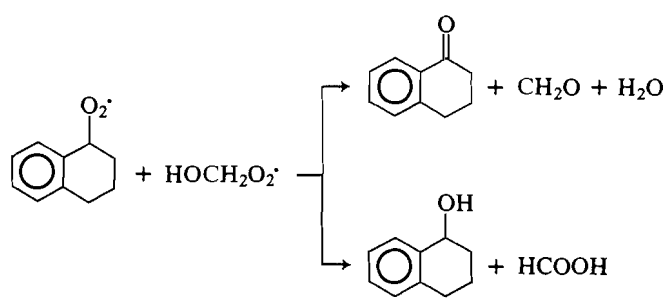
$C_{10}H_{11}OOOOC_{10}H_{11} \rightarrow (C_{10}H_{11})_2O_2 + O_2$

This mechanism can, however, only account for ~5–10% of the products at 303 K and is significantly less important in solution than it is in the gas phase.

It could, perhaps, be argued that $(C_{10}H_{11})_2O_2$ is formed by combination of $C_{10}H_{11}^{\bullet}$ and $C_{10}H_{11}O_2^{\bullet}$, since $C_{10}H_{11}O_2^{\bullet}$ undergoes β-scission in the temperature range 303–323 K. The value of the rate constant for β-scission estimated from yields of $C_{10}H_{10}{}^{18}O$ and $C_{10}H_{11}{}^{18}OH$ is, however, less than the value of 2 s^{-1} for α-cumylperoxyl (3) which is in line with the relative stabilization energies of α-tetralyl and cumyl. The steady-state concentration of α-tetralyl would, therefore, be far too low to influence the magnitude of the overall termination rate constant for $C_{10}H_{11}O_2^{\bullet}$ and to be responsible for the low concentrations of $(C_{10}H_{11})_2O_2$ produced by autoxidation of tetralin and induced decomposition of tetralin hydroperoxide. In addition, the yield of $(C_{10}H_{11})_2O_2$ produced by autoxidation of tetralin does not depend on the oxygen pressure, as would be expected if combination of $C_{10}H_{11}^{\bullet}$ and $C_{10}H_{11}O_2^{\bullet}$ is the principal reaction pathway to peroxide formation.

The gas phase reaction of alkoxyl with oxygen to give ketone and hydroperoxyl (reaction [14]) is not an important source of ketone in solution. This is because an alkoxyl, e.g., isopropoxyl, reacts 166 times faster with hydroperoxide than with O_2 at 302 K (23). Consequently, their reactivity towards hydrocarbon and O_2 must be very similar (33). In solution $C_{10}H_{11}O^{\bullet}$ would, therefore, react with $C_{10}H_{12}$ or $C_{10}H_{11}OOH$ rather than O_2.

The low values of [A]/[K] and the low yields of termination products derived from $C_{10}H_{11}O_2^{\bullet}$, given by autoxidation of tetralin and induced decomposition of tetralin hydroperoxide in methanol and acetonitrile, suggest the involvement of solvent derived peroxyls in termination.[4] Thus, in methanol, reaction of α-hydroxylmethylperoxyl with α-tetralylperoxyl to give α-tetralone, formaldehyde, and water should be faster than reaction to give α-tetralol and formic acid because the transfer of a tertiary hydrogen from $C_{10}H_{11}O_2^{\bullet}$ will be faster than the transfer of a secondary hydrogen from $HOCH_2O_2^{\bullet}$ in the cyclic transition state (34).



The termination rate constant for $C_{10}H_{11}O_2^{\bullet}$ does not appear to be influenced by a change of solvent from tetralin to methanol (35). This is probably because the radicals in methanol were generated by reaction of $C_{10}H_{11}OOH$ with Ce^{4+}, which oxidizes the hydroperoxide very rapidly, and the present study shows that solvent-derived radicals are not involved under these conditions.

In conclusion, it is apparent from the results presented here that product yields from self-reaction of peroxyls in solution depend on the method of radical generation, the extent of reaction, and the solvent. Mechanistic conclusions from such studies should, therefore, be treated with some caution.

Hydrogen bonding and other polar interactions of 1-, 2-, and 4-octyne with organic solvents

JOHN H. HALLMAN, W. KIRK STEPHENSON, AND RICHARD FUCHS
Department of Chemistry, University of Houston, Houston, TX 77004, U.S.A.

Received January 3, 1983

JOHN H. HALLMAN, W. KIRK STEPHENSON, and RICHARD FUCHS. Can. J. Chem. **61**, 2044 (1983).

The heats of vaporization of 1-octyne (10.11 ± 0.02 kcal/mol), 2-octyne (10.63 ± 0.03 kcal/mol), and 4-octyne (10.21 ± 0.02 kcal/mol) have been determined. Heats of solution of the liquid octynes and *n*-octane have been measured in heptane, cyclohexane, 1,2-dichloroethane, *n*-butyl ether, ethanol, triethylamine, dimethyl sulfoxide, butyrolactone, dimethylformamide, and hexamethylphosphoric triamide. Enthalpies of transfer from vapor to each solvent have been calculated. Enthalpies of hydrogen bond formation, calculated by the pure base method, become more exothermic in the above solvent order. Correlations with the Taft–Kamlet solvent parameters π^* and β indicate that other polar interactions (presumably dipole – induced dipole) are appreciably larger for 1-octyne than for 2- and 4-octyne.

JOHN H. HALLMAN, W. KIRK STEPHENSON et RICHARD FUCHS. Can. J. Chem. **61**, 2044 (1983).

On a déterminé les chaleurs de vaporisation de l'octyne-1 (10,11 ± 0,02 kcal/mol), de l'octyne-2 (10,63 ± 0,03 kcal/mol) et de l'octyne-4 (10,21 ± 0,02 kcal/mol). On a mesuré les chaleurs de solution des octynes et du *n*-octane à l'état liquide dans l'heptane, le cyclohexane, le dichloro-1,2 éthane, l'éther *n*-butylique, l'éthanol, la triéthylamine, le diméthylsulfoxyde, la butyrolactone, le diméthylformamide et le triamide de l'acide hexaméthylphosphorique. On a calculé les enthalpies de transfert de la vapeur vers chaque solvant. Les enthalpies de formation de la liaison hydrogène, calculées selon la méthode de base pure, deviennent plus exothermiques quand on passe d'un solvant à un autre dans l'ordre mentionné ci-dessus. Les corrélations avec les paramètres de solvant de Taft–Kamlet π^* et β indiquent que d'autres interactions polaires (possiblement dipole – dipole induit) sont notamment plus grandes pour l'octyne-1 que pour l'octyne-2 et l'octyne-4.

Hydrogen bonding by the acetylenic hydrogen (—C≡C—H) to electron-pair donating solvents has been examined (1) by infrared spectroscopy (1, 2), ^{1}H and ^{13}C nmr (1, 3), thermodynamically (1, 4), and by other methods (1). Enthalpies of hydrogen bond formation (ΔH_f) have been evaluated from (*i*) the temperature variation in equilibrium constants (3) (*K* measured by ir or nmr), (*ii*) enthalpies of transfer of alkynes from an "inert" solvent to basic solvents, determined from differences in the enthalpies of transfer from vapor to solvents ($\Delta H(v \rightarrow S)$) (derived from the temperature variation of partition coefficients measured by gas chromatography) (4), and (*iii*) the combination of equilibrium constants from spectrophotometric measurements and calorimetric enthalpies of mixing (2).

Each of these methods has some inherent problems. Equilibrium constants measured by ir or nmr are believed to reflect only hydrogen bonding interactions, but the sometimes poor agreement between the two methods, and the variation in *K* with the "inert" solvent medium are distressing. After measurement of the temperature variation of *K*, the resulting uncertainties in ΔH_f (0.3–0.6 kcal/mol) are typically 20–30% of the experimental values (1–3 kcal/mol). Direct enthalpy measurements, whether by gc or calorimetrically, are intrinsically less uncertain, but provide no information about the nature of the solute–solvent interactions, the completeness of the interactions, and other factors, which determine that enthalpy. Kurkchi and Iogansen's enthalpies of transfer of acetylene, propyne, and 1-butyne from "isooctane" to basic solvents (4) have been correlated (5) with the solvent parameters π^* and β, representing the dipolarity–polarizability and H-bond acceptor abilities, respectively:

$$\Delta H_{tr}(H—C\equiv C—H) = -0.10 - 1.56\pi^* - 3.56\beta \text{ kcal/mol}$$

$n = 8$ solvents; correlation coefficient, $r = 0.997$;

standard deviation, sd = 0.14 kcal/mol

$$\Delta H_{tr}(CH_3C\equiv CH) = -0.06 - 1.24\pi^* - 1.17\beta \text{ kcal/mol}$$

$r = 0.980$, sd = 0.15 kcal/mol

$$\Delta H_{tr}(CH_3CH_2C\equiv CH) = -0.04 - 1.12\pi^* - 0.88\beta \text{ kcal/mol}$$

$r = 0.976$, sd = 0.15 kcal/mol

The correlations indicate that each of the two H-bonds of acetylene, and the H-bonds of propyne and 1-butyne are comparable to the other solvent – alkyne polar interactions (mainly dipole – induced dipole). Kamlet and Taft (5) note that the solvents are all H-bond acceptors at an oxygen atom, and the enthalpy correlations with π^* and β would likely be poorer for solvents with other acceptor sites. This follows from the observation (6) that ΔH and ΔG of H-bonding of *p*-fluorophenol with a wide variety of solvents are poorly correlated except within closely related families, and the suggestion (7) that the solvatochromic parameters are generally correlated with ΔG.

There are other reservations about the above correlation (5) of the ΔH_{tr} data (4). One is the substantial correlation of π^* and β for this particular group of solvents ($\pi^* = 0.156 + 0.921\beta$, $r = 0.881$, sd = 0.123), which makes the quantitative separation of H-bonding and other polar interactions somewhat tenuous. The other problem is more serious. ΔH_{tr} (isooctane → solvent) results not only from exothermic H-bonding and other polar interactions with the solvent, but also from an endothermic contribution from the enthalpy of cavity formation within the solvent structure. The latter quantity tends to increase with increasing solvent polarity, and with increasing solute size. The apparent decreasing response to changes in solvent π^* and β in the series acetylene > propyne > 1-butyne, attributed (5) to the electronic properties of the H, CH_3, and CH_3CH_2 substituents, may result, in part, from failure to take into account variations in the cavity formation term.

With these reservations in mind, we have undertaken a cal-

orimetric study of the interactions of 1-, 2-, and 4-octyne and *n*-octane with 10 solvents, *n*-heptane, cyclohexane, 1,2-dichloroethane, *n*-butyl ether, butyrolactone, triethylamine, ethanol, dimethylformamide, hexamethylphosphoric triamide, and dimethyl sulfoxide. This solvent group has a much reduced correlation of π^* with β, and includes triethylamine, with a non-oxygen H-bond acceptor atom. The use of *n*-octane as a nonpolar model compound for the octynes is intended to eliminate cavity formation considerations. 2-Octyne and 4-octyne cannot donate a hydrogen for H-bonding, but are capable of other polar (dipole − induced dipole) interactions; in this way they may be useful models for evaluating H-bonding by 1-octyne.

Experimental

The solvents were commercial samples in excess of 99% purity, dried over 3A molecular sieve (ethanol), 10X (HMPT), or 4A molecular sieve. Triethylamine was distilled from ninhydrin to remove primary and secondary amine impurities. The octynes (Farchan Labs) were freshly fractionally distilled, and refrigerated. Heat of vaporization samples were 1-octyne (99.96%), 2-octyne (99.80%), 4-octyne (99.95%), and *n*-octane (99.9%). Purities were established by gas chromatography using a Shimadzu Mini 2 gc with a glass lined system, a 30 m × 0.25 mm id SE-30 silica capillary column, and a Hewlett-Packard 3390A integrator.

The calorimetric procedure and apparatus have previously been described (8). The calorimeter was immersed in a 25.0°C water bath regulated to ±0.002°C. Liquid solutes were introduced from 20- or 50-μL syringes, and corrections in ΔH_s were made for the heat capacity of the samples which were at 21−23°C. The uncertainties reported for ΔH_s in Table 1 are twice the standard deviation of three or more determinations. In measuring ΔH_s of *n*-octane in DMSO the glass top of the vacuum jacketed solution calorimeter was replaced by a Teflon top which nearly eliminates vapor space above the liquid.

Heats of vaporization were determined by evaporation of 100 μL samples into a slow stream of nitrogen (0.5−3 mL/min) under reduced pressure (12−49 torr) at 25.0°C. The vaporization calorimeter consists of a coiled 4.76 mm od nickel tube imbedded in a copper heat sink in which are mounted a thermistor and heater. The assembly is contained in a vacuum jacketed solution calorimeter. The evaporative cooling was compensated by heating powered by a timed constant current source (9). The values of ΔH_v are averages of 4−6 determinations, and the uncertainties are twice the standard deviation.

Results and discussion

The measured values of ΔH_v are: *n*-octane, 9.91 ± 0.02 kcal/mol (reported (10) 9.92 ± 0.01); 1-octyne, 10.11 ± 0.02; 2-octyne, 10.63 ± 0.03; and 4-octyne, 10.21 ± 0.02. These values have been combined with heats of solution (Table 1) to obtain the enthalpies of transfer from vapor to solvents in Table 2: $\Delta H(v \rightarrow S) = \Delta H_s - \Delta H_v$.

Two methods may be used to evaluate the enthalpies of H-bonding (ΔH_f) of 1-octyne. In one (the $\Delta\Delta H(v \rightarrow S)$ method) (11) the assumption is made that the more exothermic value of $\Delta H(v \rightarrow S)$ for 1-octyne, relative to the values of comparable non-donor model compounds (2-octyne, 4-octyne), can be attributed entirely to the enthalpy of hydrogen bond formation. It has been pointed out (11), however, that the H-bond donor and model compound must be very carefully matched with respect to molar volume and the ability to undergo other interactions. The solute molar volumes are: *n*-octane, 162.6 mL; 1-octyne, 147.7 mL; 2-octyne, 145.1 mL; and

HMPT	−1.26	−1.88	−1.72	−2.01
DMSO	0.05	−0.57	−0.39	−0.68

4-octyne, 146.8 mL. The MV increment for the CH_2 group is ~ 16 mL. The octynes are well matched in this respect, but at this point we cannot confidently equate the polar interactions (other than H-bonding) of each.

An alternative approach is the pure base method (12), by which ΔH_f is evaluated in a basic solvent with reference to a nonpolar solvent incapable of H-bonding (heptane):

$$\Delta H_f = (\Delta H_s^A - \Delta H_s^M)_B - (\Delta H_s^A - \Delta H_s^M)_{ref}$$

where A is the H-bond donor solute (1-octyne), M is the model compound (2- or 4-octyne), B is a basic (H-bond acceptor) solvent, and ref is the nonpolar reference solvent.

ΔH_f values for 1-octyne have been calculated by both methods using both model compounds (Table 3). It has been demonstrated (11) that the two methods are equivalent only when

$$\Delta H^A(v \rightarrow ref) = \Delta H^M(v \rightarrow ref)$$

and that is not the case for this system (Table 2). The values of ΔH_f for 1-octyne in heptane calculated by the $\Delta\Delta H_f$ (v → S) method (0.62 vs. 2-octyne, 0.29 vs. 4-octyne) are indications of the degree to which the model compounds are inappropriate. One could normalize the values of ΔH_f by assigning the value ΔH_f(heptane = 0, and adjusting ΔH_f in other solvents accordingly, but this is exactly what is accomplished by the pure base method without the need of measuring ΔH_v values and calculating ΔH (v → S). However, the pure base method is also dependent on appropriate model compounds. If we fail to obtain values of ΔH^A (v → ref) and ΔH^M (v → ref), there will be no independent way to assess the quality of the model compound. It should be noted that the difference of 0.62 kcal/mol between ΔH (v → heptane) for 1-octyne and 2-octyne leads to an error at least this large in ΔH_f values in each solvent by the $\Delta\Delta H$ (v → S) method, but this error is partially cancelled by the pure base method. But if 1-octyne and the model compound have different values of ΔH (v → S) in nonpolar, non-hydrogen bonding heptane due to differences in molar volume, dipole moment, steric hindrance to solvation, etc., then the difference in the other more polar and associated solvents may very well be larger. In the pure base method we must assume that the 0.62 kcal/mol correction (for 1-octyne vs. 2-octyne) remains substantially unchanged in other solvents, but this cannot be experimentally verified. Values of ΔH_f by the pure base method (Table 3) for 1-octyne vs. 2-octyne indicate that (within little more than the combined uncertainties) no H-bonding occurs in *n*-heptane, cyclohexane, and 1,2-dichloroethane. ΔH_f in butyl ether is surprisingly weak, although this may reflect, in part, incomplete complexation. It was also unexpected that ΔH_f is more exothermic in butyrolactone and DMF than in DMSO. Values in butyl ether and HMPT are somewhat less exothermic than previous values for phenylacetylene (2, 3) (−1.4 ± 0.3 kcal/mol in ethyl ether, −3.7 ± 0.3 kcal/mol in HMPT).

In order to examine correlations of polar interactions of the octynes with the Taft−Kamlet solvent parameters π^* and β (13) in the absence of substantial solvent cavity formation enthalpy complications, the enthalpies of polar interaction (ΔH_p) (including ΔH_f for 1-octyne) have been calculated. This is entirely analogous to the pure base method except that the model compound for all the octynes is *n*-octane. These results are presented in Table 4.

The resulting regression equations are:

$$\Delta H_{f,p}\text{ (1-octyne)} = -0.03 - 2.62\pi^* - 1.05\beta$$

$$n = 9,\ r = 0.993,\ \text{sd} = 0.114$$

$$\Delta H_p\text{ (2-octyne)} = -0.18 - 2.28\pi^*$$

$$r = 0.982,\ \text{sd} = 0.134$$

$$\Delta H_p\text{ (4-octyne)} = -0.11 - 2.16\pi^*$$

$$r = 0.977,\ \text{sd} = 0.151$$

Ethanol has been omitted from the correlations because of the present uncertainty in the solvent parameter values for amphiprotic solvents. The non-zero intercept results, in part, from our use of *n*-heptane as the reference solvent, whereas the π^* scale uses cyclohexane as the reference (π^*(heptane) = −0.08, π^* (cyclohexane) = 0.00). Multiple correlations with π^* and β for 2-octyne and 4-octyne lead to inappreciable improvement in the correlation coefficients and standard deviations. This would be expected for species which are not H-bond donors. Because of the substantial uncertainty in π^* and β values for hexamethylphosphoric triamide (13) the regression equation for 1-octyne has been recalculated omitting HMPT (and ethanol):

$$\Delta H_{p,f}\text{ (1-octyne)} = -0.08 - 2.63\pi^* - 0.82\beta$$

$$n = 8,\ r = 0.996,\ \text{sd} = 0.080$$

We suspect that this is a more accurate representation of the weak H-bonding behavior of 1-octyne. Values for HMPT of $\pi^* = 0.71$, $\beta = 2.10$ would fit the present data rather well, but there is no reason to believe that these are appropriate to

Raman spectra of sodium sulphamate single crystal

P. MUTHUSUBRAMANIAN AND A. SUNDARA RAJ
School of Physics, Madurai Kamaraj University, Madurai - 625 021, India

Received March 16, 1982

P. MUTHUSUBRAMANIAN and A. SUNDARA RAJ. Can. J. Chem. **61**, 2048 (1983).

Vibrational assignments are proposed for solid $NaNH_2SO_3$ on the basis of room temperature polarized Raman spectra of single crystals. Infrared data for the region 4000–50 cm^{-1} of the polycrystalline sample are also presented. The results indicate that (*1*) there is no water of crystallization, (*2*) the hydrogen bonding is extremely weak, and (*3*) the strength of N—S bond is stronger than in sulphamic acid.

P. MUTHUSUBRAMANIAN et A. SUNDARA RAJ. Can. J. Chem. **61**, 2048 (1983).

On propose des attributions vibrationnelles pour le $NaNH_2SO_3$ à l'état solide sur la base du spectre Raman polaire à température ambiante de cristaux uniques. On présente également les données IR s'étendant de 4000 à 50 cm^{-1} se rapportant à un échantillon polycristallin. Les résultats indiquent que (*1*) il n'y a pas d'eau de cristallisation, (*2*) les liaisons hydrogènes sont entièrement faibles et (*3*) la force de la liaison N—S est supérieure à celle de l'acide sulphamique.

Introduction

The wide industrial applications of the salts of sulphamic acid necessitate a thorough study of their various physical and chemical properties in the crystalline state. The review article by Benson and Spillane (1) describes the present status of these salts in the literature. We have already reported the polarized Raman spectra of potassium (2) and ammonium (3) sulphamates. We report here the results obtained for the laser Raman spectra of a single crystal of sodium sulphamate ($NaNH_2SO_3$) together with the ir spectra of the polycrystalline sample.

Some pre-laser Raman (4) and ir studies (4, 5) have been reported. Katiyar and Krishnan (4) observed only eight lattice modes and this is the latest Raman data on this crystal. Also, there is a discrepancy regarding the presence of water molecules in the crystal. The present study was undertaken in order to investigate this discrepancy and the nature of hydrogen bonding as well as to make a complete analysis of the vibrational spectra of the crystalline solid.

Experimental

Single crystals of sodium sulphamate were grown by slow evaporation at room temperature (30–35°C) from a solution of sulphamic acid neutralized with sodium carbonate. From the small needle-type crystals a rectangular parallelopiped of size 3 × 1.5 × 1 mm with its faces parallel to the crystallographic axes was cut using crossed polaroids. The axes were identified by X-ray photographs. The Raman spectra were excited using a 40 mW He–Cd laser (4416 Å) and recorded on a double monochromator of resolution about 2.5 cm^{-1}. A constant scanning speed of 40 cm^{-1}/min was employed throughout the experiment with a time constant of 10 s. The other experimental details about the recording of polarized Raman spectra have been described in an earlier paper (2).

The ir spectrum of polycrystalline $NaNH_2SO_3$ (KBr pellet) in the 4000–200 cm^{-1} region was recorded on a Perkin-Elmer Model 577 spectrophotometer. The far-ir spectrum (500–50 cm^{-1}) was recorded using a Polytec FIR 30 spectrometer.

Crystal structure

No complete crystal structure data are yet available for $NaNH_2SO_3$. However, the preliminary X-ray diffraction study (6) shows that the compound crystallizes in the orthorhombic system with 12 molecules per unit cell and belongs to the space group D_2^4 ($P2_12_12_1$). There is no water of crystallization in this crystal. The site symmetry of the sulphamate ion is C_1. Finally, sodium sulphamate is not isomorphous to the potassium salt (7).

TABLE 1. Mode distribution of the $NaNH_2SO_3$ crystal

	A	B_1	B_2	B_3	Total
Internal	45	45	45	45	180
Libratory	9	9	9	9	36
Translatory	18	17	17	17	69
Acoustic		1	1	1	3

Factor group analysis

The symmetry of the sulphamate ion is C_s, which is lowered to C_1 in the crystal. Correlating the free state symmetry with the factor group D_2 of the crystal through the site symmetry leads to the distribution of modes shown in Table 1. Since the crystal is noncentrosymmetric, all modes are Raman-active and all modes except those belonging to A species are ir-active. Out of the total 288 modes, 180 are internal modes of the $(NH_2SO_3)^-$ ion and they are equally distributed in the four different representations. The free state distribution is $\Gamma_{int.}^{free} = 9A' + 6A''$. Thus, we expect a triplet for each internal vibration in each species of the polarized Raman spectra. The remaining 108 modes are due to the external vibrations consisting of (*i*) libratory modes of $(NH_2SO_3)^-$, (*ii*) translatory modes of $NaNH_2SO_3$, and (*iii*) acoustic modes. The polarizability tensors (8) for this crystal are the same as those of the space group D_{2h}.

Results and discussion

The observed Raman and ir frequencies are given in Tables 2 and 3. The Raman and ir measurements are accurate to ±2 cm^{-1} and ±1 cm^{-1} respectively. Due to practical difficulties, the α_{zz} component of the Raman spectra was not recorded. The assignments of external and internal modes are discussed separately in the following sections.

External modes

From the factor group analysis, there are nine libratory modes in each representation. Also, a total of 69 translatory modes is expected. This large number of modes is due to the presence of 12 molecules in the unit cell. However, we observed only 13 libratory and 15 translatory modes. Even though fewer modes than expected are detected, the observed frequencies contain the three libratory and six translatory modes. The large number of missing bands may be due to very small correlation field splitting.

The observed Raman and far-ir frequencies along with their assignments are given in Table 2. Typical Raman spectra in different orientations are shown in Fig. 1 and the far-ir spec-

trum in Fig. 2. The assignment of the frequencies has been made on the basis of a comparison of the lattice modes in other sulphamates (2, 3). Also, it has been assumed that the moment of inertia of sulphamate ion is smaller than the mass of sodium sulphamate molecule. The assignments reveal that the frequencies of libratory modes of $(NH_2SO_3)^-$ ion in this crystal are slightly higher than those in potassium and ammonium sulphamates. In the *A* species of the spectrum, the *xx* polarization

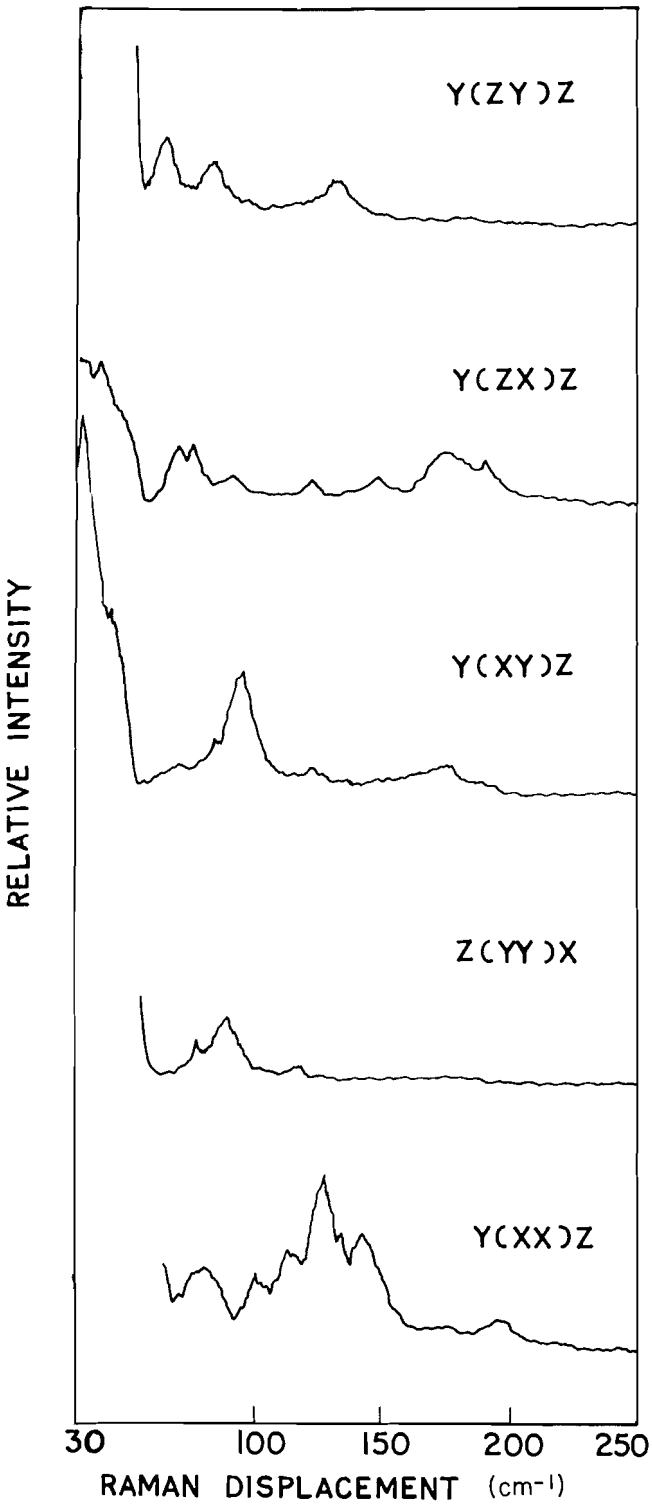

FIG. 1. Raman spectra of $NaNH_2SO_3$ (single crystal) in the 250–30 cm^{-1} region.

component is much stronger than the *yy* polarization component. The intensities given in parentheses are relative intensities of bands throughout the whole region (3600–30 cm^{-1}) including the internal modes. In the far-ir spectra, seven bands are observed and they have been assigned in conjunction with the Raman frequencies.

Internal modes

The observed Raman displacements of crystalline

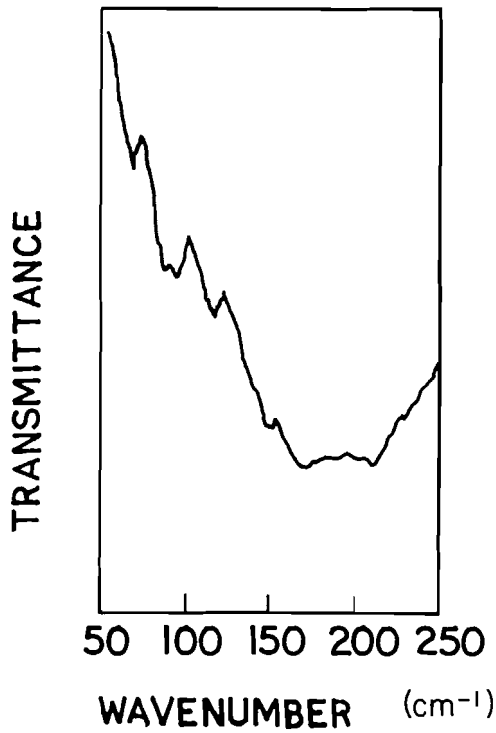

FIG. 2. Far-ir spectra (250–50 cm^{-1}) of polycrystalline $NaNH_2SO_3$.

$NaNH_2SO_3$ together with their assignments (based on the free molecular symmetry, C_s) are given in Table 3. Infrared frequencies of the polycrystalline samples are entered in column six of this table. The internal mode frequencies of $(NH_2SO_3)^-$ ion appear almost at the same region as those of potassium or ammonium sulphamates with a small shift or broadening. Theoretically, triplets are expected for each vibration; but, except in one or two cases, doublets or singlets are observed.

Katiyar and Krishnan (4) reported H—O—H bending modes at 1590 cm^{-1} in both the Raman and the ir. However, we observed no such band in the ir spectrum. A very weak band at 1604 cm^{-1} was detected in the B_2 component of the Raman spectra which may be due to the overtone of $\nu_6(A')$, the N—S stretching vibration. Katiyar and Krishnan assigned the bands observed at 3370 cm^{-1} in the Raman and 3392 cm^{-1} in the ir to the O—H stretching mode. Normally, in crystals, the OH stretching frequencies of water never appear below 3400 cm^{-1} unless strong hydrogen bonding is present. We observed bands around 3370 cm^{-1} (Raman) and 3352 cm^{-1} (ir). The region 3530–3000 cm^{-1} for different orientations of the Raman spectra are shown in Fig. 3. The ir spectrum in the 4000–250 cm^{-1} region is shown in Fig. 4. As seen in the figures, the bands at 3370 and 3352 cm^{-1} are not so broad as expected for OH stretching frequencies. In calcium sulphamate, we observed the OH stretching frequencies around 3510 cm^{-1} in the Raman and 3526 cm^{-1} in the ir with broad peaks (to be published). The X-ray diffraction study at room temperature (6) and the thermogravimetric analysis also do not show any evidence for the presence of water molecule. Moreover, if there is a H_2O in sodium sulphamate, it amounts to $12H_2O$ in the unit cell which should split the fundamental frequencies. These splittings are also absent. Also, the broad bands due to rocking and wagging modes of lattice water are found missing in the librational region (<1000 cm^{-1}) (9). Based on these considerations, it is clear that the frequency at 3370 cm^{-1} is due to the NH_2 asym-

For personal use only.

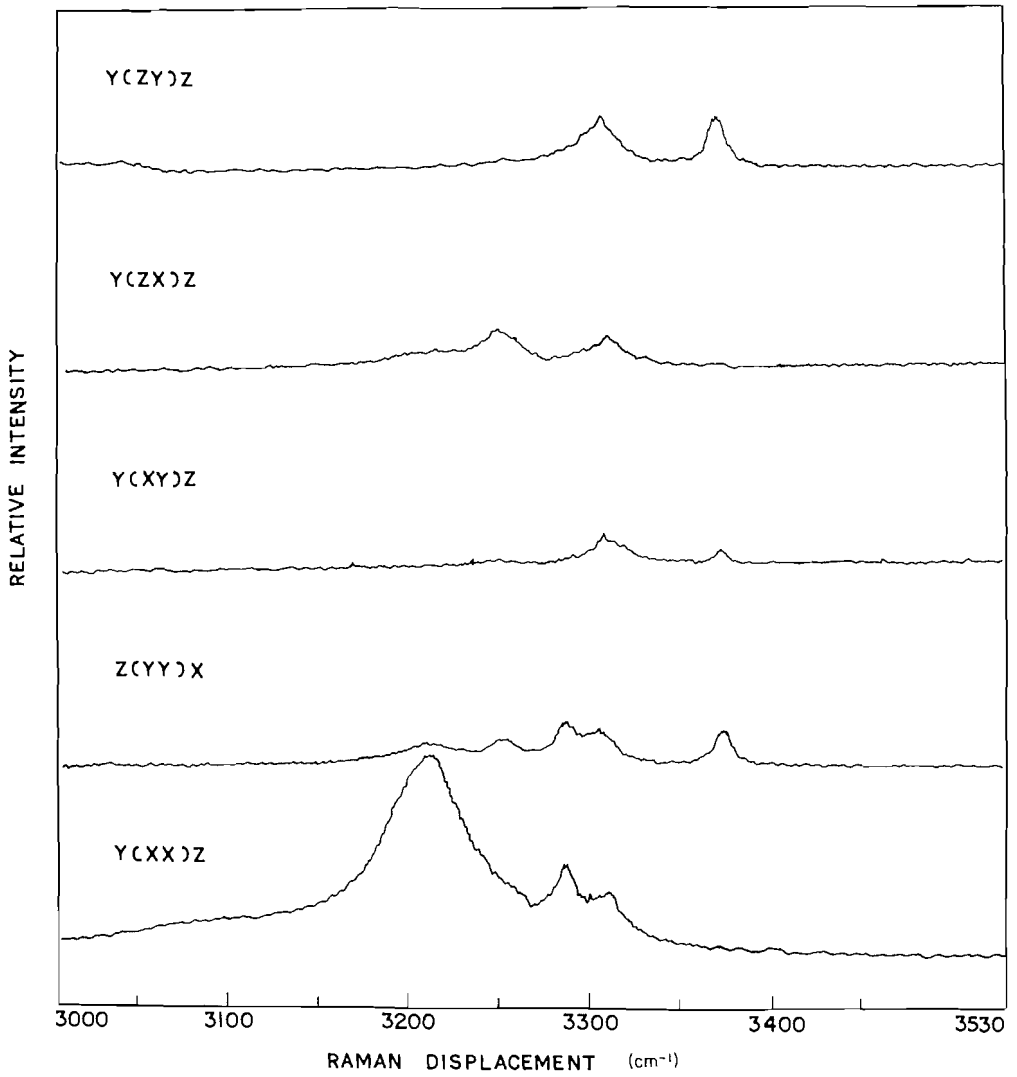

FIG. 3. Raman spectra of $NaNH_2SO_3$ (single crystal) in the region 3530–3000 cm^{-1}.

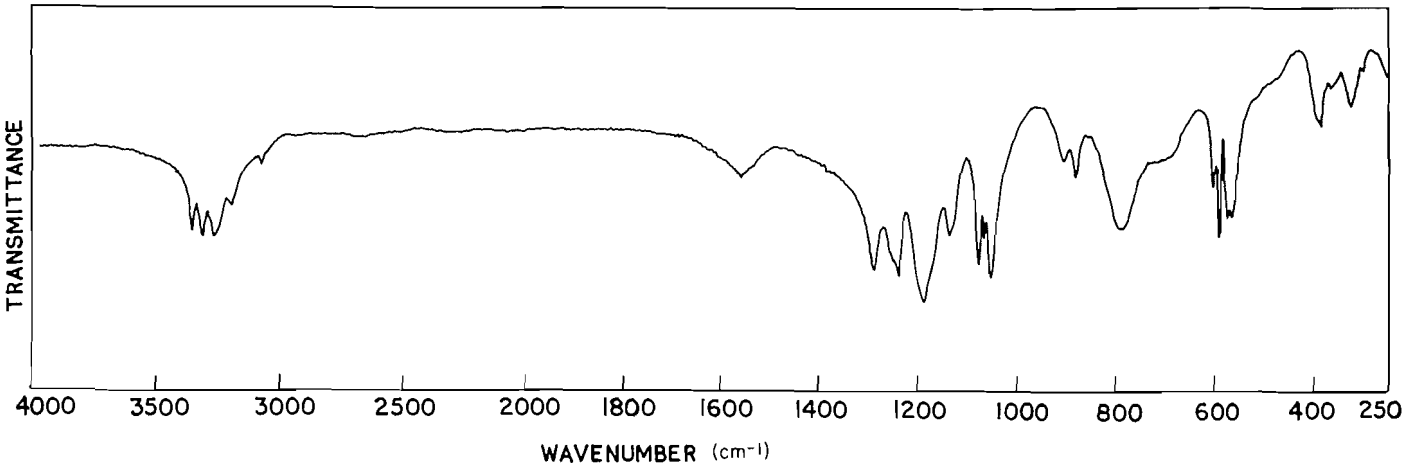

FIG. 4. Infrared spectra (4000–250 cm^{-1}) of polycrystalline $NaNH_2SO_3$.

metric stretching mode (ν_{10}).

The band at 285 cm^{-1} was assigned to N—S torsion, which was not observed in potassium and ammonium sulphamates. Lucazeau *et al.* (10) observed this around 244 cm^{-1} in sulphamic acid, having medium strength hydrogen bonding. We found the same at 300 cm^{-1} in calcium sulphamate and at 288 cm^{-1} in barium sulphamate (to be published).

The N—S stretching frequency appears around 790 cm^{-1} in sodium sulphamate. According to Banister *et al.* (11), this higher value of N—S stretching frequency in sulphamate as compared to sulphamic acid is due to the increase in double bond character of the N—S bond. In sulphates, the S—O

stretching modes have been reported below 1200 cm^{-1} by different workers (12, 13). But, in $NaNH_2SO_3$, we observed the SO_3 asymmetric stretching above 1200 cm^{-1} and this shows that the NSO_3 structure is not tetrahedral and the strength of S—O bond is larger. The correlation field splitting (about 35 cm^{-1}) is at a maximum for this mode.

When we analyse and compare the frequencies in different sulphamates, we find that the hydrogen bonding in $NaNH_2SO_3$ is extremely weak. In KNH_2SO_3, the NH_2 asymmetric stretching (ν_{10}) appears at 3320 cm^{-1} and in ammonium sulphamate at 3307 cm^{-1}. However in $NaNH_2SO_3$, it is at 3370 cm^{-1}. Thus ν_{10} is approaching the free NH_2 stretching frequency (14) of 3410 cm^{-1}. The lowering of NH_2 symmetric wagging frequency (ν_5) also indicates that the magnitude of hydrogen bonding is very small in this crystal.

Dielectric evidence for the formation of a clathrate hydrate by sulfuryl chloride[1]

S. R. GOUGH, J. A. RIPMEESTER, and D. W. DAVIDSON
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received March 24, 1983

S. R. GOUGH, J. A. RIPMEESTER, and D. W. DAVIDSON. Can. J. Chem. **61**, 2053 (1983).

A hydrate formed by SO_2Cl_2 at −20°C is shown by its low temperature dielectric absorption to be a structure II clathrate hydrate. The activation energy for reorientation of encaged SO_2Cl_2 molecules is 1.1 kcal mol^{-1} between 19 and 41 K.

S. R. GOUGH, J. A. RIPMEESTER et D. W. DAVIDSON. Can. J. Chem. **61**, 2053 (1983).

On rapporte qu'un hydrate, formé par SO_2Cl_2 à −20°C, possède la structure II d'un hydrate clathrate tel que démontré par son absorption diélectrique à basse température. L'énergie d'activation pour la réorientation des molécules de SO_2Cl_2 encageés est de 1.1 kcal mol^{-1} entre 19 et 41 K.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

In 1901 Baeyer and Villiger reported (1) the formation of a crystalline hydrate when sulfuryl chloride was poured into ice-cold water. The hydrate was found to have a composition of $SO_2Cl_2 \cdot 15.9\ H_2O$, and, since it readily reformed after heating and recooling, was considered not to contain chemically-bound water. There appear to have been no other experimental studies of this hydrate. In a review (2) written after gas hydrates had been found to be clathrates, it was suggested that SO_2Cl_2 is too large to form a normal clathrate hydrate and that impurities such as SO_2 and Cl_2 (which individually form clathrate hydrates) could have been responsible for Baeyer and Villiger's "sulfuryl chloride hydrate".

Since dipolar molecules encaged in clathrate hydrates undergo rapid reorientation which characteristically gives radio-frequency absorption at very low temperatures (2, 3), dielectric measurements may be used to show the existence (or not) of a clathrate hydrate of SO_2Cl_2 even in the presence of such impurities as acidic hydrolysis products, ice, and solid SO_2Cl_2. The values of the permittivity and loss so obtained, however, do not quantitatively characterize the pure homogeneous hydrate.

Addition of commercial sulfuryl chloride (Matheson, Coleman and Bell) to cold water failed to produce hydrate. However, hydrate formed immediately as a white solid when water was sprayed as a fine mist into liquid SO_2Cl_2 at −20°C. The solid was filtered at −20°C and stored in liquid nitrogen. Sample conditioning was avoided because of the tendency of SO_2Cl_2 to hydrolyse. Sample disks were prepared by pressing the powder in a cold mould before insertion into the dielectric cell which was mounted in a cryostat (4). Dielectric measurements (5) were made at frequencies between 1 Hz and 10 MHz and at temperatures between 4 and 200 K.

The dielectric absorption and dispersion measured below 100 K are illustrated in Fig. 1. The reproducible loss peak observed at low temperatures (e.g., at 28 K and 10 kHz) is ascribed to reorientation of encaged SO_2Cl_2 molecules. The rise in absorption and permittivity at higher temperatures continues monotonically to above 200 K where the values reached are much higher than can be ascribed to simple reorientation of water molecules in the hydrate lattice. Such irreproducible polarization effects must be attributed to acidic impurities and the attendant large proton conductance of the host lattice. Hydrolysis of SO_2Cl_2 to HCl, HSO_3Cl, and H_2SO_4 is well known (6).

There is no evidence of dielectric absorption from encaged species other than SO_2Cl_2. In particular, exploratory studies of

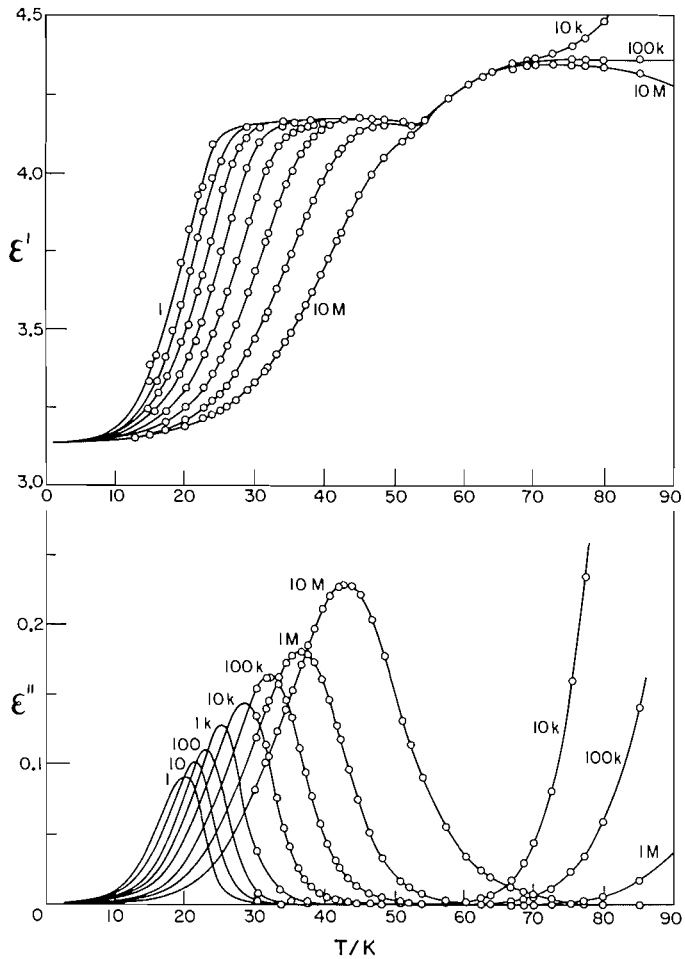

FIG. 1. Dielectric permittivity (ε′) and loss (ε″) curves of sulfuryl chloride hydrate at the frequencies indicated (in Hz). Many experimental points have been omitted for reasons of clarity.

SO_2 hydrate show the absorption of SO_2 to occur at much lower temperatures (e.g., 14 K for the loss maximum at 10 kHz) than the absorption found here.

The dielectric behaviour of enclathrated SO_2Cl_2 shows the features common to guest molecule reorientation in 22 other clathrate hydrates for which low-temperature dielectric measurements have been made (7): broad absorption–dispersion curves which are skewed in the direction of increased absorption at high frequencies, and permittivities on the low-frequency (high-temperature) side of the guest-molecule dispersion region which hardly change with decreasing

[1] NRCC No. 21271.

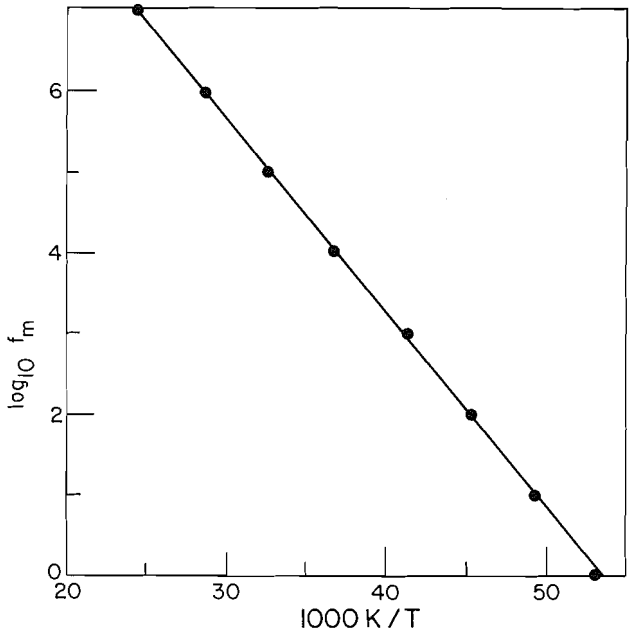

FIG. 2. Temperature dependence of the frequency of maximum dielectric absorption by SO_2Cl_2 in the hydrate.

temperature. Such features are attributable to the presence of orientations of different energy in individual cages and to a distribution of such energies in different cages arising from the disordered orientations of the lattice water molecules.

The linear Arrhenius plot between 19 and 41 K of the frequency of maximum absorption (Fig. 2) gives an "activation energy" of 1.1$_1$ kcal mol^{-1}, a fairly average value for guest-molecule reorientation in structure II clathrate hydrates (7).

From the geometry of SO_2Cl_2 (8) and van der Waals radii r_v of 1.40 Å for O and 1.80 Å for Cl, the sphere of minimum size which can enclose SO_2Cl_2 is 6.79 Å in diameter. The average free diameter of the largest clathrate cage, the 16-hedron of structure II, is only 6.56 Å for a unit cell dimension of 17.3 Å (2). However, in addition to 12 pentagonal faces, this cage consists of four almost planar hexagonal rings of hydrogen-bonded water molecules which are tetrahedrally disposed with respect to the cage centre. Since SO_2Cl_2 has a distorted tetrahedral shape, it is possible for this molecule to be accommodated within the cage by protrusion of the O and Cl atoms into the free space within the hexagonal rings. A similar situation occurs for CCl_4 which has a van der Waals diameter of 7.13 Å and yet forms a structure II hydrate stable up to 0.67°C (9).

We conclude that SO_2Cl_2 forms a structure II clathrate hydrate with composition close to $SO_2Cl_2 \cdot 17H_2O$. Remeasurement of the low temperature dielectric properties after heating the sample to a variety of temperatures and recooling showed eutectic melting of excess SO_2Cl_2 to occur near −75°C and the hydrate to decompose near −14°C. The hydrate formed by Baeyer and Villiger at 0°C probably was SO_2Cl_2 hydrate stabilized by the incorporation of SO_2 and/or Cl_2 "help gas" impurities in the small, otherwise empty cages of the structure II lattice (2).

Structure of rhodocladonic acid. X-ray crystal structure analysis of its triacetate

STEWART MCLEAN, PAUL MAHLER, STANLEY C. NYBURG, JEFFERY F. SAWYER, COLIN J. WEBSTER, AND WINNIE WONG-NG

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received January 28, 1983

STEWART MCLEAN, PAUL MAHLER, STANLEY C. NYBURG, JEFFERY F. SAWYER, COLIN J. WEBSTER, and WINNIE WONG-NG. Can. J. Chem. **61**, 2055 (1983).

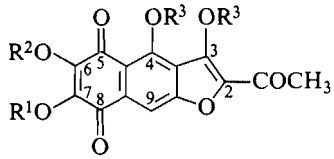
The structure of the lichen pigment rhodocladonic acid, 2-acetyl-3,4,6-trihydroxy-7-methoxynaphtho[2,3-*b*]furan-5,8-dione (**1***a*), has been assigned on the basis of an X-ray crystal structure analysis of its triacetate (**1***c*). Crystals of the triacetate are triclinic, space group $P\bar{1}$ with cell dimensions a = 13.609(3) Å, b = 15.009(3) Å, c = 5.456(2) Å, α = 106.66(4)°, β = 103.45(3)°, γ = 72.30(4)°, U = 1004(1) Å^3, and D_{calc} = 1.47 g cm^{-3} for Z = 2; R_1 = 0.0505 for 1644 observed ($F > 6\sigma(F)$) reflections.

STEWART MCLEAN, PAUL MAHLER, STANLEY C. NYBURG, JEFFERY F. SAWYER, COLIN J. WEBSTER et WINNIE WONG-NG. Can. J. Chem. **61**, 2055 (1983).

On a déterminé la structure du pigment du lichen: l'acide rhodocladonique, acétyle-2 trihydroxy-3,4,6 méthoxy-7 naphto[2,3-*b*] furannedione-5,8 (**1***a*) en analysant la structure du cristal de son triacétate (**1***c*) par cristallographie de rayons-X. Les cristaux du triacétate sont tricliniques et appartiennent au groupe d'espace $P\bar{1}$ avec a = 13,069(3) Å, b = 15,009(3) Å, c = 5,456(2) Å, α = 106,66(4)°, β = 103,45(3)°, γ = 72,30(4)°, U = 1004(1) Å^3 et D_{calc} = 1,47 g cm^{-}3, Z = 2; R_1 = 0,0505 pour 1644 réflexions ($F > 6\sigma$ (F)) observées.

[Traduit par le journal]

The structure of rhodocladonic acid, a red pigment of many lichens in the genus *Cladonia*, has been a subject of interest for many years. In 1941 Shibata (1) assigned it a substituted anthraquinone structure on the basis of an erroneous molecular formula. Baker and Bullock (2) determined the correct molecular formula, established that rhodocladonic acid is a naphthoquinone (unprecedented in lichens), and, on the basis of degradative studies, assigned it a furonaphthoquinone structure having an acetyl side chain, three hydroxyl substituents, and one methoxyl substituent; structures **1***a* and **1***b* were considered



1*a* R^1 = Me; R^2 = R^3 = H
b R^2 = Me; R^1 = R^3 = H
c R^1 = Me; R^2 = R^3 = Ac

the most reasonable on biogenetic grounds, but the location of the methoxyl group in the native pigment could not be assigned since the key degradation was carried out on the trimethyl ether.

Our own independent investigation had led us to the same conclusion concerning the naphthoquinone part of the skeleton and the hydroxyl and methoxyl substituents, but we felt that the identity of the third ring, undoubtedly corresponding to a condensed polyketonic unit, could not be assigned unequivocally on the basis of an alkali-induced degradation (3). For this reason we undertook to determine the complete structure unambiguously by X-ray crystal structure analysis. Because of its extreme insolubility in common solvents, crystals of rhodocladonic acid itself suitable for this purpose were not available; of the simple derivatives that could reasonably be expected to be prepared without risk of skeletal rearrangement, the triacetate proved the most suitable.

Experimental

Rhodocladonic acid was isolated from the apothecia of *Cladonia cristatella* collected in southern Ontario. Treatment of the pigment with acetic anhydride and triethylamine overnight at room temperature afforded the triacetate which was carefully recrystallized from acetone and obtained as a yellow aggregate, mp 211–213°C (lit. (2) mp 210–212°C). Individual crystals appear as almost colorless plates,

X-Ray crystal structure determination

Preliminary Weissenberg photographs indicated no symmetry higher than triclinic, and cell parameters were obtained from the diffraction angles of 14 well-centred reflections on an automated Picker four-circle diffractometer by the use of Ni-filtered Cu K$\bar{\alpha}$ radiation. Reflections were collected in the $\theta-2\theta$ mode on the same instrument using an orientation matrix based on this cell. For each reflection the scan range was 1° to either side of the $\alpha_1\alpha_2$ peaks using a scan rate of 2° min^{-1}; stationary counter background levels were obtained at each side of the reflection. A standard reflection measured after every 50 reflections collected showed no systematic variations with time. Of a total of 3138 independent reflections collected within the limits $0.1 < \sin\theta < 0.88$, 1494 were considered significant on

the criterion $F > 6\sigma(F)$[1] and were used in subsequent refinements.

Structure solution

Initial attempts at structure solution in the centric space group $P\bar{1}$ (indicated by statistical tests on the E values) by the use of direct method routines in the programs MULTAN (4) and SHELX (5) only led to confusing "chicken-wire" patterns of hexagonal rings. Inspection of a sharpened $E \times F$ Patterson map indicated that the plane of the molecule was virtually parallel to (131), and a single hexagonal ring in this plane was developed using damped least-squares and Fourier refinements into a crude distorted fragment of a postulated condensed tricyclic structure with a residual $R \sim 0.50$. Subsequent direct-method phasing with the original origin and starting reflections as well as several phases calculated on the basis of the current model gave several further E-maps in which the model was shifted with respect to the (131) plane, but invariably it was too close to one of the centres of symmetry in the unit cell. An expanded fragment of the molecule in one E-map did, however, serve as a good phasing model in the acentric space group $P1$ and enabled a second molecule related by a noncrystallographic centre of symmetry to be located. This arrangement was then shifted to conform to the space group $P\bar{1}$, and subsequent least-squares and Fourier refinements proceeded routinely. All hydrogen atoms were successfully located in a Fourier map calculated using a Sims weighting scheme. Least-squares refinement minimizing $\Sigma w(|F_o| - |F_c|)^2$ converged (max. shift/error = 0.17) to the final agreement indices $R_1 = 0.0505$ and $R_2 = 0.0560$. In the final cycles of refinement the weights used were $1/\sigma(F)^2$ such that $\langle w\Delta F^2 \rangle$ was independent of F_{obs} and sin θ everywhere. A final ΔF-map was featureless.

All calculations were performed on an SEL 75 computer, using the programs MULTAN (4), SHELX (5), and ORTEP (6), as well as local programs. Neutral-atom scattering factors were taken from International Tables (7). The final atomic positional parameters are given in Table 1; anisotropic thermal parameters and parameters for hydrogen atoms have been deposited.[2] Interatomic distances and bond angles and some least-squares mean planes in the molecule are given in Tables 2 and 3.[3] Of the three acetoxy substituents, those at C(1) and C(6) exhibit large librational motion about their O—CO bonds, giving rise to quite large temperature factors for O(28), C(29), and O(24), C(25). There seems to be no similar large libration of the acetate at C(12).

Results and discussion

The X-ray analysis establishes unequivocally that the tri-

[1] $\sigma(F) = \{[\sigma(I)\cdot Lp]^2 + 0.02F_o^4\}^{1/2}/2F_o$ and $\sigma(I) = [a\ (\text{peak} + \text{background})]^{1/2}$ where a = attenuation factor and Lp is the Lorentz-polarization correction for each reflection.

[2] These tables, along with tables of observed and calculated structure factors and of temperature factors, are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[3] The atomic numbering system used in all tables corresponds to that defined by the connectivity map shown in Fig. 1. This system is used for clarity when molecular geometry is discussed. The locants required for purposes of systematic nomenclature are shown in structure **1**.

acetate of rhodocladonic acid has structure **1***c* (2-acetyl-3,4,6-triacetoxy-7-methoxynaphtho[2,3-*b*]furan-5,8-dione). Since it can safely be assumed that the acetate was formed without rearrangement of the molecule, it follows that rhodocladonic acid is the corresponding trihydric phenol, **1***a*. The novel structural features proposed by Baker and Bullock (2) are confirmed, and the ambiguity concerning the position of the methoxyl group is removed.

In the crystal, the naphtho[2,3-*b*]furan-5,8-dione framework is planar to within ±0.027 Å and is virtually parallel to the (131) plane. Bond distances and bond angles within this unit are normal, being comparable to those in analogous compounds. The C-acetyl substituent has normal dimensions and is approximately coplanar with the molecular framework. The three acetoxy groups at C(1), C(6), and C(12)[3] have the same dimensions, within the measured standard deviations, and appear normal; their planes (Table 3) are rotated from the plane of the tricyclic framework by angles of 67.0(2)°, 88.1(2)°, and 72.9(2)°, respectively. The methoxyl group at C(11) has a C(12)—C(11)—O(16)—C(17) torsion angle of 6.9(1)°.

The closest intermolecular contact is H(91)···O(15) ($\bar{x}$ $\bar{y}$ $\bar{z}$) of length 2.57(2) Å.

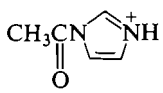
The imidazole group of a histidine residue has been implicated as a necessary part of the catalytically active centre of a large number of enzymes. Its exact role has not as yet been established and the studies reported here were carried out to define more fully the properties and mechanisms of reaction of acylimidazole compounds in nonenzymatic reactions in order to provide a more complete background for consideration of their possible role in enzymatic catalysis.

Jencks and Carriuolo (1*a*) have shown that *N*-acetylimidazole (**1**) hydrolyzes by acid, neutral, and base pathways according to eq. [1] (Scheme 1).

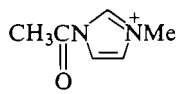
$$[1] \quad v = 2.8\,[H^+] + 0.005\,[\mathbf{1}] + 19000\,[\mathbf{1}]\,[OH^-]$$

At low pH, the rate is controlled by the reaction of [**1**H$^+$] (pK_a = 3.6) (1*a*) and the pH rate profile is level at pH's where the imidazole is completely protonated (k_{obs} = 2.8 min^{-1}, ref. 1*a*). In a later study Marlburg and Jencks (1*c*) showed that [**1**H$^+$] and its *N*-methyl analogue (**2**) decomposed rapidly in



1H$^+$

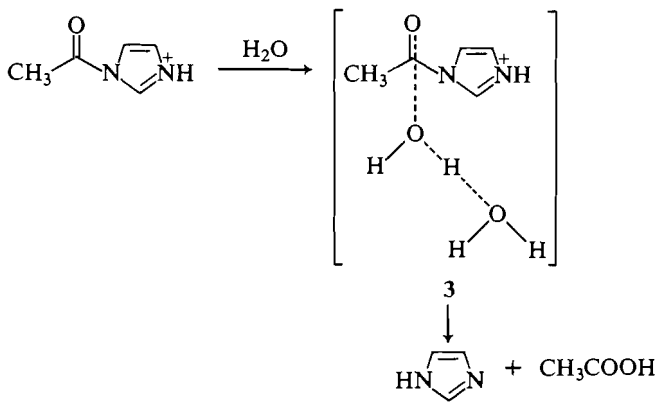
k_{H_2O} = 2.8 min^{-1}
k_{H_2O/D_2O} = 2.5



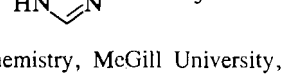
2

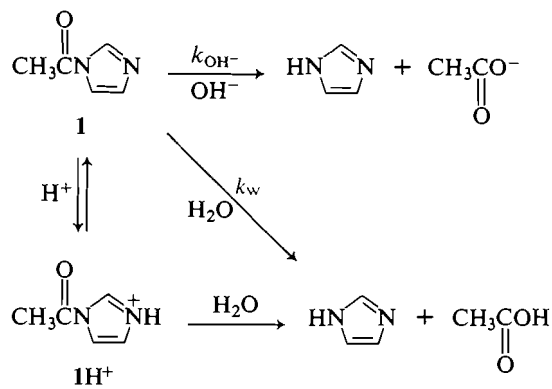
k_{H_2O} = 2.8 min^{-1}
k_{H_2O/D_2O} = 2.6

H_2O and exhibited solvent isotope effects. Proton inventory studies (2) indicate that the pH-dependent, water-catalyzed hydrolysis of 1-acetylimidazolium ion probably involves a transition state such as that shown in **3**.



3



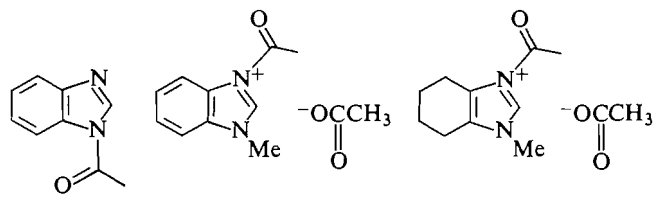


SCHEME 1

To further this examination of the hydrolysis rates of *N*-acetylimidazole compounds, *N*-acetylbenzimidazole (**4**), *N*-acetyl-*N'*-methylbenzimidazolium acetate (**5**), and *N*-acetyl-*N'*-methyltetrahydrobenzimidazolium acetate (**6**) were synthesized and their hydrolysis rates studied.

Results and discussion

N-Acetylbenzimidazole (**4**) was synthesized from the reaction of acetyl chloride with benzimidazole, while both



4 **5** **6**

N-acetyl-*N'*-methylbenzimidazolium acetate (**5**) and *N*-acetyl-*N'*-methyltetrahydrobenzimidazolium acetate (**6**) were synthesized by reacting the corresponding *N*-methylimidazole compounds with acetic anhydride. The hydrolysis of *N*-acetylbenzimidazole (**4**) and *N*-acetyl-*N'*-methylbenzimidazolium acetate (**5**) was followed spectrophotometrically at 290 nm while the decomposition of *N*-acetyl-*N'*-methyltetrahydrobenzimidazolium acetate was monitored at 265 nm. In Fig. 1 are shown the hydrolysis rates for compounds **4**, **5**, and **6** in 29.4% EtOH/H_2O at 25°C as a function of pH, obtained by determining the rate at each pH at several different buffer concentrations and then extrapolating to zero buffer concentration. For *N*-acetylbenzimidazole (**4**) the rate of hydrolysis increases sharply above and below neutrality. The rate law can be formulated as in eq. [2].

[1]Present address: Department of Chemistry, McGill University, Montreal, P.Q., H3A 2K6.

[2]Revision received March 7, 1983.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12

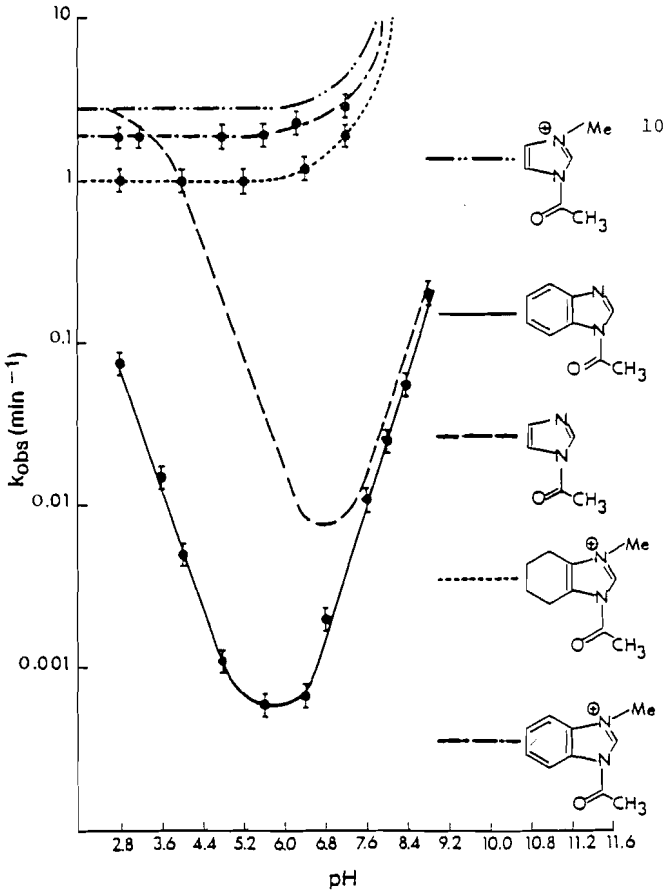

FIG. 1. The pH–rate profiles for the hydrolysis of *N*-acetylbenzimidazole (**4**), *N*-acetyl-*N'*-benzimidazolium acetate (**5**), and *N*-acetyl-*N'*-tetrahydrobenzimidazolium acetate (**6**) in 29.4% (v/v) ethanol–H_2O at 25°C. The pH–rate profiles for the hydrolysis of *N*-acetylimidazole and *N*-acetyl-*N'*-methylimidazole in H_2O at 25°C as reported by Jencks and co-workers (1).

$$[2] \quad \nu = 5.3 \pm 0.7 \times 10^{1} [H^+][\mathbf{4}] + 3.7 \pm 1.4 \times 10^{-4} [\mathbf{4}] + 2.8 \pm 0.4 \times 10^{4} [\mathbf{4}][OH^-]$$

The pH–rate profile found for *N*-acetylbenzimidazole (**4**) and that found for *N*-acetylimidazole (**1**) (*1a*) appear to be quite similar, with the exception that for *N*-acetylbenzimidazole (**4**) a plateau region in the pH–rate profile, in the pH range studied, is not visible, indicating a lower pK_a for this compound. Again, as in Jencks' results (1) for *N*-acetyl-*N'*-methylimidazolium chloride (**2**), whose rate law is formulated in eq. [3], the pH–rate profiles for *N*-acetyl-*N'*-methylbenzimidazolium acetate (**5**) and *N*-acetyl-*N'*-methyltetrahydrobenzimidazolium acetate (**6**) remain constant from pH 1 to pH 6 and

$$[3] \quad \nu = 2.8 [\mathbf{2}] + 9.0 \times 10^{6} [\mathbf{2}][OH^-]$$

increase as neutrality is approached (Fig. 1). The rate laws obtained for compounds **5** and **6** are formulated in eqs. [4] and [5] respectively.

$$[4] \quad \nu = 1.9 \pm 0.1 [\mathbf{5}] + 1.2 \pm 0.1 \times 10^{7} [\mathbf{5}][OH^-]$$

$$[5] \quad \nu = 1.0 \pm 0.05 [\mathbf{6}] + 6 \pm 0.1 \times 10^{6} [\mathbf{5}][OH^-]$$

It appears that all three classes of imidazole compounds act in a similar manner in spite of the uncertain differences in resonance stabilization and steric effects amongst them. It is interesting to note that the parent imidazole compounds have widely varying pK_a values (Table 1). These differences in basicities do not appear to affect the hydrolysis rates of the *N*-acyl derivatives extensively. For the *N*-acetylimidazole compounds studied, it appears that the hydrolysis rates remain reasonably constant as long as the imidazole ring is maintained in its protonated form, the driving force for the hydrolysis presumably being the gain in resonance stabilization obtained.

TABLE 1. Dissociation constants of imidazole derivatives

Compound	pK_a
Imidazole	6.9[a]
Benzimidazole	5.54[b]
1-Methylbenzimidazole	5.44[b]
1-Methyltetrahydrobenzimidazole	8.20[b]

[a]Determined in 23.3% ethanol/H_2O (v/v) solvent (ref. 6).

[b]Typically 0.025 mmol of the substance to be titrated was dissolved in 2 mL ethanol, 3.0 mL 0.5 *N* KCl, and 1 mL 0.1051 *N* HNO_3 and titrated with 0.1000 *N* NaOH.

Experimental

N-*Acetylbenzimidazole (4)*

Benzimidazole (1 g, 0.0085 mol) and 1.1 equivalents of acetyl chloride were added to dry THF (100 mL) and stirred for 1 h. The hydrochloride salt of benzimidazole precipitated out of solution and was filtered off. The THF was then removed *in vacuo* and the residue washed with ether. Any precipitate which formed was filtered off and the ether removed under reduced pressure. The product could be recrystallized from benzene/pentane: mp 112–114°C (lit. (3) mp 113°C). The hydrochloride salt of 1-acetylbenzimidazole could be made directly by bubbling dry HCl gas through the ethereal solution to precipitate 0.3 g (0.0015 mol, 18% yield) of product: mp 195–196°C; ir (KBr disc): 1760, 1545, 1490, 1315, 1245, 1170, 760 cm^{-1}; nmr $C_9H_8N_2O \cdot HCl$ (DMSO-d_6, 100 MHz), δ: 2.78 (s, 3H, CH_3), 7.38–8.26 (m, 4H), and 9.00 (s, 1H). Mass spectrum *m/e* (rel. intensity): 160 (M^+, 77), 118 (100). *Exact Mass* calcd. for $C_9H_8N_2O$: 160.0632; found: 160.0635.

N-*Acetyl*-N'-*methylbenzimidazolium acetate (5)*

The hydrochloride salt of 1-methylbenzimidazole (1 g, 0.0059 mol) was added to acetic anhydride (10 mL) and stirred at room temperature until all of the solid had dissolved. Dry ether was then added until the solution became cloudy and 0.7 g of a mixture of the chloride and acetate salts of 1-acetyl-3-methylbenzimidazole and 1-methylbenzimidazole precipitated out of solution.

Due to the extremely labile nature of this salt, separation from the unreacted starting material could not be effected. The mixture was used for pseudo-first order decomposition kinetics. Spectral analyses of the kinetic mixtures after reaction were identical with those made up from *N*-methylbenzimidazole in the same buffer.

Infrared (KBr, disc): 1765, 1752, 1570, 1460, 1375, 1330, 1230, 1130, 770 cm^{-1}; nmr (DMSO-d_6, 100 MHz), δ: 1.92 (s, 3H, OAc), 2.92 (s, 3H, NAc), 4.22 (s, 3H, NMe), 7.70–8.44 (m, 4H), and 9.68 (s, 1H). D_2O exchange yielded 1-methylbenzimidazole. Mass spectrum *m/e* (rel. intensity): 160 (M^+ – Me, 1.85), 133 (23), 131 (100). *Exact Mass* calcd. for $C_{10}H_{11}N_2O$ – Me: 160.0637; found: 160.0639.

N-*Methyltetrahydrobenzimidazole*

1-Methylbenzimidazole (1 g, 0.0076 mol), 5% rhodium on carbon (1 g), glacial acetic acid (20 mL), and 1.1 equivalents of concentrated HCl were placed in a hydrogenation bomb and heated at 120°C under 1000 lb H_2 pressure overnight (4). After cooling, the rhodium was filtered off and the acetic acid removed under reduced pressure (rotoevaporator at 60°C). The residue was dissolved in H_2O (20 mL) and taken to a pH of 9–10 with saturated aqueous potassium carbonate, and the aqueous layer extracted several times with chloroform. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

combined chloroform extracts were dried with $MgSO_4$ and the solvent removed under reduced pressure. The gummy residue was then dissolved in dry Et_2O (200 mL) and dry HCl gas was bubbled through the solution. A white powder precipitated which was recrystallized from 98% EtOH/ether to give 0.5 g (0.0029 mol, 38% yield) of 1-methyltetrahydrobenzimidazole: mp 194–195°C.

Infrared ($CHCl_3$, cast): 1670, 1500, 1450, 800 cm^{-1}; nmr $C_8H_{11}N_2$ ($CDCl_3$, 90 MHz), δ: 1–1.9 (m, 4H), 2.35–2.7 (m, 4H), 2.48–2.64 (m, 4H), 3.70 (s, 3H, NCH_3), and 8.90 (s, 1H). Mass spectrum *m/e* (rel. intensity): 136 (M^+, 96), 135 (80), 108 (100). *Exact Mass* calcd. for $C_8H_{11}N_2$: 136.1000; found: 136.0998. *Anal.* calcd. for $C_8H_{11}N_2 \cdot HCl$: C 55.65, H 7.59, N 16.22; found: C 55.38, H 7.49, N 16.28.

N-*Acetyl*-N′-*methyltetrahydrobenzimidazolium acetate* (**6**)

The hydrochloride salt of 1-methyltetrahydrobenzimidazole (1 g, 0.0058 mol) was added to acetic anhydride (10 mL) and stirred at room temperature until all of the solid had dissolved. Dry ether was then added until the solution became cloudy and 0.65 g of a mixture of the chloride and acetate salts of 1-acetyl-3-methyltetrahydrobenzimidazole and 1-methyltetrahydrobenzimidazole precipitated out of solution. Due to the extremely labile nature of this salt, separation from the unreacted starting material could not be effected. The mixture was used for pseudo-first order decomposition kinetics. Spectral analyses of the kinetic mixtures after reaction were identical with those made up from *N*-methyltetrahydrobenzimidazole in the same buffer.

Infrared (KBr, disc): 1641, 1543, 1445, 740, 628 cm^{-1}; nmr (DMSO-d_6, 100 MHz), δ: 1.6–1.9 (m, 4H), 1.92 (s, OAc^-), 1.4–2.0 (m, 4H), 2.74 (s, NAc), 3.86 (s, NMe), and 8.94 (s, 1H). Addition of D_2O results in spectrum of 1-methyltetrahydrobenzimidazole. Mass spectrum *m/e* (rel. intensity): 164 (M^+ − Me, 0.1), 108 (100). *Exact Mass* calcd. for $C_{10}H_{15}N_2O - CH_3$: 164.0095; found: 164.0022.

Determination of dissociation constants

The pK_a's were determined potentiometrically using a modified version of Albert and Sergeant's method (5). The pK_a determinations were performed in a jacketed cell kept at 25 + 0.1°C with a Colora Ultra Thermostat constant temperature bath. Air was excluded from the cell by passing a gentle stream of nitrogen through the cell. The pH was recorded as a function of added 0.1000 *N* NaOH (delivered by a Radiometer ABU12) using a titration assembly consisting of a Radiometer TTT2 titrator and PHA943B titration module in conjunction with a Radiometer 6K2402B combined electrode and recorded on a Radiometer SBR3 titrigraph. The electrode was standardized by using dilute acid solutions in the ethanol/H_2O medium in the low pH region and dilute base solutions in the high pH region. A typical run was performed by adding 3.0 mL of 0.5 *N* KCl, 1 mL of 0.1051 *N* HNO_3, 1 mL 95% ethanol, and 0.025 mmol of the substance to be titrated in 1 mL ethanol to the thermostatted cell (25°C) and titrating with 0.1000 *N* NaOH. Each pK_a was the average of at least three reproducible runs.

Rates of hydrolysis

The decomposition of *N*-acetyl-*N*′-methylbenzimidazolium acetate and *N*-acetylbenzimidazole was monitored at 290 nm in 29.4% ethanol/H_2O (v/v) with an ionic strength equal to 0.345 *M* by addition of a calculated amount of KCl (after correction for the amount of ionized buffer). The reaction was checked for buffer catalysis by using 0.21 *M*, 0.13 *M*, and 0.02 *M* buffers and the final rate constant obtained by extrapolation of k_{obs} to zero [buffer]. Sodium formate/formic acid buffer was used from pH 2.8 to 4.0, sodium acetate/acetic acid from 4.4 to 5.2, MES (2(*N*-morpholino)ethane sulfonic acid) from 5.6 to 6.4, HEPES (*N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid) from 6.8 to 7.2, TRICINE (*N*-tris(hydroxymethyl)methylglycine) from 7.6 to 8.8, CHES (2(*N*-cyclohexylamino)ethanesulfonic acid) from 9.2 to 10.0. Buffer reagents were used as supplied from Sigma. Data were fit to a nonlinear least-squares program and each rate constant was the result of at least three reproducible results. Product analysis was done by comparison of the final spectrum of the kinetic run with the uv–vis spectrum of the corresponding "NH" compound. In all three cases the expected products were obtained.

STEPHEN W. LIBLONG, RICHARD T. OAKLEY, A. WALLACE CORDES, and MARK C. NOBLE. Can. J. Chem. **61**, 2062 (1983).

The reaction of norbornadiene with (triphenylphosphoranediyl)aminocyclotrithiatriazene produces the cycloadduct $Ph_3PN—S_3N_3 \cdot C_7H_8$. The crystal and molecular structure of this compound has been determined by X-ray crystallography. Crystals of $Ph_3PN—S_3N_3 \cdot C_7H_8$ are monoclinic, space group $P2_1/c$, a = 9.757(1), b = 15.114(1), c = 16.535(2) Å, β = 100.73(1)°, V = 2395.7(9) Å^3, and Z = 4. The structure was solved by direct methods and refined by Fourier and full-matrix least-squares procedures to give a final R of 0.040 and R_w of 0.058 for 2620 observed reflections. The structure reveals that the S_3N_3 ring adds to norbornadiene in an *exo* fashion via two sulphur atoms. The S_3N_3 ring adopts a chair conformation with the three ligands occupying axial positions on the same side of the ring. The relative rates of this and other cycloadditions involving SN substrates and olefins are discussed in terms of the energies of the interacting frontier orbitals. The results suggest that HOMO(olefin)–LUMO(SN substrate) interactions control the kinetics of these reactions.

STEPHEN W. LIBLONG, RICHARD T. OAKLEY, A. WALLACE CORDES et MARK C. NOBLE. Can. J. Chem. **61**, 2062 (1983).

La réaction du norbornadiène avec le (triphénylphosphoranediyl)aminocyclotrithiatriazène conduit au produit de cycloaddition: $Ph_3PN—S_3N_3 \cdot C_7H_8$. On a déterminé la structure du cristal et la structure moléculaire de ce composé par cristallographie de rayons-X. Les cristaux de $Ph_3PN—S_3N_3 \cdot C_7H_8$ sont monocliniques et appartiennent au groupe d'espace $P2_1/c$ avec a = 9,757(1), b = 15,114(1), c = 16,535(2) Å, β = 100,73(1)°, V = 2395,7(9) Å^3 et Z = 4. On a résolu la structure par les méthodes directes et on l'a affinée par la méthode de Fourier et la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de R = 0,040 et de R_w = 0,058 pour 2620 réflexions observées. La structure révèle que le cycle S_3N_3 s'additionne sur le norbornadiène d'une façon *exo* par l'intermédiaire de deux atomes de soufres. Le cycle S_3N_3 adopte une conformation chaise avec trois ligands en position axiale du même côté du cycle. On discute des vitesses relatives de cette réaction ainsi que celles d'autres réactions de cycloaddition impliquant des substrats du type SN et des oléfines en fonction des énergies d'interaction des orbitales frontières. Les résultats suggèrent que les interactions HOMO(oléfine)–LUMO(SN) contrôlent la cinétique de ces reactions.

[Traduit par le journal]

Introduction

The rates of organic electrocyclic reactions have been successfully interpreted using frontier molecular orbital (FMO) theory (1, 2). Although the same concepts are equally applicable to the study of the analogous reactions of conjugated inorganic systems, insufficient experimental and theoretical information has been available to allow the extrapolation of ideas. However, recent work on the cycloaddition of 2e-olefins to binary sulphur–nitrogen (SN) derivatives suggests that such studies would be useful. For example, the regiochemistry of the addition of norbornadiene (NBD) to tetrasulphur tetranitride S_4N_4 (3) and phosphadithiatriazenes $R_2PS_2N_3$, **1** (4) (equation [1]) can be rationalized in terms of the symmetries of the interacting frontier orbitals. As a development of this work we are currently examining the reactions of closely related SN ring systems with different olefins. Through studies of this kind the relationships between the energies and distributions of the interacting frontier orbitals and overall reaction rates can be assessed. In the present paper we report the preparation and molecular structure of the cycloadduct **4** formed between (triphenylphosphoranediyl)aminocyclotrithiatriazene, **3**, and norbornadiene (equation [2]). The relative reactivities of **1** and **3** with olefins are discussed in the light of their π-electronic structures.

Experimental

Starting materials

(Triphenylphosphoranediyl)aminocyclotrithiatriazene, **3**, was prepared by the reaction (5) of S_4N_4 (6) with *N*-trimethylsilyltriphenylphosphinimine (7). Norbornadiene was a commercial product (Aldrich). Methylene chloride (reagent grade) was purified by distillation from phosphorus pentoxide. Nuclear magnetic resonance spectra were obtained using a Varian XL-200 nmr spectrometer. Chemical analyses were performed by Mr. Lada Malek of the Department of Chemistry, University of Calgary.

Preparation of $Ph_3PN—S_3N_3 \cdot C_7H_8$

A large excess of norbornadiene (1.40 g, 15 mmol) was added to

a solution of $Ph_3PN—S_3N_3$ (0.349 g, 0.84 mmol) in 15 mL methylene chloride, and the mixture heated to reflux under an atmosphere of nitrogen. After 36 h the light brown solution was cooled to room temperature and concentrated *in vacuo* to a volume of ca. 5 mL. Diethyl ether (50 mL) was then added, inducing the precipitation of an off-white solid. This material was filtered off and recrystallized from methylene chloride/acetonitrile to give colourless crystalline blocks of $Ph_3PN—S_3N_3 \cdot C_7H_8$, **4** (0.26 g, 0.51 mmol, 61%), decomp. >140°C. *Anal.* calcd. For $C_{25}H_{23}N_4PS_3$: C 59.3, H 4.6, N 11.1; found: C 59.0, H 4.5, N 11.3. ^1H nmr ($CDCl_3$) δ: 7.0–8.0 (15H, m, phenyl rings), 6.43 (2H, s, $H_{5,6}$), 5.39 (2H, s, $H_{1,4}$), 3.19 (2H, s, $H_{2,3}$), 1.90 and 1.19 (2H, AB, $H_{7,7'}$ = 8.5). ^{31}P nmr ($CDCl_3$, ref. ext. H_3PO_4) δ, 18.7.

X-ray analysis of $Ph_3PN—S_3N_3 \cdot C_7H_8$

Crystals of **4** suitable for X-ray work were obtained by slow evaporation of a methylene chloride/acetonitrile solution. The 0.31 × 0.30 × 0.51 mm crystal used for data collection was mounted with epoxy on a glass fiber. All data were collected using an Enraf-Nonius CAD-4 diffractometer and graphite-monochromated MoK_α (λ = 0.71073 Å) radiation. A least-squares calculation using the diffractometer settings for 25 carefully centred reflections gave the following cell dimensions (at 21°C): a = 9.757(1), b = 15.114(1), c = 16.535(2) Å, β = 100.73(1)°, V = 2395.7(9) Å^3. For $PS_3N_4C_{25}H_{23}$ with mw = 506.65 and Z = 4, D_c = 1.41 g cm^{-3}, F_{000} = 1056 and $\mu(MoK_\alpha)$ = 3.84 cm^{-1}.

Systematic absences of $h0l$ for l odd and $0k0$ for k odd uniquely indicated the space group $P2_1/c$. A total of 4550 unique reflections were measured using θ–θ scans for 2θ from 4 to 50 (h = −11 to 11, k = 0 to 18, l = 0 to 19). The scan range was (1.2 + 0.35 tan θ) and the scan speeds varied from 5 to 20 deg min^{-1}. 1930 reflections had $I < 3\sigma(I)$ and were considered unobserved. The intensities of three reflections (0 1 4, 3 3 0, 6 1 0) which were measured periodically during the data collection varied by less than 2.5% and thus indicated crystal and electronic stability. An absorption correction based on ψ scans gave correction factors which varied from 97.9 to 99.9.

The structure was solved by direct methods (MULTAN 78) (8) and refined by Fourier and least-squares techniques. The final full-matrix least-squares refinement based on F^2 included 298 parameters (positional and anisotropic thermal parameters for all non-hydrogen atoms) and had a parameter:reflection ratio of 1:8.8. Hydrogen atoms were not refined but were included in the structure factor calculations at calculated positions with isotropic thermal parameters of 5.0 Å^2. The weighting scheme, based on counting statistics with an instability factor of 5%, gave no systematic variation of $\Delta F/\sigma(F)$ as a function of either F or sin θ. No secondary extinction correction was made. In the final cycle of refinement the maximum shift/error was 0.06, R = 0.040, R_w = 0.058, and GOF = 1.21. The final difference map had a maximum value of 0.24 e Å^{-3}. Neutral atom scattering factors corrected for real and imaginary anomalous dispersion corrections were used (9). The computer programmes used were those provided by the Enraf-Nonius SDP programme package.

Molecular orbital calculations

The modified neglect of diatomic overlap (MNDO) method (10) is recognized as providing reliable estimates of occupied orbital energies (i.e. ionization potentials) for sulphur–nitrogen derivatives (11). Calculations using this procedure were carried out on several model compounds related to **1** and **3**. Numerical results relating to $R_2PS_2N_3$ molecules refer to a calculation on a $H_2PS_2N_3$ model, for which the geometry was fully optimized within the bounds of C_{2v} symmetry. In the case of **3**, calculations were performed on a $H_3PN—S_3N_3$ model. Full geometry optimization (within C_s symmetry) was again invoked, except for the following restrictions: the ligand geometry was held fixed (d(P—N) = 1.65 Å, d(P—H) = 1.4 Å, ∠SNP = 120°) as was the angle (40°) between the S_2N_3 plane and the plane formed by the substituted sulphur and its two endocyclic neighbours. Variations in either of the models produced small changes in orbital energies (<0.2 eV), but the orbital ordering remained essentially unchanged.

*Electrochemistry of **1** (R = Ph) and **3***

Electrochemical oxidation of **1** (R = Ph) and **3** was carried out in acetonitrile at a rotating platinum electrode with 0.1 *M* $Bu_4N^+ClO_4^-$ as supporting electrolyte. Reductions were performed at a dropping mercury electrode using the same solvent and electrolyte. Half-wave potentials are quoted with reference to a saturated calomel electrode (sce).

Results and discussion

Molecular structure of $Ph_3PN—S_3N_3 \cdot C_7H_8$

The crystal structure of the title compound is composed of discrete molecules of **4**; there are no unusually short intermolecular contacts. Figure 1 shows an ORTEP drawing of the molecule and indicates the atom numbering scheme. Table 1 provides a limited compilation of nonhydrogen atom coordinates (all those designated in Fig. 1) and Table 2 gives a listing of the bond lengths and angles relevant to the present discussion.[2]

Molecules of **4** consist of a six-membered S_3N_3 ring possessing three S-ligands. The orientation of the norbornenyl residue indicates that, as in all other SN–olefin electrocyclic reactions reported to date, the $Ph_3PN—S_3N_3$ molecule **3** adds to NBD in an *exo* fashion.[3] The S_3N_3 ring adopts a chair conformation, with the ligands occupying axial positions. While this orientation is dictated for the S—C bonds by the chelating nature of the norbornenyl group, the —NPPh$_3$ ligand is, in principle, free to occupy either an equatorial or axial position. In $Ph_3PN—S_3N_3$ itself, the choice is equatorial (13). The substitution pattern of the S_3N_3 ring is reminiscent of that observed in $S_3N_3Cl_3$ (14) and $S_3N_3F_3$ (15), where the ligands also occupy axial positions. However, although these structures tend towards chair conformations, the rings are, as a whole, much flatter. The dihedral angles between the planes of three-atom segments and the planes of the four atoms flanking the segment in these molecules are given in Table 6. The more acute puckering in the present case can be attributed to the small "bite" size of the norbornenyl group, which draws the S4 and S6 atoms together. This effect is most easily demonstrated through a comparison of the N5 angle (106.2°) with the angles at N7 (118.2°) and N3 (118.9°). In $S_3N_3Cl_3$ and $S_3N_3F_3$ the mean angles at nitrogen are still larger (at 123.3° and 123.2° respectively). Thus, in order to achieve the small angles at nitrogen without affecting the corresponding angles at sulphur (all of which are similar to those observed in $S_3N_3Cl_3$ and $S_3N_3F_3$), the ring is forced to fold into a more pronounced chair shape.

*Reactivity of **1** and **3** olefins*

In our recent discussion of the electronic structures of $R_2PS_2N_3$ molecules **1** we noted that the symmetries of the highest occupied and lowest unoccupied molecular orbitals (HOMO and LUMO) were such that the concerted addition of a 2e-olefin, e.g. equation [1], was a symmetry-allowed process (4). MNDO molecular orbital calculations on a model

[2]A structure factor table and tables containing the coordinates of the phenyl hydrogen atoms (Table 3), the structural parameters for the phenyl groups (Table 4), and anisotropic thermal parameters for all non-hydrogen atoms (Table 5) are available at a nominal charge from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[3]This stereochemistry is consistent with recent calculations on the geometry of norbornadiene (12), which reveal a slight pyramidalization of the olefinic CH bonds in the *endo* direction, and hence a slight preference for *exo* addition.

*Anisotropically refined atoms are given in the form of the isotropic equivalent thermal parameter B defined as $(4/3)[a^2\beta_{11} + b^2\beta_{22} + c^2\beta_{33} + ab\beta_{12} \times \cos\gamma + ac\beta_{13}\cos\beta + bc\beta_{23}\cos\alpha]$.

$H_3PN—S_3N_3$ derivative indicate that the analogous cycloaddition for **3** (equation [2]) is equally allowed. The π-like frontier orbitals for the $H_3PN—S_3N_3$ model are illustrated in Fig. 2. However, in spite of the correct symmetry conditions for both reactions (equations [1] and [2]), one is considerably faster than the other. Although we have not measured the actual rate constants for the addition of NBD to **1** and **3**, it is clear

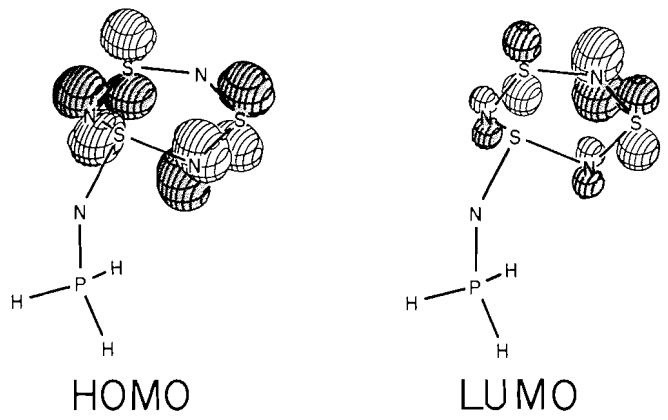

FIG. 2. Frontier orbitals of $H_3PN—S_3N_3$.

from the preparative procedures for **2** and **4** that they must differ by several orders of magnitude. Thus, while the reaction of **1** (R = Ph, Me) with a 10% excess of NBD is complete within 2–3 min, that involving **3** requires a large excess of NBD, prolonged reaction times (~36 h), and elevated temperatures (40°C). In addition to this dichotomy, we also point out that if norbornadiene is replaced by cyclohexene, no addition occurs to either **1** or **3**. It is therefore apparent that simple symmetry rules are, by themselves, inadequate guides to the reactivity of SN systems with olefins. A better understanding can be developed through an analysis of the relative energies of the interacting frontier orbitals.

Frontier molecular orbital analysis

As a standard application of frontier orbital theory (1, 2), the stabilization term ΔE_{FMO} for the concerted addition of an olefin to either **1** or **3** may be written as:

$$[3]\quad \Delta E_{FMO} = 2\beta_{sc}^2 \frac{2C_s(\text{HOMO})C_c(\text{LUMO})}{|E_s(\text{HOMO}) - E_c(\text{LUMO})|} + \frac{2C_s(\text{LUMO})C_c(\text{HOMO})}{|E_s(\text{LUMO}) - E_c(\text{HOMO})|} = 2\beta_{sc}^2(\Delta E_1 + \Delta E_2)$$

where β_{sc} is the resonance integral for the interaction of a sulphur $3p$ with a carbon $2p$ orbital, and C and E refer respectively to the eigenvector coefficients and eigenvalues associated with a given orbital (HOMO or LUMO) of the SN ring (subscript s) or olefin (subscript c). As in many organic cycloadditions, for which similar expressions can be written, one of the terms $\Delta E_{1,2}$ can be expected to dominate the value of ΔE_{FMO} (by virtue of a small denominator for that term). Using these principles Fukui and co-workers have recently pointed out that the addition of 2e-olefins to S_4N_4 is governed by the interaction of the LUMO of S_4N_4 with the HOMO of the olefin (3). In accord with this interpretation, less nucleophilic olefins, i.e., those with a lower lying HOMO, do not react with S_4N_4 (16).

The reactivities of **1** and **3** with olefins can be rationalized similarly. Evidence regarding the relative frontier orbital energies E_s(HOMO) and E_s(LUMO) for the two types of molecule has been obtained from a variety of physical measurements (e.g. $\pi^* \rightarrow \pi^*$ transition energies, redox potentials) as well as from theoretical (MNDO) calculations. However, before discussing the numerical details it is instructive to examine qualitatively the differences in the electronic structures of the two

compounds. This can achieved by means of a simple perturbation treatment in which the π-system of each molecule (**1** or **3**) is generated by the incorporation of either (*i*) a $[>PR_2]^+$ group or (*ii*) a $[>S—NPPh_3]^+$ group into an open chain 5-atom NSNSN fragment with 8 π-electrons. The fusion of a $[>PR_2]^+$ group into this fragment to produce **1** will extend the π-system of the latter to include the 3*d*-orbitals of phosphorus. As our earlier *ab initio* Hartree–Fock–Slater MO analysis of $H_2PS_2N_3$ has shown (4), the magnitude of the 3*d*-orbital mixing is small, but it will lead to a slight stabilization of the HOMO and the LUMO levels of the pentadienyl-like $S_2N_3^-$ unit (see Fig. 3). By contrast, the introduction of a $[>S—NPPh_3]^+$ moiety will, to a first approximation, leave the HOMO unaffected, since the orbital is nodal at the substituted sulphur atom (*d*-orbital effects will be smaller than in **1**). However, the interaction of the lone pair orbital on sulphur with the LUMO of $S_2N_3^-$ will cause a substantial destabilization of this orbital and a consequent increase in the HOMO–LUMO gap (relative to **1**).

The redox potentials and the $\pi^* \rightarrow \pi^*$ (HOMO–LUMO) transition energies (4, 17, 18) for **1** (R = Ph) and **3** (Table 7) substantiate the conclusions of this simple description. $Ph_3PN—S_3N_3$ is more readily oxidized than $Ph_2PS_2N_3$, and is less easily reduced, in agreement with the frontier orbital ordering illustrated in Fig. 3. Likewise the larger $\pi^* \rightarrow \pi^*$ transition energy for $Ph_3PN—S_3N_3$ is consistent with a larger HOMO–LUMO gap. MNDO molecular orbital calculations on two model compounds $H_2PS_2N_3$ and $H_3PN—S_3N_3$ also support

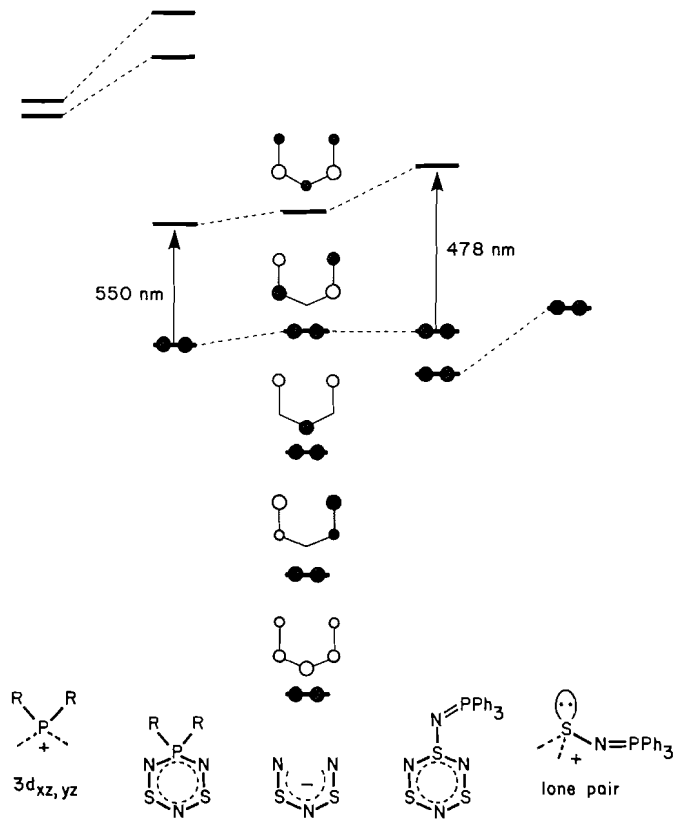

FIG. 3. Qualitative correlation diagram illustrating the interaction of (*i*) a PR_2^+ group and (*ii*) a $S—NPR_3^+$ group with the π-system of a hypothetical $S_2N_3^-$ ion.

the above description, but provide a HOMO–LUMO gap which is unrealistically large. However, the energies of the HOMO's are probably quite reliable (in terms of their correspondence to ionization potentials) (11); for $H_2PS_2N_3$ and $H_3PN—S_3N_3$ the calculated values are −8.7 and −8.5 eV, respectively. Using these numbers (which are not critical) to approximate E_s (HOMO) in **1** and **3** and the $\pi^* \rightarrow \pi^*$ transition energies of $Ph_2PS_2N_3$ and $Ph_3PN—S_3N_3$ to represent the HOMO–LUMO gap, the frontier orbital energy diagram shown in Fig. 4 can be constructed. Inspection of the energy separations of the interacting HOMO–LUMO pairs for the reaction of **1** and **3** with an arbitrary olefin[4] reveals at once that the ΔE_2 term will dominate the ΔE_{FMO} expression. Furthermore it is readily apparent that the higher lying LUMO of **3** will give rise to a larger denominator for the ΔE_2 term of eq. [3], and hence a smaller ΔE_{FMO}. The lower reactivity of **3** can thus be attributed, at least in part, to this effect. The fact that neither **1** nor **3** react with less electron-rich olefins can also be understood. If E_{HOMO}(olefin) is lowered, the ΔE_2 term and hence ΔE_{FMO} will be reduced.

[4]HOMO and LUMO energies indicated for the olefin in Fig. 4 represent an average value obtained from several electron rich olefins (see ref. 19).

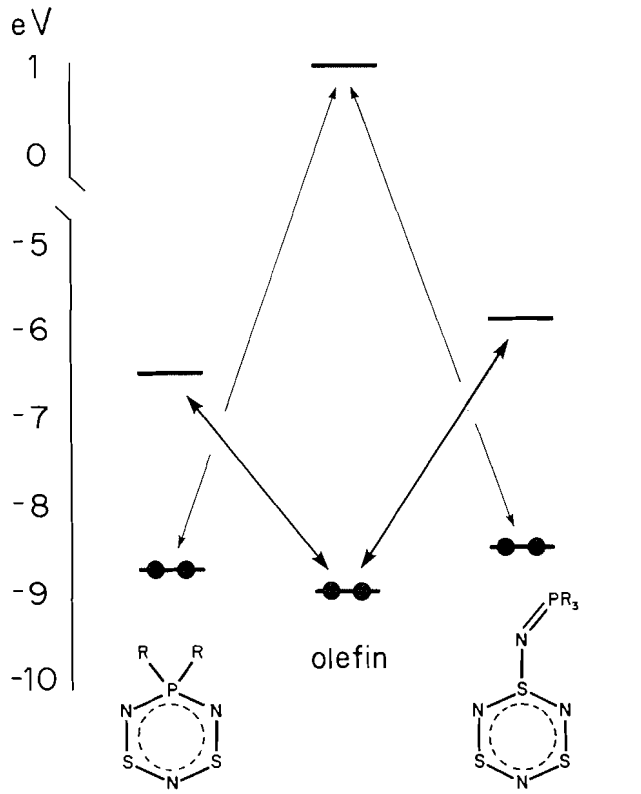

FIG. 4. Frontier orbital energies (estimated) for $Ph_2PS_2N_3$, $Ph_3PN—S_3N_3$, and an arbitrary electron-rich 2e-olefin.

Conclusion

The results reported here suggest that the concerted addition of 2e-olefins to conjugated binary sulphur nitrogen systems is under strong kinetic control; reactivity is dependent on the interaction of the HOMO(olefin) with the LUMO(SN substrate). Further studies of the electrocyclic reactions of SN molecules with olefins should take into consideration the need for (*a*) electron-rich olefins and (*b*) SN substrates with a sufficiently low lying acceptor orbital (of the correct symmetry). However, reactions involving reverse electron demand may also be possible.

On the basis of MNDO, MINDO/3, and STO-3G calculations, the regioselectivity of radical additions to substituted olefins is rationalized in terms of an electronic effect.

JOSEP M. POBLET, ENRIC CANADELL et TOMÁS SORDO. Can. J. Chem. **61**, 2068 (1983).

A partir de calculs MNDO, MINDO/3 et STO-3G, on montre que la regioselectivité des additions radicalaires à des olefines substituées peut être rationalisée par un éffet orbitalaire.

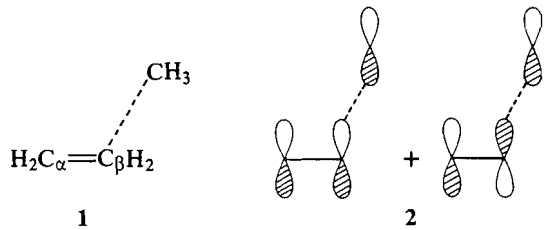
The interplay of polar, steric, and bond strength effects has been invoked to explain the orientation of free radical additions to olefins (1). Usually, the attack is at the less substituted end of the olefin. It is well known that both the SOMO–LUMO and SOMO–HOMO interactions can be important to explain the reactivity of radicals. In a study of the addition of $\dot{C}H_3$ to ethylene, Fukui and co-workers (2) proposed that the SOMO–LUMO interaction was more important than the SOMO–HOMO one. This is rather surprising if we take into account the ionization potential and the electronic affinity of ethylene (−10.5 and 1.8 eV, respectively) and the ionization potential of $\dot{C}H_3$ (−9.8 eV). Recent results of Ponec and Malek (3), as well as Arnaud *et al.* (4) do not support the suggestion of Fukui and co-workers (2). In the course of a general theoretical study of these reactions (5, 6) we have found evidence in favour of the dominance of the SOMO–HOMO interaction in the first steps of the reaction even for the addition of a radical traditionally considered to be a nucleophile as the $\dot{C}H_3$.

The relative importance of the two interactions can be inferred by inspection of the shape of the SOMO of the system methyl + olefin. This orbital initially localized on the methyl radical correlates with the SOMO of the product, mostly localized on the α carbon (1).[2] The transfer of the radical character from the incoming radical to the C_α center is made by mixing of the SOMO ($\dot{C}H_3$) with π (out-of-phase) and π* (in phase) as represented in **2**. As long as the SOMO–HOMO interaction predominates the *p* orbitals on the ethylene stay in phase in the SOMO of the supersystem.



1 **2**

We have examined the shape of this orbital along a reaction coordinate defined by the distance of approach C_{methyl}—C_β. For different values of the approach distance the structure was optimized with respect to all other geometrical parameters at the MNDO and MINDO/3 levels. Using these geometries, the orbitals were recalculated at the STO-3G level. The additions studied were those of $\dot{C}H_3$ to CH_2=CHX (X = H, CH_3, F, Cl) and CH_2=CF_2. All these reactions involve a reactant-like transition state with a σ type geometry. The olefinic bond remains practically unaltered and the C...C_β approach distance lies between 2.40 and 2.25 Å, depending on the olefin (5, 6).

In all cases, the contribution at C_β along the reaction coordinate and even at the transition state remains noticeable and in phase with the contribution at C_α.[3] We can therefore be confident that the SOMO–HOMO interaction is dominating in the first steps of the reaction.[4] Model calculations show this three-electron interaction is stabilizing[5] and, consequently, the addition should preferentially occur at the carbon having the larger coefficient in the π orbital.

As pointed out by Libit and Hoffman (9), the alkyl substituents increase the coefficient at the non-substituted end of the ethylene HOMO. So, as long as alkyl substituents are considered, the addition will always be at the less substituted end of the olefin. Experimental proof comes, among others, from the systematic work by Boldt and co-workers (10).

The rule can be made more general if we recall that fluorines (and halogens in general) polarize the ethylene HOMO in the same way as CH_3 (11). Extending the conjugation or substitution with acceptor groups like CO or CN places the greater coefficient at the less substituted end of the olefin in both the HOMO and LUMO. Consequently, **the addition at the less substituted end of the olfein has an electronic origin**. Let us point out that even if steric and electronic effects go in the same direction, it is difficult to believe that steric effects are behind the regioselectivity in the additions of hydrogen atoms (12)

[2]SOMO: singly occupied orbital in open shell Nesbet type calculations or highest occupied α spin-orbital in UHF calculations.

[3]See Fig. 3 of ref. 4 and ref. 7.

[4]Consequently, the $\dot{C}H_3$ radical should be considered electrophilic. The charge density for the $\dot{C}H_3$ fragment in the transition states substantiate this conclusion. The same result was found for other alkyl radicals as the cyclopropyl radical (5).

[5]The calculations were done for the attack of $\dot{C}H_3$ to CH_2=CHX (X = H, CH_3, F) and CF_2=CHX (X = H, F) with the usual perturbation expressions with overlap (8). The approach distance was taken to be 3.0 Å. The interfragment overlaps were calculated with standard Slater orbitals and the fragment orbitals were both MINDO/3 and INDO. The results are completely coincident in both cases (6).

which, in turn, can be easily explained by the electronic effect.[6]

It is clear that the model developed in this paper is oversimplified.[7] Nevertheless, the experimental results for the most part (1) substantiate it. Only few exceptions have been noticed. For instance, the additions of $\dot{C}H_3$ and $\dot{C}H_2F$ to $CF_2{=}CHF$ are at the more substituted end of the olefin. Strikingly, both the polarization of the HOMO and full MNDO determination of the transition state predict the wrong product in this case. This reversal in the orientation can not be attributed to an increase in the SOMO–LUMO interaction overriding the effect of the SOMO–HOMO one. Experimental ionization potentials and STO-3G calculations (15) both place the SOMO of $\dot{C}Cl_3$ higher than that of $\dot{C}H_3$ and indeed, the addition of $\dot{C}Cl_3$ (like the more electrophilic $\dot{C}F_3$) is at the less substituted end of the olefin. Extended basis set *ab initio* calculations for these systems are now under way in order to clarify the origin of these few exceptions to the rule.

Condensed-phase reactions of O_3 with NH_3 and NH_2OH[1,2]

THERESA HUSTON, I. C. HISATSUNE, AND JULIAN HEICKLEN

Department of Chemistry and Center for Air Environment Studies, The Pennsylvania State University, University Park, PA 16802, U.S.A.

Received November 17, 1982

THERESA HUSTON, I. C. HISATSUNE, and JULIAN HEICKLEN. Can. J. Chem. **61**, 2070 (1983).

The reactions of O_3 with NH_3 and NH_2OH were studied in the condensed phase. A yellow ozonide was formed immediately upon the addition of O_3 to the NH_2OH solid maintained at $-190°C$, but the yellow–orange ozonide seen in the NH_3 case was not formed until the system was warmed to $-170°C$. These ozonides could be reconverted to reactants by photolysis with near ultraviolet light or by heating to $-90°C$ ($NH_3^+O_3^-$) or $-115°C$ ($NH_2OH^+O_3^-$).

Upon warming the NH_3-O_3 system to $-130°C$, $NH_4NO_3 \cdot 3NH_3$ appeared. It started to deamminate at about $-105°C$ to give NH_4NO_3. In the NH_3-O_3 system a second species, tentatively identified as $NH_2O^+HO_2^-$, was also formed at $-170°C$. It began to decompose with the evolution of O_2 at about $-10°C$.

In the NH_2OH-O_3 system, HNO_3 was also seen immediately upon addition of O_3 to NH_2OH. It appeared as $NH_2OH \cdot HNO_3$, a hydrogen-bonded complex with NH_2OH. At about $-100°C$, NH_2OH started to anneal and the $NH_2OH \cdot HNO_3$ bands grew rapidly and converted to $NH_3OH^+NO_3^-$.

There was no evidence of NH_2OH as an intermediate in the NH_3-O_3 system, but since NH_2OH reacted so readily with O_3, this possibility could not be ruled out. These ozonolysis reactions may be represented as

$$NH_3^+O_3^- + O_3 \xrightarrow{NH_3} NH_4NO_3 + H_2O + O_2$$

and

$$NH_2OH^+O_3^- \xrightarrow{NH_2OH} NH_3OH^+NO_3^- + H_2O$$

THERESA HUSTON, I. C. HISATSUNE et JULIAN HEICKLEN. Can. J. Chem. **61**, 2070 (1983).

On a étudié les réactions du O_3 avec le NH_3 en phase condensée. Il se forme immédiatement un ozonide jaune lorsqu'on ajoute du O_3 au NH_2OH solide maintenu à $-190°C$, mais l'ozonide jaune orange observé dans le cas du NH_3 ne se forme pas tant que l'on ne chauffe pas le système à $-170°C$. On peut retransformer ces ozonides en réactifs par photolyse dans le proche ultraviolet ou par chauffage à $-90°C$ ($NH_3^+O_3^-$) ou à $-115°C$ ($NH_2OH^+O_3^-$). Il se forme du $NH_4NO_3 \cdot 3NH_3$ lorsqu'on chauffe le système NH_3-O_3 à $-130°C$. Le $NH_4NO_3 \cdot 3NH_3$ commence à se désaminer à environ $-105°C$ en donnant du NH_4NO_3. Dans le système NH_3-O_3 il se forme également une deuxième espèce à $-170°C$ que l'on pense être le $NH_2O^+HO_2^-$. Il commence à se décomposer à environ $-10°C$ en dégageant de l'oxygène.

Dans le système NH_2OH-O_3 il se forme également du HNO_3 dès qu'on ajoute du O_3 au NH_2OH. Il se manifeste sous la forme d'un complexe de $NH_2OH \cdot HNO_3$ lié au NH_2OH par des liaisons hydrogènes. Le NH_2OH commence à se décomposer à environ $-100°C$, les raies du $NH_2OH \cdot HNO_3$ croissent rapidement, et se transforme en $NH_3OH^+NO_3^-$.

Il n'y a pas de preuve de l'existence d'un intermédiaire du type NH_2OH dans le système NH_3-O_3, mais puisque le NH_2OH réagit facilement avec O_3 on ne peut pas écarter cette éventualité.

On peut représenter ces réactions d'ozonolyse de la façon suivante:

$$NH_3^+O_3^- + O_3 \xrightarrow{NH_3} NH_4NO_3 + H_2O + O_2$$

et

$$NH_2OH^+O_3^- \xrightarrow{NH_2OH} NH_3OH^+NO_3^- + H_2O$$

[Traduit par le journal]

Introduction

The NH_3-O_3 reaction has been studied for over 70 years. Early studies (1) showed that an intense reddish-orange color was produced when O_3 was bubbled into liquid ammonia cooled to $-78°C$. As the sample was warmed the color became fainter and disappeared by $-60°C$. If the ammonia was evaporated or if it was reacted with O_3 in the gas phase at room temperature, major products were NH_4NO_3, O_2, and H_2O, with the overall reaction being

[1] $2NH_3 + 4O_3 \rightarrow NH_4NO_3 + 4O_2 + H_2O$

Spectroscopic studies of the reddish-orange compound have been performed in several investigations. Solomon *et al.* (2) took an esr spectrum of the solid which showed a *g*-value of 2.0119 indicating an unpaired electron. They identified the compound as ammonium ozonide $NH_4^+O_3^-$. The ir spectrum was obtained by Herman and Giguère (3) who found two strong bands at 800 and 1140 cm^{-1} and two weak bands at 1260 and 2053 cm^{-1} which they assigned to ν_2, ν_3, ν_1, and $\nu_1 + \nu_2$ modes of O_3^-, respectively. The ir spectrum also showed the characteristic bands of NH_4^+ and NO_3^- ions.

Jacox and Milligan (4) examined the spectra of alkali metal ozonides at 14 K. In all cases a band at about 800 cm^{-1} was present. By isotopic studies, they showed that this band belonged to O_3^- and should be assigned as the ν_3 fundamental of

the ion. The other absorptions reported by Herman and Giguère (3) were not observed, thus showing that at least the 1140 cm^{-1} band was not due to the ozonide ion.

Spiker and Andrews (5) and Thomas and Andrews (6) also obtained the ir spectra of the alkali metal ozonides at 15 K. They found the intense band near 800 cm^{-1} assigned to ν_3 and also weak bands in the 500–600 cm^{-1} region which were assigned to ν_2. Raman studies performed by Andrews and Spiker (7) showed a band at about 1010 cm^{-1} which was assigned to ν_1, the symmetric stretch mode.

Several studies have been done on the uv–visible spectrum of the ozonide. The reddish-orange solid from the NH_3–O_3 reaction showed an absorption peak at 460 nm (2). Jacox and Milligan (4) showed that $Na^+O_3^-$ had an absorption between 510 and 370 nm with an average vibrational spacing of 819 cm^{-1} corresponding to the O_3^- ν_3 band. Giguère and Herman (8) found $K^+O_3^-$ to absorb between 300 and 600 nm with a peak at 457 nm. This absorption was confirmed by Andrews (9) and by Ault and Andrews (10).

The kinetics of the NH_3–O_3 reaction to produce NH_4NO_3 were studied in aqueous solution by Papko (11) and by Hoigné and Bader (12), and in the gas phase by Olszyna and Heicklen (13). In solution the reaction was found to be first order in each reactant at pH < 9, but for pH > 9 or in the gas phase the rate law was complex and indicated a free-radical chain oxidation. Because of the complexity of the reaction kinetics, it was decided to re-examine the low-temperature condensed-phase reaction between NH_3 and O_3 to see if reaction intermediates could be identified.

Experimental

Ammonia and ozone gases were introduced separately into a reaction cell at liquid nitrogen temperature and then warmed slowly. Infrared and uv–visible spectra were taken after the warmed samples were recooled.

The cells were evacuated for at least 12 h before cooling with liquid nitrogen in preparation for the condensation of reactants onto the cold window. Low-temperature cells, similar to those described by Miller (14), were used. The bodies of the cells were made of Pyrex glass and fitted with external CsBr or fused quartz windows. An inner window of AgCl, CsBr, CsI, KBr, or fused quartz was attached to the cold finger in different experiments.

The gases were handled in conventional vacuum lines with Teflon stopcocks fitted with Viton "O" rings and ground-glass stopcocks lubricated with Dow Corning Silicon High Vacuum Grease. After deposition of each gas, the cell was opened to vacuum. After evacuation the cell was removed from the vacuum line to examine its spectrum.

Both Perkin-Elmer Model 225 and 521 grating infrared spectrophotometers were used in this study. Spectra were scanned from 4000 to 250 cm^{-1}. A Cary Model 14 uv–visible spectrophotometer whose sample compartment was modified to accommodate the low-temperature cell was used to scan from 650 to 190 nm.

Ammonia (Matheson Co.) was liquefied in a vacuum line and then distilled at 50 Torr vapor pressure, with the central fraction being collected in one-liter storage bulbs. Deuterated ammonia (Merck, Sharp, and Dohme of Canada, Ltd.) was used directly.

Ozone was prepared immediately before each use by means of a Tesla coil discharge through purified oxygen at a reduced pressure and immersed in a liquid nitrogen bath. Any excess oxygen was removed by pumping with an oil diffusion pump on the liquid ozone maintained at −196°C. The oxygen (Philip Wolf and Sons) was purified by collecting it as a liquid in a trap cooled with liquid nitrogen. About half of this liquid was allowed to boil off slowly, after which samples were collected in one-liter gas storage bulbs. The last fraction was discarded.

Nitric acid was prepared by the distillation of an H_2SO_4–HNO_3 solution as described by Nightingale *et al.* (15). Also, nitric acid and deuterated nitric acid were prepared by the addition of H_2O or D_2O to N_2O_5. The pentoxide was made by the ozonolysis of NO_2, which was prepared by the reaction of oxygen with nitric oxide. Nitric oxide (Matheson Co.) was purified by fractional distillation.

Tertiary hydroxylammonium phosphate was prepared from hydroxylamine hydrochloride and tertiary sodium phosphate after the method described by Uhlenhuth (16). All condensable material produced during the thermal decomposition of the phosphate salt was collected in a tube cooled by liquid nitrogen. The pressure in the vacuum line was kept at about 200 mTorr or less during this time because Back and Betts (17) found the NH_2OH thermal decomposition to be enhanced by increasing NH_2OH pressure. After any noncondensable gas had been pumped away, the material in the tube was warmed slowly by replacing a Dewar flask around it. About half of this material was removed, by which time the pressure during pumping was steady. The sample was then recooled while any noncondensable gas was removed by evacuation. The NH_2OH again was warmed slowly and the amount needed for that day's experiment was deposited on the cold window while pumping through the low-temperature cell. Any remaining material was discarded. No impurities were ever detected in these samples by ir spectroscopy.

When a larger amount of NH_2OH (estimated to be enough for ten experiments) was produced at one time, purification problems were encountered. All the decomposition products except H_2O were removed by passing the sample through a trap maintained at −95°C. When kept in an ice–water bath the NH_2OH formed a white solid ring above the level of liquid H_2O in the bottom of the tube. Before each use this sample was evacuated for 1 to 10 min until a steady pressure of about 200 mTorr was obtained. The ice–water bath was then removed from the storage tube and NH_2OH was deposited on the cold window for 1 to 3 min. The first three samples obtained in this manner had no observable ir bands due to H_2O. The next six samples showed increasing amounts of H_2O as the amount of NH_2OH solid in the sample tube decreased.

NH_3–O_3 reaction

Various amounts of NH_3, ranging from 1.2×10^{-6} to 1.0×10^{-4} mol, and O_3, ranging from 9.3×10^{-6} to 5.7×10^{-5} mol, were condensed separately onto the cold window at −196°C and then warmed slowly to initiate the reaction. The first sign of reaction occurred at −170°C at the same time that the solid NH_3 was annealing on the cold window and ozone was already in the vapor phase. Even though the liquid O_3 had wetted the window earlier, no reaction was evident until this temperature. By comparison, proton transfer reaction from gaseous HCl to solid NH_3 was seen to occur only from −145°C when the hydrogen bonds of solid NH_3 evidently became weaker (18).

By observing and plotting the growth and decay of the bands first appearing at −170°C, it became evident that two species were always forming at the same time. One of these substances, which we identified as the charge-transfer complex $NH_3^+O_3^-$ was yellow to orange in color depending on the amount produced. The other compound was tentatively identified as $NH_2O^+HO_2^-$. The ir bands for both products along with their deuterated analogs can be found in Table 1. In order to enhance the spectral features, a sample was warmed to −130°C and then recooled to −190°C to give the spectrum shown in Fig. 1. Because of this warming a small amount of the product $NH_4NO_3 \cdot 3NH_3$ also was formed and gave rise to a weak peak due to NO_3^- at 830 cm^{-1} on the high frequency shoulder of the 800 cm^{-1} peak of the ozonide species. Other bands (18) of $NH_4NO_3 \cdot 3NH_3$ overlapped those listed in Table 1 and also those of solid NH_3 whose spectrum is the upper curve in Fig. 1.

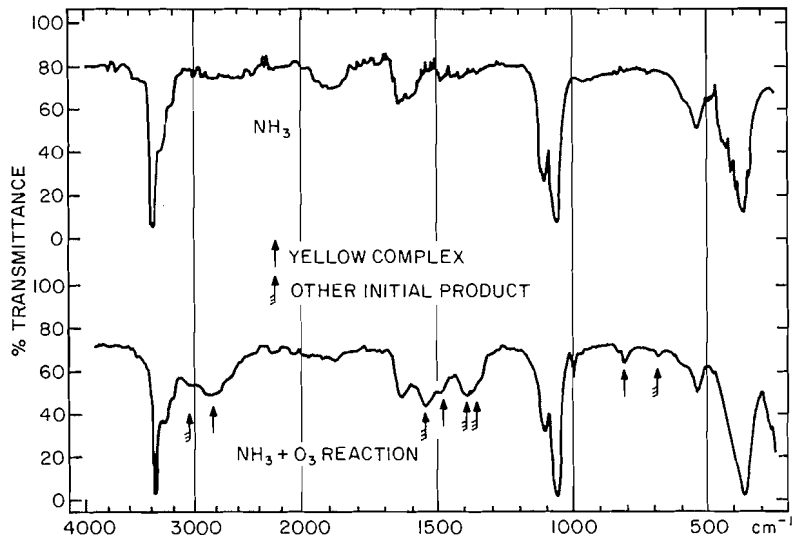

FIG. 1. Infrared spectra of NH_3 before reaction and of the two initial products in the NH_3-O_3 reaction. Spectra recorded at −190°C. The absorption at 1000 cm^{-1} is an artifact caused by changing gratings.

TABLE 1. Infrared frequencies (cm^{-1}) of the initial products of the NH_3-O_3 reaction

Infrared frequency			
$NH_3 + O_3$	$ND_3 + O_3$	ν_H/ν_D	Assignment
	$NH_3^+O_3^-$		
~2800 s	~2120 s	1.32	N—H stretch
~1490 w	~1125 w	1.32	N—H bend
800 s	795 s	1.01	ν_3 of O_3^-
	$NH_2O^+HO_2^-$		
3440 w			O—H stretch
~3020 s	~2350 s	1.29	N—H stretch
1550 s	1530 m	1.01	N—O stretch
	~1430 w		
~1400 m	~1080 w	1.30	N—H bend
~1370			O—H bend
~1120 w			OOH bend
~800 vw	~800 vw	~1.0	O—O stretch
675 w	605 w	1.12	N—O bend

We identified the colored complex to be $NH_3^+O_3^-$ rather than $NH_4^+O_3^-$ as reported by Solomon *et al.* (2) and by Herman and Giguère (3) for the following reasons. First, all bands in Table 1 assigned to this ozonide, including those associated with N—H vibrational modes, disappeared when the ozonide was photolyzed with a mercury lamp. Ammonium ion bands, when they were present in the spectrum, did not disappear during photolysis. Second, during the initial formation of the ozonide, no bands due to such ions as the nitrate or the nitrite were generated. The infrared bands of NO_3^- and NO_2^- are much more intense than those from NH_4^+, and they would have been detected were they formed in our system. Hence, there were no ready sources of proton to form the ammonium ion at −170°C.

The most distinguishing feature in the spectrum of $NH_3^+O_3^-$ is the band at 800 cm^{-1}. Upon deuteration this band shifted only slightly from 800 to 795 cm^{-1} indicating that a hydrogen atom was not directly involved with this vibrational mode. Bands at similar frequencies were observed by Spiker and Andrews (5) and by Thomas and Andrews (6) in alkali and alkaline earth metal ozonides, respectively. These authors had assigned this band to ν_3, the antisymmetric stretch fundamental, of the ozonide ion. Small shifts were seen by them due to the different metal cations used. A similar interpretation can be made for our 800 cm^{-1} band from the NH_3-O_3 reaction: the small shift observed upon deuteration was attributed to the cation effect. The small frequency shift upon deuteration is further evidence that the cation is NH_3^+ where bonding with the O_3 can occur through the nitrogen atom. If the cation had been the ammonium ion, the O_3^- anion would have had to bond to it through a hydrogen atom and a much larger isotopic shift should have been observed. For example, a shift of 15 cm^{-1} was observed in the ν_3 stretching fundamental of the nitrate ion when the cation is changed from NH_4^+ to ND_4^+. Our yellow–orange color is also consistent with the yellow to red colors reported previously for metal ozonides.

The deuterated studies showed that the 2800 and 1490 cm^{-1} bands were shifted by the amount expected for N—H stretching and bending vibrations, respectively. The low value of 2800 cm^{-1} suggests hydrogen bonding. For example, the ν_1 fundamental of the ammonium ion in $NH_4NO_3 \cdot 3NH_3$ is at 2800 cm^{-1} (18). Furthermore, the bending mode ν_4 of the NH_4^+ ion in this ammoniated species is also at 1490 cm^{-1}. The NH_3 molecule was still very likely hydrogen bonded to other NH_3 molecules in the solid matrix since it was seen in separate experiments (18) to be unreactive to HCl at these temperatures. Because the present reaction took place between gaseous ozone and solid ammonia, it is unlikely that the ammonium ion could have formed at these low temperatures.

Additional experiments were done following the uv–visible spectra of the reaction system. For these runs the O_3/NH_3 ratio was varied between 0.5 and 3.0. The sample sizes ranged from 4.4×10^{-6} to 4.3×10^{-5} mol for NH_3 and from 9.9×10^{-6} to 2.4×10^{-5} mol for O_3. For this study the low-temperature cell had outer SiO_2 windows and either a thin CsBr or SiO_2 inner window. The temperature of the SiO_2 window was more difficult to control, so the CsBr window was used for about half of the experiments. This CsBr window had good transmission from 650 to 250 nm but began absorbing strongly below this. The instrument cut-off was 190 nm and the SiO_2 windows still transmitted most of the radiation down to that wavelength.

Initially, NH_3 absorbed from the cut-off limit to about 250

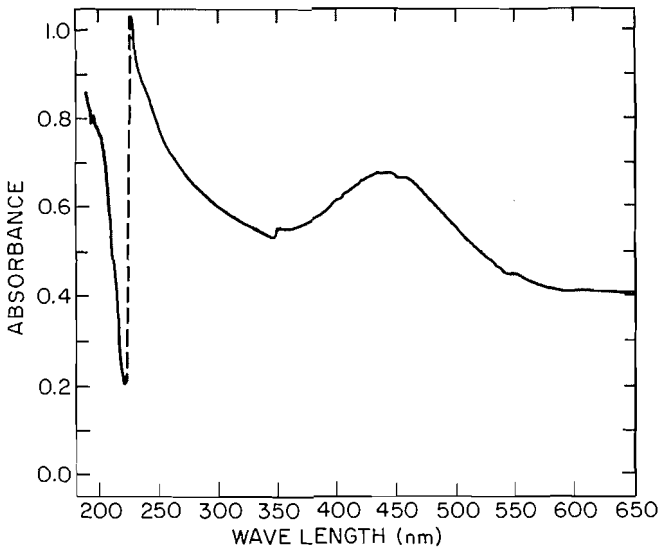

FIG. 2. Ultraviolet–visible spectrum of ammonia ozonide at −190°C.

nm for a typical sample used in these experiments. If more material was deposited on the window, it absorbed to a longer wavelength. No sign of absorption near 250 nm could be found when O_3 was introduced into the low-temperature cell. If the cell was allowed to warm slowly and the 250 nm wavelength was followed with time, O_3 was detected as it formed a liquid film on the window before vaporizing. Many attempts to keep the O_3 on the cold window either alone or on top of NH_3 failed. When both the NH_3 and O_3 were in the cell, and O_3 was allowed to form a liquid film on the window before recooling the cell, no change at all in the spectrum could be found from the initial spectrum. It was discovered that ozone had to be in the gas phase before any reaction occurred at about −170°C with the still solid NH_3.

The initial change in the spectrum came with the formation of the yellow complex. The visible absorption consisted of a broad band from 550 to 350 nm with the peak occurring at 438 nm as shown in Fig. 2. In the deuterated analog the band seemed to be shifted slightly with the peak at 435 nm. The 438 nm band had the same temperature dependence as that shown by $NH_3{}^+O_3{}^-$ in the ir scans. It started to form at −170°C, reached its maximum value at about −105°C, and decreased upon further warming. If the sample was warmed until −90°C when the sample had become clear and the 438 nm peak had disappeared, recooled to −196°C and then rewarmed to only −125°C, both the yellow color and the absorption peak returned, although not as strong as before warming to −90°C. The absorption seen here agrees with visible spectra recorded for ozonide species by many workers listed in the Introduction. The assignment of the yellow species as an ozonide is thus strengthened by this spectrum.

The initial reaction

[1] $NH_3 + O_3 \rightarrow NH_3{}^+O_3{}^-$

was never seen to be complete. The purple color of O_3 could be seen upon recooling the sample, sometimes surviving to room temperature, even when unreacted NH_3 was still present in the cell. This had also been seen in the gas cell when NH_3 and O_3 both remained for several hours. The O_3 was found to decrease slowly with no further consumption of NH_3. Thus the ammonia molecule in reaction [1] appears to require activation in addition to having its nitrogen atom exposed for attack by the ozone molecule.

Ammonia ozonide can be photolyzed. A medium-pressure mercury lamp which transmitted light in the 300–760 nm region (Pyrex envelope) was used for this purpose. Photolysis was done through either the Pyrex glass walls of the cell or through a quartz window. The complete photolysis of the material seemed to take less time when a quartz window was used but no other differences were noted. The yellow complex was bleached white by the exposure to the Hg lamp, regenerating O_3. Infrared and uv–visible scans after photolysis showed that all the bands of $NH_3{}^+O_3{}^-$ had disappeared and a weak band at 1230 cm^{-1} (1240 cm^{-1} in the deuterated case) had appeared. There was also some increase in absorptions where NH_4NO_3 had strong bands. The ratio of the decrease in the absorbance of the 800 cm^{-1} band to the increase of the 1230 cm^{-1} band ranged from 1.6 to 3.2. This would indicate that more than one reaction was involved in the photolysis. This 1230 cm^{-1} band remained until about −110°C, but there was no indication of its altering the rest of the reaction in any way. In most cases both the O_2 and any excess O_3 were evacuated from the cell before photolysis. This was to insure that any spectroscopic changes were not due to the photolysis of O_3 with subsequent reaction of its products. Since the lamp produced a large amount of heat, and the outer body of the cell became warm even when air was constantly circulated around the lamp, the noncondensable gas had to be removed in larger samples to insure a vacuum within the cell so as to keep the sample at −190°C. Several samples were photolyzed while keeping both the O_2 and O_3 in the cell. No spectroscopic differences were observed from those samples in which these two compounds had been removed. If excess O_3 and O_2 had been removed from the cell before photolysis, only a small amount of O_2 was found to have formed during irradiation but enough O_3 was generated to show its purple color when condensed on the cold finger. The yellow ozonide reformed upon warming, but not as much as before photolysis. If the O_3 released during photolysis was removed by evacuation before the sample was rewarmed, no ozonide reformed.

Apparently, the main photolytic reaction is

[2] $NH_3{}^+O_3{}^- + h\nu \rightarrow NH_3 + O_3$

but some of the time the product with the weak 1230 cm^{-1} band and very likely the final reaction product NH_4NO_3 must also be produced. The 1230 cm^{-1} band is in the N—O stretch region of the spectrum, and the small shift to 1240 cm^{-1} upon deuteration would indicate that H-atoms were not directly involved in this band. The small amount of O_2 produced during photolysis could come from the same reaction producing this ir band. One attractive assignment of this band is to the species NH_3O formed by reaction [3].

[3] $NH_3{}^+O_3{}^+ + h\nu \rightarrow NH_3O + O_2$

Theoretical studies on ammonia oxide (NH_3O) have been carried out by Hart (19) who deduced that it has a bound ground state with an unusually long N—O bond. This oxide was found to be less stable by 30 kcal/mol than its tautomeric form of hydroxylamine (NH_2OH) and correlated with the dissociation products $NH_3(^1A_1) + O(^1D)$ in a well of depth 35 kcal/mol. This makes NH_3O unstable to dissociation to the spin forbidden products $NH_3(^1A_1) + O(^3P)$. Presumably the latter spin-forbiddenness and hydrogen-bonding in the NH_3 matrix at low temperatures may contribute to the stability of NH_3O if it is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

produced by reaction [3]. Since the presence of the 1230 cm^{-1} band did not affect the course of the overall reaction, NH_3O can generate the observed products by reaction [4].

$$[4]\quad NH_3O + O_3 \xrightarrow{NH_3} NH_4NO_3 + H_2O$$

The assignment of the infrared bands of the second product listed in Table 1 to NH_3O can be ruled out. According to Hart's calculation (19), the reaction

$$[5]\quad NH_3 + O_3 \rightarrow NH_3O + O_2$$

in the gas phase is endothermic by 35 kcal/mol. It is, therefore, unlikely that reaction [5] can be initiated thermally by warming the reactants from liquid nitrogen temperature to −170°C, which was the experimental condition when the second product was generated. Furthermore, the N—O bond in NH_3O is reported to be a weak single bond (19), whereas the value of 1550 cm^{-1} for the stretching frequency of the second product suggests a double bond.

In order to establish the identity of the second product, a closer examination of the experimental results is required. It formed at −170°C with essentially no evolution of oxygen and continued to grow at the same rate as the ozonide until about −110°C, after which it remained constant. The spectroscopic data show that this colorless solid possesses an N—H bond, an N—O double bond, and possibly an O—O bond. It remained stable until about −10°C when it decomposed with the evolution of oxygen. These results suggest that the atomic compositions of the ozonide and this second product may be similar, and that both may be ion pairs.

In spite of these similarities in behavior, the electronic structures of the ozonide and this second product are very different. The ozonide is photolyzed readily but the second product is not when they are exposed to the 300–760 nm radiation from a mercury lamp at liquid nitrogen temperature. Thus, the second product may be a tautomer of the ozonide, and we tentatively suggest it to be $NH_2O^+HO_2^-$. Fox and co-workers (20) have shown that the very toxic and reactive gas NF_3O, which is distinct from NF_2OF, combines readily with acceptors of fluoride ion, such as BF_3, SbF_5, and AsF_5, to form relatively stable 1:1 adducts. For example, $NF_2O^+SbF_6^-$ is reported to be stable even at 100°C but reacts violently with water at room temperature. The association of the hydroperoxide anion HO_2^- with the ozonide ion is based on the studies of Landi and Heidt (21). These authors observed the formation of O_3^- during flash photolysis of basic aqueous hydrogen peroxide and showed that the kinetics of the system involved both O_3^- and HO_2^- ions. An ir spectrum of solid $NH_4^+HO_2^-$ was obtained by Knop and Giguère (22). This sample was prepared by depositing a layer of NH_3 on top of a layer of H_2O_2 on an ir window at −190°C. Upon warming to −80°C $NH_4^+HO_2^-$ formed. Other than the NH_4^+ ion absorptions a broad band at 1100 cm^{-1} and a weaker but sharper band at 836 cm^{-1} were seen. These were assigned as the bending and O—O stretching vibrations, respectively, of the HO_2^- ion. The bands seen at 1120 and 800 cm^{-1} in the second product are assigned in like manner. No NH_4^+ bands were present in the spectrum of our product. $NH_4^+HO_2^-$ had been found by Maass and Hatcher (23) to have a melting point of 24.5°C and to be stable in the absence of H_2O. Although our second product was normally stable until −10°C, when H_2O was added to the NH_3–O_3 system it decomposed at −85°C as the H_2O left the cold window.

The $NH_4NO_3 \cdot 3NH_3$ was seen to start forming at −130°C as the NH_3 matrix bands began to decrease. Copious amounts of O_2 were released simultaneously. The spectrum of $NH_4NO_3 \cdot 3NH_3$ was identical to that produced when HNO_3 was reacted with excess NH_3, a reaction which also started at about −130°C (18). The $NH_4NO_3 \cdot 3NH_3$ started to deammonate at about −105°C to form NH_4NO_3 simultaneously with the disappearance of the remaining $NH_3^+NO_3^-$. When the final reaction mixtures were recondensed back onto the low-temperature window, their spectra showed the presence of water.

A possible reaction sequence for this system may be as follows:

$$[1]\quad NH_3 + O_3 \rightarrow NH_3^+O_3^-$$

$$[6]\quad NH_3^+O_3^- + O_3 \xrightarrow{NH_3} NH_4NO_3 + H_2O + O_2$$

$$[7]\quad NH_3 + O_3 \rightarrow NH_2O^+HO_2^-$$

$$[8]\quad 2NH_2O^+HO_2^- \rightarrow 3O_2 + 2NH_3$$

Reactions [1] and [6] show an O_3-to-NH_3 consumption ratio of 1.0. Reactions [7] and [8] are essentially a catalytic decomposition of O_3. In a number of experiments we measured, although with great difficulty and experimental uncertainty, the O_3-to-NH_3 consumption ratio and found it to vary between 1.1 and 2.3, consistent with the ratio of 2.0 found by Strecker and Thieneman (1*c*). From the reaction sequence, it can be seen that this ratio would vary depending on the amount of $NH_2O^+HO_2^-$ that formed in each separate experiment.

NH_2OH–O_3 reaction

A possible mechanism for the ozonolysis of NH_3 could include NH_2OH as an intermediate. Therefore we thought it would be useful to examine the ozonolysis of NH_2OH. The reaction of NH_2OH with O_3 in the low-temperature cell can be divided into two groups. The reaction pattern of each sample depended upon whether the NH_2OH had been annealed before the O_3 was added to the cell. Annealed and unannealed solid NH_2OH had readily distinguishable spectra (18). The results of the annealed samples will be discussed first.

The reaction of annealed NH_2OH solid with gaseous O_3 was not seen until about −65°C when NH_2OH started to sublime off the low-temperature window. At about −50°C, a hydrogen-bonded complex $NH_2OH \cdot HNO_3$ was seen with the subsequent appearance of crystalline $NH_3OH^+NO_3^-$ at −10°C. The latter solid remained unchanged while kept under vacuum at room temperature overnight but subsequently it slowly changed to NH_4NO_3 with evolution of non-condensable gas presumably according to reaction [9].

$$[9]\quad 2NH_3OH^+NO_3^- \rightarrow 2NH_4NO_3 + O_2$$

In many runs it was evident that much of the reaction took place after NH_2OH had sublimed off the window. In these cases $CsNO_3$ was observed on the inner and outer windows of the cell. Similar results were obtained when HNO_3 was reacted with NH_2OH in the low-temperature cell (18).

Quite a different reaction pattern was observed when O_3 was introduced into the low-temperature cell containing unannealed NH_2OH. The samples were seen to turn from white to yellow as soon as the O_3 being introduced into the cell struck the surface of the NH_2OH on the cold window. The ir spectrum also showed changes after the introduction of O_3: a band at 1035 cm^{-1} and $NH_2OH \cdot HNO_3$ were both observed.

The yellow color was present from −190°C to about −115°C. It sometimes grew deeper in color during the warm-

ing cycles, but it did not approach the intensity of the yellow color seen in the NH_3-O_3 reaction from $-170°C$ to its decrease at $-105°C$. Photolysis of the sample while kept at $-190°C$ with a medium-pressure mercury lamp caused the material to turn white, but no change in the ir spectrum could be detected. The mercury lamp used here transmitted from 300 to 760 nm. The sample again turned yellow when it was warmed to about $-120°C$, but no change in the ir spectrum could be attributed to this yellow color. In the NH_3-O_3 system the ir bands at 800 and 2800 cm^{-1} belonging to the yellow species were detectable before the yellow color was visible. Thus in the NH_2OH-O_3 system not only was less charge-transfer complex formed but its ir bands appear to be much weaker. During all this time the major portion of the O_3 could be seen on the colder Cu frame and cold finger. This was especially noticeable when the samples were first recooled and the purple color of the ozone could be seen very distinctly on the cold finger.

The 1035 cm^{-1} band which was present at $-190°C$ disappeared, or at least significantly decreased, upon the first warming. The only other change at this temperature was a small increase in $NH_2OH \cdot HNO_3$. The 1035 cm^{-1} band was unchanged by photolysis. Once this band disappeared it was never seen to reform upon recooling and rewarming. There was always a large portion of the O_3 still present in the cell at this time because its purple color could be seen upon recooling. It could also be seen to wet the window upon warming. The NH_2OH did not anneal at these low temperatures. In the samples with the largest absorption of the 1035 cm^{-1} band, this band was completely gone by $-105°C$. The intensity of the 1035 cm^{-1} band increased with the amount of material used, but there was no definite dependence upon the amount of either reactant.

$NH_2OH \cdot HNO_3$, which was also seen in the ir spectra immediately after O_3 introduction into the cell, exhibited slow growth during warming until NH_2OH started to anneal around $-100°C$. At this temperature $NH_2OH \cdot HNO_3$ grew rapidly and converted to amorphous $NH_3OH^+NO_3^-$ as all the unreacted NH_2OH annealed. The intensity of the ir bands of amorphous $NH_3OH^+NO_3^-$ continued to increase up to room temperature. After the sublimation of NH_2OH and H_2O (another reaction product), this was the only change seen in the spectrum for some runs. In other cases NH_4NO_3 formed at room temperature as the NH_3OH^+ ion converted to NH_4^+ ion.

Only in two runs did crystalline $NH_3OH^+NO_3^-$ form at $-15°C$. No amorphous $NH_3OH^+NO_3^-$ was seen in these runs,. and the crystalline $NH_3OH^+NO_3^-$ formed as the $NH_2OH \cdot HNO_3$ disappeared.

Experiments were also performed following the $NH_2OH + O_3$ reaction by uv–visible spectroscopy. Solid NH_2OH itself absorbed from 220 nm to the instrumental cut-off at 190 nm. An increase in absorption due to sample scattering occurred at $-90°C$ as the hydroxylamine annealed and turned milky white. Sublimation from both CsBr and SiO_2 windows was noted at $-40°C$. Only NH_3 gas was observed in the low-temperature cell when a uv–visible spectrum was recorded at room temperature.

In only one experiment was a weak absorption observed at 255 nm when liquid O_3 was alone in the low-temperature cell. The CsBr window had been cooled with liquid nitrogen for a long time before O_3 was introduced into the cell and was evidently cold enough for some liquid O_3 to remain on it. Most of the ozone could be seen to have condensed on the Cu frame and cold finger.

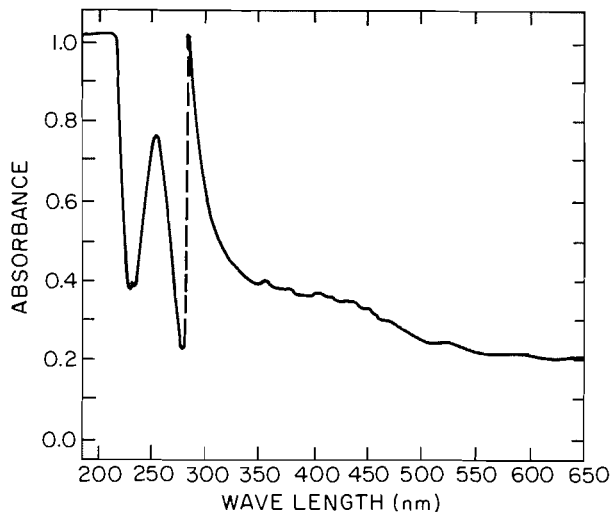

FIG. 3. Initial uv–visible spectrum of $NH_2OH + O_3$ at $-190°C$.

As soon as O_3 was introduced into the low-temperature cell already containing condensed NH_2OH, two new peaks appeared in the spectrum. They can be seen in Fig. 3. One was in the visible region exhibiting a broad peak at 440 nm and corresponded to the yellow color of the sample. The 440 nm peak was present in 3 out of 5 runs using the distilled NH_2OH and in 2 out of 4 runs using the partially decomposed samples. Since none of these samples had been annealed before O_3 was added, the yellow color was expected to be present in every sample as was seen in the ir studies. It was then noted that the yellow color and the 440 nm peak were never observed in those samples in which a uv–visible spectrum of the NH_2OH alone was recorded before the O_3 was added. When the O_3 was added to the NH_2OH in the low-temperature cell before a uv–visible spectrum was taken, the yellow color appeared as expected. These phenomena were observed when both the SiO_2 and CsBr window were used. The cell was always placed in the instrument so that the sample was on the side of the cold window towards the light source. However, the yellow color was seen when O_3 was added to NH_2OH after its ir spectrum had been recorded. Thus, only the shorter wavelength ultraviolet radiation appears to destroy the trapping sites for the yellow complex.

The intensity of the 440 nm absorption remained unchanged until about $-130°C$ when it started to decrease. This band disappeared upon photolysis with a medium-pressure mercury lamp and reappeared upon rewarming, as did the yellow color. No ir band had exhibited this same behavior, so the species corresponding to this 440 nm band must have absorbed only very weakly and below our detection limit in the ir region. This visible band behaved essentially the same as the 438 nm band seen in the NH_3-O_3 reaction. In that reaction the absorption was much stronger and was present from -170 to $-105°C$ where it started to decrease in intensity. Due to the great similarity in absorption and behavior, we believe that an ozonide also formed with NH_2OH and absorbed at 440 nm.

The other initial peak had its maximum absorption at about 255 nm. In the only case already mentioned when O_3 itself produced an absorption at 255 nm, the intensity of the absorption increased by a factor of 15 when NH_2OH was condensed on the CsBr window on top of this O_3. The absorption again increased slightly when more O_3 was introduced into the cell. In all of these experiments the major portion of the O_3 was seen

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

to condense on the Cu frame. When O_3 was introduced into the low-temperature cell in several portions instead of all at one time, the 255 nm band was seen to increase a small amount with each addition. The major part of the absorption was produced by the first addition of O_3. At the same time no change was seen in the 440 nm band. The absorbance of the 255 nm band increased with the amount of O_3 used for each experiment, but a graph of these results produced a random scattering of data points. This peak started to decrease as soon as the sample was warmed. In the run containing the strongest 255 nm absorbance the peak was completely gone by −130°C. When the samples were photolyzed with the Hg lamp, the intensity of the 255 nm band either remained unchanged or decreased. The decrease could have been caused by the heating effect of the lamp. One sample displayed different results: the 255 nm peak had already disappeared before photolysis but reappeared even stronger than initially as the 440 nm peak disappeared upon photolysis.

This 255 nm band agreed with the temperature dependence and photolysis results of the 1035 cm^{-1} band seen in the ir work. As with the 1035 cm^{-1} band, once it disappeared upon warming it could not be made to reappear by recooling and rewarming to a temperature at which it had previously been present. The similarity of the 255 nm uv band to that of ozone and the close approximation of the 1035 cm^{-1} ir band seen here with the strong ν_3 band of O_3 indicate that these absorptions are due to ozone adsorbed on active surface sites of solid NH_2OH.

Other than the change in absorption from the annealing of NH_2OH, no other change was seen in the spectra until the NH_2OH started to sublime off the window. Only then was it possible to observe a white solid on the window with a continuously increasing absorption from 450 nm to the instrument cut-off at 190 nm. In thicker samples the absorption due to this solid extended even farther into the visible region. This solid remained on the window even at room temperature. In all samples using the SiO_2 window, a small peak at 200 nm was also seen at room temperature and remained upon recooling of the sample. It was already seen at −60°C in one case but only after warming to room temperature in the other three cases. Since the CsBr window itself completely absorbed the radiation at this wavelength, it was impossible to tell if the 200 nm peak was ever present in about half of the experiments performed. Since the 200 nm absorption was seen using both distilled and partially decomposed NH_2OH, its presence was not determined by the initial state of this reactant. The presence or absence of the 440 nm band did not affect its formation. This peak was never seen in the NH_4NO_3 formed from the reaction of NH_3 with O_3. Since the only other solid ever seen in the ir spectra at room temperature was $NH_3OH^+NO_3^-$, this would be the most likely compound absorbing at 200 nm.

We were unable to observe in the NH_2OH-O_3 system any reaction intermediates common to those observed in the NH_3-O_3 system. The NH_2OH-O_3 system was more reactive since $NH_2OH \cdot HNO_3$ was seen even at −190°C. Thus, the possibility that NH_2OH may be an intermediate in the NH_3-O_3 system cannot be ruled out. In the NH_2OH-O_3 system, reaction sequences similar to those with NH_3 occur, i.e.

$$[9] \quad NH_2OH + O_3 \rightarrow NH_2OH^+O_3^-$$

$$[10] \quad NH_2OH^+O_3^- \xrightarrow{NH_2OH} NH_3OH^+NO_3^- + H_2O$$

The charge-transfer complex $NH_2OH^+O_3^-$ is decomposed into reactants either by photolysis or thermally. Active surface sites, where the charge-transfer complexes are formed, are destroyed by ultraviolet radiation. In order to account for O_2 and N_2O evolution, both of which were seen, we propose the additional reaction

$$2NH_2OH^+O_3^- \rightarrow N_2O + 3H_2O + 2O_2$$

THERESA HUSTON, I. C. HISATSUNE, and JULIAN HEICKLEN. Can. J. Chem. **61**, 2077 (1983).

Low-temperature infrared spectroscopy has been used to examine the systems $NH_3 + H_2O$, $NH_3 + HCl$, $H_2O + HCl$, $NH_3 + HNO_3$, and $NH_2OH + HNO_3$. Hydrogen-bonding in the solid states greatly reduces the reactivities in these systems. Temperatures where reactions initiated in the systems $NH_3(s) + HCl(g)$, $HNO_3(s) + NH_3(g)$, $H_2O(s) + HCl(g)$, and $NH_2OH(s) + HNO_3(s)$ were, respectively, −145, −130, −127, and −125°C. Infrared spectra of $2NH_3 \cdot H_2O$, $NH_3 \cdot H_2O$, $NH_4Cl \cdot 3NH_3$, $NH_4NO_3 \cdot 3NH_3$, $NH_4NO_3 \cdot 2HNO_3$, $NH_2OH_2^+NO_3^-$, $NH_3OH^+NO_3^-$, $H_3O^+Cl^-$, $H_5O_2^+Cl^-$, and $H_5O_2^+Cl^- \cdot H_2O$ have been identified in these reaction systems.

THERESA HUSTON, I. C. HISATSUNE et JULIAN HEICKLEN. Can. J. Chem. **61**, 2077 (1983).

On a fait appel à la spectroscopie infrarouge à basse température pour étudier les systèmes suivants: $NH_3 + H_2O$, $NH_3 + HCl$, $H_2O + HCl$, $NH_3 + HNO_3$ et $NH_2OH + HNO_3$. La présence de liaisons hydrogènes dans l'état solide réduit de beaucoup la réactivité de ces systèmes. On a initié les systèmes: $NH_3(s) + HCl(g)$, $HNO_3(s) + NH_3(g)$, $H_2O(s) + HCl(g)$ et $NH_2OH(s) + HNO_3(s)$ à des températures respectives de: −145, −130, −127 et −125°C. Dans ces systèmes on a identifié les spectres infrarouges des composés suivants: $2NH_3 \cdot H_2O$, $NH_3 \cdot H_2O$, $NH_4Cl \cdot 3NH_3$, $NH_4NO_3 \cdot 3NH_3$, $NH_4NO_3 \cdot 2HNO_3$, $NH_2OH_2^+NO_3^-$, $NH_3OH^+NO_3^-$, $H_3O^+Cl^-$, $H_5O_2^+Cl^-$ et $H_5O_2^+Cl^- \cdot H_2O$.

[Traduit par le journal]

Introduction

In the infrared spectroscopic studies (1) of low-temperature ozonolysis of NH_3 and NH_2OH, numerous absorption bands other than those from the expected products NH_4NO_3 and H_2O were observed. These bands showed complex temperature dependences, suggesting formation and breaking of hydrogen-bonds and changes in molecular structures at different temperatures. In order to identify the origins of these absorption bands, we have found it necessary to examine the infrared spectra of various mixtures of NH_3, NH_2OH, H_2O, HCl, and HNO_3 at liquid nitrogen temperature and to follow their changes with temperature. The experimental results from these studies are presented here.

Experimental

Spectroscopic equipment used in this work has been described already in the companion report (1). Various combinations of NH_3, NH_2OH, H_2O, HCl, and HNO_3 were deposited on a liquid-nitrogen cooled window (AgCl, CsBr, or CsI) of a low-temperature cell either as mixtures or as separate layers. These samples were warmed to various temperatures and then recooled to examine their spectra. Window temperatures were determined by a copper–constantan thermocouple attached to the metal window bracket (2).

Preparations of most of the chemicals used here have been described before (1). The reagents H_2O (triply distilled) and D_2O (Volk Radiochemical Co., 99.8%) were degassed and distilled in the vacuum line before use. Hydrogen chloride (Matheson Co.) was also subjected to a low-temperature fractional distillation. Gas pressures were measured on either a mercury manometer or a manometer containing Ke1-F3 polymer oil (3M Co.) with a density of 1.93 g/cm^3 at 23°C.

Results and discussion

NH_3–H_2O system

The infrared spectrum of NH_3 at liquid nitrogen temperature has been reported by Reding and Hornig (3). Our results at −190°C were in agreement with this earlier study. Prominent bands of NH_3 and of ND_3 in parentheses were at ν_3 = 3380 s (2508 s), ν_1 = 3290 m (2390 vw), ν_4 = 1650 m (1198 m), and ν_2 = 1060 vs (816 vs) in cm^{-1} units. Solid NH_3 also has a moderately intense lattice mode band at 360 cm^{-1}. Typical samples of NH_3 were already crystalline when they were deposited on the cooled window, but in thicker samples some amorphous forms were trapped. Annealing of the latter to −165°C caused the relative intensities of ν_3, ν_2, and the lattice band to increase while the other bands in the spectrum became weaker. Sublimation of the samples started at about −160°C.

Our spectrum of water at −190°C also agreed with the earlier results of Hornig *et al.* (4). Although the bands were all broad, annealing effects were evident when samples were warmed to about −90°C and recooled. The initial spectrum with bands at ν_1 = 3400 w (2530 w), ν_3 = 3220 vs (2430 s), ν_2 = 1620 w (1210 vw), and ν_L = 780 s (580 w) shifted on annealing to ν_1 = 3350 w (2550 w), ν_3 = 3200 s (2400 s), ν_2 = 1570 w (1210 vw), and ν_L = 810 s (610 w) where the frequencies are in cm^{-1} units and those of the deuterated species are given in parentheses. At about −85°C water began to sublime off the cooled window.

Two ammoniates of water, $NH_3 \cdot H_2O$ and $2NH_3 \cdot H_2O$, are known, and their thermodynamic properties have been measured by Hildenbrand and Giauque (5). The crystal structures of $NH_3 \cdot H_2O$ and $2NH_3 \cdot H_2O$ have been determined, respectively, by Olovsson and Templeton (6) and by Siemons and Templeton (7). When our experiments were done (late 1970s), the only infrared study of these complexes appeared to be one of a preliminary nature reported by Waldron and Hornig (8*a*). Because of severe overlapping of the spectra of these ammoniates, Waldron and Hornig were able to assign clearly only a single band at 1120 cm^{-1} for $NH_3 \cdot H_2O$ and three bands at 3140, 1091, and 1020 cm^{-1} for $2NH_3 \cdot H_2O$. Peaks at 3365, 3220, 2950, and 1625 cm^{-1} were assigned commonly to both complexes. Since our work has been completed there have been numerous studies of the infrared spectra of the ammonia hydrates (8*b*–*f*).

In the present investigation, the identity of the complex $2NH_3 \cdot H_2O$ was readily established. When gaseous mixtures of NH_3 and H_2O with mole ratio NH_3/H_2O ranging from 2.0 to 36.5 were condensed on the low-temperature window, the

same product whose spectrum is shown in Fig. 1 (upper curve) was obtained. In these experiments each gaseous mixture was allowed to stand at least for 12 h at room temperature to insure complete mixing of the components, and the total pressure of H_2O in the mixture was kept below about one-half the equilibrium vapor pressure of H_2O. Higher H_2O pressures caused condensation in the gas storage bulb. At lower ratios of NH_3/H_2O, some ice formation was also observed, but the initial product of these excess NH_3 samples was amorphous $2NH_3 \cdot H_2O$ which appeared as a glassy solid. Warming of these samples to about $-150°C$ caused the samples to become crystalline white which upon recooling to $-190°C$ produced the spectrum shown in Fig. 1 (lower curve). During recooling excess NH_3 had sublimed off the cooled window. Peak frequencies in the spectra of amorphous and crystalline $2NH_3 \cdot H_2O$ are listed in Table 1.

When a white crystalline sample of $2NH_3 \cdot H_2O$ from excess NH_3 matrices was warmed to $-130°C$ and then recooled to $-190°C$, it changed into a clear crystalline solid having the spectrum shown in Fig. 2 (lower curve). This clear crystal melted at about $-100°C$ and upon recooling to $-190°C$ changed into a glassy solid whose spectrum is the upper curve in Fig. 2. At about $-85°C$, the samples sublimed off the cooled window. When the cell contents in these experiments were recondensed on the low-temperature window, the entire sequence of spectroscopic changes could be reproduced by warming to various temperatures and then recooling to liquid nitrogen temperature.

The spectra shown in Fig. 2 and peak frequencies given in Table 2 are attributed to the complex $NH_3 \cdot H_2O$. When a gaseous mixture with a composition of $NH_3/H_2O = 1.0$ was deposited on the liquid nitrogen cooled window, the initial spectrum was identical to the upper curve of Fig. 2. Warming of this sample to $-125°C$ and then recooling caused the spectrum to change to the lower curve in this figure.

Experiments were also performed in which NH_3 was deposited on top of a previously deposited layer of H_2O, or *vice versa*. The initial spectra were indistinguishable from those of NH_3 or H_2O alone at $-190°C$. First changes in the spectra of these layered samples occurred at about $-125°C$ when the ammonia bands began to get weaker. By $-115°C$, the strongest bands of crystalline $NH_3 \cdot H_2O$ and $2NH_3 \cdot H_2O$ became visible. Further warming to higher temperatures caused the formation of ice without a significant increase in the yield of either com-

plex. Thus, the data summarized in Tables 1 and 2 were obtained from gaseous reactant mixtures. The deuterium work was done with a mixture having the composition ND_3/D_2O = 22.0.

Bertie and Morrison (8*b*, *d*) obtained the ir spectra of these two ammonia hydrates as mulls in various substances at −178°C. Using an FTIR spectrometer they were able to obtain better resolution of the broad peaks than we were with our instrumentation. This is most evident in the N—H stretching region of the spectra. Their reported absorption frequencies and assignments for the major peaks agree with our results within the error limits for these broad absorption bands. With the $2NH_3 \cdot H_2O$ species, their reported values of 1092 and 1083 cm^{-1} for δ(NH) are much closer to the value of 1090 cm^{-1} that we found for the amorphous solid than to the 1085 and 1055 cm^{-1} values found after crystallization (Table 1). The spectrum of $NH_3 \cdot H_2O$ reported by Sill *et al.* (8*c*) is very similar to that of Bertie and Morrison (8*b*) with the exception of a stronger absorption at 1542 cm^{-1}. We found only a very weak absorption at 1540 cm^{-1}.

Solid NH_3 by itself did not react with the AgCl window, but as $2NH_3 \cdot H_2O$ or $NH_3 \cdot H_2O$ it combined with AgCl to form $Ag(NH_3)_2Cl$. Infrared bands of the $Ag(NH_3)_2^+$ ion appeared as the NH_3 hydrates upon warming to about −70°C and then disappeared at about −45°C, leaving behind a coarse white layer of crystalline AgCl. The spectrum of $Ag(NH_3)_2Cl$ is shown in Fig. 3 and band assignments based on a previous work on $Ag(NH_3)_2NO_3$ by Geddes and Bottger (9) are summarized in Table 3.

NH_3–HCl system

Pure HCl could be kept on the cooled window of our cell only by pumping on the liquid nitrogen refrigerant. At −198°C the spectrum of solid HCl showed two peaks at 2700 and 2745 cm^{-1} in agreement with the report by Hornig and Osberg (10). When HCl was introduced into the low-temperature cell with a previously deposited film of solid NH_3 at −190°C, it immediately sublimed to the coldest metal parts of the refrigerant compartment. No reaction was observed until the cell was warmed to −145°C when absorption bands of NH_4Cl started to appear. In contrast to this behavior, NH_3 and HCl isolated in a N_2 matrix at 15 K first forms the hydrogen-bonded complex

[b]This study.

$NH_3 \cdot HCl$ which on warming to 40 K produces NH_4Cl (11). Thus, the hydrogen-bonded NH_3 matrix is substantially less reactive toward HCl. In fact, the reaction in the latter case was relatively slow until at about −115°C when NH_3 itself started to sublime off the window. By about −90°C, however, the reaction was complete and no further increase in the product spectrum was observed. The infrared spectrum of the product NH_4Cl at −190°C and at 25°C agreed with that reported by Schumaker and Garland (12).

Just as NH_3 started to leave the cooled window at −115°C, new bands appeared in the spectrum of the reaction system near 1450 and 1140 cm^{-1}. These bands are assigned to $NH_4Cl \cdot 3NH_3$ whose crystal structure and phase properties have been reported, respectively, by Olovsson (13) and by Billy and Jarrige (14). The yield of this ammoniate was generally low and its spectrum is compared to that of NH_4Cl in Fig. 4. Peak frequencies in this spectrum are summarized in Table 4. They compare reasonably well with those reported by Corset *et al.* (15) who dissolved NH_4Cl in liquid NH_3 and then cooled the solution to −130°C. The complex $NH_4Cl \cdot 3NH_3$ deamminated at about −95°C. Interestingly, when NH_3 was deposited on top of a film of solid NH_4Cl and then warmed to −100°C, no bands due to this ammoniate were observed. The presence of water also complicated the spectra of the reaction mixtures through formation of hydrates of NH_3 and HCl. Temperatures where NH_4Cl first formed and where reaction was complete were also increased somewhat when water was in the system. For example, when NH_3 was reacted with a mixture having a mole ratio HCl/H_2O = 1.0, NH_4Cl appeared at −117°C and the reaction was complete at −75°C. With dry HCl the respective temperatures were −145°C and −90°C.

H_2O–HCl system

Infrared spectra of hydrates of HCl were studied by examining the temperature dependencies of matrices formed from reactant mixtures with the mole ratio HCl/H_2O ranging from 0.13 to 7.3. Partial pressures of H_2O were kept below the equilibrium vapor pressure in order to prevent condensation of the reactant mixtures before use. Only an AgCl cooled window was used in this series of experiments.

When HCl/H_2O mole ratios were 1.0 or greater, identical initial spectra were displayed by the samples. A spectrum is illustrated in Fig. 5 (upper curve) and peak frequencies are listed in Table 5. This spectrum is assigned to the monohydrate of HCl and its agreement with earlier results of Ferriso and Hornig (16) and of Gilbert and Sheppard (17) is reasonable in

view of the very broad bands. Warming of the samples to −125°C caused an abrupt change in the spectra characterized by sharpening and increases in absorbances as illustrated by the lower curve in Fig. 5. Since this type of change often occurs when amorphous solids transform into crystalline phases, we make a similar interpretation and assign the upper and lower curves of Fig. 5 to amorphous and crystalline monohydrate of HCl, respectively. Peak frequencies of our crystalline sample agreed with those reported by Desbat and Huong (18) and also by Gilbert and Sheppard (17) who, however, attributed this spectrum to the dihydrate of HCl. The latter investigators found their complex to be formed at −103°C and to remain on the cooled window until −83°C. The best yield of the crystalline monohydrate of HCl in the present study was when the reactant mixture mole ratio HCl/H_2O was 5.0 or greater. The crystal structure of the monohydrate has been reported by Yoon and Carpenter (19) to be $H_3O^+Cl^-$ with H_3O^+ having a C_{3v} symmetry with an H—O—H angle of 117°.

Additional changes in the spectrum occurred when a sample of crystalline $H_3O^+Cl^-$ was warmed to −95°C. The bands became very broad once again as illustrated in Fig. 6 (upper curve). Peak frequencies are summarized in the first column of Table 6. A better yield of this spectrum was obtained when the mole ratio HCl/H_2O was 1.0. Continued warming of the sample caused the matrix to sublime off the cooled window at −80°C. The entire change described above could be repeated many times by recondensing the recovered reactant mixture and subjecting these matrices to warming and recooling cycles.

When the HCl/H_2O mole ratios were less than 1.0, these samples had clear glassy appearances and showed initial spectra resembling the upper curve of Fig. 6 more than they did of amorphous $H_3O^+Cl^-$ (Fig. 5). In fact, essentially the same spectrum as that of Fig. 6 was obtained when samples with mole ratio HCl/H_2O near 0.5 were warmed to −130°C. Thus, the origin of this spectrum is attributed to the dihydrate of HCl. When HCl/H_2O was less than 0.5, less dihydrate was formed and the spectra were overlapped with that of amorphous ice which has a characteristic strong band at 780 cm^{-1}. Continued warming of samples with $HCl/H_2O < 1$ to −120°C caused the matrices to become crystalline white and their spectra to change to that illustrated by the lower curve in Fig. 6. We assigned this spectrum to that of crystalline dihydrate of HCl whose ir and Raman spectra have been reported by Rozière and Potier (20). Peak frequencies in the spectrum of this dihydrate are given in Table 6. Also listed here are two sets of data from the work of Gilbert and Sheppard (17). These authors assigned one set to the trihydrate because it was formed from the "dihydrate" in the

temperature range of −83 to −53°C and the second set to the tetrahydrate since it was produced from the "trihydrate" by warming from −53 to −38°C. Our crystalline dihydrate sublimed off the cooled window at −70°C.

In one experiment H_2O was condensed first to give amorphous ice and then HCl was introduced into the low-temperature cell. No reaction was observed until −127°C when a large amount of amorphous dihydrate formed. It began to decay at −80°C but only a small amount of crystalline dihydrate was detected in the temperature range of −88 to −65°C.

Lundgren and Olovsson (21) have determined the crystal structure of the HCl dihydrate and showed it to be $H_5O_2^+Cl^-$. The cation $[H_2O—H—OH_2]^+$ has a relatively short central oxygen–oxygen distance of 2.41 Å. Rozière and Potier (20) have made a tentative assignment of their spectra based on this cation structure. Our assignments given in Table 6 essentially follow those of the latter authors with only minor modifications. Uncertainties in these assignments suggest more spectroscopic investigation of carefully prepared samples.

Very little crystalline dihydrate was formed when the HCl/H_2O ratio was 0.25 or less. Warming of these matrices to −120°C produced instead a new set of absorption bands characterized by relatively sharp peaks at 615 and 1625 cm^{-1} which were visible even when amorphous ice was present in the sample. The spectrum of this species and that of amorphous ice are shown in Fig. 7. Distinction of this hydrate from the monohydrate and dihydrate is particularly evident in the 400–800

cm^{-1} region in the spectra of Figs. 5, 6, and 7. Although the vibrational spectrum of the trihydrate apparently has not been reported, its crystal structure has been determined by Lundgren and Olovsson (22) to be represented by $H_5O_2^+Cl^- \cdot H_2O$. Also, the spectrum of $HBr \cdot 4H_2O$ has been reported by Rudolph and Zimmerman (23), and it differs considerably from that shown in Fig. 7. Therefore, we assign the lower spectrum of Fig. 7 to that of crystalline $H_5O_2^+Cl^- \cdot H_2O$ with peaks at 3410 m, 3330 vs, 3200 s, 1625 m, 1140 w, 1050 m, 790 m, and 615 s in cm^{-1} units. The trihydrate sublimed off the cooled window at −70°C. Absorption bands attributable to another known hydrate $HCl \cdot 6H_2O$ (24) or to complexes such as $HCl \cdot H_2O$ (25, 26) or $2HCl \cdot H_2O$ (26) observed in Ar and N_2 matrices at 15 K were not detected in the present work.

Complex mixtures of products were obtained when NH_3 was present in the H_2O–HCl system. A matrix with $NH_3/H_2O = 20$ reacted with HCl to produce NH_4Cl at −140°C with the reaction being over at −75°C. During this reaction in the tem-

perature range of −160°C to −83°C, $2NH_3 \cdot H_2O$, $NH_3 \cdot H_2O$, $H_3O^+Cl^-$, $H_5O_2^+Cl^-$, and $NH_4Cl \cdot 3NH_3$ were detected. When NH_3 was decreased to $NH_3/H_2O = 1.0$, NH_4Cl continued to be formed until −60°C and $NH_3 \cdot H_2O$, $H_5O_2^+Cl^-$, and $H_5O_2^+Cl^- \cdot H_2O$ were observed.

NH_3–HNO_3 system

A large difference in sublimation temperatures of these reactants required HNO_3 to be deposited on the cooled window first. Mole ratios of NH_3/HNO_3 ranged from 0.5 to 60, and both CsBr and AgCl windows were used. By the time the initial amorphous HNO_3 transformed into a crystalline solid (27) at −140°C, NH_3 had sublimed off the cooled window. The first sign of reaction occurred at −130°C when a set of new absorption bands appeared in the spectrum. These new bands were assigned to $NH_4NO_3 \cdot 3NH_3$ which has a melting point of about −40°C according to phase studies of Kuriloff (28). Peak frequencies of this triammoniate spectrum obtained at −190°C are listed in Table 4. This spectrum was similar to that of $NH_4Cl \cdot 3NH_3$ (Fig. 4) except for the presence of bands due to the NO_3^- ion. Frequencies from the most recent Raman studies of liquid NH_3 solutions of NH_4NO_3 by Lundeen and Tobias (29) are also listed in Table 4 for comparison. The band assignments given here are essentially those of the latter authors. Deammination of $NH_4NO_3 \cdot 3NH_3$ began at about −100°C under our experimental conditions.

Matrices with $NH_3/HNO_3 < 1$ also showed signs of reaction at −130°C. At this temperature NH_3 was already off the cooled window, and HNO_3 had annealed and was decreasing. The product bands at 1420 and 1305 cm^{-1} were the first to become evident, and they continued to grow until about −70°C when the reaction was complete. The spectrum of the resulting sample recooled to −190°C is illustrated in Fig. 8, and it is due to the complex $NH_4NO_3 \cdot 2HNO_3$. The composition of this complex had been determined by Potier and Potier (30) from phase studies, and subsequent refinement of X-ray data by Einstein and Tuck (31) has shown that the structure of this complex may be represented by $NH_4^+[NO_3 \cdot 2HNO_3]^-$ where the nitrate is hydrogen-bonded to two HNO_3 molecules. Peak frequencies in the spectrum of Fig. 8 are 3460 m, 3240 s, 2950 w, 2600 s, 1660 s, 1420 s, 1345 w, 1305 vs, 1260 m, 1070 m, 1045 w, 950 m, 815 m, 775 m, 705 w, and 695 w in cm^{-1} units. Prominent peaks in this set are in reasonable agreement with those reported earlier by Diop and Potier (32) who also presented a tentative assignment of the spectrum. The trinitrate complex on the cooled window started to decompose at −50°C and only NH_4NO_3 remained upon warming to 25°C. If HNO_3 was deposited on top of NH_4NO_3 and then warmed to −90°C, the same complex was formed.

In experiments with excess HNO_3, only the CsBr cooled window was used. It was noted that during the final warming of these samples to room temperature, $CsNO_3$ was being formed causing the band intensity ratio of NH_4^+/NO_3^- to vary from that in NH_4NO_3. In a pair of comparison experiments where HNO_3 or NH_3 was in excess but the amount of the second limiting reagent was the same, the intensity of the NH_4^+ ion band was only about one-half of that expected when HNO_3 was in excess. In the excess HNO_3 case, the NO_3^- ion band was three times stronger than expected. Thus, in addition to the reaction with the CsBr window, HNO_3 appeared to be destroying the NH_4^+ ion although the cell contents after completion of the experiments contained no detectable noncondensable gas. Also, when HNO_3 was deposited on top of NH_4NO_3 on the cooled window and the sample was warmed to

[b]From Nightingale and Wagner (34).

room temperature, there was about a 30% decrease in the absorbance of the NH_4^+ ion band and an increase of about 50% in the strength of the NO_3^- ion band. Since the outer CsBr windows of the cell were also attacked by HNO_3 the acid was removed from the cell at about −50°C as the trinitrate complex decomposed. The spectra of NH_4NO_3 and ND_4NO_3 at 25 and −190°C were in agreement with the results of Thèorêt and Sandorfy (33).

NH_2OH–HNO_3 system

The investigation of this reaction system was complicated by severe changes with temperature in the spectrum of solid NH_2OH itself as Nightingale and Wagner (34) had observed previously. When solid NH_2OH at room temperature was sublimed onto a cooled window at −190°C, it formed a clear amorphous film with a spectrum as shown in Fig. 9. The sharp peak near 2200 cm^{-1} in this spectrum is due to N_2O, a known decomposition product of NH_2OH. Warming of the amorphous solid to −90°C caused the sample to become white, and the spectrum changed irreversibly to that of crystalline NH_2OH. At −45°C, NH_2OH samples sublimed off the cooled window. Peak frequencies in the spectra of amorphous and crystalline NH_2OH are summarized in Table 7. Earlier data from Nightingale and Wagner (34) and from Giguère and Liu (35)

are also presented here for comparison. Assignments of the fundamentals are those of Nightingale and Wagner.

When HNO_3 was deposited on top of a film of amorphous NH_2OH at −190°C or *vice versa*, there was no reaction. Warming of these layered samples to −135°C caused HNO_3 to become crystalline. Only at about −125°C was there evidence of any chemical change, and new infrared bands first appeared at 1335 and 1390 cm^{-1}. These bands as well as others shifted slightly on warming and are listed in Table 8. They continued to grow as the temperature of the matrix approached the annealing temperature of −90°C. An example of a spectrum of amorphous NH_2OH with HNO_3 reaction intermediate but without excess HNO_3 is shown in Fig. 10. Arrows identify peaks whose frequencies are identical to those formed from the $NH_2OH-HNO_3$ reaction and are listed in Table 8. This spectrum was obtained from the reaction of amorphous NH_2OH and O_3 at low temperatures (1). When amorphous NH_2OH at −190°C was exposed to O_3, the same HNO_3 reaction intermediate was formed immediately. Growth of infrared bands of this intermediate was slow as the matrix was warmed but it became rapid as NH_2OH started to anneal at −90°C. At the same time new absorption bands due to amorphous $NH_3OH^+NO_3^-$ or occasionally crystalline $NH_3OH^+NO_3^-$ began to appear. As NH_2OH started to sublime off the cooled window at about −45°C, the absorption bands of the hydroxylammonium nitrate became stronger and remained to room temperature. In contrast to the above behavior, crystalline NH_2OH reacted with O_3 only on warming to −50°C, but it too formed the same HNO_3 reaction intermediate. The intermediate from the latter reaction as well as that from the $NH_2OH-HNO_3$ reaction converted into amorphous or crystalline hydroxylammonium nitrate at about −45°C as the remaining NH_2OH sublimed off the cooled window. Spectra of amorphous and crystalline $NH_3OH^+NO_3^-$ at −190°C are illustrated in Fig. 11 and their frequencies are summarized in Table 9. In this table, data for the room temperature sample are from Rocchiccioli (36) and those for the chloride salt are from Frasco and Wagner (37).

Our experimental evidence from the $NH_2OH-HNO_3$ and NH_2OH-O_3 reaction systems suggests that the HNO_3 reaction intermediate is a precursor of the final product $NH_3OH^+NO_3^-$ and that it is a complex of NH_2OH and HNO_3. A reasonable structure of this complex is one in which the proton transfer from the acid occurs at the oxygen atom to give $NH_2OH_2^+NO_3^-$. The absence of the characteristic strong $-NH_3^+$ group deformation fundamental at 1465 cm^{-1} (Table 9) and the presence of hydronium ion-like bands at 2760, 1650, and 995 cm^{-1} in Table 8 provide additional support for the proposed structure of this intermediate. For example, in the spectrum of $H_3O^+NO_3^-$, Savoie and Giguère (38) have reported bands at 2780 s, 1680 m, 1386 s, 1340 m, 1253 w, 1135

s, 930 w, and 815 s in cm^{-1} units. Thus, the data in Table 8 have been assigned on the basis of the structure $NH_2OH_2^+NO_3^-$.

Summary

Acid–base reactions among various pairs of reactants NH_3, NH_2OH, H_2O, HCl, and HNO_3 have been examined by low-temperature infrared spectroscopy. Hydrogen-bonding in the solid state greatly reduces the reactivities of these reagents. In the systems $NH_3(s) + HCl(g)$, $HNO_3(s) + NH_3(g)$, $H_2O(s) + HCl(g)$, and $NH_2OH(s) + HNO_3(s)$ reactions become observable at −145, −130, −127, and −125°C, respectively. In the $NH_3–H_2O$ system, no proton transfer took place and the products were $2NH_3 \cdot H_2O$ and $NH_3 \cdot H_2O$. In the $NH_2OH–HNO_3$ system, both $NH_2OH_2^+NO_3^-$ and $NH_3OH^+NO_3^-$ were observed. Other species whose spectra were observed were $NH_4Cl \cdot 3NH_3$, $NH_4NO_3 \cdot 3NH_3$, $NH_4^+[NO_3 \cdot 2HNO_3]^-$, $H_3O^+Cl^-$, $H_5O_2^+Cl^-$, and $H_5O_2^+Cl^- \cdot H_2O$.

Reçu le 30 juin 1981[1]

JEAN-CLAUDE RICHER et SIMONE ODIOT. Can. J. Chem. **61**, 2089 (1983).

Nous avons synthétisé, d'une façon non ambigue, le chloro-1 diméthoxy-2,6 naphtalène-d_3 (**5**) et nous avons examiné son spectre de masse sous impact électronique. Nous rapportons aussi des calculs théoriques sur les stabilités relatives des chloro-1 et chloro-5 méthoxy-6 naphtols-2 (**4***a* et **4***b*) et sur les stabilités relatives des liaisons O—CH_3 en positions 2 et 6 du composé **5**.

JEAN-CLAUDE RICHER and SIMONE ODIOT. Can. J. Chem. **61**, 2089 (1983).

In an unambiguous manner we have synthesized 1-chloro-2,6-dimethoxy-d_3-naphthalene (**5**) and examined its electron impact mass spectrum. We report here calculations on the relative stabilities of 1-chloro and 5-chloro-6-methoxy-2-naphthols (**4***a* and **4***b*) and on the relative stabilities of the O—CH_3 bond in the 2 and 6 positions of compound **5**.

[Journal translation]

Introduction

Au cours d'une étude antérieure (1) sur la spectrométrie de masse du diméthoxy-2,6 naphtalène et de ses dérivés, nous avons suggéré que ces composés subissent la perte d'un radical méthyle (voir Schéma 1) et nous avons indiqué (1) que le choix du méthyle éliminé est arbitraire. Nous avions d'ailleurs noté, dans le cas de **1***a* (X^1 = Cl et X^2 = H), que l'ion à (M − 15) est plus intense que l'ion correspondant pour la molécule non substituée, **1***b* (X^1 = X^2 = H); nous avons supposé qu'un tel comportement peut être dû à la tendance marquée du chlore à partager l'un de ses doublets non liant et à stabiliser ainsi l'ion de type quinonique qui peut être formé (Schéma 2).

C'est dans le but de confirmer expérimentalement cette hypothèse que nous avons synthétisé des dérivés marqués d'une façon spécifique; nous avons ensuite comparé les résultats expérimentaux obtenus par spectrométrie de masse avec les résultats des calculs théoriques relatifs aux forces des diverses liaisons O—CH_3.

Résultats et discussion

Les produits dérivés ont été obtenus en effectuant les réactions représentées dans le schéma 3.

La structure **4***a* plutôt que **4***b* est attribuée sur la base du spectre rmn du ^{13}C. La première observation a trait au fait que le spectre du produit **4***a* ne comporte qu'un signal pour un O$\underline{C}H_3$. Cette observation suggère que la chloration de **3** ne conduit qu'à un seul dérivé chloré et cette sélectivité doit probablement être attribuée à une interaction entre le réactif SO_2Cl_2 et le OH libre du naphtol. Ces considérations suggèrent donc la structure **4***a* pour le produit chloré. Cette conclusion est

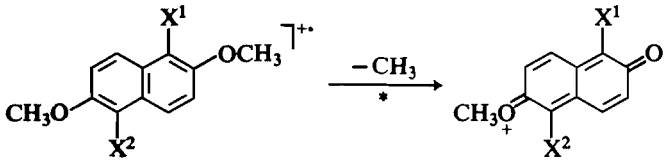

SCHÉMA 1

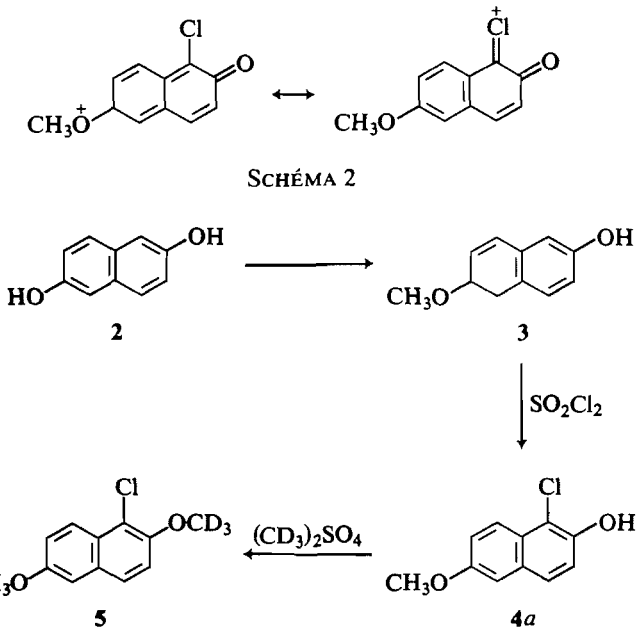

SCHÉMA 3

confirmée par l'examen du tableau 1 où sont rassemblés les déplacements chimiques des OCH_3 de naphtalènes apparentés. Ces données mettent en évidence le fait que les déplacements chimiques des OCH_3 qui ne sont pas soumis à l'influence d'un chlore en *ortho* sont de l'ordre de 55,5 ± 0,2 ppm alors que les valeurs équivalentes pour des OCH_3 en *ortho* d'un chlore sont de l'ordre de 57,5 ppm. La structure des composés **4***a* et **5** est donc établie sans ambiguité.

Sous impact électronique, la molécule **5** perd beaucoup plus facilement le CD_3 que le CH_3; le rapport est de 95:5 (voir Fig. 1) correspondant à une différence d'énergie de rupture d'environ 1,7 kcal/mol. Des calculs théoriques portant sur une évaluation des énergies relatives de dissociation des deux types de liaisons O—CH_3 vont dans le sens de cette observation, même s'ils sont loins d'être concluants; la différence liée à la présence du chlore est évaluée à 0,13 kcal/mol.

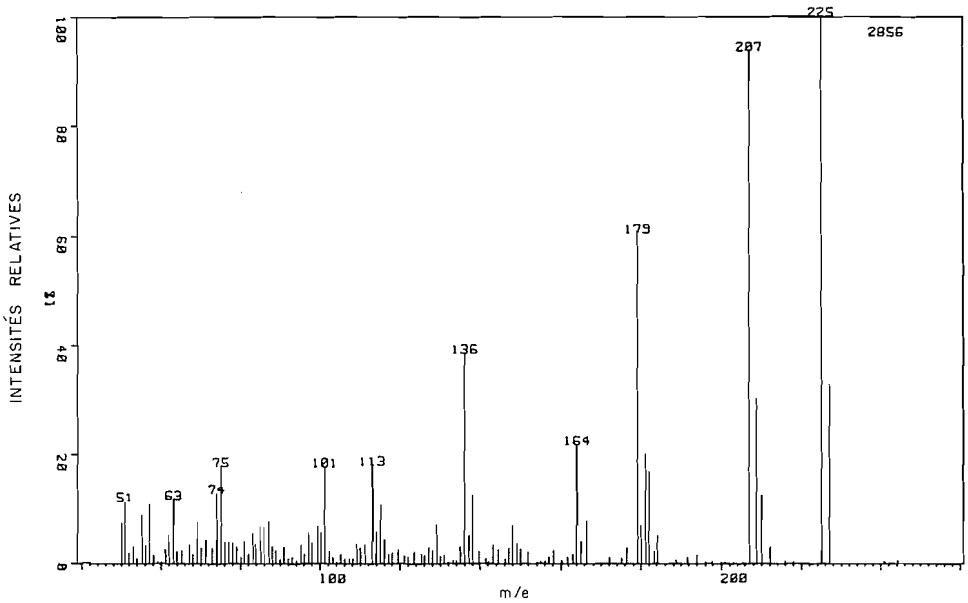

FIG. 1. Spectre de masse du chloro-1 diméthoxy-2,6 naphtalène-d_3 (**5**).

TABLEAU 1. Déplacements chimiques, en rmn du ^{13}C, des OCH_3

Composés	Déplacements chimiques (ppm/TMS)
3	55,44
4*	55,44
5 (léger)*	55,70 et 57,39
5-d_3*	55,76
5-d_3†	55,71 et 57,53

* Les spectres ont été enregistrés pour des solutions saturées dans l'acétone-d_6 sur un appareil Bruker WH-90 opérant à 22,63 MHz dans le mode de découplage en large bande. Les paramètres d'acquisition des spectres réalisés par transformation de Fourier sont: largeur spectrale 6024 Hz; temps d'acquisition −0,655 s; délai entre deux impulsions: 7 μs.

† Le spectre a été enregistré sur un appareil Bruker WP-80 opérant à 20,15 MHz et avec lequel un délai de 25 s était accordé entre deux impulsions.

Partie expérimentale

Les techniques expérimentales générales ont été décrites antérieurement (voir par exemple les réfs. 2, 3).

Synthèse des produits

Méthoxy-6 naphtol-2 (3)

La méthylation du dihydroxy-2,6 naphtalène est conduite d'après les indications de Downing et Woodcock (4).

