5,10,15,20-Tetranitrooctaethylporphyrinato zinc (**1**) (7) (100 mg) was placed in a mixture of glacial acetic acid (100 mL) and hydrochloric acid (30 mL, 37%). The reaction mixture was stirred for 50 h at room temperature in the dark. Water (300 mL) was added and the mixture filtered. The residue was dissolved in dichloromethane and the organic phase washed with saturated sodium bicarbonate and water. The solvent was removed under reduced pressure and the residue crystallized from chloroform/methanol. This product was then chromatographed on silica (200 × 200 × 1 mm) using benzene/hexane (2:1, v/v). The main (second) band was extracted and crystallized from chloroform/methanol to give 54 mg (62%); uv/vis CH_2Cl_2 (log ε): 274 (4.39), 304 (4.37), 442 (5.29), 548 (4.20), 591 (4.10), 630 sh (3.90), 703 (3.09); CH_2Cl_2/TFA (log ε): 280 (4.36), 307 (4.33), 462 (5.48), 573 sh (3.75), 612 (4.09), 684 (4.42); ^{1}H nmr: 1.17 (t, 6H), 1.42 (t, 12H), 1.46 (t, 6H), 3.18 (q, 4H), 3.52 (q, 8H), 3.60 (q, 4H); ms: 683, 681 (100), 637, 635 (70), 601 (20). *Anal.* calcd. for $C_{36}H_{42}N_5O_2Cl_2\cdot 3H_2O$: C 58.66, H 6.56, N 9.50, Cl 14.43; found: C 58.59, H 6.70, N 9.56, Cl 16.31.

5,10,15,10-Tetrachlorooctaethylporphyrin (6)

5,10,15,20-Tetranitrooctaethylporphyrinato zinc (**1**) (7) (50 mg) was placed in a mixture of glacial acetic acid (50 mL) and hydrochloric acid (15 mL, 37%). The mixture was heated in an oil bath at 100°C for 7 h. After cooling, water (400 mL) was added and the green solid collected by filtration. The filtrate was extracted with ether and the residue dissolved in ether. The combined ether layers were washed with saturated sodium bicarbonate, then water, and dried over Na_2SO_4. The ether was removed and the residue chromatographed on silica (200 × 100 × 1 mm) using dichloromethane/carbon tetrachloride (1:2 v/v). The major (third) green band was removed and crystallized from chloroform/methanol to give 13.7 mg (31%). The product was identical to an authentic sample (8); uv/vis CH_2Cl_2 (log ε): 280 (4.12), 306 (4.06), 356 (4.29), 446 (5.18), 550 (3.92), 593 (3.89), 640 sh (3.44), 714 (3.58); CH_2Cl_2/TFA (log ε): 283 (4.18), 312 (4.07), 401 (4.20), 457 (5.32), 582 sh (3.32), 629 (3.80), 684 (4.36).

5,10,15-Trichlorooctaethylporphyrin (7)

5,10,15,20-Tetranitrooctaethylporphyrinato zinc (**8**) (7) (50 mg) was placed in glacial acetic acid (50 mL) and treated with concentrated hydrochloric acid (15 mL, 37%). The solution was heated at 100°C for 6 h. After cooling, the product was isolated, as above, and purified on silica (200 × 200 × 1 mm) using benzene/hexane (2:1 v/v). The major band, after crystallization from methanol/chloroform, gave 14.8 mg (31%) of the product identical to an authentic sample (8); uv/vis CH_2Cl_2 (log ε): 268 (400), 299 (3.99), 348 sh (4.24), 430 (5.17), 532 (4.03), 572 (3.83), 611 (3.60), 672 (3.21); CH_2Cl_2/TFA (log ε): 273 (4.05), 395 sh (3.58), 443 (5.33), 554 sh (3.49), 595 (3.92), 652 (4.09). An additional 12.2 mg of 5,10-dichloro-15-nitrooctaethylporphyrin (**9**) (see below) was recovered from the tlc plate.

5,10-Dichloro-15-nitrooctaethylporphyrin (9)

5,10,15-Trinitrooctaethylporphyrinato zinc (**8**) (7) (100 mg) was stirred for 1 h at room temperature with a mixture of glacial acetic acid (80 mL) and hydrochloric acid (30 mL, 37%). Dichloromethane (40 mL) and water (200 mL) were added. The organic layer was separated, washed with saturated sodium bicarbonate, water, and then dried over sodium sulphate. After filtration, the solvent was removed and the residue was dissolved in benzene (5 mL); methanol (10 mL) was added and the solution stored at 4°C for 12 h. The precipitate was collected and chromatographed on silica (200 × 200 × 1 mm) using dichloromethane/carbon tetrachloride (1:3 v/v). The major band was recrystallized from chloroform/methanol to give 65 mg (73%) of the product (**9**); uv/vis CH_2Cl_2 (log ε): 263 (3.98), 300 sh (3.99), 423 (5.06), 528 (4.00), 569 (3.76), 604 (3.71), 607 (3.12); CH_2Cl_2/TFA (log ε): 271 (4.02), 447 (5.22), 550 (3.49), 591 (3.98), 6647 (3.99); ^{1}H nmr: 1.25 (t, 3H), 1.41 (t, 3H), 1.46 (t, 3H), 1.53 (t, 3H), 1.61 (t, 3H), 1.63 (t, 3H), 1.64 (t, 3H), 1.66 (t, 3H), 3.37 (9, 2H), 3.39 (q, 2H), 3.66 (q, 2H), 3.71 (q, 2H), 3.72 (q, 2H), 3.77 (q, 2H), 3.79 (q, 2H), 3.92 (q, 2H), 9.44 (s, 1H). *Anal.* calcd. for $C_{36}H_{43}N_5O_2Cl_2$: C 66.66, H 6.68, N 10.30, Cl 10.93; found: C 66.84, H 6.48, N 10.92, Cl 10.77.

5-Chloro-15-nitrooctaethylporphyrin (10)

5,15-Dinitrooctaethylporphyrinato zinc (**11**) (7) (50 mg) was placed in a mixture of glacial acetic acid (50 mL) and hydrochloric acid (15 mL, 37%). The mixture was heated at 100°C for 3.5 h. After cooling and washing with saturated sodium bicarbonate and water the organic phase was taken to dryness and the residue crystallized from chloroform/methanol to give 25.1 mg of **10** (51%); uv/vis CH_2Cl_2 (log ε): 250 sh (3.95), 274 (3.80), 405 (5.15), 510 (4.13), 544 (3.80), 581 (3.77), 634 (3.42); CH_2Cl_2/TFA (log ε): 268 sh (3.85), 429 (5.30), 540 (3.42), 574 (4.07), 621 (3.81); ^{1}H nmr: 1.68 (t, 6H), 1.86 (t, 6H), 1.89 (t, 6H), 1.93 (t, 6H), 3.70 (q, 4H), 4.08 (q, 4H), 4.10 (q, 4H), 4.22 (q, 4H), 10.25 (s, 2H). *Anal.* calcd. for $C_{36}H_{44}N_5O_2Cl$: C 70.40, H 7.22, N 11.40; found: C 70.17, H 7.34, N 11.20.

5,10-Dibromo-15,20-dinitrooctaethylporphyrin (12)

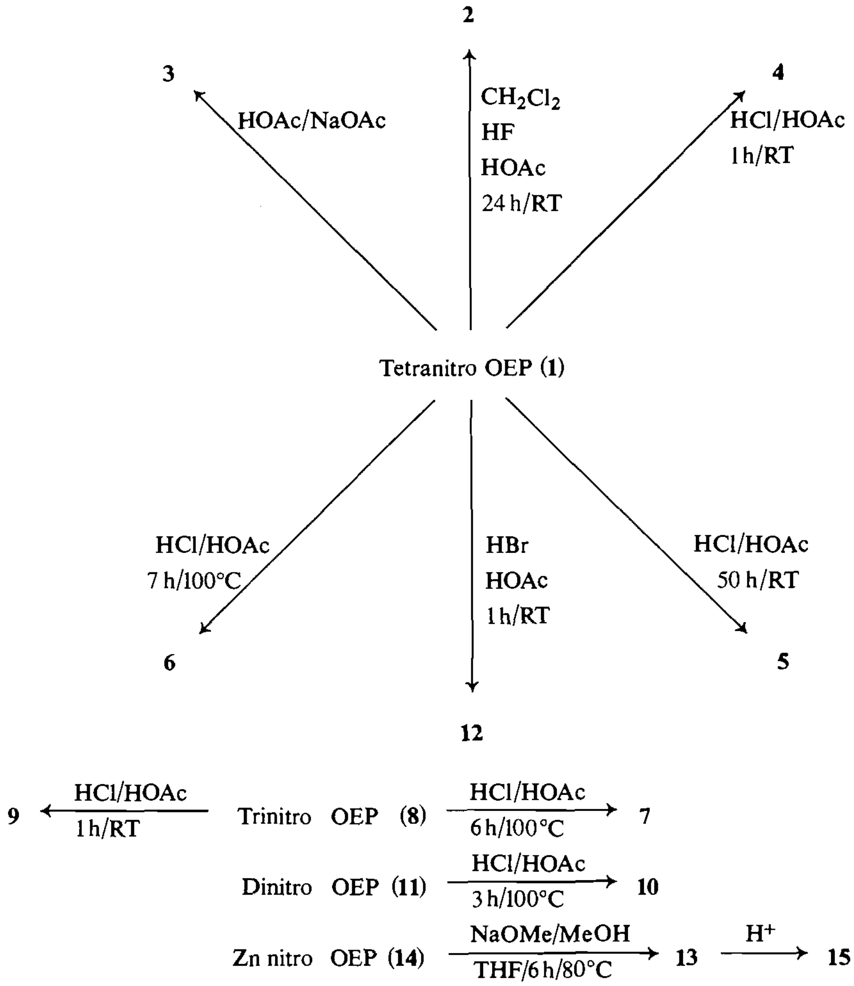
The reaction was carried out in the same way as for the preparation of the corresponding dichloro derivative (**4**) but using 48% HBr; 10% of octaethylxanthoporphyrinogen (**3**) and 20% of the product (**12**) were isolated; ^{1}H nmr: 1.14 (t, 6H), 1.19 (t, 6H), 1.30 (t, 6H), 1.44 (t, 6H), 3.10 (q, 8H), 3.30 (1, 4H), 3.52 (q, 4H). *Anal.* calcd. for $C_{36}H_{442}N_6O_4Br_2$: C 55.25, H 5.41, N 10.74, Br 20.43; found: C 55.27, H 5.82, N 11.10, Br 21.07.

5-Methoxy-15-nitrooctaethylporphyrinato zinc(II) (13)

5-Nitrooctaethylporphyrinato zinc (**14**) (7) (100 mg) was dissolved in dry THF (50 mL) and 8 *M* NaOMe in methanol (5 mL) was added. Solvent was evaporated by a stream of nitrogen until solid sodium methoxide appeared. The mixture was then refluxed and stirred. The progress of the reaction was monitored by tlc on silica gel (CH_2Cl_2/CCl_4 1:3 (v/v)) and the reaction continued until the starting material disappeared. After 6 h the mixture was cooled, dry THF (50 mL) was added, and the mixture was filtered through silica gel. The silica was washed with THF and the combined filtrates were taken down to dryness. The residue was chromatographed on silica gel (200 × 200 × 1 mm) using dichloromethane/carbon tetrachloride 1:3 (v/v). The major band was extracted and crystallized from dichloromethane/hexane to give 39 mg (37%) of product; uv/vis CH_2Cl_2 (log ε): 250 sh (4.07), 346 (4.32), 408 (4.46), 502 sh (3.41), 539 (4.22), 577 (3.92); ^{1}H nmr: 1.70 (t, 6H), 1.86 (t, 6H), 1.90 (t, 6H), 1.94 (t, 6H), 3.73 (q, 4H), 4.10 (q, 12H), 4.41 (s, 3H), 10.20 (s, 2H); ms: 671 (60), 656 (25), 641 (50), 626 (100), 611 (60). *Anal.* calcd. for $C_{37}H_{45}N_5O_3Zn$: C 66.02, H 6.74, N 10.48; found: C 66.11, H 7.02, N 10.40.

5-Methoxy-15-nitrooctaethylporphyrin (15)

5-Methoxy-15-nitrooctaethylporphyrin zinc (30 mg) was dissolved in methylene chloride (25 mL) and then trifluoroacetic acid (1 mL) was added with stirring. After 10 min the solution was washed with water, sodium bicarbonate, and again with water. The organic phase



SCHEME 1

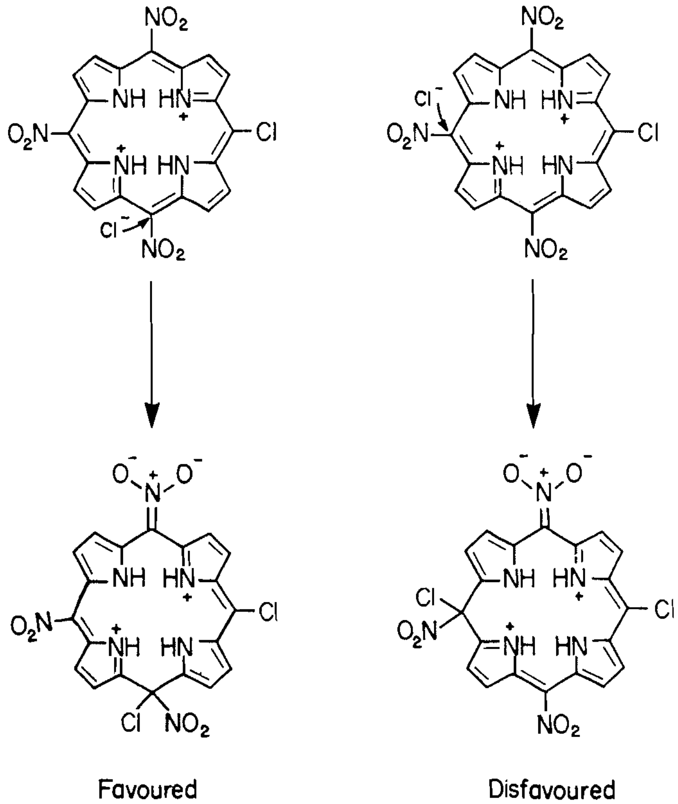
was dried over Na_2SO_4, filtered, and the filtrate taken down to dryness. The product was crystallized from chloroform/methanol to give 22.9 mg (84%) of **15**; uv/vis CH_2Cl_2 (log ϵ): 250 (3.99), 275 (3.83), 404 (5.15), 508 (4.19), 542 (3.66), 577 (3.79), 631 (3.09); CH_2Cl_2/TFA (log ϵ): 427 (5.22), 537 (3.47 sh), 573 (4.03), 622 (3.82); ^1H nmr: 1.68 (t, 6H), 1.82 (t, 6H), 1.87 (t, 6H), 1.91 (t, 6H), 3.70 (q, 4H), 4.08 (q, 12H), 4.48 (s, 3H), 10.18 (s, 2H); ms: 609 (100), 594 (25), 579 (35), 564 (60), 548 (20). *Anal.* calcd. for $C_{37}H_{47}N_5O_3$: C 72.87, H 7.77, N 11.49; found: C 73.04, H 7.69, N 11.21.

Results and discussion

Several mechanistic pathways to achieve nucleophilic aromatic substitution are known (9, 10). In general, when the aromatic system bears strongly electron-withdrawing groups (such as nitro) an addition–elimination (activated) mechanism is seen. Formation of Jackson–Meisenheimer complexes is now well established, though in many cases the initially formed (kinetically controlled) complexes are in equilibrium with the thermodynamically more stable complex which leads to product formation. The stability of the delocalized anion of the Meisenheimer complex is the driving force for the reaction and the collapse of the anion and loss of the leaving group gives the net nucleophilic substitution.

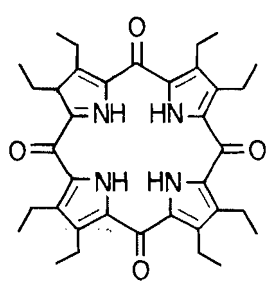
The loss of nitro groups during such reactions is well known, and, indeed, the leaving group ability of the nitro group can be about 200 times greater than that of chloride (11). Scheme 1 outlines the nucleophilic substitutions observed in this study. In the presence of HCl, tetranitrooctaethylporphyrin[1] can be made to undergo stepwise replacement of each nitro by a chloro group. As subsequent nitro groups are placed on the porphyrin ring more vigorous conditions must be employed for further substitution, suggesting that the rate-limiting step is indeed the formation of the corresponding Jackson–Meisenheimer complex. The monochloro-trinitro derivative gives only the 5,10-dinitrooctaethylporphyrin and none of the more symmetric "5,15" isomer. Scheme 2 shows some of the canonical resonance structures of intermediates for both of these reactions. Delocalization of the negative charge onto the nitro group, which leaves all atoms with an octet of electrons, is possible on both nitro groups for both intermediates. However, attack at the 10-position generates a symmetric canonical form (favoured) where both halves represent stable dipyrromethenium moieties with the charges, resulting from protonation, distributed one on each "dipyrromethene". On the other hand, attack at the 15-position gives a higher energy canonical form (disfavoured) in which there is a "pyrrolic unit" and a "tripyrromethene" bearing both charges. Thus, formation of the 5,10-dichloro isomer is favoured thermodynamically as well as statistically.

[1] The zinc complex **1** was used in these studies as a matter of convenience. It is, however, immediately demetallated under the acid reaction conditions.



SCHEME 2

The same substitution pattern is observed when HBr is used. In this case substitution is slower, due presumably to the larger covalent radius of bromine and the considerable steric crowding that will ensue in both the transition state and the product (see below). The slow rate for substitution by bromide allows for competing side-reactions to occur with the formation of octaethylxanthoporphyrinogen (**3**). The xanthoporphyrinogen



3

was also observed when tetranitrooctaethylporphyrin (or its zinc complex) was reacted with hydrofluoric acid. No fluorine-substituted porphyrins were observed, due presumably to the low nucleophilicity of fluoride under these conditions. However, monochloro trinitrooctaethylporphyrin was produced. The chlorine must be derived from the dichloromethane, possibly during the radical oxidation of the dihydroxanthoporphyrinogen (a hydroquinone-like material). The xanthoporphyrinogen was obtained in high yield when tetranitrooctaethylporphyrin was treated with acetic acid in the presence of sulfuric acid, or with acetic acid and sodium acetate when the only reasonable nucleophile is the acetate ion.

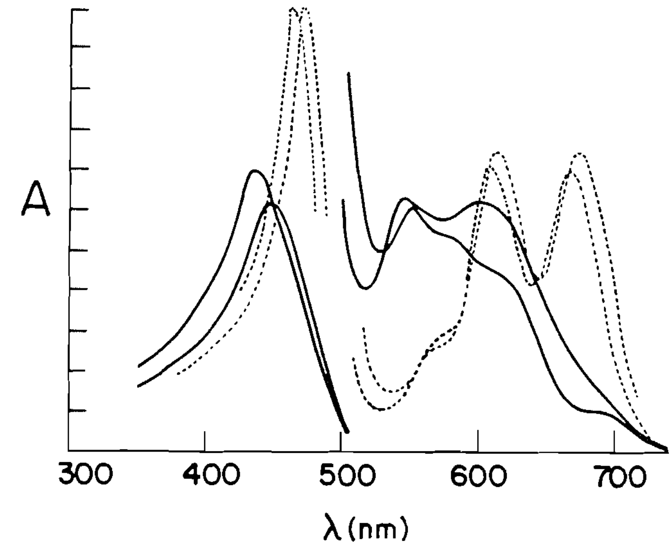


FIG. 1. Optical spectra of 5,10-dichloro- and 5,10-dibromooctaethylporphyrin. Free bases in CH_2Cl_2 (------), protonated species in CH_2Cl_2/1% TFA (------). In each case the bromo derivatives are slightly bathochromically shifted.

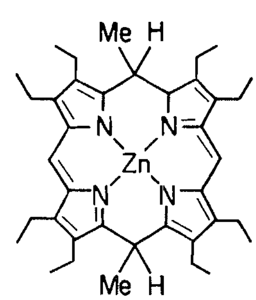
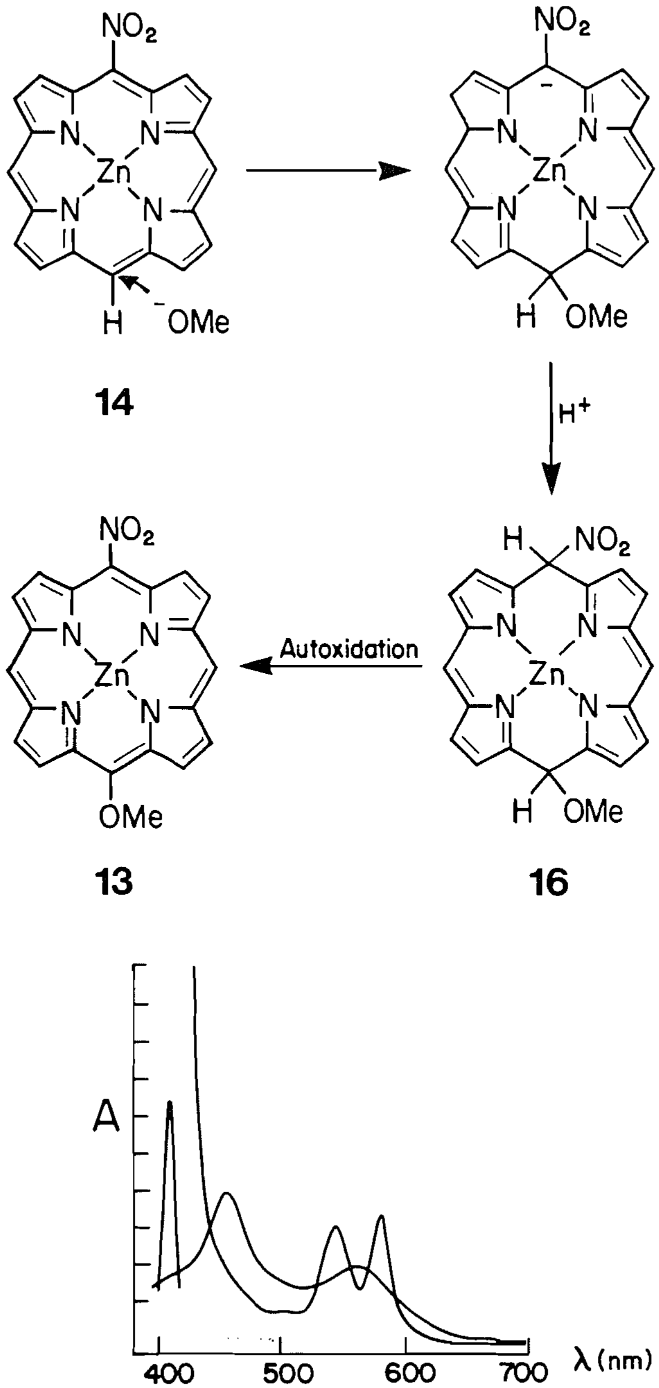
The 5,10-dibromo-15,20-dinitrooctaethylporphyrin exhibited (Fig. 1) a visible spectrum which was broader and more diffuse than the corresponding dichloro complex, attesting to the greater distortion from planarity due to the larger bromine atoms. However, upon N-protonation, when even more distortion occurs due to the repulsion of positive charge on the inner nitrogen (7), the dinitro and dichloro show very similar electronic spectra (Fig. 1).

Nucleophilic substitutions under basic conditions gave far more intractable by-products than under acidic conditions, due presumably to the increased electrophilicity of the porphyrin upon N-protonation and the improved leaving-group properties of the nitro group (as nitrous acid) upon protonation. Nevertheless, reaction of mononitrooctaethylporphyrinato zinc with sodium methoxide in THF proved of interest. As the reaction proceeded, the optical spectrum of the starting material was replaced by a spectrum (Scheme 3) in which the porphyrin absorptions were replaced by two weaker bands in the visible region. After several hours at reflux the optical spectrum again resembled a porphyrin and 5-methoxy-15-nitrooctaethylporphyrinato zinc(II) could be isolated at this stage. As outlined in Scheme 3, nucleophilic attack at the *meso*-position of **14** opposite the nitro group will give, upon protonation, the dihydroporphyrin (porphodimethene) **16**. Autoxidation of **16** will give the observed product **13**. Consistent with this interpretation is the observation that α,γ-dimethyl-α,γ-dihydrooctaethylporphyrinato zinc(II) (**17**) shows a qualitatively similar optical



17



SCHEME 3

spectrum to **16** and undergoes rapid autoxidation to the corresponding 5,15-dimethyloctaethylporphyrin (12).

We have shown (7) that the redox properties of octaethylporphyrin are dramatically changed with successive nitration at the *meso*-positions. For instance, the first ring oxidation of **1** occurs at a potential 620 mV higher than for the corresponding unsubstituted ZnOEP. Similarly tetranitrooctaethylporphyrin oxidizes at 690 mV higher than the parent porphyrin. In addition to more difficult oxidations, the nitro groups allow for more facile reductions; thus **1** reduces at a potential 1190 mV more positive than ZnOEP. Chlorine with a σ_m value of 0.37

TABLE 1. Redox potentials[a]

	Half-wave potentials			
Compound[b]	$E^{ox}_{1/2}$ (1)	$E^{ox}_{1/2}$ (2)	$E^{red}_{1/2}$ (1)	$E^{red}_{1/2}$ (2)

2	1.45 (1.57)[c]	—	−0.18[d,e] (−0.22)	−0.96[c]
4	1.22 (1.45)	—	−0.32 (−0.49)	—
5	1.10 (1.23)	—	−0.44 (−0.85)	—
6	0.86 (1.04)	1.72	−0.80 (−1.19)	—
7	0.96	1.36	−0.86	—
9	1.17	—	−0.50[d]	
10	1.22	1.42	−0.62	
ZnOEP	0.87	1.19	−1.47	−1.86
13	0.97[d]	1.18[d]	−1.08[d]	−1.16[d]
15	1.12	1.26	−0.85[d]	−0.96[d]

[a]Potentials were measured against Ag/AgCl at a scan rate of 100 mV/s.
[b]Oxidations were measured in CH_2Cl_2 (dried over CaH_2)/tetra-*n*-propylammonium fluoroborate (~0.1 *M*) and reductions in DMF (distilled from solid KOH).
[c]Figures in parentheses refer to the derivative where chlorine is replaced by hydrogen (7).
[d]Reversible or quasi-reversible.
[e]A two-electron process.

(13) would be expected to show a smaller effect than the nitro group. Table 1 lists the redox properties of the halogenated complexes described above and it is apparent that the chlorine atoms have only a minimal effect, with the oxidation potentials being dominated by the nitro substituents. In fact, the electronegative chlorine atoms facilitate the oxidation by approximately 100–200 mV. The reductions are somewhat more affected by chlorine substitution but even the tetrachloro derivative (**6**) is reduced at a potential only 400 mV more negative than OEP.

In the case of the methoxy-nitroporphyrin (**15**), the two electronically opposed groups tend to neutralize each other and only small differences in redox properties are seen compared to OEP.

Received May 8, 1984

T. P. Forrest, G. A. Dauphinee, and S. A. Deraniyagala. Can. J. Chem. **63**, 412 (1985).

The commonly accepted mechanism for the acid-catalyzed disproportionation of 1,2-dihydroquinolines involves a hydride transfer from C-2 of one dihydroquinoline molecule to C-4 of another molecule which has already been protonated at C-3. This mechanism is shown to be incorrect. The proposed intermediate is shown to react by solvent addition and not by reduction under the conditions of the reaction. Evidence has been obtained which shows that the reaction proceeds by way of a 3,4-dihydroquinoline intermediate. A possible mechanism for the formation of the intermediate is discussed.

T. P. Forrest, G. A. Dauphinee et S. A. Deraniyagala. Can. J. Chem. **63**, 412 (1985).

Le mécanisme communément accepté pour la dimérisation, catalysée par les acides, des dihydro-1,2 quinoléines implique un transfert d'hydrure de la position C-2 d'une molécule de dihydroquinoléine à la position C-4 d'une autre molécule déjà protonée en C-3. On montre que ce mécanisme est inexact. On démontre que, dans les conditions utilisées pour la réaction, l'intermédiaire proposé réagit par addition de solvant et non par réduction. On a obtenu des indications qui indiquent que la réaction se produit via un intermédiaire dihydro-3,4 quinoléine. On discute du mécanisme possible pour la formation de cet intermédiaire.

[Traduit par le journal]

Introduction

The aromatization of an electron-rich dihydroaromatic system by hydride transfer is a well-known reaction typified by the ubiquitous hydride transfer reagents of nature, the reduced pyridine nucleotides. These reduced pyridine nucleotides are commonly considered (1) to function by transfer of a hydride ion directly to the substrate being reduced. Although this mechanism for the reduction step is commonly cited, a controversy regarding its validity has arisen during the past decade (2). Reduced quinolines are frequently used as models in the investigation of these mechanisms because they are more stable under the conditions required for reaction than are the corresponding N-alkyl-1,4-dihydronicotinamides, the other models commonly employed in these studies (3).

The 1,2-dihydroquinoline system is an example of a partially reduced heteroaromatic system which in a formal sense could act as both hydride donor and hydride acceptor, as do the reduced and oxidized pyridine nucleotides respectively. Such a redox reaction of 1,2-dihydroquinolines results in a disproportionation reaction yielding a quinoline and a tetrahydroquinoline. The mechanism of acid-catalyzed disproportionation of 1,2-dihydroquinolines (4), as well as their sulphur (5) (thiachromens) and oxygen (6) (Δ^3-chromens) analogues, has been commonly accepted as a protonation of the 3,4-double bond at C-3, thus creating a carbocation at C-4 which accepts a hydride ion from another molecule of the dihydroquinoline (Scheme 1). We wish to present results of our investigation of the acid-catalyzed disproportionation of 1,2-dihydroquinolines, which revealed that the generally accepted mechanism shown in Scheme 1 cannot be correct, and to indicate an alternate pathway for such a reaction.

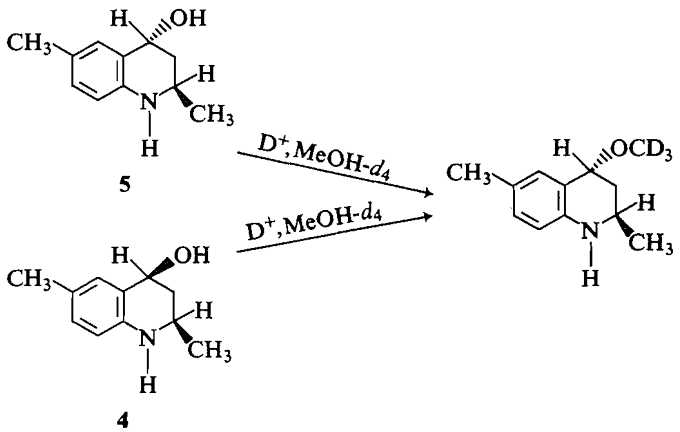
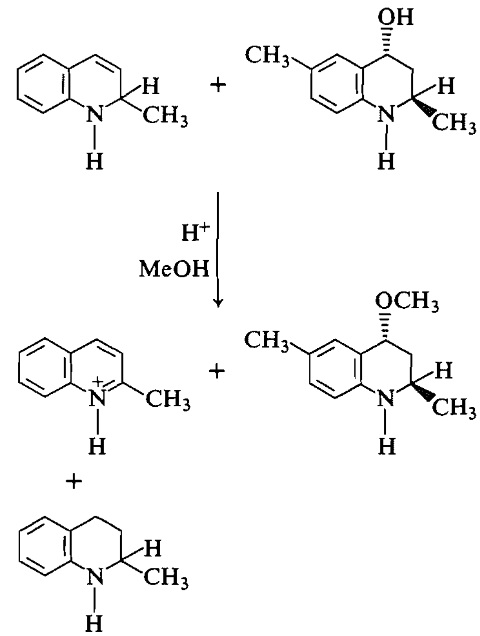
Scheme 1

Results and discussion

The commonly accepted intermediate for the disproportionation reactions, a carbocation at C-4, has been shown (7) to be formed by the acid-catalyzed hydrolysis of 4-phenylamino-2,6-dimethyl-1,2,3,4-tetrahydroquinolines. Since this carbocation underwent solvent addition during these hydrolysis reactions we were suspicious of its intermediacy in the disproportionation reactions because no solvent addition products were formed. To show that the intermediate would also add methanol, the solvent used in disproportionation reactions, we investigated the methanolysis of *cis* (**4**) and *trans* (**5**) 4-hydroxy-2,6-dimethyl-1,2,3,4-tetrahydroquinoline under conditions similar to those required by the disproportionation reaction. The kinetic product of methanolysis of 4-hydroxy-2,6-dimethyl-1,2,3,4-tetrahydroquinoline had the same stereochemistry (*trans*), irrespective of whether the starting material was the *cis* or the *trans* isomer (Scheme 2). When the methanolysis reaction was conducted in deuterated media no deuterium was incorporated at the C-3 position of the methoxy product, which indicated the absence of an elimination–addition pathway. When the methanolysis reaction was allowed to remain overnight, an equilibrium mixture of the *cis* and *trans* 4-methoxy-2,6-dimethyl-1,2,3,4-tetrahydroquinoline was obtained with the *trans* isomer in predominance (*trans*/*cis* = 2.5:1). These results are similar to those obtained (7) from the hydrolysis reaction, and support the existence of a C-4 carbocation intermediate during the methanolysis of 4-hydroxy-2,6-dimethyl-1,2,3,4-tetrahydroquinolines. No solvolysis products are observed in the disproportionation reactions of 1,2-dihydro-



SCHEME 2



SCHEME 3

quinoline (**1***c*), 2-methyl-1,2-dihydroquinoline (**1***a*), 2,6-dimethyl-1,2-dihydroquinoline (**1***d*), or 2-phenyl-1,2-dihydroquinoline (**1***b*), although, under the conditions employed, they might be expected to be the predominant products.

The lack of solvent addition products from the 1,2-dihydroquinolines might not be inconsistent with the intermediacy of a carbocation in the disproportionation reactions, as the formation of the solvolysis product is reversible (*vide infra*) and, as such, the carbocation is continuously regenerated and could eventually be completely reduced. It was therefore necessary to obtain confirmation of the non-participation of the carbocation in the disproportionation reaction. This was done by conducting a disproportionation reaction in the presence of an independent source of a similar carbocation to determine whether the added carbocation would be reduced. The experiment was performed by conducting the disproportionation of 2-methyl-1,2-dihydroquinoline (**1***a*) in weakly acidic methanol with *trans*-4-hydroxy-2,6-dimethyl-1,2,3,4-tetrahydroquinoline (**5**) added as the source of the additional carbocation (identical to that which would be formed from **1***a* except for the extra methyl group in the 6-position) (Scheme 3). The mixed reaction gave no 2,6-dimethyl-1,2,3,4-tetrahydroquinoline, the reduction product which would have been formed from **5** if the carbonium ion was reduced. The products of the reaction were the normal disproportionation products from **1***a*, and the normal solvolysis product from **5**. By following the progress of the reaction by ^{1}H nmr spectroscopy it could be seen that the disproportionation reaction was only slightly faster (half-life = 50 min) than the solvolysis of **5** (half-life = 70 min), thus indicating that the dihydroquinoline would have been available to carry out the reduction while the carbocation from **1***a* was present. In a similar experiment no 2,6-dimethyl-1,2,3,4-tetrahydroquinoline was obtained when a mixture of 2-phenyl-1,2-dihydroquinoline (**1***b*) and *trans*-4-hydroxy-2,6-dimethyl-1,2,4-tetrahydroquinoline was allowed to react in weakly acidic methanol.

In order to determine the origin of the hydrogens added to the dihydroquinoline, the disproportionation reactions were conducted in deuterated media. 2-Methyl-1,2-dihydroquinoline (**1***a*) yielded 2-methyl-1,2,3,4-tetrahydroqinoline (**2***a*), which had deuterium in position 3, as might be expected from the carbocation mechanism (Scheme 1); however, the labelling pattern was not simply that of one deuterium having been added at carbon-3. Nuclear magnetic resonance (nmr) spectroscopy (^{1}H and ^{2}H) indicated that the *cis* and *trans* hydrogens on carbon-3 each contained about 76% deuterium and that the methyl group was about 22% deuterated.[1] The mass spectrum of the product also showed the presence of monodeuterated, dideuterated, and trideuterated molecules. 2-Methylquinoline (**3***a*), the other product of the disproportionation reaction, also had deuterium in the methyl group (about 21%),[2] but it had no deuterium at carbon-3.

These labelling results may also be used as evidence against the mechanism shown in Scheme 1. The presence of deuterium at C-3 in the tetrahydroquinoline product (**2***a*) is compatible with the reversible protonation of the dihydroquinoline (**1***a*), but if reversible protonation had taken place, the 2-methylquinoline (**3***a*), the oxidized product of the reaction, would also have been labelled at carbon-3. It would appear that in order to explain the difference in the labelling pattern of the two products at C-3 it is necessary to postulate the irreversible formation of an intermediate which can exchange at C-3 and which is converted exclusively to the reduced product. This intermediate could not be the carbocation because it would in the exchange process revert to the starting material, and thus also label the oxidized product.

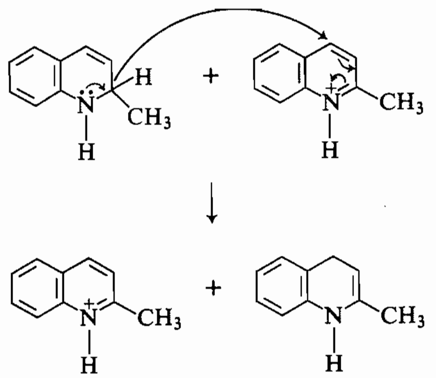
If the reduction does occur by a hydride transfer, it is necessary to propose the formation of an acceptor species other than the proposed carbocation intermediate.

The 1,2-dihydro species is quite stable to attack by hydride (8) (e.g. $LiAlH_4$), but the 3,4-dihydro species, as the imine tautomer, would be susceptible to attack by hydride (9). This intermediate could exchange at carbon-3 via the enamine–iminium equilibration.

Evidence in support of the 3,4-dihydro species as an intermediate was obtained from the deuterium labelling results of the disproportionation of differently substituted dihydro-

[1] That no deuterium was incorporated into the tetrahydro product after it was formed was shown by allowing 2-methyl-1,2,3,4-tetrahydroquinoline (**2***a*) to equilibrate in acidic methanol under identical conditions.

[2] 2-Methylquinoline (**3***a*), when equilibrated in deuterated acidic methanol under similar conditions to that of the disproportionation reaction, incorporated 26% into the methyl group.



SCHEME 4

quinolines. Disproportionation of 2-phenyl-1,2-dihydroquinoline (**1***b*) in deuterated media gave 2-phenyl-1,2,3,4-tetrahydroquinoline (**2***b*) which was almost completely deuterated at C-3 and 2-phenylquinoline (**3***b*) which contained no deuterium, whereas disproportionation of 1,2-dihydroquinoline (**1***c*) under similar conditions gave 1,2,3,4-tetrahydroquinoline (**2***c*) containing only 50% deuterium at C-3, indicating no exchange. The variation in the percentage of deuterium at C-3 with the change in the substituent at C-2 (phenyl = 100%, CH_3 = 76% (52% exchange), H = 50% (0% exchange)) is consistent with the stability of the proposed exchangeable intermediate. The most stable, longer-lived phenyl intermediate showed full exchange while the least stable intermediate showed only one deuterium at C-3, indicating no exchange had taken place.

The feasibility of reduction of the 3,4-dihydroquinoline intermediate (tautomeric with 1,4-dihydroquinoline) was determined by reacting 1,4-dihydroquinoline (**6**) with an equivalent amount of 2-methyl-1,2-dihydroquinoline (**1***a*) in acidic methanol. The products of the reaction, 1,2,3,4-tetrahydroquinoline and 2-methylquinoline, indicated that the 1,4-dihydroquinoline was completely reduced by the 1,2-dihydroquinoline. The inability of the 1,4-dihydroquinoline intermediate to produce the oxidized product of the reaction is indicated by the lack of formation of quinoline in this reaction. Similar results were obtained for the reaction of 1,4-dihydroquinoline (**6**) and 6-methyl-1,2-dihydroquinoline (**1***f*).

In the disproportionation reaction of 1,2-dihydroquinolines, the 3,4-dihydroquinoline intermediate could conceivably arise from a 1,4-reduction of a quinoline nucleus by a hydride transfer from a 1,2-dihydroquinoline (Scheme 4). The trace amounts of quinoline required for the initiation of the reaction would be unavoidably present in the samples of the 1,2-dihydroquinoline.

The susceptibility of the quinoline nucleus to reduction by 1,2-dihydroquinolines was investigated by reacting 2-methyl-1,2-dihydroquinoline (**1***a*) in different experiments with equimolar amounts of 6-methylquinoline (**3***f*), 2,6-dimethylquinoline (**3***d*), and 6-methyl-2-phenylquinoline (**3***g*). In each case the added quinoline was partially reduced to the respective 1,2,3,4-tetrahydroquinoline. Similarly, 6-methylquinoline (**3***f*), 2,6-dimethylquinoline (**3***d*), and 6-methyl-2-phenylquinoline (**3***g*) were reduced by 2-phenyl-1,2-dihydroquinoline (**1***b*) to the respective 1,2,3,4-tetrahydroquinoline.

Furthermore, when a mixed-label disproportionation was conducted using 2,6-dimethyl-1,2-dihydroquinoline (**1***d*) and 2-deutero-2-methyl-1,2-dihydroquinoline (**1***e*) as reactants, the deuterium labelling pattern of the tetrahydroquinoline products (determined by ^{13}C triple resonance spectroscopy with decoupling of ^{1}H and ^{2}H) showed that 42% of the 2,6-dimethyl-1,2,3,4-tetrahydroquinoline molecules had deuterium at C-2 and 37% had one deuterium at C-4. 2-Methyl-1,2,3,4-tetrahydroquinoline, the other reduced product of the mixed-label disproportionation, had 56% of the molecules with a deuterium on C-2 and 46% with a deuterium on C-4, thus confirming the exchange at C-2. The finding of deuterium at C-2 and C-4 of the tetrahydroquinoline product derived from the non-deuterated dihydroquinoline indicates that the dihydroquinoline had gone through the quinoline stage, being reduced by the deuterated 1,2-dihydroquinoline to the 4-deutero-1,4-dihydroquinoline intermediate followed by reduction of the latter (via its imine tautomer) at C-2 by another molecule of the deuterated 1,2-dihydroquinoline. The presence of ^{1}H at C-2 of the tetrahydroquinoline derived from the deuterated dihydroquinoline verifies this conclusion.

The above results clearly show that a 1,4-dihydroquinoline is an intermediate in the disproportionation reaction, and that this intermediate can be formed by reduction of a quinoline nucleus. Although at this point a mechanism involving a 1,4-reduction of a quinoline nucleus seems the most obvious pathway for the formation of the 1,4-dihydroquinoline intermediate, in the absence of detailed kinetic results such a proposal is unconfirmed and it may well be that the disproportionation of 1,2-dihydroquinolines takes place by somewhat a less obvious pathway; kinetic investigations are in progress.

Experimental

The nmr spectra were recorded on Varian T-60, Varian CFT-20, XL-100, Bruker-250, and Nicolet 360-MHz spectrometers in solvents as indicated. The chemical shifts are delta (δ) values and are given in ppm relative to TMS as internal standard. The "*J*" values reported are in hertz as line separations measured directly from the spectra. Mass spectra were recorded on a DuPont-CEC model 21-104 spectrometer with an ionizing voltage of 70 eV. The melting points were recorded on a Fisher Johns apparatus and are uncorrected.

Materials

Quinoline (Fisher), 6-methylquinoline (Fluka), and 2-methylquinoline (Aldrich) were distilled under reduced pressure and stored under nitrogen away from light. 2,6-Dimethylquinoline (mp 57–59°C) was obtained from Aldrich.

2-D-Quinoline

This was prepared by the reduction of 2-chloro quinoline with tin in D_2O by the method of Metzger *et al.* (10); nmr ($CDCl_3$, 60 MHz) δ: 7.28 (d, $J_{3,4}$ = 8.0, H-3), 7.36–8.20 (m, H-4 – H-8); ms *m/e* (relative intensity): 131(11), 130 (M^+, 100), 129(22), 103(8), 102(7).

1,2-Dihydroquinoline (1c)

A solution of quinoline (2.0 g, 15.5 mmol) in anhydrous ether (5.0 mL) was slowly added with stirring to lithium aluminium hydride (1.2 g, 31.6 mmol) in the same solvent (50.0 mL). The solution was stirred for 1.5 h. It was then cooled and water added dropwise under nitrogen until the solution turned colorless. Filtration, followed by drying the filtrate with anhydrous sodium sulphate and evaporation of the solvent (using minimum heat as necessary), yielded 1,2-dihydroquinoline as a white crystalline solid; mp 66.0–69.5°C (lit. (11) mp 70–72°C); nmr ($CDCl_3$, 60 MHz) δ: 3.50 (br, NH), 4.00 (dd, $J_{2,3}$ = 4.0, $J_{2,4}$ = 2.0, H-2), 5.43 (td, $J_{3,4}$ = 10.0, $J_{3,2}$ = 4.0, H-3), 6.0–6.85 (m, H-4 and aromatic protons); ms *m/e* (relative intensity): 131(100), 130(46), 104(6), 103(7).

6-Methyl-1,2-dihydroquinoline (1f)

This was prepared by a procedure identical to that of 1,2-dihydroquinoline, with the exception that 6-methylquinoline (2.2 g, 15.3 mmol) was used instead of quinoline; mp 57–59°C (lit. (12) mp 61°C); nmr ($CDCl_3$, 60 MHz) δ: 2.10 (s, CH_3), 3.97 (dd, $J_{2,3}$ = 4.0, $J_{2,4}$ = 1.0, H-2), 5.53 (dt, $J_{3,4}$ = 10.0, $J_{3,2}$ = 4.0), 6.40–6.70 (m, aromatic protons).

2-Methyl-1,2-dihydroquinoline (1a)

Methyl lithium (Aldrich, 1.3 *M* in ether, 8.0 mL, 10.4 mmol) was added to quinoline (0.6 g, 4.7 mmol) in anhydrous ether under an atmosphere of nitrogen. After 2 min, water was added dropwise until the yellow solution became colourless. The solution was filtered, dried with anhydrous sodium sulphate, and the solvent evaporated (colourless oil, 87% yield). The nmr and mass spectra are consistent with those reported (13).

2,6-Dimethyl-1,2-dihydroquinoline (1d)

This was prepared using an analogous procedure to that of 2-methyl-1,2-dihydroquinoline, with the exception that 6-methylquinoline was used instead of quinoline. Yield: 94%, mp 65.5–67.0°C (lit. (11) mp 60–63°C). The nmr and mass spectra are consistent with those reported (13).

2-D-2-Methyl-1,2-dihydroquinoline (1e)

Preparative procedure was identical to that of 2-methyl-1,2-dihydroquinoline with the exception that 2-D-quinoline was used instead of quinoline; nmr ($CDCl_3$, 60 MHz) δ: 1.18 (s, CH_3), 3.69 (br NH), 5.43 (d, $J_{3,4}$ = 10.0, H-3), 6.19–7.00 (m, H-4 and aromatic protons).

2-Phenyl-1,2-dihydroquinoline (1b)

Phenyl lithium (Aldrich, 1.8 *M* in cyclohexane–ether, 8.0 mL, 14.4 mmol) was added to quinoline (0.60 g, 4.7 mmol) in anhydrous ether under an atomosphere of nitrogen. After 2 min, water was added dropwise until the solution became colorless. The solution was filtered, the filtrate dried with anhydrous sodium sulphate, and the solvent evaporated. The compound was purified by column chromatography on silica gel (merck 70–230 mesh) using a 60:40 mixture of petroleum ether (30–60°C)/benzene as eluant. Yield: 83%, mp 51–52°C (lit. (14) mp 49–50°C); nmr ($CDCl_3$, 360 MHz) δ: 4.05 (br, NH), 5.39 (dd, $J_{2,4}$ = 1.6, $J_{2,3}$ = 3.9, H-2), 5.57 (dd, $J_{3,4}$ = 9.8, $J_{3,2}$ = 3.9, H-3), 6.34 (d, $J_{8,7}$ = 7.3, H-8), 6.36 (dd, $J_{4,3}$ = 9.8, $J_{4,2}$ = 1.6, H-4), 6.58 (t, $J_{6,7}$ = 7.3, $J_{6,5}$ = 7.3, H-6), 6.87 (d, $J_{5,6}$ = 7.3, H-5), 6.95 (t, $J_{7,8}$ = 7.3, $J_{7,6}$ = 7.3, H-7), 7.27–7.42 (m, phenyl protons); ms *m/e* (relative intensity): 207 (M^+, 20), 206(35), 205(24), 204(16), 130(100).

6-Methyl-2-phenyl-1,2-dihydroquinoline (1g)

The preparative procedure was identical to that of 2-phenyl-1,2-dihydroquinoline with the exception that 6-methylquinoline was used instead of quinoline. Yield: 88%, mp 58.0–60.5°C; nmr ($CDCl_3$, 60 MHz) δ: 2.16 (s, CH_3), 3.50 (br, NH), 5.28 (dd, $J_{2,3}$ = 4.0, $J_{2,4}$ = 2.0, H-2), 5.43 (td, $J_{3,4}$ = 10.0, $J_{3,2}$ = 4.0, H-3), 6.0–6.85 (m, H-4 and aromatic protons); ms *m/e* (relative intensity): 221 (M^+, 43), 220(73), 219(57), 218(19), 144(100).

1,4-Dihydroquinoline (6)

This was prepared by lithium in liquid ammonia reduction of quinoline according to the method of Birch and Lehman (15), mp 45–46°C. The compound was found to polymerize at room temperature, but was relatively stable in ether solution for 24 h under nitrogen at −15°C. The compound polymerized in $CDCl_3$ but was somewhat more stable in deuterobenzene; nmr (C_6D_6, 60 MHz) δ: 3.43 (dd, $J_{4,3}$ = 3.0, $J_{4,2}$ = 1.5, H-4), 4.36 (m, $J_{3,2}$ = 7.0, $J_{3,4}$ = 3.0, $J_{3,1}$ = 1.0, H-3), 4.90 (br, NH), 5.76 (m, $J_{2,4}$ = 1.5, $J_{2,3}$ = 7.0, $J_{2,1}$ = 4.0, H-2), 6.26–7.26 (m, aromatic protons).

2-Phenylquinoline (3b)

To a solution of 2-phenyl-1,2-dihydroquinoline (*1b*) (1.0 g, 4.8 mmol) in 95% ethanol (15.0 mL) was added dropwise with stirring a solution of iodine (15% in ethanol, ca. 12 mL). After ca. 20 min the excess of iodine was destroyed by the dropwise addition of sodium thiosulphate (20% aqueous). Removal of the ethanol, followed by extraction into ether, gave 2-phenylquinoline, which was recrystallized from ethanol/H_2O. Yield: 67%, mp 79.5–81.0°C (lit. (16) mp 84°C); nmr ($CDCl_3$, 60 MHz) δ: 8.3–7.4 (m, aromatic protons); ms *m/e* (relative intensity): 206(17), 205 (M^+, 100), 204(67), 103(9), 102(13).

6-Methyl-2-phenylquinoline (3g)

This was prepared by an analogous procedure to that of 2-phenylquinoline, using 2-phenyl-6-methyl-1,2-dihydroquinoline (*1g*) instead of 2-phenyl-1,2-dihydroquinoline. The compound was recrystallized from ethanol/H_2O. Yield: 70%, mp 64–65.5°C (lit. (17) 67°C); nmr ($CDCl_3$, 60 MHz) δ: 2.53 (s, 6-CH_3), 7.37–8.16 (m, aromatic protons); ms *m/e* (relative intensity): 220(19), 219 (M^+, 100), 218(37), 204(16).

Cis (4) and trans (5) 4-hydroxy-2,6-dimethyl-1,2,3,4-tetrahydroquinoline

This was synthesized according to the procedure of Edwards *et al.* (18) from acetaldehyde and *p*-toluidine; *cis* isomer, mp 164.0–165.0°C (lit. (7) 165°C); *trans* isomer, mp 110.0–111.0°C (lit. (7) 110°C). The spectroscopic data were identical to those reported by Forrest *et al.* (7).

Methanolysis of cis *(4) and* trans *(5) 4-hydroxy-2,6-dimethyl-1,2,3,4-tetrahydroquinoline*

Trans 4-hydroxy-2,6-dimethyl-1,2,3,4-tetrahydroquinoline (5) (200 mg, 1.1 mmol) was allowed to remain overnight in methanolic HCl (25.0 mL of 0.02 *M*), after which it was basified with 10% sodium hydroxide, and the solvent evaporated. The residue was then extracted into ether (2 × 20.0 mL). The ether extracts were washed with water (2 × 20.0 mL), dried over anhydrous sodium sulphate, and the solvent evaporated. The residue was identified as *cis* and *trans* 4-methoxy-2,6-dimethyl-1,2,3,4-tetrahydroquinoline, with the *trans* isomer in predominance (*trans/cis* = 2.5:1).

Cis 4-hydroxy-2,6-dimethyl-1,2,3,4-tetrahydroquinoline, when allowed to remain overnight in acidic methanol under identical conditions to that of the *trans* isomer, yielded the *cis* and *trans* methanolysis products in the same ratio as that observed for the *trans* isomer; nmr ($CDCl_3$, 360 MHz) *trans* isomer, δ: 4.12 (unresolved quartet, $J_{4e,3a}$ = 3.2, $J_{4e,3e}$ = 2.5, H-4e), 3.54 (m, $J_{2a,3e}$ = 2.5, $J_{2a,3a}$ = 12.2, J_{2a,CH_3} = 6.3, H-2) 3.39 (s, OCH_3), 2.22 (s, 6-CH_3), 2.06 (dt, $J_{3e,3a}$ = 13.5, $J_{3e,4e}$ = 2.5, $J_{3e,2a}$ = 2.5, H-3e), 1.45 (m, $J_{3a,4e}$ = 3.2, $J_{3a,3e}$ = 13.5, $J_{3a,2a}$ = 12.2, H-3a), 1.20 (d, $J_{CH_3,2a}$ = 6.3, CH_3). For the *cis* isomer, as obtained from the product mixture, nmr ($CDCl_3$, 360 MHz) δ: 4.55 (dd, $J_{4a,3a}$ = 10.1, $J_{4a,3e}$ = 5.8, H-4), 3.44 (s, OCH_3), 2.22 (s, 6-Me), 1.62 (apparent quartet, $J_{3a,3e}$ = 11.8, $J_{3a,2a}$ = 11.5, $J_{3a,4a}$ = 10.1, H-3a), 1.21 (d, $J_{CH_3,2}$ = 6.3, CH_3).

The progress of the methanolysis reaction was monitored by scanning the nmr spectrum of a reaction mixture containing *trans* 4-hydroxy-2,6-dimethyl-1,2,3,4-tetrahydroquinoline (30.5 mg, 0.17 mmol) in methanol-d_4 (0.50 mL) with DCl/D_2O (2.0 μL, 2.0 *M*) as acid catalyst.

The methanol-d_4 was evaporated from the reaction mixture, the residue basified, extracted into ether, and subjected to mass spectroscopic analysis. Mass spectrum, *m/e* (relative intensity): 195(5.8), 194(42), 161(7.0), 160(50), 158(53), 157(100), 144(94), 145(12).

The formation of the *trans* 4-methoxy-2,6-dimethyl-1,2,3,4-tetrahydroquinoline as the kinetic product of methanolysis from *cis* 4-hydroxy-2,6-dimethyl-1,2,3,4-tetrahydroquinoline (30.0 mg, 0.17 mmol) was observed by following its reaction in methanol-d_4 (0.50 mL) with DCl/D_2O (4.0 μL, 2.0 *M*) as acid catalyst.

Disproportionation reactions of 1,2-dihydroquinolines

All disproportionation reaction mixtures were worked up as follows: the methanol was evaporated from the reaction mixture, and the residue was made basic with 10% sodium hydroxide and extracted into ether (2 × 40.0 mL). The ether extracts were washed with water (2 × 40.0 mL), dried over anhydrous sodium sulphate, and the solvent evaporated.

Disproportionation of 2-methyl-1,2-dihydroquinoline (1a)

2-Methyl-1,2-dihydroquinoline (300 mg, 2.1 mmol) was allowed to remain overnight in methanolic HCl (50 mL, 0.02 *M*) under an atmosphere of nitrogen.

The product mixture after work-up was chromatographed on silica gel (Merck, 70–230 mesh). The 2-methyl-1,2,3,4-tetrahydroquinoline was eluted out with benzene, while the 2-methylquinoline was eluted out with chloroform.

2-Methyl-1,2,3,4-tetrahydroquinoline (2a): nmr ($CDCl_3$, 60 MHz) δ: 1.11 (d, $J_{CH_3,2}$ = 6.0), 1.30–2.16 (m, H-3), 2.30–2.66 (m, H-4), 3.13–3.67 (m, H-2), 3.53 (br, NH), 6.33–7.10 (m, aromatic protons) (lit. (19)). Mass spectrum, *m/e* (relative intensity): 147 (M^+, 34), 132(100), 130(11), 117(10).

2-Methylquinoline (3a): nmr ($CDCl_3$, 60 MHz) δ: 2.67 (s, CH_3), 7.10–8.18 (m, H-3 – H-8). Mass spectrum, *m/e* (relative intensity): 143 (M^+, 100), 128(14), 115(12).

Disproportionation of 1,2-dihydroquinoline (1c)

Methanolic HCl (28.0 mL, 0.02 *M*) was added to 1,2-dihydroquinoline (150 mg, 1.2 mmol) and allowed to remain overnight under an atmosphere of nitrogen. After usual work-up, the products were identified by comparison of the nmr spectrum of the product mixture to that of authentic quinoline and 1,2,3,4-tetrahydroquinoline.

Disproportionation of 2-phenyl-1,2-dihydroquinoline (1b)

2-Phenyl-1,2-dihydroquinoline (300 mg, 1.4 mmol) was allowed to disporportionate in methanolic HCl (35.0 mL, 0.02 *M*) under an atmosphere of nitrogen. Usual work-up gave a product mixture which was chromatographed on silica gel (Merck, 70–230 mesh). The 2-phenyl-1,2,3,4-tetrahydroquinoline was separated from the 2-phenylquinoline with a mixture of light petroleum ether/benzene = 60:40, and the 2-phenylquinoline eluted out with chloroform.

2-Phenyl-1,2,3,4-tetrahydroquinoline (2b): nmr ($CDCl_3$, 60 MHz) δ: 2.37 (m, H-3), 2.73 (m, H-4), 3.70 (bs, NH), 4.29 (dd, $J_{2,3a}$ = 8.0, $J_{2,3e}$ = 5.0, H-2), 6.40–7.30 (m, aromatic protons) (lit. (20)). Mass spectrum, *m/e* (relative intensity): 209 (M^+, 100), 208(41), 132(78), 130(21).

2-Phenylquinoline (3b): nmr ($CDCl_3$, 60 MHz) δ: 7.40–8.31 (m, aromatic protons). Mass spectrum, *m/e* (relative intensity): 206(17), 205 (M^+, 100), 204(68), 103(10), 102(13).

Disproportionation of 2-methyl-1,2-dihydroquinoline (1a) in the presence of trans *4-hydroxy-2,6-dimethyl-1,2,3,4-tetrahydroquninoline (5)*

2-Methyl-1,2-dihydroquinoline (150 mg, 1.0 mmol) and *trans* 4-hydroxy-2,6-dimethyl-1,2,3,4-tetrahydroquinoline (160 mg, 0.90 mmol) were allowed to remain overnight in methanol (6.0 mL, 0.02 *M*) with aqueous ammonium chloride (0.15 mL, 2.0 *M*) as acid catalyst, under an atmosphere of nitrogen. Following work-up, the product mixture was analyzed by mass spectroscopy to determine the presence of 2,6-dimethyl-1,2,3,4-tetrahydroquinoline from its molecular ion expected at *m/e* 161. Mass spectrum, *m/e* (relative intensity): 191(61), 161(12), 160(84), 158(52), 157(15), 147(20), 145(19), 144(100), 143(72), 132(50).

The progress of the reaction was monitored by repeated scanning of the nmr signals of a mixture containing 2-methyl-1,2-dihydroquinoline (10 mg, 0.07 mmol) and *trans* 4-hydroxy-2,6-dimethyl-1,2-dihydroquinoline (12 mg, 0.07 mmol) in methanol-d_4 (0.40 mL), with NH_4Cl in D_2O (0.01 mL, 2.0 *M*) as acid catalyst. The half-life for the methanolysis of *trans* 4-hydroxy-2,6-dimethyl-1,2-dihydroquinoline was obtained by following the integration for the disappearance of the upfield triplet of the C-3 equatorial proton relative to the integration of dioxane as internal standard. The half-life for the disproportionation of 2-methyl-1,2-dihydroquinoline was obtained by monitoring the disappearance of its proton at C-3. $t_{1/2}$ for the methanolysis of 4-hydroxy-2,6-dimethyl-1,2,3,4-tetrahydroquinoline = 70 min; $t_{1/2}$ for the disproportionation of 2-methyl-1,2-dihydroquinoline = 50 min.

Disproportionation of 2-phenyl-1,2-dihydroquinoline in the presence of 4-hydroxy-2,6-dimethyl-1,2,3,4-tetrahydroquinoline

2-Phenyl-1,2-dihydroquinoline (150 mg, 0.72 mmol) and 2,6-dimethyl-4-hydroxy-1,2,3,4-tetrahydroquinoline (130 mg, 0.73 mmol) were allowed to remain overnight in methanolic HCl (18.0 mL, 0.02 *M*) under an atmosphere of nitrogen. Following work-up of the reaction mixture in the usual manner, the mass spectrum of the product mixture was recorded to determine the presence of 2,6-dimethyl-1,2,3,4-tetrahydroquinoline from its molecular ion expected at *m/e* 161. By slowly increasing the source temperature, no peak at 161 was observed until the molecular ion (191) for the methoxy product appeared, and then only at the intensity expected for the isotope (*M* + 1) of the 160 ion. Mass spectrum, *m/e* (relative intensity): 209(4), 205(20), 191(11), 161(4), 160(28), 158(31), 145(13), 144(100), 132(10), 130(16).

Reaction of 2-methyl-1,2-dihydroquinoline (1a) with 1,4-dihydroquinoline (6)

A mixture of 2-methyl-1,2-dihydroquinoline (220 mg, 1.5 mmol) and 1,4-dihydroquinoline (180 mg, 1.4 mmol) as allowed to remain overnight in methanolic HCl (25.0 mL, 0.02 *M*) under an atmosphere of nitrogen. Following work-up, the nmr spectrum of the product mixture was recorded, from which 1,2,3,4-tetrahydroquinoline and 2-methylquinoline were identified as the major products of the reaction. A small amount of 2-methyl-1,2,3,4-tetrahydroquinoline was also present but no quinoline was observed.

Reaction of 6-methyl-1,2-dihydroquinoline (1f) with 1,4-dihydroquinoline (6)

6-Methyl-1,2-dihydroquinoline (200 mg, 1.5 mmol) and 1,4-dihydroquinoline (165 mg, 1.3 mmol) were left overnight in methanolic HCl (25.0 mL, 0.02 *M*) under an atmosphere of nitrogen. Following work-up, the product mixture was analyzed by nmr spectroscopy; the products of the reaction were 1,2,3,4-tetrahydroquinoline, 6-methylquinoline, and small amounts of 6-methyl-1,2,3,4-tetrahydroquinoline. No quinoline was formed.

Disproportionation of 1,2-dihydroquinoline in deuterated media

2-Methyl-1,2-dihydroquinoline (1a)

2-Methyl-1,2-dihydroquinoline (150 mg, 1.0 mmol) was allowed to remain overnight in contact with DCl/methanol-O-*d* (12.0 mL, 0.04 *M*), under an atmosphere of nitrogen. Following work-up in the usual manner, the product mixture was column chromatographed on silica gel (Merck, 70–230 mesh). 2-Methyl-1,2,3,4-tetrahydroquinoline was eluted with benzene, while chloroform was used to elute the 2-methylquinoline.

2-Methyl-1,2,3,4-tetrahydroquinoline (2a): nmr ($CDCl_3$, 250 MHz) δ: 1.23 (d, $J_{CH_3,2}$ = 6.8, 2.35 H), 1.62 (m, H-3a, 0.24H), 1.95 (m, H-3e, 0.23H), 2.81 (m, H-4, 2H), 3.43 (m, H-2, 1H), 3.63 (br, NH, 1H), 6.48–7.05 (m, aromatic protons, 4H); ^2H nmr ($CDCl_3$, 38.4 MHz) δ: 1.15, 1.50, and 1.86. Mass spectrum, *m/e* (relative intensity): 152(4), 151(9), 150(17), 149(30), 148(33), 147(18), 146(9), 145(11), 144(13), 143(9), 135(18), 134(100), 133(91), 132(38), 131(15), 130(9).

2-Methylquinoline (3a): mass spectrum, *m/e* (relative intensity): 145(5.6), 144(37.0), 143(100.0), 142(9.1), 129(1.7), 128(17.0).

2-Phenyl-1,2-dihydroquinoline (1b)

2-Phenyl-1,2-dihydroquinoline (155 mg, 0.75 mmol) was left overnight in DCl/methanol-O-*d* (9.0 mL, 0.04 *M*). Following work-up, the nmr spectrum of the product mixture was recorded; nmr ($CDCl_3$, 60 MHz) δ: 2.70 (s, (AB quartet at 360 MHz), H-4), 3.60 (br, NH), 4.30 (s, H-2), 6.40–8.23 (m, aromatic protons). The product mixture was then chromatographed on silica gel as for the reaction in protic media. Mass spectrum, *m/e* (relative intensity): 206(17.0), 205(100.0, M^+), 204(68.4), 103(10.5), 102(18.5). The mass spectrum was identical to that of authentic 2-phenylquinoline.

1,2-Dihydroquinoline (1c)

A reaction mixture consisting of 1,2-dihydroquinoline (150 mg, 1.1 mmol) in DCl/methanol-O-*d* (14.0 mL, 0.04 *M*) was allowed to remain overnight under an atmosphere of nitrogen. Work-up was carried out in the usual manner; nmr ($CDCl_3$, 60 MHz) δ: 1.86 (m, H-3, 1H), 2.73 (m, H-4, 2H), 3.18 (m, H-2), 3.79 (br, NH, 1H), 6.30–8.16 (m, aromatic protons), 9.80 (dd, *J* = 2.0, 4.5).

Blank experiments

2-Methyl-1,2,3,4-tetrahydroquinoline (**2***a*) isolated from the disproportionation of 2-methyl-1,2-dihydroquinoline (**1***a*) in protic media was allowed to equilibrate overnight in DCl/methanol-O-*d* (20.0 mL, 0.04 *M*), and the product was analyzed by nmr spectroscopy after work-up.

The product mixtures obtained from disproportionation of 1,2-dihydroquinoline (**1***c*) and 2-phenyl-1,2-dihydroquinoline (**1***b*) were similarly allowed to remain in deuterated media and then analyzed by nmr spectroscopy. The nmr spectra obtained in each of these three cases were identical to that of the compounds before equilibration in deuterated media.

2-Methylquinoline was similarly allowed to remain overnight in acidic methanol-O-*d*, and subjected to mass spectroscopic analysis after the usual work-up. Mass spectrum, *m/e* (relative intensity): 145(11), 144(52), 143(100).

Disproportionation of 1,2-dihydroquinolines in the presence of added quinolines

*Reaction of 2-methyl-1,2-dihydroquinoline (1*a*) in the presence of added quinolines*

2-Methyl-1,2-dihydroquinoline (**1***a*) (150 mg, 1.0 mmol) was allowed to remain overnight in methanolic HCl (26.0 mL, 0.02 *M*) under an atmosphere of nitrogen in the presence of each of 6-methylquinoline (**3***f*) (150 mg, 1.0 mmol), 6-methyl-2-phenylquinoline (**3***g*) (225 mg, 1.0 mmol), and 2,6-dimethylquinoline (**3***d*) (165 mg, 1.0 mmol). Following work-up, the relative percentages of the tetrahydroquinolines were calculated by integration of the singlet at δ 2.18 (6-methyl of 6-methyl-2-R-substituted-1,2,3,4-tetrahydroquinoline (R = CH_3, H, Ph)) and the doublet (J = 6.0) at δ 1.12 (2-CH_3 of 2-methyl-1,2,3,4-tetrahydroquinoline) in its nmr spectrum. Percentage of tetrahydroquinoline formed by the reduction of the added quinoline from that of the total tetrahydroquinoline content (relative percentages): 6-methylquinoline (49.1 ± 4.3%), 6-methyl-2-phenylquinoline (52.0 ± 4.8%), 2,6-dimethylquinoline (77.0 ± 2.5%). Errors are the mean deviations obtained from three sets of experiments.

*Reaction of 2-phenyl-1,2-dihydroquinoline (1*b*) in the presence of added quinolines*

2-Phenyl-1,2-dihydroquinoline (**1***b*) (150 mg, 0.7 mmol) was allowed to remain overnight in methanolic HCl (18.0 mL, 0.02 *M*) under an atmosphere of nitrogen in the presence of each of 6-methylquinoline (**3***f*) (103 mg, 0.7 mmol), 2-phenyl-6-methylquinoline (**3***g*) (160 mg, 0.7 mmol), 2,6-dimethylquinoline (**3***d*) (110 mg, 0.7 mmol). Thereafter, product mixtures obtained after usual work-up were analyzed for the relative percentages of the tetrahydroquinolines by integration of the peak at δ 4.29 (dd, 2-H of the 2-phenyl-1,2,3,4-tetrahydroquinoline) and δ 2.18 (s, 6-CH_3 of 6-methyl-2-R-1,2,3,4-tetrahydroquinoline (R = CH_3, H, Ph)) in its nmr spectrum. Percentage of tetrahydroquinoline obtained by reduction of the added quinoline from that of the total tetrahydroquinoline content (relative percentages): 6-methylquinoline (51.3 ± 4.2%), 6-methyl-2-phenylquinoline (72.4 ± 3.9%), 2,6-dimethylquinoline (60.0 ± 7.1%). Errors are the mean deviations obtained from three sets of experiments.

*Mixed labelled disproportionation of 2,6-dimethyl-1,2-dihydroquinoline (1*d*) and 2-d-2-methyl-1,2-dihydroquinoline (1*e*)*

2,6-Dimethyl-1,2-dihydroquinoline (**1***d*) (1.40 g, 8.8 mmol) and 2-*d*-2-methyl-1,2-dihydroquinoline (**1***e*) (1.30 g, 8.9 mmol) were dissolved in ethanol and 2 *M* aqueous ammonium chloride (1.0 cc) was added, and the solution allowed to remain under an atmosphere of nitrogen for 48 h. Following work-up, the product mixture was column chromatographed on silica (Merck, 70–230 mesh). Benzene was used to separate the tetrahydroquinolines from the quinolines and a 50:50 mixture of benzene – petroleum ether (30–60°C) was used to separate the individual tetrahydroquinolines. The ^{13}C nmr spectra, with proton and deuterium decoupling and chromium triacetylacetonate as relaxation reagent, were recorded for both. The product ratio of 2,6-dimethyl-1,2,3,4-tetrahydroquinoline to 2-methyl-1,2,3,4-tetrahydroquinoline was approximately 8:2.

2,6-Dimethyl-1,2,3,4-tetrahydroquinoline: ^{13}C nmr ($CDCl_3$, 25.2 MHz) δ: 47.44, 46.97 (C-2), 30.89 (C-3), 26.82, 26.44 (C-4).

2-Methyl-1,2,3,4-tetrahydroquinoline: ^{13}C nmr ($CDCl_3$, 25.2 MHz) δ: 47.74, 47.27 (C-2), 30.43 (C-3), 27.12, 26.72 (C-4).

RONALD F. CHILDS and ARAVAMUTHAN VARADARAJAN. Can. J. Chem. **63**, 418 (1985).

The circumambulatory rearrangements of some 8,8-dimethylhomotropylium cations and their corresponding iron tricarbonyl complexes have been examined. 8,8-Dimethylhomotropylium cation, **4**, has been prepared by protonation of 8,8-dimethylbicyclo[5.1.0]octa-3,5-dien-2-ol in FSO_3H/SO_2ClF. Evidence for homoaromatic delocalization in **4** was found in its characteristic ^1H nmr spectrum, particularly when this was compared to that of the non-cyclically delocalized 8,8-dimethylbicyclo[5.1.0]octadienyliron tricarbonyl complex **7**. Cation **4** was found to be stable at low temperatures but to isomerize to isopropyltropylium ion, **8**, at −50°C, $k = (4.6 \mp 0.2) \times 10^{-4}\ s^{-1}$. The specifically deuterated cation **4D** was prepared and a slow circumambulation of C8 around the basal 7-membered ring of this cation was found to occur at −90°C. The free energy of activation for this circumambulation is 14.5 kcal/mol. Homotropylium cation **4** was also prepared by protonation of 8,8-dimethylbicyclo[3.2.1]octa-3,6-dien-2-ol, **14**, at −120°C. No evidence for the presence of the corresponding bicyclo[3.2.1]octadienyl ion **12** was obtained. The 2,8,8-trimethylhomotropylium cation, **17**, was prepared and shown to undergo a circumambulatory rearrangement to give the 4,8,8-trimethyl substituted cation **20** as the major product. In this trimethyl series it also proved possible to generate the 2,8,8-trimethylbicyclo[3.2.1]octadienyl cation, **18**, and observe its ^1H nmr spectrum at very low temperatures (−116°C). The proton chemical shifts of **18** suggest that the charge is predominantly located on the 3-carbon bridge. Cation **18** isomerized to **17**, **20**, and other products at temperatures above −100°C. The 2,8,8-trimethylbicyclo[5.1.0]octadienyliron tricarbonyl complex **22** was also shown to undergo a circumambulatory rearrangement in which both C8 and the $Fe(CO)_3$ grouping migrate.

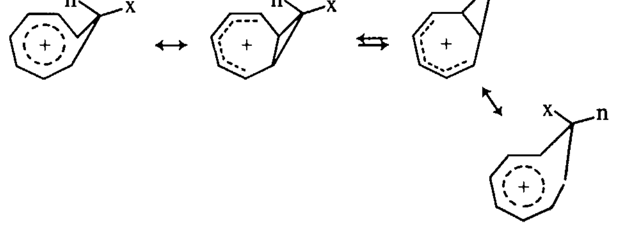
RONALD F. CHILDS et ARAVAMUTHAN VARADARAJAN. Can. J. Chem. **63**, 418 (1985).

On a étudié les transpositions circambulatoires des quelques cations diméthyl-8,8 homotropylium et des complexes fer-tricarbonyles correspondants. On a préparé le cation diméthyl-8,8 homotropylium (**4**) par protonation du diméthyl-8,8 bicyclo[5.1.0]octadiène-3,5 ol-2 dans un mélange FSO_3H/SO_2ClF. C'est dans son spectre rmn ^1H caractéristique que l'on a trouvé des indices de l'existence d'une délocalisation homoaromatique dans **4** et particulièrement lorqu'on l'a comparé au spectre rmn du complexe **7**, le diméthyl-8,8 bicyclo[5.1.0]octadiènyl-fer-tricarbonyle, qui n'est pas délocalisé d'une façon cyclique. On a trouvé que le cation **4** est stable à basses températures mais qu'il s'isomérise en ion isopropyltropylium (**8**) à −50°C avec une constante $k = (4{,}6 \mp 0{,}2) \times 10^{-4}\ s^{-1}$. On a préparé le cation **4D** spécifiquement deutéré et on a trouvé que, à −90°C, il se produit une circambulation lente de C8 autour du cycle de base à 7 chaînons de ce cation. L'énergie libre d'activation de cette circambulation est de 14,5 kcal/mol. On a aussi préparé le cation homotropylium **4** par protonation du diméthyl-8,8 bicyclo[3.2.1]octadiène-3,6 ol-2 (**14**) à −120°C. Les résultats obtenus n'ont pas permis de mettre en évidence la présence de l'ion bicyclo[3.2.1]octadiènyle correspondant, **12**. On a préparé le cation triméthyl-2,8,8 homotropylium (**17**) et on a observé qu'il subit une transposition circambulatoire conduisant au cation triméthyl-4,8,8 substitué (**20**) comme produit principal. Dans la série des produits triméthylés, on a aussi pu générer le cation triméthyl-2,8,8 bicyclo[3.2.1]octadiènyle (**18**) et observer son spectre de rmn ^1H à de très basses températures (−116°C). Les déplacements chimiques des protons du composé **18** suggèrent que la charge est localisée principalement sur le pont à trois chaînons. A des températures supérieures à −100°C, le cation **18** s'isomérise pour donner, entre autres, les cations **17** et **20**. On a aussi démontré que le complexe triméthyl-2,8,8 bicyclo[5.1.0]octadiènyl-fer-tricarbonyle (**22**) subit aussi une transposition circambulatoire dans laquelle le C8 ainsi que la $Fe(CO)_3$ migrent tous les deux.

[Traduit par le journal]

The homotropylium cation can potentially undergo a degenerate circumambulatory rearrangement in which the bridging methylene group migrates around the basal carbons that form the "seven-membered ring", eq. [1] (1). As a suprafacial [1,6] sigmatropic shift, this rearrangement would be expected to proceed thermally with retention of configuration at C8. This would lead to an overall interconversion of the *exo* and *endo* substituents at each step.

[1]



In contrast to the frequent occurrence of comparable circumambulation rearrangements with the analogous bicyclo[3.1.0]-hexenyl cations, there are few reports of such reactions with homotropylium cations. The activation energies required for circumambulation to occur in homotropylium ions appear to be high. For example, the parent cation has been investigated in some detail and it has been shown that the barrier to circumambulation must be at least 26–27 kcal/mol (2).

The high energy barriers associated with thermally induced circumambulation of homotropylium cations would seem to stem from two factors, first, the constraints of orbital symmetry and, second, the thermodynamic stability of these cations. If circumambulation were to occur by a concerted, symmetry-allowed process then the transition state for the reaction would have an unfavourable geometry. Migration with retention of configuration, the thermally allowed process, involves a large twisting motion of C8 and this type of migration would be expected to be difficult on geometric grounds. In contrast, the ground state symmetry-forbidden but photochemically allowed

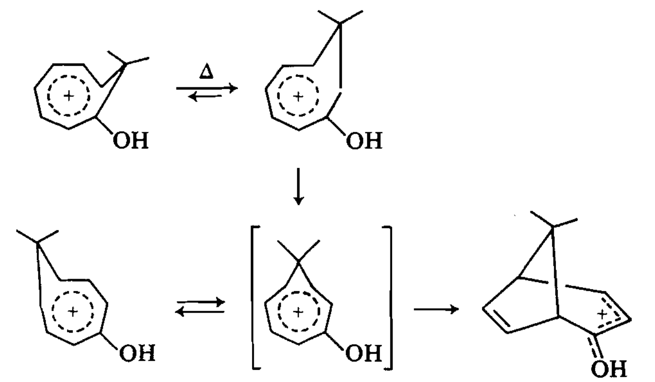


SCHEME 1

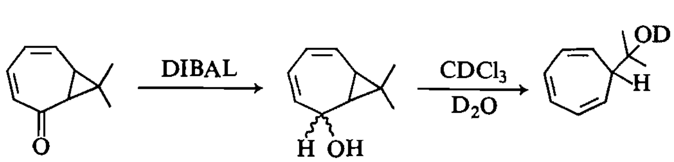
migration involving inversion of configuration at the migrating carbon is a least-motion reaction and, indeed, stereoselective circumambulatory rearrangements have been detected on irradiation of 2-hydroxyhomotropylium cations (3, 4).

Compounding these geometrical factors is a thermochemical consideration. Homotropylium cations are homoaromatic and the cyclic delocalization in these cations results in a measurable stabilization (5). For circumambulation to proceed it is necessary to disrupt this cyclic delocalization and this will be reflected in the high activation energies associated with this process. As an increased fraction of the positive charge is transferred onto C8, the migrating carbon in the transition state, the aromatic stabilization of the ground state of these cations can be partly offset by placing charge stabilizing groups at C8. Thus we have shown that 8,8-dimethyl substituted hydroxyhomotropylium cations undergo the series of thermally induced circumambulations shown in Scheme 1 (4, 6, 7).

In this present paper we extend our studies of these perambulating systems to the parent 8,8-dimethylhomotropylium cation. In particular we hoped that circumambulations with this ion might be sufficiently facile to permit observation by dynamic nmr methods and thus enable the stereochemistry of these reactions to be probed. Secondly, it was intended to further explore the nature of the conversion of the homotropylium cations to bicyclo[3.2.1]octodienyl shown in Scheme 1. This intriguing reaction involves the conversion of a homoaromatic cation to what may be considered formally to be an "anti-bis-homoaromatic system", a reaction which at first glance seems to be going in the wrong direction.

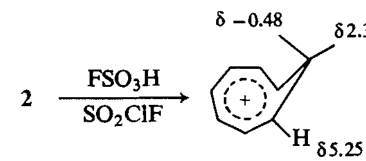
Results and discussion

Reduction of homotropone **1** (8) with diisobutylaluminum hydride (9) gave the reactive alcohol **2**. The ^{1}H nmr spectra of **2** were consistent with its assigned structure. In attempting to exchange the OH proton of **2** with deuterium in order to simplify the nmr spectrum using D_2O in $CDCl_3$ at room temperature, it was noted that **2** isomerized to cycloheptatriene **3** (10). The extreme ease of this isomerization precluded storage of **2** for any length of time and this alcohol was used directly in subsequent reactions.



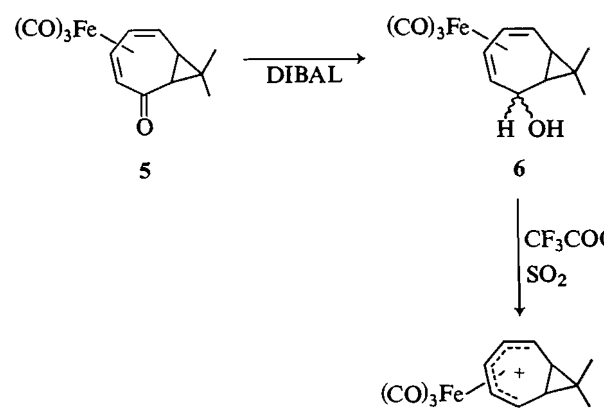
1 **2** **3**

Dissolution of **2** in FSO_3H/SO_2ClF at −78°C led to the formation of **4**. The ^{1}H nmr spectrum of this cation, obtained at −80°C, consisted of four resonances (Table 1), the positions of which were clearly indicative of the formation of the 8,8-dimethylhomotropylium cation. The chemical shift difference between the two methyl groups was large, as would be expected for such a homotropylium cation, and the positions of the resonances of the ring protons show a similar pattern to those of the parent homotropylium cation (11). Interestingly, the bridgehead protons (H1, H7) occur about 1 ppm upfield of the comparable protons of homotropylium cation itself, suggesting perhaps more cyclopropyl character for the C1, C7 bond in **4**. Comparable effects of a *gem*-dimethyl group have been observed with the bridged [10]-annulenes (12). The signal corresponding to the *exo* methyl protons was relatively broad at low temperature (−80°C) but sharpened as the temperature was raised. Similar broadenings of the *exo*-methyl resonances were observed with corresponding neutral compounds and presumably result from restricted rotation of the methyl group at low temperatures.



4

As a model for the chemical shifts to be expected for a nonaromatic counterpart of **4**, the corresponding iron complex was prepared. Reduction of **5** (8) gave **6**, which was again found to be unstable. Ionization of **6** in a CF_3COOH/SO_2 mixture gave **7**, which exhibited an ^{1}H nmr spectrum (Table 1) which was completely different from that of **4**. The chemical shift difference between the resonances of the C8 methyl groups was only 0.02 ppm. Apart from the resonance attributed to the methyl groups, the nmr spectrum of **7** was comparable to the corresponding iron complex of the parent system (13).



7

In order to determine whether circumambulatory rearrangements occurred with **4**, its ^{1}H nmr spectra were examined at higher temperatures. No evidence for the broadening or averaging of the ring proton resonances in the nmr spectra of **4** was observed at temperatures up to −50°C. Degenerate circumambulatory rearrangements of this cation must therefore be slow on the nmr time scale ($\Delta G^{\neq}$ >12 kcal/mol).

At −50°C, **4** was observed to isomerize irreversibly to iso-

TABLE 1. ^{1}H nuclear magnetic resonance spectra

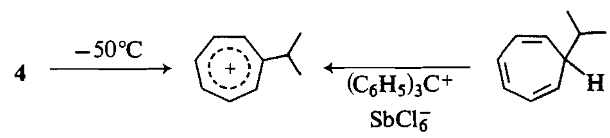
[b] Assignments may be reversed.

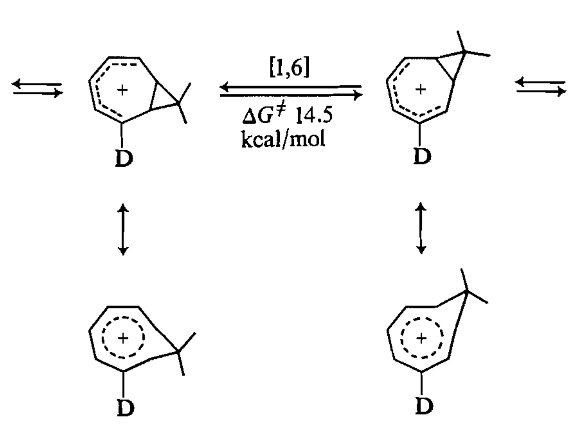
propyltropylium cation, **8** (14). This cation was identified by its independent synthesis from 7-isopropylcycloheptatriene. The first-order rate constant for the isomerization of **4** to **8** was $(4.6 \mp 0.2) \times 10^{-4}\ s^{-1}$ at −50°C, corresponding to a $\Delta G^{\neq} = 16.3$ kcal/mol.



8 9

The occurrence of this irreversible isomerization to **8** precluded the investigation of possible circumambulations of **4** at higher temperatures by dynamic nmr methods. Instead it was decided to label the seven-membered ring with a single deuterium atom at C2. A degenerate circumambulatory rearrangement would distribute the label equally over all the seven carbons. This process will result in an increase in intensity of the signals for the vinyl protons H2–H6 and a decrease in the intensity of the signal for the methine protons H1 and H7, in the ^{1}H nmr spectrum. Thus, the intensity of the signal for the vinyl protons H2–H6 would change from the relative value of 4 in the starting cation before the rearrangement, to 4.29 after complete equilibration, and that of the signal for the methine protons H1 and H7 would change from the starting relative value of 2 to the final value of 1.71. In other words, the ratio of the relative intensities of these two signals would increase from a starting value of 2 to the final value of 2.51 after complete equilibration.

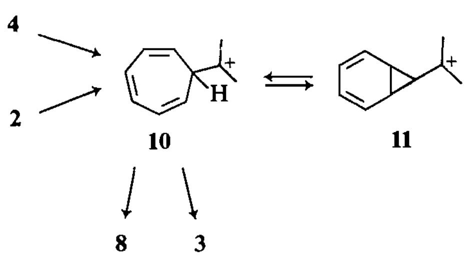
The alcohol **2D** was prepared by the lithium aluminium deuteride reduction of **1** in ether at −78°C. Protonation of this alcohol in $CFCl_3$–SO_2ClF–FSO_3H medium at −116°C led to the formation of **4D**. On warming from −120°C to −70°C in steps of 10°C, the ratio of the integrals for the vinyl and the methine proton signals in the ^{1}H nmr spectrum of **4D** increased from 1.9 to 2.55. At −70°C this value remained constant at 2.45 ∓ 0.09 for several minutes. On the basis of the predictions made earlier, this observation would indicate the occurrence of deuterium scrambling in **4D**, presumably via circumambulation of the C8 group. Continued observation of the same sample at −70°C by nmr showed that the intensities of the signals for all the protons decreased slowly with time. This could be attributed to the slow formation ($k = (3.7 \mp 0.06) \times 10^{-5}\ s^{-1}$) of the isopropyltropylium cation **8D**. As the resonances of the ring protons of **8** occur as a singlet in its ^{1}H nmr spectrum, it was not possible to locate the positions of the deuterium in **8D**.



In a further attempt, observations were made on the cation **4D** at −90°C, in order to obtain the rate constant for the circumambulation. Conversion to the isopropyltropylium cation **8D** would be expected to slow down considerably at this temperature. Measurement of the increase in the relative intensity (peak height) of the signal for the vinyl proton with time yielded a rate constant of $(2.0 \mp 1) \times 10^{-5}\ s^{-1}$ corresponding to a free energy of activation of 14.5 kcal/mol.

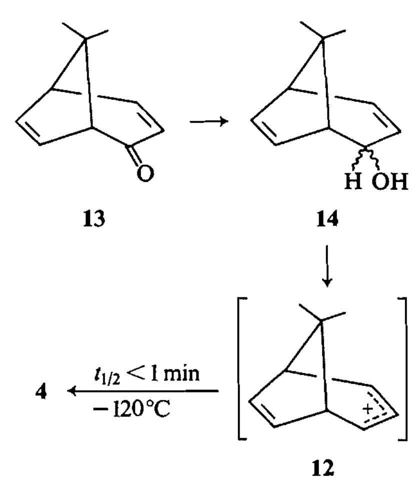
No stereochemical information could be obtained here about the course of this reaction. Hehre has suggested, on the basis of calculations at the STO-3G level, that the barrier to circumambulation by the symmetry-forbidden inversion process should be 13 kcal/mol while the formally allowed retention mechanism requires 28 kcal/mol (15). The agreement between the calculated and measured barrier for this process is gratifying but it should not be taken as definitely establishing the steric course of circumambulation in these ions.

The conversion of **4** to **8** and analogous isomerization of **2** to **3**, presented earlier, could formally involve a cation such as **10**. A hydride shift from C7 of **10** to the cationic center would lead to **8**, whereas attack by water would yield **3**. The difficulty with such a mechanism is that cycloheptatriene carbinyl cations are known to exist primarily as their norcaradiene valence tautomers, e.g. **11**, which readily collapse to benzenoid species (16). While nucleophilic attack on **11** could still lead to species such as **3**, a hydride shift is unlikely to occur. Alternatively it may be possible, as suggested by Hehre (15), that **10** is stabilized by hydrogen bridging of the proton on C7. For such a bridging to occur the conformation of **10** must be the same as that involved in the transition state from symmetry-allow circumambulation.



8,8-Dimethylbicyclo[3.2.1]octadienyl cation

Unlike the hydroxy substituted analogues referred to in Scheme 1, homotropylium ion **4** does not appear to rearrange to a bicyclo[3.2.1]octadienyl cation. In order to check the properties of this latter ion, attempts were made to prepare **12**



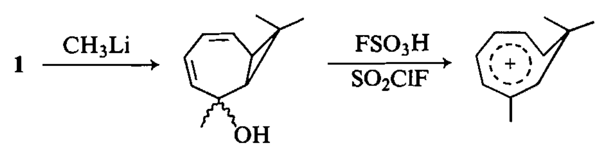
independently by an alternative route.

Reduction of **13** (4) gave **14**, which was subsequently protonated and ionized by dissolution in FSO_3H/SO_2ClF at −120°C. The ^1H nmr spectrum of the solution was recorded at −120°C and only signals attributable to **4** could be detected. By working rapidly and keeping prepared cation samples frozen at liquid nitrogen temperatures, it was possible to obtain a spectrum within 3 min of the initial preparation. Even under these conditions, no resonance other than those of **4** could be detected. The half-life of **12** at −120°C must be less than 1 min. At higher temperatures **4** rearranged to **8** as described before.

The isomerization of **12** to **4** is the reverse of the reaction observed with the hydroxy system, Scheme 1, indicating that the position of the equilibrium between homotropylium and bicyclo[3.2.1]octadienyl cations is delicately balanced. Clearly substituents can alter the position of the equilibrium. Viewing the situation in a simplistic way, there is proportionately less positive charge on each of the seven basal carbons of **4** than there is on C2 or C4 of the allyl portion of **12**. Consequently charge stabilizing substituents will affect the relative energy of **12** more than that of **4**. It is interesting that Hart, in his extensive studies of polymethylated bicyclo[3.2.1]octadienyl cations, uncovered a variety of isomerization pathways but never detected a rearrangement to a substituted homotropylium cation (17). Presumably multiple alkyl substitution pushes the equilibrium constant well in favour of the bicyclo[3.2.1]octadienyl form.

Trimethyl substituted systems

Entry into the trimethyl substituted systems was provided by the reaction of ketones **1** and **13** with methyl lithium to give **15** and **16**, respectively. The low temperature protonation of **15** led to the formation of **17**, which was characterized by the very large chemical shift difference between the C8 methyl resonances and typical positions of the ring protons. This ion was stable at −80°C although it underwent a complex series of rearrangements at higher temperatures.



15 **17**

The protonation of **16** was carried out at −120°C using a mixture of $FSO_3H/SO_2ClF/SO_2F_2$. Observation of the resulting solution by ^1H nmr at −116°C suggested that the bicyclic cation **18** was formed.

The ^1H nmr of **18** (Table 1) showed the presence of three methyl groups with one of them occurring at δ 3.08, a relatively low field position for a methyl resonance. In addition, there were four vinyl protons with one being at a very low field position (δ 9.55). The low field methyl and vinyl resonances are very suggestive of the presence of a methyl substituted allyl cation. For example, the 1-methylcyclohexenyl cation exhibits resonances at δ 9.73, 8.08, and 3.36 (H3, H2, and CH_3, respectively) (18). The positions of the other resonances of the cation produced on protonation of **16** are entirely consistent with its formulation as **18**, with the bulk of the positive charge being located on the allyl portion of the molecule. The spectrum of **18** is similar to that of the corresponding protonated

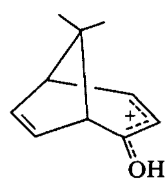
18

ketone **19** but with all the resonances moved somewhat further downfield, as would be expected for an allyl cation lacking the stabilizing effect of a hydroxy substituent.



19

Both **17** and **18** are thermally labile and undergo a complex series of rearrangements. A solution of **17** was heated to −70°C for 1 h and an ^1H nmr spectrum obtained, Fig. 1. A very similar spectrum was obtained with a solution of **18** which had been heated to −60°C for 10 min. One or more uncharacterized intermediary cations were observed during the course of this latter isomerization. The major cation present in the final mixtures, in addition to **17**, appeared to be a further homotropylium cation. It exhibited methyl resonances at δ −0.27, 2.37, and 2.87 and ring proton resonances which were very similar to that of **17**. By obtaining ^{13}C nmr spectra of **17** at low temperatures prior to isomerization and of the mixture after the isomerization, and using a spectral subtraction technique, it was possible to obtain the ^{13}C nmr spectra of this additional trimethylhomotropylium cation and show that it had the struture **20**. In particular, the ^{13}C spectra exhibited a symmetry which is only consistent with this structure, Table 2.

The other cations present in these solutions were not identified. At higher temperatures still (−30°C), further isomerizations occurred to give what appeared to be a mixture of isopropylmethyltropylium ions. These reactions were not followed in detail.

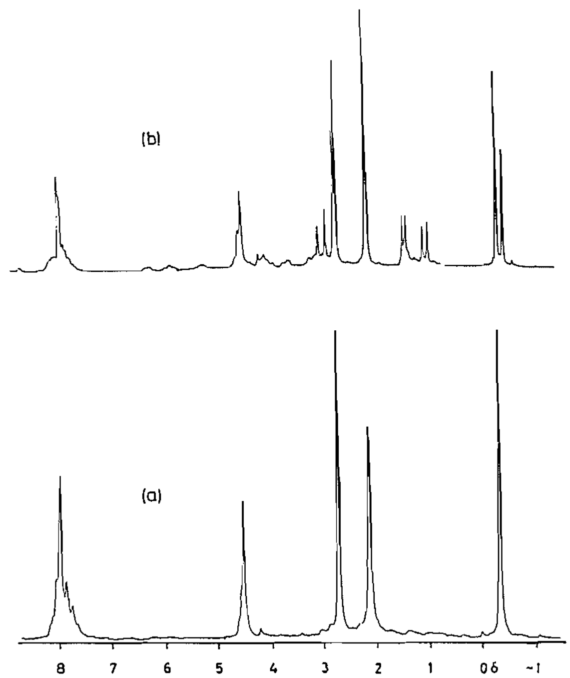


FIG. 1. The ^1H nmr spectrum of **17** in FSO_3H/SO_2ClF (a) at −80°C and (b) after 1 h at −70°C.

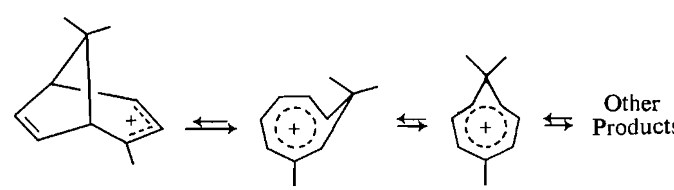


18 (trace) **17** (48%) **20** (29%) (23%)

While it has not been possible to completely characterize all the cations present in these rearrangements, several important points emerge from these rather complex rearrangements of the trimethyl substituted cations **17**, **18**, and **20**. First, it is clear that the bicyclo[3.2.1]octadienyl cation **18** is thermodynamically less stable than the homotropylium cations **17** and **20**. The fact that **18**, in contrast to **10**, can be directly observed by ^1H nmr at low temperatures suggests that the energy difference between these trimethyl substituted bicyclo[3.2.1]octadienyl, homotropylium cations is more closely balanced. Second, the isomerization of **17** to **20** represents a further example of a circumambulation in homotropylium cations. Third, of the four possible methyl substituted 8,8-dimethylhomotropylium cations the 2(6)- and 4-substituted isomers **17** and **20** are the most stable. Bearing in mind entropy factors, the symmetrical isomer **20** is marginally more stable than **17** (~80 cal/mol). The 1(7)- and 3(5)-methyl substituted isomers were present to less than 1%, meaning that they are some 1700 cal/mol less stable than **20**. These results suggest that the greatest fraction of positive charge in the homotropylium cations is at C2, C4, and C6. A similar conclusion was reached in the case of the hydroxy-8,8-dimethylhomotropylium cations (4).

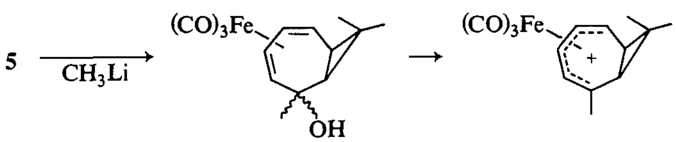
Structure of bicyclo[3.2.1]octadienyl cations

Diaz *et al.* (19) and Shin (20) have concluded on the basis of solvolytic work and nmr studies, respectively, that the bicyclo[3.2.1]octadienyl cations are antihomoaromatic, a conclusion which is at odds with that of Mayr and co-workers (21). It is clear from the results described above that the 8,8-dimethylbicyclo[3.2.1]octadienyl and homotropylium cations are relatively close in energy and this would suggest that there is no large destabilization of the former cations.

The trimethyl substituted cation **18** is the simplest bicyclo-[3.2.1]octadienyl cation which has yet been prepared as a long-lived species in solution, and [1]H nmr chemical shifts of the various protons are informative in terms of the delocalization in this ion. As was mentioned earlier, chemical shifts of the allyl portion of **18** are similar in position to those of other similarly substituted allyl cations. The question, however, is whether there is involvement of the electrons of other double bonds. On protonation, the H6 and H7 resonances of **16** are shifted downfield by 1.13 and 1.37 ppm, respectively (Table 1). The magnitude of this shift is larger than would be expected on the basis of inductive effects alone and is suggestive of a π-type overlap. However, it should be noted that the downfield shift of H4 (2.71 ppm) and H3 (3.62 ppm) is three times as great as those seen for H6 and H7, indicating that **18** can be viewed primarily as an allylic system.

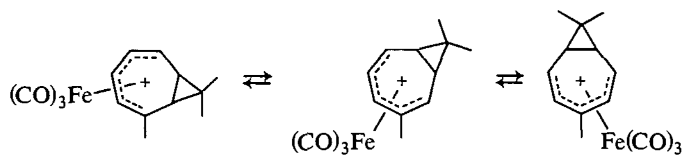
Circumambulations in bicyclo[5.1.0]octadienyliron tricarbonyl complexes

The presence of the iron tricarbonyl group on **7** does not necessarily preclude circumambulations from taking place in this system. While no broadening of the various resonances of the [1]H nmr spectrum of **7** could be detected on heating the acid solutions to −10°C, a slow circumambulation could be occurring with this cation. To examine this, the trimethyl cation **22** was prepared, in which the methyl group can serve as a ring label.

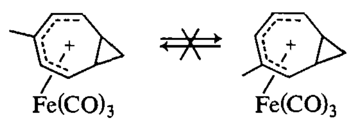


21 **22**

Treatment of **5** with methyl lithium gave **21**, which was subsequently converted to **22** by adding it to a mixture of CF_3COOH and SO_2 at low temperatures. The low temperature (−50°C) [1]H nmr spectrum of **22** (Table 1) was entirely consistent with the indicated structure, it being very similar, apart from the C2-Me signal, to that of **7** and other bicyclo[5.1.0]-octadienyliron tricarbonyl complexes (13). As the acid solution of **22** was warmed to −40°C, it partially isomerized to two additional cations. It was apparent from their [1]H nmr spectra



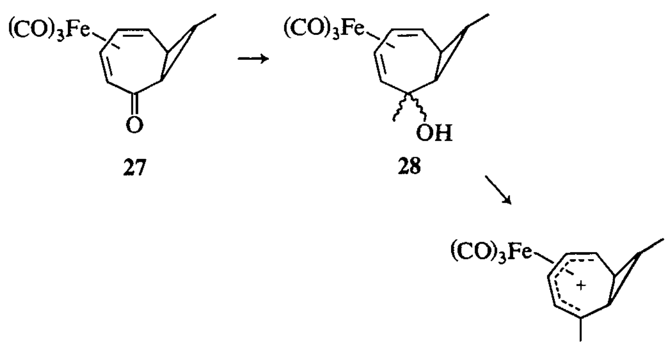
22 (18%) **23** (43%) **24** (29%)



25 **26**

that these ions were similar in structure to **22** and they have been assigned the structures **23** and **24**. The resonances of the various protons of **22** and **23** were assigned on the basis of decoupling experiments and comparison with the shifts of **25** and **26** reported by Brookhart *et al.* (13). An equilibrium was established between these three cations containing **22** (18%), **23** (43%), and **24** (39%).

No comparable interconversions of **25** and **26** have been reported. In order to see if a single methyl group at C8 were sufficient to permit circumambulations in these iron complexes, cation **29** was prepared. This species was unchanged when heated at 0°C for 16 h and seemingly no circumambulatory rearrangements take place in this system ($\Delta G^{\neq} >$ 22.9 kcal/mol).



27 **28** **29**

It is clear from these results that circumambulatory rearrangements in these bicyclic iron complexes require the presence of a *gem*-dimethyl grouping at C8, the migrating carbon, indicating that considerable positive charge is localized on this carbon during the migration. The iron tricarbonyl moiety has also to migrate during this unusual type of circumambulation. The timing of the two migrations which are involved in the overall circumambulation, stereochemical considerations, and the possible occurrence of any intermediates remain speculative.

Experimental

General

The [1]H nmr spectra were obtained on Varian EM-390 and HA-100, and Bruker WP-80, WH-90, and WM-250 spectrometers. Probe temperatures were measured using an iron–constantan thermocouple. Chemical shifts of cations are referred to tetramethylammonium tetrafluoroborate taken as δ 3.1 ppm. The ir spectra were obtained on a Perkin–Elmer model 283 spectrometer and mass spectra were run on a VG-7070-F mass spectrometer operating at an ionization potential of

70 eV.

FSO_3H was purified before use by distillation from a small quantity of anhydrous NaF. The distilled acid was stored in glass ampoules. SO_2ClF and SO_2F_2 were used as supplied.

*2-Deutero-8,8-dimethylbicyclo[5.1.0]octa-3,5-dien-2-ol, **2D***

$LiAlD_4$ (29.1 mg) was added to a solution of **1** (85.3 mg) in anhydrous ether (5 mL) kept at −78°C under nitrogen. The resulting heterogeneous mixture was stirred at this temperature, under nitrogen for 1 h, after which time the yellow color of the starting material disappeared. CH_3OH (10 mL) was added, and the solution stirred for 15 min. The solution was warmed to room temperature and filtered twice through Celite to remove the coagulated solid. The solvent was evaporated to give the crude alcohol **2D** as a pale yellow liquid. The product was purified by bulb-to-bulb distillation (110°C/7.5 Torr; 1 Torr = 133.3 Pa), yield: 67.5 (mg).

In the ^1H nmr spectrum of **2D**, the signal at δ 4.78 corresponding to the resonance for H2 in **2** was absent; ms *m/e* (rel. abund.%): 151 (M^+, 81.3), 118 (54.3), 93 (49.6), 92 (100), 91 (56.8), 83 (95.7), 82 (43.5), 80 (64), 79 (71.2), 78 (50.7), 77 (55.8), 68 (47.1), 67 (52.2), 59 (44.6), 51 (42.4).

*8,8-Dimethylbicyclo[5.1.0]octa-3,5-dien-2-ol, **2***

Diisobutylaluminum hydride (0.85 mL of a 25% solution in C_6H_6) was slowly added to **1** (74 mg) in C_6H_6 (3 mL) at 0°C. The solution was sitrred for 2 h at 0°C. CH_3OH (20 mL) was added and the aluminum salts removed by filtration through Celite. The solvent was evaporated *in vacuo* and the residual oil distilled in a short path length bulb-to-bulb apparatus (110°C/5 Torr) to give a colourless oil; ^1H nmr spectrum, Table 1. Alcohol **2** allowed to stand in $CDCl_3$ or CS_2 solutions in contact with D_2O in nmr tubes rearranged to give **3** over a period of several hours; ^1H nmr ($CDCl_3$) of **3**, δ: 7.65 (t, 2H), 6.22 (bd, 2H), 5.35 (q, 2H), 1.32 (s, 6H).

*8,8-Dimethylbicyclo[5.1.0]octa-3,6-dien-2-ol, **14***

A solution of 8,8-dimethylbicyclo[3.2.1]octa-3,6-dien-2-one, **13**, (74 mg) in 3 mL dry benzene was kept stirred under nitrogen at 0°C; 5 mL of a 1 *M* solution of diisobutylaluminum hydride in hexane was added slowly at this temperature. The solution was stirred at this temperature for 2 h. Excess CH_3OH (10–15 mL) was then added and the mixture stirred at room temperature for a further 15 min. It was then filtered through Celite and the solvent evaporated to give a pale yellow oil; ^1H nmr analysis of this product showed that two isomeric compounds were present in an approximate ratio of 2:1. The crude mixture was distilled bulb-to-bulb (100°C/7.5 Torr) and a white solid sublimed over. Yield: 35 mg; mp 81–83°C; ^1H nmr, Table 1; ir (CS_2) cm^{-1}: 3600, 2920, 1020, 780, 735, 700. High res. ms (*m/e*), M^+ calcd.: 162.1045; M^+ found: 162.1029.

*2,8,8-Trimethylbicyclo[5.1.0]octa-3,5-dien-2-ol, **15***

A solution of **1** (101 mg) in dry ether (10 mL), kept under nitrogen, was cooled to −78°C. To this was added a 1.4 *M* solution of CH_3Li in ether (0.7 mL). The reaction mixture was stirred at −78°C for 1 h. After warming at 0°C, ice-cold water (5 mL) was added to quench the reaction. The ether layer was separated from the aqueous layer and the aqueous layer extracted with ether (3 × 10 mL). The combined ether extract was washed with water, dried over anhydrous $MgSO_4$, filtered, and the solvent removed to give a pale-yellow solid. Bulb-to-bulb distillation (110°C/7.5 Torr) resulted in the sublimation of **15** as a colorless solid. Yield: 113.2 mg; mp 61–64°C; ^1H nmr, Table 1; ir (KBr pellet) cm^{-1}: 3300, 2940, 1380, 1105, 975, 970, 730, 690. High res. ms (*m/e*), M^+ calcd.: 164.1201; M^+ found: 164.1207.

*2,8,8-Trimethylbicyclo[3.2.1]octa-3,6-dien-2-ol, **16***

This compound was prepared from **13** (140.9 mg) and a 1.4 *M* solution of CH_3Li in ether (1 mL) by the same method as that described for **15**. The crude product was obtained as a colorless liquid. The product was purified by bulb-to-bulb distillation (100°C/7.5 Torr). The oil solidified to give colorless crystals upon storage in the freezer. Yield: 148.7 mg; mp 38–40°C; ^1H nmr, Table 1; ir (CS_2) cm^{-1}: 3600, 3480, 2925, 1365, 1265, 1105, 1095, 915, 780, 730, 710. High res. ms (*m/e*), M^+ calcd.: 164.1201; M^+ found: 164.1255.

*Isopropyltropylium hexachloroantimonate, **8***

To a solution of 7-methoxycycloheptatriene (300 mg) in 15 mL dry ether, a 2 *M* solution of isopropylmagnesiumchloride in ether (5 mL) was added slowly under nitrogen at 0°C. The solution was stirred at this temperature for 3 h. A solution of NH_4Cl (2 g) in water (15 mL) was added and the solution was stirred at 0°C for 30 min. The ether layer was removed and the aqueous layer was extracted with ether (3 × 10 mL). The combined organic layer was dried over anhydrous $MgSO_4$, filtered, and the solvent evaporated to give a brown oil. Bulb-to-bulb distillation (80°C/7.5 Torr) of this oil yielded the pure 7-isopropylcycloheptatriene **9** (133.8 mg). This product was added to a solution of triphenylmethyl hexachloroantimonate (305 mg) in CH_2Cl_2 (15 mL) at room temperature, under nitrogen. The mixture was kept overnight under nitrogen at room temperature, when a dark solution was obtained. The solvent was evaporated under vacuum and the off-white solid product was washed with dry ether several times to remove triphenylmethane and the excess 7-isopropylcycloheptatriene. The crude product was recrystallized from dry CH_2Cl_2 at −20°C to give isopropyltropylium hexachloroantimonate **8** as colorless crystals. Yield: 230 mg; ^1H nmr, Table 1.

*8,8-Dimethylbicyclo[5.1.0]octa-3,5-dien-2-oliron tricarbonyl, **6***

Diisobutylaluminum hydride (0.5 mL of a 20% solution in hexane) was added to a solution of **5** (70 mg) in C_6H_6 (10 mL) kept at 0°C. The mixture was stirred for 1 h before CH_3OH (20 mL) was added. The aluminium salts were filtered off through Celite and the salts well washed with ether. The combined filtrate and washings were evaporated to dryness. The oily residue was chromatographed rapidly on alumina (activity II), eluting with benzene. The second fraction obtained was **6**, with the first being unreacted **5**. The ^1H nmr spectrum of **6** is given in Table 1. The alcohol **6** was unstable and was used directly for protonation studies.

*2,8,8-Trimethylbicyclo[5.1.0]octa-3,5-dien-2-oliron tricarbonyl, **21***

A solution of **5** (72 mg; 0.25 mmol) in anhydrous ether (2 mL) was cooled to −78°C under argon and treated dropwise with methyl lithium solution (0.31 mmol in ether). The solution was stirred at −78°C for 2 h, allowed to warm to 0°C, and treated with water (3 mL). The organic layer was separated from the aqueous phase and the latter washed with ether (3 × 1 mL). The combined organic fractions were dried over K_2CO_3 and the ether evaporated *in vacuo* to give a brown oil. The material was chromatographed very rapidly on a short (2 in.) alumina column (activity II), eluting with benzene. The second fraction collected was **21**; ^1H nmr spectrum, Table 1. This material was used directly in the protonation studies.

Protonation of the bicyclic alcohols

Each of the alcohols (20 mg) was dissolved in CD_2Cl_2 (a few drops) and cooled to −78°C in a 5.0-mm nmr tube. SO_2ClF (about 0.2 mL) was condensed into the nmr tube at this temperature. The tube was transferred to an ether – liquid nitrogen slush bath (−116°C) and 1 mL of a solution of FSO_3H in SO_2ClF (1:4 v/v) at the same temperature was added to the alcohol solution. The solution was rapidly stirred with a thin quartz rod previously cooled in liquid nitrogen, to effect complete mixing. The tube was quickly transferred to the probe of the nmr spectrometer, kept at −120°C.

*Low temperature protonation of **2D** and kinetics of deuterium scrambling in **4D***

This protonation was carried out exactly in the same way as that reported for the other bicyclic alcohols, except for the use of $CFCl_3$ instead of CD_2Cl_2 as the solvent in this case. Kinetics of deuterium scrambling at −90°C was followed by measuring the increase in the intensity (peak height) of the vinyl proton signal or the decrease in the intensity (peak height) of the bridgehead methine proton signal, with time. The error quoted in the value of *k* is the standard deviation of the individual values from the mean.

Réactions de Wittig et d'Horner–Emmons en série trifluorométhylée : synthèse de nouveaux F-alkyl esters isomères α,β et β,γ-insaturés

HEDI TRABELSI, BRIGITTE BERTAINA ET AIMÉ CAMBON
Laboratoire de Chimie Organique du Fluor, U.E.R. — I.M.S.P., Université de Nice, Parc Valrose, 06034 Nice Cedex, France

Reçu le 8 mai 1984

HEDI TRABELSI, BRIGITTE BERTAINA et AIMÉ CAMBON. Can. J. Chem. **63**, 426 (1985).

Les réactions de Wittig et Horner–Emmons sont réalisées en utilisant la n-butyl trifluorométhyl cétone et la benzyl trifluorométhyl cétone. De nouveaux F-alkyl esters α,β et β,γ-éthyléniques sont obtenus. Le mode de formation de ces derniers est discuté.

HEDI TRABELSI, BRIGITTE BERTAINA, and AIMÉ CAMBON. Can. J. Chem. **63**, 426 (1985).

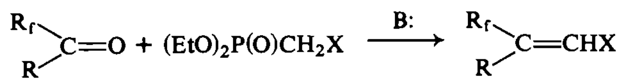
New F-alkyl α,β and β-γ-unsaturated esters were obtained by Wittig and Horner–Emmons reactions using n-butyl and benzyl trifluoromethyl ketones. A mechanism for formation is discussed.

Introduction

Les réactions de Wittig, Wittig–Horner ou Horner–Emmons, très utilisées en série hydrocarbonée (1–5), se sont également révélées de bonnes méthodes pour synthétiser des alcènes F-alkylés activés par des groupements électro-attracteurs (6–10): la réaction de condensation d'un dérivé carbonylé, d'accès facile (9), sur un ylure de phosphore ou un phosphonate conduit alors, essentiellement à un composé α,β-insaturé et F-alkylé.

(réf. 7)

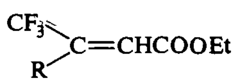
$R_f = CF_3$
R = Me, Ph...



(réf. 9)

$R_f = C_nF_{2n+1}$ ($n = 3,5,7...$)
R = Me, Ph, Et, nPr...
X = COOMe, CN, $COCH_3$...

Nous avons souhaité utiliser ces réactions pour synthétiser des composés du type:

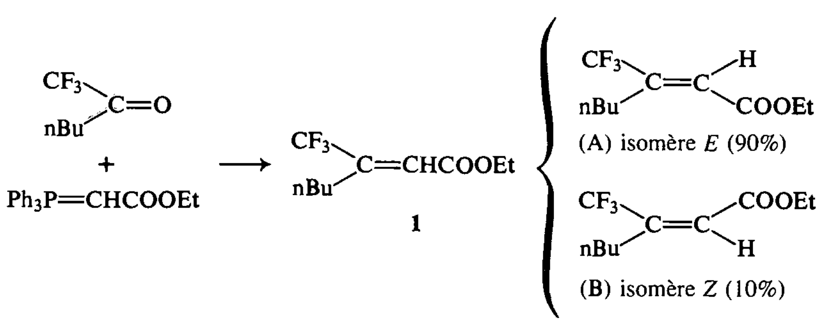


en vue de l'obtention de polymères à bas indice de réfraction utilisables dans l'industrie des fibres optiques (11).

Si la méthode de Wittig a répondu à nos espérances, celle d'Horner–Emmons a conduit majoritairement à des esters β,γ-insaturés.

Résultats et discussion

Dans le cas de la réaction de Wittig, la condensation de la n-butyl trifluorométhyl cétone avec le carboéthoxyméthylène-triphénylphosphorane conduit aux résultats suivants:

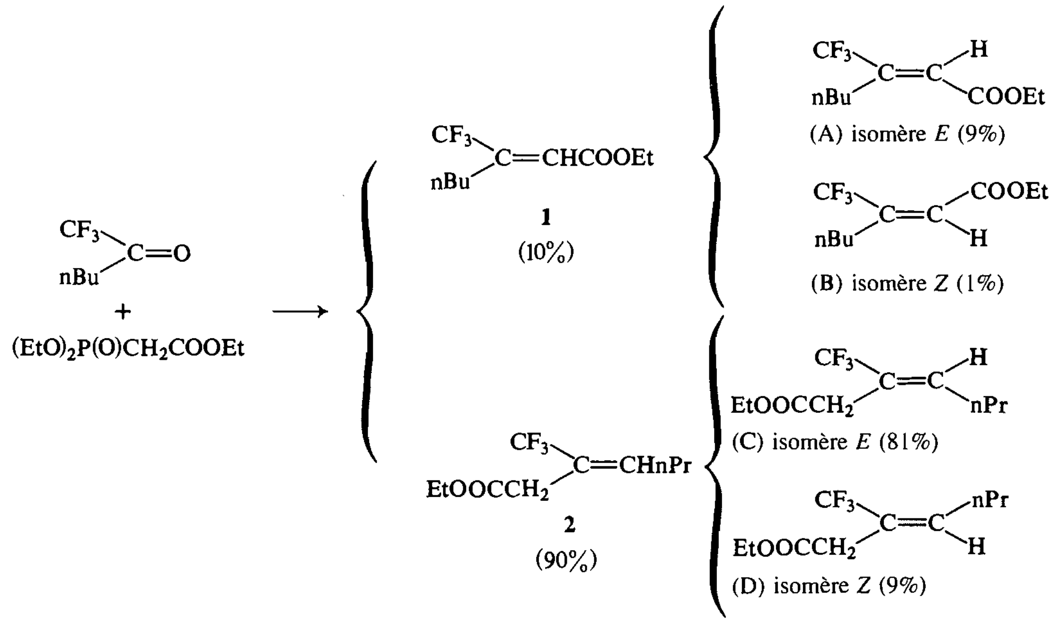


1

(A) isomère *E* (90%)

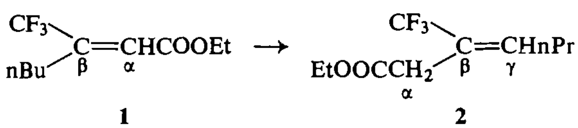
(B) isomère *Z* (10%)

Dans le cas de la réaction d'Horner–Emmons, la même cétone a été condensée avec le carboéthoxyméthyl diéthyl phosphonate en présence de NaH. Les résultats sont les suivants:

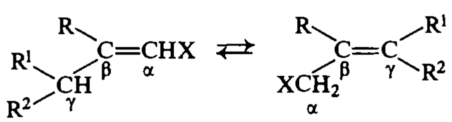


On voit clairement que la réaction d'Horner–Emmons donne un mélange de trifluorométhyl oléfines activées α,β-insaturées (**1**) ((A) + (B) = 10%) et β,γ-insaturées (**2**) ((C) + (D) = 90%).

La formation de **2** peut être envisagée par une isomérisation prototropique en milieu basique de **1** comme cela été montré en série hydrocarbonée (12–17).



En effet, il est bien connu qu'il existe un équilibre entre les formes α,β et β,γ-insaturées des ions carboxylates, des esters carboxyliques, des cétones et des nitriles.



X = COO^-, COOEt, $COCH_3$, CN …

Afin de démontrer l'existence d'une telle prototropie en série trifluorométhylée nous avons procédé aux essais suivants.

(a) Nous avons fait agir sur le mélange (*Z* + *E*) du composé **1** à température ambiante et en milieu THF (conditions de la réaction d'Horner–Emmons).

(b) Nous avons mis le composé **1** au reflux du THF pendant 24 h, afin de déterminer si ce dernier était responsable de l'éventuelle prototropie.

(c) Nous avons fait réagir Ph_3P=CHCOOEt respectivement sur les composés **1** et **2** au reflux du THF pour savoir si l'éventuelle isomérisation se produisait sous l'influence de l'ylure.

(d) Nous avons effectué la même réaction avec le phosphonate $(EtO)_2P(O)CH_2COOEt$.

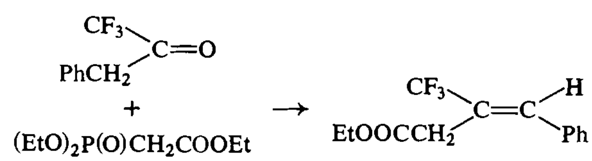
Les résultats suivants ont été obtenus: les essais (b) et (c) se sont révélés négatifs et les produits de départ ont été intégralement récupérés. Dans les essais (a) et (d), c'est-à-dire en milieu fortement basique (en présence de NaH ou du carbanion dérivé du phosphonate), nous constatons qu'environ 95% des composés **1** (isomères *Z* et *E*) sont réarrangés en composés **2**.

Ceci permet de conclure que les esters β,γ-insaturés obtenus au cours de la réaction d'Horner–Emmons résultent de la prototropie catalysée par le milieu basique des esters α,β-insaturés. Seuls ces derniers sont obtenus par la réaction de Wittig qui ne nécessite pas l'utilisation d'une base.

En série hydrocarbonnée, Kon et Linstead (13, 14) ont montré que l'équilibre entre les formes α,β et γ,β-insaturées dépend peu de la nature de X, mais est très sensible à la nature des groupements sur l'atome de C en position γ.

Ainsi, dans le cas où R^1 = Ph, R^2 = H, l'équilibre est complètement déplacé vers la formation de l'ester β,γ-éthylénique.

Afin de démontrer une éventuelle analogie en série trifluorométhylée, nous avons condensé la benzyl trifluorométhyl cétone avec le carboéthoxyméthyl diéthyl phosphonate dans les conditions d'Horner–Emmons.[1] Les résultats sont les suivants:



3 isomère *E*

Dans ce cas, seul l'ester β,γ-insaturé est obtenu et la réaction est stéréospécifique (100% *E*).

Nous avons alors synthétisé l'isomère α,β-éthylénique[2] par une réaction de Wittig et nous l'avons soumis aux essais (a), (b), (c) et (d). Nous avons constaté que les essais (b) et (c) sont négatifs comme précédemment alors que (a) et (d) donnent uniquement le composé **3** (isomère *E*). Sous l'effet de la base NaH ou du carbanion dérivé du phosphonate, le benzyl-3

[1]La réaction d'Horner–Emmons avec $(CF_3)C(O)Ph$ est stéréospécifique et conduit au produit $(CF_3)C(Ph)$=CH—COOEt (isomère *E*).

[2]Dans le cas de la réaction de Wittig, cette cétone condensée avec le carboéthoxyméthylènetriphénylphosphorane conduit au benzyl-3 trifluoro-4,4,4 butène-2 oate d'éthyle (isomère *E* (75%); isomère *Z* (25%)).

trifluoro-4, 4, 4 butène-2 oate d'éthyle (*Z* + *E*), s'isomèrise intégralement en un composé unique **3**.

Identification des divers composés obtenus

*(**1**)* (E, Z)

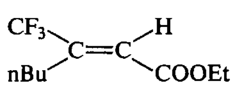
L'analyse élémentaire jointe à la détermination de la masse moléculaire par spectrométrie de masse (M^+ 224), conduit à la formule brute $C_{10}H_{15}F_3O_2$. Le spectre ir montre que nous avons affaire à des oléfines conjuguées avec un groupement ester: $\nu_{(C=O)} = 1709\ cm^{-1}$, $\nu_{(C=C)} = 1653\ cm^{-1}$. On note également $\nu_{(C-F)} = 1100-1250\ cm^{-1}$. Le spectre[3] rmn du ^1H montre: à 6,05 ppm et 6,33 ppm les signaux des H éthyléniques; à 4,21 et 1,3 ppm respectivement un quadruplet et un triplet (OCH_2CH_3); entre 2,66 et 1,5 ppm un large multiplet correspondant aux CH_2 de nBu; et à 0,95 ppm, le CH_3 du groupement n-butyle.

La présence de 2 signaux attribuables aux H éthyléniques, l'un vers 6,33 ppm, l'autre vers 6,05 ppm (moins déblindé et environ 3 fois moins intense), montre l'existence d'un mélange de 2 stéréoisomères.

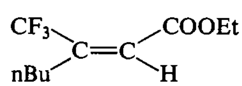
La configuration (*Z, E*) a été déterminée grâce au couplage allylique du proton éthylénique et du groupement CF_3.

En effet, en rmn du ^{19}F, on observe sur le spectre du mélange, deux groupes de signaux à −63,8 ppm et à −69,6 ppm correspondant aux CF_3. La résolution de ces signaux a permis de déduire les constantes de couplage ^4J allylique de H et CF_3. Le CF_3 résonant à −69,6 ppm se présente sous forme de doublet $^4J_{H-CF_3} = 1{,}6$ Hz. La résolution du signal de CF_3 à −63,8 ppm ne fait apparaître aucun couplage ($^4J_{H-CF_3} = 0$ Hz).

Il est communément admis que la constante de couplage ^4J allylique $H-CF_3$ est pratiquement nulle si H est en *trans* par rapport à CF_3 et peut atteindre 2,1 Hz, si H est *cis*. La confrontation de ces données expérimentales (18−20) avec celles tirées des spectres nous a permis d'attribuer la constante de couplage $^4J = 1{,}6$ Hz au composé *E*. L'absence de couplage



E



Z

$^4J_{H-CF_3}$ est donc attribuable au composé *Z*. L'intensité relative des signaux nous permet d'attribuer la configuration *E* au produit majoritaire (90%).

*(**2**)* (E, Z)

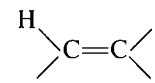
La caractérisation des composés **2** peut s'opérer à partir des observations suivantes.

Composé majoritaire

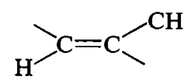
L'analyse élémentaire jointe à la masse moléculaire, déterminée par spectrométrie de masse (M^+ 224), conduit à la formule brute $C_{10}H_{15}F_3O_2$. En ir, $\nu_{(C=O)} = 1724\ cm^{-1}$ correspond à un ester éthylique qui est confirmé en rmn du ^1H par le quadruplet à 4,16 ppm d'intensité *2* et un triplet à 1,3 ppm d'intensité *3*. La fréquence de celui-ci est augmentée de 15 cm^{-1} par rapport à la bande $\nu_{(C=O)}$ du composé **1**. Ceci démontre la non conjugaison du groupement ester. Cette situation suggère qu'il existe au moins un groupement méthylénique susceptible de former un écran. Le singulet à 3,18 ppm d'intensité *2* correspond à un CH_2 en α d'un C=O. On a le groupement $—CH_2—C(=O)—O—CH_2CH_3$.

Compte-tenu de la formule brute, il nous reste: $C_6H_8F_3$ avec un centre d'insaturation. L'insaturation peut être une double liaison ou un cycle.

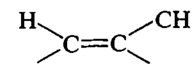
La position de la bande ir à 1669 cm^{-1}, la présence du triplet d'intensité *1* à 6,33 ppm dans la zone des "éthyléniques" et le couplage mis en évidence par ce triplet (*J* = 7,5 Hz), témoignent en faveur d'un système du type:



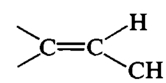
Le couplage H−H est variable selon le schéma envisagé:



$^4J_{trans} = -0{,}8$ à $-2{,}5$ Hz

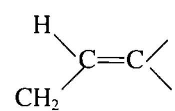


$^4J_{cis} = -0{,}8$ à -2 Hz



$^3J_{gem} = 4$ à 10 Hz

La valeur expérimentale *J* = 7,5 Hz démontre que H est couplé avec un CH_2 géminé absorbant à 2,66 ppm. Ceci est en accord avec la structure:

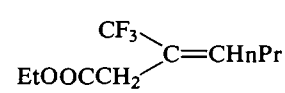


Il reste donc à affecter $C_3H_5F_3$.

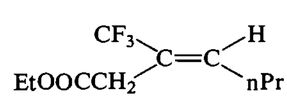
L'infra-rouge suggère que l'absorption à 1100−1250 cm^{-1} peut être attribuée à une vibration $\nu_{(C-F)}$ (confirmée en rmn du fluor par un signal à −68,5 ppm, caractéristique d'un groupement CF_3). Il reste donc C_2H_5.

Le triplet à 0,91 ppm (*J* = 7,5 Hz), d'intensité *3* et le multiplet à 1,43 ppm, d'intensité *2* font partie du groupement $CH_3CH_2CH_2$ porté par la double liaison.

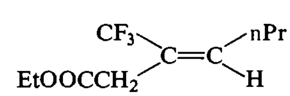
Ceci nous conduit à la formule:



Ce composé peut exister sous deux formes stéréoisomères:



isomère *E*



isomère *Z*

Avant d'aborder la détermination de la stéréochimie de ce composé, nous allons voir si le composé minoritaire est l'une de ces deux formes stéréoisomères envisagées.

Composé minoritaire

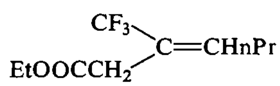
Un raisonnement analogue au précédent est appliqué.

L'analyse élémentaire associée à la masse moléculaire déterminée par spectrométrie de masse (M^+ 224), conduit à la formule brute $C_{10}H_{15}F_3O_2$. Ce composé présente en ir, les bandes suivantes: à 1728 cm^{-1} $\nu_{(C=O)}$, à 1667 cm^{-1} $\nu_{(C=C)}$ et à

[3]Le spectre rmn a été réalisé sur une fraction enrichie du mélange dans la proportion 75%:25%.

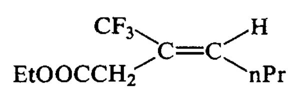
1100–1250 cm^{-1} $\nu_{(C-F)}$. En rmn du ^1H on observe: un triplet à 5,88 ppm, un quadruplet à 4,16 ppm, un singulet à 3,16 ppm, un multiplet à 2,28 ppm, un multiplet à 1,46 ppm, un triplet à 1,23 ppm, un triplet à 0,93 ppm avec un rapport d'intensités relatives *1/2/2/2/2/3/3*. Le spectre rmn du ^{19}F montre un signal à −60,2 ppm caractéristique d'un CF_3.

La seule structure compatible avec les spectres ir, rmn ^1H, ^{19}F, la masse et l'analyse élémentaire (C, H, F, O) est:

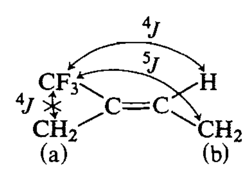


Les deux produits isolés sont donc bien deux stéréoisomères. La configuration correspondante à chaque isomère a été attribuée par étude des constantes de couplage ^4J allylique du proton et du fluor (rmn ^1H, rmn ^{19}F).

En rmn du ^1H, le signal du proton éthylénique, pour le composé majoritaire, résonant à 6,33 ppm, est constitué par un triplet de quadruplet dû à la multiplicité avec le CF_3 $^4J_{H-CF_3}$ = 1,8 Hz. Ce couplage est compatible avec un couplage allylique *cis* $^1H-^{19}F$. La configuration attribuée à ce composé est donc *E*.



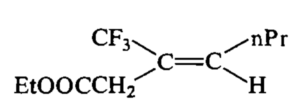
Ceci est confirmé par la rmn du ^{19}F. Le signal correspondant au CF_3 paraît être un quadruplet bien résolu. En réalité, c'est un faux quadruplet. En effet, le CF_3 est couplé d'une part au proton éthylénique et d'autre part au CH_2 (b):



Le couplage $^4J_{CH_2\,(a)-CF_3\,(\text{géminé})}$ n'est pas observable.

On devrait s'attendre à un triplet de doublet. Les composantes des triplets sont séparées par $^5J_{CH_2\,(b)-CF_3\,(trans)}$ = 2 Hz, tandis que le dédoublement correspond à $^4J_{H-CF_3\,(cis)}$ = 2 Hz confirmant une configuration *E* pour ce composé.

Quant au composé minoritaire, en rmn du ^1H la résolution du triplet à 5,88 ppm du proton éthylénique fait apparaître un quadruplet mal résolu $^4J_{H-CF_3}$ = 0,8–0,7 Hz résultant d'un couplage *trans* du H et du CF_3. La configuration attribuée à ce composé est *Z*:



La rmn du ^{19}F est en accord avec cette stéréochimie. En effet, le signal du CF_3 est un triplet très mal résolu et résulte d'un couplage *trans* $^4J_{H-CF_3}$ = 0 Hz.

Seul apparaît le couplage homoallylique $^5J_{CH_2\,(b)-CF_3}$ = 2 Hz.

(3) (E)

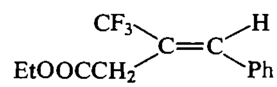
L'analyse élémentaire jointe à la masse moléculaire déterminée par spectrométrie de masse (M^+ 258), conduit à la formule brute $C_{13}H_{13}F_3O_2$.

L'infra-rouge montre une bande $\nu_{(C=O)}$ non conjuguée d'ester éthylique à 1724 cm^{-1}. Cette fonction est confirmée en rmn par un quadruplet à 4,2 ppm d'intensité *2* et un triplet à 1,26 ppm d'intensité *3*.

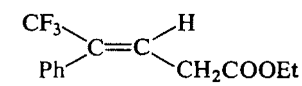
En ir, une bande à 1621 cm^{-1} correspond à $\nu_{(C=C)}$ conjuguée avec un noyau aromatique (bandes fines entre 1450 et 1600 cm^{-1}). La double liaison ainsi mise en évidence n'est pas conjuguée avec la fonction ester éthylique. Nous envisageons entre les deux un groupement CH_2. Cette hypothèse est en accord avec un signal unique rencontré en rmn du ^1H à 3,36 ppm d'intensité *2*.

Par ailleurs, un signal à 7,4 ppm d'intensité *6*, indique que le signal du noyau aromatique se superpose à l'absorption d'un H éthylénique. En rmn du fluor, on observe à −68 ppm un signal attribuable à un groupement CF_3 porté par une double liaison. La résolution de ce signal se présente sous forme d'un doublet, la constante de couplage 1,6 Hz est compatible avec un couplage $^4J_{H-CF_3\,(cis)}$.

Deux structures peuvent être proposées:



(a)



(b)

La structure (b) doit être rejetée à cause de la multiplicité du signal du CH_2 en α du groupement ester qui se présente sous forme d'un singulet.

Le produit obtenu est donc le phényl-4 trifluorométhyl-3 butène-3 oate d'éthyle, de configuration *E*.

Conclusion

Si nous récapitulons les résultats obtenus, nous observons que quelque soit la cétone $(CF_3)C(O)R$ avec R = nBu et $PhCH_2$, la réaction de Wittig conduit toujours aux trifluorométhyl oléfines activées α,β-insaturées. Par contre, la réaction d'Horner–Emmons, réalisée sur les phosphonates en milieu fortement basique, donne un mélange d'esters α,β-éthyléniques (**1**) (*Z* + *E*) et β,γ-éthyléniques (**2**) (*Z* + *E*) majoritaires quand R = nBu ou exclusivement le composé (**3**) (*E*) quand R = $PhCH_2$.

Le produit transposé est dû à une prototropie de l'oléfine attendue sous l'influence de la base.

Donc la réaction d'Horner–Emmons ne permet pas d'obtenir de manière spécifique les trifluorométhyl oléfines activées α,β-insaturées.

Il est à noter également une différence de réactivité des cétones en série hydrocarbonée et fluorée vis-à-vis du phosphorane $Ph_3P{=}CHCOOEt$. Les réactions de condensation avec les trifluorométhyl cétones s'effectuent dans des conditions douces (7) comparativement à celles requises pour les cétones classiques hydrocarbonées. En effet, il est bien connu, en série hydrocarbonée, que les ylures stabilisés par un groupement carbonylé réagissent avec les aldéhydes, mais pas avec les cétones sauf dans des conditions dures, alors que l'utilisation d'un carbanion phosphonate permet une réaction beaucoup plus aisée (21–25).

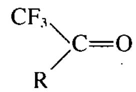
Partie expérimentale

Les spectres rmn ^1H et ^{19}F ont été enregistrés sur Bruker Spectroscope WH-90-DS (^1H = 90 MHz; ^{19}F = 84,67 MHz). Les spectres ir ont été effectués sur un spectromètre Leitz–Wetzlar, modèle IIIG. Les spectres de masse ont été enregistrés sur un appareil Ribermag R 10-10 couplé à la chromatographie en phase gazeuse. Les analyses élémentaires ont été effectuées par les laboratoires d'analyse du

CNRS à Lyon.

La pureté des produits a été contrôlée sur C.P.V. Girdel (séries 30 et 3000), colonne 1,3 m inox SE30 10% Chromosorb WHMDS 80/100; colonne 1,5 m inox 5% OV 17 Gas-Chrom Q 80/100, colonne capillaire Pyrex SE30 30 m, ϕ = 0,30 mm, et colonne capillaire Carbowax 20M-25 m.

Synthèse des trifluorométhyl cétones



Deux trifluorométhyl cétones (R = nBu, Ph—CH_2) ont été synthétisées par action des organomagnésiens sur les F-acides (26, 27).

1. *n-Butyl trifluorométhyl cétone (trifluoro-1,1,1 hexanone-2)*

Préparation du bromure de n-butyl magnésium (réf. 28)

Dans un ballon rodé de 500 mL équipé d'un agitateur magnétique, d'une ampoule à brome et maintenu sous atmosphère d'azote, on place 6,48 g (0,27 at-g) de Mg en tournure et un petit cristal d'iode. Quinze millilitres d'une solution de 34 g (0,25 mol) de bromobutane dans 100 mL d'éther anhydre sont ajoutés par l'ampoule à brome. Dès que la réaction a démarré, on ajoute le reste de la solution de bromobutane de façon à maintenir un léger reflux. L'addition terminée, le mélange réactionnel est maintenu au reflux de l'éther pendant 30 min.

Synthèse de la cétone

On ajoute 11,4 g (0,1 mol) d'acide trifluoroacétique goutte à goutte à la solution de bromure de n-butyl magnésium agitée et refroidie à 15°C par un bain d'eau thermostaté. L'addition terminée, l'agitation est poursuivie pendant 3 h à température ambiante. Le mélange est hydrolysé à froid par environ 100 mL d'une solution de HCl à 15%. La phase éthérée est séparée par décantation, traitée à l'aide d'une solution saturée de bicarbonate de sodium, lavée à l'eau, séchée sur $MgSO_4$ puis P_2O_5. L'éther est évaporé aux 2/3 puis le résidu est purifié par distillation fractionnée à pression atmosphérique. Nous obtenons 8,47 g de produit, Rt 55%, Eb 89°C (lit. (26) Eb 91°C); ir (CCl_4) ν en cm^{-1}: 1754 (C=O), 1100–1250 (C—F); rmn ^{19}F ($CDCl_3$, référence interne $CFCl_3$) δ en ppm: −79,6 (CF_3).

2. *Benzyl trifluorométhyl cétone (phényl-3 trifluoro-1,1,1 propanone-2)*

Cette cétone est obtenue de la même façon que la trifluoro-1,1,1 hexanone-2. À une solution de chlorure de benzylmagnésium, obtenu à partir de 0,27 at-g de Mg en tournure et 0,25 mol de chlorure de benzyle (refroidie à 15°C par un bain d'eau thermostaté), on ajoute lentement 11,4 g (0,1 mol) d'acide trifluoroacétique. Le mélange est ensuite agité à température ambiante pendant 3 h. Après traitement, l'éther est évaporé et le résidu est distillé sous vide. Nous obtenons 9,4 g de produit, Rt 50%, Eb/160 Torr 120°C (lit. (29) Eb 66/16 Torr) (1 Torr = 133.3 Pa); ir (CCl_4) ν en cm^{-1}: 1754 (C=O), 1100–1250 (C—F); rmn ^{19}F ($CDCl_3$, référence interne $CFCl_3$) δ en ppm: −78,7 (CF_3).

*Synthèse de **1** (E, Z)*

Nous avons utilisé la technique décrite dans la littérature (7). À partir de 0,015 mol de carboéthoxyméthylènetriphénylphosphorane et 0,015 mol de trifluoro-1,1,1 hexanone-2 on obtient un mélange de deux composés avec un rendement global de 90%, Eb/280 Torr 80°C. La composition du mélange a été determinée par cpv (90/10%); ir (CCl_4) ν en cm^{-1}: 1709 (C=O), 1653 (C=C), 1100–1250 (C—F); rmn ^1H ($CDCl_3$, référence interne TMS) δ en ppm: 6,05 et 6,33 (q et s, H, =CH— (**1**) (*E*) et (**1**) (Z), $^4J_{H-CF_3\,(cis)}$ = 1,6 Hz), 4, 21 (9, 2H, —OCH_2—, $^3J_{H-H}$ = 7,5 Hz), 1,3 (t, 3H, —CH_3, $^3J_{H-H}$ = 7,5 Hz), 2,66–1,5 (m, 6H, —$(CH_2)_3$—), 0,95 (t, 3H, —CH_3, $^3J_{H-H}$ = 7,5 Hz); rmn ^{19}F ($CDCl_3$, référence interne $CFCl_3$) δ en ppm: −69,6 et −63,8 (d et s, CF_3 (**1**) (*E*) et (**1**) (Z), $^4J_{H-CF_3\,(cis)}$ = 1,6 Hz); spectrométrie de masse: M^+ = 224. *Anal.* calc. pour $C_{10}H_{15}F_3O_2$: C 53,57, H 6,69, F 25,44; trouvé: C 53,42, H 6,82, F 25,28.

*Synthèse du mélange **1** (E, Z) + **2** (E, Z)*

À 0,96 g de NaH (préalablement lavé deux fois à l'hexane et deux fois au THF) mis en suspension dans 30 mL de THF anhydre, on ajoute goutte à goutte 0,02 mol de carboéthoxyméthyl diéthyl phosphonate. On laisse 1 h sous agitation magnétique et sous courant d'azote, puis on ajoute lentement 0,02 mol de trifluoro-1,1,1 hexanone-2. Après 3 h de réaction, le mélange est porté au reflux du THF pendant 1/2 h. On laisse refroidir, puis le mélange est traité par l'eau et extrait à l'éther. La phase éthérée est lavée à l'eau et séchée. Après évaporation du solvant, le mélange est analysé par un appareil de spectrométrie de masse couplé à la chromatographie en phase vapeur.

Nous avons obtenu un mélange complexe de 2 produits attendus **1** = 10%, déjà caractérisés et 2 produits inattendus **2** dans la proportion 81/9%, Rt 62%; **2** Eb/125 Torr 104°C; **1** Eb/280 Torr 80°C.

Les composés **2** sont séparés par chromatographie en phase liquide, colonne d'alumine d'activité neutre, calibre 0,063–0,200 mm, éluant hexane–éther 9:1 (v/v).

***2** (E, Z)*

Isomère E: ir (CCl_4) ν en cm^{-1}: 1724 (C=O), 1669 (C=C), 1100–1250 (C—F); rmn ^1H ($CDCl_3$, référence interne TMS) δ en ppm: 6,33 (tq, H, =CH—, $^3J_{H-H}$ = 7,5 Hz, $^4J_{H-CF_3\,(cis)}$ = 1,8 Hz), 4,16 (q, 2H, —OCH_2—, $^3J_{H-H}$ = 7,5 Hz), 1,23 (t, 3H, —CH_3, $^3J_{H-H}$ = 7,5 Hz), 3,18 (s, 2H, —CH_2COO—), 2,11–1,43 (m, 4H, —$(CH_2)_2$—), 0,91 (t, 3H, —CH_3, $^3J_{H-H}$ = 7,5 Hz); rmn ^{19}F ($CDCl_3$, référence interne $CFCl_3$) δ en ppm: −68,5 (q, CF_3, $^4J_{H-CF_3\,(cis)}$ = $^5J_{CH_2-CF_3\,(trans)}$ = 2 Hz); spectrométrie de masse: M^+ = 224. *Anal.* calc. pour $C_{10}H_{15}F_3O_2$: C 53,57, H 6,69, F 25,44; trouvé: C 53,48, H 6,72, F 25,31.

Isomère Z: ir (CCl_4) ν en cm^{-1}: 1728 (C=O), 1667 (C=C), 1100–1250 (C—F); rmn ^1H ($CDCl_3$, référence interne TMS) δ en ppm: 5,88 (tq, H, =CH—, $^3J_{H-H}$ = 6,5 Hz, $^4J_{H_3-CF_3\,(trans)}$ = 0,8 Hz), 4,16 (q, 2H, —OCH_2—, $^3J_{H-H}$ = 7,5 Hz), 1,23 (t, 3H, —CH_3, $^3J_{H-H}$ = 7,5 Hz), 3,16 (s, 2H, —CH_2COO—), 2,28–1,46 (m, 4H, —$(CH_2)_2$—), 0,93 (t, 3H, —CH_3, $^3J_{H-H}$ = 7,5 Hz); rmn ^{19}F ($CDCl_3$, référence interne $CFCl_3$) δ en ppm: −60,2 (t, CF_3, $^5J_{H-CF_3}$ = 2 Hz); spectrométrie de masse: M^+ = 224. *Anal.* calc. pour $C_{10}H_{15}F_3O_2$: C 53,57, H 6,69, F 25,44; trouvé: C 53,62, H 6,82, F 25,35.

*Synthèse de **3** (E)*

Les conditions opératoires sont identiques aux précédentes (Horner–Emmons), avec la benzyl trifluorométhyl cétone; Rt 74,5%, Eb/30 Torr 121°C; ir (CCl_4) ν en cm^{-1}: 1724 (C=O), 1621 (C=C), 1100–1250 (C—F); rmn ^1H ($CDCl_3$, référence interne TMS) δ en ppm: 7,4 (s, 6H, protons aromatiques et proton éthylénique), 4,2 (q, 2H, —OCH_2—, $^3J_{H-H}$ = 7,5 Hz), 1,26 (t, 3H, —CH_3, $^3J_{H-H}$ = 7,5 Hz), 3,36 (s, 2H, —CH_2COO—); rmn ^{19}F ($CDCl_3$, référence interne $CFCl_3$) δ en ppm: −67,6 (d, CF_3, $^4J_{H-CF_3\,(cis)}$ = 1,6 Hz); spectrométrie de masse: M^+ = 258. *Anal.* calc. pour $C_{13}H_{13}F_3O_2$: C 60,46, H 5,03, F 22,09; trouvé: C 60,38, H 5,10, F 22,14.

The formation of branched-chain deoxypentofuranosides by ring contraction in the reductive desulfonyloxylation of hexopyranoside *p*-toluenesulfonates[1]

HANS H. BAER, DAVID J. ASTLES, HO-CHI CHIN, AND LISA SIEMSEN
Ottawa–Carleton Institute for Research and Graduate Studies in Chemistry, Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received May 23, 1984

HANS H. BAER, DAVID J. ASTLES, HO-CHI CHIN, and LISA SIEMSEN. Can. J. Chem. **63**, 432 (1985).

Several methyl 6-deoxy-, 6-deoxy-6-halo-, and 6-*O*-*p*-tolylsulfonylhexopyranoside 2- and 4-*p*-toluenesulfonates reacted readily with lithium triethylborohydride in boiling tetrahydrofuran under reductive desulfonyloxylation at C-2 and C-4, respectively, and with reduction at C-6 where applicable. The desulfonyloxylations proceeded with ring contraction to furnish, in 40–60% isolated yields, new branched-chain pentofuranoside derivatives, namely, methyl 2,5-dideoxy-2-*C*-(hydroxymethyl)pentofuranosides having the α-L-*xylo*, α-D-*xylo*, and α-D-*ribo* configurations (from 2-tosylates), and methyl 3,5-dideoxy-3-*C*-(hydroxymethyl)pentofuranosides having the α-D-*arabino* and α-D-*ribo* configurations (from 4-tosylates). In some of the reactions, reductively desulfonyloxylated but unrearranged products were formed in addition. Methyl 4,6-*O*-benzylidene-2,3-di-*O*-*p*-tolylsulfonyl-α-D-galactopyranoside reacted by partial de-*O*-sulfonylation and partial desulfonyloxylation, with and without ring contraction, to give methyl 3,5-*O*-benzylidene-2-deoxy-2-*C*-(hydroxymethyl)-α-D-*lyxo*-pentofuranoside, methyl 4,6-*O*-benzylidene-3-deoxy-α-D-*lyxo*-hexopyranoside, and the parent 2,3-diol.

HANS H. BAER, DAVID J. ASTLES, HO-CHI CHIN et LISA SIEMSEN. Can. J. Chem. **63**, 432 (1985).

Plusieurs méthyl-6-désoxy-, 6-désoxy-6-halo- et 6-*O*-*p*-tolylsulfonylhexopyranosides 2- et 4-*p*-toluènesulfonates donnent lieu à désulfonyloxylation réductive en C-2 et C-4 respectivement, ainsi qu'à réduction en C-6 s'il y a lieu, sous l'action du triéthylborohydrure de lithium dans le tétrahydrofuranne à reflux. La désulfonyloxylation s'accompagne de contraction de cycle et conduit, avec des rendements de 40–60% en produits isolés, à des nouveaux dérivés pentofuranosides ramifiés, les méthyl-2,5-didésoxy-2-*C*-(hydroxyméthyl)pentofuranosides de configuration α-L-*xylo*, α-D-*xylo* et α-D-*ribo* partant du sulfonate en C-2, ou encore méthyl-3,5-didésoxy-3-*C*-(hydroxymethyl)pentofuranosides de configuration α-D-*arabino* et α-D-*ribo* partant du sulfonate en C-4. Dans quelques cas, une désulfonyloxylation réductive sans réarrangement est également observée. Le méthyl-4,6-*O*-benzylidène-2,3-di-*O*-*p*-tolylsulfonyl-α-D-galactopyranoside donne ainsi lieu, à la fois à dé-*O*-sulfonylation et désulfonyloxylation avec, et sans contraction de cycle respectivement, pour conduire aux méthyl-3,5-*O*-benzylidène-2-*C*-(hydroxyméthyl)-α-D-*lyxo*-pentofuranoside, méthyl-4,6-*O*-benzylidène-3-désoxy-α-D-*lyxo*-hexopyranoside ainsi que au diol en C-2, C-3 correspondant.

Introduction

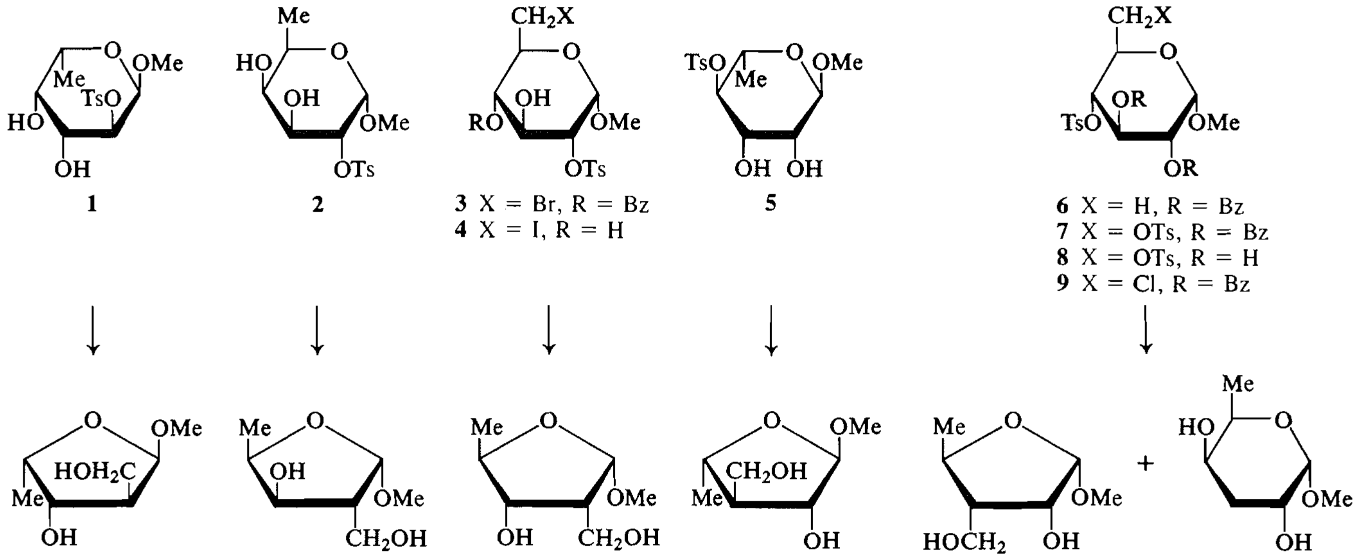
Recently we reported on the reductive desulfonyloxylation of methyl 4,6-*O*-benzylidene-α- and -β-D-glucopyranoside *p*-toluenesulfonates by means of lithium triethylborohydride (LTBH), which permitted the convenient preparation of certain 2- and 3-deoxyhexopyranoside derivatives in high yields (1). The method has also been applied to various tosylates of the analogous bisacetal from the disaccharide α,α-trehalose (2). A structural prerequisite for facile desulfonyloxylation appeared to be the presence of a free, or potentially free, hydroxyl group adjacent and *trans* to the sulfonate ester, and it was established that the reaction proceeds through intermediary epoxides, the formation and subsequent reductive ring-opening of which is governed by well-known stereochemical prinicples. One of the factors promoting high regioselectivity in the sense of the Fürst–Plattner rule doubtless was the conformational rigidity imparted to the intermediates by their *trans*-fused, cyclic acetal structures. It became of interest, therefore, to examine the degree to which this structural constraint contributed to the stereochemical outcome of the reaction, and it was decided to study the action of LTBH upon a number of simple, non-acetalated hexopyranoside tosylates, particularly of the 6-deoxy type. Appropriate derivatives of the latter class of sugars are readily available and it was considered that, stereochemical interest apart, LTBH reduction might offer practical advantages for the preparation of 2,6- and 3,6-dideoxyhexoses. Such sugars have great biological importance as they occur widespread in nature, in the form of plant glycosides (e.g., digitoxose in *Digitalis*), as components of antibiotics (e.g., chromose and oleandrose in chromomycins and oleandomycin), and as bacterial constituents (e.g., abequose, paratose, and tyvelose in *Salmonella* polysaccharides).

Results and discussion

Ring contraction effected by lithium triethylborohydride

Reaction of methyl 2-*O*-tosyl-α-L-fucopyranoside (**1**) with LTBH was expected to lead to internal displacement of the ester group, followed by reductive opening of the resulting 2,3-epoxide, to give one or both of the dideoxyhexopyranosides which this sequence of events can provide. However, no such product was detected upon treatment of **1** with an excess of the reductant in boiling oxolane, although all of **1** was consumed within 30 min and desulfonyloxylation did take place. Instead, ring contraction occurred and the branched-chain glycoside **10**, methyl 2,5-dideoxy-2-*C*-(hydroxymethyl)-α-L-*xylo*-pentofuranoside, was isolated crystalline in ca. 60% yield. Evidently the loss of the tosyloxy group was coupled with a skeletal rearrangement by migration of the C-3—C-4 bond. Performance of the reaction with the D enantiomer **2** provided the D enantiomer **11**, likewise in crystalline form. When methyl 4-*O*-benzoyl-6-bromo-6-deoxy-2-*O*-tosyl-α-D-glucopyranoside (**3**) or methyl 6-deoxy-6-iodo-2-*O*-tosyl-α-D-glucopyranoside (**4**) were used as substrates, the crystalline α-D-*ribo* isomer of the foregoing 2,5-dideoxy-2-*C*-(hydroxymethyl)pentofuranosides was obtained.

[1] The essential results of this work were included in preliminary form in the communication (I-37) presented by H. H. Baer, H. R. Hanna, and D. J. Astles at the XIth International Carbohydrate Symposium, Vancouver, B.C., August 22–28, 1982.



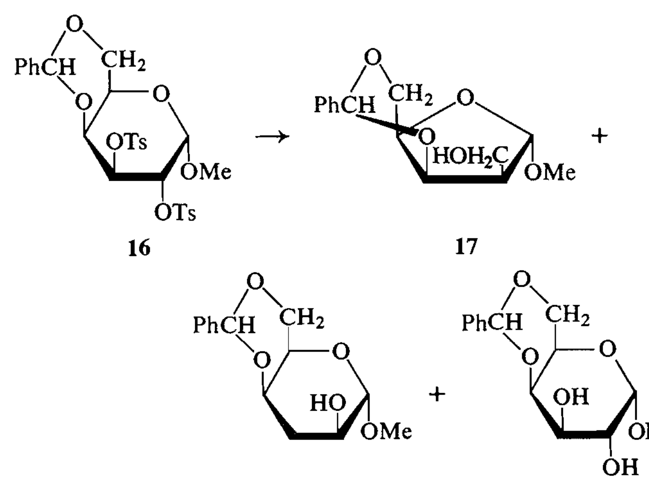
1, 2, 3 X = Br, R = Bz; 4 X = I, R = H; 5; 6 X = H, R = Bz; 7 X = OTs, R = Bz; 8 X = OTs, R = H; 9 X = Cl, R = Bz

10, 11, 12, 13, 14, 15

In corresponding hexopyranoside 4-tosylates, ring contraction took place in the opposite direction, i.e., by migration of the C-2—C-3 bond, furnishing isomeric 3,5-dideoxy-3-*C*-(hydroxymethyl)pentofuranosides. Thus, methyl 4-*O*-tosyl-α-L-rhamnopyranoside (**5**) produced the crystalline α-L-*arabino* isomer (**13**), and methyl 2,3-di-*O*-benzoyl-4-*O*-tosyl-α-D-quinovoside (**6**) gave the α-D-*ribo* isomer **14**, which failed to crystallize but was isolated chromatographically in pure condition. In all of these experiments, the starting tosylates reacted rapidly and completely (provided a sufficient excess of hydride reagent, normally 8 mol. equiv., was employed), and no unrearranged dideoxyhexopyranosides were detected, although traces of unidentified by-products were usually seen in tlc. The crude reaction mixtures apparently contained the product glycosides as alkali-stable organoboron complexes, and because of a high (and not unexpected) acid-sensitivity of the dideoxyfuranosides the products tended to behave somewhat capriciously in processing and during isolation. Isolated yields of chromatographically pure products generally were in the 40–60% range.[2]

In contrast to the 6-deoxy sugar **6**, the analogous methyl 2,3-di-*O*-benzoyl-4,6-di-*O*-tosyl-α-D-glucopyranoside (**7**) gave the ring-contracted product (**14**) *and* the unrearranged hexopyranoside **15**, in a ratio of ~3:2. Although complete chromatographic separation was difficult to achieve and the reaction was therefore of limited preparative value, the isomers were obtained sufficiently pure for unambiguous spectroscopic identification, and **15** was identified as methyl 3,6-dideoxy-α-D-*xylo*-hexopyranoside (methyl α-abequoside) by comparison with an independently-prepared (3) sample. The de-*O*-benzoylated 4,6-ditosylate[3] **8** and the 6-chloro-6-deoxyglycoside **9** on treatment with LTBH gave mixtures of **14** and **15** in approximately equal proportions.

The exclusive or predominant occurrence of ring contraction here reported stands in sharp contrast to the desulfonyloxylations that had been performed (1) in 4,6-*O*-benzylidenated glucopyranoside tosylates. In the latter, an analogous rearrangement would require the formation of a highly strained system comprising a six-membered acetal ring *trans*-fused to a five-membered furanose ring, and presumably is disfavored for this reason. To test this hypothesis, methyl 4,6-*O*-benzylidene-2,3-di-*O*-tosyl-α-D-galactopyranoside (**16**) was subjected to reduction with LTBH, the surmise being that a *cis*-fused acetal might not interdict furanoside formation. Indeed, ring-contracted methyl 3,5-*O*-benzylidene-2-deoxy-2-*C*-(hydroxymethyl)-α-D-*lyxo*-pentofuranoside (**17**) was isolated crystalline (38%), although methyl 4,6-*O*-benzylidene-3-deoxy-α-D-*lyxo*-hexopyranoside (**18**) was a second, major product (22%), and a significant proportion (18%) of the diol **19** was formed by



16, 17, 18, 19

[2] The crude reaction products showed in tlc a slow-moving spot that corresponded to that given by the isolated, rearranged glycoside, and an additional strong spot (fast moving, but slightly slower than the starting tosylate) which was invisible under uv light and therefore represented tosyl-free material also. Upon chromatographic isolation, this fast-moving material showed the same ^{1}H nmr features as the rearranged glycoside but additionally gave strong resonances near δ 0.9, presumably attributable to alkylboron moieties. Treatment of the alkaline reaction mixtures with hydrogen peroxide diminished the proportion of these products whose more-detailed characterization must await further study. So far it seems that the primary hydroxyl group present in the glycosides formed must be involved in the occurrence of this complication, which was not encountered in the LTBH reductions previously (1) studied.

[3] Obtained from **7** by deacylation with methanolic ammonia. For complex results obtained on attempted deacylation with sodium methoxide, see the experimental section.

[a]From 200-MHz spectra of solutions in $CDCl_3$ containing tetramethylsilane as the standard. Spectra with spin–spin decoupling by double irradiation and spectra with D_2O exchange were additionally obtained for all compounds.
[b]Signal multiplicities are indicated as cm (complex multiplet), d (doublet), nm (narrow multiplet), m (multiplet), q (quartet), qn (quintet), s (singlet), and t (triplet). Values refer to signal midpoints.
[c]Apparent qn; width 20.3 Hz, compatible with dddd having splittings of 4.5, 5.0, 5.2, and 5.6 Hz; collapsing to q, width 14.7 Hz, on H-1 irradiation.
[d]Giving on D_2O exchange an apparent t, width 11.2 Hz, by removal of a 3.8-Hz splitting.
[e]Width, 23.8 Hz; reduced to td on H-1 irradiation, with remaining splittings of 5.8, 6.7, and 6.7 Hz.
[f]The signals for H-2′a, -2′b, and -3 were poorly resolved in the regular spectrum.
[g]Sharp dd on D_2O exchange, and d (with broadened lines because of coupling with OH) on irradiation of H-2.
[h]Upon D_2O exchange, a clearly visible dd superimposed on the H-3 multiplet; without exchange, but with irradiation of H-2, a dd due to coupling with H-2′a and OH was seen.
[i]In the presence of D_2O, a singlet was observed, probably due to a slight change in overall conformation related to hydrogen bonding.
[j]Simplified to d in the presence of D_2O, due to coupling with H-3 only; see also *i*.
[k]Simplified to dd on D_2O exchange, and further to d upon subsequent irradiation of H-3.
[l]After D_2O exchange, the signal was an AB-q, as part of an ABX system.
[m]Collapsing to q on irradiation of H-3.
[n]Spectrum of the di-*O*-acetyl derivative. The acetyl singlets were at δ 2.05 and 2.11.

[a]From 20-MHz spectra, obtained with a Varian FT-80 spectrometer, for solutions in $CDCl_3$ containing TMS as the internal standard.

twofold S—O cleavage (desulfonylation) of **16**. The last-mentioned side reaction was markedly more pronounced than in the *gluco* series (1).[4]

Structure of the branched glycosides

The constitutions of the methyl 2,5(or 3,5)-dideoxy-2(or 3)-*C*-(hydroxymethyl)pentofuranosides **10–14** followed from elemental analysis (excepting **14**) and nuclear magnetic resonance data. The 200-MHz ^{1}H nmr spectra (Table 1) showed the appropriate substituent resonances, and the ring proton signals were for the most part well resolved. In particular, there was in each case a *single* proton resonating at high field, indicating a methine, rather than methylene, structure for C-2 or C-3 and, therefore, chain branching. The position of the branch was confirmed by spin decoupling, which proved the methine proton to be vicinal to the anomeric proton in **10–12**, and vicinal to H-2 and H-4 in **13** and **14**. Isomeric 2- and 3-deoxyhexopyranosides, by contrast, show at high field two proton signals, sometimes well resolved as, for example, in **15** (7). The ^{13}C nmr data (Table 2) clearly supported the constitutions. The proton-coupled spectra each contained two quartets (for *C*-methyl and *O*-methyl), a triplet (for hydroxymethyl), a doublet at relatively high field for the branch-point carbon, and three doublets for the remaining ring carbon atoms in the usual shift ranges. Spectral data establishing the structures of the benzylidene acetals **17** and **18** are listed in the experimental section.

The question of configuration at the branch point was somewhat more difficult to decide. The vicinal ^{1}H—^{1}H coupling constants (Table 1) were all in accord with the assigned config-

[4]A similar difference in sulfonate ester stability between **16** and its α-D-*gluco* epimer had been noted in their reactions with lithium aluminum hydride, in which **16** suffered far-reaching O—S fission at both O-2 and O-3 (4), whereas the *gluco* epimer was more stable toward this type of cleavage, particularly in position 3 (1, 5, 6).

urations, but, for some of the compounds, the alternative branch-point configuration could not be excluded with any certainty on this basis alone. Such difficulty was not unexpected for conformationally flexible, furanoid systems where reasonable models accommodating spectral data can often be constructed for more than one configuration. Comparisons with known conformational preferences in unbranched furanosides (8, 9) were helpful, but the possibility of bias associated with the *C*-hydroxymethyl branch had to be borne in mind. The assignments indicated were arrived at on the basis of the discussion that follows, which considers both ^{1}H and ^{13}C nmr parameters and is predicated on the assumption that only the branch-point configuration is at issue, with the other chiral centers not having been involved in the reaction and having, therefore, retained their original stereochemistry. (See also the subsequent section on the mechanism.)

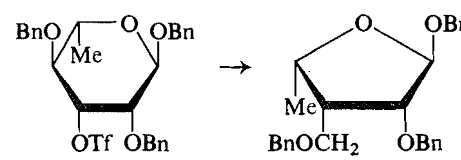
Beginning with the C-3 branched isomers, the α-L-*arabino* configuration of **13** can be regarded as secure. The $^3J_{H,H}$ values (Table 1) demand dihedral angles of $\phi_{1,2} > 90° < 120°$, and $\phi_{3,4} \leq 180°$, corresponding to a conformation in the $E_0 \rightleftharpoons {}^4T_0 \rightleftharpoons {}^4E$ segment of the pseudorotational itinerary for this configuration. This is in good agreement with Perlin's (8) and Angyal's (9) deduction of E_0 as the favored conformation of methyl α-L-arabinofuranoside. A shift towards $^4T_0$, as suggested by the particularly large $J_{3,4}$ value (8 Hz) in **13**, appears reasonable because it permits the hydroxymethyl group to become quasi-equatorial without sacrificing the quasi-axial orientation of the anomeric methoxyl group.[5] The ^{13}C chemical shifts (Table 2) indicate for **13** the largest overall deshielding (Σ = 459.6 ppm) among all the isomers, signifying the least amount of crowding in harmony with the all-*trans* substituent pattern (10). In the stereoisomer **14**, markedly increased shielding is experienced by C-1, C-2, and C-3 while C-4 and C-5 are affected little, which strongly suggests a *cis,cis,trans* substituent pattern, i.e., the α-D-*ribo* configuration. The $^3J_{H,H}$ data fit the $^0E \rightleftharpoons {}^0T_4$ conformation thereof, which has $\phi_{1,2}$ ~30°, $\phi_{2,3}$ ~0°, and $\phi_{3,4}$ ~160°, and in which the bulky C-3 substituent occupies a somewhat more outward position than does OH-3 in methyl α-D-ribofuranoside for which the adjacent segment $E_1 \rightleftharpoons {}^0T_1 \rightleftharpoons {}^0E$ has been proposed (8, 9). Although the ^{1}H couplings are equally consistent with the α-D-*xylo* ($^2E \rightleftharpoons {}^2T_3$) arrangement, we prefer the α-D-*ribo* assignment for **14** in view of the ^{13}C data just mentioned.

Turning now to the C-2 branched isomers **11** and **12**, we note their closely similar ^{13}C shifts for C-1, upfield in comparison with **13**, and therefore assume an identical, 1,2-*cis* arrangement. (The shielding effect of a *cis*-2-(hydroxymethyl) upon C-1 appears smaller than that of a *cis*-2-hydroxyl, cf. **14**.) This is borne out by the remaining shift data. The C-2 is shielded in **12**, relative to **11**, by the *cis*-vicinal OH-3. Conversely, C-4 in **11** is shielded, relative to **12**, due to the 3,4-*cis* arrangement which, incidentally, has also a marked effect on C-5, moving this signal upfield by 5–6 ppm from the resonance position in all the other isomers. The C-3 shifts are similar for **11** and **12**, as either compound possesses one *cis* and one *trans* pattern surrounding that carbon atom. The assignments resulting from these considerations are α-D-*xylo* for **11** and α-D-*ribo* for **12**. The $^3J_{H,H}$ values for **12** are in excellent accord therewith, fitting the $E_1 \rightleftharpoons {}^0T_1$ conformation ($\phi_{1,2}$ ~30°, $\phi_{2,3}$ ~25°, $\phi_{3,4}$ ~120°) that has been suggested (8, 9) for methyl α-D-ribofuranoside, and they are inconsistent with the 2-epimeric, α-D-*arabino* configuration.[6] The $^3J_{H,H}$ data for **11** allow no distinction, as they agree with both the α-D-*xylo* and the α-D-*lyxo* configuration in the respective conformations ^2E ($\phi_{1,2}$ ~30°, $\phi_{2,3}$ ~150°, $\phi_{3,4}$ ~30°) and ^3E ($\phi_{1,2}$ ~150°, $\phi_{2,3}$ and $\phi_{3,4}$ ~30°) or close pseudorotational variants. Our decision in favor of the former therefore rests solely on the foregoing interpretation of the ^{13}C data. However, it receives support from mechanistic considerations (see below). Compound **10**, being the enantiomer of **11**, requires no extra discussion.

The acetal **17** shows $J_{3,4}$ = 2.1 Hz as expected for the *gauche* orientation of the protons situated at the ring junctions, and $J_{1,2} = J_{2,3}$ = 4.8 Hz. The size of $J_{2,3}$ requires H-2 and H-3 to be *cis* ($\phi_{2,3}$ <60°); if they were *trans* ($\phi_{2,3}$ ~90°), a very small coupling would result. Clearly, the α-D-*lyxo* configuration is indicated. Compound **18** gave a two-proton multiplet at δ 2.13 attributable to a ring methylene group. The anomeric proton signal occurring at δ 4.79 was a slightly broadened singlet as is normal, in benzylidenated hexopyranosides, for a 1,2-diequatorial proton arrangement and is indicative of absence of a 1,2 axial–equatorial proton relationship. Double irradiation at δ 2.13 caused spin decoupling in the signal (δ 3.58) which was due to the ring proton at the hydroxylated position, and in the H-4 signal (δ 4.12). These features, whose interpretation was corroborated by comparison with data from several related isomers (1), established the structure shown.

Preliminary mechanistic considerations

While this work was in progress, we became aware of a precedent for LTBH-induced ring contraction in pyranosides. Pozsgay and Neszmélyi (12) obtained from benzyl 2,4-di-*O*-benzyl-3-*O*-trifluoromethylsulfonyl-α-L-rhamnopyranoside (**20**)



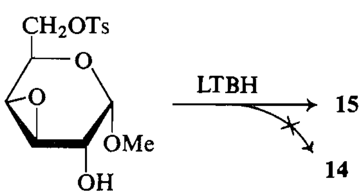
20 **21**

in 40% yield the ring-contracted product **21**. They interpreted the reaction as being initiated by departure of the sulfonyloxy group, to generate a pyranosid-3-yl carbocation that would rearrange by migration of the C-4,5 bond (which is antiparallel to the leaving group), and the rearranged ion would then accept hydride ion at the branch carbon atom, giving the 3-*C*-(benzyloxymethyl)-3-deoxypentofuranoside **21**. Whereas such a mechanism, which is supported by similar rearrangements occurring in solvolyses of pyranoside 3-sulfonates and in nitrous acid deamination of 3-amino sugars (13), may well apply for **20**, its operation in the present context could not be confidently presumed, for two main reasons. First, for the 2- and

[5] For a discussion of the factors which govern furanoside conformation, see ref. 9. The $^3J_{H,H}$ values for **13** would also be compatible with the 3-epimeric, α-L-*lyxo* glycoside, but only for a conformation close to ^1E. This is a highly unlikely form as it has three contiguous, *cis*-oriented substituents severely eclipsed; it is avoided by methyl α-L-lyxofuranoside (8, 9) and should be favored even less by the C-3 branched analog.

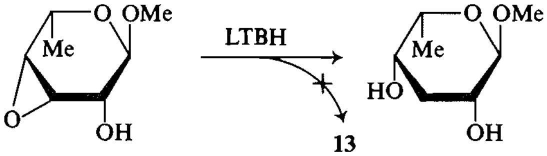
[6] For a series of 10 diversely substituted, C-2 branched α-L-arabinofuranosides, structurally related to our compounds but obtained in a different way, Jarý and co-workers (11) reported $J_{1,2}$ values in the range of 1.3–3.8 Hz (average, 2.1 Hz), and $J_{3,4}$ values in the range of 5.1–7.5 Hz (average, 6.5 Hz).

4-sulfonates **1–9**, it would imply the development of positive charge on C-2 or C-4, respectively. Although examples of pyranoside ring contraction involving incipient carbonium ions at those sites are in fact known in the domains of solvolysis and deamination mentioned (13), the dominant course of rearrangement in these cases is by participation of the ring oxygen atom, and alternative migrations of a carbon atom (C-2 to $^{+}$C-4, or C-4 to $^{+}$C-2) have been encountered as subordinate events only (14). In the present study, no evidence for the formation of products originating from ring oxygen migration was found. Secondly, in contrast to **20** the glycosides considered here all contain a free or potentially free (i.e., esterified) hydroxyl group positioned *trans*-vicinal to the sulfonate function, a feature which should play a key role in the observed transformations. Alcohols, including sugar hydroxyls, react instantly with alkali metal trialkylborohydrides to give hydrogen and alkoxytrialkylboronates (15). As we have seen earlier (1, 2), such boronates formed from tosylated sugars and LTBH can undergo internal displacement to produce epoxides, provided the proper geometry exists. Although in the previous examples (1, 2) the epoxides incurred ring opening with excess reductant as expected (16), giving deoxyhexopyranosides, an intermediacy of epoxides in the ring contractions now observed could not a priori be ruled out. Epoxide → carbonyl rearrangements, including instances with alkyl migration, are known and are, relevantly, catalyzed by lithium salts (halides or perchlorate) (17). Lithium salt produced in the epoxide-forming step (and by C-6 reduction, where applicable) might have induced rearrangement. In fact, when the ditosylate **7** was treated with an amount of LTBH insufficient for its complete conversion into the final products **14** and **15**, the 3,4-anhydrohexopyranoside **22** could be isolated from the reaction mixture. However, independently-synthesized **22** was rapidly (within 5 min) and almost quantitatively converted into **15** (isolated yield, 94%) under the same conditions, and no trace



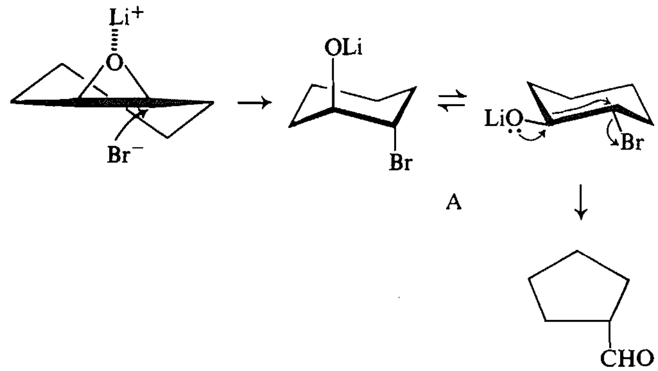
22

of **14** was detected (7). Similarly, the 3,4-anhydrohexopyranoside **23**, obtainable from **5** by action of base, reacted (7) with LTBH in the same way, to give methyl 3,6-dideoxy-α-L-*lyxo*-hexopyranoside (**24**) in the same yield and without any **13**. There was no discernible difference between the reductions of **22** and **23**, and lithium tosylate engendered during the reaction

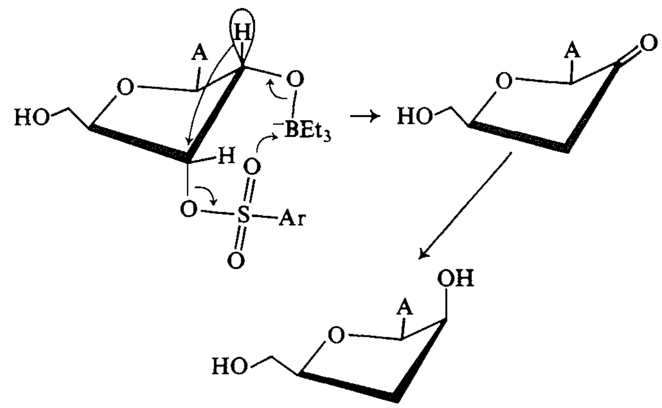


23 **24**

of the former appeared without influence. We therefore conclude that epoxides, where they do arise, are precursors for the unrearranged, minor products (**15**, **18**, and possibly others which may have escaped detection), but *not* for the ring-



SCHEME 1

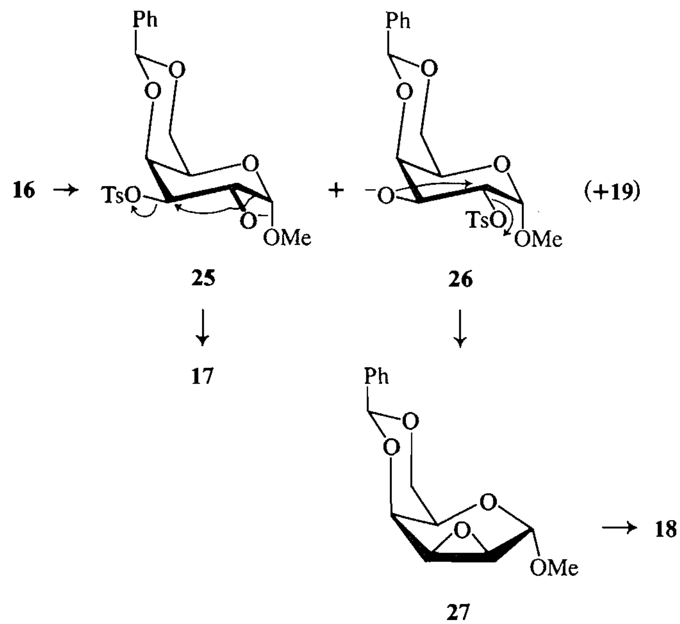


SCHEME 2

contracted furanosides, the formation of which must be due to some other mechanism.

One plausible mechanism would nevertheless be akin to the lithium salt-catalyzed epoxide → carbonyl rearrangement (17) just considered. It is assumed in the latter that intermediary halohydrin salts (A) arise from epoxides and react as shown in Scheme 1. Ring contraction as in A could well occur in the lithium alkoxytriethylboronates formed from glycoside tosylates; it would of course be followed by reduction of the carbonyl species primarily formed. The configurations assigned to our branched products would in every case accord with this process, the stereochemistry of which is determined by migration of a C—C bond that is antiparallel to the leaving group and gives retention of configuration. Support for the idea is provided by recent work of Hansske and Robins (18), who have deoxygenated ribonucleoside monotosylates with LTBH. Understandably there was no carbon migration in their furanosidic substrates, but hydride shifts following the same principle were demonstrated to occur (Scheme 2).

It appeared puzzling at first sight that the galactoside **16** gave a ring-contracted product (**17**) having the *lyxo* configuration and thus appeared to have incurred inversion at C-2. However, this is readily explained (see Scheme 3) by initial, partial desulfonylation (with little discrimination between O-2 and O-3) to produce monosulfonates. The 3-sulfonate **25** is then seen as the precursor for **17**, which is formed by migration of the C-1,2 bond, and retention at the original C-3 (that becomes C-2) is seen to hold. The 2-sulfonate **26**, on the other hand, reacting in this instance not by ring contraction but through the *talo* epoxide **27**, is the source of the 3-deoxyhexopyranoside derivative **18** which was obtained.



SCHEME 3

Although the mechanistic hypothesis outlined in this section appears attractive at the present time, it will probably require refinement in the light of additional observations which are being made in our currently continuing studies, and which are not fully understood as yet. One intriguing point is that the use of other metal trialkylborohydrides instead of LTBH apparently leads to quite different results. It is hoped that the investigations in progress will throw more light on the nature and scope of these interesting and synthetically useful desulfonyloxylations.

Experimental

Apparatus, materials, and methods

Lithium triethylborohydride (Super Hydride[R], LTBH) was purchased from Aldrich Chemical Co. as an *M* solution in oxolane (THF). Optical rotations were measured at ~25°C with a Perkin–Elmer 241 polarimeter and refer to chloroform solutions. Melting points were determined with a Gallenkamp apparatus and are uncorrected. Thin layer chromatography (tlc) was performed on precoated plates of silica gel SIL-25UV$_{254}$ (Macherey–Nagel & Co., Germany). Spots were made visible by spraying the plates with 5% sulfuric acid in ethanol, and heating them briefly on a hot plate. Column chromatography was performed on Merck Silica Gel 60, 230–400 mesh, or on basic aluminum oxide suitable for chromatography (Shawinigan), as referred to by SiO_2 and Al_2O_3, respectively. Unless otherwise indicated, the following solvent mixtures (v/v) were employed for chromatography: A, ethyl acetate – hexane, 1:2; B, the same solvents, but 1:1; C, the same, but 2:1, and D, ethyl acetate.

Preparation of the starting glycosides

(a) *Known compounds*

Published procedures were employed, occasionally with minor technical modifications, for the preparation of **1** (19), **5** (20), **6** (21), **7** (22), **9** (22), and **16** (23). Compound **2** (mp 156–157°C, $[\alpha]_D$ +86.3°) was obtained from its known (24) 3,4-*O*-isopropylidene derivative as described (19) for **1** (mp 157–158°C, $[\alpha]_D$ −85°). The ir and nmr spectra of **1** and **2** were identical.

(b) *Methyl 4-O-benzoyl-6-bromo-6-deoxy-2-O-p-tolylsulfonyl-α-D-glucopyranoside (3)*

Pure (1) methyl 4,6-*O*-benzylidene-2-*O*-*p*-tolylsulfonyl-α-D-glucopyranoside (9.1 g) was heated for 2.5 h with *N*-bromosuccinimide (4.72 g) and barium carbonate (10 g) in refluxing carbon tetrachloride (350 mL). Processing as for the analogous 2-*O*-mesyl compound (25) gave **3** (5.1 g, 47.5%) after crystallization from a small volume of CCl_4; mp 50–51°C, $[\alpha]_D$ +48.7° (*c* 0.25). The ^{1}H nmr data (200 MHz, $CDCl_3$) δ: 8.04–7.26 (9H, arom.), 5.05 (dd, $J_{3,4}$ = 9, $J_{4,5}$ = 9.9 Hz, H-4), 4.87 (d, $J_{1,2}$ = 3.7 Hz, H-1), 4.34 (dd, $J_{2,3}$ = 9.5 Hz, H-2), 4.19 (dt, $J_{3\text{-}OH}$ = 13.7 Hz; t upon D_2O exchange, $J_{2,3}$ = $J_{3,4}$ = 9.3 Hz, H-3), 4.06 (ddd, $J_{4,5}$ = 10, $J_{5,6}$ = 2.8, $J_{5,6'}$ = 7.2 Hz, H-5), 3.44 (m, 2H, H-6,6′), 3.42 (s, *O*-Me), and 2.44 (s, *Ar*Me); *m/z* (DCI mode): 515, 517 (*M* + 1), 483, 485 (M + 1 − OCH_3), 405 (M + 1 − OCH_3 − Br). *Anal.* calcd. for $C_{21}H_{23}BrO_8S$ (515.4): C 48.93, H 4.50, Br 15.51; found: C 49.01, H 4.60, Br 15.4.

(c) *Methyl 6-deoxy-6-iodo-2-O-p-tolylsulfonyl-α-D-glucopyranoside (4)*

Crystalline (mp 119.5–121°C, from ethyl acetate – hexane) 3,4-di-*O*-acetyl derivative (26) of **4** (5.42 g, 10.6 mmol) was deacetylated by treatment with sodium methoxide (2 mL of a 2 *M* solution) in a mixture of chloroform (50 mL) and methanol (10 mL), at room temperature during 1 h. Complete saponification of the diacetate (R_f 0.65) to **4** (R_f 0.5) was indicated by tlc (solvent B), and pilot runs had shown that **4** is stable for several hours under these conditions, with only minute traces of a faster-moving by-product arising. The solvents were removed at low temperature, and 3 portions of added THF were evaporated from the residue, which was obtained as a slightly yellowish foam and used without purification, after drying in a desiccator.

(d) *Methyl 4,6-di-O-p-tolylsulfonyl-α-D-glucopyranoside (8) by ammonolysis of 7*

Methanolic ammonia (160 mL, saturated at 0°C) and a solution of **7** (4.11 g) in methanol (160 mL) were mixed and stored in a refrigerator for 3 days; tlc with solvent A revealed clean replacement of the fast-moving **7** by slow-moving **8**. The solvent was removed at low temperature and the residue chromatographed on a short column of SiO_2 by means of solvent B. Compound **8** was obtained as a colorless syrup (2.37 g, 82%), $[\alpha]_D$ +102° (*c* 1.1). A 60-MHz nmr spectrum indicated complete removal of the benzoate and retention of the tosyl groups.

(e) *Attempted Zemplén deacylation of 7*

Although **7** is known to give the anhydro sugar **22** on heating with sodium methoxide in methanol solution (21), we attempted to prepare the presumed intermediate, **8**, by employing milder conditions. In spite of its failure in this regard, the experiment is recorded because of unexpected results concerning relative stabilities of different ester functions.

To a solution of **7** (3.55 g, 5 mmol) in 1:1 chloroform–methanol (50 mL) was added at 0°C an *M* sodium methoxide solution (1 mL). After standing for 4 h at 0°C, the mixture showed a complex pattern in tlc (solvent B), which changed little during another hour and after addition of another 0.5 mL of methoxide. There were 5 spots, R_f 0.8, 0.6, 0.35, 0.1, and 0.0. Work-up included neutralization with Dry Ice, evaporation, deionization in methanolic medium with cation and anion exchange resins, and evaporation of added toluene from the material which was obtained as a syrup. Trituration of the syrup with toluene and refrigeration (2 days) caused crystallization of the immobile component (R_f 0.0), which evidently was the major reaction product (1.735 g). Recrystallized from a small amount of ethyl acetate, it had mp 103–104°C, whereas from chloroform it gave long needles of mp 122–123.5°C. From a small amount of water a hydrate (mp 55–56°C) crystallized readily. These data, together with ir and ^{1}H nmr data showing absence of benzoyl and presence of only one tosyl group besides hydroxyl, identified the product as methyl 6-*O*-*p*-tolylsulfonyl-α-D-glucopyranoside (lit. (27) mp 124°C (anhydrous) and 56–58°C (hydrate)). Addition of a little hexane to the above toluene mother liquor gave a gummy deposit containing some of the same product together with the component of R_f 0.1. The latter probably was ditosylate **8**, but the amount was small and it could not be isolated pure. The three faster-moving components, contained in the toluene–hexane solution that was decanted from the gum, were separated on a column (16 × 1 cm) of SiO_2 (solvent B). There was obtained some unchanged **7**, R_f 0.8, mp 132°C (from methanol); a small amount of crystalline product R_f 0.6, mp 145.5°C (from ethanol), whose ir and ^{1}H nmr spectra suggested that it was the 3-monobenzoate of **8**; and methyl 3,4-anhydro-6-*O*-*p*-tolylsulfonyl-α-D-galactopyranoside (**22**), R_f 0.3, needles upon trituration with water and a few drops of ethanol on a steam bath, mp 95–96°C (lit. (21) mp 94–95°C). The extensive de-*O*-sulfonylation at the 4-position, to give the major product (R_f 0.0) under conditions where even debenzoylation was incomplete, appears rather remarkable.

General procedure for reactions of glycoside tosylates with LTBH

The starting sugar derivative was dissolved in reagent-grade THF that had been dried, immediately before use, by refluxing it over, and distilling it from, potassium metal in the presence of benzophenone. All operations were carried out under a nitrogen atmosphere. The *M* LTBH solution was introduced by syringe into the magnetically stirred and chilled (ice-water bath) solution of the substrate. Cooling was then discontinued and the mixture was boiled under reflux, with periodic monitoring of the progress of reaction by tlc. Amounts of materials and reaction times are given for each individual experiment. For processing, the reaction mixture was chilled to 0°C, and methanol was added dropwise in slight excess to ensure the complete decomposition of remnant hydride. The solution was then concentrated on the rotary evaporator at 35°C to a small volume (one-quarter to one-fifth) and poured into 10 volumes of ice water. The mixture was stirred at ambient temperature for several hours (or overnight). An amount of 30% hydrogen peroxide as specified was diluted with water and added cautiously and dropwise to the mixture, preferably with cooling. (**Violent reaction may occur if this addition is done too rapidly**.) After 1 h, the solution was carefully neutralized to pH 7 with aqueous sodium hydrogen sulfate solution unless otherwise indicated; any excess of acid must be avoided. The solution was then evaporated to about one-third its volume, and exhaustively extracted with chloroform or ethyl acetate as specified. Finally, the aqueous phase was evaporated to dryness, and the residue was checked by tlc. If it still contained a significant amount of organic material, it was extracted with ethyl acetate or chloroform. The combined extracts were dried ($MgSO_4$ or Na_2SO_4), and evaporated to give the crude reaction product.

*Methyl 2,5-dideoxy-2-C-(hydroxymethyl)-α-L-*xylo*-pentofuranoside (10)*

The reaction was performed with **1** (4.10 g, 12.35 mmol) in THF (100 mL) and LTBH solution (100 mL, 8.1 mol. equiv.) during 30 min, after which tlc (solvent D) showed absence of **1** (R_f 0.7) and presence of a new spot, R_f 0.35. The oxidative treatment was performed with 33 mL of 30% hydrogen peroxide. Extraction of the aqueous phase with ethyl acetate, and of the residue of evaporation with chloroform, gave a combined yield of 1.27 g (63.5%) of crude **10** which crystallized in part from ethyl acetate – hexane; mp 73°C. Chromatography of the mother liquor material on Al_2O_3, using solvent B followed by solvent D as eluants, furnished additional, crystalline **10**. The combined crops were recrystallized from chloroform, affording 1.06 g (53%) of analytically pure **10**, mp 74–74.5°C, $[\alpha]_D$ −174.5° (*c* 2.2). *Anal.* calcd. for $C_7H_{14}O_4$ (162.2): C 51.84, H 8.70; found: C 51.60, H 8.67.

*Methyl 2,5-dideoxy-2-C-(hydroxymethyl)-α-D-*xylo*-pentofuranoside (11)*

Compound **11** was obtained from **2** in 61% crude yield, as described for the enantiomer **10**. After purification by chromatography and crystallization, it showed mp 73–75°C and $[\alpha]_D$ +173° (*c* 0.9). Its ir, ^{1}H nmr, and ^{13}C nmr spectra were superposable on those of **10**.

*Methyl 2,5-dideoxy-2-C-(hydroxymethyl)-α-D-*ribo*-pentofuranoside (12)*

(a) *From the 6-bromo glycoside 3*

Compound **3** (5.15 g, 10 mmol) in THF (60 mL) and LTBH solution (100 mL) were allowed to react for 2 h. Processing included a peroxide treatment with 35 mL of 30% reagent, and was performed as described before, except that neutralization with $NaHSO_4$ was dispensed with. Chloroform extraction of the partially evaporated, aqueous solution afforded crude **12** (868 mg, 53.6%) as a solid after solvent evaporation. Recrystallized from 1:1 carbon tetrachloride – hexane, it had mp 41–42°C and $[\alpha]_D$ +133° (*c* 2.2). *Anal.* calcd. for $C_7H_{14}O_4$ (162.2): C 51.84, H 8.70; found: C 51.91, H 8.48.

(b) *From the 6-iodo glycoside 4*

The crude **4** obtained in the aforedescribed saponification of 5.42 g (10.6 mmol) of its diacetate was dissolved in THF (60 mL) and allowed to react with LTBH solution (80 mL) during 1.75 h. In this instance, the treatment with 30% hydrogen peroxide (26 mL) included in the work-up was followed by neutralization of the reaction mixture with $NaHSO_4$, and the partially evaporated solution was extracted with ethyl acetate. There was obtained crude **12** (1.27 g, 62%) as a yellow syrup. Column chromatography on Al_2O_3 using solvent C as the eluant gave, from chromatographically homogeneous fractions, compound **12** as a colorless syrup that crystallized on refrigeration but proved difficult to recrystallize; mp 34–35°C and $[\alpha]_D$ +118° (*c* 4.4). Although the physical constants were somewhat lower than in **12** prepared under (a), the ir, ^{1}H nmr, and ^{13}C nmr spectra of the two preparations were identical.

*Methyl 3,5-dideoxy-3-C-(hydroxymethyl)-α-D-*arabino*-pentofuranoside (13)*

Compound **5** (3.40 g, 10.23 mmol) in THF (80 mL) and LTBH solution (82 mL) were allowed to react for 30 min, after which all of the **5** was consumed (tlc with solvent D). In this and similar, preceding experiments with **5** no peroxide treatment was included in the work-up procedure as the studies were performed at an early stage before the beneficial effect of such treatment on yields was realized. The yield of pure **13** (506 mg, 30.5%) obtained upon chloroform extraction and column chromatography on Al_2O_3 with solvent B followed by solvent D, and recrystallization from ether – petroleum ether (bp 30–60°C). was therefore low, and a considerable proportion of product emerged from the column as a fast-moving organoboron conjugate. Crystalline **13** showed R_f 0.35 (solvent D), mp 64°C, $[\alpha]_D$ −112° (*c* 2.3). *Anal.* calcd. for $C_7H_{14}O_4$ (162.2): C 51.84, H 8.70; found: C 51.67, H 8.47.

*Methyl 3,5-dideoxy-3-C-(hydroxymethyl)-α-D-*ribo*-pentofuranoside (14)*

(a) *From the 6-deoxy glycoside 6*

Compound **6** (4.32 g, 8.0 mmol) in THF (32 mL) was allowed to react with LTBH solution (64 mL, 8 mol. equiv.) during 45 min. Normal processing, but with addition of potassium carbonate in the treatment with hydrogen peroxide (22 mL), and prolongation of this treatment overnight, furnished 1.00 g (77%) of **14**, R_f 0.34 (solvent D), by chloroform extraction. Compound **15** (R_f 0.40, see below) was not detected. Compound **14** resisted all attempts at crystallization. After chromatography on SiO_2 with solvent A (recovery, 74%) it showed $[\alpha]_D$ +162.2° (*c* 1.2). To corroborate the structure, a sample of **14** was acetylated in the conventional manner (acetic anhydride – pyridine), and the 200-Mz nmr data of the diacetate are included in Table 1.

(b) *From the 4,6-ditosylate 7*

Compound **7** (3.70 g, 5.21 mmol) in THF (40 mL) and LTBH solution (37 mL) was boiled for 2 h, after which time another 7 mL of LTBH was added (for a total of 8.4 mol. equiv.), and boiling was continued for 1 h. Work-up included oxidation with 15 mL of 30% H_2O_2, and chloroform extraction. It gave a syrupy glycoside mixture (470 mg, 56%) that showed two partially overlapping spots, R_f 0.40 and 0.35, in tlc with solvent D. The ^{1}H nmr spectral features of **14** were superposed on those of methyl α-abequoside (**15**), as was ascertained by comparison with the spectra of pure **14** and independently prepared (7), pure **15**. A ratio of 3:2 was found by signal integration for H-1, *O*-CH_3, and *C*-CH_3 at δ 4.96, 3.49, and 1.29 (for **14**), and 4.68, 3.45 and 1.21 (for **15**), respectively.

Several similar experiments were carried out using 10 mol. equiv. of LTBH and reaction times of 2–6 h, and results were always similar. However, in a 30-min reaction, desulfonyloxylation was incomplete, and from the mixture of products a small proportion of the 3,4-epoxide

22 was chromatographically isolated crystalline (mp 93°C). It was identified by comparison with an authentic sample (21).

Separation of **14** and **15** was difficult to achieve and required multiple chromatography. While it was possible to isolate part of **14** in spectroscopically homogeneous form, the abequoside **15** was never obtained free from small proportions of **14**. Nevertheless, its identity was established beyond doubt as the 200-MHz ^{1}H nmr data matched those published (7).

(c) *From the 4,6-ditosylate 8 and the 6-chloro glycoside 9*

A 40-min reaction performed with **8** (2.3 g, 4.58 mmol) and 13.5 mol. equiv. of LTBH gave, after standard processing, a mixture of **14** and **15** (yield not recorded), for which the nmr spectrum indicated an approximate 1:1 ratio. A 60-min reaction of **9** (1.49 g, 2.6 mmol) with 10 mol. equiv. of LTBH gave a similar, 1:1 mixture (200 mg, 47%).

*Methyl 3,5-*O*-benzylidene-2-deoxy-2-*C*-(hydroxymethyl)-α-*D*-*lyxo*-pentofuranoside (17) and methyl 4,6-*O*-benzylidene-3-deoxy-α-*D*-*lyxo*-hexopyranoside (18)*

To a solution of **16** (1.00 g, 1.75 mmol) in THF (10 mL) was added LTBH solution (10 mL), followed after 30 min of refluxing by another 10 mL of the same. After 20 h of boiling, the solution showed 3 spots, at R_f 0.57, 0.22, and ~0.1 (tlc with 1:4 ethyl acetate – chloroform). Processing was unproblematic and was performed as in the work (1) with benzylidenated glucosides. It included addition of methanol to the chilled reaction mixture followed by dilution with water, evaporation to remove most of the THF, and extraction of the products by ethyl acetate. Peroxide treatment was not required. The product mixture was chromatographed on a silica gel column by use of 1:4 ethyl acetate – chloroform. The component emerging first (R_f 0.57) proved to be the pyranoside **18**; yield, 100 mg (21.5%); mp 88.5–89°C; $[\alpha]_D$ +56.8° (*c* 0.9); ^{1}H nmr (200 MHz, $CDCl_3$) δ: 7.52–7.26 (m, 5H, Ph), 5.49 (s, *Ph*-CH), 4.79 (s, slightly broadened, H-1), 4.30 (dd, $J_{5,6}$ = 1.6, $J_{6,6'}$ = 12.5 Hz, H-6), 4.12 (nm, W_H = 3.2 Hz, H-4), 4.075 (dd, J = 1.6 and 12.5 Hz, H-6′), 3.70 (d, $J_{2,OH}$ = 11.5 Hz, OH-2, strongly hydrogen-bonded with O-4), 3.69 (nm, $J_{4,5}$ ~1.5 Hz, H-5), 3.58 (d of nm; on double irradiation at δ 2.13: dd, $J_{2,OH}$ = 11.5, $J_{2,4}$ = 1.6 Hz, H-2), 3.44 (s, 3H, OMe), and 2.13 (nm, 2H, H-3,3′); *m/z* (FAB mode): 267 (*M* + 1) and 235 (M − OCH_3). *Anal.* calcd. for $C_{14}H_{18}O_5$ (266.3): C 63.14, H 6.81; found: C 63.00, H 6.75.

The second product (R_f 0.22) eluted from the column was the furanoside **17**; yield, 177 mg (38%); mp 121–122°C, $[\alpha]_D$ +51.4° (*c* 0.9); ^{1}H nmr (200 MHz, $CDCl_3$) δ: 7.49–7.34 (m, 5H, Ph), 5.47 (s, *Ph*-CH), 5.30 (d, $J_{1,2}$ = 4.8 Hz, H-1), 4.63 (dd, $J_{2,3}$ = 5.0, $J_{3,4}$ = 2.1 Hz, H-3), 4.46 (d, $J_{5,5'}$ = 13.2 Hz, H-5), 4.16 (dd, $J_{4,5'}$ = 2.2, $J_{5,5'}$ = 13.2 Hz, H-5′), 4.00 (m, 3H, H-4 and H-2′,2″ (hydroxymethyl)), 3.47 (s, 3H, OMe), and 2.46 (ddt, $J_{1,2} \approx J_{2,3} \approx$ 4.8, $J_{2,2'}$ = 4.5, $J_{2,2''}$ = 6.2 Hz, H-2); *m/z* (FAB mode): 267 (*M* + 1) and 235 (M − OCH_3). *Anal.* calcd. for $C_{14}H_{18}O_5$ (266.3): C 63.14, H 6.81; found: C 63.14, H 6.73.

The third component (R_f ~0.1) eluted from the column amounted to 90 mg (18%) and was identified as the diol **19** by spectral comparison with an authentic sample.

Acknowledgments

We acknowledge gratefully the financial support of this work by the Natural Sciences and Engineering Research Council of Canada. Professor A. S. Perlin, Montreal, is thanked for valuable discussion concerning the interpretation of nuclear magnetic resonance data. Professor R. Köster, Mülheim/Ruhr, provided stimulating suggestions relating to problems associated with organoboron reactions. Ms. Cristine Lajeunesse and Mr. Fabio Zanetti have skilfully participated in the preparation of starting compounds and the performance of preliminary experiments.

HANS H. BAER, BRUNO RADATUS, and JACQUES DEFAYE. Can. J. Chem. **63**, 440 (1985).

A practical, four-step synthesis of the title compound starting from 2-*O*-benzyl-4,6-*O*-benzylidene-α-D-altropyranosyl 2-*O*-benzyl-4,6-*O*-benzylidene-α-D-altropyranoside is described. Trifluoromethylsulfonylation followed by azide displacement furnished the corresponding α-D-*manno*,α-D-*manno* 3,3′-diazido-3,3′-dideoxy derivative, and subsequent hydrolytic deacetalation, followed by catalytic transfer hydrogenolysis to simultaneously reduce the azido groups and cleave the benzyl ether groups, gave the title disaccharide in 30% overall yield. As preceding work had provided the blocked starting disaccharide in a sequence of four facile operations departing from commercial α,α-trehalose (overall yield, 53%), the title compound can now be prepared conveniently on a multigram scale.

HANS H. BAER, BRUNO RADATUS et JACQUES DEFAYE. Can. J. Chem. **63**, 440 (1985).

Le 3-amino-3-désoxy-α-D-mannopyranosyl-3-amino-3-désoxy-α-D-mannopyranoside est obtenu commodément en quatre étapes partant du 2-*O*-benzyl-4,6-*O*-benzylidène-α-D-altropyranosyl-2-*O*-benzyl-4,6-*O*-benzylidène-α-D-altropyranoside. Une trifluorométhylsulfonylation suivie de déplacement par l'ion azide conduit au dérivé α-D-*manno*,α-D-*manno* 3,3′-diazido-3,3′-didésoxy qui, par hydrolyse des groupes protecteurs acétaliques, puis hydrogènolyse catalytique simultanée par transfert, des groupes azide et des groupes protecteurs benzyle, permet d'obtenir le disaccharide aminé attendu avec un rendement global de 30%. L'altroside de départ étant lui-même obtenu en quatre étapes commodes et un rendement global de 53% partant de l'α,α-tréhalose commercial, ce disaccharide aminé est donc désormais accessible à l'échelle préparative.

Introduction

Some years ago, we undertook chemical syntheses of several new, nitrogenous disaccharides structurally related to the important natural sugar α-D-glucopyranosyl α-D-glucopyranoside (α,α-trehalose, **1**). They included 3-amino-3-deoxy-α,α-trehalose (1) as well as 3,3′-diamino-3,3′-dideoxy-α,α-trehalose and its stereoisomers having the α-D-*gluco*,α-D-*manno* and α-D-*manno*,α-D-*manno* configurations (2). One point of interest attaching to these compounds relates to their use as substrate analogs for studies of the specificity and mechanism of action of the enzyme trehalase (3). Furthermore, the synthetic work was prompted by the fact that some naturally occurring amino disaccharides related to α,α-trehalose, which are produced as metabolites by certain *Streptomyces* species, had been found to show antibiotic activity (4). These were the 2-amino-2-deoxy (5) and 4-amino-4-deoxy (6) derivatives of **1**, and 2-amino-2-deoxy-α-D-glucopyranosyl α-D-mannopyranoside (7). It has subsequently been determined that one of the disaccharides obtained by us (2), namely 3-amino-3-deoxy-α-D-mannopyranosyl 3-amino-3-deoxy-α-D-mannopyranoside dihydrochloride (**11**), possesses a remarkable inhibitory activity (at 10 μg/mL in vitro) against *Mycobacterium tuberculosis* (human strain H37RV) and *Mycobacterium avium*, whereas the two stereoisomers mentioned showed no significant activity.[2] Unfortunately, the reported synthesis (2), based on the nitromethane cyclization methodology, had furnished chiefly the inactive isomers while **11** was formed as a minor product only, and was rather tedious to isolate. A more efficient procedure was therefore required in order to provide **11** conveniently in quantities which would enable detailed, pharmacological evaluation to be undertaken.

Several possible approaches were devised. One of them involved osmium tetraoxide-catalyzed *cis*-oxyamination, with chloramine-T, of a 2,2′-bis-enoside related to α,α-trehalose. This approach, expected to lead to diaminated disaccharides having the D-*manno*,D-*manno* configuration, did in fact afford **11** but, once again, in low yield, with the 2,3′- and 2,2′-diamino regioisomers constituting the major products (8). Although these latter disaccharides, which were previously unknown and have not thus far been evaluated biologically, command interest of their own, the problem of rendering **11** more readily available remained unsolved until an alternative synthesis, to be reported here, could be achieved.

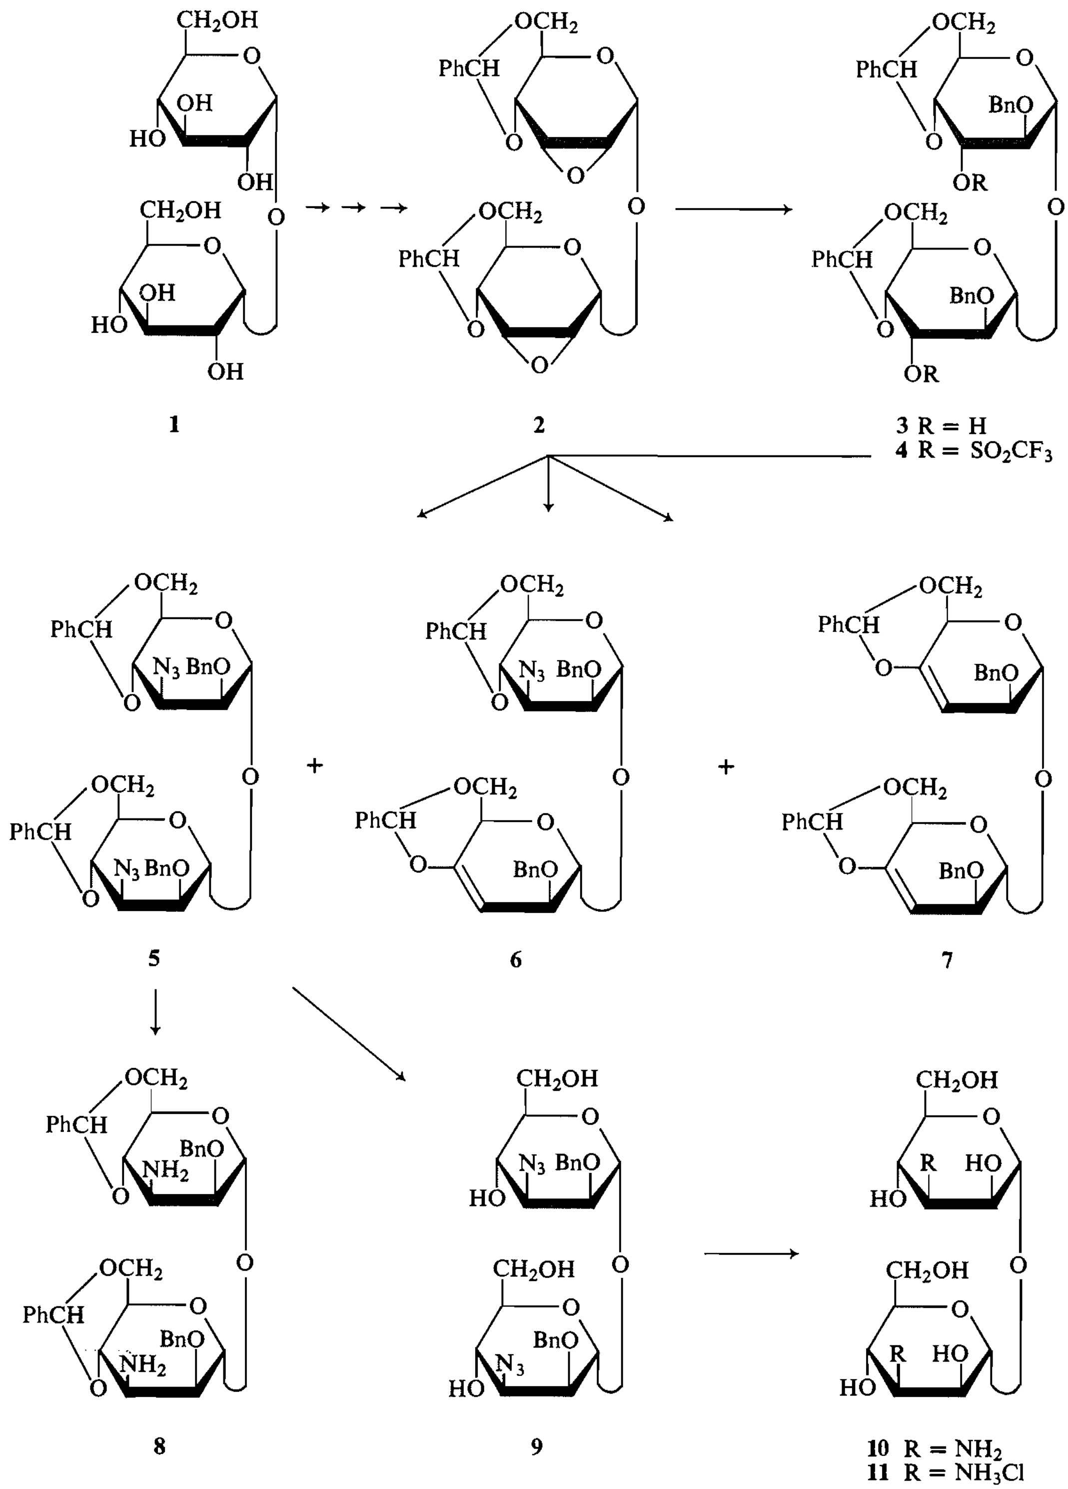
Results

The synthesis departs from commercially available α,α,-trehalose (**1**), which is readily converted, in three high-yielding steps involving known procedures, into the bis-benzylidenated diepoxide **2**. As already reported (9), the latter reacted with sodium benzoxide in benzyl alcohol by predominantly diaxial opening of the oxirane ring, in accord with the Fürst–Plattner rule, affording the key intermediate **3**, 2-*O*-benzyl-4,6-*O*-benzylidene-α-D-altropyranosyl 2-*O*-benzyl-4,6-*O*-benzylidene-α-D-altropyranoside. The overall yield of **3** from **1** was 53% (9).

From **3**, the crystalline ditriflate **4** was obtained in 94% yield. The next step consisted of nucleophilic displacement with azide ion, to give the *manno,manno* diazide **5**. This crucial reaction was the only somewhat problematical point in the sequence of operations. The difficulty arose from a strong tendency for elimination to compete with substitution, resulting in the formation of the unwanted mono- and di-alkenes **6** and

[1] Author to whom inquiries may be directed.

[2] The authors are indebted to Dr. H. L. David, Chef du Service de la Tuberculose à l'Institut Pasteur, Paris, for performing the assays. (Private communication, October 1979).



7. In an analogous operation previously executed (1), a trehalose-derived 3-triflate had been very easily displaced at ambient to slightly elevated temperature, giving an 80% yield of the desired product and showing no evidence for elimination,[3] and that experience encouraged us in our present endeavor. However, the analogous substrate in question had possessed the D-*allo* configuration, with an equatorial benzoate ester function at C-2, and it was understandable that, in **4**, the axial benzyl ether group in that position would be apt to interfere seriously in the transition state of a parallel approach of nucleophile to C-3. We investigated the azide displacement in **4** under a wide variety of conditions, and invariably obtained mixtures of **5**, **6**, and **7**, generally with the desired diazide **5** present in an unsatisfactory proportion. However, we eventually succeeded in specifying conditions under which **5** was the main product. On a multigram scale, the reaction was best performed with sodium azide in a refluxing mixture of benzene

[3] The reaction was performed with lithium azide in a mixture of DMF and DMSO. The corresponding 3-mesylate reacted much more sluggishly (12 h at 105°C in DMSO–HMPA), and did suffer partial elimination.

and water, in the presence of tetrabutylammonium hydrogen sulfate as a phase transfer catalyst. The slow process was essentially complete after five days, and chromatographic separation of the products afforded crystalline **5** in 51.5% yield, and the unsymmetrical azidoalkene **6** and the dialkene **7**, both crystalline, in 40 and ~2% yield, respectively.

In order to convert **5** most efficiently into the target compound, several possibilities for sequential or simultaneous operations to reduce the azido functions and remove the protecting groups were considered, and tested in pilot experiments. Catalytic hydrogenation of **5**, or reduction with lithium aluminum hydride, gave the blocked diamino sugar **8**, but difficulties experienced in its complete deprotection caused us not to pursue this route any further. Instead, **5** was first debenzylidenated by hydrolysis with 80% acetic acid, affording the partially deprotected diazide **9**, crystalline in 91% yield. This product was then subjected to catalytic transfer hydrogenolysis (10) with cyclohexene in the presence of palladium on charcoal, which effected rapid reduction of the azido groups and simultaneously, although more slowly, cleavage of the benzyl ethers (11). The 3,3′diamino-3,3′-dideoxy disaccharide (**10**) was obtained as a crystalline monohydrate in 61% yield after purification. The crude **10** contained a small proportion of a by-product which was removed by recrystallization, and was judged to be a mono-*N*-ethyl derivative of **10**, on the basis of its ^{1}H nmr spectrum.[4] The free base **10** was converted into its dihydrochloride **11** that proved in every respect identical with previously synthesized (2, 8) material.

In summary, the present synthesis allows the convenient preparation of the title compound in four steps with ~30% overall yield from the intermediate (9) disaccharide **3**, or in eight steps from commercial trehalose with ~16% overall yield. The reactions can be performed on a multigram scale and require only common reagents and standard operations.

NOTE ADDED IN PROOF. The base **10** was submitted for testing to Dr. H. L. David, Institut Pasteur, Paris, and Dr. A. Laszlo, National Reference Centre of Tuberculosis, Ottawa. Neither laboratory was able to observe antimycobacterial activity as previously found[2] for the dihydrochloride **11** prepared by our first (2) method. The reason for this apparent discrepancy is being investigated.

Experimental

Instruments and general methods

Optical rotations were measured at ~25°C with a Perkin–Elmer 241 polarimeter. The ^{1}H nmr data refer to 300-MHz spectra recorded on a Varian XL-300 instrument, unless otherwise indicated. Melting points were determined with a Gallenkamp apparatus, and are uncorrected. Column chromatography was performed on Silica Gel 60, 230–400 mesh (E. Merck AG, West Germany), and the medium-pressure technique was usually employed for separations on a multigram scale. For tlc, precoated silica gel plates were used, and components were made visible by spraying the plates with 5% sulfuric acid in ethanol, and heating them briefly on a hot plate. Frequently used solvent combinations were ethyl acetate and hexane in the proportions (v/v) 1:9 (solvent A), 1:4 (solvent B), and 1:1 (solvent C).

[4] It may be assumed that ethanol, which was employed as a co-solvent, acted to some extent as a hydrogen donor (10) in the system, producing acetaldehyde that, with **10**, formed an imine whose hydrogenation gave the by-product. To optimize the transfer hydrogenation, it may be worthwhile to try modified conditions such as, for example, the use of 1,4-cyclohexadiene, which has been recommended (12) for the efficient debenzylation of protected peptides.

2-O-Benzyl-4,6-O-benzylidene-3-O-trifluoromethylsulfonyl-α-D-altropyranosyl 2-O-benzyl-4,6-O-benzylidene-3-O-trifluoromethylsulfonyl-α-D-altropyranoside (4)

Trifluoromethanesulfonic anhydride (7.3 mL, 43 mmol) in dry dichloromethane (200 mL) was added dropwise over a period of 30 min to a chilled (−17°C) solution of the diol (9) **3** (7.0 g, 10 mmol) in dry dichloromethane (70 mL) and pyridine (6 mL). After the end of the addition, spots of about equal strength were seen for starting **4** and what appeared to be its monotriflated derivative (tlc with chloroform). The triflation was then allowed to continue at room temperature and was complete after 2.5 h. The mixture was shaken with added water and, after phase separation, the organic layer was washed twice with sodium hydrogen carbonate solution and once with water. The combined aqueous phase and washings were extracted twice with dichloromethane. The combined organic phases were dried (Na_2SO_4), and evaporated (bath temperature, 35°C), and remnant pyridine was removed by two coevaporations with toluene. The residue was eventually obtained as a syrupy foam. Trituration of the material with ethanol (20 mL) gave a first crop (8.157 g) of slightly yellowish crystals, which were collected and washed with cold ethanol; mp 97–98.5°C, with decomposition starting at 91°C. The ethanolic mother liquor was diluted with several volumes of benzene, washed with aqueous $NaHCO_3$ solution, dried (Na_2SO_4), and evaporated, to give a thin syrup from which a second crop of **4** (0.644 g) was obtained by crystallization from ethanol. The combined crops were recrystallized by dissolution in benzene, evaporation of the solvent, and trituration of the residue with ethanol (20 mL), to give 8.61 g of pure **4**. The mother liquor of recrystallization was combined with the original mother liquor, and the solute was chromatographed on a short column of silica gel, with solvent A followed by solvent B as eluants, yielding another crop of crystalline **4** (0.246 g). The mother liquor therefrom was evaporated, and the residue was treated with triflic anhydride as described before (with appropriate proportions of reagents). Similar processing gave a final crop of **4** (0.239 g), for a total of 9.092 g (94.4%) of chromatographically homogeneous product.