Chloro-1 méthoxy-6 naphtol-2 (4a)

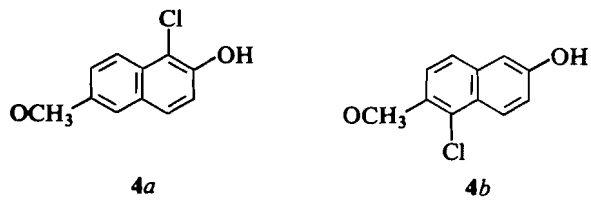
On ajoute 0,5 g de **3** en solution dans 10 mL de chloroforme dans 0,37 g de SO_2Cl_2 en solution dans 10 mL de chloroforme et l'on maintient le mélange dans un bain de glace pendant 15 h. On ajoute alors 21 mL d'éther puis 10 mL d'eau pour décomposer l'excès de SO_2Cl_2. La solution ainsi obtenue est décantée, lavée à l'eau, séchée sur du Na_2SO_4 et évaporée. On obtient ainsi 0,2 g (34% de rendement) de **4***a*; pf: 110–112°C (après sublimation).

Chloro-1 diméthoxy-2,6 naphtalène-d_3 *(5)*

On traite une solution de 1,6 g (8 mmol) de chloro-1 méthoxy-6 naphtol dissous dans 8 mL de méthanol par 1,1 mL de diméthylsulfate deutéré en présence de soude en suivant le procédé suggéré par Vyas et Shah (5). On obtient ainsi 625 mg (35% de rendement théorique) de **5**, pf 118–120°C (litt. (4) pf 117–118°C) dont le spectre de masse (Figs. 1 et 2) a été déterminé sur un appareil Micromass 12-12F de la compagnie VG opérant à 70 eV.

Calculs théoriques

Les calculs ont été effectués dans le cadre classique de la méthode



4a **4b**

FIG. 2

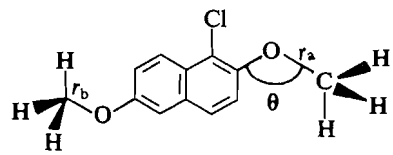


FIG. 3

C—C du cycle = 1,40 Å; C—O = 1,36 Å; O—CH_3 fixe = 1,35 Å soit pour r_b ou r_a; r = O—CH_3 variable soit pour r_a ou r_b; C—H = 1,09 Å; θ = C—O—C = 121°; H—CH—(H) = 109° 28′. Tous les autres angles du cycle sont pris égaux à 120°.

CNDO/2 (6, 7) après optimisation de la géométrie et minimisation de l'énergie E sur le paramètre géométrique θ = C—O—H (conformation s-*cis* de la figure 3). On obtient les valeurs suivantes:

4*a*	E = −138,094563 ua	θ = 108° 16′
4*b*	E = −138,090350 ua	θ = 108° 31′

On note que l'angle θ est insensible au voisinage soit de Cl ou de H et que le composé **4***a* est plus stable que **4***b* par 4213×10^{-6} ua soit 2,6 kcal/mol. L'évaluation des énergies relatives de dissociation des liaisons O—CH_3 (qui sont identifiées aux valeurs correspondantes pour O—CD_3) du composé **5** donnée par la différence d'énergie ΔE entre la valeur calculée pour la distance r_e à l'équilibre (O—CH_3) et celle pour r (limite de convergence du calcul) est en rapport avec la fragilité relative de ces liaisons (Tableau 2).

Cette différence d'énergie $\Delta_{\Delta E} = \Delta E_{OCH_3(2)} - \Delta E_{OCH_3(6)} = 0{,}355586 - 0{,}355794 = 208 \times 10^{-6}$ ua = 130 cal/mol. La géométrie adoptée est donnée dans la figure 3 où la forme s-*trans*, θ = 121° est la plus stable.

Conclusion

Les résultats expérimentaux obtenus au cours de ce travail

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12

TABLEAU 2. Variation de l'énergie en fonction de la distance r (O—CH_3)

r_a	E (ua)	r_b	E (ua)
1,15	−146,586947	1,35	−146,76748
1,25	−146,721776	1,36	−146,768487
1,35	−146,767488	1,37	−146,768950
r_e = 1,38063	−146,768925	r_e = 1,37238	−146,768989
1,45	−146,756508	1,38	−146,768914
1,80	−146,54445	1,39	−146,768392
		1,40	−146,767413
2,00	−146,413339	2,00	−146,413195
Limite de convergence		Limite de convergence	
	ΔE_{ua} = 0,355586		ΔE_{ua} = 0,355794

nous permettent donc de confirmer l'hypothèse formulée dans le travail antérieur (1) selon laquelle la liaison du O—CH_3 en position 2 du Cl se rompt plus aisément que la liaison du O—CH_3 en position 6 par rapport au chlore (voir Schéma 1).

On a aussi démontré, par des calculs théoriques semi-empiriques relativements simples que l'énergie de dissociation de la liaison O—CH_3 du groupement en α du chlore est plus faible que l'énergie de dissociation du O—CH_3 en position 6; ces calculs confirment l'expérience ainsi que l'hypothèse préconisée antérieurement et représentée dans les schémas 1 et 2.

Solvolytic studies with 2-methyl[1-^{13}C]-1-propyl tosylate

CHOI CHUCK LEE AND HUSSEIN F. ZOHDI

Department of Chemistry, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received March 11, 1983

CHOI CHUCK LEE and HUSSEIN F. ZOHDI. Can. J. Chem. **61**, 2092 (1983).

Solvolysis of 2-methyl[1-^{13}C]-1-propyl tosylate was carried out in HOAc or CF_3COOH without or with the presence of 2.0 equivalents of NaOAc or CF_3COONa, respectively. Isobutyl, *sec*-butyl and *tert*-butyl products were obtained. With the use of ^{13}C as label, isotopic scramblings were analyzed by ^{13}C nmr, avoiding the necessity of chemical degradations associated with the use of ^{14}C. There was no isotopic scrambling in the isobutyl product and scrambling of the ^{13}C-label was observed only between C-2 and C-3 in the *sec*-butyl product, indicating 1,2-hydride shifts in the *sec*-butyl cation. In contrast to the involvement of equilibrating protonated methylcyclopropane intermediates observed in the trifluoroacetolysis of [1-^{14}C]-1-butyl tosylate, the present results indicated that protonated methylcyclopropane intermediates did not play a significant role in the acetolysis or trifluoroacetolysis of isobutyl tosylate.

CHOI CHUCK LEE et HUSSEIN F. ZOHDI. Can. J. Chem. **61**, 2092 (1983).

On a effectué la solvolyse du tosylate de méthyle-2 [^{13}C-1] propyle-1 dans du AcOH ou du CF_3COOH en présence ou non de 2 équivalents de AcONa ou de CF_3COONa respectivement. On a obtenu des produits du type isobutyle, *sec*-butyle et *tert*-butyle. Faisant appel au marquage par le ^{13}C on a analysé le mélange isotopique par la rmn du ^{13}C évitant ainsi la nécessité de recourir à des dégradations chimiques associées à l'utilisation du ^{14}C. Il n'y a pas de mélange isotopique dans le cas de l'isobutyle et on a observé un mélange du marqueur au ^{13}C uniquement entre le C-2 et le C-3 du *sec*-butyle, ce qui indique un glissement 1,2 d'hydrure dans le cation *sec*-butyle. Contrairement à l'implication des intermédiaires méthylcyclopropane protonés à l'équilibre observés dans la trifluoroacétolyse du tosylate de [^{14}C-1] butyle-1 les résultats actuels indiquent que les intermédiaires méthylcyclopropanes protonés ne jouent pas un rôle significatif dans l'acétolyse ou la trifluoroacétolyse du tosylate d'isobutyle.

[Traduit par le journal]

In the trifluoroacetolysis of [1-^{14}C]-1-butyl tosylate, extensive isotopic scramblings were observed in the chief product, *sec*-butyl trifluoroacetate, the mean ^{14}C distribution at C-1, C-2, C-3, and C-4, respectively, being 48.1, 2.3, 3.3, and 46.3% (1). These results were explained by invoking the occurrence of two processes, the main pathway being the degenerate rearrangement interconverting *sec*-butyl cations through 1,2-hydride shifts, with a minor process involving equilibrating protonated methylcyclopropanes as reaction intermediates (eq. [1]) to account for the small amounts of scrambling of the label into the C-2 and C-3 positions (1). Similar scrambling

[1] 
results indicating a minor contribution by protonated methylcyclopropane intermediates have also been observed in the trifluoroacetolysis of [1-^{14}C]-1-butylmercuric perchlorate (2) and in the HNO_2 deamination of [1-^{14}C]-1-butylamine (3). It is of interest to find out whether protonated methylcyclopropane intermediates would play a part in solvolytic reactions with the isobutyl system. In the present work, 2-methyl[1-^{13}C]-1-propyl tosylate (**1**-OTs-1-^{13}C) was solvolyzed in HOAc or CF_3COOH in order to ascertain if the isotopic scrambling data would indicate a role for protonated methylcyclopropanes in these reactions. ^{13}C instead of ^{14}C was used as label and the scrambling was analyzed by ^{13}C nmr so as to avoid the chemical degradations required in the use of ^{14}C.

The solvolysis of **1**-OTs-1-^{13}C was carried out in HOAc or CF_3COOH, without or with the presence of 2.0 equivalents of NaOAc or CF_3COONa, respectively. The ester products obtained in each experiment were hydrolyzed to give a mixture of isobutyl, *sec*-butyl, and *tert*-butyl alcohols (**1**-OH-*x*-^{13}C, **2**-OH-*x*-^{13}C, and **3**-OH-*x*-^{13}C, respectively) which were separated by preparative vpc. The yields of these alcohols are summarized in Table 1.

To determine the ^{13}C distributions in the **1**-OH-*x*-^{13}C and **2**-OH-*x*-^{13}C, these alcohols were converted to the corresponding phenylurethanes and the ^{13}C nmr spectra of these solid derivatives were obtained in the presence of 0.1 *M* $Cr(AcAc)_3$ (chromium acetylacetonate) as a relaxation agent. The presence of the $Cr(AcAc)_3$ strongly quenched the nuclear Overhauser enhancements, thus allowing for a quantitative correlation between peak intensity and ^{13}C content (4). Shown in Fig. 1A is the ^{13}C spectrum, obtained in $CDCl_3$ in the presence of 0.1 *M* $Cr(AcAc)_3$, for a typical sample of isobutyl phenylurethane prepared from **1**-OH-*x*-^{13}C derived from a solvolysis reaction. This spectrum indicated that only the C-1 CH_2 carbon was enriched with ^{13}C, the integrated intensity of the two CH_3 groups being very similar to those of the two *o*- or *m*-carbons of the phenyl group, and the integrated intensity of the C-2 CH carbon being very similar to that of the one carbon absorption of the *p*-carbon of the phenyl group. Thus there was essentially no scrambling of the ^{13}C-label from C-1 and the **1**-OH-*x*-^{13}C obtained from all of the solvolysis reactions studied was actually the unrearranged **1**-OH-1-^{13}C.

Figures 1B and 1C, respectively, are the ^{13}C spectra, obtained in the presence of 0.1 *M* $Cr(AcAc)_3$, for the *sec*-butyl phenylurethane prepared from **2**-OH-*x*-^{13}C derived from Run 1 of Experiment 1 (acetolysis, no added NaOAc) and from Run 1 of Experiment 4 (trifluoroacetolysis, 2.0 equiv. CF_3COONa). The assignments for C-1, C-2, C-3, and C-4 of the *sec*-butyl group and the *o*-, *m*-, and *p*-carbons of the phenyl group are shown in the spectra, the remaining two downfield peaks being due to the quarternary carbon of the phenyl group and the carbonyl carbon of the urethane function. From the integrated intensities as shown in Tables 2 and 3, the ^{13}C enrichments in the *sec*-butyl carbons were calculated using the integrated in-

[a]The isomeric butyl alcohols were derived from hydrolysis of the butyl esters obtained in each experiment.
[b]Based on vpc.
[c]Calculated as shown in Tables 2 and 3.
[d]Two molar equivalents of NaOAc or CF_3COONa were present in the reaction mixture.

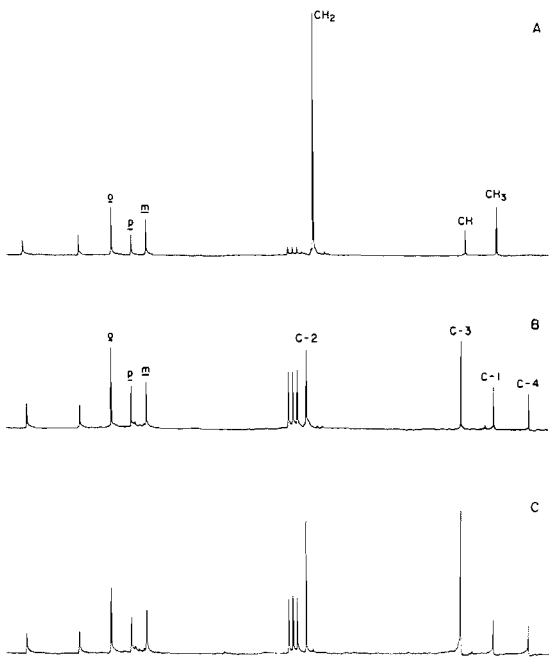

FIG. 1. ^{13}C nuclear magnetic resonance spectra in $CDCl_3$ containing 0.1 *M* $Cr(AcAc)_3$. A. [*x*-^{13}C]Isobutyl phenylurethane; B. [*x*-^{13}C]-*sec*-butyl phenylurethane derived from Run 1, Expt. 1; C. [*x*-^{13}C]-*sec*-butyl phenylurethane derived from Run 1, Expt. 4.

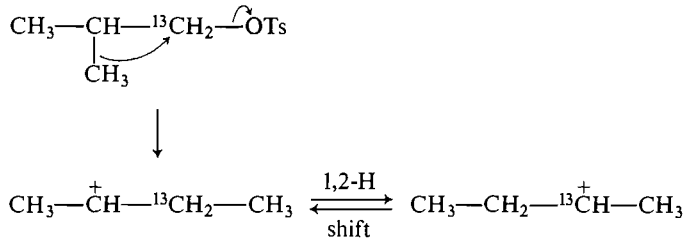
tensity of the *o*-, *m*-, or *p*-carbon of the phenyl group as a reference standard.

It is seen from Tables 2 and 3 that, for both of these experiments, there was no ^{13}C enrichment in C-1 and C-4, but there was scrambling of the ^{13}C between C-2 and C-3. Although the precision obtained for the extent of scrambling in the acetolysis experiment was relatively poor, the present results did show that, with the use of $Cr(AcAc)_3$, the ^{13}C spectra were capable of being used to measure the extents of scrambling of the ^{13}C-label. Similar treatment of the data from the ^{13}C spectra of samples of *sec*-butyl phenylurethane derived from the other experiments also showed scramblings between C-2 and C-3, but no scrambling to C-1 and C-4. The extents of such scramblings between C-2 and C-3 for all of the solvolysis reactions studied in the present work are included in Table 1.

The kinetics of solvolysis of **1**-OTs, including acetolysis and trifluoroacetolysis, have been studied by Winstein and coworkers (5, 6). At 75°C, the titrimetric rate constants for the acetolysis and trifluoroacetolysis of **1**-OTs were found to be 0.234×10^{-6} s^{-1} and 55.4×10^{-6} s^{-1}, respectively. These results were interpreted as indicating anchimeric assistance in CF_3COOH due to participation of the neighboring H or CH_3 to give the *tert*-butyl or *sec*-butyl product (6). The present results are in agreement with Winstein's conclusions and the use of the isotopic label further showed that, in the *sec*-butyl cation, 1,2-hydride shifts took place, leading to the scrambling of the label between C-3 and C-2.



For the reaction under the least nucleophilic conditions, i.e. trifluoroacetolysis with no added CF_3COONa (Experiment 3), complete equilibration of the label between C-3 and C-2 in the *sec*-butyl product was observed. On the other hand, as would be expected, the least extent of scrambling was found for the acetolysis carried out in the presence of added NaOAc (Experiment 2).

In the trifluoroacetolysis of [1-^{14}C]-1-butyl tosylate (1), small amounts of scrambling to the C-2 and C-3 positions of the *sec*-butyl product were observed. Consideration of the possible mechanisms that might be responsible for the appearance of the label at C-2 and C-3 led to the conclusion favoring the involvement of equilibrating protonated methylcyclopropane intermediates rather than the occurrence of 1,2-ethyl shifts in the 1-butyl cation (1). A similar involvement of protonated methylcyclopropanes in the solvolysis of **1**-OTs-1-^{13}C would lead to the scrambling of the label into C-1 and C-4 of the *sec*-butyl product. In the present work, the complete absence of any ^{13}C enrichment in C-1 and C-4 of the *sec*-butyl product, as well as the absence of any scrambling in the isobutyl product, indicated that, in contrast to the trifluoroacetolysis of 1-butyl tosylate, protonated methylcyclopropane intermediates did not play any significant part in the formation of products during the acetolysis or trifluoroacetolysis of **1**-OTs-1-^{13}C. This conclusion is also in agreement with the findings of Karabatsos *et al.* (7) that the aqueous acid deamination of 2-methyl(1,1-$^2H_2$)-1-propylamine (**1**-NH_2-1,1-d_2) did not give any isotopic scrambling results in support of protonated methylcyclopropanes.

[b]The integrated intensity of the *m*-carbons was 1.94 or 0.97 per C, the enrichments being the difference between the observed intensity of C-1, C-2, C-3, or C-4 and 0.97.
[c]The integrated intensity of the *p*-carbon was 1.07, the enrichment being the difference between the observed intensity of C-1, C-2, C-3, or C-4 and 1.07.
[d]Mean value ± maximum deviation from the mean.

Experimental

*2-Methyl[1-^{13}C]-1-propyl tosylate (**1**-OTs-1-^{13}C)*

The substrate, **1**-OTs-1-^{13}C, was prepared using conventional methods. Treatment of isopropylmagnesium bromide with [^{13}C]CO_2 (from 90% enriched [^{13}C]$BaCO_3$ supplied by MSD Isotopes of Montreal) gave the labeled isobutyric acid which was reduced with $LiAlH_4$ to isobutyl alcohol and then treated with *p*-toluenesulfonyl chloride in pyridine to give **1**-OTs-1-^{13}C, mp 11−12°C (lit. (5) mp 12.0−12.5°C).

Solvolysis reactions

In the acetolysis, 5.0 g (22 mmol) of **1**-OTs-1-^{13}C in 50 mL of HOAc was heated under reflux at 100 ± 2°C for 13 days. The reaction time was chosen after nmr monitoring of preliminary trial reactions, with the disappearance after 13 days of the doublet due to the C-1 CH_2 of the substrate as an indication of complete reaction. From the kinetic data of Winstein and Marshall (5), for the acetolysis, a reaction time of 13 days at 100°C would correspond to about 6 half-lives. For the acetolysis in the presence of NaOAc, the same conditions were used except that the reaction mixture also contained 3.6 g (44 mmol) of NaOAc.

In the trifluoroacetolysis, a solution of 5.0 g (22 mmol) of **1**-OTs-1-^{13}C in 50 mL of CF_3COOH, without or with the presence of 6.0 g (44 mmol) of CF_3COONa, was heated under reflux at 60 ± 1°C for 60 h, the reaction time again being chosen after preliminary monitoring by nmr. According to the data of Winstein and co-workers (6), the half-life for the trifluoroacetolysis at 75°C was about 3.5 h.

Each reaction mixture was worked up using a procedure similar to that employed in the trifluoroacetolysis of [1-^{14}C]-1-butyl tosylate (1). This involved the addition of a sufficient amount of aqueous KOH to neutralize the reaction mixture and leave a final solution containing 20% KOH, the refluxing of the basic solution overnight to effect the hydrolysis of the ester products, and the recovery of the isomeric butyl alcohols by continuous ether extraction. A small amount of the recovered products was used for vpc analysis through a capillary column packed with Carbowax 20M to give the relative yields of the isobutyl, *sec*-butyl, and *tert*-butyl alcohols (**1**-OH-*x*-^{13}C, **2**-OH-*x*-^{13}C, and **3**-OH-*x*-^{13}C, respectively). The remainder of the product mixture, with some added carriers if necessary, was separated by preparative vpc to give samples of **1**-OH-*x*-^{13}C, **2**-OH-*x*-^{13}C, and **3**-OH-*x*-^{13}C, the first two of these alcohols being converted to the corresponding phenylurethanes for nmr analysis in $CDCl_3$ in the presence of 0.1 *M* $Cr(AcAc)_3$.

Sulfoxydes et sulfones hétérobicycliques dérivés de l'α-thioglycérol. 2,8-Dioxa-6-oxo-6-thiabicyclo[3.2.1]octanes et 2,8-dioxa-6,6′-dioxo-6-thiabicyclo[3.2.1]octanes[1]

PIERRE CALINAUD ET JACQUES GELAS

Université de Clermont-Ferrand, École Nationale Supérieure de Chimie, Ensemble Scientifique des Cézeaux, BP 45, 63170 Aubière, France

Reçu le 21 decembre 1982

PIERRE CALINAUD et JACQUES GELAS. Can. J. Chem. **61**, 2095 (1983).

Les réactions d'oxydation de sulfures hétérobicycliques dérivés de l'α-thioglycérol (alkyl-2,8-dioxa-6-thiabicyclo-[3.2.1]octanes), menant respectivement aux sulfoxydes et aux sulfones correspondants, ont été étudiées. La stéréochimie de l'oxydation en fonction de l'agent utilisé (eau oxygénée, acide *méta*-chloroperbenzoïque, hypochlorite de *tert*-butyle) a été examinée. L'attribution de la structure des sulfoxydes repose sur la discussion d'un ensemble de critères spectrographiques et chimiques propre à ce type de composé.

PIERRE CALINAUD and JACQUES GELAS. Can. J. Chem. **61**, 2095 (1983).

The oxidation reactions of heterobicyclic sulfides derived from α-thioglycerol (alkyl-2,8-dioxa-6-thiabicyclo[3.2.1]-octanes), leading to sulfoxides and the corresponding sulfones, have been studied. The stereochemistry of the oxidation as a function of the reagent used (H_2O_2, *meta*-chloroperbenzoic acid, and *tert*-butyl hypochlorite) has been examined. Structural assignments of the sulfoxides arise from the spectroscopic and chemical properties of these compounds.

Depuis une dizaine d'années un intérêt considérable est apparu concernant la détermination des préférences conformationnelles des substituants portés par un hétéroatome d'un cycle (Fig. 1) et ceci particulièrement pour les hétérocycles à six maillons (3). En effet, outre l'intérêt fondamental évident que présentent ces études, les conséquences d'une telle détermination pourraient être particulièrement utiles dans l'avenir pour les substances douées d'activité biologique.

Disposant avec les 2,8-dioxa-6-thiabicyclo[3.2.1]octanes préparés au laboratoire (1) d'un modèle particulièrement approprié (équilibre conformationnel pratiquement bloqué) pour envisager les problèmes posés par l'oxydation au niveau de l'atome de soufre, nous avons entrepris l'étude des sulfoxydes et sulfones de cette série. Nous y avons été d'autant plus incités que les seuls travaux dans cette dernière ont été publiés sous forme d'une note préliminaire (4) décrivant la formation des deux sulfoxydes stéréoisomères correspondant au dioxathiabicyclooctane non substitué et préparé à partir du 1,6-anhydro-β-D-glucopyranose. Une tentative d'attribution de la stéréochimie respective de ces deux sulfoxydes était proposée sur la base de la vitesse de réduction par le diborane plus grande pour le sulfoxyde à liaison S—O *axiale* que pour l'isomère à liaison S—O *équatoriale*. En revanche l'étude des sulfoxydes dérivés des 2-hydroxy ou 2-méthoxy-1,4-oxathiannes a été plus approfondie et constitue d'ailleurs une des toutes premières définition de critères d'attribution de la stéréochimie *axiale* ou *équatoriale* de la liaison S—O dans les hétérocycles à six maillons (5).

2,8-Dioxa-6-oxo-6-thiabicyclo[3.2.1]octanes

Les dioxathiabicyclooctanes de départ ont été décrits précédemment (1). Les sulfoxydes correspondants (Tableau 1) ont été obtenus par trois méthodes.

(a): L'oxydation par l'eau oxygénée selon Rigau *et al.* (6); l'agent oxydant est utilisé en quantité stoechiométrique, seul le sulfoxyde est obtenu à côté d'une très faible quantité de sulfone et du sulfure de départ inattaqué.

(b): L'oxydation par l'acide *méta*-chloroperbenzoïque en solution dans le dichlorométhane (7) semble être plus rapide et surtout moins dangereuse que la précédente pour laquelle nous avons observé un cas d'explosion violente.

(c): L'oxydation par l'hypochlorite de *tert*-butyle selon la méthode décrite par Johnson et McCants (8) a été utilisée pour obtenir préférentiellement des sulfoxydes à liaison S—O *axiale* (proportion S—O *axiale* environ 70%), alors que les deux méthodes précédemment citées conduisent essentiellement dans notre cas à des sulfoxydes où la liaison S—O est *équatoriale* (plus de 90%). La préparation du couple de stéréoisomères dans un certain nombre de cas (sulfoxydes **1**, **2** et **4**) a permis de lever toute ambigüité quant à l'attribution de la

stéréochimie des sulfoxydes pratiquement purs obtenus par les deux autres méthodes.

Critères d'attribution de la structure et de la configuration des sulfoxydes

Bien que d'autres critères d'identification (voir notamment points de fusion et R_f dans la partie expérimentale) puissent être utiles, ce sont certaines données de spectrographie de rmn qui apparaissent en fait des moins discutables pour attribuer la configuration d'un sulfoxyde. (Pour une revue critique de ces critères se reporter à la publication de Lett et Marquet (9) et références citées.)

1. *Déplacements chimiques*

Si l'on compare les sulfoxydes aux dioxathiabicyclooctanes de départ (1) l'effet le plus remarquable est l'inversion des déplacements chimiques des protons portés par les atomes de carbone en α du groupement sulfinyle, particulièrement dans le cas d'un sulfoxyde *équatorial*: les protons *équatoriaux* (qui résonnent à champ plus fort que les protons *axiaux* dans les sulfures) résonnent à champ faible dans les sulfoxydes alors que les protons *axiaux* résonnent à champ fort. L'attribution *équatoriale–axiale* des protons en 5 a pu être faite grâce à la constante de couplage à longue distance en W $^4J_{3,5}$ qui n'existe qu'entre le proton H-3 *exo* et le proton H-5 *axial*. Nous détaillons dans le tableau 2 un exemple particulièrement net fourni par les spectres des sulfoxydes **5** *axial* et *équatorial* pour lesquels on a rappelé les déplacements chimiques pour le sulfure de départ. Ces déplacements s'expliquent très bien en reprenant l'interprétation du blindage ou du déblindage de protons par un groupe sulfinyle (9). Si on considère les différents sites spatiaux possibles (Fig. 2), un proton dans le site *B* sera le plus

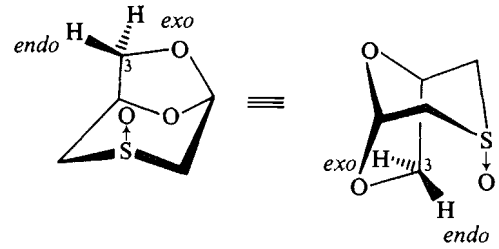

FIG. 4.

TABLEAU 3. Effets de déblindage exercé sur le proton H-3 *endo* par un groupe sulfinyle *axial* (solvant Me_2CO-d_6)

Proton	Composés	δ SO *éq*	δ SO *ax*	Δδ
H-3 *endo*	**1**	4,60	4,90	+0,30
	2	3,90	4,77	+0,87
	5	3,91	4,82	+0,91
H-3 *exo*	**1**	3,93	3,92	+0,01
	2	3,90	3,92	+0,02
	5	3,41	3,53	+0,12

TABLEAU 4. Différences entre les déplacements chimiques des protons géminés en α du groupe sulfinyle

Composés	Δν H-5	Δν H-7
2 *éq*	1,07	0,99
2 *ax*	0,69	0,69
5 *éq*	1,22	1,32
5 *ax*	0,10	0,10

déblindé de tous alors que les protons dans les sites *A* ou *C* seront soit légèrement déblindés, soit blindés. Si nous reprenons ce modèle pour nos propres sulfoxydes on constate (Fig. 3) que pour le sulfoxyde *équatorial* le proton *axial* en α est dans un site *C* (*anti* par rapport à la paire libre et *gauche* par rapport à SO) et le proton *équatorial* en α dans un site *B* (*gauche* par rapport à la paire libre et à la liaison SO). Inversement, pour le sulfoxyde *axial* le proton *axial* en α est dans un site *A* (*anti* par rapport à la liaison SO et *gauche* par rapport à la paire libre) et le proton *équatorial* en α dans un site *B*. Les effets observés (Tableau 2) sont conformes aux prévisions tirées du modèle de la figure 2. Cependant en général l'effet de déblindage est de l'ordre de 0,4 ppm (9). L'écart entre nos propres valeurs peut être dû à au moins deux facteurs: (*i*) nos composés sont pratiquement dans une conformation bloquée et de ce fait les effets peuvent être plus marqués; (*ii*) si on admet (ainsi qu'on a déjà eu l'occasion de le discuter pour les homologues oxygénés (1)) que le cycle 1,4-oxathianne des bicycles est aplati dans la région C-5—S-6—C-7, on doit obtenir un effet de déblindage d'autant plus prononcé pour un site *B* et pour un sulfoxyde *équatorial* (tendance à éclipser le proton avec la paire libre); inversement le léger blindage observé pour les protons *axiaux* d'un sulfoxyde *équatorial* serait dû à la tendance à éclipser le proton dans le site *C* avec la liaison SO.

Une observation intéressante est l'effet de déblindage exercé sur H-3 *endo* par l'atome d'oxygène du groupe sulfinyle lorsque celui-ci est *axial* (Fig. 4). A titre d'exemple nous indiquons dans le tableau 3 les valeurs relevées pour les couples des sulfoxydes **1**, **2** et **5**.

Un autre critère d'attribution de la configuration de la liaison SO est l'examen de la différence des déplacements chimiques

TABLEAU 5. Effets de solvant sur les déplacements chimiques des sulfoxydes *équatoriaux* et *axiaux*

$\Delta\delta = \delta_{Me_2CO\text{-}d_6} - \delta_{C_6D_6}$

Composés	H-4	H-3 *endo*	H-3 *exo*	H-5 *ax*	H-5 *éq*	H-7 *ax*	H-7 *éq*
1 *éq*	1,26	0,23	0,40				
2 *éq*	0,73	0,43	0,40	−0,09	0,52	−0,04	0,42
2 *ax*	0,72	0,11	0,17	—	—	—	—
4 *éq*	0,55	0,16	0,16	—	0,31	—	—
5 *ax*	—	0,34	0,31	0,07	0,65	0,04	0,65

TABLEAU 6. Constantes de couplages entre protons géminés en α de la liaison S → O (solvant C_6D_6)

	SO *équatorial*		SO *axial*	
Composés	$^2J_{H\text{-}5ax,\ H\text{-}5éq}$	$^2J_{H\text{-}7ax,\ H\text{-}7éq}$	$^2J_{H\text{-}5ax,\ H\text{-}5éq}$	$^2J_{H\text{-}7ax,\ H\text{-}7éq}$
1	13,0	13,0	16,0	16,0
2	12,6	12,4	14,8	14,2
5	12,6	12,4	15,6	14,0

entre le proton *axial* et le proton *équatorial* en α du groupe sulfinyle (règle du ΔνHα (9)). La littérature indique qu'en général ΔνHα est plus grand pour un sulfoxyde *équatorial* (par exemple pour les sulfoxydes du thiacyclohexane on trouve (10): Δν 0,87 et 0,48 ppm). Pour nos sulfoxydes les valeurs relevées (Tableau 4) sont en accord avec ce principe, ainsi qu'avec le fait que ΔνHα est sensible à la substitution où qu'elle soit dans la molécule.

2. *Effets de solvant*

Il est possible (9) d'appliquer aux sulfoxydes le modèle du complexe de collision proposé par Ledaal (11) (solvatation du site polaire par l'extrémité positive du dipôle) qui implique que les protons situés sur la face opposée à la liaison SO soient les plus blindés lorsqu'on compare les spectres réalisés dans la tétrachlorure de carbone à ceux obtenus dans le benzène (axe du benzène colinéaire avec l'axe du dipôle). Nos résultats (Tableau 5) sont en accord avec ces propositions. Les effets les plus marquants sont ceux observés pour les protons *équatoriaux* dans les cas de sulfoxydes *équatoriaux*. En ce qui concerne les sulfoxydes *axiaux* la complexité des signaux ne permet pas une attribution sûre des déplacements en cause.

3. *Constantes de couplage*

Les constantes de couplage entre protons géminés sont nettement différentes de celles observées (1) pour les dioxathiabicyclooctanes. En accord avec la littérature (voir la réf. 9 et réfs. citées), les constantes de couplage entre les protons géminés situés en α du groupe sulfinyle (Tableau 6) sont plus fortes lorsque la liaison SO est *axiale* ($|^2J|$14–15 Hz) que lorsque celle-ci est *équatoriale* ($|^2J|$ 11–13 Hz). Ce critère d'attribution de stéréochimie parait être le plus précieux de tous ceux utilisés jusqu'ici.

Les constantes entre protons géminés en C-3 (cyclo dioxolanne) sont du même ordre de grandeur (~7,2 Hz) que celles correspondant aux protons en même position dans les trioxabicyclooctanes (~7,0 Hz) (12), mais légèrement plus fortes que celles mettant en cause les mêmes protons dans les dioxathiabicyclooctanes (~6,5 Hz) (1). En revanche, aux erreurs de mesure près, on n'observe pas de différence lorsqu'on compare la constante de couplage des protons géminés en C-3 pour un sulfoxyde *axial* ou pour un sulfoxyde *équatorial*.

Ainsi que nous l'avons déjà signalé, un couplage ^4J (en W) met en cause le proton *exo* sur C-3 et le proton *axial* porté par C-5. Son intensité (mesurée directement sur le spectre analysable au premier ordre) atteint parfois une valeur anormalement importante (par exemple 2,8 Hz pour le composé **5**).

Stéréochimie de l'oxydation

Il est intéressant de revenir brièvement sur l'origine de l'importante *stéréo*sélectivité observée dans les réactions d'oxydation des dioxathiabicyclooctanes. En effet, l'utilisation comme agent oxydant de l'eau oxygénée ou de l'acide *méta*-chloroperbenzoïque conduit presqu'exclusivement aux sulfoxydes *équatoriaux;* même la mise en jeu de l'hypochlorite de *tert*-butyle, connu (8) pour donner très préférentiellement des sulfoxydes *axiaux*, ne mène dans notre cas qu'à 70% environ de composés présentant cette stéréochimie. Des facteurs stériques sont très vraisemblablement responsables en majeure partie de cette *stéréo*sélectivité. On peut en effet rapprocher nos résultats de ceux obtenus (Schéma 1) pour le thiacyclohexane (13) et pour les 6-méthoxy-2-hydroxyméthyl-1,4-oxathiannes (5) qui montrent l'influence déterminante de la présence d'un groupement *axial* en β de l'atome de soufre. On peut considérer que les dioxathiabicyclooctanes possèdent effectivement en β de l'atome de soufre un pont méthylènoxy stériquement proche de deux groupements en interaction *syn–axiale* avec une éventuelle liaison SO *axiale* (cf. Fig. 4).

Deutériation en α du groupe sulfinyle

Toutes nos attributions de la stéréochimie de nos sulfoxydes reposant jusqu'ici sur des critères de rmn, il était logique de tenter de les confirmer par une méthode chimique. Nous avons envisagé l'échange qui peut être réalisé entre un proton en α du groupement sulfinyle et un atome de deutérium. Katritsky et coll. (14) ont montré que le proton en conformation *trans* s'échange préférentiellement aux autres (l'échange pouvant être compétitif et mener aux deux composés en concurrence). Pour un sulfoxyde où la liaison S—O est *équatoriale*, c'est donc le proton *équatorial* en α qui doit s'échanger avec le deutérium. Nous avons étudié cette réaction en mettant en jeu le sulfoxyde **4** (Schéma 2), qui ne pose pas de problème de *régio*sélectivité. Après avoir été porté à 90°C pendant 72 h au sein de soude et dans l'oxyde de deutérium, le sulfoxyde **4** présente un spectre de rmn où le proton *équatorial* en 5 a disparu à plus de 95%; seul le signal du proton *axial* est observé

SCHÉMA 1

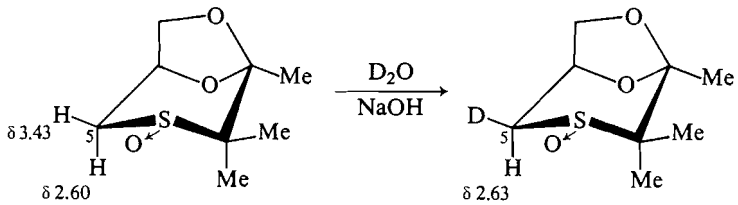

SCHÉMA 2

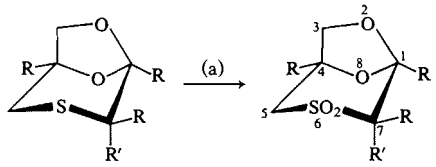
TABLEAU 7. Sulfones dérivés des 2,8-dioxa-6-thiabicyclo[3.2.1.]octanes



(a): *m*-$ClC_6H_4CO_3H$, CH_2Cl_2

Composés	R-1	R-4	R-7	R′-7
7	H	H	H	H
8	Me	H	H	H
9	Me	H	Me	H
10	Me	H	Me	Me
11	Me	Me	H	H
12	Ph	H	H	H

(à la précision près des mesures par spectrographie de rmn).

La position *axiale* du proton résiduel est déduite sans ambigüité de (*i*) la valeur du déplacement chimique du signal correspondant et (*ii*) de la présence d'un couplage ($^4J_{3,5}$ 1,5 Hz) en W avec le proton H-3 *exo*. Il semble que dans les conditions réactionnelles il n'y ait pratiquement pas de compétition entre les deux échanges stéréochimiques possibles. Ceci pourrait être dû à l'absence quasi-totale d'équilibre conformationnel dans la molécule de départ.

2,8-Dioxa-6,6′-dioxo-6-thiabicyclo[3.2.1]octanes

Les sulfones rassemblées dans le tableau 7 peuvent être préparées par oxydation des sulfoxydes correspondants par l'eau oxygénée en quantité stoechiométrique dans un solvant (généralement l'acétone); la réaction présente un rendement médiocre et n'est pas sans danger. Nous avons préféré opérer par oxydation directe du sulfure par un excès d'acide *méta*-chloroperbenzoïque.

L'intérêt de ces sulfones réside en premier lieu dans la comparaison de leurs caractéristiques spectrales (notamment en spectrographie de masse (15)) avec celles des sulfoxydes. Par ailleurs ces sulfones bicycliques sont intéressantes sur le plan synthétique notamment en raisons des possibilités de modifications structurales offertes par la réaction de Ramberg-Bäcklund.

On trouvera dans la partie expérimentale les critères d'identification des sulfones préparées. Indiquons simplement ici les points les plus importants concernant leurs spectres de rmn.

Si on compare les déplacements chimiques des sulfones à ceux des sulfoxydes correspondants, l'effet le plus remarquable est la disparition du déblindage que l'on pouvait observer sur les protons *axiaux* en α du groupe sulfinyle (particulièrement lorsque la liaison SO est *équatoriale*). Sauf pour le composé **12** les valeurs de $\Delta\delta$ ($\delta_{SO_2} - \delta_{SO}$) sont comprises entre 0,5 et 1,0 ppm. Cet effet peut être expliqué par la présence sur l'atome de soufre à la fois d'une liaison SO *équatoriale* et d'une liaison SO *axiale*.

En ce qui concerne les constantes de couplage entre les protons géminés en α du groupement sulfonyle, par exemple en position 5, leurs valeurs sont intermédiaires entre celles observées pour les protons portés par C-5 en α du groupe sulfinyle selon que la liaison SO est *axiale* ou *équatoriale*. (Exemple: $|^2J_{5,5}|$ 13,4 et 13,2 Hz pour les sulfones **8** et **11**; comparer avec les valeurs identiques dans le tableau 6 pour les sulfoxydes **2** et **4**.) Pour les autres protons de la molécule les valeurs des

[a]Les déplacements chimiques des atomes de carbone des sulfures **13**, **14** (deux stéréoisomères Me-7*éq* et Me-7*ax*) et **15**, correspondant respectivement aux sulfoxydes **2**, **3** et **4** sont donnés ici à titre de comparaison.

constantes de couplage sont du même ordre de grandeur (cf. partie expérimentale) que celles relevées dans le cas des sulfoxydes.

Spectres de rmn ^{13}C des dioxathiabicyclooctanes, de leurs sulfoxydes et de leurs sulfones

Les données de la littérature sur la rmn ^{13}C des molécules hétérobicycliques étant restreintes[2] nous pensons utile de commenter brièvement les résultats marquants, volontairement limités à l'étude des seuls déplacements chimiques (Tableau 8).

Si on compare les spectres des dioxathiabicyclooctanes à ceux des trioxabicyclooctanes homologues[3] on constate un déplacement important à champ fort des atomes de carbone en α de l'atome de soufre, tandis que cet effet est beaucoup moins marqué pour les autres atomes du bicycle.

Pour les sulfures, l'atome présentant le plus fort déplacement est le carbone acétalique C-1 tri ou tétrasubstitué et voisin de deux atomes d'oxygène. Son déplacement chimique augmente quand le nombre des substituants porté par l'atome de carbone voisin C-7 augmente. A 30 ppm environ à champ plus fort on trouve l'atome C-4 trisubstitué et voisin d'un atome d'oxygène. L'atome C-3 résonne environ à 4 ppm plus bas. Enfin les deux atomes C-5 et C-7 porteurs de l'atome de soufre résonnent à champ beaucoup plus fort et l'écart qui est observé entre leurs signaux respectifs (6 à 9 ppm) est attribuable à la différence d'environnement due à l'atome C-3 et à l'atome O-2 du pont méthylènoxy.

Quand on passe des sulfures aux sulfoxydes on observe un déblindage important (de 14 à 25 ppm) sur les atomes C-5 et C-7 dû à l'effet de l'atome d'oxygène de la liaison SO qui diminue la densité électronique sur ces atomes de carbone, ainsi qu'au changement d'hybridation de l'atome de soufre. Il est particulièrement intéressant de déceler les éventuels effets de la configuration *axiale* ou *équatoriale* de la liaison SO. Les rares travaux réalisés dans ce domaine (par exemple pour des sulfites cycliques (19), pour le sulfoxyde 1,4-oxathianne (20) ou pour les *cis* et *trans* 4-*tert*-butyle-5-thiane oxyde (21)) indiquent un blindage des atomes de carbone en β de la liaison SO *axiale*. Pour notre part lorsqu'on passe d'un sulfoxyde *équatorial* à un sulfoxyde *axial* on constate pour les atomes de carbone en β (atomes de carbone en tête de pont) un effet de blindage faible, bien que net, d'environ 1 à 2 ppm. Un effet de même sens est observé en ce qui concerne les atomes de carbone en α du groupe sulfinyle (Δδ 6 à 7 ppm).

Enfin il est intéressant de noter que l'atome de carbone C-3 du pont méthylèneoxy subit un blindage de 1 à 6 ppm lorsque le sulfoxyde est *axial*.

Un autre déblindage se manifeste quand on compare les déplacements de C-5 et C-7 dans les sulfoxydes à ceux observés dans les sulfones (de 2 à 5 ppm quand on passe du sulfoxyde *équatorial* à la sulfone, et de l'ordre de 9 ppm quand on passe du sulfoxyde *axial* à la sulfone). Il parait concevable que la présence de deux atomes d'oxygène sur l'atome de soufre modifie plus encore l'environnement des carbones voisins C-5 et C-7 et peut être tenu pour responsable du déblindage observé. Il est alors logique de penser que l'introduction d'un atome d'oxygène *axial* sur un sulfoxyde *équatorial* (où l'effet de blindage est le plus important) provoque un déplacement plus faible que dans le cas contraire où un atome d'oxygène vient en position *équatoriale* sur un sulfoxyde *axial*.

Partie expérimentale

Les points de fusion ont été déterminés sur un appareil Büchi SMP 20 K et ne sont pas corrigés. Les chromatographies en couches minces (ccm) ont été réalisées sur des plaques 5 × 2 cm prêtes à l'emploi Merck (couche de 0,25 mm de gel de silice 60); la détection est obtenue par projection d'une solution aqueuse d'acide sulfurique (30%), et chauffage à 150°C. Les R_f ont été mesurés sur des plaques de 20 cm de longueur, et leurs valeurs sont suivies de l'indication,

[2]Pour des séries hétérocycliques apparentées on peut citer les travaux réalisés sur les 1,4-oxathiannes (16), les sulfites cycliques (17) ou sur les sulfoxydes de pénicillines (18).

[b]Analyse effectuée sur le mélange des stéréoisomères.

entre parenthèses, de l'éluant utilisé. Les séparations sur colonne ont été obtenues avec le gel de silice 60 (granulométrie 70–230 ASTM, Merck). Les solvants utilisés ont été séchés selon les méthodes classiques et distillés sur une colonne statique de 130 cm de longueur. Les analyses par chromatographie en phase vapeur (cpv) ont été réalisées sur un appareil Hewlett–Packard modèle 5750 équipé d'une colonne Carbowax 20 M (3 mm × 3 m) et d'un détecteur à catharomètre (gaz vecteur: 30 mL d'hydrogène par minute). Les séparations d'échantillons par cpv ont été effectuées sur un appareil Varian–Aerograph 705 N muni d'une colonne Carbowax 20 M (9 mm × 6 m), détecteur à ionisation de flamme (gaz vecteur: 120 mL d'azote par minute). Les analyses ont été réalisées au Service Central de Microanalyse du CNRS. Les spectres de rmn du proton ont été réalisés sur les appareils Varian A 60 et Varian T 60 (découplage de spin); les abréviations classiques sont utilisées dans la description de ces spectres: s: singulet; d: doublet; dd: doublet de doublet; t: triplet; q: quadruplet; m: multiplet. Les déplacements chimiques sont indiqués en ppm par rapport au tétraméthylsilane; l'intensité relative de chaque signal est indiquée entre parenthèses; les constantes de couplage mesurées sur les agrandissements sont exprimées en Hz. Les spectres de rmn ^{13}C ont été enregistrés sur un appareil Brucker HFX 90 ou sur un appareil JEOL FX 60 avec découplage des protons par bruit. Les spectres ir ont été enregistrés sur un appareil Beckman IR 8.

L'étude de la fragmentation de ces composés sous l'impact électronique et (pour certains d'entre eux) par ionisation chimique a été publiée par ailleurs (15).

*2,8-Dioxa-6-oxo-6-thiabicyclo[3.2.1]octanes (**1–6**)*

Synthèse

(*i*) *Oxydation des sulfures par l'eau oxygénée*

A une solution de 20 mmol de dioxathiabicyclooctane (préparée selon la réf. 1) dans 40 mL d'acétone refroidie par un bain d'eau glacée, on ajoute en deux ou trois portions 20 à 25 mmol d'eau oxygénée à 110 volumes (solution commerciale). On agite et laisse le mélange revenir à température ambiante. On suit par ccm (éluant: acétate d'éthyle – méthanol 4:1) l'avancement de l'oxydation. Quand celle-ci est pratiquement terminée, on vérifie l'absence de peroxyde dans la solution et chasse l'acétone. Le résidu qui cristallise contient plus de 90% de sulfoxyde pour moins de 10% de produit de départ et des traces de sulfone. Le sulfoxyde est purifié par chromatographie sur colonne de gel de silice (éluant: acétate d'éthyle – méthanol 4:1). Rdt environ 50%.

(*ii*) *Oxydation par l'acide* méta-*chloroperbenzoïque*

On ajoute goutte à goutte un équivalent d'acide *méta*-chloroperbenzoïque en solution dans le chlorure de méthylène (20 mmol dans 20 mL de solvant) à une solution de 20 mmol de sulfure dans 40 mL de chlorure de méthylène refroidie à 0°C et agitée. On abandonne pendant une nuit au réfrigérateur. On filtre le précipité d'acide benzoïque, lave le filtrat avec une solution saturée de $NaHCO_3$, sèche (Na_2SO_4) et évapore le chlorure de méthylène après avoir vérifié l'absence de peroxyde. Rdt environ 90%.

(*iii*) *Oxydation par l'hypochlorite de* tert-*butyle*

A une solution de 10 mmol de sulfure dans 50 mL de méthanol, refroidie à −70°C et agitée magnétiquement, on ajoute, assez rapidement, 10 mmol d'hypochlorite de *tert*-butyle fraîchement préparé (22). On laisse la température remonter à −40°C et ajoute Na_2CO_3 anhydre. Quand le mélange est revenu à température ambiante, on filtre et chasse le méthanol. La ccm du résidu cristallisé indique alors la présence des deux sulfoxydes qui sont séparés par chromatographie sur colonne de gel de silice (éluant acétate d'éthyle – méthanol 8:1).

Identification

Les constantes physiques sont rassemblées dans le tableau 9. Dans tous les cas où la paire de sulfoxydes *axial* et *équatorial* a été obtenue, le point de fusion du stéréoisomère *axial* est supérieur (de 20 à 40°) à celui du sulfoxyde *équatorial*. Ceci est en accord avec ce qui est généralement observé dans la littérature (9). Nous mesurons des R_f plus faibles pour les sulfoxydes *axiaux* que pour les sulfoxydes *équatoriaux*.

Tous les composés décrits montrent en spectrographie ir une bande entre 1026 et 1046 cm^{-1} (solutions à 0,2% dans le méthanol) caractéristique (23) du groupement sulfinyle.

Les déplacements chimiques des protons sont donnés dans le tableau 10.

Deutériation en α du groupement sulfinyle

Elle est réalisée selon la méthode décrite par Katritzky et coll. (14). A une solution de 0,8 g du sulfoxyde **4** dans 10 mL de D_2O est additionné 0,2 g de NaOH pure. On porte alors au bain-marie pendant 72 h. Après retour à la température ambiante on extrait trois fois la solution par 30 mL de chloroforme, sèche (Na_2SO_4) et distille le solvant. Le produit brut isolé (0,7 g, rdt·87%) et purifié par chromatographie sur colonne de gel de silice (éluant: acétate d'éthyle – méthanol 4:1) est identifié au deutéro-5 triméthyl-1,7,7 dioxa-2,8 oxo-6 thia-6 bicyclooctane **4***d* (pf 146–147°C).

*2,8-Dioxa-6,6'-dioxo-6-thiabicyclo[3.2.1]octanes (**7–12**)*

Ces sulfones ont été préparées selon le mode opératoire décrit pour les sulfoxydes et utilisant l'acide *méta*-chloroperbenzoïque (soit une

For personal use only.

quantité stoechiométrique au départ des sulfoxydes, soit une quantité double au départ des sulfures). Rendements de 80 à 97% en produit purifié.

Les points de fusion des sulfones (Tableau 11) sont beaucoup plus élevés que ceux des sulfoxydes correspondants ce qui est sans doute l'indice d'une asymétrie moins prononcée pour la molécule. Les R_f des sulfones sont plus élevés que ceux des sulfoxydes correspondants et plus faibles que ceux des sulfures du départ. Ceci pourrait traduire une diminution de la polarisation (ou de la polarisabilité) de la liaison SO.

Toutes les sulfones décrites présentent en spectrographie ir une bande vers 1300–1301 cm^{-1} caractéristique (24) du groupement sulfonyle.

Les déplacements chimiques des protons sont donnés dans le tableau 12.

Reçu le 21 décembre 1982

PIERRE CALINAUD et JACQUES GELAS. Can. J. Chem. **61**, 2103 (1983).

La réaction de transformation de sulfoxydes hétérobicycliques (alkyl-2,8-dioxa-6-oxo-6-thiabicyclo[3.2.1]octanes) en α-acétoxysulfures (5-acétoxy- ou 7-acétoxy-2,8-dioxa-6-thiabicyclo[3.2.1]octanes) sous l'action de l'anhydride acétique (réaction de Pummerer) est décrite. La *régio-* et la *stéréo*-sélectivités de la réaction sont discutées.

PIERRE CALINAUD and JACQUES GELAS. Can. J. Chem. **61**, 2103 (1983).

The transformation of heterobicyclic sulfoxides (alkyl-2,8-dioxa-6-oxo-6-thiabicyclo[3.2.1]octanes) to α-acetoxysulfides (5-acetoxy- or 7-acetoxy-2,8-dioxa-6-thiabicyclo[3.2.1]octanes) by acetic anhydride (Plummerer reaction) is described. The regio- and stereoselectivities of the reaction are discussed.

Il a été montré par Pummerer (2) que l'anhydride acétique réagit sur les sulfoxydes au sein d'un solvant pour donner un α-acétoxysulfure. Bien qu'étendu à de nombreux sulfoxydes (3) le champ d'application de cette transposition n'a été que peu élargi à des molécules d'intérêt biologique. On peut cependant citer les travaux (*i*) de McCormick et McElhinney (4) qui préparent des analogues de sucres à atome de soufre dans le cycle à partir de composés thiophanniques; (*ii*) de Szarek et coll. (5) accédant à des modèles de nucléosides dérivés de 1,4-oxathiannes; (*iii*) de Kuszmann et Sohar (6) étudiant le réarrangement des sulfoxydes de thioanhydrohexitols; (*iv*) enfin de Matsumoto *et al.* (7) dans la série des illudines.

Les sulfoxydes des 2,8-dioxa-6-thiabicyclo[3.2.1]octanes (Fig. 1) constituent une base d'étude particulièrement intéressante puisque les α-acétoxysulfures *B* qu'ils peuvent permettre d'atteindre sont des hémiacétals cycliques sulfurés homologues structuraux de 1,6-anhydropyranoses et que les données physiques (concernant notamment l'effet anomère) ou chimiques de tels modèles ne sont pas nombreuses.

L'action de l'anhydride acétique à reflux sur les 2,8-dioxa-6-oxo-6-thiabicyclo[3.2.1]octanes (préparés par ailleurs (1)) permet d'accéder aux acétoxy-2,8-dioxa-6-thiabicyclo[3.2.1]-octanes. Un double problème est posé par une telle réaction: il s'agit d'une part de celui de la *régio*sélectivité de la réaction (le groupement acétoxyle pouvant être introduit en position 5 ou 7) et d'autre part de celui de la stéréochimie du groupement acétoxyle soit *axial*, soit *équatorial*. La détermination des déplacements chimiques et des constantes de couplages protoniques en rmn permet de résoudre ces deux problèmes, grâce à la connaissance de ces paramètres dans les dioxathiabicyclo-octanes (8).

Lorsqu'on met en jeu successivement les trois sulfoxydes **1**, **2** et **3** (Schéma 1), on obtient dans chaque cas avec un bon rendement (environ 75% après purification) le produit majoritaire de la réaction. Les spectres de rmn de ces composés (Tableau 1) sont très proches les uns des autres et correspondent aux structures des α-acétoxysulfures **6**, **7** et **8** pour les raisons suivantes. D'une part, tous ces spectres montrent vers 2,0 ppm un unique singulet dû au groupe acétoxyle. D'autre part, un doublet également unique apparait vers 6,0 ppm et correspond à un proton au pied du groupe acétoxyle. La cohérence de ces caractéristiques dans cette série fait attribuer la position 5 au groupe acétoxyle; en effet: (*i*) dans le cas du sulfoxyde **3** aucune *régio*isomérie n'est possible et le doublet à champ faible ne peut être dû qu'à un proton sur C-5; (*ii*) le spectre du composé **7** montre la persistance du quadruplet vers 3,30 ppm dû au proton *axial* sur C-7; (*iii*) le spectre du composé **6** montre par rapport à celui du sulfure homologue **1** (8) le maintien du signal dû aux protons en C-7. Enfin, dans les trois cas la valeur de la constante de couplage pour ce doublet (3,2 Hz) est compatible avec une stéréochimie *axiale* (H-5) et *équatoriale* (H-4) des protons en cause. Ce point est confirmé par la présence d'une structure fine sur les signaux de H-5 *axial* et H-3 *exo* et qui est due au couplage ^4J 0,8 Hz.

Que le produit nettement majoritaire dans ces réactions soit le dérivé *équatorial* 5-acétoxy est confirmé par le spectre de rmn effectué sur le produit brut de la réaction. Par exemple dans le cas de la réaction menant au dérivé **8**, on observe (outre un doublet à 6,18 ppm, J 3,2 Hz) un doublet (proportion environ 20%) dont les caractéristiques (δ 5,48 ppm, J 2,2 Hz) sont celles du proton H-5 *équatorial*.

Une confirmation est également fournie par l'observation du

FIG. 2.

déplacement chimique du quadruplet dû à H-7 *axial* pour le composé **7**: ce proton résonne à la même fréquence que celle observée dans le sulfure homologue non acétoxylé préparé par ailleurs (8) et on est contraint de rejeter la stéréochimie *axiale* de OAc-5 qui n'aurait pas manqué de déblinder le proton *syn–axial* H-7.

Lorsqu'on examine les spectres de rmn des fractions de purification contenant éventuellement des substances très minoritaires, il est parfois possible de faire des hypothèses sur la nature des sous-produits. Ainsi dans le cas de la mise en jeu du sulfoxyde **1** il nous a été possible d'isoler, avec un rendement n'atteignant pas 5%, un mélange dont le spectre de rmn montre, notamment, à champ faible, trois signaux d'inégale intensité, successivement: un singulet à 5,77 ppm attribuable à H-7 *axial* dans le dérivé **6***a* (Fig. 2); un doublet (δ 5,27 ppm, *J* 2,4 Hz) attribuable au proton H-5 *équatorial* dans le sulfure **6***b*; un singulet large (δ 5,16 ppm) attribuable au proton H-7 *équatorial* du composé **6***c*, l'élargissement observé étant très vraisemblablement dû à un couplage en W à travers l'atome de soufre avec le proton H-5 *équatorial* ($^4J < 0,5$ Hz).

Afin de confirmer la très forte *régio*sélectivité ainsi observée, nous avons examiné le cas du réarrangement des sulfoxydes **4** et **5** (Schéma 2). Pour ces deux cas l'analyse des produits de la réaction est plus délicate. Le sulfoxyde **4** conduit

à un mélange complexe qui ne peut être résolu par chromatographie sur colonne (pratiquement une seule tache en ccm, mais quatre pics très mal résolus en cpv). Son spectre de rmn révèle à champ faible quatre signaux dont les déplacements et les multiplicités sont en faveur de l'existence des quatre *régio* et *stéréo*isomères possibles du sulfure **9**. En revanche, il est possible d'isoler le composé majoritaire du mélange obtenu à partir du sulfoxyde **5**.

Son spectre de rmn est compatible avec la structure **10** (couplage ^4J en W) observé pour les protons H-5 *axial* et H-3 *exo* d'une part et d'autre part spectre de masse (9) cohérent avec les fragmentations observées pour les composés **6**, **7** et **8** et

[a]Éluant: acétate d'éthyle – méthanol 4:1.

démontrant[2] que le groupe OAc est fixé sur C-5.

En conclusion, nos observations peuvent se résumer de la manière suivante: une forte *régiosélectivité* est observée dans le réarrangement, le groupement acétoxyle se fixant de préférence sur C-5; une forte *stéréosélectivité* est constatée puisque le composé majoritaire (sinon unique) est celui où le groupe acétoxyle est en conformation *équatoriale*.

La connaissance du mécanisme du réarrangement de Pummerer a progressé considérablement, particulièrement ces dernières années (voir notamment la réf. 10, et références citées). Les auteurs s'accordent en général (11) pour proposer l'intervention d'un ion sulfocarbénium mésomère. Dans notre cas, il parait possible de proposer un mécanisme tel que celui indiqué sur le schéma 3. Selon ce mécanisme l'atome d'hydrogène en α de l'atome de soufre qui serait éliminé dans la première étape serait celui (*équatorial*) que nous avons par ailleurs reconnu comme étant spécifiquement échangeable par du deutérium (1). Un composé *équatorial* serait obtenu finalement par l'attaque selon (a), l'isomère *axial* étant obtenu par l'attaque (b) concurrente. On peut imaginer une participation de l'atome d'oxygène O-8 qui stabiliserait l'ion sulfocarbénium et modifierait la conformation du bicycle pour favoriser l'attaque selon (a) tant que le substituant Z (ici Z = H) en position 3 n'est pas suffisament encombrant pour l'empêcher.

Il est à remarquer enfin que l'effet anomère (qui est présent dans les trioxabicyclooctanes (12) et stabilise un groupement tel que OR en α de l'atome d'oxygène en conformation *axiale*) entre vraisemblablement en jeu dans nos modèles. Le caractère "cinétique" des produits obtenus semble donc acquis, mais il demande cependant à être confirmé par l'équilibration de ceux-ci. Malheureusement, nous n'avons pu jusqu'ici dans les conditions utilisées (acide paratoluènesulfonique ou éthérate de trifluorure de bore ou chlorure de zinc anhydre) réaliser cette anomérisation sans décomposition importante.

[2]Dans ce cas, il ne serait pas prudent de tirer des conclusions basées sur des spectres de rmn de mélange; en effet, en raison de la présence de deux groupements méthyle en tête de pont les protons au pied des groupes OAc se présentent tous sous forme de singulet plus ou moins large, et seule la spectrométrie de masse (9) permet une attribution définitive de structure.

Partie expérimentale

Pour les méthodes et indications générales, ainsi que pour la synthèse des sulfoxydes (**1–5**) voir la réf. 1.

*Synthèse des α-acétoxysulfures (**6–10**)*

Une solution du sulfoxyde (1 g) dans l'anhydride acétique (1 g) et 30 mL de benzène sec sont chauffés à reflux avec une trace d'acide paratoluènesulfonique pendant 3 à 12 h (on suit la disparition du sulfoxyde par ccm). On laisse refroidir la solution, neutralise ($NaHCO_3$) et distille le benzène. Les α-acétoxysulfures sont ensuite purifiés par chromatographie sur gel de silice (éluant: acétate d'éthyle – méthanol 5:1).

Identification

Les constantes physiques des acétoxydioxathiabicyclooctanes sont indiquées dans le Tableau 2. Tous les composés décrits montrent en spectrographie ir, par rapport aux sulfures de départ, l'apparition d'une bande située vers 1735–1745 cm^{-1} (solutions dans CCl_4) caractéristique du groupement OAc. Les spectres de rmn ont été décrits dans la partie théorique. Les spectres de masse ont été discutés par ailleurs (9).

Dielectric relaxation processes of some dialkyl disulfides

H. A. KHWAJA AND S. WALKER

Department of Chemistry, Lakehead University, Thunder Bay, Ont., Canada P7B 5E1

Received January 4, 1983

H. A. KHWAJA and S. WALKER. Can. J. Chem. **61**, 2107 (1983).

Dielectric relaxation studies have been performed for dimethyl, diethyl, di-isopropyl, di-n-butyl, di-*tert*-butyl, and di-n-octyl disulfides in a polystyrene matrix. For the last five compounds the absorption appears in two temperature regions. The relaxation data for the higher temperature regions are consistent with intramolecular rotation around the S—S bond with accompanying flexibility in the alkyl chains. The enthalpy barrier to this relaxation process is ~29 kJ mol^{-1} and is the *trans* (lower) barrier. This value is typical for all six dialkyl disulfides. The most likely interpretation of the low temperature process is that there is segmental relaxation of the alkyl chains which also involves movement of the main dipoles (S—S and S—C).

H. A. KHWAJA et S. WALKER. Can. J. Chem. **61**, 2107 (1983).

On a effectué des études de relaxation diélectrique sur les disulfures de méthyle, d'éthyle, d'isopropyle, de n-butyle, de *tert*-butyle et de n-octyle dans un support de polystyrène. Pour les 5 derniers composés l'absorption se manifeste dans deux zones de température. Les données de relaxation pour la région de haute température sont en accord avec une rotation intramoléculaire autour de la liaison S—S avec une flexibilité dans la chaine alkylée. La barrière d'enthalpie de ce processus de relaxation est de 29 kJ mol^{-1} environ et c'est la barrière *trans* (la plus basse). Cette valeur est typique pour tous les six disulfures d'alkyle. L'interprétation la plus courante de processus à basse température préconise une relaxation segmentaire des chaines d'alkyles qui implique également le mouvement des dipoles principaux (S—S et S—C).

Introduction

The existence of a barrier to rotation around the S—S link of a disulfide was established at least two decades ago, but experimentally determined barrier heights span quite a range. The rotation was frequently treated on a two-fold energy barrier model although in many measured values the *cis* and *trans* barriers were not separately identified. Two of the earlier studies on infrared spectra of dialkyl disulfides were those of Thompson and Trotter (1) and of Sheppard (2). At about the same time Scott and co-workers (3) reported the vibrational assignments of dimethyl disulfide (3*a*), diethyl disulfide (3*b*), and dimethyl di-n-propyl disulfide (3*c*), together with the collection of early data of infrared and Raman frequencies for thermodynamic studies. Detailed infrared and Raman spectra of di-*tert*-butyl disulfide were measured later by Scott and co-workers (3*d*). These investigations showed the presence of some rotational freedom about the S—S link. Through the use of calculated and observed entropy and heat capacity, an effective barrier height of 28.4 kJ mol^{-1} (3*c*) for the internal rotation around the S—S bond of dimethyl disulfide was deduced. El-Sabban and Scott (3*e*), using infrared data, reported a similar barrier height of 30.5 kJ mol^{-1}. From the Raman torsional frequencies for the S—S bond, barrier heights for dimethyl disulfide of 39.7 kJ mol^{-1} and 55.2 kJ mol^{-1} (3*b*) were obtained. Nuclear magnetic resonance data (4) yielded a somewhat larger barrier, 51.4 kJ mol^{-1} (*cis* barrier). By means of the millimeter-wave rotational spectrum of H_2S_2, Gordy and coworkers (5) concluded that the barrier to internal rotation is considerably higher than for the analogous H_2O_2 molecule (*cis* barrier, 29.3 kJ mol^{-1}; *trans* barrier, 4.6 kJ mol^{-1}) (6).

Molecular orbital studies on the H_2S_2 molecule have yielded barrier heights in the range 11.3–45.6 kJ mol^{-1} (*cis*) and 3.3–25.1 kJ mol^{-1} (*trans*). Boyd (7), using the EH method, has calculated a somewhat lower barrier for H_2S_2 of 6.3 kJ mol^{-1} (*cis*) and a *trans* barrier of 3.8 kJ mol^{-1}. For dimethyl disulfide, the PC1LO method (8) provided an equilibrium CS—SC dihedral angle of 100°, a *cis* barrier of 12.1 kJ mol^{-1}, and a *trans* barrier of 5.4 kJ mol^{-1}. Unlike the PC1LO method (8), the EH calculations produced a dihedral angle of about 90°, staggered methyl groups, and a barrier for rotation about the S—S bond of 29.3 kJ mol^{-1} (*cis*) and 9.2 kJ mol^{-1} (*trans*). More recently, Allinger *et al.* (9) have examined a two-fold barrier for dimethyl disulfide with a *cis* barrier height of 44.4 kJ mol^{-1} and a *trans* barrier height of 29.3 kJ mol^{-1}. Using the ZDO-SCF method, Perahia and Pullman (10), however, have estimated a surprisingly high *cis* barrier (~192 kJ mol^{-1}) and a *trans* barrier (60.7 kJ mol^{-1}).

Barrier heights to rotation about the C—S link in some dialkyl disulfides are reported in the literature. From an entropy approach (3*a*), a barrier height of 4.8 kJ mol^{-1} was determined for methyl group rotation in dimethyl disulfide. The EH calculation (7) indicated that, when the CSSC dihedral angle is large enough to avoid steric hindrance between the methyl groups, the barrier to rotation around C—S bonds in $(CH_3)_2S_2$ is 5.0 kJ mol^{-1}, which is in agreement with the experimental (11) barrier of 6.7 kJ mol^{-1}.

No dielectric study of the intramolecular energy barriers in dialkyl sulfides exists, and this approach offers a means of determining this and of studying the flexibility within these systems.

Experimental

The dialkyl disulfides treated here have the general formula R—SS—R (where R is methyl, ethyl, isopropyl, n-butyl, *tert*-butyl, and n-octyl). All of them were commercial samples (K & K and Aldrich Chemical Company) and their physical properties were in accord with the literature values. Each solute molecule was examined in a polystyrene matrix. The concentrations of solute in the polymer disks were sufficiently low (~5% by weight) to eliminate concentration effects (12). Atactic polystyrene was used which had a molecular weight ($\bar{M}_w$) value of 230 000. The preparation of the polystyrene matrices was the same as described by Davies and Swain (13).

Dielectric constants and the loss factor of solutes in the polymer matrix were obtained in the frequency range 50 to 10^5 Hz using a General Radio 1615A capacitance bridge incorporated with a suitable measuring cell from liquid nitrogen temperature to approximately 350 K. A detailed description of the apparatus, measurement techniques, and accuracy of the measurements is reported elsewhere (14, 15). In one case additional measurements were made on a Hewlett–Packard Q-meter type HP 4342A in the range 2.2×10^4 to 2.7×10^7 Hz.

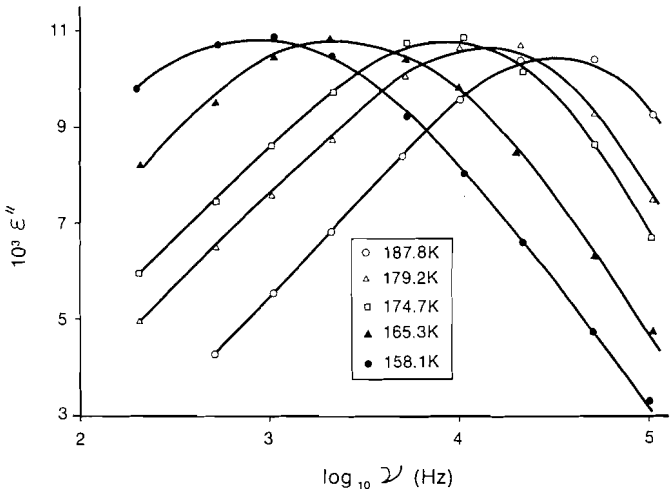

FIG. 1. Plot of loss factor against $\log_{10}$(frequency) at five temperatures for dimethyl disulfide in a polystyrene matrix.

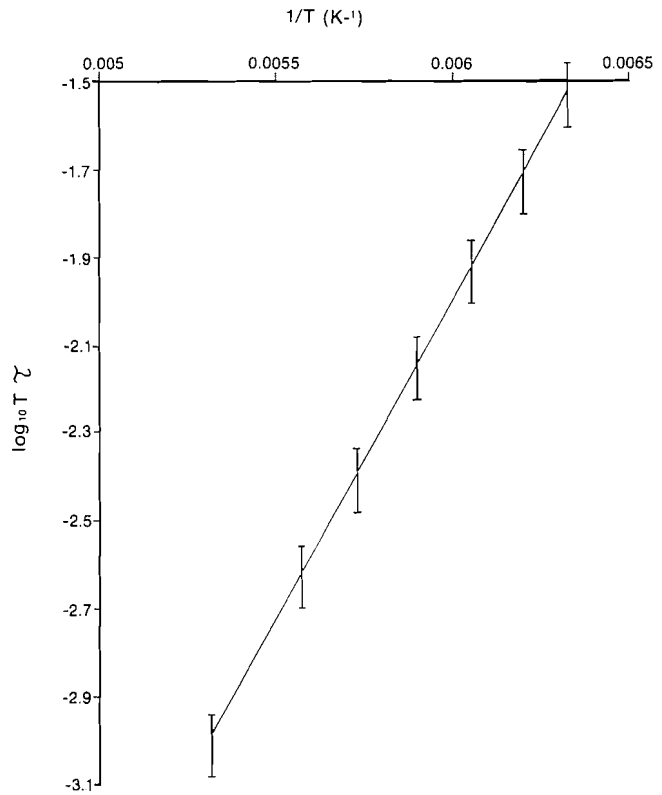

FIG. 2. Eyring plot for dimethyl disulfide in a polystyrene matrix.

Results

The loss due to the solute itself (ϵ''_{solute}) is calculated by subtracting the loss value of the pure polystyrene itself at that frequency and the same temperature. Thus, the loss due to the solute itself is given by

$$[1] \quad \epsilon''_{solute} = \epsilon''_{measured} - \epsilon''_{polystyrene} = \epsilon''$$

In Fig. 1 the ϵ'' values are plotted against $\log_{10}$(frequency) for dimethyl disulfide at five temperatures. Analyses of such curves through the use of the Fuoss–Kirkwood equation (16) (eq. [2]) yielded the maximum loss factor, ϵ''_{max}, mean relaxation time, $\tau\left(\frac{1}{2\pi\nu_{max}}\right)$, and the distribution parameter, β.

$$[2] \quad \cosh^{-1}(\epsilon''_{max}/\epsilon'') = 2.303\ \beta \log (\nu_{max}/\nu)$$

The resultant data for the molecules examined at a variety of temperatures are summarized in Table 1.

The energy barriers opposing the dipole reorientation were evaluated by using the Eyring rate expression:

$$[3] \quad \ln (T\tau) = \frac{\Delta H_E}{RT} - \frac{\Delta S_E}{R} + \ln (h/k)$$

where the terms have their usual significance. The enthalpies of activation and the entropies of activation were obtained from the slope and intercept, respectively, of the plot of $\ln (T\tau)$ against $1/T$, and with the help of a computer program. The program also calculated the relaxation time and the free energies of activation at different temperatures where:

$$[4] \quad \Delta G_E = \Delta H_E - T\Delta S_E$$

The Eyring analysis results are recorded in Table 2.

Standard statistical techniques were employed in the fitting and analyses of the data with the various computer programs, and the results such as the activation enthalpies and entropies were obtained with different confidence interval widths (17). For the present purpose, however, the 95% confidence interval was chosen as a good representation of experimental error: the error in ΔH_E was at worst $\pm 10\%$ or ± 3 kJ mol^{-1}, whichever is the greater, and the error of ΔS_E may be as high as $\pm 50\%$ of the nominal value in some cases, since the latter is often a small part of the intercept of the Eyring plot (1, 15). The errors could be reduced by extending the temperature and/or the frequency range.

Discussion

In symmetrical dialkyl disulfides, the components of the dipole moment of the two substituent groups along the long axis of the molecule (S—S bond) cancel, thus leaving zero permanent molecular dipole moment component along that axis. However, if there is no freedom of rotation about the S—S bond, the perpendicular components of the moment lead to a permanent dipole moment (μ). This is a similar situation to that of 1,4-diacetyl benzene (18) and terephthaldehyde (19). The possible relaxation processes relating to the perpendicular components of the μ are (*i*) molecular rotation, (*ii*) motion involving rotation about the S—S bond, or (*iii*) segmental motion involving rotation about flexible bonds which results in the movement of the S—S group.

All the dialkyl disulfides examined here except dimethyl disulfide exhibited two distinct families of absorption peaks, one in the 80–150 K region and the other in the 160–220 K region.

For dimethyl disulfide, a high temperature absorption in the range 158–188 K was observed with $\Delta H_E = 28$ kJ mol^{-1} and $\Delta S_E = 10$ J K^{-1} mol^{-1}. With rising temperature, the magnitude of ϵ''_{max} decreases for these dialkyl disulfides, which is in line with the observation of Davies and Swain (13) who recorded similar behaviour for an intramolecular process in cyclohexyl chloride and cyclohexyl bromide in polystyrene matrices. Also, the appreciably large Fuoss–Kirkwood distribution parameter, $\beta \sim 0.4$, is greater than that normally found for a molecular process in this temperature region. Such a large β suggests an intramolecular process.

The next member of the dialkyl disulfide series, diethyl disulfide, yields an activation enthalpy of 26 kJ mol^{-1} and absorbs around 180 K, which is in similar ranges of tem-

perature and frequency to dimethyl disulfide. As the data in Table 1 clearly show, the distribution parameter, β, values are significantly large (0.4–0.45) while the maximum loss factor, ϵ''_{max}, decreases with increasing temperature. The free energy of activation (ΔG_E = 28 kJ mol^{-1}) and relaxation time ($\tau = 4.6 \times 10^{-6}$ s) at 200 K also compare reasonably well with the corresponding data for dimethyl disulfide (ΔG_{E200} = 26 kJ mol^{-1} and $\tau_{200} = 1.7 \times 10^{-6}$ s). Such close similarity in relaxation data for the two systems of different molecular size suggests a common intramolecular process. For dimethyl disulfide, rotation about the S—S bond is the only feasible detectable dielectric absorption process for an intramolecular motion. This absorption cannot be attributed to an impurity in the polystyrene itself as this is taken into account in eq. [1] in the $\epsilon''_{polystyrene}$ term which includes the loss due to any impurity. Further, the difference in loss factor between the intramolecular process and $\epsilon''_{polystyrene}$ is appreciable, since the ϵ''_{max} of the intramolecular process is $\sim 11 \times 10^{-3}$ whereas the highest loss exhibited by the $\epsilon''_{polystyrene}$ at any of the temperatures and frequencies is 0.7×10^{-3}. Thus, even if $\epsilon''_{polystyrene}$ were neglected in eq. [1], it would not alter appreciably the Eyring parameters derived from the loss data.

For the high temperature absorption, when the size of the alkyl group is increased, di-isopropyl, di-n-butyl, di-*tert*-butyl,

and di-n-octyl disulfides, activation enthalpies of 31, 32, 30, and 28 kJ mol^{-1}, respectively, are obtained. For the temperature range of absorption in a given frequency range, significantly high "β" values (~0.4) and the decreasing behaviour of ϵ''_{max} with the rise of temperature (exception being the di-n-octyl disulfide) for these systems in each instance show similarity with the high temperature process of dimethyl and diethyl disulfides. In addition, the activation enthalpy does not reveal any sign of appreciable increase with increasing size of the molecule (20) on passing from dimethyl to di-n-octyl disulfide. On the contrary, it shows little variation, within the limits of experimental accuracy, and immediately discounts the relaxation of the molecule as a whole in favour of intramolecular relaxation in each of these dialkyl disulfides. Thus, altogether, the compounds have a similar ΔH_E value for the higher temperature process; in fact, the variation is only between 28 to 32 kJ mol^{-1} and shows no dependence on size or shape. This is in harmony with an intramolecular process and is strongly supported by the relatively high β values.

It is perhaps surprising that in the series dimethyl disulfide, diethyl disulfide, di-n-butyl disulfide, and di-n-octyl disulfide the ΔH_E values are 28, 26, 32, and 28 kJ mol^{-1}, and there is no increasing trend in the energy barrier as the size of the alkyl group increases since the activation energy for the intramolecular process may be expected to increase as the substituent size increases. In fact, the experimental error being ±3 kJ mol^{-1}, all the barriers are about 29 kJ mol^{-1}. An analogous study was made by Mazid *et al.* (21) on phenyl-alkyl ketones (C_6H_5COR, where R was varied between CH_3 to $C_{10}H_{21}$) in a polystyrene matrix. For eight such compounds the ΔH_E values ranged between 30 to 25 kHJ mol^{-1} with no apparent trend with increasing size of R. The main conclusion to be drawn from these Eyring activation parameters is that the length of the alkyl chain does not appreciably influence the energy barrier of the intramolecular process, which is essentially the same as that for acetyl group relaxation in acetophenone. It would seem likely that there is facile rotation about the $C_{aliphatic}$—$C_{aliphatic}$ bonds and that the effective volume swept out in the intramolecular motion is similar in each case.

Probably the results for the disulfide could be interpreted in precisely the same way where: (a) for dimethyl disulfide the rotation is about the S—S bond (and C—S bonds, but this would not be detected dielectrically for dimethyl disulfide); (b) for the other disulfides, relaxation about the S—S, C—S, and C—C bonds may occur. There is excellent agreement between our energy barrier value (ΔH_E = 28 kJ mol^{-1}) for intramolecular rotation in dimethyl disulfide and the 29.3 kJ mol^{-1} obtained for the *trans* barrier by Allinger *et al.* (9), one of the most recent studies on dimethyl disulfide. As Tay *et al.* (15) observed, for a two-fold energy barrier system the dielectric absorption technique yields a ΔH_E corresponding to the switch from the isomer with the higher energy to that of the lower. In the case of dimethyl disulfide, in terms of literature terminology this is described as the *trans* barrier. Allinger *et al.* (9) reviewed both the experimental and theoretical studies and concluded "that the *trans* barrier height of 29.3 kJ mol^{-1} is in good agreement" with those found from calorimetric data (3*d*) and from infrared data (3).

Dimethyl disulfide did not show a low temperature absorption although it was carefully measured from the lowest available temperature (77 to 300 K); this was also the case when the frequency range was extended to 2×10^7 Hz by measurement on a Hewlett–Packard Q-meter. The low temperature absorption of diethyl disulfide, di-isopropyl disulfide, di-n-butyl disulfide, and di-*tert*-butyl disulfide yielded enthalpies of activation of 11, 18, 18, and 12 kJ mol^{-1}, respectively. Examination of the data in Table 2 indicates similarity in behaviour amongst diethyl disulfide, di-isopropyl disulfide, di-n-butyl disulfide, and di-*tert*-butyl disulfide in the temperature range of absorption, the activation enthalpy and entropy, the relaxation of time, and free energy of activation at 100 K.

For the low temperature process there is probably an increase in ΔH_E with increasing size for the straight chain compounds. Thus, the ΔH_E values for diethyl, di-n-butyl, and di-n-octyl disulfides are 11, 18, and 25 kJ mol^{-1}. The relaxation times at 100 K follow the sequence 5.3×10^{-7}, 5.3×10^{-4}, and 2.8×10^{-1} s and also suggest that the size of the relaxing unit increases with increasing chain length. This is not the case, however, for the two non-straight chain compounds diisopropyl disulfide (ΔH_E = 18 kJ mol^{-1}, $\tau_{100\ K} = 2.6 \times 10^{-4}$ s), the values of which are correspondingly greater than for the slightly larger molecule di-*tert*-butyl disulfide (ΔH_E = 12 kJ mol^{-1}, $\tau_{100\ K} = 2.8 \times 10^{-6}$ s). The most likely interpretation of the low temperature process is that there occurs segmental relaxation of the alkyl chains which also involves movement of the main dipoles (S—S and S—C). For the straight chain compounds the longer chains involve contributions from larger reorienting units and in the limit could involve contributions from a molecular process. These concepts are in line with the findings of Khwaja and Walker (22) in a detailed study of

relaxation processes in alkyl-CHO compounds.

For all the five R—S—S—R compounds from dimethyl disulfide to di-*tert*-butyl disulfide, the temperature regions for relaxation of types (*ii*) and (*iii*) are well separated. However, in the case of di-n-octyl disulfide the two regions almost merge and the relaxation parameters will thus be subject to greater error.

The absence of the low temperature process for dimethyl disulfide is quite striking. This molecule is capable only of dielectric absorption involving molecular rotation and relaxation about the S—S bonds. A small molecule such as pyridine absorbs in the region of liquid nitrogen temperature (23). However, dimethyl disulfide is a significantly smaller molecule than this and would absorb at lower temperatures than liquid nitrogen (the lowest we have available) in our frequency range since the molecular relaxation time of the polar solute in a polystyrene matrix is highly dependent on size (20).

Conclusion

All the higher temperature dielectric relaxation data are consistent with the notion that in all dialkyl disulfides an intramolecular relaxation process occurs around the S—S bond with the enthalpy of activation barrier around 29 kJ mol^{-1}. The enthalpies of activation do not alter significantly when the size of the molecule is varied, and they all fall in the range 29 ± 3 kJ mol^{-1}. There is probably considerable flexibility about the C—C bonds in the alkyl groups.

Tay *et al.* (15) showed that the nmr, ultrasonic, and dielectric methods, which all employ transition state theory, yield similar energy barriers for intramolecular processes. However, the calorimetric, Raman, microwave, and infrared approaches yield barriers based upon the representation of the barrier (V) in terms of a Fourier series expansion and do not invoke the concept of entropy of activation. Only when the ΔS_E value is small, would agreement between ΔH_E and V values be sought. It is striking that for the intramolecular processes of dimethyl disulfide, where ΔS_E is quite small, there is excellent agreement between our ΔH_E, and the ones from theoretical calculations, and infrared and calorimetric methods (9). The main objectives of our work were to study flexibility in the dialkyl disulfides and to establish an intramolecular energy barrier from transition state theory for rotation about the S—S bond.

Structural analysis of 3-*C*-phosphonates, -phosphinates, and -phosphine oxides of branched-chain sugars[1,2]

JEAN-RICHARD NEESER,[3] JEAN M. J. TRONCHET,[4] AND ETIENNE J. CHAROLLAIS
Institut de Chimie Pharmaceutique et Pavillon des Isotopes de l'Université, 30 quai Ernest Ansermet, CH 1211, Genève 4, Switzerland

Received February 8, 1983

JEAN-RICHARD NEESER, JEAN M. J. TRONCHET, and ETIENNE J. CHAROLLAIS. Can. J. Chem. **61**, 2112 (1983).

A complete nmr study (^{1}H, ^{13}C, ^{31}P) of twelve 3-*C*-phosphonates, -phosphinates, and -phosphine oxide derivatives of 3-*C*-branched-chain pento- and hexo-furanoses is reported. For all compounds the configuration at C_3 is determined and, for oxaphospholanes **9** to **12**, the configuration at the asymmetric phosphorus atom. The $^3\boldsymbol{T}_2$ conformation of the furanose ring of acyclic derivatives **1** to **8** and the conformationally rigid *cis*-fused oxaphospholane-furanose bicyclic systems of **9** to **12** have been used to study the $^3J_{PCCH}$ vs. $\theta_{P,H}$ and $^3J_{PCCC}$ vs. $\theta_{P,C}$ relationships which are specific to this series of compounds. The use of the ν P=O ir stretching frequency, δ ^{31}P chemical shift, and $^1J_{P,C}$ coupling constant values in structural analysis of *C*-phosphorus-bearing sugars is also reported and discussed.

JEAN-RICHARD NEESER, JEAN M. J. TRONCHET et ETIENNE J. CHAROLLAIS. Can. J. Chem. **61**, 2112 (1983).

Nous décrivons l'étude par rmn (^{1}H, ^{13}C, ^{31}P) de douze dérivés ramifiés et phosphorés en C_3 (*C*-phosphonates, -phosphinates et -oxydes de phosphine) de pento- et d'hexo-furannoses. Pour tous les composés, la configuration en C_3 a été attribuée, de même que la configuration au niveau de l'atome de phosphore asymétrique pour les oxaphospholannes **9** à **12**. L'adoption de la conformation $^3\boldsymbol{T}_2$ par le cycle furannique des dérivés **1** à **8** d'une part, et la rigidité conformationnelle des systèmes bicycliques oxaphospholanno-furannosiques présentés par les produits **9** à **12** d'autre part, ont servi de base à l'établissement des relations $^3J_{PCCH}$ vs. $\theta_{P,H}$ et $^3J_{PCCC}$ vs. $\theta_{P,C}$, spécifiques à cette série de composés. Nous décrivons également comment les valeurs de la fréquence de vibration ir ν P=O, du déplacement chimique δ ^{31}P et de la constante de couplage $^1J_{P,C}$ peuvent contribuer à l'analyse structurale des dérivés phosphorés de sucres.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

Considering the increasing importance of branched-chain sugars, together with the biological interest of *C*-phosphorus-bonded derivatives of carbohydrates (as analogues of naturally occurring sugar phosphates), we were prompted to study the synthesis and the spectroscopic properties of a series of 3-*C*-phosphorus-bearing 3-*C*-branched chain sugars.

Syntheses, analytical data, and experimental details for compounds **1** to **12** (Fig. 1) have been reported elsewhere (2, 3). The present study concerns the spectroscopic properties and the structural analysis of the new derivatives, including configurational assignments at the new asymmetric centers (C_3 for **1** to **12** and the phosphorus atom for **9** to **12**) and conformational determinations. The ir P=O stretching frequency values for all compounds are given in Table 1 and the nmr data in Tables 2 to 6. The present work completes our previous spectroscopic studies of phosphate esters of pentofuranoses (1).

1. Structural analysis of phosphine-oxide derivatives 1 and 2

Examination of Table 2 immediately shows that configurational assignments at the C_3 atom for **1** and **2** can be simply deduced from a comparison between the δ H—C_1 chemical shift values of both of these compounds. Indeed, this proton is shielded by 0.72 ppm for **2**, compared with compound **1**. Such a strong shielding effect is best explained by postulating a preferred conformation for one of the phenyl groups attached to the phosphorus of **2**. Examination of Dreiding models clearly shows that only the *xylo* configuration (S_{C3}) allows a spatial arrangement for a phenyl group such that its anisotropic effect could influence the shift of the H—C_1 resonance of **2**.

Looking now at the coupling constant values (Table 2), it appears that the vicinal couplings $^3J_{PCCH}$ for **1** and **2** are very different: $J_{2,P}$ = 0 (**1**) or 8.3 Hz (**2**) and $J_{4,P}$ = 5.3 (**1**) or 22.6 Hz (**2**). The dependence of $^3J_{PCCH}$ values on dihedral angles has already been reported and related "Karplus-like" correlation relationships have already been proposed (4–8). As will be discussed later in the text, the literature survey shows that almost all previous studies are limited to the phosphonate derivatives (5–8). On the other hand, it is well known that such ^3J vs. θ relationships are always susceptible to factors other than dihedral angles, such as the electronegativity of the coupled atom substituents, the electronegativity of the substituents on the coupling route (as well as the orientation of these substituents), ring strain, and bond angle distortions. This observation rules out any hope of using a correlation established with phosphonate model-compounds for conformational assignment of the furanose ring of phosphine oxides **1** and **2**. However, a wide range of 1,2-*O*-isopropylidene-furanose derivatives has been extensively studied in many previous works (1, 9–11), including studies of 3-*O*-phosphate derivatives (1) and 3-*C*-phosphonate derivatives (10, 11). In almost all the cases, the $^3\boldsymbol{T}_2$ conformation (or the $_2\boldsymbol{T}^3$, which is very similar) was assigned as being preferred for the furanose ring; furthermore, this same conformation for the sugar ring enabled Evelyn and Hall (10, 11) to rationalize the very different $J_{2,P}$ and $J_{4,P}$ values of 1,2-*O*-isopropylidene-3-*C*-phosphonate derivatives of pento- and hexo-furanoses, which are epimeric at C_3. In like fashion, assignment of the $^3\boldsymbol{T}_2$ conformation (see Fig. 2) for the furanose ring of **1** and **2**, leads to a unique assignment of the *ribo* configuration for **1** (R_{C3}) and the *xylo* for **2** (S_{C3}). Thus, the $^3\boldsymbol{T}_2$ conformation for the furanose ring of **1** (*ribo* configuration) is consistent with the zero value of $J_{2,P}$ and the same twist form for **2** (*xylo* configuration) explains the large $J_{4,P}$ value (22.6 Hz) observed for this derivative. It is interesting to note that this latter coupling constant is much smaller than the same one measured by Evelyn and Hall (10, 11) on the spectra of similar

[1] Phosphorated sugars VII; V (ref. 1); VI (ref. 2).

FIG. 2. Configuration at C_3 and conformation of the furanose ring of acyclic derivatives **1** to **8**.

2. Structural analysis of acyclic phosphonate derivatives 3 to 8[5]

(A) *^1H nuclear magnetic resonance*

Examination of the data in Table 3 shows the influence of the diethoxyphosphono group on the chemical shift of the protons in its close neighbourhood. For pentofuranose derivatives epimeric at C_3 (e.g. **5** and **7**), H—C_4 of **5** is deshielded by 0.38 ppm with respect to its chemical shift value for compound **7**. A similar difference is observed for the chemical shifts of hexofuranose derivatives epimeric at C_3; thus for **6**, H—C_4 is deshielded with respect to **8** and an analogous deshielding for H—C_5 of **8** is observed with respect to the shift for **6**. Assuming that the three oxygenated substituents of the diethoxyphosphono group are responsible for such through-space deshielding effects, these observations immediately suggest assignment of the R_{C3} configuration for **5** and **6** (*ribo* for **5** and *allo* for **6**) and the S_{C3} configuration for **7** and **8** (*xylo* for **7** and *gluco* for **8**).

Looking now at the values of the $^3J_{PCCH}$ coupling constants for compounds **3** to **8**, Table 4 clearly shows the occurrence of differences which are of the same order of magnitude as those mentioned above for **1** and **2**. The comparison between **5** (**3**, **4**, **6**) and **7** (**8**) includes the zero value of $J_{2,P}$ for **5** (**3**, **4**, **6**) and the very large value of $J_{4,P}$ = 31.3 Hz for **7**. There are many previous reports relating the "Karplus-like" dependency of the $^3J_{PCCH}$ vicinal coupling constants on dihedral angles, for phosphonate derivatives. The first studies on this topic were made by Benezra and Ourisson (5, 6). Evelyn *et al.* (8), as well as Benezra (7), have extended this approach to various phosphonate derivatives, including phosphonates attached to 3-, 5-, or 6-membered rings, linear phosphonates, and α-hydroxy-phosphonates; Benezra has proposed the following $^3J_{PCCH}$ vs. θ_{PH} relationship (7):

$$^3J_{PCCH} = 18 \cos^2 \theta; \quad 0° < \theta < 90° \qquad [1]$$

$$^3J_{PCCH} = 41 \cos^2 \theta; \quad 90° < \theta < 180°$$

Application of the above equation seems, however, limited to the linear phosphonates and those attached to 5- and 6-membered rings; the α-hydroxy-phosphonates and the 3-membered ring containing derivatives involve much smaller vicinal coupling constant values. In the case of compounds **3** to

[5] In this text, the term "acyclic" refers to the phosphorus atom, where it is not involved in a heterocycle, distinguishing compounds **1** to **8** from "cyclic" derivatives having an oxaphospholane ring (**9** to **12**). Compounds **1** to **12** all contain a furanose ring.

TABLE 4. Coupling constants of acyclic phosphonates **3** to **8**

$^3J_{P,C3''}$	8.7	10.0	8.9	5.9	7.5	<4

8, smaller ^3J values than the ones predicted by eq. [1] can be anticipated, because of the presence of the electronegative $-O_2$ substituent on the $J_{2,P}$ coupling route and the electronegative $-O_4$ substituent on the $J_{4,P}$ coupling route. But, on the other hand, the $J_{2,P}$ and $J_{4,P}$ values typical for compounds **3** to **8** are very close to the ones measured by Evelyn and Hall for similar derivatives (10, 11) and, again, examination of Dreiding models leads to the unambiguous assignment of the same $^3T_2$ conformation for the furanose ring of all these derivatives (**3** to **8**), together with the R_{C3} configuration for **3**–**6** and the S_{C3} one for **7** and **8** (see Fig. 2).

(B) *^{13}C nuclear magnetic resonance*

Table 4 shows that another series of differences between **5** (**3**, **4**, **6**) and **7** (**8**) can be emphasized, based on the $^3J_{PCCC}$ coupling constant values measured from the ^{13}C nmr spectra of compounds **3** to **8**. Thus $J_{P,C1} = 10.1$–10.9 Hz (**3**–**6**) or zero (**7**, **8**), and $J_{P,C5} = 0$ (**3**–**6**) or 3.8–3.9 Hz (**7**, **8**). Previous workers have already reported a "Karplus-like" $^3J_{PCCC}$ vs. $\theta_{P,C}$ correlation for phosphonate derivatives (12, 13), and have discussed (14, 15) the susceptibility of this relationship to the electronegativity of substituents on the coupling route, their orientation, as well as its susceptibility to ring strain and bond angle distortions. From the $^3J_{PCCC}$ coupling constants measured on the ^{13}C nmr spectrum of a conformationally rigid phosphonate derivative of camphane, Thiem and Meyer have established the following correlation (16):

$$[2] \cdot \ ^3J_{PCCC} = 7.35 - 1.76 \cos\theta + 7.86 \cos 2\theta$$

These authors noted that α-hydroxy- or α-alkoxy-phosphonates involved coupling constant values 2–5 Hz smaller than those predicted by the above equation (16). More recently, consideration of various conformationally rigid 2-phosphorus-bearing norbornyl derivatives led Quin *et al.* to propose the following general equation (17):

$$[3] \quad ^3J_{PCCC} = A \cos^2\theta + B \cos\theta + C$$

with the following A, B, C values for the phosphonates:

$$A = 17.3; \qquad B = -4.7; \qquad C = -0.9$$

In the case of compounds **3** to **8**, we can expect smaller ^3J values than those predicted by eq. [2] or [3], because of the presence of the electronegative $-O_2$ and $-O_4$ substituents on the $J_{P,C1}$ and $J_{P,C5}$ coupling routes, respectively. However, examination of Dreiding models clearly shows that, in complete agreement with our previous conformational and configurational assignments, the large $J_{P,C1}$ values for **3**–**6** correspond to a large dihedral angle ($\theta \approx 150°$), the $J_{P,C5}$ values for **7** and **8** (3.8–3.9 Hz) for a θ angle close to 40°, and the zero values for $J_{P,C1}$ (**7**, **8**) and $J_{P,C5}$ (**3**–**6**) are typical for angles close to 70–80° (see Fig. 2 and Table 4). It is of interest to note that, if the $^3J_{PCCC}$ vs. $\theta_{P,C}$ relationship specific to our compounds has the same general form as that predicted by eq. [3], the typical minimum value has to correspond to a dihedral angle close to 80°. Thus, from the above correlations, we can infer that the $^3J_{PCCC}$ vicinal couplings typical for phosphonates **3** to **8** describe a "Karplus-like" dependency.

Examination of the $^1J_{P,C3}$ coupling constants for compounds **3** to **8** (Table 4) leads to the following observation: $^1J_{P,C3}$ for derivatives of R_{C3} configuration (**3**–**6**) is larger than the same value for derivatives of S_{C3} configuration (**7**, **8**). In previous works (15, 18–20) it has been reported that the values of one-bond ^{13}C—^{31}P couplings depend on the orientation of the phosphorus atom, when the dialkoxy-phosphoryl group substitutes a ring: $^1J_{C,Peq} > {}^1J_{C,Pax}$ (ref. 18). Thus from a comparison between this value for either **5** (151.2 Hz) and **7** (143.8 Hz) or **6** (150.2 Hz) and **8** (140.9 Hz), we observe differences of the order of 7.4 and 9.3 Hz, which are in complete agreement with previously reported values (18) between an equatorial orientation of the phosphorus atom and an axial one. In our case, this observation is an additional proof for our conformational and configurational assignments (see Fig. 2).

(C) *^{31}P nuclear magnetic resonance*

Examination of the δ ^{31}P chemical shift values (Table 3) for C_3 epimeric phosphonate derivatives leads to the following observation: this value is larger for **5** (R_{C3}) than for **7** (S_{C3}) and for **6** (R_{C3}) than for **8** (S_{C3}). Paulsen and Greve have already reported (21) a dependence of δ ^{31}P on the orientation of the phosphorus atom, similar to that of $^1J_{P,C}$: δ ^{31}Peq > δ ^{31}Pax (ref. 21). Again we consider this difference between the δ ^{31}P

chemical shift of epimeric phosphonate derivatives **5** and **7** (or **6** and **8**) as an additional proof of structure (see Fig. 2).

3. Structural analysis of oxaphospholane-ring-containing derivatives 9 to 12

(A) *Configurational assignment at the phosphorus atom of phosphinates 11 and 12*

Examination of Table 5 shows that the chemical shift values of the sugar ring protons for derivatives **9** to **12** provide excellent information for configurational assignment at the phosphorus atom of **11** and **12**; however, for phosphonates **9** and **10** the proton chemical shifts are much too close to allow any interpretation. For **11** and **12** the most important source of chemical shift differences between H—C_1 and H—C_2 (0.96 and 0.80 ppm respectively) must be the close proximity of the phenyl group to H—C_1 and H—C_2. Examination of Dreiding models immediately shows that the phosphorus configuration arising from an *endo* substitution of the phosphorus by the phenyl group (with respect to the oxaphospholane-furanose bicyclic fusion) is the only one which allows the appropriate orientation of the phenyl ring. This leads directly to the assignment of the *endo* configuration at the phosphorus atom of **12** (S_P) and to the assignment of the *exo* one for **11** (R_P).

(B) *Configurational assignment at the phosphorus atom of phosphonates 9 and 10*

Assignment of the configuration at the phosphorus atom for **9** and **10** poses a more difficult problem than for **11** and **12**. Dealing first with the $J_{P,H}$ coupling constant values, it appears that three groups of ^3J vicinal couplings emphasize the difference between **9** (**11**) and **10** (**12**): $J_{4,5proR}$ and $J_{4,5proS}$, $J_{P,5proR}$ and $J_{P,5proS}$, and finally $J_{P,3'A}$ and $J_{P,3'B}$; the first two groups of two coupling constants concern the conformation of the oxaphospholane ring for **9** to **12**, although the last two ^3J values relate to the conformational equilibria around the C_3—$C_{3'}$ bond. Compounds **9** to **12** present conformationally very restricted oxaphospholane-furanose bicyclic systems and the preferred conformation of the phosphorated heterocycle comes very probably as a result of the varying degrees of steric hindrance that both the *endo* or *exo* configurations at phosphorus can imply. The very similar $J_{4,5proR}$, $J_{4,5proS}$, $J_{P,5proR}$, and $J_{P,5proS}$ couplings for **9** and **11**, as well as the similarity between these same values for **10** and **12**, lead then to assignment of the same *endo* configuration at the phosphorus atom for **10** and **12** and the same *exo* one at this atom for **9** and **11**. Furthermore, examination of Dreiding models shows that the position of the phosphorus substituents can widely influence the conformational equilibria around the C_3—$C_{3'}$ bond, as a result of the close juxtaposition between the phosphorus substituents and the —CH_2CN chain. Thus the similar $J_{P,3'A}$ and $J_{P,3'B}$ coupling constants for **9** and **11** and the same relationship between these values for **10** and **12** confirms the above configurational assignment for **9** and **10**.

TABLE 6. Coupling constants of cyclic oxaphospholanes **9** to **12**

J (Hz)	Compounds			
	9	**10**	**11**	**12**
$J_{1,2}$	3.5	3.3	3.7	4.0
$J_{2,P}$	6.0	6.0	5.7	7.4
$J_{4,P}$	24.5	24.3	19.9	20.7
$J_{4,5proR}$	2.4	2.0	3.0	2.0
$J_{4,5proS}$	0	0	0	0
$J_{P,5proR}$	4.0	2.2	6.3	0
$J_{P,5proS}$	12.0	21.0	11.0	22.0
$J_{P,3'A}$	16.5	20.0	17.5	15.0
$J_{P,3'B}$	18.0	14.0	17.5	10.0
$^1J_{P,C3}$	122.2	122.5	79.5	79.3
$^2J_{P,C2}$	6.1	8.7	7.3	12.2
$^2J_{P,C3'}$	0	3.4	1.5	0
$^2J_{P,C4} + {}^3J_{P,C4}$	9.2	7.6	6.5	0
$^2J_{P,C5} + {}^3J_{P,C5}$	6.1	6.3	0	0
$^3J_{P,C1}$	0	0	0	0
$^3J_{P,C3''}$	6.1	3.8	4.3	<2
$^1J_{P,C(Ph)}$	—	—	138.5	144.0

Considering now the $J_{P,C}$ coupling constants, examination of Table 6 suggests the following comment: for compounds **9** to **12**, the $J_{P,C4}$ and $J_{P,C5}$ values represent the sum of a ^2J geminal coupling ($^2J_{POC}$ or $^2J_{PCC}$) plus a ^3J vicinal coupling ($^3J_{POCC}$ or $^3J_{PCCC}$). For P=O phosphoryl bond-containing organophosphorus compounds, the $^2J_{POC}$ (probably negative (14)) and the $^2J_{PCC}$ (which can change sign (14)) couplings are dependent on the ring strain (22), and on the stereochemistry of the phosphorus atom (23, 24); thus, it appears that the analysis of the $J_{P,C4}$ and $J_{P,C5}$ values cannot be completed for oxaphospholanes **9** to **12** because too many factors are responsible for both the $^2J_{P,C}$ and $^3J_{P,C}$ couplings.

Finally, observation of the $^3J_{P,C3''}$ couplings for compounds **9** to **12** suggests the following comment (see Table 6): a desire to estimate the precise contribution of this $^3J_{P,C}$ vicinal coupling in the conformational analysis of the rotameric composition around the C_3—$C_{3'}$ bond for **9** to **12** prompts comparison of this last constant with the $^3J_{P,3'A}$ and $^3J_{P,3'B}$ proton–phosphorus couplings, assuming that these three values represent the average between populations of three low-energy rotamers. In this regard, because $J_{P,3'A} + J_{P,3'B} = 35$ Hz for **11** and 25 Hz for **12**, we can anticipate a larger $J_{P,C3''}$ value for **12** than for **11**. Surprisingly, it is not so and $J_{P,C3''}$ is larger for **11** (4.3 Hz) than for **12** (<2 Hz); this observation emphasizes a probable susceptibility of the $^3J_{PCCC}$ couplings on the stereochemistry of the asymmetric phosphorus atom for phosphinates **11** and **12**: an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

anticlinal or *antiperiplanar* orientation between P=O and the C_3—$C_{3'}$ bond (*exo* configuration: **11**) implies a larger $^3J_{P,C3''}$ value than a *synperiplanar* one (*endo* configuration: **12**), against the anticipation deduced from the rotameric composition around the C_3—$C_{3'}$ bond. It is now of interest to note that similarly, $^3J_{P,C3''}$ is larger for phosphonate **9** than for **10**, together with the same value of $(J_{P,3'A} + J_{P,3'B})$ for both compounds. Thus, if the susceptibility of the $^3J_{P,C3''}$ coupling on the stereochemistry of the phosphorus atom for phosphonates **9** and **10** is similar to the one for phosphinates **11** and **12**, this observation would confirm the above configurational assignment for **9** and **10**.

(C) *Conformational assignment of the oxaphospholane-furanose bicyclic system for derivatives 9 to 12*

Use of ^3J coupling constants for conformational analysis requires careful selection of the constants and of the ^3J vs. θ correlation equations. Many authors have previously proposed correlation equations related to such proton–proton and proton–phosphorus couplings for various 1,2-*O*-isopropylidene-furanose derivatives (9), sugar-phosphates (1, 25), or phosphonate derivatives (see eq. [1]) (7). Given that the ^{1}H nmr spectra of compounds **9** to **12** exhibit three sets of vicinal coupling constants, $^3J_{HCCH}$ ($J_{1,2}$, $J_{4,5proR}$, and $J_{4,5proS}$), $^3J_{POCH}$ ($J_{P,5proR}$ and $J_{P,5proS}$), and $^3J_{PCCH}$ ($J_{2,P}$ and $J_{4,P}$), these compounds provide a stringent test. Furthermore, because these bicyclic systems are rigid and because the $J_{4,5proR}$ and $J_{4,5proS}$ values (as well as $J_{P,5proR}$ and $J_{P,5proS}$) are complementary, these couplings can be interpreted *qualitatively* by comparison of the observed values with those established for other derivatives. Thus the couplings between both the H—C_5 protons and the proton H—C_4 or the phosphorus atom can be compared with the values predicted by both the Lee and Sarma relationships (25) (which are well established for conformational assignment of 6-membered phosphate rings fused *cis* or *trans* to a five-membered sugar ring):

[4] $^3J_{HCCH} = 10.5 \cos^2 \theta - 1.2 \cos \theta$ (25)

[5] $^3J_{POCH} = 18.1 \cos^2 \theta - 4.8 \cos \theta$ (25)

In the same way, the $J_{2,P}$ and $J_{4,P}$ values can be compared with those predicted by the Benezra relationship (7) (see section 2, eq. [1]).

Dealing first with the $J_{4,P}$ values for derivatives **9** to **12** (Table 6), the large value of this coupling constant (19.9 to 24.5 Hz) implies an *anti-periplanar* orientation between H—C_4 and the phosphorus atom. Secondly, the small $J_{4,5proR}$ value (2–3 Hz), together with the zero $J_{4,5proS}$ value, indicates a very restricted conformational mobility around the C_4—C_5 bond. Examination of Dreiding models clearly shows that the couplings for compounds **9** to **12** are only compatible with five possible forms ($^3T_2$, ^3E, $^3T_4$, E_4, and $^0T_4$) for the furanose ring and three (^4E, $^4T_5$, and E_5) for the oxaphospholane ring.

The $J_{P,5proR}$ and $J_{P,5proS}$ values emphasize the difference between the preferred conformation of the oxaphospholane ring of **9** and **11**, and that preferred for the same ring of **10** and **12**. Thus, from examination of Dreiding models, together with the order of magnitude of these coupling constants, we derive:

for **9** and **11**:

$J_{P,5proR} = 4.0–6.3$ Hz; $90° < \theta \leq 120°$

$J_{P,5proS} = 11–12$ Hz; $120° < \theta < 150°$

for **10** and **12**:

$J_{P,5proR} = 0–2.2$ Hz; $\theta < 90°$

$J_{P,5proS} = 21–22$ Hz; $\theta > 150°$

Even from these approximate dihedral angles, we can assign unambiguously the ^4E conformation for the oxaphospholane ring of **9** and **11**, and a conformation intermediate between $^4T_5$ and E_5 for **10** and **12**. The adoption of this last conformation for **10** and **12** implies that the furanose ring is held in a conformation intermediate between the E_4 and the $^0T_4$ forms, which completes the conformational assignment for both the heterocycles of **10** and **12**.

The $J_{1,2}$, $J_{2,P}$, and $J_{4,P}$ values (Table 6) are very similar for compounds **9** to **12**. They clearly indicate that the furanose rings of **9** and **10** adopt the same form, which was assigned above for **10**, as $E_4/^0T_4$. The smaller value of $J_{2,P}$ for **11** than for **12** implies an increase of the related dihedral angle ($\theta < 90°$) for **11** and, in the context of the ^4E from previously assigned for the oxaphospholane ring, this requirement is only compatible with the $^3T_2$ conformation for the furanose ring of **11**. The above conformational assignments for derivatives **9** to **12** are depicted in Fig. 3.

Finally, it is of interest to note that, for dioxaphosphorinane derivatives of phosphonates, the ν P=O stretching frequency, the δ^{31}P chemical shift, and the $^1J_{P,C}$ coupling constant between an aliphatic substituent on phosphorus and this last atom, all these three values can be used in structural analysis, because of their dependence on the orientation of the P=O bond with respect to the ring conformation (26). For derivatives **9** to **12**, it has not been possible to study if such a dependence existed in the case of oxaphospholane rings, because the ^4E form (**9**, **11**) as well as the $^4T_5/E_5$ one (**10**, **12**) allow an isoclinal orientation of both the substituents on phosphorus. Thus **9** and **10** (and **11** and **12**) cannot be compared with respect to the orientation of the P=O bond, this orientation being the same for the four compounds.

4. Spectroscopic properties of 3-*C*-phosphorus-bearing derivatives of pento- and hexo-furanoses

(A) *"Karplus like" relationships for* $^3J_{P,H}$ *vs.* $\theta_{P,H}$

As discussed in sections 1 and 2, the available nmr data suffice for assignment of the $^3T_2$ conformation for the furanose ring of acyclic derivatives **1** to **8**; furthermore, the conformational rigidity of the bicyclic systems for **9** to **12** allows for the assignments given in section 3. Thus, we can now measure the relevant dihedral angles from Dreiding models of the assigned conformations (for **1** to **8**, see Fig. 2; for **9** to **12**, see Fig. 3), and finally report the $^3J_{PCCH}$ coupling constants as a function of the dihedral angles; this is summarized graphically in Fig. 4. Some comments are appropriate.

Assuming that the $^3J_{PCCH}$ dependence on dihedral angle can be represented by a function having the form $[A \cos^2 \theta + B \cos \theta + C]$, the values for the phosphonate derivatives **3** to **8** correspond to eq. [6]:

[6] $^3J_{PCCH} = 24.8 \cos^2 \theta - 10.0 \cos \theta$

A comparison between the above equation and the Benezra relationship (7) (eq. [1]) leads to the conclusion that the typical vicinal coupling constants for phosphonates **3** to **8** are slightly smaller than those predicted by the Benezra equation. As anticipated, very probably this is because of the presence of electronegative substituents along the coupling routes ($-O_2$ for $J_{2,P}$ and $-O_4$ for $J_{4,P}$) in the carbohydrate derivatives.

From a comparison of the $^3J_{PCCH}$ values of the phosphine oxide derivatives **1** and **2** with those of the phosphonates **3** to **8**, it is clear that those of the phosphine oxides (**1**, **2**) are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

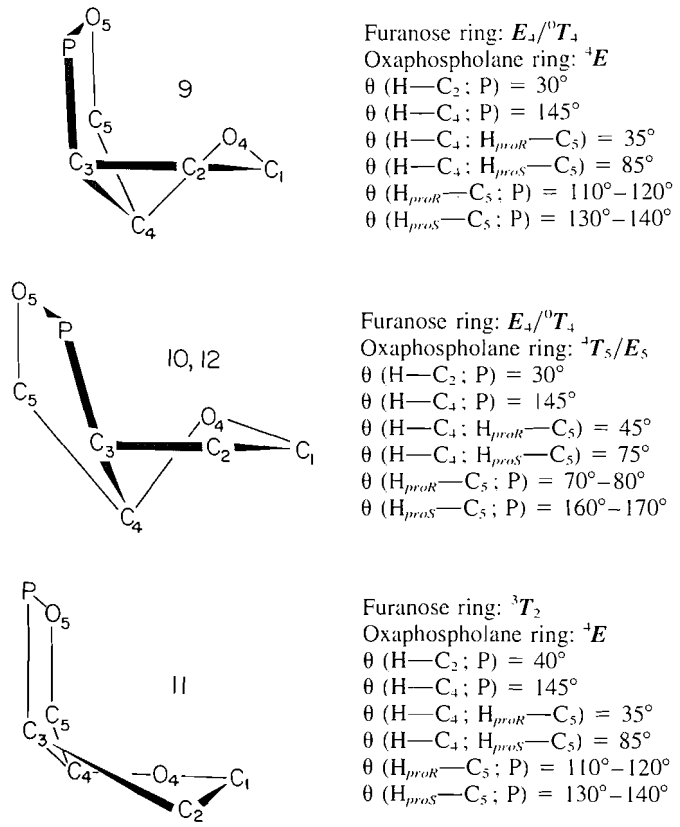

FIG. 3. Conformations of furanose and oxaphospholane rings of cyclic derivatives **9** to **12**.

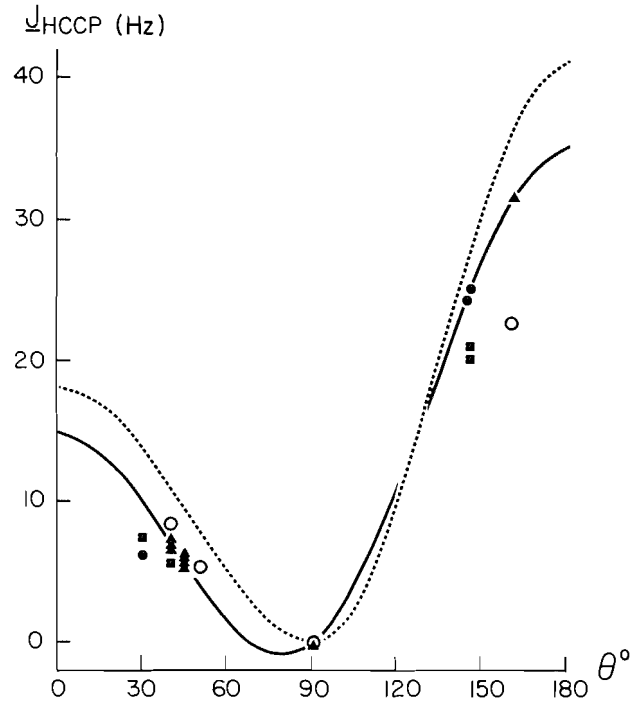

FIG. 4. $^3J_{HCCP}$ vs. $\theta_{P,H}$ relationships; (——) ▲, acyclic phosphonates **3** to **8**; ○, phosphine oxides **1** and **2**; ●, cyclic phosphonates **9** and **10**; □, cyclic phosphinates **11** and **12**; (- - -) phosphonates studied in ref. 7.

slightly larger in the first part of the curve ($0 \leq \theta < 90°$), but smaller for $90° < \theta \leq 180°$ (see Fig. 4). This observation suggests that in the general "Karplus-like" correlation equation, the importance of the *B* factor (operating on the cos θ term) decreases with the electronegativity of the phosphorus substituents; similar observations can be deduced from a comparison of the $^3J_{POCH}$ values of phosphonates and phosphates (27), as well as from a comparison of the $^3J_{PCCC}$ values of phosphonates and phosphine oxides (17).

To estimate the effect of the *cis*-fused oxaphospholane ring closure on the $^3J_{PCCH}$ coupling constants, we can now compare the typical values reported for the phosphonates **9** and **10** with the specific ones for acyclic derivatives **3** to **8** (see Fig. 4). Thus, although closure of the oxaphospholane ring seems to affect drastically the $^3J_{PCCH}$ value related to $\theta = 30°$, its effect on the coupling corresponding to $\theta = 145°$ is very small. In this regard, it is of interest to note that the $^3J_{HCCH}$ coupling constants specific for phosphonates **9** and **10** ($J_{4,5proR}$ and $J_{4,5proS}$), which correspond to small dihedral angles, are drastically smaller than those predicted by the Lee and Sarma relationship (25) (eq. [4]); on the other hand, the $^3J_{POCH}$ coupling constants specific for the same phosphonates **9** and **10** ($J_{P,5proR}$ and $J_{P,5proS}$), but which correspond to large dihedral angles, are in complete agreement with the Lee and Sarma relationship (25) (eq. [5]). Thus, it seems that the $^3J_{HCCH}$, $^3J_{PCCH}$, and $^3J_{POCH}$ vicinal coupling constant values are susceptible to the closure of a *cis*-fused oxaphospholane ring only when they are related to small dihedral angles ($0° < \theta < 90°$).

(B) *"Karplus-like" relationships for* $^3J_{P,C}$ *vs.* $\theta_{P,C}$

Here too, examination of Dreiding models permitted measurement of the typical carbon–phosphorus dihedral angles which could be correlated with the $^3J_{PCCC}$ coupling constants of the acyclic phosphonate derivatives **3** to **8**. Again, assuming that the dependence of these coupling constants on the dihedral angles has the general form predicted by eq. [3], the corresponding $^3J_{PCCC}$ vs. $\theta_{P,C}$ relationship (Fig. 5) is summarized in eq. [7]:

$$[7] \quad {}^3J_{PCCC} = 10.3 \cos^2 \theta - 3.0 \cos \theta$$

A comparison between the above equation and that proposed by Quin *et al.* (17) (eq. [3]) shows that the specific vicinal coupling values for compounds **3** to **8** are much smaller than those predicted by eq. [3]. If this decrease in ^3J values is attributed solely to the presence of electronegative substituents along the coupling routes for **3** to **8**, it is interesting to note that these substituent effects are much larger on the $^3J_{PCCC}$ values than on the $^3J_{PCCH}$ couplings.

(C) *Use of* ν P=O, δ ^{31}P, *and* $^1J_{P,C}$ *values in structural analysis of* C-*phosphorus-bearing carbohydrates*

Many empirical "rules" have already been reported whereby the value of the ν P=O stretching frequency, the δ ^{31}P chemical shift value, or the $^1J_{P,C}$ coupling constant can be used for the structural analysis of organophosphorus compounds (1, 15, 18–21, 26, 28–32). It appears that these three parameters are frequently dependent on the same structural factors. Fig. 6 illustrates this dependence for compounds **3** to **12**, and three points merit comment.

(*i*) Examination of Table 1 clearly shows that the ν P=O ir stretching frequency value, as expected, decreases with the electronegativity of the phosphorus substituents. A comparison of the δ ^{31}P and $^1J_{P,C}$ values of **9** (**10**) and **11** (**12**) leads to the same observation (see Fig. 6).

(*ii*) As already stated (see sections 2(B) and 2(C)) two C_3-epimeric 3-*C*-phosphonate derivatives (**5** and **7**, or **6** and **8**)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12

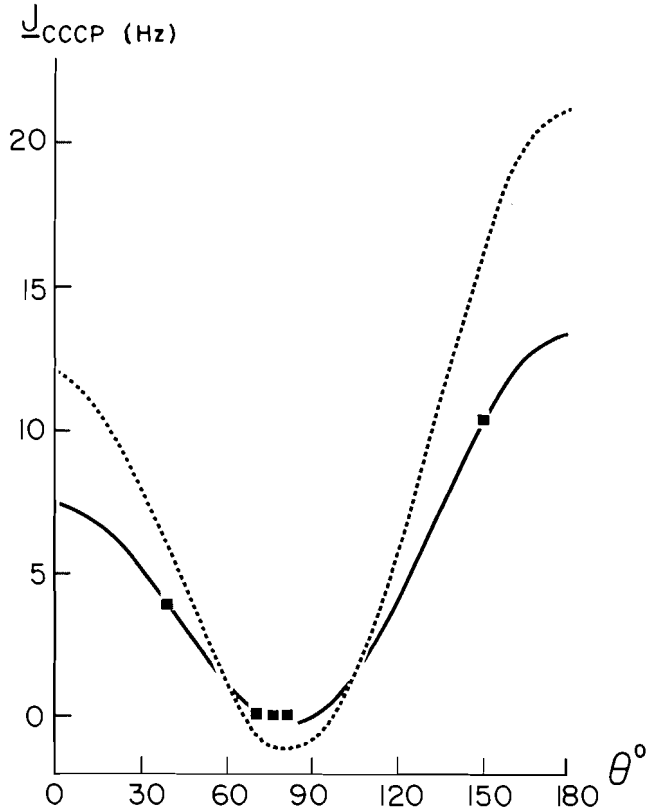

FIG. 5. $^3J_{CCCP}$ vs. $\theta_{P,C}$ relationships; (——) ■, acyclic phosphonates **3** to **8**; (- - -) phosphonates studied in ref. 17.

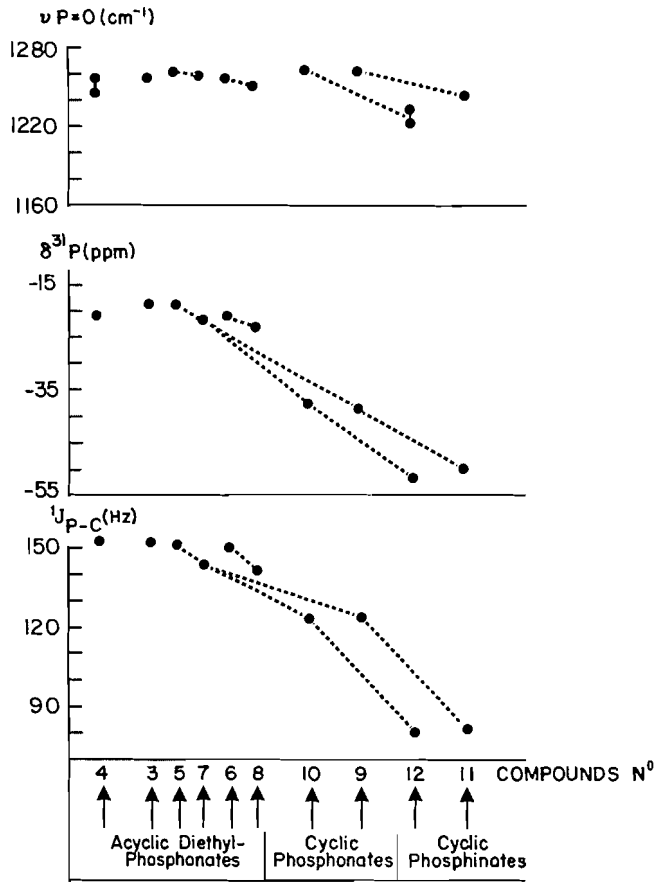

FIG. 6. Correlations of ir/nmr data and structure of *C*-phosphorus-bearing sugars.

can be compared using these values because of their dependence on the orientation of the phosphorus atom with respect to the furanose ring conformation.

(*iii*) The oxaphospholane ring closure does not affect the ν P=O stretching frequency value, although it does affect both the δ ^{31}P and the $^1J_{P,C}$ values (compare **7** and **9** (**10**)).

Réduction électrochimique de cétones aromatiques encombrées en milieu aprotique et en présence de chlorure de manganèse

FRANÇOISE FOURNIER, JACQUES BERTHELOT ET YVES-LOUIS PASCAL
Laboratoire de Chimie Organique Structurale, CNRS ERA 557, Université Pierre et Marie Curie, Bâtiment F, 4 Place Jussieu, 75230 Paris Cedex 05, France

Reçu le 27 janvier 1983

FRANÇOISE FOURNIER, JACQUES BERTHELOT et YVES-LOUIS PASCAL. Can. J. Chem. **61**, 2121 (1983).

La réduction électrochimique de cétones aromatiques encombrées et peu réductibles est réalisable en milieu aprotique (DMF), sur cathode de mercure, en présence de chlorure de manganèse, à un potentiel correspondant au système Mn(II)/Mn(0), mais beaucoup moins négatif que celui de réduction de la cétone elle-même. Il y a hydrodimérisation sélective en glycol-α et absence totale de polymérisation. Dans le cas de cétones dissymétriques, les diastéréoisomères *dl* sont formés préférentiellement. L'action du manganèse est dûe soit à la réduction d'un complexe de manganèse (à bas degré d'oxydation) – cétone, soit à la réduction de la cétone par un film de manganèse colloïdal sur la surface de l'électrode.

FRANÇOISE FOURNIER, JACQUES BERTHELOT, and YVES-LOUIS PASCAL. Can. J. Chem. **61**, 2121 (1983).

The electrochemical reduction of hindered aromatic ketones which are difficult to reduce can be achieved in an aprotic medium (DMF) on a mercury pool cathode, in presence of Mn(II) chloride, at the reduction potential of the Mn(II)/Mn(0) system, but less negative than that of the ketone itself. There is selective hydrodimerization into an α-glycol, with total lack of polymerization. With dissymmetric ketones, the *dl* diastereoisomers of the diols are produced preferentially. The effect of manganese is due either to the reduction of a Mn(I) or Mn(0) – ketone complex or to the reduction of the ketone by a film of colloidal manganese on the electrode surface.

Introduction

La réduction électrochimique d'aldéhydes et cétones aromatiques en milieu aprotique, en particulier dans le diméthylformamide (DMF), a suscité quelques travaux (1). L'avantage d'un tel milieu est surtout une grande étendue de la zone d'électroactivité d'où une bonne séparation des potentiels de réduction correspondant aux différents transferts électroniques. Selon les cas, l'électrolyse conduit à des glycols-α et à des alcools, mais les rendements sont souvent très diminués par des réactions de polymérisation.

La réduction de cétones aromatiques dans le DMF en présence de Cr(II), électrogénéré à partir de sels de Cr(III) favorise souvent l'hydrodimérisation en diol et inhibe totalement les polymérisations. En règle générale, que la cétone seule soit plus facile ou plus difficile à réduire que Cr(II), la réduction en présence du métal se fait toujours à un potentiel moins négatif que le $E_{1/2}$ de la cétone (2–5). Malgré tout, la sélectivité de cette réaction d'électroréduction assistée est difficile à relier aux valeurs respectives des potentiels de réduction des composés organiques et du sel métallique. De plus, pour les cétones dont le $E_{1/2}$ est plus positif que celui de Cr(II), on pourrait penser qu'il s'agit là de réduction chimique par les espèces Cr(II) électrogénérées; en effet les résultats sont les mêmes que ceux obtenus par action du chlorure ou de l'acétate chromeux (5).

Nous présentons ici les résultats de la réduction électrochimique de cétones aromatiques, en milieu organique aprotique, en présence de sel de manganèse Mn(II). Par rapport aux sels de chrome précédemment étudiés (4, 5), ce système ne présente pas la complexité engendrée par l'existence du système Cr(III)/Cr(II) et évite la compétition entre le phénomène électrochimique et la réduction chimique par le chrome(II). Les cétones étudiées dans ce travail sont représentées dans Fig. 1.

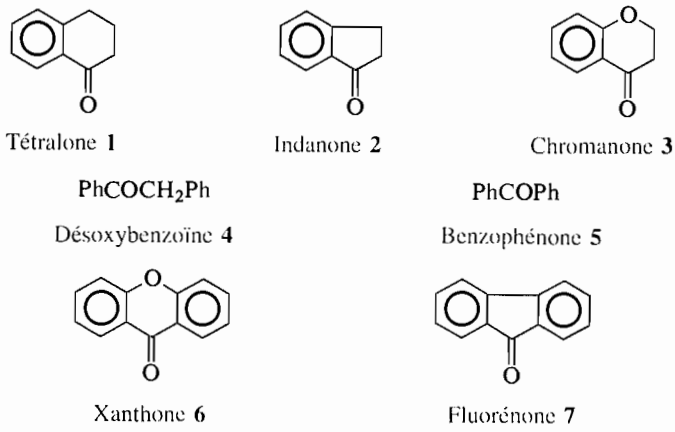

FIG. 1

Résultats et discussion

Analyse polarographique et voltammétrique

Les mesures ont été effectuées par rapport à l'électrode au calomel saturé (ECS) à double jonction, l'électrolyte support étant une solution de bromure de tétrabutyl ammonium (TBABr) 0,1 *M* dans le diméthylformamide (DMF).

Dans ces conditions, le polarogramme d'une solution de $MnCl_2 \cdot 4H_2O$ (10^{-3} *M*) présente une seule vague de réduction biélectronique, irréversible à $E_{1/2} = -1{,}55$ V (système Mn(II)/Mn(0)); dans le DMSO, pour le même système, $E_{1/2} = -1{,}68$ V (6). En voltammétrie cyclique, en utilisant une goutte de mercure chaque fois renouvelée (électrode de Kémula) et pour des balayages effectués après agitation sous argon, de la solution de chlorure de manganèse, on observe une variation linéaire du potentiel du pic de réduction du système Mn(II)/Mn(0) avec le logarithme de la vitesse de balayage v (dans l'intervalle 5 mV s^{-1} à 500 mV s^{-1}), avec une pente très faible d'environ 20 mV par décade de v. Avec une goutte non renouvelée, les voltamogrammes se modifient à chaque cycle.

Les cétones étudiées (Tableau 1) présentent toutes une première vague polarographique de nature réversible. Cette vague correspond à l'échange d'un électron comme le montre la comparaison avec le polarogramme du benzaldéhyde (à 10% près) dont la première vague est monoélectronique (7) et le coefficient de diffusion peu différent de ceux des cétones étudiées. Leur deuxième vague de réduction (monoélectronique et irréversible) n'est pas toujour visible car masquée par la décharge du sel de fond.

$^{a}E_{1/2}$ (V) = potentiel de demi-vague polarographique, par rapport à l'électrode à calomel au KCl saturé. Solvant DMF; sel de fond TBABr 0,1 *M*.
$^{b}E_{1/2}$ (V) = vague du complexe cétone – Mn(II).
$^{c}E_{1/2}$ (V) = vague du complexe cétone – Cr(II).

Si à une solution 10^{-3} *M* en cétone, on ajoute des quantités croissantes de Mn(II), on observe d'abord une diminution régulière des vagues de la cétone tandis qu'apparaît une nouvelle vague aux alentours de −1,50 V. La hauteur de cette vague devient maximale pour un mélange équimoléculaire de cétone et de sel de manganèse. Pour ce rapport 1:1 les vagues de la cétone ont complètement disparu.

De la même façon, lorsqu'on ajoute la cétone à une solution 10^{-3} *M* de chlorure de manganèse(II), la vague de réduction Mn(II)/Mn(0) se déplace très peu jusqu'à la valeur précédemment obtenue (−1,50 V) (mélange cétone – sel de manganèse). Après l'équimolarité, les vagues propres à la cétone se superposent à la courbe $i-E$ précédente.

Les mêmes observations avaient été faites dans le cas d'un mélange cétone – sel de chrome. Dans ce dernier cas, à l'équimolarité, la vague polarographique unique (système Cr(II)/Cr(0)) est controlée par la diffusion et avait été attribuée à l'existence d'un complexe chrome(II)–cétone (2–5).

L'analyse par voltammétrie cyclique de ce mélange Mn(II)–cétone a été réalisée en prenant la tétralone comme exemple.

Sur le voltammogramme du mélange équimolaire (Fig. 2) le pic de réduction Mn(II) en Mn(0) n'est pas modifié par la présence de la cétone; de même le pic de réduction de la cétone n'est pas modifié par la présence de l'espèce Mn(II). Enfin au balayage retour, apparaît le pic de réoxydation de la cétone (système réversible). Cette indépendance des deux systèmes en présence est vérifiée pour toute vitesse de balayage supérieure à 5 mV s^{-1}. Pour 5 mV s^{-1} (vitesse d'enregistrement usuelle du polarogramme), il apparaît un seul pic de réduction à un potentiel voisin du potentiel de réduction Mn(II)/Mn(0) et en balayage retour n'apparaît aucun pic de réoxydation de la cétone. A cette vitesse, la seule espèce réduite forme avec son produit de réduction un système irréversible.

Pour un mélange équimolaire de sel de manganèse et de cétone, la variation avec la vitesse de balayage (v) du potentiel E_{Pc} du premier pic de réduction (réaction Mn(II) → Mn(0)) est la même qu'en absence de cétone ($\partial E_{Pc}/\partial \log v \simeq -20$ mV) dans l'intervalle 10 à 500 mV s^{-1} et dans le même temps, il apparaît le pic de réduction de la tétralone libre vers −1,975 V pour $v > 10$ mV s^{-1}. Celui-ci d'intensité d'abord très faible et

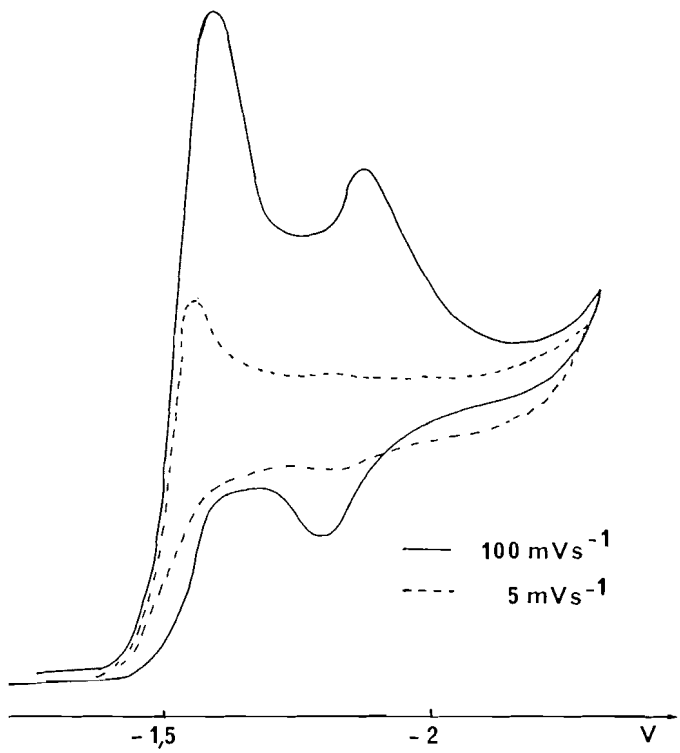

FIG. 2. Voltammogrammes du mélange tétralone (10^{-3} *M*) et Mn(II) (10^{-3} *M*) dans DMF, TBABr 0,1 *M*.

se déplaçant légèrement vers des potentiels moins négatifs se fixe à −1,96 V à partir de 100 mV s^{-1} tandis que sa hauteur relative croît et que le système devient de plus en plus réversible.

Il apparaît donc que le complexe cétone–manganèse, mis en évidence par la polarographie, ne se forme que très lentement et n'affecte les voltammogrammes que pour des balayages à très faible vitesse. Une confirmation est apportée par l'étude de l'influence de la concentration en cétone en présence de Mn(II) (10^{-3} *M*) pour une vitesse de balayage fixée à 50 mV s^{-1}. Le premier pic de réduction reste fixe, celui de la cétone n'apparaissant que pour une concentration de 0,75 × 10^{-3} *M*

(−1,955 V) et se déplaçant légèrement vers des potentiels plus négatifs, pour atteindre −2,015 V pour une concentration en cétone de 10^{-2} *M*. Tout au long de cette étude, il a été vérifié qu'une goutte de mercure non renouvelée reste passivée, et entraîne en conséquence la non-reproductibilité des voltammogrammes. Tout cela semble indiquer en fait, la formation d'un film, les modifications irréversibles de la surface de l'électrode étant imputables aux espèces Mn(0) formées (amalgame ou film de métal colloïdal); le film superficiel formé sur l'électrode étant plus ou moins inhibiteur pour la réduction des ions complexes métalliques mais non pour les molécules de cétone. On peut penser qu'il en est de même dans les conditions d'une électrolyse préparative à un potentiel contrôlé plus négatif que celui de la réduction de Mn(II) en Mn(0).

Electrolyse à potentiel contrôlé

Une autre méthode d'étude de la réaction qui se produit au niveau du pic correspondant au complexe manganèse–cétone est l'identification des produits préparés par électrolyse au potentiel de ce pic. Ces réductions ont été conduites sur des mélanges, en proportions équimolaires de cétone et chlorure de manganèse. Le résultat des électrolyses préparatives pour chaque cétone étudiée est consigné dans le tableau 1 et peut être comparé aux résultats obtenus pour ces mêmes cétones en présence de chlorure de chrome (4, 5).

Le potentiel de demi-vague correspondant au complexe manganèse–cétone permet de classer les cétones **1** à **7** en 3 catégories.

(*i*) Les cétones beaucoup moins réductibles que Mn(II) et dont le $E_{1/2}$ du complexe est voisin de celui de Mn(II)/Mn(0) seul: **1** à **4**. Pour ces composés, la réduction électrochimique en présence de Mn(II) conduit à des résultats semblables à ceux de la réduction effectuée en présence de Cr(II) en imposant le potentiel de la vague du complexe Cr(II)–cétone.

(*ii*) Une cétone de potentiel de réduction légèrement inférieur à celui de Mn(II) et dont le $E_{1/2}$ du complexe est voisin de celui de Mn(II): la benzophénone **5** qui conduit quantitativement au benzhydrol alors qu'avec Cr(III) on isolait à côté du benzhydrol (18%), un pourcentage assez élevé de diol (74%).

(*iii*) Les cétones de potentiel de réduction voisin ou supérieur à celui de Mn(II) et dont le $E_{1/2}$ du complexe est déplacé vers les potentiels moins négatifs: la xanthone **6** et la fluorénone **7** où il y a récupération quantitative du produit de départ alors qu'avec Cr(III) la xanthone **6** donnait le xanthol et la fluorénone **7** un mélange du diol (38%) et du fluorénol (48%). Pour ces trois dernières cétones (**5**, **6**, **7**), nous ne pouvons actuellement apporter une explication satisfaisante de ces différences expérimentales. Une électrolyse à un potentiel correspondant au palier de la vague de réduction du complexe manganèse–cétone, permet d'obtenir avec un bon rendement les glycols-α d'hydrodimérisation lorsque le potentiel de demi-vague de la cétone est beaucoup plus négatif que celui de Mn(II). Les glycols-α obtenus avec les cétones dissymétriques sont en majorité comme avec le chrome (4, 5) les diastéréoisomères *dl*, ce qui s'explique bien par des effets stériques, si on admet qu'au moment de la soudure des radicaux ions cétyles, ceux-ci sont fixés au manganèse par leurs atomes d'oxygène, conduisant alors au pinacolate fixé sous sa forme cisoïde, dont la configuration, *dl* est beaucoup moins encombrée (un raisonnement analogue est développé dans la ref. 8 pour la réduction chimique de l'indanone). Seules les configurations des diols correspondants à **1** et **2** ont été jusque là déterminées de façon rigoureuse (8, 9), mais nous avons pu mettre au point une méthode spectrale d'attribution de toutes les configurations (10). Il est à remarquer que la réduction directe des cétones dans le DMF au potentiel de leur première vague polarographique donne surtout des polymères (plus de 80%).

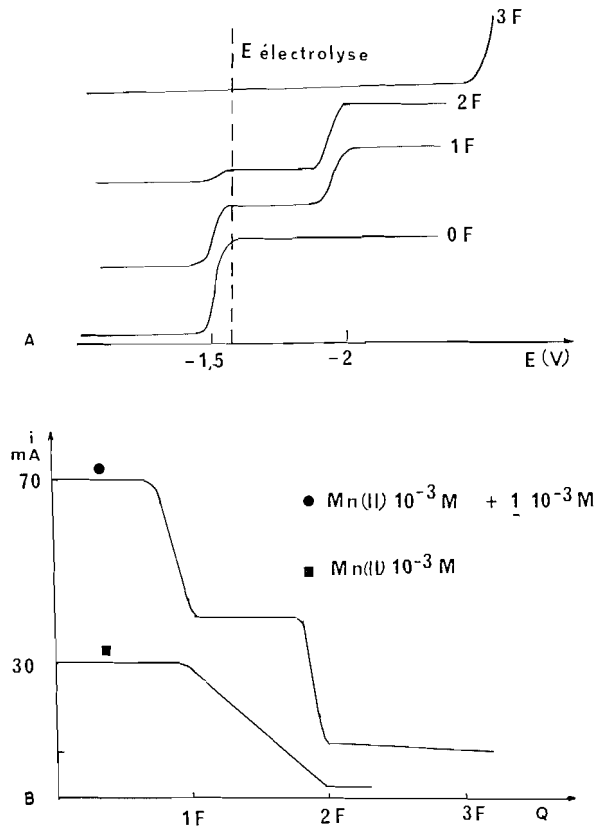

FIG. 3. Electrolyse de **1** dans le DMF–TBABr en présence de Mn(II) en quantité équimolaire. A. Polarogrammes enregistrés à 0, 1, 2 et 3 Faradays. B. Courbe $i = f(Q)$ pour la même électrolyse.

Pour tenter d'analyser le mécanisme de la réduction indirecte, en présence de sel de manganèse, particulièrement dans le cas des cétones les moins réductibles, nous avons enregistré les polarogrammes sur des échantillons prélevés en cours d'électrolyse et ramenés à des concentrations de 10^{-3} *M* (Fig. 3). Pour l'équimolarité entre le manganèse et la tétralone **1** par exemple, au début de l'électrolyse, le polarogramme présente la seule vague de réduction du complexe manganèse – cétone. Pendant le passage du premier Faraday, outre la décroissance de cette vague proportionnellement au nombre de coulombs consommés on note l'apparition de la vague de la cétone libre. Pour 1 Faraday, les deux vagues ont même hauteur. Entre 1 et 2 Faradays, la vague du complexe cétone – manganèse continue à décroître pour disparaître à 2 Faradays et alors seule la vague de réduction de la cétone libre apparaît. Après 2 Faradays la vague de la cétone diminue et disparaît peu après 3 Faradays. L'intensité du courant d'électrolyse (Fig. 3) est faible et constante (70 mA) jusque vers 0,6 F, décroît linéairement jusque 1 F à 40 mA, reste de nouveau constante jusque 1,6 F, décroît de nouveau linéairement pour rester sensiblement constante et très faible (de l'ordre de 10 mA) entre 2 et 3 F. Pour une électrolyse de Mn(II) seul, le courant initial est très faible vers 30 mV, constant jusque 0,6 F puis décroît linéairement pour s'annuler à 2 F. Il y a donc libération d'une partie de la cétone en cours d'électrolyse, cela pourrait s'expliquer par la disparition progressive de Mn(II) sous forme de

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

métal déposé et en suspension, ce qui libérerait les molécules de cétone complexées, quant aux courbes $i = f(Q)$ elles seraient en faveur d'un complexe Mn(I)–cétone montré par l'existence d'un palier de courant de 1 à 1,6 F lors de l'électrolyse du mélange équimolaire cétone – Mn(II). L'électrolyse a nécessité le passage total de 3 F pour obtenir les produits de réduction et disparition totale de la cétone initiale (1 F est nécessaire à la réduction de la cétone, 2 F pour réduire Mn(II) au stade Mn(0)).

Une autre façon d'évaluer le nombre d'électrons consommés par la réaction est d'arrêter l'électrolyse avant qu'elle soit terminée. Après passage de 2,2 F et traitement immédiat, on récupère 19% de cétone (tétralone **1**) et il s'est formé 63% de diol (*d, l:* 45%; *méso:* 18%); 80% du produit initial a donc réagi dès le passage d'environ 2 F. D'autre part, en amenant Mn(II) sous forme Mn(0) par électrolyse puis en ajoutant ensuite la tétralone **1** dans le milieu, la cétone de départ est récupérée intégralement que l'on maintienne ou non le potentiel de réduction imposé lors des électrolyses normales.

Il semble donc, que l'hydrodimérisation se fait pendant l'électrolyse par réaction entre la cétone et une espèce électrogénérée instable contenant du manganèse à bas état d'oxydation. Une condition impérative étant la présence de la cétone dès le début de l'électrolyse pour obtenir les meilleurs rendements (Tableau 1) (85% de diol pour la tétralone **1**), en effet, l'addition de la cétone à 1,5 F puis poursuite normale de l'électrolyse jusqu'à 3 F fournit 65% de diol (*d, l:* 50%; *méso:* 15%) et polymérisation.

Conclusion

Comme dans le cas du chrome (2–5), le système actif est le système Mn(II)/Mn(0). L'avantage certain du manganèse par rapport à Cr(II) est la stabilité de l'espèce Mn(II), ce qui entraine une plus grande simplicité du système et notamment supprime toute sorte de réactions parasites. Il faut aussi bien sûr pour le temps d'électrolyse décompter l'étape Cr(III)/Cr(II) inutile à la réduction électrochimique. Ceci permet de distinguer la réaction électrocatalysée (uniquement présentée avec Mn(II)) de la réduction chimique (cas de Cr(II)). Cette réduction parasite, qui complique les phénomènes, explique peut-être la non-réactivité de la xanthone et de la fluorénone avec Mn(II) (Tableau 1), bien que les 2 systèmes soient actifs avec Cr(III).

L'existence d'un complexe entre le métal et le composé carbonylé n'a pas pu être établie avec certitude mais est hautement probable. Pour les cétones **1** à **4** (plus difficiles à réduire que Mn(II) ou Cr(II)) où ΔV ($E_{1/2}$ métal $-$ $E_{1/2}$ cétone) est de l'ordre de 400 mV, les résultats sont à toute fin pratique identiques en présence de Mn(II) et en présence de Cr(II): rendements, proportions de glycol et d'alcool, proportions de diastéréoisomères *dl* et *méso*. Il semble que le mécanisme puisse être le même avec les deux espèces métalliques: réduction d'un complexe entre le métal à bas degré d'oxydation (I ou 0) et la cétone ou le radical cétyle, soit encore formation d'un film de métal colloïdal à la surface de l'électrode (5) sans toutefois éliminer complètement la réduction d'un complexe avec Cr(II) ou Mn(II) (2–5). Par contre, avec les cétones **5** et **6**, où ΔV est voisin de 150 mV, le mécanisme serait différent selon l'espèce métallique formée à l'électrode. Avec la cétone **7**, plus réductible que Cr(II) ou Mn(II) (ΔV de l'ordre de -300 mV), la réduction pourrait être, au moins en partie, réalisée directement par le métal(II) électrogénéré pendant la durée de l'électrolyse, comme le montre la similitude des résultats des réactions chimiques et électrochimiques (5). Pour rendre compte de l'inhibition de la polymérisation, il semble nécessaire que le radical électrogénéré directement ou indirectement, soit fixé par coordination ou chimisorption grâce à son atome d'oxygène sur un site agissant comme acide de Lewis. Cela explique en même temps la formation préférentielle des isomères *dl* des diols quand la cétone est dissymétrique, ainsi que le gain d'énergie d'activation observé pour la réduction de la cétone.

Nous ne pouvons, faute de données suffisantes, proposer pour l'instant un mécanisme précis quant à cette réduction. Nous avons entrepris l'étude du film par des méthodes spectroscopiques et électrochimiques. Cependant, un premier mécanisme peut être envisagé pour l'ensemble des différentes étapes réactionnelles:

L = DMF

$L_6\,Mn^{II} + \bar{e} \rightleftarrows L_6\,Mn^{I}$ rapide

$L_6\,Mn^{I} + R^1\,R^2\,C{=}O \rightleftarrows$ "complexe cétone – Mn^{I}" lent

"Complexe" $+ \bar{e} \rightleftarrows$ cétone $+ Mn^0$ (colloïdal) rapide

$Mn^0 + R^1\,R^2\,C{=}O \rightarrow$ produits de réduction (diols ou alcool) $+ Mn^{I}$ lent

(ou M^0 + cétone $\rightarrow M^0\cdots$ cétone adsorbée $\xrightarrow{\bar{e}}$ produits de réduction)

Ce mécanisme rend compte de l'apparition de la cétone libre en cours d'électrolyse et du caractère catalytique de la réduction (5). Nous poursuivons l'étude de cette réaction électrochimique avec d'autres sels de métaux de transition.

Partie expérimentale

Les points de fusion ont été déterminés au banc de Köfler et au microscope à platine chauffante Leitz. Les spectres ir ont été obtenus avec un spectromètre Pye–Unicam SP 3 200; ceux de rmn ^{1}H avec les appareils Bruker WP 80 et Bruker SY 250. Les chromatographies sur couche mince ont été réalisées sur gel de silice fluorescente "Merck PF-254", (plaque 20 × 20, e = 0,1 cm).

En électrochimie, tous les potentiels ont été mesurés par rapport à une électrode de référence au calomel et KCl saturé, à double jonction Tacussel RDJ/C 10. Les polarogrammes ont été enregistrés sur une table traçante XY Iffelec IF 3802 couplée à un polarographe PAR 174 A. Les voltammogrammes ont été réalisés grâce à un potentiostat PAR 173 gouverné par un générateur de signaux PAR 175, sur goutte de mercure fournie par une électrode de Kémula à piston micrométrique.

Les électrolyses ont été réalisées en atmosphère d'argon, à 20°C, avec un potentiostat PAR 173 muni d'un coulomètre PAR 179, sur une cathode de mercure de 26 cm^2 environ de surface et agitée avec un barreau aimanté. Les compartiments anodique et cathodique sont séparés par une pastille de verre fritté de porosité 4 et de 2,5 cm de diamètre. L'anode est un disque de platine de 2 cm de diamètre.

Le DMF utilisé contient du bromure de tétrabutylammonium 0,1 M et un peu d'eau 2×10^{-2} M environ (dosage de Karl–Fischer). Ainsi pour les analyses voltammétriques avec des concentrations en $MnCl_2 \cdot 4H_2O$ de 10^{-3} M, la concentration d'eau est de l'ordre de 2 à 3×10^{-2} M, pour les électrolyses où la concentration de sel de manganèse est en général de 7×10^{-2} M (5×10^{-3} mol dans 70 cm^3 de solvant), la concentration d'eau est de 0,45 M environ.

En fin de réaction (déterminée par analyse polarographique) le mélange obtenu est versé dans un grand volume d'eau (700 cm^3 au moins), extrait à l'éther et séché sur sulfate de sodium. Le solvant est chassé sous vide, le résidu séparé par chromatographie en couche mince de silice.

Beaucoup de produits obtenus sont connus (11–14) et nous les avons identifiés par leurs caractéristiques physiques et spectroscopiques, par comparaison avec celles d'échantillons authentiques. Les particularités observées et les spectres de rmn des glycols obtenus sont donnés dans les réfs. 5 et 10.

Synthèse et thermolyse de vinyl-2 aziridines N-non substituées

MOHAMED EL MEKKI ATTIA, YVONNE GELAS-MIALHE ET ROGER VESSIERE
Ecole Nationale Supérieure de Chimie, Université de Clermont 2, B.P. 45, 63170 Aubiere, France

Reçu le 16 décembre 1982

MOHAMED EL MEKKI ATTIA, YVONNE GELAS-MIALHE et ROGER VESSIERE. Can. J. Chem. **61**, 2126 (1983).

Les vinyl-2 aziridines N-non substituées sont préparées par action de phosphoranes sur des acyl-2 aziridines N-non substituées. L'étude de leurs spectres de rmn permet de préciser leur stéréochimie. Leur thermolyse conduit à des imines formées par ouverture vraisemblablement hétérolytique de la liaison carbone–carbone du cycle et migration du proton initialement lié à l'atome d'azote.

MOHAMED EL MEKKI ATTIA, YVONNE GELAS-MIALHE, and ROGER VESSIERE. Can. J. Chem. **61**, 2126 (1983).

N-unsubstituted 2-vinylaziridines are prepared from N-unsubstituted 2-acylaziridines and phosphoranes. Their stereochemistry is established from a study of their nmr spectra. Thermal isomerization of these compounds gives imines by a reaction involving heterolytic cleavage of the carbon–carbon bond of the ring and migration of hydrogen initially bound to nitrogen.

Plusieurs études consacrées à l'isomérisation thermique de vinyl-2 aziridines tertiaires ont mis en évidence le rôle important des substituants portés par l'hétérocycle sur l'évolution de la réaction. Celle-ci fait généralement intervenir, soit une rupture hétérolytique de la liaison carbone–carbone du cycle, soit une transposition sigmatropique (1).

Il nous a semblé intéressant de poursuivre les travaux que nous avions engagés dans ce domaine par l'étude du comportement thermique des vinyl-2 aziridines secondaires (N-non substituées) pour lesquelles aucun résultat n'était connu.

Seules, quelques méthodes particulières avaient été publiées concernant la synthèse des vinyl-2 aziridines secondaires (2), aussi avons-nous cherché, préalablement à notre étude, à mettre au point un procédé de préparation de ces produits aussi général que possible.

I. Préparation des vinyl-2 aziridines secondaires

Les vinyl-2 aziridines secondaires ont été préparées par un procédé identique à celui que nous avons mis en oeuvre pour accéder aux vinyl-2 aziridines tertiaires (1*a*) (Schéma 1).

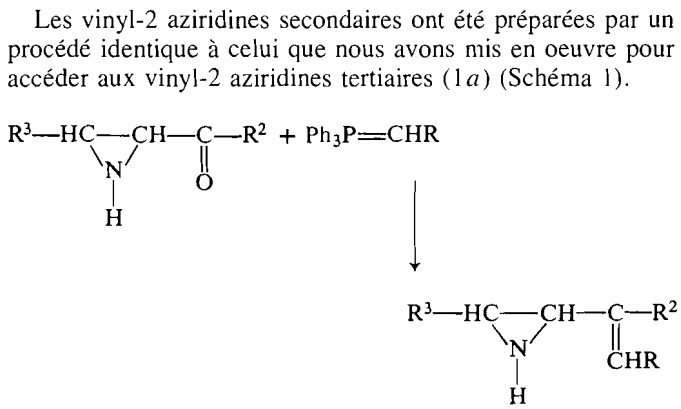

SCHÉMA 1

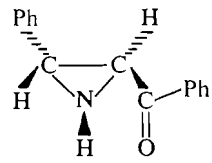
Les acyl-2 aziridines **1**, **2** et **3** (Tableau 1) utilisées dans cette réaction sont obtenues par action de l'ammoniac sur des cétones α,β-dibromées (réaction de Cromwell (3)). L'action sur ces dérivés de divers phosphoranes permet d'obtenir les vinyl-2 aziridines **4** à **11** (Tableau 1) avec des rendements en produits purs compris le plus souvent entre 40 et 60%.

Deux vinyl-2 aziridines isomères sont obtenues dans les expériences 4, 5 et 6 (Tableau 1). Seuls ont pu être séparés par chromatographie sur colonne les composés **9***a* et **9***b*.

La préparation du composé **11** (réaction 8, Tableau 1) n'est past toujours reproductible en raison de la grande sensibilité de ce produit à la chaleur (*vide infra*); il peut également être obtenu par une réaction de Horner entre la cétone **1** et le



1 *S*R* trans*

SCHÉMA 2

diéthylphosphonoacétate d'éthyle; cette dernière réaction présente l'avantage d'être réalisée à température ambiante, toutefois son rendement est inférieur à celui de la réaction précédente.

L'identification et la détermination de la stéréochimie des acyl-2 et vinyl-2 aziridines ont été réalisées par étude de leurs spectres de résonance magnétique nucléaire. La configuration relative *S*R** ou *R*R** des atomes de carbone C-2 et C-3 du cycle[1] est déduite de la valeur de la constante de couplage $J_{H\text{-}2—H\text{-}3}$. Dans le cas des composés **4**, **7**, **8** et **9***b* cette constante ne peut être mesurée. Cependant, les résultats des expériences 2, 3, 6, 7 et 8 montrent que, comme pour les aziridines tertiaires (1*a*) la configuration relative des atomes de carbone C-2 et C-3 de la vinyl-2 aziridine est la même que celle de l'acyl-2 aziridine qui lui a donné naissance. Par analogie, nous avons donc attribué une configuration *R*R** aux dérivés **4**, **7**, **8** et **9***b*.

La position de l'atome d'hydrogène lié à l'atome d'azote par rapport aux substituants du cycle peut également être précisée; elle est déduite de la valeur des couplages $^3J_{H—N—C—H\text{-}2}$ et $^3J_{H—N—C—H\text{-}3}$ (4). Dans le cas des composés **1** et **9***a*, la mise en évidence de ces couplages (voir partie expérimentale) à 25°C et à 60°C montre que dans cet intervalle de température les deux molécules possèdent la configuration pour laquelle l'atome d'hydrogène lié à l'atome d'azote et le substituant fixé sur le carbone C-2 sont en position *cis* (Schéma 2). Une constatation identique a été faite par Lopez (5).

Le spectre de l'aziridine **4** est mal résolu à température ambiante. Par contre, il peut être analysé à −40°C, il indique

[1]Dans le cas d'une acyl-2 aziridine de configuration *S*R** les atomes d'hydrogène liés aux atomes de carbone C-2 et C-3 du cycle sont en *trans* par rapport au plan du cycle (schéma 2). Ces mêmes atomes sont, par contre, en *cis* chez la vinyl-2 aziridine de configuration de même désignation *S*R**. L'aziridine est dite *trans* (*cis*) lorsque l'atome d'hydrogène lié à l'atome d'azote est en position *trans* (*cis*) par rapport à l'atome d'hydrogène porté par le carbone C-2.

[a]Déterminée par rmn de ^1H; les symboles *R** et *S** définissent la configuration relative des atomes de carbone C-2 et C-3 du cycle; les symboles *E* et *Z* concernent la configuration de la double liaison. L'aziridine est dite *trans* (*cis*) lorsque l'atome d'hydrogène lié à l'atome d'azote est en position *trans* (*cis*) par rapport à l'atome d'hydrogène porté par le carbone C-2.
[b]L'aziridine **9***a* possède la configuration *trans*.

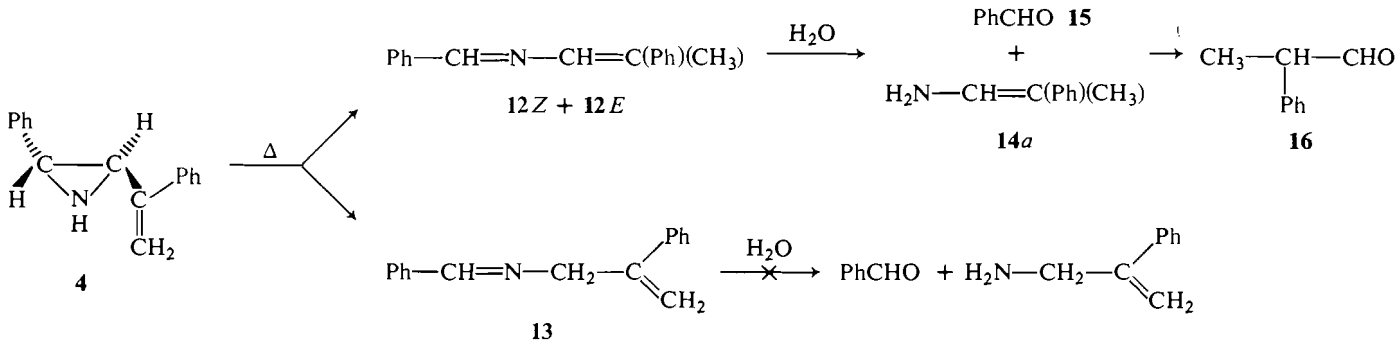

SCHÉMA 3

que l'on est alors en présence des deux invertomères *cis* et *trans* de l'aziridine **4** dans les proportions *cis*/*trans* = 47:53, ce qui correspond pour le phénomène d'inversion à une énergie libre $\Delta G_0 = -0{,}05$ kcal/mol. Le spectre obtenu à +60°C montre qu'à cette température la vitesse d'inversion est importante; la température de coalescence correspond à la température ambiante (les spectres sont donnés dans la partie expérimentale).

L'étude des spectres de rmn ^1H des vinyl-2 aziridines permet également de déterminer la configuration de la double liaison. La configuration *E* des composés **7***b* et **8***b* est déduite de la présence d'un couplage homoallylique entre le proton H-2 et le groupement méthyle fixé sur la double liaison; ce couplage correspond à une disposition transoïde des protons considérés. La configuration *Z* de l'isomère **9***a* se déduit du déplacement vers les champs faibles du proton H-2 par rapport à celui de **9***b*; en effet, dans cette configuration, le groupement phényle situé dans le plan du proton H-2 provoque son déblindage.

II. Isomérisation thermique des vinyl-2 aziridines

Les conditions optimales dans lesquelles les réactions d'isomérisation ont été réalisées, ainsi que la nature des produits identifiés, sont précisées dans le tableau 2.

L'examen par rmn du produit brut de thermolyse de l'aziridine **4** (expérience 9) permet d'identifier les composés **12** et **13** que nous avons séparés par chromatographie liquide à haute pression. Le composé **12** est, d'après son spectre, un mélange des deux isomères éthyléniques *E* et *Z*, l'isomère le plus abondant étant le dérivé *E* pour lequel le signal du groupement méthyle résonne au champ le plus faible en raison de sa situation en *cis* par rapport à l'atome d'azote. Le produit brut de thermolyse se décompose au cours de la séparation de ses constituants par chromatographie sur colonne de gel de silice. En sortie de colonne on obtient un mélange des produits **14***a*, **15** et **16** identifiés par comparaison avec des échantillons authentiques. L'hydrolyse du produit brut de thermolyse conduit à la formation de ces trois mêmes composés que l'on obtient également en abandonnant le produit brut quelques jours à température ambiante. Ces résultats montrent clairement que le produit primaire de l'isomérisation thermique de l'aziridine **4** est constitué des imines **12** et **13**, lesquelles sont facilement hydrolysées en benzaldéhyde et énamine **14***a*; cette dernière donne naissance à l'aldéhyde **16** (Schéma 3).

La (phényl-2 éthyl)amine, produit d'hydrolyse de l'imine **13**, n'est pas isolée. On peut penser qu'elle s'isomérise dans le milieu réactionnel en amine conjuguée **14***a*. On peut également envisager que l'isomérisation de l'imine **13** en imine conjuguée **12** est plus rapide que son hydrolyse.

Les expériences 10, 11 et 16 (Tableau 2) montrent que les réactions d'isomérisation thermique des aziridines **9***a*, **9***b* et **11** se déroulent de façon analogue à la réaction précédemment décrite; les produits primaires sont constitués par des imines dont l'hydrolyse (expérience 10) conduit à un mélange d'aldéhyde et d'amine. On peut rapprocher de l'expérience 16 la réaction décrite par Heine *et al.* (6) concernant l'action de l'éthoxycarbonylméthylènetriphénylphosphorane sur la *p*-nitrophényl-3 benzoyl-2 aziridine, réaction dans laquelle seule une imine est isolée (Schéma 4).

Dans les expériences 12, 13, 14 et 15, nous avons uniquement identifié les dérivés d'hydrolyse des produits de thermolyse. Les produits isolés dans l'expérience 13 sont les mêmes

[a]Conditions optimales établies après avoir fait varier température et temps de thermolyse, le produit brut étant analysé par rmn ^{1}H. Dans ces conditions, à l'exception de l'expérience 14, le rendement de la thermolyse est quantitatif.

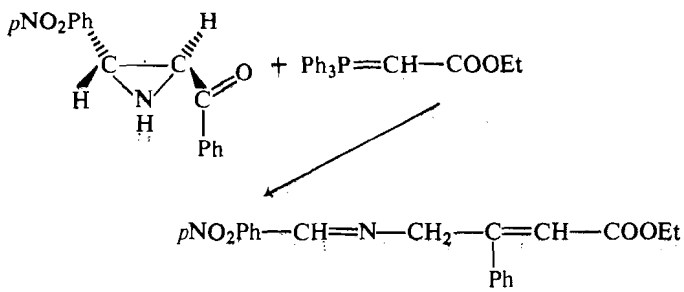

SCHÉMA 4

que ceux obtenus dans l'expérience 9, indiquant un comportement analogue des composés **4** et **6**. L'énamine **14**b isolée dans l'expérience 12 est le stéréoisomère du dérivé **14**a isolé dans les expériences 9 et 13. Le groupement méthyle du produit **14**b (δ = 2,60 ppm) résonne à champ plus faible que celui de **14**a (δ = 2,53 ppm), ce qui nous incite à lui attribuer la configuration E.

L'α-phénylcrotonaldéhyde **23** isolé dans l'expérience 14 provient très vraisemblablement de l'hydrolyse de l'imine formée dans l'ouverture thermique de l'aziridine **7** (schéma 5).

Le deuxième produit d'hydrolyse de cette imine, la benzylamine, n'est pas isolé; cependant, sa formation est prouvée par l'obtention de la dihydropyridine **24**. En effet, nous avons vérifié que ce produit se formait par action de la benzylamine sur l'α-phénylcrotonaldéhyde; il résulte très vraisemblablement de la dimérisation de l'imine née de la condensation de l'amine sur l'aldéhyde (7).

Au cours de l'expérience 14 seule est isomérisée l'aziridine **7**a; la purification du produit brut de thermolyse permet alors d'obtenir l'isomère **7**b pur. A température plus élevée (150°C)

SCHÉMA 5

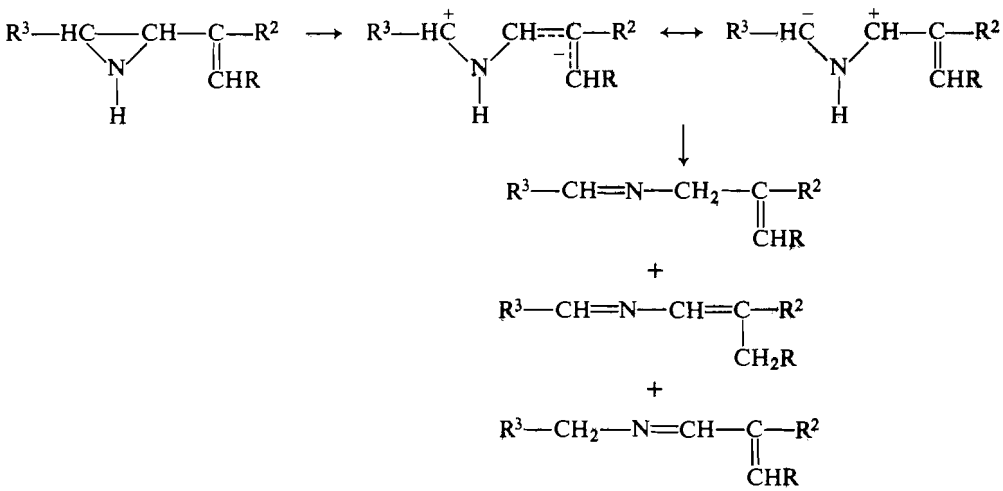

SCHÉMA 6

ce dernier se réarrange, conduisant à la dihydropyridine **24** (exp. 15).

Discussion des résultats

La structure des produits de thermolyse implique une rupture de la liaison carbone–carbone du cycle aziridine, rupture favorisée par la présence d'un groupement phényle sur le carbone C-3 comme le montre la comparaison des expériences 9 et 12. Une ouverture radicalaire semble peu probable. En effet, on ne connaît pas d'exemple d'ouverture thermique d'aziridines par homolyse de la liaison carbone–carbone du cycle. Cette isomérisation met plus vraisemblablement en jeu une ouverture conrotatoire de l'aziridine en ylure d'azométhine suivie d'une migration intramoléculaire de proton vers le centre le plus nucléophile du dipôle (schéma 6).

III. Conclusion

Au cours de ce travail, nous avons montré que les vinyl-2 aziridines secondaires étaient aisément accessibles à partir des acyl-2 aziridines secondaires par réaction de Wittig. Leur thermolyse conduit à des imines formées par ouverture vraisemblablement hétérolytique de la liaison carbone–carbone du cycle et migration du proton initialement lié à l'atome d'azote.

Ce comportement, différent de celui des vinyl-2 aziridines tertiaires pour lesquelles on observe généralement un agrandissement de cycle (1), met parfaitement en évidence le rôle capital du substituant lié à l'atome d'azote pour l'évolution des thermolyses des vinylaziridines.

Partie expérimentale

Les spectres de résonance magnétique nucléaire ont été enregistrés à l'aide des appareils Varian A 60, Varian T 60 ou Jeol 60 pour ^1H et Jeol FX 60 pour ^{13}C en utilisant le tétraméthylsilane comme référence interne. Les déplacements chimiques sont exprimés en ppm et les constantes de couplage en Hertz. Les solutions utilisées pour étudier le phénomène d'inversion de l'atome d'azote ont été soigneusement séchées, soit sur alumine, soit sur pastilles de soude. Les spectres infrarouge ont été effectués sur un spectrophotomètre Perkin–Elmer 157. Les spectres uv ont été enregistrés sur un appareil Cary 14. Les chromatographies sur colonne ont été réalisées, soit sur gel de silice (Merck 7734), soit à moyenne pression sur Lichoprep Si 60 (colonnes Merck Lobar). Les chromatographies liquides à haute pression ont été effectuées sur un appareil Waters 440 avec pompe M 6000 A et réfractomètre différentiel R 401 (colonnes Microporasil).

Préparation des acyl-2 aziridines 1, 2 et 3

Préparées selon le mode opératoire décrit par Weber et Bandlow (8).

Phényl-3 benzoyl-2 aziridine ***1***

Rdt = 82%; F = 97−98°C (litt. (9) F = 100−102°C); ir (cm^{-1}): 1670, 3235; rmn ^1H ($CDCl_3$): 2,72 (t large, N—H), 3,17 (dd, H-2, J = 2,4 (*trans*), J = 8,8 (*cis*)), 3,50 (dd, H-3, J = 2,4 (*trans*), J = 6,8 (*trans*)), 7,20 à 7,80 (m, C_6H_5); rmn ^{13}C ($CDCl_3$): 43,5 (C-2), 44,1 (C-3), 126,4, 128,1, 128,5, 128,7, 129,0, 134,0, 136,1, 138,5, (C_6H_5), 196,0 (C=O).

Méthyl-3 benzoyl-2 aziridines ***2*** *et* ***3***

Le produit brut (Rdt = 88%) est constitué d'un mélange des isomères **2** (50%) et **3** (50%). Ils sont séparés par chromatographie sur colonne (chloroforme/acétate d'éthyle 1:1).

Isomère ***2*** S*R*: ir (cm^{-1}): 3325, 1680; rmn ^1H ($CDCl_3$): 2,72 (pic large, N—H), 2.18 (dq, H-3, J = 2,5 (*trans*), J = 5,3), 3,24 (d, H-2, J = 2,5), 1,33 (d, CH_3, J = 5,3), 7,20 à 8,20 (m, C_6H_5); rmn ^{13}C ($CDCl_3$): 18,6 (CH_3), 38,1 (C-3), 40,5 (C-2), 128,1, 128,6, 133,4, 136,2 (C_6H_5), 196,8 (C=O).

Isomère ***3*** R*R*: ir (cm^{-1}): 3320, 1680; rmn ^1H ($CDCl_3$): 2,26 (pic large, N—H), 2,55 (dq, H-3, J = 6,2 (*cis*), J = 5,8), 3,53 (d, H-2, J = 6,2 (*cis*)), 1,11 (d, CH_3, J = 5,8), 7,25 à 8,20 (m, C_6H_5); rmn ^{13}C ($CDCl_3$): 12,7 (CH_3), 36,6 (C-2), 39,8 (C-3), 128,1, 128,7, 133,5, 136,6 (C_6H_5), 195,9 (C=O).

Préparation des vinyl-2 aziridines

Dans un réacteur muni d'un agitateur et traversé par un courant d'argon, on place 0,045 mol d'hydrure de sodium préalablement lavé au pentane et ajoute 35 mL de diméthylsulfoxyde sec. On chauffe à 75−80°C pendant 45 min puis, le mélange étant refroidi par un bain glace−sel, on ajoute 0,045 mol de sel de phosphonium en solution dans 40 mL de diméthylsulfoxyde et poursuit l'agitation pendant 45 min à température ambiante. On introduit alors 0,03 mol d'acyl-2 aziridine en solution dans 20 mL de diméthylsulfoxyde. L'agitation est maintenue pendant 14 h à température ambiante, puis pendant 2 h à 60°C. Le mélange réactionnel est alors refroidi et versé dans l'eau glacée. On extrait à l'éther, lave les extraits à l'eau, sèche et concentre. Les produits sont alors purifiés.

Phényl-3 (phényl-1 vinyl)-2 aziridine ***4***

Le produit brut est purifié par chromatographie sur colonne (benzène/acétone 9:1): Rdt = 59%; F = 73−75°C; ir (cm^{-1}): 3270, 1640, 1600; rmn ^1H (CCl_4 + NaOH) −40°C: 0,98 (t, 0,47 H, J = 9, J = 8), 1,38 (t, 0,53 H, J = 9, J = 8), 2,40 à 3 (m, 2H), 4,98 et 5,30 à 5,50 (m, 2H, $=CH_2$), 7 à 7,50 (m, C_6H_5); +25°C: 1,05 (m, 1H, signal très large, largeur à mi-hauteur = 37 Hz), 2,65 (m de quatre pics mal résolus, 2H, largeur à mi-hauteur = 27 Hz), 5,0 et 5,32 (2 pics larges, 2H, $=CH_2$), 7,0 à 7,50 (m, C_6H_5); +60°C: 1,15 (m, 1H, N—H), 2,75 (2 pics larges séparés par 8,2 Hz, largeur à mi-hauteur = 15 Hz, 2H), 5,10 et 5,38 (s, 2H, $=CH_2$), 7 à 7,50 (m, C_6H_5); rmn ^1H ($CDCl_3$): 1,45 (s large, 1H, N—H), 2,83 (s, 2H, H-2 et H-3), 5,23 et 5,43 (s, 2H, $=CH_2$), 7,10 à 7,60 (m, C_6H_5); rmn ^{13}C ($CDCl_3$): 42,1, 43,8, 125,7, 126,2, 127,3, 128,0, 128,5, 128,6, 139,0, 139,6, 110,4, 146,6. *Anal.* calc. pour $C_{16}H_{15}N$: C 86,88, H 6,79, N 6,33; trouvé: C 86,69, H 6,85, N 6,38.

Méthyl-3 (phényl-1 vinyl)-2 aziridine ***5***

Le produit brut est purifié par chromatographie sur colonne (chloroforme/acétate d'éthyle 1:1): Rdt = 48%; ir (cm^{-1}): 3220, 1630, 1600; rmn ^1H ($CDCl_3$): 0,95 (s large, 1H, N—H), 1,27 (d, 3H, J = 5, CH_3), 1,81 (dq, 1H, H-3, J = 5, J = 2,8 (*trans*)), 2,35 (d, pics larges, 1H, H-2, J = 2,8 (*trans*)), 5,10 dd et 5,29 d (2H, $=CH_2$, J = 0,8 (*gem*) et ^4J = 1); rmn ^{13}C ($CDCl_3$): 19,2 (CH_3), 35,3 (C-3), 40,5 (C-2), 126,0, 128,3, 127,7, 139,4 (C_6H_5), 110,2 et 146,9 (C=C). *Anal.* calc. pour $C_{11}H_{13}N$: C 83,02, H 8,18, N 8,81; trouvé: C 82,83, H 8,34, N 8,89.

Méthyl-3 (phényl-1 vinyl)-2 aziridine ***6***

Purifiée par chromatographie sur colonne (chloroforme/acétate d'éthyle 1:1): Rdt = 46%; ir (cm^{-1}): 3220, 1630, 1600; rmn ^1H ($CDCl_3$): 0,95 (d, 3H, CH_3, J = 5,2), 1,20 (s large, N—H), 2,25 (dq, 1H, H-3, J = 6,2 (*cis*), J = 5,2), 2,75 (d, 1H, H-2, J = 6,2 (*cis*)), 5,31 d et 5,59 d (2H, $=CH_2$, J = 0,7 (*gem*)), 7,15 à 7,60 (m, C_6H_5). *Anal.* calc. pour $C_{11}H_{13}N$: C 83,02, H 8,18, N 8,81; trouvé: C 83,12, H 8,14, N 8,83.

Phényl-3 (phényl-1 propène-1 yl)-2 aziridine ***7***

Purifiée par chromatographie sur colonne (chloroforme/acétone 98:2). On obtient un mélange des isomères **7***a* et **7***b* dans le rapport **7***a*/**7***b* = 55:45: Rdt = 62%; ir (cm^{-1}): 3200, 1600; rmn ^1H ($CDCl_3$) de **7***a*: 1,1 (s large, 1H, N—H), 1,52 (d, 3H, J = 6,9, CH_3), 2,73 (s, 2H, H-2 et H-3), 5,79 (dq, 1H, =CH, ^4J = 1,6, J = 6,9), 7,10 à 7,50 (m, C_6H_5); rmn ^1H ($CDCl_3$) de **7***b*: 1,84 (dd, 3H, CH_3, ^5J = 0,8, ^3J = 6,9), 2,80 (m, 2H, H-2 et H-3), 5,92 (dq, 1H, =CH, ^3J = 6,9, ^4J = 1,4), 7,10 à 7,50 (m, C_6H_5); rmn ^{13}C ($CDCl_3$) de **7***a*: 14,6, 39,2, 46,7, 123,4, 126,2, 127,4, 129,1, 136,7, 139,9; rmn ^{13}C ($CDCl_3$) de **7***b*: 14,3, 39,8, 41,3, 125,7, 127,0, 127,2, 127,6, 128,2, 128,4, 138,8, 139,8. *Anal.* calc. pour $C_{17}H_{17}N$: C 86,81, H 7,23, N 5,96: trouvé: C 86,61, H 7,13, N 5,91.

Méthyl-3 (phényl-1 propène-1 yl)-2 aziridine ***8***

Le produit brut est, d'après son spectre de rmn ^1H, constitué d'un mélange des isomères **8***a* et **8***b* dans le rapport **8***a*/**8***b* = 50:50; on relève en effet sur le spectre deux doublets à 1,85 (J = 7) et 1,50 (J = 7) et deux quadruplets à 5,73 et 5,85. Il est purifié par chromatographie sur colonne (chloroforme/acétate d'éthyle 1:1). On obtient l'isomère **8***b* pur: Rdt = 44%; ir (cm^{-1}): 3220, 1670, 1610; rmn ^1H ($CDCl_3$): 1,22 (d, 3H, J = 5,5), 1,85 (dd, 3H, J = 7, J = 0,8), 2 à 2,70 (m, 3H), 5,80 (dq, 1H, J = 7, ^4J = 1,2), 7 à 8,10 (m, C_6H_5). *Anal.* calc. pour $C_{12}H_{15}N$: C 83,24, H 8,67, N 8,09; trouvé: C 83,51, H 8,63, N 8,28.

Phényl-3 (phényl-1 styryl)-2 aziridine ***9***

Le produit brut est purifié par chromatographie sur colonne (benzène/acétate d'ethyle 80:20). On obtient un mélange des isomères **9***a* et **9***b* dans le rapport **9***a*/**9***b* = 70:30: Rdt = 58%. Ils sont séparés par chromatographie sur colonne (éther de pétrole/acétate d'éthyle 85:15).

Isomère ***9***a: F = 106−107°C; ir (cm^{-1}): 3200, 1600, 1590; rmn ^1H ($CDCl_3$): 1,20 (s large, 1H, N—H), 2,81 (d, 1H, H-3, J = 2,8 (*trans*)), 3,08 (dd, 1H, H-2, J = 2,8 (*trans*), ^4J = 1), 6,89 (s large, 1H, =CH), 7,10 à 7,70 (m, C_6H_5); rmn ^1H (C_6H_6 + NaOH), +25°C: 0,97 (t, pics larges, 1H, N—H, J = 9,2 (*cis*), J = 8,4 (*trans*)), 2,62 (dd, 1H, H-3, J = 9,2 (*cis*), J = 3 (*trans*)), 2,98 (d, pics larges, largeur à mi-hauteur = 6,4 Hz, 1H, H-2, J = 8,4 (*trans*)); rmn ^1H (C_6H_6 + NaOH), +60°C: 1,0 (t, 1H, N—H, J = 8,4 (*trans*), J = 9,2 (*cis*)), 2,75 (dd, H-3, J = 3 (*trans*), J = 9,2 (*cis*)), 3,08 (ddd, H-2, ^4J = 1,5, J = 3 (*trans*), J = 8,4 (*trans*)); rmn ^{13}C ($CDCl_3$): 41,3, 42,6, 125,9, 127,1, 127,3, 127,9, 128,3, 128,9, 129,0, 129,4, 131,2, 136,4, 139,4, 139,6, 139,9. *Anal.* calc. pour $C_{22}H_{19}N$: C 88,89, H 6,40, N 4,71; trouvé: C 88,71, H 6,47, N 4,76.

Isomère ***9***b: F = 101−102°C; ir (cm^{-1}): 3200, 1600, 1590; rmn ^1H ($CDCl_3$): 1,62 (s large, 1H, N—H), 2,83 (s large, 2H, H-2 et H-3), 6,71 (s, 1H, =CH), 6,90 à 7,60 (m, C_6H_5); rmn ^{13}C ($CDCl_3$): 39,6, 47,6, 125,9, 126,8, 127,1, 127,5, 127,9, 128,4, 128,9, 129,0, 129,2, 136,3, 136,8, 139,6, 139,7. *Anal.* calc. pour $C_{22}H_{19}N$: 88,89, H 6,40, N 4,71; trouvé: C 88,93, H 6,52, N 4,64.

Méthyl-3 (phényl-1 styryl)-2 aziridine ***10***

Le produit brut est purifié par chromatographie sur colonne (chloroforme/acétate d'éthyle 1:1): Rdt = 12,5%; ir (cm^{-1}): 3250, 1600, 1580; rmn ^1H ($CDCl_3$): 1,21 (d, 3H, CH_3, J = 5,2), 1,80 (dq, 1H, H-3, J = 5,2, J = 2,5 (*trans*)), 2,72 (dd, 1H, H-2, J = 2,5 (*trans*), ^4J = 1), 6,80 (d, 1H, =CH, ^4J = 1), 7,15 à 7,70 (m, C_6H_5). *Anal.* calc. pour $C_{17}H_{17}N$: C 86,81, H 7,23, N 5,96; trouvé: C 86,41, H 7,10, N 5,76.

Phényl-3 (éthoxycarbonyl-2 phényl-1 vinyl)-2 aziridine ***11***

(a) On chauffe à reflux pendant 24 h une solution de 0,005 mol d'aziridine **1** et de 0,005 mol d'éthoxycarbonylméthylènetriphénylphosphorane dans 150 mL de chloroforme anhydre. On évapore ensuite le solvant, reprend à l'alcool, filtre et concentre. Le produit brut est purifié par chromatographie sur colonne (éther de pétrole/acétate d'éthyle 85:15): Rdt = 20%; ir (cm^{-1}): 3200, 1720, 1640, 1600; rmn ^1H ($CDCl_3$): 1,50 (s large, 1H, N—H), 2.78 (spectre AB, 2H, H-2 et H-3, J = 2,5), 6,15 (s, 1H, =CH), 1,03 (t, 3H, J = 7), 3,98 (q, 2H, J = 7), 7,10 à 7,60 (m, C_6H_5). *Anal.* calc. pour $C_{19}H_{19}NO_2$: C 77,82, H 6,48, N 4,78; trouvé: C 77,42, H 6,42, N 4,83.

For personal use only.

(b) A 0,005 mol de NaH mis en suspension dans 10 mL de THF, on ajoute 0,005 mol de phosphonate en solution dans 10 mL de THF. On laisse 45 min sous agitation et sous argon puis on ajoute 0,005 mol d'aziridine **1** dissoute dans 15 mL de THF. Après 5 heures de réaction à température ambiante on verse le mélange réactionnel dans de l'eau glacée, extrait à l'éther, sèche puis concentre. Le produit brut est ensuite purifié comme précédemment: Rdt = 10%.

Isomérisation thermique des vinyl-2 aziridines

Un échantillon de 5 mmol de vinyl-2 aziridine pure, en ampoule scellée sous argon, est chauffé au bain d'huile. Les conditions expérimentales particulières à chaque composé sont données dans le tableau 2. En fin de réaction le produit brut est analysé en rmn puis purifié.

Isomérisation de la phényl-3 (phényl-1 vinyl)-2 aziridine ***4***

La purification du produit de thermolyse par hplc (isooctane/acétate d'éthyle 98:2) permet de séparer les imines **12** et **13**.

N-*benzylidène méthyl-2 styrylamine* ***12***: F = 64−66°C; ir (cm^{-1}): 1680, 1627, 1602; rmn ^1H ($CDCl_3$): 2,22 (s large, 0,3H), 2,51 (s large, 2,7H), 7 à 8 (m, C_6H_5 et CH=C), 8,28 (s large, 1H, CH=N); rmn ^{13}C ($CDCl_3$): 15,5, 125,8, 127,5, 128,4, 128,6, 130,7, 136,8, 139,2, 141,1, 159,2.

N-*benzylidène phényl-2 allylamine* ***13***: ir (cm^{-1}): 1680, 1642, 1600; rmn ^1H ($CDCl_3$): 4,62 (m, 1H), 4,80 (m, 1H), 5,25 (m, 1H), 5,50 (m, 1H), 7 à 8 (m, C_6H_5), 8,28 (s large, 1H); rmn ^{13}C ($CDCl_3$): 64,1, 96,0, 113,5, 125,3, 126,0, 126,5, 127,0, 127,2, 128,3, 130,7, 162,2.

L'hydrolyse en milieu chlorhydrique du produit de thermolyse conduit à un mélange des aldéhydes **15** et **16** identifiés par comparaison avec des échantillons authentiques et de l'énamine **14***a* identifiée par comparaison avec un échantillon préparé selon une méthode décrite (10).

Enamine ***14***a: rmn ^1H ($CDCl_3$): 2,53 (s large, 3H), 7 à 8 (m, 8H).

Isomérisation thermique de la phényl-3 (phényl-1 styryl)-2 aziridine ***9***

Le produit de thermolyse de **9***b* est purifié par chromatographie liquide haute pression (isooctane/acétate d'éthyle 98:2). On obtient l'imine **17***a* pure et un mélange des dérivés **18** et **19** (**18**/**19** = 75:25).

Imine ***17***a: ir (cm^{-1}): 1600, 1615, 1660, 1685, 1715; rmn ^1H ($CDCl_3$): 4,7 (pic large, 2H), 8,30 (s large, 1H), 6,90 à 7,90 (m, C_6H_5 et C=CH); rmn ^{13}C ($CDCl_3$): 65,0, 127,0, 127,8, 128,0, 128,3, 128,6, 129,0, 129,2, 129,4, 129,7, 129,9, 130,8, 162,0.

Imine ***18***: ir (cm^{-1}): 1600, 1685; rmn ^1H ($CDCl_3$): 4,5 (pic large, 2H), 8,15 (s large, 1H), 6,90 à 7,90 (m, C_6H_5 et C=CH); rmn ^{13}C ($CDCl_3$): 35,3, 125,7, 126,6, 126,9, 127,4, 128,3, 128,6, 129,4, 129,9, 130,1, 130,9, 139,9, 140,5, 160,0.

Imine ***19***: rmn ^1H ($CDCl_3$): 4,20 (pic large, 2H), 8,40 à 8,60 (s large, 1H), 6,90 à 7,90 (m, C_6H_5 et C=CH).

Le produit de thermolyse de l'aziridine **9***a* est, d'après ses spectres de rmn, composé des imines **17***a* (40%), **17***b* (35%) et **18** (25%); rmn ^1H ($CDCl_3$): 4,5 (pic large, 0,5H), 4,7 (pic large, 0,8H), 4,8 (pic large, 0,7H), 6,90 à 7,90 (m, C_6H_5 et C=CH), 8,15 (s large, 0,25H), 8,30 (s large, 0,75H); rmn ^{13}C ($CDCl_3$): 35,3, 59,3, 65,0, 125,7, 125,9, 126,6, 126,8, 127,0, 127,2, 127,5, 128,4, 129,0, 129,4, 129,8, 130,1, 130,7, 131,4, 131,6, 136,4, 136,8, 137,3, 138,4, 139,4, 139,5, 140,0, 140,5, 140,7, 160,0, 161,6, 161,9.

Le produit d'hydrolyse du produit de thermolyse de **9***a* est purifié par chromatographie sur colonne (chloroforme/acétone 99:1). On identifie le benzaldéhyde, l'énamine **20**: ir (cm^{-1}): 1590, 1600, 1680, 3400; rmn ^1H ($CDCl_3$): 4,30 (s, 2H), 7,20 à 8,20 (m, C_6H_5, C=CH et NH_2); et l'aldéhyde α-phénylcinnamique **21**: ir (cm^{-1}): 1605, 1615, 1685; rmn ^1H ($CDCl_3$): 9,87 (s, 1H), 7,10 à 7,90 (m, C_6H_5 et C=CH). Spectre de masse: 208 (96, $M^{+\cdot}$), 207 (45, $M^{+\cdot} - H^{\cdot}$), 179 (53, $M^{+\cdot} - {}^{\cdot}CHO$), 105 (76), 102 (25, 179 − $^{\cdot}C_6H_5$), 77 (32, $C_6H_5^+$), 71 (32), 44 (42), 40 (100).

Le produit de thermolyse de l'aziridine **9** est purifié par chromatographie sur colonne (chloroforme/acétone 99:1). On identifie les aldéhydes **15** et **21** et l'énamine **20** par comparaison avec des échantillons précédemment décrits. On isole également l'aldéhyde **22**: ir (cm^{-1}): 1610 1730; rmn ^1H ($CDCl_3$): 2,88 (dd, 1H, J = 8 et J = 14), 3,45 (dd, 1H, J = 7,5 et J = 14), 3,78 (4 doublets, 1H, J = 7,5, J = 8 et J = 1,5), 7 à 8 (m, C_6H_5), 9,67 (d, 1H, J = 1,5). Spectre de masse: 210 (10, $M^{+\cdot}$), 181 (6, $M^{+\cdot} - {}^{\cdot}CHO$), 107 (37), 106 (95), 105 (98), 104 (4, 181 − $^{\cdot}C_6H_5$), 94 (35), 92 (13), 91 (50, $PhCH_2^+$), 79 (61), 78 (85), 77 (76, $C_6H_5^+$), 63 (65), 52 (25), 51 (97), 50 (51), 44 (82), 40 (100).

Isomérisation de la méthyl-3 (phényl-1 vinyl)-2 aziridine ***5***

Le produit brut est purifié par chromatographie sur colonne ($CHCl_3$). On isole la phényl-2 propèn-1 yl amine **14***b*: ir (cm^{-1}): 1615, 1690, 3250, 3400; rmn ^1H ($CDCl_3$): 2,60 (s, 3H), 7,25 (s, 1H), 7,30 à 7,80 (m, C_6H_5 et NH_2).

Isomérisation de la méthyl-3 (phényl-1 vinyl)-2 aziridine ***6***

Le produit brut est purifié par chromatographie sur colonne ($CHCl_3$). Les dérivés **14***a* et **16** sont identifiés par comparaison avec des échantillons précédemment décrits.

Isomérisation de la phényl-3 (phényl-1 propèn-1 yl)-2 aziridine ***7***

(a) Le produit de thermolyse d'un mélange **7***a*/**7***b* = 45:55 est purifié par chromatographie sur colonne (chloroforme/acétone 98:2). On sépare ainsi l'isomère **7***b* des produits de thermolyse qui sont ensuite séparés par chromatographie sur colonne (chlorure de méthylène/éther de pétrole 3:2).

α-*Phénylcrotonaldéhyde* ***23***

Identifié par comparaison avec un échantillon authentique préparé selon un mode opératoire décrit (11): Eb_8 = 103−103,5°C (litt. (11) Eb_{750} = 233−235°C); ir (cm^{-1}): 1610, 1645, 1700; rmn ^1H ($CDCl_3$): 2,0 (d, 3H, J = 7), 6,85 (q, 1H, J = 7), 7,20 à 7,50 (m, C_6H_5), 9,6 (s, 1H).

N-*benzyl diphényl-3,5 méthyl-4 dihydropyridine* ***24***

Spectre ir (cm^{-1}): 1600, 1665. Spectre uv (EtOH): 375 nm (ε 3360), 290 nm (ε 4440), 240 nm (ε 11 645); rmn ^1H ($CDCl_3$): 1,23 (d, 3H, J = 6,5), 4,14 (q, 1H, J = 6,5), 4,50 (s, 2H), 6,53 (s, 2H), 7 à 7,60 (m, 15H); rmn ^{13}C ($CDCl_3$): 21,8, 31,3, 57,8, 114,0, 124,1, 125,3, 126,9, 127,6, 128,5, 128,8, 129,2, 138,5, 139,3. Spectre de masse: 337 (10, $M^{+\cdot}$), 323 (22), 322 (81, $M^{+\cdot} - {}^{\cdot}CH_3$), 260 ($M^{+\cdot} - {}^{\cdot}C_6H_5$), 246 ($M^{+\cdot} - {}^{\cdot}C_6H_5 - {}^{\cdot}CH_2$), 245 (3, 322 − $^{\cdot}C_6H_5$), 232 ($M^{+\cdot}$ − Ph—CH=NH), 231 (3, 232 − $^{\cdot}H$), 106 (9), 105 (13, $Ph—CH=\overset{+}{N}H^{\cdot}$), 92 (9), 91 (100, $Ph—\overset{+}{C}H_2$), 88 (4), 86 (26), 85 (15), 84 (40), 83 (22), 77 (12, Ph^+), 65 (7), 47 (13). Préparation de la pyridine **24**: une solution composée de 0,009 mol de phényl-2 crotonaldéhyde, 0,015 mol de benzylamine et 0,5 mL d'acide acétique dans 50mL de méthanol anhydre est chauffée à reflux pendant 2 h. On évapore le solvant et purifie le résidu par chromatographie sur colonne (chlorure de méthylène/éther de pétrole 3:2). On obtient 1,35 g de produit pur identifié à la pyridine **24**: F = 130−131°C.

(b) Le produit de thermolyse de l'isomère **7***b* est purifié par chromatographie sur colonne (chlorure de méthylène/éther de pétrole 3:2). On obtient un produit dont le spectre de rmn est identique à celui décrit pour la dihydropyridine **24**.

Isomérisation thermique de la phényl-3 (phényl-1 éthoxycarbonyl-2 vinyl)-2 aziridine ***11***

Une solution de 0,2 g d'aziridine **11** dans 5 mL de chloroforme est chauffée à reflux pendant 4 jours. Après concentration, le produit brut constitué de l'imine **25** est purifié par chromatographie sur colonne (éther de pétrole/acétate d'éthyle 85:15): ir (cm^{-1}): 1730, 1710, 1660, 1645, 1605; rmn ^1H ($CDCl_3$): 1,18 (t, 3H, J = 7), 4,10 (q, 2H, J = 7), 4,08 (s, 2H), 7 à 8 (m, 11H), 8,30 (s, 1H); rmn ^{13}C ($CDCl_3$): 14,1, 35,4, 60,5, 126,0, 127,7, 128,6, 131,0, 133,6, 136,5, 139,4, 141,3, 160,5, 171,8.

Les spectres vibrationnels d'une série de *N*-méthyl-chloro et *N*-méthyl-bromotriazoles-1,2,4 ont été étudiés, et une interprétation en a été proposée dans le but d'essayer de résoudre le problème de la tautomérie des triazoles-1,2,4 *C*-substitués.

M. Saidi Idrissi, M. Senechal, H. Sauvaitre, and C. Garrigou-Lagrange. Can. J. Chem. **61**, 2133 (1983).

Vibrational spectra of some *N*-methyl chloro and *N*-methyl bromotriazoles-1,2,4 are reported. An assignment of the normal modes is proposed. This study was done in order to find new elements to solve the problem of tautomerism in *C*-substituted triazoles-1,2,4.

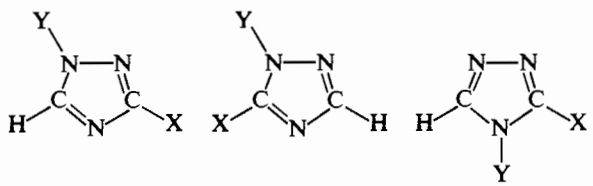
I. Introduction

Dans le cadre de nos travaux sur la tautomérie des halogénotriazoles-1,2,4 (1–3), nous nous sommes intéressés à l'étude par spectroscopie de vibration de leurs dérivés *N*-méthylés dans lesquels l'hydrogène mobile a été substitué par un groupement CH_3 ou CD_3 noté ci-dessous Y, empêchant ainsi toute possibilité de tautomérie.



On peut penser a priori que ce groupement influence peu le spectre du noyau triazolique et que les résultats que nous obtiendrons avec ces molécules "bloquées" comme modèle pourront se transposer aux halogénotriazoles *C*-substitués.

Les spectres vibrationnels de ces composés n'ont fait l'objet d'aucune analyse détaillée. Seuls à notre connaissance Mel'nikov *et al.* (4, 5) ont publié les spectres infrarouges et Raman de quelques méthyl-1-nitro-3 triazoles-1,2,4 et ont proposé une attribution basée sur un calcul de modes normaux.

Dans ce travail, nous avons étudié les *N*-méthyl-chlorotriazoles et *N*-méthyl-bromotriazoles dont nous avons analysé les spectres infrarouges dans différents états physiques (état condensé, solution dans CCl_4 ou CS_2, vapeur) et les spectres Raman (liquide, solide ou solution aqueuse). L'examen des spectres vibrationnels de quelques molécules marquées au deutérium nous a permis de justifier nos attributions.

Nous discuterons, séparément, les modes de vibration cycliques et extracycliques (6–9) ce qui n'exclut pas la possibilité d'interaction entre ces deux catégories.

Les nombres d'onde attribués aux vibrations fondamentales du noyau triazolique et du groupement méthyle (CH_3 ou CD_3) sont consignés dans les tableaux 1 et 2 respectivement. A titre d'illustration, nous présentons dans les figures 1 et 2 les spectres infrarouges des trois Me-1Cl-3 TA étudiés dans les régions 3300–2000 cm^{-1} et 1600–200 cm^{-1}.

L'analyse des spectres se fera par région.

II. Discussion des attributions

II-1. *Région 3200–2000 cm^{-1}*

Dans ce domaine spectral, on attend toutes les vibrations de valence ν CH (ou ν CD) du cycle triazolique et du groupement méthyle.

II-1-1. *Vibrations de valence ν CH (ou ν CD) triazolique*

Entre 3150 et 3100 cm^{-1}, le spectre infrarouge du Me-1 TA présente une seule bande large attribuable aux vibrations de valence des deux vibrateurs CH aromatiques (Tableau 1). Dans le cas des *N*-méthyl-halogenotriazoles, la seule absorption relevée dans cette région est due à la vibration de valence de l'unique vibrateur CH de ces molécules. Cette bande se déplace vers 2300 cm^{-1} sur les spectres de leurs homologues *C*-deutériés (Fig. 1). La fréquence de ce mode n'est pas sensible à la nature du substituant.

II-1-2. *Vibrations du groupement méthyle*

Les spectres infrarouges de tous les composés étudiés présentent entre 3030 et 2800 cm^{-1} des bandes d'absorption dont les positions et les intensités sont caractéristiques des vibrations du groupement CH_3. Elles sont déplacées vers 2200 cm^{-1} sur le spectre du CD_3-1-Cl-5 TA (Fig. 1). La bande observée vers 2950 cm^{-1} sur les spectres Raman des méthyl-1 halogénotriazoles est due à la superposition des vibrations ν_s et ν'_s CH_3. Dans le cas du Me-4Br-3TA, une bande infrarouge assez intense à 2918 cm^{-1} pourrait correspondre à la vibration ν_s CH_3. L'absorption relevée vers 3000 cm^{-1} sur les spectres infrarouges de l'ensemble des dérivés examinés est attribuée au mode ν_a CH_3.

II-2. *Région 1600–900 cm^{-1}*

Les calculs de modes normaux effectués sur des hétérocycles, et en particulier sur le triazole-1,2,4 (10) et le chloro triazole-1,2,4 (11) montrent qu'il est impossible d'individualiser les vibrations des différentes liaisons du cycle, et qu'elles sont toutes couplées. C'est pourquoi, dans la suite de ce mémoire, nous notons les vibrations du squelette triazolique R_1 à R_9.

Seules certaines vibrations planes du squelette (R_1 à R_7, δ CH) et cinq vibrations de déformation du groupement méthyle sont attendues dans cette zone spectrale. L'approximation des vibrations de groupe dans ce domaine est moins rigoureuse que

dans le domaine des hautes fréquences. Néanmoins, nous l'utiliserons pour proposer une interprétation des spectres et nous discuterons successivement les vibrations δ CH, les vibrations du noyau triazolique et les vibrations du groupement méthyle.

II-2-1. *Vibrations de déformation δ CH (ou δ CD)*

Les deux vibrations de déformation dans le plan δ CH du Me-1TA sont attribuées aux bandes observées vers 1215 et 1145 cm^{-1} (Tableau 1). Les spectres infrarouges des *N*-méthyl-halogénotriazoles présentent une absorption moyenne à forte vers 1200 cm^{-1} que nous attribuons au mode δ CH de ces composés car cette bande n'apparait pas sur les spectres de leurs homologues *C*-deutériés. La vibration δ CD est relevée vers 880 cm^{-1} (Fig. 2).

II-2-2. *Vibrations du cycle triazole-1,2,4*

Aux vibrations R_1 à R_7, nous avons fait correspondre des bandes infrarouges et des raies Raman de fréquences voisines de celles observées dans le cas du triazole-1,2,4 (1, 10) (Tableau 1). La position de la vibration R_1 est fonction de la position de l'halogène sur le cycle. Dans le cas des Me-1TA et Me-1X-3TA, le mode R_5 est observée à fréquence plus basse, les modes R_6 et R_7 à fréquences plus élevées que sur les spectres des autres composés (Tableau 1). Rappelons que dans les halogénotriazoles, les vibrations R_5 et δ CH sont en forte interaction (2).

Remarque: lors de son étude des spectres des monohalogénotriazoles et de leurs sels de potassium et d'argent, Grinshtein *et al.* (12) avaient observé un multiplet vers 1270 cm^{-1} qu'ils avaient expliqué par l'existence de plusieurs formes isomères.

Sur les spectres des *N*-méthyl-halogénotriazoles que nous avons examinés, alors que l'absorption attribuée au mode R_4 vers 1275 cm^{-1} est simple dans le cas des Me-1TA et Me-1X-5TA, elle apparait sous forme de multiplet sur les spectres des Me-1X-3TA (Fig. 2). Le spectre du Me-4Br-3TA présente dans cette région deux bandes de faible intensité. L'apparition du multiplet sur les spectres de ces "formes bloquées" nous amène à exclure l'hypothèse de Grinshtein.

Il ne peut s'agir d'une autoassociation mettant en jeu le vibrateur CH en position 5, le plus acide (cf. partie expérimentale), puisque ce multiplet existe sur les spectres des Me-1diX-3,5TA.[1] Il ne peut pas s'agir non plus d'une harmonique car la région de 600–700 cm^{-1} est assez semblable pour tous les composés. Seule reste donc, pour expliquer l'existence de ces bandes multiples, l'hypothèse d'une ou plusieurs combinaisons.

II-2-3. *Vibrations de déformation et de balancement du groupement méthyle*

Par analogie avec les interprétations déjà proposées pour les spectres de molécules aromatiques méthylées (13), nous attribuons l'absorption faible observée vers 1480 cm^{-1} sur les spectres infrarouges des Me-1TA, Me-1X-3TA, Me-4Br-3TA et l'épaulement relevé à 1510 cm^{-1} sur les spectres des

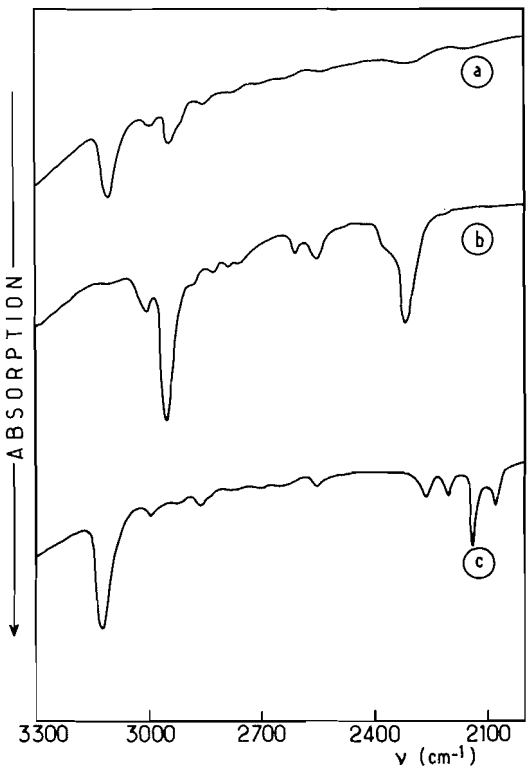

FIG. 1. Spectres infrarouges des Me-1Cl-3TA (a), Me-1Cl-3D-5TA (b) et CD_3-1Cl-3TA (c) à l'état liquide entre 3300 et 200 cm^{-1}.

Me-1X-5TA à la vibration de déformation δ_s' CH_3 (Tableau 2). Les modes δ_a et δ_s sont situés vers 1450 et 1370 cm^{-1} respectivement. Notons que, dans le cas du Me-1Cl-3TA, la bande à 1360 cm^{-1} correspond à une superposition des modes δ_s CH_3 et R_3.

Les vibrations de balancement du groupement méthyle $r_\perp$ et $r_\parallel$ sont observées vers 1070 et 960 cm^{-1} respectivement (Tableau 2). Le spectre du CD_3-1-Cl-3TA confirme ces attributions (Fig. 2).

II-3. *Région 900–200 cm^{-1}*

On attend cinq vibrations de type A" (γ CH, R_8, R_9, γ C—X, γ N—CH_3) et quatre vibrations A' (ν N—CH_3, δ N—CH_3, ν C—X, δ C—X) dans la région 900–200 cm^{-1}, la vibration de torsion du groupement méthyle ayant très vraisemblablement une fréquence inférieure à 200 cm^{-1}.

II-3-1. *Vibrations de symétrie A"*

La vibration γ CH des Me-1X-5TA est relevée vers 880 cm^{-1} (Tableau 1), celle des Me-1X-3TA vers 860 cm^{-1}. Sur le spectre infrarouge du Me-1TA à l'état dissous, on observe deux absorptions à 882 et 850 cm^{-1}; nous les attribuons, par comparaison avec les molécules précédentes, aux deux modes γ CH faisant intervenir respectivement les vibrateurs CH en positions 3 et 5 du cycle. La vibration γ CH du Me-4Br-3TA est relevée à 848 cm^{-1}, fréquence voisine de celle observée dans le cas des Me-1X-3TA (Tableau 1). Notons que dans ces deux cas, l'hydrogène occupe une position analogue par rapport au groupement méthyle. Cette interprétation est confirmée par le déplacement de ces bandes vers 560 cm^{-1} après deutériation sur le carbone (Fig. 2).

Les mouvements de déformation du cycle triazole R_8 et R_9 donnent lieu aux absorptions situées respectivement vers 700 et 630 cm^{-1} sur les spectres infrarouges de tous les composés (Tableau 1, Fig. 2).

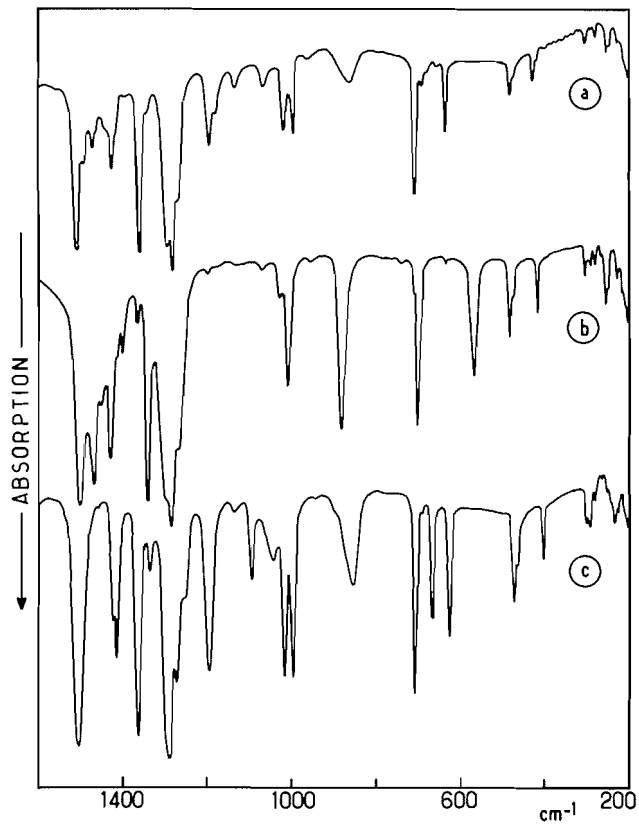

FIG. 2. Spectres infrarouges des Me-1Cl-3TA (a), Me-1Cl-3D-5TA (b) et CD_3-1Cl-3TA (c) à l'état liquide; région 1600–200 cm^{-1}.

Toutes ces bandes présentent bien un contour de type C sur les spectres de l'état gazeux (14).

Notons, comme prévu, qu'aucune de ces vibrations n'a été observée sur les spectres Raman des solutions aqueuses.

Les vibrations γ N—CH_3 et γ C—X n'ont pas pu être localisées, soit parce qu'elles sont en dehors de notre domaine d'étude en infrarouge, soit parce qu'elles sont d'intensité trop faible.

II-3-2. *Vibrations de symétrie A'*

La bande moyenne à forte relevée vers 700 cm^{-1} sur les spectres infrarouges de l'ensemble des molécules et à laquelle correspond une raie Raman intense et polarisée est due à la vibration ν N—CH_3. Cette attribution est en accord avec celle donnée pour le *N*-méthyl pyrrole (15).

A la vibration de déformation dans le plan δ N—CH_3, nous rattachons les fréquences observées vers 420 cm^{-1}.

Une absorption infrarouge et une raie Raman très forte et polarisée sont observées vers 480 cm^{-1} sur les spectres des Me-1Cl-3TA (Tableau 1, Fig. 2); nous les attribuons à la vibration ν C—Cl. Dans le cas des Me-1Cl-5TA, on retrouve cette vibration vers 512 cm^{-1} (Fig. 2). La vibration de déformation δ C—Cl est située vers 300 cm^{-1}.

La vibration ν C—Br apparait sur les spectres des *N*-méthyl bromotriazoles sous la forme d'une raie Raman intense et polarisée et d'une absorption moyenne vers 360 cm^{-1}; le mode δ C—Br est observée vers 280 cm^{-1} (Tableau 1).

Ces attributions sont proches de celles données dans le cas des ClTA (2) et BrTA (14, 16).

III. Conclusion

Les spectres de vibration des *N*-méthyl monohalogénotriazoles-1,2,4 ont été analysés. Une attribution pour l'ensemble

des mouvements a été proposée. Toutefois, contrairement à d'autres techniques physicochimiques, notamment la détermination de moments dipolaires en solution (17), l'étude par la spectroscopie de vibration de ces "formes bloquées" n'a pas permis d'apporter des éléments nouveaux à l'élucidation du problème de la tautomérie des *C*-halogénotriazoles-1,2,4. En effet, les spectres des composés examinés présentent une grande similitude et il nous a été impossible de relever une région spectrale présentant une variation notable entre les spectres des différents *N*-méthyl halogénotriazoles-1,2,4.

IV. Conditions expérimentales

IV-1. *Synthèse des composés étudiés*

Les *N*-méthyl halogénotriazoles-1,2,4 ont été obtenus selon le mode opératoire décrit dans les réfs. 1 et 17, les composés *C*-deutériés ont été préparés par échange avec D_2O à 120°C pendant une journée pour les Me-1X-3TA et une semaine pour les Me-1X-5TA.

Le CD_3-1Cl-3TA a été synthétisé en milieu neutre en utilisant ICD_3 comme agent méthylant.

IV-2. *Étude spectroscopique*

Les spectres infrarouges dans la région 4000–200 cm^{-1} ont été enregistrés avec des spectromètres P.E. 225 et 577.

Les échantillons ont été étudiés dans différents états physiques (solide dispersé dans le Nujol ou le Fluorolube ou en pastille de KBr, liquide pur et vapeur). Des cellules à fenêtres en CsI et une cellule chauffante P.E. ont été utilisées.

Les spectres Raman des composés liquides ou des solutions aqueuses ont été obtenus en utilisant deux spectromètres Coderg, l'un équipé d'un laser à Argon ionisé émettant à 4880 Å, l'autre d'un laser Hélium Néon (λ = 6328 Å).

Remerciements

Nous sommes reconnaissants à Monsieur A. Bernardini de l'école des Sciences et Techniques de Montpellier, à Mme E. Dupart du Centre de Recherche Paul Pascal de nous avoir aidés à obtenir certains composés et à Mme C. Dacié d'avoir enregistré pour nous quelques spectres de composés à l'état gazeux.

KOTTAYIL I. VARUGHESE, MARIA PRZYBYLSKA, KAZIMIR SESTANJ, FRANCESCO BELLINI, and LESLIE G. HUMBER. Can. J. Chem. **61**, 2137 (1983).

The crystals of $C_{16}H_{14}F_3NO_3S_2$ belong to the monoclinic space group $P2_1/c$ with a = 11.577(1), b = 12.404(1), c = 12.366(1) Å, β = 90.01(1)°, and Z = 4. The structure was solved by MULTAN 78. The parameters were refined by block-diagonal least-squares to a final R of 0.047 for 2679 observed reflections. Of particular interest is an intramolecular attractive interaction between the sulfur and oxygen atoms with an S···O distance of 2.879(2) Å, in which oxygen appears to act as an electrophile. Intermolecular hydrogen bonds between the hydroxyl and keto groups join the molecules related through a centre of symmetry into dimers.

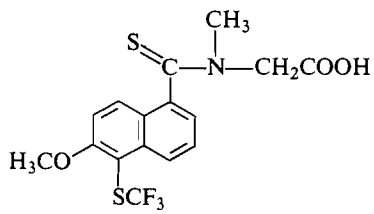
KOTTAYIL I. VARUGHESE, MARIA PRZYBYLSKA, KAZIMIR SESTANJ, FRANCESCO BELLINI et LESLIE G. HUMBER. Can. J. Chem. **61**, 2137 (1983).

Les cristaux de $C_{16}H_{14}F_3NO_3S_2$ appartiennent au groupe d'espace monoclinique $P2_1/c$ avec a = 11,577(1), b = 12,404(1), c = 12,366(1) Å, β = 90,01(1)° et Z = 4. On a résolu la structure par la méthode MULTAN 78 et on l'a affinée par la méthode des moindres carrés jusqu'à une valeur de R = 0,047 pour 2679 réflexions observés. L'attraction intramoléculaire entre l'atome de soufre et les atomes d'oxygènes avec une distanee S···O de 2,879(2) Å dans laquelle l'oxygène semble agir comme un électrolyte est d'un intérêt particulier. Les liaisons hydrogènes intermoléculaires entre les groupes hydroxyle et cétone réunissent en dimères les molécules apparentées via un centre de symétrie.

[Traduit par le journal]

Introduction

N-[[6-Methoxy-5-(trifluoromethyl)thio-1-naphthalenyl]thioxomethyl]-*N*-methylglycine, **1**, is a compound which inhibits aldose reductase (1), an enzyme which reduces glucose to sorbitol in certain tissues, and which is involved in the manifestation of some of the disabling complications of chronic diabetes (2).



1

Compound **1** contains a thioamide grouping in the side chain, wherein the zwitterionic iminothiol resonance structures can exist in *cis* or *trans* forms. In addition, free rotation of the side chain about the bond joining it to the naphthalene ring is likely restricted due to the bulk of the sulfur atom as well as the peri effect of the hydrogen atom at position 8.

For these reasons a crystallographic study was undertaken to determine the structure of **1** and the conformation of the side chain.

Experimental

Crystal data:

$C_{16}H_{14}F_3NO_3S_2$ fw = 389.4

Monoclinic, $P2_1/c$, a = 11.577(1), b = 12.404(1), c = 12.366(1) Å, β = 90.01(1)°, Z = 4, ρ_c = 1.46 g cm^{-3}, λ(CuKα) = 1.54178 Å, μ(CuKα) = 31.0 cm^{-1}.

[1]NRCC No. 21306.

The crystals of the title compound, mp 168–169°C, were obtained from a mixture of ethyl acetate and ether (~1:2). The data were measured at room temperature on a Nonius CAD-4 diffractometer using a crystal of dimensions 0.5 × 0.3 × 0.25 mm and Ni-filtered Cu radiation. The cell parameters were derived from the least-squares fit to the angular settings of 25 well-centered reflections with 2θ values from 38.2 to 50°. The scan mode ω–2θ was used to a limit of 2θ = 140°. The peaks were scanned at a 4° take-off angle with $\Delta\omega = (0.7 + 0.25 \tan\theta)°$ extended 25% on each side for background, and at a maximum speed of 5°/min for strong reflections. Three reflections were used to monitor the changes in intensities and no systematic decrease was observed.

A total of 3370 unique reflections was measured of which 2679 (79%) were above threshold of 1.43$\sigma(I_{net})$. The net intensities were corrected for Lorentz and polarization effects but not for absorption.

The structure was solved by MULTAN 78 (3) and refined by block-diagonal least-squares to an R = 0.047 and R_w = 0.055 for observed reflections.

The weighting scheme was $\sqrt{w} = 1/\{1 + [(|F_o| - 10)/15]^2\}^{1/2}$ if $\sin^2\theta \geq 0.27$ and $\sqrt{w} = [1/\{1 + [(|F_o| - 10)/15]^2\}^{1/2}]$ $(\sin^2\theta/0.27)$ if $\sin^2\theta < 0.27$. The constants were chosen to make $\Sigma w(|F_o| - |F_c|)^2$ independent of $|F_o|$. During the final stages of refinement three reflections ($20\bar{2}$, 012, $12\bar{4}$) which showed extinction effects were excluded.

Mean and maximum shifts/esd for all atoms were 0.07 and 0.98, respectively. The scattering factors were those of Hanson, Herman, Lea, and Skillman (4) for non-hydrogen atoms and of Stewart, Davidson, and Simpson (5) for H. All calculations were carried out with the NRCC crystallographic computer programs by Ahmed, Hall, Pippy, and Huber (6).

The refined atomic coordinates are given in Table 1.[2]

[2]Tables of observed and calculated structure factors and of temperature factors are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Discussion

The stereochemistry of the molecule is shown in Fig. 1 and the bond lengths and angles are presented in Fig. 2. The C—H bonds are in the range 0.87 to 1.04 Å (mean = 0.94 Å and esd ≤ 0.04 except for C(12)—H(12,3) for which it is 0.06 Å). The bond lengths of the naphthalene moiety agree well with those in naphthalene (7) and perdeuteronaphthalene (8) (cf. values in Table 2), with the exception of C(4)—C(10) and symmetrically related C(8)—C(9), which are significantly shorter (1.402(3) and 1.406(3) Å). It is interesting that these bond lengths match the corresponding values in 1,5-dimethylnaphthalene obtained from a neutron diffraction study (9), but not those from the less accurate X-ray analysis of 1,5-dimethylnaphthalene (10). The endocyclic angles fall into two categories: the smaller angles at C(9) and C(10) vary from 118.3 to 119.0°; the remaining angles range from 119.8 to 122.0°. Similar differences, although smaller, were observed in naphthalene, perdeuteronaphthalene, and in 1,5-dimethylnaphthalene (9).

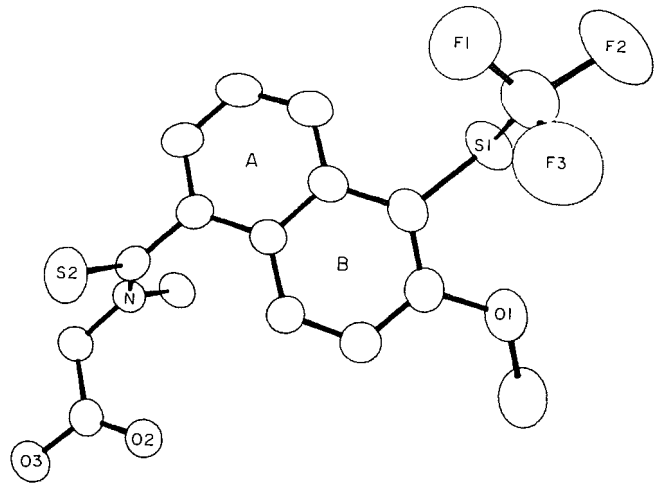

FIG. 1. An ORTEP drawing showing thermal ellipsoids at the 50% probability level.

The lengthening of C—F bonds (1.319−1.331(4) Å) and the shortening of S(1)—C(11) to 1.779(3) Å seem to be due to the attraction of electrons by the CF_3 group. In (R)-*N*-trifluoroacetyl-1-(1-naphthyl)ethylamine (11) the C—F bonds vary from 1.303−1.314(7) Å. The S(1)—C(sp^2) bond is 1.770(2) Å.

The C(13)—N bond length is 1.336(3) Å, suggesting considerable double bond character. A stereoscopic pair (Fig. 3) shows that the naphthalene moiety and the acetic acid chain are *trans* to each other with respect to that C—N bond, and that S(2) is far removed from the hydrogens at positions 2 and 8 of the naphthalene ring (3.35(3) and 3.46(3) Å, respectively). The shortest S(2) intramolecular contact is 2.66(3) Å, with H(15,2).

The naphthalene moiety deviates significantly from planarity. The distances of its atoms from the calculated plane, given by $0.1582X + 0.8768Y - 0.4542Z = 5.5754$, where X, Y, Z are orthogonal coordinates in Å, are shown in Table 3. Both S(1) and O(1) atoms are situated above that plane and the S···O intramolecular distance is 2.879(2) Å, which is considerably shorter than the sum of the van der Waals radii of 3.32 Å (r(O) = 1.52 Å, r(S) = 1.80 Å (12)). The angles S(1)—C(5)—C(6) and O(1)—C(6)—C(5) are appreciably smaller (118.5 and 117.9°, respectively) than the adjoining C(10)—C(5)—S(1) and C(7)—C(6)—O(1) (120.5 and 122.3°). All these observations indicate the presence of an attractive S···O interaction.

Rosenfield, Parthasarathy, and Dunitz (13) examined nonbonded atomic contacts with divalent sulfur in 69 structures and found directional preferences for the approach of electrophiles and nucleophiles to the sulfur atom. Electrophiles tend to approach S roughly 20° from the perpendicular to the plane through atoms Y—S—Z, with values ranging from 0° to 40°. In terms of the "frontier orbital" model (14, 15), this direction corresponds to the highest occupied molecular orbital (HOMO), which is a sulfur lone-pair orbital. Nucleophiles, on the other hand, were shown to approach the sulfur atom approximately along the extension of one of the two covalent bonds to S, which was identified as the lowest unoccupied molecular orbital (LUMO), the antibonding orbital, σ*.

In a later study Row and Parthasarathy (16) surveyed structures with S···S intermolecular interactions and found that the majority of these contacts correspond to electrophile−nucleo-

phile pairing involving a HOMO orbital of one sulfur atom and LUMO of the other.

In most cases the S···O interactions (17, 18) are along one of the covalent bonds to S, the oxygen atom acting as a nucleophile. However, the examination of the stereochemistry of the title compound revealed that O(1) acts as an electrophile, as it is approaching the sulfur atom at 36.0° to the perpendicular to the plane defined by C(5), S(1), and C(11), i.e. along the HOMO orbital of S.

The S···O interaction is also nearly along the extension of

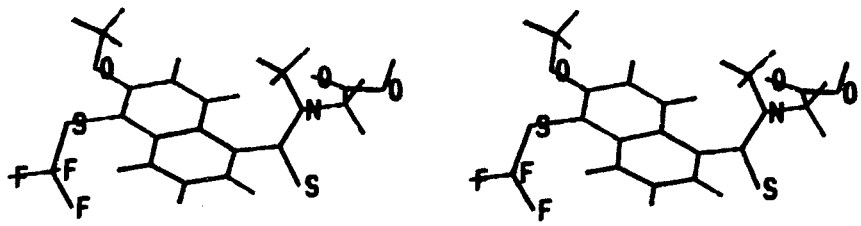

FIG. 3. Stereoscopic view of the molecule.

TABLE 3. Distances of atoms from the mean plane of the naphthalene moiety ($\times 10^3$) and their esd's[a]

Atom	Distance (Å)	Atom	Distance (Å)
C(1)	−16(2)	C(8)	2(2)
C(2)	−4(3)	C(9)	−11(2)
C(3)	31(3)	C(10)	−20(2)
C(4)	10(3)	S(1)*	16(1)
C(5)	−31(2)	O(1)*	53(2)
C(6)	14(2)	C(12)*	339(4)
C(7)	24(3)	C(13)*	−116(2)

[a]Atoms marked by an asterisk were not included in the calculation of the plane.

the O(1)—C(12) bond (<S(1)···O(1)—C(12) = 166.5(2)°), and is therefore directed towards the σ* orbital of O(1). It brings the C(12) atom close to the plane of the naphthalene moiety (Δ = 0.339 Å; see Table 3) and leads to the small value of 10.8(4)° for the torsion angle C(7)—C(6)—O(1)—C(12).

The hydrogen atoms of C(12) straddle H(7) giving smallest possible H···H contacts of 2.23(5) and 2.26(6) Å (see Fig. 3). The repulsion between these hydrogens is responsible for the widening of C(7)—C(6)—O(1) to 122.3° as compared to the corresponding angle C(10)—C(5)—S(1) of 120.5°, and to the increase of the C(6)—O(1)—C(12) angle to 118.6°. All these observations indicate that the sterically strained orientation of the methoxy group must be caused by a rather strong S···O interaction. This preferred orientation may be of importance in the biological activity of this compound.

Intermolecular hydrogen bonds between O(3) and O(2′) as well as between O(2) and O(3′) join the molecules related through a centre of symmetry into dimers. The pertinent data are: O(3)—H···O(2′) = 172.9(3.9)°, O(3)···O(2′) = 2.646(3) Å, O(3)—H = 0.87(4) Å, and H···O(2′) = 1.78(4) Å. There are no other short intermolecular contacts.

The electrochemical synthesis of β-diketonato complexes of cadmium(II), and their adducts; the crystal and molecular structure of $Cd(acac)_2phen$

LUIS BUSTOS, JAMES H. GREEN, J. LAWRENCE HENCHER, MASOOD A. KHAN, AND DENNIS G. TUCK[1]

Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received October 21, 1982

LUIS BUSTOS, JAMES H. GREEN, J. LAWRENCE HENCHER, MASOOD A. KHAN, and DENNIS G. TUCK. Can. J. Chem. **61**, 2141 (1983).

The cadmium β-diketonate complexes $Cd(RCOCHCOR')_2$ (R = CH_3, R' = CH_3; R = CF_3, R' = CH_3, *i*-C_3H_7, *i*-C_4H_9, *t*-C_4H_9, C_6H_5, 2-naphthyl) can be prepared in good yield by the direct room temperature electrochemical oxidation of the metal into a solution of the parent diketone in acetonitrile. Adducts of the type $Cd(RCOCHCOR')_2L$ (L = 2,2'-bipyridine, 1,10-phenanthroline, *N,N,N',N'*-tetramethylethylenediamine) can be prepared *in situ*, or by subsequent addition of the ligand to the electrolytic solution. X-ray studies show that the molecular structure of both $Cd(acac)_2phen$ and $Cd(CF_3COCHCOC_6H_5)_2phen$ is based on a CdO_4N_2 kernel, distorted from octahedral stereochemistry by the bite of the ligands.

LUIS BUSTOS, JAMES H. GREEN, J. LAWRENCE HENCHER, MASOOD A. KHAN et DENNIS G. TUCK. Can. J. Chem. **61**, 2141 (1983).

On peut préparer les complexes de β-dicétonates de cadmium $Cd(RCOCHCOR')_2$ (R = CH_3, R' = CH_3; R = CF_3, R' = CH_3, *i*-C_3H_7, *i*-C_4H_9, *t*-C_4H_9, C_6H_5, naphtyl-2) avec un bon rendement en réalisant une oxydation électrochimique directe, du métal en présence de la dicétone en solution dans l'acétonitrile à la température de la pièce. On peut préparer *in situ* les adduits du type $Cd(RCOCHCOR')_2L$ (L = bipyridine-2,2'; phénanthroline-1,10, *N,N,N',N'*-tétraméthyléthylène diamine) ou par addition subséquente du ligand à la solution électrolytique. Les études de rayons-X révèlent que la structure moléculaire des deux $Cd(acac)_2phen$ et $Cd(CF_3COCHCOC_6H_5)_2phen$ comprend un noyau de CdO_4N_2, et a une stéréochimie octaédrique déformée par le pincement du ligand.

[Traduit par le journal]

Introduction

Complexes of cadmium(II) with neutral or anionic oxygen-donor ligands have received some attention in the study of the coordination chemistry of this element. A number of adducts of cadmium halides with urea and similar ligands are known (1), and X-ray structural results have been reported for some of these (2). The most common coordination number is six, but four- and five-coordinate species have also been identified, and in keeping with other features of the coordination chemistry of cadmium and other d^{10} metal ions, relatively slight alteration in ligand properties, reaction conditions etc., may bring about changes in the coordination number. One especially interesting example of such effects is the compound $CdZn_2(PO_4)_2$, in which cadmium is found in CdO_4, CdO_5, and CdO_7 coordination (3). More relevant to the present work are the compounds $Cd(acac)_2$ (4) and $K[Cd(acac)_3]\cdot H_2O$ (5) (acac = 2,4-pentanedionate), both of which involve a CdO_6 kernel, with an infinite chain structure in $Cd(acac)_2$ giving rise to the increase in coordination number beyond the expected value of four.

We have now investigated the acceptor properties of $Cd(acac)_2$ and some analogous complexes in a preparative study involving the direct electrochemical synthesis of these compounds and their adducts. This aspect of the work follows previous electrochemical syntheses of other β-diketonate complexes in this laboratory (6–8). X-ray crystallographic studies show that the molecular structure of both of the adducts $Cd(acac)_2phen$ and $Cd(CF_3COCHCOC_6H_5)_2phen$ (phen = 1,10-phenanthroline) is based on a pseudo-octahedral CdO_4N_2 kernel.

Experimental

General

Cadmium metal was used as supplied, in the form of flattened sheets (ca. 1 × 1 cm, 1–2 g). All other materials were as in previous work (9). Cadmium analysis was by atomic absorption spectrophotometry.

Infrared spectra were recorded on a Beckman IR-12 spectrometer; ^1H and ^{19}F nmr spectra were run on a Bruker CXP-100 instrument. Mass spectra were recorded with a Varian MAT CH-5DF instrument operating in the field desorption mode, and interfaced with an Incos Model 2000 computer.

Electrochemical procedures

The electrochemical methods were essentially those used in previous experiments (6–8). A 100 mL beaker containing approximately 50 mL of solution phase served as the reaction vessel; the cathode was a thin platinum plate, and the cadmium anode (1–2 g) was a flattened sheet suspended on a platinum wire. One important experimental point which quickly emerged is that too high a current caused disintegration of the anode, with consequent contamination of the product. The conditions quoted in Table 1 gave a reasonable rate of reaction without such complications. Details of some specific preparations are given below.

The products were characterised by cadmium analysis, infrared spectroscopy, and in some cases mass spectrometric determination of molecular weight. Analytical results are given in Table 2. The ^1H nmr spectra, detailed in Table 3, are very similar to these reported for complexes of indium with the same β-diketonates (10).

Preparative

(a) Bis(2,4-pentanedionate)cadmium(II). As the electrochemical oxidation proceeded, hydrogen gas was evolved at the cathode, and a colourless precipitate formed at the anode. This air-stable material was collected by filtration and dried *in vacuo*.

(b) Adducts of $Cd(acac)_2$. The oxidation was carried out using the conditions given in Table 1. The products deposited in the cell were collected, washed with acetonitrile and petroleum ether, and dried *in vacuo*.

(c) $Cd(CF_3COCHCOR)_2$. The products of the electrochemical oxidation of cadmium in the presence of CF_3COCH_2COR (see Table 1) are soluble in the reaction mixture. The solution was filtered after electrolysis to remove any particles of cadmium metal etc., and solvent removed from the filtrate *in vacuo*. The resultant oil was dissolved in the minimum amount of acetone, and petroleum ether added to precipitate the product, which was collected and dried *in vacuo*.

[b]Integration of low accuracy.
[c]L = $CF_3COCHCOC_6H_5$; L′ = $CF_3COCHCO$(2-naphthyl).
[d]Integration not attempted.
[e]Naphthyl and donor ligand resonances not resolved.

(d) Adducts of $Cd(CF_3COCHCOR)_2$ (R = C_6H_5, 2-naphthyl). A solution of the cadmium β-diketonate and an equimolar quantity of 2,2′-bipyridine or 1,10-phenanthroline was stirred at room temperature for ca. 3 h. The solvent was removed by evaporation, and diethyl ether, and then petroleum ether, added to precipitate the adduct, which was collected and dried *in vacuo*. Yields were in the range of 70–80%. The product of the reaction of 1,10-phenanthroline and $Cd[CF_3COCHCO(2\text{-naphthyl})]_2$ did not analyse satisfactorily.

Crystal structure determination

The crystal data for $Cd(acac)_2phen$ are given in Table 4. A suitable crystal with dimensions of 0.2 × 0.2 × 0.3 mm was chosen, and the data were collected on a Syntex $P2_1$ diffractometer. The procedure for data collection and processing is described elsewhere (11). During the data collection, the intensities of three monitor reflections decreased by 4% and this was accounted for by applying appropriate scaling factors. The space group *Pbcn* (No. 60) was determined from the systematic absences ($0kl$, $k = 2n$; $h0l$, $l = 2n$; $hk0$, $h + k = 2n$). The data were corrected for Lorentz and polarization effects, and an analytical absorption correction was also applied.

The position of the cadmium atom on a two-fold axis was obtained from a sharpened Patterson synthesis, and the subsequent difference Fourier map revealed the positions of all other non-hydrogen atoms. The structure was refined anisotropically by full-matrix least-squares methods to $R = 0.0369$. A difference map at this stage showed peaks for some plausible hydrogen atom positions, and all the hydrogen atoms were included in the subsequent refinement in the "idealized" position (C—H = 0.95 Å, $U = 0.06$ Å^2 for phenyl hydrogens and $U = 0.11$ Å^2 for methyl hydrogens). Full-matrix least-squares refinement yielded the final values $R = 0.0233$, $R_w = 0.0280$, for 1324 "observed" reflections. In the last cycle the largest shift/error ratio was 0.01 and the final difference map had no features of chemical significance, the maximum peak being ~0.2 e Å^{-3}. Least-squares refinement minimized the function $\Sigma w(\lvert F_o\rvert - \lvert F_c\rvert)^2$. Unit weights were used in the initial stages of refinement, while in the final cycles of calculation a weighting scheme of the form $w = (1/(\sigma^2(F) + 0.02F^2))$ was employed.

Scattering factors for all non-hydrogen atoms, including the anomalous disperson correction terms $\Delta f'$ and $\Delta f''$ of cadmium were obtained from ref. 12, and for the hydrogen atoms from ref. 13. All calculations were carried out on the University of Windsor IBM 3031 computer with the programmes CHECK and PROC (14), ABSORB (15), SHELX 77 (16), XANADU (17), and ORTEP (18). The final atomic coordinates[2] are given in Table 5, and bond lengths and angles are presented in Table 6. Figure 1 illustrates the molecular structure, with the atomic numbering scheme, and the unit cell packing is shown in Fig. 2.

A single crystal of $Cd(CF_3COCHCOC_6H_5)_2phen$ was subjected to an exactly analogous treatment and refined to $R = 0.0691$ (see Table 4). At this stage it was clear that the molecular geometry of this molecule is essentially identical to that of $Cd(acac)_2phen$ insofar as the CdO_4N_2 kernel is concerned.

Results and discussion

Preparative

The experiments described above demonstrate another application of the method of direct electrochemical synthesis in the preparation of cadmium β-diketonates and their adducts. This latter group of new complexes can be synthesised in a one-step procedure, or by using solutions of the cadmium diketonates prepared previously. The $Cd(CF_3COCHCOR)_2$ compounds have not been previously reported.

The mechanism of the electrochemical synthesis of β-diketonate complexes has been described earlier in terms of

[2]The observed and final calculated structure amplitudes, calculated hydrogen atom coordinates, and the anisotropic thermal parameters are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

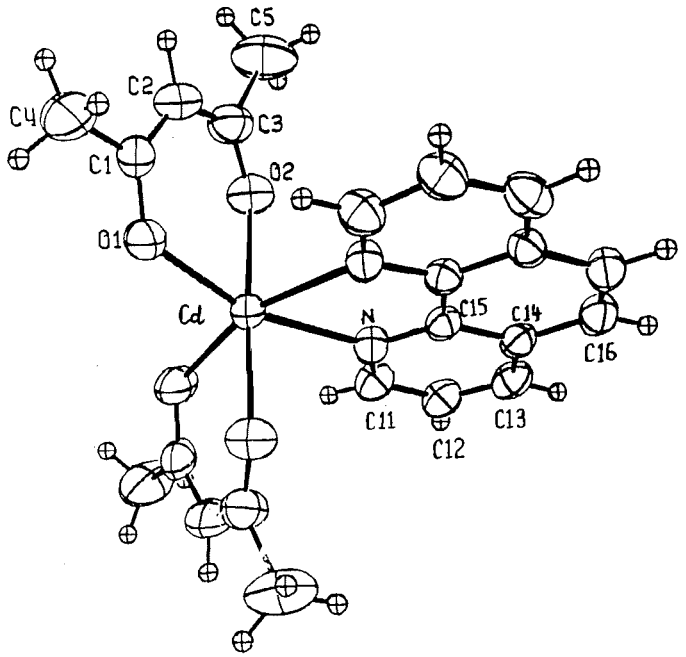

FIG. 1. Stereochemistry of $Cd(acac)_2phen$, $CdC_{22}H_{22}N_2O_4$.

the following processes:

cathode: $n\text{Hacac} + ne \rightarrow n\text{acac}^- + (n/2)H_2$

anode: $n\text{acac}^- + M \rightarrow M(acac)_n$

In keeping with this mechanism, we observed formation of gas at the cathode; equally the electrochemical efficiency, defined as moles of metal dissolved per Faraday, was close to the calculated value of 0.5 mol F^{-1} (experimental, for Cd/Hacac 0.54 mol F^{-1}; for Cd/Hacac/bipy 0.52 mol F^{-1}). The chemical yields, measured in terms of moles of product per mole metal dissolved, are in the range 55–75% (Table 1), so that the method is a simple and efficient route to these chelate complexes.

Electrochemical synthesis is also a convenient route to adducts of cadmium β-diketonates with bidentate ligands. The compound $Cd(acac)_2bipy$ has been previously prepared from $Na[Cd(acac)_3]$, but the product of this method with 1,10-phenanthroline is the hydrate $Cd(acac)_2phen \cdot H_2O$ (19). The formation of such adducts is a reflection of the Lewis acid character of $Cd(acac)_2$, as is the solid state homopolymeric structure of this compound, and the preparative results show that this property is retained even when bulky β-diketonate ligands such as $[CF_3COCHCO(2\text{-naphthyl})]^-$ are used. This electron pair acceptor character is one of the many examples of the tendency of d^{10} metal ions to exceed the four-coordination predicted by the inert gas configuration rule. We were unable to obtain adducts of $Cd(acac)_2$ with monodentate ligands such as pyridine, dimethylsulphoxide, or acetonitrile by the electrochemical method, although adducts of $Cd(acac)_2$ with R_3PO (R = *n*-octyl, phenyl) have been reported (20).

Finally, we note that the presence of bulky substituents in the β-diketonate ligand does not inhibit the acceptor character of the resultant CdL_2 species toward bidentate ligands, and pre-

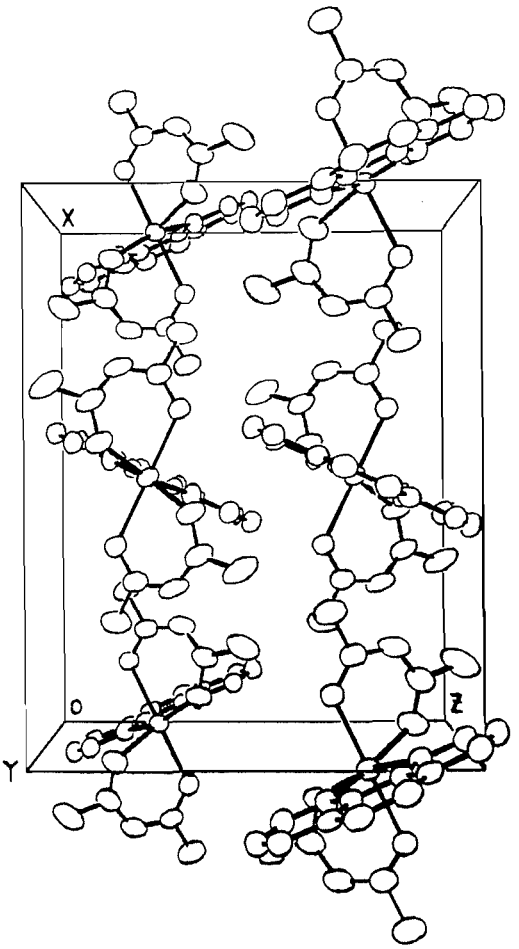

FIG. 2. Packing diagram for $Cd(acac)_2phen$, $CdC_{22}H_{22}N_2O_4$.

liminary X-ray investigation confirmed that $Cd(CF_3COCHCOC_6H_5)_2phen$ has essentially the same CdO_4N_2 structure as $Cd(acac)_2phen$. It is unfortunate that we were not able to obtain samples of any of the $Cd(CF_3COCHCOR)_2$ compounds in sufficiently good quality for X-ray structural determination, so that the question of the molecularity of these compounds in the solid state presently remains unanswered.

Structure of $Cd(acac)_2phen$

The molecular structure of $Cd(acac)_2phen$ (Fig. 1) is based on CdO_4N_2 octahedral coordination, necessarily distorted as the result of the bidentate character of the ligands. The Cd—O bond distances are in the middle of the range of 2.25–2.50 Å derived earlier (2) for six-coordinate species, but the detailed values show a clear *trans*-effect, in that Cd—O bonds opposite oxygen are significantly longer (2.272(3) Å) than Cd—O *trans* to nitrogen (2.223(3) Å). This is readily understood in terms of the formal negative charge distributed between the two oxygen atoms of $acac^-$, as opposed to the neutral nitrogen atoms of 1,10-phenanthroline. Comparison of the Cd—O bond distances with those in $Cd(acac)_2$, or $Cd(acac)_3^-$, are rendered difficult by the range of values in these compounds. For $Cd(acac)_2$, Cd—O_{br} spans the range 2.288(4)–2.353(4) Å, while for the non-bridging oxygen atoms Cd—O is 2.221(5) and 2.250(4) Å. In $Cd(acac)_3^-$, the values range from 2.247(9) to 2.325(9) Å, with an average of 2.28 Å, close to the present result for Cd—O *trans* to oxygen. The O—Cd—O angles within the chelate ring are in good agreement in all three compounds, namely, 80.4° in $Cd(acac)_2$, 79.5° in $Cd(acac)_3^-$, and 81.5(1)°, in $Cd(acac)_2phen$; the values for the first two compounds are the mean angles for the various independent ligands (4, 5). The CdO_2C_3 ring formed by the β-diketonate ligand is almost planar, with the maximum deviation of 0.017 Å at C(1). The C—C and C—O bond lengths are again close to those published for this ligand in complexes with cadmium (4, 5), and with the isoelectronic In^{3+} ion (21).

The literature contains two previous reports of structures involving cadmium complexed by 1,10-phenanthroline, namely, $(phen)Cd[Mn(CO)_5]_2$ (22) and $(phen)Cd(S_2COEt)_2$ (23). The Cd—N distances and the N—Cd—N angle found in the present work agree with the earlier values within experimental error. Results for other neutral donors (2) yield Cd—N distances in the range 2.10–2.80 Å, with a mean value of ca. 2.40 Å, in agreement with the experimental result given in Table 6. The structure of the coordinated 1,10-phenanthroline calls for little comment; the aromatic rings are planar, and the C—C and C—N bond lengths are in keeping with published values.

As noted earlier, the structure of $Cd(CF_3COCHCOC_6H_5)_2phen$ has been refined to $R = 0.069$. The average bond distances are Cd—O = 2.25(3) Å, and Cd—N = 2.32(3) Å, the mean O—Cd—O angle is 80(1)°, and N—Cd—N is 72(1)°. In all respects then the structure is the same as that reported for $Cd(acac)_2phen$ within the experimental error. The structure of the ammonium salt of the anion $Cd[CF_3COCHCO(2\text{-furyl})]_3^-$ shows very similar values (24), and given these similarities the refinement was not carried further.

Mass spectrometric results

We have commented elsewhere (25) on the advantages of field desorption mass spectrometry in inorganic and organometallic chemistry. The case of $Cd(CF_3COCHCOR)_2$ complexes is further evidence of this, with the spectra all being effectively identical. That of $Cd(CF_3COCHCOC_6H_5)_2$ consists of two main features, to wit, a group of peaks corresponding to the molecular ions $CdL_2^{+\cdot}$ of various isotopes and ions of the neutral ligand $HL^{+\cdot}$. The intensities of the $CdL_2^{+\cdot}$ region are in agreement, within experimental error, with those calculated on the basis of the known isotopic masses and abundances. Certain significant low mass species are tentatively identified on the basis of m/e values as $CF_2^{+\cdot}$ (50.0), $F_2^{+\cdot}$ (38.00) and $FO^{+\cdot}$ (35.00). These low mass ions represent less than 20% of the total ion intensity, of which 65% is in the $CdL_2^{+\cdot}$ manifold.

Excess volumes of binary mixtures of cyclohexanone with some monosubstituted benzenes at 298.15 K

B. CHAWLA,[1] S. K. MEHTA, R. V. JASRA, AND S. K. SURI[2]

Department of Chemistry, Indian Institute of Technology, New Delhi - 110016, India

Received May 13, 1982[3]

B. CHAWLA, S. K. MEHTA, R. V. JASRA, and S. K. SURI. Can. J. Chem. **61**, 2147 (1983).

Molar excess volumes for the binary mixtures of cyclohexanone with benzene and some monosubstituted benzenes, namely, toluene, ethylbenzene, isopropylbenzene, tertiary butylbenzene, chlorobenzene, bromobenzene, iodobenzene, *N*,*N*-dimethylaniline, nitrobenzene, benzaldehyde, and benzonitrile have been calculated from the precise and accurate experimental density data at 298.15 K over the entire composition range. The results have been discussed in terms of the strength of molecular interactions in the binary mixtures.

B. CHAWLA, S. K. MEHTA, R. V. JASRA et S. K. SURI. Can. J. Chem. **61**, 2147 (1983).

Faisant appel aux données précises de densité expérimentale à 298,1 K sur toute l'étendue de de composition, on a calculé les volumes molaires en excès des mélanges binaires de quelques benzènes monosubstitués tels le toluène, l'éthylbenzène, l'isopropylbenzène, le *tert*-butylbenzène, le chlorobenzène, le bromobenzène, l'iodobenzène, la *N*,*N*-diméthylaniline, le nitrobenzène, la benzaldéhyde et le benzonitrile. On discute des résultats en fonction de la force des interactions moléculaires dans les mélanges binaires.

Introduction

In continuation of our earlier studies on thermodynamic properties of binary liquid mixtures (1–4), we report in this paper the results of molar excess volumes for mixtures of cyclohexanone with benzene and some monosubstituted benzenes at 298.15 K. The monosubstituted benzenes studied are toluene, ethylbenzene, isopropylbenzene, tertiary butylbenzene, chlorobenzene, bromobenzene, iodobenzene, *N*,*N*-dimethylaniline, benzaldehyde, nitrobenzene, and benzonitrile. These studies were aimed to determine the effect of changing polarity of monosubstituted benzenes on the volumetric behaviour of their cyclohexanone solutions with a view to understand the factors determining the unlike interactions between molecules in such mixtures.

Experimental

Analar reagent grade samples of benzene, toluene, and benzaldehyde and commercial laboratory reagent grade samples of ethylbenzene, chlorobenzene, bromobenzene, nitrobenzene, benzonitrile, *N*,*N*-dimethylaniline, and cyclohexanone supplied by BDH, and samples of isopropylbenzene and iodobenzene supplied by Aldrich were purified according to established procedures (5). The sample of tertiary butylbenzene was prepared by reacting tertiary butylchloride (obtained by reacting tertiary butylalcohol with concentrated hydrochloric acid) with benzene in presence of anhydrous aluminium chloride (6). The resultant material was first dried over anhydrous magnesium sulphate and then fractionally distilled. All of the reagents were stored in brown bottles and fractionally distilled immediately before use. The densities and refractive indices of the solvents have been compared with the accepted literature values (5, 7–9) in Table 1.

The molar excess volumes of mixing have been calculated from the experimental density data. The solutions for the measurement of densities were prepared by weight and corrections for buoyancy were applied. The details of the experimental technique for the preparation of solutions have been described earlier (10).

The densities were measured with a vibrating tube digital density meter Model DMA 602/DMA 60 (Anton Paar, Austria). Water from a constant temperature bath was circulated through the metal block of the density meter at a flow rate of ~ 3 dm^3 min^{-1}. The temperature of the water bath was controlled to $\pm 1 \times 10^{-3}$ K using a Tronac PTC 40 proportional temperature controller. The density meter was calibrated with dried air and degassed ion-exchanged water. The density of water was taken to be 0.9970429 g cm^{-3} at 298.15 K (11). Duplicate densities of liquids and liquid mixtures studied agreed within 3×10^{-5} g cm^{-3}. This propagates a maximum uncertainty of about ± 0.008 cm^3 mol^{-1} in molar excess volumes.

Results and discussion

The molar excess volumes, V_m^E, for the binary mixtures at 298.15 K are recorded in Table 2 and plotted as a function of solution composition in Fig. 1. Each set of results was fitted with a polynomial form:

$$[1] \quad V_m^E/(\text{cm}^3\ \text{mol}^{-1}) = x(1-x)\sum_{i=0}^{n-1} A_i(2x-1)^i$$

where x is the mole fraction of a cyclohexanone. Values of the coefficients A_i were determined by the method of (unweighed) least squares. It was found that the best fit was obtained using three to four parameters in the equation. The values of A_i along with the standard derivation for the molar excess volume $\sigma(V^E)$ are listed in Table 3.

It is observed from Fig. 1 that V_m^E varies almost symmetrically with the mole fraction of cyclohexanone and shows a maximum (or minimum) somewhere around $x = 0.50 \pm 0.15$ for all the binary systems reported in this paper. For binary mixtures of cyclohexanone with benzaldehyde, iodobenzene, nitrobenzene, and *N*,*N*-dimethylaniline, V_m^E at 298.15 K is positive over the entire composition range whereas for all other solutions, it is negative. Solutions containing bromobenzene and benzonitrile were found to exhibit only small negative values of V_m^E. To the best of our knowledge, no V_m^E data have been reported in the literature to compare with our results.

The large negative V_m^E values for the binary mixtures of cyclohexanone with benzene are indicative of specific interactions between the lone pair of electrons on the oxygen of

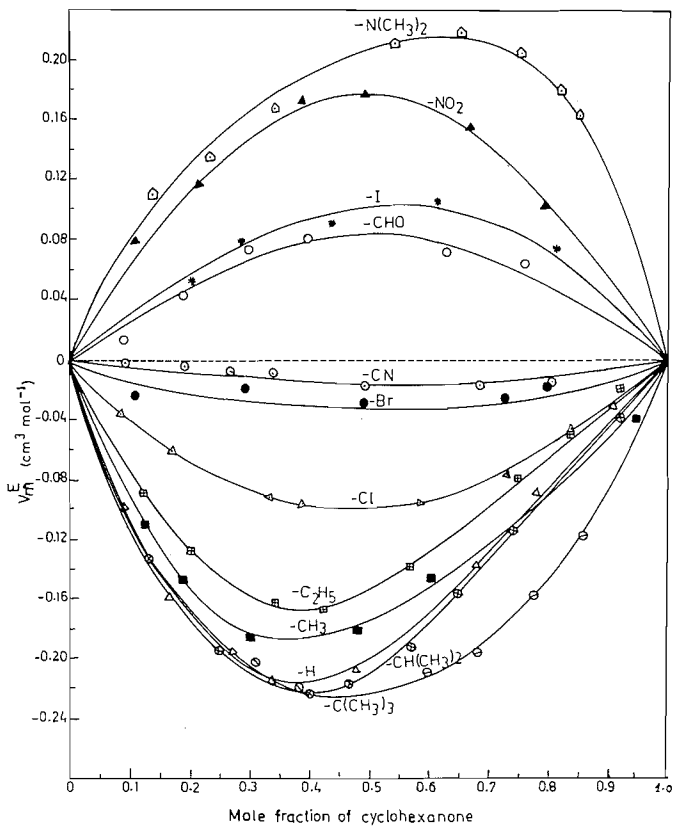

FIG. 1. Molar excess volumes, V_m^E, as a function of composition at 298.15 K for the binary mixtures of cyclohexanone with various monosubstituted benzenes: △, benzene; ■, toluene; ⊞, ethylbenzene; ⊗, isopropylbenzene; ∅, tertiary-butylbenzene; △, chlorobenzene; ●, bromobenzene; ✻, iodobenzene; ⬠, *N*,*N*-dimethylaniline; ▲, nitrobenzene; ○, benzaldehyde; ⊙, benzonitrile.

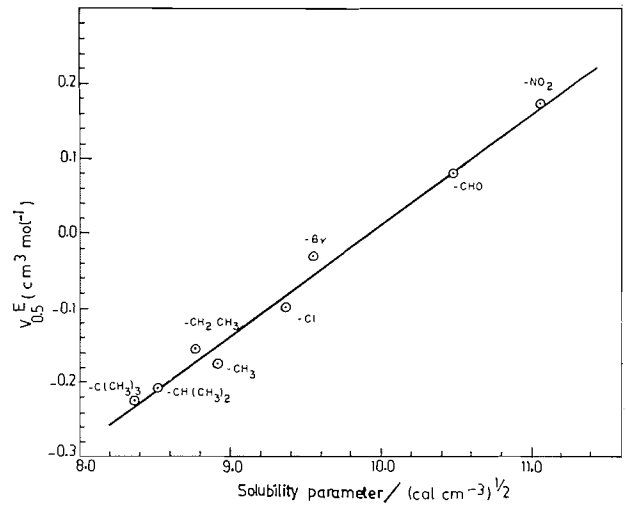

FIG. 2. Molar excess volumes for the binary mixtures at equimolar concentration, $V_{0.5}^E$ plotted against the solubility parameter of the monosubstituted benzenes at 298.15 K.

cyclohexanone and the easily polarizable π-electron system of the benzene ring (12). The V_m^E for *n*-alkyl substituted benzenes follow the order: ethylbenzene > toluene > benzene. This can be attributed to the increased positive contribution to V_m^E arising from an increase in π-electron density on the benzene ring (due to the *n*-alkyl substitution) (12). It is observed that the branched chain alkyl substitution, in spite of the significant contribution to the increase in π-electron density of the aromatic ring (and hence increased positive contribution to the polarity component of V_m^E) tend to decrease V_m^E, the magnitude of which has been found to be dependent on the extent of branching. It is apparent that the steric factors in isopropylbenzene and tertiary butylbenzene play predominant role in determining the volumetric behaviour of their cyclohexanone solutions. A similar observation has been made for the binary mixtures of cyclohexanone with alkanes (4).

The excess volumes for the binary mixtures at equimolar concentration, $V_{0.5}^E$, have been tabulated in Table 4 along with

some of the physical properties of benzene and the mono-substituted benzenes. For *n*-alkyl substituted and halo substituted benzenes, $V_{0.5}^E$ show an increase with decreasing ionization potential. Other binary mixtures studied do not show any systematic relationship with the electron-donor, -acceptor ability or with the polarity parameters (Hammett or Taft inductive effect parameters) of the component molecules (13). This is an indication of the presence of the combined contribution of steric and polarity factors to the volumetric behaviour of these solutions. In order to determine the extent of specific like and unlike interactions present in these mixtures, it is necessary to evaluate the contribution to V_m^E by size and polarity components. The attempts in this direction are being made and will be discussed subsequently.

It is interesting to observe a linear relationship between $V_{0.5}^E$ of these mixtures and solubility parameter values of the substituted benzenes at 298.15 K (Fig. 2). A tentative explanation for this seems to be the presence of dipoles in the mixtures.

Received July 14, 1982[1]

MICHELLE M. PETIT-RAMEL, GAËL DE RYCKE, ANDRÉ RIO, and PIERRE E. BLOND. Can. J. Chem. **61**, 2151 (1983).

The binary and ternary complexation in aqueous solution between copper(II) ion, *N,N'*-dimethyltartramide (H_2A) and mandelic acid (HB), were studied by potentiometric measurements in the 5–10 pH range at 25°C and μ = 1 *M* in $NaClO_4$. The titrations were analyzed using a pit-mapping method and the concentration distribution of the various simple and mixed complexes were plotted versus a pH gradient. A significant stereoselective effect is displayed in the ternary complexes only.

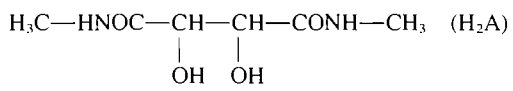
MICHELLE M. PETIT-RAMEL, GAËL DE RYCKE, ANDRÉ RIO et PIERRE E. BLOND. Can. J. Chem. **61**, 2151 (1983).

Les complexations binaires et ternaires des ions Cu^{2+} par le *N,N'*-dimethyltartramide (H_2A) et l'acide mandélique (HB) ont été étudiées, en solution aqueuse, entre les pH 5 et 10, à 25°C et à une force ionique μ = 1 *M* en $NaClO_4$. Les données expérimentales ont été analysées à l'aide d'une méthode de pit-mapping et les courbes de distribution de chacune des espèces simple et mixte ont été tracées en fonction du pH. Un effet stéréoselectif significatif n'est observé que dans le cas des complexes ternaires formés avec les énantiomères de l'acide malique.

Introduction

The dependance of the thermodynamic stability of copper complexes with optically active ligands on the resolution of racemates was first reported about ten years ago during ligand exchange chromatography of racemates by Davankov and Rogozhin (1, 2), mainly for α-amino acids (3–5). On the other hand, little work has appeared on the separation of α-hydroxy-acids or diols enantiomers, probably because these compounds show a less uniform behaviour than the amino acids. However, the complexing properties of dihydroxy compounds such as mandelic acid (6, 7) or catechol derivatives (8) with some metals, especially Cu, Zn, and Cd, have already been described and used in several analytical techniques (9, 10).

Preliminary to a chromatographic study, it is necessary to follow the formation of the copper complexes with amides derived from tartaric acid, such as *N,N'*-dimethyltartramide (H_2A), and hydroxyacid such as mandelic acid (HB):



In order to examine the complexing properties of the hydroxyl groups of the asymmetric carbons, the ends of the amide structure were deliberately blocked with non-ionizable protecting groups for the range of pH corresponding to the ionization of the alcoholic functions.

In this paper, we wish to report the possibility of obtaining: firstly a ternary complex between copper ions, *N,N'*-dimethyltartramide and mandelic acid; and secondly, a significant stereoselective interaction when the ternary complexation occurs with enantiomeric forms of mandelic acid.

Results

(1) Binary complexation of copper ions with N,N'*-dimethyltartramide (H_2A)*

Quantitative information about the interactions, firstly between protons and the hydroxyl groups of a ligand A, and secondly between copper ions, M, and the same ligand in a protic solvent, may be conventionally given (11) by the apparent equilibrium constant β_{pqr} of the species H_qA (β_{0q1}) and $M_pH_qA_r$ (β_{pqr}). Considering

$$[1] \quad A + qH \rightleftarrows H_qA$$

and

$$[2] \quad pM + qH + rA \rightleftarrows M_pH_qA_r$$

with

$$[3] \quad \beta_{0q1} = \frac{[H_qA]}{[H]^q[A]}$$

and

$$[4] \quad \beta_{pqr} = \frac{[M_pH_qA_r]}{[M]^p[H]^q[A]^r}$$

For every pH corresponding to the experimental curve, we can define an average number of undissociated protons per mol of ligand:

$$[5] \quad \bar{q} = \frac{C_H - [H] + [OH]}{C_A}$$

where C_A is the total concentration of ligand, [H] and [OH] the concentrations at equilibrium of H^+ and OH^-, respectively, and C_H the concentration of protons.

$$[6] \quad C_H = qC_A - B'$$

where B' is the concentration of hydroxide added.

We can obtain the transformed analogue of the titration curve, $\bar{q} = f(pH)$. The function becomes linear by a development in Fourier series. The normal equation drawn from this new expression is derived by the Gauss technique, and the derivation corresponds to minimization of the sum $\Sigma(\bar{q}_{exp} - \bar{q}_{calcd})^2$. Standard deviations are calculated by a pit-mapping method from the residual variance and the matrix of the covariances.

		CuA(−)B	CuA(+)B
CuAB	1011	17.78 (0.10)	17.06 (0.10)

*The numbers in parentheses are the confidence limits.

For *N,N'*-dimethyltartramide, as is usually justifiable in the case of substituted amides, the acidities of the amide groups are neglected, the ligand being considered bidentate with a general formula H_2A. The presence of two amide groups enhances the polarization of the OH bonds and provides them with a certain mobility in very alkaline medium. Unfortunately, the only potentiometric data are inadequate in this pH range, and it is useful to complete them by one other parameter, the rotatory power, whose value is in direct connection with the releasing of the two alcoholic protons (12). Discontinuous polarimetric measurements are performed on various solutions of *N,N'*-dimethyltartramide using known additions of super-concentrated sodium hydroxide solution (16 *N*). The successive deprotonation constants β_{021} and β_{011} can then be refined with a convenient precision between the two polarimetric levels corresponding with the H_2A and A^- forms respectively (Fig. 1).

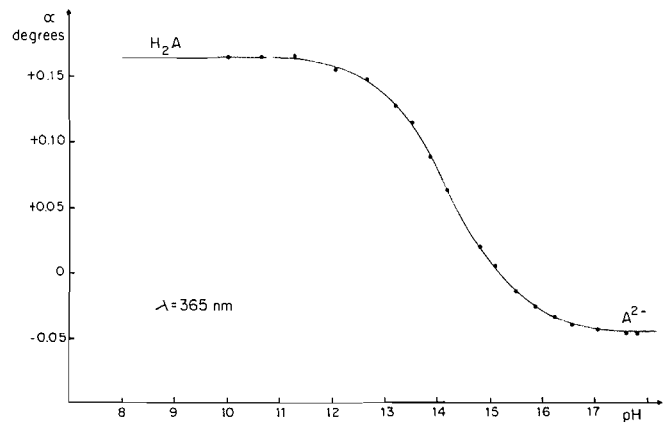

FIG. 1. Cu–*N,N'*-dimethyltartramide system: rotatory power versus pH in high-alkalinity region [A] = 2×10^{-3} *M*.

To establish the stability of the copper complexes, pH measurements were performed on solutions containing the same ligand concentration, C_A, and the various concentrations of metallic ion, C_M. For the different ratios C_A/C_M, one can superpose the formation curves, which implies the formation of two successive complexes MA and MA_2 without the formation of protonated species. The β_{0q1} constants (ligand) and β_{10r} constants (complexes) given in Table 1 allow us to determine the proportions of each species for each concentration of metallic ion and chelating agent.

(2) Binary complexation of copper ions with mandelic acid (HB)

Although metallic mandelate complexes have previously been reported (6, 7, 13), a quantitative study of the equilibria involved does not seem to have been undertaken under our experimental conditions. We have found very little information about the soluble MB complex; Meites (14) and Sengupta *et al.* (15) have described a way of obtaining information about the dissociation constant of the slightly soluble MB_2 complex, as well as the solubility product of the salt. The neutralization curves show no evidence of the ionization of two protons, but only that from the carboxyl group since the hydroxyl group does not dissociate below pH 13. Potentiometric determinations are limited by the precipitation of the MB_2 copper mandelate near pH 4, though the appearance of this complex, already mentioned, was verified by rapid experimentation. Only the formation of the MB complex can be interpreted in terms of equilibrium constants.

The titration curves for racemic and optically active mandelic acid are exactly superposable. In the presence of copper ions, they are again superposable, leading to identical $\bar{q}$, pH plots and hence to identical stability constants.

(3) Ternary complexation of copper ions with N,N'*-dimethyltartramide (H_2A) and mandelic acid (HB)*

According the general equilibrium:

[7] $pM + qH + sB \rightleftarrows M_pH_qB_s$

or, in absence of polynuclear and protonated species,

[8] $M + rA + sB \rightleftarrows MA_rB_s$

the stability constant of the MA_rB_s ternary complex is expressed by:

$$[9] \quad \beta_{10rs} = \frac{[MA_rB_s]}{[M][A]^r[B]^s}$$

Numerous potentiometric investigations (16, 17) dealing with the formation of ternary chelates with different ligands have appeared. Significant differences in the neutralization curves in this system indicate the formation of only one MAB mixed species, as long as there are no interactions between the ligands themselves. Its stoichiometry may be directly determined by a detailed numerical analysis of the data, and calculations lead to a precise value of the stability constant (Table 1) and show there is a significant stereoselectivity in the ternary complexes with tartramide and mandelic acid enantiomers.

In conclusion, the present work is preliminary to a chromatographic separation of mandelic enantiomers on an active

support based on tartramide groups. The ligands of the stationary and mobile phases must permit the formation of the previous mixed species and the difference in retention of the antipode must reflect a significant stereoselective effect. Obviously the efficacy of this mechanism depends on the difference between the stability constants of the CuA(+)B and CuA(−)B complexes which are proportional to the stereoselectivity of the mixed species. Distribution curves (Fig. 2) show that the optimal pH of the separation is near 8.

Experimental

Potentiometric titrations were conducted under a nitrogen atmosphere in a water-jacketed glass titration cell whose temperature was maintained at 25 ± 0.1°C by a circulating bath. Measurements were performed using a Philips PW 9409 pH meter with a combined Philips CA 11 electrode. In the 2–11 pH range, an average linear correction to the measured pH was made (ΔpH = 0.21) based on the usual calibration with Bates standard buffers, under the same conditions of ionic strength. The OH^- concentration was evaluated from the ionic product of water at 25°C in $NaClO_4$ 1 *M*, in this work pK_w = 13.770. Beyond pH 11, the alkaline medium concerning the two successive deprotonations of the *N,N'*-dimethyltartramide is obtained with the Scharzenbach and Sulberger's abacus (18) which permits the reaching of the theoretical pH values between 11 and 17 by using a serie of super-concentrated sodium hydroxide solutions. The correlation between the pH and the sodium hydroxide solution normalities is given in Table 2.

Rotatory powers were taken on a Perkin-Elmer M141 spectropolarimeter at 365 nm at room temperature with a 1 dm cell.

Mandelic acid was a Fluka puriss product. The *N,N'*-dimethyltartramide was synthesized in our laboratory from anhydrous and gaseous Roth methylamine and a chilled Merck ethyl tartrate alcoholic solution. After recrystallisation, the optical activity of the product was tested and found in good agreement with the values of Frankland and Slator (19).

Electron spin resonance and optical absorption studies are carried out on bis(8-hydroxyquinolinato)copper(II) and seven ternary copper(II) complexes with 8-hydroxyquinoline and salicylic acid or substituted salicylic acids. Electron spin resonance spectra of all these complexes give well-resolved lines. An unusual splitting of the parallel lines in frozen solution spectra and four line fluid (DMF) solution spectra at room temperature are observed. It is explained on the basis of either partial dissociation of 8-hydroxyquinoline ligand or the solvation effect of DMF which solvates some copper chelate molecules even at room temperature. This is more prominent on the parallel lines in frozen solution spectra of all the ternary complexes. The molecular orbital coefficients are estimated assuming an axial symmetry and these indicate that the in-plane π bonding is weak compared to σ-bond in the ternary complexes. The value of χ, which is proportional to hyperfine constants, indicates that it is quite independent of either ligand substitutions or substitutions in the ligand, but purely depends upon the immediate environment which constitutes the coordination around the paramagnetic ion.

Y. ANJANEYULU, N. V. S. RAO, R. Y. SWAMY, R. P. RAO et V. G. K. M. PISIPATI. Can. J. Chem. **61**, 2154 (1983).

On a étudié l'absorption en rpe at l'absorption optique du bis(hydroxy-8 quinolinato) de cuivre(II) et de sept complexes ternaires du cuivre(II) avec l'hydroxy-8 quinoléine, l'acide salicylique ou avec des acides salicyliques substiutés. Les spectres rpe de tous ces complexes donnent des raies bien résolues. On observe un dédoublement inhabituel des raies parallèles dans les spectres en solution gelée et quatre raies dans les spectres en solution fluide (DMF) à la température de la pièce. On explique ces faits en fonction d'une dissociation partielle du ligand hydroxy-8 quinoléine ou en fonction de l'effet de solvatation du DMF qui solvate quelques molécules de chélate de cuivre même à la température de la pièce. Cet effet est plus marqué dans les raies parallèles des spectres de tous les complexes ternaires en solution gelée. On évalue les coefficients d'orbitale moléculaire en supposant une symétrie axiale et ces coefficients indiquent que la liaison π dans le plan est faible comparativement à la liaison σ des complexes ternaires. La valeur de χ qui est proportionnelle aux constantes hyperfines, indique qu'elle est tout à fait indépendante des substitutions des ligands ou des substitutions dans le ligand, mias qu'elle dépend de l'environnement immédiat qui constitue la coordination autour de l'ion paramagnétique.

[Traduit par le journal]

Introduction

Electron spin resonance measurements of ternary copper(II) complexes are meagre compared to those of simple complexes (1–3). Particular importance is attached to the esr study on ternary complexes due to their prominence in biological systems. In these complexes, copper(II) is bound to two chelating ligands and the way in which each ligand influences the formation of a typical structure is important. No systematic study of esr of biologically active ternary copper(II) complexes regarding the hyperfine contact term in the hyperfine interactions of the paramagnetic ion was made.

The parameter χ proposed by Abragam *et al.* (4) and related to the hyperfine contact term K, is

$$[1] \quad \chi = \frac{4\pi}{S_T} \left\langle \psi \left| \sum_i \delta(r_i)\, S_{zi} \right| \psi \right\rangle$$

where χ = the effective field per unpaired electron, S_T = the total spin of the ion, $\delta(r_i)$ = the delta function term (the Fermi contact term), and S_{zi} = the spin of the ith electron. The parameter χ is negative and nearly constant in magnitude for the ions in the first row of transition element series (5). McGarvey extensively carried out the calculations on χ for the first row transition elements with different ligands and concluded that the value can vary 30% in magnitude depending upon the ligand, the host lattice, and the geometry of the chelate. Allen *et al.* (6) studied the nature of χ for a number of tetradentate Schiff base complexes of copper(II), where the immediate environment is two nitrogen atoms and two oxygen atoms, with the nitrogen atoms *cis* to each other. They concluded that the χ value is constant and quite independent of ligand substitution, with an average value = −3.918. It has been reported that the nature of χ in aliphatic polyamine complexes of copper(II) (7, 8), where the immediate environment is four nitrogen atoms, is nearly constant with a value = −3.700, confirming that the χ is nearly independent of ligand substitution but only depends upon the immediate environment. This paper presents esr and optical absorption data on bis(8-hydroxyquinolinato)copper(II) and ternary copper(II) complexes formed with 8-hydroxyquinoline and salicylic acid or substituted salicylic acids in an attempt to understand the nature of the metal–ligand bond and the parameter χ. The details of the complexes studied are shown in Fig. 1*a* and *b*.

Experimental

Equimolar solutions (0.2 *M*) of copper(II) acetate monohydrate, 8-hydroxyquinoline, and salicylic acid (or substituted salicylic acid) are prepared in 80% aqueous methanol from AnalaR Chemicals.

For preparing the ternary complexes (2–8), 50 mL each of copper(II) acetate monohydrate and the corresponding salicylate solution are mixed and stirred for half an hour. To this mixture, 50 mL of 8-hydroxyquinoline is added slowly whereby the solid mixed complex

(*a*) **1** $Cu(OX)_2$ bis(8-hydroxyquinolinato)copper(II); (*b*) ternary complexes of copper(II) with 8-hydroxyquinoline and salicylic acid or substituted salicylic acid, where R = H or $COCH_3$; X = O or S; Y = Cl, Br, I, NO_2, H. **2**, Cu(OX)(SA); **3**, Cu(OX)(Ace-SA); **4**, Cu(OX)(Cl-SA); **5**, Cu(OX)(2Br-SA); **6**, Cu(OX)(2I-SA); **7**, Cu(OX)(2NO_2-SA); **8**, Cu(OX)(Thio-SA) where OX = 8-hydroxyquinoline, SA = salicylic acid, Ace-SA = acetylsalicylic acid, Cl-SA = 5-chlorosalicylic acid, 2Br-SA = 3,5-dibromosalicylic acid, 2I-SA = 3,5-diiodosalicylic acid, 2NO_2-SA = 3,5-dinitrosalicylic acid, Thio-SA = thiosalicylic acid.

separates. After stirring for another half an hour the solid product is removed by filtration and washed with several volumes of distilled water. The solid is then boiled in acetone to remove any trace of excess ligand. In the case of binary complex **1**, 1 mol of copper(II) acetate monohydrate (25 mL) and 2 mol of 8-hydroxyquinoline (50 mL) are mixed. All the complexes are dried at 110°C for 12 h.

The first derivative tracings of the esr signals in dimethyl formamide (DMF) solutions of the complexes are recorded at room and liquid nitrogen temperatures using Varian E4 X-band ESR spectrometer. The optical absorption spectra are recorded in solution using Beckman DK-2 ratio recording spectrophotometer.

Theoretical background

In all these complexes, the crystal field symmetry of the copper ion may be taken as tetragonal (distorted), arising out of two oxygen atoms and two nitrogen atoms with a *trans* configuration in complex **1** and two oxygen atoms of salicylic acids and nitrogen and oxygen atoms of 8-hydroxyquinoline in complexes **2** to **7**, while in complex **8** sulphur replaces one oxygen atom in the salicylic acid, forming a distorted square planar coordination (distorted D_{4h} symmetry). Electronic and esr spectra of copper(II) complexes with square planar or square pyramidal stoichiometry can be easily understood using Fig. 2. Such a distortion will be smallest for strongly coordinating axial ligands and will increase when the coordinating power of the axial ligands decreases, resulting in the observation of only one overlapping band (9). Gersmann and Swalen (10) reported three d–d optical transitions for $Cu(OX)_2$ in a frozen solution for which the solvent was a mixture of chloroform and toluene while Kokoszka *et al.* (11) observed three d–d optical transitions for the $Cu(OX)_2 \cdot 2\,H_2O$ polycrystalline sample. In the present work all these complexes exhibited only a broad maximum in solution around ~15 000 cm^{-1} to 16 000 cm^{-1} at room temperature. Hence we believe that the three d–d optical

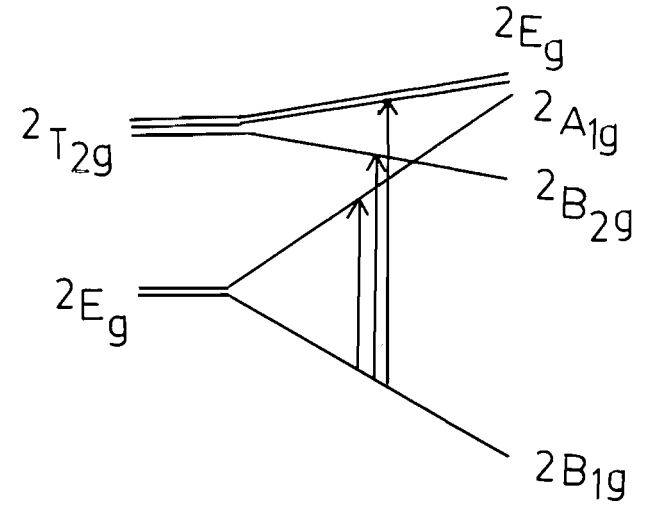

FIG. 2. Ligand-field splittings for tetragonal copper(II) complexes.

transitions observed by the other authors are due to the different experimental conditions.

The metal–ligand antibonding molecular orbitals are constructed taking $2s$, $2p_x$, $2p_y$, and $2p_z$ orbitals of the four ligand atoms into coordination with copper $3d$ orbitals and they are (10)

$$B_{1g} = \alpha d_{x^2-y^2} - \frac{1}{2}\alpha' [-\sigma_x^{(1)} + \sigma_y^{(2)} + \sigma_x^{(3)} - \sigma_y^{(4)}]$$

$$B_{2g} = \beta d_{xy} - \frac{1}{2}(1-\beta^2)^{1/2} [p_y^{(1)} + p_x^{(2)} - p_y^{(3)} - p_x^{(4)}]$$

[2] $$A_{1g} = \gamma d_{3z^2-r^2} - \frac{1}{2}(1-\gamma^2)^{1/2} [\sigma_x^{(1)} + \sigma_y^{(2)} - \sigma_x^{(3)} - \sigma_y^{(4)}]$$

$$E_g = \delta d_{xz} - \sqrt{\frac{(1-\delta^2)}{2}} [p_z^{(1)} - p_z^{(3)}]$$

$$= \delta d_{yz} - \sqrt{\frac{(1-\delta^2)}{2}} [p_z^{(2)} - p_z^{(4)}]$$

The wave functions are written in order of increasing energy. The locations of A_{1g} are uncertain but this state does not effect the magnetic parameters and, hence, is unobservable (γ^2). The B_{1g} and A_{1g} states account for the in-plane σ bonding (α^2) to the copper. The B_{2g} state represents the in-plane π bonding (β^2). Of the molecular orbital coefficients, δ^2 could not be calculated, since no higher d–d transitions are observed. It is further noted (6, 7) that the value of δ^2 varies from 0.9 to 1.0 and that the change in χ value is only about 2%. In view of this, δ^2 is taken as equal to 1 while calculating the other parameters.

sp-Hybridized ligand σ orbitals are represented by

[3] $$\sigma = np \mp (1-n^2)^{1/2} s$$

Overlap is included only for the B_{1g} state, where α and α' are related by

[4] $$\alpha^2 + \alpha'^2 - 2\alpha\alpha' S = 1$$

where S is the overlap integral between the $d_{x^2-y^2}$ and the normalised ligand σ orbitals.

When the wave functions for the ground state B_{1g} are applied to the Hamiltonian,

[5] $$\mathcal{H} = g_\parallel \beta_e H_z S_z + g_\perp \beta_e (H_x S_x + H_y S_y) + A_\parallel S_z I_z + A_\perp (S_x I_x + S_y I_y)$$

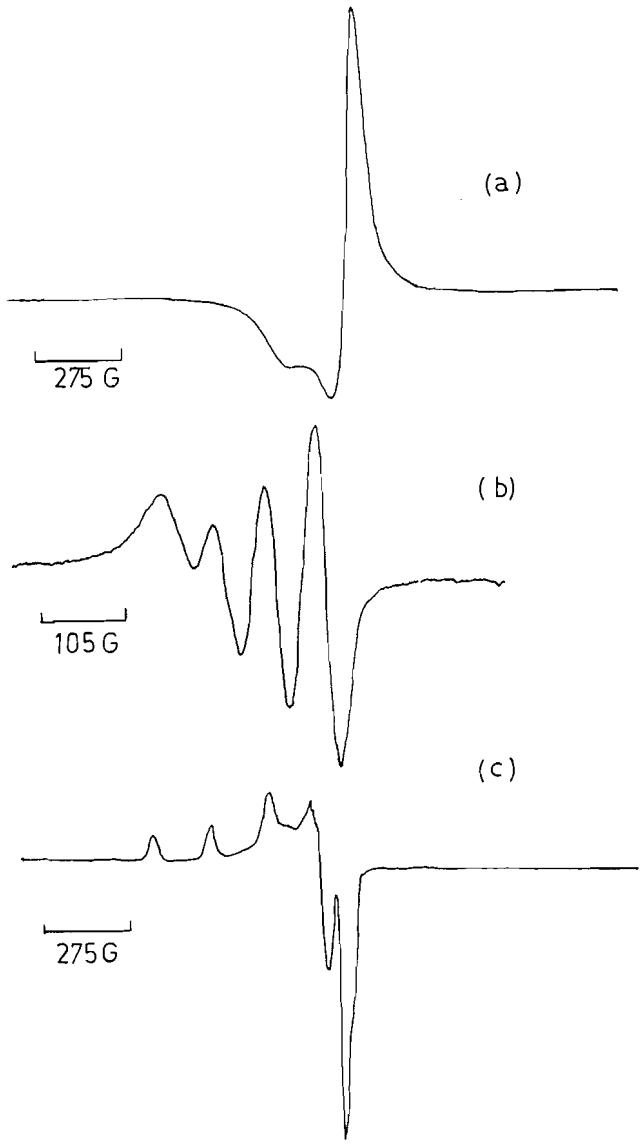

FIG. 3. Electron spin resonance spectra of $Cu(OX)_2$: (*a*) powder at room temperature; (*b*) in DMF at room temperature; (*c*) in DMF at liquid nitrogen temperature.

the principal values of the g and A tensors in the above equation are related to the free ion spin–orbital coupling constant (λ), the electronic energy levels (ΔE), and the molecular orbital coefficients through the following simplified (assuming $\delta^2 = 1$) equations (5, 12).

$$[6] \quad (g_\parallel - 2.0023) = \frac{-8\lambda\beta}{\Delta E}\left[\alpha^2\beta - \alpha\alpha'\beta S + \frac{\alpha\alpha'}{2}(1-\beta^2)^{1/2}T(n)\right]$$

and

$$[7] \quad A_\parallel = -K - \frac{4}{7}\alpha^2 P + (g_\parallel - 2.0023)PZ_\parallel + \frac{3}{7}(g_\perp - 2.0023)PZ_\perp$$

$$[8] \quad A_\perp = -K + \frac{2}{7}\alpha^2 P + \frac{11}{14}(g_\perp - 2.0023)PZ_\perp$$

where

$$[9] \quad Z_\parallel = \frac{\alpha\beta}{\alpha\beta - \alpha'\beta S - \frac{1}{2}\alpha'(1-\beta^2)^{1/2}T(n)}$$

$$[10] \quad Z_\perp = \left[\frac{\alpha}{\alpha - \alpha' S}\right]$$

The values of α^2 and K can be easily calculated from eqs. [7] and [8] and in the approximation $Z_\parallel = Z_\perp = 1$ the equation for the isotropic contact term K is

$$[11] \quad A_{ave} = -K + (g_{ave} - 2.0023)P$$

the isotropic contact term K is related to χ through the relationship (5)

$$[12] \quad \chi = -\frac{3}{2}\left[\frac{hca_0^3}{2.0023 g_N \beta_e \beta_N}\right] K$$

in atomic units. The values of the parameters (13) used in this work are $P = 0.0036\ cm^{-1}$, $T(n)_N = 0.333$, $T(N)_O = 0.220$, $T(N)_S = 0.440$, $\lambda = -828\ cm^{-1}$, $S_N = 0.093$, $S_O = 0.076$, and $S_S = 0.005$.

Results and the treatment of the data

The esr spectra of complexes **1**, **3**, and **7** as powder at room temperature and in solution (DMF) at room and liquid nitrogen temperatures are shown in Figs. 3 to 5. The room temperature spectra in solution of complexes **1**, **2**, **3**, and **8** (DMF) show four spin-dependent hyperfine lines as expected (Fig. 3) whereas the other complexes exhibit an unusual line shape, showing (Fig. 5) an extra line; each line with slightly different line widths. Similar observations were recorded at room temperature in the case of complex bis(*n*-methylbenzothiohydroxamato)copper(II) at Q band (14) in DMF and acetonitrile solvents. It was explained that either dimethylformamide or acetonitrile solvates some of the copper chelate molecules such that the tumbling molecules can be differentiated even at room temperature. This solvation effect is clearly observed in case of frozen solution spectra of ternary complexes by the splitting of axial lines (Figs. 4 and 5), giving rise to a spectrum due to isolated ions of two species. We believe that the species **I** belongs to all the ternary copper complexes reported (**2**–**8**) in the present work, while species **II** can be identified as $Cu(OX)_2$ (1). This identification is made from the reasonable agreement of the computed values of $g_\parallel$ and $A_\parallel$ for the species **II** in all the complexes (**2**–**8**) with the value of $Cu(OX)_2$ (Table 2). This may be arising out from the partial dissociation of the ternary complex into $Cu(OX)_2$.

The average g_0 and A_0 values obtained from the solution spectra at room temperature together with ΔE values are given in Table 1. The $g_\parallel$ and $A_\parallel$ values are obtained from frozen solution spectra by the method developed by Neiman *et al.* (15). The values of $g_\perp$ and $A_\perp$ obtained from the following equations

$$g_0 = (g_\parallel + 2g_\perp)/3 \text{ and } A_0 = (A_\parallel + 2A_\perp)/3$$

are given in Table 2 together with the g values obtained from polycrystalline spectra.

The molecular orbital parameters are calculated assuming an axial symmetry and assuming $\delta^2 = 1$. Initial values of α^2 are obtained from eqs. 7 and 8 assuming $Z_\parallel = Z_\perp = 1$. α' is then calculated using eq. [4], while β^2, the in-plane π-bonding coefficient, is calculated using eq. [6]. These values, together with the value of $\delta^2 = 1$, allow one to obtain the values of $Z_\parallel$

and $Z_\perp$ which are used to recalculate a better approximation of α^2.

This iteration is continued until there is no change in the molecular orbital coefficients. Three to four iterations are usually sufficient. The spin Hamiltonian parameters (Table 2) and the molecular orbital coefficients (Table 3) are somewhat different from those reported earlier for compound **1** (10, 11). This difference probably arises due to the following reasons: (*a*) the studied compounds are different, $Cu(OX)_2$ in DMF and the polycrystalline sample is anhydrous $Cu(OX)_2$, whereas Gersmann and Swalen (10) used $Cu(OX)_2$ in solvent (60% $CHCl_3$ + 40% toluene) and Kokoszka *et al.* (11) used hydrated polycrystalline sample $Cu(OX)_2 \cdot 2H_2O$; (*b*) the difference may be due to the different ligands on the *Z*-axis. Similar difference in magnetic properties is reported for copper diethyl dithiocarbamates in different solvents and the difference is identified due to the solvent effect (10). The value of K is calculated using eqs. [7] and [8] and using it, the value of χ is obtained using eq. [12]. The results are presented in Table 3.

Discussion

From a study of the molecular orbital coefficients (Table 3) it is inferred that in all the ternary complexes **2** to **8** the in-plane π bonding is weak compared to the σ bond. The β^2 value tends to unity in other complexes except in the case of complex **4**. Comparing the β^2 values of these ternary complexes with the binary $Cu(OX)_2$, it is clear that by replacing a molecule of 8-hydroxyquinoline either by salicylic acid or substituted salicylic acids, the strength of in-plane π bonding is decreased irrespective of the type of substitution in salicylic acid. This is

[a] The accuracies in the evaluated values of $g_\parallel$, $g_\perp$, $A_\parallel$, and $A_\perp$ are ± 0.004, ± 0.006, $\pm 5 \times 10^{-4}$, and $\pm 10 \times 10^{-4}$, respectively.
[b] Values in parentheses indicate corresponding values of species **II**.

TABLE 3. Values of $Z_\parallel$, $Z_\perp$, molecular orbital coefficients, and χ

Complex No.	$Z_\parallel$	$Z_\perp$	α^2	α'^2	β^2	$-\chi$
1	1.119	1.060	0.748	0.337	0.824	3.923
2	1.087	1.087	0.735	0.345	~1.000	3.820
3	1.073	1.053	0.771	0.307	0.968	3.803
4	1.088	1.050	0.798	0.278	0.865	3.754
5	1.081	1.061	0.721	0.367	0.967	3.831
6	1.065	1.057	0.746	0.334	0.992	3.886
7	1.069	1.062	0.708	0.375	0.995	3.868
8	1.069	1.040	0.765	0.295	0.930	3.908

quite reasonable as 8-hydroxyquinoline is a much better π acceptor than salicylic acids due to the difference in bonding parameters of heterocyclic nitrogen and carboxylato group. Similar type of consistency is observed in $Z_\parallel$ and $Z_\perp$ values for all these complexes.

The χ value of -3.923 for complex **1** with a copper(II) environment of two oxygen atoms and two nitrogen atoms in *trans* position is consistent with the average value of -3.918 reported for other copper complexes with similar type of environment (6, 16) formed with different types of ligands. In the case of ternary complexes **2** to **7**, where the immediate environment of copper(II) is different from complex **1**, with three oxygen atoms and a nitrogen atom, the χ value varies from -3.754 (complex **4**) to -3.886 (complex **6**) giving rise to an average value of -3.827, which lies in between the value reported for other systems, -3.918 for complex **1** and -3.700 for complexes of copper(II) with four nitrogen atoms in the immediate environment (7, 8). In the case of complex **8**, in which the environment of Cu(II) is different from other ternary complexes by the replacement of oxygen atom by sulphur from thiosalicylic acid, the value is -3.908.

Conclusions

From a study of the molecular orbital coefficients and the parameter in these ternary complexes the salient features are: *1*, the in-plane π bonding is weak compared to that in $Cu(OX)_2$ and *2*, the characteristic χ value is found to be independent of ligand substitution but depends on the immediate coordination environment.

Mass spectrometric analysis of the products from the isotopomeric cationic intermediates in the solvolysis of 1,2-dianisyl-2-*p*-($^2H_3$)methoxyphenyl[2-^{13}C]vinyl bromide in 70% HOAc – 30% H_2O

CHOI CHUCK LEE, XIAN-DA YU, and CHARLES Y. FIAKPUI. Can. J. Chem. **61**, 2159 (1983).

Solvolyses were carried out with 6.0 m*M* doubly labeled 1,2-dianisyl-2-*p*-($^2H_3$)methoxyphenyl[2-^{13}C]vinyl bromide in 70% HOAc – 30% H_2O in the presence of 0, 1, 5, 10, or 400 molar equivalents of added NaOAc. The distributions of products derived from the 4 possible isotopomeric trianisylvinyl cationic intermediates were determined from the mass spectra of the isotopomeric dianisyl ketones obtained from degradation of the reaction products, the spectra being obtained by the chemical ionization teehnique in order to minimize possible complications by multiple fragmentations. The mass speetrometrie results obtained showed agreement with previously obtained ^{14}C serambling data and with the ^{13}C scramblings obtained in the present study using ^{13}C nmr. Increasing amounts of added NaOAc had the effect of decreasing the extents of scrambling from 1,2-anisyl shifts as previously observed. However, the formation of products from all 4 possible doubly labeled isotopomeric trianisylvinyl cations definitely demonstrated the occurrence of successive 1,2-anisyl shifts in the trianisylvinyl cation, and the detection of sueh successive shifts was not possible in previous work using a singly labeled substrate. The observed distribution of products derived from the 4 isotopomeric cations could be calculated assuming various contributions from equilibrations among these isotopomeric cations, and the mechanistic implications of the results are discussed.

CHOI CHUCK LEE, XIAN-DA YU et CHARLES Y. FIAKPUI. Can. J. Chem. **61**, 2159 (1983).

On a solvolysé des solutions 6,0 m*M* de bromure de dianisyl-1,2-*p*-($^2H_3$) méthoxyphényl[^{13}C-2] vinyle-2 doublement marqué dans un mélange à 70% de AcOH et 30% de H_2O en présence de 0, 1, 5, 10 ou 400 équivalents molaires de AcONa ajouté. On a déterminé les distributions des produits provenant des 4 intermédiaires cationiques trianisylvinyles isotopomères obtenus à partir de la dégradation des produits de la réaction. On a obtenu les spectres par la technique d'ionisation chimique afin de minimiser les complications possibles dues aux fragmentations multiples. Les résultats obtenus en spectrométrie de masse sont en accord avec les données de mélange du ^{14}C obtenues précédemment et avec les données de mélange du ^{13}C obtenues dans ce travail à l'aide de la rmn du ^{13}C. Des quantités croissantes de AcONa ajouté ont pour effet de diminuer le taux de mélange provenant des glissements 1,2 d'anisyle tels qu'observés antérieurement. Cependant la formation des produits à partir des 4 cations trianisylvinyles isotopomères possibles doublement marqués démontrent de façon définitive la présence successive de glissement anisyle-1,2 dans le cation trianisylvinyle que l'on ne pouvait déceler dans un travail antérieur en utilisant des substrats contenant un seul marqueur. On peut calculer la distribution des produits provenant des 4 cations isotopomères en supposant des contributions diverses des phénomènes d'équilibration parmi ces cations isotopomères et on discute de l'importance de ces résultats dans le mécanisme réactionnel.

[Traduit par le journal]

The first study on the trianisylvinyl cation was reported in 1969 by Rappoport and Gal (1). These workers investigated the kinetics of solvolysis of trianisylvinyl bromide and chloride (**1**-Br and **1**-Cl) in 80% ethanol and concluded that these reactions proceeded via the intermediate trianisylvinyl cation. Subsequently, additional solvolytic studies with trianisylvinyl substrates by Rappoport and co-workers (2–5) all provided further kinetic results in support of the intermediacy of the trianisylvinyl cation. The first observation of a degenerate rearrangement arising from 1,2-anisyl shifts in the trianisylvinyl cation was reported from this laboratory in 1975 (6). The reaction of trianisyl[2-^{13}C]vinyl bromide (**1**-Br-2-^{13}C) with HOAc–AgOAc or with CF_3COOH–CF_3COOAg was found to give 20% or 50% scrambling, respectively, of the label from C-2 to C-1 in the reaction product (6). Similarly, 1,2-anisyl shifts in the trianisylvinyl cation were also observed in the solvolysis of 1,2-dianisyl-2-*p*-($^2H_3$)methoxyphenylvinyl bromide (**1**-Br-2-methoxy-d_3) in a number of solvent systems (7). Subsequently, the extents of isotopic scrambling resulting from the solvolysis of **1**-Br-2-^{14}C under a variety of experimental conditions have been investigated using a 9:1 mixture of HOAc–Ac_2O (8) or 70% HOAc – 30% H_2O (9) as solvent.

In giving rise to degenerate rearrangements in triarylvinyl cations, it is probable that repeated cycles of 1,2-aryl shifts may take place. In the acetolysis of **1**-Br-2-^{14}C, for example, scrambling of the label from C-2 to C-1 was found in both the reaction product and the recovered, unconsumed reactant (8). In the latter stages of reaction, the scrambling in the recovered reactant was higher than in the corresponding product and it was suggested (8) that this finding indicated the occurrence of many cycles of ionization, 1,2-shift, and return to covalent bonding, leading to the accumulation of large amounts of scrambled reactant. A more definitive measure of successive 1,2-shifts in a triarylvinyl cation could be obtained from studies using a doubly labeled substrate. With a single isotopic label, such as **1**-Br-2-^{14}C or **1**-Br-2-methoxy-d_3, only two isotopomers could arise from the 1,2-shift process as shown in eqs. [1] and [2].

$$[1]\quad An_2C^*{=}\overset{+}{C}An \underset{2k_r}{\overset{2k_r}{\rightleftharpoons}} An\overset{+}{C}^*{=}CAn_2$$

$$[2]\quad An(An^*)C{=}\overset{+}{C}An \underset{2k_r}{\overset{k_r}{\rightleftharpoons}} An^*\overset{+}{C}{=}CAn_2$$

With a doubly labeled substrate, as illustrated in Scheme 1 for the trianisylvinyl system, four isotopomeric cations, **2**, **3**, **4**, and **5**, would be possible and their detection would demonstrate unequivocally the occurrence of successive 1,2-shifts.

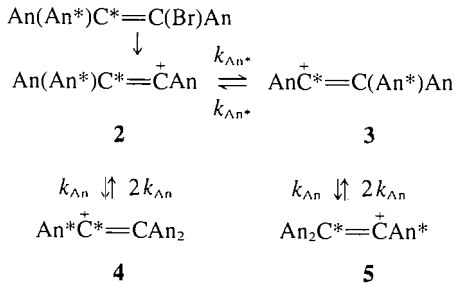
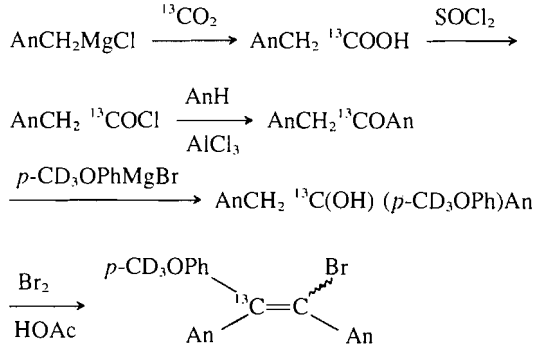


SCHEME 1

An earlier study on the acetolysis of **1**-Br labeled with ^{13}C and ^{14}C, namely, 1,2-dianisyl-2-*p*-[^{14}C]methoxyphenyl[2-^{13}C]-vinyl bromide (**1**-Br-2-^{13}C-2-methoxy-^{14}C), however, failed to demonstrate the formation of isotopomeric ions **2**, **3**, **4**, and **5** (10). The scrambling results obtained from the acetolysis of **1**-Br-2-^{13}C-2-methoxy-^{14}C were the same as those derived from analogous reactions with a 1:1 mixture of singly labeled **1**-Br-2-^{13}C and **1**-Br-2-methoxy-^{14}C because the ^{13}C and ^{14}C contents were determined by two independent methods (10). Since labeling with a radioisotope would involve a tracer amount of the label, double labeling with two radioisotopes would only give an intermolecular mixture of singly labeled substrates. To obtain a truly doubly labeled substrate, two highly enriched stable isotopes could be employed. Recently, we have prepared such a doubly labeled system, namely, 1,2-diphenyl-2-($^2H_5$)phenyl[2-^{13}C]vinyl bromide (**6**-Br-2-^{13}C-2-Ph-d_5), and studied its solvolysis in 70% HOAc – 30% H_2O (to be designated 70% HOAc; the solvolysis of **6**-Br in HOAc alone would be too slow) (11). In this study, the formation of the isotopomeric products derived from cations analogous to **2**, **3**, **4**, and **5** was analyzed by mass spectrometry (11). In the present work, such studies were extended to include an investigation on the solvolysis in 70% HOAc of a doubly labeled **1**-Br, namely, 1,2-dianisyl-2-*p*-($^2H_3$)methoxyphenyl[2-^{13}C]-vinyl bromide (**1**-Br-2-^{13}C-2-methoxy-d_3).

The doubly labeled **1**-Br-2-^{13}C-2-methoxy-d_3 was prepared in the same way as described in the preparation of **1**-Br-2-^{13}C-2-methoxy-^{14}C (10) except that the Grignard reagent from *p*-($^2H_3$)methoxybromobenzene instead of that from *p*-[^{14}C]methoxybromobenzene was employed in the reaction with 1,2-dianisyl[1-^{13}C]ethanone, the reactions utilized being given below:



1-Br-2-^{13}C-2-methoxy-d_3

No attempt was made in separating the possible *Z*- and *E*-isomers of the **1**-Br-2-^{13}C-2-methoxy-d_3. The isotopic enrichments, as indicated by the supplier, were 90 and 99%, respectively, for ^{13}C and D (as $Ba^{13}CO_3$ and CD_3I). However, for most of the experiments, the doubly labeled substrate was prepared from [^{13}C]$BaCO_3$ slightly diluted to 80% enrichment. The **1**-Br-2-^{13}C-2-methoxy-d_3 that was obtained was analyzed by mass spectrometry (described in the experimental section) and the 80% ^{13}C enrichment and essentially complete deuteration were confirmed.

Solvolytic experiments were carried out with 6.0 m*M* **1**-Br-2-^{13}C-2-methoxy-d_3 in 70% HOAc in the presence of 0, 1, 5, 10, or 400 molar equivalents of added NaOAc. These conditions were similar to some of those employed in the studies with **1**-Br-2-^{14}C (9). Again, as in the previous study with **1**-Br-2-^{14}C (9), the product mixtures of isotopomeric trianisylvinyl acetates and 1,2,2-trianisylethanones were reduced with $LiAlH_4$ to give the labeled 1,2,2-trianisylethanols **7**, **8**, **9**, and **10** derived, respectively, from the isotopomeric cations **2**, **3**, **4**, and **5**. Since the ^{13}C enrichment was 80%, 20% of the isotopomeric 1,2,2-trianisylethanols would contain no ^{13}C. Thus along with **7**, **8**, **9**, and **10**, **7′**, **8′**, **9′**, and **10′**, respectively, would also be derived from cations **2**, **3**, **4**, and **5**, the ratio of **7**:**7′**, **8**:**8′**, **9**:**9′**, and **10**:**10′** being 80:20.

In the work with the doubly labeled triphenylvinyl system, **6**-Br-2-^{13}C-2-Ph-d_5, it was found that electron impact (EI) mass spectrometry on the mixture of isotopomeric 1,2,2-triphenylethanones or 1,2,2-triphenylethanols failed to give consistent or reproducible results on the relative amounts of products derived from the various possible isotopomeric triphenylvinyl cations (11). To minimize complications arising from possible multiple fragmentations in the EI spectrum, chemical ionization (CI) mass spectrometry (12, 13) was utilized in evaluating the distribution of products from various precursor triphenylvinyl cations (11). Thus in the present work, each sample of isotopomeric 1,2,2-trianisylethanols derived from a given

experiment was oxidized to the corresponding dianisyl ketones, the CI spectrum of which was used to determine the distribution of products derived from isotopomeric cations **2**, **3**, **4**, and **5**.

The CI spectrum, with NH_3 as the reagent gas, for ordinary dianisyl ketone, $(p\text{-}CH_3OC_6H_5)_2CO$, gave the molecular ion, $[M + H]^+$, at m/z 243 as the base peak. The relative abundance of the peaks in the molecular ion region were 4.11, 100.00, 17.97, and 2.11%, respectively, for m/z 242, 243, 244, and 245. The only other peak, with a relative abundance of 5.24%, appeared at m/z 135 for $[p\text{-}CH_3OC_6H_4CO]^+$.

From each solvolysis experiment, oxidation of the isotopomeric 1,2,2-trianisylethanols gave a mixture of isotopomeric dianisyl ketones, $(p\text{-}CH_3OC_6H_4)_2CO$, $(p\text{-}CH_3OC_6H_4)_2{}^{13}CO$, $p\text{-}CH_3OC_6H_4(p\text{-}CD_3OC_6H_4)CO$, and $p\text{-}CH_3OC_6H_4(p\text{-}CD_3OC_6H_4)^{13}CO$, with $[M + H]^+$ ions appearing, respectively, at m/z 243, 244, 246, and 247. The relative abundances of these molecular ions, after appropriate corrections, were then utilized to calculate the distrbution of products derived from precursor trianisylvinyl cations **2**, **3**, **4**, and **5**. Given in Table 1 are the observed relative abundances of the peaks in the $[M + H]^+$ region of the CI spectra for the isotopomeric dianisyl ketones derived from the various solvolysis reactions with **1**-Br-2-^{13}C-2-methoxy-d_3. After correcting for the $[M + H + 1]^+$ and $[M + H + 2]^+$ peaks and for the presence of only 90 or 80% enrichment of the ^{13}C label, the distributions of products formed from cations **2**, **3**, **4**, and **5** were calculated, a detailed illustration of the calculations being given in the experimental section. The results are summarized in Table 2.

In our previous work on the solvolysis of **1**-Br-2-^{14}C in 70% HOAc (9), the extents of scrambling of the ^{14}C label from C-2 to C-1 were determined. Included in Table 2 are the ^{14}C scrambling results obtained for the solvolysis of **1**-Br-2-^{14}C under conditions that were similar, though not identical, to those used in the present studies. It may be noted from Scheme 1 that if the substrate were labeled only with ^{13}C, the sum of the products from cations **3** and **4** would be equal to the scrambling of the ^{13}C label from C-2 to C-1. Such ^{13}C scramblings from C-2 to C-1 were measured in the present work from the ^{13}C nmr spectra of the 1,2,2-trianisylethanols derived from the various solvolysis reactions using the method previously described by Oka and Lee (6). The results are also included in Table 2. It is seen from Table 2 that the products derived from cations **3** and **4** are in fairly good agreement with the corresponding extents of scrambling of the ^{13}C or ^{14}C label from C-2 to C-1.

In the solvolysis of **1**-Br-2-^{14}C in 70% HOAc (9), it was found that the extent of scrambling was decreased with in-

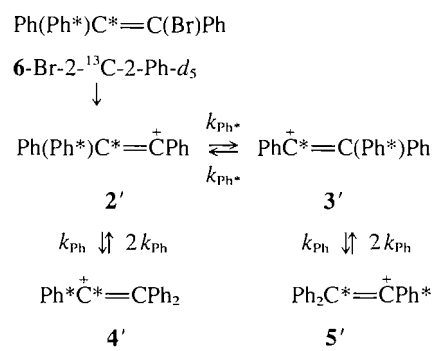
creasing amounts of added NaOAc. The present results, as indicated by the amounts of product derived from ions **3**, **4**, and **5**, also showed this trend. As previously suggested (9), these results were interpreted as support for the formation of the dissociated trianisylvinyl cation as reaction intermediate. Since such dissociated ions could competitively give rise to 1,2-anisyl shifts and be captured by nucleophiles to give product, the presence of the more nucleophilic acetate ion in the reaction mixture would favor the formation of more unscrambled product at the expense of 1,2-shifts, resulting in the observed decrease in the extents of scrambling with increasing amounts of added NaOAc. On the other hand, with the triphenylvinyl cationic system, solvolysis in 70% HOAc for both the singly labeled **6**-Br-2-^{14}C (9) or the doubly labeled **6**-Br-2-^{13}C-2-Ph-d_5 (11) resulted in isotopic scramblings the extent of which was not significantly affected by the presence of added NaOAc. It has been shown recently that both common ion rate depression and ^{82}Br exchange took place in the solvolysis in 70% HOAc of **1**-Br or **6**-Br, indicating the involvement of the dissociated trianisylvinyl or triphenylvinyl cation, and it was suggested that the insensitivity of the extent of scrambling in the solvolysis of labeled **6**-Br might be due to a low selectivity of the less stable triphenylvinyl cation (14).

As pointed out earlier in this paper, with the use of a singly labeled substrate, successive 1,2-shifts would not be directly detectable. With the use of double labeling, the formation of products derived from all isotopomeric cations **2**, **3**, **4**, and **5** from **1**-Br-2-^{13}C-2-methoxy-d_3 as observed in the present work (Table 2), and the formation of such products from the 4 analogous cations from **6**-Br-2-^{13}C-2-Ph-d_5 (11), definitely demonstrated the occurrence of successive 1,2-aryl shifts in the trianisylvinyl and triphenylvinyl cations. Aside from this conclusion, it may also be of interest to compare in more detail the results in Table 2 with the analogous data derived from **6**-Br-2-^{13}C-2-Ph-d_5 (11).

Similar to Scheme 1, the 4 isotopomeric cations derived from **6**-Br-2-^{13}C-2-Ph-d_5 may be designated as **2′**, **3′**, **4′**, and **5′** as shown in Scheme 2. From 9 solvolysis experiments with



SCHEME 2

6-Br-2-^{13}C-2-Ph-d_5 carried out in 70% HOAc containing 0, 5, or 10 molar equivalents of NaOAc, the mean values for the products derived from **2′**, **3′**, **4′**, and **5′** were found to be 84.7 ± 2.2, 7.3 ± 1.2, 6.6 ± 1.2, and 1.5 ± 0.5%, respectively (11). Since the initially formed ion **2′** would rearrange to ions **3′** and **4′** in the first stage of the 1,2-shift process while ion **5′** was formed subsequently from ion **3′**, it was suggested that one-half of **2′** could be equilibrated between ions **2′** and **4′** and the other half equilibrated between **2′**, **3′**, and **5′** (11). Such a mechanism would qualitatively explain the observation that roughly the same amounts of products were derived from ions **3′** and **4′** while the least amount of product was derived from ion **5′**.

Taking into account the statistical factors involved in the equilibration processes, complete equilibration of 50% of **2′** between **2′** and **4′** would give 33.3% of **2′** and 16.7% of **4′**. Similarly, complete equilibration of 50% of **2′** between **2′**, **3′**, and **5′** would give 25% of **2′**, 16.7% of **3′**, and 8.3% of **5′**. The net result in the distribution of products derived from **2′**, **3′**, **4′**, and **5′** would be 58.3 (33.3 + 25.0), 16.7, 16.7, and 8.3%, respectively. The observed result of about 85% product from **2′**, 6–7% from **3′** or **4′**, and about 2% from **5′** clearly showed that not all of ion **2′** has undergone equilibration (11).

The above interpretations, which were discussed in the previous study (11), may be modified by assuming that only part of ion **2′** would equilibrate through 1,2-shifts while the rest could be captured directly by nucleophiles to give unscrambled product. If only 36% of **2′** were to equilibrate and 64% were captured directly to give unscrambled product, equilibration of one-half of the 36% of **2′** between **2′** and **4′** would give 12% **2′** and 6% **4′**. Similarly, equilibration of the other 18% between **2′**, **3′**, and **5′** would give 9% **2′**, 6% **3′**, and 3% **5′**. The net distribution of products from **2′**, **3′**, **4′**, and **5′** would be 85 (64 + 12 +9), 6, 6, and 3%, respectively. One could make a further assumption that complete equilibration between **3′** and **5′** was not quite achieved since it took place in a later stage subsequent to the formation of **3′** from **2′**. Instead of the statistical 2:1 distribution of 6% **3′** and 3% **5′**, the products from **3′** and **5′** could be modified to 7% and 2%, respectively. With such a modification, the overall distribution of products from **2′**, **3′**, **4′**, and **5′** would be 85, 7, 6, and 2%, respectively, in excellent agreement with the results observed in the solvolysis of **6**-Br-2-^{13}C-2-Ph-d_5 in 70% HOAc (11).

Similar treatments can be applied to the data in Table 2 obtained in the present studies with **1**-Br-2-^{13}C-2-methoxy-d_3. For example, in Expt. 1 (solvolysis in 70% HOAc with no added NaOAc), the observed average distributions of products from ions **2**, **3**, **4**, and **5**, respectively, were 67, 15, 14, and 4%. Assuming that 16% of **2** was captured directly to give unscrambled product, 42% of **2** was equilibrated between **2** and **4** to give 28% **2** and 14% **4**, and the other 42% of **2** was equilibrated between **2**, **3**, and **5** to give 21% **2**, 14% **3**, and 7% **5**, the net distribution of products from **2**, **3**, **4**, and **5** would be 65 (16 + 28 + 21), 14, 14, and 7%, respectively. Again, if complete equilibration between **3** and **5** was not achieved, the 14% product from **3** and 7% product from **5** could be modified to 15% and 6%, respectively, giving an overall distribution of products from **2**, **3**, **4**, and **5** of 65, 15, 14, and 6%, respectively, in reasonably good agreement with the observed data.

In the same way as described above for Expt. 1, the distributions of products derived from **2**, **3**, **4**, and **5** were calculated for the other experiments and the results are summarized in Table 3. For Expt. 2, the same calculated distribution of products as for Expt. 1 could be utilized, suggesting that the presence of 1 equiv. of added NaOAc did not materially affect the scrambling processes. In Expts. 3–5, as expected, the proportion of ion **2** that was captured directly to give unscrambled product was found to increase with increasing amounts of added NaOAc. It is also of interest to note from Table 3 that the statistical distribution of 2:1 for the products from **3** and **5** was not achieved in Expts. 1 and 2, suggesting that equilibration was more complete when the solvolysis was carried out in the presence of more added NaOAc as in Expts. 3–5. A similar

conclusion was reached in the previous study on the acetolysis of **1**-Br-2-^{13}C-2-methoxy-^{14}C (10). In this earlier work, comparisons of the extents of rearrangements of the ^{13}C chain label and the ^{14}C ring label led to the conclusion that more complete equilibration of the labels was achieved when the reaction was carried out in the presence of high concentrations of added salts.

To account for the effect of added salts, it was suggested (10) that in the absence or presence of low concentrations of added salts, some of the 1,2-shifts might have occurred in the ion-pair stage and the presence of the leaving group as the counterion would give a frontside hindrance to the 1,2-migration, preventing a complete equilibration. On the other hand, in the more polar medium with the presence of higher concentrations of added salts, dissociation would proceed further, the 1,2-shifts would be unhindered by any counterion and more complete equilibration would be attained. A similar mechanism may be used to account for the present results. In the solvolysis of **1**-Br-2-^{13}C-2-methoxy-d_3 in 70% HOAc, under conditions of Expts. 1 and 2, a small portion of the 1,2-shifts may have taken place in the ion-pair stage, while under conditions of Expts. 3–5, the 1,2-shifts occurred essentially with dissociated ions. Support for a minor role for ion-pairs in the process of 1,2-anisyl shifts has also been obtained recently by Ikeda *et al.* (15). These workers studied the solvolysis of 2,2-dianisyl-1-phenylvinyl bromide specifically labeled by *p*-(^{2}H$_3$)CH$_3$O (methoxy-d_3) in the *cis*- or *trans*-anisyl group. A slight preference, 53:47 or 51:49, respectively, was found for the migration of the anisyl group *trans* to bromine for the solvolysis in 2,2,2-trifluoroethanol/2,6-lutidine or in HOAc/AgOAc. It was proposed that this preference was due to the intervention of ion-pairs in the rearrangement process, with the leaving group as the counterion hindering the migration of the anisyl group *cis* to bromine.

Experimental

*1,2-Dianisyl-2-*p*-($^2H_3$)methoxyphenyl[2-^{13}C]vinyl bromide (**1**-Br-2-^{13}C-2-methoxy-*d*$_3$)*

The doubly labeled substrate, **1**-Br-2-^{13}C-2-methoxy-d_3, was prepared in the same way as previously described for the preparation of 1,2-dianisyl-2-*p*-[^{14}C]methoxyphenyl[2-^{13}C]vinyl bromide (10), except that CD_3I instead of [^{14}C]methyl iodide was used to methylate *p*-bromophenol to give the labeled *p*-methoxybromobenzene, which in turn was converted to the Grignard reagent for reaction with 1,2-dianisyl[1-^{13}C]ethanone, eventually leading to **1**-Br-2-^{13}C-2-methoxy-d_3.

The isotopically labeled starting materials, [^{13}C]$BaCO_3$ and CD_3I, were supplied by MSD Isotopes of Montreal and the enrichments for the ^{13}C and D were specified as 90 and 99%, respectively. For most of the solvolysis reactions, the substrate was prepared from [^{13}C]$BaCO_3$ diluted to 80% enrichment. A sample of **1**-Br-2-^{13}C-2-methoxy-d_3 obtained from 80% enriched [^{13}C]$BaCO_3$ and 99% enriched CD_3I gave a CI spectrum with relative intensities at m/z 428, 429, 430, 431, and 432, respectively, of 2.71, 10.34, 5.42, 10.84, and 2.96% of the base peak, the base peak being m/z 349 for the $[M + H - Br]^+$ ion. For **1**-Br containing ^{79}Br, the $[M + H]^+$ peaks with only the methoxy-d_3 label and with both methoxy-d_3 and ^{13}C labels would appear at m/z 428 and 429, respectively. Since the relative intensities for m/z 428 and 429 were 2.71 and 10.34, the presence of **1**-Br-2-methoxy-d_3 and **1**-Br-2-^{13}C-2-methoxy-d_3 would correspond to 2.71/(2.71 + 10.34) and 10.34/(2.71 + 10.34) or 21 and 79%, respectively. Similarly, for **1**-Br containing ^{81}Br, the $[M + H]^+$ peaks with only the methoxy-d_3 label and with both methoxy-d_3 and ^{13}C labels appeared at m/z 430 and 431, respectively, with relative intensities of 5.42 and 10.84. Since there was an m/z 432 peak with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

relative intensity of 2.96 or 27.3% of the intensity of the 431 peak, a correction for $[M + H + 1]^+$ was made on m/z 430, the correction being 27.3% of the intensity of m/z 429. The corrected intensity for m/z 430 would thus be $5.42 - (0.273 \times 10.34) = 2.50$. With relative intensities of 2.50 and 10.84 for m/z 430 and 431, the presence of **1**-Br-2-methoxy-d_3 and **1**-Br-2-^{13}C-2-methoxy-d_3 would correspond to 19 and 81%, respectively. The mean values from the ^{79}Br and ^{81}Br peaks of 20% **1**-Br labeled only with methoxy-d_3 and 80% **1**-Br labeled with both methoxy-d_3 and ^{13}C thus may be regarded as a confirmation of the 80% ^{13}C enrichment and essentially complete deuteration for the doubly labeled substrate.

Solvolysis reactions

The solvolysis of **1**-Br-2-^{13}C-2-methoxy-d_3 in 70% HOAc in the presence of various amounts of NaOAc was carried out in a similar manner as previously described for the solvolysis of **1**-Br-2-^{14}C in 70% HOAc (9). Typically, a solution of 258 mg (0.60 mmol) of **1**-Br-2-^{13}C-2-methoxy-d_3 and 49 mg (0.60 mmol) of NaOAc in 100 mL of 70% HOAc in a sealed tube was heated at 120 ± 1°C for 2 h. Similar reactions were carried out in the absence of any NaOAc or in the presence of 5, 10, or 400 molar equivalents of NaOAc. After cooling in an ice bath, the sealed tube was opened and each reaction mixture was extracted with $CHCl_3$ (3 × 50 mL). The extract was washed with a dilute $NaHCO_3$ solution and then with H_2O. Titration of the liberated Br^- ion in the combined aqueous phase showed that in all of these experiments, the reaction was essentially complete. The $CHCl_3$ extract was dried over $MgSO_4$ and the solvent was removed by distillation. The residual organic product was reduced twice with $LiAlH_4$ (6) to give the isotopomeric 1,2,2-trianisylethanols. Samples of the 1,2,2-trianisylethanols were analyzed for the extents of scrambling of the ^{13}C label from C-2 to C-1 using ^{13}C nmr as described by Oka and Lee (6). $KMnO_4$ oxidation (8, 16) of the isotopomeric 1,2,2-trianisylethanols obtained from each solvolysis reaction gave the isotopomeric dianisyl ketones for mass spectral analysis.

Mass spectral analysis

The CI spectra of the various samples of dianisyl ketones were obtained with 0.3 torr of NH_3 as reagent gas. A gc–ms instrument was employed, each sample being passed through the gc before the CI spectrum was obtained using a VG-16F mass spectrometer supplied by Micromass Ltd. Given in Table 1 are the CI spectra in the $[M + H]^+$ region for the isotopomeric dianisyl ketones derived from the various solvolysis experiments with **1**-Br-2-^{13}C-2-methoxy-d_3, the $[M + H]^+$ ions for $(p\text{-}CH_3OC_6H_4)_2CO$, $(p\text{-}CH_3OC_6H_4)_2\ ^{13}CO$, $p\text{-}CH_3OC_6H_4(p\text{-}CD_3OC_6H_4)CO$, and $p\text{-}CH_3OC_6H_4(p\text{-}CD_3OC_6H_4)^{13}CO$ appearing at m/z 243, 244, 246, and 247, respectively.

As an illustration of the calculations, consider the data for run 1 of Expt. 2 in Table 1. Since the abundance of $[M + H + 1]^+$ and $[M + H + 2]^+$ at m/z 248 and 249, respectively, were 17.37% and 2.35% of the abundance of m/z 247, corrections were made as follows:

$$\begin{array}{lcl} \text{Corrected abundance of } m/z \text{ 247} & = & \text{Observed abundance of 247} - \text{17.37\% of the abundance of 246} - \text{2.35\% of the abundance of 245} \\ & = & 100.00 - (0.1737 \times 49.85) - (0.0235 \times 5.08) = 91.22 \end{array}$$

Similarly, the corrected abundance of m/z 246 would equal (the observed abundance of 246) − (17.37% of the abundance of 245) − (2.35% of the abundance of 244). In this way, the corrected relative abundances for m/z 247, 246, 244, and 243, respectively, were calculated to be 91.22, 48.73, 6.21, and 23.00.

Since the ^{13}C enrichment was 80%, cation **2**, for example, would give rise to an 80:20 mixture of **7** and **7′**, and oxidation of **7** and **7′** would give, respectively, $p\text{-}CH_3OC_6H_4(p\text{-}CD_3OC_6H_4)^{13}CO$ ($[M + H]^+$ at m/z 247) and $p\text{-}CH_3OC_6H_4(p\text{-}CD_3OC_6H_4)CO$ ($[M + H]^+$ at m/z 246). Similarly, **3** would give rise to an 80:20 mixture of **8** and **8′**, both of which would oxidize to $p\text{-}CH_3OC_6H_4(p\text{-}CD_3OC_6H_4)CO$ ($[M + H]^+$ at m/z 246). In the same way, the isotopomeric dianisyl ketones derived from the products of ions **4** and **5** could also be deduced, the overall results being summarized in eqs. [3] to [6].

[3] **2** → 80% **7** + 20% **7′** → 80% m/z 247 + 20% m/z 246

[4] **3** → 80% **8** + 20% **8′** → 100% m/z 246

[5] **4** → 80% **9** + 20% **9′** → 100% m/z 243

[6] **5** → 80% **10** + 20% **10′** → 80% m/z 244 + 20% m/z 243

From eqs. [3] to [6], the sources of the m/z 247, 246, 244, and 243 peaks could be obtained as summarized in eqs. [7] to [10].

[7] Abundance of m/z 247 = 0.80 (product from **2**)

[8] Abundance of m/z 246 = product from **3** + 0.20 (product from **2**)

[9] Abundance of m/z 244 = 0.80 (product from **5**)

[10] Abundance of m/z 243 = product from **4** + 0.20 (product from **5**)

Using the corrected relative abundances of 91.22, 48.73, 6.21, and 23.00, respectively, for m/z 247, 246, 244, and 243 and applying eqs. [7] to [10], the relative amounts of products from ions **2**, **3**, **4**, and **5** were calculated to be 114.03, 25.93, 21.45, and 7.76, respectively. Expressing these amounts of products on a percentage basis, the distribution of products from **2**, **3**, **4**, and **5**, respectively, would become 67.4, 15.3, 12.7, and 4.6%, as given in Table 2.

Acknowledgments

We wish to express our sincere thanks to Professor K. K. Midha of the College of Pharmacy of this University for permission to use the VG-F16 mass spectrometer, to Mr. K. Hall for obtaining the CI spectra, and to the Natural Sciences and Engineering Research Council of Canada for financial support.

Reactions of steroidal 4,5- and 5,6-epoxides with strong bases

HERBERT L. HOLLAND AND JAHANGIR

Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received February 17, 1983

HERBERT L. HOLLAND and JAHANGIR. Can. J. Chem. **61**, 2165 (1983).

A series of C-3 oxygenated and unsubstituted (4,5)α, (4,5)β, (5,6)α, and (5,6)β epoxy steroids has been prepared, and the reactions of these compounds with strong bases (potassium *tert*-butoxide, LDA, and LDEA) were investigated. Only LDEA gave rise to product formation; β elimination of the epoxide to give a β-hydroxy olefin was observed in this case. The regioselectivity of product formation is consistent with a mechanism of rearrangement involving removal of a hydrogen located *syn* to the epoxide oxygen. In some cases, a directing influence from a polar substituent (OH) of the starting material was also apparent. The ^{13}C nmr spectra of the steroidal epoxides used in this study were assigned; these data are diagnostic of the conformation of ring A of (4,5)α and (4,5)β epoxy steroids.

HERBERT L. HOLLAND et JAHANGIR. Can. J. Chem. **61**, 2165 (1983).

On a préparé une série d'époxy stéroides du type (4,5)α, (4,5)β, (5,6)α et (5,6)β oxygénés en position C-3 et non substitués et on a étudié leurs réactions avec des bases fortes (*tert*-butylate de potassium, LDA et LDEA). Seule la LDEA conduit à la formation de produits; on a observé dans ce cas une élimination β de l'époxyde qui conduit à la β-hydroxy oléfine. La régiosélectivité de la formation du produit est en accord avec un mécanisme de transposition qui implique une élimination d'hydrogène situé en position *syn* de l'oxygène de l'époxyde. On note également dans quelques cas, une influence directrice du substituant polaire (OH) du produit de départ. On a identifié les spectres de rmn du ^{13}C des époxy stéroides utilisées; ces données permettent de prédire la conformation du cycles A des (4,5)α et (4,5)β époxy stéroides.

The base catalysed rearrangement of epoxides to allylic alcohols, involving β-hydrogen abstraction (eq. [1]), can be performed by strong bases such as alkyl lithiums (1), alkoxide

[1] 
[2] 
salts (2, 3), or lithium dialkylamides (4, 5). In the steroid field, a variant of this reaction has been widely used in the preparation of γ-hydroxy-α,β-unsaturated ketones by base catalysed rearrangement of β,γ epoxy ketones such as **3***b* and **6***b* (eq. [2]), in which case weaker bases such as triethylamine are successful in promoting rearrangement (6, 7).

In cases where the stereochemical details of eq. [1] have been investigated, a requirement for a *syn* coplanar arrangement of β hydrogen and epoxide oxygen has been proposed (lithium diethylamide, LDEA, as base) (8). The regioselectivity of the LDEA promoted reaction has also been studied (9); attack occurs at the least hindered site with large factors separating primary, secondary, and tertiary proton abstraction.

In an attempt to delineate the steric requirements and regioselectivity of eq. [1] when applied to the preparation of steroidal γ-hydroxy olefins, we have studied the reactions of a series of 5,6 epoxy (**1**−**6**) and 4,5 epoxy (**7**−**12**) steroids of defined configuration and conformation with several strong bases.

Epoxides **1**−**12** were prepared by published procedures. Hitherto unreported ^{13}C chemical shifts are presented in Tables 1−4. The values for the 5,6-epoxides **1**, **3***c*, **4**, and **6***c* (Tables 1 and 2) were assigned by comparison with those reported for similar androstane derivatives (10). Those for the C-3α derivatives **2** and **5**, and for the unsubstituted epoxides **3***a* and **6***a*, were thence derived by a consideration of the shifts

caused by substitution at C-3 (11).

The spectra of the (4,5)α epoxides (Table 3) were assigned by reference to the published data for 5α-cholestan-5-ol (and derivatives) (11) and support the conformation for ring A shown in Fig. 1; the γ upfield shift of C-1 caused by the C-5α pseudo axial epoxide oxygen, and the lack of a similar shift dependent upon the stereochemistry of oxygen substitution at C-3, are particularly diagnostic of the diaxial relationships involved. The spectra of the (4,5)β epoxides **10**−**12** were

assigned by reference to the spectra of 5β-cholestane and derivatives (11), and by the use of heteronuclear ($^1H/^{13}C$) decoupling and/or SFORD data. Carbons 3−5, 8−10, and 19 were thus readily assignable. The remaining rings A and B carbons were assigned by a consideration of the effects of substitution at C-3. Thus the resonance position of C-7 does not vary greatly over the series, while carbons 2, 4, and 6 show the anticipated effects caused by substitution at C-3. The values reported for **12***b* represent a correction of our previously published assignments for C-1 and C-7 (12); these latter were made without benefit of the variation in substitution pattern at C-3 available in the series now under study.

When compared with the spectrum of the alcohol **10***a*, the esters **10***b* and **10***c* show shifts (in addition to the anticipated effects at C-2 and C-4) at C-1 and C-9, which are characteristic of a change in conformation in ring A (Fig. 2). The chemical shift assignments for **10***a*, **11***a*, **11***b*, **12***a*, and **12***b* are consistent with conformation A; thus C-1 of **12***a* shows a γ upfield shift relative to the corresponding carbon of 5β-cholestane (11) characteristic of 1,3-diaxial interaction with the C-5β epoxide oxygen. A further γ upfield shift of C-1 in **10***a* and **11***a* occurs as a consequence of substitution at C-3, the interactions being 1,3 axial hydroxyl (−3.8 ppm) in the case of **10***a*, and 1,3 equatorial hydroxyl (−3.6 ppm) for **11***a* (11). In **10***b* and **10***c*, however, the greater bulk of the 3β substituent now necessitates that it occupy an equatorial position (conformation B, Fig. 2) in which the C-5 β − C-1β diaxial interaction is lost. A comparison of the chemical shifts at C-1 in **10***b* and **10***c* with that of **12***a* confirms that this is so. If the effect of oxygen substitution at C-1 is removed from the observed shifts in **10***b* and **10***c* (see above), then C-1 of these compounds would resonate at significantly lower field (ca. 3−4 ppm) than that observed for C-1 of **12***a*. In addition, the chemical shifts of C-9 in **10***b* and **10***c* are characteristic of the absence in these compounds of the interaction between the C-2α and C-9α hydrogens present in normal C-5β steroids (13), and the presence of an eclipsing γ interaction from the C-1α hydrogen possible in conformation B. The chemical shift of C-9 is particularly diagnostic of the stereochemistry of the A/B ring function in saturated steroids (11, 13), and the variations observed here are consistent with the interpretation of the effects of stereochemistry and conformation on the resonance position of C-9 (13).

None of the epoxides treated with potassium *tert*-butoxide or lithium diisopropyl amide (LDA) (see Experimental) resulted in the formation of products. In all cases, only starting material was recovered. Presumably, the steric bulk of these reagents prevents hydrogen abstraction in the cases studied. The failure to observe any rearrangements resulting from α hydrogen abstraction (14–16) by LDA may also be attributable to steric factors. Since reactions with LDA could be carried out only at low temperatures (17), further experiments used the more versatile diethyl amide LDEA. This latter reagent has proven useful in carrying out the reaction of eq. [1] in cases where LDA gave only poor yields (18, 19).

12*a*	**18***b* (60), **19***b* (30)

The reactions of epoxides **1**–**12** with LDEA are summarized in Table 5. Products were characterized as described in the Experimental section, and hitherto unreported ^{13}C chemical shifts are listed in Table 6. The assignments were routine and relied heavily on published values for steroid substituent shift parameters (11).

The product distributions summarized in Table 5 are consistent with the proposals made earlier concerning the steric requirements for opening of epoxides (8) and also suggest the presence of a directing influence from the oxygen substituents of C-3 (see Figs. 2 and 3). Thus whereas the unsubstituted (5,6)α epoxide **3***a* gave only a Δ^6 product (**15***b*), presumably via a facile *syn* elimination involving the axial C-7α hydrogen, and the equatorial C-3β alcohol **1***a* also opened only from C-7, giving **14***a*, the corresponding C-3α alcohol **2***a*, in which coordination of base to the axial alcohol group might be expected to direct subsequent proton removal from C-4α, gave rise to both Δ^4 (**16**) and Δ^6 (**15***a*) products. The 3-ethylene ketal **3***c* gave only the 6β hydroxy-Δ^4-3-ketone **17***a* (following hydrolytic work-up) (Fig. 3).

The (5,6)β epoxides gave only low yields of allylic alcohols on treatment with LDEA. Here, none of the C-4 or C-7 hydrogens is located ideally *syn* to the epoxide oxygen; the closest to a *syn* relationship exists with that at C-4β, but the latter is also located 1,3 diaxial to the C-19 methyl group, and therefore hindered to attack by base (Fig. 3).

The unsubstituted (5,6)β epoxide **6***a* therefore gave only a low yield of Δ^4-6β-ol **13***b* and the axial C-3α alcohol **5***a* was not affected by treatment with LDEA. In the latter case, additional coordination of base to the alcohol group would not only render the reagent sterically ineffective in promoting epoxide opening, but also increase electrostatic charge on the α face of the molecule, thus making the alternative (8) *anti* removal of the C-7α hydrogen unfavourable.

It is interesting that transannular reaction leading to 3,5 oxetane formation (20), even in sterically ideal cases such as **5***a*, is not an observed pathway of reaction. The C-3β hydroxy-(5,6)β-epoxide **4***a* gave a low yield of products arising from removal of either the C-4 (**13***a*) or the C-7 (**14***b*) hydrogen. The latter product is presumably formed by *anti* removal of the axial C-7α hydrogen, a possible pathway for epoxide opening in the absence of a *syn* hydrogen (8). This route can become operative in the absence of the electrostatic charge on the α face of the molecule, which would prevent such a process occurring with epoxide **5***a* (see above). The 3-ketal **6***c* gave only a low yield

1–3 **4–6**

FIG. 3. Conformations of (5,6)α and (5,6)β epoxy steroids.

of the product of opening from C-4, **17***b*, on treatment with LDEA.

The epoxide oxygen of (4,5)α epoxy steroids (Fig. 1) does not have an ideal *syn* relationship with either the C-3α or C-6α hydrogens; the dihedral angles concerned (ca. 30° in each case) are small, however, and epoxide opening occurs from both C-3 and C-6 in the case of the unsubstituted epoxide **9**. The favoured route of opening involves loss of hydrogen from C-3, giving **18***a*; in the presence of a C-3α hydroxyl group (as in **8**), the absence of a hydrogen at C-3 *syn* to the epoxide oxygen prevents reaction from occurring. The corresponding β alcohol epoxide **7***a* opens only from C-6, a result consistent with prior coordination of base to the C-3β alcohol group: in this event, removal of the C-3α hydrogen would become electrostatically unfavourable, involving as it would the development of negative charge density at a carbon (C-3) carrying a partially ionized hydroxyl function.

Of the (4,5)β epoxides, only the unsubstituted example **12***a* was opened by LDEA. In this case, both the C-3β and C-6β hydrogens are located on the same side of the molecule as the epoxide oxygen: the predominance of the Δ^3 product **18***b* may reflect the greater accessibility of the C-3β hydrogen than that at C-6β, the latter being located 1,3 diaxially to the C-19 methyl.

The results discussed above are entirely compatible with a *syn* mechanism of β epoxide opening by LDEA, and therefore complement those of Thummel and Rickborn (8). However, the application of this reaction to the preparation of hydroxy substituted steroidal olefins would seem to be limited to those examples (e.g. **15***b*) in which a simple *syn* β elimination occurs without the complication of directing influences from existing polar substituents.

Experimental

Apparatus, materials, and methods

Melting points were determined on a Kofler heating stage and are uncorrected. Infrared spectra were recorded with a Perkin–Elmer 237B spectrometer. Proton nmr spectra were obtained at 60 MHz with a Varian A-60 or Bruker WP 60, or at 80 MHz with a Bruker WP 80 CW, and ^{13}C nmr spectra with a Bruker WP 60 or WH 400 (at the Southwestern Ontario nmr Centre, Guelph) using $CDCl_3$ as solvent and TMS as internal standard. Mass spectra were obtained with an AEI MS 30 spectrometer fitted with a Kratos DS-55 data system. Thin layer chromatography was performed on Merck silica gel 60 F-254, and column chromatography on silica gel (60–200 mesh) or alumina. Elemental analyses were performed by Guelph Chemical Laboratories, Guelph, Ontario or by Galbraith Laboratories Inc., Knoxville, Tennessee.

Preparation of epoxides

The following epoxides were prepared by published procedures and exhibited satisfactory spectral, analytical and chromatographic properties. The ^{13}C nmr data are listed in the tables. (5,6)α-Epoxy-5α-cholestan-3β-ol (**1***a*) (21); (5,6)α-epoxy-5α-cholestan-3α-ol (**2***a*) (22, 23); (5,6α)-epoxy-5α-cholestane (**3***a*) (22); (5,6α)-epoxy-5α-cholestan-3-one, 3-cyclic ethylene ketal (**3***c*) (24); (5,6β)-epoxy-5β-cholestan-3β-ol (**4***a*) (24); (5,6β)-epoxy-5β-cholestan-3α-ol (**5***a*) (23, 26); (5,6β)-epoxy-5β-cholestan-3-one, 3-cyclic ethylene ketal (**6***c*) (24); (4,5α)-epoxy-5α-cholestan-3β-ol (**7***a*) (27, 28); (4,5α)-epoxy-5α-cholestane (**9**) (22); (4,5β)-epoxy-5β-cholestan-3β-ol (**10***a*) (12, 27, 28); (4,5β)-epoxy-5β-cholestan-3α-ol (**11***a*) (12, 28, 29); (4,5β)-epoxy-5β-cholestane (**12***a*) (22); and (4,5β)-epoxy-5β-cholestan-3-one (**12***b*) (12).

*(5,6β)-Epoxy-5β-cholestane (**6**b)*

This was prepared by the procedure of Watabe *et al.* (30); in our hands, the results outlined below were obtained.

A solution of *N*-bromosuccinimide (2.35 g) in perchloric acid (20 mL, 5%), was added over 30 min to a stirred solution of cholest-5-ene (2.22 g) (31) in THF (90 mL) at room temperature. The mixture was stirred for an additional 30 min, then diluted with chloroform (150 mL), neutralized (5% potassium carbonate), and saturated with sodium chloride. The organic layer was separated, washed, dried, and evaporated. The residue was then dissolved in methanol (60 mL) containing sodium hydroxide (3 g), and the solution refluxed for 30 min. Evaporation then gave a residue which was dissolved in chloroform to give a solution which was then washed, dried, and evaporated to a residue which was chromatographed (silica) using hexane–benzene gradient elution and afforded 5,6β-epoxy-5β-cholestane (**6***a*), (1.08 g), mp 53–55°C (lit. (27) mp 55–57°C). Further elution gave 5α-cholestan-5-ol-6-one (0.3 g), mp 150–152°C (lit. (32) mp 152–153°C), followed by 5α-cholestane-5, 6β-diol (0.09 g), mp 121–124°C (lit. (33) mp 125.5°C).

*(4,5α)-Epoxy-5α-cholestan-3α-ol (**8**)*

A solution of *m*-chloroperoxybenzoic acid (0.8 g) in methylene chloride (20 mL) was added to a solution of cholest-4-en-3α-ol (34) in methylene chloride (20 mL), and the resulting mixture kept at 0°C

for 20 h. The solution was then washed (sodium bicarbonate), dried, and evaporated to give noncrystalline **8**. Crystallization from methanol gave a sample of mp 92–94°C (lit. (35) mp 91–92°C).

Preparation of epoxyesters

The epoxyesters listed below were prepared by standard procedures from the corresponding alcohols, and gave satisfactory spectral and analytical data:

1*b*, **2***b* (23), **4***b* (25), **5***b* (36), **7***b* (28), **10***b* (37), **10***c* (37), and **11***b* (38).

Treatment of epoxides with potassium tert*-butoxide*

A solution of potassium *tert*-butoxide in *tert*-butyl alcohol (100 mL, 0.06 *M*) was added to a solution of the steroidal epoxide (0.1 g) in ether or THF (10 mL), and the resulting mixture refluxed under an atmosphere of dry nitrogen. After three days, the steroid was re-isolated following the addition of water and a conventional work-up. The following were obtained unchanged from this procedure: **1***a*, **2***a*, **3***a*, **3***c*, **4***a*, **5***a*, **6***a*, **6***c*, **7***a*, **8**, **9**, **10***a*, **11***a*, and **12***a*.

Treatment of epoxides with LDA

Diisopropylamine (0.8 mL) was added over 15 min to a solution of methyl lithium (3.3 mL, 1.56 *M* in ether) in dry THF (100 mL) at −20°C. The resulting mixture was stirred at −20°C for an additional 15 min and then cooled to −78°C. A solution of epoxide (0.1 g) in THF (5 mL) was then added. The reaction mixture was stirred at −78°C for 12 h, after which time the temperature was allowed to come to −10°C, and then stirring was continued for an additional 3 days. Butanol (2 mL) was then added, and the mixture neutralized (1 *M* HCl), diluted with water, and extracted with chloroform. After isolation in the conventional way, the following epoxides were obtained unreacted by the above procedure: **1***a*, **2***a*, **3***a*, **3***c*, **4***a*, **5***a*, **6***a*, **6***c*.

Treatment of epoxides with LDEA

The following general procedure was used. LDEA was generated as described above from diethyl amine (2.0 mL) and *n*-butyl lithium (5.16 mL, 2.4 *M* in hexane) in ether solution (100 mL). A solution of the epoxide (0.3 g) in THF (5 mL) was then added at −15°C, and the resulting mixture heated under reflux. Water (10 mL) was then added dropwise, and the resulting mixture washed with saturated ammonium chloride solution. Chloroform was then added, and the solution washed further (water), dried (sodium sulphate), and evaporated. Previously unpublished ^{13}C nmr data for the products described below are listed in the tables. All the compounds listed below also gave satisfactory ^{1}H nmr and mass spectral data. Yields refer to isolated, purified material. No significant amounts of other products were detected by tlc.

*(5,6α)-Epoxy-5α-cholestan-3β-ol (1*a*)*

Treatment of **1***a* as described above with LDEA for 24 h gave a residue which was chromatographed (neutral alumina) to give cholest-6-ene-3β,5α-diol (**14***a*) (56%) as the only product, mp 146–150°C (from methanol) (lit. (39) mp 147–150°C).

*(5,6α)-Epoxy-5α-cholestan-3α-ol (2*a*)*

The residue from treatment of **2***a* with LDEA for 3 days was crystallized from ethyl acetate – hexane to give cholest-4-ene-3α,6α-diol (**16**) (19%), mp 191–193°C (lit. (40) mp 189–191°C). Chromatography of the mother liquor (silica gel, gradient elution from chloroform to ethyl acetate) gave **2***a* (25%) followed by cholest-6-ene-3α,5α-diol (**15***a*) (18%), mp 146–149°C (from hexane). M^+ calcd. for $C_{27}H_{46}O_2$: 402.349; found: 402.346. R_f's: ethyl acetate, 0.55; 5% methanol/chloroform, 0.37; ether, 0.75.

*(5,6α)-Epoxy-5α-cholestane (3*a*)*

Crystallization from ethyl acetate – hexane of the residue from a 1 h reaction of **3***a* with LDEA gave 5α-cholest-6-en-5α-ol (**15***b*) (72%), mp 86°C. M^+ calcd. for $C_{27}H_{46}O$: 386.348; found: 386.354. R_f's: ether, 0.9; ethyl acetate, 0.65; 5% methanol/chloroform, 0.65.

*(5,6α)-Epoxy-5α-cholestan-3-one, 3-cyclic ethylene ketal (3*c*)*

Chromatography of the residue from a 3 day reaction of **3***c* with LDEA (silica gel, benzene–ether gradient elution), afforded cholest-4-en-6α-ol-3-one (**17***a*) (60%), identical in all respects with an authentic sample.

*(5,6β)-Epoxy-5β-cholestan-3α-ol (4*a*)*

The residue from treatment of **4***a* with LDEA for 3 days was dissolved in hexane and allowed to stand at 0°C, whereupon cholest-4-ene-3β,6β-diol (**13***a*) (17%) was obtained, identical in all respects with an authentic sample. The mother liquor was chromatographed (neutral alumina, hexane to ether gradient elution) and gave 5β-cholest-6-ene-3β,5β-diol (**14***b*) (33%), mp 137–140°C (lit. (41) mp 139–140°C).

*(5,6β)-Epoxy-5β-cholestan-3α-ol (5*a*)*

Treatment of **5***a* with LDEA for 3 days resulted in the recovery of starting material (75%) as the only identifiable steroid.

*(5,6β)-Epoxy-5β-cholestane (6*a*)*

Treatment of **6***a* with LDEA for 3 days gave a residue from which only **6***a* (85%) and cholest-4-en-6β-ol (**13***b*) (5%) (identical with an authentic sample (42)) were obtained.

*(5,6β)-Epoxy-5β-cholestan-3-one, 3-cyclic ethylene ketal (6*c*)*

The residue from treatment of **6***c* with LDEA for 3 days was chromatographed (silica, chloroform to ethyl acetate gradient elution) to give cholest-4-en-6β-ol-3-one (**17***b*) (29%) as the only identifiable steroid, identical in all respects with an authentic sample.

*(4,5α)-Epoxy-5α-cholestan-3β-ol (7*a*)*

Chromatography of the residue from a three day reaction of **7***a* with LDEA (neutral alumina, hexane to ether gradient elution) gave **7***a* (50%), followed by cholest-5-ene-3β,4α-diol (**20**) (10%), mp 216–219°C (from aqueous methanol) (lit. (43) mp 223°C from acetone).

(4,5α)-Epoxy-5α-cholestan-3α-ol (8)

Treatment of **8** with LDEA for three days gave no detectable reaction products (tlc).

(4,5α)-Epoxy-5α-cholestane (9)

The residue from a three day reaction of **9** with LDEA was chromatographed (neutral alumina, hexane to ether gradient elution) to give 5α-cholest-3-en-5α-ol (**18***a*) (40%), mp 79–80°C (from aqueous acetone) (lit. (44) mp 75–76°C), followed by cholest-5-en-4α-ol (**19***a*) (15%), mp 140–142°C (from acetone–pentane) (lit. (45) mp 144–145°C).

*(4,5β)-Epoxy-5β-cholestan-3β-ol (10*a*) and (4,5)β-epoxy-5β-cholestan-3-α-ol (11*a*)*

Treatment of **10***a* or **11***a* with LDEA for three days resulted in the recovery of unreacted starting materials only.

*(4,5β)-Epoxy-5β-cholestane (12*a*)*

The residue from a three day reaction of **12***a* with LDEA was dissolved in ether, passed through a short column of neutral alumina, and then subjected to preparative tlc (silica gel, hexane–ether, 1:1). The band of higher R_f was identified as cholest-5-en-4β-ol (**19***b*) (30%), mp 128–130°C (from aqueous methanol) (lit. (43) mp 131–132°C) and the other as 5β-cholest-3-en-5β-ol (**18***b*) (60%), mp 90–92°C (from aqueous methanol) (lit. (45) mp 89–91°C).

On the reaction of furan with bromine in aqueous solution. Observation of the slow hydration of malealdehyde

OSWALD S. TEE[1] AND B. E. SWEDLUND[2]

Department of Chemistry, Concordia University, 1455 de Maisonneuve Ouest, Montreal, P.Q., Canada H3G 1M8

Received February 2, 1983

OSWALD S. TEE and B. E. SWEDLUND. Can. J. Chem. **61**, 2171 (1983).

The rate of reaction of furan with bromine in aqueous solution has been measured and the rate constant obtained by Williamson and Coller is confirmed. However, it is now found that the reaction of bromine with furan in water has two distinct stages: attack of bromine leading to the formation of malealdehyde **3** and hydration of **3** to a 2:1 mixture of the geometrical isomers of its cyclic hydrate **4**. This second, slower process is observable by stopped-flow uv spectrophotometry occurring after the consumption of bromine. The observed kinetics are very similar to those recently found for the analogous hydration of phthalaldehyde by McDonald and Martin.

OSWALD S. TEE et B. E. SWEDLUND. Can. J. Chem. **61**, 2171 (1983).

On a mesuré la vitesse de la réaction du furanne avec le brome en solution aqueuse et on a confirmé la constante de vitesse obtenue par Williamson et Coller. Cependant on trouve maintenant que la réaction du brome avec le furanne dans l'eau a deux étapes distinctes: l'attaque du brome qui conduit à la formation du maléaldéhyde **3** et l'hydratation du composé **3** qui conduit à un mélange 2:1 des isomères géométriques de son hydrate cyclique **4**. Ce second processus, le plus lent, peut être observé par la spectrophotométrie uv à flux stoppé que l'on utilise après la disparition du brome. Les cinétiques observées sont semblables à celles trouvées récemment pour l'hydratation analogue du phthalaldéhyde par McDonald et Martin.

The halogenation of furans is complex with the nature of products varying widely with the substrate, reagent, solvent, and reaction conditions (1–4). However, two broad classes of reaction may be recognized, viz. addition and substitution, with the former often leading to ring-opening (1–4).

Bromination of furan in CCl_4 gives a mixture of 2-bromo- and 2,5-dibromofuran (5). Using ^{1}Hmr spectroscopy, Baciocchi *et al.* (6) observed the formation of 1,4- and 1,2-dibromo adducts from furan and bromine in the non-nucleophilic solvent carbon disulphide, at low temperature. With time, and on warming, the adducts underwent elimination to 2-bromofuran (6).

In hydroxylic solvents the reaction of furan (**1**) follows a different course. With bromine (or chlorine) in an alcohol solvent at low temperatures, reaction leads to the formation of a

[1] 
1 **2**

2,5-dialkoxy-2,5-dihydro derivative, **2** (7, 8). Similarly, in acetic acid containing potassium acetate, the corresponding diacetoxy compound **2** (R = Ac) is obtained (9). Recently, Williamson and Coller studied the reaction of furan with bromine, generated electrochemically, in aqueous solution (10).

[2] 
3

They diagnosed the product as being butenedial **3** (malealdehyde), eq. [2], on the basis of being able to form its bis-phenylhydrazone from the product mixture. They also measured the rate of reaction of bromine with furan using a coulochronopotentiometric method (10).

In contrast to these results, Linda and Marino (11) reported

[3] 
that bromination of methyl furoate in 50% aqueous acetic acid gives the substitution product, eq. [3], the same product as can be obtained under other reaction conditions (12).

We have begun to study the bromination of furans systematically to try to ascertain why some derivatives undergo addition, whereas others show substitution. Our initial approach to this problem was to study the effect of substituents and solvents upon the rate of bromination.[3,4] To anchor a correlation of results for aqueous solution a reliable value for furan was required.[5] During measurement of this value we found that another, slower process is observable, which is the subject of the present paper.

Results

Kinetic studies

We first measured the second-order rate constant (k_2) for the reaction of bromine with furan in aqueous solution. We found $k_2 = 1.4 \times 10^6\ M^{-1}\ s^{-1}$ (25°C, $I = 0.1\ M$ (KBr)), as measured by the stopped-flow uv method (13–15). This value is in reasonable agreement with $k_2 = 1.8 \times 10^6\ M^{-1}\ s^{-1}$ (25°C, extrapolated[6] to $I = 0$), obtained electrochemically by Williamson and Coller (10).

While we were carrying out the above measurement we observed that the final absorbance value slowly drifted downwards, suggesting a second, slower process occurring after the

[e][Buffer] = 0.02 M.

consumption of bromine. This behaviour is most evident at 230−240 nm. At these wavelengths there is a sizeable absorption which appears on the side of the large absorption at 200−220 nm due to the various other species in solution. Monitoring the disappearance of the transient absorption gave excellent first-order kinetics, and appropriate rate constants (k_{obs}) were obtained in the normal way (14).

Table 1 shows values of k_{obs} found under various conditions; Table 2 and Fig. 1 show how k_{obs} varies with pH. The rate is essentially invariant in the pH region 4.5−6, and so most of the data in Table 1 pertain to this region.

The value of k_{obs} is unaffected by the initial concentration of furan or bromine (Table 1). Moreover, the same value is obtained in 0.1 M $NaClO_4$ as in 0.1 M KBr. In addition, the intensity of the initial absorbance at 240 nm varies in proportion to the concentration of the limiting reagent, be it furan or bromine. These observations are all consistent with the transient absorption being due to an intermediate which is formed rapidly and essentially irreversibly from furan and bromine.

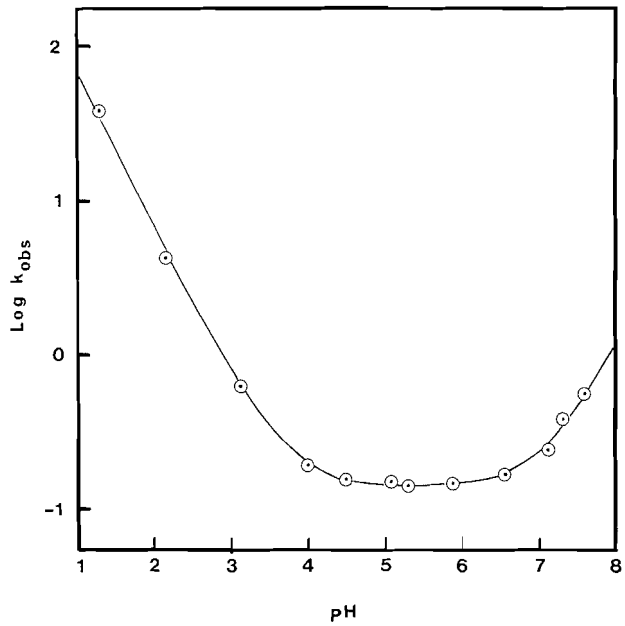

FIG. 1. The pH−rate profile for disappearance of the intermediate. Data in Table 2.

Increasing the ionic strength with KBr or $NaClO_4$ causes similar reductions in rate (Table 1). These experiments are evidence against the intermediate being a bromo species undergoing solvolysis (*vide infra*). The observation that k_{obs} is reduced (0.15 to 0.03 s^{-1}) in 50% aqueous dioxane is not inconsistent with water being involved in the process being followed.

The pH−rate profile (Fig. 1)[7] can be described by eq. [4] with $k_0 = 0.140$ s^{-1}, $k_H = 657$ M^{-1} s^{-1}, and $k_{OH} = 1.11 \times 10^6$ M^{-1} s^{-1}.

$$[4] \quad k_{obs} = k_H[H^+] + k_0 + k_{OH}[OH^-]$$

Furthermore, the reaction is subjected to buffer catalysis. Data obtained at pH 4.49 (Table 1) show that increasing the buffer (acetic acid/acetate) concentration causes a linear increase in k_{obs} (intercept = 0.151 s^{-1}, slope = 0.980 M^{-1} s^{-1}, r = 0.997). Likewise, on the basic side of the profile, values of k_{obs} (not shown) obtained at [buffer] = 0.08 M fall above those shown in Fig. 1.[8] Given then that buffer catalysis occurs, the values of k_0, k_H, and k_{OH} quoted above may be somewhat elevated. However, since the data on which they are based were obtained at low buffer concentration, the elevation is probably no more than 10−20%.

Product studies

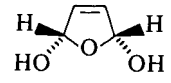
Using normal titrimetric methods, we confirmed that the 1:1 reaction of furan with bromine in water does indeed produce two mole equivalents of hydrobromic acid, as required by eq. [3] (10). There is a reaction with a second equivalent of bromine, but it occurs much more slowly.

Proton nmr analysis of reaction mixtures was most re-

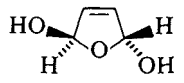
[7]Below pH 1 the rate of disappearance of the intermediate approaches that of bromine attack on furan. Above pH 5 the rate of bromination decreases due to the formation of HOBr (15). Around pH 8 this reduction begins to interfere with the process of interest. These factors limit the pH range accessible for the rate profile.

[8]For example, at pH = 7.42, [buffer] = 0.08 M, we found k_{obs} = 0.84, whereas interpolating between the last two points in Table 2 gives k_{obs} = 0.47.

vealing. We observed only two major signals not arising from the medium: a broadened singlet at δ 6.20 and a fairly sharp singlet at δ 5.90, with integrated areas in the ratio of about 2:1. These peaks are not attributable to malealdehyde **3**, which should give two doublets of equal intensity at about δ 10.3 and 6.5 (16). They can, however, be explained by a mixture of the *cis* and *trans* isomers (**4***c*, **4***t*) of the cyclic hydrate of **3**. The sharp singlet at δ 5.90 is assigned to the methine protons of the *cis* isomer **4***c*. The broadened larger peak at δ 6.20 is attributed



4*c*

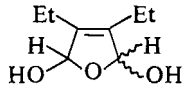


4*t*

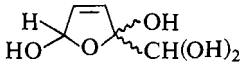
to the vinylic protons of **4***c* and to the methine *and* vinylic protons of the *trans* isomer **4***t*. A 2:1 mixture of **4***c* and **4***t* then gives rise to the observed peak ratios.

These assignments are supported by experiments we have carried out, as well as by the nmr spectra of many derivatives of the general type **2** observed by earlier workers (6, 17–21). In general, the methine protons of *cis* adducts appear upfield of those of the *trans* (6, 17–21). The position of both these types relative to the vinylic protons varies depending upon the particular structure and the solvent (17, 18). Often, however, the vinylic protons of the geometrical isomers are essentially coincident (17, 18, 20). For comparative purposes, Table 3 shows data we have obtained, together with that for three closely related cases from the literature.

For the dimethoxy compound **2** (R = Me), which exists as a 7:3 mixture of the *cis* and *trans* isomers (17), we find that in D_2O the vinyl protons of both isomers are at δ 6.20, the *cis* methine protons at δ 5.71, and the *trans* methine protons at δ 6.02. In CCl_4 the same relative peak positions are maintained, but signals are shifted upfield by ~0.2 ppm (17). Table 3 also contains data for the diacetoxy isomers **2** (R = Ac) and the cyclic hydrates **5**. The last (**5**) were prepared by anodic oxidation[9] of 3,4-diethylfuran in acetonitrile containing saturated aqueous sodium bicarbonate (19). The methine protons of the two isomers of **5** appear as broadened singlets at δ 5.71 and 6.05 (19).



5



6

We also observed the hydrolysis of the dimethoxy compounds **2** (R = Me) in D_2O containing a few drops of DCl. The peaks due to **2** (R = Me) gradually diminish and eventually a stage is reached in which the hydrates **4** predominate. However, there are other signals in the same area attributable to partial hydrolysis (**2** with one hydroxyl and one methoxyl). Presumably, at the concentration of **2** used, there is insufficient driving force for total conversion to the hydrates **4**.

As a final point supporting the assignment of **4**, we note that the isomeric hydrates **6** have been observed (by nmr) among the products obtained from the reaction of furfural (furan-2-carboxaldehyde) with aqueous bromine (22).

Discussion

From the evidence just presented it seems clear that the stoichiometry of the 1:1 reaction of furan with bromine in water is as shown in eq. [5]. The organic product is the cyclic hydrate **4**, which is formed as a 2:1 mixture of the *cis* and *trans*

[5] $\mathbf{1} + Br_2 + 2H_2O \longrightarrow \mathbf{4} + 2HBr$

isomers (**4***c*, **4***t*). Thus the overall reaction in water is completely analogous to the reaction in methanol, eq. [1], which produces a similar 7:3 mixture of diastereomers (17), and to the reaction in acetic acid (9).

The conclusion of Williamson and Coller that the product is malealdehyde was based upon the isolation of an appropriate derivative (10). This result in no way conflicts with our conclusion that the product is **4**, since it is well-known that the hydration of aldehydes is sufficiently reversible that free aldehyde can be trapped by suitable reagents (23).

Initially we made another observation which appears at variance with **4** being the reaction product. As noted above, there is reaction with a second equivalent of bromine, but it is very slow. At first glance one expected the CC double bond of **4** to be fairly reactive towards bromine, whereas, of course, that of malealdehyde should be quite unreactive.[10] However, we find that the dimethoxy compound **2** (R = Me) also reacts only slowly with bromine. Clearly then, the oxygens of **2** and **4** substantially reduce the reactivity of their double bonds, compared to what is normal for an alkene (24, 25). Presumably this is due to the combined inductive effects of all three oxygens.

We now consider the nature of the process that can be observed by uv spectrophotometry and for which we have obtained kinetic data. We believe this to be the relatively slow hydration of malealdehyde to produce the hydrates **4** (eq. [6]).

[6] 
3 **4**

The strong transient absorption observed below 245 nm is consistent with the intermediacy of malealdehyde (20, 26). Moreover, other potential intermediates are insufficiently conjugated to absorb significantly above 220 nm. However, the strongest evidence for the process in eq. [6] is the similarity of

[a]At 25°C, I = 0.1 M.
[b]At 28°C, I = 1.0 M, from ref. 27.
[c]Following McDonald and Martin, we take this to be due to water acting as a general base (27).
[d]Approximate value based on one series of measurements at pH 4.49 (Table 1).

our kinetic results to those of McDonald and Martin (27). They recently reported a thorough study of the analogous hydration of phthalaldehyde **7** to its cyclic hydrate **8**, eq. [7]. Our rate

[7] 
7 **8**

profile (Fig. 1) is very similar to theirs (Fig. 5, ref. 27), but it is displaced vertically since the process we have followed is about 15 times faster. Correspondingly, the catalytic constants for the two studies are quite similar (Table 4), with those from the present work being 9–25 times larger.

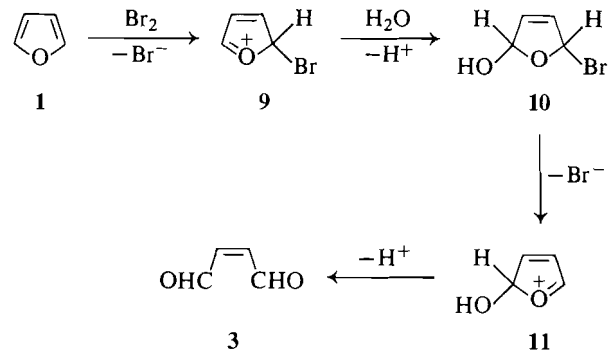
It seems reasonable that the rate constants for the hydration of **3** should be somewhat greater than those for the hydration of **7**. In malealdehyde the transmission of the conjugative effect from one formyl group to the other occurs through a simple CC double bond. In phthalaldehyde the corresponding transmission is through a benzene ring that is stabilized by aromaticity. Accordingly, the transmission of the conjugative effects in **7** may be attenuated relative to that in **3**, and the rate constants for **7** thus be somewhat smaller. A further point which supports these arguments concerns the position of the hydration equilibrium. McDonald and Martin observed 10% free phthalaldehyde in equilibrium with its hydrate **8**. In contrast, we observe no appreciable free malealdehyde in equilibrium with its hydrate **4**. This is also consistent with the view that the formyl groups of malealdehyde exert a stronger influence on one another than those in phthalaldehyde.

Mechanisms

The observations and the kinetic results obtained in the present study clearly point to the reaction of bromine with furan in water having two distinct stages (eq. [8]): attack of bromine leading to the formation of malealdehyde **3** and hydration of **3** to the cyclic hydrate **4**.

[8] **1** $\xrightarrow[-2HBr]{Br_2,H_2O}$ **3** $\xrightarrow{H_2O}$ **4**

The sequence of steps involved in the formation of **3** are probably those shown in Scheme 1. Attack of bromine upon furan gives a transient cation **9** which is captured by water to produce the 2-bromo-5-hydroxy adduct **10**.[11] Ionization of this



1 **9** **10** **3** **11**

SCHEME 1

intermediate should be facile since it is an allylic bromide and an α-bromo ether, and the process leads to the delocalized cation **11**. Proton loss and CO bond cleavage, probably concerted, then converts **11** into malealdehyde **3**.

In an alcohol solvent a similar sequence of steps presumably takes place, except that the alkoxy cation analogous to **11** is captured by solvent to give the product **2**. At the outset we favored such a mechanism for the reaction in water, expecting that the cation **11** would be captured by solvent to give the hydrate **4**, which subsequently equilibrated with malealdehyde **3**. However, our results are much more consistent with **3** being formed first and equilibration with **4** occurring second.[12]

The steps involved in the hydration of malealdehyde are presumably analogous to those for phthalaldehyde hydration (27). On the basis of buffer catalysis studies, McDonald and Martin argued convincingly that the slow step involves hydration of one formyl group and that the subsequent cyclization is relatively fast (27). Since the catalytic constants we have obtained are all elevated to a similar extent relative to those for phthalaldehyde hydration (Table 4), the Bronsted α and β for malealdehyde hydration must be similar.[13] It seems reasonable, therefore, to postulate that malealdehyde hydration likewise involves rate-limiting hydration of one formyl group, followed by fast cyclization (Scheme 2). The slow step may be either general acid- or general base-catalyzed (Scheme 2), as indicated by the kinetic results, and as is normal for aldehyde hydration (23, 28).

Experimental

Furan (Aldrich) was distilled before use. 2,5-Dihydro-2,5-dimethoxyfuran (**2**, R = Me) (Aldrich) was used as received. Solutions (buffers, bromine, etc.) used in kinetics experiments were as in other recent work (13–15, 29).

Ultraviolet spectral measurements were made with Unicam SP 800 and Aminco DW-2 spectrophotometers. The proton nmr spectra re-

[11]Several authors have written the reaction in alcoholic solvents as involving a 2,5-dibromo adduct, analogous to **10** (e.g. ref. 22). It seems more likely to us that the cation **9** is largely captured by solvent in nucleophilic solvents, such as water and methanol (7).

[12]As a referee has pointed out, we cannot exclude the partitioning of the intermediate cation **11** since the actual concentration of malealdehyde **3** is unknown. If the capture of **11** by water (to give hydrates **4**) is similar in rate to the ring-opening (**11** → **3**), then a significant proportion of **4** may be formed directly. In this case the observed kinetics pertain to that fraction of the reaction which is temporarily diverted to malealdehyde **3** and which subsequently equilibrates with the hydrates **4**.

[13]From the catalytic constants for hydronium ion and acetic acid one can estimate α = 0.43. Likewise, from the values for water (see Table 4, footnote *c*) and hydroxide ion we estimate β = 0.40. For comparison, the values for phthalaldehyde hydration are α = 0.52, β = 0.51 (27) and for acetaldehyde hydration α = 0.54, β = 0.45 (28).

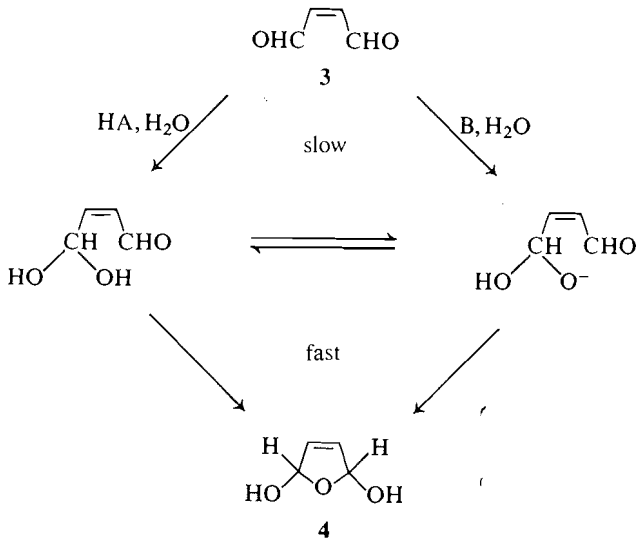

SCHEME 2

ported above were recorded on a Varian T-60 machine, using D_2O as solvent and DSS as internal standard.

Kinetics

Measurements of rates were made using an Aminco DW-2 spectrophotometer with stopped-flow accessory. Data acquisition employed the equipment recently described (14) and data analysis followed standard practice (13–15, 29).

The rate of reaction of furan with bromine was measured by monitoring the disappearance of bromine (λ = 267 nm, tribromide ion band) under pseudo first-order conditions (furan = 10^{-4} *M*, bromine = 10^{-5} *M*) in acetate buffer (pH = 3.98) and in 0.1 *M* KBr, at 25°C (15). The second-order rate constant given in the text was obtained from the observed first-order rate constant (45.2 s^{-1}) by correcting for the substrate concentration and for the actual concentration of free bromine in the normal way (15).

Since the solubility of furan in water is quite low, a concentrated stock solution was made up in methanol. Furan solutions for kinetics experiments were made up by diluting a few microlitres of this stock into an appropriately large volume of the desired medium.

Monitoring the disappearance of the tail-end absorption at 230–240 nm, ascribed to malealdehyde **3**, gave excellent first-order kinetics in the pH range 1–8. Final absorbance values (more than 10 half-lives) were stable and rate constants calculated by the normal, Kezdy–Swinbourne, and Guggenheim methods (30) agreed very well. Outside of the pH range 1–8, rate constants were not obtained for the reasons given above.[7]

Product studies

Because of the low solubility of furan in water and its propensity for resinification in the presence of acid, the analysis of product mixtures by nmr was not easy. Two basic approaches were employed, as detailed below.

In the first, a small amount of bromine was weighed into a small test-tube and covered with sufficient sodium bicarbonate to neutralize the acid to be produced.

An appropriate volume of deuterium oxide was added to these reagents and then a known amount of furan was added as a layer on top of the heavy water. The total mixture was cooled in ice and then was very *gently* stirred to bring about gradual reaction of the furan and bromine in the D_2O. After reaction was complete any residual solid was filtered off and the filtrate was submitted to nmr analysis.

The second approach was essentially the same, except that the furan was added gradually as a solution in dioxane. The two approaches gave the same results. The only nmr peaks of any significance, other than HDO (or dioxane), were those ascribed to the cyclic hydrates **4**.

Various unsuccessful attempts were made to isolate malealdehyde **3**. Unfortunately, as earlier workers have found (31), it is quite labile. It undergoes rapid polymerization in concentrated solutions and isomerization to the *E*-isomer (fumaric dialdehyde) in dilute solution (31). Formation of the latter causes solutions to turn yellow due to an absorption band at 354 nm (31). This yellowing was evident in product solutions left to stand for prolonged periods of time.

Preparation and stereochemistry of 8- and 9-hydroxy-2,5-ethano-3-benzazocines

PATRICE C. BÉLANGER, JOHN SCHEIGETZ, AND ROBERT N. YOUNG

Medicinal Chemistry Department, Merck Frosst Canada Inc., P.O. Box 1005, Pointe-Claire/Dorval, P.Q., Canada H9R 4P8

Received October 21, 1982[1]

PATRICE C. BÉLANGER, JOHN SCHEIGETZ, and ROBERT N. YOUNG. Can. J. Chem. **61**, 2177 (1983).

Two isomers of a novel ring system, 1,2,3,4,5,6-hexahydro-2,5-ethano-3-benzazocine, were prepared by a Beckmann rearrangement of *syn*- and *anti*-2-hydroxy-11-oximino-6,9-methano-5,6,7,8,9,10-hexahydrobenzocyclooctene, **4***a* and **4***b* respectively. Because of the similarity in their ir, nmr, and ms, it was impossible to distinguish between the different isomers. To resolve this problem, selective benzylic oxidation and nmr shift reagent studies gave results that determined the structures.

PATRICE C. BÉLANGER, JOHN SCHEIGETZ et ROBERT N. YOUNG. Can. J. Chem. **61**, 2177 (1983).

Deux isomères d'un nouveau système polycyclique, l'hexahydro-1,2,3,4,5,6-ethano-2,5-benz-3-azocine ont été préparés en effectuant le réarrangement de Beckmann sur les isomères *syn* et *anti* de l'hydroxy-2-oximino-11-méthano-6,9-hexahydro-5,6,7,8,9,10-benzocyclooctene **4***a* et **4***b* respectivement. La similarité de leur spectre infrarouge, de résonance magnétique nucléaire et de masse a rendu impossible la distinction des isomères. Il a fallu effectuer une oxydation sélective du carbone benzylique *para* au groupe méthoxy. Des études de résonance magnétique nucléaire avec des réactifs de contact ont résolu ce problème et ont permis d'assigner de façon non ambiguë les structures.