An analytical sample was recrystallized twice more as described; mp 98–102°C, $[\alpha]_D$ +80.0° (*c* 0.5, chloroform); δ ($CDCl_3$): 7.44 (m, Ph), 5.64 (s, *Ph*-CH), 5.12 (narrow t, H-3), 4.66 (s, H-1), 4.82 and 4.57 (AB-q, J_{gem} = 12.0 Hz, *Ph*-CH_2), 4.13 (dd, $J_{5,6e}$ = 5.0, $J_{6a,6e}$ = 10.0 Hz, H-6e), 4.08 (dd, $J_{3,4}$ = 2.7, $J_{4,5}$ = 9.7 Hz, H-4), 3.91 (d, $J_{2,3}$ = 3.0 Hz, H-2), 3.72 (t, $J_{5,6a}$ = $J_{6a,6e}$ = 10.0 Hz, H-6a), 3.58 (dt, $J_{4,5}$ = 9.7, $J_{5,6a}$ = 10.0, $J_{5,6e}$ = 5.0 Hz, H-5). *Anal.* calcd. for $C_{42}H_{40}F_6O_{15}S_2$ (962.8): C 52.39, H 4.19, S 6.66; found: C 52.58, H 4.25, S 6.81.

*3-Azido-2-O-benzyl-4,6-O-benzylidene-3-deoxy-α-D-mannopyranosyl 3-azido-2-O-benzyl-4,6-O-benzylidene-3-deoxy-α-D-mannopyranoside (5), 3-azido-2-O-benzyl-4,6-O-benzylidene-3-deoxy-α-D-mannopyranosyl 2-O-benzyl-4,6-O-benzylidene-3-deoxy-α-D-*threo*-hex-3-enopyranoside (6), and 2-O-benzyl-4,6-O-benzylidene-3-deoxy-α-D-*threo*-hex-3-enopyranosyl 2-O-benzyl-4,6-O-benzylidene-3-deoxy-α-D-*threo*-hex-3-enopyranoside (7)*

A solution of **4** (8.158 g) in benzene (1.6 L) and a solution of sodium azide (10.0 g) and tetrabutylammonium hydrogen sulfate (3.0 g) in water (200 mL) were mixed with efficient stirring and heated under reflux for 2 days. (Smaller volumes of solvent tended to lead to decreased yields of **5**.) Additional sodium azide (10.0 g) and tetrabutylammonium salt (3.0 g), suspended in 25 mL of water, were introduced and refluxing continued for 3 more days. Progress of the reaction was monitored by two-dimensional tlc using solvent B in the first direction, and double irrigation with chloroform in the second. For processing, solvent was distilled from the reaction mixture until 1250 mL of distillate (~1075 mL of benzene and 175 mL of water) had been collected. The remaining mixture was cooled, the phases were separated, and the benzene phase was washed 4 times with water. The aqueous phase and washings were back-extracted with benzene. The combined benzene solutions were again washed repeatedly with water (as nmr spectroscopy had revealed the presence of remnant tetrabutylammonium salt), then dried with Na_2SO_4, and evaporated to give a mixture of carbohydrate material (7.34 g). The mixture was applied to a column of silica gel (58 × 4.5 cm) with the aid of a small amount of benzene, and chromatographed with solvent A. The effluent fractions were examined by tlc with solvent B. Appropriate fractions were combined and gave 3.278 g (51.5%) of the diazide **5** (R_f 0.4) as an amorphous material, 2.575 g of a mixture containing chiefly the azidoalkene **6** (R_f 0.3), and 0.295 g of a mixture rich in the dialkene **7** (R_f 0.25).

For analysis, a sample of **5** was dissolved in a large proportion of methanol and recovered as a white, gummy precipitate by partial evaporation of the solvent. The gum was washed with a little methanol, and dried under high vacuum with occasional rubbing by spatula to give a brittle solid that melted to a glass at 78–87°C; $[\alpha]_D$ +42.4° (*c* 0.7, chloroform); ν_{max} neat: 2115 (azide) cm^{-1}; δ ($CDCl_3$): 7.43 (m, Ph), 5.67 (s, *Ph*-CH), 4.85 (d, $J_{1,2}$ = 1.4 Hz, H-1), 4.86 and 4.63 (AB-q, J_{gem} 12.0 Hz, *Ph*-CH_2), 4.21 (dd, $J_{4,5}$ = 9.5, $J_{3,4}$ = 10.5 Hz, H-4), 4.09 (dd, $J_{5,6e}$ = 5.0, $J_{6a,6e}$ = 10.5 Hz, H-6e), 3.81 (t, $J_{5,6a} \approx J_{6a,6e}$ = 10.5 Hz, H-6a), 3.76 (dd, $J_{2,3}$ = 3.4, $J_{3,4}$ = 10.5 Hz, H-3), 3.69 ($J_{1,2}$ = 1.4, $J_{2,3}$ = 3.3 Hz, H-2), 3.46 (~dt, *J* = 5.0, 9.5, and 10.5 Hz, H-5). *Anal.* calcd. for $C_{40}H_{40}N_6O_9$ (748.8): C 64.16, H 5.38, N 11.22; found: C 64.29, H 5.44, N 11.31.

The aforementioned column eluate (2.575 g) containing **6** (R_f 0.3) was crystallized from hot methanol (200 mL), yielding pure **6** (1.852 g, plus 0.53 g by concentration of the mother liquor; 39.7%); mp 110–112°C, unchanged after recrystallization; $[\alpha]_D$ +118° (*c* 0.5, chloroform); ν_{max}: 2111 (azide) and 1694 (vinyl ether) cm^{-1}; δ ($CDCl_3$) for the azido moiety: 5.71 (s, *Ph*-CH), 4.93 (s, H-1), 4.92 and 4.67 (AB-q, J_{gem} 12.0 Hz, *Ph*-CH_2), 4.25 (H-4, not separated from H-6e and H-6′e), and 3.81 (dd, $J_{2,3}$ = 3.4, $J_{3,4}$ = 11.0 Hz, H-3); δ for the alkenic moiety: 5.63 (s, *Ph*-CH), 5.46 (d, $J_{2,3}$ = 5.5 Hz, H-3), 5.17 (s, H-1), 4.64 (AB-q having the inner lines at 4.66 and 4.62; *Ph*-CH_2); δ for both moieties: 7.45 (m, Ph), 4.27 (m, H-6e and H-6′e), 3.90 and 3.77 (2 m, H-2,2′, 5,5′, 6a,6′a). (The assignments were made by comparison with the data for the symmetrical derivatives **5** and **7**). *Anal.* calcd. for $C_{40}H_{39}N_3O_9$ (705.7): C 68.07, H 5.57, N 5.95; found: C 67.94, H 5.43, N 5.89.

The column eluate (0.295 g) containing **7** (R_f 0.25) was chromatographed again on silica gel, using 1% ethyl acetate in dichloromethane as the eluant, and fractions further enriched in **7** were eluted. The syrupy material obtained from these was crystallized in part, from ethanol, by inoculation with seed crystals of **7** that had formed in a previous, syrupy preparation after storage for several months. The mother liquor of crystallization was combined with the less-pure fractions from the column, and preparative tlc (3 irrigations with dichloromethane) furnished additional **7** that was recrystallized from ethanol, for a total yield of 116 mg (2%). The crystals still contained an impurity (R_f 0.2) even after several subsequent recrystallizations, and the entire material was therefore purified once more by ptlc (solvent B), to give 87 mg (1.5%) of pure **7**; mp 106–108°C; $[\alpha]_D$ +176.7° (*c* 0.5, chloroform); ν_{max}: 1692 (vinyl ether; azide band absent) cm^{-1}; δ ($CDCl_3$): 7.43 (m, Ph), 5.67 (s, *Ph*-CH), 5.49 (d, $J_{2,3}$ = 5.4 Hz, H-3), 5.28 (s, H-1), 4.72 and 4.65 (AB-q, J_{gem} = 12.0 Hz, *Ph*-CH_2), 4.40 (dd, $J_{5,6e}$ = 6.6, $J_{6a,6e}$ = 10.8 Hz, H-6e), 4.14 (m, H-5), 3.97 (dd, $J_{2,3}$ = 5.4, $J_{2,5}$ = 1.8 Hz, H-2), 3.89 (t, $J_{6a,6e}$ = $J_{5,6a}$ = 10.8 Hz, H-6a). *Anal.* calcd. for $C_{40}H_{38}O_9$ (662.7): C 72.49, H 5.78; found: C 72.36, H 5.71.

By-product

The methanolic mother liquor from the crystallization of **6** showed a spot at R_f 0.52 in addition to one for residual **6** (tlc with CH_2Cl_2). After standing for several days at room temperature, partial decomposition was noticed (appearance of an immobile spot, and smell of benzaldehyde), but the component R_f 0.52 was still visible. The methanol was evaporated and the residue dissolved in dichloromethane, washed with aqueous $NaHCO_3$, dried, and subjected to ptlc, with CH_2Cl_2 as irrigant. About 20 mg of the fast-moving compound was isolated. Its ir spectrum was similar to that of the ditriflate **4** in the 1550–600 cm^{-1} region but also showed a strong azide band at 2112 cm^{-1}. The 300-MHz nmr spectrum revealed the structure of an unsymmetrically substituted disaccharide, showing the essential features of both **4** and **5**, with a narrow, one-proton triplet at δ 5.1 characteristic for the 3-triflate moiety. Evidently, the substance was the monoazidomonotriflate intermediate of the reaction **4** → **5**.

3-Amino-2-O-benzyl-4,6-O-benzylidene-3-deoxy-α-D-mannopyranosyl 3-amino-2-O-benzyl-4,6-O-benzylidene-3-deoxy-α-D-mannopyranoside (8)

Compound **5** (140 mg) in ethanol (25 mL) was hydrogenated with 10% palladium on charcoal (200 mg) for 17 h at room temperature, in a Parr flask under 400 kPa of hydrogen pressure. The solution thereafter showed one major product spot, R_f 0.24, in tlc using 95:5 ethyl acetate – ethanol. Isolation of the product by ptlc with the same solvents, but 98:2, gave ~100 mg of **8**. The ir spectrum showed no azido-group absorption. The [1]H nmr data (200 MHz, $CDCl_3$), δ: 7.41 (m, Ph), 5.56 (s, *Ph*-CH), 5.05 (s, H-1), 4.69 (s, *Ph*-CH_2), 4.12 (dd, $J_{6a,6e}$ = 10.0, $J_{5,6e}$ = 4.5 Hz, H-6e), 3.84–3.63 (m, H-2,4,6a), 3.55 (m, $J_{4,5}$ = $J_{5,6a}$ = 10, $J_{5,6e}$ = 4.5 Hz, H-5), 3.18 (dd, $J_{2,3}$ = 3.7, $J_{3,4}$ = 10.0 Hz, H-3), and 1.70 (broad s, removable by D_2O exchange, NH_2).

The same product was obtained by treatment of **5** in ether with lithium aluminum hydride for 15 min.

3-Azido-2-O-benzyl-3-deoxy-α-D-mannopyranosyl 3-azido-2-O-benzyl-3-deoxy-α-D-mannopyranoside (9)

A suspension of **5** (3.73 g) in 80% acetic acid (50 mL) was agitated on a steam bath, whereby the initially formed oil dissolved within 10 min. The debenzylidenation was complete after 30 min, as judged by tlc (solvent C). The solution was cooled, and evaporated repeatedly with added portions of ethanol until the smell of acetic acid was no longer noticeable, and a dry foam was obtained (~2.94 g). The foam crystallized on treatment with dichloromethane (20 mL), giving 2.167 g of **9** (R_f 0.17), mp 140–142°C, contaminated by a trace of a product having R_f 0.34. The mother liquor showed components having R_f 0.17, 0.34, and 0.43 (solvent C). Upon removal of the solvent, this mixture was subjected to hydrolysis as previously described, using 10 mL of 80% acetic acid, which caused disappearance of the component having R_f 0.43. After processing as before, the material was heated on the steam bath for 15 min in a mixture (10 mL) of methanol–water–triethylamine (5:3.5:1.5). Evaporation, followed by crystallization from dichloromethane, gave an additional 308 mg of **9**, plus 153 mg from the mother liquor after its passage through a short column of silica gel (solvent C). The combined crops (2.628 g, 92.5% yield) were recrystallized as described, by treating with dichloromethane the dry foam obtained on evaporation of an ethanolic solution of the compound. Pure **9** so prepared (2.589 g, 91.1%) had mp 141–143°C; $[\alpha]_D$ +83.2° (*c* 0.5, ethanol); ν_{max}: 3350 (OH) and 2111 (N_3) cm^{-1}; δ (CD_3COCD_3): 7.46 (m, Ph), 5.18 (d, $J_{1,2}$ = 1.8 Hz, H-1), 4.78 (d, $J_{4,OH}$ = 6.4 Hz, OH-4), 4.76 (s, 4H, 2 *Ph*-CH_2), 4.17 (dt, $J_{4,OH}$ = 6.4, $J_{3,4} \approx J_{4,5}$ = 10.2 Hz, H-4), 4.03 (dd, $J_{1,2}$ = 1.8, $J_{2,3}$ = 3.2 Hz, H-2), 4.00–3.90 (m, 6H, H-6, H-6′, and OH-6), 3.85 (dd, $J_{2,3}$ = 3.2, $J_{3,4}$ = 10.4 Hz, H-3), and 3.78 (octet, H-5). When D_2O was added to the solution, the OH-4 signal disappeared, H-4 gave a clear triplet, the *Ph*-CH_2 singlet became an AB quartet (J_{gem} = 12.6 Hz), the δ 4.0–3.9 region was resolved and revealed H-6 at δ 4.00 (dd, $J_{5,6}$ = 2.6, $J_{6,6'}$ = 12 Hz) as well as H-6′ at δ 3.88 (dd, $J_{5,6'}$ = 5.6 Hz). All assignments were verified by spin decoupling experiments. *Anal.* calcd. for $C_{26}H_{30}N_6O_9$ (570.5): C 54.73, H 5.30, N 14.73; found: C 54.58, H 5.40, N 14.88.

3-Amino-3-deoxy-α-D-mannopyranosyl 3-amino-3-deoxy-α-D-mannopyranoside (10) and its dihydrochloride (11)

A solution of **9** (2.567 g) in 95% ethanol (40 mL) together with 10% palladium on charcoal (2.5 g) was heated with magnetic stirring, and cyclohexene (20 mL) was added when refluxing started. Progress of the reaction was monitored by tlc using 5:4:1 methanol–chloroform – ammonium hydroxide (concentrated, aqueous) as the irrigant. After 6 min, the presence of 5 products was indicated: R_f 0.10 (**10**), 0.34 (diaminomonobenzyl derivative), 0.44 (weak; monoaminomonoazidomonobenzyl derivative), 0.73 (diaminodibenzyl derivative), and 0.86 (**9**). After 12 min, the product having R_f 0.44 was no longer detectable. To promote the reaction, the following was added to the boiling mixture: cyclohexene (10 mL, after 45 min), water (2 mL, after 1 h), and Pd catalyst (0.5 g, after 2 h). About 140 min after the start of the reaction only a trace of **9** had remained, and after 3 h there were intense spots for **10** (R_f 0.1) and a by-product (R_f 0.2), accompanied only by weak spots of more-mobile intermediates. Refluxing was stopped, the mixture was filtered, and the catalyst was washed with hot 95% ethanol followed by hot 90% ethanol (100 mL each). Evaporation of the filtrate and washings gave ~1.6 g of a material, which was dissolved in a methanol–water mixture. The solution was evaporated to a thin syrup to which some fresh methanol was added, and scratching with a glass rod then initiated crystallization of **10** (1.045 g) contaminated by a trace of the compound having R_f 0.2. Twice recrystallized from methanol, the substance (988 mg, 61.3%) was chromatographically homogeneous (R_f 0.11), but faintly yellowish. The coloration was removed by vacuum filtration of the compound, in concentrated aqueous solution (3 mL of water), through a plug of activated carbon and Celite. The recovered, colorless compound (874 mg, plus 95 mg from the mother liquor; see below) had mp 177–180°C; $[\alpha]_D$ +105.7° (*c* 0.7, water); δ (D_2O, acetone lock signal): 4.95 (d, $J_{1,2}$ = 2.0 Hz, H-1), 3.74 (narrow m, H-2), 3.72 (dd, $J_{5,6}$ = 2.0, $J_{6,6'}$ = 12.0 Hz, H-6), 3.56 (dd, $J_{5,6'}$ = 7.0, $J_{6,6'}$ = 12 Hz, H-6′), 3.47 (m, J = 2.0, 7.0, and 10.0 Hz, H-5), 3.29 (t, $J_{3,4}$ = $J_{4,5}$ = 10 Hz, H-4), 3.15 (dd, $J_{2,3}$ = 3.0, $J_{3,4}$ = 10.0 Hz, H-3). All assignments were confirmed by spin decoupling; ^{13}C nmr data, δ (H_2O, with acetone lock signal 29.8 ppm from TMS): 94.5 (C-1), 73.2, 69.5, and 67.3 (C-2, -4, and -5), 60.6 (C-6), and 51.5 (C-3). *Anal.* calcd. for $C_{12}H_{24}N_2O_9 \cdot H_2O$ (358.3): C 40.22, H 7.31, N 7.82; found: C 40.20, H 7.18, N 7.66.

A sample of **10** was converted into its dihydrochloride **11** by precipitation from methanolic solution with ether containing anhydrous hydrogen chloride (2); mp 199.5°C (dec.), $[\alpha]_D$ + 84.2°, in excellent agreement with the reported (2, 8) values. The ^{13}C chemical shift data, differing slightly from those of the free base, above, completely matched those reported (8) for **11**.

The N-*ethyl derivative as by-product*

The mother liquors from the isolation and purification of **10** were combined and evaporated. The residue was chromatographed on a column of powdered cellulose by means of 85:13:2 ethanol–water–ammonium hydroxide (concentrated, aqueous) as the eluant. The fractions containing the faster-moving (R_f ~0.25) by-product were inhomogeneous, whereas from subsequent fractions some additional **10** was obtained in crystalline form (95 mg). The inhomogeneous fractions were passed through the same column again, with a 90:8:2 mixture of the previous solvents, and 45 mg of the compound showing R_f 0.25 could thereby be isolated pure. The ^1H nmr spectrum (D_2O, acetone lock signal) indicated unequal substitution of the disaccharide due to the presence of one *N*-ethyl group; δ: 5.05 and 5.02 (two d, J = 2 Hz, H-1 and H-1′), 4.12 and 3.98 (two narrow dd, H-2 and H-2′), 3.8–3.5 (unresolved m, 8H, H-4,4′, 5,5′, 6a,6a′, 6b,6b′), 3.38 and 3.32 (two dd, $J_{2,3}$ and $J_{2',3'}$ = 3.5 Hz, $J_{3,4}$ and $J_{3',4'}$ = 10.5 Hz, H-3 and H-3′), 3.04 (complex symm. multiplet, 2H, CH_2 of Et), and 1.14 (t, 3H, CH_3 of Et). The assignments were verified by spin decoupling.

ALLAN K. COLTER, CHARLES C. LAI, A. GREGG PARSONS, N. BRUCE RAMSAY, and GUNZI SAITO. Can. J. Chem. **63**, 445 (1985).

Oxidation of *N,N'*-dimethyl-9,9'-biacridanyl (DD) has been investigated as a model for single electron transfer (SET)-initiated oxidation of NADH coenzyme models such as *N*-methylacridan (DH). Oxidants investigated cover a 10^{10}-fold range of reactivity in acetonitrile and include the π acceptors 1,4-benzoquinone (BQ), 2,6-dichloro-1,4-benzoquinone (DClBQ), *p*-chloranil (CA), 2,3-dicyanobenzoquinone (DCBQ), 2,3-dicyano-1,4-naphthoquinone (DCNQ), 2,3-dicyano-5-nitro-1,4-naphthoquinone (DCNNQ), 9-dicyanomethylene-2,4,7-trinitrofluorene (DCMTNF), 9-dicyanomethylene-2,4,5,7-tetranitrofluorene (DCMTENF), 7,7,8,8-tetracyanoquinodimethane (TCNQ), and tetracyanoethylene (TCNE), and the one-electron oxidant *tris*(2,2'-bipyridyl)cobalt(III), $Co(bipy)_3^{3+}$. The oxidation product is, in every case, *N*-methylacridinium ion (D^+). A mechanism involving a rate-determining electron transfer with simultaneous fragmentation to D^+ and *N*-methyl-9-acridanyl radical (D·) is proposed. This mechanism is supported by the observed dependence of the rate on oxidant reduction potential, by spin-trapping experiments, by kinetic isotope effects in oxidation of 9,9'-dideuterio-DD, and by substituent effects in oxidation of 2,2'- and 3,3'-dimethoxy-DD. The rate of oxidation of DD relative to that of DH is 3.4×10^2 with $Co(bipy)_3^{3+}$, and with the π acceptors varies from ca. 0.3 (BQ) to 8.1×10^4 (DCMTENF). The results rule out a SET-initiated mechanism for oxidation of DH by all of the oxidants studied except TCNQ and DCMTENF.

ALLAN K. COLTER, CHARLES C. LAI, A. GREGG PARSONS, N. BRUCE RAMSAY et GUNZI SAITO. Can. J. Chem. **63**, 445 (1985).

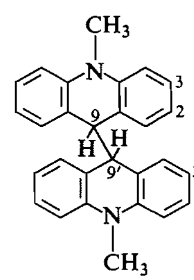
On a étudié l'oxydation du *N,N'*-diméthylbiacridanyl-9,9' (DD), un modèle pour l'oxydation, initiée par le transfert d'un seul électron (TSE), de modèles de la coenzyme NADH, comme le *N*-méthylacridan (DH). Avec les oxydants étudiés dans l'acétonitrile, on couvre dix ordres de grandeur de réactivité et les oxydants comprennent des accepteurs π comme la benzoquinone-1,4 (BQ), la dichloro-2,6 benzoquinone-1,4 (DClBQ), le *p*-chloranil (CA), la dicyano-2,3 benzoquinone (DCBQ), la dicyano-2,3 naphtoquinone-1,4 (DCNQ), la dicyano-2,3 nitro-5 naphtoquinone (DCNNQ), le dicyanométhylène-9 trinitro-2,4,7 fluorène (DCMTNF), le dicyanométhylène-9 tétranitro-2,4,5,7 fluorène (DCMTENF), le tétracyano-7,7,8,8 quinodiméthane (TCNQ) et le tétracyanoéthylène (TCNE) ainsi que l'oxydant à un électron, *tris*(bipyridyl-2,2')cobalt(III), $Co(bipy)_3^{3+}$. Dans tous les cas, le produit de l'oxydation est l'ion *N*-méthylacridinium (D^+). On propose un mécanisme impliquant, dans l'étape qui détermine la vitesse de la réaction, un transfert d'un électron avec une fragmentation simultanée conduisant à D^+ et au radical *N*-méthylacridanyl-9 (D·). Ce mécanisme est en accord avec le fait que la vitesse de la réaction dépend du potentiel de réduction de l'oxydant, avec des expériences de trappage de spin, avec les effets isotopiques cinétiques du dideutéro-9,9' DD et avec les effets des substituants sur l'oxydation des diméthoxy-2,2' (et 3,3') DD. Les vitesses d'oxydation du produit DD par rapport à celles du produit DH sont égales à $3,4 \times 10^2$ avec le $Co(bipy)_3^{3+}$ et, avec les accepteurs π, elles varient d'environ 0,1 (BQ) à $8,1 \times 10^4$ (DCMTENF). On discute des implications de ces résultats en relation avec les mécanismes d'oxydation du composé DH.

[Traduit par le journal]

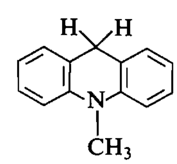
Introduction

The mechanisms of hydride transfer reactions of nicotinamide coenzyme models continue to attract considerable attention (1, 2 and references cited). Much of this interest has focused on the experimental distinction between a one-step hydride transfer mechanism and stepwise mechanisms involving an initial single electron transfer (SET). This distinction has proven to be very elusive for oxidants, such as quinones and carbonyl compounds, that are capable of reacting either as hydride or one-electron acceptors. One of the difficulties lies in the fact that the responses of the rate to changes in structure or solvent predicted by the stepwise and one-step mechanisms are very similar. For this reason, it would be instructive to examine model oxidation reactions that could be guaranteed to occur via an initial SET.

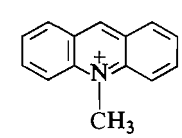
In principle, two approaches to the investigation of oxidation of NADH models by SET-initiated pathways are possible. The first is to investigate oxidants capable of reaction as one-electron acceptors only (3–5). A second approach is to design NADH models in which oxidation by hydride transfer either cannot occur or is strongly inhibited. We were encouraged to examine the oxidation of *N,N'*-dimethyl-9,9'-biacridanyl (DD)



1, DD



2, DH



3, D^+

as a model for SET-initiated oxidation of *N*-methylacridan (DH) to *N*-methylacridinium ion (D^+) (5, 6) for the following reasons. DD is reported to be oxidized by iodine to D^+ (7), a reaction corresponding to removal of 2 electrons (and no protons) from DD, with fragmentation. In contrast, removal of hydride from DD would lead to the known (8) conjugate acid of *N,N'*-dimethyl-9,9'-biacridylidene which, after the loss of a proton, would be further oxidized to *N,N'*-dimethyl-9,9'-biacridinium ion (luzigenin) (9). The dimeric dihydronicotinamides analogous to DD are similarly oxidized by methyl-

viologen and 2,6-dichloroindophenol (10) as well as electrochemically (11, 12) to the corresponding monomeric nicotinamide salts. The electrochemical oxidations of the dimeric dihydronicotinamides occur at lower positive potentials than the oxidations of the corresponding monomeric dihydronicotinamides (11, 12).

Results

The biacridanyls investigated included DD as well as 2,2′- and 3,3′-dimethoxy-*N*,*N*′-dimethyl-9,9′-biacridanyl (2,2′-dimethoxy-DD and 3,3′-dimethoxy-DD), the last two as diastereomeric mixtures. DD and 2,2′-dimethoxy-DD were obtained by reduction of the corresponding *N*-methylacridinium salts (D^+ and 2-methoxy-D^+, respectively) by phenylhydrazine (13), Raney Nickel (14), or various Grignard reagents (15), while 3,3′-dimethoxy-DD was obtained by the last two methods only. The oxidants investigated kinetically included four benzoquinones (**4–7**), two naphthoquinones (**8–9**), four dicyanomethylene π acceptors (**10–13**), and the one-electron oxidant *tris*(2,2′-bipyridyl)Co(III) ($Co(bipy)_3^{3+}$).

The oxidation product in reaction of DD with oxidants **4–13**, 2,3-dicyano-5,6-dichloro-1,4-benzoquinone (DDQ), and triphenylmethyl fluoborate, all in acetonitrile (AN), was identified by uv–visible spectral examination of reaction solutions or of product isolated as the perchlorate salt. In every case the only detectable oxidation product was *N*-methylacridinium cation (D^+). The uv–visible spectrum of D^+ (λ_{max} = 356 nm in AN) is easily distinguishable from that of *N*,*N*′-dimethyl-9,9′-biacridinium ion (λ_{max} = 367 nm in AN), the oxidation product expected from initial hydride transfer (above), even though they are very similar. Quantitative formation of $2D^+$ from each DD was confirmed by absorbance measurements on reaction mixtures with the oxidants BQ, CA, TCNE, and $Co(bipy)_3^{3+}$ at 356 nm, and with DClBQ at 420 nm. With DCNQ, DCNNQ, TCNQ, DCMTNF, and DCMTENF the spectrum of D^+ is masked by that of the radical anion reduction product. In oxidations with these five oxidants, plus CA, DCBQ, TCNE, and DDQ, the oxidation product was isolated as $D^+ClO_4^-$ in yields greater than 90%. With DCNQ, DCNNQ, TCNQ, DCMTNF, and DCMTENF, formation of 2 mol of acceptor radical anion (i.e., $DCNQ^{\dot{-}}$, etc.) was confirmed by absorbance measurements on reaction solutions. Finally, the stoichiometry of oxidation of DD with CA was investigated by measuring the absorbance due to D^+ (356 nm) in a series of experiments involving reaction of CA with excess DD. All of the product and stoichiometry studies are consistent with the stoichiometry represented by reaction [1].

$$[1]\quad DD + 2A \rightarrow 2D^+ + 2A^{\dot{-}}$$

The complete oxidation of DD by BQ in AN requires a proton source such as acetic acid, presumably because of the instability of $BQ^{\dot{-}}$. For example, in one experiment in pure AN, oxidation of DD (3.4×10^{-5} *M*) by BQ (6.6×10^{-2} *M*) occurred to the extent of roughly 20%.

In earlier work (6) transient charge-transfer (CT) absorptions were observed in solutions containing DH and any of several π acceptors. In order to compare the π donor properties of DD and DH, the positions of their CT maxima with several π acceptors were measured (Table 1). These measurements in general require much higher concentrations of both DD and π acceptor than those used in the kinetic studies (below) and are limited to less reactive π acceptors because of interference from formation and precipitation of product. To conform that the measured maxima are due to CT absorption pyrene was also included in the comparison. A plot of $\bar{\nu}_{max}$(DD) vs. $\bar{\nu}_{max}$(pyrene) is reasonably linear (r = 0.979) with a slope close to unity (1.01 ± 0.09) as required (16). A similar plot for DH vs. pyrene including data for two additional acceptors reported earlier (6) has a slope of 0.94 ± 0.07, r = 0.982.

TABLE 2. Rates of oxidation of DD[a]

Oxidant	$E°$, V[b]	[Oxidant], M	k (M^{-1} s^{-1})[c]

The most important observation is that the CT maximum for DD consistently appears at lower energy than that for DH with the same acceptor, indicating that DD should undergo one-electron oxidation more easily than DH (16, 17). This difference, for two compounds having identical π electron systems, is consistent with the predictions of current theory on orbital interactions through σ bonds (18). The interaction of π orbitals through three σ bonds is possibly enhanced by the elongated (1.58 Å) (19) C_9—$C_{9'}$ bond (20). Secondly, the results of the comparison of DD, 2,2′- and 3,3′-dimethoxy-DD with 1,3,5-trinitrobenzene (Table 1) parallel those obtained with the corresponding *N*-methylacridans (5) and indicate that the HOMO energies lie in the order 2,2′-dimethoxy-DD > 3,3′-dimethoxy-DD > DD.

The results of a kinetic investigation of oxidation of DD with oxidants **4**–**13** are summarized in Table 2. Rate measurements were carried out under pseudo first-order conditions using a 30-fold or greater molar excess of oxidant over DD for all oxidants. Pseudo first-order rate constants so obtained are proportional to acceptor concentration within experimental error. Complex formation between DD and π acceptor oxidants could, in principle, cause some error in calculated second-order rate constants if the association constants are large enough (6). However, judging from the intensities of the CT absorptions in benzene solution, the equilibrium constants for complexation of DD and DH with the same acceptor are of similar magnitude, and hence too small to produce significant errors at the concentrations of the rate measurements (6). With CA, TCNQ, and TCNE lower ratios of oxidant to DD were investigated as well, and the rate constant obtained by a second-order analysis.

N-Methylacridinium ion (D^+) was also examined as an oxidant by measuring the rate of reaction of D^+ with DD (reaction [2]) using DD labelled with $^{14}CH_3$.

[2] $D^+ + {}^*DD \rightleftharpoons {}^*D^+ + DD$

In order to assist in the characterization of the oxidation transition state, rates of oxidation of 9,9′-dideuterio-DD with CA, and of DD, 2,2′- and 3,3′-dimethoxy-DD with CA and $Co(bipy)_3^{3+}$ were measured. These results are summarized in Table 3. The dimethoxybiacridanyls were obtained as a mixture of the *meso* and *dl* diastereomers. First-order plots were strictly linear through 90% reaction indicating that the two diastereomers do not differ significantly in oxidation rate for the two oxidants investigated.

TABLE 3. Kinetic isotope effects and substituent effects in oxidation of *N,N′*-dimethyl-9,9′-biacridanyls[a]

Biacridanyl	Oxidant	k (M^{-1} s^{-1})	Relative rate[b]
DD	CA	4.77	(1)
9,9′-Dideuterio-DD	CA	4.25	0.89 ± 0.03[c]
2,2′-Dimethoxy-DD	CA	5.79 × 10^{2}	1.2 × 10^{2}
3,3′-Dimethoxy-DD	CA	1.05 × 10^{2}	2.2 × 10
DD	$Co(bipy)_3^{3+}$	8.50 × 10	(1)
2,2′-Dimethoxy-DD	$Co(bipy)_3^{3+}$	6.69 × 10^{3}	7.9 × 10
3,3′-Dimethoxy-DD	$Co(bipy)_3^{3+}$	5.57 × 10^{2}	6.8

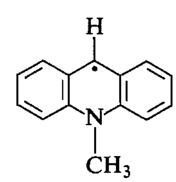
To test for the occurrence of C_9—$C_{9'}$ bond fission in DD (reaction [3]) under the conditions of the kinetic measurements,

[3] $DD \rightleftharpoons 2D^{\bullet}$

spin-trapping experiments (27) were carried out using the spin trap 2-nitroso-2-methylpropane (NtB). A solution of DD (5.2 × 10^{-4} mol) and NtB (2.0 × 10^{-4} mol) in acetonitrile was mixed with a solution of DCBQ (2.6 × 10^{-4} mol) in acetonitrile under nitrogen, and the solid D^+ $DCBQ^{\bar{\cdot}}$ product removed by filtration through a cotton plug. The esr spectrum of the filtrate showed a clean persistent triplet of doublets characteristic of *t*-butyl 9-acridanyl nitroxide, the spin adduct of $D^{\bullet}$ (**14**) and NtB (28). In contrast, solutions containing



14, D·

DD and NtB alone in acetonitrile (in the dark) showed no detectable esr signal.

Because one of the objectives of this work was to compare reactivity patterns in oxidations of DH and DD, we have extended earlier (5, 6) kinetic measurements of oxidation of DH to the acceptors DCNQ, DCNNQ, DCMTNF, and DCMTENF. The stoichiometry of oxidation of DH by the four new acceptors is identical to that previously determined for **7**, **10**, and **11** (6). These rates were measured under pseudo first-order conditions following the progress of the reaction as with the corresponding oxidation of DD. These rates, along with earlier rates of oxidation of DH by the oxidants investigated in this study, and the relative reactivites of DD and DH toward each oxidant, are listed in Table 4.

Discussion

Mechanism of oxidation of DD

The possibility of mechanisms in which C_9—$C_{9'}$ bond fis-

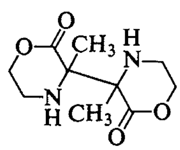
sion occurs prior to oxidation must be considered. A mechanism analogous to [4] with $k_2[D^\cdot][A] \gg k_{-1}[D^\cdot]^2$ is observed in oxidations of 3,5,5-trimethyl-2-morpholinon-3-yl radical dimer (**15**) investigated by Koch and co-workers (29). Such a

$$[4] \quad DD \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} 2D^\cdot \qquad D^\cdot + A \xrightarrow{k_2} D^+ + A^{\overline{\cdot}}$$



15

mechanism is excluded for the oxidations of DD in this work by the strong dependence of the rate on acceptor structure and by the first-order dependence of the rate on oxidant concentration over the full range of oxidant reactivity. Mechanism [4] with $k_{-1}[D^\cdot]^2 \gg k_2[D^\cdot][A^{\overline{\cdot}}]$ is likewise excluded because it would lead to a 0.5-order dependence on DD concentration. All mechanisms involving formation of free $D^\cdot$ prior to oxidation are also inconsistent with the observation that $D^\cdot$ can be trapped in oxidation of DD with DCBQ but not in the absence of oxidant.

Reversible formation of N-methylacridanyl π-*mer* (30), $(D^\cdot)_2$, which reforms DD more rapidly than it is oxidized is consistent with the rate law. However, for the D^+ + DD exchange reaction, the electron-transfer step in such a mechanism ($*D^+ + D^\cdot D^\cdot \rightarrow *D^\cdot D^\cdot + D^+$) would have $\Delta G^0 = 0$ and should therefore have a very small activation barrier. The electron transfer from $(D^\cdot)_2$ would then be exoergic for all of the other oxidants except BQ. It is then impossible to account for the 13.6 kcal mol^{-1} decrease in $\Delta G^\ddagger$ (corresponding to a 2.1×10^8-fold increase in rate) observed between DClBQ and DCNNQ.

A plot of log k vs. oxidant reduction potential, which is essentially a plot of $\Delta G^\ddagger$ for oxidation vs. ΔG^0 for electron

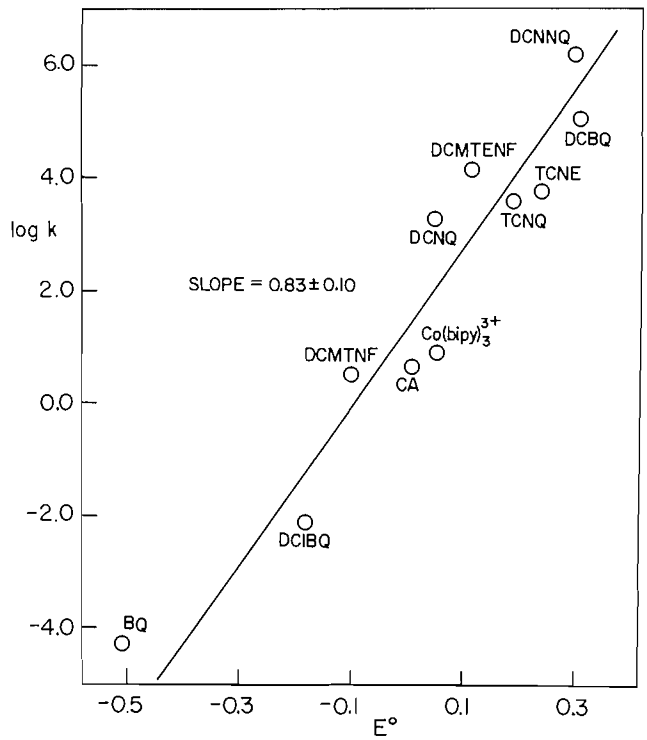


FIG. 1. Plot of log k for oxidation of DD vs. oxidant reduction potential.

transfer from the species oxidized to the oxidant, is shown in Fig. 1. To compare $Co(bipy)_3^{3+}$ with the electrically-neutral oxidants it is necessary to correct either ΔG^0 or E^0 for differences in coulombic stabilization of the product, i.e., $DD^{\dagger}A^{\overline{\cdot}}$ or $DD^{\dagger}$ $Co(bipy)_3^{2+}$ (31). For $DD^{\dagger}A^{\overline{\cdot}}$ we estimate this stabilization to be about 0.06 eV (1, 32). Taking the stabilization in $DD^{\dagger}$ $Co(bipy)_3^{2+}$ to be about -2×0.06 eV we have subtracted 0.18 V from the reduction potential of $Co(bipy)_3^{3+}$ in plotting Fig. 1.

Allowing for the considerable variation in oxidant structure as well as some spread in reported E^0 values for certain acceptors it is clear that a reasonable linear relationship exists between log k and E^0. The slope is strongly influenced by the BQ point, for which the rate constant has a substantial uncertainty. Expressed as a plot of $\Delta G^\ddagger$ vs. ΔG^0 (i.e., observed slope × RT/F) the slope is 0.75 sd 0.07 (r = 0.960) (all points, 3.2×10^{10}-fold range of reactivity) or 0.83 sd 0.10 (r = 0.936) (BQ excluded, 2.1×10^8-fold range of reactivity). Omission of the $Co(bipy)_3^{3+}$ point does not affect the slope significantly. Some regularities in the deviations from the best fit straight line in Fig. 1 are evident. The naphthoquinones are 1 to 2 powers of 10 more reactive than benzoquinones of similar reduction potential. Similarly, the 9-dicyanomethylenefluorenes are 1 to 2 powers of 10 more reactive than expected. These deviations are in the direction expected if the transition state resembles a π–π complex since complex stabilities typically increase with increasing area of donor–acceptor contact (33). For the three benzoquinones DClBQ, CA, and DCBQ, the slope (as defined above) is 0.87 sd 0.00 (r = 1.00).

A mechanism involving an initial reversible and strongly-endothermic electron transfer followed by a slow step in which the C—C bond is broken at a rate independent of the oxidant should lead to a plot of $\Delta G^\ddagger$ vs. ΔG^0 that is linear, with a slope of 1.0 (31, 34) and with very little scatter. The slope of ca.

0.80, together with the kind of regular scatter observed is best accommodated by a mechanism such as [5] in which electron-transfer within a reversibly-formed charge-transfer complex, DDA, occurs with simultaneous C—C bond fission.

$$[5]\quad \begin{aligned} &\mathrm{DD + A} \overset{K}{\rightleftharpoons} \mathrm{DDA} \\ &\mathrm{DDA} \xrightarrow{\text{slow}} \mathrm{D^+ + D^{\cdot} + A^{\cdot-}} \\ &\mathrm{D^{\cdot} + A} \xrightarrow{\text{fast}} \mathrm{D^+ + A^{\cdot-}} \end{aligned}$$

In principle the extent of C—C bond fission in the transition state should be reflected in the secondary deuterium kinetic isotope effect (Table 3). However, in the absence of a reliable estimate of the isotope effect for complete bond fission, the observed value (k_H/k_D = 1.12 or 1.06 per deuterium) provides little quantitative information. By comparison, secondary 9-deuterium kinetic isotope effects in oxidation of DH are in the neighborhood of 1.1 ± 0.05 (6) and α-deuterium isotope effects in E2 reactions range from 1.0 to 1.15 (50°C) (35). The results in oxidation of DD by CA therefore suggest a transition state in which the C—C bond is less than half broken.

A second measure of the extent of C—C bond fission in the transition state is provided by the substituent effects. In oxidation of 2- and 3-methoxy-*N*-methylacridans (2- and 3-methoxy-DH) with BQ, CA, and DCBQ, 2-methoxy-DH is 1/3.9, 1/5.4, and 1/9.2 times as reactive, respectively, as 3-methoxy-DH (5). The greater rate of oxidation of 3-methoxy-DH with quinones reflects the greater stability (relative to the corresponding acridan) of 3-methoxy-D^+. In contrast, in oxidation by $Co(bipy)_3^{3+}$, a reaction believed to occur by rate-determining SET, 2-methoxy-DH is 56 times as reactive as 3-methoxy-DH, reflecting the greater relative stability of 2-methoxy-$DH^{\cdot+}$. In the present work 2,2′-dimethoxy-DD is more reactive than 3,3′-dimethoxy-DD by factors of 5.5 (CA) and 12 ($Co(bipy)_3^{3+}$). Consequently, assuming that the substituent effects on the stability of $D^{\cdot}$ (relative to DD) are negligible, these results indicate that the transition state resembles $DD^{\cdot+}$ more closely than $D^+ + D^{\cdot}$.

Implications concerning the mechanisms of oxidation of DH with π acceptors

In earlier papers (1, 6) we have considered the possibility that oxidation of *N*-methylacridan (DH) and related compounds occurs via a mechanism in which a reversible SET is followed by a slow proton transfer [6]. The agreement between deuterium isotope effects determined kinetically and by isotope partitioning ratios

$$[6]\quad \begin{aligned} &\mathrm{DH + A} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{DH^{\cdot+}\,A^{\cdot-}} \\ &\mathrm{DH^{\cdot+}\,A^{\cdot-}} \xrightarrow[\text{slow}]{k_2} \mathrm{D^{\cdot}AH^{\cdot}} \\ &\mathrm{D^{\cdot}AH^{\cdot}} \xrightarrow{\text{fast}} \mathrm{D^+ + AH^-} \end{aligned}$$

for π acceptors covering a 10^7-fold range of reactivity (BQ to DCBQ) (6) requires that for any such mechanism k_{-1} be much larger than k_2. We have presented arguments based on the estimated standard free energy of formation of $DH^{\cdot+}\,A^{\cdot-}$ to rule out this species as an intermediate in oxidation of DH by BQ or CA (1). However, it was not possible using these arguments to exclude $DH^{\cdot+}\,A^{\cdot-}$ as an intermediate in oxidation of DH by TCNE, TCNQ, or DCBQ. Indeed, we have shown that the *N*-methyl-9-acridanyl radical, $D^{\cdot}$, can be trapped in oxidation of DH with DCBQ (28).

The results of our studies of the oxidation of DH with $Co(bipy)_3^{3+}$ are consistent with a mechanism involving an initial irreversible SET with concurrent or rapid subsequent loss of H^+ (5). If, in the corresponding oxidation of DD, each electron transfer leads to bond fission, the observed rates of oxidation of DD and DH by $Co(bipy)_3^{3+}$ provide a measure of the relative rates of SET from DD and DH (Table 4). The greater ease of one-electron oxidation of DD is consistent with the charge-transfer maxima (Table 1), and parallels the greater ease of oxidation of the dimeric reduced nicotinamides than the corresponding dihydronicotinamides by one-electron oxidants (10) and electrochemically (11, 12).

Because oxidation of DH with π acceptors via a mechanism such as [6] necessarily involves a *reversible* electron transfer (above), such a mechanism requires that for the π acceptors $k_{DD} \div k_{DH}$ (Table 4) be substantially (perhaps 5 to 10 ×) larger than 3.4×10^2, the ratio for $Co(bipy)_3^{3+}$. Consequently any value of $k_{DD} \div k_{DH}$ less than about 1.5×10^3 would exclude a stepwise mechanism involving an initial SET for the DH oxidation. On this basis, an electron–proton–electron mechanism can be excluded for all of the quinones investigated, as well as for DCMTNF and TCNE. For oxidation of DH by these π acceptors electron and hydrogen transfer must be strongly coupled. Only for TCNQ and DCMTENF does mechanism [6] remain a possibility. This conclusion would seem to be at odds with the successful trapping of $D^{\cdot}$ in oxidation of DH by DCBQ (28). We are presently uncertain as to how to interpret this result. Possibly the formation of $D^{\cdot}$ in reaction of DH with DCBQ is unrelated to the major pathway leading to D^+.

Experimental

Melting points were measured in open capillary tubes and are uncorrected. Proton nmr spectra were measured using a Varian EM-360 spectrometer. Chemical shifts are reported in δ units, with tetramethylsilane as internal standard. Ultraviolet-visible spectra were obtained using Beckman 24 or Cary 118C spectrophotometers. Electron spin resonance spectra were recorded at room temperature on a Varian E-104 spectrometer. Radioactivity measurements utilized Beckman LS-255 and LS-7000 liquid scintillation counters. Elemental microanalyses were performed by Guelph Chemical Laboratories, Guelph, Ontario.

Reagents and solvents

BQ, CA, TCNE, TCNQ, DCBQ, and $Co(bipy)_3(ClO_4)_3 \cdot 3H_2O$ were obtained and purified as previously described (5, 6). Eastman Kodak White Label DClBQ was crystallized twice from 30–60°C petroleum ether and sublimed under vacuum. DCMTNF, prepared following Mukherjee (36) and purified by recrystallizing twice from AN, had mp 263–264°C (lit. (36) mp 266–268°C). DCMTENF (37) was prepared from 2,4,5,7-tetranitrofluorenone and malononitrile following the procedure used to prepare DCMTNF (36) and purified by recrystallizing twice from AN, mp ca. 380–382°C (dec.) (lit. (37) mp > 400°C (dec.)). DCNQ was prepared from 2,3-dichloro-1,4-naphthoquinone (Aldrich) following the procedure of Reynolds (38) and purified by vacuum sublimation, recrystallization from benzene–toluene and from AN, mp 268–272°C (lit. (38) mp 274–275°C). DCNNQ was prepared from 2,3-dichloro-5-nitro-1,4-naphthoquinone (6) following Wallenfels (39) and purified by recrystallizing three times from methylene chloride – heptane. *Anal.* calcd. for $C_{12}H_3N_3O_5$: C 56.93, H 1.19, N 16.60; found: C 56.86, H 1.60, N 16.46. 2-Methyl-1,4-benzoquinone and 1,3,5-trinitrobenzene were obtained from commercial sources and were purified by sublimation or recrystallization before use. *N,N′*-Dimethyl-9,9′-biacridinium nitrate, for spectral comparison with D^+ salts, was obtained from K & K Laboratories. $^{14}CH_3$-labelled $D^+ClO_4^-$ was prepared by methylation of acridine (6) using ^{14}C-enriched methyl iodide. The preparation of *N*-methylacridan (DH) has been described (6). AN was Fisher Certified ACS grade further purified by distillation over phosphorus pentoxide followed by distillation over calcium hydride. 2-Nitroso-2-methylpropane was prepared by the procedure of Calder *et al.* (40).

N,N-*Dimethyl-9,9'-biacridanyl* (DD) was synthesized in 82% yield from *N*-methylacridinium iodide (D^+I^-) (6) and phenylhydrazine following Chupakhin (13) and recrystallized from dimethylformamide, mp 261–263°C (lit. (13) mp 280–281°C, (41) 270–271°C). ^1H nmr ($CDCl_3$) δ: 2.97 (s, 6H, N—CH_3), 3.88 (s, 2H, 9-H), 6.27–7.21 (m, 16H, aromatic). *Anal.* calcd. for $C_{28}H_{24}N_2$: C 86.56, H 6.23, N 7.21; found: C 86.54, H 6.06, N 7.21. This compound was also obtained in 41% yield by reduction of D^+I^- with Raney Nickel (14) and as a minor product in addition of several Grignard reagents to D^+I^- (15) as described below for 3,3'-dimethoxy-DD. 9,9'-Dideuterio-DD was prepared from 9-deuterio-D^+I^- (6) by Chupakhin's method (13).

*2,2'-Dimethoxy-*N,N'*-dimethyl-9,9'-biacridanyl* (2,2'-dimethoxy-DD) was obtained in 62% yield from 2-methoxy-D^+I^- (5) using Chupakhin's procedure (13). Recrystallization from pyridine–methanol afforded white crystals, mp 231–233°C. ^1H nmr ($CDCl_3$) δ: 3.27 (s, 6H, N—CH_3), 3.71 (s, 6H, OCH_3), 3.82 (s, 2H, 9-H), 6.57–7.33 (m, 14H, aromatic). In C_6D_6 solvent the two high-field peaks appear as a pair of peaks of relative intensity 48:52, respectively, at δ 2.58 and 2.62, and at 3.25 and 3.27, showing that the *meso* and *dl* diastereomers are produced in almost equal amounts. *Anal.* calcd. for $C_{30}H_{29}N_2O_2$: C 80.33, H 6.29, N 6.25; found: C 80.78, H 6.50, N 6.38. This compound was also obtained by treatment of 2-methoxy-D^+I^- with Raney Nickel (14) and as a byproduct in the treatment of 2-methoxy-D^+I^- with various Grignard reagents (15) as described below for 3,3'-dimethoxy-DD.

*3,3'-Dimethoxy-*N,N'*-dimethyl-9,9'-biacridanyl* (3,3'-dimethoxy-DD) was prepared from 3-methoxy-D^+I^- by a procedure modeled after that described by Grigorovskii and Simeonov for DD (14). 3-Methoxy-D^+I^- (0.28 g (8.0×10^{-4} mol)) was added to a slurry of 1 g of Raney Nickel W2 (42) that had been stirred for 15 min. The mixture was heated under reflux for 15 min during which time the solution turned yellow to colorless and a white precipitate appeared. The methanol suspension was separated from the Raney Nickel by decantation and the methanol removed under reduced pressure. Recrystallization from dimethylformamide led to 0.82 g (46%) of yellow crystalline product, mp 220–224°C. ^1H nmr ($CDCl_3$) δ: 2.91 (s, 6H, N—CH_3), 3.74 (s, 6H, OCH_3), 3.81 (s, 2H, 9-H), 6.0–7.2 (m, 14H, aromatic). In C_6D_6 the two high field peaks were again shifted upfield (to δ 2.53 and 3.35, respectively) but peaks due to the two diastereomers, if present, were not resolved. *Anal.* calcd. for $C_{30}H_{29}N_2O_2$: C 80.33, H 6.29, N 6.25; found: C 80.39, H 6.21, N 6.21. This compound was also obtained as a byproduct in the reaction of 3-methoxy-D^+I^- with several Grignard reagents. The following preparation is typical. To a suspension of 0.47 g (1.3×10^{-3} mol) of 3-methoxy-D^+I^- in 15 mL of dry ether was added 2 mL of a 2 *M* solution of *t*-butylmagnesium chloride in ether (4.0×10^{-3} mol) (Aldrich). After stirring for 4 h the excess Grignard reagent was decomposed with water, the ether solution washed with water, dried (K_2CO_3), filtered, and the ether evaporated. The solid was heated with 10 mL of absolute ethanol, dissolving the 9-*t*-butyl-3-methoxy-*N*-methylacridan and leaving the biacridanyl as a residue. Filtration and recrystallization from pyridine–methanol led to 0.080 g (27%) of 3,3'-dimethoxy-DD. All attempts to prepare this compound by reduction of 3-methoxy-D^+I^- with phenylhydrazine failed.

Kinetic measurements

Kinetics of oxidation were measured spectrophotometrically using methods and instrumentation described earlier (1, 6). Stopped flow methods were used with acceptors more reactive than CA. In reaction of DD with six of the oxidants the formation of D^+ was followed at 357 nm (BQ, CA, TCNE, DCBQ, $Co(bipy)_3^{3+}$) or at 420 nm (DClBQ, CA, DCBQ, $Co(bipy)_3^{3+}$). The formation of the acceptor radical anion was followed for DCMTNF (440, 550, or 600 nm) (36, 43), DCNQ (520 nm) (44), DCMTENF (550 nm) (45), TCNQ (680 nm) (46) and DCNNQ (520 nm) (47). Oxidation of 2,2'- and 3,3'-dimethoxy-DD by CA and $Co(bipy)_3^{3+}$) was followed at the 2- and 3-methoxy-D^+ absorption at 367 nm. Measurements were carried out under pseudo first-order conditions using a 30-fold or greater excess of oxidant over DD, except with some of the CA, TCNE, and TCNQ rates where a second-order analysis (1) was used. Both first-order and second-order plots were linear through at least 85% reaction. Final absorbances were constant for 10–20 half-lives with all acceptors except DCMTNF and DClBQ. The absorbance due to $DCMTNF^{\cdot-}$ reached a maximum after 6 to 8 half-lives, thereafter decreasing approximately linearly with time. Experimental final absorbance readings were corrected for this decrease; these corrections led to an increase of 0–2% in k. With DClBQ final absorbances continued to increase slowly after 10 half-lives due to instability of the acceptor and possibly its reduction product. While uncertainties in final absorbances (±1–3%) due to this source contributed to some of the scatter in the rate constants for DClBQ, we do not believe this to be the sole source of error.

Rates of radiochemical exchange of D^+ with DD were measured using DD labeled at the N—CH_3 position with ^{14}C. A 25.0 mL volume of solution containing D^+I^- (ca. 4×10^{-3} *M*) and labeled DD (ca. 8×10^{-5} *M*) in dry AN was maintained at 25°C. Aliquots (1.0 mL) were withdrawn at measured intervals and quenched by addition to a separatory funnel containing 8.0 mL of toluene and 50 mL of water. The toluene layer was extracted three times with 50 mL portions of water to remove D^+I^- and AN and then dried over K_2CO_3. A 5.0 mL aliquot of the dried toluene solution was mixed with 10.0 mL of PPO/POPOP scintillation cocktail (Fisher ScintiPrep 2 diluted 24:1 with toluene) and counted. The sample radioactivity decreased with time. The reported second-order rate constant is the pseudo first-order rate constant obtained in the usual way divided by the D^+I^- concentration.

Product isolations

$D^+ClO_4^-$ was isolated in yields of 90% or greater in oxidation of DD with CA, DCBQ, DDQ, DCNQ, DCNNQ, TCNE, TCNQ, DCMTNF, and DCMTENF as described earlier (1, 6).

Received May 15, 1984

This paper is dedicated to Professor Adrian G. Brook on the occasion of his 60th birthday

J. BRYAN JONES, R. SCOTT HINKS, and PHILIP G. HULTIN. Can. J. Chem. **63**, 452 (1985).

Preparative-scale pig liver esterase-catalyzed hydrolyses of five-membered ring *meso*-1,3-diesters are enantiotopically selective. While pro-*S* enantiotopic selectivity is exhibited in each case, the absolute configuration sense of the hydrolysis in the cyclopentyl series is opposite to that of both the tetrahydrofuranyl and tetrahydrothiophenyl diesters. The enantiomeric excess levels induced are in the 34–46% range.

J. BRYAN JONES, R. SCOTT HINKS et PHILIP G. HULTIN. Can. J. Chem. **63**, 452 (1985).

Les hydrolyses préparatives, catalysées par l'estérase du foie de cochon, de *méso*-diesters-1,3 incorporés dans des cycles à cinq chaînons sont énantiosélectives. Même si on observe une énantiosélectivité pro-*S* dans chaque cas, le sens de la configuration absolue de l'hydrolyse obtenu en série cyclopentanique est l'inverse de celui observé avec des diesters tant tétrahydrofurannique que tétrahydrothiophénique. Les niveaux d'excès énantiomériques induits sont de l'ordre de 34 à 46%.

[Traduit par le journal]

The asymmetric synthetic opportunities provided by the abilities of enzymes to discriminate between enantiotopic groups of symmetrical substrates such as *meso* compounds are now widely recognized (2). Alcohol dehydrogenases (3) and esterases (4) have already proven particularly valuable in this regard. Of these two enzyme groups, esterases are the more convenient to use because they do not require expensive coenzymes.

One of the synthetically most useful hydrolytic enzymes reported so far is pig liver esterase (PLE). PLE is a commercially available enzyme that is capable of effecting stereospecific hydrolyses on a broad structural range of ester substrates (4, 5). Its asymmetric synthetic potential is receiving increasing attention and recently several stereospecific PLE-mediated transformations of acyclic and cyclic 1,2-diesters to useful chiral synthons have been documented (4). We now report that PLE-catalyzed hydrolyses of the monocyclic *meso*-1,3-diesters **1–3** also proceed with considerable enantiotopic stereoselectivity.

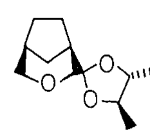
Results

The *cis* diester substrates **1–3** were prepared by Fischer esterification of the corresponding anhydrides, obtained by literature methods (6, 7*a*, 8). In the case of **1** and **2**, a methanol esterification procedure was used to give the acid-esters (±)-**4** and (±)-**5**. These were then transformed into **1** and **2** respectively by treatment with diazomethane. For **3**, direct Fischer esterification of the anhydride was performed.

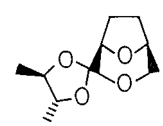
Each of the *cis* diesters was a substrate of the enzyme. The rates of PLE-catalyzed hydrolyses were assayed using ethyl butyrate as the reference substrate (9). Diesters **1** and **3** were excellent substrates, with rates of hydrolysis 51% and 35% respectively of that of the ethyl butyrate standard. Although **2** was hydrolyzed more slowly, with a rate of 3% that of the standard, it remained an excellent candidate for a preparative-scale reaction.[2]

Preparative-scale hydrolyses of **1–3** were performed in aqueous solution at room temperature (20°C) on up to 20 mmole of substrate using up to 100 units of PLE per mmole of substrate. The pH was maintained at 7.0 by pH-stat-controlled addition of 0.4 *M* sodium hydroxide. The reactions were terminated after the addition of 1 equivalent of base. The acid-esters **4–6** were isolated without difficulty. Their reductions to the corresponding hydroxyesters **7–9** also proceeded smoothly. The results are summarized in Scheme 1. On treatment with acid, the alcohol esters **7** and **8** lactonized readily to give **10** and **11** respectively. In contrast, the thiophenyl derivative **9** could not be induced to form the corresponding lactone.

The enantiomeric excesses(ee's) of the chiral products in the carbocyclic and tetrahydrofuranyl series were determined on the hydroxyesters **7** and **8**. Treatment of **7** and **8** with (+)-(*R*,*R*)-2,3-butanediol afforded the orthoesters **12** and **13**,



12

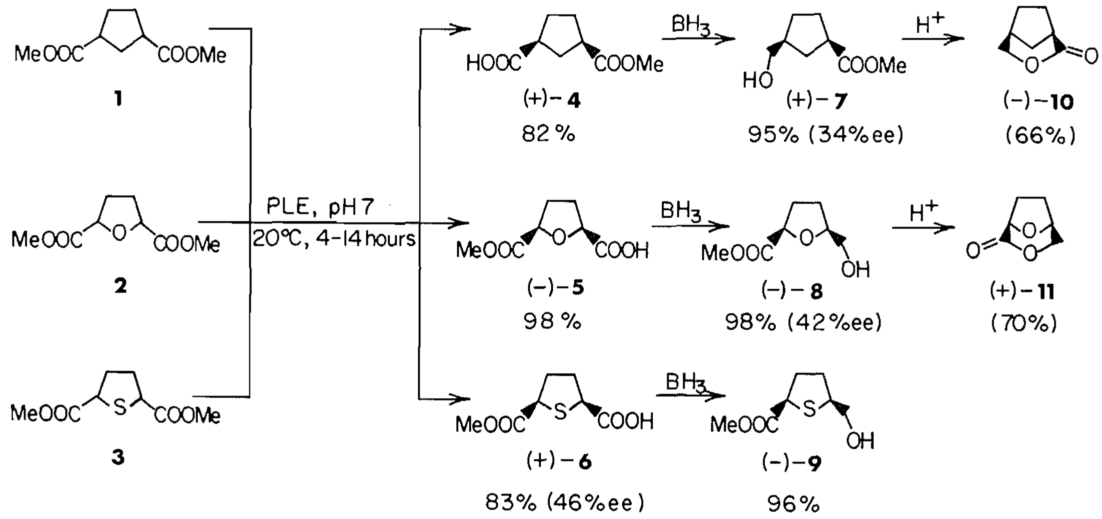


13

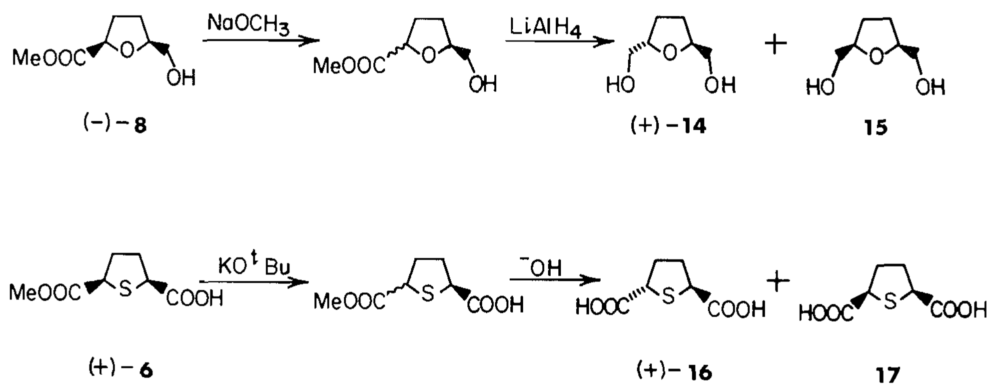
whose diastereomeric ratios were determined by glc analysis (10). The orthoesters obtained from (±)-**7** and (±)-**8** were used as reference standards. For the tetrahydrothiophenyl compounds, it was found more convenient to establish the enantiomeric excess of the series by ^{1}H nmr spectroscopic examination of the methoxyl protons of the acid ester **6** in the presence of (−)-(*S*)-1-methylbenzylamine (4*e*). For the (+)-**6** sample used as the reference, a $\Delta\Delta\delta$ value of 0.018 ppm was observed at 200 MHz. The ee values obtained are recorded in Scheme 1.

The absolute configurations of the Scheme 1 compounds were established by their conversions to known compounds. In the carbocyclic series, the (+)-enantiomer of **10** was available for direct comparison (3*a*). The furanyl hydroxyester (−)-**8** and the thiophenyl acid ester (+)-**6** were converted to the known (12) (+)-*trans* diol **14** and diacid **16** respectively, as summarized in Scheme 2. The *meso* diol **15** and *meso* diacid **17**

[1] For Part 32, see ref. 1.
[2] We currently consider that any substrate hydrolyzed at a rate ≤ 0.02% of that of ethyl butyrate will give good results in preparative-scale hydrolyses.



SCHEME 1



SCHEME 2

by-products of the correlation reactions do not affect the absolute configuration assignments since they are optically inactive.

Discussion

The preparations of the substrates **1–3** and of the racemic reference compounds (±)-**4–9** were straightforward. While use of a pH-stat is convenient for assaying the relative rates of hydrolysis of **1–3**, pH-stat control of the preparative-scale reactions is not essential. The use of a buffer, or of pH control via periodic burette-addition of base, is quite satisfactory. The reaction has a built-in fail-safe control in that the pH falls as the hydrolysis proceeds, thereby automatically switching off the reaction if it is left unattended for too long.

The hydrolyses were performed at pH 7. At this pH, the concurrent chemical hydrolysis that can reduce the ee levels in pH 8 reactions (4, 5) is avoided. The enzyme also appears to be intrinsically more stereospecific at lower pH (5*d*) and the ee levels of the Scheme 1 reactions could be significantly higher for pH <7 reactions.

Also, since one enantiotopic group is hydrolyzed faster than the other, allowing the reaction to proceed beyond the point at which one ester equivalent is hydrolyzed should progressively increase the ee of the acid ester that remains (13). The fact that the pH-stat curves for the hydrolyses of **1–3** show a sharp reduction in rate after one ester equivalent has been hydrolyzed augurs well for this approach. These aspects are being evaluated.

Chiral acid-ester products such as **4–6** are valuable synthetic intermediates since they may be converted to either enantiomer of hydroxyesters **7–9** or lactones **10** and **11** by appropriate choice of reducing agent. In this study, only the borane-mediated carboxyl reductions were performed. Preparations of the opposite enantiomeric series via the complementary selective lithium borohydride reductions of the carbomethoxy functions of **4–6** should present no problem (4, 5).

The reluctance of the thiophenyl hydroxyester **9** to undergo lactonization under a variety of acidic conditions was surprising, particularly since the corresponding anhydride required for the synthesis of **3** was readily formed.[3] The sulfur atom is clearly exerting an unusual effect here, since sulfur is easily accommodated in other bridged bicyclic structures (14).

As Scheme 1 shows, the absolute configuration sense of the enantiotopically selective PLE-catalyzed hydrolyses of **1–3** changes, with that of the **1** → (−)-**4** reaction being opposite to those of the **2** → (−)-**5** and **3** → (+)-**6** hydrolyses.[4] A reversal of enzymic stereospecificity dictated only by the presence or

[3] Reduction of the anhydride with sodium borohydride afforded the expected acid-alcohol, but this also failed to lactonize under a variety of acidic conditions.

[4] Due to the selection rules of the Cahn–Ingold–Prelog system, while (−)-**5** and (+)-**6** are of opposite absolute configuration type to (+)-**4**, the hydrolyses of each of **1–3** proceed with a pro-*S* ester preference.

absence of a heteroatom has not, to our knowledge, been observed before. PLE is clearly remarkable with regard to its penchant for inducing unusual switches of stereospecificity within related series of substrates (4*g*). The factors controlling such reversals are being investigated. The substrate orientation model proposed recently (4*d*) does not enable such stereospecificity reversals to be interpreted.

Experimental

Pig liver esterase (EC 3.1.1.1, Sigma Type I) was obtained from Sigma Chemical Co. All enzymic reactions were monitored using a Radiometer RTS 822 pH-stat. The ^{1}H nmr spectra were recorded on Varian T60 or XL 200 instruments and ^{13}C nmr spectra on a Varian CFT-20 spectrometer. The ir spectra were recorded on a Nicolet 5DX FT-IR system, optical rotations on a Perkin–Elmer 141 polarimeter, and glc analyses on a Hewlett–Packard HP 57/019 chromatograph using a methylsilicone capillary column at 11 psi (1 psi = 6.9 kPa) and 100°C.

cis-1,3-Dicarbomethoxycyclopentane (1)

cis-Cyclopentane-1,3-dicarboxylic acid anhydride (0.34 g, 2.5 mmol, prepared by the method of Carleer *et al.* (6)) was refluxed in dry MeOH (20 mL) for 3 h and then rotoevaporated. Kugelrohr distillation yielded (±)-*cis*-carbomethoxycyclopentane carboxylic acid ((±)-**4**, 0.42 g, 99% yield), bp 80°C/0.05 Torr (1 Torr = 133.3 Pa); ir (film) ν: 1735, 1705 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.87–2.40 (6H, m), 2.50–3.10 (2H, m), 3.72 (3H, s), and 11.76 (1H, s) ppm. This monoester (0.41 g, 2.4 mmol) in ether (20 mL) was esterified with diazomethane to give *cis*-1,3-dicarbomethoxycyclopentane (**1**, 0.46 g, 97% yield), bp 70°C/0.05 Torr (lit. (6) bp 130°C/25 Torr); ir (film) ν: 1732 cm^{-1}; ^{1}H nmr ($CDCl_3$) (lit. (15)) δ: 1.90–2.32 (6H, m), 2.60–3.10 (2H, m), and 3.70 (6H, s) ppm; ^{13}C nmr ($CDCl_3$) δ: 28.60 (t), 32.83 (t), 43.21 (d), 51.05 (q), and 174.94 (s) ppm.

cis-2,5-Dicarbomethoxytetrahydrofuran (2)

cis-Tetrahydrofuran-2,6-dicarboxylic acid anhydride (3.03 g, 21.3 mmol, prepared by the method of Moore and Kelly (7*a*)) was refluxed in dry MeOH (10 mL) for 1 min and rotoevaporated to give (±)-*cis*-5-carbomethoxytetrahydrofuran-2-carboxylic acid ((±)-**5**, 3.71 g, 99%), bp 100°/0.15 Torr; ir (film) ν: 1761, 1720 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 2.0–2.6 (4H, m), 3.86 (3H, s), 4.5–4.9 (2H, m), and 10.42 (1H, br s) ppm; ^{13}C nmr ($CDCl_3$) δ: 29.00 (t), 29.67 (t), 52.52 (q), 77.76 (d), 172.79 (s), and 175.76 (s) ppm. This monoester (3.94 g, 22.6 mmol) was esterified with diazomethane as above to give *cis*-2,5-dicarbomethoxytetrahydrofuran (**2**, 4.16 g, 98% yield), bp 70°C/0.05 Torr (lit. (16) bp 81–83°C/0.1 Torr); ir (film) ν: 1738 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 2.23 (4H, m), 3.76 (6H, s), and 4.56 (2H, m); ^{13}C nmr δ: 28.10 ($CDCl_3$) δ: (t), 50.87 (q), 77.20 (d), and 171.09 (s) ppm.

cis-2,5-Dicarbomethoxytetrahydrothiophene (3)

cis-Tetrahydrothiophene-2,5-dicarboxylic acid anhydride (1.5 g, 9.5 mmol, prepared by the method of Horak (17)) was esterified for 21 h at 20°C with HCl-saturated MeOH (125 mL) containing triethyl orthoformate (1 mL, 9 mmol). The solution was rotoevaporated and saturated aqueous $NaHCO_3$ (100 mL) added. Extraction with CH_2Cl_2 (6 × 150 mL) followed by rotoevaporation of the dried ($MgSO_4$) extracts and Kugelrohr distillation afforded *cis*-2,5-dicarbomethoxytetrahydrothiophene (**3**, 1.34 g, 69% yield), bp 90°C/0.03 Torr (lit. (18) bp 70°C/0.1 Torr); ir (film) ν: 1740 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.83–2.80 (4H, m), 3.70 (6H, s), and 4.03 (2H, m) ppm; ^{13}C nmr ($CDCl_3$) δ: 33.10 (t), 48.89 (d), 52.47 (q), and 172.55 (s) ppm.

(±)-cis-5-Carbomethoxytetrahydrothiophene-2-carboxylic acid ((±)-6)

This reference compound was prepared as described for (±)-**4** and -**5** above from *cis*-tetrahydrothiophene-2,6-dicarboxylic acid anhydride (103 mg, 0.65 mmol, obtained by the method of Della and Kendall (18)). The acid-ester (±)-**6** (105 mg, 85% yield) had bp 95°C/0.1 Torr, mp 61–63°C (lit. (18) mp 50–53°C); ir (film) ν: 3500–2400, 1739, 1712 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 2.00–2.85 (4H, m), 3.75 (3H, s), 4.00–4.20 (2H, m), and 11.28 (1H, s) ppm.

Relative rates of PLE-catalyzed hydrolyses of meso *diesters 1–3*

The assays were performed at pH 7.0 at 20°C on 10-mL aliquots of 0.1 *M* aqueous KCl 1–2 m*M* in substrate diester. The reaction was initiated by the addition of 1 unit of PLE. The uptake of 0.02 *M* aqueous NaOH as each hydrolysis proceeded was monitored using a pH-stat. As a standard reference, the rate of ethyl butyrate hydrolysis under the same conditions was performed for each substrate. The initial rates of hydrolyses of **1**, **2**, and **3**, relative to ethyl butyrate = 100, were found to be 51, 3, and 35 respectively.

Preparative-scale PLE-catalyzed hydrolyses of meso *diesters 1–3*

(a) *Of* cis-*1,3-dicarbomethoxycyclopentane (1)*

The diester **1** (0.56 g, 3 mmol) was suspended in 0.1 *M* aqueous KCl (50 mL) at room temperature (20°C) and the mixture adjusted to pH 7.0. PLE (90 units) was added and the pH maintained at 7.0 by the addition of 0.4 *M* aqueous NaOH (via a burette or pH-stat). The reaction slowed down, but did not stop, after the addition of 1 equiv. of base and was terminated after 1.06 equiv. of NaOH had been added (4 h). The mixture was first extracted at pH 7.0 with ether (75 mL) to remove unchanged diester and then acidified to pH 2.0 with 12 *M* hydrochloric acid. Re-extraction with ether (5 × 75 mL) followed by rotoevaporation of the dried ($MgSO_4$) ether extracts afforded an oil (0.5 g) which was Kugelrohr-distilled twice to remove diacid and yielded (+)-*cis*-(1*S*,3*R*)-3-carbomethoxycyclopentane carboxylic acid ((±)-**4**, 0.43 g, 82% yield), bp 80°C/0.06 Torr; $[\alpha]_D^{25}$ +0.2° (*c* 3.5, $CHCl_3$); ir and ^{1}H nmr spectra identical with those of (±)-material above.

(b) *Of* cis-*2,5-dicarbomethoxytetrahydrofuran (2)*

The above procedure was followed using diester **2** (3.54 g, 18.8 mmol) and PLE (1050 units). The reaction was terminated after the addition of 1.1 equiv. of base (12 h). In this case the product was extracted from the pH 2 solution with CH_2Cl_2 (10 × 75 mL). The (−)-(2*S*,5*R*)-*cis*-5-carbomethoxytetrahydrofuran-2-carboxylic acid ((−)-**5**, 2.77 g, 85% yield) obtained had bp 100°C/0.15 Torr; $[\alpha]_D^{25}$ −20.3° (*c* 1.4, $CHCl_3$) and ir and ^{1}H nmr spectra identical with the (±)-monoester.

(c) *Of* cis-*2,5-dicarbomethoxytetrahydrothiophene (3)*

With diester **3** (1.01 g, 4.9 mmol) and PLE (262 units) 1.03 equiv. of base was consumed in 8 h. Work-up using ether extraction gave (+)-(2*S*,5*R*)-*cis*-5-carbomethoxytetrahydrothiophene-2-carboxylic acid ((+)-**7**, 0.8 g, 83% yield, 46% ee) as a solidifying oil, bp 80°C/0.1 Torr; $[\alpha]_D^{25}$ +6.34° (*c* 1.4, $CHCl_3$); ^{1}H nmr as for (±)-**6**, ^{13}C nmr ($CDCl_3$) δ: 34.41, 34.76, 50.51, 54.05, 174.35, and 179.05 ppm.

Reductions of acid-esters 4–6 to the hydroxyesters 7–9

(a) *Of (+)-1S,3R)-cis-3-carbomethoxycyclopentanecarboxylic acid ((+)-4)*

The acid-ester ((±)-**4**, 0.31 g, 1.8 mmol) was dissolved in dry THF (5 mL) under N_2 and $BH_3 \cdot Me_2S$ (1.5 mL of 2 *M* THF solution, 3.0 mmol) added at −78°C to the stirred solution. The mixture was allowed to warm to 20°C during the 30 min and then stirred for a further 3 h at 20°C. The mixture was then cooled to −20°C and quenched slowly with stirring with 1 *M* aqueous KH_2PO_4 (5 mL). After rewarming to 20°C and stirring for 20 min more, the mixture was extracted with ether (4 × 50 mL) and the dried ($MgSO_4$) ether solution rotoevaporated. MeOH (25 mL) was added and the solution re-evaporated. The residual oil was then Kugelrohr-distilled to give (+)-*cis*-(1*R*,3*S*)-3-hydroxymethyl-1-carbomethoxycyclopentane ((±)-**7**, 0.271 g, 95% yield, 34% ee), bp 70°C/0.05 Torr; $[\alpha]_D^{25}$ +0.2° (*c* 1.6, $CHCl_3$); ir (film) ν: 3393, 1732 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.3–2.4 (7H, m), 2.47 (1H, br s, OH), 2.92 (1H, m), 3.70 (3H, s), and 3.50–3.75 (2H, m); ^{13}C nmr ($CDCl_3$) δ: 28.28 (t), 29.01 (t), 32.91 (t), 42.04 (d), 43.54 (d), 51.39 (q), 66.12 (t), and 179.79 (s) ppm.

The hydroxyester (+)-**7** (150 mg, 0.9 mmol) in dry benzene (5 mL) containing toluene-*p*-sulfonic acid (5 mg) was refluxed for 2.5 h. The cooled solution was then filtered through a silica plug (5 g), and the solvent rotoevaporated. Kugelrohr distillation yielded (−)-(1*R*,5*S*)-3-oxabicyclo[3.2.1]octan-2-one ((−)-**10**, 81 mg, 66% yield), bp 80°C/0.25 Torr; $[\alpha]_D^{25}$ −1.9° (*c* 1.3, $CHCl_3$) (lit. (3*a*) (1*S*,5*R*)-enantiomer $[\alpha]_D^{25}$ +4.33° (*c* 1.5, $CHCl_3$)); ir and ^{1}H nmr spectral data identical with literature values (3*a*).

(b) *Of (−)-(2*S,5R*)-cis-5-carbomethoxytetrahydrofuran-2-carboxylic acid ((−)-5)*

The acid-ester (−)-**5** (1.33 g, 7.1 mmol) in dry THF (8 mL) was reduced with $BH_3 \cdot Me_2S$ (5.3 mL of 2 *M* THF solution, 7.1 mmol) as described above except that the reaction mixture was worked up by the dropwise addition of MeOH (5 mL) in place of KH_2PO_4.[5] The (−)-(2*R*,5*S*)-*cis*-5-hydroxymethyl-2-carbomethoxytetrahydrofuran ((−)-**8**, 1.21 g, 98% yield, 42% ee) isolated had bp 80°C/0.06 Torr (lit. (7*b*) (±) bp 50°C/0.2 Torr); $[\alpha]_D^{25}$ −9.4° (*c* 1.8, $CHCl_3$); ir (film) ν: 2463, 1734 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.70–2.50 (4H, m), 3.79 (3H, s), and 3.3–4.7 (5H, m) ppm; ^{13}C nmr ($CDCl_3$) δ: 25.24 (t), 30.36 (t), 51.55 (q), 63.08 (t), 76.15 (d), 81.41 (d), and 174.50 (s) ppm. *Anal.* calcd. for $C_7H_{12}O_4$: C 52.50, H 7.55%; found: C 52.38, H 7.55%.

The hydroxyester (−)-**8** (219 mg, 1.37 mmol) was lactonized as described above for (−)-**10** to give (+)-(1*R*,5*S*)-3,8-dioxabicyclo-[3.2.1]octan-2-one ((±)-**11**, 124 mg, 70% yield), bp 80°C/0.4 Torr (lit. (7*b*) bp 45°C/0.2 Torr); $[\alpha]_D^{25}$ +1.7° (*c* 1.1, $CHCl_3$); ir (film) ν: 1755 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 2.13 (4H, m) and 4.00–4.61 (4H, m) ppm; ^{13}C nmr ($CDCl_3$) δ: 26.03 (t), 29.96 (t), 71.29 (d), 73.74 (t), 75.19 (d), and 168.56 (s) ppm.

(c) *Of (+)-(2*S,5R*)-cis-5-carbomethoxytetrahydrothiophene-2-carboxylic acid ((+)-6)*

The acid-ester (+)-**6** (193 mg, 1.01 mmol) in dry THF (5 mL) was reduced with $BH_3 \cdot Me_2S$ (0.8 mL of 2 *M* THF solution, 1.62 mmol) as for (−)-**5** above to give (−)-(2*R*,5*S*)-*cis*-5-hydroxymethyl-2-carbomethoxytetrahydrothiophene ((−)-**9**, 172 mg, 96% yield), bp 60°C/0.05 Torr; $[\alpha]_D^{25}$ −14.5° (*c* 1, $CHCl_3$); ir (film) ν: 3416, 1733 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 2.0–2.6 (4H, m), 3.63 (3H, m), 3.70 (3H, s), and 3.9 (2H, m) ppm; ^{13}C nmr ($CDCl_3$) δ: 32.27, 32.86, 47.81, 51.95, 52.18, 65.27, and 173.97 ppm. *Anal.* calcd. for $C_7H_{12}O_3S$: C 47.71, H 6.86; found: C 47.92, H 7.00%.

Enantiomeric excess determinations

For the cyclopentyl and tetrahydrofuran series, the ees were established by capillary column glc analysis (10) of the orthoesters **12** and **13** derived from (+)-**7** and (−)-**8** respectively, using the orthoesters from (±)-**7** and (±)-**8** as reference standards.[6]

The hydroxyester (+)-**7** (32 mg, 0.21 mmol) in benzene (15 mL) containing toluene-*p*-sulfonic acid (2 mg) and (+)-(2*R*,3*R*)-butane-2,3-diol (41 mg, 0.45 mmol) was refluxed for 12 h to give, after Kugelrohr distillation, orthoester **12** (29 mg, 72% yield), bp 70°C/0.05 Torr; ^{1}H nmr ($CDCl_3$) δ: 1.28 (6H, d, J = 6 Hz), 1.40–2.33 (8H, m), and 3.30–43.0 (4H, m) ppm; glc retention times: 7.33 min (33%), 7.52 min (67%); 34% ee.

The hydroxyester (−)-**8** (41 mg, 0.26 mmol) was similarly converted to orthoester **13** (46 mg, 88% yield), bp 70°C/0.05 Torr; ^{1}H nmr ($CDCl_3$) δ: 1.26 (3H, d, J = 6 Hz), 1.33 (3H, d, J = Hz), 2.03 (4H, m), and 3.40–4.40 (6H, m) ppm; glc retention times: 9.56 min (71%), 9.85 min (29%); 42% ee.

For the tetrahydrothiophene series, the ee was established by 200-MHz ^{1}H nmr examination of the acid-ester (+)-**6** (15 mg, 0.077 mmol) and (−)-(*S*)-1-methylbenzylamine (12 mg, 0.1 mmol) in $CDCl_3$ (0.5 mL) (4*e*). The diastereomeric methyl peaks were cleanly resolved with ΔΔδ 0.018 ppm. Integration, using the (±)-**6** spectrum as the reference standard, showed the ee to be 46 ± 4%.

Absolute configuration determinations

(a) *Of* cis-*(1*R*,3*S*)-3-hydroxymethyl-1-carbomethoxycyclopentane ((±)-7)*

The absolute configuration assignment of this compound was accomplished by its conversion to the known (3*a*) (1*R*,5*S*)-3-oxabicyclo[3.2.1]octan-2-one ((−)-**10**) described above.

(b) *Of* cis-*(2*R*,5*S*)-5-hydroxymethyl-2-carbomethoxytetrahydrofuran ((−)-8)*

The hydroxyester (−)-**8** (0.8 g, 5 mmol) in MeOH (50 mL) containing NaOMe (from Na 1.78 g, 77 mmol in MeOH (100 mL)) was refluxed for 4 h (20). The cooled mixture was then poured into 1 *M* hydrochloric acid at 0°C, and the pH adjusted to 7.0 with 1 *M* aqueous NaOH. The solution was then saturated with NaCl and extracted with ether (7 × 50 mL). The dried ($MgSO_4$) ether extracts were rotoevaporated and the residual oil Kugelrohr-distilled to give a 1 : 1 mixture of the (2*R*/*S*,5*S*)-diastereomers of **8** (0.46 g, 57% yield), bp 72°C/0.05 Torr; glc retention times: 4.65 min (55%, *cis*) and 5.10 min (45%, *trans*); ir (film) ν: 3464 (br) and 1736 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.8–2.4 (4H, m), 3.76 (3H, narrowly split "singlet"), and 3.4–4.7 (5H, m) ppm; ^{13}C nmr ($CDCl_3$) *cis*-isomer, δ: 25.23, 30.57, 51.75, 63.16, 76.25, 81.57, and 174.74; *trans*-isomers, δ: 26.30, 27.75, 51.45, 63.90, 76.75, 80.57, and 173.28 ppm. This *cis*–*trans* mixture of **8** (207 mg, 1.3 mmol) in dry THF (10 mL) was added dropwise during 5 min to a refluxing suspension of $LiAlH_4$ (202 mg, 5.3 mmol) in dry THF (30 mL) under N_2. After refluxing for 1 h, the reaction was quenched with saturated aqueous Na–K tartrate (Rochelle salt, ref. 21). The mixture was then refluxed for 30 min, filtered, and the residue washed with hot THF (2 × 15 mL). The combined THF solutions were dried ($MgSO_4$), rotoevaporated, and Kugelrohr-distilled to give a mixture of the *trans*-((+)-**14**) and *cis*-(**15**)-isomers of 2,5-bis(hydroxymethyl)tetrahydrofuran (144 mg, 84% yield), bp 75°C/0.05 Torr; glc retention times: 3.04 min (45%, *trans*) and 3.20 min (55% *cis*); $[\alpha]_D^{25}$ +13.6° (*c* 1, $CHCl_3$) (lit. (11) $[\alpha]_D^{22}$ +42° (*c* 1.1, $CHCl_3$) for (+)-**14**); ir (film) ν: 3368 (br); ^{1}H nmr ($CDCl_3$) δ: 1.6–2.2 (4H, m) and 3.4–4.4 (8H, m) ppm; ^{13}C nmr ($CDCl_3$) *cis*-isomer, δ: 26.76, 64.37, and 79.93; *trans*-isomer, δ: 27.25, 64.37, and 76.92 ppm.

(c) *Of cis-(2*S,5R*)-5-carbomethoxytetrahydrothiophene-2-carboxylic acid ((+)-6)*

To the acid-ester (+)-**6** (91 mg, 0.48 mmol) and 18-crown-6 (16 mg, 0.06 mmol) in THF (5 mL) at 0°C under N_2 was added potassium *tert*-butoxide (108 mg, 0.96 mmol). The yellow suspension was stirred for 15 min at 0°C, and then for 24 h at 20°C. The mixture was then acidified to pH 2 with 1 *M* hydrochloric acid and the solvent rotoevaporated. 5% Aqueous $NaHCO_3$ (10 mL) was added and the mixture washed with CH_2Cl_2 (2 × 10 mL). The aqueous layer was acidified to pH 2 with 6 *M* hydrochloric acid and extracted with ethyl acetate (5 × 10 mL). Evaporation of the dried ($MgSO_4$) extracts gave an oil (85 mg, a mixture of methyl and *tert*-butyl acid-esters) which was refluxed with 15% aqueous NaOH (10 mL) for 30 min. Water (10 mL) was then added and the cooled solution washed with ethyl acetate (2 × 10 mL). The aqueous layer was acidified to pH 2 with 6 *M* hydrochloric acid and extracted with ethyl acetate (4 × 10 mL). Evaporation of the dried ($MgSO_4$) ethyl acetate solutions yielded (after decolorization with Norite) a mixture of *cis*-(**17**) and *trans*-((+)-**16**) 2,5-dicarboxytetrahydrothiophene (45 mg, 53% yield) as a solid, $[\alpha]_D^{25}$ +2.3° (*c* 0.9, EtOH) (lit. (12) $[\alpha]_D^{25}$ +258.5° (EtOH) for (+)-**16**).[7] A *cis*/*trans* ratio of 0.72 : 1 in this diacid was estimated by its conversion to the diester with diazomethane and examination of the 50.3-MHz ^{13}C nmr spectrum in $CDCl_3$; *cis*-isomer, δ: 32.93, 48.71, 52.46, and 172.51; *trans*-isomer, δ: 32.75, 48.28, 52.41, and 173.18 ppm.

JOHN S. TSE, EMMANUEL PELLACH, and G. MICHAEL BANCROFT. Can. J. Chem. **63**, 457 (1985).

We report the observation of satellite structures associated with the core C 1*s* and F 1*s* levels in the photoelectron spectra of CH_3F, CF_3H, and CF_4. These structures are attributed to monopole "shakeup" excitations. Qualitative assignments aided by theoretical Xα-SW calculations are presented. We found shakeup intensities in the C 1*s* spectrum of CF_4 are enhanced by barrier created by the fluorine lone pair electrons. However, this effect is less apparent in the F 1*s* core hole photoelectron spectra.

JOHN S. TSE, EMMANUEL PELLACH et G. MICHAEL BANCROFT. Can. J. Chem. **63**, 457 (1985).

Dans les spectres photoélectroniques du CH_3F, du CF_3H et du CF_4, on a observé des structures satellites associées avec les niveaux 1*s* tant du C que du F. On attribue ces structures à des excitations de "secousse". On présente des attributions qualitatives faites à l'aide de calculs théoriques Xα-SW. On a trouvé que, dans les spectres 1*s* du C du CF_4, les intensités des "secousses" sont augmentées par la barrière créée par la paire d'électrons libres de fluor. Toutefois, cet effet est moins apparent dans les spectres photoélectroniques des électrons 1*s* du F.

I. Introduction

Apart from the usefulness of X-ray photoelectron spectra in providing chemical shift information on the core levels of molecules which can be correlated to their ground state electronic properties, recent studies on the satellites often associated with the core photoionization reveal the possibility of extracting information on the excited ionic states and the mode of bonding of the molecules (1). To advance the understanding of this interesting phenomenon, considerable effort has been devoted to improve experimental instrumentation and theoretical models in the last few years (2, 3). The prevailing theory suggests that these satellites are the result of many-electron relaxation processes accompanying the creation of the core hole during photoionization (1). In the photoelectron spectra, these structures usually appear as satellite bands situated on the higher binding energy region of the intense core hole photoelectron peak. For molecules with no low lying excited states (e.g. main group compounds), the satellite structure can be ascribed as simple secondary electron processes such as double ionization (shakeoff) and simultaneous monopole excitations (shakeup). A detailed description of the theory is given in a recent review article (1). Our previous experimental and theoretical studies on this subject (4−10) demonstrate that for simple molecules such as the ten-electron hydrides (5) CH_4, NH_3, and H_2O, when the valence and virtual orbitals are dominated by one central atom, the core hole spectra can be interpreted on the basis of a simple "atomic" model. Our results suggest the effect of the bonding hydrogen on the shakeup spectra is minimal. In the present work, we sought to investigate the perturbation of the shakeup pattern by systematically substituting hydrogen atoms in methane by the heavier fluorine atoms. There are several reasons for selecting the fluoromethanes in our studies. First, for neutral monomeric gas phase molecules, the complication due to intermolecular interactions on the shakeup transitions can be eliminated (3). Second, the shakeup spectrum of the parent molecule methane is well documented and any changes in the spectral pattern of fluoromethanes can be correlated with it. Third, the electronic structure of the fluoromethanes is relatively simple and theoretical molecular orbital calculations can be used to assist the assignment. Finally, substitution of hydrogen by fluorine in methane will establish a potential barrier (11, 12). This "potential wall" helps to localize the lower energy Rydberg orbitals and may, therefore, enhance shakeup transitions of these orbitals. We wish to observe this phenomenon through the analysis of intensity distributions in the core hole spectra within the fluoromethanes.

In this paper we report the results of a study on shakeup satellites on the C 1*s* and F 1*s* core level spectra of CH_3F, CHF_3, and CF_4 in the gaseous phase. In Section II, we present the details of the experimental procedure and the theoretical model. The electronic structures of the fluoromethanes are examined in Section III. Finally, in Section IV assignments of the core hole spectra are made and discussed.

II. Experimental and theoretical model

(A) Experimental

Tetrafluoromethane (Freon 14) was purchased from Matheson (99.7%) purity, trifluoromethane was purchased from PCR (99% purity), and methylfluoride from Calions Inc., (99% purity). All samples have been used directly without further purification. Core level spectra of the above mentioned compounds were measured in the gas phase on a McPherson ESCA-36 spectrometer. Duplicate spectra were obtained with MgKα and AlKα radiation sources. The observed satellite structures were found to be independent of the source of ionization used. Owing to the low intensity of the satellite structures, we had to accumulate a large number of scans covering the appropriate energy region in order to achieve good statistics. Typically 110−150 scans (~10 min per scan) were taken for the C 1*s* core level spectra and 50−70 scans were sufficient for F 1*s* core level spectra. The operating

[b]Exchange parameters for atoms from ref. 35.

pressure in the ionization chamber of the spectrometer is ca. $1-5 \times 10^{-5}$ Torr. We found that the F 1s shakeup was slightly pressure dependent indicating inelastic scattering (13). However, this pressure dependence is small compared to the reported spectra of HF and therefore should not hamper our discussion.

The photoelectron spectra were fitted with a combination Lorentzian–Gaussian function (14). The weak satellite structure was analyzed separately so that the intense main photoelectron line would not dominate the fitting procedure. For the weaker satellite peaks, in particular those at higher binding energy, there exists a significant uncertainty on the fitted peak energy and intensity.

(B) Theoretical model

To interpret the satellite structures observed in the core level spectra, it is essential to understand the electronic structure of both the ground and excited states of the molecule. We employed the Xα-SW (15) method to generate the wavefunctions of the molecules (16). The merit and accuracy of this theoretical method have been discussed in several publications (4–10). Within the sudden approximation (17), the shakeup excitation energy is given by the difference in total energy of the excited hole state with the neutral ground state (ΔSCF). An alternative method is to use Slater's "transition-state" (TS) procedure (15). The intensity of a shakeup transition is determined by the matrix element (18).

$$[1] \quad I_{n\to 1} \propto \left| \langle \Psi^{N-1}_{n \to 1} \left| a_k \right| \Psi^{N}_{0} \rangle \right|^2$$

where $\Psi^{N-1}_{n\to 1}$ is the $(n \to 1)$ shakeup state of the ion and Ψ^{N}_{0} is the ground state of the neutral molecule and a_k is the electron annihilation operator that creates a core hole in orbital k. This matrix element can be easily evaluated within the Xα-SW formalism once the wavefunctions of the ground and excited state are known (10, 19).

In the calculations of the F 1s hole states in CF_4 and CHF_3, a localized core hole scheme was adopted. In principle, the calculation of the final ionic states of a symmetrical molecule is formally equivalent within the localized (symmetry unrestricted) or delocalized (symmetry restricted) core hole approximation (20–22). The fluctuation of the core hole between symmetry equivalent atoms through scattering processes breaks the symmetry of the final state. This symmetry breaking lessens the restrictions governing monopole and dipole shakeup transitions. The summation over all possible excitations simply represents the response of the system to a hole localization on symmetry equivalent nuclei (23–25). However, the calculation of the relaxation shift of a delocalized hole requires a larger basis set with extensive configuration interaction. Earlier calculations on the shakeup spectra of dialkyl metal compounds showed the core hole localization scheme gave reasonably good agreement with experiments (6).

We have performed Xα-SW calculations using the touching spheres approximation on the ground and hole excited states for CH_4, CH_3F, CHF_3, and CF_4. Table 1 summarizes the symmetries and sphere parameters employed in the calculations. Partial wave expansions are truncated at l_{max} = 1(sp), 2(spd), and 3($spdf$) for the hydrogen, heavy atoms (carbon and fluorine) and outersphere, respectively. Core orbitals were never frozen during the SCF interactions. The convergence criteria used required the difference in constant potential between successive cycles be less than 0.001 Ryd.

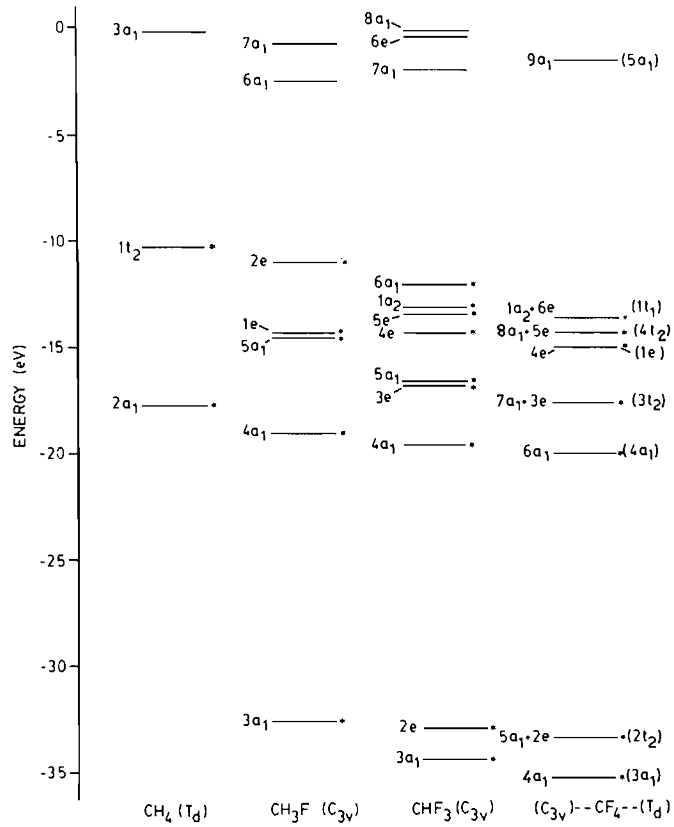

FIG. 1. Molecular orbital diagrams for CH_4, CH_3F, CHF_3, and CF_4; * indicates occupied orbitals.

III. Electronic properties of the fluoromethanes

(A) Ground state

To facilitate the discussion, we present the molecular-orbital (MO) diagram for CH_4, CH_3F, and CF_3H in the ground electronic state in Fig. 1.

We observe from the diagrams that the valence orbital energies stabilize gradually with the degree of fluorination. Our results agree very well with both the *ab initio* (27) and an earlier Xα calculation (26). The slight discrepancy between the present results and the previous calculation is due to the different parameters employed in the computations. It is gratifying that the sequence of the valence orbitals is consistent with the experimental assignments (28).

In Fig. 1 we also display the bound unoccupied orbitals found from an energy search up to −0.01 Rydberg. In contrast to our previous studies on the ten-electron hydrides (5) (e.g., CH_4), where the LUMO is mostly 3s Rydberg in character, the fluoromethanes showed a significant shift of the electron density from the outersphere region into the intersphere. However, we do not observe a concerted electron migration into the atomic sphere regions. A careful examination of the individual wavefunctions reveals the predominantly Rydberg nature of the orbitals with only a slight admixture of C—F antibonding character. The accumulation of charge inside the intersphere region in the fluoromethanes is probably an artifact owing to the larger size of the outersphere used in the calculations. We can assign the first symmetry allowed electronic transition in the partly fluorinated molecules as the σ(C—H) → 3s excitation. In the case of CF_4, this transition corresponds to the σ(C—F) → 3s excitation. The small hypsochromic shift observed experimentally (29) substantiates this assignment. In

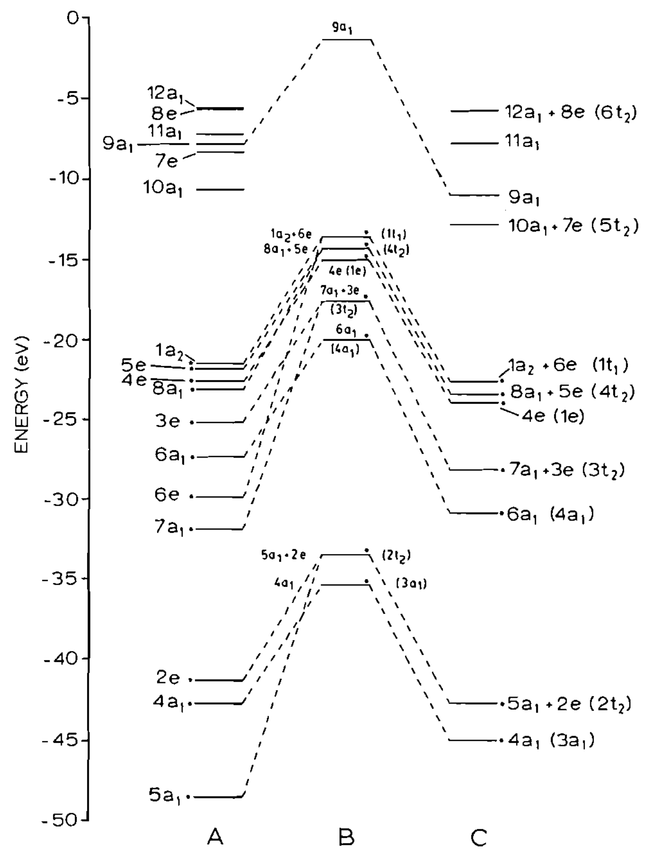

FIG. 2. Molecular orbital diagrams for CF_4: (*A*) F 3*s* hole state, (*B*) ground state, (*C*) C 1*s* hole state.

addition, the predicted order for the transition energies: CF_4 $(1t_1 \rightarrow 4a_1) > CHF_3\ (6a_1 \rightarrow 7a_1) > CH_4\ (1t_2 \rightarrow 3a_1) > CH_3F$ $(2e \rightarrow 6a_1)$ complies with the observed sequence. It is noteworthy that a HOMO-LUMO separation of ca. 8 eV in the fluoromethanes precludes the possibility of any "shakedown" processes. Therefore the most intense photoelectron line can be regarded as the primary hole state.

(B) Primary hole states

The carbon and fluorine core ionized states of the fluoromethanes were generated by removing one electron from the core 1*s* orbital from the respective atom in the molecule. Removal of the core electron from the central carbon atom retains the symmetry of the neutral molecule and therefore the carbon hole state MO diagram is relatively simple and resembles that of the ground state molecule. In the calculations of the F 1*s* hole state, we lower the molecular symmetry of CF_4 from T_d to C_{3v}, and C_{3v} to C_s in the CHF_3. Owing to computation restriction we are not able to perform calculation on the F 1*s* hole state of CF_3H. Instead, a schematic MO diagram was constructed from information obtained in CF_4 and CH_3F (for details, see Section IV). The energy of the molecular orbitals in the hole states are compared with the ground state values in Figs. 2–4 for CF_4, CHF_3, and CH_3F, respectively.

In the case of C 1*s* ionizations, we observe that there is a uniform shift (ca. 11 eV) to higher binding energies for all the valence orbitals. This shift is the result of decreased screening when an electron is removed from the core. This observation is of practical significance. Since the energy intervals between valence orbitals of a molecule do not change appreciably from the neutral ground state to the hole state, therefore, within the

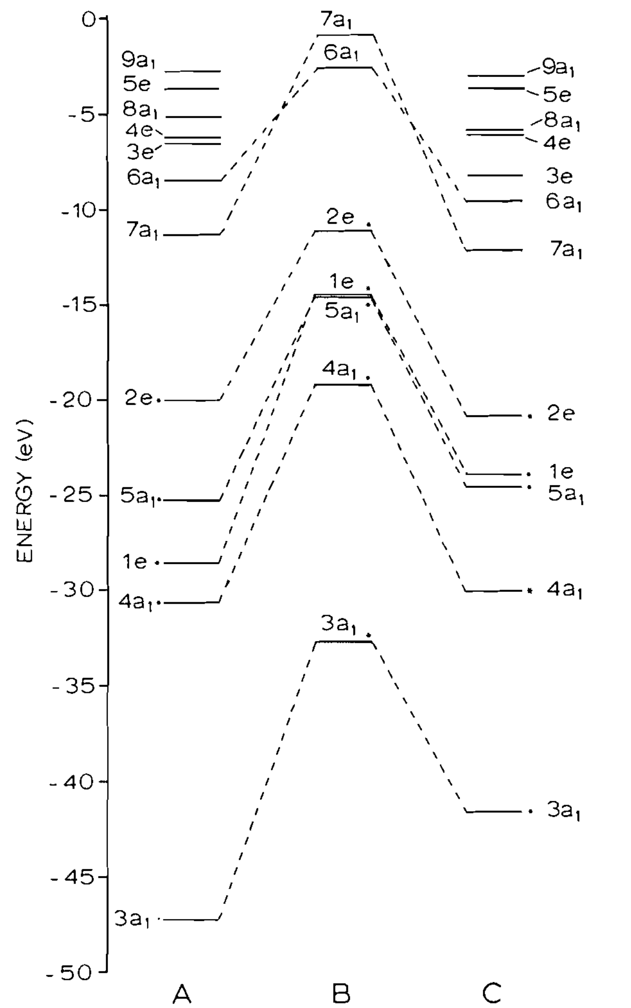

FIG. 3. Molecular orbital diagrams for CF_3H: (*A*) F 1*s* hole state, (*B*) ground state, (*C*) C 1*s* hole state.

one-electron approximation, we can correlate the shakeup transitions with the optical electron transitions (28, 29).

The lowering of molecular symmetry in the F 1*s* hole state lifts the degeneracy of the generate levels. For illustration, let us analyze the $2t_2$ orbital in CF_4 in more detail. The $2t_2$ orbital splits into the $5a_1$ and $2e$ representations in the C_{3v} symmetry of the hypothetical CF_3F^* molecule. On symmetry grounds, the charge distribution inside the fluorine spheres of each representation need not be the same anymore. In fact, the charge density of the axial fluorine (F^*) atom is concentrated in the $5a_1$ orbital and the other three equatorial fluorines atoms are evenly distributed in the $2e$ orbital (Table 2). Removal of a core electron from the axial fluorine atom produces a much larger shift of binding energy for the $5a_1$ orbital (15.2 eV) than the more remote fluorine $2e$ orbital (7.9 eV). (See Fig. 2.)

The seemingly complicated F 1*s* hole state MO diagrams can now be interpreted in a more systematic manner. For each fluorine atom in the molecule, there should be three valence orbitals associated with the lone pairs and the C—F bond pair. These orbitals will be most affected by the creation of a core hole. Electrons localized on the other atoms in the molecule will be perturbed to a lesser degree. Furthermore, if we assume the interaction between the electrons with the ionized fluorine atom is entirely electrostatic in nature, we would then expect a fairly uniform shift to higher binding energies for these or-

bitals. This anticipation is in full accord with our theoretical calculations. It is quite clear from the MO diagrams, that the energy shift of the orbitals with majority F* character, such as $1e$, $7a_1$, in CH_3F, $5a'$, $7a'$, $10a'$ in CHF_3 and the $6e$ and $7a_1$, orbital in CF_4 are the most significant.

(C) The hole state unoccupied orbitals

Unlike the unoccupied orbitals in the ten electron hydrides, it was found that in fluoromethanes there is a tendency of electron migration from the outersphere region into the intersphere and atomic sphere region. Although as we have explained earlier this may be an artifact due to the larger size of the outersphere, the increase of charge density inside the atomic region cannot be overlooked. It is generally understood that the size of an antibonding orbital is not much larger than the molecular core (30). On the contrary, Rydberg type orbitals are diffuse and in most cases essentially nonbonding. Unfor-

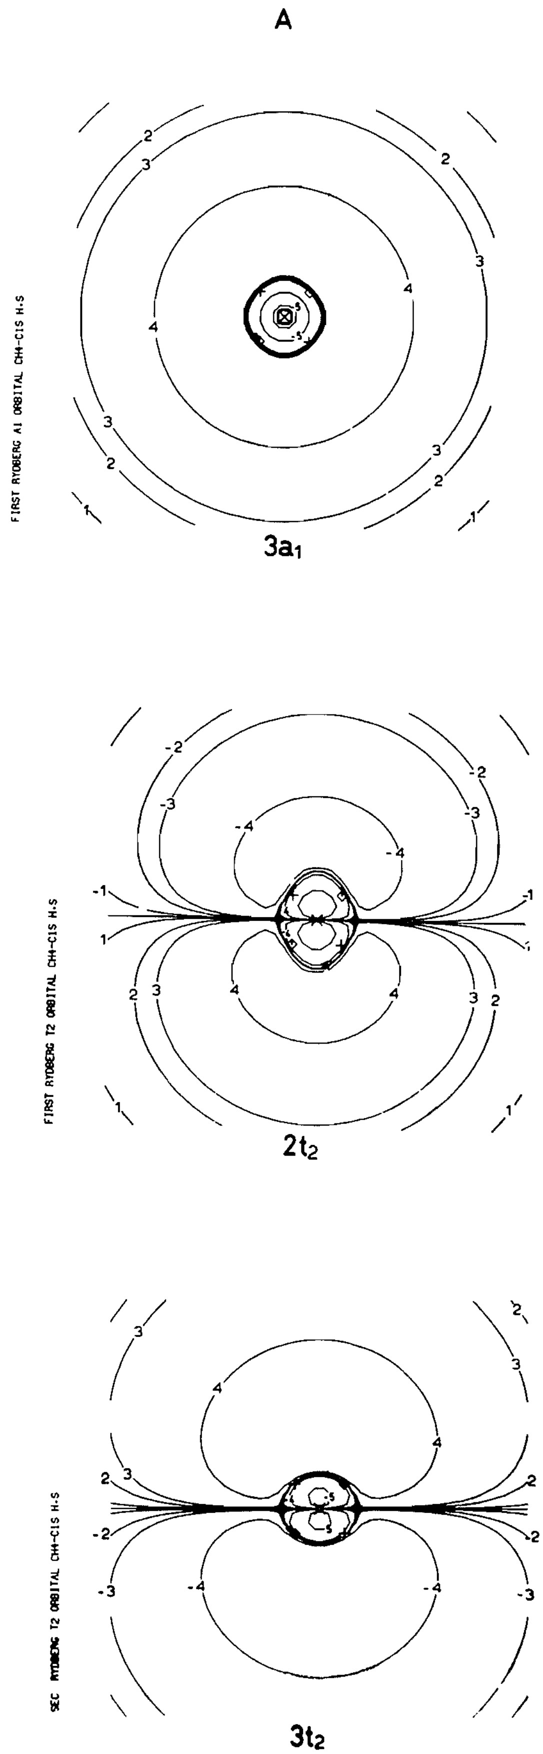

FIG. 5. Contour diagrams for the unoccupied orbitals of CH_4 in the C 1*s* hole state.

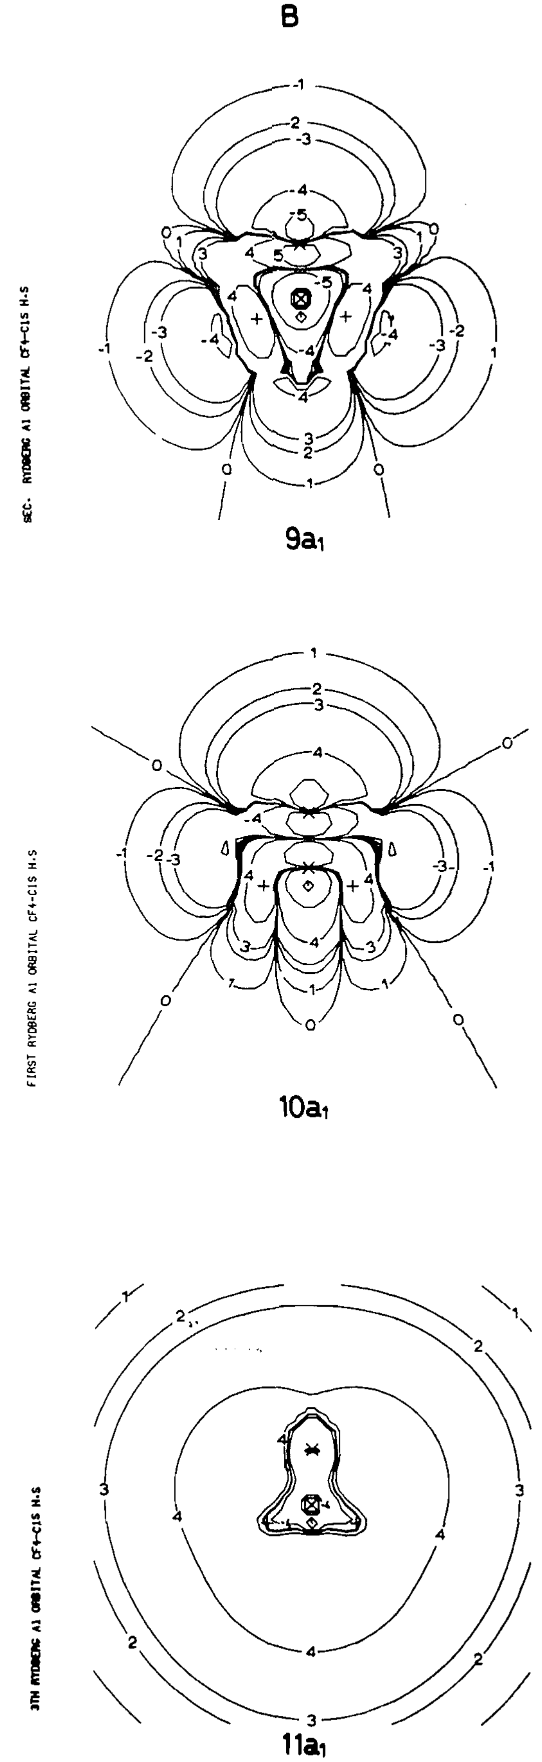

FIG. 6. Contour diagrams for the unoccupied orbitals of CF_4 in the C 1*s* hole state.

tunately, in some cases, the distinction is not so clear-cut. To avoid confusion, we define our terminology according to the orbital charge distribution in spheres as determined by the Xα-SW calculation. We define a Rydberg orbital if 50% or more of the orbital electrons are located outside the outersphere region. An orbital is regarded as having mixed Rydberg–valence character if the majority of the electrons reside within the intersphere region. Concentration of charge density inside the atomic sphere regions indicates an antibonding orbital. This way of defining orbital character of course is subject to the arbitrariness of the sphere sizes used in the calculations. To this end we present the contour drawings for some unoccupied orbitals of CH_4 and CF_4 in the C 1*s* hole state in Figs. 5 and 6. Several interesting observations emerge from this comparison. First, all the unoccupied orbitals of CH_4 retain their Rydberg character even in the core hole state. This is in contrast to the $9a_1$ and $10a_1$ orbitals of CF_4, which are obviously C—F antibonding in character in the hole state. This is also reflected in the large charge localization in the atomic spheres as tabulated in Table 3. The Rydberg character of the unoccupied orbital is more apparent as the term value of the orbital decreases.

The behaviour of the unoccupied orbitals in the fluoromethanes substantiates the presence of an inner–outer potential wall (11). The positive hole from the central carbon atom pulls the unoccupied orbitals to lower energies. These orbitals become more contracted, thus losing their diffuse character. The localization process is reinforced by the effective potential created by the peripheral nonbonding fluorine electrons which act as a repulsive barrier on the outer rim of the molecule enhancing the stability of the inner empty orbitals (12, 31, 32). Therefore, as the number of fluorine atoms increases, the orbitals become more tightly bound. The charge densities reported in Table 3 for the fluoromethanes clearly show this trend. Another important point from our calculations is that there is a change in the MO sequence of the virtual orbitals in the hole states with the exception of the CH_4 molecule. The "*p*-type" unoccupied orbitals involving strong (C—F) σ antibonding character are lowered in energy more than the "*s*-type" Rydberg orbital. This is another indication of the existence of the effective potential barrier which confines the antibonding orbitals. This interchanging of the MO order is reflected in the gradual merging of absorption peaks observed in the soft X-ray absorption carbon K-edge spectra of the fluoromethanes (33).

IV. The core-hole spectra of the fluoromethanes

The redistribution of molecular charges following the removal of a core electron is related to the core-hole relaxation and correlation. We have demonstrated previously (8) for main group compounds that the individual orbital contribution to the relaxation energy accompanying photoionization is proportional to the amount of charge reorganization within that molecular orbital, and intense shakeup transitions are expected to originate from these orbitals. In Tables 4 and 5 we tabulate the charge transfer within each orbital of the fluoromethanes when an electron is removed from the 1*s* core of the carbon atom and the fluorine atom respectively. For the C 1*s* hole states except for CF_4, the core hole is more than totally screened (total charge transfer more than one electron). We find that the $1t_2$ orbital in CH_4, the $1e$ and $2e$ orbitals in CH_3F, the $3e$ and $5a_1$ in CHF_3, and the $3t_2$ ($7a_1$ + $3e$) and $6a_1$ orbitals in CF_4 constitute most of the screening electrons. The F 1*s* core holes in the fluoromethanes are slightly less than totally screened. The most involved molecular orbitals are the $1e$ in CH_3F and $6e$ in CF_4.

[a]a.b. = antibonding.

(A) The C 1s satellite spectra

The satellite structures associated with the C 1s core hole spectra of the fluoromethanes are enlarged in Fig. 7. The general spectral features are very similar within this series of compounds. The satellite bands started at ca. 12.5 eV on the higher binding energy side of the primary photoline. Several prominent peaks can be resolved with the aid of computer deconvolution. Above ca. 25 eV, the satellite spectra extend into a structureless tail.

Within the independent electron model we have adopted here, the intensity of the monopole excitation is determined primarily by the overlap integral between the originating and terminating orbital. To a first approximation we expect strong satellite bands only from those orbitals having similar spatial arrangement. Examining the character of the occupied and unoccupied orbitals given in Tables 3 and 4 we anticipate the following monopole excitations, $3t_2 \rightarrow 5t_2$ in CF_4; $2e \rightarrow 3e$ and $1e \rightarrow 3e$ in CH_3F; and $3e \rightarrow 6e$ and $5a_1 \rightarrow 8a_1$ in CF_3H will be mainly responsible for the satellites. These transitions are responsible for transferring electrons from the C—F and the C—H bonds to the antibonding orbitals which are localized on the carbon centre, thus, shielding the core hole. The experimental and theoretical Xα-SW results for the C 1s hole states of the fluoromethanes are summarized in Table 6.

Because of the low resolution of the satellite spectra it is impossible for us to give an unambiguous individual assignment to each excitation. We simply group the calculated monopole transitions into bands and identify them with the structure observed in the spectra. Our assignments are mainly based on the theoretical predicted order.

The CF_4 hole state spectrum is the simplest among the fluoromethanes. The first band exists as a weak structure situated 12.26 eV from the higher binding energy side of the primary photoline. According to our calculation, this band can be assigned to the non-bonding fluorine to antibonding C—F orbital, $4t_2 \rightarrow 5t_2$ transition. Since the lone pair electrons localized on the fluorine atoms are less mobile, the amount of charge transfer will be small. The second band having a significantly larger intensity is assigned to the bonding–antibonding $3t_2 \rightarrow 5t_2$ transition which represents the major screening mechanism. The calculated intensity of 9.8% is higher than the observed value of 4.7% and the predicted energy is off by 3.0 eV. The third band centered at 23.65 eV is assigned to a combination of $5e \rightarrow 8e$ and $6a_1 \rightarrow 9a_1$ transition. The band at 26.26 eV probably is the onset of the shake off processes. The double ionization of the valence orbitals starts at 23.5 eV, and this may explain the unexpected high intensity of the bands. It should be emphasized that the calculated intensities and energies are only approximate since configuration interaction between shakeup states of the same symmetry has been ignored completely (3).

The satellite spectra of CH_3F and CF_3H are assigned in a similar fashion. The results are given in Table 6. Once again, the calculated transition energies are not in good agreement with experiments especially for the higher energy excitations in which the theory underestimates the transition energies by ca. 3 eV. Despite the complexity of the spectra and the inherent deficiency of the independent electron model, the theoretical

predicted intensity distributions are in qualitative agreement with the experiments. Assignments above 25 eV are even more difficult and perhaps will not be too useful as the spectra are probably dominated by double ionization processes. The onset of the ionization limit for the valence electrons is predicted to occur at ca. 23 eV. The featureless tail extending from ca. 25 eV to 50 eV can be attributed to these shakeoff processes. Electron shakeoffs are the dominant relaxation processes accompanying the photoionization of a core electron (1).

The satellite spectrum of the CF_4 molecule possesses several features that are distinct from the other fluoromethanes. First, the main satellite peaks observed in CF_4 are more closely packed and their line widths are relatively smaller than in the other fluoromethanes. Second, the intensity of the extended high energy structures shakeoff tail in CF_4 is much weaker than in CH_3F and CF_3H. These two points suggests that the potential barrier concept is important in CF_4. The potential wall confines the CF_4 antibonding and low-lying Rydberg orbitals therefore reducing the energy separation between orbitals and enhancing the intensity of the excitations. By the same token, the repulsive potential restrains electron transitions to the outer diffuse Rydberg and continuum orbitals, thereby decreasing the

probability of double ionizations. Furthermore, the higher molecular symmetry of the CF_4 molecule restricts the number of monopole allowed transitions resulting in a relatively simple satellite pattern as compared to CH_3F and CF_3H.

(*B*) *the F 1*s *satellite spectra*

The satellite spectra accompanying the F 1*s* core ionization of the fluoromethanes are displayed in Fig. 8. At first glance, the observed features are much simpler than in the corresponding C 1*s* hole spectra. However, this does not necessarily make the assignments easier. The lowering of molecular symmetry in the F 1*s* hole state relaxes the symmetry selection rules and more monopole transitions become allowed. The charge reorganization accompanying photoionization of a F 1*s* electron calculated in the localized hole approximation for CF_4 and CH_3F is depicted in Table 5. The screening process is not as effective as for photoionization at the carbon site. In both cases, the fluorine spheres only gain ca. 0.9 e in the relaxed hole states. A majority of the screening electrons are derived from the intersphere region indicating the C—F and C—H bonding orbitals are strongly involved in the relaxation mechanism. It is quite surprising to note that the net change in electron population in the carbon and unionized fluorine spheres does not vary appreciably. As explained above, owing to computer limitations we are not able to perform calculations on the F 1*s* hole state of CF_3H in C_s symmetry. The spectrum of this molecule was assigned by extrapolating the MO diagrams in Fig. 3 and inferring from the assignments of CF_4 and CH_3F. The theoretical and experimental results with the proposed assignments are given in Table 7.

As one might expect from the arguments presented earlier, the excitations originating from the C—H and C—F bonding

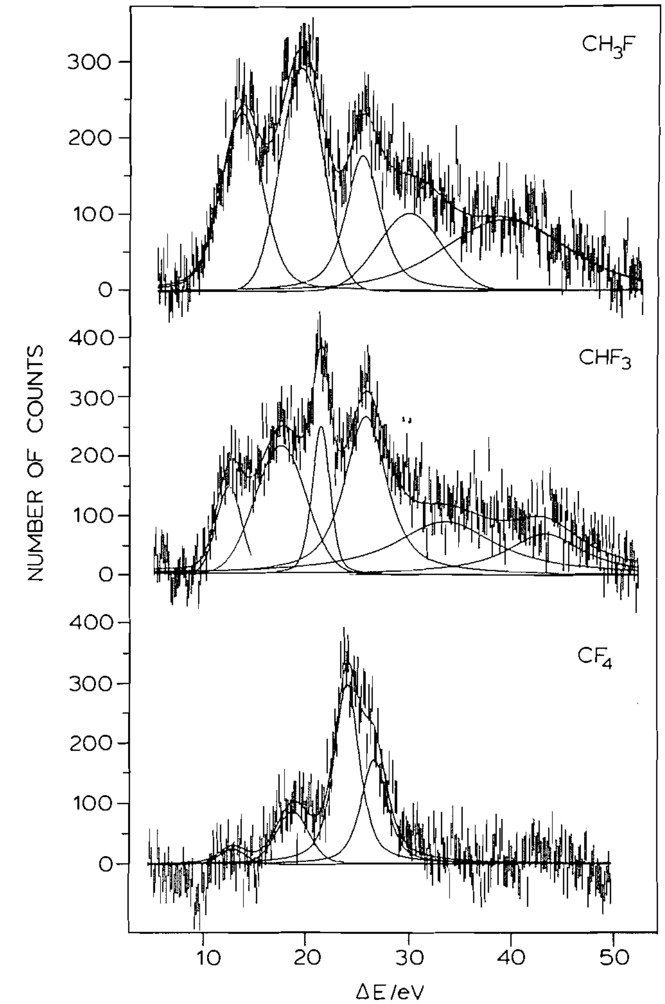

FIG. 7. C 1s satellite photoelectron spectra for CH_3F, CHF_3, and CF_4.

orbitals will give the most intense shakeups. In the case of CH_3F, the transitions from the $4a_1$ and $5a_1$ orbitals dominate the spectrum. The calculated mean excitation energy ($5a_1 \rightarrow 7a_1$ and $4a_1 \rightarrow 7a_1$) is 17.50 eV with a total intensity of 10.4% relative to the main photoline. These are in good agreement with observed band maximum at 17.10 and a relative intensity of 13.4%. Excitation out of the $1e$ orbital is largely responsible for the intensity of the second band located at 25.92 eV. The theory predicts a total intensity of 4.8% for this band centered at about 25.5 eV. The profile above 30 eV is dominated by shakeoff transitions, although the calculation puts the $1e \rightarrow 5e$ transition at 28.02 eV with relative intensity of 2.4% which is, fortuitously, in good agreement with the peak at 30.07 eV.

The first satellite band in CF_4 is observed at 14.20 eV. We assign this to a combination of the $8a_1 \rightarrow 10a_1$ and $6a_1 \rightarrow 10a_1$ transitions. By far the most intense shakeup is the $7a_1 \rightarrow 10a_1$ transition. This transition removes electrons from the C—F bonding region into the F* sphere. The calculated energy and intensity of 22.59 eV and 12.2% are in fair agreement with experiment. Once again the band observed at 30.80 eV can be attributed to the overlap of discrete shakeup transitions and shakeoff. Excitations out of the $6e$ orbital fall into this region and the calculated intensities seem to justify the assignment.

The shakeup in CHF_3 can be estimated from the theoretical data obtained for CHF_3 and CF_4. To construct the F 1s hole

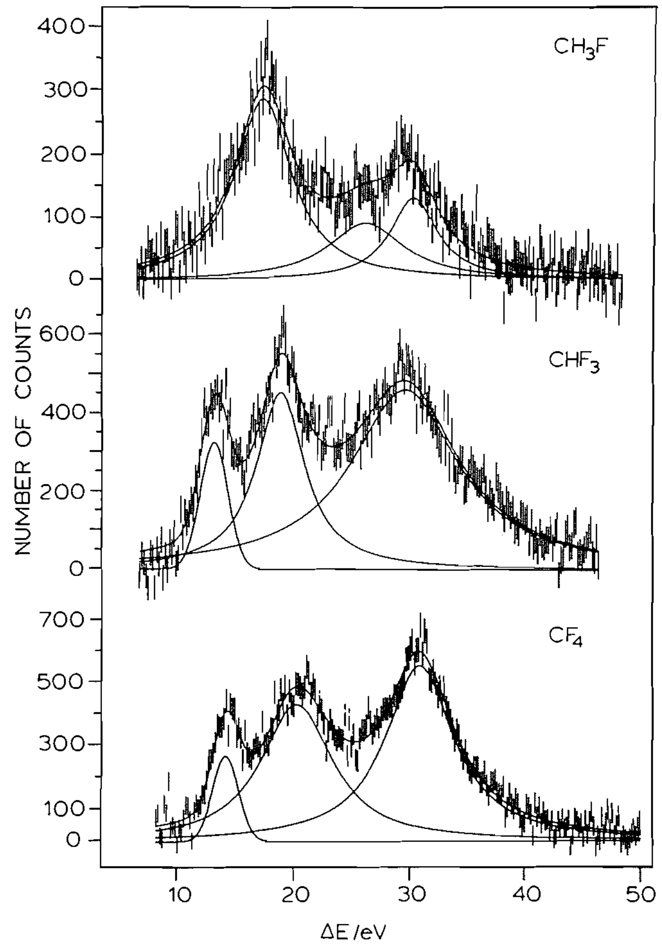

FIG. 8. F 1s satellite photoelectron spectra for CH_3F, CHF_3, and CF_4.

state molecular orbital diagram we shifted the C—H bonding orbitals and the unionized fluorine atoms from their ground state values by 7.9 eV and the ionized fluorine orbitals by 15.2 eV (*vide supra*). The unoccupied $6e$ and $8a_1$ orbitals are shifted down by 6.5 eV. Assuming intense shakeup only occurs for transitions to the antibonding orbitals we can then estimate the shakeup energies from the energy difference of the terminating and originating orbitals (Fig. 3). The results are presented in Table 7. We made no attempt here to rationalize our results any further due to the lack of intensity information. However, the assignments seem to be quite reasonable.

Conclusion

We have shown that by counting to high statistics, satellite structures of relatively low intensities can be observed in the core level photoelectron spectra of the fluoromethanes. The structures can be reasonably attributed to monopole $\sigma \rightarrow \sigma^*$ excitations (shakeup). The intense transitions observed in the C 1s core hole spectrum of CF_4 support the prevailing belief of the existence of a potential wall created by the fluorine lone pair electrons in this molecule. The effect of the potential barrier is less apparent in the F 1s core hole photoelectron spectra. Although the physics of the relaxation mechanism can be understood within the simple independent electron model, the actual calculations of the spectra should include the effect of electron correlation and spin couplings. For molecules of the size studied here, the Xα-SW method is still a very useful and

GHULAM GHAUS CHOUDHRY, FRANS W. M. VAN DER WIELEN, G. R. BARRIE WEBSTER, and OTTO HUTZINGER. Can. J. Chem. **63**, 469 (1985).

Laboratory photochemical studies of aqueous acetonitrile solutions of some polychlorinated phenols (PCPs) such as 2,3,4,5-tetrachlorophenol (2,3,4,5-Cl_4-Pn) (**1**), 2,3,4,6-Cl_4-Pn (**2**), 2,3,5,6-Cl_4-Pn (**3**), and pentachlorophenol (Cl_5-Pn) (**4**) at $\lambda > 285$ nm have been carried out for 6 and 24 h exposure times. All the investigated PCPs underwent reductive dechlorination. This process was dependent not only upon the position of OH group but also upon the relative positions of the Cl substituents on the benzene ring. The Cl_4-Pn **2** (and **3**) and Cl_5-Pn (**4**) also yielded photoproducts of molecular formulae $C_8H_4Cl_3NO$ ($M^{+\cdot}$ = 235) and $C_8H_3Cl_4NO$ ($M^{+\cdot}$ = 269), respectively. Furthermore, phenol **3** is unique amongst the investigated PCPs; in addition to the above mentioned photoproducts, it yielded hexa-, hepta-, and octachlorodihydroxybiphenyl(s) as well as heptachlorohydroxydiphenyl ether.

GHULAM GHAUS CHOUDHRY, FRANS W. M. VAN DER WIELEN, G. R. BARRIE WEBSTER et OTTO HUTZINGER. Can. J. Chem. **63**, 469 (1985).

Opérant à des $\lambda > 285$ nm et pour des temps d'exposition de 6 et de 24 h, on a effectué des études photochimiques en laboratoire de quelques phénols polychlorés (PPC), comme le tétrachloro-2,3,4,5 phénol (Cl_4-2,3,4,5 Pn) (**1**), Cl_4-2,3,4,6 Pn (**2**), Cl_4-2,3,5,6 Pn (**3**) et le pentachlorophénol (Cl_5Pn) (**4**). Tous les PPC étudiés subissent des déchlorations réductives. Ce processus ne dépend pas seulement de la position du groupement OH mais aussi des positions relatives des substituants Cl sur le noyau benzénique. Les composés Cl_4-Pn (**2** et **3**) et Cl_5-Pn (**4**) fournissent aussi respectivement des photoproduits de formules moléculaires $C_8H_4Cl_3NO$ ($M^{+\cdot}$ = 235) et $C_8H_3Cl_4NO$ ($M^{+\cdot}$ = 269). De plus, le phénol **3** est unique parmi les PPC étudiés: en plus des photoproduits mentionnés plus haut, il fournit aussi des hexa-, hepta- et octa-chlorodihydroxybiphényles ainsi que de l'heptachlorohydroxydiphényl éther.

[Traduit par le journal]

Introduction

Polychlorophenols (PCPs) are ubiquitous environmental contaminants which have been found in several aquatic environments around the world. For instance, Wegman and his associates have reported the occurrence of 19 individual PCPs in surface waters (2) and in river sediments (3) located in The Netherlands. Likewise PCPs are known to occur in mussels, pike, and sediments in the lakes of central Finland (4). Chlorophenolic pollutants originate from pulp bleaching and the disinfection of waters, but are also contaminants and degradation products of pesticides (4). Furthermore, pentachlorophenol (Cl_5-Pn) itself has been widely used in agriculture and industry as a fungicide, bactericide, herbicide, molluscicide, algicide, and insecticide (5, 6). Currently, Cl_5-Pn is utilized mainly as a wood preservative, which has led to its widespread presence in the environment (5). A large number of organic compounds including PCPs have also been identified in the flue gas and fly ash from some municipal and industrial incinerators (7).

In the past, several publications have reported photoconversions and photodegradations of (poly)chlorinated phenols. Photolyses of basic aqueous solutions of all three monochlorophenols at wavelengths of 254 nm and ≥290 nm are well known (8–10). Photoreactions (11) of 2,5-dichlorophenol (2,5-Cl_2-Pn), 2,6-Cl_2-Pn, 3,4-Cl_2-Pn, and 3,5-Cl_3-Bz in deuteriated methanol at λ = 254 nm as well as riboflavin photosensitized oxidation (12) of 2,4-Cl_2-Pn at $\lambda \geq 280$ nm in aqueous solution have been described. Furthermore, several authors have reported photolyses of pentachlorophenol in organic solvents such as hexane, cyclohexane, acetone, and 95% ethanol at 254 nm (13) and on wood (14). Photolysis of the sodium salt of Cl_5-Pn in water using natural sunlight and sunlamps has also been documented (14).

Previously, we have observed that, in addition to reductively dechlorinated products (major), polychlorobiphenyls (PCBs) appear as photoproducts in the case of irradiation of solutions of 1,3,5-trichlorobenzene (1,3,5-Cl_3-Bz) (15), tetrachlorobenzenes (16), and pentachlorobenzene (16) in various water–acetonitrile mixtures. Under such photochemical circumstances, 1,2,3-Cl_3-Bz (15), 1,3,5-Cl_3-Bz (15), and all three isomers of tetrachlorobenzene (1, 16) undergo photoconversions, eventually giving rise to the production of photoisomerized chlorobenzenes. More recently, we have reported

[1]For Part V, see ref. 1.
[2]To whom all correspondence should be addressed.

that laboratory irradiation (at $\lambda \geqslant 285$ nm) of tetra-, penta-, and hexachlorobenzenes in aqueous acetonitrile containing phenol yields polychlorinated dibenzofurans (PCDFs) possessing two Cl atoms less than the starting chlorobenzenes (17). It was concluded that, during these photochemical reactions, products such as PCBs (15, 16) and PCDFs (17) are apparently formed through the intermediate involvement of some polychlorophenyl radical species which are circumstantially longer surviving. In view of our interest in the photochemical fate of pollutants such as halogenated benzene derivatives in the environment (1, 15–18), we decided to investigate the photochemistry of polychlorophenols (PCPs). The present paper is concerned with the results of our laboratory photochemical studies on some PCPs, viz., three tetrachlorophenols and pentachlorophenol in different acetonitrile–water mixtures using radiation of wavelength $\geqslant$285 nm with special emphasis on reductive dechlorination and formation of dihydroxypolychlorobiphenyls, hydroxypolychlorodiphenyl ethers, and other products.

Experimental

Substrates and standards

All chemicals were purchased from Aldrich Chemical Co., Inc.

Solvents and procedures for the preparation of solutions and irradiation experiments

Solvents and procedures utilized have been described previously (16).

Extraction procedures

One millilitre of aqueous solution of 0.589 *M* NaOH was added to a photolyzed sample and shaken well, the pH value of the resulting solution being $\geqslant$11. Subsequently, 2 mL of *n*-hexane containing pentachlorobenzene (0.108×10^{-3} *M*) as an internal standard (IS) were added. After shaking well, the *n*-hexane layer was separated from the water–acetonitrile layer. To the *n*-hexane fraction, a few drops of *n*-nonane were added; the solution was then reduced in volume to ca. 0.2 mL under a stream of dry nitrogen. One millilitre of 1.080–1.400 *M* HCl in water was added to the water–acetonitrile fraction to adjust the pH to $\leqslant$1. The *n*-hexane extract (ca. 0.2 mL) containing the IS was prepared by following the method described above. An unphotolyzed sample solution was also subjected to the extraction procedure as cited.

Gas chromatography

Qualitative and quantitative analyses of the *n*-hexane extracts were carried out on a Hewlett-Packard 5830A instrument equipped with a flame ionization detector (FID) and an 18850 GC terminal.

Column A: Glass column (2 m × 0.2 cm) containing 3% SE 52 on 160–180 Mesh Chromosorb WAW; temperature 1 (T_1) = 60°C, time 1 (t_1) = 2 min, rate 8°/min, temperature 2 (T_2) = 240°C, time 2 (t_2) = 20 min, carrier gas (N_2) flow = 30 mL/min, injector temperature = 250°C and FID temperature = 300°C.

Column B: Glass column (2 m × 0.2 cm) containing 3% FFAP/SP 1000 on 160–180 mesh Chromosorb WAW; T_1 = 60°C, t_1 = 2 min, rate 8°/min, T_2 = 240°C, t_2 = 25 min, carrier gas (N_2) flow = 26 mL/min, injector temperature = 250°C and FID temperature = 300°C.

Gas chromatography – mass spectrometry

A Hewlett-Packard 5894 A gas chromatograph mass spectrometer (gc–ms) was used in the electron-impact mode at 70 eV. All photoproducts (documented in Table 1) were identified using a fused silica capillary column (25 m × 0.25 mm i.d.) coated with 0.4 μm CP-SIL 5 (Chrompack). The procedure of Grob and Grob (19) was followed for operating the capillary injection system. The gc conditions for this capillary system were T_1 = 70°C, t_1 = 0 min, rate = 32°/min; after 2 min rate being 8°/min, T_2 = 300°, t_2 = 30 min. The mass (*M*)

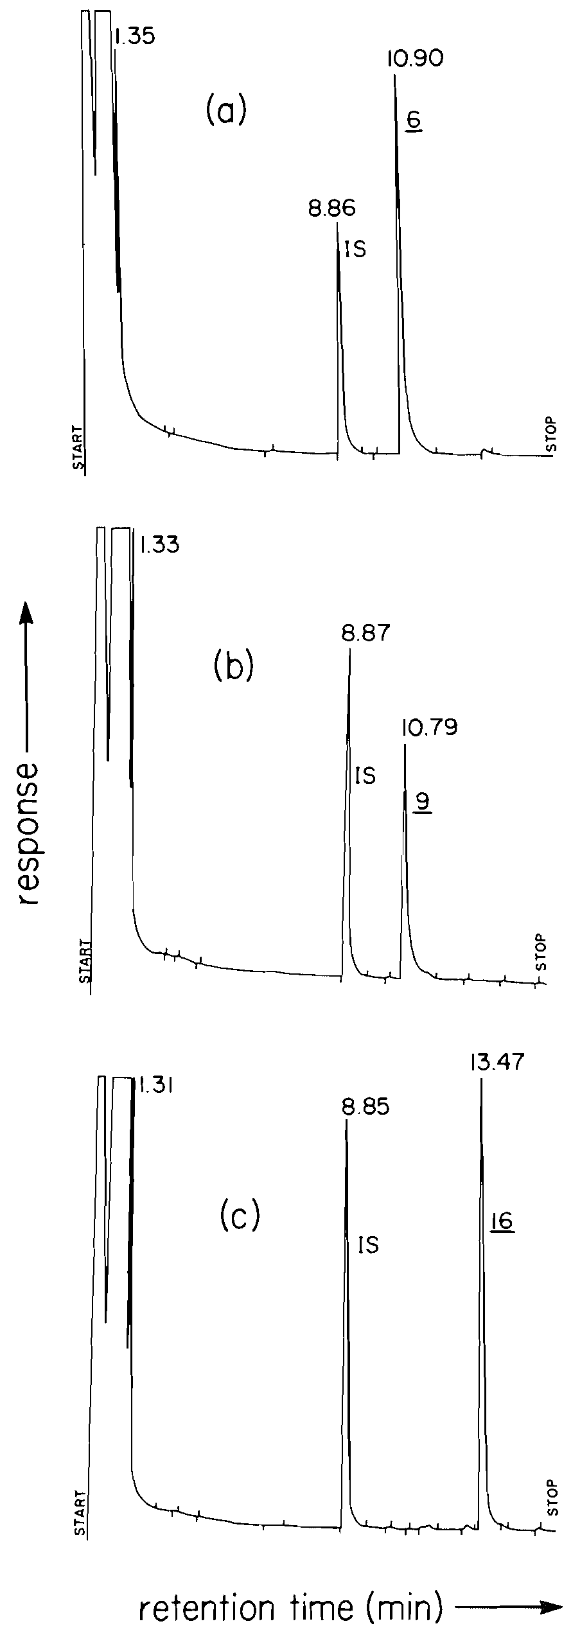

FIG. 1. Typical gas chromatograms of the *n*-hexane extracts at pH $\geqslant$ 11 of the 6 h photolyzates of (*a*) 2,3,4,6-tetrachlorophenol (**2**), (*b*) 2,3,5,6-tetrachlorophenol (**3**), and (*c*) 2,3,4,5,6-pentachlorophenol (**4**). The peaks labelled with numbers and "IS" indicate the photoproducts and internal standard (pentachlorobenzene), respectively; 4 μL were injected. (Mass spectra are described in Fig. 2, and other conditions are given in Table 1 and Experimental.)

[a]Sample solutions in Pyrex tubes which transmit less than 1% of the radiation below 287 nm were irradiated in a Rayonet Photoreactor, equipped with RPR 3000 Å uv lamps, having an energy output of 90% between 290 and 310 nm.
[b]*n*-Hexane extracts were treated with diazomethane.
[c]Quantifications were carried out by fid-gc utilizing pentachlorobenzene as the internal standard.
[d]Percentages in the parentheses represent chemical yields calculated from the amount of photoconverted starting material.
[e]Quantitative analyses were performed by gc equipped with Column A (see Experimental).
[f]Typical gas chromatograms and mass spectra of the photoproducts **6**, **9**, and **16** are shown in Figs. 1 and 2, respectively.
[g]Quantitative analyses of chlorophenols were conducted by gc equipped with Column B (see Experimental), whilst those of other compounds were performed as described in the footnote *e*.
[h]Typical total ion chromatograms (TICs) of *n*-hexane extract of photolyzates of the substrate **3** subjected to halogen test computer program (20) are given in Fig. 3.
[i]Structures: 2,3,5-Cl_3-Pn = 2,3,5-trichlorophenol; Cl_6-$(OH)_2$-BP = hexachlorodihydroxybiphenyl; Cl_7-(OH)-DPE = heptachlorohydroxydiphenyl ether; etc.
[j]Typical mass spectrum of this product is shown in Fig. 4.

ranges were: $100 \leqslant M \leqslant 500$. To identify chlorine-containing photoproducts in the photolyzate, the computer programme for specific detection of organochlorine and organobromine compounds (20) was used.

Identification of photoproducts

n-Hexane extracts (at pH $\leqslant$ 1) of the sample solutions were treated with diazomethane in ether. Methylated photoproducts such as PCPs were identified by comparing their retention times (Column B) and mass spectra with those of authentic chlorophenols treated with CH_2N_2. Identification of all other photoproducts (recorded in Table 1) are tentative pending availability of standards. Structures of such compounds were ascribed from their mass spectra.

Results

Table 1 lists the photoproducts of PCPs (**1**–**4**) after 6 and 24 h irradiation. The 6 h photolyses of **2** and **3** yield photoproducts of molecular formula $C_8H_4Cl_3NO$; whereas **4** following 6 and 24 h exposure times provide 11 and 3% of $C_8H_3Cl_4NO$, respectively. Typical gas chromatograms and mass fragmentation pattern of these products yielded from 6 h photochemical reactions of PCPs **2**, **3**, and **4** are shown in Figs. 1 and 2, respectively.

The last column of Table 1 records phenolic products identified in the *n*-hexane extracts of the photolyzates after changing their pH value of >11 to <1. Such photoproducts were derivatized with CH_2N_2 prior to gc and gc–ms analysis. With the exceptional case of 2,3,5,6-tetrachlorophenol (2,3,5,6-Cl_4-Pn) (**3**), the *n*-hexane extracts (at pH < 1) of all other photolysed PCPs contain only reductively dechlorinated photoproducts; e.g., on irradiating **1** for 6 and 24 h, 10 and 9% of the disappeared starting compound **1** are photoconverted into **5**. But in the case of photoreaction of **3** for 24 h, in addition to the usual reductively dechlorinated photoproduct **5** (9%), hexachlorodihydroxybiphenyl (**12**), heptachlorodihydroxybiphenyl (**10**), heptachlorohydroxydiphenyl ether (**13**), another isomer of biphenyl **10** (**14**), and octachlorodihydroxybiphenyl (**15**) at yields 0.5, 1.5, 0.2, 0.2, and 1.0%, respectively, together with an unidentified photoproduct **11** (0.5%) are seen. It is noteworthy that the biphenyl **10** (4% yield) is also produced during the 6 h exposure of **3**. Using the Olie and Hutzinger computer search technique to locate chlorinated organic compounds (20), typical total ion chromatograms (TICs) of the methylated *n*-hexane extracts of the unphotolysed and photolysed aqueous acetonitrile solutions of the tetrachlorophenol **3** are given in

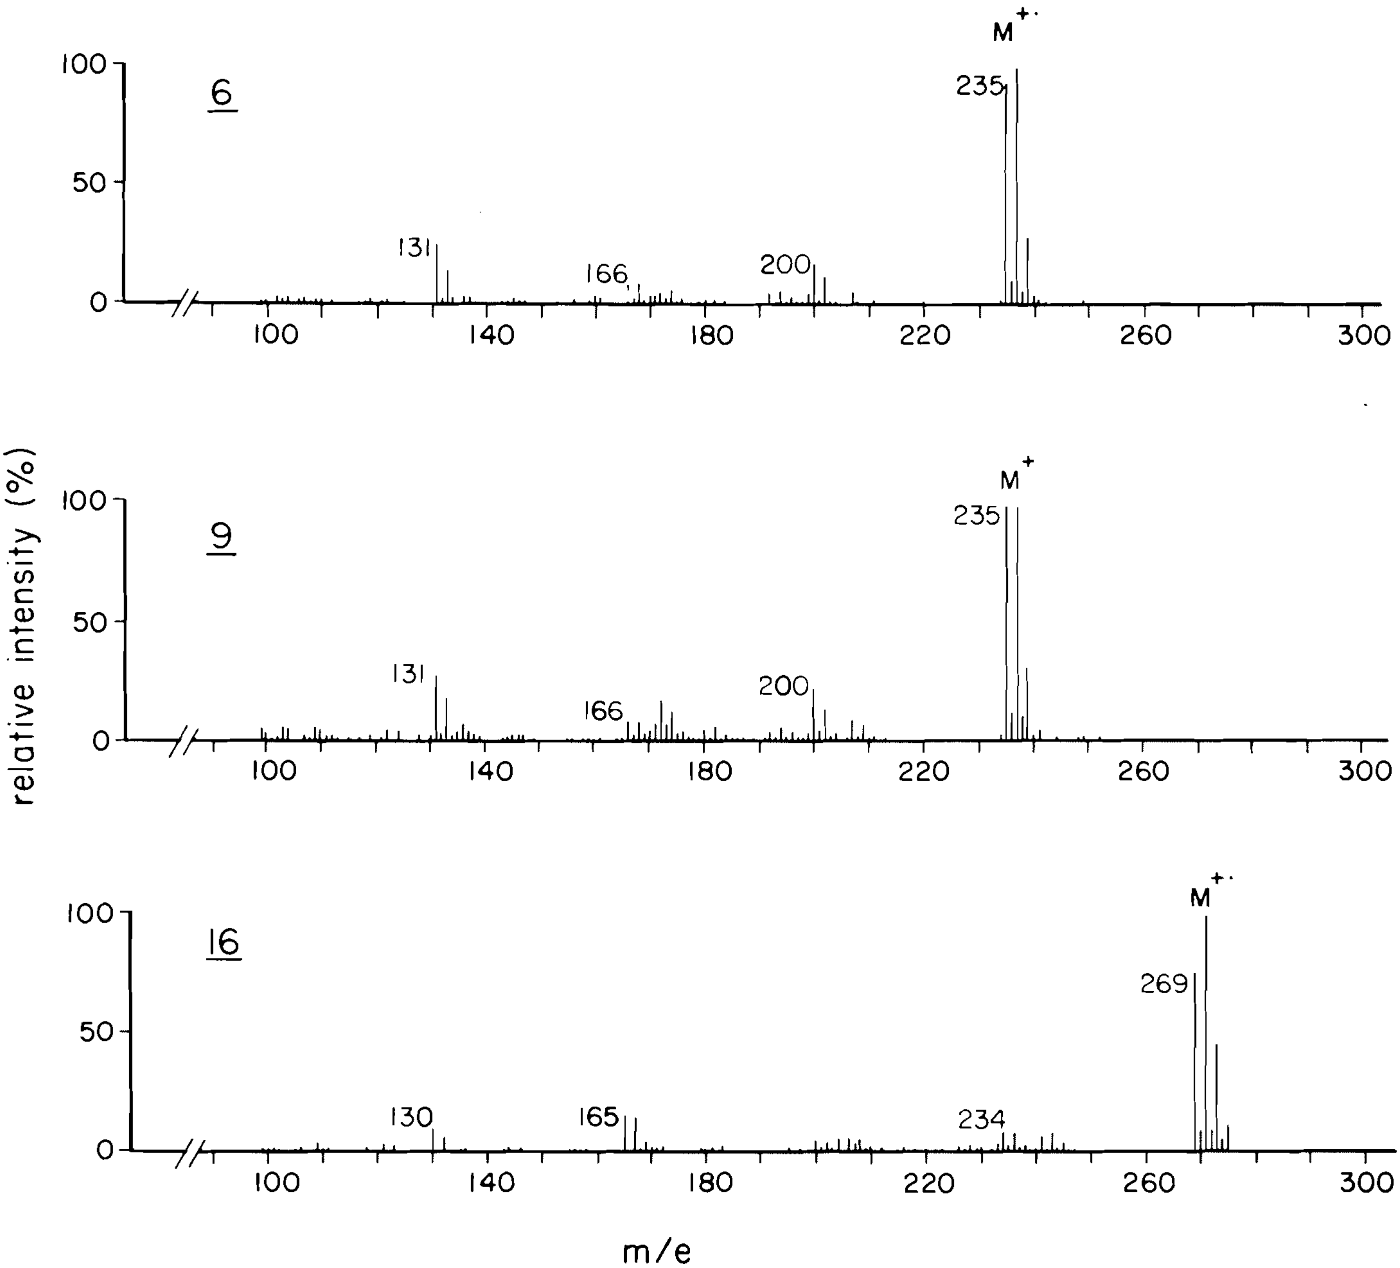

FIG. 2. Mass spectra of the peaks labelled with numbers **6**, **9**, and **16** in the gas chromatograms shown in Fig. 1. (See Experimental and Table 1 for further details.)

Fig. 3. The mass fragmentation pattern of the unidentified product **11** is described in Fig. 4. Finally, when pentachlorophenol **4** in water–acetontrile (4:6 v/v) is exposed to uv radiation for 24 h, besides the above mentioned non-phenolic product **16**, 7% **1** and 8% **2** and/or **3** are formed (Table 1). We and other researchers (21) did not succeed in separating 2,3,4,6- and 2,3,5,6-tetrachloroanisole by gc or gc–ms.

Discussion

It is evident (Table 1) that the photoreactions of the Cl_4-Pns **1–3** in water–acetonitrile (1:1 v/v) produce photoproducts through reductive dechlorination dependent on the relative positions of the hydroxyl (OH) and chlorine substituent groups on the benzene ring. In the case of all tetrachlorophenols, the Cl atom(s) present at the *meta* position(s) (relative to the OH group) do *not* undergo photoreaction. 2,3,4,5-Tetrachlorophenol (**1**) yields only 2,3,5-Cl_3-Pn (**5**) (for both exposure times) via the reduction of the *para* Cl substituent; whilst the product of **3** is also **5**, formed by reductive dechlorination at the *ortho* position (Table 1). So far as photochemical reductive dechlorination is concerned, **2** is unique amongst the three isomers of tetrachlorophenol giving (**7**) and (**8**) through the reduction of the *ortho* and *para* substituents, respectively. It is worth noting that 2,4,5-trichlorophenol (expected from photolysis at the ortho chlorine) is *not* detected amongst the reductively dechlorinated photoproducts of **2**, thereby indicating that, in the case of the photolyses of polychlorinated phenols, isomeric distribution of the photoreductively dechlorinated products is dependent not only upon the position of the OH group but also upon the relative positions of the chlorine substituents. As cited in the previous section, because of our failure to separate 2,3,4,6-tetrachlorophenol (**2**) from its

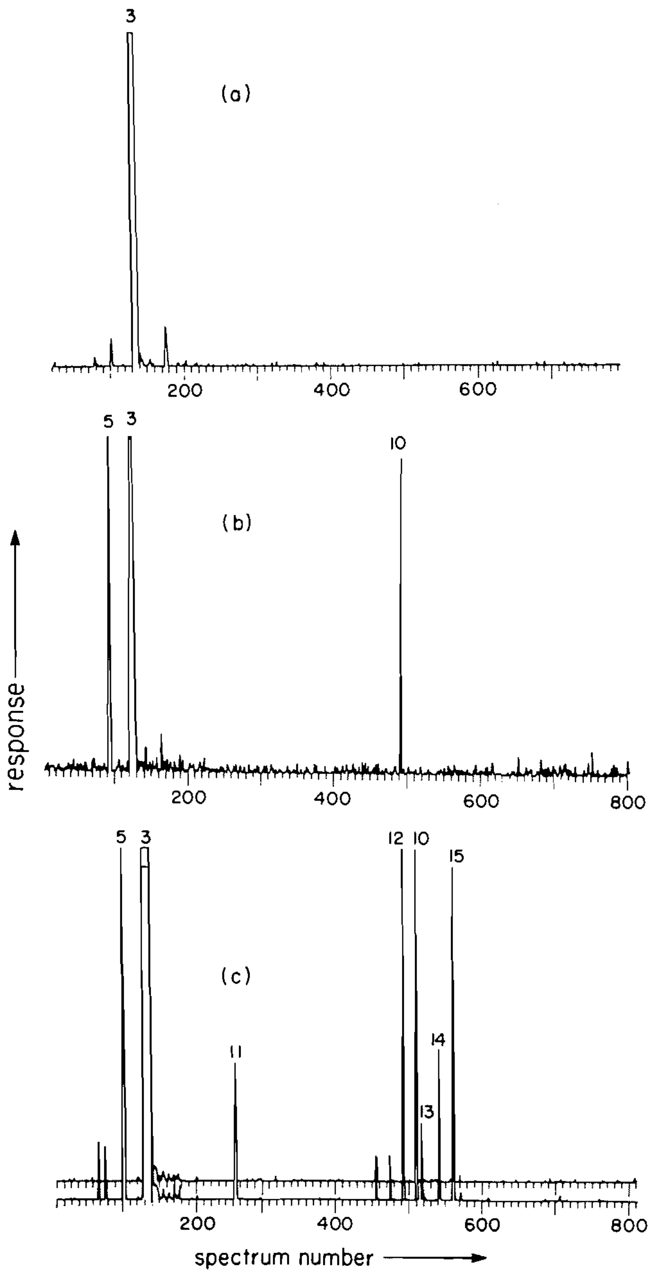

FIG. 3. Plots of the total ion chromatograms (TICs) of the methylated n-hexane extracts at pH $\leq$ 1 of the sample solutions of unirradiated (a), and irradiated 2,3,5,6-tetrachlorophenol (3) for 6 h (b) and 24 h (c) subjected to the halogen test computer program (20) for locating chlorine containing compounds. The peaks with numbers exhibit the compounds which have been identified (Table 1). (For conditions of gc–ms, see Experimental.)

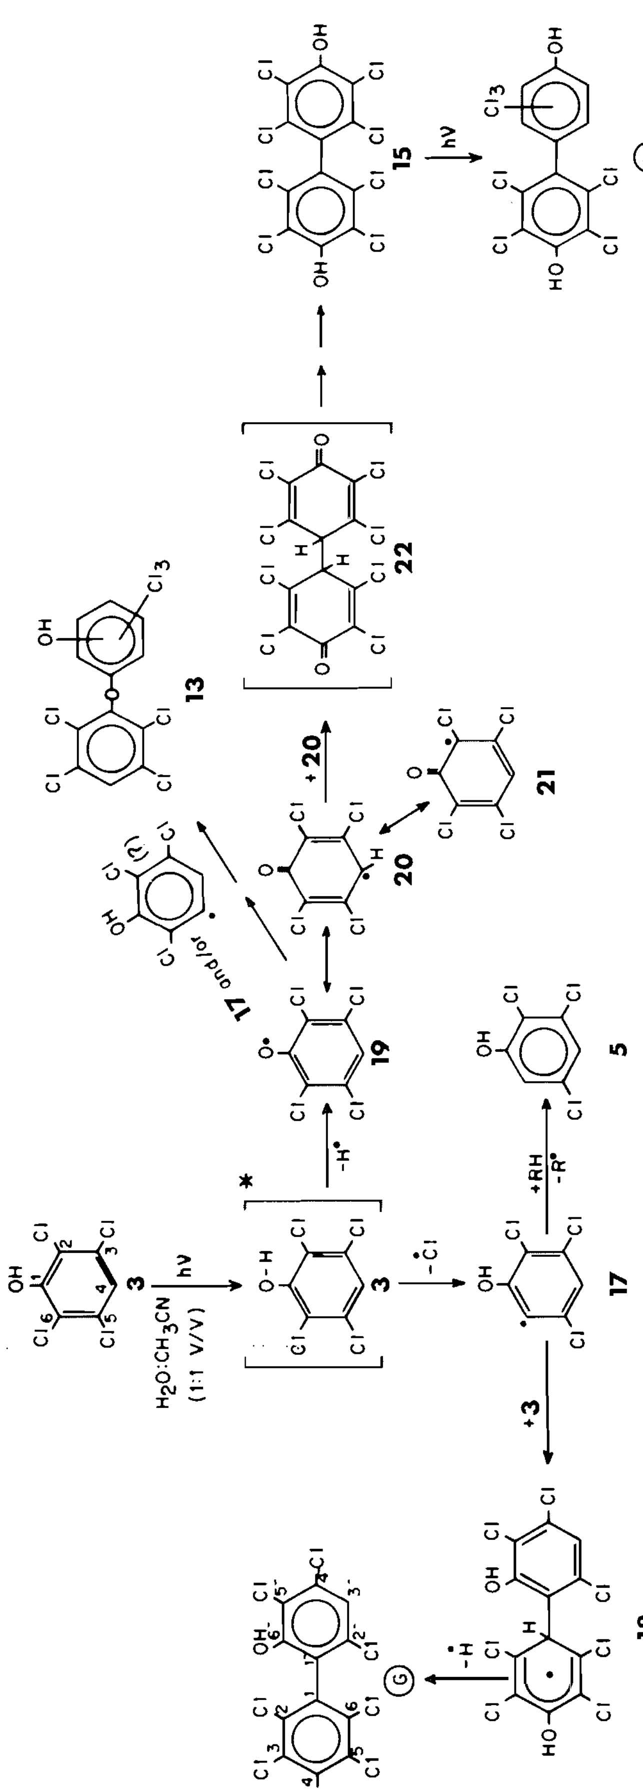
isomer **3**, we are unable to conclude whether *meta* or *para* Cl substituent(s) or both is (are) photolabile in case of photoreductive dechlorination of pentachlorophenol (**4**). It is interesting to mention that, under the present circumstances, on irradiating Cl_5-Pn (**4**) for 6 and 24 h, Cl_4-Pns namely **1** and **2** and/or **3** in the ratios of ca. 1:1.5 and 1:1, respectively, appear as photoproducts. Our findings differ from those of Crosby and Hamadmad (13) who report that irradiation (λ = 254 nm) of **4** for 32 h in organic solvents yields **3** (30%) as the major decomposition product accompanied by a minor product, ca. 10% assumed to be an isomeric tetrachlorophenol.

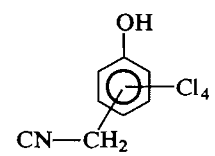
In order to account for the products arising from the irradiation of **3**, the following postulated scheme can be considered: A molecule of 2,3,5,6-Cl_4-Pn (**3**) in the ground state absorbs a photon, yielding the excited state of **3**. Homolytic scission of the C—Cl bond at position 2 (or position 6) of **3** in the excited state gives 2,4,5-trichloro-6-hydroxyphenyl radicals (**17**). Radical species **17** abstracts hydrogen atoms from the solvent to provide 2,3,5-Cl_3-Pn (**5**). Likewise, attack of intermediate radicals **17** on the ground state molecules of the starting substance **3** results in the formation of σ-complex species **18**, which lose hydrogen atoms leading to the eventual generation of 2,2′,3,4′,5,5′,6-heptachloro-4,6′-dihydroxybiphenyl (**G**). The structure **G** may be ascribed to the photoproduct **10** or **14** (Table 1 and Fig. 3b and c). Due to the unavailability of an authentic standard, structure **G** is tentative. However, it is well known that under the similar photochemical circumstances, the intermediate polychlorophenyl radicals such as 3,5-dichlorophenyl radicals (15) and all trichorophenyl radicals (16) and tetrachlorophenyl radicals (16), produced via the homolytic cleavage of the C—Cl bond on the polychlorobenzenes (PCBzs), interact with the corresponding starting PCBz to provide the corresponding polychlorobiphenyl(s) (PCB(s)). The alternative structure 2,2′,3,4′,5,5′,6-heptachloro-3′,4-dihydroxybiphenyl (not shown in Scheme 1), possibly attributable to the product **10** or **14** formed by the arylation of **3** by 2,4,5-trichloro-3-hydroxyphenyl radicals can be ruled out due to the fact that 2,3,6-trichlorophenol, which is likely to be generated by the abstraction of H atoms from solvents by these anticipated trichlorohydroxyphenyl radicals, has not been identified amongst the photoproducts of **3**. Furthermore, some of the photoexcited molecules of **3** provide 2,3,5,6-tetrachlorophenoxy radicals (**19**) generated through the photohomolysis of the OH bond on **3**. In addition, phenoxy radicals **19** may also be yielded by a process involving the abstraction of the H atom of the hydroxyl group on **3** by radical species like Cl, CH_2CN and **17**. The phenoxy radicals **19** combine with 2,4,5-trichloro-3-hydroxyphenyl radicals and/or isomeric radicals (**17**), thereby forming heptachlorohydroxydiphenyl ether (Cl_7-(OH)-DPE) (**13**). The involvement of the former trichlorohydroxyphenyl radicals in the production of the DPE **13** seems highly unlikely, as discussed above. Moreover, the unpaired electron on the oxygen atom of the phenoxy species **19** is delocalized over the benzene nucleus as depicted by resonance structures **20** and **21**. The radicals **20** dimerize giving rise possibly to the generation of intermediate compound **22**. The substance **22** aromatizes to give 2,2′,3,3′,5,5′,6,6′-octachloro-4,4′-dihydroxybiphenyl (**15**). Although this structure designated to the photoproduct Cl_8-$(OH)_2$-BP (**15**) (Table 1 and Fig. 3c) is again tentative, no other logical structure for product **15** can be considered. Furthermore, photodegradation of biphenyl **15** may yield heptachlorodihydroxybiphenyl (Cl_7-$(OH)_2$-BP) (product **10** or **14**) (structure **H** given in Scheme 1). The absence of an expected product, Cl_8-(OH)-DPE (a likely structure being 2,2′,3,3′,5,5′,6,6′-octachloro-4-hydroxydiphenyl ether), in the photolyzate of **3** (Table 1) evidently reflects that (i) 2,3,5,6-tetrachlorophenoxy radicals (**19**) do not attack at the position 4 of ground state molecules of **3** and (ii) radical **19** does not interact with radical **20**. It can be inferred from this fact that reactions of the sort **20** + **3** $\twoheadrightarrow$ **15**, another possible route for the production of the photoproduct **15**, do not take place in the present solvent system. Likewise, reaction **20** + **21** $\twoheadrightarrow$ **G** does not occur. However, **20** + **17** $\twoheadrightarrow$ **G** may contribute in the generation of photoproduct **G**, because tri-



SCHEME 1. Proposed mechanism.

chlorohydroxyphenyl radicals **17** are more reactive (less stable) compared to the phenoxy radical **19** and its mesomeric structures **20** and **21**. Finally, the discussion presented above leads one to conclude that, in the $H_2O:CH_3CN$ solvent system, in the context of replacement of a H atom of a (chlorinated) benzene nucleus by a phenoxy radical, the intermediate phenoxy species are less reactive and are unable to undergo such reaction. Therefore, the scheme showing the mechanism of formation of 2,3-dichlorodibenzofuran during the irradiation of solution of 1,2,4,5-tetrachlorobenzene in $H_2O:CH_3CN$ (4:6 v/v) containing phenol, previously postulated by Choudhry *et al.* (17), can be modified by including phenoxy radicals bearing full (instead of partial) radical character on the oxygen atom which interact with photochemically generated 2,4,5-trichlorophenyl radicals.

For instance, the photoproduct **16** of **4** (Figs. 1 and 2) has molecular ion ($M^{+\bullet}$) *m/e* 269 and the molecular formula $C_8H_3Cl_4NO$ has been assigned by interpreting its mass spectrum. Structure **I**, namely hydroxytetrachlorophenylacetonitrile, can be considered for compound **16**, formed presumably through the coupling between $\dot{C}H_2CN$ (which may



I

have been generated via abstraction of hydrogen atoms from the cosolvent acetonitrile by intermediate free radical species) and photolytically produced hydroxytetrachlorophenyl radical. Because the product **16** has been detected in the *n*-hexane extract at pH $\geqslant$ 11 and because the phenolic compound **I** at such a high pH is expected to remain in the $H_2O:CH_3CN$ layer as is the case of the starting phenol **4**, the structure **I** proposed for **16** is ruled out. The rejection of structure **I** is supported by the lower retention time and the shape of the gc peak for product **16** (Fig. 1*c*). It should be mentioned that Lemaire and co-workers (9, 10), during their photochemical investigations on 2-chlorophenol (in the anionic form), have suggested the intermediary of 1,2-ketocarbene and its contraction to a five member ring ketene. With the aid of our present experimental data, we are unable to conclude whether such a ring contraction also occurs during the photolyses of tetra- and pentachlorophenols. However, it is interesting to note that **1** does not provide a photoproduct of molecular formula $C_8H_4Cl_3NO$. In addition, during the irradiation of **1** 3,4,5-Cl_3-Pn, expected via the homolysis of the 2-Cl, is not seen. These two facts lead to the conclusion that products such as $C_8H_3Cl_4NO$ and $C_8H_4Cl_3NO$ are possibly produced through the intermediate involvement of tetrachloro- and trichloro-2-hydroxyphenyl radicals, respectively. It is notable that Choudhry and Hutzinger (16) have recently reported the photoformation of $C_8H_5Cl_2NO$ from 1,2,3,4- and 1,2,3,5-tetrachlorobenzene as well as $C_8H_4Cl_3NO$ from pentachlorobenzene, water–acetonitrile being used as the solvent. Similar products (viz. $C_8H_5Cl_2NO$) may be formed during the photolysis of appropriate trichlorophenols. The full characterisation of these reaction pathways and the compounds so yielded will be the subject of another paper.

Conclusions

Our laboratory photochemical investigations at $\lambda \geqslant 285$ nm

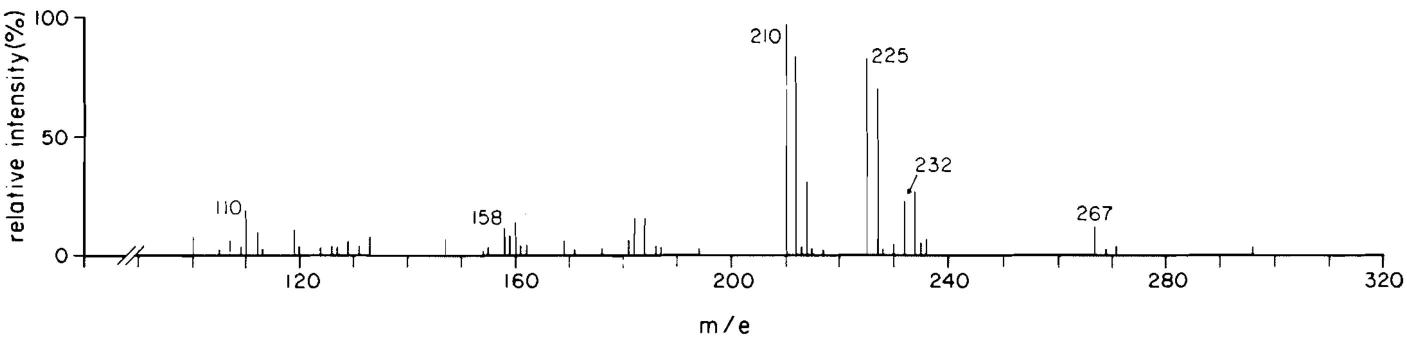


FIG. 4. Mass spectrum of peak No. 11 in the total ion chromatogram (TIC) shown in Fig. 3(*c*).

on 4–5 × 10^{-3} *M* solutions of tetra- and pentachlorophenols in water–acetonitrile mixtures lead us to conclude that, in the context of reductive dechlorination of tetrachlorophenols (Cl_4-Pns), the 4-Cl substituent of 2,3,4,5-Cl_4-Pn (**1**); 4-Cl and 6-Cl substituent of 2,3,4,6-Cl_4-Pn (**2**); and 2-Cl (6-Cl) substituent of 2,3,5,6-Cl_4-Pn are photolabile, whilst 3-Cl (and 5-Cl) substituent(s) on this substrate(s) is (are) not photochemically reactive. In the case of pentachlorophenol **4**, it can be concluded that the C—Cl bond at position 2 (and 6) is labile to homolytic cleavage, but the question whether the C—Cl bond at position 3 (and 5) or 4 or at both positions undergoes such a photoreaction remains unanswered. Failure to yield $C_8H_4Cl_3NO$ ($M^{+\cdot}$ = 235) from **1** stresses that similar products observed in the case of other PCPs **2**–**4** are formed through the intermediacy of hydroxypolychlorophenyl radicals generated via the homolytic cleavage of a C—Cl bond *ortho* to the OH group (Scheme 1). Likewise, among the Cl_4-Pns, only the irradiation of 2,3,5,6-tetrachlorophenol (**3**) provides the relatively longer surviving trichlorohydroxyphenyl radicals in addition to (possibly) tetrachlorophenoxy radicals (and their mesomeric form bearing unpaired electron at the *para* position), which act as sources of photoproducts such as hexa-, hepta-, octa-chlorodihydroxybiphenyl(s) and heptachlorohydroxydiphenyl ether. Finally, contrary to our previous observations in the case of irradiation of polychlorobenzenes (PCBzs), namely, 1,2,3-, 1,3,5-trichlorobenzene (15), all three tetrachlorobenzenes (1, 16) and 2,4,5-trichlorodiphenyl ether (17), it is very unlikely that photoisomerization occurs during the photolyses of tetrachlorophenols in $H_2O:CH_3CN$.

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received June 25, 1984

DEREK G. LEAIST and ROBERT A. NOULTY. Can. J. Chem. **63**, 476 (1985).

A general method for the determination of multicomponent diffusion coefficients is developed using the algebraic technique of matrix diagonalization. When linear combinations of measurements from several multicomponent diffusion experiments performed with different initial concentration gradients (but with the same final composition) are analyzed as simple binary data, particular combinations may be found that transform the multicomponent diffusion coefficient matrix **D** to diagonal form and thus yield time-invariant, pseudo-binary diffusion coefficients: the eigenvalues of **D**. Since the matrix that diagonalizes **D** is given by the coefficients used to form the linear combinations, **D** is easily recovered by the inverse transformation. The advantages of the eigenvalue method are briefly discussed. For testing purposes, ternary diffusion coefficients are determined from conductance measurements for dilute aqueous NaOH + NaCl mixtures. Diffusion of NaOH in aqueous NaCl is significantly more rapid than in pure water, and large coupled flows of NaCl are observed. The results are in close agreement with behavior predicted by Onsager–Fuoss theory.

DEREK G. LEAIST et ROBERT A. NOULTY. Can. J. Chem. **63**, 476 (1985).

Faisant appel à une technique algébrique de diagonalisation des matrices, on a développé une méthode générale permettant de déterminer les coefficients de diffusion à plusieurs composantes. Lorsqu'on analyse, sous forme de données binaires simples, des combinaisons linéaires de mesures provenant de plusieurs expériences de diffusion à plusieurs composantes, réalisées avec des gradients différents de concentrations initiales (mais avec la même composition finale), on peut trouver des combinaisons particulières qui permettent de transformer en une forme diagonale la matrice **D** du coefficient de diffusion à plusieurs composantes; on peut ainsi obtenir des coefficients de diffusion peudo-binaires qui ne varient pas avec le temps. Puisque la matrice qui diagonalise **D** est obtenue à partir des combinaisons utilisées pour former les combinaisons linéaires, on peut facilement récupérer **D** par la transformation inverse. On discute brièvement des avantages de la méthode des valeurs de eigen. Pour fins de vérification, on a déterminé les coefficients de diffusion ternaires à partir de mesures de conductivité sur des solutions aqueuses diluées de mélanges de NaOH + NaCl. La diffusion du NaOH dans le NaCl aqueux est beaucoup plus rapide que dans l'eau pure et on observe d'importantes migrations couplées de NaCl. Les résultats obtenus sont en bon accord avec le comportement prédit par la théorie de Onsager–Fuoss.

1. Introduction

Multicomponent diffusion is of theoretical interest and considerable practical importance (1, 2). In many cases the diffusivity of a solute in a multicomponent mixture is significantly different from its binary diffusivity, especially if the solutes are electrolytes or they react chemically (3–8). Moreover, because diffusional flows interact, multicomponent diffusion of a component produces countercurrent or cocurrent flows of other components in the mixture. If the interaction is strong, a gradient in concentration of one component can effectively control transport of a second component.

Multicomponent diffusion is measured by classical gradient techniques (8–16). Typically, a system is prepared with initial concentration differences across a sharp boundary. As the system relaxes toward thermodynamic equilibrium, changes in a concentration-dependent property (such as the refractive index) are measured along the diffusion path. Diffusion coefficients are then obtained by fitting mathematical solutions of the multicomponent diffusion equations to the measurements. Because these solutions are complicated functions which contain the diffusion coefficients as non-linear parameters, determination of diffusivities for multicomponent systems by this procedure is substantially more difficult than for binary systems (17).

The purpose of this work is to develop a simpler method for the analysis of multicomponent diffusion data. Rather than fit solutions of the diffusion equations to measurements from individual experiments, we propose to treat linear combinations of measurements from experiments performed with different initial conditions as simple binary diffusion data. Particular combinations diagonalize (18, 19) the multicomponent diffusion equations and yield time-invariant, pseudo-binary diffusion coefficients — the eigenvalues of the multicomponent diffusion coefficient matrix **D**. The eigenvalues provide **D** in diagonal form. We show that the coefficients used to form the linear combinations define the matrix that diagonalizes **D**, and that **D** is easily reconstructed by the inverse transformation using matrix inversion and multiplication.

To evaluate the eigenvalue method, ternary diffusion coefficients have been determined for NaOH + NaCl + H_2O mixtures. This system was chosen in order to test recent predictions (21) that aqueous hydroxides diffuse much more rapidly in supporting electrolytes than in pure water. Another purpose of the study was to determine whether or not pH gradients produced by hydroxide gradients, like pH gradients produced by acid gradients (6–8), can generate large coupled flows of salts. Coupled transport driven by pH gradients has applications to separation technology and plays vital roles in biological systems (22–24).

2. Theory

n + 1 components

Provided the concentration gradients are not too large, isothermal diffusion in a system containing $n + 1$ components may be described by n coupled equations (25)

$$[1] \qquad \partial c_i/\partial t = \sum_{k=1}^{n} D_{ik}\nabla^2 c_k \qquad i = 1, 2, \ldots, n$$

where c_i is the concentration of component i in moles per unit

[1] To whom all correspondence should be addressed.

volume, t is the time, and ∇^2 denotes the Laplacian operator. Multicomponent diffusion coefficient D_{ik} measures the flux of component i produced per unit concentration gradient in component k. In matrix notation

$$[2] \quad \partial \boldsymbol{c}/\partial t = \mathbf{D}\nabla^2\boldsymbol{c}$$

where $\boldsymbol{c}$ denotes the column vector of n component concentrations and $\mathbf{D}$ is the $n \times n$ matrix of diffusion coefficients.

Consider linear combinations (18, 19) u_i of the component concentrations defined by

$$[3] \quad c_i = \sum_{k=1}^{n} A_{ik}u_k$$

Upon substitution of $\boldsymbol{c} = \mathbf{A}\boldsymbol{u}$ into eq. [2] and multiplying by $\mathbf{A}^{-1}$, the diffusion equations may be rewritten as

$$[4] \quad \partial \boldsymbol{u}/\partial t = (\mathbf{A}^{-1}\mathbf{D}\mathbf{A})\, \nabla^2\boldsymbol{u}$$

If coefficients A_{ik} are chosen so that the columns of $\mathbf{A}$ are eigenvectors of $\mathbf{D}$, the transform of $\mathbf{D}$ is diagonal (20)

$$[5] \quad \mathbf{A}^{-1}\mathbf{D}\mathbf{A} = \begin{pmatrix} D_1 & & & \\ & D_2 & & 0 \\ & & \ddots & \\ 0 & & & D_n \end{pmatrix}$$

and the transformed diffusion equations

$$[6] \quad \partial u_i/\partial t = D_i\nabla^2 u_i$$

are de-coupled. D_i are eigenvalues of $\mathbf{D}$ and u_i are solutions of the binary diffusion equations.

Reduction to diagonal form is a powerful technique (18, 19) that is frequently used to *solve* coupled differential equations. Can the same technique be used to *measure* multicomponent diffusion coefficients? Consider n diffusion experiments run at the same final composition of the system but with different initial concentration gradients. The idea is to use measurements from these runs as a "basis set" of data from which suitable linear combinations may be taken that diagonalize $\mathbf{D}$ and thus simplify the analysis.

Let Y represent the refractive index (4–6, 8–13), conductance (14, 21), density (26), optical absorbance (27), or another concentration-dependent property measured along the path of diffusion during an experiment. For initial concentration differences $\Delta c_i(0)$ across a sharp diffusion boundary, the corresponding difference in Y is

$$[7] \quad \Delta Y(0) = \sum_{i=1}^{n} S_i \Delta c_i(0)$$

where S_i are derivatives

$$[8] \quad S_i = \partial Y/\partial c_i$$

evaluated at the final composition of the system. X_i will be used to denote the fraction of $\Delta Y(0)$ contributed by component i.

$$[9] \quad X_i = S_i\Delta c_i(0)/\sum_{k=1}^{n} S_k\Delta c_k(0)$$

Apparent binary diffusion coefficients $D_a(t)$ may be obtained from multicomponent experiments by analyzing measured values of Y as if they were from a binary experiment (8, 11, 21, 28, 29). Apparent diffusion coefficients obtained in this manner usually vary with time. For example, if an experiment is performed with initial concentration gradients in solutes 1 and 2, and 1 diffuses rapidly compared to 2, values of $D_a(t)$ will be large initially but will decrease toward the end of the experiment as the initial gradient in 1 decays rapidly and diffusion of slower solute 2 predominates.

Although apparent diffusion coefficients are generally time-dependent, consider an experiment with particular initial conditions $X_i^{(k)}$ such that the column vector of initial concentration differences $\Delta c^{(k)}$ (0) is an eigenvector of $\mathbf{D}$

$$[10] \quad \mathbf{D}\begin{pmatrix} \Delta c_1^{(k)}(0) \\ \Delta c_2^{(k)}(0) \\ \vdots \\ \Delta c_n^{(k)}(0) \end{pmatrix} = D_k \begin{pmatrix} \Delta c_1^{(k)}(0) \\ \Delta c_2^{(k)}(0) \\ \vdots \\ \Delta c_n^{(k)}(0) \end{pmatrix}$$

Under these conditions

$$[11] \quad \partial c_i^{(k)}/\partial t = D_k\nabla^2 c_i^{(k)}$$

and hence

$$[12] \quad \partial Y^{(k)}/\partial t = D_k\nabla^2 Y^{(k)}$$

Consequently, the experiment behaves as a simple binary diffusion experiment with time-invariant, pseudo-binary diffusion coefficient equal to eigenvalue D_k. Once values of $X_i^{(k)}$ and D_k are established, the multicomponent diffusion coefficients are easily determined using

$$[13] \quad A_{ik} = X_i^{(k)}/S_i$$

and the inverse transformation

$$[14] \quad \mathbf{D} = \mathbf{A}^{-1}\begin{pmatrix} D_1 & & & \\ & D_2 & & 0 \\ & & \ddots & \\ 0 & & & D_n \end{pmatrix}\mathbf{A}$$

Since $\mathbf{D}$ is unknown at the start of the experiments, it is of course virtually impossible to choose the exact initial conditions that diagonalize $\mathbf{D}$. Nevertheless, by taking linear combinations of data from experiments with different (specifically, linearly independent values of $\Delta c(0)$) initial conditions, measurements corresponding to arbitrary initial conditions may be obtained. For instance, if $\Delta Y_i(t)/\Delta Y_i(0)$ symbolizes normalized measurements of property Y for an experiment in which the initial concentration gradient is entirely in component i ($X_i = 1$), measurements corresponding to arbitrary initial conditions X_i may be constructed from

$$[15] \quad \Delta Y(t)/\Delta Y(0) = \sum_{i=1}^{n} X_i\Delta Y_i(t)/\Delta Y_i(0)$$

A detailed example is given later.

In order to establish the initial conditions that reduce the diffusion equations to diagonal form, the standard deviation of measured values of the apparent diffusion coefficient

$$[16] \quad \sigma_D = \left[(N-1)^{-1}\sum_{i=1}^{N}(D_a(t_i) - \bar{D}_a)^2\right]^{1/2}$$

may be evaluated as a function of X_i. $\bar{D}_a$ is the mean apparent diffusion coefficient

$$[17] \quad \bar{D}_a = N^{-1}\sum_{i=1}^{N}\bar{D}_a(t_i)$$

For the particular initial conditions $X_i^{(k)}$, the apparent diffusion coefficient is effectively constant over the duration of a run, and hence σ_D is minimized. Therefore, values of $X_i^{(k)}$ may be obtained from the positions of the minima in σ_D. Eigenvalue D_k is obtained from the mean value of the apparent diffusion coefficient evaluated at $X_i^{(k)}$.

Ternary diffusion (n = 2)

When the standard deviation of the apparent diffusion coefficient for a ternary system is plotted against X_1, minima are found at $X_1^{(1)}$ and $X_1^{(2)}$. Since $X_1 + X_2 = 1$, we have

$$[18] \quad \mathbf{A} = \begin{pmatrix} X_1^{(1)}/S_1 & X_1^{(2)}/S_1 \\ (1-X_1^{(1)})/S_2 & (1-X_1^{(2)})/S_2 \end{pmatrix}$$

The mean diffusion coefficients evaluated at $X_1^{(1)}$ and $X_1^{(2)}$ equal eigenvalues D_1 and D_2, respectively. The ternary diffusion coefficients are evaluated from eq. [14].

$$[19] \quad \begin{pmatrix} D_{11} & D_{12} \\ D_{21} & D_{22} \end{pmatrix} = \mathbf{A}^{-1} \begin{pmatrix} D_1 & 0 \\ 0 & D_2 \end{pmatrix} \mathbf{A}$$

3. Experimental

Ternary diffusion coefficients of dilute aqueous NaOH + NaCl mixtures were measured at 25°C using a simplified version (14) of Harned's conductimetric procedure (30). In this technique, initial concentration gradients are formed by introducing a small volume of electrolyte into the bottom of a column of solution. The rate of diffusion is followed by monitoring changes in electrical conductance measured near the top and bottom of the column.

Because Harned's technique employs very small concentration gradients, changes in the transport coefficients due to compositional changes along the diffusion column are negligible, and the measured diffusion coefficients correspond to differential values defined by eq. [1]. (For diaphragm cell results (31), and to a lesser extent for optical results (32, 33), small but troublesome corrections are required to allow for the concentration-dependence of the diffusion coefficients.) Moreover, the conductimetric technique is reliable at low ionic strength where the transport coefficients can be estimated from limiting ionic conductances (14). Comparison of measured diffusion coefficients with theoretical predictions will provide a check on the reliability of the proposed eigenvalue method.

Equipment and procedure

The diffusion cells used in this work had cylindrical diffusion channels (height 0.04560 m, diameter 0.0126 m). The cells were constructed from high density polyethylene rather than glass in order to resist leaching by hydroxide. Pairs of circular platinum electrodes (diameter 10^{-3} m, cell constant $k \sim 10^3$ m^{-1}) were positioned at levels one-sixth of the distance from the top and bottom of the channel. At the start of each experiment, 0.1–0.3 mL of electrolyte was carefully injected with a calibrated syringe into the bottom of each solution-filled chamber. Initial concentration differences across the diffusion boundary were 0.05–0.2 mol L^{-1}. Conductances were measured six times per day for four consecutive days beginning one day after injection of electrolyte. Further details of the equipment and procedure have been reported (14, 34). Cell constants were obtained by calibration with 0.01 mol L^{-1} aqueous KCl (conductance 0.01413 m^2 S mol^{-1} (35)). Values of S_1 and S_2 were determined using an auxiliary conductance cell.

Reagents

Reagent grade NaCl was dried in a vacuum oven at 140°C and used without further purification. Stock solutions of NaOH were prepared by diluting saturated solutions that had been filtered to remove insoluble carbonate. The NaOH solutions were stored in polyethylene bottles and protected from the atmosphere. Concentrations of NaOH were determined by titration against potassium hydrogen pthalate. Winkler analyses (36) before and after the experiments indicated that the solutions contained less than 0.05% carbonate based on total alkali. Water used to make up the solutions was doubly-distilled and deionized (conductivity 0.8 × 10^{-4} ohm^{-1} m^{-1}). Corrections for solvent conductance were negligible.

Data analysis

For binary diffusion in a Harned cell, the difference in electrolyte concentration between the top (T) and bottom (B) electrode positions is given by (30)

$$[20] \quad \Delta c(t) = c_B(t) - c_T(t) = C \exp(-\pi^2 Dt/a^2)$$

where C is a constant, D is the binary diffusion coefficient, t is the time elapsed since introduction of electrolyte, and a is the height of the diffusion channel. For strong electrolytes, $\Delta c(t)$ is directly proportional to the conductance difference defined by (14, 21, 30)

$$[21] \quad \Delta K(t) = (k_B/k_T)K_B(t) - K_T(t)$$

where k_B/k_T denotes the ratio of cell constants of the top and bottom electrode pairs. Values of D are conveniently determined from the difference equation

$$[22] \quad D = -\frac{a^2}{\pi^2}\frac{\Delta \ln \Delta K(t)}{\Delta t}$$

by pairing each conductance reading with the corresponding reading taken on the following day.

In order to determine ternary diffusion coefficients, conductance differences $\Delta K_1(t)$ and $\Delta K_2(t)$ were measured for experiments run with the initial concentration gradient entirely in NaOH ($X_1 = 1$) or NaCl ($X_1 = 0$), respectively. Apparent diffusion coefficients for initial condition X_1 were calculated using the difference equation

$$[23] \quad D_a\left(\frac{t'+t''}{2}\right) = -\frac{a}{\pi^2}\frac{\ln \Delta K(t'') - \ln \Delta K(t')}{t''-t'}$$

wherein

$$[24] \quad \Delta K(t) = X_1 \frac{\Delta K_1(t)}{S_1 \Delta c_1(0)} + (1 - X_1)\frac{\Delta K_2(t)}{S_2 \Delta c_2(0)}$$

4. Results and discussion

Diffusion coefficients for NaOH(c_1) + NaCl(c_2) + H_2O mixtures were measured at a total electrolyte concentration of 0.020 mol L^{-1} for ratios of $c_1:c_2$ equal to 1:3, 1:1, and 3:1. Paired experiments with the initial concentration gradient in NaOH or NaCl were carried out in triplicate at each of the three compositions studied.

Typical results for a pair of experiments for $c_1 = 0.0150$ and $c_2 = 0.0050$ mol L^{-1} are shown in Figs. 1 and 2. In Fig. 1, values of the apparent diffusion coefficient computed from eq. [23] are plotted against t for various initial conditions. It is evident from the figure that the apparent diffusion coefficient varies substantially over the duration of a run when the initial concentration gradient is entirely in NaOH or NaCl ($X_1 = 1$ and $X_1 = 0$, respectively). It may be noted, however, that values of $D_a(t)$ are essentially constant for values of X_1 near 0.6 and 1.2. The "stationary" values of $D_a(t)$ (the eigenvalues of **D**) were found by plotting the standard deviation of the apparent diffusion coefficients against X_1, the fraction of the conductance difference across the initial diffusion boundary due to NaOH. From the two minima in σ_D shown in Fig. 2, initial conditions $X_1^{(1)} = 1.21$ and $X_1^{(2)} = 0.64$ that diagonalize **D** were obtained. From the mean apparent diffusion coefficients evaluated at these two values of X_1, eigenvalues $D_1 = 2.58 \times 10^{-9}$ and $D_2 = 1.71 \times 10^{-9}$ m^2 s^{-1} were obtained.

The results of the experiments are summarized in Tables 1 and 2. As shown in Table 2, values of D_{11}, the ternary dif-

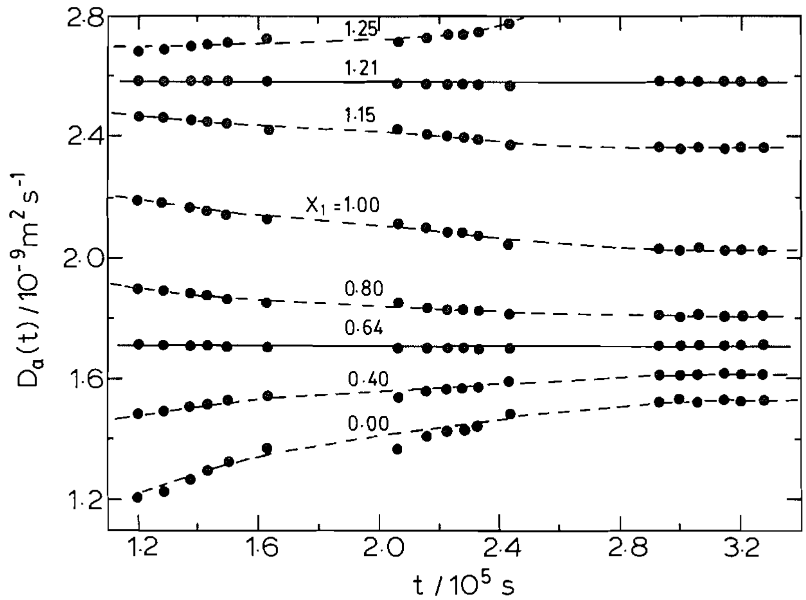

FIG. 1. Apparent binary diffusion coefficients of aqueous NaOH(1) + NaCl(2) for c_1 = 0.015 mol L^{-1} and c_2 = 0.005 mol L^{-1} for selected initial conditions. For the experiment with the initial concentration gradient entirely in NaCl (X_1 = 0), 0.32 mL of solution containing 0.015 mol L^{-1} NaOH and 0.0712 mol L^{-1} NaCl was injected into a cell filled with solution containing 0.015 mol L^{-1} NaOH and 0.001 mol L^{-1} NaCl. For the experiment with the initial gradient in NaOH (X_1 = 1), 0.32 mL of solution containing 0.254 mol L^{-1} NaOH and 0.005 mol L^{-1} NaCl was injected into the same cell filled with 0.001 mol L^{-1} NaOH and 0.005 mol L^{-1} NaCl. The curves for X_1 = 0.4, 0.64, 0.80, 1.15, 1.21, and 1.25 were obtained by analysis of linear combinations of data from the two experiments run with X_1 = 0.00 and X_1 = 1.00. The volume of the cell was 5.78 mL.

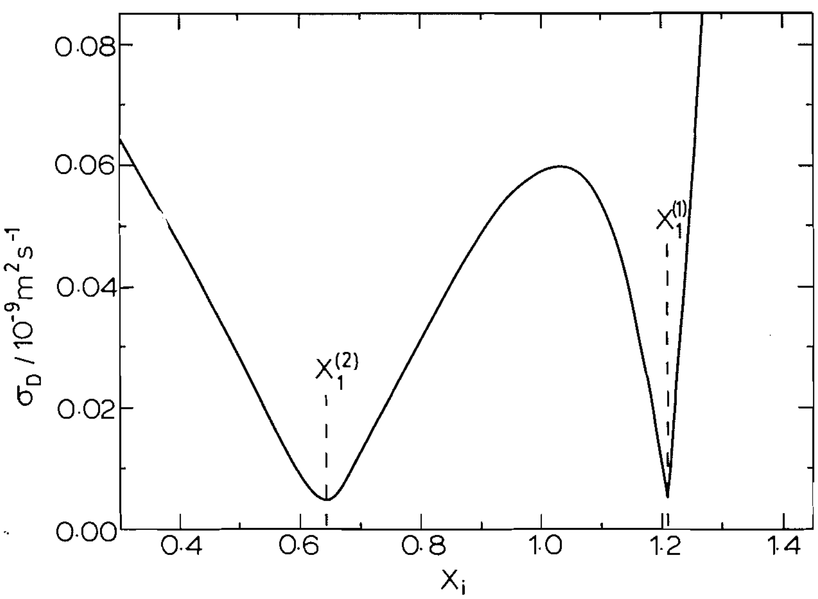

FIG. 2. Standard deviation of the apparent diffusion coefficient of aqueous NaOH(1) + NaCl(2) for c_1 = 0.015 mol L^{-1} and c_2 = 0.005 mol L^{-1}. See caption of Fig. 1 for details.

fusivity of NaOH in aqueous NaCl, increase steadily as the system becomes richer in NaCl. At the same ionic strength, in contrast, the binary diffusivity of aqueous NaOH is only 1.99 $\times 10^{-9}$ m^2 s^{-1} (34). In binary solutions of NaOH, however, the condition of electroneutrality requires that Na^+ and OH^- diffuse at the same rate, even though OH^- has approximately four times the mobility of Na^+ (35); the electric field produced by flow of the electrolyte slows down OH^- and speeds up Na^+ so that they travel at the same rate and the electric current is zero. In ternary NaOH(1) + NaCl(2) + H_2O mixtures, on the other hand, the electric field along the NaOH gradient which slows down OH^- also generates counterflow of Cl^-. Highly mobile OH^- can thus diffuse down the NaOH gradient more rapidly than Na^+ while still maintaining electroneutrality. This mechanism accounts for the increased diffusivity of the NaOH component in aqueous NaCl as well as the large negative values of D_{21} (the cross-diffusion coefficient measuring coupled flow of NaCl produced per unit concentration gradient in NaOH). Similar diffusional behavior has been observed for HCl + NaCl + H_2O and other acid-containing mixed electrolytes (6, 8, 21). In those systems, the electric field generated by diffusion of highly mobile protons produces counterflow of cations.

The difference in mobility between Na^+ and Cl^- is not as great as the difference in mobility between Na^+ and OH^-: Cl^- is about 50% more mobile than Na^+ (35). The electric field per unit concentration gradient in NaCl is therefore weaker than for NaOH, and values of D_{12} for aqueous NaOH(1) + NaCl(2) are proportionally smaller than for D_{21}. Also, the increase in the diffusivity D_{22} of NaCl in NaOH-rich mixtures is not as dramatic as for D_{11} in NaCl-rich mixtures.

Onsager's equations (25)

$$[25] \quad J_i = -\sum_{k=1}^{n} L_{ik} \nabla \mu_k$$

relate molar fluxes, J_i, of components to gradients in the chemical potentials of the components. Conveniently, values for the L_{ik} phenomenological coefficients can be estimated (14) for dilute mixed electrolytes from limiting ionic conductances and Onsager–Fuoss theory (37, 38) of the electrophoretic and relaxation effects. Details of the calculations have been reported (14). Given L_{ik} values, diffusion coefficients are calculated from (25)

$$[26] \quad D_{ik} = \sum_{m=1}^{n} L_{im} \partial \mu_m / \partial c_k$$

The parameters used to predict the transport coefficients of aqueous NaOH(1) + NaCl(2) are listed in Table 4. Values of $\partial \mu_m / \partial c_k$ were calculated by differentiation of expressions

ical constants which allow for specific ion interactions.

Experimental transport coefficients are compared with predicted values in Tables 2 and 3. Agreement is very good. The observed values of the L_{ik} coefficients are consistent with the Onsager reciprocal relation (2, 25) $L_{12} = L_{21}$ which lends further confidence to the reliability of the eigenvalue method.

A general procedure for the determination of ternary diffusion coefficients from conductance measurements using non-linear least squares has been reported (40). In practice, we found that the eigenvalue method was much easier to use. The non-linear least-squares procedure, for instance, requires lengthy computations in order to simultaneously optimize values of the four diffusion coefficients. Experimental diffusion coefficients determined for NaOH + NaCl mixtures by the non-linear least-squares method are given in Table 5. Comparison of Tables 2 and 5 indicates that the eigenvalue and non-linear least-squares procedures give essentially identical results. With the eigenvalue method, however, the problem of locating the minimum in the variance in four dimensions is replaced by the more manageable problem of locating two minima in one dimension (i.e. minima in σ_D as a function of X_1).

In effect, the eigenvalue method reduces the analysis of coupled, multicomponent transport equations to an analysis based on de-coupled, well-understood binary equations. This transformation enables the determination of ternary diffusivities without explicitly solving multicomponent diffusion equations or resorting to non-linear curve fitting procedures.

The eigenvalue method holds especial promise for the measurement of quaternary diffusion (17). For those systems, the non-linear least-squares method requires simultaneous optimization of nine parameters (a formidable task), while the eigenvalue method would involve searching for three minima in only two dimensions.

The present study has employed time invariance of the apparent diffusion coefficient to locate the eigenvalues of **D**. This criterion is well suited to the Harned technique and other restricted diffusion experiments (1, 41) in which the concentrations are measured at two positions along the path of diffusion. On the other hand, optical methods (4–6, 8–13) such as Rayleigh or Gouy experiments employ free diffusion boundary conditions. In those experiments the position of interference fringes is followed as a function of time. The apparent diffusion coefficient obtained by analysis of the position of a single fringe will generally vary from fringe to fringe. By locating the minimum in σ_D as a function of fringe number the eigenvalue technique can also be used to analyze multicomponent optical data.

An evaluation of high resolution nuclear magnetic resonance experiments and protocols in the structure elucidation of organic molecules. I. A relatively simple system, brucine[1]

MICHAEL A. BERNSTEIN[2] AND LAURANCE D. HALL
Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received April 5, 1984

MICHAEL A. BERNSTEIN and LAURANCE D. HALL. Can. J. Chem. **63**, 483 (1985).

Using a *combination* of one-dimensional (1D) and two-dimensional (2D) high resolution nmr methods, the ^{1}H nmr spectrum of brucine was fully assigned. The 2D *J*-resolved and homonuclear chemical shift correlated (COSY) experiments provided assignments without full structural information; this was obtained from nuclear Overhauser effect (nOe) enhancement experiments (1D and 2D). With the proton spectrum fully assigned, proton-bearing carbons in the ^{13}C nmr spectrum were easily assigned using the 2D heteronuclear chemical shift correlation map (CSCM) experiment.

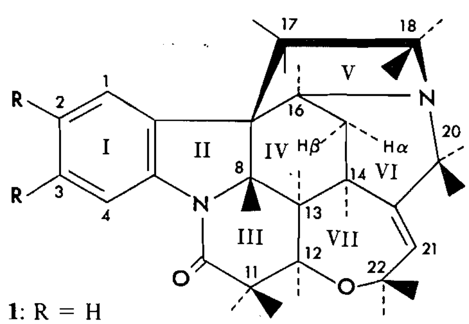
MICHAEL A. BERNSTEIN et LAURANCE D. HALL. Can. J. Chem. **63**, 483 (1985).

Faisant appel à une *combinaison* de méthodes rmn à haute résolution en une dimension (1D) et en deux dimensions (2D), on a fait une attribution complète de tout le spectre rmn ^{1}H de la brucine. Grâce à des expériences en 2D résolues pour *J* impliquant une corrélation des déplacements chimiques homonucléaires (COSY), on a pu obtenir des attributions sans avoir d'informations structurales complètes; on a obtenu ceci à l'aide d'expériences de rehaussement d'effet nucléaire Overhauser tant en 1D qu'en 2D. L'ensemble du spectre du proton étant attribué, on a pu facilement faire une attribution des carbones portant des protons dans le spectre rmn du ^{13}C en utilisant l'expérience de la carte de corrélation des déplacements chimiques hétéronucléaires en 2D (CCDC).

[Traduit par le journal]

Introduction

It is already obvious from the literature that modern nmr methods used singly can have very high information content, and that *synergistic combinations* of these can result in a further dramatic increase in chemical insight. This laboratory has reported the combination of 2D *J*-resolved spectroscopy with homonuclear chemical shift correlated spectroscopy as part of a sequence for oligosaccharide sequence determination (1, 2), and related approaches have been utilized with protein studies (3, 4). An exhaustive survey of all such combined experiments is not in order, but a report by Kessler and Eierman (5) on the combined use of homo- and heteronuclear correlated 2D nmr with cyclic peptides merits mention. The purpose of this study is to evaluate the combined use and sequence of high resolution 2D nmr methods for molecular structure and conformation determination in the natural products area. Given the exploratory nature of this work, we have chosen the well-known alkaloid brucine (**2**), which is very similar to strychnine (**1**), as an exemplar.



1: R = H
2: R = OCH_3

We shall not discuss in detail individual experiments since all have been adequately reviewed (1, 6); however, some brief comments are pertinent. The 2D *J*-resolved experiment has been widely applied to organic molecules (see, for example, ref. 7) since it efficiently simplifies spectra that have a complex, overlapping set of resonances. Projection of the tilted data matrix onto the F_2 axis yields one line at the chemical shift of each proton; "slices" (F_1 traces) taken at each chemical shift give a "*J*-spectrum" for that proton – its coupling pattern, with high resolution (due to the removal of magnetic inhomogeneity contributions to line-width). That information which the 2D *J*-resolved experiment does not provide is the coupling pathway. A quick and convenient 2D experiment that does this (8) is homonuclear 2D spectroscopy[3] (COSY). Normally viewed "from above," along the signal intensity axis and represented as a contour plot, this experiment shows a series of peaks along the "diagonal" where $F_1 = F_2$. *J*-coupling is encoded in "off diagonal" correlation peaks whose positions exactly indicate the frequencies of the coupled protons (9).

It is well known that dipolar relaxation effects occur "through space" and their observation, either as the nuclear Overhauser enhancement effect (nOe) or in relaxation rates, is invaluable for molecular structure elucidation and the measurement of precise interproton distances (10). We have found the nOe experiment particularly useful, especially when performed in the difference mode (SSNOEDS ≡ steady state nOe difference spectroscopy). A "control" spectrum with the decoupler placed well out of the spectral region is digitally subtracted from an "experiment" where a set of resonances is *selectively* irradiated for a number of T_1 periods prior to an observation pulse and signal acquisition (11 and 12 for a recent review). In the difference mode, only protons experiencing an nOe (plus the proton irradiated) will appear and all other resonances will exactly cancel; this experiment can reproducibly measure nOe's of <1% even for an overlapping multiplet.

Although the SSNOEDS experiment is extremely powerful and relatively quick to perform, it suffers from the sometimes

[1]Abstracted in part from ref. 1.
[2]Present address: Merck Frosst Canada Inc., P.O. Box 1005, Pointe Claire – Dorval, Quebec, Canada H9R 4P8.

[3]An analogous experiment with identical information content is SECSY–spin-echo correlation spectroscopy.

important limitation that it is impossible to perform without ambiguity due to the nonselectivity of irradiation which is inescapable when the signal of a proton overlaps with that of another. Here, the 2D experiment, NOESY (2D nOe spectroscopy) can be useful (13). The output from this experiment is identical to that of the COSY experiment, but off-diagonal peaks now correlate protons relaxing one another via the dipole–dipole mechanism (in the extreme-narrowing limit and in the absence of chemical exchange). Correlation peaks are relatively small for molecules in the fast-tumbling regime and this has probably deterred many experimenters from using this experiment with this chemical system. However, in our limited experience with the experiment, we have found it to be quite tractible.

Given adequate quantities of a substance and its fully assigned ^{1}H nmr spectrum, it is now almost a trivial matter to assign all proton-bearing carbons in the ^{13}C nmr spectrum without recourse to selective irradiation experiments. Initially, it is helpful to know the number of protons attached to each carbon. Classically, this is achieved by single frequency off-resonance decoupling (SFORD), but this experiment (14) is not without difficulties, (a) in a spectrally crowded region and (b) when a carbon bears magnetically inequivalent protons. A number of multi-pulse methods provide the necessary information very efficiently, and we have found utility for one, dubbed DEPT (distortionless enhancement and polarization transfer) (15). Now, the proton chemical shift may be correlated with carbons in a "single" 2D experiment termed CSCM – the heteronuclear chemical shift correlation map (16). The experiment is designed to show a proton multiplet at the coordinates defined by the respective chemical shifts of a carbon nucleus and its attached proton or protons. The ability to differentiate between spectrally close carbons and define proton multiplets is limited by the data storage capability of the spectrometer and the amount of time available for collection and processing of what are invariably very large data matrices. Usually, ^{1}H multiplet detail is forsaken in the interest of conserving experimental time; this is no great sacrifice since those details are most efficiently derived from the 2D *J*-resolved experiment.

Experimental

Our experience with the above experiments suggested that there are two levels of structure elucidation, one requiring a modest investment of instrument time and the other somewhat more. The statements below on the ^{1}H nmr experiments pertain to the user with access to a modern high-field nmr instrument, and ca. 5 mg of organic material of mol. wt. <1000. Obviously this should be used as a guide, as it does not exclude, for example, the protocol being applied to smaller amounts of material with appropriate allowances made for additional signal-averaging.

The proton nmr spectrum is readily assigned to the point of identifying coupling pathways, chemical shifts, and coupling constants by a combination of the 2D *J*-resolved experiment (yielding δ and *J* information) and the COSY experiment (providing coupling pathways). In fortunate circumstances this information may be sufficient to assign the spectrum fully and determine the structure. In some instances, however, as is the case with brucine, this level of analysis does not necessarily answer all questions since it may fail to distinguish axial and equatorial geminal protons,[4] and may leave unanswered questions on conformation.

These latter points are amply covered with selected nOe experiments, which report on the local environment of the saturated spin(s), often with the added bonus of a confirmation of previous assignments from the two, 2D nmr experiments mentioned above. It should be stressed that SSNOEDS experiments are time consuming, and the experimenter is advised to construct a molecular model of the compound, consider the available data, and establish which nOe experiments will have unambiguous conformational implications. Although it is, in principle, possible to calculate accurate *inter*-proton distances with such methods (10), we point out the utility of a qualitative inspection of the results, and the possibility for an unambiguous structural assignment with this non-mathematical approach. This approach has the further advantage that the conditions for data collection are relaxed, in that saturation of a multiplet need not be complete,[5] and relaxation delays and saturation times may be trimmed to speed up signal acquisition.

In certain instances a key SSNOEDS experiment may not be accessible; such is the case when several proton signals overlap and none can be selectively irradiated without ambiguity. Here the NOESY experiment is useful, since no irradiations are performed, *per se*.

Given sufficient sample, it is possible now to proceed with the assignment of protonated carbons in the molecule. A spectral editing sequence such as DEPT will not only serve to identify the number of protons attached to each carbon, but also usefully determine the pulse lengths necessary for the execution of the heteronuclear CSCM experiment. These two experiments, along with the assigned proton spectrum, should expedite the assignment of the carbon resonances.

Results

The overall strategy chosen was first to fully assign the proton nmr spectrum and then use this to assign the nonquaternary signals in the carbon-13 spectrum. The former was achieved primarily using COSY, with some assistance from 2D *J*-resolved spectroscopy, and 1D and 2D nOe experiments and chemical shift arguments. With this completed, the ^{13}C nmr spectrum was easily assigned using the CSCM experiment, with spectral editing performed using DEPT.

Portions of the ^{1}H nmr spectrum of brucine are presented in Fig. 1. Two singlets in the aromatic region are omitted, and the multiplet in the vinyl region is shown in an inset. Analysis at 360 MHz began with the COSY spectrum. The experiment was performed with coherence transfer echo selection, on a ca. 0.01 *M* solution in $CDCl_3$. A relaxation delay of only 0.2 s and the minimum of 4 acquisitions per t_1 interval meant that 20 min was required for the collection of a 512 * 1K data set; the sweep-width was 10 ppm in both frequency dimensions. Next, a 2D *J*-resolved experiment was set up, and this experiment required ca. 54 min for collection of the data; this was somewhat longer than that for the COSY due to the necessarily longer relaxation delay and the need for more scans. Whilst these *J*-resolved data were being collected, the COSY data set was processed and plotted. By this time, acquisition of the 2D *J*-resolved data set was complete, and data processing was performed. All the above operations were performed automatically in a MACRO program on the Nicolet system.[6] Minimal operator intervention was required, except at the plotting stage, where decisions were made to expand certain spectral regions for clarification. Details of these "survey-condition" parameters are in Table 1.

The COSY spectrum of brucine is shown in Fig. 2. Only the

[4]This is especially a problem in distorted ring systems, where coupling constants may not unambiguously assign a proton's orientation.

[5]This point takes on special significance in crowded spectra, where frequency selectivity may only be possible under sub-saturating conditions.

[6]All experiments at 360 MHz were performed at Nicolet Magnetics Corp., Fremont, CA, U.S.A.

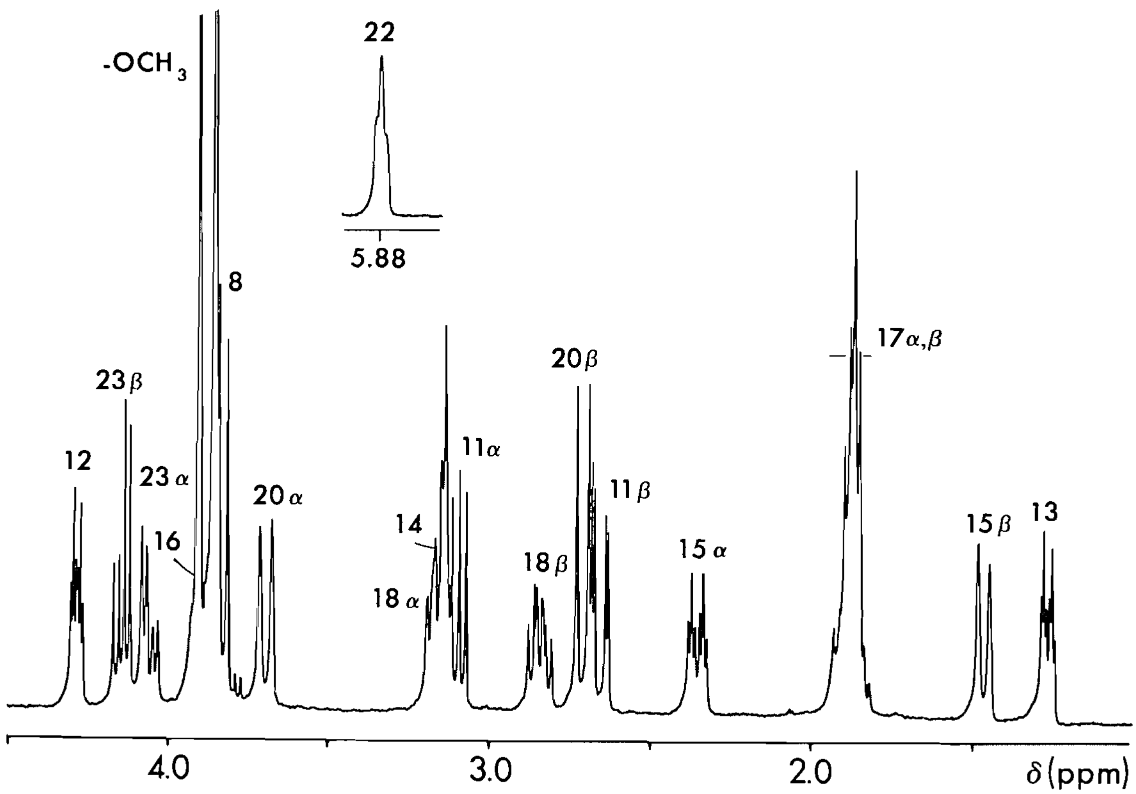


FIG. 1. 400-MHz ^{1}H nmr spectrum of brucine (ca. 0.02 M in $CDCl_3$), showing the assignment of non-aromatic protons.

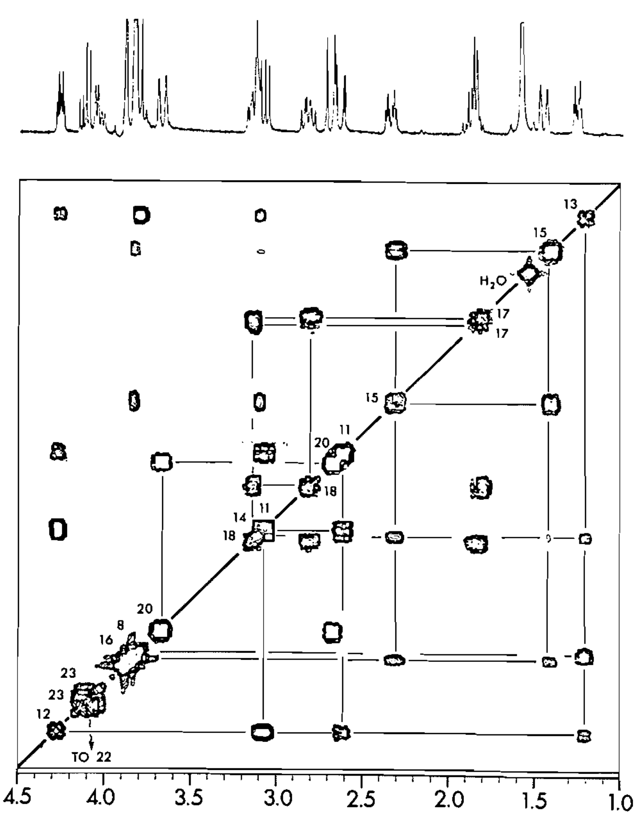

FIG. 2. 360-MHz COSY spectrum of brucine in the region δ 4.5 and 1.0. Connectivities to the vinylic proton are indicated, though they are not on the diagram.

region between δ 4.5 and 1.0 is plotted here, for the sake of clarity. The analysis began with the realization that four "pockets" of coupled spins exist in the molecule, with little or no coupling between them: namely (a) H-20α and H-20β; (b) H-17α, H-17β, H-18α, and H-18β; (c) H-22, H-23α, and H-23β; and (d) H-11α, H-11β, H-12, H-13, H-8, H-14, H-15α, H-15β, and H-16. COSY succeeded in assigning all protons in spin sets (a), (c), and (d). With the H-17 and H-18 protons it was necessary to invoke a chemical shift argument, namely that the protons on C-18 are relatively deshielded by the ring nitrogen atom. Herewith, the protons in spin set (b) were assigned in the COSY spectrum. However, it was not possible at this stage to differentiate α from β geminal protons.[7] The connectivities are indicated along with the assignments in the figure; these were made without ambiguity. The large —OCH_3 peaks that resonate very close to H-8 and H-16 could have hindered the assignment had H-8 and H-16 been scalar coupled to each other, as they might then have obscured a set of cross peaks; this was not the case. Special considerations were required for the tightly coupled geminal protons, which were assigned to the H-23 and H-17 pairs. Distortion of peak intensities indicated tight coupling, especially in the case of the H-17 pair. To assess the reliability of the COSY spectrum, it is interesting to consider H-15β (ca. δ 1.4), which shows one large splitting and several smaller (≤1.5 Hz) ones. In the COSY spectrum, the expected three connectivities are clear, even though the digitization is less than 7 Hz per point.