Introduction

The benzomorphan ring system has been a popular model for structural modifications in the preparation of analgesics (1). The system is a 3-benzazocine and is further characterized by a 2,6-methano bridge. While preparation and analgesic properties of other methano bridged benzazocines have been reported (2), the corresponding 2,5-ethano bridged 3-benzazocine is a novel system. During our investigation of the chemistry of the 5,6,7,8,9,10-hexahydro-6,9-methanobenzocyclooctene (3) system, we found that such a ring system **1** may be used to generate isomeric 3-benzazocines **2** and **3**. The analgesic properties of derivatives of these and related novel systems will be the subject of a future publication. In this paper we wish to report on the preparation and the proof of structure of two isomers of the 3-benzazocine system.

Discussion

A mixture of *syn*- and *anti*-2-hydroxy-11-oximino-6,9-methano-5,6,7,8,9,10-hexahydrobenzocyclooctene **4***a*, **4***b* was prepared as previously reported (3). The separation of the *syn* and *anti* isomers was easily accomplished by preparative high pressure liquid chromatography (hplc) on silica gel. The definitive assignment of their structures was not possible either by ^{1}H or ^{13}C nmr. Each of the oxime isomers was converted to its corresponding isomeric 3-benzazocine as is outlined in Scheme 1.

The key step in generating this novel 2,5-ethano-3-benzazocine ring system from the 6,9-methanobenzocyclooctene ring system is based on the Beckmann rearrangement (4). Several conditions were tried and the best results for ring expansion to the cyclic amides were obtained by using *p*-toluenesulfonyl chloride in pyridine (5). The product from the Beckmann rearrangement is known to be highly dependent on the stereochemistry of the starting oxime (6). Thus it was expected that the *syn* isomer would lead to only the 8-hydroxy-2,5-ethano-3-benzazocine **6** after hydrolysis of the *p*-toluenesulfonate **5***a* and lithium aluminium hydride reduction of the resulting amide **5***b*. Similarly, the *anti* isomer **4***b*

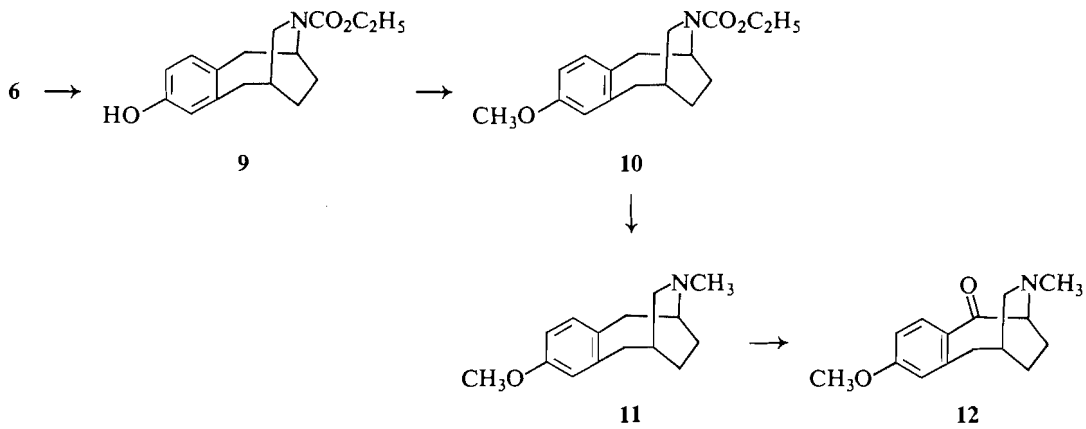
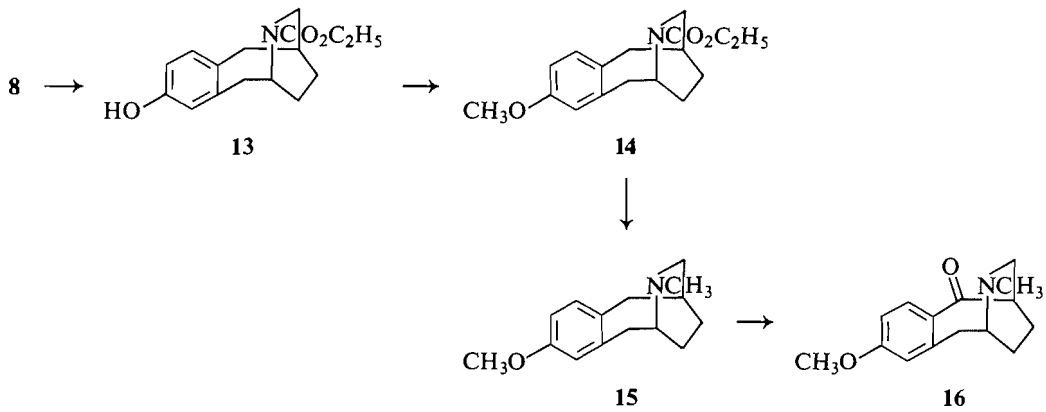


SCHEME 2



SCHEME 3

would be converted to 9-hydroxy-2,5-ethano-3-benzazocine **8**.

The structure assignment of the isomeric Beckmann rearrangement products could not be deduced by conventional methods. Thus, it was decided that the selective oxidation of the benzylic methylene group *para* to the phenolic hydroxyl would produce a β-aminoketone **16** versus an α-aminoketone **12**, therefore permitting better nmr differentiation of the bridgehead protons in **6** and **8**.

Direct oxidation on the free phenolamine **6** or **8** gave only decomposition products. To avoid these complications it was necessary to protect the phenol function as its methyl ether. The synthetic sequence utilized in the preparation of the isomeric ketones **12** and **16** is outlined in Schemes 2 and 3.

Reaction of **7***b* with ethyl chloroformate gave a product in which both the phenol and the amine were protected. On treatment with base, the carbonate was hydrolyzed rapidly. The carbamate **9** was now methylated with dimethylsulfate and potassium carbonate in acetone and the resulting methoxy derivative **10** was reduced with LAH/THF to give the methoxy-*N*-methylamine **11** in an overall yield of 87% from amine **6**. Oxidation with CrO_3/10% H_2SO_4 as reported in the preparation of ethylketocyclazocine (7) gave the desired ketone **12**. The isomer **16** was prepared in a similar manner.

Although the oxidation yields were not optimized, the isomer **15** gave better yields of the corresponding ketone **16** which seemed to be more stable in the oxidation mixture. The ketone **12** obtained from the oxidation of the isomer **11** is an α-aminoketone and as such appears to be much more susceptible to overoxidation. We speculate that the reason for the low yield is due to possible β-elimination, giving a product subject to further degradation.

Nuclear magnetic resonance shift reagent studies

A nmr shift reagent study, using $Eu(fod)_3$, was undertaken on ketones **12** and **16** to prove unambiguously their structure.

In the 90 MHz spectrum of ketone **16**, the bridgehead proton H-5 signal is buried in complex absorptions around 3.1 ppm. The gradual downfield displacement of the absorption due to H-5, using various amounts of shift reagent, can be followed as shown in Table 1. After the addition of 1.0 mmol of $Eu(fod)_3$ to 1.5 mmol of ketone, proton H-5 is shifted to 6.13 ppm and, as can be seen in Fig. 1, it has the characteristics of a poorly resolved multiplet, which is expected from the bridgehead proton of isomer **16** on coupling with three adjacent protons. Somewhat surprisingly (8), the europium appears to complex most strongly with the carbonyl oxygen. This is apparent from the doublet observed for H-7 which is most affected by the shift reagent.

The 90 MHz spectrum of the ketone **12** was in excellent agreement with that expected of isomer **12**. As seen in Fig. 2, the absorption due to the bridgehead proton H-2 is clearly visible at 3.5 ppm without the use of shift reagent and its position corresponds to the expected value from shielding constants (9).

Nevertheless, the addition of $Eu(fod)_3$ was carried out and the results are listed in Table 2. As is the case for isomer **16**, the complexation of europium is with the carbonyl oxygen. Proton H-2 appears as a doublet of doublets with coupling

*Chemical shift expression in ppm downfield from TMS.

constants of 2 Hz and 7 Hz. Examination of molecular models indicates that the piperidine ring in **12** can exist in two possible conformations. In one conformer (A) the methylene protons at C-11 are bisected by the bridgehead proton H-2 when viewing along the (C_2—C_{11}) bond and one would expect to observe a triplet for H-2 with a coupling constant of about 4 Hz.

In the other conformer (B) the dihedral angles between H-2 and the adjacent methylene protons are about 90° and about 30° giving expected couplings of 1–2 Hz and 7–8 Hz respectively according to Karplus (10). Therefore, the doublet of doublets at 3.5 ppm, having coupling constants of 7 Hz and 2 Hz, appears to correspond to this particular conformer.

This nmr study clearly established the structure of both isomers **12** and **16** and, therefore, their relationship to *syn* and *anti* oximes **4***a* and **4***b*. Compound **16** was obtained from the more polar *syn* isomer **4***a*, whereas **12** originated from the less polar *anti* isomer **4***b*.

Mass spectral analyses

The mass spectral analyses of all the 8-hydroxy-2,5-ethano-3-benzazocine analogues, as well as all the 9-hydroxy-2,5-ethano-3-benzazocine analogues, were found to produce similar fragmentation patterns. They all produced as major fragments a dihydropyridinium ion and a *p*-hydroxy or *p*-methoxy-2-methyl tropylium ion. In this series of derivatives there was only one notable exception. The keto derivative **12**, besides giving the above fragmentation, also fragmented the bridge containing the amine as seen by the $M - 57$ peak. The significance of the relative abundance of the $M - 57$ peak (58%) can be interpreted as due to the α-amino ketone nature of this derivative **12**.

Experimental

Melting points were taken on a Thomas–Hoover apparatus in open capillary tubes and are uncorrected. Infrared spectra were recorded on a Perkin-Elmer 267 grating spectrophotometer. A Varian EM-390 spectrometer was used to record nmr spectra. Proton chemical shifts are relative to tetramethylsilane (TMS) as internal standard. A Waters Prep LC/500 System was used to perform the hplc preparative separations, using one silica gel cartridge with a flow rate of 250 mL/min. Elemental analyses were performed by Galbraith and Associates, Knoxville, TN. The low resolution mass spectral analyses were performed by the Morgan-Schaffer Corporation, Montreal.

All reactions as well as column chromatography were monitored routinely with the aid of thin layer chromatography (tlc) using precoated 0.25 mm silica gel plates (Eastman Kodak) or silica gel GF plates (Analtech).

LC/500, eluting with hexane/ethyl acetate, 1:1 v/v, to provide 7.3 g of the more polar *syn*-isomer **4***a* and 7.6 g of the less polar *anti*-isomer **4***b*.

Isomer **4**a: mp 190–192°C; (EtOAc/hexane 1:10 v/v); ir (KBr): 3300 (OH^-), 1680 (C=N) cm^{-1}; nmr ($CDCl_3$): 6.4–7.1 (m, 3H), 3.2–3.8 (m, 2H), 2.6–3.0 (m, 4H), 1.1–1.9 (m, 4H). *Anal.* calcd. for $C_{13}H_{15}NO_2$: C 71.86, H 6.95, N 6.44; found: C 71.82, H 6.76, N 6.41.

Isomer **4**b: mp 178–180°C; (EtOAc/hexane 1:1 v/v); ir (KBr): 3320 (OH^-), 1690 (C=N) cm^{-1}; nmr ($CDCl_3$): 6.4–7.1 (m, 3H), 3.2–3.8 (m, 2H), 2.6–3.0 (m, 4H), 1.1–1.9 (m, 4H). *Anal.* calcd. for $C_{13}H_{15}NO_2$: C 71.86, H 6.95, N 6.44; found: C 71.79; H 6.73, N 6.64.

*2,5-Ethano-8-*p*-toluenesulfonyloxy-4-oxo-1,2,3,4,5,6-hexahydro-3-benzazocine (**5**a)*

syn-2-Hydroxy-11-oximino-6,9-methano-5,6,7,8,9,10-hexahydrobenzocyclooctene (**4***a*) (3.0 g, 13.8 mmol) and *p*-toluenesulfonyl chloride (5.8 g, 30.4 mmol) in pyridine (50 mL) was stirred at room temperature overnight. The reaction mixture was concentrated *in vacuo* to a residue that was purified by chromatography ($CH_3OH/CHCl_3$, 1:100 v/v) to yield 3.18 g (70%) of the title compound; mp 128–131°C; ir (KBr): 3400 (NH), 1660 (C=O) cm^{-1}; nmr ($CDCl_3$): 6.4–7.8 (m, 7H), 3.5–4.0 (m, 2H), 2.6–3.2 (m, 4H), 2.4 (s, 3H), 1.4–2.1 (m, 4H). *Anal.* calcd. for $C_{20}H_{21}NSO_4$: C 64.66, H 5.69, N 3.77, S 8.63; found: C 64.51, H 5.88, N 3.72, S 8.89.

*2,5-Ethano-9-*p*-toluenesulfonyloxy-4-oxo-1,2,3,4,5,6-hexahydro-3-benzazocine (**7**a)*

By the same procedure used for the preparation of **5***a*, *anti*-2-hydroxy-11-oximino-6,9-methano-5,6,7,8,9,10-hexahydrobenzocyclooctene (**4***b*) (3.0 g, 13.8 mmol) was converted to 3.13 g (69%) of the title compound, mp 182–186°C; ir (KBr): 3300 (NH), 1670 (C=O) cm^{-1}; nmr ($CDCl_3$): 6.4–7.8 (m, 7H), 3.5–4.0 (m, 2H), 2.6–3.2 (m, 4H), 2.4 (s, 3H), 1.4–2.1 (m, 4H). *Anal.* calcd. for $C_{20}H_{21}NSO_4$: C 64.66, H 5.69, N 3.77, S 8.63; found: C 64.50, H 5.57, N 3.75, S 8.81.

*2,5-Ethano-8-hydroxy-4-oxo-1,2,3,4,5,6-hexahydro-3-benzazocine (**5**b)*

A solution of 2,5-ethano-8-*p*-toluenesulfonyloxy-4-oxo-1,2,3,4,-5,6-hexahydro-3-benzazocine (**5***a*) (3.55 g, 9.56 mmol) and sodium methoxide (1.9 g, 36.0 mmol) in methanol (17 mL) was stirred at room temperature overnight. Hydrochloric acid (3 *N*; 35 mL) was added and the reaction mixture extracted twice with chloroform. The combined organic layers were washed with water, dried (Na_2SO_4), and concentrated *in vacuo* to yield an oil. After triturating in water, the solid was filtered and dried to yield 1.58 g (76%) of the title compound, mp 241–245°C; ir (KBr): 3400 (OH^-), 3320 (NH), 1650 (C=O) cm^{-1}; nmr (CD_3OD): 6.4–7.0 (m, 3H), 3.6–4.1 (m, 2H), 2.6–3.2 (m, 4H), 1.5–2.1 (s-broad, 4H).

*2,5-Ethano-9-hydroxy-4-oxo-1,2,3,4,5,6-hexahydro-3-benzazocine (**7**b)*

By the same procedure used for the preparation of **5***b*, 2,5-ethano-9-*p*-toluenesulfonyloxy-4-oxo-1,2,3,4,5,6-hexahydro-3-benzazocine (**7***b*) (3.25 g, 8.76 mmol) was converted to 1.66 g (87%) of the title compound, mp 305–309°C; ir (KBr): 3400 (OH^-) 3300 (NH), 1650 (C=O) cm^{-1}; nmr (DMSO-d_6): 6.3–7.0 (m, 3H), 3.3–3.9 (m, 2H), 2.7–3.0 (m, 4H), 1.4–1.9 (bs, 4H). *Anal.* calcd. for $C_{13}H_{15}NO_2$: C 71.86, H 6.95, N 6.44; found: C 71.46, H 6.90, N 6.18.

*2,5-Ethano-8-hydroxy-1,2,3,4,5,6-hexahydro-3-benzazocine hydrochloride (**6**)*

To a solution of 2,5-ethano-8-hydroxy-4-oxo-1,2,3,4,5,6-hexahydro-3-benzazocine (**5***b*) (1.54 g, 7.07 mmol) in tetrahydrofuran (70 mL) was added, in small portions, lithium aluminium hydride (1.34 g, 35 mmol). The mixture was refluxed overnight. The reaction mixture was treated with a saturated ammonium chloride solution (3 mL) and then with 1 *N* sodium bicarbonate (8 mL). The mixture was stirred for 15 min and then filtered. The filtrate was concentrated *in vacuo*. The oil was taken up in methanol, treated with hydrogen chloride, and evaporated to dryness. The residue was triturated in ether to yield 1.04 g (62%) of a solid which, after recrystallization from methanol/chloroform, had mp 234–240°C; ir (KBr): 3400 (OH^-), 3360 (NH) cm^{-1}; nmr (CD_3OD): 6.4–7.1 (m, 3H), 3.7–4.2 (m, 1H), 2.5–3.5 (m, 7H), 1.4–2.2 (m, 4H). *Anal.* calcd. for $C_{13}H_{17}NO \cdot HCl$: C 65.12, H 7.56, N 5.84, Cl 14.78; found: C 64.56, H 7.65, N 5.65, Cl 14.69.

*2,5-Ethano-9-hydroxy-1,2,3,4,5,6-hexahydro-3-benzazocine hydrochloride (**8**)*

Similarly, 2,5-ethano-9-hydroxy-4-oxo-1,2,3,4,5,6-hexahydro-3-benzazocine (**7***b*) (1.40 g, 6.45 mmol) in tetrahydrofuran (65 mL) was reduced by lithium aluminium hyride (1.2 g, 32 mmol) to yield 1.33 g (87%) of the title compound, mp 275°C; ir (KBr): 3440 (OH^-), 3320 (NH) cm^{-1}; nmr (CD_3OD): 6.4–7.1 (m, 3H), 3.7–4.2 (m, 1H), 2.5–3.5 (m, 7H), 1.4–2.2 (m, 4H). *Anal.* calcd. for $C_{13}H_{17}NO \cdot HCl$: C 65.12, H 7.56, N 5.84, Cl 14.78; found: C 65.09, H 7.60 N 5.77, Cl 15.37.

*N-Ethoxycarbonyl-2,5-ethano-8-hydroxy-1,2,3,4,5,6-hexahydro-3-benzazocine (**9**)*

To a solution of 2,5-ethano-8-hydroxy-1,2,3,4,5,6-hexahydro-3-benzazocine (**6**) (200 mg, 0.98 mmol), 1.0 mL of triethylamine, and 40 mL of THF was added a solution of ethyl chloroformate (122 mg, 1.14 mmol) in 1 mL of THF. The reaction mixture became slightly warm and after stirring for 30 min was concentrated. The residue was partitioned between chloroform and 1 *N* HCl. The chloroform layer was washed with water, dried (Na_2SO_4), and concentrated to yield an oil. An infrared spectrum showed a carbonate band at 1755 cm^{-1} and a carbamate band at 1680 cm^{-1}.

The unpurified *N*-ethoxycarbonyl-2,5-ethano-8-ethoxycarbonyloxy-1,2,3,4,5,6-hexahydro-3-benzazocine was dissolved in 25 mL of methanol and 4 mL of 3 *N* NaOH solution was added. After 5 minutes, the mixture was concentrated and the residue partitioned between 15 mL of 1 *N* HCl and chloroform. The chloroform layer was dried (Na_2SO_4) and concentrated to yield 233 mg (85%) of the title compound, mp 127–131°C; ir (KBr): 3340 (OH^-), 1665 (C=O) cm^{-1}; nmr ($CDCl_3$): 6.3–7.0 (m, 3H), 4.2–4.5 (m, 1H), 3.8–4.2 (q, 2H), 3.4–3.8 (t, 1H), 2.2–3.2 (m, 7H), 0.9–1.9 (m, 7H); *m/e*: 275 (M^+, 67%), 154 (90%), 153 (41%), 122 (100%), 121 (48%). *Anal.* calcd. for $C_{16}H_{21}NO_3$: C 69.79, H 7.68, N 5.08; found: C 69.10, H 7.80, N 4.94.

*N-Ethoxycarbonyl-2,5-ethano-9-hydroxy-1,2,3,4,5,6-hexahydro-3-benzozocine (**13**)*

By the same procedure used for the preparation of **9**, 2,5-ethano-9-hydroxy-1,2,3,4,5,6-hexahydro-3-benzazocine (**13**) (910 mg, 4.48 mol) was converted to 1.1 g (90%) of the title compound. The product was triturated with hexane; mp 103–106°C; ir (KBr): 3340 (OH^-), 1665 (C=O) cm^{-1}; nmr ($CDCl_3$): 6.1–7.0 (m, 3H), 4.2–4.6 (m, 1H), 3.75–4.2 (q, 2H), 3.3–3.75 (t, 1H), 2.2–2.3 (m, 7H), 0.9–2.0 (m, 7H); *m/e*: 275 (M^+, 81%), 154 (83%), 121 (100%). *Anal.* calcd. for $C_{16}H_{21}NO_3$: C 69.79, H 7.68, N 5.08; found: C 69.68, H 7.68, N 5.12.

*N-Ethoxycarbonyl-2,5-ethano-8-methoxy-1,2,3,4,5,6-hexahydro-3-benzazocine (**10**)*

A mixture of *N*-ethoxycarbonyl-2,5-ethano-8-hydroxy-1,2,3,4,5,6-hexahydro-3-benzazocine (**9**) (233 mg, 0.84 mmol), dimethyl sulfate (0.23 g; 8.0 mmol), and anhydrous potassium carbonate (0.47 g, 1.7 mmol) in acetone (20 mL) was stirred at room temperature for 3 days. The mixture was filtered and the filtrate concentrated *in vacuo*. The residue was taken up in chloroform and washed with water, dried (Na_2SO_4), filtered, and concentrated *in vacuo* to yield 227 mg (93%) of the title compound as an oil; ir (thin film): 1690 (C=O) cm^{-1}; nmr ($CDCl_3$): 6.5–7.0 (m, 3H), 4.2–4.6 (m, 1H), 3.8–4.2 (q, 2H), 3.75 (s, 3H), 3.4–3.8 (m, 1H), 2.2–3.2 (m, 7H), 1.0–1.9 (m, 7H); *m/e*: 289 (M^+, 37%), 154 (25%), 153 (12%), 136 (100%), 135 (24%).

Anal. calcd. for $C_{17}H_{23}NO_3 \cdot \frac{1}{2}H_2O$: C 68.43, H 8.10, N 4.69; found: C 68.08, H 8.02, N 4.57.

N-*Ethoxycarbonyl-2,5-ethano-9-methoxy-1,2,3,4,5,6-hexahydro-3-benzazocine (**14**)*

By the same procedure used for the preparation of **10**, *N*-ethoxycarbonyl-2,5-ethano-9-hydroxy-1,2,3,4,5,6-hexahydro-3-benzazocine (**13**) (1.0 g, 3.6 mmol) was converted to 1.04 g (96%) of the title compound as an oil; ir (thin film): 1690 (C=O) cm^{-1}; nmr ($CDCl_3$): 6.5−7.0 (m, 3H), 4.2−4.6 (m, 1H), 3.8−4.2 (q, 2H), 3.75 (s, 3H), 3.4−3.8 (m, 1H), 2.2−3.2 (m, 1H), 2.2−3.2 (m, 7H), 1.0−1.9 (m, 7H); *m/e*: 289 (M^+, 9%), 154 (26%), 135 (100%). *Anal.* calcd. for $C_{17}H_{23}NO_3$: C 70.56, H 8.01, N 4.84; found: C 69.97, H 8.13, N 4.68.

N-*Methyl-2,5-ethano-8-methoxy-1,2,3,4,5,6-hexahydro-3-benzazocine (**11**)*

To a solution of *N*-ethoxycarbonyl-2,5-ethano-8-methoxy-1,2,3,4,-5,6-hexahydro-3-benzazocine (**10**) (277 mg, 0.768 mmol) in 10 mL of THF was added lithium aluminum hydride (175 mg, 4.6 mmol) under a nitrogen atmosphere. The mixture was refluxed for 1 hour. After cooling to room temperature, the mixture was treated with a saturated NH_4Cl solution (2.1 mL) followed by 1 *N* $NaHCO_3$ (5.7 mL). The mixture was filtered and the salts washed with THF. The filtrate was concentrated *in vacuo*. The residue was dissolved in chloroform, dried (Na_2SO_4), filtered, and concentrated *in vacuo* to yield 200 mg (85%) of the title compound as an oil. The hydrochloride melted at 160°C; ir (KBr): 1605, 1580, 1260, 1040 cm^{-1}; nmr ($CDCl_3$): 6.5−7.1 (m, 3H), 3.8 (s, 3H), 2.5−3.4 (m, 8H), 2.4 (s, 3H), 1.1−2.0 (m, 4H); *m/e*: 231 (M^+, 14%), 96 (100%), 94 (25%).

N-*Methyl-2,5-ethano-9-methoxy-1,2,3,4,5,6-hexahydro-3-benzazocine (**15**)*

By the same procedure used for the preparation of **11**, *N*-ethoxycarbonyl-2,5-ethano-9-methoxy-1,2,3,4,5,6-hexahydro-3-benzazocine (**14**) (703 mg, 18.5 mmol) was reduced to 831 mg (90%) of the title compound as an oil. The hydrochloride melted at 255−258°C; ir (thin film): 1610, 1585, 1270, 1050 cm^{-1}; nmr ($CDCl_3$): 6.5−7.1 (m, 3H), 3.8 (s, 3H), 2.5−3.4 (m, 8H), 2.4 (s, 3H), 1.1−2.0 (m, 4H); *m/e*: 231 (M^+, 21%), 135 (11%), 96 (100%). *Anal.* calcd. for $C_{15}H_{21}NO \cdot H_2O$: C 72.25, H 9.29, N 5.61; found: C 72.19, H 8.67, N 5.78.

N-*Methyl-2,5-ethano-8-methoxy-1-oxo-1,2,3,4,5,6-hexahydro-3-benzazocine (**12**)*

To a mixture of *N*-methyl-2,5-ethano-8-methoxy-1,2,3,4,5,6-hexahydro-3-benzazocine (**11**) (200 mg, 0.86 mmol) in 5 mL of 10% H_2SO_4 was added, in one portion, a solution of chromium trioxide (135 mg, 1.35 mmol) in 5 mL of 10% H_2SO_4. The resultant mixture was heated in an oil bath at 65°C for 1 hour. The mixture was brought to room temperature and basified with NH_4OH. After diluting with THF and stirring for 5−10 minutes, the salts were filtered off and washed with THF. The THF layer was separated and concentrated *in vacuo*. The residue was dissolved in chloroform, dried (Na_2SO_4), filtered, and concentrated *in vacuo* to an oil, which was purified on a silica gel preparative plate, developing with 2% $CH_3OH/CHCl_3$ plus NH_3 vapour to yield 10 mg (5%) of the ketone (**12**): ir (thin film): 1665 (C=O), 1600, 1260 cm^{-1}; nmr ($CDCl_3$): 7.4−8.6 (d, 1H), 6.5−6.8 (m, 2H), 3.8 (s, 3H), 3.4−3.6 (d, 1H), 2.2−3.1 (m, 5H), 2.2 (s, 3H), 1.0−2.2 (m, 4H); *m/e*: 245 (M^+, 50%), 188 (58%), 96 (100%), 94 (68%).

N-*Methyl-2,5-ethano-9-methoxy-6-oxo-1,2,3,4,5,6-hexahydro-3-benzazocine (**16**)*

By the same procedure used for the preparation of **12**, *N*-methyl-2,5-ethano-9-methoxy-1,2,3,4,5,6-hexahydro-3-benzazocine (**15**) (231 mg, 1.0 mmol) was oxidized to 204 mg (83%) of the title compound as an oil. The hydrochloride melted at 233−235°C; ir (thin film): 1670 (C=O), 1260, 1050 cm^{-1}; nmr ($CDCl_3$): 7.2−7.4 (d, 1H), 6.5−6.8 (m, 2H), 3.8 (s, 3H), 2.5−3.4 (m, 6H), 2.4 (s, 3H), 1.4−2.4 (m, 4H); *m/e*: 245 (M^+, 14%), 149 (23%), 96 (100%). *Anal.* calcd. for $C_{15}H_{19}NO_2 \cdot H_2O$: C 68.41, H 8.03, N 5.31; found: C 69.22, H 7.56, N 5.65.

Equilibrium decomposition pressures of the compounds Cs_2ZrCl_6 and Cs_2HfCl_6 and X-ray identification of Na_2HfCl_6, K_2HfCl_6, and Cs_2HfCl_6

G. J. KIPOUROS[1] AND S. N. FLENGAS

Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ont., Canada M5S 1A4

Received November 9, 1982

G. J. KIPOUROS and S. N. FLENGAS. Can. J. Chem. **61**, 2183 (1983).

The chemical equilibria representing the reactions

$$Cs_2ZrCl_{6(s\text{ or }l)} = 2CsCl_{(s\text{ or }l)} + ZrCl_{4(vap,P,T)}$$

and

$$Cs_2HfCl_{6(s\text{ or }l)} = 2CsCl_{(s\text{ or }l)} + HfCl_{4(vap,P,T)}$$

were investigated by direct vapour pressure measurements and thermodynamic data such as free energies and enthalpies of reaction have been calculated. The X-ray powder patterns of the compounds Na_2HfCl_6, K_2HfCl_6, and Cs_2HfCl_6 are also reported.

With reference to the separation of Hf from Zr by a recently developed process based on the selective reactivity of $ZrCl_4$ and $HfCl_4$ vapours with alkali chlorides, it is shown that the efficiency of alkali chlorides as separating agents increases in the order CsCl → LiCl → NaCl → KCl.

G. J. KIPOUROS et S. N. FLENGAS. Can. J. Chem. **61**, 2183 (1983).

On a étudié les équilibres chimiques suivants:

$$Cs_2ZrCl_{6(s\text{ ou }l)} = 2CsCl_{(s\text{ ou }l)} + ZrCl_{4(vap,P,T)}$$

et

$$Cs_2HfCl_{6(s\text{ ou }l)} = 2CsCl_{(s\text{ ou }l)} + HfCl_{4(vap,P,T)}$$

en faisant appel aux mesures directes de pression de vapeur et aux données thermodynamiques telles que les énergies libres et les enthalpies de réaction que l'on a calculées. On rapporte également les diagrammes de poudre de rayons-X des composés suivants: Na_2HfCl_6, K_2HfCl_6 et $CsHfCl_6$.

En ce qui concerne la séparation du Hf à partir du Zr selon un procédé mis au point récemment et qui fait appel à la réactivité sélective des vapeurs de $ZrCl_4$ et de $HfCl_4$ avec les chlorures de métaux alcalins, on montre que l'efficacité des chlorures de métaux alcalins, en tant qu'agents de séparation, augmente dans l'ordre suivant: CsCl → LiCl → NaCl → KCl.

Introduction

In previous publications from this laboratory the vapour pressures of $ZrCl_4$ in equilibrium with its solutions containing alkali chlorides such as LiCl (1), NaCl (2, 3), KCl (4, 5), and CsCl (6), and of $HfCl_4$ in equilibrium with its solutions containing alkali chlorides such as LiCl (1), NaCl (3), KCl (5), and CsCl (6), have been determined by direct experimental techniques involving the use of a spoon type Bourdon gauge (2, 4), a molten tin isoteniscope (1, 6), or a quartz spiral type Bourdon gauge (3, 5).

In the present investigation, a fused silica spiral type Bourdon gauge has been applied to the determination of the vapour pressures of $ZrCl_4$ and $HfCl_4$ in equilibrium with the two pure compounds Cs_2ZrCl_6 and Cs_2HfCl_6, respectively, over a temperature range extending below and above their melting points. The compounds Na_2HfCl_6, K_2HfCl_6, and Cs_2HfCl_6 were synthesized and were identified by means of their X-ray powder diffraction patterns.

From the results of this study, the equilibrium dissociation constants, free energies, and enthalpies for the reactions

$$[1]\quad Cs_2MCl_{6(s)} \leftrightarrows 2CsCl_{(s)} + MCl_{4(vap)}$$

where M represents Zr or Hf, have been calculated.

The equilibrium constant for the exchange reaction

$$[2]\quad \underset{\text{(in solid or liquid solution)}}{Cs_2ZrCl_6} + \underset{\text{(vapour)}}{HfCl_4} \leftrightarrows \underset{\text{(in solid or liquid solution)}}{Cs_2HfCl_6} + \underset{\text{(vapour)}}{ZrCl_4}$$

was also calculated and the theoretical efficiency for the separation of hafnium from zirconium by a previously developed process based on the selective reactivity of $ZrCl_4$ and $HfCl_4$ vapours with alkali chlorides (7–9) has been calculated.

Experimental

At specific partial pressure and temperature pure $ZrCl_4$ and $HfCl_4$ vapours react with solid alkali chlorides to form the stoichiometric solid complex compounds A_2ZrCl_6 and A_2HfCl_6, respectively, where A is an alkali metal like Na, K, or Cs.

The general method applied for the preparation of the pure stoichiometric compounds was developed in this laboratory earlier (1, 2) and involves the reaction of finely ground alkali chloride, having a particle size of less than 325 mesh, with $ZrCl_4$ or $HfCl_4$ vapours at 1 atm pressure.

The $ZrCl_4$ and $HfCl_4$ salts were purchased from the Wah Chang Corporation of America, Albany, NY. As they were always received in a partially hydrolyzed condition, they were purified by repeated sublimations in vacuum through a molten tin plug, as reported earlier (1).

The alkali chlorides used in the present investigation were reagent grade containing less than 0.01% total impurities, were supplied by Cerac Inc., and were dried under vacuum, at 500°C.

Crystal structure: tetragonal a = 15.99 Å, c = 13.21 Å				Crystal structure: cubic a = 10.036 ± 0.003 Å				Crystal structure: cubic a = 10.3945 ± 0.004 Å			

Handling of materials, preparation of samples, and transfer to the reaction cells were conducted in a dry box filled with helium gas.

The apparatus for measuring the equilibrium vapour pressures of $ZrCl_4$ and $HfCl_4$ over the pure complex compounds Cs_2ZrCl_6 and Cs_2HfCl_6, respectively, consisted of a hollow fused silica Bourdon spiral pressure gauge connected to a fused silica reaction cell as has been described elsewhere (5).

For these measurements the temperature of the sample container was varied between 360 and 930°C while the upper part of the apparatus containing the Bourdon spiral was maintained at temperatures about 30°C higher than the corresponding normal sublimation points of pure $ZrCl_4$ and $HfCl_4$.

The Cs_2ZrCl_6 or Cs_2HfCl_6 compounds were introduced into the sample container of the apparatus in the form of powders. It was found that large quantities of absorbed gas were released from the salt upon heating. This introduced a systematic error into the measurements. Accordingly, an elaborate degassing procedure was employed in which the cell was repeatedly heated, cooled, reopened, and evacuated. When the residual gas was no longer present upon cooling, equilibrium vapour pressures were measured.

Experimental results

(a) X-ray diffraction powder patterns

The X-ray powder patterns of the compounds Na_2HfCl_6, K_2HfCl_6, and Cs_2HfCl_6 were obtained with a Debye-Scherrer 114.8 mm camera, exposed for various periods of time (1 to 12 h) to CuK_α radiation (λ = 1.5418 Å) filtered through nickel. The diffractometer powder method was also used.

The specimens which were the stoichiometric compounds were ground and screened to −200 mesh in a dry box filled with argon. Then they were hermetically sealed in 0.3 mm silica glass capillaries.

Radiated Cs_2HfCl_6 produced the diffraction pattern shown in Table 1. The results of this work are in agreement with earlier work by Barskaya and Toptygina (10) who prepared their sample by precipitation using hafnium oxychloride as starting material. The extra lines reported by these authors are due to the use of unfiltered radiation.

The X-ray diffraction patterns for the compounds Na_2HfCl_6 and K_2HfCl_6 obtained in this laboratory are also given in Table 1. This study was the first to identify these compounds and no comparison can be made with existing data.

Tentative crystal structures of the hexachlorohafnate compounds were also determined. Although the data in Table 1 are those of polycrystalline samples, it was possible to test whether the structures were cubic, tetragonal, or hexagonal by means of nomographs (11).

Indexed powder X-ray diffraction patterns for the compounds Na_2HfCl_6, K_2HfCl_6, and Cs_2HfCl_6 are given in Table 1, and include the calculated values.

Good agreement with the measured pattern of Na_2HfCl_6 was obtained by assuming this compound to have a tetragonal structure, having a = 15.99 Å and c = 13.21 Å. Table 1 compares the data with the spectrum of the proposed structure.

As seen in Table 1, the measured powder pattern of K_2HfCl_6 and that generated on the assumption that the crystal structure is cubic with a cell dimension having a = 10.036 Å are in good agreement.

The measured powder pattern of Cs_2HfCl_6 is compared with that generated on the assumption that its crystal structure is cubic with a cell dimension a = 10.395 Å. The agreement between observed and calculated d-spacings is excellent. A cubic structure has also been assumed in an earlier investigation (10).

(b) Determination of equilibrium vapour pressures

The vapour pressures of $ZrCl_4$ and $HfCl_4$, in equilibrium with the pure compounds Cs_2ZrCl_6 and Cs_2HfCl_6 respectively, were determined and are given in Table 2. In Fig. 1 these data are plotted as $\ln P_{MCl_4}$ vs. $1/T$. The lines shown on the graphs are calculated by the least-squares method, while the points are experimental.

Some experimental points for the equilibrium decomposition

*Pressures were measured in mm Hg, and corrections were made for mercury expansion and for gravity effects (12, 13) to convert to standard conditions, i.e. at 273.15 K and an acceleration of free fall of 9.80665 m/s^2. Pressures given in mm Hg may be converted to bars by multiplying by the factor 1.333×10^{-3}. Temperatures reported in this table are based on the IPTS-68 (14).

pressures of Cs_2ZrCl_6 and Cs_2HfCl_6 obtained previously in the laboratory (6) using a molten tin isoteniscope are also shown in Fig. 1 and are in good agreement with the present work for the Cs_2ZrCl_6 compound. These previous data were obtained only at higher temperatures near the melting temperature of Cs_2ZrCl_6 as at lower temperatures the measurements became unreliable due to gases absorbed by the sample. The previous vapour pressure data over Cs_2HfCl_6 are substantially higher than those obtained in the present study and they become even higher as the temperature increases, due to the evolution of the residual gas which probably had remained in the system.

As was pointed out above, the spiral type gauge used in the present work can withstand large pressure gradients and sudden decompression and is well suited for extensive degassing procedures, thus making possible accurate measurements at low pressures.

Also shown in Fig. 1 are equilibrium pressures reported by Morozov and Sun-In-Chzu (15), which are in disagreement with the values measured in the present study. Transportation techniques have been employed by these authors and no mention was made of the problem of depleting $ZrCl_4$ or $HfCl_4$ from the condensed Cs_2ZrCl_6 and Cs_2HfCl_6 phases during the course of an experiment. The quantitative determination of transported $ZrCl_4$ and $HfCl_4$ was done colorimetrically and by flame photometry.

The corresponding equations for the temperature dependence of the equilibrium pressures within the characteristic temperature ranges were calculated and are given in Table 3.

Reaction [1] in Table 3 defines the equilibrium pressure of $ZrCl_4$ over pure solid Cs_2ZrCl_6 and solid CsCl at temperatures lower than the eutectic temperature shown in Fig. 1.

Reaction [2] in Table 3 represents the equilibrium pressure of $ZrCl_4$ over pure solid Cs_2ZrCl_6 at temperatures higher than the eutectic temperature and in the presence of a solution of CsCl and Cs_2ZrCl_6 of liquidus composition, as given by the phase diagram (6). Due to the temperature dependence of the activity of CsCl in this region, the $\ln P_{ZrCl_4}$ vs. $1/T$ plot exhibits the curvature shown.

Reaction [3] in Table 3 represents the equilibrium pressure of $ZrCl_4$ over pure molten Cs_2ZrCl_6 at temperatures higher than its melting point.

Similar considerations apply to reactions [4], [5], and [6] for Cs_2HfCl_6 given in Table 3. It should be noted that the non-linear and upper linear portions of the pressure curves for Cs_2ZrCl_6 and Cs_2HfCl_6 in Fig. 1 intercept at temperatures which are in agreement with the corresponding melting points of the compounds.

Discussion

The alkali metal hexachlorozirconates and hexachlorohafnates represent stable compounds in which the activities of the corresponding tetrachlorides are particularly low. This is manifested by the dramatic reduction in the pressures of MCl_4 over the pure A_2MCl_6 compounds, shown in Fig. 2 which represents the temperature dependence of the partial pressure of $ZrCl_4$ and $HfCl_4$ in equilibrium with alkali hexachlorozirconates and hexachlorohafnates. As shown in Fig. 2 the vapour pressure of pure $ZrCl_4$, at 450°C, is about 25 atm (16) as compared to the partial pressure of $ZrCl_4$ of 0.01 atm over the pure Cs_2ZrCl_6 at 450°C.

The thermodynamic stability of the A_2MCl_6 compounds, where A represents an alkali metal and M represents Zr or Hf, may be related to the size of the alkali cation A^+. In Fig. 2 the decomposition temperature of the alkali metal hexachlorozirconate and hexachlorohafnate compounds, which is defined as the temperature at which the partial vapour pressure of MCl_4 over the pure A_2MCl_6 compound becomes 1 atm, increases as in the sequence $Li_2MCl_6 \rightarrow Na_2MCl_6 \rightarrow K_2MCl_6 \rightarrow Cs_2MCl_6$, i.e. as the size of the alkali metal cation increases.

Thermodynamic data for the decomposition of the compounds Cs_2ZrCl_6 and Cs_2HfCl_6 may be obtained from the following considerations.

Below the corresponding eutectic temperatures of the pseudobinary systems $CsCl-Cs_2ZrCl_6$ and $CsCl-Cs_2HfCl_6$ respectively, the thermal decomposition of the chlorozirconate and chlorohafnate complex compounds are described by the reactions:

[3] $Cs_2ZrCl_{6(s)} = 2CsCl_{(s)} + ZrCl_{4(vap)}$

[4] $Cs_2HfCl_{6(s)} = 2CsCl_{(s)} + HfCl_{4(vap)}$

By choosing the standard states for the condensed phases as

		A	B	Corr. coeff. $\hat{r}$	Std. error $\hat{s}$
[1] $Cs_2ZrCl_{6(s)} = 2CsCl_{(s)} + ZrCl_{4(v)}$	625–862	−2.752	−1 392	0.9927	0.0217
[2] $Cs_2ZrCl_{6(s)} = \underline{2CsCl}_{(l)} + ZrCl_{4(v)}$	862–1083		Non-linear		
[3] $\underline{Cs_2ZrCl_6}_{(l)} = \underline{2CsCl}_{(l)} + ZrCl_{4(v)}$	1083–1200	10.726	−13 788	0.9996	0.0126
[4] $Cs_2HfCl_{6(s)} = 2CsCl_{(s)} + HfCl_{4(v)}$	645–864	−2.781	−1 536	0.9984	0.0604
[5] $Cs_2HfCl_{6(s)} = \underline{2CsCl}_{(l)} + HfCl_{4(v)}$	864–1100		Non-linear		
[6] $\underline{Cs_2HfCl_6}_{(l)} = \underline{2CsCl}_{(l)} + HfCl_{4(v)}$	1100–1177	13.974	−17 790	0.9840	0.0626

the pure solids at all temperatures and for the vapour phase, the pure vapour at 1 atm, the thermodynamic equilibrium constants for the decomposition reactions [3] and [4] can be written as:

$$[5] \quad K = P_{ZrCl_{4(vap)}}$$

$$[6] \quad K = P_{HfCl_{4(vap)}}$$

Actual pressures have been used in these equations, instead of fugacities, as the zirconium tetrachloride vapour is known to be unimolecular and ideal (17, 18), and hafnium tetrachloride vapour would be expected to be quite similar.

The standard heat ΔH_R^0 for the decomposition reactions may be obtained from the van't Hoff equation, written as:

$$[7] \quad \mathrm{d} \ln K/\mathrm{d}T = -\Delta H_R^0/RT^2$$

while the standard free energy and the average standard entropy can be determined from the well known equations

$$[8] \quad \Delta G_R^0 = -RT \ln K$$

$$[9] \quad \Delta G_R^0 = \Delta H_R^0 - T\Delta S_R^0$$

The results of these calculations for pure Cs_2ZrCl_6 and Cs_2HfCl_6 are given in Table 4, including the thermodynamic values for the decomposition of the other pure alkali hexachlorozirconate and hexachlorohafnate compounds (19). From these data the equilibrium constant of the exchange reaction:

$$[10] \quad \underset{(vap)}{HfCl_4} + \underset{\text{(as a solid solution of } Cs_2ZrCl_6 \text{ in } Cs_2HfCl_6)}{Cs_2ZrCl_6} = \underset{(vap)}{ZrCl_4} + \underset{\text{(as a solid solution of } Cs_2HfCl_6 \text{ in } Cs_2ZrCl_6)}{Cs_2HfCl_6}$$

is calculated as

$$[11] \quad K_{ex} = \left(\frac{P_{ZrCl_4}}{P_{HfCl_4}}\right)_{vap} \left(\frac{X_{Cs_2HfCl_6}}{X_{Cs_2ZrCl_6}}\right)_{\text{in solid solution}}$$

In this equation, mole fractions (X's) have been substituted for activities, because of the suggested ideal behaviour of the solid solutions (19).

Since [10] was derived by subtracting [3] from [4] given in Table 3, the temperature dependence of the equilibrium constant given by [11] may be calculated by combining [5] and [6] as:

$$[12] \quad \ln K_{ex} = 0.029 + 144/T$$

A plot of K_{ex} vs. T (in °C) is shown in Fig. 3. Data for the previously investigated systems employing LiCl (1), NaCl (3),

and KCl (5) are also included in this figure for comparison purposes.

It has been shown in a previous publication (8) that impure $ZrCl_4$ containing $HfCl_4$ may be purified in a closed two-compartment reaction cell in which the impure $Zr(Hf)Cl_4$ mixture is placed in the first compartment, which is kept at a temperature T_1, while the alkali chloride ACl is placed in the second compartment which is kept at a temperature T_2.

The separation proceeds through the formation of the complex compounds A_2ZrCl_6 and A_2HfCl_6 which appear in the second compartment as a solid solution. The efficiency of the separation process depends upon the magnitude of the equilibrium constant for the exchange reaction [10].

The efficiency of separation η defined as:

$$[13]\quad \eta = \frac{(\text{wt\% } HfCl_4)_{initial} - (\text{wt\% } HfCl_4)_{final}}{(\text{wt\% } HfCl_4)_{initial}} \times 100$$

may be calculated from the previously derived relationship (8)

$$[14]\quad K_{ex} = \frac{2(X'_{ZrCl_4})a - b + 2Z}{2(X'_{HfCl_4})a - 2Z}\left(\frac{P^0_{ZrCl_4}}{P^0_{HfCl_4}}\right)_{T_1}\frac{2Z}{b - 2Z}$$

where X'_{ZrCl_4} and X'_{HfCl_4} are the mole fractions of $ZrCl_4$ and $HfCl_4$ respectively in the $Zr(Hf)Cl_4$ mixture initially present in the first compartment of the separation cell prior to reaction; a represents the total number of moles of $Zr(Hf)Cl_4$ present in the first compartment of the reactor, prior to separation; b represents the number of moles of ACl present in the second compartment of the reactor; Z is the number of moles of $HfCl_4$

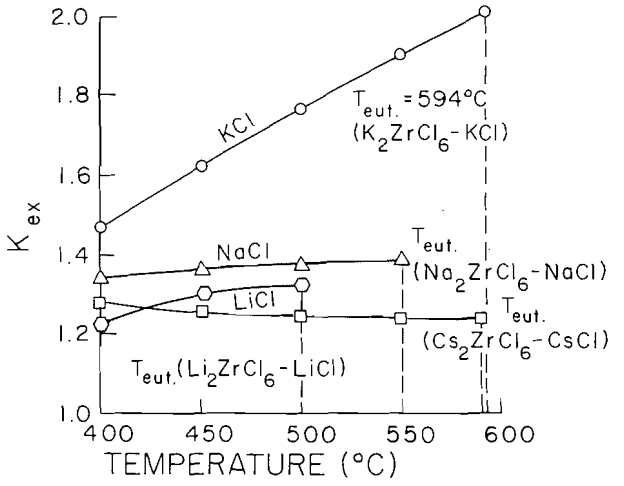

FIG. 3. Temperature dependence of the equilibrium constants K_{ex} for the exchange reactions:

$$HfCl_{4(v)} + A_2ZrCl_{6(sol.solution)} \leftrightarrows A_2HfCl_{6(sol.solution)} + ZrCl_{4(v)}$$

where A = Li^+, Na^+, K^+, or Cs^+.

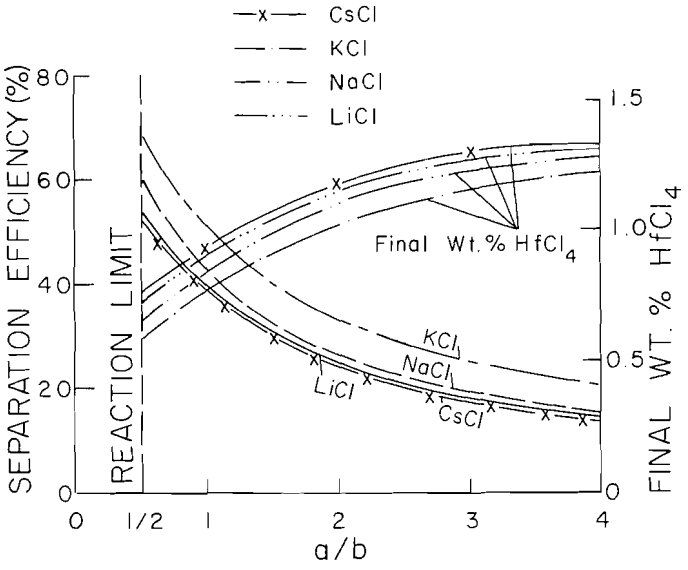

FIG. 4. Variation of the separation efficiency and of the final wt% $HfCl_4$ with the molar ratio a/b of Zr(Hf)Cl_4 to ACl, for a Zr(Hf)Cl_4 mixture initially containing 1.54 wt% $HFCl_4$. T_1 and T_2 are respectively 330 and 450°C.

which have reacted with ACl and are retained in the second compartment of the reactor after equilibrium has been reached; $P^0_{ZrCl_4}$ and $P^0_{HfCl_4}$ are the sublimation pressures (16) of pure $ZrCl_4$ and $HfCl_4$ respectively, at temperature T_1.

Considering a reactor containing CsCl and T_1 and T_2 temperatures of 330 and 450°C respectively, the separation efficiency factor η may be calculated from the determined values of K_{ex} and for various ratios of a/b.

Figure 4 illustrates the variation of η with the a/b ratio for LiCl, NaCl, KCl, or CsCl. As is seen, η increases as the a/b ratio decreases. Hence the separation becomes more efficient when the amount of Zr(Hf)Cl_4 mixture placed in compartment I is close to that required by the stoichiometry for the formation of Cs_2ZrCl_6 and Cs_2HfCl_6. The reaction limit is reached at a/b = 0.5, at which point all the added tetrachloride vapours react with the CsCl. On the other hand, as the a/b ratio approaches the value of 0.5, most of the Zr(Hf)Cl_4 is present as a Cs_2ZrCl_6–Cs_2HfCl_6 solid solution in compartment II. Hence for practical purposes, the a/b ratio must be larger than 0.5, and a value of about 0.8 to 1.0 appears optimum. At a/b = 0.8 the calculated separation efficiency is about 40%.

By comparing LiCl, NaCl, KCl, and CsCl as separating agents for Hf, it is evident that at 450°C the separation efficiency increases in the order CsCl → LiCl → NaCl → KCl.

In a recent publication from this laboratory (9) the separation of Hf from Zr has been described using a liquid alkali chloride or mixtures of alkali chlorides as separating agents. When liquid CsCl is used the exchange reaction may be written as:

[15] $HfCl_4$ (vap) + Cs_2ZrCl_6 (as a liquid solution of Cs_2ZrCl_6 in Cs_2HfCl_6) = $ZrCl_4$ (vap) + Cs_2HfCl_6 (as a liquid solution of Cs_2HfCl_6 in Cs_2ZrCl_6)

the equilibrium constant of which may also be approximated to that given by [12].

C. A. PICKLES, G. J. KIPOUROS, S. N. FLENGAS, and R. G. V. HANCOCK. Can. J. Chem. **61**, 2189 (1983).

A procedure for the determination of Hf in both mixtures of $HfCl_4-ZrCl_4$ and $A_2HfCl_6-A_2ZrCl_6$, where A = Li, Na, K, Rb, or Cs, is described. The method involves conversion of the chlorocompounds into HfO_2-ZrO_2 mixtures and subsequent analysis by either X-ray fluorescence or neutron activation analysis. The two analytical techniques are compared with regard to accuracy and simplicity.

C. A. PICKLES, G. J. KIPOUROS, S. N. FLENGAS et R. G. V. HANCOCK. Can. J. Chem. **61**, 2189 (1983).

On décrit une méthode de détermination du HF dans les mélanges de $HfCl_4-ZrCl_4$ et de $A_2HfCl_6-A_2ZrCl_6$, ou A = Li, Na, K, Rb ou Cs. La méthode fait intervenir la transformation des composés chlorés en des mélanges de HfO_2-ZrO_2 suivie d'une analyse par fluorescence de rayons-X ou d'une analyse par activation neutronique. On a comparé ces deux techniques d'analyse dans le but de déterminer la technique la plus précise et la plus simple.

[Traduit par le journal]

Introduction

Hafnium and zirconium have almost identical chemical properties and therefore separation of the two elements is both difficult and expensive. At the present time hafnium is separated from zirconium by solvent extraction (1, 2). This process has certain disadvantages and therefore a number of alternative processes have been proposed, which include fractional crystallization (3), ion exchange (4), and fractional distillation (5). It is also possible to separate hafnium from zirconium by the selective reaction of $HfCl_4-ZrCl_4$ vapour mixtures with either solid or molten alkali chlorides (ACl where A = Li, Na, K, Rb, or Cs) (6, 7). In order to determine the separation efficiency of the process, a method was devised for determining the concentration of hafnium in both mixtures of $HfCl_4-ZrCl_4$ and in mixtures of A_2HfCl_6 and A_2ZrCl_6, where the hafnium concentration ranged from 0.1 to 3.9 wt.% $HfCl_4$ in the $HfCl_4-ZrCl_4$ mixtures. Quantitative chemical analysis of hafnium–zirconium systems is impossible by standard chemical methods. X-ray fluorescence has been employed successfully under carefully controlled conditions for analysis of mixtures of zirconium and hafnium oxides in the concentration range from 0.5 to 99.5 wt.% hafnium (8). This technique suffers from both matrix effects and a strong dependence on the sample preparation method. To avoid these potential problems neutron activation analysis was employed and compared with the X-ray fluorescence technique.

Sample preparation

Because the chlorocompounds of zirconium and hafnium hydrolyse readily it is necessary to convert them to a stable form which in this case is the respective oxide. The synthetic standards were prepared by weighing the appropriate amounts of spectrographic grade $ZrCl_4$ and $HfCl_4$ containing less than 100 ppm $HfCl_4$ and $HgCl_4$ in a dry box. Then the sample was dissolved in distilled water and the HfO_2-ZrO_2 mixture was precipitated by the addition of ammonium hydroxide. The oxide was filtered, dried, and fired at 1000°C in a platinum crucible for 12 h. This method results in mixtures which are more homogeneous than those obtained by the mechanical mixing of the oxides.

X-ray powder diffraction patterns were employed to verify that the hydrolysis of the chlorides to the oxides was complete, and the results confirmed that $HfCl_4$ and $ZrCl_4$ were completely converted to the respective oxides. Furthermore, to confirm that the hydrolysis of A_2MCl_6 proceeded according to the reaction:

$$[1] \quad 2A_2MCl_6 + H_2O \rightarrow 2MO_2 + 8HCl + 4ACl$$

the filtrate, which contained dissolved ACl, was evaporated to dryness. The X-ray powder pattern of the dried filtrate corresponded to that of ACl in each case.

Results

Neutron activation analysis

Powdered samples, weighing approximately 300 mg, were placed in polyethylene vials. They were irradiated in the SLOWPOKE nuclear reactor in a neutron flux of 1.0×10^{11} n/cm^2 s for 10 s. The hafnium isotope measured was ^{179m}Hf with a γ-ray energy of 214.3 keV and a half-life of 19.0 s. After a decay time of about 180 s, the irradiated samples were counted for 20 s. Thus, the total cycle time for a single analysis was less than 1 min. Measurements of γ-ray activities were made with a Canberra Ge–(Li) detector coupled to a Canberra 8180 series 4096 channel analyzer. The detector had a nominal relative counting efficiency of 6.7% and FWHM resolution of 1.9 keV for the 1332 keV γ-ray of ^{60}Co. It is mounted horizontally in a model 7600 cryostat. γ-Ray peak intensities were evaluated by automatic analyzer integration of suitable manually selected spectral regions of interest at each peak. The teletype output integrals were then processed using a Texas Instrument TI-55 calculator to determine elemental concentrations.

Whenever a set of samples was analyzed, a standard was also irradiated. The hafnium measurements of the standards were best represented by a least-square line. Thus, the elemental hafnium content of a sample was determined by comparison with the standard line.

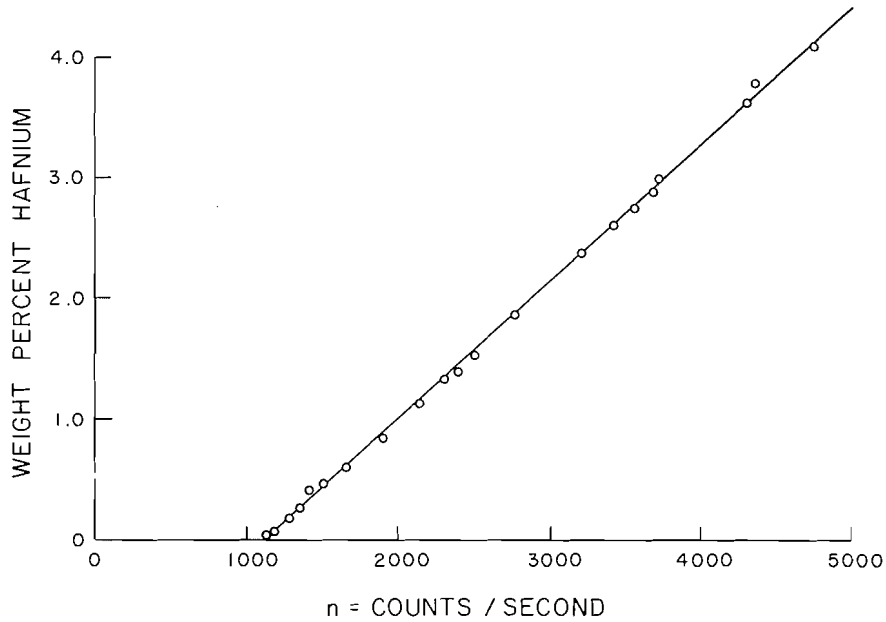

FIG. 1. Calibration curve for hafnium contents in the range 0 to 4 wt.% by neutron activation analysis.

Typical results are as follows:
In the range $0 < \text{wt.\% Hf} < 4$

$$[2] \quad \text{wt.\% Hf} = 2.63 \times 10^{-5}\, n - 1.62 \times 10^{-1}$$

where n is the number of counts per s. The correlation coefficient was $r = 0.9986 \pm 0.0018$ to within 95% certainty and the standard error of estimate was $S_{y.x} = 1.22$. The results of the analyses and the least-square line are shown in Fig. 1.

The corresponding amount of HfO_2 present in the sample was then calculated, and the difference between this and the total mass of the sample was presumed to be the mass of ZrO_2. From this value the mass of elemental zirconium was calculated. The zirconium concentration was reported as wt.% zirconium in the ZrO_2-HfO_2 mixture. The hafnium concentration had an absolute error estimate of less than 0.1 wt.% for hafnium contents of less than 4%. The lower limit of detection by this method using samples such as those described herein was determined to be about 100 ppm of hafnium in ZrO_2 (10).

This method is accurate provided that the sample consists of only HfO_2-ZrO_2. In order to check the analysis, the entire γ spectrum of each sample was examined to detect the presence of any other metals. In samples prepared from the tetrachloride mixtures only zirconium and hafnium were found. However, samples prepared from $A_2ZrCl_6-A_2HfCl_6$ mixtures contained small but measurable amounts of alkali metals. The concentration of these metals was less than 5% of the total mass of the sample. Since the chlorine content was below the lower limit of detection (about 50 μg) it was concluded that the alkali metal was not present as a chloride. Therefore it was assumed that the alkali metal was present as oxide, A_2O, and the appropriate small correction was made to the zirconium concentration. Table 1 gives the isotope which was measured for each element.

X-ray fluorescence analysis

A weighed amount (1 g) of the prepared standard was ground to minus 325 mesh, mixed with 1/2 g of methylcellulose and pressed to form tablets.

The hafnium line L_{β_2} at $2\theta = 38.47°$, was resolved from the zirconium second order K_{β_1} line at $2\theta = 40.14°$ and the counts over 40 s were measured in a SIEMENS SRI spectrometer with a tungsten target and a lithium fluoride (200) diffracting crystal. The counts over 40 s were also measured at an angle at which there was no peak present and the intensity was found to be independent of the hafnium content. This angle was found at 35°.

TABLE 1. Nuclear data for sample analysis (9)

Element	Isotope measured	Half-life	γ-Ray (keV)
Hf	^{179m}Hf	19.0 s	214.3
Na	^{24}Na	15 h	1368.4
K	^{42}K	12.52 h	1524.7
Rb	^{80m}Rb	1.02 min	2118.6
Cs	^{134m}Cs	3.15 h	127.4
Cl	^{38}Cl	37.29 min	1642.0

The hafnium measurement on the standards was best represented by a least-square line and the elemental hafnium content of the sample was determined by comparison with the standard line.
In the range $0 < \text{wt.\% Hf} < 4$

$$[3] \quad \text{wt.\% Hf} = 1.14 \times 10^{-3}\, n - 1.28$$

where n is the number of counts per s. The correlation coefficient was $r = 0.9955 \pm 0.0006$ to within 95% certainty and the standard error of estimate was $S_{y.x} = 1.32$. The results of the analyses and the least-square line are shown in Fig. 2. Again the absolute error estimate was less than 0.1 wt.% and the detection limit was about 100 ppm.

From a comparison of the correlation coefficients and the standard errors of estimate for both neutron activation and X-ray fluorescence, it is clear that the accuracy of the methods is similar for hafnium contents in the composition range up to 4 wt.%. However, the neutron activation technique requires less sample preparation and the cycle time is reduced, and for the same accuracy it should be considered as superior to the X-ray fluorescence technique.

Bis(diethylammonium) hexachlorostannate(IV), $(Et_2NH_2)_2SnCl_6$, and tris-(di-*n*-propylammonium) hexachlorostannate(IV) chloride, $(n\text{-}Pr_2NH_2)_3(SnCl_6)Cl$: crystal structure and hydrogen bonding[1]

Received March 1, 1983

T. STANLEY CAMERON, MARGARET ANN JAMES, OSVALD KNOP, and MICHAEL FALK. Can. J. Chem. **61**, 2192 (1983).

The crystal structure of $(Et_2NH_2)_2SnCl_6$ ($P2_1/n$, $Z = 2$, $a = 9.078(1)$ Å, $b = 10.644(2)$ Å, $c = 9.801(2)$ Å, $\beta = 93.02(1)°$) consists of a monoclinically distorted antifluorite arrangement of $Et_2NH_2^+$ and $SnCl_6^{2-}$ ions. The $SnCl_6$ octahedra are linked by hydrogen bonds to form infinite chains separated from one another by the Et groups. The temperature variation of the spectral features in the NH and ND stretching regions points to the existence of a transition in the vicinity of 320 K. The structure of $(n\text{-}Pr_2NH_2)_3(SnCl_6)Cl$ ($P2_1/c$, $Z = 4$, $a = 10.265(4)$ Å, $b = 30.428(4)$ Å, $c = 10.380(2)$ Å, $\beta = 92.75(3)°$) consists of $n\text{-}Pr_2NH_2^+$ cations of three types, $SnCl_6^{2-}$, and Cl^-. All the ions are interconnected by hydrogen bonds, those to Cl^- being of a strength comparable to the strength of the short, linear N—H···Cl^- bond in Et_3NHCl. Spectroscopic evidence indicates the probable existence of a transition at ~170 K.

T. STANLEY CAMERON, MARGARET ANN JAMES, OSVALD KNOP et MICHAEL FALK. Can. J. Chem. **61**, 2192 (1983).

Le composé $(Et_2NH_2)_2SnCl_6$ cristallin représente une variété monocline ($P2_1/n$, $Z = 2$, $a = 9{,}078(1)$ Å, $b = 10{,}644(2)$ Å, $c = 9{,}801(2)$ Å, $\beta = 93{,}02(1)°$) de la structure antifluorine déformée comportant les ions $Et_2NH_2^+$ et $SnCl_6^{2-}$. Les octaèdres $SnCl_6$ sont reliés par des liaisons hydrogène; les chaînes infinies qui en résultent sont séparées l'une de l'autre par des groupes éthyle. Les variations thermiques des caractéristiques spectrales, dans les régions d'élongation du NH et du ND, indiquent une transition à environ 320 K. La structure cristalline du $(n\text{-}Pr_2NH_2)_3(SnCl_6)Cl$ ($P2_1/c$, $Z = 4$, $a = 10{,}265(4)$ Å, $b = 30{,}428(4)$ Å, $c = 10{,}380(2)$ Å, $\beta = 92{,}75(3)°$) comprend des cations $n\text{-}Pr_2NH_2^+$ de trois types et des anions $SnCl_6^{2-}$ ainsi que Cl^-. Tous les ions sont reliés par des liaisons hydrogène. La force de la liaison hydrogène dans le cas de l'ion Cl^- s'approche de celle de la courte liaison rectiligne N—H···Cl^- du Et_3NHCl. Les preuves spectroscopiques indiquent l'existence probable d'une transition à 170 K environ.

In previous papers (1, 2) we dealt at some length with the structural and hydrogen-bonding aspects of a number of alkylammonium hexachlorostannates(IV), $(R_nNH_{4-n})_2SnCl_6$. Among the ir spectra described in ref. 2 were those of $(Et_2NH_2)_2SnCl_6$ (2EHS) and $(n\text{-}Pr_2NH_2)_3(SnCl_6)Cl$ (2PHS.PCl) (the last-named compound having been initially taken for $(n\text{-}Pr_2NH_2)_2SnCl_6$ = 2PHS), but in the absence of crystal-structure determinations of the two compounds the interpretation of the spectra was largely tentative.

The crystal structures of these two salts have now been determined and are described below, together with additional information on the NH and ND stretching regions of the ir spectra. Details of the preparation and crystal-structure determination are given in ref. 2 and will not be repeated here. The crystal data of both compounds are presented in Table 1.

$(Et_2NH_2)_2SnCl_6$

From optical measurements Ries (3) concluded that the point-group symmetry of 2EHS was C_{2h} (the same as that of the corresponding hexachloroplatinate, ref. 4). This agrees with our observation. With the N—H and C—H bond lengths constrained to 1.02 and 1.08 Å, respectively, the structure was refined anisotropically (except for the isotropic temperature factors on the hydrogens) to $R = 0.030$. The positional parameters are listed in Table 2, the thermal parameters in Table 3,[2]

†Constrained in refinement.

the structure factors in Table 4,[2] and interatomic distances and bond angles in Table 5.

The cation/anion packing in 2EHS is yet another example of the antifluorite arrangement, monoclinically distorted (cf. refs. 2 and 5) (Fig. 1). The centrosymmetric $SnCl_6$ octahedra are practically regular, the mean of d(Sn—Cl) being 2.427(8) Å. This is statistically indistinguishable from the mean for $(R_nNH_{4-n})_2SnCl_6$, 2.425(12) Å (2). There is only one type of NH_2 group in the structure. One of the N-hydrogens, H(12), participates in a slightly asymmetrically bifurcated N—H···2Cl bond, with H···Cl distances of ~2.45 and ~2.63 Å and NHCl angles of 145° and 129°, respectively.[3] The other hydrogen, H(11), forms a slightly bent N—H···Cl bond, H···Cl ~ 2.33 Å, NHCl ~ 170° (Fig. 2).

As would be expected for an $(R_2NH_2)_2SnCl_6$ structure containing small alkyls (cf. ref. 2), the hydrogen bonds join the $SnCl_6$ octahedra so as to form infinite chains separated from one another by the Et groups (Fig. 1). 2EHS is thus similar to the corresponding Me salt, 2MHS. However, both salts undergo thermally induced transitions, 2MHS at ~100 K (2) and 2EHS to all appearances at ~320 K (*vide infra*), i.e. at room temperature 2MHS is above but 2EHS below T_{tr}. This difference is reflected in the two room-temperature structures. High-temperature polymorphs generally have higher symmetries than the corresponding low-temperature forms. Indeed, the $Me_2NH_2^+$ ion in 2MHS has C_s symmetry at room temperature, with the two N—H bonds equivalent, but this equivalence is destroyed by cooling through T_{tr} (2). This would suggest that the N—H(11) and N—H(12) bonds, which are dissimilar in the room-temperature structure of 2EHS, become equivalent on heating through T_{tr}, so that the 2EHS structure would then resemble even more closely the room-temperature structure of 2MHS.

Features of the ir spectra in the NH and ND stretching regions and their temperature dependence have already been described (2). Their interpretation is now supported by the knowledge of the crystal structure. The nonequivalent N—H(11) and N—H(12) bonds would be expected to give rise to 1:1 NH and ND stretching doublets, and this is what is observed at all temperatures below 293 K (Fig. 21 of ref. 2).

[3]The N—H(12)···Cl(1),Cl(2) grouping is close to planar.

*All values for nonhydrogen atoms have been multiplied by 10^4 and those for hydrogens by 10^3.

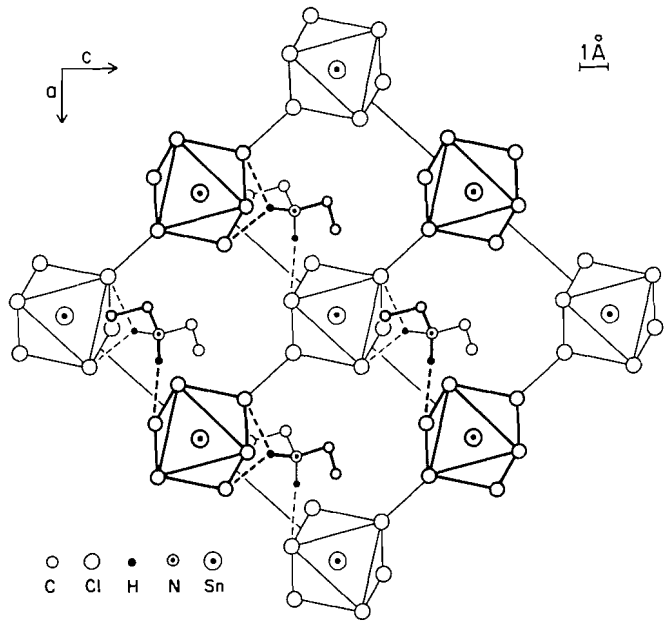

FIG. 1. Projection of the 2EHS structure on (010) displaying the antifluorite-type cation/anion packing. Only one half of the unit cell is shown; the other half is obtained by inversion in a centre of symmetry in one of the Sn atoms. The ethyl hydrogens have been omitted.

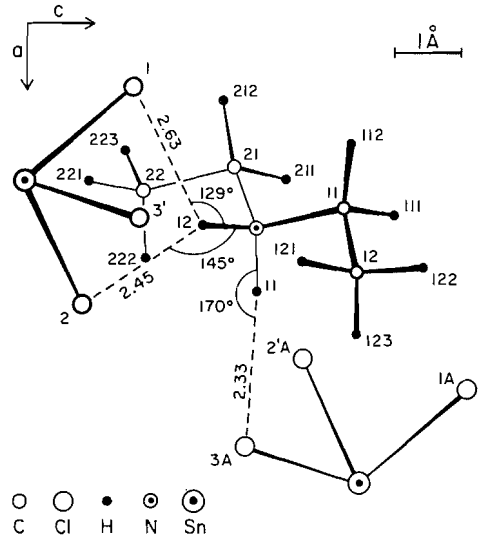

FIG. 2. Hydrogen bonding in 2EHS. Projection on (010). The distances are in Å. For additional interatomic distances, bond angles, and symmetry code, see Table 5.

Attention is drawn to the temperature dependence of the ν(NH) and ν(ND) doublets (Fig. 20 of ref. 2) which indicates the existence of a thermal collapse of the two components of each doublet somewhere in the vicinity of 320 K, pointing to a structural transition. From the similarity with 2MHS and a number of complex NH_4 halides (6, 7) the high-frequency branch of the ν vs. T plot can be expected to have its continuation in a single ν vs. T line above T_{tr}, while the lower-frequency branch increasingly approaches the high-frequency branch and disappears at T_{tr}. Furthermore, the temperature coefficient of the upper branch is negative and that of the lower branch positive. This behaviour indicates that the high-frequency component, which corresponds to a weaker hydrogen bond, originates in a highly bent N—H···Cl bond (8) and the lower-frequency component in a stronger, more normal hydrogen bond. The hydrogen-bonding geometry (Fig. 2) is in agreement with the spectroscopic evidence. The bifurcated bond, although involving longer H···Cl distances and small NHCl angles, 145° and 129°, is not appreciably weaker than the normal bond, as indicated by the doublet splitting of only 29 cm^{-1} for ν(NH) and 12 cm^{-1} for ν(ND) at 10 K.

Since the quality of the probe-ion spectra deteriorated rapidly as the sample temperature approached 293 K, attempts to obtain usable spectra in the vicinity of the expected T_{tr} seemed unpromising and no effort was made to extend the investigation of 2EHS above room temperature. A direct demonstration of the transition will have to rely on another method.

(n-Pr_2NH_2)$_3$($SnCl_6$)Cl

As reported in ref. 2, preparations intended to yield 2PHS

have resulted in 2PHS.PCl instead. This mixed-anion salt does not properly belong to the hexachlorostannate(IV) series investigated in refs. 1 and 2, but its crystal structure was determined regardless of this, partly to account for the unexpected features of the ir spectrum in the region of NH and ND stretching absorptions (cf. ref. 2) and partly because it was considered opportune to augment the meager inventory of known structures of this type $((NH_4)_3(SiF_6)F$ (9), $K_3(SiF_6)F$ (10), and the thermochromic $[(NH_3CH_2CH_2)_2NH_2](CuCl_4)Cl$ (11)).

With the N—H and C—H bond lengths constrained to 1.02 and 1.08 Å, respectively, the structure was refined isotropically (except for the anisotropic Sn and Cl) to $R = 0.044$. The positional parameters are listed in Table 6, those of the alkyl hydrogens in Table 7,[2] the thermal parameters in Table 8,[2] and the structure factors in Table 9.[2]

The structure consists of $SnCl_6^{2-}$ and Cl^- anions and of $n\text{-}Pr_2NH_2^+$ cations of three types (Fig. 3). All the H_N atoms

engage in hydrogen bonding: H(21) and H(31) exclusively to Cl^-; H(11), H(12), and H(22) exclusively to Cl_{Sn}; and H(32) to one Cl^- and one Cl_{Sn} (Table 10, Figs. 4–6). The H(21)···Cl^- and H(31)···Cl^- distances are quite short and correspond to almost straight N—H···Cl bonds. All the other hydrogen bonds are bifurcated, although N(1)—H(12)···Cl(6A") is only marginally so, the H(12)···Cl(5B) distance being 3.09 Å and

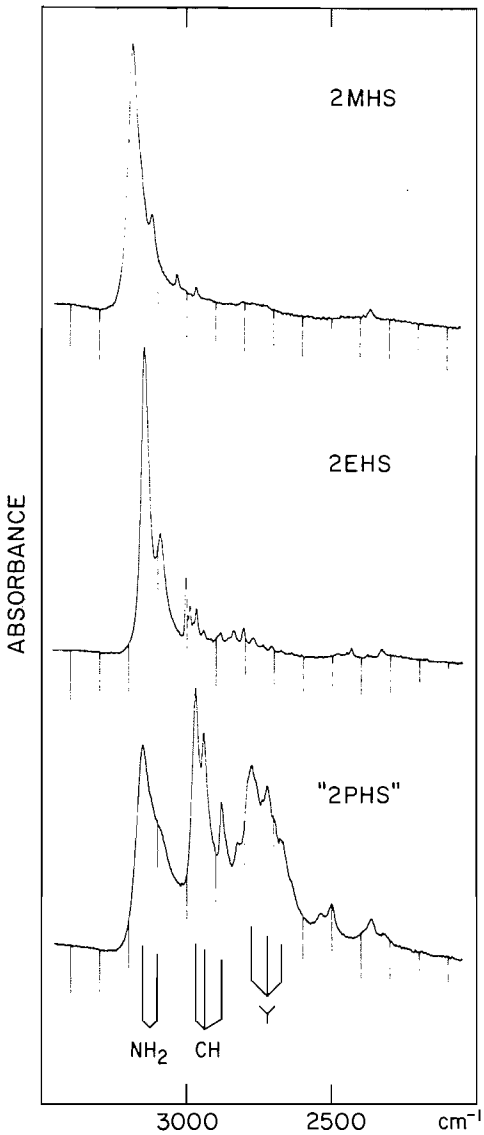

FIG. 7. Room-temperature spectra of undeuterated $(Me_2NH_2)_2SnCl_6$ (2MHS), $(Et_2NH_2)_2SnCl_6$ (2EHS), and $(n\text{-}Pr_2NH_2)_3(SnCl_6)Cl$ ("2PHS") in the NH stretching region (mulls in fluorocarbon oil). The bands marked *Y* correspond to the strongly hydrogen-bonded N—H···Cl^- groupings.

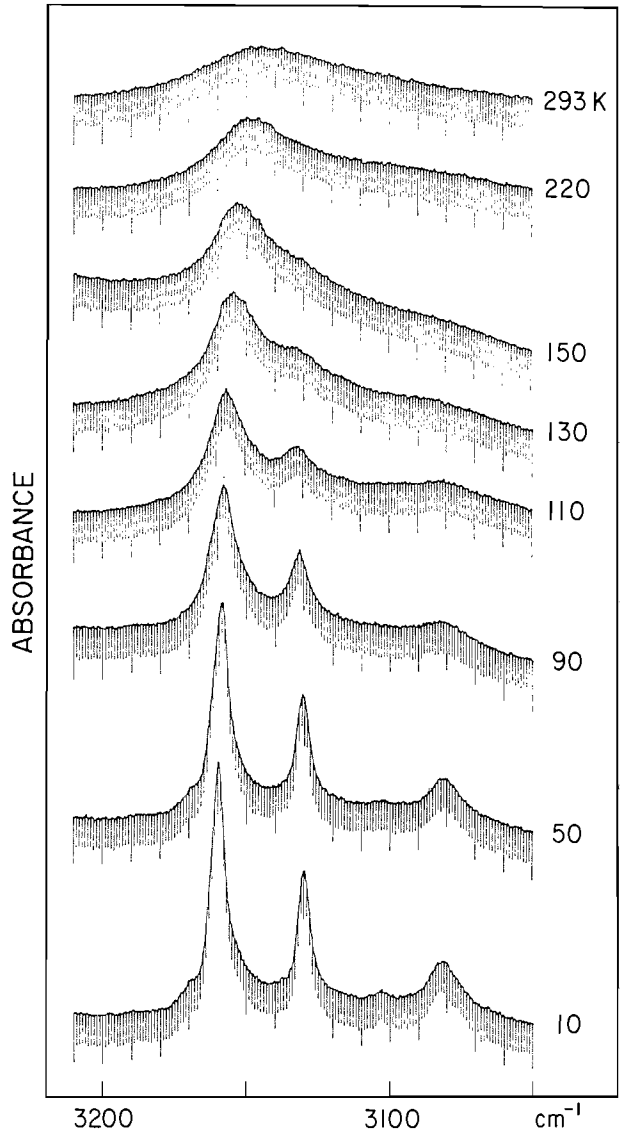

FIG. 8. The high-wavenumber portion of the NH stretching fundamental of $(n\text{-}Pr_2NH_2)_3(SnCl_6)Cl$ (94% D) at different temperatures (mulls in fluorocarbon oil).

the N(1)—H(12)—Cl(5B) angle only 98°.

Each Cl^- is the recipient of three hydrogen bonds, from H(21), H(31), and H(32), the last-named hydrogen being involved through one component of a bifurcated bond (Fig. 6). The first two of these H···Cl^- distances are considerably shorter than the other H···Cl distances and about the same as the H···Cl^- distance in Et_3NHCl, ~2.08 Å (N···Cl, 3.11 Å), where the N—H···Cl^- bond is linear by symmetry (12).

The Sn—Cl distances (Table 11) range from ~2.38 to ~2.45 Å (mean, 2.417(30) Å). This fairly large spread, ca. 0.07 Å ~ 3% of *d*(Sn—Cl), is explained by the asymmetry of the hydrogen-bonding scheme in which the $SnCl_6^{2-}$ ion is involved. With the exception of Sn—Cl(5), *d*(Sn—Cl) increases steadily with the decrease in the Cl_{Sn}···H distance, i.e., with the strength of the Cl_{Sn}···H bond. Some of the SnClH angles are quite small.

The structure as a whole may be viewed as an arrangement of flat, almost planar bands of alternating $SnCl_6$ octahedra and N(1)H_2 groups. The axes of the bands are parallel to the *c*-axis and their planes to (100) (Figs. 3*A* and 4). Each band consists of two parallel rows of $SnCl_6$ octahedra related by a glide mirror plane and cross-linked into zig-zag chains by the H(11) and H(12) hydrogens. The bands in turn are cross-linked by a system of hydrogen bonds involving the N(2)H_2 and N(3)H_2 groups and the Cl^- ions (Fig. 3*A*). The alkyl groups extend their carbon chains in directions more or less parallel to the crystallographic axes, those on N(1) to *a*, those on N(2) to *b*, and those on N(3) to *c* (Fig. 3*B*). This, together with the mutually more or less perpendicular systems of *inter*- and *intra*-band hydrogen bonds, makes the structure a truly three-dimensional edifice. At the same time, the presence of the alkyl groups renders the structural arrangement quite dissimilar to that found for $(NH_4)_3(SiF_6)F$ (9).

Figure 7 contrasts the spectrum of undeuterated 2PHS.PCl in the NH stretching region with the corresponding spectra of 2MHS and 2EHS. The 2PHS.PCl spectrum exhibits absorption in the 3100−3150 cm^{-1} region which matches that in the spectra of 2MHS and 2EHS and clearly corresponds to the stretch-

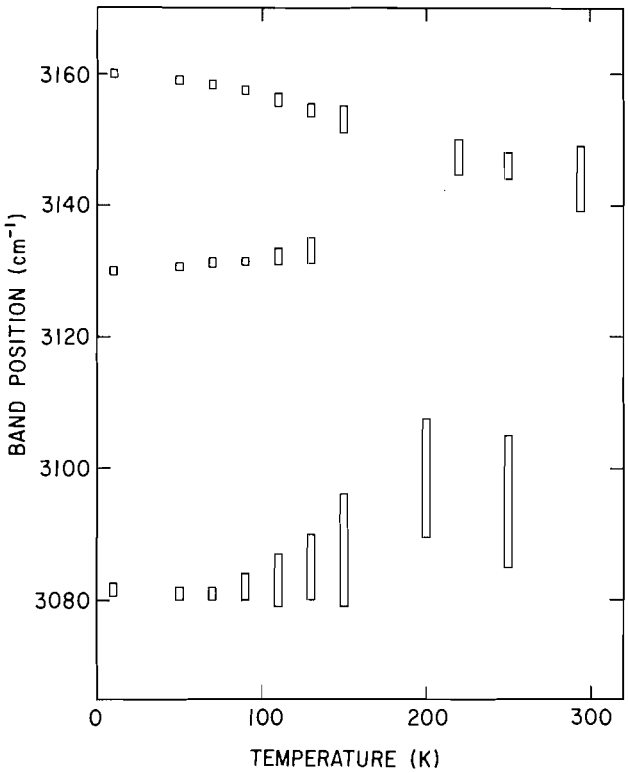

FIG. 9. Positions of the high-wavenumber NH stretching maxima vs. temperature for $(n\text{-}Pr_2NH_2)_3(SnCl_6)Cl$ (from Fig. 8).

ing of $—NH_2^+$ groups hydrogen-bonded to the $SnCl_6^{2-}$ anions (cf. also $MeNH_3^+$ in $(MeNH_3)_2PtCl_6$ (13) and $(MeNH_3)_2CdCl_4$ (14)). In addition, the spectrum contains a complex absorption (*Y* in Fig. 7) between 2500 and 2900 cm^{-1}. NH stretching absorptions at wavenumbers as low as this have been reported to occur in the spectrum of solid Et_3NHCl (refs. 15, 16; unpublished work) as well as in the solution spectra of Et_3NH^+ salts (17); corresponding absorptions in crystalline methylammonium halides, $Me_nNH_{4-n}X$ (X = F, Cl, Br, I) are well documented (18–20). It is thus reasonable to attribute *Y* to NH stretching modes arising from the $—NH_2^+$ groups strongly hydrogen-bonded to the Cl^- ions. Such absorptions are notorious for undergoing complicated Fermi resonance (17). They are unlikely to be understood in detail without extensive ancillary experiments. No attempt has therefore been made to assign the individual features of these spectra to the structurally distinct NH protons.

The temperature shifts of the NH stretching fundamentals in a highly deuterated sample (Figs. 8 and 9) show a gradual collapse of the high-wavenumber doublet, pointing to a probable transition at about 170 K.

Chalcogenide esters as reactive intermediates in selenium and tellurium purifications

SANTOKH S. BADESHA,[1] PAUL MONCZKA,[2] AND STEVEN D. SMITH[2]
Xerox Corporation, Webster Research Center, Webster, NY 14580, U.S.A.

Received March 7, 1983

SANTOKH S. BADESHA, PAUL MONCZKA, and STEVEN D. SMITH. Can. J. Chem. **61**, 2199 (1983).

This paper describes a novel application of chalcogenide esters to purify selenium and tellurium to the 99.999% purity level. The chalcogenide esters were prepared from a variety of source materials which include: crude selenium and tellurium and commercial grade selenium dioxide, tellurium dioxide, and selenous acid. Crude selenium and tellurium were first converted to their respective oxides by treatment with concentrated nitric acid. The oxides were condensed with alcohols or diols to obtain the corresponding esters which, on reduction with hydrazine in organic media, provided high purity elemental selenium and tellurium.

SANTOKH S. BADESHA, PAUL MONCZKA et STEVEN D. SMITH. Can. J. Chem. **61**, 2199 (1983).

On décrit une nouvelle utilisation des chalcogénures dans la purification du sélénium et du tellure avec une pureté de 99,999%. On a préparé les chalcogénures à partir de divers produits de départ tels le sélénium et le tellure à l'état brut, le bioxyde de sélénium, le bioxyde de tellure et l'acide séléneux de qualité commerciale. On a d'abord transformé le sélénium et le tellure à l'état brut en oxydes en les faisant réagir avec l'acide nitrique concentré. On a ensuite condensé les oxydes sur des alcools ou des diols afin d'obtenir les esters correspondants qui par réduction avec l'hydrazine en milieu organique donnet le sélénium et le tellure avec une grande pureté.

Introduction

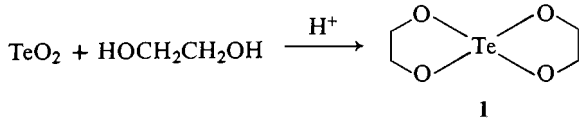
The purity of selenium, tellurium, and their alloys for use in electrophotographic and semiconductor devices is very important. Materials less than 99.999% purity level are considered unsuitable for such devices. The contaminants which are generally found in chalcogenide materials are Mo, Mn, Ni, Pb, Sb, Sn, Si, Ti, Tl, Zn, W, Ag, Al, As, B, Ba, Bi, Ca, Cd, Co, Cr, Cu, Fe, Hg, Na, Mg, S, Cl, and O, depending on the source and method of recovery.

Selenium purification has been reviewed briefly by Scholten (3), Lumbroso (4), Pleteneva (5), and more extensively by Chizhikov and Schastlivyi (6), and Jennings and Yannopoulos (7). There are relatively few reports in the literature on the purification of tellurium (8, 9). Procedures for purification of these chalcogenides are very diversified; however, they can be divided into two major categories, namely chemical and physical. These two methods are usually employed in a sequential fashion, in that high temperature distillations generally are used in the final step. Chemical methods of purification have a common objective; the preparation of an intermediate compound amenable to purification and from which chalcogens can be easily recovered. The intermediate compounds which have been reported to date in the literature are selenides and tellurides, oxides, chlorides, and cyanates. To arrive at the 99.999% purity level, the manufacturers of selenium and tellurium must go through several derivatization and purification stages. The most difficult and expensive of these are repeated ion-exchange and high temperature distillations. It is worth noting that while most manufacturers use similar purification steps, samples of high purity selenium obtained from different sources have significantly different electrical properties. Electrolytic reduction of selenium(IV) on a mercury cathode has also been used for purification. Similarly, electrochemical methods have been exploited to effect separations of tellurium as its salts from impurities, especially selenium (10). These salts are then removed from the anode compartment, dissolved in strong alkali, and chemically reduced to elemental tellurium. Zone refining has also been used extensively for small scale purification of tellurium (11), whereas its application to selenium has been reported ineffective (12).

Despite the fact that selluranes and telluranes have been known since the early 1960's, very little has been done in exploring their chemistry and their possible use as reaction intermediates. In this paper we describe a novel chemical process in which these chalcogenide esters have been reduced to high purity (99.999%) selenium and tellurium.

Results and discussion

Tetraalkoxytelluranes have been prepared by the condensation of tellurium tetrachloride with sodium alkoxides in the presence of excess alcohols (13). Aromatic (14) and aliphatic (15) diols have also been reported to condense with tellurium dioxide or telluric acid to give the corresponding tetraalkoxytelluranes. The tellurane (**1**) used in this report was prepared from two source materials which include: crude tellurium and commercial grade tellurium dioxide. The procedure used by Simon and Heintz (15) for the condensation of tellurium dioxide with ethylene glycol was modified by using *p*-toluenesulfonic acid as reaction catalyst. It was observed that use of the catalyst reduces the reaction time and improves the yield of the product (**1**) over that period earlier (15).



1

In the case of crude tellurium as source material, it was first converted to a mixture of tellurium dioxides by treatment with hot nitric acid. The completion of the reaction was generally indicated by the disappearance of black metallic tellurium. The white precipitate of tellurium oxides was collected in quantitative yield by filtration, washed free of acid with water, and dried. Sulfuric acid or its mixtures with nitric acid, hydrogen peroxide, or molecular oxygen at elevated temperatures can also be used for this oxidation reaction (8). The resulting tellu-

[a]The values are in ppm. At values above 1 ppm, a variability of ±1 ppm may be expected; "m" means that amount is >500 ppm; "—" means that the element is not expected.
[b]These impurities come from glass apparatus and spatula used in the process.

rium dioxide was then heated at 120°C for 1 h in excess ethylene glycol using *p*-toulenesulfonic acid as a catalyst. The temperature of the reaction mixture was raised to 150°C for 5 min during which time the solution became clear. On cooling to room temperature, a white crystalline solid separated out, which was filtered out and recrystallized from 2-ethoxyethanol, yielding tetraalkoxytellurane (**1**) in 80–85% yields. The yield can be further improved by reducing the volume of the filtrates.

The literature reports that strongly acidic solutions of tellurium dioxide (16, 17) and telluric acid (16) have been reduced with ammonia or hydrazinium hydroxide. We have found that tetraalkoxytellurane (**1**) can be easily reduced to high purity tellurium with hydrazine in organic media.

$$\mathbf{1} + H_2NNH_2 \rightarrow Te^0 + N_2\uparrow + HOCH_2CH_2OH + H_2O$$

The reaction is exothermic and the completion is generally indicated by the cessation of nitrogen gas. The black precipitate of elemental tellurium is collected in quantitative yield by filtration. We have also found that ascorbic acid and sulfur dioxide can be used to reduce **1** to elemental tellurium. The optical emission spectral analysis indicated that the resulting tellurium is of the 99.999% purity level (see Table 1, samples #4 and 5).

The chemistry of tetracoordinated selenium is somewhat less developed than tellurium; it has been reviewed by Paetzold and Reichenbacher (18) and Irgolic and Kudchadker (19). Dialkyl selenites have been prepared by the action of (*a*) alkyl halides on silver selenite (20), (*b*) sodium alkoxide on selenyl chloride (21), and (*c*) selenium dioxide on alcohols (22, 23), and dialkyl sulfites (24). Simon and Paetzold (25) have prepared dimethyl and diethyl selenites employing methylene insertion reaction on selenium dioxide dissolved in methanol or ethanol while Mehrotra and co-workers (26) have prepared alkyl selenites by the action of selenous acid on alcohols. We prepared dimethyl and diethyl selenites from a variety of source materials which include: crude selenium, commerical grade selenium dioxide, and commerical grade selenous acid. In the case of crude selenium as source material, it was first converted to a mixture of selenium oxides by treatment with concentrated nitric acid. Sulfuric acid or its mixture with nitric acid or molecular oxygen at elevated temperatures can also be used for this reaction (27). The oxides were then dissolved in ethanol and filtered, any residue being discarded. The filtrate was then converted to diethyl selenite by azeotropic removal of water. The diethyl selenite is purified by vacuum distillation. A variety of aliphatic and aromatic hydrocarbons can be used to make binary and ternary azeotropes with water (28). Those which we have used include pentane, cyclohexane, benzene, and toluene, with pentane being preferred. Diethyl selenite distills as a colorless liquid at 78°C/11 mm Hg in yields in excess of 90%. The residue left in the flask after the distillation can be again dissolved in ethanol and another crop of diethyl selenite can be obtained. This reaction is depicted in the following scheme:

$$\begin{matrix} SeO_2 \\ \text{or} \\ H_2SeO_3 \end{matrix} + ROH \xrightarrow[R = \text{alkyl}]{} (RO)_2SeO + H_2O$$

For personal use only.

Pure diethyl selenite was also prepared by the literature method (26) by the condensation of commercial grade selenous acid or selenium dioxide with ethanol. Pentane was used for azeotropic removal of water.

Alicino and Kowald (29) have reviewed the use of different reducing agents for reduction of selenous acid to elemental selenium. Detailed kinetic studies have also been made on the reduction of selenous acid in acidic media with hydrazine (30) and sulfur dioxide (31).

We have found that diethyl selenite can be reduced to high purity selenium by chemical methods. Chemical reagents used to reduce the selenium ester (**2**) in this study include hydrazine and sulfur dioxide. In both cases, the precipitated selenium is of the 99.999% purity level. In a typical procedure, a solution of diethyl selenite in 2-ethoxyethanol was reduced to selenium by the dropwise addition of hydrazine. The reaction is exothermic and nitrogen gas is evolved. The cessation of nitrogen gas normally indicates the completion of the reaction. The resulting black powder was collected by filtration, washed with cellosolve, and dried, affording high purity selenium in quantitative yield (see Table 1, sample #2). The reaction is shown in the following scheme:

$$(RO)_2SeO + H_2NNH_2 \rightarrow ROH + Se^0 + N_2\uparrow + H_2O$$

In the case of the sulfur dioxide reduction, sulfur dioxide gas was bubbled through an aqueous solution of the ester (**2**) at 75°C and selenium was precipitated in quantitative yield. The resulting black precipitate was washed several times with hot water to ensure the complete removal of sulfate ions and was then dried. The emission spectral analysis performed on the powders obtained above indicates that the selenium is of high purity (see Table 1, samples #1 and 3).

$$(RO)_2SeO \xrightarrow{SO_2/H_2O} H_2SO_4 + Se^0 + ROH$$

Other reducing agents which can be used include: hydroxylamine salts, thioureas, hydroquinones, ascorbic acid, glyoxal, phosphines, and active methylene compounds, etc.

Experimental section

General comments

The following instruments were used for spectral measurements: Bruker WP-80 (nmr), Nuclide model-12-90G (mass spectrum), Perkin-Elmer 267 (ir), Baird-Atomic (optical emission spectrograph). The pyrex glass apparatus was bought from Ace Glass, Inc. All the chemicals were commercial grade and obtained from either VWR Scientific or Aldrich Chemical Co. Commercial grade selenium and tellurium were obtained from CCR[R] and Fisher Scientific Co., respectively, and the purity levels were determined by optical emission spectral analysis. The standards used in optical emission spectral analysis were obtained from National Bureau of Standards (SRM #726). The amounts of the reagents and the reaction conditions are not optimized; the same high purity level is maintained on scaling down to a 5 g scale.

Preparation of diethyl selenite from crude selenium

Crude selenium powder (453 g) was dissolved in 1 L of concentrated nitric acid by stirring and warming over a period of 3 h. When a clear solution was obtained, nitric acid was distilled off at 110–112°C. The traces of nitric acid were then removed under high vacuum. The resulting white residue was dissolved in 700 mL of absolute ethanol and water was removed azeotropically with 600 mL of benzene. The solvents were removed by distillation at atmospheric pressure and the residue was then fractionally distilled under high vacuum. Diethyl selenite which distills at 78°C/11 Torr (lit. (26) 76°C/10 Torr) was collected. The grey residue left in the flask was again dissolved in absolute ethanol (800 mL) and benzene (600 mL). The water was removed azeotropically as before and an additional crop of diethyl selenite was collected by fractional distillation. Overall yield of diethyl selenite was 956 g (90%). One can improve the yield of the ester further by recycling the grey residue left in the flask.

Preparation of diethyl selenite from commercial grade selenous acid (94%)

Diethyl selenite was preopared from commercial grade selenous acid in 91% yield (lit (26), 84%) using *n*-pentane to remove water azeotropically.

Preparation of diethyl selenite from commercial grade selenium dioxide

Diethyl selenite was also prepared in 73% yield by the condensation of commercial grade selenium dioxide with absolute ethanol (26).

Reduction of diethyl selenite obtained from crude selenium with hydrazine

Diethyl selenite (956 g) was dissolved in 1 L of cellosolve in a 2 L 3-necked RB flask equipped with reflux condenser, graduated addition funnel, and a Teflon[R] paddle stirrer. A solution of 175 g of hydrazine in 200 mL of cellosolve was added dropwise over a 2 h period through the addition funnel to the stirred solution of the ester. The reaction was exothermic and N_2 gas was evolved. The resulting black precipitate was collected by filtration on a sintered glass filter, washed with 200 mL (4 × 50 mL) of cellosolve, dried, and weighed. The overall yield of the high purity selenium is 403 g (99%). Emission spectral analysis indicated that the material was 99.999% pure and the details are shown in Table 1 (sample #1).

Reduction of diethyl selenite from commercial grade selenous acid with hydrazine

A solution of diethyl selenite obtained from commercial grade selenous acid in cellosolve was reduced with hydrazine, yielding high purity selenium in 99% yield. The purity was determined by emission spectral analysis and the results are summarized in Table 1 (sample #2).

Reduction of diethyl selenite from commercial grade selenous acid with sulfur dioxide

Sulfur dioxide gas was slowly bubbled at room temperature through a solution of 400 g of diethyl selenite in 1 L of deionized water in a 2 L Erlenmeyer flask. Red precipitates of amorphous selenium separate out. Sulfur dioxide was bubbled through the above slurry for 2 h at 85°C. The precipitate was then collected by filtration, washed several times with water until the washings were neutral, vacuum dried, and weighed. A total yield of 163 g (96%) of red amorphous selenium was obtained. The yield can be improved by increasing the reaction temperature and by bubbling sulfur dioxide until no more red color develops in the filtrate. Emission spectral analysis indicated that material is 99.999% pure. The details are given in Table 1 (sample #3).

Preparation of high purity tellurium from commercial grade tellurium dioxide

A mixture of commercial grade tellurium dioxide (160 g), *p*-toluenesulfonic acid (5 g), and ethylene glycol (1600 mL) was heated and stirred under argon atmosphere at 120°C for 3 h and then at 160°C until a clear solution resulted. The above solution was cooled to room temperature and then allowed to stand on the bench for 5 h. Tetraalkoxytellurane, which separated as white needles, was collected by filtration, washed with 100 mL (2 × 50 mL) of cellosolve, and recrystallized from cellosolve. The overall yield of the ester was 86%; mp 203–204°C (lit. (15) 207–218°C). The filtrates were discarded. One can obtain an additional crop of tetraalkoxytellurane by concentrating the above filtrates.

The above tellurium ester was dissolved in 1 L of warm cellosolve. A solution of 35 g of hydrazine in 100 mL of cellosolve was added dropwise through an addition funnel over a period of 30 min. The

reaction was exothermic and N_2 gas was evolved. The black slurry was further stirred for 1 h and filtered. The black precipitate was collected, washed with 100 mL (2 × 50 mL) cellosolve, dried, and weighed. A total yield of 84% high purity tellurium was obtained. The purity was determined by emission spectroscopy and the details are given in Table 1 (sample #5).

Purification of commercial grade tellurium

Concentrated nitric acid (300 mL) was charged into a 1 L RB flask equipped with a reflux condenser. Commercial grade tellurium (50 g) was added to the above flask. The suspension was stirred and refluxed until all the tellurium dissolved and a white slurry resulted. This conversion takes approximately 6 h. Nitric acid was then distilled off at 110–112°C. The traces of nitric acid were removed under high vacuum. The white residue, which is tellurium dioxide, was converted to tetraalkoxytellurane by treatment with 500 mL of ethylene glycol and 5 g of *p*-toluenesulfonic acid as above.

Pure tetraalkoxytellurane was then dissolved in 500 mL of cellosolve by stirring and warming. A solution of 15 g of hydrazine in 50 mL of cellosolve was then added dropwise over a period of 20 min. The reaction is exothermic and N_2 is evolved. The black precipitate was collected by filtration, washed with 50 mL (2 × 25 mL) of cellosolve, dried, and weighed. A total of 42 g (84%) of high purity tellurium was obtained. The purity was determined by emission spectroscopy and the details are given in Table 1 (sample #4).

Acknowledgments

We wish to thank D. Shuba for emission spectral analysis, CCR[R] for a sample of crude selenium, and A. S. Dellario for typing the manuscript.

Dissolution enthalpies of NaI in binary mixtures of water with aliphatic alcohols and methylcellosolve at 298.15 K. Enthalpic pair interaction coefficients of NaI–nonelectrolyte in water solution

HENRYK PIEKARSKI

Department of Physical Chemistry, Institute of Chemistry, University of Łódź, ul. Nowotki 18, 91-416 Łódź, Poland

Received December 15, 1982

HENRYK PIEKARSKI. Can. J. Chem. **61**, 2203 (1983).

The enthalpy of solution, ΔH_{sol}, of NaI in methanol + water, ethanol + water, *n*-propanol + water, isopropanol + water, and methoxyethanol + water at all compositions and ΔH_{sol} of NaI in *s*-butanol + water and *tert*-butanol + water from 0 to 5 mol% alcohol was measured.

The NaI–nonelectrolyte pair interaction enthalpies were determined and correlated with the functions describing some properties of the nonelectrolyte. A functional group additivity concept, introduced by Savage and Wood for non-ionic solutes, was applied to the interactions between NaI and nonelectrolytes.

HENRYK PIEKARSKI. Can. J. Chem. **61**, 2203 (1983).

On a mesuré l'enthalpie de solution ΔH_{sol} du NaI en solution dans les solvants suivants: méthanol + eau, éthanol + eau, *n*-propanol + eau, isopropanol + eau et méthoxyéthanol + eau en toutes proportions et on a mesuré le ΔH_{sol} du NaI en solution dans les mélanges de *s*-butanol eau et de *tert*-butanol eau dont la teneur en alcool varie de 0 à 5 mol%.

On a déterminé les enthalpies d'interaction de la paire: NaI–nonélectrolyte et on les a reliées aux fonctions qui décrivent certaines propriétés d'un non électrolyte. On a appliqué un concept d'addivité de groupe fonctionnel, introduit par Savage et Wood pour les solutés non ioniques, aux interactions entre le NaI et les non électrolytes.

Introduction

A simple way of representing solute–solute interactions in dilute solutions is through virial expansion in solute concentration, as shown by McMillan and Mayer (1). The virial coefficients of such an expansion represent, respectively, pair, triplet, and higher order interactions between the molecules of the same dissolved substance in two-component systems, as well as among different molecules in three-component systems. Any changes in the solute–solvent interactions are considered to be contained in the coefficients of interactions between the molecules of the solutes. Enthalpic pair interaction coefficients in both two- and three-component systems have been dealt with in a number of studies, but few of them concerned interactions between electrolyte and nonelectrolyte (2–6). The aim of this study was to fill this gap, if only to some extent. The systems studied were aqueous mixtures of NaI and alcohols at 298.15 K. Sodium iodide was used as the electrolyte due to its relatively good solubility in the investigated mixtures.

As is well known, enthalpic interaction coefficients may be determined on the basis of dissolution enthalpies in a two- or three-component system (2–5, 7). Accordingly, the enthalpies of NaI dissolution in methanol, ethanol, propanol, isopropanol, and methoxyethanol + water mixtures were determined over the entire range of concentrations of the mixed solvent as well as in *s*-butanol and *tert*-butanol + water in the range of several mol% of alcohol at 298.15 K. Some of the above mentioned systems had previously been studied by calorimetric method (8–12). However, in view of the small number of experimental points in the water-rich mixtures, those data could not be used for the present purpose.

Experimental

Materials

Sodium iodide, "Baker Analyzed", manufactured by J. T. Baker Chemicals B.V. (Holland), crystallized from a water–acetone mixture, was dried under vacuum for several days at ca. 335 K. Methanol, ethanol, propanol, and isopropanol — all analytically pure — manufactured by POCh Gliwice (Poland): *s*-butanol and *tert*-butanol — A. R. manufactured by Reanal (Hungary) were purified and dried by standard methods (13). Methoxyethanol p.a. manufactures by Merck (Germany) was subjected to fractional distillation. All solvents were kept over molecular sieves 3A. The water content in alcohols was determined by the Fischer method and it did not exceed 0.02% by weight. The water was deionized and twice distilled. The water–alcohol mixtures were prepared by weight.

Apparatus and method of measurement

Enthalpies of NaI dissolution in water–methoxyethanol mixtures were determined using an LKB 8700-1 calorimeter provided with a 100 cm^3 glass measuring vessel.[1]

All other measurements were made using a home-made non-isothermic, non-adiabatic calorimeter with the surrounding medium at constant temperature as described in an earlier paper (14).

Results and discussion

Enthalpy of NaI dissolution

Enthalpies of NaI dissolution in water + alcohol mixtures were determined in the range of small electrolyte concentrations (0.002–0.02 mol dm^{-3}). The measured enthalpies were extrapolated to infinitely dilute solution using the method of Criss and Cobble (15). The dielectric permittivity and density of the water + alcohol mixtures required for the calculations were taken from the literature (16–19). The calculated standard enthalpies of NaI dissolution in methanol, ethanol, propanol, isopropanol, *s*-butanol, *tert*-butanol, and methoxyethanol mixtures with water at 298.15 K are presented in Table 1 and Fig. 1. The literature data concerning the systems under study are also included in Table 1 and Fig. 1.

As can be seen in Fig. 1, the $\Delta H^0 = f(x)$ plot for the water + alcohol mixtures under study shows a maximum in the range of small alcohol concentrations, similar to the case of other electrolyte + water + alcohol systems studied earlier (8–12, 14, 20–27). The maximum in question is generally taken to be connected with the ordering or stabilization of water structure

[1]The research was done by the author while on a post-doctoral fellowship at the Physical Chemistry Department of Free University, Amsterdam.

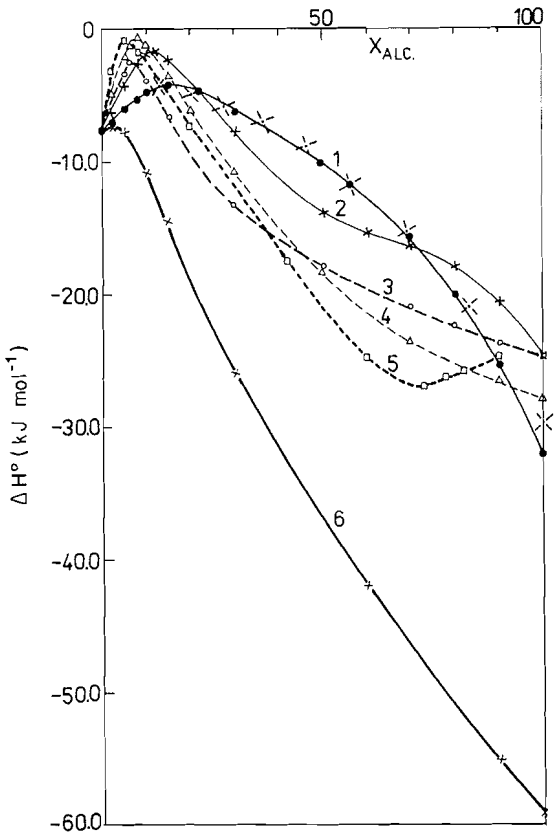

FIG. 1. Standard solution enthalpy of NaI in the mixtures of water with alcohols as a function of solvent composition at 298.15 K: (*1*, methanol; *2*, ethanol; *3*, propanol; *4*, isopropanol; *5*, *tert*-butanol; *6*, methoxyethanol)× literature data (8).

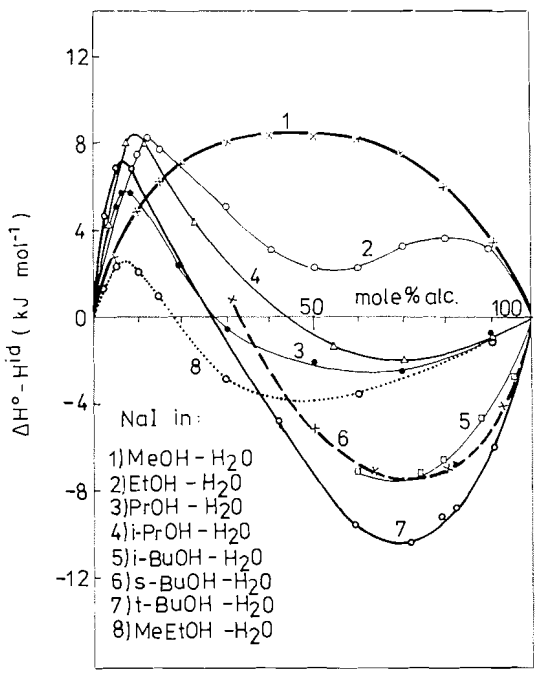

FIG. 2. Deviations from the additivity of the standard solution enthalpy of NaI in water−alcohol mixtures at 298.15 K.

by alcohol molecules (32−36). It follows from the literature data as well as from the results of this study, that the shape and position of the ΔH^0 peak depends on the size of the alcohol molecules. As the molecule size increases, the peak shifts towards smaller alcohol content in the mixture.

It is interesting to compare the course of the $\Delta H^0 = f(x)$ NaI plots for mixtures of the different alcohols with water, from methanol to *tert*-butanol (Fig. 1). The plots change their courses as the size of the alcohol molecule increases, similar to the heats of mixing curves for the same alcohols with water (37). This correspondence becomes even more obvious if NaI dissolution enthalpy is replaced by a function which represents deviations from additivity of NaI dissolution enthalpies in the above mixtures (Fig. 2).

$$\delta\Delta H^0 = \Delta H^0 - \Delta H^{id}$$

This similarity may well reflect the effect of changes in the structure of water–alcohol mixture on ion solvation in these mixtures.

Thermochemically, the NaI–water–methoxyethanol system behaves similarly to known NaI–water–alcohol systems. This is in agreement with the finding of Petrucci (38) who observed a similar behaviour of water–methylcellosolve and water–methanol mixtures as solvents of electrolytes. The standard enthalpy of NaI dissolution determined in the present study passes through a maximum in the range of small cellosolve contents (ca. 2 mol%). However, this maximum is considerably lower than the ones in other water–alcohol solvents (Fig. 1).

Also noteworthy is the large thermal effect of NaI dissolution in pure methoxyethanol (59.3 kJ mol^{-1}) which is comparable to the enthalpy of NaI dissolution in DMF (57.1 kJ mol^{-1}) (39), but quite different from the enthalpy of NaI dissolution in simple aliphatic alcohols (Table 1). This is probably due to the presence of an internal H-bond in methylcellosolve molecule (40, 41) which makes the formation of a more complex structure in pure solvent difficult, as in the case of the structure of lower aliphatic alcohols. Consequently, less energy is required to break a methoxyethanol molecule from its surrounding medium in order to form an ion solvation shell and, as a result the enthalpy of solution becomes more exothermic.

Enthalpic pair interaction coefficients

In order to calculate the enthalpic interaction coefficient h_{EN} for pairs NaI + alcohol in water solution, the method proposed by Friedman and Krishnan (4) and Desnoyers *et al.* (7) as modified by Heuvelsland *et al.* (3) was used. The standard enthalpy of NaI dissolution in mixtures of water with a small amount of alcohol was presented as a function.

$$[1] \quad \Delta H^0(\text{E in N + W}) = \Delta H^0(\text{E in W}) + bX_N + cX_N^2$$

where E is the electrolyte, N the cosolvent, W, water, X_N is molar fraction of the cosolvent, and b and c are coefficients which can be determined by the least-squares method.

Parameter b in eq. [1], which represents limiting slope of function ΔH^0(E in N + W), is connected with the McMillan–Mayer interaction coefficient h_{EN}:

$$[2] \quad b = 2\nu h_{EN}(\partial m_N/\partial X_N)_{X_N \to 0}$$

Denoting the molecular weight of water by M_w, we have, for dilute solutions

$$[3] \quad \left(\frac{\partial m_N}{\partial X_N}\right)_{X_N \to 0} = \frac{1}{M_w}$$

where m_N is in mol kg^{-1}, M_w in kg mol^{-1}. Hence

$$[4] \quad h_{EN} = b\frac{M_w}{2\nu}$$

where ν is the number of ions. The pair interaction coefficient defined as above constitute, for the systems containing an electrolyte of the 1–1 type, a half of the sum of the enthalpic effect of the interaction between a molecule of a given nonelectrolyte and cation (K^+) and anion (A^-)

$$[5] \quad h_{NE} = (1/2)\, h(K^+A^- - \text{nonelectrolyte}) = (1/2)[h(K^+ - \text{nonelectrolyte}) + h\,(A^- - \text{nonelectrolyte})]$$

TABLE 2. Enthalpic pair interaction coefficients for electrolyte–nonelectrolyte pairs in water solution at 298.15 K

	h_{EN} (J kg mol^{-2})	
Nonelectrolyte	NaI	NaCl
Methanol	+157	+150(2)

Methoxyethanol	+97	
THF	+172[b]	−200[b]
DMF	−212[b]	
DMSO	−314[b]	
Formamide	−348[b]	
Sulpholane[a]	−542[b]	
Acetone	−46[b]	

[a] T = 303.15 K.

[b] The values calculated from literature data: isobutanol (14), DMF and formamide (39), DMSO (42), THF (43), sulpholane (44), acetone (45).

The values of h_{EN} calculated this way are collected in Table 2. For the sake of comparison, the table also contains pair interaction coefficients for the NaI–nonelectrolyte system calculated on the basis of literature data (39, 42–44) as well as h_{EN} values obtained by other authors for the same or similar systems (2).

It follows from the data above that the pair interaction coefficients obtained exhibit considerable variation depending on the kind of nonelectrolyte; there are both negative and positive values of h_{EN}. The pair parameters for systems containing one of the first three aliphatic alcohols have values similar — within the limit of error — to the corresponding parameters for NaCl + alcohol + water system. This coincides with the finding of Perron *et al.* (2) about the weak dependence of parameters h_{EN} on ion size. However, in the case when the nonelectrolyte is TBA or THF, the values of h_{EN} coefficients for NaI and NaCl exhibit considerable differences. Considering the results of Perron (2), it seems that the differences observed in the present study may have been due to specific behaviour of I^- ion in the systems under investigation.

When analyzing the pair interaction coefficients obtained in this study, an attempt was made to find out whether simple relations could be established between h_{EN} and the functions characterizing the different properties of the nonelectrolytes under study. The interaction parameters h_{EN} relative to the polarizability (α) of the nonelectrolyte molecule are presented in Fig. 3. As can be seen, the pairwise interaction coefficients for NaI with MeOH, EtOH, PrOH, *i*-PrOH, *i*-BuOH, *s*-BuOH produce a linear function when plotted against polarizability of the alcohol. It may well be that in the systems mentioned above electrostatic interactions make the leading contribution to h_{EN} coefficients.

Electrolyte–nonelectrolyte interactions are to some extent connected with the donor–acceptor properties of the nonelectrolyte molecule. Therefore, an analysis was made of the dependence of h_{EN} for NaI–nonelectrolyte on the various parameters which define the acidic and basic properties of the

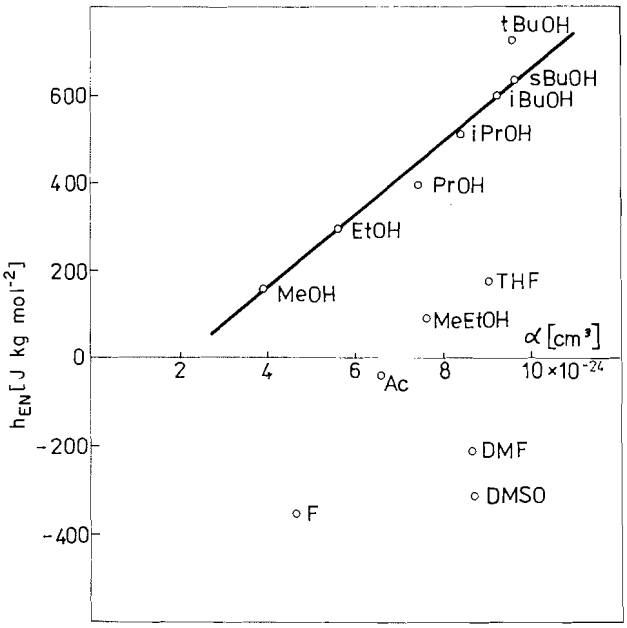

FIG. 3. Plot of enthalpic pair interaction coefficients of NaI–nonelectrolyte in water solutions versus the polarizability of the nonelectrolyte molecule.

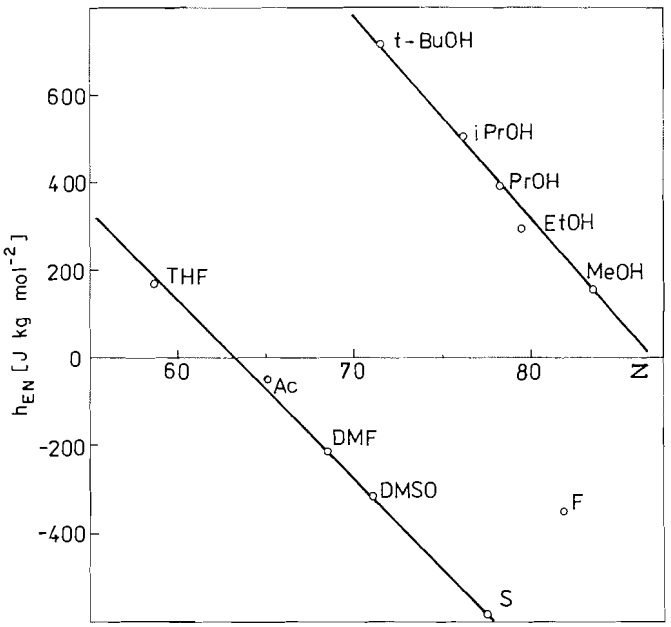

FIG. 4. Plot of h_{EN}(NaI–nonelectrolyte) vs. the Kosower acidity parameter (Z).

cosolvent. It turned out that there is no direct correlation between the enthalpic interaction coefficients obtained by us and the functions defining the basic properties of the nonelectrolyte, such as Gutmann donor number DN (46) or the Kamlett–Taft β_{KT} (47) or Koppel–Paiu β (48) basicity parameter. By contrast, there exists a correlation in the case of acidity functions, as can be seen in Fig. 4, which shows the plot of h_{EN} vs. the Kosower acidity parameter Z (49).

Here there are two, almost parallel straight-line segments one of which refers to aliphatic alcohols and the other represents nonelectrolytes whose molecules are aprotic in character (DMF, sulpholane, THF, acetone, DMSO). The h_{EN} value corresponding to the NaI + formamide interaction is not located on either of the two straight lines. The plots of the interaction coefficients under discussion against the other acidity functions, such as the Dimrot–Reichardt parameter E_T (50), present a similar picture.

The observed dependence of h_{EN} vs. Z makes it possible to divide the nonelectrolytes under study into two groups. The first group contains aliphatic alcohols which are known to bring about stabilization or ordering of the water structure (32–39). Their molecules exhibit both electron-donor and electron-acceptor properties. The second group comprises (as follows from Fig. 4) DMF, THF, DMSO, acetone, and sulpholane which, although they do affect water structure in different ways, all exhibit electron-donor properties.

The above findings seem to permit the conclusion that enthalpic pair interaction coefficients for an NaI–nonelectrolyte–water system depend primarily on two effects: a structural-hydration one and an electrostatic one. The former divides nonelectrolytes because of differences in the mechanism of their hydration, while within a given group of nonelectrolytes it is the electrostatic interactions that seem to play the most important role (Fig. 3).

On the other hand, the coefficients h_{EN} of NaI interaction with nonelectrolyte calculated in the present work constitute, according to formula [5], half of the sum of the enthalpic effect of the interaction between a molecule of a given nonelectrolyte

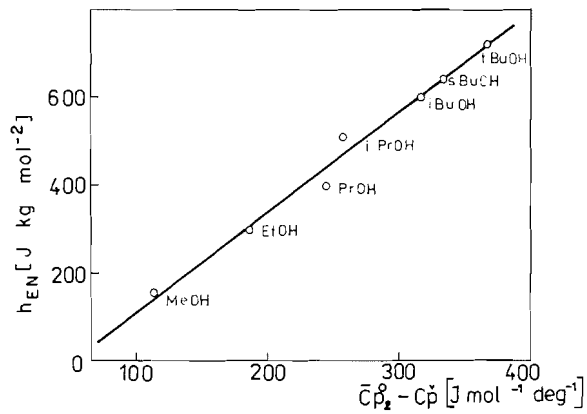

FIG. 5. Correlation of h_{EN}(NaI–alcohol) and heat capacity ($\bar{C}^0_{p_2} - C^v_p$) of transfer of the alcohols from the vapor phase to high dilution in water.

and cation (Na^+) and anion (I^-). The absence of an electron acceptor group in a DMF, DMSO, THF, acetone, and sulpholane may be responsible for the weak interaction between the molecules of the above mentioned substances with the anion under study. The parallel shift of the straight line segments $h_{EN} = f(Z)$ for the two nonelectrolyte groups discussed above (Fig. 4) may thus be due to differences in the effect of iodide ion interactions with a molecule of group one or group two nonelectrolyte.

In order to find out which of the above interpretations of the course of functions $h_{EN} = f(Z)$ is correct, one would have to divide coefficient h_{EN} into ionic contributions. This, however, is not possible at the moment in view of insufficient data.

Since heat capacity data are known to be very sensitive to structural changes in solution (51), it seemed interesting to find out whether the h_{EN} coefficients obtained in this study correlate with the C_p data for water solutions of the nonelectrolytes under investigation.

As can be seen in Fig. 5, there is a linear dependence between h_{EN} and ($\bar{C}^0_{p_2} - C^v_p$) for the alcohols where $\bar{C}^0_{p_2}$ denotes partial molal heat capacity of alcohol in high dilution in water,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12

and C_p^v is heat capacity of pure vapour of alcohol. The observed dependences seems particularly interesting in view of the fact that, as established by Arnett, Kover, and Carter ($\bar{C}_{p_2}^0 - C_p^v$), the heat capacity of solution for alcohols from the vapour phase to water does give some correlation with the entropies ΔS^0 for the same process (52). It follows that the interaction coefficients h_{EN}(NaI−alcohol) also correlate with transfer entropy ΔS^0. Unfortunately, since appropriate data were not available, it was not possible to find out whether the h_{EN} vs. ($\bar{C}_{p_2}^0 - C_p^v$) plots obtained also hold for the other nonelectrolytes of Table 2.

It follows from the data collected in Table 2 that the h_{EN} coefficients for all NaI + alcohol pairs in water are positive and they increase steadily with increasing alkyl group size. A similar effect of the alkyl group size on h_{EN} values was observed in the case of other systems described in the literature (3, 5, 53, 54). This regularity suggested that the interaction coefficients might have an additive nature. As is well known, Savage and Wood (53) have found that coefficients h_{EN} for nonelectrolytes are made up additively from contributions of the different functional groups. Basic to their approach is the assumption that each functional group in molecule "E" interacts with each functional group in molecule "N" and that each of these interactions has its own contribution to the enthalpy, regardless of the nature of the molecule. Steric effects are neglected and, consequently, it is assumed that interactions between the given groups are independent of their position in the molecule. In their study, Savage and Wood (53) selected the methyl (CH_2), hydroxymethylene (CHOH), and amide (HNCO) groups as the functional groups and, as a result, they considered six possible interactions corresponding to the following pairs: CH_2−CH_2, CH_2−CHOH, CH_2−HNCO, CHOH−CHOH, CHOH−HNCO, and HNCO−HNCO.

In the present study we are dealing with an electrolyte−alcohol system. Since without additional extra thermodynamic assumptions it is impossible to divide h_{EN} into ionic contributions, the values calculated by us represent mean ionic coefficient of the ion − alcohol molecule interaction or, more accurately, (1/2) (Na^+I^-)−alcohol molecule. The model assumed takes account of three types of interaction in the systems under study: (1/2) (Na^+I^-)−CH_2, (1/2) (Na^+I^-)−OH, and (1/2) (Na^+I^-)−O ether oxygen atom. In such a case, h_{EN} may be represented in the form of a summation

$$[6] \quad h_{EN} = \sum_i n_{Ei} h_{Ei}$$

where h_{Ei} is the characteristic contribution to coefficient h_{EN} from mean ionic interactions with the selected group of type "i" in molecule "N". Following other authors (3, 5, 53, 54), we assumed the CH_3 group to be equivalent to 1.5 of the CH_2 group. In order to solve eq. [6] for the seven h_{EN} values available, multiple linear regression was employed and the following group contributions to h_{Ei}: (1/2)(NaI−CH_2) = +(140.6 ± 5.7) J kg mol^{-2}, (1/2)(NaI−OH) = −(61.8 ± 22.4) J kg mol^{-2}, (1/2)(NaI−O) = −(333.3 ± 171.8) J kg mol^{-2}, were obtained.

In Fig. 6 are collected the values of h_{EN} determined from experimental data as well as those calculated on the basis of the above mentioned contributions of the interactions from the different selected groups.

As can be seen, in spite of the simplicity of the model of interactions the two sets of data are in satisfactory agreement. Further work of electrolyte−nonelectrolyte interaction coefficients is envisaged for other electrolytes in order to gain a better understanding of the electrochemistry of three-component systems, when one of the components is an electrolyte.

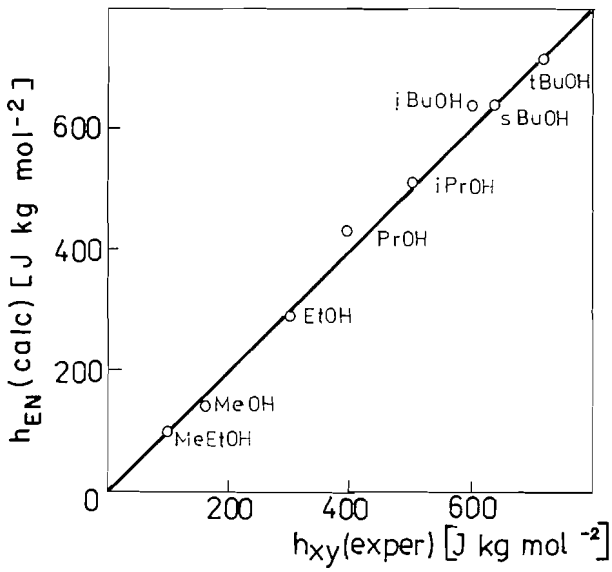

FIG. 6. Plot of calculated versus experimental values of h_{EN}(NaI−alcohol) in water at 298.15 K.

Acknowledgements

I would like to thank the authorities of the Free University of Amsterdam for the generous grant of a post-doctoral fellowship at their Thermochemical Laboratory. I have a special debt of gratitute to Professor G. Somsen (Free University of Amsterdam) and Professor S. Taniewska-Osińska (University of Łódź) for discussing with me earlier drafts of the paper and offering valuable comments and useful suggestions.

On the analysis of calorimetric data in the study of dimerization of carboxylic acids in nonpolar solvents

PAWEŁ GÓRALSKI AND STEFANIA TANIEWSKA-OSIŃSKA
Department of Physical Chemistry, University of Łódź, ul. Nowotki 18, 91-416 Łódź, Poland

Received September 17, 1982[1]

PAWEŁ GÓRALSKI and STEFANIA TANIEWSKA-OSIŃSKA. Can. J. Chem. **61**, 2209 (1983).

The calorimetric dilution method was analyzed for the accuracy with which the equilibrium constant (K_d) and dimerization enthalpy (ΔH_d) can be determined. The calculations were carried out using the ideal monomer–dimer model. It was found that the error in determining the functions describing dimerization increases strongly with rising K_d values but is independent of ΔH_d values. Doubt is expressed whether dimerization and trimerization can be studied simultaneously by the calorimetric method. A suggestion is made to use spectroscopy and calorimetry jointly rather than separately to determine K_d and ΔH_d values rapidly and conveniently, producing, in many cases, more accurate results.

PAWEŁ GÓRALSKI et STEFANIA TANIEWSKA-OSIŃSKA. Can. J. Chem. **61**, 2209 (1983).

On a évalué la précision de la méthode de dilution calorimétrique dans la détermination de la constante d'équilibre (K_d) et de l'enthalpie de dimérisation (ΔH_d). On a effectué les calculs en utilisant un modèle monomère–dimère idéal. En déterminant les fonctions qui décrivent la dimérisation on trouvé que l'erreur augmente de façon márquée lorsque la valeur de K_d augmente mais elle ne dépend pas de ΔH_d. On doute que l'on puisse étudier simultanément la dimérisation et la trimérisation par la méthode calorimétrique. On propose d'utiliser la spectroscopie conjointement avec la calorimétrie et non séparément pour déterminer rapidement de façon convenable les valeurs de K_d et de ΔH_d. On obtient dans plusieurs cas des résultats plus précis.
[Traduit par le journal]

Introduction

The vast majority of studies devoted to self-association of carboxylic acids in nonpolar solvents have assumed the monomer–dimer equilibrium to be the only equilibrium present in the system. Such was the case, e.g., with calorimetric studies of a number of acids conducted by Calvet and Paoli (1), Mokrzan *et al.* (2), or Zaugg and co-workers (3–6). Zaugg *et al.* (6) and Krishnan *et al.* (7) were the first to employ the technique of minimizing the experimental data to determine K_d and ΔH_d values from calorimetric measurements. Such a method of treating the results was also employed (7) to determine the equilibrium constant and enthalpy of trimerization of benzoic acid (HBz) in benzene. That trimers, dimers, and monomers coexist in solutions of carboxylic acids has also been suggested in osmometric studies (8, 9).

The present study analyzes the error involved in K_d and ΔH_d values determined with the calorimetric method for the case in which the data are subjected to minimization. Also discussed will be the possibility of studying trimerization of carboxylic acids by the calorimetric method.

Methods

The use of minimization in determining K_d *and* ΔH_d *of carboxylic acids*

Application of minimization to calorimetric heat measurements makes it possible to avoid errors typical of other data processing procedures such as, e.g., the extrapolation error involved in determining the apparent relative molar enthalpy (ϕ_L). The one snag of minimization is the subjective choice of the criterion of minimization which, in principle, can be any of the measuring or searched quantities or their combination (sum, product, weighted average, etc.). Our calculations, performed on the data obtained by Krishnan *et al.* (7), show that the use of different criteria can produce K_d and ΔH_d values differing by as much as 50–70%. The discussion is based on the monomer–dimer type association model. Using the procedure described by Rollett (10), we have calculated standard deviation (SD) values for both quantities sought (δK_d and $\delta \Delta H_d$).

$$\delta K_d = \sqrt{\sum_i \left(\frac{\partial X_i}{\partial \Delta H_d}\right)^2 \Big/ \det} \cdot \delta_X$$

$$\delta \Delta H_d = \sqrt{\sum_i \left(\frac{\partial X_i}{\partial K_d}\right)^2 \Big/ \det} \cdot \delta_X$$

where:

$$\delta_X = \sqrt{\frac{\sum_i (X^i_{exp} - X^i_{calc})^2}{n - 2}}$$

$$\det = \sum_i \left(\frac{\partial X_i}{\partial \Delta H_d}\right)^2 \cdot \sum_i \left(\frac{\partial X_i}{\partial K_d}\right)^2 - \left[\sum_i \left(\frac{\partial X_i}{\partial K_d} \cdot \frac{\partial X_i}{\partial \Delta H_d}\right)\right]^2$$

X is the parameter selected as the criterion of minimization (ΔH_{dil}, Q_{exp}, etc.) and n is the number of experimental measurements.

In spite of the divergences in K_d and ΔH_d values mentioned above and related to the use of different minimization criteria, the determined SD values never exceeded ca. 10% of the values sought. This makes the SD values of K_d and ΔH_d an insufficient indicator of the accuracy of the results obtained. It seems to us that an acceptable degree of accuracy of results would be achieved if it gave some indication of the differences between results obtained for a variety of reasonably selected minimization criteria. In the case under discussion the set of relevant quantities relating to the data of ref. 7 obtained for HBz solution in a Picker calorimeter are collected in Table 1.

As can be seen from the above, the assumed resultant error may be as much as 4–5 times higher than the calculated δK_d and $\delta \Delta H_d$, when ΔH_{dil} is selected as the minimization criterion. A similar ratio of uncertainty intervals relative to the SD of dimerization enthalpy was found by Zaugg *et al.* (6) for ΔH_d of a series of acetic and propionic acid derivatives. Thus the resultant error given in Table 1 should be taken to faithfully represent the error involved in the values obtained.

$\sum_i (\Delta H^i_{dil(exp)} - \Delta H^i_{dil(calc)})^2$	575	36.8	±25	±0.4	±100	±2.1

*See ref. 7.
†$\omega = Q^{i}_{calc}{}^{-2}$, K_d (L/mol), ΔH (kJ/mol).

TABLE 2. The values of various kind of errors in K_d and ΔH_d for benzoic acid in benzene*

Errors determined	Magnitude of error: K_d (L/mol)	Magnitude of error: ΔH_d (kJ/mol)
Pre-experimentally predicted†	$\delta K_d = \pm 9$	$\delta \Delta H_d = \pm 0.21$
After experiment (Table 1)	$\delta K_d = \pm 25$	$\delta \Delta H_d = \pm 0.42$
Real (resultant) error (Table 1)	err $K_d = \pm 100$	err $\Delta H_d = \pm 2.1$

*We adopted K_d = 575 L/mol and $\Delta H_d = -36.8$ kJ/mol, resulting from minimizing ΔH_{dil}, Table 1, $N = 2.0$.
†Assumed in test $N = 2.0$ ($N = C_{initial}/C_{final}$).

Pre-experimental prediction of error in K_d *and* ΔH_d

There is no information in the relevant literature on the relation between the values of K_d and ΔH_d and the accuracy with which they are determined using the calorimetric method. An attempt to predict the error involved was made using the following assumptions.

(*i*) The minimization criterion was always the same:

$$\sum_i (\Delta H^i_{dil(exp)} - \Delta H^i_{dil(calc)})^2 \rightarrow \min \text{ [as in ref. 7]}$$

(*ii*) Only monomer–dimer equilibrium is present in the solution, i.e. the concentration dependence of the heat of dilution results only from the shifting of that equilibrium. The system is perfectly associated.

(*iii*) The set of "experimental" points consisted in each case of 25 single "measurements" evenly spaced in the function of concentration with constant accuracy of heat measurement ±0.5%.

The choice of the limits of concentrations for testing was determined by the possibility of measuring the heat with the required accuracy. For Picker's calorimeter we assumed minimal $Q_{dil} = 0.008$ J, while for batch solution calorimeter it was $Q_{dil} = 0.2$ J.

Standard deviation values (δK_d and $\delta \Delta H_d$) were calculated on the basis of the 0.5% error in the "measurement" of the dilution enthalpy whose values were determined for the assumed K_d and ΔH_d of the process. It should be stressed that, thus calculated, the δK_d and $\delta \Delta H_d$ values are not to be identified with the expected error in the experimental determination of the two quantities. The differences between the two sets of quantities are shown in Table 2 for the HBz + C_6H_6 system. The fact that in the case of experimental results the SD values are higher than those calculated before the experiment may be due to the presence, in the experiment, of accidental errors exceeding 0.5%, as well as to the possibility of a systematic error in the model for which it was impossible to make allowances during testing. The uncertainty vs. predicted SD ratio is ca. 10:1. Figures 1 and 2 show the effect of the dimerization constant (log K_d) on δK_d and $\delta \Delta H_d$ for different values of the $C_{initial}/C_{final}$ ratio (N).

The assumed error of calorimetric measurement Q_{exp} (±0.5%), which is constant regardless of the effect measured, coincides with the constant values of the relative error ΔH_{dil}. Consequently, the value of dimerization enthalpy has no effect whatever on δK_d or $\delta \Delta H_d$. Assuming that the ratio of real error to that calculated before experiment is approximately constant (10:1) and independent of K_d, it can be noticed that heat of dilution measurements yield the most accurate results when: a low N dilution calorimeter is used (error is lowest when $N = 4$ for log $K_d > 1.5$ and $N = 2$ for log $K_d < 1.5$); and the expected value of the dimerization constant is low. The minimum error for both quantities (K_d, ΔH_d) occurs when $50 > K_d > 5$ L/mol.

Regardless of the above, the accuracy increases when a wide range of acid concentrations in nonpolar medium is employed, although high concentrations should be avoided because of the possibility of specific and nonspecific interactions which are not taken into account in the model. One can expect that for systems for which $K_d < 1000$ L/mol, the accuracy of K_d and ΔH_d determination by the calorimetric method should be satisfactory (err. $K_d < 25\%$, err. $\Delta H_d < 10\%$), and it will rise as the value of K_d decreases.

Trimerization of carboxylic acids and calorimetric measurements

Minimizing experimental calorimetric data ΔH_{dil}, Krishnan *et al.* (7) described in thermodynamic terms the process of benzoic acid trimerization in benzene. According to the authors, the following considerations suggest that the solution contains trimers: (*a*) the calorimetrically determined dimerization constant of HBz in benzene is lower than those reported in the literature and obtained in other ways; (*b*) the plot of ϕ_L vs. $(-\phi_L/C)^{1/2}$ diverges from linearity (ϕ_L is the relative apparent molar enthalpy of acid in benzene); and (*c*) there is a distinct (the authors claim) concentration dependence on K_d obtained for the monomer–dimer model. The analysis and calculations we have carried out on Krishnan's results suggest that the above divergences may be accounted for in some other way. Let us thus consider the trimerization evidence (7) item by item.

(*a*) It seems to us that the difference between the K_d value obtained by Krishnan (500 L/mol) and those obtained by other

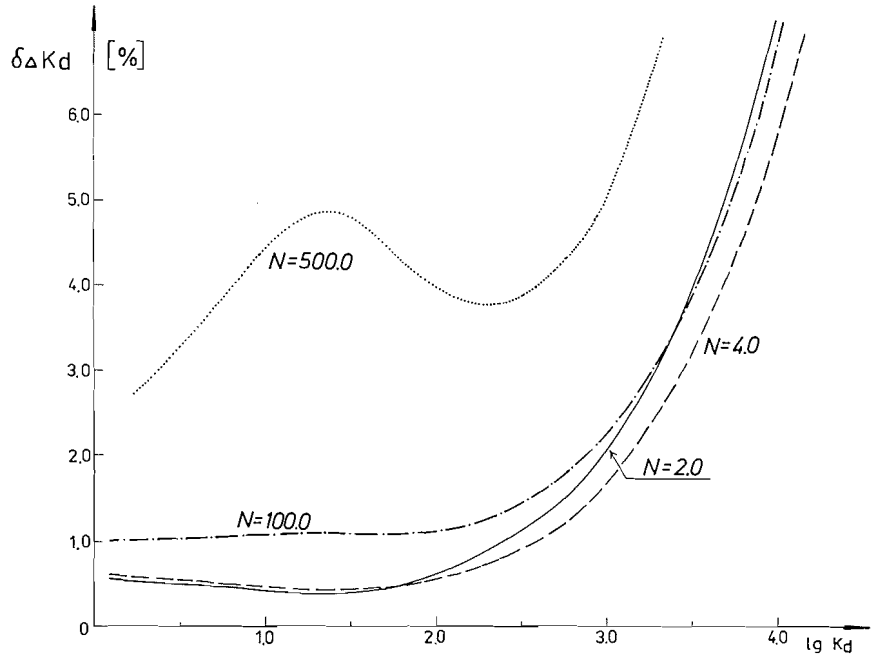

FIG. 1. The effect of the equilibrium constant of dimerization (as log K_d) on the SD of calorimetrically determined K_d values. (ΔQ_{exp} = ±0.5%).

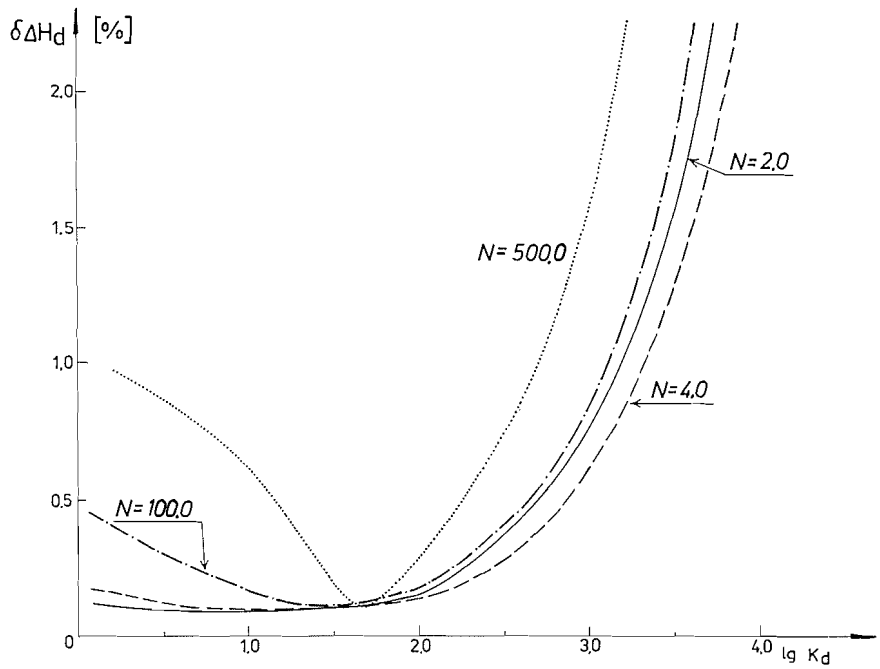

FIG. 2. The effect of the equilibrium constant of dimerization (as log K_d) on the SD of calorimetrically determined ΔH_d values.

methods (11–14), which amounts to about 100 L/mol, does not necessarily have to indicate the presence of trimers in the HBz–benzene system. As can be seen in Table 1, the use of ΔH_{dil} as the minimization criterion produces K_d values of 575 L/mol, δK_d = 25 L/mol, which practically coincide with literature data. Krishnan used the same minimization criterion for the description of the monomer–dimer–trimer model and obtained K_d = 625 L/mol. The convergence of all the data becomes especially evident when account is taken of the error in K_d determination, usually set at ca. 15–20%, which corresponds to ~100 L/mol independent of the method used.

(*b*) The curvature of the plot ϕ_L vs. $(-\phi_L/C)^{1/2}$ observed by Krishnan becomes considerably less pronounced when it is drawn on the basis of ϕ_L values with the lower limit of error reported in the cited work. The error in the value of ϕ_L is in this case ~1000 J/mol, which corresponds to 7–15% of the absolute value of ϕ_L. The slight divergence from linearity can be reduced still further if concentration is replaced by unknown activity; in concentrated solutions "*a*" may well be smaller than "*C*", with the difference growing with increasing concentration. The distinct nonideality of the system may be due to interactions between systems of π-electrons in the rings of both the acid and benzene molecules. Another type of interaction may be weak H-bonds of H···π type arizing with monomers whose number changes with changes in the concentration, or 1.5% hydration of monomers (7).

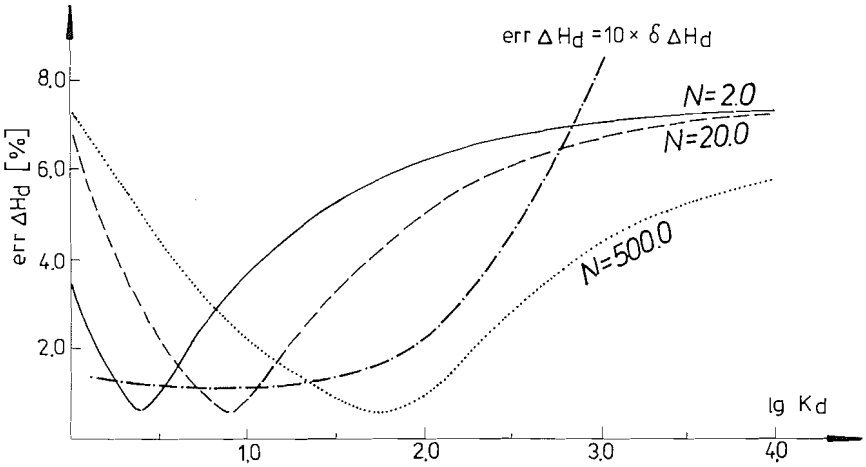

FIG. 3. Plot of the predicted error in ΔH_d vs. dimerization constant in the approach combining spectroscopy and calorimetry (dot-and-dash line, estimated; approximate error involved in calorimetry used alone, err $\Delta H_d = 10 \times \delta\Delta H_d$, see text).

(*c*) The strong, systematic dependence of the dimerization constant on the concentration may, in fact, indicate the presence of another equilibrium, not included in the model employed. Using the "best" of the values obtained by us $\Delta H_d = -36.81$ kJ/mol (Table 1), we calculated once again the K_d values for all the experimental points (7). The plot of $K_d = f[(C_i + C_f)/2]$, where C_i is the initial concentration and C_f is concentration of the acid after dilution, appears to be a collection of points which does not exhibit any distinct (rising or falling) functional dependence. The strong random scatter of K_d values (from ~450 L/mol to ~650 L/mol) is doubtless related to the considerable sensitivity of the equilibrium constant to even slight (±0.5%) error in ΔH_{dil}. It seems to us that the calorimetric method used alone should not be employed in studies of the other forms of association in acid solutions. The reason is the weak sensitivity of thermal effects to the presence (or absence) of relatively minor amounts of different stoichiometry associates.

Determination of ΔH_d by the combined use of spectroscopy and calorimetry

The analysis carried out above of the accuracy with which the functions of dimerization are determined made us look for ways of improving that accuracy. This, we think, is possible if calorimetry is used together with spectroscopy. The approach, which consists in determining the thermal effects calorimetrically and the equilibrium constant spectroscopically, has not, so far, been used in studies of carboxylic acid dimerization. Nevertheless, already in the 1960's Lamberts *et al.* (15, 16) and Arnett *et al.* (17, 18) combined the spectroscopically determined value of the equilibrium constant with calorimetric heat measurements in an attempt to establish the enthalpy of 1 : 1 donor–acceptor complex formation. The combined use of the two methods has also been found useful in studies of relatively complex associative systems (19, 20).

The value of K_d, established by spectroscopy, makes it possible to calculate the value of ΔH_d on the basis of a single calorimetric experiment, for all the variables appearing in the function $\Delta H_d = f(K_d, \Delta H_{dil}, C_{initial}, C_{final})$ are known. Practically speaking, the required number of measurements is such that the obtained value of ΔH_{dil} should not involve random error exceeding the assumed level of ±0.5%. We have considered the applicability of such a combined approach to the monomer–dimer equilibrium. The aim of the exercise was to find the range of K_d and ΔH_d values for which the combined approach produces more accurate ΔH_d data than either method employed independently of the other. The expected error in ΔH_d determination was calculated using the differential method. The constant sources of error adopted in the calculations included the value quoted, e.g., by Zhukova *et al.* (21) ($\Delta K_d = 15\%$) and $\Delta Q_{exp} = 0.5\%$ (error in calorimetric measurement). We found that the error due to possible inaccuracy of concentration measurement was negligible. The results obtained for different values of N are presented in Fig. 3 as plots of err $\Delta H_d = f(\log K_d)$.

Similarly, as before, the change of ΔH_d has no effect on the magnitude of the predicted error (err ΔH_d). Also the value of concentration C_i at which the experiment is carried out has little effect on it. As can be seen from Fig. 3, for equilibrium constants for which $\log K_d > 1.5$, the most accurate ΔH_d value can be achieved using 500 times dilution with, e.g., a batch solution calorimeter. Of greatest importance for the experimenter is the range of K_d values which closely approaches the minimum of the function err $\Delta H_d = f(\log K_d)$ as well as the fact that it shifts as N changes. The spectroscopically determined value of K_d makes it possible to select the experimental conditions (i.e. N) in such a way that the sought value of ΔH_d involves minimum error. By appropriately selecting the ratio of initial and final concentrations in heat measurements, it is possible to determine the value of ΔH_d for any K_d (when $\log K_d > 0.2$) more accurately than when calorimetry alone is used (Fig. 3). Regardless of the value of the dimerization constant, the procedure proposed here should yield more accurate results than the spectroscopic method, where the error in ΔH_d determination is estimated to be 10% or more (22).

It is thus possible to select optimal experimental conditions and the most appropriate method of determining the parameters which describe the equilibrium state in a solution even before measurements are carried out. We hope that it will also be possible to predict errors and to identify ways of reducing them in the case of more complex donor–acceptor systems, such as those we dealt with in earlier studies (19, 20).

Complexes of platinum group metals with the ambidentate ligands $Ph_2P(CH_2)_nSPh$ (n = 1, 2)

ALAN R. SANGER

Alberta Research Council, 11315 - 87 Avenue, Edmonton, Alta., Canada T6G 2C2

Received November 24, 1982

ALAN R. SANGER. Can. J. Chem. **61**, 2214 (1983).

The potentially bidentate ligands $Ph_2P(CH_2)_nSPh$ (n = 1, 2) form complexes of rhodium(I), iridium(I), palladium(II), or platinum(II) in which ligands are coordinated to a metal centre either by the phosphine function alone, or by the phosphine and thioether functions, or both. Successive displacement of chloro-ligands from $[MCl_2(Ph_2PCH_2CH_2SPh)_2]$ (M = Pd, Pt) gives the cationic complexes $[MCl(Ph_2PCH_2CH_2SPh)_2]^+$ and $[M(Ph_2PCH_2CH_2SPh)_2]^{2+}$. In the latter each ligand is chelating, but in the former, one ligand is monodentate and the other bidentate. Homopolynuclear complexes may also be synthesized in which metal centres are bridged by $Ph_2P(CH_2)_nSPh$. The complex $[RhCl(Ph_2PCH_2SPh)(C_8H_{12})]$ contains cyclooctadiene as a monodentate ligand.

ALAN R. SANGER. Can. J. Chem. **61**, 2214 (1983).

Les ligands potentiellement bidentates du type $Ph_2(CH_2)_nSPh$ (n = 1, 2) forment des complexes de rhodium (I), d'iridium (I), de palladium (II) ou de platine (II) dans lesquels les ligands sont coordonnés au centre métallique soit par la fonction phosphine uniquement, soit par les fonctions phosphine et thioéther, ou par les deux. Les déplacements successifs des ligands chlorés du $[MCl_2(Ph_2PCH_2CH_2SPh)_2]$ (M = Pd, Pt) donnent les complexes cationiques de $[MCl(Ph_2PCH_2CH_2SPh)_2]^+$ et de $[M((Ph_2PCH_2CH_2SPh)_2]^{2+}$. Dans ce dernier, chaque ligand est chélatant, mais dans le premier complexe un ligand est monodentate, et l'autre est bidentate. On peut également synthétiser des complexes homopolynucléaires dans lesquels les centres métalliques sont pontés par le $Ph_2P(CH_2)_nSPh$. Le complexes $[RhCl(Ph_2PCH_2SPh)(C_8H_{12})]$ contient le cyclooctadiène comme ligand monodentate.

Introduction

Potentially bidentate ligands may form a variety of complexes in which such ligands are monodentate, bidentate chelating, or bidentate bridging in behaviour (1). Within each of these classes further variation can arise depending on the site(s) of coordination of the ligand, mutual conformation of ligands about each metal centre, and, especially in the case of the bidentate bridging mode, the presence or absence of a metal–metal interaction and any other bridging ligand. Previously, we in this laboratory have shown that the diphosphines $Ph_2P(CH_2)_nPPh_2$ (n = 1–4) or the dithioethers $PhS(CH_2)_nSPh$ (n = 1–6) form platinum-group metal complexes of each type (2–5). The coordination mode of a bidentate ligand and degree of aggregation of each complex depend upon not only the nature and oxidation state of the central metal atom, but also steric effects. These effects are largely determined by the angle that a ligand would subtend at the metal centre if it chelated the metal ion, and this in turn is directly determined by the value of n (2–5). In each case the thioether ligands are more labile than the corresponding phosphine ligands.

Recently, interest has grown in complexes of ligands with dissimilar donor sites (6–10). These have included phosphine or arsine ligands which also contain nitrogen or oxygen donor sites (e.g., refs. 6, 7), or dissimilar phosphorus donor sites (e.g., ref. 8). 2-Diphenylphosphinoethanethiol, or its derived anion, has been considered as a 1-, 2-, 3-, or 5-electron donor ligand (9), demonstrating the versatility of such a system. A small number of other P and S donor ligands have been investigated, but much less intensely than either (P, P) or (S, S) bidentate ligands (10).

In addition to features in common with other potentially bidentate ligands, the ligands $Ph_2P(CH_2)_nSPh$ (herein abbreviated as "PS(n)") are of interest for the following reasons. (*1*) When the phosphine and thioether functions are both coordinated to a platinum-group metal the thioether is expected to be more labile than the phosphine, permitting facile generation of a "vacant site" at the metal centre. Consequently, oxidative addition or substitution reactions may be more readily effected. Further, the phosphine function may confer sufficient stability to an intermediate containing a vacant site to permit such a complex to behave as an effective catalyst. (*2*) Preferential coordination of phosphine and thioether functions to different metals offers the possibility of formation of heterodinuclear complexes, in a manner similar to that of 2-diphenylphosphinopyridine (6). (*3*) There exists the potential for both geometric and coordination isomerism in complexes of these ligands. Consequently, an investigation into the chemistry of systems containing the ligands PS(n) and platinum-group metals is being performed. Data concerning some complexes of rhodium(I) have been reported in a letter (5), and a series of complexes of ruthenium(II) and -(III) with PS(2) has been described (11). Herein the preparation of complexes of PS(1) and PS(2) with rhodium(I), iridium(I), palladium(II), and platinum(II) will be reported.

Experimental

All manipulations were performed in dry, oxygen-free solvents, except where so noted. Analyses were performed by Alfred Bernhardt Mikroanalytisches Laboratorium, Germany, or Canadian Microanalytical Service Ltd., Vancouver, B.C. Spectra were obtained using the following instruments: ir, Perkin Elmer 283; nmr, Bruker WP80. Conductivities were determined for solutions in acetone (2×10^{-4} to 2×10^{-3} M) or other solvents using a Radiometer CDM2e conductivity meter.

The metal complexes $[RhCl(cod)]_2$, $[RhCl(CO)_2]_2$, $[IrCl(cod)]_2$, $PdCl_2$, $[PdCl_2(PhCN)_2]$, $K_2[PtCl_4]$, and $[PtCl_2(PhCN)_2]$ (cod is 1,5-cyclooctadiene) were either commercially available (Strem, Alfa, Terochem) or synthesized using standard procedures. The ligand $Ph_2PCH_2CH_2SPh$, PS(2), was prepared by a published method (12).

Preparation of Ph_2PCH_2SPh, PS(1) (synthesis by C. G. Lobe)

CAUTION! Chloromethyl sulfides are suspected carcinogens, and should be treated as hazardous materials.

Chloromethylphenylsulfide (7.89 g, 0.05 mol) was added dropwise

to a stirred solution of potassium diphenylphosphide (0.05 mol) in tetrahydrofuran (70 mL). The mixture was successively stirred overnight at room temperature, refluxed (4 h), and cooled to room temperature. Water (50 mL) was added to destroy remaining $KPPh_2$ and to dissolve KCl. The organic layer was then separated, and most of the solvent was removed under reduced pressure. The white wax so formed was dissolved in acetone, water was added, and the mixture was filtered to give $Ph_2PCH_2CH_2SPh$ as white crystals (6.9 g, 45%) which were then dried under vacuum. Evaporation of acetone from the mother liquor gave further crops of impure material. *Anal.* calcd.: C 74.00, H 5.56; P 10.04, S 10.40%; found: 73.93, H 5.63, P 9.46, S 10.32. NMR: ^{1}H: doublet (CH_2) δ 3.6 (J = 3.1 Hz), multiplet (Ph) δ 7.4 ppm (vs. $(CH_3)_4Si$); ^{31}P: δ_P −18.0 ppm (vs. 85% H_3PO_4). $Ph_2P(CH_2)_nSPh$ (n = 3, 4) and related materials may be prepared in a similar manner.

Both PS(1) and PS(2) are white, crystalline materials. The former is much more sensitive to both oxidation and thermal decomposition than the latter. PS(3) and 2-diphenylphosphinothiophene are extremely air-sensitive waxy or oily materials which are difficult to manipulate.

Preparation of metal complexes of PS(1) or PS(2)

These syntheses were each performed at room temperature or gentle reflux, and are listed in Table 1. Examples are given below. Analyses and conductivities of the products are listed in Table 2, and the ir and ^{31}P nmr spectra are listed in Table 3.

Example 1: Preparation of [Rh($Ph_2PCH_2CH_2SPh$)$_2$]BPh_4 and [Rh(CO)($Ph_2PCH_2CH_2SPh$)$_2$]BPh_4

A mixture of ethanol (50 mL), $Ph_2PCH_2CH_2SPh$ (0.591 g, 1.835 mmol) and $[RhCl(cod)]_2$ (0.224 g, 0.455 mmol) was stirred (1 h) under an atmosphere of nitrogen. A solution of Na[BPh_4] (0.4 g, excess) in ethanol (20 mL) was slowly added, and a yellow precipitate formed rapidly. The mixture was stirred (15 min), filtered, and the precipitate washed with ethanol and then dried under vacuum to give, as a yellow product, [Rh($Ph_2PCH_2CH_2SPh$)$_2$]BPh_4 (0.775 g, 80%).

A sample of the above complex (0.270 g, 0.253 mmol) was dissolved in dichloromethane (25 mL) under an atmosphere of CO. Ethanol (40 mL) was added to form a separate layer. The layers were gradually mixed, and the dichloromethane slowly evaporated to give, as a yellow, microcrystalline product, [Rh(CO)($Ph_2PCH_2CH_2SPh$)$_2$]-BPh_4 (0.223 g, 80%). Further evaporation of solvents gave additional product.

Example 2: Preparation of trans-*[IrCl(CO)($Ph_2PCH_2CH_2SPh$)$_2$]*

Under an atmosphere of carbon monoxide $[IrCl(cod)]_2$ (0.142 g, 0.212 mmol) was added to a solution of $Ph_2PCH_2CH_2SPh$ (0.279 g, 0.868 mmol) in dichloromethane (25 mL), and the mixture was stirred until a lemon−yellow solution was formed. Ethanol (10 mL) was added, and the mixture allowed to slowly evaporate under a stream of CO to leave a sticky mass. Pentane (25 mL) was added and the mixture successively stirred (1.5 h), filtered, and the bright lemon−yellow product dried under vacuum. The first crop of *trans*-[IrCl(CO)-($Ph_2PCH_2CH_2SPh$)$_2$] was 0.184 g (48%). Successive crops could be retrieved by further trituration of the sticky material in the flask under pentane.

Results and discussion

(A) Complexes of rhodium(I) and iridium(I)

In this and the following section complexes will be designated by the appropriate number from Tables 1−3.

Cleavage of the dinuclear complexes $[MCl(cod)]_2$ (M = Rh or Ir) occurs upon reaction with PS(1). The 1:1 complex [RhCl{PS(1)}(cod)], **4**, was readily isolated (eq. [2]), but the analogous iridium complex was not.

[2] $[RhCl(cod)]_2 + 2Ph_2PCH_2SPh \rightarrow 2[RhCl(cod)(Ph_2PCH_2SPh)]$

The ir spectrum of **4** exhibits a band assigned as Rh—Cl stretch, and the material is a non-electrolyte in solution in acetone. The ^{31}P nmr parameters are appropriate for a square-planar complex of rhodium(I). The ^{1}H nmr spectrum at 223 K of a solution of **4** in $CDCl_3$ revealed signals appropriate for the ligand PS(1) and 1,5-cyclooctadiene (1:1). The signals for PS(1) are at δ_H 4.1 (J(PH) = 5.4 Hz) and 7−8 ppm (($Si(CH_3)_4$ = 0), in the ratio 2:15. The cyclooctadiene signals at δ_H 5.6, 3.0, and 1.4−2.8 ppm, in the ratio 2:2:8, demonstrate that this ligand is monodentate in this complex. No coupling to rhodium was observed; signals for cyclooctadiene protons are each 10−15 Hz wide at half-heights, compared to 2−4 Hz for

signals for the PS(1) protons. The ^{1}H nmr of either $[MCl(cod)]_2$ (M = Rh or Ir) exhibits signals at δ 4.3 and 0.8–2.8 ppm in the ratio 4:8; no coupling to rhodium is observed. Therefore **4** contains PS(1) as a bidentate ligand. With an excess of PS(1), the iridium complex isolated from a reaction similar to [2], above, is the 2:1 complex $[IrCl\{PS(1)\}_2(cod)]$, **7**. In the absence of a metal–phosphorus coupling constant the ^{31}P nmr spectrum is less informative about the nature of **7** than of **4**. However, it should be noted that the phosphorus atoms are equivalent. An Ir—Cl stretching band is observed in the ir

[b]Spectra were normally obtained at 223 K from solutions in dichloromethane-d_2 except where so noted in the text, and are ^{1}H-decoupled. Chemical shifts are in ppm versus external 85% H_3PO_4, and coupling constants are in Hz.
[c]$^2J(P_A—P_B)$ = 14.9 Hz.

spectrum, and the material is a non-electrolyte. If complex **7** contained a chloro-ligand, coordinated cyclooctadiene, and two bidentate PS(1) ligands it would be a 20- or 22-electron complex, and so it must instead be a five-coordinate complex of iridium containing two equivalent monodentate(P) PS(1) ligands.

Reaction of **7** with Na[BPh_4] gave the complex [Ir{PS(1)}$_2$]-BPh_4, **9**, in which the phosphorus ligands are again equivalent (^{31}P nmr) (eq. [3]).

[3] [IrCl(cod)(η^1-Ph_2PCH_2SPh)$_2$] + Na[BPh_4] → NaCl + [Ir(η^2-Ph_2PCH_2SPh)$_2$]BPh_4 + cod

Reaction of an excess of PS(2) with [IrCl(cod)]$_2$ gave the complex [IrCl{PS(2)}$_2$], **8**. The rhodium analog has not been isolated in an analytically pure state, but its existence in solution can be inferred from a subsequent reaction. Reaction of a solution of either chloro-complex with Na[BPh_4] gave [M{PS(2)}$_2$]BPh_4 (**5**, M = Rh; **10**, M = Ir). In each case the product is of limited solubility in ethanol but readily soluble in either dichloromethane or acetone, in which they are 1:1 electrolytes. Reaction of solutions of **5** or **10** with CO gave the corresponding monocarbonyl complexes, **6** or **11**. The phosphorus atoms are in each case equivalent down to 203 K (^{31}P nmr), and the phosphorus−rhodium coupling constant (100.7 Hz) is appropriate for equatorial phosphine ligands. For [Rh(CO)$_2$(η^1-diop)(η^2-diop)]$^+$ the corresponding values are J(Rh—P_{ax}) = 131 Hz and J(Rh—P_{eq}) = 106 Hz, and for [Rh(CO)(η^2-$Ph_2PCH_2CH_2CH_2PPh_2$)$_2$]$^+$ they are J(Rh—P_{ax}) = 115 Hz and J(Rh—P_{eq}) = 86 Hz (2). For the phosphorus atoms to be equivalent each PS(2) must be coordinated to Rh the same. These data are consistent with complexes **6** and **11** being trigonal bipyramidal, with axial thioether ligands (Fig. 1), or being a square-pyramidal structure. However, this latter option is less-precedented.

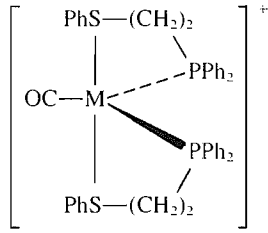

FIG. 1. Trigonal bipyramidal complexes with axial thioether ligands (M = Rh, Ir).

Although addition of CO to the complex cation, [Rh($Ph_2PCH_2CH_2CH_2PPh_2$)$_2$]$^+$, to form trigonal bipyramidal [Rh(CO)($Ph_2PCH_2CH_2CH_2PPh_2$)$_2$]$^+$ is facile, no similar reaction occurs for [Rh($Ph_2PCH_2CH_2PPh_2$)$_2$]$^+$ (2). The ready formation of **6** by addition of CO to **5** is therefore noteworthy. The ring size in chelated complexes of $Ph_2PCH_2CH_2PPh_2$ and $Ph_2PCH_2CH_2SPh$ will be very similar, and addition of CO to square-planar complexes to form trigonal bipyramidal complexes of each would be expected to affect each in a similar manner. The thioether functions in the latter, however, furnish one pendant phenyl group less than the corresponding phosphine function, thereby removing some of the potential steric constraints to formation of a five-coordinate, bis-chelated, complex. The singular inability of [Rh($Ph_2PCH_2CH_2PPh_2$)$_2$] to add CO to form such a five-coordinated complex cation must therefore be due to the unfavourability of the required conformation of the pendant phenyl groups in the anticipated product. The longer chain-length of $Ph_2PCH_2CH_2CH_2PPh_2$ requires that the conformations of the phenyl groups in the corresponding carbonyl complex are different, and do not prevent the formation of the five-coordinate complex.

Reaction of either [RhCl(CO)$_2$]$_2$ or [RhCl(cod)]$_2$ under an atmosphere of CO, with an equivalent amount of PS(2) gave the *cis*, chelated, mononuclear complex **1** (Fig. 2). The ir and ^{31}P nmr parameters of **1** are entirely comparable with the parameters of the corresponding complex of $Ph_2PCH_2CH_2PPh_2$ (2), or of [RhCl(CO)($Ph_2PC_6H_4NMe_2$)] (14).

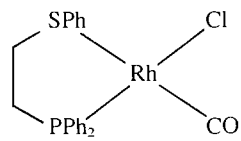

FIG. 2. Chelated, *cis*-, mononuclear complex **1**.

Reaction of either [MCl(cod)]$_2$ (M = Rh or Ir) or [RhCl-(CO)$_2$]$_2$, under an atmosphere of CO, with an excess of either PS(1) or PS(2) gave in each case the complexes [MCl(CO)(L)$_2$], **2**, **3**, and **12**. The ir spectrum of each product features single carbonyl and metal−chlorine stretching bands. The ^{31}P nmr spectra show that the phosphorus nuclei are equivalent in each complex. Complexes **2**, **3**, and **12** are therefore each of *trans* geometry, and each PS(1) or PS(2) ligand is monodentate (P) (Fig. 3).

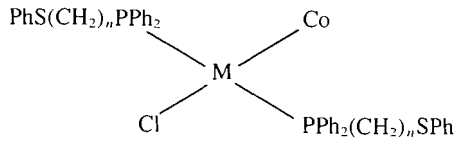

FIG. 3. Geometry (*trans*-) of **2**, **3**, and **12** (M = Rh, Ir).

Although attempts to prepare the homodinuclear complexes $[MCl(CO)\{PS(1)\}]_2$ have so far only given impure materials, complexes related to "A-frame" complexes of $Ph_2PCH_2PPh_2$ have been prepared. Attempts to prepare the above dinuclear complexes in an analytically pure state are continuing.

(B) Complexes of palladium(II) or platinum(II)

Reaction of an equivalent amount of PS(2) with $[PdCl_2(PhCN)_2]$ slowly displaced benzonitrile to give the 1:1 complex $[PdCl_2(Ph_2PCH_2CH_2SPh)]$, **14**. The observation of two metal–chlorine stretching bands in the ir spectrum is consistent with a *cis*, chelated structure (Fig. 4), analogous to $[PdCl_2(o\text{-}Ph_2PC_6H_4SPh)]$ (15). In contrast, the 1:1 product (**13**) of the reaction of $[PdCl_2(PhCN)_2]$ with an equimolar amount of PS(1) exhibits only one ir band assigned as a metal–chlorine stretch.

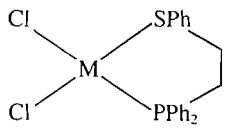

FIG. 4. Chelated (*cis*) structure (M = Pd, Pt).

Although the limited solubility of complex **13** in appropriate solvents renders a determination of the molecular weight less reliable than is desirable, the value obtained indicates that the product is tetranuclear. All phosphorus atoms are equivalent (^{31}P nmr). Because only one Pd—Cl band was observed in the ir spectrum it is unlikely that two phosphine moieties are coordinated to two palladium atoms while two thioether moieties are coordinated to the other two. Complex **13** is therefore presumed to have the structure shown in Fig. 5.

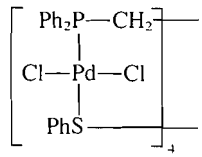

FIG. 5. Cyclic complex.

Reaction of $[MCl_2(PhCN)_2]$ (M = Pd, Pt) with an excess of PS(1) or PS(2) gives the corresponding 2:1 complexes **15** or **16** (M = Pd) and **19** or **20** (M = Pt) respectively. Reaction of an ethanolic solution of **16** or **20** with an equimolar amount of $NaBPh_4$ gave in each case the 1:1 electrolyte $[MCl\{\eta^1\text{-}PS(2)\}\{\eta^2\text{-}PS(2)\}]BPh_4$, **21** (M = Pd) or **22** (M = Pt). Reaction of an acetone solution of **21** or **22** with an excess of $NaBPh_4$ gave the 2:1 electrolytes $[M\{\eta^2\text{-}PS(2)\}_2](BPh_4)_2$, **23** and **24**, respectively.

Complex **15** is a non-electrolyte and exhibits only one Pd—Cl band in the ir spectrum, and is therefore presumed to be of *trans* geometry with monodentate(P) PS(1) ligands. The ^{31}P nmr spectrum at 309 K or 223 K exhibits only a broad signal; the reason for the breadth of this signal at all temperatures is not yet clear. Complexes **19** and **20** each exhibit two Pt—Cl bands in the ir spectra and a single environment for phosphorus in the ^{31}P nmr spectra. These complexes are therefore of *cis* geometry, also with monodentate PS(1) or PS(2) ligands respectively. Complex **16** exhibits not only an ir band at 325 cm^{-1}, close to the Pd—Cl band for **15**, but also a strong band at 363 cm^{-1}, the origin of which is not yet clear. Complex **16** is a 1:1 electrolyte in acetonitrile, but a weak electrolyte in dichloromethane, suggesting that an equilibrium (eq. [4]) may exist.

[4] 
The ^{31}P nmr spectra of CD_2Cl_2 solutions of the 1:1 electrolytes **21** and **22** at room temperature each show only a single, very broad signal. However, for a solution of **22** at 233 K signals due to different phosphorus nuclei are resolved, each of which is coupled to ^{195}Pt, corresponding to mono- and bidentate PS(2) ligands. At 203 K fine structure due to coupling of each to ^{195}Pt and to each other is resolved. The values for $^1J(Pt—P_A)$ and $^1J(Pt—P_B)$ demonstrate that each phosphorus is coordinated to platinum. The value of $^2J(P_A—P_B)$ shows that the phosphine ligating moieties are mutually *cis*. Unfortunately, attempts to obtain comparable spectra for **21** again gave only broad signals to 223 K. The ^1H nmr spectrum for each complex is unexceptional, with signals appropriate for the methylene and aromatic protons in approximately correct ratios for the monocationic tetraphenylborate complexes.

The dicationic complexes **23** or **24** are 2:1 electrolytes in acetone, and the ^{31}P nmr spectra show a single environment for phosphorus in each complex. It is noteworthy that the more rigid related ligand $o\text{-}Ph_2PC_6H_4SPh$ is constrained to exhibit only bidentate, chelating behaviour in its complexes with palladium (15).

Intimate agitation of an aqueous solution of $K_2[PtCl_4]$ and a dichloromethane solution of PS(2) gave the 1:1 complex, **17**, as a white precipitate. Complex **17** exhibits only one Pt—Cl band in the ir spectrum, and is therefore presumed to be of *trans* geometry. Attempts to recrystallize this material, or to prepare solutions for nmr or molecular weight determination, gave pale yellow solutions. When evaporated to dryness these solutions yielded a pale yellow powder of which the ir spectrum was dissimilar from that of **17**. This novel material, **18**, exhibits two Pt—Cl bands, and the ^{31}P nmr parameters (δ_p 40.3 ppm, $^1J(Pt—P)$ 3.594 Hz) are very similar to those of $[PtCl_2(Ph_2PCH_2CH_2PPh_2)]$ (δ_p 45.3, $^1J(Pt—P)$ 3.618 Hz) (16). Therefore it is deduced that **18** is a *cis*, mononuclear, chelated complex (Fig. 4), while **17** is considered to be a *trans*, polynuclear, bridged complex, similar to **13** (Fig. 5).

(C) Attempts to prepare heterodinuclear complexes

To date all attempts using **2** or **3** to prepare complexes of PS(1) or PS(2) containing both a rhodium and a palladium or

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

platinum centre have been unsuccessful.

Reaction of *trans*-[RhCl(CO){PS(2)}$_2$] with [PdCl$_2$(PhCN)$_2$] or K$_2$[PtCl$_4$] gave a mixture of [RhCl(CO){PS(2)}], **1**, and [PdCl$_2${PS(2)}], **14**, or [PtCl$_2${PS(2)}], **18**, respectively. Similarly, reaction of *trans*-[RhCl(CO){PS(1)}$_2$], **2**, with [PdCl$_2$-(PhCN)$_2$] gave, as a bright orange precipitate, [PdCl$_2${PS(1)}]$_4$, **13**, and a solution containing a rhodium complex which has not yet been fully characterized. From none of these reactions was a complex containing P-coordinated rhodium and S-coordinated palladium or platinum isolated. A number of dithioether complexes of palladium and platinum have been prepared which are very stable and contain bridging dithioether ligands (4, 17). The failure to isolate bridged heterodinuclear complexes is therefore ascribed not to any lack of propensity to form Pd—S or Pt—S bonds in such complexes, but to the lability of the Rh—P bond which permits rapid internuclear exchange of ligands.

In contrast, reactions with mercury halides have given a series of mercury and either rhodium or palladium heterodinuclear complexes (18).

Conclusions

Complexes of rhodium(I), iridium(I), palladium(II), and platinum(II) containing the ligands Ph$_2$PCH$_2$SPh or Ph$_2$PCH$_2$-CH$_2$SPh have been synthesized. These ligands may be monodentate, coordinating via the phosphine function only, or bidentate(P, S) bridging or chelating. When the central metal atom is coordinated by two such ligands but no others, they are both bidentate and chelating. When the central metal nucleus is also coordinated to a chloro, cyclooctadiene, or carbonyl ligand, one or two Ph$_2$P(CH$_2$)$_n$SPh ligands may be monodentate(P). However, in the cationic complexes, [M(CO)(Ph$_2$PCH$_2$CH$_2$SPh)$_2$]BPh$_4$ (M = Rh, Ir), each such ligand remains bidentate and chelating.

COMMUNICATION

The synthesis of cofacial porphyrin dimers

JOHN HIOM, JOHN B. PAINE III, UDO ZAPF, AND DAVID DOLPHIN
Department of Chemistry, The University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received May 31, 1983

JOHN HIOM, JOHN B. PAINE III, UDO ZAPF, and DAVID DOLPHIN. Can. J. Chem. **61**, 2220 (1983).

A cofacial dimeric porphyrin joined by two hydrocarbon chains has been prepared using a bis-porphyrin already linked by a single hydrocarbon chain. When each porphyrin bears an acetylenic group, copper catalyzed coupling followed by catalytic hydrogenation gives a doubly linked cofacial porphyrin. However, a far superior and more flexible route, involving the use of a dimeric biladiene-*ac*, gives in one step the same cofacial porphyrin. This latter route has been used to prepare dimeric porphyrins with hydrocarbon linkages of varying lengths.

JOHN HIOM, JOHN B. PAINE III, UDO ZAPF et DAVID DOLPHIN. Can. J. Chem. **61**, 2220 (1983).

On a préparé une porphyrine cofaciale dimère liée par deux chaînes carbonées en faisant appel à une bis-porphyrine déjà liée par une seule chaîne carbonée. Lorsque chaque porphyrine porte un groupe acétylène, un couplage catalysé par le cuivre, suivi par une hydrogénation catalytique, conduit à une porphyrine cofaciale doublement liée. Toutefois, une autre voie beaucoup plus flexible et supérieure, impliquant l'utilisation d'un biladiène *ac* dimère conduit à la même porphyrine cofaciale en une étape. On a utilisé cette dernière voie pour préparer des porphyrines dimères comportant des chaînes carbonées de diverses longueurs.

[Traduit par le journal]

Our interest in the synthesis and study of covalently-linked bis-porphyrins has continued since we first reported such compounds in 1972 (1). Although these first examples were linked via the readily-synthesized amide function, it soon became apparent, even though others have followed these early strategies, that the improved stability and solubility conferred by inert hydrocarbon (polymethylene) linkages could lead to superior substrates for subsequent study.

Our initial studies in these areas resulted in the preparation of dimeric porphyrins singly linked by polymethylene chains (2). The starting point for those compounds and the ones reported here were the bispyrroles (**1**) (the initial reaction described in Scheme I was for R′ = R = Et in **2**–**6**). It was apparent at the outset of our work that dimeric pyrromethenes of type **4** could in principle be made to couple in head-to-tail fashion, to afford doubly linked cofacial porphyrin dimers (**6**). Only the Johnson porphyrin synthesis (3) (cyclization of 1-bromo-19-methyl-biladienes-*ac*) held any reasonable hope of success and to this end a convenient, high yielding route to brominated dimeric pyrromethenes (**4**) had to be found. The traditional bromination (bromine in hot acetic or formic acid) of the dimeric pyrromethene **3** led only to intractable tars. A new procedure was devised whereby the pyrromethene **3** was allowed to stand at room temperature for several days with a modest excess of bromine in dichloromethane (or 1,2-dichloroethane) containing up to 40% (by volume) trifluoroacetic acid. These mild conditions ensure negligible loss to over-oxidation, hydrolysis, or self-condensation and provided the brominated pyrromethene (**4**) pure and in near quantitative yield.

The high dilution coupling of the brominated pyrromethene (**4**) with its precursor **3** was achieved by adding dilute dichloromethane solutions of the components to stannic chloride in dichloromethane–nitromethane. The dimeric biladienes-ac (**5**) were isolated in a crude form and cyclized to porphyrin in dimethylsulfoxide–pyridine for several days at room temperature in the dark. The product (**6**) was then isolated chromatographically. Using the route outlined in Scheme 1 the symmetric porphyrins $m = n = 10$ and 8 (R′ = R = Et) and $m = n = 5$ (R′ = R = octyl) have been prepared. In addition, by using two different chain lengths at the pyrromethene stage (**3**, **4**) cofacial porphyrins with unequal chain-lengths can be made and we have prepared the "clam-shell" porphyrins, $m = 8$, $n = 6$ (R′ = R = Et) and $m = 6$, $n = 5$ (R′ = Et, R = octyl).

While all the spectroscopic and analytical evidence[1] is consistent with the cofacial formulation for the products obtained in the reaction sequences outlined in Scheme 1, we have so far not obtained a crystal suitable for X-ray analysis for any of the dimeric porphyrins. In order to definitively establish the nature of our systems we have devised a rational stepwise synthesis of a cofacial porphyrin. Diborane reduction of 2-benzyloxycarbonyl-4-(2-methoxycarbonylethyl)-3,5-dimethylpyrrole (5) gave the corresponding 3-hydroxypropyl analog which was acetylated and then hydrogenated (Pd/C, THF) to give 4-(3-acetoxypropyl-3,5-dimethylpyrrole-2-carboxylic acid which, condensed with 3-ethyl-2-formyl-4-methylpyrrole, gave the pyrromethene **7** (Scheme 2). Bromination of **7** in the manner described above gave **8** which was condensed with the C-10 bis-dipyrromethene (**3**, R = Et, $n = 10$) to give **9** which was cyclized to the singly linked porphyrin **10**. The acetoxy groups were converted by standard means (6, 7) to the terminal acetylenes (**11**–**13**). Copper catalyzed oxidative coupling of the terminal acetylenic groups of the zinc complex of **13** gave, in moderate yield, the deca-4,6-diynl-10-ylidene decamethylbisporphyrin **14**. Careful hydrogenation (palladium oxide, formic acid) of **14** followed by aerial oxidation of the intermediary porphodimethene gave the bis-porphyrin **15** which proved identical to the porphyrin **6** ($n = m = 10$) prepared by the route outlined in Scheme 1. While the stepwise synthesis establishes the nature of the dimeric porphyrins, the synthetic route outlined in Scheme 1 is clearly the synthetic procedure of choice.

Using polymethylene chains as bridging groups we have overcome one of the major problems of stability, namely hydrolytic cleavage of the bridge if amide or ester linkages are employed. However, the dimeric porphyrins reported here ex-

[1]Satisfactory mass and nmr spectra were obtained for all new compounds.

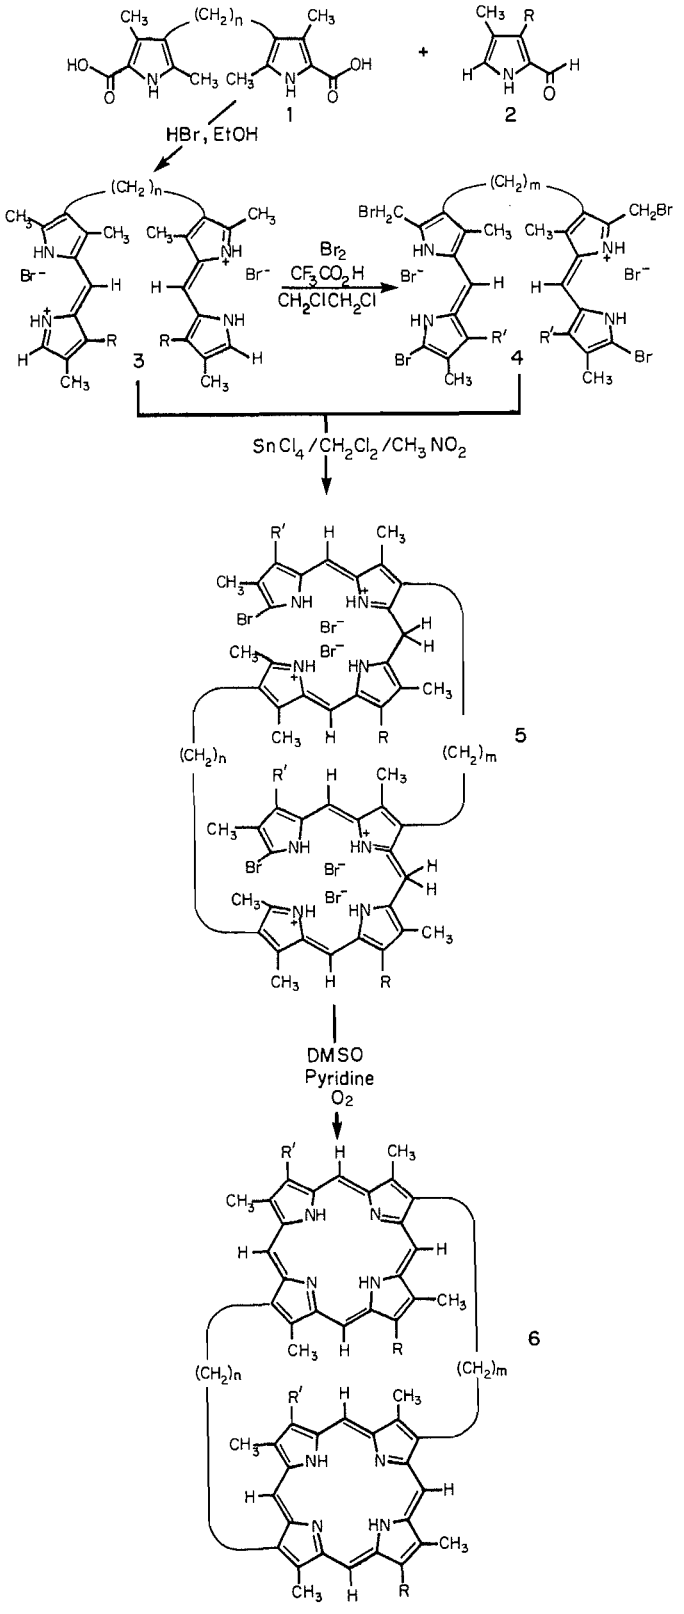

SCHEME 1

hibited low solubility, like previously reported dimeric porphyrins (8). In order to overcome these problems of solubility we have modified the reactions outlined in Scheme 1 by incorporating two octyl side chains in **3** (R = octyl, instead of ethyl as above). This dramatically increases the solubility of the final dimeric products and we now have in hand soluble stable

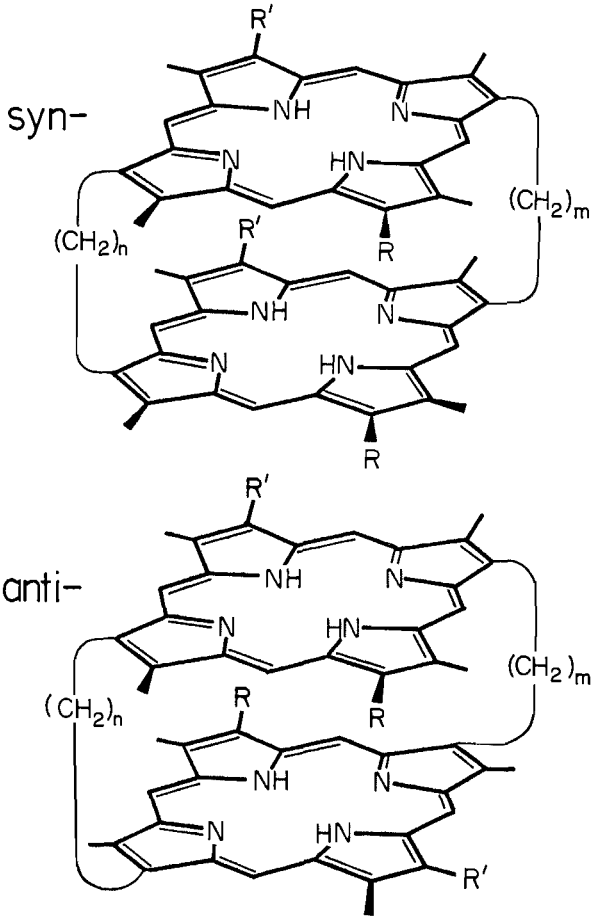

FIG. 1

dimers for future investigation.

The optical spectra of cofacial porphyrins have been reported, and varying degrees of interactions between the porphyrin rings have been observed. Both Chang (9) and Collman *et al.* (10) have observed a blue-shift of about 15 nm in the Soret bands of their cofacial systems with smaller bathochromic shifts in the visible region. Table 1 shows the same qualitative changes with the present systems. However, not only is there an hypsochromic shift in the Soret region, but these bands become progressively broader as the distance between the rings lessens. Furthermore, not only is the distance between the rings important but their relative geometries play a role in these interactions, thus the C_{6-8} dimer shows less of a change relative to etioporphyrin I[2] than the C_{8-8} dimer. Similar but smaller changes were observed (Table 1) with the zinc complexes (prepared by treating the free base in CH_2Cl_2 with zinc acetate in methanol, followed by chromatography over silica), and with the tetraprotonated salts.

During the purification of **6** (m = 6, n = 5; R′ = Et, R = octyl) and **6** (m = n = 5; R′ = R = octyl) two chromatographically separable isomers were obtained in each case. While each pair of isomers show identical mass spectra, their ^{1}H nmr spectra show the same pattern but with slightly different chemical shifts (Table 2). The possibility of forming *syn* and *anti* isomers (Fig. 1) has been alluded to previously for cofacial

[2]Etioporphyrin I (2,7,12,17-tetraethyl-3,8,13,18-tetramethyl-porphyrin) has the same structure as all of the porphyrins described here except that the groups at C_2 and C_{12} are replaced by ethyl groups.

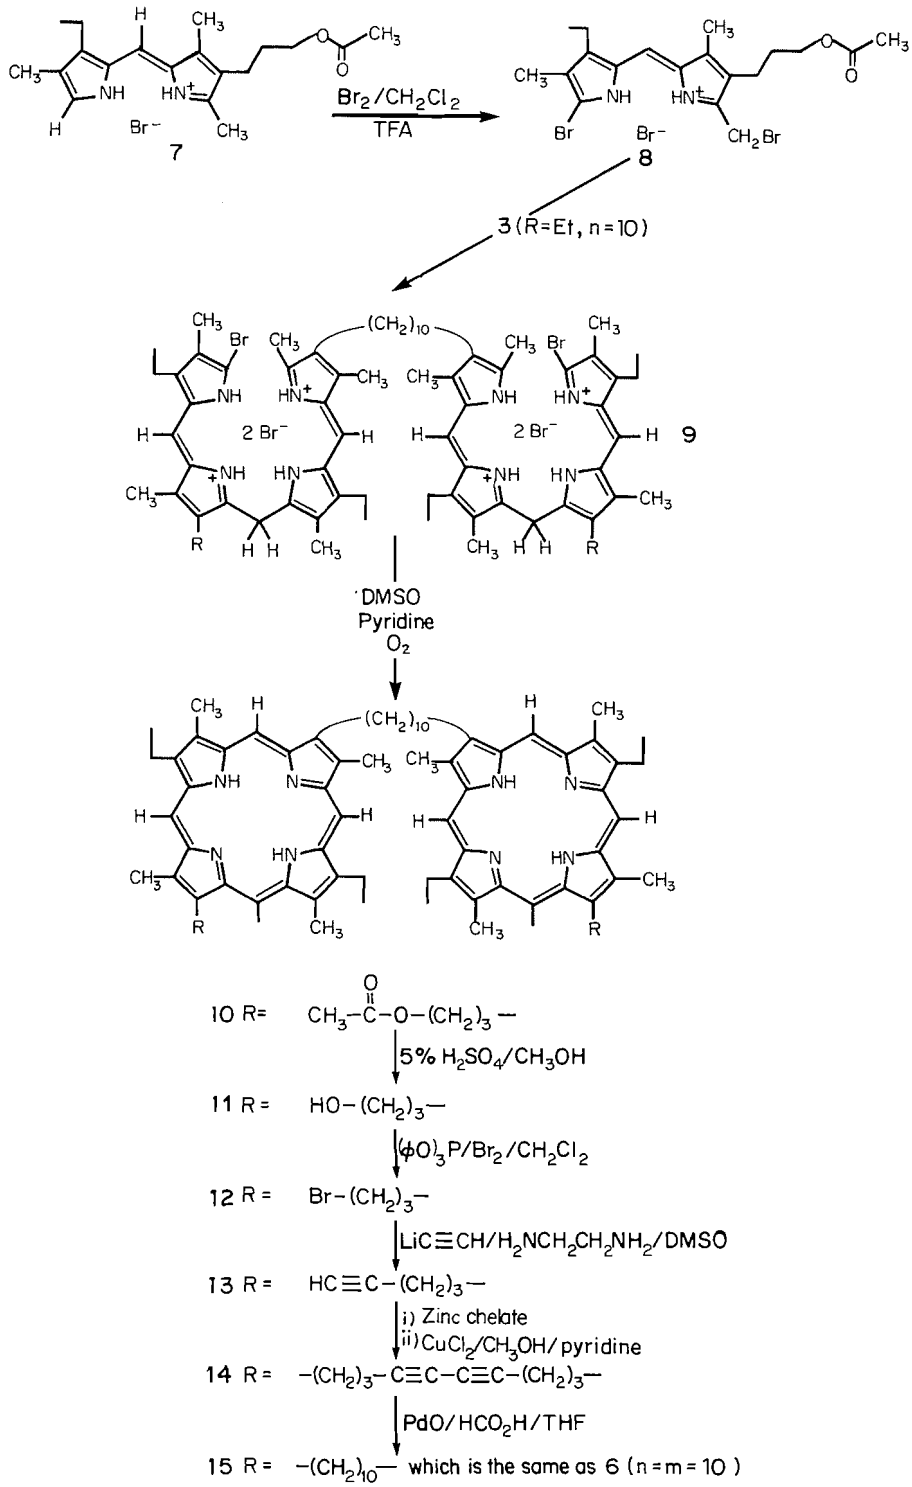

SCHEME 2

porphyrins and such isomers are known when two porphyrins are held cofacial by a common mercuric ion (11). We suspect, in the formation of cofacial porphyrins linked by amides or esters (8, 9), that a single isomer is formed due to the highly strained tetrahedral transition state generated during the formation of the last linkage. However, in the chemistry outlined in Scheme 1, the final intermediate, before oxidation to a porphyrin, is the very flexible porphodimethene. Thus intermediates leading to both *syn* and *anti* isomers will be formed. In the cases **6** ($m = 6$, $n = 5$) and **6** ($m = n = 5$), where the two rings are sufficiently close together that equilibrium between the *syn* and *anti* isomers cannot occur, then both are isolated. However, as the joining chains become longer, equilibrium may occur and, as in the case of **6** ($m = n = 10$), only one isomer is isolated.

Collman, Anson, and their colleagues (4) have shown that dramatic changes in the chemistry of cofacial dimeric porphyrins occur when the rings are forced to be very close (particularly when there are no more than four linking atoms). Our initial attempts at the preparation of **6** ($m = n = 4$) have given

REVIEW/SYNTHÈSE

Acidity functions: an update

ROBIN A. COX AND KEITH YATES
Department of Chemistry, University of Toronto, 80 St. George St., Toronto, Ont., Canada M5S 1A1

Received February 14, 1983

ROBIN A. COX and KEITH YATES. Can. J. Chem. **61**, 2225 (1983).

The subject of acidity functions is reviewed, with emphasis on modern developments. H_0 and other scales determined in acid media, using the Hammett cancellation assumption (zero'th order approximation) are discussed briefly. The extension to strongly basic systems is also documented. Literature references to acidity function scales in aqueous acid, aqueous acid/organic solvent, and aqueous base media are tabulated, together with those in aqueous base/organic solvent mixtures at both variable and fixed base concentration. Over 400 acidity functions are referenced, including several electrochemical scales. Various approaches to developing universal functions from the data are discussed. Proton activity scales, based on the Yates–McClelland method of pK_{BH^+} determination, and on electrochemical H_{GF} scales, are prominent among these. Carpentier's method is mentioned, and the first-order approximation, assumed linearity among log activity coefficient ratios, is used to introduce the Bunnett–Olsen and excess acidity (X-function) methods. A brief critical discussion of which method to use is provided. Future developments anticipate the second-order approximation, with a quadratic dependence of log ionization ratios upon X-functions. The review cites 337 individual references.

ROBIN A. COX et KEITH YATES. Can. J. Chem. **61**, 2225 (1983).

On étudie de nouveau les fonctions d'acidité en tenant compte des nouvelles théories. On discute brièvement des échelles H_0 et des autres échelles déterminées en milieu acide en utilisant l'hypothèse d'annulation de Hammett (approximation d'ordre zéro). On a également étudié les échelles en milieu fortement basique. On a compilé les références de la littérature portant sur les échelles de fonctions d'acidité en milieu acide, en milieu aqueux/solvant organique, et en milieu basique aqueux ainsi que celles portant sur les fonctions en milieu basique aqueux/mélanges de solvants organiques à des concentrations fixes et à des concentrations variables de bases. On a dressé une liste de plus de 400 fonctions d'acidité incluant plusieurs échelles électrochimiques. On discute des différentes approches utilisées pour développer des fonctions universelles à partir des données. Les échelles d'activité du proton basées sur la méthode de détermination du pK_{BH^+} de Yates–McClelland et sur les échelles électrochimiques H_{GF} tiennent la première place. On mentionne la méthode de Carpentier et on utilise l'approximation d'ordre un en supposant la linéarité du logarithme des rapports du coefficient d'activité pour introduire la méthode d'acidité en excès de Bunnett–Olsen (fonction X). On discute brièvement de l'utilisation de telle ou telle méthode. Les développements futurs anticipent une approximation d'ordre deux, avec une influence quadratique des fonctions X sur le logarithme des rapports d'ionisation. La nouvelle étude comporte 337 références.

[Traduit par le journal]

Introduction

The pH scale is open-ended. Just as a hydrogen ion concentration of 1×10^{-4} M translates to a pH of 4, logically it would seem that a 10 M solution should have a pH of -1. Similarly a pH of 15 should apply to a 10 M hydroxide solution. The difficulty, of course, is that these concentrated solutions are non-ideal. Below a pH of about 1.5, and above one of about 13, solutions of acids and bases become much more "acidic" and "basic" than their concentrations would suggest. Since the pH scale cannot be used, acidity scales in non-ideal media have to be measured; these are known as acidity functions, or more recently as excess acidities or basicities.

With acidity scales available, acidity constants outside the range accessible in water can be estimated (1–8), and much useful information concerning the mechanisms of acid- (1–3, 9) and base-catalyzed (1, 11–14) reactions obtained. The subject in its various aspects has been extensively reviewed (4–20); three books have been written on it (1–3), and it is covered in many physical organic textbooks (19, 21–25). An extensive tabulation of acidity functions is available (10). Here we will only be concerned with aqueous or aqueous/organic media, the developments subsequent to 1970 are emphasized. The literature coverage extends to the end of 1982.

Theory

In acid solutions, K_{BH^+} (i.e. K_a) is defined as the dissociation constant of the conjugate acid BH^+ of base B, eq. [1]; in terms of activity a its value is given by eq. [2]. Taking logs and substituting the ionization ratio $I = C_{BH^+}/C_B$ ($= a_{BH^+}/a_B$ in ideal solution) gives the familiar eq. [3]. The standard state is a hypothetical acid solution of unit activity, and the reference state (unit activity coefficients) is infinite dilution in water, for eq. [3] and most other equations in this review.

$$[1] \quad B + H^+ \overset{K_{BH^+}}{\rightleftharpoons} BH^+$$

$$[2] \quad K_{BH^+} = a_B a_{H^+}/a_{BH^+}$$

$$[3] \quad pK_{BH^+} = \log I + pH$$

$$[4] \quad K_{BH^+} = C_B C_{H^+} f_B f_{H^+}/C_{BH^+} f_{BH^+}$$

$$[5] \quad pK_{BH^+} = \log I - \log C_{H^+} - \log (f_B f_{H^+}/f_{BH^+})$$

In the non-ideal solutions under consideration here activities and concentrations cannot be equated; using molarities C and molar activity coefficients f, eqs. [2] and [3] become eqs. [4] and [5], respectively. The acidity function problem then becomes, essentially, a question of how to deal with the activity coefficient term in eq. [5].

Zero'th order approximation

$$[6] \quad pK_{AH^+} - \log I_A = -\log C_{H^+} - \log (f_A f_{H^+}/f_{AH^+}) = H_0$$

$$[7] \quad pK_{BH^+} - \log I_B = -\log C_{H^+} - \log (f_B f_{H^+}/f_{BH^+}) = H_0$$

[8] $$pK_{AH^+} - \log I_A - pK_{BH^+} + \log I_B = \log (f_B f_{AH^+}/f_A f_{BH^+}) = H_0$$

Paraphrasing Hammett (19, 26), the Hammett acidity function H_0 is defined, so as to be similar to pH, by eqs. [6] and [7] for bases A and B. On subtracting these, eq. [8] is obtained; the *Hammett cancellation assumption* is that of equating this to zero. This is the zero'th order approximation. If this is true then immediately a way of measuring pK_{BH^+} values outside the readily accessible range is available from eq. [8], if pK_{AH^+} of an *anchor* compound is known, by measuring ionization ratios as a function of some measure of acidity, usually % acid w/w or molarity. With an overlapping series of these available, H_0 values can be calculated, using eqs. [6] and [7] in a stepwise manner. Once derived, H_0 can be used directly, like pH, to obtained unkown acidity constants from ionization ratio measurements: $pK_{BH^+} = H_0 + \log I$.

Hammett acidity functions

By 1964 it was generally realized that the cancellation assumption was only adequate for weak bases which were closely related in structure (27–29). Nowadays the symbolism H_0 is restricted to acidity functions obtained using nitro-substituted primary aromatic amines only (30). H_0 scales are available for a very wide variety of aqueous acid systems, the same one often having been studied by several different groups (one receives the distinct impression that several pounds of *p*-nitroaniline must have been used for this purpose over the last 50 years). We do not propose to quote them here except for the tabulated references in Tables 1 and 2 (based on ones given by Capen (180)).

Tables 1 and 2 are confined to the most widely used aqueous and aqueous/organic solvent systems; within these bounds an attempt has been made to be comprehensive, at least as far as the readily available literature is concerned. In the authors' experience (83, 181) it is usually necessary to have all the available data on hand when deciding on a suitable acidity function to use in a given medium. Not included are (*a*) superacid systems (41, 182), (*b*) wholly non-aqueous systems (183), (*c*) systems containing added salts (184), (*d*) molten salt systems (185), (*e*) ternary systems (102, 186, 187), (*f*) solid surfaces (188), (*g*) micelles (189), or (*h*) acidity functions obtained at fixed acid concentration and variable organic solvent content (190).

Almost all existing H_0 scales have been obtained using the overlap method outlined above (for details see refs. 1 and 2), although very recently Cox and Yates have described a method for calculating H_0 scales from ionization ratio data which requires neither an "anchor" compound nor overlap between adjacent indicators (83). H_0 scales are useful for comparing different acid media for strength; in Fig. 1 plots of H_0 against mole fraction of acid are given for some representative aqueous systems. The change which several of them exhibit at the 0.5 mole fraction point shows that H_0 scales can also reflect the structure of acid media, at least to some extent.

Other acidity functions

Equation [8] does not apply when A is a primary aromatic amine and B is, say, an amide or a tertiary amine or a thioester. If a set of ionization ratios is plotted against H_0, compounds are said not to "follow" H_0 if the slope of the graph differs from unity (the plots are usually linear). However, it is quite possible to obtain acidity functions using series of amides, tertiary amines, etc., and many of these are available. They are given here in Tables 1 and 2. Perhaps the most widely used after H_0 is the H_A scale, originally derived using amides (29), which is followed by several other carbonyl compounds (191–193), by some heterocycles (54, 55), and by pyridine *N*-oxides (44, 53).

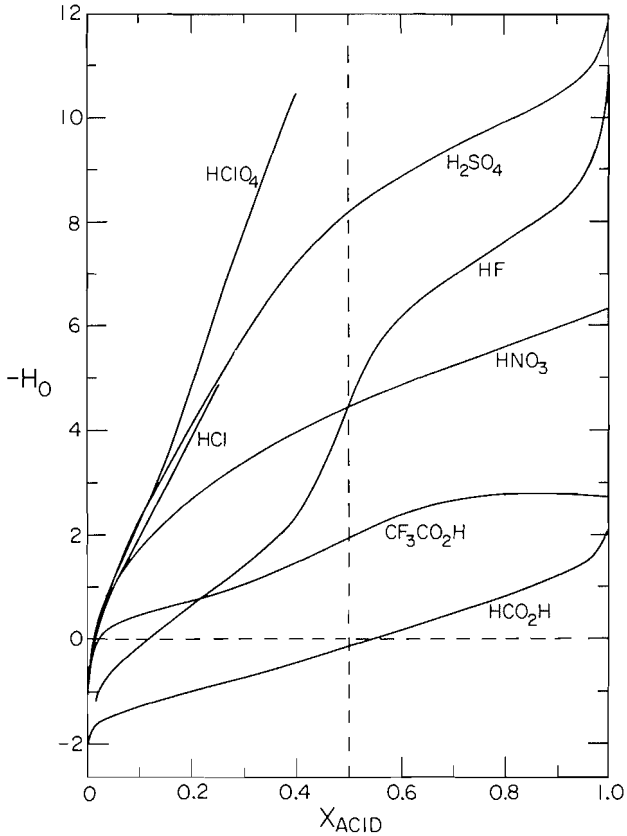

FIG. 1. H_0 vs. mole fraction of acid, for aqueous $HClO_4$ (83), H_2SO_4 (39, 41), HCl (83), HNO_3 (111), HF (112, 113), CF_3CO_2H (128), and HCO_2H (132).

[9] $$R_3COH + H^+ \overset{K_{R^+}}{\rightleftharpoons} R_3C^+ + H_2O$$

[10] $$H_R = pK_{R^+} - \log I = -\log C_{H^+} - \log (f_{R_3COH} f_{H^+}/f_{R_3C^+}) + \log a_w$$

The H_R acidity function is defined for protonation–dehydration processes, eq. [9], in eq. [10], where a_w is the activity of water (48); it is usually measured using triarylcarbinol indicators (49). From this, $H_R' = H_R - \log a_w$ can be defined. This is comparable to the other acidity functions and has been used, for instance, in alkene protonation studies (194).

Strongly basic media

[11] $$HA + HO^- \overset{K_b}{\rightleftharpoons} A^- + H_2O$$

[12] $$H_- = pK_{HA} + \log (C_{A^-}/C_{HA}) = pK_w + \log C_{HO^-} - \log a_w - \log (f_{A^-}/f_{HA} f_{HO^-})$$

For the deprotonation of eq. [11] we can write eq. [12], since K_{HA} (i.e. K_a) $= K_w/K_b$, which defines the acidity function H_-. (The usual terminology is H_- for neutral species → negative ion, H_0 for positive ion → neutral species, H_{2-} for negative ion → dinegative ion, etc. (11).) Two methods for producing strongly basic media are in common use. Firstly, the base concentration can be increased, affecting the last three terms in eq. [12], and secondly, the water activity can be progressively

TABLE 1. Acidity functions for aqueous acid media

AF[a]	T[b]	In.[c]	Acid conc.[d]	Year	Comments	Reference
	H_2SO_4					
"H_0"	?	15	0.3–100.1%	1932	Colourimetry. See refs. 1, 15, 17, 18	26
H_0	?	1	0.352–2.11 *M*	1954	Poor *p*-nitroaniline pK_a	31
H_0	20,40,60,80	7	4–100%	1956	See ref. 16	32
H_0	17	5	2.20–29.2 *N*	1958		33
H_0	25	6	0.005–38.6%	1959	See ref. 1. Best near water	34
H_0	15,25	1	85.46–99.94%	1959	2,4,6-Trinitroaniline	35
H_0	22	2	0.032–1.28 *M*	1962		36
H_0	?	4	60–99.44%	1963	See refs. 1, 7, 18	30
H_0	24	12	1–100%	1964,1966	See refs. 1, 2, 16	37
H_0	?	1	92.0–99.9%	1968	2,4,6-Trinitroaniline	38
H_0	25,40,60,80,90	12	2–99%	1969	Best general-purpose scales	39
H_0	15,25,35,45,55	10	4–98%	1970	See ref. 1	40
H_0	22	4	98.0–100.0%	1971	Best near 100% acid	41
H_0	25	2	0.25–24%	1972,1982		42
H_0	25	5	0–44%	1972	Fluorinated primary amines	43
"H_0"	25,40,60,80,90	9	14–58%	1974	Substituted pyridines	44
H_0	25	2	0.20–2.80 *M*	1976		45
H_0	25	3	0.5–20.0%	1979		46
H_0	25,60	6	20.9–58.9%	1980		47
"H_R"	25	—	5–95%	1951	By calculation from H_0	48
H_R	25	17	0.5–98%	1955	See refs. 1, 2, 15, 17, 18	49
H_R	0,15,30,45	8	0.75–98%	1964	See refs. 1, 15	50
"H_R"	20	11	28–86%	1971	Benzhydrols	51
H_R	25,40,60,80,90	13	6–90%	1975	Disagrees with ref. 50	52
H_R	25	2	0.5–20.0%	1979		46
H_A	25	10	16.1–81.8%	1964	See refs. 2, 17, 18	29
H_A	?	1	82–93%	1967	Phenazine-9,10-dioxide	53
H_A	25,40,60,80,90	9	2–80%	1974	Azine *N*-oxides	44
H_A	25	4	85.0–100.0%	1975	Pyrimidine monocations	54
H_A	25	3	2.5–90%	1977	Re-anchors H_A scale	55
H_A	15,25,40	5	1.0–45.0%	1982	2 H_0 indicators, 3 amides	56
H_C	25	10	0.5–14.0 *M*	1969	Azulenes, carbon bases. See ref. 17	57
H_C	25	7	0–80%	1968–1971	Azulenes	58
H_C	25	3	0.5–20.0%	1979	Azulenes	46
H_0'''	26	14	1–94%	1964	Tertiary amines. See refs. 2, 17, 18	27
H_0'''	25	3	0.5–20.0%	1979	Tertiary aromatic amines	46
H_0'''	25	7	2–70%	1978	Secondary aromatic amines	59
H_-	25	3	0.25–10 *M*	1961,1963	Cyanocarbons. See refs. 2, 17, 18	60
H_-	25	1	0.5–4.0 *M*	1964	Formate ion oxidation kinetics	61
H_-	?	1	$10^{-1.5}$–$10^{0.4}$ *M*	1973	Graphical only. Picrate ion	62
H_+	25	12	0.02–15.0 *M*	1968	1,2-Phenylenediamines. See ref. 2	63
H_T	25	11	10–80%	1972	Thiocompounds	64
H_T	25	16	10–90%	1977	Thiocompounds	65
H_I	25	9	0.1–12.0 *M*	1964	Indoles. See refs. 2, 17, 18	28
H_B	?	13	40–90%	1966	Benzophenones. See ref. 18	66
H_{ROH}	0	1	33–93%	1971	Ethanol	67
H_{PO}	?	12	4.9–78.0%	1973	Phosphine oxides	68
H_E	37	2	60–98%	1974	Aliphatic esters	69
H_{CA}	37	2	55–85%	1976	Aliphatic carboxylic acids	70
H'_{CA}	37	2	60–90%	1976	Halogenated carboxylic acids	70
$H_{C(OH)_2}$	25	3	0.005–10.3 *M*	1981	Hydrated aldehydes	71
H_D	25	5	3.1–49.5%	1983	1,3-Dioxan-2-ylium cations	72
$H_S^{\ddagger}$	25	9	1–12 *M*	1972	Styrene hydration kinetics	73
$H_C^{\ddagger}$	?	1	5–100%	1977,1979	H/D exchange kinetics	74
"p*H*"	?	3	2.00–8.88 *N*	1942	Thiazines	75
R_0	25	1	17.8–100%	1961	Fe^{+}/Fe^{2+}	76
R_0	20	1	0.027–0.326*x*	1972	Fe^{+}/Fe^{2+}	77
H_{GF}	25	1	0.25–11.0 *M*	1972	Fe^{+}/Fe^{2+}	78

H_0	20	2	0.0104–0.251 *M*	1982		139

[a]Acidity function; see text and comments. Quotes indicate that other than "usual" indicators were used.
[b]Temperature, °C. A query means value unreported, presumably "room temperature", about 22°C.
[c]Number of indicators used.
[d]Concentration range studied. % = percent by weight; *M* = molarity; *N* = normality; *m* = molality; *x* = mole fraction.
[e]A qualitative study is given in ref. 106.
[f]Also given are H_0 scales for 0.010–0.240 *M* solutions in 40 vol.% dioxane and 0.00406–0.203 *M* solutions in 94.5 vol.% HOAc (139).

reduced by replacing the water by a dipolar aprotic solvent such as DMSO or sulfolane, at fixed hydroxide concentrations. This affects only the last two terms in eq. [12]. Suitable series of overlapping indicators can be used, in the same way as in acidic media, to give acidity functions; see the reviews by Bowden (11) and Rochester (1, 12). Superscripts are used to delineate the indicator type, H_-^I for indoles, H_-^P for purines and pyrimidines, etc. H_- scales themselves are obtained with substituted aniline and diphenylamine indicators (205), and H_{2-} scales with diphenylamine carboxylates or sufonates, or aminobenzoates (207).

Scales of the first type have received comparatively little attention; tabulated references to those that exist are given in Tables 3 and 4. The H_-^I scales of Yagil (198) are shown in Fig. 2 as a function of log hydroxide concentration. As can be seen, little deviation from ideality is apparent until pH 13, or even pH 14 for NaOH, and although NaOH and KOH are much more basic than their concentrations would predict at, say 5 *M*, LiOH solutions are not. Scales for hydroxide *addition*, as in eq. [13], are known as J_- (200) and are defined as in eq. [12] but without the log a_w term (compare eqs. [11] and [13]); some have been measured by Zuman *et al.* for the addition of hydroxide ion to a series of substituted benzaldehydes (201, 208).

$$[13] \quad S + HO^- \rightleftharpoons [SOH]^-$$

Scales of the second type are more common. Those available are summarized in Table 5; various acidity scales for 0.011 *M* tetramethylammonium hydroxide in aqueous dimethyl sulfoxide, as a function of mole fraction DMSO, are shown in Fig. 3. Aqueous DMSO is the most widely studied medium of this type, and one of the most useful. As Fig. 3 shows, a basicity range of at least 14 orders of magnitude is available, depending on the indicator system used. Figure 3 also shows, however, that different indicator types lead to very different acidity functions, in this medium as in most others. A J_- scale is available (108) as are W_0 scales, measured by Stewart and Van Dyke (222). These refer to the hydration of a series of substituted trifluoroacetophenones, eq. [14], rather than a reaction involving base.

$$[14] \quad ArC(OH)_2CF_3 \overset{K_d}{\rightleftharpoons} ArCOCF_3 + H_2O$$

Electrochemical scales

It is apparent that an acidity function measurable over a wide range using a single indicator would have advantages when compared to functions obtained by the overlap of several indicators. The very low indicator concentrations necessarily re-

sulting can best be measured electrochemically. Strehlow *et al.* (234) suggested the use of the ferrocene/ferricinium ion (Fec/Fec^+) and cobalticinium ion/cobaltocene (Coc^+/Coc) redox systems as a reference against which to measure hydrogen electrode potentials. Subsequently Strehlow and Wendt (76) measured the redox function $R_0(H)$ (abbreviated R_0 in Tables 1 and 2); $R_0(H) = F[E(x) - E(1)]/RT \ln 10$, where $E(1)$ is the emf of the cell

[a–d]As in Table 1.

$$Pt|H_2(g, 1\ atm)|aq.\ acid\ (a_{H^+} = 1),\ Fec/Fec^+\ (1:1)|Pt$$

R_0 scales have been measured for several acid media (76, 77, 115, 116, 130, 134, 156).

$$[15] \quad -H_{GF} = \log a_{H^+} + \log (f_{Fec}/f_{Fec^+})$$

Janata and Jansen (78) refined this approach by introducing a polarographic procedure to measure the Fec/Fec^+ half-wave potential, using this as a reference for a glass electrode. The resulting scales are called H_{GF} (glass, ferrocene), and are now available for quite a number of acid media (78, 110, 125, 145, 148). H_{GF} is defined like the other acidity functions, eq. [15], with the addition of the polarographic assumption that the diffusion coefficients for the oxidized and reduced species approximately cancel (see the discussion in ref. 78). In basic media the Coc^+/Coc redox couple is used, and several H_{GC} (glass, cobaltocene) scales are listed in Tables 3 and 5 (202, 206, 221). Janata and Taylor (202) have shown that the glass and hydrogen electrodes give the same scales in basic solution, and report some H_{HC} (hydrogen, cobaltocene) functions.

Universal functions

It is evident that Tables 1–5 summarize almost too much information to be useful, insofar as the requirement for a simple method for studying rates and equilibria in these non-ideal systems is concerned. Several approaches to the goal of determining one universal function per medium form most of the remainder of this review.

Yates–McClelland method

The Hammett H_0 has acquired, perhaps deservedly, some of the status of a "universal" acidity function for various reasons, among them its use in the Yates–McClelland and Bunnett–Olsen methods.

$$[16] \quad \log I = mH_0 + pK_{BH^+}$$

It has long been observed that log ionization ratios obtained for compounds other than primary aromatic amines give straight lines when plotted against H_0, see eq. [16], although the slopes often differ from unity. From these graphs, the log $I = 0$ intercept gives H_0 values at half-protonation $(H_0)_{1/2}$, useful in their own right for comparison purposes (235); multiplication by the slope m can then give a pK_{BH^+} estimate as the $H_0 = 0$ intercept (6, 8, 236). This allows bases treated in this way essentially to define their own acidity functions, *vide infra* (236, 237). However, the approach is empirical, and runs into trouble near the aqueous region, since in the p*H* range all slopes must be unity, see eq. [3] (8, 42).

Proton activity scales

Related to the above method of pK_{BH^+} determination is the observation that, at least away from the origin, all acidity functions are linear in each other (236). Also the differences between acidity functions, $H_X - H_Y = \log(f_X f_{YH^+}/f_Y f_{XH^+})$, are reasonably linear functions of acid molarity (85, 99). Yates *et al.* showed that lines with similar slopes result if the activity coefficients of suitable compounds are used directly (85). Solubilities of neutral bases can be used to obtain f_B, and solubilities of pentacyanopropenide (PCP^-) salts give estimates of f_{BH^+}, using the Boyd approximation (17, 238) that the activity coefficient of the tetraethylammonium ion (TEA^+) does not vary greatly with acidity, see eq. [17]. With these available, it becomes possible to calculate a scale of log $a^*_{H^+}$ values using acidity functions and the activity coefficients of suitable indicators, eq. [18] (20, 85).

$$[17]\quad f^*_{BH^+} = [f_{\pm(BH^+PCP^-)}]^2/[f_{\pm(TEA^+PCP^-)}]^2 = (f_{BH^+}f_{PCP^-})/(f_{TEA^+}f_{PCP^-}) = f_{BH^+}/f_{TEA^+}$$

$$[18]\quad \log a^*_{H^+} = \log f^*_{XH^+} - \log f_X - H_X$$

Scales of log $a^*_{H^+}$, derived from a number of acidity functions, have been calculated for aqueous H_2SO_4 and $HClO_4$ (20, 85), and the former confirmed by H_{GF} measurements (239). More recent proton activity scales are available from H_{GF} for several acid media (110), those for H_2SO_4 and $HClO_4$ agreeing well with the ones given by Haldna and Koppel (240). They have found use in the investigation of reaction mechanisms in strong acids, since they enable estimation of transition state activity coefficients (TSAC), and the behaviour of these as a function of acidity is mechanistically revealing (110, 241–243). They have not so far been used for pK_{BH^+} determinations.

Carpentier's method

Carpentier noticed that the differences between certain acidity functions are approximately equal at given acidities: $(H_0 - H_0''') = (H_0''' - H_C) = (H_C - H_R) = \Delta(S)$. Acidity functions can be redefined on the basis of this "fundamental variable" $\Delta(S)$ using the "solvation coefficient" τ as a proportionality constant; $H_X = pH(H_2O) + \tau\Delta(S)$ where τ is one of seven whole numbers (46, 244). Values of log $a^*_{H^+}$ identical to those obtained from H_{GF} (110) were derived using this treatment (244). Accordingly there would be only seven fundamental acidity functions, which Carpentier distinguishes by prefixes: ${}^0H \equiv H_R$, ${}^1H \equiv H_C$, ${}^2H \equiv H_0'''$, and ${}^3H \equiv H_0$ (46), with ${}^4H$, ${}^5H$,

and ^6H for pyridine *N*-oxides, amides, ketones, alcohols, etc. (245). The method has not been widely adopted; τ is essentially a whole-number variant of m^* and $(1 - \phi_e)$, see below.

First-order approximation

Most reasonable uses of acidity functions require two parameters; if one is pK_{BH^+} the other may be the slope m of eq. [16], or a specification of which acidity function is being followed, or τ. Several other two-parameter treatments are available, based on the assumption that activity coefficient ratios of the form $\log (f_B f_{H^+}/f_{BH^+})$ are linear functions of one another, rather than cancelling out. This is the first-order approximation.

Bunnett–Olsen method

This widely-used method was first proposed in 1966 (246). Taking the definition of H_0, eqs. [6] and [7], and writing the activity coefficient term as an "average" for the amines used in measuring H_0, Am, gives eq. [19]. Assuming that an equivalent term for any one base B is linear in this is eq. [20], which, on substituting into eq. [5] and suitable rearrangement gives the Bunnett–Olsen equation [21].

$$[19] \quad H_0 + \log C_{H^+} = -\log (f_{Am} f_{H^+}/f_{AmH^+})$$

$$[20] \quad \log (f_B f_{H^+}/f_{BH^+}) = (1 - \phi_e) \log (f_{Am} f_{H^+}/f_{AmH^+}) = (\phi_e - 1)(H_0 + \log C_{H^+})$$

$$[21] \quad \log I + H_0 = \phi_e (H_0 + \log C_{H^+}) + pK_{BH^+}$$

Using eq. [21], ionization ratio measurements give pK_{BH^+} values in the standard state by extrapolation, together with a slope parameter ϕ_e (ϕ_e, equilibrium, to distinguish it from the related kinetic parameter ϕ_r or $\phi_\ddagger$ (247)). The method has been widely accepted and works well in acids (see refs. 7, 65, 69, 246, 248, 249, etc.), acid/organic solvent media (145, 148), and basic solutions (216, 220).

Excess acidity method

This is referred to in the literature as the "Marziano–Cimino–Passerini" or the "Cox–Yates" method, which is unfortunate since both are the same. The term "excess acidity method" is preferred; "*X*-function method" is also used.

$$[22] \quad \log I - \log C_{H^+} = \log (f_B f_{H^+}/f_{BH^+}) + pK_{BH^+} = n \log (f_{B^*} f_{H^+}/f_{B^*H^+}) + pK_{BH^+} = nM_C + pK_{BH^+}$$

In its original form, pioneered by Marziano *et al.* in 1973 (250), an anchor compound B* and a series of overlapping

indicators were utilized, but not to derive an acidity function. The anchor pK_{BH^+}, say of *p*-nitroaniline, is used with eq. [5] to calculate values of log $(f_B f_{H^+}/f_{BH^+})$, abbreviated M_C (250), in dilute acid. The second set of ionization ratios, extending to more concentrated acid, are then plotted against these according to eq. [22], within the region of overlap, giving the second pK_{BH^+} as an intercept, and a slope n. These known values can then be used to extend M_C, working backwards, see eq. [22]. The process is repeated stepwise until the entire acidity range is covered. "Graphical" M_C scales of this type are available for aqueous H_2SO_4 and $HClO_4$ (250), DMSO/water basic mixtures (216), and aqueous KOH (251); they can easily be derived from existing sets of ionization ratios as necessary (216, 251).

Subsequently, Marziano's group introduced a refined computerized calculation method (252), enabling many sets of data to be treated simultaneously. In the course of this work, they extensively tested the concept of linearity of activity coefficient ratios assumed in this section (slopes n_{ij}), and found it valid in all cases (253); this assumption thus acquires the status of an "empirical fact" (J. F. Bunnett, personal communication). Cox and Yates confirmed and extended this work (83, 181), preferring the terminology m^* for the slope parameters and X for the activity coefficient ratio, eq. [23]. X represents the "excess acidity" (a term first used by Perrin (254)) as it is the difference between the observed acidity and that which the system would have if it were ideal (83, 181).

$$[23] \quad \log I - \log C_{H^+} = m^*X + pK_{BH^+}$$

The computer calculation method has several advantages. Any number of bases of widely differing types can be accommodated; X for aqueous sulfuric acid is derived from 165 different compounds, covering protonation at N, O, C, and S atoms, and negative, neutral, positive, and dipositive bases (181). Overlap between adjacent indicators is unnecessary (83, 181). Anchoring with a compound of known pK_a is also unnecessary, since X or M_C automatically becomes zero in the standard state (compare eqs. [22] and [23] with eq. [3]). Scales obtained in this way are available for aqueous HCl (83), and aqueous H_2SO_4 and $HClO_4$ (181, 252, 255), and the method has been used to calculate H_0 scales (essentially) for aqueous HBr (83) and $DClO_4$ (122). The latest refinement, again due to Marziano *et al.* (255), is to calculate scales for H_2SO_4 and $HClO_4$ simultaneously, ensuring that indicators have the same pK_{BH^+} regardless of medium, as they should.

There is no doubt that excess acidity scales represent the closest approach so far to "universal" acidity functions. They have been used to calculate pK_{BH^+} values (eq. [23]) by several groups (42, 83, 181, 193, 255–258). A method for evaluating pK_{BH^+} and m^* in the presence of quite severe medium effects has been developed (259) and used (260). The excess acidity method has been extended to reaction kinetics (261) and used to investigate the mechanisms of a number of different reactions (256, 257, 261–165). Temperatures other than 25°C can be easily accommodated (257), and the thermodynamics of ionization of 48 compounds in aqueous H_2SO_4 have been investigated (266).

Which method to use?

This is a valid question, considering the number of different methods of pK_{BH^+} determination already mentioned. Each method has its equivalent for kinetic studies also, and there are others not specifically discussed here, for instance the various hydration parameter treatments (1–3, 267–268).

The Bunnett–Olsen and excess acidity methods differ insofar as the former uses H_0, and hence the cancellation assumption involved in its derivation, whereas the latter only uses the linearity assumption of eq. [22]. There are other minor differences. Bunnett and Olsen in 1966 used the acid molarity as C_{H^+} in eq. [21], which may result in degrees of dissociation being included in the activity coefficient ratio, for instance of HSO_4^- in H_2SO_4 media (246). Subsequent physical studies produced better values of C_{H^+} in H_2SO_4; those given by Robertson and Dunford (169) are used with M_C (252), and recalculated literature values are used with X (83, 181). It has been found that these different C_{H^+} values cannot be interchanged among the latter two methods (270), although there is no reason in principle why either could not be used with the Bunnett–Olsen method. In sulfuric acid, differences in the pK_{BH^+} values supplied by the three methods appear at very high acidity (270), probably due to the very long extrapolations necessary. The Bunnett–Olsen method has been found to be less reliable when used with acidity functions other than H_0 (271), not that the use of other acidity functions has ever been advocated in this connection.

These differences, however, are theoretical rather than practical. The Bunnett–Olsen and excess acidity methods have been shown to be essentially equivalent, giving the same pK_{BH^+} and $(m^* = 1 - \phi_c)$ values (272). In practice the Yates–McClelland method often gives similar results too, despite its more empirical nature; many authors list pK_{BH^+} values obtained using all three methods. Probably the excess acidity method is to be preferred, if only because of the large amount of data used in calculating X, in well-studied acid media. X is not based on a single set of overlapping indicators, as is H_0. In less well-studied acid systems, where only H_0 may be available, the Bunnett–Olsen method is still unsurpassed. In basic DMSO media, the excess acidity and Bunnett–Olsen methods have been found to be practically equivalent; for the latter the choice of acidity function makes little difference to the pK_a values found (216).

Acidity functions themselves, apart from H_0 (H_- in basic media), are probably declining in importance. The newer methods have shown up several discrepancies in existing scales. For instance the Bunnett–Olsen (246), excess acidity (181), and Carpentier (273) methods all show that the original H_A scale was mis-anchored by 0.3 units, a point later confirmed directly by Edward and Wong (55). It has been suggested (216) that a variation among m^* values of less than 0.1 is necessary to define a good "acidity function" set of compounds, and several exisiting scales have been found wanting in this regard (181, 216). However, in those cases where only poor ionization ratio data for a single compound are available, good pK_a estimates can still be obtained by using the most "likely" acidity function from Tables 1–5 (219).

H_0 will probably continue to be useful in kinetic applications, at least pictorially. Plots of log rate constants against H_0 or pH/H_0 are qualitatively useful; they illustrate rate accelerations, rate maxima, etc. in an easily-understood way. For more quantitative information in the well-studied media, however, the excess acidity method is undoubtedly superior, if for no other reason than that it encompasses most of the other kinetic treatments; for details see ref. 261. It provides standard-state rate constants (256, 261, 263) and activation enthalpies and entropies (257, 262), and for reactions involving water, kinetically-involved water molecules are easily distinguished

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12

from solvation water (262). In sulfuric acid, reaction with the other species present (274, 275) can readily be studied, e.g. with undissociated H_2SO_4 (237, 263), $H_3SO_4^+$ (274), and HSO_4^- (256, 262, 276). In cases where the activity coefficient of the substrate can be measured, the TSAC treatment is useful, enabling straightforward mechanistic distinctions (241, 242). Note that neither of these methods uses a traditional acidity function. In less well-studied media, again the Bunnett–Olsen method (247) is probably best; related kinetic treatments are available for basic solutions (277).

Second-order approximation

All of the methods discussed so far are approximations, and, one hopes, of increasing accuracy. Occasionally papers appear which remind us of the assumptions inherent in both the zero'th (278) and first-order (279) approximations; for instance Wojcik points out that either one leads to pK_{BH^+} values containing an "indeterminate constant" (279). This is thought to be small in most cases, however, as large discrepancies would cause noticeable effects in several of the above treatments.

Recently Edward, Sjöström, and Wold (280) subjected to factor analysis some data obtained in basic aqueous DMSO mixtures by Hallé *et al.* (281). These data consist of ionization ratios obtained using buffers at particular solvent compositions, and the resulting pK_a values refer to a standard state of infinite dilution in that solvent mixture. Thus acidity functions comparable to those discussed here were not derived (although it is possible to extrapolate to the aqueous standard state (282)), and the data are not strictly comparable to those used in compiling standard acidity functions. Nevertheless the factor analysis result, that *two* principal factors rather than one are required to explain the data (280), undoubtedly shows that even the first-order approximation is, in the limit, inaccurate. Indicated was a quadratic term (280); in the language of the excess acidity method this would necessitate an expansion of eq. [23] to eq. [24], which defines the second-order approximation.

$$[24] \quad \log I - \log C_{H^+} = pK_{BH^+} + m^*X + m^{**}X^2$$

Future acidity function work will probably concentrate on evaluating terms such as m^{**}. This is not going to be easy, as a great deal of accurate ionization ratio data will be necessary. Using Marziano's refinement, i.e. necessarily allowing only one value for pK_{BH^+} while using data in several different acid media (255), with the assumption that m^* is medium invariant, enough data probably exist at present to enable calculation of m^{**} and refined X values for perhaps three acid systems. Whether or not this is warranted at this time, whether or not m^* is really medium invariant, and what the physical meaning of m^{**} would be, are open questions. Preliminary work (P. G. Traverso, private communication) indicates that m^{**} may be very small in H_2SO_4 and $HClO_4$ media.

This is still a very healthy area of physical organic chemistry, as a glance at the list of references makes clear; 60% of them have appeared since the publication of Rochester's book (1) in 1970. We can certainly continue to expect new insights into equilibria and reactions in non-ideal media, resulting from the development and use of acidity functions.

Acknowledgements

We would like to thank the many people who discussed this work with us, particularly Professors J. F. Bunnett, Ülo Haldna, A. J. Kresge, Ross Stewart, and P. G. Traverso. Financial support is by the Natural Sciences and Engineering Research Council of Canada.

A. LACHAPELLE, M. ST-JACQUES, A. C. GUIMARAES, and P. DE ALMEIDA. Can. J. Chem. **61**, 2244 (1983).

The conformational and dynamic properties of the stereoisomers of 4-methyl-5,6-benzo-2-oxo-1,3,2-dioxathiepin (**5**) and of the 4,7-dimethyl derivative (**6**) have been investigated by ^1H and ^{13}C dnmr methods, as well as by ir spectroscopy. Analysis of the nmr spectra at low temperature (−125°C), together with the conformational interpretation of the stretching vibration bands of the S=O bond in the ir spectra, indicate that the most stable conformations detected for solutions in CHF_2Cl are *C*-a (82%) and *TB*-*t*-Me_e (18%) for **5***a*, *TB*-*c*-Me_e (96%) and *TB*-*c*-Me_a (4%) for **5***b*, *C*-a for **6***a*, *TB*-*t*-Me_e, *c*-Me_e for **6***b* and *C*-e for **6***c*. The substituent effects of a methyl group at the benzylic position on both the conformational and dynamic properties of the seven-membered sulfite are discussed.

A. LACHAPELLE, M. ST-JACQUES, A. C. GUIMARAES et P. DE ALMEIDA. Can. J. Chem. **61**, 2244 (1983).

Les propriétés dynamiques et conformationnelles des stéréoisomères de la méthyl-4 benzo-5,6 oxo-2 dioxa-1,3,2 thiépine (**5**) et du dérivé diméthyl-4,7 ont été étudiées à l'aide des méthodes de rmn dynamique du ^1H et du ^{13}C ainsi que de la spectroscopie ir. L'analyse des spectres de rmn à basse température (−125°C), de concert avec l'interprétation conformationnelle des bandes de vibration d'élongation de la liaison S=O observées sur les spectres ir, indique que les conformations les plus stables en solution dans le CHF_2Cl sont *C*-a (82%) et *TB*-*t*-Me_e (18%) pour le composé **5***a*, *TB*-*c*-Me_e (96%) et *TB*-*c*-Me_a (4%) pour le composé **5***b*, *C*-a pour le composé **6***a*, *TB*-*t*-Me_e, *c*-Me_e pour le composé **6***b* et *C*-e pour le composé **6***c*. Les effets d'un ou deux groupes méthyles en position benzylique sur les propriétés dynamiques et conformationnelles des sulfites à sept chaînons sont discutés.

Introduction

Sulfites (**1**) have drawn particular attention over the years owing to the stereochemical rigidity of the pyramidal S atom. But while 5- and 6-membered sulfites have been extensively investigated by numerous techniques (ir (2–4), ^1H and ^{13}C nmr (1, 2, 5–12), dipolar moments measurements (7)), only a few studies of the larger cyclic molecules have been reported (13–16).

It is now well known that 2-oxo-1,3,2-dioxathiane (**1**) exists exclusively in the chair form (17), with the S=O bond axially oriented; furthermore, this *C*-a form has been estimated to be about 2–3 kcal/mol more stable than the equatorial form (*C*-e) in CCl_4 (18). While many reports (7, 19–21) have shown that the *C*-a form is the only one observed for *trans*-4-methyl-2-oxo-1,3,2-dioxathiane (**2**), the conformational assignment for *cis*-4-methyl-2-oxo-1,3,2-dioxathiane (**3**) has been the subject of much debate (18, 21, 22) during the last decade. Recently, Cazaux *et al.* (23), using nmr and ir techniques as well as dipolar moments calculations, proposed that **3** exists as a rapidly equilibrating mixture of *C*-a (**3***a*), *C*-e (**3***b*), and two twist forms (*TOA*-**3***c* and *TS*-**3***d*) at room temperature. On the other hand, recent reports by Pihlaja and co-workers (4) question the reliability of the ir method for identifying the existence of twist forms, and the authors interpret experimental data uniquely in terms of **3***a* and **3***b*.

Seven-membered cyclic sulfites, such as **4** and its methyl derivatives, in principle provide a better model to study the properties of twist forms because, contrary to six-membered cyclic sulfites, there can be only one *TB* ring geometry. Recent (24) ir and ^1H and ^{13}C dynamic nmr results for **4** showed the existence of a 1:1 mixture of *C*-a and *TB* in CHF_2Cl at −100°C. That result, although consistent with the fact that dipole–dipole interactions and stereoelectronic back-donation should disfavor *C*-e relative to *C*-a and *TB*, is in marked contrast with the absence of a conformational equilibrium noted for trimethylene sulfite (**1**).

Our interest in seven-membered cyclic molecules, combined with the uncertainty for *cis*-4-methyl-2-oxo-1,3,2-dioxathiane (**3**), led us to investigate the conformational dynamics

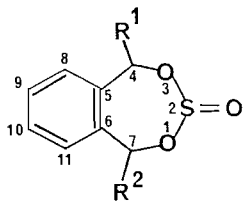
properties of *trans*-4-methyl-2-oxo-1,3,2-benzodioxathiepin[2] (**5***a*), *cis*-4-methyl-2-oxo-1,3,2-benzodioxathiepin (**5***b*), *trans,trans*-4,7-dimethyl-2-oxo-1,3,2-benzodioxathiepin (**6***a*), *cis,trans*-4,7-dimethyl-2-oxo-1,3,2-benzodioxathiepin (**6***b*), and *cis,cis*-4,7-dimethyl-2-oxo-1,3,2-benzodioxathiepin (**6***c*) using ir and ^1H and ^{13}C dynamic nmr. Our observations, in addition to characterizing the effects of methyl substitution on the ring conformation of the seven-membered sulfite, confirm the utility of the combined ir–dnmr approach.



4 $R^1=R^2=H$
5a $R^1=CH_3, R^2=H$ (trans)
5b $R^1=CH_3, R^2=H$ (cis)
6a $R^1=CH_3, R^2=CH_3$ (trans,trans)
6b $R^1=CH_3, R^2=CH_3$ (cis,trans)
6c $R^1=CH_3, R^2=CH_3$ (cis,cis)

Results

Sulfites **5***a* and **5***b* were prepared from the reaction of α-methyl-*o*-xylene-α,α′-diol and thionyl chloride; after separation they were first identified by comparison with dipole moments of the six-membered sulfite analogs (21) (the *trans* isomer being less polar (μ = 3.25 D in CCl_4) than the *cis* isomer (μ = 4.66 D in CCl_4) in that series). The first compound isolated from an hplc run is therefore considered as the *trans*-isomer (**5***a*), while the second compound eluted is the *cis*-isomer (**5***b*). The interpretation of the spectroscopic data that follows confirms this assignment.

Sulfites **6***a*, **6***b*, and **6***c* were obtained in a two-step synthesis involving: (1) a Grignard reaction with methylmagnesium iodide on benzene-1,2-dicarboxaldehyde to yield α,α′-dimethyl-*o*-xylene-α,α′-diol and (2) a reaction with thionyl chloride. As was the case for isomers **5***a* and **5***b*, isomers **6***a*, **6***b*, and **6***c* were first identified by comparison with the dipolar moments of the 4,6-dimethyl-2-oxo-1,3,2-dioxathiane isomeric analogs for which the *trans,trans* and *cis-trans* isomers have very similar polarity (μ = 3.51 D and 3.93 D respectively, in CCl_4) (21), while the *cis,cis* isomer is much more polar (μ = 5.31 D in CCl_4) (21). This trend was reflected on the hplc chromatogram. The product mixture, on separation, first gave a substance consisting of a mixture of two isomers tentatively identified as the *trans,trans* (**6***a*) and *cis,trans* (**6***b*) isomers, and then a third compound, identified as the *cis,cis* isomer (**6***c*). The isomeric mixture of **6***a* and **6***b* was used without further separation for the spectroscopic investigations because several attempts to separate them were not successful. Spectroscopic data presented later confirm this assignment.

[2] The terms *trans* and *cis* define here the relationship between the methyl group(s) and the S=O bond orientation.

Infrared spectra

The ir spectra of 0.05 *M* solutions of compounds **5***a*, **5***b*, and of the isomeric mixture **6***a*–**6***b*, recorded in CCl_4 and in CH_3CN, showed stretching vibrations for the S=O bond in the 1175–1260 cm^{-1} region, as reported in Table 1. Compound **5***a* showed two bands of unequal intensity in both solvents: the most intense band at 1186 cm^{-1} (s) and the other at 1225 cm^{-1} (m) in CCl_4 integrated for 75:25 respectively. In CH_3CN the two bands shifted to 1184 cm^{-1} (s) and 1218 cm^{-1} (m), integrating for 65:35 respectively. Compound **5***b*, on the other hand, showed only one band, both in CCl_4 (1226 cm^{-1}) and in CH_3CN (1215 cm^{-1}). The mixture **6***a*–**6***b* showed a slightly split band centered at 1222 cm^{-1} (s) (i.e. 1223 cm^{-1} and 1221 cm^{-1}) and a less intense band at 1187 cm^{-1} (m) in CCl_4. In CH_3CN the spectrum revealed a slightly split band centered at 1211 cm^{-1} (s) (i.e. 1212 cm^{-1} and 1209 cm^{-1}) and a band at 1183 cm^{-1} (m).

Because of solubility problems, the ir spectra of compound **6***c* were taken as a 0.001 *M* solution in CS_2 instead of CCl_4 and as a 0.01 *M* solution in CH_3CN. The spectrum in CS_2 showed two bands of unequal intensity, one at 1240 cm^{-1} and the other at 1225 cm^{-1}, integrating for 41:59 respectively. The spectrum in CH_3CN, on the other hand, showed only one split band centered at 1225 cm^{-1} (i.e. 1231 cm^{-1} and 1220 cm^{-1}). The very small trough between these two maxima supports the description as a split band (3). The ir spectrum of **4** was taken in CS_2 for reference purposes. Table 1 contains a summary of the ir results.

Nuclear magnetic resonance spectra

^1H (400 MHz) and ^{13}C (100.62 MHz) nuclear magnetic resonance spectra of compounds **5***a*, **5***b*, and of the isomeric mixture **6***a*–**6***b* were taken at different temperatures in the range −10° to −135°C. The ^1H spectra of compound **6***c* were also studied at different temperatures, whereas the ^{13}C spectra could be taken only at room temperature in $CDCl_3$, owing to solubility problems.

Compound **5***a* showed a spectral modification in both the ^1H and ^{13}C spectra in CHF_2Cl at low temperatures, as illustrated in Fig. 1. The ^{13}C spectra at −10°C show nine well-resolved signals (chemical shifts are given in Table 2) which were identified by substituent effects and off-resonance decoupling. At −125°C, each signal has split into a doublet of unequal intensity (82:18; the taller signals are labelled "c" while the smaller ones are labelled "b"). A free energy of activation of about 8.6 kcal/mol was estimated at −80°C (T_c) using standard equations and a transmission coefficient of 1.

The ^1H spectrum of **5***a* at −10°C (a summary of ^1H nmr parameters is given in Table 3) shows an AB pattern for the C-7 methylene protons, a quartet for the C-4 methine proton, and a doublet for the methyl protons. All signals broadened on lowering the temperature and the modified spectrum at −125°C shows a major set of signals (labelled "c", in accordance with the convention established in the ^{13}C spectra), consisting of an AB pattern, a quartet, and a doublet; the observed set of minor signals is labelled "b" and also consists of an AB pattern, a quartet, and a doublet.

The ^{13}C spectrum of compound **5***b* at −10°C also shows nine well-resolved signals which were identified by the same procedure as for those of **5***a* (Table 2). All signals broadened and split at low temperature so that, at −125°C, doublets of very unequal intensity are observed, the most intense lines accounting for 96% of the total spectrum (the minor components of quaternary C-5 and C-6 could, however, not be observed). A free energy of activation of about 8.9 kcal/mol was estimated at −85°C (T_c), using standard equations and a transmission coefficient of 1. The ^1H spectrum of **5***b* at −10°C (Table 3) shows, like that of **5***a*, an AB pattern for the C-7 methylene protons, a quartet for the C-4 methine proton, and a doublet for the methyl protons. All signals broadened at lower temperature, but no ^1H spectral splitting was observed down to −135°C.

The ^{13}C nmr spectrum of the isomeric mixture **6***a*–**6***b* at −10°C (Table 2) revealed the presence of fifteen signals which, through intensity consideration, were separated into two sets and assigned with the help of off-resonance decoupling. The major set consists of 10 lines: two quaternary aromatic carbons, four protonated aromatic carbons, two tertiary aliphatic carbons, and two methyl carbons. The minor set consists of 5 lines: one quaternary aromatic carbon, two protonated aromatic carbons, one tertiary aliphatic carbon, and one methyl carbon. No spectral change was observed down to −135°C. The ^1H spectrum of the same isomeric mixture, at −10°C (Table 3), also revealed two sets of aliphatic signals, a major set consisting of two quartets (methine protons) and two doublets (methyl protons) and a minor set consisting of only one quartet and one doublet. Again, at lower temperature, no spectral change was observed down to −135°C.

The ^{13}C spectrum of compound **6***c* (Table 2), as discussed earlier, was taken only at 25°C in $CDCl_3$: it showed five signals, which were readily identified by an off-resonance experiment. The ^1H spectrum of **6***c* in CHF_2Cl (Table 3), at −15°C, revealed, besides the aromatic resonances, one quartet (methine protons) and one doublet (methyl protons) which did not split further down to −135°C.

Discussion

Ring conformations from infrared spectra

Extensive ir investigation of the six-membered cyclic sulfites has led to the proposal that specific frequency domains are characteristic of each of the three possible arrangements (axial, equatorial, or isoclinal) of the sulfite moiety when molecular association effects are negligible, as is the case for concentrations of 0.05 *M* or less (3). Recent ir work (24) on compound **4** showed that these conformational frequency domains still hold for 7-membered cyclic sulfites. Thus, the straightforward observation of the S=O stretching bands for the isomeric compounds **5***a* and **5***b*, as well as for **6***a*, **6***b*, and **6***c*, could potentially identify the sulfite bond arrangement and thereby provide information on the different ring conformations present in solution.

The ir spectra of **5***a* (*trans* isomer) reveal two bands in both CCl_4 and CH_3CN, as summarized in Table 1. The more intense band (75%) at 1186 cm^{-1} is characteristic of an axially oriented S=O moiety and compatible with the *C*-a form because the axial boat form (*B*-a) can be excluded by the results (24) on **4**. The less intense band (25%) at 1225 cm^{-1} indicates the presence of the *TB* form. The induced solvent shifts of 2 cm^{-1} for the *C*-a band and of 7 cm^{-1} for the *TB* band, on going from CCl_4 to CH_3CN, are similar to those observed for six-membered cyclic sulfites (23) and for the parent compound **4**. Furthermore, the slight increase in amount of *TB* (Table 1) in the more polar solvent is expected since *TB* is more polar than *C*-a (24).

The fact that the ir spectra of **5***b* (*cis* isomer) reveal the existence of only one band at 1226 cm^{-1} in CCl_4 and 1215 cm^{-1} in CH_3CN is compatible with the existence of a *TB* form as the predominant or sole conformation.

Band assignment in the ir spectra of the mixture of compounds **6***a*–**6***b* made use of the integration results obtained from the ^1H and ^{13}C nmr spectra for the same mixture of isomers, as discussed later in the text. Thus, the more intense slightly split band centered at 1222 cm^{-1} in CCl_4 and at 1211 cm^{-1} in CH_3CN was assigned to the *cis*–*trans* isomer (**6***b*). These values, together with the solvent-induced shift of 11 cm^{-1}, suggest that the ring of this compound adopts a *TB* geometry. The absence of symmetry for this isomer is explicit in the ^{13}C nmr spectra discussed later. The less intense band at 1187 cm^{-1} in CCl_4 and at 1183 cm^{-1} in CH_3CN could then be attributed to the *C*-a form of the *trans*–*trans* isomer (**6***a*); the small solvent-induced shift of 4 cm^{-1} confirms that deduction. The presence of symmetry for this isomeric conformation is confirmed by the ^{13}C nmr spectrum which shows only half as many lines as that of **6***b*.

Because the ir spectrum of **6***c* could not be recorded in CCl_4, CS_2 was chosen as a replacement solvent of low polarity and compound **4** was used as reference to establish the characteristic *C*-a and *TB* S=O band. Thus, the CS_2 the spectrum of **4** showed two bands at 1223 cm^{-1} and 1184 cm^{-1} which compare well with values observed in CCl_4 (1220 cm^{-1} and 1184 cm^{-1}) for the *TB* and *C*-a forms (24).

The ir spectrum of **6***c* in CS_2 showed two bands at 1240 cm^{-1} and 1225 cm^{-1} in the ratio 41:59 respectively. Thus, the band at 1225 cm^{-1} suggests a *TB* ring geometry while the band at 1240 cm^{-1} (not detected in compounds **5***a* and **5***b*) falls well within the frequency domain (1242 ± 2 cm^{-1}) attributed to the

6*c*	−15		5.90		—	1.84
6*c*	−125		5.82		—	1.88

[a]The spectra were taken at 400 MHz with TMS as internal reference.
[b]The labels b and c are defined in the text; the ratio of c/b at −125°C is 82:18.
[c]The first row of chemical shifts refers to the less intense set of signals.

C-e form in the six-membered sulfites (23). Furthermore, the ir spectra of **6***c* in CH_3CN showed only a single split band centered at 1225 cm^{-1}, which suggests a shift in equilibrium towards a single *C*-e form. This tentative conclusion is corroborated by the large induced solvent shift of 15 cm^{-1} on going from CS_2 to CH_3CN, which is comparable to values commonly observed for the *C*-e form in six-membered cyclic sulfites, on going from CCl_4 to CH_3CN (23), and by the fact that the population of the more polar conformer (*C*-e form) increases on going from a less polar CS_2 solvent (41%) to a more polar CH_3CN solvent (~100%).

Although the analysis of the ir spectra provides valuable information on the ring geometry, it is of little value to locate the methyl groups which, as molecular models show, can adopt two different positions in the *TB* forms of **5***a*, **5***b*, and **6***b*, namely a pseudo-equatorial or axial position as shown in structures **7** (*TB*-*t*-Me_e) and **8** (*TB*-*t*-Me_a) for compound **5***a*, structures **9** (*TB*-*c*-Me_e) and **10** (*TB*-*c*-Me_a) for compound **5***b*, and structures **11** (*TB*-*t*-Me_e, *c*-Me_e) and **12** (*TB*-*t*-Me_a, *c*-Me_a) for compound **6***b*. (The letters *c* and *t* refer to *cis* and *trans* while a and e after Me refer to pseudoaxial and pseudoequatorial positions for the methyl groups.) Fortunately, ^1H and ^{13}C nmr parameters can give information on the methyl group orientation which is required to distinguish between the two possible

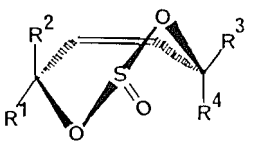
For personal use only.

TB conformers for each of these three compounds, as discussed next. Furthermore, the nmr data provide confirmation for the ring conformations deduced tentatively above from the ir data.



7 $R^3=CH_3, R^1=R^2=R^4=H$ (TB-t-Me_e)
8 $R^2=CH_3, R^1=R^3=R^4=H$ (TB-t-Me_a)
9 $R^1=CH_3, R^2=R^3=R^4=H$ (TB-c-Me_e)
10 $R^4=CH_3, R^1=R^2=R^3=H$ (TB-c-Me_a)
11 $R^1=R^3=CH_3, R^2=R^4=H$ (TB-t-Me_e, c-Me_e)
12 $R^2=R^4=CH_3, R^1=R^3=H$ (TB-t-Me_a, c-Me_a)

Methyl orientation from ^1H nuclear magnetic resonance spectra

The variable temperature 400 MHz ^1H nmr spectra of compound **5***a* (*trans* isomer) revealed only one spectral modification in the temperature range of −10° to −135°C, as shown in Fig. 1. Thus, the existence of two conformations of unequal populations, corresponding to the b and c signals, is indicated. Assuming that the $C \rightleftharpoons TB$ interconversion process is responsible for the spectral change (24), then distinct ^1H signals should be observed for a chair and *TB* forms at −125°C. The more intense AB pattern of the H-7 methylene protons (labelled c in Fig. 1), with a chemical shift difference of 2.2 ppm, identifies the *C*-a form because of the well-known anisotropic chemical shift effect of the axial S=O bond which strongly deshields the *syn*-1,3-axial proton relative to the equatorial one (8, 11). This effect, though, is more severe in the *C*-a form of **5***a* than in the *C*-a form of 2-oxo-1,3,2-dioxathiane (**1**) because of the greater puckering of the seven-membered cyclic sulfite. The quartet at 6.81 ppm can be ascribed to the axial H-4, in agreement with the fact that the axial S=O anisotropy effect should also deshield this proton somewhat comparably to the axial H-7 (6.66 ppm).

Interpretation of the ^1H nmr signals of the *TB* conformer of **5***a*, however, is not as straightforward. Firstly, our inability to slow down the pseudorotation process of the *TB* conformers at −135°C suggests two possibilities: (a) the existence of one predominant *TB* form (**7** or **8**) or (b) the existence of a mixture of **7** and **8** in rapid equilibrium at −135°C. Fortunately, closer examination of the ^1H chemical shifts leads to further insight into this question. The ^1H spectrum at −125°C (Fig. 1) shows a minor AB pattern labelled b (δ_A = 5.38 and δ_B = 5.01), showing a chemical shift difference of only 0.37 ppm. Results reported (24) for the *TB* form of the parent compound **4** show that the AB pattern of the CH_2 group *syn* to the S=O bond has a proton chemical shift difference of 1.2 ppm which is reduced to 0.3 ppm for the CH_2 group *anti* to the S=O bond. The result for **5***a* therefore suggests a predominant *TB* form of structure **7** (*TB*-*t*-Me_e) for which the methylene group is *anti* to the S=O bond. Molecular models of **7** reveal that the axial methine proton (H-4) should be well deshielded by the anisotropic effects of the S=O moiety and the presence of a broadened quartet at 6.32 ppm is clearly due to its axial-like position. It therefore appears that **7** is the predominant conformation for **5***a* although a minor amount of conformer **8** cannot be rigorously ruled out.

A similar analysis of the ^1H spectral data at −125°C for compound **5***b* (*cis*-isomer) shows a large chemical shift difference (Δ = 1.33 ppm) for the H-7 methylene protons, which correlated well with the chemical shift difference (Δ = 1.2 ppm) observed for the CH_2 group *syn* to the S=O bond in the *TB* form of **4**. It is significant that the methine proton (H-4) of **5***b* is less deshielded (5.51 ppm) than the methine proton of the *TB* form **7** of compound **5***a* (6.32 ppm). Thus H-4 in **5***b* cannot be axial-like and *syn* to the S=O bond. These parameters are therefore compatible with the *TB* form **9** as the predominant conformation of **5***b* in which H-4 is axial but *anti* to S=O.

The ^{13}C spectra confirm the above conclusions for **5***a* and **5***b*. In addition, the low temperature spectrum of **5***b* reveals the existence of another minor *TB* form as discussed later.

Finally, it should be noted that the orientation of the S=O bond in the *TB* forms **7** and **9** seems to have little influence on the ^1H chemical shifts of the equatorial methyl groups (1.83 ppm in conformation **7** and 1.85 in conformation **9**).

Conclusions derived from the ^1H spectra of monomethylated compounds **5***a* and **5***b* are useful to interpret the proton spectra of compounds **6***a*, **6***b*, and **6***c*. Firstly, the invariance of the ^1H spectra of the mixture of isomers **6***a*–**6***b* suggests either the presence of a single conformer for each isomer in the temperature range studied or the existence for each isomer of a very rapid equilibrium between two or more different conformers. The following analysis is compatible with single conformations for each of **6***a* and **6***b*.

Examination of the ^1H spectra at −125°C for the isomeric mixture **6***a*–**6***b* revealed two sets of signals of unequal intensities (Table 3). The minor set of signals (~10% of the intensity), consisting of a well-deshielded quartet (methine proton signal somewhat broadened by viscosity increase) at 6.73 ppm and of a doublet (methyl protons) at 1.70 ppm, exhibits chemical shifts similar to those of the *C*-a form of **5***a* for which the methine proton is at 6.81 ppm and the methyl protons is at 1.72 ppm. The ^1H nmr results therefore support the earlier ir suggestion that **6***a* existed solely under the *C*-a form. The plane of symmetry passing through the S=O bond of the *C*-a form explains the degenerated methine and methyl signals.

The major set of signals belonging to **6***b* (about 90% of the intensity), on the other hand, consists of two quartets and two doublets, indicating a non-symmetrical conformation for **6***b*. Furthermore, the relative integration of the major and the minor set of signals gives the same results as were determined from the two S=O bands in the ir spectrum in CCl_4 (Table 1). It therefore appears that the signals of **6***b* ought to correspond to a non-symmetrical *TB* conformation. The ^1H chemical shifts at −125°C support this ring conformation and provide information on the position of the methyl group. The quartet (methine proton) at 5.53 ppm is close to the methine proton of the *anti* carbon in the *TB*-*c*-Me_e form (**9**) of compound **5***b* (5.51 ppm), while the other quartet at 6.36 ppm has a chemical shift very similar to that of the methine proton of the *TB*-*t*-Me_e form (**7**) of compound **5***a* (6.32 ppm). Furthermore, the methyl groups of compound **6***b* (1.79 and 1.82 ppm) have about the same chemical shifts as the methyl groups of the monomethylated analogs, namely the *TB*-*t*-Me_e form (**7**) of compound **5***a* (1.83 ppm) and the *TB*-*c*-Me_e form (**9**) of compound **5***b* (1.85 ppm). Finally, the chemical shift difference between the methine protons in compound **6***b* (Δ = 0.83 ppm) is about the same as that between the two axial-like protons of the *TB* form of the parent compound **4** (Δ = 0.8 ppm) (24), therefore indicating that compound **6***b* exists under a *TB* conformer with structure **11**

TABLE 4. Carbon-13 chemical shift substituent effects[a] (Δ values) produced by methyl substitution on the benzylic carbons of 2-oxo-1,3,2 benzodioxathiepin (**4**)

Compound	Ring conformation[b]	Methyl substituent effect (Δ values)				
		α	β	γ[c]	δ[d]	γ'[e]
5*a*	*C*-a (Me_e)	+3.50	+3.28	−0.39	+0.22	−3.47[f]
5*a*	*TB*-*t*-Me_e (**7**)	+5.75	+4.72	+0.55	+0.78	−1.0[f,g]
5*b*	*TB*-*c*-Me_e (**9**)	+5.29	+4.55	+0.58	+0.82	−0.81[f]

[a] All methyl substituent effects are calculated using ^{13}C parameters of **5***a* and **5***b* at −125°C, in Table 2, relative to ^{13}C parameters of **4** in ref. 24. For γ', see footnote *f* below. A positive sign indicates a downfield shift.

[b] As determined previously in the text by ir, ^1H, and ^{13}C analysis.

[c] Defined as the methyl substituent effect on C-6. For the *TB* forms of **5***a* and **5***b*, the reference parameters for the *TB* form of **4** have assumed that the signal at 134.72 ppm belongs to the aromatic quaternary carbon adjacent to the benzylic carbon *syn* to S=O, whereas the signal at 136.15 ppm is assigned to the other quaternary carbon (24).

[d] Defined as the methyl substituent effect on C-7.

[e] Defined as the methyl substituent effect on C-8.

[f] The γ' values are obtained relative to the C-8 chemical shifts in the *C*-a or *TB* forms of **4**. These protonated carbons were assigned experimentally for a solution of **4** in CH_3OCH_3 at −125°C from the analysis of the effects of selective ^1H decoupling of the methylene protons on the coupled ^{13}C nmr spectrum. It was assumed that this assignment is also valid for a solution in CHF_2Cl at −150°C, so that C-8 (*TB*) is taken as 128.51 and C-8 (*C*-a) is taken as 130.97 ppm.

[g] The C-8 resonance of the *TB* form of **5***a* is partially obscured by the C-8 resonance of the *C*-a form of **5***a*.

(*TB*-*t*-Me_e, *c*-Me_e).

The absence of a ^1H nmr spectral change for compound **6***c* in CHF_2Cl down to −135°C suggests that, in this solvent, one conformation is strongly predominant. The observation of only one methine proton quartet at 5.82 ppm and only one methyl doublet at 1.88 ppm in the spectrum at −125°C indicates the existence of symmetry. These nmr data are compatible with the earlier suggestion from the ir spectral analysis that the *C*-e form is very predominant for **6***c* in a polar solvent. Because the *C*-e form has not been detected for other seven-membered sulfites, confirmation is less straightforward. However, since *C*-a can confidently be rejected from ^1H chemical shift and ir considerations, *C*-e is therefore reasonable. On the other hand, a small amount of the *TB* form cannot be excluded since the ir data show that in CS_2 the *TB* form is slightly favored. The ^{13}C spectra discussed next are also compatible with the strong predominance of the *C*-e form in CHF_2Cl.

^{13}C spectra

^{13}C nuclear magnetic resonance has proven to be a powerful technique sensitive to small stereochemical changes which often translate into large chemical shift differences. In compound **4** (24), the chemical shifts of the benzylic carbons (C-4 and C-7) were found to be characteristic of both the conformation (*C*-a vs. *TB* form) and the relative orientation of the S=O bond with respect to the C—O bonds in the *TB* form (*syn* carbon vs. *anti* carbon). Therefore, the methylene carbon (C-7 in Table 2) chemical shift should provide a valuable stereochemical probe for the monomethylated isomers, especially when the methyl group chooses to adopt a pseudoequatorial position as was suggested earlier for **5***a* and **5***b*.

The ^{13}C spectrum of the major conformation of **5***a*, at −125°C, shows a methylene carbon at 62.79 ppm, which is close to the reference value for the *C*-a form of **4** (62.49 ppm), while the minor conformation of **5***a* shows a methylene carbon at 67.19 ppm, fairly close to the *anti*-methylene carbon of the reference *TB* form of **4** (66.41 ppm). These results confirm the conclusions reached earlier from ir and ^1H spectra, that **5***a* exists as a mixture of *C*-a and *TB*-*t*-Me_e (**7**) conformers for which the former is predominant.

Similarly, the ^{13}C spectrum of the major conformation of **5***b*, at −125°C, indicates that the methylene carbon at 63.91 ppm is close to the *syn*-methylene carbon of the *TB* form of **4** (63.09 ppm), in agreement with the conclusion from ir and ^1H spectra that the major conformation of **5***b* should be *TB*-*c*-Me_e (**9**).

Methyl substituent effects (α, β, γ, δ, and γ') have been determined (Table 4) for the C4, C5, C6, C7, and C8 atoms of the *C*-a form of **5***a* and of the *TB* forms of **5***a* and **5***b*, relative to the same conformation of compound **4**, used as reference. The Δ parameters in Table 4 differ significantly for the *C*-a form and the *TB* form of **5***a*, as could be expected from the geometrical differences between the two conformations. However, the remarkable similarity between the methyl-substitution effects for the *TB* forms of compounds **5***a* and **5***b* supports the previous suggestion that the methyl groups are located in very similar environments for both *TB* forms, namely the pseudo-equatorial benzylic position as shown in **7** for **5***a*, and **9** for **5***b*.

The equatorial nature of these methyl groups provides interesting consequences. A close examination of molecular models of *C*-a and *TB* forms having an equatorial methyl group reveals that the angle between the C8—H bond and the C4—CH_3 bond is closer to 0° in the *C*-a form than in the *TB* form, suggesting that the γ' interaction between the C-8 hydrogen atom and the methyl group should be stronger for the *C*-a form. In fact, the 3.47 ppm upfield shift of the C-8 carbon (Table 4), for the *C*-a form of **5***a*, falls well in line with the 3.7 ppm upfield shift observed for the C-8 carbon of 1-methylnaphthalene (25). The weaker γ' interaction in the *TB* forms **7** (*TB*-*t*-Me_e) and **9** (*TB*-*c*-Me_e) leads to upfield shifts of only 1.0 ppm and 0.81 ppm respectively. Similar differences were also observed for 4-methyl-1,3-dioxa-5,6-benzocycloheptene,[3] where C-8 is shielded by 3.23 ppm in the *C*-a form and by only 0.91 ppm in the *TB* form.

Interpretation of the ^{13}C nmr signals of the minor confor-

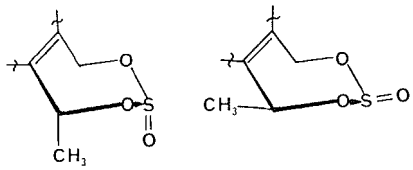
mation of **5***b* must be made with caution, since neither ^{1}H nor ir signals were detected for that form. A priori, those ^{13}C signals can be attributed to three possible conformations, namely a *C*-a form with an axial methyl (**13**), a *C*-e form with an equatorial methyl (**14**), and the *TB* form of **10** with a pseudoaxial methyl. The problem can, however, be reduced to a choice between the *TB*-*c*-Me_a form (**10**) and the *C*-e form (**14**), since the *C*-a form cannot account for the deshielding of the C-7 methylene carbon on introducing an axial methyl group on the C-4 carbon.



13 **14**

The chemical shift of the methylene carbon (66.58 ppm) of the minor conformation of **5***b* is in fact very similar to that of the *anti*-methylene carbon of the *TB* form of **4** (66.41 ppm), as would be expected for the *TB*-*c*-Me_a form (**10**). Data allowing the *C*-e form to be ruled out, however, require the analysis of the ^{13}C data observed for the *cis,cis* dimethyl isomer **6***c*. Consequently, the ^{13}C parameters of the three dimethylated isomeric compounds will now be considered.

As described earlier, the constancy of the ^{13}C spectra on going from −10°C to −135°C for the mixture of **6***a*–**6***b* indicates a single conformation for each stereoisomer. The presence of only five resonances for the *trans,trans* isomer **6***a*, as described earlier, indicates a symmetrical conformation for that isomer which must be the *C*-a form, to account for the well-shielded methine carbon (65.55 ppm) from the γ-*gauche* effect of the S=O bond. Furthermore, the upfield γ shift of C-8 (3.57 ppm) and the methyl chemical shift (18.89 ppm), being similar to the analogous values for the *C*-a form of **5***a* (3.47 ppm and δ_{Me} = 18.59 ppm), support the conclusion for **6***a*.

The stable conformation of the *cis,trans* isomer **6***b* is nonsymmetrical, as shown by its 10-line ^{13}C nmr spectrum. It is found to have a chemical shift difference of 3.50 ppm between C-4 and C-7 which is similar to the value observed for the benzylic carbons of the *TB* form of the parent compound (**4**), namely 3.32 ppm. Furthermore, the upfield γ-effect on C-8 (−0.77 ppm) and the methyl chemical shifts of 20.49 and 20.85 ppm closely resemble those of the *TB* form **7** for **5***a* (*TB*-*t*-Me_e) (γ_{effect} = −1.0 ppm and δ_{Me} = 20.28 ppm) and the *TB* form **9** for **5***b* (*TB*-*c*-Me_e) (γ_{effect} = −0.81 ppm and δ_{Me} = 20.38 ppm). The above analysis confirms the earlier conclusion that **6***b* adopts the *TB* form (**11**).

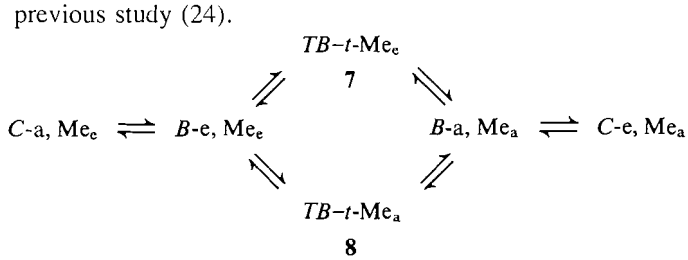
Conformational assignment in the case of isomer **6***c* proved more difficult than for the other compounds because the ^{13}C nmr spectrum of this rather insoluble product could be studied only in $CDCl_3$ at room temperature, rather than in CHF_2Cl at low temperatures. Direct comparison of chemical shifts between **6***c* and the other compounds must therefore be made with caution. The ir and ^{1}H parameters suggested that, in a polar solvent ($CDCl_3$ or CHF_2Cl), there is only one conformation for **6***c*, namely the symmetrical *C*-e with two equatorial methyl groups. The C4 and C7 signals have a chemical shift of 70.92 ppm, which is consistent with an *anti* relationship with respect to the S=O bond as revealed from a comparison with the *anti* carbon in *TB*-*c*-Me_e (**9**) located at 71.70 ppm. All spectroscopic data presented so far indicate that *C*-e is the predominant conformation of **6***c* in polar solvents.

The conclusion for isomer **6***c* can now be used to reexamine the earlier conformational assignment for the minor signals of compound **5***b*. Since the *C*-e form (**14**) possible for **5***b* differs from the *C*-e form of **6***c* only by the presence of an equatorial hydrogen atom at the C-7 position instead of a methyl group, it should in principle exhibit similar methyl and methine carbon chemical shifts if both exist in the same ring conformation. Close examination of the ^{13}C chemical shifts of **6***c* and of the minor conformation of **5***b* shows that a similarity exists for the methine carbons (70.92 ppm for **6***c* and 71.21 ppm for **5***b*) but not for the methyl group.

Recalling that both C4 and C7 chemical shifts constitute sensitive conformational probes, it was shown earlier that the CH_2 signal of the minor form of **5***b* pointed to the *TB* form **10**, based on a comparison with signals from the *TB* form of **4** used as model. The limited number of reference ^{13}C parameters for seven-membered rings limits our ability to distinguish clearly between *C*-e (**14**) and *TB* (**10**). Certainly, the observation of an ir S=O band for this minor conformer would have helped. If it is argued that the C7 methylene is a more reliable probe than the C4 methine signal, then the *TB*-*c*-Me_a form (**10**) would be preferred as the minor conformer of **5***b* and this might explain why the methyl chemical shifts differ for **5***b* and **6***c* (18.68 and 20.15 ppm respectively). But the solubility problem and the different spectral temperature limit the value of comparisons with **6***c*.

Conformational dynamic properties of **5**a

The interconversion scheme for cycloheptene consists of two basic molecular motions, namely a $C \rightleftharpoons B$ transformation and a $B \rightleftharpoons TB$ pseudorotation. This scheme (26) must be modified for **5***a* by taking into account the pyramidal nature of the S atom and the orientation of both the S=O bond and the methyl group. The appropriate interconversion pathways are indicated in Scheme 1, where letters a and e after *C* and *B* refer to the S=O orientation and the letters after Me describe the methyl group environment. This scheme supposes that flipping of the sulfite end of the molecules is less energetic than is wagging of the benzo part for the $C \rightleftharpoons B$ step, as was suggested in a previous study (24).



SCHEME 1

Because **7** is the only detected *TB* conformation for **5***a*, it is not possible to derive the pseudorotation barrier from the nmr spectra. On the other hand, compound **5***a* shows a *C*-a to *TB* interconversion barrier of about 8.6 kcal/mol which lies very close to that of compound **4** (9.0 kcal/mol) (24). This result could be explained by a similar molecular motion for **4** and **5***a*, as shown in Scheme 1. Since the environment of the methyl group remains essentially unchanged on going from *C*-a, Me_e to *B*-e, Me_e (the effect of the remote S=O bond being neglected), any significant methyl effect would necessarily be constant over the whole energy profile of this interconversion

step in agreement with the observed $\Delta G^{\ddagger}$ values for **4** and **5***a*. A flip of the benzo part, which would transform *C*-a, Me_c into *B*-a, Me_a, cannot explain the similar $\Delta G^{\ddagger}$ values for **4** and **5***a* since it would create 1,3-diaxial CH_3---O=S as well as 1,5-diaxial benzylic CH_3---H interactions in the transition state, which cannot exist in the preferred molecular motion of **4**.

Experimental

Melting points are uncorrected and were determined using a Büchi melting point apparatus. High-resolution spectra at 70 eV were recorded using a modified MS-9 spectrometer. The medium pressure liquid chromatography was performed on 0.040–0.063 μm silica gel (Merck no. 9385) with an ALTEX model 150 pressure regulator and a 254 nm uv detector. Solvents were distilled prior to use.

The ir spectra of the monomethylated derivatives **5***a* and **5***b* were taken as 0.05 *M* solutions in CCl_4 and in CH_3CN, in a 0.5 mm KBr cell using a Beckmann IR-20 spectrometer for the normal spectra and a Beckmann IR-9 spectrometer for the scale expansions. Integrations were made using a DuPont model 310 curve synthesizer which decomposes overlapping peaks by generation of Lorentzian functions.

The ir spectra of the dimethylated compounds **6***a*–**6***b* were taken as 0.05 *M* solutions in CCl_4 and in CH_3CN, but those of compound **6***c* were taken as 0.001 *M* and 0.01 *M* solutions in CS_2 and in CH_3CN respectively. Spectra of thin films between KBr windows (0.05 mm cell: nominal value) were recorded on a Digilab FTS-15C/D Fourier transform infrared spectrometer, equipped with a wide range photoconductive mercury cadmium telluride detector, a KBr beam splitter, and a LOBAR source. The instrument was purged with nitrogen before use. Typically, 200 interferograms of 2096 points each, recorded with a maximum optical retardation of 0.50 cm^{-1} and an optical velocity of 1.2 cm s^{-1}, were co-added, apodized with a triangular function, and Fourier transformed with 8 levels of zero filling, resulting in a spectral resolution of 2 cm^{-1}. The base line was corrected using multiple linear least-square functions. Integrations were performed using a PEAKAREA program (Digilab) which uses the trapezoidal rule, with a first point – last point approximation. This kind of operation leads to approximate values in the case of **6***a*–**6***b*, where partially overlapping peaks occur.

Routine ^1H nmr spectra were taken on a Bruker WH-90 spectrometer; solutions were typically 10% (w/v) in $CDCl_3$ containing Me_4Si as reference. Routine ^{13}C nmr spectra were taken on a Bruker WP-80 spectrometer; solutions were typically 15% (w/v) in $CDCl_3$ containing Me_4Si as reference.

The variable temperature ^1H nmr spectra at 400 MHz and ^{13}C nmr spectra at 100.62 MHz were obtained using a Bruker WH-400 spectrometer equipped with a variable temperature unit B-VT-1000. Temperatures were determined directly using the B-VT-100 unit. Calibration, using a thermocouple inside a solvent-containing nmr tube, indicates that the low temperatures reported are exact within 2°C.

The ^1H samples were studied as solutions in chlorodifluoromethane (5–6 mg in 0.55 mL of solution) containing Me_4Si and about 13% of CD_2Cl_2 (for locking purposes), in standard 5 mm tubes which had been degassed and sealed. The following parameters were used: flip angle = 60–65°; SW = 4000 Hz; pulse delay = none; data size = 4K; acquisition time = 0.512 s. The ^{13}C spectra were recorded with proton noise decoupling for solutions in CHF_2Cl (60–70 mg in 2.2 mL of solution) containing Me_4Si and about 13% of CD_2Cl_2, as locking agent, in standard 10 mm tubes which had been degassed and sealed. The following instrumental parameters were used: flip angle = 65–70°; SW = 17 000–22 000 Hz; data size: 16K; acquisition time = 0.328 s or 0.482 s; pulse delay = none.

Selective decoupling in the case of compound **4** was done using a decoupling power corresponding to 175.9 Hz. The rate constants were determined at the coalescence temperature using the equation $k = \pi\Delta\nu/\sqrt{2}$ for singlet to doublet splitting in ^1H (methyl signals of **5***a*) and ^{13}C nmr spectra (the equation provides an acceptable estimate for lines of unequal intensity (27)). The free energy barriers were calculated from standard equations (28) using a transmission coefficient of 1.

*α-Methyl-o-xylene-α,α′-diol (**15**)*

This compound was prepared from 2-acetyl benzoic acid (Aldrich) by a procedure already published (29). It was characterized by its melting point (65–67°C) and by its ^1H nmr spectrum, which were identical with those published.

4-Methyl-5,6-benzo-2-oxo-1,3,2dioxathiepin (cis *and* trans *isomers) (**5**)*

A solution of freshly distilled (30) thionyl chloride (1.19 g, 0.01 mol) in 50 mL of anhydrous ether was added dropwise during 30 min, at 0°C and under a nitrogen atmosphere, to a mixture of α-methyl-*o*-xylene-α,α′-diol (**15**) and triethylamine (2.02 g, 0.02 mol). After two hours at 0°C, the reaction is complete as shown by the ^1H spectrum of an aliquot. The mixture is then filtered and evaporated under reduced pressure, giving 1.5 g (76%) of a yellow oil containing the two isomers. Column chromatograpy on 15 μm silica gel (Merck 60H), using pentane/ether (97.5:2.5) as eluant, gave in the first fractions the *trans* isomer **5***a* (mp: 36–37°C) and in the last fractions the *cis* isomer **5***b* (mp: 56–57°C). The ^1H and ^{13}C nmr spectra (Tables 3 and 2) as well as high resolution mass spectra confirm their identity. *Mol. Wt.* calcd. for **5***a*, $C_9H_{10}O_3S$: 198.0351; found (mass spectrum at 70 eV): 198.0383. *Mol. Wt.* calcd. for **5***b*, $C_9H_{10}O_3S$: 198.0351; found (mass spectrum at 70 eV): 198.0339.

*α,α′-Dimethyl-o-xylene-α,α′-diol (**16**)*

This compound was prepared from 1,2-benzodicarboxaldehyde (Aldrich) by a procedure already published (31). The oily diastereoisomeric mixture thus obtained was used without further purification. The ^1H, ^{13}C nmr, and high-resolution mass spectra confirm its identity; ^1H nmr, δ: 1.47, 1.45 (2d, 6H, 2×Me), 5.15, 5.07 (2q, 2H, 2×CH), 7.52–7.20 (m, 4H, aromatic H's); ^{13}C nmr, δ: 24.4, 23.3 (2×Me), 67.1, 64.9 (2×CH), 127.7, 127.7, 126.1, 125.2 (4 × aromatic protonated carbons), 142.1, 141.9 (2 × aromatic quaternary carbons). *Mol. Wt.* calcd. for **16** – H_2O, $C_{10}H_{12}O$: 148.0888, found (mass spectrum at 70 eV): 148.0037 (no molecular ion peak could be detected).

4,7-Dimethyl-5,6-benzo-2-oxo-1,3,2-dixathiepin (trans,trans (**6**a), cis,trans (**6**b), *and* cis,cis (**6**c) *isomers)*

A solution of freshly distilled (30) thionyl chloride (2.77 g, 0.023 mol) in 120 mL of anhydrous ether was added dropwise (2 hours), at 0°C and under nitrogen, to a mixture of α,α′-dimethyl-*o*-xylene-α,α′-diol (3.9 g, 0.023 mol) and triethylamine (4.75 g, 0.046 mol). After two more hours at 0°C, the temperature was allowed to rise to 25°C overnight. The reaction was then complete, as shown by the ^1H nmr spectrum of an aliquot. The mixture was filtered and evaporated under reduced pressure, giving 3.28 g (66%) of a yellow oil containing the three isomers. Column chromatography on 0.040–0.063 μm silica gel (Merck no. 9385) using a hplc apparatus and hexane/ethyl acetate (98:2) as eluant gave, in the first fractions, a mixture of **6***a*–**6***b* and, in the last fractions, **6***c* (mp: 151–152°C). The ^1H and ^{13}C nmr spectra (Tables 3 and 2) as well as high-resolution mass spectra (at 70 eV) confirm their identity. *Mol. Wt.* calcd. for **6***a*–**6***b*, $C_{10}H_{12}O_3S$: 212.0507; found (mass spectra at 70 eV): 212.0547. *Mol. Wt.* calcd. for **6***c*, $C_{10}H_{12}O_3S$: 212.0507 (mass spectra at 70 eV): 212.0499.

A serendipitous, high yield conversion of norbornenone to tricyclo[3.2.1.$0^{2,7}$]octan-4-one[1]

ARTHUR J. RAGAUSKAS AND J. B. STOTHERS
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received February 4, 1983

ARTHUR J. RAGAUSKAS and J. B. STOTHERS. Can. J. Chem. **61**, 2254 (1983).

Simmons-Smith cyclopropanation of the trimethylsilyl enol ether of norbornenone has been found to generate the 2-trimethylsilyl ether of homoquadricyclene, homoketonization of which affords the symmetrical tricyclo[3.2.1.$0^{2,7}$]octan-4-one regiospecifically with high stereoselectivity favoring inversion of configuration.

ARTHUR J. RAGAUSKAS et J. B. STOTHERS. Can. J. Chem. **61**, 2254 (1983).

On a trouvé que la réaction de cyclopropanation de Simmons-Smith, appliquée a l'éther d'énol triméthylsilyle du norbornénone, conduit à l'éther triméthylsilyle-2 de l'homoquadricyclène. L'homocétonisation de ce dernier fournit le composé symétrique tricyclo[3.2.1.$0^{2,7}$] de façon regiospécifique et possédant un haut degré de stéréosélectivité favorisant l'inversion de configuration.

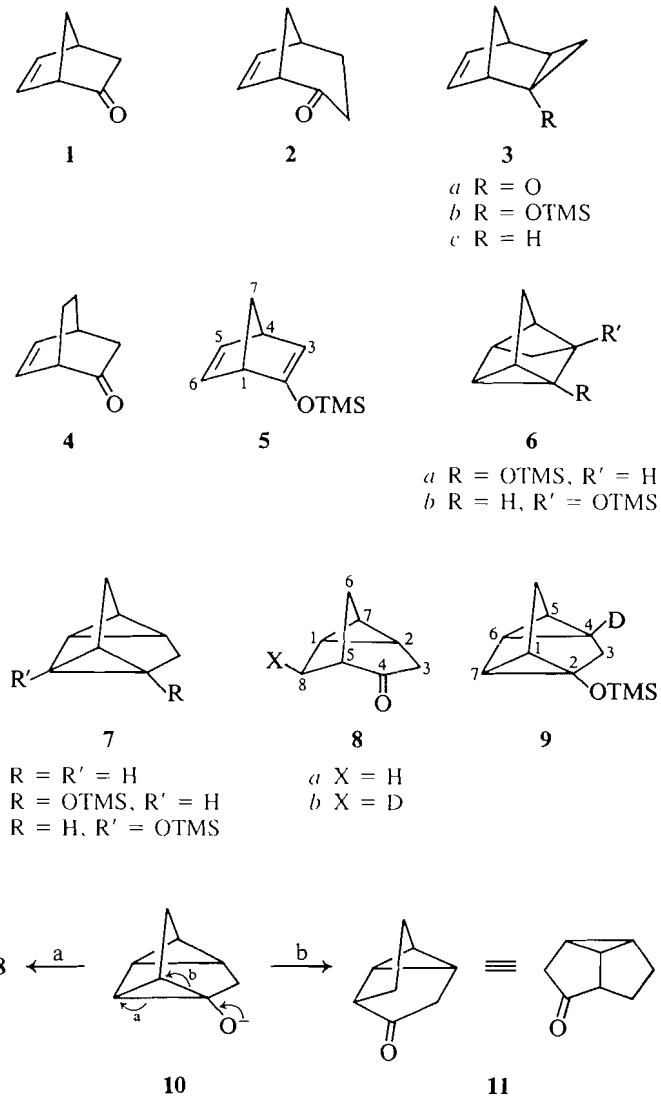
As an extension of our examination of ring expansion by homoketonization of cyclopropoxide derivatives, we were interested in the conversion of norbornenone (**1**) to bicyclo[3.2.1]oct-6-en-2-one (**2**) through cyclopropoxide **3***a*, by analogy with our results for bicyclooctenone **4** (1). We wish to describe the rather unexpected finding that the reaction sequence leads to the formation of tricyclo[3.2.1.$0^{2,7}$]octan-4-one in very good yield.

In the general sequence (1), the ketone of interest is converted to the corresponding trimethylsilyl enol ether which is then cyclopropanated with a zinc–silver couple and methylene iodide. For a variety of bicyclic ketones a single cyclopropyl derivative is formed. Cleavage of the resulting cyclopropyl ether can be accomplished with dilute HCl in THF to produce the cyclopropanol which upon addition to base readily undergoes ring opening to ketonic products, i.e. homoketonization. Alternatively, treatment of the cyclopropyl ether with base directly effects cleavage and homoketonization. Since, with ketones having bridges of two carbons or less, this sequence leads preferentially to the ring expanded ketone, we anticipated a smooth conversion of **1** → **2**.

Reaction of **1** with lithium diisopropylamide followed by the addition of trimethylsilyl chloride and triethylamine gave **5** in 79% isolated yield. Cyclopropanation afforded a single product quantitatively, having no olefinic absorption in either the ^{1}H or ^{13}Cmr spectra. Its ^{1}H spectrum consisted of four multiplets (δ(C_6D_6): 1.16 (2H), 1.76 (4H), 1.97 (2H), and 2.12 (1H)) and a strong singlet at δ 0.20 (Me_3Si), while the ^{13}C spectrum exhibited two methylene signals (δ_C 25.3, 30.7), five methine peaks (20.1, 21.5, 24.4, 27.4, and 33.7), a quaternary signal (69.2), and trimethylsilyl absorption at δ_C 1.1. The molecular formula, $C_{11}H_{18}OSi$, shown by precise mass measurement, confirmed the addition of one methylene group and readily dismissed the possibility of double cyclopropanation, i.e., at the double bond of **3***b*. High regioselectivity has been found for monocyclopropanations of trimethylsilyl enol ethers of unsaturated ketones, such that addition occurs exclusively at the enolic double bond provided a large excess of the Simmons-Smith reagent is avoided (1, 2). Nevertheless the product cannot be **3***b*.

Since it is well established that halocarbenes add to norbornadienes by both 1,2- and homo-1,4-addition (3), the product could conceivably be a bishomoprismane derivative **6**. The analog of **6***a* was found as a minor product from the reaction of difluorocarbene with **5** (4). Thus, **6***a* and **6***b* were plausible structures for the addition product. Also, in the earlier studies of halocarbene additions to norbornadiene (4) and substituted derivatives (5), it was discovered that the 1,2-adducts, corre-



[1] Part 105 in the series ^{13}Cmr studies; for part 104 see ref. 11.

For personal use only.

sponding to **3***c*, are thermally labile. While several are transformed to bicyclo[3.2.1]octa-3,6-dienyl derivatives, certain adducts undergo cycloaddition upon heating to form homoquadricyclene derivatives having carbon skeleton **7***a*. Analogy suggested that **7***b* could be our addition product, with **7***c* as a less likely possibility.

On treatment with base, the addition product gave a single ketone in essentially quantitative yield, having carbonyl absorption (ir 1727 cm^{-1}, δ_C 211.7) indicative of a six-membered ring ketone. The ^{13}Cmr spectrum contained five signals, in addition to the carbonyl peak: δ_C 9.2 (CH), 14.4 (2CH), 28.6 ($2CH_2$), 33.3 (CH_2), and 47.8 (CH). The two more intense signals remained as singlets in the presence of shift reagent ($Eu(fod)_3$), showing the ketone to be symmetric. Only **8***a*, of the several ketones which could form by homoketonization of **6***a*, **6***b*, **7***b*, and **7***c*, fits these data and the mp of the 2,4-dinitrophenylhydrazone agreed with literature values (6). The ^{1}H spectrum gave further confirmation. A 1-proton multiplet at δ 1.03 coupled to a sharp 2-proton doublet (J = 2.7 Hz) at 2.525 and a broad 2-proton doublet (J = 7.5 Hz) at 1.46 were readily ascribed to H-2, -3, and -1,7, respectively. A broadened triplet ($J \sim$ 5.3 Hz) at δ 2.50, due to H-5, and an "AB" pattern for the 6,8-protons were apparent. The A part (δ 2.01) was also coupled to H-5 ($J \sim$ 5.3 Hz) and H-1,7 ($J \sim$ 2 Hz), while the B part (δ 1.85) was a clean doublet (J_{AB} = 12.2 Hz) undoubtedly due to the *endo*-6,8-protons which have dihedral angles of ~ 90° with respect to H-5 and -1,7. All spin coupling interactions were confirmed by decoupling experiments. With ketone **8***a* identified, it followed that the addition product must be **7***b*.

To complete the ^{13}C assignments for **7***b*, the cyclopropanation was repeated using **5**-3-d_1 to generate **9** (0.8 D/molecule). In its ^{13}C spectrum the most shielded methine singlet was highly attenuated and accompanied by the expected triplet, J_{CD} = 26 Hz, exhibiting an isotope shift of −0.32 ppm. In addition, three other absorptions were altered, with the signals corresponding to those for **7***b* strongly attenuated and accompanied by prominent singlets 0.1 ppm toward higher field. These patterns are typically exhibited by carbons geminal to ^{2}H (7) and served to identify C-3, -5, and -6 at δ_C 30.7, 21.5, and 24.4, respectively. The remaining methylene signal, δ_C 25.3, was, therefore, due to C-8 and the signals at δ_C 27.4 and 33.6 arise from C-1 and -7.

Presumably cyclopropanation of **5** generates **3***b* initially, which undergoes facile intramolecular cycloaddition to form **7***b*. While it may be suggested that the cycloaddition may be catalyzed by silver, cyclopropanation with the more usual zinc–copper couple also gave **7***b*, although in lower yield (72%). It is known that **3***c* complexes with silver (8) but there are no reports of rearrangement of the complex. At present, it seems most reasonable to conclude that **3***b* is more prone to thermally induced cycloaddition than the corresponding dihalocarbene adducts which exhibit the same isomerization at higher temperatures.

Two aspects of the homoketonization merit comment. Although there are two modes of ring opening for the β-enolate formed from **7***b*, shown as a and b in **10**, the cyclopropoxide cleavage is apparently regiospecific. Since cleavage a and b both lead to secondary carbanions, the exclusive formation of **8***a* is an illustration of thermodynamic control of homoketonization, a feature which has been recognized for some years (9) and indicates that **8***a* is more stable than **11**. The second aspect, stereoselectivity of protonation (deuteriation) at the carbanionic site, required additional evidence for its clarification. For this purpose, the homoketonization was examined in a deuterated medium.

Treatment of **7***b* with *t*-BuO^-/*t*-BuOD gave **8**-d_x (1.12 D/molecule), which, from the ^{13}C spectrum, had incorporated ca. 0.9 atoms D at C-6,8 and ca. 0.2 atoms D at C-3. In the ^{1}H spectrum, the absorption for *exo*-6(8)-H was significantly attenuated while the clean doublet for *endo*-6(8)-H (δ 1.853) was accompanied by a triplet, J_{HD} = 1.85 Hz, at 1.837. Clearly ring opening of **10** proceeded primarily to **8***b* with inversion of configuration at the carbanionic site. Minor deuteration at C-3 undoubtedly occurred through α-exchange upon generation of the ketone in the deuterated medium. To check for small amounts of deuterium at the *endo*-6(8)-position, the ^{2}Hmr spectrum of the ketone was also examined. This spectrum contained signals at δ 1.85, 2.0, and 2.5 in the ratio 1.0:12.3:3.1, corresponding to 0.21 atoms D at C-3 and 0.91 atoms D at C-6(8) with the latter in the ratio of 12:1 favoring *exo*-D. Further confirmation of the marked preference for *exo*-deuteration at the β-methylene position was obtained by examination of the ketone generated by homoketonization of **9** in *t*-BuO^-/*t*-BuOD. The product (2.14 D/molecule) gave a ^{2}H spectrum having signals at δ 1.45, 1.85, 2.0, 2.5 with relative intensities 11.6:1.0:12.1:10.0 corresponding to 0.72, 0.062, 0.75, and 0.62 atoms D at C-2, *endo*-6(8), *exo*-6(8), and C-3, respectively. More extensive exchange occurred at C-3 because of a longer reaction time (11.5 vs. 3 h). In any event, homoketonization proceeds with high stereoselectivity (92 ± 1%) favoring inversion of configuration which is in agreement with findings for a wide variety of β-enolates (9).

Experimental

Gas–liquid chromatography (glc) was carried out on a Varian 920 instrument using columns (5.5 m × 0.64 cm) packed with 6% FFAP or 20% Carbowax 20 M on Chromosorb W. Infrared (ir) spectra were recorded with a Beckman 4250 spectrophotometer. Mass spectrometric (ms) data were obtained with a Varian MAT-311A instrument. The nmr spectra were recorded using a Varian XL-200 instrument at 30.7 (^{2}H), 50.3 (^{13}C), and 200 MHz (^{1}H).

Norbornenone (1)

After dropwise addition of α-chloroacrylonitrile (8.9 g, 0.1 mol) to freshly distilled cyclopentadiene (8.3 g, 0.125 mol) in benzene (17 mL), the solution was stirred at 45°C for 36 h, under a nitrogen atmosphere. Distillation gave 2-chloro-2-cyanobicyclo[2.2.1]hept-5-ene (15.1 g, 97%), bp 58–61°C/1.5 Torr; ir (film): 2235 (CN) cm^{-1}. The ^{13}Cmr spectrum indicated the presence of both epimers. The total product was dissolved in DMSO (88 mL) and a solution of KOH (16.5 g) in water (5.6 mL) was added with stirring. After 30 h, a saturated aqueous solution of NaCl (88 mL) was added, and the product extracted with pentane (4 × 50 mL). The combined extracts were washed with saturated salt solution until the washings were neutral, then once with water. The organic layer was dried ($MgSO_4$) and the solvent evaporated to give 8.7 g of product containing (glc) **1** (86%) and starting material (14%). Preparative glc (FFAP) furnished pure **1** as determined by glc and ^{13}Cmr (10).

[3,3-$^2H_2$]norbornenone

Freshly cut sodium metal (400 mg) was added to D_2O (32 mL, 99.7% D) in a flame-dried flask fitted with a reflux condenser and nitrogen purge. After cooling to room temperature, **1** (2 g) in pentane (1 mL) was added and the solution refluxed for 9.5 h. Pentane extraction as described above gave **1**-d_x (1.1 g); ms: 27.5% d_1, 66.7% d_2 (total 1.60 D/molecule).

Trimethylsilyl enol ether of 1 (5)

Freshly distilled THF (8 mL) containing diisopropylamine (1.4

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

mL, 0.01 mol), which had been dried over molecular sieves, was placed in a flask having a N_2 purge and cooled to −78°C. Upon addition of *n*-butyllithium (0.0078 mol) in *n*-hexane (3.7 mL) via syringe, the mixture was stirred for 30 min before **1** (760 mg, 0.007 mol) in THF (3 mL) was added by syringe. While stirring was continued for 30 min, a quenching solution (THF (3 mL), chlorotrimethylsilane (1.3 mL, 0.01 mol), and triethylamine (0.5 mL, 0.0037 mol)) was placed in a flame-dried, N_2-purged centrifuge tube. Traces of precipitate were removed by centrifugation and the clear quenching solution added by syringe to the cold enolate solution. The reaction mixture was maintained at −78°C for another 30 min before slowly warming to room temperature over 1 h. The mixture was then poured into a saturated aqueous solution of Na_2CO_3 (18 mL) and the product extracted with *n*-pentane (3 × 20 mL). The combined extracts were washed with saturated Na_2CO_3 and with water before drying over $MgSO_4$. After evaporation of the solvent, Kugelrohr distillation (95°C, 5 Torr) gave **5** (1.0 g, 79% yield); ir (film): 1610 cm^{-1}; ^{13}Cmr ($CDCl_3$) δ_C: 173.0 (C-2), 145.4, 141.2 (C-5, -6), 109.1 (C-3), 72.5 (C-7), 53.6 (C-1), 48.1 (C-4), 0.0 (Me_3Si).

Cyclopropanation of **5**

To a flask fitted with a reflux condenser, nitrogen purge, and magnetic stirrer was added zinc–silver couple (1.2 g, 0.018 mol) and the apparatus flame-dried. After cooling, methylene iodide (0.76 mL, 9.4 mmol) and Et_2O (3 mL) were added and the mixture warmed until refluxing occurred without external heating. Upon cessation of reflux a solution of **5** (990 mg, 5.5 mmol) in Et_2O (13 mL) was added and this mixture was refluxed for 19 h with stirring. After cooling to 0°C, pyridine (1.5 mL) was slowly added with stirring. The resulting precipitate was removed by filtration and washed with Et_2O. After removal of solvent from the filtrate, the residue was taken up in *n*-pentane; further filtration was required to remove the last traces of precipitate. Evaporation of the solvent gave **7***b* (1.06 g, 99%) which glc (FFAP) indicated to contain traces (<2%) of two impurities; ^{13}Cmr (C_6D_6) δ_C: 27.4 (C-5), 69.2 (C-4), 30.7 (C-3), 20.1 (C-2), 21.5 (C-1), 24.4 (C-7), 33.6 (C-6), 25.3 (C-8), 1.1 ($SiMe_3$). *Exact Mass* calcd. for $C_{11}H_{18}OSi$: 194.1127; found: 194.1127.

Repetition of the sequence **1** → **5** → **7***b* with [3,3-$^2H_2$]-**1** as starting material afforded **9**, ms: 20% d_0, 80% d_1 (total 0.80 D/molecule).

Homoketonization of 7b

To 28 mL of 3 *M* methanolic NaOH was added **7***b* (550 mg) and the mixture stirred for 20 min at room temperature. After the addition of H_2O (25 mL), the product was extracted with *n*-pentane (3 × 20 mL). The combined extracts were washed with saturated aqueous NaCl solution and with water. After drying and removal of the solvent, the organic phase afforded 254 mg of product while re-extraction of the aqueous phase furnished an additional 79 mg. Gas–liquid chromatography (FFAP) showed the combined product **8** (99% yield) to be reasonably pure (>98%); ir (film): 1727 cm^{-1}, ^{13}C ($CDCl_3$) δ_C: 211.8 (C=O), 47.8 (C-5), 33.3 (C-3), 28.6 (C-6,8), 14.4 (C-1,7), 9.2 (C-2). *Exact Mass* calcd. for $C_8H_{10}O$: 122.0732; found: 122.0735.

Ketone **8** gave a 2,4-dinitrophenylhydrazone, mp 191–192°C (lit. (6*a*) mp 192.5–193°C; (6*b*) mp 190–190.5°C; (6*c*) mp 194.5–195°C. *Exact Mass* calcd. for $C_{14}H_{14}O_4N_4$: 302.1016; found: 302.1017.

Preparation of **8**a-d_x

A sample of **7***b* (200 mg) was placed in 1 *M* *t*-BuO^- in *t*-BuOD (10 mL) and the solution stirred at room temperature for 3 h. After quenching with water (10 mL), the ketone was extracted with *n*-pentane as described above and purified by glc to give **8***a*-d_x; ms: 71.3% d_1, 17.3% d_2, 2.1% d_3 (total 1.12 D/molecule).

A sample of **9** (0.8 D/molecule), prepared as described above, was homoketonized in a similar fashion with an extended reaction time (11.5 h) to furnish **8***a*-d_x; ms: 19.1% d_1, 40.9% d_2, 27.3% d_3, 7.8% d_4 (total 2.14 D/molecule).

Nuclear analogs of β-lactam antibiotics. XIX.[1] Syntheses of racemic and enantiomeric *p*-nitrobenzyl carbapen-2-em-3-carboxylates

YASUTSUGU UEDA,[2] CHRISTOPHER E. DAMAS, AND VIVIANNE VINET
Bristol Laboratories of Canada, 100 Industrial Boulevard, Candiac, P.Q., Canada J5R 1J1

Received March 1, 1983

YASUTSUGU UEDA, CHRISTOPHER E. DAMAS, and VIVIANNE VINET. Can. J. Chem. **61**, 2257 (1983).

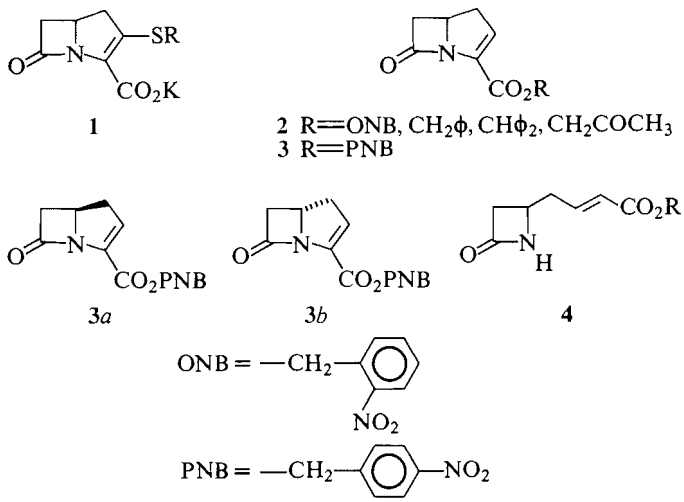
Racemic and enantiomeric *p*-nitrobenzyl carbapen-2-em-3-carboxylates **3**, **3***a*, and **3***b* were prepared starting from inexpensive sorbic acid through the key intermediates, azetidinone esters **4**, thus establishing a total synthesis of the *p*-nitrobenzyl ester of a natural product SQ 27,860. Optical resolution was achieved readily on azetidinone menthyl esters, **12**. The absolute configurations were also established.

YASUTSUGU UEDA, CHRISTOPHER E. DAMAS et VIVIANNE VINET. Can. J. Chem. **61**, 2257 (1983).

On a préparé les carbapeneme-2 carboxylates-3 de *p*-nitrobenzyle racémiques et énantiomères **3**, **3***a* et **3***b* en partant d'un réactif peu coûteux, l'acide sorbique, et en passant par des intermédiaires clés, des esters de l'azétidinone **4**; on a donc réalisé ainsi une synthèse totale de l'ester *p*-nitrobenzyle du produit naturel SQ 27,860. On a facilement effectué la résolution des antipodes optiques des esters menthyliques de l'azétidinone **12** et on a également établi les configurations absolues.

[Traduit par le journal]

In our previous paper (1) we reported a simple route to (±)-2-alkylthiocarbapen-2-em-3-carboxylate **1** (R = S-alkyl), starting from inexpensive sorbic acid via an intermediate **4** (R = PNB). Now we wish to describe the versatility of intermediates **4** by preparing racemic and enantiomeric carbapenems **3**, **3***a*, and **3***b* from **4** (R = Me, *l*-menthyl). Although racemic carbapen-2-em-3-carboxylic acid esters **2** and **3** have



been reported (2–5), their enantiomers have not been prepared in pure form.[3] The Squibb scientists (7) recently isolated a simple carbapenem antibiotic SQ 27,860 as the *p*-nitrobenzyl ester, from bacterial sources, which was found to be (+)-*p*-nitrobenzyl carbapen-2-em-3-carboxylate. Therefore, a part of this report represents a total sysnthesis of the *p*-nitrobenzyl ester of the natural product from sorbic acid.

Racemic parent carbapen-2-em-3-carboxylate **3** was synthesized by the well-established method (3, 8), originated by Woodward and co-workers , from our key intermediate **4** (R = Me). Condensation of **3** (R = Me) (1) with *p*-nitrobenzyl glyoxylate hydrate gave carbinolamides **5** as a diastereomeric mixture which was converted to chloro-compounds **6** by thionyl chloride and pyridine. Treatment of **6** with triphenylphosphine and 2,6-lutidine provided phosphorane **7** in 64% overall yield from **4** (R = Me) as yellowish crystals. Ozonolysis of **7** in CH_2Cl_2 in the presence of trifluoroacetic acid (8*c*), followed by reduction of the ozonide with dimethyl sulfide, then regeneration of the phosphorane with $NaHCO_3$, yielded aldehyde **8** which spontaneously cyclized at 35°–40°C to give racemic carbapenem ester **3** as yellowish crystals (mp 153.5°–155°C) in 60% yield (Scheme 1). This material had spectroscopic properties (^{1}Hmr, ir) consistent with data reported by Bateson *et al.* (3*b*). Preparation of carbapenem salt **2** (R = K, Na) was attempted by hydrogenolysis (H_2/Pd–C, phosphate buffer) of **3**. Although the presence of **2** (R = K, Na) was detected in the crude, dilute solution by the uv spectrum ($\lambda_{shoulder}$ ~262 nm), it was not possible to isolate it, due to the instability of the molecule (2, 3*b*, 5, 17).

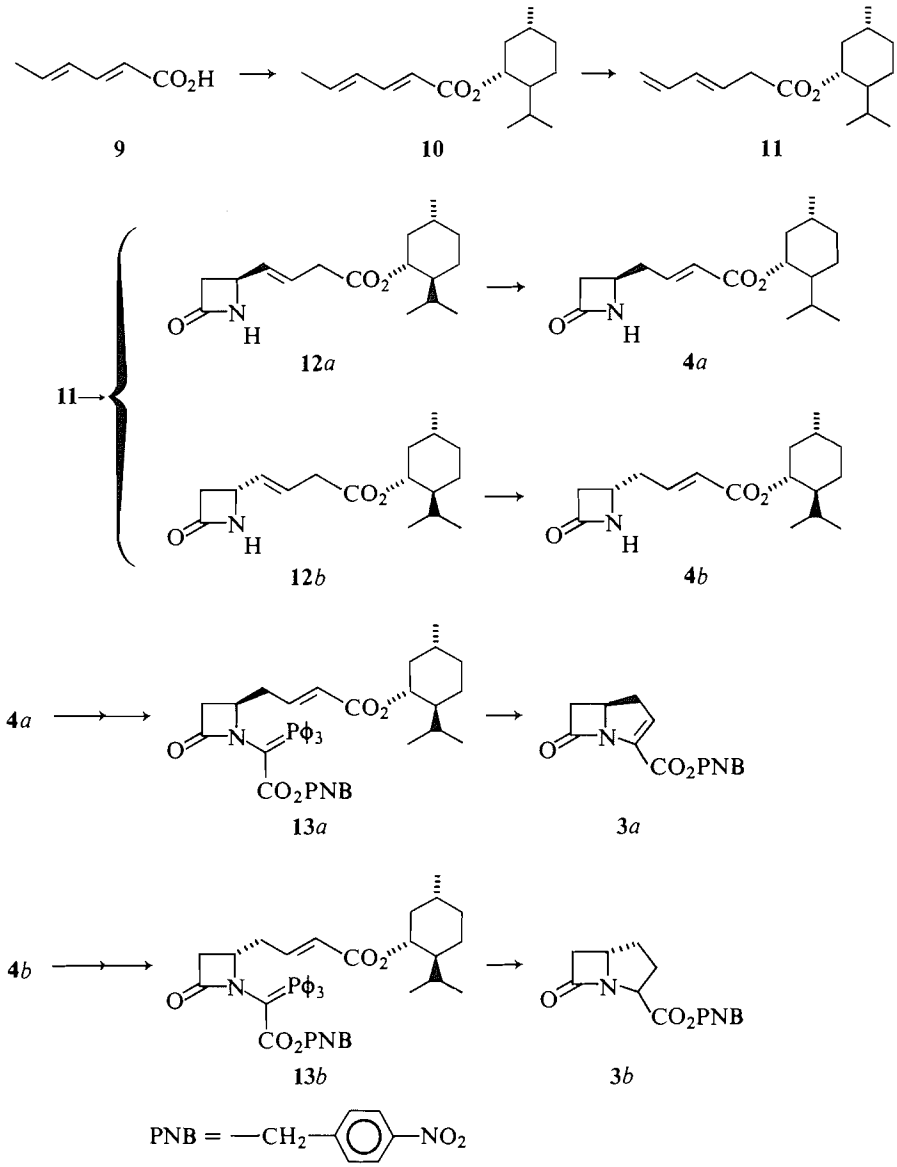

SCHEME 2

intermediate **4** provides a possibility of preparing optically active parent carbapenem carboxylates **3***a* and **3***b*. Instead of a methyl ester, an optically active ester grouping such as *l*-menthyl ester could be introduced into the intermediate **4**, producing a mixture of two diastereomers. This could make resolution of the racemate possible. After the resolution is achieved, this ester moiety is removed from the molecule to prepare optically active carbapenems.[4]

We found that although optical resolution on the intermediate **4** (R = *l*-menthyl) was possible, it was performed more conveniently on azetidinone menthyl ester **12**.

The diastereomeric mixture **12** was prepared following the method used for the preparation of methyl ester **4** (R = Me) (1), starting from sorbic acid (**9**) and optically active *l*-menthol (Scheme 2). Thus, esterification of sorbic acid (**9**) with *l*-menthol gave *l*-menthyl sorbate (**10**) which was isomerized to *l*-menthyl 3,5-hexadienoate (**11**) in 95% yield by kinetic protonation of the enolate generated from **10** with lithium diisopropylamide in THF–HMPA. Cycloaddition of chlorosulfonyl isocyanate (10) to this conjugated diene **11**, followed by a reductive work-up (11), yielded two diastereomeric azetidinones **12** in 54% yield. These two diastereomers were readily separated by crystallization to give **12***a* and **12***b* in 28% and 21% yield respectively. This facile resolution of the racemic modification depends on different solubilities of these two diastereomers in Et_2O. One crystallization from Et_2O was enough to obtain one diastereomer **12***a* (mp 120°–125°C) in a reasonably pure form. The other diastereomer **12***b* (mp 75°–78°C), which was more soluble in Et_2O, crystallized from the mother liquor by addition of pentane in the cold. In both cases, their mp and optical rotation did not change significantly by further recrystallization. Upon isomerization of the carbon–carbon double bond with 1,4-diazabicyclo[2.2.2]-octane (DABCO) in CH_3CN as described before (1), each diastereomer **12***a* and **12***b* gave **4***a* and **4***b* in good yield.

The independent transformation of the two diastereomers **4***a* and **4***b* into the optically active *p*-nitrobenzyl (5*R*)-carbapen-2-em-3-carboxylate (**3***a*): mp 123°–124°C; $[\alpha]_D$ +127.5° (*c* 1.0, CH_2Cl_2), and its 5*S*-enantiomer **3***b*: mp 122°–124°C;

[4]A similar approach has been used by Pfaendler *et al.* (9) in the preparation of enantiomeric penem-3-carboxylic acids.

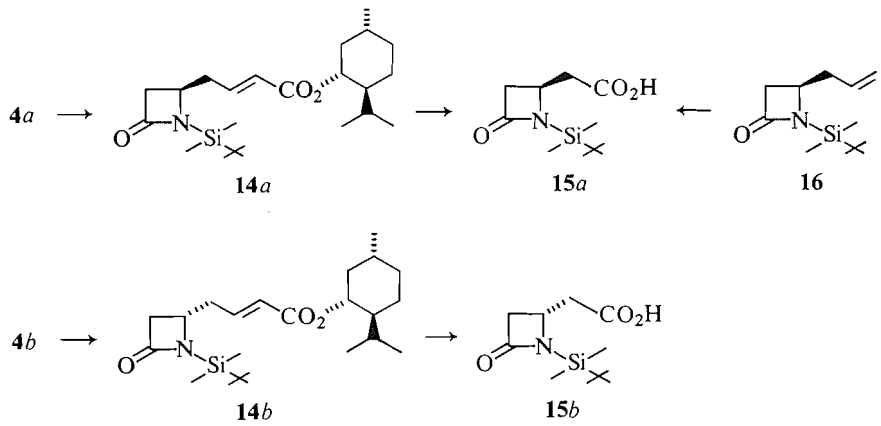

SCHEME 3

$[\alpha]_D$ −110.8° (*c* 1.0, CH_2Cl_2), was achieved through phosphoranes **13***a* and **13***b* (Scheme 2) by the same method used for the racemic series. These enantiomers had ^{1}Hmr and ir spectra identical to the racemic material. Determination of enantiomeric purities by ^{1}Hmr spectroscopic means was attempted using a chiral shift reagent (12). Examination of ^{1}Hmr spectra of racemic and each enantiomeric material obtained revealed that Eu(dcm)$_3$ (12*b*) caused separation of a doublet (a part of an AB quartet) for one of the methylene protons of the *p*-nitrobenzyl group into two sets of the doublet. The one in **3***a* appeared at slightly lower field than the one in **3***b*, $\Delta\Delta\delta$ being 0.07 ppm. Any peaks which correspond to **3***b* were not detected in the ^{1}Hmr spectrum of the enantiomer obtained with $[\alpha]_D$ of +127.5°. The isomer with $[\alpha]_D$ −110.8° showed the major peaks corresponding to the enantiomer **3***b* and a trace of peaks from the enantiomer **3***a*, indicating some contamination of **3***a* (ca. 10%). Because of the noise associated with these spectra, accurate measurements were not obtained. Nonetheless we believe that one of the isomers, **3***a*, was prepared with high enantiomeric purity.

The *l*-menthyl group, which served for racemate resolution, was removed at the last stage of the sequence (see Scheme 2). Combined with the fact that the resolution was achieved at an earlier stage, this provided the possibility of yielding a better optical purity of each final enantiomer, because further enrichment is possible at each step (e.g. **4**).

The absolute configurations were established as compounds **12***b*, **4***a*, **13***a*, and **3***a* (*R*-series) and compounds **12***a*, **4***b*, **13***b*, and **3***b* (*S*-series) by two-step conversion of **4***a* and **4***b* to **15***a*, $[\alpha]_D$ −67.5° (*c* 1.0, CH_2Cl_2), and **15***b*, $[\alpha]_D$ +36.6° (*c* 1.0, CH_2Cl_2) respectively (Scheme 3). This conversion involved protection of the β-lactam by *tert*-butyldimethylsilyl chloride and triethylamine in DMF and subsequent oxidation of the double bond by potassium permanganate under phase transfer conditions (13). The acid **15***a* was correlated to the one obtained, $[\alpha]_D$ −80.3° (*c* 1.0, CH_2Cl_2), by permanganate oxidation of allylazetidinone **16**[5] whose absolute configuration was known. Consequently, the absolute configuration of the *p*-nitrobenzyl ester of SQ 27,860, having an optical rotation $[\alpha]_D^{22}$ of +104° (7) was determined to be (5*R*)-*p*-nitrobenzyl carbapen-2-em-3-carboxylate (**3***a*).

Since racemic carbapenem ester **3** has been used as an intermediate in the preparation of 6-unsubstituted analogs of olivanic acid (6, 14), the synthesis of the (5*R*)-isomer **3***a*, described here, provides a useful and practical entry to the natural enantiomers of 6-unsubstituted carbapenem antibiotics.

In summary, we have described the syntheses of racemic and enantiomeric carbapen-2-em-3-carboxylates starting from inexpensive sorbic acid. The compounds **4** were found to be very versatile intermediates in the synthesis of carbapenems.

Experimental

Melting points were determined on a Gallenkamp melting point apparatus and are not corrected. The infrared spectra were recorded on a Perkin–Elmer 267 grating infrared spectrometer. The ^{1}H nuclear magnetic resonance spectra were taken with either a Varian EM-360 (60 MHz) or a Varian CFT-20 (80 MHz) nmr spectrometer. Tetramethylsilane was used as an internal standard and chemical shifts are reported in parts per million (δ) relative to the internal standard. The ultraviolet spectra were recorded on an Unicam SP8-100 uv spectrophotometer. Optical rotations were measured with a Perkin–Elmer Model 141 polarimeter. Tetrahydrofuran was freshly distilled from lithium aluminum hydride. Anhydrous diethyl ether (Fisher) was used without further treatment. All other solvents were reagent grade and had been stored over molecular sieves before use. n-Butyllithium (n-BuLi) in hexane and tris[*d*,*d*-dicampholylmethanato]europium (III) (Eu(dcm)$_3$) were purchased from Alfa Products and used as such. Triethylamine and diisopropylamine were distilled from CaH_2 and stored over NaOH. *p*-Nitrobenzyl glyoxylate hydrate (15) was prepared from di-*p*-nitrobenzyl fumarate by ozonolysis (CH_2Cl_2, −78°C) followed by reduction with dimethylsulfide (16). Analytical thin layer chromatography (tlc) was conducted on precoated plates (Silica Gel 60F-254, Merck). Preparative layer chromatography (plc) was performed on silica gel plates prepared from Silica Gel 60GF-254 (E. Merck). Column chromatography was carried out on Silica Gel 60 (70–230 mesh, E. Merck). The analyses were performed by Micro-Tech Laboratories, Skokie, Illinois, U.S.A.

p-Nitrobenzyl [4-(3-carbomethoxy-2-propen-1-yl)azetidin-2-on-1-yl] hydroxyacetates (5)

A mixture of 4-(3-carbomethoxy-2-propen-1-yl)-2-azetidinone (**4**, R = Me) (1) (3.19 g, 18.9 mmol) and *p*-nitrobenzyl glyoxylate hydrate (4.72 g, 20.8 mmol) in benzene (200 mL) was heated at reflux with a Dean–Stark trap for 3 h. Evaporation of the solvent gave 8.08 g of the title compound **5** as yellow foam; R_f 0.37 (Et_2O–EtOAc 1:1); ir (neat) ν_{max}: 3400 (OH), 1750 (br, β-lactam and ester), 1725 (conj. ester), 1660 (C=C), 1520, and 1350 (NO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz) δ: 2.3–2.9 (2H, m, 1″-H), 2.65 (1H, dd, *J* = 15 and 3 Hz, 3′-H_a), 3.12 (1H, dd, *J* = 15 and 5 Hz, 3′-H_b), 3.72 (3H, s, —CO_2Me), 3.95 (1H, m, 4′-H), 4.97 (1H, br, —OH), 5.33 (2H, s, —CO_2CH_2Ar), 5.48 (1H, br, 1-H), 5.85 (1H, d, *J* = 16 Hz, 3″-H), 6.6–7.2 (1H, m, 2′-H), 7.55 (2H, d, *J* = 9 Hz, ArH's), and 8.20 (2H,

[5] This compound was derived from a natural product, penicillin. A highly stereoselective conversion of 6α-bromopenicillanic acid to optically active allylazetidinone **16** is reported in Part XVII of this series. We thank Dr. A. Martel for the procedures of this conversion.

d, J = 9 Hz, ArH's) ppm. This crude material was used in the next step without any purification.

p-*Nitrobenzyl [4-(3-carbomethoxy-2-propen-1-yl)azetidin-2-on-1-yl] chloroacetates (6)*

To a stirred solution of crude *p*-nitrobenzyl [4-(3-carbomethoxy-2-propen-1-yl)azetidin-2-on-1-yl]hydroxyacetates (**5**) (8.08 g) and pyridine (2.14 mL) in THF (190 mL) was added, at −15°C to −20°C, thionyl chloride (1.66 mL) over a period of 5 min under an atmosphere of nitrogen. The mixture was stirred for 20 min at −15°C. After filtration of white precipitates and washing the precipitates with benzene, the filtrate and washings were combined and evaporated to dryness. The residue, extracted with benzene, was treated with Norit and evaporation of the solvent gave 6.64 g (16.7 mmol, crude yield 88.6% based on **4**, R = Me) of the title compounds **6** as a crude oil; R_f 0.72 (Et_2O–EtOAc 1:1); ir (neat) ν_{max}: 1770 (br, β-lactam and ester), 1660 (C=C), 1525, and 1355 (NO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz) δ: 2.2–3.4 (4H, m, 3′-H's and 1″-H's), 3.73 (3H, s, —CO_2Me), 4.2 (1H, m, 4′-H), 5.35 (2H, s, —CO_2CH_2Ar), 5.88 (1H, d, J = 16 Hz, 3″-H), 6.23 (1H, s, 1-H), 6.5–7.2 (1H, m, 2″-H), 7.55 (2H, d, J = 9 Hz, ArH's), and 8.26 (2H, d, J = 9 Hz, ArH's) ppm. This crude material was used in the next reaction without further purification.

p-*Nitrobenzyl [4-(3-carbomethoxy-2-propen-1-yl)azetidin-2-on-1-yl] triphenylphosphoranylideneacetate (7)*

To a stirred solution of crude *p*-nitrobenzyl [4-(3-carbomethoxy-2-propen-1-yl)azetidin-2-on-1-yl]chloroacetates (**6**) (6.60 g, 16.6 mmol) and triphenylphosphine (4.78 g, 18.3 mmol) in dioxane (166 mL) was added 2,6-lutidine (2.12 mL) at room temperature under a nitrogen atmosphere. The mixture was stirred (room temp., N_2) overnight (23 h). The precipitate was filtered and washed with dioxane. The filtrate and washings were combined and evaporated. The residue, redissolved in EtOAc (100 mL), was washed with 1 *N* HCl (20 mL × 2), saturated $NaHCO_3$ and then brine, dried (Na_2SO_4), and evaporated to give 11.68 g of crude phosphorane. This was purified by column chromatography (300 g, EtOAc) followed by crystallization from EtOAc–Et_2O to yield 6.64 g (10.7 mmol, yield 64.3%) of the title compound 7 as light yellow crystals; mp 172°–173°C (recrystallized from EtOAc); R_f 0.40 (EtOAc); ir (film) ν_{max}: 1745 (β-lactam), 1720 (conj. ester), 1660 (C=C), 1625 (ester), 1520, and 1350 (NO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz) δ: 3.70 (3H, s, —CO_2Me), 4.83, 5.17 (2H, 2s, —CO_2CH_2Ar), 7.55 (15H, s, φH's), and 8.19 (2H, d, J = 10 Hz, ArH's) ppm, the others are not well resolved. *Anal.* Calcd. for $C_{35}H_{31}N_2O_7P$: C 67.52, H 5.02, N 4.50; found: C 67.70, H 5.00, N 4.47.

*(±)-*p*-Nitrobenzyl carbapen-2-em-3-carboxylate (3)*

To a stirred solution of *p*-nitrobenzyl [4-(3-carbomethoxy-2-propen-1-yl)azetidin-2-on-1-yl]triphenylphosphoranylideneacetate (7) (1.24 g, 2.00 mmol) in CH_2Cl_2 (40 mL) was added, at 0°–5°C, trifluoroacetic acid (2 mL), and the yellowish mixture was cooled to −78°C. A stream of ozone was introduced until the blue colour was retained, and the solution was stirred at −78°C for another 5 min. Nitrogen was passed through the solution to remove excess ozone and then dimethyl sulfide (2 mL) was added. After removing the cooling bath, the solution was stirred at 0°–5°C for 1 h. This mixture was washed with saturated $NaHCO_3$ (50 mL × 2) and then brine, dried (Na_2SO_4), and evaporated *in vacuo* (bath temperature 35°–40°C). The residue was purified by column chromatography (30 g, EtOAc–hex 1:1), followed by crystallization from CH_2Cl_2–Et_2O to give 343 mg (1.19 mmol, yield 59.5%) of the title compound **3** as yellowish crystals; mp 153.5°–155°C; R_f 0.35 (EtOAc–hex 1:1); ir (film) ν_{max}: 1780 (β-lactam), 1730 (ester), 1520, and 1350 (NO_2) cm^{-1}; uv (EtOH) λ_{max}: 267 nm (ε 15 900); ^{1}Hmr ($CDCl_3$, 80 MHz) δ: 2.72 (1H, ddd, J_{gem} = 19 Hz, J_{1-5} = 9 Hz, J_{1-2} = 3 Hz, 1-H_a), 2.98 (1H, dd, J_{gem} = 17 Hz, $J_{6-5\,trans}$ = 3 Hz, 6-H_a), 3.02 (1H, ddd, J_{gem} = 19 Hz, J_{1-5} = 9.5 Hz, J_{1-2} = 3 Hz, 1-H_b), 3.54 (1H, dd, J_{gem} = 17 Hz, $J_{6-5\,cis}$ = 5.6 Hz, 6-H_b), 4.3 (1H, m, 5-H), 5.16–5.33–5.38–5.55 (2H, ABq, —CO_2CH_2Ar), 6.58 (1H, t, J = 3 Hz, 2-H), 7.60 (2H, d, J = 8.8 Hz, ArH's), and 8.23 (2H, d, J = 8.8 Hz, ArH's) ppm; ^{1}Hmr (**3**, 5 mg, and Eu(dcm)$_3$, 25 mg, in $CDCl_3$, 0.5 mL; 80 MHz) δ: 5.98–6.15–6.26–6.43 (1H, ABq, —CO_2CH_2Ar in the 5*S*-isomer), 5.98–6.15–6.32–6.50 (1H, ABq, —CO_2CH_2Ar in the 5*R*-isomer), 7.01 (t, J = 3 Hz, 2-H in the 5*R*-isomer), and 7.05 (t, J = 3 Hz, 2-H in the 5*S*-isomer) ppm. *Anal.* calcd. for $C_{14}H_{12}N_2O_5$: C 58.33, H 4.20, N 9.72; found: C 58.34, H 4.15, N 9.60.

(−)-Menthyl 2,4-hexadienoate (10)

A solution of 2,4-hexadienoic acid (112 g, 1.00 mol; sorbic acid), *l*-menthol (172 g, 1.10 mol), and concentrated sulfuric acid (10.3 mL) in benzene (1.85 L) was heated at reflux with a Dean–Stark trap for 5 days. The mixture was cooled and basified by slow addition of saturated $NaHCO_3$ (400 mL) with vigorous stirring. The organic layer was separated and further washed with saturated $NaHCO_3$ (2 × 400 mL). The aqueous layers were combined and extracted with EtOAc (400 mL). All organic layers were combined and washed with brine (2 × 500 mL), dried (Na_2SO_4), and evaporated *in vacuo* to obtain 191 g of amber oil. This was purified by a silica pad consisting of Mallinekrodt silicic acid (100 mesh, 1.4 L) on top of Merck silica gel 60 (70–230 mesh, 1.4 L), eluting with hexanes and then 2 and 5% Et_2O in hexanes to yield 116.9 g (0.467 mol, yield 46.7%) of the title compound **10** as an oil; bp 112°–114°C/0.3 Torr (lit. (17) bp 173°C/14 Torr); R_f 0.42 (Et_2O–hex 1:9); $[\alpha]_D^{23}$ −83.5° (*c* 0.60, CH_2Cl_2); ir (neat) ν_{max}: 1705 (ester), 1645, and 1620 (C=C) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz) δ: 0.77 (3H, d, J = 7 Hz, —Me), 0.90 (6H, d, J = 7 Hz, *gem*-Me), 0.8–2.2 (9H, m, —CH, CH_2—), 1.85 (3H, d, J = 4.5 Hz, 5-Me), 4.73 (1H, td, J_{a-a} = 9 Hz, J_{a-e} = 2 Hz, —CO_2CH—), 5.6–6.2 (3H, m, olefinic protons), and 7.0–7.45 (1H, m, 5-H) ppm.

(−)-Menthyl 3,5-hexadienoate (11)

To a stirred solution of diisopropylamine (140 mL, 1.01 mmol) in THF (2.4 L) was added at 0°–5°C, under a nitrogen atmosphere, n-butyllithium (500 mL, 2.02 *M* in hexane, 1.01 mol) over a period of 30 min. After stirring for 30 min, the light yellow solution was cooled to −75° to −78°C. A solution of hexamethylphosphoramide (180 mL, 1.00 mol) in THF (100 mL) was added over a period of 20 min, and the mixture stirred for 1 h. To this mixture was added a solution of (−)-menthyl 2,4-hexadienoate (**10**) (200 g, 0.80 mol) in THF (100 mL) during a 15 min period, and the resulting dark red mixture was stirred (−78°C, N_2) for 2 h. This was poured into a solution of concentrated HCl (200 mL) in water (800 mL) and extracted with EtOAc (3 × 500 mL). The EtOAc extracts were washed with water (5 × 500 mL) and then brine (500 mL), dried (Na_2SO_4), and evaporated *in vacuo* to yield 189.2 g (0.756 mol, crude yield 94.5%) of the title compound **11** as an amber oil. This crude oil was used in the subsequent reaction without any purification. An analytical sample was obtained by distillation followed by plc (Et_2O–hex 1:9); bp 95°–97°C/0.2 Torr; R_f 0.52 (Et_2O–hex 1:9); $[\alpha]_D^{23}$ −70.2° (*c* 1.0, CH_2Cl_2); ir (neat) ν_{max}: 1735 (ester), 1650, and 1605 (C=C) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz) δ: 0.77 (3H, d, J = 7 Hz, —Me), 0.90 (6H, d, J = 7 Hz, *gem*-Me), 0.8–2.2 (9H, m, —CH— and —CH_2—), 3.10 (2H, d, J = 6 Hz, 2-H's), 4.69 (1H, td, J_{a-a} = 9 Hz, J_{a-e} = 4 Hz, —CO_2—CH—), 5.0–5.4 (2H, m, olefinic protons), and 5.7–6.7 (3H, m, olefinic protons) ppm. *Anal.* calcd. for $C_{16}H_{26}O_2$: C 76.75, H 10.47; found: C 77.02, H 10.56.

4(S)- and 4(R)-(3-carbomenthyloxy-1-propenyl)-2-azetidinones (12a and 12b)

To a stirred solution of crude (−)-menthyl 3,5-hexadienoate (**11**) (184.2 g, 0.737 mol) in CH_2Cl_2 (2.3 L) was added at 0°–5° C, under a nitrogen atmosphere, chlorosulfonyl isocyanate (72.0 mL, 0.819 mol) over a period of 22 min. The mixture was stirred at room temperature for 24 h. This mixture was added slowly to a mechanically stirred mixture of sodium sulfite (460 g, 3.65 mol) in water (2.3 L) and CH_2Cl_2 (0.9 L) at 0°–5°C. During the addition, the mixture was adjusted to pH 7–9 by simultaneous addition of saturated $NaHCO_3$

(2.0 L). After removing the cooling bath, the milky yellow mixture was stirred for another 2 h. The cloudy organic phase was collected. The aqueous phase was saturated with sodium chloride and extracted with CH_2Cl_2 (1.0 L × 2). All organic extracts were combined, washed with brine (2L), dried (Na_2SO_4), and evaporated to yield a yellow semi-solid. This was dissolved in EtOAc and any insoluble materials were removed. Evaporation of the solvent gave 200 g of yellow oil which was crystallized from Et_2O to obtain 61.3 g (0.209 mol, yield 28.4%) of the 4*S*-isomer of the title compound **12***a*, in two crops, as yellowish powder: mp 120°–125°C; R_f 0.42 (Et_2O); $[\alpha]_D^{21}$ −69° (*c* 0.5, $CHCl_3$); ir (CH_2Cl_2) ν_{max}: 3420 (NH), 1765 (β-lactam), 1725 (ester), and 1670 (C=C) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz) δ: 0.75 (3H, d, J = 7 Hz, —Me), 0.89 (6H, J = 7 Hz, *gem*-Me), 0.7–2.2 (9H, m, —CH— and —CH_2—), 2.67 (1H, ddd, J_{gem} = 15 Hz, $J_{3-4\,trans}$ = 2.5 Hz, J_{3-1} = 1.5 Hz, 3-H_β), 3.07 (2H, d, J = 6 Hz, 3′-H's), 3.22 (1H, ddd, J_{gem} = 15 Hz, $J_{3-4\,cis}$ = 5 Hz, J_{3-1} = 2 Hz, 3-H_α), 4.13 (1H, m, 4-H_α), 4.67 (1H, td, J_{a-a} = 10 Hz, J_{a-e} = 4 Hz, —CO_2CH—), 5.65–5.9 (2H, m, olefinic protons), and 6.42 (br, 1-H) ppm. An analytical sample was obtained by several recrystallizations from EtOAc–Et_2O; mp 125°–128°C; $[\alpha]_D^{21}$ − 71.4° (*c* 0.42, $CHCl_3$). *Anal.* calcd. for $C_{17}H_{27}NO_3$: C 69.59, H 9.28, N 4.77; found: C 69.06, H 9.08, N 4.58.

The mother liquor was evaporated and crystallized from Et_2O–pentane at 0°–5°C to obtain 45.93 g (0.157 mol, yield 21.3%) of the 4*R*-isomer of the title compound **12***b* as off-white powder; mp 75°–78°C; R_f 0.42 (Et_2O); $[\alpha]_D^{21}$ −56° (*c* 0.50, $CHCl_3$); ir (CH_2Cl_2) ν_{max}: 3420 (NH), 1765 (β-lactam), 1725 (ester), and 1670 (C=C) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz) δ: 0.77 (3H, d, J = 7 Hz, —Me), 0.90 (6H, d, J = 7 Hz, *gem*-Me), 0.7–2.2 (9H, m, —CH—, and —CH_2—), 2.67 (1H, ddd, J_{gem} = 15 Hz, $J_{3-4\,trans}$ = 2.5 Hz, J_{3-1} = 1.5 Hz, 3-H_α), 3.08 (2H, d, J = 6 Hz, 3′-H's), 3.23 (1H, ddd, J_{gem} = 15 Hz, $J_{3-4\,cis}$ = 5 Hz, J_{3-1} = 2 Hz, 3-H_β), 4.16 (1H, m, 4-H_β), 4.70 (1H, td, J_{a-a} = 10 Hz, J_{a-e} = 4 Hz, —CO_2CH—), 5.6–5.9 (2H, m, olefinic protons), and 6.58 (br, 1-H) ppm. An analytical sample was obtained by two recrystallizations from Et_2O–pentane; mp 77.5°–78.5°C; $[\alpha]_D^{21}$ −57.0° (*c* 0.50, $CHCl_3$). *Anal.* calcd. for $C_{17}H_{27}NO_3$: C 69.59, H 9.28, N 4.77; found: C 69.70, H 9.10, N 4.57.

*4(*R*)-(3-carbomenthyloxy-2-propen-1-yl)-2-azetidinone (**4**a)*

A suspension of 4(*S*)-(3-carbomenthyloxy-1-propenyl)-2-azetidinone (**12***a*) (14.65 g, 50.0 mmol; mp 120°–125°C) and 1,4-diazabicyclo[2.2.2]octane (16.8 g, 150 mmol) in CH_3CN (150 mL) was stirred at room temperature under a nitrogen atmosphere for 7 days. The cloudy mixture was filtered over Celite and washed with EtOAc. The filtrate and washings were combined and evaporated. The residue, redissolved in EtOAc (100 mL), was cooled and shaken with cold 1 *N* HCl (300 mL). The aqueous layer was saturated with sodium chloride and extracted with EtOAc (30 mL × 2). All EtOAc layers were combined, washed successively with 1 *N* HCl (30 mL), saturated $NaHCO_3$ and then brine, dried (Na_2SO_4), and evaporated, yielding 14.89 g of a crude oil. This oil was crystallized from pentane to give 8.55 g (29.1 mmol, yield 58.3%) of the title compound **4***a* as white crystals; mp 74°–76°C; R_f 0.34 (Et_2O). An exiguous amount of the starting material **12***a* (R_f 0.42) was detected in this material. An analytical sample was obtained by plc (EtOAc–Et_2O 1:6) followed by recrystallization from pentane as pure white crystals; mp 80°–81°C; $[\alpha]_D^{20}$ −55.0° (*c* 1.0, CH_2Cl_2); ir (film) ν_{max}: 3300 (br, NH), 1765 (β-lactam), 1710 (conj. ester), and 1655 (C=C) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz) δ: 0.76 (3H, d, J = 7 Hz, —Me), 0.85 (6H, d, J = 7 Hz, *gem*-Me), 0.8–2.2 (9H, m, —CH— and —CH_2—), 2.52 (2H, td, J = 7 Hz, $J_{1'-3'}$ = 1.4 Hz, 1′-H's), 2.54 (1H, ddd, J_{gem} = 14.9 Hz, $J_{3-4\,trans}$ = 2.5 Hz, J_{3-1} = 1.2 Hz, 3-H_β, partially seen), 3.14 (1H, ddd, J_{gem} = 14.9 Hz, $J_{3-4\,cis}$ = 4.9 Hz, J_{3-1} = 2.3 Hz, 3-H_α), 3.75 (1H, m, 4-H_α), 4.74 (1H, td, J_{a-a} = 10 Hz, J_{a-e} = 4 Hz, —CO_2CH—), 5.87 (1H, dt, $J_{2'-3'}$ = 15.6 Hz, $J_{3'-1'}$ = 1.4 Hz, 3′-H), 5.9 (br, 1-H), and 6.85 (1H, dt, $J_{2'-3'}$ = 15.6 Hz, $J_{2'-1'}$ = 7 Hz, 2′-H) ppm. *Anal.* calcd. for $C_{17}H_{27}NO_3$: C 69.59, H 9.28, N 4.77; found: C 69.84, H 9.41, N 4.80.

*4(*S*)-(3-carbomenthyloxy-2-propen-1-yl)-2-azetidinone (**4**b)*

The crude title compound (14.62 g) was obtained from 4(*R*)-(3-carbomenthyloxy-1-propenyl)-2-azetidinone (**12***b*) (14.65 g, 50.0 mmol) by the method used for the 4*R*-isomer. This crude material was purified by column chromatography (500 g, Et_2O) to yield 12.98 g (44.3 mmol, yield 88.6%) of the pure title compound **4***b* as an oil; R_f 0.34 (Et_2O); $[\alpha]_D^{21}$ −72.1° (*c* 1.0, CH_2Cl_2); ir (neat) ν_{max}: 3300 (br, NH), 1765 (β-lactam), 1715 (conj. ester), and 1660 (C=C) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz) δ: 0.77 (3H, d, J = 7 Hz, —Me), 0.90 (6H, d, J = 7 Hz, *gem*-Me), 0.8–2.2 (9H, m, —CH— and —CH_2—), 2.54 (2H, td, J = 7 Hz, $J_{1'-3'}$ = 1 Hz, 1′-H's), 2.60 (1H, ddd, J_{gem} = 15 Hz, $J_{3-4\,trans}$ = 2 Hz, J_{3-1} = 1 Hz, 3-H_α, partially seen), 3.13 (1H, ddd, J_{gem} = 15 Hz, $J_{3-4\,cis}$ = 4.5 Hz, J_{3-1} = 2 Hz, 3-H_β), 3.75 (1H, m, 4-H), 4.73 (1H, td, J_{a-a} = 10 Hz, J_{a-e} = 4 Hz, —CO_2CH—), 5.87 (1H, dt, $J_{3'-2'}$ = 16 Hz, $J_{3'-1'}$ = 1 Hz, 3′-H), 6.57 (br, 1-H), and 6.86 (1H, dt, $J_{2'-3'}$ = 16 Hz, $J_{2'-1'}$ = 7 Hz, 2′-H) ppm. *Anal.* calcd. for $C_{17}H_{27}NO_3$: C 69.59, H 9.28, N 4.77; found: C 69.46, H 9.34, N 4.75.

p-*Nitrobenzyl [4(*R*)-(3-carbomenthyloxy-2-propen-1-yl)azetidin-2-on-1-yl]triphenylphosphoranylideneacetate (**13**a)*

A mixture of 4(*R*)-(3-carbomenthyloxy-2-propen-1-yl)-2-azetidinone (**4***a*) (2.93 g, 10.0 mmol) and *p*-nitrobenzyl glyoxylate hydrate (2.38 g, 10.5 mmol) in benzene (100 mL) was heated at reflux with a Dean–Stark trap for 3 h. Evaporation of the solvent gave 5.22 g of carbinolamides (epimeric mixture) as crude foam; R_f 0.57 (EtOAc–Et_2O 1:1); ir (neat) ν_{max}: 3440 (OH), 1760 (β-lactam and ester), 1715 (conj. ester), 1660 (C=C), 1525, and 1355 (NO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz) δ: 0.76 (3H, d, J = 7 Hz, —Me), 0.88 (6H, d, J = 7 Hz, *gem*-Me), 0.8–2.2 (9H, m, —CH— and —CH_2—), 2.4–3.3 (4H, m), 4.00 (1H, m, 4′-H), 4.65 (br, OH), 4.5–4.85 (1H, br, —CO_2CH—), 5.33 (2H, s, —CO_2CH_2Ar), 5.47 (1H, s, 1-H), 5.80, 5.86 (1H, 2d, J = 16 Hz, 3″-H), 6.5–7.2 (1H, m, 2″-H), 7.53 (2H, d, J = 9 Hz, ArH's), and 8.20 (2H, d, J = 9 Hz, ArH's) ppm.

The crude mixture of the two epimeric carbinolamides (4.71 g) was dissolved in THF (90 mL) and to this was added at −15° to −20°C pyridine (1.09 mL, 13.5 mmol), followed by thionyl chloride (0.92 mL), under a nitrogen atmosphere. The mixture was stirred (−15°C, N_2) for 30 min. After filtration of the white precipitate and washing with benzene, the filtrate and washings were combined and evaporated to dryness. The residue, extracted with benzene, was treated with Norit and evaporation of the solvent gave 5.26 g of *p*-nitrobenzyl [4(*R*)-(3-carbomenthyloxy-2-propen-1-yl)azetidin-2-on-1-yl]chloroacetates (epimeric mixture) as crude yellowish oil; ir (neat) ν_{max}: 1765 (β-lactam and ester), 1710 (conj. ester), 1660 (C=C), 1525, and 1350 (NO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz) δ: 0.76 (3H, d, J = 7 Hz, —Me), 0.89 (6H, d, J = 7 Hz, *gem*-Me), 0.8–2.1 (9H, m), 2.4–3.0 (3H, m, 3′-H_β and 1″-H's), 3.20 (1H, dd, J_{gem} = 15 Hz, $J_{3'-4'\,cis}$ = 5 Hz, 3′-H_α), 4.17 (1H, m, 4′-H), 4.72 (1H, m, —CO_2CH—), 5.33 (2H, s, —CO_2CH_2Ar), 5.85 (1H, d, J = 16 Hz, 3″-H), 6.23 (1H, s, 1-H), 6.5–7.2 (1H, m, 2″-H), 7.55 (2H, d, J = 9 Hz, ArH's), and 8.26 (2H, d, J = 9 Hz, ArH's) ppm.

To a stirred solution of the crude mixture of the two epimeric chloro compounds (5.23 g) and triphenylphosphine (2.60 g, 9.91 mmol) in dioxane (90 mL) was added 2,6-lutidine (1.16 mL, 10.0 mmol) at room temperature under a nitrogen atmosphere. The mixture was stirred overnight (20 h) and the precipitate was filtered and washed with EtOAc. The filtrate and washings were combined and evaporated. The residue, redissolved in EtOAc (50 mL), was washed with 1 *N* HCl (20 mL × 2) and then brine, dried (Na_2SO_4), and evaporated, yielding a crude oil. This was purified by column chromatography (120 g, EtOAc–Et_2O 1:1) to give 3.89 g (5.21 mmol, yield 58.1% based on **4***a*) of the title compound **13***a* as yellowish foam; R_f 0.47 (EtOAc–Et_2O 1:1); $[\alpha]_D^{21}$ − 51.5° (*c* 1.7, CH_2Cl_2); ir (film) ν_{max}: 1750 (β-lactam) 1715 (conj. ester), 1655 (C=C), 1625 (ester), 1520, and 1350 (NO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz) δ: 0.77 (3H, d, J = 7 Hz, —Me), 0.90 (6H, d, J = 7 Hz, *gem*-Me), 4.85, 5.2 (2H, 2s, —CO_2CH_2Ar), 7.2–8.0 (17H, m, ArH's), and 8.20 (2H, d, J = 9 Hz, ArH's) ppm, the rest are not well resolved. *Anal.* calcd. for

p-*Nitrobenzyl [4(S)-(3-carbomenthyloxy-2-propen-1-yl)azetidin-2-on-1-yl]triphenylphosphoranylideneacetate (**13**b)*

The title compound, 4.12 g (5.52 mmol, yield 68.0% based on **4***b*), was prepared as yellow foam from 4(*S*)-(3-carbomenthyloxy-2-propen-1-yl)-2-azetidinone (**4***b*) (2.93 g, 10.0 mmol) by the method described above for the 4*R*-isomer, through the corresponding intermediates; R_f 0.47 (EtOAc–Et_2O 1:1); $[\alpha]_D^{21}$ −0.2° (*c* 1.3, CH_2Cl_2); ir (film) ν_{max}: 1750 (β-lactam), 1715 (conj. ester), 1655 (C=C), 1630 (ester), 1420, and 1350 (NO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz) δ: 0.75 (3H, d, *J* = 7 Hz, —Me), 0.88 (6H, d, *J* = 7 Hz, *gem*-Me), 7.2–8.0 (17H, m, ArH's), and 8.2 (2H, d, *J* = 9 Hz, ArH's) ppm, the rest are not well resolved. *Anal.* calcd. for $C_{44}H_{47}N_2O_7P$: C 70.76, H 6.34, N 3.75; found: C 70.47, H 6.42, N 3.69.

p-*Nitrobenzyl 5(R)-carbapen-2-em-3-carboxylate (**3**a)*

To a stirred solution of *p*-nitrobenzyl [4(*R*)-(3-carbomenthyloxy--2-propen-1-yl)azetidin-2-on-1-yl]triphenylphosphoranylideneacetate (**13***a*) (747 mg, 1.00 mmol) in CH_2Cl_2 (20 mL) was added at 0°–5°C trifluoroacetic acid (2 mL) and the resulting yellow solution was cooled to −78°C. A stream of ozone was introduced until the blue colour was retained and the mixture was stirred at −78°C for another 5 min. Nitrogen was bubbled through the solution to remove excess ozone and then dimethyl sulfide (1.5 mL) was added. After removing the cooling bath, the mixture was stirred at 0°–5°C for 1 h and washed successively with saturated $NaHCO_3$ (50 mL × 2) and brine. The organic layer was dried (Na_2SO_4) and evaporated *in vacuo* (bath temperature 35°–40°C) to yield a crude oil. This was purified by column chromatography (30 g, Et_2O) to give 197 mg (0.683 mmol, yield 68.3%) of the title compound **3***a* as a yellow solid. An analytical sample was obtained, by recrystallization from CH_2Cl_2–Et_2O, as white crystals; mp 123°–124°C; R_f 0.35 (EtOAc–hex 1:1); $[\alpha]_D^{21}$ +127.5° (*c* 1.0, CH_2Cl_2); ir (film) ν_{max}: 1780 (β-lactam), 1725 (ester), 1520, and 1350 (NO_2) cm^{-1}; uv (EtOH) λ_{max}: 267 nm (ε 14 800); ^{1}Hmr ($CDCl_3$, 80 MHz) δ: 2.72 (1H, ddd, J_{gem} = 19 Hz, J_{1-5} = 9 Hz, J_{1-2} = 3 Hz, 1-H_a), 2.98 (1H, dd, J_{gem} = 17 Hz, $J_{6-5\,trans}$ = 3.3 Hz, 6-H_β), 3.02 (1H, ddd, J_{gem} = 19 Hz, J_{1-5} = 9 Hz, J_{1-2} = 3 Hz, 1-H_b), 3.54 (1H, dd, J_{gem} = 17 Hz, $J_{6-5\,cis}$ = 5.5 Hz, 6-H_α), 4.3 (1H, m, 5-H_α), 5.16–5.33–5.38–5.55 (2H, ABq, —CO_2CH_2Ar), 6.58 (1H, t, *J* = 3 Hz, 2-H), 7.60 (2H, d, *J* = 8.8 Hz, ArH's), and 8.23 (2H, d, *J* = 8.8 Hz, ArH's) ppm; ^{1}Hmr (**3***a*, 5 mg, and Eu(dcm)$_3$, 25 mg, in $CDCl_3$, 0.5 mL; 80 MHz) δ: 5.98–6.15–6.32–6.49 (2H, ABq, —CO_2CH_2Ar), and 7.01 (1H, t, *J* = 3 Hz, 2-H) ppm. *Anal.* calcd. for $C_{14}H_{12}N_2O_5$: C 58.33, H 4.20, N 9.72; found: C 58.37, H 4.18, N 9.72.

p-*Nitrobenzyl 5-(S)-carbapen-2-em-3-carboxylate (**3**b)*

The crude title compound was obtained from *p*-nitrobenzyl [4(*S*)-(3-carbomenthyloxy-2-propen-1-yl)azetidin-2-on-1-yl]triphenylphosphoranylideneacetate (**13***b*) (747 mg, 1.00 mmol) by the method described for the 5*R*-isomer. This material was purified by column chromatography (20 g, EtOAc–hex 1:1) to yield 182 mg (0.791 mmol, yield 79.1%) of menthyl glyoxylate hydrate as white solid; mp 78°–81°C (Et_2O–pentane); R_f 0.75 (EtOAc–hex 1:1); $[\alpha]_D^{21}$ −77.0° (*c* 1.0, CH_2Cl_2); ir (film) ν_{max}: 3420 (OH) and 1740 (ester) cm^{-1}; and 197 mg (0.683 mmol, yield 68.3%) of the title compound as a white solid; mp 122°–124°C (recrystallized from CH_2Cl_2–Et_2O); R_f 0.35 (EtOAc–hex 1:1); $[\alpha]_D^{21}$ −110.8° (*c* 1.0, CH_2Cl_2); ir (film) ν_{max}: 1780 (β-lactam), 1730 (ester), 1520, and 1350 (NO_2) cm^{-1}; uv (EtOH) λ_{max}: 267 nm (ε 15 600); ^{1}Hmr ($CDCl_3$, 80 MHz) δ: 2.73 (1H, ddd, J_{gem} = 19 Hz, J_{1-5} = 9 Hz, J_{1-2} = 3 Hz, 1-H_a), 2.98 (1H, dd, J_{gem} = 17 Hz, $J_{6-5\,trans}$ = 3 Hz, 6-H_α), 3.03 (1H, ddd, J_{gem} = 19 Hz, J_{1-5} = 9.5 Hz, J_{1-2} = 3 Hz, 1-H_b), 3.55 (1H, dd, J_{gem} = 17 Hz, $J_{6-5\,cis}$ = 5.5 Hz, 6-H_β), 4.3 (1H, m, 5-H_β), 5.16–5.34–5.38–5.56 (2H, ABq, —CO_2CH_2Ar), 6.59 (1H, t, *J* = 3 Hz, 2-H), 7.60 (2H, d, *J* = 8.8 Hz, ArH's), and 8.23 (2H, d, *J* = 8.8 Hz, ArH's) ppm; ^{1}Hmr (**3***b*, 5 mg, and Eu(dcm)$_3$, 25 mg, in $CDCl_3$, 0.5 mL; 80 MHz) δ: 5.98–6.15–6.27–6.45 (2H, ABq, —CO_2CH_2Ar), 6.34 (a part of the ABq in the 5*R*-isomer), and 7.05 (1H, t, *J* = 3 Hz, 2-H) ppm. *Anal.* calcd. for $C_{14}H_{12}N_2O_5$: C 58.33, H 4.20, N 9.72; found: C 58.08, H 4.26, N 9.93.

N-tert-*butyldimethylsilyl-4(R)-(3-carbomenthyloxy-2-propen-1-yl)-2-azetidinone (**14**a)*

To a stirred solution of 4(*R*)-(3-carbomenthyloxy-2-propen-1-yl)-2-azetidinone (**4***a*) (1.91 g, 6.52 mmol) and *tert*-butyldimethylsilyl chloride (1.11 g, 7.37 mmol) in dimethylformamide (20 mL) was added at 0°C under a nitrogen atmosphere triethylamine (1.04 mL, 7.5 mmol), causing white precipitation. The mixture was stirred at room temperature overnight (18 h), and then diluted with water (100 mL) and Et_2O (65 mL). After shaking, the separated organic layer was washed with water (80 mL × 3), then brine, dried (Na_2SO_4), and evaporated to 2.56 g of an oil. This was crystallized from pentane at 0°C, yielding 2.10 g (5.15 mmol, yield 79.0%) of the title compound **14***a* as off-white crystals; mp 80.5°–81.5°C; R_f 0.54 (EtOAc–hex 1:4); $[\alpha]_D^{20}$ −116.0° (*c* 1.0, CH_2Cl_2); ir (film) ν_{max}: 1750 (β-lactam), 1715 (conj. ester), and 1655 (C=C) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz) δ: 0.23 (3H, s, Si-Me), 0.25 (3H, s, Si-Me), 0.76 (3H, d, *J* = 7 Hz, —Me), 0.89 (6H, d, *J* = 7 Hz, *gem*-Me), 0.96 (9H, s, Si-*t*Bu), 2.64 (1H, dd, J_{gem} = 15 Hz, $J_{3-4\,trans}$ = 3 Hz, 3-H_β), 3.19 (1H, dd, J_{gem} = 15 Hz, $J_{3-4\,cis}$ = 5 Hz, 3-H_α), 3.65 (1H, m, 4-H_α), 4.75 (1H, td, J_{a-a} = 10 Hz, J_{a-e} = 4 Hz, —CO_2CH—), 5.85 (1H, dt, $J_{3'-2'}$ = 15.7 Hz, $J_{3'-1'}$ = 1.4 Hz, 3'-H), and 6.83 (1H, dt, $J_{2'-3'}$ = 15.7 Hz, $J_{2'-1'}$ = 7 Hz, 2'-H) ppm. *Anal.* calcd. for $C_{23}H_{41}NO_3Si$: C 67.76, H 10.14, N 3.44; found: C 67.85, H 10.07, N 3.76.

N-tert-*butyldimethylsilyl-4(S)-(3-carbomenthyloxy-3-propen-1-yl)-2-azetidinone (**14**b)*

The crude title compound (9.0 g) was prepared as an oil from 4(*S*)-(3-carbomenthyloxy-2-propen-1-yl)-2-azetidinone (**4***b*) (6.70 g, 22.87 mmol) by the method described for the 4(*R*)-isomer. This was purified by column chromatography (270 g, EtOAc–hex 1:4) to obtain 8.10 g (19.9 mmol, yield 87.0%) of the title compound **14***b* as a colourless oil; R_f 0.54 (EtOAc–hex 1:4); $[\alpha]_D^{21}$ +9.0° (*c* 1.0, CH_2Cl_2); ir (neat) ν_{max}: 1750 (β-lactam), 1715 (conj. ester), and 1655 (C=C) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz) δ: 0.22 (3H, s, Si-Me), 0.24 (3H, s, Si-Me), 0.75 (3H, d, *J* = 7 Hz, —Me), 0.88 (6H, d, *J* = 7 Hz, *gem*-Me), 0.95 (9H, s, Si-*t*Bu), 2.63 (1H, dd, J_{gem} = 15 Hz, $J_{3-4\,trans}$ = 3 Hz, 3-H_α), 3.18 (1H, dd, J_{gem} = 15 Hz, $J_{3-4\,cis}$ = 5 Hz, 3-H_β), 3.6 (1H, m, 4-H_β), 4.74 (1H, td, J_{a-a} = 10 Hz, J_{a-e} = 4 Hz, —CO_2CH—), 5.85 (1H, dt, $J_{3'-2'}$ = 15.7 Hz, $J_{3'-1'}$ = 1.4 Hz, 3'-H), and 6.82 (1H, td, $J_{2'-3'}$ = 15.7 Hz, $J_{2'-1'}$ = 7 Hz, 2'-H.

N-tert-*butyldimethylsilyl-3(S)-carboxymethyl-2-azetidinone (**15**a)*

(a) *From compound **14**a*

A suspension of potassium permanganate (474 mg, 3.00 mmol) in water (5 mL) was vigorously stirred for 10 min and cooled to 5°–10°C while toluene (2 mL), tetrabutylammonium bromide (50 mg), and a solution of *N-tert*-butyldimethylsilyl-4(*R*)-(3-carbomenthyloxy-2-propen-1-yl)-2-azetidinone (**14***a*) (408 mg, 1.00 mmol) in EtOAc (3 mL) were added successively. The mixture was stirred at room temperature for 1 h and then the reaction was quenched by successive addition of a solution of sodium bisulfite (937 mg) in water (9 mL), EtOAc (10 mL), and then 3 *N* HCl (3 mL). The organic layer was collected and the aqueous layer extracted with EtOAc. All organic layers were combined, washed with brine, dried (Na_2SO_4), and evaporated to obtain 507 mg of a crude gum. This was purified by column chromatography (30 g, acetone–toluene 1:1) to yield 123 mg (0.505 mmol, yield 50.5%) of the title compound **15***a* as an amorphous solid; mp 100°–105°C; R_f 0.4 (acetone–toluene 1:1, elongated spot); $[\alpha]_D^{21}$ −67.5° (*c* 1.0, CH_2Cl_2); ir (film) ν_{max}: 2500–3500 (br, —CO_2H), 1730 (β-lactam), and 1680 (—CO_2H) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz) δ: 0.22 (3H, s, Si-Me), 0.25 (3H, s, Si-Me), 0.95 (9H, s, Si-*t*Bu), 2.50 (1H, dd, J_{gem} = 16 Hz, $J_{1'-4}$ = 9.8 Hz, —*CH*—CO_2H), 2.79 (1H, dd, J_{gem} = 15.7 Hz, $J_{3-4\,trans}$ = 2.8 Hz), 2.93 (1H, dd, J_{gem} = 16 Hz, $J_{1'-4}$ = 4.1 Hz, —CH—CO_2H), 3.33 (1H, dd, J_{gem} = 15.7 Hz, $J_{3-4\,cis}$ = 5.3 Hz, 3-H_α), 3.9 (1H, m, 4-H_α), and 6.25 (br, —CO_2H) ppm.

(b) *From compound* **16**

The title compound **15***a* (97 mg, 0.40 mmol, yield 40%) was prepared as white foam from *N-tert*-butyldimethylsilyl-4(*R*)-allyl-2-azetidinone (**16**) (224 mg, 1.00 mmol) by the method described above; R_f 0.4 (acetone–toluene 1:1, elongated spot); $[\alpha]_D^{21}$ −80.3° (*c* 1.0, CH_2Cl_2). The ^{1}Hmr ($CDCl_3$, 80 MHz) and ir (film) spectra were identical with those obtained from **14***a*.

N-tert-*butyldimethylsilyl-3(*R*)-carboxymethyl-2-azetidinone (**15**b)*

The title compound **15***b* (5.07 mg, 2.08 mmol, yield 69.3%) was obtained as off-white foam from *N-tert*-butyldimethylsilyl-4(*S*)-(3-carbomenthyloxy-2-propen-1-yl)-2-azetidinone (**14***b*) (1.223 g, 3.00 mmol) by the method described above for the 4*S*-isomer; R_f 0.4 (acetone–toluene 1:1, elongated spot); $[\alpha]_D^{21}$ +36.6° (*c* 1.0, CH_2Cl_2). The ^{1}Hmr ($CDCl_3$, 80 MHz) and ir (film) spectra were identical with those of the 4*S*-isomer.

Acknowledgements

We would like to thank Professor B. Belleau of McGill University and Dr. M. Ménard for their interest in this work. We also thank Mr. G. Lacasse for 80 MHz ^{1}Hmr spectra.

Hydrolysis of phosphoranes containing a perfluoropinacolyl ring[1]

ALEXANDER F. JANZEN, ALBERTA E. LEMIRE, RONALD KIRK MARAT, AND ALAN QUEEN
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received January 26, 1983

ALEXANDER F. JANZEN, ALBERTA E. LEMIRE, RONALD KIRK MARAT, and ALAN QUEEN. Can. J. Chem. **61**, 2264 (1983).

The hydrolysis of phosphoranes $Ph_2P(pfp)Cl$, $Ph_2P(pfp)OR$, $PhP(pfp)(OR)_2$, and $(RO)_3P(pfp)$, containing a perfluoropinacolyl (pfp) ring, occurs under neutral, basic, or acidic conditions and leads to the formation of acyclic perfluoropinacolyl products, i.e. $R_2P(O)OC(CF_3)_2C(CF_3)_2OH$, as determined by ^1H, ^{19}F, ^{31}P, ^{13}C nmr and ir studies. In the presence of a base, all trifluoromethyl groups in $Ph_2P(O)OC(CF_3)_2C(CF_3)_2OH$ are equilibrated, as verified by ^{19}F and ^{13}C nmr; and from the variable temperature ^{19}F nmr line-shape analysis the activation parameters for this exchange process were found to be: E_a = 36.0 ± 3 kJ mol^{-1}, $\Delta H^{\ddagger}$ = 33.5 ± 3 kJ mol^{-1}, $\Delta S^{\ddagger}$ = −86 ± 8 J K^{-1} mol^{-1}, $\Delta G^{\ddagger}_{298}$ = 59.0 ± 0.6 kJ mol^{-1}. The reactions of phosphoranes with HF were briefly investigated.

ALEXANDER F. JANZEN, ALBERTA E. LEMIRE, RONALD KIRK MARAT et ALAN QUEEN. Can. J. Chem. **61**, 2264 (1983).

L'hydrolyse des phosphoranes: $Ph_2P(pfp)Cl$, $Ph_2P(pfp)OR$, $PhP(pfp)(OR)_2$ et $(RO)_3P(pfp)$ contenant le cycle perfluoropinacolyle (pfp) se produit en milieu neutre, acide ou basique et conduit à la formation de perfluoropinacolyles acycliques i.e. $R_2P(O)OC(CF_3)_2C(CF_3)_2OH$ comme l'indiquent la rmn du ^1H, du ^{19}F, du ^{31}P, du ^{13}C et les études en ir. La rmn du ^{19}F et du ^{13}C révèle qu'en milieu basique tous les groupes trifluorométhyle du $Ph_2P(O)OC(CF_3)_2C(CF_3)_2OH$ sont équilibrés. L'analyse de la forme des raies de la rmn du ^{19}F à température variable donne les paramètres d'activation suivants: E_a = 36,0 ± 0,3 kJ mol^{-1}, $\Delta H^{\ddagger}$ = 33,5 ± 3 kJ mol^{-1}, $\Delta S^{\ddagger}$ = −86,8 J K^{-1} mol^{-1}, $\Delta G^{\ddagger}$ = 59,0 ± 0,6 kJ mol^{-1}. On discute brièvement des réactions des phosphoranes avec le HF.

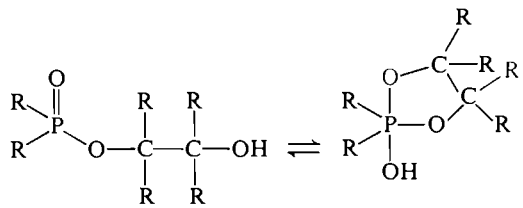
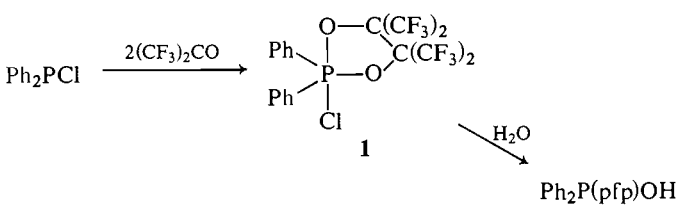
The hydrolysis of phosphoranes containing a five-membered ring may produce either an acyclic phosphoryl compound **A** or a cyclic hydroxyphosphorane **B**. In some instances, an equilibrium between isomers **A** and **B** has been observed and the equilibrium may be shifted by varying the temperature or the



A **B**

base concentration (1−5). Such equilibria, of interest because of their role in the hydrolysis of phosphorus esters in organic and biological systems, may be studied by ^{19}F nmr since the trifluoromethyl groups are often equivalent in cyclic perfluoropinacolyl phosphoranes, but non-equivalent in acyclic analogues. Recent studies with $Me_2P(O)OC(CF_3)_2C(CF_3)_2OH$ have demonstrated that ^{19}F nmr can be used to monitor an equilibrium between cyclic and acyclic phosphorus compounds (6).

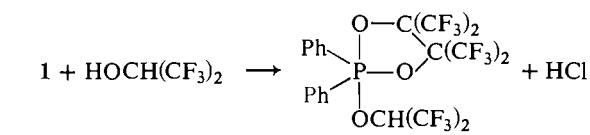
In some early work, we prepared the perfluoropinacolyl derivative **1** from chlorodiphenylphosphine and hexafluoroacetone and observed its rapid hydrolysis to $Ph_2P(pfp)OH$ (7).



1

Although **1** gave a single fluorine nmr peak in the pfp region (pfp = —$OC(CF_3)_2C(CF_3)_2O$—) and ir bands characteristic of a cyclic pfp derivative, our evidence did not distinguish between an acyclic **A** or cyclic **B** structure for the hydrolysis product. More recently, as part of a kinetic study of the hydrolysis of $PhP(pfp)[OCH(CF_3)_2]_2$ (8), we required structural information about the hydrolysis product; consequently, we have re-examined the synthesis and hydrolysis of **1**, and also studied the hydrolysis of a variety of other perfluoropinacolyl phosphoranes using ^{19}F, ^{31}P, and ^{13}C nmr to distinguish between acyclic and cyclic products and using dynamic nmr techniques to investigate the equilibrium between acyclic **A** and cyclic **B** products.

Phosphoranes **1**−**8** were prepared from hexafluoroacetone and the corresponding phosphines and identified by a combination of nmr, ir, ms, and elemental analysis. The chlorophosphorane **1**, although stable in a sealed tube, hydrolyzed rapidly and was conveniently identified by its reaction with $(CF_3)_2CHOH$ to give **2**.



2

Those ir bands previously found to be characteristic of cyclic pfp derivatives (9) are present in phosphoranes **1**−**8** (Table 1).

The fluorine nmr spectra of **1**−**8** gave single peaks in the pfp region, thus showing that the trifluoromethyl groups are equivalent in the cyclic phosphoranes. This equivalence is also evident in the carbon nmr spectra of **2** and **6** (Table 2) which show only one CF_3 and one O—C peak assigned to the pfp ring. Other perfluoropinacolyl phosphoranes also show this equivalence in their carbon nmr spectra (10).

The hydrolysis of cyclic phosphoranes **1**, **3**−**8** was carried out under neutral, basic, or acidic conditions to give products **9**−**11**. In some instances, further reaction occurred and free

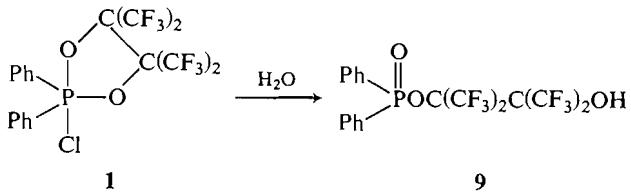
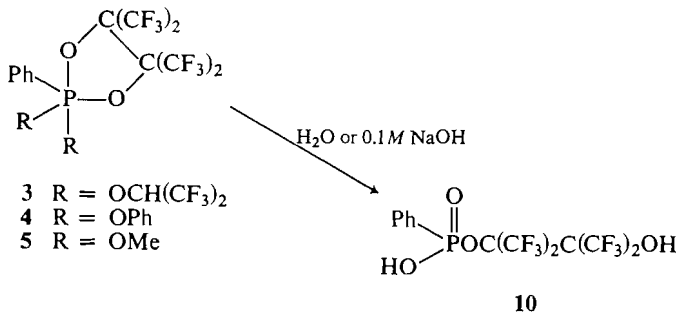
TABLE 1. Infrared bands (cm^{-1}) characteristic of cyclic pfp derivatives

Compound	Infrared band
1	1095 998 954 878 743
2	1109 1001 963 888 745
3	1108 1001 966 888 736
6	1120 1005 968 888 743
7	1120 1020 958 882 750
8	1124 998 965 880 745

perfluoropinacol was liberated but, as described in the Experimental section, products **9**–**11** could be isolated in 10–75% yield. Hydrolysis of **1** occurred on exposure to air or in solvents containing trace amounts of water or in aqueous acetonitrile. Hydrolysis of **3**–**5** was carried out in 99% ethanol or in dilute NaOH solution. Hydrolysis of **6**–**9** was accomplished with concentrated H_2SO_4 at 25°C; at higher temperatures, perfluoropinacol is liberated (11).

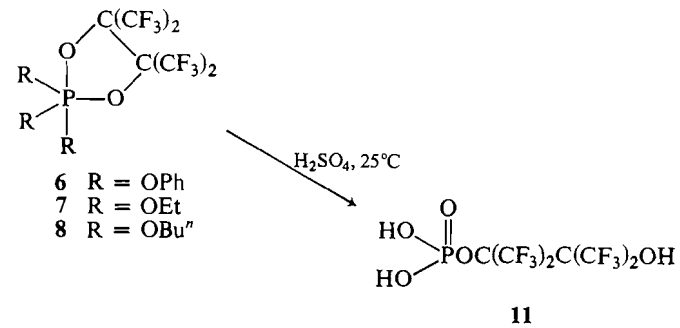


1 **9**



3 R = $OCH(CF_3)_2$
4 R = OPh
5 R = OMe

10



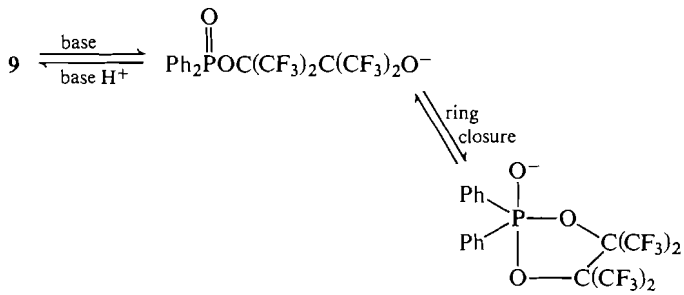
6 R = OPh
7 R = OEt
8 R = OBu″

11

An acyclic **A** or cyclic **B** structure was considered for the hydrolysis products **9**–**11**. Although a cyclic structure $(HO)_3P(pfp)$ has been proposed for the hydrolysis product of $(EtO)_3P(pfp)$, **7** (12), the following spectral evidence is entirely consistent with an acyclic phosphoryl structure **A** for **9**–**11**: (*a*) The ^{19}F nmr spectra of **9**–**11** show, in each case, two septets with $^5J_{FF}$ = 10 Hz (Table 2). A typical spectrum is shown in Fig. 1. A cyclic structure would be expected to give only a single perfluoropinacolyl peak, as found for the cyclic phosphoranes **1**–**8**. (*b*) The ^{13}C nmr spectra of **9**–**11** show non-equivalent CF_3 groups as well as non-equivalent ring carbons, whereas the ^{13}C nmr spectra of cyclic phosphoranes **2** and **6** show equivalent CF_3 groups and equivalent ring carbons in the pfp region (Table 2). (*c*) A comparison of the phosphorus chemical shifts of the cyclic phosphoranes **1**–**8** with the hydrolysis products **9**–**11** shows a significant downfield shift for **9**–**11** (Table 2). For example, on hydrolysis of **1** to **9** there is a shift from −5.4 to 41.3 ppm; from **3** to **10** there is a shift from −38.6 to 12.2 ppm; and from **7** to **11** there is a shift from −53.2 (13) to −8.6 ppm. The phosphorus chemical shift of $Ph_2P(O)OCH(CF_3)_2$ (**12**) 39.2 ppm (14), however, is very similar to that of $Ph_2P(O)OC(CF_3)_2C(CF_3)_2OH$ (**9**) 41.3 ppm, as expected if **9** has an acyclic structure.

Compound **9** was used to study the equilibrium between acyclic **A** and cyclic **B** isomers. The doublet of septets in the ^{19}F nmr spectrum of **9** collapsed to a single peak as the rate of exchange of trifluoromethyl groups increased. In solvents such as acetone, dioxane, dichloromethane, or toluene, exchange is evident above 60°C. At 25°C exchange is promoted by bases such as pyridine, imidazole, quinoline, and excess dimethylsulfoxide. Typical pyridine-promoted temperature-dependent ^{19}F nmr spectra are shown in Fig. 1. A line-shape analysis of the variable temperature spectra gave the following activation parameters: E_a = 36.0 ± 3 kJ mol^{-1}, $\Delta H^{\ddagger}$ = 33.5 ± 3 kJ mol^{-1}, $\Delta S^{\ddagger}$ = −86 ± 8 J K^{-1} mol^{-1}, $\Delta G^{\ddagger}_{298}$ = 59.0 ± 0.6 kJ mol^{-1}.