[7]The molecule is not planar and hence an upper (β) and lower (α) face is not clear. For this reason, geminal protons are defined (see **1** and **2**) for the purpose of this study.

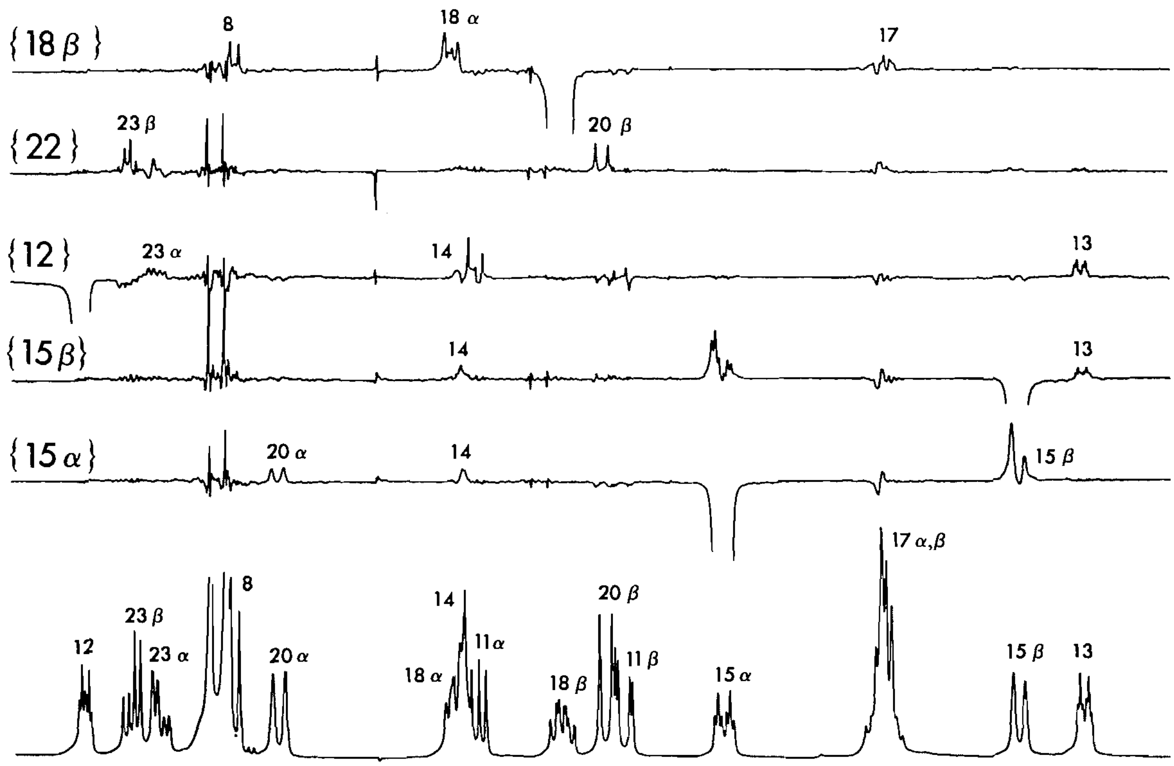

FIG. 3. SSNOEDS experiments performed on brucine at 400 MHz. At the bottom is the "control" spectrum and, next to each difference spectrum, the irradiated proton is indicated. Since the analysis was only qualitative, the sample was not degassed.

TABLE 1. Parameters used in automated "survey conditions" collection and processing of ^{1}H COSY and 2D J-resolved experiments at 360 MHz

Total time (min)		Sweep width[a] F_2	Sweep width[a] F_1	Block size[b] F_2	Block size[b] F_1	Relax. delay[c]	No. scans per t_1	Apodization[d] t_1	Apodization[d] t_2	Zerofill t_1	Symm.[e]

—	Process and plot COSY							MS	MS	No	Yes
65	Commence processing and plotting of 2D J-resolved experiment							EM DM	DM MS	Yes	No
120	End										

[a]Full-sweep width (Hz).
[b]Block sizes (words).
[c]Relaxation delay (s).
[d]Apodization function: EM = exponential multiplier; DM = double exponential multiplier; MS = sinebell multiplier. With the J-resolved experiment, the strongest resolution enhancement function is chosen for t_2 which the signal-to-noise permits.
[e]Symmetrization was not possible with the 2D J-resolved data, but would be recommended where the software is available.

The 2D J-resolved experiment did not prove very useful and these data are not included here. It would have been particularly useful in the —OCH$_3$ signal region. However, the overlapping H-16 resonance remained obscured by the familiar "tailing" in F_1 from the intense —OCH_3 singlets. The partial J-spectrum of the hidden H-18 resonance was not useful, since it suffered from the same virtual coupling effects as the other H-18 resonance at δ 2.83, making the extraction of accurate coupling constant data impossible without spectral simulation. (The geminal H-17 protons, to which they are vicinal, are tightly coupled.) The solid-state conformation determined by X-ray crystallography (18) was used to build a molecular model having the correct configuration. This was found to be a rigid structure, suggesting that the solution conformation might be very similar to that in the solid state. The experiments required to complete these ^{1}H assignments also served to corroborate this postulated solution conformation.

In the determination of conformation, techniques relying on "through-space" phenomena (e.g., T_1, nOe) prove very useful, often in conjunction with (through-bond) coupling-constant information. Axial protons taken on unusual importance in an nOe experiment. The 1,3 diaxial interaction provides important information in a six-membered ring and, with a boat conformation, the "flagpole" protons are close to one another in

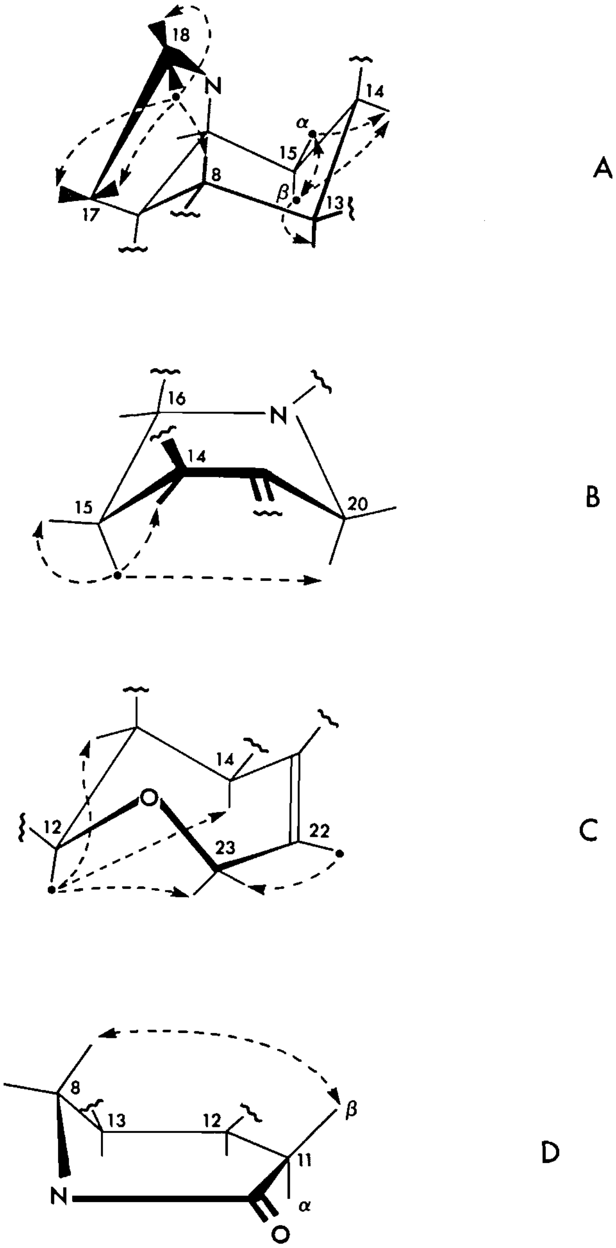

FIG. 4. Conformations of rings IV and V (A), VI (B), VII (C), and III (D) in brucine, indicating some of the results from the SSNOEDS experiments. The irradiated proton is indicated with (●) and nOe's (---).

spite of their being 5 bonds removed; an nOe experiment will also detect this.

The SSNOEDS results are presented in Fig. 3. No special effort was made to optimize the experiment and the data were collected in approximately 3 hours. A single decoupler power setting was used (which resulted in 40–80% saturation, depending on the total multiplet width). In all cases a check was made for decoupler power leakage into neighbouring resonances ("spillover"), and was found to be absent. The irradiation time was set at 0.5 s,[8] and the experiments "interleaved" by collecting scans in blocks of 16, repeated 30 times.

Let us consider ring IV, which is in a chair conformation in the solid state (Fig. 4A). Evidence for this also being so in solution comes from a consideration of coupling constants, and nOe experiments. J (8, 18) = 10.5 Hz, which indicates a *trans* or *cis* arrangement of the two protons. In keeping with the chair conformation, H-14 and H-16 are judged to be roughly coplanar since J (14, 15α) ≈ J (16, 15α), and J (14, 15β) ≈ J (16, 15β).[9] Strong confirmatory evidence for the proposed conformation[9] comes from the SSNOEDS experiment where H-15 (δ 1.46) was irradiated, inducing an nOe in H-13; the two protons must assume axial orientations in a ring having a chair conformation, and the irradiated proton is accordingly assigned to H-15β. Irradiation of the higher field of the two H-18 protons induced an nOe in H-8, thereby identifying the proton irradiated as H-18β, and H-8 to be axial, as depicted in Fig. 4A. Consider now ring VI. Since the H-20 protons have no vicinal neighbours, no conformational information can be sought from arguments based on vicinal coupling constants. The nOe experiment where H-15α was irradiated induced a strong nOe in the lower field of the two H-20 resonances. This confirms the approximate "boat" conformation of this ring (Fig. 4B), which placed the "flagpole" protons, H-15β and H-20α, close to one another; this is a "bowsprit–flagpole" interaction. Hence, this single experiment confirms the expected conformation of ring VI, and identifies H-20α (and H-20β, by default).

The analysis of ring VII was complicated somewhat by the fact that it is a seven-membered ring, with a double bond and ring hetero-atom.[10] Two nOe experiments were performed to support the structure shown in Fig. 4C. Irradiation of the vinylic H-22 induces an nOe into the pseudo-equatorial proton H-23β, the lower field of the two H-23 protons. Additionally, an nOe is induced in H-20β. Although not depicted in this diagram, H-22 and H-20β are close to one another and this confirms the assignment of the geminal H-20 protons based on the irradiation of H-15α. Irradiation of H-12 induces an nOe into other axial or axial-like protons: H-14 and H-23α.[11] The assignment of the H-23 protons is now confirmed.

The conformational analysis of ring III is more complex. Here the H-11α and H-11β protons must be assigned. The molecular model favours a boat-like conformation. A pure boat conformation would make H-12 and H-11β *trans* diaxial, and one would anticipate a large vicinal coupling constant here on the basis of the Karplus relationship; using this argument, the lower field of the two H-11 protons would be assigned to H-11β. The geminal coupling constant J (11α, 11β) is, at 17.4 Hz, unusually large. This suggests that the carbonyl on C-10 roughly bisects the angle between the geminal protons and C-11 (19), and this would *not* be the case if ring III were to be in the pure boat conformation considered above. Satisfying the condition of the relationship between the carbonyl and geminal protons "flattens" one end of the boat, placing N-9, C-10, C-11, C-12, and C-13 approximately co-planar. In this situation H-12 and H-11α have a small dihedral angle (ca. 10°), and, hence, a large vicinal coupling constant would be antici-

[8]This is far less than the time usually used for nOe build-up (ca. 3* T_1), and was chosen to minimize the experimental acquisition time and "three spin effects," without jeopardizing the observation of "direct" interactions.

[9]The H-15 protons are assigned here to allow the reader to check the statement with the reported data in Table 2, but the absolute assignment of the H-15 protons is not necessary at this stage.

[10]This is a tetrahydro-oxepin ring.

[11]Here, a negative nOe is induced in H-23β due to the "three-spin effect" (12).

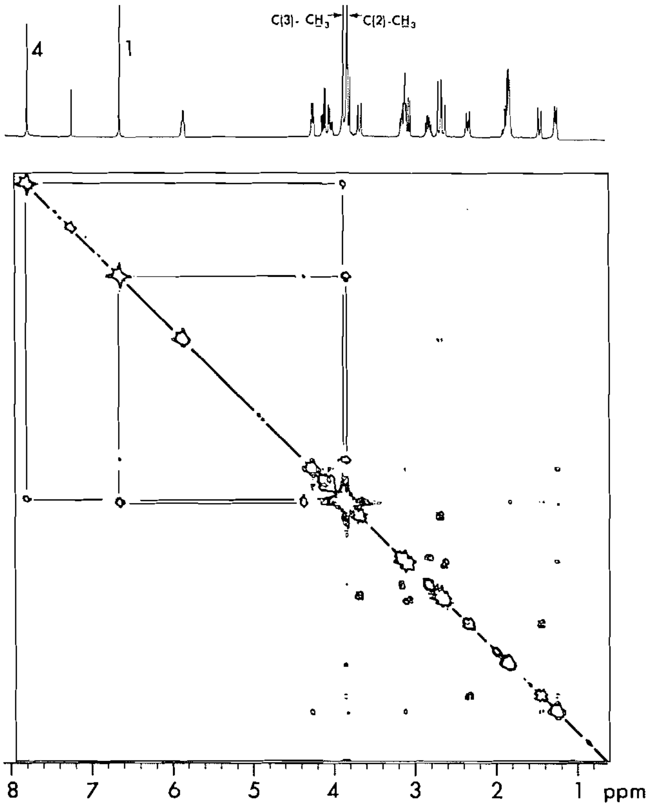

FIG. 5. 400-MHz NOESY spectrum of brucine. The 256 * 1K data matrix was collected in ca. 8 h, with relaxation delay 3.0 s, mixing time 0.6 s ± 10% and 32 scans per t_1 interval. The data were processed and plotted using a Nicolet 1280 computer and Zeta 8 recorder. The final digitization was 5.8 Hz pt^{-1} in both dimensions, after zero-fitting in F_1; the "sinebell" multiplier was used in both dimensions, and magnitude spectra calculated.

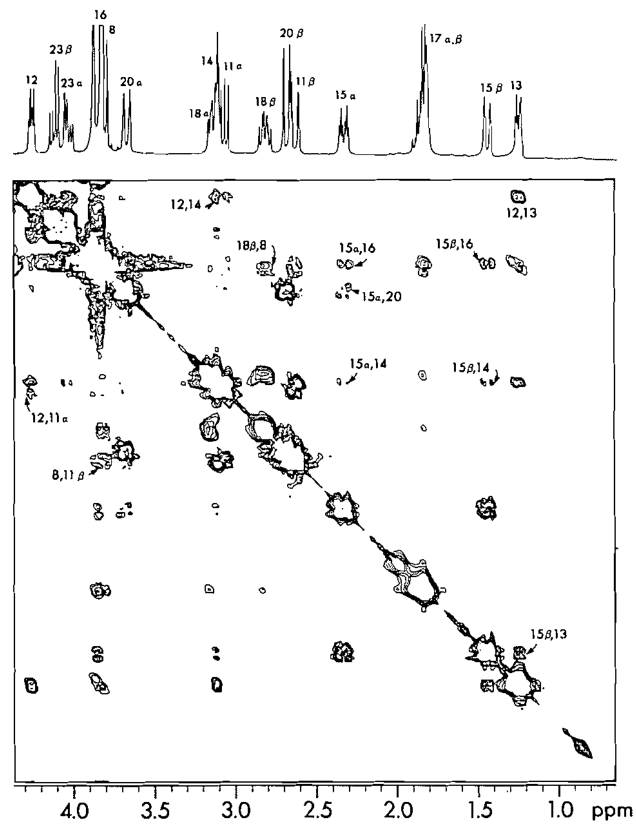

FIG. 6. The high-field region of the NOESY spectrum in Fig. 5.

pated. This argument assigns the *lower field* of the two H-11 protons as H-11β — a reversal of assignment. It is clear that in both cases H-8 and H-11β are close in space, and an nOe experiment would not suffer from these ambiguities. The H-11 protons could be assigned, and on this basis the ring conformation determined from the coupling-constant arguments.

The SSNOEDS experiment (*vide supra*) was not possible here, since all three protons — H-8, H-11α, and H-11β — overlap with other resonances, precluding decoupler irradiation selectivity. A 2D NOESY experiment was performed, and the resultant data are given in Figs. 5 and 6. Figure 5 shows the NOESY spectrum over the entire spectral width, and Fig. 6 shows the high-field portion of this data in more detail; we concentrate on the latter, for the moment. Before searching for the 8-11β nOe, it is worth checking the experiment by looking for the nOe's determined previously using SSNOEDS. These are all clearly discernable and are indicated in the upper half of Fig. 6. A number of nOe's with H-16 are clear here that were not in the 1D experiments, as a result of being obscured by subtraction errors with the overlapping sharp $O\text{-}CH_3$ singlets.

The 8-11β nOe correlation is discernable, assigning H-11β as the higher field of the H-11 resonances. This is in accord with the second argument above using vicinal and geminal *J*-coupling magnitudes and suggests a boat-like conformation, flattened at C-11 (see Fig. 4D). This is confirmed by the observation of a larger nOe between H-12 and H-11α than H-12 and H-11β.

The NOESY spectrum also provides the means for the assignment of the aromatic and *O*-methyl signals. The relaxation of H-4 would likely be dominated by the $O\text{-}CH_3$ protons on C-3, and H-1 by those on C-2. H-1 has additional relaxation contributions from H-16 and H-17α. Figure 5 shows the nOe between the aromatic and the *O*-methyl protons. Correlations between an aromatic proton and protons on ring V are below the contour threshold; slices taken at each aromatic proton's chemical shift (not shown) identify the higher field of the two aromatic resonances as that of H-1, by the above reasoning. The nOe with H-17 is not clear, as its cross peak overlaps with the strong corelation to the *O*-methyl resonance. Further, the *O*-methyl resonances are easily assigned; the higher field of the two singlets corresponds to the *O*-methyl on C-2 and the lower field to that on C-3.

The final assignments of the ^1H nmr spectrum of brucine are compiled in Table 2. These data are in complete accord with recent reports for strychnine (17, 20).

We have seen that the COSY experiment was sufficient to perform the bulk of the analysis of the ^1H nmr spectrum of brucine. The 1D and 2D nOe experiments assigned individual geminal protons and provided valuable conformational information.

Now, the ^{13}C spectrum was analysed. A ca. 0.3 *M* solution of brucine in $CDCl_3/CD_3OD$ (10:1) was prepared.[12] First, the number of protons attached to each carbon was determined using DEPT. This might have been redundant because a CSCM experiment was planned; however, in this case not all methylene protons have very different chemical shifts (*vide infra*).

[12]The proton nmr spectrum was essentially identical to the one for the more dilute $CDCl_3$ solution, used for the ^1H nmr experiments.

TABLE 2. Summarized ^1H nuclear magnetic resonance chemical shift assignments and coupling constants of brucine in $CDCl_3$ (ca. 0.02 *M*)[a]

Proton	δ (ppm)	*J* (Hz)
1	6.66	—
4	7.80	—

[a,b]May be interchanged.

The CSCM experiment required 45–60 min for data collection. The CSCM spectrum of the interesting regions of δ_C 22–80 and δ_H 1.0–4.5 is shown in Fig. 7. (All assignments outside this region are unambiguous.) The DEPT information is included. Knowing the proton assignments, the indicated carbon assignments were made. In only two cases was there any uncertainty. H-8 and H-16 resonate very close to one another, making the assignment of the carbon signals around δ 59 difficult. The carbon signals around δ 41 are very close and

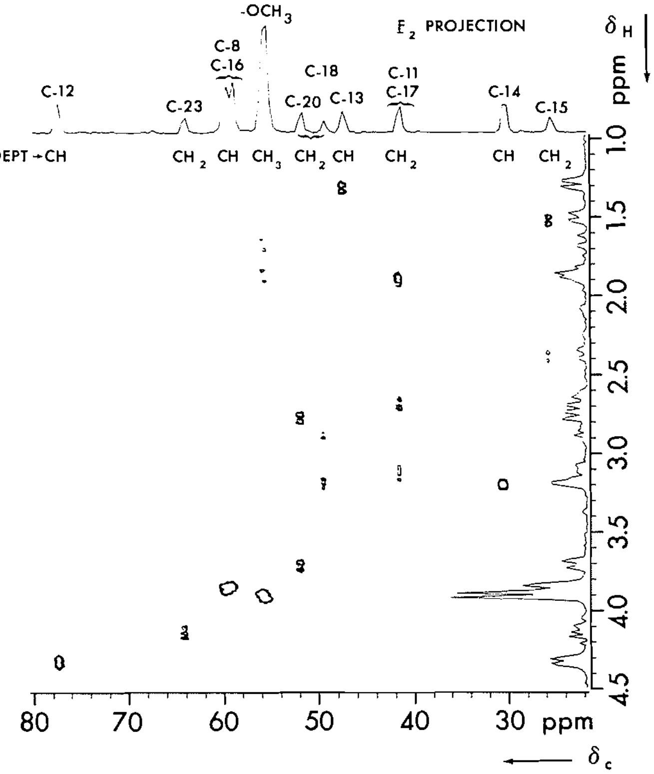

FIG. 7. 360-MHz ^1H CSCM experiment with brucine (ca. 0.3 *M* in C_6D_6/CD_3OD, 10:1). δ_C 22–80 and δ_H 1.0–4.5 is plotted in the contour mode. F_1 and F_2 projections are on the abscissa and ordinate, respectively. The results from the DEPT experiments are indicated under each ^{13}C peak.

insufficiently digitized in this case. Hence, C-11 and C-16 cannot be distinguished.

No attempt was made to assign quaternary carbons since this would not fall within the scope of the present design protocol. The data from the CSCM is compared with that of Srinivasan and Lichter (21) – that referred to whilst the work was in progress – and the now accepted assignments of Verpoorte (22). Our results are in complete agreement with the latter. These data are compiled in Table 3.

Summary

Several conclusions can be drawn from this study. First, only modest amounts of spectrometer time are necessary for the partial assignment of the ^1H nmr spectrum of a medium sized molecule such as brucine; in this case a total of ca. 2 h for the 2D *J*-resolved and COSY experiments and an additional 3–8 h for the complete spectroscopic and conformational assignment. Additional conformational information plus the assignment of individual geminal protons result from nOe experiments. Where the selective irradiation experiments can be performed, the SSNOEDS experiment is probably the most expeditious route. In the case of signal overlap, the 2D NOESY experiment will provide all the necessary relaxation pathway information in a single experiment, but with greater demands on spectrometer time. This investment of time is offset by the fact that all possible nOe experiments are "simultaneously" performed, resulting in a high return being realized in terms of information yield.

With the proton spectrum assigned at least to the point before nOe experiments are performed, non-quaternary resonances in the ^{13}C nmr spectrum can be routinely assigned providing they are not too close (ca. > 0.1 ppm) and the attached proton resonances are not badly overlapping. The ability to distinguish resonances with small chemical shift differences is limited by the intrinsic line width, the spectrometer's data storage capability, and the available spectrometer and data processing time. Within these restrictions, the data presented in Fig. 7 were acquired under conditions where the digitization in the ^{13}C frequency domain was less than optimal and resonances <0.7 ppm apart were not resolved.

We believe that the 2D *J*-resolved and COSY experimental data can be collected and processed in a highly efficient, integrated fashion, without the prior knowledge of the chemical system. The nOe data might require some educated guesswork in the selection of an irradiation time (SSNOEDS experiment) or the mixing time (NOESY), or a series of exploratory experiments could be performed. All the experiments described in this study provided the required information from the data collected the first time it was performed.

Hurd (23) has independently reported on the utility of the combination of COSY with the CSCM experiment. It is advantageous to use a ^{13}C probe to measure both the ^{13}C and ^{1}H spectra (the latter via the ^{1}H decoupler coil). In this way the COSY assignment (and NOESY, if required) is for the molecule at the same concentration as for the CSCM experiment and no time is expended changing probes. This approach has the further merit that with automated changeover of the probe circuits, it is possible to automate the acquisition and processing of all ^{1}H and ^{13}C data into a single (overnight) run. Given its high efficiency, it seems probable that the mode of analysis described in this study will find a place for those organic structural investigations that warrant more than a few, disrelated nmr measurements.

Acknowledgments

This work was supported by operating grants from the Natural Sciences and Engineering Research Council of Canada (A 1905 to LDH). Many of the measurements were made using a 360-MHz spectrometer located in the Nicolet applications laboratory; we are indebted to Nicolet for their generous hospitality and in particular wish to thank Dr. Ralph Hurd and Dr. L.F. Johnson for numerous stimulating discussions.

Reçu le 24 février 1984

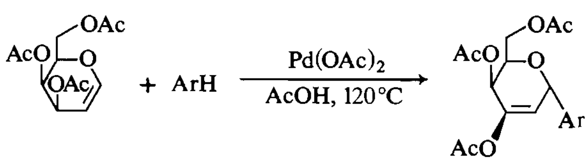
HÉLÈNE GILLIER-PANDRAUD, RACHID BRAHMI, VÉRONIQUE BELLOSTA-DECHAVANNE et STANISLAS CZERNECKI. Can. J. Chem. **63**, 491 (1985).

La structure du tri-*O*-acétyl-3,4,6-désoxy-2-α-D-*thréo*-hexéno-2-pyrannosyle benzène **1** a été déterminée par diffraction des rayons X. Les cristaux de **1** sont orthorhombiques et appartiennent au groupe d'espace $P2_12_12_1$ avec a = 22,946(10), b = 10,319(6), c = 7,684(4) Å, V = 1819,42 Å^3, Z = 4, ρ_c = 1,27 g cm^{-3}. La conformation du cycle glucidique est demi-chaise $^0H_5$ dans laquelle le noyau aromatique est quasi-axial. Le carbone anomère possède la configuration α. La comparaison des données de rmn ^{1}H avec les données cristallographiques a permis d'établir que la conformation de **1** en solution est très vite voisine de celle adoptée à l'état cristallin.

HÉLÈNE GILLIER-PANDRAUD, RACHID BRAHMI, VÉRONIQUE BELLOSTA-DECHAVANNE, and STANISLAS CZERNECKI. Can. J. Chem. **63**, 491 (1985).

The structure of 3,4,6-tri-*O*-acetyl-2-deoxy-α-D-*threo*-hexeno-pyranosyl benzene **1** has been determined by X-ray diffraction methods. Crystals of **1** are orthorhombic, space group $P2_12_12_1$ with a = 22.946(10), b = 10.319(6), c = 7.684(4) Å, V = 1819.42 Å^3, Z = 4, ρ_c = 1.27 g cm^{-3}. The sugar moiety exhibits a half-chair $^0H_5$ conformation in which the aromatic ring is quasi-axial. The anomeric carbon has the α configuration. The comparison of the ^{1}H nmr data with the crystallographic data established that, in solution, the conformation of **1** is very similar to that in the crystalline state.

L'arylation des glycals peracétylés catalysée par les sels de palladium constitue une nouvelle méthode de synthèse de *C*-glycosides (1). Appliquée au tri-*O*-acétyl-3,4,6-anhydro-1,5-désoxy-2-D-*lyxo*-hexène-1-itol (tri-*O*-acétyl-D-galactal), elle conduit à des *C*-glycosides insaturés, selon la réaction:



La structure de ces composés a été déterminée par les méthodes spectroscopiques classiques (1) exceptée la configuration du carbone anomère. En effet, à cause de la présence d'une double liaison entre les carbones C-2 et C-3, l'examen du spectre de rmn ^{1}H ne permet pas de trancher, car le couplage $^3J_{1,2}$ se fait à travers un carbone hybridé sp^2 et la valeur observée (3,9 Hz) est compatible avec les deux configurations, sans préjuger de la conformation. D'autre part, comme la réaction est stéréospécifique, nous ne possèdons qu'un seul des anomères, et, de ce fait, l'utilisation du pouvoir rotatoire ne peut être que spéculative. En effet, si les *C*-glycosides pyranniques suivent, en général, les règles de Hudson (2), des exceptions concernant des composés à cycle pyrannique insaturé ont été cependant signalées (3).

Aussi la structure du tri-*O*-acétyl-3,4,6-désoxy-2-α-D-*thréo*-hexèno-2-pyrannosyle benzène, **1** (Ar = Ph), a-t-elle été déterminée par diffraction des rayons X et corrélée avec les données de rmn ^{1}H pour écarter toute ambiguité en ce qui concerne la stéréochimie de la réaction.

Partie expérimentale

Les cristaux, obtenus par recristallisation dans l'éthanol 95% se présentent sous l'aspect de petites plaquettes transparentes allongées. Les paramètres de la maille orthorhombique ont été déterminés sur diffractomètre automatique Philips PW 1100 à partir de 24 réflexions telles que $20 < \theta < 50°$ pour λCu Kα.

Les données de diffraction, enregistrées en premier lieu avec le rayonnement MoKα, ont été mesurées à nouveau avec celui du cuivre en raison du pouvoir diffractant limité des cristaux, dans les conditions suivantes: λCuKα monochromatisée, $2\theta_{max}$ = 138°, $-27 < h < 27$, $0 \le k < 12$, $0 \le l < 9$, balayage θ/2θ, μ = 8,36 cm^{-1}. Sur les 3989 intensités mesurées, 1964 étaient indépendantes. Parmi celles-ci 1786, telles que $I > 2\sigma(I)$, ont été déclarées observées.

La mise en oeuvre de la chaîne de programmes MULTAN (4) a fourni les positions des atomes de carbone et d'oxygène qui ont été affinées par moindres carrés dans l'hypothèse d'une agitation thermique isotrope puis anisotrope (X RAY (5)). Les atomes d'hydrogènes ont été localisés sur des séries de Fourier différence et pris en compte dans les derniers cycles d'affinement, leurs paramètres restant toutefois bloqués. Le facteur R final non pondéré est de 0,08 (valeurs maximale et moyenne du rapport déplacement/erreur: 0,9 et 0,3), S = $[\Sigma W(F_o - F_c)^2/(m - n)]^{1/2}$: 10,2. La densité électronique résiduelle est de l'ordre de 0,3 e Å^{-3}.

Les coordonnées et le B équivalent[1] des atomes de carbone et d'oxygène sont donnés dans le tableau 1.

Le spectre de rmn a été enregistré dans $CDCl_3$ à 250 MHz sur un appareil Brücker en utilisant le tétraméthylsilane comme référence interne: 7,3–7,5 (5H, s, H aromatiques), 5,54 (H-1, d, J_{1-2} = 3,9

[1] Les valeurs des six coefficients d'agitation thermique anisotrope de chacun de ces atomes et les coordonnées des atomes d'hydrogène ont été déposées et peuvent être obtenues à un prix nominal, en s'adressant au Dépôt de données non publiées, ICIST, Conseil national de recherches du Canada, Ottawa, Ont., Canada K1A 0S2.

Hz), 6,07 (H-2, d), 5,44 (H-4, d, J_{4-5} = 1,5 Hz), 4,19 (H-6, dd, J_{5-6} = 9 Hz), massif centré à 4,07 (H-5 et H-6'), 1,96–2,14 et 2,18 (3s, 3 × $OCOCH_3$).

Résultats et discussion

La figure 1 donne la représentation de la molécule, dessinée à l'aide du programme ORTEP (6), et précise le numérotage adopté pour les atomes. Les valeurs des distances interatomiques et lès angles de valence sont présentées dans les tableaux 2 et 3 respectivement.

Conformation dans le cristal

Le cycle du composé étudié, **1**, adopte la conformation demi-chaise $^{0}H_5$ dans laquelle les atomes C(1), C(2), C(3) et C(4) déterminent un plan (π) de part et d'autre duquel se situent les atomes C(5) et O(5) aux distances respectives de 0,32(1) et de 0,44(1) Å (fig. 2 et tableau 4). Cette conformation de cycle se retrouve dans les composés analogues suivants qui peuvent être comparés à **1**: le tri-*O*-acétyl-1,4,6-*N*-acétylacétamido-2-didésoxy-2,3-α-D-*thréo*-hexéno-2-pyrannose **2** (7*a*), le di-*O*-acétyl-4,6-didésoxy-2,3-α-D-*thréo*-hexéno-2-pyrannoside de méthyle **3** (7*b*), le (methyl *N*-acétylamino-2-*O*-acétyl-6-tri-désoxy-2,3,4-β-D-*thréo*-hexéno-2-pyrannosidyle-4)-7 théophylline **4** (7*c*) et le (*O*-acétyl-4-didésoxy-2,3-β-L-*glycéro*-pentèno-2-pyrannosyl)-2-dichloro-5,6-benzotriazole **5** (7*d*).

Pour le composé **1**, la configuration de l'atome C(1) est telle que le noyau benzénique qui lui est lié se situe de l'autre côté du plan moyen π par rapport à C(6): elle correspond donc à l'anomère α qui, du fait de la conformation du cycle éno-pyrannique, impose la position axiale au noyau benzénique.

Le plan π et celui du benzène sont proches de l'orthogonalité (81, 7(7)°). Cette valeur est en bon accord avec celle trouvée pour les éno-2-pyrannosides **4** et **5** qui sont liés à un hétérocycle en α de la double liaison (7*c*, *d*). L'orientation du noyau aromatique autour de la liaison hétérocyclique C(1)—C(7) (fig. 3) l'amène à s'engager sous le cycle éno-pyrannique du côté où la coplanéité de C(1), C(2), H(2), C(3) et C(4) résultant de la présence de la double liaison occasionne une répulsion moindre. Ce phénomène est encore plus prononcé dans le cas de **5** (7*d*), car le cycle triazole est moins volumineux qu'un noyau aromatique.

O(6)—C(17)	1,366(9)	C(17)—O(9)	1,173(10)

La conjugaison entre la double liaison cyclique et le groupe acétyle porté par l'atome C(3) devrait assurer la coplanéité entre ce groupe et le plan π. Il n'en est rien, puisque l'angle entre les deux plans est de 74(7)°. Une situation analogue se présente avec le dérivé **2** dont l'atome C(2) est porteur d'un groupe *N*-acétyl-acétamide. Dans ce cas, l'absence de co-planéité (angles dièdres de 79,3 et 74,7°) se justifie par un encombrement stérique très important.

La configuration de l'atome C(4) met en position axiale le groupe acétyle qui lui est lié. L'épimérisation qui était à craindre pour un acétate allylique en présence de sel de palladium ne s'est donc pas produite. Le plan de ce groupe acétyle est quasi-orthogonal au plan π (85(7)°). L'augmentation de cette valeur par rapport à celle observée pour les dérivés désoxy-3, **2** et **3** qui possèdent également un acétoxy en

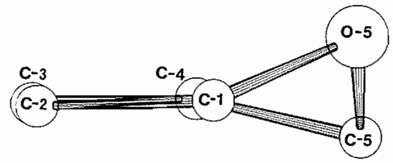

FIG. 2. Vue du cycle énopyrannique suivant la direction de C(2)—C(3).

position allylique (7*a*, *b*) est attribuable à la répulsion entre les groupements acétoxy en C(4) et C(3) dans le composé **1**.

La conformation autour de la liaison C(5)—C(6) qui met O(6) en position *gauche-trans* respectivement par rapport à O(5) et C(4) pour les trois composés **1**, **2** et **3**, a été signalée comme la plus probable pour les résidus galactopyrannosyles (8).

Conformation en solution

L'examen des données de rmn ^{1}H à 250 MHz du composé **1** permet de conclure que celui-ci adopte également la conformation demi-chaise $^0H_5$ en solution. En effet, il existe un bon accord entre les valeurs expérimentales des constantes de couplages ^3J et les valeurs calculées à partir des angles dièdres mesurés dans le cristal. De plus, nous n'avons pas observé de modifications notables du spectre à basse température (90 MHz, −60°C) ce qui montre que la molécule n'est pas en équilibre conformationnel rapide.

TABLEAU 4. Angles de torsion énopyranniques

	Angle (deg)
O(5) C(1) C(2) C(3)	17,7 (5)
C(1) C(2) C(3) C(4)	1,1 (5)
C(2) C(3) C(4) C(5)	12,1 (5)
C(3) C(4) C(5) O(5)	−45,7 (5)
C(4) C(5) O(5) C(1)	68,7 (5)
C(5) O(5) C(1) C(2)	−52,5 (5)

Pour les constantes de couplage des protons H-4, H-5, H-6 et H-6′, mis à part $^3J_{5,6'}$ que nous n'avons pas pu déterminer car H-5 et H-6′ ont des déplacements chimiques très voisins, les valeurs expérimentales ($^3J_{4,5}$ = 1,5 Hz et $^3J_{5,6}$ = 9 Hz) sont en bon accord avec les valeurs calculées ($^3J_{4,5}$ = 0,8 Hz, $^3J_{5,6}$ = 9 Hz et $^3J_{5,6'}$ = 3,1 Hz) à l'aide de la relation de Altona et Haasnoot (9) pour la conformation décrite.

Le couplage $^3J_{1,2}$ se faisant à travers un carbone hybridé sp^2 mérite un commentaire particulier. En effet, dans ce cas, la relation la plus utilisée pour calculer la constante de couplage en fonction de l'angle dièdre ψ est celle de Garbisch (10) ($^3J = 4\cos^2\psi + 2{,}6$; $0 \le \psi \le 90°$). En l'appliquant au composé **1** avec la valeur de ψ mesurée dans le cristal (ψ = 42°), on trouve $^3J_{1,2}$ calc. = 4,8 Hz ± 0,15 en tenant compte de la valeur de l'écart type sur l'angle ψ, alors que la valeur mesurée est plus faible ($^3J_{1,2}$ exp. = 3,9 Hz). Avant de conclure à des déformations de la molécule, il faut remarquer que Baer et Hanna (11) et Anet (12) avaient déjà noté que la constante 2,6 était vraisemblablement trop grande dans cette relation. De plus, celle-ci a été établie pour des hydrocarbures et, ne prenant pas en compte la nature des groupements fixés sur la double liaison, elle ne convient pas pour calculer des valeurs de constante de couplage dans le cas des énopyrannosides.

En revanche, en utilisant la relation publiée plus récemment (13) dans laquelle un terme correctif a été introduit pour essayer de tenir compte de l'environnement chimique, on trouve une valeur ($^3J_{1,2}$ = 3,6 Hz ± 0,05) qui est en bon accord avec la valeur expérimentale.

On the structure of rubrifacine[1]

Gottfried Feistner[2] and Herbert Budzikiewicz
Institut für Organische Chemie, Universität zu Köln, Greinstr. 4, 5000 Köln 41, West Germany

Received January 9, 1984

Gottfried Feistner and Herbert Budzikiewicz. Can. J. Chem. **63**, 495 (1985).

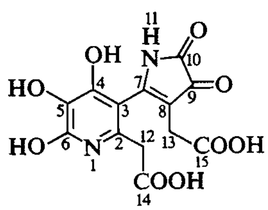
Evidence is presented that rubrifacine, the red pigment of *Erwinia rubrifaciens*, is 3-(3-carboxymethyl-4,5-dihydro-4,5-dioxo-2-pyrrolyl)-4,5,6-trihydroxypyridine-2-acetic acid, based on mass spectrometric and nmr data of rubrifacine, its hydrolysis and reduction products as well as their methyl derivatives.

Gottfried Feistner et Herbert Budzikiewicz. Can. J. Chem. **63**, 495 (1985).

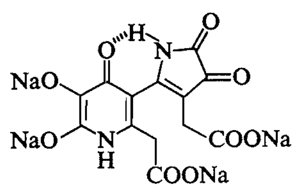
En se basant sur des données de spectrométrie de masse et de rmn obtenues avec la rubrifacine et ses dérivés méthylés, sur la nature de leurs produits d'hydrolyse et de réduction, on présente des données qui permettent d'affirmer que la rubrifacine, le pigment rouge de la *Erwinia rubrifaciens*, est l'acide (carboxyméthyl-3 dihydro-4,5 dioxo-4,5 pyrrolyl-2)-3 trihydroxy-4,5,6 pyridineacétique-2.

[Traduit par le journal]

Recently we reported on the isolation and characterization of rubrifacine, a red pigment of *Erwinia rubrifaciens* (1). Mass spectrometric analysis had established a molecular weight of 338 u and nmr measurements had shown that the compound contained thirteen carbon atoms two of which were in isolated methylene groups (Table 1). Here we want to present further analytical results which led us to assign formula **1** to rubrifacine.



1



1*a*

Results

Determination of the empirical formula

Permethylation of rubrifacine with CH_2N_2 yielded two colorless, uv-active compounds which according to high resolution mass spectrometry (HMS) possess the elemental compositions $C_{21}H_{26}N_2O_9$ (**2**) (m/z 450) and $C_{20}H_{24}N_2O_9$ (**3**) (m/z 436), respectively. Comparison with the molecular weight of **1** (m/z 338) showed that seven and eight CH_2 units, respectively, had been introduced. From this it was possible to calculate an empirical formula $C_{13}H_{10}N_2O_9$ for the parent compound **1**. Taking into account that four hydrogen atoms are contained in the two methylene groups (v. supra), only six acidic hydrogens can be present in **1**. Therefore the seventh methylene unit must have been inserted into the chromophore, most likely in the pyrrolindione ring which undergoes expansion to a 3-hydroxy-2-pyridone and further derivatization to a 3-methoxy-2-pyridone. Such reaction sequences have been established for isatin **4** and coumarandione **5** (4).

Determination of functional groups

By incomplete methylation with CH_2N_2 a tetramethyl derivative **6** was obtained with a still intact chromophore. The electron impact mass spectrum (EI-MS) of **6** showed (besides some loss of $CH_3^{\cdot}$) twice the loss of $CH_3O^{\cdot}/CH_3OH$ (31/32 u) followed by the loss of CO (28 u) typical for carbomethoxy groups. No other fragmentation of importance was observed, especially none which yielded N_1-products. This excluded structural formulas with a nitrogen atom in a peripheral functional group. The two nitrogens had to be elements of a conjugated ring system and the methylene groups could only be incorporated in side chains probably terminated by the aforementioned carbomethoxy groups. The existence of —CH_2—COONa groups in the sodium salt of rubrifacine **1*a*** was supported by the ^{13}C chemical shifts of 181.3 and 181.4 ppm (Table 1) close to that of tetramethylammonium acetate (181.4 ppm (5)).

Table 1. Tentative assignment of ^{13}C chemical shifts of rubrifacine **1*a*** (sodium salt) and its hydrolysis product **7*a*** (sodium salt), both in H_2O (reference CD_3OD δ 49.0)

Hydrolysis of rubrifacine

Rubrifacine **1** was easily hydrolyzed with discoloration by

[1] Part XIX of the series "Bacterial constituents". For Part XVIII see ref. 1, Part XVII ref. 2, Part XVI ref. 3.

[2] To whom all correspondence should be addressed. Present address: Department of Bacteriology, University of California, Davis, CA 95616, USA.

1 *N* KOH whereby two carbon atoms were lost. This could directly be seen from the ^{13}C-nmr spectrum of the product **7** (Table 3; for **7***a*, sodium salt of **7** see Table 1). Correspondingly, HMS of its tetramethyl derivative **8** gave the elemental composition $C_{15}H_{19}NO_8$ which also indicated the loss of one nitrogen. By HMS only one nitrogen-free fragment ion with a mass > 100 u could be identified, viz. *m/z* 115, which will be discussed below. From this we concluded that the remaining nitrogen had to be part of an aromatic ring. For the ^{13}C signals of this heteroaromate, except for that of C-2, one can easily find a pendant among those of the intact pigment. Apparently this aromatic ring is little effected by hydrolysis. The elemental composition as well as the mass spectrometric and chemical behavior made the presence of a trihydroxy pyridine ring very likely, which has been substantiated (v. infra) by comparison with an authentic compound. As a recent ^{13}C-nmr investigation of nicotine metabolites (6) shows, the difference in the chemical shifts of C-2 cannot be accounted for by the newly generated carbonyl group per se. However, **1***a* and **7***a* do not exist necessarily in the same tautomeric form. ^{13}C data of various isomeric hydroxy and methoxy pyridines have been published (7), but too little is known about the influence of two negative charges on the ^{13}C chemical shifts of such heterocycles to allow assignment of definitive tautomeric structures for **1***a* and **7***a*.

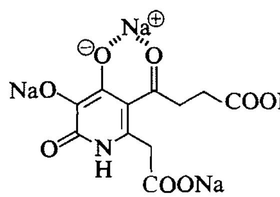
13, R_{1-5} = Me



7a

The side chains of 7

Whereas rubrifacine (**1***a*) showed ^{13}C signals for two isolated methylene groups, only one was retained as such in its hydrolysis product **7** while the other one had become part of a —CH_2—CH_2— unit. This was concluded from the presence of an AA′BB′-system in the ^1H-nmr spectrum as well as from the ^{13}C-nmr spectrum (Tables 1–3). The ^{13}C-nmr spectrum also showed the generation of an α,β-unsaturated carbonyl function (192 ppm). Altogether this led to a partial structure Ar—CO—CH_2—CH_2—CO_2H which was confirmed by mass spectrometric comparison of **7**-dimethylester **9** with two differently deuterated derivatives, **10** and **11**. α-Cleavage of the side chain led to CH_3O_2C—CH_2—CH_2—CO^+ (*m/z* 115), CH_3O_2C—CH_2—C^2H_2—CO^+ (*m/z* 117), and $C^2H_3O_2C$—CH_2—CH_2—CO^+ (*m/z* 118), respectively. If one assumes that the aromatic portion of **7** is a trihydroxy pyridine ring the other —CH_2—COOH group postulated has to be attached directly to the ring.

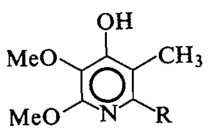
Substitution pattern of 7

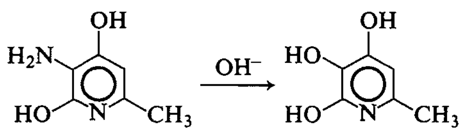
Three hydroxy groups can be placed in six different arrangements around the pyridine ring (two of which are symmetrical) which would give ten (4 × 2 and 2 × 1) possible isomeric structures for the hydrolysis product. Of these only one, viz. **7**, is in accordance with the observed splitting pattern in the ^1H coupled ^{13}C-nmr spectrum which shows three non-coupling carbon atoms. Since the $^2J(C_{py}—CH_2)$ and the $^3J(C_{py}—C_{py}—CH_2)$ coupling constants are both to be expected in the range of 4–7 Hz (8) the —CH_2—COOH group cannot be located in a β- or γ-position because in either case only two non-coupling carbons should be observed. The four-carbon side chain has to be in the β-position neighboring the acetic acid group: in any other position $^3J(C_{py}—CO—CH_2)$ coupling would result in the splitting of a further ring carbon.

Comparison of 7 with piericidins (9, 10) of known structure

Piericidins (**12**) and our tetramethyl derivative (**8**) possess the same 2,3-dimethoxy-4-hydroxypyridine partial structure. The ^1H chemical shifts for the methoxy groups of **12** and **8** are in good agreement (Table 2). That indeed the 2,3-dimethoxy derivative **8** and not the 2,4- or 3,4-dimethoxy derivative had been obtained upon methylation can be seen from the chemical shift (4.07 ppm) of the γ-methoxy group in the pentamethyl derivative **13** caused by the anisotropy of the side chain carbonyl function. The ^{13}C data (Table 3) exclude any *N*-methylation as no δ($N\text{-}CH_3$) ≤ 50 ppm is observed (7). Moreover, the ^{13}C data of **8** are in good agreement with those for **12** except for differences for the γ-C-atom which must be the result of hydrogen bridging with the exocyclic carbonyl function. In order to study the interaction of the underivatized phenolic functions in **7** and its influence on the ^{13}C chemical shifts of the trihydroxy pyridine ring, we have synthesized 2,3,4-trihydroxy-6-methyl-pyridine **15** according to the procedure of Lapworth and Collie (11) which has recently been repeated by Findlay *et al.* (12). However, we encountered difficulties in converting 3-amino-2,4-dihydroxy-6-methylpyridine **14** to 2,3,4-trihydroxy-6-methylpyridine **15**, as we obtained mainly the dimerization product mentioned in the literature (11) and only a few milligrams of **15** which did not allow us to obtain a $^{13}C-^{1}H$ coupled ^{13}C-nmr spectrum needed to unambiguously assign δ = 139.1 ppm to C-4 of **15**. This will be the subject of further investigations.



12, R = modified isoprenyl side chains



14 **15**

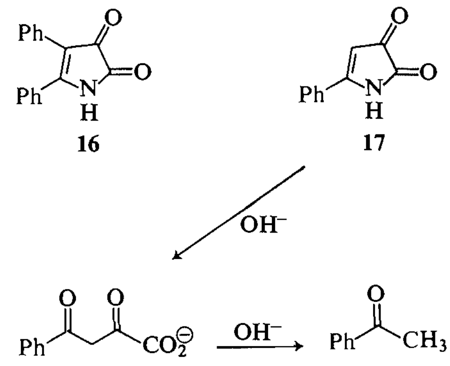
The nature of the second ring

The exocyclic carbonyl function of the hydrolysis product **7** probably stems from an imino function in **1**. The —CH_2— group neighboring the carbonyl function is most likely the one which has been generated during hydrolysis. This could result from a retro-Claisen cleavage of a β-diketone. Taking into account the chemical composition of **1** and the atoms contained in the established partial structures, there remains a difference of only one carbonyl function which suggests for the second ring a pyrrolindione structure.

The presence of a pyrrolindione ring is strongly supported by comparison of **1** with known 2,3-dihydro-2,3-dioxo-5-phenyl-pyrroles: (*a*) 2,3-dihydro-2,3-dioxo-4,5-diphenyl pyrrole (**16**) has a VIS absorption of 483 nm (13), close to that of rubrifacine in the free-acid form (490 nm). (*b*) In strong alkali 2,3-dihydro-2,3-dioxo-5-phenylpyrrole (**17**) undergoes ring opening to **18** and further to acetophenone **19** (14–17). (*c*) Both **17** (17) and rubrifacine give colorless addition products with $NaHSO_3$ from which the colored starting compounds can be regenerated by acidification and passage of air. (*d*) A pyrrolindione ring is likely to undergo ring expansion upon derivatization with diazomethane (4).

Catalytic reduction of rubrifacine

Rubrifacine has been hydrogenated catalytically. Thereby the high field (^1H-nmr) methylene signal split up to the same AB-system at 3.5 ppm both on reduction with H_2 and D_2. The two hydrogens of the methylene group obviously were now diastereotopic because C-7 became chiral upon reduction of the



16 **17** **18** **19**

$\Delta^{7,8}$ double bond (for numbering see formula **1**). The additional hydrogen at C-7 gave rise to a ^1H-nmr signal at about 5.6 ppm whereas no signal was observed for the hydrogen at C-8 due to enol formation of the C-9 carbonyl. The pyridine ring was not reduced under these conditions (18). On standing in air the reduced pigment **20** is reoxidized, as is known for pyrrolindiones (19).

R = 2-carboxymethyl-4,5,6-trihydroxy-3-pyridyl

Experimental

Material

Cation exchange: Dowex AG 50 WX8, Serva; Reversed phase TLC (RP-TLC): KC_{18}, Whatman; Normal phase HPLC: LiChrosorb Si 100, 10 μ, 25 cm × 9.2 mm, Knauer; Reversed phase HPLC: Zorbax ODS, 10 μ, 25 cm × 4.6 mm, Du Pont; Polyamide (<0.07): Macherey Nagel & Co. Düren, FRG.

Instrumental analysis

EI-MS: CH7A, Varian MAT; HMS and field desorption mass spectrometry (FD-MS): MAT 731, Varian MAT; both connected to a Finnigan-MAT SS200 data system; ir: Perkin-Elmer model 720; uv: Beckman model 25; nmr: Varian EM 390, Bruker WP-60, WP-80, WM-300.

Microanalysis of rubrifacine 1a

For a microanalysis 30 mg **1***a* have again been produced in a 12 L culture and purified according to ref. 1. The ^1H-nmr signals of this batch showed slightly different chemical shifts for the two methylene groups than reported: δ = 3.48 and 3.20 compared to δ = 3.32 and 3.22 according to ref. 1 thereby indicating a different pH of the solution. Acetone was used as reference (2.09 ppm) in both cases. *Anal.* calcd. for $C_{13}H_6N_2(Na_{3.5}H_{0.5})O_9 \cdot 4H_2O$: C 32.05, H 3.00, N 5.75, Na 16.5; found: C 32.15, H 3.01, N 5.79, Na 16.4. This analysis confirms the result from fast atom bombardment mass spectrometry (1) which showed that **1***a* exists as a tetrasodium salt.

Thermolability of rubrifacine 1a

The chromophore of **1***a* will be destroyed at about 50°C. **1***a* was therefore stored in a frozen aqueous stock solution at −30°C, solvents were evaporated i.v. at 35°C, and all reactions were performed at room temperature (23°C).

Methylation of rubrifacine 1

In a preliminary investigation a few milligrams crude rubrifacine **1** in dilute hydrochloric acid (pH 2) were treated with excess diazomethane in glyme (20). Derivatives **2** and **3** were separated on LiChrosorb (hexan: *i*-PrOH = 9:1, flow 4 mL/min, retention time 6.4 min (**2**) and 8.4 min (**3**)) in microgram quantities for EI-MS: **2**: *m/z* 450.1651 (100%, calcd. for $C_{21}H_{26}N_2O_9$: 450.1638, M^+) 419 (10%) 391.1517 (30%, calcd. for $C_{19}H_{23}N_2O_7$: 391.1505) 375.1188 (63%, calcd. for $C_{18}H_{19}N_2O_7$: 375.1192); **3**: *m/z* 436.1480 (100%, calcd. for $C_{20}H_{24}N_2O_9$: 436.1482, M^+) 404.1210 (11%, calcd. for $C_{19}H_{20}N_2O_8$: 404.1220) 377.1342 (13%, calcd. for $C_{18}H_{21}N_2O_7$: 377.1348) 361.1034 (31%, calcd. for $C_{17}H_{17}N_2O_7$: 361.1036) 329.0775 (23%, calcd. for $C_{16}H_{13}N_2O_6$: 329.0773) 317.1140 (23%, calcd. for $C_{16}H_{17}N_2O_5$: 317.1137) 299.1032 (18%, calcd. for $C_{16}H_{15}N_2O_4$: 299.1034). To obtain the tetramethyl-derivative **6** 30 mg rubrifacine **1***a* were converted into the free acid form (Dowex, 33 cm high, 3.5 cm in diameter, H^+-form) and dissolved in 3 mL methanol. The methylation (6 mL diazomethane in glyme) was controlled by RP-TLC (KC_{18}, MeOH:H_2O = 3:2) on which **6** had R_f = 0.5. The reaction was stopped at the maximum yield of **6**, which was then chromatographed on Zorbax ODS (MeOH:H_2O = 1:1, flow 1.75 mL/min, retention time 13 min) to give 6 mg pure **6**. ^{1}H-nmr ($CDCl_3$, TMS): 4.30 (s, 3H), 3.95 (s, 3H), 3.80 (s, 3H), 3.69 (s, 3H), 3.62 (s, 2H), 3.57 (s, 2H). EI-MS: *m/z* 394.1008 (100% calcd. for $C_{17}H_{18}N_2O_9$: 394.1012) 379.0821 (10%) 363 (13%) 362 (12%) 335 (15%) 334.0802 (18%, calcd. for $C_{15}H_{14}N_2O_7$: 334.0801), 319.0569 (21%, calcd. for $C_{14}H_{11}N_2O_7$: 319.0566) 303 (28%) 302.0557 (70%, calcd. for $C_{14}H_{10}N_2O_6$: 302.0539) 287.0310 (32%, calcd. for $C_{13}H_7N_2O_6$: 287.0304) 275.0656 (48%, calcd. for $C_{13}H_{11}N_2O_5$: 275.0668) 259.0343 (16%, calcd. for $C_{12}H_7N_2O_5$: 259.0355) 231.0417 (7%, calcd. for $C_{11}H_7N_2O_4$: 231.0406).

Hydrolysis of rubrifacine

To a solution of 10 mg rubrifacine **1***a* in 3 mL H_2O a few milliliter 1 *N* KOH were added drop-wise until discoloration occurred (5 min). The solution was then neutralized with Dowex (22.5 cm high, 2 cm in diameter, H^+-form) to give **7**. ^{1}H-nmr (D_2O, $(CH_3)_2CO$ 2.09 ppm): 3.69 (s, 2H), 2.5–3.2 (AA′BB′, 4H); FD-MS: $[M + H]^+$ 286; EI-MS: *m/z* 285 (1.2%, M^+) 267 (1.7%) 249 (1.9%) 239 (1.6%) 223 (5%) 221 (6%) 205 (2%) 203 (3%) 193 (4%) 177 (5%) 166 (10%) 148 (9%) 122 (4%) 44 (100%); uv: λ_{max} 370, 305 (pH 12), 295, 230 (pH 2). **7***a* was obtained by cation exchange (Dowex, Na^+-form). When the hydrolysis was carried out in D_2O H/D exchange at C-8 occurred and yielded compound **10** after esterification.

Tetra- 8 and pentamethyl- 13 derivatives of 7

1*a* (30 mg) was converted into **7** as described above and dissolved in 25 mL methanol. Gaseous diazomethane (21) was passed through this solution until a maximum yield of **8** was obtained (checked by mass spectrometry). **8** (4 mg) could be separated on LiChrosorb (Hexan, 5% *i*-PrOH, flow 3 mL/min, retention time 4 min). Ir (KBr): ν_{max} 3275 (OH), 2962, 2930, 1743, 1723, 1714, 1651, 1315, 1269; uv (MeOH): λ_{max} 295; EI-MS: *m/z* 341.1114 (41%, calcd. for $C_{15}H_{19}NO_8$: 341.111, M^+) 310.0935 (21%, calcd. for $C_{14}H_{16}NO_7$: 310.0927) 282.0972 (22%, calcd. for $C_{13}H_{16}NO_6$: 282.0978) 281 (16%) 254.0674 (18%, calcd. for $C_{11}H_{12}NO_6$: 254.0665) 250.0722 (28%, calcd. for $C_{12}H_{12}NO_5$: 250.0715) 222.0752 (32%, calcd. for $C_{11}H_{12}NO_4$: 222.0766) 194.0457 (100%, calcd. for $C_{10}H_8NO_4$: 194.0453) 190.0507 (18%, calcd. for $C_{10}H_8NO_3$: 190.0505) 115.0393 (10%, calcd. for $C_5H_7O_3$: 115.0395). **8** was converted into **13** by permethylation and chromatography in the same system like **8** (retention time 2.8 min); uv (MeOH): λ_{max} 294; EI-MS: *m/z* 355.1263 (100%, calcd. for $C_{16}H_{21}NO_8$: 355.1267, M^+) 324 (36%) 323 (20%) 296 (57%) 268 (81%) 264 (20%) 241 (19%) 236 (31%) 194 (46%) 182 (22%) 180 (23%) 115 (31%).

Dimethylesters of 7

The carboxyl function could be esterified with methanol under acidic catalysis or by autocatalysis on standing in methanolic solution for several days. The dimethylester could be separated from the monoesters by chromatography on Zorbax (H_2O:MeOH = 7:3, flow 1.4 mL/min, retention time: monoesters 7.5 and 9 min, diester 22 min). 0.01% acetic acid was added to reduce dissociation but this had the disadvantage that the ester was partially saponified on concentrating the eluate. Therefore, the following procedure was applied to obtain mass spectra of pure dimethylesters: **7** was precipitated on Dowex (H^+-form) by evaporating to dryness a solution of **7** (5 mg) in 10 mL H_2O together with 1 g wet cation exchange resin. This was then suspended in 5 mL methanol or methanol-d_3, respectively, in which only the di- but not the monoester is soluble. After 3 h a few μL of these solutions were directly used for mass spectrometric investigations.

EI-MS: **7**: *m/z* 313 (54%, M^+) 282 (26%) 281 (31%) 254 (24%) 253 (30%) 249 (28%) 226 (20%) 222 (43%) 221 (75%) 203 (28%) 194 (39%) 193 (31%) 180 (22%) 176 (50%) 167 (28%) 166 (40%) 148 (60%) 115 (53%) 55 (100%); **8**: *m/z* 315 (100%, M^+) 284 (44%) 283 (62%) 256 (32%) 255 (45%) 251 (41%) 226 (40%) 223 (95%) 205 (34%) 204 (36%) 194 (63%) 178 (61%) 166 (63%) 148 (75%) 117.0518 (52%, calcd. for $C_5H_5D_2O_3$: 117.0520); **9**: *m/z* 319 (50%, M^+) 285 (25%) 284 (31%) 257 (20%) 256 (24%) 249 (30%) 222 (41%) 221 (70%) 203 (24%) 194 (35%) 193 (23%) 185 (28%) 176 (33%) 166 (29%) 148 (36%) 118 (41%) 55 (100%).

Reduction of rubrifacine

1*a* (5 mg) in 15 mL dilute hydrochloric acid (pH 2) were catalytically reduced at atmospheric pressure for 10 min using 2 mg Pd/C which had been prehydrogenated for 15 min. The catalyst was centrifuged off, the solution evaporated to dryness, and the residue dissolved in D_2O for ^{1}H-nmr measurement. In case of reduction with D_2 in D_2O/DCl the probe was ready for nmr-measurement after centrifugation and concentration to 1 mL.

2,3,4-Trihydroxy-6-methyl-pyridine 15

The final purification of **15** (ca. 10 mg) was achieved by chromatography on polyamide (50 cm long, 1 cm in diameter) in 0.2% acetic acid. EI-MS: *m/z* 141.0426 (100%, calcd. for $C_6H_7NO_3$: 141.0426, M^+) 112 (13%) 95 (4%) 84 (7%) 68 (12%) 57 (8%); uv (H_2O): λ_{max} 289 (E 67700); uv (KOH): λ_{max} 318 (E 19700); ^{1}H-nmr (D_2O, MeOH δ 3.39): 6.10 (s, 1H) 2.25 (s, 3H); ir (KBr) ν_{max} 3520 (sharp), 3700–2400 (broad), 1670 (shoulder), 1660 (shoulder), 1640, 1590, 1460, 1400.

Acknowledgments

We wish to thank Professor Dr. E. Breitmaier (Univ. Bonn), Dr. H. Schmickler, Dipl.-Chem. C. Schnieders, and Dipl.-Chem. H. Unterberg for the nmr measurements, and G. Briskot for the synthesis of 2,3,4-trihydroxy-6-methyl-pyridine.

Reçu le 11 avril 1984

ODILON CHALVET, JEAN-FRANÇOIS GOURVEST, HÉLÈNE STRAPELIAS et MAURICE DUQUESNE. Can. J. Chem. **63**, 500 (1985).

La première étape de la métabolisation d'une molécule d'hydrocarbure polybenzénique est la saturation d'une double liaison et la formation d'un époxyde puis d'un dihydrodiol. Après séparation par chromatographie, les spectres d'absorption de ces dihydrodiols peuvent être établis et comparés directement aux prévisions théoriques qui, pour des molécules planes, sont très aisées à établir. Une identification du site de la première attaque enzymatique est alors possible sans avoir recours à des molécules modèles.

ODILON CHALVET, JEAN-FRANÇOIS GOURVEST, HÉLÈNE STRAPELIAS, and MAURICE DUQUESNE. Can. J. Chem. **63**, 500 (1985).

The first step in the metabolization of a polycyclic hydrocarbon molecule is the saturation of a double bond, the formation of an epoxide, then of a dihydrodiol. Once separation has been achieved by chromatography, the absorption spectra of these dihydrodiols can be established and directly compared with theoretical predictions which are reasonably easy to elaborate in the case of plane molecules. The initial site of enzyme attack can then be identified without using model molecules.

Introduction

Dans une précédente publication (1), l'un de nous, au moyen d'une méthode de "reconnaissance de formes", a montré que la forme des molécules d'hydrocarbures polybenzéniques est corrélée à leur pouvoir cancérogène.

Pour éprouver, sur le plan expérimental, la validité de certains concepts suggérés par cette étude, il était intéressant de considérer en premier lieu le rôle de la topologie de ce type de molécule au niveau de l'acte de métabolisation de la molécule.

La métabolisation des benzo[*a*]pyrène et benzo[*e*]pyrène a été particulièrement étudiée ces dernières années (2, 3). Il nous a donc paru intéressant d'étudier la métabolisation du dibenzo[*a,e*]pyrène (DB[*a,e*]P), molécule qui présente dans sa structure à la fois la topologie du benzo[*a*]pyrène (B[*a*]P), cancérogène, et celle du benzo[*e*]pyrène (B[*e*]P), non cancérogène (Fig. 1).

Généralement, l'identification d'une espèce chimique se fait à l'aide de molécules modèles synthétisées spécialement pour cette identification. Celle-ci se fait soit à partir des paramètres de chromatographie, soit à partir des propriétés spectroscopiques (absorption, fluorescence, excitation de fluorescence . . .). Cette méthode est extrêmement lourde et coûteuse, surtout lorsque l'objectif de la recherche est de comparer la métabolisation de plusieurs molécules d'une même famille comme les dibenzopyrènes.

Compte tenu des propriétés particulières liées à la structure des molécules d'hydrocarbures polybenzéniques, il nous est apparu qu'il était possible de faire cette identification du site de la première attaque enzymatique, à partir des données spectroscopiques, c'est-à-dire d'une manière directe, sans avoir recours à la synthèse de molécules modèles.

Bases expérimentales et discussions

Métabolisation

Dans nos expériences, la métabolisation in vitro est effectuée en plaçant l'hydrocarbure dans un milieu incubateur comprenant le système enzymatique (4). Les métabolites qui retiennent notre attention sont les dihydrodiols, eux-mêmes formés à partir des époxydes par l'action de l'époxyde hydrolase. Ces dihydrodiols sont identifiés dans l'ensemble des pics du profil de chromatographie par le fait que certains pics de ce profil disparaissent lorsque l'on ajoute au milieu d'incubation un oxyde stable (TCPO)[1] qui inhibe l'action de l'époxyde hydrolase.

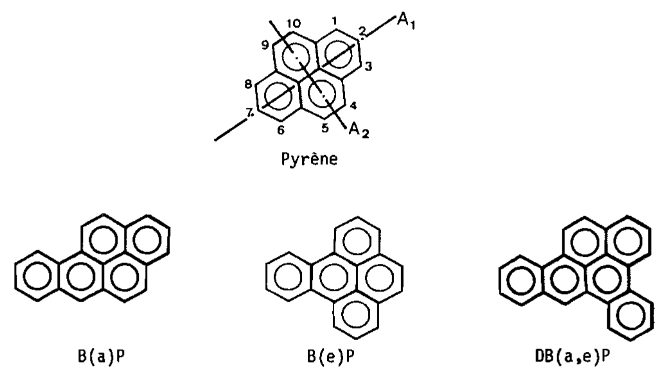

FIG. 1. Topologie de la molécule de pyrène et des trois molécules qui en dérivent par adjonction d'un ou deux noyaux benzéniques.

L'identification des molécules du type "dihydrodiol" informe sur la position du site de la première attaque enzymatique qui sature une double liaison pour former un époxyde. L'utilisation de molécules marquées permet de connaître en plus l'importance de cette attaque.

La quantité de métabolites extraite par chromatographie hplc étant souvent inférieure à 10 µg, l'identification par rmn est pratiquement impossible. Par contre, la sensibilité de la fluorescence et le rendement quantique élevé des hydrocarbures polybenzéniques rendent souvent possible l'identification de la double liaison attaquée.

[1]Epoxy-1,2 trichloro-3,3,3 propane.

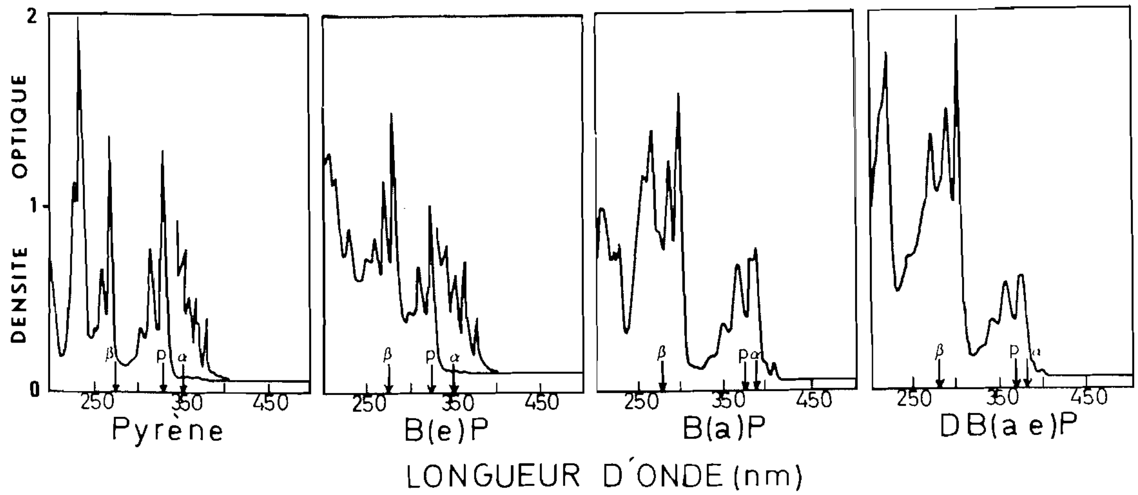

FIG. 2. Spectres d'absorption des 4 molécules: pyrène, benzo[*e*]pyrène, benzo[*a*]pyrène et dibenzo[*a,e*]pyrène. Les positions des bandes α, *p* et β, qui sont indiquées sur l'échelle des longueurs d'ondes exprimées en nanomètres, résultent de calculs effectués par la méthode CNDO/S.

Spectroscopie

Les spectres d'absorption et d'excitation de fluorescence des 3 molécules B[*a*]P, B[*e*]P et DB[*a,e*]P présentent une grande analogie avec ceux du pyrène (Fig. 2).

En effet, en parcourant le spectre d'absorption du rouge vers l'ultraviolet, on rencontre, pour ces 4 molécules, suivant la nomenclature de E. Clar (5), une bande de très faible intensité (bande α) et une bande d'intensité moyenne (bande *p*). Les énergies relatives attachées à ces bandes permettent de séparer ces 4 molécules en 2 groupes: le pyrène et le B[*e*]P d'une part, le B[*a*]P et le DB[*a,e*]P d'autre part (Fig. 2).

Pour les deux molécules du premier groupe, les différences d'énergie entre les bandes α et *p* sont nettement plus importantes que pour celles du second groupe. Il faut noter en outre un déplacement vers les grandes longueurs d'onde de la bande *p* lorsqu'on passe du premier au second groupe, alors que la position de la bande α est sensiblement stable. En raison de la loi d'annelation (5), si le déplacement bathochrome de la bande *p* paraît normal dans la série pyrène, B[*a*]P, DB[*a,e*]P, par contre l'absence de déplacement dans le cas du B[*e*]P apparaît comme une exception (Fig. 2). C'est cette exception que nous exploiterons pour l'identification des métabolites du type "dihydrodiol".

Il convient toutefois de noter que cette loi d'annelation n'est valable que pour la série des hydrocarbures polybenzéniques plans, sans substituants ni hétéroatomes.

Cette absence de déplacement bathochrome peut être constatée pour d'autres polybenzéniques dérivés du pyrène. Le pyrène possède, entre autres éléments de symétrie, deux axes binaires, l'un (A_1) passant par les carbones 2 et 7, et l'autre (A_2) bissecteur des liaisons 4−5 et 9−10 (Fig. 1). On vérifie aisément que toute adjonction de cycles benzéniques respectant la symétrie de la molécule par rapport à l'axe A_2 perturbe peu la position de la bande *p* (5). Au niveau des métabolites, la formation d'un dihydrodiol revient, en première approximation, à rompre le système conjugué de la molécule. Ainsi le 7,8 dihydrodiol et le 9,10 dihydrodiol du B[*a*]P peuvent être, dans une approximation raisonnable, assimilés au 8 vinyl pyrène et au 7 vinyl pyrène supposés plans (Fig. 3). Les spectres d'absorption et d'excitation de fluorescence des deux premiers composés montrent une situation relative des bandes α et *p* différente (Fig. 3). Pour le 7,8 dihydrodiol, la bande *p* est déplacée vers le rouge et recouvre en partie les bandes α. Pour le 9,10 dihydrodiol au contraire, la bande *p* n'est pas déplacée, laissant visibles les bandes α.

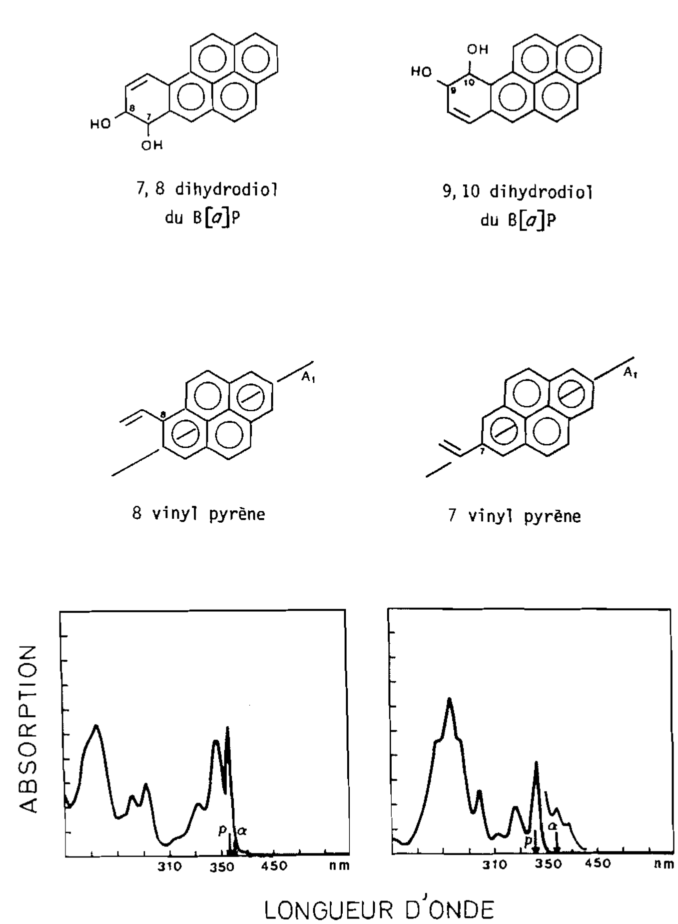

FIG. 3. Deux des hydrodiols du benzo[*a*]pyrène et leurs spectres d'absorption. Le déplacement vers les grandes longueurs d'ondes de la bande *p* du 7,8 dihydrodiol du benzo[*a*]pyrène est nettement visible (d'après la réf. 6 et nos propres résultats).

D'une manière générale, la conjugaison d'un groupe vinylique, bien que faible, est plus importante lorsque la partie vinylique est liée à un carbone situé hors de l'axe de symétrie (A_1) du pyrène. Dans le 9,10 dihydrodiol, cette partie vinylique du système conjugué est liée à un carbone situé sur l'axe de

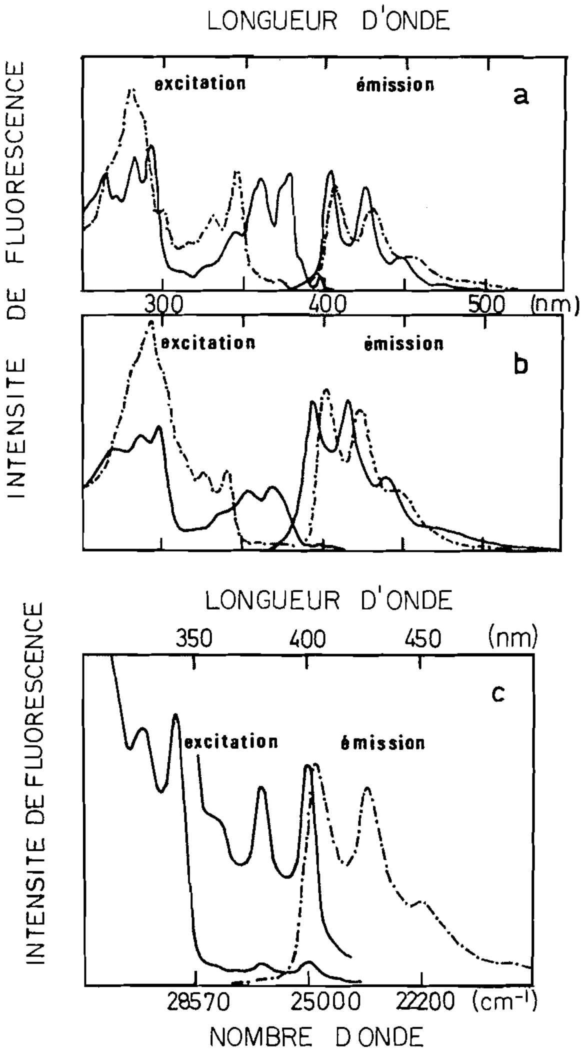

FIG. 4. (*a*) Spectres d'émission et d'excitation de fluorescence des B[*a*]P (—) et 9,10 dihydrodiol B[*a*]P (------).

	Spectre d'émission	Spectre d'excitation
B[*a*]P	$\lambda_{exc.}$ = 380 nm	$\lambda_{analyse}$ = 400 nm
9,10 dihydrodiol B[*a*]P	$\lambda_{exc.}$ = 342 nm	$\lambda_{analyse}$ = 405 nm

(b) Spectres d'émission et d'excitation de fluorescence du DB[*a*,*e*]P (—) et du dihydrodiol majoritaire de cet hydrocarbure (------).

	Spectre d'émission	Spectre d'excitation
DB[*a*,*e*]P	$\lambda_{exc.}$ = 372,5 nm	$\lambda_{analyse}$ = 395 nm
Dihydrodiol majoritaire du DB[*a*,*e*]P	$\lambda_{exc.}$ = 342 nm	$\lambda_{analyse}$ = 405 nm

(c) Spectres détaillés d'émission ($\lambda_{exc.}$ = 342 nm) et d'excitation de fluorescence ($\lambda_{analyse}$ = 405 nm) du métabolite majoritaire du DB[*a*,*e*]P, le 11,12 dihydrodiol du DB[*a*,*e*]P.

symétrie (A_1) du pyrène et le déplacement est beaucoup moins important que dans le cas du 7,8 dihydrodiol.

Conclusion

Pour le métabolite majoritaire (12,5%) correspondant à un dihydrodiol du DB[*a*,*e*]P, son spectre d'excitation montre sans ambiguité une bande *p* située dans la zone d'énergie de celle du 9,10 dihydrodiol du B[*a*]P (Fig. 4). Forts de notre remarque sur l'adjonction d'un cycle benzénique en position [*e*] du pyrène, nous pouvons conclure que le dihydrodiol majoritaire de la métabolisation du DB[*a*,*e*]P correspond à une saturation de la liaison 11–12 de cette molécule. Nous avons par ailleurs vérifié que le spectre d'émission de fluorescence est bien l'effet miroir d'une bande α nettement séparée de la bande *p* comme c'est le cas pour le B[*e*]P.

BRENDA M. LOUIE, STEVEN J. RETTIG, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **63**, 503 (1985).

Details of the synthesis and physical properties of $[Me_2Ga(3,5\text{-}Me_2pz)_2]Rh(CO)PPh_3$ are given. Crystals of [dimethylbis(3,5-dimethyl-1-pyrazolyl)gallato-N,N'](triphenylphosphine)carbonylrhodium(I) − toluene (1:1) are triclinic, a = 10.690(2), b = 12.928(2), c = 13.998(2) Å, α = 77.44(1), β = 83.50(1), γ = 72.70(1)°, Z = 2, space group $P\bar{1}$. The structure was solved by conventional heavy-atom methods and was refined by full-matrix least-squares procedures to R = 0.039 and R_w = 0.048 for 5987 reflections with $I \geq 3\sigma(I)$. The Rh(I) is in a distorted square planar environment with Rh—N = 2.090(3) and 2.097(2), Rh—CO = 1.815(4), and Rh—P = 2.2700(8) Å. The central six-membered $RhGaN_4$ ring has a steep boat conformation with a Rh···Ga separation of 3.3819(4) Å.

BRENDA M. LOUIE, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **63**, 503 (1985).

On rapporte les détails relatifs à la synthèse et aux propriétés physiques du $[Me_2Ga(Me_2\text{-}3,5\ pz)_2]Rh(CO)PPh_3$. Les cristaux du [diméthyl bis(diméthyl-3,5 pyrazolyl-1) gallato-N,N'](triphénylphosphine) carbonyl rhodium(I) − toluène (1:1) sont tricliniques, a = 10,690(2), b = 12,928(2), c = 13,998(2) Å, α = 77,44(1), β = 83,50(1), γ = 72,70(1)°, Z = 2, groupe d'espace $P\bar{1}$. On a résolu la structure par des méthodes conventionnelles avec des atomes lourds et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de R = 0,039 et R_w = 0,048 pour 5987 réflexions avec $I \geq 3\sigma(I)$. Le Rh(I) se trouve dans un environnement plan carré déformé avec Rh—N = 2,090(3) et 2,097(2), Rh—CO = 1,815(4) et Rh—P = 2,2700(8) Å. Le cycle central à six chaînons, $RhGaN_4$, existe dans une conformation bateau et la séparation entre Rh···Ga est égale à 3,3819 Å.

[Traduit par le journal]

Introduction

An earlier paper (1) has described the synthesis and characterization of a number of Rh(I) square planar complexes incorporating the chelating gallate ligand $Me_2Gapz_2^-$ (where pz = pyrazolyl, $N_2C_3H_3$). Attempts to synthesize analogous complexes containing the ligand $Me_2Ga(3,5\text{-}Me_2pz)_2^-$ (where 3,5-Me_2pz = 3,5-dimethylpyrazolyl, $N_2C_5H_7$) were thwarted by the ready formation of the Rh(I) dimer species, e.g. $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(CO)_2]_2$. Recently our perseverance in this area has been rewarded with the isolation and structural characterization of the complex $[Me_2Ga(3,5\text{-}Me_2pz)_2]Rh(CO)PPh_3$, the subject of this report.

Experimental

Air-sensitive materials were handled in oxygen-free dry nitrogen. Tetrahydrofuran (THF) was dried by refluxing over sodium benzophenone and used immediately following distillation. Methylene chloride was dried by refluxing over P_2O_5 prior to distillation and n-hexane by distillation from $CaSO_4$. $[Rh(CO)_2Cl]_2$ (Strem Chemicals) was sublimed *in vacuo* before use. PPh_3 (MCB) was used as supplied and the sodium salt of the gallate ligand $[Me_2Ga(3,5\text{-}Me_2pz)_2]$- was prepared as a THF solution as described earlier (2).

Preparation of $[Me_2Ga(3,5\text{-}Me_2pz)_2]Rh(CO)PPh_3$

$Na^+[Me_2Ga(3,5\text{-}Me_2pz)_2]^-$ (0.941 mmol in 50 mL THF) was added dropwise to a stirred solution of $[Rh(CO)_2Cl]_2$ (0.183 g, 0.471 mmol) and PPh_3 (0.247 g, 0.943 mmol) in 100 mL THF at −78°C. The resultant solution was allowed to warm gradually to room temperature. Approximately 100 mL of n-hexane was then added to the mixture and the lemon−yellow solution subsequently filtered. Removal of the solvents from the filtrate *in vacuo* left a yellow−orange residue. Recrystallization of this residue from CH_2Cl_2/n-hexane yielded lemon−yellow prisms of $[Me_2Ga(3,5\text{-}Me_2pz)_2]Rh(CO)PPh_3$ in approximately 35% yield, together with needles of $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(CO)PPh_3]_2$. *Anal.* calcd. for $[Me_2Ga(3,5\text{-}Me_2pz)_2]Rh(CO)PPh_3$: C 54.50, H 5.16, N 8.20; found: C 54.43, H 5.10, N 8.19. ^{1}H nmr (C_6D_6, τ values refer to $\tau(C_6H_6)$ = 2.84 ppm): 9.28 s, 9.73 s ($GaMe_2$); 7.35 s, 7.85 s, 7.86 s, 8.14 s (pz—Me); 4.24 s, 4.71 s (pz—H^4); 2.42 m, 3.01 m (PPh_3). Ir (cyclohexane) ν_{co} = 1985 s. The mass spectrum of the compound displayed a weak signal due to the parent ion, P^+ (1%), with major signals arising from the P − Me^+ (93%), P − Me − CO^+ (34%), and P − Me − CO − $(3,5\text{-}Me_2pzH)^+$ (100%) ions.

Spectra

The ir spectrum was recorded on a Perkin-Elmer 598 spectrometer, the ^{1}H nmr spectrum on a Varian XL 100 instrument using FT techniques, and the mass spectrum on a Varian MAT CH4B spectrometer at 70 eV and 200°C.

X-ray crystallographic analysis of $[Me_2Ga(3,5\text{-}Me_2pz)_2]Rh(CO)PPh_3\cdot CH_3C_6H_5$

The crystal used for the X-ray analysis was obtained by recrystallization from benzene (later shown by mass spectrometry to be contaminated by toluene) and sealed in a Lindemann glass capillary. A crystal ca. 0.40 × 0.45 × 0.55 mm in size was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 35−40°) measured on a diffractometer with Mo-$K\alpha$ Radiation ($\lambda(K\alpha_1)$ = 0.70930, $\lambda(K\alpha_2)$ = 0.71359 Å). Crystal data at 22°C are:

$C_{31}H_{35}GaN_4OPRh\cdot C_7H_8$ fw = 775.38
Triclinic, a = 10.690(2), b = 12.928(2), c = 13.998(2) Å, α = 77.44(1), β = 83.50(1), γ = 72.70(1)°, V = 1800.5(6) Å^3, Z = 2, ρ_c = 1.430 Mg m^{-3}, $F(000)$ = 796, μ(Mo-$K\alpha$) = 12.74 cm^{-1}. Absent reflections: none, space group $P\bar{1}$ (C_i^1, No. 2, reduced cell) from structure analysis.

Intensities were measured with graphite-monochromated Mo-$K\alpha$ radiation on an Enraf-Nonius CAD4-F diffractometer. An ω−2θ scan at 1.26−10.06° min^{-1} over a range of (0.75 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 55°. The intensities of three check reflections, measured every 3600 s throughout the data collection, decreased uniformly by approximately 30%, the data being scaled accordingly. After data reduction,[1] an absorption correction

[1]The computer programs used include locally written programs for data processing and locally modified versions of the following: ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

was applied using the Gaussian integration method (3, 4). Transmission factors ranged from 0.574 to 0.654 for 148 integration points. Of the 8254 independent reflections measured, 5987 (72.5%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The centrosymmetric space group $P\bar{1}$ was indicated by both the Patterson function and the E-statistics. The structure was solved by conventional heavy-atom methods; the coordinates of the Rh, Ga, and P atoms being determined from the Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference map. There was no indication of disordering of the toluene methyl carbon atom (C(38)). This is substantiated by comparison of the equivalent isotropic thermal parameters obtained for the toluene ring atoms (C(32–37), mean U = 0.215 Å^2) with the value of 0.298 for the methyl carbon, the latter expected to be somewhat larger. In the final stages of refinement all non-hydrogen atoms were refined with anisotropic thermal parameters and hydrogen atoms were included as fixed contributors in idealized positions (C(sp^3)—H = 0.98, C(sp^2)—H = 0.97 Å). The scattering factors of ref. 5 were used for non-hydrogen atoms and those of ref. 6 for hydrogen atoms. Anomalous scattering factors from ref. 7 were used for the Rh, Ga, and P atoms. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and $\sin\theta/\lambda$ and was employed in the final stages of refinement. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.039 and R_w = 0.048 for 5987 reflections with $I \geq 3\sigma(I)$. For all 8254 reflections R = 0.071. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.05 and 1.26σ, respectively. The maximum parameter shift was associated with the U_{33} parameter of the toluene atom C(34), all shifts for the complex molecule were less than 0.08σ. The mean error in an observation of unit weight was 1.800. A final difference map showed maximum fluctuations of −1.94 to +0.57 e Å^{-3} near Rh and was essentially featureless away from the heavy atoms. The final positional and thermal parameters appear in Tables 1 and 5,[2] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (8). The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0065 Å^2. Analysis of the entire molecule indicated significant independent motion of several structural subunits. The following fragments were analysed separately: 3PPh, 2Me$_2$pz, GaC$_2$N$_2$, and RhGaPN$_4$C(1) (rms ΔU_{ij} = 21, 25, 19, 16, 14, 16, and 27 × 10^{-4} Å^2, respectively). The appropriate bond distances have been corrected for libration (8, 9), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 2 along with the uncorrected values; corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 3. Intra-annular torsion angles defining the conformation of the central RhGaN$_4$ ring are listed in Table 4. Calculated hydrogen coordinates and thermal parameters (Table 6 and 7) are included as supplementary material.[2]

TABLE 1. Final positional (fractional × 10^4; Rh, Ga, and P × 10^5) and isotropic thermal parameters (U × 10^3 Å^2) with estimated standard deviations in parentheses

Results and discussion

In a recent paper (1) we discussed the preparation and characterization of a number of Rh(I) complexes containing the ligand Me$_2$Gapz$_2^-$ and compared these new complexes with Rh(I) complexes containing pyrazolyl borate ligands (10–18). At that time we were unable to isolate compounds of the type [Me$_2$Ga(3,5-Me$_2$pz)$_2$]Rh(L—L) (where L—L = (CO)$_2$ or COD, COD = 1,5-cyclooctadiene), postulating that facile disproportionation of the Me$_2$Ga(3,5-Me$_2$pz)$_2^-$ ligand led to the formation of stable Rh(I) dimers of the formulation [Rh-(μ-3,5-Me$_2$pz)L—L]$_2$. However, the complex [Me$_2$Ga(3,5-Me$_2$pz)$_2$]Rh(CO)PPh$_3$, has now been isolated as an air-stable lemon−yellow crystalline material, albeit in low yield, together with two dimer species, viz.

$$4Na^+[Me_2Ga(3,5\text{-}Me_2pz)_2]^- + 2[Rh(CO)_2Cl]_2 + 4PPh_3 \rightarrow 2[Me_2Ga(3,5\text{-}Me_2pz)_2]Rh(CO)PPh_3 + [Rh(\mu\text{-}3,5\text{-}Me_2pz)(CO)PPh_3]_2 + [Me_2Ga(\mu\text{-}3,5\text{-}Me_2pz)]_2 + 4NaCl + 4CO$$

[2]The structure factor table, Table 5 (anisotropic thermal parameters), and other material mentioned in the text are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

The ir spectrum of the title complex in cyclohexane solution displays a single, strong, carbonyl stretching frequency at 1985 cm^{-1}, slightly lower than the corresponding ν_{CO} band at 1995 cm^{-1} reported for $[Me_2Gapz_2]Rh(CO)PPh_3$ (1). This shift to lower ν_{CO} frequencies with methyl substitution on the pyrazolyl rings of the ligands reflects the enhanced electron donating power of the substituted ligands, which in turn leads to increased $d\pi-\pi^*$ interaction with the ancillary carbonyl ligands.

It is of interest to compare the room temperature ^1H nmr spectra of the two analogous complexes $[Me_2Ga(3,5\text{-}Me_2pz)_2]$-$Rh(CO)PPh_3$ (Fig. 2) and $[Me_2Gapz_2]Rh(CO)PPh_3$ (1). The spectrum of the latter compound exhibits one sharp singlet in the "$GaMe_2$" region of the spectrum whilst the title complex displays two sharp singlets in this region. Indeed it is not until −65°C that the unsubstituted pyrazolyl complex gives two sharp "GaMe" singlets comparable to those observed at room temperature for the title complex. Evidently the fluxional process proposed for the Rh(I) complexes incorporating the $Me_2Gapz_2^-$ ligand (1) is considerably less facile for the $[Me_2Ga(3,5\text{-}Me_2pz)_2]Rh(CO)PPh_3$ compound. Rapid inversion of the Ga—$(N—N)_2$—Rh boat conformation predicted for this complex, **1**, would be severely hindered by steric interactions in a planar intermediate, particularly between the bulky PPh_3 ligand and the pz—Me group. The boat conformation of the title complex, in addition to two singlets for the $GaMe_2$ protons, gives rise to four pz—Me singlets and two pz—H^4 singlets in its ^1H nmr spectrum (Fig. 2).

The crystal structure of [dimethylbis(3,5-dimethyl-1-pyra-

1

zolyl)gallato-*N*,*N′*](triphenylphosphine)carbonylrhodium(I) − toluene (1:1) consists of discrete molecules of $[Me_2Ga(3,5\text{-}Me_2pz)_2]Rh(CO)PPh_3$ and toluene, separated by normal van der Waals distances. The Rh(I) atom is in a distorted square planar environment with Rh—N = 2.090(3) and 2.097(2), Rh—CO = 1.815(4), and Rh—P = 2.2700(8) Å. These distances are similar to those reported for related molecules (1, 16, 19, and references therein). The Rh—N distances are slightly longer than the corresponding mean values of 2.087(2), 2.063(6), and 2.084(1) Å reported for $[Me_2Gapz_2]Rh(COD)$, $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(CO)_2]_2$, and $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(COD)]_2$, respectively (1). The Rh—CO distance is shorter than the mean value of 1.852(9) Å reported for $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(CO)_2]_2$. The N(1)—pyrazolyl and C(26)—phenyl rings are planar within experimental error (χ^2 = 1.9 and 2.8) while the N(3)—pyrazolyl and the two remaining phenyl rings are slightly but significantly nonplanar (χ^2 = 15.3−41.0, maximum deviation from the mean plane 0.014(5) Å). The geometry of the toluene molecule (Tables 2 and 3) is far from ideal, probably a result of the relatively large degree of thermal motion undergone by the solvate molecule and/or some form of minor disordering.

As a result of steric interaction between the PPh_3 ligand and the *cis* Me_2pz group, the central six-membered $RhGaN_4$ ring has a steeper boat conformation than that observed in the less strained μ-pz_2 molecule $[Me_2Gapz_2]Rh(COD)$. This leads to a significant shortening of the cross-ring Rh···Ga distance, from 3.5527(5) in $[Me_2Gapz_2]Rh(COD)$ to 3.3819(4) Å in the present structure. The dependence of ring folding and the associated M···M′ distance in M—(μ-$R_2pz)_2$—M systems upon intramolecular steric requirements has been discussed in ref. 1. The PPh_3−Me_2pz interaction manifests itself as a marked torsional twist about the N(3)—N(4) bond (see Table 4) and may also be responsible for the nonplanarity of the N(3)—pz and C(20)—phenyl rings. The Rh and Ga atoms are displaced by 0.1299(3) and −0.4993(4) Å, respectively, from the mean plane of the N(3)—pyrazolyl ring, compared to corresponding values of −0.0544(3) and −0.1546(4) Å for the N(1)—pyrazolyl ring.

Received July 16, 1984

W. KLIEGEL, L. PREU, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **63**, 509 (1985).

Crystals of 3-(phenylmethylidene)-4-methyl-1-phenyl-2,6,7-trioxa-3-azonia-1-boratabicyclo[2.2.2]octane are orthorhombic, a = 8.0732(7), b = 11.8499(10), c = 31.679(2) Å, Z = 8, space group *Pbca*, and those of *N*-(4-nitrophenylmethylidene)-5-methyl-2-phenyl-1,3-dioxa-2-bora-5-cyclohexaneamine *N*-oxide are monoclinic, a = 6.1873(6), b = 23.206(2), c = 11.3081(11) Å, β = 92.326(5)°, Z = 4, space group $P2_1/n$. Both structures were solved by direct methods and were refined by full-matrix least-squares procedures to final R values of 0.041 and 0.036 for 943 and 1679 reflections with $I \geq 3\sigma(I)$, respectively. Both compounds are condensation products of bis(hydroxyalkyl)nitrones and phenylboronic acid. 3-(Phenylmethylidene)-4-methyl-1-phenyl-2,6,7-trioxa-3-azonia-1-boratabicyclo[2.2.2]octane was found to possess a bicyclic structure resulting from intramolecular O→B coordination (O—B = 1.604(7) Å) and is the first such bicyclic boron compound to be structurally characterized. In *N*-(4-nitrophenylmethylidene)-5-methyl-2-phenyl-1,3-dioxa-2-bora-5-cyclohexaneamine *N*-oxide, which has weakened nitrone basicity, the O→B interaction does not occur, resulting in a monocyclic system incorporating a trigonal planar boron atom.

W. KLIEGEL, L. PREU, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **63**, 509 (1985).

Les cristaux du (phénylméthylidène)-3 méthyl-4 phényl-1 trioxa-2,6,7 azonia-3 borata-1 bicyclo [2.2.2] octane sont orthorhombiques avec a = 8,0732(7), b = 11,8499(10), c = 31,679(2) Å, Z = 8 et groupe d'espace *Pbca* alors que ceux du *N*-oxyde de la *N*-(nitro-4 phénylméthylidène) méthyl-5 phényl-2 dioxa-1,3 bora-2 cyclohexylamine-5 sont monocliniques avec a = 6,1873(6), b = 23,206(2), c = 11,3081(11) Å, β = 92,326(5)°, Z = 4 et groupe d'espace $P2_1/n$. On a résolu les deux structures par des méthodes directes et on les a affinées par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs finales de R de 0,041 et 0,036 respectivement pour 943 et 1679 réflexions avec $I \geq 3\sigma(I)$. Les deux composés sont des produits de condensation de bis(hydroxyalkyl)nitrones et de l'acide phénylboronique. On a trouvé que le (phénylméthylidène)-3 méthyl-4 phényl-1 trioxa-2,6,7 azonia-3 borata-1 bicyclo [2.2.2] octane possède une structure bicyclique qui résulte d'une coordination O→B intramoléculaire (O—B = 1,604(7) Å) et il s'agit du premier composé bicyclique de ce type et contenant du bore à être caractérisé du point de vue de la structure. Dans le *N*-oxyde de la *N*-(nitro-4 phénylméthylidène) méthyl-5 phényl-2 dioxa-1,3 cyclohexylamine, pour laquelle la basicité de la nitrone est plus faible, l'interaction O→B ne se produit pas et il en résulte que le composé est un système monocyclique comportant un atome de bore plan et trigonal.

[Traduit par le journal]

Introduction

The condensation products of bis(hydroxyalkyl)nitrones such as **1** and phenylboronic acid can generally have an intramolecularly coordinated bicyclo[2.2.2]octane structure **2** and/or a simple monocyclic diester structure **3** (1). Sufficient electron density at the nitrone oxygen atom should qualify the nitrone **1** as a tridentate ligand and should result in the formation of a bicyclic chelate of the type **2**. A comparable "cage" structure has been postulated for similar trialkylamine-*N*-oxide chelates (2). On the other hand, weakening of the nitrone basicity by *para*-nitro substitution of the arylaldehyde moiety, generally attainable for *C*-arylnitrones (3), should favor the monocyclic ester structure **3** which could be stabilized by $pp(\pi)$ back-donation from both oxygens of the boronate ester function into the vacant *p*-orbital of the trigonal planar boron atom.

From a series of various arylboronates, synthesized from nitrones of the type **1** (1), we chose the phenylboronates of benzaldehyde nitrone (**1***a*) and of 4-nitrobenzaldehyde nitrone (**1***b*) on the basis of their distinct ^{1}H nmr spectra which suggested different structures for the boronate ring systems of the two compounds. For the benzaldehyde derivative (Ar = C_6H_5) the "cage" structure **2** was postulated, whereas the monocyclic boronate structure **3** was ascribed to the 4-nitrobenzaldehyde derivative (Ar = 4-$NO_2C_6H_4$) (1). To prove unambiguously the intramolecular O→B coordination in **2** and the noncoordination in **3**, X-ray crystallographic analyses of both compounds were undertaken.

Experimental

Compounds **2** (Ar = C_6H_5) and **3** (Ar = 4-$NO_2C_6H_4$) were prepared by refluxing solutions of 1 mmol of phenylboronic acid and 1 mmol of *N*-benzylidene-1,3-dihydroxy-2-methyl-2-propanamine *N*-oxide (**1***a*) (1, 4) or 1 mmol of 1,3-dihydroxy-2-methyl-*N*-(4-nitrophenylmethylidene)-2-propanamine *N*-oxide (**1***b*) (1), respectively, in 60 mL ethanol for 15 min. After evaporation of the solution the residue is crystallized, if necessary, by addition of ether.

X-ray crystallographic analyses

3-(Phenylmethylidene)-4-methyl-1-phenyl-2,6,7-trioxa-3-azonia-1-boratabicyclo[2.2.2]octane (2, Ar = C_6H_5)

A crystal bounded by the six faces (followed by their distances in mm from a common origin): ±(0 0 1), 0.053 ±(1 0 0), 0.188, ±(0 1 0), 0.265 was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 25–36°) measured on a diffractometer with Mo-$K\alpha$ Radiation ($\lambda(K\alpha_1)$ = 0.70930, $\lambda(K\alpha_2)$ = 0.71359 Å). Crystal data at 22°C are:

$C_{17}H_{18}BNO_3$ fw = 295.17
Orthorhombic, a = 8.0732(7), b = 11.8499(10), c = 31.679(2) Å, V = 3030.6(4) Å^3, Z = 8, ρ_c = 1.294 g cm^{-3} $F(000)$ = 1248, μ(Mo-$K\alpha$) = 0.82 cm^{-1}. Absent reflections: $0kl$, k odd, $h0l$, l odd, and $hk0$, h odd uniquely indicate the space group *Pbca* (D^{15}_{2h}, No. 61).

Intensities were measured with graphite-monochromated Mo-$K\alpha$ radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 0.67–6.71° min^{-1} over a range of (0.85 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 52°. The intensities of three check reflections, measured every 3600 s throughout the data collection, remained constant to within 1.5%. Of the 2959 independent reflections measured and processed[2], 943(32%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count. The crystals were poor scatterers, most of the "observed" data having θ < 18°. Higher angle data, a few of which had significant intensities, were collected in order to maximize the number of observations. Using a 2σ cutoff would only have increased the total by 35.

The structure was solved by direct methods, the positions of the non-hydrogen atoms being determined from an E-map. After full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters to R = 0.088, a difference map gave the positions of the hydrogen atoms. Refinement of the structure with fixed hydrogen atoms (idealized geometry) reduced R to 0.058. In the final stages of refinement the hydrogen atoms were refined with isotropic thermal parameters in spite of the small number of observations. This action may be justified by the better residuals eventually obtained, the esd's of derived parameters being essentially the same for the refinements with fixed and varied hydrogen parameters (the smaller m/n ratio being balanced by the better agreement between observed and calculated structure factors). The scattering factors of ref. 5 were used for non-hydrogen atoms and those of ref. 6 for hydrogen atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of refinement. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.041 and R_w = 0.049 for 943 reflections with $I \geq 3\sigma(I)$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.03 and 0.19σ, respectively. The mean error in an observation of unit weight was 1.993. A final difference map showed no unusual features, residual densities ranging from −0.22 to +0.20 e Å^{-3}. The final positional and thermal parameters appear in Tables 1 and 5,[3] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[3]

[2]The computer programs used include locally written programs for data processing and locally modified versions of the following: MULTAN 80, multisolution program by P. Main, S. J. Fiske, S. E. Hull, L. Lessinger, G. Germain, J. P. Declercq, and M. M. Woolfson; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

[3]The structure factor table, Table 5 (anisotropic thermal parameters) and other material mentioned in the text are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

N-(4-nitrophenylmethylidene)-5-methyl-2-phenyl-1,3-dioxa-2-bora-5-cyclohexaneamine N-oxide (3, Ar = 4-$NO_2C_6H_4$)

Experimental details are as above except where noted. The bounding planes of the crystal used for data collection were ±(0 2 −1), 0.100, ±(0 2 1), 0.148, ±(1 0 0), 0.310 mm. Reflections employed in the refinement of the unit-cell constants had 2θ = 30−37°. Crystal data:

$C_{17}H_{17}BN_2O_5$ fw = 340.17

Monoclinic, a = 6.1873(6), b = 23.206(2), c = 11.3081(11) Å, β = 92.326(5)°, V = 1622.3(3) Å^3, Z = 4, ρ_c = 1.393 g cm^{-3}, $F(000)$ = 712, μ(Mo-$K\alpha$) = 0.96 cm^{-3}. Absent reflections: 0k0, k odd, and h0l, $h + l$ odd uniquely indicate the space group $P2_1/n$ (non-standard setting of $P2_1/c$, C^5_{2h}, No. 14 with equivalent positions ±(x, y, z; 1/2 − x, 1/2 + y, 1/2 − z)).

An ω − 2θ scan at 1.06−10.06° min^{-1} over a range of (0.65 + 0.35 tan θ)° in ω was employed. Of 3698 independent reflections measured (to 2θ = 55°), 1679 had intensities greater than 3σ(I) above background. The intensities of the standard reflections remained constant to within 1.5%.

The structure was solved by direct methods, all non-hydrogen atoms being positioned from an E-map. After refinement of the non-hydrogen atoms with anisotropic thermal parameters to R = 0.076, all 17 hydrogen atoms were located on a difference map and were refined with isotropic thermal parameters in subsequent least-squares cycles. Convergence was reached at R = 0.036 and R_w = 0.044 for 1679 reflections. The mean and maximum parameter shifts on the final cycle of refinement were 0.05 and 0.6σ (H(17), y coordinate) and the mean error in an observation of unit weight was 1.950. A final difference map showed fluctuations in the range −0.22 to +0.16 e Å^{-3}.

Analysis of thermal motion

The thermal motion in the two molecules (Fig. 1) has been analysed in terms of the rigid-body modes of translation, libration, and screw-motion (TLS model) (7). The rms errors in the U_{ij} (derived from the least-squares analyses) are 0.0037 and 0.0014 Å^2, respectively, for **2** and **3**. Analyses of the entire molecules indicated significant independent motion of the phenyl rings in each case. Fragments of each molecule were separately analysed. In the case of **2** these were PhB,

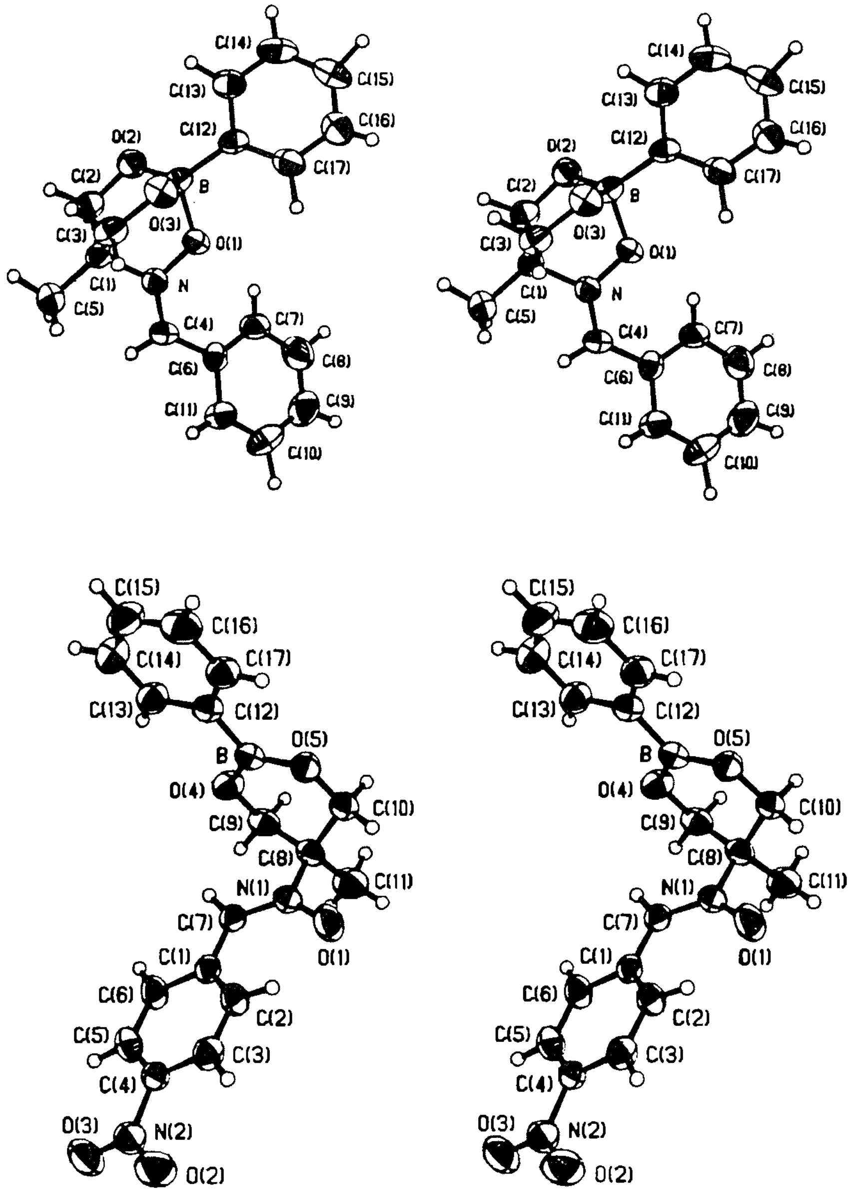

FIG. 1. Stereoscopic views of 3-(phenylmethylidene)-4-methyl-1-phenyl-2,6,7-trioxa-3-azonia-1-boratabicyclo[2.2.2]octane (top) and *N*-(4-nitrophenylmethylidene)-5-methyl-2-phenyl-1,3-dioxa-2-bora-5-cyclohexaneamine *N*-oxide bottom) molecules; 50% probability thermal ellipsoids are shown. Hydrogen atoms are assigned arbitrarily small thermal parameters for clarity.

PhC(4), and the bicyclic system plus C(4) and C(5) (rms ΔU_{ij} = 52, 33, and 43 × 10^{-4} Å^2) and for **3**, PhB, O_2NArC(7), and the six-membered heterocycle plus C(7)N(1)C(11) (rms ΔU_{ij} = 23, 31, and 36 × 10^{-4} Å^2). The appropriate bond distances have been corrected for libration (7, 8), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 2 along with the uncorrected values; corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 3. Intra-annular torsion angles defining the conformations of the heterocyclic rings are listed in Table 4. Bond lengths and angles involving hydrogen and a complete listing of torsion angles (Tables 6–8) are included as supplementary material.[3]

Results and discussion

Both compounds **2** and **3** show the expected structures which are consistent with the predictions made on the basis of the electronic influence of the *C*-aryl moiety of the nitrone group (1). In compound **2**, with a tetrahedral sp^3-boron, the 1,3-dioxa-2-boracyclohexane ring system is forced into a slightly distorted boat conformation by coordinative acceptance of the Lewis-base nitrone oxygen atom. This is the first report of the structural dimensions of a bicyclic boron complex of this type. In compound **3**, with a trigonal planar sp^2-boron atom, the 1,3-dioxa-2-boracyclohexane ring has a "semi-planar" (9, 10) (envelope) conformation in which C(8) deviates from the approximate plane formed by the five remaining ring atoms. Very similar conformations have been reported for the 1,3-dioxa-2-boracyclohexane rings in the borate of *meso*-2,4-pentanediol **4** (11) and the 2,4-phenylboronate of *N*-(4-bromophenyl)-α-*D*-ribopyranosylamine **5** (12).

The mean[4] B—O bond length in the boronate ester grouping of **3** (1.367(4) Å) is significantly shorter than in **2** (1.453(9) Å),

[4]Here and elsewhere in this report mean values refer to weighted means with rms deviations from the mean in parentheses.

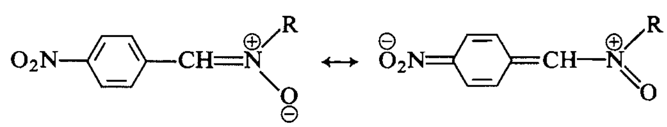
demonstrating the partial π-bond character which results from $pp(\pi)$ back-donation in the trigonal planar boronate ester group of **3**. Similar values were found for the mean B(sp^2)—O distances in **4** (11) and **5** (12) (1.362(8) and 1.396(2) Å, both uncorrected), and in free boronic acids such as 4-$BrC_6H_4B(OH)_2$ (13) (1.36 Å, uncorrected) and $C_6H_5B(OH)_2$ (14) (1.371(6) Å). The approximate coplanarity of the B-phenyl ring and the COBOC plane of the 1,3-dioxa-2-boracyclohexane ring in **3** (the dihedral angle between normals to the mean planes being 1.8(2)°) enables a π-interaction between the aromatic system and the boronate group. The B—C bond length of 1.564(4) Å in **3** is nearly identical to the corresponding distance of 1.565(3) Å in phenylboronic acid (14). The B—C distance of 1.591(8) Å in **2** is longer, indicating little or no π-interaction with the sp^3-boron atom. Comparable bond distances ranging from 1.582 to 1.613 Å have been observed in various tetracoordinated phenylboronates (15–18). The coordinative B—O bond between the nitrone and boronate groups in **2** (B—O(1) = 1.604(7) Å) is very long. Even longer bonds of this type, however, have been observed in boron complexes with weak interactions between B and O atoms of an amide group (1.621 Å, uncorrected) (19) and of a sulphone group (1.710(3) Å, uncorrected) (20).

The nitrone group in **3** has a longer C=N bond than in **2**, and shorter N—O and C—C(aryl) distances (in the latter case this difference, although not statistically significant, is in the expected direction). This indicates a lesser degree of double bond character for the C=N bond and a cetain π-bond contribution to the N—O and C—C(aryl) bonds as demonstrated by the following resonance hybrid:



The C=N and N—O bond lengths in **3** (1.311(3) and 1.291(2) Å, respectively) may be compared to those reported for other free nitrones of various structure: 1.309(7) and 1.284(6) (21), 1.299(6) and 1.298(6) (22), 1.309(8) and 1.284(8) (22), 1.327(5) and 1.300(5) Å (23). The nitrone chelate **2** has shorter C=N (1.286(6) Å) and longer N—O (1.355(5) Å) distances, indicating a more pronounced iminium salt character for the B,N-betaine complex.

Both crystal structures consist of discrete molecules separated by normal van der Waals distances, the only notable intermolecular contact occurring in **2** where H(5b)···O(2) ($1/2 + x$, $3/2 - y$, $-z$) = 2.50(6) Å. The nitrone O atoms and the phenyl groups are *cis* with respect to the C=N double bond in both molecules, the phenyl groups being rotated out of the nitrone group mean planes by 19.7(5) and 21.4(2)° for **2** and **3**, respectively. The formation of six-membered NO···HCCC rings via intramolecular C—H···O hydrogen bonds (H···O = 2.22(5) and 2.29(2), C···O = 2.816(7) and 2.819(3) Å, C—H···O = 125(3) and 117(2)°, respectively, for the two compounds) may be responsible for this near coplanarity of nitrone and phenyl groups. In **2** the nitrone group is planar within experimental error while both phenyl rings are slightly but significantly nonplanar (χ^2 = 11.7 and 15.6, maximum deviation from the mean plane 0.019(7) Å). In **3** the nitro, the B-phenyl, and B-coordination groups are all planar to within

OSVALD KNOP, T. STANLEY CAMERON, S. P. DERANIYAGALA, D. ADHIKESAVALU, and MICHAEL FALK. Can. J. Chem. **63**, 516 (1985).

The crystal structure of $(NH_4)_2AlF_5 \cdot H_2O$ = $(NH_4)_2[AlF_5(H_2O)]$ (*Pbcn*, a = 10.192(4) Å, b = 8.037(2) Å, c = 7.844(1) Å, Z = 4) consists of isolated $[AlF_5(H_2O)]^{2-}$ octahedra and NH_4^+ ions. The octahedra are linked by F···H—O—H···F bonds to form zigzag chains parallel to c and the chains are cross-linked by normal N—H···F hydrogen bonds to the NH_4^+ ions. The ir characteristics of the hydrogen bonds in this and the other two title compounds were probed with the NH_3D^+ ion between 10 and 293 K. The probe-ion spectra confirm the C_1 symmetry of the ammonium ion in $(NH_4)_2[AlF_5(H_2O)]$ and point to N—H···F bonding of moderate strength. For NH_4AlF_4 the spectra agree with the expectation from the known crystal structure of both the ordered and the disordered phase, but the transition at ~150 K is not evident in the evolution of the spectra with temperature. Detailed assignment of the ND stretching and bending component absorptions of NH_3D^+ is not possible for $(NH_4)_3ZnCl_5$ = $(NH_4)_3(ZnCl_4)Cl$. However, the unusually low frequencies of two of the components of the ND stretching absorptions in this crystal indicate the existence of N—H···Cl^- bonds stronger than those in NH_4Cl. The filiation of the known AMF_4 structures deriving from $TlAlF_4$ is presented in terms of two-colour space groups.

OSVALD KNOP, T. STANLEY CAMERON, S. P. DERANIYAGALA, D. ADHIKESAVALU et MICHAEL FALK. Can. J. Chem. **63**, 516 (1985).

La structure cristalline du $(NH_4)_2AlF_5 \cdot H_2O$ = $(NH_4)_2[AlF_5(H_2O)]$ (*Pbcn*, a = 10,192(4) Å, b = 8,037(2) Å, c = 7,844(1) Å, Z = 4) est formée d'ions NH_4^+ et d'ions $[AlF_5(H_2O)]^{2-}$ octaédriques isolés. Les octaèdres sont reliés par des liaisons F···H—O—H···F qui forment des chaînes en zigzag le long de l'axe c alors que les chaînes sont réticulées par des liaisons hydrogènes N—H···F normales avec les ions NH_4^+. Opérant entre 10 et 293 K et utilisant l'ion NH_3D^+ comme sonde, on a étudié les caractéristiques infrarouges de ces liaisons hydrogènes ainsi que celles des deux autres composés mentionnés dans le titre. Le spectre de l'ion sonde confirme la symétrie C_1 de l'ion ammonium dans le produit $(NH_4)_2[AlF_5(H_2O)]$ et suggère que la force de la liaison N—H···F est modérée. Dans le cas du NH_4AlF_4, le spectre correspond à ce que l'on aurait pu escompter sur la base de ce que l'on connait de la structure cristalline des phases tant ordonnée que désordonnée; toutefois, la transition autour de 150 K n'est pas évidente si l'on examine l'évolution du spectre avec la température. Dans le cas du $(NH_4)_3ZnCl_5$ = $(NH_4)_3(ZnCl_4)Cl$, on ne peut pas faire d'attributions détaillées aux absorptions dues aux composantes d'élongation et de déformation angulaire de la liaison ND du NH_3D^+. Toutefois, les fréquences anormalement basses de deux des composantes des absorptions dues aux élongations de la liaison ND dans ce cristal suggèrent l'existence de liaisons N—H···Cl^- qui sont plus fortes que celles que l'on observe dans le NH_4Cl. On présente la filiation des structures connues de AMF_4 dérivant du $TlAlF_4$ en fonction de groupes d'espace en deux couleurs.

[Traduit par le journal]

In the course of our recent investigation of ammonium cryolites, $(NH_4)_3MF_6$, we had occasion to prepare two related compounds, $(NH_4)_2AlF_5 \cdot H_2O$ and NH_4AlF_4. The very good quality of exploratory ir spectra of the NH_3D^+ probe ion in both these compounds at 10 K encouraged us to undertake a systematic study of the spectra between 10 K and room temperature. Although the $\nu_1(NH_3D^+)$ and $\nu_{4bc}(NH_3D^+)$ frequencies in NH_4AlF_4 at liquid-nitrogen temperature had been recorded earlier (2), the recently reported (3) transition in this compound, in the vicinity of 150 K, made a more thorough investigation desirable. Neither a structural nor a spectroscopic study of $(NH_4)_2AlF_5 \cdot H_2O$ seems to have been published previously. In view of the crystallographic diversity of known $A_2MF_5 \cdot H_2O$ compounds[3] it did not seem safe to interpret the spectra of $(NH_4)_2AlF_5 \cdot H_2O$ on a presumed structural analogy with one of the other monohydrates, and we have therefore determined the crystal structure of this fluoride. In addition, to test the potential of the probe-ion method realizable with an FT ir spectrometer, we have obtained NH_3D^+ spectra, between 10 and 293 K, of $(NH_4)_3ZnCl_5$ = $(NH_4)_3(ZnCl_4)Cl$, which has been

[1] For Part XII, see ref. 1.
[2] NRCC No. 23854.

[3] The $A_2MF_5 \cdot H_2O$ fluorides reported to date fall in two classes, $A_2[MF_5(H_2O)]$ and $A_2[MF_4F_{2/2}] \cdot H_2O$. The structures in the first class contain isolated $[MF_5(H_2O)]$ octahedra and have symmetry *Cmcm* (CsFe, ref. 4) or *Fm3m* (TlV and RbCr, refs. 5 and 6). The structures in the second class are characterized by *trans*-linked chains of $[MF_6]$ octahedra. The following symmetries are represented: $P2_1/m$ — KMn (7); *Cmcm* — KAl (8, 9), RbAl (10), TlAl (10), RbMn (11), RbFe (10); *Cmmm* — CsMn (12).

reported (13) to contain two types of ammonium ions at sites of low symmetry.

Experimental

Preparation

According to Novoselova (14) the three compounds that exist in the system $NH_4F-AlF_3-H_2O$ at 25°C are $(NH_4)_3AlF_6$, $(NH_4)_2AlF_5\cdot H_2O$, and NH_4AlF_4. The hydrate has not been investigated previously. The structural aspects of the two anhydrous salts were studied by Brosset (8, 9); that of NH_4AlF_4 also by Thilo (15). Brosset prepared NH_4AlF_4 by neutralizing a strongly HF-acid solution of AlF_3 with concentrated NH_4OH, whereas Thilo decomposed $(NH_4)_3AlF_6$ thermally at temperatures below 350°C. Both authors reported NH_4AlF_4 to be tetragonal, $a \sim 3.59$ Å, $c \sim 6.35$ Å, with a structure of the same type as that proposed for $TlAlF_4$ by Brosset (16).

We prepared NH_4AlF_4 by slowly adding a stoichiometric amount of solid NH_4F to a hot solution of AlF_3 obtained by dissolving Al in 48% HF. The precipitate was digested for 1/2 h on a steam bath, filtered, washed with weak HF followed by EtOH, and dried over P_2O_5. Because of its slight solubility in weak HF the salt could not be deuterated by recrystallization from H_2O-D_2O; partially deuterated samples were obtained by repeating the preparation from aqueous HF containing D_2O.

$(NH_4)_2AlF_5\cdot H_2O$ was prepared in a similar manner using an NH_4F/AlF_3 ratio of 2.5/1. The precipitate was filtered and washed etc., as under NH_4AlF_4. It was deuterated by repeating the procedure with solutions containing D_2O.

$(NH_4)_2ZnCl_4$ and $(NH_4)_3ZnCl_5$ are reported to be the only two compounds in the system $NH_4Cl-ZnCl_2-H_2O$ between 0 and 30°C (cf. ref. 13). $(NH_4)_3ZnCl_5$ was prepared by slow evaporation over $CaCl_2$, at room temperature, of a 3/1 molar aqueous solution of NH_4Cl and $ZnCl_2$ (13, 17). It was deuterated by repeating the preparation with H_2O-D_2O solutions. Unlike $(NH_4)_2ZnCl_4$ (18, 19), crystals of $(NH_4)_3ZnCl_5$ are not deliquescent under ordinary atmospheric conditions.

The identity of NH_4AlF_4 and $(NH_4)_3ZnCl_5$ was confirmed by internal evidence from the ir spectra and for NH_4AlF_4 also by comparison with a published spectrum (20). The authenticity of $(NH_4)_2AlF_5\cdot H_2O$ was guaranteed by the crystal-structure determination. However, the reported narrowness of the stability range of this phase in the $NH_4F-AlF_3-H_2O$ system (14) invited caution as to the homogeneity of the bulk sample. Of particular concern was the absence of typical H_2O absorptions in the ir spectra (see below). To prove that the products did contain H_2O, samples of separately prepared material with zero, low and high D contents were heated in a mass spectrometer and the low-resolution spectra were recorded at increasing sample temperatures. The intensity vs. temperature plots for these dynamic thermolysis conditions indicated clearly that water was present and that it was given off over a temperature range below ~100°C, the bulk of it at ca. 70°C and in any case before the liberation and dissociation of NH_4F.

Infrared spectra

Finely ground sample powders were mulled in Nujol or fluorolube and the mulls were supported between CaF_2 plates. The spectra were obtained with a Fourier-transform ir spectrometer (Bomem DA3.02) fitted with a closed-cycle He refrigerator (Displex model 202, Air Products and Chemicals Co.). The variable-temperature spectral runs were made in the heating mode.

$(NH_4)_2AlF_5\cdot H_2O$: structure determination

A CAD-4 four-circle diffractometer was used in the determination of the unit cell dimensions and to collect intensities (θ = 2–25°). The intensities were reduced by routine procedures (21). Corrections for Lorentz and polarization factors were applied but not for absorption or extinction. The scattering factors for neutral atoms were taken from ref. 22. The structure was solved from 344 unique reflections by Patterson and Fourier methods using the SHELX system (23). Full-matrix least-squares ($w\Delta F^2$ = minimum) refinements were carried out with isotropic temperature factors on the heavy atoms until R was reduced to a suitably low value. The hydrogen atoms were located from a difference map. The N—H, O—H, and H—H distances were appropriately constrained to ensure convergence. The final refinement, with anisotropic temperature factors on the nonhydrogen atoms and isotropic factors on the hydrogens gave $R = 4.6\%$, $R_w = 4.4\%$. Least-squares weights were calculated from the expression $0.5267w^{-1} = \sigma^2|F_o| + 0.000500F_o^2$, where σ is the weight for an individual reflection derived from the diffractometer counting statistics. The anisotropic temperature factor is defined as $T = \exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{23}klb^*c^* + 2U_{13}hla^*c^* + 2U_{12}hka^*b^*)]$.

The positional and thermal parameters are listed in Table 1, structure factors in Table 2,[4] and interatomic distances and bond angles in Table 3.

Results and discussion

$(NH_4)_2AlF_5 \cdot H_2O$: crystal structure

The structure consists of isolated $[AlF_5(H_2O)]$ octahedra (of symmetry C_2) and NH_4^+ ions arranged in a distorted antifluorite packing (Fig. 1). In each layer of $[AlF_5(H_2O)]$ octahedra parallel to (001) all the Al—O bonds are oriented in the same direction; the directions alternate from plane to plane in an "antiferro" manner. In layers parallel to (100) the octahedra are linked by F(2)···H—O—H···F(2) hydrogen bonds to form zigzag chains parallel to the c-axis. These chains in turn are cross-linked within *and* between these layers by normal, somewhat bent N—H···F(1) and N—H···F(3) hydrogen bonds (Figs. 2 and 3). Each ammonium ion is surrounded by four $[AlF_5(H_2O)]$ octahedra, each N-hydrogen being bonded to a fluorine in a different octahedron.

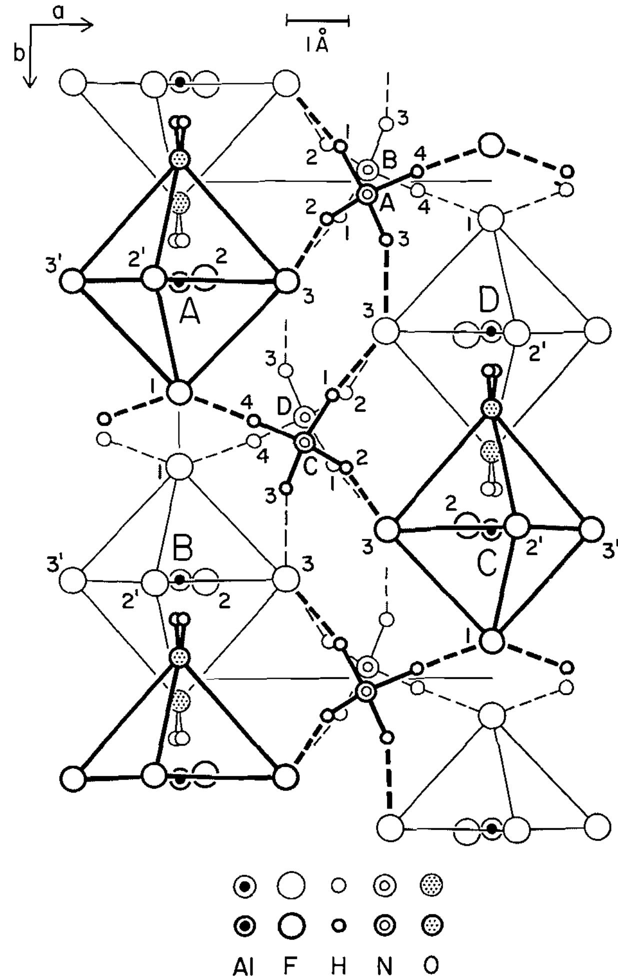

FIG. 2. $(NH_4)_2[AlF_5(H_2O)]$: projection of the unit cell on (001) displaying the N—H···F bonding scheme. The H_w···F bonds are not shown. For symmetry code, interatomic distances and bond angles see Table 3.

The F(2) atoms are hydrogen-bonded exclusively to the water molecules. Each F(1) atom is symmetrically bonded to two H(4) hydrogens (H···F, 1.80 Å), and each F(3) atom is bonded to three H atoms, H(1), H(2), and H(3) (mean H···F distance, 1.85(3) Å). The four H···F distances are quite similar (mean H···F, 1.84(4) Å) and would be classified as moderately strong. The O···F(2) and H_w···F(2) distances, however, are quite short, 2.551(3) and 1.59(6) Å, respectively. The O···F(2) distance, which compares with the corresponding distance in $RbVF_4 \cdot 2H_2O$, 2.56 Å (24), $ZnF_2 \cdot 4H_2O$, 2.57 Å (25), and $Cs_2[FeF_5(H_2O)]$, 2.61 Å (4), is at the lower limit of the O···F range in metal fluoride hydrates (26), as also is the $OH_wF(2)$ angle of 163(5)°.

The filiation of the $(NH_4)_2[AlF_5(H_2O)]$ and related structures from the $Fm3m$ antifluorite aristotype will be discussed elsewhere. It is, however, interesting to note that $Rb_2AlF_5 \cdot H_2O$, which contains a cation dimensionally similar to NH_4^+, has a structure built of chains of $[AlF_6]$ octahedra sharing opposite

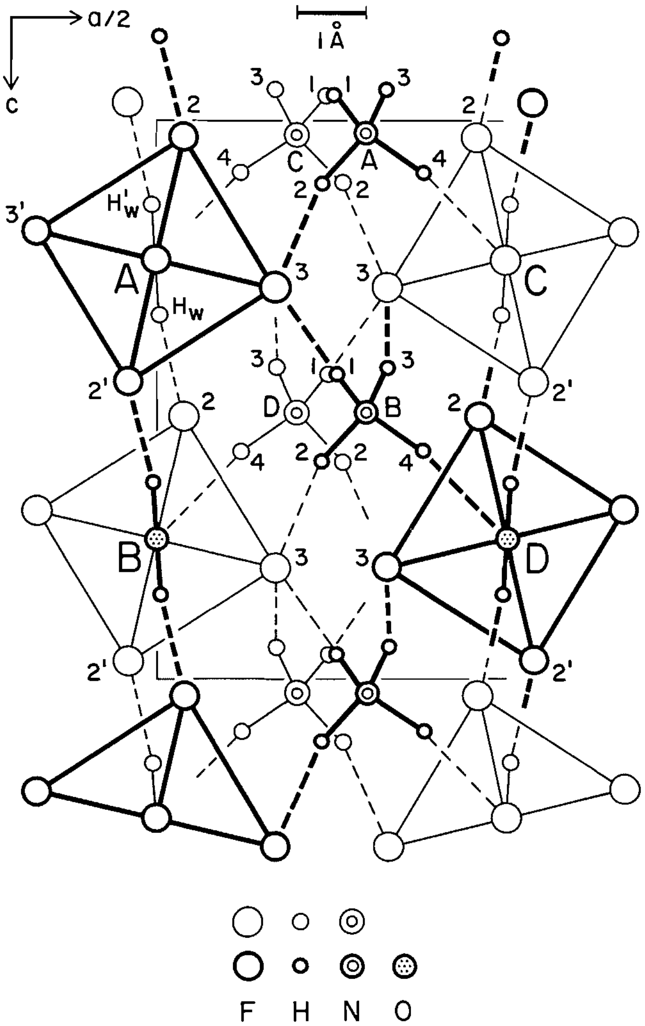

FIG. 3. $(NH_4)_2[AlF_5(H_2O)]$: projection of a portion of the unit cell on (010) displaying details of the O—H_w···F and N—H···F hydrogen-bonding scheme. For symmetry code, interatomic distances and bond angles see Table 3. The following values have been added to the coordinates of Table 1: ammonium ions, B + (0, 0, 1), C + (0, −1, 0), D + (0, −1, 1); anions, B + (0, 0, 1), C + (0, −1, 0), D + (0, 0, 1).

corners, $Rb_2[AlF_4F_{2/2}]\cdot H_2O$, and not of isolated $[AlF_5(H_2O)]^{2-}$ ions (10). It is not clear to what extent this difference is attributable to the hydrogen bonding of the ammonium ions. The volume per formula unit V_1 of $(NH_4)_2[FeCl_5(H_2O)]$ is smaller than the V_1 of $Rb_2[FeCl_5(H_2O)]$; this and spectroscopic evidence (2, 27) indicate that N—H···Cl bonding is present in the ammonium compound. Yet these two compounds, and similarly $(NH_4)_2[VCl_5(H_2O)]$ and $Rb_2[VCl_5(H_2O)]$, form isostructural pairs.[5] This lack of structural distinction may of course arise from the relative weakness of the N—H···Cl bonding compared with the N—H···F bonding. On the other hand, $Cs_2FeF_5\cdot H_2O$, though not isostructural with $(NH_4)_2AlF_5\cdot H_2O$, contains isolated $[FeF_5(H_2O)]$ ions despite the absence of N—H···F bonding (4); and as the following list shows, ionic size may not be a strong determining factor either (**A**, $A_2[MF_5(H_2O)]$; **B**, $A_2[MF_4F_{2/2}]\cdot H_2O$):

[5] In fact, all the known $A_2MCl_5\cdot H_2O$ chlorides contain isolated $[MCl_5(H_2O)]$ ions (cf. ref. 27).

$(NH_4)_2AlF_5\cdot H_2O$: probe-ion spectra

The expectation for a single type of ammonium ion at sites of symmetry C_1 ideally would be a ν_1 quartet and a ν_{4bc} octet, each with all the components of equal weight. From ν(ND) vs. d(N···F) or d(H···F) and ν_{4bc} vs. ν_1 plots (cf. ref. 2 and updated versions to be published) the mean $\bar{\nu}_1$ and $\bar{\nu}_{4bc}$ frequencies at room temperature would be predicted as ~2370 and ~1285 cm^{-1} respectively, and since they correspond to somewhat bent but normal (i.e. to a single acceptor atom) N—H···F bonds, the $\bar{\nu}_1$ frequency would be expected to increase and the $\bar{\nu}_{4bc}$ frequency to decrease with increasing temperature.

The 10 K spectrum indeed contained a well-resolved ν_1 quartet, with components at 2313, 2333, 2346, and 2364 cm^{-1} ($\bar{\nu}_1$ (10) = 2339 cm^{-1}, total range = 51 cm^{-1}); the ν_{4bc} absorption consisted of six resolved components, with frequencies between 1273 and 1307 cm^{-1} ($\bar{\nu}_{4bc}$ (10) = 1288 cm^{-1}, total range = 34 cm^{-1}) (Fig. 4). The halfwidths were 6–10 cm^{-1}.

With increasing temperature the components of the ν_1 as well as the ν_{4bc} absorption gradually broadened and coalesced, with no apparent discontinuities in the evolution with temperature. By 220 K the ν_1 absorptions had collapsed to a single broad band centred at 2350 cm^{-1}. The centre of gravity kept moving to higher frequencies and went over smoothly into the peak of the broad band, ending up at 2356 cm^{-1} at room temperature (a total shift of +16 cm^{-1}). The halfwidth at room temperature was about 46 cm^{-1}, corresponding roughly to the spread of the component frequencies at low temperature.

The ν_{4bc} components also coalesced with increasing temperature but only partially: even at room temperature three components could still be discerned. At the same time the $\bar{\nu}_{4bc}$ frequency shifted to lower values, about 1280 cm^{-1} at room

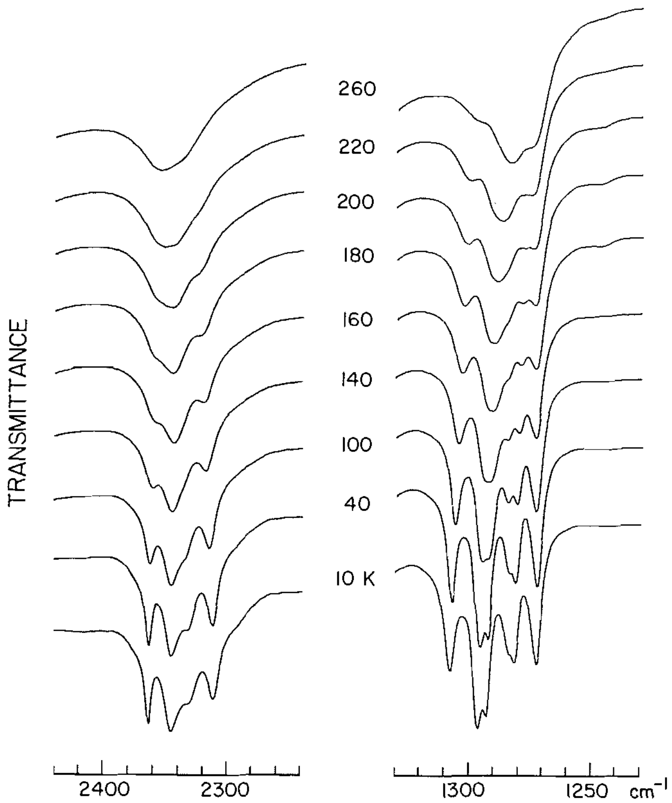

FIG. 5. $(NH_4)_2[AlF_5(H_2O)]$: survey spectrum at room temperature (fluorolube mull).

temperature, which corresponds to a total shift of ca. -8 cm^{-1}. The above prediction is thus seen to be quite successful.

As the observed ν_1 and ν_{4bc} frequencies indicate, the N—H···F bonding in $(NH_4)_2[AlF_5(H_2O)]$ is moderately strong.

The absence of typical H_2O absorptions in the room-temperature spectrum of this hydrate (Fig. 5) was puzzling. While the small band at ~1641 cm^{-1} *may* arise from the HOH bending fundamental, the spectrum contained no obvious features that could be assigned to the OH stretching fundamental — and this in spite of the fact that, in the ir spectra of crystalline hydrates, the absorption due to the OH stretching mode is generally many times more intense than the bending absorption (20, 28). At the same time, however, there are almost no hydrate spectra in the literature that could usefully serve as precedents for the absorptions of an H_2O molecule as strongly bonded as that in $(NH_4)_2[AlF_5(H_2O)]$, with an O···F distance of only 2.55 Å. The nearest comparison would be with $(NH_4)_2[Cr(H_2O)_6]F_5$, which we have also studied recently (results to be published). In this fluoride the O···F distances are similarly short, 2.53–2.57 Å (29), and the OH stretching fundamental is found as an extremely broad absorption extending from 2000 to 3800 cm^{-1} and centred at ~2900 cm^{-1}. We should then expect a similar band in the spectrum of $(NH_4)_2[AlF_5(H_2O)]$ if allowance is made for the difference of stoichiometry, which would make the intensity of the band about six times weaker relative to the NH stretching bands in this region. It is concluded that the OH stretching absorption in Fig. 5 underlies the group of peaks at 3223, 3105, and 2915 cm^{-1} originating in $\nu_3(NH_4^+)$ and $2\nu_2(NH_4^+)$ and complicated by factor-group splitting and Fermi resonance.

The corresponding OD stretching absorptions of HDO and D_2O, expected in the 2800–1500 cm^{-1} region, are probably also very broad. In any event they could not be located in our spectra of the partially deuterated compound.

The untypical nature of the H_2O molecule in $(NH_4)_2[AlF_5(H_2O)]$ is undoubtedly also reflected in the very strong anisotropy of the U_{ii} thermal parameters of the oxygen atom (Table 1): $U_{22} \sim U_{33}$, $2U_{11}/(U_{22} + U_{33}) = 5(1)$, where U_{11} refers to a direction perpendicular to the Al—O bond and almost perpendicular to the HOH plane (Fig. 3).

If a low-temperature transition in $(NH_4)_2[AlF_5(H_2O)]$ exists, there was no evidence of it in the probe-ion spectra.

NH_4AlF_4

A recent X-ray powder and single-crystal diffraction study by Fourquet *et al.* (30) gave a tetragonal cell four times larger than that originally proposed (cf. Experimental): $a' = a\sqrt{2} = 5.078(2)$ Å, $c' = 2c = 12.715(4)$ Å, $Z' = 4$. With the H atoms not included the space group was $I4/mcm$, with N in $4(b)$-$0\frac{1}{2}\frac{1}{4}$ etc., Al in $4(c)$-000 etc., F_{ax} in $8(f)$-$00z$ etc., and F_{eq} in $8(h)$-$x, \frac{1}{2}+x, 0$ etc. These authors further proposed that inclusion of the hydrogens would yield a noncentrosymmetric space group (consistent with the observed generation of the second harmonic) and settled on $I\bar{4}c2$, with the H atoms in $16(i)$-xyz etc. Re-investigation by neutron diffraction from a single crystal (31) and from a powder profile refinement (3) led to a revision of the space group to $I4/mcm$, with the hydrogens distributed over the $32(m)$-xyz etc. equipoint in a way consistent with a statistical distribution of the ammonium ions over two possible orientations. In this structure the site symmetry at N is D_{2d}. No evidence of a transition between room temperature and 350°C was observed either by dta or ^{1}H nmr (30).

An X-ray investigation between 80 and 300 K did not reveal any noticeable departure from tetragonal symmetry or from the body-centering (3). However, an esr study of NH_4AlF_4:Fe^{3+} and NH_4AlF_4:Cr^{3+} indicated the existence of a structural phase transition in the vicinity of 150 K (31, 32). Neutron powder diffraction at 5 K (3) led to $P4_2/mbc$ as the space group of the low-temperature phase (N in $4(b)$-$00\frac{1}{4}$ etc., Al in $4(c)$-$0\frac{1}{2}0$ etc., F_{ax} in $8(f)$-$0\frac{1}{2}z$ etc., F_{eq} in $8(h)$-$xy0$ etc. ($x \sim y$), and H in $16(i)$-xyz etc.), and to S_4 as the site symmetry at N. The ammonium ions in this structure are orientationally ordered; the ordering is described by the authors as "ferro" within the ammonium layers ‖(001) and "antiferro" between these layers. The intra-layer ordering is present already at temperatures more than 100° above T_{tr}, whereas the inter-layer ordering sets in only at T_{tr} (33). The shortest H···F distances (to F_{ax}) are 1.898(4) Å at 300 K and 1.852(3) Å at 5 K; the corresponding N···F_{ax} distances are 2.900(1) Å and 2.893(1) Å, and the NHF_{ax} angles are 171.2(5)° and 170.8(1)° (N—H = 1.010(4) and 1.043(2) Å). These distances and angles are unchanged on passage through T_{tr}.

The expectation for the NH_3D^+ probe-ion spectrum is a single ν_1 absorption and a ν_{4bc} 1:1 doublet for both $S = D_{2d}$ and $S = S_4$ (Table 1, ref. 34). Consequently there should be no change in the number of the ν_1 and ν_{4bc} absorptions on passage through T_{tr}, though the ordering might affect the linewidths and frequencies of these absorptions.

The 10 K spectrum (Fig. 6) contained a single ND stretching absorption ν_1, at 2347 cm^{-1} ($\Delta\nu_{1/2}$ = 12 cm^{-1}). The ND bending ν_{4bc} was an approximately 3:2 doublet at 1287 and 1303 cm^{-1}, also with a ca. 12 cm^{-1} component halfwidth. With increasing temperature the frequency of the ν_1 band increased, the shift between 10 and 293 K amounting to +9(3) cm^{-1}, while the ν_{4bc} doublet partially collapsed and shifted to 1283.5 and 1294 cm^{-1} at 293 K, i.e. a total shift of −6(1) cm^{-1}. These results are in agreement with those reported earlier (2) for liquid-nitrogen temperature (probably ~100 K). At room temperature the halfwidths were about 45 cm^{-1} for ν_1 and ca. 36 cm^{-1} for the ν_{4bc} components.

The observed number of ν_1 and ν_{4bc} bands is consistent with a single type of ammonium ion in the structure, of effective symmetry D_{2d}, S_4, or D_2 and at a site of nonpolar tetragonal or D_{2h} or D_2 symmetry. This confirms the site symmetries reported in ref. 3. The signs of the temperature coefficients of the ν_1 and ν_{4bc} frequencies indicate (35) that the N—H···F bonds are normal, i.e. essentially straight. This too is consistent with the reported crystal structures. The observed ν_1 frequency points to a hydrogen bonding substantially weaker than that in NH_4F and even NH_4HF_2 (2); this would be expected in view of the relatively long H···F distance (cf. Fig. 1 of ref. 2). The smallness of the ν_1 frequency shift on cooling from room temperature to 10 K indicates that the hydrogen bonding does not strengthen appreciably, and this again is consistent with the constancy of the N···F_{ax} distance, although the change in the reported H···F distance, ca. 0.05 Å, might suggest a larger ν_1 shift.

The changes, with temperature, in the probe-ion spectra were gradual. There was no evidence of the transition in the vicinity of 150 K, nor of changes in the degree of the intra-layer ordering above 150 K. This lack of sensitivity to the orientation of the ammonium ion is paralleled in the Raman spectrum of neat NH_4AlF_4 (36): of the observed features the only ones that were found to respond to the ordering below 150 K were those due to the E_g translatory (~150 cm^{-1}) and rotatory (~250 cm^{-1}) modes of NH_4^+.

The nature of the ordering in NH_4AlF_4 is most directly described by the use of two-colour space-group symmetry. In the (fully ordered) intermediate phase the [AlF_6] octahedra in layers ‖(001) are rotated about their tetragyres and the rotational displacements are "antiferro" ordered; the orientations of these "antiferro" nets in adjacent layers alternate.[6] This arrangement is derived from the arrangement of the octahedra in the highest-symmetry ($P4/mmm$) aristotype structure[7] by the dichromatic Bravais translation $(\mathbf{a}_1' + \mathbf{a}_2)/2$ of the Shubnikov group Sh_{140}^{550}-I_c4/mcm: four unit cells of the aristotype structure (a_0, c_0, $Z = 1$) combine to generate the intermediate structure ($a_0\sqrt{2}$, $2c_0$, $Z = 4$),[8] and the chromatic component of the translation, interpreted as orientation reversal, assures the "antiferro" intralayer ordering of the [AlF_6] octahedra and the alternation of the orientations of the octahedra in adjacent layers. In this structure, describable in terms of $I4/mcm$, the ammonium ions are in a twofold orientational disorder. The ordering process, which sets in at T_{tr}, results in an ordered arrangement of the ammonium ions, leaving the rest of the structure essentially unchanged. This orientational order of NH_4^+ is derivable from the intermediate structure by the dichromatic Bravais translation $(\mathbf{a}_1' + \mathbf{a}_2' + \mathbf{c}')/2$ of the Shubnikov group

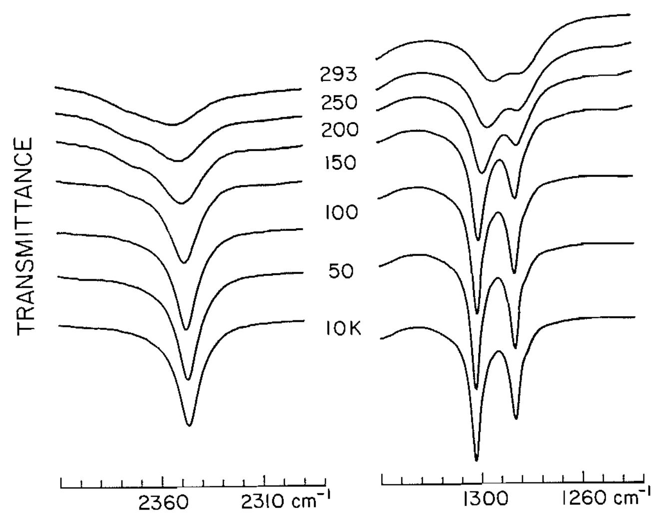

FIG. 6. NH_4AlF_4: the ND stretching and bending regions of the NH_3D^+ probe-ion spectrum at different temperatures (~5% D).

Sh_{135}^{494}-P_I4_2/mbc. This translation, again associated with orientation reversal, generates a "ferro" ordering of the ammonium ions *within* the NH_4^+ layers ‖(001) but an "antiferro" stacking arrangement of these layers. The low-temperature structure, describable in terms of $P4_2/mbc$, can thus be regarded as doubly ordered relative to the $P4/mmm$ aristotype (cf. Figs. 4 and 5 of ref. 33, and Figs. 3 and 5 of ref. 3).

The presence of the ammonium ion does not appear to lead, apart from the orientational effects on the space-group symmetry, to specific types of AMF_4 structure: NH_4AlF_4(HT) (3, 33) and $TlAlF_4$(RT) (33) appear to be isostructural, and so do NH_4CrF_4(HT) (37) and $CsFeF_4$(LT) (38, 39). On the other hand, NH_4MnF_4 (2/2/1) is triclinic (40), and the symmetry of NH_4FeF_4 has been reported as $P2_12_12$ (ref. 41; cf. also refs. 42 and 43).

Structural filiation of AMF_4 fluorides

In spite of their simple stoichiometry and M coordination the $A[MF_2F_{4/2}]$ fluorides deriving from the tetragonal $TlAlF_4$ (1/1/1) aristotype exhibit a remarkable variety of structural detail. Of the many compounds reported in the literature those with known crystal structures are included in Fig. 7. The formal symmetry relationship between a higher- (H) and a lower-symmetry (L) space group SG(H)|SG(L) is presented in terms of a two-colour (Shubnikov) space group. While ultimately not different from considerations of "zellengleiche" and "klassengleiche" subgroups, this formulation has the advantage that the type of ordering of the [MF_6] orientations within and between MF_6 layers ‖(001) is immediately evident. When a dichromatic Bravais translation is present in the Shubnikov group (type IV, cf. ref. 44), the [MF_6] orientations in the L structure must be "antiferro" ordered with respect to the H structure, and the type of order follows from the chromatic operations of the group. The symmetry elements lost on going from H to L are the chromatic symmetry elements of the Shubnikov group, the essential of which are identified in the group symbol. Composite cations are affected in a similar manner, as are also [MF_6] distortions without "tilt", i.e. without rotational [MF_6] displacement.

The relevant Shubnikov groups Sh_p^q are the following:

---

[6] If the axial fluorines in NH_4AlF_4(HT) were shared by adjacent AlF_6 layers, the structure would be analogous to $KCuF_3$.

[7] The highest-symmetry phase does not appear to be accessible because of the thermal instability of NH_4AlF_4 (cf. ref. 30).

[8] In the following the unit-cell size will be indicated by $\sqrt{2}/\sqrt{2}/2$ etc.: a (or a_1) ~ $a_0\sqrt{2}$, b (or a_2) ~ $a_0\sqrt{2}$, c ~ $2c_0$.

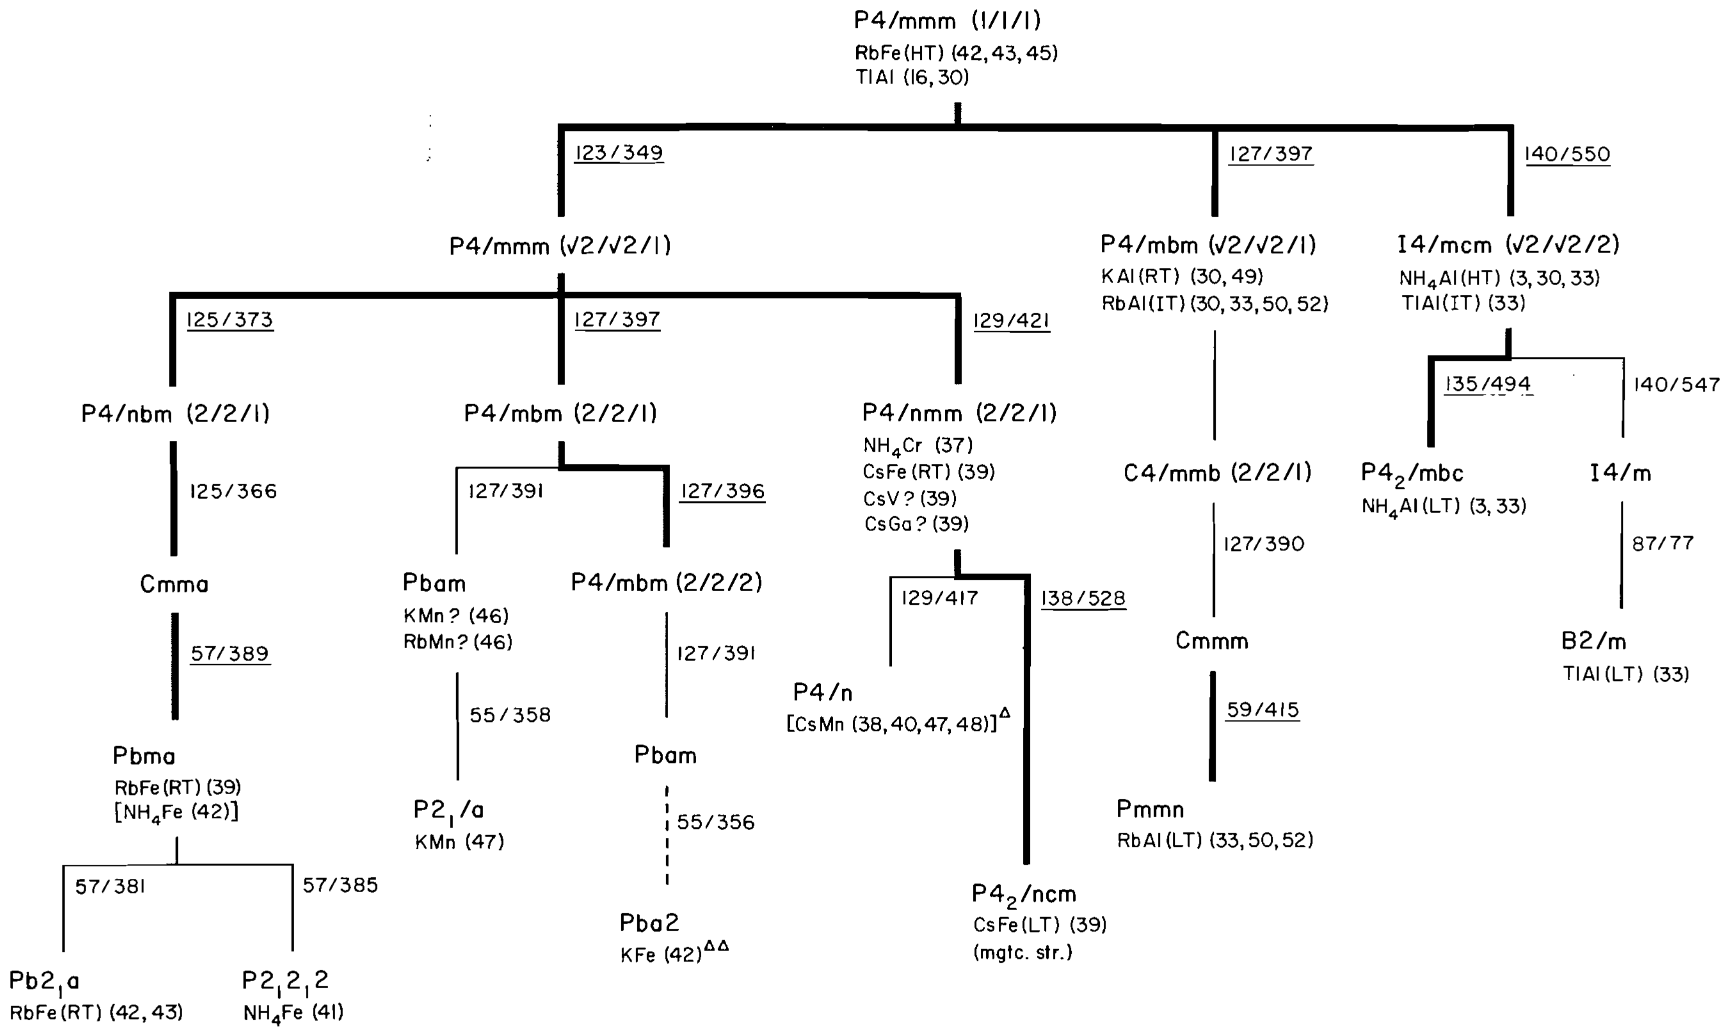

FIG. 7. Filiation of AMF_4 structures deriving from the $TlAlF_4$ aristotype. HT high, IT intermediate, LT low-temperature phase. 123/349 stands for Sh_{123}^{349} etc. (see text); heavy connecting lines and underlining refer to dichromatic Bravais translations. For the meaning of $\sqrt{2}/\sqrt{2}/2$ etc. (shown only when Z changes) see footnote[8]. —$^{\Delta}$ A Jahn–Teller structure; symmetry actually observed, *P*4/*nmm*. —$^{\Delta\Delta}$ According to ref. 51 the structure of $KFeF_4$ (and probably also KVF_4) can be described adequately in terms of a 2/1/2 pseudocell of symmetry *Amma*; the magnetic structure with a 2/2/4 cell (Fig. 5 of ref. 51) appears to be of Sh_{60}^{427} symmetry, P_bbcn-2$Pmca|Pbcn$.

For the sake of brevity, in Fig. 7 the groups are denoted by p/q, with those involving a dichromatic Bravais translation underlined.

Some doubt seems to exist about the symmetry of the room-temperature form of $RbFeF_4$. In ref. 45 it (and $RbVF_4$) is reported to be tetragonal, 2/2/1. Tressaud *et al.* (42, 43) concluded that the space group was *Pbma* or $Pb2_1a \subset Pbma$ and opted for the latter, while Babel *et al.* (39), on re-refining the structure from the data of ref. 43, favoured the centrosymmetric group. Of the $TlMF_4$ fluorides investigated by powder diffraction, those with M = V, Fe, Ga (39), and Mn (46) are reported to be orthorhombic, $\sqrt{2}/\sqrt{2}/2$, and that with M = Cr (39) tetragonal, 2/2/2. No definite conclusion has yet been arrived at for $CsCrF_4$ (39).

It is possible that examples of actual structures will be found for the intermediate formal symmetries in Fig. 7; additional theoretical possibilities exist for generating derivative structures from the *P4/mmm* aristotype.

$(NH_4)_3ZnCl_5$

The structure determination by Klug and Alexander (13) shows that this compound should be formulated $(NH_4)_3(ZnCl_4)Cl$. The orthorhombic *Pnma* unit cell contains four $NH_4^+(1)$ ions at sites of symmetry C_s and eight $NH_4^+(2)$ ions at sites of symmetry C_1. The coordination figures of the ammonium ion are irregular and their description depends to some extent on what N···Cl distance is assumed to represent the limit of hydrogen-bonding interaction between the two atoms.

The Cl environments of $NH_4^+(1)$ and $NH_4^+(2)$ are shown in Fig. 8. The eight N(1)···Cl distances range from 3.14 to 3.69 Å (Table 4). If we assume (somewhat arbitrarily) N···Cl = 3.4 Å as the limit of effective N—H···Cl bonding, the Cl atoms within this bound form a distorted octahedron round N(1). Although the H positions are not known, it is highly probable that one of the hydrogens forms a normal N—H···Cl^- bond to the Cl^- ion involved in the shortest N···Cl distance, 3.14 Å, in which case at least one of the three other bonds would be bifurcated or trifurcated.

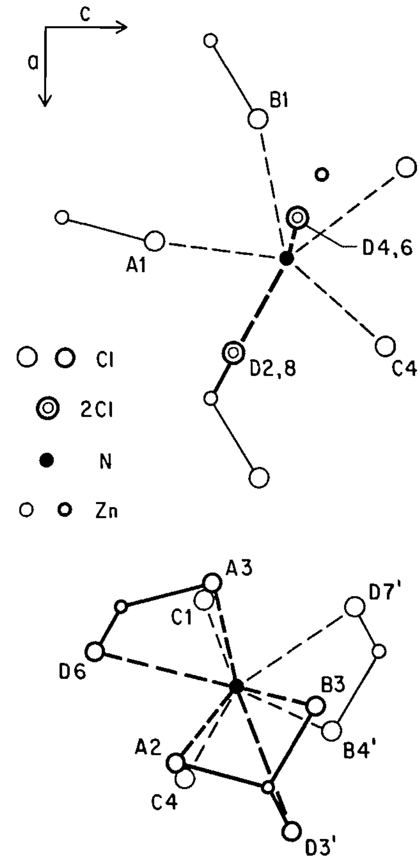

FIG. 8. $(NH_4)_3(ZnCl_4)Cl$: environments of the N(1) (*top*) and N(2) (*bottom*) atoms (after ref. 13). The chloride atoms are C1 and C4, the other Cl atoms belong to $ZnCl_4^{2-}$ ions. The N(1) atom is in the plane of reflection at $y = \frac{1}{4}$ and the N(2) is at $y = \frac{1}{2}$. For N···Cl distances see Table 4.

TABLE 4. N···Cl distances (Å) in $(NH_4)_3(ZnCl_4)Cl$*

Cl	N(1)···Cl	Cl	N(2)···Cl
C(4)	3.14†	B(3)	3.24
D(4), D(6)	3.20	A(2)	3.33
		C(1)	3.35†
D(2), D(8)	3.28	D(6)	3.40
A(1)	3.30	C(4)	3.48†
B(1)	3.49	A(3)	3.56
C(1)	3.69†	B(4')	3.66
		D(7')	3.68
		D(3')	3.82

*Calculated from the data of ref. 13. See Fig. 8 for identification of Cl atoms. The designating letters follow Table 1 of ref. 13.
†N···Cl^- distance.

The nine Cl neighbours of $NH_4^+(2)$ correspond to N···Cl distances from 3.24 to 3.82 Å (Table 4). Klug and Alexander describe the coordination figure as an augmented trigonal prism, but in view of the limited accuracy of the determination and of the uncertainty of the N···Cl cut-off it is impossible at

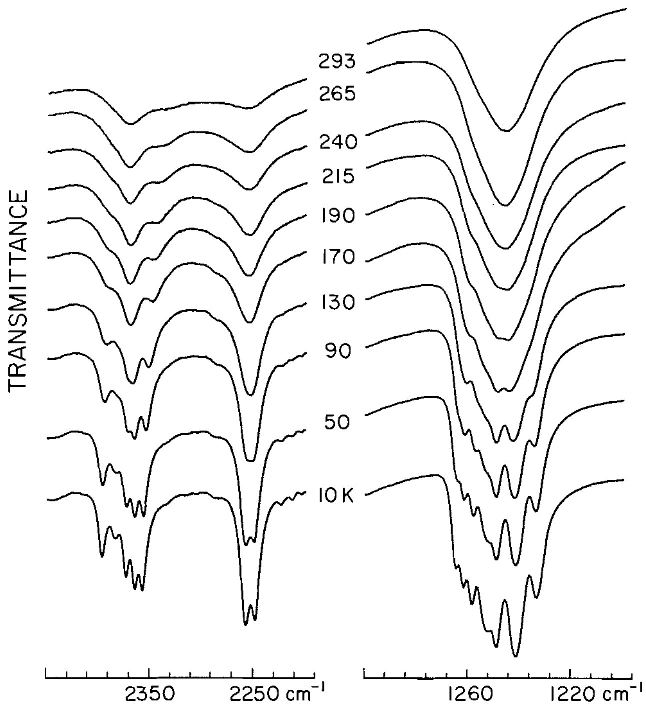

FIG. 9. $(NH_4)_3(ZnCl_4)Cl$: the ND stretching and bending regions of the NH_3D^+ probe-ion spectrum at different temperatures (~5% D).

present to say what the N(2) coordination figure relevant to hydrogen bonding really is.

The spectroscopic expectation from this structure ideally would be a 1:1:2 ν_1 triplet and a 1:1:1:1:2:2 ν_{4bc} sextet for $NH_4^+(1)$, and an equiponderant ν_1 quartet and an equiponderant ν_{4bc} octet for $NH_4^+(2)$. Allowing for the 2:1 abundance ratio of the two ions the expected overall spectrum would be a 1:1:2:2:2:2:2 ν_1 septet and a 14-line ν_{4bc} absorption consisting of four components of single and ten components of double weight. Furthermore, if the assumption of a normal N(1)—H···Cl⁻ bond corresponding to N···Cl = 3.14 Å is correct, at least one of the single-weight ν_1 components would have a significantly lower frequency than the rest.

The ν_1 spectrum at 10 K consisted of seven components arranged in two groups, a quintet at 2397.1, 2384.2, 2373.7, 2365.1, and 2357.7 cm^{-1}, and an approximately 1:1 doublet, of higher intensity, at the much lower frequencies of 2258 and 2249 cm^{-1} (Fig. 9). The component halfwidths were about 8 cm^{-1}. The ν_{4bc} absorption at 10 K consisted of seven *resolved* components covering the range from 1264.9 to 1233.7 cm^{-1}, with halfwidths of 4–6 cm^{-1}.

Increasing temperature produced a gradual coalescence of the ν_1 components, maintaining, however, the separation of the two groups (Fig. 9). At room temperature only three broad bands remained, at 2370, 2332, and 2260 cm^{-1}. The ν_{4bc} components gradually coalesced into a single broad band at room temperature.

There was no evidence in either ND absorption of abrupt changes pointing to the existence of a transition between 10 and 293 K. The 10 K spectrum can therefore be regarded as a resolved version of the room-temperature spectrum and interpreted from the room temperature crystal structure. The seven ν_1 components correspond to the expectation in number though not in relative intensity. However, the higher intensity of the lower-frequency bands (corresponding to stronger hydrogen bonding) is not surprising (cf. ref. 53). The appearance of *two* rather than one lower-frequency components points to a second N—H···Cl⁻ bond, almost certainly involving N(2). A more detailed interpretation of the NH_3D^+ probe-ion spectrum in this compound cannot be offered at present.

The relative strength of the N—H···Cl bonding in $(NH_4)_3(ZnCl_4)Cl$ can be estimated from the ν_{4bc} vs. ν_1 plot of Fig. 3 of ref. 2 (or from its updated version, to be published). Combining the highest ν_1 component frequency with the lowest ν_{4bc} component frequency yields a point falling in the region of the plot typical of trifurcated N—H···3Cl bonds, e.g. in $(NH_4)_2PdCl_6$ and $(NH_4)_2PtCl_6$. The point corresponding to the combination of the lowest ν_1 and highest ν_{4bc} component frequency falls in an unpopulated region which may be characterized as representing strong normal N—H···Cl⁻ bonds, stronger than those in NH_4Cl. The two ν_1 absorptions with the lowest frequencies, 2258 and 2249 cm^{-1}, are in fact among the lowest-lying ND stretching absorptions encountered with N—H···Cl bonds, comparable to similar absorptions in alkylammonium halides, e.g. in Et_3NHCl and $(n\text{-}Pr_2NH_2)_3(SnCl_6)Cl$ (54, 55), but unlike the latter they are unencumbered by the extensive Fermi resonance. The probable reason for the much stronger N—H···Cl bonding in these crystals is the possibility of formation of privileged normal N—H···Cl⁻ bonds to the chloride ions, which exists where the Cl coordination figure of the cation consists of isolated Cl⁻ ions *and* the weaker Cl acceptors of MCl_n^{m-} anions, but not with homogeneous, more symmetric NH_4^+ or $R_nNH_{4-n}^+$ chlorine environments, such as those in NH_4Cl of $(NH_4)_2MCl_6$.

NOTES ADDED IN PROOF. The existence of a transition in NH_4AlF_4 has been confirmed in a recent ^1H and ^{19}F nmr investigation (56); the transition is described as continuous in nature, with T_{tr} = 147 K. The results of further esr studies of NH_4AlF_4: Fe^{3+}, undertaken to elucidate the nature of the ordering process in NH_4AlF_4, have also been reported (57–59), and a rigid-ion model has been proposed (and tested on $RbAlF_4$) to describe the lattice dynamics of $AAlF_4$ (60). The redetermination of the crystal structure of $(NH_4)_3ZnCl_5$ (61) has confirmed the essential correctness of Klug and Alexander's structure, but it has not provided a direct clarification of the hydrogen-bonding scheme. An abstract of ref. 62 has only just come to our attention. The crystal data given there (original paper not seen at proof time) would suggest that $(NH_4)_2[GaF_5(H_2O)]$ is isostructural with $(NH_4)_2[AlF_5(H_2O)]$.

Acknowledgments

We are indebted to Dr. J. S. Grossert for the mass spectra of $(NH_4)_2AlF_5 \cdot H_2O$. Research grants from the Natural Sciences and Engineering Research Council of Canada to O.K. and T.S.C. are acknowledged.

Homoenolization of 1,3,3-trimethylbicyclo[2.2.1]heptan-2-one in perdeuterated *tert*-butyl alcohol. Evidence that the medium potassium *tert*-butoxide – *tert*-butyl alcohol is unstable at elevated temperatures

NICK HENRY WERSTIUK AND GEORGE TIMMINS

Department of Chemistry, McMaster University, Hamilton, Ont., Canada, L8S 4M1

Received May 9, 1984

NICK HENRY WERSTIUK and GEORGE TIMMINS. Can. J. Chem. **63**, 526 (1985).

Homoenolization of 1,3,3-trimethylbicyclo[2.2.1]heptan-2-one (**1**) (fenchone) in potassium *tert*-butoxide – *tert*-butyl alcohol-O-*d* and perdeuterated potassium *tert*-butoxide – *tert*-butyl alcohol at 220°C established that there is significant deterioration of the medium and dilution of the deuterium pool. We show that the major pathway of deterioration of the medium and dilution of the pool involves formation of isobutene by elimination of water from the alcohol. Exchange data already accumulated in the literature are used to support our view that the elimination also occurs at 185°C, the temperature commonly used to homoenolize ketones.

NICK HENRY WERSTIUK et GEORGE TIMMINS. Can. J. Chem. **63**, 526 (1985).

L'homoénolisation, à 220°C, de la triméthyl-1,2,3 bicyclo[2.2.1]heptanone-2 (**1**) (fenchone) en présence de *tert*-butylate de potassium/*tert*-butanol O-*d* ou de *tert*-butylate de potassium/*tert*-butanol perdeutéré montre qu'il se produit une détérioration importante du milieu et une dilution de la quantité de deutérium. Nous démontrons que la voie principale de la détérioration du milieu et de la dilution de la quantité de deutérium implique une élimination d'eau de l'alcool conduisant à de l'isobutène. On a utilisé les données d'échange déjà accumulées dans la littérature pour appuyer notre conclusion selon laquelle l'élimination se produit également à 185°C, la température couramment utilisés pour provoquer l'homoénolisation des cétones.

[Traduit par le journal]

Introduction

Potassium *tert*-butoxide in *tert*-butyl alcohol-O-*d* has been used routinely to study hydrogen isotope exchange of carbon acids at elevated temperatures (1, 2). In fact, it has been the medium of choice for homoenolizing ketones (3–5). Although it was suggested by Cram *et al.* that alkoxide bases react with glass (6) during exchange reactions at elevated temperatures, and recycling has been used by Nickon, Stothers, and co-workers in homoenolization studies (7, 8) to increase deuterium incorporation, no definitive information was available as regards the stability of *t*-BuOK – *t*-BuOH(D) solutions. In this paper we show, through homoenolization of 1,3,3-trimethylbicyclo[2.2.1]heptan-2-one (fenchone) (**1**) at 220°C, that the solution definitely is unstable at elevated temperatures, determine the major pathway of its deterioration, and establish that perdeuterated *tert*-butyl alcohol should be used as a solvent to improve the stability of the medium and maximize deuterium incorporation.

Results

Homoenolizations of fenchone (**1**) were carried out in Pyrex tubes at 220 ± 3°C for 300–330 h. To equalize pressure and reduce the possibility of tube rupture, the tubes were placed in a 600-mL Parr reaction vessel that contained water. Base solutions were freshly prepared by dissolving clean potassium in the appropriate alcohol in a glove bag pressurized with dry nitrogen. Recoveries of deuterated **1** ranged between 70 and 80% and the other minor products reported by Stothers and co-workers (8) also were observed. Total deuterium content was determined mass spectrometrically at low ionizing voltage and the distribution was established by computerized curve fitting of 38.4-MHz ^{2}H nmr spectra to Lorentzian curves. Figure 1(A) shows the 250-MHz ^{1}H nmr spectrum of **1** and the assignments that were established by double irradiation experiments at 400 MHz, consideration of the ^{1}H nmr spectrum (Fig. 1(B)) of deuterated **1**-$d_{3.75}$ (Table 1, entry 3), comparison with the ^{1}H nmr spectrum of 3,3,6,6-tetramethylbicyclo-[2.2.1]heptan-2-one (9), and the shift of the ^{2}H signals of **1**-$d_{3.52}$ in the presence of 0.25 equivalents of Eu(fod)$_3$. The signal at 1.75 ppm assigned to *syn*-7-D was shifted downfield, essentially to the same extent (0.34 ppm) as the *exo*-methyl at C-3 (0.33 ppm) and the bridgehead methyl (0.43 ppm). If the signal at 1.75 ppm was due to deuterium located at the *anti*-7 position, the shift would not be as large as the methyl shifts.

The results of homoenolizations of **1** at 220 ± 3°C in $C(CH_3)_3OD$ and $C(CD_3)_3OD$ are given in Table 1. As is indicated in entries 1 and 2, heating **1** for 304 h at 220 ± 3°C leads to the incorporation of 1.5–1.6 deuterium atoms. Figure 1(C) shows the 38.4-MHz ^{2}H nmr spectrum of deuterated **1**-$d_{1.52}$ along with the deuterium distribution. While there is an increase in incorporation to 2.51 deuterons per molecule after recycling once (entry 2), there is no significant increase in the amount of deuterium located *exo* and *endo* at C-6. Clearly, in both cases the *exo* and *endo* positions are equilibrated with a deuterium pool that has been diluted by 150%. That this is the case is seen from the data listed in entries 3 and 4. When **1** is exchanged in $C(CD_3)_3OD$, twice as much deuterium is incorporated and the equilibrated *exo* and *endo* positions at C-6 each contain nearly one atom of deuterium. The difference between the homoenolizations described in entries 3 and 4 results from temperature variations and the fact that it is difficult to reproduce homoenolization solutions exactly. Figure 1(D) shows the ^{2}H nmr spectrum of **1**-$d_{3.75}$ (entry 3). The results of this study are also in keeping with our recent findings that *syn*-7 exchange is preferred over *anti*-7 exchange (9). Significant incorporation occurs at the *syn*-7 position. Since the *exo*-6 and *endo*-6 resonances are equal in area within experimental error and the anti-7 resonance overlaps with the *exo*-6 resonance, it is clear that *anti* exchange must be substantially slower than *syn* exchange.

When 0.3 *M* *t*-BuOK – *t*-BuOH was heated for 300 h at 220 ± 3°C in the absence of ketone and an ^{1}H nmr spectrum of the solution was obtained, resonances at 1.65 (t) and 4.63 (m) ppm in addition to the resonances due to $C(CH_3)_3OH$ were observed. The relative areas, chemical shifts, and couplings correspond to those reported for isobutene (10), thereby establishing that

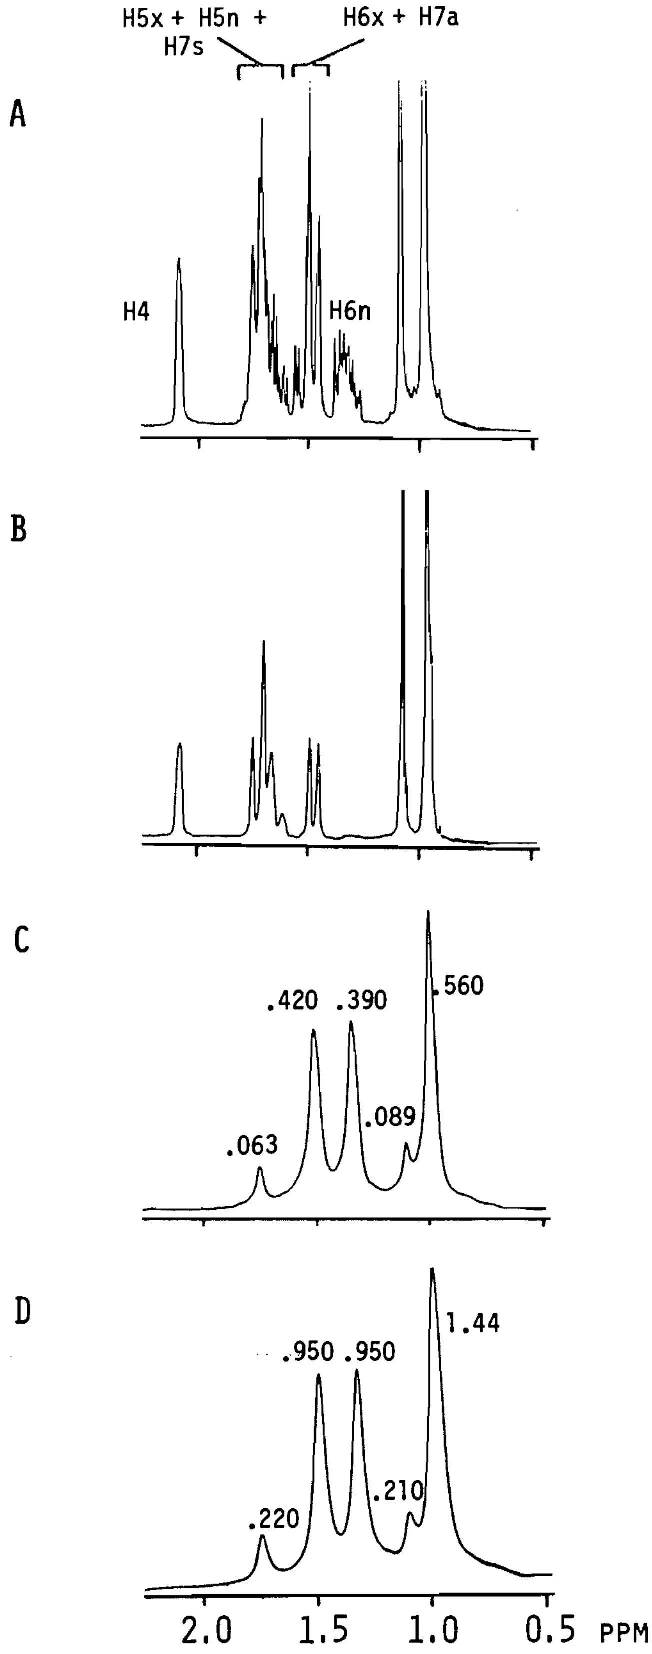

FIG. 1. (A) High-field (250-MHz) ^{1}H nmr spectrum of fenchone (**1**) in $CDCl_3$. (B) High-field (250-MHz) ^{1}H nmr spectrum of deuterated fenchone (**1**-$d_{3.75}$) in $CDCl_3$. (C) High-field (38.4-MHz) ^{2}H nmr spectrum of deuterated fenchone (**1**-$d_{1.52}$) in $CHCl_3$. (D) High-field (38.4-MHz) ^{2}H nmr spectrum of deuterated fenchone (**1**-$d_{3.75}$) in $CHCl_3$.

H_2O is eliminated from *t*-BuOH at elevated temperatures. Integration established that 5−7% of the mixture consisted of isobutene. To work up the reactions the tubes were cooled in liquid N_2, opened, and allowed to warm to ambient temperature. When the solid reaction mixture, with or without ketone, began to melt, bubbling occurred and an hydrocarbon odor was detected. Since isobutene boils at −6.6°C, a substantial amount is lost during work-up and nmr analysis.

When 0.3 *M* *t*-BuOK − *t*-BuOD was heated for 300 h at 220 ± 3°C and an ^{2}H nmr spectrum was obtained of the solution, in addition to a resonance at 4.32 ppm that corresponded to the deuteroxyl group, signals at 1.65 and 4.63 ppm with relative intensities of 3:1 indicated that the hydrogens of isobutene were equilibrated with the deuterium pool. An additional resonance at 1.21 indicated that deuterium was located in the methyls of *t*-BuOD as well. The relative areas of O—D and methyl resonances established that there was approximately 3.5% exchange of the methyl groups. Whether the exchange occurs by deprotonation−deuteronation or by nucleophilic addition of $^-$OD to isobutene presently is unknown.

Gas chromatographic (gc) analysis of the concentrated pentane extracts obtained from the homoenolization of **1** showed that three minor components (~5%) of shorter retention time than **1** were present in a ratio of 6:1:5. The same compounds were formed when *t*-BuOK was heated in *t*-BuOH and *t*-BuOD in the absence of ketone. The gc−ms analysis of the mixture obtained from heating *t*-BuOK − *t*-BuOH established molecular ions at *m/z* 136 ($C_{10}H_{16}$) for the major components. Analysis of the mixture obtained from an homoenolization in *t*-BuOD (entry 1) established that the components were highly deuterated. Comparison of the ms fragmentation patterns with standard spectra of a number of unsaturated hydrocarbons of molecular formula $C_{10}H_{16}$ revealed common features. It is conceivable that the C_{10} hydrocarbons are derived from the dehydration of an alcohol formed by the addition of methide to an enone derived from the trimerization of acetone, methide and acetone being derived from *t*-BuO$^-$. However, due to the small amount of the products, further studies were not undertaken.

To establish whether dehydration of *t*-BuOH occurs in the absence of base, *t*-BuOH was heated for 240 h at 220°C. The ^{1}H nmr spectrum showed resonances at 1.61 and 4.63 ppm characteristic of isobutene. Integration establshed that ~5% of the mixture consisted of isobutene.

Discussion and conclusions

This work clearly establishes the instability of *t*-BuOK − *t*-BuOH(D) solutions at elevated temperatures and the major source of deterioration of the medium. Based on the degree of dilution of the deuterium pool observed in the exchange reactions in $C(CH_3)_3OD$ (entries 1 and 2), if dilution occurs primarily by exchange of isobutene, then a maximum of 16% elimination occurs after 300 h at 220 ± 3°C. But the small amount of elimination has an enormous impact on the medium; the deuterium pool is diluted by 150%, the base concentration is reduced, and the water produced by elimination most likely significantly reduces the basicity of the medium (11, 12). While Herndon and Reid (13) established that *t*-BuOH dehydrates at 300°C,[1] this study establishes that elimination occurs slowly at temperatures around 200°C.

A number of studies have been reported in which *t*-BuOK −

[1]We thank a referee for bringing this work to our attention.

[a]The base solutions were prepared in a glove bag under N_2.
[b]Determined mass spectrometrically at low voltage. Recoveries of the ketone usually were 70−80%.
[c]Determined by ^2H nmr at 38.4 MHz. Incorporations were determined by computerized curve-fitting of the spectra to Lorentzian line shapes. Multiple fittings established that the average errors for fitting large peaks were <5% and for fitting small peaks 10−20%.
[d]The deuterated ketone was isolated and recycled.
[e]Not determined.

t-BuOH(D) was used at temperatures >200°C. Cram *et al.* (6) studied base-catalyzed exchange and racemization of 2-phenylbutane and 1-phenyl methoxyethane in t-BuOK − t-BuOH(D) and $KO(CH_2)_2O(CH_2)_2OH(D)/((D)HOCH_2CH_2)_2O$ at temperatures ranging from 215 to 260°C for periods up to 240 h. The authors reported that a tremendous pressure build-up occurred when potassium diethylene glycolate − diethylene glycol was heated at 260°C and stated that the base was completely destroyed by reaction with the glass. It is conceivable that elimination occurred to yield volatile divinyl ether and acetaldehyde. In the presence of base, divinyl ether could yield acetylene and acetaldehyde which could decarbonylate (13).

A number of homoenolizations have been carried out in t-BuOK − t-BuOH(D) at temperatures above 200°C where deterioration of the medium is expected to be significant. Nickon *et al.* (7) studied the homoenolization of camphenilone at 250°C and after two cycles at 216 and 215 h observed incorporation of 3.8 deuterium atoms, but the location of the deuterium was not established. Coates and Chen (14) have documented the partial homoenolate rearrangement of longicamphenilone after 14 h at 275°C. Hunter, Stothers, Nickon and co-workers (15) reported on the homoenolate rearrangement of fenchone and the *exo*- and *endo*-isocamphanones at 220−250°C. Nickon *et al.* (16) studied the rearrangement and exchange of camphor and the *exo*- and *endo*-isocamphanones at 220−250°C.

While it is evident that dehydration of t-BuOH is a major problem at temperatures above 200°C, it must also lead to deterioration of the medium even at 185°C, especially if long reaction periods (>100 h) are used − a common practice in homoenolization studies. Data (Table 2) for exchange of fenchone at C-6, accumulated by Stothers and co-workers (8), support our view.

It is clear from this study that $C(CD_3)_3OD$ should be used for hydrogen isotope exchange studies at elevated temperatures to maximize the deuterium incorporation and improve the stability of the medium, since we expect that primary and secondary KIEs should slow the rate of elimination. It may be useful to develop a medium − perhaps adamantanol-O-d and its alcoholate in DMSO-d_6 − where elimination of water is not possible (17).

Finally, we now wonder about the source of carboxylic acids − the products of Haller−Bauer cleavage − produced in quantity in some reactions. Although it has been postulated that nucleophilic attack by t-BuO$^-$ at the carbonyl group leads to ring opening which is followed by base-promoted elimination of the acid from the *tert*-butyl ester (18), it is conceivable that ring opening is initiated by attack of the smaller nucleophile hydroxide (deuteroxide).

TABLE 2. H−D exchange of fenchone at C-6 in t-BuOK − t-BuOD at 185°C[a]

Experimental

General

The ^1H and ^2H nmr spectra were obtained on a Bruker WM-250 spectrometer. Resonances are reported as ppm downfield form TMS. Mass spectral deuterium analyses were carried out at low voltage (12−15 eV) on a Micromass VG 7070 mass spectrometer. A Tracor 560 gas chromatograph with 6 ft × 4 mm id 3% OV-1 on 100−120 mesh Chromosorb W was used for analysis of reaction mixtures, and preparative collection of fenchone was carried out with a 5 ft × 1/4 in. 15% SE-30 on 80−100 mesh Chromasorb W in a Varian A-700 gas chromatograph. Perdeuterated *tert*-butyl alcohol was obtained from Aldrich Chemical Co. and distilled from potassium prior to use in the experiments.

Homoenolization reactions

In a typical reaction, in a glove bag pressurized with dry nitrogen, clean potassium (0.207 g) was added to dry $(CD_3)_3COD$ (4 mL) and reaction carried out to completion by heating. To the base solution was added fenchone (0.176 g) and the tube was sealed under vacuum after three freeze/pump/thaw cycles for degassing. The reaction tube was heated at 220 ± 3°C for 304 h in a 600-mL Parr pressure apparatus that contained water to equalize pressure. The reaction mixtures were worked up by adding saturated aqueous NaCl (10 mL) and extracting with pentane (5 × 10 mL); extracts were washed with saturated aqueous NaCl (5 mL), dried over anhydrous Na_2SO_4, and filtered. Solvent was removed by distillation through a 12-cm glass helices column. Analytical gc showed that fenchone was 73.5% of the product mixture and collection by preparative gc gave 0.115 g (88.9%).

Medium-deterioration reactions

Reactions to study the deterioration of the basic medium were carried out as above with 0.3 *M* *t*-BuOK − *t*-BuOH(D) for 300 h at 220 ± 3°C. A small amount of the reaction mixture was added to benzene-d_6 (benzene) for ^{1}H (^{2}H) nmr studies. The ^{1}H nmr spectrum showed, in addition to the resonances for $(CH_3)_3COH(D)$, resonances at 1.65(t) and 4.63(m) ppm corresponding to chemical shift, coupling, and area with those reported for isobutene (10).

The ^{2}H nmr spectrum of deuterated reaction medium had resonances at 4.32 ppm (deuteroxyl group), 1.65 and 4.63 ppm (area ratio 3:1 − isobutene equilibrated with the deuterium pool), and an additional resonance at 1.21 ppm (deuterium in the methyl of *t*-BuOD). Comparison of the area of this resonance with that for O—D indicated ~3.5% exchange of the methyl groups in *t*-BuOD.

Protium–deuterium exchange of cyclic and acyclic alkenes in dilute acid medium at elevated temperatures

NICK HENRY WERSTIUK AND GEORGE TIMMINS
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received May 14, 1984

NICK HENRY WERSTIUK and GEORGE TIMMINS. Can. J. Chem. **63**, 530 (1985).

A modification of the high temperature – dilute acid (HTDA) method for deuterium labelling of aromatic compounds has been applied to the H–D exchange of a number of cyclic and acyclic alkenes. Cyclopentene, cyclohexene, cyclododecene, and tetramethylethylene have been completely exchanged in excellent yield. 1-Methylcyclopentene and 1-methylcyclohexene have also been perdeuterated and cycloheptene and cyclooctene partially labelled but require spinning band distillation or preparative glpc for separation from rearrangement products. A variety of C5–C8 acyclic alkenes have also been treated under HTDA conditions.

NICK HENRY WERSTIUK et GEORGE TIMMINS. Can. J. Chem. **63**, 530 (1985).

On a appliqué une modification de la méthode à haute température en milieu acide dilué, développée pour marquer des composés aromatiques avec du deutérium, à l'échange H–D d'un certain nombre d'alcènes cycliques et acycliques. Le cyclopentène, le cyclohexène, le cyclodécène et le tétraméthyléthylène s'échangent tous complètement avec d'excellents rendements. Le méthyl-1 cyclopentène et le méthyl-1 cyclohexène sont aussi perdeutérés alors que le cycloheptène et le cyclooctène ne sont que partiellement marqués; toutefois, dans ces cas, il faut faire appel soit à des distillations à l'aide de bande tournante soit à la cpg préparative pour séparer les produits désirés des produits de transposition. On a aussi traité de la même manière un certain nombre d'alcènes acycliques comptant de 5 à 8 C.

[Traduit par le journal]

Introduction

In an attempt to develop high temperature – dilute acid exchange (HTDA) (1–6) into a general technique for preparing deuterated (or tritiated) organic compounds we have extended our studies from aromatic compounds to alkenes.

Early attempts to label alkenes using heterogeneous platinum catalysis resulted in extensive (up to 100%) disproportionation with only low levels of deuterium incorporation (7). Also, radiation induced methods such as the Wilzbach technique for tritium labelling lead to addition products in preference to substitution (8). In attempting to avoid some of these problems, Calf *et al.* (9) carried out exchange reactions in dilute DCl/D_2O at temperatures of 110–130°C. They were successful in achieving incorporations of up to 35 at.% D.

In this paper we describe deuterium labelling of alkenes using a modification of the HTDA method (1–5). Exchange reactions were carried out with dilute DCl/D_2O in sealed Pyrex tubes at elevated temperatures (165–280°C) in the presence and absence of decalin as a cosolvent and with or without mixing by shaking. In general, reactions were run to near equilibration (92–95 at.% D) with the deuterium pool in one cycle. For example, cyclopentene was labelled with 7.38 D atoms of deuterium per molecule (92.2 at.%; entry 5, Table 1) in one cycle, whereas, Calf *et al.* (9) reported the incorporation of only 2.39 D atoms at 130°C.

Results and discussion

The results of application of the modified high temperature – dilute acid (HDTA) protium–deuterium exchange method to cyclopentene (**1**), cyclohexene (**2**), cycloheptene (**3**), cyclooctene (**4**), cyclododecene (**5**), cyclohexanol (**6**), *E*-2-pentene (**7**), 1-hexene (**8**), 1-heptene (**9**), 1-octene (**10**), 1-pentanol (**11**), 1-hexanol (**12**), 1-heptanol (**13**), 1-octanol (**14**), and tetramethylethylene (**15**) are given in Tables 1 and 2. Reactions in deuterated and nondeuterated medium were carried out concurrently in a Parr pressure vessel. Products were identified by isolating the components from the reactions in nondeuterated medium by preparative glpc or distillation, in some cases as mixtures, and using high field (250 and 400 MHz) ^1H nmr spectroscopy. Spectra were compared with spectra of standards or spectra obtained from the Sadtler NMR Index. In the case of the acyclic alkenes it was necessary to use a 10-m, SP1700 (Supelco) column formulated specifically for gc separation of low molecular weight alkenes. The relative yields of products were determined using gc and ^1H nmr data and the E/Z ratio of 2.8 for the 2-pentenes was used to confirm the assignment of the E/Z ratios for the hexenes, heptenes, and octenes. It was noted that more rearrangement occurred in DCl/D_2O than in HCl/H_2O.

That alcohols **6**, **11**, **12**, **13**, and **14** yield the same products as alkenes **2**, **7**, **8**, **9**, and **10**, respectively, indicates that any substrate which yields a carbocation under HTDA conditions and has β-hydrogens, in principle, can undergo exchange. In fact alcohols **6**, **11**, **12**, **13**, and **14** yielded greater than 95% of elimination products.[1]

Initial attempts to deuterate by simply heating the alkenes in the presence of dilute acid produced large amounts of higher molecular weight products (shown by mass spectrometry to be dimers and trimers) which were not further examined (for example see Table 1, entry 1). In an attempt to reduce the extent of addition, decalin was added in order to dilute the substrate and, as documented in Table 1, entries 1 and 2, this was successful; the proportion of higher molecular weight products was greatly reduced. In our initial study of cyclododecene using decalin as cosolvent we observed an unusual saddle-shaped pattern of deuterium incorporation which ranged from 17.5% d_0 and 7% d_1 species down to 0.9% d_{10} and then increased to 11.7% d_{21} and 6.5% of d_{22} species. This distribution was attributed to the fact that phase transfer rather than exchange was rate determining for large molecules. The reactions were repeated in an apparatus which agitated the reaction mixtures by a rocking motion. This modification allowed the use of lower reaction temperatures and (or) shorter reaction times

[1]Calf *et al.* (9) reported that up to 80°C, hydrogen halides add to alkenes, but at approximately 110°C elimination of HX occurs.

[d]With decalin, without mixing.
[e]With decalin, with mixing.
[f]Unidentified minor products.
[g]Unidentified higher molecular weight products; total.

and in general led to cleaner reactions and a normal deuterium distribution in cyclododecene (**5**) (Table 1, entries 3 and 4). While decalin is a good inert cosolvent for exchange of low molecular weight alkenes, it would be a simple matter to replace decalin with a lower boiling solvent if the substrate had a boiling point close to decalin.

Examination of Table 1 shows that all products were perdeuterated and usually equilibrated with the deuterium pool. The incorporation of 22 deuterium atoms into cyclododecene in a single reaction is remarkable. Calf *et al.* (9) observed no incorporation of deuterium into **5** at 130°C.

For the cycloalkenes (except cyclopentene and cyclododecene) the product mixtures consisted largely or solely of ring-contracted isomers of the parent substrate as shown in Table 1, entries 5–8. Involvement of corner-protonated cyclopropanes (Scheme 1) can lead to ring-contracted and rearrangement products and consecutive protonation–deprotonations can produce all products. Ring contraction of the cyclohexyl, cycloheptyl, and cyclooctyl cations to tertiary species is exactly what is observed for the species in strongly acidic media (10, 11). Rings smaller than C_5 were not observed, presumably because of their lower stability. That the medium-sized rings cascade to cyclopentenes and cyclohexenes while cyclododecene rearranges only slowly is in keeping with the degree of ring strain in the series of cycloalkenes.

Formation of 1-ethylcyclopentene (**1***e*) and 1-ethylcyclohexene (**2***d*) from cycloheptene and cyclooctene, respectively, is easily rationalized by invoking involvement of methyl-substituted protonated cyclopropanes as indicated in Scheme 1.

Cyclopentene (**1**), cyclohexene (**2**), cyclododecene (**5**), 1-methylcyclopentene (**1***a*), 1-methylcyclohexene (**2***a*), 1-ethylcyclohexene (**2***d*) (containing ~10% other products), and a variety of other alkylated C-5 and C-6 cycloalkenes can be perlabelled. While cycloheptene and cyclooctene undergo facile ring contraction even at 200°C, reactions carried out at 175°C yield partially labelled substrates (entries 10 and 11, Table 1). These products may be obtained in pure form by spinning band distillation or preparative gas chromatography.

Acyclic alkenes also undergo exchange and extensive rearrangement. *E*-2-pentene (**7**) can be perlabelled (entry 1, Table 2) with little rearrangement. At higher temperatures substantial rearrangement occurs and perdeuterated 2-methyl-2-butene and 2-methyl-1-butene are obtained. As expected, 1-pentanol (entry 5, Table 2) yields a similar mixture of al-

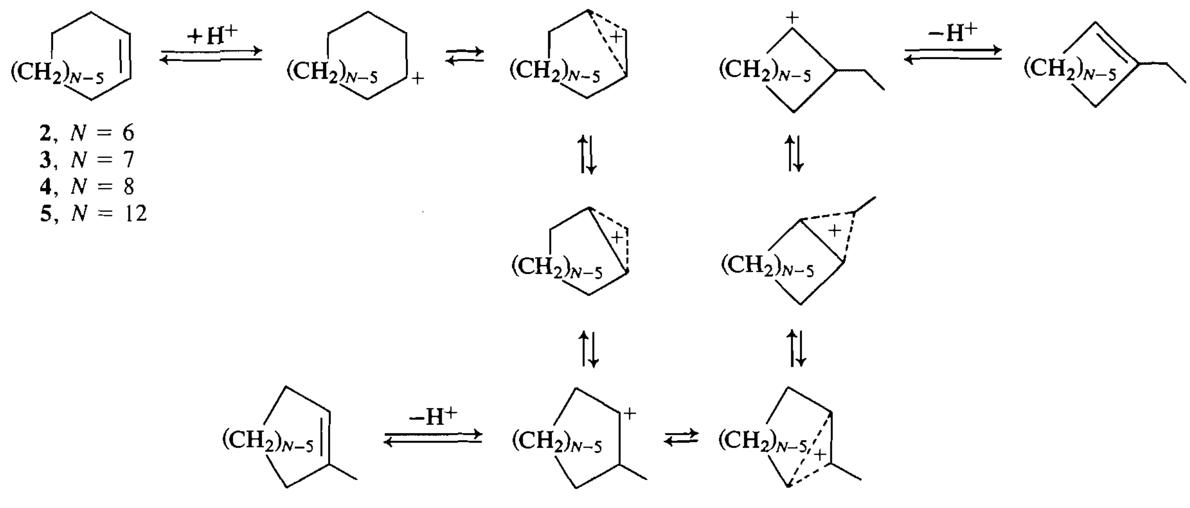
kenes. Similar results are observed for 1-hexene, 1-heptene, 1-octene, and the corresponding alcohols **12**, **13**, and **14** (entries 2, 3, 4, 6, 7, and 8, Table 2). At 205°C 1-hexene, 1-heptene, and 1-octene are isomerized mainly to the 2- and 3-alkenes and the deuterium incorporation decreases as the chain length increases. When 1-hexene, 1-heptene, and 1-octene are heated at 215°C to increase deuterium incorporation, extensive rearrangement occurs. The corresponding primary alcohols (entries 6, 7, and 8, Table 2) yield similar results. Although acyclic alkenes may be perdeuterated by the HTDA technique, the considerable rearrangement occurring in most cases necessitates that reactions be carried out on a fairly large scale and spinning band distillation or preparative gas chromatography equipment used to separate the components. In some cases, products may only be obtainable as mixtures. As documented in entry 9, Table 2, tetramethylethylene (**15**) is easily perdeuterated in good yield and perlabelled 2,3-dimethyl-1-butene also is formed. Perhaps methyl groups can be used generally to anchor double bonds and minimize rearrangement.

Since the yields are quite good (65–85%) and alkenes can easily be converted into other classes of compounds, HTDA exchange is established as a valuable route to a wide range of deuterated cyclic compounds. Certain deuterated acyclic compounds may also be prepared, but with the limitations expressed above. Since D_2O can be replaced by THO after exchange conditions have been determined, the method, in principle, can be used to tritiate organic compounds with the added advantage that the degree of exchange and the location of the label can be inferred from the studies in deuterated medium.

Experimental

General

Proton and deuteron magnetic resonance spectra were recorded on Bruker WP-250 and 400 spectrometers with $CDCl_3$ as internal standard. Samples were dissolved in chloroform or chloroform-*d*. Chemical shifts are expressed in parts per million downfield from tetramethylsilane. Deuterium assay analyses were performed on a VG Micromass 7070 mass spectrometer at low ionization voltage (12–



SCHEME 1

15 eV) and are expressed as atoms of deuterium per molecule in excess of natural abundance deuterium. Analytical gas−liquid partition chromatography was performed on a Tracor 560 dual column analytical gas chromatograph equipped with flame ionization detectors using helium as the carrier gas. Flow rate was usually 20−30 mL/min. Columns used were 6 ft × 4 mm id 3% OV-1 on 100−120 mesh Chromosorb W and 30 ft × 1/8 in. 23% SP-1700 on 80−100 mesh Chromosorb PAW (Supelco, Inc.). Preparative gas−liquid partition chromatography was carried out on a Varian Aerograph Model A-700 gas chromatograph with a thermal conductivity detector at a helium flow rate of 50−60 mL/min with a 5 ft × 1/4 in. 15% SE-30 on 60−80 mesh Chromosorb W column.

Exchange reactions

In a typical exchange reaction, substrate (0.20 g) was added to 1% w/v DCl/D_2O (5 mL) in a medium-walled glass tube, the mixture was degassed via three freeze−pump−thaw cycles and sealed under vacuum. The tube was placed in a 600-mL Parr pressure vessel which contained water to equalize pressure and heated at the desired temperature for an appropriate period.

For later reactions the procedure was slightly modified. Decalin (1 mL) was added as a cosolvent and reaction was carried out in a 600-mL Parr pressure apparatus which was heated in an apparatus which agitated the reaction mixture by a rocking motion. After reaction, the decalin layer was decanted from the frozen aqueous solution and analysed by gc and in some cases by gc−ms. The deuterium content of samples isolated by preparative gc was determined mass spectrometrically at low ionizing voltage (12−15 eV).

Structure elucidation of products

In a typical reaction, substrate (0.20 g) was added to 1% w/v HCl/H_2O (5 mL) and decalin (1 mL) in a medium-walled glass tube, the mixture was degassed via three freeze−pump−thaw cycles and sealed under vacuum. The tube was placed in a 600-mL Parr pressure vessel which contained water to equalize pressure and heated with agitation at the desired temperature for an appropriate period. The decalin layer was decanted from the frozen aqueous layer and analyzed by analytical gc. The products were isolated by preparative gc, in some cases as mixtures, and analyzed by high-field ^{1}H nmr (250 and 400 MHz).

Large scale reactions

Preparation of deuterated cyclopentene

Three tubes, each containing cyclopentene (0.32 g), 1% w/v DCl/D_2O (8 mL), and decalin (1.6 mL), prepared in the usual manner, were heated at 200°C for 24 h with agitation. The deuterated cyclopentene was isolated from the combined decalin solutions by flash distillation through a 9-cm Vigreux column. The yield was 0.58 g (60%) of cyclopentane with deuterium incorporation of 87.0% (6.96 excess D atoms/molecule).

Preparation of deuterated pentenes

Three tubes, each containing *E*-2-pentene (0.30 g), 1% w/v DCl/D_2O (8 mL), and decalin (1.5 mL) were heated for 24 h at 198°C with agitation. The deuterated pentenes (see entry 1, Table 2) were isolated from the combined decalin layers by flash distillation through a 9-cm Vigreux column. The yield was 0.58 g (64%). See entry 1, Table 2 for the approximate product composition.

Preparation of deuterated hexenes

Eight tubes, each containing 1-hexanol (0.32 g), decalin (1.6 mL), and 1% w/v DCl/D_2O (8 mL) were rocked for 72 h at 205°C. The organic layer was separated from the combined reaction mixtures and the deuterated *E*-2- and *E*-3-hexenes (2.76 g, 73.7%) were flash distilled from the decalin at atmospheric pressure through a 9-cm vacuum-jacketed Vigreux column. Mass spectrometric analysis established that exchange was 91.4% complete, corresponding to an incorporation of 10.97 deuterium atoms per molecule.

Preparation of octenes

Four tubes each containing 1-octene (0.30 g) 1% w/v HCl/H_2O (8 mL) and decalin (1.5 mL) were prepared in the usual manner and heated for 24 h at 200°C with agitation. The octenes (1.00 g, 83%) were isolated from the combined decalin layers by flash distillation through a 9-cm Vigreux column; see entry 4, Table 2 for the approximate product composition.

Received January 30, 1984[2]

NICK HENRY WERSTIUK and SUJIT BANERJEE. Can. J. Chem. **63**, 534 (1985).

A study of acid- and base-catalyzed hydrogen isotope exchange of bicyclo[2.2.1]heptan-2-one (**1***a*) and its 3-deuteriated analogs has been carried out. We find that the k_{exo}/k_{endo} ratio (658 ± 66) for deuteroxide-catalyzed H → D exchange of **1***a* at C-3 is 7.2 ± 1.5 times greater than the k_{exo}/k_{endo} ratio (91 ± 9) for hydroxide-catalyzed D → H exchange of **1***b*. For acid-catalyzed exchange in $CH_3COOD(H)-D(H)Cl$ the rate ratios are 156 ± 20 and 29 ± 2 for H → D and D → H exchange, respectively. Equations which relate the observed selectivity k_{exo}/k_{endo} (k_{fast}/k_{slow}) to the intrinsic selectivity and the primary, secondary, and solvent KIEs are developed. The differences between the rate ratios for H → D and D → H exchange are interpreted on the basis of a significant contribution of an inversion pathway to exchange of the slow proton (deuteron). The significance of our study – it relates to the mechanism of hydrogen isotope exchange of diastereotopic protons (deuterons, tritons) of any carbon acid – is discussed.

NICK HENRY WERSTIUK et SUJIT BANERJEE. Can. J. Chem. **63**, 534 (1985).

On a effectué une étude de l'échange d'isotopes d'hydrogène, catalysé soit par les acides ou par les bases, de la bicyclo[2.2.1]heptanone-2 (**1***a*) et de ses analogues deutérés en position 3. On trouve que le rapport (658 ± 66) des vitesses k_{exo}/k_{endo} pour l'échange H → D, catalysé par l'ion deutéroxyde, en C-3 de **1***a* est 7,2 ± 1,5 fois plus grand que le rapport (91 ± 9) des vitesses k_{exo}/k_{endo} pour l'échange D → H, catalysé par l'ion hydroxyde, de **1***b*. Pour l'échange catalysé par les acides, $CH_3COOD(H)/D(H)Cl$, les rapports de vitesse sont respectivement 156 ± 20 et 29 ± 2 pour les échanges H → D et D → H. On a développé des équations qui permettent de relier la sélectivité observée k_{exo}/k_{endo} (k_{rapide}/k_{lent}) avec la sélectivité intrinsèque et les EIC primaire, secondaire et du solvant. On interprète les différences observées entre les rapports de vitesses pour les échanges H → D et D → H en fonction d'une contribution importante d'une voie d'inversion pour l'échange du proton lent (deutéron). On discute de l'importance de notre travail dans sa relation avec le mécanisme d'échange isotopique de protons diastéréotopes (deutérons et tritons) d'acides carboxyliques.

[Traduit par le journal]

Introduction

Acid- and base-catalyzed enolizations of carbonyl compounds are two of the most important organic reactions, and, in keeping with that fact, have been the focus of considerable research designed to establish mechanistic details (1–3). Hydrogen isotope exchange, in particular, has played an important role in many mechanistic studies (2, 3). It was clear to us, however, from a review of the literature, that there was a paucity of mechanistic information in the area of hydrogen isotope exchange (enolization) of polycyclic monoketones and diketones. In fact, prior to 1970 there were no accurate rate data for base-catalyzed exchange of diastereotopic protons of ketones even though there were reports (4–7) of the preparation of 80–90% stereochemically pure 3-monodeuterated bicyclo[2.2.1]heptan-2-ones. Of particular interest to us was the possibility of exchange of diastereotopic protons by an inversion mechanism, which had been recognized, but not quantified (8). A research program was initiated at that time to detail the mechanistic intricacies of hydrogen isotope exchange (enolization) of bicyclic ketones and determine the effect of groups located remote (β or γ) from an α enolizable site. A number of papers documenting our work have been published (9–16). We noted, most importantly, from a study of the stereoselectivity of H → D and D → H exchange of **1***a* and its 3,3-dideuteriated analog **1***b*, that the k_{exo}/k_{endo} (k_{fast}/k_{slow}) ratio decreased from 660 for exchange of **1***a* in deuteriated medium to 72 for exchange of **1***b* in nondeuteriated medium. We published a preliminary account (10) of an analysis that established that the difference was due to involvement of an inversion pathway for exchange of the *endo* (slow) proton (deuteron) at C-3. In this paper we give a complete account of our work on bicycloheptanones **1***a*, **1***b*, **1***c*, and **1***d*, develop equations including primary, secondary, and solvent KIEs (kinetic isotope effects) which relate the observed selectivity to the intrinsic selectivity *S*, and interpret the difference between $(k_{exo}/k_{endo})^{H\to D}$ and $(k_{exo}/k_{endo})^{D\to H}$ on the basis of a significant contribution of an inversion pathway to exchange of the slow proton (deuteron) of a diastereotopic pair. The importance of our study – it details the mechanism of hydrogen isotope exchange of diastereotopic protons, deuterons, or tritons of any carbon acid – is discussed.

Results

Hydrogen isotope exchange of bicyclo[2.2.1]heptan-2-ones

The rates of NaOD(H)-catalyzed H → D and D → H exchange of **1***a* and **1***b* were measured at 30°C in 60% dioxane – 40% D_2O or H_2O by following the uptake or loss of deuterium mass spectrometrically at low voltage (12–15 eV) (13).

[1] Present address: Safety and Environmental Protection Division, Brookhaven National Laboratory, Upton, New York 11973.
[2] Revision received August 1, 1984.

TABLE 1. Second-order rate constants for hydrogen isotope exchange of bicyclo[2.2.1]heptan-2-ones at 30.00 ± 0.05°C

				$k(M^{-1}\ s^{-1})^c$		
Entry	Substrate	Medium	[$^-$OH(D)]	*exo* × 10^2	*endo* × 10^5	k_f/k_s
1	**1***a*	D[a]	0.045	5.89 ± 0.26		
2	**1***a*	D	0.045		9.07 ± 0.55	
3	**1***a*	D	0.045		8.83 ± 0.43	658 ± 66[d]
4	**1***b*	H[b]	0.008	0.721 ± 0.021		
5	**1***b*	H	0.020	0.704 ± 0.033		
6	**1***b*	H	0.040	0.658 ± 0.007		
7	**1***b*	H	0.200	0.594 ± 0.008		
8	**1***b*	H	0.020		7.89 ± 0.28	
9	**1***b*	H	0.040		7.22 ± 0.69	
10	**1***b*	H	0.100		6.72 ± 0.28	91 ± 9[e]

[a]The medium was composed of 60% dioxane – 40% D_2O (v/v).
[b]The medium was composed of 60% dioxane – 40% H_2O (v/v).
[c]Errors quoted are the standard deviations.
[d]Obtained as a ratio of k_{exo} (entry 1) and k_{endo} (average of entries 2 and 3).
[e]Obtained as a ratio of k_{exo} (entry 6) and k_{endo} (entry 9).

The pseudo-first-order rate constants were obtained by computerized analysis of the kinetic data and the second-order rate constants, obtained by dividing the first-order rate constants by the base concentration, are given in Table 1. A correction for dilution of the deuterium pool was not made in these studies because a previous study (13) showed that the corrected and uncorrected rate constants usually differed by less than 10%. A computer generated plot of the kinetic data for a typical run on **1***b* is given in Fig. 1(A).

Since it was not possible to determine the primary KIE for *endo* exchange of **1***a* directly, **1***c* and **1***d* were prepared and the rates of exchange were determined by monitoring the rates of isomerization in deuteriated and nondeuteriated medium as described previously (13). The second-order rate constants for isomerization of **1***c* and **1***d* obtained by computer analysis of isomerization data are listed in Table 2. A computer generated plot of the kinetic data for a typical run is given in Fig. 1(B).

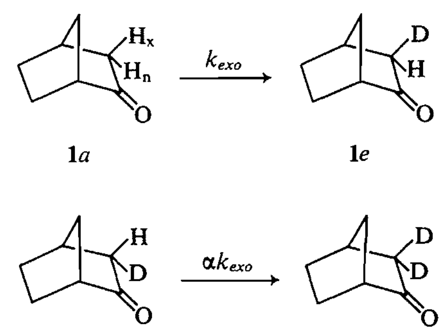
The rates of acid-catalyzed H → D and D → H exchange of **1***a* and **1***b* were measured at 100°C in 90% CH_3COOD – 10% 2.08 *N* DCl and 90% CH_3COOH – 10% 2.00 *N* HCl, respectively. The pseudo-first-order rate constants uncorrected for dilution of the deuterium pool and obtained by computer analysis of the data are listed in Table 3. A computer generated plot of the kinetic data obtained from a typical run is given in Fig. 1(C).

Determination of the secondary KIE for exo *proton abstraction in deuterated medium*

A competition method was used to determine the secondary KIE (ν_D) for *exo* exchange of **1***a* in deuteriated medium. Mixtures (~50:50) of **1***a* and its *endo*-3-*d* analog **1***f* of known composition were reacted in 60% dioxane – 40% NaOD/D_2O for periods ranging from 0.9 to 2.8 half-lives, quenched by a buffer, and analyzed by mass spectrometry. If the processes shown in Scheme 1 are considered, then eqs. [1]–[5] are obtained and the secondary KIE for *exo* deprotonation = $1/\alpha$. Since eq. [1] describes α and $[\mathbf{1}a]_0 = [d_0]_0$, $[\mathbf{1}a]_t = [d_0]_t$, and $[\mathbf{1}f] = [d_1]_0$, eqs. [2], [3], [4], and [5] are obtained.

$$[1] \quad \alpha = \frac{\ln([\mathbf{1}f]_t/[\mathbf{1}f]_0)}{\ln([\mathbf{1}a]_t/[\mathbf{1}a]_0)}$$

$$[2] \quad [\mathbf{1}f]_t = [d_1]_t - [\mathbf{1}e]_t$$



1*a* **1***e* **1***f* **1***e*

7	**1***d*	D	0.061	1.64 ± 0.05

[a]The medium was composed of 60% dioxane – 40% H_2O (v/v).
[b]The medium was composed of 60% dioxane – 40% D_2O (v/v).
[c]Errors quoted are the standard deviations.

$$[3] \quad [\mathbf{1}f]_t = [d_1]_t - ([\mathbf{1}a]_0 - [\mathbf{1}a]_t)$$

$$[4] \quad [\mathbf{1}f]_t = [d_1]_t - [d_0]_0 + [d_0]_t$$

$$[5] \quad \alpha = \frac{\ln[([d_1]_t - [d_0]_0 + [d_0]_t)/[d_1]_0]}{\ln([d_0]_t/[d_0]_0)}$$

The results of our study are given in Table 4 and the secondary KIE for *exo* proton abstraction $\nu_D = 1/\alpha = 1.12 \pm 0.03$. It is interesting to note that Tidwell and co-workers (8) obtained a value of 1.064 ± 0.047 for exchange of bicyclo[2.2.2]octan-2-one by using a fitting routine. While the competition method

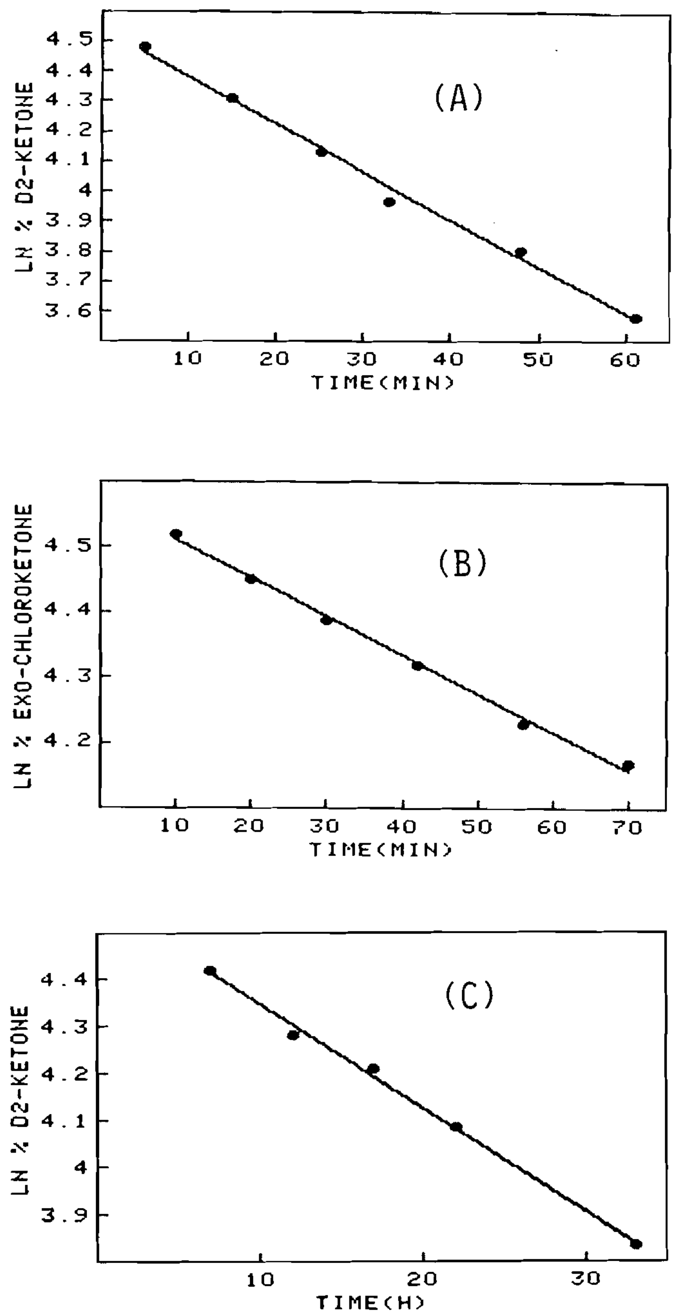

FIG. 1. (A). Plot of ln % bicyclo[2.2.1]heptan-2-one-*exo,endo*-3,3-d_2 versus time (min) for D → H exchange in 60% dioxane – 40% 0.040 *M* NaOH at 30.00 ± 0.05°C (entry 6, Table 1). (B). Plot of ln % *exo*-3-chlorobicyclo[2.2.1]heptan-2-one-*endo*-3-*d* versus time (min) for D → H exchange in 60% dioxane – 40% 0.061 *M* NaOD at 30.00 ± 0.05°C (entry 7, Table 2). (C). Plot of ln % bicyclo[2.2.1]-heptan-2-one-*exo,endo*-3,3-d_2 versus time (h) for D → H exchange in 90% HOAc – 10% 2 *M* HCl at 100.0 ± 0.5°C.

described here is useful for determining secondary KIEs, there are several sources of error which must be considered. Dilution of the deuterium pool must be negligible. In this study, since 2 mg of a mixture of ketones were used in 1 mL of 60% dioxane – 40% $NaOD/D_2O$, the dilution was ~0.1%. The stereoselectivity of exchange (k_f/k_s) is important as well – d_0-ketone is converted to d_1-ketone by *exo* and *endo* deprotonations and *endo*-3-*d* ketone can be isomerized to the *exo*-3-*d* species. A computerized simulation was carried out to probe the effects of the magnitude of k_f/k_s, the reaction period, and the $[d_0]/[d_1]$ ratio on the observed secondary KIE. The results are given in Table 5. It is clear that for high selectivities the observed KIE is a good measure of the intrinsic KIE. This is not the case when the selectivity is low, an initial $[d_0]/[d_1]$ ratio > 1 is used, and the reaction is allowed to proceed for more than one half-life.

Discussion and conclusions

It is seen from the data listed in Table 1 that $(k_f/k_s)^{D\to H}$ is considerably smaller than $(k_f/k_s)^{H\to D}$ for base-catalyzed hydrogen isotope exchange of the diastereotopic protons and deuterons of **1***a* and **1***b*, respectively. The $(k_f/k_s)^{H\to D}/(k_f/k_s)^{D\to H}$ ratio is 7.2 ± 1.5.[3] As is documented in Table 3, $(k_f/k_s)^{D\to H}$ is considerably less than $(k_f/k_s)^{H\to D}$ for acid-catalyzed exchange as well and the ratio is 5.4 ± 1.1. Since $k_f >> k_s$, in our view Scheme 2 is an adequate representation of the exchange of diastereotopic protons α to a carbonyl group. Since a common enolate is undoubtedly involved,[4] a steady-state treatment involving *E* and *S'* leads to eq. [6] as the expression for the rate constant for slow H → D exchange.[5]

[3] The ratio of 7.2 is somewhat smaller than the ratio of 9.1 reported in our preliminary communication (10). The difference arises from the fact that the ratios were obtained in a slightly different manner. As is seen in Table 1, there is a significant medium effect on the fast and slow exchanges. In our earlier account, $k_f^{D\to H}$ and $k_s^{D\to H}$ were obtained from plots of k_f (obs) and k_s (obs) versus $[OH^-]$. In the present analysis the $(k_f/k_s)^{H\to D}$ and $(k_f/k_s)^{D\to H}$ ratios were obtained by using second-order rate constants obtained at similar base concentrations since a study of the variation of $k_{exo}^{H\to D}$ and $k_{endo}^{H\to D}$ with $[OH^-]$ was not carried out.

[4] Warkentin and Tee (17), through a study of the hydrogen isotope exchange of 2-butanone, have supported earlier suggestions that base-catalyzed enolization of ketones in aqueous medium involves concerted formation of enols rather than enolates. However, if hydroxide-catalyzed enolization occurs to generate enols directly, then it is difficult to account for the fact that solvent KIEs for base-catalyzed enolization of ketones ((k_{D_2O}/k_{H_2O}) for acetone × 1.47) (18) are very similar to the solvent KIEs for H–D exchange of other carbon acids; 9-fluorenylmethanol 1.49 (19), 1,4-dicyano-2-butene 1.39 (20), and phenylacetylene 1.33 (21). In fact, a recent study by Kresge and co-workers (22) has established that acetone yields the enolate in dilute aqueous NaOH. However, whether enolates or enols are involved is immaterial to our analysis.

[5] We thank a referee for pointing out an alternative, perhaps more quantitative, analysis that involves Scheme A (for H → D exchange), development of differential equations for the change in concentrations of various species, and utilization of a steady-state analysis based on enolates E and E'. Following a solution of the resulting differential equations using the Carson–Laplace transformation, the k_f/k_s ratios could be obtained by fitting isotopic composition–time data to theoretical curves generated from different k_f/k_s values. While this approach would probably lead to a "final" general solution, the calculations are difficult and the fitting of the experimental data would not be a simple matter. It is noteworthy that Ohnishi (23) utilized a scheme similar to the one referred to above to discuss the kinetics of $^-$OD-catalyzed H → D exchange of 6,6-dimethylbicyclo[3.1.1]-heptan-2-one (nopinone), but used a different analysis of the rate equation. In our view, our approach, which uses experimentally determined parameters – k_f/k_s, primary and secondary KIEs and SIEs – which have been documented and discussed in the literature, is a viable account of the acid- or base-catalyzed exchange of diasterotopic protons (deuterons or tritons) in cases where $k_f >> k_s$.

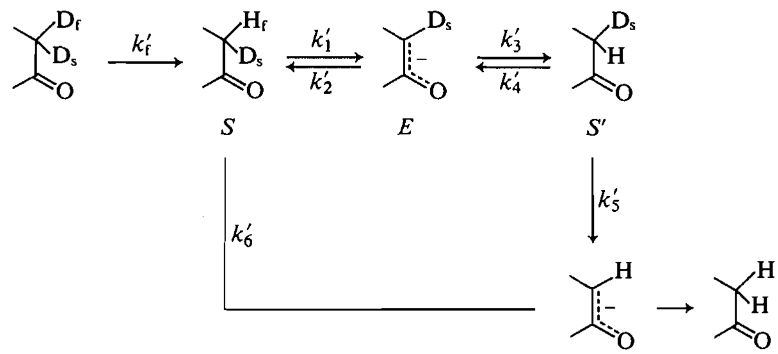
[c] Obtaned as an average of 14 determinations of α from 14-ms scans.
[d] Obtaned as an average of 13 determinations of α from 13-ms scans.
[e] Obtaned as an average of 12 determinations of α from 12-ms scans.

$$[6] \quad k_{s_{obs}}^{H\to D} \simeq k_6 + k_1\left[1 - \frac{k_2(k_4 + k_5)}{(k_2 + k_3)(k_4 + k_5) - k_3k_4}\right]$$

Since $(k_2 + k_3)(k_4 + k_5) >> k_3k_4$ in cases where $k_f > k_s$, eq. [6] can be approximated by eq. [7]. Although k_2 is greater

$$[7] \quad k_{s_{obs}}^{H\to D} \simeq k_6 + k_1\left(1 - \frac{k_2}{k_2 + k_3}\right)$$

than k_3, if $k_f > k_s$ and $k_2/(k_2 + k_3)$ approaches unity, because $k_1 >> k_6$ the $k_1(1 - (k_2/k_2 + k_3))$ term – basically a measure of the contribution of inversion to exchange of the slow proton – can make a significant contribution to $(k_s)_{obs}^{H\to D}$. If S_D = intrinsic selectivity in deuteriated medium, V_D and L_D are the primary KIEs for fast and slow deprotonation, V_D' and L_D' are the isotope effects for fast and slow protonation, and v_D and l_D are the secondary KIEs for fast and slow proton exchange in deuteriated medium, then $S_D \simeq k_1V_D/k_6l_D \simeq k_2 V_D'/k_3 L_D'$, $k_3/k_2 \simeq V_D'/S_DL_D'$, and $k_6 \simeq k_1V_D/S_Dl_D \simeq k_{f_{obs}}/S_Dl_D$. By mak-



SCHEME 3

TABLE 5. Variation of secondary KIEs for base-catalyzed enolization

k_f/k_s	Actual k_H/k_D	Initial d_0/d_1 ratio	Number of half-lives (calcd. k_H/k_D)		
750	1.11	25:75	1(1.11)	2(1.11)	3(1.11)
750	1.11	50:50	1(1.11)	2(1.11)	3(1.10)
750	1.11	75:25	1(1.11)	2(1.10)	3(1.09)
250	1.11	50:50	1(1.11)	2(1.10)	3(1.09)
50	1.11	25:75	1(1.13)	2(1.11)	3(1.09)
50	1.11	50:50	1(1.11)	2(1.07)	3(1.00)
50	1.11	75:25	1(1.07)	2(0.96)	3(0.73)

ing the appropriate substitution into eq [7],[6] eq. [8] is obtained.

$$[8] \quad (k_f/k_s)_{\text{obs}}^{\text{H}\to\text{D}} \simeq \frac{(S_DV_Dl_D)(S_DL_D' + V_D')}{V_D\left(\dfrac{S_DV_D'l_D}{V_D} + S_DL_D' + V_D'\right)}$$

If $S_D >> V_D$ or V_D', then eq. [9] is obtained

$$[9] \quad (k_f/k_s)_{\text{obs}}^{\text{H}\to\text{D}} \simeq \frac{S_DL_D'l_D}{\left(L_D' + \dfrac{V_D'}{V_D}l_D\right)}$$

and the intrinsic selectivity is given by eq [10].

$$[10] \quad S_D \simeq \frac{(k_f/k_s)_{\text{obs}}^{\text{H}\to\text{D}}\left(L_D' + \dfrac{V_D'}{V_D}l_D\right)}{L_D'l_D}$$

If the assumption is made that the protonation isotope effects are approximately equal to the deprotonation isotope effects, then eq. [11] is obtained.

$$[11] \quad (k_f/k_s)_{\text{obs}}^{\text{H}\to\text{D}} \simeq \frac{S_DL_D'l_D}{L_D' + l_D}$$

Presently there is little information available on the relative magnitudes of the deprotonation and protonation isotope effects and it is difficult to make predictions.[7] From the limited data available it appears that the protonation KIE is less than the deprotonation KIE. Pocker (24) has shown that the protonation KIE for acetone enolate (enol) in basic aqueous medium is ~5.5 while the deprotonation KIE, neglecting secondary effects, is 7.5. Long and Watson (25) have established that the primary KIE for protonation of methylacetylacetone enolate by $CH_3COOH(D)$ in aqueous medium is 5.6. The acetate-catalyzed enolization of the ketone is characterized by a primary KIE of 5.8 in H_2O.

If a further assumption is made that $V_D \simeq V_D' \simeq L_D \simeq L_D' = i$ and the secondary KIEs v_D and l_D are set equal to 1, then eq. [11] can be approximated by eq. [12]. That l_D is small,

$$[12] \quad (k_f/k_s)_{\text{obs}}^{\text{H}\to\text{D}} \simeq \frac{S_Di}{i+1}$$

1.12 ± 0.03 according to our studies, indicates that the assumption regarding v_D and l_D is reasonable.

If an analogous mechanism for D → H exchange in nondeuteriated medium is considered (Scheme 3), then a steady-state treatement using E and S' yields eq. [13]. If S_H is the intrinsic selectivity in nondeuteriated medium, V_H and L_H are

$$[13] \quad (k_s)_{\text{obs}}^{\text{D}\to\text{H}} \simeq k_6' + k_1'\left(1 - \frac{k_2'}{k_2' + k_3'}\right)$$

the primary KIEs in fast and slow exchange, respectively, in nondeuteriated medium, and v_H and l_H are the respective α-secondary KIEs, then $S_H \simeq k_2'l_H/k_3'v_H \simeq k_f^{\text{H}\to\text{H}}/k_s^{\text{H}\to\text{H}}$, $k_1 \simeq k_f^{\text{H}\to\text{H}}/V_H$, $k_6' \simeq k_s^{\text{H}\to\text{H}}/L_H$, and $k_f^{\text{D}\to\text{H}} \simeq k_f^{\text{H}\to\text{H}}/V_Hv_H$. By making the appropriate substitutions into eq. [13] and since $S_H >> v_H$ and l_4, eq. [14] is obtained. If v_H and l_H are set equal to 1 and $V_H \simeq L_H = i$ then eq. [14] is reduced to eq. [15].

$$[14] \quad (k_f/k_s)_{\text{obs}}^{\text{D}\to\text{H}} \simeq \frac{S_HL_Hv_H}{V_H(L_Hl_H + v_H^2)}$$

That $V_D \simeq V_H \simeq L_D \simeq L_H = i$ is reasonable since the protonation

$$[15] \quad (k_f/k_s)_{\text{obs}}^{\text{D}\to\text{H}} \simeq \frac{S_H}{i+1}$$

KIE is expected to be similar in magnitude to the deprotonation KIE and primary KIEs measured in nondeuteriated and deuteriated medium are very similar. Pocker (24) studied the hydroxide (deuteroxide) bromination of actone and perdeuteroacetone and established that $(k_H/k_D)_{H_2O} = (k_H/k_D)_{D_2O} = 7.5$. Jones (18), in a more recent study of the rates of abstraction of hydrogen, deuterium, and tritium from acetone by OH^- (OD^-),

[6] Even though $(k_f)_{\text{obs}}$ is actually equal to $k_f + k_s$, the assumption that $(k_f)_{\text{obs}} \simeq k_1V_D$ is valid because $k_f \simeq 650 \times k_s$.

[7] If the ZPEs (zero point energies) for C—H and C—D of substrate and the transition state are considered and a common intermediate is generated, then if ΔZPE in the transition state is ½ ΔZPE for substrate, k_H/k_D for protonation ≃ k_H/k_D for deprotonation.

TABLE 6. Kinetic isotope effects for hydrogen isotope exchange of *exo*-3-chlorobicyclo[2.2.1]heptan-2-ones

Entry	KIE	
1	SIE^{H}	1.60 ± 0.04[a]
2	SIE^{D}	1.68 ± 0.16[b]
3	$(k_H/k_D)_{H_2O}$	6.9 ± 0.5[c]
4	$(k_H/k_D)_{D_2O}$	6.6 ± 0.3

[a] A ratio of the averages of entries 1 and 2 and 3 and 4 of Table 2.
[b] A ratio of entry 5 and the average of entries 6 and 7 of Table 2.
[c] A ratio of the averages of entries 1 and 2 and entry 5 of Table 2.
[d] A ratio of the averages of entries 3 and 4 and 6 and 7 of Table 2.

established that $(k_H/k_D)_{H_2O} = 9.8 \pm 0.5$ and $(k_H/k_D)_{D_2O} = 11.2 \pm 0.4$. The secondary KIE for 5 deuterium atoms was shown to be 1.067. The reason for the difference between Pocker's and Jones' findings is not clear. It is interesting to note that the solvent KIEs for acetone and perdeuterated acetone were 1.47 ± 0.07 and 1.28 ± 0.05, respectively. Long and Watson (25) studied the acetate-catalyzed bromination of methylacetylacetone in H_2O and D_2O and found $(k_H/k_D)_{H_2O} = 5.8$ and $(k_H/k_D)_{D_2O} = 5.6$. As is seen from the data in Table 6, the primary KIEs for *endo*-proton abstraction of **1***c* and **1***d*, perhaps a better model for exchange of **1***a*, in H_2O and D_2O are 6.9 ± 0.5 and 6.6 ± 0.3, respectively. The solvent KIEs for *endo*-proton abstraction from **1***c* and *endo*-deuteron abstraction from **1***d* are 1.60 ± 0.04 and 1.68 ± 0.16, respectively. The data establish that the primary KIEs are not substantially different in nondeuteriated and deuteriated medium. The same surely holds for the secondary KIEs as well. Consequently, we predict that if exchange by inversion contributes significantly to exchange of the slow proton of a diastereotopic pair, then $(k_f/k_s)_{obs}^{H\to D}$ should differ substantially from $(k_f/k_s)_{obs}^{D\to H}$. The ratio of eqs. [12] and [15] yields eq. [16]

$$[16] \quad (k_f/k_s)_{obs}^{H\to D}/(k_f/k_s)_{obs}^{D\to H} \simeq \frac{S_D i}{i+1} \Big/ \frac{S_H}{i+1} \simeq i$$

and i should range between $4 \to 8$. A number of examples where this is the case have now been documented and are listed in Table 7. It is interesting to note that Lamaty and co-workers (30) have corroborated our findings for exchange of **1***a*. It is clear that our prediction is supported in every case where the intrinsic selectivity is greater than the primary isotope effects. If exchange occurred only with retention, then, neglecting solvent isotopic effects, the ratios of the rate constants for $H \to D$ and $D \to H$ exchange yield eq. [17]

$$[17] \quad \frac{(k_f/k_s)_{obs}^{H\to D}}{(k_f/k_s)_{obs}^{D\to H}} \simeq \frac{S_D l_D}{\dfrac{L_H S_H}{V_H \nu_H}} \simeq \frac{V_H l_D \nu_H}{L_H}$$

since $S_H = S_D$. It can be argued that vastly different primary KIEs for $D \to H$ exchange, especially for the cases where k_f and k_s are substantially different, could, coupled with secondary KIEs, account for the observed difference between $(k_f/k_s)_{obs}^{H\to D}$ and $(k_f/k_s)_{obs}^{D\to H}$. Since the secondary KIEs are small ($\simeq 1.1$) and the primary KIEs are expected not to be vastly different, certainly not by a factor of 4 or more, especially for exchange of camphor (**3**), the experimental results are not in accord with exchange by retention only. From Table 6 it is seen that k_H/k_D for *endo* abstraction in **1***c* in H_2O is 6.9 ± 0.5. Bell and Grainger (31), by a study of the mutarotation of *endo*-3-bromo-(+)-camphor and its *exo-d* analog, established that k_H/k_D for *exo* abstraction was 6.9 in 15% DMSO/H_2O at 25°C. Since k_H was 0.54 M^{-1} s^{-1} and 0.49 M^{-1} s^{-1} in 15% DMSO/H_2O and 45% dioxane/H_2O, respectively, the primary KIE is expected to be similar in dioxane/H_2O. Since *endo*-3-bromo-camphor should be a reasonably good model for *exo* exchange of *endo*-3-chlorobicyclo[2.2.2]heptan-2-one, the data suggest that the *exo* and *endo* KIEs for exchange of [2.2.1]-ketones should not be vastly different. Tidwell and co-workers have shown that the primary KIE for *exo* abstraction of **1***a* is 5 in 2:1 dioxane/NaOD/D_2O (8). If solvent isotope effects (SIEs) are included for $H \to D$ exchange (Scheme 2) then with

$$S_D \simeq \frac{k_1 V_D SIE_6}{k_6 l_D SIE_1} \simeq \frac{k_2 V_D' SIE_2}{k_3 L_D' SIE_3},$$

$$k_6 \simeq \frac{k_1 V_D SIE_6}{S_D l_D SIE_1} \simeq \frac{k_f SIE_6}{S_D l_D SIE_1}$$

appropriate substitution into eq. [7] yields eq. [18]. A ratio of eqs. [18] and [14] yields eq. [19].

$$[18] \quad (k_f/k_s)_{obs}^{H\to D} \simeq \frac{S_D L_D' l_D SIE_1}{\left[L_D' + \dfrac{SIE_1 SIE_3}{SIE_6 SIE_2}\left(\dfrac{V_D' l_D}{V_D}\right)\right] SIE_6}$$

$$[19] \quad \frac{(k_f/k_s)_{obs}^{H\to D}}{(k_f/k_s)_{obs}^{D\to H}} \simeq \frac{(V_H L_D' l_D)(L_H l_H + \nu_H^2) SIE_1}{\left[L_D' + \dfrac{SIE_1 SIE_3}{SIE_6 SIE_2}\left(\dfrac{V_D' l_D}{V_D}\right)\right] SIE_6} \left(\frac{1}{L_H \nu_H}\right)$$

If ν_H and l_H are set equal to 1 and V_D, V_D', V_H, L_H, and L_D' are set equal to i, then in the case where exchange of the slow proton occurs by inversion, eq. [20] is obtained.

$$[20] \quad \frac{(k_f/k_s)_{obs}^{H\to D}}{(k_f/k_s)_{obs}^{D\to H}} \simeq \left[\frac{i(i+1)}{i + \left(\dfrac{SIE_1 SIE_3}{SIE_6 SIE_2}\right)}\right] \frac{SIE_1}{SIE_6}$$

For the case where exchange occurs by retention only, inclusion of SIEs into eq. [17] yields eq. [21].

$$[21] \quad \frac{(k_f/k_s)_{obs}^{H\to D}}{(k_f/k_s)_{obs}^{D\to H}} \simeq \frac{V_H l_D \nu_H SIE_1}{L_H SIE_6}$$

Thus, if SIE_1 was substantially greater than SIE_6 and $V_H > L_H$, the difference between $(k_f/k_s)_{obs}^{H\to D}$ and $(k_f/k_s)_{obs}^{D\to H}$ could be indicative of a mechanism which involves exchange only by retention. Unfortunately there are no data available in the literature on the relative magnitudes of the SIEs for exchange of diastereotopic protons. However, there is no reason to expect the SIEs to be substantially different, especially in the cases, i.e. camphor, where k_f and k_s are not vastly different. It is interesting to note that on the basis of our proposal, using eqs. [9] and [14], given eq. [22], and assuming that $SIE_1 \simeq SIE_6$ and $SIE_2 \simeq SIE_3$,

TABLE 7. Ratios of rate constants for base-catalyzed hydrogen isotope exchange of ketones

	$(k_f/k_s)^{H \to D}$	$(k_f/k_s)^{D \to H}$	$(k_f/k_s)^{T \to H}$
	658 ± 66 (this work) 700 (ref. 30)	91 ± 9 (this work) 100 (ref. 30)	81 (ref. 28)
	18 (ref. 26) 21 (ref. 27)	2 (ref. 26)	4 (ref. 28)
	120 (ref. 27)		19 (ref. 28)
	293 ± 20 (ref. 29)	63 ± 5 (ref. 29)	

$$[22] \quad \frac{k_f^{H \to D}}{k_f^{D \to H}} \simeq V_H \nu_H \mathrm{SIE}_I$$

eq. [23] is obtained and rearranged into eq. [24].

$$[23] \quad (k_s/k_f)_{obs}^{H \to D} \times (k_f/k_s)_{obs}^{D \to H} \simeq \left[\frac{L_D' + \dfrac{V_D'}{V_D} l_D}{S_D L_D' l_D}\right]\left[\frac{S_H L_H \nu_H}{V_H(L_H l_H + \nu_H^2)}\right]$$

$$[24] \quad \left(\frac{k_s^{H \to D}}{k_s^{D \to H}}\right)_{obs} \simeq \left[\frac{L_D' + \dfrac{V_D' l_D}{V_D}}{S_D L_D' l_D}\right]\left[\frac{S_H L_H \nu_H}{V_H(L_H l_H + \nu_H^2)}\right][V_H \nu_H \mathrm{SIE}_I]$$

If $S_D = S_H$, $L_D \simeq L_D' \simeq L_H$, $V_D \simeq V_D'$, and $l_D = l_H = \nu_H = 1$ then eq. [24] is reduced to eq. [25].

$$[25] \quad \left(\frac{k_s^{H \to D}}{k_s^{D \to H}}\right)_{obs} \simeq \mathrm{SIE}_I$$

If exchange of the slow proton occurs by retention only, then eq. [21] is rearranged into eq. [26]

$$[26] \quad \left(\frac{k_f}{k_s}\right)_{obs}^{H \to D}\left(\frac{k_s}{k_f}\right)_{obs}^{D \to H} \simeq \frac{V_H l_D \nu_H \mathrm{SIE}_I}{L_H \mathrm{SIE}_6}$$

that yields eq. [27] using eq. [22] and assuming $l_D \simeq 1$.

$$[27] \quad \left(\frac{k_s^{H \to D}}{k_s^{D \to H}}\right)_{obs} \simeq L_H \mathrm{SIE}_6$$

It is seen from the data in Table 1 (entries 2, 3, and 9) that $(k_s^{H \to D}/k_s^{D \to H})_{obs} = 1.24 \pm 0.19$, in accord with our proposal, but not with the latter case, since L_H is expected to be ≥ 5.

While our analysis[8] is based on hydrogen isotope exchange α to a carbonyl group, it must also hold for exchange of diastereotopic protons for all carbon acids such as sulfoxides (32–35), sulfones (35), sulfonium salts (36), and *N*-nitrosoamines (37)[9] where a common intermediate is generated or the barrier to inversion of the incipient diastereomeric anions is less than the barrier to protonation. Although the barriers to inversion of carbanions appear to be quite low (38), we expect that in the case where diastereomeric anions are formed and the inversion barrier is high, provided the primary, secondary, and SIEs are not vastly different for the fast and slow protons, $(k_f/k_s)^{H \to D} \simeq (k_f/k_s)^{D \to H}$.

Presently, we are studying H → D and D → H exchange in several sulfoxides and plan to report our findings in the near future.

Experimental

Bicyclo[2.2.1]heptan-2-one (**1**) was obtained from Aldrich Chemical Co. and was purified by preparative gas chromotagraphy prior to use. *exo*-3-Chlorobicyclo[2.2.1]heptan-2-one and its deuteriated analog were prepared by the chlorination of **1***a* and **1***b*, respectively, according to the method of Tobler *et al.* (39) and were separated and purified by preparative gas chromatography.

Kinetic methods

Base-catalyzed exchange

(a) *Ketones* **1**a *and* **1**b

The method described in a previous publication (14) was used to determine the rates of H → D and D → H exchange of the diastereotopic protons and deuterons of **1***a* and **1***b*, respectively.

(b) *Chloroketones* **1**c *and* **1**d

The method described previously (13) was used to determine the rates of H → D and D → H exchange of **1***c* and **1***d*, respectively.

[8] All the derivations of equations have been deposited as Supplementary Material. Copies may be obtained at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada, K1A 0S2.

[9] The references listed are only representative of the systems which have been studied. Many other examples have been documented.

Acid-catalyzed exchange

Stock solutions of 2.00 *N* HCl and 2.08 *N* DCl were prepared by diluting concentrated HCl and DCl in H_2O and D_2O, respectively. In a typical run, ketone (0.020–0.030 g) was dissolved in 1–2 mL of CH_3COOH/2.00 *N* HCl or CH_3COOD/2.08 *N* DCl and aliquots (~0.1 mL) were sealed in thick-walled tubes and placed in a fluidized sand bath maintained at 100.0 ± 0.5°C. The tubes were withdrawn at appropriate intervals, quenched with liquid nitrogen, and stored in a freezer. Mass spectrometric analyses were carried out on a Hitachi–Perkin–Elmer RMU6A mass spectrometer at low voltage by simply subliming the volatile ketone into the spectrometer inlet system.

Bicyclo[2.2.1]heptan-2-one-3,3-d_2 *(1*b*)*

Ketone **1***a* (3 g) was heated in a sealed tube with 20 mL of 0.5 *N* NaOD/D_2O for 16 h at 140°C. The aqueous layer was extracted with purified pentane (3 × 20 mL), the combined pentane extracts were dried over Na_2SO_4, and most of the pentane was distilled off through a 30-cm Vigreux column. The final traces of solvent were removed under vacuum to yield 2.6 g (87%) of deuterated ketone. Mass spectrometric analysis established that the ketone was composed of 94.30% d_2, 3.91% d_1, and 1.83% d_0 species. The ketone was purified by preparative gas chromatography prior to its use in kinetic runs.

Bicyclo[2.2.1]heptan-2-one-endo-*3*-d *(1*f*)*

The 3,3-dideuterated ketone (0.2 g) was heated in 60% dioxane – 40% aqueous NaOH and was monitored periodically by mass spectrometry until <1% dideuterated ketone was present. The solution was worked up as described above to yield the desired monodeuterio substrate.

The gas-phase photochemistry and thermal decomposition of glyoxylic acid[1]

R. A. BACK AND S. YAMAMOTO[2]

Division of Chemistry, National Research Council of Canada, 100 Sussex Drive, Ottawa, Ont., Canada K1A 0R6

Received April 24, 1984

R. A. BACK and S. YAMAMOTO. Can. J. Chem. **63**, 542 (1985).

The photolysis of glyoxylic acid vapour has been studied at five wavelengths, 382, 366, 346, 275, and 239 nm, and pressures from about 1 to 6 Torr, at a temperature of 355 K. Major products were CO_2 and CH_2O, initially formed in almost equal amounts, while minor products were CO and H_2. Except at 382 nm, the system was complicated by the rapid secondary photolysis of CH_2O. Three primary processes are suggested, each involving internal H-atom transfer followed by dissociation.

The absorption spectrum is reported and shows the three distinct absorption systems. A finely-structured spectrum from about 320 to 400 nm is attributed to a transition to the first excited $\pi^* \leftarrow n_+$ singlet state; a more diffuse absorption ranging from about 290 nm to a maximum at 239 nm is assigned to the $\pi^* \leftarrow n_-$ state, while a much stronger absorption beginning below 230 nm is attributed to the $\pi^* \leftarrow \pi$ transition. Product ratios vary with wavelength and depend on which excited state is involved.

The thermal decomposition was studied briefly in a static system at temperatures from 470 to 710 K and pressures from 0.4 to 8 Torr. Major products were again CO_2 and CH_2O, but the latter was always less than stoichiometric. First-order rate constants for the apparently homogeneous formation of CO_2 are described by Arrhenius parameters log A (s^{-1}) = 7.80 and E = 30.8 kcal/mol. Carbon monoxide and H_2 were minor products, and the CO/CO_2 ratio increased with increasing temperature and showed some surface enhancement at lower temperatures. The SF_6-sensitized thermal decomposition of glyoxylic acid, induced by a pulsed CO_2 laser, was briefly studied, with temperatures estimated to be in the 1100−1600 K range, and the CO/CO_2 ratio increased with increasing temperature, continuing the trend observed in the static system.

R. A. BACK et S. YAMAMOTO. Can. J. Chem. **63**, 542 (1985).

Opérant à des pressions allant de 1 à 6 Torr et à une température de 355 K, on a étudié la photolyse de l'acide glyoxylique en phase vapeur aux cinq longueurs d'onde suivantes: 382, 366, 346, 275 et 239 nm. Les produits principaux sont le CO_2 et le CH_2O qui se forment initialement en quantités pratiquement égales; il se forme aussi du CO et du H_2 comme produits mineurs. Excepté à 382 nm, le système est compliqué par la photolyse secondaire rapide du CH_2O. On suggère l'existence de trois processus primaires qui impliquent tous un transfert interne d'un atome d'hydrogène qui serait suivi par une dissociation.

On rapporte le spectre d'absorption qui présente trois systèmes distincts d'absorption. On attribue le spectre à structure fine, qui s'étale de 320 à 400 nm, à une transition vers le premier état singulet excité $\pi + \leftarrow n_+$; on attribue une absorption plus diffuse, qui va de 290 nm jusqu'à un maximum à 239 nm, à l'état $\pi^* \leftarrow n_-$ alors que l'absorption beaucoup plus forte qui commence en dessous de 239 nm serait due à la transition $\pi^* \leftarrow \pi$. Les rapports des quantités de produits obtenus varient avec la longueur d'onde utilisée pour provoquer la photolyse et ils dépendent de l'état excité impliqué.

Opérant à des températures allant de 470 à 710 K et à des pressions allant de 0,4 à 8 Torr, on a brièvement étudié la décomposition thermique dans un système statique. De nouveau, les produits majeurs sont le CO_2 et le CH_2O; toutefois, la quantité formée de ce dernier composé est toujours inférieure à la stoïchiométrie. Les constantes de vitesse du premier ordre, pour la formation apparement homogène de CO_2, est décrite par les paramètres d'Arrhénius suivants: log A (s^{-1}) = 7,80 et E = 30,8 kcal/mol. Le CO et le H_2 sont formés comme produits mineurs; le rapport CO/CO_2 augmente avec une augmentation de la température et, à basse température, il est rehaussé par la présence de surfaces. On a brièvement étudié la décomposition thermique de l'acide glyoxylique, sensibilisée par du SF_6 et induite par un laser pulsé au CO_2; on a évalué que les températures se situaient entre 1100 et 1600 K et, comme dans le système statique, le rapport CO/CO_2 augmente avec une augmentation de la température.

[Traduit par le journal]

Introduction

The photolysis and spectroscopy of glyoxal and biacetyl have been the subjects of much investigation and interest, but few other α-dicarbonyl compounds have been studied in the gas phase. We have recently completed studies of the spectroscopy (1) and photochemistry (2) of oxalic acid vapour, and the present paper describes the extension of this work to glyoxylic acid, H—C(=O)—C(=O)—O—H. The thermal decomposition and the decomposition induced by a pulsed infrared laser were also studied for comparison with the photolysis.

Experimental

The apparatus and techniques were similar to those used with oxalic acid (2). Photolyses were done in a cylindrical quartz vessel, 10 cm long and 5 cm in diameter, with the vessel and gas-handling manifold kept at a temperature of 355 K, high enough to permit an adequate vapour pressure but low enough so that thermal dark reaction was minimal, and no correction was needed. The thermal decomposition was studied in a static system, a cylindrical quartz vessel 11 cm long and 3 cm in diameter heated in a tube furnace. The laser-induced pyrolysis was done in a cylindrical Pyrex vessel, 10 cm long and 4 cm in diameter, fitted with NaCl windows, also held at 355 K.

The light source for the ultraviolet photolysis was a 1000 W Hg-Xe high pressure arc lamp with matching monochromator that gave a band width of about 20 nm. For the laser-induced decomposition, a Lumonics Model 203 pulsed CO_2 TEA laser was used, as previously described (2, 3).

Glyoxylic acid (98% pure) was obtained from Aldrich as the hydrate, and was dehydrated by judicious heating and pumping until a constant vapour pressure was attained; it was thoroughly pumped to remove any decomposition products before each experiment. Propylene was Phillips Research grade.

Results

Absorption spectrum

The absorption spectrum of glyoxylic acid vapour, previously unreported, was measured in a modified Heath spectrophotometer fitted with a 4 m heated cell, and is shown in Fig. 1. Three absorption systems are evident. The highly structured spectrum extending from about 320 to 400 nm undoubtedly corresponds to excitation of the $\pi^* \leftarrow n_+$ first excited singlet state. The absorption beginning at about 290 nm and extending to a maximum at 239 nm, with broad diffuse vibrational features, is probably due to the $\pi^* \leftarrow n_-$ excitation, while the much stronger absorption setting in below about 230 nm is most probably from a $\pi^* \leftarrow \pi$ excited state. The photolysis was studied at the five wavelengths indicated in Fig. 1, three in the first absorption system and two in the second. A more detailed account and analysis of this spectrum will be published elsewhere (4).

Ultraviolet photolysis

Major primary products of the photolysis were CO_2 and formaldehyde, with much smaller amounts of H_2 and CO. The time dependence of products at 366 nm is shown in Fig. 2. Production of CO_2 was linear with time at this and all other wavelengths. Yields of H_2CO, however, fell with increasing time, and those of CO increased, and similar behaviour was observed at 346, 275, and 239 nm. In the photolysis at 382 nm, however, both CO_2 and CO were linear functions of time; yields of H_2CO could not be measured accurately because the amounts were quite small at this wavelength.

Experiments at 366 nm with added air or propylene at pressures up to 50 Torr showed no difference in the production of CO_2, indicating that neither free radicals nor triplet states were involved in its formation.

Some light emission was observed on excitation between 340 and 380 nm, but the excitation spectrum was almost exactly that of formaldehyde and thus the emission was very probably from excitation of formaldehyde product; there may have been some weak underlying emission from glyoxylic acid itself.

Thermal decomposition

The thermal decomposition was studied in a static system at pressures from 0.4 to 8 Torr and temperatures from 470 to 710 K. Products observed and measured were those observed in the photolysis, CO_2, H_2CO, CO, and H_2, all volatile at dry-ice temperature. No systematic search was made for higher products. Figure 3 shows an Arrhenius plot of the first-order rate-constant for the formation of CO_2. No trend with pressure was observed between 2.5 and 8 Torr, and all the data shown were obtained in this range. At lower pressures the rate constant decreased substantially (Fig. 4). Formaldehyde was always less than CO_2, with the ratio reaching a constant value of about 0.8

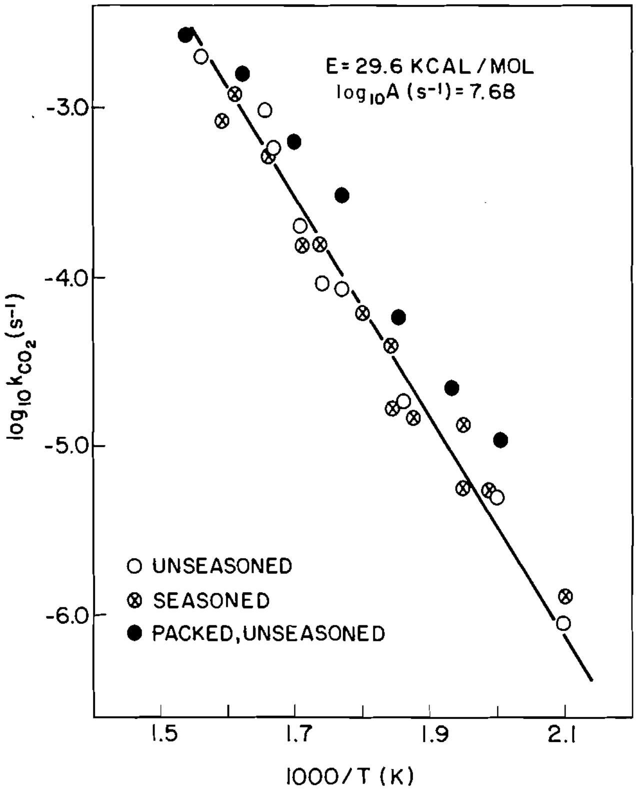

FIG. 3. Arrhenius plot for the first-order rate constant for the formation of CO_2 in the thermal decomposition of glyoxylic acid.

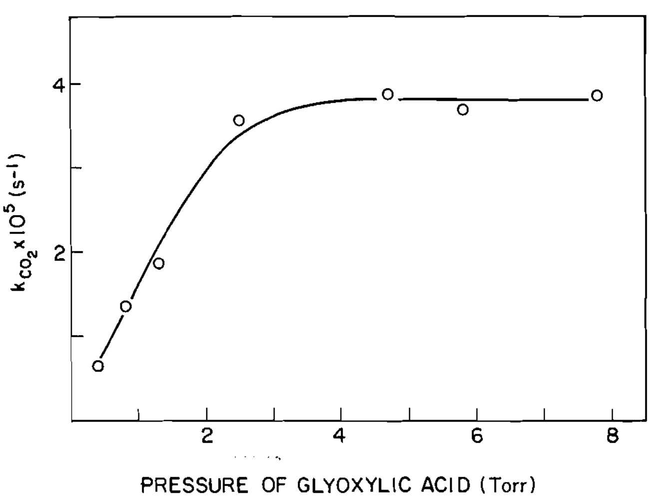

FIG. 4. Pressure dependence of the first-order rate constant for the formation of CO_2.

above 625 K, and falling markedly at lower temperatures (Fig. 5). Yields of CO and H_2 were each less than 10% of the CO_2 and decreased with decreasing temperature (Fig. 6). All products were linear functions of time at the low conversions attained in the experiments.

Decomposition induced by a pulsed infrared laser

Glyoxylic acid did not itself absorb infrared radiation at the wavelengths of the CO_2 laser, but its decomposition was easily sensitized by a small pressure of SF_6, which is a strong absorber. Two sets of experiments were done, one with a constant pressure of 1.2 Torr of SF_6 and varying pressures of glyoxylic acid, the other with a constant pressure of 2.8 Torr of glyoxylic acid and variable SF_6 pressure. Results are shown in Figs. 7 and 8. Although the extent of decomposition of the reagent in the laser beam (1.2 cm diameter) was quite high in some of these experiments, product yields were proportional to the number of pulses up to about four pulses, with the reagent in the beam presumably replenished in the 2 s between pulses by diffusion and convection. All the data shown were obtained with two pulses per experiment.

The probability of decomposition, P, and the CO/CO_2 ratio, behaved in a parallel manner (Figs. 7 and 8), reflecting changes in the effective temperature of the system with changing gas composition. The major effect is that caused by dilution of the absorbing SF_6 by non-absorbing glyoxylic acid with consequent decrease in temperature. The decrease in P in Fig. 7 is less than expected, however, and the increase in P in Fig. 8 more than expected on this basis, as shown more clearly in a plot of P vs. mole fraction of SF_6 (Fig. 9). The explanation probably lies in a pressure dependence of the multiphoton absorption by SF_6, evident from the dependence of P on total pressure (indicated on Fig. 9 beside each experimental point). There is also probably an additional increase in P with pressure due to an increase in reaction time, as the hot gas cools more slowly after the pulse at higher pressure. A reaction time of the order of 1 ms can be estimated, and if the decomposition follows the Arrhenius parameters found in the static thermal decomposition (Fig. 3), reaction temperatures between about 1100 and 1500 K are indicated for the experiments shown in Figs. 7 and 8.

Figure 10 shows the effect of added air on the laser-induced decomposition. The decrease in P and in the CO/CO_2 ratio are again less than expected from simple dilution, and countervailing effects of total pressure on energy absorption and reaction time are again probably responsible. Figure 11 shows the effect of laser fluence (varied by means of a long-focus lens (4)) on the CO/CO_2 ratio.

Discussion

The photolysis products, their time dependence, and the lack of effect of O_2 and propylene, suggests strongly that the major primary process at all wavelengths is a simple photodissociation into CO_2 and formaldehyde. The increase in CO and the decrease in H_2CO production with increasing time points to a secondary photolysis of formaldehyde, a conclusion supported by the absence of this behaviour at 382 nm where formaldehyde is almost transparent. The secondary CO was not accompanied by H_2 in comparable amounts, and it appears that disproportionation reactions involving excited H_2CO and HCO, similar to those invoked in the photolysis of formaldehyde alone (5), are probably involved in CO formation. There were also smaller yields of CO and H_2 formed as primary products, and the following set of reactions accounts for our observations.

$$[1]\quad \mathrm{H{-}\overset{\overset{\displaystyle O}{\|}}{C}{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}O{-}H} + h\nu \rightarrow CO_2 + H_2CO$$

$$[2]\quad \rightarrow CO_2 + CO + H_2$$

$$[3]\quad \rightarrow CO + HCOOH \text{ (or } 2CO + H_2O)$$

$$[4]\quad H_2CO + h\nu \rightarrow H_2CO^*$$

$$[5]\quad H_2CO^* \rightarrow CO + ?$$

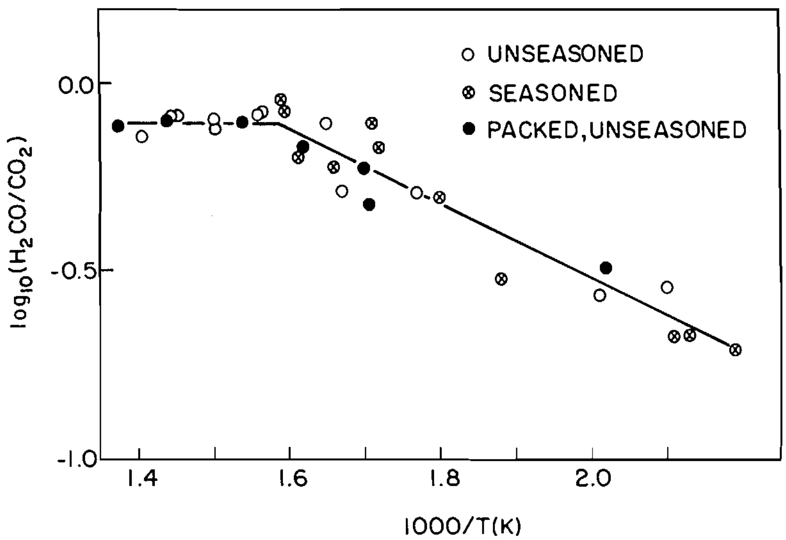

FIG. 5. Arrhenius plot of the ratio of formaldehyde to CO_2 from the thermal decomposition of glyoxylic acid.

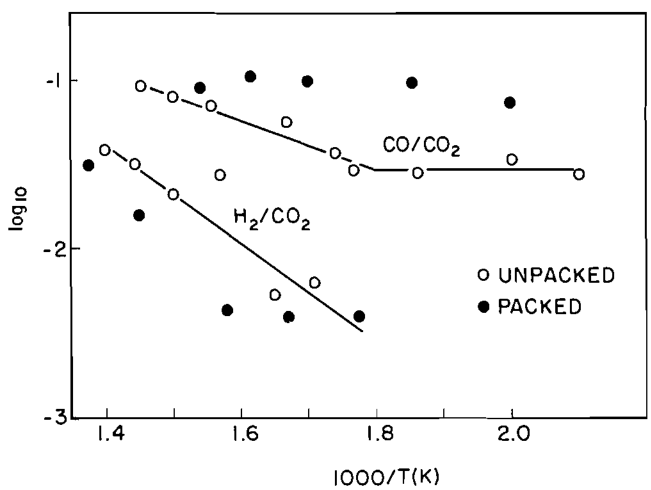

FIG. 6. Arrhenius plot of product ratios CO/CO_2 and H_2/CO_2 from the thermal decomposition of glyoxylic acid.

[6] $H_2CO^* \rightarrow$ other products

Reaction [1] was the predominant primary process at all wavelengths, while reaction [2], measured by the yield of H_2, was consistently about 3% of reaction [1] under all conditions. Reaction [3] is suggested to account for the primary production of CO unaccompanied by H_2. This process was clearly evident at 382 nm and easily measured directly. At 366 and 346 nm it was obscured by secondary production of CO via reaction [5] (Fig. 2). Reactions [5] and [6] are not elementary reactions, but simply represent formally the photochemical loss of formaldehyde with and without formation of CO. A simple mathematical modelling of reactions [1] to [6] to give the best fit to the time dependence of the CO/CO_2 ratio (Fig. 12) led to estimates of reaction [3] at these two wavelengths by extrapolation to zero time. At 275 and 239 nm a simple empirical extrapolation was used. Values for the yields of reactions [2] and [3], relative to that of [1], are shown in Table 1. Values of ϕ_3 are based on formation of CO + HCOOH; if 2CO + H_2O are formed instead, these would be halved. Neither HCOOH nor H_2O was measured in these systems, as the absolute amounts were small and easily lost by adsorption in the vacuum

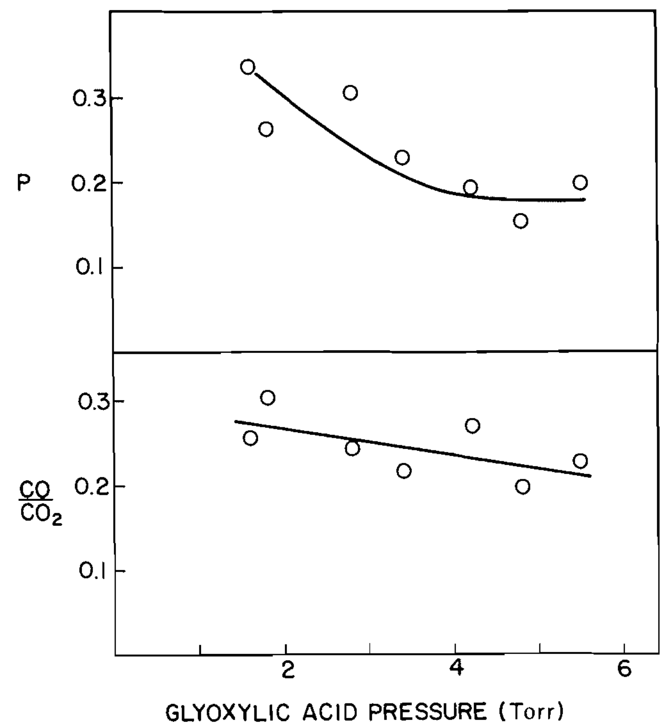

FIG. 7. Probability, P, decomposition of glyoxylic acid in the laser beam in a single pulse, and the CO/CO_2 product ratio, for the SF_6-sensitized thermal decomposition induced by a pulsed CO_2 laser. Pressure of SF_6 = 1.2 Torr.

line.

Absolute quantum yields of CO_2 were estimated at the three longest wavelengths using azomethane as an actinometer, and values of 0.08, 0.66, and 0.76 were obtained at 382, 366, and 346 nm, respectively. The trend with wavelength is probably real, but absolute values are rather uncertain, especially at 382 nm, because of the difficulty in estimating the light absorbed by the glyoxylic acid. Absorption was too weak to be measured directly in the 10-cm photolysis cell (the spectrum in Fig. 1 was obtained in a 4-m cell), and the sharp structure of the spectrum, especially at the longest wavelengths, made it hard to estimate effective extinction coefficients for the photolytic light. There

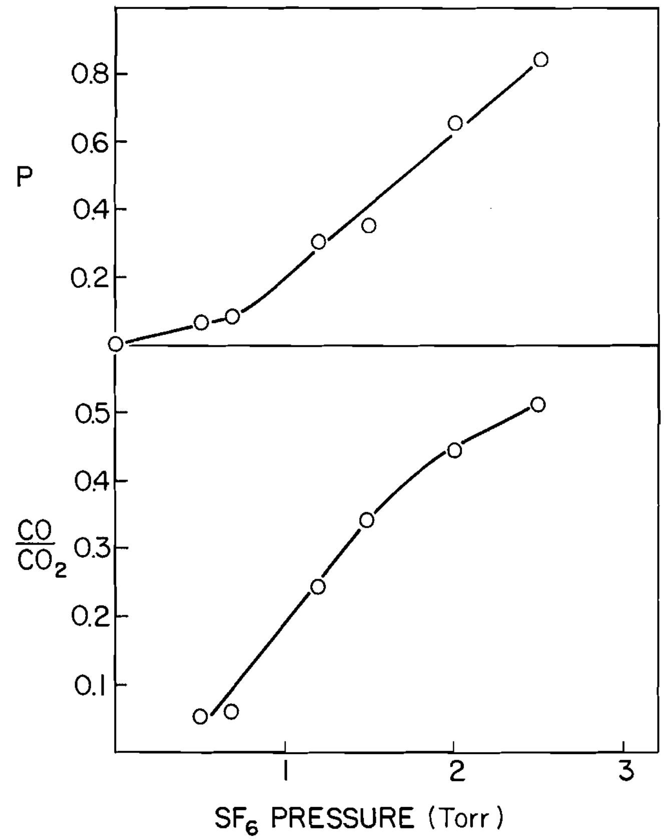

FIG. 8. Dependence of P and CO/CO_2 product ratio on pressure of added SF_6 in the laser-induced thermal decomposition of 2.8 Torr of glyoxylic acid.

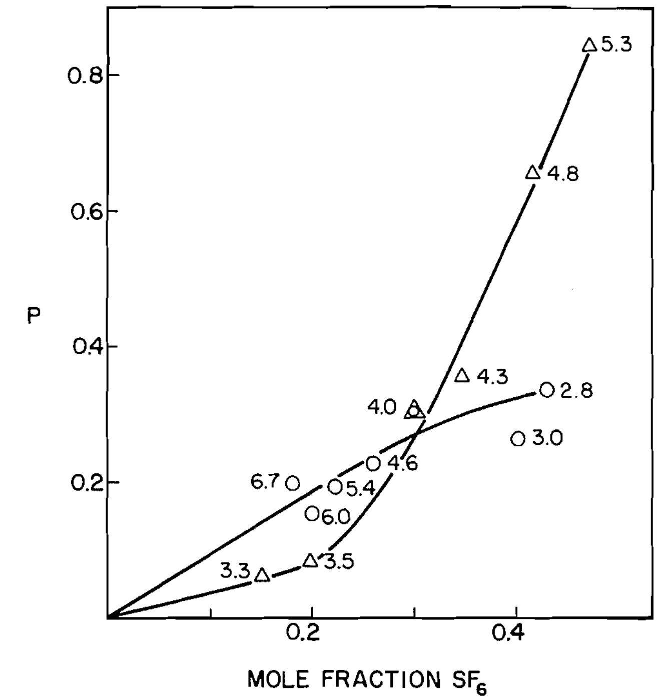

FIG. 9. Probability, P, of decomposition of glyoxylic acid vs. mole fraction of SF_6. Numbers show total pressure in Torr for each experiment.

was no evidence for collisional quenching of the photodissociation by added gas (air or propylene) up to 50 Torr at 366 nm, and no strong fluorescence was seen, so it seems probable that the absolute quantum yield at 366 nm and shorter wavelengths may have been close to unity; the lower value at 382 nm is probably real.

The photochemistry of glyoxylic acid differs from that of oxalic acid (2) in that the ratio Φ_1/Φ_3, and thence the CO/CO_2 ratio, depends strongly on wavelength (Table 1). At the three longest wavelengths, the CO/CO_2 ratio *decreases* with increasing photon energy, although in the thermal decomposition the same ratio *increases* with increasing temperature (see below). This indicates that the photolysis does not proceed through internal conversion and dissociation of the vibrationally-excited ground state, but probably occurs directly from the $\pi^* \leftarrow n_+$ singlet state or perhaps a short-lived triplet. As in oxalic acid, internal transfer of H to the carbonyl oxygen may be involved, with rearrangement of the resulting carbenes leading to H_2CO and HCOOH.

[7]  $\rightarrow CO_2 + \text{H}\ddot{\text{C}}\text{OH}$

[8]  $\rightarrow CO + \text{HO}\ddot{\text{C}}\text{OH}$

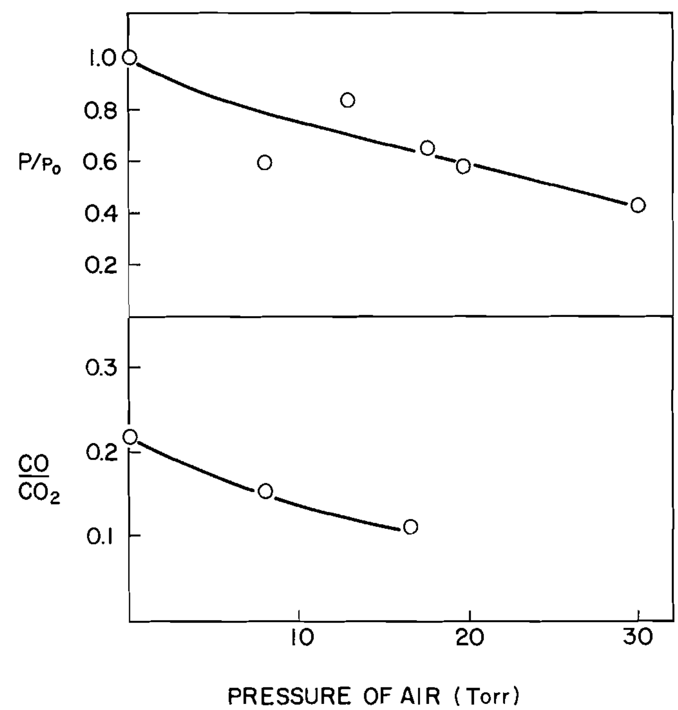

FIG. 10. Effect of added air on P and on the product ratio CO/CO_2 in the laser-induced thermal decomposition of glyoxylic acid. Glyoxylic acid = 2.8 Torr, SF_6 = 1.2 Torr, P_0 = probability of decomposition in the absence of air.

The observed minor formation of H_2 (reaction [2]) might arise from an alternative decomposition of HCOH into H_2 and CO. At the two shortest wavelengths, the CO/CO_2 ratio *increases* with increasing photon energy. It is clear from the absorption spectrum (Fig. 1) that the excitation here involves the second

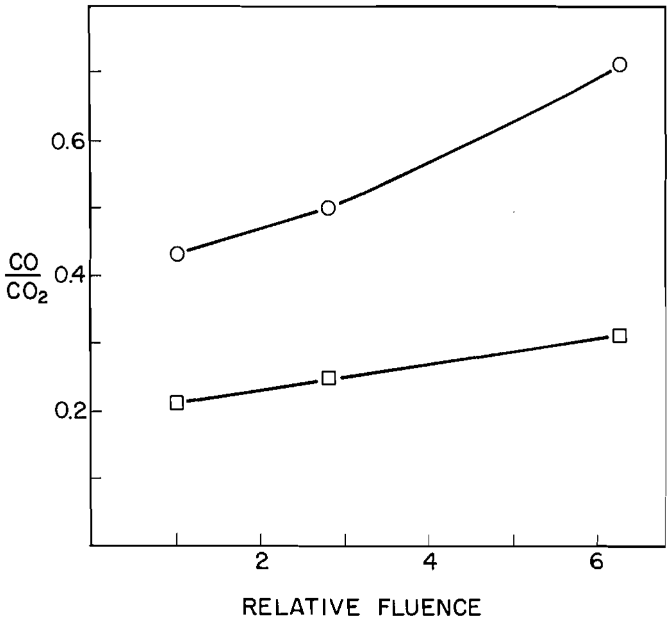

FIG. 11. Effect of laser fluence on CO/CO_2 product ratio in the laser-induced thermal decomposition of glyoxylic acid. Relative fluence is in arbitrary units. □ = 2.8 Torr glyoxylic acid, 1.2 Torr SF_6, ○ = 2.8 Torr glyoxylic acid, 2.6 Torr SF_6.

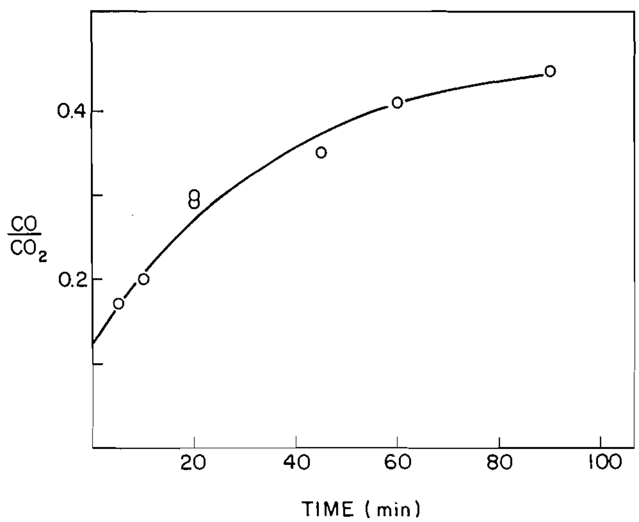

FIG. 12. Time dependence of the CO/CO_2 product ratio from the photolysis of glyoxylic acid at 366 nm. Curve is calculated from model based on mechanism in text. Points are experimental.

excited singlet state, $\pi^* \leftarrow n_-$, and perhaps the $\pi^* \leftarrow \pi$ state, which probably has a strong absorption tail underlying the former. A different decomposition mechanism, perhaps through the vibrationally excited ground state, is probably operative at these wavelengths.

The thermal decomposition is more complicated than the photolysis, although there seems to be no secondary decomposition of products as all yields were linear with time. At the higher temperatures, the major process is again the formation of CO_2 and H_2CO, but the latter remains at only 80% of its stoichiometric yield; at lower temperatures much more is missing (Fig. 5), perhaps lost through polymerization or reaction with glyoxylic acid to give higher products. Production of CO_2 showed some enhancement in the packed vessel, in which the

TABLE 1. Relative quantum yields of primary processes in the photolysis of glyoxylic acid

239	1.0	0.03	0.37

surface/volume ratio was increased by a factor of 4 (Fig. 3). A correction for surface reaction, assuming simple additivity with the gas-phase decomposition, led to corrected Arrhenius parameters of log A (s^{-1}) = 7.80 and E = 30.8 kcal/mol, not much changed from the values obtained before correction (Fig. 3). If these parameters can be ascribed to a simple homogeneous process,

[9] 
they may be compared with those for the similar formation of CO_2 and HCOOH from oxalic acid (6). The activation energies are almost the same (30.8 vs. 30 kcal/mol) but the frequency factor for glyoxylic acid is four orders of magnitude smaller. This is much too low for a normal simple unimolecular reaction. As with the corresponding decomposition of oxalic acid (2), one might expect reaction [9] to proceed by internal transfer of the O—H hydrogen through a four-membered transition state:[3]

[10] 
It is difficult to see why this should be a factor of 10^4 slower in glyoxylic acid, or in simpler terms, why glyoxylic acid should be so much more stable towards thermal decomposition than oxalic acid.

Formation of CO, at least at the lower temperatures, showed a strong surface enhancement while H_2, a very minor product, was somewhat reduced (Fig. 6). Carbon monoxide was not a product of the thermolysis of oxalic acid, which suggests that in glyoxylic acid it is formed by transfer of the aldehydic hydrogen:

[11] 
[12] 
[3]Transfer of H to the carbonyl oxygen as in reaction [7] is unlikely in the thermal reaction because of the expected high energy required to form hydroxymethylene.

Neither H_2O nor HCOOH was detected, but their analysis in this system in the amounts expected is difficult, and either reaction [11] or [12] may have occurred. The upward trend in the CO/CO_2 ratio with increasing temperature evident in Fig. 6 continues in the laser-induced pyrolysis, reaching values as high as 0.71 at the highest fluence (Fig. 11).

It has been shown (7) that the most stable structure of glyoxylic acid in the gas phase is planar, with the two carbonyl groups in a *trans* configuration maintained by strong hydrogen bonding. All the processes we have suggested, both in the thermal and the photochemical decomposition, proceed from this configuration except for reaction [11] which would require a *cis* structure. The barrier to isomerization is probably less than 10 kcal/mol, and would not hinder the occurrence of reaction [11] in the thermal decomposition.

Received May 30, 1984

S. YAMAMOTO and R. A. BACK. Can. J. Chem. **63**, 549 (1985).

The photolysis of pyruvic acid vapour has been studied at wavelengths of 366, 345, and 320 nm, at a temperature of 340 K and pressures from about 1 to 10 Torr. Products observed were CO_2 and CH_3CHO, with the former always in excess, and a quantum yield of CO_2 of 0.9 ± 0.1 at 366 nm. Light emission was also observed, and from the effect of added O_2 it was concluded that emission occurred from both singlet and triplet states. It is suggested that the primary process in the photolysis is an internal hydrogen-atom transfer followed by dissociation into CO_2 and CH_3—C—OH, with the latter then rearranging to give CH_3CHO and other products.

The absorption spectrum is reported; the first system begins at about 380 nm, rising to a maximum at about 350 nm, with $\epsilon_{max} \approx 10\ M^{-1}\ cm^{-1}$, and is attributed to the first excited $\pi^* \leftarrow n_+$ singlet state. Weak absorption below 300 nm is probably due to the $\pi^* \leftarrow n_-$ state and much stronger absorption below 220 nm to the $\pi^* \leftarrow \pi$ state.

The thermal decomposition was studied briefly at temperatures from 455 to 584 K and pressures from about 0.8 to 7 Torr. Products were the same as in the photolysis, and Arrhenius parameters of log A (s^{-1}) = 7.19 and E = 27.7 kcal/mol were obtained, based on the formation of CO_2, which was apparently a simple, homogeneous unimolecular process.

S. YAMAMOTO et R. A. BACK. Can. J. Chem. **63**, 549 (1985).

Opérant à une température de 340 K et à des pressions allant de 1 à 10 Torr, on a étudié la photolyse de l'acide pyruvique en phase vapeur à des longueurs d'onde de 366, 345 et 320 nm. Parmi les produits observés, on note le CO_2 et le CH_3CHO et le premier est toujours présent en excès; à 366 nm, le rendement quantique en CO_2 est égal à 0,9 ± 0,1. On a aussi observé une émission de lumière et, sur la base des résultats obtenus par addition de O_2, on en conclut que l'émission se fait tant de l'état singulet que de l'état triplet. On suggère que le processus primaire de la photolyse est un transfert interne d'un atome d'hydrogène qui est suivi par une dissociation en CO_2 et en CH_3—C—OH et éventuellement par une transposition de cette dernière entité en CH_3CHO et en d'autres produits.

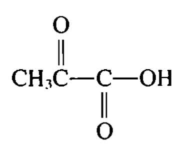
On rapporte le spectre d'absorption; le premier système commence à 380 nm, il augmente pour atteindre un maximum à environ 350 nm, avec un $\epsilon_{max} = 10\ M^{-1}\ cm^{-1}$, et on l'attribue au premier état singulet excité $\pi^* \leftarrow n_+$. L'absorption faible que l'on observe à une longueur d'onde inférieure à 300 nm est probablement due à l'état $\pi \leftarrow n_-$ alors que l'absorption beaucoup plus forte apparaissant à une longueur d'onde inférieure à 220 nm est attribuée à l'état $\pi^* \leftarrow \pi$.

Opérant à des températures allant de 455 à 584 K et à des pressions allant de 0,8 à 7 Torr, on a brièvement étudié la décomposition thermique. Les produits sont les mêmes que ceux obtenus par photolyse; sur la base de la formation du CO_2, qui est apparemment un processus unimoléculaire simple et homogène, on a aussi obtenue les paramètres d'Arrhénius qui sont: log A (s^{-1}) = 7,19 et E = 27,7 kcal/mol.

[Traduit par le journal]

Introduction

With the exception of glyoxal and biacetyl, the photochemistry of α-dicarbonyl compounds in the gas phase has largely been neglected. Recently, the photolyses of oxalic acid (1) and glyoxylic acid (2) have been studied in this laboratory, and the present paper describes an investigation of the gas-phase photochemistry of pyruvic acid,



which was studied only very briefly before by Vesley and Leermakers (3) in 1964. A brief examination of the thermal decomposition, apparently not studied previously, is also reported.

Experimental

Techniques and apparatus were very similar to those used and described before (1, 2). The light source was a Hg-Xe high-pressure arc lamp with matching monochromator, and the cylindrical quartz photolysis vessel was 10 cm long and 5 cm in diameter. Light emission was measured with a photomultiplier in a traditional T-shaped fluorescence cell 5 cm in diameter with a Wood's horn light trap and filters to remove scattered exciting light. All experiments were done at a temperature of 340 K. The thermal decomposition was studied in a static quartz cylindrical reaction vessel, 10 cm long and 3 cm in diameter, mounted in a tube furnace. Pyruvic acid (>98% pure) was obtained from Kodak.

Results

Ultraviolet absorption spectrum

This is shown in Fig. 1, with the arrows showing wavelengths used for photolysis. By analogy with glyoxylic and oxalic acids (1, 2, 4) and other α-dicarbonyl compounds, the first absorption system, beginning at about 385 nm and reaching a maximum ($\epsilon \approx 10\ M^{-1}\ cm^{-1}$) at 350.6 nm, can be assigned to a $\pi^* \leftarrow n_+$ transition, the first excited singlet state. Some vibrational structure is evident at the longer wavelengths, and the sharp feature at 369.8 nm probably marks the (0, 0) band, since no further bands could be seen to the red even at four times higher pressures. A second weak absorption system with broad vibrational features begins below 300 nm, probably the $\pi^* \leftarrow n_-$ transition, which disappears beneath a much stronger absorption setting in about 220 nm (not shown), probably the $\pi^* \leftarrow \pi$ transition. The three wavelengths used in the photolysis experiments all fall within the $\pi^* \leftarrow n_+$ system (Fig. 1).

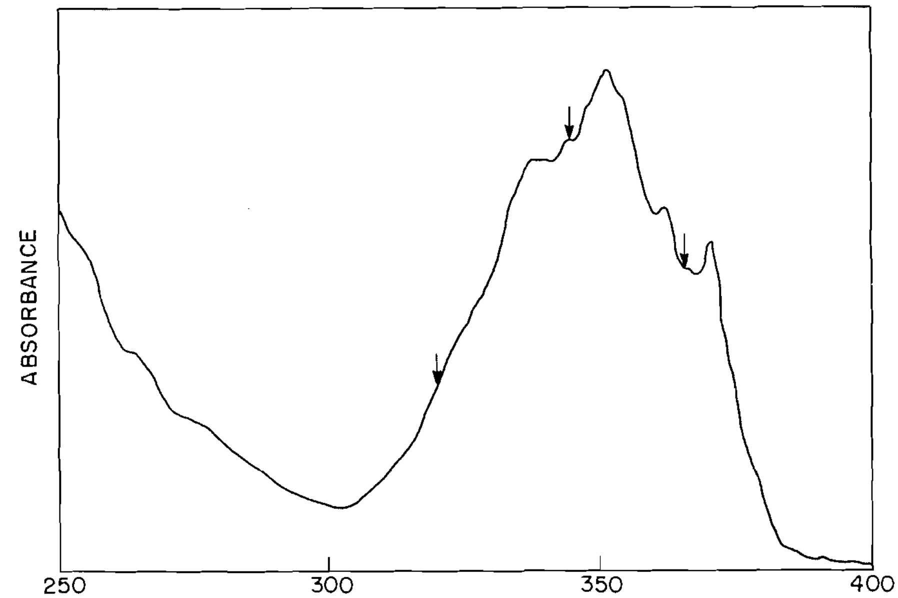

FIG. 1. Absorption spectrum of pyruvic acid vapour, measured in a 4-m tube at a pressure of 4.85 Torr at 85°C. Absorbance is in arbitrary units.

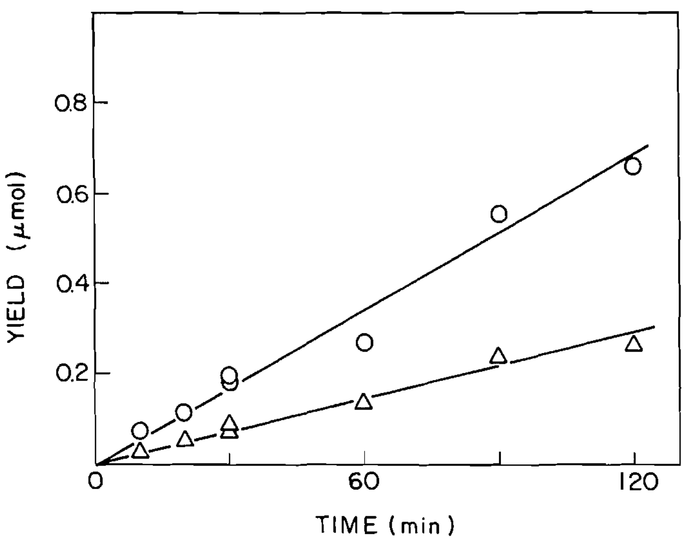

FIG. 2. Time dependence of photolysis products at 366 nm and pressure of 5 Torr. ○ = CO_2, △ = CH_3CHO.

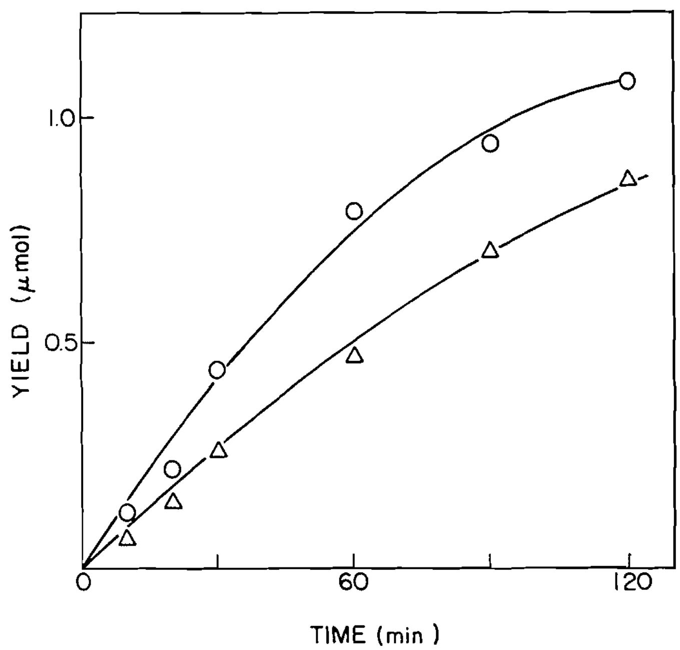

FIG. 3. Time dependence of photolysis products at 345 nm and pressure of 5 Torr. ○ = CO_2, △ = CH_3CHO.

Photolysis

At all wavelengths, the only products of the photolysis volatile at room temperature were CO_2 and CH_3CHO. These were measured by gas chromatography, and their time dependence is shown in Figs. 2–4. Both products were linear with time at 366 nm, but at the shorter wavelengths, yields of one or both products fell off with time; the cause of this behaviour is not clear. Yields of acetaldehyde were always much less than those of CO_2, 45% of the CO_2 at 366 nm, and varying between about 30 and 80%, and increasing with time, at 345 and 320 nm (Figs. 3, 4). Figure 5 shows the pressure dependence of product yields at 345 nm; similar linear dependence was found at the other two wavelengths, and as the light absorption was small, quantum yields must have been independent of pressure, at least up to about 10 Torr. The absolute quantum yield of CO_2 at 366 nm was measured using azomethane actinometry to be 0.9 ± 0.1; this may be compared with the value of 1.02 ± 0.06 reported by Vesley and Leermakers (3) at the same wavelength. Realistically, both these values are indistinguishable from unity within experimental uncertainty. Figure 6 shows the effect of air on the photolysis product ratio at 345 and 366 nm; CO_2 was unaffected, but CH_3CHO fell steadily to a constant value of about 10% of the CO_2 above 100 Torr.

Light emission

Light was emitted upon irradiation between 335 and 390 nm. An excitation spectrum is shown in Fig. 7, normalized to constant incident light intensity. Comparison with the absorption spectrum (also shown) makes it clear that the strongest emission came from the first vibrational band at 369.6 nm (probably

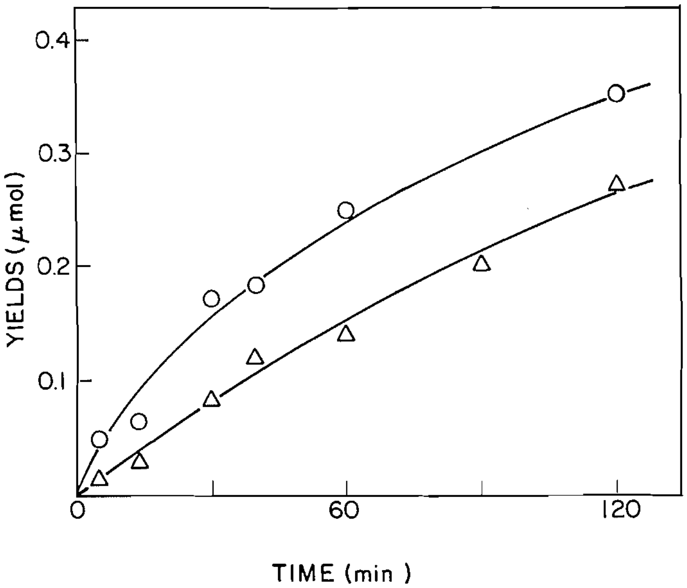

FIG. 4. Time dependence of photolysis products at 320 nm and pressure of 5 Torr. ○ = CO_2, △ = CH_3CHO.

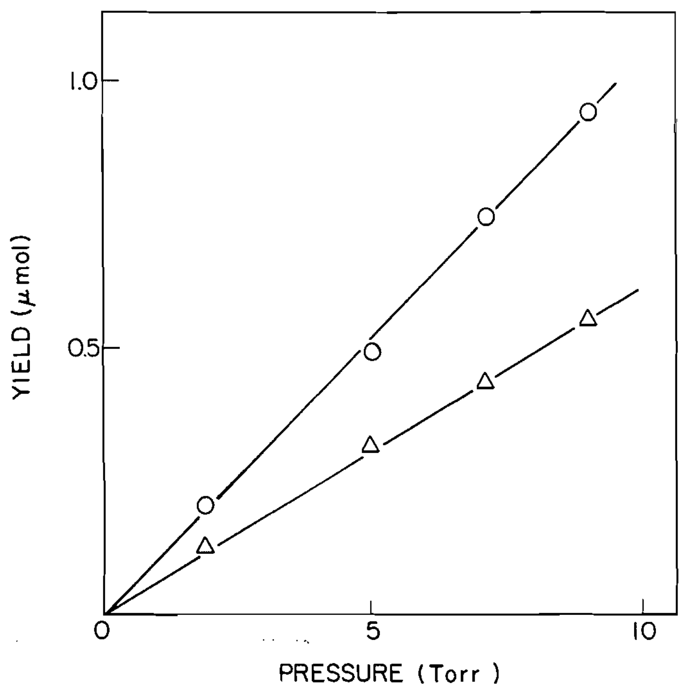

FIG. 5. Pressure dependence of photolysis products at 345 nm. ○ = CO_2, △ = CH_3CHO.

the (0,0) band) at the long-wavelength end of the spectrum. Emission on excitation at the maximum absorption around 350 nm was much less, probably reflecting more rapid loss of excited molecules by dissociation at the shorter wavelengths (*vide infra*). Figure 8 shows the effect of air on the emission excited at 366 and 350 nm. It appears that at both wavelengths the emission consisted of two components, one air-sensitive (presumably triplet emission) and one not affected (presumable singlet fluorescence). Figure 9 shows the effect of cyclohexane vapour on the emission intensity excited at 350, 366, and 380 nm.

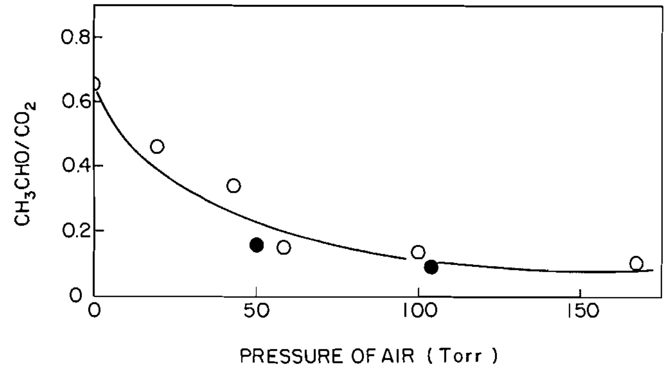

FIG. 6. Effect of air on photolysis product ratio at a pressure of 5 Torr of pyruvic acid. ○ = 345 nm, ● = 366 nm.

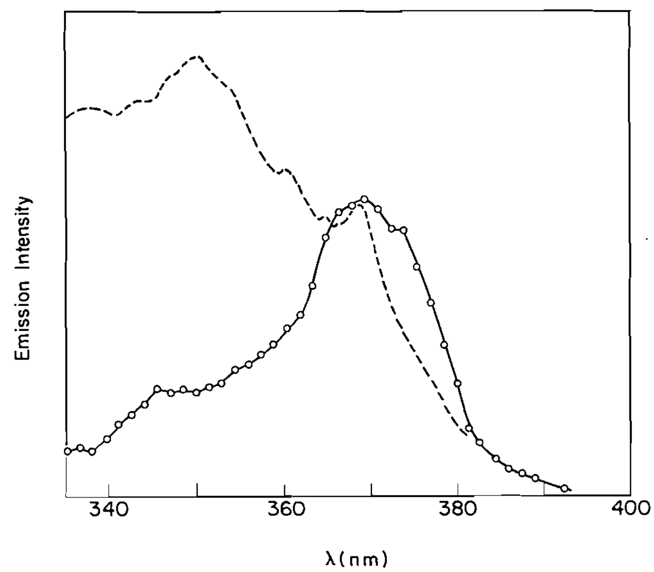

FIG. 7. Excitation spectrum of emission normalized to constant lamp intensity. Dashed curve is the absorption spectrum.

Thermal decomposition

The decomposition was studied at temperatures from 455 to 584 K and pressures between 0.8 and 7 Torr. Products again were CO_2 and CH_3CHO, and Fig. 10 shows that yields of both were linear with time. The positive intercept in the CO_2 plot is apparently due to CO_2 formed during the vaporization of the liquid pyruvic acid; when this was subtracted,[3] the ratio CH_3CHO/CO_2 was unity at 1 Torr but fell significantly with increasing pressure (Fig. 11). Figure 12 shows an Arrhenius plot of the first-order rate constant based on CO_2 formation, with the straight line corresponding to log A (s^{-1}) = 7.19 and E = 27.7 kcal/mol. Values of k showed no effect of pressure between 0.8 and 8 Torr, and no significant enhancement in the packed vessel, in which the surface/volume ratio was increased by a factor of 4.

Discussion

The mechanism of the photolysis

The simplicity of the volatile products, and the absence of products such as CH_4, C_2H_6, and CO, argue against a free-radical mechanism, although there is probably enough energy

[3]A similar correction was made in the photolysis experiments.

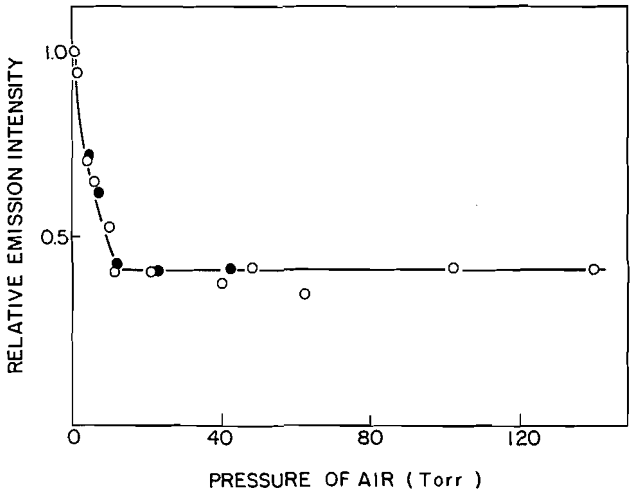

FIG. 8. Effect of air on light emission. ○ = 366 nm, ● = 350 nm.

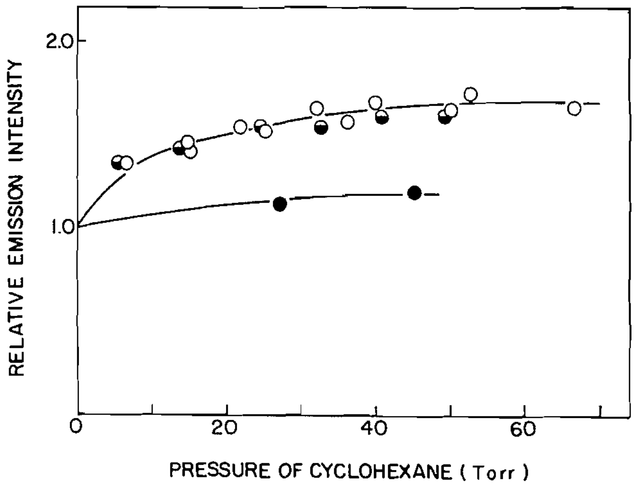

FIG. 9. Effect of cyclohexane on light emission ○ = 350, ◒ = 366 nm, ● = 380 nm.

even at 366 nm (78 kcal/mol) to break the CH_3—C bond. The deficit of CH_3CHO relative to CO_2 (Figs. 2–5), and the selective effect of air on the yield of CH_3CHO (Fig. 6) also rule out a simple molecular dissociation into CO_2 and CH_3CHO, while the emission of light indicates appreciable lifetimes for excited singlet and triplet states. The following mechanism is suggested:

[1] $PY + h\nu \rightarrow PY_s^*$

[2] $PY_s^* \rightarrow CO_2 + CH_3\text{—}\ddot{C}\text{—}OH$

[3] $\rightarrow PY + h\nu_f$

[4] $\rightarrow PY_t^*$

[5] $PY_t^* \rightarrow PY + h\nu_p$

[6] $PY_t^* + O_2 \rightarrow$ quenching

[7] $CH_3\text{—}\ddot{C}\text{—}OH \rightarrow CH_3CHO$

[8] $\rightarrow$ other products

[9] $O_2 + CH_3\text{—}\ddot{C}\text{—}OH \rightarrow$ other products

where PY, PY_s^*, and PY_t^* represent the ground state, the first excited singlet, and the first excited triplet states of pyruvic acid.

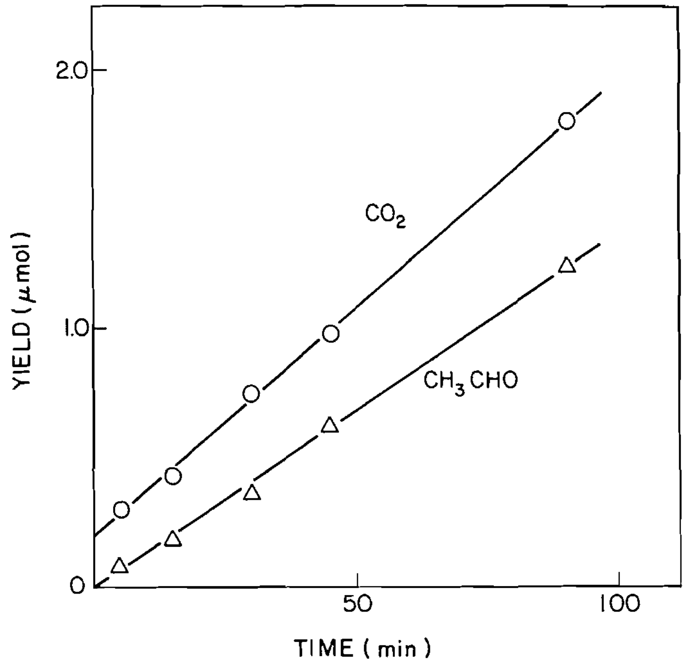

FIG. 10. Product yields vs. time in the thermal decomposition at 3.6 Torr and T = 522 K.

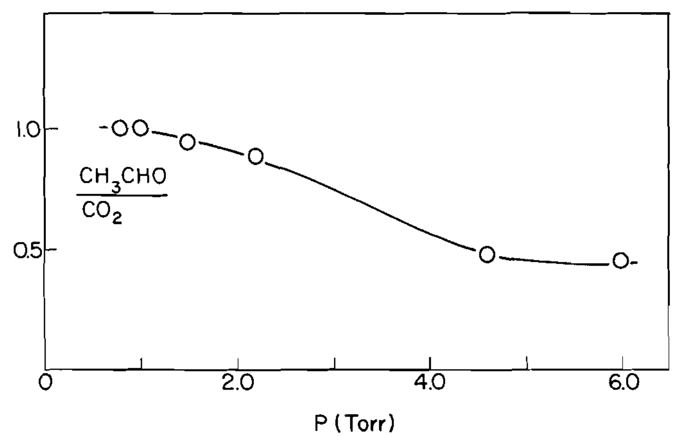

FIG. 11. Dependence of the product ratio on the pressure of pyruvic acid in the thermal decomposition at 540 K.

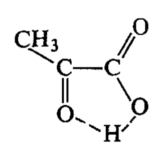
Direct dissociation of the excited singlet state (reaction [2]) following hydrogen-atom transfer through a five-membered transition state,



is suggested as the source of CO_2. The lack of effect of 160 Torr of air on the yield of CO_2 would appear to rule out both the triplet state and a vibrationally excited ground state as precursors. With the quantum yield of CO_2 close to unity, and the fluorescence and phosphorescence weak, reaction [2] appears to be the only important loss process for the initially-formed singlet state.

The effect of air on the light emission (Fig. 8) suggests that both fluorescence (unaffected by O_2) and phosphorescence

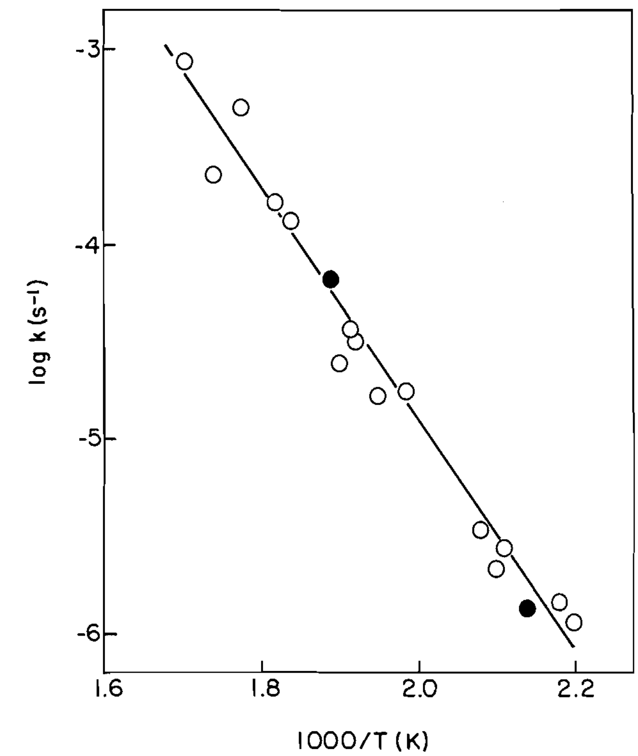


FIG. 12. Arrhenius plot of first-order rate constant for the thermal decomposition of pyruvic acid, based on the formation of CO_2. Filled circles are for packed vessel.

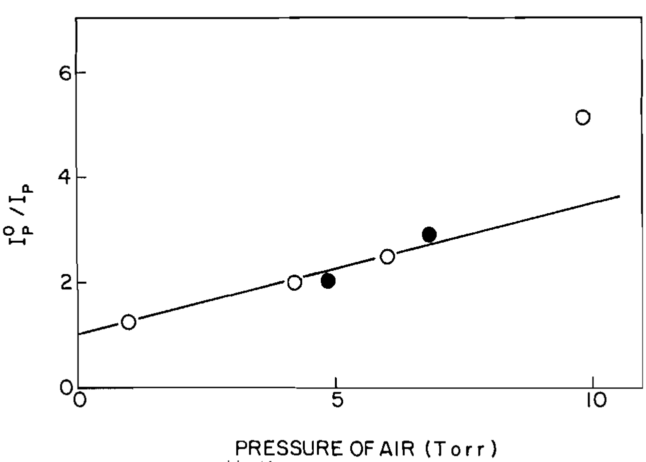

FIG. 13. Stern–Volmer plot for quenching of emission by air. ○ = 366 nm, ● = 350 nm.

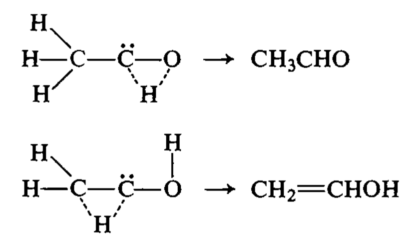
(quenched by O_2) were occurring. The constant emission intensity at pressures of air above 15 Torr shows that there was little collisional electronic deactivation of the excited singlet state in these experiments. In fact, the addition of cyclohexane *enhanced* the emission appreciably at 350 and 366 nm, and perhaps slightly at 380 nm (Fig. 9). The most probable explanation of this behaviour is vibrational deactivation of PY_s^*, which would decrease the rate of dissociation via reaction [2], and hence increase its lifetime and the probability of emission (reaction [3]). Similar anomalous pressure dependence of fluorescence in biacetyl has been explained in a similar way (5). The excitation spectrum (Fig. 7) supports this view, with the yield of emission falling markedly with increasing photon energy and consequent increased vibrational excitation of PY_s^*. The relative lack of effect of cyclohexane on excitation at 380 nm (Fig. 9) similarly reflects the lesser vibrational excitation at this wavelength, probably not far from the (0,0) band of the transition (Fig. 1). The data in Fig. 8 may also be somewhat affected by vibrational deexcitation superimposed on the effect of O_2 on the triplet emission, although the effect would be small since air should be much less efficient than cyclohexane for vibrational relaxation. The triplet quenching in Fig. 8 follows simple Stern–Volmer kinetics (Fig. 13), and from the slope a half-quenching pressure of 0.78 Torr was obtained for O_2, not untypical for triplet quenching.

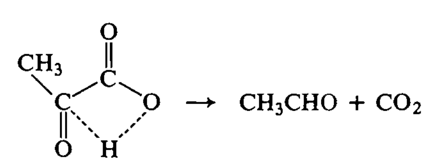
The fate of the $CH_3\ddot{C}$—OH carbene formed in reaction [2] requires some comment. Reaction [7], a simple rearrangement to CH_3CHO, is suggested as the source of this product, and because the latter was always less than the CO_2, reaction [8] is suggested. Because the CH_3CHO/CO_2 ratio was independent of the pressure of pyruvic acid (Fig. 5, text), loss of CH_3—$\ddot{C}$—OH by reaction with pyruvic acid is ruled out. One possibility for reaction [8] is the formation of vinyl alcohol, CH_2=CHOH, which would probably have been lost by polymerization before or during analysis (6). Although vinyl alcohol is about 20 kcal/mol less stable thermodynamically than CH_3CHO (6), formation of either compound from the carbene should be considerably exothermic; both would require hydrogen transfer through three-membered transition states which might be about equally probable:



Reaction [9] is suggested to explain the reduction in CH_3CHO on the addition of air (Fig. 6), although it is unusual for a carbene of this type to have a lifetime long enough to permit removal by chemical reaction with an additive.

The mechanism of the thermal decomposition

As with oxalic and glyoxylic acid, if the activation energy measured for the decomposition of pyruvic acid can be ascribed to a simple homogeneous unimolecular reaction, the energy is too low to permit access to the carbene postulated as an intermediate in the photolysis. The only alternative appears to be hydrogen transfer through a four-membered transition state, forming CH_3CHO directly:



Again, there was a deficit of CH_3CHO, although the product ratio now showed a pressure dependence and at low pressures approached unity (Fig. 11). The mechanism of loss of CH_3CHO is not clear. Simple secondary reactions can be ruled out as formation of both products was linear with time. The pressure dependence (Fig. 11) suggests a bimolecular reaction yielding CO_2 and higher products, not detected, although pro-

TABLE 1. The gas-phase thermal decomposition of α-carbonyl acids

Acid	Structure	Products	k_{450} (s^{-1})	log A (s^{-1})	E (kcal/mol)
Oxalic (7)		$HCOOH + CO_2$	1.9×10^{-3}	11.9	30
Glyoxylic (2)		$H_2CO + CO_2$	6.2×10^{-8}	7.8	30.8
Pyruvic		$CH_3CHO + CO_2$	4.9×10^{-7}	7.2	27.7

duction of CO_2 was always approximately first-order.

Table 1 summarizes the results of the three α-carbonyl acids that have been studied. The decompositions all appear to proceed by homogeneous unimolecular internal hydrogen-atom transfer through four-membered transition states, and have similar activation energies. Oxalic acid, however, is much less stable than the other two (note $k_{450\,K}$ values), with most of the difference arising from the frequency factors. Values of the latter for glyoxylic and pyruvic acid are much too low for a normal unimolecular reaction. Both decompositions *appear* to be simple, largely homogeneous, first-order reactions, and the cause of the low frequency factors is not clear; quantum mechanical tunnelling is perhaps one possibility. It is also not clear why oxalic acid should be so much less stable than the other two.

COMMUNICATION

Thermolysis of unsymmetrically substituted vinylcyclopropanes. Regarding the effect of oxygen substituents on the site-selectivity of homo-[1,5]-sigmatropic hydrogen migrations

EDWARD PIERS, ANDERSON RICHARD MAXWELL, AND NEIL MOSS
Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Y6

Received September 19, 1984

EDWARD PIERS, ANDERSON RICHARD MAXWELL, and NEIL MOSS. Can. J. Chem. **63**, 555 (1985).

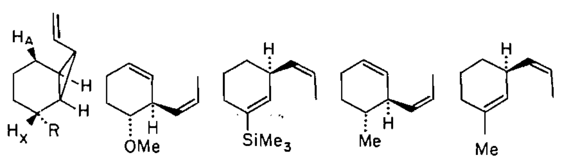
Thermal rearrangement of compounds **1**, **8–11**, and **20** results, in each case, in the exclusive migration of the hydrogen (H_A) not associated with the oxygen substituent. On the other hand, thermolysis of **19**, **22**, and **23** provides, in each case, a mixture of the two possible sigmatropic rearrangement products. Similar bond reorganization of the hydrocarbon **21** affords the dienes **27** and **28** (98:2, respectively). On the basis of these results, along with those reported earlier, it is proposed that in the transition states for these rearrangements (a) there is an accumulation of electron density at the carbon from which the hydrogen migrates, and (b) this carbon center has a planar or nearly planar geometry.

EDWARD PIERS, ANDERSON RICHARD MAXWELL et NEIL MOSS. Can. J. Chem. **63**, 555 (1985).

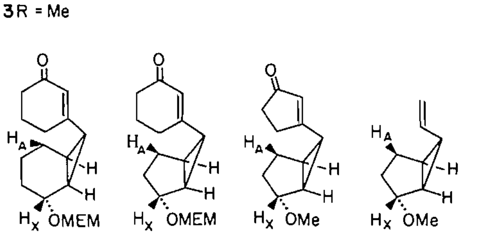
La transposition thermique des composés **1**, **8–11** et **20** conduit, dans chaque cas, à la migration exclusive de l'hydrogène (H_A) qui n'est pas associé avec le substituant de l'oxygène. Par ailleurs, la thermolyse des composés **19**, **22** et **23** conduit, dans chaque cas, à un mélange des deux produits possibles de transposition sigmatropique. Une répartition semblable des liaisons de l'hydrocarbure **21** conduit aux diènes **27** et **28** dans des proportions respectives de 98 et 2. En se basant sur ces résultats, ainsi que ceux rapportés antérieurement, on croit que dans les états de transition de ces transpositions: (a) il y a une accumulation de la densité électronique au niveau du carbone à partir duquel l'hydrogène migre et (b) que ce carbone possède une géométrie plane ou presque plane.

[Traduit par le journal]

In a previous communication (1), we reported that in the thermal rearrangement of a number of unsymmetrically substituted vinylcyclopropane systems, there is an impressive substituent effect on the site-selectivity of homo-[1,5]-sigmatropic hydrogen migrations. For example, while thermolysis of *trans*-2-methoxy-*endo*-7-vinylbicyclo[4.1.0]heptane (**1**) afforded exclusively the product **4** resulting from migration of H_A,[1] similar rearrangement of the trimethylsilyl-containing substrate **2** gave only substance **5** (H_X migration). On the other hand, a methyl substituent was shown to have only a small rate-retarding effect on hydrogen migration, since thermolysis of compound **3** provided products **6** (H_A shift) and **7** (H_X shift) in a ratio of 3:2, respectively. Furthermore, with respect to the effect of OR substituents on the site-selectivity of the process, it was found that thermolysis of the substrates **8–11** produced, in each case, only the product resulting from migration of H_A.



1 R = OMe 4 5 6 7
2 R = $SiMe_3$
3 R = Me



8 9 10 11
MEM = $CH_2OCH_2CH_2OMe$

In each of compounds **1** and **8–11**, the OR substituent is external to the ring from which the hydrogen H_X would have migrated. Although, in these substances, there is free rotation about the C—O bonds, the carbocycles are conformationally quite rigid. As an extension to this study, it was of interest to obtain information that would answer the following question. Would thermolysis of substrates in which the structural relationship between an oxygen substituent and the adjacent H_X is quite different from that in **1** and **8–11** produce products resulting from H_X migration? We report herein some results which relate to this question and which provide a clue regarding the geometry of the transition state for hydrogen migration.

Reduction (n-Bu_3SnH, neat, room temperature) of 7,7-dibromo-3-oxabicyclo[4.1.0]heptane (**12**)[2] (2) gave a mixture of the *endo* bromide **13** and the corresponding *exo* isomer (ratio 2.2:1, respectively), which were separated by chromatography (41% isolated yield of **13**). Conversion of the latter substance into the bicyclic vinylcyclopropane **19** (59% overall) was accomplished via a series of standard reactions: 2.4 equiv. t-BuLi, Et_2O, −78°C; dimethylformamide, −78°C → room temperature, 7.5 h; Ph_3P=CH_2, tetrahydrofuran. A similar sequence of reactions was employed to convert the dibromocyclopropane **14** (obtained by dibromocyclopropanation (3) of *cis*-2-oxabicyclo[3.3.0]oct-7-ene (4)) into the tricyclic alkene **20**.

[1] Throughout this communication, hydrogens migrating from carbons bearing no substituent and those migrating from carbons containing a substituent are designated H_A and H_X, respectively.

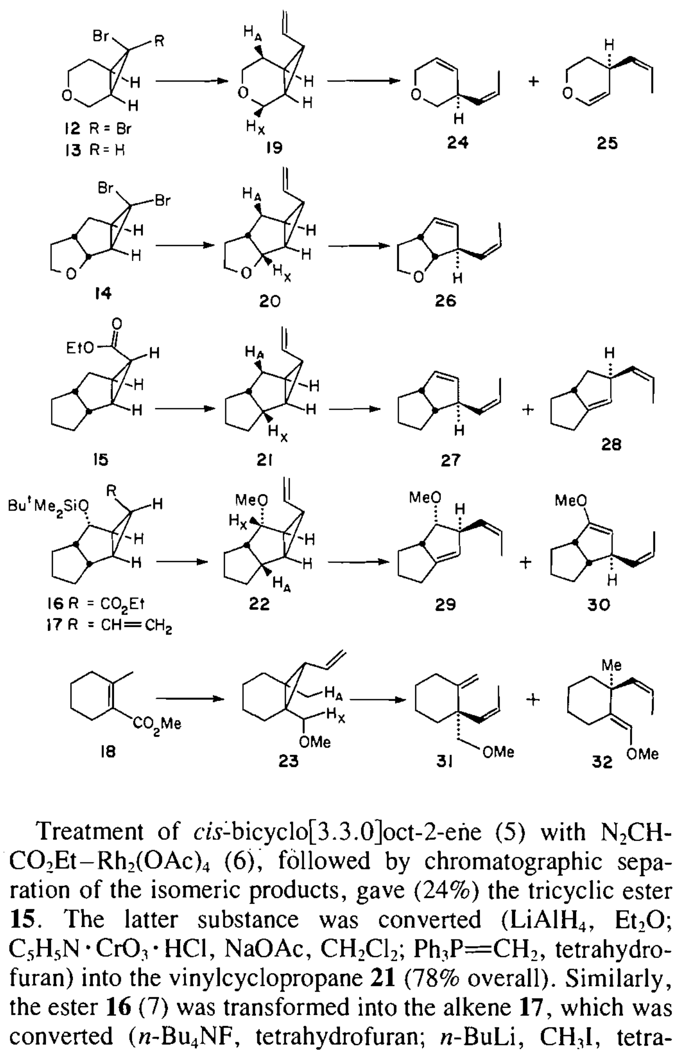
[2] All compounds reported herein gave spectral data consistent with assigned structures. New compounds provided satisfactory molecular mass determinations (high resolution mass spectrometry).

TABLE 1. Thermal rearrangement of vinylcyclopropanes **19–23**[a]

Experiment	Substrate	Product(s) (ratio)	Yield (%)[b]
1	**19**	**24** + **25** (66:34)	98
2	**20**	**26**	89
3	**21**	**27** + **28** (98:2)	96
4	**22**	**29** + **30** (15:85)	96
5	**23**	**31** + **32** (64:36)	94

[a]Thermolysis of each of the substrates was performed in benzene solution (230–240°C, 4.5–8 h) in sealed, base-washed silylated glass tubes. In each case, the cooled reaction mixture was analyzed directly by gas–liquid chromatography (glc). The benzene was removed, the product (s) was (were) distilled and subjected again to analysis (glc, ^{1}H nmr spectroscopy).

[b]Yield of isolated, distilled product(s).



Treatment of *cis*-bicyclo[3.3.0]oct-2-ene (5) with N_2CH-CO_2Et–$Rh_2(OAc)_4$ (6), followed by chromatographic separation of the isomeric products, gave (24%) the tricyclic ester **15**. The latter substance was converted ($LiAlH_4$, Et_2O; $C_5H_5N \cdot CrO_3 \cdot HCl$, NaOAc, CH_2Cl_2; $Ph_3P{=}CH_2$, tetrahydrofuran) into the vinylcyclopropane **21** (78% overall). Similarly, the ester **16** (7) was transformed into the alkene **17**, which was converted (n-Bu_4NF, tetrahydrofuran; n-BuLi, CH_3I, tetrahydrofuran) into the methyl ether **22** (61% from **16**).

Methyl 2-methylcyclohexene-1-carboxylate (**18**) (8) was transformed into the substrate **23** as follows: i-Bu_2AlH, Et_2O; NaH, CH_3I; N_2CHCO_2Et, copper bronze, heat; $LiAlH_4$, Et_2O; $C_5H_5N \cdot CrO_3 \cdot HCl$, NaOAc, CH_2Cl_2; $Ph_3P{=}CH_2$, tetrahydrofuran; separation of *endo* and *exo* vinyl isomers (ratio 1:2) by preparative thin-layer chromatography.

The results obtained from thermolysis of compounds **19–23** are summarized in Table 1. As was the case for the previously reported thermolyses (1), the reactions were very clean. In experiment 2, we were unable to detect any of the product which would have resulted from migration of H_X in substrate **20**. Each of the product pairs from experiments 1, 4, and 5 were separated and all six substances (**24**, **25**, **29–32**) were individually characterized. Although a pure sample of the minor product from experiment 3 was not obtained, a ^{1}H nmr study (including decoupling experiments) of a 2:1 mixture of **27** and **28**, obtained by partial chromatographic separation of the thermolysis products, showed clearly that the minor rearrangement product was the diene **28**.

In the thermolysis of substrates **1**, **8–11**, **19**, **20**, **22**, and **23**, only three (**19**, **22**, **23**) produced products resulting from migration of H_X. For two of these (**19**, **23**) the major product was that derived from a H_A shift. Indeed, of the number of oxygen-containing substrates that we have studied, the only one which exhibited predominant H_X migration was substance **22**. Interestingly, the structural relationship between H_X and the OMe substituent in the latter substrate is very similar to that in other compounds (e.g. **10**, **11**) which exhibited no H_X migration. Furthermore, since a previous result (1) (thermolysis of **3**) had shown that the effect of an alkyl group on site-selectivity is small, the result derived from rearrangement of **21** (Table 1, experiment 3) indicates that other molecular characteristics affect the magnitude of the site-selectivity. In any case, it is clear that (a) the site-selectivity of the sigmatropic rearrangement does vary with the structural relationship between an oxygen substituent and the adjacent H_X (compare, for example, substrates **1**, **19**, and **23**), and (b) other structural features are important as well (compare substrates **3**, **21**; **11**, **22**).

In the earlier communication (1), we had postulated tentatively that, in the transition states for these sigmatropic rearrangements, electron density accumulates at the carbon from which the hydrogen migrates.[3] Although the effect of an oxygen atom on the stability of an adjacent negative charge has been the subject of considerable recent discussion,[4] it appears that an OR group stabilizes the charge when the latter is associated with an sp^3 orbital (pyramidal geometry) and destabilizes the charge when it is associated with a p orbital (planar geometry) (9, 10). Thus, it is possible to suggest that not only do the transition states for these reactions have a "partial negative charge" on the carbon from which the hydrogen shift occurs, but that the carbon has an sp^2-like geometry (double bond character in the transition state). On this basis, the results derived from the thermolyses of substrates **20–23** are particularly interesting. In each case, the transition state for migration of the bridgehead hydrogen (H_X in **20** and **21**, H_A in **22**) would be (would have been) destabilized by the fact that a strained double bond (bridgehead in a bicyclo[3.3.0]octane system (11)) is being introduced into the molecule. In **20**, further transition state destabilization by the oxygen atom excludes H_X migration and, thus, **26** is the only product. In the absence of an oxygen atom (substrate **21**), a small amount of H_X migration does occur. Introduction of a methoxy group (substrate **22**)

[3] An alternative rationale, suggested by one of the referees, involves the postulate that in the transition states for these rearrangements there is a build-up of *positive* charge at the carbon center where fragmentation of the cyclopropane ring takes place, i.e. at the cyclopropyl carbon adjacent to the H_A- or H_X-bearing carbons in substrates **1–3**, **8–11**, and **19–23**. This electron-deficient center would be stabilized by a β-trimethylsilyl group (substrate **2**) and destabilized (via an inductive effect) by oxygen-containing substituents.

[4] See citations in ref. 1. For a very recent pertinent report, see ref. 9.

would be expected to disfavor H_X migration and thus increase (relatively) the amount of bridgehead alkene **29**. This expectation was observed, although the extent of the increase (2% **28** to 15% **29**) was quite small.

Synthesis of heterocyclic 1,4-dihydropyridylacetic acid derivatives of 6-aminopenicillanic acid and D-α-aminobenzylpenicillin with antibacterial activity

SUSHIL K. DUBEY AND EDWARD E. KNAUS[1]

Faculty of Pharmacy and Pharmaceutical Sciences, University of Alberta, Edmonton, Alta., Canada T6G 2N8

Received April 2, 1984

SUSHIL K. DUBEY and EDWARD E. KNAUS. Can. J. Chem. **62**, 559 (1984).

Condensation of 4-substituted 3-(4,4-dimethyloxazolin-2-yl)-1,4-dihydropyridylacetic acids **3** with the C-2 *p*-bromophenacyl esters of 6-aminopenicillanic acid salt **4** and D-α-aminobenzylpenicillin **8** afforded the respective 1,4-dihydropyridylacetic acid analogs **6** and **10** which exhibited moderate antibacterial activity toward Gram-positive strains. The 6-APA derivatives **6** exhibited dual ^{1}H nmr resonances for H2′, H2, H5, and one of the C3-Me groups, suggesting the presence of two rotamers which differ in configuration at the carbonyl-to-nitrogen bond. The D-aminobenzylpenicillin derivatives **9** may exist in more than one conformation, one of which may be an intramolecular hydrogen bonded species such as **11**.

SUSHIL K. DUBEY et EDWARD E. KNAUS. Can. J. Chem. **62**, 559 (1984).

La condensation d'acides X-4 (diméthyl-4,4 oxazolinyl-2)-3 dihydro-1,4 pyridylacétiques (**3**) avec les esters *p*-bromophénacyles en C-2 du sel de l'acide amino-6 pénicillanique **4** et de la D-α-aminobenzylpénicilline **8** fournissent respectivement les analogues **6** et **10** de l'acide dihydro-1,4 pyridylacétique qui présentent une activité antibactérienne modérée contre les souches Gram-positives. Les spectres rmn ^{1}H des dérivés **6** de l'acide amino-6 pénicillanique présentent des résonances doubles pour H2′, H2, H5 et pour l'un des groupes C3-Me et ces résultats suggèrent la présence de deux rotamères qui diffèrent de configuration au niveau de la liaison carbonyl−azote. Les dérivés **9** de la D-α-aminobenzylpénicilline peuvent exister sous plus d'une conformation et l'une d'elle pourrait être une espèce comportant une liaison hydrogène intramoléculaire, comme dans **11**.

[Traduit par le journal]

The β-lactam antibiotics are the most widely used class of antimicrobial agents. However, the bacterial development of β-lactamase enzymes which decrease the effectiveness of β-lactam antibiotics has prompted a continued search for structurally modified antibiotics (1). A variety of 2- and 4-pyridone derivatives have been used for the preparation of some penicillin and cephalosporin analogs (2, 3). It was therefore of interest to investigate the utility of stabilized 1,4-dihydropyridines (4) as medicinal synthons (5). The 3-(4,4-dimethyloxazolin-2-yl) substituent of **3** could serve the dual role of stabilizing the 1,4-dihydropyridine ring system and provide increased penicillinase resistance due to electronic and steric effects, respectively. We now describe the synthesis and antibacterial activity of some novel 1,4-dihydropyridyl derivatives of 6-aminopenicillanic acid (6-APA) and D-α-aminobenzylpenicillin (Ampicillin).

The reaction of 3-(4,4-dimethyloxazolin-2-yl)pyridine (**1**) with organolithium reagents in tetrahydrofuran at −78°C afforded the *N*-lithio-1,4-dihydropyridyl intermediates **2***a*−*c* (4*b*, 5). The *in situ* reaction of **2***a*−*c* with lithium bromoacetate gave the required 4-substituted 1,4-dihydropyridyl acetic acids **3***a*−*c* in 65−80% yield (Scheme 1). Condensation of **3***a*−*c* with the *p*-bromophenacyl penicillate benzenesulfonic acid salt **4** (6) under a variety of reaction conditions (*N*,*N*′-dicyclohexylcarbodiimide (DCC), $MeOCOCl/Et_3N$) yielded **5***a*−*c*. However, the products **5***a*−*c* were obtained in optimum yield (69−72%) and highest purity when trimethylacetyl chloride (Me_3COCl/Et_3N) was employed as the condensation reagent. Reaction of **5***a*−*c* with potassium thiophenoxide afforded the desired 1,4-dihydropyridyl acetic acid derivatives **6***a*−*c* in 51−57% yield (Scheme 2).

In a similar sequence of reactions, treatment of D-α-aminobenzylpenicillin (**7**) with α,*p*-dibromoacetophenone afforded **8**, which was used immediately in subsequent reactions since it was unstable upon storage. Condensation of **8** with the 1,4-dihydropyridyl acetic acids **3***a*−*c* in the presence of DCC yielded **9***a*−*c* in 60−80% yield. Reaction of **9***a*−*c* with potassium thiophenoxide afforded the target compounds **10***a*−*c* in 45−68% yield, as illustrated in Scheme 3. The use of DCC for the conversion of **8** to **9** in the D-α-aminobenzylpenicillin series provided higher yields than trimethylacetyl chloride or methoxycarbonyl chloride − triethylamine reagents.

The ^{1}H nmr spectra of **6***a*−*c* and **9***a*−*c* displayed some interesting conformational characteristics which are worthy of

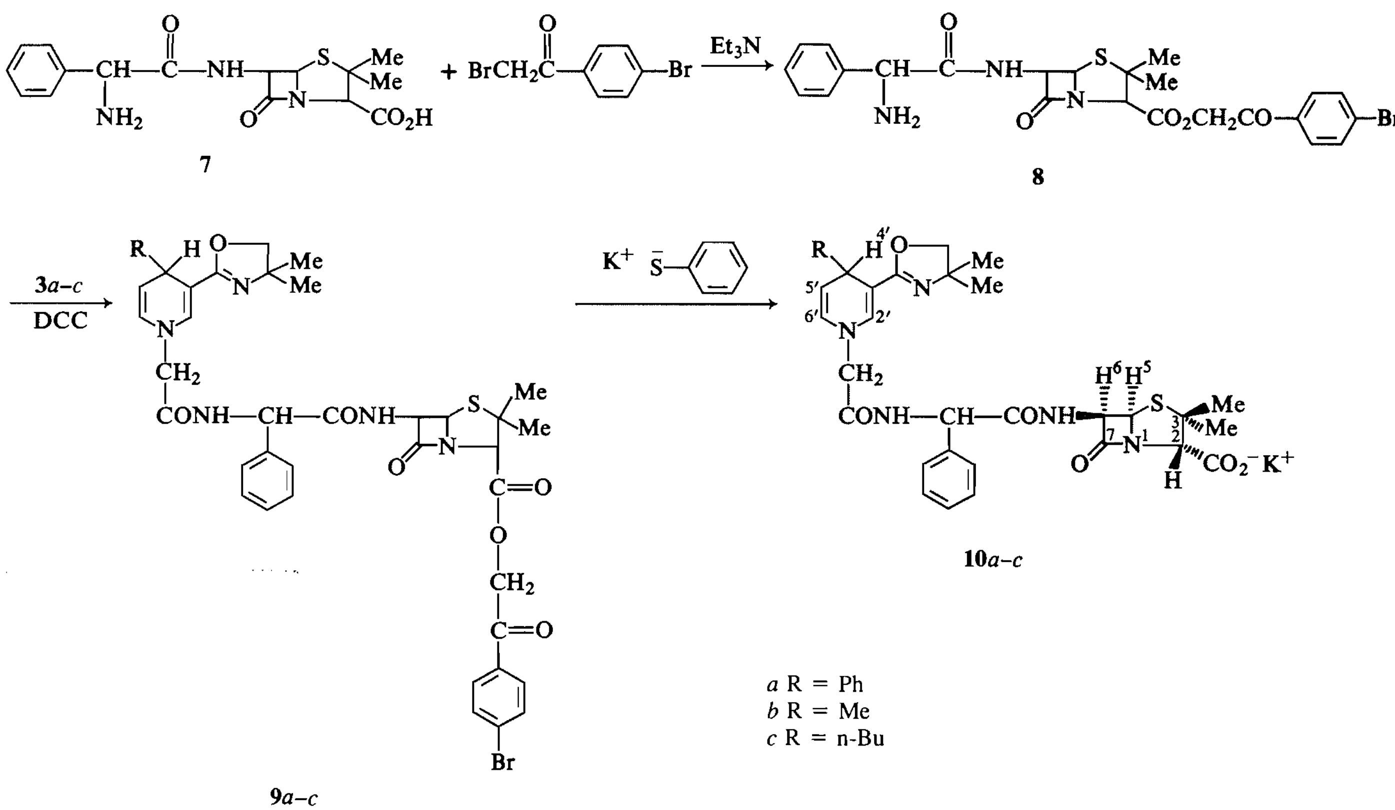
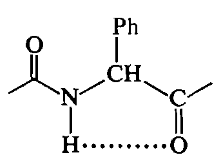


SCHEME 3

discussion. The assignments were confirmed by extensive double irradiation experiments. The ^{1}H nmr spectrum of **6***c* exhibited the following spectral data (D_2O), δ: 6.88 and 6.92 (two doublets, $J_{2',6'}$ = 1.15 Hz, 1H, H2′), 6.0 (d, $J_{5',6'}$ = 8 Hz of d, $J_{2',6'}$ = 1.15 Hz, 1H, H6′), 5.62 (d, $J_{5,6}$ = 4 Hz, 1H, H6), 5.54 and 5.56 (two overlapping doublets, $J_{5,6}$ = 4 Hz, 1H, H5), 4.88 (d, $J_{5',6'}$ = 8 Hz of d, $J_{4',5'}$ = 5 Hz, 1H, H5′), 4.26 and 4.28 (two s, 1H, H2), 1.63 and 1.66 (two s, 3H, C3-βMe), and 1.57 (s, 3H, C3-αMe). The ^{1}H nmr spectra of the structurally related **6***a*–*b* also exhibited dual absorptions for H2′, H2, H5, and the C-3 β-methyl substituent. In contrast, the ^{1}H nmr spectrum (D_2O) of potassium benzylpenicillin exhibited single resonances for H2, H5, and each of the C3-Me substituents. The possibility that epimerization at the C-6 position of the penicillin moiety occurred during the reaction has been excluded since epimerization would provide for two sets of doublets for the C5-H and C6-H, having different coupling constants due to different dihedral angles between H5 and H6 in the two epimers. The possibility that long range coupling between H2 and H5 was present was excluded since irradiation of the H2 resonances at δ 4.26 and 4.28 did not influence the resonances for the H5 proton at δ 5.54 and 5.56. A similar irradiation at δ 5.54 had no effect on the resonances at δ 4.26 and 4.28. Therefore, the existence of two conformers is most likely due to restricted rotation about the carbonyl-to-amide bond, in which the two rotamers are somehow stabilized by the dihydropyridyl moiety. The dual absorptions observed for H2′, H2, H5, and the C-3 β-methyl substituent indicate that these atoms are located in significantly different molecular environments in the two rotamers. The observation that the NH proton of **5***a* appears as two overlapping doublets ($J_{NH,C6\text{-}H}$ = 6 Hz) at δ 8.86 and 8.88 when the ^{1}H nmr spectrum was determined in DMSO-d_6 also supports the presence of two rotamers.

The ^{1}H nmr spectra of the D-α-aminobenzylpenicillin derivatives **9***a*–*c* were more complex than those of **6***a*–*c* since there are two amide groups. The conformational effects for **9***a*–*c* were more evident for the dihydropyridyl moiety than for the penicillin moiety since H2, H5, and the C3-Me_2 substituents appear as single resonances. The ^{1}H nmr spectra were different in deuteriochloroform and dimethylsulfoxide-d_6 since the latter solvent disrupts hydrogen bonding. The ^{1}H nmr spectrum of **9***a* ($CDCl_3$) exhibited dual resonances for H2′ at δ 6.88 and 7.0 and for H6′ at δ 5.91 and 5.96. Decoupling experiments indicated that the absorption for H2′ of one conformer at 7.0 is related to the absorption at δ 5.91, while the resonance for H2′ of the other conformer at 6.88 is coupled to the H6′ proton at δ 5.96. On the other hand, the dual absorptions observed for H2′ and H6′ in $CDCl_3$ appear as singlets in DMSO-d_6 at δ 6.92 and 6.04. This observation suggests that one of the preferred conformations in $CDCl_3$ has a strong hydrogen bond, as illustrated by **11**, in which case the H2′ and H6′ would be located



11

in either a deshielding or shielding zone of the —CH_2CO— or phenyl ring attached to the —CH— moiety of **11**, resulting in dual absorptions. Further double irradiation studies for **9***a*–*c* indicated that there are at least two stable conformations present. For example, in DMSO-d_6 the —C*H*-Ph resonance of **9***a* appears at δ 5.76 as two closely overlapped doublets while the NH moiety attached to it appears at δ 8.74 and 8.76 as two partially overlapped doublets. Irradiation of the C*H*-Ph resonances at 5.76 resulted in the appearance of two single peaks at δ 8.74 and 8.76, which suggests that these two peaks for the CH_2CONH moiety are due to two different conformers. The fact that the C6—N*H*CO moiety also appears as two overlapping doublets ($J_{NH,6}$ = 7.5 Hz each) further supports the presence of two different stable conformations for compounds **9**.

A variable temperature ^{1}H nmr study for **9***a* in DMSO-d_6 was performed to determine if the dual absorptions observed for *CH*Ph, *NH*CHPh, and CO*NH*—C6 were due to rotamers as described or to a mixture of two diastereomers. When a sample of **9***a* in DMSO-d_6 was heated to +100°C, the two sets of doublets assigned to CO*NH*—C6 coalesced to one doublet whereas the two sets of doublets due to *CH*-Ph partially coalesced and the resonances for *NH*CHPh became more broad. At +120°C complete coalescence of the two sets of doublets for *CH*Ph occurred to give one doublet at δ 5.76. This study shows that the dual resonances observed for **9** are not due to the presence of two diastereomers but to the presence of conformational isomers as described. The derivatives of 6-aminopenicillanic acid **6** do not have an asymmetric carbon in the C-6 side chain. There is, however, a chiral center at the C-4′ position of the 1,4-dihydropyridyl ring. It is difficult to visualize how this remote chiral center could cause H-2, H-5, and one of the C-3 methyl groups to appear as dual resonances. The dual resonances observed for H-2′ of **6** are most likely due to the effect of rotamers rather than a mixture of diastereomers since H-2 of **3** appear as single resonances. The low solubility of **6***c* in DMSO-d_6 and the low boiling point of deuterium oxide precluded a ^{1}H nmr variable temperature study to determine the coalescence temperature. However, it is not known if these different conformations influence the antibacterial activity of these compounds.

The antibacterial activity of some selected compounds has been investigated (Table 1). All of the compounds tested showed reasonable activity against Gram-positive strains (Organisms 1–5) with the exception of a β-lactamase producing strain of *Staphylococcus aureus* (Organism 6). In contrast, their antibacterial activity toward Gram-negative strains (Organisms 7–9) was poor. The best overall spectrum of activity was shown by the D-α-aminobenzyl analog **10***c*, although it was not better than D-α-aminobenzylpenicillin (Ampicillin®).

Experimental

Infrared spectra (potassium bromide unless otherwise noted) were taken on a Unicam SP 1000 or Perkin–Elmer 267 spectrometer. Nuclear magnetic resonance spectra were determined with a Bruker WH-200, AM-300, or Varian EM-360A spectrometer. The purity of the bio-assay samples was determined to be greater than 95% by the absence of extraneous peaks in the ^{1}H nmr spectra. Mass spectra were measured on a AEI-MS 50 mass spectrometer. The antibacterial screen was performed by Bristol–Myers, Syracuse, New York.

1-[4-n-Butyl-3-(4,4-dimethyloxazolin-2-yl)-1,4-dihydropyridyl]acetic acid (3c)

A solution of n-butyllithium (1.28 g, 0.02 mol) in 5 mL dry tetrahydrofuran was added dropwise to a solution of **1** (4*a*) (3.52 g, 0.02 mol) in 50 mL dry tetrahydrofuran at −78°C with stirring under an atmosphere of nitrogen. The reaction mixture was stirred at −78°C for 30 min and then lithium bromoacetate (2.9 g, 0.02 mol) was added. The reaction mixture was allowed to warm to 25°C and stirring was continued for 12 h. The reaction mixture was cooled to 0°C, water (10 mL) was added, and the pH was adjusted to 4 using 5% aqueous hydrochloric acid. Extraction with chloroform–methanol (9:1 v/v; 10 × 20 mL), washing the combined organic extracts with 10 mL water, drying (Na_2SO_4), and removal of the solvent *in vacuo* afforded **3***c* as a foam. Repeated washing with ether gave pure **3***c* (4.6 g, 78.7%); ir: 1740 (CO); nmr ($CDCl_3$) δ: 12.1 (br, s, 1H, COO*H*, exchanges with deuterium oxide), 7.9 (s, 1H, H2), 5.94 (d, $J_{5,6}$ = 8 Hz, 1H, H6), 5.06 (d, $J_{5,6}$ = 8 Hz of d, $J_{4,5}$ = 5 Hz, 1H, H5), 4.34 (s, 2H, NCH_2—), 4.02 (s, 2H, OCH_2), 3.34–3.64 (m, 1H, H4), 1.06–1.7 (m, 12H, C—$(CH_3)_2$, —$(CH_2)_3CH_3$), 0.86 (t, J = 7 Hz, —$(CH_2)_3$—CH_3). *Exact Mass* calcd. for $C_{16}H_{24}N_2O_3$: 292.1787; found (high resolution ms): 292.1783.

Compounds **3***a* and **3***b* were prepared using a similar procedure.

1-[4-Phenyl-3-(4,4-dimethyloxazolin-2-yl)-1,4-dihydropyridyl]acetic acid (3a)

Yield 80%; ir: 1737(CO); nmr ($CDCl_3$) δ: 8.75 (br s, 1H, COO*H*, exchanges with deterium oxide), 8.3 (s, 1H, H2), 7.24 (m, 5H, Ph), 5.96 (d, $J_{5,6}$ = 8 Hz, 1H, H6), 5.15 (d, $J_{5,6}$ = 8 Hz of d, $J_{4,5}$ = 4.5 Hz, 1H, H5), 4.55 (d, $J_{4,5}$ = 4.5 Hz, 1H, H4), 4.3 (br s, 4H, NCH_2, OCH_2), 1.45 (s, 6H, C—$(CH_3)_2$). *Exact Mass* calcd. for $C_{18}H_{20}N_2O_3$: 312.1474; found (high resolution ms): 312.1472.

1-[4-Methyl-3-(4,4-dimethyloxazolin-2-yl)-1,4-dihydropyridyl]acetic acid (3b)

Yield 65%; ir: 1740(CO); nmr ($CDCl_3$ and DMSO-d_6) δ: 10.8 (br s, 1H, COO*H*, exchanges with deuterium oxide), 8.0 (s, 1H, H2), 5.9 (d, $J_{5,6}$ = 8 Hz, 1H, H6), 5.18 (d, $J_{5,6}$ = 8 Hz of d, $J_{4,5}$ = 5 Hz, 1H, H5), 4.46 (s, 2H, NCH_2), 4.2 (s, 2H, OCH_2), 3.5 (m, 1H, H4), 1.6 (s, 6H, C—$(CH_3)_2$), 1.18 (d, *J* = 7 Hz, 3H, CH—CH_3). *Exact Mass* calcd. for $C_{13}H_{18}N_2O_3$: 250.1317; found: (high resolution ms): 250.1308.

p-*Bromophenacyl-6-β-[{4-phenyl-3-(4,4-dimethyloxazolin-2-yl)-1,4-dihydropyridylacetyl}amino]-3,3-dimethyl-7-oxo-4-thia-1-azabicyclo[3.2.0]heptane-2-carboxylate (5a)*

A solution of trimethylacetyl chloride (0.96 mL, 8 mmol) in dry tetrahydrofuran (10 mL) was added dropwise to a solution of **3***a* (2.8 g, 9 mmol) and triethylamine (2.88 mL, 20 mmol) in 150 mL dry tetrahydrofuran at −78°C with stirring. The reaction was allowed to proceed at −78°C for 30 min and then **4** (6) (2.28 g, 4 mmol) was added. The reaction was allowed to proceed at 0°C for 8 h with stirring and water (20 mL) was added. The reaction mixture was extracted with ethyl acetate (5 × 20 mL) and the combined extracts were washed successively with a saturated aqueous sodium bicarbonate solution, a solution of 4% aqueous hydrochloric acid, and water. The organic layer was dried (Na_2SO_4) and the solvent removed *in vacuo* to yield impure **5***a*. This product was then triturated with hexane and washed repeatedly with ether to give **5***a* as a foam (3.5 g, 70%); ir: 3300–3400 (NH), 1785 (β-lactam CO), 1755 (CO_2), 1705 (CH_2CO), 1675 (CONH); nmr (DMSO-d_6) δ: 8.86 and 8.88 (two overlapping d, J_{NH,C_6H} = 6 Hz, 1H, NH, exchanges with deuterium oxide), 7.8 and 7.9 (d, *J* = 8 Hz, 2H each, —C_6H_4-Br), 7.08–7.42 (m, 5H, Ph), 6.92 (s, 1H, H2′), 6.0–6.1 (d, $J_{5',6'}$ = 8 Hz, 1H, H6′), 5.4–5.8 (m, 4H, H5, H6, OCH_2CO), 4.74 (d, $J_{5',6'}$ = 7.6 Hz of d, $J_{4',5'}$ = 4.6 Hz, 1H, H5′), 4.52 (s, 1H, H2), 4.4 (d, $J_{4',5'}$ = 4.6 Hz, 1H, H4′), 4.06 (s, 2H, NCH_2CO), 3.75 (s, 2H, O$CH_2$$CMe_2$), 1.66 and 1.70 (two s, 3H, C3-Me), 1.6 (s, 3H, C3-Me), 1.12 and 1.14 (two s, 3H each, OCH_2C*Me*$_2$). Mass, FAB (positive), $(M + 1)^+$: 707 and 709, $(M + 2H)^+$: 708 and 710.

Compounds **5***b* and **5***c* were prepared using a similar procedure.

p-*Bromophenacyl-6-β-[{4-methyl-3-(4,4,-dimethyloxazolin-2-yl)-1,4-dihydropyridylacetyl}amino]-3,3-dimethyl-7-oxo-4-thia-1-azabicyclo[3.2.0]heptane-2-carboxylate (5b)*

Yield 69%; ir: 3300–3400 (NH), 1780 (β-lactam CO), 1760 (CO_2), 1705 ($CH_2COC_6H_4Br$), 1675 (NHCO); nmr (DMSO-d_6) δ: 8.76 and 8.78 (overlapping d, J_{NH,C_6H} = 6 Hz, 1H, NH, exchanges with deuterium oxide), 7.8 and 7.9 (d, *J* = 8 Hz, 2H each, —C_6H_4-Br), 6.7 (s, 1H, H2′), 5.85 (d, $J_{5',6'}$ = 8 Hz, 1H, H6′), 5.42–5.8 (m, 4H, H5, H6, OCH_2CO), 4.6 (d, $J_{5',6'}$ = 8 Hz of d, $J_{4',5'}$ = 5 Hz, 1H, H5′), 4.38 (s, 1H, H2), 3.84 and 3.96 (two s, 2H each, NCH_2CO and O$CH_2$$CMe_2$), 3.2–3.34 (m, 1H, H4′), 1.64 and 1.67 (two s, 3H, C3-Me), 1.58 (s, 3H, C3-Me), 1.02–1.22 (m, 9H, OCH_2C*Me*$_2$, C4′-Me). Mass, FAB (positive), $(M + 1)^+$: 645 and 647, $(M + 2H)^+$: 646 and 648.

p-*Bromophenacyl-6-β-[{4-n-butyl-3-(4,4-dimethyloxazolin-2-yl)-1,4-dihydropyridylacetyl}amino]-3,3-dimethyl-7-oxo-4-thia-1-azabicyclo[3.2.0]heptane-2-carboxylate (5c)*

Yield 72%; ir: 3360 (NH), 1790 (β-lactam CO), 1760 (CO_2), 1710 ($CH_2COC_6H_4Br$), 1680 (CONH); nmr (DMSO-d_6) δ: 8.64 and 8.67 (overlapping d, J_{NH,C_6H} = 6 Hz, 1H, NH, exchanges with deuterium oxide), 7.8 and 7.9 (d, *J* = 8 Hz, 2H each, C_6H_4-Br), 6.74 (s, 1H, H2′), 5.9 (d, $J_{5',6'}$ = 8 Hz, 1H, H6′), 5.42–5.72 (m, 4H, H5, H6, OCH_2CO), 4.52–4.64 (m, 1H, H5′), 4.5 (s, 1H, H2), 3.92 (br s, 4H, NCH_2CO, O$CH_2$$CMe_2$), 3.74–3.86 (m, 1H, H4′), 1.58 (s, 3H, C3-Me), 1.65 and 1.68 (two s, 3H, C3-Me), 1.1–1.4 (m, 12H, OCH_2C*Me*$_2$, —$(CH_2)_3$Me), 0.82 (t, *J* = 7 Hz, 3H, $(CH_2)_3$—CH_3).

Mass, FAB (positive), $(M + 1)^+$: 687 and 689, $(M + 2H)^+$: 688 and 690.

6-β-[{4-n-Butyl-3-(4,4-dimethyloxazolin-2-yl)-1,4-dihydropyridylacetyl}amino]-3,3-dimethyl-7-oxo-4-thia-1-azabicyclo[3.2.0]-heptane-2-carboxylic acid potassium salt (6c)

A mixture of **5c** (0.755 g, 1.1 mmol) and potassium thiophenoxide (0.148 g, 1 mmol) in 5 mL dry DMF was stirred at 0°C for 1 h. Ether (25 mL) was added and the solid which precipitated was filtered. The residue was washed repeatedly with dry ether and acetone to yield **6c** (0.3 g, 56.8%); ir: 3400 (NH), 1780 (β-lactam CO), 1685 (CONH), 1610−1635 (CO_2); nmr (D_2O) δ: 6.88 and 6.92 (two d, $J_{2',6'}$ = 1.15 Hz, 1H, H2′), 6.0 (d, $J_{5',6'}$ = 8 Hz of d, $J_{2',6'}$ = 1.15 Hz, 1H, H6′), 5.62 (d, $J_{5,6}$ = 4 Hz, 1H, H6), 5.54 and 5.56 (overlapping d, $J_{5,6}$ = 4 Hz, 1H, H5), 4.88 (d, $J_{5',6'}$ = 8 Hz of d, $J_{4',5'}$ = 5 Hz, 1H, H5′), 4.26 and 4.28 (two s, 1H, H2), 4.05 (br s, 4H, OCH_2, NCH_2), 3.3−3.44 (m, 1H, H4′), 1.63 and 1.66 (two s, 3H, C3-Me), 1.57 (s, 3H, C3-Me), 1.1−1.4 (m, 12H, CH_2CMe_2, —$(CH_2)_3$—CH_3), 0.86 (t, J = 7 Hz, 3H, —$(CH_2)_3$—CH_3). Mass, FAB (negative), $(M - 1)^+$: 527.

Compounds **6a** and **6b** were prepared from **5a** and **5b** respectively using a similar procedure.

6-β-[{4-Phenyl-3-(4,4-dimethyloxazolin-2-yl)-1,4-dihydropyridylacetyl}amino]-3,3-dimethyl-7-oxo-4-thia-1-azabicyclo[3.2.0]-heptane-2-carboxylic acid potassium salt (6)

Yield 54%; ir: 3380−3440 (NH), 1765 (β-lactam CO), 1685 (CONH), 1610 (CO_2); nmr (D_2O) δ: 7.32−7.42 (m, 5H, Ph), 7.12 and 7.14 (overlapping d, $J_{2',6'}$ = 1.15 Hz, 1H, H2′), 6.0 (d, $J_{5',6'}$ = 8 Hz, 1H, H6′), 5.6 (d, $J_{5,6}$ = 4 Hz, 1H, H6), 5.48 and 5.52 (two d, $J_{5,6}$ = 4 Hz, 1H, H5), 5.03 (d, $J_{5',6'}$ = 8 Hz of d, $J_{4',5'}$ = 5 Hz, 1H, H5′), 4.5 and 4.52 (two overlapping d, $J_{4',5'}$ = 5 Hz, 1H, H4′), 4.24 and 4.26 (two s, 1H, H2), 4.1 (s, 2H, NCH_2CO), 3.9 (s, 2H, OCH_2), 1.56 and 1.59 (two s, 3H, C3-Me), 1.48 (s, 3H, C3-Me), 1.18 (s, 3H, OCH_2CMe), 1.0 (s, 3H, OCH_2CMe). Mass, FAB (negative), $(M - 1)^+$: 547.

6-β-[{4-Methyl-3-(4,4-dimethyloxazolin-2-yl)-1,4-dihydropyridylacetyl}amino]-3,3-dimethyl-7-oxo-4-thia-1-azabicyclo[3.2.0]-heptane-2-carboxylic acid potassium salt (6b)

Yield 51%; ir: 3380−3440 (NH), 1765 (β-lactam CO), 1685 (NHCO), 1605 (CO_2); nmr (D_2O) δ: 6.87 and 6.89 (overlapping d, $J_{2',6'}$ = 1.15 Hz, 1H, H2′), 5.92 (d, $J_{5',6'}$ = 8 Hz, 1H, H6′), 5.4−5.66 (m, 2H, H5, H6), 4.94 (d, $J_{5',6'}$ = 8 Hz of d, $J_{4',5'}$ = 5 Hz, 1H, H5′), 4.26 and 4.28 (two s, 1H, H2), 4.04 (br s, 4H, NCH_2, OCH_2), 3.3 (m, 1H, H4′), 1.58 and 1.62 (two s, 3H, C3-Me), 1.5 (s, 3H, C3-Me), 1.04−1.3 (m, 9H, C4′*Me*, OCH_2CMe_2). Mass, FAB (negative), $(M - 1)^+$: 485.

p-Bromophenacyl-6-β-[(aminophenylacetyl)amino]-3,3-dimethyl-7-oxo-4-thia-1-azabicyclo[3.2.0]heptane-2-carboxylate (8)

A suspension of Ampicillin (6.98 g, 20 mmol) and triethylamine (5.76 mL, 40 mmol) was stirred at 0°C in dry methylene chloride (300 mL) for 30 min to give a clear solution, after which α,*p*-dibromoacetophenone (5.56 g, 20 mmol) in 50 mL dry methylene chloride was added dropwise. The reaction mixture was stirred at 0°C for 4 h and then 25 mL water was added. The organic layer was separated and washed in succession with a saturated solution of sodium bicarbonate and then water (2 × 20 mL). The organic layer was dried (Na_2SO_4) and the solvent removed *in vacuo* to yield **8** as a viscous oil which under vacuum for 1 h afforded a foam (6.0 g, 58.8%); ir: 3300−3380 (NH_2, CONH), 1790 (β-lactam CO), 1760 (CO_2), 1680−1705 (CH_2CO—C_6H_4-Br, CONH); nmr ($CDCl_3$) δ: 8.07 (d, J_{NH,C_6H} = 9 Hz, 1H, NH exchanges with deuterium oxide), 7.55 and 7.68 (d, J = 8 Hz, 2H each, C_6H_4-Br), 7.28−7.44 (m, 5H, Ph), 5.7 (d, $J_{5,6}$ = 4.12 Hz of d, J_{NH,C_6H} = 9 Hz, 1H, H6), 5.56 (d, $J_{5,6}$ = 4.12 Hz, 1H, H5), 5.5 (d, J_{gem} = 16.48 Hz, 1H, O—*CH*—CO), 5.28 (d, J_{gem} = 16.48 Hz, 1H, O*CH*CO), 4.58 and 4.59 (two s, 2H, *CH*-Ph and H2), 1.84 (br s, 2H, NH_2, exchanges with deuterium oxide), 1.7 and 1.75 (two s, 6H, C3-Me_2).

p-Bromophenacyl-6-β-[{4-phenyl-3-(4,4-dimethyloxazolin-2-yl)-1,4-dihydropyridylmethylcarbonylaminophenylacetyl}amino]-3,3-dimethyl-7-oxo-4-thia-1-azabicyclo[3.2.0]heptane-2-carboxylate (9a)

A solution of DCC (0.824 g, 4 mmol) in 10 mL dry methylene chloride was added dropwise with stirring to a solution of **3a** (1.56 g, 5 mmol) and **7** (2.176 g, 4 mmol) in 50 mL dry methylene chloride. The reaction was allowed to proceed for 12 h at 25°C with stirring prior to filtration. The filtrate was washed successively with a saturated solution of sodium bicarbonate (2 × 10 mL), 2% aqueous hydrochloric acid (2 × 5 mL), and then water (2 × 10 mL). The organic fraction was dried (Na_2SO_4) and the solvent removed *in vacuo* to afford impure **9a**. Trituration of this material with hexane and extensive washing with ether yielded **9a** (2.7 g, 80%); ir: 3340 (NH), 1795 (β-lactam CO), 1770 (CO_2), 1710 ($CH_2COC_6H_4Br$), 1675−1690 (CONH); nmr (DMSO-d_6) δ: 9.37 (two overlapping d, J_{NH,C_6H} = 7.5 Hz, 1H, CHCO*NH*, exchanges with deuterium oxide), 8.74 and 8.76 (two overlapping d, J_{NHCH} = 7.5 Hz, 1H, $CH_2CONHCH$, exchanges with deuterium oxide), 7.8 and 7.92 (d, J = 8 Hz, 2H each, COC_6H_4-Br), 7.04−7.56 (m, 10H, Ph, CH-*Ph*), 6.92 (s, 1H, H2′), 6.04 (d, $J_{5',6'}$ = 7.5 Hz, 1H, H6′), 5.76 (br d, J_{NHCH} = 7.5 Hz, 1H, *CH*-Ph), 5.54−5.7 (m, J_{NH,C_6H} = 7.5 Hz, $J_{5,6}$ = 4 Hz, 3H, H6 and $CH_2COC_6H_4Br$), 5.48 (d, $J_{5,6}$ = 4 Hz, 1H, H5), 4.7 (d, $J_{5',6'}$ = 8 Hz of d, $J_{4',5'}$ = 5 Hz, 1H, H5′), 4.44 (s, 1H, H2), 4.38 (d, $J_{4',5'}$ = 5 Hz, 1H, H4′), 4.1 (s, 2H, NCH_2CO), 3.72 (s, 2H, OCH_2CMe_2), 1.5 and 1.61 (two s, 6H, C3-Me_2), 1.0 (s, 3H, OCH_2-*Me*), 0.98 (s, 3H, OCH_2CMe); nmr ($CDCl_3$) δ: 7.63 and 7.73 (two d, J = 8 Hz, 2H each, C_6H_4Br), 7.08−7.56 (m, 12H, $CH_2CONHCH$, CHCO*NH*, CH-*Ph*, C4′-*Ph*, NH exchanges with deuterium oxide), 6.88 and 7.0 (two s, 1H, H2′), 5.91 and 5.96 (two d, $J_{5',6'}$ = 7.6 Hz, 1H, H6′), 5.6−5.8 (m, 2H, *CH*-Ph, H6), 5.33−5.4 (m, J_{CH_2gem} = 16 Hz, 2H, $CH_2COC_6H_4Br$), 5.26 (d, $J_{5,6}$ = 4 Hz, 1H, H5), 4.98 (d, $J_{5',6'}$ = 8 Hz of d, $J_{4',5'}$ = 5 Hz, 1H, H5′), 4.66 (d, $J_{4',5'}$ = 5 Hz, 2H, H4′), 4.5 (s, 1H, H2), 3.66−4.0 (m, 4H, NCH_2CO, OCH_2CMe_2), 1.63 (s, 6H, C3-Me_2), 1.08 and 1.23 (two s, 3H each, OCH_2CMe_2). Mass, FAB (positive) $(M + 1)^+$: 840 and 842; $(M + 2H)^+$: 841 and 843.

Compounds **9b** and **9c** were prepared by the respective reaction of **3b** and **3c** with **8**.

p-Bromophenacyl-6-β-[{4-methyl-3-(4,4-dimethyloxazolin-2-yl)-1,4-dihydropyridylmethylcarbonylaminophenylacetyl}amino]-3,3-dimethyl-7-oxo-4-thia-1-azabicyclo[3.2.0]heptane-2-carboxylate (9b)

Yield 80%; ir: 3340−3400 (NH), 1800 (β-lactam CO), 1770 (CO_2), 1715 ($CH_2COC_6H_4Br$), 1680 (CONH); nmr (DMSO-d_6) δ: 9.3 and 9.32 (two overlapping d, J_{NH,C_6H} = 7.5 Hz, 1H, CO*NH*-C_6), 8.6 and 8.64 (two overlapping d, $J_{CONHCH\text{-}Ph}$ = 7.5 Hz, 1H, CO*NH*CH-Ph, exchanges with deuterium oxide), 7.8 and 7.9 (d, J = 8 Hz, 2H each, COC_6H_4-Br), 7.24−7.5 (m, 5H, CH-*Ph*), 6.7 (s, 1H, H2′), 5.88 (d, $J_{5',6'}$ = 8 Hz, 1H, H6′), 5.72 (two overlapping d, J_{CHNH} = 7.5 Hz, 1H, *CH*Ph), 5.52−5.7 (m, 3H, $OCH_2C_6H_4Br$ and H6), 5.47 (d, $J_{5,6}$ = 4.4 Hz, 1H, H5), 4.61 (d, $J_{5',6'}$ = 8 Hz of d, $J_{4',5'}$ = 5 Hz, 1H, H5′), 4.46 (s, 1H, H2), 3.98 (two s, 2H, NCH_2CO), 3.83 (s, 2H, OCH_2CMe_2), 3.4 (m, 1H, H4′), 1.54 and 1.65 (two s, 3H each, C3-Me_2), 1.1−1.3 (m, 9H, C4′-Me, OCH_2CMe_2); nmr ($CDCl_3$) δ: 7.64 and 7.74 (d, J = 8 Hz, 2H each, C_6H_4Br), 7.36 (m, 5H, Ph), 6.84 (two d, 2H, CO*NH*CHCO*NH*), 6.67 and 6.7 (two d, $J_{2',6'}$ = 1.15 Hz, 1H, H2′), 5.74 and 5.78 (two overlapping d, $J_{5',6'}$ = 8 Hz of d, $J_{2',6'}$ = 1.15 Hz, 1H, H6′), 5.54−5.56 (m, 2H, *CH*Ph, H6), 5.38−5.5 (m, J_{CH_2gem} = 16 Hz, 2H, $CH_2C_6H_4Br$), 5.26 (d, $J_{5,6}$ = 4.5 Hz, 1H, H5), 4.98 (d, $J_{5',6'}$ = 8 Hz of d, $J_{4',5'}$ = 5 Hz, 1H, H5′), 4.47 (s, 1H, H2), 3.86−3.90 (m, 4H, NCH_2CO, OCH_2CMe_2), 3.4−3.55 (m, 1H, H4′), 1.6 (s, 6H, C3-Me_2), 1.2−1.34 (m, 9H, C4′-*Me*, OCH_2CMe_2). Les volumes molaires partiels de l'eau et du nitrate d'éthylammonium ont été déterminés avec précision dans leurs différents mélanges entre l'eau pure et le sel fondu pur à 298 K. Il est montré dans cette étude que le volume molaire partiel de l'eau suit une loi linéaire avec la fraction molaire x du sel dès que x devient supérieur à 0,04. Les lois décrivant les variations des principales grandeurs thermodynamiques relatives aux volumes sont établies pour le sel, l'eau et la solution. Il est également montré que le volume intrinsèque du sel dans les solutions salines concentrées ($x > 0{,}04$) s'identifie en première approximation au volume molaire du sel fondu pur, et que la valeur du volume molaire apparent de l'eau correspond à une estimation convenable du volume effectif moyen attribuable à chaque molécule d'eau dans la solution.

M. HADDED, M. BIQUARD, P. LETELLIER, and R. SCHAAL. Can. J. Chem. **63**, 565 (1985).

Partial molar volumes of water and ethylammonium nitrate EAN are determined accurately in all water–EAN mixtures, between pure water and pure fused salt at 298 K. It has been found that the partial molar volume of water decreases linearly with molar fraction of salt, x, in concentrated solution of EAN ($C > 2$ mol L^{-1}, $x > 0.04$). The main thermodynamic relations are established to describe the volumetric behaviour of salt, water, and solution. It has been shown that the intrinsic volume of salt can be identified roughly with the molar volume of the pure fused salt and the value of apparent molar volume of water with the actual volume of water in solution.

L'étude des propriétés volumiques des mélanges eau – sel fondu, à des températures très supérieures à l'ambiante a permis de proposer et de discuter différents modèles de solvatation pour les espèces ioniques, particulièrement pour les milieux les plus riches en sel (1, 2, 20).

Toutefois, la difficulté de mesurer avec une très grande précision les masses volumiques de solutions à des températures éloignées des conditions standard ne permet généralement pas une détermination suffisamment précise des propriétés individuelles de l'eau et du sel dans leurs différents mélanges, pour pouvoir vérifier l'intégralité des conséquences impliquées par les modèles.

L'utilisation d'un sel à bas point de fusion (14°C), le nitrate d'éthylammonium (NEA), miscible à l'eau en toutes proportions, nous a permis en revanche d'effectuer ce type d'étude. Le but de cet article est donc, tout d'abord de présenter une technique expérimentale donnant accès à des valeurs précises des volumes molaires partiels de l'eau et du NEA à 298 K dans leurs différents mélanges, puis d'examiner les valeurs expérimentales à l'aide d'un formalisme développé dans une publication antérieure (3).

I. Technique expérimentale

I-1. *Le nitrate d'éthylammonium* pur a été préparé par une technique proche de celle proposée par Evans *et al.* (4): une solution d'éthylamine à 33% (Prolabo) a été neutralisée par de l'acide nitrique de densité égale à 1,33 (Prolabo) dans un bécher refroidi dans un bain de glace. La solution saline a été concentrée à l'évaporateur rotatif à 60°C pendant 3 h. L'eau, de la solution concentrée, a été éliminée par séchage sous vide pendant 3 jours, en présence de P_2O_5. Le point de fusion du sel a été trouvé égal à 14°C.

L'eau utilisée pour réaliser les différents mélanges a été bidistillée. Sa masse volumique a été prise égale à 0,997047 g/cm^3 pour les calculs de volumes molaires partiels.

Les mesures de masses volumiques ont été effectuées au moyen d'un densimètre vibratomètre Picker modèle 03D régulé à 298 ± 2 × 10^{-3} K par un thermostat Setaram.

I-2. *Détermination des volumes molaires partiels de l'eau et du sel dans les différents mélanges eau–NEA*

La technique classique de détermination du volume molaire partiel d'un constituant 1 dans un mélange binaire 1–2 consiste généralement à mesurer le volume molaire apparent de 1, ϕ_1, pour différentes fractions molaires x de 2 et d'en déduire le volume molaire partiel $\bar{V}_1$ par la relation:

$$[1] \quad \bar{V}_1 = \phi_1 - x(1-x)\left[\frac{\partial \phi_1}{\partial x}\right]_{(n_1+n_2)}$$

ce qui nécessite l'estimation toujours délicate d'une grandeur dérivée.[1] L'utilisation d'une telle technique ne conduit généralement qu'à des valeurs approchées des volumes molaires partiels de 1 et de 2. Afin d'obtenir des valeurs précises (incertitudes inférieures à 0,1 cm^3 mol^{-1}) des volumes molaires partiels de l'eau et du nitrate d'éthylammonium, notés respectivement 1 et 2 par la suite dans le texte, dans leurs melanges nous avons utilisé une technique de *détermination directe*, exposée en détail dans un précédent travail (3). Cette technique fait appel à une "méthode d'ajouts" dont les principes sont rappelés brièvement ci-dessous.

"Méthode d'ajouts"

Le volume d'une solution contenant n_1 moles d'eau et n_2 moles de sel est égal à:

$$V = n_1\bar{V}_1 + n_2\bar{V}_2$$

Si l'on ajoute à cette solution *une très faible quantité* ϵ de l'un des deux constituants, le volume change et devient V'. On peut caractériser la variation du volume total de la solution en la ramenant à une mole de soluté additionné.

On aurait, par exemple, pour un ajout ϵ_1 d'eau dans un mélange eau–NEA

$$P_1 = \frac{V' - V}{\epsilon_1}$$

[1]Lorsque l'on connaît sans ambiguité les volumes molaires des composés 1 et 2 respectivement V_1^0 et V_2^0 on peut également déterminer $\bar{V}_1$ à partir du volume d'excès, V_{ex}, par la relation:

$$\bar{V}_1 = V_1^0 + V_{ex} - x\left[\frac{\partial V_{ex}}{\partial x}\right]_{(n_1+n_2)}$$

Là également l'estimation de $\left[\frac{\partial V_{ex}}{\partial x}\right]_{(n_1+n_2)}$ est particulièrement délicate et peut conduire à d'importantes incertitudes près des bornes ($x = 0$ et $x = 1$) (5).

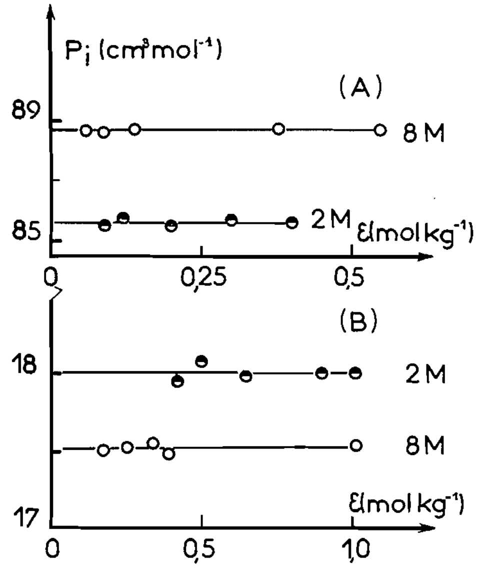

FIG. 1. Exemple d'extrapolation à "ajout nul" ($\epsilon = 0$) des grandeurs P_i pour le sel (A) et pour l'eau (B) dans les solutions 2 et 8 mol L^{-1} en NEA.

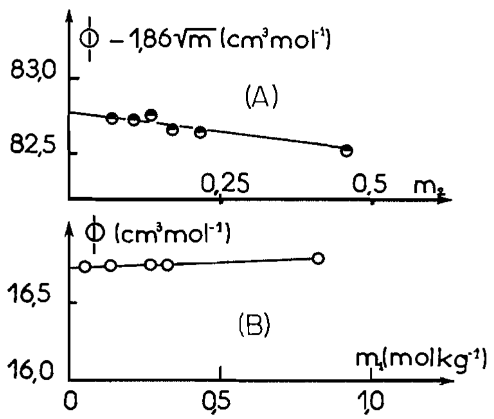

FIG. 2. (A) Détermination du volume molaire partiel à "dilution infinie" du nitrate d'éthylammonium dans l'eau à partir de la technique d'extrapolation proposée par Redlich et Rosenfeld. (B) Détermination du volume molaire partiel à "dilution infinie" de l'eau dans le sel fondu.

Par définition de la grandeur molaire partielle, la grandeur P_1 admet pour limite $\bar{V}_1$, lorsque l'ajout ϵ_1 tend vers zéro

$$[2] \quad \lim_{\epsilon_1 \to 0} P_1 = \bar{V}_1$$

On aurait bien évidemment pour un ajout ϵ_2 de sel dans le même mélange

$$[2a] \quad \lim_{\epsilon_2 \to 0} P_2 = \bar{V}_2$$

Dans la pratique, on détermine les volumes molaires partiels de l'eau et du sel en utilisant la procèdure suivante.

(*a*) On prépare par *volumétrie* le mélange eau−sel désiré.

(*b*) On effectue dans ce mélange 4 à 6 additions d'eau puis de sel. Les quantités ajoutées sont déterminées avec précision *par gravimétrie*.

(*c*) On calcule les quantités P_i correspondant aux ajouts du constituant i par la relation

$$[3] \quad P_i = \frac{1000}{\epsilon_i}\left(\frac{1}{\rho_i} - \frac{1}{\rho_M}\right) + \frac{M_i}{\rho_i}$$

où ρ_M et ρ_i sont respectivement les masses volumiques du mélange avant et après l'ajout; ϵ_i est le nombre de moles du constituant i ajouté à 1000 g de mélange.

(*d*) On extrapole ensuite les valeurs de P_i linéairement avec ϵ_i à "ajout nul" ($\epsilon_i = 0$). La justification de cette technique d'extrapolation a été exposée précédemment (3). Les volumes molaires partiels de l'eau et du NEA ont été déterminés pour 7 mélanges eau−sel régulièrement répartis sur l'échelle des fractions molaires.

Plusieurs exemples d'extrapolation à "ajout nul" sont reportés sur la fig. 1. Les droites obtenues possèdent toutes des pentes faibles conduisant à des valeurs extrapolées à $\pm 0,1$ cm³ mol⁻¹.

TABLEAU 1. Exemple des variations de P_1 et P_2 obtenues pour différents ajouts d'eau (ϵ_1) et de sel (ϵ_2) dans un mélange eau−NEA ($x = 0,625$). Les valeurs de $\bar{V}_2$ et $\bar{V}_1$ sont reportées en correspondance de $\epsilon = 0$

Nitrate d'éthylammonium

II. Résultats expérimentaux

À titre d'exemple, les résultats expérimentaux obtenus pour le milieu $x = 0,625$ sont reportés dans le tableau 1.

La valeur du volume molaire partiel du nitrate d'éthyl ammonium à dilution infinie dans l'eau a été obtenu par extrapolation selon la méthode proposée par Redlich et Rosenfeld (6) (fig. 2(A)). Cette valeur (82,9 cm³ mol⁻¹) est sensiblement supérieure à celle que l'on peut calculer à partir de la valeur de $\bar{V}^0$ publiée pour le bromure d'éthylammonium (81,9 cm³ mol⁻¹) (7), en supposant l'additivité des $\bar{V}^0$ individuels des ions (8).

La valeur du volume molaire partiel de l'eau à dilution infinie dans le sel pur a été obtenue par extrapolation linéaire avec la molalité de l'eau dans la solution (fig. 2(B)). Les valeurs des volumes molaires partiels de l'eau et du nitrate d'éthylammonium sont regroupées dans le tableau 2. Les variations des volumes molaires partiels de l'eau et du sel dans leurs différents mélanges sont reportées sur la fig. 3.

La masse volumique du sel pur a été trouvée égale à:

$$\rho_{NEA} = 1,21062 \text{ g/cm}^3 \text{ à } 298 \text{ K}$$

ce qui correspond à une concentration de 11, 2 moles par litre de sel. La valeur de la masse volumique est supérieure à celle que l'on peut calculer à partir de la relation proposée par Sugden et Wilkins (9).

TABLEAU 2. Valeurs des volumes molaires partiels de l'eau $\bar{V}_1$ et du nitrate d'éthylammonium $\bar{V}_2$ pour les différents mélanges eau–NEA à 298 K

C (mol L^{-1})	0	2,02	4,04	6,02	8,08	8,96	10,03	10,75	11,2
x	0	$4{,}22\times10^{-2}$	0,100	0,186	0,336	0,441	0,625	0,819	1
$\bar{V}_1$ (cm^3 mol^{-1})	18,07	18,0	17,9	17,8	17,5$_5$	17,4	17,2	16,9	16,7
$\bar{V}_2$ (cm^3 mol^{-1})	82,8	85,6	87,2	88,1	88,7	89,0	89,2	89,3	89,3
$\bar{V}_2$ (cm^3 mol^{-1}) calculé	—	86,11	87,29	88,06	88,70	88,94	89,18	89,29	89,32

III. Discussion des résultats

Comme le montre la fig. 3, le volume molaire partiel de l'eau varie linéairement avec la fraction molaire, x, du sel entre ses deux valeurs limites V_1^0 et $\bar{V}_1^0$ (volume molaire et volume molaire partiel à dilution infinie de l'eau dans le sel pur).

À partir de cette simple représentation graphique, on serait donc tenté d'adopter pour rendre compte des variations de $\bar{V}_1$, la relation suivante:

$$[4] \quad \bar{V}_1 = V_1^0 - x\,(V_1^0 - \bar{V}_1^0)$$

sur l'intervalle des fractions molaires comprises entre 0 et 1, bornes incluses. Or ce choix conduirait à une description tout à fait incorrecte des propriétés du sel dans le domaine des solutions diluées en électrolyte.

En effet, on peut montrer que la description des variations du volume molaire partiel du constituant 1 dans le binaire 1–2, au moyen d'une équation polynomiale en x (x = fraction molaire du constituant 2) ne peut *au minimum* débuter qu'à l'ordre 2, l'ordre unité conduisant à une valeur infinie pour $\bar{V}_2$ lorsque x tend vers zéro (5).

Le domaine correspondant aux solutions diluées doit donc être impérativement exclu de l'intervalle de définition de la reaction 4, ce qui conduit à envisager deux intervalles d'étude: (*a*) un premier intervalle très étroit, correspondant aux solutions salines diluées, pour des fractions molaires inférieures à 4×10^{-2} (la valeur choisie pour cette borne sera justifiée ultérieurement); (*b*) un second intervalle beaucoup plus large, correspondant aux solutions concentrées en NEA pour x supérieur à 4×10^{-2} dans lequel le comportement des deux constituants de la solution sera entièrement déterminé, par les conséquences de la relation [4].

III-1. *Solutions concentrées en NEA dans l'intervalle $4 \times 10^{-2} < x \leq 1$*

III-1-1. *Volumes molaires partiels du sel*

L'utilisation conjointe de la relation de Gibbs–Duhem et de la relation [4] permet d'établir une loi de variation pour le volume molaire partiel du NEA en fonction de x:

$$d\bar{V}_2 = \frac{1-x}{x}\,(V_1^0 - \bar{V}_1^0)\,dx$$

Cette équation différentielle peut être intégrée entre la borne limite correspondant au sel pur (x = 1) et une autre borne caractéristique de l'une des solutions appartenant à l'intervalle de définition de l'équation [4].

On obtient alors, pour décrire les variations de $\bar{V}_2$, l'expression suivante:

$$[5] \quad \bar{V}_2 = V_2^0 + (V_1^0 - \bar{V}_1^0)\,(\ln x + 1 - x)$$

Les valeurs de $\bar{V}_2$ calculées au moyen de la relation [5] sont reportées dans le tableau 2 en regard des valeurs expérimentales.

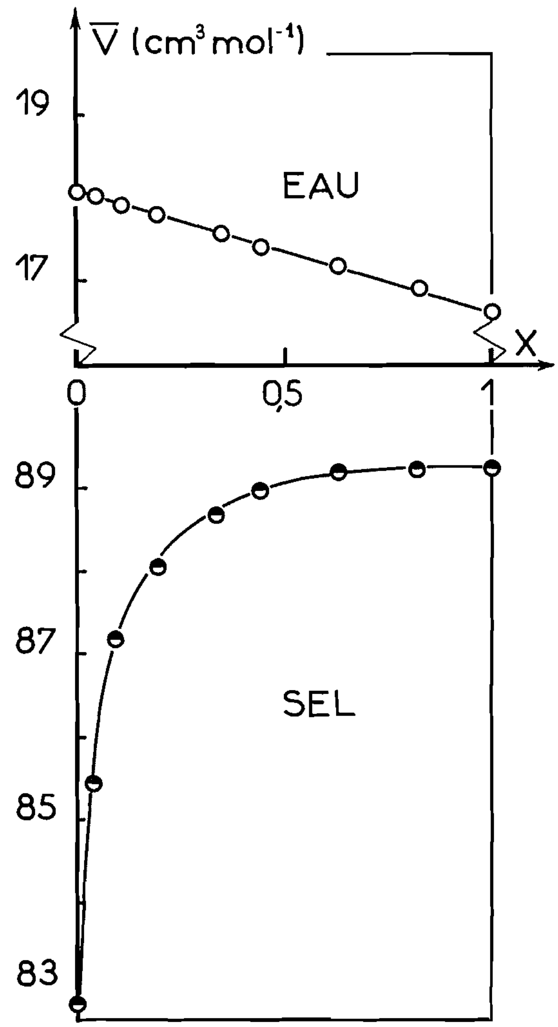

FIG. 3. Volumes molaires partiels de l'eau et du sel à 298 K dans leurs différents mélanges en fonction de la fraction molaire du NEA.

Les valeurs calculées sont en excellent accord avec les valeurs expérimentales pour l 'ensemble des mélanges étudiés ce qui justifie la forme polynomiale au premier ordre adoptée pour décrire les variations de $\bar{V}_1$. Le système d'équation choisi est auto-cohérent.

Les expressions de $\bar{V}_1$ et $\bar{V}_2$ étant établies en fonction de la fraction molaire du NEA, on peut compléter la description du binaire au moyen des autres grandeurs molaires. Certaines d'entre elles seront utiles lors de la discussion concernant les différents modèles pouvant rendre compte des résultats expérimentaux.

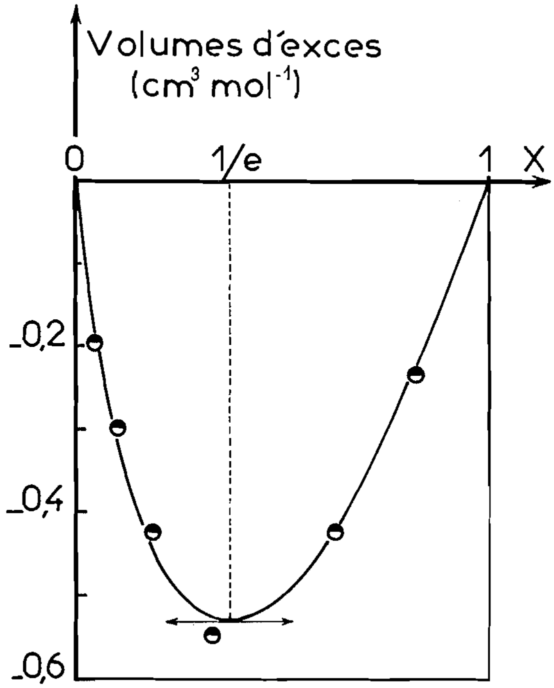

FIG. 4. Volumes d'excès des mélanges eau–NEA. La courbe représentative a été tracée à partir des valeurs calculées au moyen de la relation [9].

III-1-2. *Autres grandeurs molaires du sel et de l'eau dans leurs mélanges*

(a) *Volumes molaires apparents du NEA*

Par définition le volume molaire apparent ϕ_2 du sel s'écrit

$$\phi_2 = \bar{V}_2 + \frac{1-x}{x}(\bar{V}_1 - V_1^0)$$

soit en substituant $\bar{V}_2$ par son expression

$$[6] \quad \phi_2 = V_2^0 + (V_1^0 - \bar{V}_1^0) \ln x$$

(b) *Volumes molaires apparents de l'eau*

Les volumes molaires apparents de l'eau ϕ_1 et du sel ϕ_2 sont reliés par:

$$\phi_1 = V_1^0 + \frac{x}{1-x}(\phi_2 - V_2^0)$$

soit

$$[7] \quad \phi_1 = V_1^0 + (V_1^0 - \bar{V}_1^0)\frac{x}{1-x} \ln x$$

(c) *Volumes réduits et volumes d'excès*

Par définition le volume réduit, V_R, représente le volume du mélange ramené à 1 mole de constituants, soit

$$V_R = x\bar{V}_2 + (1-x)\bar{V}_1$$

$$[8] \quad V_R = xV_2^0 + (1-x)V_1^0 + (V_1^0 - \bar{V}_1^0)x \ln x$$

Conventionnellement le volume d'excès, V_{ex}, rend compte de l'écart entre les propriétés réelles de la solution et celles du système modèle que constitue la solution idéale.

$$V_{ex} = V_R - x V_2^0 - (1-x) V_1^0$$

$$[9] \quad V_{ex} = (V_1^0 - \bar{V}_1^0)x \ln x$$

Les variations du volume d'excès sont représentées sur la fig. 4; le maximum de la courbe se situe à $x = 1/e$.

III-2. *Solutions diluées en NEA dans l'intervalle* $0 \leqslant x \leqslant 4 \times 10^{-2}$

Loi limite de Debye–Hückel

Lorsque les solutions salines sont suffisamment diluées le volume molaire partiel du sel peut être décrit au moyen de la relation

$$[10] \quad \bar{V}_2 = \bar{V}_2^0 + 2{,}8\sqrt{m}$$

dans laquelle m est la molalité du sel. La valeur 2,8 est celle que l'on obtient de manière théorique par dérivation de l'expression proposée par Debye et Hückel pour décrire les variations du coefficient d'activité du sel (6) référé à la solution infiniment diluée.

Les variations de $\bar{V}_2$ peuvent être aisément exprimées en fonction de la fraction molaire. La molalité m et x sont reliées par:

$$m = \frac{x}{1-x}\frac{1}{M_1}$$

où M_1 est la masse molaire de l'eau exprimée en kg mol^{-1}. Dans le domaine des solutions salines diluées, la fraction molaire x reste toujours très petite devant l'unité.

La relation [10] peut donc encore être écrite:

$$[11] \quad \bar{V}_2 = \bar{V}_2^0 + 20{,}8\sqrt{x}$$

soit pour la grandeur molaire apparente

$$[12] \quad \phi_2 = \bar{V}_2^0 + 13{,}87\sqrt{x}$$

Le volume molaire partiel de l'eau obéit alors à la loi limite

$$[13] \quad \bar{V}_1 = V_1^0 - 6{,}93\, x^{3/2}$$

Dans le domaine de validité de la loi limite de Debye–Hückel les variations du volume molaire partiel de l'eau sont inférieures à l'erreur expérimentale et ne peuvent de ce fait être mises en évidence, tout au moins par la technique qui a été utilisée.

Le changement de comportement du sel lorsque l'on passe des solutions très diluées aux solutions concentrées apparaît sur la fig. 5 où sont reportées, en traits pointillés les deux lois limites correspondant aux relations [6] et [12], et en trait plein la courbe expérimentale.

Pour une concentration en NEA supérieure à 2 moles par litre soit $x > 4 \times 10^{-2}$, le comportement de la solution peut être décrit au moyen de la relation [4]. Cette valeur a donc été adoptée comme borne inférieure de son intervalle de définition.

IV. Interprétation des résultats

L'analyse des résultats expérimentaux peut être effectuée au moyen d'un formalisme, développé dans une étude antérieure concernant les mélanges eau–KCl (3,19) qui suppose qu'à l'échelle macroscopique toutes les molécules d'eau de la solution sont perturbées d'une manière identique par la présence du sel (10–12). Il a été ainsi montré que le volume intrinsèque V_i^{I} d'un électrolyte est directement proportionnel à son volume cristallin V_i^{c} calculé à partir des rayons de Pauling.

$$[14] \quad V_i^{\mathrm{I}} = 1{,}92\, V_i^{\mathrm{c}}$$

La validité de cette relation a été vérifiée pour de nombreux électrolytes pour toutes les solutions concentrées en KCl comprises entre 0,5 mol L^{-1} et la saturation.

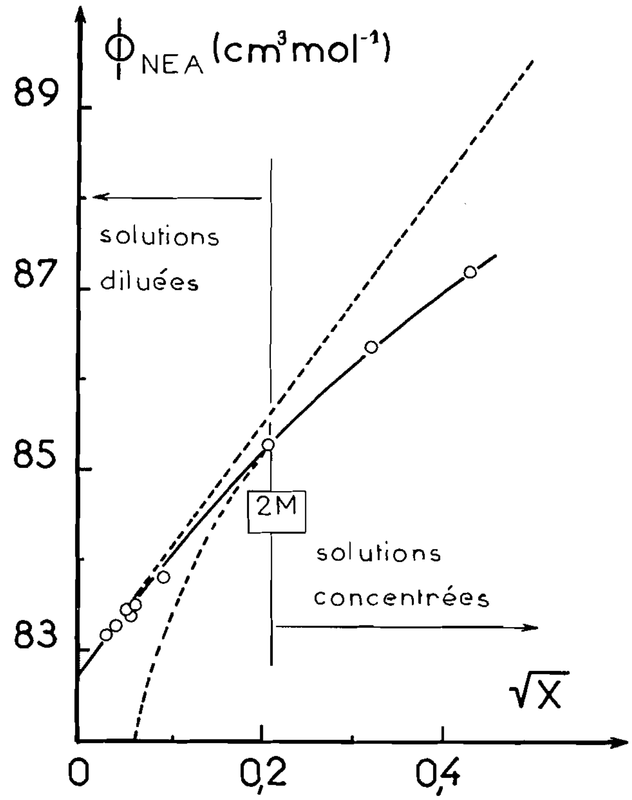

FIG. 5. Variation des volumes molaires apparents du NEA reportée en fonction de $x^{1/2}$. Pour les solutions les plus diluées en sel le comportement du NEA peut être décrit au moyen de la loi limite de Debye et Hückel. Pour les solutions concentrées de molarité supérieure à 2 mol L^{-1} ($x = 4 \times 10^{-2}$) le comportement de la solution est décrit au moyen de la relation [4].

Le volume de la solution saline concentrée s'écrit alors en gardant les notations habituelles (indice 1 pour l'eau et 2 pour le sel)

$$[15]\quad V = n_1 V_{\phi_1} + 1{,}92\, n_2 V_2^c$$

V_{ϕ_1} est une grandeur molaire qui caractérise le volume effectif moyen attribuable à chaque molécule d'eau dans le milieu salin. L'avantage de ce formalisme est de faire apparaître d'une manière explicite l'intervention des propriétés de l'eau dans l'expression du volume molaire partiel de l'électrolyte

$$[16]\quad \bar{V}_2 = 1{,}92\, V_2^c + (1 - x)^2 \left[\frac{\partial V_{\phi_1}}{\partial x}\right]_{(n_1 + n_2)}$$

Dans le cas des mélanges eau–NEA le calcul du volume intrinsèque du sel peut être effectué à partir d'une évaluation des volumes cristallins individuels des ions nitrate et éthylammonium, obtenue par une technique de corrélation exposée en détail dans un article précédent (13). Les valeurs des volumes cristallins des deux ions sont données avec une incertitude de l'ordre de 1%:

$$V^c_{NO_3^-} = 19{,}9 \text{ cm}^3 \text{ mol}^{-1}$$

$$V^c_{EtNH_3^+} = 27{,}0 \text{ cm}^3 \text{ mol}^{-1}$$

soit pour le sel

$$V^c_{NEA} = 46{,}9 \pm 0{,}5 \text{ cm}^3 \text{ mol}^{-1}$$

Si l'on admet que le coefficient de proportionnalité intervenant dans la relation [14] reste du même ordre pour les mélanges eau–NEA, le volume intrinsèque du sel peut être estimé à:

$$V^I_{NEA} = 90 \text{ cm}^3 \text{ mol}^{-1}$$

Cette valeur, tout à fait comparable à celle du volume molaire V^0_{NEA} du sel fondu (89, 3 cm^3 mol^{-1}), laisse supposer que le *volume intrinsèque du nitrate d'éthylammonium dans les mélanges eau–NEA s'identifie en première approximation à son volume molaire*

$$[17]\quad V^0_{NEA} \simeq V^I_{NEA} = 89{,}3 \text{ cm}^3 \text{ mol}^{-1}$$

et que le sel en solution garde "l'empreinte" de sa structure lorsqu'il est pur à l'état liquide.

Cette particularité des mélanges eau–NEA permet d'écrire la relation [15] sous la forme:

$$V = n_1 V_{\phi_1} + n_2 V_2^0$$

V_{ϕ_1} s'identifie alors au volume molaire apparent de l'eau ϕ_1 dans le mélange et ses variations avec la composition peuvent être décrites au moyen de la relation [7].

Comme on peut le remarquer (fig. 6), la variation du volume effectif moyen de l'eau est maximum dans les milieux les plus aqueux et s'atténue pour atteindre une valeur limite pour les solutions les plus riches en sel. Cette limite est liée à la valeur du volume molaire partiel à dilution infinie $\bar{V}_1^0$ de l'eau dans le sel fondu.

$$\lim_{x\to 1} \left|\frac{\partial \phi_1}{\partial x}\right| = -\frac{1}{2}(V_1^0 - \bar{V}_1^0) = \left|\frac{\partial \phi_1}{\partial x}\right|^L$$

soit

$$[18]\quad \bar{V}_1^0 = V_1^0 + 2\left|\frac{\partial \phi_1}{\partial x}\right|^L$$

$\bar{V}_1^0$ représente alors le volume molaire effectif attribuable à une mole d'eau infiniment diluée dans le sel pur.

Sa valeur reste supérieure aux estimations faites par Millero *et al.* (14) et Shimizu (15) pour le volume de l'eau participant à la solvatation directe des ions dans le cas des solutions diluées.

L'utilisation du volume molaire apparent de l'eau pour analyser les propriétés des solutions salines concentrées avait déjà été signalée par Kodejš et Slama (16) qui ont proposé de décrire ses variations par la relation:

$$[19]\quad \phi_1 = x V_1^0 + \left[A + C\frac{1 - x}{1 + x(D - 1)}\right](1 - x)$$

A, C, D sont des paramètres empiriques.

Sacchetto et Kodejš (2) supposent que cette relation est définie sur tout l'intervalle des fractions molaires, *bornes comprises*, et simplifient cette expression en:

$$[20]\quad \phi_1 = V_1^0 + (\bar{V}_1^0 - V_1^0)\, D\, \frac{x}{1 + x(D - 1)}$$

Par un calcul de mécanique statistique, ils relient la valeur de D à l'enthalpie de dilution de l'eau à dilution infinie dans le sel pur (2).

Bien que la forme mathématique proposée par ces auteurs pour décrire les variations de ϕ_1 avec la fraction molaire du sel diffère de celle présentée par la relation [7], nous avons tenté l'examen de nos résultats expérimentaux à l'aide de cette formulation.

La relation [20] ayant été établie en supposant que les bornes $x = 0$ et $x = 1$ appartenaient au domaine de définition de l'éq. [19], il est licite de calculer la valeur de D à partir des

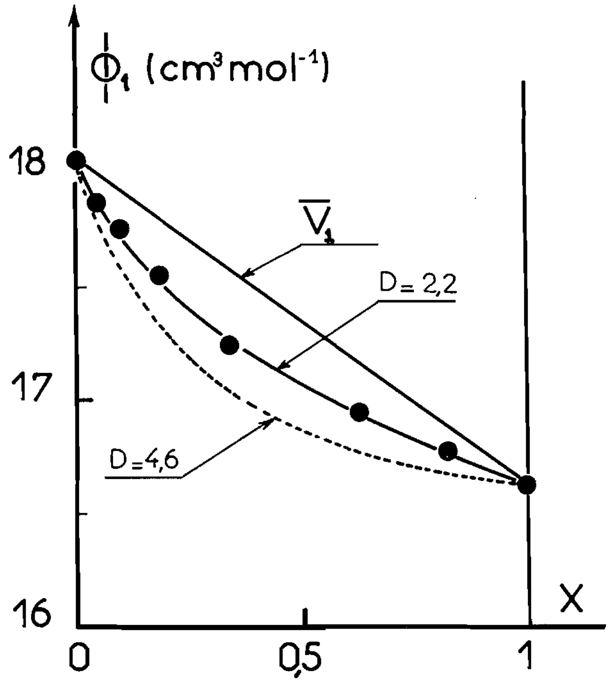

FIG. 6. Variation du volume molaire apparent de l'eau en fonction de la fraction molaire du sel. Les courbes calculées à partir de la relation [19] pour les valeurs D = 2,2 et D = 4,6 sont reportées sur le graphe.

différentes valeurs limites.

Le volume molaire apparent ϕ_2 du sel peut être écrit:

$$\phi_2 = V_2^0 + \frac{1-x}{x}(\phi_1 - V_1^0)$$

soit encore

$$[21]\quad \phi_2 = V_2^0 + [\bar{V}_1^0 - V_1^0]D\,\frac{1-x}{1+x(D-1)}$$

Le volume molaire apparent du sel s'identifie à son volume molaire partiel $\bar{V}_2^0$ lorsque x tend vers zéro soit:

$$\lim_{x\to 0} \phi_2 = \bar{V}_2^0 = V_2^0 + D(\bar{V}_1^0 - V_1^0)$$

La valeur de D est donc égale à

$$[22]\quad D = \frac{V_2^0 - \bar{V}_2^0}{V_1^0 - \bar{V}_1^0}$$

Dans le cas des mélanges eau−NEA, la valeur de D serait donc égale à 4,6. La description des variations de ϕ_1 à l'aide de cette valeur est pour le moins imparfaite (fig. 6).

Toutefois, la similitude de formes entre les courbes expérimentale et calculée nous a incités à tenter cette exploitation avec d'autres valeurs de D, *empiriques cette fois-ci.*

La valeur D = 2,2 conduit à une excellente description des valeurs de ϕ_1 sur toute la gamme des fractions molaires (fig. 6). On peut également vérifier, au moyen des relations suivantes déduites de l'éq. [20], que cette valeur de D permet de retrouver avec précision les résultats expérimentaux pour $\bar{V}_1$ et $\bar{V}_2$, en excluant cependant le domaine des solutions diluées.

$$[23]\quad \bar{V}_1 = V_1^0 - (V_1^0 - \bar{V}_1^0)\left[\frac{Dx}{1+x(D-1)}\right]^2$$

$$[23a]\quad \bar{V}_2 = V_2^0 - (V_1^0 - \bar{V}_1^0)\,D\left[\frac{1-x}{1+x(D-1)}\right]^2$$

$$D = 2{,}2$$

L'utilisation de la relation [20] proposée par Sacchetto et Kodejš conduit à une description précise des résultats expérimentaux à la condition toutefois d'exclure la borne $x = 0$ de son domaine de validité, ce qui paraît contradictoire avec le traitement de l'éq. [19] à l'origine de la relation [20].

Conclusion

L'étude volumétrique des mélanges eau − nitrate d'éthylammonium à 298 K montre que le volume intrinsèque du sel dans ses solutions aqueuses s'identifie à son volume molaire.

La description des comportements individuels de l'eau et du NEA dans leurs différents mélanges a pu être effectuée à partir d'un système d'équations basé sur l'existence d'une relation linéaire entre le volume molaire partiel de l'eau et la fraction molaire du sel. Toutefois ce système d'équations n'est pas unique, et il a été montré que les relations proposées par Kodejš et Sacchetto permettaient également une excellente description des comportements des constituants de la solution à condition d'exclure la borne $x = 0$ de leur domaine de validité. Plus généralement, les mélanges entre l'eau et le nitrate d'éthylammonium apparaissent comme des milieux très particuliers, le sel pur ayant par ses propriétés de nombreuses similitudes avec l'eau pure (17, 18). À titre d'exemple, il a été observé, dans le sel fondu pur, des phénomènes de micellisation comparables à ceux mis en évidence dans l'eau par les composés tensio-actifs.

Five-coordinate dicarbonyl complexes of rhodium(I): $[RhX(CO)_2(PPh_3)_2]$ (X = Cl, Br, I)

ALAN R. SANGER

Alberta Research Council, 11315-87 Avenue, Edmonton, Alta., Canada T6G 2C2

Received July 23, 1984

ALAN R. SANGER. Can. J. Chem. **63**, 571 (1985).

The complexes *trans*-$[RhX(CO)PPh_3)_2]$ (**1**, X = Cl, Br, I) react with CO to form $[RhX(CO)_2(PPh_3)_2]$ (**2**), and not to form *cis*-$[RhX(CO)(PPh_3)_2]$. Complexes **2** contain equivalent axial carbonyl ligands. It is proposed that a series of dicarbonyl complexes, including **2**, is formed during decarbonylation reactions catalyzed by **1**.

ALAN R. SANGER. Can. J. Chem. **63**, 571 (1985).

La réaction des complexes $[RhX(CO)(PPh_3)_2]$-*trans* (**1**, X = Cl, Br, I) avec le CO conduit aux complexes $[RhX(CO)_2(PPh_3)_2]$ (**2**) et il ne se forme pas de complexe $[RhX(CO)(PPh_3)_2]$-*cis*. Les complexes **2** contiennent des ligands carbonyles axiaux équivalents. On suggère l'hypothèse qu'il y a formation d'une série de complexes dicarbonyles, y compris **2**, lors des réactions de décarbonylations catalysées par **1**.

[Traduit par le journal]

Introduction

The complexes *trans*-$[RhX(CO)(PPh_3)_2]$ (**1***a*, X = Cl; **1***c*, X = I) were first synthesized by Vallarino (1), **1***a* from $[Rh_2Cl_2(CO)_4]$, and **1***c* by halogen ligand exchange. Recrystallization of each from various solvents gave unchanged material. Solutions of **1***c* were unstable under the conditions reported, becoming progressively darker. Synthesis of **1***a*, **1***b* (X = Br), or **1***c* under various conditions yields in most cases a product with a single obvious carbonyl band and one rhodium–halogen stretching band in the ir spectrum. However, the reported positions of the bands vary. For products described as **1***a* the carbonyl bands fall into the range 1961 to 1989 cm^{-1}, for **1***b*, 1968 to 1980 cm^{-1}, and for **1***c*, 1968 to 1985 cm^{-1} (e.g. refs. 1–8). For both **1***a* and **1***c*, it has been observed that the materials giving rise to these disparate bands may be formed in mixtures, and it has been assumed that the mixtures were of *cis*- and *trans*-isomers (6, 7). For **1***a* the mixture arose from the decarbonylation of aroyl chlorides catalyzed by $[RhCl(PPh_3)_3]$ (7). For **1***c* the mixture and each component were formed in separate experiments in which halogen exchange of **1***a* with iodide ion was attempted under various conditions (6). It has been reported that *cis*-$[RhI(CO)(PPh_3)_2]$ isomerizes to **1***c* in the solid state within one month (6).

Because the assignment of a "*cis*-$[RhX(CO)(PR_3)_2]$" structure has been made only because of the observation of an extra or displaced CO band in the spectra of such materials, and because the mechanism of decarbonylation catalysed by **1***a* is not fully understood, it was considered appropriate to reinvestigate these materials. A convenient probe is the ^{13}C nucleus, and consequently both the ^{12}CO and ^{13}CO (90% enriched) complexes **1***a*, **1***b*, and **1***c* have been prepared using literature methods (1–6) under either ^{12}CO or ^{13}CO (90% enriched), respectively. Complexes **1***a* and **1***b* enriched with ^{13}CO have previously been described (8, 9). Herein, reactions of **1***a*, **1***b*, and **1***c* (enriched with 90% ^{13}CO) with additional ^{13}CO to give $[RhX(^{13}CO)_2(PPh_3)_2]$ (**2***a*, X = Cl; **2***b*, X = Br; **2***c*, X = I) are reported. Materials previously described as "*cis*-$[RhX(CO)(PPh_3)_2]$" are now considered to be **2***a* and **2***c*, similar to the complex $[RhCl(CO)_2(Ph_2PC_4H_3S)_2]$, reported earlier (10). The complex **2***a* has previously been postulated as an intermediate in the S_N2 exchange of labelled CO with **1***a* (11).

Experimental

All reactions were performed under dry, oxygen-free N_2 or CO. Reagents were either commercially available or prepared by standard literature methods; ^{13}CO (90% ^{13}C-enriched) was purchased from Merck, Sharp, and Dohme Canada Limited, and used as supplied.

Microanalyses were performed at the Microanalytical Laboratory, Department of Chemistry, University of Alberta. Molecular weights were determined osmometrically. Spectra were obtained using the following instruments: ir, Perkin–Elmer 283; ^{13}C and ^{31}P nmr, Bruker WP80. The nmr spectra were obtained from solutions in either dichloromethane-d_2 or toluene-d_8 at +30 to −80°C; at room temperature rapid exchange of ligands prevented observation of coupling.

Reaction of $[Rh_2Cl_2(CO)_4]$ with PPh_3 in CH_2Cl_2

Addition of 4 equiv. of PPh_3 to a solution of $[Rh_2Cl_2(CO)_4]$ in dichloromethane under an atmosphere of CO gave a yellow solution which, after stirring for a few minutes, yielded pale yellow microcrystals. The ir spectrum of the product exhibited carbonyl bands at 1990 (vs) and 1967 (m) cm^{-1}. All attempts to recrystallize this material from benzene or dichloromethane under CO gave similar materials, the ir spectra of which showed the band at 1990 with reduced intensity and the band at 1967 with increased intensity.

Successive recrystallizations of the above material from dichloromethane under an atmosphere of N_2 gave *trans*-$[RhCl(CO)(PPh_3)_2]$ (ν(CO) 1967 cm^{-1}). (*Anal.* calcd.: C 64.3, H 4.4, Cl 5.1; found: C 64.3, H 4.6, Cl 5.25.) Recrystallization from benzene gave the 1 : 1 solvated complex. (*Anal.* calcd.: C 67.2, H 4.7, Cl 4.6; found: C 66.9, H 4.85, Cl 4.7.)

The ^{13}CO (90% ^{13}C-enriched) complexes were prepared under ^{13}CO.

Preparation of the bromo complexes

A solution of $[Rh_2Cl_2(cod)_2]$ in ethanol was stirred with a large excess of KBr under an atmosphere of CO for 4 h. Subsequently 4 equiv. of PPh_3 were added and the mixture was stirred overnight. The mixture was then filtered, and the precipitate was washed with successively water, ethanol, and diethyl ether to give, as a yellow powder, *trans*-$[RhBr(CO)(PPh_3)_2]$ (ν(CO) 1974 cm^{-1}). (*Anal.* calcd.: C 60.4, H 4.1, Br 10.9; found: C 60.4, H 4.1, Br 11.1.)

When the original product was recrystallized from dichloromethane under an atmosphere of N_2, the product was unchanged (ir).

When the original product was recrystallized very slowly from benzene under CO the product was $[RhBr(CO)_2(PPh_3)_2]\cdot C_6H_6$ (ν(CO) 1984 cm^{-1}) (*Anal.* calcd.: C 62.8, H 4.3, Br 9.5, mw 842; found: C 62.4, H 4.4, Br 10.4, mw 879.)

Recrystallization of the latter complex under an atmosphere of N_2

regenerated the original product.

The ^{13}CO complexes were prepared by the same reactions.

Preparation of the iodo complexes

A solution of $[Rh_2Cl_2(cod)_2]$ in ethanol was stirred with a large excess of KI under an atmosphere of CO for 4 h. Then 4 equiv. of PPh_3 were added and the mixture was stirred to form a yellow solution which rapidly gave a yellow precipitate. The mixture was filtered, and the precipitate was washed with successively water, ethanol, and diethyl ether to give, as an orange–yellow powder, $[RhI(CO)_2(PPh_3)_2]$ (ν(CO) 1965 cm^{-1}). (*Anal.* calcd.: C 56.3, H 3.7, I 15.7; found: C 56.1, H 3.8, I 15.4).

Recrystallization of the above product from benzene under an atmosphere of N_2 readily gave *trans*-$[RhI(CO)(PPh_3)_2]\cdot C_6H_6$ (ν(CO) 1989 cm^{-1}). (*Anal.* calcd.: C 60.0, H 4.2, I 14.75; found: C 59.75, H 4.3, I 15.0.) Prolonged stirring of a solution under a stream of N_2 gave $[RhI(PPh_3)_2]_2$ (see also ref. 6).

Recrystallization of the latter product from either benzene or dichloromethane under an atmosphere of CO readily gave large, soft crystals of the original product.

The ^{13}CO complexes were also prepared.

Results and discussion

Reactions of trans-*[RhX(CO)(PPh$_3$)$_2$] with CO*

When preparation of **1***a* was attempted under an atmosphere of CO, a mixture of products was apparently obtained. The carbonyl bands in the ir spectrum were very similar to those reported for what was assumed to be a mixture of the *cis* and *trans* isomers. The complex giving rise to the band at 1990 cm^{-1} was unresolvable, but recrystallization of the mixture under N_2 readily gave the *trans* complex (ν(CO) 1967 cm^{-1}). When a solution of **1***b* in benzene was treated with CO the material isolated was of a different shade of yellow from **1***b*, and the ir spectrum also differed from that of **1***b*. Similarly, attempted preparation of **1***c* under CO, or treatment of **1***c* with CO, gave in each case a novel material, the carbonyl band in the ir spectrum of which coincides with that reported for "*cis*-$[RhI(CO)(PPh_3)_2]$".

The chloro complex giving rise to the ir band at 1990 cm^{-1}, and the new materials obtained by treating **1***b* or **1***c* with CO, are all stable in solution if maintained under an atmosphere of CO. They are assigned the structure $[RhX(CO)_2(PPh_3)_2]$ on the basis of elemental analyses, the following ^{13}C and ^{31}P nmr spectroscopic evidence, and by comparison of the spectroscopic parameters of complexes **1***a* and **2***a* with those of *trans*-$[RhCl(CO)(Ph_2PC_4H_3S)_2]$ and $[RhCl(CO)_2(Ph_2PC_4H_3S)_2]$, respectively (Table 1), which have each been isolated as pure crystals (10).

Solutions of **1***a*, **1***b*, and **1***c* under N_2 were each of a darker hue than the same solutions after treatment with CO, significantly so for **1***c* but only slightly so for **1***a*. The ^{31}P or ^{13}C nmr spectra in each case showed only one environment for either ^{31}P or ^{13}C. In no case was free PPh_3 observed in the ^{31}P nmr spectra of the solutions. Only in the spectrum of **1***c* was a byproduct complex of rhodium observed, which is probably $[RhI(PPh_3)_2]_2$ (6). The ^{31}P nmr spectra of the ^{12}CO complexes **1***a*, **1***b*, or **1***c* in each case showed, as expected, a doublet due to coupling of equivalent ^{31}P nuclei to ^{103}Rh. The spectra of the corresponding ^{13}CO complexes at -50°C each showed a doublet of doublets, due to ^{31}P coupling also to one ^{13}C nucleus. The ^{13}C nmr spectra of **1***a*, **1***b*, or **1***c* each showed a doublet of triplets, confirming that each ^{13}C was coupled to one ^{103}Rh and two equivalent ^{31}P nuclei. The values for **1***a* are consistent with literature values (8).

The ^{31}P nmr spectra of solutions prepared by treatment of solutions of complexes **1***a*, **1***b*, or **1***c* with CO showed that novel complexes **2***a*, **2***b*, or **2***c*, respectively, are formed. The ^{31}P nuclei are in each case chemically equivalent, but the chemical shift and coupling constant to ^{103}Rh of each complex **2** are greatly changed from those of the corresponding complex **1**. For solutions under ^{13}CO each ^{31}P nucleus couples to two equivalent ^{13}C nuclei, observable at -50°C for **2***c*, and at -80°C for **2***b*. For **2***a* broadening of the doublet occurs below -70°C, but coupling to ^{13}C is not resolved. At $+30$°C couplings are not observed due to rapid exchange of ligands. The ^{31}P and ^{13}C nmr spectra of $[RhCl(CO)_2(Ph_2PC_4H_3S)_2]$ differ in a similar manner from those of *trans*-$[RhCl(CO)(Ph_2PC_4H_3S)_2]$ (10) (see Table 1). The ^{13}C nmr spectra of the ^{13}CO-enriched complexes **2***a*, **2***b*, and **2***c* differ from those of **1***a*, **1***b*, and **1***c*. For **2***b* and **2***c* coupling of each ^{13}C nucleus to ^{103}Rh and to two ^{31}P nuclei is resolved. The ^{13}C nmr spectrum of **2***a* remains a singlet to -70°C due to rapid exchange of ligands, but is broad (17.5 Hz) at this temperature. The complexes **2***a*, **2***b*, and **2***c* must be $[RhX(CO)_2(PPh_3)_2]$ because (*i*) the solutions are nonconducting, (*ii*) no free PPh_3 is detected in the ^{31}P nmr spectra, (*iii*) for **2***b* and **2***c* two equivalent ^{31}P nuclei are seen to couple to two equivalent ^{13}C nuclei, and (*iv*) the ^{31}P nmr spectra in no way resemble that of $[RhCl(CO)(Ph_2PCH_2CH_2PPh_2)]$ (P_A: δ_P 97.8 ppm; $^1J_{RhP}$ 158 Hz; P_B: δ_P 76.6 ppm, $^1J_{RhP}$ 124 Hz; $^2J_{P_AB_B}$ 34 Hz) (12).

Large crystals of complex **2***c* are very soft, and light orange–yellow. On standing under an atmosphere other than CO they darken rapidly and steadily to first form yellow–brown **1***c*. Under air **2***c* readily oxidizes within days (c.f. ref. 6). Complex **2***b* is a light yellow, microcrystalline material which appears to be more stable than **2***c* in the solid state. However, in solution it also readily loses 1 mol of CO to form **1***b*. The apparent isomerization of "*cis*-[RhI((CO)-$(PPh_3)_2]$" to **1***c* (6) is now readily understood as loss of CO from **2***c* to form **1***c*.

The ir spectra of complexes **2** are very similar in character to those of **1**, except that the carbonyl and rhodium-ligand bands (Table 2) differ in position and intensity.

The structure of complexes **2** differs from that of the iridium analogs. The complex $[IrCl(CO)_2(PPh_3)_2]$ exhibits two carbonyl bands of similar intensity in the ir spectrum, at 1976 and 1923 cm^{-1} (13), arising from two equatorial carbonyl ligands (14). If complexes **2** were of similar structure, with axial PPh_3 ligands, two carbonyl bands of similar intensity (A_1 and B_2) should also have been observed. Instead, Nujol mulls of complexes **2***a*, **2***b*, and **2***c* each exhibit a single very strong carbonyl band. However, in solution the carbonyl band appears to be an envelope (**2***a*, **2***b*) or broader band (**2***c*). For either a trigonal-bipyramidal structure (Fig. 1), or a *trans*-square-pyramidal structure (Fig. 2), two stretching bands ($A_1 + B_1$) should be ir active, but, for two colinear carbonyl ligands, one stretching band will be weaker than the other. Rapid exchange of ligands (nmr) may include a facile rearrangement between the possible structures. Interconversion of trigonal-bipyramidal

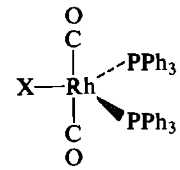

FIG. 1. Trigonal-bypyramidal structure.

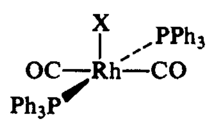

FIG. 2. Square-pyramidal structure.

and square-pyramidal structures occurs for $[RhCl_2(COR)(PPh_3)_2]$ (R = CH_3, CH_2CH_2Ph) (15). Nevertheless, the nmr data for **2** indicate that the trigonal-bipyramidal is the most probable structure, based on a comparison of coupling constants between complexes **1** and **2**. The Rh—C coupling constants for complexes **2** are less than for complexes **1** by 5 to 8%. The Rh—P coupling constants for **2** are less than for **1** by 9 to 27%. For a trigonal-bipyramidal structure with equatorial phosphine ligands and axial carbonyl ligands (Fig. 1) the degree of *s*-character in the equatorial bonds would be expected to drop more in comparison to the corresponding *trans*-square-planar complex than would the *s*-character of the axial bonds. Consequently the Rh—P coupling constant is more greatly reduced than the Rh—C coupling constant.

The existence of complexes **2** has implications for various reactions catalysed by phosphine complexes of rhodium, especially carbonylation and decarbonylation reactions. Under mild conditions $[RhCl(PPh_3)_3]$ is an effective reagent for the stoichiometric decarbonylation of aldehydes and aryl or aroyl halides, but complex **1***a* (which is formed) is not (5, 7, 15, 18). Under more rigorous conditions each material is an effective *catalyst* for such decarbonylation reactions, and intermediates are formed which contain alkyl and hydrido or halogen ligands (15–21). Although the mechanism of the stoichiometric reaction is well understood, the subsequent reactions of **1***a* in the catalytic process, especially elimination of CO, have remained subject to speculation. Catalytic activity is inhibited by the presence of excess PPh_3 (22), and loss of CO from **1***a* is far from facile (23). Consequently it is proposed that catalytic decarbonylation occurs by initial loss of a PPh_3 ligand from **1***a*. Oxidative addition and ligand migration reactions similar to those of the stoichiometric reaction will subsequently afford dicarbonyl complexes, including **2***a*. Elimination of CO from the dicarbonyl complexes will be facile.

The reaction between 2,2-di(4-nitrophenyl)-1,1,1-trifluoroethane and the alkoxide bases $\bar{O}CH_3$, $\bar{O}C_2H_5$, $\bar{O}nC_4H_9$, $\bar{O}CH(CH_3)_2$, and $\bar{O}C(CH_3)_3$ in their corresponding alcohol solvents is a multistep reaction with several intermediates: 2,2-di(4-nitrophenyl)-1,1-difluoro-1-alkoxyethane (A), 2,2-di(4-nitrophenyl)-1-fluoro-1-alkoxyethene (B), 2,2-di(4-nitrophenyl)-1,1-dialkoxyethene (C), 2,2-di(4-nitrophenyl)-1,1-difluoroethene (D), and 4,4′-dinitrobenzophenone (E). Rate constants and activation parameters have been measured for the appearance of the two stable products B and C. The kinetic deuterium isotope effects for the appearance of B fell in the range of k_H/k_D = 1 to 2 at 25°C for the primary and secondary alkoxides, whereas k_H/k_D = 5.4 at 30°C for the appearance of D with *tert*-butoxide. Exchange experiments showed that H/D exchange took place between the substrate and solvent to the extent of 100% with methoxide, 50% with ethoxide and isopropoxide, and 0% with *tert*-butoxide. It is concluded the HF elimination from the substrate follows an $(E1cB)_R$ mechanism with methoxide/methanol, changing to $(E1cB)_I$ or E2 with *tert*-butoxide/*tert*-butanol.

ARNOLD JARCZEWSKI, GRZEGORZ SCHROEDER, WLODZIMIERZ GALEZOWSKI, KENNETH T. LEFFEK et URSZULA MACIEJEWSKA. Can. J. Chem. **63**: 576 (1985).

La réaction du di(nitro-4 phényl)-2,2 trifluoro-1,1,1 éthane avec les alcoolates $CH_3\bar{O}$, $C_2H_5\bar{O}$, $nC_4H_9\bar{O}$, $(CH_3)_2CH\bar{O}$ et $(CH_3)_3\bar{O}$, dans leurs alcools agissant comme solvants, est un processus en plusieurs étapes impliquant plusieurs intermédiaires: di(nitro-4 phényl)-2,2 difluoro-1,1 alkoxy-1 éthane (A), di(nitro-4 phényl)-2,2 fluoro-1 alkoxy-1 éthène (B), di(nitro-4 phényl)-2,2 dialkoxy-1,1 éthène (C), di(nitro-4 phényl)-2,2 difluoro-1,1 éthène (D) et dinitro-4,4′ benzophénone (E). On a mesuré les constantes de vitesse et les paramètres d'activation pour l'apparition des deux produits stables B et C. Pour les alcoolates primaires et secondaires, à 25°C, les effets isotopiques cinétiques du deutérium, k_H/k_D, varient entre un et deux alors que, pour l'apparition de D sous l'influence du *tert*-butylate à 30°C, k_H/k_D = 5,4. Des expériences d'échange ont permis de démontrer qu'il se produit des échanges H/D entre le substrat et le solvant qui vont jusqu'à 100% avec le méthylate, 50% avec l'éthylate et 0% avec le *tert*-butylate. On en conclut que l'élimination du HF à partir du substrat se fait par un mécanisme $(E1cB)_R$ avec le méthylate/méthanol et que le mécanisme évolue vers un mécanisme $(E1cB)_I$ ou E2 avec le *tert*-butylate/*tert*-butanol.

[Traduit par le journal]

Introduction

The reaction between 2,2-di(4-nitrophenyl)-1,1,1-trifluoroethane and alkoxide bases has already been examined (1–4) and found to be a multistep process with several intermediates which exhibit different reactivity.

The reaction between the substrate and methoxide ion in methanol (1) was found to have a product absorbing at λ_{max} = 325 nm which was assigned to the olefin $(O_2NC_6H_4)_2C{=}CF_2$. From the rate of formation of the product and the absence of a primary kinetic isotope effect, a preequilibrium carbanion $(E1cB)_R$ mechanism was proposed.

The reaction of the substrate with *tert*-butoxide in tertiary butanol was found to be a more complex reaction (2) yielding four different products by sequential reactions. The first product, absorbing at λ_{max} = 525 nm, was thought to be the anion produced by proton removal from the substrate, which then decomposed to the difluoroolefin and subsequently to two additional products absorbing at λ_{max} 530 and 625, and 267 nm. However, the isotope effect, k_H/k_D = 1.42 at 26°C on the appearance of the 525 peak was very low for a proton transfer reaction.

The dissimilarity of the reactions with the two bases led to a further study of the methoxide reaction (3) in which it was found that the first product did react further in a slow reaction to give a substituted product di(4-nitrophenyl)ketene dimethyl acetal with λ_{max} = 350 nm.

Since the mechanism of the reaction of the substrate with the alkoxide bases appeared to take place by a set of sequential reactions which differ with the alkoxide/alcohol system, the present study was initiated of the reaction of the substrate with a series of alkoxides in their corresponding alcohols in order to obtain a clear and self-consistent understanding of the mechanism of the whole set of reactions.

Results and discussion

Product analysis

The reaction of the substrate was carried out with the alkoxide bases in the corresponding alcohol solvent with the base in large excess over the substrate. The products were isolated by preparative scale thin-layer chromatography. Each reaction gave several different products, which are summarized in Table 1.

The major features of the mass spectra and nmr spectra for these products for the ethoxide/ethanol reaction are given in Table 2, together with the structures assigned to them.

The product $(O_2NC_6H_4)_2C{=}CF(OR)$, B in Table 2, formed as an intermediate with all the alkoxide bases except *tert*-butoxide, absorbs at λ_{max} = 332 nm. This material was previ-

TABLE 1. Products of the reaction of 2,2-di(4-nitrophenyl)-1,1,1-trifluoroethane with alkoxide bases

Alkoxide base/solvent	No. of products	Product designation
Methoxide/methanol	3	A, B, C
Ethoxide/ethanol	4	A(trace), B, C, D
n-Butoxide/n-butanol	3	B, C, D
iso-Propoxide/isopropanol	4	B, C, D, E(trace)
tert-Butoxide/*tert*-butanol	2	D, E

ously erroneously thought to be the olefin D (1). This intermediate B undergoes further reaction in a slow step with an excess of alkoxide base giving product C, $(O_2NC_6H_4)_2C{=}C(OR)_2$, absorbing at λ_{max} = 358 nm. This is the final product for the methoxide reaction (2). For the other alkoxides, however, the olefin D, $(O_2NC_6H_4)_2C{=}CF_2$ was formed and the amount of this product increased with decreasing dielectric constant of the solvent alcohol used. Thus, the reaction of the substrate with *tert*-butoxide in *tert*-butanol gives the largest amount of olefin D together with the product E, 4,4′-dinitrobenzophenone.

When the olefin D was treated with small amounts of methoxide or ethoxide, the monosubstituted compound B was again obtained.

The complete reaction sequence is shown in Scheme 1.

Kinetic study

The reaction of the substrate to yield B is much faster than the conversion B to C; therefore, it was possible to measure the kinetics of these two processes separately. Pseudo first-order rate constants were determined by measuring the rate of appearance of B by monitoring the growth of the absorption at 325 nm. These rate constants and the derived second-order rate constants for the normal and deuterated substrate with several alkoxide bases are given in Table 3.

In general, the second-order rate constants increase with the chain length of the normal alkoxide/alcohol systems and the secondary systems show larger k_2 values than the primary ones. However, except for the 140-fold change between methoxide (2) and ethoxide, the rate changes are rather modest.

The isotopic rate ratios k_H/k_D for all the systems were small, confirming the k_H/k_D = 1 previously observed for methoxide (1). Thus, for the ethoxide and n-propoxide reactions, where k_H/k_D is unity or very slightly above unity, the elimination of the HF step proceeds by an $(E1cB)_R$ mechanism. For the other alkoxide bases k_H/k_D ranges up to a value of 2, indicating that proton transfer is partially rate determining.

The activation parameters calculated from the second-order rate constants in Table 3 are given in Table 4, together with those previously measured for methoxide. The enthalpy of activation values show a clear differentiation between the primary and secondary alkoxides, and the entropy of activation values are similarly differentiated in a compensating manner so that the free energy of activation shows little variation.

The rate constants for the appearance of the absorption at about 355 nm corresponding to the product C are given in Table 5. The k_2 values are larger for the primary alkoxides than for the secondary ones. The activation parameters derived from these rate constants, given in Table 6, show compensating behaviour and give rise to free energies of activation 1 to 2 kcal mol^{-1} larger for the secondary systems than for the primary.

In order to verify that the olefin D is an intermediate in all the reactions studied, the substrate was reacted with alkoxide bases with the substrate in large excess. It was determined by mass spectroscopy that under these conditions the olefin D is the main product. Therefore, it is assumed that the olefin D is an intermediate under the conditions of an excess of base. Also, the olefin D was isolated and purified, then used to follow the reaction kinetically from D to product B by again monitoring the appearance of the absorption at 325 nm. The rate constants are shown in Table 7 for the reaction with methoxide, ethoxide, and isopropoxide bases. The second-order rate constants are at least three times larger than the corresponding rate constant for the trifluoro substrate so that the rate constants and activation parameters in Tables 3 and 4 must refer to the elimination of the HF step from the substrate to form the olefin D. In the case of methoxide, the rate of reaction of the olefin D is 2000 times that of the trifluoro substrate, so that in this reaction no D product was observed (Table 1).

In a previous paper (1) it was concluded from the isotope effect of unity and from exchange experiments that the trifluoro substrate reacts with methoxide in methanol by an $(E1cB)_R$ mechanism. The exchange experiment was repeated with methoxide, ethoxide, isopropoxide, and *tert*-butoxide. The reaction of deuterated substrate was carried out with a 10-fold molar excess over the alkoxide base and the degree of deuteration remaining in the substrate was determined by mass spectroscopy. The substrate was completely exchanged in the methoxide reaction, about 50% exchanged in the ethoxide and isopropoxide reactions, and almost completely deuterated in the *tert*-butoxide reaction.

Therefore, the mechanism of the HF elimination from the trifluoro substrate is $(E1cB)_R$ for methoxide/methanol and gradually becomes more $(E1cB)_I$ or E2 with secondary and tertiary bases. The activation parameters in Table 4 show characteristically high $\Delta H^{\neq}$ values for the removal of F^- for the primary alkoxides and much smaller $\Delta H^{\neq}$ values for the secondary bases characteristic of proton abstraction reactions (5).

The solvent isotope effects for the reaction of the substrate leading to the product B were measured in methanol-*d* and ethanol-*d*. At 25°C, k_{2H} in methanol-*d* is 0.97 dm^3 mol^{-1} s^{-1}, which, when combined with the previous measurement (4) of 0.30 for the normal solvent, gives $k_{2H}(CH_3OD)/k_{2H}(CH_3OH)$ = 3.2. For ethanol at 20°C the K_{2H} value from Table 3 is 30.8 and the corresponding value in ethanol-*d* was measured as 31.0,

giving $k_{2H}(C_2H_5OD)/k_{2H}(C_2H_5OH) = 1.0$. These results are also consistent with an $(E1cB)_R$ mechanism for methoxide and $(E1cB)_I$ or E2 for ethoxide.

The tert-*butoxide*/tert-*butanol reaction*

The reaction of the substrate with *tert*-butoxide in *tert*-butanol gives markedly different products from the other systems in that no significant amount of substituted olefins are produced. It was previously reported (3) that the *tert*-butoxide reaction goes via a stable carbanion to olefin D and then to butoxy substituted compounds.

It has now been discovered that the products of the reaction with *tert*-butoxide in *tert*-butanol are very dependent on the purity of the solvent. In particular a very small amount of secondary or primary alcohol as impurity causes the reaction of the olefin D to produce the substituted olefins B and C.

When very carefully purified *tert*-butanol was used, the only products which could be detected by thin-layer chromatography were the olefin D and 4,4′-dinitrobenzophenone. With the *tert*-butoxide in large excess over the substrate, this reaction gave a violet colour with a broad absorption band with maxima at 525 nm and 430 nm. No maxima at 332 or 358 nm were observed, but upon the addition of a small amount of either primary or secondary alcohol the 332-nm peak developed rapidly. The larger the excess of *tert*-butoxide used, the greater was the proportion of 4,4′-dinitrobenzophenone in the product.

The rate of the elimination reaction of the substrate with *tert*-butoxide to yield the olefin D was measured by following the appearance of the absorption at 290 nm. This fast reaction was measured with the stopped-flow spectrophotometer at five different base concentrations and yielded $k_2 = 2.51 \pm 0.07 \times 10^3$ dm^3 mol^{-1} s^{-1} at 30°C.

The rate of reaction of the olefin D with *tert*-butoxide was determined using a pure sample of D and monitoring the disappearance of the absorption at 290 nm. This reaction is considerably slower and gave $k_2 = 49$ dm^3 mol^{-1} s^{-1} at 30°C.

The rate of appearance of the coloured species (λ_{max} 525 nm) from the trifluoro substrate was measured previously (3) and the value of k_2 as 25 dm^3 mol^{-1} s^{-1} at 30°C was confirmed in this work.

Thus, the trifluoro compound undergoes a fast elimination reaction to yield the difluoro-olefin D, which subsequently reacts with the excess *tert*-butoxide in slower processes to yield violet-coloured species which are eventually oxidized to 4,4-dinitrobenzophenone.

If the elimination mechanism is $(E1cB)_I$ or E2 as concluded above, the rate of appearance of the olefin D at 290 nm should show a primary deuterium isotope effect. The deuterated substrate gave a k_{2D} of 464 ± 9 dm^3 mol^{-1} s^{-1} at 30°C to yield a primary isotope effect $k_H/k_D = 5.4 \pm 0.2$ at 30°C. Thus,

the primary deuterium isotope effects and the deuterium exchange experiments indicate that the HF elimination mechanism for 2,2-di(4-nitrophenyl)-1,1,1-trifluoroethane is $(E1cB)_R$ with methoxide/methanol, changing to $(E1cB)_I$ or E2 with *tert*-butoxide/*tert*-butanol.

Experimental

Materials

2,2-Di(4-nitrophenyl)-1,1,1-trifluoroethane and its deuterated analogue were prepared by reduction of α,α,α-trifluoroacetophenone (Aldrich, bp 165−155°C) in dry ether by $LiAlH_4$ or $LiAlD_4$ (6) to yield the carbinol, which was dissolved in a four-fold molar excess of benzene and cooled to 0°C. Then 102% oleum was added dropwise with vigorous stirring, and the product 2,2-di(phenyl)-1,1,1-trifluoroethane was isolated.

The nitration of the phenyl groups was accomplished according to the method of Skerrett and Woodcock (7) using fuming nitric acid at −30°C. The raw 2,2-di(4-nitrophenyl)-1,1,1-trifluoroethane was recrystallized from methanol to yield light yellow crystals of mp 117°C.

The alcohols were purified by standard methods using fractional distillation under oxygen-free dry nitrogen. The *tert*-butanol was purified as above and only the middle fraction distilling at 82.4°C was collected.

The olefin $(O_2NC_6H_4)_2C{=}CF_2$ (D) was prepared by the reaction of 2,2-di(4-nitrophenyl)-1,1,1-trifluoroethane with a three molar excess of t-BuO̅ in t-BuOH. The products of the reaction were purified by thin-layer chromatography using benzene as the eluent. The mass spectra and λ_{max} data are given in Table 2.

Kinetic measurements

The reaction rates were measured using a Specord uv-vis and a stopped-flow spectrophotometer, fitted with a temperature controlled cell block.

The technique and calculations were as previously described (1,8).

The crystal structures of the title compounds have been determined from X-ray data collected on a four-circle diffractometer and refined by the full-matrix least-squares method. The former compound crystallizes in the orthorhombic system, space group *Pbcn*, with a = 14.346(8), b = 7.239(1), c = 17.276(2) Å, and has been refined to a conventional R factor of 0.043 for 890 observed reflections. Corresponding results for the latter compound are monoclinic, $P2_1/n$, a = 12.222(4), b = 7.482(2), c = 14.170(8) Å, β = 94.06(4)°, R = 0.060 for 2128 observed data. The triazine rings of both compounds exhibit short N(1)—N(2) bonds and tetrahedral geometry at C(4); however, the ring is puckered in the first compound but flat in the second. Molecules in both crystals are linked by O(4)—H···N(1) hydrogen bonds.

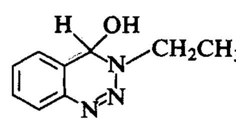
KWONG KHEE LAI, CARL H. SCHWALBE, KEITH VAUGHAN, RONALD J. LAFRANCE et CLIVE D. WHISTON. Can. J. Chem. **63**, 581 (1985).