Deprotonation, following by ring-closure, adequately accounts for the nmr results. An exchange mechanism involving



complete loss of the perfluoropinacolyl ligand was eliminated by adding perfluoropinacol to a rapidly exchanging system and observing separate ^{19}F nmr peaks for bound and free perfluoropinacol. That exchange in **9** can occur by a ring-closing and ring-opening process, with rates that are rapid on the nmr time scale, is of interest in view of alternative mechanisms of exchange in cyclic phosphoranes such as Berry pseudorotation or turnstile rotation (15).

Attempts to observe exchange of the $OCH(CF_3)_2$ group in $PhP(pfp)[OCH(CF_3)_2]_2$ (**3**) with free $HOCH(CF_3)_2$ in solvent dimethoxyethane, or with $HOCH(CF_3)_2$ in the presence of pyridine, or with $NaOCH(CF_3)_2$ in dimethylformamide, all at 25°C, were unsuccessful; in each case separate fluorine nmr signals were observed for free and bound $OCH(CF_3)_2$ groups.

Finally, as part of our interest in reactions of HF, we briefly investigated the reactions of phosphoranes with anhydrous HF. With 1 mol HF, $PhP(pfp)[OCH(CF_3)_2]_2$ (**3**) gave a mixture of $PhPF(pfp)OCH(CF_3)_2$ and $PhPF_2(pfp)$ while adding 2–4 mol HF gave mainly $PhPF_2(pfp)$, but on standing at 25°C, perfluoropinacol was liberated. After 6 days, $PhP(pfp)(OPh)_2$ and 2 mol HF showed mainly $PhPF_2(pfp)$ and perfluoropinacol. Reaction of $(PhO)_5P$ with 1 or 2 mol HF gave $(PhO)_4PF$ and $(PhO)_3PF_2$ but on standing at 25°C or on increasing the ratio of HF, the formation of $(PhO)_4P^+PF_6^-$ (16) was favoured. $PhP(OMe)_2(pfp)$ (**5**) with 1 mol HF liberated perfluoropinacol.

TABLE 2. Nmr spectral parameters of some perfluoropinacolyl phosphorus compounds[a]

Compound	δ_P	δ_F	δ_C (CF_3)	δ_C (—OC)
1	−5.4	−67.4		
2	−18.7	−67	121.9	82.4
		−72	121.2 (J_{CP}4.9)	72.7 ($^1J_{CH}$149.5, $^2J_{CP}$11.1, $^2J_{CF}$33.2)
3	−38.6	−67		
		−72		
5	−31.2	−68		
6		−68	120.9 ($^3J_{CP}$8.9)	81.7
8		−68.9		
9	41.3	−67.3 ($^5J_{FF}$10)	121.7	88.0 (J_{CP}14.4)
		−69.4	120.7 (J_{CP}4.8)	81.9

[a]Chemical shifts in ppm are positive to low field of TMS, $CFCl_3$, and 85% H_3PO_4. Coupling constants in Hz.

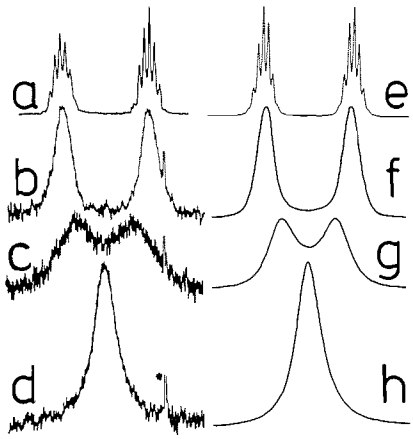

FIG. 1. Typical pyridine-promoted, temperature-dependent experimental (left) and calculated (right) ^{19}F nmr spectra of $Ph_2P(O)OC(CF_3)_2C(CF_3)_2OH$, **9** (0.19 *M*), in 1:1 CD_2Cl_2−toluene. (*a*) 300 K, [py] = 0 *M*; (*b*) 270 K, [py] = 0.20 *M*; (*c*) 300 K, [py] = 0.20 *M*; (*d*) 320 K, [py] = 0.21 *M*; (*e*) τ = 0.2 s; (*f*) τ = 0.02 s; (*g*) τ = 0.0044 s; (*h*) τ = 0.00125 s. *Impurity peak is perfluoropinacol.

$PhP(OPh)_2$ with 2 mol HF gave a mixture of PhPF(OPh), $PhPF_2$, and $PhPF_3H$, while $PhP[OCH(CF_3)_2]_2$ with 2 mol HF gave a mixture of $PhPFOCH(CF_3)_2$, $PhPF_2$, and $PhPF_3H$.

Experimental

Infrared spectra were measured on a Perkin-Elmer 337 spectrophotometer in Nujol and hexachlorobutadiene on NaCl plates. Mass spectra were obtained on a Finnigan 1015 quadrupole instrument operating at 70 eV. ^1H, ^{13}C, ^{19}F, and ^{31}P nmr spectra were recorded on a Bruker WH-90 spectrometer at 90, 22.63, 84.66, and 36.44 MHz, respectively. Fluorine decoupling of ^{13}C nmr spectra was accomplished with a modified Bruker BSV3 decoupler operating at 84.7 MHz with a power level of 10 W and a 3 dB noise bandwidth of 500 Hz. The nmr lineshapes were calculated with a matrix-expanded and modified version of the program DNMR3 (17) on an Amdahl 470-V7 computer with the IBM Fortran H (extended) compiler. Elemental analyses were carried out by Micro-Tech Laboratories, Skokie, Illinois.

The following compounds were prepared by the literature methods: $PhP(pfp)[OCH(CF_3)_2]_2$ (**3**), ref. 8; $PhP(pfp)(OPh)_2$ (**4**), ref. 18; PhP(pfp)$(OMe)_2$ (**5**), ref. 18; $(PhO)_3P(pfp)$ (**6**), ref. 19; $(EtO)_3P(pfp)$, ref. 13; $Ph_2P(O)OCH(CF_3)_2$ (**12**), ref. 22; $PhP[OCH(CF_3)_2]_2$, ref. 20; $(PhO)_5P$, ref. 21; and perfluoropinacol, ref. 11. Other compounds were commercial samples. HF solutions were made by condensing anhydrous HF into acetonitrile to give approximately 0.7 *M* solutions. Solvents were dried and redistilled prior to use. The following compounds were not isolated but identified by their published spectra: $(PhO)_4P^+PF_6^-$ (16), $(PhO)_3PF_2$ (23), and $PhPF_2(pfp)$ (24).

$Ph_2P(pfp)Cl$ (1)

Ph_2PCl (2.54 g, 11.5 mmol) and $(CF_3)_2CO$ (4.5 g, 27 mmol) were sealed in a tube and kept at 25°C for 1 week. Excess $(CF_3)_2CO$ was removed and an oil remained which decomposed in air. It was identified as $Ph_2P(pfp)Cl$ (**1**) by ir (Table 1), ^{19}F and ^{31}P nmr (Table 2), and by its reaction with an equimolar amount of $HOCH(CF_3)_2$ in toluene−C_6D_6 to give $Ph_2P(pfp)OCH(CF_3)_2$ (**2**).

Under the same conditions, $PhPCl_2$ and $(CF_3)_2CO$ did not react to give a phosphorane product.

$Ph_2P(pfp)OCH(CF_3)_2$ (2)

$Ph_2POCH(CF_3)_2$ (5.6 g, 16 mmol) and excess $(CF_3)_2CO$ were sealed in a reaction tube and kept at 25°C for 3 days. Volatile products were removed and an oily liquid solidified on standing. Recrystallization from petroleum ether gave white crystals identified as $Ph_2P(pfp)OCH(CF_3)_2$ (**2**), 10%, mp 61−62°C, stable in air and soluble in benzene, dichloromethane, dimethoxyethane, and dioxane. *Anal.* calcd. for $C_{21}H_{11}F_{18}O_3P$: C 36.86, H 1.62, F 49.98; found: C 35.63, H 1.52, F 50.55. A variable temperature fluorine nmr spectrum of **2** showed only slight changes over temperature range +25 to −65°C.

(n-$C_4H_9O)_3P(pfp)$ (8)

Excess $(CF_3)_2CO$ (4.0 g, 24 mmol) was added to $(n\text{-}C_4H_9O)_3P$ (2.79 g, 11.1 mmol) and the reaction tube sealed and kept at 25°C for 4 days. Vacuum fractionation of the mixture yielded $(n\text{-}C_4H_9O)_3P(pfp)$ (**8**) (95%), identified by ir (Table 1) and ^{19}F nmr (Table 2). *Anal.* calcd. for $C_{18}H_{27}F_{12}O_5P$: C 37.12, H 4.67; found: C 36.92, H 4.63.

$Ph_2P(O)OC(CF_3)_2C(CF_3)_2OH$ (9)

Water was added to $Ph_2P(pfp)Cl$ (**1**), prepared as described above, in acetonitrile until a solid precipitated. The solid was filtered, washed with water, and recrystallized by dissolving in a minimum of hot CH_2Cl_2, adding hexane, and then evaporating on a rotary evaporator until the solid just begins to precipitate. The solid, identified as $Ph_2P(O)OC(CF_3)_2C(CF_3)_2OH$ (**9**) (44%, mp 125−126°C) by ^{19}F, ^{31}P, and ^{13}C nmr (Table 2), is air stable and soluble in CH_2Cl_2, dioxane, acetone, and acetonitrile. *Anal.* calcd. for $C_{18}H_{11}F_{12}O_3P$: C 40.47, H 2.07, F 42.68; found: C 40.49, H 1.96, F 41.28. Infrared (hexachlorobutadiene): 3100 (b, OH); on deuteration, 2310 (b, OD) cm^{-1}.

$PhP(O)(OH)OC(CF_3)_2C(CF_3)_2OH$ (10)

Ethanol (containing 1% water) was added, with stirring, to $PhP(pfp)[OCH(CF_3)_2]_2$ (**3**) (0.5 g, 0.6 mmol). Ethanol was removed under vacuum and benzene added, repeatedly, until no free $HOCH(CF_3)_2$ remained in the oil, as monitored by ^{19}F nmr. A solid precipitated on adding CH_2Cl_2 which was washed with cold CH_2Cl_2, dried under vacuum, and sublimed to give $PhP(O)(OH)OC(CF_3)_2C(CF_3)_2OH$ (**10**) (45%, mp 98–99°C), identified by nmr (Table 2) and ir: 3200 (b, OH) cm^{-1}. *Anal.* calcd. for $C_{12}H_7F_{12}O_4P$: C 30.39, H 1.49, F 48.09; found: C 30.26, H 1.51, F 50.43.

The neutral and basic (0.1 *M* NaOH) hydrolysis of $PhP(pfp)(OPh)_2$ (**4**) and $PhP(pfp)(OMe)_2$ (**5**) also gave **10** as a major product, as determined by nmr.

$(HO)_2P(O)OC(CF_3)_2C(CF_3)_2OH$ (11)

Concentrated H_2SO_4 (6 mL) was added with stirring to $(EtO)_3P(pfp)$ (**7**) (2.5 g, 10 mmol) at 25°C. A precipitate formed immediately, which was filtered, washed with hexane, and dried under vacuum to give a white solid identified as $(HO)_2P(O)OC(CF_3)_2C(CF_3)_2OH$ (**11**), 75%, ir: 3400 (b, OH) cm^{-1}; nmr (Table 2). It is soluble in H_2O and CH_3CN. A portion of this solid was sublimed to yield a product with mp 99–100°C. Another portion was recrystallized from hexane to give fine needle crystals with mp 104–105°C. Sublimed and recrystallized products had identical ^{19}F nmr spectra. *Anal.* calcd. for $C_6H_3F_{12}O_5P$: C 17.40, H 0.73, F 55.07; found: C 16.80, 15.26, H 0.92, 1.48, F 51.22. The elemental analyses are low in C and F but high in H, suggesting the presence of water in the sample.

A similar procedure was used to prepare **11** from $(PhO)_3P(pfp)$ (**6**).

Mass spectra

The characteristic peaks in the mass spectra are given below:

Compound	Peaks
1	M−19, M−35, M−69, M−77, M−167

Received February 10, 1983

This article is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

BELA VERKOCZY, ALDEN G. SHERWOOD, IMRE SAFARIK, and OTTO P. STRAUSZ. Can. J. Chem. **61**, 2268 (1983).

The gas phase reactions of $S(^1D_2)$ and $S(^3P_J)$ atoms with alkynes have been studied by photolyzing COS in the presence of CH≡CH, $CF_3C{\equiv}CH$, and $CF_3C{\equiv}CCF_3$. In the reactions with CH≡CH, CS_2, benzene, and thiophene were formed; with $CF_3C{\equiv}CH$, eight products were found with disubstituted thiophenes and trisubstituted benzenes as the major products. In the case of $CF_3C{\equiv}CCF_3$, only perfluorotetramethylthiophene was detected at low conversion but at long photolysis several new products were observed. Many of the reaction products characterized here have not been reported before.

The formation and distribution of the reaction products could be rationalized by an overall mechanism in which the formation of the highly reactive primary adducts, thiirene and thioformylmethylene, is followed by bimolecular reactions yielding the principal end products. The formation of minor products could be explained by secondary photoisomerizations, secondary photolysis, and by secondary decompositions and the secondary reactions of sulfur atoms with primary products.

BELA VERKOCZY, ALDEN G. SHERWOOD, IMRE SAFARIK et OTTO P. STRAUSZ. Can. J. Chem. **61**, 2268 (1983).

On a étudié les réactions en phase gazeuse des atomes de $S(^1D_2)$ et de $S(^3P_J)$ avec les alcynes en photolysant le COS en présence du CH≡CH, du $CF_3C{\equiv}CH$ et du $CF_3C{\equiv}CCF_3$. Les réactions impliquant le CH≡CH conduisent à la formation du CS_2, du benzène et du thiophène. Celles impliquant le $CF_3C{\equiv}CH$ donnent 8 produits comprenant des thiophènes disubstitués et des benzènes trisubstitués comme produits principaux. Dans le cas du $CF_3C{\equiv}CCF_3$ on a décelé uniquement du fluorotétraméthylthiophène au début de la photolyse, mais sur une longue période on observe plusieurs produits nouveaux. Plusieurs des produits caractérisés dans ce travail ne sont pas répertoriés dans la littérature.

On peut rationaliser la formation et la distribution des produits de la réaction en faisant appel à un mécanisme global dans lequel la formation des adduits primaires très réactifs, thiirène et thioformylméthylènes, est suivie de réactions bimoléculaires qui conduisent aux produits finaux principaux. On peut expliquer la formation des produits secondaires par des photo-isomérisations secondaires, par une photolyse secondaire, par des décompositions secondaires et par des réactions secondaires des atomes de soufre avec les produits primaires.

Introduction

Systematic studies in the last two decades (1–4) have provided a comprehensive knowledge of the reactions of sulfur atoms with olefins. Both ground ^3P_J and excited $^1D_2$ state atoms react readily with olefins but the type of reaction depends on the spectroscopic state. The reaction with ^3P_J atoms yields the corresponding lowest excited triplet state thiirane as the sole product in a single step, stereospecific cycloaddition followed by collisional deactivation to the ground state. $S(^1D_2)$ atoms, on the other hand, react via simultaneous, competing cycloaddition to give vibrationally excited singlet ground state thiiranes and C—H insertion to yield the corresponding thiols.

Both $S(^3P_J)$ and $S(^1D_2)$ atoms have also been found to react with acetylenes, but the elucidation of the mechanism of these reactions proved to be difficult because of the inherent instability of the primary products (5, 6). These reactions are generally characterized by low product recovery and extensive polymerization. When COS was photolyzed with acetylene, propyne, 2-butyne, or hexafluoro-2-butyne, the products were small amounts of CS_2, benzenes, and thiophenes. The primary sulfur adducts were detected in flash photolysis – kinetic mass spectrometric studies and their mean lifetimes determined to be between 0.1 and 7 seconds. These were postulated to be thiirenes formed in the symmetry allowed addition of $S(^1D_2)$ atoms to the acetylenes. Absolute rate constants and Arrhenius parameters have been determined for the addition of $S(^3P_J)$ atoms to a number of alkynes (7, 8) by flash photolysis with vacuum uv kinetic absorption spectroscopy. The room temperature rate constants are somewhat lower and the activation energies and preexponential factors somewhat higher for the alkynes than those for the corresponding olefins. The variation in activation energies, however, shows the same decreasing trend with increasing alkyl substitution on the acetylenic carbon atoms in accordance with the electrophilic character of the $S(^3P_J)$ atoms.

In our continuing effort aimed at the elucidation of the reactivity of sulfur atoms and at gaining an insight into the chemistry of thiirenes we have carried out further, more comprehensive studies on their reactions with alkynes. The results of these studies are being reported here.

Experimental

The high vacuum apparatus and procedures employed were similar to those described in previous reports from this laboratory (4).

The light source was a Hanovia medium pressure mercury arc equipped with a 6 mm Vycor 7910 filter ($\lambda \geq 240$ nm). Photolyses were carried out in cylindrical quartz cells 10.0 cm long and 5.0 cm in diameter, connected through stainless steel high temperature Hoke valves to a conventional grease-free vacuum system. One of the quartz cells was placed in an aluminum block furnace (2.5 cm thick) equipped with four 500 watt pencil heaters, powered and regulated by

an API 2 Mode proportional electronic controller, for temperature studies. Temperatures, accurate to ±0.5°C, were measured with an iron–constantan thermocouple.

After photolysis, the noncondensable gas, CO, was quantitatively collected and measured in a gas buret with the aid of a Toepler pump. Substrates and products were then separated by trap-to-trap distillations at 1–3 Torr pressure. Product separation was achieved by passing the photolyzed mixture through three traps at −196°C and a solid N_2 (−210°C), then through three traps at −98°C. The product fraction was distilled into an evacuated gas chromatograph sample loop and passed through a 2 mm id × 122 cm glass column containing 60/80 mesh Chromosorb W.A. coated with 10% tricresyl phosphate, and maintained at 23°C. A microthermistor cell fitted with Gow-Mac 13-502 thermistors was employed as a detector and was operated at 30°C with a bridge current of 8.0 mA. Helium was used as the carrier at a flow rate of 25 cm^3/min. Retention times are listed in Tables 3, 4, and 9. Product samples were collected downstream from the detector for identification.

Mass spectra were obtained on an AEI MS 12 instrument with the ion source operating at 70 eV and the ionization chamber kept at about 50°C. The resulting data were interpreted using a computer, Data General Nova 3, employing a DS 50 program.

Ultraviolet spectra were recorded on a Unicam 1800 spectrometer using a 10.0 × 1.6 cm quartz cell equipped with a cold finger.

Infrared spectra of Ar matrix-isolated species were recorded by a Nicolet 7199 FT infrared spectrophotometer at 1 cm^{-1} resolution. The samples were prepared by an Air-Products and Chemicals Inc., Model CS-202 Displex closed-cycle helium refrigeration system coupled to a high vacuum line.

Three nmr spectrometers were used for structural determination: Bruker WP-60, Bruker 200 and 400 MHz instruments, equipped with proton (^1H) or fluorine (^{19}F) probes. Gas samples were condensed into medium walled nmr sample tubes containing degassed, solidified $CDCl_3$ as solvent and as an internal standard. In the case of ^{19}F nmr, trifluoroacetic acid was employed as an external standard. The nmr samples were run either at room temperature (24°C) or −30°C, depending on the stability of the material.

Materials

Carbonyl sulfide (Matheson) was purified as described previously (2). Carbon dioxide (Airco, 99.9%) was used as such. Acetylene (Matheson, 99%) was degassed at −186°C.

3,3,3-Trifluoropropyne (Columbia Organic Chemicals, 99.0%) was distilled repeatedly at −115°C and the purity checked on a 6 ft gc Porapak N column, and by gc–ms.

Perfluoro-2-butyne (Columbia Organic Chemicals, 99.0%) was distilled at −98°C several times. The remaining impurities, as analyzed by gc were less than 0.2%.

Perfluorotetramethylthiophene (PFTMT) was prepared according to Krespan (9) for calibration purposes.

Results

1. *$COS + C_2H_2$*

We have photolyzed 80 Torr COS with 240 Torr C_2H_2 at 160°C, hoping for improved product recovery at higher temperature. Recovery was found to be very low, only about 5%, in the room temperature study. The product yields are given in Table 1. As can be seen, CS_2, benzene, and thiopene are formed in the photolysis with relative yields of 10:3:1. In the room temperature photolysis, the same products were found with relative yields of 4:3:1 at the same $[C_2H_2]/[COS]$ ratio of 3 (5). The product recovery showed a substantial increase at the higher temperature, the combined yield of CS_2 and thiophene being about 86% in terms of sulfur atoms consumed.

In a subsequent experiment, 80 Torr COS and 240 Torr C_2H_2 were photolyzed with 1400 Torr added CO_2 at 144°C. CO_2 deactivates the excited $S(^1D_2)$ atoms to the ground state; this way the yields and distribution of the products in the reaction of the $S(^3P_J)$ atoms with C_2H_2 can be determined. The results are shown in Table 2. The same products, CS_2, benzene, and thiophene are formed with relative yields of 3.5:1.5:1, as in the absence of CO_2 at room temperature. Product yields were low, on the order of 4% in terms of sulfur atoms consumed.

TABLE 1. Product yields from the S + C_2H_2 reaction at 160°C[a]

Product	Yield (μmol)
Carbon disulfide	0.426
Benzene	0.124
Thiophene	0.041

[a]λ > 240 nm; photolysis time = 4.0 min; $P(C_2H_2)$ = 240 Torr; $P(COS)$ = 80 Torr; R^0_{CO} = 0.726 μmol min^{-1}; R_{CO} = 0.465 μmol min^{-1}.

TABLE 2. Product yield from the $S(^3P_J)$ + C_2H_2 reaction at 144°C[a]

Product	Yield (μmol)
Carbon disulfide	0.040
Benzene	0.0182
Thiophene	0.0118

[a]λ > 240 nm; photolysis time = 20.0 min; $P(COS)$ = 40 Torr; $P(C_2H_2)$ = 120 Torr; P_{CO_2} = 1400 Torr; R^0_{CO} = 0.325 μmol min^{-1}; R_{CO} = 0.208 μmol min^{-1}.

2. *COS + 3,3,3-trifluoropropyne*

Photolysis of a mixture of 80 Torr COS and 480 Torr C_3HF_3 at 150°C led to the formation of eight products, the structure, relative yield, and modes of identification of which are presented in Table 3. With the exception of CS_2, none of these compounds have been previously reported in the literature. A short description of the assignment of the structure together with mass and ^{19}F nmr spectra are given in paragraph 9 of this section.

The yields of all the major products were lower at 25°C but their relative distribution was unchanged, indicating that all the observed products are thermally stable.

3. *$COS + C_3HF_3 + C_2H_2$*

The photolysis for 60 min of a mixture of 80 Torr COS, 510 Torr C_3HF_3, and 170 Torr C_2H_2 at 150°C yielded no additional products, but it was observed that the product yields were considerably lower than those obtained in the absence of C_2H_2.

4. *$COS + C_3HF_3$ + perfluoro-2-butyne (PFB-2)*

Eighty Torr COS was photolyzed with a mixture of 300 Torr C_3HF_3 and 300 Torr PFB-2 at 150°C for 60 min. The observed products, together with their relative distribution, are given in Table 4.

One of the major products, compound **9**, is also a novel structure previously unreported in the literature (*vide infra*). The other major product of this sytem is perfluorotetramethylthiophene (PFTMT), **10**. The preparation and spectral and thermal properties of this compound have been described by Krespan (9).

Products **11** and **12** were only formed in trace amounts and hence could not be characterized. The tentative structure given in Table 4 are based partly on their ms and partly on kinetic considerations (*vide infra*).

The yields of products **6** and **8** were very small. The tri-

[a] $\lambda > 240$ nm; photolysis time 60 min; $P(C_3HF_3) = 300$ Torr; $P(C_4F_6) = 300$ Torr; $P(COS) = 80$ Torr.

substituted benzene, **4**, the monosubstituted thiophene, **7**, and the unknown compound, **3**, were demonstrably absent.

5. *COS + PFB-2*

In order to assess the absorption characteristics of the substrate at room temperature, the gas phase uv spectrum of 422 Torr PFB-2 was obtained. Absorption begins at about $\lambda \sim 250$ nm, becoming quite strong below 234 nm. $\epsilon \simeq 5 \times 10^{-6}$ Torr^{-1} cm^{-1} at 240 nm and 1.7×10^{-4} Torr^{-1} cm^{-1} at 228 nm. Gas-chromatographic analysis of a sample of 500 Torr C_4F_6, photolyzed for 60 min, showed no sign of products, as expected, owing to the very small extinction coefficient at the effective photolyzing wave length ($\lambda \geq 240$ nm).

In the photolysis of COS with C_4F_6 under conditions of low conversion the only detectable product, besides CO, is PFTMT. The yields of both products depend on the substrate pressure, as shown in Fig. 1. With increasing C_4F_6 pressure, the PFTMT yield increases; the CO yield decreases, ap-

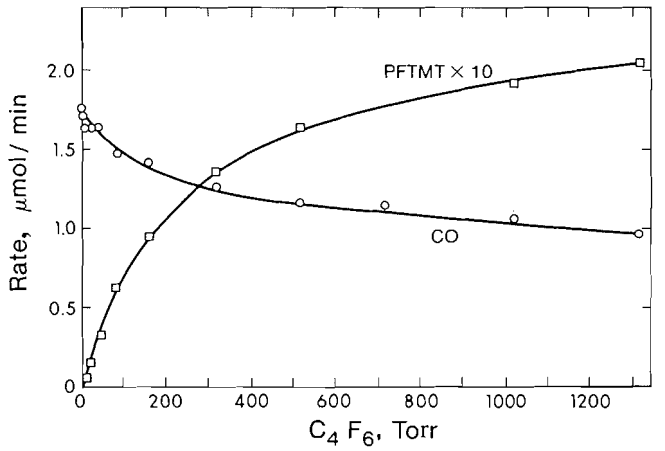

FIG. 1. The effect of PFB-2 pressure on the yields of PFTMT and CO. $P(COS)$ = 300 Torr.

proaching half of its initial value at high pressures.

Increasing the total pressure from 200 to 1200 Torr at a constant $[C_4F_6]/[COS]$ ratio of 1.0 effected a small but definite enhancement in the PFTMT yield.

In order to study the reactions of $S(^3P_J)$ atoms separately, 40 Torr COS and 120 Torr C_4F_6 were photolyzed in the presence of increasing amounts of CO_2 to deactivate the $S(^1D_2)$ atoms. The PFTMT yield gradually decreased with increasing CO_2 concentrations to a limiting value of about 14% of the primary generated sulfur atoms at 1500 Torr CO_2. No new products were detected and further increase of the C_4F_6 content resulted only in a slightly higher PFTMT yield.

Next we have investigated the effect of temperature on the product yields of the photolysis. Blank experiments showed that both PFB-2 and PFTMT are stable at 160°C and, moreover, allowing the photolyzate to remain standing for 3 hours at room temperature, do not affect the product yields.

The variation of product yields with the temperature is shown in Table 5. It is seen that the PFTMT yield increases with increasing temperature and at 160°C reaches 60−100% of the primarily formed sulfur atom. The CO yield from abstraction shows similar increase with the temperature, which is probably due mainly to the increased competition from the reaction of $S(^3P_J)$ with COS at higher temperatures. The results of a temperature study carried out in the presence of a large excess of added CO_2 also gave similar results for $S(^3P_J)$ atoms, as seen from the data in Table 6.

6. *COS + PFB-2 + C_2H_2*

Photolysis of COS with mixtures of PFB-2 and C_2H_2 yielded PFTMT and 2,3-bis(trifluoromethyl)thiophene (b-TFMT) as major products, together with traces of a symmetrical bis(trifluoromethyl)thiophene (2,5 or 3,4) and CS_2. Benzene and thiophene were demonstrably absent.

The effect of C_2H_2 pressure on the PFTMT and b-TFMT yields at two different temperatures, 25 and 132°, are given in Tables 7 and 8, respectively. As is seen, a sharp initial drop is followed by a gradual decrease in the PFTMT yield with an increase of the added C_2H_2; the b-TFMT yield shows a gradual increase in the whole pressure range. Temperature has a significant effect on the yield of both products; at 130°C the yield of PFTMT increased about three-fold and that of b-TFMT over ten-fold compared to the yields at room temperature.

7. *COS + PFB-2 (high conversion experiments)*

The photolysis of a mixture of 280 Torr COS and 480 Torr C_4F_6 for 192 min at 25°C led to the formation of ten products, the elution times and tentative structure assignments of which are listed in Table 9. The spectral and thermal characteristics of the products, together with the pertinent ms and ^{19}F nmr spectra, are given in paragraph 9 of this section.

The products of **15**, **16**, **19**, and **20** were detected only in very small amounts, and because of their thermal and surface instabilities it was not possible to characterize them further.

The dependence of the yields of the major products on exposure time is given in Table 10, and illustrated in Fig. 2. It is seen that the rate of increase of **10** is increasing slightly less than linear with time whereas the yields of **13** and **17** increase dramatically after ca. 10 min exposure time. The yields for **16** and **18** are rather scattered but they indicate a trend towards stationary concentrations. The other products **14**, **15**, **19**, **20**, and **21** were not detected in the first 15 minutes and formed only in traces at 30 minutes photolysis time.

At very long exposure time (192 min) the following general trends were observed.

(a) A near correspondence between the rate of increase of **13** and the rate of decrease of **10**, suggesting that the former arises from photoconversion of the major product PFTMT, **10**.

(b) The yield of **14** increased slightly.

(c) Several large and unresolved peaks appeared at elution times corresponding to those of the trimer **17** and dimer **18**.

(d) The trimers **19**, **20**, and compound **21** were detected.

The effect of exposure time on the yields of products **14**, **15**, **16**, **18**, **19**, and **20**, was found to be small and appeared to indicate that the concentration of these products had reached a photostationary state.

When a mixture of 280 Torr COS and 480 Torr C_4F_6 was photolyzed for 46 min the yield of the trimer, **17**, increased approximately two-fold as compared to that from a mixture of 280 Torr COS and 240 Torr C_4F_6 at 46 min photolysis time. Thus the yield of **17** is not only a function of exposure time but also of the PFB-2 concentration and probably the photostationary state concentration of **16** which may be one of the immediate precursors of **17**. Assuming equal detector responses, the other products, **13**, **16**, and **18** were formed in the ratio 1:1:1.

Photolysis of 80 Torr COS and 240 Torr C_4F_6 for 36 min led to the formation of the compounds **10**, **13**, **16**, **17**, and **18**. Compounds **17** and **18** were formed in a 1:1 ratio but **13** only in small amounts. In order to establish the effect of COS pressure on the product yields, 200 Torr COS was added to this mixture and photolyzed. At 16 minutes photolysis time the yield of the dimer, **16**, doubled but remained unchanged at longer exposure time. Only a small amount of trimer **17** was detected for the 16 minutes photolysis but longer exposure time, 46 min, greatly enhanced its yield (approximately six-fold increase). This confirms the above conclusion that **16** is one of the principal precursors of **17**. The effect of added PFTMT on the product yields has also been studied. Photolysis of a mixture of 280 Torr COS and 480 Torr C_4F_6 with 2.5 Torr added PFTMT led to: (a) a 25-fold increase in the yield of PFTMDT, **13**, a clear indication that this product arises from secondary photolysis of PFTMT; (b) a substantial increase in the yield of compound **14**; (c) a 35−40% decrease in the yield of trimer **17** and a slight decrease in the yield of dimer **18**.

In order to examine the thermal stabilities of the products, 80 Torr COS with 240 Torr C_4F_6 was photolyzed for 30 min at 160°C. Only the yields of products **10** and **13** increased as compared to room temperature experiments.

$(C_4F_6S)_2$) were also detected.

The photolysis of a mixture of 300 Torr C_4F_6 and 3.3 Torr PFTMT for 40 min led to the exclusive formation of **13**. The original concentration of **10** was depleted by half.

9. *Identification of the photolysis products*[1]

Product 1

Product **1** was only obtained in trace amounts, but its ms fragmentation pattern is consistent with the 3,3,3-trifluoromethylthioketene structure. The molecular ion ($M^+ = 126$) signal has a relative intensity of 74.4. The $(M - 32)^+$ signal, of relative intensity 37.2, likely corresponds to the loss of a sulfur atom. The most intense peak $(M - 51)^+$ may be associated with the loss of S and F atoms. This type of fragmentation pattern strongly militates against the $CF_3C{\equiv}C{-}SH$ isomeric structure.

Product 4

The mass spectrum featured the parent ion ($M^+ = 282$) at a relative intensity of 87.6. The ^{19}F nmr spectrum (Appendix I) consists of a single peak at 99.35 ppm, which resolves into a complex quartet under high resolution.

The uv spectrum of **4** consists of an absorption maximum at 201 nm and a less intense one at 272 nm. These features are similar to those of the uv spectrum reported by Barlow *et al.* (10) for hexakis(trifluoromethyl)benzene in n-pentane, which has an absorption maximum at 212 nm.

The proposed structure (Table 3) of **4** is consistent with the above spectral properties; moreover, by analogy with the S + C_3H_6 reaction (5), 1,3,5-tris(trifluoromethyl)benzene was expected to be a product in the S + C_3F_3H system.

[1]The detailed mass spectra are available as supplementary material and may be obtained, at nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

For personal use only.

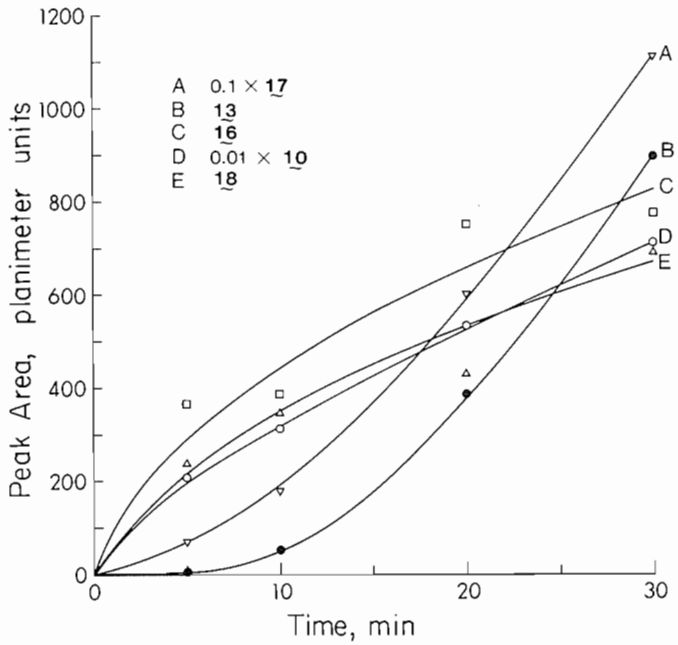

FIG. 2. Exposure time dependence of the product yields in the photolysis of 300 Torr COS and 300 Torr PFB-2. Product **10**: ○; product **13**: ●; product **16**: □; product **17**: ▽; product **18**: △.

Product 5

The mass spectrum yielded the parent ion ($M^+ = 220$) as the most intense peak. The uv spectrum shows one maximum at $\lambda = 226$ nm, suggesting a substituted thiophene. Since the 2,3- and 2,4-isomers can be discounted on the basis of the ^{1}H nmr spectra (Appendix II), this product is therefore either 2,5- or 3,4-bis(trifluoromethyl)thiophene.

Product 6

The mass spectrum features the parent ion ($M^+ = 220$) as the second most intense peak, with relative intensity of 98.0. The uv spectrum of this product features an absorption maximum at $\lambda = 226$ nm. This absorption is common to all CF_3 substituted thiophenes (5, 9) examined to date and may vary by ±2 nm depending on the degree and type of substitution.

The ^{19}F nmr spectrum yields two single peaks of equal intensity at 99.66 and 103.65 ppm.Under high resolution both peaks give rise to complex doublets. 2,3-Bis(trifluoromethyl)-thiophene has been synthesized, and the recorded ^{1}H and ^{19}F nmr spectra (Appendices I and II) and its uv spectrum differ from the ones described above; therefore the only remaining reasonable structure for **6** is 2,4-bis(trifluoromethyl)thiophene.

Product 7

The parent ion ($M^+ = 152$) is the most intense peak in the mass spectrum. In the uv spectrum a strong absorption occurs at $\lambda = 224$ nm and a weak one at $\lambda = 272$ nm, in good agreement with the uv spectrum obtained for 2,3,4-tris(trifluoromethyl)thiophene (*vide infra*). The ^{19}F nmr spectrum of **7** yields a single peak at 100.29 ppm. This chemical shift is consistent with that observed for **6** (99.66 ppm). A careful study of all the available ^{19}F nmr spectra of various CF_3-substituted thiophenes strongly suggests that the high field shifted positions (i.e., 99.66 ppm as compared to 103.65 ppm in **6**) correspond to a CF_3 group adjacent to the sulfur atom. On this basis **7** is tentatively identified as 2-trifluoromethylthiophene.

Product 8

The relative intensity of the parent ion ($M^+ = 282$) is 98.1. The ^{19}F nmr spectrum featured two peaks integrating into 2:1 at 99.81 and 96.06 ppm, respectively, indicating that two equivalent and one nonequivalent CF_3 groups are present in the molecule. High resolution of the first peak at 99.81 ppm led to a very complex pattern but the other one remained a broad single peak.

The uv spectrum features three absorption maxima, a strong one at 203 nm and two weak ones of equal intensity at 263 and 269 nm. The first absorption is in agreement with the value $\lambda_1 = 202.5$ nm reported by Barlow *et al.* (10) for hexakis(trifluoromethyl)dewar benzene. Moreover, exposure time studies have shown that **8** is a photolysis product of **4** and thus the assigned Dewar benzene structure is the most reasonable one.

Product 9

Its mass spectrum yields the parent ion ($M^+ = 288$) as the most intense peak. The uv spectrum features a strong absorption maximum at 226 nm and a weak one at 272 nm, in close resemblance to the uv spectrum of 2-trifluoromethylthiophene. Its ^{19}F nmr spectrum consists of three peaks of equal intensity, indicating that three chemically distinct CF_3 groups are present in the molecule. Under high resolution the peak at 105.02 ppm yields a complex quartet, the peak at 103.26 ppm a quartet, and the third peak at 101.57 ppm also resolves into a set of quartets. On the basis of these spectral data and those of similar systems (5, 9), it is reasonable to assign the 2,3,4-tris(trifluoromethyl)-thiophene structure to **9**.

Product 13: perfluorotetramethylDewar-thiophene (PFTMDT)

The ms gives the parent ion ($M^+ = 356$) as the second most intense peak at 99.0 on the relative scale. The gas phase uv spectrum of PFTMDT features two maxima at 247.5 and 336.5 nm, with corresponding extinction coefficients of 1.3×10^{-2} and 2.7×10^{-3} $Torr^{-1}$ cm^{-1}, respectively. The uv and ms spectra of this compound have been described by Heicklen and co-workers (11) in detail and are identical to those of product **13**.

At room temperature **13** is stable; its conversion to PFTMT at higher temperature was described by Kobayashi *et al.* (12) who found the uncatalyzed reaction to be very slow even at 160°C ($\tau_{1/2} \approx 5$ h in benzene).

Product 14

The structural assignment for this compound was made partly on the basis of kinetic considerations and partly on the basis of its ms and ^{19}F nmr spectra, listed in Appendix I. The ms gives only a low intensity peak (7.5) for the parent ion ($M^+ = 550$). The ^{19}F nmr spectrum consists of four single peaks which integrate in the ratio 2:2:1:1. The high resolution spectrum leaves the low field peak at 109.70 ppm unresolved (integration 2), resolves the second peak at 103.19 into two similar complex structures (integration 2), the third peak at 99.74 ppm leads to a very complex structure (integration 1), and the high field peak at 87.00 ppm is again resolved into a very complex structure. This product appears to be unstable in the gas phase at room temperature, and disappears after several hours without forming any recoverable products.

Product 17

The mass spectrum features only a low intensity signal, 9.3 for the parent ion ($M^+ = 582$). The ^{19}F nmr spectrum consists of six lines of equal intensities at 106.38, 106.04, 101.93, 98.61, 97.88, and 89.21 ppm. The high resolution spectrum is described in Appendix I.

The uv spectrum of **17** shows continuous absorption from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

190 to about 320 nm, with several maxima of comparable intensities at λ = 208, 225, 244, 256, 288 nm.

The FT−ir spectrum was obtained in an argon matrix at 10 K; however, the weak absorptions observed in the region 1600−1650 cm^{-1} could not be clearly assigned to the $\diagdown C{=}C \diagup$ stretching frequency.

On the basis of the molecular weight and the ^{19}F nmr spectrum, which shows the presence of six unequivalent CF_3 groups, the most reasonable structures for this product are **17***a* and **17***b* (Table 9), although a more definitive structural assignment cannot be made.

Gas-chromatographic analysis of a gaseous sample of **17**, stored in a quartz cell for about 16 h at room temperature, showed the presence of PFTMT and traces of undecomposed trimer. No products could be detected after storage in a quartz tube at −196°C for 48 h; however, the original peak size decreased by about 30%.

Product 18: perfluoro 3,4,5,6-tetramethyl 1,2-dithiin

This compound is thermally unstable and sensitive to surfaces. When a gaseous sample of the dimer **18** was stored in a quartz cell at room temperature for about 16 h it decomposed completely. Gas-chromatographic analysis of the decomposition products showed the presence of PFTMT, PFB-2, and a very broad trailing peak having variable elution times (7 to 15 min). Storage at −196°C in a quartz tube for about 14 h effected 50% decomposition. Only very small amounts of PFTMT and PFB-2 were detected, and the broad peak was absent.

The relative intensity of the parent ion (M^+ = 388) is only 39.5. The uv spectrum of **18** is ill defined; the weak absorption range is between ~280 to 190 nm, but features at least one maximum at 250 nm. The ^{19}F nmr spectrum (Appendix I) shows the presence of two equivalent pairs of CF_3 groups at 108.47 and 99.45 ppm. Under high resolution both peaks yield complex spectra. The FT-ir spectrum (in argon matrix at 10 K) features weak absorptions in the region 1600−1650 cm^{-1}, suggesting the presence of double bonds in this molecule.

Only 1,4-dithiins have been reported in the literature but, in their photolysis studies on substituted thiadiazoles, Zeller *et al.* (13) postulated the transient existence of 1,2-dithiins in order to explain the mode of formation of some of the products. The 1,2-dithiin structure for product **18** is consistent with the above spectral data and also with kinetic mechanistic considerations (*vide infra*).

Product 21

The parent ion (M^+ = 420) is a medium intensity signal 37.9 in the mass spectrum of **21**.

The ^{19}F nmr spectrum features two signals of 1:1 integration, hence two sets of equivalent pairs of CF_3 groups are present in the molecule. High resolution yields two sets of very complex spectra at 103.50 and 101.00 ppm, respectively.

Additional support for the structure assigned to **21**, given in Table 9 on the basis of molecular weight and the ^{19}F nmr spectrum, comes from the kinetic mechanistic considerations (*vide infra*).

Storage of product **21** for several days at 25°C in a quartz tube effected no appreciable loss; therefore, it appears to be thermally stable. Its thermal stability at higher temperatures was not investigated.

The remaining products of the high conversion experiments, **15**, **16**, **19**, and **20**, were detected only in very small amounts and because of their thermal and surface instabilities, it was not possible to characterize them further.

Discussion

The primary adducts formed in the reactions of $S(^1D_2)$ and $S(^3P_J)$ atoms with the acetylenes studied to date (5), HC≡CH, $CH_3C{\equiv}CH$, $CH_3C{\equiv}CCH_3$, $CF_3C{\equiv}CH$, and $CF_3C{\equiv}CCF_3$, are all highly reactive and can readily undergo further bimolecular reactions to yield the observed principal end products, dimer, trimer benzene, thiophene, polymeric solid, etc. According to *ab initio* SCF MO CI calculations (14), sulfur atoms may interact with the parent acetylene in the following exothermic, spin and orbital symmetry-allowed, elementary reactions:

[1] $S(^1D_2) + HC{\equiv}CH \rightarrow$ (S_0) $\Delta H \sim -60$ kcal/mol

[2] $S(^1D_2) + HC{\equiv}CH \rightarrow H\dot{C}{=}CH{-}\dot{S}\ (S_1)$ $\Delta H \sim -46$ kcal/mol

[3] $S(^1D_2) + HC{\equiv}CH \rightarrow HC{\equiv}CSH$ $\Delta H \sim -87$ kcal/mol

[4] $S(^3P_J) + HC{\equiv}CH \rightarrow H\dot{C}{=}CH{-}\dot{S}\ (T_0)$ $\Delta H \sim -6$ kcal/mol

The cycloadduct, thiirene, formed in [1] is 27 kcal/mol less stable than the insertion product, ethynylthiol, formed in [3] and about 14 kcal/mol more stable than its ring opened isomer, the S_1 state thioformylmethylene from reaction [2]. The $4n-\pi$ electron antiaromatic character of thiirene is manifested by the low C—S bond energy, 14 kcal/mol (14), as compared to that in the saturated counterpart, thiirane, which has a value of >40 kcal/mol (14−16) and explains the ability of thiirene to undergo a facile ring expansion reaction with acetylene to give thiophene

[5] 
Since the late seventies, thiirene and a series of its derivatives, thioketene and ethynylthiol, have been isolated and identified by ir spectroscopy in low temperature inert matrices from the photolysis of 1,2,3,-thiadiazoles (17−20), where the intervention of thiirene as a novel intermediate had been postulated a decade earlier (3, 5, 6). Recently, the photolysis of trithiocarbonates has been shown to be a superior source of thiirene (19) and the isolation and esr identification of a thioketocarbene, namely, the T_0 state thiobenzoylphenylmethylene, has also been accomplished (21). The T_0 state of the thioketocarbene, formed in [4], is nearly isoenergetic with the S_1 state; both are double open shell species and are better represented by the 1,3-diradical structure as indicated above. The closed shell thioketocarbene $H\ddot{C}{-}C(=S){-}H$ is the S_2 state of the diradical lying 17 kcal/mol above the T_0 ground state. The isomerization of the S_1 state diradical to the thioketene or thiirene features a very small energy barrier and therefore it could not be isolated to date. The stabilization of the T_0 state diradical could not be accomplished to date either, probably because intersystem crossing on account of the small T_0-S_1 energy splitting, ~1 kcal/mol (computed), is quite efficient and isomerization to the thioketene, ethynylthiol, and thiirene on the lowest singlet energy surface cannot be arrested. In the case of thiobenzoylphenylmethylene, the experimental T_0-S_1 energy splitting is about 5 kcal/mol and that is the reason why it could

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

be readily stabilized below ca. 150 K in the solid matrix of its precursor 4,5-diphenyl-1,2,3-thiadiazol polycrystal (21). The near degeneracy of the T_0-S_1 states in HĊ=CH—Ṡ and probably in its mono- and dimethyl derivatives, as well, explains why the electronic state does not have a major impact on the nature of their chemistry, although the distribution of the products from them is somewhat affected. The direct insertion of $S(^1D_2)$ atoms into the C—H bond has been well documented (3) and in the gas phase it is nearly statistical with alkanes. In its reaction with ethylene, $S(^1D_2)$ atom gives vibrationally excited thiirane via cycloaddition and vinylthiol via direct insertion into the C—H bonds in a ratio of 0.9 (4). Since the rate of cycloaddition with $S(^1D_2)$ atoms should be about the same to the triple bond in acetylene as to the double bond in ethylene, but the number of C—H bonds in the former are less and their strength is higher (by 10 kcal/mol), insertion would be expected to be inefficient and negligible. Nonetheless, ethynyl thiol may form in the secondary photolysis of thiirene or the diradical, as in the low temperature matrix photolysis of thiirene and trifluoromethyl thiirene, or via the spontaneous, pressure dependent unimolecular isomerization of the initially hot cycloadducts, as in the gas phase addition of $S(^1D_2)$ atoms to ethylene, propylene, allene, and methylallene. The unimolecular isomerization reactions again would be less important than in the case of hot thiirane because the excess energy available is considerably lower, 60 kcal/mol compared to 87 kcal/mol in the case of thiirane. Therefore we conclude that ethynylthiol plays a minor role, if any, in the gas phase reaction of $S(^1D_2)$ atoms with acetylenes.

The gas phase photolysis of COS at $\lambda = 230-250$ nm yields about 70% $S(^1D_2)$ and 30% $S(^3P_J)$ atoms while, in the presence of >14-fold excess of CO_2, nearly all $S(^1D_2)$ atoms are deactivated to the ^3P_J ground state prior to reaction with the substrate

$$[6a]\quad COS + h\nu \xrightarrow{\lambda > 230\ nm} CO + S(^1D_2) \qquad 70\%$$

$$[6b]\quad \xrightarrow{\lambda > 230\ nm} CO + S(^3P_J) \qquad 30\%$$

$$[7]\quad COS + h\nu \xrightarrow[CO_2]{\lambda > 230\ nm} CO + S(^3P_J) \qquad 100\%$$

followed by

$$[8]\quad COS + S(^1D_2) \rightarrow CO + S_2$$

$$[9]\quad COS + S(^3P_J) \rightarrow CO + S_2$$

The S + C_2H_2 system

The yield of retrievable products, CS_2, benzene, and thiophene, is low at 25°C from both the $S(^1D_2)$ and $S(^3P_J)$ atom reactions. Raising the temperature to 160°C causes a large increase in product yields from 5% to 86% in the $S(^1D_2)$ atom reaction but has no observable effect on the $S(^3P_J)$ atom reactions, Tables 1 and 2.

The products can be rationalized in terms of the reaction sequence [6] or [7], [1], [2], [4], followed by [5], and

$$[10]\quad \dot{S}—CH=\dot{C}H(T_0) + HC\equiv CH \rightarrow \dot{S}(CH)_3\dot{C}H(T_0) \xrightarrow{C_2H_5} \text{(benzene)} + S(^3P_J)$$

$$\dot{S}(CH)_3\dot{C}H(T_0) \xrightarrow{M} \text{(thiophene)}$$

$$[11]\quad \dot{S}(CH)_3\dot{C}H \xrightarrow{nC_2H_2} \text{polymer}$$

$$[12]\quad \text{(thiirene)} + \text{(vinylthiol)} \rightarrow CS_2 + C_3H_4$$

$$[13]\quad H\dot{C}=CH—\dot{S}(S_1) \rightleftarrows H\dot{C}=CH—\dot{S}(T_0)$$

$$[14a]\quad H\dot{C}=CH—\dot{S}(S_1) \rightarrow H_2C=C=S$$

$$[14b]\quad \rightarrow \text{(thiirene)}$$

The low yield of recoverable products from the reactions of $S(^3P_J)$ atoms (~4%) suggests that, as with other free radicals, polymerization of the acetylene is efficient and it is the main sink of sulfur.

The higher yields of CS_2, benzene, and thiophene from the reactions of $S(^1D_2)$ atoms at elevated temperature show that the corresponding steps, [5], [10], and [12] are more efficient here.

The S + $CF_3C\equiv CH$ system

The major products, Table 3, are 2,4-bis(trifluoromethyl)-thiophene, **6**, and 1,3,5-tris(trifluoromethyl)benzene, **4**, in analogy to the reactions of S atoms with $CH_3C\equiv CH$ where trimethylbenzene and dimethylthiophene have been observed as major products (6).

The disubstituted thiophenes are formed in the addition reactions between S and the substrate followed by

$$[15]\quad \text{(CF}_3\text{-substituted thiirene)} + \text{(CF}_3\text{-substituted acetylene)} \rightarrow \text{(thiophene)}$$

The preponderance of **6** over **5** may be explained with the preferential opening of the substituted side of the C—S bond in thiirene, which is a trend opposite to that found before for methylthiirene (22) probably owing to the inverse polarities of the CH_3 and CF_3 groups and with the preferential addition of the substituted acetylenic carbon to the sulfur of the thiirene ring (*vide infra*). The Dewar benzene, **8**, and thiophene, **5**, may then result from the secondary photoisomerization of **4** and **6**, respectively, and **7** from the secondary photolysis of **5** and **6**. Alternatively, **5** may form from reactions of $S(^3P_J)$ atoms. CS_2 and the trifluoromethyl thioketene are formed in trace quantities.

The S + $CF_3C\equiv CH$ + $CF_3C\equiv CCF_3$ system

When sulfur atoms are reacted with an equimolar mixture of the above two substrates, the yields of disubstituted thiophenes and trisubstituted benzenes are drastically suppressed and tri- and tetra-substituted thiophenes become the dominant products, Table 4. A plausible way to rationalize product distribution is to assume that $S(^1D_2)$ atoms react with approximately equal rates with the two substrates,

$$[16]\quad S(^1D_2) + CF_3C\equiv CH \xrightarrow{k_{16}} \text{(thiophene)}$$

$$[17]\quad S(^1D_2) + CF_3C\equiv CCF_3 \xrightarrow{k_{17}} \text{(thiophene)}$$

where $k_{16} \approx k_{17}$, but scavenging of thiirenes occurs preferentially with C_4F_6.

[18]  → **9**

[19]  → **10**

[20] $S + 2CF_3C{\equiv}CH + C_4F_6 \longrightarrow \mathbf{11} + S$

The dimeric product(s) **12***a* and/or **12***b* appears to form from the dimerization of two primary adducts. The quantities of these products were too small for structural identification.

The S + C_4F_6 system

In low conversion experiments the only measurable sulfur product is **10**, PFTMT. The effect of the concentration of C_4F_6 on product yields at 23°C is shown in Fig. 1. As seen, the CO yield drops first more steeply up to ca. 80 Torr C_4F_6, owing to preferential scavenging of $S(^3P_J)$ atoms by C_4F_6 which becomes complete at ca. 80 Torr, and then more gradually on account of the competition between C_4F_6 and COS for $S(^1D_2)$ atoms,

[21] $S(^3P_J) + C_4F_6 \longrightarrow \cdot S{-}C(CF_3){=}\dot{C}{-}CF_3$ (T_0)

and

[22] $S(^1D_2) + C_4F_6 \longrightarrow$

[8] $S(^1D_2) + COS \longrightarrow CO + S_2$

where $k_{22} \approx k_8$. The yield of **10** is 25% in terms of sulfur atoms consumed in the addition reaction at the highest pressure of C_4F_6 employed, 1320 Torr. The rest of the sulfur appears to end up in the solid polymer.

The effect of temperature on the yield of **10** was examined in a series of experiments reported in Table 5. As seen from the data, the yield of **10** increases with rising temperature. Here, the possibility of a minor contribution to the CO yield from the attack on COS of any of the free radicals involved in the reaction

[23] $COS + R^{\cdot} \rightarrow RS^{\cdot} + CO$

cannot be excluded with certainty. Therefore the percentage yields for **10**, listed in Table 5, represent a lower limit if reaction [23] does contribute to CO formation and the correct values if [23] is not operative. At the highest temperature this lies between 60 and 97% theoretical. This temperature effect is due to the scavenging reaction of the thiirene with the acetylene

[19]  → **10**

A similar study on the reactions of $S(^3P_J)$ atoms from the photolysis of 40 Torr COS in the presence of 120 Torr C_4F_6 and 1400 Torr CO_2, which yields over 90% $S(^3P_J)$ atoms, gave entirely analogous results, Table 6. Even though at room temperature the yield of **10** is lower here, 14% versus 25% from $S(^1D_2)$ atoms, at 144°C the yields become identical, 60−100%.

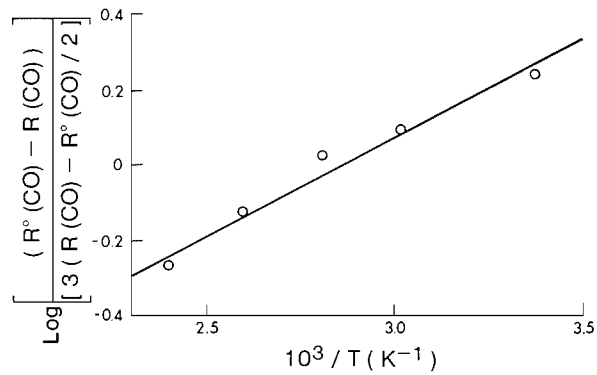

FIG. 3. Arrhenius plot for the $S(^3P_J)$ + PFB-2 system.

In this system it is possible to assess the importance of reaction [23] because the rate constants for the reaction

[9] $COS + S(^3P_J) \rightarrow CO + S_2$

and

[21] $C_4F_6 + S(^3P_J) \rightarrow \cdot S{-}C(CF_3){=}\dot{C}{-}CF_3$ (T_0)

are known. From simple kinetic treatment

$$\frac{R_{21}}{R_9} = \frac{k_{21}[S(^3P_J)]\,[C_4F_6]}{k_9[S(^3P_J)]\,[COS]} = \frac{R^0_{CO} - R_{CO}}{R_{CO} - R^0_{CO}/2}$$

if [23] is inoperative. Values for the expression $\{[R^0_{CO} - R_{CO}] \cdot [COS]\}/\{[R_{CO} - R^0_{CO}/2][C_4F_6]\}$, which is equal to k_{21}/k_9, have been calculated at different temperatures using the data in Table 6 and have been plotted in the Arrhenius form, Fig. 3. The plot gives a good straight line; from the slope, $E_9 - E_{21} = 2.4 \pm 0.2$ and from the intercept, $A_{21}/A_9 = 0.032 \pm 0.005$. Since $k_9 = (9.2 \pm 1.2) \times 10^{11} \exp[-(3630 \pm 120)/RT]$ cm^3 mol^{-1} s^{-1} (23), the Arrhenius parameters for the addition of $S(^3P_J)$ atoms to C_4F_6 would be

$$k_{21} = (2.95 \pm 0.59) \times 10^{10} \exp[-(1240 \pm 200)/RT] \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

At room temperature, $k_{21} = 3.8 \times 10^9$ cm^3 mol^{-1} s^{-1}, a value far too low compared to the value, $k_{21} = 2.1 \times 10^{11}$ cm^3 mol^{-1} s^{-1} obtained from direct flash photolysis/kinetic absorption spectroscopic measurements (8).

Therefore we are forced to conclude that reaction [23] does indeed contribute to the rate of CO formation in the triplet and, by inference, in the singlet system as well, and the true yield of **10** in both systems at 144−160°C may be estimated to be slightly above 60%. The loss is due to polymerization and the ratio of the product-forming steps to the polymer-forming steps can be estimated by

[22] $$\frac{R_{PFTMT}}{R_{(loss)}} = \frac{\%\ \text{PFTMT yield}}{100 - \%\ \text{PFTMT yield}}$$

The RHS of eq. [22] calculated from the data in Tables 5 and 6 when plotted in the Arrhenius form gives a straight line in the region of lower temperatures. The slope of the obtained straight line gives an activation energy of $\Delta E = 4.4$ kcal/mol. It is reasonable to assume that the polymerization reactions feature activation energies which are small but not zero, hence $E_a(\mathbf{10}) > 4.4$ kcal/mol.

Thus, for the overall reaction, the following scheme may be considered:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12

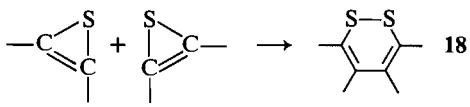
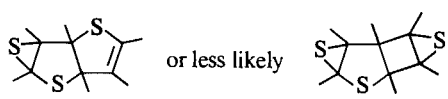
In higher conversion experiments several additional products could be detected in small quantities and in some cases identified. At least three of them appear to be primary products, Table 9 and Fig. 3, and others are clearly secondary products. Thus, compound **18**, identified as the novel perfluoro-3,4,5,6-tetramethyl-1,2-dithiin is a primary product formed in small yields, probably from the symmetrical dimerization of vibrationally relaxed thiirenes along with another isomeric dimer,



15, whose structure could not be established. The stability of **18** is attributable to the strong electron withdrawing effect of the four CF_3 groups. Also, three isomeric trimers **17**, **19**, and **20** were detected, of which the structure of only **17** could be established as



17*a* **17***b*

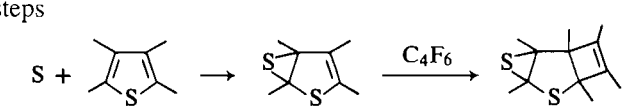
They could be formed either via the addition of S to **16** or via the addition of another thiirene molecule to the dimers

$$(C_4F_6S)_2 + C_4F_6S \rightarrow (C_4F_6S)_3$$

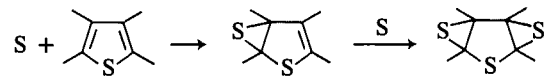
Product **16** is apparently also a primary product and could be formed via the addition of a secondary triplet adduct to a primary adduct

$$\dot{C}=C-C=C-\dot{S} + \dot{C}_4F_6\dot{S} \rightarrow (C_4F_6)_3S_2 \qquad \mathbf{16}$$

The Dewar thiophene **13** is a known photolysis product of the thiophene **10** (11) and, accordingly, its yield rapidly increases with photolysis time at the expense of **10**, Fig. 2. Its formation from **10** was confirmed in separate experiments by photolyzing 280 Torr COS and 480 Torr C_4F_6 with 2.5 Torr added **10** which resulted in a 25-fold increase in the yield of **13**. Since in the above experiment the yield of **14** has also shown a substantial increase, it would appear that it is formed via the steps

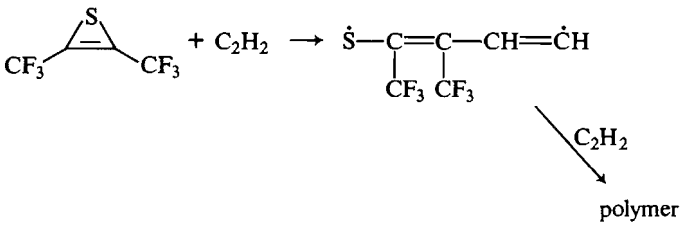


And finally the novel compound, product **21**, forms by the stepwise addition of two sulfur atoms to **10**, as shown by the photolysis of 300 Torr COS in the presence of 3.3 Torr of **10** which resulted in the formation of **21** as the major product.



The superior scavenging ability of the strongly nucleophile C_4F_6 among acetylenes for thiirenes was recognized at the earliest stage in the study of thiirene chemistry (6). In order to get a better insight into these reactions the effect of varying amounts of added C_2H_2 was examined on the photolysis of 80

Torr COS in the presence of 500 Torr C_4F_6, cf. paragraph 6 in Results and Tables 7 and 8. $S(^3P_J)$ atoms have equal rate constants for addition to C_2H_2 and C_4F_6 (k = 2.3 and 2.1 $\times 10^{11}$ cm^3 mol^{-1} s^{-1}) (8) and the rate constants for reaction with the $S(^1D_2)$ atoms should also be nearly equal. Yet, from the data presented in Tables 7 and 8, it is clear that addition of even small quantities of C_2H_2, ~5%, has a much larger suppressing effect on the yield of **10** with the simultaneous appearance of the cross product, bis(2,3-trifluoromethyl)thiophene. This occurs at both temperatures, 25 and 132°C, studied and, while increasing amounts of added C_2H_2 increase the yield of b-TFMT, the sum of PTMT and b-TFMT decreases as the concentration of added C_2H_2 increases. This strongly suggests that C_2H_2 is capable of intercepting bis(trifluoromethyl)thiirene even more efficiently than C_4F_6, but that the adduct is largely a diradical which undergoes polymerization with the excess acetylenes resulting in a decrease of recoverable product yields,



This observation is in line with the results of earlier studies on S + C_2H_2, CH_3—C≡CH, and CH_3—C≡C—CH_3 (5, 6) and also of studies on the photolysis of 1,2,3-thiadiazoles in the presence of acetylenes (22).

Bis(trifluoromethyl)thiirene is probably more stable than any of the other thiirenes discussed in this article and it is possible that, at sufficiently low temperature in the presence of low concentrations of C_4F_6, it would be sufficiently stable to study its spectroscopic properties in the gas phase.

The study of the reaction of sulfur atoms with acetylenes, apart from its inherent interest, has shed new light on the gas phase chemistry of thiirenes and their isomeric thioketocarbenes and resulted in the synthesis of a series of novel and interesting molecules.

Low frequency vibrational spectra of lithium formate monohydrate and its aqueous solutions

A. AGARWAL, D. P. KHANDELWAL, AND H. D. BIST
Department of Physics, Indian Institute of Technology, Kanpur-208016, India

Received February 14, 1983

A. AGARWAL, D. P. KHANDELWAL, and H. D. BIST. Can. J. Chem. **61**, 2282 (1983).

The far infrared and Raman spectra of polycrystalline lithium formate monohydrate and the Rayleigh wing scattering of its aqueous solutions are reported. Three new bands in solid and bands due to librations of $HCOO^-$ and the quasi-tetrahedral structure of water in solutions have been identified.

A. AGARWAL, D. P. KHANDELWAL et H. D. BIST. Can. J. Chem. **61**, 2282 (1983).

On rapporte les spectres dans l'infrarouge lointain et les spectres Raman du monohydrate de formiate de lithium polycristallin et la dispersion de Rayleigh Wing de sa solution aqueuse. On a identifié: trois nouvelles raies dans le solide, les raies dues aux librations du $HCOO^-$ ainsi que la structure quasi-tétraédrique de l'eau dans les solutions.

Introduction

The spectrum of lithium formate monohydrate in the low frequency region, which covers the librations of the non-spherical $HCOO^-$ ion, has been studied by the Raman technique in the solid state (1, 2); however, the corresponding infrared (ir) spectrum has not been reported. The spectra of aqueous solutions have not been examined by either method. In the present work the ir spectrum of a microcrystalline sample in the low frequency region (300−20 cm^{-1}) and the Raman spectra of aqueous solutions of various concentrations in the same region are being presented for the first time, along with a re-examination of the Raman spectrum of the solid. The Raman spectra of the solutions are examined in the $R_2(\nu)$ format (3−5), which is useful for an analysis of the Rayleigh wing scattering. Since the bands of the $HCOO^-$ librations in the aqueous solutions are masked by two characteristic translational bands of water falling in the same region (4−9), we have used the technique of suitable subtractions of the $R_2(\nu)$ contribution due to pure water from those of the solutions so as to get better information about the $HCOO^-$ librations in the solution phase.

Experimental

For Raman spectra the samples were excited with the 514.5 nm line from a Spectra Physics 165 Ar^+ laser, using ~150 mW power at the sample. The spectra were recorded using the Spex 1403 double monochromator with a digital detection and recording system (DPC-2 and Linear chart recorder). The far ir spectrum was recorded in a polystyrene pellet on the Polytex FTIR instrument at the Regional Sophisticated Instruments Centre, IIT, Madras. The accuracy of measurements for the sharper bands is ±1 cm^{-1} and for the broader resolved components from the $R_2'(\nu)$ curves (see below) is about ±4 cm^{-1}.

Results

Figure 1(*a*) shows the Raman spectrum of polycrystalline $HCOOLi.H_2O$ along with the corresponding ir spectrum. Figure 1(*b*), (*c*), and (*d*) show the Raman spectra of 4 *M*, 2 *M*, and 0.5 *M* aqueous solutions, respectively, taken under identical excitation and other conditions. The curves are given in the $R_2'(\nu)$ format (see below) and the contour in each case is resolved into the minimum number of Lorentzian bands warranted by the peaks or humps. These components are shown by dotted curves, and the pertinent data are presented in Table 1.

The $R_2'(\nu)$ format was obtained as follows. The observed $I(\nu)$ versus ν curves were first recast into the $R_2(\nu)$ format (3), showing $\nu^2\bar{I}(\nu)$ versus ν, where $\bar{I}(\nu)$ is the mean of the Stokes and anti-Stokes intensities at ν. The $R_2(\nu)$ format of the curves makes it possible to compare the Raman spectra with the ir spectra, the Rayleigh scattering being appropriately suppressed (3). From this $R_2(\nu)$ curve for the solution a suitable fraction of the $R_2(\nu)$ curve for pure water was subtracted to optimize the information about contributions of the $HCOO^-$ ion in the solution phase. We call this the $R_2'(\nu)$ format of the curve. The fraction, f, of the $R_2(\nu)$ of water to be subtracted was decided as follows. For the solution with the highest concentration the value of f was set so as to keep the lowest $R_2'(\nu) = 0$. The same fraction f was then used to deduce the $R_2'(\nu)$ for the other solutions.

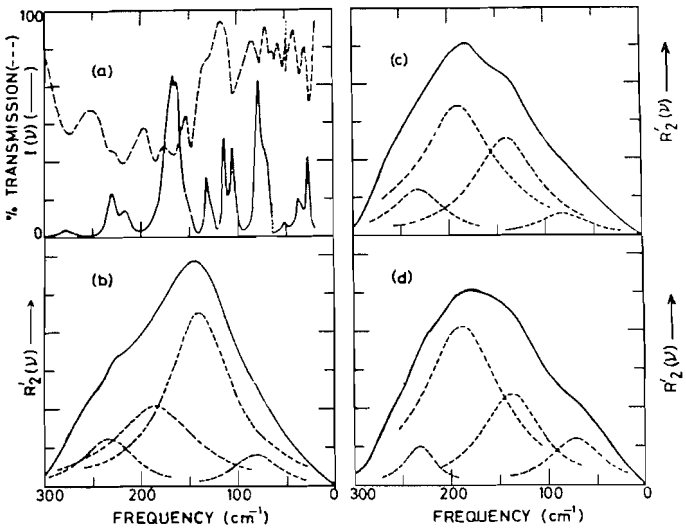

FIG. 1. (*a*) The infrared and Raman spectra of microcrystalline solid lithium formate monohydrate; the broken-line curve is for infrared, and the continuous curve for Raman. (*b*), (*c*), and (*d*) are the Raman $R_2'(\nu)$ spectra respectively of 4 *M*, 2 *M*, and 0.5 *M* solutions of the salt; the dotted curves under each spectrum are the resolved bands with Lorentzian shape.

Discussion

Polycrystalline solid

Our Raman spectrum of the solid sample essentially agrees with that reported by Hase (1), except for the bands at 70, 37, and 27 cm^{-1} which were not reported earlier. The assignments

TABLE 1. Peak positions of the bands for lithium formate monohydrate at 300 K[a]

Solid					Aqueous solutions, Raman $R_2'(\nu)$ format[b]

53	m	51	m	T(F)				
36	m	37	m	105−70				
25	s	27	s	78−51				

[a]The positions are in cm^{-1}. The quantities in parentheses after the band positions are the peak intensities, half widths (cm^{-1}), and relative integrated intensities, respectively. The symbols have the following meanings: (F) = formate; (W) = water; T = translation, τ = twist, ω = wag, ρ = rock; s = strong, m = medium, w = weak, sh = shoulder; T_1, T_2 = hindered translations.

[b]See text.

[c]Overtone of 78 cm^{-1} band.

in column 3 of Table 1 follow Hase, who used isotopic shifts with $^6Li/^7Li$, H/D in the formate group, and H/D in water for the purpose. We have assigned the second rocking mode of formate ion, $\rho(F)$ to the 70 cm^{-1} band, now observed, instead of the 51 cm^{-1} band. This shows the two $\rho(F)$ modes occurring as a close doublet (78 and 70 cm^{-1}), like the two twisting, $\tau(F)$, and the two wagging, $\omega(F)$ modes of formate ion. The 51 cm^{-1} band is now assigned to a translational mode, T(*F*), so that the second set of three T(*F*) modes is now placed at 113, 105, and 51 cm^{-1}, like the first set placed at 277, 230, and 216 cm^{-1}. The information obtained by Hase (1) from the isotopic shift studies is not violated in these changed assignments.

The far ir bands agree with the Raman bands, including those at 70, 37, and 27 cm^{-1}. Three additional bands show up in ir at 183, 148, and 62 cm^{-1}. These are apparently second order bands. The $\omega(F)$ and one T(*F*) (at 113−105 cm^{-1}) doublets in the Raman spectrum are unresolved in the ir spectrum.

Aqueous solutions

(i) The band around 140 cm^{-1}

The band around 140 cm^{-1} is the strongest resolved band in the $R_2'(\nu)$ spectrum for 4 *M* solution (Fig. 1(*b*)). This band exhibits considerable diminution in intensity as the concentration is decreased, suggesting that the band is associated with the $HCOO^-$ group.

From the Raman spectra of microcrystalline (1) and single crystal samples (2), the twisting and wagging modes of the $HCOO^-$ ion in this salt are known to fall around 129−133 cm^{-1} and 164−174 cm^{-1}, respectively. Our ir spectrum (Table 1) of the solid supports these assignments. In the aqueous solutions the environment around the $HCOO^-$ ion will be quite different, since the probability of coordination with Li^+ will be replaced by that with the oxygen of free water with increasing dilution. The wagging and twisting modes of $HCOO^-$ could therefore have frequencies quite different from those in the solid. In any case the corresponding bands would be much broader due to diffusional motion. The 140 cm^{-1} band in aqueous solutions, with its large half-width (~80 cm^{-1}), thus represents the unresolved twisting and wagging motions of the formate ion. That its frequency (140 cm^{-1}) is lower than the weighted mean of the twist and wag frequencies in the solid (~150 cm^{-1}) means the coordination around $HCOO^-$ is weaker in solution than in solid, as is to be expected.

(ii) The band around 188 cm^{-1}

The next prominent band in the $R_2'(\nu)$ curves of aqueous solutions is around 188 cm^{-1}. This band shows continuous decrease in intensity as we go from pure water to the solution having the highest concentration (4 *M*). Therefore, it may pertain to free water in the solutions also. In free water the corresponding band has position 191 cm^{-1} and it is assigned to hindered translation of the centre of mass parallel to the molecular plane (4, 6). With increasing amount of the solute, this band could weaken on two counts. Firstly, increasing fractions of water molecules will go into coordination with the solute, leaving smaller fractions as free water. Secondly, the hydrogen bonding between the free water molecules will also decrease, if the structure around the formate ion does not fit that of free water (4), as in the present case (see section (*iv*)). The effect is not a pH effect because in these solutions the pH changes very marginally with concentration: 7.36 for 0.5 *M* to 7.60 for 4 *M* solution.

(iii) The lowest frequency band

The lowest frequency band in the $R_2'(\nu)$ spectra of the aqueous solutions appears at 82 cm^{-1} for the 4 *M* and 2 *M* solutions (with almost equal intensities) and at 72 cm^{-1} for the 0.5 *M* solution with increased intensity. In the Raman spectrum of the microcrystalline solid the rocking doublet falls at 78 and 70 cm^{-1} (Fig. 1(*a*)). In the single crystal Raman spectra the four components appear in the range 70−80 cm^{-1} for different symmetry species (2). Thus the above-mentioned band in the $R_2'(\nu)$ spectra can be assigned to the rocking mode of $HCOO^-$ ion.

The changes in intensity and peak frequency of the band on reducing the concentration from 2 *M* to 0.5 *M* are not clearly understood. One suggestion could be that it has some contribution from the reported hindered translation perpendicular to the molecular plane (hydrogen bond bending mode) of water at 60 cm^{-1} (5−9). Though Brooker *et al.* (4) raise doubt on the presence of this band, the model calculations for liquid water (6, 7) support the earlier experimental evidence. Its contribution will distinctly increase at low concentration, as is observed.

(iv) The band around 232 cm^{-1}

The fourth band in the $R_2'(\nu)$ spectra of aqueous solutions is around 232 cm^{-1}. The diminution in the integrated intensity of this band with decreasing concentrations of the solute may suggest that this band originates from the free formate ions. However, this view is ruled out because the $R_2'(\nu)$ curve for acetone solution (not shown here) did not give any trace of such a band.

Liquid water has a quasi-tetrahedral structure in which each water molecule is striving to bond itself tetrahedrally to four neighbouring molecules (10, 11). Though the bonds are continuously breaking and reforming, the tetrahedral features may be revealed in Raman scattering which involves short-time interactions (5). Eriksson and Lindgren (12) calculated a vibrational frequency for water in the tetrahedral environment at 239 cm^{-1}. In the lithium solution the Li^+ ions coordinate tetrahedrally with the surrounding water molecules forming a tetrahedral $Li(OH_2)_4^+$ complex (13). As in the tetrahedral complex the lithium atom does not move in a totally symmetric Li—O vibration and only the reduced mass of water enters into the corresponding **G** matrix (13), it is only slightly different from the water vibration considered by Eriksson and Lindgren (12) for pure water in tetrahedral environment. Thus we suggest that the 232 cm^{-1} band is the totally symmetric vibration of the tetrahedrally surrounded water molecules against the central lithium ion. The enhancement in the intensity of this band with increasing solute concentration is accounted for by the fact that the more available the lithium ions in the solution, the more stable the tetrahedral structure of water becomes.

Pentaketide metabolites from *Potebniamyces gallicola* n. sp.

CAMILLE A. BOULET AND GERALD A. POULTON[1]
Department of Chemistry, University of Victoria, Victoria, B.C., Canada, V8W 2Y2

Received March 7, 1983

CAMILLE A. BOULET and GERALD A. POULTON. Can. J. Chem. **61**, 2285 (1983).

The fungus *Potebniamyces gallicola* n. sp. has been isolated from cankered swellings of western hemlock (*Tsuga heterophylla* (Raf.) Sarg.) produced by the dwarf mistletoe (*Arceuthobium tsugense* (Rosendahl) G. N. Jones), and has been implicated in the induction of disease in the infected trees. *P. gallicola* was cultured on malt extract, and four isoprenylated pentaketide metabolites were isolated by extraction; these were identified as the known compounds fuscin **1** and dihydrofuscin **2**, and two related compounds secofuscin **3** and dihydrosecofuscin **4**, not previously reported in nature.

CAMILLE A. BOULET et GERALD A. POULTON. Can. J. Chem. **61**, 2285 (1983).

On a isolé le champignon *Potebniamyces gallicola* n. sp. du gonflement nécrosé de la cigue de l'ouest (*Tsuga hétérophylla* (Raf.) Sarg.) produit par le gui nain (*Arceuthobium tsugense* (Rosendahl) G.N. Jones). Ce champignon est impliqué dans l'induction de la maladie des arbres infestés. On a cultivé le *P. gallicola* dans un extrait de malt et on en a extrait quatre métabolites pentacétides isoprénylés. On a identifié ces derniers comme étant les composés connus: la fuschine **1** et la dihydrofuschine **2** et deux composés apparentés la sécofuschine **3** et la dihydrosécofuschine **4** non encore répertorié dans la nature.

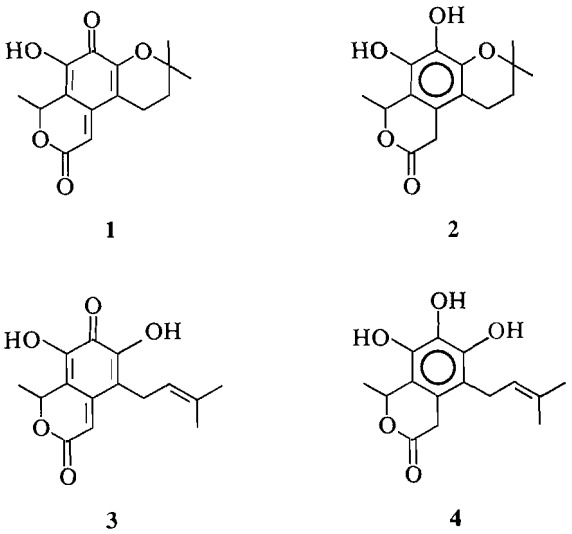
For personal use only.

The fungus *Potebniamyces gallicola* n. sp. has been isolated (1) from cankered swellings of western hemlock (*Tsuga heterophylla* (Raf.) Sarg.) produced by the dwarf mistletoe (*Arceuthobium tsugense* (Rosendahl) G.N. Jones). Slant agar cultures of this fungus showed visible amounts of a metabolite as surface rosettes. Since the metabolite of a related pathogenic fungus, *Potebniamyces balsamicola* Smerlis var. *boycei* Funk, had been shown (2) to possess interesting anti-fungal and anti-bacterial activity, we undertook the isolation and structure elucidation of the metabolites of *P. gallicola*.

P. gallicola was cultured on 3% malt extract, unshaken, at 15°C, and the metabolites were isolated by extraction of the homogenized culture medium. Examination of the crude extract by hplc showed the presence of two pairs of compounds; the main metabolite was isolated by trituration with pentane. Recrystallization from benzene/pentane gave yellow crystals, mp 225–227°C, which were identified as the known compound fuscin **1** (Experimental), and confirmed by comparison with an authentic sample of fuscin obtained from Prof. D. H. R. Barton. Fuscin (9,10-dihydro-5-hydroxy-4,8,8-trimethyl-2*H*,4*H*-benzo[1,2-*b*;4,3-*c*']dipyran-2,6(8*H*)dione) has previously only been isolated from two closely related species of *Oidiodendron* (3–9).

The presence of a second metabolite was obvious from the crude nmr spectrum and hplc of the extract. An interpretation of the spectrum suggested that it was closely related to that of fuscin, and it was assumed that the metabolite could be the known dihydrofuscin **2**; this identity was confirmed by chemical conversion of fuscin into dihydrofuscin, and by co-injection on the hplc.

Extraction of a second culture series containing greater amounts of the second pair of metabolites was carried out in a manner similar to that described above. Trituration of the crude extract with pentane yielded a quantity of the pure third metabolite **3**, mp 159–163°C, which proved to be isomeric with fuscin. The proton nmr of **3** showed two exchangeable protons at δ 6.72, an olefinic proton at δ 6.50, a methyl (δ 1.57) coupled to a methine (δ 5.73), and signals at δ 3.32 (2H doublet), 5.04 (1H triplet), 1.75 and 1.67 (each 3H singlets)



which correspond to an aromatic prenyl side chain (10). This evidence suggested that the quinonoid system is essentially the same as in fuscin with the only major change being that the pyranoid ring has not been formed. The structure of this metabolite was therefore assigned as 5,7-dihydroxy-4-methyl-8-(3'-methyl-2'-butenyl)-4*H*-benzo[*c*]pyran-2(1*H*),6-dione **3** (secofuscin). Support for this tentative identification was forthcoming from the ready cyclization of secofuscin to fuscin by dilute acid.

The hplc evidence suggested that the third and fourth metabolites were also related as an oxidation/reduction pair, and thus the fourth metabolite was assigned the structure **4**, dihydrosecofuscin, in accord with its nmr spectrum.

Secofuscin and dihydrosecofuscin have not been previously reported as natural products, although they have been described as intermediates in the total synthesis of fuscin. It is interesting to speculate that they should also co-occur with fuscin and dihydrofuscin in *Oidiodendron* species, and might have been missed during the extraction due to the work-up which was used. Secofuscin and dihydrosecofuscin complete the isolation, as compounds in nature, of all the intermediates in the biosynthetic scheme leading to fuscin (9, 11). A simple pen-

taketide **5** is cyclized, **6**, and prenylated, **7**, oxygen is introduced to produce dihydrosecofuscin, which is readily converted to fuscin.

Experimental

General

Melting points were determined on a Kofler hot stage and are uncorrected. Proton nmr spectra were determined on a Perkin–Elmer R32 spectrometer at 90 MHz in $CDCl_3$ solution and are with reference to TMS. Infrared spectra were obtained on a Perkin–Elmer 283 spectrometer, and ultraviolet spectra on the Beckman DU-8 spectrophotometer. The hplc analyses were made on a Varian 5000 liquid chromatograph equipped with a Varichrom detector (detection at 254 nm) and a 30 cm MCH-10 reverse phase column (4 mm id, 10 μ particle size) using the binary solvent system water–methanol. Accurate mass measurements were kindly provided by the University of British Columbia mass spectrometry centre using the Kratos MS-50 instrument.

Cultures

P. gallicola (1) was cultured on 200 mL of 3% malt extract (DIFCO) in 500 mL Erlenmeyer flasks. Three culture series of twenty flasks each were started from inocula selected from agar culture plates showing greatest production of crystals.

Extractions

Mycelial mats were removed from the culture medium after 75 days, and the medium macerated in a blender and extracted with benzene (4 × 1000 mL). The crude extract was concentrated, and the product crystallized out by the addition of a small amount of pentane. The crude crystals were dried and recrystallized from benzene–pentane. Culture series B yielded predominantly fuscin **1**, and culture series C yielded predominantly secofuscin **3**. The presence of the dihydro compounds in the extracts and the presence of all four metabolites in the culture series A was established by hplc analysis as indicated above.

Metabolites

Fuscin, **1**, mp 225–227°C (lit. (3) mp 230°C); ν_{max} (KBr disc): 3345 (OH), 1695 (C=C—COOR), 1650, 1620, 1590 (quinone) cm^{-1}; λ_{max} (log ε): 352 nm (4.92); ^{1}Hmr δ: 6.89 (1H, br s, OH), 6.35 (1H, s, H-1), 5.73 (1H, q, J = 6.6 Hz, H-4), 2.61 (2H, dt, J = 6.7, 1.5 Hz, H-10), 1.87 (2H, t, J = 6.6 Hz, H-9), 1.60 (3H, d, J = 6.6 Hz, 4-Me), 1.42, 1.39 (3H, s, 8-Me's). *Exact Mass* calcd. for $C_{15}H_{16}O_5$: 276.09978; found: 276.1000.

Dihydrofuscin, **2**, ^{1}Hmr δ: 5.84 (1H, q, J = 7.0 Hz, H-4), 3.68 and 3.38 (each 1H, d, J = 20 Hz, H-1), 2.55 and 1.83 (each 2H, t, J = 6.0 Hz, H-9 and H-10), 1.57 (3H, d, J = 7.0 Hz, 4-Me), and 1.31, 1.35 (each 3H, s, 8-Me's).

Application en série benzofurannique d'un nouveau procédé de nitration par l'acide nitrique en présence de chlorure stannique[1]

JACQUES EINHORN, PIERRE DEMERSEMAN ET RENÉ ROYER[2]

Service de Chimie de l'Institut Curie, E.R. no. 213 du CNRS 26 rue d'Ulm, 75231 Paris Cédex 05, France

Reçu le 18 janvier 1983

JACQUES EINHORN, PIERRE DEMERSEMAN et RENÉ ROYER. Can. J. Chem. **61**, 2287 (1983).

On détermine la possibilité d'étendre en série benzofurannique une nouvelle technique de nitration par l'acide nitrique, en présence de chlorure stannique, dans le chlorure de méthylène. Cette technique mérite d'être retenue pour la commodité de sa mise en oeuvre et la diversité des produits qu'elle est susceptible de fournir, selon les conditions expérimentales.

JACQUES EINHORN, PIERRE DEMERSEMAN, and RENÉ ROYER. Can. J. Chem. **61**, 2287 (1983).

A new nitration technique, using nitric acid in the presence of stannic chloride in dichloromethane, has been extended to a series of benzofurans. The ease of performing the reaction as well as the diversity of products that can be obtained under various experimental conditions make it a worthwhile technique.

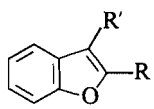
Le benzofuranne et la plupart de ses dérivés dont l'hétérocycle n'est pas substitué sont trop fragiles pour que leur nitration puisse être effectuée avec des rendements satisfaisants dans les conditions usuelles, au moyen, par exemple, d'acide nitrique dans l'acide ou l'anhydride acétique (1–16). Or, nous avons récemment montré que la nitration des composés aromatiques peut être assurée de façon commode et rentable au moyen d'un complexe – $Cl_4Sn(NO_2)_2$ – que forment l'acide nitrique et le chlorure stannique dans le chlorure de méthylène (17). Il nous a semblé intéressant de préciser dans quelle mesure cette méthode pouvait être étendue en série benzofurannique, étant donné notamment la diversité et l'importance des propriétés biologiques des nitro-2 benzofurannes (10, 13, 18–24).

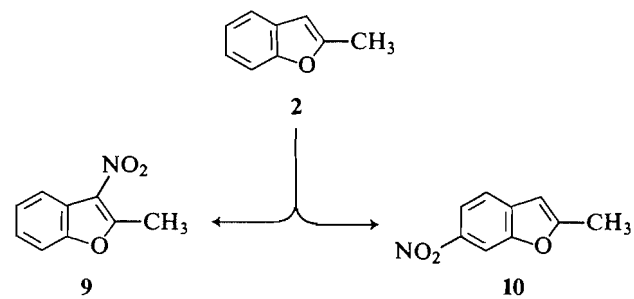
Nous l'avons donc appliquée au benzofuranne **1** lui-même, ainsi qu'au méthyl-2 benzofuranne **2** et, pour comparaison, au méthyl-3 benzofuranne **3**.



1 R = R′ = H
3 R = H; R′ = CH_3

Des résultats exposés sur le tableau ci-joint, il ressort que la méthode en question présente les mêmes avantages en série benzofurannique qu'en série benzénique. Bien qu'elle ne convienne pas mieux que d'autres pour assurer la nitration des benzofurannes **1** et **3** non substitués en position 2, elle est parfaitement utilisable dans le cas du méthyl-2 benzofuranne **2**. Si, en effet, le benzofuranne **1** ne donne ainsi que des traces de nitro-2 benzofuranne **4** (2), tandis que le méthyl-3 benzofuranne **3** est complètement décomposé, le méthyl-2 benzofuranne **2** fournit une petite quantité du dérivé nitré en 3 **9** qui avait déjà été décrit (25), à côté d'une majorité de son isomère **10** inconnu jusqu'à présent.

Par ailleurs, comme un bon nombre de nitro-2 benzofurannes ont été obtenus jusqu'ici par déplacement "ipso" d'un groupement acétyle plutôt que par substitution directe en position 2, nous avons utilisé la même méthode pour traiter l'acétyl-2 benzofuranne **5** et l'acétyl-2 triméthyl-3,5,6 benzofuranne **6**



2

9 **10**

(12). Nous y avons enfin soumis, à titre complémentaire, l'acide coumarilique **7** et l'acide méthyl-3 coumarilique **8**, afin de préciser dans quelle mesure des dérivés fonctionnels relativement labiles du benzofuranne étaient susceptibles de supporter cette sorte de nitration.

La nature et le rendement des divers produits obtenus à partir de ces benzofurannes substitués en 2 par un groupement électro-attractif dépendent plus ou moins, selon les cas, de la proportion des réactifs.

C'est ainsi que l'acétyl-2 benzofuranne **5** donne pratiquement les mêmes quantités des mêmes produits **11** (14), **12** (14) et **13** (14), aussi bien avec un qu'avec cinq équivalents d'agent nitrant. Il fournit en outre, dans le premier cas, un peu de nitro-2 benzofuranne **4**.

14 **15**

16

Dans les mêmes conditions, l'acétyl-2 triméthyl-3,5-6 benzofuranne **6** conduit respectivement aux deux dérivés mononitrés **14** et **15** (8) ou au seul dérivé dinitré **16**, dont les structures sont déduites, sans ambiguité, de leurs spectres de rmn ^1H.

L'acide coumarilique **7** quant à lui, peut donner exclusivement des dérivés mononitrés sur l'hétérocycle **4** ou sur l'homocycle **17** (26) et **18** (27) mais aussi des quantités non négligeables des dérivés dinitrés **19** (14) et **20** (13), dont la formation implique l'élimination préalable du carboxyle en 2. Il en est de même de l'acide méthyl-3 coumarilique **8** à partir duquel on peut obtenir soit des dérivés mononitrés sur l'hétérocycle **21** ou sur l'homocycle **22** et **23**, soit des dérivés dinitrés tout à la fois sur l'homocycle et sur l'hétérocycle **24** et **25**.

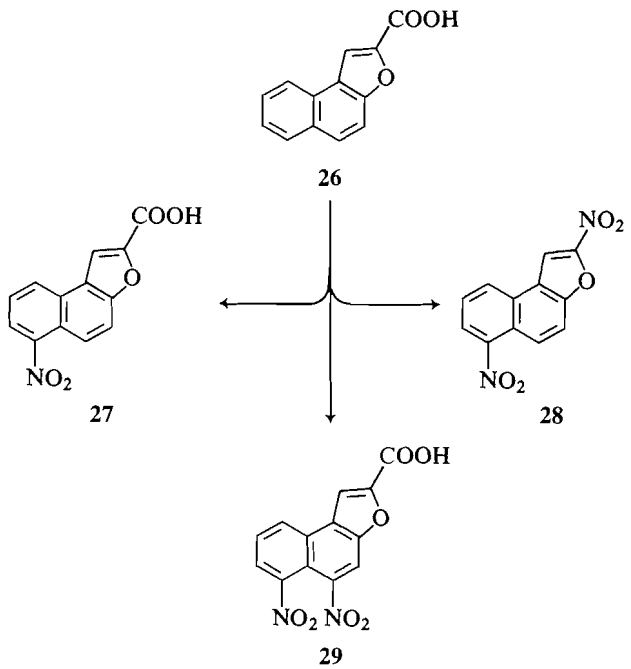
C'est dans le souci pratique d'ouvrir une nouvelle voie d'accès aux nitro-2 naphtofurannes qui se singularisent en particulier par leurs exceptionnelles propriétés mutagènes (28–31), que nous avons appliqué la même méthode de nitration à l'acide naphto[2,1-*b*]furanne carboxylique-2 **26** (32). En fait, celui-ci donne principalement (64%) de l'acide nitro-6 naphto-[2,1-*b*]furanne carboxylique-2 **27**, à côté d'une petite quantité (8%) de dinitro-2,6 naphto[2,1-*b*]furanne **28** lorsqu'on le traite pendant 2 h avec une quantité équimoléculaire de mélange nitrant. Lorsqu'on emploie un excès de ce dernier, il y a résinification importante et on obtient seulement 30% environ d'acide dinitro-5,6 naphto[2,1-*b*]furanne carboxylique-2 **29**, au bout du même temps de réaction.



En conclusion, la méthode de nitration développée ici mérite d'être retenue tout autant pour la commodité de sa mise en oeuvre que pour la diversité des produits qu'elle est susceptible de fournir, selon les conditions expérimentales. C'est ainsi qu'elle est beaucoup moins susceptible que d'autres méthodes de nitration de provoquer l'élimination des groupements électroattractifs situés en 2 sur le benzofuranne. Elle permet ainsi de préparer avec des rendements satisfaisants des benzofurannes nitrés peu accessibles ou inaccessibles d'autre manière. C'est le cas notamment des dérivés nitrés sur l'homocycle de l'acide méthyl-3 coumarilique **22** et **23** et de l'acide nitro-6 naphto[2,1-*b*]furanne carboxylique **27**.

Partie expérimentale

Les structures des composés originaux décrits ici ont été confirmées par rmn, la position en 5 ou en 6 d'un groupe nitro sur l'homocycle benzofurannique pouvant être facilement déduite grâce aux profils particuliers des signaux présentés par l'une ou l'autre des deux substitutions (14). Les spectres rmn ^{1}H ont été enregistrés à 60 MHz ou à 90 MHz (cas des composés **26** à **29**), en utilisant le TMS comme référence interne.

Procédé général de nitration

A une solution refroidie à 0°C (ou à −50°C dans le cas des benzofurannes **1**, **2** et **3**) du composé à nitrer (0,012 mol) dans 10 mL de dichlorométhane anhydre, on ajoute en cinq minutes, sous agitation, une solution fraîchement préparée du mélange nitrant constitué avec des quantités équimolaires de chlorure stannique puis d'acide nitrique d = 1,52 dans le dichlorométhane (20 mL par gramme de NO_3H). Si la solution de mélange nitrant est conservée trop longtemps avant l'utilisation, un fin précipité incolore peut apparaître, qui ne gêne en rien la réaction. Après abandon sous agitation pendant le temps et à la température indiqués sur le tableau, on verse sur 250 mL d'eau glacée, sépare la phase organique, extrait la phase aqueuse deux fois avec du chloroforme, réunit les extraits organiques et les lave jusqu'à neutralité. Après élimination des solvants sous pression réduite à 30°C, le produit brut de la réaction est traité selon les cas, de différentes façons qui sont indiquées ci-après.

Nitration du benzofuranne 1

La chromatographie sur colonne de silice avec élution au toluène permet d'isoler de très petites quantités de nitro-2 benzofuranne **4** (2).

Nitration du méthyl-2 benzofuranne 2

Le produit brut de la réaction est d'abord débarrassé de ses résines par filtration de sa solution chloroformique sur une très courte colonne de silice. Après élimination du solvant, une chromatographie sur silice avec élution au toluène fournit d'abord le méthyl-2 nitro-3 benzofuranne **9** (25) puis le méthyl-2 nitro-6 benzofuranne **10** sous forme de microcristaux beiges, F = 99°C (de l'éthanol); rmn ^{1}H (DMSO): 2,55 (sl, 3H, CH_3), 6,85 (sl, 1H, H_3), 7,75 (d, 1H, H_4, J_{4-5} = 9 Hz), 8,10 (d de d, 1H, H_5, J_{5-4} = 9 Hz, J_{5-7} = 2,5 Hz), 8,35 (m, 1H, H_7, le profil multiplet est dû aux couplages 7–5 et 7–3). *Anal.* calc. pour $C_9H_7NO_3$: C 61,02, H 3,98, N 7,90; trouvé: C 61,12, H 3,95, N 8,01.

Nitration de l'acétyl-2 benzofuranne 5

L'identification et le dosage des composés formés sont effectués par cpv suivant les conditions que nous avons déjà décrites (14) en utilisant les composés originaux comme témoins. Chacun des benzofurannes nitrés **4**, **11**, **12** et **13** est séparé par cristallisation comme nous l'avions déjà décrit (14).

Nitration de l'acétyl-2 triméthyl-3,5,6 benzofuranne 6

Après élimination des résines par filtration sur très courte colonne de silice d'une solution chloroformique du produit brut de la réaction, on procède à une chromatographie sur soixante fois son poids de silice, avec élution par le chloroforme. On isole ainsi successivement:

(*i*) le triméthyl-3,5,6 nitro-2 benzofuranne **15**, microcristaux beiges, F = 168°C (du toluène); rmn ^{1}H ($CDCl_3$): 2,40 (sl, 6H, CH_{3_5} et CH_{3_6}), 2,60 (s, 3H, CH_{3_3}), 7,30 et 7,40 (2 × s, 2H, H_4 et H_7);

(*ii*) le triméthyl-3,5,6 dinitro-2,7 benzofuranne **16**, microcristaux paille, F = 124°C (de l'éthanol); rmn ^{1}H ($CDCl_3$): 2,30 (s, 3H, CH_{3_5}), 2,55 (s, 6H, CH_{3_3} et CH_{3_6}), 7,55 (s, 1H, H_4). L'attribution de la structure est déduite de la résonance à 2,60 ppm du méthyle le plus déblindé. Comme le méthyle en 3 du triméthyl-3,5,6 nitro-2 benzofuranne (**15**) présente également sa résonance à 2,60 ppm, il est exclu que le deuxième nitro du dérivé dinitré **16** soit en 4, c'est à dire en *péri* par rapport au méthyle en 3, ce qui entraînerait alors une résonance de ce dernier à un champ différent, nettement plus faible (33). *Anal.* calc. pour $C_{11}H_{10}N_2O_5$: C 52,85, H 4,03, N 11,21; trouvé: C 52,98, H 3,91, N 11,12.

(*iii*) L'acétyl-2 triméthyl-3,5,6 nitro-7 benzofuranne **14**, souillé du dérivé dinitré **16**, que l'on purifie par une nouvelle chromatographie sur silice ($CHCl_3$), ce qui fournit des microcristaux jaune, F = 135°C (du méthanol); rmn ^{1}H ($CDCl_3$): 2,30 (s, 3H, CH_{3_5}), 2,45 (sl, 6H, CH_{3_3} et $COCH_3$), 2,60 (s, 3H, CH_{3_6}), 7,50 (s, 1H, H_4). La situation en 7 du groupe nitro est déduite de façon analogue à celle utilisée dans le cas précédent pour le composé **16**. En effet, le méthyle le plus déblindé présente un signal à 2,60 ppm, incompatible avec une éventuelle situation du groupe nitro en *péri* du méthyle en 3. *Anal.* calc. pour $C_{13}H_{13}NO_4$: C 63,15, H 5,30, N 5,66; trouvé: C 63,00, H 5,41, N 5,70.

Nitration de l'acide coumarilique 7

(a) *Avec 1,1 mol d'agent nitrant*

La solution chloroformique du produit brut de réaction est extraite avec une solution aqueuse de CO_3Na_2 1 *N*. L'évaporation de la solution organique fournit le nitro-2 benzofuranne **4** (2) et la précipitation par l'acide chlorhydrique de la phase aqueuse basique libère un mélange en parties égales des acides **17** (26) et **18** (27) que l'on dose par rmn ^{1}H et sépare par recristallisations fractionnées de l'éthanol.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

(b) *Avec 5 mol d'agent nitrant*

On procède comme ci-dessus, mais il est nécessaire de chromatographier sur silice (avec élution au toluène) le résidu obtenu par évaporation de la phase organique, pour séparer les dinitrobenzofuranes **19** (14) et **20** (13). La précipitation acide de la phase organique fournit directement l'acide **17** (26) à l'état pur.

Nitration de l'acide méthyl-3 coumarilique 8

(a) *Avec 1,1 mol d'agent nitrant*

Par extraction de la solution chloroformique du produit brut de réaction à l'aide d'une solution 1 *N* de CO_3Na_2 suivie de précipitation acide, on obtient le mélange des deux acides nitrés **22** et **23** que l'on sépare par recristallisation fractionnée de l'éthanol (35 mL par gramme de mélange). On obtient ainsi l'acide méthyl-3 nitro-5 coumarilique **22** sous forme de microcristaux jaune pâle, F = 295°C, après une nouvelle cristallisation de l'acide acétique; rmn ^{1}H (DMSO): 2,75 (s, 3H, CH_3), 8,05 (d, 1H, H_7, J_{7-6} = 9 Hz), 8,50 (d de d, 1H, H_6, J_{6-7} = 9 Hz, J_{6-4} = 2,5 Hz), 8,95 (d, 1H, H_4, J_{4-6} = 2,5 Hz), OH indiscernable. La structure de dérivé nitré en 5 est déduite de la résonance à champ faible (8,95 ppm) du proton couplé en *méta*, par rapport à celle (8,55 ppm) que l'on observe pour le proton analogue du dérivé nitré en 6, conformes à ce que l'on observe chez les acides nitro-5 coumarilique (δ = 8,90 ppm) et nitro-6 coumarilique (δ = 8,60 ppm) dont les structures étaient précédemment établies (26 et 27). *Anal.* calc. pour $C_{10}H_7NO_5$: C 54,35, H 3,19, N 6,34; trouvé: C 54,42, H 3,05, N 6,28.

La concentration de moitié des eaux-mères de recristallisation fournit l'acide méthyl-3 nitro-6 coumarilique **23** qui est purifié par une nouvelle recristallisation du toluène: microcristaux jaune pâle, F = 215°C; rmn ^{1}H (DMSO): 2,60 (s, 3H, CH_3), 7,95 (d, 1H, H_4, J_{4-5} = 9 Hz), 8,20 (d de d, 1H, H_5, J_{5-4} = 9 Hz, J_{5-7} = 2,5 Hz), 8,55 (d, 1H, H_7, J_{7-5} = 2,5 Hz), OH indiscernable. *Anal.* calc. pour $C_{10}H_7NO_5$: C 54,35, H 3,19, N 6,34; trouvé: C 54,33, H 3,25, N 6,18.

L'évaporation sous pression réduite de la phase organique fournit le méthyl-3 nitro-2 benzofuranne **21**: microcristaux beige, F = 98°C (de l'éthanol); rmn ^{1}H ($CDCl_3$): 2,40 (s, 3H, CH_3), 7,40 à 7,80 (m, 4H arom.). *Anal.* calc. pour $C_9H_7NO_3$: C 61,02, H 3,98, N 7,90; trouvé: C 59,85, H 4,00, N 7,99.

(b) *avec 5 mol d'agent nitrant*

Le produit brut de réaction est recristallisé dans un mélange toluène–cyclohexane (8:2), ce qui fournit le méthyl-3 dinitro-2,5 benzofuranne **24** sous forme de microcristaux jaune, F = 192°C; rmn ^{1}H (DMSO): 2,75 (s, 3H, CH_3), 8,05 (d, 1H, H_7, J_{7-6} = 9 Hz), 8,50 (d de d, 1H, H_6, J_{6-7} = 9 Hz, J_{6-4} = 2,5 Hz), 8,95 (d, 1H, H_4, J_{4-6} = 2,5 Hz). La structure de dérivé nitré en 5 est déduite comme ci-avant pour le cas de l'acide **22**. *Anal.* calc. pour $C_9H_6N_2O_5$: C 48,69, H 2,75, N 12,62; trouvé: C 48,75, H 2,70, N 12,57.

Les eaux-mères de cristallisation sont évaporées sous pression réduite et le résidu obtenu, recristallisé deux fois de l'éthanol, conduit au méthyl-3 dinitro-2,6 benzofuranne **25**, microcristaux jaune, F = 140°C; rmn ^{1}H (DMSO): 2,70 (s, 3H, CH_3), 8,25 (sl, 2H, H_4 et H_5), 8,70 (d, H_7, J_{7-6} = 2,5 Hz). *Anal.* calc. pour $C_9H_6N_2O_5$: C 48,69, H 2,75, N 12,62; trouvé: C 48,81, H 2,72, N 12,50.

Nitration de l'acide naphto[2,1-b]furanne carboxylique-2 26

(a) *Avec 1,1 mol d'agent nitrant*

Le produit brut de réaction est mis en solution dans le chloroforme. L'épuisement par une solution 1 *N* de CO_3Na_2 permet de libérer, par acidification, l'acide nitro-6 naphto[2,1-*b*]furanne carboxylique-2 **27**, microcristaux beige, F = 190°C (de l'acide acétique dilué); rmn ^{1}H(DMSO): 7,50 à 7,75 (m, 2H, H_8 et H_9), 7,80 (d de d, 1H, H_4, J_{4-5} = 9 Hz, J_{4-1} = 0,8 Hz), 8,05 (d, 1H, H_5, J_{5-4} = 9 Hz), 8,35 (d, 1H, H_1, J_{1-4} = 0,8 Hz), 8,55 (d de d, 1H, H_7, J_{7-8} = 9 Hz, J_{7-9} = 2,5 Hz), OH indiscernable. *Anal.* calc. pour $C_{13}H_7NO5$: C 60,76, H 2,75, N 5,45; trouvé: C 60,70, H 2,80, N 5,42.

Par évaporation de la solution chloroformique et recristallisation du résidu obtenu dans le toluène, on obtient le dinitro-2,6 naphto[2,1-*b*]-furanne **28**, microcristaux jaune, F = 170°C; rmn ^{1}H (DMSO): 7,75 (d de d, 1H, H_4, J_{4-5} = 9 Hz, J_{4-1} = 0,8 Hz), 7,95 (d, 1H, H_5, J_{5-4} = 9 Hz), 8,00 à 8,50 (m, 3H arom.), 8,60 (d, 1H, H_1, J_{1-4} = 0,8 Hz). *Anal.* calc. pour $C_{12}H_6N_2O_5$: C 55,87, H 2,34, N 10,86; trouvé: C 55,76, H 2,10, N 10,81.

(b) *Avec 5 mol d'agent nitrant*

En procédant comme ci-dessus, la solution organique ne contient que des produits résineux. La précipitation acide de la solution aqueuse fournit l'acide dinitro-5,6 naphto[2,1-*b*]furanne carboxylique-2 **29**, F > 290°C (microcristaux jaune de l'éthanol); rmn ^{1}H (DMSO): 8,00 (t, 1H, H_8, J = 9 Hz), 8,45 (d de d, 1H, H_7, J_{7-8} = 9 Hz, J_{7-9} = 2,25 Hz), 8,60 (d, 1H, H_1, J_{1-4} = 0,8 Hz), 8,90 (d de d, 1H, H_9, J_{9-8} = 9 Hz, J_{9-7} = 2,25 Hz), 8,95 (d, 1H, H_4, J_{4-1} = 0,8 Hz), OH indiscernable. *Anal.* calc. pour $C_{13}H_6N_2O_7$: C 51,70, H 2,00, N 9,28; trouvé: C 51,67, H 2,10, N 9,18.

Received April 21, 1983

GEORGE R. PETTIT, KENNETH D. PAULL, CHERRY L. HERALD, DELBERT L. HERALD, and JOSEPH R. RIDEN. Can. J. Chem. **61**, 2291 (1983).

The photochemical reaction between benzene and maleic anhydride or benzene and maleimide affords respectively anhydride **6***a* and imide **6***b*. Unequivocal structures **6***a* and **6***b* were assigned on the basis of an X-ray crystal structure determination of amide **5** derived from imide **6***b*. Because of pronounced activity (e.g., PS T/C 206 at 50 mg/kg) against several of the U.S. National Cancer Institute's key experimental tumor systems, imide **6***b* has been designated mitindomide and is being prepared for eventual clinical trial.

GEORGE R. PETTIT, KENNETH D. PAULL, CHERRY L. HERALD, DELBERT L. HERALD et JOSEPH R. RIDEN. Can. J. Chem. **61**, 2291 (1983).

La réaction photochimique entre le benzène et l'anhydride maléïque ou entre le benzène et le maléimide donne respectivement l'anhydride **6***a* et l'imide **6***b*. On a établi sans équivoque les structures des composés **6***a* et **6***b* en se basant sur l'amide **5**, provenant de l'imide **6***b*, dont on a déterminé la structure par diffraction de rayons-X. La grande activité (par exemple PS T/C 206 à 50 mg/kg) de l'imide **6***b* vis à vis de plusieurs tumeurs de type expérimental de l'Institut national du cancer des Etats-Unis porte à le désigner sous le nom de mitindomide et on le prépare en vue d'un éventuel essai clinique.
[Traduit par le journal]

The photochemical addition of maleic anhydride to benzene was first recorded in 1959 (1). Shortly thereafter, the same high-melting (dec. 350°C) photoadduct was reported by other groups (2) and the mechanism was studied in detail (3). The unsensitized singlet reaction (irradiation at 50°C for 8 h) (3*d*) is believed to proceed from maleic anhydride (**1***a*) via ionic intermediate **2***a* to diene **3***a* and thence to the product formulated as anhydride **4***a* (3*a*). The sensitized addition employing benzophenone under the same conditions affords more than double the yield of anhydride **4***a* and appears to involve a triplet state where intermediate **2***a* may not be implicated (3*a*). In the latter experiments dibromomethane (as solvent) was found to promote the triplet process.

In studies of the parallel reaction involving addition of maleimide (**1***b*) to benzene, an analogous high melting (mp 345–352°C (4*a*) or dec. near 400°C (4*b*)) photoadduct was isolated (4). Irradiation at 25°C over 20 h with an acetophenone concentration of 0.16 mol per liter was found by Arkhipova *et al.* (4*b*) to give the best yield (65%) of diimide (**4***b*). Reaction of anhydride **4***a* with ammonium hydroxide or urea (at 140°C), followed by a thermally induced intramolecular cyclization, was found to yield imide **4***b* and provided evidence for the overall structure (**4***b*; ref. 4*b*). Although the structures of these classic benzene photoproducts have been deduced by chemical means (4*a*, *b*, *e*) none of them or their related derivatives (4*a*, *b*) has ever been rigorously established by X-ray crystallographic methods. We are now pleased to report (*i*) that the

photoaddition product **4***b*, which for the sake of simplicity[5] will be designated mitindomide (NSC 284356), strongly inhibits growth of the National Cancer Institute's 3 CD breast (T/C ~ 0, at 125 mg/kg, implanted $CD8F_1$, mammary), LE (T/C 188 at 100 mg/kg, implanted L1210 lymphocytic leukemia), and PS (T/C 206 at 50 mg/kg, implanted P388 lymphocytic leukemia) murine tumor systems, and (*ii*) the unequivocal assignment of structure **6***b* to this potentially important substance. Interpretation of the spectral data, particularly the ^{13}C nmr spectra of imide **4***b*, gave results consistent with structure **4**. But unequivocal assignment of the stereochemistry required an X-ray crystal structure determination.

A number of attempts to obtain mitindomide (**4***b*) in a crystalline form (e.g., microcrystals from DMF–water) suitable for X-ray crystallographic analysis were unsuccessful. A variety of simple derivatives such as sodium and potassium salts also proved unsatisfactory. However, when mitindomide was dissolved (over 15 min) in water using ammonium hydroxide and the solution allowed to remain at room temperature for 14 days, amide **5** crystallized as needles melting above 340°C. Recrystallization of amide **5** from ammonium hydroxide solution provided rod-like crystals. A suitable specimen (0.075 × 0.07 × 0.37 mm) was selected for diffraction studies and found to correspond with:

$C_{14}H_{15}N_3O_4$ fw 289.3

Monoclinic, a = 6.309(3), b = 9.971(3), c = 20.096(2) Å, β = 96.91°; V = 1255.05 Å^3; $F(000)$ = 304; ρ_o = 1.510 g/cc; Z = 4; ρ_c = 1.531 g/cc (25°C; CuKα, λ = 1.54184 Å).

Systematic extinctions ($0k0$ absent if $k = 2n + 1$; $h0l$ absent if $l = 2n + 1$) and achirality were consistent with space group $P2_1/c$. The observed density of ρ_o = 1.510 g/cc indicated one molecule of $C_{14}H_{15}N_3O_4$ per equivalent position (4 molecules/cell). The cell parameters were obtained by a least-squares fit of the reciprocal lattice positions of 25 diffractometer measured reflections with θ values in the range of 4–47°. Intensities of all unique reflections with $2\theta < 150°$ were measured at 25°C using a variable speed $\omega/2\theta$ scan technique on an Enraf-Nonius (Delft) CAD4 diffractometer employing graphite monochromated CuKα radiation (λ = 1.54184 Å). The scan angle was calculated for each reflection as (0.90 + 0.14 tan θ)°. The detector aperture, with a variable width of (4.0 + 0.5 tan θ) mm and a constant vertical height of 4 mm was located at a distance of 173 mm from the crystal. Maximum scan time for each reflection was 1 min. Two-thirds of that time was used to scan the peak and one-sixth in measuring each of the two backgrounds. Also the intensities of three monitor reflections were recorded every 250 min and found to have varied by a maximum of 2.66% during the entire data collection process (33.4 h). A total of 2577 unique reflections were retained for subsequent processing. All intensity data were corrected for anisotropic decay using the monitor intensities as standards. The data were corrected for Lorentz-polarization and corrections were included to the scattering factors for anomalous dispersion effects.[6] No extinction or absorption adjustments were made or were necessary (μ = 9.11 cm^{-1}).

[5]Systematically, mitindomide is 3a,3b,4,4a,7a,8,8b-octahydro-4,-8-ethenopyrrolo[3′,4′:3,4]cyclobut[1,2-*f*]isoindole-1,3,5,7[2*H*,6*H*]-tetrone.

[6]Atomic scattering factor coefficients were taken from appropriate tables (see ref. 5).

*Starred atoms were refined isotropically. Anisotropically refined atoms are given in the form of the isotropic equivalent thermal parameter defined as: (4/3) [$a^2B(1,1) + b^2B(2,2) + c^2B(3,3) + ab(\cos\gamma)B(1,2) + ac(\cos\beta)B(1,3) + bc(\cos\alpha)B(2,3)$].

Structural determination of amide **5** was achieved by direct methods using a multisolution weighted tangent formula approach.[7] Of the 32 phase sets generated, the set with the highest figure of merit provided coordinates for all of the non-hydrogen atoms. After correct assignment of atomic species, three cycles of full matrix least-squares refinement[8] on all

[7]All crystallographic calculations were accomplished with a PDP 11/23 computer using the Enraf-Nonius (Delft) Structure Determination Package (SDP-PLUS) software system developed by B. A. Frenz and Associates, Inc., College Station, Texas, 1982. Principal programs used were; START, PAINTR, REJECT, CHORT, data reduction programs; LSB, a full-matrix least-squares refinement program; SEARCH, a connectivity peak search program; ORTEP-II, the crystallographic illustration programs; MULTAN 11/82 "A System of Computer Programs for the Automatic Solution of Crystal Structures from X-ray Diffraction Data," a direct methods program by P. Main and colleagues, University of York, York, England. For a description of MULTAN see: ref. 6.

[8]The non-Poisson contribution weighting scheme was used in least-squares refinement, where $w = 1/\sigma^2_{(F)} = 4 \times F^2/(\sigma_{F^2})^2$ and $\sigma_{(F^2)} = \sqrt{\sigma^2_{(I)} + (P \times F^2)^2}$, where P is an adjustment factor to downgrade intense reflections and w is the weight for the reflection. A value of 0.05 was used for P.

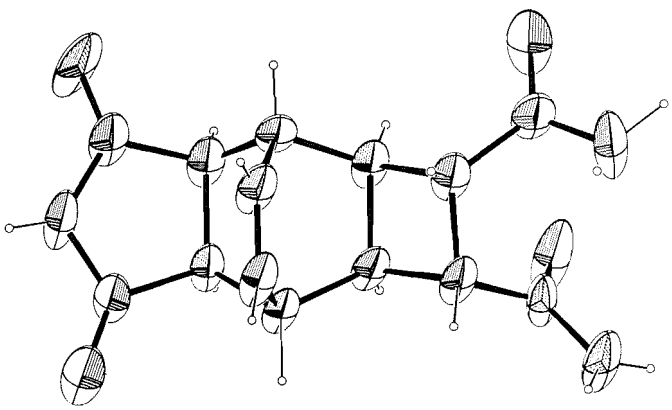

FIG. 1. Computer-generated perspective drawing of the final X-ray structure of mitindomide diamide (**5**). An ORTEP-H representation.

coordinates, scale factor, and isotropic temperature factors resulted in a rapid reduction in the conventional unweighted crystallographic discrepancy index $R(\Sigma|F_o - F_c|/\Sigma F_o|)$ to 0.080 (for observed reflections, $I > 2\sigma(I)$). A subsequent difference electron density synthesis revealed all of the hydrogen atoms in diamide **5**. Finally, several additional cycles of full-matrix least-squares refinement employing all variables (SF, x, y, z, and B's) with anisotropic nonhydrogen atoms and isotropic hydrogens (B's fixed at 5.0) caused convergence to $R = 0.045$ ($R_w = 0.049$). Refinement was discontinued when parameter shifts became insignificant (maximum shift-to-error ratio was 0.46). A final difference map showed no electron densities greater than 0.25 e Å^{-3}. All bond lengths and angles agreed well with expected values.

The relatively selective nucleophilic attack of ammonia on the cyclobutane-bearing imide that gave rise to amide **5** was confirmed by the crystal structure determination. As would be predicted, opening of this imide with concomitant release of steric compression seems a most favorable pathway. The resulting *cis*-configuration of both cyclobutane carbonyl groups indicates that no inversion of configuration took place during treatment with ammonium hydroxide. Therefore, the photoaddition product of benzene and maleic anhydride must have structure **6***a*, and mitindomide, structure **6***b*.

With the correct molecular geometry (Fig. 1) of mitindomide (**6***b*) now established, the opportunity for structure/activity and mechanism of action studies has been greatly enhanced. In respect to biological properties, particularly antineoplastic activity, the ease and direction of nucleophilic attack shown by the transformation **4***b* → **5** should prove significant. Also, the ability of mitindomide to selectively complex and remove zinc (and, under more controlled conditions, copper, see ref. 7) from aqueous solution may prove to be another important property leading to antineoplastic activity.

The very convenient one-step photosynthetic preparation of mitindomide, combined with its unique structure in terms of antineoplastic properties, suggests that a number of related systems (cf., ref. 8) derived from benzene and other aromatic and/or heterocyclic precursors should be explored. Presently mitindomide (NSC 284356) is being readied by the National Cancer Institute for eventual clinical trial.

Experimental

Melting points are uncorrected and were observed using a Koefler melting point apparatus. The ^{13}C nmr and ^{1}H nmr spectra were provided by Dr. J. Witschel, Jr. using Bruker WH-90 and Varian XL-100 nmr spectrometers. Mass spectra were determined by Mr. D. Adams with a MAT-312 mass spectrometer. Infrared spectra were obtained using a Nicolet FTIR Model MX-1 spectrometer.

Mitindomide **4**b

The benzene–maleimide photoadduct **4***b* was prepared as described previously (4) and found to exhibit: mp(dec.) > 340°C with sublimation near 300°C; ir (KBr): 3222, 3070, 2962, 2930, 1766, 1702 (very strong), 1373, 1351, 1255, 1190, 1164 cm^{-1}; ^{1}H nmr (100 MHz, DMSO-d_6 solution), δ: 2.50 (DMSO-d_6 overlap), 2.76 (s, 2H), 3.08 (br s, 2H), 3.30 (br s, 2H), 6.30 (d, J = 4 Hz, 1H), 6.34 (d, J = 4 Hz, 1H), and 11.20 (br s, 2H); ^{13}C nmr (22.63 MHz, DMSO-d_6 solution): 180.05, 179.3, 131.7 with 47.79 and 42.17 obscured by solvent, 39.09, and 34.5; mass spectrum (EI, 70 eV, m/e, 272 (M^+): 244, 201, 136, 130, 104, 78, 50, 51, 52, 44, 43, 31, 29 and 28; *Anal.* calcd. for $C_{14}H_{12}N_2O_4$: C 61.76, H 4.44, N 10.29; found: C 61.78, H 4.40, N 10.28.

*Ammonolysis of mitindomide (***4**b → **5***)*

To 64 mg of mitindomide (**4***b*) was added concentrated (28–30%) aqueous ammonium hydroxide (6 mL) and solution was complete in 15 min. After 14 days at room temperature, amide **5** crystallized as needles (4 mg) melting over 340°C; ir (KBr): 3446, 3332, 3190, 2979, 2949, 2927, 1763, 1709 (strong), 1643 (strong), 1597, 1410, 1342, and 1189 cm^{-1}. A crystal was selected for X-ray crystallographic analysis. The crystal structure (Fig. 1) was determined as summarized in the discussion and in Supplementary Material available from this journal upon request.[9]

[9]Further crystallographic details (supplementary data) including tables of observed and calculated structure factor amplitudes, fractional atomic co-ordinates, and temperature factor data are available at a nominal charge from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 052.

Réactions radicalaires du percarbonate de *O,O-tert*-butyle et *O*-isopropényle: acétonylations assistées par un co-amorceur

RABIH JAOUHARI, CLAUDE FILLIATRE ET JEAN-JACQUES VILLENAVE[1]

Laboratoire de Chimie Appliquée, Ecole Nationale Supérieure de Chimie et de Physique, Université de Bordeaux I, 351, cours de la Libération, 33405 Talence-cédex, France

Reçu le 4 mai 1983

RABIH JAOUHARI, CLAUDE FILLIATRE et JEAN-JACQUES VILLENAVE. Can. J. Chem. **61**, 2295 (1983).

L'acétonylation "assistée" d'alcanes, éthers, cétones, acides, esters et nitriles a été réalisée en décomposant dans ces solvants des mélanges équimoléculaires de percarbonate de *O,O-tert*-butyle et *O*-isopropényle et de peracétate de *tert*-butyle. La présence du co-amorceur permet d'accroître sensiblement l'intérêt de la méthode de synthèse radicalaire de dérivés acétonylés en supprimant la formation d'acétonylacétone, produit secondaire parfois gênant, et en améliorant nettement les rendements en dérivés acétonylés tout en conservant ou même augmentant la régiosélectivité des processus.

RABIH JAOUHARI, CLAUDE FILLIATRE, and JEAN-JACQUES VILLENAVE. Can. J. Chem. **61**, 2295 (1983).

By decomposition in alkanes, ethers, ketones, acids, esters and nitriles of equimolecular mixtures of *O,O-tert*-butyl and *O*-isopropenyl peroxycarbonate and *tert*-butyl peroxyacetate, the "assisted" acetonylation of the solvents has been accomplished. The presence of the co-initiator allows the yield of the free radical acetonylation to be markedly improved: the formation of the by-product acetonylacetone is avoided and the yield of acetonylated derivatives is strongly enhanced while the regioselectivity of the processes is preserved and even increased in some cases.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

Au cours d'une étude générale (1), nous avons eu l'occasion de mettre en évidence l'aptitude du percarbonate de *O,O-tert*-butyle et *O*-isopropényle **1** à se comporter comme un agent d'acétonylation; en effet, la décomposition de cet amorceur radicalaire en solution dans divers substrats permet, par substitution d'atomes d'hydrogène plus ou moins activés, d'accéder à des dérivés acétonylés **2**. Dans de nombreux cas, cette méthode de fonctionnalisation radicalaire s'est avérée supérieure à d'autres techniques de synthèse (2, 3) mais il n'en reste pas moins qu'elle comporte un certain nombre d'inconvénients.

C'est ainsi que ses rendements ne sont pas toujours très élevés (de 30 à 50%, par rapport au percarbonate **1** mis en jeu, en fractions acétonylées purifiées par rectification). De plus, à chaque fois que le substrat comporte plusieurs sites de substitution possibles, on se rend compte que la réaction n'est sélective que si l'on opère avec des solutions de percarbonate fortement diluées mais aussi que, dans ces conditions, les rendements se trouvent abaissés de manière sensible. Ce phénomène est particulièrement marqué dans le cas des cyclanones pour lesquelles l'acétonylation ne se produit sélectivement en α du carbonyle que si les proportions initiales de percarbonate et de substraat sont dans un rapport de 1/50; dans ce cas, le rendement en dérivé acétonylé atteint à peine 30%.

Nous préoccupant de rechercher des solutions à ces divers problèmes, nous avons effectué une analyse du mécanisme, décrit dans le Schéma 1, de formation des divers produits de réaction.

Suivant ce schèma, c'est la décomposition du percarbonate **1** induite par l'addition des radicaux $S^{\cdot}$ sur sa double liaison qui constitue le processus "principal", conduisant au dérivé acétonylé **2**, l'homolyse "spontanée" étant responsable, indirectement, de la formation des produits secondaires, acétonylacétone en particulier. Dans ces conditions, il est clair que toute production de radicaux $S^{\cdot}$ indépendante de la décomposition "spontanée" du percarbonate est susceptible d'augmenter les taux de transformation en dérivés **2** et, donc, d'améliorer les rendements des réactions d'acétonylation.

Nous avons pensé que l'introduction dans le milieu réactionnel d'un amorceur susceptible de fournir, à des températures plus basses que celles provoquant l'homolyse du percarbonate, des radicaux capables d'arracher des atomes d'hydrogène au solvant pouvait constituer un bon moyen pour obtenir des radicaux $S^{\cdot}$ "supplémentaires". Nous nous sommes alors intéressés à l'acétonylation assistée par un co-amorceur définissant dans un premier temps les conditions opératoires optimales pour

réaliser ensuite une étude complète dans le cas de la cyclohexanone, choisie comme composé modèle, et envisager enfin l'application de la technique mise au point à diverses familles de substrats (alcanes, cétones, éthers, acides et dérivés).

Choix des conditions opératoires

Température

Pour éviter au mieux l'homolyse du percarbonate mais aussi dans le but de limiter la formation des produits de terminaison à partir des radicaux S$^{\bullet}$, on serait tenté d'opérer à une température la plus basse possible. En fait, on se heurte très rapidement à une limitation imposée par le mode de décomposition du percarbonate.

Des études cinétiques (4) nous ont permis d'établir la loi de vitesse de cette décomposition:

$$-\mathrm{d}C/\mathrm{d}t = k_d C + k_i C^2$$

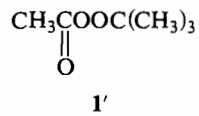
la constante k_i étant proportionnelle aux constantes de vitesse k_d et k_s. Nous avons également constaté que les valeurs de k_i diminuent beaucoup plus vite, quand la température diminue, que celles de k_d. Au-dessous de 80°C, k_i est très faible ce qui signifie qu'à partir de ce seuil, l'addition des radicaux S$^{\bullet}$ sur la double liaison du percarbonate ne se produit plus que de manière négligeable. L'obtention de dérivés acétonylés n'est alors plus envisageable.

Tenant compte de cette limitation, nous avons décidé de réaliser les acétonylations assistées à 95°C, température où l'addition des radicaux S$^{\bullet}$ se produit encore de manière convenable; en corollaire, les durées de réaction ont dû être portées à 16 heures, temps nécessaire pour que la totalité du percarbonate mis en jeu ait réagi (rappelons les conditions adoptées au cours des études sur l'acétonylation non-assistée (1): 130°C; 2,5 h).

Co-amorceur

L'impossibilité d'opérer à basse température excluant l'utilisation des amorceurs "fragiles", du type dipercarbonate (décomposition rapide dès 40°C), auxquels on aurait pu penser, nous avons décidé de faire appel à des composés de stabilité thermique voisine de celle du percarbonate **1**. Entre le perbenzoate de *tert*-butyle, les percarbonates de *O,O-tert*-butyle et *O*-éthyle ou *O*-isopropyle et le peracétate de *tert*-butyle **1'** c'est le premier qui a donné les moins bons et le dernier les meilleurs résultats lors d'essais préliminaires.

Tous les essais par la suite ont été réalisés en mettant en oeuvre le peracétate de *tert*-butyle **1'** comme co-amorceur. On



1'

peut noter à son propos que sa thermolyse donne des radicaux *tert*-butoxyle et acétoxyle capables, pour les premiers, d'arracher de l'hydrogène au solvant et, pour les derniers, de conduire par décarboxylation à des radicaux méthyle; dans la mesure où l'on ne trouve pas le produit correspondant à leur addition sur le percarbonate (méthyléthylcétone) on peut penser que l'évolution principale des radicaux méthyle est le transfert au solvant.

*Proportions relatives initiales de **1** et **1'***

Différents essais préliminaires nous ont montré qu'il était préférable d'opérer avec des quantités équimoléculaires de percarbonate et de peracétate. Avec un défaut de peracétate, la vitesse de décomposition du percarbonate est plus grande que celle du peracétate ce qui va à l'encontre du but recherché. Avec un excès de peracétate ce qui va à l'encontre du but recherché. Avec un excès de peracétate, l'augmentation du rendement en dérivé acétonylé ne compense pas les pertes liées à la séparation plus difficile de quantités sensiblement augmentées de déhydrodimère du solvant.

Décomposition "assistée" du percarbonate 1 dans la cyclohexanone

Dans le tableau 1, nous avons consigné des éléments de comparaison, pour différentes concentrations initiales en percarbonate, entre des décompositions assistées et non-assistées réalisées à 95°C.

La première constatation qui doive être faite est que les rendements sont nettement augmentés quand on opère en présence du co-amorceur mais qu'une sorte de saturation semble se produire et qu'il existe un taux de dilution optimal: proportions relatives **1**/**1'**/SH égales à 1/1/20. Ce taux de dilution est celui à partir duquel on observe une acétonylation sélective en α du carbonyle et, donc, le rendement de 71% doit être comparé non pas aux 39% ou même aux 55% obtenus pour des proportions relatives de **1** et SH égales à 1/20 ou 1/5 (le processus n'est alors pas sélectif) mais bien aux 30% de l'acétonylation, exclusivement en α, avec des proportions relatives de 1/50.

La seconde observation concerne l'absence d'acétonylacétone dans les mélanges réactionnels des acétonylations assis-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

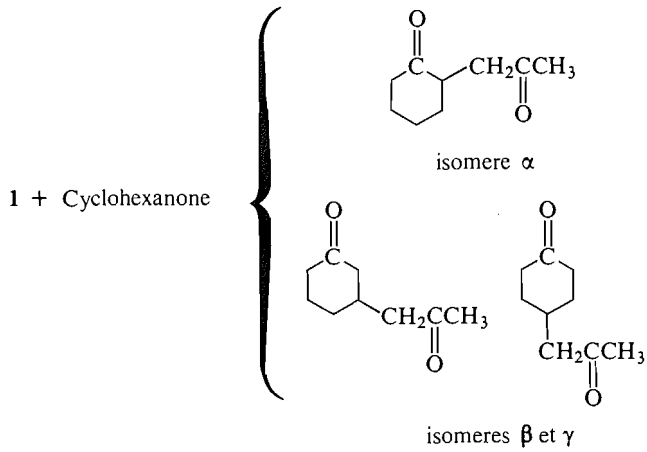


SCHÉMA 2

tées. Ceci est en bon accord avec le fait que la mise en oeuvre du co-amorceur défavorise la décomposition spontanée du percarbonate par rapport à la décomposition induite; la concentration instantanée en radicaux acétonyle $CH_3C(O)CH_2^{\bullet}$ est très abaissée et l'addition de ces radicaux sur la double liaison du percarbonate **1** ne se manifeste plus. Concernant l'acétonylacétone, on peut rappeler qu'à 130°C, les proportions de ce produit, dans le cas de la cyclohexanone, étaient de 11%. Ainsi, le fait d'opérer à plus basse température contribue à limiter la formation de l'acétonylacétone mais c'est bien l'utilisation du co-amorceur qui joue le rôle décisif dans l'élimination de ce produit secondaire des mélanges réactionnels.

En résumé, *la mise en oeuvre du co-amorceur permet d'atteindre, avec une régiosélectivité totale, des rendements très élevés en dérivé acétonylé de la cyclohexanone* (compte-tenu des pertes lors de la distillation, un rendement de 70% en produit pur correspond à un taux de transformation de **1** en **2** de l'ordre de 90%). Notons que des constatations analogues faites avec d'autres cyclanones (cycles en C_7 ou C_8) ouvrent la voie à des essais de généralisation du procédé.

Application de l'acétonylation assistée à diverses familles de substrats

Souhaitant comparer les "performances" des acétonylations assistée et non-assistée (1), nous avons repris, comme substrats, les cyclohexane, tétrahydrofuranne, cyclopentanone, acide propionique, propionate de méthyle et propionitrile représentatifs, respectivement, des alcanes, éthers, cétones, acides, esters et nitriles.

Dans le tableau 2, nous avons indiqué les rendements obtenus en opérant sans co-amorceur dans les conditions les plus favorables (130°C; 2,5 h; rapport molaire **1**/SH = 1/5) et avec le co-amorceur (95°C; 16 h; rapport molaire **1**/**1'**/SH = 1/1/20). Il convient cependant de préciser que, pour les acides, esters et nitriles, les meilleurs résultats ont été observés pour des proportions différentes de réactifs: **1**/SH = 1/50 à 130°C et **1**/**1'**/SH = 1/1/100 à 95°C.

Conclusions

L'utilisation du peracétate de *tert*-butyle comme co-amorceur lors de la décomposition du percarbonate de *O,O-tert*-butyle et *O*-isopropényle en solution permet d'augmenter sensiblement les rendements de l'acétonylation radicalaire de nombreux substrats fonctionnels ou non. En outre, lorsque des problèmes d'orientation de la réaction se posent, c'est le cas surtout avec les cétones, les rendements élevés vont de pair avec une régiosélectivité totale.

Comme la réalisation de la réaction ne pose aucun problème pratique et que les produits sont faciles à extraire des milieux réactionnels et à purifier, l'acétonylation radicalaire assistée apparaît comme une bonne méthode d'obtention de cétones, en particulier γ-fonctionnelles.

TABLEAU 2. Acétonylation assistée et non-assistée de divers substrats

Partie expérimentale

Percarbonate 1 et peracétate 1'

La préparation du percarbonate **1**, précedemment décrite (1) consiste à condenser le chloroformiate d'isopropényle, produit commercial,[2] et l'hydroperoxyde de *tert*-butyle en présence de pyridine. Suivant cette méthode "classique" de préparation des peresters (5), le peracétate **1'** a été obtenu par réaction du chlorure d'acétyle avec l'hydroperoxyde de *tert*-butyle. Aucune purification particulière des amorceurs n'a été réalisée avant leur utilisation.

Dérivés acétonylés

Pour la plupart, ils ont été décrits lors de l'étude générale (1). Dans le cas de l'acétonylation de la cyclohexanone, l'acétonyl-2 cyclohexanone (dérivé de substitution en α du carbonyle) a été identifiée en comparant ses caractéristiques avec celles d'un échantillon préparé comme réf. 6. En ce qui concerne les isomères β et γ (acétonyl-3 et -4 cyclohexanone), leur caractérisation, en même temps que celle du dérivé α, a été réalisée après des études en spectrométrie de masse et spectroscopie de rmn ^{13}C (7).

Protocole opératoire type (dans le cas de la cyclohexanone)

Une solution de 0,01 mol de percarbonate **1** (1,74 g) et 0,01 mol de

[2] Société Nationale des Poudres et Explosifs, 12, quai Henri IV, 75181 Paris Cédex 04, France.

For personal use only.

peracétate **1'** (1,32 g) dans 0,2 mol de solvant (~20 g) a été chauffée à 95°C pendant 16 h dans un autoclave placé dans une étuve thermorégulée. Après refroidissement, les produits secondaires (*tert*-butanol et acétone) et l'excès de solvant ont été séparés par distillation. Après rectification du résidu de distillation, le dérivé acétonylé a été obtenu pur (Eb_5 = 105–107°C; N_D^{20} = 1,4605), sa masse permettant le calcul du rendement (par rapport au percarbonate **1** mis en jeu).

Dans le cas de la cyclohexanone et pour des opérations réalisées dans des conditions où la réaction n'était pas sélective, la fraction acétonylée obtenue après distillation des produits secondaires et de l'excès de solvant a été fractionnée par chromatographie liquide–solide, sur alumine (pentane et benzène puis benzène et éther éthylique comme éluants, respectivement, de l'isomère α-acétonylé et de mélanges des isomères β- et γ-acétonylés); c'est sur les fractions obtenues que nous avons réalisé les identifications. La fraction acétonylée a été par ailleurs analysée en chromatographie en phase vapeur (chromatographe Intersmat ICG 12 à ionisation de flamme; gaz vecteur: N_2 (35 mL min^{-1}); colonnes d'acier inox (l = 1,50 m; diamètre intérieur: 2 mm) garnies de FFAP (10%) ou de SE-52 (5%) sur Chromosorb W (80–100 mesh; AW, traité DMCS)), les dosages étant réalisés suivant la méthode de l'étalon interne (benzoate d'éthyle).

Note sur la détermination des durées de réaction

L'augmentation de la vitesse de réaction que provoque l'addition du co-amorceur rendrait très imprécis tout calcul de durée de réaction à partir de données cinétiques concernant les amorceurs seuls. Dans ces conditions, nous avons réalisé un essai préalable d'acétonylation de la cyclohexanone (dans un ballon type Grignard), au cours duquel nous avons examiné par spectroscopie ir et de rmn des échantillons prélevés à différents instants. Après 15 à 16 h, nous avons constaté que les signaux caractéristiques de l'insaturation du percarbonate **1** avaient disparu.

Received March 15, 1983

GEORGE I. BIRNBAUM, WAYNE J. P. BLONSKI, and FRANK E. HRUSKA. Can. J. Chem. **61**, 2299 (1983).

The three-dimensional structure of 5-methoxyuridine (mo^{5}U) was determined with much higher precision than in a previous study (Hillen *et al.* J. Carbohydr. Nucleosides Nucleotides, **5**, 23 (1978)). The crystals belong to the monoclinic space group $P2_1$ and the cell dimensions are a = 8.916(2), b = 14.372(2), c = 4.714(1) Å, β = 97.44(2)°. Intensity data were measured with a diffractometer and the structure was solved by direct methods. Least-squares refinement, which included all hydrogen atoms, converged at R = 0.031. The conformation about the glycosyl bond is *anti* (χ_{CN} = 23.1°), the pucker of the ribose ring is C(3′)*endo*, and the conformation of the —CH_2OH side chain is *gauche*$^+$. A comparison of the bond lengths N(3)—C(4) and C(4)—O(4) with those in uridine does not support the conclusion of Hillen *et al.* about a shift to the enol tautomer in mo^{5}U. However, there are other changes in the geometry of the pyrimidine ring due to substitution at C(5). A conformational analysis, based on ^{1}H and ^{13}C nmr data, shows that the preferred conformation in solution is that observed in the solid state.

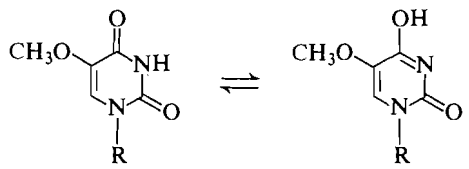
GEORGE I. BIRNBAUM, WAYNE J. P. BLONSKI et FRANK E. HRUSKA. Can. J. Chem. **61**, 2299 (1983).

On a déterminé avec une précision supérieure à celle d'une étude antérieure (Hillen *et al.* J. Carbonhydr. Nucléosides Nucléotides, **5**, 23 (1978)) la structure tridimensionnelle de la méthoxy-5 uridine (mo^{5}U). Les cristaux appartiennent au groupe spatial monoclinique $P2_1$ avec des dimensions de maille de: a = 8,916(2), b = 14,373(2), c = 4,714(1) Å, β = 97,44(2)°. On a mesuré les intensités à l'aide d'un diffractomètre, on a résolu la structure par des méthodes directes et on l'a affinée, tous les atomes d'hydrogène inclut, par la méthode des moindres carrés jusqu'à une valeur de R = 0,031. La conformation autour de la liaison glycosyle est *anti* (χ_{CN} = 23,1°), le gauchissement du cycle ribose est C(3′) *endo* et la chaine latérale —CH_2OH a une conformation *gauche*$^+$. Une comparaison des longueurs de liaison N(3)—C(4) et C(4)—O(4) avec celles de l'uridine ne confirme pas la conclusion de Hillen *et al.* en ce qui a trait à la transformation en l'énol tautomère du mo^{5}U. Cependant il y a d'autres changements de géométrie du cycle pyrimidine provoqués par la substitution en C(5). Une analyse conformationnelle qui s'appuie sur les données de la rmn du ^{1}H et du ^{13}C montre que la conformation privilégiée en solution est celle observée à l'état solide.

[Traduit par le journal]

Introduction

5-Methoxyuridine (mo^{5}U) is one of the modified nucleosides which occur in the first anticodon ("wobble") (1) position of various tRNAs (2). It has been suggested (3) that its codon recognition is affected by a shift in the keto–enol tautomerism in the pyrimidine moiety, caused by the electron donating methoxy group.



This view seemed to be supported by an X-ray analysis of 5-methoxyuridine (3) which indicated an elongation of the C(4)—O(4) carbonyl bond and a shortening of the N(3)—C(4) bond. Based on our review of 5-substituted deoxyuridines (4), we had reasons to question these results, particularly since their precision was rather low. Since a keto–enol shift has also been implicated in the mechanism of action of antiviral 5-halouridines (5), it seemed important to establish whether 5-substituents do indeed cause such shifts in uridines, giving rise to altered bond lengths. We decided, therefore, to determine the crystal structure of 5-methoxyuridine with much higher precision and, in extension of our recent studies (4, 6–9), to compare its conformation in the solid state with the solution conformation, as determined by an ^{1}H and ^{13}C nmr study.

Experimental

5-Methoxyuridine was crystallized from water to give colorless prisms. Precession photographs indicated space group $P2_1$. A crystal fragment measuring 0.15 × 0.25 × 0.40 mm was mounted on an Enraf-Nonius CAD4 diffractometer; it provided the following data: $C_{10}H_{14}N_2O_7$ fw = 274.2
Monoclinic, a = 8.916(2), b = 14.372(2), c = 4.714(1) Å, β = 97.44(2)°, V = 599.0 Å^3, ρ_o = 1.51(1), ρ_c = 1.52 g cm^{-3}, Z = 2 (21°C; CuKα$_1$, λ = 1.54056 Å); F(000) = 288, μ(CuKα) = 10.8 cm^{-1}.

Cell dimensions were determined from angular settings of 23 high-order (2θ > 90°) reflections. Intensities were measured with Ni-filtered CuKα radiation, using ω/2θ scans with variable scan ranges and speeds. There were 1296 unique reflections accessible to the diffractometer (2θ ≤ 152.0°); all of them had $I > \sigma(I)$ and were considered observed. The intensities were corrected for Lorentz and polarization factors; absorption corrections were considered unnecessary.

The structure was determined by direct methods (Hillen *et al.* (3) did not publish the atomic coordinates) with the aid of the computer program MULTAN78 (10). Of the 24 starting sets subjected to tangent refinement, the solution with the highest combined figure of merit yielded an E map on which all 19 nonhydrogen atoms were located. Atomic parameters were refined by block-diagonal least squares. All hydrogen atoms were located on difference Fourier maps and refined

with isotropic temperature parameters. The scattering factors were taken from the International tables for X-ray crystallography (11) and the oxygen curve was corrected for anomalous dispersion. Throughout the refinement the function $\Sigma w(|F_o| - |F_c|)^2$ was minimized and a factor of 0.8 applied to all shifts. The following weighting scheme was used during the final stages: $w = w_1 \cdot w_2$, where $w_1 = 1$ for $|F_o| \leq 4.0$, $w_1 = 4.0/|F_o|$ for $|F_o| > 4.0$; and $w_2 = \sin^2\theta/0.2$ for $\sin^2\theta < 0.2$, $w_2 = 1$ for $\sin^2\theta \geq 0.2$. This scheme made the average values of $w(\Delta F^2)$ independent of $|F_o|$ and $\sin^2\theta$. After the final cycle the average parameter shift equalled 0.1σ and the largest one 0.8σ. The conventional residual index *R* is 0.031 and the weighted index *R′* is 0.040 for 1295 reflections (110 suffered from extinction and was given zero weight). A final difference Fourier map showed no significant features. The coordinates are listed in Table 1; lists of anisotropic temperature parameters, deviations of atoms from the mean plane of the pyrimidine ring, and of observed and calculated structure factors are available.[2]

[2] These tables may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1S 0S2.

Results and discussion

A stereoscopic view of 5-methoxyuridine, showing the overall conformation in the crystal and the atomic numbering scheme, is presented in Fig. 1. Details of the conformation can be seen in the Newman projections (Fig. 2) and in Fig. 3 which also shows the bond lengths and bond angles. It should be emphasized that the precision of this structure determination is four times higher than that of Hillen *et al.* (3).

Pyrimidine moiety

Table 2 lists the bond lengths determined in this and in the previous structure analysis of mo^{5}U as well as those in the parent uridine (12). The differences between the first two columns are quite substantial, ranging up to 0.018 Å for the crucial N(3)—C(4) bond. However, owing to the high estimated standard deviations (esd's, σ's) in the previous study, this difference is equivalent to only 2σ and thus statistically not significant. A comparison of our values with those in uridine shows that, while N(3)—C(4) is somewhat shorter in mo^{5}U and C(4)—O(4) somewhat longer, these differences are also no larger than 2σ and therefore of questionable significance. Consequently, we do not believe that postulating a shift to the enol tautomer in mo^{5}U (3) can be justified.

On the other hand, the presence of a substituent at C(5) does alter the geometry of the uracil ring. We were particularly interested in the effects of substitution on endocyclic bond angles. For our comparison we used only precisely determined structures, i.e. those in which σ(C—C) ≤ 0.005 Å. The exception, for reasons given below, was 5-aminouridine (13). The results of our survey are given in Table 3. There is a definite trend in the angles at C(5) and the range of 3.0° is highly significant (with the exception noted above, the esd's of these angles are ≤0.4°). There is also a fairly good correlation between the angles at C(5) and C(4): as the former decrease, the latter increase. The angles at C(6) do not vary as much and show no clear correlation with those at C(5). The other endocyclic angles (not listed in Table 3) remain within a narrower range and vary randomly.

The angular deformations caused by substitution in aromatic systems have been extensively studied by Norrestam (14) and by Domenicano (15). In general, it has been found that π-electron-withdrawing groups cause an increase of the endocyclic bond angle at the *ipso* atom and a decrease at the *ortho* atoms. The effects on the angles at the *meta* and *para* atoms are not as large and are not significantly correlated to the electronegativities of the substituents. Of the substituents listed in Table 3, NO_2, Cl, OH, NH_2, and CH_3 also appear in a table given by Norrestam and Schepper (14). It is noteworthy that these substituents appear in the same order in both tables.

The lengthening of the ring bonds adjacent to C(5), relative to uridine, could be explained by the inductive effect of the OCH_3 group which causes a withdrawal of σ electrons from the ring. The longer C(5)—C(6) bond could also be attributed to a partial single bond character resulting from a delocalization of π electrons from the substituent to C(6).

The pyrimidine ring is significantly nonplanar, the deviations from the mean plane ranging up to −0.020(2) Å for C(2) and 0.021(2) Å for C(4). The deviations of the ring substituents range from −0.033(1) Å for O(5) to 0.128(2) Å for C(1′). We note that the ring atoms deviate from the mean plane in the same direction as the substituents attached to them. The methoxy group is almost, but not exactly, in the mean plane of the ring. Its methyl group is on the less hindered side, i.e. *syn* to

H(6) rather than to O(4). The conformation about the glycosyl bond is, as usual, *anti* with χ_{CN}[C(6)—N(1)—C(1')—O(4')] = 23.1°.

Ribose moiety

The ribose ring is in an envelope conformation, corresponding very closely to a C(3')*endo* (^3E) pucker. The phase angle of pseudorotation (P) is 13.0° and the maximum amplitude of puckering (τ_m) is 38.9° (16). Both P and τ_m represent average values for one of the two most common conformations of ribose rings, the other being ^2E. The bond lengths are also unexceptional and require no comments. On the other hand, some endocyclic bond angles differ from the values calculated with an equation derived by Birnbaum *et al.* (17) which correlates these angles with P and τ_m. The calculated angles at O(4'), C(1'),.....C(4') are 109.7, 107.2, 101.5, 101.9, 104.7°. The differences at O(4'), C(2'), and C(4') are statistically highly significant. Unfortunately, we are unable to explain these distortions.

The conformation of the —CH_2OH side chain is *gauche*$^+$ (Fig. 2). This rotamer is the one most commonly observed. It is stabilized not only by the *gauche* effect of the C(4')—O(4')/C(5')—O(5') interaction (18) but also by the intramolecular C(6)—H···O(5') hydrogen bond. Such hydro-

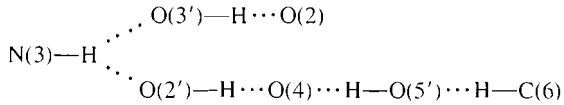
gen bonds are by no means uncommon (19) and probably play a significant role in determining the overall conformation of a nucleoside.

Hydrogen bonding and packing

In addition to the intramolecular hydrogen bond mentioned above there are five intermolecular ones. All potential proton donors participate in the hydrogen bond network which can be represented schematically as follows:



H(3) is involved in a bifurcated hydrogen bond, being donated to both O(2′) and O(3′). Such bonds have been observed in the past (20, 21); they are characterized by longer than normal H···*A* distances and larger deviations from linearity of the *D*—H···*A* angle. As expected, N(3), H(3), and the two acceptor O atoms are coplanar. The two O···H distances are unequal, indicating that this is an asymmetric bifurcated hydrogen bond. The precise geometry of all hydrogen bonds is shown in Table 4. As commonly observed in X-ray analyses, the C—H, N—H, and O—H bonds appear shorter than their real values. By extending the covalent bond lengths to their nominal values (1.00, 1.04, and 0.97 Å, respectively) one obtains corrected H···*A* distances which reflect more accurately the strengths of these hydrogen bonds. The bonds involving H(3) are relatively weak and so is the C—H···O bond. The other three hydrogen bonds are of medium strength.

The packing of the molecules in the crystal can be seen in Fig. 4. The pyrimidine rings are almost perpendicular to the *c* axis. They are hydrogen-bonded to ribose rings but not to each other. There are no base-stacking interactions, but hydrophobic and hydrophilic regions can be discerned perpendicular to the *b* axis.

Nuclear magnetic resonance solution data

For comparison with the crystal, we have obtained ^{1}H and ^{13}C nmr data for mo^{5}U in aqueous solution (Table 5). The analyses of the ^{1}H nmr spectra were carried out using standard techniques (22). The ^{13}C chemical shifts were obtained from ^{1}H-decoupled spectra; the spectral assignments were made using literature data for nucleosides (23) and confirmed with ^{13}C—^{1}H shift correlation plots (24). From $J(1',2')$ and $J(3',4')$ we calculated (22) that the C(3′)*endo* pucker (58%) is favored

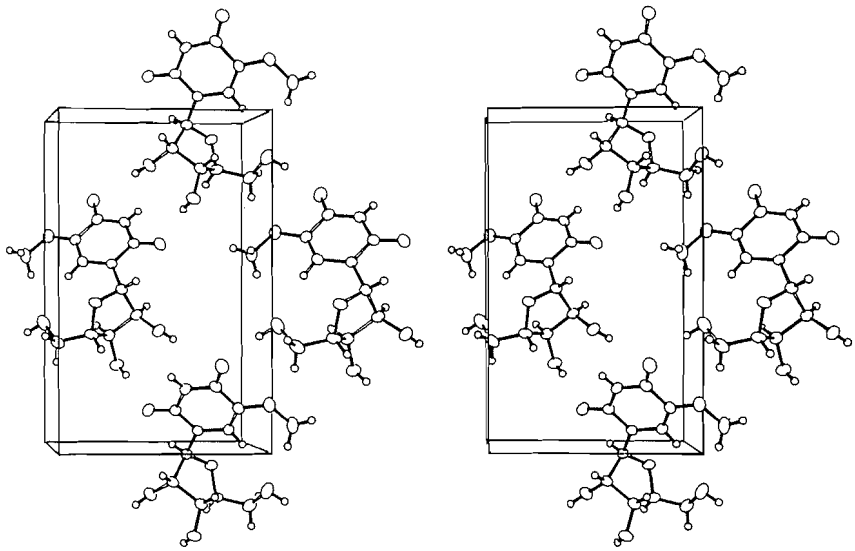


FIG. 4. Stereoscopic view along z of the molecular packing in the crystal.

over C(2′)*endo*; this distribution is similar to that in uridine (U), 53% C(3′)*endo*. From the $J(4',5')$ and $J(4',5'')$ data we estimate (25) the following populations for the side chain conformations in mo^{5}U (and U): 77% (62%) *gauche*$^+$; 18% (32%) *trans*; 4% (5%) *gauche*$^-$. Thus the sugar conformation observed in the solid state for both mo^{5}U and U (^3E, *gauche*$^+$) is also favored in aqueous solution. The enhanced *gauche*$^+$ population in mo^{5}U relative to U suggests that the C(6)—H···O(5′) hydrogen bond observed in solid state may also exist, to a small extent, in an aqueous solution.

The similarity of the ribose ^{1}H and ^{13}C nmr chemical shifts of mo^{5}U and U suggests a similar *anti-syn* distribution about their N-glycosyl bonds (22). This view is supported by the similarity in their ^3J(C6,H1′) couplings (mo^{5}U: 3.8 Hz; U: 3.7 Hz) and in their ^3J(C2,H1′) couplings (mo^{5}U: 2.2 Hz; U: 2.2 Hz) which we obtained from ^{1}H-coupled ^{13}C spectra. The fact that the ^3J(C6,H1′) couplings are greater than ^3J(C2,H1′) suggests a preference for the *anti* conformation in both instances (23). Attempts were made to estimate the *anti-syn* distribution with ^{1}H–^{1}H nOe experiments, but due to the tightly-coupled nature of the ribose protons at 90 MHz the results were inconclusive. However, the enhancement in the H(1′) intensity observed when H(6) is irradiated suggests a sizeable contribution from the *syn* conformation in some pyrimidine nucleosides (26, 27).

The OCH_3 substituent induces the following ^{13}C nmr chemical shift changes relative to uridine (a positive sign indicates a decrease in shielding): C(2) −1.7, C(4) −4.6, C(5) 34.3, C(6) −22.4 ppm. Similar trends have been observed (28) in the *free* uracil and 5-methoxyuracil bases in DMSO solution: C(2) −0.8, C(4) −3.5, C(5) 35.6, C(6) −19.5 ppm. This suggests similar electronic effects of the 5-methoxy substitution in both situations. The large deshielding of the directly substituted C(5) atom is in line with substituent electronegativities. The increased shielding of the *ortho* C(6) can be rationalized in terms of a mesomeric donation of electrons by the OCH_3 group (see above), as has been proposed for the analogous vinyl derivative (29). The much smaller changes at the *ortho* C(4) and *para* C(2) atoms indicate that the electronic interactions between the carbonyl groups and the 5-substituent are relatively unimportant. It is also interesting to report that we observed, in the ^{1}H-coupled ^{13}C spectra, ^1J(C6,H6) couplings of 181.5 and 184.0 Hz in mo^{5}U and U, respectively, whereas, for the corresponding bases in DMSO solution, couplings of 180 and 180.5 Hz were reported by Ellis *et al.* (28). Further measurements of this one-bond coupling in free bases and in their nucleosides could provide useful structural information.

Acknowledgements

Apart from the MULTAN program (10), all crystallographic computations were carried out with programs written by Ahmed *et al.* (31). Figures 1 and 4 were drawn with the ORTEP program of Johnson (32). We thank Drs. W. Niemczura and W. Gibbons for the 270 MHz spectra (Bruker WH270; Madison, Wisconsin) and Mr. K. Marat for obtaining the ^{13}C nmr spectra. F.E.H. acknowledges the Natural Sciences and Engineering Council of Canada for financial support.

JOHN L. HOLMES, F. P. LOSSING, JOHAN K. TERLOUW, and PETER C. BURGERS. Can. J. Chem. **61**, 2305 (1983).

The title ions have been generated by dissociative ionisation of appropriate precursor molecules and have been unequivocally identified by collisional activation and collisional ionisation mass spectrometry. Their heats of formation, $[\Delta H_f^0]$, have been measured and were found to be similar to those for their ionic isomer of conventional structure, $[CH_3X]^{+\cdot}$. The exception is $[CH_2NH_3]^{+\cdot}$ whose ΔH_f^0 is ca. 30 kcal mol^{-1} higher than that of $[CH_3NH_2]^{+\cdot}$. The shapes and appearance energies of metastable peaks in conjunction with isotopic labelling experiments, show that these novel ions do not interconvert with their conventional isomer at internal energies below the threshold for their fragmentation of lowest energy requirement, namely, loss of H$^{\cdot}$. However, unimolecular H$^{\cdot}$ loss from all $[CH_2XH]^{+\cdot}$ ions is preceded by a rate determining isomerisation to $[CH_3X]^{+\cdot}$, followed by fast dissociation. The results are generally in good agreement with recent *ab initio* calculations. Also described are the properties of the homologous ion $[CH_2CH_2NH_3]^{+\cdot}$.

JOHN L. HOLMES, F. P. LOSSING, JOHAN K. TERLOUW et PETER C. BURGERS. Can. J. Chem. **61**, 2305 (1983).

Les ions mentionnés dans le titre ont été produits par ionisation dissociante des precurseurs adéquats et identifiés sans ambiguité par spectrométrie de masse à activation et à ionisation par choc. On a mesuré leurs chaleurs de formation $[\Delta H_f^0]$ et on a trouvé qu'elles sont semblables à celles de leurs isomères ioniques à structure conventionelle $[CH_3X]^{+\cdot}$. L'ion $[CH_2NH_3]^{+\cdot}$ fait exception car son ΔH_f^0 est d'environ de 30 kcal mol^{-1} supérieure à celui de l'ion $[CH_3NH_2]^{+\cdot}$. Les formes et l'apparence des énergies des pics métastables de concert avec les expériences de marquage isotopique montrent que ces nouveaux ions ne s'interconvertissent pas en leurs isomères conventionnels à des énergies internes inférieures au seuil requis par leur plus faible énergie de fragmentation, en particulier, la perte de H$^{\cdot}$. Cependant l'étape déterminante de l'isomérisation en $[CH_3X]^{+\cdot}$ précède la perte unimoléculaire de H$^{\cdot}$ à partir de tous les ions $[CH_2XH]^{+\cdot}$ qui est suivie d'une dissociation rapide. En général les résultats s'accordent bien avec les récents calculs *ab initio*. On décrit également les propriétés de l'ion homologue $[CH_2CH_2NH_3]^{+\cdot}$.

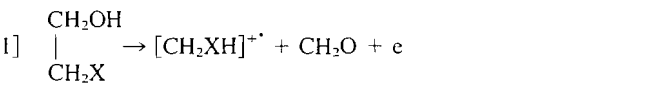
[Traduit par le journal]

Introduction

Recently published experimental (1–7) and theoretical studies (8–12) have firmly established the existence of novel, stable, gas phase radical cations whose neutral counterparts do not represent stable molecules. For example, although the neutral species $[CH_2OH_2]$ can at best be considered as a weakly bound, transient, water–methylene complex (6), the ionised form $[CH_2OH_2]^{+\cdot}$ has been shown (4) to be thermodynamically more stable than its conventional isomer, the methanol radical cation, $[CH_3OH]^{+\cdot}$.

We have referred to these new ions as "radical–ion dipole complexes" (4); the ion $[CH_2OH_2]^{+\cdot}$, for example, can formally be represented as a tightly bound complex between ionised methylene and the dipolar water molecule, $[CH_2^{+\cdot}OH_2]$, but it may also be described as the "methylene oxonium radical cation" (3, 6). Higher homologues have been observed and could be described either as individually named onium radical cations or by placing them in two radical cation-dipole categories, one involving a carbene, e.g. $[CH_3CHClH]^{+\cdot}$ (7), and the other an olefin, e.g. $[CH_2CH_2OH_2]^{+\cdot}$ (2, 4).

The general method for the formation of the new ions involves a dissociative ionisation in which an appropriate rearrangement is followed by the elimination of a small stable molecule, such as CH_2O, CO_2, and CO, e.g.



[1] $\rightarrow [CH_2XH]^{+\cdot} + CH_2O + e$

[2] $\rightarrow [CH_2XH]^{+\cdot} + CO_2 + e$

[3] $\rightarrow [CH_2XH]^{+\cdot} + CO + e$

In this paper we fully describe observations on the ions $[CH_2XH]^{+\cdot}$, X = OH, NH_2, SH, halogen, which we briefly reported earlier (4), together with those for some higher homologues.

Results and discussion

1. *Oxygen-containing ions*

$[CH_3OH]^{+\cdot}$, **1**, and $[CH_2OH_2]^{+\cdot}$, **2** (generated by all three reactions above; X = OH), have been shown to be readily distinguishable by means of their collisional activation (CA) mass spectra (3, 4) and their charge stripping (CS) mass spectra (4). The heat of formation, ΔH_f^0, of **2**, reported earlier (4) to be 195 ± 2 kcal mol^{-1}, is in good agreement with that obtained from *ab initio* calculations, 191 kcal mol^{-1} (8). These calculations also examined the barrier to interconversion of **1** and **2**, relative to the dissociation pathway of lowest energy requirement, the loss of H$^{\cdot}$. The calculated and experimental results are shown in Fig. 1*a*. That $[CH_3OH]^{+\cdot}$ dissociates by H$^{\cdot}$ loss without an excess energy requirement is known from the photoionisation appearance energy (AE) for this reaction, 11.66 eV (13); calculated for $[\dot{C}H_2OH]$ = 11.66 eV ($\Delta H_f^0[\dot{C}H_2OH]$ =

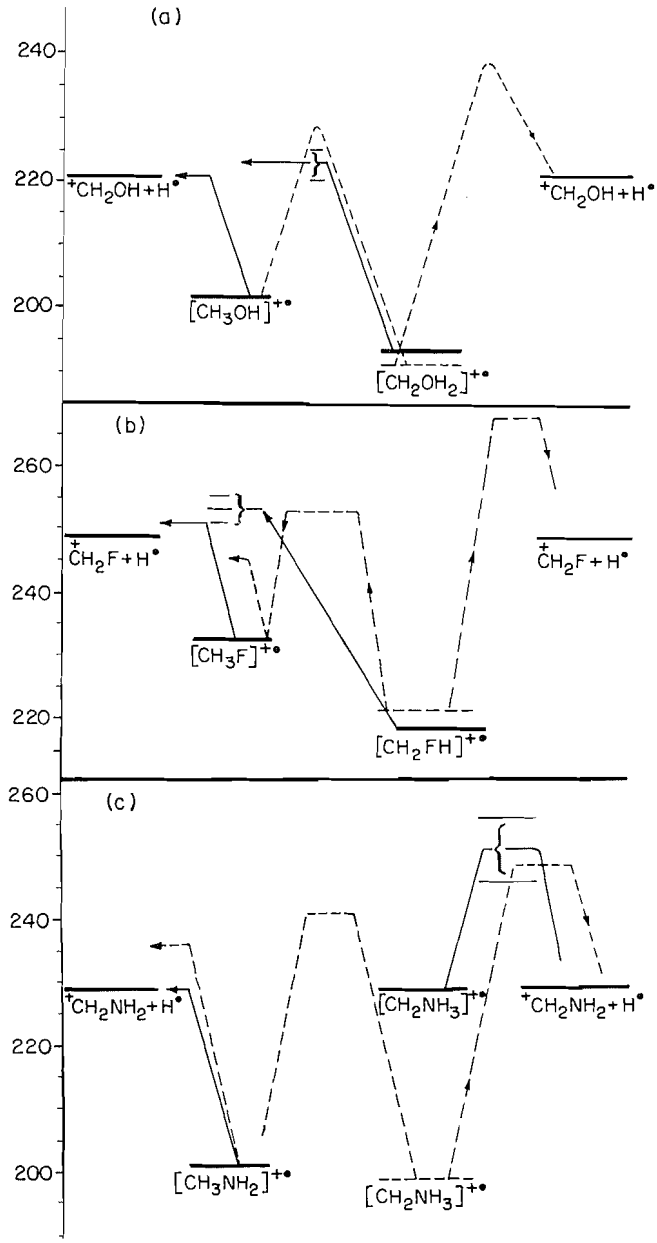

FIG. 1. (*a*) Energy diagram for the dissociation of $[CH_4O]^{+\bullet}$ ions. (*b*) Energy diagram for $[CH_3F]^{+\bullet}$ ions. (*c*) Energy diagram for $[CH_5N]^{+\bullet}$ isomers. Full lines are for experimentally determined energies (see text), broken lines are from *ab initio* calculations (8, 11, and 10) respectively.

169 kcal mol^{-1} (14), ΔH_f^0 [CH_3OH] = −48.0 kcal mol^{-1}, $\Delta H_f^0[H^{\bullet}]$ = 52.1 kcal mol^{-1} (13)). The AE for the metastable peak for loss of $H^{\bullet}$ from $[CH_2OH_2]^{+\bullet}$ was measured using $(CH_2OH)_2$ as the precursor molecule. The standard metastable peak for this comparative measurement (15) was the m/z 74 → m/z 43 fragmentation of methyl acetate. The observed AE, 12.5 ± 0.15 eV, is the same as that calculated for the overall reaction

$$(CH_2OH)_2 \rightarrow \dot{C}H_2OH + H^{\bullet} + CH_2O + e$$

($\Delta H_f^0[(CH_2OH)_2]$ = −92.6 kcal mol^{-1}, $\Delta H_f^0[CH_2O]$ = −26.0 kcal mol^{-1} (16)). The Gaussian-type metastable peaks for $H^{\bullet}$ loss from **1** and **2** have significantly different kinetic energy releases, $T_{0.5}$, measured from the peak width at half height; 9 meV for the former and 34 meV for the latter. Two explanations are formally possible: (*a*) that **2** can dissociate directly to $[\dot{C}H_2OH]$ (*without prior rearrangement* to **1**) or (*b*) that **2** dissociates via rearrangement to $[CH_3OH]^{+\bullet}$. The rearrangement must, however, be the rate determining step, in order to account for the different metastable peak shapes. With reference to Fig. 1, either of the two dissociation barriers must be lower than those from *ab initio* calculations. Explanation (*a*) requires that the ion $[CH_2OD_2]^{+\bullet}$ (produced for example from $(CH_2OD)_2$) should lose only $D^{\bullet}$ whereas (*b*) should proceed via $[CH_2DOD]^{+\bullet}$ and be capable of losing $H^{\bullet}$ or $D^{\bullet}$. The latter is indeed the case, the ion generated from $(CH_2OD)_2$, m/z 34, loses both $H^{\bullet}$ and $D^{\bullet}$, with larger $T_{0.5}$ values (55 and 68 meV respectively) indicative of an isotope effect in the rearrangement step, and in a ratio of approximately 4.6:1.

The homologous ion $[CH_2CH_2OH_2]^{+\bullet}$ has been fully described elsewhere (2, 4) and the ΔH_f^0 for its isomer $[CH_3HOCH_3]^{+\bullet}$ has been given as 176 ± 1 kcal mol^{-1} (4), making it the $[C_2H_6O]^{+\bullet}$ isomer of lowest observed ΔH_f^0. *Ab initio* calculations (9) gave a higher value for ΔH_f^0 $[CH_3HOCH_3]^{+\bullet}$, 185 kcal mol^{-1}, only 1 kcal below that for $[CH_3OCH_3]^{+\bullet}$ and the same as $\Delta H_f^0[CH_3CH_2OH]^{+\bullet}$. The optimum geometry for the ion relates it to a complex between a $CH_3^{\bullet}$ radical and the O atom in $[\dot{C}H_2OH]$ rather than one between ionised methylene and methanol (9) (i.e. the (H_3C)—O bond is longer than (H_2C)—O or H—O). Its only significant unimolecular fragmentation (other than $H^{\bullet}$ loss) is loss of $CH_3^{\bullet}$ to yield $[\dot{C}H_2OH]$, $T_{0.5}$ = 21 meV, an observation which supports its structural assignment. This fragmentation is completely absent in the MI spectra of $[CH_3OCH_3]^{+\bullet}$, $[CH_3CH_2OH]^{+\bullet}$, and $[CH_2CH_2OH_2]^{+\bullet}$. The disagreement between the *ab initio* ΔH_f^0 and the experimental value (185 vs. 176 kcal mol^{-1}) deserves comment. If one considers the ion from the point of view of the effect of methyl substitution on $[CH_2OH_2]^{+\bullet}$, it is difficult to accept the very small reduction in ΔH_f^0 resulting therefrom, 5 kcal mol^{-1}, in the *ab initio* calculations; the observed stabilisation, ca. 19 kcal mol^{-1}, is more characteristic of methyl substitution effects at formal charge bearing or sharing sites (17).

Halogen-containing ions

The ions $[CH_2XH]^{+\bullet}$, isomers of the ionised methyl halides, were made by reaction [2], with X = F, Cl, Br, and I. The ions were readily characterised by their distinctive CA mass spectra which are shown together with those for $[CH_3X]^{+\bullet}$ in Fig. 2. Major differences are apparent in all pairs of spectra except for the iodo-analogues where only small peak intensity differences serve to distinguish the species. For this pair the shapes of the $[M - 15]^{+}$ peaks are complex and different. Reasons for the complex peak shapes have been discussed elsewhere (18, 19).

The CA mass spectra of $[CH_3F]^{+\bullet}$ and $[CH_2FH]^{+\bullet}$ have already been reported (5) and the results are in fair overall agreement with those reported here. The energetics of the ion $[CH_2FH]^{+\bullet}$ have been investigated by *ab initio* calculations (11) and it was predicted to be 11 kcal mol^{-1} more stable than $[CH_3F]^{+\bullet}$. The AE of m/z 34 from FCH_2COOH was measured as 11.6 ± 0.2 eV, whence $\Delta H_f^0[CH_2FH]^{+\bullet}$ = 217 ± 4 kcal mol^{-1}. ($\Delta H_f^0[FCH_2COOH]$ = −145 kcal mol^{-1} (20), $\Delta H_f^0[CO_2]$ = −94.1 kcal mol^{-1} (13)).

The calculations also indicated that $[CH_2FH]^{+\bullet}$ rearranges to $[CH_3F]^{+\bullet}$ prior to H atom loss (the fragmentation of lowest energy requirement) rather than undergo direct dissociation. We have measured the metastable peak AE values for $H^{\bullet}$ loss

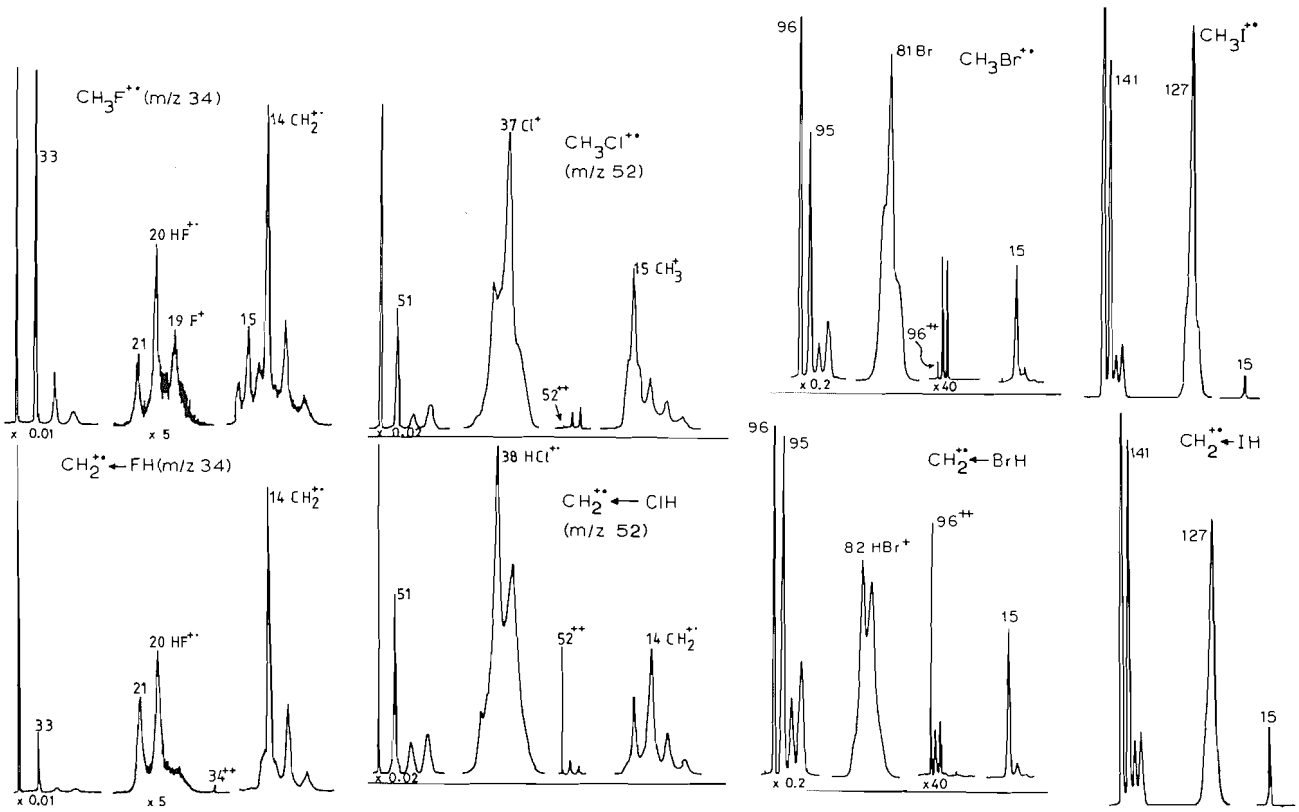

FIG. 2. Collisional activation mass spectra for $[CH_3X]^{+\cdot}$ and $[CH_2XH]^{+\cdot}$ ions, X = F, Cl, Br, I.

from the two ions and the results are shown in Fig. 1*b*. AE$[\dot{C}H_2F]$ from CH_3F was measured as 13.6 ± 0.2 eV (13.4 eV by photoionisation [13]). AE$[\dot{C}H_2F]$ from $[CH_2FH]^{+\cdot}$ generated from CH_2FCOOH was 13.4 ± 0.1 eV, calculated 13.1 eV using $\Delta H_f^0[\dot{C}H_2F]$ = 200 kcal mol^{-1} (13). This system behaves similarly to the oxy-analogue, producing Gaussian-type metastable peaks; $T_{0.5}$ for $[CH_3F]^{+\cdot} \rightarrow [\dot{C}H_2F] + H^{\cdot}$ is 12 meV; for the $[CH_2FH]^{+\cdot}$ fragmentation $T_{0.5}$ = 33 meV. The ion produced by loss of CO_2 from $[CH_2FCOOD]^{+\cdot}$ loses both $H^{\cdot}$ and $D^{\cdot}$, $T_{0.5}$ values 36 and 31 meV, respectively; relative metastable peak abundances 5.5:1 in favour of $H^{\cdot}$ loss. It is concluded that the barrier to rearrangement of $[CH_2FH]^{+\cdot}$ to $[CH_3F]^{+\cdot}$ is only slightly greater than that for the dissociation of the latter to $[\dot{C}H_2F] + H^{\cdot}$.

The heats of formation of $[CH_2ClH]^{+\cdot}$ and $[CH_2BrH]^{+\cdot}$ were measured from their AE values from chloroacetic acid and 2-bromoethanol, respectively. AE *m/z* 50 from $ClCH_2COOH$ = 11.08 ± 0.05 eV; $\Delta H_f^0[ClCH_2COOH] = -104 \pm 2$ kcal mol^{-1} (16) and AE *m/z* 94 from $BrCH_2CH_2OH$ = 11.36 ± 0.05 eV, $\Delta H_f^0[BrCH_2CH_2OH] = -51.4$ kcal mol^{-1} (20). Whence $\Delta H_f^0[CH_2ClH]^{+\cdot} = 246 \pm 3$ kcal mol^{-1} (compare $\Delta H_f^0[CH_3Cl]^{+\cdot} = 239$ kcal mol^{-1} (13)) and $\Delta H_f^0[CH_2BrH]^{+\cdot} = 237 \pm 3$ kcal mol^{-1}, allowing for ± 2 kcal mol^{-1} uncertainty in the additivity calculation (compare $\Delta H_f^0[CH_3Br]^{+\cdot} = 234$ kcal mol^{-1} (13)). Although these two methylene halonium ions clearly are stable species, unlike the oxonium ion they are not thermodynamically more stable than their isomers of conventional structure.

It is worth recording that loss of CO from ionised CH_2ClCHO and CH_2BrCHO produced a mixture of $[CH_3X]^{+\cdot}$ and $[CH_2XH]^{+\cdot}$ ions, clearly shown by the appropriate CA mass spectra. Moreover, the metastable peaks for the reactions $[CH_2XCHO]^{+\cdot} \rightarrow [CH_3X]^{+\cdot} + CO$ were both of composite shape, in keeping with the cogeneration of the above pairs of daughter ions.

Nitrogen-containing ions

The ion $[CH_2NH_3]^{+\cdot}$ is readily generated by the loss of CH_2O from ionised ethanolamine. Its CA mass spectrum, together with that of $[CH_3NH_2]^{+\cdot}$, is shown in Fig. 3. The large differences in these CA spectra and the presence of an intense *m/z* 15.5 (charge stripping) ion, $[CH_2NH_3]^{2+}$, are similar to those observed in the $[CH_3OH]^{+\cdot}$, $[CH_2OH_2]^{+\cdot}$ system and clearly show that $[CH_2NH_3]^{+\cdot}$ is a stable species. The AE of *m/z* 31 could not readily be measured because that of *m/z* 30 $[\dot{C}H_2NH_2]$ was significantly lower. However, a careful comparison of *m/z* 31 vs. *m/z* 30 at low electron energies showed that below ca. 10.9 eV *all* of *m/z* 31 consisted of the ^{13}C or ^{15}N contribution from *m/z* 30. Thus $\Delta H_f^0[CH_2NH_3]^{+\cdot} \geq 229$ kcal mol^{-1} ($\Delta H_f^0[CH_2OHCH_2NH_2] = -48.2$ kcal mol^{-1} (20)), appreciably higher than $[CH_3NH_2]^{+\cdot}$, 201 kcal mol^{-1} (13). Recent *ab initio* calculations (10) give 199 kcal mol^{-1} for $[CH_2NH_3]^{+\cdot}$; the energy diagram for $[CH_5N]^{+\cdot}$ is shown in Fig. 1*c*. Ionised methylamine fragments by $H^{\cdot}$ loss at the thermochemical threshold (21) and the accompanying Gaussian-type metastable peak is associated with only a small kinetic energy release, $T_{0.5}$ = 5 meV. The calculations (10) indicate a reverse activation energy of 6.5 kcal mol^{-1} for this fragmentation. The metastable peak for $H^{\cdot}$ loss from $[CH_2NH_3]^{+\cdot}$ is rather weak and is of composite shape with $T_{0.5}$ = 150 meV (see Fig. 4), probably consisting of a narrow Gaussian-type peak superimposed upon a broad, dished or flat-topped signal. The latter is in keeping with the large excess energy (~1 eV) required for this fragmentation. The metastable peak AE could not be accurately measured because of the low intensity of the signal; hence the

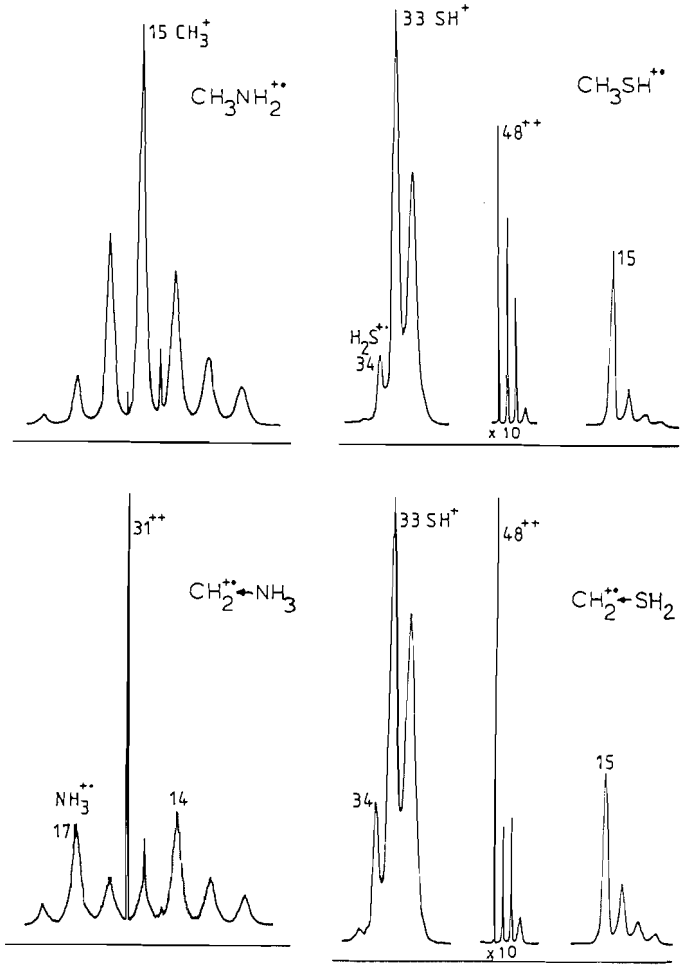

FIG. 3. Partial collisional activation mass spectra for the $[CH_5N]^{+\cdot}$ isomers (m/z 31–26 omitted) and partial collisional activation mass spectra for $[CH_3SH]^{+\cdot}$ and $[CH_2SH_2]^{+\cdot}$ ions (m/z 48 → 44 omitted).

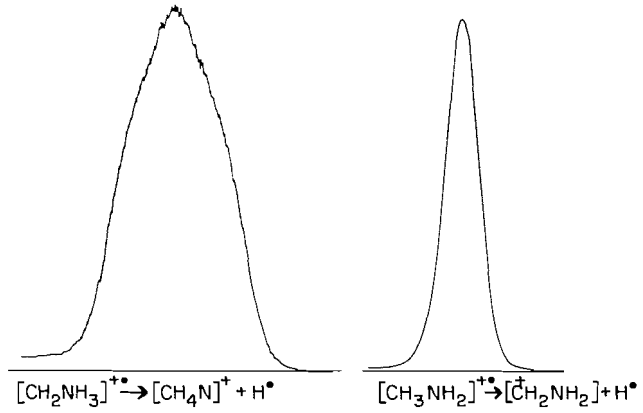

FIG. 4. Metastable peaks for loss of $H^\cdot$ from $[CH_5N]^{+\cdot}$ isomers.

wide error bars in Fig. 1*c*. The narrow component could arise from the cogeneration of an isomeric daughter ion, but ΔH_f^0 values for $CH_3\dot{N}H$ or $CH\dot{N}H_3$ are not available.

The ion derived by loss of $[CH_2NH]$ from $[H_2NCH_2CH_2CH_2NH_2]^{+\cdot}$, m/z 45, was also examined. Its CA mass spectrum was markedly different from those of $[CH_3CH_2NH_2]^{+\cdot}$ and $[(CH_3)_2NH]^{+\cdot}$, being dominated by an intense m/z 18 ion, $[NH_4]^+$, partly unimolecular in origin. The three CA mass spectra are presented in Table 1. Note that only the new ion has a charge stripping peak, m/z $[45]^{2+}$. The MI spectrum of the new ion contains only m/z 30, $[\dot{C}H_2NH_2]$ and m/z 18, abundance ratio 3:1, $T_{0.5}$ for the two Gaussian-type metastable peaks being 18 and 19 meV, respectively. The MI spectra of $[CH_3CH_2NH_2]^{+\cdot}$ and $[(CH_3)_2NH]^{+\cdot}$ are dominated by $CH_3^\cdot$ loss and $H^\cdot$ loss respectively, with minor contributions (ca. 10%) from m/z 18, $[NH_4]^+$. The new ion is best represented as $[CH_2CH_2NH_3]^{+\cdot}$, the ethylene ammonium ion (or the ethene–ammonia radical ion dipole complex), whose fragmentation behaviour is similar to that of its oxy-counterpart (2). This structure assignment is also supported by the observation that the ion $[C_2H_4D_3N]^{+\cdot}$, derived by loss of CH_2ND from $[D_2NCH_2CH_2CH_2ND_2]^{+\cdot}$, loses only $C_2H_3^\cdot$ unimolecularly and that m/z 18 and 17 in the CA mass spectrum of the unlabelled ion are cleanly shifted to m/z 21 and 20 ($[ND_3H]^+$ and $[ND_3]^{+\cdot}$). It should be noted that the facile fragmentations to $[NH_4]^+ + C_2H_3^\cdot$ and to $[\dot{C}H_2NH_2] + CH_3^\cdot$ are similarly endoergic ($\Delta H_f^0[NH_4]^+ = 155$ kcal mol^{-1} (22), $\Delta H_f^0[C_2H_3^\cdot] = 63$ kcal mol^{-1} (23); $\Delta H_f^0[\dot{C}H_2NH_2] = 178$ kcal mol^{-1} (13), $\Delta H_f^0[CH_3^\cdot] = 34$ kcal mol^{-1} (13)) and appreciably less energy demanding than dissociation to $[C_2H_4]^{+\cdot} + NH_3$ or $C_2H_4 + [NH_3]^{+\cdot}$ ($\Delta H_f^0[C_2H_4]^{+\cdot} = 255$ kcal mol^{-1} (13); $\Delta H_f^0[NH_3] = -11$ kcal mol^{-1} (13); $\Delta H_f^0[C_2H_4] = 12.5$ kcal mol^{-1} (13), $\Delta H_f^0[NH_3]^{+\cdot} = 255$ kcal mol^{-1} (13)).