Faisant appel à des données de rayons-x obtenues à l'aide d'un diffractomètre à quatre cercles et affinées par la méthode des moindres carrés (matrice complète), on a déterminé les structures cristallines des composés mentionnés dans le titre. Le premier composé cristallise dans le système orthorhombique, groupe d'espace *Pbcn*, avec a = 14,346(8), b = 7,239(1), c = 17,276(2) Å et on a affiné sa structure jusqu'à un facteur R de 0,043 pour 890 réflexions observées. Les résultats correspondants pour le dernier composé sont: monoclinique, $P2_1/n$, a = 12,222(4), b = 7,482(2), c = 14,170(8) Å, β = 94,06(4)°, R = 0,060 pour 2128 réflexions observées. Les cycles triazines des deux composés sont caractérisées par des liaisons N(1)—N(2) qui sont courtes et une géométrie tétraédrique en C(4); toutefois, alors que le cycle du premier composé est plissé, celui du deuxième est plan. Dans chacun des cristaux, les molécules sont rellées par des liaisons hydrogènes O(4)—H···N(1).

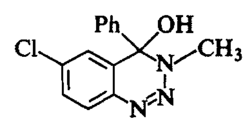
[Traduit par le journal]

Introduction

This paper describes the X-ray crystal structure determination of 3-ethyl-4-hydroxy-1,2,3(4*H*)-benzotriazine (**1**) and 6-chloro-4-hydroxy-3-methyl-4-phenyl-1,2,3-benzotriazine (**2**).

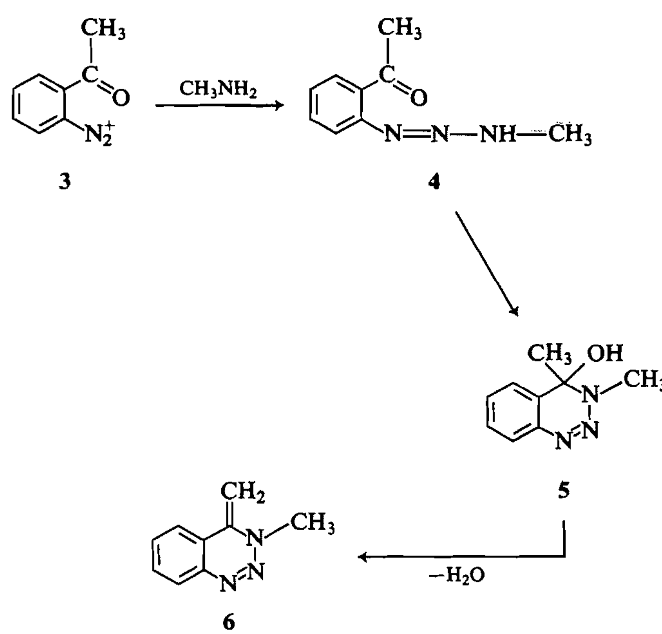


1



2

Interest in the chemistry of the 4-hydroxy-1,2,3-triazines was stimulated by the study of Fong and Vaughan (1) in which the diazonium salt (**3**) from *o*-aminoacetophenone was coupled with an excess of aqueous methylamine. The initial coupling product, the monomethyltriazene (**4**), could not be isolated due to the facility of the cyclodehydration of **4** to give the novel methylenetriazine (**6**). The intermediate 4-hydroxy-1,2,3-benzotriazine (**5**), itself a novel heterocyclic structure, could not be isolated from this reaction. An alternative route to **6**, via the reaction of methyl magnesium bromide with 3-methyl-4-oxo-1,2,3(4*H*)-benzotriazine, likewise proceeds directly without isolation of **5** (2).



3 **4** **5** **6**

Stable 4-hydroxytriazines should be available from analogous reactions with diazonium salts in which the *o*-acyl group is lacking the α-hydrogen necessary for the dehydration step **5** → **6**. Indeed it has now been shown (3) that coupling the diazonium salt from *o*-aminobenzaldehyde (**7***a*) or *o*-aminobenzophenone (**7***b*) with alkylamines leads to stable

crystalline 4-hydroxytriazines (**9**) via the apparently unstable monoalkyltriazene (**8**). The spectroscopic characteristics of these products definitely point to the cyclic structure **9**, rather than the valence tautomer **8**. The elucidation of the crystal structures of representative examples of both types of triazine, **1** and **2**, was undertaken (*a*) to verify the heterocyclic structure of the molecules, (*b*) to ascertain the nature of the stereochemistry at the C-4 chiral centre of molecules of type **9**, and (*c*) to compare with the structures of other benzo-1,2,3-triazines.

Experimental

The title compounds **1** and **2** were prepared and recrystallized as in ref. 3. The specimen of **1** chosen for crystallographic analysis was a laterally elongated hexagonal prism $0.9 \times 0.3 \times 0.25$ mm^3, and that of **2** was a tabular crystal $1.0 \times 0.6 \times 0.25$ mm^3. Unit cell dimensions were obtained by least-squares analysis of the setting angles of 25 reflections measured on an Enraf-Nonius CAD4 diffractometer.

Crystal data for 1
$C_9H_{11}N_3O$ fw = 177.21
Orthorhombic, space group *Pbcn* (D_{2h}^{14}, No. 60), $a = 14.346(8)$, $b = 7.239(1)$, $c = 17.276(2)$ Å, $V = 1794.1$ Å^3, $Z = 8$, $\rho_c = 1.31$ g cm^{-3}, $\mu(\text{MoK}\alpha) = 0.54$ cm^{-1}, $\lambda = 0.71069$ Å, $t = 20$°C.

Crystal data for 2
$C_{14}H_{12}ClN_3O$ fw = 273.73
Monoclinic, space group $P2_1/n$ (C_{2h}^5, No. 14), $a = 12.222(4)$, $b = 7.482(2)$, $c = 14.170(8)$ Å, $\beta = 94.06(4)$°, $V = 1292.5$ Å^3, $Z = 4$, $\rho_c = 1.41$ g cm^{-3}, $\mu(\text{MoK}\alpha) = 2.43$ cm^{-1}, $\lambda = 0.71069$ Å, $t = 18$°C.

Intensity data for both structures were measured by the $\omega-2\theta$ scan method between $2° \le \theta \le 25°$ with graphite-monochromated MoKα radiation. Data for **2** were collected under conditions of minimum absorption by using the Enraf-Nonius option "FLAT" (for paths parallel to a crystal edge the maximum and minimum transmission factors for *F* are 0.970 and 0.886). The ω scan angle was $(1.0 + 0.35 \tan\theta)°$ for **1** and $(1.2 + 0.35 \tan\theta)°$ for **2** extended on each side by 25% for background measurement. The scan rate was set from 0.8 to 3.3 deg min^{-1} for **1** and 1.3 to 4.0 deg min^{-1} for **2**, depending on the intensity of a particular reflection. Two standard reflections were remeasured every 3600 s; for **1** these changed negligibly with time. However, for **2** they declined by about one-quarter during data collection, and a linear correction factor for intensity versus time was derived from them and applied to all reflections. Data were corrected for Lorentz and polarization effects but not for absorption or extinction. Estimated standard deviations σ were assigned on the basis of counting statistics and an allowance of $0.02F_o$ for the minimum expected instability of the diffractometer. For **1**, 1580 unique reflections were measured, of which 890 were considered observed ($F > 3\sigma$). For **2** 3349 reflections were collected, of which 2828 were unique ($R_{int} = 0.091$) and 2128 observed.

Structure determination and refinement

Both structures were solved by direct methods: **1** by the EEES routine in SHELX (4) and **2** by MULTAN (5). All the non-hydrogen atoms of **1** and all but one phenyl carbon atom of **2** were located in *E*-maps; this missing atom was found after calculation of structure factors and an electron density map. Least-squares refinement ensued under the following conditions: SHELX system, scattering factors stored therein, refinement to minimize $\Sigma w(|F_o| - |F_c|)^2$. Positions and isotropic temperature factors were first refined for the non-hydrogen atoms with unit weights for all observed reflections. All hydrogen atoms of **1** and some hydrogen atoms of **2** (including the hydroxyl hydrogen atom) were revealed by difference electron density maps. In the final refinement cycles for both structures the parameters were refined until no shift exceeded 0.195 esd and the observed reflections were weighted by $w = k/[\sigma^2(F_o) + gF_o^2]$, where *k* converged to 1.4946 for **1** and 3.2435 for **2** and *g*, representing unexpected additional instrument instability, refined to 0.000213 for **1** and 0.000248 for **2**. For **1** the parameters refined included a scale factor, coordinates and anisotropic thermal parameters for non-hydrogen atoms, and coordinates and isotropic temperature factors for hydrogen atoms. Similar parameters were refined in **2**, but all benzene ring hydrogen atoms were assumed to ride on their attached carbon atom at a distance of 1.080 Å, and the hydrogen atoms of the 3-methyl group were subjected to constraints on their C—H, H···H, and N(3)···H distances. The 1 7 8 reflection was eliminated from the data set of **2** because F_o was only 40% of F_c, a discrepancy of 17σ, and impairment of the measurement due to temporary loss of beam intensity or physical obstruction is suspected. The final discrepancy indices were $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.043$ for **1** and 0.058 for **2**, and $R_g = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.046$ for **1** and 0.081 for **2**.

No peak on a final difference Fourier synthesis for **1** exceeded 0.15 e Å^{-3}. Although a similar map of **2** contained residual peaks as high as 0.56 e Å^{-3}, these were near the chlorine atom and elsewhere no peak exceeded 0.27 e Å^{-3}. Final atomic coordinates are given in Tables 1 and 2. The molecules are displayed in Figs. 1 and 2. Measured and calculated structure factors, anisotropic thermal parameters for non-hydrogen atoms, and parameters for phenyl and alkyl hydrogen atoms have been deposited.[4]

*Equivalent isotropic temperature factors are calculated from anisotropic thermal parameters by the equation $U_{eq} = (1/3)(U_{11} + U_{22} + U_{33})$.

Discussion

The 4-hydroxybenzotriazine structure for **1** and **2** established from spectra (3) is confirmed here. These molecules may be

[4]These tables are available at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

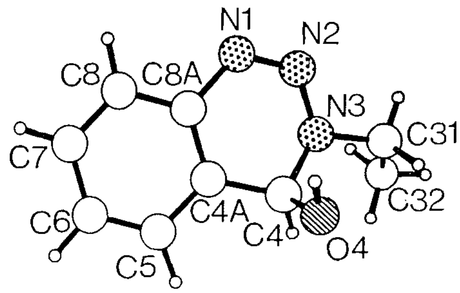

FIG. 1. The molecule of 3-ethyl-4-hydroxy-1,2,3(4*H*)-benzotriazine projected onto its least-squares plane, showing the numbering scheme. Nitrogen atoms are stippled and oxygen atoms hatched.

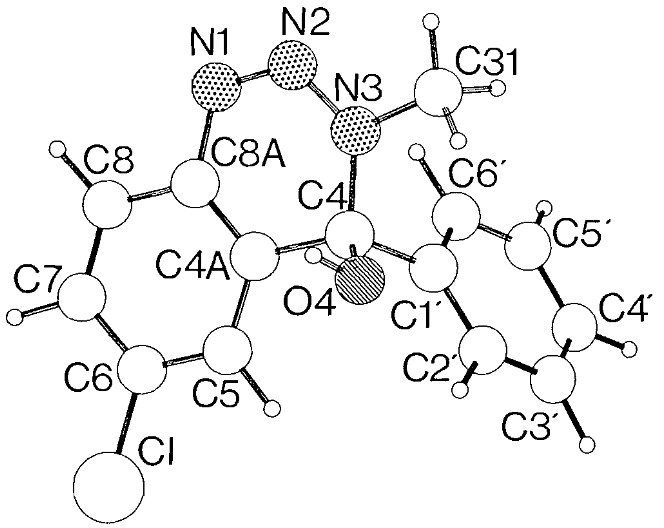

FIG. 2. The molecule of 6-chloro-4-hydroxy-3-methyl-4-phenyl-1,2,3-benzotriazine in projection onto its least-squares plane. Nitrogen atoms are stippled and oxygen atoms hatched.

regarded as 1-aryl-3,3-dialkyltriazenes, one of whose 3-alkyl groups has been tied back to the ring. Bond distances (Table 3) and bond angles (Table 4) can be compared with those in a series of open-chain triazenes: 1-*p*-tolyl-3-methyltriazene (6), 1-(4-carbethoxyphenyl)-3-hydroxymethyl-3-methyltriazene (7), 2-(3,3-dimethyl-1-triazeno)phenyl-1-carboxamide (8), and two independent tautomers of 5-(3,3-dimethyl-1-triazenyl)imidazole-4-carboxamide (9) and its hydrochloride (10). The title compounds may also be regarded as reduced forms of 1,2,3-benzotriazin-4(3*H*)-ones (henceforth abbreviated triazinones), for which crystal structure determinations exist on 1,2,3-benzotriazin-4(3*H*)-one (11), 3-hydroxy-1,2,3-benzotriazin-4(3*H*)-one (12), and *O*,*O*-dimethyl-*S*-(4-oxo-1,2,3-benzotriazin-3-yl) methyl phosphorodithioate (13).

The N(1)—N(2) bond remains very strong across this entire series of compounds: 1.268(3) Å in **1**, 1.263(3) Å in **2**, an average of 1.281 Å over the independent molecules of the triazenes, and an average of 1.255 Å in the triazinones. The N(2)—N(3) bond is affected little by ring closure: 1.333(3) Å in **1**, 1.316(3) Å in **2**, and 1.325 Å in the triazenes. However, introduction of conjugation at C(4) considerably weakens this bond; for N(2)—N(3) is 1.385 Å in the triazinones. The "natural" bond angles averaging 112.1° at N(1) and 113.8° at N(2) in the unrestrained triazenes are increased by ring closure to 120.0(2)° and 119.3(2)° at N(1) and 120.3(2)° and 122.3(2)° at N(2) in **1** and **2** respectively. Oxidation at C(4) has little effect on these angles: they are 120.3° at N(1) and 118.6° at N(2) in the triazinones.

In both **1** and **2** carbon atom C(4) shows the expected tetrahedral geometry. In the relatively uncrowded **1** the OH group is able to avoid both the 3-ethyl substituent and the fused ring by increasing the O—C(4)—N(3) and O—C(4)—C(4A) angles above tetrahedral values to 111.3(2)° and 113.4(3)°. The requirement to accommodate a phenyl group in **2** and the dim-

inution of the 3-substituent to methyl allow the OH group to move closer to N(3): O—C(4)—N(3) is 109.7(2)° while O—C(4)—C(4A), Ph—C(4)—N(3), and Ph—C(4)—C(4A) are 112.6(2)°, 108.8(2)°, and 111.2(2)°, respectively. In **1** the single bond C(4)—C(4A) is only 1.475(4) Å long; in **2** this increases to 1.507(3) Å.

Torsion angles (Table 5) show that the degree of planarity is quite different in these two molecules. In the triazine ring of **1** there are deviations from pure *cis* geometry of 22° about N(2)—N(3) and 35° about N(3)—C(4). In **2** these alterations are only 2°. Apparently the unconjugated triazine ring in these systems is flexible. In **1** it distorts, allowing the C(31)···O(4) contact to reach 3.025(4) Å. The distortion is not simply a

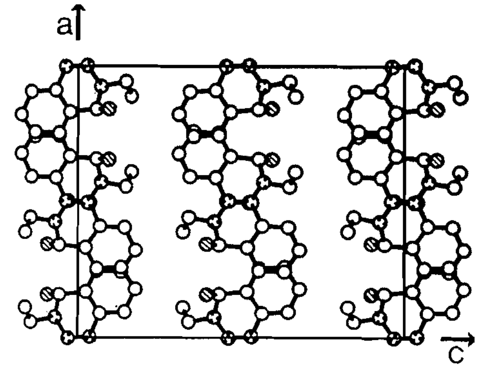

FIG. 3. Packing of molecules of 3-ethyl-4-hydroxy-1,2,3(4*H*)-benzotriazine in the unit cell viewed down b with hydrogen atoms omitted for clarity.

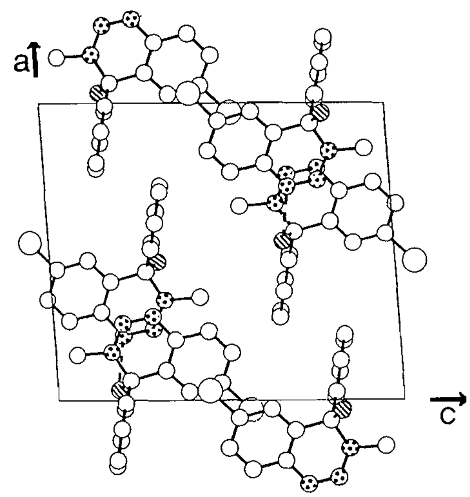

FIG. 4. Packing of molecules of 6-chloro-4-hydroxy-3-methyl-4-phenyl-1,2,3-benzotriazine in the unit cell viewed down b. The O(4)—H···N(1) hydrogen bonds are shown by dashed lines. All hydrogen atoms have been omitted for clarity.

twisting of bonds N(2)—N(3) and N(3)—C(4); some pyramidalization of N(3) is also involved since the deviation of N(3) from the plane of N(2), C(4), and C(31), the atoms bonded to it, is 0.164(4) Å. However, in **2** the 3-substituent is sandwiched between the 4-hydroxyl and 4-phenyl moieties at C(31)···O(4) and C(31)···C(1′) contact distances of 2.870(4) and 3.022(4) Å. Apparently there is no energy gain from distorting the ring since one contact would be relieved only at the expense of the other. The deviation of N(3) from the plane of the atoms bonded to it is only 0.015(4) Å in **2**.

As expected, the OH group in each molecule acts as a proton donor in an intermolecular hydrogen bond. Of the various proton acceptors available, N(1) plays this role in both molecules. The OH···N distance and O—H···N angle are 2.842(4) Å and 169° in **1**, 2.778(3) Å and 180° in **2**. Although these hydrogen bonds are similar in **1** and **2**, the mode of association is quite different (Figs. 3 and 4). Molecules of **1** dimerize about a center of symmetry with the heterocyclic rings resembling two treads of a staircase and the N(1)···N(1)′ contact being only 3.139(3) Å. The hydroxyl group of each molecule is turned back over its own ring so that it can associate with N(1) of the other ring. In **2** the hydrogen-bonded contact is generated by the action of a screw axis, thereby producing chains of molecules. The presence of centers of symmetry within the unit cells of both **1** and **2** guarantees that the populations of these chiral molecules are equal.

Crystal structures of tetrakis(ammoniomethyl)methane tetrachloride, $C(CH_2NH_3)_4Cl_4$, and disulfate, $C(CH_2NH_3)_4(SO_4)_2$

T. STANLEY CAMERON, WALTER J. CHUTE, AND OSVALD KNOP[1]
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received April 18, 1984

T. STANLEY CAMERON, WALTER J. CHUTE, and OSVALD KNOP. Can. J. Chem. **63**, 586 (1985).

The crystal structures of $C(CH_2NH_3)_4Cl_4$ ($P4_2/n$, a = 9.503(1) Å, c = 6.549(1) Å, Z = 2) and $C(CH_2NH_3)_4(SO_4)_2$ ($P2_12_12_1$, a = 8.382(2) Å, b = 10.508(3) Å, c = 14.400(3) Å, Z = 4) have been determined. Both crystals contain strong N—H···X bonds; in the sulfate the hydrogen-bonding network is particularly extensive. The thermal motion of the cation can be described satisfactorily as a rigid-body motion.

T. STANLEY CAMERON, WALTER J. CHUTE et OSVALD KNOP. Can. J. Chem. **63**, 586 (1985).

On a déterminé les structures cristallines du $C(CH_2NH_3)_4Cl_4$ ($P4_2/n$, a = 9,503(1), c = 6,549(1) Å, Z = 2) et du $C(CH_2NH_3)_4(SO_4)_2$ ($P2_12_12_1$, a = 8,382(2), b = 10,508(3), c = 14,400(3) Å, Z = 4). Les deux cristaux contiennent de fortes liaisons N—H···X; dans le sulfate, le réseau des liaisons hydrogènes est particulièrement étendu. Utilisant le mouvement d'un corps rigide comme modèle, on peut décrire adéquatement le mouvement thermique du cation.

[Traduit par le journal]

The high symmetry of "globular" $C(CH_2X)_4$ molecules and the regular tetrahedral configuration at the central carbon atom have made pentaerythritol and its derivatives and cognates the subjects of numerous structural and other investigations (cf. ref. 1 and Table 1). Most of the crystals listed in Table 1 are molecular, and easy molecular reorientation and the occurrence of plastic phases in these compounds are not surprising. What would be less expected is the existence (5) of a plastic phase in pentaerythritol itself (X = OH), where at room temperature the molecules are bonded to sheets parallel to (001) by strong, only weakly bent O—H···O bonds, d(O···O) ~ 2.71 Å, d(H···O) ~ 1.9 Å, OHO ~ 163° (9–15). At 457 K the ordered crystal goes over into a plastic phase of cubic symmetry; the volume per formula unit of this phase is about the same as for neopentane (X = H), but the strong resistance to thermal breakdown of the order in the pentaerythritol crystal is reflected in the much higher T_{tr} (Table 1).

In view of the possibility that other, not purely molecular (and in particular ionic) crystals containing globular units of this type may exhibit unusual behaviour, we have undertaken an exploratory survey of several such compounds. The crystal structures of the first two, $C(CH_2NH_3)_4Cl_4$ and $C(CH_2NH_3)_4(SO_4)_2$, are reported in the following. The hydrogen bonding in both crystals is of interest in its own right, particularly as it involves a compact quadruply-charged cation.

The chloride was investigated crystallographically as early as 1938 by Cox, whose preliminary report (24) stated it correctly to be tetragonal, a = 9.44 Å, c = 6.53 Å, space group $P4_2/n$, with the central carbon on an S_4 axis. However, no mention of a completed structure determination could be found in the literature. The sulfate does not appear to have been investigated previously.

Experimental

The title compounds were prepared by the method described by Litherland and Mann (ref. 25; cf. also ref. 26). The chloride was recrystallized by dissolving it in a minimum volume of distilled water and allowing HCl from 36% aqueous acid to diffuse into the filtered solution.

The sulfate is only slightly soluble in water, but it dissolves in concentrated sulfuric acid (25). In an early attempt to obtain crystals suitable for X-ray studies H_2O + EtOH vapour was allowed to diffuse into a solution of the sulfate in 80% sulfuric acid placed in a desiccator. The crystals that formed were of inferior quality and crystallization by slow evaporation at room temperature of a hot-saturated aqueous solution of the sulfate was eventually resorted to, yielding gem-like crystals. Surprisingly, the material obtained from the sulfuric solution led to a tetragonal unit cell, a = 7.549(6) Å, c = 26.87(2) Å, c/a = 3.56, V = 1521(4) Å^3. The identity of this compound was not investigated further.

According to ref. 25, the chloride appears to remain unaffected up to 300°C when heated rapidly; on slow heating it decomposes above ca. 260°C. The mp of the sulfate is reported to be 303°C (dec.).

$C_5H_{20}N_4O_8S_2$ fw = 328.36
Orthorhombic, $P2_12_12_1$ (No. 19; systematic absences, $h00$ for $h = 2n + 1$, $0k0$ for $k = 2n + 1$, $00l$ for $l = 2n + 1$); a = 8.382(2) Å, b = 10.508(3) Å, c = 14.400(3) Å, V = 1268.3(9) Å^3, Z = 4, ρ_c = 1.720 g/cm^3; μ_{Mo} = 4.00 cm^{-1}, $F(000)$ = 696 e. Total reflections measured, 1049; unique reflections, 1035 (of which 908 with $I \geq 3\sigma(I)$). Final R = 0.056, R_w = 0.060 (R = 0.060 for full data).

Structure determination

A CAD-4 four-circle diffractometer was used in the determination of the unit-cell dimensions and to collect intensities. The intensities were reduced by routine procedures (27). Corrections for Lorentz and polarization factors were applied but not for absorption or extinction. The scattering factors for neutral atoms were taken from ref. 28. The structures were solved by Patterson and Fourier methods using the SHELX system (29). Full-matrix least-squares ($w\Delta F^2$ = min.) refinements were carried out with isotropic temperature factors on the heavy atoms until R was reduced to a suitably low value. The locations of the hydrogen atoms were determined according to their geometric requirements: the C—H, N—H, and H—H distances were appropriately constrained (29) to ensure convergence (C—H to 1.08 Å, N—H to 1.02 Å, and H—H to ~1.66 Å), and the NH_3 groups were refined as rigid groups rotationally adjustable about the C—N axis.

The final refinement was with anisotropic temperature factors on the nonhydrogen atoms and isotropic factors on the hydrogens. Least-

*Temperatures in K; S.G., space group; V_1, volume per formula unit, Å^3; λ, λ-point; F, first-order transition. The first set of references concerns crystallographic and the second, caloric data.

†Z = 1 cannot be correct for an ordered crystal. A preliminary re-examination of the bromide at room temperature has indicated a monoclinic unit cell with double the c-dimension reported in ref. 6 (a = 7.127 Å, b = 6.287 Å, c = 10.796 Å, β = 104.23°, Z = 2; probable space group, $P2_1/n$), but even this may be a subcell of the real unit cell.

‡ADDENDUM TO TABLE 1. The structure of $C(CH_2ONO_2)_4$ was recently re-refined from the data of ref. 17 (36). The $\bar{4}$ molecular symmetry is not retained in the structure of pentaerythrityl tetracinnamate: $P\bar{1}$, Z = 2, V_1 = 987 Å^3 (37).

*U_{iso}. The NH_3 group was refined as a rigid body.

squares weights were calculated from expressions of the type $w^{-1} = k_1\sigma^2|F_o| + k_2F_o^2$, where σ is the weight for an individual reflection derived from the diffractometer counting statistics. The anisotropic temperature factor is defined as $T = \exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{23}klb^*c^* + 2U_{13}hla^*c^* + 2U_{12}hka^*b^*)]$.

The positional and thermal parameters are listed in Tables 2, 6, and 7[2], structure factors in Tables 3[2] and 8[2], and interatomic distances and bond angles in Tables 4, 5, 9, and 10.

Results and discussion

$C(CH_2NH_3)_4Cl_4$

A projection of the structure is shown in Fig. 1. Like in pentaerythritol at room temperature and in some of its derivatives (Table 1), the high symmetry of the central tetrahedral group of the cation is reflected in the symmetry of the crystal: the space group contains the element $\bar{4}$ characteristic of the maximum-symmetry conformation of the $C(CH_2X)_4$ molecule, and the cation is on this axis.

The cations and anions are arranged in layers ∥ (001). The side chains of the cations are folded flat and inward in such a way (Fig. 2) that the thickness of each cation/anion slab (as defined by the atomic coordinates of C and N) does not exceed 2 Å. The slabs are separated by vertical gaps, a little over 1 Å wide, which contain the CH_2 hydrogens.

Each N-hydrogen is involved in H···Cl bonding to one or more Cl^- ions (Fig. 2, top; Table 5). The shortest of these hydrogen bonds, H(1)···Cl = 2.15(3) Å, is almost straight and not much longer than the H···Cl bond in $Et_3NH^+Cl^-$, 2.08 Å (30), where the N—H···Cl group is linear by symmetry.

The H(2)···Cl bond is asymmetrically trifurcated and the H(3)···Cl bond, asymmetrically bifurcated. However, one of the NHCl angles in the trifurcated and one in the bifurcated bond are only 100°, and the H···Cl distances corresponding to these angles are about 2.8 Å. The N—H(2)···Cl bond may then equally well be regarded as an asymmetrically bifurcated, nonplanar N—H(2)···2 Cl bond, and the N—H(3)···Cl bond

[2]These tables have been deposited. Complete set of data is available, at a nominal charge, from the Depository of Unpublished data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

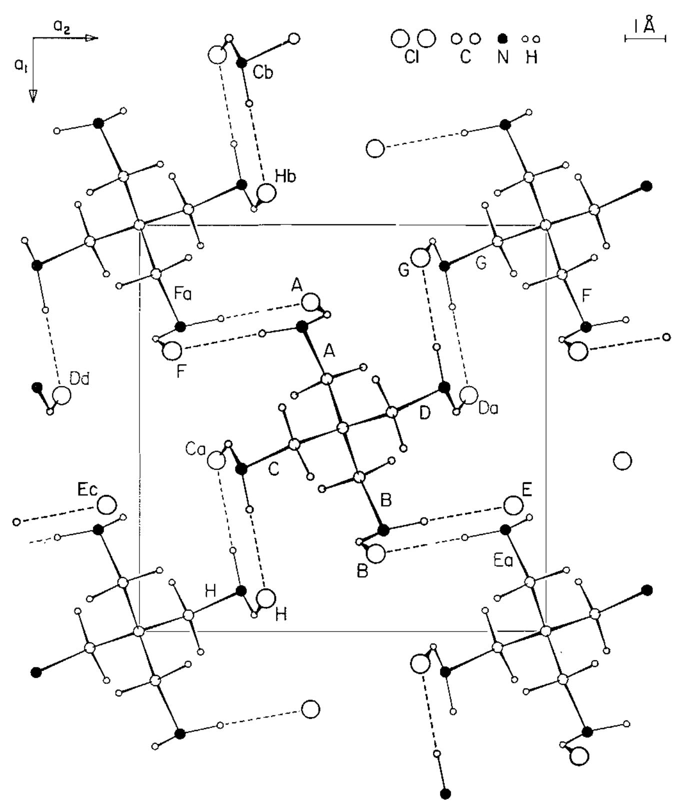

FIG. 1. Projection of the $C(CH_2NH_3)_4Cl_4$ structure on (001). The H(2) N-hydrogens are not shown. The shortest hydrogen bonds, H(1)···Cl, are indicated by broken lines; because of their shortness in the projection the H(3)···Cl bonds are shown as solid lines or not at all. For symmetry code see Table 4.

could similarly be described as a highly-bent hydrogen bond to a single acceptor atom.

Each Cl^- ion is surrounded by six N-hydrogens, with Cl···H distances ranging from 2.15 to ~2.8 Å (Fig. 2, bottom). The cations and the Cl^- ions in the cation/anion slabs ‖ (001) are connected by the N—H(1)···Cl bonds, with participation of the much longer N—H(2)···Cl bonds. The slabs are cross-linked vertically by the N—H(3)···Cl bonds, which are more or less parallel to the c-axis.

The overall cation/anion packing scheme and the organization of this $A^{4+}X^-_4$ structure can be visualized more directly by considering the structure to be composed of tetragonally compressed Cl_{12} cuboctahedra packed in such a way that each Cl atom is shared by three adjacent cuboctahedra (Fig. 3). The centre of each cuboctahedron is occupied by the central carbon C(1), and the N atoms are slightly inward of the centres of the vertical faces. The N—H(1)···Cl bonds are then approximately parallel to the (001) plane and the N—H(3)···Cl are roughly parallel to the c-axis.

$C(CH_2NH_3)_4(SO_4)_2$

In this chiral $A^{4+}X^{2-}_2$ structure (Fig. 4) the cation does not display its characteristic tetragonal symmetry. The cation/anion packing can be described as being of a very distorted fluorite type. There are two nonequivalent sets of SO_4^{2-} ions in the structure; the mean uncorrected S—O bond length is 1.465(6) Å (Table 9).

The cations and the sulfate groups are interconnected by an exhaustive three-dimensional system of hydrogen bonds (Fig. 5). Every N-hydrogen forms a H···O bond to a single acceptor, the H···O distances ranging from 1.74(10) to 2.14(10) Å, and the NHO angles from 126(5)° to 170(5)° (Table 10). The two shortest H···O distances, H(21)···O(3)

= 1.74(10) Å and H(31)···O(8) = 1.76(11) Å, are significantly shorter than the H···O distances in pentaerythritol, 1.983(23) Å (14), while the corresponding NHO angles, ~160°, are comparable to the OHO angle in pentaerythritol, 163°.

All the oxygens are hydrogen-bonded, but there being more N-hydrogens than sulfate oxygens, three of the oxygen atoms, O(1), O(4), and O(7), are involved in two hydrogen bonds each.

Infrared spectra

The strength of the N—H···Cl and N—H···O bonding in the title compounds is reflected in the very broad, unresolved NH (+ CH) stretching absorptions between ~3300 and ~2200 cm^{-1}. The spectra of the two compounds in this region are quite similar, with visually estimated centres of gravity near 2900 cm^{-1} for the chloride and near 2800 cm^{-1} for the sulfate. The broad absorption in the chloride spectrum showed somewhat more structure, in particular in the NH bending region.

Since the NH stretching absorptions in the ir spectra of ammonium and alkylammonium salts are also quite complex (cf. refs. 31−33), numerical frequency comparisons bearing on relative strength of the hydrogen bonding are difficult to make. However, the frequency of the centroid of the NH stretching absorption in the sulfate is roughly 200 cm^{-1} lower

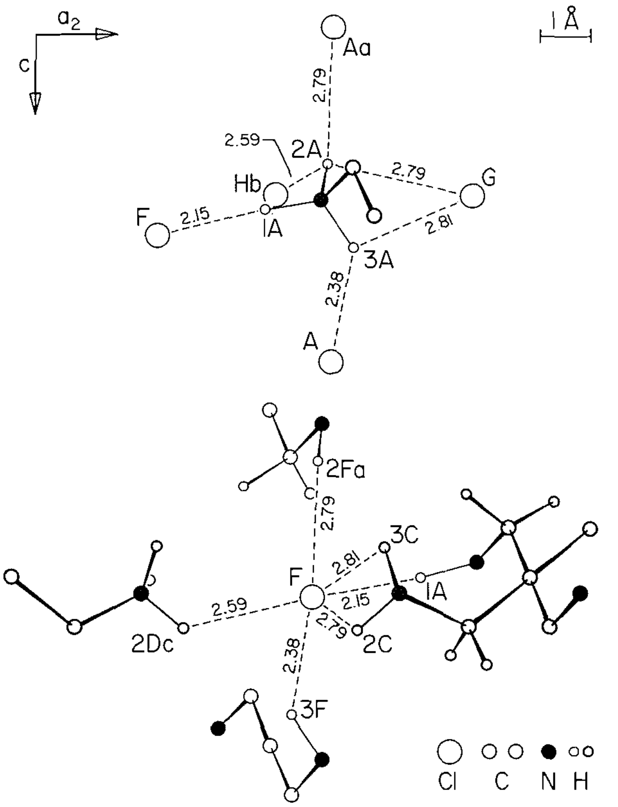

FIG. 2. Hydrogen bonding in $C(CH_2NH_3)_4Cl_4$ (projection on (100)). (*Top*) Environment of a nitrogen atom. (*Bottom*) Environment of a chlorine atom. For symmetry code and NHCl angles see Tables 4 and 5.

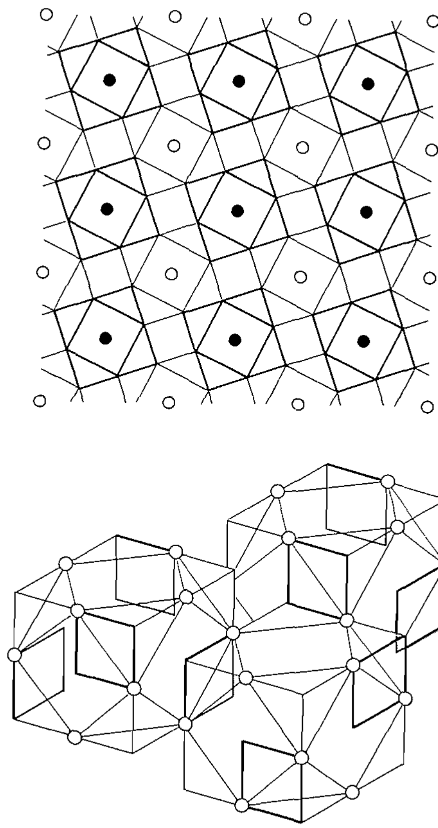

FIG. 3. (*Top*) Schematic representation of the packing of the $[C(CH_2NH_3)_4]Cl_{12}$ coordination cuboctahedra (projection on (001)). The C(1) atoms are at the centres of the cuboctahedra (filled circles, $z = 0$; open circles, $z = 1/2$). Each Cl (at a vertex of a cuboctahedron) is shared by three cuboctahedra. (*Bottom*) Representation of the hydrogen-bonding scheme. The corners and the centres of the vertical faces of the cubes correspond approximately to the positions of the NH_3 groups; the cuboctahedra inscribed in the cubes are the Cl_{12} groupings. The C(1) atoms are located at the cube centres. The two shortest N—H···Cl bonds are indicated by heavy lines: horizontal, H(1)···Cl ~ 2.15 Å; vertical, H(3)···Cl ~ 2.33 Å.

than the corresponding value in $(NH_4)_2SO_4$ (34) and in fact comparable to the corresponding frequency in NH_4F, which is the lowest so far reported for ammonium-containing halides. The strength of the N—H···O bonding in $C(CH_2NH_3)_4(SO_4)_2$ is undoubtedly intensified by the high ionic-charge combination and may well be, together with the extent of the hydrogen bonding in this crystal, responsible for the unexpected slight solubility of this salt in water.

Rigid-body motion of the cation

In view of the significant motion reported for the molecule in the pentaerythritol crystal (14), the refined parameters of the $C(CH_2NH_3)_4^{4+}$ cation in the chloride and sulfate were analysed for rigid-body translation and libration.[3] The results for the chloride indicated that the cation indeed acts as a rigid body. The rms amplitudes of translation were essentially isotropic, 0.12(2) Å along the two equivalent axes and 0.13(2) Å along c. These values are about 20% lower than the corresponding values in pentaerythritol, where some anisotropy is observed. The rms librational amplitudes were 3.3(10)° about a_1 and a_2 and 2.2(6)° about the c-axis, i.e. in each case about half the value in pentaerythritol. These results are compatible with the existence of the two short N—H···Cl bonds in the structure and point to a greater restraining potential in the ionic chloride crystal compared with the molecular pentaerythritol crystal.

In the sulfate the rigid-body motion hypothesis is satisfactory but less so than in the chloride, and the cation motion is less simple to interpret. The translation tensor **T** (in Å^2), the libration tensor **L** (in deg^2) and other relevant details of the analysis are given in Table 11.[2] The rms amplitudes relative to the crystallographic axes were 0.12(4), 0.14(4), and 0.14(4) Å for the translation and 2.7(15)°, 2.8(13)°, and 2.4(13)° for the libration components, i.e. essentially isotropic. Referred to the principal axes of the translation motion the rms amplitudes remained much the same, 0.15, 0.14, and 0.12 Å. However, with respect to the principal axes the ratio L_{11}/L_{33} of the elements of **L** was 4.8 and the corresponding rms amplitudes were 3.2(12)°, 2.9(11)° and 1.5(6)°, pointing to the existence of anisotropy of the librational motion. The L_3 axis is displaced by ~3 Å from the centre-of-gravity origin and its direction is roughly perpendicular to the N(2A)—N(3A) line (Figs. 4 and 5). These two N atoms are involved in the very short N(2)—H(21)···O(3) and N(3)—H(31)···O(8) bonds, and it is this involvement that seems to be responsible for the small libration amplitude about L_3.

In neither of the title compounds are the librational amplitudes at room temperature of a magnitude comparable to that in known precursors of plastic phases. If a transition to a plastic crystal exists, one would expect the T_{tr} to be quite high, probably higher than in pentaerythritol (Table 1). An investigation of the thermal behaviour of both salts is planned.

[3]The MGTLS program of Schomaker and Trueblood (35) was used in this analysis.

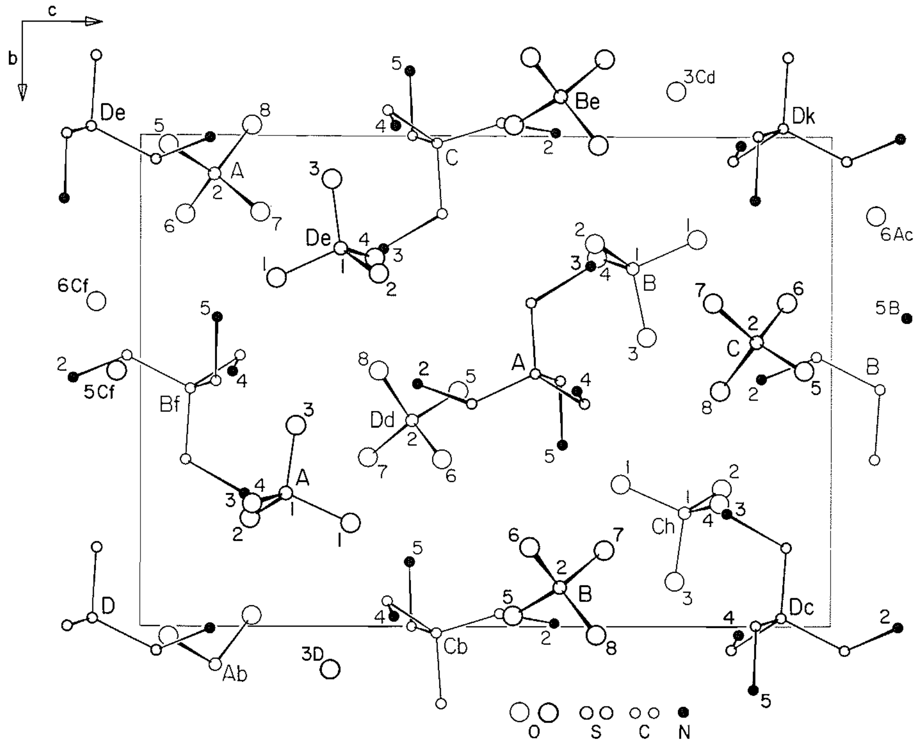

FIG. 4. Projection of the $C(CH_2NH_3)_4(SO_4)_2$ structure on (100). The hydrogen atoms have been omitted for clarity. For interatomic distances, bond angles and symmetry code see Tables 9 and 10.

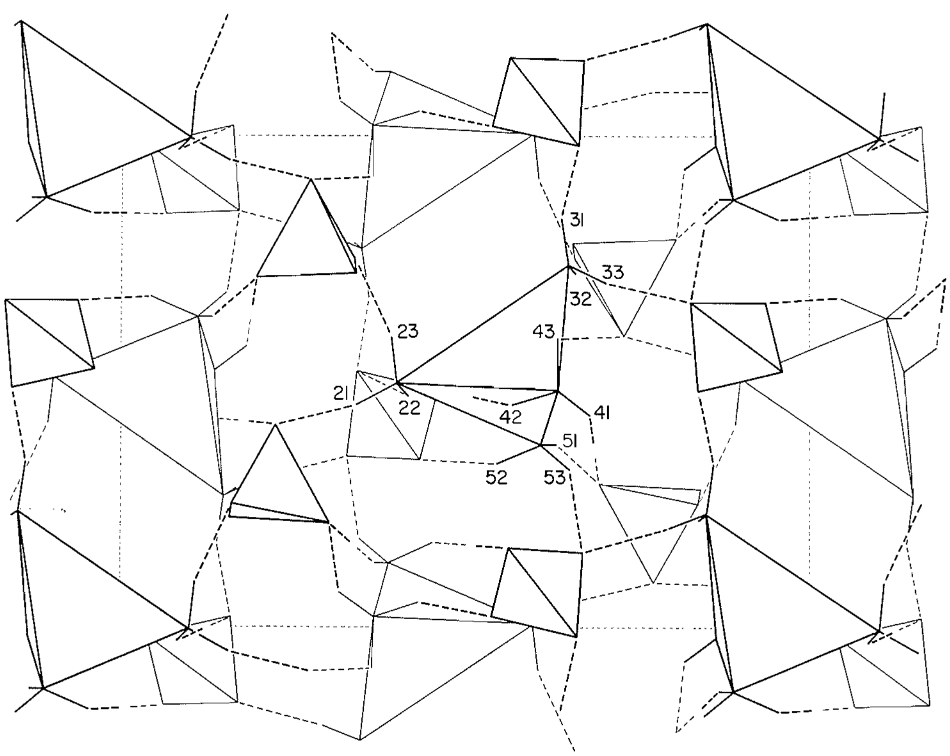

FIG. 5. Hydrogen bonding in $C(CH_2NH_3)_4(SO_4)_2$ (projection on (100), as in Fig. 4). The small tetrahedra represent the SO_4 groups. Each large tetrahedron is defined by the N atoms of a cation; the NH bonds are represented by the solid lines radiating from the vertices. H···O bonds are shown as broken lines. The H(32)···O(2) bonds project awkwardly on (100) and are not included in the drawing.

Geometry of the $C(CH_2NH_3)_4^{4+}$ cation

The bond lengths and angles obtained for the cation are listed in Table 12. They are the same in the chloride and the sulfate, whether corrected or uncorrected, and the corrected C(1)—C distances are statistically indistinguishable from the corresponding corrected distance in pentaerythritol. Corrections to the bond angles were insignificant.

The two C—C(1)—C angles in the chloride differ by

Reçu le 28 février 1984

M. PERSIN et J. Y. GAL. Can. J. Chem. **63**, 593 (1985).

L'ensemble des résultats obtenus montre qu'en milieu fortement complexant le mercure s'oxyde en mercure(II) avec formation des complexes supérieurs HgX_4^{2-}, HgX_3^-. Il n'en est plus de même en milieu peu complexant ou l'on doit envisager la formation de complexes avec le Hg(I). Ceci complique l'exploitation des courbes de titrage par suite de la transformation progressive des complexes du mercure II en complexes du mercure I au contact du mercure métallique. Les systèmes du mercure ne montrent cependant pas un comportement fondamentalement différent de celui observé dans de nombreux solvants organiques.

M. PERSIN and J. Y. GAL. Can. J. Chem. **63**, 593 (1985).

The results obtained show that, in a strongly complexing medium, mercury is oxidized to mercury(II) with the concomitant formation of more highly oxidized complexes like HgX_4^{2-} and HgX_3^-. When the reactional medium is less strongly complexing, however, the formation of complexes with Hg(I) can be considered. This complicates the exploitation of titration curves resulting from the progressive transformation of the complexes of mercury(II) into complexes of mercury(I) by contact with metallic mercury. Compared to the behavior observed in numerous organic solvents, the behavior of these systems is not fundamentally different.

[Journal translation]

Introduction

Au cours de nos travaux antérieurs (1–4) nous avons déjà décrit l'étude des propriétés acide base et de divers complexes avec les ions argent dans l'oxydipropionitrile. Nous avons pensé qu'il était souhaitable de compléter ceci en nous intéressant au comportement des systèmes des ions du mercure dans ce solvant.

Le mercure présente habituellement trois degrès d'oxydation (0, 1 et 2). La stabilité de l'espèce intermédiaire correspondant au degré +(I) dépend du milieu considéré. L'ion mercureux existe ainsi dans l'eau avec un taux de dismutation voisin de 1% (5); la dismutation est également partielle dans le DMF (6), la *N*-méthylpyrrolidone (7) et le DMSO (8). Par contre dans l'éthanolamine (9), l'éthylène diamine (10), la *N*-méthylacétamide (11) la dismutation du mercure(I) est totale.

En milieu complexant on assiste souvent à la dismutation totale du degré intermédiaire par suite de la formation de complexes supérieurs plus stables avec le degré d'oxydation (II) du mercure. Ainsi généralement en milieu halogénure rencontre-t-on les complexes HgX_2, HgX_4^{2-} comme le montrent les résultats publiés dans le DMF (12), le DMSO (8), l'acétonitrile (13), le HMPT (14).

Au cours de ce travail nous avons étudié par polarographie et titrages potentiométriques les complexes du mercure avec les ions halogénures et observé que les résultats obtenus sont compatibles avec ceux déjà publiés pour d'autres solvants.

Partie expérimentale

Synthèse et purification du solvant

Nous avons repris la synthèse et la purification du solvant mises au point au laboratoire et déjà décrites (3, 4).

Réactifs

Les sels de mercure utilisés proviennent des établissements K et K, de même que le perchlorate de tétrabutyl ammonium et les halogénures de tétrabutylammonium. Les chlorure, bromure et iodure mercuriques sont des produits pour analyse Prolabo.

Réalisation des mesures

Le tracé des courbes intensité–potentiel a été réalisé à l'aide d'un montage à 3 électrodes comprenant un enregistreur Tacussel EPL 2 couplé à un tiroir Typol. Le potentiel de l'électrode de travail était contrôlé par un millivoltmètre S6 Tacussel.

Les titrages potentiométriques à courant nul ont été effectués à l'aide d'un millivoltmètre Tacussel S6, la température d'exécution des mesures était régulée à 25°C par un thermostat à circulation.

Les potentiels rapportés dans le texte sont donnés par rapport à une électrode de référence Ag/Ag^+ dans le solvant qui a déjà été décrite par ailleurs (1).

Résultats expérimentaux

1. *Etude des systèmes du mercure en milieu non complexant*

1-1. *Etude à l'électrode à goutte de mercure*

Le perchlorate mercureux est soluble dans l'oxydipropionitrile en milieu acide. Les tracés des polarogrammes pour des concentrations variables d'ions Hg_2^{2+} sont très déformés par des maximums polarographiques que nous n'avons pu éliminer, néanmoins la hauteur du palier est proportionnelle à la concentration des ions Hg_2^{2+}.

La réduction des ions mercuriques dans les mêmes conditions conduit à des résultats analogues et en particulier la hauteur des vagues est identique pour des concentrations égales en ions Hg^{2+} ou Hg_2^{2+}; ce qui est compatible avec l'existence du dimère Hg_2^{2+}. La position des vagues observées laisse penser qu'en réalité on réduit toujours le mercure(I) par suite de la réduction chimique du mercure(II) par le mercure métallique de l'électrode selon:

$$Hg^{2+} + Hg \rightleftharpoons Hg_2^{2+}$$

1-2. *Etude à l'électrode de platine poli*

Les résultats obtenus à l'électrode à goutte s'avérant inexploitables, une étude des systèmes du mercure sur électrode de platine poli a été entreprise.

Cas des ions Hg_2^{2+}

La figure 1 montre que les ions mercureux sont réductibles

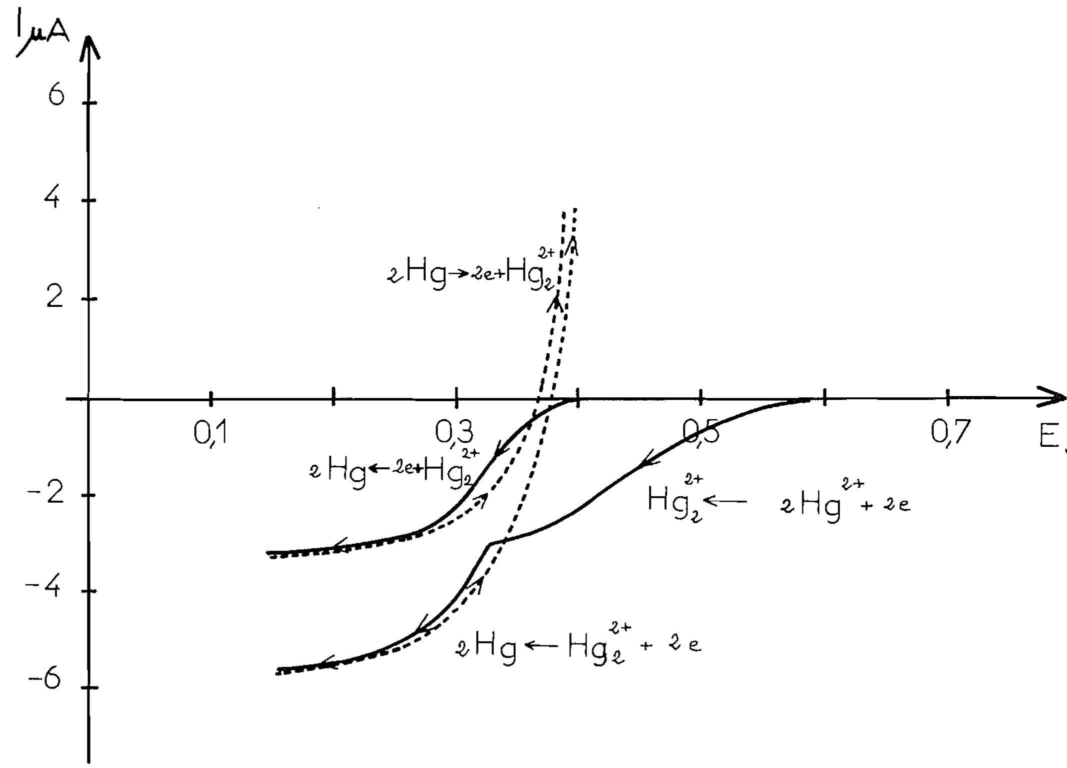

FIG. 1. Courbe voltamperométrique des systèmes $Hg/Hg_2^{2+}/Hg^{2+}$ à l'électrode de platine poli ($[Hg_2(ClO_4)_2] = 3 \times 10^{-3}$ M; $[Hg(ClO_4)_2] = 1,5 \times 10^{-3}$ M).

à l'électrode de platine poli; par ailleurs il est possible d'observer la redissolution du mercure déposé sur l'électrode lors du balayage retour des potentiels. La transformée logarithmique de la courbe intensité–potentiel obtenue en portant log ($I_l - i$) en fonction de E confirme l'irréversibilité partielle du système (pente de 80 mV au lieu des 29 mV attendus). On observe que le potentiel mesuré à courant nul au cours de la redissolution du film du mercure répond à la loi de Nernst avec une pente de 29 mV conformément à la relation

$$E = E^0 + \frac{0,06}{2} \log [Hg_2^{2+}]$$

L'extrapolation à log $[Hg_2^{2+}] = 0$ permet de déterminer le potentiel normal apparent[1] du couple Hg_2^{2+}/Hg soit 0,450 V ± 0,005 V. Ces données confirment l'existence dans l'oxydipropionitrile du dimère Hg_2^{2+}. Comme dans les autres solvants organiques (6–8) les ions Hg_2^{2+} ne sont pas électroactifs en oxydation contrairement à ce qui est observé dans l'eau; ce qui implique la non réversibilité du couple Hg^{2+}/Hg_2^{2+}.

cas des ions Hg^{2+}

La courbe intensité–potentiel de réduction des ions Hg^{2+} présente deux vagues de hauteur égale qui correspondent aux deux étapes:

$$2\,Hg^{2+} + 2e \rightleftharpoons Hg_2^{2+}$$
$$Hg_2^{2+} + 2e \rightleftharpoons 2\,Hg \downarrow$$

Le balayage retour effectué à partir du second palier de réduction montre que le mercure s'oxyde bien en ions mercureux Hg_2^{2+} et non en ion Hg^{2+}.

[1] En milieu $HClO_4$ 10^{-2} M.

Tentative d'évaluation de la constante de dismutation des ions Hg_2^{2+}

Dans la mesure où après une oxydation coulométrique d'une nappe de mercure, on observe uniquement à l'électrode de platine poli la vague de réduction des ions Hg_2^{2+}, on peut dire que ceux-ci sont peu dismutés, il s'en suit que les potentiels normaux apparents des couples Hg_2^{2+}/Hg et Hg^{2+}/Hg_2^{2+} sont tels que:

$$E^0_{Hg^{2+}/Hg_2^{2+}} > E^0_{Hg_2^{2+}/Hg}$$

Si l'on agite du mercure métallique en presence d'une solution d'ion Hg^{2+}, pour déterminer la constante de dismutation il faut pouvoir connaître le rapport des concentrations Hg^{2+}/Hg_2^{2+} à l'équilibre. M. Breant (6) a mis a profit le fait que l'ion Hg_2^{2+} est oxydable dans l'eau pour déterminer la concentration en ion Hg_2^{2+} dans le DMF par dilution aqueuse. Connaissant la concentration initiale en ions Hg^{2+} introduits on en déduit la concentration en ion Hg^{2+} restante. Cette méthode n'est valable que dans la mesure où les ions Hg_2^{2+} sont moins dismutés dans l'eau que dans le solvant étudié. Par ailleurs J. Courtot Coupez a proposé une méthode indirecte de détermination potentiométrique du potentiel normal du couple Hg^{2+}/Hg (8).

L'ordre de grandeur de cette constante de dismutation dans l'oxydipropionitrile a été obtenue en évaluant les concentrations en ions Hg^{2+} et Hg_2^{2+} après agitation d'une solution d'ions Hg^{2+} en présence de mercure métallique, à partir des hauteurs des vagues de réduction observées sur platine poli. Avant agitation on observe une vague de réduction des ions Hg^{2+} de hauteur h, après celle-ci on constante une forte diminution de la hauteur de la vague de réduction de ces derniers et l'augmentation de la vague de réduction des ions Hg_2^{2+}. On peut observer que la hauteur totale des deux vagues est constante conformément au bilan:

$[Hg^{2+}]_i = [Hg^{2+}]_r + [Hg_2^{2+}]_r$

Dans ces conditions $K_D = [Hg^{2+}]/[Hg_2^{2+}] = 10^{-1,3}$. On peut observer que la dismutation des ions Hg_2^{2+} dans l'oxydipropionitrile apparaît légèrement plus importante que dans l'eau où K_D est égale à 10^{-2}. Compte tenu de la méthode utilisée cette valeur reste un ordre de grandeur que nous avons utilisé pour calculer le potentiel normal du couple Hg^{2+}/Hg nécessaire à la détermination des constantes de stabilité des complexes mercuriques. On obtient aisèment

$$E^0_{Hg^{2+}/Hg_2^{2+}} = E^0_{Hg_2^{2+}/Hg} - 0,06 \log K_D = 0,530 \text{ V} \pm 0,010 \text{ V}$$

et

$$E^0_{Hg^{2+}/Hg} = \frac{E^0_{Hg^{2+}/Hg_2^{2+}} + E^0_{Hg_2^{2+}/Hg}}{2} = 0,490 \text{ V} \pm 0,010 \text{ V}$$

2. *Etude des systèmes du mercure en milieu halogénures complexant*

Le présent travail est consacré à l'étude du comportement des systèmes du mercure en présence de chlorure, bromure et iodure. Comme nous l'avons précédemment indiqué la présence d'un complexant stabilise généralement l'un des dégrés d'oxydation (I) ou (II) du mercure et par conséquent favorise ou défavorise la dismutation du degré intermédiaire.

2-1. *Etude polarographique*

2-1.1. *Etude des complexes Hg(II) iodure*

L'oxydation polarographique du mercure en présence d'iodure à concentration variable s'effectue en deux étapes, la première vague étant trois fois plus haute que la seconde. Cela est compatible avec les mécanismes d'oxydation suivants:

$$Hg\downarrow + 4I^- \rightleftharpoons HgI_4^{2-} + 2e$$

$$Hg\downarrow + 3\,HgI_4^{2-} \rightleftharpoons 4\,HgI_3^- + 2e$$

La hauteur des deux vagues est proportionnelle à la concentration d'iodure mais l'analyse mathématique des courbes $I = f(E)$ conduit à des droites de pente très supérieure à 30 mV confirmant l'irréversibilité des systèmes mis en jeu. Il est donc impossible d'atteindre les constantes de stabilité de ces complexes directement par le traitement des courbes $I = f(E)$.

2-1.2. *Etude des complexes Hg(II) chlorure et bromure*

L'oxydation polarographique du mercure en présence de ces deux halogénures conduit à des résultats identiques, on observe la présence de deux vagues de hauteurs égales proportionnelles à la concentration d'halogénures. On peut proposer le mécanisme

$$Hg\downarrow + 4X^- \rightleftharpoons HgX_4^{2-} + 2e$$

$$HgX_4^{2-} + Hg\downarrow \rightleftharpoons 2\,HgX_2 + 2e$$

Tout comme dans le cas de l'iodure l'analyse mathématique des vagues obtenues ne conduit à aucun résultat satisfaisant par suite de l'irréversibilité des systèmes mis en jeu.

2-2 *Etude potentiométrique*

2-2.1. *Cas de l'iodure*

La figure 2 montre que la courbe de titrage potentiométrique à l'électrode de mercure d'une solution d'iodure par les ions mercuriques présente trois points singuliers correspondant respectivement à la formation des complexes HgI_4^{2-}, HgI_3^- et HgI_2.

Cette hypothèse est confirmée par l'analyse mathématique

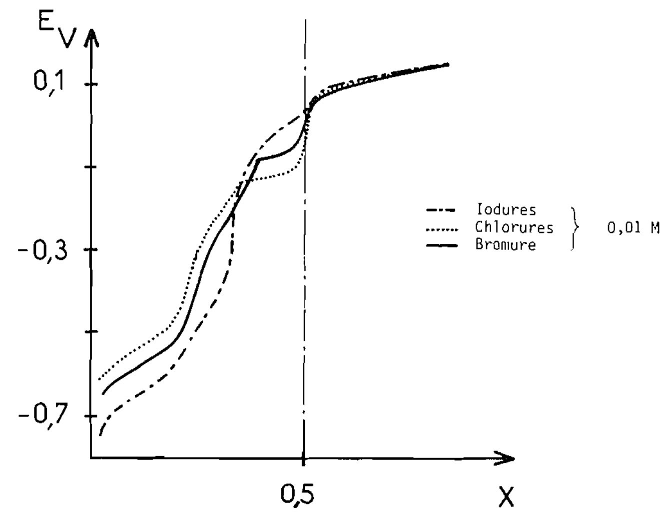

FIG. 2. Titrage potentiométrique des ions halogénures par le perchlorate mercurique (milieu Bu_4NClO_4 0,1 *M*; électrode indicatrice de mercure).

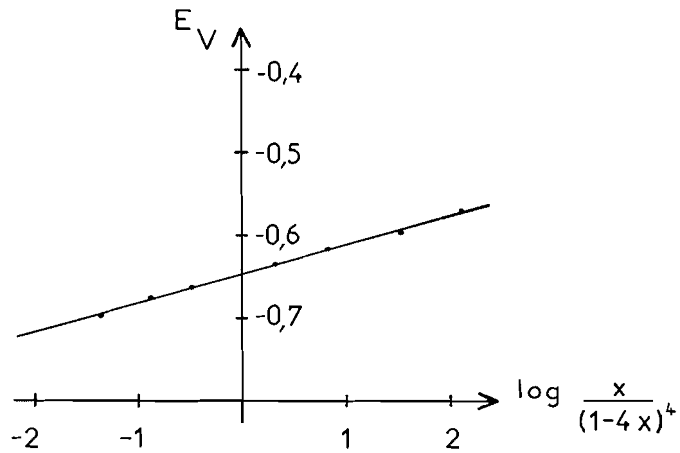

FIG. 3. Transformée logarithmique de la première partie de la courbe de titrage de l'iodure par le cation Hg^{2+} ($x < 0,25$).

de la courbe de titrage. Pour une fraction titrée x telle que $0 < x < 0,15$ on observe une variation linéaire du potentiel en fonction de $\log x/(1-4x)^4$ avec une pente de 31 mV au lieu des 29 mV théoriques attendus. L'ordonnée à l'origine de la droite obtenue (fig. 3) reliée à la constante β_{41} de formation du complexe HgI_4^{2-} par la relation:

$$H_1 = E^0_{Hg/Hg^{2+}} - 0,03 \log \beta_{41} - 0,03 \log C_0^3$$

permet connaissant $E^0_{Hg/Hg^{2+}}$ et la concentration C_0 de l'espèce titrée, de déterminer $\log \beta_{41}$.

Pour une fraction titrée $0,25 < x < 0,30$ la réaction de titrage mise en jeu est:

$$3HgI_4^{2-} + Hg^{2+} \rightleftharpoons 4HgI_3^-$$

de constante

$$K = \frac{[HgI_3^-]^4}{[HgI_4^{2-}]^3[Hg^{2+}]}$$

La transformée logarithmique de la courbe de titrage obtenue est une droite de pente 28 mV et d'ordonnée à l'origine:

$$H_2 = E^0_{Hg/Hg^{2+}} - 0,03 \log K - 0,03 \log C_0$$

TABLEAU 1. Constantes d'équilibre des complexes Hg(II) halogénures (chlorure, bromure, iodure)

Halogénures	HgX_4^{2-} log β_{41} ± 0,2	HgX_3^- log β_{31} ± 0,2	Équilibre $HgX_4^{2-} \rightleftharpoons HgX_3^- + X^-$ log K
Iodure	43,8	39,3	4,5
Bromure	41,6	37	4,6
Chlorure	40,2	35,5	4,7

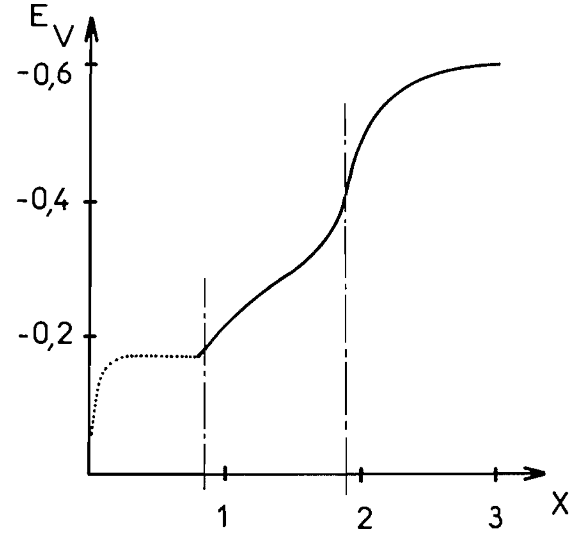

FIG. 4. Titrage potentiométrique de $HgBr_2$ par les ions Br^- (milieu Bu_4NClO_4 0,1 M; électrode indicatrice de mercure).

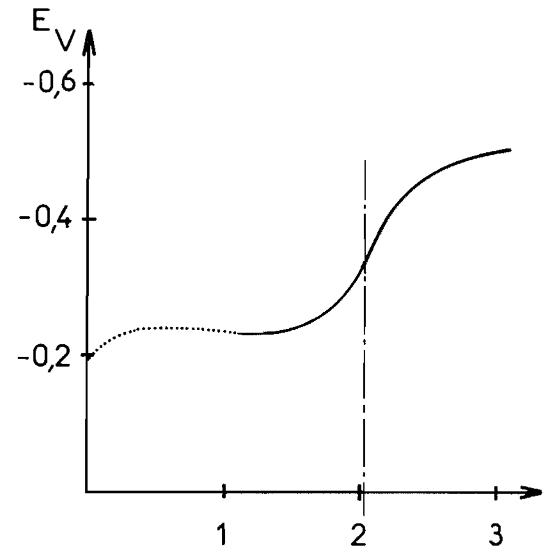

FIG. 5. Titrage potentiométrique de $HgCl_2$ par les ions Cl^- (milieu Bu_4NClO_4 0,1 M; électrode indicatrice de mercure).

on déduit aisèment

$$\beta_{31} = \frac{[HgI_3^-]}{[Hg^{2+}][I^-]^3} = \sqrt[4]{\beta_{41}^3\ K}$$

Au delà du deuxième point équivalent l'analyse de la courbe de titrage ne conduit à aucun résultat satisfaisant tendant à confirmer la formation de HgI_2 et l'on observe l'apparition d'un précipité jaune vert tandis que le mercure de l'électrode s'oxyde. Ces observations permettent de penser que le milieu n'est plus assez complexant pour dismuter totalement le mercure mercureux, celui-ci apparaît alors selon la réaction:

$$2HgI_3^- + Hg^{2+} + 3Hg \rightleftharpoons 3Hg_2I_2\downarrow$$

2-2.2 *Cas des chlorures et bromures*

Les résultats obtenus sont identiques et en milieu fortement concentré en halogénures nous avons bien l'existence de HgX_4^{2-}. La poursuite du titrage laisse apparaître un point équivalent pour $x = 0{,}33$ correspondant à la formation de HgX_3^- cependant moins net que dans le cas de l'iodure (fig. 2). Le point équivalent observé pour $x = 0{,}5$ correspond à l'apparition d'un précipité qui ne peut être attribué à la formation de HgX_2 car les chlorures et bromures mercuriques sont solubles dans l'oxydipropionitrile. Comme dans le cas de l'iodure nous pensons avoir formation des complexes Hg_2Br_2 et Hg_2Cl_2 tout deux insolubles dans l'oxydipropionitrile. Il y a de nouveau oxydation du mercure au niveau de l'électrode selon:

$$2\ HgX_3^- + 3Hg + Hg^{2+} \rightleftharpoons 3Hg_2X_2\downarrow$$

Le tableau 1 rassemble les différentes constantes d'équilibre des complexes déterminées.

2-2.3 *Titrage potentiométrique de $HgCl_2$ et $HgBr_2$ par les ions Cl^- et Br^-*

Le début du titrage est caractérisé par des potentiels mesurés peu stables qui proviennent en fait de la réaction de HgX_2 sur le mercure de l'électrode, on observe en effet l'apparition au contact du mercure d'un précipité qui ne peut qu'être attribué à Hg_2X_2:

$$HgX_2 + Hg\downarrow \rightleftharpoons Hg_2X_2\downarrow$$

La poursuite de l'ajout d'halogénure indique que le potentiel devient stable pour une quantité d'halogénure ajoutée identique à la quantité de HgX_2 présent. On observe un saut de potentiel dans le cas du titrage par les ions bromures (fig. 4). Ceci indique qu'en milieu de plus en plus complexant l'oxydation du mercure par le mercure (II) cesse et par conséquent le degré (I) du mercure est de plus en plus dismuté. Un second saut de potentiel est observé pour une quantité double d'halogénures versée (figs. 4, 5). Les réactions de titrages mises en jeu sont:

$$HgX_2 + X^- \rightleftharpoons HgX_3^-$$

$$HgX_3^- + X^- \rightleftharpoons HgX_4^{2-}$$

Entre les deux sauts de potentiel on peut écrire la variation du potentiel de l'électrode à l'aide du couple oxydoréducteur:

$$3HgX_4^{2-} + Hg\downarrow \rightleftharpoons 4HgX_3^- + 2e$$

$$E = E^0_{HgX_4^{2-}/HgX_3^-} + \frac{0{,}06}{2}\log\frac{[HgX_3^-]^4}{[HgX_4^{2-}]^3}$$

On vérifie que la pente de la droite obtenue est de 31 mV dans les conditions expérimentales, l'ordonnée à l'origine conduit à

TABLEAU 2. Constantes d'équilibre des complexes Hg(II) halogénures dans quelques solvants

	HgX_4^{2-} log β_{41}			HgX_3^- log β_{31}			$HgX_4^{2-} \rightleftharpoons HgX_3^- + X^-$ log K		
Solvant	I	Br	Cl	I	Br	Cl	I	Br	Cl
Eau	29,8	21	15,1	27,6	19,7	14,1	2,2	1,3	1
Acétonitrile[a]	48,7	46,7	45,5	44,5	42,9	42,7	4,2	3,8	2,8
DMSO[b]	32,6	30,4	26,9	30,4	28	23,5	2,2	2,4	3,4
ODPN	43,8	41,6	40,2	39,3	37	35,5	4,5	4,6	4,7

[a]D'après réf. 13.
[b]D'après réf. 8.

$E^0_{HgX_4^{2-}/HgX_3^-}$.

Au delà du point équivalent l'électrode répond selon

$$E = E^0_{HgX_4^{2-}/X^-} + \frac{0,06}{2}\log\frac{[HgX_4^{2-}]}{[X^-]^4}$$

La transformée logarithmique présente également une pente voisine de 30 mV et permet de calculer $E^0_{HgX_4^{2-}/X^-}$. Un simple calcul montre que:

$$K = \frac{[HgX_4^{2-}]}{[HgX_3^-][X^-]} = \frac{\beta_{41}}{\beta_{31}} = 10^{\Delta E^0/0.12}$$

Nous avons pu vérifier tout au moins dans le cas du titrage du complexe $HgBr_2$ que la valeur de K trouvée est très voisine de celle déterminée précédemment.

Conclusion

L'ensemble des résultats obtenus montre qu'en milieu fortement complexant le mercure s'oxyde en mercure(II) avec formation des complexes supérieurs HgX_4^{2-}, HgX_3^-. Il n'en est plus de même en milieu peu complexant ou l'on doit envisager la formation de complexes avec le Hg(I). Ceci complique l'exploitation des courbes de titrage par suite de la transformation progressive des complexes du mercure (II) en complexes du mercure (I) au contact du mercure métallique. Les systèmes du mercure ne montrent cependant pas un comportement fondamentalement différent de celui observé dans de nombreux solvants organiques (Tableau 2).

Reaction of hydroxide ion with 1,3,5-trinitrobenzene in cationic micelles: evidence of variable counterion binding to micellar head groups

LEONG-HUAT GAN
Department of Chemistry, University of Malaya, Pantai Valley, Kuala Lumpur, Malaysia

Received March 30, 1984

LEONG-HUAT GAN. Can. J. Chem. **63**, 598 (1985).

Cationic micelles of hexadecyltrimethylammonium bromide, chloride, and hydroxide (CTABr, CTACl, and CTAOH) greatly enhance the stability of anionic σ-complex formed by hydroxide ion and 1,3,5-trinitrobenzene (TNB). The counterion binding to the micellar head groups is assumed to vary but is governed by a distribution constant. Different distribution constants are used for different types of counterion. Using this treatment, the rate constant − surfactant concentration profiles for the reactions of TNB with hydroxide ion in CTAOH, CTABr, and CTACl can all be satisfactorily accounted for, yielding consistent results in various conditions. The ion distribution constants, $K_{OH} = 55$ mol^{-1} dm^3, $K_{Br} = 1800$ mol^{-1} dm^3, and $K_{Cl} = 420$ mol^{-1} dm^3 and the rate constant $k_M = 3600$ s^{-1} are obtained. In view of the success of this treatment, the assumption of a constant β value associated with the pseudophase model at best could only be viewed as an approximation, valid only for micellar systems with tightly bound counterions such as those in the micelles of CTABr.

LEONG-HUAT GAN. Can. J. Chem. **63**, 598 (1985).

Les micelles cationiques des bromure, chlorure et hydroxyde de l'hexadécyltriméthylammonium (CTABr, CTACl et CTAOH) augmentent considérablement la stabilité des complexes anioniques σ formés par l'ion hydroxyde et le trinitro-1,3,5 benzène (TNB). On fait l'hypothèse que la fixation de l'ion complémentaire sur les groupes de têtes de la micelle varie; toutefois, cette fixation est gouvernée par une constante de distribution. On utiise des constantes de distribution différentes pour différents types d'ions complémentaires. Utilisant cette approche, on peut expliquer d'une façon satisfaisante les profils de constantes de vitesse/concentration d'agents tensioactifs pour les réactions du TNB avec l'ion hydroxyde dans des micelles cationiques de CTABr, de CTACl et de CTAOH; les résultats sont cohérents sous diverses conditions. On a obtenu les constantes de distribution des ions, $K_{OH} = 55$ mol^{-3} dm^3, $K_{Br} = 1800$ mol^{-3} dm^3 et $K_{Cl} = 420$ mol^{-3} dm^3 ainsi que la constante de vitesse $K_M = 3600$ s^{-1}. Compte tenu des résultats excellents obtenus en faisant appel à notre approche, il apparait que, dans le meilleur des cas, on ne doit considérer l'hypothèse suivant laquelle il faut associer une constante de valeur β avec le modèle de la pseudophase que comme une approximation qui ne serait valide que pour des systèmes micellaires comportant des ions complémentaires intimement liés comme ceux présents dans les micelles de CTABr.

[Traduit par le journal]

Introduction

Micellar catalysis in water for unimolecular reaction and bimolecular reaction between two uncharged reactants can generally be interpreted in accordance with the pseudophase model (1−3). The rate enhancements or inhibitions are rationalized in terms of medium effect or concentration effect or both (3, 4). For reactions in ionic micelles, it is generally assumed that the extent of charge neutralization at the micellar headgroups, β, remains constant once the micelle is formed. This assumption, widely used in kinetic analysis, has been found to be satisfactory for a large number of reactions between hydrophilic ions and neutral substrates, especially in micelles of CTABr (4−8). More recently, however, this kinetic treatment has been shown to have failed for micelles with more hydrophilic counterions, specifically micelles of CTAOH and CTAF (9). While several possible reasons for the failure of this simple kinetic model in these systems have been discussed (9), it is believed that the assumption of a constant β value could be a major cause. By discarding the constraint of this invariance in β value and assuming instead that the binding of the counterions to the micellar phase be represented by an equilibrium process similar to that for the distribution of an organic substrate, Bunton *et al.* (10) have shown that many observed "anomalous" rate−surfactant profiles can be satisfactorily accounted for. This treatment has recently been applied to an alkoxide functionalized micellar system (11). To furnish further evidence for the support of this approach, a reversible reaction between OH^- and TNB is now reported.

Experimental

Materials

Hexadecyltrimethylammonium bromide and chloride (CTABr and CTACl) were obtained from Tokyo Kasei, Japan and were purified by repeated recrystallization from Et_2O−EtOH. The purities of these surfactants were checked by surface tension measurements. Solutions of hexadecyltrimethylammonium hydroxide (CTAOH) were prepared by the method described previously (10). Eastman 1,3,5-trinitrobenzene (TNB) was recrystallized several times from ethanol.

Binding of TNB to micelles of CTABr

The binding constant of TNB, K_S, defined by eq. [1]

$$[1] \quad K_S = \frac{[\text{TNB.D}_n]}{[\text{TNB}_W][\text{D}_n]}$$

where TNB.D_n denotes TNB in micellar phase, in micelles of CTABr, was determined by the solubility method. A Cary 17 spectrophotometer was used to determine the concentrations of TNB. Saturated solutions of TNB in various concentrations of CTABr at 25°C were diluted to ~5 × 10^{-5} mol dm^{-3} by isopropanol. Suitable amounts of NaOH were then added so that the NaOH concentrations of the final solutions were ~5 × 10^{-3} mol dm^{-3}. Essentially all the TNB would be reacted to form anionic σ-complexes. This method is sensitive, as both the equilibrium constant and the molar extinction coefficient of the complex in isopropanol are high (12). The binding constant thus obtained is $K_S = 46 \pm 2$[1] mol^{-1} dm^3 with the solubility of TNB in water being 1.9 × 10^{-3} mol dm^{-3} at 25°C.

[1]Least-square errors from five determinations in various CTABr concentrations.

Equilibrium and kinetic studies

A Durrum–Gibson (new name: Dionex) D-110 stopped-flow spectrophotometer connected with a Tektronix R5103N oscilloscope was used for both the kinetic and equilibrium studies. The cuvette has an optical path length of 2 cm. All the reactions were carried out at a thermostated temperature of 25 ± 0.1°C. Reactions were followed at λ = 500 nm. The concentrations of the substrate solutions were ~3 × 10^{-5} mol dm^{-3}, and the observed first-order rate constants k_ψ are in s^{-1}. A much faster reaction was observed to precede the formation of the TNB–OH^- complex. They were found in all the micellar systems studied, i.e., CTABr, CTACl, $CTANO_3$, CTACN, and CTAOH, hence unlikely to have resulted from the impurities in the surfactants.

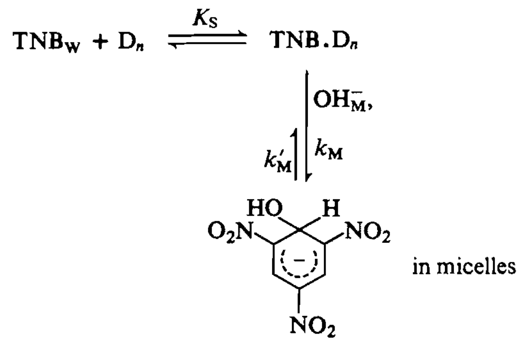
While it is regrettable that the nature of this fast reaction has yet to be identified, its existence should not have had any effect on the values of k_ψ. This is because the slower formation of the TNB–OH^- complex begins only well after this fast reaction has been completed, and good first-order reactions are observed throughout. Furthermore, in most cases, especially those at lower hydroxide ion concentrations, the absorbances due to these fast reactions were small relative to those of the TNB–OH^- complexes. Due to the extremely low equilibrium constant of TNB–OH^- in water as compared to that in the micelles (see results and discussion), the observed absorbances were attributed solely to the TNB–OH^- complexes in the micellar phase.

Results and discussion

Hydroxide ion reacts reversibly with TNB to form an anionic σ-complex. The equilibrium constant in water is low, K = 2.7 mol^{-1} dm^3 at 25°C with the forward and reverse rate constants being 25.3 mol^{-1} dm^3 s^{-1} and 13.4 s^{-1} respectively (12). Micellar effects on the rate and equilibrium constants of anionic σ-complexes have been reported (13, 14). It is found that the formation of the TNB–OH^- complex is affected by the presence of cationic micelles of CTABr, CTACl, and CTAOH. Quantitative kinetic analyses for the reactions in these systems are now presented.

Kinetics

Reaction of OH^- with TNB in micelles is assumed to follow the pathways outlined in Scheme 1.



I

SCHEME 1

Reaction in water is neglected because of its low equilibrium constant. The observed first-order rate constant is given by

$$[2] \quad k_\psi = \frac{K_S k_M [OH_M^-]}{1 + K_S [D_n]}$$

Here the reverse rate constant of complex **I** is again omitted (see discussion later for justification of its omission).

Reactions in micelles of CTAOH

Reactions of TNB in CTAOH with and without the addition of NaOH are shown in Figs. 1 and 2. These results do not conform to the pseudophase model with a constant value of β as have been found for the reactions with other substrates such as 2,4-dinitrochlorobenzene (DNCB), 2,4-dinitrochloronapthalene (DNCN), and p-nitrophenyldiphenylphosphate (pNPDPP) (10). The concentration of hydroxide ion in the micellar phase $[OH_M^-]$ is assumed to be governed by a distribution constant and is calculated from eq. [3].

$$[3] \quad K_{OH} = \frac{[OH_M^-]}{[OH_W^-]([D_n] - [OH_M^-])}$$

where the micellized surfactant $[D_n]$ = C_D = CMC (CMC is critical micelle concentration). Reasonably good fits are obtained by using K_{OH} = 55 mol^{-1} dm^3, k_M = 3600 s^{-1}, and the

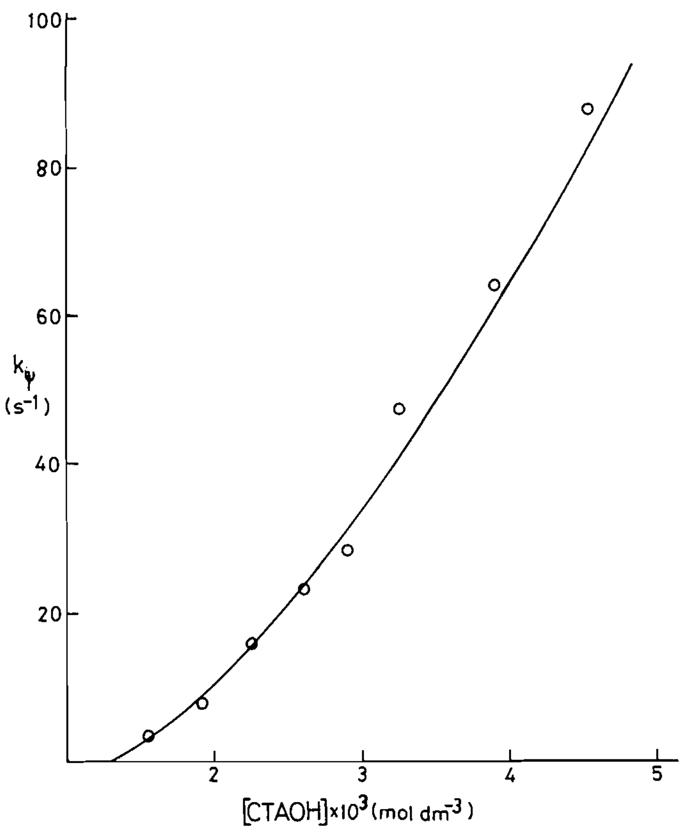


FIG. 1. Rate constant – surfactant profile for the reaction of TNB in CTAOH. Calculated k_ψ values are shown by the solid line.

experimentally determined K_S = 46 mol^{-1} dm^3.

Reactions in micelles of CTABr and CTACl at constant [NaOH]

The values of k_ψ for the formation of **I** as a function of surfactant concentrations are shown in Fig. 3. The competition between OH^- and X^- (X = Br or Cl) is assumed to be governed by two equilibra with equilibrium constants K_X and K_{OH} as given in eqs. [4] and [5].

$$[4] \quad K_X = \frac{[X_M^-]}{[X_W^-]([D_n] - [X_M^-] - [OH_M^-])}$$

$$[5] \quad K_{OH} = \frac{[OH_M^-]}{[OH_M^-]([D_n] - [OH_M^-] - [X_M^-])}$$

Expanding eqs. [4] and [5] yields eqs. [6] and [7] respectively.

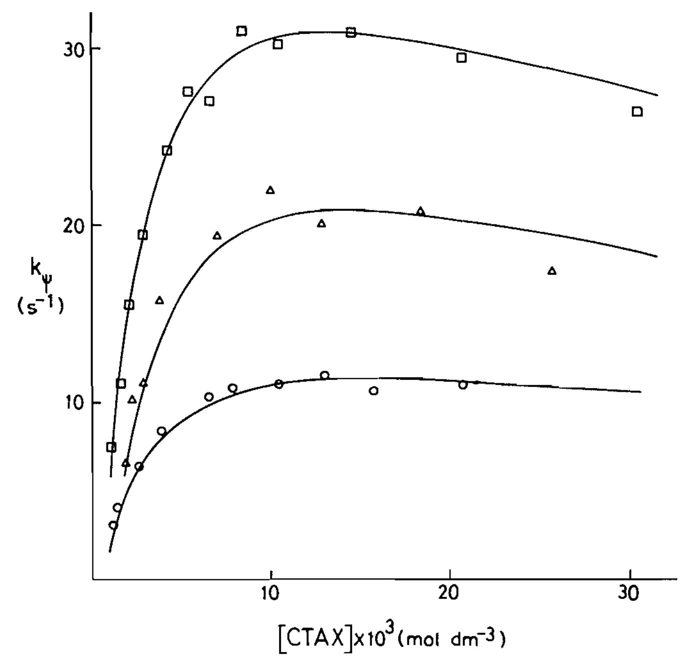

FIG. 3. Reactions of TNB with OH^- in CTAX (X = Br and Cl). X = Br; ○, [NaOH] = 7.88 × 10^{-4} mol dm^{-3}; □, [NaOH] = 1.97 × 10^{-3} mol dm^{-3}; X = Cl; △, [NaOH] = 7.88 × 10^{-4} mol dm^{-3}. The lines are predicted.

$$[6] \quad K_X[X_M^-]^2 - [X_M^-](1 + K_X[D_n] + K_X[X^-]_0) + K_X[OH_M^-][X_M^-] - K_X[X^-]_0(OH_M^-] + K_X[D_n][X^-]_0 = 0$$

$$[7] \quad K_{OH}[OH_M^-]^2 - [OH_M^-](1 + K_{OH}[D_n] + K_{OH}[OH^-]_0) + K_{OH}[X_M^-][OH_M^-] - K_{OH}[OH^-]_0[X_M^-] + K_{OH}[D_n][OH_0^-] = 0$$

Values of $[OH_M^-]$ and $[X_M^-]$ are obtained by iterative methods using a computer. The sets of parameters that give reasonably good fits to the rate – surfactant concentration profiles (Fig. 3) are listed in Tables 1 and 2. It is noted that while maintaining constant values for K_{OH}, K_X, and k_M, a slightly different value of K_S at different [NaOH] is used in order to give a good fit to the experimental data. The fact that K_S varies with [NaOH] is, however, not unusual for a substrate which does not bind strongly to micelles. A similar effect was observed for another more hydrophilic substrate, DNCB in CTABr (K_S = 75 mol^{-1} dm^3) (10).

Effect of NaOH on k_ψ *at constant [CTABr]*

At constant surfactant concentration, increasing NaOH concentration increases $[OH_M^-]$, hence increases k_ψ (Fig. 4). Using the method described earlier, $[OH_M^-]$ are obtained. It is, however, more difficult to predict an accurate value for k_ψ because K_S may vary slightly as the concentration of NaOH changes. Nevertheless, with the same set of values for K_{OH}, K_{Br}, and k_M listed in Table 1, the calculated k_ψ values agree reasonably well with the experimental data if an average value of K_S = 82 mol^{-1} dm^3 is assumed (Fig. 4).

*Equilibrium constant of complex **I** in CTABr*

In a fixed concentration of CTABr, the absorbance of complex **I** increases with increasing [NaOH] (Table 3). Referring to Scheme 1, the equilibrium constant for complex **I** in the micelles is

$$[8] \quad K_I = \frac{[\mathbf{I}_M]}{[OH_M^-][TNB.D_n]}$$

Combining eq. [8] with eq. [1] for K_S yields

$$[9] \quad K_S \cdot K_I = \frac{[\mathbf{I}_M]}{[OH_M^-][TNB_W][D_n]}$$

and

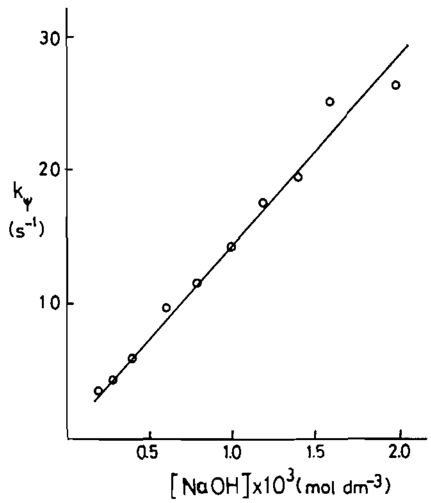

FIG. 4. Reaction of TNB with OH^- at constant [CTABr]. The line is predicted.

TABLE 3. Absorbance (A_∞) of complex **I** for reaction of TNB with OH^- in CTABr[a]

10^3[NaOH] (mol dm^{-3})	$10^4[OH_M^-]$ (mol dm^{-3})	A_∞
0.2	0.166	0.3893
0.3	0.248	0.4584
0.4	0.330	0.5258
0.6	0.493	0.5654
0.8	0.653	0.5784
1.0	0.813	0.6055
1.2	0.970	0.6234
1.4	1.130	0.6345
1.6	1.286	0.6421
2.0	1.593	0.6491

[a][CTABr] = 8.560×10^{-3} mol dm^{-3}; [TNB] = 2.179×10^{-5} mol dm^{-3}; λ = 500 nm.

$$[10] \quad [TNB_W] = [TNB]_0 - [TNB \cdot D_n] - [\mathbf{I}_M] \approx [TNB]_0 - [\mathbf{I}_M]$$

$[TNB \cdot D_n]$ is neglected in eq. [10] because K_I is large. By rearranging eq. [10], ones gets

$$[11] \quad \frac{1}{[OH_M^-]} = [D_n] \cdot K_I \cdot K_S \frac{[TNB]_0}{[I_M]} - K_I \cdot K_S [D_n] = [D_n] \cdot K_I \cdot K_S \frac{[TNB]_0 \epsilon l}{A_\infty} - K_I \cdot K_S [D_n]$$

Using the same values of K_{OH} and K_{Br}, the calculated values of $[OH_M^-]$ are also shown in Table 3. A plot of $[OH_M^-]^{-1}$ versus A_∞^{-1} gives a straight line as expected if eq. [11] were to be followed. From the slope and intercept of the plot, $\epsilon = 1.65 \times 10^4$ mol^{-1} dm^3 cm^{-1} is obtained. This agrees very well with those of other anionic σ-complexes of TNB (12). To obtain K_I, however, requires a knowledge of K_S. If K_S = 82 mol^{-1} dm^3 is used, $K_I = 1.09 \times 10^5$ mol^{-1} dm^3.

The second-order rate constant calculated by eq. [12] (9)

$$[12] \quad k_2^m \approx 0.14\, k_M$$

is k_2^m = 504 mol^{-1} dm^3 s^{-1}. This in turn yields the reverse rate constant $k'_M = 4.6 \times 10^{-3}$ s^{-1}. The very low value of k'_M thus justifies its omission in the treatment of the rate data described earlier. When the rate constants for the formation of complex **I** in water and those in micelles are compared, it can be seen that the high K_I value is a result of a marked increase in forward rate constant and an even larger decrease in reverse rate constant for the reactions in micelles. These can be rationalized in terms of stabilization of the transition state and the complex **I** in the presence of the positively charged micellar head groups.

While the inadequacies of the pseudophase model with a constant β value have been demonstrated in many systems involving hydroxide ions (9, 15), the equilibrium model for the binding of counterions on the other hand, as has been shown here, has more success as far as kinetic treatment is concerned. A very low value of β (0.3) for the micelles of CTAOH reported recently by Lianos and Zana (16) is in agreement with the finding that K_{OH} is much lower than K_{Br}, thus augmenting the validity of this equilibrium model.

Preparation and properties of a linked porphyrin–cyclodextrin[1]

MONICA C. GONZALEZ[2] AND ALAN C. WEEDON[3]

Photochemistry Unit, Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received June 28, 1984

MONICA C. GONZALEZ and ALAN C. WEEDON. Can. J. Chem. **63**, 602 (1985).

The synthesis of the linked porphyrin–cyclodextrin **3** and its zinc complex **4** is described and their characterization by ^{1}H nmr, ^{13}C nmr, circular dichroism, ultraviolet, and infrared spectroscopy is reported. The linked porphyrin–cyclodextrin compounds exhibited perturbed electronic absorption and emission spectra which are consistent with their adopting two conformations, one extended with little interaction between the porphyrin and cyclodextrin, and the other folded with the cyclodextrin weakly complexed to the porphyrin. Quenching of the porphyrin excited state of **3** by benzoquinone was examined by measurement of the fluorescence lifetime as a function of quinone concentration; the results suggest that the porphyrin excited state can be quenched intermolecularly by benzoquinone and also intramolecularly by quinone complexed within the cyclodextrin cavity.

MONICA C. GONZALEZ et ALAN C. WEEDON. Can. J. Chem. **63**, 602 (1985).

On décrit la synthèse du composé **3** (cyclodextrine–porphyrine liées) et de son complexe de zinc (**4**) ainsi que leur caractérisation par les spectroscopies infrarouge, ultraviolette et rmn ^{1}H et ^{13}C ainsi que par leur dichroïsme circulaire. Les composés liés de cyclodextrine–porphyrine présentent des spectres d'absorption et d'émission électronique qui sont perturbés et qui sont en accord avec le fait qu'ils adoptent deux conformations: une étendue, dans laquelle il n'existe que peu d'interactions entre la cyclodextrine et la porphyrine, et une autre repliée, dans laquelle la cyclodextrine est faiblement complexée par la porphyrine. En mesurant le temps de vie de la fluorescence en fonction de la concentration de quinone, on a examiné la réaction de piégeage, par la benzoquinone, de l'état excité de la porphyrine présente dans **3**; les résultats suggèrent que l'état excité de la porphyrine peut être piégé d'une façon intermoléculaire par la benzoquinone et aussi d'une façon intramoléculaire par de la quinone qui est complexée dans la cavité de la cyclodextrine.

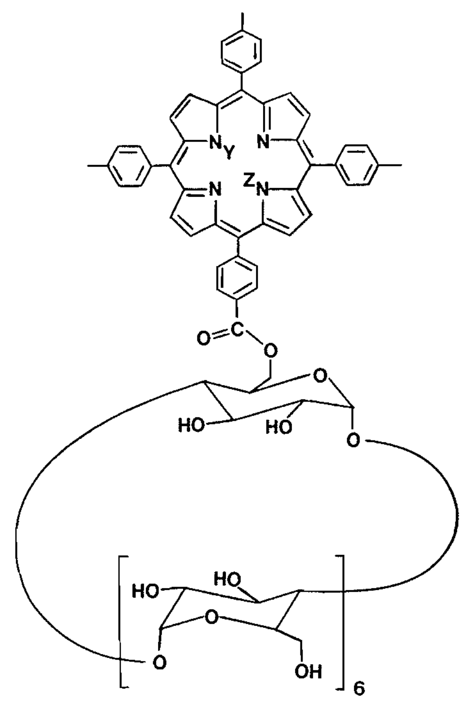
Introduction

The primary event in the reaction centre of photosynthesis is believed to involve the transfer of an electron from a visible light excited porphyrin chromophore to a nearby acceptor, and there has been considerable recent interest in the synthesis and study of molecules which mimic this photosynthetic reaction (1). These artificial electron transfer systems consist of a donor (usually also the light absorber) chemically linked to an electron acceptor such as a benzoquinone derivative. These compounds have been prepared with the aim of elucidating the effect of degree of separation of donor and acceptor upon the efficiency of the light-induced electron transfer reaction and subsequent back electron transfer (1). Another parameter which would be expected to have an important effect upon this process is the relationship between the oxidation potential of the donor and the reduction potential of the acceptor.

To examine the effect of variation of redox potentials would require the synthesis of a series of compounds in which the oxidation potential of the donor or the reduction potential of the acceptor is systematically varied. The lengthy synthetic effort involved in such a study could be avoided by constructing a system consisting of a donor linked to a moiety capable of complexing potential acceptors; in this way a single molecule could be prepared and the electron transfer efficiency to a large number of acceptors examined. Such a system is shown in structure **3**, which can also be represented as shown in Fig. 1. Structure **3** consists of a tetra-aryl porphyrin chemically linked to a β-cyclodextrin; in Fig. 1 the porphyrin is shown as a disc and the β-cyclodextrin as a truncated hollow cone.

The β-cyclodextrin consists of seven glucose rings joined by α-(1,4)-linkages to form a cylindrical molecule. From one end of the cylinder project the primary hydroxyl groups of the six position of glucose. The secondary hydroxyl groups of the two and three positions of the glucose rings project from the other end of the cylinder. The interior cavity of the β-cyclodextrin ring has been shown capable of complexing a variety of different types of molecule (2).

3 Y=Z=H
4 Y,Z=Zn



Many functional derivatives of β-cyclodextrin have been described (3), including some involving the attachment of porphyrins (4, 5), but these have not all been well characterized. Described here are the details of the preparation and

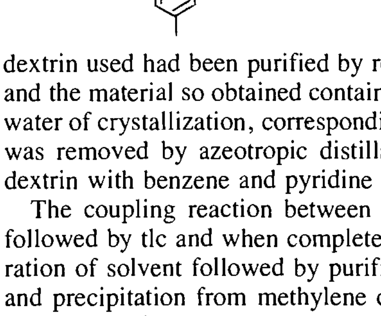
characterization of the linked porphyrin–cyclodextrin 3 and its zinc derivative **4**.

Results and discussion

Preparation of 3

The linked porphyrin–cyclodextrin 3 was prepared by reaction of excess β-cyclodextrin with the acid chloride 2 in pyridine solution. In order to avoid hydrolysis of 2 under the reaction conditions it was found to be necessary to ensure that the β-cyclodextrin was completely free of water; the β-cyclo-



1 X=OH, Y=Z=H
2 X=Cl, Y=Z=H
5 X=OH Y,Z = Zn

dextrin used had been purified by recrystallization from water and the material so obtained contained up to 14% by weight of water of crystallization, corresponding to 90 mol% water. This was removed by azeotropic distillation of predried β-cyclodextrin with benzene and pyridine (see Experimental).

The coupling reaction between **2** and β-cyclodextrin was followed by tlc and when complete was worked up by evaporation of solvent followed by purification by chromatography and precipitation from methylene chloride and pyridine. The product obtained was homogeneous by tlc and gave a satisfactory combustion analysis; as expected for a free base (as opposed to protonated or metallated) porphyrin, it was purple in colour.

The linked compound **3** was completely converted to its zinc complex **4** by treatment with zinc acetate in pyridine, and was isolated by addition of water and purified by precipitation from pyridine–acetonitrile.

Confirmation of structures of 3 and 4

That coupling had occurred between the β-cyclodextrin and the porphyrin was confirmed by infrared spectroscopy. A spectrum of **3** recorded as a KBr disc exhibited bands due to both the β-cyclodextrin and the porphyrin, along with extra peaks at 1720 and 1275 cm^{-1} assignable to the ester function. These usually strong peaks were of only moderate intensity, the major bands being cyclodextrin derived (broad hydroxyl band around 3400 cm^{-1} and several bands assignable to carbon–oxygen single bonds in the 1000–1100 cm^{-1} region). These relative intensities are consistent with the structure of **3** which possesses seven glucose rings (along with their associated hydroxyl groups and ether linkages) for each ester linkage.

The circular dichroism (cd) spectrum of **3** was also recorded. The spectrum is shown in Fig. 2. As might be expected, the inherently achiral porphyrin ring is found to give rise to a weak cd spectrum when chemically attached to a β-cyclodextrin (the latter is constructed from *d*-glucose and so is optically active). This effect could simply be due to the formation of complexes between unlinked β-cyclodextrin and porphyrin; that this was not so was demonstrated by comparing the spectrum obtained from a solution of an unlinked porphyrin (the mono-acid **1**) and a large excess of free β-cyclodextrin (see Fig. 2). In this case no cd spectrum was seen unless large amounts of β-cyclodextrin were present, and even then it was extremely weak and different in appearance compared with the spectrum obtained from **3**. Cyclodextrin-induced circular dichroism has previously been observed for a linked porphyrin–cyclodextrin (4) and also in solutions of porphyrins containing β-cyclodextrin as a cosolute (6).

Benzoylation of β-cyclodextrin, as in the preparation of **3**, could in principle occur either at one of the primary hydroxyl groups or at one of the secondary hydroxyl groups. The primary hydroxyl function would normally be favoured on steric grounds; however, it has been shown that cyclodextrins can undergo selective esterification at a secondary site when esters are used as acyl transfer agents (2, 3). Esterification at a secondary site is thought to proceed by complexation of the alcohol-derived portion of an ester into the cyclodextrin cavity, followed by acyl transfer to one of the cyclodextrin hydroxyls and release of the alcohol produced. This yields the product linked through a secondary alcohol of the cyclodextrin, since the ester is complexed by entry into the opening of the

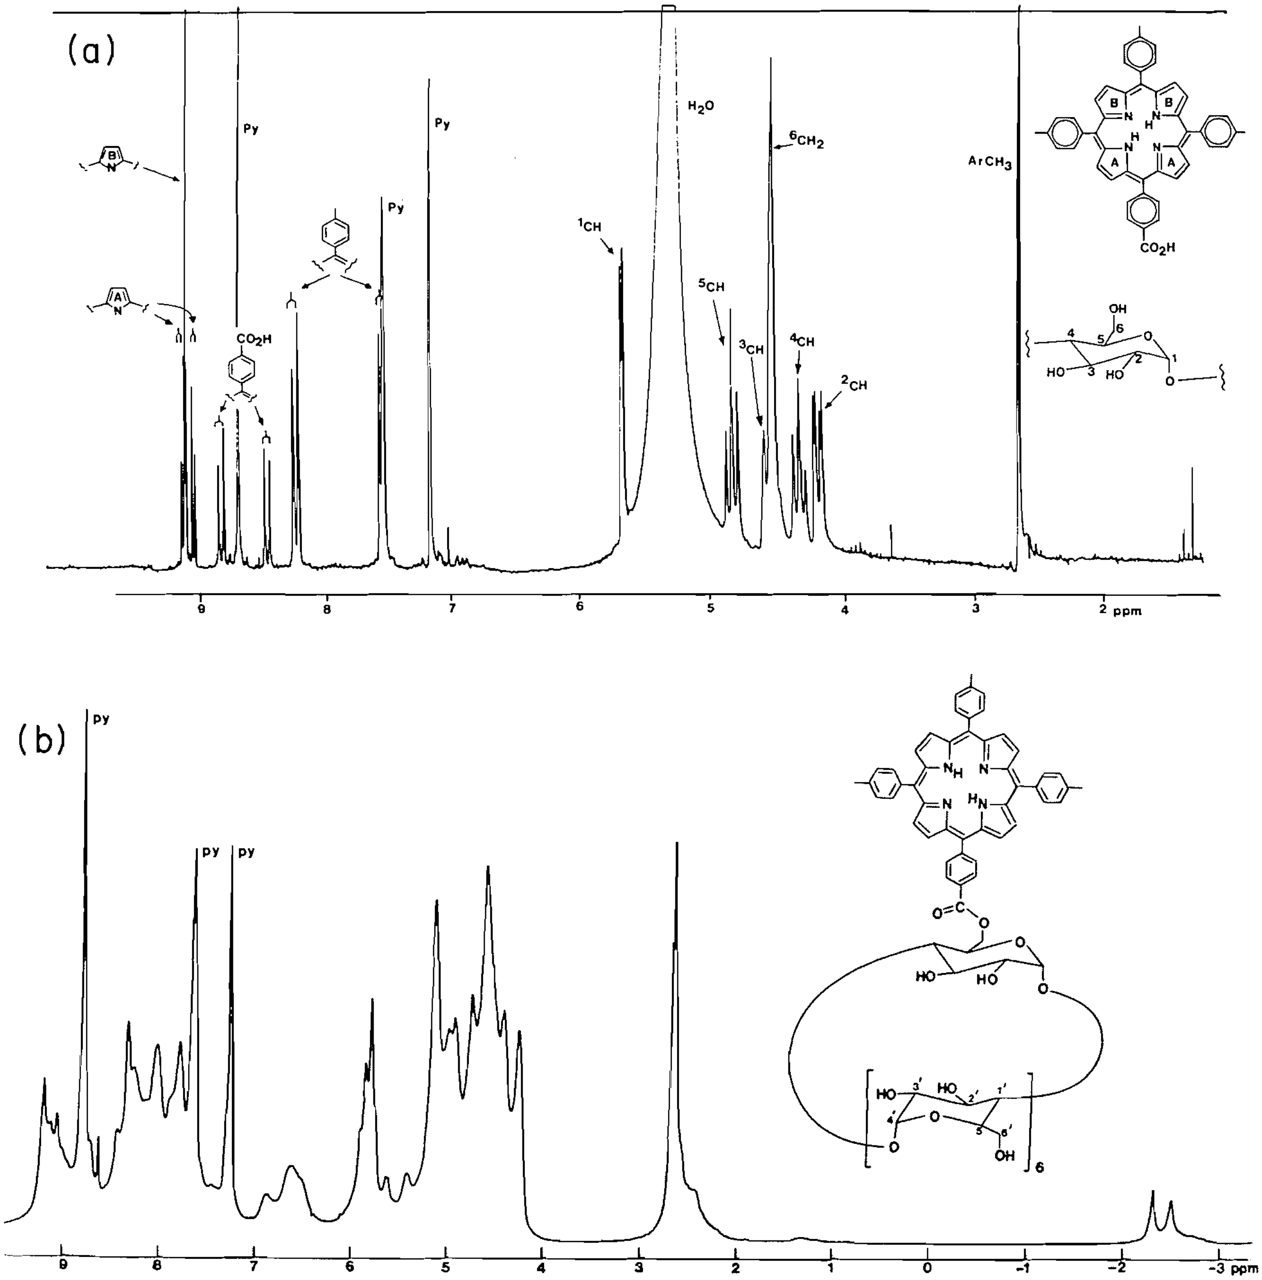


FIG. 3. (a) The [1]H nmr spectrum (200 MHz) of an equimolar mixture of β-cyclodextrin and the porphyrin **1** in pyridine-d_5. (b) The [1]H nmr spectrum (400 MHz) of the linked porpyrin–cyclodextrin **3** in pyridine-d_5.

cyclodextrin cavity bearing the secondary alcohol functions; the primary alcohol functions block the other end of the cyclodextrin (2, 3).

If a complex were formed between cyclodextrin and **2** during the benzoylation reaction, it would be expected to involve insertion of one of the tolyl groups into the cyclodextrin cavity. Under these circumstances the acid chloride function of the porphyrin would be held at a considerable distance from the cyclodextrin hydroxyls and "intramolecular" esterification could not occur. Consequently reaction of the acid chloride **2** with β-cyclodextrin would be expected to yield the product derived from reaction of one of the primary hydroxyl groups. Attempts were made to confirm this by examination of the [1]H nmr spectrum of **3**.

The [1]H nmr spectrum of **3** was compared with that of an equimolar mixture of β-cyclodextrin and **1**. In Fig. 3*a* is shown the spectrum of the mixture of **1** and predried β-cyclodextrin recorded at 200 MHz in pyridine-d_5. Despite the complexity of the molecules, most of the signals can be identified and assignments are made in Fig. 3*a*. The spectrum of β-cyclodextrin has been reported previously (7). In Fig. 3*b* is shown the spectrum of **3** recorded in pyridine-d_5 at 400 MHz, and it is seen to be considerably broadened, presumably because of the non-equivalence of the seven glucose rings of β-cyclodextrin, which in β-cyclodextrin itself are all equivalent. This broadening precludes assignment of the signals to different protons in **3**, particularly those at either C-6 or C-2 and C-3, which would be adjacent to the new ester function were it on a primary or secondary hydroxyl function, respectively.

The site of esterification was eventually determined un-

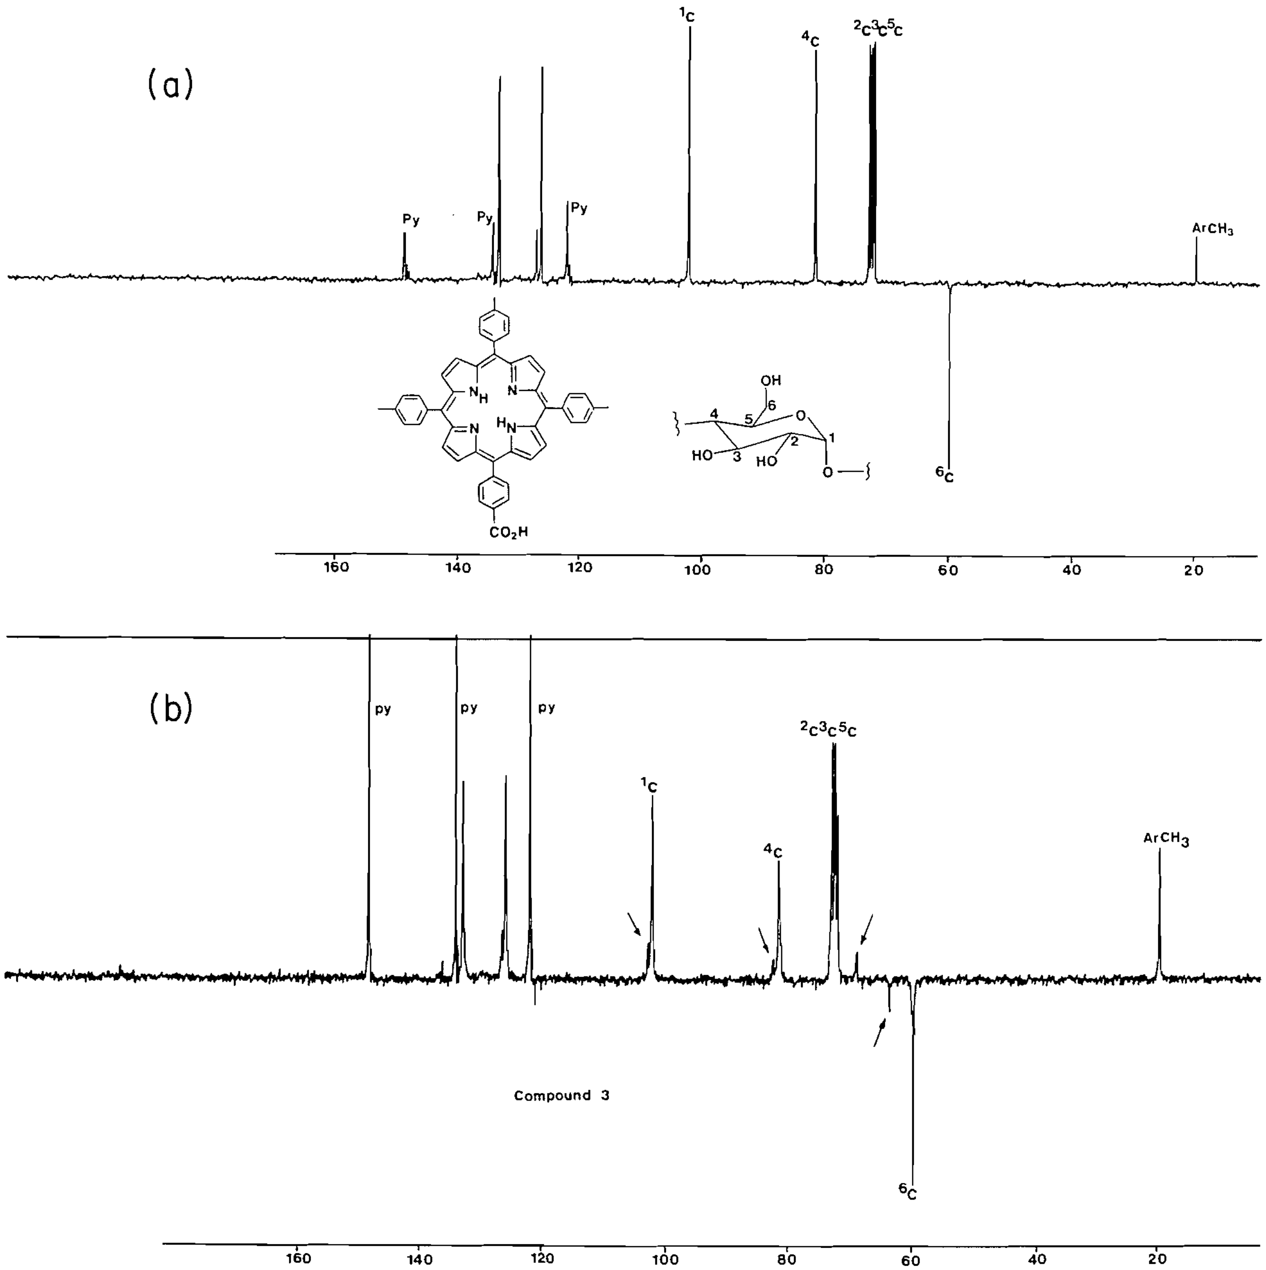

FIG. 4. (a) The ^{13}C nmr spectrum of an equimolar mixture of β-cyclodextrin and porphyrin **1** in pyridine-d_5. (b) The ^{13}C nmr spectrum of the linked porphyrin–cyclodextrin **3** in pyridine-d_5. The signals due to the carbon atoms in the esterified ring of the cyclodextrin are arrowed. The spectra were recorded in the DEPT mode so that methylene signals appear inverted.

ambiguously by the use of ^{13}C nmr spectroscopy. The spectrum of an equimolar mixture of β-cyclodextrin and **1** in pyridine-d_5 is shown in Fig. 4*a*, and that of **3** in Fig. 4*b*. These spectra were recorded using cross polarization so that the quaternary carbons do not appear. As was the case in the ^{1}H nmr spectrum of **3**, slight broadening of some of the signals has occurred due to the nonequivalence of the seven glucose rings of the cyclodextrin. Also, peaks can be seen at 70.7 and 65.4 ppm, of smaller intensity than the rest, corresponding to shifted carbons on the single esterified glucose ring. These signals can be assigned unambiguously to a downfield shifted C-6 carbon and an upfield shifted C-5 carbon respectively, indicating that esterification of the cyclodextrin ring has occurred at the C-6 position. Very slightly downfield shifted peaks corresponding to the C-1 and C-4 carbons of the esterified glucose ring can also be seen. If the benzoylation had occurred at either C-2 or C-3, then no change in C-6 would have been expected and the new signals would have corresponded to shifted C-2 and C-3 carbons. Similar arguments have been used previously to distinguish between 6-tosyl cyclodextrin and the 2-tosyl isomer (8).

Properties of 3 and 4

Neutral free base tetra-aryl porphyrins are usually readily soluble in moderately polar organic solvents such as methylene chloride and insoluble in water, whilst β-cyclodextrin is fairly soluble in water (ca. 3 g/100 mL (2)), dimethylsulphoxide, and pyridine but is insoluble in less polar organic solvents, including methylene chloride. The linked porphyrin–cyclodextrin **3** was totally insoluble in water and methylene chloride

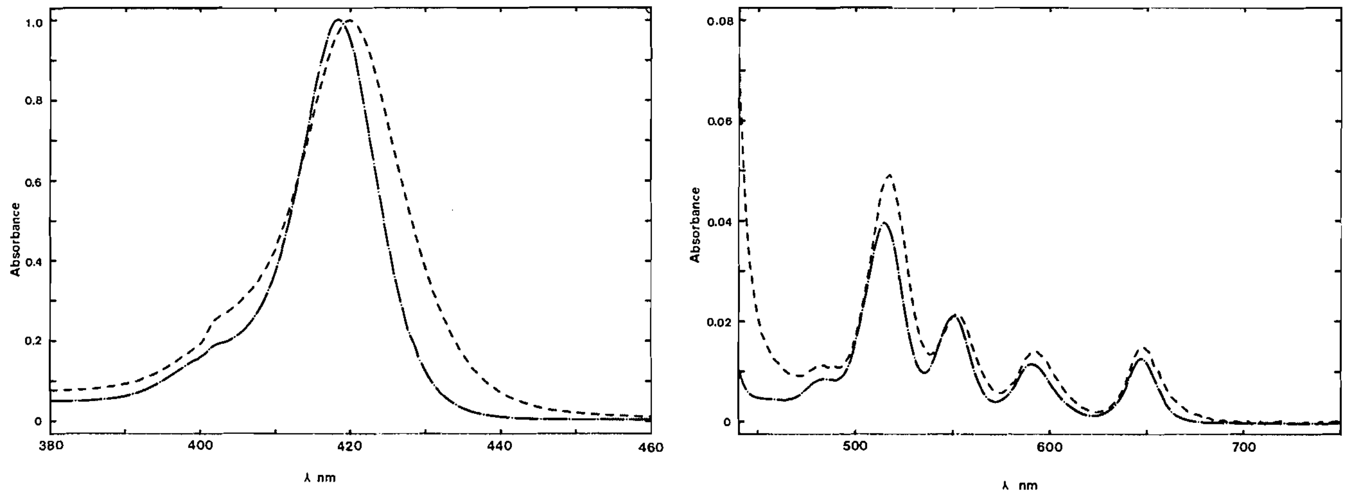

FIG. 5. Ultraviolet/visible absorption spectra of the unlinked porphyrin **1** and the linked porphyrin–cyclodextrin **3** in DMSO. The spectra are normalized at the Soret band maxima (418 nm for **1** and 420 nm for **3**). –•–•–•–• **1**, ----- **3**.

TABLE 1. Fluorescence lifetimes for the linked porphyrin–cyclodextrin **3** and the unlinked porphyrin **1**, and their zinc derivatives **4** and **5**

λ_{ex}[a]	Compound	Lifetime[b]	Ratio[c]

[c]Ratio of amplitudes of fluorescence of the short and long lived fluorescent species (A_S/A_L).

but did dissolve quite readily in polar solvents such as dimethylsulphoxide and pyridine.

The electronic absorption spectra of **3** and **4** were recorded and compared with those of the unlinked porphyrin **1** and its zinc derivative **5**. The linked derivative **3** exhibited normal porphyrin absorption bands in the near uv and visible regions, namely the Soret band at 420 nm and the less intense Q bands at 518, 552, 592, and 648 nm. However, these were all slightly red shifted compared with the corresponding bands in the spectrum of the unlinked compound **1** (see Fig. 5). A similar red shift was observed in the spectra of the zinc derivatives of **1** and **3**. Such red shifts have been observed previously in porphyrins attached to benzoquinones and hydroquinones through flexible linkages (1) and were there ascribed to folded conformations of the molecules in which the porphyrin was interacting with the linked species. A similar effect may be occurring in **3** and **4**, and the following results of steady-state fluorescence and fluorescence lifetime measurements support this hypothesis.

Porphyrins fluoresce from the first excited singlet state with moderate efficiency and **1** and **3** were found to be no exception. The spectrum of **1** was independent of the excitation wavelength, whereas that of **3** was not. Excitation at the red end of the Soret band of **3** yielded an emission spectrum which was slightly shifted and broadened relative to the spectrum obtained when excitation was performed at the blue end of the Soret band. The spectrum obtained by excitation of the blue end of the Soret band is similar to that obtained from the unlinked porphyrin **1**. These observations are consistent with the existence of two conformations (or families of conformations) for **3**, one in which the molecule is extended and there is no interaction between the porphyrin chromophore and the cyclodextrin during the excited state lifetime, and one in which the porphyrin and cyclodextrin are interacting in the ground state, resulting in shifted absorption and emission spectra as compared with the unlinked porphyrin **1**.

The fluorescence lifetimes of **1** and **3** reflect this situation (Table 1). When excited by irradiation of the Soret band the unlinked porphyrin **1** exhibited a single fluorescent decay of 11 ns, whereas **3** showed two decays, one of similar magnitude and one much shorter. The contribution of the latter was enlarged as the excitation wavelength was moved to the red edge of the Soret band. It would therefore appear that in the postulated interacting species the interaction results in a shortening of the singlet excited state lifetime, due either to enhancement of the rate of radiationless decay to the ground state or to an increase in the rate of intersystem crossing to the triplet excited state.

Whilst comparison of the absorption and emission spectra of **4** and **5** suggested the same type of interaction as in **3**, the fluorescence lifetimes of **4** and **5** were similar (ca. 2 ns)[4] and no shorter component was seen for **4**, although this may have been present but hidden by the excitation flash.

Inclusion complexes of 3 with benzoquinone

Cyclodextrins form inclusion complexes with hydrophobic compounds in polar media (2). The preferred solvent is water, where the polarity of the solvent and the driving force for complexation in the hydrophobic cavity of the cyclodextrin are maximized. Because of the insolubility of **3** in water, dimethylsulphoxide was chosen as the solvent for studies of the ability of **3** to include benzoquinone. Complexes are known to form between cyclodextrins and hydrophobic compounds in this solvent although the equilibrium constants for complexation are less favourable than when water is the solvent (11).

It had been hoped to study the ability of the linked por-

[4]The shortening of the singlet lifetime resulting from insertion of zinc into the porphyrin may arise from an enhancement of the rate of intersystem crossing. Such a decrease in lifetime is commonly observed when porphyrins are metallated (1).

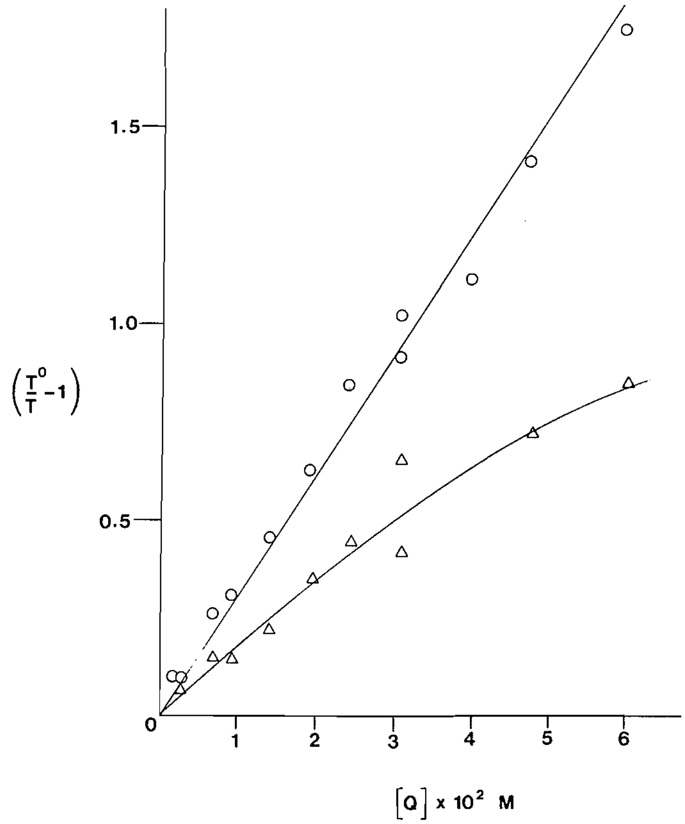

FIG. 6. Stern–Volmer plots for the quenching of the two fluorescent states of **3** by benzoquinone in dimethylsulphoxide at room temperature. [Q] = concentration of benzoquinone; τ = fluorescent lifetime in the presence of quencher; τ^0 = lifetime in the absence of quencher; ○ = long lifetime; △ = short lifetime.

phyrin–cyclodextrin **3** to complex benzoquinone by observation of the ^{1}H nmr and electronic absorption spectra of solutions of the two compounds. However, the complexity and broadness of the nmr spectrum precluded this. When the electronic absorption spectrum of **3** was recorded in the presence of benzoquinone it was found that charge transfer complexation of benzoquinone by the porphyrin was competitive with complexation by the cyclodextrin.[5] This prevents analysis of the complexing ability of the cyclodextrin moiety in **3** by this method. The ability of **3** to complex benzoquinone was, however, successfully demonstrated by observation of the kinetics of electron transfer quenching of porphyrin fluorescence by quinones.

The two fluorescence lifetimes exhibited by **3** were measured in dimethylsulphoxide in the presence of varying amounts of benzoquinone.[6] The results are shown in Fig. 6, where they are plotted to fit the Stern–Volmer expression:

$$\frac{\tau^0}{\tau} - 1 = k_q\tau^0[Q]$$

where τ^0 is the unquenched lifetime, τ is the lifetime in the presence of quencher Q, and k_q is the quenching rate constant. It can be seen that the species giving rise to the longer-lived emission apparently undergoes normal Stern–Volmer quenching. The slope of the line corresponds to the Stern–Volmer constant $k_q\tau$, and taking an unquenched lifetime of 11 ns indicates a quenching rate constant of 2.7×10^9 L M^{-1} s^{-1}. This suggests that quenching of the long-lived porphyrin fluorescence is proceeding intermolecularly at close to the diffusion controlled rate which can be calculated as 3.3×10^9 L M^{-1} s^{-1} in this solvent.[7] The quenching of the species giving rise to the shorter-lived fluorescence appears to occur at a rate of 5×10^9 L M^{-1} s^{-1} (assuming an unquenched lifetime of 3.5 ns) at lower benzoquinone concentrations, but becomes less efficient at benzoquinone concentrations greater than 3×10^{-2} M, causing the line shown in Fig. 6 to depart from linearity. A similar experiment performed with **1** and benzoquinone showed Stern–Volmer quenching of the single emitting species with a rate similar to that of the longer-lived component of **3**, corresponding to normal diffusion controlled intermolecular quenching.

These observations can be understood in terms of different modes of quenching of the two conformations postulated for **3**: in the extended conformation of **3** the porphyrin fluorescent state undergoes diffusional intermolecular quenching only, whereas the interacting conformer (i.e. that in which it is postulated that the porphyrin is folded over the cyclodextrin cavity, resulting in a shorter-lived fluorescence) can undergo intermolecular quenching and, if a benzoquinone molecule is in the cyclodextrin cavity, competitive intramolecular quenching. At high benzoquinone concentrations the cyclodextrin cavity always contains a quinone molecule and subsequent increase in quinone concentration increases the efficiency of intermolecular quenching only, without affecting the efficiency of intramolecular quenching. Consequently the line for quenching the shorter fluorescent state of **3** in Fig. 6 shows downward curvature at high benzoquinone concentrations and the apparent rate constant for diffusional quenching at lower benzoquinone concentrations is greater than the maximum possible rate, viz. the rate of diffusion in this solvent.

The departure from linearity in the quenching of the shorter-lived component shown in Fig. 6 commences when the benzoquinone concentration reaches approximately 3×10^{-2} M; if it is assumed that at this point 90% of **3** contains a quinone in the cyclodextrin cavity, then a very approximate equilibrium constant for complexation of benzoquinone by **3** in dimethylsulphoxide can be calculated, and is found to be of the order of 10 L M^{-1}. This value is comparable to the constants reported elsewhere (11) for complexation by β-cyclodextrin in dimethylsulphoxide.

The quenching of **3** by benzoquinone presumably occurs by an electron transfer process since the alternative process, energy transfer, is endothermic.[8] Studies of the efficiency of the quenching reaction in the presence of quinones of different reduction potential are being made to confirm this and to determine the effect of variation of acceptor reduction potential upon the light-induced electron transfer reaction.

[5]M. C. Gonzalez, J. R. Bolton, and A. C. Weedon, unpublished work.

[6]The ground state complexes referred to in the citation to footnote 4 were non-emissive and so do not interfere with this analysis.

[7]Calculated from the Debye equation, $k = 8RT/3000\eta$, taking the viscosity η of dimethylsulphoxide as 1.996 centipoise at 25°C.

[8]From the absorption spectra of benzoquinone and tetratolyl porphyrin the singlet excited state energies of these compounds can be estimated as approximately 60 kcal/mol and 44 kcal/mol, respectively. This corrsponds to a endothermicity for energy transfer from the singlet excited porphyrin to the quinone of 16 kcal/mol.

Experimental

Preparation of the linked porphyrin–cyclodextrin 3

The porphyrin acid chloride, **2**, was prepared from the free acid **1** and thionyl chloride using the published procedure (9). It was found to be important to ensure complete removal of all traces of excess thionyl chloride from the porphyrin **1** for the subsequent reaction with β-cyclodextrin. Failure to do so resulted in the formation of unidentified by-products when **1** was dissolved in pyridine.

β-Cyclodextrin was purchased from the Aldrich Chemical Company, and also from the Sigma Chemical Company, and was dried before use to prevent hydrolysis of the porphyrin acid chloride, **2**, during the coupling reaction. The β-cyclodextrin was purified and dried by the reported methods (10) which required recrystallization from water and drying at 70°C/1 Torr (1 Torr = 133.3 Pa) overnight. The β-cyclodextrin was further dried by distilling a solution of the cyclodextrin in a mixture of dry pyridine and benzene under a nitrogen atmosphere until all of the benzene had been removed and the temperature of the distilling vapours had reached the boiling point of pyridine. The resulting solution was used for the reaction with the porphyrin acid choride **2**.

The porphyrin acid chloride **2** (263 mg) and β-cyclodextrin (a three-fold excess) were stirred together in pyridine under dry nitrogen for 15 h after which time tlc (fluorescor-free silica gel; benzene–pyridine, 1:1) of a sample of the reaction mixture treated with methanol indicated that the acid chloride **2** (observed as the methyl ester) was ca. 95% converted to products. The greater part of the pyridine solvent was removed by distillation under vacuum at 40°C until the product began to precipitate. At this point all porphyrin-containing products were precipitated by addition of water. The solids were washed with water (to remove excess β-cyclodextrin) and dried under vacuum at 40°C.

The dried precipitate was redissolved in a small volume of pyridine and the linked porphyrin–cyclodextrin was precipitated and so separated from other porphyrins by addition of methylene chloride. The precipitated linked compound was chromatographed on a column of silica gel using pyridine was eluent. The major fraction was filtered and concentrated under vacuum; addition of methylene chloride gave a purple precipitate of the linked porphyrin–cyclodextrin **3** which was dried under vacuum at room temperature. The yields obtained by this route were 40–50%.

The linked compound was homogeneous by tlc on fluorescor-free silica gel (see Table 2); however, attempts to obtain a satisfactory combustion analysis were frustrated by the apparent ability of **3** to complex solvent into the cyclodextrin cavity. Analyses were obtained corresponding to **3** containing non-integral numbers of pyridine molecules. Eventually, prolonged drying under vacuum at room temperature gave a sample which had C 59.23%, H 5.48%: $C_{90}H_{104}N_4O_{36}$ requires C 59.47, H 5.77%. The linked compound **3** had: ir (KBr disc): 3400 (s, br), 2920 (m), 1720 (m), 1635 (w), 1610 (w), 1275 (m), 1160 (s), 1080 (s), 1030 (vs), 800 (m), 700 (m) cm^{-1}; uv/vis (DMSO): 420 ($\epsilon = 3.08 \times 10^5$), 518 ($\epsilon = 1.63 \times 10^4$), 552 ($\epsilon = 7.51 \times 10^3$), 592 ($\epsilon = 4.94 \times 10^3$), 648 ($\epsilon = 4.97 \times 10^3$) (see Fig. 5). The ^1H nmr spectrum of **3** is shown in Fig. 3; ^{13}C nmr (pyridine-d_5): 21.3 (CH_3), 61.5 (CH_2), 65.4 (CH_2, approximately 1/6 the intensity of the signal at 61.5 ppm), 70.7 (CH, approximately 1/6 the intensity of the signal at 73.9 ppm), 73.9 (CH), 74.3 (CH), 74.7 (CH), 83.3 (CH), 104.0 (CH), 128.0 (CH), 134.9 (CH) ppm (see Fig. 4); cd ($c = 4.65 \times 10^{-6}$ *M*, DMSO, 25°C): $[\theta]_{445}$ 0, $[\theta]_{427}$ −438.4, $[\theta]_{421}$ 0, $[\theta]_{416}$ +168, $[\theta]_{400}$ 0 (see Fig. 2).

Preparation of the zinc complex of 3 (4)

The linked porphyrin–cyclodextrin **3** (50 mg) was dissolved in pyridine (10 mL) along with a 50% excess of anhydrous zinc acetate and the mixture was stirred at room temperature in the dark. The electronic absorption spectra of aliquots of the mixture were monitored to follow the reaction (upon metallation the free porphyrin absorption at 518 nm is shifted to 562 nm) and this indicated complete conversion after 20 h. The major part of the pyridine was removed under vacuum at room temperature and excess water was added to the residue to precipitate the porphyrin-containing products. The solid obtained was vacuum dried and redissolved in the minimum of pyridine; addition of acetonitrile induced deposition of **4**, which was homogeneous by tlc (benzene/pyridine, 1:3). For **4**: uv/vis, (DMSO): 430 ($\epsilon = 3.8 \times 10^5$), 522 ($\epsilon = 3.9 \times 10^3$), 562 ($\epsilon = 1.61 \times 10^4$), 602 ($\epsilon = 8.5 \times 10^3$) nm (see Fig. 5); cd ($c = 2.88 \times 10^{-6}$ *M*, DMSO, 25°C): $[\theta]_{450}$ 0, $[\theta]_{434}$ −253, $[\theta]_{420}$ 0; Γ = 12 nm.

Fluorescence lifetime measurements

Fluorescence lifetime measurements were performed on a Photochemical Research Associates Model 300 nanosecond lifetime fluorimeter by the method of time-correlated single photon counting. The measurements were made at room temperature on solutions of concentration $10^{-5} - 10^{-6}$ *M*; the fluorescence lifetimes were independent of concentration over the range $10^{-4} - 10^{-7}$ *M*.

Structure and fragmentation of $C_5H_{11}O^+$ ions formed by chemical ionization

JOHN V. HEADLEY[1] AND ALEX. G. HARRISON
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received May 30, 1984

JOHN V. HEADLEY and ALEX. G. HARRISON. Can. J. Chem. **63**, 609 (1985).

The proton transfer chemical ionization mass spectra of eleven $C_5H_{10}O$ isomers have been obtained using H_3^+, N_2H^+, HCO^+, and D_3^+ as reagent ions. The chemical ionization mass spectra in combination with isotopic labelling and metastable ion studies have made it possible to elucidate the major fragmentation reaction channels of the $C_5H_{11}O^+$ ions formed and their dependence on precursor structure. From collision induced dissociation studies nine stable distinct $C_5H_{11}O^+$ ion structures have been identified; protonated 3-methylbutanone and protonated 2,2-dimethylpropanal readily interconvert by a pinacolic – retro-pinacolic rearrangement.

JOHN V. HEADLEY et ALEX. G. HARRISON. Can. J. Chem. **63**, 609 (1985).

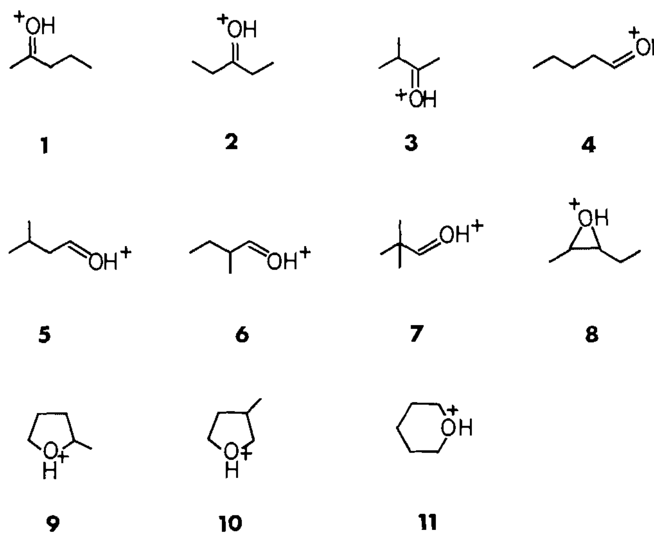
Utilisant les ions H_3^+, N_2H^+, HCO^+ et D_3^+ comme ions réactifs, on a examiné les spectres de masse par ionisation chimique des transferts de protons de onze isomères $C_5H_{10}O$. En combinant les spectres de masse par ionisation chimique avec des études de marquage isotopique et d'ions métastables, on a pu élucider les principales voies de fragmentations des ions $C_5H_{11}O^+$ formés ainsi que leurs dépendances sur la structure de leurs précurseurs. En se basant sur des études de dissociations induites par des collisions, on a pu identifier neuf structures stables distinctes de l'ion $C_5H_{11}O^+$; la méthyl-3 butanone protonée et le diméthyl-2,2 propanal protoné se transforment facilement l'un dans l'autre par le biais d'une transposition pinacolique/rétropinacolique.

[Traduit par le journal]

Introduction

The $C_nH_{2n+1}O^+$ ions are abundant fragment ions in the electron impact mass spectra of aliphatic alcohols and ethers (1) and, because of their widespread occurrence, have received extensive study with respect to their thermochemistry, structures, and unimolecular fragmentation reactions. The thermochemistry of the lower members of the series (up to C_4) is well established as a result of the elegant work of Lossing (2). The structures and low energy (metastable) unimolecular fragmentation reactions of the $C_2H_5O^+$, $C_3H_7O^+$, and $C_4H_9O^+$ ions formed by electron impact have been studied exhaustively by many groups and are now well understood (for a review and summary of these studies see ref. 3). Indeed, the study of these systems played a large role in the development of the potential energy profile approach (4–6) to the interpretation of the low energy unimolecular chemistry of isolated gaseous organic ions. The $C_nH_{2n+1}O^+$ ions also can be prepared by proton transfer chemical ionization of carbonyl compounds and cyclic ethers and, recently, the chemistry of the $C_3H_7O^+$ ions (7, 8) and $C_4H_9O^+$ ions (9) formed by proton transfer chemical ionization have been studied in detail and interpreted in terms of the potential energy profiles established from the earlier EI studies. In this chemical ionization approach a number of structures, such as protonated cyclic ethers inaccessible by electron impact methods, become available for study.

In contrast to the extensive studies of the lower members of the series, the higher members of the $C_nH_{2n+1}O^+$ series have received much less attention. McLafferty and Sakai (10) have reported the collision-induced dissociation (CID) mass spectra of a few $C_5H_{11}O^+$ ions, while Zahorszky (11) has surveyed briefly the unimolecular ion chemistry of higher members of the series. The most extensive study has been that of Audier *et al.* (12) of the $C_5H_{11}O^+$ ions of nominal structures **1** to **7** (Scheme 1) prepared by electron impact methods. They studied not only the unimolecular metastable ion chemistry but also the CID mass spectra, and were able to show that all the ions



SCHEME 1

except **3** and **7** gave distinct CID mass spectra indicating single structures or mixtures of structures; structures prepared initially as **3** and **7** gave identical CID mass spectra and it was concluded that these two ions interconverted freely by way of pinacolic – retro-pinacolic rearrangements. Using deuterium isotopic labelling for a number of the species, they delineated a number of the metastable isomerization and fragmentation mechanisms and proposed detailed reaction pathways. Their work will be discussed later in relation to the results obtained in the present study, which reports an extensive investigation of the $C_5H_{11}O^+$ ions of nominal structures **1** to **11** (Scheme 1) prepared by proton transfer chemical ionization. The present study consisted of three parts: first, a study of the proton transfer chemical ionization (CI) mass spectra using H_3^+, N_2H^+, and HCO^+ as reagent ions to examine the higher energy fragmentation reactions of $C_5H_{11}O^+$ ions and their dependence on internal energy; second, collision-induced dissociation (CID) studies to characterize the structures of non-decomposing $C_5H_{11}O^+$ ions; and, third, the use of isotopic labelling in conjunction

[1] Present Address: Alberta Environment Centre, Vegreville, Alberta.

with CI mass spectra and metastable ion studies to obtain information on detailed fragmentation reaction pathways. In part, the present study serves to confirm and extend the results obtained in the earlier EI study (12) and, in part, it provides the opportunity to compare the metastable reactions of ions prepared by chemical ionization and electron impact methods. As Holmes and Terlouw (13) have pointed out, there have been relatively few studies of metastable ion fragmentation reactions following chemical ionization.

Experimental

The chemical ionization mass spectra were obtained using a DuPont 21-490 mass spectrometer equipped with a high pressure chemical ionization source. The source temperature was ~100°C and the ionizing electron energy 70 eV, with the repellers at cage potential. The liquid samples were introduced through a heated inlet system held at ~100°C. Reagent gas pressures were not measured directly but were estimated to be 0.2 to 0.3 Torr (1 Torr = 133.3 Pa). The H_3^+ and D_3^+ reactant ions were produced by electron impact ionization of H_2 and D_2, respectively, at high pressure, while the N_2H^+ and HCO^+ reagent ions were prepared by electron impact ionization of the appropriate gas X (10%) in H_2 as described previously (7, 14).

Unimolecular (metastable) fragmentation reactions of the $C_5H_{11}O^+$ ions and deuterated analogues (formed by CH_4 or CD_4 chemical ionization) were recorded for fragmentation reactions occurring in the second drift region (between the magnetic and electric sectors) of a ZAB-2F mass spectrometer (University of Ottawa) using the MIKES (mass analyzed ion kinetic energy spectroscopy) technique. In this technique the ion of interest is selected by adjusting the magnetic field and undergoes fragmentation in the drift region (either unimolecular or, on addition of a collision gas, collision induced) with the fragmentation products being selected and identified according to their kinetic energy by scanning the voltage on the electric sector. The kinetic energy releases associated with the metastable fragmentation reactions, evaluated as $T_{1/2}$, were obtained from the peak widths after correction for the main beam width according to the relation (13): $\omega_{corr} = (\omega^2_{met} - \omega^2_{main\ beam})^{1/2}$. The collision-induced dissociation (CID) mass spectra were obtained by the MIKES technique with the ZAB-2F instrument using helium gas; the helium was admitted to the collision cell to reduce the main beam intensity to 50%. Source temperatures for the ZAB experiments were ~150°C and the ion accelerating potential was 8 keV.

Chemical ionization reagent gases were of the highest possible purity while the $C_5H_{10}O$ compounds were commercial samples of high purity. The majority of the labelled compounds were prepared by base-catalyzed exchange of the appropriate carbonyl compound with D_2O. The syntheses of 2-pentanone-1,1,1-d_3 and 2-pentanone-5,5,5-d_3 have been described previously (15). Final purification was by gas chromatography.

Results and discussion

Unimolecular ion chemistry

The proton transfer chemical ionization mass spectra of the eleven $C_5H_{10}O$ isomers studied are presented in Tables 1 to 4 for the reagent ions H_3^+, N_2H^+, HCO^+, and D_3^+ respectively. The results clearly indicate that the following fragmentation reactions of the $C_5H_{11}O^+$ ion are occurring:

$$[1]\quad C_5H_{11}O^+ \xrightarrow{-CH_4} C_4H_7O^+\ (m/z\ 71)$$

$$[2]\quad \xrightarrow{-H_2O} C_5H_9^+\ (m/z\ 69)$$

$$[3]\quad \xrightarrow{-C_2H_4} C_3H_5^+\ (m/z\ 41)$$

[4] $\xrightarrow{-CH_2O/C_2H_6} C_4H_9^+/C_3H_5O^+$ (*m/z* 57)

[5] $\xrightarrow{-C_3H_6} C_2H_5O^+$ (*m/z* 45)

[6] $\xrightarrow{-C_3H_8/C_2H_4O} C_2H_3O^+/C_3H_7^+$ (*m/z* 43)

In two cases, reactions [4] and [6], we cannot distinguish between two possible compositions of the fragment ion observed and it appears that the elemental composition of these ions depends on the molecule involved. The CI mass spectrum of $CH_3CD_2COCD_2CH_3$ showed that the *m/z* 57 ion (reaction [4]) shifted cleanly to *m/z* 59, while the D_2CI mass spectrum (Table 4) showed that the added proton was not contained in the ion. Thus we conclude that in this case the ion is the acyl ion $C_2H_5C{\equiv}O^+$; on the other hand, it is possible that for 2,2-dimethyl propanal (ion **7**) the *m/z* 57 fragment is $C_4H_9^+$. Similarily the CI mass spectra of $CD_3COCH_2CH_2CH_3$ and $CD_3COCH(CH_3)_2$ showed that the *m/z* 43 fragment (reaction [6]) largely incorporated the Cl methyl and is the acyl ion $CH_3{-}C{\equiv}O^+$, while for 3-methyl pentanal (ion **5**) the ion appears to be largely $C_3H_7^+$ (essentially no shift in the CI mass spectrum of $(CH_3)_2CHCD_2CHO$ or in the D_2CI mass spectrum). In other cases the elemental composition of these ions is not known. Reaction [1] and that part of reaction [4] leading to formation of $C_3H_5O^+$ may occur either by elimination of CH_4 or C_2H_6, respectively, from MH^+ or may occur by direct alkide ion abstraction; the CID spectra (see below) indicate that elimination of neutral alkanes is a significant reaction channel for decomposition of activated $C_5H_{11}O^+$ ions. The $(M - H)^+$ ion (*m/z* 85) is of low abundance except for the cyclic ethers where it becomes a major ion in the CI mass spectra. This product does not contain the added proton (see the D_2 CI mass spectra) and may arise primarily by direct hydride abstraction. The $C_3H_5^+$ ion is assumed to arise by fragmentation of $C_5H_9^+$ (*m/z* 69, $MH^+ - H_2O$); interestingly, this fragmentation reaction seems to be much more facile for the $C_5H_9^+$ ions arising from **4**, **9**, **10**, and **11** than for the $C_5H_9^+$ ions arising from **3** and **7**.

The H_2 CI mass spectra permit a distinction to be made between the eleven compounds studied, with the possible exception of 3-methyl tetrahydrofuran and tetrahydropyran (ions **10** and **11**) where the CI mass spectra are quite similar. Ions **1**, **2**, **6**, and **8** show reaction [5] as the major fragmentation channel while ions **3**, **4**, **7**, **9**, **10**, and **11** show $C_5H_9^+$ as the dominant fragment ion. In the H_2 CI mass spectrum, ion **5** shows $C_3H_7^+$ as the base peak (reaction [6]) although reaction [2] becomes the major reaction channel as the protonation exothermicity decreases from H_3^+ to CHO^+. As expected, the total extent of fragmentation decreases as the protonation exothermicity decreases.

In agreement with the EI study of ions **1** to **7** (12), only two metastable fragmentation reactions of $C_5H_{11}O^+$ ions were observed, corresponding to elimination of H_2O (reaction [2]) and elimination of C_3H_6 (reaction [5]). Table 5 records the intensity ratio $(C_5H_9^+ + C_3H_5^+)/C_2H_5O^+$ observed in the CI mass spectra and in the metastable ion mass spectra following both CI and EI ionization; this ratio represents the relative importance of fragmentation reactions [2] and [5] for the ions studied. The enthalpy of formation of $C_5H_9^+ + H_2O$ (~527 kJ mol^{-1}) is

significantly less than that of $CH_3CHOH^+ + C_3H_6$ (~602 kJ mol^{-1}) yet both fragmentation reactions are observed as metastable ions (for the thermochemical data, see the Appendix). On the other hand $\Sigma\Delta H_f^0(CH_3C{\equiv}O^+ + C_3H_8) \approx 557$ kJ mol^{-1}, yet this reaction is not observed as a metastable fragmentation reaction even for ions such as **1** and **3** where the ion is observed in the CI mass spectra. Presumably the critical reaction energy for formation of $CH_3C{\equiv}O^+ + C_3H_8$ must be considerably higher than the reaction endothermicity. The fact that both reactions [2] and [5] are observed for metastable ions must mean that the critical reaction energies are similar despite the lower reaction endothermicity for reaction [2]. The ratio $(C_5H_9^+ + C_3H_5^+)/C_2H_5O^+$ increases with decreasing mean internal energy (Table 5), particularly for those ions which show reaction [2] as the major reaction channel. This is consistent with reaction [2] having both a lower critical reaction energy and a lower frequency factor. It should also be noted that the intensity ratio is larger for the metastable ions gener-

ated by EI than for the ions generated by CI. This is in agreement with earlier conclusions (8) that metastable ions generated by CI have a higher mean internal energy than the same ions generated by EI methods. The kinetic energy releases ($T_{1/2}$) for metastable loss of H_2O were essentially invariant (26 ± 5 meV) for all $C_5H_{11}O^+$ structures, as were the $T_{1/2}$ values (22 ± 4 meV) for metastable elimination of C_3H_6. No distinction between ion structures can be made on this basis. In passing, we would note that our $T_{1/2}$ results for **1** to **7** are in reasonable agreement with the $T_{22\%}$ data of Audier *et al.* (12) but not in agreement with their $T_{50\%}$ data, which are more than two times larger.

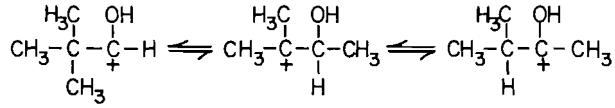
Characterization of $C_5H_{11}O^+$ ion structures

The comparison of the collision-induced dissociation (CID) mass spectra of gaseous ions has proven (16, 17) to be an extremely useful method for characterizing and comparing the structures of such ions. Accordingly we have obtained the CID mass spectra of the ions of nominal structures **1** to **11** with the results tabulated in Tables 6 and 7 (m/z 69 and m/z 45, which may have unimolecular contributions, are not included in this tabulation). The results obtained for **1** to **7** are in good agreement with those reported earlier (12).

The $C_5H_{11}O^+$ ions can be classified in terms of the base peak observed in the CID mass spectrum. Thus, the ions **1**, **3**, **5**, **7**, and **8** (the first five entries in Table 6) have m/z 43 as the base peak, while **2** (entry six, Table 6) has m/z 57 as the base peak and **6** (entry seven, Table 6) shows m/z 43 and m/z 57 at almost equal intensity. The remaining ions **4**, **9**, **10**, and **11** (Table 7) show m/z 41 as the base peak in the CID mass spectra.

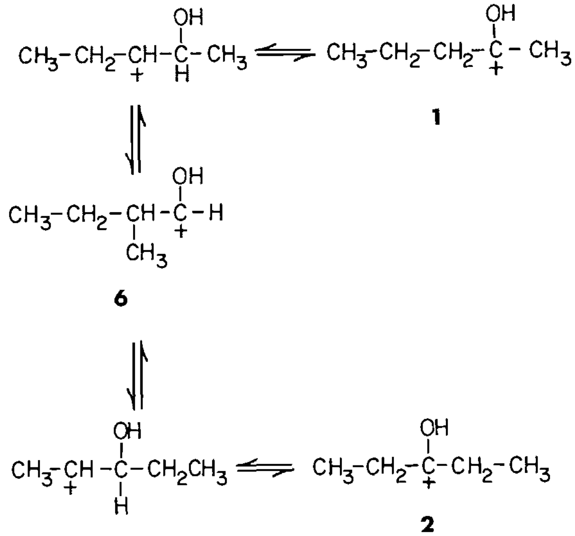
Within the first group (m/z 43 base peak) **1** and **8** are clearly distinguishable from **3**, **5**, and **7** by the relative intensities at m/z 58, while **1** and **8** are distinguishable from each other by the m/z 59, 57, and 42 ion intensities. Structure **5** is distinguished from **3** and **7** by the relative intensities of the ion signals at m/z 71, 57, 44, and 42. On the other hand, **3** and **7** have very similar CID mass spectra and cannot be distinguished. This similarity has been interpreted by Audier *et al.* (12) in terms of a facile interconversion of **3** and **7** by the pinacolic – retro-pinacolic rearrangment outlined in Scheme 2. Thus, in this case, the collisional activation process samples the same mixture of ion structures whether we start with **3** or **7**. (Further evidence for this interchange comes from the isotopic labelling results discussed below.)

A similar type of rearrangement could lead to interconversion of **1**, **2**, and **6** (Scheme 3). However, it is clear from



7 **3**

SCHEME 2



SCHEME 3

the results in Table 6 that the collisional activation process is not sampling the same (equilibrium) mixture of structures in the three systems; in particular, the CID spectrum of **6** cannot be reproduced by a linear combination of the spectra of **1** and **2**. We conclude that **1**, **2**, and **6** are stable species existing in potential wells, although we cannot discount some interconversion. The fragmentation reactions of **6**, particularly the formation of CH_3CHOH^+, are more readily rationalized if we allow the isomerizations of Scheme 3. Similarly, the formation of $CH_3CH{=}OH^+$ from **2** obviously requires skeletal isomerization which may occur as outlined in Scheme 3.

Alternatively, it is possible that the ions of nominal structures **1**, **2**, and **8** interconvert through the rearrangements outlined in Scheme 4. However, once again the results indicate that we are not dealing with the same mixture of structures in the CID process and, in particular, that the spectrum of **8** is not a linear combination of the spectra of **1** and **2**. Consequently, we conclude that **8** also erpresents a stable ion, although rearrangement to **1** or **2** probably occurs prior to fragmentation.

The ions **4**, **9**, **10**, and **11** all show m/z 41 ($C_3H_5^+$) as the base peak in their CID mass spectra (Table 7). The structure **4** is clearly distinct from **9** to **11** while the latter three show substantial differences in the m/z 67–72 and m/z 56–59 regions which indicate different structures for the three ions.

In summary, the CID results indicate that the ions of nominal structures **3** and **7** freely interconvert and cannot be distinguished from each other. The remaining ions appear to be structurally distinct although in a number of cases some limited interconversions may be occurring.

Mechanistic considerations

Deuterium isotopic labelling both in the EI study (12) and in the present CI study have provided some insight into the mech-

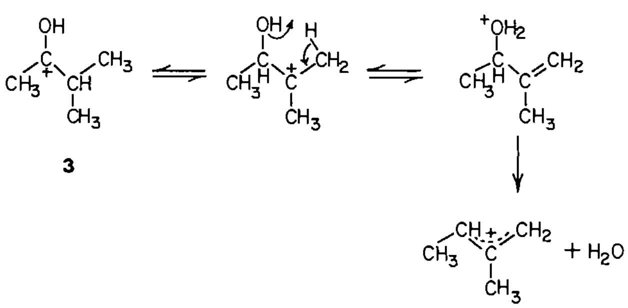

SCHEME 5

ion production are very similar. The most notable feature of these results is that, with few exceptions, the added hydrogen (oxygen-bonded hydrogen) is not always lost with the neutral water but undergoes interchange with carbon-bonded hydrogens. In general, the extent of this interchange decreases with increasing internal energy (decreasing lifetime) as shown by the results from the D_2 CI mass spectra. The extent of interchange is particularly pronounced in the metastable fragmentation of the protonated aldehydes **4–6** and cyclic ethers **8–11**, but is significant even in the D_2 CI mass spectra. Similar results have been reported earlier in chemical ionization studies (18–20).

Further information concerning the water elimination comes from deuterium labelling on the carbon skeleton. Thus **4**-2,2-d_2 and **5**-2,2-d_2 showed loss of H_2O only in metastable ion fragmentation reactions, although 10–15% HDO elimination was

observed in the CI mass spectra. Audier *et al.* (12) have shown that only H_2O is eliminated from **5**-1-*d* and **6**-1-*d* metastable ions. These results are in agreement with the labelling results of Fales *et al.* (18) who showed that water elimination from protonated n-heptanal involved only the added proton and hydrogens on C3 to C7.

The metastable ion intensities for loss of $(H,D)_2O$ from labelled **3** ions are recorded in Table 9. Again the CI and EI results are in good agreement. The results can be readily rationalized in terms of Scheme 5 after equilibration of the methyl groups by the retro-pinacolic rearrangement of Scheme 2. The

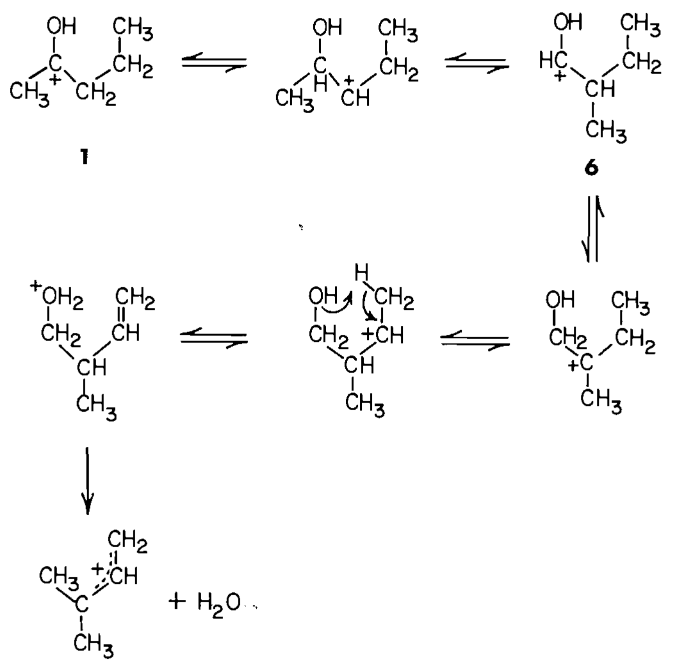

SCHEME 6

equilibration of methyl groups also occurs prior to the higher energy fragmentation in the CI mass spectra; **3**-1,1,1,3-d_4 showed ~26% HDO loss and 74% H_2O in the H_2, N_2/H_2, and CO/H_2 CI mass spectra.

The metastable ion intensities for loss of $(H,D)_2O$ from labelled **1** ions are recorded in Table 10 for EI and CI studies. It is clear from these results that the oxygen-bonded hydrogen and the hydrogens of C1 and C5 are the major origins of the hydrogens lost as H_2O, with extremely minor participation of the C3 hydrogens; the extent of participation of the C4 hydrogens is not clearly established but appears to be relatively minor. A possible mechanism for H_2O loss which rationalizes the important participation of the C5 hydrogens, involving isomerization to **6**, is presented in Scheme 6. The participation of the C1 hydrogens can be rationalized by a migration of the hydroxyl function from C2 to C4 prior to the sequence shown in Scheme 6; evidence for this hydroxy migration comes from the study of the propylene elimination reaction discussed below.

Finally, the study of **2**-2,2,4,4-d_4 showed that the hydrogens in the 2 and 4 positions are involved in H_2O elimination only to a minor extent.

$C_5H_{11}O^+ \rightarrow CH_2CH{=}OH^+ + C_3H_6$

The relative metastable ion intensities for formation of $C_2(H,D)_5O^+$ ions from isotopically labelled **3** ions are presented in Table 11. The results for **3**-O-*d* show that in metastable ions approximately half have interchanged the oxygen-bonded deuterium with a carbon-bonded hydrogen prior to fragmentation. By contrast, in the D_2 CI mass spectrum ~84% of the fragment ions contain the added deuteron; clearly the extent of interchange is lifetime dependent. The metastable ion spectrum of **3**-1,1,1-d_3 shows that only ~37% of the fragment ions contain the C1 methyl group. This is consistent with the facile interchange of methyl groups indicated in Scheme 2. The origin of the other two hydrogens in the fragment ion obviously is complex, as indicated by the distribution of metastable ion signals. Unfortunately, a large signal for $CD_3C{\equiv}O^+$ in the CI mass spectra of the compounds labelled at C1 made complete evaluation of the relative $C_2(H,D)_5O^+$ intensities in the mass spectra impossible. However, for **3**-1,1,1,3-d_4 the relative intensities in the H_2 CI mass spectrum were $C_2H_5O^+/C_2H_3D_2O^+/C_2H_2D_3O^+/C_2HD_4O^+$ = 1.0:0.35:1.0:0.4 compared to 0.67:0.33:1.0:0.22 in the metastable ion spectrum. Similarly for **3**-1,1,1,3,0-d_5 the relative intensities were $C_2H_5O^+/C_2H_3D_2O^+/C_2H_2D_3O/C_2HD_4O^+/C_2D_5O^+$ = 0.18:1.0:0.23:0.63:0.24 compared to 0.14:1.0:0.38:0.72:0.10 in the metastable ion spectrum. Clearly, even in the higher energy CI system, the methyl groups are equilibrating and the origin of the remaining hydrogens is complex; detailed mechanisms would only be speculative.

TABLE 12. Metastable formation of $C_2(H,D)_5O^+$ ions from labelled **1** ions[a]

Ion		% Formation of					
		$C_2H_5O^+$	$C_2H_4DO^+$	$C_2H_3D_2O^+$	$C_2H_2D_3O^+$	$C_2HD_4O^+$	$C_2D_5O^+$
	**1**-O-*d*	51 (59)	49 (41)	—	—	—	—
	**1**-1,1,1-d_3	12 (12)	8 (8)	—	80 (80)	—	—

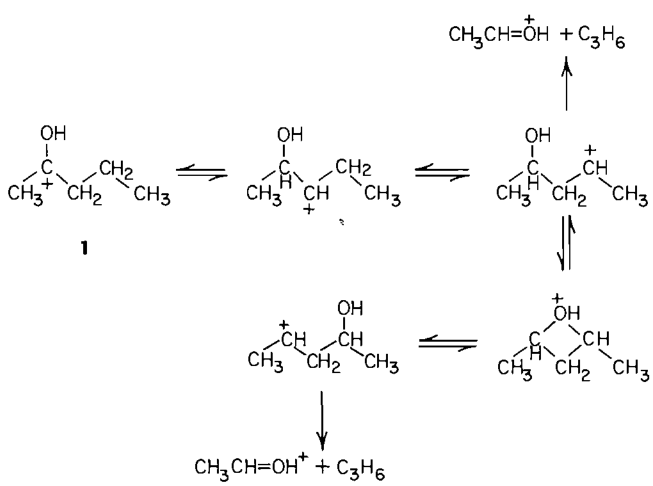
	**1**-1,1,1,3,3-d_5	6 (5)	11 (10)	3 (2)	11 (11)	61 (64)	8 (8)
	**1**-1,1,1,3,3,O-d_6	2	12	6	5	36	40

[a] Data in parentheses from metastable EI study of ref. 12.



SCHEME 7

The relative metastable ion intensities for formation of $C_2(H,D)_5O^+$ ions from labelled **1** ions are presented in Table 12. Again there is good agreement between EI and CI results. The results for **1**-O-*d* show that in metastable ions approximately half have exchanged the oxygen-bonded hydrogen prior to fragmentation. By contrast, in the D_2 CI mass spectrum (Table 4) only ~17% of the ions have exchanged the oxygen-bonded hydrogen with a carbon-bonded hydrogen prior to fragmentation. The most interesting result, indicated most clearly by the results for **1**-5,5,5,-d_3, is the significant specific inclusion of the C5 methyl group in the $CH_3CH{=}OH^+$ fragment ion. This is true not only for metastable ions but also for ions which fragment in the ion source, since in the H_2 CI mass spectrum **1**-5,5,5-d_3 gave the relative intensities $C_2H_5O^+/C_2H_4DO^+/C_2H_3D_2O^+/C_2H_2D_3O^+ = 67:18:2:13$, very similar to the distribution observed in the metastable ion spectrum. Clearly the oxygen function must migrate ~20% of the time to C4 prior to fragmentation. This could occur through the sequence of interchanges outlined in Scheme 4 or may involve the mechanism of Scheme 7, proposed by Audier *et al.* (12). The origin of the remaining hydrogens clearly is complex.

Appendix

The heat of formation of the most stable $C_5H_9^+$ structure is 770 kJ mol^{-1} (21) while $\Delta H_f(CH_3CH{=}OH^+)$ = 582 kJ mol^{-1} (2) and ΔH_f $(CH_3C{\equiv}O^+)$ = 661 kJ mol^{-1} (22). The neutral heats of formation (H_2O = −243 kJ mol^{-1}, C_3H_6 = 19.7 kJ mol^{-1}, C_3H_8 = −104 kJ mol^{-1}) were taken from Cox and Pilcher (23).

Synthesis and thermolysis of 2-(phenylthio)ethanesulfonyl chloride. The absence of a reported "rearrangement of radicals with migration of the chlorine atom from sulfur to carbon"[1]

JAMES FREDERICK KING AND KISHAN CHAND KHEMANI

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received July 3, 1984

JAMES FREDERICK KING and KISHAN CHAND KHEMANI. Can. J. Chem. **63**, 619 (1985).

2-(Phenylthio)ethanesulfonyl chloride (**1**) is the major product of the reaction of (a) lithium 2-(phenylthio)ethanesulfinate (**6**) and chlorine, and, notwithstanding contrary reports, also of (b) benzenethiol (**3**) and ethenesulfonyl chloride (**4**), and (c) sodium 2-(phenylthio)ethanesulfonate (**5**) and phosphorus pentachloride. The rearrangement referred to in the title, which was proposed to account for the isolation of 2-(phenylthio)ethyl chloride (**2**) rather than **1** from **3** and **4**, therefore does not occur. Desulfonylation of **1** to form **2**, however, readily takes place thermally and, in accord with a rate-determining internal displacement of the chlorosulfonyl group with formation of the episulfonium ion, shows a substantial increase in rate with increase in solvent polarity.

JAMES FREDERICK KING et KISHAN CHAND KHEMANI. Can. J. Chem. **63**, 619 (1985).

Le chlorure de (phénylthio)-2 éthanesulfonyle (**1**) est le produit majeur de la réaction du (a) (phénylthio)-2 éthanesulfinate de lithium (**6**) et du chlore et, malgré les rapports qui énoncent le contraire, c'est aussi le produit principal lors des réactions du (b) benzènethiol (**3**) et du chlorure d'éthène sulfonyle (**4**) et du (c) (phénylthio)-2 éthanesulfonate de sodium (**5**) avec le pentachlorure de phosphore. La transposition à laquelle il est fait allusion dans le titre, qui a été proposée pour expliquer le fait que la réaction (b) conduirait au chlorure de (phénylthio)-2 éthyle plutôt qu'au produit **1**, ne se produit donc pas. La désulfonylation de **1** conduisant à **2** se produit toutefois facilement sous l'influence de la chaleur et, en accord avec un mécanisme impliquant un déplacement interne du groupe chlorosulfonyle comme étape déterminant la vitesse de la réaction qui conduit à la formation d'un ion épisulfonium, la vitesse de cette réaction augmente considérablement avec une augmentation de la polarité du solvant.

[Traduit par le journal]

One focus of recent work in this laboratory has been the investigation of the effect that other functional groups have on the reactions and reactivity of sulfonyl-containing species.[2] It was therefore with considerable interest that we noted two reports of two quite different reactions which in each case might reasonably have been expected to yield 2-(phenylthio)-ethanesulfonyl chloride (**1**), but which describe instead only the identification of the formal desulfonylation product, 2-(phenylthio)ethyl chloride (**2**). In the first of these papers Kandror and Freidlina reported that reaction of benzenethiol (**3**) and ethenesulfonyl chloride (**4**) gives **2**, and, to account for this product, put forward a free radical rearrangement mechanism involving migration of a chlorine atom from sulfur to carbon followed by loss of sulfur dioxide (7). In the second paper McManus *et al.* describe the formation of **2** instead of **1** by the reaction of sodium 2-(phenylthio)ethanesulfonate (**5**) with phosphorus pentachloride or other inorganic acid chlorides (8). Significantly, both of these accounts describe the product only after it had been subjected to heating (glc analysis at 135°C or higher, and distillation at 97°C/2 Torr, respectively) (1 Torr = 133.3 Pa) and it seemed reasonable to hope that milder conditions of reaction and work-up might well enable us to obtain **1**. We wish to report (a) that with appropriate work-up these two reactions, and another route as well, all yield **1** as the major product (see Scheme 1), and (b) that **1** is readily thermally desulfonylated to **2**, probably by way of the episulfonium ion (**7**) as initially suggested by McManus *et al.* (8).

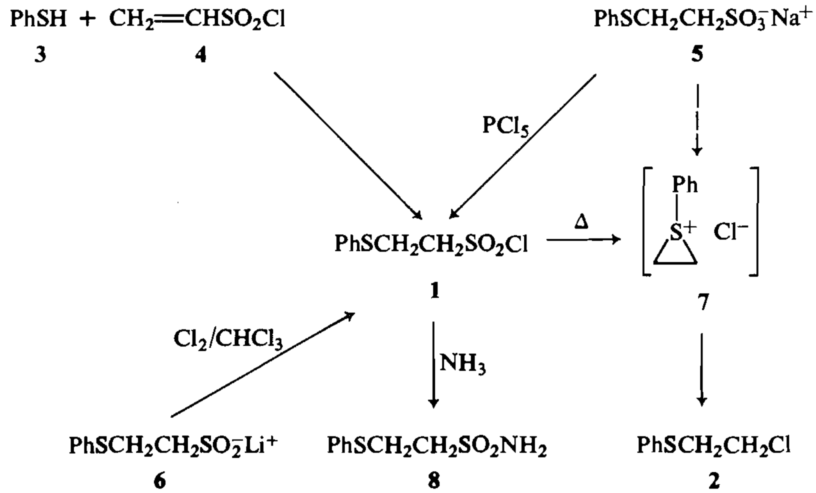
To obtain **1** under gentle conditions, lithium 2-(phenylthio)-ethanesulfinate (**6**), prepared by the method of Vilsmaier and Becker (9), was treated with an equimolar amount of chlorine in chloroform for a short time and the solvent evaporated. The product showed appropriate ^{1}Hmr and ^{13}Cmr spectra (see Experimental) and strong ir bands at 1375 and 1165 cm^{-1} characteristic of the chlorosulfonyl group; the ir and ^{13}Cmr spectra of **1** are readily distinguished from those of **2** but the ^{1}Hmr spectra of **1** and **2** are quite similar and easily confused. All attempts to obtain pure **1** by distillation proved fruitless (see below) and **1** was characterized by conversion to the amide **8** with ammonia.

Reaction of benzenethiol (**3**) and ethenesulfonyl chloride (**4**) following the procedure of Kandror and Freidlina (4 mmol of **3** and 2 mmol of **4** under argon at room temperature for 2.5 h) gave a product which, from its ^{13}Cmr spectrum, contained mostly unreacted **3** and **4** along with a small amount (~7%) of **1**. With a much longer reaction time (144 h) at room temperature the product consisted of **1** (~75%, based on **4**), diphenyl disulfide (~25%, based on **3**), an unidentified material (~15%), and unreacted **3** (27%) and **4** (7%). In our hands the best yield of **1** was obtained by reaction of **3** (3 mmol) and **4** (2 mmol) at 3°C (in air) for 20 days; this gave **1** (~85%), PhSSPh (~16%), a reduced amount of the unidentified product (~5%), plus unreacted **3** (22%) and **4** (8%). The presence of **1** in the product from **3** and **4** was confirmed by isolation of crystalline **8** in good yield by reaction with ammonia. Since **1** and not **2** is clearly the primary product of the reaction of **3** with **4**, it is obvious that the unprecedented "rearrangement of radicals with migration of the chlorine atom from sulfur to carbon" simply does not occur. Reaction of **3** and **4** to form **1** was unaffected by (a) replacing argon by air, (b) bubbling in oxygen, or (c) irradiation with visible light. It would seem reasonable, therefore, to regard the reaction not as a free radical

---

[1] Part 28 in the series Organic Sulfur Mechanisms; for part 27 see ref. 1.

[2] e.g. (a) 1-alkene-1-sulfonyl chlorides (2); (b) "betylates" and "*S*-betylates" (ammonio- and sulfonio-alkanesulfonate esters, respectively) (3, 4); (c) hydroxyalkanesulfonyl chlorides (ref. 5, and unpublished work in this laboratory by M.R. Webster, N. Chiba, K. J. M. Parker, J. K. Allen, and S. Skonieczny); and (d) 2-substituted alkanesulfonyl chlorides (6).



SCHEME 1

process but rather as an ionic addition possibly proceeding by way of a carbanionic or zwitterionic intermediate. As precedent for such an ionic reaction of **4**, we recall the formation of *N*-(2-chlorosulfonylethyl)pyridinium chloride ($C_5H_5N^+CH_2CH_2$-$SO_2Cl\ Cl^-$) on treatment with pyridinium chloride and a trace of pyridine (2).

Following McManus *et al.* (8), sodium 2-(phenylthio)-ethanesulfonate (**5**) was treated with equimolar phosphorus pentachloride to yield **1** in 70% yield (>95% pure as judged by ^{1}Hmr and ^{13}Cmr spectra), with its identity again confirmed by conversion to crystalline **8** as before. In view of the purity of the product relative to that from **3** and **4**, and the ease with which **5** is obtained as compared to **6**, the reaction of **5** with PCl_5 is the current method of choice for preparing **1**. Use of a larger proportion of PCl_5 gave a higher yield of crude product which was, however, contaminated with another compound: the latter material was not isolated but its ^{1}Hmr and ^{13}Cmr spectra suggested that it might be 2-chloro-2-(phenylthio)-ethanesulfonyl chloride. Reaction of **5** with thionyl chloride – *N,N*-dimethylformamide also led to **1**, but the reaction at room temperature was relatively slow and gave the same unidentified second product; at the temperature of refluxing thionyl chloride some **2** was formed as well.

Since mild reaction and work-up conditions give **1**, it seemed likely that the **2** reported by previous workers arose as a result of subsequent thermal conversion. This was confirmed by simple heating of neat **1**, which was cleanly transformed at 135°C into **2** with a half-life of about 4 min. In our hands all attempts to distil **1** gave only **2** in the distillate; by contrast Krutak *et al.* (10) report that 2-(phenylthio)ethanesulfonyl fluoride distils without apparent decomposition under normal conditions (96°C, 0.5 Torr).[3] Precedent for nucleophilic displacement of the chlorosulfonyl group (perhaps in a concerted fragmentation to sulfur dioxide and chloride ion) may be found elsewhere (12–14) and evidence for the intermediacy of the episulfonium ion (**7**), as shown in Scheme 1, has already been presented by McManus *et al.* (8), though for a different starting material and somewhat different reaction conditions. Also in agreement with this picture is the comparative stability of the next homologue of **1**, 3-(phenylthio)-1-propanesulfonyl chloride ($PhSCH_2CH_2CH_2SO_2Cl$) (4), which distils at ~100°C (0.1 Torr) without decomposition (S. Skonieczny, unpublished observation); the much lower reactivity of 3-(phenylthio)-propyl systems, presumably because of the comparative slowness of the formation of the four-membered ring sulfonium ion, is well known from the work of Bordwell and Brannen (15). To shed further light on the mechanism, the rate of thermolysis of **1** in acetophenone solution was examined and found to show first-order behavior to >80% reaction. The following approximate rate constants for the reaction at 114°C were estimated for a range of solvents: sulfolane 4×10^{-3}, acetophenone 4×10^{-4}, tetrachloroethylene 4×10^{-6}, and cyclohexane $5 \times 10^{-7}\ s^{-1}$. A plot of log k against Hildebrand's solubility parameter, δ, gave a rough straight line (r = 0.955) corresponding to $\log k = 0.84\delta - 12.9$. This, when taken with the correlation of δ with the Grunwald–Winstein Y value (16), corresponds to an m value of about 1.6. This, though much too inaccurate for any detailed mechanistic discussion, does, however, provide a clear indication of substantial charge development in the transition state, in full accord with a rate-determining formation of **7** as shown in Scheme 1.

Experimental

Reagent grade chemicals and solvents were used without additional purification unless otherwise noted. Melting points were determined on a Kofler Hot Stage and are uncorrected. Infrared spectra were obtained with a Beckman 4250 spectrophotometer and refer to chloroform solutions. The ^{1}Hmr spectra were obtained using Varian T60 and XL100 spectrometers, with all reported chemical shifts from the latter instrument; ^{13}Cmr spectra were determined on Varian XL200 and XL300 instruments using a sweep width of 15 K with 65 K transforms. Mass spectra were run on a Varian MAT-311A spectrometer. Solvent evaporation on work-up was carried out using a Büchi rotary evaporator connected to a water aspirator. Except as otherwise noted, organic starting materials were supplied by Aldrich Chemical Co. (Milwaukee). An authentic specimen of 2-(phenylthio)ethyl chloride (**2**) was made by the reaction of 2-(phenylthio)ethanol with thionyl chloride (17); the distilled product (**2**) gave the following spectra: ir

[3] The preparation of the sulfonyl fluoride given by these authors prescribes the addition of **3** to $CH_2{=}CHSO_2F$ with tributylphosphine as catalyst; such catalysis of the addition of **3** to **4** is precluded by the rapid reaction of tertiary phosphines with sulfonyl chlorides (11). Both this preparation and the observed stability of the sulfonyl fluoride to distillation serve to point up the low reactivity of sulfonyl fluorides as compared to sulfonyl chlorides; as with alkyl fluorides vs. alkyl chlorides, the behavior of one is not a reliable guide to that of the other.

ν_{max}: 3060 (w), 1585 (w), 1470 (m), 1440 (m), 1200 (w) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 7.38–7.16 (m, 5H), 3.65–3.48 and 3.23–3.06 (symmetrical A_2B_2 pattern, 4H); ^{13}Cmr ($CDCl_3$) δ: 134.1, 130.2, 129.0, 126.8, 42.4, 35.9.

Chlorination of lithium 2-(phenylthio)ethanesulfinate (6)

Chlorine gas was bubbled into dry, alcohol-free chloroform at room temperature for 10 min, and the chlorine concentration determined by treating an aliquot with excess KI and titrating the liberated iodine against standard sodium thiosulfate solution using starch as indicator: the Cl_2–$CHCl_3$ solution was used immediately. Lithium 2-(phenylthio)ethanesulfinate (**6**) (9) (42 mg, 0.20 mmol) was suspended in dry, alcohol-free chloroform (1 mL) in a round-bottom flask at 0°C. An equimolar amount of Cl_2–$CHCl_3$ solution was added with stirring. Filtration and evaporation of the solvent after 5 min gave **1** as a colorless liquid (38 mg, 0.18 mmol, 90%); ir ν_{max}: 3000 (w), 2920 (w), 1585 (w), 1480 (m), 1440 (m), 1375 (vs), 1165 (vs), 1020 (w), 905 (m), and 685 (m) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 7.47–7.29 (m, 5H), 3.91–3.75 and 3.49–3.33 (symmetrical A_2B_2 pattern, 4H); ^{13}Cmr ($CDCl_3$) δ: 132.3, 131.2, 129.7, 128.1, 64.3, and 28.1.

Compound **1** (38 mg, 0.18 mmol) was dissolved in anhydrous ether (30 mL) and anhydrous NH_3 bubbled in for 15 min at 25°C. The precipitated white solid was removed by filtration and washed with more ether. The filtrate and washings were all combined, dried with $MgSO_4$, and evaporated to yield **8** as a white solid which was purified by flash chromatography (Kieselgel 60, 35:65 (v/v), ethyl acetate – petroleum ether) and recrystallized from chloroform (30 mg, 0.14 mmol, 77%); mp 104–105°C; ir ν_{max}: 3345 (s), 3245 (s), 1318 (vs), 1134 (vs), and 1120 (vs) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 7.35–7.26 (m, 5H), 4.79 (s, br, 2H), and 3.32 (s, 4H); ^{13}Cmr ($CDCl_3$) δ: 133.5, 130.5, 129.4, 127.4, 54.6, and 27.8. *Exact Mass* calcd. for $C_8H_{11}NO_2S_2$: 217.0231; found: 217.0238.

Reaction of benzenethiol (3) with ethenesulfonyl chloride (4)

Neat **3** and **4** (both freshly distilled) in a 5-mL round-bottom flask were stirred together using the quantities and conditions as specified in the main text; the irradiation experiment was carried out using a 400-W medium pressure Hg lamp (high intensity discharge. Canadian General Electric) encased in a Pyrex envelope with fluorescer. Reaction products were determined from ^{13}Cmr spectra of dilute solutions ($CDCl_3$) and the relative amounts of various compounds present in the reaction mixture estimated; integrations have an estimated precision of ±5%.

In a typical run, **3** (440 mg, 4 mmol) and **4** (253 mg, 2 mmol) were stirred together in an argon atmosphere at room temperature in a 5-mL round-bottom flask for 144 h. The reaction mixture was dissolved in anhydrous ether (30 mL) and anhydrous ammonia was bubbled in for 15 min at room temperature. Work-up, followed by purification by chromatography and recrystallization as described previously, gave pure crystalline **8** (213 mg, 0.98 mmol, 49% based on **4**) with mp, ir, ^{1}Hmr, and ^{13}Cmr identical to those reported above.

Reaction of sodium 2-(phenylthio)ethanesulfonate (5) with phosphorus pentachloride

Sodium 2-(phenylthio)ethanesulfonate (**5**) (8) (1.115 g, 4.65 mmol) was ground with PCl_5 (0.96 g, 4.65 mmol) in a dry mortar. Reaction occurred after a few seconds to yield a pasty liquid, to which water (10 mL) was added. The mixture was extracted with pentane (4 × 50 mL) in a separatory funnel, all organic extracts were combined, dried with $MgSO_4$, and the solvent evaporated to yield **1** (0.765 g, 3.19 mmol, 69%). A portion of this product (200 mg, 0.85 mmol) was treated with anhydrous ammonia in anhydrous ether (30 mL) and the mixture worked up by the procedure described above to yield pure crystalline **8** (141 mg, 0.65 mmol, 76%) with mp, ir, ^{1}Hmr, and ^{13}Cmr identical to those reported above.

In another experiment, **5** (2.5 g, 10.4 mmol) was treated with excess PCl_5 (4.0 g, 19.2 mmol) in a dry mortar and worked up as above to yield a colorless liquid (2.153 g, crude yield 88%) which showed, in addition to the characteristic signals due to **1**, an apparent ABX pattern (δ 5.68, 1H, dd, J = 6 and 7.5 Hz, plus a multiplet at 4.5–4.1) in the ^{1}Hmr spectrum and ^{13}Cmr absorptions at 134.9, 130.2, 71.4, and 59.6 ppm, evidently derived from a $PhSCHCH_2$-system, perhaps as in $PhSCHClCH_2SO_2Cl$. From ^{1}Hmr integrals the relative amounts of **1** and the second material were estimated as 87 and 13% respectively.

Reaction of 5 with thionyl chloride – N,N*-dimethylformamide*

(a) *At room temperature*

Compound **5** (104 mg, 0.433 mmol) was stirred with 3 mL of freshly distilled $SOCl_2$ and 4 drops of DMF at room temperature for 24 h. Ice-water (10 mL) was then added and the mixture extracted with CH_2Cl_2 (4 × 50 mL) in a separatory funnel; all organic extracts were combined, dried with $MgSO_4$, and evaporated to yield a colorless liquid (120 mg), which showed major peaks in ^{13}Cmr at δ ($CDCl_3$): 164.1, 134.9, 132.1, 130.8, 130.2, 129.3, 127.8, 71.4, 64.1, 59.7, 38.6, 33.2, and 27.9. The peaks were assigned to **1** (132.1, 130.8, 129.3, 127.8, 64.1, and 27.9 ppm), DMF (164.1, 38.6, and 33.2 ppm), and the unidentified product (134.9, 130.2, 71.4, and 59.7 ppm) with the ratio of the peak areas corresponding to approximate relative proportions of 57, 30, and 10% respectively. No sign of any **2** was seen in the ^{13}Cmr spectrum.

(b) *At reflux*

Compound **5** (205 mg, 0.85 mmol) was refluxed with stirring for 11 h with 5 mL of freshly distilled $SOCl_2$ containing 1 drop of DMF in a round-bottom flask and the mixture worked up as above yielding a colorless liquid (215 mg) which by ^{13}Cmr ($CDCl_3$) was found to contain peaks at δ: 134.9, 134.0, 132.1, 130.8, 130.2, 129.3, 129.0, 127.8, 126.8, 71.3, 64.1, 59.7, 42.3, 35.9, and 27.9. The peaks were assigned to **1** (132.1, 130.8, 129.3, 127.8, 64.1, and 27.9 ppm), **2** (134.0, 130.2, 129.0, 126.8, 42.3, and 35.9 ppm), and the unidentified product (134.9, 130.2, 71.3, and 59.7 ppm) with the ratio of the peak areas corresponding to approximate relative proportions of 79, 11, and 10% respectively.

Thermolysis of 2-(phenylthio)ethanesulfonyl chloride (1)

Conventional as well as flash distillation of compound **1** was attempted at various temperatures (80°, 95°, 110°, 120°, and 135°C) and under reduced pressure (0.2 Torr). The ^{13}Cmr spectra of the distillate (in $CDCl_3$) showed the presence of only **2** (>95% pure), with no trace of any **1**.

Neat **1** (33 mg, 0.14 mmol) was sealed under nitrogen in an nmr tube and thermolysed for 2 min in a preheated oil bath (135°C). The ^{13}Cmr spectrum in $CDCl_3$ solution gave the relative amounts of **1** and **2** as 78 and 22% respectively. Chloroform was driven off by blowing nitrogen over the surface and the liquid obtained sealed under nitrogen as before and thermolysed further for 6 min at the same temperature. The ^{13}Cmr spectra in $CDCl_3$ solution gave the relative amounts of **1** and **2** as 31 and 69% respectively (integrations have an estimated precision of ±5%). No sign of any other side products was seen in the ^{13}Cmr spectra. The above data give an approximate half-life of 4 min for the above conversion.

2-(Phenylthio)ethanesulfonyl chloride (**1**) (130.5 mg, 0.55 mmol) was dissolved in freshly distilled acetophenone (3 mL) in a 5-mL round-bottom flask containing a magnetic stirring bar and flushed with dry nitrogen gas. The flask was lowered into a preheated oil bath (114°C) mounted on a stirring base, and the timer started. Aliquots (0.5 mL each) of the acetophenone solution were removed after 5, 15, 30, 60, and 120 min and ^{13}Cmr spectra run immediately. The relative amounts of **1** and **2** in the reaction mixtures were determined by monitoring the high-field peaks; integrations have an estimated precision of ±5%. A plot of ln ($[\mathbf{1}]_0/[\mathbf{1}]$) vs. t gave a straight line passing through the origin (r = 0.999); the slope of the line gave a rate constant of 4.2×10^{-4} s^{-1}.

Solutions of compound **1** (25–50 mg) in freshly distilled sulfolane, acetophenone, tetrachloroethylene, and cyclohexane solvents (0.4 mL each) were sealed under nitrogen atmosphere in different nmr tubes and thermolysed for various times (3 min, 5 min, 2974 min, and 3560 min respectively) in a preheated oil bath (114°C). At the end of these times, the rate constants for the conversion of **1** to **2** were calculated from relative amounts as given by the [13]Cmr spectra using the first-order rate equation.

Metal-free copper and cobalt(II) binuclear phthalocyanines, in which the two phthalocyanine nuclei are covalently linked through five-atom bridges, have been prepared and characterized. Some new metal-free, copper, cobalt(II), and zinc 2,9,16,23-tetraalkoxyphthalocyanines, some of which are extremely soluble in organic solvents, are described.

On a préparé et caractérisé une série de phtalocyanines, libres ou complexées par du cuivre ou du cobalt(II), dans lesquelles les deux noyaux de phtalocyanines sont liés d'une manière covalente par des ponts de cinq atomes. On décrit quelques nouvelles tétraalkoxy-2,9,16,23 phtalocyanines, libres ou complexées avec du cuivre, du cobalt(II) ou du zinc, qui sont extrèmement solubles dans les solvants organiques.

[Traduit par le journal]

The use of cobalt phthalocyanine as a catalyst for the electroreduction of oxygen has been known for some time (1) and extensive research efforts have shown that porphyrins and phthalocyanines can act as potential catalysts for energy conversion processes (2–4). It is well known that iron(II) porphyrins decompose oxygen through a mechanism involving two porphyrins acting on one oxygen molecule (5). Binuclear porphyrins (6–9) have been prepared and used in the 4-electron reduction of molecular oxygen to water. Under operating conditions, however, binuclear porphyrins lose catalytic activity with time (7) and it may be that the porphyrin nucleus itself is not sufficiently stable to be used as a long term photocatalyst. For this reason, we envisioned that binuclear photocatalysts based on the thermally (10) and photochemically stable phthalocyanine nucleus would be worthwhile molecules to synthesize and examine in electrochemical and photocatalytic studies.

Using a solid phase method of synthesis we have recently prepared some unsymmetrical phthalocyanines which are very soluble in organic solvents (11, 12), compared with most phthalocyanines which are notoriously insoluble. These soluble, unsymmetrical, mononuclear phthalocyanines contained the necessary handle, a hydroxy functional group, which could be used to attach the phthalocyanine to electrodes (13, 14). The synthesis of a very soluble mononuclear phthalocyanine in our earlier studies (11, 12) and the development of chromatographic methods for the separation of phthalocyanines in general (12) has enabled us to contemplate the syntheses of the hitherto unknown binuclear phthalocyanines.

Although we believed that a solid phase approach could be advantageously used in the synthesis of binuclear phthalocyanines, as a first experiment, prior to adopting solid phase methodology, we tried to synthesize a binuclear phthalocyanine in solution. As shown below, binuclear phthalocyanines *can* be separated chromatographically from mononuclear phthalocyanines using our unusual eluting solvent mixture (12), and hence the more elaborate scheme using polymer supports was unnecessary.

Synthesis of mononuclear phthalocyanines, soluble in organic solvents

Treatment of 4-nitrophthalonitrile (**1**) with 2-propanol (**2**), 2-methyl-1-propanol (**3**), and 2,2-dimethyl-1-propanol (**4**) with potassium carbonate in dimethylformamide (DMF) in a useful modification (15) of published procedures (16, 17) gave in some instances at high temperatures the unwanted by-products 4-hydroxyphthalonitrile (**5**) (18) and bis(3,4-dicyanophenyl)-ether (**6**), but at room temperature (15) the desired 4-isopropoxyphthalonitrile (**7**) (11, 15), 4-isobutoxyphthalonitrile (**8**), and 4-neopentoxyphthalonitrile (**9**) respectively in 69 to 87% yield. Phthalonitriles **7–9** were readily converted, using gaseous ammonia and sodium methoxide in methanol (19, 20), to 5-isopropoxy-1,3-diiminoisoindoline (**10**), 5-isobutoxy-1,3-diiminoisoindoline (**11**), and 5-neopentoxy-1,3-diiminoisoindoline (**12**) respectively. The solvent was evaporated and compounds **10–12** were next used without further purification. We have previously reported the condensation of **10** in 2-*N*,*N*-dimethylaminoethanol (Method A) (19) to give the metal-free 2,9,16,23-tetraisopropoxyphthalocyanine (**13***a*) (12), but had not described any metallated derivatives of **13***a*. In fact, several methods exist for the direct condensation of phthalonitriles to metallated phthalocyanines without the necessity of forming isoindolines. Thus, treatment of **7** with CuCN in DMF (Method B) (20) or with $CuCl_2$ and diazabicyclononane (DBN) in ethanol (Method C) (21) gave 2,9,16,23-tetraisopropoxyphthalocyaninato copper (**13***b*) in 34 and 49% yield respectively (Table 1). Compound **7** was similarly converted to 2,9,16,23-tetraisopropoxyphthalocyaninato cobalt(II) (**13***c*) and 2,9,16,23-tetraisopropoxyphthalocyaninato zinc (**13***d*) using Methods B and C (Table 1; Scheme 1).

Isoindoline **11** was converted to the metal-free 2,9,16,23-tetraisobutoxyphthalocyanine (**14***a*) by Method A and **14***a* was converted to 2,9,16,23-tetraisobutoxyphthalocyaninato copper (**14***b*) by simple treatment of **14***a* with cupric acetate in toluene (Method D) (19), in this example (Table 1). Similarly, isoin-

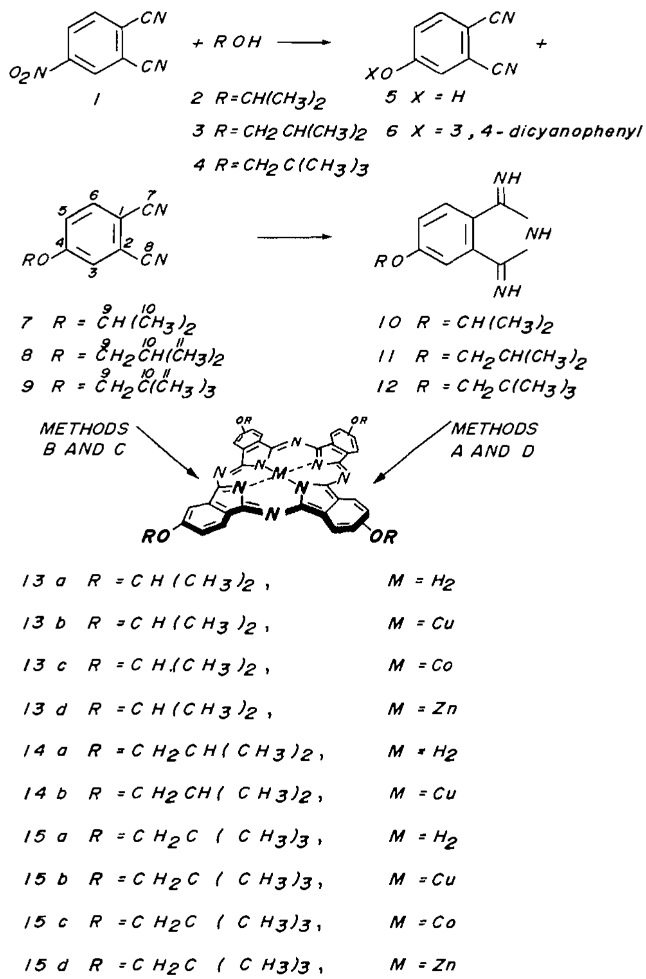

SCHEME 1

doline **12** was converted to 2,9,16,23-tetraneopentoxyphthalocyanine (**15***a*) (Method A) and subsequently to 2,9,16,23-tetraneopentoxyphthalocyaninato copper (**15***b*) and 2,9,16,23-tetraneopentoxyphthalocyaninato cobalt(II) (**15***c*) (Method D). Treatment of phthalonitrile **9** under the conditions of Method B using copper, cobalt, and zinc salts yielded **15***b*, **15***c*, and 2,9,16,23-tetraneopentoxyphthalocyaninato zinc (**15***d*) in varying yields (Table 1; Scheme 1). The structures of **13***a*–*d*, **14***a*–*b*, and **15***a*–*d* were confirmed by spectroscopic and elemental analysis (see experimental section and Table 2).

A comparison of the yields of metallophthalocyanines by three different routes (Table 1) shows that a combination of Methods A and D, i.e. formation of metal-free phthalocyanines followed by metal insertion, or Method C, using DBN as a condensing agent, is superior to Method B. In fact, in our hands, organic soluble metallophthalocyanines are most conveniently prepared in the purest state, and in the highest yield, by metal insertion into metal-free phthalocyanines (Methods A and D). Direct preparation of metallophthalocyanines by Method C gives metallophthalocyanines contaminated by impurities difficult to remove by chromatographic methods.

The selection of the 4-isopropoxy group as a substituent of a phthalonitrile and hence of its isoindoline was predicated on the fact that a bulky isopropoxy group in **7** and **10** similar to the less accessible 4-*tert*-butylphthalonitrile (22) would inhibit aggregation processes and lead to organic solvent soluble phthalocyanines. Indeed, **13***a* proved to be exceedingly soluble (Table 2) in organic solvents and hence was readily separable from polymer-supported phthalocyanines (11, 12) and, as shown below, separable from a binuclear phthalocyanine. Although **13***a*–*d* were prepared as pure compounds, it was noted that some deterioration occurred with age and, indeed, old samples had to be rechromatographed before their use in electrochemical studies. Since the phthalocyanine nucleus is reputed to be extremely stable to decomposition, we believed for two reasons that the isopropoxy group was responsible for this instability. Firstly, isopropyl ethers are known to readily form peroxides and, secondly, base catalyzed elimination of the isopropyl group may occur as shown in Scheme 2.

TABLE 1. Yields of monomeric metallophthalocyanines by different synthetic methods

Starting material	Method[a]	Salt	Product	Yield (%)
7	A	[b]	**13***a*	38
7	B	CuCN	**13***b*	34
7	B	$CoCl_2$	**13***c*	20
7	B	$Co(CN)_2$	[c]	—
7	B	$Co(OAc)_2$	**13***c*	37
7	B	$ZnCl_2$	**13***d*	35
7	C	$CuCl_2$	**13***b*	49
7	C	$CoCl_2$	**13***c*	46
7	C	$Co(OAc)_2$	**13***c*	35
7	C	$ZnCl_2$	**13***d*	31

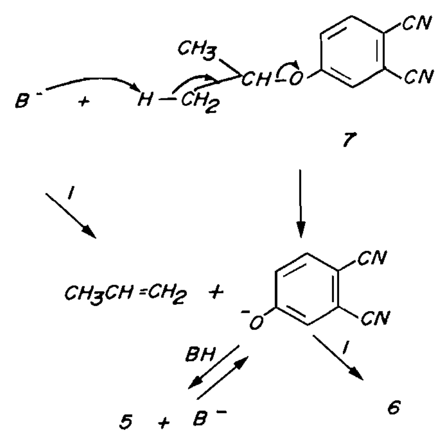
9	B	CuCN	**15***b*	17
9	B	$Co(OAc)_2$	**15***c*	29
9	B	$ZnCl_2$	**15***d*	2
9	B	$Zn(OAc)_2$	**15***d*	27
14*a*	D	$Cu(OAc)_2$	**14***b*	74
15*a*	D	$CuCl_2$	**15***b*	94[d]
15*a*	D	$CoCl_2$	**15***c*	94[d]

[a]See text for reaction conditions and references for Methods A–D.
[b]Method A gives metal-free phthalocyanines and no salt is used.
[c]No reaction.
[d]The overall yield, which is a combination of Methods A and D, is 42%.



SCHEME 2

The formation of **6** in the preparation of **7** at temperatures higher than room temperature shows that the mechanistic scheme shown in Scheme 2 is at least partially operative. We have shown that pure **7** on reaction with K_2CO_3 or KNO_2 at 80°C does liberate, upon protonation, **5** without concomitant formation of **6**, since no **1** is available. Some earlier studies (23) on the formation of *tert*-butyl aryl ethers have shown that

27*a*	332 (5.00)	384 (4.66)	610 (4.76)	638 (4.90)	670 (4.81)	700 (4.66)	0.35
27*b*	320 (4.95)	380 (4.37)		626 (4.77)	668 (4.76)		0.039

eliminative processes as described above do occur but also that elimination more likely occurs through an alternate pathway involving the initial nucleophilic addition adduct. In any case, it became apparent that the 4-isopropoxy group of **7** and **10** was not ideally suited to subsequent use as a "partner" in the synthesis of binuclear phthalocyanines. It was for these reasons that the isobutoxy derivatives **8** and **11** were prepared. The isobutoxy group is not a secondary ether and hence is less susceptible to peroxide formation, and in addition only contains one hindered β-hydrogen for participation in possible elimination reactions. It was subsequently shown, however, that the isobutoxyphthalocyanines, **14***a* and **14***b*, prepared from **11**, were considerably less soluble than their isopropoxy analogs, **13***a* and **13***b* (Table 2). The 4-neopentoxy derivatives, **9** and **12**, are primary hindered ethers and contain no β-hydrogens for possible elimination reactions. Most importantly, the neopentoxyphthalocyanine, **15***a*, derived from **12**, proved to be exceedingly soluble in organic solvents (Table 2) and ultimately exhibited little decomposition with age. The formation of **9** at room temperature using the standard procedure (15) gave **9** in 86% yield in 84 h in a small scale reaction. On a large scale, the reaction was only completed after 144 h. Since **9** could not undergo β-elimination processes such as **7**, an evaluation of the yield of **9** at different temperatures was undertaken and it was shown that **9** should be prepared in optimal yield in reasonable times at 60°C (Table 3). At higher temperatures, the formation of **5** by the displacement of the nitro group by carbonate or nitrite becomes important (18).

TABLE 3. Yields of **9** from **1** at different temperatures and reaction times

Temperature (°C)	Time (h)[a]	Yield (%)
22	84	86
60	18	82
70	10	76
80	5	66

[a]Starting material **1** was completely consumed after the given reaction times.

The syntheses of binuclear phthalocyanines

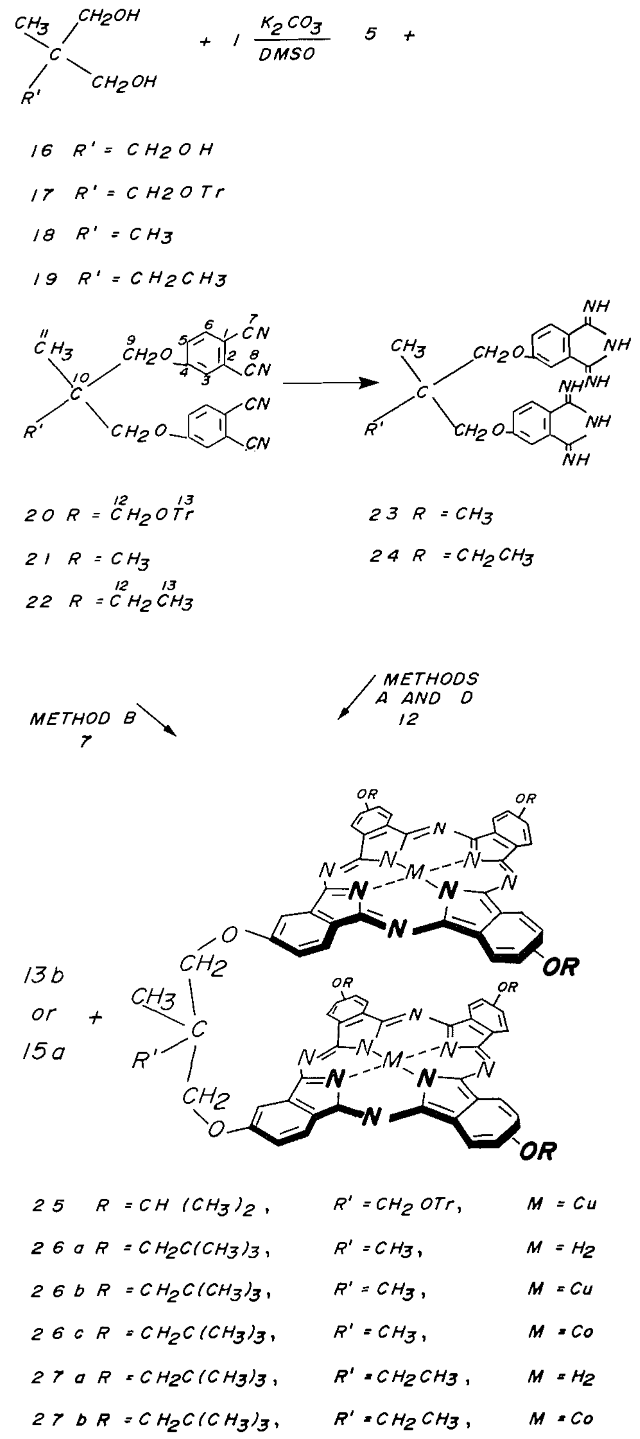
A straightforward route to binuclear phthalocyanines would involve a *mixed* condensation of a bisphthalonitrile or its isoindoline derivatives with a simple phthalonitrile or isoindoline in solution. Since phthalocyanines are so insoluble, the above simple approach would give insoluble, inseparable mixtures of mononuclear phthalocyanines, binuclear phthalocyanines, and by-products, as even good preparations of mononuclear phthalocyanines occur in less than 50% yield. The development (11, 12) of exceedingly soluble mononuclear phthalocyanines and particularly **15***a* described above indicated that even binuclear phthalocyanines may be soluble and separable by chromatography (12).

Initially, we had been interested in preparing not only binuclear phthalocyanines but also one containing a "handle" suitable for attachment to electrodes (13), polymers (24), or micelles (25). In addition, we wished to prepare binuclear phthalocyanines, incorporating five-, four-, or three-atom covalent bridges, as these bridges seemed most likely to yield phthalocyanine dimers having electrocatalytic and photocatalytic activity. Bisphthalonitriles can be readily prepared (16) by treatment of symmetrical diols with **1**. The goal of obtaining binuclear phthalocyanines incorporating a five-atom bridge thus requires a bisphthalonitrile incorporating a five-atom bridge. The symmetrical diol forming this bridge should not have hydrogen atoms available for β-elimination. Treatment of excess 2-hydroxymethyl-2-methyl-1,3-propanediol (**16**) with triphenylmethyl chloride (trityl chloride) in pyridine yielded upon column chromatography 68% (based on trityl chloride) of 2-methyl-2-trityloxymethyl-1,3-propanediol (**17**).

Symmetrical diols **17**, 2,2-dimethyl-1,3-propanediol (**18**), and 2-ethyl-2-methyl-1,3-propanediol (**19**), reacted with more than two equivalents of **1** and K_2CO_3 in dimethylsulfoxide (DMSO) (16) to give 1,3-bis(3′,4′-dicyanophenoxy)-2-methyl-2-trityloxymethylpropane (**20**), 1,3-bis(3′,4′-dicyanophenoxy)-2,2-dimethylpropane (**21**), and 1,3-bis(3′,4′-dicyanophenoxy)-2-ethyl-2-methylpropane (**22**) respectively. Bisnitriles **21** and **22** were converted to their bisisoindolines **23** and **24** as before and used in subsequent condensations without further purification. For our first mixed condensation for the preparation of binuclear phthalocyanines we decided to try the direct route of reacting bisphthalonitrile **20** with 4-isopropoxyphthalonitrile

(7) using cuprous cyanide in DMF (Method B), as Method C was known to generate many by-products. Flash chromatography (26) using 2-methoxyethanol − toluene (5:200) as eluant removed the mononuclear copper phthalocyanine **13***b*, formed by self-condensation of **7**. Further elution gave the binuclear phthalocyanine, 1,3-bis-2′-(9′,16′,23′-triisopropoxyphthalocyaninato copper)-2-methyl-2-trityloxymethylpropane (**25**), in 1% yield (Scheme 3). Characterization of **25** was based on elemental and spectroscopic analysis and its method of synthesis. Elemental analysis of **25**, which still contains the trityl blocking group, is more meaningful than elemental analysis of any detritylated dimer, as **25** exhibits a more considerable difference in its calculated analysis than the related monomer **13***b*. Indeed, the close but not perfect analysis indicates the structure **25**, rather than a monomeric species. The mass spectrum of **25** was most informative and, after much effort using the FAB techniques (27) and using thioglycerol as solvent, a parent ion with m/z centered at 1859.5 amu was observed. A major fragment ion at 1816 ($M^+ - 43$) was indicative of loss of an isopropyl group, consistent with structure **25**. The much slower chromatographic mobility of **25** compared to **13***b* further suggested **25** as the most likely structure. The infrared spectrum of **25** gives us an indication of the purity of our compounds, as by-product impurities exhibit absorptions in the nitrile or carbonyl regions of the spectra which are absent in both pure mononuclear and binuclear phthalocyanines. The ultraviolet spectrum of **25** and all mononuclear and binuclear phthalocyanines are given in Table 2 for comparison purposes, as small but significant differences are apparent between metal-free and metallophthalocyanines and between mononuclear and binuclear phthalocyanines.

Although the synthesis of the first binuclear phthalocyanine **25** was achieved using Method B and **7** as the "partner" in the condensation, the yield was very low. For this reason the formation of binuclear phthalocyanines using Method A (via diiminoisoindolines) and using 5-neopentoxy-1,3-diiminoisoindoline (**12**) as the "partner" was attempted. Heating the bis-isoindolines **23** or **24** at 150°C with a large excess of **12** in 2-*N*,*N*-dimethylaminoethanol for 24 h (Method A) under argon yielded a dark blue solution which was diluted with water giving blue coloured residues. Flash chromatography of solutions of these residues separated the mononuclear phthalocyanine **15***a* from the desired binuclear phthalocyanines 1,3-bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninoxy)-2,2-dimethylpropane (**26***a*) and 1,3-bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninoxy)-2-ethyl-2-methylpropane (**27***a*) respectively. The relatively high yields of **26***a* (17%) and **27***a* (10%) achieved by Method A as compared to Method B for **25** (1%) more than compensated for the extra effort of making the isoindolines. Simple treatment of **26***a* with anhydrous cupric acetate in toluene at 100°C for 17 h gave the binuclear phthalocyaninato dicopper derivative **26***b* in 54% yield, while similar reactions of **26***a* or **27***a* with anhydrous cobaltous chloride gave the binuclear phthalocyaninato dicobalt(II) derivatives **26***c* and **27***b* in 60 and 74% yields respectively. Binuclear phthalocyanines, **26***a*–*c* and **27***a*–*b*, exhibited parent ions in their mass spectra using the FAB system and *o*-nitrophenyl octyl ether (ONPOE) as solvent. The infrared spectra of **26***a* and **27***a* exhibit characteristic N—H absorptions at 3300 and 1020 cm^{-1} (28), similar to metal-free mononuclear phthalocyanines **13***a*, **14***a*, and **15***a*. The ^{1}H nmr spectra of **26***a* and **27***a* show a characteristic broad N—H absorption peak at approximately −6.0 ppm as do **13***a*, **14***a*, and **15***a* at high concentrations.



SCHEME 3

Other peaks in the ^{1}H nmr spectra, however, are also very broad, which renders ^{1}H nmr spectroscopy less useful for characterization of phthalocyanines, both monomeric and dimeric. It is likely that the ^{1}H nmr signals are broad due to both aggregation effects and the fact that all the mononuclear and binuclear phthalocyanines described herein are a mixture of a large number of possible positional isomers. Even using a high field instrument and multiple scans, a dilute solution of **15***a* yielded a spectrum showing broad absorptions, and hence the multiplicity of positional isomers is the likely primary cause of this effect. The ^{13}C nmr spectra (see Experimental), of **13***a*,

[a]The numbering of the carbon atoms in **7–9** and **20–22** follows that given for these structures in Schemes 1 and 2 and does not follow from the names of these compounds. All compounds were run in $CDCl_3$ except **21**, which was run in CD_2Cl_2.
[b]These assignments may be interchanged.
[c]These assignments may be interchanged.
[d]This value is typical of methyl carbon atoms and correlates well with carbon 11 for other compounds in the table.
[e]This assignment is for the quaternary carbon of the trityl group. The phenyl groups absorb at 143.3, 128.4, 127.7, and 127.0, consistent with previous assignments (30).

13*d*, **14***a*, **15***a*, **15***d*, **26***a*, and **27***a* give sharp absorbancies, characteristic of the given structures. The reduced solubilities of **26***a* and **27***a* compared to **13***a* and **15***a* meant that even overnight scans of these samples on a Bruker 400-MHz nmr spectrometer could not show most of the quaternary carbon atoms. The ^{13}C nmr of **7–9** and **20–22** have been assigned using standard correlations (29) (Table 4). The absorption spectra of all mononuclear and binuclear phthalocyanines reported herein are reported in Table 2. Mononuclear metal-free and metallophthalocyanines give well-known characteristic absorption spectra (10) and the present availability of binuclear metal-free and metallophthalocyanines shows that these dimeric phthalocyanines are different from the monomeric phthalocyanines and from each other. Both mononuclear and binuclear metal-free phthalocyanines exhibit absorption maxima between 700 and 706 nm with the binuclear ones absorbing near 700 nm. Metallophthalocyanines do not give absorption maxima at this wavelength. Other differences, especially between monomers and dimers, are reflected in intensity changes which in tabular form appear minor, but in graphic form (Fig. 1) of one example of each class show that simple inspection can often identify the phthalocyanine as mononuclear or binuclear, and metal-free or containing metal.

The successful syntheses of the first characterized binuclear phthalocyanines rest largely on the preparation of monomeric phthalocyanines, which are exceedingly soluble in organic solvents, and their subsequent separation from binuclear phthalocyanines which still exhibit significant solubility in organic solvents. From Table 2 one can see that metallophthalocyanines are generally less soluble than metal-free phthalocyanines, and binuclear phthalocyanines are understandably less soluble than mononuclear phthalocyanines. Thus the difference in solubility of metal-free mononuclear phthalocyanine (**15***a*) and a binuclear metallophthalocyanine (**26***c*) is over three orders of magnitude, but **26***c* and other

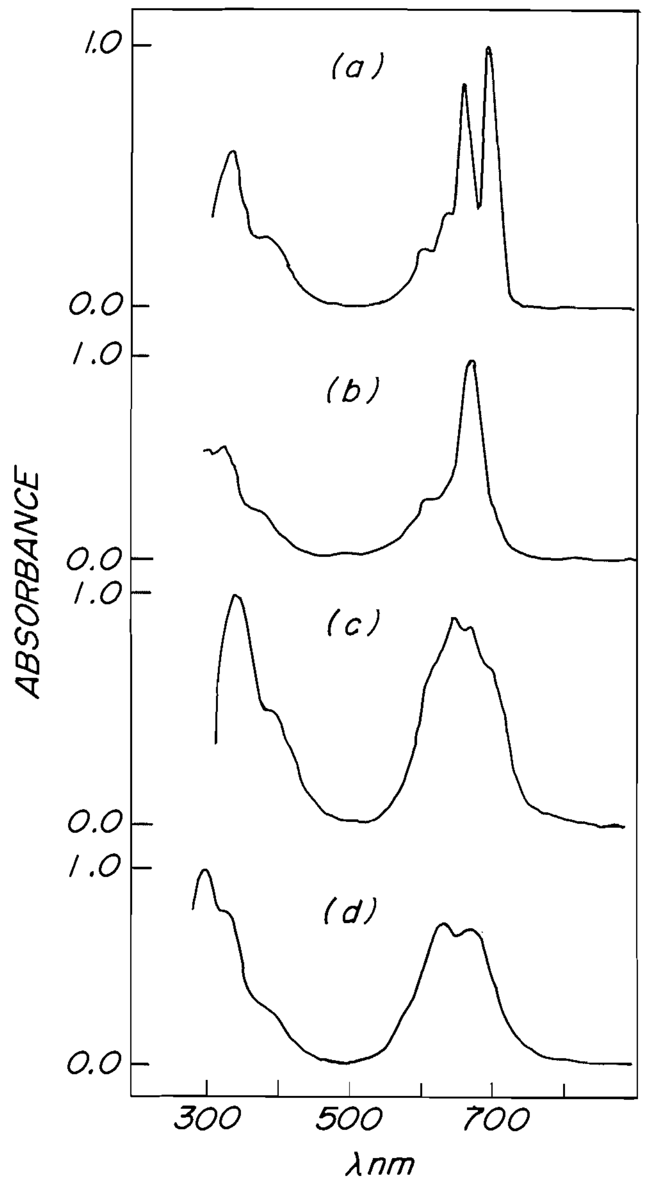

FIG. 1. The λ (nm) visible spectra in CH_2Cl_2 at room temperature of (a) a mononuclear metal-free phthalocyanine, **13***a*, (b) a mononuclear metallophthalocyanine, **13***c*, (c) a binuclear metal-free phthalocyanine, **27***a*, (d) a binuclear metallophthalocyanine, **27***b*.

phthalocyanine dimers are still sufficiently soluble to purify and characterize. A full analysis of **26***a–c* and **27***a–b* by visible spectroscopy and electrochemical methods under a variety of conditions has been undertaken and a preliminary report has appeared (31).

Experimental

Matheson high purity argon was used to maintain inert atmosphere conditions. Infrared (ir) spectra were recorded on a Pye Unicam SP1000 infrared spectrophotometer using KBr discs for solids or as neat films between NaCl discs. Nuclear magnetic resonance (nmr) spectra for protons were recorded on a Varian LM 360 spectrometer using deuterochloroform as solvent and tetramethylsilane as the internal standard. The positions of the signals are reported in δ units. (The splittings of the signals are described as singlets (s), doublets (d), triplets (t), quartets (q), or multiplets (m).) A Bruker WH250 or WH400 spectrometer was used for all ^{13}C nmr spectra and for ^{1}H nmr spectra of **13***a*, **13***d*, **14***a*, **15***a*, **15***d*, **26***a*, and **27***a* at 10^{-2} to 10^{-1} *M*.

The visible–ultraviolet spectra (uv) were recorded on a Perkin–Elmer–Hitachi 340 spectrometer. Mass spectra (ms) were recorded at 70 eV on a VG Micromass 16F mass spectrometer in the EI mode.

The FAB spectra were obtained with a Kratos MS-50 triple analyzer mass spectrometer equipped with a FAB ion source of standard Kratos design and an Ion Tech atom gun. The sample was dissolved in chloroform and a microliter of the resulting solution added to a microliter of *o*-nitrophenyloctylether on the probe tip. The spectra of the molecular ions of the binuclear phthalocyanines were obtained by signal averaging up to 256 scans over the appropriate mass range. The number in parentheses after the indicated ion shows the percentage of the base peak represented by that ion. Melting points (mp) were determined using a Kofler hot stage melting point apparatus and are uncorrected. Thin-layer chromatography (tlc) was performed using silica gel G as the adsorbent. All reactions were stirred with a magnetic stirrer. All solvents were freshly distilled before use. Microanalyses were performed by Guelph Chemical Laboratories Ltd., Guelph, Ont.

*Bis-(3,4-dicyanophenyl)ether (**6**) and 4-isopropoxyphthalonitrile (**7**)*

At room temperature

In a minor modification of Siegl's procedure (15) 4-nitrophthalonitrile (1.64 g, 9.49 mmol), isopropanol (2.0 mL, 26 mmol), and anhydrous potassium carbonate (2.94 g, 21.3 mmol) were stirred at room temperature under an argon atmosphere in 10 mL of dry DMF for 43 h. The potassium carbonate was added in three portions. The crude reaction mixture was poured into water (300 mL). The precipitate was collected by filtration, washed thoroughly with water, and dried. The crude product was purified by silica gel column chromatography using ether – petroleum ether (2:3) as the eluting solvent. It was then recrystallized from a mixture of ether–hexanes to give 1.21 g of slightly yellow crystals of 4-isopropoxyphthalonitrile (**7**), mp 58–59°C (lit. (11, 15) mp 56–57°C) in 69% yield.

At 50–60°C

In another experiment, 17.3 g of 4-nitrophthalonitrile (0.10 mol) reacted with 24 mL of isopropanol (0.31 mol) and 32 g of anhydrous potassium carbonate (0.23 mol) in 120 mL of dry DMF and the mixture *was heated at 50–60°C* under Ar for 93 h. Under these conditions and using an identical work-up as before, a mixture of bis(3,4-dicyanophenyl)ether (**6**) (15) and (**7**) was obtained. Compound **7** was separated from the insoluble **6** by extraction with ether. The 4-isopropoxyphthalonitrile (**7**) was further purified by column chromatography, followed by recrystallization as before to yield 6.10 g of (**7**) in 33% yield.

Further purification of **6** by recrystallization from acetonitrile gave in 44% yield 6.0 g of **6**, mp 256–257°C (lit. (15) mp 254–256°C).

*4-Isobutoxyphthalonitrile (**8**)*

Treatment of 5.19 g (30 mmol) of **1** with 4.44 g (60 mmol) of isobutyl alcohol (**3**) in DMF for 240 h at room temperature as described above for the preparation of **7** yielded after distillation in a Kugelrohr apparatus 5.3 g of 4-isobutoxyphthalonitrile (**8**) in 87% yield. Thin-layer chromatography of the crude reaction mixture indicated the presence of a small amount of 4-hydroxyphthalonitrile (**5**) (18) but this product was not isolated. Crystallization of a small sample of **8** from ethyl acetate – petroleum ether gave colourless crystals of **8**, mp 49–49.5°C; ir (cm^{-1}): 2240 (CN), 1600 (C=C), 1562 (C=C); ^{1}H nmr ($CDCl_3$) δ: 7.9–7.2 (m, 3H, aromatic), 3.9 (d, 2H, CH_2O, J = 6 Hz), 2.2 (m, 1H, CH), 1.1 (d, 6H, $(CH_3)_2C$, J = 6.0 Hz); ms, m/z: 200 (M$^+$, 29), 142 (42), 144 (40), 127 (21), 57 (100), 56 (70), 55 (21), 43 (24), 41 (43), 39 (56). *Anal.* calcd. for $C_{12}H_{12}N_2O$: C 71.98, H 6.04, N 13.99; found: C 72.08, H 5.84, N 13.98.

*4-Neopentoxyphthalonitrile (**9**)*

A solution of 1.73 g (10 mmol) of **1**, 2.30 g (26 mmol) of neopentyl alcohol, and 3.4 g (25 mmol) of potassium carbonate was stirred *at 60°C* (Table 3) as described for the preparation of **7** above. Column chromatography of the reaction product on silica using ethyl acetate – petroleum ether (1:19) gave in 82% yield 1.60 g of 4-neopentoxyphthalonitrile (**9**), mp 61.5–62°C; ir (cm^{-1}): 2230 (CN), 1590 (C=C), 1562 (C=C); ^{1}H nmr ($CDCl_3$) δ: 7.9–7.2 (m, 3H, aromatic), 3.75 (s, 2H, CH_2O), 1.05 (s, 9H, CH_3C); ms, m/z: 214 (M$^+$, 9), 199 (16), 157 (2), 145 (3), 72 (7), 71 (91), 70 (14), 57 (31), 55 (22), 43 (100), 41 (11). *Anal.* calcd. for $C_{13}H_{14}N_2O$: C 72.87, H 6.58, N 13.07; found: C 72.89, H 6.66, N 12.89.

Thin-layer chromatography of the crude reaction product indicated the presence of a small amount of **5** (18) but this product was not isolated.

*Preparation of 5-isopropoxy-1,3-diiminoisoindoline (**10**), 5-isobutoxy-1,3-diiminoisoindoline (**11**), and 5-neopentoxy-1,3-diiminoisoindoline (**12**)*

All diiminoisoindolines were prepared as previously described (19). In a typical example 246 mg (1.15 mmol) of **9** was converted to 297 mg of **12** which was used directly in condensation reactions without further purification. Compounds **10**–**12** did not exhibit nitrile absorptions in their ir spectra.

*Preparation of 2,9,16,23-tetraisopropoxyphthalocyanine (**13**a), 2,9,16,23-tetraisobutoxyphthalocyanine (**14**a), and 2,9,16,23-tetraneopentoxyphthalocyanine (**15**a) (Method A)*

Compound **13***a* was previously prepared in our laboratory (11, 12) from **10** using the procedure of Beach *et al.* (19) and purified by column chromatography using ether – petroleum ether as eluant.

A solution of **11** derived from 600 mg of **8** in 2-*N*,*N*-dimethylaminoethanol underwent self-condensation as for the preparation of **13***a* to give 285 mg of a crude reaction product. Flash chromatography (26) of this product using 2-methoxyethanol – toluene (1:40) as eluant gave upon evaporation of the solvent a purer product, still containing a trace of fluorescent material on examination by tlc. Further purification by flash chromatography yielded upon evaporation of the solvent 163 mg of very pure 2,9,16,23-tetraisobutoxyphthalocyanine (**14***a*) as a shiny blue solid in 27% yield; ir (cm^{-1}): 3300 (NH), 1630 (C=C), 1245, 1100, 1015 (NH), 750; ^{1}H nmr (CD_2Cl_2, 400 MHz) δ: 7.5–6.6 (m, 12H, aromatic), 3.7 (br s, 8H, CH_2O), 2.2 (m, 4H, CH), 1.2 (br s, 24H, CH_3), −5.8 (very br s, 2H); ^{13}C nmr (CD_2Cl_2, 400 MHz) δ: 159.9 (aromatic C—O), 121.9, 121.7, 117.2, 103.6, 74.5 (CH_2—O), 28.6 ($CHCH_2$), 19.3 (CH_3); ms m/z: 804 (M$^+$, 54), 803 (100), 802 (82), 746 (17). *Anal.* calcd. for $C_{48}H_{50}N_8O_4$: C 71.79, H 6.29, N 13.95; found: C 72.02, H 5.84, N 13.98.

Similarly, the isoindoline **12**, derived from 246 mg of phthalonitrile **9**, yielded on condensation a crude product. Flash chromatography using freshly distilled toluene as eluant gave upon evaporation of the solvent 112 mg of a dark blue, shining solid in 45% yield; ir (cm^{-1}): 3290 (NH), 1620 (C=C), 1240, 1100, 1060, 1015 (NH), 750; ^{1}H nmr (CD_2Cl_2, 250 MHz) δ: 7.6–6.0 (m, 12H, aromatic), 3.8 (s, 8H, CH_2O), 1.5 (s, 36H, CH_3), −6.5 (br, 2H, NH); ^{13}C nmr (CD_2Cl_2, 250 MHz) δ: 160.6 (aromatic C—O), 122.1, 117.4, 117.2, 78.6 (CH_2—O), 78.4 (CH_2O), 32.5 (CH_3C), 27.3 (CH_3C); ms, m/z: 859 (M$^+$, 100), 858 (62), 801 (2), 789 (23). *Anal.* calcd. for $C_{52}H_{58}N_8O_4$: C 72.70, H 6.80, N 13.04; found: C 72.78, H 6.86, N 13.00.

General procedures for the preparation of mononuclear metallophthalocyanines (Methods B and C)

Mononuclear metallophthalocyanines were prepared in varying yields (Table 1) according to the procedures of Pawlowski and Hanack (20) (Method B) and Tomoda *et al.* (21) (Method C) from the corresponding phthalonitriles. The metallophthalocyanines were isolated from the reaction mixture by dilution with water, filtration, and thorough washing with water, except for the case in which cuprous cyanide was used as the salt, in which the reaction mixture was treated with aqueous ammonia prior to washing with water. The metallophthalocyanines were purified by flash chromatography (26) using 2-methoxyethanol – toluene 1:40 as the eluting solvent.

*2,9,16,23-Tetraisopropoxyphthalocyaninatocopper (**13**b)*

In a typical procedure (Method B) (20), 0.21 g (1.15 mmol) of 4-isopropoxyphthalonitrile (**7**) reacted with 0.15 g (1.66 mmol) of cuprous cyanide in 2 mL of DMF at 145°C for 20 h to give, after the standard work-up described above, 0.080 g of 2,9,16,23-tetraisopropoxyphthalocyaninatocopper (**13***b*) in 34% yield as a dark blue solid; ir (cm^{-1}): 1610 (C=C), 1245, 1100, 1055, 750; ms, *m/z*: 809 (100), 808 (M$^+$, 55), 807 (67), 765 (36), 724 (16). *Anal.* calcd. for $C_{44}H_{40}N_8O_4Cu$: C 65.37, H 4.99, N 13.86, Cu 7.86; found: C 65.00, H 5.24, N 13.53, Cu 7.47.

In a typical procedure using Method C (21), 0.38 g (2.0 mmol) of **7** reacted with 0.14 g (1.0 mmol) of cupric chloride and 0.62 g (5 mmol) of diazabicyclononane (DBN) in 10 mL of absolute alcohol at reflux temperatures for 24 h to give, after the standard work-up, 0.20 g of **13***b* in 49% yield. Although Method C gave **13***b* in higher yields than Method B, repetitive flash chromatography of the reaction product was necessary to remove some fluorescent impurities and hence, in general, Method B or Method D (see below) is preferred.

*2,9,16,23-Tetraisopropoxyphthalocyaninatocobalt(II) (13*c*)*

Using Methods B and C, **7** was readily converted (Table 1) into 2,9,16,23-tetraisopropoxyphthalocyaninatocobalt(II) (**13***c*), isolated as a shining dark blue solid; ir (cm^{-1}): 1615 (C=C), 1245, 1100, 1060, 755; ms, *m/z*: 804 (M$^+$, 100), 803 (49), 762 (19). *Anal.* calcd. for $C_{44}H_{40}N_8O_4Co$: C 65.75, H 5.02, N 13.94, Co 7.33; found: C 65.73, H 4.99, N 13.63, Co 7.49.

*2,9,16,23-Tetraisopropoxyphthalocyaninatozinc (13*d*)*

Using methods B and C, **7** was converted (Table 1) into 2,9,16,23-tetraisopropoxyphthalocyaninatozinc (**13***d*), isolated as a shining, dark blue solid; ir (cm^{-1}): 1610 (C=C), 1240, 1100, 1050, 750; ^{13}C nmr (CD_2Cl_2, 400 MHz) δ: 159.3 (aromatic C—O), 125.4, 121.7, 109.4, 71.5 (CH_2—O), 70.6 (CH_2—O), 22.7 (CH_3), 21.8 (CH_3); ms, *m/z*: 813 (64), 812 (79), 811 (96), 810 (M$^+$, 95), 809 (100), 808 (70), 767 (31). *Anal.* calcd. for $C_{44}H_{40}N_8O_4Zn$: C 65.23, H 4.98, N 13.83, Zn 8.07; found: C 65.41, H 5.00, N 13.76, Zn 7.76.

*Metal insertion reactions on metal-free phthalocyanines. 2,9,16,23-Tetraisobutoxyphthalocyaninatocopper (14*b*) (Method D in toluene)*

To a solution of 100 mg (0.12 mmol) of 2,9,16,23-tetraisobutoxyphthalocyanine (**14***a*) in 10 mL of toluene was added 150 mg (0.83 mmol) of cupric acetate. The solution was stirred at 100°C under an argon atmosphere for 3 h. The crude reaction mixture was applied to 3 tlc preparative plates, and eluted 3 times with 2-methoxyethanol − toluene (1:100) to give a dark green band which was extracted with toluene in a Soxhlet extractor. Further purification by flash chromatography using 2-methoxyethanol − toluene (1:20) gave in 74% yield 80 mg of 2,9,16,23-tetraisobutoxyphthalocyaninatocopper (**14***b*) as a dark blue, shining solid; ir (cm^{-1}): 1620 (C=C), 1250, 1105, 1065, 755; ms, *m/z*: 867 (28), 866 (M$^+$, 56), 865 (71), 864 (100), 863 (59), 808 (25). *Anal.* calcd. for $C_{48}H_{48}N_8O_4Cu$: C 66.53, H 5.60, N 12.77, Cu 7.02; found: C 66.68, H 5.61, N 12.96, Cu 7.35.

*2,9,16,23-Tetraneopentoxyphthalocyaninatocopper (15*b*) and 2,9,16,23-tetraneopentoxyphthalocyaninatocobalt(II) (15*c*) (Method D, in DMF and 2-*N,N*-dimethylaminoethanol)*

To a solution of 41 mg (0.048 mmol) of **15***a* in 3 mL of a 1:2 mixture of dry DMF and 2-*N,N*-dimethylaminoethanol was added 10 mg (0.074 mmol) of anhydrous cupric chloride. The mixture was heated for 1 h under an argon atmosphere using an oil bath heated to 110°C. The mixture was cooled to room temperature and directly subjected to flash chromatography using freshly distilled toluene as the eluting solvent to give in 94% yield (Table 1) 41 mg of 2,9,16,23-tetraneopentoxyphthalocyaninatocopper (**15***b*) as a dark blue, shining solid; ir (cm^{-1}): 1615 (C=C), 1240, 1100, 1060, 745; ms, *m/z*: 922 (78), 921 (M$^+$, 81), 920 (100), 864 (4), 850 (9). *Anal.* calcd. for $C_{52}H_{56}N_8O_4Cu$: C 67.84, H 6.13, N 12.17, Cu 6.90; found: C 68.10, H 6.24, N 11.89, Cu 6.97.

Similarly, 33 mg of **15***a* gave in 94% yield (Table 1) 33 mg of 2,9,16,23-tetraneopentoxyphthalocyaninocobalt(II) (**15***c*) as a dark blue, shining solid; ir (cm^{-1}): 1615 (C=C), 1240, 1100, 1065, 750; ms, *m/z*: 916 (M$^+$, 100), 915 (47), 859 (7), 846 (19). *Anal.* calcd. for $C_{52}H_{56}N_8O_4Co$: C 68.18, H 6.16, N 12.23, Co 6.43; found: C 68.22, H 6.14, N 12.07, Co 6.94.

Compounds **15***b* and **15***c* were also prepared directly from **9** by the methods of Pawlowski and Hanack (20) (Method B, Table 1).

*2,9,16,23-tetraneopentoxypthalocyaninatozinc (15*d*)*

Using a modification of the procedure of Pawloski and Hanack (20) (Method B), 394 mg (1.84 mmol) of 4-neopentoxyphthalonitrile (**9**) was suspended in 2 mL of dry DMF. Zinc acetate (1.04 g, 5.66 mmol) was added and the mixture heated using an oil bath at 155°C under argon. The clear reaction mixture turned yellow after 1 h and dark green after an additional 1 h. After heating for 20 h at 155°C, the mixture was cooled to room temperature, diluted with water, filtered, and washed thoroughly with water. The crude product was purified by flash chromatography using petroleum ether − ether (6:1) as the eluting solvent to give in 27% yield (Table 1) 114 mg of 2,9,16,23-tetraneopentoxyphthalocyaninatozinc (**15***d*) as a dark blue, shining solid; ir (cm^{-1}): 1610 (C=C), 1240, 1100, 1060, 750; ^{1}H nmr (CD_2Cl_2, 250 MHz) δ: 7.7−6.1 (m, 12H, aromatic), 3.5 (s, 8H, CH_2O), 1.3 (s, 36H, CH_3); ^{13}C nmr (CD_2Cl_2, 250 MHz) δ: 160.1 (aromatic C—O), 149.5, 121.7, 121.3, 116.9, 116.6, 104.2, 103.9, 78.2 (CH_2O), 78.1 (CH_2O), 32.2 (CH_3C), 27.1 (CH_3C), 26.8 (CH_3C), 26.5 (CH_3C); ms, *m/z*: 925 (52), 924 (84), 923 (91), 922 (M$^+$, 97), 921 (100), 868 (2), 853 (40). *Anal.* calcd. for $C_{52}H_{56}N_8O_4Zn$: C 67.71, H 6.12, N 12.15, Zn 7.07; found: C 67.80, H 6.39, N 11.85, Zn 6.94.

2-Methyl-2-trityloxymethyl-1,3-propanediol (17)

To a solution of 1,1,1-tris(hydroxymethyl)ethane (**16**) (6.48 g, 54.00 mmol) in 15 mL of dry pyridine, triphenylmethyl chloride (2.60 g, 9.32 mmol) was added and the mixture was stirred for 22 h at room temperature under exclusion of moisture ($CaCl_2$ drying tube). The mixture was then poured into 180 mL of ice-water and extracted 4 times with ether. The combined ether extracts were washed six times with water, dried over anhydrous $MgSO_4$, and evaporated to give a viscous oil which was dried under high vacuum for 4 h. The crude product was purified by column chromatography on silica gel using a mixture of chloroform−hexane (3:1) as the eluting solvent. Evaporation of the solvent yielded a product which was recrystallized from a mixture of ether−hexane to give in 68% yield 2.18 g of white crystals, mp 127−128°C; ir (cm^{-1}): 3360 (OH), 1600 (C=C), 1500, 1495, 1050, 770, 710, 705; ^{1}H nmr ($CDCl_3$, 60 MHz) δ: 7.6−7.2 (m, 15H, aromatic), 3.65 (d, 4H, CH_2O, J = 6 Hz), 3.2 (s, 2H, CH_2O), 2.4 (t, 2H, OH, J = 6 Hz), 0.8 (s, 3H, CH_3); ^{13}C nmr ($CDCl_3$, 400 MHz) δ: 143.7 (aromatic C-1′), 128.6 and 127.9 (aromatic C-2′, C-6′, C-3′, C-5′), 127.1 (aromatic C-4′), 86.7 (PhC), 67.8 (CH_2OC), 67.0 (CH_2OH), 41.1 (CCH$_2$), 17.3 (CH_3); ms, *m/z*: 362 (M$^+$, 3), 285 (20), 259 (50), 239 (100), 183 (80), 105 (75), 77 (23). *Anal.* calcd. for $C_{24}H_{26}O_3$: C 79.53, H 7.23; found: C 79.58, H 7.19.

1,3-Bis(3′,4′-dicyanophenoxy)-2-methyl-2-trityloxymethylpropane (20) 1,3-bis(3′,4′-dicyanophenoxy)-2,2-dimethylpropane (21), and 1,3-bis(3′,4′-dicyanophenyl)-2-ethyl-2-methylpropane (22)

A solution of 1.09 g (3.01 mmol) of **17**, 1.07 g (6.18 mmol) of **1**, and 1.75 g (12.68 mmol) of anhydrous potassium carbonate was heated at 65°C in 7 mL of dry DMSO by the method of Keller *et al.* (16). The reaction mixture was filtered and washed with methylene chloride (CH_2Cl_2). The filtrate was diluted with CH_2Cl_2 and washed thoroughly 6 times with water and finally with saturated sodium chloride. After drying over anhydrous magnesium sulfate ($MgSO_4$), the solvent was evaporated to give 1.77 g of a light brown solid. The crude product was purified by flash chromatography using chloroform−hexane (3:1) as the eluting solvent. Evaporation of the solvent yielded an oil which was dissolved in warm methanol and rapidly cooled to −35°C (but not lower) to give in 56% yield 1.02 g of 1,3-bis(3′,4′-dicyanophenyl)-2-methyl-2-trityloxymethylpropane (**20**) as light yellow crystals, mp 89−92°C; ir (cm^{-1}): 2240 (CN), 1600 (C=C), 1495, 1255, 1090, 1030, 710, 700; ^{1}H nmr ($CDCl_3$, 60 MHz) δ: 7.80−7.05 (m, 21H, aromatic), 4.03 (s, 4H, CH_2O), 3.30 (s, 2H, CH_2O), 1.30 (s, 3H, CH_3); ms, *m/z*: 614 (M$^+$, 18), 537 (20), 283 (10), 243 (65), 240 (100), 183 (48), 144 (19), 105 (58). *Anal.* calcd. for $C_{40}H_{30}N_4O_3$: C 78.16, H 4.92, N 9.11; found: C 78.18, H 4.72, N 8.92.

Similarly, a solution of 1.04 g (10.0 mmol) of 2,2-dimethyl-1,3-propanediol (**18**), 3.81 g (22 mmol) of **1**, and 6.7 g (48.6 mmol) of anhydrous K_2CO_3 in 10 mL of dry DMSO gave a crude reaction product. The reaction mixture was filtered and washed with ethyl acetate. The filtrate was diluted with ethyl acetate, thoroughly washed with water until the aqueous layer was clear, and finally washed with a saturated sodium chloride solution. After drying over anhydrous $MgSO_4$, the solvent was evaporated to give a dark brown solid. The crude product was purified by column chromatography on silica gel using benzene–acetonitrile (9:1) as the eluting solvent. Evaporation of the solvent and recrystallization of the residue from acetonitrile–water gave 1.36 g (38%) of 1,3-bis(3′,4′-dicyanophenoxy)-2,2-dimethylpropane (**21**) as creamy crystals, mp 168–169°C; ir (cm^{-1}): 2240 (CN), 1600 (C═C), 1260, 1100, 1040, 845; ^{1}H nmr (acetone-d_6, 60 MHz) δ: 8.10–7.42 (m, 6H, aromatic), 4.27 (s, 4H, CH_2OC), 1.27 (s, 6H, CH_3); ms, *m/z*: 356 (M$^+$, 11), 213 (30), 171 (88), 127 (43). *Anal.* calcd. for $C_{21}H_{16}N_4O_2$: C 70.78, H 4.52, N 15.72; found: C 70.74, H 4.37, N 15.43.

In a manner similar to that described above for the preparation of **21**, 1.60 g of 2-ethyl-2-methyl-1,3-propanediol (**19**) yielded a crude reaction product. Thin-layer chromatography of this product using benzene–acetonitrile (9:1) as eluant exhibited the presence of a minor amount of 4-hydroxyphthalonitrile (**5**). Thus, the ethyl acetate filtrate was washed several times with water, followed by 0.5 *M* cold NaOH, water, and finally saturated NaCl solution. The ethyl acetate solution yielded upon the normal work-up a dark brown solid. The aqueous layer was acidified with dilute HCl and the organic material was extracted into ethyl acetate. The ethyl acetate was dried over anhydrous $MgSO_4$, filtered, and evaporated to give 560 mg of **5** (18) which was not further purified. Purification of the dark brown solid, obtained from the original ethyl acetate extract above, yielded, upon recrystallization from ethyl acetate – hexanes, 1.84 g (37%) of 1,3-bis-(3′,4′-dicyanophenoxy)-2-ethyl-2-methylpropane (**22**) as creamy crystals, mp 157–158°C; ir (cm^{-1}): 2240 (CN), 1600 (C═C), 1260, 1095, 1025, 845; ^{1}H nmr ($CDCl_3$, 60 MHz) δ: 7.87–7.18 (m, 6H, aromatic), 4.03 (s, 4H, CH_2O), 1.62 (q, 2H, CH_2C, *J* = 7 Hz), 1.18 (s, 3H, CH_3C), 1.10 (t, 3H, CH_3CH$_2$, *J* = 7 Hz); ms, *m/z*: 370 (M$^+$, 23), 227 (46), 185 (60), 171 (65), 127 (52). *Anal.* calcd. for $C_{22}H_{18}N_4O_2$: C 71.34, H 4.90, N 15.12; found: C 71.30, H 5.03, N 15.09.

Preparation of the bis-1,3-diiminoisoindolines **23** *and* **24**

Compounds **23** and **24** were prepared from **21** and **22** respectively as described above for **10**–**12** with one minor exception. As **21** and **22** were only slightly soluble in methanol at room temperature, these compounds were dissolved in a solution of sodium methoxide in methanol at 65°C and ammonia was bubbled into this solution for 1 h at 65°C and for 3 h under reflux conditions.

1,3-Bis-2′-(9′,16′,23′-triisopropoxyphthalocyaninoxycopper)-2-methyl-2-trityloxymethylpropane (25)

A mixture of 0.14 g (0.23 mmol) of **20**, 1.0 g (5.4 mmol) of **7**, and 1.54 g (17.23 mmol) of cuprous cyanide was heated at 130°C (oil bath) in 7.5 mL of dry DMF for 20 h under argon atmosphere (Method B) (20). After dilution with ammonia, the product was filtered and washed with water. The dark blue-green residue was dissolved in toluene and chromatographed under argon using the flash chromatography technique. Elution with 2-methoxyethanol – toluene (1:40) gave, upon solvent evaporation, 340 mg of 2,9,16,23-tetraisopropoxyphthalocyaninatocopper (**13***b*) in 31% yield. Elution with 2-methoxyethanol – toluene (1:4) gave a slightly impure product. Thin-layer chromatography of this product exhibited a major blue spot and slightly faster moving green impurity (2-methoxyethanol – toluene, 1:4 as eluant). Further purification by flash chromatography using a small diameter column (1 cm) gave in 1% yield 6 mg of the pure dimer, 1,3-bis-2′-(9′,16′,23′-triisopropoxyphthalocyaninatocopper)-2-methyl-2-trityloxymethylpropane (**25**) as a dark blue, shining solid; ir (cm^{-1}: 1615 (C═C), 1250, 1120, 1105, 1060, 755; ms, *m/z*: 1859.5 (M$^+$), 1816 (*M*$^+$ – 43). *Anal.* calcd. for $C_{106}H_{90}N_{16}O_9Cu_2$: C 68.48, H 4.88, N 12.05; found: C 67.85, H 5.34, N 12.53.

*1,3-Bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninoxy)-2,2-dimethylpropane (26*a*) and 1,3-bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninoxy)-2-ethyl-2-methylpropane (27*a*)*

The two crude diiminoisoindolines **12** and **23** obtained from 4.2 g (19.6 mmol) of 4-neopentoxyphthalonitrile (**9**) and 249 mg (0.7 mmol) of 1,3-bis-(3′,4′-dicyanophenoxy)-2,2-dimethylpropane (**21**), respectively, were heated at 150°C (oil bath) in 30 mL of 2-*N*,*N*-dimethylaminoethanol for 23 h under an argon atmosphere. The mixture gradually changed colour from yellow to dark blue. After cooling to room temperature, the mixture was diluted with water and the blue coloured residue was filtered and washed thoroughly with water until the filtrate was colourless. The crude product was purified in two separate batches by flash chromatography using a 5 cm wide column packed with silica gel 9 cm high. The dark blue-green product was preadsorbed on silica and eluted with 1500 mL of freshly distilled toluene to give 1.92 g of the monomeric 2,9,16,23-tetraneopentoxyphthalocyanine (**15***a*) in 46% yield. Further elution with 2-methoxyethanol – toluene in ratios of 1:40 and 1:10 yielded, after solvent evaporation, 340 mg of a purified product, containing traces of monomer **15***a* and some green material (fluorescent under uv) which moved closely behind the desired product when examined by tlc (2-methoxyethanol – toluene, 1:40 as eluting solvent). Flash chromatography of this purified material on a smaller column 3 cm wide removed, on elution with toluene and 2-methoxyethanol – toluene (1:100), all traces of monomer **15***a*. Further elution with 2-methoxyethanol – toluene (1:20) yielded some fractions of a very pure, dark blue product. Other fractions were still contaminated with the green material. Purification of these fractions was achieved using preparative tlc and 2-methoxyethanol – toluene (1:20) as eluting solvent. Finally, the product was purified by flash chromatography as above to give in 17% yield 195 mg of 1,3-bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninoxy)-2,2-dimethylpropane (**26***a*) as a very pure, dark blue, shining solid; ir (cm^{-1}): 3300 (NH), 1615 (C═C), 1240, 1100, 1055, 1020 (NH), 750; ^{1}H nmr (CD_2Cl_2, 400 MHz) δ: 8.21–7.12 (br), 4.05–3.65 (br), 1.42 (br), –6.12 (br); ^{13}C nmr (CD_2Cl_2, 400 MHz) δ: 32.35 (CH_3*C*), 27.20 (*C*H_3C); ms, *m/z*: 1645 (100), 1644 (M$^+$, 84). *Anal.* calcd. For $C_{99}H_{104}N_{16}O_8$: C 72.24, H 6.37, N 13.61; found: C 72.47, H 6.27, N 13.49.

Similarly, the two crude isoindolines **12** and **24** obtained from 5.6 g (26.2 mmol) of **9** and 0.4 g (1.08 mmol) of **22**, respectively, yielded 1.72 g of **15***a* in 31% yield and 184 mg in 10% yield of 1,3-bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninoxy)-2-ethyl-2-methylpropane (**27***a*) as a dark blue, shining solid; ir (cm^{-1}): 3310 (NH), 1618 (C═C), 1240, 1100, 1058, 1020 (NH), 750; ^{1}H nmr ($CDCl_3$, 400 MHz) δ: 9.4–6.8 (br), 4.2–3.6 (br), 1.8–0.8 (br), –5.8 – (–6.4) (br); ^{13}C nmr (CD_2Cl_2, 400 MHz) δ: 78.6 (*C*H_2O), 32.4 (*C*CH$_3$), 30.1 (*C*CH$_2$), 27.2 (*C*H$_3$C), 26.6 (CCH$_2$*C*H$_3$); ms, *m/z*: 1662 (100), 1660 (M$^+$, 41), 1658 (30). *Anal.* calcd. for $C_{100}H_{106}N_{16}O_8$: C 72.35, H 6.44, N 13.50; found: C 72.51, H 6.77, N 13.56.

*1,3-Bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninoxycopper)-2,2-dimethylpropane (26*b*), 1,3-bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninoxycobaltII)-2,2-dimethylpropane (26*c*), and 1,3-bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninoxycobaltII)-2-ethyl-2-methylpropane (27*b*)*

A mixture of 50 mg (0.03 mmol) of **26***a*, 23 mg (0.13 mmol) of anhydrous cupric acetate, and 10 mL of freshly distilled toluene was heated at 100°C for 17 h under an argon atmosphere. The solution was cooled and purified by flash chromatography (26) by direct application of the crude reaction product to the column. Elution with 2-methoxyethanol – toluene (7:200) gave, after solvent evaporation, 29 mg (54% yield) of a dark blue, shining product which was washed with anhydrous ether to remove very minor fluorescent impurities (detected by tlc) leaving 28 mg of very pure 1,3-bis-2′-(9,16,23-trineopentoxyphthalocyaninoxycopper)-2,2-dimethylpropane (**26***b*); ir (cm^{-1}): 1615 (C=C), 1240, 1100, 1060, 750; ms, m/z: 1772, 1771, 1770, 1769, 1768 (M^+), 1767. *Anal.* calcd. for $C_{99}H_{100}N_{16}O_8Cu_2$: C 67.22, H 5.70, N 12.67, Cu 7.18; found: C 67.41, H 5.52, N 12.40, Cu 6.83.

Similarly, 50 mg (0.03 mmol) of **26*a*** and 105 mg (0.81 mmol) of anhydrous cobaltic chloride in 15 mL of a 1:2 mixture of 2-methoxyethanol − toluene was heated at 100°C for 20 h to give, after purification as above, 32 mg (60% yield) of 1,3-bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninoxycobaltII)-2,2-dimethylpropane (**26*c***) as a dark blue, shining solid: ir (cm^{-1}): 1615 (C=C), 1240, 1100, 1068, 755; ms, m/z: 1761 (61), 1760 (M^+, 100), 1759. *Anal.* calcd. for $C_{99}H_{100}N_{16}O_8Co_2$: C 67.57, H 5.73, N 12.73, Co 6.70; found: C 67.92, H 5.88, N 12.84, Co 6.25.

Similarly, 70 mg (0.04 mmol) of **27*a*** and 57 mg (0.44 mmol) of anhydrous cobaltic chloride in 10 mL of a 3:7 mixture of 2-methoxyethanol − toluene were heated at 110°C for 24 h under an argon atmosphere. Purification as above gave 55 mg (74% yield) of pure 1,3-bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninatocobaltII)-2-ethyl-2-methylpropane (**27*b***) as a dark blue, shining solid; ir (cm^{-1}): 1620 (C=C), 1245, 1100, 1068, 758; ms, m/z: 1774 (M^+, 100). *Anal.* calcd. for $C_{100}H_{102}N_{16}O_8Co_2$: C 67.71, H 5.80, N 12.63, Co 6.64; found: C 68.14, H 6.21, N 12.61, Co 6.64.

Received August 13, 1984

V. K. MAHESH, MAMTA MAHESWARI, RAKESH SHARMA, and RASHMI SHARMA. Can. J. Chem. **63**, 632 (1985).

Tetrahydrocannabinol **1**, the active constituent of *Cannabis sativa Linn*, is a well-known CNS-active compound and introduction of a nitrogen atom at the ring junction of the pyran and alicyclic ring is of considerable interest. This prompted the synthesis of 7*H*-indolo[1,2-*c*] [1,3]-, 5*H*-imidazolo[1,2-C] [1,3],- and 7*H*-benzimidazolo[1,2-*c*] [1,3]-benzoxazine, a novel heterocyclic system. 2-(2′-Hydroxyphenyl) indoles, 2-(2′-hydroxyphenyl) imidazoles, and 2-(2′-hydroxyphenyl) benzimidazoles are suitable intermediates for the preparation of this type of benzoxazines, as the second heterocycle (ring B) can then be constructed by introduction of a methylene bridge between the hydroxyl of the 2′-hydroxy phenyl substituent and the imino group of the heterocyclic system.

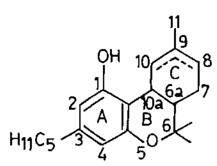
V. K. MAHESH, MAMTA MAHESWARI, RAKESH SHARMA et RASHMI SHARMA. Can. J. Chem. **63**, 632 (1985).

Le tétrahydrocannabinol (**1**), le constituant actif du *Cannabis sativa Linn* est un composé dont l'activité sur le CNS est bien connue et l'introduction d'un atome d'hydrogène à la jonction entre le cycle pyranne et l'alicycle présente beaucoup d'intérêt. Ceci nous a conduit à réaliser la synthèse des 7*H*-indolo[1,2-*c*], 5*H*-imidazolo[1,2-*c*] et 7*H*-benzimidazolo[1,2-*c*] [1,3]benzoxazines, un nouveau système hétérocyclique. Les (hydroxy-2 phényl)-2 indoles, (hydroxy-2 phényl)-2 imidazoles et (hydroxy-2 phényl)-2 benzimidazoles sont des intermédiaires bien adaptés à la préparation de ce type de benzoxazines puisque le deuxième hétérocycle (cycle B) peut alors être construit par l'introduction d'un pont méthylène entre l'hydroxyle du substituant hydroxy-2′ phényle et le groupe imino du système hétérocyclique.

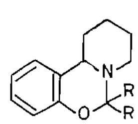
[Traduit par le journal]

Introduction

Tetrahydrocannabinols **1**, active constituents of *Cannabis sativa Linn*, are among a very small number of non-nitrogenous compounds which are central nervous active. To bring about a suitable modification in the activity, several nitrogen-containing analogs have been synthesized; some of these compounds showed CNS activity, but no separation of biological activities could be achieved (1–6). Introduction of a nitrogen atom at the ring junction of the pyran ring (ring B) and the alicyclic ring (ring C) of THC appears to be of considerable interest in studying the structure–activity relationship among this class of compounds. 9,10,11,11a-Tetrahydro 6*H*,8*H*-pyrido[1,2-*c*] [1,3]benzoxazine **2** has been prepared as a model compound containing a nitrogen atom at the ring junction (7).



1

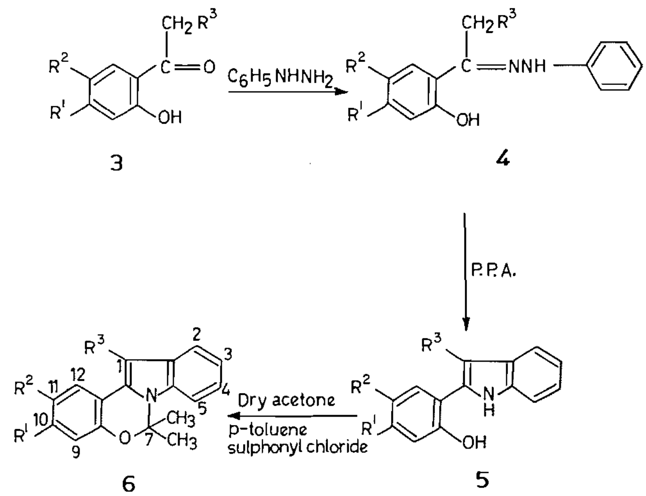


2

Some well-known CNS-active agents are reported to have indole, imidazole, and benzimidazole in their structural makeup (8–10); therefore it was thought that molecules having mixed features of cannabinoids (ring A and B) and substituted pyrrole and imidazole as ring C, with a nitrogen atom as a part of both ring B and C, would be of great pharmacological interest. Such heterocyclic systems would be novel and have not been prepared before. In this paper we wish to report on the preparation and studies of 7,7-dimethyl-7*H*-indolo[1,2-*c*] [1,3]benzoxazines, 5*H*-imidazolo[1,2-*c*] [1,3]benzoxazines, and 7*H*-benzimidazolo[1,2-*c*] [1,3]benzoxazine.

Discussion

For the preparation of the benzoxazine systems an ingenious method has been developed. A methylene bridge has been constructed between the hydroxyl group of the 2′-hydroxy-



SCHEME 1

phenyl substituent and the imino group of the heterocyclic system – indole, imidazolo, or benzimidazole. This is achieved by boiling the properly substituted heterocyclic compound with either (a) dry acetone in presence of *p*-toluene sulphonyl chloride (11) or (b) methylene dibromide in potassium carbonate – dimethylformamide mixture. 2-(2′-Hydroxyphenyl) indoles, on refluxing in dry acetone in presence of *p*-toluene sulphonyl chloride, gave the expected product, 7,7-dimethyl-7*H*-indolo[1,2-*c*] [1,3]benzoxazines, in good yields. The use of methylene dibromide, however, resulted in a number of compounds, from which the expected 7*H*-indolo[1,2-*c*] [1,3]benzoxazine could not be isolated (12). Condensation of 2-(2′hydroxyphenyl) imidazoles and 2-(2′-hydroxyphenyl) benzimidazoles with methylene dibromide in K_2CO_3–DMF gave 5*H*-imidazolo[1,2-*c*] [1,3]benzoxazines and 7*H*-benzimidazolo[1,2-*c*] [1,3]benzoxazines. It has also been noted that the phenolic group in ring A is essential for the biological activity (13, 14).

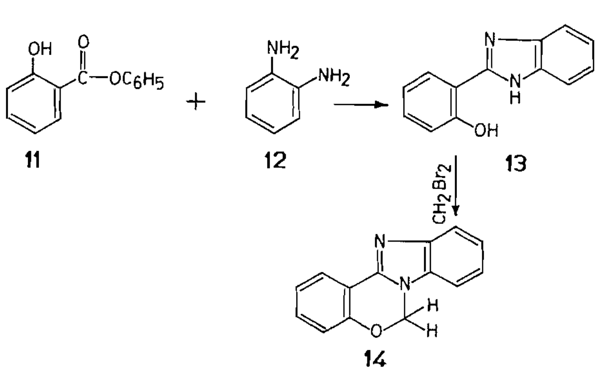

SCHEME 3

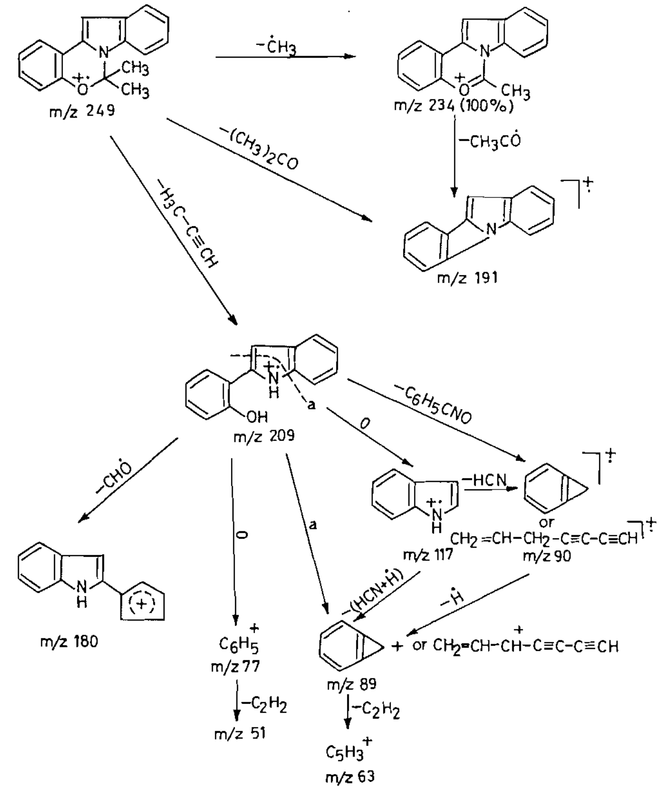

CHART 1

Nuclear magnetic resonance studies

The nmr spectrum of 7,7-dimethyl-7*H*-indolo[1,2-*c*] [1,3]-benzoxazine **6***a* showed a sharp singlet at δ 1.81 for the *gem*-dimethyl at the 7 position. The other protons of benzoxazine are at comparable values to the 2-(2′-hydroxyphenyl indole) protons. In the case of the imidazolo benzoxazines, in addition to the signals for aromatic protons, a singlet at δ 5.67 integrating for two protons which can be assigned to methylene protons at position 5 in the molecule has been observed.

Mass spectral analyses

The molecular ions in the mass spectra of compounds 7,7-dimethyl-7*H*-indolo[1,2-*c*] [1,3]benzoxazine **6***a* and its 10-hydroxy derivative **6***g* appeared at *m/z* 249 to 265 respectively. Loss of one methyl radical from molecular ion **6***a* at position 7 resulted in the predominant fragment at *m/z* 234 which is the base peak. The molecular ions undergo a loss of propyne molecule to yield an ion at *m/z* 209 which corresponds to the molecular weight of the 2-(2′-hydroxyphenyl) indole ion. These ions split into further fragments which are common in 2-phenyl indoles (15), shown in Chart 1. However, a peak at *m/z* 117 which corresponds to unsubstituted indoles definitely results by a rearrangement process. The ion displays all the characteristic fragmentations reported for indoles (16).

The molecular ion of compound **6***a* also suffers a loss of acetone molecule resulting in an ion at *m/z* 191. An alternative pathway to this ion, *m/z* 191, involves the loss of acetyl radical from the peak cation appearing at *m/z* 234 (Chart I). The most intense peaks in the mass spectra of the compound **6***a* are *m/z* 249, 234(100%), 209, 191, 180, 117, 90, 89, 77, 63, and 51. Spectral peaks *m/z* 265, 250(100%), 225, 196, 117, 89, 77, 63, and 51 in the case of the 10-hydroxy derivative can be explained in a similar way.

Experimental

All melting points reported are uncorrected. Infrared spectra were reported on a Beckman IR-20 spectrophotometer (λ_{max} in cm^{-1}) and nmr spectra were recorded on Varian A-60D and Brucker WH-270 spectrometers with TMS as an internal standard. The mass spectra were scanned on a spectrophotometer equipped with a direct inlet system at 70 eV and at filament current 100 μA. Compounds were routinely checked for their homogeneity by tlc on silica gel-G plates and spots were visualized by exposure to iodine vapours.

Corresponding phenylhydrazones were prepared by condensation of phenylhydrazine with respective acetophenones, propiophenones, and butrophenones (17), which in turn were prepared by condensation of phenols or resorcinols with the corresponding carboxylic acids.

2-(2′-Hydroxyphenyl) indole (*5*)

A mixture of 2-hydroxyacetophenone phenylhydrazone (8.4 g, 0.04 mol) and polyphosphoric acid (60 g, prepared from 40 g phosphorous pentoxide and 20 g orthophosphoric acid) was heated on an oil bath at 120°C for 1 h and left overnight at room temperature. The reaction mixture was poured into ice-cold water. The precipitated product was filtered, washed with water, and dried. It was crystallized from methanol to yield 5.0 g (68%) of the title compound, mp 162–164°C; ir (KBr): 3445, 3440 (OH and NH) cm^{-1}; nmr (DSS) (NaOD): 6.68 (t, 1, H-3′), 6.82 (m, 1, H-5′), 7.18–7.35 (m, 4, H-3, H-4, H-4′, H-6′), 7.54 (d, *J* = 6.7 Hz, 1, H-5), 7.65 (d, *J* = 6.7 Hz, 1, H-6), 7.70 (d, *J* = 6.7 Hz, 1, H-7).

*7,7-Dimethyl-7*H*-indolo[1,2-c] [1,3]benzoxazine* (*6a*)

A mixture of 2-(2′-hydroxyphenyl) indole (**5**) (3.0 g, 0.015 mol), *p*-toluene sulphonyl chloride (0.05 g), and dry acetone (50 mL) was refluxed on a steam bath for 50 h. The solvent was removed *in vacuo*. The residue was taken up in chloroform and washed with water, dried (Na_2SO_4), filtered, and concentrated to yield 2 g (56%) of the title compound which, after recrystallization from ethanol/ethyl acetate (1:1), had mp 110–112°C; nmr: ($CDCl_3$): 6.00 (s, 2H, $2CH_3$), 6.88–7.97 (m, 9H, ArH); ms *m/e* (%): 249(55), 234(100), 209(27), 180(19), 117(48), 90(20), 89(26), 77(25), 63(32), 51(28), 191(31).

*11-Methoxy-7,7-dimethyl-7*H*-indolo[1,2-*c*] [1,3]benzoxazine (***6**b*)*

Condensation of 2(2′-hydroxy-5-methoxyphenyl) indole (2.4 g, 0.01 mol) in a similar way with dry acetone and *p*-toluene sulphonyl chloride yielded the 11-methoxy derivative (**6***b*). It was crystallized from ethanol/ethyl acetate (1:1) to give 1.28 g (55%) of the title compound, mp 110–111°C; nmr ($CDCl_3$): 1:818 (6H, $(CH_3)_2$), 2:22 (s, 3H, CH_3), 6.81–7.59 (m, 8H, ArH).

*10-Hydroxy-7,7-dimethyl-7*H*-indolo[1,2-*c*] [1,3]benzoxazine (***6**g*)*

By the same procedure used for the preparation of **6***a*, 2-(2′,4′-dihydroxyphenyl) indole (2.25 g, 0.01 mol) was converted to 1.3 g (55%) of the title compound, mp 170–173°C; nmr ($CDCl_3$ + DMSO-d_6): 1.75 (s, 6H, $(CH_3)_2$), 4.83 (m, 1H, OH), 6.83–7.71 (m, 8H, ArH).

*2-(2′-Hydroxyphenyl)-4,5-diphenyl imidazole (***9**a*)*

A mixture of salicylaldehyde (6.1 g, 0.05 mol), benzil (10.5 g, 0.05 mol), ammonium acetate (30 g), and glacial acetic acid (150 mL) was refluxed for a period of 2 h, cooled, and treated with ice-cold water to give 10 g (64%) of the title compound which, after recrystallization from methanol/ether, had mp 238–240°C; ir(KBr): 3435, 3250 (OH and NH) cm^{-1}. *Anal.* calcd. for $C_{21}H_{16}N_2O$: C 80.76, H 5.13, N 8.9; found: C 80.45, H 5.00, N 8.87.

*2,3-Diphenyl-5*H*-imidazolo[1,2-*c*] [1,3]benzoxazine (***10***)*

A mixture of 2-(2′-hydroxyphenyl)-4,5-diphenyl imidazole (**9***a*) (3.12 g, 0.01 mol), anhydrous potassium carbonate (10 g), methylene bromide (7 mL), and dry dimethylformamide (40 mL) was heated on a steam bath for 16 h. It was filtered to remove the inorganic salts and the filtrate was concentrated under vacuum. The residue was triturated with water to yield 2.4 g (74%) of the title compound, mp 60–62°C; nmr ($CDCl_3$): 7.60–7.03 (m, 14, ArH), 1.67 (s, 2, H-5).

*2-(2′-Hydroxyphenyl)-4,5-bis(*p*-methoxyphenyl) imidazole (***9**b*, $R' = OCH_3$)*

This compound was prepared in a similar way as **9** from 4,4′-dimethoxy benzil (**8***b*) (2.7 g, 0.01 mol) and salicylaldehyde (**7**) (1.22 g, 0.01 mol) to yield 2.38 g (70%) of the title compound, mp 92–95°C; nmr (TFA): 3.90 (s, 6, $(OCH_3)_2$, 6.65–7.45 (m, 12, ArH), 3.16 sweep of set 500 Hz (m, 2, NH, OH). *Anal.* calcd. for $C_{23}H_{20}N_2O$: N 8.23; found: N 8.00.

*2,3-Bis(*p*-methoxyphenyl)-5*H*-imidazolo[1,2-*c*] [1,3]benzoxazine (***10***, $R' = OCH_3$)*

This compound was prepared by condensation of 2-(2′-hydroxyphenyl)-4,5-bis(*p*-methoxyphenyl) imidazole (**9***b*) (1.7 g, 0.005 mol) with methylene bromide, as in the method described above for **9***a* (R′ = H) to yield 1.23 g (70%) of the title compound, mp 80°C; nmr($CDCl_3$): 3.97 (s, 6, $(OCH_3)_2$), 5.80 (s, 2, H-5), 7.10–8.30 (m, 12, ArH). *Anal.* calcd. for $C_{24}H_{20}N_2O$: C 81.82, H 5.68, N 7.95; found: C 81.65, H 5.50, N 7.72.

*2-(2′-Hydroxyphenyl) benzimidazole (***13***)*

A mixture of phenyl salicylate (8.56 g, 0.04 mol) and *O*-

phenylenediamine (4.32 g, 0.04 mol) was heated at 180°C in an oil bath for 5 h; the reaction mixture was cooled and then dissolved in 10% sodium hydroxide solution. It was acidified with ice-cold acetic acid to give 6.0 g (71%) of the title compound, mp 240–241°C (lit. (18) mp 238°C); ir(KBr): 3430, 3320 (OH and NH) cm^{-1}.

7H-Benzimidazolo[1,2-c] [1,3]benzoxazine (14)

To a solution of 2-(2′-hydroxyphenyl) benzimidazole (4.2 g, 0.02 mol) in dry dimethylformamide (40 mL) in the presence of anhydrous potassium carbonate (5 g), methylene bromide (7 mL) was added and the reaction mixture was filtered and concentrated under vacuum. The residue was treated with chilled water to yield 3.1 g (70%) of the title compound, mp 151–153°C; nmr ($CDCl_3$): 6.00 (s, 2H, —CH_2), 7.10–8.17 (m, 8H, ArH); *m/e* (%) ms: 222(100), 221(100), 220(10), 194(83), 193(100), 169(53), 168(100), 167(67), 140(34), 113(100), 104(41), 103(50), 98(71), 93(35), 91(34), 85(41), 79(100).

Hétérocycles organiques de l'arsenic. Synthèse d'arsinimines hétérocycliques par la "réaction de Staudinger." Mécanisme de la réaction

PIERRE MARONI, YVES MADAULE, TULA SEMINARIO ET JEAN-GÉRARD WOLF

Laboratoire de Synthèse et Physicochimie Organique, Unité Associée au Centre National de la Recherche Scientifique n° 471, Université Paul Sabatier, 118, route de Narbonne, F 31062 Toulouse Cedex, France

Reçu le 24 février 1984

PIERRE MARONI, YVES MADAULE, TULA SEMINARIO et JEAN-GÉRARD WOLF. Can. J. Chem. **63**, 636 (1985).

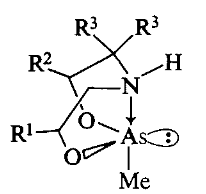
La réaction de Staudinger a été appliquée à des hétérocycles arséniés. L'action des azotures de picryle et de para-toluènesulfonyle sur une série d'arsatranes tétracoordinés conduit à des arsinimines originales pentacoordinées, avec maintien de la liaison atrane N → As. Ces arsinimines se dimérisent pour donner des diarsadiazacyclobutanes comportant des atomes d'arsenic hexacoordinés. La réactivité des arsanes est plus faible. Seul l'azoture de picryle donne lieu à réaction. Les arsinimines obtenues se dimérisent plus ou moins rapidement dans pratiquement tous les cas, sauf un où l'arsinimine reste sous forme monomère. L'étude de la réaction en ultraviolet permet de mettre en évidence un complexe intermédiaire, différent de celui de la réaction "classique" des homologues phosphorés.

PIERRE MARONI, YVES MADAULE, TULA SEMINARIO, and JEAN-GÉRARD WOLF. Can. J. Chem. **63**, 636 (1985).

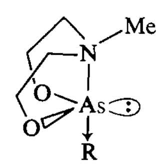
Staudinger's reaction is applied on arsenic heterocycles. Picryl and tosyl azides lead, by action on tetracoordinated arsatranes, to previously unknown pentacoordinated arsinimines with an "atran" bond (N → As). In a second step, they dimerize to diarsadiazacyclobutanes, bearing hexacoordinated arsenic atoms. Heterocyclic arsanes react only with picryl azide. All imines were obtained as dimers or oligomers, with the single exception of **8A**. Ultraviolet studies give evidence for an intermediate complex different from the one demonstrated in the "classical" Staudinger's reaction with phosphorus compounds.

La réaction de Staudinger, synthèse de phosphinimines par action d'azotures sur les phosphanes tertiaires, connue dès 1919 (1) a été depuis largement étendue (2). Cadogan et Gosney (3) ont été parmi les premiers à l'utiliser dans la chimie de l'arsenic, à partir d'arylazotures contenant des groupes attracteurs d'électrons. Cependant, les arsinimines sont obtenues le plus souvent par action d'arsanes sur des chloramines (4, 5) ou par condensation d'oxydes de triarylarsane avec des isocyanates et des N-sulfinylamides (6, 7).

Pour notre part nous avons appliqué la réaction de Staudinger à la synthèse d'arsinimines hétérocycliques originales, en faisant agir des azotures sur des hétérocycles organiques de l'arsenic appartenant à deux grandes séries: (*i*) des arsatranes, composés originaux stables de l'arsenic tétracoordiné synthétisés au laboratoire (8)

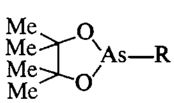


1 {R¹ = R² = Me; R³ = H}
2 {R¹ = Ph, R² = H; R³ = Me}

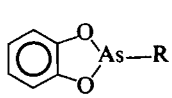


3 R = Me
4 R = Ph

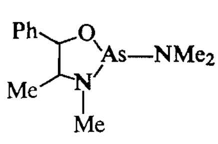
(*ii*) des arsanes tricoordinés dérivant du pinacol (**5**, **6**), du pyrocatéchol (**7**, **8**) et de la (−) éphédrine (**9**)



R = {Me **5**; Cl **6**}



R = {Me **7**; Cl **8**}

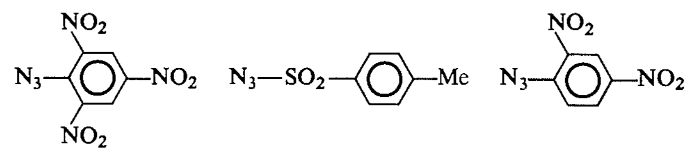


9

Ces hétérocycles possèdent sur l'arsenic une paire électronique libre. La disponibilité de ce doublet, déjà montrée sur les arsatranes (8), permet d'envisager une bonne réactivité vis à vis des azotures.

Pour obtenir ces nouvelles arsinimines hétérocycliques, pour lesquelles l'arsenic est relié à d'autres hétéroatomes (N, O) nous avons opéré par voie thermique et photochimique.

La gamme des azotures utilisables est relativement large. Nous en avons essayé six: d'abord



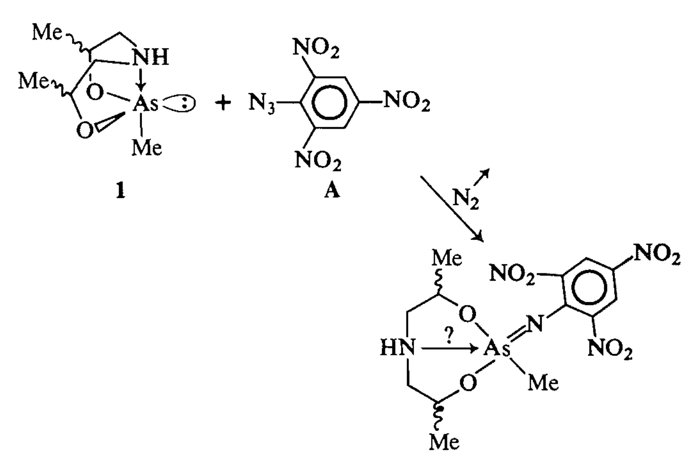
A **B** **C**

tous porteurs de groupements attracteurs et qui se sont révélés au moins partiellement réactifs sur tous les composés arséniés; puis N_3COPh, N_3Ph et N_3SiMe_3 qui n'ont pas réagi.

I. Action des azotures sur les arsatranes

A. *Résultats*

La réaction entre les composés **1** et **A** est un bon modèle: elle pourra conduire à l'arsinimine **1A**, possédant ou non une structure atrane.

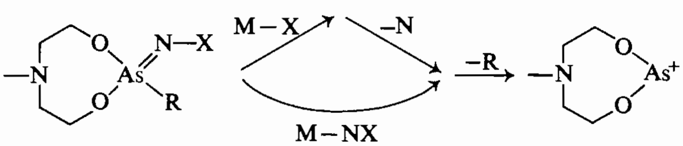


1A

Dans tous les cas, les composés obtenus à partir de **C** sont très instables et n'ont pu être étudiés de manière satisfaisante. Par contre, les réactions ont lieu dès la température ordinaire à partir de **A** et **B**. La vitesse de la réaction est fortement augmentée par voie photochimique mais les résultats et les rendements sont les mêmes que pour la voie thermique. Les composés obtenus à partir de **A** et **B** se décomposent très rapidement une fois isolés, et ont été étudiés principalement en solution. Leur structure a été déterminée par spectrométrie de masse, infrarouge et rmn.

1. *Spectrométrie de masse*

Nous avons entièrement dépouillé les spectres de masse de quatre composés, qui présentent tous des modes de rupture comparables:



Pour **1B**, **3A**, **3B** et **4A**, respectivement: pic moléculaire faible (1 à 3%) (m/z = 390, 433, 376, 495), M − X (235, 221, 221, 283), M − NX (221, 209, 207, 269) de l'ordre de 70% et l'ion arsénium M − NX − R (206, 192, 192, 192). On relève ensuite pour **1B** deux pics à m/z = 178 (100%) et 149 (60%) qui correspondent vraisemblablement à la rupture du cycle arsénium et la perte succesive de CHMe et $NHCH_2$. Pour **3A**, **3B** et **4A**, le fragment à m/z = 177 (50%) est dû à la perte par l'ion arsénium du substituant méthyle de l'azote cyclique. Le pic de base à 147 pour ces 3 composés correspond à la rupture du cycle et la perte supplémentaire de OCH_2.

2. *Infrarouge*

L'infrarouge montre la disparition progressive de la bande ν_{N_3} de l'azoture (2120 et 2110 cm^{-1} respectivement pour **A** et **B**), et l'apparition d'une bande dans la région des $\nu_{As{=}N}$ que nous avons comparée à la vibration correspondante du composé $Ph_3As{=}N{-}SO_2$Me (1250 cm^{-1} d'après la référence 3) (tableau 1). La valeur de ces fréquences pour les composés obtenus à partir de l'azoture de paratoluènesulfonyle **B** est bien en concordance avec celle du composé de référence (1250 cm^{-1}). Les dérivés de l'azoture de picryle **A** présentent un déplacement de 30 à 40 cm^{-1} attribuable à l'effet des groupes NO_2. En outre, les spectres infrarouge d'une solution enregistrés à intervalles régulier et pendant 24 h après la fin de la synthèse montrent un phénomène supplémentaire: la bande As=N disparaît progressivement, alors qu'apparaît une nouvelle vibration vers les fréquences plus basses, dans la région des $\nu_{As{-}N}$, par exemple pour les composés **3A** (1290 → 1010 cm^{-1}) et **3B** (1250 → 1130 cm^{-1}).

3. *Résonance magnétique nucléaire*

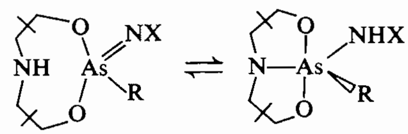
La rmn ^1H (60 et 90 MHz) confirme la formule brute des composés. En outre, elle permet de suivre une évolution identique à celle révélée par l'infrarouge: on observe, dès la fin de la synthèse, la présence de deux entités, (m) et (d), dans des proportions relatives 40−60% (tableau 2), qui présentent les mêmes types de signaux. Ceux attribués à (m) disparaissent en 24 h en même temps que la bande As=N en infrarouge.

B. *Interprétation*

La disparition de la vibration $\nu_{As{=}N}$ et l'apparition d'une bande $\nu_{As{-}N}$ peuvent être dues pour **1A**, **1B**, **2A** et **2B** à une tautomérie prototropique donnant un arsorane

TABLEAU 1. Fréquences des vibrations $\nu_{As{=}N}$ (cm^{-1}), solutions $M/20$ dans CCl_4

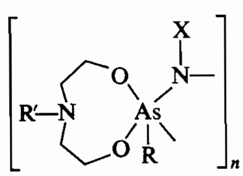
		Arsatrane			
	Azoture	1	2	3	4
A		1280	1290	1290	1285
B		1255	1260	1250	1250



Mais ce type de passage à la pentacoordination, connu à partir des phosphinimines comportant un groupe à hydrogène mobile (NH ou OH) (9, 10), n'a jamais pu être mis en évidence dans le cas de composés arséniés.[1]

Dans notre cas, la présence initiale dans tous les composés d'une bande As=N infirme la structure arsorane pour (m). La transformation (m) → (d) qui s'accompagne de l'apparition d'une bande dans la région des $\nu_{As{-}N}$ et de la disparition de la vibration $\nu_{As{=}N}$ ne conduit pas non plus à l'arsorane à groupement NH: le phénomène est identique quel que soit le substituant sur l'azote du cycle (H ou Me). Pour tous les composés, l'apparition de (d) pourrait correspondre à une dimérisation (ou une oligomérisation) des formes arsinimines, souvent observée pour les phosphinimines (11).

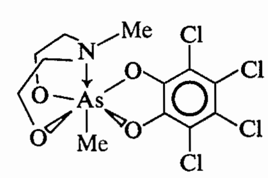
Cette hypothèse est étayée par une cryométrie dans le benzène qui montre, au bout de 24 h, que l'on est en présence du dimère, la bonne résolution des spectres rmn permettant d'autre part d'exclure la présence en proportions notables d'oligomères de rang supérieur. On peut donc considérer que (m) et (d) correspondent à la structure globale:



n = 1 (m)
n = 2 (d)

L'atome d'azote du cycle à huit chaînons se trouvant en position 5 on peut envisager qu'il va former une liaison "atrane" avec l'atome d'arsenic.

Pour démontrer cette structure atrane éventuelle, nous avons comparé les composés **3A** et **3B** avec l'atrane tétracoordiné **3** et l'atrane hexacoordiné **3**^{VI}, préparés antérieurement au laboratoire. La structure de **3**^{VI} a été déterminée par RX (8a).



3^{VI}

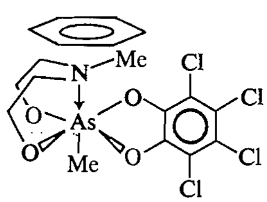
*Entité (d). Les valeurs de Δδ de (m) sont identiques à 0,02 près.

Nous avons rapporté les résultats de rmn dans les tableaux 3 à 5: déplacement chimique des protons de cycle, comparés à ceux de la N-méthyl-morpholine (tableau 3); effet de solvant (tableau 4); déplacements chimiques des carbones (tableau 5). On observe dans tous les cas un comportement de **3A** et **3B** intermédiaire entre celui des arsatranes tétra- et hexacoordinés. Les tableaux 3 et 4 montrent de plus une forte similitude au niveau du cycle entre les entités (m) et (d). D'autres remarques sont en faveur de la structure atrane: (*i*) les protons du cycle sont nettement déblindés par rapport à la N-méthylmorpholine; (*ii*) le fort effet de solvant aromatique (effet ASIS), comparable pour (m) et (d) lorsque l'on passe de $CDCl_3$ à C_6D_6 ne peut s'expliquer que si ces deux composés ont des structures et donc des sites de complexation identiques, qui pourraient être proches de celui trouvé pour $\mathbf{3}^{VI}$ (8); (*iii*) en rmn ^{13}C, l'écart entre



les signaux N—CH_2 et OCH_2, de l'ordre de 4 ppm pour **3A** et **3B** est plus faible que pour la morpholine (21 ppm), la N-éthyl morpholine (14,4 ppm) et le tris-morpholino-arsane (20,3 ppm) (12) (dans ce dernier composé l'azote est directement lié à l'arsenic par une liaison covalente). Cette diminution est en particulier dûe au déblindage de N—CH_2. Elle peut s'expliquer par un affaiblissement de la densité électronique sur l'azote compatible avec la présence d'une liaison de coordination N → As.

Les observations sont identiques pour les autres composés, bien que les spectres rmn soient généralement plus complexes et que les vibrations caractéristiques ν_{SO_2} ne permettent pas d'attribuer la bande $\nu_{As—N}$ en infrarouge pour **1B**, **2B** et **4B**.

Le phénomène de dimérisation, observé pour **3A** et **3B** semble cependant général: la cryométrie des composés indique dans tous les cas la présence de dimères; l'infrarouge montre la disparition progressive de la bande $\nu_{As=N}$ et l'apparition d'une vibration $\nu_{As—N}$; les spectres rmn ^1H révèlent dans la plupart des cas la présence initiale de deux entités qui évoluent au cours du temps.

Les modifications les plus caractéristiques se situent au niveau des signaux: AsMe pour **1B** et **2B** (deux pics vers 1,80 et 1,90 ppm; $CDCl_3$) et SO_2—⟨◯⟩—Me pour **1B**, **2B** et **4B** (deux pics méthyle vers 2,40, $CDCl_3$) et superposition de deux systèmes phényle *para* disubstitués vers 7,50 ppm ($CDCl_3$).

Pour les composés obtenus à partir de l'azoture de picryle, nous avons observé particulièrement la position des protons du cycle picryle: les spectres rmn ^1H du composé **3A** montrent en effet que la transformation monomère−dimère se traduit par un net déblindage de ces protons (de 8,40 à 9,33 ppm dans $CDCl_3$, de 8,35 à 8,77 ppm dans C_6D_6).

Les spectres de **4A** présentent deux pics à 8,47 et 9,26 ppm ($CDCl_3$) le premier disparaissant au bout de 30 h. Nous n'avons pas relevé le pic aux champs forts pour **1A** et **2A**, mais un seul signal (à respectivement 9,31 et 9,21 ppm; $CDCl_3$) qui correspond à l'apparition rapide du dimère. Le maintien de la structure atrane des monomères et des dimères est corroboré par un fort effet ASIS, comparable à celui relevé pour **3A** et **3B**. On peut donc conclure que l'action d'azotures sur les arsatranes conduit dans une première étape à des arsinimines pentacoordinées possédant une structure atrane, et ne donnant pas lieu à la tautomérie prototropique. Ces arsinimines se dupliquent ensuite pour conduire à un dimère possédant deux atomes d'arsenic hexacoordiné de structure atrane.

II. Synthèse d'arsinimines à partir d'arsanes

Pour connaître l'influence de la structure atrane sur le phénomène de dimérisation observé, nous avons tenté d'effectuer la synthèse d'arsinimines à partir de modèles plus simples, les arsanes **5** à **9** et des azotures de picryle **A** et de tosyle **B**, qui se sont révélés les plus réactifs sur les arsatranes.

On observe des différences notables: (*i*) l'azoture de tosyle **B** ne conduit ni à l'arsinimine ni au dimère: il se décompose sans réagir avec **5** et **8** et n'est pas modifié par action sur **6**, **7** et **9**; (*ii*) la réactivité de l'azoture de picryle **A** est moins importante que celle observée à partir des arsatranes. Alors que la réaction sur ces derniers composés se fait à la température ambiante, elle nécessite dans tous les cas un long chauffage à reflux. D'une manière générale, les rendements observés sont plus faibles et les réactions parfois incomplètes (persistance d'azoture).

Enfin, la synthèse par voie photochimique ne donne pas lieu à réaction ou conduit à des résultats non exploitables (formation de goudrons).

Pour interpréter les résultats, nous nous sommes intéressés au déplacement chimique des protons du cycle picryle dont le blindage ou déblindage relatifs indique la présence de monomère ou de dimère.

La position de ces protons révèle la formation directe du dimère à partir de **5** (9,38 ppm) et **6** (9,40 ppm) bien que les vibrations caractéristiques du cycle pinacolique ne permettent de distinguer que la bande $\nu_{As—N}$ de **6A** (1165 cm^{-1}; CCl_4). Inversement, le blindage des protons picryle (8,15 ppm) et la présence d'une bande $\nu_{As=N}$ à 1230 cm^{-1} indiquent que **8A** est une arsinimine monomère stable, la seule obtenue. Notons que la valeur de la fréquence infrarouge est différente de celle des As=N picryle relevée pour les arsatranes (~1280 cm^{-1}).

Nous avons constaté que, si l'azoture **A** se décompose en présence de **7**, la réaction ne conduit pas au monomère ou au dimère.

Les spectres rmn ^1H du composé **9A** enregistrés dans un mélange C_7D_8 − DMSO-d_6 car peu soluble dans $CDCl_3$, montrent la transformation progressive du monomère (8,36 ppm) en dimère (8,83 ppm) (à comparer avec le déplacement de 8,35 à 8,77 ppm observée pour **3A** dans C_6D_6).

Nous constatons donc que, dans la plupart des cas, la dimérisation est prépondérante.

Si l'on considère les différences observées entre les atranes et les arsanes tricoordinés (réactivité plus faible de ces derniers, pas de réaction par voie photochimique), on peut penser qu'elles sont dues à l'originalité de l'environnement de l'arsenic dans les arsatranes par rapport aux arsanes rendant le doublet plus réactif:

III. Synthèse des arsinimines: mise en évidence d'un intermédiaire de réaction

Nous pouvons formuler deux hypothèses quant au comportement de l'azoture vis à vis du composé arsénié.

1. *La formation préalable de nitrène*

$$X—N_3 \longrightarrow X—N\!: + N_2\uparrow$$

qui s'additionnerait sur l'atome d'arsenic.

La synthèse d'arsinimines par photochimie n'a pas été réalisée avant nous. Horner et Christmann (13) ont cependant synthétisé par cette voie des sulfonylimines, ce qui peut laisser supposer que l'irradiation des azotures engendre des nitrènes. Cadogan et Gosney (3) effectuent la synthèse d'arsinimines à haute température, ou font intervenir un catalyseur: ils considèrent l'attaque sous forme de nitrène, le catalyseur abaissant la température de décomposition de l'azoture.

Nous ne pouvons passer sous silence cette hypothèse, au vu des synthèses sous irradiation. Nous pouvons cependant l'écarter dès maintenant, pour deux raisons. Les synthèses par voie thermique ont lieu à la température ordinaire pour les atranes. Et surtout (*vide infra*) nous avons mis en évidence un intermédiaire réactionnel.

2. *Une addition de l'azoture sous forme non décomposée* sur l'atome d'arsenic, comme cela a déjà été montré dans le cas de l'action des azotures aromatiques sur la triphénylphosphine (14) (intermédiaire dit de Staudinger):

$$Ph_3P + ArN_3 \longrightarrow Ph_3P=N—N=N—Ar \xrightarrow{-N_2\uparrow} Ph_3P=N—Ar$$

Goldwhite *et al.* ont isolé un intermédiaire de ce type lors de la réaction entre l'azoture de phényle et $(Me_2N)_3P$ (15). Ils présentent un arrangement linéaire:

$$(Me_2N)_3P=N—N=N—Ph$$

Généralement instable, cet intermédiaire conduit aux phosphinimines par libération d'une mole d'azote, suivant un processus décrit par Leffler et Temple (16), mettant en jeu deux états de transition équiénergétiques. Le phosphore se charge

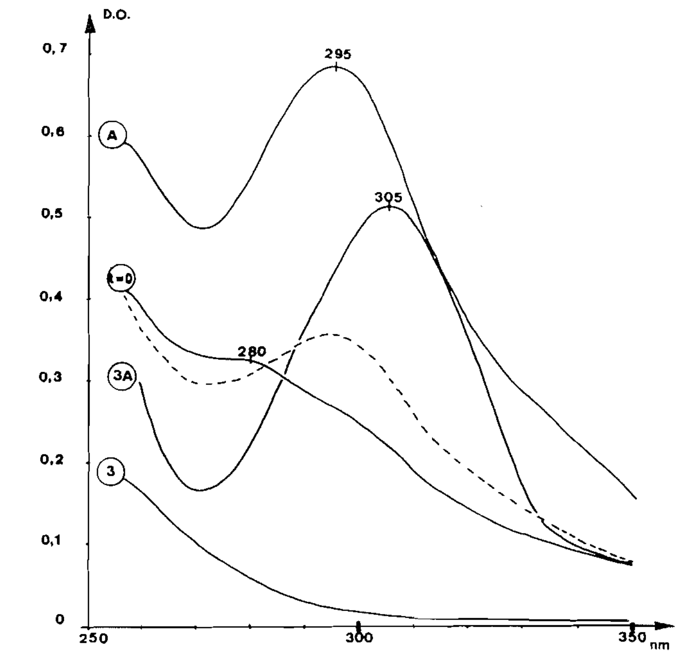

FIG. 1. Spectres ultraviolet (CCl_4). **A** et **3**: produits de départ ($0{,}66 \times 10^{-4}$ *M*); $t = 0$: spectre initial du mélange **A** + **3** $\left(\text{en pointillé } \sum \frac{DO}{2}\right)$; **3A**: spectre du produit final isolé ($0{,}66 \times 10^{-4}$ *M*).

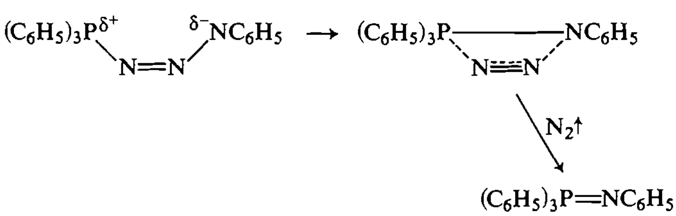
positivement, l'azote en γ négativement, la neutralisation de ces charges conduisant à la formation d'une liaison



Nous avons suivi par ultraviolet l'action de l'azoture de picryle **A** sur **3** et **5** en mélangeant les réactifs à 10^{-2} *M* et en enregistrant les spectres de prélèvements successifs dilués à $0{,}66 \times 10^{-4}$ *M* (fig. 1). Le spectre initial ($t = 0$) est différent de la somme des densités optiques des composés de départ (en pointillé) et révèle la présence d'une entité possédant un maximum d'absorption vers 280 nm pour **3** + **A** et 285 nm pour **5** + **A**. Le spectre évolue ensuite progressivement pour aboutir au produit final (λ_{max} = 305 nm, ϵ = 7800 pour **3A** et **5A**).

Ces résultats montrent l'apparition, comme dans le cas du phosphore d'un intermédiaire réactionnel. La comparaison des bandes d'absorption uv de l'azoture (λ_1 = 295 nm; ϵ = 10 300 pour **A**), de l'intermédiaire réactionnel (λ_i) et de l'imine (λ_2) pour les deux composés étudiés avec les résultats rapportés par Goldwhite dans la chimie du phosphore (15) (intermédiaire réactionnel isolé) montre que, dans les trois cas, $\lambda_2 - \lambda_1$ est de l'ordre de 10 nm. Mais, alors que dans le cas du phosphore, l'intermédiaire réactionnel est déplacé vers les grandes longueurs d'ondes (+51 nm par rapport à l'azoture initial) on observe un phénomène inverse pour **3A** et **5A** (respectivement −15 et −10 nm) (fig. 2).

Un intermédiaire de type Staudinger (I.S.) possédant un

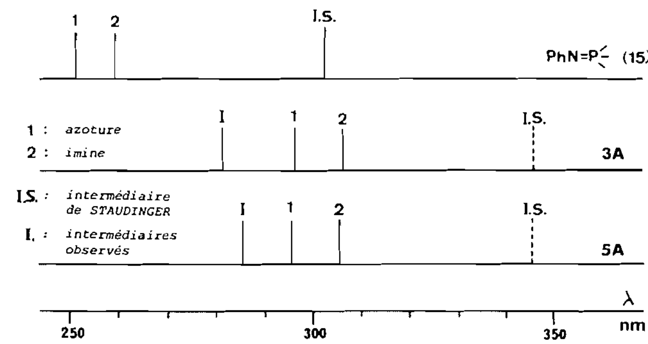


FIG. 2. Spectres ultraviolet de **3A** et **5A**, comparaison avec le phosphore.

enchaînement linéaire $>As{=}N{-}N{=}N{-}X$ aurait présenté une bande vers 345 nm (en pointillé sur la fig. 2) par extension de la conjugaison du cycle picryle. Nous avons donc été conduits à envisager un complexe par transfert de charge As^{IV} — azoture.

A l'appui de cette hypothèse, nous avons noté pour **3A** que les spectres infrarouge enregistrés en cours de synthèse présentent une bande à 1320 cm^{-1}, absente des spectres des réactifs et du produit final, qui pourrait correspondre au complexe.

En outre, en isolant au cours du temps des fractions du mélange réactionnel et en les concentrant par évaporation, nous n'observons en infrarouge et en rmn que les produits initiaux et le produit final: on aurait brisé le complexe qui se trouvait en équilibre avec les composés de départ.

A partir des atranes, cet intermédiaire serait le même par voie "thermique" et par voie "photochimique", l'utilisation des deux méthodes conduisant au même produit final, avec le même rendement. La grande différence de vitesse observée (la voie photochimique est environ dix fois plus rapide dans nos conditions expérimentales) pourrait être due à l'accélération de la destruction du complexe par photolyse.

En résumé, il semble raisonnable d'admettre, pour les réaction entre nos composés et les azotures **A** et **B**, un mécanisme réactionnel en deux étapes: la première comportant, comme dans le cas du phosphore, un intermédiaire réactionnel, mais de nature différente, la second conduisant à l'arsinimine par départ d'azote.

IV. Conclusion

Les travaux réalisés au cours de ce mémoire nous ont permis de faire les constatations qui suivent.

1. La gamme des azotures réactifs pour l'arsenic est plus restreinte que pour les dérivés phosphorés (11). La réactivité des arsatranes est cependant très supérieure à celle des arsanes.

2. Nous n'avons jamais observé de tautomérie $As^{IV} \rightleftharpoons As^{V}$ conduisant à un arsorane homologue des dérivés phosphorés (9, 10) lorsqu'elle est théoriquement envisageable (atranes à groupement NH: **1A**, **1B**, **2A** et **2B**). La structure atrane s'est toujours révélée la plus stable.

3. Les phosphinimines peuvent soit exister sous la forme monomère, soit donner par dimérisation, un cycle diazadiphosphacyclobutane (17). Nous n'avons obtenu une forme monomère stable que dans un seul cas (**8A**). Pour le reste, on obtient la forme dimère, soit directement sans observer le monomère, soit par transformation progressive du monomère en dimère.

Une explication de cette prépondérance à la dimérisation est possible à partir des résultats infrarouge. Nous avons noté une grande dispersion dans la position des $\nu_{As=N}$ et ν_{As-N}, qui doit traduire une variation du caractère π de ces liaisons, comme cela a été noté pour la liaison P=N des phosphinimines (18).

Il est connu par ailleurs que, si l'azote est plan dans les aminophosphanes, il est pyramidal pour $>$As—N$<$ (19) ce qui indique que la liaison As—N est moins proche d'une double liaison que P—N.

Enfin, l'écart entre les $\nu_{M=N}$ et ν_{M-N} est de l'ordre de 250 cm^{-1} pour nos composés (M = As) alors qu'il est de 600 cm^{-1} lorsque M = P (20).

Ces observations dénotent un faible caractère π de la liaison As=N, et donc une plus grande polarité $As^{+}—N^{-}$. Or, on sait que la frontière dimère $(P)^{V} \leftrightarrow$ monomère $(P)^{IV}$ est très sensible à la polarisation de la liaison P=N (11), dont l'accentuation favorise la dimérisation.

Partie expérimentale

I. *Synthèse*

Les réactifs

Les azotures peuvent se décomposer par action de la lumière, et ont été utilisés fraîchement préparés, selon la référence 21 pour **A** (ν_{N_3} = 2120 cm^{-1}, CCl_4; rmn ^1H: singulet à 8,90 ppm, $CDCl_3$, 60 MHz) et la référence 22 pour **B** (ν_{N_3} = 2110 cm^{-1}, CCl_4; rmn ^1H: singulet à 2,33 ppm, quadruplet autour de 7,50 ppm, $CDCl_3$, 60 MHz).

Les arsatranes **1** à **4** ont été préparés suivant la référence 8, ainsi que les arsanes **5** (δ_{AsMe} = 1,04 ppm, δ_{Me_2C} = 1,17 ppm, C_6D_6, 60 MHz) et **7** (δ_{AsMe} = 0,78 ppm, C_6D_6; 1,30 ppm, CCl_4, 60 MHz).

Les autres arsanes ont été préparés selon les références 23, 24 et 25 pour **6**, **8** et **9** respectivement.

Les arsinimines. Voie thermique

Synthèse de **3A**

On dissout dans 200 cm^3 de solvant (CCl_4 ou C_6H_6) 2,07 g (0,01 mol) de l'atrane **3** et 2,54 g (0,01 mol) de l'azoture de picryle (**A**). On agite pendant 6 h à la température ambiante. On mesure le rendement par le dégagement d'azote (90%).

La même procédure est utilisée pour tous les arsatranes, le temps de réaction variant de 6 à 8 h. Les rendements varient de 70% (**2A** et **3B**) à 85% (**1A**, **1B**, **2B**) (légèrement supérieurs dans C_6H_6). Les composés sont isolés par évaporation du solvant, mais se dégradent rapidement même conservés sous azote sec.

Les mesures physicochimiques sont effectués sur des échantillons préparés "*in situ*", la fin de la synthèse étant indiquée par la disparition de la bande azoture en infrarouge.

Synthèse de **5A**

On place 2,06 g (0,01 mol) de **5** dilués dans 100 cm^3 de toluène dans un erlenmeyer à deux voies; 2,54 g (0,01 mol) d'azoture dissous dans 100 cm^3 du même solvant sont introduits goutte à goutte. On chauffe à reflux du solvant pendant 3 h. Le composé est isolé par distillation du toluène sous vide, et recristallisé dans le minimum de benzène. Le rendement massique est de 80%.

A partir des autres arsanes, le temps de chauffage varie entre 3 et 12 h. Les rendements massiques sont compris entre 50% (**9A**) et 80% (**5A**).

Voie photochimique

Les réactifs dissous en quantités stoechiométriques (0,02 mol) dans 250 cm^3 de solvant (CCl_4 ou C_6H_6) sont placés dans un réacteur en quartz équipé d'une lampe Hanovia 450 W. La réaction a lieu en moins de 40 min. Les rendements à partir des arsatranes sont identiques à ceux observés par voie chimique.

Analyse élémentaire

Elle n'a pu être effectuée que pour les produits **5A** à **9A**. Les autres composés ne sont en effet stables qu'en solution.

	Calc.			Tr.

II. *Physicochimie*

Cryométrie: elles ont été réalisées "*in situ*" à l'aide d'un cryostat différentiel réalisé au laboratoire (1 cm^3 de benzène pour 40 mg de soluté environ). Les réactifs (arsatrane et azoture) sont dissous en quantité stoechiométrique dans C_6H_6. L'évolution du mélange réactionnel est suivie régulièrement.

Les mesures physicochimiques sont effectuées sur les appareils suivants: spectrographe de masse Riber QSM à 70 eV; spectrographe de masse Varian MAT; spectromètres Varian T 60, Perkin Elmer R 32 (90 MHz) pour la rmn ^1H; spectromètre rmn ^{13}C WP 60 Bruker 15,08 MHz; spectromètre ir: Beckman IR 20 – IR 9; spectromètre uv Cary 15.

A survey of DPASV signals for Cu in a variety of media and under varying conditions has been undertaken. It is possible to identify the circumstances associated with two distinct problems in Cu determination which have not been clearly distinguished in earlier literature. The role of Cl^- in influencing the Hg wave form (which in turn affects the relative apparent peak heights and widths of the two Cu signals arising from Cu(Hg) amalgam and undissolved Cu(solid)) is distinguished from the role of Cl^- as a complexing agent in solution at higher Cl^- concentration. Effects of dissolved organic matter in natural waters are shown to resemble Cl^- effects. Data are also presented on two related matters: (*1*) some factors in a natural water sample that confuse the use of DPASV as a tool for Cu species identification, and (*2*) the effects of high Cl^- concentration on Cd, Pb, and Cu signals.

Following the study of medium effects and interferences influencing DPASV signals, a fresh water sample has been examined at the conventional hanging Hg drop electrode, thin Hg films on graphite and Hg thin films on a novel reticulated vitreous carbon flow-through electrode. Hg thin film electrodes deposited *in situ* are confirmed to be very sensitive for analysis of river water samples. The flow-through electrode has excellent sensitivity. Promising storage characteristics of the flow-through electrode are evaluated with a view to suggesting an ASV system using a simple electronic unit for field sampling.

IBRAHIM K. ALZAND et COOPER H. LANGFORD. Can. J. Chem. **63**, 643 (1985).

On a entrepris un relevé des signaux DPASV du cuivre dans divers solvants et sous des conditions variées. Il est possible d'identifier deux problèmes distincts associés à la détermination du Cu qui n'avaient pas été relevés antérieurement. On établit une distinction entre le rôle du Cl^- lorsqu'il influence la forme de la vague du Hg (qui affect à son tour les hauteurs et les largeurs relatives apparentes des pics des deux signaux provenant de l'amalgame Cu(Hg) et du Cu(solide) qui n'est pas dissous) et le rôle du chlore agissant comme agent complexant dans des solutions contenant des concentrations plus élevées de Cl^-. On démontre que les effets des matières organiques dissoutes dans les eaux naturelles ressemblent à ceux des ions Cl^-. On présente aussi des données relatives à deux sujets apparentés: (*1*) quelques facteurs dans un échantillon d'eau naturelle qui provoque de la confusion lors de l'utilisation du DPASV comme méthode d'identification des espèces Cu et (*2*) les effets de concentrations élevées en Cl^- sur les signaux du Cd, Pb et Cu.

A la suite de l'étude sur les effets du milieu et sur les facteurs influençant les signaux DPASV, on a examiné un échantillon d'eau fraîche à l'aide d'une électrode conventionnelle à goutte de mercure tombante, de films fins de Hg sur du graphite et de films fins de Hg sur une nouvelle électrode poreuse de carbone vitreux réticulé. On a confirmé que les électrodes utilisant des films fins de Hg déposés *in situ* sont très sensibles pour l'analyse d'échantillons d'eau de rivières. La sensibilité de l'électrode poreuse est excellente. Dans le but de suggérer un système ASV qui utiliserait une unité électronique pour des études dans le champ, on a évalué des caractéristiques de storage prometteuses de l'électrode poreuse.

[Traduit par le journal]

Introduction

This report was motivated by the effort to develop a flow-through electrode using reticulated vitreous carbon. The purpose is to evaluate its possible usefulness in a field sampling device which would allow a simple electronic unit to be exploited in the field with the sample returned to the laboratory for anodic stripping. However, the evaluation of this electrode requires first examination of the electrode in comparison to various electrodes used in anodic stripping voltammetry (ASV). This has led us to explore some of the problems shared by all these electrodes. The work emphasizes the effects that occur in the mercury film and at the interface, and some observations on the use of ASV data for "speciation" studies in natural water systems. The report is organized around studies of Cu^{2+}.

A number of papers have discussed the application of DPASV to the differentiation of various trace metal species in natural water samples (1–4). The idea is sufficiently accepted that it has appeared in a review for the reader of general chemistry (5). The basis is to associate changes in peak position, peak multiplicities, and peak widths with changing speciation in the natural water. Unfortunately, these parameters are also influenced by speciation in the Hg phase of the electrode, the electrochemistry of Hg at the electrode, and interfacial phenomena. The presence of Cl^- causes problems in the determination of Cu by anodic stripping voltammetry (6–8). This has not yet been completely elucidated. Two different factors have been established; copper complexing by Cl^- (7) and the limited solubility of Cu in Hg (8). It is important to resolve any ambiguities because the widespread use of ASV to study speciation (3) requires that effects due to speciation in the Hg phase be distinguished from effects due to speciation in the aqueous sample. There is a third problem as well. Cl^- alters the Hg wave in such a way that the peak heights and widths for nearby Cu peaks are affected (Hg_2Cl_2).

In Part A of this paper the chloride interference is studied in depth. Part B deals with the effects of natural water organic matter. They are shown to be very similar to Cl^- effects. The final goal of this study is the characterization of a flow through electrode for differential pulse anodic stripping voltammetry (DPASV) of natural waters which might be used in an electron-

ically simple field device to collect samples which could be analyzed later in the laboratory.

Experimental

Apparatus

Differential pulse anodic stripping voltammetry (DPASV) was carried out in a conventional manner using a PAR 264 Polarographic Analyzer equipped with a standard PAR cell for three electrodes and an N_2 purge. Instrumental parameters were a 5 mV s^{-1} scan rate, and a 50 mV modulation amplitude. Most commonly, deposition was carried out at -1.00 (vs. sce) with a deposition time of 5 min. Specific conditions are mentioned below. The reference electrode was sce connected to the cell via a salt bridge filled with either 1 *M* KNO_3 or 0.5 *M* $NaNO_3$ and terminated at a vycor frit sealed into a length of heat shrinkable Teflon tubing. The counter electrode was a Pt wire coil. pH was measured with an Orion model 701A digital analyzer.

Four types of electrodes were employed: (*i*) a hanging mercury drop (HMDE, PAR model 9323), (*ii*) a mercury thin film electrode with *in situ* mercury deposition (MTFE *in situ*), (*iii*) a MTFE predeposited (MTFE *predep.*), and (*iv*) a mercury-coated reticulated vitreous carbon flow-through electrode (MCRVCE). The films were deposited on a wax-impregnated graphite electrode supplied by PAR instruments (Model 9319). This electrode had a diameter of 0.625 cm. The end was polished and the remainder of the lower half of the rod was covered with a tight-fitting Teflon tube pressed on from the polished end. The electrode was polished before each use with fine emery paper washed with ethanol and wiped with lens tissue.

The reticulated vitreous carbon electrode was fabricated from 100 pore per inch RVS (Chemtronics International Inc., Ann Arbor, MI). The configuration is shown in Fig. 1. The electrochemical cell consisted of two sections connected by polyethylene tubing to allow easy replacement and storage of the RVC electrodes. The upper section, constructed from a Pyrex tube 7 mm id housed the reference electrode salt bridge and the Pt counter electrode. The lower Pyrex section was 1 mm id at the upper end and 2 mm id at the lower, and housed the 7 mm by 5 mm RVC disc. Electrical contact was made by a Pt wire sealed from the outside by epoxy glue. The sce was connected to the cell via a 1 *M* $NaNO_3$ salt bridge.

A peristaltic pump (Markson Scientific) was placed downstream from the cell to pull solution through the RVC electrode and recirculate it to a sample reservoir which was deoxygenated with purified N_2. Acetate buffer (100 mL of 0.012 *M*) containing 1 mL of 0.01 *M* Hg^{2+} was introduced into the reservoir.

Materials

Mercury was triply distilled and was transferred only with a clean dry siliconized capillary. Hydrochloric acid and nitric acid were Ultrex grade (J. T. Baker). KCl, KNO_3, and sodium acetate were reagent grade. All solutions were prepared from water purified from "tap" distilled water by passing through a high efficiency mixed bed ion exchanger followed by distillation from alkaline permanganate in all glass apparatus. Solutions were stored in preleached linear polyethylene bottles. The Hg(II) plating solution was prepared by dissolution of triply distilled Hg in a minimum amount of Ultrex HNO_3 and dilution with distilled water to give a 0.010 *M* $Hg(NO_3)_2$ stock solution. Stock standard solutions of metals were prepared by dissolution of 1 g of pure metal (99.9%, previously cleaned with acid and dried) in a minimum amount of 8 *M* Ultrex HNO_3 followed by dilution with 1% v/v HNO_3 to 1000 μg mL^{-1}. More dilute secondary stock solutions were prepared by diluting these solutions just prior to use. N_2 gas was scrubbed of residual O_2 by passage through a gas washing bottle containing V(II) and a second containing the supporting electrolyte of the experiment in question.

Procedure

Part A: Small aliquots of solutions were transferred to the cell using Eppendorf 500−100 and 20−200 μL pipettes with disposable tips. Initial deaeration was by N_2 purging for 10 min. During the deposition period the solution was stirred with a magnetic stirrer and a slow N_2

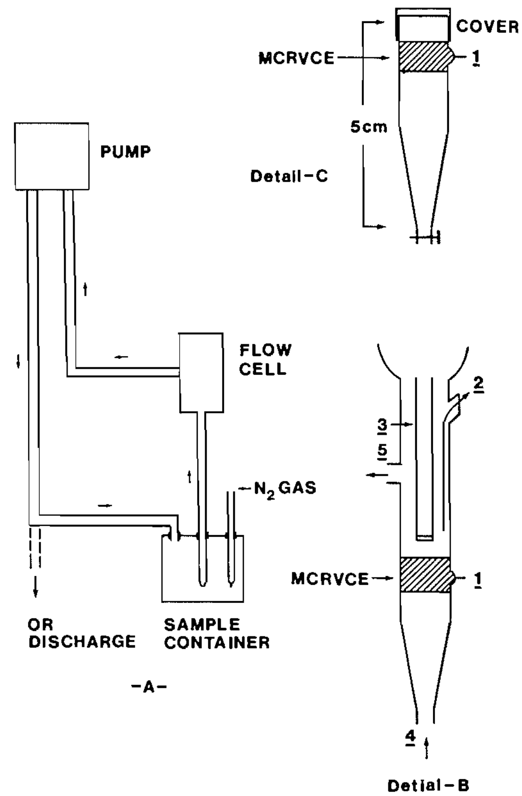

FIG. 1. The flow-through MCRCVE system. Parts are (*1*) the RCVE, (*2*) the counter electrode, (*3*) the reference electrode chamber, (*4*) the input from the reservoir, (*5*) the output to the peristaltic pump. The arrows indicate flow direction.

flow passed over the solution during deposition and stripping. All glassware was leached with 5 *M* HNO_3 between uses.

Part B: To coat the MCRVCE the Hg film was deposited by holding the potential at -0.8 V and passing the deaerated mercury solution through the electrode at 4.8 mL min^{-1} for 20 min. After plating, the flow was stopped and the reservoir was replaced with a blank solution. Holding the MCRVCE at $+0.05$ V for 10 min followed by 2 min at -1.0 V and stripping anodically to 0.0 V removed any co-deposited contaminants. Finally, the sample solution was buffered and placed in the reservoir. During dearation, the MCRVCE was held at 0.0 V. As with the previous experiments (Part A) deposition of Cd, Pb, and Cu was at -1.0 V and DPASV was preformed with a 5 mV s^{-1} scan rate and a 50 mV modulation amplitude. The scan was stopped at 0.0 V and the electrode was held for 1 min at this potential after which it was ready for the next determination.

For the storage experiments, the stability during storage of the MCRVCE's was evaluated by first rinsing the electrode with circulating deareated blank immediately after plating. During this flow, potential was held at -1.0 V. The unit containing the MCRVCE and 2 mL of blank was closed and stored for a period of up to 96 h.

The natural water samples used in the analyses were collected from the Rideau River adjoining the Carleton University Campus at an Environment Canada gauging station.

The collection containers were high density polyethylene bottles which had been leached with 3 *M* HNO_3 for at least 2 weeks and then rinsed with doubly distilled water followed by river water. River water was allowed to stand in the bottle for 1/2 h before a fresh sample was collected. Samples were filtered through acid washed millipore 0.45 μm membrane filters. Analyses were normally completed on the same day.

Procedure for "uv digestion" involved addition of 50 μL of 80% H_2O_2 to a 25 mL aliquot of sample which had been acidified to pH = 2 with 2 *M* Ultrex HNO_3. The irradiation was carried out with a 1 kW medium pressure mercury vapour lamp for 4 h with stirring. A final

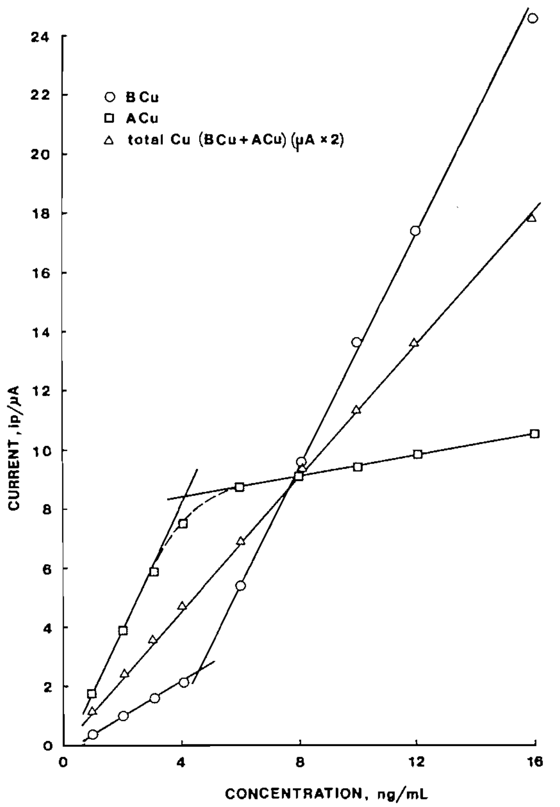

FIG. 2. Analytical curves for standard Cu solutions showing the response of total Cu (A + B) to the total concentration. Note that for total Cu the current axis is to be multiplied by two. Films were "preformed" so that Hg film thickness is independent of Cu plating time.

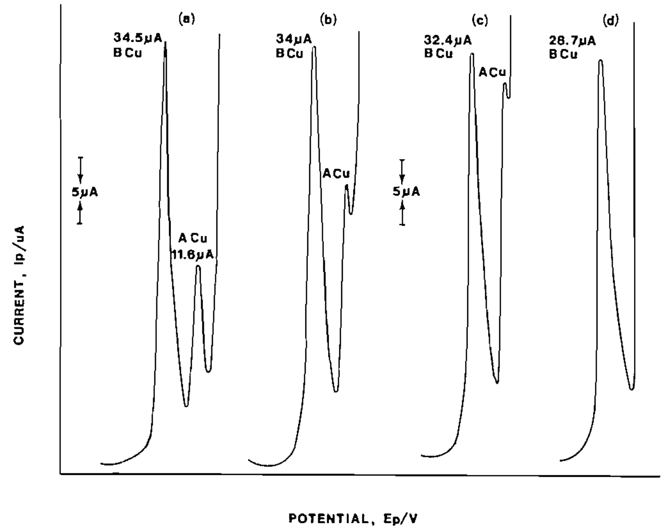

FIG. 3. ASV voltammograms demonstrating the effect of chloride concentration on the peak currents of A-type Cu and B-type Cu. (*a*) ASV obtained from 20 ng mL^{-1} Cu and 4 × 10^{-5} *M* Hg^{2+} on a MTFE *in situ* with a 5 min plating time at −1.0 V; (*b*), (*c*), and (*d*) were recorded after the addition of 5 × 10^{-4}, 1 × 10^{-3}, and 2 × 10^{-3} *M* KCl, respectively.

5 min irradiation with purified N_2 bubbling removed residual peroxide.

Acid digestion of samples was carried out as follows. Aliquots (25 mL) of filtered river water were acidified to pH = 0.7 and reduced to 1 mL on a hot plate (without boiling). This residual sample was diluted with doubly distilled water and brought to pH = 5.0.

Insoluble particles retained on the millipore filters from 1.00 L of river water were dissolved for analysis by wet ashing. Filters plus 10 mL of 2 *M* Ultrex HNO_3 were heated for 1/2 h at 70°C. The solutions were filtered through new membrane filters and the filters were washed with doubly distilled water and the resulting solutions finally diluted to 50.0 mL. Aliquots (1.25 mL) were transferred to the electrolysis cell and diluted with doubly distilled water and acetate buffer to give 25.0 mL at pH = 5.0. The fractionation and treatments just described is used below to classify metal ions into "bound", "labile", and "particulate" fractions. These terms have the operational meaning given by this procedure.

Results

Part A

In preliminary experiments, KCl was used in the salt bridge. A change from saturated KCl to 1 *M* KNO_3 or 0.5 $NaNO_3$ affected the Cu signal MTFE's. In the absence of Cl^-, two Cu peaks appeared; the first (cathodic side) at −0.21 V in these experiments had a half width, $b_{1/2}$, of 55 mV; the second at a more anodic potential of −0.08 V had a half width of 45 mV. The height of each of these two Cu peaks and their relation to each other proved to be a function of the thickness of the Hg film, the plating time for *in situ* electrodes, deposition potential, the chloride concentration, and the Cu^{2+} concentration.

The more anodic peak (called A-Cu) dominates at low (1 ng mL^{-1}) concentration but that the more cathodic peak (called B-Cu below) grows in faster as the concentration rises. (Behaviour at the HMDE was quite similar.) An analysis of the contribution to the total Cu signal from each peak as Cu concentration increases is given in Fig. 2. (A quite similar analysis can be derived from the HMDE experiments.) The *sum* of peak currents, i_p, for the two peaks is linear in added Cu.

Mercury film thickness in MTFE's was also a parameter. This report follows the equations of Stojek and co-workers to estimate film thickness (8, 9). When Cu at 1.00 μg mL^{-1} is deposited for 5.0 min at −1.0 V a preformed MTFE of 77 Å thickness results. The peaks for B-Cu and A-Cu have i_p values of 0.80 and 1.3 μA, respectively. As the film thickness was increased to 500 Å in four steps between 50 and 200 Å each, the height of the B-Cu peak decreased reaching "zero" at 500 Å. Conversely, the A-Cu peak height increased to a maximum value of 2.30 μA. (The sum increased slowly from 2.10 to 2.30 μA.) When *in situ* film formation is used, films become thicker at the same time as the quantity of Cu plated increases. The second factor ultimately dominates. The change in peak height with plating time for 1.00 ng mL^{-1} of Cu is similar to the change of peak height with Cu concentration. (Long plating times can deplete the Cu. Non-linearity was observed beyond 60 min.)

From this, the effect of Cl^- ion can now be examined in the case of *in situ* MTFE analysis. The most revealing experiment is presented in Fig. 3 where the effects on Cu peaks of 0.50 × 10^{-4} *M*, 1.0 × 10^{-3} *M*, and 2.0 × 10^{-3} *M* KCl are recorded. The B-Cu peak is affected slightly at most. The A-Cu peak "disappears". Careful inspection of the figure, however, reveals that it is disappearing into the large Hg wave which is advancing cathodically with increasing Cl^- concentration. There is no evidence available for a change in the A-Cu peak height because that peak cannot be resolved clearly from the chloro Hg peak at Cl^- concentration 5 × 10^{-4} *M*. In this concentration range, there is little literature precedent for Cl^- complexing of Cu unless the cuprous state is involved (note the nearly constant B-Cu peak height). There appears to be loss of

*HMDE: 25 mL solution contains 10 ng mL^{-1} Zn, Cd, and Pb and 15 ng mL^{-1} copper deposition time 3 min. Scan rates 5 mV s^{-1}. In all cases where HMDE was used, 0.03 cm drop area was used.

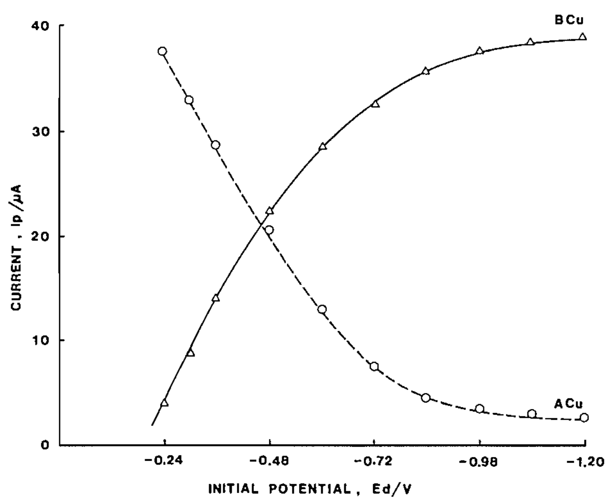

FIG. 4. Relationship between the varying peak currents of both A-Cu and B-Cu and the initial plating potential in the absence of chloride.

information concerning the probably nearly constant A-Cu peak which is a consequence of Cl$^-$ "complexing" Hg not Cu.

These observations do not deny the effect that Cl$^-$ complexation can exert on voltammograms. At higher Cl$^-$ concentration both peak potential, E_p, and peak current, i_p, for the well resolved B-Cu signal become a function of Cl$^-$ ion concentrations. Relevant results, in this case at an HMDE, are collected in Table 1. Results involving Cd, and Pb are also included. The effect of Cl$^-$ on E_p and i_p of the B-Cu band begins to be significant at $1.2-1.5\times10^{-3}$ M KCl. In the Cd peak, the effect is observable at 5×10^{-3} M KCl and for Pb it emerges at 0.10 M KCl.

Finally, for Part A, the two Cu peaks, A and B, can be altered relative to each other absolutely by the choice of plating potential in the absence of Cl$^-$. An example of this is shown in Fig. 4 which refers to an experiment conducted on an Ottawa drinking water buffered at pH = 5.0 with sodium acetate/acetic acid and which utilized a preformed MTFE of 1500 Å thickness. It is seen that the B-Cu peak is strongly favoured by more cathodic deposition potential.

Part B

Two preliminary experiments were performed in which a DPASV was run on an untreated river water sample. The first experiment used a HMDE and it was observed that the background signal could be reduced and the Cu signal enhanced. This was done by cycling the pH down to 2 and then back to pH = 5. Schonberger (4) has reported similar pH effects.

The intermetallic effect of Zn on the Cu signal which has been discussed elsewhere (10) was seen when a DPASV was run on the same untreated river water using a MTFE.

Table 2 is a summary of the analytical results for the analysis of river water by various methods and with various methods of sample treatment. Little difference among the three types of electrodes (HMDE, MTFE (*in situ*), MTFE (predep.)) is seen from the tabulated results. The problems encountered with one of the electrodes is shared by all. The results show that sample pretreatment is clearly critical. This is reinforced by Table 3 which indicates how the sample divides in percentage terms, what is the total concentration identified by each method, and the sensitivity of each of the three types of electrodes.

While previous figures and tables record the data on performance of conventional DPASV electrodes and the explanation of some Cu "pecularities" the remaining results concern synthetic samples and river water samples studied with the new electrode, the MCRVCE. The first results involve immediate analysis of synthetic samples, which were prepared in the same manner as samples used in Part A. Analytical calibration curves for Cd, Pb, and Cu using 2 min deposition times are linear. Linear regression gave with R^2 values in excess of 0.999 except for B-Cu where R^2 is 0.957. (Total Cu has an R^2 0.999.) All intercepts (blanks) are 0.5 μA and slopes (sensitivities) range from 1.93 ± 0.2 to 2.30 ± 0.2 μA/ng mL^{-1}. These are good and analyte quantities near 0.1 ng mL^{-1} require deposition times of only about 10 min. The enhanced sensitivity compared to stationary systems is one advantage of the flow through electrode. The peak potentials are: Cd, −0.73 V; Pb, −0.57 V; A-Cu, −0.21 V; and B-Cu, −0.11 V.

Characteristic DPASV's recorded with river water samples (buffered to pH = 5.5) using MCRVC's are shown in Fig. 5. Peak potentials at natural levels are: Cd^{2+}, −0.73 V; Pb −0.59 V; A-Cu, −0.30 V; B-Cu, −0.11 V. The concentrations are

estimated from spiking results.

The peaks for Pb and Cu are reduced and difficult to resolve because of the cathodic shift of the Hg oxidation wave background *similar to that seen above induced by* Cl^- *in Part A*. Cl^- cannot be the cause here. The interference becomes more severe in repeated runs on a sample, probably because of adsorption following exposure of the surface to a larger volume of river water. The magnitude of the interference with Pb and Cu is documented by the spiking experiments shown in Fig. 6. That the effect arises from organic matter and from the adsorption on the electrode and not complexing in the solution is shown, because, first uv digestion improves the signals and second the inteference can be reintroduced by treating the unpolarized electrode with untreated river water that has not been uv-digested, rinsing the electrode, and only then carrying out plating and DPASV on a solution which had *been uv-digested*.

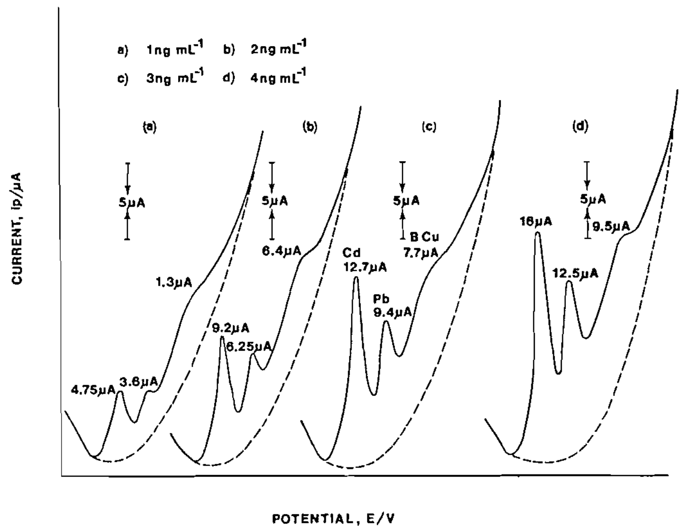

FIG. 5. Analysis by spiking of river water using the MCRVCE. (Plating −2 min at −1.0 V; 5 mV s^{-1} scan rate and 4.8 mL min^{-1} flow rate).

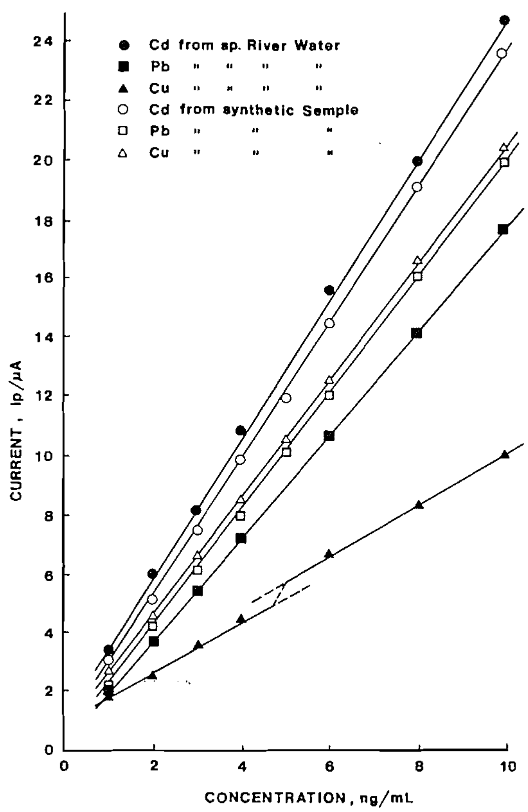

FIG. 6. Comparison of analytical curves obtained by the MCRVCE of synthetic and spiked river water samples.

Some of the adsorbed film survives the rinsing and produces the cathodic shift of the Hg wave! In a related experiment it was demonstrated that the background interference was additive. An electrode that had been through six successive runs involving 6 min deposition times was compared to a fresh electrode with a mercury film deposited from an entirely synthetic solution. The fresh electrode was found to have a substantially lower background interference. This experiment was also intended to test the role of irreversible adsorption on the electrode

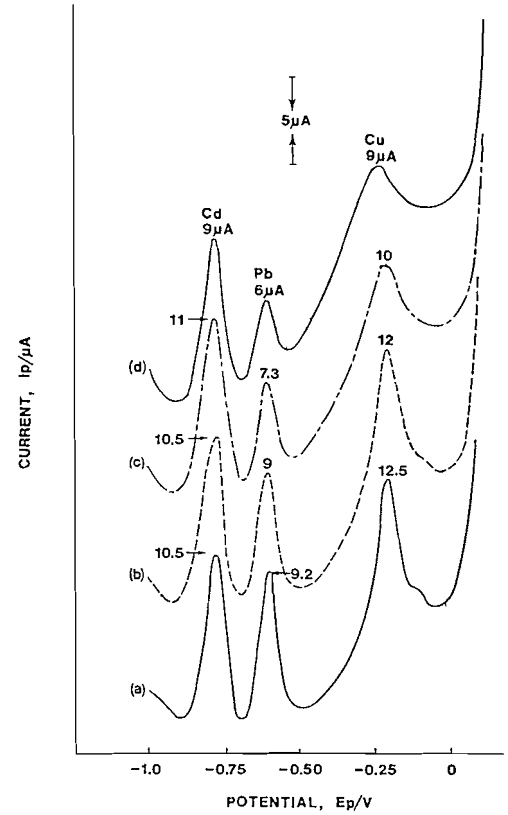

FIG. 7. ASV voltammograms demonstrating the effect of fulvic acid concentration on the peak currents of metal species in a synthetic river water sample. (*a*) ASV obtained from 1 ng mL^{-1} of Cd and Pb and 1.5 ng μL^{-1} Cu; (*b*), (*c*), and (*d*) were recorded after the addition of 1, 4, and 8 μg mL^{-1} of fulvic acid.

as opposed to complexation in the solution.

Finally, an effort was made to model the inteference effect in river water with a purified sample of a soil organic acid (fulvic acid) which has been characterized extensively (11). The results appear in Fig. 7. As fulvic acid concentration increases, Cu peaks decrease and broaden in a manner similar to that observed in river water samples. However, for this low molecular weight relatively hydrophilic soil organic, the Hg wave cathodic shift is not as pronounced as it is in river water where typical organic colloids would be expected to be of greater molecular weight and more hydrophobic.

On balance, the MCRVCE is fully competitive with other ASV electrodes for analysis of trace metals in water samples such as drinking water or Rideau river water.

In the interest of testing the idea of using the MCRVCE for plating in a simple field sampler to be followed by stripping using a more sophisticated laboratory polarograph, MCRVCE electrodes were rinsed with blank and stored closed with air free blank inside after plating. After storage for 12 to 96 h the unit was remounted in the flow system and 8 mL additional blank (total volume 10.0 mL) was circulated while potential was held at −1.0 V for 5 min to replate any oxidized metal. At the end of this period the DPASV scan was recorded.

Typical results of analysis of stored electrodes are shown in Fig. 8. There is evidence of loss of each of the metal ions, especially in the case of Cd. The mechanism is not clear. One aspect, however, is encouraging. The calibration curves for all metals remain linear after up to 96 h. The scatter of points in Fig. 8 also show results from independent runs which suggest

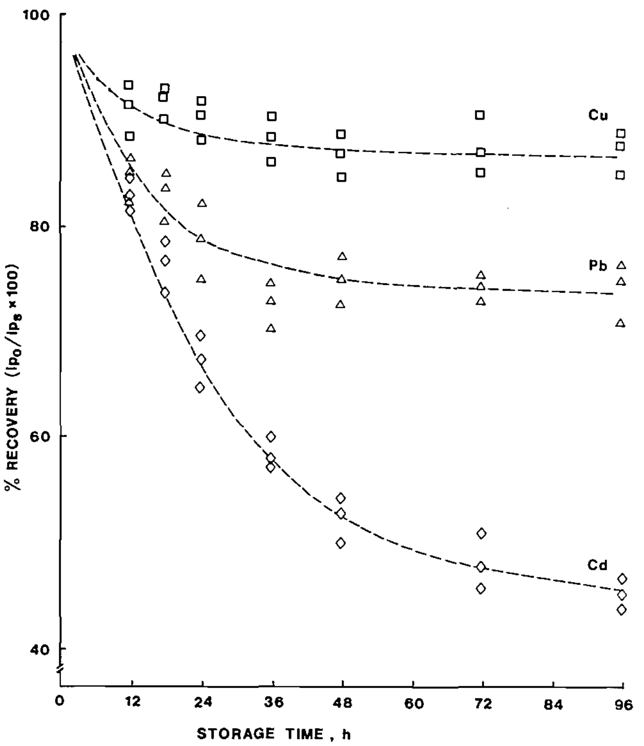

FIG. 8. Effect of storage on percentage recovery from the MCRVCE.

that losses are fairly reproducible. One experiment tends to reveal the nature of the losses. Dissolving of stored metal ions in 10 mL of blank solution followed by replating the dissolved metal ions for 20 min on freshly prepared MCRVCE followed by stripping improves the sensitivity for Cd and Pb.

Discussion

Part A

The results presented first cannot be associated with complex formation and clearly reflect the ASV consequences of the limited solubility of Cu in Hg (first demonstrated in ref. 8). The B-Cu peak is that for particles of solid Cu suspended in, or plated on, the Hg electrode. The A-Cu peak is the peak for a Cu amalgam. The results presented are selected to give a clear idea of a cross section of our many experiments. Double peaks for Cu on all four electrode types were observed, with the Cu (solid) peak being most prominent at low Hg film thickness as would be expected. The conclusion is reinforced by data in Fig. 4. There it is obvious that "fast" deposition of Cu at highly cathodic voltages favours precipitation of Cu where as "slow" deposition at voltages much nearer the reversible values favours Cu atom formation and amalgamation.

A confusion appears to have infected some earlier discussions with respect to the role of Cl^-. It is apparent that Cl^- complexing of Cu is not the only way Cl^- can affect Cu signals. Rather, Fig. 5 shows that the major effect at low concentration can be on Hg as the relative interaction energy with Cu and Hg would imply. Since ASV studies are frequently directed to identification of speciation in the sample (3), it is especially important to be aware of which circumstances affect properties of Hg and not the analyte. Chloride can mask "labile" Cu by the shift of the Hg wave which is subtle and easily overlooked. This is the effect reported in ref. 6.

An analogy to this "masking" can be drawn from the studies done by Forsmann (12). In his studies of the cathodic stripping voltammetry of Penicillamine he reported that the measurement of the Penicillamine amalgam peak was interferred with by the presence of cupric ions. This is the inverse of what we discuss.

Two general points may be made. First, effects of Cl^- will follow usual inorganic chemical complexity constant sequences. Second, the effect of Cl^- appears only at relatively high Cl^- concentrations *except* for the case of the one metal present at high concentration, Hg.

Part B

In Part A it was shown that interferences in DPASV of simple inorganic species like Cl^- arise not only from complexation of the analyte ions in solution but also from interactions at the interface and in the Hg phase which affect *inter alia* the Hg background wave. In Part B we first observed that very similar effects arise in natural fresh waters which are low in Cl^-. The emphasis on interfacial effects was confirmed by the variation of interferences on pH cycling. Moreover, the effects which resemble Cl^- effects are reduced by procedures which are expected to destroy organic matter. Synthetic solutions containing organic matter do exhibit similar interferences. The clearest demonstration that the effects arise from adsorption is the fact that they survive the removal of carbon electrodes and light rinsing. Since the shape and scale of the anodic stripping voltammogram is very sensitive to effects connected to the interface and the Hg phase, it seems unlikely that the voltammograms can be reliably interpreted in terms of speciation of metals in the solution phase.

Turning to the new electrode, Trojanek and Opekar (13) in a paper describing a flow-through electrode for ASV point out that flow through electrodes in general have the advantages of permitting treatment of large solution volumes and attaining high sensitivity. Furthermore, Batley (14) notes the problem of possible contamination during trace metal analysis in natural waters. Techniques that require sample handling and multiple reagent additions are prone to errors whereas the use of the *in situ* preconcentration methods forego these problems. For these reasons, the results obtained with our electrode (MCRVCE) imply a potential for trace metal analyses in natural waters. The ageing studies indicate that the use in an electronically simple field device for plating with the transport of the electrode to the laboratory for stripping at an electronically sophisticated device is plausible. The interferences discussed here suggest that photochemical H_2O_2 treatment in the reservoir chamber would be needed in the field for river water but perhaps not for drinking water.

Synthesis and resolution of $R(-)$-5-hexyn-3-ol

BERNARD L. ROY[1] AND PIERRE DESLONGCHAMPS
Laboratoire de synthèse organique, Département de chimie, Faculté des Sciences, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received June 26, 1984

BERNARD L. ROY and PIERRE DESLONGCHAMPS. Can. J. Chem. **63**, 651 (1985).

The resolution of (±)-5-hexyn-3-ol (**1**) was effected by high performance chromatography of its *O*-methyl mandelic esters **3** and **4**. The absolute configuration of (−) and (+)-5-hexyn-3-ol were determined by comparison with an authentic sample prepared from D(+)-glucose.

BERNARD L. ROY et PIERRE DESLONGCHAMPS. Can. J. Chem. **63**, 651 (1985).

La résolution du (±)-hexyne-5 ol-3 (**1**) fut réalisée grâce à la chromatographie à haute performance de ses esters *O*-méthyl mandélique **3** et **4**. La configuration absolue du (−) et (+)-hexyne-5 ol-3 fut déterminée par comparaison avec un échantillon préparé à partir du D(+)-glucose.

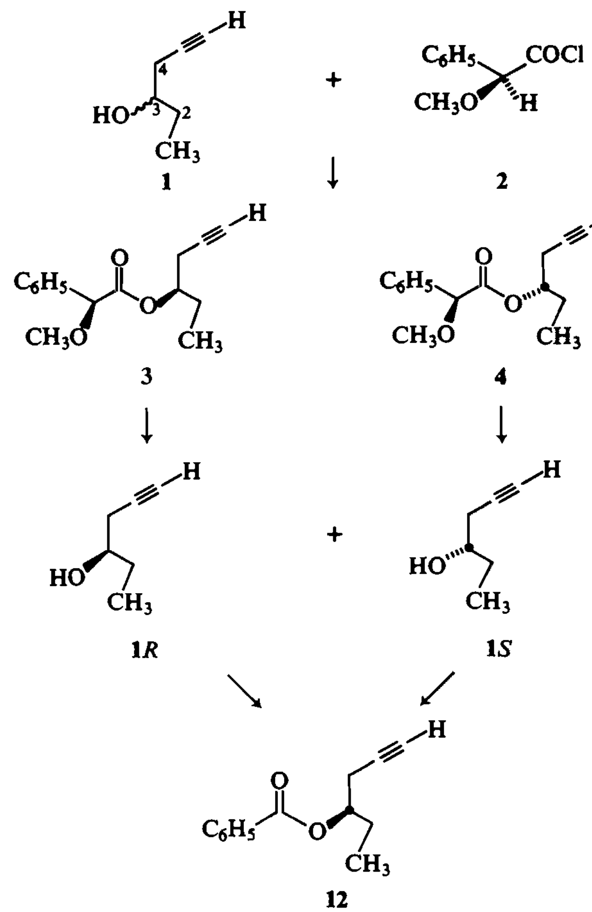
As part of our work on the total synthesis of erythromycin *A*,[2] the *R* enantiomer of 5-hexyn-3-ol (**1***R*) was required as starting material. We have obtained this compound by resolution and wish to report this work.

The racemic form of **1** (Scheme 1), which is readily available from the condensation of propargyl magnesium bromide on propionaldehyde (3), was transformed into the corresponding diasteroisomeric *O*-methyl mandelic esters **3** and **4** by reaction with optically active acid chloride **2** (4). The separation of diastereoisomers **3** and **4** was carried out by high performance chromatography using toluene − ethyl acetate (99.5:0.5) as the solvent. After separation, the more polar compound had an $[\alpha]_D^{25}$ +86° (*c* 1.1, $CHCl_3$) and the less polar had an $[\alpha]_D^{25}$ +28° (*c* 1.9, $CHCl_3$).

Referring to Mosher's work (4) on the anisotropic effect of the phenyl ring on proton chemical shifts, we were able to predict that the more polar diastereoisomer would correspond to **3** and the less polar to **4**, having respectively the *SR* and the *SS* absolute configuration. This assignment is based on the fact that (a) the protons at C1 and C2 in **3** (Table 1) absorb at a higher field than those in **4**, and (b) the protons at C4 and C6 in **3** absorb at a lower field than those in **4**.

Hydrolysis of the more polar diastereoisomer **3** gave an alcohol ($[\alpha]_D^{25}$ −4° (*c* 1.1, $CHCl_3$)) which must therefore have the *R* absolute configuration, whereas the less polar diastereoisomer **4** yielded an alcohol ($[\alpha]_D^{25}$ +4° (*c* 2.1, $CHCl_3$)) having the *S* configuration.

This configurational assignment based on Mosher's work (4), was rigorously established by preparing a sample of alcohol **1***R* starting from D-glucose using the method described in Scheme 2. The known compound **5** (5, 6) was prepared in four steps from D-glucose. The alcohol **1***R* obtained from compound **11** was levorotatory ($[\alpha]_D^{25}$ −4° (*c* 1.1, $CHCl_3$)), so our original assignment was correct. The alcohol **1***S* can also be transformed into the benzoate **12** of alcohol **1***R* using the Mitsunobu inversion procedure (7). The benzoate **12** obtained had a rotation ($[\alpha]_D^{25}$ +28° (*c* 1.6, $CHCl_3$)) essentially identical to that of an authentic sample of **12** ($[\alpha]_D^{25}$ +29° (*c* 1.2, $CHCl_3$)) prepared by benzoylation of alcohol **1***R*.



SCHEME 1

Experimental

The infrared (ir) spectra were taken on a Perkin−Elmer 681 spectrophotometer. Proton nmr spectra were recorded on a Bruker WP-60 or a Bruker WP-250 instrument. The following abbreviations have been used: s, singlet; d, doublet; dd, doublet of doublet; t, triplet; q, quadruplet; m, multiplet. Chemical shifts are reported in δ values relative to tetramethylsilane as internal standard. A Waters prep LC/System 500 A chromatograph was used for separation of **3** from **4**. The mass spectra (ms) were recorded on a VG Micromass ZAB-1F mass spectrometer.

Reactions were carried out under argon. Anhydrous magnesium sulfate was used as the drying agent in work-up of reactions.

R(−)-5-hexyn-3-ol (1R) from 3

Ester **3** (5 g, 20.3 mmol) and an aqueous sodium hydroxide solution (15 mL, 1 *N*) were stirred at room temperature for 40 h. The solution was extracted with ether (3 × 100 mL) and the ethereal extracts were

dried. The ether was distilled off at atmospheric pressure and the residue was distilled (75–80°C, 45 Torr (1 Torr = 133.3 Pa)) to afford $R(-)$-5-hexyn-3-ol (**1*R***) (1.53 g, 76%); ir ($CHCl_3$): 3580, 3460, 3310, and 2100 cm^{-1}; nmr ($CDCl_3$) δ: 3.65 (1H, quintuplet, —C*H*—OH), 2.40 (3H, m, —*CH*$_2$—C≡C—H, O*H*), 2.05 (1H, t, —C≡C—*H*), 1.58 (2H, m, CH_3—*CH*$_2$—CHOH—), 0.96 (3H, t, J = 6.3 Hz, *CH*$_3$—CH_2—); ms m/e: 98 (M^+); $[\alpha]_D^{25}$ −4° (c 1.1, $CHCl_3$).

$S(+)$-5-hexyn-3-ol (**1*S***) was prepared in the same manner from **4**; $[\alpha]_D^{25}$ +4° (c 2.1, $CHCl_3$).

*R(−)-5-hexyn-3-ol (1*r*) from 11*

n-Butyllithium (1.6 M in hexane, 712 μL, 1.14 mmol) was added to a solution of dibromoolefin **11** (94.8 mg, 0.367 mmol) in ether (8 mL) at −78°C. The mixture was stirred for 5 min and then quenched by the addition of a saturated aqueous solution of ammonium chloride (5 mL). The organic layer was separated and the aqueous layer extracted twice with ether (2 × 10 mL); the combined organic phase was dried and distilled at atmospheric pressure. Microdistillation *in vacuo* afforded $R(-)$5-hexyn-3-ol (**1*R***) (29 mg, 80%); $[\alpha]_D^{25}$ −4° (c 1.1, $CHCl_3$).

Esters 3, 4

Oxalyl chloride (50.1 g, 386 mmol) was added to $S(+)$-O-methyl mandelic acid (42.8 g, 258 mmol) and the solution was allowed to stir for 2 h at room temperature. The excess oxalyl chloride was pumped off and the residue pumped under vacuum for 1 h. Benzene (150 mL) was added to the residue and to this solution was added (±)-5-hexyn-3-ol (22.7 g, 232 mmol) in benzene (50 mL) and pyridine (21 mL). After addition, water (100 mL) was added and the reaction mixture was extracted with ether (2 × 200 mL). The ethereal extracts were washed successively with hydrochloric acid (1 N, 50 mL), saturated aqueous sodium chloride solution (100 mL), dried, and evaporated to give a 1:1 mixture of diastereoisomers **3** asnd **4** (54.5 g, 95%).

TABLE 1. Chemical shifts of diastereoisomers **3** and **4**

	CH_3 (C1)	CH_2 (C2)	*CH*$_2$C≡C (C4)	C≡C*H* (C6)
3	0.61	1.60	2.45	1.95
4	0.87	1.68	2.33	1.73

Chromatographic separation of 3 and 4

The separations were done on a Waters prep LC/System 500 A chromatograph with two 500-mL cartridges. The average run was as follows: the columns were charged with 6 g of esters **3** and **4**; as the compounds started to elute, the mixed fractions were recycled and the pure ones were collected. This way it was possible to collect 2 g of **3**, 2 g of **4**, and 2 g of a mixture which was rechromatographed. After extensive chromatography of the "mixed fractions" the esters **3** and **4** were completely separated.

Ester **3**: ir ($CHCl_3$): 3310, 3020, 2990, 1750, 1460, 1260, and 1180 cm^{-1}; nmr ($CDCl_3$) δ: 7.45 (5H, m, phenyl), 4.89 (1H, quintuplet, J = 5.9 Hz, —*CH*—CH_2—C≡C—H), 4.77 (1H, s, —*CH*—OCH_3), 3.41 (3H, s, CH_3O—), 2.45 (2H, dd, J = 2.7 Hz, 5.9 Hz, —*CH*$_2$—C≡C—H), 1.95 (1H, t, J = 2.7 Hz, —C≡C—*H*), 1.60 (2H, m, CH_3—*CH*$_2$—), 0.61 (3H, t, J = 7.4 Hz, *CH*$_3$—CH_2—). *Mol. Wt.* (ms) calcd.: 246.1256; found: 246.1255; $[\alpha]_D^{25}$ + 86° (c 1.1, $CHCl_3$).

Ester **4**: ir ($CHCl_3$): 3310, 3020, 2990, 1750, 1460, 1260, and 1180 cm^{-1}; nmr ($CDCl_3$) δ: 7.45 (5H, m, phenyl), 4.92 (1H, quintuplet, J = 5.9 Hz, —*CH*—CH_2—C≡CH), 4.78 (1H, s, —*CH*—OCH_3), 3.43 (3H, s, *CH*$_3$O—), 2.33 (2H, dd, J = 2.6 Hz, 5.9 Hz, —CH—*CH*$_2$—C≡CH), 1.73 (1H, t, J = 2.6 Hz, —C≡C*H*), 1.68 (2H, m, CH_3*CH*$_2$—), 0.87 (3H, t, J = 7.4 Hz, *CH*$_3$—CH_2—). *Mol. Wt.* calcd.: 246.1256; found: 246.1255; $[\alpha]_D^{25}$ +28° (c 1.9, $CHCl_3$).

Dimesylate 6

Methanesulfonyl chloride (4 g, 35 mmol) was added to a solution of diol **5** (1.43 g, 7 mmol) in methylene chloride (50 mL) containing triethylamine (7.08 g, 40 mmol) at 0°C. The reaction was complete after the addition of the mesyl chloride. Water was added and the layers were separated, the organic layer was washed with an aqueous solution of saturated sodium bicarbonate (30 mL), dried, and evaporated. Dimesylate **6** (2.5 g, 98%) could be used in the next step without purification; ir ($CHCl_3$): 2990, 1370, and 1180 cm^{-1}; nmr ($CDCl_3$) δ: 5.84 (1H, d, J = 3.2 Hz, anomeric proton), 4.85 (2H, m, H-C2, H-C3), 4.51 (3H, m, MsO*CH*$_2$—*CH*(OMs)—), 3.12 (3H, s, *CH*$_3$—SO_3—), 3.09 (3H, s, *CH*$_3$—SO_3—), 2.15 (2H, m, H2-C3), 1.53 (3H, s, CH_3—), 1.33 (3H, s, CH_3—); ms m/e: 345 (M^+ − 15). *Mol. Wt.* (ms) calcd.: 345.0314; found: 345.0314; $[\alpha]_D^{25}$ −1.6° (c 3.3, $CHCl_3$).

Olefin 7

Sodium iodide (2.2 g, 33.4 mmol) and zinc (5.0 g, 33.4 mmol) were added to a solution of dimesylate **6** (2.4 g, 6.68 mmol) in dimethoxyethane (50 mL). The mixture was allowed to reflux for 2h, after which the solution was filtered, hexane was added (100 mL), and the hexane solution was washed once with water (50 mL) and once with an aqueous solution of saturated sodium thiosulfate. The organic phase was then dried and evaporated to afford olefin **7** (1.0 g, 89%) as an oil which could be used in the next step without purification; ir ($CHCl_3$): 2980 and 1375 cm^{-1}; nmr ($CDCl_3$) δ: 5.83 (1H, d, J = 3.4 Hz, anomeric proton), 5.5−5.0 (3H, m, CH_2=CH—), 4.72 (2H, m, H-C2, H-C4), 2.03 (2H, m, H2-C3), 1.52 (3H, s, CH_3—), 1.31 (3H, s, CH_3—); ms m/e: 155 (M^+ − 15). *Mol. Wt.* (ms) calcd.: 155.0708; found: 155.0708; $[\alpha]_D^{25}$ −38° (c 1.1, $CHCl_3$).

Acetonide 8

Olefin **7** (462 mg, 2.72 mmol) was dissolved in ethyl acetate (3 mL). This solution was added to a suspension of platinum(IV) oxide (50 mg) in ethyl acetate (3 mL) and shaken under hydrogen atmosphere (45 psi (1 psi = 6.9 kPa)) for 30 min. The solution was filtered and evaporated to afford acetonide **8** (463 mg, 99%) as an oil which could be used in the next step without purification; ir ($CHCl_3$): 1375, 1460, 1385, and 1240 cm^{-1}; nmr ($CDCl_3$) δ: 5.81 (1H, d, J = 3.8 Hz, anomeric proton), 4.70 (1H, t, J = 4.1 Hz, H1-C2), 4.17 (1H, sextuplet, J = 6.4 Hz, H-C4), 2.17 (2H, m, H2-C3), 1.75 (2H, m, CH_3—*CH*$_2$—), 1.50 (3H, s, CH_3—), 1.30 (3H, s, CH_3—), 0.93 (3H, t, J = 7.0 Hz, *CH*$_3$—CH_2—); ms m/e: 157 (M^+ − 15). *Mol. Wt.* (ms) calcd.: 157.0865; found: 157.0865; $[\alpha]_D^{25}$ −5.5° (c 1.2, $CHCl_3$).

Hemiketal alcohol 9

To a solution of acetonide **8** (500 mg, 2.9 mmol) dissolved in dioxane (15 mL) was added a 4% aqueous sulfuric acid solution (15 mL); the resulting mixture was stirred under reflux for 1 h. The reaction was cooled to 25°C and carefully neutralized with solid sodium carbonate. The layers were separated and the aqueous layer was extracted with dioxane (25 mL). The dioxane was evaporated and the residue was taken up in ethyl acetate, the layers were separated, and the aqueous layer was extracted twice with ethyl acetate (2 × 50 mL). The combined organic layers were dried and evaporated to give hemiketal alcohol **9** (313 mg, 82%) which could be used without purification; ir ($CHCl_3$): 3610, 3400, and 1250 cm^{-1}; nmr ($CDCl_3$) δ: 5.33 (1H, t, J = 4.0 Hz, anomeric proton), 4.26 (3H, m, 2 × OH, CH_3—CH_2—*CH*—O—), 3.73 (1H, m, H-C2), 1.97 (2H, m, H2-C3), 1.4 (2H, m, CH_3—*CH*$_2$—), 0.90 (3H, t, J = 7.6 Hz, *CH*$_3$—CH_2—); ms m/e: 114 (M^+ − 18).

Dibromoolefin 10

Sodium periodate (369 mg, 1.72 mmol) was added to a solution of hemiketal alcohol **9** (136 mg, 1.03 mmol) in ether (5 mL) and water (1 mL). The reaction mixture was stirred for 1 min, water (3 mL) was then added, the layers were separated, and the aqueous layer was extracted with ether (2 × 10 mL). The combined ethereal extracts were dried and distilled off at atmospheric pressure. The crude compound was dissolved in dry ether (2 mL) and added to a solution of carbon tetrabromide (689 mg, 2.07 mmol) and triphenylphosphine (1.06 g, 4.04 mmol) in methylene chloride (15 mL). The reaction mixture was stirred for 10 min, after which pentane was added to precipitate the phosphine oxide. The mixture was then filtered and the solvent evaporated. Pentane was added to the residue to precipitate out additional phosphine oxide, the mixture was then filtered, and the solvent was evaporated; this was repeated until no more precipitate was formed. The residue was distilled (84−86°C, 0.4 Torr) to afford pure compound **10** (110 mg, 37%). The distillation residue contained a very small quantity of deformylated compound **11** mixed with some other impurities (76.7 mg). Compound **10**: ir ($CHCl_3$): 2920, 1720, 1625, 1470, and 1180 cm^{-1}; nmr ($CDCl_3$) δ: 8.09 (1H, s, H—C(O)—), 6.42 (1H, t, J = 7.2 Hz, —*H*C=CBr_2), 5.03 (1H, quintuplet, J = 5.9 Hz, —*CH*—O—CHO), 2.43 (2H, t, J = 5.9 Hz, —CH—*CH*$_2$—CH=CBr_2), 1.64 (2H, q, J = 6.3 Hz, CH_3—*CH*$_2$—), 0.94 (3H, t, J = 6.3 Hz, *CH*$_3$—CH_2—); ms m/e: 240 (M^+ − 46). *Mol. wt.* (ms) calcd.: 239.8974; found: 239.8974; $[\alpha]_D^{25}$ +26° (c 3.0, $CHCl_3$).

Dibromoolefin alcohol 11

Potassium bicarbonate (200 mg, 2 mmol) was added to a solution of formate olefin **10** (110 mg, 0.385 mmol) in methanol (5 mL) and was allowed to stir for 1.5 h. The methanol was then evaporated and water (5 mL) was added to the residue. The aqueous phase was extracted with ethyl acetate (3 × 10 mL) and the combined organic layer was dried and evaporated to afford pure dibromoolefin alcohol **11** (94.8 mg, 96%); ir ($CHCl_3$): 3600, 3485, and 1650 cm^{-1}; nmr ($CDCl_3$) δ: 6.54 (1H, t, J = 7.0 Hz, —*CH*=CBr_2), 3.69 (1H, quintuplet, J = 6.1 Hz, *CH*—OH), 2.28 (2H, m, —*CH*$_2$—CH=CBr_2), 1.45 (3H, q, J = 5.7 Hz, CH_3*CH*$_2$—, OH), 0.97 (3H, t, J = 5.7 Hz, *CH*$_3$—CH_2—); $[\alpha]_D^{25}$ −8.7° (c 0.9, $CHCl_3$).

*Benzoate 12 from 1*R

Benzoyl chloride (88.8 mg, 0.58 mmol) was added to a solution of R(−)-5-hexyn-3-ol (**1***R*) (56.3 mg, 0.574 mmol) in pyridine (3 mL). The reaction mixture was stirred at room temperature for 10 h. Methylene chloride (10 mL) was then added and the solution washed with hydrochloric acid (2 N, 10 mL), dried, and evaporated to give pure benzoate **12** (113 mg, 98%); ir ($CHCl_3$): 3310, 3020, 2990, 1720, and 1280 cm^{-1}; nmr ($CDCl_3$) δ: 8.13−7.20 (5H, m, phenyl), 5.25 (1H, quintuplet, J = 6.3 Hz, —*CH*—OBz), 2.60 (2H, dd, J = 3.0 Hz, 6.3 Hz, —*CH*$_2$—C≡CH), 2.01 (1H, t, J = 3.0 Hz, —C≡C—*H*), 1.88 (2H, m, CH_3—*CH*—), 1.00 (3H, t, J = 6.9 Hz, *CH*$_3$—CH_2—); ms m/e: 202 (M^+). *Mol. Wt.* (ms) calcd.: 202.0994; found: 202.0979; $[\alpha]_D^{25}$ +28° (c 1.6, $CHCl_3$).

*Benzoate 12 from 1*S

Benzoic acid (165 mg, 1.35 mmol) was added to a solution of S(+)-5-hexyn-3-ol (**1***S*) (121 mg, 1.23 mmol) and triphenylphosphine (354 mg, 1.35 mmol) in tetrahydrofuran (5 mL). To this mixture was added diethyl azodicarboxylate (234 mg, 1.35 mmol) in tetrahydrofuran (2 mL); the reaction mixture was allowed to stir overnight. Water (5 mL) was then added and the mixture extracted with ether (3 × 20 mL); the ethereal extracts were dried and evaporated. The crude residue was purified on silica gel with hexane − ethyl acetate (6:1) as the eluent to afford pure benzoate **12** (114 mg, 46%); $[\alpha]_D^{25}$ +29° (c 1.2, $CHCl_3$).

Kinetics of the reduction of 1-methylquinolinium cations by 1-benzyl-1,4-dihydronicotinamide

JOHN W. BUNTING AND NORMAN P. FITZGERALD
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received November 3, 1983[1]

JOHN W. BUNTING and NORMAN P. FITZGERALD. Can. J. Chem. **63**, 655 (1985).

The reduction of a series of 3-W-1-methylquinolinium cations (**1**: W = H, Br, $CONH_2$, CO_2CH_3, CN, NO_2) by 1-benzyl-1,4-dihydronicotinamide has been investigated. In all cases the kinetically controlled product from these reactions is the appropriate 3-W-1,4-dihydro-1-methylquinoline. Only for W = Br is any significant amount of the 1,2-dihydro isomer obtained (15% in this case). This kinetic preference for C-4 attack over C-2 attack in dihydronicotinamide reductions contrasts with the kinetically preferred attack at C-2 by hydroxide ion and in borohydride reductions. Rates of reduction were measured for each **1** and also 1,2-dimethyl- and 1,4-dimethylquinolinium cations in 20% CH_3CN – 80% H_2O, ionic strength 1.0 at 25°C, under pseudo-first-order conditions. Kinetic saturation due to nonproductive 1 : 1 complex formation was observed for several cations at high concentrations (>0.1 *M*). Second-order rate constants (k_2^H) were evaluated for each W, and also kinetic isotope effects from second-order rate constants (k_2^D) for reduction by 1-benzyl-4,4-dideuterio-1,4-dihydronicotinamide. Second-order rate constants are correlated with σ_p^- for W with $\rho = 4.5$, and are also closely correlated with pK_{R^+} for pseudobase formation at C-4 of these quinolinium cations by: $\log k_2^H = -0.56\ pK_{R^+} + 7.3$. Values of k_2^H/k_2^D vs. pK_{R^+} describe a Westheimer curve reaching a maximum of 5.8 for W = Br and falling to 1.5 for W = NO_2 and 4.2 for W = H. These data are consistent with an intrinsic barrier of 2.9 ± 0.5 kcal/mol for hydride transfer between this 1,4-dihydronicotinamide and quinolinium cations. However, quinolinium cations display a dramatically enhanced rate of dihydronicotinamide reduction relative to hydroxide ion attack when compared with isoquinolinium cations. This observation, and the predominance of C-4 rather than C-2 reduction, suggests that these reactions may not be simple one-step hydride transfer processes.

JOHN W. BUNTING et NORMAN P. FITZGERALD. Can. J. Chem. **63**, 655 (1985).

On a étudié la réaction de réduction d'une série d'ions W-3 méthyl-1 quinolinium (W = H, Br, $CONH_2$, CO_2CH_3, CN et NO_2) par la benzyl-1 dihydro-1,4 nicotinamide. Dans tous les cas, le produit de contrôle cinétique de ces réactions est la W-3 dihydro-1,4 méthyl-1 quinoléine appropriée. Ce n'est que dans le cas où W = Br que l'on obtient des quantités significatives de l'isomére dihydro-1,2 (15% dans ce cas). Cette préférence pour une attaque en C-4 par opposition à une attaque en C-2 lors de réductions par la dihydronicotinamide est en opposition avec les résultats obtenus lors de réactions avec l'ion hydroxyde ou avec le borohydrure alors que l'attaque cinétique préférentielle se fait en position C-2. Opérant à 25°C, à une force ionique de 1,0, sous des conditions de pseudo-premier ordre et dans des solutions contenant 20% de CH_3CN et 80% de H_2O, on a mesuré les vitesses de réduction de tous les ions **1** ainsi que celles des cations diméthyl-1,2 ainsi que diméthyl-1,4 quinolinium. Dans les cas de plusieurs cations, à des concentrations élevées (>0,1 *M*), on a observé une saturation cinétique due à la formation non productive de complexes 1 : 1. Pour chacun des W, on a évalué les constantes de vitesse du deuxième ordre (k_2^H) ainsi que les effets isotopiques cinétiques, évalués à partir des constantes de vitesse du deuxième ordre (k_2^D), pour la réduction par la benzyl-1 dideutéro-4,4 dihydro-1,4 nicotinamide. On a pu établir une corrélation entre les constantes de vitesse du deuxième ordre et les valeurs σ_p^- des substituants W et la valeur de $\rho = 4{,}5$; il existe aussi une bonne corrélation avec les valeurs de pK_{R^+} pour la formation de la pseudobase en C-4 de ces cations quinolinium et cette corrélation est définie par l'équation $\log k_2^H = -0{,}56\ pK_{R^+} + 7{,}3$. Les valeurs de k_2^H/k_2^D vs. pK_{R^+} décrivent une courbe de Westheimer qui atteint un maximun de 5,8 pour W = Br et qui tombe à 1,5 pour W = NO_2 et à 4,2 pour W = H. Ces valeurs sont en accord avec la présence d'une barrière intrinsèque de 2,9 ± 0,5 kcal/mol pour le transfert d'hydrure entre la dihydro-1,4 nicotinamide et les cations quinolinium. Toutefois, si l'on compare les cations quinolinium aux cations isoquinolinium, on observe que dans le premier cas les vitesses de réduction par la dihydronicotinamide sont de beaucoup augmentées par rapport aux vitesses d'attaque par l'ion hydroxyde. Cette observation et le fait que la réduction se fait de préférence en C-4 plutôt qu'en C-2 suggèrent que ces réactions ne sont peut-être pas des transferts simples d'hydrures qui se produiraient en une étape.

[Traduit par le journal]

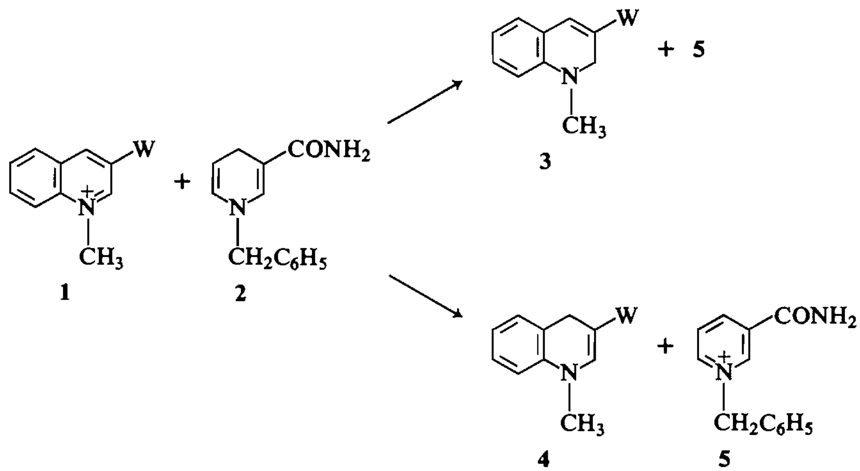
There has been considerable recent interest in kinetic studies as mechanistic probes of the reductions of nitrogen heteroaromatic cations by 1,4-dihydronicotinamide derivatives. Isoquinolinium cations (1–3) and acridinium cations (4–16) have been extensively investigated as acceptors in what are formally hydride transfer reactions. Extensive substituent and kinetic isotope effect data indicate that the mechanisms of the reductions of isoquinolinium cations by 1,4-dihydronicotinamides are best represented as simple one-step hydride transfer processes in aqueous reaction media (1, 2). Reductions of acridinium cations by 1,4-dihydronicotinamides have been the subjects of considerable mechanistic controversy. However, the recent elegant work of Powell and Bruice (14, 15) has considerably clarified the situation in this area, and these workers have concluded that the reduction of the 10-methylacridinium cation by 1,4-dihydronicotinamides in acetonitrile solution is also best represented as a direct hydride transfer process. On the other hand, kinetic data for the reductions of acridinium cations in predominantly aqueous solvents cannot be readily rationalized in the same way, and we have recently suggested (16) that the two-step $e^- + H^\cdot$ mechanism occurs in these latter solvent systems.

Comparisons of relative rates of 1,4-dihydronicotinamide reduction of isoquinolinium and acridinium cations with relative rates of hydroxide ion attack upon these cations indicate that acridinium cations are unusually reactive (approximately 40,000-fold) towards dihydronicotinamide reductants (16). This observation also supports a mechanism other than simple nucleophilic ("hydride") attack occurring in acridinium cation reductions in aqueous solutions. Furthermore, isoquinolinium and acridinium cations differ in that the former formally generate 1,2-dihydropyridine derivatives upon reduction whereas the

[1] Revision received September 5, 1984.

latter formally give 1,4-dihydropyridines.

In the light of these observations, we felt that a detailed kinetic study of the 1,4-dihydronicotinamide reduction of quinolinium cations would be very appropriate, since these cations are readily susceptible to attack at either C-2 or C-4 to give 1,2-dihydro- and 1,4-dihydroquinolines respectively. Our initial investigation in this area has concentrated upon the reduction of 3-W-1-methylquinolinium cations (**1**) by 1-benzyl-1,4-dihydronicotinamide, since detailed quantitative data are now available (17) upon the relative rates of nucleophilic (hydroxide ion) attack at C-2 and C-4 of these cations, and also upon the relative thermodynamic stabilities of the isomeric dihydroquinoline products (**3** and **4**). The current paper reports kinetic studies of these reductions, and also upon the assignment of the structures of the reaction products.



Experimental

Most 3-W-1-methylquinolinium cations **1** were available from the accompanying study (17). Salts of the 1-methyl-3-nitro-,1,2-dimethyl-, and 1,4-dimethyl-quinolinium cations, which were also available from other work in our laboratories, were recrystallized several times before use. 1-Benzyl-1,4-dihydronicotinamide and its 4,4-dideuterio derivative (using 5 oxidation–reduction cycles) were prepared as previously described (1).

3-Bromo-1,2-dihydro-1-methylquinoline

3-Bromo-1-methylquinolinium bromide (0.5 g) was treated with lithium aluminum hydride (0.02 g) in anhydrous ether for 5 min. Saturated aqueous ammonium chloride was added at 0°C, and the inorganic salts were removed by filtration. The filtrate was dried over magnesium sulfate, and the solvent removed on the rotary evaporator; ^{1}Hmr ($CDCl_3$) δ: 2.78 (3H, s), 4.20 (2H, d), 6.3–7.2 (5H, m).

Isolation of reduction products

An acetonitrile solution (2 mL) of 1-benzyl-1,4-dihydronicotinamide (0.1 *M*) was mixed with a buffered aqueous solution (5 mL) of the 3-W-1-methylquinolinium cation (0.04 *M*) and water was added to a final volume of 10 mL. This reaction mixture was stirred for 20 min after which the organic product was extracted into chloroform. After drying with magnesium sulfate, the solvent was removed on the rotary evaporator and the product was characterized by ^{1}Hmr and uv–visible spectroscopy.

Kinetic studies

All reactions excepting **1**:W = NO_2 were studied spectrophotometrically with the quinolinium cations in 20- to 10,000-fold excesses over the 1-benzyl-1,4-dihydronicotinamide (0.1 m*M*) in 20% CH_3CN – 80% H_2O (v/v) buffered at pH 7 (0.005 *M* phosphate), ionic strength 1.0 (quinolinium salt + KCl) at 25°C. Absorbance changes due to the consumption of the reductant were monitored at 390 nm. This method was not applicable to **1**:W = NO_2 since its reduction product absorbs strongly in the vicinity of 400 nm. In this case, formation of this product was monitored at 450 nm for reactions containing 20- to 200-fold excesses of reductant over the 1-methyl-3-nitroquinolinium cation. It was also necessary to study this cation (pK_{R^+} 6.82 (18)) at pH 4 (acetate buffer) since it exists significantly in the form of its C-4 pseudobase at pH 7. Control studies using **1**:W = CN indicated that rates of reduction were identical at pH 4 and pH 7.

Kinetic data were collected on either a Varian Cary 219 spectrophotometer or Durrum Gibson stopped-flow instrument (for W = CN and NO_2). All reactions proved to be kinetically strictly first order in dihydronicotinamide (or quinolinium cation, in the case of W = NO_2). Pseudo-first-order rate constants were calculated from absorbance vs. time data by standard methods.

Results

Reaction products

1-Benzyl-1,4-dihydronicotinamide reacted with each of the 1-methylquinolinium cations **1**:W = H, Br, $CONH_2$, CO_2CH_3, CN, and NO_2 in aqueous acetonitrile solution at room temperature at rates that were strongly influenced by the nature of W. For W = NO_2 the reaction is essentially instantaneous, although amenable to investigation by stopped-flow methods, while for W = H significant reaction rates are only observed when at least one of the reactants is present at relatively high concentration (0.1–1 *M*). As shown below, these reaction rates are quantitatively correlated with the electron-withdrawing effects of W.

For each substituent, the reaction products have been isolated and(or) characterized spectroscopically. After the completion of this work, Roberts *et al.* reported (19) extensive ^{1}Hmr spectral characterization of the reaction products from the reduction of **1**:W = Br, $CONH_2$, and CN by 1-benzyl-1,4-dihydronicotinamide. Since our results, including the observation of a 6:1 product ratio of **4** and **3** for W = Br, are in exact agreement with these observations, we will not detail our own ^{1}Hmr spectral study. Apart from the 3-bromo derivative, all reduction products appear to be exclusively the 1,4-dihydroquinolines (**4**) rather than their 1,2-dihydro isomers (**3**).

TABLE 1. Absorption spectra of products from the reduction of 1 by 1-benzyl-1,4-dihydronicotinamide

	λ_{max} (nm)

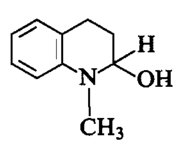
[b] Literature references in parentheses; unreferenced data from current work.
[c] Data for 3-aminocarbonyl-1,4-dihydroquinoline.
[d] Data for ethyl ester.

These conclusions are confirmed by the electronic absorption spectra listed in Table 1 for the reaction products, both in the aqueous acetonitrile reaction solvent and also in chloroform extracts of these solutions. 3-Bromo-1,2-dihydro-1-methylquinoline was prepared by lithium aluminum hydride reduction of the 3-bromoquinolinium cation, and its long wavelength absorption maximum at 344 nm in chloroform solution confirms that the predominant 1,4-dihydronicotinamide reduction product (λ_{max} = 318 nm) is the 1,4-dihydro isomer as suggested by the ¹Hmr spectral data.

We have been unable to obtain a clean ¹Hmr spectrum for the product from the reduction of the parent 1-methylquinolinium cation by 1-benzyl-1,4-dihydronicotinamide. The ¹Hmr spectra of chloroform extracts of these reactant solutions indicate complex mixtures. Ultraviolet spectra of chloroform extracts from more dilute solutions of these reactants have λ_{max} = 303 nm, which is essentially identical with the absorption maximum reported (20) for 1,4-dihydro-1-methylquinoline, and quite different from λ_{max} = 345 nm for the 1,2-dihydro isomer (21). However, we note that **4**:W = H is an enamine and would be expected to undergo hydration of the C(2)—C(3) double bond in aqueous solution to give **6**, which would also be expected to



6

absorb in the vicinity of 300 nm (e.g. 1-methyl-1,2,3,4-tetrahydroquinoline has λ_{max} 305 nm (22)). Thus while we cannot be sure of the identity of the species absorbing at 303 nm, it nevertheless seems to indicate that the primary reduction product is the 1,4-dihydro derivative **4**:W = H. This species is known to be relatively unstable towards decomposition (20), and this fact is consistent with our inability to obtain clean ¹Hmr spectra of this reaction product. Reduction at C-4 rather than at C-2 of the 1-methylquinolinium cation is also consistent with the relative rates of reduction reported below for the 1,2-dimethyl- and 1,4-dimethylquinolinium cations, and with the overall substituent effects observed for W on the rates of reduction of **1** at C-4.

Kinetic studies

Rates of reduction of the 3-W-1-methylquinolinium cations (**1**) by 1-benzyl-1,4-dihydronicotinamide were measured in 20% CH_3CN – 80% H_2O (v/v), ionic strength 1.0, at 25°C. Time-dependent electronic absorption spectra with reactants in stoichiometric ratio (excepting W = H which reacts too slowly, and W = NO_2 which reacts too rapidly, to study in this way) contain several clean isosbestic points. All reactions proved to be strictly first order kinetically for at least three reaction half-lives. Pseudo-first-order rate constants (k_{obs}) for W = H and Br display kinetic saturation effects at high concentrations of **1**. For all other W, solubility considerations only allow the use of lower concentrations of **1**. In these cases the pseudo-first-order rate constants are strictly proportional to the concentration of **1** over at least a tenfold concentration range of these cations. Second-order rate constants (k_2) evaluated from $k_2 = k_{obs}/[\mathbf{1}]$ are listed in Table 2.

For W = H and Br, plots of $1/k_{obs}$ vs. $1/[\mathbf{1}]$ are linear in the range where kinetic saturation is found. This situation is similar to that reported previously for the reduction of isoquinolinium cations (1, 2), and indicates the presence of a 1:1 complex between the quinolinium cation and 1-benzyl-1,4-dihydronicotinamide. The assumption that this complex is nonproductive, as was previously established for isoquinolinium cations, allows the evaluation of the second-order rate constants and association constants reported in Table 2.

Similar rate measurements were also made for the reduction of each quinolinium cation by 1-benzyl-4,4-dideuterio-1,4-dihydronicotinamide. These second-order rate constants are also included in Table 2, along with the (predominantly) primary kinetic isotope effects calculated from these data.

Rates of reduction were also measured for the reaction of the 1,2-dimethylquinolinium and 1,4-dimethylquinolinium cations with 1-benzyl-1,4-dihydronicotinamide. Kinetic saturation was observed for the former cation; however, solubility considerations prevented the investigation of this phenomenon for the latter cation. Kinetic parameters for these two cations are also included in Table 2.

Discussion

Reaction products

The above spectral data are consistent with the products of reduction of 3-W-1-methylquinolinium cations by 1-benzyl-1,4-dihydronicotinamide being predominantly (and possibly exclusively for most W) the corresponding 3-W-1,4-dihydro-1-methylquinolines. The 3-bromo derivative is the only case where any significant amount (15%) of the 1,2-dihydro isomer can be detected spectroscopically. These product distributions contrast with those observed for the borohydride ion reductions of these same cations (19, 23); such reductions give the 1,2-dihydro derivatives as the major kinetic products, although significant amounts of the 1,4-dihydro isomers are also usually present in the initial product mixture.

Roberts *et al.* (19) have shown that 3-cyano-1,2-dihydro-1-methylquinoline isomerizes to its 1,4-dihydro isomer with the equilibrium between these two species favouring the latter isomer by about 20:1 in 80% 2-propanol – 20% water. This ratio is consistent with the observation that the thermodynamic mixture of pseudobases derived from the 3-cyano-1-methylquinolinium cation favours the C-4 hydroxide adduct over the C-2 adduct in a 26:1 ratio (17). Studies of pseudobase formation indicate the greater thermodynamic stability of the 1,4-dihydroquinoline over its 1,2-dihydro isomer for 3-W-quinolines having W = NO_2, CN, CO_2CH_3, and $CONH_2$, whereas the 1,2-dihydroquinolines are the thermodynamically more stable pseudobases for W = H and Br (17). On the

TABLE 2. Kinetic parameters for the reduction of **1** by 1-benzyl-1,4-dihydronicotinamide[a]

W	k_2^H (M^{-1} s^{-1})	K (M)	k_2^D (M^{-1} s^{-1})	K (M)	k_2^H/k_2^D
H	$5 (\pm 0.5) \times 10^{-3}$	1.9 ± 0.2	$1.2 (\pm 0.1) \times 10^{-3}$	2.1 ± 0.1	4.2 ± 0.7
Br	0.38 ± 0.01[b]	0.70 ± 0.05	0.065 ± 0.005[b]		5.8 ± 0.5
$CONH_2$	2.8 ± 0.1		0.54 ± 0.04		5.2 ± 0.4

CN	121 ± 2		67 ± 2		1.8 ± 0.1
NO_2	$6.5 (\pm 0.2) \times 10^3$		$4.4 (\pm 0.1) \times 10^3$		1.5 ± 0.1
1,2-Dimethylquinolinium	$1.3 (\pm 0.2) \times 10^{-3}$	1.9 ± 0.2			
1,4-Dimethylquinolinium	$2.8 (\pm 0.5) \times 10^{-4}$				

[a]Data in 20% CH_3CN – 80% H_2O (v/v), ionic strength 1.0 at 25°C.
[b]Combined rate constant for reduction at C-2 and C-4.

assumption that these relative thermodynamic stabilities of pseudobases are also applicable to the corresponding dihydroquinolines, it becomes clear that the reduction of **1** by 1-benzyl-1,4-dihydronicotinamide gives the thermodynamically more stable products for W = $CONH_2$, CO_2CH_3, CN, and NO_2 but the less stable products for W = H and Br.

The 1,4-dihydroquinolines can be established to be the products of kinetic control for these four strongly electron-withdrawing W substituents in the following way. The clean isosbestic points observed for stoichiometric ratios of reactants does not allow the presence of any significant buildup of an intermediate species during the course of these reactions. If any significant amount of the 1,2-dihydro isomer were initially produced in these reductions its presence would become quite obvious from its characteristic electronic absorption spectrum (Table 1), and the fact that its isomerization to the 1,4-dihydro isomer is expected to be much slower than the observed rates of reduction. For instance, Roberts *et al.* (19) report the second-order rate constant to be 0.05 M^{-1} s^{-1} for the reaction of 3-cyano-1,2-dihydro-1-methylquinoline with the 3-cyano-1-methylquinolinium cation to give the 1,4-dihydro isomer in 80% 2-propanol – 20% water at room temperature. This reaction, which represents the most probable mechanism for all such isomerizations, is over 2000-fold slower than the measured second-order rate constant (Table 2) for the reaction of **1**:W = CN with 1-benzyl-1,4-dihydronicotinamide. Thus in this case, and presumably for other W substituents too, the 1,2-dihydro species can be ruled out as an intermediate in these reductions, and there can be little doubt that the observed products are also the predominant products of kinetic control.

Our spectroscopic observations also give no evidence for covalent adduct formation between C-5 of the 1,4-dihydronicotinamide and either C-2 or C-4 of the quinolinium cation, as has been speculated upon (13, 51), but never established, for acridinium cations. We note that Roberts *et al.* (19) also did not observe such adducts in their studies of the reduction of quinolinium cations, and we can conclude that if such species do exist, they can only be present in insignificant concentrations under the current reaction conditions.

This preponderance of C-4 attack in the reduction of **1** by 1-benzyl-1,4-dihydronicotinamide contrasts with the somewhat greater rate of attack at C-2 than at C-4 in the borohydride ion reduction of these cations (19), and with the much greater rate of hydroxide ion attack at C-2 than at C-4 in pseudobase formation (17). 4-Cyano-1,4-dihydro-1-methylquinoline is the sole product isolated from reaction of cyanide ion with **1**:W = H (26–28). It is not clear, however, whether this is the product of kinetic control, thermodynamic control, or simply the species which has the lowest aqueous solubility.

TABLE 3. Comparison of relative rates of attack at C-2 and C-4 of the 3-bromo-1-methylquinolinium cation[a]

Reagent	k^4/k^2	Rel. k^4/k^2
1-Benzyl-1,4-dihydronicotinamide[b]	6	9000
Borohydride ion[c]	<0.05	<70
Hydroxide ion[d]	7×10^{-4}	1

[a]k^4/k^2 represents the ratio of the second-order rate constants for attack at C-4 and C-2 by the indicated reagent.
[b]Data from current work.
[c]Data from ref. 19.
[d]Data from ref. 17.

The only quantitative measure that we can obtain of the relative rates of 1-benzyl-1,4-dihydronicotinamide reduction at C-2 and C-4 is for the case of **1**:W = Br. We feel that the 6:1 product ratio observed in this case probably represents kinetic control, since this ratio proved to be independent of whether the quinolinium cation or the reductant was in excess. This ratio should vary for such differences in reactant excess if an isomerization involving the quinolinium cation is occurring at any significant rate. The overall second-order rate constant for reduction of **3**:W = Br has therefore been partitioned in this ratio. Table 3 compares the relative rates of dihydronicotinamide reduction and borohydride ion and hydroxide ion attack at C-2 and C-4 for the 3-bromo-1-methylquinolinium cation. These data indicate that although the product ratio is only 6:1 in this reduction, this ratio actually represents a kinetic preference for C-4 over C-2 of 9000-fold in dihydronicotinamide reduction relative to hydroxide ion attack, and of at least 120-fold relative to borohydride ion.

This pronounced difference in kinetic preferences for attack at C-2 and C-4 in borohydride and dihydronicotinamide reductions of quinolinium cations requires that, whatever the mechanistic details of these reactions may be, they cannot both be represented by rate-determining transition states which formally involve hydride migration without a further role for either the nicotinamide or boron-containing species. If one accepts that cyanide ion does show a kinetic preference for C-4, then one might suggest that soft nucleophiles (29) such as this preferentially attack C-4, whereas harder nucleophiles such as hydroxide ion show a kinetic preference for C-2. In this light, at the very least it must be concluded that the transition states for borohydride and dihydronicotinamide reductions differ in having a much "harder" hydridic nucleophile in the former case than in the latter.

Lithium aluminum hydride also reduces both the 1-methylquinolinium cation (20, 30) and its 3-bromo derivative (current work) cleanly at C-2. Reduction of 3-W-1-methylquinolinium cations (W = $CONH_2$, CO_2CH_3, or CN) with triethylammonium formate gives the 1,4-dihydro derivatives (24, 31, 48) which are also expected to be the thermodynamically more stable dihydro isomers. Labelling experiments using DCO_2^- suggest that these 1,4-dihydro derivatives are also the products of kinetic control (48). Thus formate and 1,4-dihydronicotinamide reductions of quinolinium cations seem to show a kinetic preference for C-4 reduction in contrast to the preference for C-2 shown by complex metal hydride reductants. Dithionite reduction of **1**: W = Br or $CONH_2$ gives exclusively the 1,4-dihydro isomer (19, 32); however, the product from this reaction depends upon the relative reactivities of the C-2 and C-4 dithionite ion adducts. Interestingly, a transient orange species is reported as an intermediate in the dithionite reduction of **1**: W = $CONH_2$ (32). Although this intermediate has been assumed to be a charge-transfer complex, it seems equally possible that it is a 1,2-dihydroquinoline derivative as the product of kinetic control.

Sodium amalgam reduction of the 1-methylquinolinium cation does give the 1,4-dihydro derivative without any evidence for the presence of the more stable 1,2-dihydro isomer (20). This reaction, like other sodium amalgam reductions (33), probably proceeds through radical intermediates. It is also known that alkyl radicals show about equal reactivities at C-2 and C-4 of quinolinium cations (34, 35), and this contrasts with the specific addition at C-2 observed for dialkyl cadmiums and Grignard reagents (36).

These examples seem to suggest that reactions of quinolinium cations which occur via radical intermediates show a more pronounced kinetic preference for C-4 over C-2 relative to what is observed for direct nucleophilic attack on these cations. Thus the observation of exclusively C-4 reduction products from the kinetic control of dihydronicotinamide reduction of quinolinium cations is consistent with expectations for reaction via one of the one-electron mechanisms ($e^- + H^{\bullet}$ or $e^- + H^+ + e^-$) that are often considered for these reductions. This possibility is considered further below.

Kinetic studies

The kinetic saturation effects observed for the pseudo-first-order rate constants for reduction of several quinolinium cations are similar to those observed previously for the reduction of a number of isoquinolinium cations (1–3). It has been concluded that this phenomenon arises from the formation of nonproductive 1:1 complexes between the isoquinolinium cation and dihydronicotinamide, with complexation involving an interaction between the dihydronicotinamide and the homocyclic ring of the isoquinoline. A similar interpretation seems reasonable for the quinolinium cations of the current study since the association constants reported in Table 2 are essentially identical to those found for the 2-methylisoquinolinium (K = 2.1 M^{-1} (2)) and 2-methyl-3,4-dihydroisoquinolinium (K = 1.4 M^{-1} (3)) cations. This interpretation allows evaluation of second-order rate constants for reduction, and is supported by the clean substituent effects upon k_2 discussed below.

The second-order rate constants given in Table 2 for reduction at C-4 of **1** are correlated with the Hammett σ constants for the substituents W as indicated in eqs. [1] and [1a] for k_2^H and [2] and [2a] for k_2^D.

[1] $\log k_2^H = 4.5\ (\pm 0.3)\ \sigma_p^- - 2.1\ (\pm 0.2)$ (corr. coeff. = 0.991)

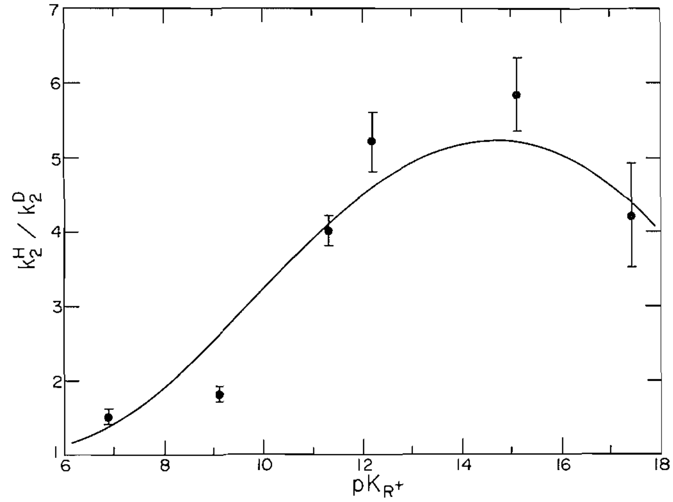

FIG. 1. Dependence of the primary kinetic isotope effects for the reduction of **1** by 1-benzyl-1,4-dihydronicotinamide (and its 4,4-dideuterio derivative) on pK_{R^+} for **1**. The curve is calculated from eq. [6] using the parameters given in the text.

[1a] $\log k_2^H = 7.5\ (\pm 0.5)\ \sigma_p - 2.3\ (\pm 0.3)$ (corr. coeff. = 0.990)

[2] $\log k_2^D = 4.9\ (\pm 0.3)\ \sigma_p^- - 2.9\ (\pm 0.2)$ (corr. coeff. = 0.992)

[2a] $\log k_2^D = 8.2\ (\pm 0.6)\ \sigma_p - 3.2\ (\pm 0.3)$ (corr. coeff. = 0.990)

The correlations with either of the *para* substituent constants are quite acceptable, while correlations with σ_m are much poorer (correlation coefficients of 0.931 and 0.930 for k_2^H and k_2^D respectively). In each case the use of σ_p^- rather than σ_p gives a correlation that is marginally better. Alternatively these rate constants may be correlated with the pK_{R^+} values for pseudobase formation at C-4 of these quinolinium cations (17):

[3] $\log k_2^H = -0.54\ (\pm 0.04)\ pK_{R^+} + 7.3\ (\pm 0.4)$ (corr. coeff. = 0.991)

[4] $\log k_2^D = -0.59\ (\pm 0.04)\ pK_{R^+} + 7.4\ (\pm 0.5)$ (corr. coeff. = 0.992)

Equations [3] and [4] imply that positive charge neutralization is 55–60% complete in the rate-determing transition state for the dihydronicotinamide reduction of these quinolinium cations. This implication, that charge development in the transition state is similar for all W, is difficult to rationalize, however, in view of the pronounced substituent dependence of the primary kinetic isotope effects in Table 2. These isotope effects imply significant variations in the extent of C—H bond-breaking at C-4 of the dihydronicotinamide species in the transition state, and also presumably signal variations in the extent of C—H bond-making at C-4 of the quinolines. It seems unlikely that significant differences in C—H bond formation at C-4 of these quinolines can be achieved without influencing the effective charge on the quinoline moiety as a whole in the transition state.

The overall dependence of k_2^H/k_2^D in Table 2 appears to vary smoothly with the electronic effect of W, and to pass through a maximum value in the vicinity of W = Br. This relationship is illustrated in Fig. 1, in which the substituent effect is quantitated in terms of pK_{R^+} for pseudobase formation at C-4 of **1**.

Although eqs. [3] and [4] individually give quite reasonable fits to the experimental data, the combination of these equations cannot predict the maximum observed for k_2^H/k_2^D. The maximum four-fold variation in isotope effect is hidden in the greater that 10^6-fold variation in k_2^H and k_2^D individually. Stewart and Toone (37) have studied substituent effects upon the reduction of triphenylmethyl cations by formate ion and found these data to be well correlated with a quadratic equation of the form of eq. [5]:

$$[5] \quad \log k_2 = a\,(pK_{R^+})^2 + b\,pK_{R^+} + c$$

We have attempted to fit both k_2^H and k_2^D to eq. [5]. Although we are able to obtain reasonable fits of our experimental data, the uncertainties in the values of the parameters a, b, and c are quite large because of the very shallow curvature required to fit the data.

The data of Fig. 1 may be fitted to eq. [6]. An iterative curve-fitting routine allowed evaluation of the parameters as: $d = 1.66 \pm 0.13$; $e = 14.6 \pm 0.2$; $f = 8.4 \pm 1.4$.

$$[6] \quad \ln (k_2^H/k_2^D) = d\,(1 - ((pK_{R^+} - e)/f)^2)$$

Equation [6] has the form of the Marcus relationship in eq. [7] (38, 39), with $d = \ln (k_2^H/k_2^D)^{max}$, $\Delta G^0 = -2.3RT\,(pK_{R^+} - e)$, and $f = 4\Delta G_0^{\ddagger}/2.3RT$.

$$[7] \quad \ln (k_2^H/k_2^D) = \ln (k_2^H/k_2^D)^{max}\,(1 - (\Delta G^0/4\Delta G_0^{\ddagger})^2)$$

These relationships allow the evaluation of $(k_2^H/k_2^D)^{max} = 5.3 \pm 0.7$ and $\Delta G_0^{\ddagger} = 2.9 \pm 0.5$ kcal/mol. This latter value is similar to the intrinsic barrier reported for other reactions which are formal hydride transfer processes. Thus Bethel *et al.* (40) report 3.5 kcal/mol for hydride transfer between di- or triarylmethanes and 9-arylfluorenyl cations, while Stewart and Toone's data for the reduction of triphenylmethyl cations by formate anions yield an intrinsic barrier of 2.5 kcal/mol (37, 40). To the best of our knowledge, these latter two reactions represent the only previous examples of "Westheimer maxima" (41) for primary kinetic isotope effects in reactions which formally involve hydride transfer.

The maximum isotope effect of 5.3 found in the present study is considerably larger than the maxima of 3.9 and 2.8 reported in these earlier two investigations of hydride transfer reactions. It is therefore much closer to the theoretical maximum of 6.9 at 25°C for a symmetrical transition state for a one-step hydrogen transfer process (42). The e parameter in eq. [6] represents the pK_{R^+} for the quinolinium cation for which the maximum value of k_2^H/k_2^D is achieved (i.e. $\Delta G^0 = 0$). Thus $pK_{R^+} = 14.6$ should correspond to a transition state which most closely approximates equivalent bond-breaking at C-4 of the nicotinamide moiety and bond-formation at C-4 of the quinoline species. On the assumption that these reactions do involve one-step hydride migration processes, one would predict that such a symmetrical transition state would occur for that quinolinium cation that most closely matches the 1-benzylnicotinamide cation in its susceptibility to nucleophilic attack.

This then suggests that, to a first approximation, one might assign $pK_{R^+} = 14.6$ to the 1-benzylnicotinamide cation. Several linear free energy relationships between rate and equilibrium constants for hydroxide ion attack are available for quinolinium and isoquinolinium cations (17, 43), although analogous data are not readily obtainable for pyridinium cations. For nicotinamide cations, pK_{R^+} values are not directly measurable because of the ionization of the amide proton in basic solution rather than hydroxide ion attack (44). For the 3-acetyl-1-methylpyridinium cation a value of $pK_{R^+} = 13.3$ has been measured (44). If one assumes that the known substituent effects upon equilibrium constants for cyanide ion addition at C-4 of pyridinium cations exactly parallel substituent effects for hydroxide ion addition, one might attempt to predict pK_{R^+} for the 1-benzylnicotinamide cation using $\Delta pK_{R^+} = +2.2$ for $CONH_2$ vs. $COCH_3$ (45), and $\Delta pK_{R^+} = -1.1$ for benzyl vs. methyl (46). Thus $pK_{R^+} = 13.3 + 2.2 - 1.1 = 14.4$, which is remarkably close to the value of e obtained for eq. [6].

This analysis makes it clear that the maximum in the curve in Fig. 1 occurs at, or close to, $\Delta pK_{R^+} = 0$, i.e. an equilibrium constant of 1 for hydride transfer in the reaction

$$\mathbf{1} + \mathbf{2} \rightleftharpoons \mathbf{4} + \mathbf{5}$$

This observation is consistent with theoretical considerations.

The substitution of $pK_{R^+} = 14.6$ into eq. [3] leads to $k_2^H = 0.26\,M^{-1}\,s^{-1}$ at the maximum on the curve in Fig. 1. This value is six-fold larger than the largest of the range of second-order rate constants $((6.5 \times 10^{-4}) - (4.3 \times 10^{-2})\,M^{-1}\,s^{-1})$ reported by Roberts *et al.* (49) for a series of degenerate hydride transfers in 80% 2-propanol – 20% water at 25°C. However, in view of the 66-fold variation in the second-order rate constant for these degenerate hydride transfers, and the small solvent change, it would not be unreasonable to suggest that the current value represents a member of this class of one-step hydride transfers having $K = 1$.

The elucidation of the dramatically enhanced susceptibility towards dihydronicotinamide reduction of acridinium cations relative to isoquinolinium cations (16) was one of the major considerations in our undertaking the current study. Our product studies clearly indicate that the dihydronicotinamide reduction of quinolinium cations shows a pronounced kinetic preference for the formation of the 1,4-dihydroquinoline products over their 1,2-dihydro isomers, despite the inherently greater susceptibility of C-2 to nucleophilic attack. As indicated above, attack at C-4 of quinolinium cations seems to be more readily attributable to a mechanism involving a radical intermediate than to a direct hydride transfer. We have recently argued for an $e^- + H^\bullet$ mechanism in the case of the acridinium cations (16) and so a consideration of this possibility in the case of the quinolinium cations seems necessary.

Assuming that eq. [3] may also be applicable to acridinium cations, one would predict a second-order rate constant of 80 $M^{-1}\,s^{-1}$ for the reduction of the 10-methylacridinium cation ($pK_{R^+} = 10.01$ (47)) by 1-benzyl-1,4-dihydronicotinamide. This value is five-fold smaller than the experimental value of 400 $M^{-1}\,s^{-1}$ (16) under the current experimental conditions. Equation [6] predicts $k_2^H/k_2^D = 3.2$ for the reduction of the 10-methylacridinium cation. This value is somewhat larger than the experimental isotope effect of 1.56 (16). However, if k_2^H/k_2^D is considered as function of $\log k_2^H$ (Fig. 2) rather than of pK_{R^+} as in Fig. 1, then the acridinium cation does appear to conform to the data for these substituted quinolinium cations.

We previously attributed (16) this relatively small isotope effect in the reduction of the 10-methylacridinium cation to the fact that the electron transfer and the hydrogen atom transfer occur at similar rates and thus neither step is clearly rate determining. The isotope effects for W = CN and NO_2 in Table 2 are similar in magnitude to those observed for the acridinium cation, and may possibly arise in this same way. However, for the other W substituents in Table 2 the much larger isotope effects seem to imply that hydrogen atom transfer is rate deter-

TABLE 4. Comparison of relative rates of 1-benzyl-1,4-dihydronicotinamide reduction (k_2) and hydroxide ion attack (k_{OH}) on heterocyclic cations of $pK_{R^+} = 10.0$

Cation	$k_2(M^{-1}\ s^{-1})$	$k_{OH}(M^{-1}\ s^{-1})$	k_2/k_{OH}	$(k_2/k_{OH})^{rel}$
10-Methylacridinium	400[a]	550[b]	0.7	9×10^4
Quinolinium	80[c]	5000[d]	0.016	2×10^3
Isoquinolinium	1.3[e]	1.7×10^5[f]	8×10^{-6}	1.0

[a]From ref. 16.
[b]From ref. 47.
[c]Calculated from eq. [3] for $pK_{R^+} = 10.0$.
[d]Calculated from $\log k_{OH} = -0.46\ pK_{R^+} + 8.3$ (ref. 17) for hydroxide attack at C-4 with $pK_{R^+} = 10.0$.
[e]Calculated from $\log k_2 = -0.50\ pK_{R^+} + 4.9$ (ref. 2) for $pK_{R^+} = 10.0$.
[f]Calculated from $\log k_{OH} = -0.36\ pK_{R^+} + 8.84$ (ref. 43) for $pK_{R^+} = 10.0$.

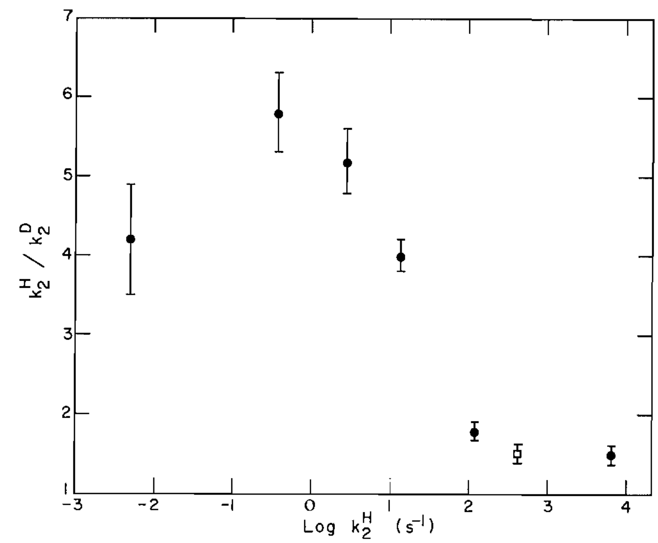

FIG. 2. Dependence of the primary kinetic isotope effects for the reduction of quinolinium cations **1** (●) and the 10-methylacridinium cation (□) by 1-benzyl-1,4-dihydronicotinamide (and its 4,4-dideuterio derivative) upon $\log k_2^H$.

mining. It is difficult to accommodate this within the $e^- + H^{\bullet}$ mechanism since this would require that complete positive charge neutralization should occur on the quinoline prior to hydrogen atom transfer. Equation [3] implies that such does not seem to be the case.

A quantitative comparison of the relative susceptibilities of acridinium, quinolinium, and isoquinolinium cations to dihydronicotinamide reduction and hydroxide ion attack is given in Table 4. From the linear free energy relationships that are available for the rates of both dihydronicotinamide reduction and hydroxide ion attack upon quinolinium and isoquinolinium cations it is possible to estimate rate constants for each of these processes for quinolinium (at C-4) and isoquinolinium cations of $pK_{R^+} = 10.0$. Because the 10-methylacridinium cation also has $pK_{R^+} = 10.0$, the kinetic data in Table 4 are uncomplicated by thermodynamic effects, since the equilibrium constants are identical in each of these three heterocyclic systems for each of these reactions. From Table 4 it is clear that while the isoquinolinium cation is much more reactive towards hydroxide ion than the other two heterocyclic cations, it is much less reactive in dihydronicotinamide reductions. The relative reactivities of these cations indicate that the quinolinium and acridinium cations are 2×10^3 and 9×10^4 respectively more reactive in dihydronicotinamide reductions than expected on the basis of relative reactivities to nucleophilic attack as exemplified by hydroxide ion as the nucleophile.

Dihydronicotinamide reductions of isoquinolinium cations have been established to involve a transition state in which the attacking hydride species bears a significant fractional negative charge (1, 3). The dramatically enhanced rates of dihydronicotinamide reduction in the quinolinium and acridinium series argue against such an "hydridic" transition state in these cases. We have previously argued in favour (16) of the $e^- + H^{\bullet}$ two-step mechanism for acridinium cation reduction.

The primary kinetic isotope effects observed for the 3-cyano- and 3-nitro-1-methylquinolinium cations and the 10-methylacridinium cations are significantly smaller than the range $k_2^H/k_2^D = 4.42-5.95$ reported by Ostovic *et al.* (50) for a series of analogous reactions which are believed to be one-step hydride transfer processes to various nitrogen heterocyclic cations. This in itself is suggestive of a mechanism other than direct hydride transfer in these three cases. On the other hand, reduction of the quinolinium cations **1**:W = H, Br, $CONH_2$, and CO_2CH_3 does give k_2^H/k_2^D values in the range associated with one-step hydride transfers (50), and, as indicated above, the Marcus fit in eq. [7] does give an intrinsic barrier similar to that observed in two other classes of reactions which have been interpreted as direct hydride transfers. At the present time we cannot definitively rule out the possibility of a change in mechanism between these two groups of substituents in **1**.

We have then a situation in which C-4 attack in the dihydronicotinamide reduction of these quinolinium cations seems to be too rapid to be consistent with an "hydridic" transition state such as is indicated in the corresponding isoquinolinium cation reductions. However, the alternative $e^- + H^{\bullet}$ mechanism attributed to the acridinium cations does not seem to be suitable for all W in **1**. We are currently pursuing the electronic structure of the transition state in these reactions via further substituent effect studies in the hope that such data will further clarify the mechanisms of these reactions.

Kinetics and mechanisms of oxidations by metal ions. Part IV.[1] Oxidation of phenylphosphinic acid by aquavanadium(V) ions

RAJ NARAIN MEHROTRA
Department of Chemistry, University of Jodhpur, Jodhpur 342 001, India

Received January 16, 1984[2]

RAJ NARAIN MEHROTRA. Can. J. Chem. **63**, 663 (1985).

The kinetics of the oxidation of phenylphosphinic acid by quinquevalent vanadium ion have been investigated in aqueous perchlorate media under pseudo-first order conditions (phenylphosphinic acid in excess). The reaction has a first order dependence in [V(V)] and [phenylphosphinic acid] and the observed pseudo-first order rate constant k_{obs} is given by $k_{obs} = a + b[H^+]$.

The acid-independent path is considered to be due to the reaction between VO_2^+ (aq.) and $C_6H_5P:(OH)_2$, the active form of phenylphosphinic acid, while the reaction between $V(OH)_3^{2+}$ (aq.) and $C_6H_5P(O)(OH)H$, the inactive form of phenylphosphinic acid, is considered to explain the acid-dependent path. Phenylphosphinic acid in aqueous acidic solution is known to exist as an equilibrium mixture of the active and inactive forms. The composite activation and thermodynamic parameters associated with the constants a and b are reported.

RAJ NARAIN MEHROTRA. Can. J. Chem. **63**, 663 (1985).

Opérant dans un milieu aqueux d'acide perchlorique et sous des conditions de pseudo-premier ordre (acide phénylphosphinique en excès), on a étudié l'oxydation de l'acide phénylphosphinique par l'ion vanadium pentavalent. La réaction est du premier ordre en vanadium(V) et en acide phénylphosphinique et la constante de vitesse du pseudo-premier ordre qui est observée (k_{obs}) est définie par l'équation $k_{obs} = a + b[H^+]$.

On croit que la voie d'oxydation qui n'est pas influencée par la présence d'acide est due à la réaction du VO_2^+ (aq.) avec le $C_6H_5P:(OH)_2$, la forme active de l'acide phénylphosphinique; par ailleurs, on croit que la voie d'oxydation qui est influencée par les acides peut être expliquée en faisant appel à une réaction entre l'ion $V(OH)_3^{2+}$ (aq.) et la forme inactive de l'acide phénylphosphinique, $C_6H_5P(O)(OH)H$. Il est connu que l'acide phénylphosphinique, en milieu acide aqueux, existe sous la forme d'un mélange à l'équilibre entre les formes active et inactive. On rapporte les valeurs observées pour les paramètres thermodynamiques et d'activation associés avec les constantes a et b.

[Traduit par le journal]

Introduction

The structure of phenylphosphinic acid in form **A** has been confirmed by nuclear magnetic resonance and infrared spectroscopy (2). However, on the basis of chemical evidence a suggestion was made (3) about the existence of the tautomer **B** too, with tautomer **A** as the overwhelming predominant species. The tautomer **A** is known as the inactive form and the tautomer **B** is known as the active form.

[1] 
Form A Form B

The oxidation of phenylphosphinic acid by quinquevalent vanadium ion in 3.5–6.0 mol dm^{-3} perchloric acid has been reported (4). This study (4) suggested that the form **B** predominated in aqueous acidic solution and therefore it was considered to be the reactive species. Assuming that the equilibrium constant for [1] is not appreciably different from the equilibrium constant for the similar equilibrium in hypophosphorous acid for which K is of the order of 10^{-12} (2), the assumption that form **B** predominated seemed to be erroneous. The formation of phosphonium ion, $Ph\overset{+}{P}O_2H$, in the rate-limiting step was also suggested, which by implication meant that vanadium(V) underwent a two-electron change. Since the reaction was studied in perchloric acid solution > 3.5 mol dm^{-3}, nothing is known about the nature of the reaction at lower acid concentration, particularly the dependence of k_{obs} on lower [H$^+$]. Hence a reinvestigation became desirable to gain the insight about the reactive form of phenylphosphinic acid and other parameters.

The reinvestigation was therefore carried out at lower concentrations of perchloric acid, 0.5–3.0 mol dm^{-3}, at constant ionic strength of 3.0 mol dm^{-3}. The results thus obtained have indicated a different dependence of k_{obs} on [H$^+$], the formation of a free radical in the rate-limiting step indicating vanadium(V) to be a one-electron oxidant and that both of forms **A** and **B** are reactive.

Experimental

Reagents

The stock vanadium(V) solution was prepared from ammonium trioxovanadate(V) (Hopkin and Williams, GPR grade). The perchloric acid (E. Merck, GR) concentration present in the stock solution was taken as the difference between the known amount added minus the amount neutralised by the standard aqueous vanadium(V) solution according to the relation [2]. Hence an extrapolation of the rate to zero concentration of perchloric acid would mean that vanadium(V) species present in the system is VO_2^+(aq.).

[2] $VO_3^- + 2H^+ \rightarrow VO_2^+ + H_2O$

Phenylphosphinic acid (Fluka) was twice recrystallised from hot water, mp 70–71°C (lit. 5, 71°C). Solutions were prepared by direct weighing of the recrystallised sample and strength determined against a standard alkali. Because of its limited solubility, values of k_{obs} at high concentrations of phenylphosphinic acid could not be determined.

Perchloric acid was suitably diluted and standardised against a standard alkali. Sodium perchlorate, used to maintain the ionic strength at 3.0 mol dm^{-3}, was prepared by the neutralisation of sodium carbonate by perchloric acid.

All other chemicals were of standard grade and used as supplied.

[1]For Part III, see ref. 1.

[2]Revision received September 6, 1984.

Distilled water was once redistilled from alkaline permanganate using an all-glass still.

Kinetic studies

The kinetic experiments were carried out under pseudo-first order conditions where excess concentration of phenylphosphinic acid over vanadium(V) was present in the reaction mixtures. The disappearance of vanadium(V) was followed by using a volumetric method described elsewhere (6). However, in adopting the method it was ensured that the presence of phenylphosphinic acid in a concentration present in the reaction mixtures did not change the titre value of ferrous ammonium sulphate solution, in which the reaction mixture was quenched, with vanadium(V). Barium *N*,*N*-diphenylsulphamate in the presence of phosphoric acid was used as indicator. The runs were studied until the reaction was 80–90% complete. The pseudo-first order rate constant k_{obs} was calculated from the gradient of the linear plots obtained between ln [V(V)] and time. Such plots were linear for three half-lives and beyond. The k_{obs} values from replicate runs were reproducible within ±3% and the mean values are in the tables.

Stoichiometry

A series of determination carried out in reaction mixtures having [V(V)] > [PPA] (PPA is the abbreviated form of phenylphosphinic acid) at different acidities indicated that $\Delta[V(V)]/\Delta[PPA] = 1.93 \pm 0.1$. That phenylphosphonic acid, the reaction product, was not further oxidised was confirmed by the failure of an authentic sample to reduce vanadium(V). Hence the stoichiometric equation of the reaction is given by [3].

$$[3]\quad C_6H_5P(O)(OH)H + 2V(V) + H_2O \rightarrow C_6H_5P(O)(OH)_2 + 2V(IV) + 2H^+$$

Results

The invariance of k_{obs} with varying [V(V)] is indicative of the first-order dependence of the reaction in vanadium(V). The order with respect to phenylphosphinic acid, Table 1, was one. The plot between k_{obs} and [PPA] was linear and passed through the origin. The effect of $[H^+]$ on k_{obs} was investigated at different temperatures. The results are reported in Table 2. The plot between k_{obs} and $[H^+]$, Fig. 1, was linear for all the five temperatures with an intercept on the rate ordinate. The k_{obs} at constant [PPA] and $[H^+]$ was independent of ionic strength (Table 3). Thus the previous observations (4) about the order of the reaction with respect to the oxidant and substrate are confirmed.

Mechanism and discussion

The hydrogen atom attached to phosphorous in phenylphosphinic acid undergoes isotopic exchange with deuterium in H_2O/D_2O solution, probably via the formation of an intermediate having structure **B**. The rate of the acid catalysed hydrogen exchange in 50% ethanol-*d*–D_2O(v/v) solution has been studied (7) and the following mechanism with reaction [5] as the rate determining was suggested.

[4] 
[5] 
[6] 
[7] 
The above mechanism yields the rate law given in eq. [8] which is consistent with the observed first-order dependence in phenylphosphinic acid.

[8] 
$$= \frac{k_1k_3[C_6H_5P(O)(OH)H][D^+]}{k_2 + k_3}$$

Since the plot between observed first order exchange rate constant k_{ex} for hydrogen exchange, with respect to phenylphosphinic acid, and [DCl] had an intercept on the rate ordinate, it was suggested (7) that

$$[9]\quad k_{ex} = k_H[D^+] + k_w$$

where k_H is the catalysis constant for the hydrogen (deuterium) ion and k_w is the specific rate of acid-independent exchange of the unprotonated pentacovalent species in the stated solvent. The value of k_H is 3.5×10^{-4} dm^3 mol^{-1} s^{-1} and $k_w = 2.0 \times$

10^{-4} s^{-1}, both at 23°C (7).

The k_H and k_w values for aqueous solution from the data (7) could not be determined. However, an assumption that could be made without any serious error is that the order ($\sim 10^{-4}$) of the k_H and k_w values will not be changed for the aqueous solution. The correlation between k_H and k_1, k_2, and k_3, deduced from eq. [8] and [9] is given in [10].

$$[10] \quad k_H = \frac{k_1 k_3}{k_2 + k_3}$$

where in view of the reactions [4]–[7] it is understood that $k_1 > k_2$, $k_3 > k_2$, and k_4, $k_5 \gg k_3$.

The pK_a value of monobasic phenylphosphinic acid is 1.75 at 25°C (8). Hence it is clear that almost all of it will exist in the undissociated state in the presence of [$HClO_4$] used in the study which will be therefore the reactive species. It might be mentioned here that if the phenylphosphinate ion were to be the reactive species a retardation in the k_{obs} was expected with increasing [H^+] which is not the case.

In view of the dependence of k_{obs} on [H^+], Fig. 1, the following reactions are considered for the mechanism of the reaction and the justification for the same is deferred to a later stage of discussion.

The rate of disappearance of vanadium(V) in terms of reactions [1] and [11]–[14] with reactions [12] and [13] as rate

[1] 
$$[11] \quad VO_2^+(aq.) + H_3O^+ \overset{K_1}{\rightleftharpoons} V(OH)_3^{2+}(aq.)$$

[12] 
[13] 
[14] 
determining is given by eq. [15] because $1 \gg K_1[H^+]$ in the range 1–5 mol dm^{-3} perchloric acid (9–13), and $1 \gg K$ because K for phenylphosphinic acid is considered to be not much different from K for hypophosphorous acid for which it has a value of the order of 10^{-12} (2, 14).

$$[15] \quad k_{obs} = 2(k_6K + k_7K_1[H^+])[C_6H_5P(O)(OH)H]$$

The above mechanism thus differs from that proposed by earlier workers (4) in the sense that (*a*) VO_2^+(aq.) and $V(OH)_3^{2+}$(aq.) ions are reactive where VO_2^+(aq.) is written for $(VO_2.2H_2O)^+$ (15), (*b*) both inactive **A** and active **B** forms of phenylphosphinic acid are reactive, (*c*) k_{obs} is the sum total of two components, one independent and the other is dependent on [H^+], and (*d*) the rate-controlling step is the formation of a free radical instead of phosphonium ion (4).

The formation of the free radical was checked by the induced

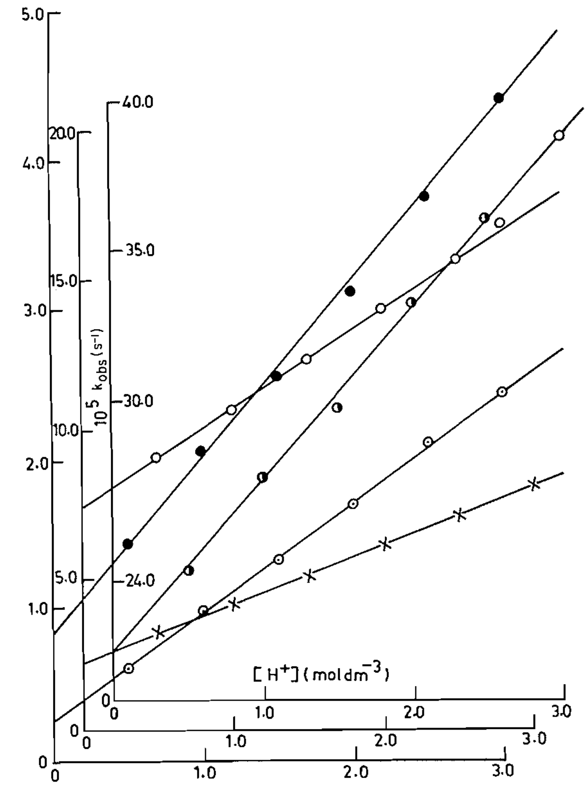

FIG. 1. Dependence of k_{obs} on [H^+] in the reaction with 10^2 [V(V)] = 1.0, 10^2 [PPA] = 8.0, and I = 3.0 mol dm^{-3} at 40°C (⊙), 45°C (●), 50°C (×), 55°C (○), and 60°C (◑).

polymerisation of acrylonitrile by the partially oxidised reaction mixtures previously degassed with nitrogen. No such polymerisation of the monomer was observed when it was added under similar conditions to the solutions of vanadium(V), or phenylphosphinic acid taken separately. It might be noted that the previous workers (4) too noted the induced polymerisation of the monomer in reaction mixtures prepared in sulphuric acid. The induced polymerisation of the monomer established vanadium(V) to be a one-electron oxidant. Sengupta and co-workers (4) claimed vanadium(V) to be a two-electron equivalent oxidant in perchloric acid solution and one equivalent in sulphuric acid solution. These authors, however, did not explain how a change from one mineral acid to another changed the very character of the oxidant.

It is known that in the reaction [16] the rate law has a strong dependence upon $[H^+]^{-1}$ (16). This prompted Kustin and Toppen (17) to suggest that the possibility of the formation of V(IV) through the reaction between V(V) and V(III) can be safely ruled out in any reaction if its rate law is independent of $[H^+]^{-1}$ term. The application of this criterion to the present reaction reinforces the view that vanadium(V) acted as a one-electron equivalent oxidant.

$$[16] \quad V(V) + V(III) \rightarrow 2V(IV)$$

The slope of the linear plots (0.61 at 40°C, 0.49 at 45°C, 0.47 at 50°C, 0.33 at 55°C, and 0.25 at 60°C) between log k_{obs} and $-H_0$ is not unusual primarily because the ideal slope of the unity is expected for the protonation of the amide bases and, secondly, it is known (18) that groups of indicators with different structures specially with different basic sites often show significant deviations from ideal value of unity. The H_0 is the Hammett acidity function (19) and the values used are those of Day and Wyatt (20). The decreasing slope value with tem-

perature is considered due to possible changes of H_0 values with temperature. The H_0 values are, unfortunately, known only at one temperature.

Active vs. inactive form

The problem which of the two forms, present in equilibrium with each other in an acidic solution, are reactive is attempted to be answered by comparing k_{ex} [9] and k_{redox} [18]. The need for deriving eq. [18] is that k_{ex} [9] and k_{obs} [15] cannot be directly compared because the former is derived with respect to phenylphosphinic acid whereas the latter is derived with respect to vanadium(V). Hence it is essential that k_{obs} is first converted to a rate constant k_{redox} which is the first-order rate constant with respect to phenylphosphinic acid itself. The correlation between k_{obs} and k_{redox} is given in eq. [17] which is derived on the basis of stoichiometry of the reaction.

[17] $k_{obs}[V(V)] = 2k_{redox}[C_6H_5P(O)(OH)H]$

[18] $k_{redox} = (k_7K_1[H^+] + k_6K)[V(V)]$

Equation [18] is obtained by substituting the k_{obs} value given in [15] into [17]. The comparison of equations [9] and [18] makes it apparent that k_H has to be compared with $k_7K_1[V(V)]$ and k_w with $k_6K[V(V)]$.

The values of k_7K_1 (dm^6 mol^{-2} s^{-1}) and k_6K (dm^3 mol^{-1} s^{-1}) computed from the slope and intercept of the linear plots between $k_{redox}/[V(V)]$ and $[H^+]$ at each temperature are given in Table 4. The values at 23°C were obtained by extrapolating the linear plots between $\log k_7K_1$ or $\log k_6K$ against T^{-1} because k_H is known at 23°C only (9). The $k_H/k_7K_1[V(V)]$ thus obtained is 5.6×10^3 and $k_w/k_6K[V(V)]$ is 8.0×10^4 both at 23°C, indicating that the rate of transformation of inactive form into active form is much higher than the rate of oxidation of phenylphosphinic acid. Thus the oxidation may apparently involve selectively either form of phenylphosphinic acid or both of them.

The next approach to the problem was therefore to compare k_7 with k_1, and k_6 with k_4 to give a firm support to the proposed mechanism. Unfortunately neither k_1 nor k_4 are known. Nevertheless, an approximate estimate of k_1 value with relation to the known value of k_H is possible on the basis of the two following plausible assumptions ($k_2 \gg k_3$ is improbable): (*i*) $k_2 \sim k_3$, whence $k_H = k_1/2$; (*ii*) $k_2 \ll k_3$, whence $k_H = k_1$.

Similarly k_7 can be estimated if K_1 is known. Unfortunately, K_1 is not known. Nevertheless, the inequality $1 \gg K_1[H^+]$, valid in several studies (9–13) in the range 1–5 mol dm^{-3} perchloric acid will be rendered invalid if $K_1 \geqslant 10^{-2}$ dm^3 mol^{-1}. Hence the inequality is valid only for any value of $K_1 \leqslant 10^{-3}$ dm^3 mol^{-1}. Since $k_7K_1 \sim 10^{-6}$ dm^6 mol^{-2} s^{-1} at 23°C, k_7 is estimated to be $\sim 10^{-3}$ dm^3 mol^{-1} s^{-1} when $K_1 \sim 10^{-3}$ dm^3 mol^{-1}, which is its maximum permitted value. Thus k_7 (dm^3 mol^{-1} s^{-1}) is one order greater than the value of $k_1 \sim 10^{-4}$ dm^3 mol^{-1} s^{-1}. The consequence of this result is that the form **B** cannot be involved in the oxidation. It must be noted that the ratio k_7/k_1 will be much greater for K_1 values $< 10^{-3}$ dm^3 mol^{-1} which will further strengthen the conclusion.

Again k_6 is found to be $\sim 10^5$ dm^3 mol^{-1} s^{-1} with the assumption that $K \sim 10^{-12}$. This high value of k_6 exceeds the k_4 value, which is not exactly known though it may not be of this high order. Considering the values of the constants k_1, k_2, and k_3, all of which are necessarily of the order of 10^{-4}, there will be no difficulty in justifying the inclusion of reaction [12] in the proposed mechanism.

The reactions of sulfur atoms with propadiene and 1,2-butadiene

MARTINA GREEN[1], BELA VERKOCZY[2], ELIZABETH M. LOWN, AND OTTO P. STRAUSZ
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada, T6G 2G2

Received March 26, 1984

MARTINA GREEN, BELA VERKOCZY, ELIZABETH M. LOWN, and OTTO P. STRAUSZ. Can. J. Chem. **63**, 667 (1985).

The gas phase reactions of both $S(^1D)$ and $S(^3P)$ atoms with propadiene afford methylenethiirane in nearly quantitative yields at high pressure. With 1,2-butadiene the three novel unsaturated isomeric thiirane products, resulting from addition to the 2,3 double bond and *cis*- and *trans*-addition to the 1,2 double bond, have been characterized. The yields are pressure and exposure-time dependent and, at zero conversion and high pressures, comprise ~94% of the C_4H_6S adducts, the remainder being two thiol insertion products. The ratio of 2,3-addition to 1,2-addition is ~1.3 for $S(^1D)$ atoms and ~2.1 for $S(^3P)$ atoms. Rate parameters for the $S(^3P)$ + 1,2-butadiene reaction were determined in competition with the $S(^3P)$ + 1-C_4H_8 reaction and found to be $A = 6.4 \pm 1.1 \times 10^{10}\ M^{-1}\ s^{-1}$ and $E_a = 1.4 \pm 0.2$ kcal mol^{-1}. The E_a's associated with 1,2- and 2,3-addition are comparable but the preexponential factors are slightly different.

MARTINA GREEN, BELA VERKOCZY, ELIZABETH M. LOWN et OTTO P. STRAUSZ. Can. J. Chem. **63**, 667 (1985).

A des pressions élevées, les réactions en phase gazeuse des atomes de $S(^1D)$ et de $S(^3P)$ avec le propadiène fournissent le méthylènethiiranne avec un rendement pratiquement quantitatif. Lors des mêmes réactions avec le butadiène-1,2, on a pu caractériser les trois nouveaux thiirannes insaturés isomères qui proviennent de l'addition sur la double liaison en 2,3 et des additions *cis* et *trans* sur la double liaison en 1,2. Les rendements dépendent de la pression et du temps d'exposition et, à des pressions élevées et à des conversions nulles, ils sont composés d'environ 94% d'adduits C_4H_6S alors que le reste correspond à deux produits d'insertion des thiols. Les rapports des additions en position 2,3/position 1,2 sont d'environ 1,3 et 2,1 respectivement pour les atomes $S(^1D)$ et les atomes $S(^3P)$. On a déterminé les paramètres de vitesse pour la réaction du $S(^3P)$ + butadiène-1,2 par compétition avec la réaction du $S(^3P)$ + butène-1 et on a trouvé que $A = 6{,}4 \pm 1{,}1 \times 10^{10}\ M^{-1}\ s^{-1}$ et $E_a = 1{,}4 \pm 0{,}2$ kcal mol^{-1}. Les valeurs de E_a associées avec les additions en 1,2 ou en 2,3 sont comparables; toutefois, les facteurs préexponentiaux sont légèrement différents.

Introduction

The chemistry of sulfur atoms has been explored for over two decades (1). In most studies the source of sulfur atoms was the uv photolysis of carbonyl sulfide (1, 2):

[1] $\quad COS + h\nu\ (240\ nm) \rightarrow CO + S(^1D_2)\ (67\%),\ S(^3P_J)\ (33\%),\ \phi = 0.91$

The ensuing reactions are:

[2*a*] $\quad S(^1D) + COS \rightarrow S_2 + CO$

[2*b*] $\quad \rightarrow S(^3P) + COS^*$

[3] $\quad S(^3P) + COS \rightarrow S_2 + CO$

A lower limit $k_{2a} \geq 4.0 \times 10^{10}$ L mol^{-1} s^{-1} has been reported from flash photolysis experiments (3) and the abstraction/deactivation rate constant ratio, k_{2a}/k_{2b}, is estimated to be $\simeq 2$ (2). Step [3] has been studied using flash photolysis – resonance fluorescence techniques, from which $k_3 = 2 \times 10^6$ L mol^{-1} s^{-1} (4). In the presence of >ca. 15-fold excess of CO_2 nearly all the initially produced $S(^1D)$ atoms are collisionally deactivated to the ground state and thus this system can be used to study the reactions of $S(^3P)$ atoms exclusively.

The reactions of ground (^3P_J) and metastable ($^1D_2$) excited sulfur atoms have been extensively studied (5) with alkenes. $S(^1D)$ atoms add to the double bond in a spin and symmetry allowed reaction to yield a vibrationally excited ground state thiirane molecule as shown by the example of propylene:

$$S(^1D) + CH_3CH{=}CH_2 \rightarrow CH_3\overline{CH{-}CH_2S}\ (S_0)^\dagger$$

Parallel, and in competition with addition, C—H insertion can also take place (5, 6):

$$S(^1D) + CH_3CH{=}CH_2 \rightarrow HSCH_2CH{=}CH_2,\ CH_3C(SH){=}CH_2,\ CH_3CH{=}CHSH$$

The rates of addition and insertion are rapid, being close to the gas kinetic collision frequencies. $S(^3P)$ atoms, on the other hand, do not insert into C—H bonds and the primary adduct is the vibrationally excited lowest triplet state thiirane (7) which is subsequently collisionally deactivated to the ground state:

$$S(^3P) + CH_3CH{=}CH_2 \rightarrow CH_3\overline{CH{-}CH_2S}\ (T_1)^\dagger \xrightarrow{M} CH_3\overline{CH{-}CH_2S}\ (S_0)$$

Absolute rate constants and Arrhenius parameters have been reported for a variety of alkenes (8, 9) and the room temperature values range from 8×10^8 to 4.3×10^{10} L mol^{-1} s^{-1} on going from ethylene to tetramethylethylene. The activation energies decrease, eventually becoming negative, with increasing alkyl substitution, and are linearly related to the ionization potential of the alkene. With the exception of vinylthiols, all the reaction products are reasonably stable and under suitable experimental conditions essentially quantitative product recoveries can be achieved.

The reactions of S-atoms with only one diene substrate, namely 1,3-butadiene, have been investigated (10). The major product is vinylthiirane and the rate of the $S(^3P)$ + 1,3-C_4H_6 reaction is, as expected, somewhat (about fourfold) faster than that with the butenes (5). Cumulated double bonds might be expected to exhibit a somewhat different chemical reactivity from that of conjugated dienes. For this reason we have undertaken the first study of the reactions of S-atoms with the cumulated dienes propadiene and 1,2-butadiene, the results of which are reported here.

Experimental

Photolyses were carried out in 10 × 5 cm cylindrical quartz cells, one of which (for the study of the S + 1,2-C_4H_6 reaction) was equipped with Suprasil windows. The latter was enclosed in a cylindrical aluminium block furnance, 16 cm long, 12.5 cm od, and 6 cm id, covered at both ends by 2 mm thick quartz plates and around the sides by 1-in. fibreglass. Heating was achieved by four 10 cm long 150-W pencil heaters inserted axially into the block. Temperatures were maintained by an API 2-mode temperature controller and measured by standard iron–constantan thermocouples.

The light source was a Harovia medium pressure mercury arc equipped with three 2 mm thick Vycor 7910 filters to limit the effective wavelength to >240 nm.

COS (Matheson) was purified as described previously (11). CO_2 (Airco, >99.9% pure) was used as such. C_3H_4 (Matheson, teaching grade, 99%) was degassed at −186°C and distilled at −132°C; <0.5% C_3H_6 remained. 1-C_4H_8 (Linde, research grade) was degassed at −196°C and distilled at −115°C. 1,2-C_4H_6 (Chemical Sample Co., 99%) was degassed at −139°C and distilled at −105°C.

Non-condensable products were collected and measured in a gas burette and, for the S + 1,2-C_4H_6 reaction, analyzed on a 3 ft × 2 mm 80/100 mesh molecular sieve 5 A column at 27°C. The sulfur-containing products were isolated following low pressure distillations of the reaction mixtures and analyzed by gc as follows: 305 cm × 3.2 mm Teflon column, 60/80 mesh Chromosorb W.A. coated with 10% tricresylphosphate (C_3H_4S); 7 ft × 2 mm quartz column, 5% Ucon polar 50 HB 2000 on 80/100 mesh Chromosorb P, AW-DMCS (C_4H_6S).

The nmr, ir, uv, and mass spectra were obtained using either a Bruker 200 or 400 MHz, a Nicolet 7199 FTIR, a Unicam SP-1700 spectrophotometer, and an AEI MS-12 spectrometer, respectively.

Results

Because propadiene and 1,2-butadiene exhibit small but measurable absorptions at λ 240 nm, at least a fourfold excess of COS was used throughout in order to ensure that at least 95% of the incident radiation would be absorbed by COS.

1. *The S + C_3H_4 reaction*

Photolysis of COS in the presence of C_3H_4 led to the formation of methylenethiirane as the major product, identified on the basis of its mass, nmr, and ir spectra (12). Smaller amounts of CS_2 and methylthiirane were also detected, the latter as a result of S-atom addition to C_3H_6, an unresolvable impurity in the substrate.

In the gas phase, methylenethiirane is somewhat more stable than claimed before (13); the rate of disappearance (0.9 Torr at 25°C, in a 10 × 1.6 cm quartz vessel) (1 Torr = 133.3 Pa) of its large uv absorption band at 231 nm appeared to be a second-order process with a half-life of about 12 h, without producing any new uv absorptions. This compound is, however, very sensitive to Pyrex and metal surfaces, polymerizing upon prolonged storage at −196°C.

The effects of exposure time and total pressure on the product yields are listed in Table 1. C_3H_4S is photolabile, its rate of formation declining by a factor of 2 over the course of a 7-min photolysis in the two pressure regimes examined. A twofold increase in the total pressure (for COS/C_3H_4 ~10) results in a significant enhancement in the product recoveries, in terms of the amount of S-atoms reacting with C_3H_4, and at short conversions the reaction is nearly quantitative.

The presence of 600 Torr CO_2, which quenches a large proportion of the $S(^1D)$ atoms to the ground (^3P) state, has little discernible effect on the product yields (Table 1).

2. *The S + 1,2-C_4H_6 reaction*

Photolysis of COS in the presence of 1,2-C_4H_6 led to the formation of five isomeric products (**1–5**) of molecular weight 86, corresponding to the adduct C_4H_6S. A gc/ms analysis using a mass-86 cross-scan showed the presence of two additional mass-86 peaks, **6** and **7**, but because these were formed in only trace quantities their structural identification was not attempted. Mass spectral data for the C_4H_6S products are summarized in Table 2.

TABLE 1. Effects of exposure time and total pressure on the product yields from the S + C_3H_4 reaction

[a] % Recovery = $[\Sigma(C_3H_4S + 2CS_2 + C_3H_6S)/(CO^0 - CO)] \times 100$. For *P*(COS) = 545 Torr, R^0(CO) = 3.14 μmol min^{-1}. For *P*(COS) = 1090 Torr, R^0(CO) = 4.15 μmol min^{-1} for the first 4 min, then 3.90 μmol min^{-1}.
[b] In the presence of 600 Torr CO_2.

The structures of the C_4H_6S adducts **1–5** were identified on the basis of their nmr spectral characteristics, summarized in Table 3, and, for the cases of **1**, **4**, and **5**, supportive ir spectra. Moreover, the resonance shifts and coupling constants reported for 2-isopropylidine-3,3-dimethylthiirane (14) and methylenethiirane (12) are very similar to those assigned to the isomeric vinylidenethiiranes **1**, **3**, and **4**. Assignment of the *Z* and *E* isomers to **3** and **4**, respectively, is based on the relative chemical shifts of the ethylenic proton H_A. According to the literature (15), an *RS*-group in a substituted ethylene shifts a proton *cis* to it by about 0.24 ppm to higher field, whereas a *trans* proton will be shifted by only 0.04 ppm to higher field, relative to the unsubstituted ethylene. Consequently, **3** (δ_{H_A} = 6.05) is assigned to the *Z* isomer and **4** (δ_{H_A} = 5.62) to the *E* isomer. Not surprisingly, the ir spectra of **1** and **4** were very similar, both featuring strong C—H out-of-plane deformations at 840 and 895 cm^{-1}, C=C(st) at 1715 and 1700 cm^{-1}, and vinyl C—H(st) around 3060 cm^{-1}. The 1,3-butadiene skeleton structure was assigned to **2** because it is a C_4H_6S isomer that has five protons in the vinyl region of the nmr spectrum but no methyl absorptions. The allene structure of compound **5** is assigned on the basis of the typical C=C=C(st) absorption at 1960 cm^{-1}, clearly evident in the ir spectrum, and its nmr spectrum, Table 3.