The sulphur-containing ions $[CH_4S]^{+\cdot}$

The CA mass spectra of ionised thiomethanol and the ion generated by loss of CH_2O from $[CH_2OHCH_2SH]^{+\cdot}$ are shown in Fig. 3. The differences between the CA peaks are not nearly so striking as in the oxy-analogues. Nevertheless, the enhanced charge stripping peak $[CH_4S]^{2+}$ and the greater relative abundances of m/z 34 and 14, $[H_2S]^{+\cdot}$ and $[CH_2]^{+\cdot}$, are in keeping with the behaviour of the ion $[CH_2SH_2]^{+\cdot}$. The above differences are unlikely to arise from internal energy effects which are usually only important with respect to fragmentations of lowest energy requirement (25). The AE of m/z 48 from CH_2OHCH_2SH was measured as 10.42 ± 0.05 eV, leading to $\Delta H_f^0[CH_2SH_2]^{+\cdot} = 219$ kcal mol^{-1} ($\Delta H_f^0(CH_2OHCH_2SH) = -47.4$ kcal mol^{-1} (21)). $\Delta H_f^0[CH_3SH]^{+\cdot}$ is 212 kcal mol^{-1} (13). The metastable peak for $H^\cdot$ loss from the two ions were of Gaussian type and identical shape, $T_{0.5} = 28$ meV. It seems likely, therefore, that the barrier to the interconversion of these ions lies below the dissociation threshold, calculated to be 48 kcal mol^{-1} above $[CH_3SH]^{+\cdot}$; $\Delta H_f^0[\dot{C}H_2SH] = 208$ kcal mol^{-1} (24). The AE for $[\dot{C}H_2SH]$ from CH_3SH was measured in this laboratory as 11.48 ± 0.05 eV, (calculated = 11.52 eV ($\Delta H_f^0[CH_3SH] = -5.5$ kcal mol^{-1} (16)).

Experimental

Collisional activation mass spectra and metastable peak shapes were measured with the VG ZAB-2F mass spectrometer in Utrecht as described elsewhere (26). Metastable peak shapes were also obtained using an AEI MS902S mass spectrometer; all kinetic energy release values were corrected for the main beam width (27). Appearance energies (except those measured on metastable peaks) were measured with an apparatus comprising an electrostatic electron monochromator with a quadrupole mass analyser and mini computer data system (28). Metastable peak appearance energies were obtained on the AEI MS902S mass spectrometer using the metastable peaks m/z $74^{+\cdot} \rightarrow m/z$ 43^+ in methylacetate or m/z $204^{+\cdot} \rightarrow m/z$ 77^+ in iodobenzene as the standards (15).

All compounds, except those below, were commercially available and, where necessary, purified by gc. CH_2FCOOH was a gift from

1,*n*-Radical ions: the nature of the one-electron two-centre bond in cyclopropane radical cations. An *ab initio* SCF MO approach

DANIAL D. M. WAYNER, RUSSELL J. BOYD,[1] AND DONALD R. ARNOLD[1]
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada, B3H 4J3

Received February 2, 1983

DANIAL D. M. WAYNER, RUSSELL J. BOYD, and DONALD R. ARNOLD. Can. J. Chem. **61**, 2310 (1983).

The nature of the one-electron two-centre bond in the cyclopropane and 1,2-divinylcyclopropane radical cations is elucidated by use of *ab initio* self consistent field (SCF) molecular orbital (MO) calculations. The charge and spin distributions in the 90,90 and 90,0 conformations are compared at the STO-3G and 4-31G basis set levels. From energy differences between the radical cations in the 90,90 conformation and the 90,0 (transition state) conformation, the activation barriers for *cis*–*trans* isomerization in the $^2A_1$ state of $C_3H_6^+$ and of the 1,2-divinylcyclopropane radical cation are estimated. These results are compared to previous calculations and experimental data where possible.

DANIAL D. M. WAYNER, RUSSELL J. BOYD et DONALD R. ARNOLD. Can. J. Chem. **61**, 2310 (1983).

Faisant appel aux calculs *ab initio* d'orbitale moléculaire (OM) à champ autocohérent (CAC) on a élucidé la nature de la liaison à deux centres et à un électron des cations radicalaires du cyclopropane et du divinyl-1,2 cyclopropane. On a comparé la charge et les distributions de spin des conformations 90,90 et 90,0 au niveau des ensembles de base STO-3G et 4-31G. A partir des différences d'énergie entre les cations radicalaires de la conformation 90,90 et de la conformation 90,0 (état de transition), on a évalué les barrières d'activation de l'isomérisation *cis*–*trans* de l'état $^2A_1$ du $C_3H_6^+$ et du cation radicalaire du divinyl-1,2 cyclopropane. On a comparé ces résultats avec les calculs antérieurs et les données expérimentales disponibles.

Introduction

The structure and reactivity of the radical cations of cyclopropane and its derivatives are of considerable interest and have been the subject of both experimental and theoretical investigation. Most of the theoretical studies (1) have been directed toward the interpretation of the photoelectron spectrum of the parent molecule. In cyclopropane, removal of the electron from either of the two degenerate Walsh MO's of *e'* symmetry (2) leads to two possible structures for the radical cation (Fig. 1). One of these species, having the trimethylene type structure, will have a $^2A_1$ ground state while the other, which resembles the π-complex between ethylene and CH_2^+, will have a $^2B_2$ ground state. Recent calculations by Collins and Gallup (1*a*), using the method of *targeted correlation*, suggest that these two species correspond to saddle points on the radical cation surface. The minimum, having C_s symmetry, is approximately halfway between these structures on the surface.

Although these theoretical studies have been useful in explaining the photoelectron spectrum of cyclopropane, they generally have not provided information that can be used to understand the reactivity of the radical cation. Evidence obtained from chemically induced dynamic nuclear polarization (CIDNP) spectra (3) indicates that most radical cations of alkyl and aryl substituted cyclopropanes tend to favour the $^2A_1$ type structure. There is evidence, however, that in some special cases, such as the radical cation of benzonorcaradiene, the radical cation may assume the $^2B_2$ structure (3*c*).

Theoretical calculations investigating some of the reactions of $C_3H_6^+$ (4) have yielded estimates of the activation energies for the loss of H, H_2, H_2^+, and CH_2^+. One important reaction, which has received little attention from a theoretical point of view, is the thermal *cis*–*trans* isomerization of the cyclopropane radical cation. This reaction is particularly interesting because of the implication of the nature of the one-electron two-centre bond.

Much that is known about the nature of bonding in cyclopropanes (5) and olefins (6) comes from experimental investigation of their thermal reactions, particularly *cis*–*trans* isomerization. Since direct observation of the parent cyclopropane radical cation is difficult, similar data for this system is not available. There is evidence, however, that the radical cation of 1,2-diphenylcyclopropane (3*a*, *b*) does *not* rapidly isomerize. In this work, however, the radical cations were generated by photosensitization (electron transfer). Under these conditions, all other reactions must compete with back electron-transfer. Since it is unlikely that there is a significant activation barrier for this process, it is impossible to determine the lower limit for the barrier to *cis*–*trans* isomerization.

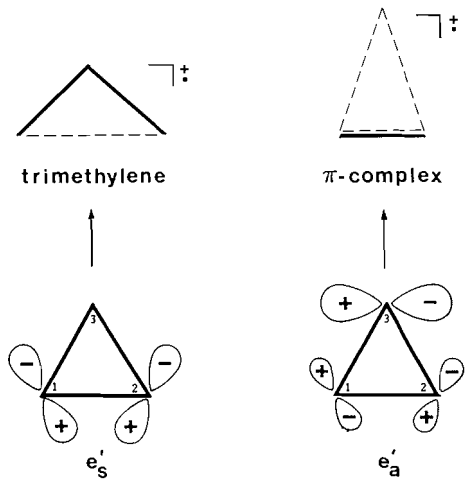

FIG. 1. Walsh MO's leading to the "trimethylene" and "π-complex" structures for the cyclopropane radical cation.

The purpose of this paper is to try to understand the nature of the one-electron two-centre bond in the cyclopropane radical cation. We have used *ab initio* calculations to obtain optimized geometries for the cyclopropane radical cation in the 90,90 conformation (7) (both $^2A_1$ and $^2B_2$ states) and in the 90,0 conformation. The difference in the energies of these species provides an estimate of the strength of the one-electron two-centre bond. This study has been extended to the 1,2-divinylcyclopropane radical cation; the results are pertinent to the

1,2-diphenyl derivative for which some experimental data are available.

Details of calculations

The *ab initio* MO calculations were obtained by the use of the GAUSSIAN 76 program (8*a*). The energies of the radical cations were computed using the open-shell, spin-unrestricted (UHF) procedure (8*b*). Complete geometry optimization of $C_3H_6^+$ in the $^2A_1$ and $^2B_2$ states (C_{2v} symmetry) was carried out using both STO-3G and 4-31G basis sets. The optimization of $C_3H_6^+$ in the 90,0 conformation also was carried out using both STO-3G and 4-31G basis sets; however, in this case a plane of symmetry through the centre of each methylene was maintained.

Calculations on the 1,2-divinylcyclopropane radical cation ($DVCP^+$) were carried out using only the STO-3G basis set. A complete geometry optimization was not feasible. The 4-31G optimized geometry for $C_3H_6^+$ ($^2A_1$) was used as a model for the cyclopropane group while the STO-3G optimized geometry for the allyl cation (9) was used to represent the vinyl groups. The vinyl groups were placed in the plane of the corresponding methylene to ensure maximum overlap through the π-system. In *trans*-$DVCP^+$, the C_2 axis was maintained and in *cis*-$DVCP^+$ the plane of symmetry was maintained. The conformations are best described using the nomenclature derived for conjugated polyenes (in this case 1,3,5-hexatriene), since $DVCP^+$ is structurally similar. Four conformations in the 90,90 conformation were considered (Fig. 2): 2s-*trans*-4s-*trans*-3-*trans* (**1**), 2s-*trans*-4s-*trans*-3-*cis* (**2**), 2s-*cis*-4s-*cis*-3-*trans* (**3**) and 2s-*cis*-4s-*cis*-3-*cis* (**4**). The geometry for $DVCP^+$ in the 90,0 conformation was derived using a similar approach. In this case, however, the STO-3G geometry for the allyl radical (9) was used as a model for the vinyl group on C_2, which was twisted into the plane of the cyclopropane group (*vide infra*). In all cases, the $C_1C_3C_2$ angle (θ) of the cyclopropane group was optimized.

[a]4-31G.

Discussion

Structure of $C_3H_6^+$

The optimized geometries (4-31G) of the cyclopropane radical cation in the 90,90 conformations ($^2A_1$ and $^2B_2$ states) and 90,0 conformation are shown in Table 1. These structures for the $^2A_1$ and $^2B_2$ states are qualitatively similar to those using semi-empirical (1*b*,*c*,*d*, 4) and other *ab initio* methods (1*a*). The geometry in the 90,0 conformation has not been reported previously. While the structures of these species are of great interest, the changes in spin and charge distributions in relation to the structural changes are the important factors in the study of reactivity.

An interesting feature of the $^2A_1$ structure is that the value of α (defined in Table 1, Fig. 3) indicates that C_1, C_3, H_1, and H_2 lie in one plane while C_2, C_3, H_3, and H_4 lie in another plane (indicative of sp^2 hybridization at C_1 and C_2). This geometry allows effective bonding between C_1 and C_2 (Table 2) even though θ has increased relative to that of cyclopropane. The magnitude of θ (only 81.7°) is another indication that there is considerable C_1C_2 bonding interaction in this species. Another interesting aspect of this structure is the geometry at C_3. Although substantial changes have occurred at C_1 and C_2, virtually no change (relative to cyclopropane) in the C_3H bond length or the HC_3H angle occurs. This may be rationalized using the Walsh model for bonding; since the electron has been removed from a molecular orbital which is bonding between C_1 and C_2, large changes at C_3 are not expected if there is still substantial bonding between C_1 and C_2 in the radical cation.

The value of α in the $^2B_2$ structure is much smaller than that in the $^2A_1$ state. Since this structure is described as a π-complex between ethylene and CH_2^+, it is useful to consider an angle β which we define as the angle between the C_1C_2 bond and the

[b]Atomic units.

intersection of the plane of the methylene with the plane of the carbons (Fig. 3). In this case, β has a value of 167.2° (for ethylene the corresponding angle would be 180.0°). The lengthening of the C_1C_3 and C_2C_3 bonds and concurrent shortening of the C_1C_2 bond are consistent with the structure predicted by the Walsh model. The antisymmetric MO extends over all three carbons; consequently, the geometries of all three methylenes in this state differ substantially from those in cyclopropane.

The cyclopropane radical cation in the 90,0 conformation shows no evidence for bonding between C_1 and C_2 (Table 2). The C_1C_3 bond has shortened while the C_2C_3 bond (the plane of the C_2 methylene has rotated 90°) has lengthened. The C_1H and C_2H bond lengths are essentially unchanged compared to cyclopropane. On the other hand, the longer C_3H bond, the large value of θ, and the smaller HC_3H angle are characteristic of a normal alkane bond. Further investigation, in fact, reveals that the C_1C_3 and C_2C_3 bond lengths are similar to those calculated for the 1-propyl cation (9). In the case of the 1-propyl cation, the C_1C_3 and C_2C_3 bond lengths (using a 3-21G basis set) were found to be 1.438 Å and 1.536 Å respectively.

The charge and spin distributions in each of these structures are shown in Table 3. In the $^2A_2$ structure only 20% of the charge is delocalized to the C_3 methylene. Similarly, most of the spin density remains between C_1 and C_2. This, of course, is consistent with the Walsh model described previously. In the $^2B_2$ structure the charge is almost equally distributed between the three methylenes, 30% on the C_3 methylene and 35% on each of the C_1 and C_2 methylenes. The spin density, however, is almost entirely localized on C_3. Thus, the description of the $^2B_2$ state as a complex between CH_2^+ and ethylene is appropriate.

The charge and spin distributions in the 90,0 conformation are also consistent with its structures. The charge is localized essentially on the C_1 methylene (71%) and to a lesser extent on C_2 and C_3 (21% and 8% respectively). The spin, on the other hand, is localized almost completely on C_2; the remainder is on C_3. These spin and charge distributions may be understood qualitatively by considering two possibilities. In the first, the spin is localized on C_2. This may be described as an "ethyl cation−methyl radical" pair. In the other case the charge is localized on C_2; this would be an "ethyl radical−methyl cation" pair. Since the ionization potential of the methyl radical is greater than the ionization potential of the ethyl radical (10) the former case would be expected to be energetically favourable. The alternate lengthening of the C_2C_3 bond and shortening of the C_1C_3 bond may be a result of the charge polarization. The C_1 carbon atom has a net positive charge (Table 3) while the C_3 carbon atom and C_2 carbon atom are both negatively charged. The Coulombic interactions between the carbons may be responsible for this alternation in bond lengths.

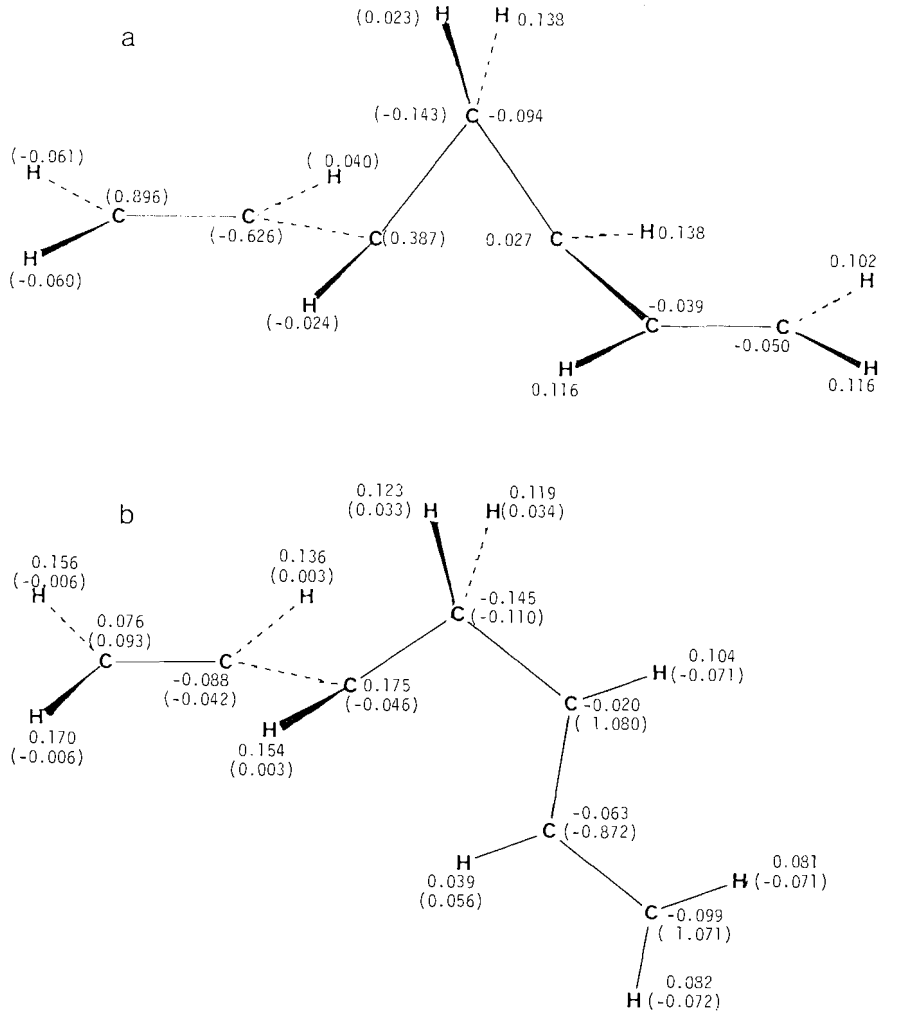

FIG. 4. Charge and spin distributions in $DVCP^+$ in the 90,90 and 90,0 conformations. The spin densities are in parentheses.

imizes the π-overlap between the vinyl groups and the respective cyclopropane carbons. This could have the result of lengthening the C_1C_2 bond since it may be expected that the more effectively the electron density is delocalized, the weaker the C_1C_2 bond should become. The value of θ in the 90,0 conformation is larger than that in the unsubstituted radical cation. This may be a consequence of the increased steric interactions with the allyl system at C_1. The steric repulsions in structure **4** are predominant. Because of CPU time restrictions it was not feasible to optimize the dihedral angles about the methylenes. However, it seems likely that the radical cation in this conformation should undergo a facile Cope rearrangement since the activation energy for the analogous rearrangement of *cis*-1,2-DVCP is only 20 kcal mol^{-1} (11).

The charge and spin distributions in the 1,2-divinylcyclopropane radical cation in the lowest energy 90,90 conformation (**1**) and in the 90,0 conformation are shown in Fig. 4. Only the $^2A_1$ structure was considered for the cyclopropane system. The experimental evidence obtained from CIDNP studies (3) is best interpreted in terms of a structure of this type. Involvement of the $^2B_2$ structure would render two substituents in spacially nonequivalent environments. The loss of the symmetry would complicate the choice of model geometries for each vinyl group. Finally, we are primarily interested in the *cis–trans* isomerization of the radical cations; it seems likely that a structure similar to the $^2A_1$ geometry would be involved.

The geometry of the vinyl groups was based on the STO-3G geometry of the allyl cation. Since almost all of the spin density appears on C_2 in the 90,0 conformation, the geometry of the allyl radical was used for the C_2 vinyl group in this case. The difference in energy using the allyl cation geometry at C_2 and that using the allyl radical geometry was only 1.8 kcal mol^{-1}.

In the 90,90 conformation, both charge and spin are delocalized into the vinyl groups. The C_3 methylene still has 18% of the charge (compared to approximately 20% in the unsubstituted case). Similarly, in the 90,0 conformation, only 10% of the charge is delocalized to the C_3 methylene and 12% to the C_2 vinyl system (compared to 8% and 21% respectively in the unsubstituted radical cation). Essentially all of the spin density remains at the C_2 vinyl system in this conformation.

Isomerization of $C_3H_6^+$

The surface for *cis–trans* isomerization of cyclopropane has been investigated (12). In this study, the activation energy was estimated as the difference in energy between cyclopropane and the trimethylene diradical in the 90,0 conformation. One interesting point which we are now able to discuss is the comparison of the calculated barrier for isomerization in cyclopropane with that in the radical cation.

A similar study investigating the rotational barrier in the ethylene radical cation has recently appeared (13). It has long been accepted that the electronic structure of cyclopropanes is

[c]Reference 12.
[d]Reference 5.

conceptually similar to the electronic structure of olefins (14). Another point which we are now able to discuss is whether or not this analogous behaviour is evident in the radical cations.

The calculated activation energies for isomerization of C_3H_6, $C_3H_6^+$, and $C_2H_4^+$ are shown (Table 5). There is still substantial bonding between C_1 and C_2 in $C_3H_6^+$. However, one might expect the bond strength to decrease by at least one-half of the value in cyclopropane since the electron has been removed from the symmetric Walsh orbital. The calculated activation energy for *cis–trans* isomerization of $C_3H_6^+$ is *less* than half that for C_3H_6. It is important to point out that the work of Collins and Gallup (1*a*) predicted the energy of the $^2A_1$ structure to be 6.65 kcal mol^{-1} higher than that of the $^2B_2$ structure. Our results have predicted the energy of the $^2A_1$ structure to be 6.19 kcal mol^{-1} lower than that of the $^2B_2$ structure. Interpretation of the photoelectron spectrum of cyclopropane obviously requires inclusion of correlation (1*a*). However, it is not clear how correlation would affect the relative energy of the 90,0 conformation. The geometry of the $^2A_1$ structure predicted by the calculations of Collins and Gallup still appears to have a small value of θ. It is, therefore, not unlikely that the relative energy of the 90,0 conformation would be similar to that which we predict. The qualitative conclusions in which we are interested would be essentially unchanged even if the relative energy was to change by as much as 5 kcal mol^{-1}.

It is interesting to note that the experimentally determined π-bond strength in ethylene (6) is approximately the same as the σ-bond strength in cyclopropane (5). The difference in the calculated activation energies (at the 4-31G level) of $C_3H_6^+$ and $C_2H_4^+$ should therefore be discussed. The one-electron oxidation of ethylene leads to a species which has little internal strain. We are tempted, therefore, to attribute the difference between the activation energies for *cis–trans* isomerization of $C_3H_6^+$ and $C_2H_4^+$ to the ring strain in the cyclopropane radical cation. We must use caution, however, since the difference between the calculated activation barrier for isomerization in C_3H_6 and C_2H_4 using the same basis set is, to our knowledge, not available. If the calculated activation barrier for C_2H_4 is significantly higher than that for C_3H_6, the difference in the radical cations may be meaningless. (One calculation using a double-zeta basis set with polarization and diffuse functions estimates the activation barrier for ethylene to be 62.5 kcal mol^{-1} (15)). It should be noted that the twist angle at the energy minimum in $C_2H_4^+$ is 25 degrees, apparently a compromise between π-overlap and hyperconjugation (16). The planar structure, however, is only 0.67 kcal mol^{-1} higher in energy than the twisted minimum.

Isomerization of DVCP$^+$

The *cis–trans* isomerization of the 1,2-diphenylcyclopropane radical cation has been studied by CIDNP techniques (3*a*,*b*). When 1,4-dicyanonaphthalene was used as the photosensitizer (electron transfer), *cis–trans* isomerization occurred and nuclear polarization for both isomers was observed. However, when chloranil was used as the photosensitizer (electron transfer), no isomerization was observed (3*b*) but the starting material showed nuclear polarization. The results of these CIDNP experiments led to the conclusion that, in the case of 1,4-dicyanonaphthalene, back electron-transfer in the radical ion pair generated the triplet state of 1,2-diphenylcyclopropane which then isomerized. On the other hand, back electron-transfer to the 1,2-diphenylcyclopropane radical cation from the chloranil radical anion only generated the ground state singlet of the cyclopropane since the triplet energy of the radical ion pair was insufficient to generate the triplet of the cyclopropane. The observed polarization of the starting material gave evidence for a radical cation of the $^2A_1$ type, while the lack of the other isomer indicated that the radical cation did not efficiently isomerize. Since there is probably no activation barrier for back electron-transfer in the radical ion pair, any activation barrier for isomerization will effectively inhibit this process.

An estimate of the activation barrier for isomerization of the 1,2-diphenylcyclopropane radical cation may be obtained by comparing the energies of the 90,90 and 90,0 conformations of $DVCP^+$. This is a reasonable model, considering the C—H bond dissociation energies of toluene and propene are approximately equal (17). The calculated energies of $DVCP^+$ relative to structure **1** are shown in Table 4.

The relative energies of **1**, **2**, and **3** are consistent with the results of recent calculations on vinylcyclopropane (18), s-*trans* being more stable. Structure **1** and **2** are geometric isomers having the same conformation of the vinyl groups (s-*trans*). The energy difference between **1** and **2** (4.25 kcal mol^{-1}) is similar to the energy difference observed from the thermal isomerization of 1,2-diphenylcyclopropane (about 2.3 kcal mol^{-1}) (19).

The energy difference between **1** and the radical cation in the 90,0 conformation represents the activation barrier for isomerization of the radical cation. The value of 14.23 kcal mol^{-1} indicates a bond weakening of approximately 9 kcal mol^{-1} relative to the unsubstituted radical cation (Table 5). This may be compared to the difference in σ-bond strength observed experimentally between cyclopropane and 1,2-diphenylcyclopropane, about 30 kcal mol^{-1}. The effect of the substituents on the stability of the transition state relative to the ground state in the neutral molecule is expected to be far greater than in the radical cation; there is charge and spin delocalization in both the ground and transition states in the radical cation.

In the photochemical generation of the radical ions, this activation barrier would prevent *cis–trans* isomerization of the radical cation. If a preexponential factor of 10^{14} is assumed for the isomerization (20), the rate constant for *cis–trans* isomerization of the radical cation would be only 4.3×10^3 s^{-1} at 300 K.

Conclusions

The calculated barrier to *cis–trans* isomerization (18.2 kcal mol^{-1}), the Mulliken overlap population, and the value of θ (81.7°) indicate that there is significant bonding between C_1 and C_2 in the cyclopropane radical cation ($^2A_1$). In the 90,90 conformation both spin and charge are extensively delocalized; however, in the 90,0 conformation the spin density is localized

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

on C_2.

The charge and spin densities in the 1,2-divinylcyclopropane radical cation are both delocalized into the vinyl groups. The small value for θ as well as the calculated barrier to *cis*–*trans* isomerization (14.2 kcal mol^{-1}) indicate that even in this species the strength of the one-electron two-centre bond is substantial. These results have been related to the 1,2-diphenyl derivative (for which experimental data are available) and indicate that *cis*–*trans* isomerization should be observed if the lifetime of the radical cation is in the order of 100 μs.

Laser interferometric galvanostatic studies in the $Zn/ZnSO_4/Zn$ system with gelled electrolyte short time electrolysis

R. N. O'BRIEN AND W. MICHALIK

Department of Chemistry, University of Victoria, P.O. Box 1700, Victoria, B.C., Canada V8W 2Y2

Received January 7, 1983

R. N. O'BRIEN and W. MICHALIK. Can. J. Chem. **61**, 2316 (1983).

Electrolysis in the system $Zn/ZnSO_4/Zn$ with gelled electrolyte was followed for short times to allow use of the first term only of the solution to Fick's Second Law for transient conditions. Sufficiently good agreement was found between theory and experiment to confirm that no convection occurred in the gelled electrolyte. Similarly sufficiently good agreement with liquid electrolyte runs confirmed that no convection occurred in parallel plate, horizontal electrodes when the cathode was over the anode. The conductivity of the gelled electrolyte was about 11% lower than the liquid electrolyte.

R. N. O'BRIEN et W. MICHALIK. Can. J. Chem. **61**, 2316 (1983).

On a utilisé le système $Zn/ZnSO_4/Zn$ dans un électrolyte sous forme de gel afin d'étudier l'électrolyse pendant de courtes périodes dans le but de permettre uniquement l'emploi du premier terme de la solution de la seconde loi de Fick relative aux conditions transitoires. L'accord entre la théorie et l'expérience est sufissamment parfait pour confirmer l'absence de convection dans l'électrolyte en gel. D'une manière analogue l'accord relativement parfait avec les essais portant sur des électrolytes liquides confirme qu'il n'y a pas de convection lorsque des électrodes horizontaux sont dans un plan parallèle avec la catode placée en dessus de l'anode. La conductivité de l'électrolyte sous forme de gel est d'environ 11% plus faible que celle de l'électrolyte liquide.

Introduction

In electrolysis in galvanostatic conditions, constant concentration polarization and consequently a constant concentration gradient at the working electrodes is to be expected when certain limiting conditions obtain. The simplest condition to produce a constant concentration profile at a working electrode surface is the natural convection at a vertical electrode which results from depletion (and usually a lower density) of solution at the cathode and enrichment at the anode (1). The convective flow limits the thickness of the diffusion layer and its concentration gradients.

The case of horizontal plane parallel electrodes with the anode over the cathode (A/C) results in turbulent, intense natural convection and a general average concentration polarization which is constantly changing at any individual point (1*a*). Rapid forced convection (stirring) produces a reduced and constant thickness, constant concentration gradient diffusion layer. The more sophisticated system of the rotating disc limits the diffusion layer and supplies the electroactive ion by convective diffusion (2). Thus, convective flow, the more efficient supplier of reactants to the electrode surface, replaces diffusion (and migration) as the dominant transport mechanism at all but the shortest distances from the electrode surface. A calculation of relative effects of the two mechanisms has been done (3). At short distances viscous shear forces eventually limit transport by convection.

Usually diffusion and migration are lumped together and the effect of migration in convectionless transport equations is supposed to be adequately accounted for by applying the appropriate transference number to account for the lowered concentration changes found for the unsteady state (4). However, since approximately pure migration has been observed before diffusion begins when a well characterized Teflon electret is immersed in electrolyte (5) and since constant concentration gradients, where diffusion exactly balances migration (in the absence of convection), have been observed (6), it is obvious that this method of accounting for migration is inadequate and in fact of the wrong mathematical form. The correct analytical form of the differential equation has resisted efforts to solve it to date. But it is clear that for some electrolyte concentrations, current profile, and electrode separations (in the C/A orientation), the diffusion layer will attain a constant thickness and concentration gradient while in most cases this transient condition will cause continued expansion of the diffusion layer. However, according to Wagner (7) (and observed by us qualitatively) (1*b*, 4) the concentration gradient near the electrode remains constant. Small changes do appear in the concentration gradient near the electrode with time in this work and will be discussed.

Rosebrough and Miller (8) showed that at long times of electrolysis, when the conditions could no longer be considered to conform to the semi-infinite diffusion constraints used in all recent solutions to Fick's Second Law, a straight line concentration profile should be attained. They also predicted that when this transition point is reached, new (less steep) concentration gradients near the electrode will occur.

Addressing only the case for a constant concentration gradient where migration and diffusion are equal it appears likely that if a proper solution (of mathematically correct form and fitting the best data) to the Fick's Second Law differential equation could be found, that transference numbers, diffusion coefficients, and effective electric fields would follow. The present work was undertaken to investigate, and it is hoped to settle, whether convection plays a role, other than minor in the C/A orientation where none is conventionally expected. Elimination on a truly sound experimental basis would therefore be a useful exercise, not possible by other presently forseeable means than a gelled electrolyte in an interferometric electrodeposition cell.

Theory

The complete electrochemical transport equation can be written (12)

$$[1] \quad J_i = -D_i\left(\frac{\partial C_i}{\partial x}\right) + u_i\nu_i C_i E + \nu C_i$$

where J is total flux (mol cm^{-2} s^{-1}), D is the diffusion coefficient (cm^2 s^{-1}), C_i is concentration (mol cm^{-3}), x is distance

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

perpendicular to the working electrode face (cm), u is mobility ($cm^2\ s^{-1}\ V^{-1}$), ν_i is the charge on the ion, E is the electric field ($V\ cm^{-1}$), and v is the fluid velocity ($cm\ s^{-1}$). The terms on the right hand side are, successively, diffusion, migration, and convection (9, 10).

Convection is eliminated by using a stagnant solution and then arranging the cathode over the anode. Because all salts are heavier than water, in water solution, this results in density layering because the concentration decreases at the top electrode (cathode) and increases at the bottom for systems of the type $Zn/ZnSO_4/Zn$. Further for any random perturbation a strong (relative to expected disturbing forces) restoring force exists and grows with time.

Considering next the remaining transport modes, no diffusion can occur unless a diffusion or concentration gradient $\partial c/\partial x$, exists since the diffusion force is a free energy gradient

$$\frac{\partial G}{\partial x} = -\mu \frac{\partial n}{\partial x}$$

where μ is the electrochemical potential. Clearly at some set of conditions of current density, concentration of electrolyte, and temperature, a balance between migration creating a concentration gradient (as adjacent ions are attracted and discharged) and diffusion eliminating it must exist and has been recently demonstrated (5). Such a condition has been attained under semi-infinite diffusion conditions (6) and under non-semi-infinite conditions (11). These data are good evidence for no convective transport because (1*b*, 4) the diffusion layer thickness is very large compared to that of convecting systems and the diffusion layer and concentration gradient grew normally for much longer times (1200 s compared to 60 s) than it does under convecting systems.

The concentration changes in the diffusion layer under galvanostatic and non-convective conditions can be obtained by solving Fick's Second Law for the appropriate conditions. If the Laplace transform solution, rather than the Fourier transform (8) is found, it is a series solution which transforms to

$$[2]\quad \Delta C_{(x,t)} = \frac{2I}{\nu F}\frac{t^{1/2}}{D^{1/2}}(1 - t_+)\left[\text{ierfc}\left(\frac{2l - x}{2\sqrt{Dt}}\right) - \text{ierfc}\left(\frac{x}{2\sqrt{Dt}}\right)\right]$$

where I is the current density ($A\ cm^{-2}$), t is time (s), ν is the number of charges per ion, F is the Faraday (coulombs per equivalent), ierfc is the integrated error function complement, t_+ the cation transference number, and the other symbols have their previously defined significance.

When the time of electrolysis is short (<180 s) only the first term is required, and if literature arguments are agreed to (12, 13) the effect of migration is taken care of by multiplying the whole expression by one minus the transport number of the electro-active ion ($1 - t_+$) in this case. Clearly this modification to the diffusion expression cannot suffice in the cases of a constant concentration gradient where t_+ must approach one and t_-, zero. This condition arises because since the anion cannot be discharged it ceases to migrate or diffuse and (at least in the bulk) merely provides electroneutrality as required.

Some optical problems require discussion. McLarnon, Muller, and Tobias have shown (14) that in thick interferometric cells, the point on which one focusses the optical recording device (a film or video camera) is important and that for any cell with a high refractive index gradient corrections are necessary to the position of the electrode and the value found for the concentration. However, errors in analysis in their paper for our thin cells used under the present conditions (low concentration, low current density, and low concentration or refractive index gradient) are less than the experimental errors encountered in hand measurements which are about $\pm 1\%$. We have, therefore, made no calculated corrections although much simpler, and for our systems, satsifactory methods have been evolved (12). In one of these systems, two selected points on an interference fringe at different distances from the electrode are evaluated for ΔC. The time is known and x is selected so using the ΔC calculated from the interference fringe, the current density, I, can be calculated from eq. [2] for each point. If the two c.d.'s are not the same, then a small increment of x is added at the anode (or subtracted at the cathode) successively until the c.d.'s approach each other which they must do in these galvanostatic experiments. Usually a minimum difference in current density is quickly found (4–6 trials) and the concentration gradient can be replotted using the new values of x.

Experimental concentrations were calculated in the usual way (4, 15, 16).

Experimental

Gels of 0.3% by weight agar containing also 0.1 *M* $ZnSO_4$ were difficult to cast in an interferometer where some wedge adjustments must be made. The liquid gel was introduced by syringe into the cell and adjustments made before and during solidification. The gel was very fragile and frequently fractures would occur and hence fringes were often unsatisfactory because they were discontinuous or blurred in some part of their length.

The cell was similar to those often described (1, 4, 16).

The zinc electrodes were recast from 99.999% pure Zn supplied by Cominco Ltd. (Trail, B.C.) to ensure a fine-grained structure. Both electrodes were mechanically polished on 600 grit emergy paper before use. All solutions were made from Analar grade materials and four times distilled water. All runs were done at a room temperature of 22 ± 0.5°C.

Only short times in some very long runs were analysed for this paper.

The electrodes were horizontal, cathode over anode, were 8 mm apart and each was 3 mm thick.

Results and discussion

It is generally considered that agar gels of less than 1% should behave as if the solution were liquid (17). This was found to be a good approximation both as regards the appearance of interferograms as shown in Fig. 1 and in a plot of the results Fig. 2, if convection is assumed absent.

Figure 1 shows interferograms at elapsed times of electrolysis of zero, 15 s, 60 s, and 180 s in the gelled electrolyte at 0.5 $mA\ cm^{-2}$. The concentration gradient can be seen to develop in a normal way for convectionless sytems with times elapsed. Figure 2 is a plot of concentration change vs. distance out from the electrode. The three times associated with the interferograms in Fig. 1 are plotted; 15 s, 60 s, and 180 s and values calculated from eq. [2] are also plotted for comparison. The experimental and calculated values obviously have the same form and the actual values agree to about within 15%, the largest absolute discrepancies being the value at the electrode surface. This discrepancy is greatest at the cathode. At both electrodes, the discrepancy at the electrode surface becomes a smaller fraction of the reading with time. Since the concentration of Zn^{2+} is 0.1 *M* and at the natural pH of 4.7 the H^+ is $\sim 2 \times 10^{-5}$ *M*, the hydrogen ion which has a molar refraction

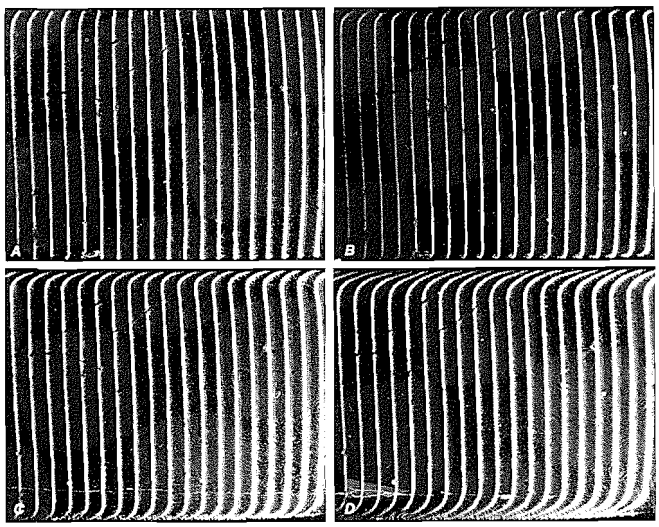

FIG. 1. Panels *a–d* show interferograms at zero, 15 s, 60 s and 120 s elapsed time of electrolysis in 0.3% agar gel, 0.1 *M* $ZnSO_4$ solution in the system $Zn/ZnSO_4/Zn$ at 22 ± 0.5°C and 0.5 mA cm^{-2} current density. The electrodes are 8 mm apart.

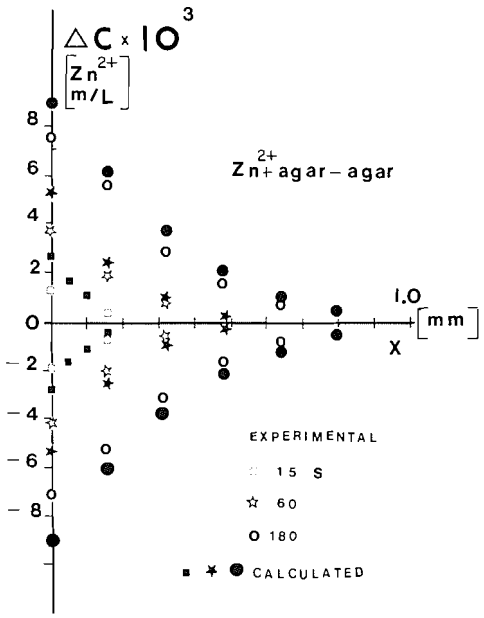

FIG. 2. Concentration change vs. distance vertically from the electrode face at three times of electrolysis, experimental and calculated values.

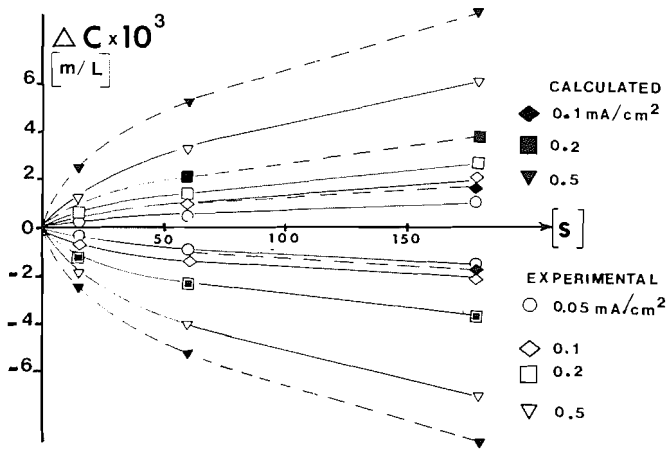

FIG. 3. Concentration change vs. time, calculated and experimental for three current densities.

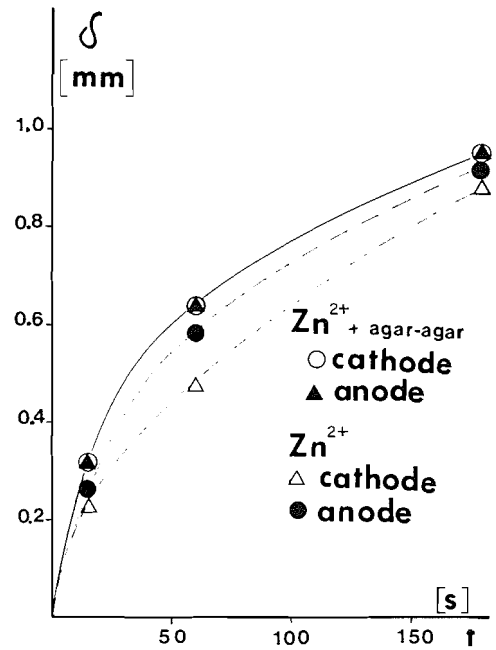

FIG. 4. Diffusion layer thickness vs. time of electrolysis in gelled and liquid electrolyte.

(14) of ~ −0.5 (compared to zinc ion at ~ +0.3) will lower the apparent concentration change at the cathode as calculated from the refractive index of the solution near the cathode (see Appendix 1). Since the mobility of the hydrogen ion is much larger than the zinc ion the effect of hydrogen ion migrating to the cathode but not being reduced and therefore forming a steep concentration gradient would be to lower the refractive index (and apparent concentration). At shorter times and shorter distances this is the effect noted, which agrees with previous work on pH changes at working electrodes (15). It is also an assumption in Wagner's electro-neutrality argument (16).

At the anode, the hydroxyl ion has greater mobility than the sulfate ion and their molal refractions are 5.15 and 7.36 respectively and again it would be expected the ΔC values would be too low especially at short times and small distances from the anode. This appears to be the case, and again this agrees with other experimental findings (13, 20, 21). At approximately 0.15 mm, these effects seem to have disappeared.

Figure 3 shows the value of ΔC at the electrode surface for 0.1, 0.2, and 0.5 mA cm^{-2} plotted against time with the calculated values also plotted. The plot shows that absolute differences increase but the relative error at the electrode decreases, the opposite tendency expected for optical anomalies (14). The D_{ZnSO_4} used was 6.87×10^{-5} cm^2 s^{-1} calculated from its infinite dilution conductivity; the anion transport number used was 0.616. Since both are limiting values, they are probably a little too high.

The thickness of the diffusion layer with time should be the same for liquid and gelled electrolytes if agar does not change the mobilities. Figures 4 and 5 show that very little change can be noted, but perhaps the attainment of a slightly thicker layer at shorter times and perhaps a slightly greater slope to diffusion

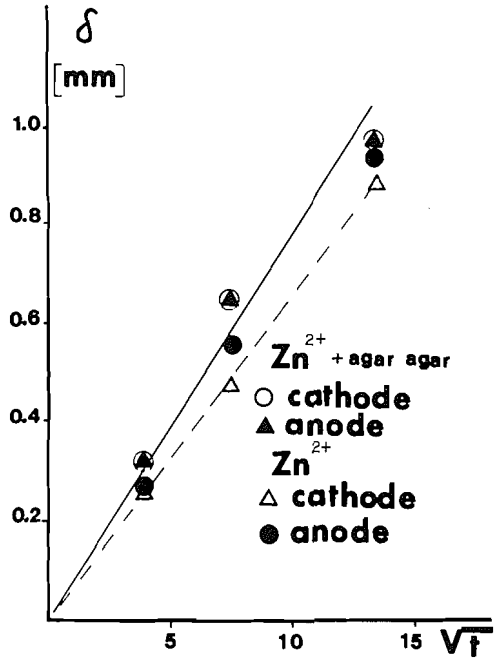

FIG. 5. Diffusion layer thickness vs. the square root of electrolysis time, experimental and calculated.

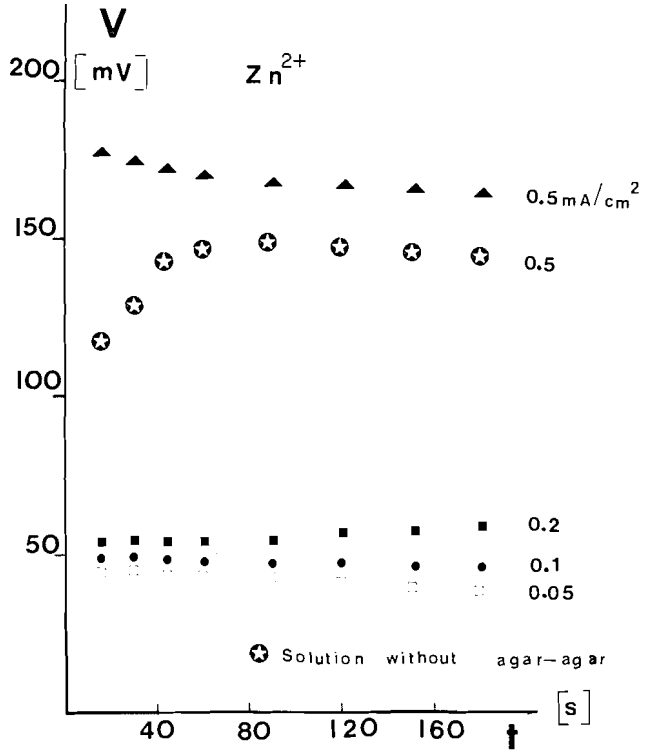

FIG. 6. Impressed potential to give various current densities vs. time.

layer thickness vs. the square root of time.[1] Figure 6 tends to confirm these results though for 0.2 mA cm^{-2}, polarisation increases with time. Concentrating on 0.5 mA cm^{-2} the liquid electrolyte conductivity (if impressed voltages are compared for identical runs in the same cell) appears to go through a maximum whereas with agar the conductivity appears to increase.[2] If hydrogen ions are associated with the polysaccharide agar then because a certain time of residence is implied and hence a slowing of the rate of migration and diffusion of hydrogen, it seems reasonable that conductivity should increase rather than go through a maximum. Note also that the conductivity and polarisation of the gelled solutions settles to about 11% less than the liquid electrolyte. Clearly Walden's rule ($\Lambda\eta = k$) is not obeyed, nor should it be expected to be obeyed in such gels. Finally Zn^{2+} is not paramagnetic and so does not give a magnetic fluid in solution and the observed magnetic field induced convection in Cu^{2+} solutions should not occur (22, 23).

Conclusions

At short times of electrolysis, gelled electrolytes at least in the $Zn/ZnSO_4/Zn$ system behave in a closely similar way to the liquid electrolyte. It can therefore be concluded that gelling with small amounts of polysaccharides, in this case agar, does not change the diffusion coefficient very much. This implies that the very open network of polysaccharide molecules which causes the gelling must allow solvated molecules and some ions almost free passage.

It is concluded that convection is absent in parallel plate horizontal electrodes in the cathode over anode configuration. The conductivity, concentration profiles and diffusion layer thickness all conform with these predicted by the transient diffusion expression as well as can be expected in its present imperfect form. It now seems possible that transport numbers will become available by calculation. Also the state of non-semi-infinite diffusion can be confidently approached.

[1] Note that for agar-agar solution the thicknesses of diffusion layers for both anode and cathode are the same within 180 s of electrolysis.

[2] In both solutions, aqueous and agar-agar, the polarisation is a diffusion polarisation (see Fig. 5) and the gradient of concentration at the surface is very similar. Therefore the differences in the applied voltage could be referred to the differences in the conductivity of these solutions.

Appendix

Polukarpov (19) found changes up to 4 pH units at the electrodes at high current densities using a universal indicator. If a pH change of 2 units at each electrode is assumed (cathode $4.7 \rightarrow 2.7$, anode $4.7 \rightarrow 6.7$), the refractive index change can be calculated. Remembering the Lorentz–Lorentz expression

$$R = \frac{M}{P}\left(\frac{n^2 - 1}{n^2 + 2}\right)$$

and for mixtures (solutions)

$$R_{sp} = \frac{p_1 R_1 + p_2 R_2 + \ldots}{p_1 + p_2}$$

where R is the molar refraction (cm^3), M the molecular weight (g), ρ the density (g cm^{-3}), n the refractive index (a ratio), R_{sp} the specific refraction, and p the proportion of the material (ion) present, and assuming electrical neutrality so that the change in hydrogen concentration ($\sim 2 \times 10^{-3}\ M$) is subtracted from the change in zinc ion concentration ($\sim 7.2 \times 10^{-3}\ M$) to give $[Zn^{2+}] \simeq 7.0 \times 10^{-3}$, then

$$\Delta C_{exp} = \frac{2 \times 10^{-3}(-0.5) + 5.2 \times 10^{-3}(0.3)}{7.2 \times 10^{-3}(0.3)} \times 9.0 \times 10^{-3}$$
$$= 2.33 \times 10^{-3}$$

which is much too low compared to 7.2×10^{-3} found and 9.0×10^{-3} calculated. For $\Delta pH = 2$ pH units

$$\Delta C_{exp} = \frac{2 \times 10^{-4}(-0.5) + 7.0 \times 10^{-3}(0.3)}{7.2 \times 10^{-3}(0.3)} \times 9.0 \times 10^{-3}$$
$$= 8.33 \times 10^{-3}\ M$$

which is too large. A pH of 3.3 would give almost the exact value or a change of 1.4 pH units which does not seem improbable.

At longer times it would be expected that the discrepancies would become smaller because the faster diffusing hydrogen ion would now replace the zinc ion. It should also be remembered the sulfate ion has a higher diffusion constant than zinc and a higher refractive index. The complications of the sulfate–bisulfate equilibrium have been dealt with by Newman (13) but, we believe, do not really alter the basic argument.

Thermodynamics of ternary mixtures of non-electrolytes: excess volumes

PREM P. SINGH[1] AND VINOD K. SHARMA

Chemistry Department, Maharshi Dayanand University, Rohtak-124001 (Haryana), India

Received September 9, 1982[2]

PREM P. SINGH and VINOD K. SHARMA. Can. J. Chem. **61**, 2321 (1983).

Molar excess volumes, V^E_{ijk}, of some $(i + j + k)$ ternary mixtures of non-electrolytes have been determined dilatometrically at 298.15 and 308.15 K and the same have been analysed in terms of (*a*) Lacombe and Sanchez theory and (*b*) an approach based on the mathematical discipline of graph theory utilizing information on the $(i + j)$, $(j + k)$, and $(k + i)$ binary mixtures alone. It has been observed that the V^E_{ijk} data predicted by the graph theoretical approach employing the graph theoretical binary interaction coefficients α_{ij}, α_{jk}, and α_{ki} compare better with the corresponding experimental values than the V^E_{ijk} values predicted by Lacombe and Sanchez theory utilizing Lacombe and Sanchez's binary interaction coefficients χ_{ij}, χ_{jk}, and χ_{ki} of the $(i + j)$, $(j + k)$, and $(k + i)$ mixtures. The V^E_{ijk} data have also been utilized to extract, via the Mayer–McMillan approach, self and cross volume interaction coefficients V_{jj}, V_{kk}, V_{jk}, V_{jjk}, and V_{jkk} and the V_{jk} values have been utilized to study molecular interactions between the *j*th and the *k*th components in the presence of the *i*th component of these $(i + j + k)$ mixtures.

PREM P. SINGH et VINOD K. SHARMA. Can. J. Chem. **61**, 2321 (1983).

On a déterminé les volumes molaires en excès V^E_{ijk} de quelques mélanges ternaires $(i + j + k)$ de non électrolytes, par dilatométrie à 298,15 et 308,15 K et on les a analysés (*a*) en fonction de la théorie de Lacombe et Sanchez et (*b*) en fonction d'une approche basée sur la théorie graphique qui utilise l'information relative à $(i + j)$, $(j + k)$ et $(k + i)$ des mélanges binaires seuls. On a observé que les données de V^E_{ijk} prédites par l'approche de la théorie graphique qui utilise la courbe théorique des coefficients d'interaction binaire α_{ij}, α_{jk} et α_{ki} s'approchent d'avantage des valeurs expérimentales correspondantes que les valeurs de V^E_{ijk} prédites par la théorie de Lacombe et Sanchez χ_{ij}, χ_{jk} et χ_{ki} des mélanges de $(i + j)$, de $(j + k)$ et de $(k + i)$. On a également utilisé les données de V^E_{ijk} pour obtenir, via l'approche de Mayer–McMillan, les coefficients d'interaction du volume et du covolume V_{jj}, V_{kk}, V_{jk}, V_{jjk} et V_{jkk}. On a utilisé la valeur de V_{jk} pour étudier l'interaction moléculaire entre les composants *j*th et *k*th en présence des *i*th composants de ces mélanges de $(i + j + k)$.

[Traduit par le journal]

Introduction

Thermodynamics of ternary mixtures of non-electrolytes has not received as much attention as the thermodynamics of binary mixtures in spite of the fact that all thermodynamic properties of ternary mixtures should, in principle, be determinable from the properties of the respective binary mixtures. Lacombe and Sanchez have recently formulated a unified molecular theory (1, 2) of fluids and fluid mixtures which defines the thermodynamic properties of ternary and higher order mixtures in terms of the pure fluid parameters and the binary interaction coefficients. This theory (2) has been shown (2–4) to be quite successful to predict molar excess volumes, V^E, and molar excess enthalpy, H^E, of a number of binary mixtures of non-electrolytes. More recently, an approach employing the graph theoretical concept of connectivity parameters has been successfully applied (5, 6) to predict V^E and H^E of quite a number of binary mixtures of non-electrolytes. This approach (5, 6) can be easily extended to ternary mixtures of non-electrolytes. It would, therefore, be interesting to see how these two approaches explain the V^E_{ijk} data of ternary $(i + j + k)$ mixtures of non-electrolytes.

Experimental

Materials and their purification

Benzene (B.D.H. A.R. grade) was purified following the method of Rastogi and Nigam (7). Toluene, *o*- and *p*-xylene (B.D.H., A.R. grade) were purified as suggested by Vogel (8). Methylene bromide (V/O Sojuzchimeyport, Moscow) was purified by treating with 5% sodium carbonate solution. If was then washed with water followed by drying over anhydrous calcium chloride and fractionally distilled.

The purity of the treated samples was checked by measuring their densities at 298.15 ± 0.01 K and they agreed to within ±0.00005 g cm^{-3} with the corresponding literature values (9–11). (The density of methylene bromide at 298.15 ± 0.01 K was obtained from the density vs. temperature plot; the necessary density data were taken from literature (11)).

Excess volumes were determined in a dilatometer similar to that used by Brown and Smith (12); the only difference being that there were now three limbs for the three components. The temperature of the bath was controlled to better than ±0.01 K by means of a toluene regulator. In order to ensure that the liquid in the capillary stem had the same composition as that of the bulk solution on mixing, the dilatometer (after mixing the components) was placed in a cold bath so that there was minimum liquid in the capillary and then again placed in the experimental water bath. This process was repeated twice or thrice. The uncertainty in our measured excess volumes is about 0.5%.

Results

V^E_{ijk} data for the various ternary mixtures as a function of composition at 298.15 and 308.15 K are recorded in Table 1 and are expressed (13) as

$$[1]\quad V^E_{ijk} = x_ix_j[A_{ij} + B_{ij}(x_i - x_j) + C_{ij}(x_i - x_j)^2] + x_jx_k[A_{jk} + B_{jk}(x_j - x_k) + C_{jk}(x_j - x_k)^2] + x_ix_k[A_{ik} + B_{ik}(x_i - x_k) + C_{ik}(x_i - x_k)^2] + x_ix_jx_k[A_{ijk} + B_{ijk}(x_j - x_k)x_i + C_{ijk}(x_j - x_k)^2x_i^2]$$

where x_i and x_j are the mole fractions of the *i*th and the *j*th components in the $(i + j + k)$ ternary mixture and A, B, and C are parameters characteristic of the $(i + j)$, $(j + k)$, and $(k + i)$ binary mixtures and are taken from literature (14). The A_{ijk}, B_{ijk}, and C_{ijk} coefficients of [1] are evaluated by fitting the V^E_{ijk} data to [2].

$$[2]\quad [V^E_{ijk} - \{x_ix_j(A_{ij}B_{ij}(x_i - x_j) + C_{ij}(x_i - x_j)^2) + x_jx_k(A_{jk} + B_{jk}(x_j - x_k) + C_{jk}(x_j - x_k)^2) + x_ix_k(A_{ik} + B_{ik}(x_i - x_k) + C_{ik}(x_i - x_k)^2)\}]/x_ix_jx_k = [A_{ijk} + B_{ijk}(x_j - x_k)x_i + C_{ijk}(x_j - x_k)^2x_i^2]$$

by the method of least squares and are recorded together with the standard deviation, $\sigma(V^E_{ijk})$ defined by

$$\sigma(V^E_{ijk}) = \left[\frac{\Sigma(V^E_{ijk(\text{expt})} - V^E_{ijk} \text{ from [1]})^2}{m - n}\right]^{1/2}$$

where m is the number of data points and n is the number of adjustable parameters in [1], in Table 2.

Discussion

We are unaware of any V^E data with which to compare our results for these $(i + j + k)$ mixtures.

The V^E_{ijk} data for these mixtures are analysed with Lacombe and Sanchez theory of classical fluids (1) and their mixtures (2). While the classical theory of pure fluids (1) characterizes the model fluid as an Ising or Lattice fluid (this approach has been shown (1) to be capable of describing the thermodynamic properties of a large variety of fluids), the mixture theory (2) is akin to the lattice theory of Flory and Huggins (14) but differs in the most important aspect of making an allowance for empty lattice sites thereby allowing volume change on mixing. This theory (2) expresses the molar excess volume, V^E_{ijk}, of a ternary mixture by

$$[3] \quad V^E_{ijk} = r_{\text{mix}} v^*_{\text{mix}}[\tilde{v}_{\text{mix}} - \sum_i \phi_i \tilde{v}_i]$$

where

$$[4] \quad \phi_i = m_i(\rho^*_i)^{-1}(\Sigma(m_i/\rho^*_i)^{-1})$$

$$[5] \quad m_i = x_i M_i(\Sigma x_i M_i)^{-1}$$

$$[6] \quad r_{\text{mix}} = \Sigma x_i r_i$$

$$[7] \quad r_i = r^0_i(v^*_i(v^*_{\text{mix}})^{-1})$$

$$[8] \quad v^*_{\text{mix}} = \Sigma \phi^0_i v^*_i$$

$$[9] \quad \phi^0_i = m_i(\rho^*_i v^*_i)^{-1}/\sum_i (m_i/\rho^*_i v^*_i)$$

$$[10] \quad \tilde{v}_{\text{mix}} = 1/\tilde{\rho}_{\text{mix}}$$

and all the terms have the same significance as described by Lacombe and Sanchez (2).

Evaluation of V^E_{ijk} by [3] requires a knowledge of $\tilde{\rho}_{\text{mix}}$, the reduced density of the mixture, which in principle could be calculated from the following equation of state of the mixture

$$[11] \quad (\tilde{\rho}_{\text{mix}})^2 + \tilde{P} + \frac{RT}{\epsilon^*_{\text{mix}}}[\ln(1 - \tilde{\rho}_{\text{mix}}) + (1 - \frac{1}{r_{\text{mix}}})\tilde{\rho}_{\text{mix}}] = 0$$

where

$$[12] \quad \epsilon^*_{\text{mix}} = \sum_i \phi_i \epsilon^*_{ii} - RT \Sigma\Sigma \phi_i \phi_j \chi_{ij}$$

$$[13] \quad \chi_{ij} = (\epsilon^*_{ii} + \epsilon^*_{jj} - 2\epsilon^*_{ij})/RT$$

and

$$[14] \quad \tilde{P} = P v^*_{\text{mix}}/\epsilon^*_{\text{mix}}$$

but this would require a knowledge of binary interaction energies ϵ^*_{ij}, ϵ^*_{jk}, ϵ^*_{ik} of the $(i + j)$, $(j + k)$, and $(i + k)$ binary mixtures. Such information, however, is not readily available but could be obtained from a single molar excess enthalpy datum of each of these binary mixtures by means of [11] and [15]. Since the calculations in this process are too involved, a simple approach (3) would be to evaluate ϵ^*_{ij}, ϵ^*_{jk}, and ϵ^*_{ik} for these binary mixtures from their single molar excess enthalpy, H^E, and molar excess volume, V^E, datum at $x = 0.5$ at one temperature T only by means of

$$[15] \quad H^E_{(i+j)} = 2\phi_i \phi_j r_{\text{mix}} \tilde{\rho}_{\text{mix}}[\epsilon^*_{ii} + \epsilon^*_{jj} - 2\epsilon^*_{ij}] + RTr_{\text{mix}}\left[\sum_i \left(\frac{\phi_i \tilde{\rho}_i - \tilde{\rho}_{ij}\phi_i}{T_i}\right)\right]$$

where

$$[16] \quad \tilde{T}_i = RT/\epsilon^*_{ii}$$

and

$$[17] \quad \tilde{\rho}_{\text{mix}} = [\{V^E_{(i+j)}/(\Sigma x_i r^0_i(v^*_i/\Sigma \phi_i v^*_i))(\Sigma \phi_i v^*_i)\} + \Sigma \phi_i \tilde{v}_i]^{-1}$$

Once ϵ^*_{ij}, ϵ^*_{jk}, and ϵ^*_{ik} parameters of $(i + j)$, $(j + k)$, and $(i + k)$ binary mixtures are known, $\tilde{\rho}_{\text{mix}}$ for the $(i + j + k)$ mixture

*The A, B, C parameters of [1] for the $(i + j)$, $(j + k)$, and $(k + i)$ mixtures denote here A_{ij}, B_{ij}, C_{ij} etc. (see text) while for the $(i + j + k)$ mixture they denote A_{ijk}, B_{ijk}, and C_{ijk} respectively.
†Reference 14.

can be evaluated from [11]−[14] and hence from a knowledge of a single V^E and H^E datum at a given temperature for an equimolar $(i + j)$, $(j + k)$, and $(i + k)$ binary mixtures it should be possible to predict V^E_{ijk} for a ternary $(i + j + k)$ mixture if it is assumed that the binary interaction coefficients χ_{ij}, χ_{jk}, and χ_{ik} for these binary mixtures are independent of composition and temperature and that these binary mixtures satisfy [11] for binary mixtures. It was, however, shown (14) that V^E and H^E values so calculated at 298.15 and 308.15 K from V^E and H^E (T = 308.15 K, x_i = 0.5) datum alone for (methylene bromide (i) + aromatic hydrocarbon (j or k) mixtures were in very poor agreement with the corresponding experimental values. This failure of the theory (2) was traced to the failure of these $(i + j$ or $k)$ mixtures to satisfy [11] for binary mixtures (perhaps due to weak donor−acceptor interactions between their j or k and i components). Consequently an alternate approach was employed to evaluate V^E or H^E values for these binary mixtures by first evaluating $\tilde{\rho}_{ij}$ and χ_{ij} through [15] and [17] utilizing the experimental V^E and H^E values for an equimolar mixture at 308.15 K and then employing them (i.e. $\tilde{\rho}_{ij}$ and χ_{ij}) to see how much the mixture deviated from [11]. (The extent to which the $(i + j)$, $(j + k)$, and $(i + k)$ binary mixtures deviated from [11] at 308.15 K (i.e. the right hand side of [11] for these mixtures) was found (14) to vary from 0.007 to 0.011). Knowing the right hand side of [11] for a binary mixture, $\tilde{\rho}_{ij}$ and hence V^E and H^E for the $(i + j)$ etc. mixture as a function of temperature and composition were shown (14) to be in reasonably good agreement with their corresponding experimental values. Since the $(i + j)$, $(j + k)$, and $(k + i)$ mixtures do not satisfy [11] but satisfy [18],

$$[18]\quad (\tilde{\rho}_{ij})^2 + \tilde{P}^2 + \frac{RT}{\epsilon^*_{mix}}[\ln(1 - \tilde{\rho}_{ij}) + (1 - r^{-1})\tilde{\rho}_{ij}] = 0.0071 \text{ to } 0.011$$

it follows that the $(i + j + k)$ mixtures would also not satisfy [11] and hence the V^E_{ijk} values predicted by [3] through [3]−[17] in the manner originally proposed by Sanchez and Lacombe would not compare well with their corresponding experimental values.

In view of the fact that the present $(i + j)$ mixtures satisfy [18], and as the addition of a k etc. component to an $(i + j)$ etc. mixture would not drastically alter the nature of i−j, j−k, and i−k interactions, the present ternary $(i + j + k)$ mixtures would also satisfy an equation of state like [18]. Now the extent to which a ternary $(i + j + k)$ mixture deviated from [11] would be nearly one third of the sum to which the $(i + j)$, $(j + k)$, and $(i + k)$ equimolar mixtures deviated at 308.15 K from [11], i.e. [11] for a ternary $(i + j + k)$ mixture (assuming it to be composed of three binary $(i + j)$, $(j + k)$, and $(i + k)$ mixtures) would reduce to

$$[19]\quad (\tilde{\rho}_{ijk})^2 + \tilde{P}^2 + \frac{RT}{\epsilon^*_{mix(i+j+k)}}[\ln(1 - \tilde{\rho}_{ijk}) + (1 - r^{-1}_{ijk})\tilde{\rho}_{ijk}] = \tfrac{1}{3}[\Sigma\text{R.H.S. of [11] for } (i + j), (j + k), \text{ and } (i + k) \text{ mixtures}]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

where $\epsilon^{*}_{\text{mix}(i+j+k)}$ and $\tilde{\rho}_{ijk}$ are defined by [12] and [10], respectively. Once the equation of state for a ternary $(i + j + k)$ mixture, such as [19], has been established (utilizing V^{E} (x = 0.5, T = 308.15 K) and H^{E} (x = 0.5, T = 308.15 K) datum for $(x)i + (1 - x)j$, $(x)j + (1 - x)k$ and $(x)i + (1 - x)k$ mixtures), V^{E}_{ijk} for the $(i + j + k)$ mixture as a function of temperature and composition can be readily evaluated. Such V^{E}_{ijk} values at 298.15 K and 308.15 K for the various ternary mixtures are recorded in Table 1 and are also compared with their corresponding experimental values.

Examination of Table 1 reveals that the V^{E}_{ijk} values predicted by [3] compare reasonably well with the corresponding experimental values. Even in those cases where the agreement between the two values is not good, the predicted V^{E}_{ijk} values are of the right order of magnitude; in some cases, however, this is not true. Nevertheless, the present ternary $(i + j + k)$ mixtures satisfy [19] reasonably well over most of x_i and x_j. The deviations of the $V^{E}_{ijk(\text{calcd})}$ values from the corresponding experimental values at 298.15 and 308.15 K for low values of x_i, x_j, or x_k especially may be attributed to the failure of the assumption that the right hand side of [11] for the constituent $(i + j)$, $(j + k)$, and $(i + k)$ binary mixtures (evaluated from their equimolar V^{E} and H^{E} datum at 308.15 K only) was constant over the entire values of x_i, x_j, or x_k, and T.

The V^{E}_{ijk} data for these ternary mixtures are then analysed in terms of an approach (5) that employed the "graph theoretical" concept of connectivity parameters (16) to characterize its pure components. According to this approach (5) V^{E}_{ij} for a binary $(i + j)$ mixture is given by

$$[20]\quad V^{E}_{ij} = \alpha_{ij}\left[\frac{1}{\sum_i x_i({}^3\xi_i)} - \sum_i \frac{x_i}{{}^3\xi_i}\right]$$

where α_{ij} is a constant assumed to be independent of composition and characteristic of the $(i + j)$ mixture and x_i is the mole fraction of the ith component in the mixture. Further ${}^3\xi_i$ is a connectivity parameters of the third degree of the ith molecule and is defined (16) by

$$[21]\quad {}^3\xi_i = \sum_{l<m}\sum_{m<n}\sum_{n<o}(\delta_l\delta_m\delta_n\delta_o)^{-1/2}$$

where δ_l, δ_m, δ_n, and δ_o etc. denote the degrees of the l, m, n, and oth etc. vertices of the "graph" (16) of the ith molecule and were evaluated as described earlier (6). This approach (5) is based on the fact (5) that the molar volume of an ith molecule can be expressed in terms of its connectivity parameters of the first and third order by means of

$$[22]\quad V_i = (\alpha_i/{}^3\xi_i) + \beta_i{}^1\xi_i + \gamma_i$$

where α_i, β_i, and γ_i are constants and ${}^1\xi_i$ (connectivity parameters of the first degree of i) is defined by

$$[23]\quad {}^1\xi_i = \sum_{l<m}(\delta_l\delta_m)^{-1/2}$$

and that

$$[24]\quad V^{E}_{ij} = V_{\text{mix}} - V_{\text{id}} = V_{\text{mix}} - \sum x_i V_i$$

It was further assumed that V_m for the $(i + j)$ mixture should also be represented by an expression analogous to

$$[25]\quad V_m = (\alpha_m/{}^3\xi_m) + \beta_m({}^1\xi_m) + \gamma_m$$

Since the connectivity parameters of the first degree of molecule depends on the degree of the closest vertices in its molecular graph taken two at a time, it has been assumed to represent a measure of the oscillations of its C—C bond length and as mixing the ith and the jth components in the $(i + j)$ binary mixture is not going to materially alter these C—C bond lengths in this mixture, $\beta_m({}^1\xi_m)$ was assumed (5) to be given by

$$[26]\quad \beta_m({}^1\xi_m) = \sum_i x_i\beta_i({}^1\xi_i)$$

Further, $1/({}^3\xi_i)$ of an ith molecule has also been taken to represent a measure of the probability that its surface area interacts effectively with the corresponding surface areas of other molecules so that in a binary $(i + j)$ mixture containing x_i mole fraction of i, $({}^{1/3}\xi_m)$ was assumed to be given by [27].

$$[27]\quad ({}^3\xi_m)^{-1} = (\sum x_i{}^3\xi_i)^{-1}$$

Further γ_m and α_m were expressed as

$$[28]\quad \gamma_m = \sum_i x_i\gamma_i$$

$$[29]\quad \alpha_m = \alpha_i = \alpha_j = \alpha_{ij}$$

In view of this approach V^{E}_{ijk} for a ternary mixture would be given by

$$[30]\quad V^{E}_{ijk} = \alpha_{ijk}\left[\frac{1}{\sum_{i=1}^{3} x_i({}^3\xi_i)} - \sum_{i=1}^{3}\frac{x_i}{{}^3\xi_i}\right]$$

where $\alpha_m = \alpha_i = \alpha_j = \alpha_k = \alpha_{ijk}$.

Prediction of V^{E}_{ijk} for the ternary mixture by means of [30] requires a knowledge of α_{ijk} for this mixture. α_{ijk}, in principle, should be predictable from the corresponding α's of the $(i + j)$, $(j + k)$, and $(i + k)$ binary systems. A useful approximation would be to regard a ternary $(i + j + k)$ mixture to be composed of three binary $(i + j)$, $(j + k)$, and $(i + k)$ systems. Now an i and a j molecule can pack themselves in the $(i + j)$ system in two ways, i.e.

ij or *ji*

Consequently three components give six different binary arrangements in the three binary $(i + j)$, $(j + k)$, and $(i + k)$ mixtures. These six different binary packing arrangements taken two at a time will give rise to ${}^6C_2$ or 15*ijk* ternary combinations. But in actual fact, *i*, *j*, and *k* molecules can pack themselves in three ways only i.e. *ijk*, *jik*, *jki*. It is thus apparent that the number of ternary packing arrangements from the binary packing arrangements is 5 times more than the actual ternary packing arrangements. Hence it is expected that α_{ijk} should be expressible in terms of α_{ij}, α_{jk}, α_{ik}, the binary interaction coefficients, by

$$[31]\quad \alpha_{ijk} = (1/5)(\alpha_{ij} + \alpha_{jk} + \alpha_{ik})$$

so that [29] reduces to

$$[32]\quad V^{E}_{ijk} = (1/5)(\alpha_{ij} + \alpha_{jk} + \alpha_{ik})\left[\frac{1}{\sum_{i=1}^{3} x_i({}^3\xi_i)} - \sum_{i=1}^{3}\frac{x_i}{{}^3\xi_i}\right]$$

Thus if the binary interaction coefficients α_{ij}, α_{jk}, and α_{ik} are known it should be possible to predict V^{E}_{ijk} for the ternary mixture. These binary interaction coefficients were evaluated by fitting the V^{E} datum for an equimolar composition at a given temperature to [20], as described earlier (5), and then employed to predict V^{E}_{ijk} for the ternary mixture at that temperature. Such V^{E}_{ijk} values are recorded in Table 1 and are also compared with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

the corresponding experimental values.

Examination of Table 1 reveals that the predicted V^{E}_{ijk} values (except in the range $x_i \leq 0.1$ for which $V^{E}_{ijk(exp)} > V^{E}_{ijk(eq.[32])}$) compare well with the corresponding experimental values. Even in those cases where the agreement between the two values is not good, the predicted V^{E}_{ijk} values are of the right order of magnitude. The failure of [32] to correctly predict V^{E}_{ijk} for most of the present $(i + j + k)$ mixtures, in the range $x_i \leq 0.1$, may be traced to the presence in them of ternary contacts (which depend on the nature of molecular interactions between the i, j, and k components of these mixtures and which have not been presently considered), other than the ijk contacts. For such solutions α_{ijk} values, as evaluated from [31], would therefore be lower than their actual values and so V^{E}_{ijk} values as calculated from [32] would be lower than their corresponding experimental values.

Thus while Lacombe and Sanchez theory (2) has the advantage of a rigorous theory of fluid and fluid mixtures which has been shown (1, 2) to describe several other aspects of binary mixtures, expressions [20] and [32] present an alternative view point (of binary and ternary mixtures of non-electrolytes) which has the advantage of simplicity and brings out the versatility of the mathematical discipline of "graph theory" (16–19). In any case these approaches cannot be expected to fare better because of: (*i*) the complicated nature of molecular interactions between the components of these ternary mixtures; and (*ii*) the still limited success with binary systems.

These approaches, however, clearly suggest that even with the present stage of knowledge about binary mixtures, it still is possible to predict, reasonably well, V^{E}_{ijk} for ternary mixtures of non-electrolytes. Preliminary studies with H^{E}_{ijk} data of ternary mixtures of non-electrolytes in terms of these two approaches support these observations and again suggest that the "graph theoretical" approach has some distinct advantages over Sanchez and Lacombe's theory (2) although it lacks the rigour of the latter theory.

We may now extract some information about the nature of molecular interactions between the components of these ternary mixtures.

Although several thermodynamic techniques (20) can be utilized for the purpose, the McMillan–Mayer formalism (21) appears to be an attractive one. According to this treatment any change in the properties of the solvent appears in the magnitudes of the solute–solute virial coefficients and the self-interaction coefficients for a binary system remain unchanged when an additional solute is added to this binary system. This is expected to be true in the present case as the solute–solute interactions would be of a short-range nature (since they have been usually expressed in terms of the Lennard–Jones potential function). According to this formalism (21) any excess function say $V^{E(3)}$ of a solution containing n solute species can be expressed as

$$[33]\quad V^{E(3)}_{(m_i \cdots m_n)} = V - V_{sol} - \sum_{i=1}^{n} V^{0}_{i} m_i$$

$$[34]\quad = \sum_{i=1}^{n}\sum_{j=1}^{n} V_{ij} m_i m_j + \sum_{i=1}^{n}\sum_{j=1}^{n}\sum_{k=1}^{n} V_{ijk} m_i m_j m_k$$

where V and $V^{E(3)}_{(m_i \ldots m_n)}$ are the volume and excess volumes respectively of a solution containing 1 kg of solvent and $m_i \ldots m_n$ moles of each solute species, V_{sol} is the standard volume of 1 kg of the solvent, and V^{0}_{i} is the partial molal volume of each solute. For a ternary $(i + j + k)$ solution, [34] reduces to

$$[35]\quad V^{E(3)}_{(m_j \cdot m_k)} = V_{jj} m_j^2 + 2V_{jk} m_j m_k + V_{kk} m_k^2 + V_{jjj} m_j^3 + 3V_{jjk} m_j^2 m_k + 3V_{jkk} m_j m_k^2 + V_{kkk} m_k^3 + \ldots.$$

and for the two binary $(i + p)(p = j \text{ or } k)$ solutions [34] yields

$$[36]\quad V^{E(3)}_{(m_j)} = V_{jj} m_j^2 + V_{jjj} m_j^3$$

$$[37]\quad V^{E(3)}_{(m_k)} = V_{kk} m_k^2 + V_{kkk} m_k^3$$

In order to evaluate the cross volume coefficients V_{jk}, V_{jkk}, and V_{jjk} from [35], we following Barone *et al.* (22), used an auxiliary function ΔV^{E*} defined as

$$[38]\quad \Delta V^{E*} = V^{E(3)}_{(m_j \cdot m_k)} - V^{E(3)}_{(m_j)} - V^{E(3)}_{(m_k)}$$

which, in view of [35]–[37], yields

$$[39]\quad \Delta V^{E*}_{(m_j \cdot m_k)^{-1}} = 2V_{jk} + 3V_{jjk} m_j + 3V_{jkk} m_k + \ldots.$$

Thus if $V^{E(3)}_{(m_j \cdot m_k)}$ data for the $(i + j + k)$ ternary mixture along with the $V^{E(3)}_{(m_p)}$ $(p = j \text{ or } k)$ for the $(i + p)$ binary mixtures are known, it should be possible to evaluate the cross volume interaction coefficients. Ideally $V^{E(3)}_{(m_j \cdot m_k)}$ or $V^{E(3)}_{(m_p)}$ $(p = j \text{ or } k)$ data for dilute solutions should be utilized to evaluate these cross volume coefficients but as the H^{E} and V^{E} data for (methylene bromide (i) + aromatic hydrocarbons (p)) mixtures at 398.15 or 298.15 K are very small ($H^{E}_{x_i=0.3} \approx 50$ J mol^{-1} or less, $V^{E}_{x_i=0.5} = 0.25$ cm^3 mol^{-1} or less), we expect [36] and [37] to be valid for a considerable larger m_p $(p = j \text{ or } k)$ values. This led to us to utilize the $V^{E(3)}_{(m_p)}$ data for methylene bromide (i) + aromatic hydrocarbons (p) mixtures in the range $0.5 \leq m_p \leq 1.8$, where $V^{E(3)}_{(m_p)^{-2}}$ are almost linear functions of m_p, to evaluate the self volume interaction coefficients V_{pp}, V_{ppp} $(p = j \text{ or } k)$ between aromatic hydrocarbon (p) molecule in the presence of i. Consequently, $V^{E(3)}_{(m_j \cdot m_k)}$ data for the methylene bromide (i) + benzene (j) + toluene or *p*-xylene or *o*-oxylene (k) ternary mixtures in the $0.5 \leq m_j, m_k \leq 1.8$ range were combined with the corresponding $V^{E(3)}_{(m_p)}$ data in the range $0.5 \leq m_p$ $(p = j \text{ or } k) \leq 1.8$ to evaluate V_{jk}, V_{jjk}, and V_{jkk} from [39] by the method of least squares. For this purpose the $V^{E}(x_j, x_k)$ data in cm^3 mol^{-1} of the methylene bromide (i) + benzene (j) + toluene or *p*-xylene or *o*-xylene (k) or methylene bromide (i) + toluene (j) + *p*-xylene or *o*-oxylene (k)) mixtures were converted to $V^{E(3)}_{(m_j \cdot m_k)}$ data in cm^3 mol^{-1} (mol kg of i)$^{-1}$ by means of

$$[40]\quad V^{E}_{(m_j \cdot m_k)}\ \text{cm}^3\ \text{mol}^{-1}\ (\text{mol kg of } i)^{-1} = [V^{E}_{x_j, x_k}\ \text{cm}^3\ \text{mol}^{-1}\ \text{of } (i + j + k)\ \text{mixture}] \times \left[\frac{1000}{x_i \cdot (\text{mol wt of } i)}\right]$$

while the m_p $(p = j \text{ or } k)$ values were obtained from

$$[41]\quad m_p = \frac{x_p \cdot 1000}{x_i \cdot (\text{mol. wt. of } i)}$$

The corresponding $V^{E}_{(m_p)}$ $(p = j \text{ or } k)$ values in cm^3 mol^{-1} (mol kg of i)$^{-1}$ in the $(p + i)$ binary mixtures were read from the $V^{E}_{(m_p)}$ vs. m_p plots; the $V^{E}_{(x_p)}$ data in cm^3 mol^{-1} of the $(p + i)$ solution were first converted to the $V^{E}_{(m_p)}$ data by means of

$$[42]\quad V^{E}_{(m_p)}\ (p = j \text{ or } k)\ \text{cm}^3\ \text{mol}^{-1}\ (\text{mol kg of } i)^{-1} = \frac{V^{E}_{(x_p)} \cdot 1000}{x_i \cdot (\text{mol. wt. of } i)}$$

TABLE 3. Self and cross volume interaction coefficients in cm^3 $(mol\ kg)^{-1}$ at 298.15 K

System	V_{jj}	V_{kk}	V_{jk}	V_{jjk}	V_{jkk}
Methylene bromide (i) + benzene (j) + toluene (k)	2.64	2.65	−0.054	−0.175	0.0032
Methylene bromide (i) + benzene (j) + *p*-xylene (k)	2.64	4.40	0.198	0.140	−0.1713
Methylene bromide (i) + benzene (j) + *o*-xylene (k)	2.64	5.60	0.655	0.082	−0.429
Methylene bromide (i) + toluene (j) + *p*-xylene (k)	2.65	4.40	−0.018	−0.013	−0.0046
Methylene bromide (i) + toluene (j) + *o*-xylene (k)	2.65	5.60	0.216	0.108	−0.1906

Such V_{jk}, V_{jjk}, and V_{jkk} values along with the V_{jj} and V_{kk} values determined earlier (14) at 298.15 K are recorded in Table 3.

Examination of Table 3 reveals that while the V_{jk} interaction coefficients of benzene (j) with toluene, *p*-xylene, and *o*-xylene (k) in the presence of methylene bromide vary in the order

toluene < *p*-xylene < *o*-xylene

those of toluene (j) with *p*-xylene and *o*-xylene (k) in the presence of methylene bromide vary as

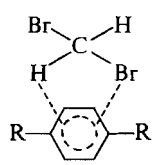
p-xylene < *o*-xylene

and that V_{jk}^{E} (j = benzene and k = *p*-xylene or *o*-xylene) > V_{jk} (j = toluene and k = *p*-xylene or *o*-xylene). V_{jk} values thus clearly bring out the influence of the number and position of $-CH_3$ substituents in the aromatic ring of k in its interaction with j in the presence of methylene bromide (i).

It would now be instructive to compare these V_{jk} coefficients at 298.15 K with the corresponding V_{jk} coefficients at 298.15 K of *tert*-Butanol (*t*-BuOH) (j) with methanol, ethanol, *n*-propanol, and *n*-butanol (k) in the presence of water which vary in the order

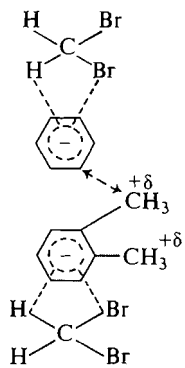
n-BuOH < *n*-propanol < ethanol < methanol

If the V_{jk} data of *tert*-butanol (j) with the alkanols (k) is attributed to the mutual destructive overlapping of Gurney's cospheres (24) on alkyl chains on j and k and the subsequent repacking of j and k molecules (which would be maximum in BuOH and minimum in methanol) as the alkanols (j and k) in water come close enough to let their cospheres overlap, the V_{jk} data of benzene (j) with toluene, *p*-xylene and *o*-xylene (k) in the presence of methylene bromide (i) suggests that compared to *o*-xylene, toluene comes closer to benzene. This is understandable since the nmr data (25) on methylene bromide + benzene and methylene bromide + *p*-xylene mixtures have been interpreted to suggest contact charge transfer interactions beween the components of these mixtures; the vacant 3*d* orbitals of one bromine atom of methylene bromide accommodating the π-charge of the aromatic ring thereby shielding the methylene bromide proton and leading to the formation of a 1:1 molecular complex having the geometry



(R = H or $-CH_3$)

The addition of *o*-xylene to benzene in methylene bromide as a solvent would cause *o*-xylene to approach the now electron-deficient benzene in the above molecular complex with the electron-deficient end, i.e.



Such an interaction between benzene and toluene in the presence of methylene bromide should evidently be comparatively much stronger than that between benzene and *o*-xylene in the presence of methylene bromide. The small interaction between benzene and *p*-xylene in the presence of methylene bromide as compared to that between benzene and *o*-xylene in the presence of methylene bromide is thus understandable.

This scheme of molecular interactions would evidently envisage that if benzene is replaced by toluene in (methylene bromide (i) + benzene (j) + xylene (k)) mixtures, the jk interactions between toluene (j) and *o*-xylene (k) in the presence of methylene bromide (i) should be comparatively weaker than that between toluene and *p*-xylene in the presence of the same solvent. The V_{jk} data support this conjecture.

Received January 24, 1983

W. KLIEGEL, D. NANNINGA, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **61**, 2329 (1983).

Details of the synthesis, physical properties, and molecular structure of 4-isopropylidene-2,5,5-triphenyl-1,3-dioxa-4-azonia-2-bora-5-boratacyclopentane are reported. Crystals of this compound are monoclinic, a = 14.126(3), b = 16.008(1), c = 8.642(2) Å, β = 99.052(8)°, Z = 4, space group $P2_1/n$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to R = 0.032 and R_w = 0.033 for 1117 reflections with $I \geq 3\sigma(I)$. The molecule contains a nearly planar five-membered B—O—B—O—N ring which incorporates both trigonal planar boron (B—O = 1.333(4) and 1.418(4), B—C = 1.548(5) Å) and tetrahedral boron atoms (B—O = 1.495(4), B—N = 1.676(4), B—C = 2 at 1.603(5) Å). Other important libration-corrected bond distances include: C=N = 1.284(3) and N—O = 1.418(3) Å.

W. KLIEGEL, D. NANNINGA, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **61**, 2329 (1983).

On rapporte les détails relatif à la synthèse, aux propriétés physiques et à la structure moléculaire de l'isopropylidène-4 triphényl-2,5,5 dioxa-1,3 azonia-4 bora-2 borata-5 cyclopentane. Les cristaux de ce composé sont monocliniques et appartiennent au groupe d'espace $P2_1/n$ avec a = 14,126(3), b = 16,008(1), c = 8,642(2) Å, β = 99,052(8)°, Z = 4. On a résolu la structure par les méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de R = 0,032 et de R_w = 0,033 pour 1117 réflexions avec $I \geq 3\sigma(I)$. La molécule contient un cycle à 5 chainons de B—O—B—O—N quasi planaire qui englobe à la fois l'atome de bore trigonal plant (B—O = 1,333(4) et 1,418(4), B—C = 1,548(5) Å) et l'atome de bore tétraédrique (B—O = 1,495(4), B—N = 1,676(4), B—C = 2 à 1,603(5) Å). Les autres liaisons importantes corrigées pour la libration sont: C=N = 1,284(3) et N—O = 1,418(3) Å.

[Traduit par le journal]

Introduction

An attempt to synthesize the (isopropylideniminoxy)-diphenylborane **3** (1) from acetone oxime, **1**, and oxybis-(diphenylborane) resulted in a crystalline product the elemental analysis of which indicated the formation of an adduct between the monomer **2** and "phenylboroxide" (**2** + PhBO).[2] This supposed addition compound, **4**, proved to be identical with the reaction product, obtained in nearly quantitative yield, of acetone oxime, **1**, with equivalent quantities of oxybis-(diphenylborane) and phenylboronic acid.

Compound **4** contains diphenylborinic and phenylboronic acid moieties, both of which are detectable by chemical methods such as the blue color reaction with diphenylcarbazone (2, 3) or chelate formation with 2-hydroxyethylamine (or bis(2-hydroxyéthyl)amine) which indicates the presence of diphenylborinic acid (or phenylboronic acid) (3, 4).

The ir spectrum of **4** shows a distinct absorption in the C=N stretching region at 1668 cm^{-1}. This band is shifted to a higher frequency compared with compound **3** (1639 cm^{-1}) (1) which can be explained by a more pronounced iminium salt character of **4**.

The ^{1}H-nmr spectrum of **4** features resonance signals for the 15 phenyl protons of the PhB— and Ph_2B— moieties as well as two sharp singlets, separated by 0.35 ppm, for the two magnetically non-equivalent methyl groups of the isopropylidene substituent.

According to the synthetic method, the elemental analysis, and the available spectroscopic data of **4**, both structures **4***a* and **4***b* were possible. Structure **4***a* resembles the formulation, **5**, proposed by Shitov *et al.* (5) for the decomposition product of the O-(diethylboryl) derivative of 2-aci-nitropropane which was obtained by the analogous reaction of acetone oxime and diethylborinic acid anhydride. The ^{11}B-nmr spectrum of **5** exhibits two singlets with $\delta(BF_3OEt_2)$ = −12.8 and −32 ppm indicating three- and four-coordinate boron atoms (5). Neither the ^{11}B nor the ^{1}H nmr spectra contradict an alternative structure such as **4***b* which could be understood as an addition product of **2** and "phenylboroxide" (phenylboronic acid anhydride).[2]

The mass spectrum of **4** does not show a peak corresponding to the molecular ion. This indicates the thermolability of the compound. Shitov *et al.* (5) also found only a "very weak" molecular ion peak in the mass spectrum of **5**. The base beak in the mass spectrum of **4** represents the mass (m/e) 264 which corresponds to a $(M - C_6H_5)^+$ fragment. The loss of a phenyl group is a common feature of diphenylboron chelates (6) and leads mostly to very stable fragments. A peak of m/e 264 was also observed in the mass spectrum of **3** (1) and was interpreted as a (monomer **2** + BO)$^+$ ion, like similar particles which were found as prominent peaks in the mass spectra of other (alkylideniminoxy)diorganylboranes and considered as characteristic fragments of this type of compound (7). This demonstrates the high stability of the heterocyclic particle $(4 - C_6H_5)^+$ or analogs of it. In support of these findings the mass spectrum of **5** contains the prominent fragment $(5 - C_2H_5)^+$ (5). The peak with the highest mass (m/e 312) and a relatively high abundance in the spectrum of **4** suggests the formation of $(PhBO)_3$

[1]Previous paper in this series: ref. 25.

[2]Phenylboronic acid anhydride ("phenylboroxide") exists only as the trimer $(PhBO)_3$ (triphenylboroxin) under normal conditions.

in a thermolytic reaction of **4** within the inlet system.

In view of the failure of chemical and spectroscopic methods to determine the structure of **4**, a full X-ray crystallographic analysis seemed the best way to distinguish unambiguously between the alternative formulations **4***a* and **4***b*.

Experimental

4-Isopropylidene-2,5,5-triphenyl-1,3-dioxa-4-azonia-2-bora-5-boratacyclopentane

Method a

A solution of oxybis(diphenylborane) (0.70 g, 2 mmol) and acetone oxime (0.30 g, 4 mmol) in 50 mL benzene was refluxed for 20 min using a Dean-Stark trap for the continuous removal of water. After partial evaporation of solvent and addition of petroleum ether 0.18 g (26% yield) of colorless crystals were obtained.

Method b

A solution of oxybis(diphenylborane) (0.70 g, 2 mmol), phenylboronic acid (0.49 g, 4 mmol), and acetone oxime (0.30 g, 4 mmol) in 50 mL benzene was refluxed for 45 min using a Dean-Stark trap for water removal. Partial evaporation of solvent followed by the addition of petroleum ether resulted in the precipitation of 1.25 g (92% yield) of colorless crystals which were then recrystallized from tetrahydrofuran and petroleum ether, mp 159°C. *Anal.* calcd. for $C_{21}H_{21}B_2NO_2$ (341.03): C 73.90, H 6.20, B 6.34, N 4.10; found: C 73.75, H 6.17, B 6.20, N 4.19. Ir (KBr): 1668 cm^{-1} (C=N). ^1H nmr ($CDCl_3$/TMS) δ (ppm): 1.93 (s, CH_3), 2.28 (s, CH_3), 7.2–8.0 (m, Ph_2B and PhB). Mass spectrum (70 eV, 140°C, direct inlet), *m/e* (relative abundance, assignment): 312 (80, $[PhBO]_3$), 264 (100, M − C_6H_5), 235 (12), 217 (32), 208 (22, $[PhBO]_2$), 181 (10, Ph_2BO), 165 (45, Ph_2B), 154 (22), 144 (18), 131 (38), 118 (12), 104 (58, PhBO), 87 (26), 77 (58, C_6H_5), 56 (85).

The methanolic solution of the substance gives a dark blue color reaction (2) with diphenylcarbazone and yields the well known diphenylboron chelate with 2-hydroxyethylamine (8) and monophenylboron bidentate chelate with bis(2-hydroxyethyl)amine (9) in aqueous ethanol solution.

X-ray crystallographic analysis of 4-isopropylidene-2,5,5-triphenyl-1,3-dioxa-4-azonia-2-bora-5-boratacyclopentane

A crystal bounded by the six faces (followed by their distances in mm from a common origin): ±(1 0 0), 0.100 ±(0 1 0), 0.075, ±(0 0 1), 0.190 was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 20–35°) measured on a diffractometer with Mo-Kα_1 radiation (λ = 0.70930 Å). Crystal data at 22°C are:

$C_{21}H_{21}B_2NO_2$ fw = 341.03

Monoclinic, a = 14.126(3), b = 16.008(1), c = 8.642(2) Å, β = 99.052(8)°, V = 1929.6(5) $Å^3$, Z = 4, ρ_c = 1.174 g cm^{-3}, $F(000)$ = 720, μ(Mo-Kα) = 0.68 cm^{-1}. Absent reflections: $h0l$, $h + l$ odd, and $0k0$, k odd, uniquely determine the space group $P2_1/n$ (nonstandard setting of $P2_1/c$, C_{2h}^5, No. 14, equivalent positions: ±(x, y, z; 1/2 − x, 1/2 + y, 1/2 − z)).

Intensities were measured with graphite-monochromatized Mo-Kα radiation (λ = 0.71073 Å) on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 0.96–6.71° min^{-1} over a range of (0.70 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 52°. The intensities of three check reflections, measured every 3600 s throughout the data collection, showed a uniform decrease to final values 4.7% less than the initial values. The data were corrected for isotropic decay. Of the 3782 independent reflections measured and processed,[3] 1117 (30%) had intensities greater than 3σ(I) above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count. High-order reflections (2θ >

*U_{eq} = (1/3)trace U_{diag}.

40°) were generally unobserved in spite of good crystal quality, probably due at least in part to the relatively small volume of the crystal.

The structure was solved by direct methods, all non-hydrogen atom positions being taken from an E-map. Refinement of the non-hydrogen atoms with anisotropic thermal parameters gave R = 0.078, a difference map at this point clearly revealing all 21 hydrogen atoms. Refinement with fixed contributions from the hydrogen atoms reduced R and R_w to values of 0.044 and 0.056 respectively. In spite of the small number of observed data (using a 2σ cutoff would give only 30 more reflections) the hydrogen atoms positions and isotropic thermal parameters were refined. We feel that this action is justified by the dramatic improvement in the R value. The scattering factors of ref. 10 were used for non-hydrogen atoms and those of ref. 11 for hydrogen atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of refinement. Convergence was reached at R = 0.032 and R_w = 0.033 for 1117 reflections with $I \geq 3\sigma(I)$. The function minimized was $\sum w(|F_o| - |F_c|)^2$, $R = \sum||F_o| - |F_c||/\sum|F_o|$ and $R_w = (\sum w(|F_o| - |F_c|)^2/\sum w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.04 and 0.34σ respectively. The mean error in an observation of unit weight was 1.473. A final difference map showed maximum fluctuations of ±0.12 e Å^{-3}. The final positional and thermal parameters appear in Tables 1 and 2[4] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[4]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (12). The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0030 Å^2. Analysis of all 26 non-hydrogen atoms indicated significant independent motion of the phenyl groups. Four smaller groups were then separately analysed, the three PhB groups and all atoms except the unsubstituted phenyl carbon atoms (rms ΔU_{ij} = 0.0049, 0.0027, 0.0035, and 0.0059 Å^2 respectively). The appropriate bond distances have been corrected for libration (12, 13), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3 along with the uncorrected values; corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 4. Intra-annular torsion angles defining the conformation of five-membered heterocyclic ring are listed in Table 5. Bond lengths and angles involving hydrogen and a complete listing of torsion angles (Tables 6–8) are included as supplementary material.

Results and discussion

The X-ray crystallographic analysis of **4** unambiguously establishes **4***a* as the correct structural formulation. The two methods of preparing the adduct **4** involve different types of reactions. The low-yield method *a* proceeds via a boron–carbon bond cleavage reaction:

$$\mathbf{1} + (Ph_2B)_2O \rightarrow \mathbf{4} + C_6H_6$$

while the more efficient method *b* involves elimination of water:

$$\mathbf{1} + (1/2)(Ph_2B)_2O + PhB(OH)_2 \rightarrow \mathbf{4} + (3/2)\ H_2O$$

The crystal structure consists of discrete molecules separated by normal van der Waals distances.

The molecule contains a nearly planar B—O—B—O—N ring (χ^2 = 36.6, mean and maximum deviations from the mean plane are 0.007 and 0.010(3) Å respectively), very similar to that found in **6** (14). The trivalent atoms N(1), C(1), and B(1) exhibit planar coordination within the limits of experimental error; being displaced from the mean planes of their substituent atoms by 0.004(3), 0.008(3), and 0.010(4) Å respectively. The $Me_2C{=}N(O)B$ moiety is significantly non-planar (χ^2 = 107.6, mean and maximum deviations from the six-atom mean plane are 0.011 and 0.020(7) Å), the C(1) and N(1) coordination groups being twisted by 1.6° about the C=N double bond. The $Me_2C(1)$ moiety and the B(1) phenyl group are oriented roughly in the same plane as the five-membered heterocyclic ring (angles between normals to the mean planes being 1.7 and 5.8°

[4]The structure factor table, Table 2 (anisotropic thermal parameters) and other material mentioned in the text are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

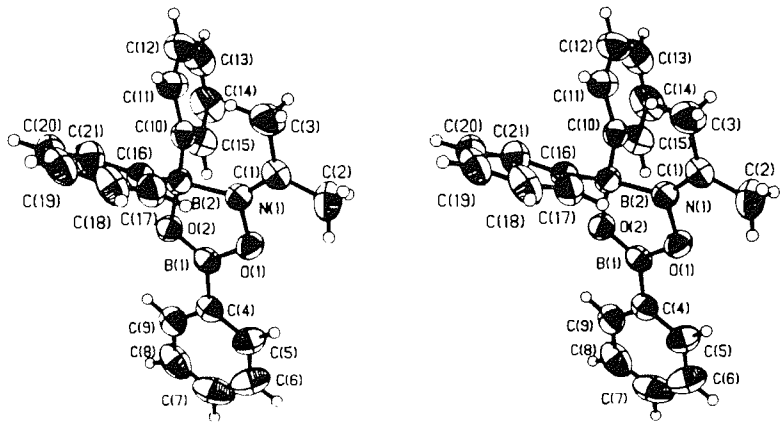

FIG. 1. Stereoscopic view of the 4-isopropylidene-2,5,5-triphenyl-1,3-dioxa-4-azonia-2-bora-5-boratacyclopentane molecule. 50% probability thermal ellipsoids are shown for the non-hydrogen atoms; hydrogen atoms have been assigned arbitrarily small thermal parameters for the sake of clarity.

TABLE 5. Intra-annular torsion angles (deg) standard deviations in parentheses

Atoms	Torsion angle (deg)
B(1)—O(1)—N(1)—B(2)	1.7(3)
O(1)—N(1)—B(2)—O(2)	−1.4(3)
B(1)—O(2)—B(2)—N(1)	0.6(3)
B(2)—O(2)—B(1)—O(1)	0.4(4)
N(1)—O(1)—B(1)—O(2)	−1.4(4)

respectively). The latter value is similar to those in the range 2.5−21.4° observed for other derivatives of phenylboronic acid (14−17).

The bond distances in the B—O—B—O—N ring of **4***a* are, in general, significantly different from those in **6**. These discrepancies undoubtedly arise from both steric factors (the ring in **6** being fused to another five-membered ring) and the chemical differences between corresponding nitrogen and four-coordinate boron atoms. It is noteworthy, however, that the sums of the libration-corrected bond distances in the five-membered heterocyclic rings of **4***a* and **6** are identical (7.340 Å in each case). Both **4***a* and **6** show the characteristic short anhydridic B(1)—O(2) bond (1.333(4) in **4***a*, 1.337(2) Å in **6**), believed to result from stronger π-back donation at this point in the ring. The B(1)—O(1) bonds in **4***a* and **6** (1.418(4) and 1.404(2) Å) are significantly longer than the short anhydridic bonds to B(1) but the average B(trigonal planar)—O distances in **4***a* and **6** (1.376 and 1.371 Å) compare well with a corresponding mean[5] value of 1.371(6) Å in $C_6H_5B(OH)_2$ (16). The B(2)—N(1) bond in **4***a* (1.676(4) Å) is significantly longer than the mean of 1.654(1) Å in ethanolamine esters of diarylborinic acids **7** (8, 18, 19) containing tetrahedral nitrogen, and also significantly longer than the value of 1.601(4) Å in **8** (20) which contains trigonal planar nitrogen but in a six-membered ring. This demonstrates the weaker binding and points to the lower basicity of the oxime nitrogen compared to amine or imine nitrogen. The B(2)—O(2) distance of 1.495(4) Å is significantly longer than corresponding bonds in compounds **7** (mean 1.477(2) Å) and the value of 1.467(2) Å in **6**.

The C=N and N—O distances of 1.284(3) and 1.418(3) Å are both at the long ends of the ranges previously noted for oximes (21) (1.25−1.288 and 1.32−1.426 Å respectively). A slight lengthening of the C=N bond upon coordination of nitrogen is expected relative to that of the free oxime (22). In the present case there is no significant difference between the C=N distance reported here and that found for the free oxime (23), C=N = 1.29(3) Å. For example, in salicylaldoxime (24), C=N = 1.270(5) Å, and in the complex bis-[(salicylaldoximato)phenylboron] (25), C=N = 1.278(1) Å. The B—C distances and the substituent-induced distortions of the phenyl rings are as expected (26).

[5]Here and elsewhere in this report mean values refer to weighted means with rms deviations from the mean in parentheses.

Structural studies of organoboron compounds. XV.[1] Crystal and molecular structures of (3-aminopropanolato)diphenylboron, (2-*N*,*N*-dimethylaminoethanolato)diphenylboron, and (2-*N*,*N*-dimethylaminoethanolato)diphenylboron − diphenylborinic acid (1:1)

STEVEN J. RETTIG AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received January 25, 1983

STEVEN J. RETTIG and JAMES TROTTER. Can. J. Chem. **61**, 2334 (1983).

Crystals of (3-aminopropanolato)diphenylboron are monoclinic, a = 9.6717(13), b = 9.8867(6), c = 14.452(2) Å, β = 99.500(7)°, Z = 4, space group $P2_1/n$; those of (2-*N*,*N*-dimethylaminoethanolato)diphenylboron are monoclinic, a = 7.0721(4), b = 16.8829(4), c = 12.0975(8) Å, β = 97.875(3)°, Z = 4, space group Cc; and those of (2-*N*,*N*-dimethylaminoethanolato)diphenylboron − diphenylborinic acid (1:1) are monoclinic, a = 11.3231(10), b = 19.3190(12), c = 12.2451(11) Å, β = 109.321(4)°, Z = 4, space group $P2_1/n$. All three structures were solved by direct methods and were refined by full-matrix least-squares procedures to final R values of 0.038, 0.031, and 0.040 for 1522, 1649, and 2420 reflections with $I \geq 3\sigma(I)$ respectively. Each structure contains a tetrahedrally coordinated boron atom. The libration-corrected B—O, B—N, and mean B—C distances are: 1.481(2), 1.643(3), and 1.623(3) Å for (3-aminopropanolato)diphenylboron; 1.476(2), 1.691 (2), and 1.625(7) Å for (2-*N*,*N*-dimethylaminoethanolato)diphenylboron. The Ph_2BOH molecule contains a trigonal-planar boron atom with B—O = 1.354(3) Å and mean B—C = 1.572(3) Å.

STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **61**, 2334 (1983).

Les cristaux des (aminopropanolato-3) diphénylbore sont monocliniques et appartiennent au groupe d'espace $P2_1/n$ avec a = 9,6717(13), b = 9,8867(6), c = 14,452(2) Å, β = 99,500(7)°, Z = 4. Les cristaux de (*N*,*N*-diméthylaminoéthanolato-2) diphénylbore sont monocliniques et appartiennent au groupe d'espace Cc avec a = 7,0721(4), b = 16,8829(4), c = 12,0975(8) Å, β = 97,875(3)°, Z = 4, et les cristaux de (*N*,*N*-diméthylaminoéthanolato-2) diphénylebore − acide diphénylboromique (1:1) sont monocliniques et appartiennent au groupe d'espace $P2_1/n$ avec a = 11,3231(10), b = 19,3190(12), c = 12,2451(11)Å, β = 109,321(4)°, Z = 4. On a résolu les trois structures par des méthodes directes et on les a affinées par la méthodes des moindres carrés (matrice entière) jusqu'à des valeurs respectives de R = 0,038, 0,031 et 0,040 pour 1522, 1649 et 2420 réflexions observés avec $I \geq 3\sigma(I)$. Chaque structure contient un atome de bore coordonné de façon tétraédrique. Les distances moyennes de liaison B—O, B—N et B—C corrigées pour la libration sont de 1,481(2), 1,643(3) et de 1,623(3) Å pour l'(aminopropanolato-3)diphénylbore; de 1,476(2), 1,691(2) et de 1,625(7) Å pour le (*N*,*N*-diméthylaminoéthanolato-2) diphénylbore. La molécule de Ph_2BOH contient un atome de bore plan-trigonal avec B—O = 1,354(3) Å et une distance moyenne B—C = 1,572(3) Å.

Introduction

As part of a continuing structural investigation of organoboron compounds (1) we report the crystal and molecular structures of (3-aminopropanolato)diphenylboron, **1**, (2-*N*,*N*-dimethylaminoethanolato)diphenylboron, **2**, and (2-*N*,*N*-dimethylaminoethanolato)diphenylboron − diphenylborinic acid (1:1), **3**. Both **1** and **2** are closely related to the structurally characterized (2-aminoethanolato)diarylboron compounds **4** where R = H (2, 3), F (4), and CH_3 (3). Both the size of the chelate ring and, in particular, substitution at nitrogen are known to affect the rate of hydrolytic cleavage of the intramolecular N → B bond which stabilizes this type of diarylborinic ester (5). The object of this investigation is to determine if and how these factors influence the molecular geometry. The molecular complex **3** was isolated during the preparation of **2**, making possible the structure determination of the unstable parent acid Ph_2BOH.

[1]Previous paper in this series: ref. 1.

Experimental

Compounds **1** and **2** were prepared by reacting the appropriate aminoalcohol with an equimolar quantity of diphenylborinic acid (obtained by acid hydrolysis of (2-aminoethanolato)diphenylboron) in ethanol/diethyl ether (6). A small amount of the molecular complex **3** was isolated from the reaction mixture during the preparation of **2** as colorless crystals suitable for X-ray analysis. Colorless crystals of **1** and **2** were obtained by recrystallization from ethanol.

X-ray crystallographic studies

(3-aminopropanolato)diphenylboron, 1

A crystal ca. 0.10 × 0.33 × 0.45 mm in size was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 30−40°) measured on a diffractometer with Mo-Kα_1 radiation (λ = 0.70930 Å). Crystal data at 22°C are:

$C_{15}H_{18}BNO$ fw = 239.13

Monoclinic, a = 9.6717(13), b = 9.8867(6), c = 14.452(2) Å, β = 99.500(7)°, V = 1363.0(3) Å^3, Z = 4, ρ_c = 1.165 g cm^{-3}, F(000) = 512, μ(Mo-Kα) = 0.66 cm^{-1}. Absent reflections: $h0l$, $h+l$ odd, and $0k0$, k odd uniquely indicate the space group $P2_1/n$ (non-standard setting of $P2_1/c$, C_{2h}^5, No. 19, equivalent positions: ± (x, y, z; 1/2 − x, 1/2 + y, 1/2 − z)).

Intensities were measured with graphite-monochromated Mo-Kα radiation (λ = 0.71073 Å) on an Enraf-Nonius CAD4-F diffractometer. An ω−2θ scan at 0.80−10.06° min^{-1} over a range of (0.60 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 55°. The intensities of three check reflections, measured every 3600 s throughout the data collection, remained constant to within 2%.

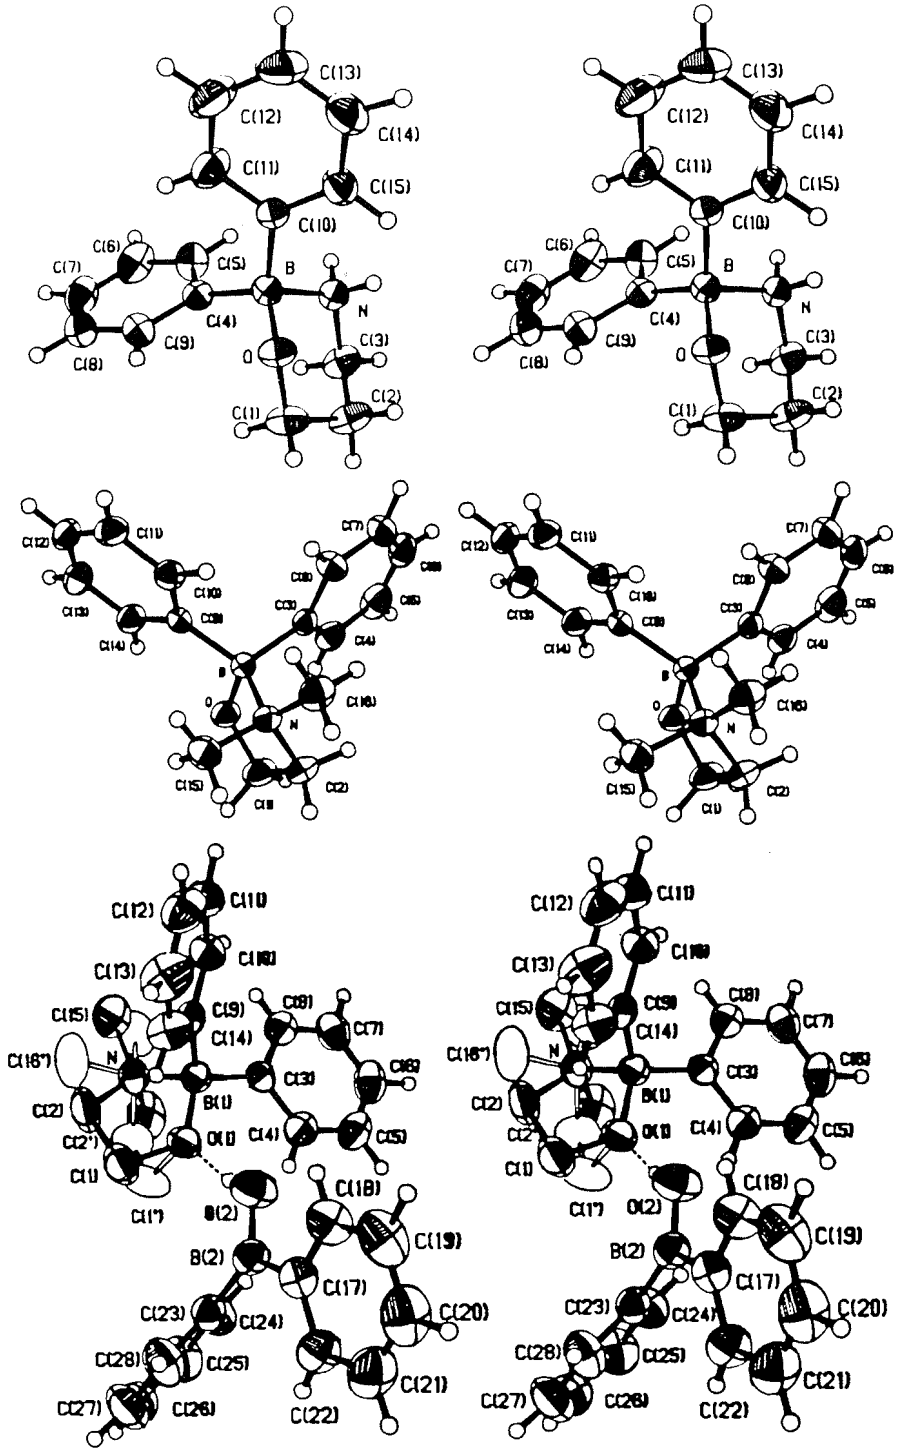

FIG. 1. Stereoscopic views of (3-aminopropanolato)diphenylboron (top), (2-*N*,*N*-dimethylaminoethanolato)diphenylboron (middle), and (2-*N*,*N*-dimethylaminoethanolato)diphenylboron − diphenylborinic acid (1:1) (bottom). 50% probability thermal ellipsoids are shown for the non-hydrogen atoms, hydrogen atoms have been assigned arbitrarily small thermal parameters for the sake of clarity.

Of the 3113 independent reflections measured and processed,[2] 1522 (48.9%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The structure was solved by direct methods, the positions of all non-hydrogen atoms being determined from an *E*-map. After full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters to $R = 0.074$, a difference map revealed the positions of all 18 hydrogen atoms which were refined with isotropic thermal parameters in subsequent least-squares cycles. The scattering factors of ref. 7 were used for non-hydrogen atoms and those of ref. 8 for hydrogen atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform

[2]The computer programs used include locally written programs for data processing and locally modified versions of the following: MULTAN 80, multisolution program by P. Main, S. J. Fiske, S. E. Hull, L. Lessinger, G. Germain, J. P. Declerq, and M. M. Woolfson; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

TABLE 1. Final positional (fractional × 10^5, disordered C and all H × 10^4) and isotropic thermal parameters ($U \times 10^3$ Å^2) with estimated standard deviations in parentheses*

*Primed and double-primed atoms have occupancies of 0.60 and 0.40 respectively.

average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and $\sin\theta/\lambda$ and was employed in the final stages of refinement. Convergence was reached at $R = 0.038$ and $R_w = 0.047$ for 1522 reflections with $I \geq 3\sigma(I)$. For all 3113 reflections $R = 0.112$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.03 and 0.28σ respectively. The mean error in an observation of unit weight was 1.677. A final difference map showed no unusual features. The final positional and thermal parameters appear in Tables 1 and 2[3] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[3]

(2-N,N-dimethylaminoethanolato)diphenylboron, 2

Experimental details are as above except where noted. Crystal dimensions were ca. 0.10 × 0.46 × 0.50 mm. Crystal data:

$C_{16}H_{20}BNO$ fw = 253.16

Monoclinic, $a = 7.0721(4)$, $b = 16.8829(4)$, $c = 12.0975(8)$ Å, $\beta = 97.875(3)°$, $V = 1430.8(1)$ Å^3, $Z = 4$, $\rho_c = 1.175$ g cm^{-3}, $F(000) = 544$, μ(Mo Kα) = 0.67 cm^{-1}. Absent reflections: hkl, $h+k$ odd, and $h0l$, l odd, space group Cc (C_s^4, No. 9) assumed on the basis of the number of molecules in the unit-cell.

An $\omega-2\theta$ scan at 0.96−10.06° min^{-1} over a range of (0.75 + 0.35 tan θ)° in ω was employed. Of 2067 independent reflections measured (to $2\theta = 60°$), 1649(79.8%) had intensities greater than $3\sigma(I)$ above background. Data were corrected for an isotropic decay of 3.4% which occurred during the course of the data collection.

The structure was solved by direct methods. After refinement of the non-hydrogen atoms with anisotropic thermal parameters to $R = 0.067$, the coordinates of all 20 hydrogen atoms were determined from a difference map. Convergence was reached at $R = 0.031$ and $R_w = 0.040$ for 1649 reflections with $I \geq 3\sigma(I)$, for all 2067 reflections $R = 0.044$. The mean and maximum parameter shifts on the final cycle of refinement corresponded to 0.12 and 0.59σ respectively, and the mean error in an observation of unit weight was 1.392.

(2-N,N-dimethylaminoethanolato)diphenylboron − diphenylborinic acid (1:1), 3

Crystal dimensions were ca. 0.27 × 0.33 × 0.37 mm. Crystal data:

$C_{28}H_{31}B_2NO_2$ fw = 435.19

Monoclinic, $a = 11.3231(10)$, $b = 19.3190(12)$, $c = 12.2451(11)$ Å, $\beta = 109.321(4)°$, $V = 2527.7(4)$Å^3, $Z = 4$, $\rho_c = 1.144$ g cm^{-3}, $F(000) = 928$, μ(Mo Kα) = 0.65 cm^{-1}. Absent reflections: $h0l$, $h+l$ odd, and $0k0$, k odd uniquely indicate the space group $P2_1/n$.

An $\omega-2\theta$ scan at 1.34−10.06° min^{-1} over a range of (0.65 + 0.35 tan θ)° in ω was employed. Of 4422 independent reflections measured (to $2\theta = 50°$), 2420(54.7%) had $I \geq 3\sigma(I)$. Data were corrected for an isotropic decay of 3.0% during the data collection.

The structure was solved by direct methods, all non-hydrogen atoms being located from an *E*-map. After two cycles of refinement with isotropic thermal parameters to $R = 0.167$, a difference map indicated twofold conformational disorder of the five-membered chelate ring. Site occupancies of the resolved atoms C(1), C(2), C(15), and C(16) were then refined, resulting in normalized average values of 0.60 and 0.40 for the two sets of positions. These parameters were kept fixed during subsequent cycles of refinement. The non-hydrogen atoms were then refined with anisotropic thermal parameters to $R = 0.097$ at which point a difference map revealed all of the ordered hydrogen atoms, these being subsequently refined with isotropic thermal parameters. The disordered hydrogen atoms were included as fixed atoms with C—H = 0.98 Å and an isotropic thermal parameter 25% larger than that associated with the carbon atom to which it is bonded. Convergence was reached at $R = 0.040$ and $R_w = 0.049$ for 2420 observed reflections, for all 4422 reflections, $R = 0.093$. The mean and maximum parameter shifts on the final cycle of refinement were 0.16 and 0.70σ, and the mean error in an observation of unit weight was 1.760.

Analysis of thermal motion

The thermal motion in each of the three structures (Fig. 1) has been analysed in terms of the rigid-body modes of translation, libration, and screw-motion (9). The rms errors in the U_{ij} (derived from the least-squares analyses) are 0.0012, 0.0009, and 0.0015 Å^2 for **1**, **2**, and the ordered non-hydrogen atoms of **3** respectively. Analysis of entire molecules in each case indicated significant independent motion of the phenyl rings. PhB groups were separately analysed in each structure (rms ΔU_{ij} = 0.0014 − 0.0031 Å^2). The chelate rings plus atoms

[3]The structure factor table, Table 2 (anisotropic thermal parameters) and other material mentioned in the text are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

directly bonded to these rings were also analysed (rms ΔU_{ij} = 0.0017 and 0.0015 Å^2 for **1** and **2**, 0.0060 and 0.0085 Å^2 for the alternate rings in the disordered (2-*N*,*N*-dimethylaminoethanolato)diphenylboron molecule of **3**). The appropriate bond distances have been corrected for libration (9, 10), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3 along with the uncorrected values; corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 4. Intra-annular torsion angles defining the conformations of heterocyclic rings are listed in Table 5. Bond lengths and angles involving hydrogen and a complete listing of torsion angles (Table 6–8) are included as supplementary material.

Results and discussion

The chelates **1** and **2** are formed by simple esterification of diphenylborinic acid (water being eliminated) followed by intramolecular N → B coordination. The molecular complex **3** (**2**·Ph_2BOH, stabilized by an O—H···O hydrogen bond) is formed as a result of the presence of excess Ph_2BOH in the reaction mixture. In reactions of this type an excess of (2-aminoethanolato)diphenylboron is employed to compensate for losses during the hydrolysis step of the synthesis.

The crystal structure of **1** consists of discrete molecules, each linked to two others by N—H···O hydrogen bonds

C(1a)—O(1)—B(1)—N	24.0(5)

(N—H(Nb)···O(1/2 − x, 1/2 + y, 1/2 − z), H···O = 1.88(3), N···O = 2.814(2) Å, N—H···O = 163(2)°) to form continuous spirals about the twofold screw axes. The structure of **2** consists of individual molecules separated by normal van der Waals distances, and that of **3** contains hydrogen-bonded $Ph_2BOCH_2CH_2NMe_2$—Ph_2BOH units (O(2)—H(O2)···O(1), H···O = 1.87(3), O···O = 2.729(2) Å, O—H···O = 166(3)°), separated from other such units by normal van der Waals distances.

The six-membered heterocyclic ring in **1** has a slightly distorted chair conformation (see Table 5). The intraannular bond angles in this ring are, as expected, nearer the tetrahedral value than are those in the five-membered rings of **2** and **4**. The O—B, N—B, mean[4] C—B, O—C, and N—C bond lengths in **1** (1.481(2), 1.643(3), 1.623(3), 1.437(2), and 1.498(3) Å respectively) may be compared with the corresponding mean values for compounds **4** (1.477(2), 1.654(1), 1.618(1), 1.412(2), and 1.488(2) Å). The only statistically significant differences between corresponding parameters are a lengthening of the O—C bond by 0.025(3) Å and a shortening of the N—B bond by 0.011(3) Å in **1** relative to those in compounds **4**.

The five-membered heterocyclic ring in **2** has an envelope conformation, the nitrogen atom being displaced from the approximate plane of the other four ring atoms. The two conformations of the disordered ring in the (2-*N*,*N*-dimethylaminoethanolato)diphenylboron molecule in **3**, mirror images of one another, are essentially the same as that found in the ordered structure **2** (see Table 5). Bond lengths and angles for the (2-*N*,*N*-dimethylaminoethanolato)diphenylboron molecules in **2** and **3** are generally the same; all bonds to boron are equal within experimental error except the B—O distance (1.476(2) Å in **2**, 1.492(3) Å in **3**). In spite of the fact that the ring oxygen atom in **3** is involved in a hydrogen bond,unlike that in **2**, most of this discrepancy probably arises from imperfect modelling of the conformational disorder in **3**.

The major structural differences between the (2-*N*,*N*-dimethylaminoethanolato)diphenylboron molecule and compounds **4** are the expected (on steric grounds) increases of the N—B and N—C(ring) distances (by 0.037(2) and 0.018(3) Å) to 1.691(2) and 1.506(2) Å respectively. The N—B distances in compounds **1**, **2**, and **4** are thus found to be directly proportional to the rates of hydrolytic cleavage of the N—B bonds (5, 11).

The trigonal planar boron atom in the Ph_2BOH molecule of **3** is displaced 0.017(3) Å from the plane of its substituents. The C(17) and C(23) phenyl groups are twisted out the B(2) coordination plane by 16.1 and 47.8° respectively. The C—B—C angle is 122.6(2)° while the C—B—O angles are significantly different, 115.5(2)° for C(17) and 121.8(2)° for C(23). The mean C—B(2) distance of 1.572(3) Å lies between the mean values of 1.566(3) Å in $PhB(OH)_2$ (12) and 1.580(9) Å in Ph_3B (13), and the B(2)—O(2) distance of 1.354(3) Å is significantly shorter than the corresponding mean of 1.371(6) Å in $PhB(OH)_2$.

The phenyl rings in all three structures are slightly, but significantly, non-planar (χ^2 = 12.7−70.5), the maximum deviation of any phenyl carbon atom from its respective mean plane being 0.015 Å. The geometry of the B-substituted phenyl rings is as expected (14).

[4]Here and elsewhere in this report mean values refer to weighted means with rms deviations from the mean in parentheses.

Uranium recovery from phosphate ores through sintering

L. A. GUIRGUIS
Nuclear Materials Corporation, Cairo, Egypt

Received May 7, 1982[1]

L. A. GUIRGUIS. Can. J. Chem. **61**, 2341 (1983).

The use of an alkaline reactant for phosphate processing is an alternative to the current methods of using acid reagents.

In this work the possibilities of attacking low-grade phosphate ores by sintering with sodium carbonate at moderate temperature are considered. The carbonate liquor obtained by a water leach contains uranium in the form of uranyl tricarbonate complex, as well as the equivalent dissolved phosphate. Uranium from such liquor was recovered as sodium uranate on addition of sodium hydroxide, while pure sodium phosphate, useful as a chemical, was recovered by fractional crystallization.

Finally, a flowsheet was designed for the proposed process.

L. A. GUIRGUIS. Can. J. Chem. **61**, 2341 (1983).

L'utilisation d'un réactif alcalin pour le traitement des phosphates offre la possibilité de rompre avec les méthodes usuelles basées sur les réactifs acides.

Dans ce travail, on considère la possibilité de traiter les minerais à faible teneur en phosphate en les agglomérant avec le carbonate de sodium à température modérée. La solution carbonatée obtenue par lavage à l'eau contient de l'uranium sous forme de carbonate d'uranyle, en plus de l'équivalent en phosphate dissout. On récupère l'uranium sous forme d'uranate de sodium en ajoutant de l'hydroxyde de sodium à la solution tandis qu'on récupère, par cristallisation fractionné, le phosphate à l'état pur.

Finalement on propose un cheminement pour cette technique.

[Traduit par le journal]

Introduction

To convert the phosphorus in apatite to a soluble form for use as a plant nutrient, the phosphate, along with impurities such as uranium, are commonly dissolved in sulphuric acid to produce superphosphate or phosphoric acid for further processing. Such acid processes are not so readily applied to low-grade ores; in particular, they are unsuitable for treatment of ores in which calcareous gangue would lead to acid wastage and the production of unwanted calcium salts. Thus the use of new chemical process routes is necessary.

High-temperature, or sinter-reaction, treatment of phosphate rock has been studied widely (1–3). However, most of the processes described aim at the defluorination of apatite. Separation of products of high phosphate content is not normally contemplated. The Rhenania process, thus far the most successful example of a sintering process, produces a fertilizer containing at best 30% P_2O_5. In this sinter reaction, apatite reacts with silica and sodium carbonate at a temperature in the range 1100–1200°C, yielding a complex product that may be either a sodium calcium silicophosphate or a mixture of sodium calcium orthophosphate and calcium orthosilicate. In fact, the sintering temperature used in the Rhenania process is fairly high.

In the present study, the examined phosphate sample was found to be amenable to attack by sintering with sodium carbonate in the presence of sodium fluoride at 700°C, a temperature much lower than that used in a typical Rhenania process. Moreover, the formation of the soluble uranyl tricarbonate anion, $UO_2(CO_3)_3^{4-}$ permits the use of this method for the nearly selective dissolution of uranium from the sintered material.

Experimental procedure

The present study was carried out on a low-grade phosphate sample from the Abu Shegella area, phosphate horizon (c), Red Sea region, Egypt. The analysed chemical composition (in wt%) was as follows: SiO_2 28.0, CaO 33.19, MgO 0.40, Al_2O_3 0.53, Fe_2O_3 0.38, FeO 2.28, TiO_2 0.32, Cr_2O_3 0.66, P_2O_5 13.90, Na_2O 0.54, K_2O 0.05, SO_4 1.80, Cl 0.32, F 3.71, CO_2 9.28, H_2O 0.83, organic matter 2.80, U 0.014.

TABLE 1. Effect of particle size on extraction process

Mesh size	P_2O_5 leached, %
30	7.35
100	18.58
200	40.92
325	80.00
400	79.93

Sodium carbonate and sodium fluoride were milled to the same mesh size as that of the ore, and thoroughly mixed with the ore in an agate mortar. The prepared sample fraction was placed in a fused magnesite crucible and inserted inside a tube furnace heated to the required temperature.

Atmospheric carbonate leaching experiments were done using the carbonate sintered milled ore in 1 L round bottom glass vessels with three openings. The large opening in the middle through which the stirrer rod passes was water sealed in order to minimize the evaporation of solution and subsequent increase in the pH during the leaching process. One of the smaller openings was connected to a reflux water condenser to prevent the eventual escape of condensable gases; the other opening supported a thermometer. The leaching vessels were clamped in a temperature-regulated oil bath.

Sodium bicarbonate and air or $KMnO_4$ were added in the appropriate amounts and then water was added in equal volume to the ore. After the end of a leaching experiment, an aliquot of the slurry was cooled to measure the pH, followed by filtration through Buchner funnels with suction. The spent ore cake was washed by an equal weight of hot 5 g/L Na_2CO_3 solution in two successive steps to displace the soluble values. The original filtrate and washings were collected in a measuring flask, the volume was adjusted using a 5 g/L Na_2CO_3 solution and a sample was analysed for uranium, phosphorus, and other constituents. The wet residue was weighed, dried in a drying oven at 110°C, reweighed, ground to 300 mesh size, quartered, and then analysed for its unleached uranium content.

A number of pressure-leaching tests were conducted on the sintered

TABLE 2. Effect of amount of sodium carbonate on the extraction process

Amount of Na_2CO_3 (g/kg ore)	Amount of NaF (g/kg ore)	P_2O_5 leached, %
50	2.5	34.12
100	5	46.56
200	10	62.42
300	15	80.10
400	20	79.28
500	25	80.03

ore in a stirred thermoregulated autoclave of 5-L capacity. Air was supplied from a standard cylinder by means of a 2-stage pressure regulator.

The sintered milled ore (200 g), the desired amount of sodium bicarbonate, oxidant, and water was introduced in the stainless steel reaction vessel. The autoclave was then heated to 90°C. Air was then introduced to a pressure of 5 atm and from this instant the leaching time was calculated.

Results and discussion

A large number of sintering and leaching experiments were performed on the ore, each time changing one of the different sintering factors that affect the overall extraction (sintering + leaching) process, namely, the amount of sodium carbonate, the amount of sodium fluoride, the ore grain size, the temperature, the time of sintering. Efficiency of leaching P_2O_5 did not exceed 80% at 700°C sintering temperature. The conditions of the leaching experiments were not varied.

(a) Effect of sintering time

With other parameters fixed at 300 g Na_2CO_3/kg ore, 15 g NaF/kg ore and a temperature of 700°C, the amount of P_2O_5 leached was constant at 80% ± 1% for each 5- to 30-min sintering time.

(b) Effect of grain size

Table 1 shows the effect of grain size on the sintering–extraction process. The extent of the sintering improved with the fineness of the ore. This may be due to the large surface area exposed. The optimum grain size was found to be 325 mesh.

(c) Effect of the amount of sodium carbonate

This factor has been studied over different sodium carbonate quantities ranging from 50 to 500 g/kg ore. 5% of this quantity was sometimes added as sodium fluoride. Other factors were fixed at 5-min sintering time, 700°C temperature, and ore milled to 325 mesh size.

The results given in Table 2 show that the percentage of P_2O_5 leached increased with an increase in the amount of sodium carbonate and that a minimum of about 300 g Na_2CO_3/kg ore appears to be sufficient for the maximum recovery of P_2O_5 (about 80%).

(d) Effect of temperature

Figure 1 shows the effect of sintering temperature on the leaching of the phosphate sample. It is clear that about 75–80% P_2O_5 could dissolve at 700°C after sintering in the presence of 15 g NaF/kg ore as a sintering promoter.

At this low sintering temperature calcium carbonate present as calcareous gangue does not interfere with the sintering reaction.

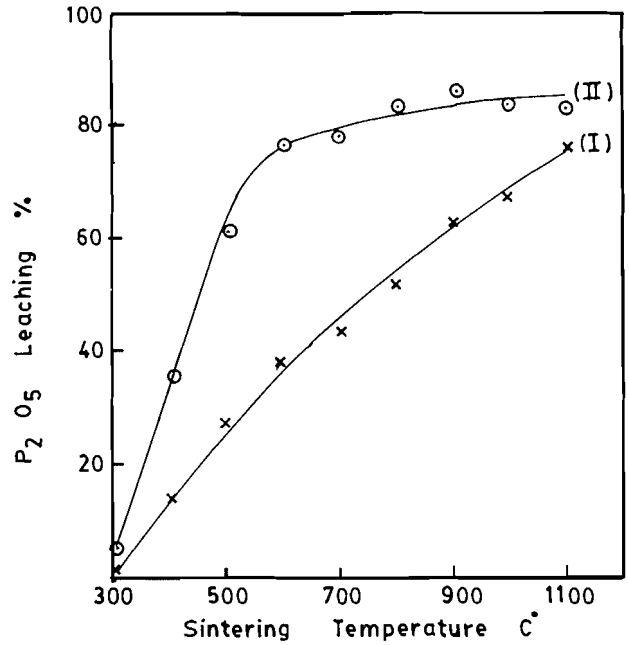

FIG. 1. Leaching efficiency of P_2O_5 versus sintering temperature using Na_2CO_3 (*I*) and Na_2CO_3 + NaF (*II*).

The 80% leachable P_2O_5 could also be obtained by sodium carbonate sintering without calcium fluoride at 1100°C. However, subsequent leaching of uranium from that product proved to be difficult.

Carbonate leaching

The chemistry of the carbonate process is discussed here, and has been fully explained by Merritt (4).

$$2UO_2 + O_2 \rightleftharpoons 2UO_3$$

$$UO_3 + Na_2CO_3 + 2NaHCO_3 \rightleftharpoons Na_4[UO_2(CO_3)_3] + H_2O$$

Bicarbonate is added to the leach solution to react with hydroxyl ion and thereby prevent reprecipitation of part of the dissolved uranium. The hydroxyl ion will form in the absence of bicarbonate by carbonate reaction with uranium as follows:

$$UO_3 + 3Na_2CO_3 + H_2O \rightleftharpoons Na_4UO_2(CO_3)_3 + 2\ NaOH$$

The results of alkaline leaching tests on the sintered ore are summarized in Table 3. In this table sodium carbonate and sodium bicarbonate are given in g/kg ore; however, the two reagents were used in equal proportions with respect to their sodium content. This investigation was carried out at a solid/liquid ratio of 1:1. To take into consideration the fact that alkaline leaching is a slow process, a series of preliminary experiments covering a range of 2 to 28 h agitation time were carried out. On the basis of the data obtained, it may be concluded that 12 h agitation time in atmospheric alkaline leaching and 3 h agitation time in pressure alkaline leaching is quite adequate to bring about the required leaching efficiency.

According to Frank (4), the optimum temperature range appears to be 80–115°C. It was therefore decided to adopt 90°C for uranium alkaline leaching.

Uranium recovery from carbonate leach liquors

The pregnant liquor thus formed can then be subjected to a sodic decomposition step whereby sodium diuranate assaying

TABLE 3. Results of atmospheric and pressure alkaline leaching

Atmospheric alkaline leaching						Pressure alkaline leaching					
Na_2CO_3 (g/kg)	$NaHCO_3$ (g/kg)	Oxidant air (m^3/kg ore)	Time (h)	Temperature (°C)	%U leached	$NaCO_3$ (g/kg)	$NaHCO_3$ (g/kg)	Oxidant $KMnO_4$ (g/kg)	Time (h)	Temperature (°C)	%U leached
300	475	—	12	90	40.07	300	475	—	3	90	42.05
300	475	0.0071	12	90	70.13	300	475	5	3	90	65.23
300	475	0.0142	12	90	80.00	300	475	10	3	90	81.00

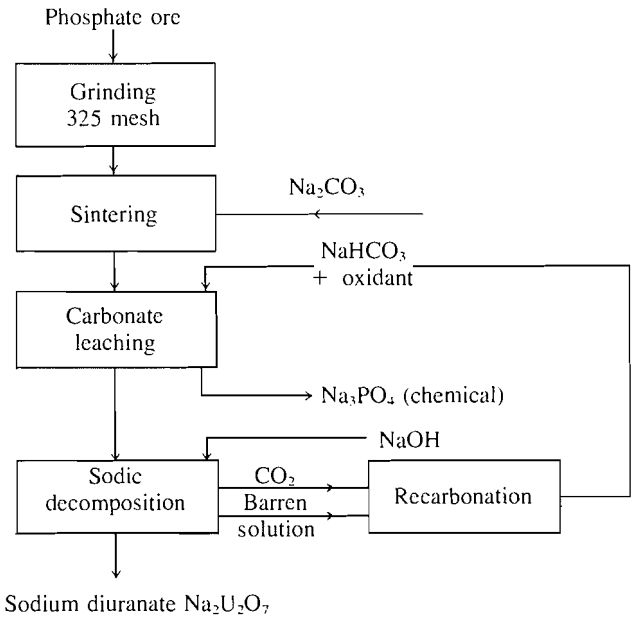

FIG. 2. Process flowsheet for uranium recovery from phosphates.

65% U is produced.

$$2UO_2(CO_3)_3^{4-} + 6OH^- + 2Na^+ \rightarrow Na_2U_2O_{7\downarrow} + 6CO_3^{2-} + 3H_2O$$

Sodium hydroxide neutralizes first the bicarbonate ions and then proceeds to precipitate the uranium at pH 11 (5).

For uranium to precipitate by the above process its concentration should be 3–4 g/L and since the liquor is very dilute, the addition of a primer such as a known amount of uranium to initiate the precipitation is essential. An alternative is to recycle the dilute liquor for further leaching in order to enrich it in uranium before precipitation. Partial evaporation of the dilute liquor could also be employed. Sodium phosphate is recovered from the carbonate liquor by fractional crystallization. A process flowsheet is shown in Fig. 2.

Conclusion

Alkaline sintering at moderate temperature of phosphate ores like the presently studied sample will allow industry to obtain by-product uranium according to local conditions, and to make effective use of a wider variety of ore material including those of low phosphate grade. The idea that alkaline leach methods are ineffective in the dissolution of uranium from phosphate is discredited.

Potentiométrie de précision à basse température dans les mélanges eau − éthylène glycol; grandeurs thermodynamiques relatives aux ionisations de l'acide acétique et du solvant mixte

HAMED BAHRI, JEAN-CLAUDE HALLÉ[1] ET ROBERT SCHAAL

Laboratoire de Physicochimie des Solutions, LA CNRS 161, E.N.S.C.P. 11 Rue Pierre et Marie Curie, F75231 Paris Cedex 05, France

Reçu le 3 janvier 1983

HAMED BAHRI, JEAN-CLAUDE HALLÉ et ROBERT SCHAAL. Can. J. Chem. **61**, 2344 (1983).

Des mesures de forces électromotrices de piles sans jonction, comportant une électrode d'hydrogène et une électrode argent − chlorure d'argent, ont permis de déterminer dans les mélanges eau − éthylène glycol contenant 50 et 70% en masse de diol, et pour 14 températures allant de −35 à 30°C, les fonctions thermodynamiques relatives à la dissociation de l'acide acétique d'une part et du solvant mixte d'autre part. Les standards primaires d'acidité de ces mélanges, tamponnés par l'acide acétique ou rendus basiques par la soude sont également donnés.

HAMED BAHRI, JEAN-CLAUDE HALLÉ, and ROBERT SCHAAL. Can. J. Chem. **61**, 2344 (1983).

Electromotive force measurements of cells without liquid-junction containing hydrogen electrodes and silver − silver chloride electrodes have been used to derive the dissociation constants of acetic acid and solvent water − ethylene glycol mixtures (50 and 70 mass % of ethyleneglycol) at 14 temperatures from −35 to 30°C. Primary acidity standards related to these acetic buffered and sodium hydroxide solutions are given.

Introduction

Au cours des dix dernières années l'utilisation d'agents cryoprotecteurs a considérablement amélioré les conditions de conservation des tissus vivants et en particulier, des organes en attente d'être greffés (1−6). La maîtrise du niveau d'acidité de ces solutions refroidies, obtenues le plus souvent en ajoutant à de l'eau des alcools ou du diméthylsulfoxyde (1, 6−8), s'est vite révélée indispensable pour une meilleure connaissance des réactions cellulaires (2−5, 9−12). A part les standardisations précises très récentes de quelques tampons, réalisées à l'électrode d'hydrogène dans des mélanges eau−DMSO (11) et eau−éthanol (12) les échelles d'acidité établies à ce jour en-dessous de 0°C, ont été construites par potentiométrie à l'électrode de verre (9, 13, 14) et doivent donc être utilisées avec circonspection tant qu'elles n'auront pas été contrôlées par des mesures absolues à l'électrode d'hydrogène (14, 15). Un des buts de ce travail est donc la standardisation jusqu'à −35°C des solutions eau − éthylène glycol (EGOH), contenant respectivement 50 et 70% d'alcool en masse, tamponnées à partir de l'acide acétique et simultanément, nous avons déterminé dans ces milieux refroidis, les fonctions thermodynamiques relatives à la dissociation de cet acide. Le bon fonctionnement de l'électrode d'hydrogène dans ces mélanges hydroorganiques rendus basiques par l'addition d'une base forte a également rendu possible la détermination des niveaux d'alcalinité élevés obtenus, permettant ainsi l'utilisation à basse température de tout le domaine acido-basique accessible.

Résultats et discussion

1. Dissociation de l'acide acétique

La constante d'acidité K_a de l'acide acétique (HAc), relative à l'équilibre d'ionisation:

$$HAc + HS \rightleftharpoons Ac^- + H_2S^+$$

dans les solvant mixte HS, et qui s'exprime par:

$$[1] \quad K_a = a_{H_2S^+} \frac{m_{Ac^-}}{m_{HAc}} \frac{\gamma_{Ac^-}}{\gamma_{HAc}}$$

est reliée à la force électromotrice E_A — ramenée à la pression d'hydrogène d'une atmosphère (15) — de la chaîne électrolytique (A) par l'expression [2]

$$[A] \quad Pt;\ H_2\ (g,\ 1\ atm) \left| \begin{array}{l} HAc\ (m_{HAc}),\ NaAc\ (m_{NaAc}) \\ \\ NaCl\ (m_{NaCl})\ dans\ HS \end{array} \right| AgCl;\ Ag$$

$$[2] \quad pK_a = \frac{E_A - E^0}{(RT \ln 10)/F} + \log_{10} \frac{m_{HAc}\, m_{Cl^-}}{m_{Ac^-}} + \log_{10} \frac{\gamma_{HAc}\, \gamma_{Cl^-}}{\gamma_{Ac^-}}$$

Dans ces expressions a, m et γ désignent respectivement les activité, molalité et coefficient d'activité des différentes espèces (H_2S^+ représente le proton solvaté par l'eau et/ou par le diol) et E^0 le potential standard de l'électrode AgCl, Ag déterminé préalablement (15). La constante diélectrique relativement élevée de ces mélanges (15) rend la dissociation des sels (NaCl et NaAc) totale.

L'expérience montre que le dernier terme de l'expression [2] est une fonction linéaire de la force ionique I du milieu qui, compte tenu des conditions expérimentales ($m_{HAc} = m_{NaAc} = m_{NaCl} = m$), est égale à $2m$. Le pK_a s'obtient donc par extrapolation à force ionique nulle du pK'_a apparent calculé à partir de [3]:

$$[3] \quad pK'_a = \frac{E_A - E^0}{(RT \ln 10)/F} + \log_{10} m = pK_a - \beta I$$

Pour chaque molalité m étudiée, il se trouve que la f.e.m. E_A de la pile (A) est une fonction linéaire de la température centigrade t. Les coefficients a et b représentatifs de cette variation apparaissent dans le tableau 1. L'extrapolation linéaire à dilution infinie de pK'_a (éq. [3]) conduit aux valeurs de pK_a rassemblées dans le tableau 2. Nous avons également reporté dans le tableau 2 les niveaux d'acidité ($pa_H = -\log a_{H_2S^+}$) des solutions tamponnées de molalité 0,01. Ils ont été calculés à partir de la relation [4]:

$$[4] \quad pa_H = pK_a + \log_{10} \frac{m_{Ac^-}}{m_{HAc}} + \log_{10} \frac{\gamma_{Ac^-}}{\gamma_{HAc}}$$

[a]Références 14 et 16, échelle molaire ($c_{HAc} = c_{Ac^-} = 0{,}01$).

en identifiant, d'une part le coefficient d'activité de la molécule d'acide acétique à l'unité ($\gamma_{HAc} \simeq 1$) ce qui est raisonnable tant que la molalité reste faible, et d'autre part, le coefficient d'activité de l'anion acétate au coefficient d'activité moyen $\gamma_\pm$ déterminé préalablement (15). Les niveaux d'acidité du même tampon acétique déterminés à l'aide d'une électrode de verre (14, 16) par Douzou et collaborateurs pour l'un des milieux étudiés (référés à l'échelle molaire) apparaissent également dans le tableau 2 (entre parenthèses). Leur conversion dans l'échelle molale n'est pas nécessaire pour conclure à l'excellent accord qui les lie à nos résultats. La majoration qu'il faudrait leur apporter pour les amener dans l'échelle molale, égale au logarithme décimal de la masse volumique (15), reste en effet inférieure à l'incertitude expérimentale des mesures de Douzou: $\Delta p a_H = 0{,}05$.

Parmi les diverses équations proposées pour rendre compte de l'influence de la température sur le pK_a (17), la plus utilisée — éq. [5], (18) — est ici encore celle qui convient le mieux:

$$[5] \quad pK_a = \frac{A}{T} - C + DT$$

Les coefficients A, C et D qui redonnent les valeurs de pK_a expérimentales à 0,001 près valent respectivement 1573,2; 5,3309 et 0,018354 pour le milieu contenant 50% de diol et 1299,3; 2,9845 et 0,014889 pour celui titrant 70% de diol. Ils permettent le calcul des fonctions thermodynamiques usuelles relatives à la dissociation de l'acide acétique soit:

$$[6] \quad \begin{aligned} \Delta G^0 &= R\ (\ln 10)\ (A - CT + DT^2) \\ \Delta S^0 &= R\ (\ln 10)\ (C - 2DT) \\ \Delta H^0 &= R\ (\ln 10)\ (A - DT^2) \\ \Delta C_p{}^0 &= R\ (\ln 10)\ (-2DT) \end{aligned}$$

La mesure au centième de millivolt des forces électromotrices, rend la détermination, par cette méthode, de l'enthalpie libre de dissociation très précise. Si la précision reste bonne après une première dérivation (ΔS^0 et ΔH^0), il faut être conscient que le $\Delta C_p{}^0$ résultant d'une seconde dérivation sera beaucoup moins fiable car il dépendra beaucoup plus de l'expression retenue pour caractériser la dépendance du pK_a avec la température (19). Les $\Delta C_p{}^0$ ainsi obtenus, ont néanmoins été consignés dans le tableau 3 avec les valeurs des autres grandeurs thermodynamiques.

Comme dans beaucoup de solvants, la dissociation de l'acide acétique est maximum au voisinage de 20°C, son ionisation athermique se situant respectivement à 19,6°C et 22,2°C pour les deux mélanges étudiés.

II. Dissociation du solvant

(1) Détermination du produit ionique

Le caractère amphotère des deux constituants du mélange permet de schématiser la réaction d'ionisation du solvant par l'expression suivante:

$$2HS \rightleftharpoons H_2S^+ + S^-$$

où H_2S^+ désigne toujours le proton solvaté sous ses différentes formes ($H_3O^+ + EGOH_2^+$) et où S^- représente la base conjuguée du solvant c'est à dire OH^- et EGO^-. Le produit ionique K_s du milieu mixte défini par:

$$[7] \quad K_s = a_{H_2S^+} a_{S^-}$$

est accessible à partir de la force électromotrice E_B de la pile B

[a] $\log_{10} m_{Cl^-}/m_{S^-} = 0{,}015$.
[b] $\log_{10} m_{Cl^-}/m_{S^-} = -0{,}081$.

[B] Pt; H_2 (g, 1 atm) | NaS (m_{NaS}), NaCl (m_{NaCl}) / solvant HS | AgCl; Ag

En effet, le pK_s du milieu (éq. [8]) s'obtient par extrapolation à dilution infinie du pK_s' aisément calculable (éq. [9])

$$[8] \quad pK_s = \frac{E_B - E^0}{(RT \ln 10)/F} + \log_{10} \frac{m_{Cl^-}\,\gamma_{Cl^-}}{m_{S^-}\,\gamma_{S^-}}$$

$$[9] \quad pK_s' = \frac{E_B - E^0}{(RT \ln 10)/F} + \log_{10} \frac{m_{CL^-}}{m_{S^-}} = pK_s - \log_{10} \frac{\gamma_{Cl^-}}{\gamma_{S^-}}$$

Un programme de régression polynomiale d'ordre multiple (calculateur Apple II 64K) montre que la force électromotrice E_B (ramenée à la pression d'une atmosphère) est une fonction du second degré en t ($E = a' + b'c + c't^2$), dont les coefficients sont rassemblés dans le tableau 4.

L'expérience montre que pK_s' est une fonction linéaire de la force ionique du milieu ce qui rend aisée et précise la détermination de pK_s (tableau 5). Il ressort du tableau 5, que nos résultats sont en bon accord avec les pK_s antérieurement mesurés au-dessus de 0°C, en utilisant l'électrode de référence argent − bromure d'argent (20).

Les niveaux d'acidité (pa_H) des solutions alcalines peuvent être calculés au moyen de la relation [10].

$$[10] \quad pa_H = pK_s + \log_{10} m_{S^-} + \log_{10} \gamma_{S^-}$$

où le coefficient d'activité de la base γ_{S^-} est identifié au coefficient d'activité moyen $\gamma_\pm$ déjà rapporté (15). Les niveaux d'acidité correspondant aux solutions 0.01 molales en base forte apparaissent dans le tableau 5.

(2) Fonction thermodynamiques

Dans la mesure où la relation [5] s'applique également au pK_s, les fonctions thermodynamiques relatives à la dissociation du solvant sont représentées par les éq. [6] avec pour A, C et D les valeurs 3103,4; −0,20907 et 0,01025 lorsque le milieu contient 50% de diol en masse et 2835,7; −1,8525 et 8,075 $\times 10^{-3}$ lorsqu'il en contient 70%. L'examen du tableau 6, où nous avons reporté quelques valeurs ainsi calculées, montre que le processus de dissociation des solvants mixtes étudiés est essentiellement enthalpique d'une part, et que nos résultats sont en bon accord avec ceux rapportés par Banerjee à 25°C (20) d'autre part.

Nous avons déjà mentionné que, contrairement aux enthalpies libres de dissociation, les fonctions dérivées entropie et

[a]Valeurs précédemment déterminées par Banerjee *et al.* (20): 41208 J mol^{-1} (c); 39129 J mol^{-1} (d); −123 J K^{-1} mol^{-1} (e); −133 J K^{-1} mol^{-1} (f).

enthalpie, sont moins précises. Il était donc souhaitable de comparer ces valeurs à celles obtenues par mesure directe. Pour ce faire nous avons déterminé par microcalorimétrie à 25°C, l'enthalpie de dissociation des deux mélanges étudiés. Les ΔH^0 ainsi obtenus et qui valent 44611 et 42102 J mol^{-1} pour les milieux hydroalcooliques contenant respectivement 50 et 70% d'éthylène glycol, sont supérieurs d'environ 5% aux déterminations potentiométriques (Tableau 6). Bien qu'un écart de cet ordre et dans ce sens ait déjà été constaté entre les résultats obtenus par ces deux techniques (21−24) aucune explication n'a été à ce jour proposée et nous ne pensons pas comme l'a suggéré l'un des Referee que la détermination des coefficients d'activité soit responsable des écarts observés.

Partie expérimentale

La purification de l'éthylène glycol (Prolabo Normapur) et les dis-

positifs expérimentaux ont déjà été décrits (15). Il en est de même de la purification de l'acide acétique et de l'acétate de sodium (Prolabo) (25). Le chlorure de sodium a été purifié par trois précipitations successives en ajoutant de l'éthanol à une solution aqueuse saturée en sel. Le produit obtenu, séché sous vide, est alors exempt de bromure (26) anion qui nuirait au bon fonctionnement de l'électrode Ag, AgCl (27). Les solutions basiques ont été obtenues à partir d'une solution mère aqueuse, préparée par dissolution de soude exempte de carbonate (J. T. Baker) dans de l'eau bidistillée soigneusement décarbonatée et standardisée à partir d'une solution chlorhydrique elle-même standardisée par gravimétrie.

Le remplissage de la cellule se fait à l'abri de l'oxygène et sous un courant d'hydrogène qui permet aussi de dégazer les solutions.

Les électrodes sont thermoélectriquement préparées (28) et la cellule potentiométrique, semblable à celle utilisée par Bates (29), a été entourée d'une gaine dans laquelle circule de l'azote gazeux thermorégulé (30). Une coque moulée de polyuréthane de 2 cm d'épaisseur assure une excellente isolation thermique à l'ensemble. L'incertitude sur la température (repérée à l'intérieur de la solution au moyen d'une sonde à résistance de platine) est de l'ordre de 0,05°C et permet d'estimer les f.e.m. à 10^{-5} V près.

Ce dispositif ne permet que très difficilement de stabiliser la température à des valeurs reproductibles pour les différentes solutions. Nous avons donc choisi de déterminer pour chaque molalité, à partir d'une vingtaine de mesures comprises entre 30 et −35°C, les paramètres de l'équation $E = f(t)$ (Tableaux 1 et 4), qui permettent ensuite de calculer les f.e.m. pour les 14 températures entières espacées de 5°.

Les mesures calorimétriques des enthalpies d'ionisation des solvants à 50 et 70% d'alcool en masse ont été réalisées sur un microcalorimètre dynamique Picker à écoulement continu (31) commercialisé en France par Sétaram. L'incertitude sur les valeurs de l'enthalpie mesurées à l'aide de cet appareil est estimée à 1%.

DAVID B. EVANS, MARY FRANCES RICHARDSON, PAUL J. MCCARTHY, A. B. LEVER, S. R. PICKENS, and I. M. WALKER. Can. J. Chem. **61**, 2349 (1983).

$CO[(CH_3)_2NCH_2CH_2NH_2]_2[CCl_3CO_2]_2$ belongs to the monoclinic crystal system, space group $P2_1/c$ with a = 7.216(1) Å, b = 12.117(3) Å, c = 13.616(4) Å, β = 103.27(2)°, V = 1158.7 Å^3, Z = 2. The structure was solved by the heavy atom method and was refined to R = 0.048, R_w = 0.056 for 1761 reflections with $I \geq 3\sigma(I)$. The complexes lie on crystallographic centers of symmetry. Deviations from regular octahedral coordination are due to steric crowding and chelate ring constraints. The Co—NMe_2 bond is longer than the Co—NH_2 bond (2.258(3) vs. 2.100(3) Å). The Co—O distance is 2.138(3) Å. The chelate rings each contain a disordered carbon atom such that these rings are 54% *gauche* and 46% envelope. There are intramolecular and intermolecular H-bonds between the Me_2en and trichloracetate ligands. The polarized single crystal spectra are interpreted in terms of D_{2h} symmetry for the complex.

DAVID B. EVANS, MARY FRANCES RICHARDSON, PAUL J. MCCARTHY, A. B. P. LEVER, S. R. PICKENS et I. M. WALKER. Can. J. Chem. **61**, 2349 (1983).

Les cristaux de $CO[(CH_3)_2NCH_2CH_2NH_2]_2[CCl_3CO_2]_2$ sont monocliniques et appartiennent au groupe d'espace $P2_1/c$ avec a = 7,216(1) Å, b = 12,117(3) Å, c = 13,616(4) Å, β = 103,27(2)°, V = 1158,7 Å^3, Z = 2. On a résolu la structure par la méthode de l'atome lourd et on l'a affinée jusqu'à des valeurs de R = 0,048 et de R_w = 0,056 pour 1761 réflexions avec $I \geq 3\sigma(I)$. Les complexes se situent sur des centres cristallographiques de symétrie. Les déviations par rapport à une coordination octaédrique régulière sont dues à un encombrement stérique et à des contraintes dans le cycle chélaté. La liaison Co—NMe_2 est plus longue que la liaison Co—NH_2 (2,258(3) contre 2,100(3) Å). La distance Co—O est de 2,138(3) Å. Chaque cycle chélaté contient un atome de carbone déformé de telle sorte que ces cycles sont à 54% *gauche* et à 64% de type enveloppe. Il y a des liaisons hydrogènes inter et intramoléculaires entre les ligands Me_2 en et trichloroacétate. On interprète les spectres polarisés du monocristal en fonction d'une symétrie D_{2h} du complexe.

Introduction

The spectra of six-coordinate d^7 and d^8 metal ions in octahedral and tetragonal symmetries have been the subject of numerous studies (1, 2). The splittings of the octahedral T-states into E and A or B states in tetragonal symmetry are well understood. The band splittings are especially well resolved when there are marked differences in the strengths of the in-plane and axial ligand fields.

Systems whose symmetries are less than D_{4h} are very numerous, yet detailed treatments of their spectra are few. The situation is complicated by the large number of possible low symmetry point groups which result from loss of the four-fold axis. Detailed X-ray structural information is essential in order to establish which of the many possible types of distortion actually applies to an individual complex.

In our early explorations of this neglected area, we reported analyses of the electronic spectra of several complexes whose C_{2v} symmetry had been previously demonstrated by detailed X-ray work (3). The reduction in symmetry from D_{4h} to C_{2v} was explored theoretically by means of the Normalised Spherical Hamiltonian (NSH), and Angular Overlap Model (AOM) methods.

More recently, we have studied complexes whose geometry is very nearly D_{2h} due to their all-*trans* nature. We have reported the X-ray structure and crystal spectrum of $Ni((C_2H_5)_2NCH_2CH_2NH_2)_2(NCS)_2$, in which the lowest triplet band is clearly resolved into three well separated peaks (4). The X-ray structure of this complex reveals that the Ni—NEt_2 distance is very much longer than usual for Ni—N distances in complexes. This provides an explanation for the rhombic spectrum in terms of a reduced AOM σ parameter for the dialkylated nitrogen bond vector. We were thus able to extend the work of Bertini *et al.* (5), thereby demonstrating a clear inverse correlation between metal ligand bond length and AOM σ bonding parameters.

As part of an on-going study related to the single crystal spectra of low symmetry transition metal complexes (1–7), we now report the X-ray crystallographic analysis and low temperature electronic spectrum of bis(trichloroacetato)bis(*N*,*N*-dimethylethylenediamine)cobalt(II).

Experimental

Crystals were grown following stoichiometric reaction of cobalt trichloroacetate with *N*,*N*-dimethylethylenediamine under a nitrogen blanket. Analyses were satisfactory.

Many of the crystals were twinned. One rather large red crystal, 0.55 × 0.35 × 0.23 mm, appeared to be single and was chosen for further work. Unit cell parameters were determined from 20 reflections ($10.2° < \theta < 16.9°$) measured on an Enraf-Nonius CAD-4

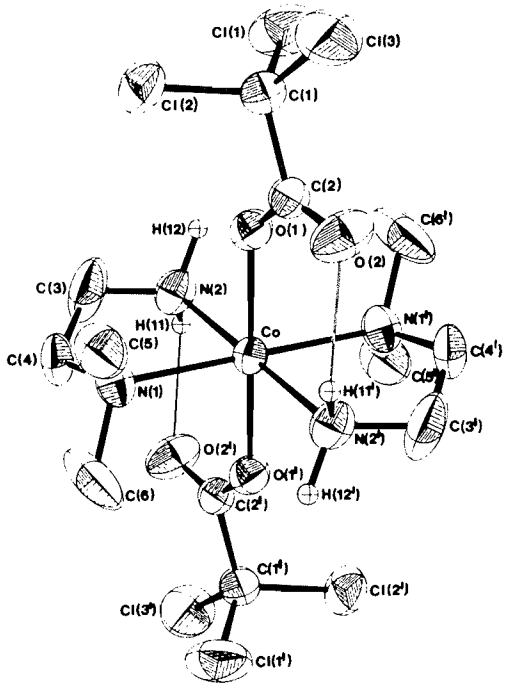

FIG. 1. The *trans*-$[Co(Me_2en)_2(CCl_3CO_2)_2]$ molecule showing the numbering scheme and thermal ellipsoids. The superscript refers to centrosymmetrically related atoms. Hydrogen atoms except those on the $—NH_2$ group have been omitted for clarity.

diffractometer with MoKα radiation (λ = 0.71069 Å). Crystal data are:

$C_{12}H_{24}Cl_6CoN_4O_4$ fw = 560.00

Monoclinic, $P2_1/c$, a = 7.216(1), b = 12.117(3), c = 13.616(4), Å, β = 103.27(2)°, V = 1158.7 Å^3, ρ_o = 1.60 g cm^{-3}, Z = 2, ρ_c = 1.60 g cm^{-3}, $F(000)$ = 570, μ(MoKα) = 14.84 cm^{-1}.

Data collection was carried out at room temperature (23 ± 3°C). The ω−2θ technique was used, with an ω scan width (degrees) of 0.80 + 0.35 tan θ, maximum ω scan speed 10° min^{-1}, maximum scan time 300 s, background counted one quarter of the scan time at each end of the scan. A standard was measured every hour, and the orientation checked every 100 measured reflections. The standard exhibited only minor variations from one measurement to the next. Two quadrants of data (3778 reflections) were measured with $2° < \theta < 25°$. The equivalences ($I_{hkl} = I_{h\bar{k}\bar{l}}$) confirmed the crystal system as monoclinic, and the systematic absences indicated space group $P2_1/c$. Intensities were corrected for background and change in the standard, and converted to structure factors after applying Lorentz and polarization corrections. Equivalent reflections were averaged. No absorption correction was made. A total of 2046 unique reflections was obtained, of which 1760 had $I > 3\sigma(I)$ and were classified as observed.

The structure was solved by the heavy atom method and refined by full-matrix least-squares techniques with the SHELX set of programs (8). Scattering factors for neutral C, H, N, O, Cl, and Co were taken from the International Tables for X-ray Crystallography (9). The function minimized was $\Sigma w\Delta^2$, where $\Delta = |F_o| - |F_c|$ and $w = (\sigma^2(F_o) + 0.0003F_o^2)^{-1}$. One of the dimethylethylenediamine carbon atoms (C(4)) was disordered; an occupancy factor was refined alternately with the temperature factors for the two locations. Peaks attributable to hydrogen atoms appeared on the difference map after a cycle of anisotropic refinement. In the final cycles of refinement, the methyl groups were treated as rigid rotors, the positions of the NH_2 hydrogen atoms (H(11) and H(12)) were refined, and the positions of the remaining hydrogen atoms were calculated. Isotropic thermal parameters were refined for the methyl hydrogens as a group (U = 0.15 Å^2) and for the remaining hydrogens (U = 0.09 Å^2). The final R and R_w were 0.048 and 0.056 for the 1761 observed reflections, and 0.064 and 0.056 for all 2046 reflections. The final difference map had no features larger than 0.7 e Å^{-3} in height. The three largest residual peaks were located near the chlorine atoms.

The numbering scheme for the complex and the thermal ellipsoids are shown in Fig. 1, and the molecular packing diagram is given in Fig. 2 (10). Atomic positional parameters are reported in Table 1. Tables 2 and 3 list important bond distances and angles. Anisotropic thermal parameters for the non-hydrogen atoms, the hydrogen atom positional parameters, and a table of observed and calculated structure factors have been placed in the Depository of Unpublished Data.[2]

Results and discussion

X-ray structure determination

The cobalt complexes lie on crystallographic centres of symmetry, with a distorted octahedral environment about the cobalt atom. Four nitrogen atoms from the two chelating Me_2en ligands define a distorted square plane, and two oxygen atoms, one from each of two trichloroacetate ligands, occupy axial positions on the octahedron. The Co—NMe_2 bond length of 2.258(3) Å is significantly longer than the Co—NH_2 bond length of 2.100(4) Å. Similar effects have been noted in other complexes of *N*,*N*-dimethylethylenediamine (12−14), and are

		Cl(2)—C(1)—Cl(3)	106.5(2)

generally attributed to steric crowding at the substituted nitrogen (13). Recent structure determinations for two octahedral cobalt(II) complexes of *N,N,N',N'*-tetramethylethylenediamine yielded Co—NM_2 bond distances of 2.205–2.239 Å (15).

The Co—O bond length (2.138(3) Å) is slightly longer than observed in other octahedral cobalt(II) complexes with carboxylate ligands. Thus, the Co—O distance is 2.074(2) Å in a monochloroacetate complex (15), and 2.039(4)–2.123(3) Å in cobalt(II) complexes of ethylenediaminetetraacetate and *o*-phenylenediaminetetraacetate (16).

Further deviations of the CoN_4O_2 chromophore from ideal D_{4h} symmetry are evident from the bond angles in the complex. The N(1)—Co—N(2) angle of 81.4(1)° is normal for a five-membered chelate ring, but the O(1)—Co—N(2) angle of 84.4(1)° is surprisingly far removed from the ideal value of 90°. This may be due to the hydrogen bonding contact between O(2) and N(2)' (Fig. 1).

The Me_2en chelate rings exhibit *gauche*:envelope disorder, as shown by the deviations from the Co—N(1)—N(2) plane (Table 4). Atom C(4), with an occupancy factor of 0.54, completes a *gauche*-type ring, whereas atom C(4a), with an occupancy factor of 0.46, completes an envelope-type ring. High correlations between the thermal parameters, occupancy factors, and positional parameters made it difficult to locate C(4) and C(4a) accurately, which accounts for the relatively large deviations from normal values of bond distances and angles involving these atoms.

One of the hydrogen atoms in the NH_2 groups is involved in two short contacts to carboxylate oxygen atoms, one in the same molecule, and one in an adjacent molecule (Figs. 1 and 2; Table 5). These are apparently not strong, as the O...H van der Waals separation is ca. 2.7 Å (17). The other NH_2 hydrogen atom, H(12), is not involved in hydrogen bonding.

Electronic spectra

The electronic spectra of single crystals of the cobalt complex were recorded in polarised light along orthogonal extinction axes of the crystals at room temperature, and at 10 K, using a Displex Cryogenic Refrigerator (11). The marked drop in intensity on cooling indicates that the quartet bands are of vibronic origin, in keeping with the presence of a centre of symmetry at the cobalt. A similar vibronic effect operates in the analogous $Ni(Me_2en)_2(CCl_3CO_2)_2$ complex. The spectrum at 10 K is shown in Fig. 3.

As was observed in the analogous nickel complex (7), splitting of the lowest *T*-state into three well-resolved bands is seen. By analogy with the nickel complex, the splitting of the upper *T*-state would be predicted to be much less (Fig. 3); this is in agreement with experiment.

While the point symmetry at the cobalt is C_i, the spectra are most conveniently fitted to theory using D_{2h} symmetry. Past experience (3) has shown that, provided angular deviations from 90° are small, one can assume angles of 90° with little

*Symmetry superscripts: *i*, $(-x, 1-y, 1-z)$; *ii*, $(x-1, y, z)$.

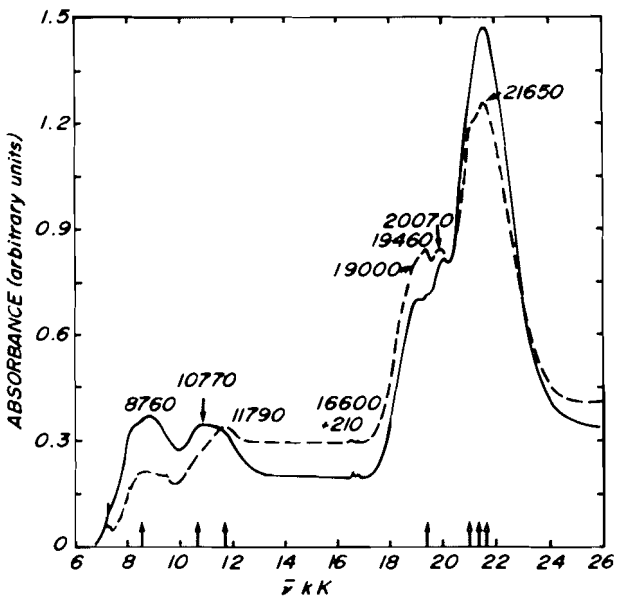

FIG. 3. The single crystal polarized spectra of $Co(Me_2en)_2(CCl_3CO_2)_2$ at 10 K. Two polarizations along orthogonal axes are displayed. The arrows indicate the calculated energies, namely: 8570, 10780, 11785, 19470, 21045, 21360, 21565 cm^{-1}.

attendant error. Major band splitting in rhombic systems of this type arises primarily from two sources: changes in the identity of the ligand atom, and variations in metal−ligand bond distance (4).

The results of our calculations are shown in Table 6, where comparative information on the nickel complex is also included. The angular overlap model (18) was employed using $e_\sigma(N(1))$, $e_\sigma(O)$, $e_\sigma(N(2))$, $e_\pi(O)$, $e_\pi(N(1))$, and B as variables, where N(1) and N(2) refer to the numbering system in Fig. 1. The $e_\pi(N(2))$ is assumed to be zero.

The relationship of the crystal extinction axes used in the spectroscopic study to the molecular axes of the chromophore has not been determined. We therefore adopt the procedure of using extensive past experience on closely related complexes (1) as our guide to the assignment of the spectrum. The association of specific σ and π parameters with specific ligands in

*Six variables were used to solve the spectra (5 × AOM, + B). Calculated transition energies are shown in the caption to Fig. 3.

†Normalized Spherical Harmonic Hamiltonian parameters (19).

Table 6 therefore follows from our knowledge of how well-defined tetragonal complexes of these ligands behave. Thus, for example, the M—O bond is known to have an $e_\sigma(O)$ value between 2500−3000 cm^{-1}, and an $e_\sigma(N)$ value for a normal length M—N bond should lie between 4000 and 4800 cm^{-1} (for M—Co(II) or Ni(II) (1)). The $e_\sigma(N)$ value for the long N—M—N bond is consistent with previous studies of such systems (1, 4). The remarkably close similarity between the data set necessary to fit the nickel spectra and that necessary to fit the cobalt spectra is noteworthy and must provide confidence in the assignment.

As anticipated, the increase in Co—N bond distance along the Me_2N—Co—NMe_2 bond vector does result in a significant decrease in the σ bonding parameter, relative to a normal length bond. The non-zero π value for this bond is small and probably not significant; it may arise because the bond angles are not strictly 90°, thus small deviations of the model from reality may be reflected in this term. The more positive value associated with the carboxylate O—Co—O bond vector is consistent with the anticipated small π-donation effect of the oxygen atoms with the previous nickel result. However, it too should not be given too much significance.

IAN R. BUTLER and WILLIAM R. CULLEN. Can. J. Chem. **61**, 2354 (1983).

A simplified procedure for the preparation of α-*N*,*N*-dialkylaminoethylferrocenes R_2NR' (R = Me, C_6H_{11}, $CHMe_2$; R' = $CH(CH_3)C_5H_4FeC_5H_5$) from the alcohol R'OH by treatment with HBr and R_2NH is described. Use of ammonia results in the isolation of $R'NH_2$, R'_2NH (major product) and R'_3N and use of the optically active amine *d*-(+)-$H_2NCH(CH_3)C_6H_5$ gives rise to diastereomers $R'NHCH(CH_3)C_6H_5$ which are separable. When diphenylphosphine is substituted for an amine the oxide $R'P(O)Ph_2$ is obtained in low yield. The secondary amine R'_2NH reacts with *n*-butyllithium and chlorodiphenylphosphine to afford R'_2NPPh_2.

IAN R. BUTLER et WILLIAM R. CULLEN. Can. J. Chem. **61**, 2354 (1983).

On décrit une méthode simplifiée de préparation des α-*N*,*N*-dialkylaminoéthylferrocènes R_2NR' (R = Me, C_6H_{11}, $CHMe_2$; R' = $CH(CH_3)C_5H_4FeC_5H_5$) à partir de l'alcool R'OH que l'on fait réagir avec le HBr et le R_2NH. L'utilisation de l'ammoniac conduit à la formation des composés $R'NH_2$, R'_2NH (produits majoritaires) et R'_3N et l'emploi de l'amine optiquement active *d*-(+)-$H_2NCH(CH_3)C_6H_5$ permet d'obtenir les diastéréoisomères $R'NHCH(CH_3)C_6H_5$ que l'on peut séparer. Si on remplace l'amine par le diphénylphosphine on obtient avec un faible rendement l'oxyde $R'P(O)Ph_2$. L'amine secondaire R'_2NH réagit avec le *n*-butyllithium et le chlorodiphénylphosphine pour donner le composé R'_2NPPh_2.

Introduction

Ferrocenylamines have been used for a considerable period as starting compounds for the synthesis of multidentate ferrocenyl ligands. α-*N*,*N*-Dimethylaminoethylferrocene, **1**, which may be prepared readily in its optically active form (1), is probably the most widely used of these. Kumada and co-workers (2, 3), Cullen and co-workers (4, 5), and Ugi and co-workers (6) have synthesised a variety of bidentate ligands which are useful in catalytic asymmetric syntheses from this precursor (Scheme 1). There are presently three major synthetic routes to **1**. The first of these, documented by Hauser and Lindsay (7), involves the conversion of the commercially available ferrocene carboxaldehyde to the aminonitrile derivative **2** which in turn is converted to **1** by methylmagnesium iodide (eq. [1]).

The second route of Ugi and co-workers (8) involves the conversion of α-hydroxyethylferrocene **3** to **1**. This is achieved via the acetylation of the alcohol followed by the reaction of the product ester with a secondary amine (eq. [2]). This route offers a less expensive synthesis starting with the easily accessible **3** (from ferrocene via acetylferrocene).

The third route again pioneered by Ugi and co-workers (9, 10) involves a one-pot method starting from ferrocene as outlined in eq. [3]. The initial reaction is carried out in strong acid solution (trichloroacetic acid/fluorosulfuric acid/acetic acid) and the overall yield of **1** is good (62%).

All three routes can be generalized using different amines, Grignard reagents, and carbonyl compounds. However, the

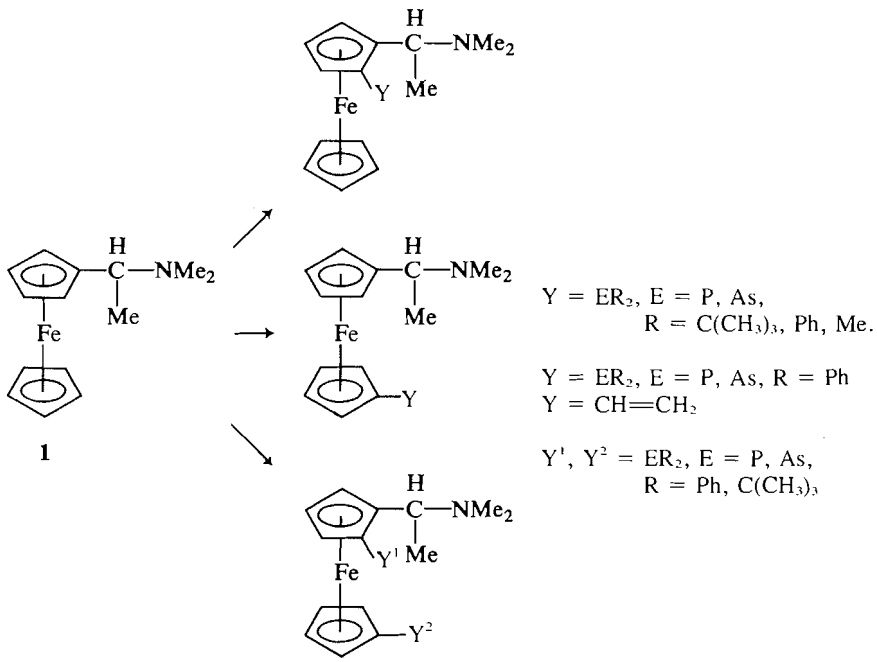

SCHEME 1.

synthesis of the important primary amines by the one-pot procedure results in low yields whilst the other protocols require synthesis of the dimethylamino derivatives first (9, 11).

The direct reaction of 1,1′-bis(α-hydroxyethyl)ferrocene with HBr and HNR_2 to give the corresponding diamines has recently been reported (12). This procedure offers a relatively simple diamine preparation since previous preparations have involved the formation of such diamines from ferric chloride and fulvenes. (Route 2 could not be used because an intramolecular reaction occurs to give a ferrocenophane derivative (13) and route 3 could not be applied because substitution on only one ring is observed (9)). We have now applied this reaction procedure to the synthesis of **1** and some related amines as well as extending it to the synthesis of primary, secondary, and tertiary α-ferrocenylethylamines. These procedures are of interest because of our continuing involvement in catalytic studies utilizing these derivatives as asymmetric ligands and because of our desire to circumvent the necessary resolution step by using a synthetic sequence which involves an asymmetric catalyzed reaction. Only the first two routes meet this requirement in that, in principle, both the Grignard coupling reaction and the ketone reduction can be carried out asymmetrically (14). We hope to use the product ferrocenylamines as ligands in metal catalyzed reactions, which breed their own chirality. (This has already been achieved in a very elegant manner in the case of the ligand (R)-prophos $(C_6H_5)_2PCH(CH_3)CH_2P(C_6H_5)$ (15)). The reaction is further developed to prepare a ferrocenylphosphine derivative but in low yield.

Experimental

All solvents were reagent grade and were used without further purification. α-Hydroxyethylferrocene was prepared by reduction of acetylferrocene using lithium aluminium hydride (16). ^1H nmr spectra were recorded on either a Varian XL-100 or a Bruker WP-80 spectrometer. Elemental analyses were performed by Mr. Peter Borda of this department. Mass spectra were obtained using a Kratos MS-50 instrument. The yields obtained in these reactions are variable because of the nature of the experimental conditions employed, therefore only approximate average yields are given.

1. Reaction of ***3*** *with HBr and* HNR_2*. Preparation of* α*-N,N-dialkylaminoethylferrocenes* ***1****,* $R = CH_3$*;* ***4****a,* $R = CH(CH_3)_2$*;* ***4****b,* $R = C_6H_{11}$

General procedure: Gaseous HBr was bubbled through a well stirred benzene solution of **3** (generally 1 g **3** per 50 mL benzene) until the solution darkened, becoming almost black. Excess of the appropriate amine[1] was then added (the solution colour changed back to yellow). The mixture was hydrolysed (H_2O, equal volume to benzene volume) and the organic layer was separated and dried over anhydrous $MgSO_4$. Following filtration, the solvent volume was reduced to a few mL and the resultant oil chromatographed on neutral alumina (activity grade III) eluting with hexane/diethyl ether, 50/50, v/v. (***4****b* was hexane eluted under these conditions.) The yellow product amine band was isolated (generally the only coloured band present, although some starting material may be present if excess HBr has not been added). The product yields were variable but generally fell in the range of 60–85%. The products were identified by comparison of their nmr spectra with those of authentic samples and by elemental analyses (where appropriate). Elemental analyses and relevant spectral data are given in Tables 1–3.

2. Reaction of ***3*** *with HBr and* NH_3 *solution*

General procedure: The previous experimental procedure (section 1) on a 1.0 g scale of **3** was applied replacing the secondary amine with concentrated ammonia solution. The work up procedure was identical. The crude reaction mixture prior to column chromatography was examined by tlc (hexane/diethyl ether, 80/20 eluant). Column chromatographic separation of the product fractions was achieved on a neutral alumina support (activity in the range III–V), eluting with progressively polar mixtures of hexane, diethyl ether, and chloroform. The product fractions were identified initially by mass spectroscopy. Analytical samples were prepared by crystallisation from hexane, hexane/diethyl ether, or hexane/methanol mixtures. The yields quoted are based on the product weight as obtained from the column following solvent removal (i.e. prior to recrystallisation).

Reaction a: HBr was bubbled through the benzene solution for 1 min (bubble rate ~2 per second using a 5 mm bore gas inlet tube). Tlc examination of the product solution following the general procedure outlined above showed five yellow product bands, two of which were in minor concentration. The three major product bands

[1]Aqueous or anhydrous amine can be used.

[a]$CDCl_3$ is the solvent, bs = broad singlet.
[b]Contains peaks from other neuclei (—C*H*Me—).
[c]Compound readily decomposes to give product with vinylic protons in $CDCl_3$.
[d]These are asymmetric singlets at 80 MHz arising from doublet overlap.

were isolated: the first was identified as the secondary amine **5***b* (hexane eluted), ~40%; the second as starting material **3**, (hexane/ether, 80/20) ~20%; and the third as the primary amine **5***a* (chloroform eluted) ~10%.

Reaction b: HBr bubbled through the solution for 5 min (bubble rate as above). Three major fractions were identified by tlc then isolated: the first **5***c* (hexane eluted) ~5%; the second **5***b* (hexane/ether, 95/5) ~65%; and the third an unidentified product with parent mass ion, *m/e* 530, **8**, (hexane/ether, 50/50 eluted).

Reaction c: The addition of the NH_3 solution to the brominated solution (HBr bubbled for 3 min) was carried out dropwise. Four major fractions were identified by tlc and isolated by column chromatography; **5***c* (hexane eluted) ~5%, **5***b* (hexane/ether, 95/5) ~40%, the unidentified compound with parent mass ion at *m/e* 530 (hexane/ether, 50/50) and an unidentified product with parent mass ion at *m/e* 636 (chloroform eluted) **10**. The last two products were isolated in very low yield.

Reaction d: The reaction was carried out as documented in reaction *b* on a 5 g scale. Five fractions (eluted with solvent mixtures as above) were identified and isolated following column chromatography; **5***c*, ~8%, **5***b*, ~50%, **3** and trace of product with parent mass *m/e* 530, the unidentified product with parent mass of 636 and **5***a*, ~15%).

Crystallisation of 5a−c: **5***a* was crystallised from diethyl ether/hexane, 70/30, **5***b* from hexane, and **5***c* from hexane/methanol; generally the two solvent layers were allowed to diffuse slowly. Elemental analyses and spectral data are given in Tables 1−3. **5***a* and **5***c* were characterised by ^{1}H nmr and mass spectroscopy only because the compounds were difficult to obtain free from solvent.

3. Reaction of **3** *with d-(+)-α-aminoethylbenzene. Preparation of* **6**

The previous experimental procedures were applied to this synthesis replacing the amine solution with *d*-(+)-α-aminoethylbenzene (Aldrich Chemical Co.). The major product isolated following column chromatography was the secondary amine **6** (>60%). This compound was obtained by crystallisation from hexane as a waxy crystalline solid. Small quantities of the tertiary amine were also identified in solution (mass spectroscopy); however, no crystallisation of this compound was attempted. Spectral and analytical data for **6** are given in Tables 1−3.

4. Lithiation of 5b *and reaction with* $ClPPh_2$. *Preparation of* **7**

The following reactions were carried out under an inert atmosphere.

(a) Reaction in ether: To an ethereal solution of **5***b* (1 g, 2.27 mmol in 50 mL) a solution of 1.6 *M n*-butyllithium in *n*-hexane (1.5 mL) was added. The solution was stirred overnight. Chlorodiphenylphosphine (0.5 g, 2.27 mmol) was then added to the chilled solution (−78°C). The solution was warmed to 20°C and stirred for a further 1 h before hydrolysis (H_2O, 20 mL). The ethereal layer was separated, dried over anhydrous $MgSO_4$ and, following filtration, the product mixture was chromatographed on neutral alumina. The red/orange product fraction was isolated and recrystallised from *n*-hexane. ^{1}H nmr and spectroscopic data are given in Tables 1 and 2. The product yield obtained was 18%.