Products **1–5** are all sensitive to Pyrex surfaces and when kept in Pyrex vessels decompose completely at room temperature over a period of ~12–15 h; under the same conditions, storage in a quartz cell effected ~50% loss. Mercury accelerates the rate of decomposition.

The results in Table 4 show that **1** and **4** are sensitive with respect to photodecomposition, whereas the rates of formation of **2**, **3**, and **5** are relatively constant. The rate of formation of CH_4 increases with exposure time, suggesting that at least part

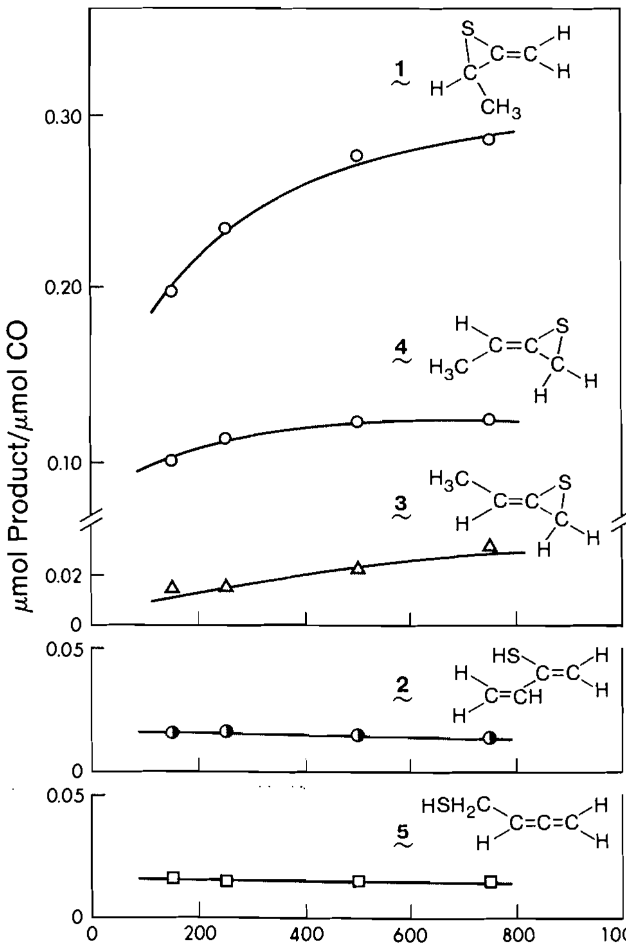

FIG. 1. Rates of product formation versus total pressure for the S + $CH_3CH{=}C{=}CH_2$ system. $P(COS)/P(C_4H_6) = 4$. Rates of **1** and **4** have been corrected to zero time.

of the CH_4 is formed in a secondary process. It is seen that the product yields, in terms of S atoms reaction with 1,2-C_4H_6, are low, even at low conversions; using the extrapolated zero time rates for **1** and **4** (0.235 and 0.115 μmol/μmol CO, respectively), the zero time extrapolated total product recovery is only marginally better, ~63%.

The effects of total pressure (at a constant COS/1,2-C_4H_6 ratio) are illustrated in Fig. 1. It is seen that the yields of thiiranes **3**, **4**, and particularly those of **1**, are markedly enhanced with increasing pressure. In order to minimize the effects of secondary photodecomposition, all the experiments were carried out at constant conversion (~5.2 μmol CO) and the rates of formation of thiiranes **1** and **4** were corrected to zero time values, assuming that their temporal behaviour at 250 Torr, Table 4, was the same over the entire pressure range studied. The overall product recoveries exhibit a similar trend, increasing from 64% at 150 Torr to 81% (corrected to zero time) at 750 Torr. These results parallel those observed for the S + C_3H_4 reaction, Table 1.

Photolysis of 100-Torr COS in the presence of 50-Torr 1,2-C_4H_6 and 1216-Torr CO_2 led to enhanced yields of **1**, **3**, and **4**, and the complete suppression of **5** and **2**; CH_4 was formed in barely detectable amounts. The rates of formation of **1**, **3**, and **4** were 0.542, 0.036, and 0.227 μmol/μmol CO, respectively, **1** and **4** being corrected to zero time.

Rate parameters for the $S(^3P)$ + 1,2-C_4H_6 reaction were determined in competitive experiments in the presence of 1-C_4H_8. The latter substrate was chosen for the reason that its vapour pressure is similar to that of 1,2-C_4H_6, thus allowing facile separation of the products from the reactants by distillation and because the rate parameters for the $S(^3P)$ + 1-C_4H_8 reaction, which affords ethylthiirane in nearly quantitative yields, have been measured directly (8, 9). For this system, then, the two competing reactions are:

$$S(^3P) + 1\text{-}C_4H_8 \xrightarrow{a} C_4H_8S$$

$$S(^3P) + 1,2\text{-}C_4H_6 \xrightarrow{b} C_4H_6S$$

If A_0 and A, and CO_0 and CO, represent the amounts of C_4H_8S and CO formed in the absence and presence of 1,2-C_4H_6, respectively, then it can be shown that

$$\frac{A_0/CO_0 - A/CO}{A/CO} = \frac{k_b}{k_a}\frac{[1,2\text{-}C_4H_6]}{[1\text{-}C_4H_8]}$$

where division of A's by the corresponding measured CO yield corrects for random fluctuations of the lamp intensity. Sources of error include the following: (a) incomplete quenching of $S(^1D)$ atoms by CO_2; (b) secondary decomposition of C_4H_8S; (c) some minor free radical reactions producing CO from COS

via unknown mechanisms. It is assumed that these complicating factors do not affect the *relative* yields of C_4H_8S measured.

Product yields as a function of the $[1,2\text{-}C_4H_6]/[1\text{-}C_4H_8]$ ratio at 27°, 60°, 90°, 120°, and 150°C are summarized in Table 5, and the corresponding plots of $(A_0/CO_0 - A/CO)/A/CO$ versus $[1,2\text{-}C_4H_6]/[C_4H_8]$ are illustrated in Fig. 2. The slopes of these plots, summarized in Table 6, are plotted in the Arrhenius form in Fig. 3, from which:

$$A_{1,2\text{-}C_4H_6}/A_{1\text{-}C_4H_8} = 5.31 \pm 0.26$$

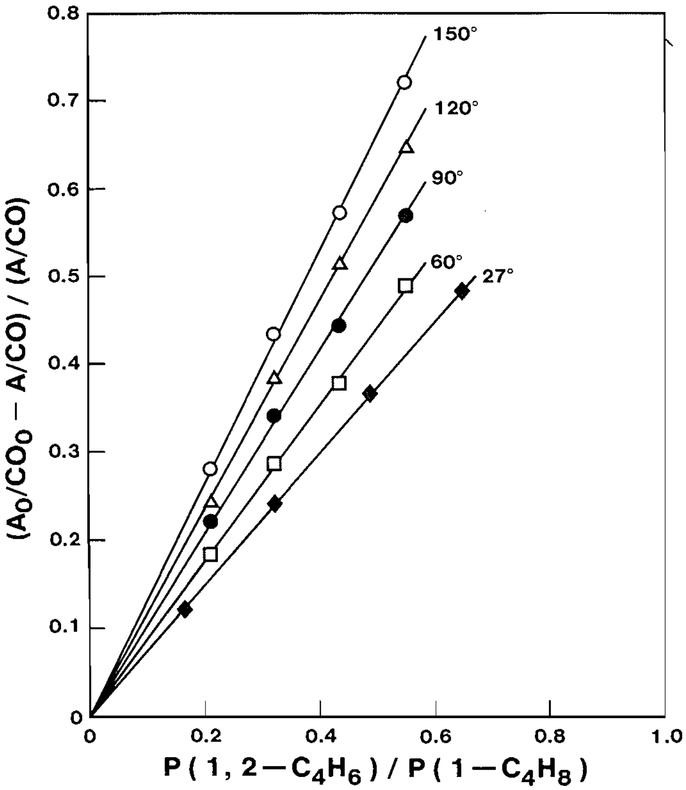

FIG. 2. $(A_0/CO_0 - A/CO)/A/CO$ versus $[CH_3CH{=}C{=}CH_2]/[CH_3CH_2CH{=}CH_2]$ at 27 (○), 60 (●), 90 (△), 120 (▲), and 150 (□) °C.

and

$$E_{1\text{-}C_4H_8} - E_{1,2\text{-}C_4H_6} = (1.17 \pm 0.03) \text{ kcal mol}^{-1}$$

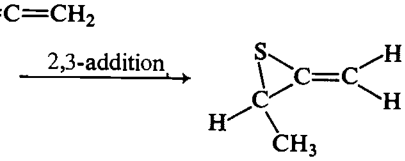
Discussion

Since $S(^1D)$ atoms insert into C—H and add to alkenic double bonds, the following reactions can be considered for propadiene:

[4*a*] $S(^1D) + H_2C{=}C{=}CH_2 \longrightarrow H_2C{=}C{=}CHSH$

[4*b*] 
For 1,2-butadiene, three cycloaddition products can be formed,

[5*a*] $S(^1D) + CH_3CH{=}C{=}CH_2$



1

[5*b*]

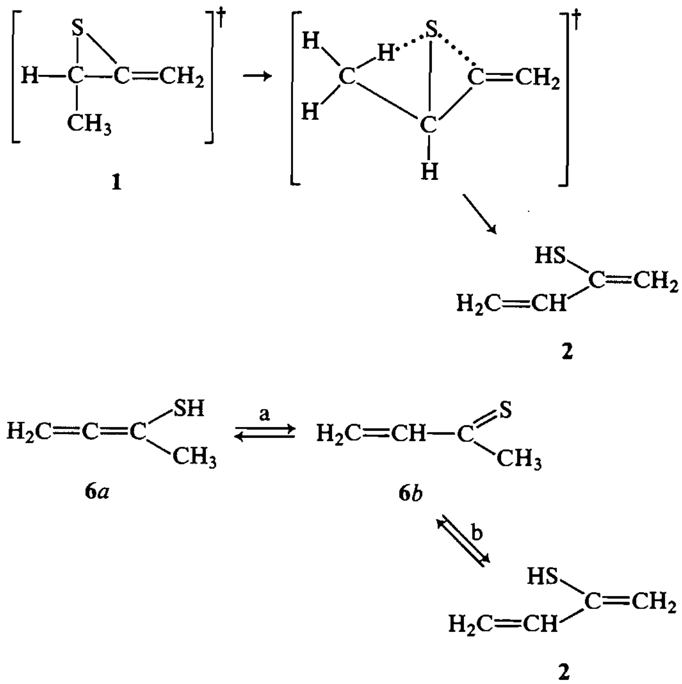
For the case of propadiene the thiol insertion product was not detected. By analogy to vinylthiol and 1,3-butadiene-3-thiol



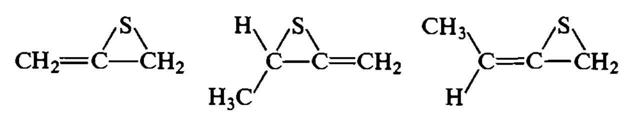
SCHEME 1

(*vide infra*), propadienethiol is expected to be prone to surface catalyzed polymerization and the fact that it was not detected in the present investigation may be due to the conditions employed; the high product yields observed at high pressures, however (Table 1), strongly suggest that insertion, if it occurs, is of very minor importance compared to cycloaddition.

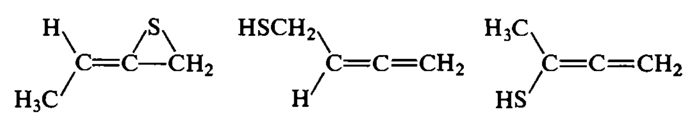
In contrast, in the case of the analogous O-atom reaction $O(^3P) + C_3H_4$, methyleneoxirane, the expected cycloaddition product, was not detected and instead CO(57%), C_2H_4(38%), and acrolein(1%) were reported to be the major products (16). Since cyclopropanone was calculated to be ~21 kcal mol^{-1} more stable than methyleneoxirane (17), it appears that the major reaction path consists of isomerization of the initial biradical adduct to cyclopropanone, which subsequently decomposes. The relative stabilities of the C_3H_4S analogues, on the other hand, are reversed, i.e. cyclopropanethione is less stable than methylenethiirane, by ~7 kcal mol^{-1} (13), and thus the latter is the end product of the $S(^3P) + C_3H_4$ reaction.

For the $S(^1D) + CH_2{=}C{=}CHCH_3$ reaction all three cycloaddition products were detected, as well as the thiol formed from insertion into the —CH_3 group. 1,3-Butadiene-3-thiol **2** was also a product, and it definitely does not arise from the reactions of $S(^1D)$ atoms with any 1,3-C_4H_6 impurity. It may, however, be formed either from a "hot" thiirane–thiol rearrangement involving thiirane **1** or via an enethiol–thioketene–enethiol tautomerization of 1,2-butadiene-3-thiol **6** formed in step [5*e*], Scheme 1. The occurrence of a hot thiirane–thiol rearrangement **1**–**2** is, however, unlikely since in chemically activated methylthiirane, which has fewer degrees of freedom than the C_4H_6S adduct, this process is of very minor importance even at low pressures (2). On the other hand, the existence of enethiol–thioketone rearrangements is well documented (18) and moreover, of the three species involved in the tautomerization of **6**, the most stable, by virtue of carbon–carbon conjugation, is expected to be 1,3-butadiene-2-thiol, **2**. The intermediate thioketone $H_2C{=}CH{-}C({=}S)CH_3$ has been synthesized by flash thermolysis techniques (19); it reportedly dimerizes at −60°C, and undergoes spontaneous polymerization at room temperature. In the present system, however, it is generated in the gas phase at high dilution, thus allowing tautomerization to compete effectively with bimolecular reactions. Tautomerization of the hypothetical thiol **7** would lead to methylthioacrolein which, like the thioketone analogs, is expected to be inherently unstable. It is therefore concluded that insertion into the =CH— and =CH_2 moieties of 1,2-C_4H_6 does occur and that tautomerization can then take place, but only in the former case can tautomerization lead to a stable product. The trace C_4H_6S adducts detected in the gc/ms cross scan may be the initial =CH— and =CH_2 insertion products **6** and **7**.

The primary adducts for the case of the $S(^1D)$ reaction are likely the ground, vibrationally excited singlet state thiiranes and thiols, and, for the case of $S(^3P)$ addition, vibrationally excited triplet state thiiranes (7). From Benson's group additivity method (20), the heats of formation of the ground state C_3H_4S and C_4H_6S adducts are estimated to be:



ΔH: 38.4 32.02 32.34 kcal mol^{-1}



ΔH: 31.34 47.02 45.81 kcal mol^{-1}

from which the thiirane-forming reactions with $S(^1D)$ atoms are computed to be exothermic by ~100–101 kcal mol^{-1} and the thiol-forming reactions, by ~85–86 kcal mol^{-1}. For C_2–C_4 alkenes, on the other hand, the corresponding cycloaddition reactions are only ~85–88 kcal mol^{-1} exothermic. Thus the enhancing effect of pressure on the thiirane yields from the $S(^1D) + C_3H_4$/1,2-C_4H_6 reactions is probably a result of collisional deactivation of the hot primary cycloadducts.

From the high pressure (750 Torr) rates of formation of **1**–**5** (Fig. 1) and the corrected zero time rates of **1** and **4** (0.283 and 0.122 μmol/μmol CO, respectively), assuming that the temporal variations of **1** and **4** at 750 Torr are the same as at 250 Torr (Table 4), the total product recovery is estimated to be 81% at zero time, of which the thiiranes comprise 94%.[3] This is high, in comparison with alkene reactions (e.g. the reaction with 1-butene affords 59% thiirane, 12% methallylthiol, and 29% alkenyl type thiols), and it may be concluded that insertion into the C—H bonds of 1,2-C_4H_6 is a very minor process compared to cycloaddition. Similarly, the S + C_3H_4 reaction at low conversions and high pressures, affords only methylenethiirane up to 100% yield (Table 1).

The high ratio of thiirane to thiols in the diene reactions is partly due to molecular structural effects and partly to the experimental conditions employed.

As was shown above, the preexponential factors for the

[3]The mass imbalance is probably due to the combined thermal and photochemical instabilities of 1–5 rather than to exclusive loss of insertion products.

$S(^3P)$ + 1,2-C_4H_6 reaction are 5.13 times higher than for the $S(^3P)$ + 1-C_4H_8 reaction owing to the presence of the elongated, orthogonal π-system. It may be assumed that the pre-exponential factors for the $S(^1D)$ + diene $\rightarrow$ thiirane reactions, [4*b*] and [5*a*–*c*], are also somewhat higher than for the $S(^1D)$ + monoalkene reactions, resulting in higher ratios for the thiirane to thiol products.

Also, the higher [COS]/[alkene] ratios used in the diene as compared to the monoalkene reactions tend to increase the ratio of $S(^3P)$ to $S(^1D)$ atom reactions with the substrate. Thus, a crude approximation of the relative proportions of (^1D) and (^3P) atoms in the system can be calculated on the basis of the experimental CO yields in the absence (CO^0) and presence (CO) of a reactive substrate, the branching ratio for step [1], and the abstraction/deactivation ratio k_{2a}/k_{2b} (cf. Introduction). For the reaction mixture consisting of 200-Torr COS and 51-Torr 1,2-C_4H_6 (Table 4) the total yield of S-atoms generated in step [1] is $CO^0/2 = 0.285$ μmol, of which 0.191 and 0.094 are in the (^1D) and (^3P) states, respectively. Step [3], abstraction from COS by $S(^3P)$, is slow compared to addition to 1,2-C_4H_6 (*vide infra*) and can be neglected. Hence, the yield of the abstraction reaction [2*a*] is $CO - CO^0/2 = 0.066$ μmol. Since $k_{2a}/k_{2b} \sim 2$, the yield of $S(^3P)$ atoms formed from deactivation, step [2*b*], is $0.066/2 = 0.033$ μmol and the combined amount of $S(^3P)$ atoms available for reaction with 1,2-C_4H_6 is $0.094 + 0.033 = 0.127$ μmol. Now the total amount of S-atoms reacting with C_4H_6 is equal to the total sulfur produced in step [1] less the yield of the abstraction reaction [2*a*], $0.285 - 0.066 = 0.219$ μmol. Hence, only 42% of the S-atoms reacting with C_4H_6 are in the $S(^1D)$ state. For the COS–C_3H_4 system where higher relative concentrations of COS were employed, only 29% of the S-atoms reacting with the substrate were in the $S(^1D)$ state. Thus, the low yields (or absence) of insertion products in these systems may also be a consequence of the fact that most of the $S(^1D)$ atoms generated in step [1] had been deactivated to the ground (^3P) state prior to reaction. It should be noted, however, that the branching ratio for step [1] and the abstraction/deactivation rate constant ratio for step [2] are indirect estimates only, and a more quantitative assessment of the relative concentrations of (^1D) and (^3P) atoms awaits our studies on direct rate measurements of these reactions.

From the data in Table 4 and Fig. 1, it can be shown that at zero time and high pressure, ($k_{2,3\text{-addition}}/k_{1,2\text{-addition}}$) is ~2.1 for the case of $S(^3P)$ addition and ~1.3 for $S(^1D)$ addition. Surprisingly few studies on the orientation of radical addition to 1,2-dienes have been reported in the literature. For EtS (21) and $(CH_3)_3Sn$ (22) radical addition to 1,2-butadiene, end product analyses show that 48.2% and 86.5% of the attack, respectively, occurs at the C2 position and addition of these radicals to 3-methyl-1,2-butadiene takes place exclusively at C2. Since the former is an electrophilic, and the latter, a nucleophilic species, it appears that polar effects do not influence the orientation of addition and, rather, that methyl substitution favours the formation of the more stable allylic radical. Subsequent hydrogen abstraction by the allylic radical takes place exclusively at the C1 position for the case of the RS adduct. The $(CH_3)_3Sn$ adduct, however, abstracts preferentially at C1, but C3 abstraction products are also formed. Thus, the final products correspond to 1,2-addition. Recently, Creary (23) has studied the regioselectivities of the additions of a variety of singlet and triplet carbenes to 3-methyl-1,2-butadiene. Singlet state carbenes led to a predominance of 2,3-addition products whereas for triplet carbenes, which add in a stepwise manner and thus more closely resemble monoradicals, 1,2-addition was favoured. The reaction was suggested to be useful as a new probe for the determination of carbene multiplicity.

As shown above, however, both $S(^3P)$ and $S(^1D)$ atoms add predominantly to the 2,3-double bond of 1,2-butadiene and the somewhat higher selectivity exhibited by $S(^3P)$ atoms might be due to their lower (by 26 kcal mol^{-1}) energy content. This result was not unexpected since our earlier results showed that $S(^3P)$ atoms, like $S(^1D)$ atoms and singlet carbenes, add to double bonds in a concerted fashion (10).

Addition to the 1,2 double bond leads to the formation of two isomers, ***E*4** and ***Z*3** in extrapolated (1200 Torr, zero time) ratios of 1.4 and 6.2 for (^1D) and (^3P) atom addition, respectively. The reason for the high stereoselectivity observed in the triplet case is not immediately apparent.

The reactions of $O(^3P)$ atoms with 1,2-butadiene, as with 1,2-propadiene, afford fragmentation products – CO (64%) and propylene (43%) – together with only small amounts (3.1%) of oxygenated material (16). The involvement of excited cyclopropanone intermediates appears to be a common feature of the $O(^3P)$ + 1,2-diene reactions.

Rate parameters for the $S(^3P)$ + 1-butene reaction have been measured by flash photolysis – kinetic absorption and flash photolysis – resonance fluorescence methods and are reported to be $k = (8.2 \pm 0.6) \times 10^9 \exp(-200 \pm 200/RT)$ (8) and $(2.4 \pm 0.2) \times 10^9 \exp(-400 \pm 100/RT)\ M^{-1}\ s^{-1}$ (9), respectively. For all the $S(^3P)$ + alkene (8, 9) and $O(^3P)$ + alkene (24) reactions studied to date, the latter method yields *A*-factors which are consistently lower than those obtained by other techniques. For the time being, we prefer to use van Roodselaar *et al.*'s data for the reference reaction and thus $k_{S(^3P)+1,2\text{-}C_4H_6} = (6.4 \pm 1.1) \times 10^{10} \exp[(-1.4 \pm 0.2)/RT]\ M^{-1}\ s^{-1}$. Experimentally, it was observed that the ratio of the 2,3- and 1,2-addition products, i.e. **1**/(**3** + **4**), was relatively constant (~2.2) in the temperature range 27–150°C. Thus, the E_a's associated with 1,2- and 2,3-addition are comparable but the *A*-factors are slightly different: $A_{1,2\text{-addition}} \simeq 4 \times 10^{10}$ and $A_{2,3\text{-addition}} \simeq 8.8 \times 10^{10}\ M^{-1}\ s^{-1}$. The corresponding entropies of activation are $\Delta S^{\ddagger}_{1,2} = -22.33$ and $\Delta S^{\ddagger}_{2,3} = -20.77$ eu. These high values reflect the newly created rotational contributions to the activated complex upon going from a linear C═C═C molecule to a bent  skeleton.

Arrhenius parameters for the reactions of $S(^3P)$, $O(^3P)$, and $OH(^2\Pi)$ with simple dienes are listed in Table 7, along with those reported for reactions with some alkenes for the sake of comparison. For $S(^3P)$ and $O(^3P)$ atoms, the reactions with dienes feature higher *A*-factors than those associated with their monounsaturated analogues, and conjugation lowers the activation energy. Not unexpectedly, the E_a's for the S + C_4H_6 and O + C_3H_4 reactions deviate from the linear E_a versus ionization potential relationships observed for the reactions with alkenes. Relative rate data (at 25°C) for the reactions of $O(^3P)$ with a number of 1,2-dienes (16) show that the rate constant increases with increasing alkyl substitution in much the same way as for the $O(^3P)$ + alkene case and therefore it is likely that there is also a linear relationship between E_a and I_p for the $S(^3P)$ and $O(^3P)$ reactions with dienes, but displaced to the left of the corresponding alkene plots. In contrast, the E_a's associated with the reactions of $OH(^2\Pi)$ with alkenes and propadiene are all negative and neither the *A*-factors nor the E_a's exhibit any

TABLE 7. Arrhenius parameters[a] for the reactions of $S(^3P)$, $O(^3P)$ and $OH(^2\Pi)$ with dienes and alkenes

obvious trend. Relative rate data (at 25°C) for OH reactions with propadiene, 1,2-pentadiene, and 3-methyl-1,2-butadiene, however, indicate that the overall rate constant increases with alkyl substitution; it was also shown that the rate constants for reaction with conjugated and isolated dienes follow empirical relationships based on additivities of double bond contributions, but those for reactions with cumulated dienes do not follow either trend (28).

To conclude, we would like to point out the synthetic utility of S + diene reactions in general. The unsaturated thiol and thiirane products are relatively unstable and difficult to prepare by conventional techniques and the reactions of sulfur atoms with dienes offer a convenient alternative route to their synthesis.

On the infrared spectrum and dipole moment of dichloroketene

M. C. L. GERRY, W. LEWIS-BEVAN, AND N. P. C. WESTWOOD
Department of Chemistry, The University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received July 23, 1984

M. C. L. GERRY, W. LEWIS-BEVAN, and N. P. C. WESTWOOD. Can. J. Chem. **63**, 676 (1985).

The failure to observe a microwave spectrum of dichloroketene prepared in a low temperature flow system is contrasted with the successful observation of its Fourier Transform infrared spectrum under the same conditions. It is concluded that the lack of a microwave spectrum is a result of a near-zero dipole moment for dichloroketene.

M. C. L. GERRY, W. LEWIS-BEVAN et N. P. C. WESTWOOD. Can. J. Chem. **63**, 676 (1985).

Dans un système continu, on ne peut observer de spectres microondes du dichlorocétène préparé à basse température; ce résultat est en opposition avec le fait que, dans les mêmes conditions, on peut observer son spectre ir par transformation de Fourier. On en conclut que l'absence de spectres microondes provient d'un moment dipôlaire pratiquement nul pour le dichlorocétène.

[Traduit par le journal]

Although dichloroketene, Cl_2CCO, has long been postulated as a reactive intermediate involved in certain organic cycloaddition reactions in solution (1, 2), there are only three unambiguous reports of its detection in isolation. Colbourne *et al.* (3) and Bock *et al.* (4) have measured the gas phase photoelectron spectrum, and Torres *et al.* (5) have reported the infrared spectrum in an argon matrix at 8 K, following photolysis of dichlorovinylene carbonate.

As part of a program to measure the microwave spectra of unstable molecules, we have attempted to observe such a spectrum for dichloroketene, since we had already shown that the spectrum of monochloroketene can be observed relatively easily following generation and continuous flow through a waveguide. The preparation method used in the current experiments involved the dechlorination of trichloroacetyl chloride over zinc metal at 300°C:

[1] 
The products were passed at low pressure through a 2 m copper X band Stark cell; the frequency range studied was 26.5–40 GHz. This reaction is known to produce dichloroketene in excellent yield (3), and the reaction and cell conditions were the same as those used to observe microwave spectra of both chloroketene (6) and bromoketene (M.C.L. Gerry, W. Lewis-Bevan, and N.P.C. Westwood, to be published). Although there is no *a priori* reason to suppose that dichloroketene is any less stable than the other two molecules observed under these conditions, no microwave spectrum was found, even when the cell length was reduced to 1 m, and additional pumping was employed.

To check the success of the preparative technique, and to obviate the possibility of decomposition of the product in the metal cell, we have carried out identical experiments to measure the gas phase infrared spectrum. The reaction products from [1] were passed through the long (~45 cm) metal inlet port of a commercial multipass cell attached to a Bomem DA3.002 Fourier Transform infrared spectrometer. The pressures employed (30–100 mTorr) were similar to those used in the microwave experiments. The results are summarized in Fig. 1. Scans were made between 700–3100 cm^{-1} at 1 cm^{-1} resolution. Initially the spectrum of the starting material was obtained (Fig. 1(*a*)), but when this material was passed over zinc at 300°C, its spectrum diminished drastically, and that of

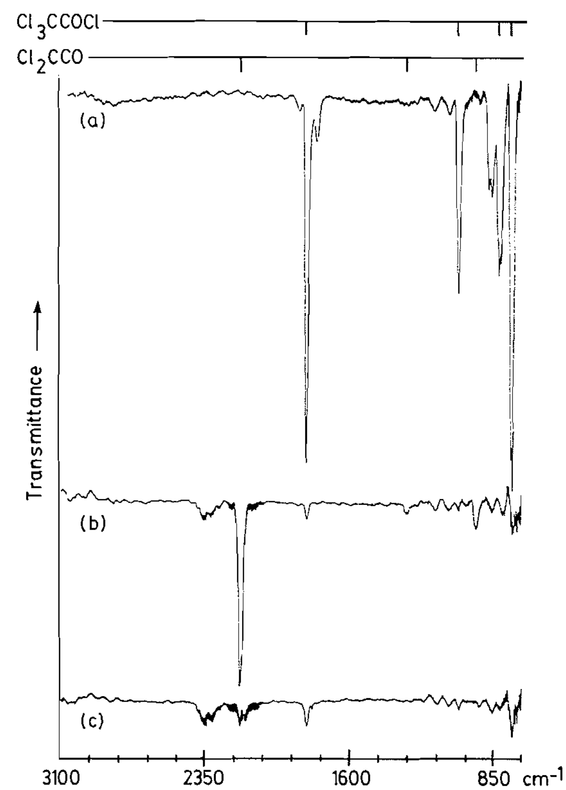

FIG. 1. The gas phase infrared spectrum of dichloroketene between 700 and 3100 cm^{-1}: (*a*) the precursor Cl_3CCOCl, (*b*) the products of the reaction of Cl_3CCOCl with zinc at 300°C (taken to be dichloroketene), (*c*) the spectrum of the reaction products after the cell had been isolated for 30 min; the lines at ~2150 cm^{-1} and ~2350 cm^{-1} are due to CO and CO_2, respectively. The transmittance scale is the same for all three spectra.

a new species appeared, with bands at 2160.3 cm^{-1} (s), 1291 cm^{-1} (w), and 935 cm^{-1} (w) (Fig. 1(*b*)). These are the same as the wavenumber values observed for dichloroketene by Torres *et al.* (5); indeed, the strong band at 2160 cm^{-1}, attributable to the CO stretching frequency, provides a unique fingerprint for ketene-like molecules (7), and in similar experiments we have observed such a band for monochloroketene. When the reaction products were isolated in the cell these bands disappeared over the space of about 30 min, leaving bands attributable to CO and CO_2 (Fig. 1(*c*)). Clearly the reaction product of Fig.

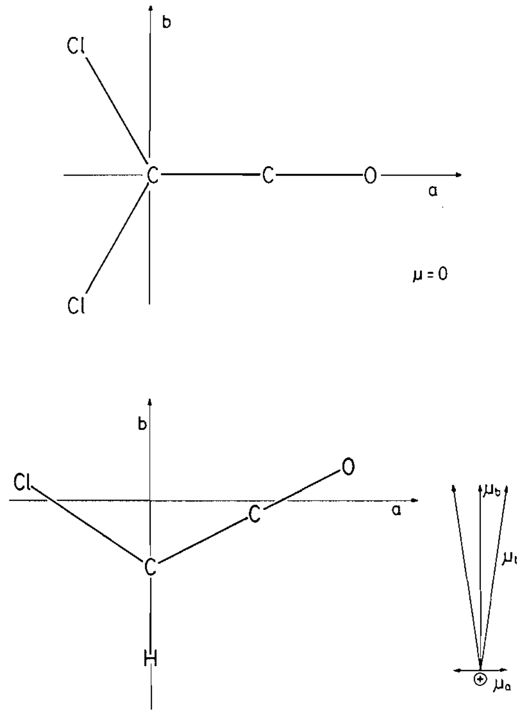

FIG. 2. Comparison of the dipole moments of dichloroketene and chloroketene (6).

1(*b*) is an unstable species, which from the infrared spectrum and the chemistry we take to be dichloroketene.

Since in both the microwave and infrared experiments the preparation conditions were identical (cf. also the photoelectron spectrum (3)) and since in both experiments the reaction products had to pass similar distances, contacting similar materials before reaching the cell, it is highly probable that dichloroketene was indeed prepared in the microwave experiment, and that it has at best an extremely weak microwave spectrum. Because the microwave spectrum is a rotational spectrum, requiring the molecule to have a permanent dipole moment, this implies that the dipole moment of dichloroketene is very small, certainly less than 0.3 D, and probably less than 0.1 D.

This result is consistent with our findings for the dipole moment of monochloroketene (6). As is shown in Fig. 2, the dipole moment of the latter molecule is almost exactly along the CH bond, implying that the C—Cl and C=C=O parts of the molecule have the same moments. Replacement of H by Cl would thus give complete cancellation, leading to a near-zero dipole moment for dichloroketene.

JACQUES FOSSEY, DANIEL LEFORT, MASSOUD MASSOUDI, JEAN-YVES NEDELEC et JEANINE SORBA. Can. J. Chem. **63**, 678 (1985).

Des hydrocarbures cyclohexane, Me-cyclohexane et adamantane sont hydroxylés par le peracide benzoïque selon un processus radicalaire. La régiosélectivité en faveur des alcools tertiaires atteint 60 à 90%. Pour les décalines *cis* et *trans*, la stéréosélectivité des décalols-9 peut atteindre 97%. Une très bonne stéréosélectivité d'hydroxylation par un peracide ne signifie pas obligatoirement que la réaction n'est pas radicalaire.

JACQUES FOSSEY, DANIEL LEFORT, MASSOUD MASSOUDI, JEAN-YVES NEDELEC, and JEANINE SORBA. Can. J. Chem. **63**, 678 (1985).

Cyclohexane, methylcyclohexane, and adamantane are hydroxylated by a radical process using perbenzoic acid. A regioselectivity of 60–90% in favour of tertiary alcohols is noted. In the case of *cis* and *trans* decalins, stereoselection leading to 9-decalols can reach 97%. Such a stereoselectivity for hydroxylation by use of a peracid does not necessarily indicate lack of a radical pathway.

[Journal translation]

L'hydroxylation directe des liaisons C—H non activées par les peroxyacides est une réaction d'intérêt général en synthèse (1–9), dont l'aspect régio- et stéréosélectif recueille une attention particulière. On sait également que le cytochrome P450 (10–13) ou les porphyrines métalliques (14, 15) catalysent cette réaction en utilisant les hydroperoxydes ou les peracides comme source d'oxygène.

Cette réaction d'hydroxylation par les peracides peut être décrite par un mécanisme de type soit oxénoïde, soit radicalaire. Dans le premier cas on observe une très bonne régio- et stéréosélectivité (6–8); par contre dans le second cas, les résultats sont de ce point de vue, beaucoup moins explicites (2–4). Pourtant les résultats de sélectivité sont souvent utilisés pour remonter au type de mécanisme mis en jeu: en clair, si une réaction est très régio- et surtout très stéréosélective, on en conclut en général que la réaction n'est pas radicalaire.

Nous nous sommes donc proposé d'apporter des réponses précises sur la régio- et stéréosélectivité d'hydroxylation d'un certain nombre d'hydrocarbures saturés cycliques par le peracide benzoïque, dans des conditions expérimentales où le mécanisme est, sans ambiguité, radicalaire.

En effet, au cours des travaux que nous avons effectués sur la réactivité homolytique des peracides, nous avons montré (16) que la décomposition du peracide benzoïque en solution, à ébullition, conduit à l'hydroxylation du solvant, dans la mesure où celui-ci est un donneur d'hydrogène, selon le mécanisme en chaîne décrit dans la fig. 1.

Quand on utilise le cyclohexane comme solvant (R—H) on obtient une mole de cyclohexanol (R—OH) par mole de peracide mis en oeuvre, montrant ainsi l'efficacité du processus.

Comme hydrocarbures saturés nous avons utilisé le cyclohexane, dont les résultats servent de références, le méthylcyclohexane et l'adamantane, pour déterminer la régiosélectivité, et les décalines *cis* et *trans* pour obtenir des informations sur la stéréosélectivité.

Résultats

Le peracide benzoïque (réf. 22) et l'hydrocarbure à étudier sont dissous dans le benzène, solvant inerte vis-à-vis des radicaux formés. On utilise toujours un excès d'hydrocarbure par rapport au peracide afin de privilégier la réaction [3] de

[1] $\phi CO_3H \rightarrow \phi CO_2^{\cdot} + HO^{\cdot}$

[2] $\phi CO_2^{\cdot} \rightarrow \phi^{\cdot} + CO_2$

[3] $\phi^{\cdot}$ (ou $\phi CO_2^{\cdot}$) + HR $\rightarrow$ ϕH (ou ϕCO_2H) + $R^{\cdot}$

[4] $R^{\cdot} + \phi CO_3H \rightarrow ROH + \phi CO_2^{\cdot}$

[5] $2\phi^{\cdot} \rightarrow \phi - \phi$

FIG. 1

formation du radical $R^{\cdot}$.

Les résultats exprimant la quantité totale d'alcools formés, secondaires et tertiaires, ainsi que la régiosélectivité observée pour le cyclohexane, le méthyl-cyclohexane et l'adamantane sont donnés dans le tableau 1. Les alcools secondaires ne sont oxydés en cétones qu'en très faibles partie (1 à 2%) comme nous l'avions montré précédemment (16) et ces données ne figurent pas dans le tableau.

En présence d'hydroquinone (0,02 *M*), une solution d'adamantane (1 *M*) et de peracide benzoïque (0,1 *M*) donne 9% d'adamantanols secondaire et tertiaire, au lieu des 60% observés sans hydroquinone. Ceci montre bien le caractère radicalaire de l'hydroxylation.

Par rapport à la solution témoin du peracide seul dans le benzène, l'addition d'un hydrocarbure a deux conséquences: (*i*) une diminution de la quantité d'acide benzoïque du fait de la réaction de décarboxylation suivie des réactions [3] et [4]; celles-ci n'ayant pas lieu dans le benzène, le peracide se décompose en acide selon un mécanisme radicalaire mettant en jeu d'autres intermédiaires (16) et plus lent; et (*ii*) une accélération de la vitesse de réaction due précisément aux étapes [3] et [4], sauf dans le cas de méthyl-cyclohexane. Celui-ci, d'ailleurs, joue un rôle inhibiteur pour la décomposition du peracide en solution dans le *cyclohexane* au lieu du benzène ($t_{1/2}$ respectivement de 5 et 100 min pour des solutions 0,1 *M* de peracide benzoïque dans le cyclohexane et dans le cyclohexane contenant 1 *M* de méthyl-cyclohexane).

Ce résultat pose le problème de la réactivité du radical méthyl-cyclohexyle tertiaire comparée à celle du radical cyclohexyle secondaire.

Quelques expériences ont été faites avec des peracides ayant des pK_a différents de celui du peracide benzoïque, tels que les

peracides *m*-chloro et *tert*-butyl-4 benzoïques. Dans le cas du cyclohexane nous avons obtenu sensiblement les mêmes quantités de cyclohexanol quelle que soit la nature du peracide.

La stéréosélectivité de l'hydroxylation a été étudiée dans le cas des décalines *cis* et *trans* (cf. Tableau 2).

Comme dans le cas des autres hydrocarbures, cf. Tableau 2, on observe une accélération de la vitesse de disparition du peracide. Mais surtout le résultat stéréochimique est intéressant: le rapport *trans*/*cis* diminue, dans le cas de la décaline *cis*, quand la concentration en peracide augmente alors qu'il reste constant pour la décaline *trans*. Dans chaque cas l'analyse du mélange réactionnel révèle la présence de diphényle, en très faible quantité, et que nous n'avons pas fait figurer dans le tableau 2.

Discussion

Nos travaux antérieurs (16, 17) ont montré que dans les conditions expérimentales décrites, c'est-à-dire en prenant soin d'éliminer efficacement l'oxygène, le peracide réagit effectivement selon le processus radicalaire.

La régiosélectivité en faveur des C—H tertiaires est déterminée par la réaction [3]; elle est exothermique de 10 à 20 kcal/mol (18) selon que l'on considère les radicaux $Ph^{\cdot}$, ou $PhCO_2^{\cdot}$ et on sait que la vitesse d'arrachement d'un H tertiaire est plus grande que celle d'un H secondaire (19). Ensuite la réaction [4] est également très exothermique et les résultats obtenus précédemment (17) montrent que la réactivité d'un radical vis-à-vis de la liaison O—O d'un peracide est d'autant plus grande que son caractère nucléophile est plus marqué; c'est-à-dire qu'un radical tertiaire est plus réactif qu'un radical secondaire. Les caractéristiques de ces deux réactions [3] et [4] expliquent pourquoi l'hydroxylation a lieu préférentiellement sur les liaisons C—H tertiaires et pourquoi le rendement en alcool croît quand on passe du méthyl-cyclohexane à l'adamantane compte tenu du nombre relatif d'atomes d'hydrogène H tertiaires dans la molécule.

Les résultats stéréochimiques des décalines *cis* et *trans* donnés dans le tableau 2 sont en accord avec ce que l'on sait sur la stéréosélectivité des radicaux décalyle-9 (20, 21). Un précurseur de radical *trans* donne toujours lieu à un maintien de configuration alors que dans le cas d'un précurseur de radical *cis* il faut opérer avec un substrat très réactif, comme l'oxygène ou un hypochlorite, et à forte concentration pour obtenir le produit de réaction *cis*. Nos résultats montrent que la réaction [4] est suffisamment rapide pour être compétitive avec l'isomérisation du radical *cis* en *trans*.

Conclusion

Les liaisons C—H, non activées, des hydrocarbures cycloaliphatiques sont hydroxylées par le peracide benzoïque, selon un processus radicalaire, avec une régiosélectivité de 70% et 80% en faveur des liaisons C—H tertiaires pour le méthylcyclohexane et l'adamantane. Dans le cas des décalines *cis* et *trans*, la stéréosélectivité des décalols-9 peut atteindre 97%.

Ces résultats montrent donc qu'une très bonne stéréosélectivité pour la réaction d'hydroxylation par un peracide ne signifie pas obligatoirement que le processus ne soit pas radicalaire.

Partie expérimentale

Le peracide benzoïque est préparé selon la méthode de Swern[1] (22) par action de H_2O_2 85% sur l'acide benzoïque dans CH_3SO_3H à 95%. La pureté est déterminée par indice de peroxyde (I.P.) (23). Il est nécessaire d'utiliser du peracide fraîchement préparé si on veut obtenir une bonne reproductibilité des résultats.

Les hydrocarbures et le benzène utilisés sont des produits commerciaux dont la pureté a été contrôlée par cpg.

Les analyses sont effectuées par cpg sur un appareil Girdel équipé d'un intégrateur Autolab.

Expérience type

Un ballon de 50 cm^3, surmonté d'un réfrigérant, contenant 10 cm^3 d'une solution à 1 *M* en hydrocarbure et 0,1–0,2 ou 0,5 *M* en peracide benzoïque, est plongé dans un bain thermostaté dont la température est fixée à 100°C. Il est indispensable d'opérer à ébullition vigoureuse pour éliminer l'oxygène dissous, ou se formant au cours de la réaction, sinon on amorce un processus de décomposition du peracide en acide (16). Pour cette raison la température du bain est fixée à 20°C au dessus de celle de l'ébullition du benzène.

On effectue deux expériences simultanées destinées l'une à suivre la vitesse de disparition du peracide par détermination de I.P. au cours du temps, l'autre à effectuer l'analyse quantitative du mélange réactionnel. Les constantes de vitesse (tableau 1) sont exprimées en ordre 1 expérimental. Après 2–3 h d'ébullition il reste seulement 1–2% de peracide. Après estérification par CH_2N_2, l'analyse des produits formés est effectuée par cpg sur deux colonnes (Carbowax 20M, 15%, 2 m ou SE 30, 30%, 4 m) en utilisant des échantillons authentiques et un témoin interne pour le dosage.

[1] L'hydroxylation peut être aussi réalisée en utilisant le peracide dodécanoïque; dans ce cas il y a compétition entre une réaction en chaîne de décarboxylation du peracide en n-undécanol-1 (16, 17) et un transfert sur l'hydrocarbure (réactions [3] et [4]); de ce fait le taux d'hydroxylation de ce dernier est moins bon mais les résultats confirment le caractère radicalaire du processus.

Some isotopic scrambling studies with singly or doubly labeled triphenylvinyl bromide[1]

CHOI CHUCK LEE AND CHARLES Y. FIAKPUI

Department of Chemistry, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received August 10, 1984

CHOI CHUCK LEE and CHARLES Y. FIAKPUI. Can. J. Chem. **63**, 681 (1985).

The solvolysis of triphenyl[2-^{14}C]vinyl bromide (**1**-Br-2-^{14}C) in 70% HOAc − 30% H_2O or in 2,2,2-trifluoroethanol (TFE) carried out in the presence of an excess of *p*-$CH_3C_6H_4SNa$ gave the triphenylvinyl *p*-tolyl thioether (**1**-STol) with a greatly decreased extent of scrambling of the ^{14}C-label from C-2 to C-1 when compared with analogous reactions without the presence of the *p*-toluenethiolate anion. For example, the **1**-STol product from the reaction of **1**-Br-2-^{14}C in 70% HOAc − *p*-$CH_3C_6H_4SNa$ showed only 0.5−0.9% scrambling, while previous studies on the reaction of **1**-Br-2-^{14}C in 70% HOAc − NaOAc gave 14.7 ± 0.7% scrambling. Previous work on the solvolysis of 1,2-diphenyl-2-[$^2H_5$]phenyl[2-^{13}C]vinyl bromide (**1**-Br-2-^{13}C-2-Ph-d_5) in 70% HOAc, as well as the present results from the solvolysis of **1**-Br-2-^{13}C-2-Ph-d_5 in TFE − 2,6-lutidine, gave products derived from all 4 possible isotopomeric triphenylvinyl cations **3**, **4**, **5**, and **6** arising from successive 1,2-phenyl shifts. On the other hand, solvolysis of **1**-Br-2-^{13}C-2-Ph-d_5 in 70% HOAc or TFE containing an excess of *p*-$CH_3C_6H_4SNa$ gave **1**-STol in which the isotopically rearranged product was derived only from ion **5** arising from a 1,2-shift of the unlabeled phenyl group with no detectable amount of production derived from a 1,2-shift of the perdeuterophenyl group. These results are interpreted by the rapid trapping of the triphenylvinyl cation by the highly nucleophilic *p*-toluenethiolate anion.

CHOI CHUCK LEE et CHARLES Y. FIAKPUI. Can. J. Chem. **63**, 681 (1985).

La solvolyse du bromure de triphényl [^{14}C-2]-vinyle (**1**-Br-^{14}C-2), en solution dans un mélange à 70% AcOH − 30% H_2O ou dans du trifluoro-2,2,2 éthanol (TFE) et en présence d'un excès de *p*-$CH_3C_6H_4SNa$, conduit au triphénylvinyl *p*-tolyl thioéther (**1**-STol); comparés aux résultats obtenus lors de réactions analogues effectuées en l'absence de l'anion *p*-toluènethiolate, le taux de brouillage du marqueur ^{14}C de la position C-2 vers la position C-1 est de beaucoup diminué. Par exemple, le taux de brouillage, observé dans le produit **1**-STol obtenu par réaction du **1**-Br ^{14}C-2 dans AcOH à 70%/*p*-$CH_3C_6H_4SNa$, n'est que de 0,5 à 0,9% alors que celui observé antérieurement, lors de la réaction du **1**-Br ^{14}C-2 dans AcOH à 70%/AcONa, s'élève à 14,7 ± 0,7%. Les résultats obtenus antérieurement, lors de la solvolyse du bromure de diphényl-1,2 [$^2H_5$]-phényl-2 [^{13}C-2]-vinyle (**1**-Br ^{13}C-2 d_5-Ph-2) dans AcOH à 70%, ainsi que les résultats obtenus dans le présent travail, lors de la solvolyse du produit **1**-Br ^{13}C-2 d_5-Ph-2 dans un mélange de TFE/lutidine-2,6, conduisent dans chaque cas aux quatre cations triphénylvinyles isotopomères possibles (**3**, **4**, **5** et **6**) provenant de déplacements 1,2 successifs des groupements phényles. Par ailleurs, la solvolyse du produit **1**-Br ^{13}C-2 d_5-Ph-2, dans AcOH à 70% ou dans le TFE contenant un excès de *p*-$CH_3C_6H_4SNa$, conduit au produit **1**-STol dans lequel le seul produit de transposition isotopique provient de l'ion **5** par le biais d'une transposition-1,2 du groupe phényle qui n'est pas marqué; on n'a pas pu déceler de produit provenant d'une transposition-1,2 du groupement phényle perdeutéré. On interprète ces résultats en invoquant un piégeage rapide du cation triphénylvinyle par l'anion *p*-toluènethiolate qui est hautement nucléophile.

[Traduit par le journal]

Introduction

In the solvolysis of triphenyl[2-^{14}C]vinyl bromide (**1**-Br-2-^{14}C) in 70% HOAc − 30% H_2O (to be called 70% HOAc), it was found that the presence of added NaOAc did not significantly affect the extent of isotopic scrambling, 14.7 ± 0.7% scrambling of the label from C-2 to C-1 arising from 1,2-phenyl shifts in the triphenylvinyl cation being observed in the reaction product, 1,2,2-triphenylethanone, when the reaction was carried out with up to 30 molar equivalents of added NaOAc (2). On the other hand, similar solvolyses of trianisyl-[2-^{14}C]vinyl bromide (**2**-Br-2-^{14}C) in 70% HOAc showed decreasing amounts of scrambling with increasing amounts of added NaOAc and the possibility was considered that 1,2-shifts in the solvolysis of **2**-Br-2-^{14}C may occur in the dissociated, free trianisylvinyl cation which may be competitively captured by different nucleophiles, while 1,2-phenyl shifts in the solvolysis of **1**-Br-2-^{14}C may take place in the ion-pair which may be insensitive to the presence of added acetate ions (2). However, subsequent studies (3) have shown that solvolyses of **1**-Br or **2**-Br in 70% HOAc both showed common ion rate depression and exchange with added ^{82}Br-labeled bromide, findings that are diagnostic of the formation of dissociated cations (4). It was, therefore, suggested that the solvolyses of **1**-Br or **2**-Br in 70% HOAc both gave rise to dissociated ions, but the triphenylvinyl cation, being less stable than the trianisylvinyl cation, would react rapidly once it is formed and would show a low selectivity or low ability to discriminate between different nucleophiles, thus resulting in no significant effect of added NaOAc on the extent of scrambling (3). It is of interest to find out if the presence of anion with stronger nucleophilic character than the acetate ion would be able to trap the triphenylvinyl cation and show a lesser extent of scrambling. The *p*-toluenethiolate anion has been used to trap triarylvinyl cations (5). The initial experiments in the present work thus involved a study on the solvolysis of **1**-Br-2-^{14}C in 70% HOAc carried out in the presence of an excess of sodium *p*-toluenethiolate.

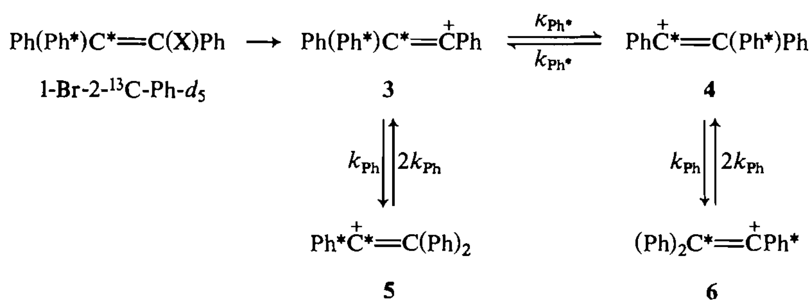
[d]The product from Expts. 1 and 2 was triphenylvinyl p-tolyl thioether (**1**-STol-^{14}C) which was degraded by ozonolysis to benzophenone; the product from Expt. 3 was 1,2,2-triphenylethanone which was oxidized by $KMnO_4$ to benzophenone.
[e]Analyzed as the oxime.



SCHEME 1

Recently, we have investigated the possibility of successive 1,2-shifts in the triphenylvinyl cation using the doubly labeled 1,2-diphenyl-2-[$^2H_5$]phenyl[2-^{13}C]vinyl bromide (**1**-Br-2-^{13}C-2-Ph-d_5) as substrate (6, 7). The present work also included a study on the solvolysis of **1**-Br-2-^{13}C-2-Ph-d_5 in 70% HOAc containing sodium p-toluenethiolate. Due to a combination of its high polarity and low nucleophilicity (8–10), 2,2,2-trifluoroethanol (TFE) is a good solvent for the observation of 1,2-shifts in solvolytic studies. The solvolysis of **1**-Br-2-^{14}C in TFE has been reported (11) and, in the present work, the solvolysis of **1**-Br-2-^{14}C in TFE containing sodium p-toluenethiolate as well as solvolyses of **1**-Br-2-^{13}C-2-Ph-d_5 in TFE with or without added sodium p-toluenethiolate were carried out.

Results and discussion

When **1**-Br-2-^{14}C was solvolyzed in 70% HOAc or in TFE with the presence of 10 molar equivalents of p-$CH_3C_6H_4SNa$, triphenylvinyl p-tolyl thioether (**1**-STol-^{14}C) was obtained as reaction product. Degradation of this thioether by ozonolysis gave benzophenone, the specific activity of which, when compared with that of the thioether from which the benzophenone was obtained, gave the extent of scrambling of the ^{14}C-label from C-2 to C-1. The results are summarized in Table 1. It is seen from Table 1 that the **1**-STol-^{14}C product from the reaction in 70% HOAc showed only 0.5–0.9% scrambling, while similar solvolyses in 70% HOAc containing various amounts of NaOAc gave 14.7 ± 0.7% scrambling (2). For the reaction in TFE, the 3.8–4.2% scrambling observed in the **1**-STol-^{14}C is also much lower than the average value of 44.1% scrambling after complete reaction in the solvolysis of **1**-Br-2-^{14}C in TFE-2,6-lutidine (11). These greatly decreased extents of scrambling, when compared with analogous reactions without the presence of added p-$CH_3C_6H_4SNa$, thus gave conformation of the expectation that the highly nucleophilic p-toluenethiolate anion could trap the triphenylvinyl cation to give **1**-STol-^{14}C and effectively compete and reduce the extent of the 1,2-shift processes.

It is also of interest to note that when **1**-Br-2-^{14}C was solvolyzed in 70% HOAc in the presence of 1, 5, or 10 molar equivalents of added $LiClO_4$, the scramblings observed were 15.3 ± 0.5%, a typical set of data being included in Table 1. This extent of scrambling is essentially the same as the 14.7 ± 0.7% scrambling found for similar solvolyses carried out with different amounts of added NaOAc (2). While $LiClO_4$ was the salt used in the classical work of Winstein showing the occurrence of a special salt effect through interactions with solvent-separated ion-pairs in systems such as the acetolysis of 3-anisyl-2-butyl brosylate (4, 12), $LiClO_4$ was found to give only a normal salt effect, and no special salt effect, in the solvolysis of **1**-Br in 70% HOAc (3). Hence the solvolysis of **1**-Br-2-^{14}C in 70% HOAc with the presence of the poorly nucleophilic perchlorate ion would show no preferential trapping of the triphenylvinyl cation and the extent of scrambling is essentially the same whether $LiClO_4$ or NaOAc is present as an added salt.

In solvolytic reactions with the doubly labeled **1**-Br-2-^{13}C-2-Ph-d_5, 4 isotopomeric triphenylvinyl cations, **3**, **4**, **5**, and **6**, derived from successive 1,2-phenyl shifts, are possible as shown in Scheme 1 (6, 7). From a steady-state treatment, assuming that $k_{Ph} = k_{Ph^*}$, eq. [1] was derived for the ratio of products formed from ions **3**–**6** in terms of α, with $\alpha = k_{SOH}/k_{Ph}$, the ratio of the rate of capture of the cations to give product (k_{SOH}) to the rate of rearrangement from 1,2-phenyl shifts (k_{Ph}) (7).

$$[1] \quad \mathbf{3}:\mathbf{4}:\mathbf{5}:\mathbf{6} = 1.0:(2+\alpha)/[(2+\alpha)^2-2]:1/(2+\alpha):1/[(2+\alpha)^2-2]$$

When a 0.12 M solution of **1**-Br-2-^{13}C-2-Ph-d_5, which was 90% enriched with ^{13}C and essentially completely deuterated (6), was solvolyzed in TFE containing 3 equivalents of 2,6-lutidine under the same conditions as those used to give complete reaction in the trifluoroethanolysis of **1**-Br-2-^{14}C (11), the product obtained was a mixture of isotopomeric triphenylvinyl 2,2,2-trifluoroethyl ethers (**1**-OTFE). Its degradation to benzophenone and analysis by mass spectrometry using the chemical ionization technique as previously described (6) gave the distribution of products derived from the precursor ions **3**, **4**, **5**, and **6** as summarized in Table 2. It has already been indicated that the analogous trifluoroethanolysis of **1**-Br-2-^{14}C gave a mean value of 44.1% scrambling of the ^{14}C-label from C-2 to C-1 (11). Using eq. [2], which has previously been employed in the treatment of such ^{14}C scrambling data (13), k_{SOH}/k_{Ph} or α is calculated to be 0.54. Using this value of α and eq. [1], the distribution of products from ions **3**–**6** in the

$$[2] \quad [\text{unrearranged product}]/[\text{rearranged product}] = 1 + (k_{SOH}/2k_{Ph})$$

trifluoroethanolysis of **1**-Br-2-^{13}C-2-Ph-d_5 was calculated and the results are also given in Table 2. For comparison, the previous data from solvolyses of **1**-Br-2-^{13}C-2-Ph-d_5 in 70% HOAc containing different amounts of added NaOAc are also included in Table 2. The finding that products are derived from all 4 possible isotopomeric triphenylvinyl cations **3**–**6** and the reasonably good agreement between the observed and calculated product distributions from these cations suggest that, under the solvolytic conditions as employed in Expts. 4 and 5 of Table 2, successive 1,2-phenyl shifts as shown in Scheme 1 do occur in the solvolysis of **1**-Br-2-^{13}C-2-Ph-d_5, and the direct demonstration of such successive 1,2-shifts would not have been possible without the use of double labeling.

When **1**-Br-2-^{13}C-2-Ph-d_5 was solvolyzed in 70% HOAc or TFE in the presence of added p-$CH_3C_6H_4SNa$ in the same way as was done earlier with **1**-Br-2-^{14}C, the thioether product, **1**-STol, that was obtained was degraded to benzophenone, analyzed by mass spectrometry (6), and the results are given as Expts. 6 and 7 in Table 2. It may be noted that the 0.5–0.9% and 3.8–4.2% scramblings of the ^{14}C label (Table 1) observed in the solvolysis of **1**-Br-2-^{14}C in 70% HOAc – p-$CH_3C_6H_4SNa$ and in TFE-p-$CH_3C_6H_4SNa$, respectively, are in fair agreement with the 1.0–1.7% and 2.4–3.6% scramblings, respectively, in the analogous solvolyses using **1**-Br-2-^{13}C-2-Ph-d_5 (Table 2). Interestingly, the rearranged **1**-STol products in Expts. 6 and 7 (Table 2) were derived only from ion **5**, with no detectable amount of rearranged products from ions **4** and **6**. These results indicate that the relatively small extent of rearrangement in the product trapped by the p-toluenethiolate anion was formed after 1,2-shifts of the unlabeled phenyl group, with essentially no trapping of any product arising from 1,2-shifts of the perdeuterated phenyl group which would give rise to ions **4** and **6** as shown in Scheme 1. Apparently, when **1**-Br-2-^{13}C-2-Ph-d_5 was solvolyzed in 70% HOAc – NaOAc or in TFE – 2,6-lutidine, the triphenylvinyl cation formed under these conditions would have a sufficiently long lifetime to allow for the occurrence of repeated cycles of successive 1,2-shifts, and even when the assumption was made that the magnitude of any isotope effect was small and $k_{Ph} = k_{Ph^*}$, the

[a]Solvolysis of 0.12 M **1**-Br-2-^{13}C-2-Ph-d_5 in TFE containing 0.36 M 2,6-lutidine at 150 ± 2°C for 20 days.
[b]Mean values from solvolyses of 60 mM **1**-Br-2-^{13}C-2-Ph-d_5 in 70% HOAc containing 0, 5, or 10 equivalents of NaOAc to 150 ± 2°C for 2 or 10 days (6, 7).
[c]Same as Expt. 1 of Table 1 except that **1**-Br-2-^{13}C-2-Ph-d_5 instead of **1**-Br-2-^{14}C was the substrate.
[d]Same as Expt. 2 of Table 1 except that **1**-Br-2-^{13}C-2-Ph-d_5 instead of **1**-Br-2-^{14}C was the substrate.
[e]Calculated using eq. [1].

calculated distribution of products from **3**–**6** was in reasonably good agreement with the observed data. On the other hand, for the analogous solvolyses carried out in the presence of the highly nucleophilic *p*-toluenethiolate anion, the triphenylvinyl cation that was formed would be trapped rapidly to give the thioether with essentially no cycles of successive 1,2-shifts. Under such conditions, the isotope effect favoring a 1,2-shift of the unlabeled phenyl over the perdeuterophenyl group is more apparent, resulting in the mass spectral detection of only the isotopically rearranged product derived from ion **5**.

Experimental

Previously reported methods were used to prepare the required reactants, **1**-Br-2-^{14}C (14), **1**-Br-2-^{13}C-2-Ph-d_5 (6), and sodium *p*-toluenethiolate (5). Illustrations of typical experimental procedures are given below.

Reactions with 1-Br-2-^{13}C-2-Ph-d$_5$

A mixture of 400 mg (1.2 mol) of **1**-Br-2-^{13}C-2-Ph-d_5 and 1.8 g (12 mmol) of *p*-$CH_3C_6H_4SNa$ in 10 mL of TFE in a sealed tube was heated at 150 ± 2°C for 15 days. The resulting material was poured into H_2O and extracted with $CHCl_3$ (3 × 25 mL). The liberated bromide ions in the aqueous layer were titrated with $AgNO_3$ (3), showing essentially complete reaction. The $CHCl_3$ extract was washed with 10% NaOH and with H_2O, dried over $MgSO_4$, and then the $CHCl_3$ was removed by evaporation. The residue was purified by passage through an alumina column with elution by an 8:1 mixture of petroleum ether (bp 40–60°C) and ether. After removal of the solvent from the eluted product, crystallization from ethanol gave 320 mg (69%) of the isotopomeric triphenylvinyl *p*-tolyl thioethers (**1**-STol) which were degraded by ozonolysis (15) to benzophenone and analyzed by mass spectrometry (6) to give the distribution of products from the isotopomeric triphenylvinyl cations **3**–**6**. From the same reaction using non-labeled materials, the recrystallized **1**-STol melted at 134–135°C. *Anal.* calcd. for $C_{27}H_{22}S$: C 85.71, H 5.82; found: C 85.60, H 6.01.

Similarly, the solvolysis of 400 mg (1.2 mmol) of **1**-Br-2-^{13}C-2-Ph-d_5 in 20 mL of 70% HOAc – 30% H_2O (by volume) containing 1.8 g (12 mmol) of *p*-$CH_3C_6H_4SNa$ in a sealed tube at 150 ± 2°C for 8 days gave a 56% yield of the isotopomeric **1**-STol.

The solvolysis of 400 mg (1.2 mmol) of **1**-Br-2-^{13}C-2-Ph-d_5 in 10 mL of TFE containing 390 mg (3.6 mmol) of 2,6-lutidine was carried out at 150 ± 2°C for 20 days and worked up as previously described (11) to give the isotopomeric triphenylvinyl 2,2,2-trifluoroethyl ethers for degradation to benzophenone and analysis by mass spectrometry.

Reactions with 1-Br-2-^{14}C

The solvolyses of **1**-Br-2-^{14}C in TFE or in 70% HOAc containing 10 molar equivalents of added *p*-$CH_3C_6H_4SNa$ were carried out as described above for the analogous reactions with **1**-Br-2-^{13}C-2-Ph-d_5, except that the product was isolated with the addition of 200–300 mg of unlabeled **1**-STol as carrier. Ozonolysis of each sample of **1**-STol-^{14}C to benzophenone and comparison of their specific activities gave the extents of scrambling as summarized in Table 1.

Solvolyses of **1**-Br-2-^{14}C in 70% HOAc in the presence of 1, 5, or 10 molar equivalents of added $LiClO_4$ (3) were also carried out. Typically, a solution of 100 mg (0.30 mmol) of **1**-Br-2-^{14}C and 160 mg (1.5 mmol) of $LiClO_4$ in 20 mL of 70% HOAc in a sealed tube was heated at 150 ± 2°C for 8 days. The mixture was worked up, with the aid of added carrier, to give 1,2,2-triphenylethanone and degraded to benzophenone to give the extent of scrambling as previously described for the solvolysis of **1**-Br-2-^{14}C in 70% HOAc containing added NaOAc (2).

Received January 24, 1984[2]

ANGELO C. BRISIMITZAKIS, DAVID I. SCHUSTER, and JAMES M. VAN DER VEEN. Can. J. Chem. **63**, 685 (1985).

Ultraviolet irradiation of 4-methyl-4-trichloromethylcyclohexa-2,5-dienone in acidic methanol resulted in the stereospecific generation of a solvent adduct, whose structure has been determined by X-ray crystallography, and whose carbon skeleton can be identified with that of the previously postulated zwitterion intermediate. It is concluded that the photochemical rearrangement of this dienone to the corresponding lumiketone proceeds with inversion of configuration at the migratory carbon.

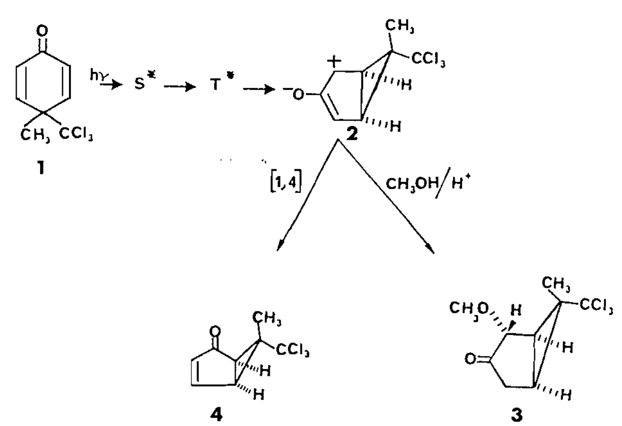
ANGELO C. BRISIMITZAKIS, DAVID I. SCHUSTER et JAMES M. VAN DER VEEN. Can. J. Chem. **63**, 685 (1985).

L'irradiation ultraviolette de la méthyl-4 trichlorométhyl-4 cyclohexadiène-2,5 one, dans du méthanol acidulé, conduit à la génération stéréospécifique d'un adduit de solvant dont on a déterminé la structure par diffraction des rayons-X et dont la structure carbonée peut être identifiée avec celle qui avait été postulée antérieurement pour l'intermédiaire zwitterionique. On en conclut que la transposition photochimique de cette diénone, en lumicétone correspondante, se produit avec une inversion de configuration au niveau du carbone qui migre.

[Traduit par le journal]

Mechanistic interpretations regarding the photochemistry of cross-conjugated cyclohexadienones have centered around a bicyclic zwitterionic intermediate (1). Indirect evidence for the intermediacy of such a species came from thermal generation of such zwitterions from appropriate precursors (2), as well as trapping of such species by cycloaddition reactions with cyclopentadiene and furan (3). Molecular and stereochemical characterization of these adducts relied on analysis of spectral data.

The first direct evidence for the intermediacy of a zwitterion in the photochemistry of dienone **1** involved the isolation of solvent adduct **3**, in which the carbon skeleton of the postulated zwitterion intermediate was preserved (4). Although the report established the overall structure of **3**, the *exo/endo* configuration of the methyl and CCl_3 groups, as well as the relative orientation of substituents to the carbonyl group, were not established.



We now report the complete structure including stereochemistry of **3** based on single crystal X-ray analysis, and its mechanistic implications with respect to the photorearrangement of **1** to lumiketone **4** (5), whose stereochemistry has been established previously (6).

Solvent adduct **3** was prepared by ultraviolet irradiation of dienone **1** in acidic methanol. Careful chromatographic separation on Florisil afforded a pure crystalline sample of **3**, which had previously been isolated only as a colorless oil (4). Spectral data of **3** (^{13}C and ^{1}H nmr, ir, ms) matched those previously reported (4) for the oily adduct, and are consistent with the proposed assignment.

Crystal data

$C_9H_{11}O_2Cl_3$ fw = 257.55

The space group was determined to be triclinic, $P\bar{1}$, with $a = 5.963(3)$, $b = 9.958(4)$, $c = 10.106(4)$ Å, $\alpha = 105.47(3)$, $\beta = 105.52(3)°$, $\gamma = 81.91(3)°$, $Z = 2$, $d_{calc} = 1.54$ g/cm³; $\lambda = 0.7107$ Å. Data was collected on a Nicolet Four-Circle Auto diffractometer using Mo-Kα radiation, a graphite monochromator, and ω-scans with a scan range of 1°. The ratio of background counting time to net scanning time was 0.50. Data were collected in two shells with a scan rate of 6.00°/min for $2\theta = 3.00° - 43.00°$ and 4.00°/min for $2\theta = 43.00° - 55.00°$. Six check reflections were monitored every three hundred reflections and showed no decay during the data collection. Of the 2546 reflections collected, 1905 with $F > 2\sigma(F)$ were treated as observed.

The structure was solved using Multan-80 (7). In the first *E*-map the three chlorine atoms and eight other atoms were located. The remaining three atoms were found in a difference map following a structure Fourier factor calculation. Isotropic refinement[3] resulted in an *R*-factor[4] of 0.192 after six least-square cycles. Three anisotropic refinement cycles reduced *R* to 0.090. All the hydrogen atoms were apparent in a difference map at this point. Six cycles of weighted least-squares refine-

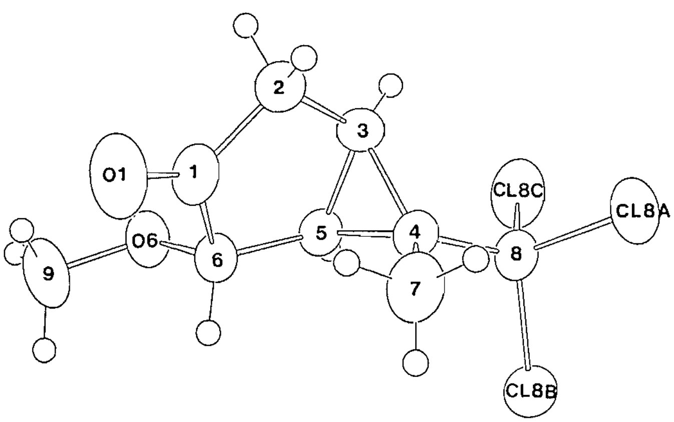

FIG. 1. Crystal structure of **3**.

ment[5] resulted in an R-factor of 0.074. Fractional coordinates, bond distances, and bond angles are shown in Tables 1, 3, and 4, while thermal factors and structure factors are reported in Tables 2 and 5 which are published as supplemental material.[6] An ORTEP (8) drawing of the molecule is shown in Fig. 1. At this point the largest peak in a difference map was 0.44 e/Å^3. None of the peaks in the difference map could be explained in terms of a disordered structure or a solvent molecule. The compound was sensitive to light and this may have contributed to the relatively high R factor, although no crystal deterioration was apparent in the intensities of the check reflections.

The X-ray structure of **3** reveals that attack of methanol occurs, as previously postulated, on the less hindered side of zwitterion **2** opposite to the three-membered ring, on which the C-6 methyl group occupies an *endo* orientation. This structure requires the zwitterion precursor to have the configuration

shown in **2**. Therefore, the [1,4]-sigmatropic shift necessary to proceed from zwitterion **2** to lumiketone **4** must involve retention of the *exo/endo* orientation of the substituents at C-6. This results in an overall inversion of configuration at the migrating carbon of **2**, consistent with Woodward–Hoffmann predictions (9) for a concerted ground state [1,4]-sigmatropic shift originating from zwitterions such as **2**.

Details of the synthesis and physical properties of (μ-Cl)(μ-pz)[Rh(CO)$_2$]$_2$ are given. Crystals of (μ-chloro) (μ-pyrazolyl)-bis(dicarbonylrhodium(I)) are monoclinic, a = 7.0970(8), b =20.5184(10), c = 15.808(2) Å, β = 94.695(6)°, Z = 8, space group $P2_1/c$. The structure was solved by conventional heavy-atom methods and was refined by full-matrix least-squares procedures to R = 0.035 and R_w = 0.038 for 2949 reflections with $I \geq 3\sigma(I)$. The complex provides a rare example of molecular stacking in a binuclear transition metal complex with Rh···Rh distances of 3.5107(8) and 3.6201(8) Å.

BRENDA M. LOUIE, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **63**, 688 (1985).

On rapporte des détails relatifs à la synthèse et aux propriétés physiques du (μ-Cl)(μ-pz)[Rh(CO)$_2$]$_2$. Les cristaux du (μ-chloro)(μ-pyrazolyl) bis(dicarbonylrhodium(I)) sont monocliniques, a = 7,0970(8), b = 20,5184(10), c = 15,808(2) Å, β = 94,695(6)°, Z = 8, groupe d'espace $P2_1/c$. On a résolu la structure par les méthodes conventionnelles avec des atomes lourds et on l'a affiné par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de R = 0,035 et R_w = 0,038 pour 2949 réflexions avec $I \geq 3\sigma(I)$. Le complexe correspond à un rare exemple d'empilement moléculaire dans un complexe binucléaire d'un métal de transition avec des distances Rh···Rh égales à 3,5107(8) et 3,6201·Å.

[Traduit par le journal]

Introduction

A recent publication (1) described a series of monomeric Rh(I) complexes involving the bidentate pyrazolyl gallate ligands, $Me_2Gapz_2^-$. In addition, the structural characterization of two binuclear Rh(I) species [Rh(μ-3,5-Me$_2$pz)L—L]$_2$ (where L—L = (CO)$_2$ or COD; 3,5-Me$_2$pz = 3,5-dimethylpyrazolyl, $N_2C_5H_7$) was reported. Our investigations in this area have subsequently produced a mixed-bridge binuclear species, namely (μ-Cl)(μ-pz)[Rh(CO)$_2$]$_2$, which we have structurally characterized and which is a rare example of molecular stacking via weak intermolecular Rh···Rh interactions in zig-zag chains.

Experimental

(μ-Chloro)(μ-pyrazolyl)bis(dicarbonylrhodium(I)) was isolated in low yield as an orange crystalline material from the benzene extract of the products from the reaction:

$$[Rh(\mu\text{-}Cl)(CO)_2]_2 + 2\ Napz \rightarrow [Rh(\mu\text{-}pz)(CO)_2]_2 + 2\ NaCl$$

The compound is readily volatile and air stable. *Anal.* calcd. for (μ-Cl)(μ-pz)[Rh(CO)$_2$]$_2$: C 20.00, H 0.71, N 6.66; found: C 20.08, H 0.70, N 6.42. ^{1}H nmr (C_6D_6, τ values refer to $\tau(C_6D_6)$ = 2.84 ppm): 2.88 d (J ~ 2 Hz, pz-H^3 and pz-H^5), 4.14 t (J ~ 2 Hz, pz-H^4). Infrared ν_{CO} (cyclohexane) 2020, 2075, and 2090 cm^{-1}. The mass spectrum displayed the parent ion grouping (P$^+$) as its strongest signal (100%) with the P − CO$^+$ (65%), P − 2CO$^+$ (75%), P − 3CO$^+$ (75%), P − 4CO$^+$ (70%), P − 4CO − pzH$^+$ (65%), and Rh$^+$ (70%) ions giving rise to other prominent signals in the spectrum.

Spectra

The ^{1}H nmr spectrum was recorded on a Varian XL 100 instrument, the ir spectrum on a Perkin-Elmer 598 spectrometer and the mass spectrum on a Varian MAT CH4B spectrometer at 70 eV and 25°C.

X-ray crystallographic analysis

A crystal bounded by the six faces (followed by their distances in mm from a common origin): ±(1 0 0), 0.345, ±(0 1 0), 0.100, ±(0 0 1), 0.025 was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 26–40°) measured on a diffractometer with Mo-$K\alpha$ Radiation ($\lambda(K\alpha_1)$ = 0.70930, $\lambda(K\alpha_2)$ = 0.71359 Å). Crystal data at 22°C are:

$C_7H_3ClN_2O_4Rh_2$ fw = 420.38
Monoclinic, a = 7.0970(8), b = 20.5184(10), c = 15.808(2) Å, β = 94.695(6)°, V = 2294.2(4) Å^3, Z = 8, ρ_c = 2.434 g cm^{-3}, $F(000)$ = 1584, μ(Mo-$K\alpha$) = 30.67 cm^{-1}. Absent reflections: $h0l$, l odd, and $0k0$, k odd, uniquely indicate the space group $P2_1/c$ (C^5_{2h}, No. 14).

Intensities were measured with graphite-monochromated Mo-$K\alpha$ radiation on an Enraf-Nonius CAD4-F diffractometer. An $\omega-2\theta$ scan at 1.12–10.06° min^{-1} over a range of (0.70 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 55°. The intensities of three check reflections, measured every 3600 s throughout the data collection, decreased uniformly to values of approximately 80% of the initial values, the data being scaled accordingly. After data reduction,[1] an absorption correction was applied using the analytical method (2, 3). Transmission factors ranged from 0.537 to 0.856. Of the 5255 crystallographically unique reflections measured, 2949 (56.1%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The structure was solved by conventional heavy atom methods, the coordinates of the Rh and Cl atoms being determined from the Patterson function and those of the remaining atoms from subsequent difference maps. In the final stages of the full-matrix least-squares refinement, the non-hydrogen atoms were refined with anisotropic and the H atoms with isotropic thermal parameters. The scattering factors of ref. 4 were used for non-hydrogen atoms and those of ref. 5 for hydrogen atoms. Anomalous scattering factors from ref. 6 were used for the Rh and Cl atoms. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of refinement. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.035 and R_w = 0.038 for 2949 reflections with $I \geq 3\sigma(I)$. For all 5255 reflections R = 0.111. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

[1]The computer programs used include locally written programs for data processing and locally modified versions of the following: ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

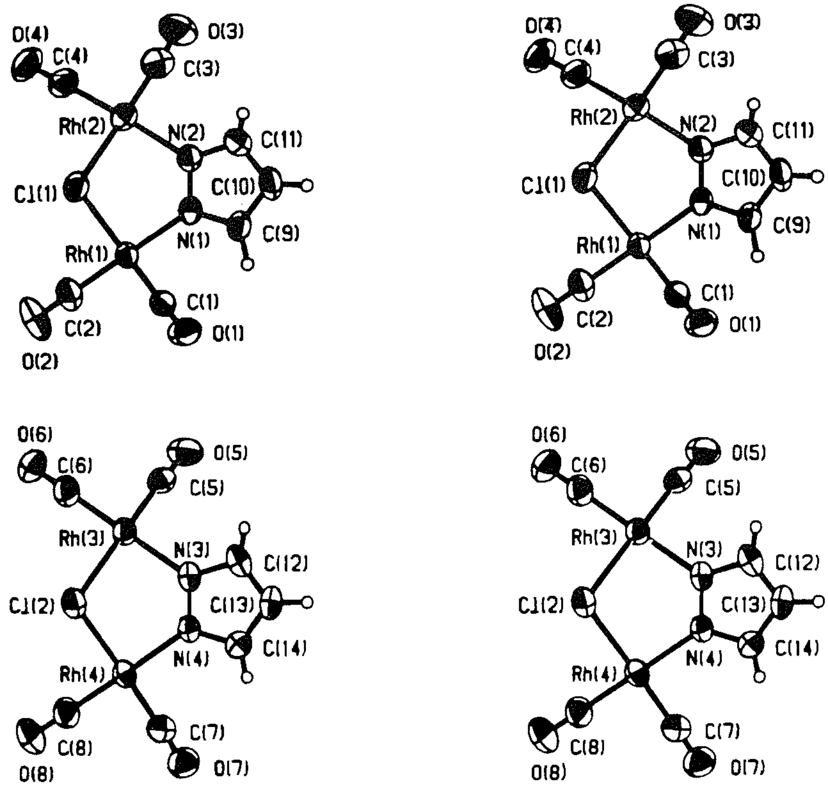

FIG. 1. Stereoscopic views of the two independent (μ-Cl)(μ-pz)[Rh(CO)$_2$]$_2$ molecules; 50% probability thermal ellipsoids are shown. Hydrogen atoms are assigned arbitrarily small thermal parameters for clarity.

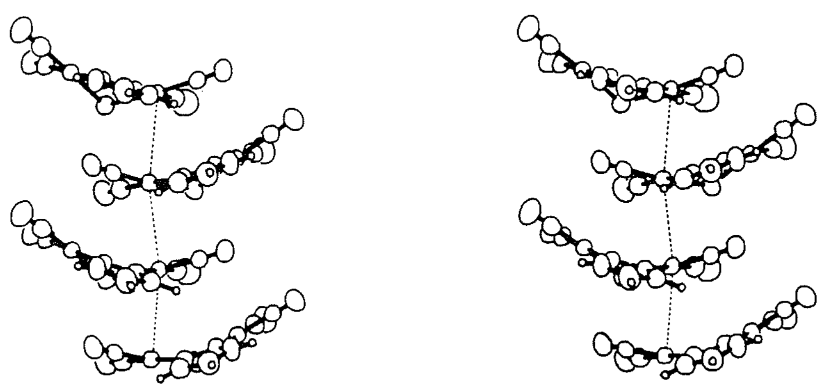

FIG. 2. Stereoscopic view of the stacking of (μ-Cl)(μ-pz)[Rh(CO)$_2$]$_2$ molecules; dotted lines indicate intermolecular Rh···Rh interactions.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.01 and 0.10σ, respectively. The mean error in an observation of unit weight was 1.438. A final difference map showed maximum fluctuations of -1.56 to $+0.97$ e Å^{-3} near Rh and was essentially featureless elsewhere. The final positional and thermal parameters appear in Tables 1 and 5,[2] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (7). The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0037 Å^2. Each of the two independent molecules behaved reasonably well as a rigid body (rms ΔU_{ij} = 0.0080 and 0.0066 Å^2). The appropriate bond distances have been corrected for libration (7, 8), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 2 along with the uncorrected values; corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 3. Intra-annular torsion angles defining the conformations of five-membered chelate rings are listed in Table 4. Bond lengths and angles involving hydrogen and a complete listing of torsion angles (Tables 6–8) are included as supplementary material.[2]

Results and discussion

To our knowledge only one previous example of a binuclear transition metal species bridged by both an exobidentate pyrazolyl and a single atom ligand has been structurally characterized. Johnson and co-workers (9) recently reported the

structure of the Pt(II) species $(Pt(\mu\text{-pz})(\mu\text{-Cl})(Cl)(C_2H_4))_2$ in which π-bonding between the pyrazolyl moiety and the Pt(II) centres was invoked to explain the planarity of the five-membered Pt_2N_2Cl ring. The title compound does not display this planarity but rather the expected puckered arrangement for the Rh_2N_2Cl rings which have conformations best described as Cl-envelopes (see Fig. 1 and Table 4). This imparts an overall bowed shape to each of the two crystallographically independent molecules, the angles between normals to the mean metal coordination planes being 41.4(2) and 34.2(2)°. The pyrazolyl rings (planar to within experimental error) are rotated out of the metal coordination planes by an average of 24.9°, individual values ranging from 17.9(2) to 29.7(2)°. The coordination about Rh is distorted square planar, each of the four indepenent RhC_2NCl groupings being significantly non-planar (maximum deviation from the mean plane 0.077(7) Å). The mean[3] structural parameters: Rh—Cl = 2.371(8), Rh—N = 2.065(6), Rh—C(*trans* to Cl) = 1.833(11), Rh—C(*trans* to N) = 1.869(8), C—O(*trans* to Cl) = 1.142(13), C—O(*trans* to N) = 1.127(8) Å, and Rh—Cl—Rh = 101.1(11)° are normal.

The structure of $(\mu\text{-Cl})(\mu\text{-pz})[Rh(CO)_2]_2$ does, however, offer a different type of rarity in that the molecules in the crystal lattice form one-dimensional stacks with alternate Rh atoms in the binuclear units interacting intermolecularly in a zig-zag chain arrangement (Fig. 2). Recently Stobart and co-workers (10) reported a similarly rare example of molecular stacking involving interactions between Rh atoms in adjacent mononuclear molecular units $Rh(CO)_2(Cl)(pzH)$, with Rh···Rh separations in the zig-zag chains of 3.4522(4) Å. The Rh···Rh distances in the present complex alternate between 3.5107(8) [Rh(1)···Rh(3) (1 + *x*, *y*, *z*)] and 3.6201(8) Å [Rh(1)···Rh(3)] with individual stacks being separated by normal van der Waals distances. A possible explanation for the longer distances in $(\mu\text{-Cl})(\mu\text{-pz})[Rh(CO)_2]_2$ is the marked non-planarity of the molecules which can be clearly seen in Fig. 2. At each Rh atom involved, one of the Rh···Rh interactions is

[3]Here and elsewhere in this report mean values refer to weighted means with rms deviations from the mean in parentheses.

more nearly perpendicular to the Rh coordination plane than the other (deviations from perpendicularity are 5.6 and 15.1° at Rh(1), 4.8 and 11.1° at Rh(2)). It is noteworthy that these intermolecular distances, involving only one metal atom of each binuclear species, are shorter than the intramolecular distances Rh(1)···Rh(2) = 3.6274(8) and Rh(3)···Rh(4) = 3.6770(8) Å. The intermolecular distances, whilst longer than those reported by Stobart and co-workers (10), are nevertheless still close to the Rh···Rh distances of 3.253 and 3.271 Å in $Rh(CO)_2(acac)$ (11) for which intrinsic semi-conductor behavior has been suggested on the basis of conductivity measurements (12). Similar ground state non-zero Rh···Rh bond orders have recently been suggested for related face-to-face Rh(I) dimers on the basis of spectroscopic evidence by Gray and co-workers (13, 14). Interestingly Ferraro and Mertes in their recent review (15) mention that in the transition metal area efforts to achieve one-dimensional chains using binuclear complexes have not been successful. It appears that the present complex provides an example in this category.

The synthesis and characterization of a number of Ir(I) complexes incorporating bidentate, chelating, pyrazolylgallate ligands are described. Non-rigidity for some of the complexes in solution has been demonstrated by variable temperature ^{1}H nmr studies. Crystal structures of three complexes, [Me_2Gapz_2]Ir(COD), [Ir(μ-pz)$(CO)_2$]$_2$, and [Ir(μ-3,5-Me_2pz)$(CO)_2$]$_2$ are reported and confirm the expected boat conformations for the six-membered M—(N—N)$_2$—Ir rings (where M = Ir or Ga) in the compounds. One of the complexes studied has exhibited measurable activity as a catalyst in the hydrogenation reaction of cyclohexene.

SOPHIA NUSSBAUM, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **63**, 692 (1985).

On décrit le synthèse et la caractérisation d'un certain nombre de complexes de Ir(I) incorporant des ligands bidentates et chélatants du type pyrazolylgallate. Faisant appel à des études de rmn du ^{1}H à températures variables, on a démontré que, en solution, quelques uns de ces complexes ne sont pas rigides. On rapporte les structures de trois complexes, soit le [Me_2Gapz_2]Ir(COD), le [Ir(μ-pz)$(CO)_2$]$_2$ et le [Ir(μ-Me_2-3,5pz)$(CO)_2$]$_2$ et on confirme que, dans ces composés, les cycles à six chaînons M—(N—N)$_2$—Ir (où M = Ir ou Ga) existent sous les conformations bateaux que l'on avait prévues. Un des complexes étudiés présente une activité mesurable comme catalyseur pour l'hydrogénation du cyclohexène.

[Traduit par le journal]

Introduction

Recently we reported a series of Rh(I) complexes involving the bidentate chelating pyrazolylgallate ligands, [Me_2Gapz_2]$^-$ and [$Me_2Ga(3,5\text{-}Me_2pz)_2$]$^-$ (where pz = pyrazolyl, $N_2C_3H_3$ and 3,5-Me_2pz = 3,5-dimethylpyrazolyl, $N_2C_5H_7$) (1, 2). We have extended our investigations in this area and now report the synthesis and characterization of a number of Ir(I) complexes, [Me_2Gapz_2]Ir(COD), [Me_2Gapz_2]Ir$(CO)_2$, [Me_2Gapz_2]Ir(CO)(PPh_3), and [$Me_2Ga(3,5\text{-}Me_2pz)_2$]Ir(CO)($PPh_3$). The X-ray crystal structures of the three complexes [Me_2Gapz_2]Ir(COD), [Ir(μ-pz)$(CO)_2$]$_2$, and [Ir(μ-3,5-Me_2pz)$(CO)_2$]$_2$ are reported.

Experimental

All reactions and purifications were performed under a nitrogen atmosphere using Schlenk glassware or a glove-box. Tetrahydrofuran (THF) was dried by refluxing over sodium/benzophenone and distilled prior to use. Benzene was dried by refluxing over molten potassium. Hexane was distilled from calcium sulphate. [Ir(COD)Cl]$_2$ (Strem Chemicals) was used as supplied or prepared according to a literature method (3). Ir(CO)Cl$(PPh_3)_2$ (Strem Chemicals) and PPh_3 (MCB) were used as supplied. Ir$(CO)_2$Cl(p-$NH_2C_6H_4CH_3$) was prepared as described in the literature (4). The sodium salts of the gallium ligands [Me_2Gapz_2]$^-$, [$Me_2Ga(3,5\text{-}Me_2pz)_2$]$^-$, and [$MeGapz_3$]$^-$ were prepared as THF solutions as described earlier (5).

Preparation of [Me_2Gapz_2]Ir(COD)

[Ir(COD)Cl]$_2$ (0.200 g, 0.30 mmol) was dissolved in 50 mL THF and cooled to −78°C. Na[Me_2Gapz_2] (8.2 mL, 0.61 mmol) was added dropwise with stirring. The dark orange mixture was stirred for an additional 1.5 h at −78°C and the solvent was then removed under vacuum at 0°C. The residue was extracted into hexane and yielded large, air-stable, crystals in ~70% yield. Mp 112°C. *Anal.* calcd. for [Me_2Gapz_2]Ir(COD): C 35.96, H 4.50, N 10.49; found: C 36.02, H 4.55, N 10.31. ^{1}H nmr and ir data are reported in Table 1. The mass spectrum of the complex shows a weak signal (1.2%) due to the parent ion P$^+$ at m/e 534 (based on ^{193}Ir and ^{69}Ga), the most intense peak (100%) being due to the P − Me$^+$ ion.

From the hexane-insoluble materials [Ir(μ-pz)(COD)]$_2$ was obtained in ~23% yield by recrystallization from benzene.

Preparation of [Me_2Gapz_2]Ir$(CO)_2$

Method 1: from [Me_2Gapz_2]Ir(COD)

CO gas was passed through a solution of [Me_2Gapz_2]Ir(COD) in hexane at −78°C. The color of the solution turned instantly from orange to pale yellow. An ir spectrum of the solution showed two strong ν_{CO} stretching vibrations at 2074 and 2005 cm^{-1}. Evaporation of the solvent under vacuum at low temperature (−78 to −30°C) resulted in the appearance of the starting material whilst evaporation of the solvent at 0°C gave a mixture of [Ir(μ-pz)$(CO)_2$]$_2$ and [Me_2Gapz_2]Ir$(CO)_2$. Samples of the latter complex were also prepared by passing CO through solutions of [Me_2Gapz_2]Ir(COD) in C_6D_6 and d_6-acetone in nmr tubes. The ^{1}H nmr spectra (Fig. 1) were recorded immediately and revealed the presence of [Me_2Gapz_2]Ir$(CO)_2$ as the main product together with up to ~25% of the corresponding Ir carbonyl dimer [Ir(μ-pz)$(CO)_2$]$_2$. The latter complex exhibits three strong bands in the ν_{CO} region of the ir spectrum at 2083, 2070, and 2011 cm^{-1}. Its ^{1}H nmr in C_6D_6 consists of a triplet at τ = 4.03 (H^4) and a doublet at τ = 2.68 ppm (H^3, H^5).

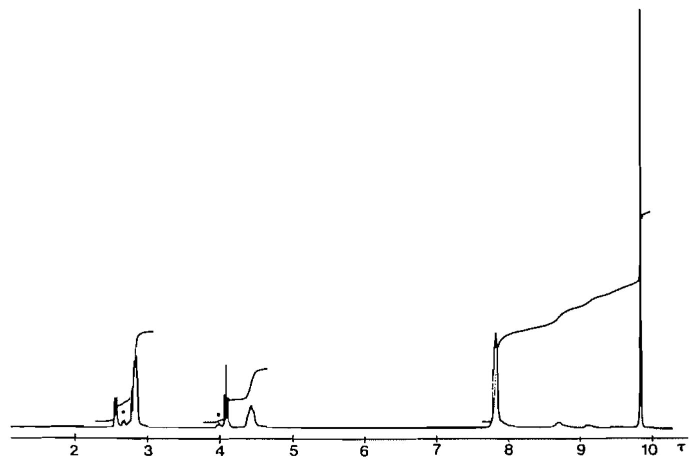

FIG. 1. Room temperature 80 MHz ^{1}H nmr spectrum of [Me_2Gapz_2]Ir$(CO)_2$ in C_6D_6 prepared directly in the nmr tube. Small peaks marked with an asterisk show the presence of the dimer species [Ir(μ-pz)(COD)]$_2$ whilst peaks at 4.4 and 7.8 τ are due to free COD.

Method 2: from Ir$(CO)_2$Cl(p-$NH_2C_6H_4CH_3$)

Ir$(CO)_2$Cl(p-$NH_2C_6H_4CH_3$) (0.100 g, 0.256 mmol) was dissolved in 20 mL THF and the solution was cooled to −78°C. Na[Me_2Gapz_2] (4.0 mL, 0.3 mmol) was added dropwise with stirring. The color turned from brown to dark yellow immediately. The solution was stirred for 30 min at low temperature and then the solvent was re-

*τ values refer to $\tau_{C_6H_6} = 2.84$ ppm, s = singlet, d = doublet, t = triplet, m = multiplet; $J_{HCCH} \approx 2$ Hz for pz protons. Assignment of pz-R^3 and pz-R^5 follows from assignment of other pyrazolyl complexes (34, 35).

moved *in vacuo* at −20°C to yield a black residue. This residue was extracted with hexane and the mixture filtered. On removal of hexane from the filtrate a dark yellow oily material, $[Me_2Gapz_2]Ir(CO)_2$, contaminated with canary-yellow crystals of $[Ir(\mu\text{-pz})(CO)_2]_2$, was obtained.

Preparation of $[Me_2Gapz_2]Ir(CO)(PPh_3)$

Method 1: from $[Me_2Gapz_2]Ir(COD)$

$[Me_2Gapz_2]Ir(COD)$ (0.0625 g, 0.117 mmol) was dissolved in about 10 mL THF and the solution was cooled to −78°C. CO gas was passed through the solution for ~45 min and then PPh_3 (0.028 g, 0.117 mmol) was added to the cold solution and the mixture stirred for an additional 30 min. The color changed from pale yellow to orange on the addition of the phosphine ligand. The solvent was evaporated *in vacuo* and the residue washed with hexane and then dissolved in benzene. The benzene solution yielded a slightly impure orange solid product (contaminated with traces of $[Ir(\mu\text{-pz})(CO)(PPh_3)]_2$) on slow evaporation of the solvent. *Anal.* calcd. for $[Me_2Gapz_2]Ir(CO)(PPh_3)$: C 45.26, H 3.77, N 7.82; found: C 45.34, H 4.09, N 6.50. The mass spectrum of the orange product gave a weak parent ion signal P^+ (0.3%) with the strongest signal being due to the $P - Me^+$ ion. In addition strong signals due to the ions $P - Me - pzH^+$ (15%) and $P - Me - CO - pzH^+$ (64%) were also observed. The hexane washings contained mainly the red dimer $[Ir(\mu\text{-pz})(CO)(PPh_3)]_2$.

Method 2: from $Ir(CO)Cl(PPh_3)_2$

$Ir(CO)Cl(PPh_3)_2$ (0.200 g, 0.256 mmol) was dissolved in ~100 mL THF and $Na[Me_2Gapz_2]$ (3.9 mL, 0.29 mmol) was added dropwise with stirring. The solution was then refluxed for 20 h. After evaporation of the solvent, the residue was washed with hexane and then dissolved in benzene. An oily orange material was again obtained upon evaporation of the benzene solvent.

Method 3: from $Ir(CO)_2Cl(p\text{-}NH_2C_6H_4CH_3)$

$Ir(CO)_2Cl(p\text{-}NH_2C_6H_4CH_3)$ (0.025 g, 0.064 mmol) and PPh_3 (0.017 g, 0.064 mmol) were dissolved in THF and $Na[Me_2Gapz_2]$ (1.0 mL, 0.074 mmol) was added dropwise with stirring. An orange solution resulted. The removal of the THF solvent yielded an orange residue which was extracted with benzene. The benzene solution on evaporation of solvent yielded an oily orange product.

In all three experiments it was found impossible to obtain analytically pure product but in all cases spectroscopic evidence and close analytical figures suggest that the oily orange material is predominantly the desired complex, $[Me_2Gapz_2]Ir(CO)(PPh_3)$.

Reaction of $[Ir(COD)Cl]_2$ with $Na[Me_2Ga(3,5\text{-}Me_2pz)_2]$

$[Ir(COD)Cl]_2$ (0.100 g, 0.15 mmol) was dissolved in ~50 mL THF and the solution cooled to −78°C. $Na[Me_2Ga(3,5\text{-}Me_2pz)_2]$ (3.6 mL, 0.32 mmol) was added dropwise with stirring. The initial light orange color darkened slowly during the addition of the gallate ligand. The solution was stirred for an additional hour at −78°C after the addition of the ligand, and then the solvent was removed under vacuum at −50°C. During the removal of the solvent the color changed gradually to purple. Although mass spectral evidence was obtained for the presence of the compound $[Me_2Ga(3,5\text{-}Me_2pz)_2]Ir(COD)$ in the solid obtained from the reaction, the main Ir-containing product isolated was the dimer $[Ir(\mu\text{-}3,5\text{-}Me_2pz)(COD)]_2$.

Preparation of $[Me_2Ga(3,5\text{-}Me_2pz)_2]Ir(CO)(PPh_3)$

$Ir(CO)Cl(PPh_3)_2$ (0.100 g, 0.125 mmol) was dissolved in ~25 mL THF and the solution cooled to −78°C. $Na[Me_2Ga(3,5\text{-}Me_2pz)_2]$ (1.5 mL, 0.14 mmol) was added dropwise with stirring. The mixture was stirred at −78°C for an additional 90 min. The solvent was then removed *in vacuo* and the residue extracted with hexane. The filtrate gave a yellow product in ~70% yield on slow evaporation of the solvent. This was recrystallized from benzene. *Anal.* calcd. for $[Me_2Ga(3,5\text{-}Me_2pz)_2]Ir(CO)(PPh_3).C_6H_6$: C 51.85, H 4.80, N 6.50; found: C 51.95, H 4.97, N 6.40. Ir and ^{1}H nmr data for the complex are reported in Table 1. The mass spectrum did not show a parent ion signal but did display the $P - Me^+$ ion signal as the strongest in the spectrum. The $P - Me - CO^+$ and $P - Me - CO - (3,5\text{-}Me_2pzH)^+$ ion signals were also observed. The hexane insoluble product was also recrystallized from benzene and proved to be a mixture of the Ir starting material and the dimer $[Ir(\mu\text{-}3,5\text{-}Me_2pz)(CO)(PPh_3)]_2$.

Reaction of $[Ir(COD)Cl]_2$ with $Na[Me_2Ga(3,5\text{-}Me_2pz)_2]$ and CO

$[Ir(COD)Cl]_2$ (0.030 g, 0.045 mmol) was dissolved in ~20 mL THF and the solution cooled to −78°C. $Na[Me_2Ga(3,5\text{-}Me_2pz)_2]$ (1.2 mL, 0.10 mmol) was added dropwise and CO gas passed slowly through the solution which was stirred at −78°C for ~2 h. The solvent was then removed at −78°C to yield an orange residue which was recrystallized from hexane to give orange crystals of $[Ir(\mu\text{-}3,5\text{-}Me_2pz)(CO)_2]_2$. *Anal.* calcd. for $[Ir(\mu\text{-}3,5\text{-}Me_2pz)(CO)_2]_2$: C 24.47, H 2.04, N 8.16; found: C 24.10, H 2.08, N 7.79. ν_{CO} (hexane) 2079, 2060, 2004 cm^{-1}. ^{1}H nmr (C_6D_6), τ = 4.25 s (H^4) and 7.75 s (pz—Me) ppm. The mass spectrum (Fig. 2*b*) displayed the parent ion signal P^+ as the strongest signal in the spectrum, other signals arising from the ions $P - CO^+$, $P - 2CO^+$, $P - 3CO^+$, $P - 3CO - MeCN^+$,

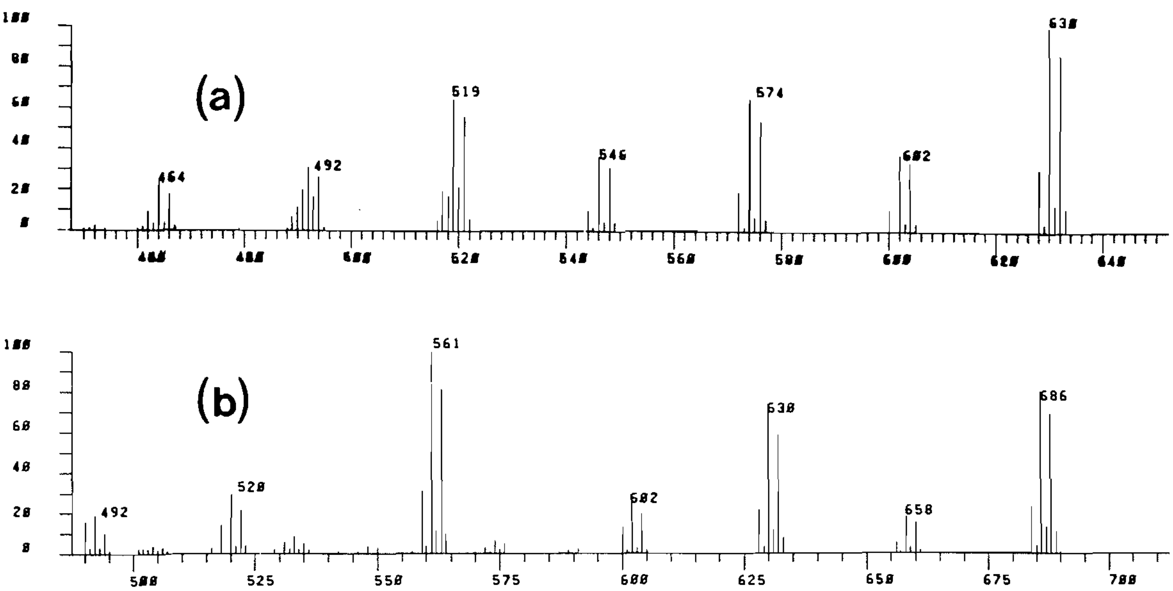

FIG. 2. Partial mass spectra of (*a*) $[Ir(\mu\text{-pz})(CO)_2]_2$ and (*b*) $[Ir(\mu\text{-}3,5\text{-}Me_2pz)(CO)_2]_2$ at 70 eV and 240°C.

and $P - 4CO - 2MeCN^+$. In this reaction, no evidence was obtained for the formation of the desired gallate complex $[Me_2Ga(3,5\text{-}Me_2pz)_2]Ir(CO)_2$.

Reaction of $[Ir(COD)Cl]_2$ with $Na[Me_2Ga(3,5\text{-}Me_2pz)_2]$, CO, and PPh_3

This reaction was identical to the one described above but after the CO had been bubbled through the solution an equimolar amount of PPh_3 was added. No signals corresponding to the gallate complex $[Me_2Ga(3,5\text{-}Me_2pz)_2]Ir(CO)(PPh_3)$ were detected by ^1H nmr spectroscopy of the product. The mass spectrum of the product corresponded to the dimer $[Ir(\mu\text{-}3,5\text{-}Me_2pz)(CO)(PPh_3)]_2$ with the strongest signal due to the parent ion P^+ (100%) and other prominent signals due to the ions $P - CO^+$, $P - CO - (3,5\text{-}Me_2pzH)^+$, and $P - 2CO - (3,5\text{-}Me_2pzH)^+$.

Reaction of $Ir(CO)_2Cl(p\text{-}NH_2C_6H_4CH_3)$ with $Na[Me_2Ga(3,5\text{-}Me_2pz)_2]$

$Ir(CO)_2Cl(p\text{-}NH_2C_6H_4CH_3)$ (0.100 g, 0.26 mmol) was dissolved in 50 mL THF and cooled to −78°C. $Na[Me_2Ga(3,5\text{-}Me_2pz)_2]$ (3.0 mL, 0.29 mmol) was added dropwise with stirring. The color of the solution changed instantly from brown to orange. The solvent was removed *in vacuo* at −50°C to yield an orange residue. This was extracted with hexane. On removal of solvent from the hexane solution orange crystals of the dimer $[Ir(\mu\text{-}3,5\text{-}Me_2pz)(CO)_2]_2$ formed together with a small amount of a yellow solid identified by mass spectral analysis to be the complex $[Me_2Ga(3,5\text{-}Me_2pz)_2]Ir(CO)_2$ (mass spectral signals observed were due to the ions $P - Me^+$ (100%), $P - Me - CO^+$ (56%), $P - Me - 2CO^+$ (19%), and $P - Me - 2CO - (3,5\text{-}Me_2pzH)^+$ (13%)).

Preparation of $[Ir(\mu\text{-pz})(CO)_2]_2$

$[Ir(\mu\text{-pz})(COD)]_2$ (0.020 g, 0.03 mmol) was dissolved in acetone and the solution cooled to −78°C. CO gas was bubbled through the solution for 2 h. The initial purple color first changed to yellow, then to bright green, and finally to dark blue. The cooling bath was then removed and the color of the solution changed back to yellow. The solvent was then allowed to evaporate slowly leaving the product as a mixture of mainly yellow crystals together with a small amount of black solid. Both materials gave virtually identical analytical results. *Anal.* calcd. for $[Ir(\mu\text{-pz})(CO)_2]_2$: C 19.03, H 0.95, N 8.88; found: C 19.05, H 1.03, N 8.74. ν_{CO}(hexane) 2083, 2070, and 2011 cm^{-1}. ^1H nmr (C_6D_6), τ = 4.03 t (H^4) and 2.68 d (H^3, H^5) ppm. The mass spectrum (Fig. 2*a*) of the complex displayed the parent ion signal P^+ as the strongest signal in the spectrum, with other strong signals arising from the ions $P - CO^+$, $P - 2CO^+$, $P - 3CO^+$, $P - 3CO - HCN^+$, $P - 3CO - 2HCN^+$, and $P - 4CO - 2HCN^+$, the latter three ions arising from partial fragmentation of the bridging pyrazolyl moieties.

Spectra

Ir spectra were recorded on a Perkin-Elmer model 598 spectrometer. ^1H nmr spectra were recorded on a Bruker WP-80, a Varian XL-100, or a Bruker WM-400 instrument. Mass spectra were recorded on an AEI MS50 spectrometer at 70 eV and 150 or 240°C. GC/GCMS measurements were performed using 12 m carbowax-20 capillary columns.

X-ray crystallographic analyses

[Dimethylbis(1-pyrazolyl)gallato-N^2,N$^{2\prime}$](cyclooctadiene)iridium(I)

A crystal bounded by the 10 faces (followed by their distances in mm from a common origin): ±(2 1 0), 0.15, ±(2 −1 0), 0.15, ±(1 0 0), 0.16, ±(0 1 0), 0.11, ±(0 1 1), 0.30 was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 45−51°) measured on a diffractometer with Mo-$K\alpha$ Radiation ($\lambda(K\alpha_1)$ = 0.70930, $\lambda(K\alpha_2)$ = 0.71359 Å). Crystal data at 22°C are:

$C_{16}H_{24}GaIrN_4$ fw = 534.33
Orthorhombic, a = 22.8123(10), b = 11.9595(5), c = 6.4497(3) Å, V = 1759.6(1) Å^3, Z = 4, ρ_c = 2.017 Mg m^{-3}, $F(000)$ = 1024, μ(Mo-$K\alpha$) = 90.58 cm^{-1}. Absent reflections: $0kl$, $k + l$ odd, and $hk0$, h odd, space group *Pnma* (D_{2h}^{16}, No. 62) from structure analysis.

Intensities were measured with graphite-monochromated Mo-$K\alpha$ radiation on an Enraf-Nonius CAD4-F diffractometer. An ω−2θ scan at 1.18−10.06° min^{-1} over a range of (0.75 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 65°. The intensities of three check reflections, measured every 3600 s throughout the data collection, showed only minor random fluctuations. After data reduction,[1] an absorption correction was applied using the analytical method (6, 7). Transmission factors ranged from 0.092 to 0.188. Of the 3298 independent reflections measured, 2205 (66.9%) had intensities

[1]The computer programs used include locally written programs for data processing and locally modified versions of the following: ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin and H. A. Levy; FORDAP, Patterson and Fourier synthesis, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

greater than or equal to $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The structure is isomorphous with that of the Rh(I) analog (1), the refinement being initiated with the non-hydrogen atom coordinates from the Rh(I) complex. After full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters to R = 0.042, a difference map gave positions for all H atoms. Attempts to refine the hydrogen atoms with isotropic thermal parameters were not successful. In the final stages of refinement the five trigonal planar H atoms were refined with isotropic thermal parameters while the remaining H atoms were included as fixed contributors in idealized positions (C—H = 0.98 Å). The scattering factors of ref. 8 were used for non-hydrogen atoms and those of ref. 9 for hydrogen atoms. Anomalous scattering factors from ref. 10 were used for the Ir and Ga atoms. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and $\sin\theta/\lambda$ and was employed in the final stages of full-matrix refinement of variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.040 and R_w = 0.046 for 2205 reflections with $I \geq 3\sigma(I)$. For all 3298 reflections R = 0.076. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.009 and 0.07σ, respectively. The mean error in an observation of unit weight was 1.724. A final difference map showed maximum fluctuations of −7.5 to +4.0 e Å^{-3} near Ir and ±0.5 e Å^{-3} away from the heavy atoms. The final positional and thermal parameters appear in Tables 2 and 8,[2] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2]

Bis(μ-pyrazolyl)bis[dicarbonyliridium(I)]

Experimental details are as above except where noted. Crystals of this compound were of poor quality, that eventually used for data collection being very irregular in shape with dimensions of approximately 0.30 × 0.45 × 0.45 mm. Unit-cell parameters were determined from least-squares on 2 sin θ/λ values for 25 reflections with 2θ = 30−37°. Crystal data:

$C_{10}H_6Ir_2N_4O_4$ fw = 630.62

Monoclinic, a = 7.270(2), b = 16.1062(13), c = 11.918(3) Å, β = 94.54(1)°, V = 1391.2(5) Å^3, Z = 4, ρ_c = 3.011 Mg m^{-3}, $F(000)$ = 1120, μ(Mo-$K\alpha$) = 190.7 cm^{-1}. Absent reflections: hkl, $h + k + l$ odd, space group $I2/m$ (non-standard setting of $C2/m$, C^3_{2h}, No. 12, equivalent positions: (0, 0, 0), (1/2, 1/2, 1/2) ±(x, y, z; x −y, z)) from structure analysis.

An ω-2θ scan at 2.24−10.06° min^{-1} over a range of (1.1 + 0.35 tan θ)° in ω was employed. Of 1655 independent reflections measured (to 2θ = 55°), 1098 (66.3%) had intensities greater than or equal to $3\sigma(I)$ above background. The intensities of the three standard reflections displayed non-uniform behaviour, one intensity decreasing (by 7%) while the other two increased (by 10 and 15%). The crystal itself, initially yellow, turned dark brown by the end of the data collection. A correction for non-uniform crystal decay was applied (11), but the irregularity of the crystal surface precluded the application of an absorption correction.

The centrosymmetric space group $I2/m$ was indicated by the Patterson function, from which the position of the Ir atom was determined. The remaining non-hydrogen atoms were positioned from subsequent difference maps and the hydrogen atom positions were calculated. In the final stages of refinement only the Ir atom was refined with anisotropic thermal parameters. Attempts to refine the O, N, and C atoms with anisotropic thermal parameters resulted in non-

[2]The structure factor table, Table 8 (anisotropic thermal parameters) and other material mentioned in the text are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

positive definite temperature factors. Convergence was reached at $R = 0.119$ and $R_w = 0.148$ for 1098 reflections with $I \geq 3\sigma(I)$, for all 1655 reflections $R = 0.159$. The use of standard errors weights resulted in no unusual trends in average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and $\sin\theta/\lambda$. The mean and maximum parameter shifts on the final cycle of refinement corresponded to 0.01 and 0.10 σ, respectively. The mean error in an observation of unit weight was 5.564. An isotropic Type I extinction correction (Thornley-Nelmes definition of mosaic anisotropy with a Lorentzian distribution) was applied (12–14). The final value of g was $0.87(17) \times 10^4$.

Bis(μ-3,5-dimethylpyrazolyl)bis[dicarbonyliridium(I)]xylene (2:1)

The bounding faces of the crystal (followed by their distances in mm from a common origin) were: ±(1 0 −2), 0.03, ±(1 0 −4), 0.06, ±(1 0 0), 0.20, ±(1 −1 0), 0.27, (0 −1 0), 0.27, (2 0 3), 0.07. Crystal data:

$C_{14}H_{14}Ir_2N_4O_4 \cdot 0.5C_8H_{10}$ fw = 739.81

Triclinic, a = 10.877(3), b = 12.532(3), c = 8.591(4) Å, α = 96.02(2), β = 96.55(2), γ = 114.12(1)°, V = 1046.9(6) Å^3, Z = 2, ρ_c = 2.347 Mg m^{-3}, $F(000)$ = 682, μ(Mo-$K\alpha$) = 126.86 cm^{-1}. Absent reflections: none, space group $P\bar{1}$ (C_i^1, No. 2, reduced cell) from structure analysis.

An $\omega-2\theta$ scan at 1.18–10.06° min^{-1} over a range of $(0.80 + 0.35 \tan\theta)°$ in ω was employed. Of 4776 independent reflections measured (to 2θ = 55°), 3437 had intensities greater than or equal to $3\sigma(I)$ above background. The intensities of the standard reflections showed only small random fluctuations. An absorption correction was applied using the Gaussian integration method (6, 15), transmission factors ranging from 0.048 to 0.467 for 364 sampling points.

The centrosymmetric space group $P\bar{1}$ was indicated by both the E-statistics and the Patterson function, from which the coordinates of the Ir atoms were determined. The positions of the remaining non-hydrogen atoms (including those associated with a centrosymmetric xylene solvate) were determined from a subsequent difference map. In the final stages of refinement all non-hydrogen atoms were refined with anisotropic thermal parameters and H atoms were included as fixed contributors in idealized positions. Convergence was reached at $R = 0.039$ and $R_w = 0.049$ for 3437 reflections with $I \geq 3\sigma(I)$; for all 4776 reflections, $R = 0.064$. The mean and maximum parameter shifts on the final cycle of refinement corresponded to 0.06 and 0.25 σ and the mean error in an observation of unit weight was 2.136. Maximum fluctuations on the final difference map corresponded to −4.4 to +3.1 e Å^{-3} near the Ir atoms with no unusual features noted elsewhere.

Bond lengths and angles appear in Tables 3 and 4, respectively and intra-annular torsion angles in Table 5. Calculated hydrogen parameters are given in Table 7.[2] Bond lengths and angles involving H atoms for $[Me_2Gapz_2]Ir(COD)$ (Tables 9 and 10) are included as supplementary material.

Results and discussion

There have been but few reports in the literature dealing with Ir complexes containing polypyrazolylborate ligands. Thus Powell and co-workers (16) reported briefly on a "few" Ir(III) complexes incorporating the $[HB(3,5\text{-}Me_2pz)_3]^-$ ligand and while Bonati *et al.* (17) were successful in isolating the complexes $[H_2Bpz_2]Ir(CO)_2$ and $[H_2Bpz_2]Ir(CO)PPh_3$, King and Bond (18) were unable to isolate any "tractable" products from their experiments in this area. This dearth of information is to be contrasted with the wealth of material available in the area of polypyrazolylborate Rh chemistry (16–24). More recently a considerable effort has focussed on pyrazolyl-bridged Ir dimers (25–29) and Bonati and co-workers (30) have reported the structure of a unique Ir(I) complex containing a monodentate pyrazolyl ligand. As part of an ongoing study of pyrazolylgallate ligands we reported recently our findings in the area of Rh(I) complexes (1, 2, 31). The present paper presents our findings in the related area of Ir(I) chemistry. Thus the two bidentate chelating gallate ligands $[Me_2Gapz_2]^-$ and $[Me_2Ga(3,5\text{-}Me_2pz)_2]^-$ have been used to prepare a number of Ir(I) complexes. In most of the reactions investigated, in addition to the pyrazolylgallate iridium complexes formed, pyrazolyl iridium dimer species were also produced and in a few of the reactions these dimers were the only isolable Ir products. The reactions performed are summarized in Schemes 1 and 2. In addition, the reactivity of some Ir(I) species towards the tridentate pyrazolylgallate ligand $[MeGapz_3]^-$ were also investigated, but in these experiments only pyrazolyl iridium dimers were obtained. The new Ir compounds prepared have been characterized by ir, ^{1}H nmr, mass spectra, and elemental analyses. In addition definitive X-ray structural analyses are presented for the three complexes $[Me_2Gapz_2]Ir(COD)$, $[Ir(\mu\text{-pz})(CO)_2]_2$, and $[Ir(\mu\text{-3,5-}Me_2pz)(CO)_2]_2$.

The complex $[Me_2Gapz_2]Ir(COD)$ was prepared in ~70% yield from $[Ir(COD)Cl]_2$ and $Na[Me_2Gapz_2]$ at low temperature in THF solution. At higher temperatures the yield of the gallate iridium complex is considerably reduced and the pyrazolyl iridium dimer $[Ir(\mu\text{-pz})(COD)]_2$ becomes the predominant product. The complex $[Me_2Gapz_2]Ir(COD)$ can be recrystallized from hexane at room temperature, yielding orange air-stable crystals. The ^{1}H nmr of the complex at room temperature in d_6-acetone displays but one singlet for the "$GaMe_2$" protons and also indicates equivalent pyrazolyl groups in the compound. However, on lowering the temperature (see Fig. 3)

*Here and elsewhere primed atoms have coordinates related to those in Table 2 by the symmetry operations x, $1/2 - y$, z; x, $-y$, z; and $1 - x$, $-y$, $2 - z$ respectively for the three compounds.

the "$GaMe_2$" singlet gradually broadens and eventually splits into two distinct singlets. In addition, a splitting of the olefinic protons on the COD ligand at ~6 τ is very noticeable at lower temperatures. A single crystal X-ray structure of the complex shows the expected boat conformation for the Ga—(N—N)$_2$—Ir six-membered ring (see Fig. 4) in agreement with the low temperature ^{1}H nmr results. Evidently, at room temperature in solution, a rapid inversion of this six-membered ring is taking place to give equivalent Ga—Me groups and olefinic protons in the spectrum, viz.

A similar phenomenon has been observed for the analogous Rh(I) species, $[Me_2Gapz_2]Rh(COD)$ (1). One distinction between the two complexes is that the iridium compound retains its fluxionality to a temperature about 10°C lower than that observed for the corresponding rhodium compound.

The COD ligand in the complex $[Me_2Gapz_2]Ir(COD)$ is

easily replaced by two CO groups when a stream of CO is passed through a solution of the compound in a variety of solvents. At low temperatures the conversion is quantitative, as indicated by two sharp bands in the ν_{CO} region of the ir spectrum in positions expected for a *cis* square planar dicarbonyl iridium complex (32). Infrared signals due to the presence of the dimer species [Ir(μ-pz)$(CO)_2$]$_2$ were not detected. Unfortunately, the [Me_2Gapz_2]Ir$(CO)_2$ complex cannot be isolated from the product solution by simple evaporation of the solvent. Even at −78°C removal of solvent results in the conversion of the [Me_2Gapz_2]Ir$(CO)_2$ complex back to the starting COD complex [Me_2Gapz_2]Ir(COD). If the solvent is removed at higher temperatures some [Ir(μ-pz)$(CO)_2$]$_2$ is formed immediately as evidenced by a more intense yellow coloration and the appearance of new signals in the ν_{CO} region of the ir spectrum. Complete evaporation of the solvent at higher temperatures results in a mixture of two Ir products, [Me_2Gapz_2]Ir$(CO)_2$ and [Ir(μ-pz)$(CO)_2$]$_2$, the latter predominating. An ^{1}H nmr spectrum (Fig. 1) of almost pure [Me_2Gapz_2]Ir$(CO)_2$ can be obtained by preparing the compound directly in an nmr tube. In this spectrum the two methyl groups on the gallium atom give rise to one singlet and this singlet, even at −90°C, broadens only slightly. This suggests either a planar conformation for the Ga—(N—N)$_2$—Ir six-membered ring in this complex, or, more likely, a very facile inversion of the boat conformation in solution. Our inability to isolate pure [Me_2Gapz_2]Ir$(CO)_2$ precluded the collection of accurate elemental analysis data but a good mass spectrum was obtained for the complex. A signal

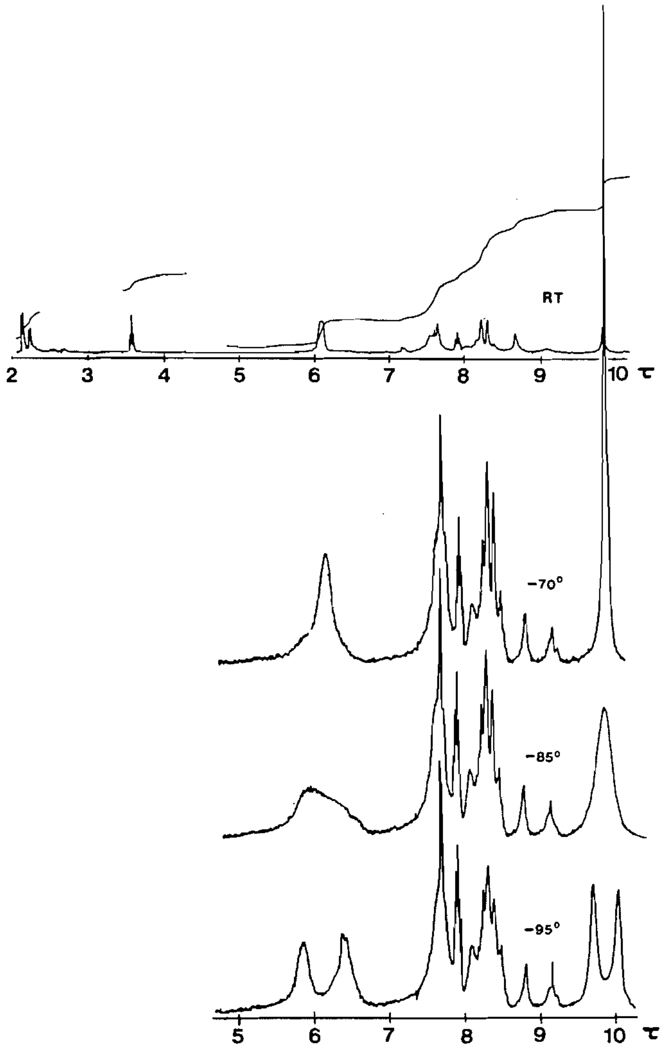

FIG. 3. Room temperature and partial low temperature 80 MHz ^{1}H nmr spectra of $[Me_2Gapz_2]Ir(COD)$ in d_6-acetone solution.

due to the parent ion itself, P^+, was not observed but the strongest signal arose from the $P - Me^+$ ion. The fragmentation pattern also shows strong signals due to the ions resulting from the consecutive loss of two carbonyl groups, $P - Me - CO^+$ and $P - Me - 2CO^+$, and characteristically a strong peak corresponding to an ion where partial loss of a pyrazolyl ring has occurred, $P - Me - 2CO - HCN^+$. The complex $[Me_2Gapz_2]Ir(CO)_2$ can also be prepared by the reaction of $Ir(CO)_2Cl(p\text{-}NH_2C_6H_4CH_3)$ with the gallium ligand. However, the $[Ir(\mu\text{-pz})(CO)_2]_2$ dimer was also produced in quantities varying with the reaction temperature but usually ~50% at −78°C. From this latter reaction the $[Ir(\mu\text{-pz})(CO)_2]_2$ dimer has been crystallized from hexane as yellow air-stable crystals. These have been fully characterized and the predicted boat structure confirmed by X-ray structural analysis (Fig. 5). A previous report (29) mentions this Ir dimer as being unstable. We have found that evaporation of solvent from solutions of the dimer yields, in addition to a yellow crystalline material, a black compound which gave identical ir, nmr, mass spectral and elemental analysis. Interestingly, a biimidazole dicarbonyl iridium complex was also reported as a black solid (33), the color being attributed to some type of weak metal−metal interactions. The black form of $[Ir(\mu\text{-pz})(CO)_2]_2$ can be recrystallized from acetone to give the yellow crystalline form. Solutions of the complex in acetone or benzene change color with temperature, from black up to −50°C through purple to yellow at 0°C and above. The $[Ir(\mu\text{-pz})(CO)_2]_2$ dimer has been prepared also from $[Ir(\mu\text{-pz})(COD)_2]$ and CO, the product having identical properties to those described above.

The $[Me_2Gapz_2]Ir(CO)(PPh_3)$ complex has been prepared via a number of routes (Scheme 1). Its ir spectrum consists of one strong band in the ν_{CO} region of the spectrum at 1980 cm^{-1}. The ^{1}H nmr spectrum of the complex indicates non-equivalence of the bridging pyrazolyl groups as expected and displays a sharp singlet for both methyl groups on the Ga atom at rt. On cooling a d_6-acetone solution of the complex "$GaMe_2$" singlet eventually collapses and is replaced by two singlets at low temperature (Fig. 6) consistent with a boat conformation for the Ga—(N—N)$_2$—Ir six-membered ring. Obviously a fluxional behaviour in solution is again responsible for these observations. The mass spectrum of this complex shows a weak molecular ion peak, P^+, and again the most intense peak is due to the $P - Me^+$ ion, followed by peaks due to the ions $P - Me - CO^+$ and $P - Me - CO - Hpz^+$. The $[Me_2Gapz_2]Ir(CO)(PPh_3)$ compound is unstable in air and, even under an inert atmosphere, decomposes slowly. This instability precluded the collection of good elemental analysis data for the complex.

Reactions involving the $Na[Me_2Ga(3,5\text{-}Me_2pz)_2]$ ligand and various Ir(I) species (Scheme 2) were less productive in terms of producing pyrazolylgallate iridium(I) complexes. Thus the $[Me_2Ga(3,5\text{-}Me_2pz)_2]Ir(CO)(PPh_3)$ complex was the only compound of the series that could be isolated. Both the COD and the dicarbonyl derivatives were unstable with respect to the corresponding iridium dimers, which were the dominant products. Traces of the dicarbonyl complex $[Me_2Ga(3,5\text{-}Me_2pz)_2]Ir(CO)_2$ and the COD complex $[Me_2Ga(3,5\text{-}Me_2pz)_2]Ir(COD)$ were identified by mass spectral analysis of reaction products, the fragmentation patterns of the complexes being similar to those of the $[Me_2Gapz_2]Ir(CO)_2$ and $[Me_2Gapz_2]Ir(COD)$ compounds, respectively.

Crystals of the $[Ir(\mu\text{-}3,5\text{-}Me_2pz)(CO)_2]_2$ dimer were found to be air-stable and have been fully characterized. The ir spectrum of this complex gives three strong ν_{CO} bands and is very similar in appearance to the spectrum of the unsubstituted analog $[Ir(\mu\text{-pz})(CO)_2]_2$. The ^{1}H nmr spectrum of the compound is consistent with the presence of two equivalent 3,5-dimethylpyrazolyl groups and consists of two singlets in the ratio of 1:6 due to the H^4 and pz-Me protons, respectively. A single crystal X-ray analysis (see below) of this dimer has again demonstrated the boat conformation for the compound in the solid state (Fig. 7) with the six-membered Ir—(N—N)$_2$—Ir ring being more puckered than in the structure of $[Ir(\mu\text{-pz})(CO)_2]_2$ (Fig. 5), presumably to relieve steric interactions between the carbonyl groups on the iridium atoms and the methyl groups on the pyrazolyl rings.

The complex $[Me_2Ga(3,5\text{-}Me_2pz)_2]Ir(CO)(PPh_3)$ could be obtained via only one route, from Vaska's complex $Ir(CO)Cl(PPh_3)_2$ and the gallate ligand. It was obtained in good yield if the reaction was performed at low temperature. The complex was recrystallized from benzene to yield yellow air-stable crystals. The ir spectrum of the compound gave one strong ν_{CO} band at 1974 cm^{-1} and the ^{1}H nmr (Fig. 8), even at room temperature, was consistent with a static boat conformation for the Ir—(N—N)$_2$—Ga six-membered ring, the $GaMe_2$ group giving two sharp singlets. Presumably steric interactions between the pz-Me groups and the PPh_3 substituent

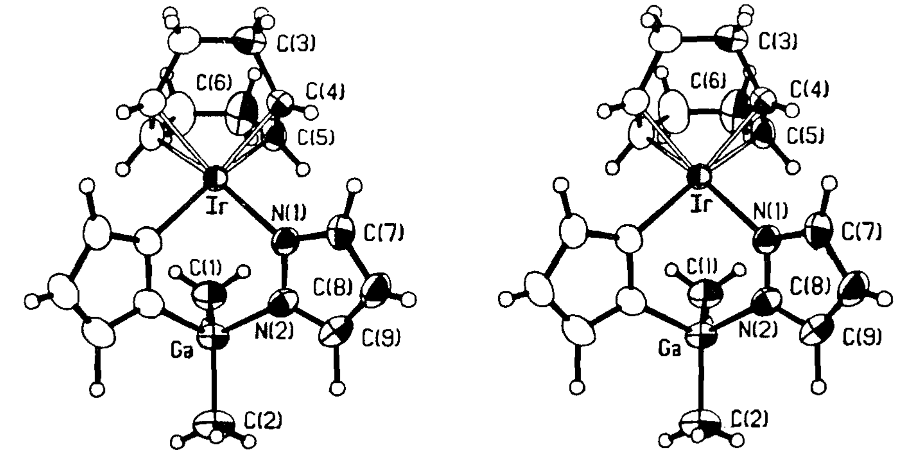

FIG. 4. Stereoview of $[Me_2Gapz_2]Ir(COD)$; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

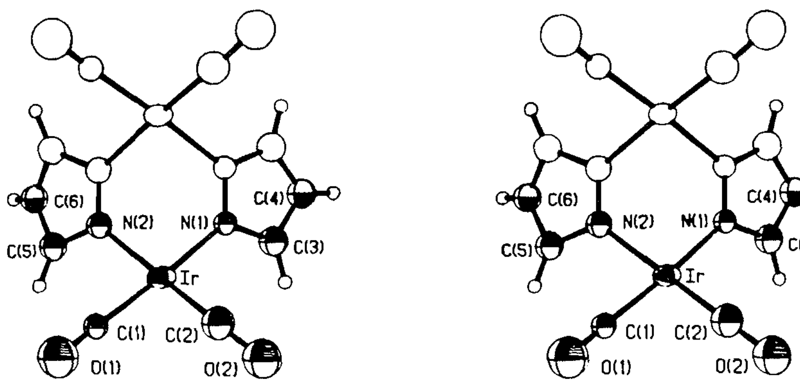

FIG. 5. Stereoview of $[Ir(\mu\text{-}pz)(CO)_2]_2$; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

on Ir severely hinder any rapid ring inversion process such as that above proposed for the compounds containing the "Me_2Gapz_2" moiety. The mass spectrum of $[Me_2Ga(3,5\text{-}Me_2pz)_2]Ir(CO)(PPh_3)$ displays a fragmentation pattern similar to that of the unsubstituted pyrazolyl derivative $[Me_2Gapz_2]$-$Ir(CO)(PPh_3)$, the strongest signal again corresponding to the P − Me^+ ion.

A number of the complexes described above were tested as potential hydrogenation catalysts for 1-hexene and cyclohexene. In general, the reactions in benzene solution were very slow and hydrogen uptake was minimal. However, in the case of $[Ir(\mu\text{-}3,5\text{-}Me_2pz)(CO)_2]_2$ as a catalyst, some conversion of cyclohexene to cyclohexane did occur over a 5 day period using 1 atm of hydrogen at 45°C. The reaction was still proceeding after this period and the catalyst was recovered unchanged from the reaction mixture. Investigations in this area are continuing.

Crystal structures of $[Me_2Gapz_2]Ir(COD)$, $(Ir(\mu\text{-}pz)(CO)_2]_2$, and $[Ir(\mu\text{-}3,5\text{-}Me_2pz)(CO_2)]_2$

All three crystal structures consist of discrete molecules (Fig. 4, 5, and 7), and in the case of $[Ir(\mu\text{-}3,5\text{-}Me_2pz)(CO)_2]_2$, a centrosymmetric xylene of crystallization. Intermolecular distances correspond to normal van der Waals interactions. The structure of $[Me_2Gapz_2]Ir(COD)$ is isomorphous with that of the Rh(I) analog (1), the molecule possessing exact mirror symmetry. The complexes $[Ir(\mu\text{-}pz)(CO)_2]_2$ and $[Ir(\mu\text{-}3,5\text{-}Me_2pz)(CO)_2]_2$ both have approximate C_{2v} symmetry, the former having crystallographic mirror symmetry with the mirror plane perpendicular to the Ir···Ir vector.

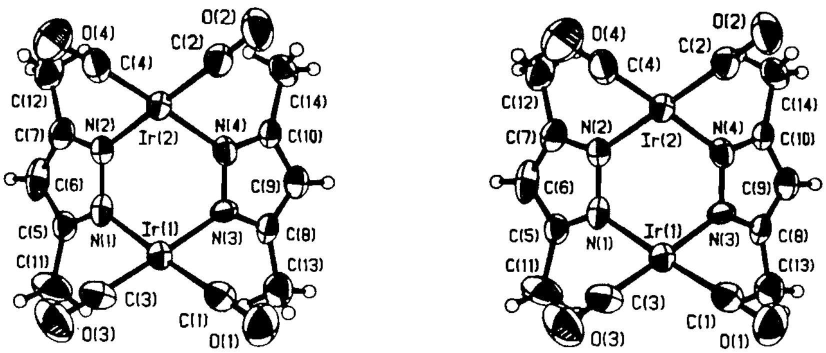

FIG. 7. Stereoview of $[Ir(\mu\text{-}3,5\text{-}Me_2pz)(CO)_2]_2$; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

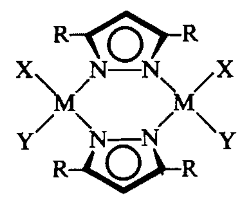
TABLE 6. M···M distances in compounds of the type



M	X	Y	R	M···M (Å)	Reference
Ir		COD	H	3.216	27, 29
Rh		COD	H	3.267	29
Ir		COD	CF_3	3.073	29
Ir		COD	CH_3, CF_3	3.066	29
Rh		COD	CH_3	3.154	1
Ir	CO	PPh_3	H	3.162	26
Ir	CO	CO	H	3.506	This paper
Ir	CO	CO	CH_3	3.245	This paper
Rh	CO	CO	CH_3	3.262	1
Rh	CO	$P(OPh)_3$	H	3.568	36

The Ir(I) atoms in all three structures have distorted square planar coordination geometry, the mean[3] bond lengths involving Ir (Ir—C = 2.124(7) and Ir—N = 2.080(5) Å in $[Me_2Gapz_2]Ir(COD)$; Ir—CO = 1.83(7) and Ir—N = 2.08(3) Å in $[Ir(\mu\text{-}pz)(CO)_2]_2$; Ir—CO = 1.837(5) and Ir—N = 2.071(11) Å in $[Ir(\mu\text{-}3,5\text{-}Me_2pz)(CO)_2]_2$) being both internally consistent and in good agreement with those reported for closely related Ir(I) complexes (26, 27, 29). It is noteworthy that the Ir—N distances in these three molecules are equal within experimental error while the Rh—N distances in the carbonyl complex $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(CO)_2]_2$ were significantly shorter than those in the COD complexes $[Me_2Gapz_2]Rh(COD)$ and $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(COD)]_2$ (1) (2.063(6) vs. 2.087(2) and 2.084(1) Å). Other bond lengths and angles in the three molecules (Tables 3 and 4) assume normal values.

The most important structural features of these molecules is the degree of folding of the central $M—(N—N)_2—M$ six-membered rings and the associated cross-ring M···M distances, the latter being compared for a number of homobinuclear Ir(I) and Rh(I) complexes in Table 6. The M···M distances are influenced most by steric interactions (discussed in refs. 1, 2, 26, 27, 29, 36), being significantly shortened by substitution at the 3- and 5-positions of the bridging pyrazolyl groups or by the introduction of bulky terminal ligands. The M···M distances are similar for Ir and Rh, those involving Rh being longer as shown in Table 6. For the heterobinuclear species $[Me_2Gapz_2]Ir(COD)$ and its Rh analog (1), Ga···Ir = 3.567(1) and Ga···Rh = 3.5527(5) Å while in the sterically hindered complex $[Me_2Ga(3,5\text{-}Me_2pz)_2]Rh(CO)(PPh_3)$ (2) the Ga···Rh distance is shortened to 3.3819(4) Å.

The pyrazolyl groups are planar within experimental error in all three structures, the metal atoms being significantly displaced from the N_2C_3 mean planes in each case. These deviations are greatest in the case of $[Ir(\mu\text{-}3,5\text{-}Me_2pz)(CO)_2]_2$ where the mean deviation from the mean plane is 0.114 Å. The Ir coordination groups are all slightly but significantly nonplanar, the maximum deviation from the ML_4 mean plane being 0.024(2) Å for $[Ir(\mu\text{-}pz)(CO)_2]_2$.

[3]Here and elsewhere in this report mean values refer to weighted means with rms deviations from the mean in parentheses.

Crystal and molecular structure of *fac*-[dimethylbis(1-pyrazolyl)gallato-N,N']-(triphenylphosphine)tricarbonylrhenium(I)

BRENDA M. LOUIE, STEVEN J. RETTIG, ALAN STORR, AND JAMES TROTTER
Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received August 3, 1984

BRENDA M. LOUIE, STEVEN J. RETTIG, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **63**, 703 (1985).

Crystals of *fac*-[dimethylbis(1-pyrazolyl)gallato-N,N'](triphenylphosphine)tricarbonylrhenium(I) are triclinic, $a = 9.479(2)$, $b = 16.258(4)$, $c = 20.412(6)$ Å, $\alpha = 110.06(1)$, $\beta = 95.46(1)$, $\gamma = 92.65(2)°$, $Z = 4$, space group $P\bar{1}$. The structure was solved by conventional heavy-atom methods and was refined by full-matrix least-squares procedures to $R = 0.027$ and $R_w = 0.031$ for 5965 reflections with $I \geq 3\sigma(I)$. The two crystallographically independent molecules have nearly identical structures. The coordination about Re is distorted *fac*-octahedral with mean bond lengths: Re—P = 2.538(4), Re—N = 2.201(5), Re—CO(*trans* to P) = 1.931(1), and Re—CO(*trans* to N) = 1.913(9) Å. The $ReGaN_4$ chelate rings have twisted boat conformations with cross-ring Re···Ga separations of 3.9396(7) and 3.8981(8) Å.

BRENDA M. LOUIE, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **63**, 703 (1985).

Les cristaux du *fac*-[diméthyl bis(pyrazolyl-1) gallato N, N'] -(triphénylphosphine) tricarbonyl rhénium(I) sont tricliniques avec $a = 9{,}479(2)$, $b = 16{,}258(4)$, $c = 20{,}412(6)$ Å, $\alpha = 110{,}06(1)$, $\beta = 95{,}46(1)$, $\gamma = 92{,}65(2)°$, $Z = 4$, groupe d'espace $P\bar{1}$. On a résolu la structure par les méthodes conventionnelles aux atomes lourds et on l'a affinée par le méthode des moindres carrés (matrice entière) jusqu'à des valeurs respectives de R et R_w de 0,027 et 0,031 pour 5965 réflexions avec $I \geq 3\sigma(I)$. Les deux molécules qui sont indépendantes du point de vue cristallographique ont des structures qui sont pratiquement identiques. La coordination autour du Re est du type *fac*-octaèdre déformé avec des longueurs moyennes de liaisons de: Re—P = 2,538(4), Re—N = 2,201(5), Re—CO (*trans* par rapport au P) = 1,931(1) et Re—CO (*trans* par rapport au N) = 1,913(9) Å. Les cycles du chélate $ReGaN_4$ adoptent des conformations bateau-croisés dans lesquels les séparations Re···Ga sont égales à 3,9396(7) et 3,8981(8) Å.

Introduction

Earlier publications have reported the synthesis and characterization of a number of manganese (1) and rhenium (2) carbonyl derivatives incorporating the bidentate chelating pyrazolyl gallate ligand $Me_2Gapz_2^-$ or $Me_2Ga(3,5\text{-}Me_2pz)_2^-$ (where pz = pyrazolyl, $N_2C_3H_3$, and 3,5-Me_2pz = 3,5-dimethylpyrazolyl, $N_2C_5H_7$). These ligands are each uninegative, four-electron donors, analogous to the well-known 1,3-diketonate anions. However, unlike many of their diketonate analogs, transition metal complexes containing the bispyrazolylgallate ligands are invariably monomeric and exhibit a puckered boat conformation as their central structural feature. Thus, in the complex $[Me_2Gapz_2]Re(CO)_4$, the central Ga—(N—N)$_2$—Re six-membered ring was proposed to adopt a boat conformation primarily on the basis of ^{1}H nmr evidence (2). Furthermore one of the carbonyl groups in this tetracarbonyl complex was found to be labile and easily replaced by other neutral two-electron donor species. Based upon steric arguments and spectral data, the favored site for this ligand substitution reaction was predicted (2). Since that time we have been fortunate enough to obtain crystals, suitable for X-ray study, of one such complex, namely $[Me_2Ga(N_2C_3H_3)_2](PPh_3)Re(CO)_3$. The present paper describes the solid state structure of this complex and confirms our earlier prediction.

Experimental

fac-[Dimethylbis(1-pyrazolyl)gallato-N,N'] (triphenylphosphine)-tricarbonylrhenium(I) was prepared as described previously (2) and crystals suitable for X-ray analysis were obtained by slow sublimation in a sealed tube under vacuum. A crystal bounded by the 6 faces (followed by their distances in mm from a common origin): ±(1 0 0), 0.138, ±(0 0 1), 0.050, (0 1 −1), 0.138, (0 −1 −1), 0.113 was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 30−40°) measured on a diffractometer with Mo-$K\alpha$ Radiation ($\lambda(K\alpha_1)$ = 0.70930, $\lambda(K\alpha_2)$ = 0.71359 Å). Crystal data at 22°C are:

$C_{29}H_{27}GaN_4O_3PRe$ fw = 766.45
Triclinic, $a = 9.479(2)$, $b = 16.258(4)$, $c = 20.412(6)$ Å, $\alpha = 110.06(1)$, $\beta = 95.46(1)$, $\gamma = 92.65(2)°$, $V = 2931(1)$ Å^3, $Z = 4$, $\rho_c = 1.737$ Mg m^{-3}, $F(000) = 1496$, μ(Mo-$K\alpha$) = 51.9 cm^{-1}. Absent reflections: none, space group $P\bar{1}$ (C_i^1, No. 2, reduced cell) from structure analysis.

Intensities were measured with graphite-monochromated Mo-$K\alpha$ radiation on an Enraf-Nonius CAD4-F diffractometer. An ω−2θ scan at 1.34−10.06° min^{-1} over a range of (0.60 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 50°. The intensities of three check reflections, measured every 3600 s throughout the data collection, showed only small random fluctuations. After data reduction,[1] an absorption correction was applied using the analytical method (3,4). Transmission factors ranged from 0.266 to 0.632. Of the 9155 independent reflections measured, 5965 (65%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The centrosymmetric space group $P\bar{1}$ was suggested by the Patterson function, from which the coordinates of the Re, Ga, and P atoms of both independent molecules in the asymmetric unit were determined. The remaining non-hydrogen atoms were positioned from a subsequent difference map. In the final stages of refinement all non-hydrogen atoms were refined with anisotropic thermal parameters and hydrogen atoms were fixed in idealized positions (based on observed positions with C(sp^3)—H = 0.98 and C(sp^2)—H = 0.97 Å). The scattering factors of ref. 5 were used for non-hydrogen atoms and those of ref. 6 for hydrogen atoms. Anomalous scattering factors from ref. 7 were used for the Re, Ga, and P atoms. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-

[1]The computer programs used include locally written programs for data processing and locally modified versions of the following: ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

*U_{eq} = (1/3)trace(U_{diag}).

matrix refinement of 703 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.027 and R_w = 0.031 for 5965 reflections with $I \geq 3\sigma(I)$. For all 9155 reflections R = 0.067. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.02 and 0.10σ, respectively. The mean error in an observation of unit weight was 1.232. A final difference map showed maximum fluctuations of ±1.65 e Å^{-3} near Re and was essentially featureless elsewhere. The final positional and thermal parameters appear in Tables 1 and 6,[2] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2] Calculated parameters for the hydrogen atoms appear in Table 5.[2] Bond distances, bond angles, and intra-annular torsion angles for the chelate rings are listed in Tables 2–4, respectively.

Results and discussion

The crystal structure of *fac*-[dimethylbis(1-pyrazolyl)gallato-*N*,*N′*](triphenylphosphine)tricarbonylrhenium(I) consists of discrete molecules, the most significant intermolecular contacts being the C(17′)—H(17′)···O(1) (1 − *x*, 1 − *y*, 1 − *z*) interaction (H···O = 2.43, C···O = 3.296(9) Å, C—H···O = 149°) and the contacts H(20)···H(5′c) (1 − *x*, −*y*, −*z*) = 2.10 and H(5′b)···H(5′b) (1 − *x*, 1 − *y*, −*z*) = 2.23 Å. All other intermolecular distances correspond to normal van der Waals interactions. The two crystallographically independent molecules (Fig. 1) are very similar, the most significant difference between the two involving the chelate ring conformation (see Table 4). These and other small but statistically significant structural differences between the two independent molecules are most likely the result of packing effects.

The coordination about Re is distorted *fac*-octahedral with mean[3] bond lengths: Re—P = 2.538(4), Re—N = 2.201(5),

[2]The structure factor table, Table 6 (anisotropic thermal parameters) and other material mentioned in the text are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[3]Here and elsewhere in this report mean values refer to weighted means with rms deviations from the mean in parentheses.

Re—CO(*trans* to P) = 1.931(1), and Re—CO(*trans* to N) = 1.913(9) Å. The central six-membered $ReGaN_4$ rings have relatively shallow, asymmetrically twisted, boat conformations with cross-ring Re···Ga distances of 3.9396(7) and 3.8981(8) Å and dihedral angles of 144.9(3) and 138.0(3)° between the normals to the pyrazolyl mean planes (180° for a planar chelate ring). This structure is similar to those observed (1) for $(MeGapz_2)Mn(pzH)(CO)_3$ and $[(Me_2Gapz_2)Mo(pzH)(CO)_3]^-$ which have the same *fac*-octahedral coordination geometry, M···Ga distances of 3.818 and 3.929 Å, and dihedral angles of 139.8 and 128.1° between the pyrazolyl mean planes. The conformations of M—$(N—N)_2$—M′ rings and the highly correlated cross-ring M···M′ distances in compounds of this type depend primarily on steric factors which have been discussed in a number of recent publications (refs. 8, 9, and references therein).

Both of the independent molecules of $[Me_2Ga(N_2C_3H_3)_2](PPh_3)Re(CO)_3$ contain an interesting intramolecular interaction between a phenyl hydrogen atom and the π-electron system of a pyrazolyl ring (C(25)—H(25)···(N(1)—N(2)), mean geometrical parameters: H···N = 2.54(5), H···(N—N midpoint) = 2.45(3), C···N = 3.42(7) Å, C—H···N = 152(7)°). The pyrazolyl and phenyl rings are all planar to within experimental error with the exception of the C(18) phenyl ring (χ^2 = 11.4; mean and maximum deviations from the C_6 plane, 0.010 and 0.016(9) Å).

Received May 16, 1984

M. ROY and T. B. MCMAHON. Can. J. Chem. **63**, 708 (1985).

Ab initio quantum chemical techniques have been used to investigate the structures and energetics of a number of hydrogen bonded adducts of F^- and C—H bonds associated with unsaturated systems as well as their structural isomers. Examination of the possible species of molecular formula $C_2H_4F^-$ reveals that the most stable isomer is a hydrogen bonded adduct of F^- and ethylene, while the classical β-fluoroethyl carbanion is found not to be bound with respect to dissociation into $F^- + C_2H_4$. Similar examination of $C_2H_2F^-$ isomers shows that a hydrogen bonded F^-–acetylene adduct is the most stable structure, however, the remaining α and β-fluorovinyl carbanions are found to be bound with respect to $F^- + C_2H_2$. These results are used to explain the unusual gas phase acidities of ethylfluoride and vinylfluoride. Calculations on $C_3H_4F^-$ isomers show the hydrogen bonded adduct of F^- and allene to be more stable than the classical 2-fluoropropenyl anion and on $C_2H_2FO^-$ isomers show the enolate of acetyl fluoride to be more stable than the hydrogen bonded adduct of F^- and ketene. These latter results are used to explain the gas phase ion molecule reactivities of $C_3H_4F^-$ (predominantly F^- transfer) and $C_2H_2FO^-$ (proton abstraction).

M. ROY et T. B. MCMAHON. Can. J. Chem. **63**, 708 (1985).

On fait appel aux techniques de la chimie quantique *ab initio* pour étudier les structures et les énergies d'un certain nombre d'adduits, liés par des liaisons hydrogènes, du F^- et de liaisons C—H associées à des systèmes insaturés ainsi que leurs isomères de structure. L'étude des espèces possibles, de formule moléculaire $C_2H_4F^-$, révèle que l'isomère le plus stable est un adduit dans lequel le F^- et l'éthylène sont liés par des liaisons hydrogènes; par ailleurs le carbanion classique β-fluoroéthyle n'est pas lié par rapport à la dissociation en F^- et C_2H_4. Une étude semblable des isomères du $C_2H_2F^-$ montre que l'adduit F^-–acétylène, qui est lié par des liaisons hydrogènes, constitue la structure la plus stable; toutefois, on a trouvé que les carbanions α et β fluorovinyles résiduels sont liés par rapport à la dissociation $F^- + C_2H_2$. On utilise ces résultats pour expliquer les acidités inhabituelles en phase gazeuse du fluorure d'éthyle et du fluorure de vinyle. Les calculs faits avec les isomères du $C_3H_4F^-$ révèlent que l'adduit de F^- et de l'allène, qui est lié par des liaisons hydrogènes, est plus stable que l'anion classique fluoro-2 propényle alors que les mêmes calculs faits sur les isomères du $C_2H_2FO^-$ montrent que l'énolate du fluorure d'acétyle est plus stable que l'adduit de F^- et du cétène, qui sont liés par des liaisons hydrogènes. On utilise ces derniers résultats pour expliquer les réactivités ion-molécule en phase gazeuse du $C_3H_4F^-$ (transfert prédominant de F^-) et du $C_2H_2FO^-$ (enlèvement d'un proton).

[Traduit par le journal]

Introduction

Fluorine substituents have been abundantly demonstrated to exhibit pronounced, and frequently ambiguous, effects on the stabilities of both positive and negative gas phase ions (1–8). However, no fluorine substituent effect is perhaps as bizarre as that found for the gas phase acidities of fluoroethanes (2). Sullivan and Beauchamp, using ion cyclotron resonance (ICR) techniques, have shown that ethyl fluoride is intermediate in gas phase acidity between ethanol and 2-propanol. With the aid of deuterium labelling experiments, they have further shown that the only proton removed in reaction with strong anionic bases is β to the fluorine. Assuming a nearly constant C—H bond strength for ethane and the β C—H bonds of ethyl fluoride, these experiments imply a stabilization of β fluoroethyl carbanion of some 30 kcal mol^{-1} relative to ethyl carbanion. This magnitude of remote inductive substituent effect is unprecedented in studies of relative stabilities of gas phase ions. Equally surprising are the effects of multiple fluorine substitution on the relative stabilities of the series of fluoroethyl carbanions. After the first large increase in gas phase acidity of 30 kcal mol^{-1} in proceeding from ethane to ethyl fluoride, no further appreciable increase is observed in successively adding up to 5 fluorines. For example, pentafluoroethane is observed to be only 3 kcal mol^{-1} more acidic in the gas phase than ethyl fluoride. All other fluoroethanes show gas phase acidities between those of ethyl fluoride and pentafluoroethane. In their discussion of these unusual substituent effects, Sullivan and Beauchamp concluded only that "simple electrostatic arguments are inappropriate to explain the order of acidities".

Recent ICR investigations in our laboratory (9, 10) of quantitative fluoride binding energies to Brønsted acids have suggested to us that hydrogen bonding of F^- to organic molecules may be a far more energetically favourable and ubiquitous phenomenon than previously supposed. In particular our studies of fluoride binding energies to fluoroethylenes suggested that the resulting anions are more likely planar hydrogen bonded adducts than pyramidal sp^3 hybridized carbanions, implying that the former species are likely the more stable. It thus seems reasonable to infer that the attack of strong anionic bases on ethyl fluoride may not lead to simple deprotonation but rather to a process of elimination in which the departing F^- remains hydrogen bonded to a proton of a newly formed ethylene group. If this is indeed the case, then the gas phase acidity measurements will not yield a measure of carbanion stability and the need to explain an unusually large substituent effect is avoided.

Recently Bach *et al.* (11) and Schleyer and Kos (12) have examined the β-fluoroethyl carbanion using *ab initio* quantum chemical techniques and have found, in the course of geometry optimization, that this carbanion is not bound with respect to $F^- + C_2H_4$. In addition, Schleyer and Kos have investigated a hydrogen bonded structure of ethylene and F^- and have found

[1] Present address: Department of Chemistry and Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1.

that this hydrogen bonded adduct of $F^- + C_2H_4$ is bound, thus supporting the conjecture above regarding the anion derived from the gas phase deprotonation of C_2H_5F.

In addition to β-fluoroethyl carbanion, Schleyer and Kos have also examined the β-fluorovinyl carbanion and the isomeric F^-–acetylene hydrogen bonded adduct. As in the fluoroethyl carbanion case the β-fluorovinyl carbanion is found to be unbound with respect to $F^- + C_2H_2$ while the hydrogen bonded complex is bound by some 20 kcal mol^{-1}.

In the course of ongoing studies in our laboratory of gas phase acidities of organo-fluorine compounds and of hydrogen bond energetics of F^- to organic acids (10) we have discovered several fluorinated species which upon deprotonation act as facile F^- transfer reagents. In order to ascertain the most probable structures of these fluorinated anions we have undertaken the present *ab initio* quantum chemical study of several fluorine containing anions. The first of these is a complete investigation of the fluoroethyl system since although Schleyer and Kos have studied β-fluoroethyl carbanion and the F^-–C_2H_4 hydrogen bonded adduct, the potentially stable α-fluoroethyl carbanion has not been investigated. Similarly the fluorovinyl system has been studied completely including the F^-–C_2H_2 hydrogen bonded adduct, both *cis* and *trans* β-fluorovinyl carbanions and α-fluorovinyl carbanion. Two possible isomers of the chemically important $C_3H_4F^-$ anion derived from deprotonation of 2-fluoropropene have been studied — the 2-fluoropropenyl anion and a hydrogen bonded adduct of F^- and allene. Finally, two possible isomers of the isoelectronic analogue, $C_2H_2FO^-$, derived from deprotonation of acetyl fluoride have also been investigated — the acetyl fluoride enolate ion and a hydrogen bonded adduct of F^- and ketene.

Computational method

Ab initio molecular orbital calculations were carried out using the Gaussian 80 (13) and Hondo 5 (14) program packages. All structures were fully optimized using the 4-31G basis set employing an analytical gradient technique (15). In several cases single point total energy calculations were carried out for the 4-31G optimized geometry using the 4-31+G basis set (16, 17). This latter basis set, incorporating additional flat *s* and *p* Gaussian functions on all heavy atoms has been demonstrated by Schleyer to provide a much more accurate description of the energetics of anions than other split valence basis sets. In the present case flat function exponents of 0.090 for fluorine 0.040 for carbon and 0.068 for oxygen were used. In the few cases where diffuse function augmented basis sets calculations were not carried out the conclusions drawn are probably valid since energy differences between isomeric ions rather than absolute energies are being considered. In all cases where 4-31G and 4-31+G calculations were carried out the order of stabilities of isomeric ions was invariant with basis set.

Results

A. Geometries

1. $C_2H_4F^-$: As noted above the β-fluoroethyl carbanion has been shown originally by Bach *et al.* (11) to dissociate without activation energy to $F^- + C_2H_4$ at the 4-31G level. Following his example, for purposes of discussion, we have used an "artificial" $CH_2FCH_2^-$ structure which was obtained from the structure optimized at the STO-3G level where it was found to be stable with respect to dissociation. Further refinement was then carried out at the 4-31G level by holding the C—F and C—H bonds constant and optimizing the C—C bond length

and bond angles. The geometry for this isomer (**I**) as well as those obtained for the α-fluoroethyl carbanion, CH_3CHF^- (**III**), and the hydrogen bonded F^-–ethylene complex, $C_2H_4\cdots F^-$ (**II**), are detailed in Fig. 1.

2. $C_2H_2F^-$: There are four possible stable isomers for anions of this formula. The *cis* (**IV**) and *trans* (**V**) β-fluorovinyl carbanions, $CHFCH^-$, and the hydrogen bonded complex of F^- and acetylene, $C_2H_2\cdots F^-$ (**IV**) have been investigated previously by Schleyer and Kos (12). To this we add in the present study the α-fluorovinyl carbanion, CH_2CF^- (**VII**). Geometries for these four species are outlined in Fig. 2.

3. $C_3H_4F^-$: Although there are probably several stable isomers of this molecular formula only those two deemed to be mechanistically feasible from deprotonation of 2-fluoropropene were investigated. The geometries of 2-fluoropropenyl carbanion, $CH_2CFCH_2^-$ (**VIII**), and the hydrogen bonded complex of F^- and allene $C_3H_4\cdots F^-$ (**IX**) are summarized in Fig. 3.

4. $C_2H_2FO^-$: Analogous to the case of $C_3H_4F^-$, only the two possible isomers of the isoelectronic $C_2H_2FO^-$ deemed to be mechanistically feasible from deprotonation of acetyl fluoride were investigated. The geometries of acetyl fluoride enolate, CH_2COF^- (**X**), and the hydrogen bonded complex of F^- and ketene, CH_2COF^- (**XI**), are detailed in Fig. 4.

B. Energies

Total energies of all relevant anionic and neutral species obtained using the 4-31G basis set are summarized in Table 1. In selected cases it was important to determine relative energies of anionic isomers somewhat more accurately and in such cases

total energies were calculated at the 4-31G optimized geometry using the 4-31+G basis set described above. Their energy values are given in parentheses in Table 1.

Discussion

$C_2H_4F^-$

It is readily apparent from the data of Table 1 that the most stable of the three possible $C_2H_4F^-$ isomers is the hydrogen bonded adduct, **II**. Even though the hypothetical structure for β-fluoroethyl carbanion, **I**, is known to dissociate at the 4-31G level to F^- + C_2H_4 this artificial structure is still found to be more stable than the α-fluoroethyl carbanion, **III**. It is noteworthy that at the 4-31G level **III** is a minimum on the potential energy surface revealing its stability toward dissociation to F^- and methyl carbene, CH_3CH:. The greater stability of **I** relative to **III** reveals a further example of the partially destabilizing nature of fluorine substituted α to negative charge centers. Further support for the destabilizing nature of the α fluorine may be found in an examination of the geometry of **III**. The C—C bond length in the α carbanion, **III** is a normal C—C single bond length, being within 0.02 Å of those in C_2H_6 and C_2H_5F. However, the C—F bond length is unusually long at 1.54 Å compared to those of 1.38 Å in CH_3F and 1.43 Å in *t*-C_4H_9F. Similar bond lengths have been found for the analogous fluoromethyl carbanion, CH_2F^-, by other investigators (16–19) and in fluorocyclohexadienyl anions (20). Such abnormally long C—F bonds appear to be readily attributable to strong electron–electron repulsions between lone pairs on fluorine and the filled $2p$ orbital on carbon in the carbanion. These effects have frequently been invoked to explain unusual stability orderings of fluorine substituted sp^2 carbanions both in the gas phase (5) and solution (21).

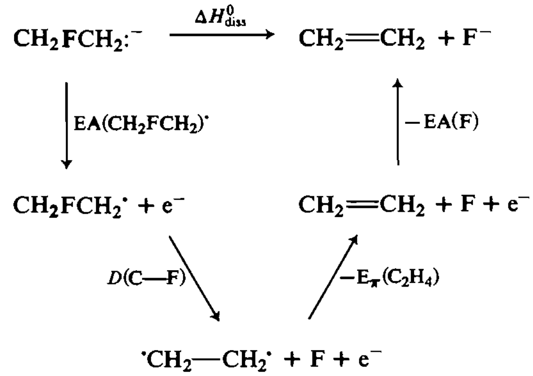
With the advantage of hindsight it is possible to rationalize the instability of the β-fluoroethyl carbanion toward dissociation to F^- and C_2H_4 and the greater stability of the hydrogen bonded complex on purely thermochemical grounds. From the thermochemical cycle shown in Scheme 1 it is possible to use known data or to make accurate predictions for the individual steps involved and to predict the exothermicity of dissociation of **I**, ΔH^0_{diss}.

The electron affinity of $CH_2FCH_2^{\bullet}$ is estimated as 8 ± 5 kcal mol^{-1} based on the approximate electron affinity of C_2H_5[2] of 0 ± 5 kcal mol^{-1} and an approximate expected inductive effect of the β fluorine of 8 kcal mol^{-1}.[3] The C—F bond strength in $CH_2FCH_2^{\bullet}$ is expected to be the same as that in C_2H_5F, 106 kcal mol^{-1} (24). The π bond energy in C_2H_4 is known to be 60 kcal mol^{-1} (25) and the electron affinity of fluorine atom to be 78 kcal mol^{-1} (26). Thus the overall dissociation enthalpy for **I** may be calculated from eq. [1].



SCHEME 1

$$[1] \quad \Delta H^0_{\text{diss}} = EA(CH_2FCH_2^{\bullet}) + D(C{-}F) - E_\pi(C_2H_4) - EA(F)$$

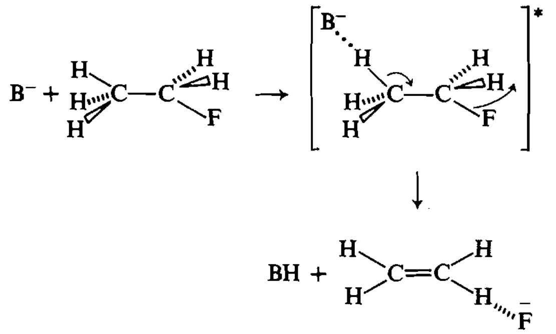
to be −24 kcal mol^{-1}. The driving force for this dissociation can readily be seen to be the π bond formation and the exothermic electron transfer from carbon to fluorine. Based on recent correlations of fluoride binding energy and gas phase acidity from our laboratory (10) it is possible to estimate a hydrogen bond energy for F^- and C_2H_4 of 5 kcal mol^{-1}. This further exothermic step, eq. [2],

[2] $F^- + C_2H_4 \rightarrow$ 
therefore reveals the greatest stability of **II** relative to other $C_2H_4F^-$ isomers. Using the 4-31+G energy data from Table 1 a fluoride binding energy of F^- to C_2H_4 for the hydrogen bonded structure of 2 kcal mol^{-1} is obtained in good agreement with the qualitative prediction above.

The much greater predicted stability of the hydrogen bonded form of $C_2H_4F^-$ has important implications for the stability of fluoroethyl anions inferred from the gas phase acidity measurements and for the mechanism of deprotonation of fluo-

[2] $EA(CH_3CH_2)$ is estimated at 0 ± 5 kcal mol^{-1} based on the assumption that the replacement of H by CH_3 in CH_4 could lead to either an increase or decrease in electron affinity. Calculations at the 4-31+G level (16, 17) show a destabilization by CH_3 for H substitution of 5.6 kcal mol^{-1}; however, at the same level, the calculations fail to reproduce the relative experimental order of stabilities of NH_2^- and CH_3NH^- and fail to indicate the large stabilization of CH_3O^- relative to OH^-. Thus we feel that relative to the experimental $EA(CH_3)$ of 2 kcal mol^{-1} (29) an estimate of $EA(CH_3CH_2)$ of 0 ± 5 kcal mol^{-1} is in order.

[3] The inductive effect of β fluorine on an anionic center is estimated from an average of $EA(CH_2COF) - EA(CH_2CHO)$ = 10.5 kcal mol^{-1} (22), $EA(FCO_2) - EA(HCO_2)$ = 13 kcal mol^{-1} (23) and $EA(CH_2CFCH_2) - EA(CH_2CHCH_2)$ = 9.3 kcal mol^{-1} (T. B. McMahon, unpublished results).



SCHEME 2

roethanes. Prior to the gas phase acidity work on fluoroethanes the acidity of ethyl fluoride might have been predicted to be 398 kcal mol^{-1} and thus deprotonation by even such strong bases as OH^- and CH_3O^- would not have been expected. The fact that an apparent deprotonation is observed suggests to us that rather than participating in a simple proton abstraction reaction, strong anionic bases react with ethyl fluoride in a concerted addition–elimination type of reaction in which the leaving group, F^-, remains hydrogen bonded to ethylene, C_2H_4. Such a mechanism is depicted in Scheme 2. Since this mechanism does not yield the true conjugate base of ethyl fluoride, the reaction cannot be regarded as a true deprotonation and an erroneous gas phase acidity determination would result. The reactions of strongly basic anions with ethyl fluoride might then be interpreted simply as HO^- and CH_3O^- binding sufficiently strongly to C_2H_5F to activate the intermediate towards elimination, whereas $C_2H_5O^-$ and more weakly basic alkoxides do not activate the intermediate to an extent sufficient for elimination to occur.

Additionally it is significant to note that our conclusion, that a hydrogen bonded form of $C_2H_4F^-$ is the most stable one and that this is the species most likely produced in deprotonation of ethyl fluoride, is supported by our experimental observations of fluoride transfer reactions (10). The anions derived from "deprotonation" of ethyl fluoride and other fluoroethanes are found *not* to readily abstract a proton from stronger gas phase acids as would be expected of a carbanion but rather readily transfer F^-, a result quite reasonable for a hydrogen bonded F^- adduct. A similar observation is made for experiments in which F^- donors transfer F^- to fluoroethylenes. For example, the anion derived from addition of F^- to trifluoroethylene, reaction [3], is found to react with strong acids by F^- donation, reaction [4*a*] rather than proton abstraction, reaction [4*b*]. This

[3] $MF^- + C_2HF_3 \rightarrow C_2HF_4^- + M$

[4*a*] $C_2HF_4^- + AH \rightarrow AHF^- + C_2HF_3$

[4*b*] $C_2HF_4^- + AH \not\rightarrow A^- + C_2H_2F_4$

result again supports a hydrogen bonded structure for $C_2HF_4^-$ rather than an sp^3 carbanion. The notable exceptions to the above observations involve reaction of pentafluoroethane, C_2F_5H, and tetrafluoroethylene. The anion derived from deprotonation of C_2F_5H is found to readily abstract protons from stronger gas phase acids and to transfer F^- only at a very slow rate, primarily to Lewis acids. Similarly, in reactions of F^- donors with C_2F_4, F^- transfer occurs very slowly. In these cases the $C_2F_5^-$ anion must have an sp^3 carbanion structure rather than a hydrogen bonded one and the chemical behaviour is completely different.

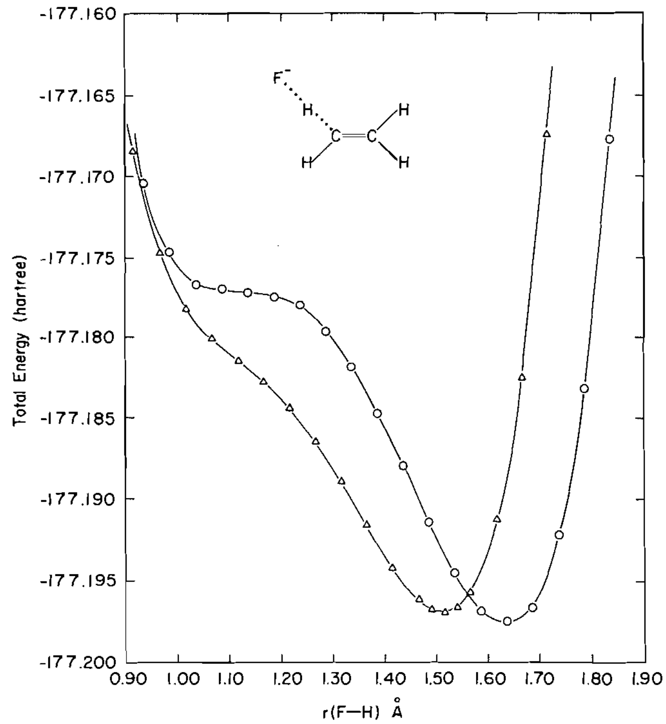


FIG. 5. Plot of potential energy surface for motion of the proton in the F^-—C_2H_4 hydrogen bonded adduct, **III**. ○, total C—F distance of 2.75 Å; △, total C—F distance of 2.63 Å.

It is of considerable interest to consider the nature of the potential for proton motion within the hydrogen bond in **II**. Quite frequently double minima potential wells are postulated for hydrogen bonded species (27). In the present case a double minimum potential well could be envisioned as having one minimum associated with a $C_2H_4\cdots F^-$ structure, **II**, and a possible second minimum of higher total energy associated with a vinyl anion – HF hydrogen bonded complex, $C_2H_3^-\cdots HF$. In order to investigate this possibility a series of calculations was undertaken in which the total C—F distance was held constant and the C—H distance was varied. The results of these calculations are shown in Fig. 5. In one case a total C—F distance of 2.75 Å was used corresponding to the global energy minimum. In addition to this a second series of calculations was carried out at a total C—F distance of 2.63 Å. The plot for the structure with the longer total C—F distance corresponding to the minimum overall geometry shows no barrier to proton motion between F and C and reveals a plateau at short F—H and long C—H distance corresponding to a structure, $C_2H_3^-\cdots HF$ only an inflection point results. This second plot, however, even though having a higher minimum than the previous one, has an overall lower potential for proton motion. This would thus suggest that during vibration about the hydrogen bond the C—H distance remains relatively constant and the F^- position would appear to oscillate.

$C_2H_2F^-$

As in the case of the $C_2H_4F^-$ anions, the most stable structure of molecular formula $C_2H_2F^-$ is a hydrogen bonded adduct, in this case the F^-–acetylene complex (**VI**). The geometry given in Fig. 2 for **VI** shows a —C≡C— bond only slightly elongated from that in acetylene (1.19 Å). Consistent with the substantially greater gas phase acidity of acetylene relative to ethylene the hydrogen bond energy is significantly increased in the F^- adduct and the overall F^-—H distance is appreciably reduced to 1.31 Å from 1.63 Å in the olefinic case. The corresponding C—H distance in the hydrogen bond is increased from the value of 1.05 Å in acetylene to 1.22 Å in **VI**.

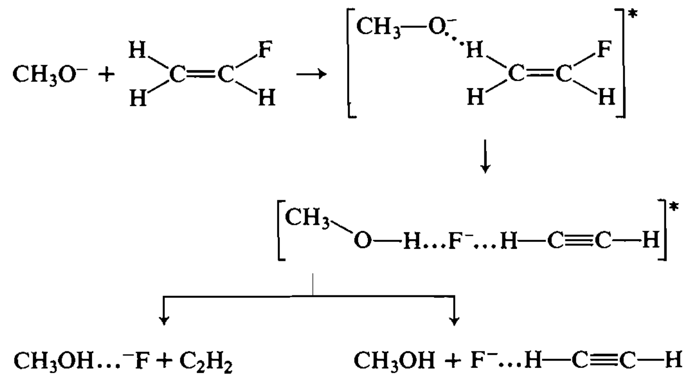
The next most stable structure of $C_2H_2F^-$ is the α-fluorovinyl carbanion, **VII**. This species has a C—F bond length of 1.52 Å, similar to that of the α-fluoroethyl carbanion, **III**. In addition, this C—F bond is somewhat longer than that in either the *cis* or *trans* β-fluorovinyl carbanions, **IV** and **V**, while the —C=C— bond length of 1.34 Å is slightly greater than in **IV** and **V**. These bond length differences and the fact that the C—C bonds are all very close in length to that in ethylene indicate that very little delocalization of negative charge is occurring from the nominal carbanion site to the β carbon. Since the charge is localized on the α carbon in **VII** the fluorine atom may undergo a repulsive interaction with the charge center just as occurred in **III**, leading to the lengthened C—F bond.

The geometries of the *cis* and *trans* β-fluorovinyl carbanions, **IV** and **V**, have been investigated previously by Schleyer using the 3-21+G basis set (12). The geometry results obtained in the present study employing the 4-31G basis set are in good agreement with those using the diffuse function augmented basis set with all bond distances lying within 0.02 Å and all bond angles within 1°.

Both the 4-31G and 3-21+G results place the hydrogen bonded structure of $C_2H_2F^-$ as the most stable. However, while the 4-31G results show all of the anions **IV**–**VII** to be stable with respect to dissociation to F^- + C_2H_2 the 3-21+G results find only the hydrogen bonded structure to be energetically lower than the separated species. The 3-21+G results do, however, yield **IV** and **V** as local minima; that is, there is some activation energy associated with their dissociation to F^- + C_2H_2. Our previous correlations of gas phase acidity and hydrogen bond energy to F^- (10) allow a prediction of some 15–20 kcal mol^{-1} for the hydrogen bond energy in **VI** in good agreement with the value of 20 kcal mol^{-1} obtained using the 3-21+G basis set.

The relative energetics of these $C_2H_2F^-$ isomers thus lead to the question of the nature of the anion obtained from deprotonation of fluoroethylene. Gas phase acidity determinations carried out by Beauchamp and Sullivan (2) place the enthalpy of dissociation of C_2H_3F into H^+ + $C_2H_2F^-$ as 380 kcal mol^{-1}. This result then allows $\Delta H_f^0(C_2H_2F^-)$ to be calculated as −18.9 kcal mol^{-1} which further yields a binding energy of F^- to C_2H_2 in the anion of 12.8 kcal mol^{-1}. Since at the 3-21+G level only the hydrogen bonded complex VI is stable with respect to F^- + C_2H_2 the gas phase acidity measurements are strongly suggestive that the hydrogen bonded species is the anion generated upon deprotonation of vinylfluoride.

The reaction of the strongly basic anions such as CH_3O^-, with vinylfluoride yields predominantly the elimination product CH_3OHF^- (81%) with $C_2H_2F^-$ (12%) and F^- (7%) as minor products. Production of CH_3OHF^- and a hydrogen bonded $C_2H_2F^-$ product can be rationalized mechanistically through Scheme 3 involving a common "disolvated" F^- intermediate. Since F^- is known to bind more strongly to CH_3OH than to C_2H_2 this would explain the 4:1 relative abundance of the hydrogen bonded F^-–methanol product. No other alkoxide ions, RO^-, undergo any reaction with vinyl fluoride even though production of ROH···F^- is quite exothermic. Thus it would seem that a partial proton transfer such as that outlined in Scheme 3 is a necessary initial step in the mechanism for ROH···F^- product. In the case of the more weakly basic alkoxide ions this initial partial proton transfer must then not be sufficiently energetically favorable to proceed.



SCHEME 3

$C_3H_4F^-$

The $C_3H_4F^-$ anion derived from deprotonation of 2-fluoropropene, reaction [5], has played an extremely important role in our previous determinations of fluoride binding energies to

[5] A^- +  → $C_3H_4F^-$ + AH

Bronsted acids. From a study employing anions, A^-, of known basicity and observation of which would and would not produce $C_3H_4F^-$ a value for $\Delta H_f^0(C_3H_4F^-)$ was obtained which allowed a calculation of the binding energy of F^- to allene, C_3H_4, of 15 kcal mol^{-1} (28). This anion was employed to act as a facile fluoride transfer reagent to species which bind F^- more weakly than H_2O, such as t-C_4H_9F, reaction [6], which may have the structure of a captured S_N2 transition state (10).

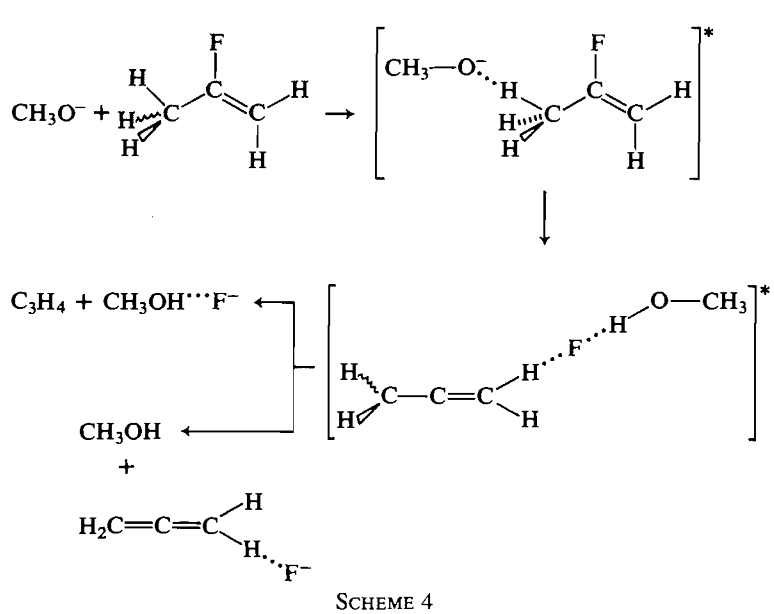
[6] $C_3H_4F^-$ + t-$C_4H_9F \rightarrow C_4H_9F_2^-$ + C_3H_4

In view of the preceding results for $C_2H_4F^-$ and $C_2H_2F^-$ isomers two probable structures for the $C_3H_4F^-$ anion were investigated: the 2-fluoropropenyl anion, **VIII**, and a hydrogen bonded complex, **IX**.

Geometry optimization and calculation of energies at the 4-31G level gave nearly identical total energies for the two $C_3H_4F^-$ isomers. However, employing the 4-31+G basis set, previously determined to give a superior description of anions, the hydrogen bonded structure **IX** was found to be more stable by 8.8 kcal mol^{-1}. At this level the hydrogen bond energy of F^- to allene obtained from the data of Table 1 is 10 kcal mol^{-1} in good agreement with the experimentally determined value of 15 kcal mol^{-1}.

The H—F^- bond distance found in **IX** of 1.80 Å is significantly longer than that in $C_2H_2F^-$, indicative of the somewhat weaker hydrogen bond strength in the allenic system. Consistent with this is the substantially shorter C—H bond in the hydrogen bond of **IX** relative to that in **VI**. The C—C distances in **IX** are very similar to those found in neutral allene.

The 2-fluoropropenyl anion, **VIII**, has a C—F bond distance of 1.44 Å. This is only slightly longer than that found in neutral olefinic fluorides indicating that to a small extent repulsive interaction between the fluorine lone pair electrons and the allyl π system may be occurring. The C—C distances found are similar to those obtained for unsubstituted allyl anion.



SCHEME 4

The slightly greater stability of the hydrogen bonded complex **IX**, relative to the allylic anion, **VIII**, has significant implications for the anion observed by deprotonation of 2-fluoropropene in ion cyclotron resonance experiments (28). The anion thus obtained, as noted above, is observed to act as a facile fluoride donor, while no tendency for reaction via proton abstraction was observed. These reactivity results are more consistent with a hydrogen bonded structure since even though the 2-fluoropropenyl anion might be expected to react via F^- transfer, some tendency for reaction by proton abstraction with species of high gas phase acidity but low fluoride binding energy, such as cyclopentadiene, would have been anticipated.

The formation of the hydrogen bonded F^-–allene adduct by reaction of strong bases such as CH_3O^- with 2-fluoropropene might then be considered to be analogous to that proposed above for formation of **VI** in vinyl fluoride. Scheme 4 which illustrates such a mechanism can be seen to also lead to formation of $CH_3OH\cdots F^-$ as in the case for reaction of CH_3O^- with C_2H_3F. Consistent with this $CH_3OH\cdots F^-$ is indeed observed in reactions of CH_3O^- with 2-fluoropropene.

$C_2H_2FO^-$

The $C_2H_2FO^-$ anion derived from deprotonation of acetylfluoride (6) has also played an extremely valuable role in our recent determinations of absolute fluoride ion binding energetics. From equilibrium proton transfer determinations of the gas phase acidity of acetyl fluoride, reaction [7], the heat of formation of CH_2COF^- had been

[7] $A^- + CH_3COF \rightleftarrows CH_2COF^- + AH$

accurately established and thus a theoretical fluoride binding energy to ketene obtained of 35.7 kcal mol^{-1} (10). By carrying out equilibrium fluoride transfer measurements between ketene and Lewis acids, reaction [8], an absolute anchor point for the fluoride binding energy scale of relative fluoride exchange equilibria was established.

[8] $LF^- + CH_2{=}C{=}O \rightleftarrows CH_2COF^- + L$

It was therefore of some interest to establish whether the fluoride adduct of ketene had enolate structure, **X**, or a hydrogen bonded structure with F^- bound to the sp^2 hydrogens of the ketene, **XI**. The data of Table 1 reveal that in this case the "classical" enolate structure is the more stable at both the 4-31G and 4-31+G levels of calculation. Significantly, however, both structures are found to be stable with respect to dissociation to F^- + ketene.

The available experimental evidence strongly suggests that the $C_2H_2FO^-$ ions derived from both deprotonation of acetyl fluoride and addition of F^- to ketene have the same structure, presumably **X**. The ions formed in both ways react with Lewis acids such as SO_2F_2 via exothermic fluoride transfer, reaction [9], and with Brønsted acids such as CF_3CH_2OH via exothermic proton transfer, reaction [10]. This latter

[9] $CH_2COF^- - SO_2F_2 \rightleftarrows SO_2F_3^- + CH_2CO$

[10] $CH_2COF^- + CF_3CH_2OH \rightleftarrows CF_3CH_2O^- + CH_2CO + HF$

reaction, in particular, is strongly suggestive of an enolate type structure for this anion since exothermic F^- transfer to CF_3CH_2OH could also occur. Thus both *ab initio* calculation and gas phase reactivity results support an enolate structure for $C_2H_2FO^-$ as the most stable and most probable form of ions derived from either deprotonation of acetyl fluoride or F^- addition to ketene.

Conclusion

The *ab initio* calculations described in the present work demonstrate that the most stable forms of $C_2H_4F^-$, $C_2H_2F^-$, and $C_3H_4F^-$ anions are hydrogen bonded adducts of ethylene, acetylene, and allene, respectively. By contrast, examination of the isoelectronic analogue to the F^-–allene adduct containing an electronegative oxygen atom, $C_2H_2FO^-$, reveals that a "classical" enolate structure is more stable than a hydrogen bonded adduct of F^- and ketene. Consideration of experimental data for gas phase ion molecule reactions of strong anionic bases with ethyl fluoride, vinyl fluoride and 2-fluoropropene show that the hydrogen bonded anions **II**, **VI**, and **IX** are the most probable reaction products. The implications of this finding for gas phase acidities of the parent species and for fluoride binding energies to unsaturated hydrocarbons have been discussed.

The results obtained also suggest that similar hydrogen bonded species might arise from other gas phase deprotonation experiments. For example, it is possible that deprotonation of ethyldimethylamine or methylethylether by strong bases such as H^- or NH_2^- could lead to novel hydrogen bond adducts, reactions [11] and [12]. Investigations of these and related systems will be the subject of future contributions from this laboratory.

Lactams of sparteine

W. MAREK GOLEBIEWSKI AND IAN D. SPENSER
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received May 18, 1984

W. MAREK GOLEBIEWSKI and IAN D. SPENSER. Can. J. Chem. **63**, 716 (1985).

(2,2-$^2H_2$)Sparteine, (6-^{2}H)sparteine, (10,10-$^2H_2$)sparteine, (15,15-$^2H_2$)sparteine, (17α-^{2}H)sparteine, (17β-^{2}H)sparteine, (17,17-$^2H_2$)sparteine, (17α-^{2}H)lupanine, and (17β-^{2}H)lupanine were prepared and employed to assign the ^{1}H nmr spectrum of sparteine. Contrary to a published report, photochemical oxidation of sparteine does not lead to 15-oxosparteine but to 17-oxosparteine.

W. MAREK GOLEBIEWSKI and IAN D. SPENSER. Can. J. Chem. **63**, 716 (1985).

On a préparé les ($^2H_2$-2,2)-, (^{2}H-6)-, ($^2H_2$-10,10)-, ($^2H_2$-15,15)-, (^{2}H-17α)- et (^{2}H-17β)-spartéines ainsi que les (^{2}H-17α)- et (^{2}H-17β)-lupanines et on les a utilisées pour faire une attribution du spectre rmn ^{1}H de la spartéine. Contrairement à ce qui a été rapporté antérieurment, l'oxydation photochimique de la spartéine ne conduit pas à l'oxo-15 spartéine mais plutôt à l'oxo-17 spartéine.

[Traduit par le journal]

In connection with our studies of the biosynthesis of the lupine alkaloids (1–3), and, in particular, of the incorporation of bond-labelled samples of ^{13}C,^{15}N-lysine and cadaverine (2), and of the prochirality (3) of the reactions leading to the incorporation of lysine and cadaverine into sparteine (**1**) and lupanine (**2**), it was essential to obtain reliable assignments of the nmr signals of the protons on the chiral and prochiral C-atoms adjacent to the nitrogen atoms of the alkaloids, as well as of the ^{13}C nmr signals of these C-atoms.

To facilitate assignment of ^{1}H nmr signals, deuteriated samples of the alkaloids were prepared by adaptation of known reactions.

The samples of sparteine, labelled at the prochiral centres adjacent to nitrogen, were prepared from the corresponding oxosparteine derivatives by reduction with lithium aluminium deuteride (4–6). Thus, 2-oxosparteine (lupanine) (**2**) yielded (2,2-$^2H_2$)sparteine (4–6), 10-oxosparteine (aphylline) gave (10,10-$^2H_2$)sparteine (5), and 15-oxosparteine (**9**) and 17-oxosparteine (**7**) gave (15,15-$^2H_2$)- and (17,17-$^2H_2$)sparteine (4–6), respectively.

Diastereotopically singly deuteriated samples of (17α-^{2}H)-lupanine (17-^{2}H-*si*, pseudo-axial) and (17β-^{2}H)lupanine (17-^{2}H-*re*, pseudo-equatorial) were obtained from 16,17-dehydrolupaninium perchlorate by methods described by Wiewiórowski *et al.* (7). Lithium aluminium hydride reduction at C-2 of these diastereotopically deuteriated lupanines gave (17α-^{2}H)sparteine (17-^{2}H-*si*, pseudo-axial) and (17β-^{2}H)-sparteine (17-^{2}H-*re*, pseudo-equatorial), respectively. As predicted (8), the ^{2}H nmr signal of the equatorially deuteriated samples (δ: (17β-^{2}H)sparteine, 2.63; (17β-^{2}H)lupanine, 2.53 ppm) appears downfield in relation to the signal of the axially deuteriated samples (δ: (17α-^{2}H)sparteine, 2.44; (17α-^{2}H)-lupanine, 1.79 ppm).

The two signals in the ^{2}H nmr spectra of (2,2-$^2H_2$)-, (10,10-$^2H_2$)-, and (15,15-$^2H_2$)sparteine can be assigned on a similar basis. The upfield signal is assigned to the axial deuteron, the downfield signal to the equatorial deuteron (δ: (2,2-$^2H_2$)sparteine, 1.84 (β-^{2}H, axial), 2.58 (α-^{2}H, equatorial); (10,10-$^2H_2$)sparteine, 1.92 (β-^{2}H, axial), 2.43 (α-^{2}H, equatorial); (15,15-$^2H_2$)sparteine, 1.97 (α-^{2}H, axial), 2.73 (β-^{2}H, equatorial)).

The sample of (6-^{2}H)sparteine, deuteriated at the chiral centre, C-6 (δ 1.63 ppm), was prepared (4,5) by sodium borodeuteride reduction of the 1,6-dehydro derivative (**4**) of sparteine, by adaptation of a reaction sequence reported by N. J. Lenoard *et al.* (9). Since reduction of the 1,6:11,16-didehydro derivative (**5**) of sparteine does not yield sparteine (**1**) but α-isosparteine (**8**), which differs from sparteine at the C-11 ring junction, (11-^{2}H)sparteine cannot be prepared by this method.

Assignment of the signal for the proton at C-11 of sparteine was made from the ^{1}H-COSY nmr spectrum of sparteine (10), on the basis of the observed coupling to the proton at C-9 and the β-proton at C-12.

The assignments of the ^{1}H nmr signals in the spectra of sparteine and some of its oxo derivatives are summarized in Table 1.

Since, until recently, lupanine perchlorate was commercially available (Fluka, Koch-Light), most of the starting materials for this study were readily accessible. The one exception is 15-oxosparteine (**9**). It has been reported (11) that this compound can be prepared in 20% yield, together with a small quantity of lupanine (**2**) and some dimeric products, by photochemical oxidation of sparteine (**1**). We have now found that photochemical oxidation of sparteine, as described (11), does not yield either 15-oxosparteine or 2-oxosparteine. The ^{13}C nmr spectrum of the crude lactam fraction isolated from the reaction mixture appeared to indicate the presence of a single lactam carbonyl signal, and the only oxo derivative that was isolated was 17-oxosparteine, identical (^{1}H nmr, ^{13}C nmr, mp, mixture mp, mp of perchlorate salt) with an authentic specimen, prepared by ferricyanide oxidation of sparteine (12, 13).

15-Oxosparteine can be obtained from sparteine by a two-step process, devised by Wiewiórowski.[1] Oxidation of the alkaloid with mercuric acetate, complexed with ethylenediaminetetraacetic acid (Hg^{2+}/EDTA), yields a mixture of 1,6:11,16-didehydrosparteinium (**5**) and 1,6-dehydro-15-oxosparteinium (**10**) ions. Subsequent borohydride reduction leads to a mixture of α-isosparteine (**8**) (from **5**) and 15-oxosparteine (**9**) (from **10**).

The ^{13}C nmr spectrum of 15-oxosparteine (**9**) was tentatively assigned on the basis of the off-resonance spectrum and by comparison with the assignments in the published (6) spectra of sparteine and its 2- and 17-oxo derivatives. The signal of C-17 in the spectrum of 15-oxosparteine is shifted upfield by 13.3 ppm (compared to sparteine) due to the shielding effect of the 15-oxo group on its peri neighbour (15). Upfield shifts are also

observed for C-11 (6 ppm), C-13 (4.9 ppm, β to CO), and C-12 (2.3 ppm, γ to CO). A downfield shift (6.7 ppm) is observed in the case of C-14 (α to CO).

Table 2 summarizes the assignments of the ^{13}C nmr signals in the spectra of sparteine and a number of related compounds.

Experimental

Lactams of sparteine

17-Oxosparteine (7) (12, 13)

Sparteine (**1**) (2.9 g, freshly prepared from sparteine sulfate, Fluka) was dissolved in dilute hydrochloric acid (0.4 *M*, 54 mL). The solution was cooled and basified with sodium hydroxide solution (10%, w/v, 81 mL), and a solution of potassium ferricyanide (17.9 g) in water (67 mL) was added. The mixture was shaken for 40 min, acidified with dilute hydrochloric acid (0.4 *M*, 48 mL), and extracted with ether (3 × 80 mL). The water layer was basified with aqueous sodium hydroxide (10% w/v) and extracted with ether. The ether solution was dried (sodium sulfate) and evaporated to dryness. The residue was recrystallized from petroleum ether (40–60°C), yielding 17-oxosparteine (2.7 g), mp 85–87°C (lit. (13) mp 86–87°C).

A sample was converted into the perchlorate salt, mp 240–41°C (lit. (16) mp 241°C).

15-Oxosparteine (9)[1]

A solution of Hg^{2+}/EDTA complex (3.4 g) in water (30 mL) was added to sparteine (0.4 g) and the mixture was shaken 2 h at room temperature in an atmosphere of argon and was then kept at 60°C for 24 h. The resulting mixture of dehydrobases was allowed to cool to room temperature and was reacted with sodium borohydride (0.4 g) which was added in small portions over 1.5 h. The pH of the mixture was adjusted to pH 3 by addition of hydrochloric acid (2 *M*), and the precipitate of mercury salts was filtered off. The solution was basified with sodium hydroxide pellets and was then extracted with ether. The ether solution was dried (KOH pellets) and the solvent evaporated. The oily residue was dissolved in methanol (2 mL), 30% hydrogen peroxide (0.15 mL) was added, and the mixture was kept for 1 h. Excess hydrogen peroxide was destroyed with 10% palladium on charcoal. The mixture was filtered through Celite and the filtrate was concentrated, dissolved in water, and extracted with ether. Evaporation of the ether solution gave a colorless oil (80 mg) which was composed of 15-oxosparteine (major product) and several other minor products whose structure is under investigation. 15-Oxosparteine was purified by column chromatography on alumina (Fisher, activity I). Elution with a mixture of benzene–chloroform 2:1 yielded 15-oxosparteine (50 mg) as a colorless oil which was converted into the perchlorate, mp 150–151°C (lit. (14) mp 152°C). The ^{1}H and ^{13}C nmr spectra of 15-oxosparteine were different from the spectra of lupanine (2-oxosparteine) and of 17-oxosparteine.

Photochemical oxidation of sparteine (11)

A solution of sparteine (390 mg) in methanol (20 mL) was placed in a Pyrex tube and irradiated 14 h with a Philips 5P 500 lamp in the presence of methylene blue (39 mg) as sensitizer, while a stream of oxygen was bubbled through the solution. Methanol was added twice to maintain the volume of the solution. After 14 h, thin-layer chromatography (silica gel, CH_2Cl_2–CH_3OH – 0.880 NH_3, 9:0.9:0.1) of a sample of the reaction mixture showed only traces of sparteine. The solvent was removed *in vacuo*, and the residue applied to a silica gel column (20 g, 70–230 mesh, BDH). The column was washed with methylene chloride (50 mL) and with a solution of methanol (10 mL) in methylene chloride (490 mL) containing 0.880 ammonia (0.6 mL). The product was then eluted with a solution of methanol (25 mL) in methylene chloride (400 mL) containing 0.880 ammonia (3 mL) and was obtained as an oil (70 mg) which crystallized on standing. The ^{1}H and ^{13}C nmr spectra of the reaction product were identical with those of 17-oxosparteine (6) and different from the spectra of 2-oxosparteine (lupanine) (6) and of 15-oxosparteine (Tables 1 and 2). Melting point (from pet. ether 40–60°C) and mixture melting point with an authentic sample of 17-oxosparteine were 85–87°C (lit. (13) mp of 17-oxosparteine 86–87°C).

17-Oxolupanine (17) (i.e., 2,17-dioxosparteine) (**11**) was prepared by permanganate oxidation of lupanine; *13-hydroxylupanine* and *methyl aphyllate* were obtained from the alkaloid collection of the late Léo Marion, National Research Council Laboratories, Ottawa.

Deuteriated samples of sparteine and lupanine

(17,17-$^2H_2$)Sparteine (4–6)

17-Oxosparteine (**7**) (70 mg) in tetrahydrofuran (2.5 mL, freshly distilled from $LiAlH_4$) was added to a stirred suspension of lithium aluminium deuteride (98 at.%, MSD Isotopes, Montreal) (27 mg) in tetrahydrofuran (0.5 mL). The mixture was refluxed with stirring for 1 h and allowed to cool. Excess of reagent was decomposed by successive addition of water (30 μL), sodium hydroxide (15% w/v, 30 μL), and water (90 μL) and the reaction mixture was filtered and the residue washed with benzene (3 × 1 mL). Water (2 mL) was added to the filtrate, the organic phase was separated, and the aqueous phase was extracted with benzene (3 × 1 mL). Evaporation of the solvent yielded (17,17-$^2H_2$)sparteine (46 mg) which was purified via the monobisulfate (79 mg); ^{2}H nmr (C_6H_6) of the free base δ: 2.63 (17β-^{2}H pseudo-equatorial), 2.44 (17α-^{2}H, pseudo-axial). The corresponding peaks were missing in the ^{1}H nmr spectrum (dd of the 17β-H partially superimposed on a doublet of multiplets of the 2α-H; multiplet of the 17α-H superimposed on dt of the 10α-H); 95% deuteriation (by ms); ^{13}C nmr (D_2O) of the sulfate: signal at δ 50.2 ppm (C-17) not discernible.

(2,2-$^2H_2$)Sparteine (4–6) was prepared similarly by lithium aluminium deuteride reduction of lupanine (**2**) (79 mg). Yield 50 mg; ^{2}H nmr (C_6H_6) δ: 2.58 (2α-^{2}H, equatorial), 1.84 (2β-^{2}H, axial); ^{13}C nmr (D_2O) of the sulfate: signal at δ 57.7 ppm (C-2) not discernible.

(10,10-$^2H_2$)Sparteine (5) (5 mg) was obtained by reduction with $LiAlD_4$ from aphylline (11 mg) (10-oxosparteine) which, in turn, had been prepared from methyl aphyllate via the corresponding amino acid (18); ^{2}H nmr (C_6H_6) δ: 2.43 (10α-^{2}H, equatorial), 1.92 (10β-^{2}H, axial); ^{13}C nmr (D_2O) of the sulfate: signal at δ 58.4 ppm (C-10) not discernible.

(15,15-$^2H_2$)Sparteine (5) (8 mg) was prepared by $LiAlD_4$ (20 mg) reduction in tetrahydrofuran (2 mL) of 15-oxosparteine (**9**) (16 mg); ^{2}H nmr (C_6H_6) δ: 2.73 (15β-^{2}H, equatorial), 1.97 (15α-^{2}H, axial); ^{13}C nmr (D_2O) of the sulfate: signal at δ 56.2 ppm (C-15) not discernible.

(6-^{2}H)Sparteine (4, 5) (12 mg) was prepared (cf. ref. 9) by reduction with sodium borodeuteride (98 at.%, MSD isotopes) of 1,6-dehydrosparteinium diperchlorate (24 mg) in methanol; ^{2}H nmr (C_6H_6) δ: 1.63 ppm; ^{13}C nmr (D_2O) of the sulfate: signal at δ 67.7 ppm (C-6) not discernible.

(17α-^{2}H)Lupanine and (17β-^{2}H)Lupanine (5, 7)

These two deuteriated derivatives of lupanine were prepared by reduction of 16,17-dehydrolupaninium perchlorate (**3**) (7). Direct reduction of the dehydrolupanine derivative (42 mg) with sodium borodeuteride (9 mg) in deuterium oxide (1 mL) gave (17β-^{2}H)lupanine (17 mg) (17-^{2}H-*re*, pseudo-equatorial); ^{2}H nmr (C_6H_6) δ: 2.53 ppm. The epimeric (17α-^{2}H)lupanine (17-^{2}H-*si*, pseudo-axial) (36 mg) was obtained by exchange of the proton at C-17 of the dehydrolupanine derivative (55 mg) by deuterium supplied by deuterium oxide (2 mL) in the presence of sodium deuteroxide (0.16 mmol), followed by reduction with sodium borohydride; ^{2}H nmr (C_6H_6) δ: 1.79 ppm.

(17α-^{2}H)Sparteine and (17β-^{2}H)sparteine, respectively, were prepared by lithium aluminum hydride reduction of the corresponding deuteriated lupanine; ^{2}H nmr (C_6H_6) δ: 2.44 (17α-^{2}H, pseudo-axial); 2.63 (17β-^{2}H, pseudo-equatorial).

Instrumental methods

The *^{1}H nmr spectra* were recorded in the Fourier mode on a Bruker WM 250 spectrometer, in 5-mm tubes, in C_6D_6 solution.

The *^{2}H nmr spectra* were recorded in the Fourier mode on a Bruker WM 250 spectrometer, in 10-mm tubes. The spectra of the deuteriated samples of sparteine and lupanine were recorded in benzene solution.

The *^{13}C nmr spectra* were recorded at 20.15 MHz in the Fourier mode on a Bruker WP 80 spectrometer, in 10-mm tubes. For solvents see Table 2.

Acknowledgments

This work was supported by the Natural Sciences and Engineering Research Council of Canada. We are grateful to Professor Dr. Maciej Wiewiórowski for informing us of his unpublished improved procedure for the preparation of 15-oxosparteine, and to Dr. O. E. Edwards for authentic samples from the lupine alkaloid collection of the late Léo Marion, National Research Council of Canada Laboratories, Ottawa.

We thank Brian G. Sayer for recording the ^{1}H- and ^{2}H nmr spectra and J. Ian A. Thompson for the ^{13}C nmr spectra. We are greatly indebted to Dr. R. E. Lenkinski, South Western Ontario NMR facility, University of Guelph, for determining COSY and 2-D *J* resolved spectra.

Influence of temperature on copper bromide formation and dissolution

R. L. Brossard and G. M. Raynaud
Institut de Recherche d'Hydro-Québec (IREQ), P.O. Box 1000, Varennes (Qué.), Canada J0L 2P0

Received April 24, 1984

R. L. Brossard and G. M. Raynaud. Can. J. Chem. **63**, 720 (1985).

The influence of temperature on copper bromide formation and dissolution has been investigated in deaerated aqueous solutions of 0.2 *M* NaBr at pH 4. The morphology of CuBr accumulated on the copper anode supports the idea that CuBr precipitates in the vicinity of the electrode. Under a constant potential of $-70\ mV_{sce}$, very large flat platelets of CuBr are observed at 71°C compared to grains at 22°C. In addition, irregular current variations are noted on the current time curves at 71°C when large cracks are present in the film. It is deduced that the irregular current variations are due to the formation and repair of the cracks in the film. The current of the anode eventually reaches a steady value equal to the dissolution rate of the copper bromide precipitate formed on the electrode.

The influence of the temperature on the dissolution rate of CuBr may be entirely predicted assuming that the rate-determining step for the dissolution of this compound is the mass transfer of intermediates, e.g., $CuBr_2^-$ from the electrode surface to the bulk electrolyte.

R. L. Brossard et G. M. Raynaud. Can. J. Chem. **63**, 720 (1985).

Opérant à un pH de 4 et sur des solutions aqueuses de NaBr à 0,2 *M* desquelles on a enlevé l'air, on a étudié l'influence de la température sur la formation et sur la dissolution du bromure cuivreux. La morphologie du CuBr qui s'accumule sur l'anode de cuivre supporte l'idée que le CuBr précipite à la proximité de l'électrode. Si on opère à un potentiel constant de $-70\ mV_{sce}$, il se forme de très grandes plaquettes de CuBr à 71°C alors que, à 22°C, le produit précipite sous forme de grains. A 71°C, alors que de grandes fissures apparaissent sur le film, on observe de plus des variations irrégulières de courant sur les courbes courant–temps. On en déduit que les variations irrégulières du courant sont dues à la formation et à la réparation des fissures dans le film. Le courant de l'anode atteint éventuellement une valeur constante qui est égale à la vitesse de dissolution du précipité de bromure cuivreux qui se forme sur l'électrode.

On peut prédire complètement l'influence de la température sur la dissolution en faisant l'hypothèse que l'étape qui détermine la vitesse de la dissolution de ce composé est le transfert de masse des intermédiaires, comme le $CuBr_2^-$, de la surface de l'électrode vers le courde de l'électrolyte.

[Traduit par le journal]

Introduction

The formation of CuBr is observed on copper surfaces (1–3) at potential values larger than the reversible potential (4, 5) for the reaction

$$[1]\quad Cu + Br^- = CuBr + e$$

Two peaks of oxidation are present on the $E-i$ curves and the dissolution current results mainly in the accumulation of copper bromide. The limitation of the current in the peaks region was ascribed to the diffusion of ions in the solution (3). Eventually, an additional current limitation is created by the presence of CuBr on the electrode surface.

Copper bromide compound is slightly soluble in aqueous bromide solution (6). The dissolution of copper bromide formed by the electrochemical oxidation of copper in aqueous sodium bromide was reported for solutions between 0.1 *M* and 1.2 *M* NaBr concentration at 22°C (2). The complete dissolution of the anodically-formed CuBr coincides with a rapid drop in potential which allows a transition time τ to be defined. The dissolution rate of CuBr can then be calculated from the value of τ.

The aim of the present work is to investigate the influence of the temperature on the formation and the dissolution of copper bromide in 0.2 *M* NaBr aqueous solution.

Experimental

The electrochemical cells, their accessories, and the test procedures have been described in detail in previous papers (2, 7). In the present investigation, the copper electrode (Ventron Corporation, 99.99%) consisted of a vertical 0.64 mm diameter wire or of a horizontal 5 mm diameter disk, which gave a sample surface area of 0.5 cm^2 and 0.196 cm^2, respectively.

The solution contained between 0.1 and 0.4 *M* of dissolved NaBr at pH = 4. A potassium-phthalate buffer, 0.05 *M*, was used to stabilize the pH. The solution was carefully deaerated by nitrogen bubbling, which was discontinued prior to the experiments.

The current–time curves were obtained on the copper wire electrode at a constant potential of $-70\ mV_{sce}$ in the temperature range of 22°C to 71°C. The value of the electrode potential was $-400\ mV_{sce}$ prior to the experiment.

The experimental technique to measure the dissolution rate of copper bromide, v, was identical to that recently developed (2). Unless otherwise noted, all electrode potential values are given in relation to the saturated calomel electrode. Dissolution rates were measured on stationary and rotating disk electrodes.

Results and discussion

Formation of copper bromide

The anodic current density is plotted against time in Fig. 1 as the copper wire electrode is maintained at a constant potential of −70 mV, in a quiescent solution of 0.2 *M* NaBr. At this potential value, the current of dissolution results in the accumulation of copper bromide on the electrode surface (2, 3).

The limitation of the current is tentatively attributed to the diffusion (3) and migration of Br^- ions in the solution while an additional current limitation is created by the accumulation of a sufficient amount of copper bromide on the surface (Fig. 2*a*, 2*b*, 2*c*). The electrode surface is entirely covered by the corrosion product after 40 s of oxidation (Fig. 2*c*). Its morphology suggests that CuBr precipitates in the vicinity of the electrode. It is expected that the solution will easily penetrate through the film since the film is relatively porous. The film tends to become more compact with the increase in the duration of the oxidation (Fig. 2*d*). The CuBr grains on the surface grew from

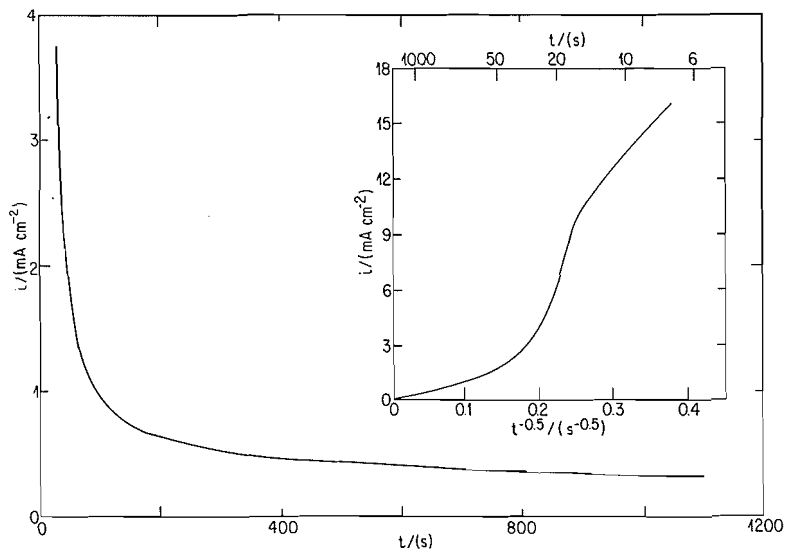

FIG. 1. Current versus time on a copper wire electrode at a constant potential of −70 mV. Just prior to oxidation, the applied potential was −400 mV. The solution is quiescent and the electrode is stationary. T = 22°C, 0.2 M NaBr. The inset shows current density versus (time)$^{-0.5}$.

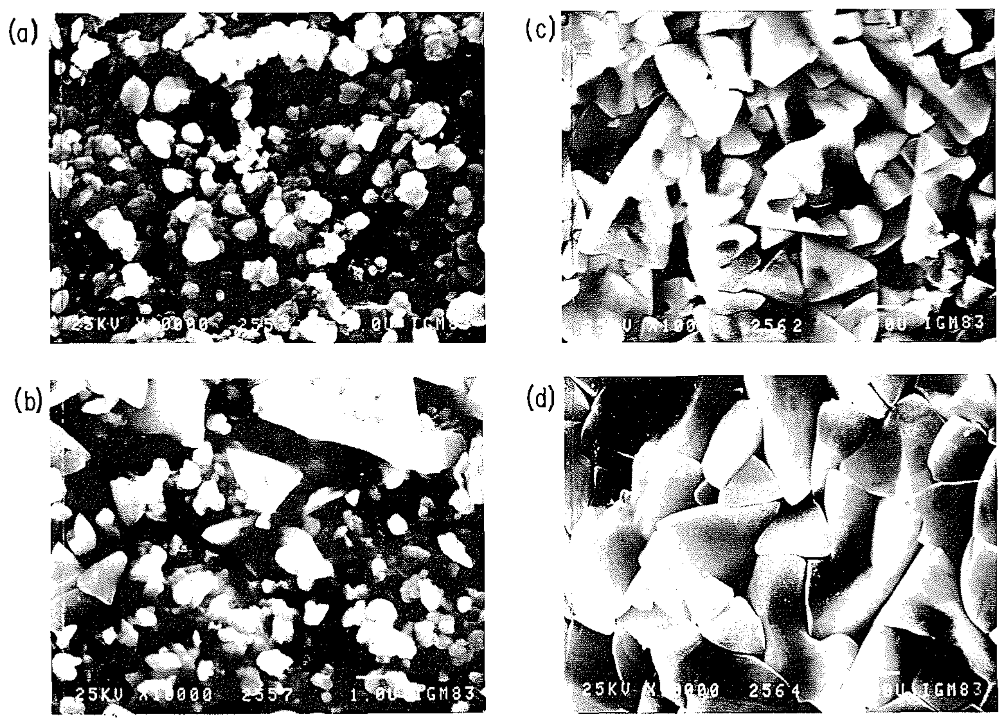

FIG. 2. Surface of copper electrode during oxidation at −70 mV and 22°C. The current–time curve is given in Fig. 1. Times of removal are (a) 5 s, (b) 20 s, (c) 40 s, (d) 5400 s.

an average size of 0.5 μm after 5 s (Fig. 2a) to 3 μm after 5400 s (Fig. 2d).

The shape of the i–t curve and the morphology of CuBr change as the temperature is increased from 22°C to 71°C (Fig. 3, Fig. 4). At 58°C, the current reaches a minimum after 300 s to 400 s while a slight increase of current with time is observed for t larger than 400 s (Fig. 3). In addition, irregular current variations suddenly appear after approximately 120 s. The anodic current and the magnitude of the current oscillations are significantly higher as the temperature is increased from 58°C to 71°C.

It is observed that the morphology of the corrosion product is quite different at 71°C. The copper electrode is partially covered with very large flat platelets of CuBr (Fig. 4a) in the region where the variation of current versus time is regular. The irregular current variations begin near the completion of the surface coverage by CuBr and large cracks are present in the film (Fig. 4b, 4c). It is deduced that the irregular current variations are due to the formation and repair of the cracks in the film.

Dissolution of copper bromide

The copper electrode becomes covered by a CuBr precipitate during the oxidation stage when polarized at potential anodic to the peak potential of the first wave of oxidation (1, 3). It was established that the dissolution rate (v) of the precipitate is

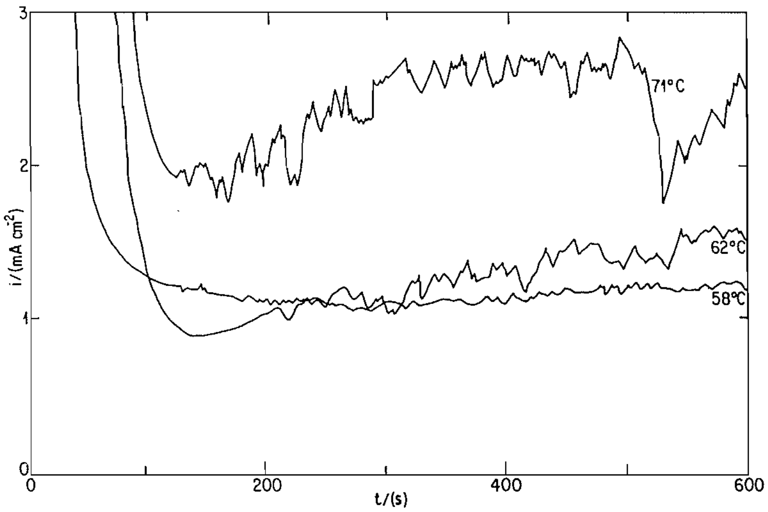

FIG. 3. Current versus time at three different temperatures. Except for temperature, the experimental conditions are those of Fig. 1.

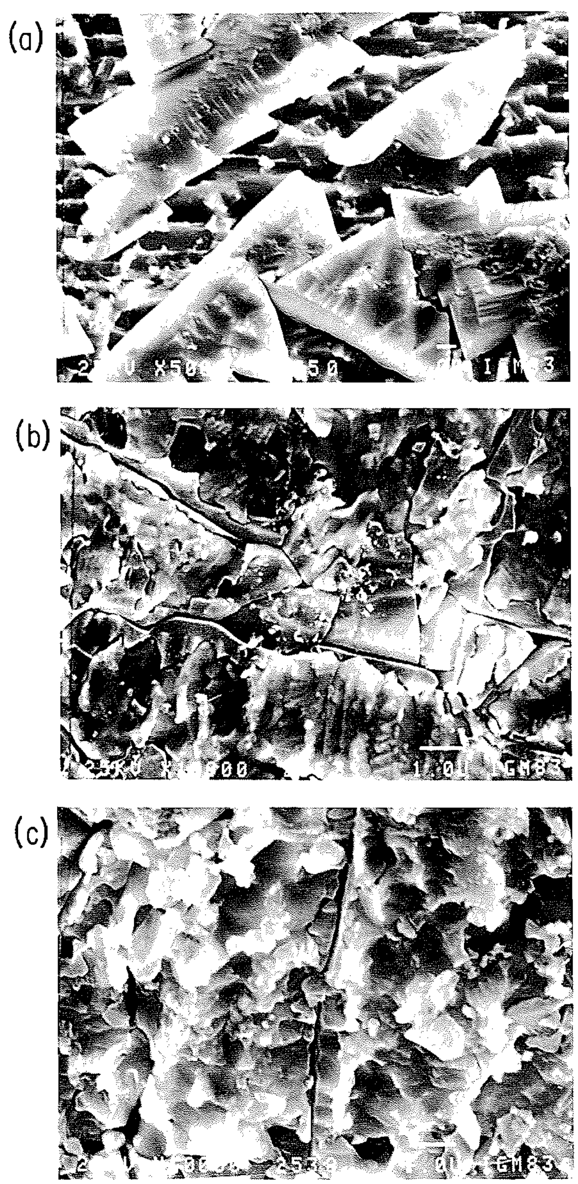

FIG. 4. Surface of copper electrode during oxidation at −70 mV and 71°C. The current–time curve is given in Fig. 3. Times of removal are (*a*) 100 s, (*b*) 200 s, (*c*) 1000 s.