(b) Reaction in hexane: Dropwise addition of *n*-butyllithium (1 mL, 1.6 *M* solution in hexane, excess) to a solution of **5***b* (300 mg, 0.68 mmol) in hexane (50 mL) resulted in the rapid precipitation of the lithium salt of **5***b* as a pale orange powder. The solution was stirred for 5 min before chlorodiphenylphosphine (0.5 g, excess) was added. The resultant mixture was heated to 50°C and was stirred at this temperature for a further 15 min. A deep orange/red colour developed in the reaction mixture with deposition of LiCl. Tlc examination at this stage showed the presence of two products, the first a yellow/orange

[a]This compound was not crystallized; the mass spectrum was obtained from a sample in solution.

compound eluting with hexane and the second a red compound which required polar solvents, e.g., CH_2Cl_2, for elution. The reaction mixture was filtered under an inert atmosphere to give a clear orange solution which was reduced in volume *in vacuo* until precipitation just began. This solution was then set to crystallize overnight. The residual red powder consisting primarily of LiCl was extracted with methylene chloride. The red methylene chloride solution was reduced in volume to ca. 3 mL and a top hexane layer (5 mL) was added. The mixture was then left to crystallize at ~−15°C. The orange/red crystalline product obtained from the latter solution was identified as **7** by mass spectroscopy (Table 3) and the yellow/orange crystalline compound obtained from the former solution was identified as the starting compound **5***b* which crystallized initially as one pure diastereomer. The yield of **7** was 8%.

5. Reaction of 3 with HBr and $HPPh_2$. Preparation of 8

A solution of **3** (1.0 g) in benzene (50 mL) was treated with HBr according to the general procedure. Excess $HPPh_2$ was then added. The solution was then hydrolysed (H_2O, 50 mL) and the organic layer separated and dried over anhydrous $MgSO_4$. Following solvent removal large quantities of phosphine by-products separated. The orange product fraction was repeatedly chromatographed on a neutral alumina support until a pure product fraction was obtained. Spectral details of **8** are given in Tables 2 and 3.

Results and discussion

The synthesis of α-*N*,*N*-dimethylaminoethylferrocene **1** from the alcohol **3** has been achieved by reaction with HBr followed by $HNMe_2$ using the method previously applied to the synthesis of diamines (9). The yields of **1** are variable (60−80%) which compare favourably with the previous syntheses. In common with the second route of Ugi and coworkers (8) the starting compound is easily accessible from ferrocene by acylation followed by reduction with lithium aluminium hydride. This procedure offers an alternative rapid synthesis of **1** with no special handling procedure necessary. Two derivatives of the type $[(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4CH(Me)\text{-}NR_2)]$ R = cyclohexyl, isopropyl, **4***a* and **4***b* have also been prepared by this method. **4***b* is not a new compound (2).

The main focus of this work has been the preparation of primary, secondary, and tertiary ferrocenylethylamines of the type $[(\eta^5\text{-}C_5H_5)Fe(\eta^2\text{-}C_5H_4C(H)Me)_xNH_{3-x}]$. The synthesis of these derivatives was conveniently achieved from **3** by the stepwise reaction with HBr and NH_3 (eq. [4]).

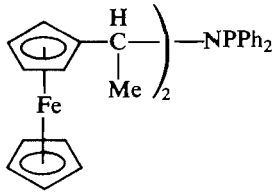
The experimental conditions were varied since it would be expected that addition of the acidified reaction solution of **3** to the aqueous amine solution would give rise to higher yields of **5***a* while the dropwise addition of the aqueous ammonia solution to the acidified reaction solution would give relatively higher yields of **5***c*. This was found to be the case; however, the combined yields of **5***a* and **5***c* were found to be generally very low under all the experimental conditions employed and that the secondary amine **5***b* predominated. **5***b* is separable by chromatography into its diastereoisomers which show a significant chemical shift in the nmr spectra, Table 2. No attempt was made to separate the isomers of **5***c*. Two unidentified products were obtained in low yield in the preparation, the first with mass ion at *m/e* 530, **9**, and the second at *m/e* 636, **10**. The identity of these compounds was not pursued although their mass spectra are given in Table 3. Addition of HBr to the benzene solution of **3** could give rise to vinylferrocene derivatives by the well documented acid catalysed dehydration of **3**, but by-product formation of this type is apparently minimised under these experimental conditions, since no evidence was found for their existence in significant quantities.

The compound **3** was reacted by an identical procedure to the above with *d*-(+)-α-aminoethylbenzene, a low cost, commercially available chiral amine. The major product isolated was the secondary amine, α-N(α′-ethylphenyl)aminoethylferrocene, **6**, obtained as a mixture of diastereomers which are separable (tlc). Thus a convenient resolution of the carbon α to ferrocene can be achieved. This could be of synthetic utility in chiral ligand preparation.

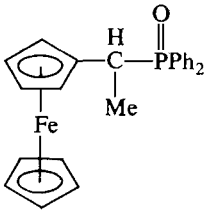
Lithiation of **5***b* followed by reaction of the product mixture with chlorodiphenylphosphine gave the N—P bonded ligand **7**, as a red/orange solid. The yield obtained, however, was extremely low (~10%) and the product was very air sensitive in solution.

The lithiation of **5***b* has been recently examined using excess *n*-butyllithium. Treatment of the lithiated solution with $ClSiMe_3$ has yielded a series of silylated compounds including ring silylated products (16).

Treatment of **3** with HBr followed by reaction with diphenylphosphine gave the phosphine oxide **8** (the phosphine is oxidised during workup); however, the isolation of this compound was found to be particularly laborious because of the significant quantities of organic solvent soluble phosphine by-products. The formation of these by-products may be minimised by the careful dropwise addition of the phosphine, however, it is difficult to conclude when the optimum quantity of phosphine has been added.



7



8

In summary, our procedure offers a rapid synthesis of **1** and related compound using essentially no special handling procedures, starting with easily accessible starting materials. The application to the preparation of potentially chiral phosphine derivatives may be somewhat limited, however, because of the extra effort required during the work up procedure necessary to obtain the pure product.

Réduction électrochimique de γ-nitrocétones. Conditions expérimentales d'accès à des dérivés de la pyrroline et de la pyrrolidine

MICHEL CARIOU, ROLAND HAZARD, MICHEL JUBAULT ET ANDRÉ TALLEC

Laboratoire d'Electrochimie, ERA CNRS 896, Université de Rennes, Campus de Beaulieu, 35042 Rennes Cédex, France

Reçu le 7 avril 1983

MICHEL CARIOU, ROLAND HAZARD, MICHEL JUBAULT et ANDRÉ TALLEC. Can. J. Chem. **61**, 2359 (1983).

Une étude détaillée du comportement électrochimique, sur cathode de mercure et en milieu hydro-alcoolique, de quelques γ-nitrocétones **1** et de leurs produits de réduction permet de définir les conditions d'électrosynthèses de trois types d'hétérocycles azotés.

Les pyrrolines *N*-oxyde **3** sont obtenues par réduction à potentiel peu négatif (cyclisation de l'hydroxylamine); les rendements sont quantitatifs dans le cas des dérivés nitrés tertiaires; dans le cas des dérivés secondaires et primaires, il y a formation parasite de cétones-oximes **6**.

Pour les autres hétérocycles, les conditions de préparation dépendent de la nature du substituant situé en α du carbonyle. Dans le cas d'un substituant méthyle, les pyrrolines **4** peuvent être obtenues par réduction du dérivé nitré **1** ou de la pyrroline *N*-oxyde **3**; les pyrrolidines **5** sont obtenues par réduction de **1** ou également de **3** et **4** dans le cas des dérivés nitrés tertiaires. Dans le cas d'un substituant phényle, les pyrrolines **4** ne peuvent être obtenues que par réduction des hétérocycles **3**, provenant d'un dérivé nitré tertiaire; les pyrrolidines **5** se préparent par réduction de **1** (dérivés primaires et secondaires) ou de **3** et **4** (dérivés tertiaires).

MICHEL CARIOU, ROLAND HAZARD, MICHEL JUBAULT, and ANDRÉ TALLEC. Can. J. Chem. **61**, 2359 (1983).

Optimal conditions for electrosynthesis, at a mercury cathode in hydroalcoholic media, of three classes of nitrogen heterocyclic compounds are set up from an exhaustive study of the electrochemical behaviour of γ-nitroketones **1** and their reduction products.

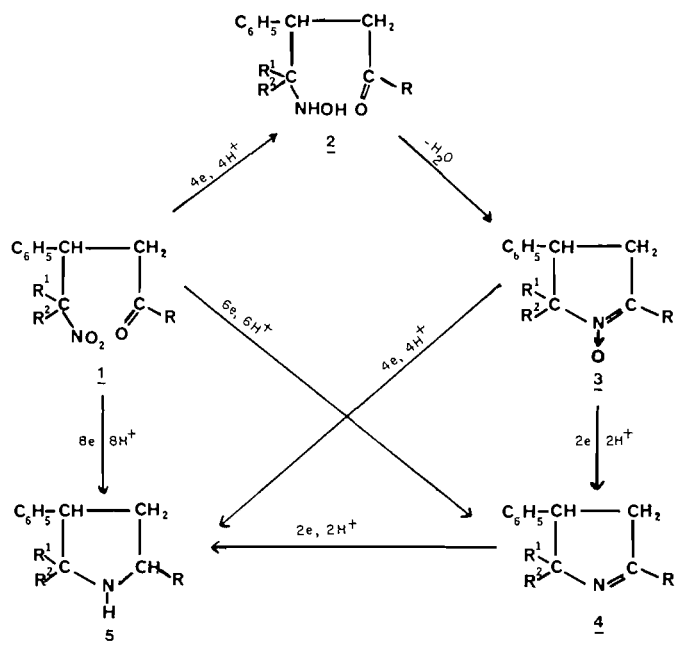
Pyrroline-*N*-oxides **3** are obtained by cyclization of the hydroxylamine when the nitro compounds are reduced at sufficiently low cathodic potentials. Quantitative yields are achieved in the case of tertiary nitro compounds. In other cases (primary and secondary nitro compounds), simultaneous formation of ketone-oximes **6** occurs.

According to the nature of the α-substituent of the carbonyl, the other heterocyclic derivatives can be prepared as follows. In the case of a methyl substituent, pyrrolines **4** can be obtained by reduction of nitro compounds **1** or of *N*-oxyde pyrrolines **3**. Pyrrolidines **5** are prepared by reduction of **1**, or **3** and **4** in the case of tertiary compounds. In the case of a phenyl substituent, pyrrolines **4** can only be obtained by reduction of compounds **3** arising from a tertiary nitro compound. Pyrrolines **5** are prepared by direct reduction of **1** (primary and secondary nitro compounds) or of **3** and **4** (tertiary nitro compounds).

L'électroréduction de dérivés nitrés aromatiques, substitués en *ortho* par des groupements susceptibles de réagir sur la fonction hydroxylamine, a été largement utilisée pour la préparation d'hétérocycles azotés (1, 2). En série aliphatique par contre, si quelques essais ont été tentés par réduction chimique de γ-nitroesters et de γ-nitrocétones (3), il ne semble pas que la méthode électrochimique ait été mise en oeuvre.

Dans une note préliminaire (4), nous avons indiqué les conditions d'obtention de pyrrolines *N*-oxydes **3**, de pyrrolines **4** et de pyrrolidines **5** (schéma 1), par électrolyse à potentiel contrôlé des γ-nitrocétones **1***a* et **1***b*.

Nous nous proposons ici de montrer comment il est possible, par une étude détaillée du comportement électrochimique des nitrocétones **1** et des hétérocycles qui en dérivent, de déterminer les conditions expérimentales optimales, permettant d'accéder sélectivement aux différents produits de cyclisation. Les rendements des électrosynthèses peuvent être rendus pratiquement quantitatifs, lorsque le groupement nitré est porté par un carbone tertiaire (composés **1***a* et **1***b*). Par contre, des réactions parasites accompagnent la réduction des dérivés nitrés secondaires (**1***c* et **1***e*) et primaires (**1***d* et **1***f*).



1_a $R^1 = R^2 = CH_3$; $R = C_6H_5$

1_b $R^1 = R^2 = CH_3$; $R = CH_3$

1_c $R^1 = CH_3$, $R^2 = H$; $R = C_6H_5$

1_d $R^1 = R^2 = H$; $R = C_6H_5$

1_e $R^1 = CH_3$, $R^2 = H$; $R = CH_3$

1_f $R^1 = R^2 = H$; $R = CH_3$

SCHÉMA 1

1. Réduction de la nitrocétone 1a

1.1 *Etude polarographique*

Les polarogrammes du dérivé nitré **1***a* et des hétérocycles **3***a* et **4***a* ont été enregistrés à différents pH, dans un milieu tampon B.R. + éthanol (1 pour 1 en volumes). Quelques résultats sont représentés sur la figure 1.

Etude du dérivé nitré ***1***a (fig. 1a)

En milieu très acide, le polarogramme présente une première vague à 4 électrons (vague A), suivie de deux vagues mal

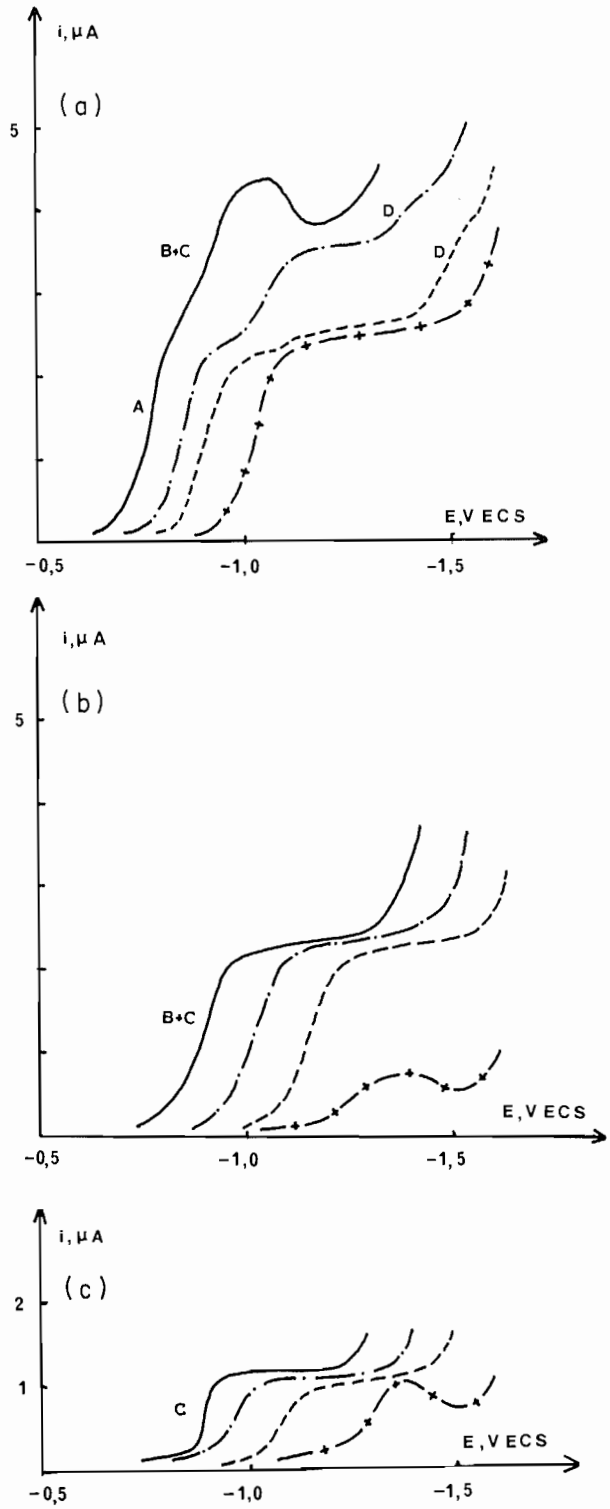


FIG. 1. (a) Polarogrammes de **1***a* en milieu tampon B.R. + éthanol (1 : 1) de pH croissant; de gauche à droite: pH = 2,0; 4,1; 6,0; 8,0. (b) Polarogrammes de **3***a* en milieu tampon B.R. + éthanol (1 : 1) de pH croissant; de gauche à droite: pH = 2,0; 4,0; 6,0; 8,0. (c) Polarogrammes de **4***a* en milieu tampon B.R. + éthanol (1 : 1) de pH croissant; de gauche à droite: pH = 2,0; 4,0; 6,0; 8,0.

séparées (B et C), dont la hauteur totale correspond pratiquement à une réduction à 8 électrons. A potentiel plus négatif, il apparaît un creux, le courant minimum correspondant à une réduction à 6 électrons.

Lorsque le pH augmente, les potentiels de demi-vague se déplacent vers des valeurs cathodiques et l'allure des polarogrammes est modifiée: la vague A est mieux dégagée (déplacement moins prononcé de son $E_{1/2}$); les vagues B et C, dès pH = 4, sont confondues en une vague unique présentant un caractère cinétique marqué: à période de chute constante des gouttes de mercure, l'intensité limite diminue quand le pH augmente (pour $\tau = 2$ s, la vague B + C disparaît pratiquement dès pH = 6); à pH donné, l'intensité diminue avec la période de chute (à pH = 4, la vague est à 4 électrons pour $\tau = 6$ s; pratiquement à 2 électrons pour $\tau = 2$ s et elle n'est plus visible pour $\tau < 0{,}5$ s). Il apparaît à potential très négatif une nouvelle vague D dont la hauteur relative augmente avec le pH; elle correspond à 2 électrons vers pH = 6 (lorsque la vague B + C a pratiquement disparu); mais en milieu basique elle est masquée par la décharge des cations de l'électrolyte-support, de sorte qu'à pH = 8, le polarogramme ne présente que la seule vague A. Cependant, en tampon ammoniacal, la vague D située vers −1,5 V persiste car elle est avancée par la présence des ions NH_4^+.

Etude des hétérocycles **3***a et* **4***a* (figs. 1b et 1c)

En milieu très acide, la pyrroline *N*-oxyde **3***a* présente les vagues B et C mal séparées tandis que seule la vague C (réduction à 2 électrons) apparaît sur le polarogramme de la pyrroline **4***a*.

Lorsque le pH augmente, les vagues B et C de **3***a* se recouvrent. Mais on remarquera que jusqu'à pH = 6, la vague unique B + C présentée par **3***a* (réduction à 4 électrons) et la vague C de **4***a* possèdent des hauteurs constantes. Leur caractère cinétique n'apparaît qu'en milieu basique; il se traduit, dès pH = 8, par l'obtention de vagues en S renversé, dont l'allure est caractéristique de l'intervention de phénomènes de protonation en surface d'électrode (5). Ces vagues disparaissent pour pH > 10.

1.2 *Interprétation*

L'étude qui précède permet l'attribution des vagues A, B, C respectivement:

à la réduction du groupement nitré de **1***a*

$$\text{Vague A}\quad \mathbf{1}a + 4H^+ + 4e \rightarrow \mathbf{2}a + H_2O$$

L'hydroxylamine **2***a* se cyclise plus ou moins rapidement en pyrroline *N*-oxyde **3***a*.

à la réduction du la fonction *N*-oxyde de **3***a*

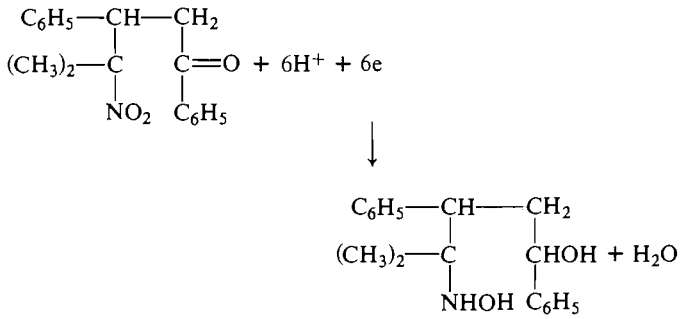
$$\text{Vague B}\quad \mathbf{3}a + 2H^+ + 2e \rightarrow \mathbf{4}a + H_2O$$

A la réduction de la liaison C=N de **4***a*

$$\text{Vague C}\quad \mathbf{4}a + 2H^+ + 2e \rightarrow \mathbf{5}a$$

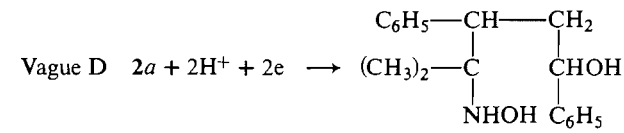
A partir de ces conclusions, il est possible d'interpréter les autres phénomènes observés en polarographie.

L'existence du creux qui apparaît un milieu très acide, vers −1,15 V ECS, sur le polarogramme de **1***a* n'est pas due à une modification de l'électroactivité des hétérocycles **3***a* et **4***a* (cf. figs. 1b et c). C'est donc la réduction de la fonction carbonyle du produit de départ qui est responsable de la diminution du courant. Dans la partie descendante du polarogramme, il y a compétition entre la réaction de cyclisation de la cétone sur le groupement hydroxylamine (suivie de la réduction de **3***a* et de **4***a*) et sa réduction en alcool; cette dernière finit par l'emporter à potentiel suffisamment négatif et l'on observe alors un processus de réduction à 6 électrons:



En milieu faiblement acide, les vagues B et C présentent une hauteur normale lorsqu'elles sont enregistrées à partir des hétérocycles. Leur caractère cinétique, qui apparaît sur les polarogrammes de **1***a*, résulte donc du fait que la cyclisation de l'hydroxylamine **2***a* est alors relativement lente, tandis qu'elle est très rapide pour pH < 2.

Cette observation permet d'attribuer la vague D, située à potentiel très négatif, à la réduction du carbonyle, d'autant plus facile à observer que la cyclisation de l'intermédiaire **2***a* est plus lente:



Cette interprétation est confirmée par une étude voltammétrique, réalisée en tampon acétique (fig. 2); à faible vitesse de balayage, on observe trois pics cathodiques: A (réduction de NO_2), B + C (réduction de **3***a* et **4***a*) et D, moins marqué (réduction du carbonyle en alcool); si l'on balaye plus rapidement, la cyclisation de **2***a* n'a plus le temps de s'effectuer et il ne subsiste, sur le voltammogramme, que les pics A et D. On notera le net déplacement du potentiel de pic A, vers les valeurs cathodiques, lorsque la vitesse de balayage augmente: ce phénomène est caractéristique d'un mécanisme EC dans lequel le transfert électronique (E) est suivi d'une réaction chimique lente (C).

Remarque: l'allure de la vague de réduction de **3***a* en milieu basique rappelle celle observée à partir d'oximes (5) et est due à des réactions de protonation, précédant le transfert électronique. Par comparaison avec un travail antérieur (6), nous avons étudié la réduction polarographique du composé **3***a* dans un tampon ammoniacal, fréquemment utilisé pour effectuer les électrolyses préparatives. La vague est alors dédoublée (fig. 3): la hauteur relative de la première vague B_1 est d'autant plus importante que la période de chute est élevée (fig. 3a) ou la proportion d'ions ammonium plus grande (fig. 3b). Cette première vague correspond alors à la réduction de 3*a* après préprotonation, en surface d'électrode, sous l'action de NH_4^+. La seconde vague B_2 (réduction sans protonation de **3***a*) est déplacée vers les potentiels anodiques, par rapport à un tampon B.R. de même pH. En résumé et comme dans le cas des oximes (6), les ions ammonium exercent une double influence: ils sont susceptibles de jouer le rôle d'agent protonant pour l'hétérocycle **3***a* et leur présence dans la double couche facilite la réduction de la forme non-protonée.

1.3 *Détermination des conditions expérimentales pour la préparation des hétérocycles* **3**a, **4**a *et* **5**a

La connaissance du comportement électrochimique de la nitrocétone **1***a* et de ses produits de réduction permet maintenant de choisir les meilleures conditions d'électrolyse (sur cathode de mercure) pour préparer sélectivement les différents hétérocycles.

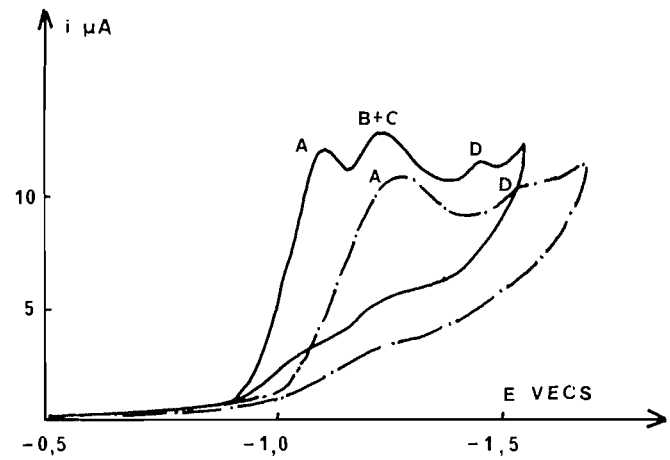


FIG. 2. Voltammogramme de **1***a* ($c = 10^{-3}$ mol L^{-1}) en milieu tampon acétique + éthanol (1:3) sur électrode de mercure, pour différentes vitesses de balayage des potentiels: $v = 0{,}1$ V s^{-1} (——); $v = 10$ V s^{-1} (– · – ·).

Préparation de la pyrroline N-*oxyde* **3**a

Ce composé doit être préparé dans un milieu où la vague A est nettement séparée des vagues B et C; les milieux très acides ne conviennent donc pas. Les électrolyses, contrôlées par coulométrie, ont été effectuées en tampon acétique et en tampon ammoniacal; mais, dans les deux cas, le choix du potentiel de travail est important.

En tampon acétique + éthanol (1:4), il faut éviter la réduction ultérieure de **3***a* et opérer à un potentiel $E_T = -1{,}1$ V ECS, correspondant au début du palier de la vague A (fig. 4); le résultat coulométrique est alors 4,0 faradays par mole et l'enregistrement d'un polarogramme en fin d'électrolyse (fig. 4, courbe 3) montre que le rendement en pyrroline *N*-oxyde formée est supérieure à 90%.

En tampon ammoniacal + éthanol (1:4), l'aspect du polarogramme initial (fig. 5, courbe 1) laisse penser que le choix du potentiel est moins drastique puisque le palier de diffusion s'étend de −1 à −1,5 V ECS. En fait, la vague de réduction de **3***a*, avec préprotonation (B_1), n'apparaît pas sur le polarogramme de la nitrocétone alors qu'elle est visible lorsque l'hétérocycle **3***a* est présent en solution (fig. 5, courbe 2). Cet exemple montre bien la nécessité d'une étude préliminaire complète pour définir les conditions d'électrolyses. Nous avons pu obtenir la pyrroline *N*-oxyde, avec un rendement pratiquement quantitatif, par réduction de **1***a* en tampon ammoniacal, à $E_T = -1{,}15$ V ECS (coulométrie à 4,0 faradays mol^{-1}).

Préparation de la pyrroline **4**a

C'est le composé pour lequel le choix des conditions expérimentales est le plus délicat, puisqu'il faut opérer dans un milieu où la vague B est suffisamment séparée de la vague C; les milieux faiblement acides et basiques sont donc à proscrire. La pyrroline **4***a* peut être préparée par réduction du dérivé *N*-oxyde **3***a*, à $E_T = -0{,}7$ V ECS, dans un milieu H_2SO_4 *N* + éthanol (1:1); on a alors $E_{1/2}$ (B) = −0,7 V ECS et $E_{1/2}$ (C) = −0,83 V ECS. Par contre, le composé **4***a* n'a pu être obtenu par réduction directe de la nitrocétone **1***a*; celle-ci étant

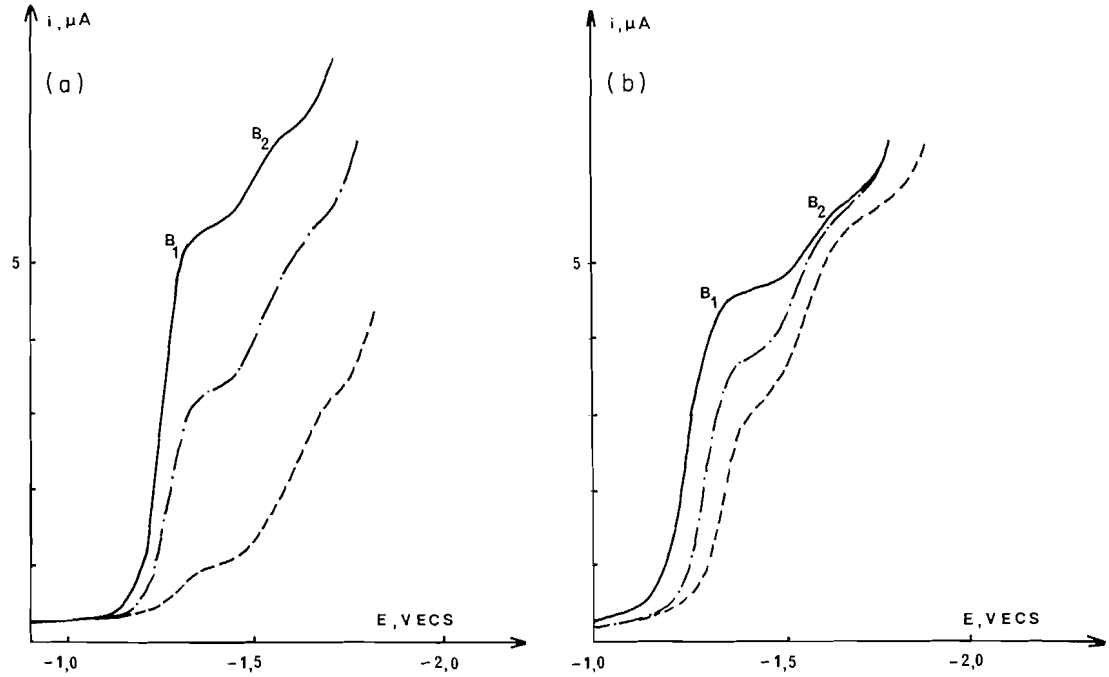

FIG. 3. (a) Polarogrammes de **3***a* en milieu tampon ammoniacal + éthanol (1:1), à différents temps de chute des gouttes de mercure; τ = 8 s (——); 2 s (— · —); 0,1 s (– – –). (b) Polarogrammes de **3***a* en milieu tampon ammoniacal + éthanol (1:1), pour différentes concentrations en ions ammonium NH_4^+. $[NH_4^+]\%$ = 90 (——); 50 (— · —); 20 (– – –).

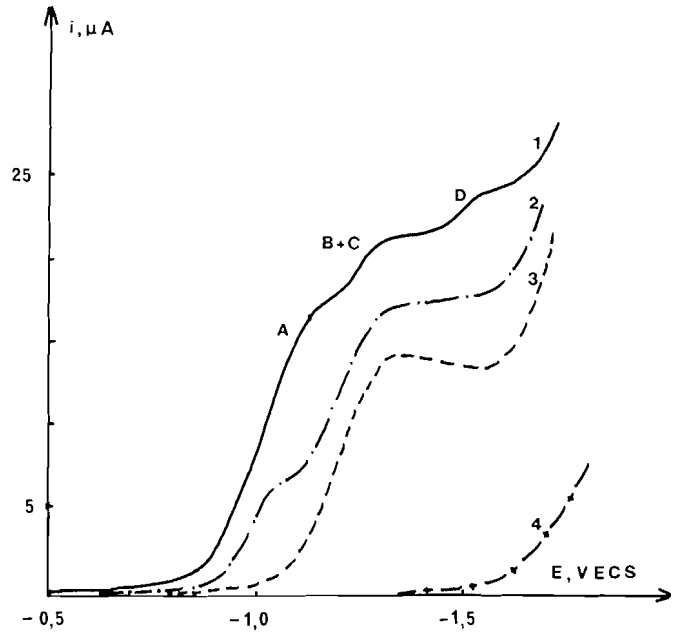

FIG. 4. Evolution des polarogrammes au cours de la réduction de **1***a* (5×10^{-4} mol) dans un mélange tampon acétique (30 cm^3) + éthanol (120 cm^3). 1: avant réduction; 2 et 3: après réduction à E_T = −1,1 V ECS (2: après passages de 2,4 F/mol; 3: après passage de 4 F/mol); 4: après réduction ultérieure à E_T = −1,35 V ECS et passage de 7,6 F/mol de **1***a*.

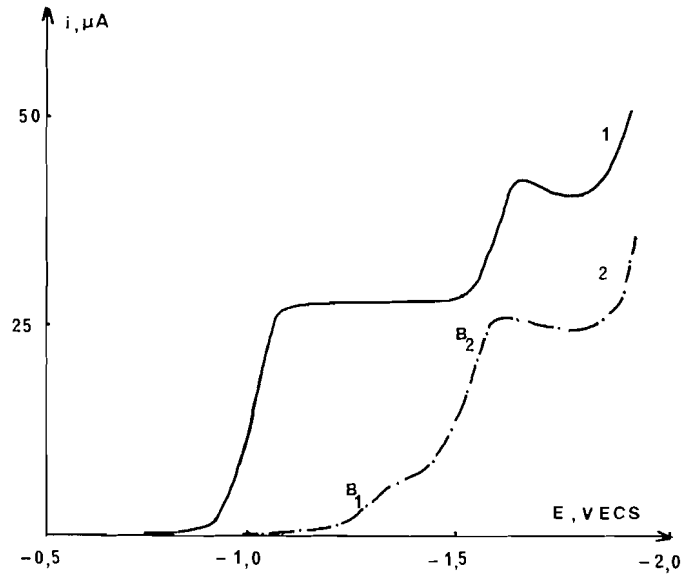

FIG. 5. Evolution des polarogrammes au cours de la réduction de **1***a* (5×10^{-4} mol) dans un mélange tampon ammoniacal (30 cm^3) + éthanol (120 cm^3). 1: avant réduction; 2: après réduction à E_T = −1,15 V ECS et passage de 4F/mol de **1***a*.

beaucoup moins soluble que les dérivés hétérocycliques, l'électrolyse devrait être réalisée dans un milieu H_2SO_4 *N* + éthanol (1:4); mais, dans ces conditions, le dérivé nitré de départ présente une vague unique de réduction à 8 électrons (superposition des vagues A, B et C).

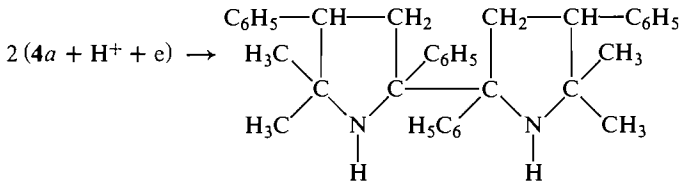
Préparation de la pyrrolidine **5**a

Il existe a priori de nombreuses possibilités pour la préparation électrochimique de ce composé.

On pourrait penser réduire directement (à 8 faradays par mole) la nitrocétone de départ, à un potentiel correspondant au palier de la vague C (ou B + C). Mais d'une part, en milieu très acide, ce palier est mal défini par suite de l'électroactivité du groupement carbonyle et la réduction n'est pas sélective; ainsi, une électrolyse de **1***a*, réalisée à environ −1,15 V ECS dans H_2SO_4 *N* + éthanol (1:4) consomme 7,0 faradays par mole et conduit à un mélange de 50% de pyrrolidine **5***a* et 50% d'hydroxylamino-alcool (correspondant à une réduction à 6 faradays par mole). D'autre part, en milieu moins acide (tam-

pon acétique ou tampon ammoniacal), compte-tenu du caractère cinétique des vages B et C, les réductions sont plus lentes; de plus, elles s'accompagnent d'un déficit coulométrique (*vide infra*).

La meilleure façon de préparer **5***a* consiste à réduire **3***a* (à 4 faradays par mole) ou **4***a* (à 2 faradays par mole). En fait, l'électroréduction de la pyrroline *N*-oxyde **3***a*, en tampon acétique (E_T = −1,25 V ECS) comme en tampon ammoniacal (E_T = −1,50 V ECS) conduit à un résultat coulométrique compris entre 3 et 4 faradays par mole. Le déficit, par rapport aux 4 faradays attendus, provient de la formation d'un produit de duplication, résultant de la réduction à 1 électron, de la pyrroline **4***a*:

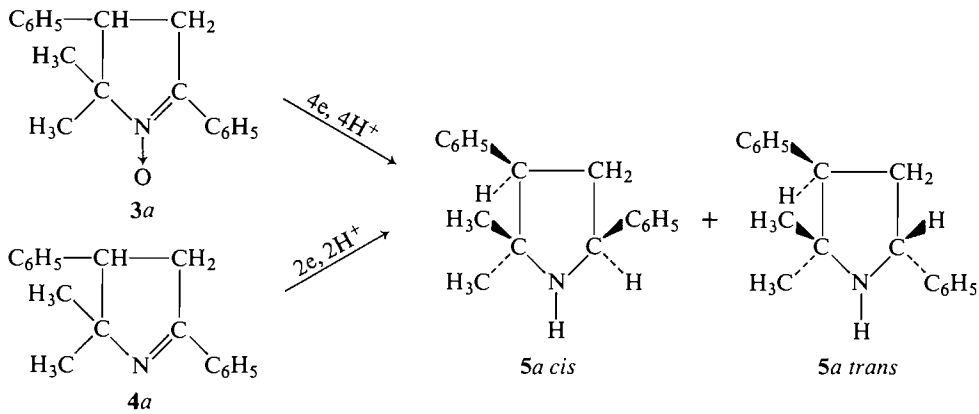


La proportion de produit de duplication formé augmente avec la concentration en substrat et la vitesse d'agitation de la cathode de mercure. Finalement, c'est en milieu H_2SO_4 *N* + éthanol (1 : 1) que la pyrrolidine **5***a* doit être préparée, par réduction de **3***a* ou de **4***a*; les électrolyses, suivies par coulométrie, sont effectuées à −0,95 V ECS et le rendement en **5***a* est alors pratiquement quantitatif.

Remarque: étude stéréochimique de la formation de **5**a

L'examen des spectres rmn de la pyrrolidine **5***a* montre qu'il se forme un mélange d'isomères *cis* et *trans*. Nous avons étudié la variation des pourcentages relatifs des deux stéréoisomères obtenus, d'une part en fonction de la nature du produit soumis à réduction (**3***a* ou **4***a*), d'autre part en fonction des conditions d'électrolyse (nature du milieu, potentiel de travail). Les résultats obtenus sont rassemblés dans le tableau 1.

L'isomère *trans*, thermodynamiquement le plus stable, est toujours majoritaire et on notera que les résultats sont sensiblement les mêmes, que l'on réduise la pyrroline ou la pyrroline *N*-oxyde. Par ailleurs, le pourcentage en isomère *trans* augmente avec le pH: il est probable qu'en milieu très acide la protonation finale s'effectue en partie à la cathode (et conduit alors au dérivé saturé *cis*); au fur et à mesure que l'acidité de la solution diminue, la proportion de carbanion subissant la protonation en solution augmente, entraînant une augmentation du pourcentage en dérivé *trans*. Cependant, en tampon ammoniacal, la proportion en isomère *cis* croît à potentiel très négatif: on peut penser que les ions ammonium s'accumulent alors à la cathode et jouent le rôle d'agent protonant vis-à-vis du carbanion; un effet semblable a déjà été observé lors de la réduction de bromocyclopropanes optiquement actifs (7).



2. Réduction de la nitrocétone 1*b*

Des études analogues à celles qui précèdent ont été réalisées sur la nitrocétone **1***b* et les hétérocycles **3***b* et **4***b*. Nous présenterons brièvement les résultats essentiels, en les analysant par comparaison aux conclusions précédentes, avant de préciser les conditions des électrolyses préparatives.

2.1 *Etude polarographique*

Le polarogramme du *dérivé nitré* **1**b présente, en milieu très acide (pH ≃ 0), deux vagues successives: la première (vague A) est à 4 électrons; la seconde (vague B) est à 2 électrons. Lorsque le pH augmente, ces deux vagues restent bien séparées, mais la hauteur de la seconde croît rapidement pour atteindre 4 électrons (vague B + C) dès pH = 3; elle conserve une hauteur constante jusqu'à pH = 5. A pH plus élevé, elle disparaît, masquée par la décharge des cations de l'électrolyte.

La pyrroline N-*oxyde* **3**b présente une vague unique de réduction à 2 électrons (vague B) à pH ≃ 0. L'intensité de diffusion augmente avec le pH et la vague est à 4 électrons (vague B + C) pour 3 < pH < 5.

TABLEAU 1. Stéréochimie de la pyrrolidine **5***a* obtenue par électroréduction des hétérocycles **3***a* et **4***a*

	Milieu							
	H_2SO_4 *N*		Tampon acétique		Tampon ammoniacal			
Composé réduit	**3***a*	**4***a*	**3***a*	**4***a*	**3***a*	**4***a*	**3***a*	**4***a*
Potentiel E_T (V ECS)	−1,00	−1,00	−1,25	−1,25	−1,35	−1,35	−1,50	−1,50
%trans	63	59	70	65	83	87	67	68

TABLEAU 2. Electroréduction de dérivés nitrés secondaires et primaires à potentiel peu négatif. Milieu: électrolyte-support + éthanol (1:1)

Electrolyte-support (E_T V ECS)	Dérivé nitré	Coulométrie n (F mol^{-1})	Rendement ρ en **3***
H_2SO_4 *N*	**1***e*	3,5	75%
(−0,75)	**1***f*	3,7	85%
Tampon acétique	**1***e*	3,4	70%
(−1,1)	**1***f*	3,5	75%
Tampon ammoniacal	**1***e*	3,7	85%
(−1,2)	**1***f*	3,8	90%

*Calculé à partir du résultat coulométrique ρ% = 50(n − 2).

Enfin, *la pyrroline* **4**b n'est électroactive que pour 3 < pH < 7,5 et présente, dans ce domaine d'acidité, une vague unique de réduction à 2 électrons (vague C).

2.2 *Comparaison avec les composés* **1**a, **3**b, *et* **4**a

Comme précédemment, les trois vagues correspondent respectivement à la réduction du groupement nitré (vague A), de la fonction *N*-oxyde (vague B) et de la double liaison carbone−azote (vague C). Les différences essentielles sont les suivantes. (*i*) En milieu acide, la vague A est mieux séparée de la vague B. (*ii*) La pyrroline **4***b*, contrairement à son homologue **4***a*, n'est pas réductible sur mercure en milieu très acide. (*iii*) Il n'apparaît jamais sur les polarogrammes de vague D (ou de creux) correspondant à la réduction du carbonyle. (*iv*) Enfin, les vagues B ou B + C, enregistrées à partir du dérivé nitré **1***b*, ne présentent pas de caractère cinétique.

Les trois premières observations relèvent de la même interprétation: les hétérocycles **3***b* et **4***b*, substitués par un groupement méthyle sur le carbone lié à l'azote sont plus difficilement réductibles que leurs homologues de la série *a*, substitués par un groupement phényle; de même, la fonction cétone du produit de départ est plus difficile à réduire en série *b*.

Enfin, l'absence de caractère cinétique des vagues de réduction de **3***b* et **4***b* prouve que la cyclisation de l'hydroxylamine **2***b* est plus rapide que celle de **2***a*.

2.3 *Conditions expérimentales de préparation des hétérocycles* **3**b, **4**b *et* **5**b

Le comportement polarographique des composés de la série *b* étant nettement simplifié, les possibilités de préparation électrochimique des hétérocycles sont plus nombreuses et le choix des conditions expérimentales moins draconien.

La pyrroline N-*oxyde* **3**b est préparée, quel que soit le milieu, par réduction au potentiel du palier de la vague A. Les rendements sont quantitatifs (coulométrie à 4,0 faradays mol^{-1}) dans les conditions suivantes: milieu H_2SO_4 *N* + éthanol (1:1), E_T = −0,75 V ECS; tampon acétique + éthanol (1:1), E_T = −1,10 V ECS; tampon ammoniacal + éthanol (1:1), E_T = −1,20 V ECS.

La pyrroline **4**b ne peut être obtenue qu'en milieu H_2SO_4 *N* + éthanol (1:1), par réduction au potentiel de la vague B (E_T = −1,10 V ECS). L'électrolyse peut être effectuée sur l'hétérocycle **3***b* (à 2,0 faradays mol^{-1}) ou directement sur le dérivé nitré **1***b* (à 6,0 faradays mol^{-1}).

La pyrrolidine **5**b peut être préparée, en tampon acétique + éthanol (1:1), par réduction de **1***b* (8,0 faradays mol^{-1}), **3***b* (4,0 faradays mol^{-1}) ou **4***b* (2,0 faradays mol^{-1}), au potentiel E_T = −1,50 V ECS, correspondant au palier de la vague B + C. Contrairement au cas de la série *a*, on n'observe jamais la formation de composé de duplication.

3. Réduction des dérivés nitrés secondaires et primaires

3.1 *Etude polarographique*

Elle apporte peu d'éléments nouveaux. Les composés **1***c* et **1***d*, porteurs d'un groupement COC_6H_5, possèdent un comportement voisin de celui de **1***a*. En milieu très acide, le polarogramme présente les trois vagues A, B et C mal séparées, suivies, à potentiel plus négatif, d'une diminution du courant de diffusion due à la réduction du groupement carbonyle. En milieu peu acide, la vague A reste très proche d'une seconde vague (de type B + C) à caractère cinétique, elle-même suivie d'une vague de type D. Ce n'est qu'en milieu basique (en particulier en tampon ammoniacal) qu'apparaît une vague A bien séparée d'une seconde vague de type D.

Les composés **1***e* et **1***f*, dont la fonction cétone est substituée par un groupement méthyle, se conduisent comme **1***b*. En milieu très acide, il existe deux vagues distinctes A et B. Lorsque le pH augmente, la vague A est suivie jusqu'à pH = 6 d'une vague B + C qui ne présente pas de caractère cinétique.

3.2 *Mesures coulométriques et électrolyses*

Contrairement à ce que l'on observe dans le cas des dérivés nitrés tertiaires, les électrolyses, réalisées au potentiel des vagues A des composés **1***c* à **1***f*, sont caractérisées par un déficit coulométrique par rapport aux 4 faradays attendus (cf. tableau 2). A côté de la pyrroline *N*-oxyde **3**, la solution obtenue contient une oxime-cétone **6**, non électroactive dans les conditions utilisées. Selon Iversen et Lund (8), cette dernière provient de la formation transitoire de dérivé nitroso dont une partie se transpose et l'autre se réduit en hydroxylamine (schéma 2):

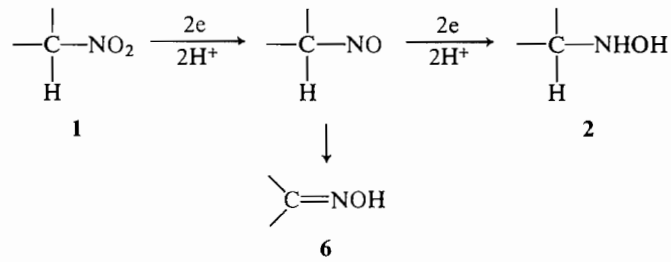


SCHÉMA 2

Il apparaît donc que l'électroréduction de dérivés nitrés primaires ou secondaires ne constitute pas une méthode sélective d'accès aux pyrrolines *N*-oxydes **3**. En conséquence, il n'apparaît pas rentable de chercher à les isoler pour les réduire ultérieurement. Nous avons alors été conduits à rechercher des conditions d'obtention des autres hétérocycles par réduction directe des dérivés nitrés **1***c* à **1***f*; si les pyrrolidines peuvent être ainsi préparées avec des rendements satisfaisants, l'obtention des pyrrolines est plus délicate et seules **4***e* et **4***f* ont pu être caractérisées.

3.21 *Obtention des pyrrolines* N-*oxydes*

Ces composés se forment à côté de la cétone-oxime **6** par réduction à potentiel peu négatif (vague A).

Dans le cas des composés méthylés **1***e* et **1***f*, les électrolyses peuvent être réalisées dans différents milieux. Les résultats coulométriques, rassemblés dans le tableau 1, montrent que les rendements en composés hétérocycliques sont plus faibles en tampon acétique.

Dans le cas des composés phénylés, il est exclu d'opérer en milieu acide, les vagues A et B (ou B + C) étant trop rapprochées. En tampon ammoniacal, on se heurte à la même

difficulté que dans le cas de **3***a*: alors que le polarogramme des nitrocétones **1***c* et **1***d* ne présente que les vagues A et D, en cours d'électrolyse, il apparaît une vague de type B_1, trop proche de A, correspondant à la réduction de la pyrroline *N*-oxyde qui s'est accumulée en solution. Le résultat coulométrique est alors peu reproductible ($3{,}8 < n(F) < 4{,}2$) et l'on obtient un mélange de l'hétérocycle cherché (**3***c* ou **3***d*) et de pyrroline (**4***c* ou **4***d*) en proportions variables selon les conditions d'électrolyse.

3.22 *Obtention des pyrrolines* ***4***

Tous les essais d'obtention des pyrrolines **4***c* et **4***d* se sont soldés par des échecs, comme le laissait prévoir l'étude polarographique.

Les dérivés méthylés **4***e* et **4***f* ont pu être préparés, en milieu sulfurique, par électrolyse au palier de la vague B de réduction de **1***e* ou **1***f* ($E_T = -1{,}0$ V ECS); les résultats coulométriques sont inférieurs aux 6 F attendus et les rendements ne sont pas quantitatifs.

3.23 *Obtention des pyrrolidines* ***5***

La réduction, à 8 faradays par mole, du dérivé nitré doit être réalisée au palier d'une vague B + C.

Pour **1***c* et **1***d*, les électrolyses ne peuvent être effectuées en milieu sulfurique (du fait de la réduction du carbonyle à potentiel très négatif) ni en tampon acétique (déficit coulométrique dû, d'une part à la formation d'oxime lors du passage par le nitroso intermédiaire, d'autre part à la formation d'un produit de duplication, lors du passage pyrroline–pyrrolidine). Ce n'est donc qu'en tampon ammoniacal, au potentiel $E_T = -1{,}45$ V ECS (supérieur au $E_{1/2}$ de la vague D) que nous avons pu préparer **5***c* et **5***d*. Les résultats coulométriques (voisins de 7,8 faradays) indiquent un rendement proche de 95%.

Pour **1***e* et **1***f*, la vague B + C n'apparaît qu'en tampon acétique. Les électrolyses, réalisées dans ce milieu à $E_T = -1{,}5$ V ECS, permettent d'obtenir **4***e* et **4***f* avec de bons rendements.

Partie expérimentale

1. *Techniques électrochimiques*

Les polarogrammes sont enregistrés à l'aide d'un appareil à trois électrodes (enregistreur EPL 2B Tacussel équipé d'un tiroir Tipol). Les coulométries et les électrolyses préparatives sont réalisées à potentiel contrôlé (potentiostat Tacussel 20-2; intégrateur IG 5) dans la cellule décrite par Moinet et Peltier (9). Les essais portent sur 0,1 à 1 g de dérivé nitré; la température est voisine de 20°C.

Les milieux aqueux utilisés comme électrolyte-support sont les suivants.

En polarographie

pH < 2: solutions d'acide sulfurique

$2 <$ pH < 12: tampons Britton-Robinson (notés B.R.) 4×10^{-2} *M* + KNO_3 0,2 *M*. Les polarogrammes sont enregistrés sur des solutions 5×10^{-4} *M* en dérivé nitré dissous dans un mélange électrolyte-support + éthanol (1:1) en volume.

En électrolyse préparative

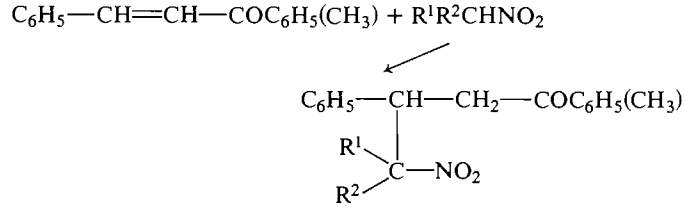
Milieux tres acides: acide sulfurique normal; milieux peu acides: tampon acétique 0,5 *M* en CH_3CO_2H et 0,5 *M* en CH_3CO_2Na (pH ≃ 4,8); milieux basiques: tampon ammoniacal 0,5 *M* en NH_3 et 0,5 *M* en NH_4Cl ou $NH_4CH_3CO_2$.

Les expériences sont conduites dans des mélanges électrolyte-support + éthanol, en proportions 1:1 ou 1:4 selon la solubilité du substrat. Les produits de réduction sont extraits à l'éther après évaporation de l'éthanol et neutralisation éventuelle de la solution par Na_2CO_3.

2. *Préparation des dérivés nitrés de départ*

Les dérivés γ-nitrés sont généralement obtenus par addition d'un nitroalcane sur un composé éthylénique activé en présence d'un catalyseur basique.

Quelques γ-nitrocétones avaient déjà été préparés antérieurement (3, 10) par condensation du nitrométhane ou du nitro-2 propane sur une benzylidène-cétone, en présence de catalyseurs variés.



($R^1 = R^2 = H$ ou $R^1 = R^2 = CH_3$)

Nous avons diminué les temps de réaction et amélioré les rendements en utilisant la tétraméthylguanidine comme catalyseur. L'addition se fait alors à température ambiante et conduit, avec de bons rendements aux γ-nitrocétones **1***a* à **1***f*.

1*a*: F = 150°C (3); **1***b*: F = 54°C (3); **1***c*: F = 75°C (mélange de deux diastéréoisomères)

1*d*: F = 99°C (10); **1***e*: $E_{b_{0,5}}$ = 148°C (mélange de deux diastéréoisomères)

1*f*: F = 96–100°C (10).

3. *Préparation et caractéristiques des produits de réduction*

3.1 *Pyrrolines* N-*oxydes*

Les conditions de préparation et les caractéristiques des pyrrolines *N*-oxydes **3***a* et **3***b*, issues de la réduction de **1***a* et **1***b*, sont données dans la note préliminaire (4).

Les hétérocycles **3***c* et **3***d* sont obtenus par réduction de **1***c* et **1***d* en milieu tampon ammoniacal + éthanol (1:4); potentiel de travail $E_T = -1{,}05$ V ECS; résultat coulométrique *n* voisin de 4 F par mole de dérivé nitré; spectres ir (CCl_4) de **3***c* et **3***d* identiques à celui de **3***a*.

Les hétérocycles **3***e* et **3***f* sont préparés par réduction de **1***e* et **1***f* en milieu tampon ammoniacal + éthanol (1:1); $E_T = -1{,}15$ V ECS; n = 3,69 F par mole pour **1***e* et n = 3,80 F par mole pour **1***f*. Spectres ir (CCl_4) de **3***e* et **3***f* identiques à celui de **3***b*.

Remarque: l'hétérocycle **3***f* a également été caractérisé à l'état de picrate: F = 133–135°C (11).

3.2 *Pyrrolines*

Les caractéristiques des pyrrolines **4***a* et **4***b* sont données dans la réf. 4. Pour les raisons invoquées précédemment, les pyrrolines **4***c* et **4***d* n'ont pu être obtenues. Les pyrrolines **4***e* et **4***f* sont préparées par réduction de **1***e* et **1***f* en milieu H_2SO_4 *N* + éthanol (1:1); $E_T = -1{,}0$ V ECS; *n* compris entre 5,8 et 6,0 F par mole pour **1***e* et n = 5,77 F par mole pour **1***f*. Les spectres ir (CCl_4) de **4***e* et **4***f* sont identiques à celui de **4***b*.

3.3 *Pyrrolidines*

Les caractéristiques rmn des pyrrolidines **5***a* et **5***b* sont données dans la réf. 4. Les spectres ir de ces deux composés enregistrés dans CCl_4 sont identiques. Composé **5***a*; ν_{max}: 3370, 3080, 3040, 2970, 2940, 2870, 1950, 1875, 1810, 1605, 1495, 1455, 1425, 1380 cm^{-1}.

Préparation de **5**c: réduction de **1***c* en tampon ammoniacal + éthanol (1:4); $E_T = -1{,}5$ V ECS; *n* voisin de 7,8 F par mole; spectre ir (CCl_4) de **5***c* identique à celui de **5***a*; l'hétérocycle **5***c* a également été caractérisé par son dérivé benzoylé: F = 142°C.

Préparation de **5**d: réduction de **1***d* en tampon ammoniacal + éthanol (1:4); $E_T = -1{,}4$ V ECS; *n* voisin de 7,6 F par mole; spectre ir (CCl_4) de **5***d* identique à ceux de **5***a* et **5***c*; l'hétérocycle **5***d* a également été caractérisé par son dérivé benzoylé: F = 120°C (litt. (10) F = 122°C).

Préparation de **5**e: réduction de **1***e* en tampon acétique + éthanol (1:1); $E_T = -1{,}5$ V ECS; *n* voisin de 7,7 F par mole; spectre ir (CCl_4) de **5***e* identique à celui de **5***b*.

Préparation de **5**f: réduction de **1***f* en tampon acétique + éthanol (1:1); $E_T = -1{,}5$ V ECS; *n* voisin de 7,7 F par mole; spectre ir (CCl_4)

de **5***f* identique à ceux de **5***b* et **5***e*.

3.4 *Les cétones oximes* **6** ont été identifiées à partir de leur spectre ir (CCl_4): ν_{OH} = 3600 cm^{-1}; $\nu_{C=O}$ = 1720 cm^{-1}.

Conclusion

Les résultats obtenus au cours de cette étude montrent que l'électroréduction, à potentiel contrôlé, de γ-nitrocétones est une méthode de choix pour la préparation de pyrrolines *N*-oxydes, de pyrrolines et de pyrrolidines, lorsque le groupement nitré est porté par un carbone tertiaire. Mais, même dans ce cas, le choix des conditions expérimentales, appropriées pour la préparation sélective de chaque hétérocycle, nécessite une étude préalable du comportement électrochimique du dérivé nitré de départ et de ses produits de réduction.

Dans le cas des dérivés nitrés secondaires et primaires, la formation parasite d'une cétone-oxime lors des réductions à potentiel peu négatif, limite les rendements en pyrrolines *N*-oxydes. Si les pyrrolidines peuvent être encore préparées par électrolyse à potentiel très négatif dans un milieu convenablement choisi, la méthode est difficilement applicable à la préparation des pyrrolines.

The techniques of factor analysis are used to investigate a data matrix constructed from magnetic resonance parameters for seventy-five 4-substituted styrenes, α-methylstyrenes, and α-*tert*-butylstyrenes and 3-substituted styrenes and α-methylstyrenes (with fifteen common substituents for each series). Two substituent factors (parameters) are clearly both *necessary* and *sufficient* to predict long-range chemical shifts within experimental uncertainty. Target testing indicates that Taft's σ_I and σ_R^0 constants are appropriate for this purpose. One additional major factor is required for each of *ipso* and *ortho* carbons and a minor factor is apparently required for *meta* carbons.

Conclusions do not appear to be sensitive to the weighting of individual variables and the specific variables included in the data matrix. However, the use of an extensive and well-chosen substituent set is essential.

WILLIAM F. REYNOLDS, ANABELA GOMES, ANTONINA MARON, DOUGLAS W. MACINTYRE, ROBERT G. MAUNDER, ATES TANIN, HECTOR E. WONG, GORDON K HAMER et IAN R. PEAT. Can. J. Chem. **61**, 2367 (1983).

On a utilisé les techniques d'analyse de facteurs pour étudier une matrice de données construite à partir des paramètres de résonance magnétique de soixante-quinze composés comprenant des styrènes substituées en position 4, des α-méthylstyrènes et α-*tert*-butylstyrènes, des styrènes substitués en position 3 et des α-méthylstyrènes (avec 15 substituants communs dans chaque série). Deux facteurs de substituant (paramètres) sont nécessaires et suffisants pour prédire les constantes de couplage à longue distance à l'intérieur des marges d'erreur expérimentale. Les tests cibles indiquent que les constantes σ_I et σ_R^0 de Taft conviennent dans ce cas. On a besoin d'un facteur principal additionnel pour chaque carbone *ipso* et *ortho* et d'un facteur secondaire pour les charbones en *méta*.

La pondération des variables individuelles et des variables spécifiques incluses dans la matrice ne semblent pas avoir d'influence sur les faits observés. Cependant il est essentiel d'utiliser un ensemble de substituants très convenablement choisis.

[Traduit par le journal]

Introduction

Ten years ago, we published the results of nmr investigations of a series of 4-substituted styrenes (**4H**), 4-substituted α-methylstyrenes (**4M**) and 4-substituted α-*tert*-butylstyrenes (**4B**) (1, 2). Nuclear magnetic resonance spectral data were obtained for more than 50 compounds, measured under inert conditions. Our two main conclusions were: (a) that a dual substituent parameter (dsp) treatment was necessary to adequately account for substituent-induced long-range chemical shifts in styrenes, and (b) that the actual chemical shifts reflected a combination of resonance, field, and π inductive (polarization) effects (1, 2). The **4H**, **4M**, and **4B** derivatives were ideal for this purpose since the increasing size of the alkyl groups progressively decreased phenyl−vinyl conjugation, thus altering the ratio of resonance to field/inductive effects in a qualitatively predictable manner (2).

Subsequently, a number of other groups have used our styrene data to test various other models of single and dual substituent parameter scales (3−9). This may be regarded as part of a more general debate concerning the relative merits of these two approaches (10). We were flattered that so many groups were sufficiently impressed by our data set to use it in their investigations, even if we didn't always agree with their conclusions (11, 12). However, we were never entirely happy with the original data set. In particular, both the **4M** and **4B** substituent sets contained only one strong acceptor group (NO_2) (2), thus not fulfilling Taft's recommended minimal substituent set for dsp correlations (13).

Consequently, the appearance of the most recent alternative explanation of our styrene data (9) catalyzed us to expand the substituent set to incorporate a better-balanced set of substituents. At the same time, we decided to synthesize 3-substituted styrenes (**3H**) and 3-substituted α-methylstyrenes (**3M**). This should again alter phenyl-vinyl conjugation by going from a conjugated to a formally unconjugated orientation of the substituent and vinyl groups.

We have now ^{13}C data for 15 common substituents (X = H, $N(CH_3)_2$, NH_2, OCH_3, SCH_3, CH_3, $Si(CH_3)_3$, F, Cl, Br, $COCH_3$, CO_2CH_3, CF_3, CN, and NO_2) in the five styrene series, well in excess of the recommended minimum substituent set (13). In this paper we report the results of factor analysis of this large data set. Factor analysis and the closely related technique of principal components analysis can be used without prior assumptions to determine the number of factors or components necessary to account for any data set (14, 15). Both techniques have recently been applied to the analysis of substituent-induced chemical shifts (9, 16−19). We chose to use factor analysis because a standard program (FACTANAL (20)) was readily available, along with a recent book which provides a very clear description of this technique (14). It was

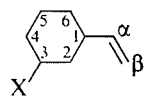
[a]Numbering:



hoped that this investigation might finally resolve the single–dual substituent parameter controversy.

The results are summarized below.

Results

^{13}C data for new **4H**, **4M**, and **4B** derivatives are summarized in Table 1.[1] Data for **3H** derivatives are in Table 2 while **3M** derivatives are in Table 3. Chemical shifts for phenyl carbons were assigned on the basis of intensities and the assumed additivity of ^{13}C chemical shifts. Fortunately styrenes show insignificant deviations from additivity, in contrast to some other di-substituted benzenes (21), thus making assignment straightforward. α and β carbon assignments were generally straightforward. In the case of 3-OCH_3, NH_2 and $N(CH_3)_2$ derivatives, INEPT spectral editing (22) was used to distinguish the β CH_2 from high-field aromatic CH carbons.

Discussion

(a) *Probable experimental errors in data*

Knowledge of the probable experimental errors in the data set is very important in factor analysis since the most obvious choice for the correct number of factors for a particular problem is the number which reproduces the data within experimental uncertainty (14). Fewer factors will result in the loss of potentially useful information while over-parameterization will only complicate the interpretation of the problem.

The data set used in this investigation has been obtained over a period of 15 years on four different nmr spectrometers

[1]Data for other 4-substituted styrenes are listed in refs. 1 and 2.

[a]Numbering is the same as in Table 2.

(Varian HA-100, XL-100, and XL-200 and Bruker WP-80). Many of the measurements have been repeated at least twice on different spectrometers with different operators, and sometimes at different concentrations. On the basis of these observations, we believe that a conservative estimate of the uncertainty in the ^{13}C data is 0.1 ppm. The use of a constant probe temperature seems particularly important since initial measurements made on the XL-200 spectrometer at 20°C differed by as much as 0.2 ppm from those made on the XL-100 at 32°C. In the case of ^1H data, chemical shifts appear to be reliable within 0.01 ppm and $^1H-^1H$ coupling constants within 0.03 Hz.

(b) *Processing of data for factor analysis*

There appears to be no single agreed "best" method for processing of data for factor analysis (14). Consequently, we will present results obtained from three different methods, in order to demonstrate that our conclusions are not significantly affected by the method of data processing.

Analyses were performed using both actual chemical shifts (including the parent compound (X = H)) and for substituent-induced chemical shifts (expressed relative to the parent compound which is then excluded from the analysis). We prefer the former approach[2] but have included the latter because it is favoured by many investigators of substituent effects (13). It should be noted that the two approaches yield a different number of factors. Expressed as Hammett type relations, the former approach is represented by

$$[1] \quad \delta_x = \delta_0 + \sum^{n} \rho_n \sigma_n$$

while the latter is given by

$$[2] \quad \Delta\delta(\equiv \delta_x - \delta_0) = \sum^{n} \rho_n \sigma_n$$

Thus the first approach requires one additional factor for the intercept.

Another area of choice is the weighting used for individual variables in constructing the data matrix. One obvious approach is to weight all variables so that they have equal experimental uncertainties, facilitating the determination of the correct number of factors (14). In our case, ^{13}C chemical shift data were multiplied by one, ^1H chemical shift data by ten, and $^1H-^1H$ coupling constants by three, yielding a common experimental uncertainty of 0.1. This approach was used in constructing data matrices from both δ and Δδ values. An alternative, commonly used (15, 16), scheme is to adjust the variance of each variable to unity so that each variable covers a similar range. This normalization procedure was used in conjunction with Δδ values. It should be noted that it leads to a different experimental uncertainty for each variable.

(c) *Tests used for determining the correct number of factors*

Of the various tests described by Malinowski and Howery (14), three were chosen. The first and simplest test is that the residual standard deviation (RSD) for the data matrix should be approximately equal to the experimental uncertainty for the correct number of factors. The second, related test is that no individual point should show a deviation more than three times the experimental uncertainty (3σ test). The third is the empirical indicator function (IND) which is defined as

$$[3] \quad \text{IND} = \text{RSD}/(x - n)^2$$

where x is the number of columns or rows (whichever is the lesser) in the data matrix and n is the number of factors. IND should reach a minimum for the correct number of factors (14).

(d) *Factor analysis of long-range substituent-induced chemical shifts*

Our initial focus was on long-range chemical shifts, in order to avoid the known complications associated with short-range effects (1, 23). The main data set incorporated *para* (to the substituent), α, and β carbon chemical shifts for **4H**, **4M**, **4B**, **3H**, and **3B** derivatives as well as β ^1H chemical shifts and $^1H-^1H$ coupling constants for **4H** derivatives. ^1H chemical shifts for other derivatives were omitted since these are very sensitive to variations in ring current effects originating in the phenyl group. These variations are due to minor substituent-induced changes in vinyl group conformation (2). The 15 common substituents listed in the Introduction were used, yielding an 18 × 15 data matrix. A more restricted data matrix incorporating only the six **4H** variables was also tested, to determine

[2]The parent compound data have experimental errors similar to those for the rest of the data set. Consequently, we see no justification in forcing the data to pass through an origin defined by the parent compound, thus giving this point infinite weight.

[g]Tests corresponding to optimum number of factors are underlined. Note that δ analyses require one addition factor for the intercept.

the sensitivity of the results to the number of columns in the data matrix.

Results of the various tests to determine the number of factors are summarized in Table 4. We will first consider the data matrices which have been scaled for a common experimental uncertainty of 0.1 (δ and $\Delta\delta$). In each of the four cases, RSD drops rapidly to ca. 0.1 and then changes much more slowly with increasing numbers of factors. Furthermore, in each case, the number of points with error greater than 3σ drops to zero or almost zero at the same time. In the case of δ, the clear break occurs at three factors (two substituent factors (parameters) plus an intercept; see eq. [1]). For $\Delta\delta$, the break occurs at two factors, again corresponding to two substituent parameters (see eq. [2]). The only difference is that RSD is slightly larger (ca. 0.02) for $\Delta\delta$ than for δ in both cases, reflecting the fact that $\Delta\delta$ values contain not only their own experimental errors but also any errors in δ for the parent compounds. The normalized $\Delta\delta$ values generally show very similar patterns of test results to the $\Delta\delta$ values, suggesting that the weighting of individual variables is not a critical parameter.

The empirical indicator function, IND, does not give as consistent results as the other two tests. For the 6 column data matrix (**4H** data only), IND drops rapidly to a sharp minimum at the point corresponding to the correct number of factors, as expected (14). However, for the full data set, IND gives a very shallow minimum extending over several factors. For the correct number of factors as indicated by the other tests, IND is not at a minimum but rather at a point on the curve corresponding to the onset of the shallow minimum. This difference apparently reflects the sensitivity of eq. [3] to the number of columns in the data matrix. For example, for a 6×15 matrix, $(x - n)^2$ changes from 9 to 4 on going from 3 to 4 factors but only from 144 to 121 for the corresponding number of factors for a 18×15 matrix. Thus for the 6×15 data matrix, IND increases suddenly at the point where RSD begins to level off but for the 18×15 matrix, the change in $(x - n)^2$ is so slow that IND only starts to level off as RSD levels off.

The data in Table 4 strongly support our previous view (12) that a dual substituent parameter treatment is both *necessary* and *sufficient* to account for long-range substituent-induced chemical shifts in aromatic derivatives. Certainly, a single substituent factor is inadequate since this gives residual errors which are four to eight times larger than experimental errors. Equally, the slow decrease in RSD for substituent parameters in excess of two suggests that the additional factors are primarily trying to accommodate experimental error. It is to be hoped that the observations in this section will finally resolve the long-standing controversy concerning single versus dual substituent parameter treatments of nmr data.

Target testing can be used to test possible candidates for the two subtituent factors (14). σ_I and σ_R^0 (13, 24) were used as initial test vectors. Both gave excellent agreement between input and predicted test vectors (see Figs. 1 and 2), suggesting that these are appropriate parameters to use in dsp treatments of aromatic chemical shifts. The F (rms error = 0.082) and R (rms error = 0.054) parameters of Swain and Lupton (25) were poorer test vectors, suggesting that they would be less appropriate. Finally, unity was also an excellent test vector for the data matrix of δ values, as expected for a data matrix incorporating an origin for each variable. The three test vectors can be used in combination to reproduce the data matrix according to eq. [4] (17*b*)

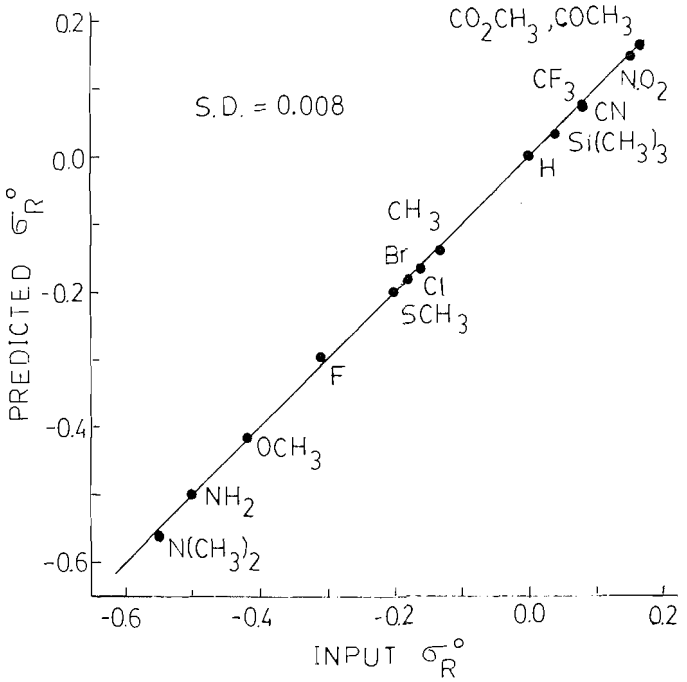

FIG. 1. Plot of input (from refs. 13 and 24) versus predicted (by target testing) σ_R^0 values.

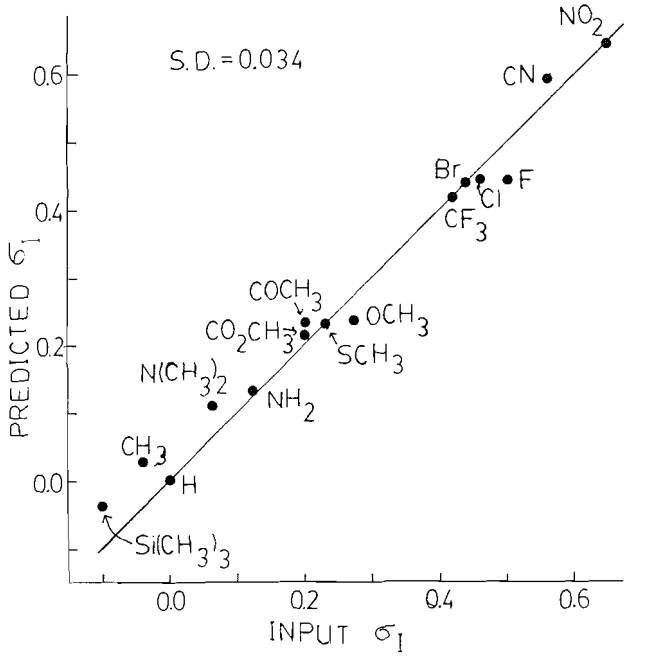

FIG. 2. Plot of input (from refs. 13 and 24) versus predicted (by target testing) σ_I values.

$$[4]\quad \delta_{xk} = a_{x1}b_{1k} - a_{x2}b_{2k} + a_{x3}b_{3k}$$

where a_{xi} are the three substituent factors (parameters) for substituent X (e.g. 1, $\sigma_{I(X)}$, and $\sigma^0_{R(X)}$) and b_{ik} are the cofactors or weighting terms for each variable k ($\delta_{0(k)}$, $\rho_{I(k)}$, and $\rho_{R(k)}$, see eq. [1]). Using the predicted σ_I and σ_R^0 values from Figs. 3 and 4, eq. [4] reproduced the data matrix with an overall rms error of 0.10 (individual variables gave rms errors of 0.05 to 0.16). Furthermore, the predicted δ_0 value for each variable was in excellent agreement with the corresponding chemical shift for the parent compound (X = H). Thus, individual long-range chemical shifts in styrene derivatives are predicted with excellent precision by

$$[5]\quad \delta_{xk} = \delta_{0(k)} + \sigma_{I(k)}\rho_{I(k)} + \sigma^0_{R(X)}\rho_{R(k)}$$

(e) *Comparison with a previous principal components analysis of long-range substituent effects on 4-substituted styrenes*

On the basis of the SIMCA method of principal components analysis (15), Edlund and Wold concluded that a single substituent parameter was sufficient to account for long-range chemical shifts in **4H**, **4M**, and **4B** derivatives (9). This is a most surprising conclusion in view of the results in the previous section. While we earlier felt that their conclusions might be biased by their method of pre-processing the data (12), the results in Table 4 suggest that this may not be of major importance. However, one obvious difference between the two investigations was that they used a much smaller substituent set ($N(CH_3)_2$, OCH_3, CH_3, $C(CH_3)_3$, F, Cl, and NO_2 (9), representing the only common substituents other than H which were available in all three series at that time). Since it is disturbing that two closely related techniques should give very different conclusions, we carried out a factor analysis for the same data matrix which they used, in order to test the effect of the size of the substituent set. Analyses were again carried out using δ, $\Delta\delta$, and normalized $\Delta\delta$ scales. Results for the δ correlations are summarized in Table 5. The other two analyses gave similar patterns of results.

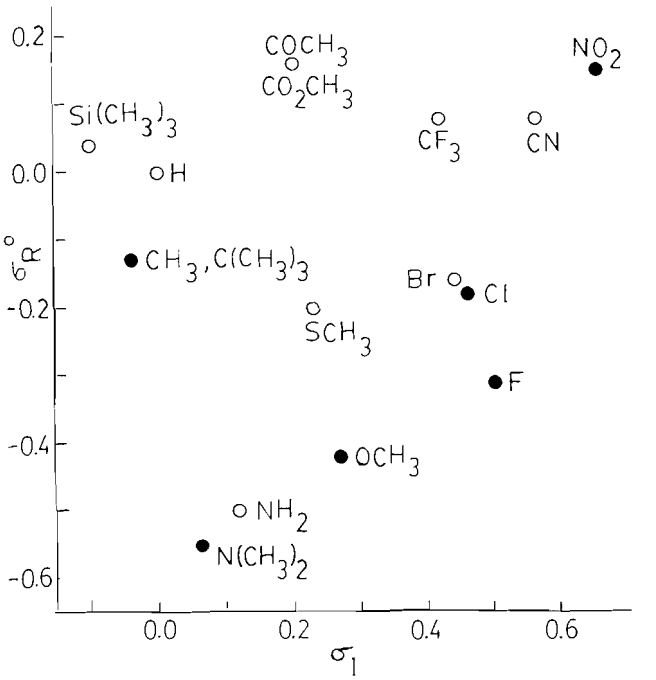

FIG. 3. Plot of σ_I versus σ_R^0 for restricted data set used in ref. 9 (filled circles) plus additional substituents in this investigation (open circles).

Using estimated error as a criterion, the factor analysis for the smaller substituent set again suggests two substituent parameters (plus an intercept). However, the distinction between one and two substituent parameters is not nearly as clear-cut as in the case of the larger substituent parameter set. Edlund and Wold used a different procedure (cross validation (15)) to determine the correct number of principal components. This purely statistical criterion obviously must accept as satisfactory the reasonably good fit given by one component.

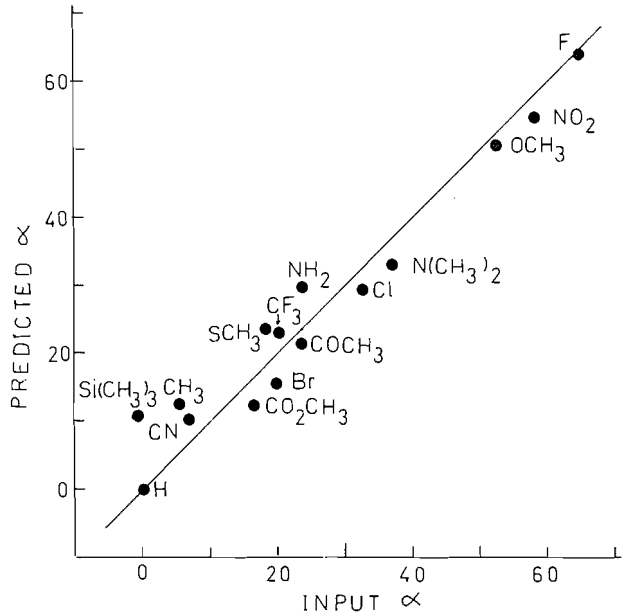

FIG. 4. Plot of input versus predicted α values for *ipso* carbons.

A plot of σ_I versus σ_R^0 for the various substituents (Fig. 3) demonstrates why the limited substituent set does not so clearly distinguish between one and two substituent factors. For five of the seven substituents, σ_I shows a fair linear relationship with σ_R^0, with only the alkyl groups deviating. Thus for the limited substituent set, σ_I and σ_R^0 are not fully independent and consequently one substituent factor provides a reasonable fit. This is not true, however, for our full substituent set where no such relationship exists. This confirms the comments made by Taft and co-workers concerning the necessity of using a well-balanced substituent set in investigations of substituent effects (13).

(f) *Factor analysis incorporating short-range chemical shifts*

Four separate factor analyses were carried out involving short-range chemical shifts. In the first, *ipso* carbon (C(4)) chemical shifts for **4H**, **4M**, and **4B** derivatives were incorporated into a data matrix in conjunction with the eighteen long-range parameters from part (d). In the second, *ortho* carbon (C(3)) chemical shifts were used with the 18 parameter set, while in the third, *meta* (C(2)) chemical shifts were used. Finally, all three variables for the three derivatives were combined with the long-range parameters to product a 27 × 15 data matrix. Results for δ and Δδ analyses are summarized in Table 6 (normalized Δδ analyses gave similar patterns of results).

In the case of C(4), one additional substituent parameter (for a total of three) is clearly required. One also appears sufficient, although a very small percentage of data points give errors greater than 3σ. With C(3), one additional parameter is again obviously needed and in this case it is also obvious that one extra is also sufficient. However, the results for C(2) are ambiguous. The δ values suggest that two substituent factors (plus an intercept) are still adequate. However, the Δδ values suggest a third factor is required. Significantly, if only two factors are used, then the six largest errors all involve C(2) (including at least one from each of **4H**, **4M**, and **4B**). Apparently a third, relatively small, factor is required for C(2). However, because it is small, it can reasonably well be incorporated in the δ analysis by having a δ_0 which differs from δ_H.

The analysis involving C(4), C(3), and C(2) simultaneously confirmed the conclusions given above. In this case four substituent factors were clearly required with a fifth of marginal significance. The only logical conclusion to draw from these results is that the original two factors (σ_I and σ_R^0) are still operative plus one additional significant factor for each of C(4) and C(3) and a minor factor for C(2).

TABLE 5. Comparison of results of factor analysis for the same data set as used in ref. 9 with the results for the 18 parameter set[a]

Factors	RSD[b]	3σ[b]	IND[b]
1	1.16(2.25)[c]	62.5(82.2)[c]	$2.4\times10^{-2}(1.1\times10^{-2})$[c]
2	0.20(0.44)	13.5(44.8)	$6.0\times10^{-3}(2.6\times10^{-3})$
3	0.10(0.09)	0.0(0.0)	$4.2\times10^{-3}(6.5\times10^{-4})$
4	0.04(0.07)	0.0(0.0)	$3.1\times10^{-3}(6.0\times10^{-4})$
5	0.03(0.07)	0.0(0.0)	$4.8\times10^{-3}(6.9\times10^{-4})$

[a]Factor analysis for actual chemical shifts. Δδ and normalized Δδ values gave similar results.
[b]Terms defined in Table 4.
[c]First values are for data set used in ref. 9, while those in brackets are data for 18 variable set from Table 4. Note the much smaller differences between two and three factors (one and two substituent factors) for first values.

Target testing of σ_I and σ_R^0 showed that these were again excellent target vectors for data matrices incorporating short range chemical shifts. As initial target vectors for the short range *ipso* (C(4)) and *ortho* (C(3)) factors, we chose the corresponding α and β chemical shifts in monosubstituted cyclohexanes. The logic was that σ_I and σ_R^0 would represent perturbation of the π electron system by field-induced π polarization and resonance respectively (26), while α and β parameters from cyclohexanes would approximately mirror any substituent-induced changes in the σ system. α turned out to be a reasonable test vector for the *ipso* factor (see Fig. 4). Furthermore, when the predicted α was used in conjunction with σ_I and σ_R^0 to reproduce the data matrix, the co-factors for α were 0.819, 0.822, and 0.824 for C(4) of **4H**, **4M**, and **4B**, respectively, while the next largest co-factor was 0.003. Thus, it is clear that the ipso factor, α, is specific to this position and contributes nothing to the long-range chemical shifts. The *ipso* factor appears to be basically a group electronegativity factor (26), as might be expected for a directly bonded substituent.

Target testing of β was less satisfactory. There are significant differences between input and predicted β values (see Fig. 5). Thus it is entirely possible that the predicted β is not a pure factor but rather some linear combination of the actual *ortho* factor and σ_I and/or σ_R^0. As an alternative, we also tried Schaefer's semi-empirical Q parameter (27), as modified by Smith for use as a predictor of *ortho* ^{13}C chemical shifts (28). There is fairly good agreement between input and predicted Q (see Table 7). However, both the input and particularly the predicted Q parameters are strongly correlated with σ_R^0, suggesting again that Q is not a pure *ortho* parameter but rather a linear combination σ_R^0 and the *ortho* factor. It appears that further work is necessary to correctly identify the true *ortho* factor.

One objective method for testing the validity of individual test vectors is the SPOIL test (14). According to Malinowski, test vectors which give a SPOIL test of 0–3 are acceptable, those with SPOIL from 3 to 6 are moderately acceptable, while those with SPOIL greater than 6 are not acceptable (14). σ_R^0, σ_I, α, β, and Q gave respective SPOIL tests of 1.69, 2.70, 8.50, 12.8, and 39.9. Thus, only σ_I and σ_R^0 are good test vectors, according to the SPOIL test. However, it should be stressed

[c]σ_R^0 values from ref. 24 or ref. 13 if not included in ref. 24.
[d]A correlation of predicted ΔQ with σ_R^0 gave a correlation coefficient, $r = 0.90$.

that α and β values are not constant, even from one aliphatic series to another (23), and, consequently, significant differences might be expected between aliphatic and aromatic derivatives.

The question of whether predicted α, β, and Q are pure factors or rather linear combinations of σ_I, σ_R^0, and the actual factors is probably best addressed by correlation analysis. This is reported in the subsequent paper (29). There we derive what we believe are the true third *ortho* and *meta* factors and suggest a possible *ipso* factor. The first two are totally independent of σ_I and σ_R^0. This allows us to separate electronic (σ_I and σ_R^0) contributions from other short-range, non-electronic contributions (29).

Comparison with previous interpretations of short-range chemical shifts

Bailey *et al.* (17*b*) have used factor analysis to analyze ^{13}C

chemical shifts in a large number of haloaromatic and haloalkene derivatives. They concluded that two major and one minor factor were necessary to account for the chemical shifts, compared to four major and one minor factor according to this investigation. The problem is that the halogens constitute an entirely unsatisfactory substituent set (13). As they acknowledge (17*b*), many different variables are strongly interrelated; e.g., σ_I, σ_R^0, and α are all linearly related to one another for this substituent set. Consequently, the number of factors will inevitably be larger for a correctly chosen substituent set. These observations reinforce our earlier comments about the necessity of using a well-balanced substituent set, as outlined by Taft and co-workers (13).

Smith and Proulx have proposed a general approach for correlation of substituent effects upon aromatic chemical shifts (30). This involves correlation with F, R, and Q. This approach has been strongly criticized on the grounds that it has never been subjected to proper statistical testing (18). The results presented above suggest that it is invalid. To begin, a third substituent parameter is unnecessary for long-range chemical shifts. Furthermore, while a third parameter is undoubtedly necessary for short-range chemical shifts, different parameters are needed for *ipso* and *ortho* positions. Finally, although Q may be an appropriate parameter for *ortho* chemical shifts, it is sufficiently strongly correlated with σ_R^0 (or R) that the weighting coefficients in a multiple linear regression analysis of *ortho* shifts are likely to be of dubious reliability (29).

Conclusions

Factor analysis of long range chemical shifts in 3- and 4-substituted styrene derivatives demonstrates that two substituent factors (parameters) are both *necessary* and *sufficient* to account for substituent-induced chemical shifts. Target testing indicates that σ_I and σ_R^0 are appropriate substituent parameters for this purpose.

σ_I and σ_R^0 are also appropriate parameters for short-range chemical shifts in styrene derivatives. However, one additional factor is needed for each of *ipso* and *ortho* carbon chemical shifts. There also appears to be a *meta* factor but this is of marginal significance. Target testing indicates that α chemical shifts in cyclohexane derivatives provide a fair model for the *ipso* factor which appears to be basically a group electronegativity factor. However, neither β cyclohexane shifts nor the empirical Q parameter appear to be good models for the *ortho* factor. Q in particular is strongly correlated with σ_R^0, suggesting that it may be some linear combination of σ_R^0 and the true *ortho* factor.

These conclusions are in good agreement with what has been observed for Hammett–Taft treatments of aromatic reactivities. For example, many investigators have used different linear combinations of σ_I and σ_R to account for *meta* and *para* reactivities (13), while a third (steric) parameter is used in conjunction with σ_I and σ_R for *ortho* reactivities (10).

The results of factor analysis are not strongly influenced by the techniques used to pre-process the data matrix. However, it is essential to use a well-balanced substituent set. While it is probably not necessary to use as extensive a substituent set as we have used, the recommendations of Taft concerning minimal substituent sets (13) should certainly be followed.

Experimental

The new **3H**, **3M**, and **4M** derivatives were all known compounds and were synthesized by known methods. Most new **4B** derivatives were synthesized by reaction of the corresponding 4-substituted acetophenone with *tert*-butylmagnesium chloride, followed by aqueous acidic work-up to yield the appropriate 2-(4-X-phenyl)-3,3-dimethyl-2-butanol. Catalytic dehydration over activated alumina (2) then yielded the appropriate 4-substituted α-*tert*-butylstyrene (X = SCH_3, $COCH_3$, CF_3, CN). The NH_2 derivative was synthesized from the NO_2 derivative (1) by reduction with Sn/HCl (31). The $Si(CH_3)_3$ and CO_2CH_3 derivatives were synthesized from the corresponding Cl derivative via Grignard routes (2). All **4B** derivatives were produced in low yield at 80–90% purity (typically contaminated with starting acetophenone) and were used without further purification. These compounds were characterized by ^1H and ^{13}C nmr spectroscopy and high resolution mass spectrometry.

^{13}C spectral data were obtained on a Varian XL-200 spectrometer operating at a probe temperature of 32°C under variable temperature control (some preliminary measurements were made on a Brüker WP-80 at 35°C). Spectra were measured for 0.2 *M* solutions in CCl_4 with 8 vol.% C_6D_{12} as internal lock and ca. 0.5% $(CH_3)_4Si$ as internal reference. 10 000 Hz spectral widths were used with 32K real points, a recycle time of 3.2 s, and 30°–40° pulse widths.

Details of calculations

Factor analyses were performed on the program FACTANAL (20), modified to operate on the Department of Chemistry SEL 75 computer. Modifications include sub-routines to calculate RSD, IND, and SPOIL, using equations from ref. 14.

Iterative multiple linear regression analysis of substituent-induced chemical shifts in 3- and 4-substituted styrene derivatives is used to redefine σ_F and σ_R^0 substituent constants (with respective standard errors of ca. 0.01 and 0.005). Correlations with the data for various model systems indicate that these substituent constants are applicable to data sets involving both chemical shift and acidity measurements in aprotic media. The approach we have used involving a homogeneous data set with a large number of variables is particularly suited for providing well-defined dual substituent parameter constants for the more common neutral substituents.

Correlations for individual nuclei are entirely consistent with a previously proposed model of substituent effects involving field, resonance, and polarization effects. From these results and the results for other model systems, it is concluded that σ_F and σ_R^0 are respectively pure field and resonance substituent constants. It is pointed out that a combination of detailed statistical testing and chemical modelling is essential for a thorough understanding of aromatic substituent effects.

Parameters for predicting non-electronic contributions to *ortho* and *meta* chemical shifts are derived, thus allowing the patterns of electronic substituent effects for these carbons to be determined. However, only an approximate *ipso* factor can be deduced.

WILLIAM F. REYNOLDS, ANABELA GOMES, ANTONINA MARON, DOUGLAS W. MACINTYRE, ATES TANIN, GORDON K. HAMER et IAN R. PEAT. Can. J. Chem. **61**, 2376 (1983).

On a utilisé l'analyse par régression linéaire multiple itérative des déplacements chimiques induits par un substituant dans les dérivés du styrène substitués en positions 3 et 4 afin de redéfinir les constantes de substituants σ_F et σ_R^0 (avec des erreurs normales respectives de 0,01 et de 0,005). Les corrélations avec les données relatives à divers systèmes modèles indiquent que ces constantes de substituants peuvent s'appliquer à des ensembles de données qui impliquent à la fois le déplacement chimique et les mesures d'acidité en milieu aprotique. Nous avons utilisé une approche qui, faisant intervenir un ensemble de données homogènes avec un grand nombre de variables, est particulièrement adéquat pour fournir des constantes de paramètre de substituant double pour les substituants neutres les plus courants.

Les corrélations avec des noyaux individuels sont tout à fait en accord avec les modèles proposés antérieurement pour des effets de substituants impliquant les effets de champ, de résonance et de polarisation. A partir de ces résultats et à partir d'autres systèmes models, on peut conclure que σ_F et σ_R^0 sont respectivement des constantes de substituant de champ pur et de résonance. On met en évidence qu'une combinaison d'essais statistique, détaillées et de modèles chimiques est essentielle pour une compréhension profonde des effets de substituant aromatique.

On a déduit les paramètres qui permettent de prédire les contributions non électronique aux déplacements chimiques des positions *ortho* et *méta*, ce qui permet ainsi de déterminer les models d'effets électroniques de substituant pour ces carbones. Cependant on ne peut déduitre qu'un facteur *ipso* approximatif.

[Traduit par le journal]

Introduction

In the preceding paper, we used the technique of factor analysis to demonstrate that a dual substituent parameter (dsp) treatment is both necessary and sufficient to account for long-range chemical shifts in 3- and 4-substituted styrene derivatives (1). Furthermore, target testing indicated that Taft's σ_I and σ_R^0 scales (2) were appropriate for that purpose.

In this paper, iterative multiple linear regression analysis of nmr data for almost ninety 4-substituted styrenes (**4H**), α-methylstyrenes (**4M**), and α-*tert*-butylstyrenes (**4B**), as well as 3-substituted styrenes (**3H**) and α-methylstyrenes (**3M**), is used to estimate refined σ_F and σ_R^0 constants for 18 substituents as well as to provide a detailed test of our previously proposed model of mechanism of transmission of substituent effects in styrene derivatives (3, 4). Finally, new **O** and **M** substituent parameters are deduced to account for non-electronic contributions to *ortho* and *meta* chemical shifts.

Results and discussion

^{13}C chemical shifts of previously unreported iodo, *tert*-butyl, and trimethyltin derivatives of styrene are listed in Table 1. All other data used in this investigation have been reported elsewhere (1, 3, 4).

(a) *Estimation of refined σ_F and σ_R^0 constants by iterative multiple linear regression and comparison with previous dsp scales*

$\sigma_F(\sigma_I)$[1] and σ_R^0 constants have been refined at least twice in recent years (2). We decided to continue this process, using our very extensive styrene data set to redefine σ_F and σ_R^0 constants (with statistically defined uncertainties) by iterative multiple linear regression. This involves two fundamental assumptions. The first is that long-range chemical shifts for styrenes can be predicted, within experimental uncertainty, by only two substituent constants. This has been clearly demonstrated by factor analysis (1). For example, the residual standard deviation (RSD) between predicted and observed long-range chemical shifts decreases from 2.24 ppm for one factor (intercept only) to 0.09 ppm for three factors (intercept plus two substituent parameters). However, four additional factors are required to reduce RSD from 0.09 to 0.05 ppm (1). Thus, it is obvious that the additional factors are attempting to fit random errors rather than additional substituent effects. The second assumption is that the substituent constants for this system are sufficiently close to Taft's σ_I and σ_R^0 constants (2) that they can be reliably estimated by iterative multiple linear regression. Target testing of σ_I and σ_R^0 against the styrene data matrix has demonstrated that this is a valid assumption (2).

We believe that there are three major advantages to the approach which we have used. First, all data are for a closely related series of compounds and are measured in the same laboratory under constant conditions. By contrast, most other dsp scales have been defined using data from different systems measured in different laboratories (2*a*, 6, 7). These scales must inevitably contain artifacts due to the use of heterogeneous data sets. Second, σ_F and σ_R^0 are defined by the solution of a large number (up to 18) of simultaneous equations, providing statistically well-defined substituent constants. Many previous dsp constants have been defined from as few as two experimental points (6, 7). Finally, the individual styrene variables show a wide range of responses to polar and resonance effects ($\lambda(\equiv\rho_R/\rho_I)$ varies from ca. 0 to 5 (see part C), compared to 0.3−1.2 for typical acidity and reactivity data (2*a*)), thus facilitating the accurate definition of σ_F and σ_R^0. For these reasons, we are convinced that iterative multiple linear regression analysis of the styrene data set will provide better defined and more reliable dsp constants than those previously available.

ρ_F and ρ_R values were first estimated by multiple linear regression analysis according to eq. [1], using the most recent values of $\sigma_F(\sigma_I)$ and σ_R^0 (2):

$$[1]\quad \delta_x = \delta_0 + \rho_F\sigma_F + \rho_R\sigma_R^0$$

Fifteen substituents were used in each correlation (X = H, $N(CH_3)_2$, NH_2, OCH_3, SCH_3, CH_3, $Si(CH_3)_3$, F, Cl, Br, $COCH_3$, CO_2CH_3, CF_3, CN, and NO_2). Correlations were carried out for the same 18 variables as used in the factor analysis of long-range chemical shifts (*para*, α, and β carbons for all five series as well as β ^1H chemical shifts and $^1H-^1H$ coupling constants for **4H** derivatives). ^1H chemical shifts were weighted by 10 and $^1H-^1H$ coupling constants by 3 to produce similar experimental uncertainties for all 3 variables (1). Without this weighting, the latter variables would have made negligible contributions in the second state of the iterative process.

In the second stage, the predicted ρ_F and ρ_R values and predicted intercepts, δ_0, from eq. [1] were used in a reverse correlation to solve for σ_F and σ_R^0 constants for individual substituents according to eq. [2]:

$$[2]\quad \delta_x - \delta_0 = \sigma_F\rho_F + \sigma_R^0\rho_R$$

This involves solving 18 simultaneous equations for only two unknowns, σ_F and σ_R^0. The process was then repeated, using the revised σ_F and σ_R^0 constants (but maintaining the standard constraint (2) that $\sigma_F = \sigma_R^0 = 0$ for X = H) as input parameters to eq. [1]. Convergence to constant σ_F, σ_R^0, ρ_F, and ρ_R values was essentially complete after 10 iterative cycles but was allowed to continue for 25 cycles, at which point changes in ρ and σ values between successive cycles was well below 0.001.

The final ρ_F and ρ_R values were also used to estimate σ_F and σ_R^0 constants for I, $C(CH_3)_3$, and $Sn(CH_3)_3$. These were not included in the iteration since data were not available for all five styrene derivatives for these substituents.

The re-determined σ_F and σ_R^0 constants are listed in Tables 2 and 3 along with the 95% confidence limits for the uncertainties in these parameters. Almost all σ_R^0 constants have uncertainties below 0.01 while typical σ_F uncertainties are about 0.02. The corresponding standard errors are ca. 0.004 for σ_R^0 and ca. 0.01 for σ_F. This represents the limits in precision possible for these parameters, given the experimental uncertainty of ca. 0.1 for individual data points (an uncertainty of 0.005 in σ_R^0 corresponds to an uncertainty of 0.1 in *para* carbon chemical shifts, since $\rho_R \sim 20$ for these carbons). The revised constants are in excellent agreement with those obtained by target testing during factor analysis (1), indicating that our iterative procedure is valid. While target testing could also have been used to redefine σ_F and σ_R^0, the approach used here has the advantage of providing a detailed statistical analysis of error.

The revised σ_R^0 values are in excellent agreement with those of Taft (2) (see Table 2). While the revised σ_F constants show somewhat larger deviations from Taft's σ_I scale (see Table 3), the only qualitative differences are for the two alkyl substituents which are predicted to have small positive σ_F values, in contrast to the previously reported small negative values (2, 8).

[1]It has recently been pointed out that σ_I should really be renamed σ_F in view of the strong evidence that it is a field parameter rather than a σ inductive parameter (5). This convention will be adopted subsequently throughout this paper when referring to the scale which we have derived.

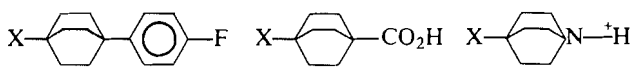
[a]This work. Estimated value ± 95% confidence limit.
[b]Reference 2.
[c]Predicted σ_R^0 values from target testing during factor analysis.
[d]These data were not include in the iterative process but rather were estimated by solving eq. [2] using all available data for these compounds (12−15 variables).
[e]No target testing was performed since these compounds were not included in the data matrix which was subject to factor analysis.



1 2 3

Interestingly, Adcock's ^{19}F chemical shift data for 1-X-4-(*p*-fluorophenyl) bicyclo[2.2.2.]octane derivatives, **1**, also suggested small positive polar constants for alkyl groups (9*a*) (see Table 3). It is possible that the previous negative σ_I values for alkyl groups (which have been estimated mainly from reactivity data) reflect small contributions from alkyl group polarizabilities (10). In any case, σ_F values for alkyl groups are statistically little different from zero, as suggested by Adcock and Abeywickrema (9*b*).

Adcock has very recently used his data for **1** to derive σ_I constants for different solvents (9*b*). His scale for CCl_4 (our solvent system) is reproduced in Table 3. There is generally excellent agreement between σ_F and σ_I scale. Interestingly, for the two substituents where there are significant differences ($COCH_3$ and F), our values are intermediate between those of Taft and Adcock.

Much larger differences are noted between our σ_F scale and the σ_I scales of Grob *et al.* (11) and Charton (6) (see Table 3), both of which are based upon acidity measurements in aqueous solutions. In particular, the latter two scales show markedly enhanced σ_I values for $N(CH_3)_2$, NH_2, OCH_3,SCH_3, $COCH_3$, and CO_2CH_3. Significantly, these are precisely the group of substituents which Taft has claimed will show enhanced polar effects in protic solvents, due to their hydrogen bond acceptor abilities (12, 13). Furthermore, Adcock's σ_I scale for CH_3OH also shows enhanced σ_I constants for several of these substituents (9*b*). This raises the obvious possibility that the σ_F scale which we have defined is best suited for measurements in aprotic media, while the σ_I scales of Grob and Charton are better for measurements in protic (particularly aqueous) media. This possibility will be considered in the following section.

(b) *Concerning the "purity" of* σ_F *and* σ_R^0 *and the range of applicability of these parameters*

The results of both target testing (1) and iterative multiple linear regression (part (a)) clearly demonstrate that σ_F and σ_R^0 are appropriate parameters for predicting chemical shifts in styrene derivatives. σ_F is considered to be a field effect parameter (5) while σ_R^0 is generally regarded as a resonance (π charge transfer) parameter (14). However, our results do not prove that σ_F and σ_R^0 are pure field and resonance substituent constants since they could also be linear combinations of the true parameters (15). In fact, Fadhil and Godfrey have recently argued that the previously defined σ_I scale is not a true (coulombic) field scale (16). If true, this would equally apply to σ_F. No amount of statistical testing alone can resolve this question. However, it can be addressed by considering appropriate model systems. Other questions which can be similarly addressed include whether σ_F and σ_R^0 are applicable to measurements in both protic and aprotic media and whether they are applicable to both spectroscopic and reactivity measurements.

An appropriate model system for addressing the first question is one in which resonance effects have been eliminated, leaving only field effects (6). One obvious choice is Adcock's ^{19}F chemical shift data set for **1** (9). This has the additional advantage that raw chemical shift data have been reported for both protic (CH_3OH) and aprotic (C_6H_{12}, C_6H_6, CH_2Cl_2, and $(CH_3)_2NCHO$ (DMF)) media (9*a*), thus allowing simultaneous consideration of questions 1 and 2. The substituent-induced chemical shifts have been correlated against σ_F and the σ_I scales of Grob (11) and Charton (6). Results are presented in Table 4. It is seen that σ_F gives uniformly excellent correlations for chemical shifts in aprotic media (while the correlation coefficient drops below 0.99 for DMF, the standard deviation of the correlation is comparable to the estimated experimental uncertainty of 0.05 (9*a*)). However, the correlation in CH_3OH is of significantly lower precision. By contrast, the correlation against σ_I scales are consistently poorer in aprotic media but significantly better in CH_3OH.

There is a dearth of good data sets (with a well-balanced range of substituents) for considering the applicability of σ_F to reactivity or acidity measurements in aprotic media. However, recently determined gas phase acidities for 4-substituted bicyclo[2.2.2]octane-1-carboxylic acids, **2**,[2] provide an ideal system in the ultimate aprotic medium. Similarly Grob's aqueous acidity data for 4-substituted quinuclidinium ions, **3** (11), provide a good test of the applicability of σ_F to acidity data in a protic medium. Results of correlations of data for **2** and **3** against σ_F and Charton's σ_I scale are summarized in Table 4. σ_F gives an excellent correlation for **2** but not for **3** while the exact reverse is found for σ_I.

Considering all of the results in Table 4, the obvious conclusion is that σ_F is a pure field parameter which is applicable to both spectroscopic and thermodynamic measurements in aprotic media. Furthermore, σ_F is applicable to measurements in both aromatic and aliphatic systems. Finally, in view of the precise correlations against σ_F for data from various aprotic

media, it appears that definition of different polar substituent parameters for different aprotic media (9*b*) is not really necessary, at least at this time. However, there do appear to be sufficient differences between results in aprotic and protic media to justify having a separate σ_F (or σ_I) scale for the latter solutions. Since Charton's σ_I scale has been extensively tested

using data for protic media (6), it is probably the most appropriate choice for this purpose at the present time.

Before considering the range of applicability of σ_R^0, one must consider the type of system to which it would apply. Historically, σ_R^0 has been considered to be applicable to systems with negligible through-conjugation between the substituent and probe group, e.g. ring-substituted phenylacetic acid derivatives (2*a*). However, more recently it has been considered as applicable to systems with π electron demand almost identical to that in benzene (2*b*, 17, 18).[3] While it is probably impossible to find a model system in which only resonance effects are present, the *para* ^{13}C chemical shifts in monosubstituted benzenes (and styrenes) provide a very good test of σ_R^0, since these chemical shifts are dominated by resonance effects (ref. 2*b*, also see Table 5). In fact, σ_F and σ_R^0 give correlations of outstanding precision for *para* carbon shifts in monosubstituted benzenes (e.g. r = 0.998, F = 13 985, S.D. = 0.12 for chemical shifts in $CDCl_3$ (data from ref. 2*b*)). Comparable correlations are obtained for *para* chemical shifts in styrenes (Table 5). Thus we believe that we have defined σ_R^0 for aprotic media to a very high degree of precision. This is important, since σ_R^0 provides the central anchor point for a proposed bilinear resonance scale (18). It is not yet clear whether a separate σ_R^0 scale will be required for protic media. We intend to investigate this by determining chemical shifts for a number of styrene derivatives in CH_3OH, applying similar statistical techniques to those used in ref. 1 and in this manuscript to determine σ_F and σ_R^0 in a protic medium.

[3]Styrene derivatives satisfy this definition due to the completely amphielectronic nature of the vinyl group (18, 19).

(c) ρ_I and ρ_R values from eq. [1] and mechanisms of transmission of long-range substituent effects in styrene derivatives

ρ_F and ρ_R values determined from eq. [1] in the final cycle of iterative multiple linear regression are given in Table 5, along with various statistical tests of individual correlations. In terms of statistical tests such as the correlation coefficient, r, and F test, the correlations range from good (for the poorest C(α) correlations) to outstanding (for all *para* carbon correlations). However, the most significant observation is that all of the standard deviations are comparable with the estimated experimental uncertainty in these variables (0.1 for ^{13}C chemical shifts, 0.01 for ^1H chemical shifts, and 0.03 for $^1H-^1H$ coupling constants). On this basis, it appears that all of the correlations are of equal validity. It is also noteworthy that the ρ_F and ρ_R values for the **4H** correlations are quite similar to the values obtained previously by simple multiple linear regression, using literature σ_I and σ_R^0 values (20). Thus no anomalies are introduced by the iterative process.

As discussed in part (b), σ_F is considered to be a field parameter while σ_R^0 is regarded as a resonance parameter. Thus ρ_F and ρ_R values for individual nuclei should reflect the relative importance of field (including π inductive) and resonance effects at those positions. Thus they can be used to test our previously proposed model for mechanism of transmission of long-range substituent effects in styrene derivatives (3, 4).

In the case of **4H** derivatives, a specific prediction was made with respect to ^1H chemical shifts. It was assumed that substituent effects which altered the π electron density at C(β) (resonance and π inductive (polarization) effects) would affect H(B) and H(C) equally. On the other hand, field effects should be greater for H(C) than H(B) because the electric field due to the

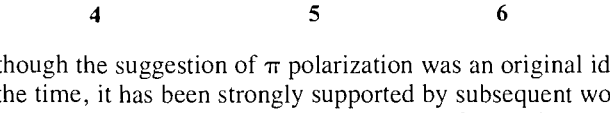
TABLE 6. Statistical testing of model for mechanism of transmission of substituent effects to β vinyl protons

	H(B)[a]	H(C)	t^b	P^c
ρ_F	0.1528±0.0123	0.2900	11.2	$<10^{-7}$
ρ_R	0.4639±0.0111	0.4724	0.77	~0.25

[a] ρ_F (or ρ_R) for H(B) ± standard error in ρ_I (or ρ_R).
[b] t test of null hypothesis.
[c] Probability that $\rho_F H(B) = \rho_F H(C)$ or $\rho_R H(B) = \rho_R H(C)$. Probability for one-sided t test for 12 degrees of freedom. $P = 0.25$ corresponds to a 75% confidence limit that $\rho_R H(B) < \rho_R H(C)$.

polar substituent is greater along C(β)—H(C) than along C(β)—H(B) (3). Thus the prediction is $\rho_F H(C) > \rho_F H(B)$ and $\rho_R H(C) \sim \rho_R H(B)$. The ρ_F and ρ_R values for H(B) and H(C) are entirely consistent with this prediction (see Table 3). However, this prediction can be subjected to even more rigorous testing by using the t test of the null hypothesis (20, 21) (see Table 6). This shows only about a 75% probability that $\rho_R H(C) > \rho_R H(B)$ but essentially 100% probability that $\rho_F H(C) > \rho_F H(B)$. Based on the usual 95% confidence limit for null hypothesis testing (11), one can state that the proposed model is clearly statistically justified.

A specific model was also proposed for ^{13}C chemical shifts in **4H**, **4M**, and **4B** derivatives (3, 4). It was assumed that resonance effects in **4H** should mainly affect the conjugated *ortho*, *para*, and β carbons (see **4**). The resonance effect at C(β) should drop off rapidly (by approximately $\cos^2 \phi$, where ϕ is the angle of twist between the phenyl and vinyl groups) from **4H** ($\phi \sim 0°$) to **4M**($\phi \sim 30°$) to **4B** ($\phi \sim 65°$) (4). The predicted field dependence of ^{13}C chemical shifts is more complex. It was suggested that the main field effect was field-induced polarization of the styrene π electron system (π polarization effect) (4). The proposed model involved two components of π polarization: (a) direct (and independent) polarization of phenyl and vinyl groups (see **5**) and (b) polarization of the entire styrene π electron system with π electron transfer from C(β) to the phenyl group (see **6**). The latter effect has recently been given the name extended π polarization (22).

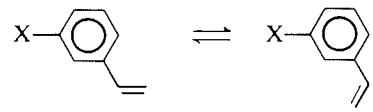


4 **5** **6**

Although the suggestion of π polarization was an original idea at the time, it has been strongly supported by subsequent work by ourselves (23) and several other groups (9, 22, 24). Evidence for π polarization has recently been reviewed (5, 25). Extended π polarization should be particularly important in the planar **4H** derivatives, resulting in a relatively large (positive) ρ_F value for C(β). However, this component should be almost entirely eliminated in **4B** derivatives, leaving a pattern of ρ_F values for the vinyl group similar to that shown in **5**.

The correlations in Table 5 strongly support this model. As expected, ρ_R is much greater for C(β) than C(α) (ρ_R for C(α) is little different from zero in any of the three derivatives). Furthermore, ρ_R for C(β) drops off rapidly from 8.8 (**4H**) to 6.9 (**4M**) to 0.9 (**4B**) as the vinyl group is twisted out of conjugation. It is interesting to note that ρ_R for C(1) increases as ρ_R for C(β) decreases. This could reflect a localization of the resonance effect of the substituent within the phenyl group as conjugation is destroyed. By contrast with ρ_R, ρ_F for C(β) drops off much less rapidly (from 5.1 to 4.2 to 2.0) as conjugation is destroyed. Furthermore, the ρ_F values for C(α) and C(β) are essentially equal and opposite in the case of **4B**. This is consistent with essentially complete elimination of extended π polarization, leaving only the direct polarization contribution (as in **5**). It is interesting to note that ρ_F is greater for C(β) than for C(1) in **4H** (by contrast ρ_R is more than twice as large for C(1) than C(β)). This reflects the relative efficiency of the two component π polarization mechanism in transmitting polar effects to remote positions in planar conjugated derivatives (5).

In the case of 3-substituted styrenes, one would reasonably expect much-reduced resonance effects in the side chain since the vinyl groups and the substituent are no longer formally conjugated. Predictions of π polarization effects are more difficult due to the presence of two non-equivalent conformations (see **7**). However, simple electrostatic calculations suggest a



7

ca. 1/3 larger direct π polarization component for either conformer of **3H** than for **4H**. On the other hand, assuming that the magnitude of the extended π polarization component will be determined by the electron deficiency of the phenyl carbon to which the vinyl group is attached (5), this component should be smaller in **3H** than in **4H**. Once again, both the resonance and extended π polarization components should decrease on going from **3H** to **3M**.

The results in Table 3 are entirely consistent with these predictions. ρ_R for C(β) in **3H** is ca. 1/4 of that in **4H** and further decreases from **3H** to **3M**. Interestingly, ρ_R for C(α) shows a significant negative value in **3H** and **3M**, nearly equal to the positive ρ_R values for C(β). It appears that the resonance component in 3-substituted styrenes may be transmitted by a secondary field mechanism in which the large resonance-induced changes in π electron density at C(2) and C(6) set up an electric field which polarizes the vinyl group.

ρ_F values for C(β) in **3H** and **3M** are only slightly smaller than the corresponding values for **4H** and **4M**, while ρ_I values for C(α) show larger negative values than in **4H** and **4M**. If one takes the magnitudes of the ρ_F values for C(α) in the two α-methylstyrenes as approximate indicators of the direct π polarization component while ρ_F values for C(β) reflect the total π polarization effect, then the relative proportions of direct to extended π polarization are ca. 2:3 in **4H** and ca. 3:1.5 in **3H**, consistent with the arguments presented above.

In concluding this section, it should be noted that the fact that we can rationalize ρ_F and ρ_R values for individual substituents in terms of a reasonable model for transmission of substituent effects provides further evidence for the view that σ_F and σ_R^0 are, respectively, pure field and resonance substituent constants. In particular, correlations of $\delta_{H(B)}$ and $\delta_{H(C)}$ for **4H** provide a separation which is in exact agreement with the predicted model of substituent effects. One would not expect such a clear-cut separation of effects if σ_F and σ_R^0 were each some linear combination of two other substituent constants.

(d) *Short-range substituent effects in styrene derivatives*

Factor analysis of the styrene data set indicated that three factors were required to predict *ipso* and *ortho* chemical shifts and that there also appeared to be a minor third factor for *meta*

[a]Correlations forced through origin.
[b]r^2 = coefficient of determination, i.e. the fraction of the dependent variable accounted for by the independent variable(s). $1 - r^2$ can be referred to as the coefficient of non-determination and gives the fragment of the variance of the dependent variable *not* accounted for by the independent variable(s).

shifts (1). Target testing revealed that σ_F and σ_R^0 were two of the factors in each case. A possible third *ipso* factor, α, was estimated using cyclohexane *alpha* ^{13}C chemical shifts to provide an input test vector. Similarly cyclohexane *beta* chemical shifts and the semiempirical Q factor of Smith and Proulx (26) were used as test vectors to estimate two possible *ortho* factors, β and Q (1). However, it was pointed out that any or all of α, β, and Q might not be true factors but rather some linear combination(s) of σ_F and/or σ_R^0 and the true factor (obviously β and Q cannot both be true *ortho* factors) (1).

To check this point, α, β, and Q were correlated against σ_F and σ_R^0. Results are summarized in Table 7. Based on the coefficient of determination, Q is a totally unreliable *ortho* parameter since only 19% of its variance is *not* accounted for by σ_F and σ_R^0. β contains a larger, but still minor, component of the actual *ortho* factor while α contains a major component of the true *ipso* factor. One can estimate the actual parameters by an orthogonalization procedure. For example, β appears to be a linear combination of σ_F, σ_R^0, and the missing *ortho* factor, **O**. Consequently, in a correlation of β with σ_F and σ_R^0, the residual error in β for a given substituent X, $\Delta(X)$, should be proportional to **O**(X), i.e.

$$[3]\quad \beta(X) = \rho_F\sigma_F(X) + \rho_R\sigma_R^0(X) + \Delta(X) = \rho_F\sigma_F(X) + \rho_R\sigma_R^0(X) + w\mathbf{O}(X)$$

Similarly, Q should be a different linear combination of σ_F, σ_R^0, and **O**, but the residuals, $\Delta(X)$, should be porportional to the residuals from eq. [3]. In fact, the two sets of differences are precisely linearly related ($r = 0.999$, $F = 49\ 400$), indicating that we have succeeded in isolating from β (or Q) an *ortho* factor which is completely orthogonal to σ_F and σ_R^0 (this is confirmed by a correlation of **O** versus σ_F and σ_R^0, see Table 7). The differences, $\Delta(X)$, have been scaled to produce **O** constants (see Table 8). The scaling factor was chosen so that the weighting factor, w, equals unity in a correlation of **O**, σ_F, and σ_R^0 versus $\delta_{C(3)}$ for **4H** (see Table 8). This correlation is much more precise than one with σ_F and σ_R^0 alone and the ρ_F and ρ_R values are consistent with the expected pattern of substituent effects as shown in **4** and **5**.

A similar approach was used to isolate the *meta* factor. γ

cyclohexane chemical shifts were used as an initial target vector (1) and the predicted γ values were used in an equation similar to eq. [3] to predict individual *meta* factors, **M**(X) (see Table 8). These factors are quite small, as previously suggested (1). Nevertheless, the correlation of $\delta_{C(2)}$ for **4H** is significantly improved by the inclusion of **M**. The ρ_F and ρ_R values are once again consistent with the expected pattern of substituent effects in **4** and **5** (see Table 8). Finally, we attempted to isolate an orthogonal *ipso* factor, **I**, from the predicted α values, using the same procedure (see Table 8). However, in this case, a correlation of σ_F, σ_R^0, and **I** versus $\delta_{C(4)}$ for **4H** gives apparently unreasonable ρ_F and ρ_R values. Based upon correlations of *ipso* π electron densities in styrenes with field and resonance substituent parameters (27), we would have expected $\rho_F \simeq -15$ and $\rho_R \simeq -20$ for $\delta_{C(4)}$.[4] Before considering the significance of this last observation, it is useful to consider the assumptions which we have made in this section.

The first assumption is that we can divide short-range substituent effects at a given position into electronic components (predicted by σ_F and σ_R^0) and an orthogonal component (predicted by **M**, **O**, or **I**) which reflects effects other than ground-state electronic effects. The second assumption is that ρ_F and ρ_R values reflect substituent-induced changes in π electron density. We will consider this latter assumption first. While the theoretical origins of linear chemical shift – π electron electron correlations remain obscure (29), there is ample empirical evidence for quite precise linear relationships in the case of long-range aromatic chemical shifts (14, 27, 30). The facts that σ_F and σ_R^0 are factors for short-range chemical shifts, and that reasonable ρ_F and ρ_R values are obtained for *ortho* and *meta* chemical shifts, suggest that these correlations still exist at short range, after non-electronic effects are factored out. With respect to the first assumption, it is significant that β and γ substituent effects in alkyl derivatives are complex and bear no apparent relationship to ground state electronic effects (31). This is also true of **O** and **M** (see Table 8). Thus the assumption of non-electronic components at these positions appears reasonable. However, α chemical shifts in aliphatic derivatives appear to be partially related to substituent group electronegativity (4, 32, 33). This may also be true of the *ipso* factor (1). While group electronegativity is not linearly related to σ_F, it is partially correlated with the latter parameter (33) and perhaps with σ_R^0 as well. The partially correlated component is factored out in deriving **I**. Consequently, when one performs a correlation with σ_F, σ_R^0, and **I**, part of the electronegativity dependence appears in ρ_F and ρ_R, giving misleading values for these parameters. Unfortunately, if the third substituent "effect" is partially electronic in nature, no unique solution exists for the third factor. Comparison of the correlations of $\delta_{C(4)}$ with **I** and α (see Table 8) with the anticipated ρ_F and ρ_R values (see above) suggests that the true *ipso* factor may have a value somewhere between **I** and α (the arithmetic mean of **I** and α gives $\rho_F = -12.6$ and and $\rho_R = -19.2$, close to the anticipated values). However, it is impossible to determine a precise scale.

To summarize this section, we believe that we have succeeded in isolating non-electronic *ortho* (**O**) and *meta* (**M**) factors for *ortho* and *meta* chemical shifts. Short-range electronic effects can be probed by correlating these chemical shifts with σ_F, σ_R^0, and **O** or **M**. However, the third *ipso* factor has not been conclusively identified, although it may fall close to the average of **I** and α.

One final point must be stressed most strongly. If one wishes to carry out a three parameter correlation of this kind, it is essential to have a large and well-balanced substituent set. Taft's minimal substituent set represents an absolute lower limit (2*a*).

Conclusions

Iterative multiple linear regression analysis of the chemical shift data for 3- and 4-substituted styrenes has given highly refined values of σ_F (standard error ~0.01) and σ_R^0 (standard error ~0.005). It is shown that these constants are, respectively, pure field and resonance substituent parameters and that they are applicable to both chemical shift and acidity measurements in aprotic media. The approach which we have adopted is particularly suitable for deriving quite precise dsp constants for most of the common neutral substituents.

The ρ_F and ρ_R values from individual correlations are entirely consistent with a previously proposed model for mechanism of transmission of substituent effects in styrene derivatives involving field, resonance, and π polarization effects. In particular, the results support the model of a two-component π polarization mechanism involving: (1) direct and independent polarization of the phenyl and vinyl groups, and (2) extended polarization of the entire styrene π electron system.

Values for non-electronic *ortho* and *meta* substituent factors have been determined, allowing the reliable estimation of electronic effects at these positions. However, a reliable *ipso* factor has still not been determined, although a possible scale is suggested.

While factor analysis has pointed out the number of substituent parameters required to describe the styrene data matrix and target testing has identified possible substituent parameter scales (particularly σ_F and σ_R^0) (1), no amount of statistical testing alone can prove that these are the actual substituent parameter scales rather than some linear combination of the true scales. It is the observation that correlations involving σ_F and σ_R^0 give chemically reasonable results in this and related systems which allows us to conclude that σ_F and σ_R^0 are pure field and resonance substituent parameter scales. Thus we conclude that in any thorough investigation of substituent effects, it is essential to prove that one's conclusions are *both* statistically valid and make chemical sense. Neither approach alone is sufficient.

Finally, if the approach we have presented for interpreting short-range substituent effects is valid, then it should be applicable to other aromatic derivatives. This will be the topic of a subsequent publication.

Experimental and details of calculations

Full experimental details are given elsewhere (1). Multiple linear regression analyses were performed with a program written for this purpose for mini-computers[5] and subsequently modified by us to allow iterative multiple linear regression. All calculations were performed on the Department of Chemistry Sel 75 Computer.

[4]Consistent with this is the large negative *ipso* shift in $C_6H_5CO^+$ ($\Delta\delta = -40.9$ ppm (28)). Even if one compares with the isoelectronic C_6H_5CN derivative to partially correct for resonance and magnetic anisotropy effects, the residual shift is ca. −25 ppm. This indicates a large negative polar constribution to this *ipso* shift (see **5**) which must outweigh any positive electronegativity contribution.

Ozonolysis of vinyl chloride in methanol: a convenient entry to methoxymethylhydroperoxide and its chemistry[1]

MARTIN MEISTER, GERHARD ZWICK, AND KARL GRIESBAUM[2]
Engler-Bunte-Institut, Bereich Petrochemie, Universität Karlsruhe (TH), D-7500 Karlsruhe, West Germany

Received February 3, 1983

MARTIN MEISTER, GERHARD ZWICK, and KARL GRIESBAUM. Can. J. Chem. **61**, 2385 (1983).

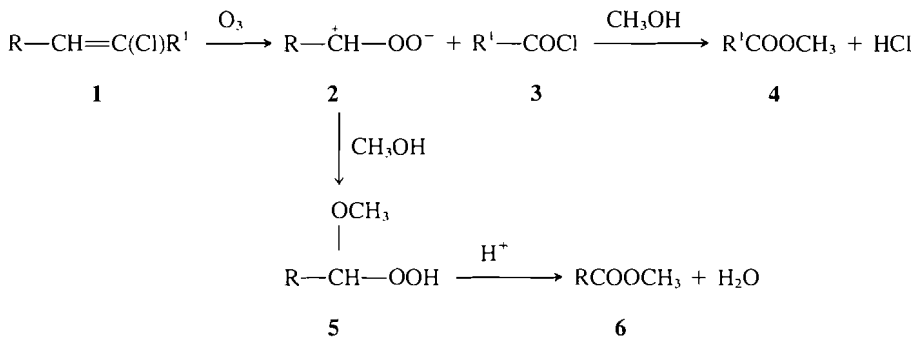
Ozonolysis of vinyl chloride (**7**) in methanol at −78°C afforded methoxymethylhydroperoxide (**10**) in high yield along with only trace amounts of methyl formate (**14**). The former (**10**) was converted into a mixture of methyl formate (**14**) as the major and dimethylformal (**18**) as the minor product by HCl-catalysis in methanol. Reduction of **10** with dimethylsulfide and subsequent treatment with HCl–methanol gave dimethylformal (**18**). Partial reduction of **10** with a deficient amount of triphenylphosphine gave formaldehyde hemiacetal (**19**) and methoxymethylhydroxymethylperoxide (**20**).

MARTIN MEISTER, GERHARD ZWICK et KARL GRIESBAUM. Can. J. Chem. **61**, 2385 (1968).

L'ozonolyse du chlorure de vinyle (**7**) dans le méthanol à la température de −78°C conduit dans un haut rendement au méthoxyméthylhydroperoxide (**10**) et seulement à des traces de formiate de méthyle (**14**). Le premier, catalysé par le chlorure d'hydrogène dans le méthanol est transformé en formiate de méthyle (**14**), produit principal, et en diméthylacétal de formaldéhyde (**18**), produit secondaire. La réduction de **10** par le sulfure de méthyle, suivi d'un traitement avec le chlorure d'hydrogène dans le méthanol conduit au diméthylacétal de formaldéhyde (**18**). La réduction partielle de **10** avec une quantité insuffisante de triphenylphosphine conduit au méthylhémiacétal du formaldéhyde (**19**) et au méthoxyméthylhydroxyméthylperoxide (**20**).

Introduction

In previous work (1) we have examined the ozonolysis in methanol of a series of olefins (**1**) having monochloro substituted double bonds. It was found that the cleavage occurred in one direction only, such that the chlorinated moiety of the double bond afforded the carbonyl fragment (**3**) and the non-chlorinated moiety afforded the zwitterion fragment (**2**). Both fragments **2** and **3** were immediately trapped by methanol to give methoxyhydroperoxides (**5**) and methyl esters (**4**), respectively, as well as hydrogen chloride as a by-product. The latter, in turn, initiated a spontaneous acid catalyzed conversion of the methoxyhydroperoxides (**5**) into the corresponding methyl esters (**6**).



There were, however, two exceptions to this reaction scheme. Thus, chloroolefins (**1**) bearing a CHCl-moiety (i.e. R^1 = H) gave carbon monoxide and not methyl formate and chloroolefins (**1**) bearing a CH_2-moiety (i.e. R = H) gave a more persistent methoxyhydroperoxide which was only slowly converted into methyl formate by the action of hydrochloric acid. It was assumed that this more persistent methoxyhydroperoxide is the methoxymethylhydroperoxide **10**. The latter had been obtained and spectroscopically characterized previously in ozonolysis reactions of methylene-terminated olefins in methanol (2, 3). To our knowledge, however, its elemental analysis has not yet been reported and its chemistry has not been studied to any extent.

The two above-mentioned moieties CHCl and CH_2, which led to the cited exceptional ozonolysis results, are jointly present in the lowest member of the class of chloroolefins, viz. vinyl chloride (**7**), which to our knowledge has not been ozonized under the conditions and aspects which were the basis of our previous investigation (1). In view of this unique structural feature and also in consideration of the potential ecological interest in methods for the destructive oxidation of this compound, we have studied the ozonolysis of vinyl chloride (**7**) in methanol.

Results and discussion

Vinyl chloride (**7**) was ozonized to completion in methanol solution at −78°C. Ozone was not completely consumed and the solution became strongly acidic as the reaction progressed. If the solution was allowed to warm up to room temperature while it was still somewhat acidic, ^{1}H nmr analysis showed the presence of **10** as the major component, along with several unidentified signals. However, if the solution was carefully neutralized by solid sodium bicarbonate at low temperatures and subsequently warmed up to room temperature, the only

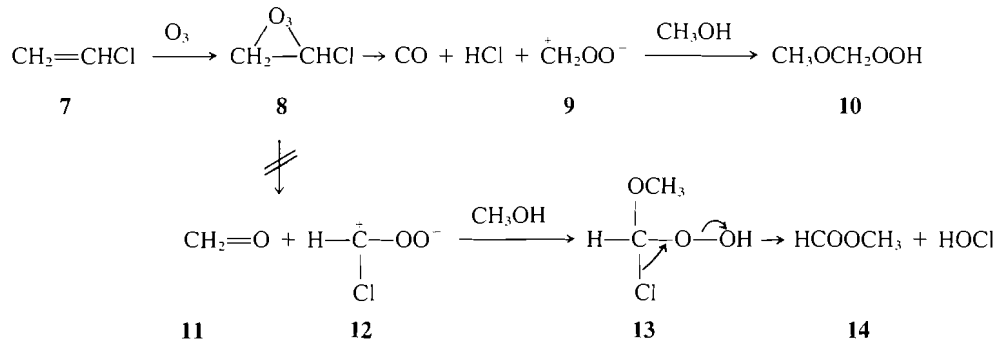
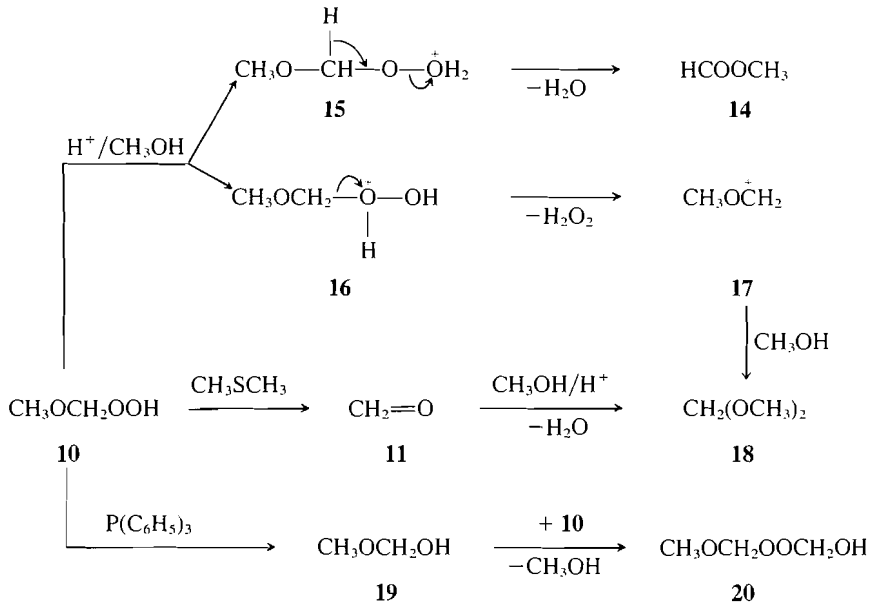
detectable products were methoxymethylhydroperoxide (**10**) and trace amounts of methyl formate (**14**). After removal of methanol, methoxymethylhydroperoxide (**10**) was the only product left as the residue. This demonstrates that the expected initial ozonide **8** reacts overwhelmingly in one direction only to form the fragments carbon monoxide, hydrogen chloride, and the zwitterion **9** as a precursor for the major product **10**. The conceivable alternate mode of cleavage of **8** into fragments **11** and **12**, on the other hand, occurs only to a very minor extent, at best. For, formaldehyde (**11**) or products derived from it like dimethylformal (**18**) or trimeric formaldehyde were not detected, and methyl formate (**14**), the end product expected from the zwitterion fragment **12** by the sequence **12** → **13** → **14** (4), was only present in trace amounts. But, as will be shown below, the sequence **8** → **12** → **13** → **14** is not the only possible mode of formation for **14**, since **14** could have also been formed by HCl-catalyzed dehydration of the major product **10** prior to the neutralization step. Hence, cleavage of **8** into fragments **11** and **12** may not have occurred at all.



Due to the above-described selective mode of cleavage, the ozonolysis of vinyl chloride (**7**) in methanol opens a convenient method for the preparation of methoxymethylhydroperoxide (**10**) in yields of ca. 70% and in high purity. It is a colorless slightly viscous liquid which, in line with a previous report (3), was found to be sensitive to heat, but also to shock. Thus, a sample of **10** exploded violently when it was hit with a hammer, and at one occasion a sample of **10** which was kept stirring at ambient temperatures exploded, too. Furthermore, an attempt at injecting a sample into the inlet port of a gas-chromatograph led to an explosion, accompanied by the disruption of the syringe and of its needle. Hence, the methoxymethylhydroperoxide **10** has to be handled with extreme care and by applying stringent safety measures.

The structure of **10** has been established by elemental analysis and by its ^{1}H nmr, ir, and chemical ionization ms spectra. This assignment was further substantiated by the results of the reactions of **10** described in the following paragraphs.

Reaction of **10** in a 1:10 mixture of anhydrous hydrogen chloride in methanol at 40°C afforded a mixture of methylformate (**14**) and of dimethylformal (**18**) in 89 and 11% yield, respectively. A similar result was obtained at ambient temperatures, albeit at a considerably slower rate. This result is rationalized by protonation of **10** at the two available oxygen



atoms of the hydroperoxide group to give the intermediates **15** and **16**, and subsequent reactions of these intermediates via **15** → **14** and **16** → **17** → **18**, respectively.

Reduction of **10** with dimethyl sulfide at room temperature and subsequent treatment with a 1:10 mixture of anhydrous hydrogen chloride in methanol afforded dimethylformal (**18**) and dimethyl sulfoxide in equimolar amounts. Partial reduction of **10** with a deficient amount of triphenylphosphine in deuteriated trichloromethane, on the other hand, gave a mixture consisting of **19** (17%), **20** (51%), and unreacted **10** (32%).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

The formation of **20** is rationalized by the reaction of unconverted starting material **10** with its reduction product(s) **11** and/or **19**. Similar reactions have been observed by us between other methoxyhydroperoxides and formaldehyde (5) as well as between **10** and other aldehydes.[3]

The hemiperacetal **20** has been isolated as a colorless, slightly viscous liquid. It was identified by elemental analysis as well as by its ir and ^{1}H nmr spectra. The latter exhibited a triplet signal for each of the two CH_2-groups,[4] indicating a coupling across the peroxide bond. Similar couplings have been also observed in the spectra of other peracetals.[3]

Materials and methods

Materials

All chemicals were of commercial grade. Methanol was dried prior to its use by refluxing and subsequent distillation over magnesium shavings. The 1:10 mixtures of hydrogen chloride in methanol were prepared by introducing gaseous anhydrous hydrogen chloride into dried methanol at 0°C and monitoring the HCl content by titration of aliquots with a standard sodium hydroxide solution using phenolphthalein as indicator.

Analytical methods

Gas–liquid chromatographic analyses were carried out on a Shimadzu GC-6A unit with flame ionization detector. Glass columns: 0.3 × 500 cm, 5% Carbowax 20M on Chromosorb G; conditions: 60°C to 160°C at 4°C per min, 30 mL N_2 per min. Nuclear magnetic resonance spectra were recorded on a Bruker WP 60, infrared spectra on a Beckman IR 4260 spectrometer.

Equipment and general procedure of ozonolysis

All ozonolyses were carried out in a calibrated narrow tubular glass reactor which was equipped with a magnetic stirring bar and with an insert containing a dropping funnel, a gas inlet tube which reached to the bottom of the reactor, and a gas outlet line. The reactor was cooled to −78°C and vinyl chloride was transferred from a cylinder via the gas inlet tube and condensed into the reactor. Then a mixture of methanol and dichloromethane was added dropwise and the reactor content was mixed by passing a slow stream of nitrogen through the reactor. Ozonolysis was carried out at −78°C, and the exit gas from the reactor was passed through a buffered aqueous solution of potassium iodide. Ozone treatment was terminated when the reactor content turned blue, and the excess of ozone was removed by flushing the reactor with nitrogen. Then 6.0 g of solid sodium bicarbonate, 6.0 g of solid sodium sulfate, and 10 mL of dichloromethane were added, the insert was replaced by a balloon filled with nitrogen, and the mixture was stirred and allowed to warm up to ca. −20°C. When the mixture had turned neutral it was filtered; the filtrate was warmed up to room temperature and analyzed by ^{1}H nmr spectroscopy. Then the solvents were removed at room temperature and at approximately 20 Torr to leave a slightly viscous, colorless liquid residue. If the latter still contained residual particles of sodium bicarbonate and/or sodium sulfate, a small amount of dichloromethane was added, the solution was removed with a pipette, and the solvent was again removed as described above.

Ozonolysis of vinyl chloride (7) and characterization of methoxymethylhydroperoxide (10)

A solution of 2 mL (ca. 32 mmol) of vinylchloride (**7**) in 7 mL of methanol and 7 mL of dichloromethane was treated with a stream of 3 vol% of ozone in oxygen as described above. Soon after starting, unreacted ozone was detected in the reactor off-gases, as indicated by iodine formation in the potassium iodide solution. The ^{1}H nmr analysis of the filtrate in $CDCl_3$/TMS showed a strong signal for the CH_2-group in **10** at δ 4.95 and very weak signals for the CH- and CH_3O-groups in **14** at δ 3.76 and 8.08, respectively, in addition to the overlapping CH_3O- signals of **10** and of methanol at δ 3.45 and the CH_2-signal of dichloromethane at δ 5.31. After removal of the solvents there remained 1.8 g of virtually pure **10**. For analytical purposes, a sample of the latter was further purified by thin-layer chromatography on silica gel using a 10:1 mixture of dichloromethane and methanol as eluent and by subsequent distillation at room temperature and 2.6 × 10^{-2} millibar.

Methoxymethylhydroperoxide (10)

Colorless, slightly viscous liquid; yield ca. 71%; ir (film): 3310, 2970, 2940, 2840, 1455, 1390, 1212, 1150, 1078, 998, 992, 917 cm^{-1}; ^{1}H nmr ($CDCl_3$, TMS) δ: 3.50 (s, 3H), 4.98 (s, 2H), ca. 9.40 (broad s, 1H); ^{13}C nmr ($CDCl_3$, TMS) δ: 56.42 (q, t, J = 143.0 and 5.0 Hz), 100.79 (t, q, J = 165.0 and 5.0 Hz); ms (chemical ionization with methane, temperature of the ionization source 100°C) m/e (relative intensities): 79 (17) $(M + 1)^+$, 61 (100) $(M - OH)^+$, 47 (14) $(M - CH_3O)^+$. *Anal.* calcd. for $C_2H_6O_3$: C 30.77, H 7.75; found: C 30.66, H 7.81.

HCl-catalyzed reaction of methoxymethylhydroperoxide (10) in methanol

A mixture of 200 mg (2.6 mmol) of **10**, 0.85 mL of CH_3OD, 0.35 mL of a 7.5 molar solution of hydrogen chloride in methanol, and 153 mg (0.91 mmol) of 1,1,2,2-tetrachloroethane (as an internal standard) was kept in a closed flask at 40°C for 24 h. Then the mixture was cooled to 0°C and analyzed; ^{1}H nmr analysis ($CDCl_3$, TMS) showed the signals of **14** at δ 3.76 (d, J = 0.8 Hz, 3H) and 8.08 (q, J = 0.8 Hz, 1H) and of **18** at δ 3.36 (s, 6H) and 4.58 (s, 2H). The assignments are based on the comparison of the above data with those obtained from authentic samples of **14** and **18**. The yields of **14** and of **18** were 89% and 11%, respectively, calculated on the basis of the signal intensities as compared with that of the internal standard 1,1,2,2-tetrachloroethane. The glc analysis showed the peaks of **14** (t_R = 4.0 min; 8%) and of **18** (t_R = 3.8 min; 2%) in addition to those of the solvents. The assignment of these peaks was confirmed by coinjection with authentic samples and by gc–ms analysis, m/e (relative intensities) for **14**: 61 (33) $(M + 1)^+$, 60 (100) M^+, 45 (6) $(M - CH_3)^+$, 44 (11) $(CO_2)^+$; for **18**: 75 (45) $(M - 1)^+$, 45 (100) $(M - OCH_3)^+$.

Reduction of methoxymethylhydroperoxide (10) with dimethylsulfide

To a stirred mixture of 120 mg (1.5 mmol) of **10** in 0.2 mL of dichloromethane was added 0.14 mL (1.9 mmol) of dimethylsulfide at 0°C. The mixture was allowed to warm up to room temperature and was kept there for 6 h. Then 0.1 mL of a 7.5 molar solution of hydrogen chloride in methanol was added and the mixture was kept at room temperature for another 15 h. The ^{1}H nmr analysis ($CDCl_3$, TMS) showed as the sole products **18** (δ 3.36 and 4.58, s, each) and dimethylsulfoxide (δ 2.62, s) in an equimolar ratio. The glc analysis showed the peaks of **14** (t_R = 4.0 min; traces only), of **18** (t_R = 3.8 min), and of dimethylsulfoxide (t_R = 29.7 min). These assignments were confirmed by coinjections with authentic samples and by gc–ms analysis.

Partial reduction of methoxymethylhydroperoxide (10) with triphenylphosphine

To a stirred solution of 700 mg (9.0 mmol) of **10** in 6 mL of deuteriochloroform was added dropwise a solution of 1.0 g (3.8 mmol) of triphenylphosphine in 3 mL of deuteriochloroform at 0°C. The ^{1}H nmr analysis showed the presence of unreacted **10** (32%; δ 4.93 for the CH_2-signal which is shifted by the presence of triphenylphosphineoxide as compared to that of pure **10**), of **19** (17%; δ 4.74 for the CH_2-signal) (5), and of **20** (51%; δ 5.16 for the CH_2-signal). For the isolation of **20**, the reaction mixture was concentrated to a volume of 3 mL by evaporation at ambient temperatures and at reduced pressure. The residue was separated by column chromatography (column 3 × 60 cm; 180 g of silicagel; ether and n-pentane in a volumetric ratio of 5:1) to give 100 mg of a mixture containing 70% of **20** and 30% of **10**. This mixture was distilled at 1

[3] M. Meister, unpublished results.

[4] In some of the spectra these triplets were not well resolved and the signals each appeared as broad singlets.

millibar and at room temperature to remove **10**. Subsequently, the residue was distilled at 1.3×10^{-3} millibar and the distillate (50 mg) was collected in a trap at 0°C. It consisted of pure **20**.

*Methoxymethylhydroxymethylperoxide (**20**)*

Colorless, slightly viscous liquid; ir (film): 3400, 2960, 1450, 1370, 1270, 1205, 1140, 1045, 960, and 910 cm^{-1}; ^1H nmr ($CDCl_3$, TMS) δ: 3.52 (s, 3H), 5.05 (t, J = 0.8 Hz, 2H),[4] 5.16 (t, J = 0.8 Hz, 2H),[4] 3.62 (broad s, 1H); ^{13}C nmr ($CDCl_3$, TMS) δ: 56.68 (q, t, J = 143.2 and 6.0 Hz), 93.14 (t, J = 165.2 Hz), 99.92 (t, q, J = 165.2 and 5.0 Hz). *Anal.* calcd. for $C_3H_8O_4$: C 33.33, H 7.46; found: C 33.16, H 7.22.

Synthesis and redox chemistry of octaethylporphyrin complexes of ruthenium(II) and ruthenium(III)

MARK BARLEY, JAMES Y. BECKER,[1] GEORGE DOMAZETIS, DAVID DOLPHIN,[2] AND BRIAN R. JAMES[2]
Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received March 9, 1983

MARK BARLEY, JAMES Y. BECKER, GEORGE DOMAZETIS, DAVID DOLPHIN, and BRIAN R. JAMES. Can. J. Chem. **61**, 2389 (1983).

The syntheses and characterization of some new octaethylporphyrin complexes of ruthenium(II) and ruthenium(III) are described; the complexes are $Ru(OEP)(P^nBu_3)_2$, $Ru(OEP)(CO)L$ (L = PPh_3, P^nBu_3), $[Ru(OEP)(P^nBu_3)_2]Br$, and $Ru(OEP)(P^nBu_3)Br$, where OEP is the dianion of octaethylporphyrin. The Ru(OEP)(CO)EtOH complex, **1**, which reversibly loses the ethanol ligand in CH_2Cl_2 solution, undergoes a one-equivalent oxidation at the porphyrin ligand to generate the cation-radical $[Ru(OEP)^{\cdot+}(CO)]^+$; a purple species of $^2A_{2u}$ ground state, produced electrochemically in perchlorate media, can coordinate bromide to generate a green $^2A_{1u}$ ground state species that also results from oxidation of **1** using bromine. Coordination of pyridine to $[Ru(OEP)^{\cdot+}CO]^+$ yields the $Ru(OEP)^{\cdot+}(CO)py$ species that can also be formed by electrochemical oxidation of Ru(OEP)(CO)py. Addition of tertiary phosphines (PR_3) to the cation-radical carbonyl species can lead to formation of $[Ru(OEP)(PR_3)_2]^+$, via an internal electron transfer process from Ru(II) to the $OEP^{\cdot+}$ that appears to be triggered by loss of the CO ligand. A reversible one-electron electrochemical oxidation of $Ru(OEP)(P^nBu_3)_2$ at 0.03 V (vs. Ag/AgCl) in CH_2Cl_2 also gives the ruthenium(III) biphosphine cation, while a further one-electron oxidation at 1.2 V generates $[Ru(OEP)^{\cdot+}(P^nBu_3)_2]^{2+}$, a ruthenium(III) π-cation radical characterized by esr. The $[Ru(OEP)(P^nBu_3)_2]Br$ complex decomposes in the solid state to a mixture of $Ru(OEP)(P^nBu_3)Br$, formed together with free phosphine via an intramolecular ligand exchange, and $Ru(OEP)(P^nBu_3)_2$, formed by reduction of the initial ionic ruthenium(III) cation with the phosphine that appears as $[P^nBu_3Br]Br$.

MARK BARLEY, JAMES Y. BECKER, GEORGE DOMAZETIS, DAVID DOLPHIN et BRIAN R. JAMES. Can. J. Chem. **61**, 2389 (1983).

On décrit la synthèse et la caractérisation de quelques nouveaux complexes d'octaéthylporphyrines du ruthénium(II) et du ruthénium(III); ce sont le $Ru(OEP)(P^nBu_3)_2$, le $Ru(OEP)(CO)L$ (L = PPh_3, P^nBu_3), le $[Ru(OEP)(P^nBu_3)_2]Br$ et le $Ru(OEP)(P^nBu_3)Br$, où OEP est le dianion de l'octaéthylporphyrine. Le complexe Ru(OEP)(CO)EtOH (**1**) qui de façon réversible perd le ligand éthanol en solution dans le CH_2Cl_2 subit une oxydation de 1 équivalent au niveau du ligand porphyrine pour donner le cation radicalaire $[Ru(OEP)^{\cdot+}(CO)]^+$; une espèce pourpre d'état fondamental $^2A_{2u}$; il se produit électrochimiquement dans un milieu contenant du perchlorate et peut coordonner le brome pour donner une espèce verte d'état fondamental $^2A_{1u}$ qui se forme aussi par oxydation du composé **1** par le brome. La coordination de la pyridine au cation $[Ru(OEP)^{\cdot+}(CO)]^+$ donne l'espèce $Ru(OEP)^{\cdot+}(CO)py$ qui peut se former également par oxydation électrochimique du complexe Ru(OEP)(CO)py. L'addition de phosphines tertiaires (PR_3) au cation radicalaire carbonylé conduit à la formation de l'ion $[Ru(OEP)(PR_3)_2]^+$ via un processus de transfert interne d'électron du Ru(II) à l'ion radicalaire $OEP^{\cdot+}$ qui semble se former par perte du ligand CO. Une oxydation électrochimique à un électron réversible du $Ru(OEP)(P^nBu_3)_2$ à 0,03 V (vs. Ag/AgCl) dans du CH_2Cl_2 donne également le cation biphosphine ruthénium(III) tandis qu'une oxydation plus poussée à un électron à 1,2 V génère le cation radicalaire $[Ru(OEP)^{\cdot+}(P^nBu_3)_2]^{2+}$, un cation radicalaire π du ruthénium(III) que l'on a caractérisé par la rpe. Le complexe $[Ru(OEP)(P^nBu_3)_2]Br$ se décompose à l'état solide en un mélange de $Ru(OEP)(P^nBu_3)Br$ et de phosphine libre qui se forme par l'intermédiaire d'un échange intramoléculaire de ligand; le $Ru(OEP)(P^nBu_3)_2$, se forme par réduction du cation initial de ruthénium(III) avec la phosphine sous forme de $[P^nBu_3Br]Br$.

Introduction

The use of synthetic porphyrins and metalloporphyrins such as $Fe^{II}(OEP)$ and $Fe^{II}(TPP)$ to model naturally occurring porphyrin systems, which are difficult to study directly, is well established (1). Interest has increased recently in the ruthenium analogues of these compounds because otherwise reactive intermediates are expected to be more stable for the ruthenium complexes than for the iron complexes (2, 3). This is particularly relevant in the study of porphyrin cation radicals which have been suggested as intermediates in a number of natural porphyrin systems such as cytochrome P450 (4) and horseradish peroxidase (5). It was hoped that the slower kinetics at ruthenium centres would allow better characterization of intermediates and products of porphyrin systems at different levels of oxidation.

The redox properties of metalloporphyrins in general have been studied extensively (6), but the studies on ruthenium systems have been limited and concentrated initially on $[Ru^{II}(porp)(CO)L]$ and $[Ru^{II}(porp)L_2]$ complexes: L = py, CH_3CN, THF, and PR_3; (porp) = dianion of octaethylporphyrin (OEP) or *meso*-tetraphenylporphyrin (TPP) (2, 7–9). Oxidation of the L_2 species electrochemically by removal of one electron is thought to give a ruthenium(III) complex as judged by the visible spectrum, and the lack of an esr signal, attributable to a cation radical (2, 9), while oxidation of the carbonyls occurs at the ring to give a π-cation radical species (7, 8).

In this study we describe the redox properties of ruthenium porphyrin complexes and report on an internal electron transfer from the metal atom to the porphyrin ring. A similar transfer has been seen in the system $[Ni^{II}(TPP^{\cdot+})]^+ \rightleftharpoons [Ni^{III}(TPP)]^+$ where it was suggested that axial ligation may trigger the electron transfer (10). The present studies strongly support this hypothesis. We also report on the preparation of two new ruthenium(III) complexes and the formation of a ruthenium(III) cation radical species. Part of this work has been described briefly elsewhere (11).

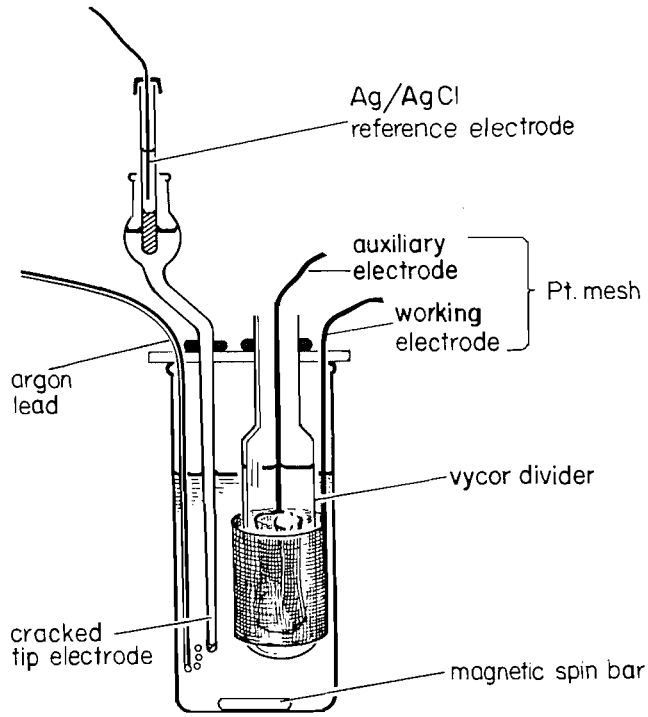

FIG. 1. The apparatus used for bulk electrochemical oxidations.

Experimental section

Materials and methods

Elemental analyses were performed by P. Borda of this department. Mass spectral data were taken on a KRATOS-AEI MS 902, source temperature 220–240°C, direct insertion probe, electron energy 70 eV.

Preparations were conducted under an inert atmosphere. Recrystallizations were carried out under a slow stream of argon which evaporated off the more volatile solvent over a period of days.

Electronic absorption spectra were recorded on a Cary 1756 spectrophotometer. Cyclic voltammograms were recorded using apparatus previously described (9) with the following modifications: the potential was controlled via an EG and G PARC Model 175 Universal Programmer linked to a Model 173 PAR potentiostat. Scan speed was 250 mV/s unless otherwise indicated.

Syntheses of oxidized species by electrochemistry and coulometry were performed using a PAR 173 module with an HDC-371 integrator attachment. The solution to be electrolyzed was placed in a cylindrical glass container. A teflon cap for this container supported a closed tube of Vycor porous glass (Corning 7930) filled with electrolyte solution, and containing the platinum mesh auxiliary electrode. The reference electrode (saturated AgCl/Ag) was held by a cracked tip electrode filled with electrolyte solution. A large platinum mesh electrode (25 cm^2) was wound around the Vycor and immersed in the solution in the glass container which thus formed the working electrode compartment. Argon was bled in via a teflon lead and the solution stirred with a magnetic spin-bar (Fig. 1). The working compartment solution was first pre-electrolyzed at a potential higher than that required for the porphyrin sample. The potential was then brought to zero, the porphyrin added and then electrolyzed at the chosen potential. All potentials are quoted with respect to the saturated AgCl/Ag electrode.

The conductivity results were obtained using a standard electrode set up (cell constant = 0.12 cm^{-1}) in conjunction with a model RCM 15B1 conductivity bridge from Arthur H. Thomas Company.

The magnetic susceptibilities were measured at room temperature on powdered samples, using a Faraday balance that has been described elsewhere (12). The esr spectra were recorded at 77 K on a Varian E-3.

Reagent grade dichloromethane (Fisher), distilled until the uv cut-off was less than 231 nm, was used as a general purpose solvent and also to charge a still over calcium hydride (MC/B). CH_2Cl_2 used for electrochemistry was freshly distilled under argon.

B.D.H. "Omnisolve" acetonitrile was used without further purification. Triphenylphosphine was recrystallized from ethanol before use. Tri-*n*-butylphosphine (MC/B) was distilled at reduced pressure and stored under argon. Tetra-*n*-butylammonium perchlorate, TBAP, (G. Frederick Smith Chemical Company) was recrystallized from Spectro grade acetone (Eastman), dried under vacuum, and stored over P_2O_5. Tetra-*n*-butylammonium tetrafluoroborate, TBATFB, was prepared by the reaction of tetra-*n*-butylammonium bromide and ammonium tetrafluoroborate in aqueous solution. The crude solid was recrystallized from methanol/water, filtered as a solution in dichloromethane and then recrystallized from hot acetone. The crystals were crushed, dried under vacuum, and stored over P_2O_5. Tetra-*n*-propylammonium trifluoromethanesulphonate (13) and tetra-*n*-butylammonium hexafluorophosphate, TBAH (9, 14), were prepared as described in the literature. Tetra-*n*-butylammonium borohydride was kindly provided by B. Tarpey, having been prepared by a method previously described (15). The solid was recrystallized from ethyl acetate, dried under vacuum, and stored over P_2O_5.

Silver tetrafluoroborate (Aldrich) was handled in a glovebag under an argon atmosphere in reduced lighting conditions, and stored under argon.

Ruthenium was available as the trichloride hydrate (42.26% Ru) from Johnson, Matthey Ltd. The dodecacarbonyl, $Ru_3(CO)_{12}$, was obtained from the chloride by a literature procedure (16), as well as commercially from Strem Chemicals. Octaethylporphyrin, H_2(OEP), was prepared by standard procedures (17).

All other solvents and chemicals were reagent grade. The uv/visible spectra of all the isolated and *in situ* species are given in Table 1.

Carbonylethanol(octaethylporphinato)ruthenium(II), (1)

In a modified method of earlier workers (18), 0.8 g of H_2(OEP) (1.5 mmol) was refluxed with 0.8 g of $Ru_3(CO)_{12}$ in toluene (150 mL) for 22 h under argon. When the uv/visible spectrum indicated complete reaction, the solvent was removed by rotary evaporation. The solid was dissolved in 100 mL of 1:1 v/v CH_2Cl_2/EtOH and the solution refluxed under argon for 1 h. Removal of the solvent gave solid Ru(OEP)(CO)EtOH, which was purified on an activity III neutral alumina column (E. Merck) by elution with CH_2Cl_2 – 2% isopropyl alcohol and recrystallization from CH_2Cl_2/EtOH (50 mL of 3:1 v/v). The crystalline product was washed with hexane and dried; yield 0.67 g (63%).

Anal. calcd. for $C_{39}H_{49}N_4O_2Ru$: C 66.24, H 6.99, N 7.93; found: C 66.27, H 7.20, N 7.79. *Mass spec. m/e* 662(10), Ru(OEP)$(CO)^+$; 634(100), Ru(OEP)$^+$; 317(15), Ru(OEP)$^{2+}$. *Nmr* δ_{TMS} ($CDCl_3$): 1.92 (t, 24H, —CH_3), 4.01 (q, 16H, —CH_2—), 9.9 (s, 4H, =CH—).

Carbonyl(octaethylporphinato)(pyridine)ruthenium(II), (2)

This was a gift from P.D. Smith; the method of preparation has already been described (19).

*(Octaethylporphinato)bis(tri-*n*-butylphosphine)ruthenium(II), (3)*

To 400 mg of Ru^{II}(OEP)(CO)EtOH (**1**) (0.56 mmol), dissolved in ~50 mL of CH_2Cl_2 under Ar, was added excess P″Bu_3 (~3 mL) until the initial 393 nm and 408 nm Soret peaks had disappeared. The CH_2Cl_2 was then removed by rotovap and the residue washed several times with acetonitrile prior to recrystallization from 50 mL of 1:1 CH_3CN/CH_2Cl_2 mixture; yield 400 mg (69%).

Anal. calcd. for $C_{60}H_{98}N_4P_2Ru$: C 69.42, H 9.51, N 5.40; found: C 69.26, H 9.60, N 5.60. *Mass spec. m/e* 1038(<0.1), Ru(OEP)(P″$Bu_3)_2^+$; 836(100), Ru(OEP)(P″$Bu_3)^+$; 634 (71), Ru(OEP)$^+$; 418 (21), Ru(OEP)(P″$Bu_3)^{2+}$. The ^{1}H nmr has been reported previously (20).

*(Octaethylporphinato)bis(tri-*n*-butylphosphine)ruthenium(III) bromide, (4)*

A solution of 420 mg of Ru^{II}(OEP)(P″$Bu_3)_2$ (**3**) (0.4 mmol), in CH_2Cl_2 (~50 mL) was titrated with a CH_2Cl_2 solution of bromine

(standardized spectrophotometrically, λ_{max} at 410 nm, $\epsilon = 210\ M^{-1}\ cm^{-1}$) until the absorption spectrum in the Soret region indicated completion of reaction (approximately 0.5 equiv. of Br_2 per Ru). The solvent was then removed and the solid recrystallized from 50 mL of 1:1 hexane/CH_2Cl_2, followed by hexane washes (5 × ~5 mL) to give a yield of 255 mg (56%). The crystals were dried and analyzed immediately, as the solid slowly decomposes to give a mixture of $Ru^{II}(OEP)(P^nBu_3)_2$ (**3**) and $Ru^{III}(OEP)(P^nBu_3)Br$ (**12**) (see below).

Anal. calcd. for $C_{60}H_{98}N_4P_2BrRu$: C 64.46, H 8.84, N 5.02, Br 7.09, P 5.55; found: C 64.11, H 8.74, N 5.00, Br 6.95, P 5.77. *Mass spec. m/e* 836(100), $Ru(OEP)(P^nBu_3)^+$; 634(75), $Ru(OEP)^+$; 418(20), $Ru(OEP)(P^nBu_3)^{2+}$.

This compound was shown by conductivity studies to be a 1:1 electrolyte in CH_2Cl_2 (Λ = 130 mho $cm^2\ mol^{-1}$), and magnetic studies showed the presence of one unpaired electron (μ ~ 1.9 BM) on the ruthenium atom.

(Octaethylporphinato)bis(triphenylphosphine)ruthenium(II), (5)

This complex, to be described elsewhere (21), was kindly provided by T. Leung.

Carbonyl(octaethylporphinato)(triphenylphosphine)ruthenium(II), (6)

Complex **1** (200 mg, 0.28 mmol) was dissolved in 50 mL of CH_2Cl_2 and refluxed for 3–4 h with 225 mg of PPh_3 (~3 equiv.) under argon. The solution was taken to dryness on a rotary evaporator, and the residue placed on a column of Florisil in hexane. The excess phosphine was eluted off with hexane/toluene, and the product with toluene/CH_2Cl_2.

Anal. calcd. for $C_{55}H_{59}N_4OPRu$: C 71.48, H 6.44, N 6.06; found: C 71.30, H 6.23, N 5.96. *Mass spec. m/e* 895(100), $Ru(OEP)(PPh_3)^+$; 711(2), $Ru(OEP)(Ph)^+$?; 662(4), $Ru(OEP)(CO)^+$; 634(100), $Ru(OEP)^+$. *Infrared* ν(CO) = 1952 cm^{-1}. *Nmr* δ_{TMS} ($CDCl_3$) 1.83 (t, 24H, —CH_3), 3.85 (m, 16H, —CH_2—), 9.45 (s, 4H, =CH—), 6.71 (t, 3H, *p*-H), 6.35 (t, 6H, *m*-H), 3.67 (t, 6H, *o*-H).

*Carbonyl(octaethylporphinato)(tri-*n*-butylphosphine)ruthenium(II), (11)*

Complex **1** dissolved in CH_2Cl_2 (~100 mL) was titrated with a CH_2Cl_2 solution of P^nBu_3 until the Soret absorption indicated complete formation of product (408 nm), prior to any formation of $Ru(OEP)(P^nBu_3)_2$ (**3**) (428 nm). The solution was evaporated to dryness under vacuum to yield 146 mg of crude product. This was purified by chromatography on activity III alumina, the product eluting off in CH_2Cl_2 well ahead of residual complex **1**.

Anal. calcd. for $C_{49}H_{71}N_4OPRu$: C 68.10, H 8.28, N 6.48; found: C 68.20, H 8.25, N 6.30.

The ^1H and ^{31}P nmr data have been reported previously (20).

*Bromo(octaethylporphinato)(tri-*n*-butylphosphine)ruthenium(III), (12)*

To 100 mg of crude $Ru(OEP)(CO)P^nBu_3$ (**11**) dissolved in 100 mL of CH_2Cl_2 was added a slight excess (~5%) of bromine in CH_2Cl_2 (0.5 Br_2/Ru). The reaction was followed by the loss of absorbance at 408 nm. The solvent was then removed under vacuum, and the crude residue (90 mg, yield 85%) was chromatographed on activity III alumina, the product eluting off in 2–4% isopropanol in CH_2Cl_2.

Anal. calcd. for $C_{48}H_{71}N_4BrPRu$: C 62.93, H 7.81, N 6.12, Br 8.72; found: C 62.93, H 7.93, N 6.00, Br 8.55.

Conductivity studies showed this compound to be a non-electrolyte when dissolved in CH_2Cl_2 (Λ = 2.0 mho $cm^2\ mol^{-1}$), showing that the bromide ligand is coordinated. Magnetic studies showed the presence of one unpaired electron (μ ~ 2.0 BM) on the ruthenium atom.

Results and discussion

There has been discussion as to whether the ethanol ligand

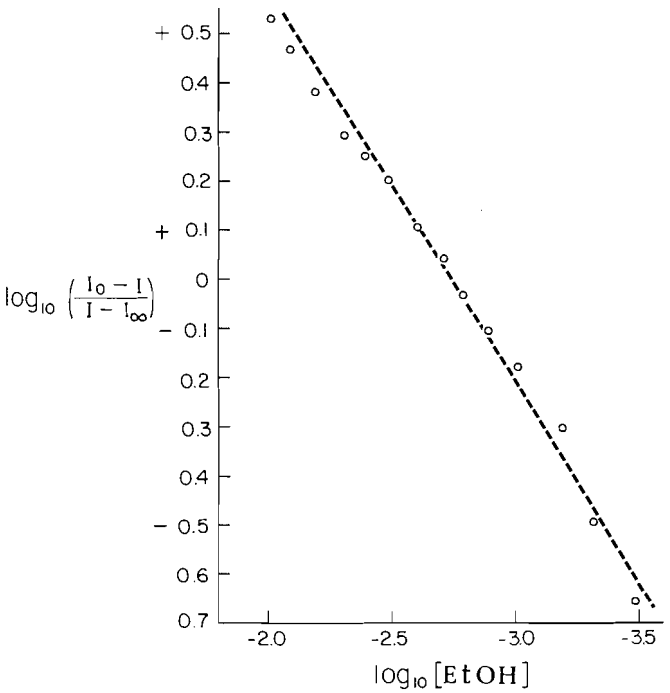

FIG. 2. Plot of $\log_{10}$ {[Ru(OEP)(CO)EtOH]/[Ru(OEP)(CO)]} vs. $\log_{10}$ [EtOH] to obtain the equilibrium constant for eq. [1]. [Ru(OEP)(CO)EtOH] is $\propto (I_0 - I)$, and [Ru(OEP)(CO)] is $\propto (I - I_\infty)$, where I_0 and I_∞ are the absorbances with no added ethanol and high [ethanol] (~1.0 *M*), respectively; I is an intermediate absorbance at a known added [ethanol]. Slope of line = 0.8 ± 0.2 and estimated equilibrium constant = 550 ± 70 M^{-1}.

in complexes of the type Ru(porp)(CO)EtOH, such as **1**, dissociates in dilute solutions of non-complexing solvents (18, 22). We find that the addition of excess EtOH (up to ~1.0 *M*) to (**1**) in CH_2Cl_2 (~5×10^{-5} *M*) causes a change in the visible spectrum in that the intensity ratio of the ~547 and ~512 nm bands decreases from ~2.6 to 2.0; the ratio was unaffected by the addition of more EtOH. This suggests that ethanol at high concentrations coordinates, and implies that an equilibrium exists between, for example, a five-coordinate Ru(OEP)(CO), (**1***a*), species (I_{547}/I_{512} = 2.6) and the six-coordinate ethanol adduct (**1**) (I_{548}/I_{515} = 2.0; compared to **1***a*, the absorptions are slightly shifted to the red):

$$[1] \quad \underset{\mathbf{1}a}{\text{Ru(porp)(CO)}} + \text{EtOH} \overset{K}{\rightleftharpoons} \underset{\mathbf{1}}{\text{Ru(porp)(CO)EtOH}}$$

Spectral changes observed during the addition of ethanol to a dilute solution (~10^{-5} *M*) of **1** in CH_2Cl_2 (presumably present as **1***a*) allows for a plot of $\log_{10}$ {[Ru(OEP)(CO)EtOH]/[Ru(OEP)(CO)]} vs. $\log_{10}$ [EtOH] (Fig. 2). This gives a straight line of slope 0.8 ± 0.2 which agrees reasonably well with the equilibrium shown in eq. [1] and gives an association constant K of 550 ± 70 M^{-1} at room temperature. Such a value shows that in all spectroscopic solutions (<10^{-4} *M*), complex **1** would be greater than 95% dissociated to **1***a*, although more concentrated solutions would show a higher degree of association. The slight decrease in the I_{547}/I_{512} ratio (from ~2.6 to 2.4) seen in samples covering a wider concentration range (up to 5×10^{-4} *M*) is consistent with the estimated K value.

Oxidation of monocarbonyl ruthenium(II) porphyrin complexes occurs at the porphyrin ring to give a π-cation radical species (8). We find that the first oxidation potential of Ru(OEP)(CO) (**1***a*), formed *in situ* from **1** in dichloromethane, is dependent upon the nature of the electrolyte used (Table 2). Of the four electrolytes, perchlorate, hexafluorophosphate, and trifluoromethanesulphonate give about the same potential while fluoroborate averages ~0.1 V higher. This effect of the fluoroborate anion has been noticed before (24), although a satisfactory explanation has not been given.

TABLE 2. Reversible potentials[a] for Ru(OEP)(CO) in CH_2Cl_2, (1.5–2.5) × 10^{-4} *M*, in the presence of 0.05 *M* electrolyte

Electrolyte anion	E_1 (V)	E_2 (V)
BF_4^-	+0.82	+1.30
ClO_4^-	+0.71	+1.19
PF_6^-	+0.70[b]	+1.20[b]
$CF_3SO_3^-$	+0.65	+1.16

[a] E_1 values are formal reduction potentials for the reaction: $[Ru^{II}(OEP)^{\cdot+}(CO)]^+ + e \rightleftharpoons [Ru^{II}(OEP)(CO)]$; E_2 values are in the range expected for reduction of ruthenium(III) π-cation radical species (refs. 7, 23, and present text), for example: $[Ru^{III}(OEP^{\cdot+})(CO)]^{2+} + e \rightleftharpoons [Ru^{II}(OEP^{\cdot+})(CO)]^+$.

[b] Reference 8 gives E_1 and E_2 values of +0.69 and +1.26 V, respectively.

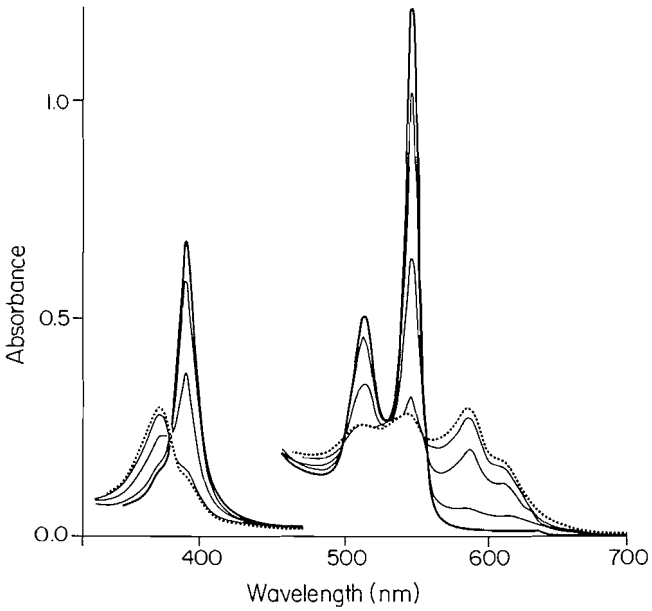

FIG. 3. Optical spectra during the electrochemical oxidation of a solution of Ru(OEP)(CO)EtOH (—) in CH_2Cl_2 (mixture of species (**1**) and (**1***a*)) in the presence of 0.05 *M* $TBA^+ClO_4^-$ to give the cation radical (**7**) (- - -). The absorbance scale refers to the 500–700 nm region; absorbance in the Soret region is reduced by a factor of 10.

Electrolysis in all cases occurred smoothly and gave good isosbestic points when followed spectroscopically (Fig. 3), to form essentially the same deep purple solution (**7**) with a strong sharp esr signal at g = 2.00, typical of an organic radical. The solution could be reconverted, by the action of reducing agents, or electrochemically, back to the pink Ru(OEP)(CO) species (**1***a*).

In contrast, addition of a dilute solution of bromine in CH_2Cl_2 to a solution of Ru(OEP)(CO) (**1***a*) gave a deep green solution (**8**) after the addition of a slight excess of bromine ((1/2)Br_2/Ru). Species **8**, which also gave a strong sharp esr

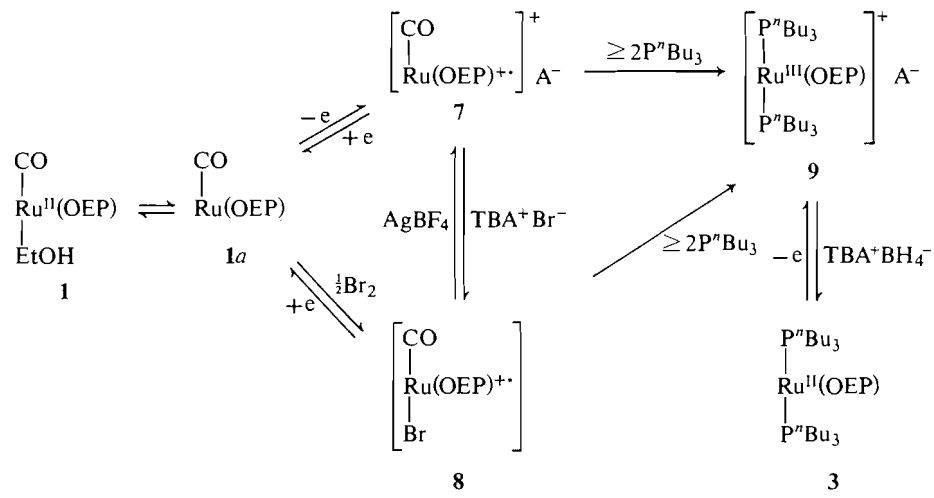

SCHEME I

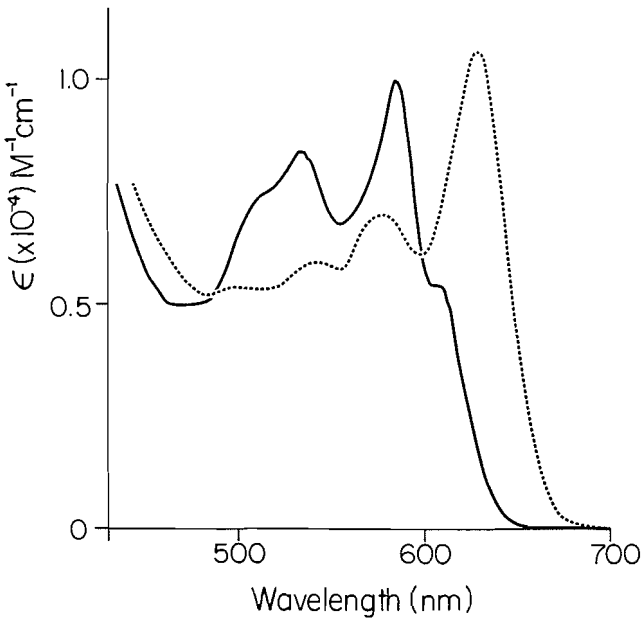

FIG. 4. Optical spectra of the cation radical (**8**) (- - -); $^2A_{1u}$ ground state, and the spectrum of the cation radical (**7**) (—), $^2A_{2u}$, obtained by the addition of $AgBF_4$ to species (**8**).

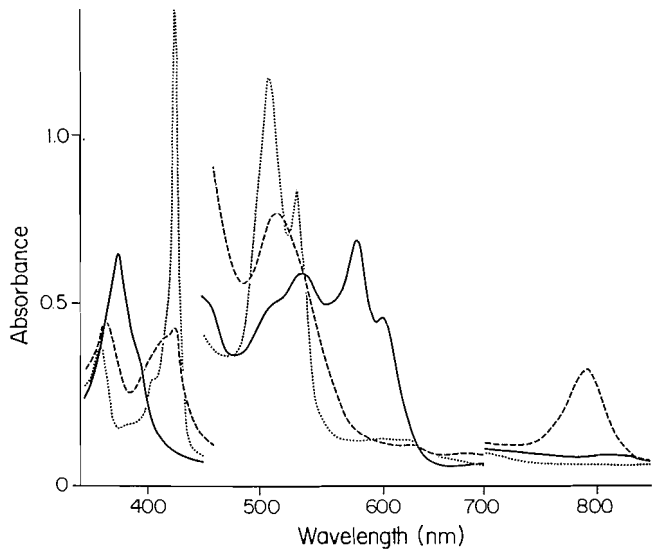

FIG. 5. Optical spectrum of the electrochemically prepared cation radical (**7**) prepared from a CH_2Cl_2 solution of Ru(OEP)(CO)EtOH in the presence of 0.05 *M* $TBA^+ClO_4^-$ (—). The spectrum of species (**9**) formed by the addition of >2 equiv. of P^nBu_3 (– – –), and the spectrum of (**3**) obtained by the reduction of this product (- - -). The absorbance scale refers to the region above 500 nm; absorbance in the Soret region is reduced by a factor of 10.

signal at $g = 2.00$ (attributed to an organic radical) was again easily converted back, chemically or electrochemically, to a species identical by uv/vis spectroscopy with **1***a*.

Addition of 1 equiv. of tetra-*n*-butylammonium bromide to a purple solution of **7** caused conversion to the green species **8**; the reverse reaction could be achieved by adding $AgBF_4$ to a solution of **8**. Scheme 1 summarizes the data including the interconvertibility of the cation radicals, whose uv/vis spectra are shown in Fig. 4.

Similar results have been seen with oxidation of $Co^{II}(OEP)$ systems (5). Electrochemical oxidation of $Co^{II}(OEP)$ in the presence of perchlorate ion gave first $[Co^{III}(OEP)]^+$ and then a cation-radical species $[Co^{III}(OEP)^{+\cdot}]^{2+}2ClO_4^-$, whose optical spectrum was considered, from theoretical calculations and comparison with that of $Zn^{II}(TPP)^{+\cdot}$, to derive from a $^2A_{2u}$ ground state. Bromine oxidation of $Co^{II}(OEP)$ to $Co^{III}(OEP)^{+\cdot}2Br^-$, however, gave a different optical spectrum for the cation-radical and that was considered to have a $^2A_{1u}$ ground state (25). The two cobalt cation-radicals could be interchanged by addition of the appropriate anions as in the ruthenium systems. On the basis of similarity in optical spectra, green species **8** would be assigned a $^2A_{1u}$ ground state and the purple form **7** a $^2A_{2u}$ ground state.

Conductivity studies show that (**8**) is essentially a non-electrolyte in CH_2Cl_2; the molar conductivity ($\Lambda \sim 1.0$ mho $cm^2\ mol^{-1}$) is comparable to that of $Ru^{III}(OEP)(P^nBu_3)Br$ ($\Lambda \sim 2.0$), which is very different to that of the 1:1 electrolyte $[Ru^{III}(OEP)(P^nBu_3)_2]^+Br^-$ ($\Lambda \sim 130$). This suggests that the coordination of bromide causes the molecule to change from a $^2A_{2u}$ to a $^2A_{1u}$ ground state. Such ligand coordination induced ground state transitions were suggested previously for the $Co^{III}(OEP)$ cation radicals (25), and such an explanation is strongly supported by the ruthenium data.

The marked similarity of the spectra of the ruthenium(II) cation radical species with those of the reported cobalt(III) analogues (5, 25) is in line with the general conclusion that such spectra are relatively insensitive to the nature of the cen-

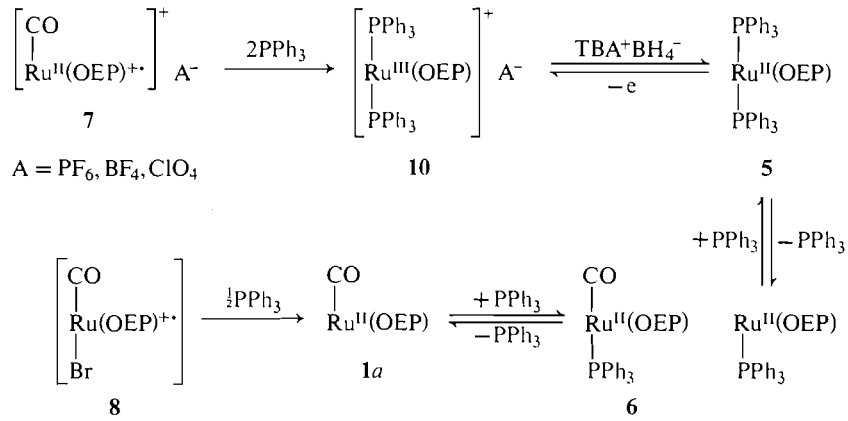
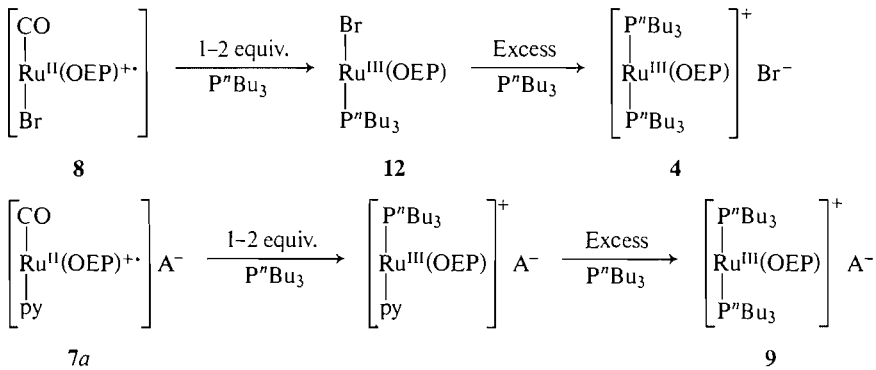


SCHEME 2



SCHEME 3

tral metal atom, at least, when the metalloporphyrin is diamagnetic (26); this supports the concept of the modelling of heme cation radicals using other metalloporphyrin complexes.

Recent magnetic circular dichroism spectral data on the cobalt π-cation radical species mentioned above and on the compound I derivatives of horseradish peroxidase and catalase (27) have confirmed the iron(IV) π-cation radical nature of the enzyme compound I species (5, 25).

Addition of two or more equivalents of tri-*n*-butylphosphine to a solution of either **7** or **8** produced the bis-phosphine ruthenium(III) cation $[Ru(OEP)(P^nBu_3)_2]^+$ (**9**), as judged by the optical spectrum which was identical with that of the characterized $[Ru^{III}(OEP)(P^nBu_3)_2]^+Br^-$ complex (**4**) (Fig. 5). Reduction of **9** with tetrabutylammonium borohydride gave a solution species identical to $Ru^{II}(OEP)(P^nBu_3)_2$ (**3**). The reversible electrochemical conversion **3** ⇌ **9** could be accomplished in CH_2Cl_2 with TBAP as supporting electrolyte ($E_{1/2} \sim 0.0$ V vs. Ag/AgCl) (Scheme 1); clean spectral changes with several isosbestic points were observed for the electrochemical conversion (cf. Fig. 5), and are consistent with no accompanying ligand exchange reactions. The reduction potential for this Ru(III)/Ru(II) couple is lower than those of related bis(tertiary phosphine) complexes of Ru(TPP) (9), and is consistent with a relative stabilization of Ru(III) by the more basic OEP ligand system.

Addition of triphenylphosphine to a solution of **7** gave a similar result with formation of what is believed to be the bis-(triphenylphosphine)ruthenium(III) cation $[Ru(OEP)(PPh_3)_2]^+$ (**10**), since borohydride reduction gave a species spectrally identical to $Ru^{II}(OEP)(PPh_3)_2$ (**5**) in the presence of excess phosphine. Genuine samples of **5** in dilute solution (Soret at 422 nm) dissociate a phosphine to give an equilibrium mixture with the five-coordinate species $Ru(OEP)(PPh_3)$ that has a Soret band at 396 nm (21); addition of excess phosphine regenerates pure **5** with concomitant loss of the 396 nm peak. Samples of **5** in the absence of excess phosphine could nevertheless be electrochemically oxidized ($E_{1/2} \sim 0.25$ V vs. Ag/AgCl with TBATFB as electrolyte) to generate **10**, Scheme 2.

The reaction of cation-radical **8** with triphenylphosphine was very different and involved a reduction to give Ru(OEP)-(CO)(PPh_3) (**6**), probably via the Ru(OEP)(CO) intermediate. A controlled addition of half a mole of phosphine per Ru to **8** generated a spectrum attributed to Ru(OEP)(CO) (Table 1); further phosphine then generated the spectrum of complex **6** (this appears to dissociate triphenylphosphine in solution, since excess phosphine is necessary to fully generate the typical spectrum of a carbonylphosphine complex (Table 1)). The mechanisms of this and similar reduction reactions of both cation radical ground states are under investigation.

Careful addition of tri-*n*-butylphosphine to a solution of the green cation-radical (**8**) showed the formation of an intermediate requiring a substantial excess of phosphine to convert completely to the final product $[Ru^{III}(OEP)(P^nBu_3)_2]^+Br^-$ (**4**). The intermediate was spectrally identical to a prepared sample of $Ru^{III}(OEP)(P^nBu_3)Br$ (**12**), which also gave **4** on the addition of excess phosphine (Scheme 3).

Electrochemical oxidation of $Ru^{II}(OEP)(CO)py$ (**2**) gave a purple cation radical species (**7***a*) whose spectrum was similar to that of **7** except that the peaks were slightly red shifted, suggesting that the pyridine was still coordinated. Addition of 1 equiv. of pyridine to **7** also generated the spectrum of **7***a*. Addition of tri-*n*-butylphosphine to **7***a* eventually gave the $[Ru^{III}(OEP)(P^nBu_3)_2]^+$ cation (**9**), but an intermediate was

detected by monitoring an increase and then a decrease of absorption at 730 nm before the 790 nm peak of **9** was fully formed. The data are consistent with the formation of the mixed phosphine pyridine ruthenium(III) complex (28), $[Ru^{III}(OEP)(P^nBu_3)py]^+$ (Scheme 3).

The mechanism of the intramolecular electron transfer in these reactions is still under investigation. However, the formation of Ru(III) intermediates with only one phosphine coordinated shows that electron transfer occurs before coordination of the second phosphine, implying that the electron transfer is triggered by the loss of the CO group (28).