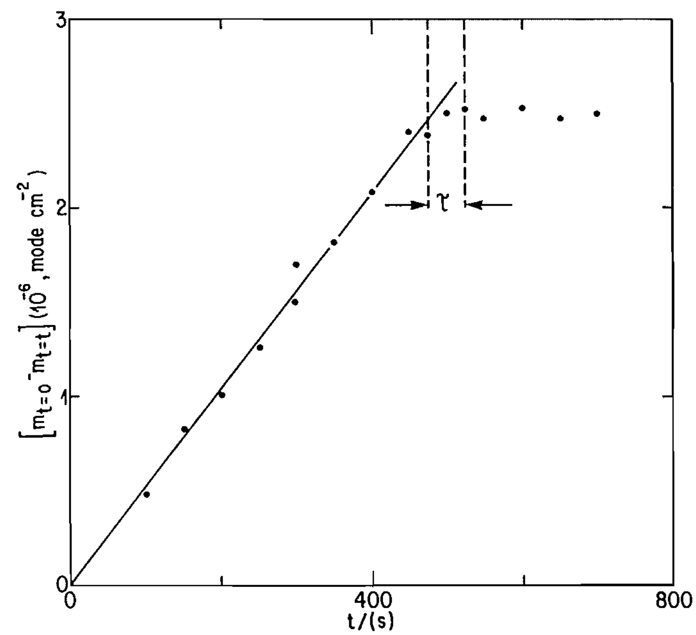

FIG. 5. The amount of precipitate dissolved from the electrode surface (m) after contact with 0.2 M NaBr solution. $m_{t=0}$: at $t = 0$. $m_{t=t}$: m at $t = t$. τ: duration of transient. No stirring in the solution. The electrode is a copper wire.

constant until the completion of its dissolution at 22°C (2). The constant value of v during the dissolution of CuBr at 50°C was confirmed from the reduction of the precipitate at −450 mV after different periods of contact with the solution (Fig. 5). The difference between the charge required for complete film reduction at $t = 0$ and at $t = t$ is ascribed to the dissolution of CuBr during time t. It was assumed that a cathodic charge of 96 500 C is required to decompose 1 g/molecule of this compound because copper ions have a valency of +1 in this compound. The slope of the curve in Fig. 5 corresponds to v; its value is 0.52×10^{-8} mol cm^{-2} s^{-1} in 0.2 M NaBr. The amount of CuBr on the electrode surface is zero as soon as $t = \tau$ where v becomes zero.

The main characteristics of the behavior of the copper electrode covered by CuBr on its surface are the following. (*i*) The open circuit potential (E_{oc}) obtained immediately after ox-

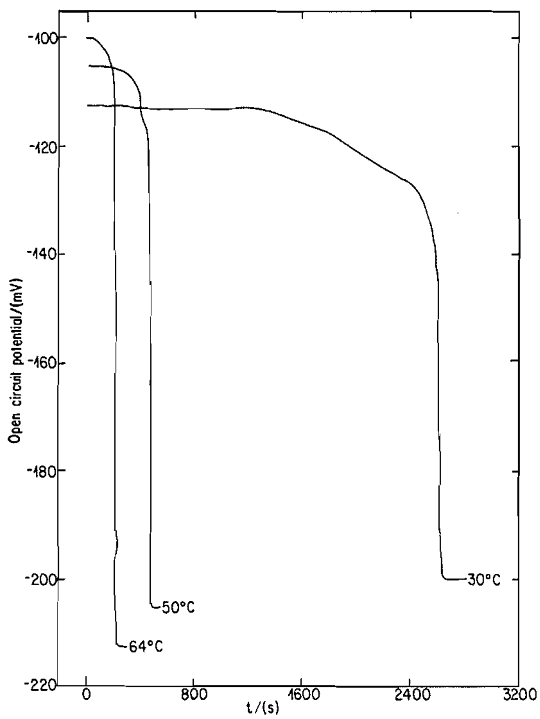

FIG. 6. The open-circuit potential of the copper wire electrode after oxidation at three different temperatures. Oxidation: linear sweep voltammetry from −450 mV to +50 mV at a rate of 5 mV s^{-1}. $m_{t=0}$ is 2.1 × 10^{-6} mol cm^{-2} at 64°C; 2.8 × 10^{-6} mol cm^{-2} at 50°C; 3.1 × 10^{-6} mol cm^{-2} at 30°C.

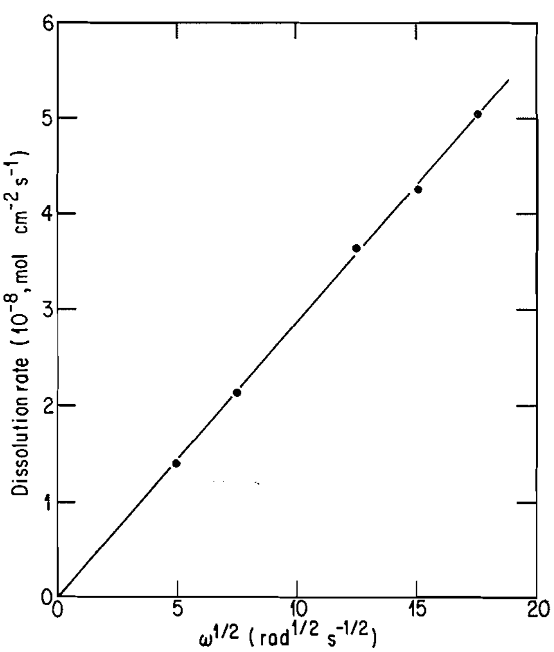

FIG. 7. Dependence of the dissolution rate of a rotating electrode on the angular velocity. Solution: 0.2 *M* NaBr, *T* = 49°C.

idation is higher while τ is considerably reduced as the temperature is increased (Fig. 6). (*ii*) The dissolution rate of copper bromide obeys a $\omega^{1/2}$ law for rotating disk electrode and v is close to zero when ω = 0 (Fig. 7). In this illustration, the solution is 0.2 *M* NaBr. (*iii*) The order of the reaction (ξ) with respect to Br^- ion concentration is 1.1 ± 0.05 (Fig. 8).

The features observed in Figs. 5, 6, and 7 are similar to characteristics previously found concerning the dissolution of

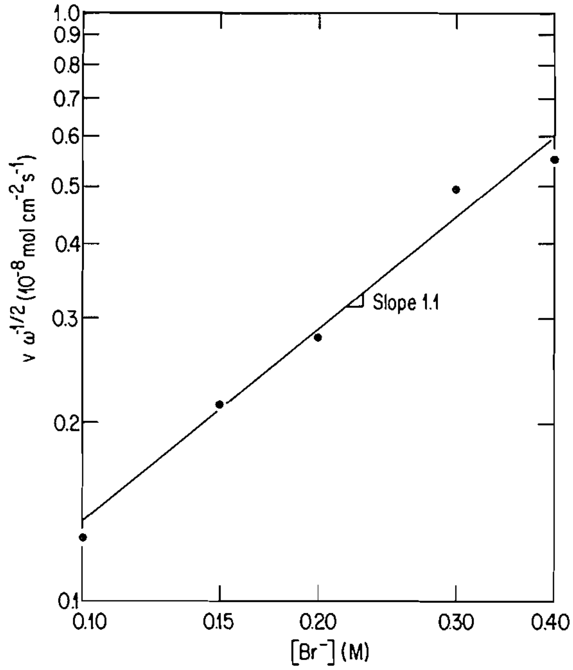

FIG. 8. $v\omega^{-1/2}$ vs. Br^- concentration at 49°C.

copper bromide solutions with up to 1.2 *M* Br^- concentration at 22°C (2). Accordingly, the dissolution process is[1]

$$[2]\quad CuBr + xBr^- = (CuBr_{1+x}^{x-})_i$$

$$[3]\quad (CuBr_{1+x}^{x-})_i \rightarrow (CuBr_{1+x}^{x-})_s \qquad \text{(rds)}$$

where the subscripts i and s refer to concentrations at the electrode solution interface and the bulk solution, respectively. The rate-determining step [3] is the diffusion transport of complexes, as $CuBr_2^-$ and $CuBr_3^{2-}$, from the interface to the bulk solution. The first step [2], the oxidation of CuBr to both $CuBr_2^-$ and $CuBr_3^{2-}$, is assumed to be in equilibrium. The dissolution rate of a rotating electrode should be given by the following application of the Levich equation

$$[4]\quad v = 0.62n\nu^{-1/6}D_{CuBr_{1+x}^{x-}}^{2/3}\ \omega^{1/2}[CuBr_{1+x}^{x-}]_i$$

In this equation, v is in mol cm^{-2} s^{-1}; n is the charge of the diffusing species which is between 1 and 2, ν the kinematic viscosity of the solution, $D_{CuBr_{1+x}^{x-}}$ the diffusion coefficient of the intermediates, ω the angular velocity of the electrode and $[CuBr_{1+x}^{x-}]_i$ is the concentration of copper in the vicinity of the electrode surface.

It is expected that the diffusing species is mainly $CuBr_2^-$ or Br^- since ξ is very close to 1 (Fig. 8). For both species, n is equal to 1. For Br^- ions as the diffusing species, the Levich equation becomes

$$[5]\quad v = 0.62\nu^{-1/6}\ D_{Br^-}^{2/3}\ \omega^{1/2}\ [Br^-]$$

In this equation, D_{Br^-} is the diffusion coefficient of the Br^- ions and [Br^-] is the concentration of Br^- ions in the bulk of the solution. The theoretical values $v\omega^{-1/2}$ calculated from eq. [4], $v\omega_{CuBr_2^-}^{-1/2}$, and [5], $v\omega_{Br^-}^{-1/2}$, are represented in Table 1 for three different temperatures.

The values of $D_{CuBr_2^-}$ and D_{Br^-} at different solution temperatures were calculated from the equation (9):

[1] $(CuBr_{1+x}^{x-})_i$ represents a mixture of $CuBr_2^-$ and $CuBr_3^{2-}$ complexes.

TABLE 1. Experimental and theoretical values of $\nu\omega^{-1/2}$ at 40°C, 49°C, and 68°C in 0.2 *M* NaBr solution

T (°C)	$[CuBr_{1+x}^{x-}]$[a] (mol cm^{-3})	$\nu\omega^{-1/2}_{CuBr_2^-}$[b] ($10^{-8}$ mol cm^{-2} s$^{-1/2}$)	$\nu\omega^{-1/2}_{Br^-}$[c]	$\nu\omega^{-1/2}_{exp}$[d] (10^{-8} mol cm^{-2} s$^{-1/2}$)
40	1.9×10^{-6}	0.20	26.2	0.18
49	2.2×10^{-6}	0.27	30.8	0.28
68	3.1×10^{-6}	0.50	80.1	0.52

[a] $[CuBr_{1+x}^{x-}]$ was determined experimentally using the experimental technique described in ref. 2.
[b] The theoretical values of $\nu\omega^{-1/2}$ were calculated from eq. [4]. ν of water (8) was used and the diffusion coefficient was calculated from eq. [6].
[c] The experimental values of $\nu\omega^{-1/2}$ were calculated from eq. [5]. ν of water (8) was used and the diffusion coefficient was calculated from eq. [6].
[d] The experimental values of $\nu\omega^{-1/2}$ were determined from ν vs. $\omega^{1/2}$ curves (Fig. 7).

TABLE 2. Influence of temperature on ν and i_{an} for a stationary electrode in a quiescent 0.2 *M* NaBr solution

T (°C)	i_{an}[a] (mA cm^{-2})	ν[b] (mA cm^{-2})
50	0.65	0.70
57	0.93	0.86
66	1.5	1.35

[a] The measured current on the copper wire anode for t larger than 8800 s at a constant applied potential of −70 mV.
[b] It is assumed that the decomposition of 1 g/molecule of CuBr corresponds to a charge of 96 500 C since the valency of copper is +1 in this compound.

$$[6] \quad \frac{D\mu}{T} = \text{constant}$$

where μ is the viscosity of the solution, given in ref. 10. It is assumed that $D_{CuBr_2^-}$ and D_{Br^-} are equal to 1.3×10^{-5} cm^2 s^{-1} (2) and 1.8×10^{-5} cm^2 s^{-1} (3), respectively, at 22°C.

The experimental values of $\nu\omega^{-1/2}$, determined from ν vs. $\omega^{1/2}$ curves (Fig. 7), are close to the theoretical values $\nu\omega^{-1/2}_{CuBr_2^-}$ and are far away from the theoretical values $\nu\omega^{-1/2}_{Br^-}$ (Table 1). Therefore, the dissolution model formed by steps [2] and [3] is applicable up to 68°C.

Table 2 contains the values of the measured current on the copper wire anode (i_{an}) when the current reaches a steady value in temperatures ranging from 50°C to 66°C. The experimental values of ν, expressed in mA cm^{-2}, are also illustrated.

The comparison between ν and i_{an} supports the idea that the current of the copper anode decreases to eventually reach a steady value equal to the dissolution rate of the copper bromide precipitate formed on the electrode.

Conclusions

The morphology of copper bromide accumulated on the copper anode suggests that CuBr precipitates in the vicinity of the electrode. Its morphology and characteristics are quite different as the temperature is shifted from 22°C to 71°C while the irregular current variations observed on the i–t curves at 71°C are ascribed to the formation and repair of the cracks in the film. The current of the anode eventually reaches a steady value equal to the dissolution rate of the copper bromide precipitate formed on the electrode. The rate-determining step for the dissolution of CuBr from 22°C to 71°C can be entirely attributed to the mass transfer of intermediates ($CuBr_2^-$, $CuBr_3^{2-}$) from the electrode surface to the bulk electrolyte.

Reçu le 25 janvier 1984

Ce memoire est dédié au Professeur Paul de Mayo à l'occasion de son 60ᵉ anniversaire

RENÉ BEUGELMANS, LEÏLA BENADJILA-IGUERTSIRA, JACQUELINE CHASTANET, GUILLERMO NEGRON et GEORGES ROUSSI. Can. J. Chem. **63**, 725 (1985).

Sous l'action du diisopropyl amidure de lithium, les *N*-oxydes d'amines aliphatiques de structures diverses **1**, **5**, **10**, **15**, **21**, **23** sont déprotonés. La monodéprotonation livre des amines secondaires et du benzaldéhyde résultant de l'hydrolyse d'un imonium (I), ou des hydroxylamines issues d'un réarrangement de type Stevens observé pour la première fois à partir d'un N-oxyde. La double déprotonation livre un intermédiaire ylure d'imonium (Y) pouvant évoluer en fonction de la structure de l'amine tertiaire initiale soit vers des pipérazines "tête–tête" (comportement de radical double (DD)), soit vers des aziridines. L'ylure d'imonium (Y5) dérivant du *N*-oxyde de triméthylamine dont la formation et la réactivité sont décrites pour la première fois possède la propriété remarquable d'entrer dans des réactions de cycloaddition avec des oléfines non activées, permettant ainsi une synthèse originale et efficace de pyrrolidines diverses.

RENÉ BEUGELMANS, LEÏLA BENADJILA-IGUERTSIRA, JACQUELINE CHASTANET, GUILLERMO NEGRON, and GEORGES ROUSSI. Can. J. Chem. **63**, 725 (1985).

Amine oxides, **1**, **5**, **10**, **15**, **21**, **23**, when treated by lithium diisopropylamide undergo deprotonation. Monodeprotonation gives rise either to secondary amines and benzaldehyde resulting from the hydrolysis of an intermediate immonium (I) or to hydroxylamines via a Stevens-like rearrangement observed for the first time on an amine oxide. Double deprotonation gives an immonium ylid (Y) which, depending upon the structure of the initial tertiary amine yields either "head to head" piperazines (biradical-like behavior of (DD)) or aziridines. The immonium ylid (Y5) derived from trimethylamine oxide, whose formation and reactivity are reported for the first time, has the remarkable property of undergoing cycloaddition reactions with unactivated olefins, leading to a new and efficient synthesis of various pyrrolidines.

La déprotonation des ammoniums quaternaires est une propriété bien connue (Réactions de Stevens, de Sommelet–Hauser), mais celle des *N*-oxydes d'amines aliphatiques tertiaires, structuralement proches restait inexplorée.[2] Cette constation fut à l'origine de l'étude systématique (2) présentée ici, dont quelques résultats préliminaires furent publiés (3, 4).

Résultats

Le *N*-oxyde de benzyldiméthylamine **1**, en présence d'un équivalent de BuLi conduit au benzaldéhyde **2**, à la benzylamine **3** et au mélange de pipérazines *cis* + *trans* **4** (15%). Le rendement en pipérazine **4** atteint 30% en présence de 2 équivalents ou plus de cette base. La nature de la base est importante et nous avons constaté que seules les bases lithiées RLi (R = CH_3, *n*-Bu, *t*-Bu, Ph, NH_2, $N(Et)_2$, $N(i\text{-prop})_2$, tétraméthylpiperidine) sont actives et que, parmi elles, le diisopropyl amidure de lithium (DAL) a permis le rendement en pipérazine **4** le plus élevé (61%), dans des conditions reproductibles (exp. 1).

C'est donc cette base qui a été utilisée pour traiter les *N*-oxydes benzyliques **1**, **5**, **10** (tableau 1).

Le *N*-oxyde **5** livre une hydroxylamine **7** (exp. 3) qui ne se forme pas à partir de **1** tandis que la quantité de pipérazine décroît comparativement à l'exp. 1. Cette tendance est plus accentuée pour le *N*-oxyde **10** dont la réaction ne livre plus de pipérazine, l'hydroxylamine **13** étant le produit majoritaire (exp. 5). Selon une publication récente, due à H. Takayama et T. Nomoto (5) qui ont étudié la réactivité de *N*-oxydes tribenzyliques différemment substitués en présence de DAL, les aziridines seraient les seuls produits formés à 0°C. En particulier, les auteurs rapportent la formation de **14** (41%) à partir de **10**. Nous avons donc pratiqué les expériences nº 2, 4 et 6 dans le but d'examiner la réactivité de **1**, **5**, **10** à 0°C. Pour le *N*-oxyde **1**, nous n'avons pas constaté de différence significative entre les expériences nº 1 et 2. Par contre, l'aziridine **9** est formée à partir de **5** traité à 0°C (exp. 4), alors qu'elle ne l'était pas à −78°C (exp. 3). En ce qui concerne la réactivité de **10** à 0°C (exp. 6), nous avons bien retrouvé **14**, avec le rendement

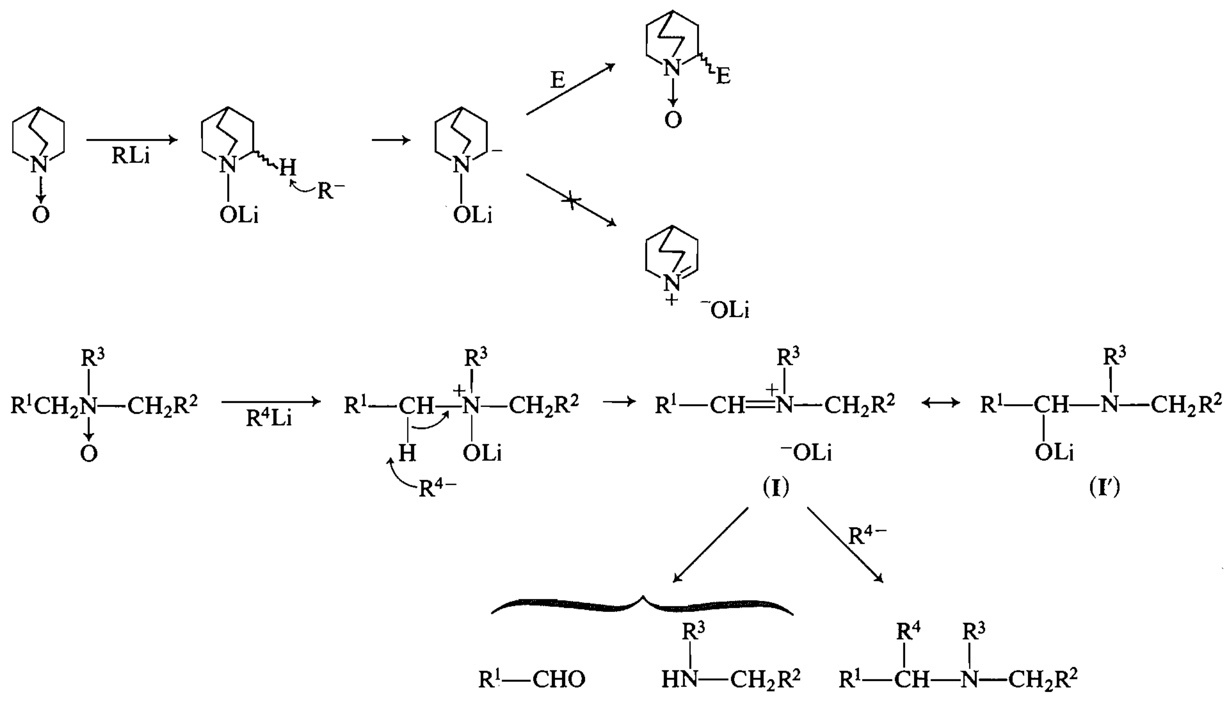
annoncé par Takayama et Nomoto, mais de plus, nous avons isolé la dibenzylamine **12** (12%) et l'hydroxylamine **13** (20%). C'est pour **10** que le contraste est le plus net puisqu'à 0°C (exp. 6) l'aziridine **14** est le produit majoritaire tandis que les quantités d'hydroxylamine **13** et de dibenzylamine **12** sont réduites de plus de la moitié par rapport à l'expérience 5. Le benzaldéhyde **2** est toujours présent, en quantités plus notables à 0°C qu'à −78°C.

Le *N*-oxyde de diméthylaniline **15** traité par le *t*-BuLi présente une réactivité différente de celle des *N*-oxydes benzyliques puisque les produits obtenus (exp. 7) (tableau 2) sont la *N*-méthylaniline **16**, l'amine tertiaire **17**, la phényl-1-pyrrolidine **18**. Le *t*-BuLi est manifestement la source des 4 atomes de carbone fixés sur **17** et par ailleurs, la formation de la pyrrolidine **18** implique la fixation de 2 atomes de carbone sur **15**. Or, le *t*-BuLi est une base suffisamment puissante pour décomposer le tétrahydrofuranne et donner de l'éthylène (6), source des deux atomes de carbone requis pour la formation de **18**. Un barbottage d'éthylène (exp. 8) provoque le doublement de la quantité de pyrrolidine et vient appuyer cette hypothèse. L'obtention de butyl-3 pyrrolidine **20** en présence de l'hexène-1 (exp. 9) confirme bien que les 2 atomes de carbone nécessaires à la formation des pyrrolidines **18** ou **19** proviennent d'un enchaînement —CH=CH—. Le *N*-oxyde de mésidine **21**



2 R[1] = C_6H_5 **3**; **6**; **12**; **16**   **17** R^4 = t-C_4H_9; R^1 = R^2 = H; R^3 = C_6H_5

comporte un cycle benzènique stériquement encombré sur les positions 2 et 6, et ne donne lieu qu'à la formation du produit **22**. Le *N*-oxyde de triméthylamine **23** livre la pipérazine **24** (exp. 11) et la pyrrolidine **25** en présence de styrène (exp. 12).

Discussion

La formation des produits obtenus à partir des *N*-oxydes **1**, **5**, **10**, **15**, **21**, **23** implique la déprotonation d'un ou de deux carbones adjacent(s) à la fonction *N*-oxyde (tableau 3).

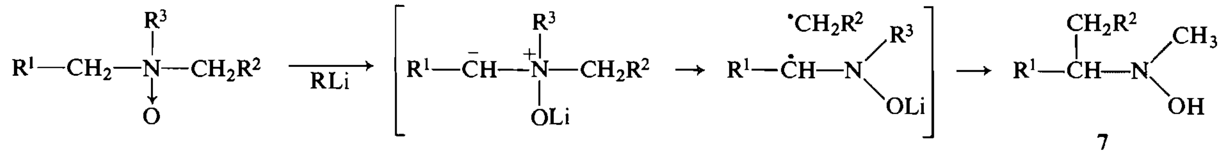
Monodeprotonation

Le premier cas clairement défini de réactivité anionique du carbone situé en α de la fonction *N*-oxyde est celui rapporté par nous en 1977, qui concerne le *N*-oxyde de quinuclidine (7).

La structure des amines tertiaires d'où dérivent les *N*-oxydes **1**, **5**, **10**, **15**, **21** et **23** permet contrairement à celle de la quinuclidine l'existence d'une liaison imonium $C{=}\overset{+}{N}{=}$ attestée par l'obtention de produits d'hydrolyse et d'attaque par un réactif nucléophile. En effet, l'intermédiaire formulé soit par $(I)^+$ OLi (sel d'imonium) soit par (I′) (amino alcoolate de Li) est hydrolysé en aldéhyde R^1—CHO et en amine secondaire HN (R^3)—CH_2R^2, tout comme dans les cas où il a été engendré à partir de la *N*-diméthylbenzylamine par d'autres voies (oxydation chimique ou électrochimique de l'amine, réduction ou décomposition catalysée par les métaux, du *N*-oxyde[3]) (schéma 2).

L'imonium (I) est également formé en série aniline et est caractérisé non seulement par l'obtention de l'amine secondaire

[3]Une discussion de ces réactions est donnée dans une révue récente (8).



7
13

5 $R^1 = R^2 = C_6H_5$; $R^3 = CH_3$
10 $R^1 = R^2 = C_6H_5$; $R^3 = CH_2C_6H_5$

SCHÉMA 3. Formation des hydroxylamines.

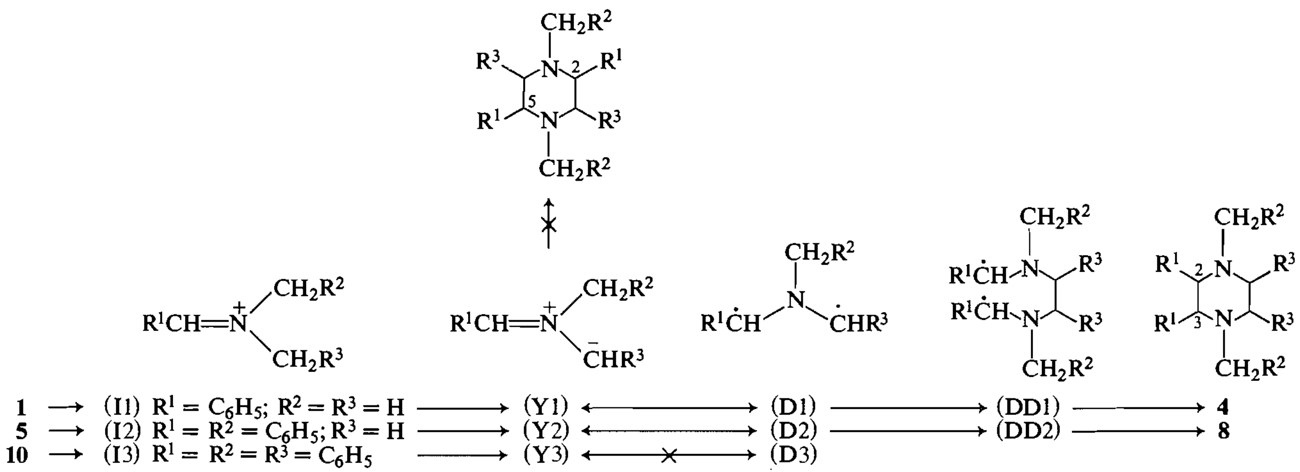


SCHÉMA 4. Formation des pipérazines tête–tête.

16 provenant de l'hydrolyse, mais aussi par celle des amines tertiaires **17** et **19** résultant de l'attaque nucléophile de t-$C_4H_9^-$ ou n-$C_4H_9^-$ sur C_6H_5—$\overset{+}{N}(CH_3)$=CH_2.

Le réarrangement en hydrolyxamines **7** (à partir de **5**) et **13** (à partir de **10**) observé pour la première fois sur des N-oxydes serait dû à un mécanisme radicalaire analogue à celui intervenant sur les sels d'ammonium quaternaires soumis à l'action des bases (Réaction de Stevens) (9, 10).

Parmi les N-oxydes étudiés ici, seuls **5** et **10** engendrent des anions pouvant subir la rupture homolytique nécessaire, avec formation de $\cdot CH_2C_6H_5$ (schéma 3).

Dans le cas du N-oxyde **10**, le processus radicalaire menant à l'hydroxylamine est plus efficace à −78°C qu'à 0°C, ce qui indique qu'il y a compétition entre la migration du radical $\cdot CH_2C_6H_5$ et la seconde déprotonation discutée plus loin.

Deprotonation double

Comme le montre le tableau 3, la monodéprotonation des N-oxydes qui est à l'origine de la formation de l'aldéhyde, des amines primaires et des hydroxylamines n'est pas sélective, puisque des pipérazines, des aziridines, des pyrrolidines sont formées également, même dans les réactions effectuées avec un seul équivalent de base. Cette seconde série de produits a pour origine une entité réactionnelle intermédiaire *difonctionnalisée*.

La déprotonation des sels d'imonium par les bases fortes a déjà été rapportée dans des cas particuliers et les produits, aziridines (11) ou pipérazines (12) selon la structure des imoniums initiaux, proviennent d'un ylure d'imonium qui a pu être piégé par le norbornène. Nous obtenons également des aziridines (**9**, **14**) et des pipérazines (**4**, **8**) à partir des N-oxydes benzyliques **5**, **10**, et de ceux dérivées de l'aniline **21** ou de la triméthylamine **23**. De plus, les pyrrolidines **18**, **20**, **25**, sont formées en présence d'une oléfine. L'origine de tous ces produits peut être rationalisée en invoquant l'existence d'un ylure d'imonium (Y) intermédiaire formé par déprotonation de (I).

Formation des pipérazines

Les pipérazines obtenues par duplication d'ylures d'imonium engendrés selon différentes voies possèdent toutes une structure "tête–queue" (substituants en positions 2 et 5) résultant d'une cycloaddition (3 + 3) (12–14).

Or, les pipérazines **4** et **8** que nous obtenons à partir des N-oxydes respectifs possèdent des structures "tête–tête" (substituants en positions 2 et 3), excluant un couplage d'ylures (Y1) ou (Y2). Cependant, ces ylures sont isoélectroniques de diradicaux (D1) et (D2) où le site benzylique ($C_6H_5\dot{C}H$—N serait stabilisé par l'effet captodatif défini par H. Viehe et coll. (15). Le radical méthylènique N—$CH_2^{\cdot}$ plus réactif réagirait donc le premier en se dupliquant, donnant ainsi un radical double (DD1) (DD2) précurseur des pipérazines "tête–tête" finales. L'interconversion photochimique **4** *cis* → **4** *trans* par l'intermédiaire d'un état excité menant à un radical double fournit un argument important en faveur de l'existence de (DD1) (16). Selon cette hypothèse, seuls les ylures d'imonium, générés à partir de N-oxydes d'amines portant au moins un substituant méthyle, *précurseur du radical méthylène* devraient donner des pipérazines, ce qui est vérifié.

Formation des aziridines

Nous avons vérifié que l'aziridine **26** est stable dans les conditions réactionnelles utilisées pour le traitement du N-oxyde **5** et qu'elle n'est donc pas à l'origine de la pipérazine **8**. L'espèce monodéprotonée (I) issue de **5** se déprotonne une seconde fois pour mener à (Y2) isoélectronique de (D2). Celle issue de **13** subit à −78°C une réaction compétitive menant à l'hydroxylamine **13** (exp. 5), la seconde déprotonation n'intervenant qu'à température plus élevée (exp. 6). La géométrie *cis* des phényles 2 et 3 portés par les aziridines **9** et **14** est conforme

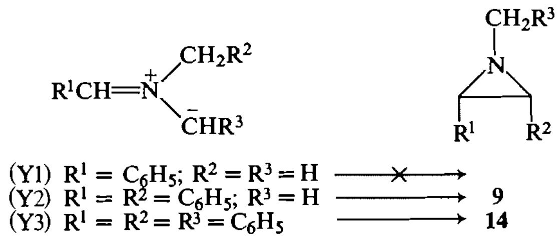

SCHÉMA 5. Formation des aziridines.

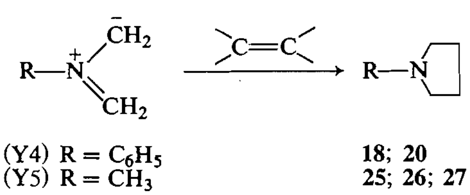

SCHÉMA 6. Formation des pyrrolidines.

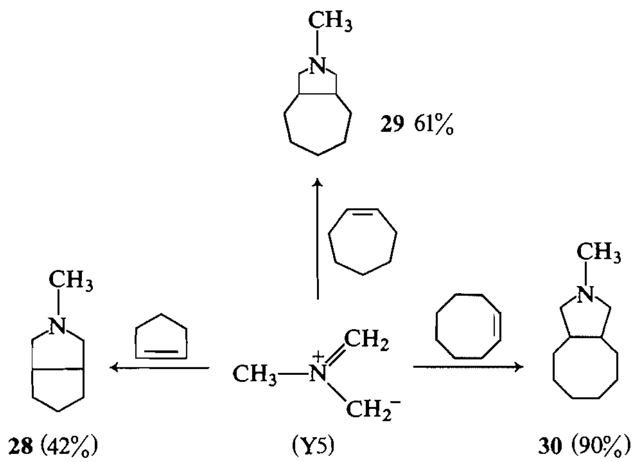

SCHÉMA 7. Réactivité de (Y5) vis-à-vis d'oléfines simples.

à celle attendue pour la cyclisation conrotatoire d'un intermédiaire ionique (Y2) ou (Y3) de conformation *trans*.

Formation des pyrrolidines

La déprotonation de l'imonium provenant du *N*-oxyde **15** livre un ylure (Y4), suffisamment réactif pour s'additionner à des oléfines simples (éthylène ou hexène-1). L'ylure d'imonium (Y5) est formé à partir du *N*-oxyde **23**, sans que l'existence d'un intermédiaire imonium soit étayée comme précédemment par l'obtention de l'amine secondaire $HN(CH_3)_2$ que nous avons recherchée sans succès. Ceci laisse penser que, en l'absence d'un substituant phényle porté sur le carbone (*N*-oxydes **1**, **5**, **10**) ou sur l'azote (*N*-oxyde **15**), l'imonium initial très réactif est déprotoné (de manière synchrone?) pour donner l'ylure (Y5).

Le styrène ajouté dans le milieu réactionnel ne se polymérise pas et livre **25** (50%), indiquant que l'intermédiaire n'est pas de nature radicalaire. D'autre part, l'addition de (Y5) au *cis* ou au *trans* stilbène livre la méthyl-1 diphényl-3,4 pyrrolidine *cis* **26** ou *trans* **27**, en conformité avec le processus de cycloaddition (3 + 2) (pour des révues récentes voir la réf. 17) (schéma 6). En l'absence d'oléfine, le seul produit isolable[4] à partir de **23** est la pipérazine **24**, qui n'étant pas substituée sur le cycle, ne peut fournir d'indice quant à la nature de l'intermédiaire mis en jeu.

Parmi les divers produits rapportés dans le tableau 3, les plus intéressants du point de vue de la synthèse sont ceux résultant de la double fonctionnalisation en α et α': pipérazines, aziridines et pyrrolidines. La réaction de cycloaddition (3 + 2) entre (Y5), *premier terme de la série des ylures d'imonium* ne portant aucun substituant et donc non stabilisé et des dipolarophiles non ou très peu activés par des groupes attracteurs d'électrons est *nouvelle* et nous semble être susceptible de développements synthétiques importants dont nous présentons ici quelques éléments.

Réactivité de (Y5) vis-à-vis d'oléfines simples

La réactivité de (Y5) est importante puisqu'il entre, à basse température, dans des réactions de cycloaddition avec des oléfines simples, ainsi qu'avec des cycloalcènes de taille variée:[5] cyclopentène, cycloheptène, cyclooctène, pour donner les systèmes hétérobicycliques **28**, **29**, **30**.

Réactivité de (Y5) vis-à-vis d'oléfins fonctionnalisées

Les possibilités synthétiques de la cycloaddition de (Y5) sont en fait plus vastes que celles montrées dans le schéma 7 puisque la double liaison de l'alcool allylique ou celle de la cyclopentenone dont la fonction carbonyle est protégée, la subissent pour donner **31** et **32**. La double liaison de la 3-pipéridéine est moins réactive et le rendement en système hétérobicyclique **33** est moindre.

Réactivité de (Y5) vis-à-vis de diènes

Les diènes conjugués cyclooctadiène, diphényl-1,4 butadiène livrent des mélanges de produits résultant d'une cycloaddition simple (**34**, **36**) ou double (**35**, **37**). Alors que **34** est instable, la pyrrolidine insaturée **36** isolée et traitée une seconde fois avec le *N*-oxyde **23** livre la bipyrrolidine **37**; aucun produit résultant d'une cycloaddition en 1,4 sur le système diénique n'a été obtenu. L'hexadiène-1,5 et l'hexadiène-1,5 3-ol se comportent de la même manière que les diènes conjugués, c'est-à-dire qu'ils subissent une ou deux cycloadditions avec (Y5) pour donner respectivement le mélange **38** + **39** et **40**.

Limites de la réaction de cycloaddition

La réaction s'avère sensible à l'encombrement stérique du dipolarophile comme nous l'avons observé à propos du comportement de (Y5) vis-à-vis du méthyl-1 cyclopentène et de l'alcool méthyl-2-allylique contrastant avec l'addition facile sur les homologues inférieurs.

Par ailleurs, (Y4) issu de **15** via (14) possède une réactivité satisfaisante vis-à-vis de l'éthylène et de l'hexène-1 et en ce qui concerne l'addition au norbornène, une expérience préliminaire conduit au produit attendu **41** dont la stéréochimie n'a pas été déterminée.

Conclusion

Les résultats de ce travail permettent de proposer pour la première fois un schéma réactionnel rendant compte de l'ensemble des données actuellement connues concernant la réactivité des *N*-oxydes d'amines aliphatiques traités par les bases fortes; ce schéma est susceptible, selon nous, de servir de fil

[4]La *N*-méthyl aziridine dont nous avons préparé un échantillon au laboratoire n'a pas été trouvée dans les produits issus de cette expérience.

[5]La faible réactivité du cyclohexène est actuellement étudié plus en détail au laboratoire, et peut, selon la remarque de l'un des rapporteurs, avoir des implications concernant le mécanisme réactionnel mis en jeu.

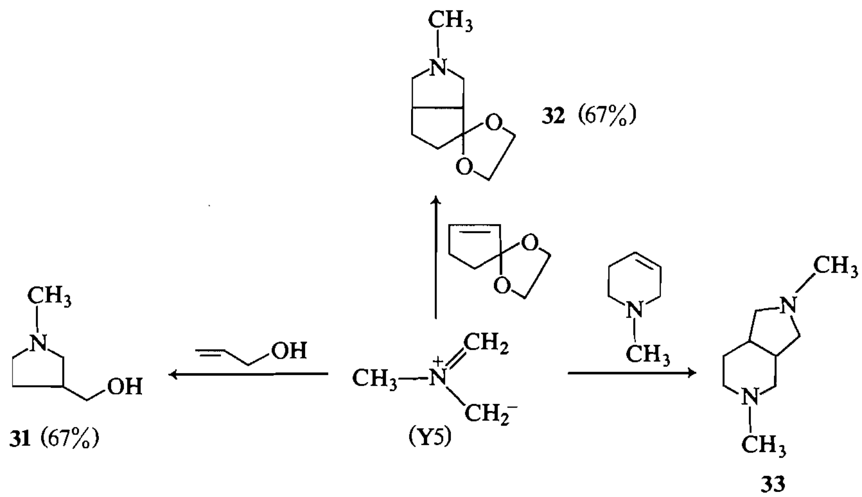

SCHÉMA 8. Réactivité de (Y5) vis-à-vis d'oléfins fonctionnalisées.

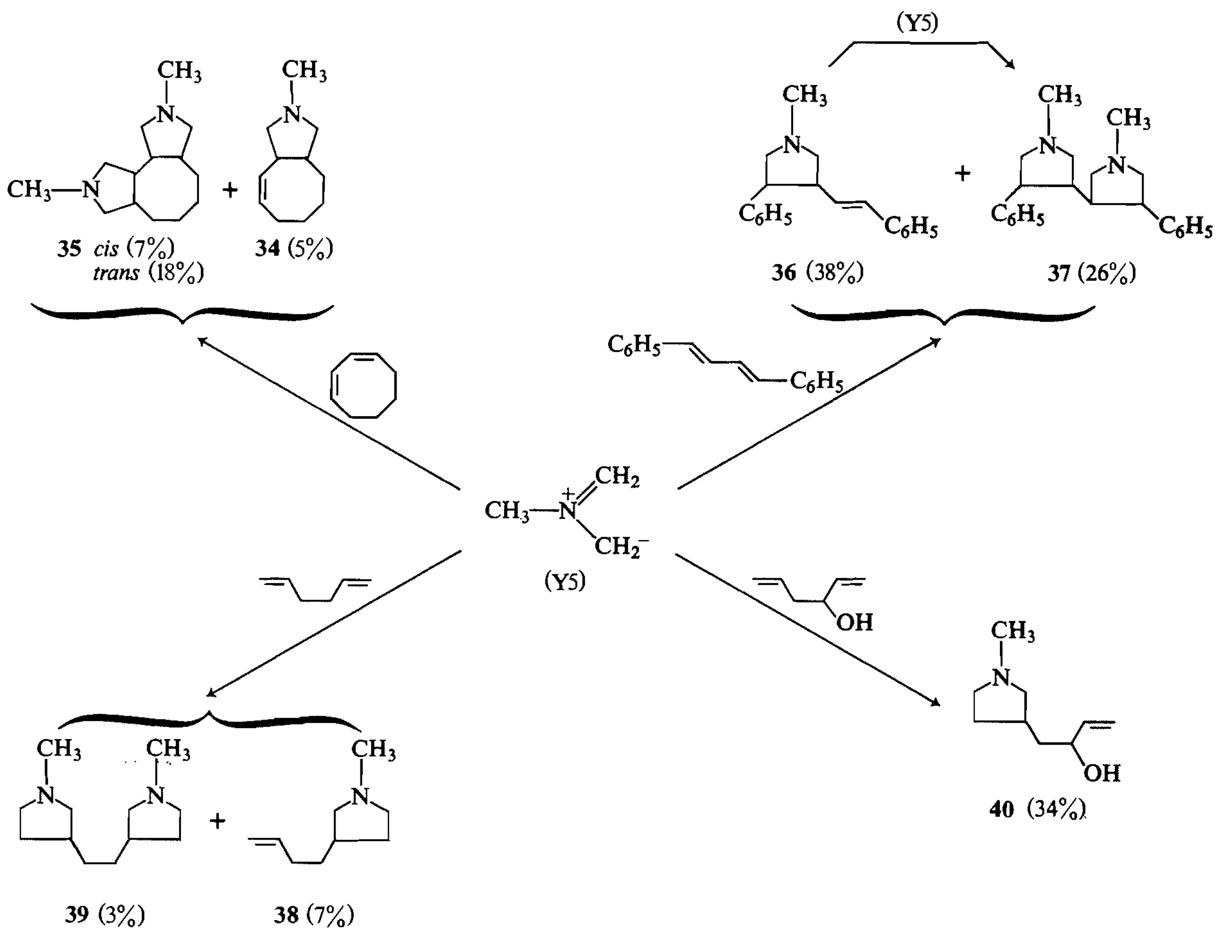

SCHÉMA 9. Réactivité de (Y5) vis-à-vis de diènes.

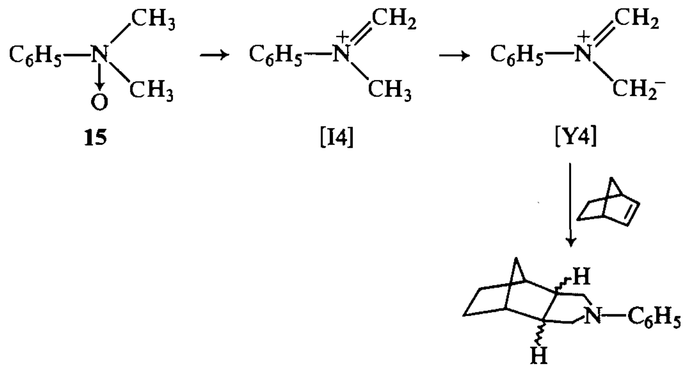
conducteur pour développer de nouvelles applications synthétiques. En ce qui concerne celles-ci notre méthode de synthèse de pyrrolidines substituées en 3 ou disubstituées en 3 et 4 complète de manière appréciable les méthodes connues fondées sur diverses réactions (18, 19) et particulièrement sur la cycloaddition (3 + 2) d'ylures d'azométhines stabilisés (12, 20, 21), masqués (22) ou diversement protégés (23, 24) avec des oléfines qui dans tous les cas sont activées (25).

Partie expérimentale

L'analyse des mélanges réactionnels et la séparation des composés ont été effectuées par chromatographie: en phase liquide sur colonne d'alumine alcaline (AA), de Florisil 60 Mesh (F), ou de gel de silice (S); sur couche mince de gel de silice Merck HF 254 + 366 neutre ou alcaline (ccm). Les proportions des solvants d'élution ont été exprimées en volume; en phase gazeuse (cpg) à l'aide d'un chromatographe Girdel série 300. Les analyses et dosages ont été réalisés sur une



41

SCHÉMA 10

colonne A: OVI 5% (phényl méthyl-silicone 300 × 0,3); B: OVI 10% (300 × 0,3); C: Pennwalt 323 (28%, KOH 4%, 300 × 0,3); D: SE30 QFI 8% (300 × 0,3) ou E: Craig−Polyester 20% (300 × 0,3). L'identification par cpg des produits obtenus a été effectuée par comparaison de leur temps de rétention (tr) avec ceux des produits de référence.

Les spectres infra-rouge (ir) ont été enregistrés sur un appareil Perkin−Elmer 297, en utilisant le chloroforme comme solvant. Les spectres ultra-violet (uv) ont été réalisés en solution dans le méthanol, à l'aide d'un spectromètre Jobin−Yvon. Les spectres de résonance magnétique nucléaire du proton (rmn) ont été enregistrés sur un appareil Perkin−Elmer R12 à 60 MHz ou Bruker WM400 à 400 MHz. Le chloroforme deutérié a été utilisé comme solvant et le TMS comme référence interne. Les spectres de masse (ms) ont été enregistrés sur un spectromètre AEI, MS 50 our sur un appareil couplé avec un chromatographe gc/ms Hewlett Packard 5992A. Les points de fusion (*F*) des composés cristallisés ont été mesurés au banc Kofler ou sur un appareil Büchi.

Les organolithiens utilisés (*n*-BuLi dans l'hexane, PhLi dans l'éther ou *t*-BuLi dans le pentane) sont des préparations commerciales qui ont été titrées avant emploi par une solution 1 *M* d'isobutanol dans le toluène en présence de phénantroline-1,10. Le tétrahydrofuranne (THF) employé a été traité par passage sur colonne d'alumine alcaline puis distillé sur sodium en présence de benzophénone, avant chaque usage.

Toutes les oléfines et les diènes sont des produits commerciaux ainsi que le *N*-oxyde de triméthylamine qui a été utilisé soit après séchage prolongé sous un vide poussé, soit après sublimation.

Préparation des N-*oxydes*

N-*oxyde de diméthylbenzylamine 1*

La diméthylbenzylamine commerciale (10 g, 66 mmol) dissoute dans le méthanol distillé (60 mL) est traitée pendant une nuit par 110 mL d'eau oxygénée à 110 volumes, selon la méthode de Cope et Towle (26). L'excès d'eau oxygénée est détruit par du palladium sur charbon activé à 10%. Un séchage poussé à 60°C sous 10^{-2} Torr (1 Torr = 133.3 Pa) livre le *N*-oxyde **1** (9,8 g, 65 mmol), Rdt = 98%; *F* = 62°C (acétate d'éthyle) (litt. (26) *F* = 64,5°−67°C); *F* picrate = 162°C (litt. (26) *F* = 158−160°C); ir ν_{N-O}: 975 cm^{-1}; rmn: 3,1 (s, 6H), 4.4 (s, 2H), 7,4−7,6 (m, 5H).

N-*oxyde de dibenzylméthylamine 5*

L'oxydation de la dibenzylméthylamine (10 g, 44 mmol) dans les conditions décrites ci-dessus, conduit après séchage prolongé à 8 g (35,2 mmol, 75%) de *N*-oxyde **5**; *F* = 150°C (acétate d'éthyle) (litt. (26) *F* = 150°C).

N-*oxyde de tribenzylamine 10*

L'oxydation de la tribenzylamine (10 g, 35 mmol) en solution dans 30 mL de chloroforme par l'acide *m*-chloroperbenzoïque (12 g, 69 mmol) conduit après purification sur colonne AA ($CHCl_3$−MeOH 3:1) à 10,3 g (33,9 mmol, 97%) de *N*-oxyde **10**; *F* = 138°C (hexane−acétone) (litt. (27) *F* = 133°C).

N-*oxyde de diméthylaniline 15*

L'oxydation par l'eau oxygénée de la diméthylaniline commerciale (3 g, 24,7 mmol) conduit à 1,5 g (11 mmol, 44%) de *N*-oxyde **15**; *F* = 150°C (méthanol) (litt. (27) *F* = 150°C).

N-*oxyde de diméthylmésidine 21*

La diméthylmésidine (2,89 g, 17,73 mmol) préparée par méthylation de la mésidine par le sulfate de méthyle (28), et oxydée par l'acide *m*-chloroperbenzoïque (2,93 g, 18,7 mmol), conduit après chromatographie sur colonne AA au *N*-oxyde **21** (364 mg, 2,01 mmol), Rdt = 11%, amorphe; rmn: 2,2 (s, 3H), 2,7 (s, 6H), 3,7 (s, 6H), 6,9 (s, 2H).

Action du DAL sur les N-*oxydes benzyliques à −78°C* et *à 0°C*

Expérience type

Toutes les réactions sont effectuées sous azote. Le DAL (3,5 mmol) en solution dans le THF est ajouté à l'aide d'une seringue, à 1 mmol de *N*-oxyde en suspension dans 25 mL de THF à −78°C. L'évolution de la réaction est suivie par des prélèvements analysés en ccm ($MeOH/CH_2Cl_2$ 1:99). Après disparition du produit de départ (environ 4 h) l'hydrolyse et l'extraction (CH_2Cl_2) conduisent à un mélange qui est séparé par chromatographie sur colonne.

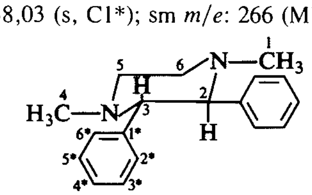
A 0°C les conditions expérimentales sont identiques à celles décrites dans le cas de réactions effectuées à −78°C, seuls les rapports des concentrations *N*-oxyde/base changent (1:3, 5 à −78°C; 1:1,2 à 0°C).

Action du DAL sur le N-*oxyde de diméthylbenzylamine 1*

(a) *Expérience n° 1 (−78°C)*

Le *N*-oxyde **1** (306 mg, 2,02 mmol) traité dans les conditions décrites ci-dessus, par le DAL (13,5 mmol) donne 310 mg de produit brut qui est chromatographié sur colonne AA. L'élution (pentane) livre des traces de benzaldéhyde identifié par cpg et par ccm analytique. L'élution (pentane/chlorure de méthylène: 90:10) livre un mélange de pipérazines-2,3 diphényl *N*,*N*-diméthyl *cis* (**4***c*) et *trans* (**4***t*) dont l'analyse par cpg sur colonne A indique un rapport **4***c*/**4***t* = 2,4 (tr **4***t* = 20 min; **4***c* = 28 min à 195°C sous 1,1 atm) (1 atm = 101,3 kPa). La cpg préparative sur colonne E permet d'obtenir **4***t* (25 mg) et **4***c* (60 mg), identifiés à des échantillons authentiques.

Pipérazine **4** *trans*: *F* = 263°C (cyclohexane) (litt. (29) *F* = 263−264°C); rmn: 2 (s, 6H), 2,5−3,1 (système AA'BB', 4H), 2,82 (s, 2H), 7−7,5 (m, 10H arom); ^{13}C: 43,54 (*c*, C1 et C4), 54,78 (t, C5 et C6), 75,06 (d, C2 et C3), 128,16 (d, C3*, C4* et C5*), 130,69 (d, C2* et C6*), 138,03 (s, C1*); sm *m*/*e*: 266 (M^+), 146, 118.



Pipérazine **4** *cis*: *F* = 90°C (cyclohexane) (non décrit dans la litt.); rmn: 2,1 (s, 6H), 2,5−3,2 (système AA'BB', 4H), 3,7 (s, 2H), 6,9−7,5 (m, 10H, arom); ^{13}C: 43,54 (q, C1 et C4), 52,85 (t, C5 et C6), 71,81 (d, C2 et C3), 127,12 (d, C4*), 127,4 (d, C3* et C5*), 130,6 (d, C2* et C6*), 136,9 (s, C1*); sm: identique à **4** *trans*.

*Synthèse de 4*c *et 4*b

*Synthèse de la diphényl-2,3 dihydro-5,6 pyrazine (*a*)*

Le benzil (10 g, 47 mmol) est mis à réagir avec de l'éthylènediamine (2,8 g , 47 mmol) dans 250 mL d'éthanol distillé. Une recristallisation dans l'éthanol livre *a* (9 g, 38 mmol), Rdt = 81%; *F* = 161°C (litt. (29) *F* = 161°C); rmn: 3,7 (s, 4H), 7,2−7,7 (m, 10H arom).

*Obtention des diphényl-2,3 pipérazines (*b cis *et* b trans*)*

Le traitement de *a* (3,5 g, 15 mmol) par le sodium (7 g, 300 mmol) dans l'éthanol à reflux livre, après une première extraction des eaux mères en milieu alcalin, le composé *b* (3 g, 13 mmol) sous forme de mélange d'isomères *b cis* et *b trans* (Rdt = 85%), séparés par cristallisation des tartrates dont l'extraction en milieu alcalin conduit à *b trans* (1 g, 4,2 mmol) et *b cis* (1,8 g, 7,6 mmol).

Composé *b trans*: *F* = 123°C (litt. (30) *F* = 123−124°C); rmn:

3,15 (s, 4H), 3,75 (s, 2H), 7,15 (s large, 10H arom).

Composé *b cis*: F = 112°C (litt. (30) F = 108–109°C); rmn: 2,7–3,5 (système $A_2A'_2$, 4H), 4,3 (s, 2H), 7–7,6 (m, 10H arom).

Un autre mode de réduction de *a* par l'hydrure de lithium et d'aluminium dans l'éther anhydre, permet d'obtenir *b cis* et *b trans* avec un rendement de 37%.

Méthylation de b cis *et* b trans

L'action d'un excès d'iodure de méthyle distillé sur *b trans* (0,5 g, 2,2 mmol) dans l'éthanol à chaud livre **4** *trans* (0,55 g, 2 mmol), Rdt = 97%, cristallisant après chromatographie sur colonne F (élution: éther/pentane, 50:50 jusqu'à 70:30). Un traitement analogue livre **4** *cis* (0,47 g, 1,7 mmol), Rdt = 84%, à partir de *b cis* (0,5 g, 2,2 mmol). Ces produits sont identiques (ir, rmn) à ceux issus de la réaction du *N*-oxyde **1**.

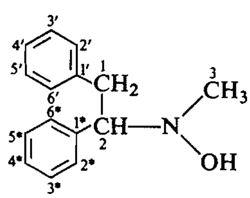
(b) *Expérience n° 2 (0°C)*

Le *N*-oxyde **1** (906 mg, 6 mmol) traité par le DAL (7,2 mmol) livre après chromatographie sur colonne S (élution: chlorure de méthylène/hexane, 5:95): (*i*) les pipérazines **4***c* et **4***t* (530 mg, 1,99 mmol), Rdt = 66%, *c*/*t* = 1,4; (*ii*) le benzaldéhyde **2** (60 mg, 0,56 mmol), Rdt = 9%; (*iii*) le *N*-oxyde **1** (élution: méthanol/chlorure de méthylène, 3:97) (35 mg) contenant de la benzylméthylamine **3**.

Action du DAL sur le N-*oxyde de dibenzylméthylamine* **5**

(a) *Expérience n° 3 (−78°C)*

Le *N*-oxyde **5** (908 mg, 4 mmol) traité par le DAL (14 mmol) livre après chromatographie sur colonne S: (*i*) la pipérazine **8** (229 mg, 0,55 mmol), éluée par CH_2Cl_2/hexane, 5:95), Rdt = 27%, F = 185°C (CH_2Cl_2/hexane); rmn (400 MHz): 2,3 (d, 2H, J = 8 Hz) 2,7–2,9 (d, 2H, J = 8 Hz et d, 2H, J = 14 Hz), 3,35 (s, 2H), 3,6–3,8 (d, 2H, J = 14 Hz), 7–7,3 (m, 20H arom); sm m/e: 417 ($M^+ - 1$), 327, 210; sm (ionisation chimique): 419 $(M + 1)^+$. (*ii*) Le composé **8**, non décrit dans la littérature, est identique (ir, rmn) à un échantillon de référence préparé par le traitement de *b trans* avec le



bromure de benzyle. (*iii*) L'hydroxylamine **7** (250 mg, 1,1 mmol, éluée par MeOH/CH_2Cl_2, 1:99), F = 104–105°C (éther), Rdt = 27%; ir ν_{OH}: 3580 cm^{-1}; rmn (400 MHz): 2,5 (s, 3H), 3 (2d, 1H, J = 1 Hz), 3,4–3,8 (2H), 6,7–7,3 (m, 10H arom); ^{13}C: 40,358 (t, C1), 46,40 (q, C3), 76,62 (d, C2), 125,8 (d, C4), 127,5 (d, C4), 127,9 (d, C3C5*), 128,2 (d, C5*C3*), 128,7 (d, C2'C6'), 129,4 (d, C2*C6*), 138,6 (s, C1'), 139,4 (s, C1*); sm m/e: 226 ($M^+ - 1$), 181, 136, 118. *Anal.* calc. pour $C_{15}H_{17}NO$: C 79,20, H 7,48, N 6,16, O 7,04; tr: C 79,18, H 7,52, N 5,90, O 7,45%.

(b) *Expérience n° 4 (0°C)*

Le *N*-oxyde **5** (908 mg, 4 mmol) traité par le DAL (4,8 mmol) livre après chromatographie sur colonne F: (*i*) le benzaldéhyde **2** (30 mg, 0,28 mmol), Rdt = 7% (élution: CH_2Cl_2/hexane, 30:70); (*ii*) la pipérazine **8** (260 mg, 0,62 mmol), Rdt = 31%, (élution: CH_2Cl_2/hexane, 30:70); (*iii*) l'aziridine **9** (23 mg, 0,12 mmol), Rdt = 3% (élution: CH_2/Cl_2 30:70); rmn: 2,7 (3H, s), 2,8 (2H, s), 7,15 (10H, s élargi); M^+ 209, m/e 194; (*iv*) l'hydroxylamine **7** (250 mg, 1,1 mmol), Rdt = 27% (élution: CH_2Cl_2/hexane, 50:50); (*v*) la méthylbenzylamine **6** (30 mg, 0,24 mmol), Rdt = 6% (élution: CH_2Cl_2); (*vi*) le *N*-oxyde **5** (90 mg, 0,4 mmol), Rdt = 10% (élution: CH_2Cl_2/MeOH 90:10).

Action du DAL sur le N-*oxyde de tribenzylamine* **10**

(a) *Expérience n° 5 (−78°C)*

Le *N*-oxyde **10** (909 mg, 3 mmol), traité par le DAL (10,5 mmol) livre après chromatographie sur colonne S: (*i*) l'hydroxylamine **13** (430 mg, 1,42 mmol), Rdt = 47% (élution: CH_2Cl_2/hexane, 50:50); F = 115°C (CH_2Cl_2/hexane); ir: 3580 cm^{-1} (OH); rmn (400 MHz): 3 (2d, 1H, J = 7 Hz), 3,6 (2d, 2H, J = 7 Hz; 1d, J = 13 Hz), 3,8 (d, 1H, J = 13 Hz), 3,9 (2d, 1H, J = 7 Hz), 6,9–7,4 (m, 10H); sm m/e: 304 ($M^+ - 1$), 196, 122, 106. *Anal.* calc. pour $C_{21}H_{21}NO$: C 83,13, H 6,98, N 4,62, O 5,27; tr.: C 82,98, H 6,90, N 4,83, O 5,21%; (*ii*) la dibenzylamine **12** (109 mg, 0,86 mmol), Rdt = 29% (élution: CH_2Cl_2/hexane, 30:70); (*iii*) le *N*-oxyde **10** (60 mg, 0,2 mmol), Rdt = 6% (élution: CH_2Cl_2/MeOH, 90:10).

(b) *Expérience n° 6 (0°C)*

Le *N*-oxyde **10** (900 mg, 3 mmol) traité par le DAL (3,6 mmol) livre après chromatographie sur colonne S: (*i*) l'aziridine **14** (350 mg, 1,22 mmol), Rdt = 42% (élution: CH_2Cl_2/hexane, 40:60); rmn identique à celle décrite (5). (*ii*) l'hydroxylamine **13** (175 mg, 0,58 mmol), Rdt = 20% (élution: CH_2Cl_2/hexane, 50:50); (*iii*) la dibenzylamine **12** (75 mg, 0,38 mmol), Rdt = 12% (élution: CH_2Cl_2/MeOH, 99:1); (*iv*) le *N*-oxyde **10** (45 mg, 0,15 mmol), Rdt = 5% (élution: CH_2Cl_2/MeOH, 90:10).

Action du t-*BuLi sur le* N-*oxyde de diméthylaniline*

Expérience n° 7

Le *N*-oxyde **15** (1,25 g, 9 mmol) traité par le *t*-BuLi (30 mmol) en solution dans le THF livre un mélange (0,600 g), analysé par cpg (colonne A, t = 100°C). Trois composés **17**, **18** et **16** dans le rapport 7,2:1,7:1 sont identifiés et la cpg préparative permet d'obtenir des échantillons pour la spectroscopie de masse. *N*-méthyl aniline **16**: (cpg: (tr) = 11 min), sm m/e: 107 (M$^+$). *N*-phénylpyrrolidine **18**: (cpg: (tr) = 7 min), sm m/e: 147 (M$^+$) 119, 104, identique à un échantillon de référence préparé selon la littérature (31). *N*-méthyl *N*-isopentyl aniline **17**: (cpg: (tr) = 4,8 min) sm m/e: 177 (M$^+$) 162, 120.

Réaction de **15** *en présence d'éthylène*

Expérience n° 8

De l'éthylène est mis à barboter à −78°C dans une solution de **15** (400 mg, 2,9 mmol) dans le THF. Le traitement par le *t*-BuLi (3,9 mL, 6 mmol) conduit à un mélange (0,2 g) analysé par comparaison (cpg, colonne A, t four = 170°C) à un essai témoin ne contenant pas d'éthylène. Les calculs à partir des chromatogrammes montrent que la quantité de **18** est doublée par rapport à l'expérience n° 7.

Réaction de **15** *en présence d'hexène-1*

Expérience n° 9

De l'hexène-1 (500 mg, 6 mmol) est ajouté à **15** (400 mg, 2,9 mmol) en solution dans le THF à −78°C. Le tout est traité par du *n*-BuLi (4,5 mL, 7,3 mmol) puis hydrolysé à basse température. Une première extraction (chlorure de méthylène) suivie d'une deuxième extraction (butanol) livre 0,26 g d'un mélange chromatographié sur colonne AA. L'élution (pentane/éther, 50:50) conduit à la *N*-méthyl *N*-pentyl aniline **19**, Rdt = 10% (cpg); sm m/e: 177 (M$^+$), 120, (M^+ − 57, C_4H_9), 106; l'élution par l'éther conduit à la *N*-phényl butyl-3 pyrrolidine **20**, Rdt = 18% (cpg); rmn: 0,8–1,6 (m, 9H), 1,9–2,4 (m, 2H), 2,6–3 (m, 1H), 3,1–3,6 (m, 4H), 6,5–7 (m, 3H arom), 7–7.5 (m, 2H arom); sm m/e: 203 (M$^+$), 119, 104.

Action du t-*BuLi sur* **21**

Expérience n° 10

Le *N*-oxyde de diméthylmésidine **21** (181 mg, 1,52 mmol) en solution dans 25 mL de THF traité à −78°C par 4 mmol de *t*-BuLi pendant 30 min livre après chromatographie (colonne S) la pipérazine **22** (54 mg, 0,17 mmol), Rdt = 22%, F = 190–191°C (EtOH) (litt. (32) F = 190–191°C).

Action du DAL sur le N-*oxyde de triméthylamine* **23**

Expérience n° 11

Le *N*-oxyde **23** (345 mg, 4,6 mmol) traité par le DAL (16 mmol) à −78°C, conduit après hydrolyse et extraction au CH_2Cl_2 à un mélange brut (72 mg) qui, sous l'action d'une solution alcoolique saturée d'acide picrique, donne le dipicrate de diméthylpipérazine **24** (86 mg, 0,26 mmol), Rdt = 12%, F = 277°C (EtOH). Une solution aqueuse de soude 10% libère la pipérazine **23** identique (cpg, rmn) au produit commercial.

Méthyl-1 phényl-3 pyrrolidine ***25***

Expérience n° 12

Le *N*-oxyde de triméthylamine **23** (91 mg, 1,21 mmol) et du styrène (138 mg, 1,33 mmol) en solution dans 25 mL de THF traité à −78°C par le DAL (4,2 mmol), conduit à la pyrrolidine **25** (111 mg, 0,60 mmol), Rdt = 50%. Picrate: *F* = 158−160°C (EtOH) (litt. (33) *F* = 155−158°C).

Méthyl-1 diphényl-3,4 pyrrolidine cis ***26***

Le *N*-oxyde de triméthylamine **23** (85 mg, 1,13 mmol) et le *cis* stilbène (211 mg, 1,17 mmol) en solution dans 25 mL de THF traité à −78°C par le DAL (3,9 mmol) livre la pyrrolidine **26** (165 mg, 0,70 mmol), Rdt = 62%; *F* = 67−69°C (EtOH); rmn: 2,55 (s, 3H), 2,93−3,33 (m, 4H), 2,73−4,0 (m, 2H), 7,1 (s élargi, 10H); sm *m/e*: 237 (M^+), 180, 57. *Anal.* calc. pour $C_{17}H_{19}N$: C 86,00, H 8,07, N 5,93; tr.: C 85,86, H 8,08, N 5,94%.

Méthyl-1 diphényl-3,4 pyrrolidine trans ***27***

Le *N*-oxyde de triméthylamine **23** (106 mg, 1,42 mmol) et le *trans* stilbène (295 mg, 1,55 mmol) en solution dans 25 mL de THF traité à −78°C par le DAL (4,9 mmol), livre la pyrrolidine **27** (241 mg, 1,01 mmol), Rdt = 72%; rmn: 2,45 (s, 3H), 2,7−3,8 (m, 6H), 7,2 (s élargi, 10H). sm *m/e*: 237 (M^+), 180, 57. Picrate: *F* = 186−187°C (EtOH). *Anal.* calc. pour $C_{23}H_{22}N_4O_8$: C 59,22, H 4,75, N 12,02, O 24,01; tr.: C 58,97, H 4,72, N 12,00, O 23,73%.

Méthyl-3 aza-3 bicyclo[3.3.0]octane ***28***

Le *N*-oxyde de triméthylamine **23** (92 mg, 1,23 mmol) et du cyclopentène (92 mg, 1,35 mmol) en solution dans 25 mL de THF traité à −78°C par le DAL (4,4 mmol) conduit à la pyrrolidine **28** (34) (65 mg, 0,52 mmol), Rdt = 42%; rmn: 1,3−1,8 (m, 6H), 1,8−2,3 (m, 2H), 2,3 (s, 3H), 2,4−2,9 (m, 4H); sm *m/e*: 237 (M^+). Picrate: *F* = 203−205°C (EtOH).

Méthyl-3 aza-3 bicyclo[5.3.0]décane ***29***

Le *N*-oxyde de triméthylamine **23** (161 mg, 2,14 mmol) et du cycloheptène (235 mg, 2,35 mmol) en solution dans 25 mL de THF traité à −78°C par le DAL (5,5 mmol) conduit à la pyrrolidine **31** (201 mg, 1,31 mmol), Rdt = 61%; rmn: 1−2 (m, 12H), 2−2,6 (m + 1s, 5H), 2,6−3 (m, 2H); sm *m/e*: 153 (M^+), 57. Picrate: *F* = 238−240°C (EtOH). *Anal.* calc. pour $C_{16}H_{22}N_4O_7$: C 50,25, H 5,80, N 14,66, O 29,29; tr.: C 50,37, H 5,87, N 14,64, O 29,32%.

Méthyl-3 bicyclo[6.3.0]undécane ***30***

Le *N*-oxyde de triméthylamine **23** (80 mg, 1,06 mmol) et du cyclooctène (129 mg, 1,16 mmol) en solution dans 25 mL de THF traité à −78°C par le DAL (4,2 mmol) livre la pyrrolidine **30** (159 mg, 0,95 mmol), Rdt = 90%; rmn: 1−1,2 (m, 14H), 1,9−2,4 (m, 3H), 2,25 (s, 3H), 2,8−3,2 (m, 2H); sm *m/e*: 167 (M^+), 57. Picrate: *F* = 218−219°C (EtOH); *Anal.* calc. pour $C_{17}H_{24}N_4O_7$: C 51,51, H 6,10, N 14,14, O 28,25; tr.: C 51,44, H 6,09, N 13,96, O 28,14%.

Méthyl-1 méthanol-3 pyrrolidine ***31***

Le *N*-oxyde de triméthylamine **23** (115 mg, 1,52 mmol) et du propen-2 ol (192 mg, 1,67 mmol) en solution dans 25 mL de THF traité à −78°C par le DAL (4,2 mmol) livre la pyrrolidine **31** (106 mg, 0,92 mmol), Rdt = 60%; rmn: 1−2 (m, 3H), 2−3 (m, 7H), 2,35 (s, 3H), 3,6 (d, 2H), 4,2 (s élargi, 1H); sm *m/e*: 115 (M^+), 57.

Méthyl-1 aza-1 (dioxolane-1,3)-4 bicyclo[3.3.0]heptane ***32***

Le *N*-oxyde de triméthylamine **23** (96 mg, 1,24 mmol) et du dioxolane de la cyclopenten-2 one (171 mg, 1,36 mmol) en solution dans 25 mL de THF traité à −78°C par le DAL (4,3 mmol) livre la pyrrolidine **32** (152 mg, 0,83 mmol), Rdt = 67%; rmn: 1,4−2,3 (m, 6H), 2,3 (s, 3H), 2,4−3 (m, 4H), 3,9 (s, 4H); sm *m/e*: 183 (M^+), 99, 57. Picrate: *F* = 171−172°C (EtOH). *Anal.* calc. pour $C_{16}H_{20}N_4O_9$: C 46,60, H 4,89, N 13,59, O 34,92; tr.: C 46,10, H 4,86, N 13,43, O 34,27%.

Diméthyl-3,8 diaza-3,8 bicyclo[4.3.0]nonane ***33***

Le *N*-oxyde de triméthylamine **23** (281 mg, 3,75 mmol) et de la méthyl-1 tétrahydro-1,2,3,6 pyridine (400 mg, 4,12 mmol) en solution dans 25 mL de THF traité à −78°C par le DAL (13 mmol) livre un mélange de produits (209 mg) dont le spectre de masse indique qu'il est constitué de diméthylpipérazine **24** (M^+ 114) et de pyrrolidine **33** (M^+ 154).

Méthyl-1 aza-1 bicyclo[6.3.0.(3.10)]undecene-4 ***34*** *et diméthyl-1,6 diaza-1,6 tricyclo[4.3.0.(3.10)(4.8)]tétradecène* cis ***35***c *et* trans ***35***t

Le *N*-oxyde de triméthylamine **23** (415 mg, 5,53 mmol) et du cyclooctadiène-1,3 (330 mg, 3,06 mmol) en solution dans 50 mL de THF traité à −78°C par le DAL (19 mmol) livre un mélange dont la chromatographie sur colonne donne la pyrrolidine instable **34** (46 mg, 0,27 mmol), Rdt = 5%, la dipyrrolidine *cis* **35***c* (40 mg, 0,18 mmol), Rdt = 7%, et la dipyrrolidine *trans* **35***t* (108 mg, 0,48 mmol), Rdt = 18%, séparées sous forme de picrates:

34 (46 mg, 0,27 mmol) instable, Rdt = 5%; sm *m/e*: 165 (M^+), 57.

35*c* (40 mg, 0,18 mmol), Rdt = 7%; rmn: 1−1,8 (m, 8H), 1,8−2,7 (m, 8H), 2,45 (s, 6H), 2,7−3,5 (m, 4H); sm *m/e*: 222 (M^+), 57. Dipicrate: *F* = 178−180°C (EtOH).

35*t* (106 mg, 0,48 mmol), Rdt = 18%; rmn: 1−1,7 (m, 8H), 1,7−2,7 (m, 8H), 2,3 (s, 6H), 2,7−3,5 (m, 4H); sm *m/e*: 222 (M^+), 57. Dipicrate: *F* = 108−110°C (EtOH). *Anal.* calc. pour $C_{26}H_{32}N_8O_{14}$: C 45,88, H 4,74, N 16,46, O 32,91; tr.: C 45,71, H 4,76, N 16,28, O 32,84%.

Méthyl-1 phényl-3 (phényl-2′ ethene-1′yl)−4 pyrrolidine ***36*** *et bis-(méthyl-1 phényl-3 pyrolidine)-4,4* ***37***

Le *N*-oxyde de triméthylamine **23** (243 mg, 3,34 mmol) et du 1,4-diphényl-1,3-butadiène (350 mg, 1,7 mmol) en solution dans 50 mL de THF traité à −78°C par le DAL (11 mmol) conduit à un mélange dont la chromatographie sur colonne AA permet de séparer:

36 (327 mg, 1,22 mmol), Rdt = 38%; uv λ_{max}: 257 nm (ϵ = 20 200), 285 nm (ϵ = 800), 294 nm (ϵ = 400); rmn: 2,4 (s, 3H), 2,5−3,2 (m, 6H), 6,3 (s élargi, 1H); 7,35 (s élargi, 11H); sm *m/e*: 263 (M^+), 57. Picrate: *F* = 130−131°C (EtOH). *Anal.* calc. pour $C_{25}H_{24}N_4O_7$: C 60,97, H 4,91, N 11,38, O 22,74; tr.: C 60.73, H 4,80, N 11,60, O 22,66%.

37 (131 mg, 0,43 mmol), Rdt = 26%; rmn: 2,1−3,2 (m, 9H), 2,4 (s, 3H), 7,25 (s élargi, 10H); sm *m/e*: 320 (M^+). Dipicrate: *F* = 240−242°C (EtOH). *Anal.* calc. pour $C_{34}H_{44}N_8O_{14}$: C 52,44, H 4,40, N 14,39, O 28,77; tr.: C 52,65, H 4,59, N 14,33, O 28,52%.

Traité par un excès de *N*-oxyde de triméthylamine **23**, la pyrrolidine **36** a conduit, quantitativement, en présence de DAL, au composé disubstitué **37**.

Méthyl-1(butène-2′yl)-3 pyrrolidine ***38*** *et bis(méthyl-1 pyrrolidine)-3 éthane-1,2* ***39***

Le *N*-oxyde de triméthylamine **23** (216 mg, 2,88 mmol) et l'hexadiène-1,5 (131 mg, 1,60 mmol) en solution dans 50 mL de THF traité à −78°C par le DAL (10,1 mmol) conduit, après chromatographie (AA) à:

38 (28 mg, 0,20 mmol), Rdt = 7%; sm *m/e*: 139 (M^+), 57.

39 (18 mg, 0,09 mmol), Rdt = 3%; rmn: 0,9−1,5 (m, 8H), 1,5−3 (m, 10H), 2,3 (s, 6H); sm *m/e*: 196 (M^+), 57.

Méthyl-1(butène-2′ yl ol-1′)-3 pyrrolidine ***40***

Le *N*-oxyde de triméthylamine **23** (245 mg, 3,26 mmol) et l'hexadiène-1,5 ol-3 (176 mg, 1,79 mmol) traités à −78°C par le DAL (16,4 mmol) conduisent à la pyrrolidine **40** (170 mg, 1,09 mmol), Rdt = 34%; ir: 3350, 1625, 920 cm^{-1}; rmn: 1−2 (m, 4H), 2−3 (m, 5H), 2,35 (s, 3H), 3,2−3,7 (m, 1H), 4,5−6,2 (m, 3H); sm *m/e*: 155 (M^+), 57.

N-*phényl-perhydro méthanoisoindole* ***41***

Le *N*-oxyde de diméthylaniline **15** (274 mg, 2 mmol) et du norbornène (198 mg, 2 mmol) en solution dans 25 mL de THF traité à −78°C par le DAL (4 mmol) pendant 30 min, conduit après chromatographie (ccm) à la pyrrolidine **41** (29 mg, 0,13 mmol), Rdt = 7%; rmn: 1−1,18 (m, 6H), 1,8−2,5 (m, 4H), 2,6−3,1 (m, 2H), 3,1−3,7 (m, 2H), 6,2−6,8 (m, 3H), 6,8−7,5 (m, 2H); sm *m/e*: 213 (M^+), 119.

The Diels–Alder reaction of 4-methoxy-7-hydroxyisobenzofuran with methyl vinyl ketone; a general method for identification of some regioisomeric α-naphthols

B. A. KEAY AND R. RODRIGO[1]

Guelph–Waterloo Centre for Graduate Work in Chemistry, Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received June 25, 1984

B. A. KEAY and R. RODRIGO. Can. J. Chem. **63**, 735 (1985).

Two regioisomeric α-naphthols **14** and **15** obtained by aromatization of the methyl vinyl ketone adducts of an unsymmetrical isobenzofuran **9** are differentiated from each other by the observation of significant upfield shifts of the *peri* proton resonances in the ^{1}H nmr spectra of their acetates **16** and **17**. Such upfield shifts of 0.3–0.6 ppm appear to be a general phenomenon and are probably due to the anisotropic effect of the acetate carbonyl group.

B. A. KEAY et R. RODRIGO. Can. J. Chem. **63**, 735 (1985).

L'aromatisation des produits de la réaction de la méthylvinylcétone avec l'isobenzofuranne non-symétrique **9** conduit aux deux α-naphtols régioisomères **14** et **15**. On peut les différencier en faisant appel à la rmn du^{1}H et aux glissements marqués vers les champs forts des résonances des protons *péri* de leurs acétates **16** et **17**. Il semble que de tels glissements de 0,3 à 0,6 ppm constituent un phénomène général et ils sont probablement dus à l'effet anisotropique du groupement carbonyle de l'acétate.

[Traduit par le journal]

In a recent publication (1) we described a short synthesis of the AB segment of daunomycinone **1** and its use in a convergent route to this anticancer antibiotic aglycone (for recent reviews, see ref. 2). Diels–Alder reaction of 4,7-dimethoxyisobenzofuran **2** (generated *in situ* (3) from the lactol **3**) with methyl vinyl ketone (MVK) provided adduct **4** which suffered reverse-Michael cleavage (4) to the enone **5**. The latter, suitably modified, was attached to the CD segment in a regiocontrolled annelation and eventually elaborated into the aglycone **1**.

In recent years a group of "second generation" anthracyclinones with reduced cardiotoxicity have been recognized. Prominent among these are aklavinone (2, 5) and some 11-deoxy analogues (2, 6) (e.g. **6**) both of which lack the C-11 hydroxyl group and thus pose an additional regiochemical challenge to the synthetic chemist attempting to assemble these molecules from constituent fragments. To adapt our procedure to a synthesis of the AB half of such compounds it is necessary to differentiate the substituents at C-4 and C-7 of **2** and to control the regiochemistry of the Diels–Alder reaction of the unsymmetrical isobenzofuran thereby resulting.

Since the phthalide **7** was available for our earlier work (1), exploratory experiments were begun with this compound. Reduction of the carbonyl group with DIBAL-H provided the lactol **8** (70% average yield) and Diels–Alder reaction of the unsymmetrical isobenzofuran **9** with MVK a mixture of regioisomeric adducts **10** and **11** in a 3.5:1 proportion by ^{1}H nmr estimation (55% total). Although some of the major isomer crystallized out from this mixture it was more convenient to subject the mixture to reverse-Michael cleavage (90%) and separate the enones **12** (major) and **13** (minor) by column chromatography. These were isolated in the same ratio and individually dehydrated with dilute hydrochloric acid to naphthols **14** and **15** respectively, whose structures must now be unambiguously assigned. This paper describes a simple, general ^{1}H nmr method for the differentiation of isomeric α-naphthols like **14** and **15**.

The spectra of **14** and **15** were very similar and unexceptional. In both compounds H-1 was a doublet, *meta* cou-

pled to H-3 ($J_{1,3}$ = 1.70 and 1.76 Hz) at 8.82 ppm. Slight *para* coupling ($J_{1,4}$ = 0.71 Hz) was observed in one isomer. A well-separated AB quartet (J_{AB} = 9 Hz) was present with H-3 at 8.0 ppm and H-4 at 8.26 ppm, assignments that are secured by the *meta*-coupling observed for H-3. Slight differences in the absorptions of H-6, H-7, methoxy, and acetyl signals in the two isomers were not of any diagnostic value. Acetylation provided the α-naphthyl acetates **16** and **17**, respectively, with consequent changes in the spectra. New three-proton singlets at 2.43 and 2.50 ppm and the expected downfield shifts of the aromatic proton *ortho* to the acetate (7) by ca. 0.3–0.4 ppm, in each case, signified the presence of the acetate moiety. The

[1]Author to whom correspondence may be addressed.

changes observed in the absorptions of H-1 and H-4 were of much greater significance to the problem at hand. In one acetate the *meta*-coupled doublet (H-1) was shifted *upfield* by 0.41 ppm (8.82→8.41) while in the other one-half of the AB quartet (H-3, H-4) shifted upfield again, this time by 0.32 ppm (8.26→7.94). Assignment of this signal to H-4 was supported by the lack of *meta*-coupling observed for the H-3 half of the AB quartet ($J_{1,3}$ = 1.46 Hz). Thus a tentative assignment of structure can be made as follows for the α-naphthols and their acetates: acetate **16** is that regioisomer in which the H-1 *meta*-coupled doublet (proton *peri* to the acetate) shifts upfield by 0.41 ppm in comparison to naphthol **14**, and acetate **17** is the other isomer in which H-4 (proton *peri* to the acetate) shifts upfield by 0.32 ppm in comparison to the parent naphthol **15**. Since naphthol **14** was obtained from the major isomer of the Diels–Alder adduct mixture this establishes the structure of adducts **10** (major) and **11** (major) and enones **12** (major) and **13** (minor) as shown. These conclusions received independent support from an X-ray structure determination[2] of the major crystalline adduct **10**.

These upfield acetylation shifts of the *peri*-proton of α-naphthols were investigated in five more examples to determine whether this was a general phenomenon. In the first instance, naphthol **18** obtained by aromatization of a known (3) Diels–Alder adduct was converted to its acetate **19**. Again, one of the aromatic singlets (at 7.19 and 7.67 ppm in **18**) was shifted upfield by 0.3 ppm (7.18 and 7.37 in **19**). The obvious question of whether this signal was due to H-1 or H-4 was answered by observation of a 20% nOe enhancement of the signal at 7.19 ppm of **18** when the C-5 methyl resonance at 2.39 ppm was irradiated. A group of aryl substituted α-naphthols (8) (**20**, **22**, **24**, and **26**) was examined next. In these compounds the two aromatic protons at C-1 and C-4 are easily differentiated because H-4, subjected to the shielding influence of

TABLE 1. Chemical shifts of *peri*-protons in α-naphthols and their acetates

Compound		*peri*-Proton, H-1 (δ) ppm		
α-Naphthol	Acetate	α-Naphthol	Acetate	Δδ (ppm)
14	**16**	8.82	8.41	−0.41
15	**17**	8.26	7.94	−0.32
18	**19**	7.67	7.37	−0.30
20	**21**	7.74	7.22	−0.52
22	**23**	7.74	7.21	−0.53
24	**25**	7.74	7.21	−0.53
26	**27**	7.74	7.16	−0.58

the pendant aryl ring (not coplanar with the naphthalene), always resonates at a higher field than H-1. Thus in all these naphthols H-1 appears as singlet at 7.74 ppm and H-4 at 6.81–6.89 ppm. Upon acetylation H-1 is observed to shift upfield by 0.52–0.58 ppm while H-4 is relatively unaffected. Thus in all seven examples we have studied, a substantial upfield shift of ca. 0.3–0.6 ppm is observed in the *peri*-proton of an α-naphthol upon acetylation (Table 1).

A recent X-ray structure (9) of the α-naphthyl diacetate **28** indicates that the O—C bond of the acetate is at an angle of 82.3° to the plane of the naphthalene ring with the carbonyl double bond directed back over the ring as shown in Fig. 1. This diagram, generated[3] from data reported in that paper, shows that in the crystal of **28** the *peri*-proton lies in the shielding zone of the acetate carbonyl group and is 2.45 Å distant from the carbonyl oxygen atom. Progressively greater shielding of the *peri*-proton in a series of 1-acyl 4-methoxy naphthalenes **29** was observed (10) as the size of the group R is increased (from hydrogen to *tert*-butyl) and the suggestion made that the increasing bulkiness of the substituent forces the

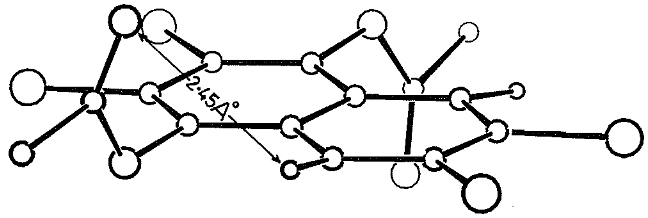

FIG. 1. The crystal structure of **28** (see footnote 3).

carbonyl group to adopt a conformation perpendicular to the plane of the naphthalene ring. This shielding effect is not confined to naphthalenes. It has been reported (11) that acetylation of the tetrahydroprotoberberine **30** causes unequal upfield shifts of the protons at C-8 of the resulting acetate **31**. The H-8 equatorial proton of this *trans*-quinolizidine (12) is shifted upfield by 0.2 ppm, while the H-8 axial proton is only slightly affected ($\Delta\delta = -0.06$ ppm) by acetylation. The inequality of the upfield shifts implies a dependence on geometry and supports the operation of an anisotropic effect. It has been convincingly demonstrated (13) that none of the simple theories of magnetic shielding provide acceptable quantitative predictions of the chemical shifts of all the protons in 1-substituted naphthalenes, but the qualitative trends described in this paper might be of value in the assignment of structures to some α-naphthols.

The 3.5:1 regioselectivity observed in the Diels–Alder reaction of **9** with MVK deserves a brief comment. Previous investigators have established that 1-substituted isobenzofurans show a preference for "*ortho*" addition with unsymmetrical dienophiles (4, 14) which depends neither on the nature of the substituent nor on the dienophile. No studies exist of the influence of substituents on the regiochemistry of the reaction when such substituents are located on the cyclohexadiene ring (i.e. C4–C7 substituted isobenzofurans) except for one example where 4-methoxyisobenzofuran provided a 1:1 mixture of adducts with a quinone (15). The present example of differential substitution on this ring (the Diels–Alder reaction of **9** with MVK), and the regioselectivity observed therein, suggests that this may well be a fruitful area for further exploration. It is possible that the formation of the major adduct **10** is favoured by hydrogen bonding between the 7-hydroxy group of **8** and the carbonyl group of the dienophile in the *endo* transition state of the reaction. We are engaged in the preparation of 4- and 5-hydroxy and methoxy isobenzofurans and in the study of the Diels–Alder reactions of these dienes with unsymmetrical dienophiles. A meaningful discussion of the problem as well as further progress towards the 11-deoxy anthracyclinones will have to await the outcome of such work.

Experimental

Melting points were determined on a Buchi model SMP-20 apparatus and are uncorrected. Elemental analyses were performed by the Guelph Chemical Laboratories, Guelph, Ontario. Proton magnetic resonance spectra were determined, unless otherwise stated, in deuteriochloroform on a BrukerWP-80 spectrometer. Coupling constants were measured directly and confirmed by decoupling where necessary. Spectra are reported in the following manner: chemical shift (δ) in ppm (multiplicity, number of protons, assignment, coupling constants in Hz). Infrared spectra were obtained on a Beckmann model IR 10 or Acculab 10 spectrophotometer in the manner specified in each case. Mass spectra were determined on a Varian VG 7070F instrument and are reported as follows: ion (relative intensity, assignment). Column chromatography was performed with silica gel (Merck, 0.063–0.20 mm, 70–230 mesh ASTM) in the specified solvent system.

4-Methoxy-1,3-dihydroisobenzofuran-3,7-diol 8

The phthalide **7** (ref. 1) (0.25 g) dissolved in dry methylene chloride (20 mL) was cooled to −60°C and diisobutyl aluminum hydride (3.5 mL of 25% solution in toluene) added. After stirring for 70 min, aqueous sodium hydroxide (7 mL, 10%) was added and the solution allowed to warm to room temperature. The methylene chloride was removed, water added, and carbon dioxide bubbled through until the solution was neutral. The aqueous mixture was extracted with ethyl acetate (3 × 10 mL). The extracts were dried (Na_2SO_4) and the solvent removed *in vacuo* at room temperature. The residue was crystallized from chloroform (175 mg, 70%), mp 113°C (dec.); ir (KBr): 3250 (br) cm^{-1}; ^1H nmr (acetone-d_6): 3.76 (s, 3H, OMe), 4.81 (d, 1H, J_{gem} = 12.9, >C*H*—O), 5.09 (dd, 1H, J_{gem} = 12.9, $J_{1,3}$ *trans* = 2.15, CH—O), 5.31 (d, 1H, J = 7.8 disappears with D_2O, OH), 6.42 (dd, 1H, $J_{H,OH}$ = 7.8, >$J_{1,3}$ = 2.15, collapses to doublet with D_2O), 6.73 (s, 2H, H-5 and H-6), 8.0 (s, 1H, phenolic H, disappears with D_2O); ms: 182 (100, $M^{\cdot+}$), 165 (75, $M^{\cdot+}$ − OH), 164 (68, $M^{\cdot+}$ − H_2O). *Anal.* calcd. for $C_9H_{10}O_4$: C 59.34, H 5.53; found: C 60.01, H 5.73.[4]

2-endo-*Acetyl-5methoxy-8-hydroxy-1,4-epoxy-1,2,3,4-tetrahydronaphthalene 10*

The hydroxyphthalan **8** (240 mg) in carbon tetrachloride (8 mL) was refluxed for 19 h with glacial acetic acid (0.5 mL) and methyl vinyl ketone (0.82 mL). Aqueous sodium bicarbonate was added to neutralize the acid and the organic phase separated, dried (Na_2SO_4), and the solvent removed. A ^1H nmr spectrum of the residual oil showed the presence of the two regioisomers **10** and **11** in the ratio of ca. 3.5:1 and a third compound identified as 4-carbomethoxy-2-butanone (2.0 (s, 3H), 2.2 (s, 3H), 2.78 (t, 2H), and 4.35 (t, 2H)) resulting from Michael addition of acetic acid to methyl vinyl ketone. The ratio of **10** to **11** in this mixture was estimated by comparison of the two proton aromatic singlets and methoxy singlets of **10** (at 6.62 and 3.78 ppm) and **11** (at 6.55 and 3.72 ppm). Column chromatography of the crude mixture (ethyl acetate − ligroin, 5:6) and removal of the solvents provided an oil (55% yield) whose ^1H nmr spectrum indicated the presence of **10** and **11** in the same ratio. Other absorptions of the minor regiosomer **11** were clearly discernible in this spectrum but were not separated sufficiently from the corresponding absorptions of **10** to be used for reliable ^1H nmr estimation of the ratio. Crystals formed upon addition of benzene to the mixture (**10**/**11**) were separated, subjected to X-ray analysis, and found to be the *endo*-isomer of **10**.

10 (*endo*-isomer); mp 153–155°C; ir (KBr): 3300, 1710 cm^{-1}; ^1H nmr: 1.67 (dd, 1H, H-3α, J_{gem} = 11.4, $J_{2,3\alpha}$ = 4.82), 2.11 (s, 3H, $COCH_3$), 2.48 (ddd, 1H H-3β, J_{gem} = 11.4, $J_{3\beta,4}$ = 3.5, $J_{2,3\beta}$ = 12.04), 3.42 (ddd, 1H, H-2, $J_{1,2}$ = 3.9, $J_{2,3\beta}$ = 12.04, $J_{2,3\alpha}$ = 4.82), 3.78 (s, 3H, OMe), 5.58 (d, 1H, H-4, $J_{3\beta,4}$ = 3.5), 5.63 (d, 1H, H-1, $J_{1,2}$ = 3.9), 5.72 (s, 1H, OH, disappears with D_2O), 6.62 (s, 2H, H-6 and H-7); ms: 234 (17, $M^{\cdot+}$), 164 (100, $M^{\cdot+}$ − $CH_3COCH{=}CH_2$ retro Diels–Alder). *Anal.* calcd. for $C_{13}H_{14}O_4$: C 66.66, H 6.02; found: C 66.43, H 5.93.

2-Acetyl-4,8-dihydroxy-5-methoxy-3,4-dihydronaphthalene 12 and 2-acetyl-4,5-dihydroxy-8-methoxy-3,4-dihydronaphthalene 13

The mixture of adducts **10** and **11** (600 mg) was suspended in dry methanol (10 mL) under a nitrogen atmosphere and cooled to 0°C. Sodium methoxide (0.5 g sodium in 10 mL of absolute methanol) was added slowly over 20 min. The solution was warmed to room temperature and stirred for 4 h. Water was added and carbon dioxide bubbled through until neutral to litmus. The solution was poured into saturated brine (100 mL) and extracted into chloroform (5 × 20 mL). The extracts were dried (Na_2SO_4) and the solvent removed *in vacuo* to leave a solid (90%) which was chromatographed on a column of silica gel in ethyl acetate − ligroin (8:2) and the two regioisomers of

[4]The somewhat high result obtained for carbon may be due to the dehydration of some of the lactol during combustion. Its physical and chemical properties are consistent with several similar compounds prepared and studied earlier (ref. 3).

12 and **13** obtained[5] in the ratio of ca. 3.5:1.

12; R_f 0.2; mp 116–117°C (ether); ir (KBr): 3500, 3310 (br), 1640, 1620 cm^{-1}; ^{1}H nmr (acetone-d_6): 2–2.4 (m, 1H, H-3β), 2.40 (s, 3H, $COCH_3$), 3.16 (dd, 1H, H-3α, J_{gem} = 18.2, $J_{3\alpha,4}$ = 2.0), 3.55 (d, 1H, C4-OH, J = 8.0, disappears with D_2O), 3.80 (s, 3H, OMe), 5.20 (dd, after D_2O, 1H, H-4, $J_{3\alpha,4}$ = 2.0, $J_{3\beta,4}$ = 6.6), 6.87, 6.94 (AB q, 2H, H-6 and H-7, $J_{6,7}$ = 8.7), 7.92 (d, 1H, H-1, $J_{1,3\beta}$ = 2.7), 8.40 (br s, 1H, C8-OH, disappears with D_2O); ms: 234 (0.5, $M^{\cdot+}$), 216 (100, $M^{\cdot+}$ – H_2O), 201 (84, $M^{\cdot+}$ – H_2O – CH_3). *Mol. Conformation of methyl 3,6-dideoxy-α-D-*arabino*-hexopyranoside, the immunodominant sugar of *Salmonella* serogroup D_1: crystal structure, ^1H nmr analysis, and semi-empirical calculations[1]

GEORGE I. BIRNBAUM AND DAVID R. BUNDLE

Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received June 25, 1984

GEORGE I. BIRNBAUM and DAVID R. BUNDLE. Can. J. Chem. **63**, 739 (1985).

Methyl 3,6-dideoxy-α-D-*arabino*-hexopyranoside (methyl tyveloside) crystallizes in the orthorhombic space group $P2_12_12_1$ and the cell dimensions are a = 7.478(1), b = 7.933(1), c = 14.064(1) Å. X-ray intensity data were measured with a diffractometer and the structure was solved by direct methods. Least-squares refinement, which included all hydrogen atoms, converged at R = 0.038. The pyranose ring exists as an almost perfect $^4C_1$ chair and the conformation adopted by the glycosidic methyl group is in agreement with the requirements of the *exo*-anomeric effect. Both acetal oxygen atoms act as hydrogen-bond acceptors, and the H···O bond distances are in agreement with this feature. The ^1H nmr spectrum shows that the conformation of the pyranose ring in aqueous solution is indistinguishable from that in the crystal. The minimum energy conformation of a pentasaccharide fragment of a *Salmonella* O-antigen, calculated with tyvelose coordinates obtained by bond modification, is in good agreement with the conformation which was calculated with tyvelose coordinates obtained from the X-ray analysis.

GEORGE I. BIRNBAUM et DAVID R. BUNDLE. Can. J. Chem. **63**, 739 (1985).

Le didésoxy-3,6 α-D-*arabino*-hexopyrannoside de méthyle (tyveloside de méthyle) cristallise sous forme orthorhombique, groupe d'espace $P2_12_12_1$ avec a = 7,478(1), b = 7,933(1) et c = 14,064(1) Å. On a mesuré les intensités à l'aide d'un diffractomètre et on a résolu la structure par des méthodes directes. L'affinement par la méthode des moindres carrés, que inclut tous les atomes d'hydrogènes, converge vers une valeur de R = 0,038. Le cycle pyrannose existe sous la forme d'une chaise $^4C_1$ qui est presque parfaite et la conformation du groupement méthyle glycosidique est en accord avec ce qui est prévu sur la base des exigences de l'effet anomère *exo*. Les deux atomes d'oxygène de l'acétal agissent comme accepteurs de liaisons hydrogènes; les distances H···O sont en accord avec cette caractéristique. Le spectre rmn ^1H démontre que, en solution dans l'eau, la conformation du cycle pyrannose ne peut pas être distinguée de celle qui existe dans le cristal. La conformation d'un pentasaccharide qui est un fragment d'un O-antigène de la *Salmonella* fut calculé à l'aide de coordonnées du tyvelose obtenues par la modification de liaisons. Cette conformation, représentant une énergie minimale, est en bon accord avec la conformation calculée en utilisant les coordonnées du tyvelose obtenues à l'aide de la diffraction des rayons-X.

Introduction

The 3,6-dideoxyhexoses are naturally occurring sugars found in the lipopolysaccharides (LPS) of Gram-negative bacterial cell walls (1). In these structures they play a major role as immunodominant sugars (2). This implies that one bacterial species may be distinguished from another possessing a lipopolysaccharide structurally identical in all respects except for the presence of an isomeric but chirally unique 3,6-dideoxyhexose (1). Three isomers exist in the D-series and these differ from each other by the configuration of the hydroxyl groups at carbon atoms C(2) or C(4) (3). The presence of these 3,6-dideoxyhexoses in otherwise identical *Salmonella* LPSs distinguishes, and serologically defines, the A, B, and D_1 serogroups (1, 2). This differentiation is achieved by antibody molecules, the combining sites of which must be capable of recognising the fine stereochemical differences of 3,6-dideoxy-*arabino*-, *xylo*-, and *ribo*-hexopyranosides (4). In order to further understanding of such fine specificity it is desirable to build reliable models which accurately describe the topography of these important antigens. Molecular modelling of related lipopolysaccharides has been carried out for *Shigella flexneri* (5) but, in order to extend the approach to *Salmonella* LPS, reliable X-ray data for the constituent monosaccharides are desirable. Accurate atomic coordinates for galactopyranose (6), mannopyranose (7), and rhamnopyranose (8) have been available but until recently no experimental data for the 3,6-dideoxyhexoses were reported.

We reported the first such X-ray structure for methyl 3,6-dideoxy-β-D-*ribo*-hexopyranoside (9), but this structure differed from the naturally occurring 3,6-dideoxyhexosides which possess the α-D or α-L configuration. In this paper we report the crystal structure of methyl 3,6-dideoxy-α-D-*arabino*-hexopyranoside (methyl tyveloside) and we use the coordinates obtained from it to calculate the conformation of an oligosaccharide by the HSEA method (10). We compare this conformation with that derived with tyvelose coordinates generated by bond modification of D-mannopyranose. This procedure has been employed when X-ray data for a specific sugar are unavailable, and in such cases closely related monosaccharides for which X-ray structures have been determined are used to construct a set of calculated atomic coordinates (11).

Results and discussion

Molecular dimensions

The final atomic parameters are listed in Table 1. The C—C bond lengths (Fig. 1) in the pyranose ring range from 1.517(2) to 1.530(2) Å. These distances as well as differences of up to ~0.01 Å are characteristic for C—C bonds in pyranose rings. The shorter C(5)—C(6) bond can be ascribed to the relatively larger thermal motion of the methyl group. It is interesting to compare the bond lengths in the sequence C(5)—O(5)—C(1)—O(1)—C(7) with values obtained from X-ray analyses of other methyl α-pyranosides and from *ab initio* molecular orbital calculations (12). The C(5)—O(5) bond in the present structure is 0.012 Å (8σ) longer than the experimental mean derived from eight other molecules. However, in manno- and altropyranoside, in which the 2-OH and 4-OH are axial and equatorial, respectively, as in the present structure, the

[a]The coordinates of nonhydrogen atoms were multiplied by 10^5, those of the hydrogen atoms by 10^3.

C(5)—O(5) bond lengths are 1.450 and 1.440 Å, respectively, and thus closer to the value we observed. Furthermore, our value of 1.447 Å is in excellent agreement with the theoretical value of 1.444 Å (12). The other three bond lengths in the acetal group are within 2σ of the mean values from previous experiments (1.416, 1.404, 1.430 Å).

The average bond angles in pyranose rings have been found to be 110.2° at C atoms and 113.4° at the O atom (13). In the present structure (Fig. 1) the angles at O(5) and C(1) are significantly larger than these averages. In the acetal group, the O(5)—C(1)—O(1) angle is 0.9° (9σ) smaller than the reported average (13), while C(1)—O(1)—C(7) is larger than previously reported values from X-ray analyses (113.0–113.5°). The bond angles at C(5) are in excellent agreement with the angles in methyl paratoside in which there is also an equatorial methyl group in that position (9). On the other hand, the angles involving the exocyclic -OH groups vary greatly from structure to structure, presumably in order to optimize the geometry of the hydrogen bonds in which they are involved.

Molecular conformation

The conformation of the molecule is shown in Figs. 2 and 3. The pyranose ring can be described by the Cremer and Pople (14) puckering parameters: $\theta = 0.9$, $\phi = 270.5°$, $Q = 0.559$. The low value of θ indicates that the ring is an almost perfect $^4C_1$ (D) chair. The substituents at C(1) and C(2) are axial while those at C(4) and C(5) are equatorial. The endocyclic torsion angles (Fig. 1) show the usual approximate mirror plane normal to the mean plane of the ring and passing through O(5) and C(3). Also as usual, the ring is most puckered at O(5) and least at C(3). The differences between mirror-related torsion angles are all <1°; in methyl paratoside these differences ranged up to 8.5° (9). The range of the absolute values of the torsion angles (53.1–59.0°) is relatively small. This is in line with the recent

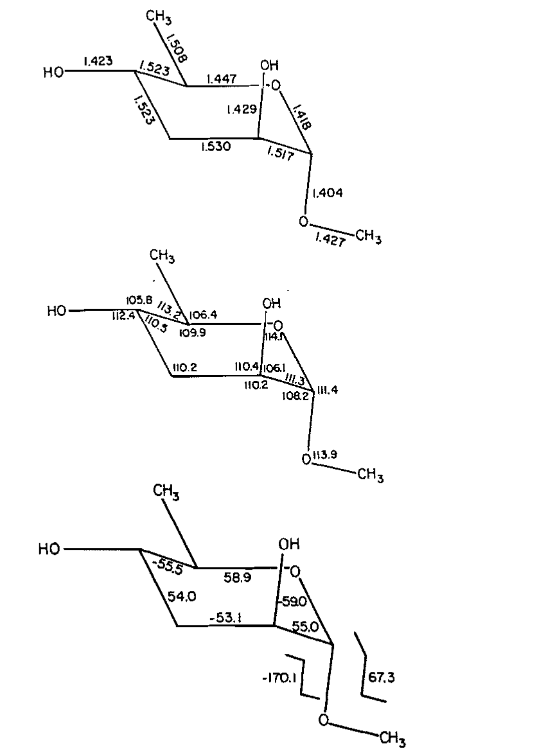

FIG. 1. Molecular geometry; (top) bond lengths, esd's are 0.0014–0.0023 Å; (center) bond angles, esd's are 0.09–0.13°; (bottom) endocyclic torsion angles, esd's are 0.13–0.15°.

observation by Jeffrey and Taylor (15) that the mean range is smaller (53.3–60.3°) in methyl pyranosides with an axial anomeric group and larger (52.7–64.2°) in those with an equatorial anomeric group.

The conformation of the exocyclic methoxy group is consistent with the *exo*-anomeric effect (16), i.e. C(7)—O(1) is *gauche* with respect to C(1)—O(5) and *trans* with respect to C(1)—C(2). The anomeric torsion angle (O(5)—C(1)—O(1)—C(7)) is 67.3°, in excellent agreement with the value (67.0°) obtained from molecular mechanics calculations for 2-methoxytetrahydropyran with an axial methoxy group (15). The experimentally observed values in methyl pyranosides range from 60.5 to 70.5°.

In view of the preceding discussion, one can conclude that the absence of an -OH group at C(3) does not give rise to any distortion of the molecule.

Hydrogen bonding and packing

Both hydroxyl groups donate their protons to symmetry related molecules and in each case an acetal oxygen acts as an acceptor. This is one of the hydrogen-bonding schemes (type II) observed in methyl pyranosides and recently described by Jeffrey and Mitra (17). Both the absence of the "cooperative effect" (···O—H···) and the involvement of chain stoppers as acceptors are expected to result in relatively weaker hydrogen bonds, with H···O distances of ~1.86 Å. Table 2 shows the geometry of the hydrogen bonds in the present structure. The corrected H···O distances were obtained by making the covalent O—H bonds 0.97 Å long, the mean neutron diffraction value. These distances show the hydrogen bonds to have the expected strength. The packing of the molecules is shown in Fig. 4. Each molecule is hydrogen-bonded to four adjacent ones. All other contacts are longer than the sums of van der Waals radii.

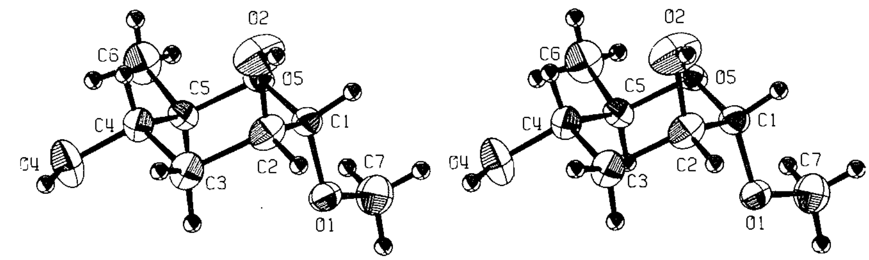

FIG. 2. Stereoscopic view of methyl tyveloside; the ellipsoids include 50% probability.

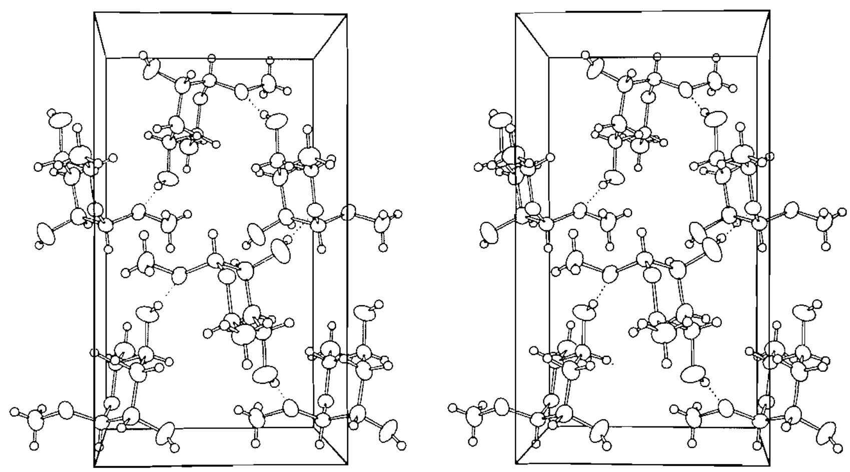

FIG. 4. Stereoscopic view along *a* of the molecular packing in the crystal.

TABLE 2. Geometry of hydrogen bonds

Bonds			Distances, Å			Angles, deg
D	*A*	*A* at	O···O	H···O	H···O$_{corr}$	O—H···O
O(2)—H	···O(5)	$-1/2 + x, 3/2 - y, 1 - z$	2.822	2.00	1.88	165
O(4)—H	···O(1)	$1 - x, 1/2 + y, 1/2 - z$	2.832	2.00	1.87	171

Nuclear magnetic resonance analysis

Proton nmr provides coupling constant data for methyl tyveloside which, via the Karplus equation (18), permits the solution conformation to be compared with that in the crystal. Since little variation was anticipated between the conformations in solution and in the solid state and none was found, it was of interest to correlate recent treatments of the Karplus equation. Altona and Haasnoot presented a simple additivity rule for pyranose rings which permits the coupling constants of the $^4C_1$ or $^1C_4$ chair conformations to be predicted to within ±0.6 Hz in the majority of cases (19). A second paper by Haasnoot *et al.* presented a quantitative analysis of the Karplus equation and an empirical generalization was presented (20). Both approaches were used here to calculate the ^3J coupling constants of methyl tyveloside on the assumption that the solution conformation was indistinguishable from that determined by the X-ray analysis. These coupling constants are presented in Table 3 together with the chemical shifts and coupling constants observed for methyl tyveloside in deuterium oxide solution.

The ^{1}H nmr spectrum was recorded at 500 MHz and spin-decoupling experiments confirmed the assignments. Later a two-dimensional homonuclear shift-correlated (COSY-90) experiment was performed. This not only confirmed the assignment of chemical shifts but also indicated a fairly extensive network of ^4J coupling constants. Inspection of a resolution-enhanced spectrum showed these to be ≤1.0 Hz in all cases. In order to properly assess the effect of these additional coupling constants, overlaid upon an already complex multiplicity resulting from the presence of two deoxy centres in the sugar, an

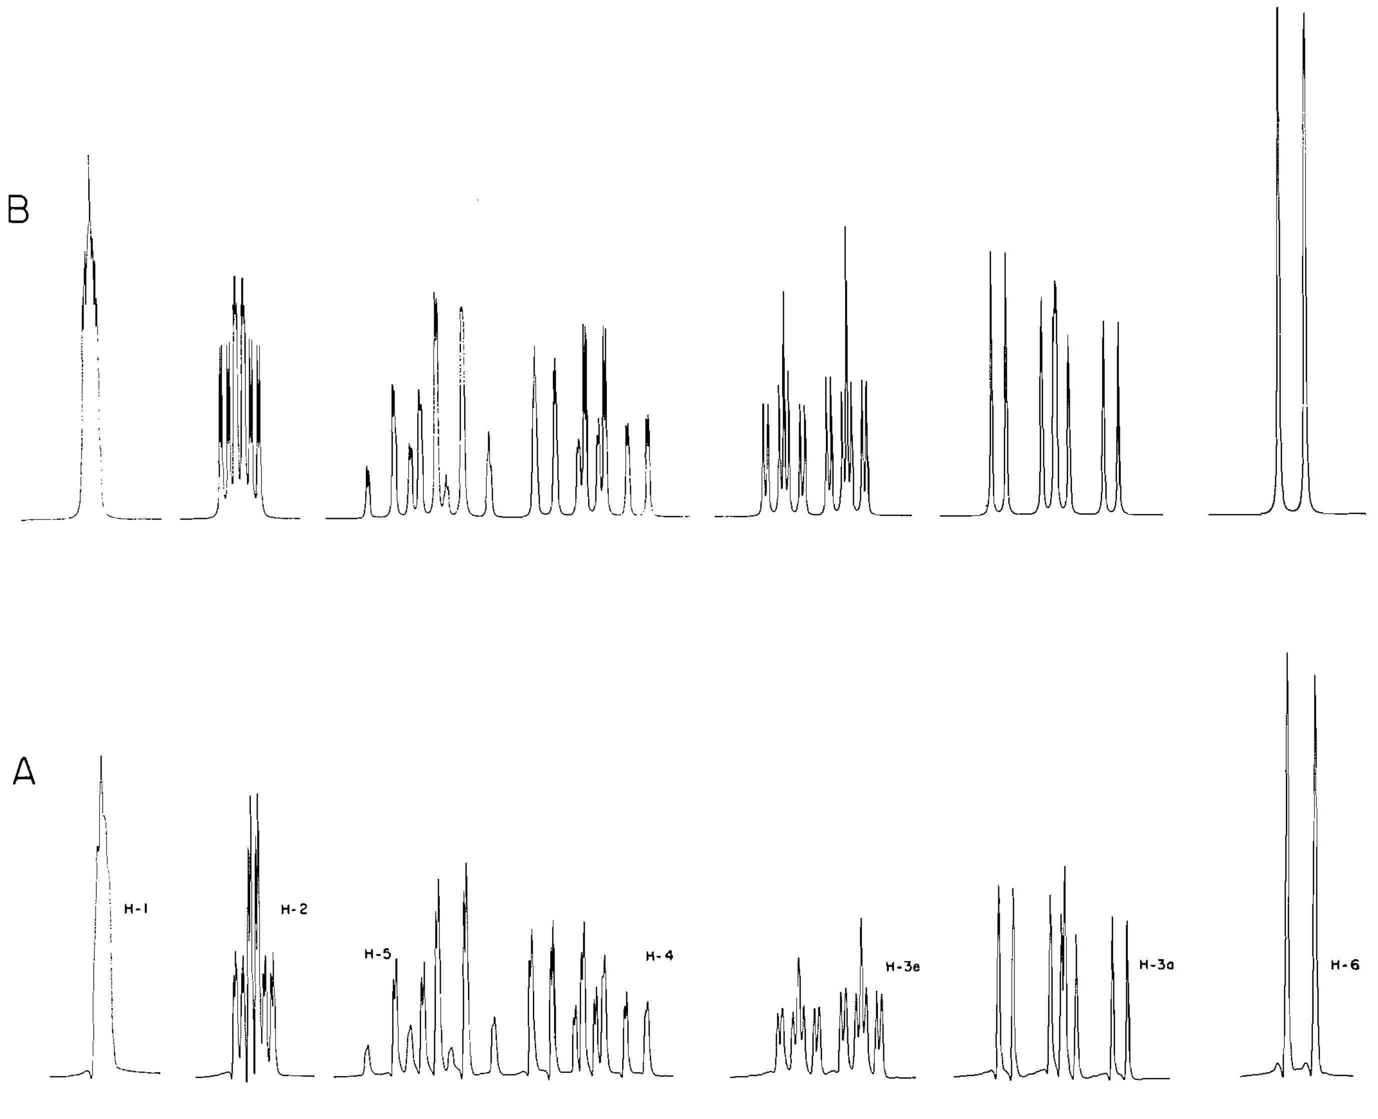

FIG. 5. Observed (A) and simulated (B) ^{1}H nmr spectra of methyl 3,6-dideoxy-α-D-*arabino*-hexopyranoside. The FID acquired in 32K data points was resolution enhanced prior to Fourier transformation by the Lorentz-to-Gauss line shape transformation of Ernst (30). The parameters LB = −0.7 and GB = 0.4 were chosen by trial to give the best compromise for signal-to-noise and resolution. The simulated spectrum (B) was calculated for Lorentzian line shape with 0.2 Hz line width. The spectra are displayed as discontinuous plots at a scale of 10 Hz/division.

iterative analysis of the spin system H1−H6 was performed. The first-order ^3J values and chemical shifts were used initially but the simulated spectrum did not reproduce the observed spectrum. Examination of a resolution-enhanced spectrum (A, Fig. 5) revealed several small, previously unresolved coupling constants. The H(3e) resonance prior to resolution enhancement appeared as two triplets separated by the geminal H(3e)/H(3a) coupling of 13.6 Hz. This now showed the largest ^4J coupling, ca. 1.0 Hz, which collapsed when the H(1) signal was irradiated. The fine detail of the H(2) and H(4) multiplets revealed a ^4J coupling between these protons of 0.5 Hz. The COSY experiment also indicated coupling between H(1)/H(5) and H(1)/H(6); however, these were barely discernible even with resolution enhancement, which failed to show significant fine structure on the H(1) resonance. Particularly interesting was the simulation incorporating the three ^4J values H(1)/H(3e) ≈ −1.0 Hz, H(1)/H(5) ≈ 0.5 Hz, and H(2)/H(4) ≈ −0.5 Hz, which showed H(1) as a broad doublet. Only after incorporation of the H(1)/H(6) ^5J coupling did the H(1) resonance assume its observed broad singlet character. Incorporation of these three ^4J and one ^5J coupling constants in the simulation gave a spectrum (B, Fig. 5) which faithfully reproduced the observed multiplicity and fine splitting of the experimental spectrum, A.

Inspection of the calculated ^3J values obtained by the methods of Altona, Haasnoot, and de Leeuw (19, 20) shows that, although these methods provide a good estimate of the observed ^3J values, the deviations are larger than for those structures upon which the authors based their estimates of accuracy. In this regard it should be noted that trisubstituted fragments such as —CH_2CHX— were observed by them to show systematic differences. Consistent with this, the largest variation between observed and calculated coupling constants occurs for $J_{2,3e}$, $J_{2,3a}$, and $J_{3e,4}$, all of which constitute trisubstituted —CH_2CHX— fragments. These variations in no way affect the interpretation of the nmr data as supporting a $^4C_1$ chair for methyl tyveloside in solution. The diaxial dispositions of H(5), H(4), and H(3a) are all consistent with the large $J_{4,5}$

[c]Absolute potential energy of the pentasaccharide described in footnote *a*.

and $J_{3a,4}$ values, which serve to fix the ring conformation as $^4C_1$. The small $J_{2,3e}$ and $J_{2,3a}$ values are also consistent with this conformation. The solution conformation of methyl tyveloside is therefore closely related to that in the crystal and since the nmr data may only be extrapolated to torsional angles varying by ca. 10° (9), the agreement with the X-ray results cannot be more accurately tested.

HSEA calculations

Semi-empirical calculations were recently performed for the repeating units of the *Salmonella* LPSs which contain the 3,6-dideoxyhexoses paratose, abequose, and tyvelose (21). For the LPS of serogroup D_1, containing tyvelose, Bock *et al.* used in those calculations a coordinate set for this saccharide derived by bond modification (11) from the neutron diffraction structure of methyl-α-D-mannopyranoside (7) to provide deoxy functions at C(3) and C(6). Since X-ray results for methyl tyveloside are now available, this provides us with an opportunity to compare the use of coordinate sets derived from bond modification with those obtained from crystal structures. In order to make this comparison, a linear tetrasaccharide α-D-Gal*p*-(1→2)-α-D-Man*p*-(1→4)-α-L-Rha*p*-(1→3)-α-D-Gal*p* was constructed according to published work (21). The dideoxyhexopyranose, α-tyvelose, was then introduced at O(3) of the α-D-mannopyranose unit and the minimum energy of the molecule was computed by the HSEA method (10, 11). The torsion angles ϕ_H (H(1)—C(1)—O(1)—C(3′)) and ψ_H (C(1)—O(1)—C(3′)—H(3′)) were obtained simultaneously for the new glycosidic linkage. It was found that the absolute potential energies of the two pentasaccharides, obtained with the tyvelose atomic coordinate set generated either by bond modification or X-ray analysis, were within 0.2 kcal/mol of each other (Table 4). It should be noted that the C—H bond lengths were normalized to 1.10 Å, the usual value obtained from neutron diffraction analyses. The two sets of ϕ_H,ψ_H values fell in a ±2° range (Table 4). Semi-empirical calculations contain many assumptions and approximations, and conformations corresponding to energy minima differing by less than 0.5 kcal/mol are considered as equally probable (10, 11). With the exception of X-ray or neutron diffraction, experimental methods could not detect such small differences. Thus, for practical purposes the bond modification procedure for generating coordinate sets is shown to offer a good approximation, in the absence of crystal structures.

Experimental

Preparation of methyl tyveloside

Methyl -2,4-di-*O*-benzoyl-3,6-dideoxy-α-D-*arabino*-hexopyranoside was synthesized from methyl α-D-glucopyranoside by the published procedure (22) and debenzoylated in absolute methanol containing a catalytic amount of sodium methoxide. The resultant solution was de-ionized with Rexyn 101 H^+ resin (Fisher Scientific), concentrated to a syrup, and chromatographed on silica gel with ethyl acetate, methanol, and water (85:10:5) as eluant. Methyl tyveloside was obtained as a homogeneous syrup which crystallized from ethyl acetate and hexane; mp 87.5–88.5°, $[\alpha]_D^{21}$ 116.2° (*c* 1.2, water). Detailed descriptions of synthetic manipulations and chromatography are to be found in other publications from this laboratory (22, 23).

X-ray analysis of methyl tyveloside

A colorless, prismatic crystal was cut to give a fragment measuring 0.30 × 0.40 × 0.50 mm. Precession photographs showed systematic absences corresponding to the space group $P2_12_12_1$. The crystal was mounted on a CAD4 diffractometer and the following data were obtained:

$C_7H_{14}O_4$ mw = 162.18
Orthorhombic, a = 7.478(1), b = 7.933(1), c = 14.064(1) Å, V = 834.32 Å^3, ρ_c = 1.291 g cm^{-3}, Z = 4 (21°C, CuKα_1, λ = 1.54056 Å), $F(000)$ = 352, μ(CuKα) = 8.5 cm^{-1}.

Unit cell dimensions were determined from a least-squares refinement of the angular settings of 22 high-order ($46 < \theta < 74°$) reflections. Intensities were measured with Ni-filtered CuKα radiation, using ω/2θ scans. Three standard reflections were monitored at regular intervals; their intensities varied by <1%. Of the 1017 unique reflections with $\theta \le 75°$ there were 998 with $I \ge 3\sigma(I)$ which were considered observed. The intensities were corrected for Lorentz and polarization factors; absorption corrections were unnecessary.

The structure was determined by direct methods with the aid of the MULTAN program (24). Refinement was carried out by the block-diagonal least-squares procedure. Anisotropic temperature parameters were used for nonhydrogen atoms, while hydrogen atoms, located on difference Fourier maps, were refined with isotropic parameters. The scattering factors were taken from the "International Tables for X-Ray Crystallography" (25) and the oxygen curve was corrected for anomalous dispersion. Throughout the refinement the function $\Sigma w(|F_o| - |F_c|)^2$ was minimized and a factor of 0.8 was applied to all shifts. The following weighting scheme was used during the final stages: $w = w_1 \cdot w_2$, where $w_1 = 1$ for $|F_o| < 7$, $w_1 = 7/|F_o|$ for $|F_o| \ge 7$, $w_2 = \sin^4\theta/0.9$ for $\sin^2\theta \le 0.9$, and $w_2 = 1$ for $\sin^2\theta > 0.9$. This scheme made the average values of $w(\Delta F^2)$ independent of $|F_o|$ and $\sin^2\theta$. After the final cycle the average parameter shift equalled 0.1σ and the largest 0.25σ. Thirteen strong, low-angle reflections suffered from extinction effects and were given zero weights. The final conventional residual index R is 0.038 and the weighted index R_w is 0.037. Lists of anisotropic temperature parameters and of observed and calculated structure factors are available.[2]

Nuclear magnetic resonance analysis of methyl tyveloside

The ^{1}H nmr spectra were recorded with a Bruker AM-500 instrument at 310K. Spectra were recorded for a 10-mM solution in deuterium oxide using 90° pulses (8 μs) and a digital resolution of ±0.12 Hz. Acetone (1%) was used as an internal reference (δ 2.225 ppm). Two-dimensional homonuclear shift-correlated, COSY-90, experiments were performed without (26) and with a delay period $\approx 0.25/J$ between 90° pulses in order to maximize correlation peaks with small couplings (J) (26). Spectrum simulation was performed with the Bruker software "PANIC", a minicomputer version of the LAOCOON type program. The seven spins H(1)−H(6), with the three H(6) protons treated as a magnetically equivalent spin system, were simulated first with the observed parameters for chemical shift and ^{3}J coupling constants. Subsequently long-range ^{4}J coupling between H(1)/H(3e) −1.0 Hz, H(1)/H(5) 0.5 Hz (27), and H(2)/H(4) −0.5 Hz were incorporated into the simulation and finally together with a ^{5}J H(1)/H(6) 0.5 Hz (27) coupling.

Semi-empirical potential energy calculations, HSEA method (10, 11), were used to compute the minimum energy for a pentasaccharide corresponding to the *Salmonella typhi* O-antigen according to published procedures (21). The atomic coordinates for α-D-mannopyranose (7), α-D-galactopyranose (6), and α-L-rhamnopyranose (8) were taken from published neutron diffraction data. The atomic coordinates of α-D-tyvelopyranose were generated by bond modification of α-D-mannopyranose according to published procedures (11) and from the X-ray analysis reported in this paper.

Acknowledgements

Apart from the MULTAN program (24), all crystallographic computations were carried out with programs written by Ahmed *et al.* (28). Figures 2 and 4 were drawn with the ORTEP program of Johnson (29). The authors would like to thank Dr. Charles Roger, Bruker Spectrospin (Canada) Ltd., for assistance in performing spin simulation and two-dimensional nmr experiments.

A formal [1,3] sigmatropic reaction involving free radical intermediates: a mechanistic investigation

GORDON S. BATES[1] AND S. RAMASWAMY
Department of Chemistry, 2036 Main Mall, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received June 14, 1984

GORDON S. BATES and S. RAMASWAMY. Can. J. Chem. **63**, 745 (1985).

The quantitative isomerization of 2,2-bis(ethylthio)-3,3-dimethylpent-4-enal to 2,2-bis(ethylthio)-5-methylhex-4-enal was studied over the temperature range 130–170°C. An investigation of the generality and specific mechanism of this formal [1,3] sigmatropic shift was conducted with six related compounds. The rearrangements were found to obey first-order kinetics, and on the basis of significant positive entropies of activation (52–106 J deg^{-1} mol^{-1}), crossover and trapping experiments, and the lack of a solvent effect (decane vs. DMF), an intermolecular, free-radical chain pathway has been proposed for the isomerization. During the rearrangement of several of the compounds esr signals were observed that were consistent with the presence of the proposed free-radical intermediates. These esr signals have been computer simulated.

GORDON S. BATES et S. RAMASWAMY. Can. J. Chem. **63**, 745 (1985).

Opérant à des températures allant de 130 à 170°C, on a étudié l'isomérization quantitative du bis(éthylthio)-2,2 diméthyl-3,3 pentène-4 al en bis(éthylthio)-2,2 méthyl-5 hexène-4 al. Utilisant six composés apparentés, on a déterminé la généralité et le mécanisme spécifique de cette transposition qui est, d'un point de vue formel, du type sigmatropique [1,3]. On a trouvé que la cinétique de ces transpositions est du premier ordre et, sur la base d'entropies d'activation qui sont assez positives (52–106 J deg^{-1} mol^{-1}), d'expériences d'échanges et de piégeages ainsi que sur le fait qu'il n'y a pratiquement pas d'effet de solvant (décane vs. DMF), on suggère que cette isomérisation se produit par le biais d'un processus radicalaire intermoléculaire. Au cours des transpositions de plusieurs composés, on a pu observer des signaux de rpe qui sont en accord avec la présence des intermédiaires radicalaires proposés. Utilisant un ordinateur, on a simulé ces signaux de rpe.

[Traduit par le journal]

Although the chemical literature contains many examples of [1,3] alkyl shifts in cyclic systems, their occurrence in acyclic analogues is relatively rare (1). Cookson and Kemp (2) have reported a benzyl migration in the thermal conversion of 3,3-dicyano-2-methyl-4-phenylpent-1-ene to 1,1-dicyano-2-methyl-4-phenylpent-1-ene which occurs with retention of configuration. Baldwin *et al.* have evidence for the presence of a radical pathway in the [1,3] sigmatropic rearrangements of a number of systems (3). More recently, Ollis and co-workers (4) have reported rearrangements of various dimethylaminobutenes that again can formally be regarded as [1,3] alkyl shifts. These authors speculate that, although a stereoselective transformation involving a concerted pathway is a likely possibility in the case of several of the compounds, a process involving a weakly interacting radical pair is not unlikely.

We recently observed[2] a high yielding[3] thermal rearrangement of 2,2-bis(ethylthio)-3,3-dimethylpent-4-enal **1** into compound **2**. This rearrangement, which is an example of a [1,3] carbon–carbon shift in an acyclic system, should be favoured since the transformation would be accompanied by relief of the steric strain associated with the two adjacent quaternary centres in **1**, as well as by formation of the more highly substituted alkene in **2**. The observation of the transformation of **1** into **2** prompted us to investigate the generality, as well as the specific mechanism, of this rearrangement. Accordingly, aldehydes **3–7** were prepared in order to investigate the steric demands of the reaction, and compounds **8** and **9** as a probe of the electronic requirements of the rearrangement.

The isomerization of **1** into **2** may be rationalized in terms of the several different reaction mechanisms shown in Fig. 1.

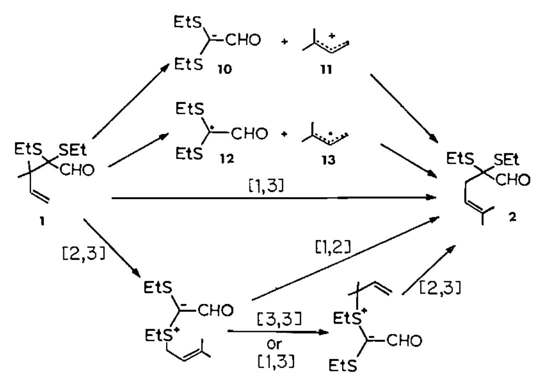

FIG. 1. Possible pathways for [1,3]-alkyl migration in the rearrangement of **1** into **2**.

A heterolytic cleavage of **1** to provide the bis(ethylthio)-ethanal anion **10** and a tertiary allylic carbonium ion **11**, followed by recombination of the ions at the less hindered site of the allylic group, could produce compound **2**. The required dimethylallyl carbonium ion is stabilized both by hyperconjugation as well as by allylic resonance. The anion also is doubly stabilized. Both the electron-withdrawing aldehyde group and the two sulphur atoms flanking the anion have a large stabilizing effect. The stability of anion **10** is easily seen from the fact that the conjugate acid of this anion, 2,2-bis-(ethylthio)ethanal, can be readily extracted into aqueous sodium hydroxide (6).

A homolytic bond cleavage of **1** would give rise to two radicals that could also recombine to provide **2** in a fashion similar to the heterolytic pathway described above. The dimethylallyl radical **13** that would be formed is stabilized by resonance. In addition to the effects due to the electron-withdrawing aldehyde, the bis(ethylthio)ethanal radical **12** is further stabilized by another factor. Stabilization of radicals by

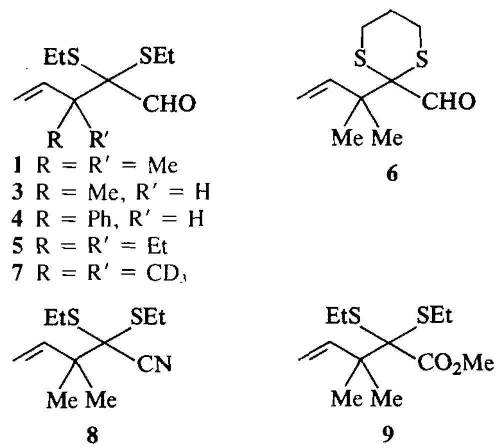
[1]Author to whom correspondence should be addressed.

[2]Portions of this work have appeared as a preliminary communication (5).

[3]Compound **2** has been isolated in 87% yield after the thermal rearrangement of 0.50 g of **1**. The proton magnetic resonance (^{1}H nmr) spectrum of the crude reaction mixture indicated a quantitative conversion.

TABLE 1. Predicted mechanistic features

Mechanism	Solvent effect	Crossover products	Entropy of activation
Concerted	No	No	Negative
Ionic (intermolecular)	Yes	Yes	Positive or negative
Ionic (intramolecular)	Yes	No	Positive or negative
Radical (intermolecular)	No	Yes	Positive
Radical (intramolecular)	No	No	Positive



SCHEME 1

heteroatoms such as sulphur is well documented (7, 8) and involves participation of a lone pair of electrons on the heteroatom in delocalization of the radical. If a radical is substituted by these two electronically complementary groups, the stability of the radical is greatly enhanced since the unpaired electron is delocalized over both the donor and the acceptor groups. This phenomenon has been designated as capto-dative stabilization (9).

Finally, the rearrangement may proceed by a concerted pathway (10). The migration of the dimethylallyl group may take place via a symmetry-allowed [1,3] suprafacial pathway, provided inversion of configuration of the migrating group occurs. Alternatively, the rearrangement may in principle occur with retention of configuration at the migrating centre but via a geometrically disfavoured antarafacial process. In addition to a direct [1,3] sigmatropic pathway, the rearrangement could occur via a series of alternate symmetry-allowed sigmatropic migrations as shown in Fig. 1, which result in the overall appearance of a [1,3] shift.

Any of the concerted processes must involve ordered transition states that should be reflected in a relatively large negative entropy of activation ($\Delta S^{\#}$).[4] For example, the well-known Cope rearrangement has $\Delta S^{\#}$'s ranging from −46.4 to −58.6 J deg^{-1} mol^{-1} (11–13). The $\Delta S^{\#}$ for the diradical process should be positive (14). On the other hand, the $\Delta S^{\#}$ for the ionic pathway could vary greatly. If there is considerable freedom in the transition state, then $\Delta S^{\#}$ would be positive. However, a negative $\Delta S^{\#}$ is also possible due to electrostriction of the solvent around the ions produced (15). Any of the proposed concerted processes must be intramolecular in nature. However, both the ionic and radical modes could follow either an intramolecular or an intermolecular pathway. A crossover experiment using isotopically labelled substrates should be sufficient to differentiate the intra- vs. the intermolecular character of the rearrangement. If the rearrangement proceeds by way of an ionic pathway, or indeed, via any process that involves significant charge development in the transition state, there should be a significant solvent effect. On the other hand, the rate of a concerted or of a radical process should be relatively independent of solvent (16). The crossover experiment, analysed in conjunction with the results of changing the solvent on the rate of the reaction, could be used to differentiate an intermolecular radical pathway from an ionic route. Thus a determination of the activation parameters of the reaction, as well as the presence or absence of a solvent effect, and the results of a crossover experiment will allow a mechanistic choice to be made. Table 1 summarizes these various mechanistic requirements.

The compounds required for the kinetic studies that will be used to determine the activation parameters for the rearrangement were prepared by a route that presumably involves a [2,3] sigmatropic rearrangement of an allylic sulphonium ylide (17). Aldehydes **1** and **3–7** were prepared by stirring the required allylic bromide and dithioketal with lithium or potassium carbonate in *N,N*-dimethylformamide overnight at room temperature. Nitrile **8** was prepared by a similar procedure; however, the reaction was incomplete even after prolonged stirring (6 days). Using the above method to form ester **9** always resulted in a mixture of desired material **9** (S_N2' product) and its isomer **14** (S_N2 product). A pure sample of **9**, uncontaminated with **14**, could be obtained by preforming the necessary sulphonium salt followed by an *in situ* deprotonation of this salt and a concomitant [2,3] sigmatropic rearrangement of the resulting ylide.

One mechanism that could account for the exclusive formation of the S_N2' products **1** and **3–8** involves an initial S_N2 attack of sulphur on the allylic halide to generate a sulphonium salt. The acidity of the proton α to the sulphur is enhanced by this salt formation and even a weak base such as lithium or potassium carbonate is strong enough to deprotonate this site. The resulting ylide then rearranges to give the observed S_N2' product. This explanation is similar to that proposed by Ogura *et al.* (18) to account for the product distribution in a related system. An alternate mechanism would be the alkylation of the preformed carbanion (19) to generate the same intermediate ylide described above, which then undergoes the sigmatropic rearrangement. If the former mechanism is the only operating pathway, then the S_N2' product **16** rather than **17** (S_N2) should always be obtained irrespective of the nature of the Z group in compound **15** or of the base used in the deprotonation step. If the alternate mechanism is operative, the product distribution would be expected to exhibit some dependence on both of the parameters mentioned above. In this context it is pertinent to present some of our observations regarding this reaction. As can be seen from Table 2, there is indeed a variation in product

[4] The enthalpy of activation ($\Delta H^{\#}$) for all of the proposed routes would be expected to be positive.

distribution with both the change in functional group (Z) and the base used in the reaction. We believe that this is consistent with the fact that *S*-alkylation of a preformed carbanion followed by a [2,3] rearrangement of the intermediate ylide is a significant pathway in the reactions leading to the S_N2' products.[5]

Authentic samples of the potential rearrangement products also were prepared. Aldehydes **2** and **18**–**22** were prepared via a metalloenamine alkylation (6) and nitrile **23** by the alkylation of the potassium salt of 2,2-bis(ethylthio)ethanenitrile (20). A sample of ester **14** was obtained by repeated thin-layer chromatographic separation of the mixture of **9** and **14** described above.

The rearrangement of aldehydes **1** and **3**–**6** was effected in decane or tetradecane solution. The solvents were freshly distilled and the samples degassed with argon before the thermolysis. The aldehyde resonances in the ^{1}H nmr spectrum of the starting materials and the products generally differ by ca. 0.1 ppm. Thus the progress of the reactions could be conveniently monitored by following the change in the relative areas of the aldehydic resonances. Neither nitrile **8** nor ester **9** contains a convenient ^{1}H nmr reference signal by which the rearrangement could be monitored. Gas chromatographic analysis therefore was used to determine the relative amounts of starting material and the rearranged product as the reaction proceeded. The rearrangements were carried out in degassed tetradecane. Control experiments were conducted to determine the relative detector responses of the starting materials and the products as well as to establish that no significant amount of rearrangement was occurring during the gas chromatographic analysis of the reaction mixture.

Figures 2–6 clearly indicate that the rarrangements of compounds **1**, **4**, **6**, **8**, and **9**, respectively, follow first-order reaction kinetics.[6] The rate constant at 150°C for the rearrangement of the more compact and less sterically demanding 1,3-dithiane derivative **6** was considerably (ca. 20-fold) lower than that for the rearrangement of the more sterically crowded analogue **1**. On the basis of a simple steric argument it was expected that **3** would rearrange more slowly than **1**, and **5** more rapidly.[7] Compound **3** was indeed less prone to rearrange and in fact no reaction was observed even after prolonged heating at 220°C. It was anticipated that **5**, in which the steric congestion at the adjacent quaternary centres was further accentuated, would show a dramatic increase in the rate of rearrangement as com-

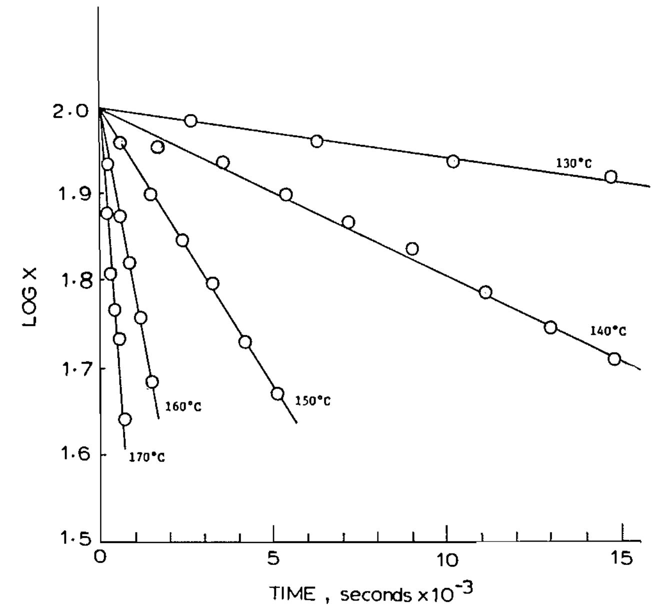

FIG. 2. Rate of rearrangement of **1**: X = 100([**1**]/[**1** + **2**]) as determined by ^{1}H nmr spectroscopy. t = 170°C, $k = 1.08 \times 10^{-3}$ s^{-1}; t = 160°C, $k = 4.70 \times 10^{-4}$ s^{-1}; t = 150°C, $k = 1.43 \times 10^{-4}$ s^{-1}; t = 140°C, $k = 4.51 \times 10^{-5}$ s^{-1}; t = 130°C, $k = 1.19 \times 10^{-5}$ s^{-1}.

[5]The products are also consistent with a one-electron transfer mechanism.

[6]The figures display typical data for the average of a minimum of three rearrangement experiments at each temperature. In each case, the kinetic data were found to agree, within 10%, with those of previous experiments. Photocopies of the kinetic data may be obtained at a nominal charge from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada, K1A 0S2.

[7]Compound **4** would be expected to have two opposing forces, electronic acceleration vs. steric decrease, affecting its rearrangement. Aldehyde **4** rearranges at approximately 1.6 times the rate of **1** over the temperature range studied, indicating that the electronic effect is dominant.

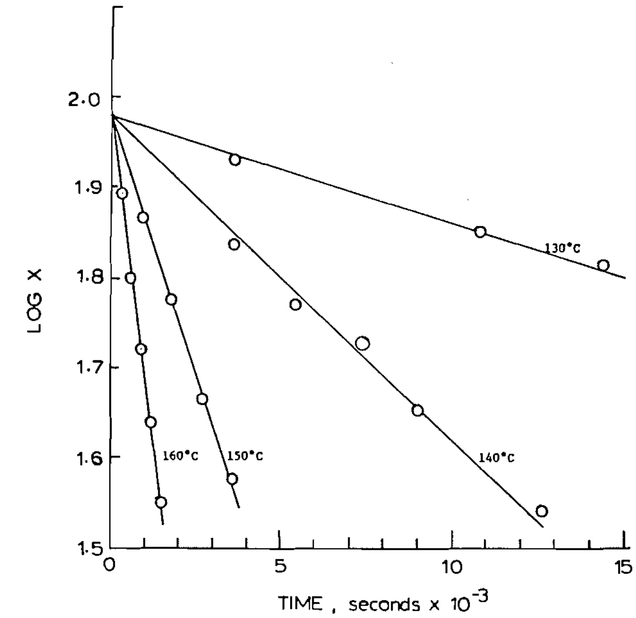

FIG. 3. Rate of rearrangement of **4**: X = 100([**4**]/[**4** + **19**]) as determined by ^{1}H nmr spectroscopy. t = 170°C, $k = 1.57 \times 10^{-3}\ s^{-1}$; t = 160°C, $k = 6.69 \times 10^{-4}\ s^{-1}$; t = 150°C, $k = 2.44 \times 10^{-4}\ s^{-1}$; t = 140°C, $k = 7.53 \times 10^{-5}\ s^{-1}$; t = 130°C, $k = 2.14 \times 10^{-5}\ s^{-1}$.

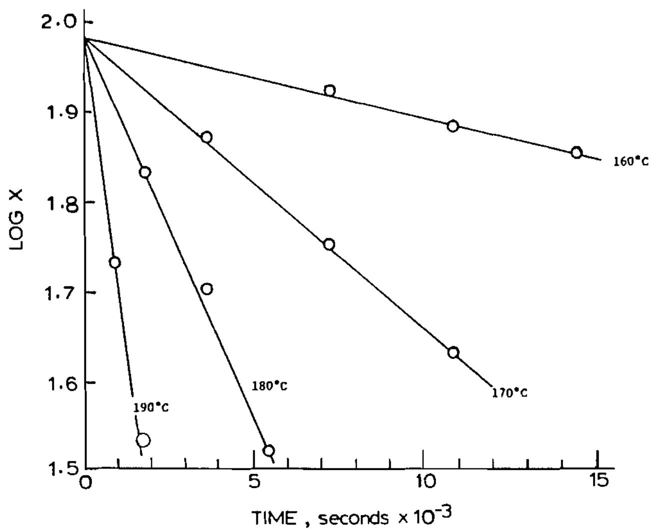

FIG. 4. Rate of rearrangement of **6**: X = 100([**6**])/[**6** + **21**]) as determined by ^{1}H nmr spectroscopy. t = 190°C, $k = 6.42 \times 10^{-4}\ s^{-1}$; t = 180°C, $k = 2.08 \times 10^{-4}\ s^{-1}$; t = 170°C, $k = 7.1 \times 10^{-5}\ s^{-1}$; t = 160°C, $k = 1.9 \times 10^{-5}\ s^{-1}$; t = 150°C, $k = 7.5 \times 10^{-6}\ s^{-1}$.

pared to **1**. Unfortunately, the thermolysis of **5** was accompanied by side reactions and hence a systematic investigation of the rearrangement kinetics could not be achieved. However, a qualitative indication of the expected greater reativity of **5** was obtained. The ^{1}H nmr spectrum of a solution of **5** that had been heated to 160°C for 4 min showed a complete absence of the signal for the aldehydic proton of **5**, whereas at the same temperature **1** has a half-life of approximately 25 min. The rearrangement thus shows a definite steric dependence. Changing the degree of steric congestion at the two adjacent quaternary centres dramatically affects the rate of the rearrangement.

The enthalpy and entropy of activation for the rearrange-

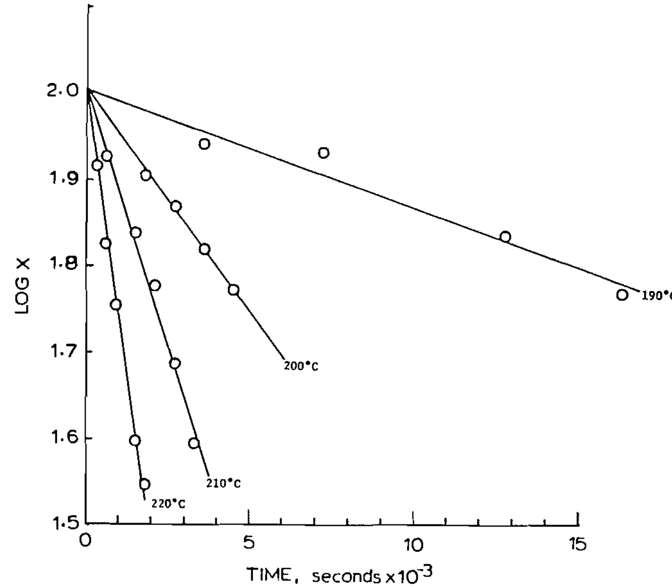

FIG. 5. Rate of rearrangement of **8**: X = 100([**8**]/[**8** + **23**]) as determined by glc analysis. t = 220°C, $k = 6.60 \times 10^{-4}\ s^{-1}$; t = 210°C, $k = 2.82 \times 10^{-4}\ s^{-1}$; t = 200°C, $k = 9.47 \times 10^{-5}\ s^{-1}$; t = 190°C, $k = 3.17 \times 10^{-5}\ s^{-1}$.

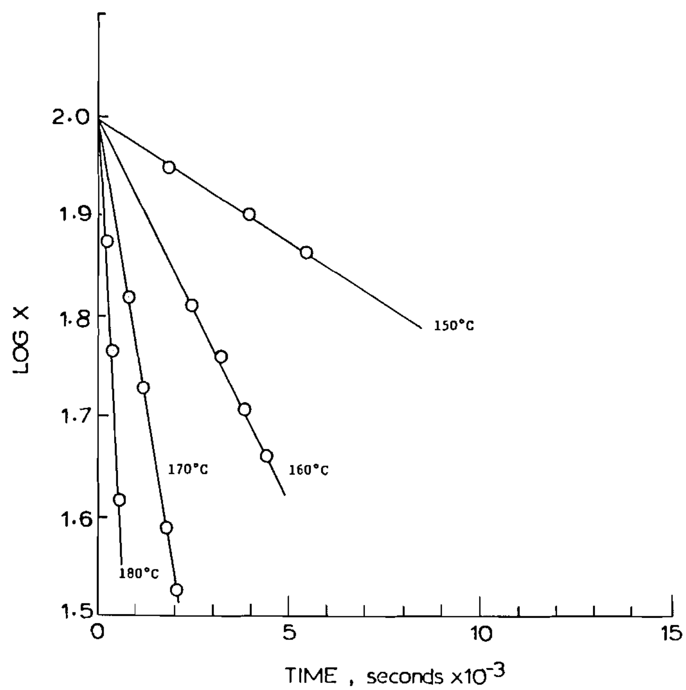

FIG. 6. Rate of rearrangement of **9**: X = 100([**9**]/[**9** + **14**]) as determined by glc analysis. t = 180°C, $k = 1.89 \times 10^{-3}\ s^{-1}$; t = 170°C, $k = 5.15 \times 10^{-4}\ s^{-1}$; t = 160°C, $k = 1.90 \times 10^{-4}\ s^{-1}$; t = 150°C, $k = 5.23 \times 10^{-5}\ s^{-1}$.

ments of **1**, **4**, **6**, **8**, and **9** were calculated from the Eyring equation (21) using the data obtained from Fig. 7 and are summarized in Table 3. The substantial positive values of $\Delta S^{\#}$ in the systems studied appear to be inconsistent with the various concerted mechanisms proposed for the rearrangement. However, it is not yet possible to absolutely preclude either an ionic or radical pathway.

The nitrile and ester functional groups are essentially equal in their ability to stabilize an adjacent negative charge, as

TABLE 3. Rearrangement activation parameters

Compound	Temperature range (°C)	$\Delta H^{\#}$ (kJ mol^{-1})	$\Delta S^{\#}$ (J deg^{-1} mol^{-1})
1	130–170	165	69
4	130–160	157	52
6	150–190	180	79
8	190–220	190	75
9*	150–180	184	106

*The kinetics used to obtain these activation parameters are uncorrected for small (<3%) amounts of methyl 2,2-bis(ethylthio)acetate formed during the rearrangement.

evidenced by their similar acidities. Both compounds have pK_a's of approximately 25 (22). An aldehyde (pK_a ~17) can stabilize an adjacent negative charge even more efficiently than either of these groups. Thus, if the rearrangements are ionic in nature, both **8** and **9** might be expected to rearrange at comparable rates, which in turn would be significantly slower than the rate of rearrangement for aldehyde **1**. In contrast, if a radical process is involved, rate differences between all three compounds might be expected. Recently Dust and Arnold (23) have shown that nitriles are less able to stabilize an adjacent radical site than are esters. It has further been shown that a methyl ketone, and thus by implication an aldehyde, is superior to either a nitrile or an ester in this stabilizing effect. Thus compounds **1**, **8**, and **9** would be expected to rearrange at different rates if a radical process is operating. Indeed, as can be seen in Figs. 2, 5, and 6, the rate of rearrangement of ester **9** is less than half that of aldehyde **1** over the temperature range studied, and the nitrile **8** is even slower. For example, at 180°C, **8** did not rearrange to any significant extent, whereas the half-life of ester **9** at this temperature is approximately 6 min. This observation of a rate difference with functional group substitution is more consistent with a radical pathway than the ionic scheme.[8]

A crossover experiment then was conducted in order to determine whether the rearrangements were proceeding via an inter- or an intramolecular pathway. A 2:1 mixture of ester **9** and deuterated aldehyde **7** was thermolyzed in degassed tetradecane at 160°C for 4 h to ensure complete rearrangement of the starting materials. The reaction mixture was separated into its rearranged ester and aldehyde components using preparative thin-layer chromatography, and the purified products analyzed by mass spectrometry in order to assess the extent of deuterium incorporation in the reaction products. The ratio of the parent ion of the protiated (m/e 262) and deuterated (m/e 268) esters was found to be 22.0:5.6. This ratio is consistent wth 20% deuteration of the vinyl methyl groups of **14**.

A similar analysis of the rearranged aldehyde established that the vinyl methyl groups of **2** were now 37% deuterated. Control experiments were performed in order to ensure that the observed scrambling was a result of only the primary fragmentation process. A mixture of deuterated aldehyde **7** and rearranged ester **14** was thermalized at 160°C for 4 h. In a second experiment a mixture of rearranged deuterated aldehyde **22** and protiated ester **14** was also thermolyzed under the same conditions. Analysis of the products of both control reactions by mass spectrometry revealed that no crossover products had been formed in either case.

[8]The above conclusion is based on the assumption that there is no secondary steric influence (linear nitrile vs. bent aldehyde and ester substituents) on the rates of rearrangements of these compounds.

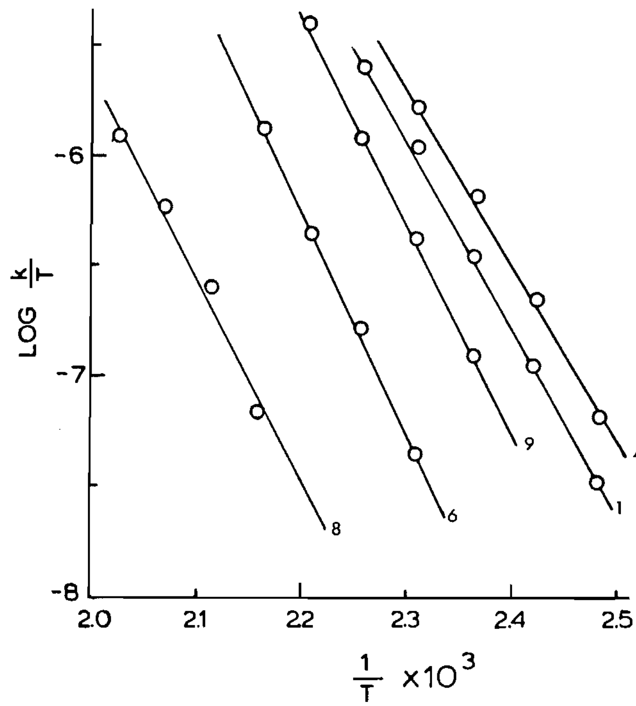

FIG. 7. Dependence of temperature of the rate constants for the rearrangements of **1**, **4**, **6**, **8**, and **9**.

The rearrangement of aldehyde **1** was also carried out in perdeuterio *N*,*N*-dimethylformamide (DMF-d_7). The rate of rearrangement of **1** was found to change by a factor of less than 1.5 with this drastic change in solvent from decane to DMF-d_7. The demonstrated intermolecular nature of the rearrangement, combined with the lack of any significant solvent effect, is clearly inconsistent with the rearrangement being accompanied by any charge separation in the transition state and thus the ionic process may be ruled out.[9] In order to confirm the proposed intermediacy of free-radical intermediates in the rearrangement, further evidence (both chemical and spectroscopic) was sought. It had been noted that the reaction product following thermolysis of ester **9** often contained a small (<3%) amount of methyl 2,2-bis(ethylthio)acetate. The formation of this compound is consistent with hydrogen atom abstraction from the solvent or other source by the proposed radical intermediate. Thermolysis of the more readily available aldehyde **1** was accordingly carried out in the presence of cumene in an attempt to intercept any radical intermediates. Although the rearrangement proceeded as usual, no evidence of hydrogen abstraction products was observed. However, when a superior

[9]See ref. 24 for an alternate view of the mechanistic significance of the lack of a solvent effect on the rate of a reaction.

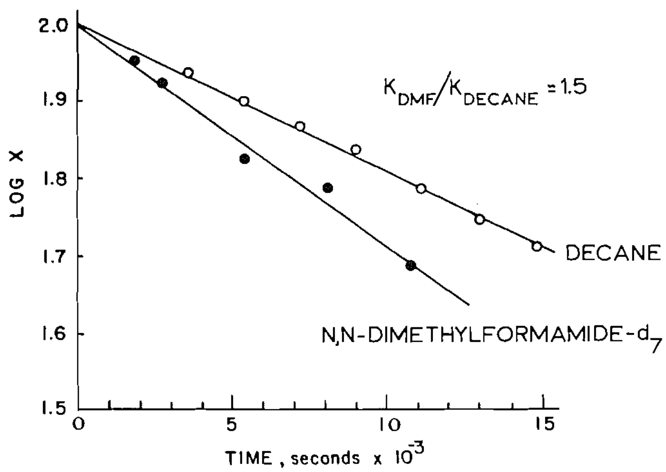

FIG. 8. Solvent effect on the rate of rearrangement of **1** at 140°C. k (decane) = 4.51×10^{-5} s^{-1}; k(DMF-d_7) = 6.52×10^{-5} s^{-1}.

hydrogen atom donor, 1,4-cyclohexadiene, was substituted for cumene the reaction mixture (2.5 h, 145°C, ca. one half-life) contained approximately 45% unreacted starting material, 25% rearranged aldehyde **2**, and 30% 2,2-bis(ethylthio)ethanal. Thus more than half of the proposed radical intermediate **12** had been trapped by the hydrogen donor solvent. This result is consistent therefore both with the free-radical as well as the intermolecular nature of the rearrangement.

Two of the most widely used techniques for the spectroscopic detection of free radicals are Chemically Induced Dynamic Nuclear Polarization (CIDNP) and electron spin resonance (esr) spectroscopy (25). Both techniques were employed in an attempt to further confirm the radical nature of the rearrangement process.

The CIDNP technique is based on the perturbation of the ^{1}H nmr signal intensity by free radicals in the system. No enhancement of any ^{1}H nmr signals was observed when a solution of **1** in decahydronaphthalene-d_{18} was heated at 170°C in the probe of an ^{1}H nmr spectrometer. However, lack of CIDNP enhancement does not rule out the possibility of radical intermediates being involved in the rearrangement.

When a solution of **1** in tetradecane was heated at 150°C in the cavity of an esr spectrometer a strong esr signal was observed (Fig. 9). This signal consisted of an apparent six-line spectrum with a hyperfine coupling of approximately 1.7 G. The line shape and hyperfine coupling were clearly inconsistent with a signal arising from the dimethylallyl radical **13** (26). However, the four hydrogens of the methylene groups and the aldehydic hydrogen of the radical **12** would be expected to couple to the free radical to produce the observed spectrum. The methylene hydrogens can interact with the free radical since considerable delocalization of the free radical onto the sulfur atom through a $p\pi - d\pi$ interaction is expected. The observed hyperfine coupling constant (1.7 G) is within the range expected for such a system. For example, the methyl protons of the methyl sulphide free radical have a hyperfine coupling constant of 3.25 G (27) and the aldehydic hydrogen of the ethanal free radical experiences a hyperfine coupling of ca. 0.5 G (28). Several unsuccessful attempts were made to record an esr spectrum of radical **13** during the rearrangement of aldehyde **1**.

Indeed, a computer simulation of the observed spectrum, assuming two pairs of diastereotopic methylene hydrogens with hyperfine couplings of 1.80 and 1.60 G, respectively, and an aldehydic hydrogen (1.90 G) coupled to a radical, produces a spectrum virtually identical to that observed experimentally. Electron spin resonance signals were also observed during the thermolyses of nitrile **8** (Fig. 10) and ester **9** (Fig. 11). Computer simulation of these signals (nitrile: methylene hyperfine couplings of 1.17 and 1.55 G, nitrogen hyperfine coupling of 2.50 G; ester: methylene hyperfine couplings of 1.50 and 1.70 G, methyl hyperfine coupling of 0.80 G) also yielded excellent agreement with the experimentally obtained spectra.

The lack of observation of an esr signal for the dimethylallyl radical **13** as well as the cleanness, i.e., no random coupling products, of this clearly intermolecular rearrangement is inconsistent with the formation of a *large* number of radical pairs via homolysis of **1**. However, the initial homolytic cleavage of a *small* number of molecules, followed by attack of the thioketal radical **12** on a molecule of **1** at the vinyl position in a *chain reaction*, is consistent with all of the available data. The reaction between **12** and **1** would result in the release of a fresh chain-carrying radical **12** as well as the concomitant inversion of the alkene side chain during the formation of the rearrangement product **2** (Fig. 12).

On the basis of the sign and magnitude of the entropy of activation for the reaction, the lack of any significant solvent effect, the trends arising from electronic perturbation of the system, and the spectroscopic observations, we propose that the compounds under study undergo a thermally induced homolytic cleavage to form two stabilized radicals, a tertiary allylic fragment and a capto-dative stabilized fragment. This latter radical then initiates a smooth, intermolecular chain reaction, which results in the formation of the product of an apparent [1,3] sigmatropic rearrangement.

Experimental

General

All reactions were carried out under an argon or nitrogen atmosphere. Stirring was accomplished using Teflon-coated magnetic stirring bars. Tetrahydrofuran was freshly distilled from sodium benzophenone ketal under a nitrogen atmosphere. All extraction, chromatography, and reaction solvents were distilled before use. Petroleum ether refers to the 30–60°C boiling fraction.

All temperatures are stated in degrees Celsius. Molecular distillations were performed by means of a Büchi Kugelrohr apparatus. Proton magnetic resonance (^{1}H nmr) spectra were obtained on one or more of the following instruments: Varian Associates T-60, EM-360L, and HA-100. Spectra were recorded in deuteriochloroform or carbon tetrachloride solution with tetramethylsilane as an internal reference. Chemical shifts are reported on the δ scale. The multiplicity, integrated peak area, and coupling constants in Hertz (Hz) (if observable) are indicated in parentheses after each signal. Infrared spectra were recorded as liquid films using a Perkin–Elmer 700 spectrometer, and were calibrated with the 1601 cm^{-1} band of polystyrene. High resolution mass spectra were obtained using an AEI MS-50 mass spectrometer. Electron spin resonance (esr) spectra were recorded on an instrument that consisted of a variable temperature 30-cm Varian magnet with an Mk II field-dial control, a Hewlett–Packard Klystron power supply and sweep unit, and a home-built AFC and 100-kHz modulation unit with an Ithanco 391A phase-lock amplifier, which was typically operated at 3210.0 ± 12.5 G, 2–5 mW microwave power, and 0.5 G modulation at 100 kHz. Computer simulations were executed using techniques described in ref. 29. Elemental analyses were performed at the Microanalytical Laboratory, University of British Columbia.

Merck Silica Gel HF-254 was used for preparative thin-layer chromatography while Merck pre-coated tlc sheets Silica Gel 60F-254 were used for analytical thin-layer chromatography. Florisil

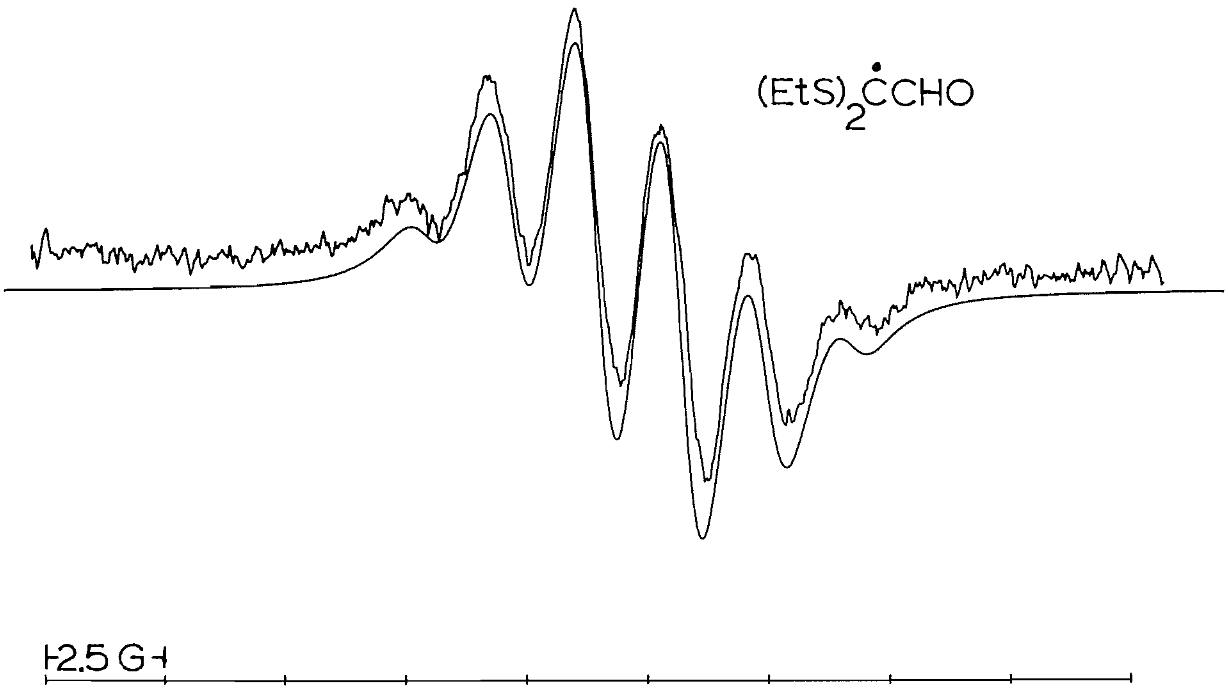

FIG. 9. The esr spectrum recorded during thermolysis of **1** (150°C) (smooth curve = simulated spectrum).

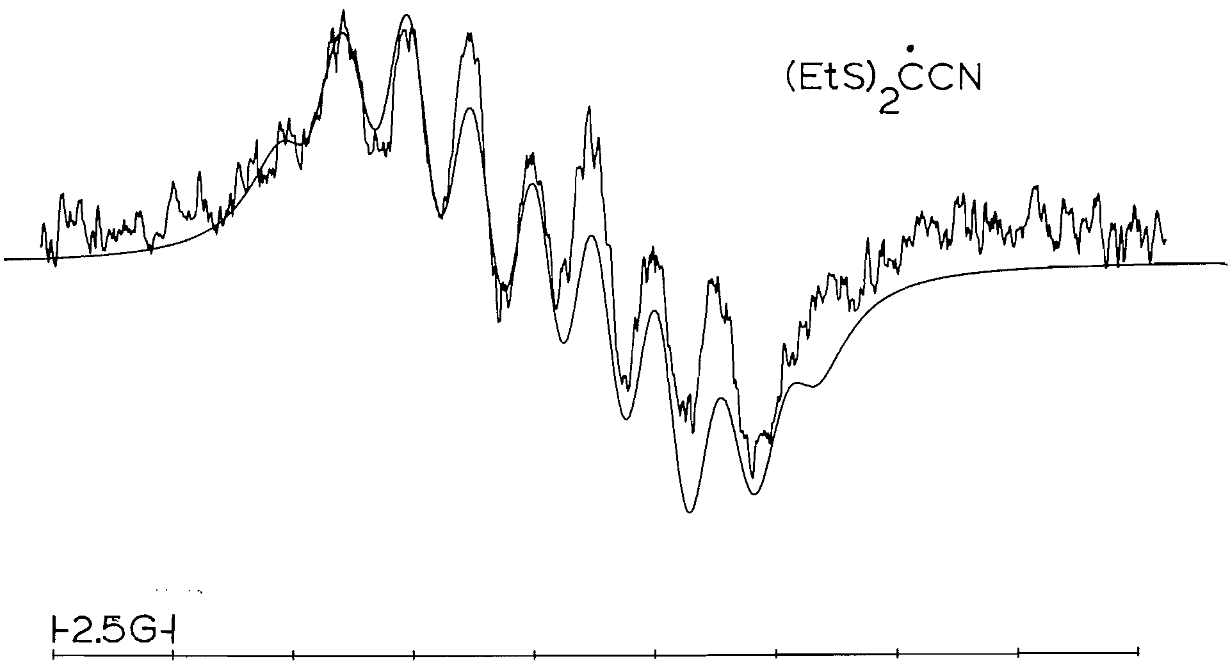

FIG. 10. The esr spectrum recorded during thermolysis of **8** (160°C) (smooth curve = simulated spectrum).

(100–200 mesh) and Merck Silica Gel 60 (230–400 mesh) were used for column chromatography. All chromatography solvent systems are expressed in ratios by volume.

Analytical gas chromatography was carried out on a Hewlett–Packard model 5830-A chromatograph equipped with 1.8 m × 0.3 cm columns packed with 3% OV-17 or 3% OV-101 or 5% Carbowax.

Thermolyses were conducted in ^{1}H nmr tubes or small ampoules heated in an insulated, stirred oil bath that was heated by means of an immersed Nichrome heater. Temperature control was achieved using an I^{2}R Thermowatch controller model L7-1100B that had been modified for use with a 0–300°C mercury contact thermometer supplied by SGA Scientific, Inc. The temperature control is estimated to be ±1°C.

The following abbreviations are used in the description of the multiplicity of each signal in the ^{1}H nmr spectrum: s = singlet, d = doublet, t = triplet, q = quartet, sept = septet, m = multiplet, dd = doublet of doublets, dt = doublet of triplets, dm = doublet of multiplets, b = broad.

The following experimental description illustrates the general procedure that was used to prepare the non-commercially available allylic bromides required for the synthesis of the rearrangement precursors and their products.

1-Bromo-3-ethylpent-2-ene

Magnesium turnings, 5 g (208 mmol), stirred in 10 mL of tetrahydrofuran were activated by the addition of a few drops of 1,2-

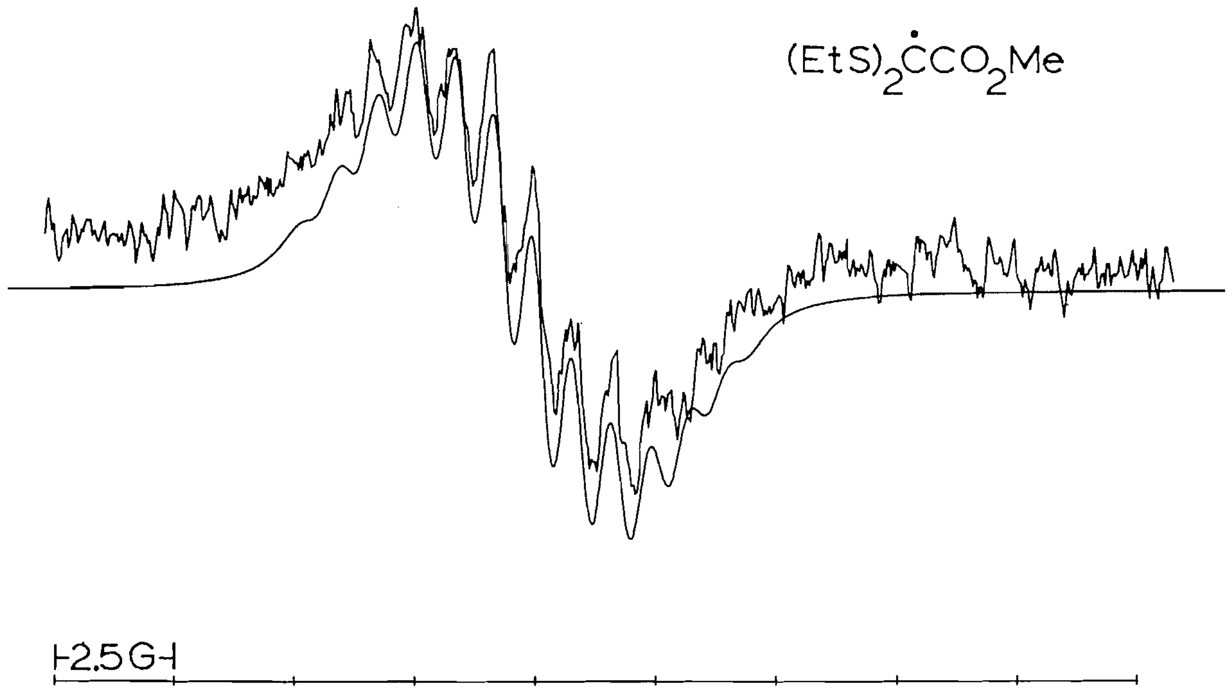

FIG. 11. The esr spectrum recorded during thermolysis of **9** (160°C) (smooth curve = simulated spectrum).

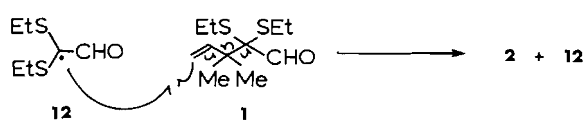

FIG. 12. Proposed free radical chain mechanism for the rearrangement of **1** into **2**.

dibromoethane. Then 15 g (127 mmol) of bromoethene was added over 0.5 h at such a rate as to maintain a gentle reflux. An additional 50 mL of tetrahydrofuran were added when the reaction was proceeding well. It was necessary to occasionally cool the reaction mixture in an ice bath in order to moderate the reaction. After the addition of the bromoethene was complete the reaction mixture was stirred for a further 1 h before an additional 50 mL of tetrahydrofuran were added. The reaction mixture was cooled to 0°C, and 15 g (104 mmol) of 3-pentanone were added over 0.5 h. The reaction mixture was stirred for an additional 1 h and then quenched with aqueous saturated NH_4Cl. The reaction mixture was diluted with 200 mL of ethyl ether, washed with 2 × 40 mL of H_2O, and dried ($MgSO_4$). The solvent was evaporated under reduced pressure to afford 10.5 g (92%) of 3-ethyl-4-penten-3-ol.

A mixture of 5.7 g (50 mmol) of the 3-ethyl-4-penten-3-ol prepared above and 8 g (ca. 100 mmol) of aqueous 48% HBr in 100 mL of pentane was stirred vigorously for 2 h. The reaction mixture was transferred to a separatory funnel and the aqueous phase was removed. The organic phase was washed with 2 × 25 mL of H_2O and dried ($MgSO_4$). The solvent was evaporated under reduced pressure at 0°C and the residual oil molecularly distilled to afford 5.9 g (66%) of 1-bromo-3-ethylpent-2-ene as a colourless liquid that was stored at −15°C until further use; bp (molecular distillation) 60°C/10 Torr (1 Torr = 133.3 Pa); infrared: 1650 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.00 (t, 3, J = 7), 1.03 (t, 3, J = 7), 2.13 (m, 4), 4.05 (d, 2, J = 8), 5.48 (bt, 1, J = 8). *Mol. Wt.* calcd. for $C_7H_{13}Br^{81}$: 178.0162; found: 178.0160.

*Standard procedure for the preparation of compounds **1** and **3**–**8***

These compounds were prepared by a modification of the procedure of Ogura *et al.* (18).

A mixture of 10 mmol of the diethylthioketal, 10 mmol of the allylic bromide, and 15 mmol of Li_2CO_3 in 5 mL of *N*,*N*-dimethylformamide was stirred for 1–6 days under a nitrogen atmosphere. The reaction mixture was diluted with petroleum ether, washed several times with H_2O, and dried ($MgSO_4$). The solvent was evaporated under reduced pressure and the product purified by flash chromatography on silica gel using 10% ethyl acetate in petroleum ether (v/v) as the eluting solvent.

Methyl 2,2-bis(ethylthio)-3,3-dimethylpent-4-enoate (9)

To a solution of 0.292 g (ca. 1.5 mmol) of $AgBF_4$ in acetonitrile was added 0.30 g (1.55 mmol) of methyl 2,2-bis(ethylthio)acetate (31) followed by 0.19 g (1.25 mmol) of 1-bromo-3-methylbut-2-ene. An immediate yellow precipitate resulted. The reaction mixture was stirred for 3 h at room temperature and then 0.300 g (ca. 2 mmol) of diazabicyclo[3.3.0]undecene was added and the reaction mixture was stirred for an additional 3 h. The reaction mixture was diluted with petroleum ether and centrifuged. The clear organic phase was washed with 2 × 2 mL of aqueous 2 N HCl, 2 mL of H_2O, and dried ($MgSO_4$). The solvent was evaporated under reduced pressure to afford a pale yellow oil, which upon flash chromatography on silica gel using 5% ethyl acetate in petroleum ether (v/v) as the eluting solvent afforded 0.117 g (42%) of compound **9**; bp (molecular distillation) 80°C/0.1 Torr infrared: 1727 cm^{-1}; ^{1}H nmr ($CDCl_3$): δ: 1.18 (t, 6, J = 7), 1.24 (s, 6), 2.63 (q, 4, J = 7), 3.72 (s, 3), 5.02 (dd, 1, J = 18, 1), 5.02 (dd, 1, J = 10, 1), 6.17 (dd, 1, J = 18, 10). *Anal.* calcd. for $C_{12}H_{22}O_2S_2$ (262.437): C 54.92, H 8.45, S 24.44; found: C 54.67, H 8.55, S 24.17. *Mol. Wt.* calcd. for $C_{12}H_{22}O_2S_2$: 262.1061; found: 262.1066.

The reference standards for the products of the rearrangement were prepared according to procedures developed in this laboratory and published previously (aldehydes, ref. 6; nitrile, ref. 20). The following data are for previously unreported compounds.

2,2-Bis(ethylthio)-5-methyl-d$_3$-hex-4-enal-6-d$_3$ (22): bp (molecular distillation) 70°C/0.1 Torr infrared: 1715 cm^{-1}; ^{1}H nmr ($CDCl_3$): δ: 1.23 (t, 6, J = 7), 2.55 (q, 4, J = 7), 2.58 (d, 2, J = 6.5), 5.28 (t, 1, J = 6.5), 9.05 (s, 1). *Mol. 2,2-(1′,3′-Propanedithio)-5-methylhex-4-enal (21)

This compound was prepared in 64% overall yield by modification of the metalloenamine procedure (6) usine 2,2-(1′,3′-propanedithio)-ethanal (32) as the starting material; bp (molecular distillation) 80°C/0.1 Torr; infrared: 1715 cm^{-1}; ^{1}H nmr ($CDCl_3$): δ: 1.61 (s, 3), 1.66 (d, 3, J = 1.5), 2.02 (m, 2), 2.54 (m, 4), 3 (m, 2), 5.12 (tm, 1), 9.04 (s, 1). *Anal.* calcd. for $C_{10}H_{16}O_2$ (216.367): C 55.51, H 7.45, S 29.64; found: C 55.77, H 7.55, S 29.38. *Mol. Wt.* calcd. for $C_{10}H_{16}OS_2$: 216.0643; found: 216.0641.

*Kinetic studies on the rearrangements of **1**, **4**, **6**, **8**, and **9***

*Aldehydes **1**, **4**, and **6***

A solution of 0.04 g of freshly purified aldehyde in 0.300 mL of freshly distilled tetradecane (or decane or N, N-dimethylformamide-d_7) in a ^{1}H nmr tube, which has been dried at 120°C and cooled in a stream of argon, was degassed by bubbling argon through the solution for 0.5 h. The tube was capped with a rubber serum cap carrying an inlet needle for argon and the tube was placed in a constant-temperature oil bath. The tube was periodically removed from the oil bath and immersed immediately in an ice-water bath to quench the reaction. The reaction progress was analyzed by ^{1}H nmr spectroscopy.

*Nitrile **8** and ester **9***

The relative gas chromatographic detector responses of the starting materials and the products were established by injecting aliquots of known mixtures of the starting material and products.

A solution of 0.005 g of the compound in 0.100 mL of tetradecane in a 4 cm × 0.5 cm tapered ampoule, which had been dried at 120°C and cooled in a stream of argon, was degassed by bubbling argon through the solution for 0.5 h. The ampoule was fitted with a rubber serum cap carrying an inlet needle for argon and the ampoule was immersed in a constant temperature oil bath. Sample aliquots were removed peridically using a microsyringe and the samples analyzed by gas chromatography to determine the progress of the reaction.

Crossover experiments

A solution of 0.012 g (0.05 mmol) of aldehyde **7** and 0.026 g (0.1 mmol) of ester **9** in 0.300 mL of freshly distilled tetradecane in a tube was degassed by bubbling argon through the solution for 0.5 h. The tube was fitted with a rubber serum cap fitted with an inlet needle for argon and was heated at 160°C for 4 h. The reaction mixture was cooled and then transferred onto a 10-g column of Florisil. Initial elution of the column was performed with 50 mL of petroleum ether in order to elute the hydrocarbon solvent. Then elution with 5% ethyl acetate in petroleum ether (v/v) provided a mixture of the reaction products. The mixture was separated by preparative thin-layer chromatography on silica gel using 10% ethyl acetate in petroleum ether (v/v) as the eluting solvent to provide 0.007 g of the rearranged aldehydes, and 0.012 g of the rearranged esters.

Aldehyde mixture

High resolution mass spectrometry:

m/e	% Intensity
238.1327 ($C_{11}H_{14}OS_2D_6$)(M^{*+})	9.0
232.0957 ($C_{11}H_{20}OS_2$)(M^+)	5.2

Ester mixture

High resolution mass spectrometry:

m/e	% Intensity
268.1434 ($C_{12}H_{16}O_2S_2D_6$)(M^{*+})	5.6
262.1061 ($C_{12}H_{22}O_2S_2$)(M^+)	22.0

Control experiments

1. A solution of 0.012 g (0.05 mmol) of aldehyde **7** and 0.026 g (0.1 mmol) of ester **14** in tetradecane was heated at 160°C for 4 h and worked up as above to provide 0.08 g of aldehyde **22** and 0.018 g of ester **14**.

2. The above experiment was repeated with 0.012 g (0.05 mmol) of aldehyde **22** and ester **14**.

In neither case were any crossover products observed by ^{1}H nmr or mass spectral analysis.

Trapping experiment

A solution of 0.232 g (1.0 mmol) of aldehyde **1** in 2.0 mL of 1,4-cyclohexadiene and 2.0 mL of freshly distilled decane in a thick-walled glass tube was degassed with argon and sealed. The tube was heated at 145°C for 2.5 h, cooled to 0°C, and opened. The reaction mixture was concentrated by evaporation at water aspirator pressure to remove the 1,4-cyclohexadiene and any benzene formed in the reaction. An ^{1}H nmr spectrum (δ 3.0−11.0) of the reaction mixture indicated that it consisted of a clean mixture of starting aldehyde **1** (45%), rearranged aldehyde **2** (25%), and 2,2-bis(ethylthio)ethanal (30%).

The syntheses of the arylindium compounds L_2InX (X = Cl, I), L_2InR (R = CH_3, C_6H_5), L_3In and $L_2InSnPh_3$ (L = 2-[(dimethylamino)methyl]phenyl) are reported. The pathway of the redistribution reactions involving $InCl_3$ and L_3In are discussed. Mass and ^1H nmr spectra are reported.

RICHARD S. STEEVENSZ, DENNIS G. TUCK, HARRY A. MEINEMA et JAN G. NOLTES. Can. J. Chem. **63**, 755 (1985).

On rapporte la synthèse de composés arylindium des types L_2InX (X = Cl, I), L_2InR (R = CH_3, C_6H_5), L_3In et $L_2InSnPh_3$ (L = [(diméthylamino)méthyl]-2 phényle). On discute des voies des réactions de redistribution impliquant le $InCl_3$ et le L_3In. On rapporte les spectres de masse et de rmn du ^1H.

[Traduit par le journal]

Introduction

This paper, and those published earlier (1, 2), represent the intersection of studies of complexes with the bidentate 2−[(dimethylamino)methyl]phenyl ligand (= L) on the one hand, and investigations of the chemistry of indium on the other. The coordination chemistry of organoindium(III) compounds and their complexes has been of considerable recent interest, and four-, five-, and six-coordinate species are now known (3). We have recently reported the preparation and X-ray crystallographic study of the five coordinate L_2InCl (1), and nmr investigations have established the fluxional behaviour of this and related molecules in solution (2).

The present investigation has focussed on the preparation of L_3In, L_2InR (R = CH_3, C_6H_5), and the use of L_2InCl as a starting point in the synthesis of In—M bonds.

Experimental

General

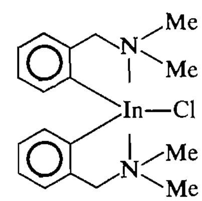
All solvents were purified and dried over sodium. Reactions were carried out under dry nitrogen. Nuclear magnetic resonance spectra were obtained on JEOL C6OHL, Varian EM360, or Bruker CXP-100 spectrometers, using tetramethylsilane as internal standard. Infrared spectra were run on a Beckman IR-12 spectrometer, using KBr or CsI cells, and mass spectra on a Varian MAT CH-5DF instrument operating in the field desorption (FD) or electron impact (EI) modes. The lithiation of (dimethylamino)methylbenzene (HL) followed the procedure described elsewhere (4, 5).

Preparation of tris{2-[(dimethylamino)methyl]phenyl}indium (L_3In)

Indium(III) chloride (1 g, 5.0 mmol) was added to a fresh preparation of LiL (22 mmol) in 60 mL diethyl ether. The reaction mixture was stirred for a period of 3 h, after which the white suspension was filtered and the ether solution evaporated to dryness. The sticky solid residue was redissolved in benzene, filtered, and the solution concentrated to give a quantitative yield of $In[C_6H_4CH_2N(CH_3)_2\text{-}2]_3$ as colourless crystals which were washed with cold petroleum ether (30−60°C) and dried *in vacuo*. *Anal.* Calcd.: In 22.2; found: In 21.9. Nuclear magnetic resonance results are given in Table 1.

Preparation of bis{2-[(dimethylamino)methyl]phenyl}indium chloride (L_2InCl) (I)

(*a*) Freshly prepared LiL (0.22 mol) was added dropwise over 45 min to a suspension of indium(III) chloride (24.0 g, 0.11 mol) in 100 mL of diethyl ether. An exothermic reaction was observed during the addition, resulting in a brown suspension. The mixture was stirred



I

for 24 h at room temperature, after which the light brown mixture was filtered and the residue washed with benzene (3 × 100 mL). The volume of the agglomerated benzene phase was reduced to 50 mL, and the white solids which formed were collected, washed with cold petroleum ether (30−60°C), and dried *in vacuo*. The benzene filtrate was further reduced in volume and again treated with petroleum ether, resulting in additional solid. A total yield of 32.0 g (74%) of $ClIn[C_6H_4CH_2N(CH_3)_2]_2$ was obtained. Melting point 190−191°C. *Anal.* calcd.: In 27.4, Cl 8.48; found: In 27.6, Cl 8.39. The nmr spectrum is tabulated in Table 1.

(*b*) Solid $InCl_3$ was added to a solution containing InL_3 in 30 mL diethyl ether. In the initial stage of the reaction, $InCl_3$ was seen to dissolve but after 24 h at room temperature, L_2InCl was present as a suspended crystalline product which was separated by vacuum filtration and dried *in vacuo*. When the quantities of $InCl_3$ (0.37 g, 1.7 mmol) and L_3In (1.7 g, 3.3 mmol) corresponded to those required for the process $InCl_3 + 2L_3In \rightarrow 3L_2InCl$, the yield of L_2InCl was essentially quantitative. In a later experiment, $InCl_3$ (1.50 g, 6.8 mmol) was used in excess over L_3In (1.09 g, 2.1 mmol), but L_2InCl was the only product isolated and no evidence was obtained for the presence of $LInCl_2$ in the reaction mixture.

Preparation of bis{2-[(dimethylamino)methyl]phenyl} indium iodide (L_2InI)

A solution of InI_3 (5.0 g, 2.0 mmol) in diethyl ether (30 mL) was treated with 2 equiv. of freshly prepared LiL in the same solvent (24 h, room temperature). The colour of the InI_3 solution underwent a series of changes following the addition of LiL, from light yellow through red and then brown to a final colourless solution. The final isolation of L_2InI followed the method used for L_2InCl. *Anal.* calcd. for $C_{20}H_{24}NInI$: In 22.1, I 24.4; found: In 22.2, I 23.8.

Preparation of bis{2-[(dimethylamino)methyl]phenyl}methyl indium (L_2InMe)

A suspension of L_2InCl (0.46 g, 1.10 mmol) in 50 mL diethyl ether was treated with methyllithium (1.2 mmol) in diethyl ether, added in one operation at room temperature. The solid L_2InCl immediately

$Li[L_2In(CH_3)_2]$	FD	383	L_2In^+	517 (L_3In^+); 134 (L^+)

[a]EI = electron impact, FD = field desorption.
[b]All masses quoted as nearest integers; identification based on most abundant isotope of each atom.

dissolved, but after less than 30 s fine white particles of LiCl began to appear. After 24 h, LiCl was removed by filtration and ether was evaporated off, leaving a colourless crystalline solid. The crude material was redissolved in benzene, filtered, and concentrated. Subsequent trituration of the sticky solids with cold petroleum ether (0°C), produced $[C_6H_4CH_2N(CH_3)_2\text{-}2]_2InCH_3$ as a white powder which was dried *in vacuo*. Yield 0.35 g (77.0%). Alternatively, the initial solid was dissolved in benzene, and the solution cooled *in vacuo* to precipitate any residual solids which were removed by filtration. After repeating this sequence a number of times, the final product was obtained by crystallizing from cold (0°C) petroleum ether. *Anal.* calcd. for $C_{19}H_{27}N_2In$: In 28.9; found: In 29.4. This compound reacts with deuterated chloroform/TMS, apparently undergoing complete decomposition in ca. 10 min, but nmr spectra confirming the structure were obtained in C_6D_6 (see Table 2).

Preparation of bis{2-[(dimethylamino)methyl]phenyl}indium tin triphenyl ($L_2InSnPh_3$)

Triphenyltin chloride (1.9 g, 4.8 mmol) was added to a solution of sodium (0.22 g, 9.7 mmol) in 70 mL liquid ammonia at −78°C. The mixture was stirred for 30 min and then allowed to reach room temperature. The yellow−brown residue (Ph_3SnNa) was taken up in diethyl ether, the solution cooled to −78°C and L_2InCl (2.0 g, 4.8 mmol) added, as a solution in diethyl ether (15 mL), plus 5 mmol of pyridine. During a period of 3 h stirring, the yellow colour faded, giving a colourless mixture. The mixture was allowed to reach room temperature, solvent was removed by evaporation, and the resultant residue extracted with petroleum ether (30−60°C). The material obtained on evaporation of the filtrate was recrystallised from petroleum ether/diethyl ether mixtures to give $L_2InSnPh_3$ in 62% yield. *Anal.* calcd. for $C_{36}H_{39}N_2InSn$: In 15.7, Sn 16.2; found: In 16.1, Sn 16.6. Mass, vibrational, and [1]H nmr spectra, discussed below, confirm the identity of this compound.

When Ph_3SnLi was used instead of Ph_3SnNa in this preparation, the products included a tin compound (Sn content 55.7%) containing only aromatic groups ([1]H nmr), plus a metallic deposit and a compound shown to be L_2InPh. *Anal.* calcd. for $C_{24}H_{29}N_2In$: In 24.9, found: In 25.0. See below for mass spectrum.

Results and discussion

Preparative

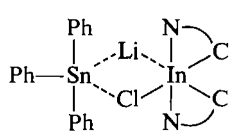
A number of points concerning the synthesis of L_3In and L_2InCl require discussion. The selective formation of either L_2InCl or L_3In is affected both by the mode of addition and by the concentration. The slow addition of 2-[(dimethylamino)-methyl]phenyl lithium (LiL) to indium trichloride produces an exothermic reaction, in which the initial tan coloured precipitate slowly turns brown. Under these conditions (LiL:$InCl_3$ mole ratio 2:1) the predominant product is L_2InCl, with little or no by-products present. Reversal of this order, that is the addition of $InCl_3$ to LiL, produces a less selective reaction, in that both L_3In and L_2InCl are formed. We also found that the rapid addition of LiL to indium trichloride (overall mole ratio LiL:$InCl_3$ = 4:1) resulted in the formation of L_2InCl and L_3In in a 2:3 ratio after 6 h, but that after 24 h, the intermediary L_2InCl complex was totally converted to L_3In. Conversely, when $InCl_3$ was added to LiL (same overall mole ratio) the reaction was complete within 3 h at room temperature, with no L_2InCl being identified.

The course of these processes, and the relative ratios of L_2InCl and L_3In in the reaction mixture, are readily estimated by utilizing the differences in the ^1H nmr spectra of the two compounds in the 2−4 ppm region (see Table 1). The isolation and purification of the complexes is facilitated by their solubilities; both are soluble in ether, but L_2InCl is only slightly soluble in benzene, and even less so in petroleum ether (30−60°C). The less polar L_3In complex is very soluble in diethyl ether and only partially soluble in petroleum ether. Both compounds are relatively stable in dry air for several hours, but readily decompose in the presence of moisture.

An interesting feature of the redistribution reactions between L_3In and $InCl_3$ is that the potentially four-coordinate compound $LInCl_2$ could not be isolated. In contrast, the reaction of triphenylindium and indium trichloride (1:2 mole ratio) gives a quantitative yield of $PhInCl_2$, as does the reaction of Ph_2InCl and $InCl_3$ (1:1 mole ratio) (6, 7). The inability of L_2InCl to react with $InCl_3$ is presumably due to the stable five-coordination of the former in both solid (1) and solution (2) states. The presence of the internal $—CH_2NMe_2$ group in L_2InCl may also be important, since its coordinating properties have been shown to influence product formation in the redistribution reactions of aryltin compounds (8).

The reaction between L_2InCl and MeLi gives L_2InMe in reasonably good yield, but side-products, which on the evidence of ^1H nmr spectra may include $LInMe_2$, are also formed. The reaction pathway presumably involves the intermediate $Li[L_2In(Cl)Me]$, and in this context we note that the addition of MeLi to InL_3 in diethyl ether at room temperature produces a variety of compounds, including the analogous $Li[L_2InMe_2]$. *Anal.* calcd. for $C_{20}H_{30}N_2InLi$: In 27.3, Li 1.65; found: In 26.9, Li 2.02.

Hydrogenolysis reactions of metal−carbon bonds (alkane elimination) have been widely used in the synthesis of organometallic compounds containing metal−metal bonds. An appropriate example in Main Group chemistry is the preparation in high yield of compounds containing Group II (Zn, Cd) − Group IV (Ge, Sn) bonds by the reaction of dialkylzinc or cadmium compounds with triphenylgermanium (or tin) hydride (9). The reaction of L_2InMe with an organometal hydride appeared to offer a useful route to In—M bonded species, but methane elimination was not observed when L_2InMe was treated under various conditions with Ph_3SnH, Ph_3GeH, or Ph_3SiH. The compound $L_2InSnPh_3$ was eventually synthesized via the reaction between L_2InCl and Ph_3SnNa. The ^1H nmr spectrum of this material ($CDCl_3$/TMS) consisted of complex aromatic multiplets plus singlet CH_2 and $N(CH_3)_2$ resonances in the integrated ratio 6.1:1:2.7 (calcd. 5.75:1:3). The Raman spectrum has an intense band at 205 cm^{-1}, with a corresponding absorption at 206 cm^{-1} in the far infrared, assigned to ν(In—Sn). An interesting feature of the reaction is that as noted earlier the use of Ph_3SnLi gives rise inter alia to L_2InPh and aryl tin species. We suggest that the reaction intermediate **II** is of the form



II

which undergoes slow decomposition by phenyl group transfer to L_2InPh and hexaphenylditin, probably via $(Ph_2Sn)_n$. The use of $NaSnPh_3$ apparently allows rapid elimination of NaCl and formation of the stable $L_2InSnPh_3$ species. The phenyl transfer process observed in the lithium case is not unusual; the organotin−zinc compound $Ph_3SnZnCl$ decomposes to PhZnCl and $(Ph_2Sn)_n$ in an apparently analogous manner (10).

Since compounds containing In—In bonds are now known (11−13), we made (unsuccessful) attempts under a wide range of conditions to synthesize L_2InInL_2 by treating L_2InCl with sodium in liquid ammonia. The blue colour of the sodium solution discharged and the mixture turned black; after ca. 10 h the ammonia was removed and the resultant solids extracted with metal were recovered in each case, along with unreacted L_2InCl, and L_3In. A related series of reactions involving sodium and L_2InI in refluxing benzene or toluene gave essentially identical results.

Finally, we note that despite extensive efforts, we were unable to reduce L_2InCl or L_2InI to L_2InH, with none of the reducing agents investigated ($LiAlH_4$, $NaBH_4$, NaH) producing any evidence of reduction of the In—X bond. Negative results were also obtained in attempts to synthesize salts of L_2In^+, for example by the reaction of L_2InCl with $NaClO_4$ or $NaBF_4$ under a variety of solvent and temperature conditions. The molar conductivity of L_2InCl in nitromethane was found to be 19 ohm^{-1} cm^2 (cf. 120−130 for 1:1 electrolytes in this solvent (14)), showing that there is essentially no spontaneous dissociation into L_2In^+ and Cl^- ions in this solvent. The mass spectral results (see below) also demonstrate quite clearly that fragmentation of L_2InCl does not give rise to L_2In^+ ions in the gas phase, as do L_2InMe and L_2InPh, but rather undergoes hydrogen chloride abstraction to $[L_2In - H]^+$. These results are in keeping with the failure to generate L_2In^+ derivatives by solution phase reactions, and we conclude that this ion is unstable. The previously reported lability of the corresponding isoelectronic L_2Cd compound in solution (5) emphasizes the inherent instability of such L_2M species.

Nuclear magnetic resonance spectroscopy

The ^1H and ^{13}C nmr spectra of L_2InCl have been discussed in detail elsewhere (2) and are noted here only for purposes of comparison. Table 1 gives the ^1H nmr spectra of this and related compounds in $CDCl_3$ and C_6D_6 solution at room temperature. The $N(CH_3)_2$ and NCH_2 protons in L_3In are at significantly higher field than for the corresponding atoms in L_2InCl and L_2InMe. Change of solvent from $CDCl_3$ to C_6D_6 results in an upfield shift for these same protons; similar results have been previously reported for 2-[(dimethylamino)methyl]-phenyl compounds of tin (8), and cadmium (5), and it seems probable that in such systems the benzene solvent molecule is oriented at the CH_2NMe_2 site in such a way that these protons are in the diamagnetic region. We have also recorded ^{13}C spectra for some of these molecules, and again the results are similar to those for L_2InCl (2).

The ^1H nmr spectrum of L_3In at 223 K shows only small differences from that at 297 K. Both $N(CH_3)_2$ and NCH_2 resonances are significantly broadened, with half-widths of 7 and 5 Hz, respectively, and a slight assymetry is observed on the high frequency side of both bands, but the effects are much less pronounced than for L_2InCl under comparable conditions. It therefore appears that the fluxional behaviour of L_3In persists even at −50°C, in keeping with the properties of other six-coordinate indium(III) compounds, for which coordination number changes $6 \rightarrow 5 \rightarrow 6$ occur easily even at low temperatures (refs. 2, 15, and references therein).

Mass spectra

Table 2 records the important features of the mass spectra of compounds prepared in this work.

The electron impact (EI) mass spectrum of LBr, taken from an earlier publication (5) shows that the principal ion is $C_7H_7Br^+$, with $C_5H_{12}N^+$, $C_5H_{10}N^+$, and $C_2H_4^+$ as the other important species. The spectrum of L_2InCl in the same mode is quite different, with $C_2H_4^+$ as the principal ion. There are no important peaks with $m/e > 85$, although many low abundant species were recorded up to $m/e \sim 300$. No simple L_nIn^+ ions were detected; the ions at $m/e = 85$ and 83 are clearly different from those at m/e and 84 from LBr. A group of ions at m/e 77−79 are tentatively assigned to doubly charged ions containing indium, as indicated by the isotopic intensities.

The field desorption (FD) spectra of L_2InCH_3, $L_2InC_6H_5$, and $Li[L_2In(CH_3)_2]$ all show L_2In^+ as the principal ion. Weak molecular ions were detected for $L_2InCH_3^+$ and $L_2InC_6H_5^+$, and $LInCH_3^+$ and $LInC_6H_5^+$ ions are also present in low but significant abundance. The formation of such singly charged MX_2^+ ions is usual for indium(III) compounds (16, 17). The FD spectrum of L_2InCl is quite different from those just discussed. The predominant ion is at $m/e = 417$, corresponding to the loss of hydrogen, and instead of L_2In^+ one finds $[L_2In - H]^+$, indicating loss of HCl. These results are in agreement with those reported above, emphasising that L_2InCl does not readily lose chlorine to yield the L_2In^+ ion. One other important feature of the spectrum of L_2InCl is the formation of oligomeric ions (e.g. $L_2In_2Cl^+$), or the formation of ions indicating ligand transfer (e.g. L_3In^+ from L_2InCH_3). Such processes are not uncommon in FD mass spectrometry, and are to be understood in terms of ionization of a condensed phase.

The FD mass spectrum of $L_2InSnPh_3$ had the predominant ion at $m/e = 308$ (InL_2^+), with other intense peaks at 346−351 arising from the isotopic $SnPh_3$ ions. The heaviest ion had $m/e = 702$, corresponding to the loss of two methyl groups from the parent molecule.

Crystal structure of di-μ-hydroxobis[*fac*-trichloroaquotin(IV)] tetrahydrate, $[Cl_3(H_2O)Sn—OH—]_2 \cdot 4H_2O$, with observations on O···O distances and MOM angles in di-μ-oxygen bridges

The present redetermination of the crystal structure of the title compound agrees well with a previous determination by Barnes *et al.*, which it supplements by providing details of the hydrogen-bonding scheme. Scrutiny of the O···O distances in homonuclear di-μ-oxygen M_2O_2 bridges in well over a hundred compounds shows that the lower limit for this distance is ~2.3 Å, and that the corresponding distance in the title compound, 2.44(1) Å, is closer to this limit than the O···O distances in the majority of the compounds surveyed. Appreciably shorter nonbonded O···O distances are found only in oxyanions, in particular those acting as bidentate ligands of metal atoms and thus forming heteronuclear di-μ-oxo bridges; an O···O distance as short as ~2.0 Å has been reported and may constitute the limit of such nonbonded O···O distances in general.

T. STANLEY CAMERON, OSVALD KNOP et BEVERLY R. VINCENT. Can. J. Chem. **63**, 759 (1985).

La redétermination de la structure cristalline du composé mentionné dans le titre est en bon accord avec celle qui a été faite antérieurement par Barnes et ses collaborateurs; le présent travail sert de complément au travail rapporté antérieurement en fournissant des détails sur le réseau des liaisons hydrogènes. Un examen minutieux des distances O···O dans des ponts homonucléaires di-μ-oxygène M_2O_2, dans plus de cent composés, montre que la limite inférieure pour cette distance se situe autour de 2,3 Å et que la distance correspondante dans le composé mentionné dans le titre, 2,44(1) Å, est plus proche de cette limite que les distances O···O dans la majorité des composés examinés. Des distances O···O relativement plus courtes ne se retrouvent que dans des oxyanions; en particulier, on en retrouve dans ceux qui agissent comme ligands bidentates d'atomes métalliques et qui forment donc des ponts hétéronucléaires di-μ-oxo. Dans un cas particulier, une distance O···O aussi courte que 2,0 Å a été rapportée et cette valeur peut constituer la limite pour de telles distances O···O non liées.

[Traduit par le journal]

In a recent attempt to crystallize piperidinium hexachlorostannate(IV) from a concentrated, strongly HCl-acid aqueous solution of the amine and H_2SnCl_6, we obtained a small quantity of well-formed crystals the ir spectra of which, unexpectedly, contained no features attributable to CH_2 absorptions (Fig. 1). The sharp bands at 3586, 3528, 3499, 1630(sh), and 1599 cm^{-1} and the two very broad bands centering at 2930 and 2320 cm^{-1}, respectively, all disappeared after the crystals had been heated to 150°C, leaving the 4000−1400 cm^{-1} region completely featureless. This and the frequencies of the sharp bands pointed to strongly held water of hydration, possibly also to OH^- ions. The clear, colourless crystals were too few for a meaningful chemical analysis, but their good quality and their stability in air rendered them suitable for single-crystal X-ray diffraction. The crystal data obtained from a 0.2 × 0.2 × 0.2 mm^3 crystal with a CAD-4 four-circle diffractometer ($MoK\alpha_1$, λ = 0.70926 Å, graphite monochromator; θ-range, 2−27°) are summarized as follows:[2]

Monoclinic, $P2_1/n$ (No. 14); a = 9.676(8) Å, b = 6.518 (13) Å, c = 12.531(15) Å, β = 92.98(9)°, V = 789.2(32) Å^3. Total reflections measured, 1529; unique reflections, 1191 (of which 1053 with $I \geq 3\sigma(I)$, corrected for extinction but not for absorption, were used in the refinement).

A straightforward interpretation of the strong Patterson maxima and of subsequent Fourier maps, together with consideration of the ir spectra and chemical reasonability, established the

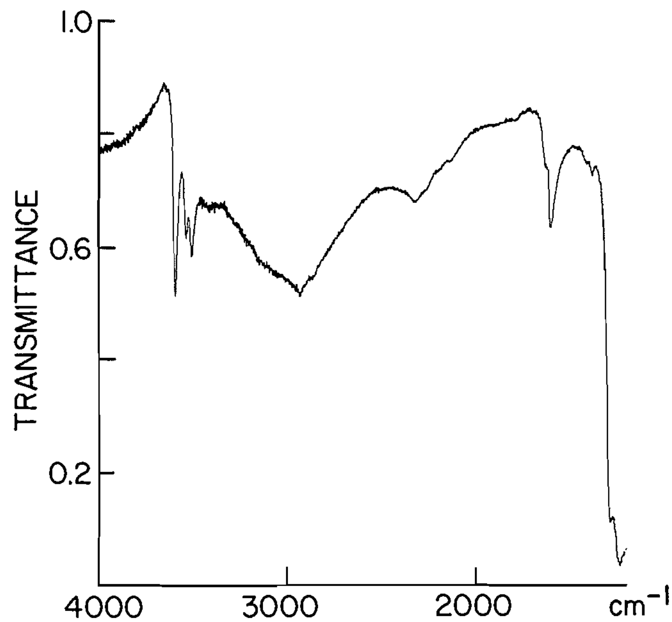

FIG. 1. Infrared spectrum of $[Cl_3(H_2O)Sn—OH—]_2 \cdot 4H_2O$ (fluorolube mull between CaF_2 plates).

minimum formula unit as $SnCl_3O_4$ (all atoms in general positions), for which Z = 4. A Mössbauer ^{119}Sn spectrum (10 mCi $CaSnO_3$ source and absorber at room temperature; single unsplit absorption, δ = +0.12(1) mm/s relative to $BaSnO_3$, FWHH = 0.54(5) mm/s) showed the tin to be exclusively Sn(IV).[3] Refinement with anisotropic temperature factors resulted in R = 0.038 and R_w = 0.039 (Table 1).

The dominant feature of the structure turned out to be a centrosymmetric binuclear di-μ-oxygen Sn(IV) complex. Its skeleton consisted of two *fac*-$SnCl_3O_3$ octahedra sharing the

[1]Holder of NSERC (1983−1985) and Killam (1984−1985) graduate fellowships.

[2]For the composition $[Cl_3(H_2O)SnOH]_2 \cdot 4H_2O$ (see below) these data can be supplemented as follows: fw for $H_{14}Cl_6O_8Sn_2$ = 592.20, Z = 2, μ_{Mo} = 39.0 cm^{-1}, $F(000)$ = 560.

[3]For $[Cl_3(H_2O)SnOH]_2 \cdot 4H_2O$ ref. 1 quotes δ = +0.30 mm/s, and ref. 2 gives δ = +0.30 mm/s for $Ag(PPh_3)_4OH \cdot [Cl_3(H_2O)SnOH]_2$, both with Δ = 0 and relative to $BaSnO_3$.

D $\frac{1}{2}+x$ $\frac{1}{2}-y$ $\frac{1}{2}+z$	d X + $(\bar{1}1\bar{1})$		Sn—O(1)—Sn(B)	108.2(2)	(10)

*The coordinates of all the atoms are as in Table 1 except where stated otherwise. The difference between the present distance and that of ref. 4 is given, with the original esd in parentheses, next to the present value.

bridging O(1)···O(1′) edge to form $[Cl_3O(2)Sn—O(1)—]_2$. The remaining oxygens, O(3) and O(4), were not closer than O(3, 4)···O(1, 2) ~2.67 Å and O(3, 4)···Cl ~3.32 Å. The compound was thus a hydrolysis product of $SnCl_6^{2-}$, but the nature of the oxygens was at this stage not clear, since the H atoms known from the ir spectrum to be present could not be located with confidence in the difference Fourier map.

Search of the literature revealed that the skeleton must belong to the $[Cl_3(H_2O)Sn—OH—]_2$ complex which has been reported in a number of adduct with various organic species (3, 4) as well as in the hydrate $[Cl_3(H_2O)Sn—OH—]_2 \cdot 4H_2O$ (4), and that moreover the serendipitous crystals must be those of the last-named compound. The unit-cell dimensions were all within twice the stated esd's of ref. 4, and the positional parameters of the non-hydrogen atoms were, except for y[O(2)], within 2σ of ref. 4 (Table 1). A similarly gratifying agreement exists for the interatomic distances and bond angles of the $[Cl_3OSn—O—]_2$ skeleton (Table 4).

Hydrogen bonding

Barnes *et al.* (4) report that their difference syntheses gave no clear indication of hydrogen atom positions. This was on the whole also the case with our difference map, but since the esd's of our Sn, Cl, and O positional parameters were 2–4 times smaller and the R was significantly lower than in ref. 4 (3.8% as against 8.4%), an attempt to include the hydrogens in the refinement seemed worthwhile. The O—H bond lengths were constrained to 0.98(2) Å, the H···H distances in the H_2O molecules to 1.55(1) Å, and the OH and H_2O groups were treated as rigid bodies. The resulting H positions (Table 1 and Fig. 2) all fall between the O,O and O,Cl pairs of atoms indicated in Fig. 4 of ref. 4 as involved in O—H···O and O—H···Cl bonds. The relevant H···O and H···Cl distances and OHO and OHCl angles are listed in Table 5.

In the overall hydrogen-bonding scheme in this crystal every H atom is involved in a hydrogen bond (Fig. 2 and Table 5). The hydrogen of the OH group and one of the hydrogens of the

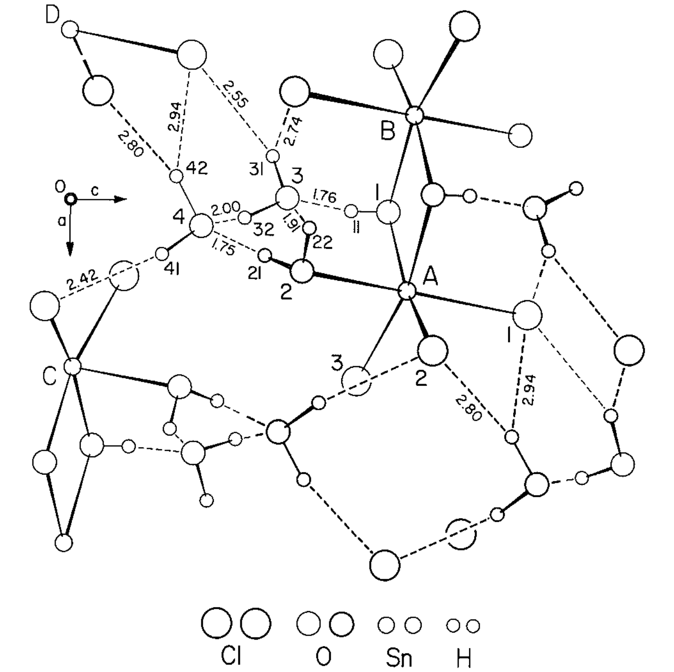

FIG. 2. Details of the hydrogen-bonding scheme in $[Cl_3(H_2O)Sn—OH—]_2 \cdot 4H_2O$. For symmetry code, interatomic distances, and bond angles see Tables 4 and 5.

water molecule of coordination participate in short, almost straight O—H···O bonds to the water molecules of hydration, $H_2O(3)$ and $H_2O(4)$. The second hydrogen of $H_2O(2)$ engages in an O(2)—H···O(3) bond of unfavourable geometry, as the longer H···O distance and the small OHO angle indicate. The hydrogens of $H_2O(3)$ and $H_2O(4)$ have, with the exception of H(32), Cl atoms as acceptors.

The H···Cl distances in the O—H···Cl bonds are on the whole long. The H(31) atom is involved in an unsymmetrically bifurcated H···2 Cl bond. The shortest H···Cl distance is H(41A)···Cl(2C), 2.42(8) Å; a second Cl atom, Cl(3C), is at 2.96(9) Å from H(41A) and at an OHCl angle of 120°, so that the O(4A)—H(41A)···Cl(2C) bond may be regarded as bent but not bifurcated. The H(42) atom, on the other hand, has two Cl neighbours at comparable H···Cl distances and OHCl angles, but the H(42)···Cl(2) and H(42)···Cl(1) distances are quite long, 2.80(5) and 2.94(3) Å, respectively, and the hydrogen-bonding interaction must be very weak.

The oxygens O(3) and O(4) act as acceptors to hydrogens bound to O atoms only: O(3) to H(11) and H(22), O(4) to H(21) and H(32). the Cl(1) atom engages H(31Bb), H(31D) and probably H(42D); Cl(2) engages H(41C) and H(42Da). The nearest H neighbour of Cl(3) is H(41C), which is only marginally eligible for hydrogen bonding (see above).

Given this wide range of O—H···O and O—H···Cl bonds in the crystal, extensive vibrational coupling must be expected, and the complexity and the lack of sharp features of the spectrum of Fig. 1 should come as no surprise.

Dimensions and symmetry of the $[Cl_3OSn—O—]_2$ skeleton

The skeletal bond lengths and angles are listed in Table 4. The Sn—Cl bonds are shorter than in the $SnCl_6^{2-}$ ion: the mean of uncorrected d(Sn—Cl) is 2.365(15) Å in the title compound, 2.427(12) Å in $(H_9O_4)_2SnCl_6 \cdot 2H_2O$ (5), and 2.425(12) Å in alkylammonium hexachlorostannates(IV) (6). The shortening, 0.06(2) Å, reflects the absence of ionic charge. The

*For symmetry code see Table 4.

mean of the uncorrected Sn—OH distances is 0.059(16) Å smaller than the uncorrected $Sn—OH_2$ distance.

The geometry of this skeleton is remarkably constant. Table 6 lists the deviations from our values of bond lengths and angles for the dimer in a number of adducts and related dimers as well as in *cis*-$[SnCl_4(H_2O)_2]$ in $SnCl_4 \cdot 5H_2O$. The deviations are generally consistent with the stated esd's, with one conspicuous exception: the $Sn—OH_2$ bond reported for $[Cl_2Et(H_2O)Sn—OH—]_2$ (7) is about 0.2 Å longer than the $Sn—OH_2$ distance in the title compound and appreciably longer than all the other $Sn—OH_2$ distances in Table 6.

The actual symmetry of the complex, C_i, derives by only a slight distortion from the idealized symmetry of the skeleton, C_{2h}. This symmetry lowering is probably as much a consequence of the packing exigencies as of the strong O—H···O bonding in certain directions. The C_{2h} symmetry does not appear to be reported for Sn(IV) di-μ-oxygen complexes, though it is observed in the related binuclear species $[(OH)O_3Te—O—]_2^{6-}$ (8). In general the C_i symmetry in such complexes prevails: $[(H_2O)_4Al—OH—]_2^{4+}$ (9), $[(OH)_4Al—OH—]_2^{4-}$ (10), $[(OH)_2O_2Te—O—]_2^{4-}$ (11), and $[(OH)O_3I—O—]_2^{4-}$ (12) are typical examples.

The O···O distance in di-μ-oxygen bridges

The shortness of the O···O′ distance and the smallness of the OSnO′ angle raise the question of what is the limit of the effective size of the oxygen atom in M_2O_2 rings in general. To investigate this matter we have plotted the OSnO′ angle against d(O···O′) in Sn(IV) compounds containing Sn_2O_2 rings (Fig. 3). The compositions and code numbers of the compounds are listed in Table 7. We have also prepared a similar plot, MOM′ vs. d(O···O′) (Fig. 4), for a more or less random selection of well over a hundred compounds, all of which contain M_2O_2 rings, either as isolated di-μ bridges or as component groupings in larger units, e.g. tri-μ M_2O_3 binuclear complexes or multiply bridged M_3O_2 and M_3O_4 trimers and M_4O_4 tetramers. These compounds (**101**−**226**) are grouped according to M in Table 8; their compositions, together with references, will be found in Table 9.[4] Three heteronuclear (M ≠ M′) rings (**224**−**226**) are included in this set.

The sample presented in Fig. 3 is small and to some extent repetitious, and the uncertainty in d(O···O′) or the OSnO′

[4]This table has been deposited. Complete set of data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A OS2.

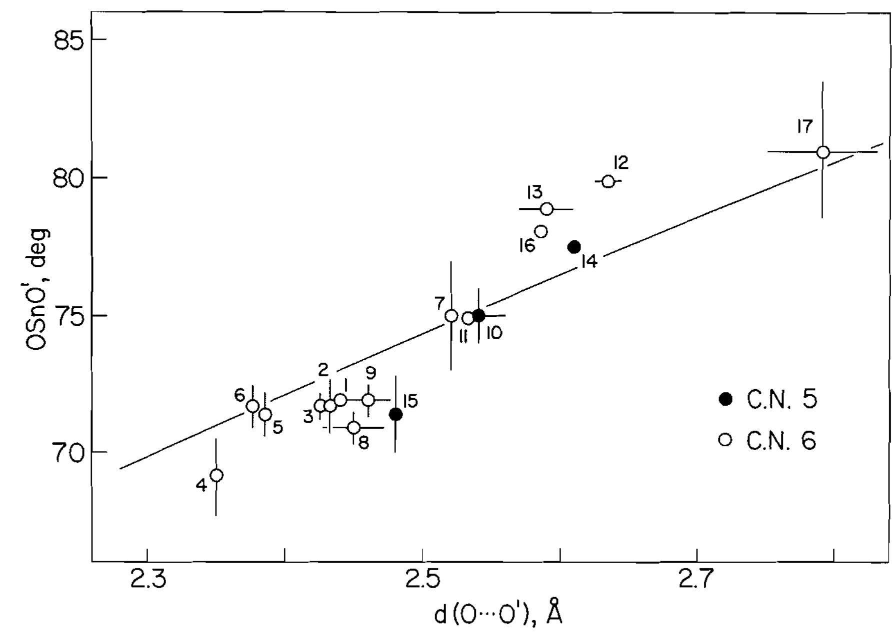

FIG. 3. Plot of the OSnO′ angle against the O···O′ distance in Sn_2O_2 rings. The curved line refers to $d(Sn \cdots Sn') = 3.3$ Å and D_{2h} ring symmetry. The esd's of the angles and distances are indicated wherever they are stated in the original reference. For code numbers see Table 7.

angle or both for some of the determinations is quite large. Within these limitations one can conclude that the C.N. of the Sn atom and the nature of the *exo*-ligand on the bridging oxygen are not significant differentiating factors, and that the relationship between $d(O \cdots O')$ and OSnO′ is largely determined by the nearly constant Sn···Sn′ distance of 3.3 Å (solid line in Fig 3; see text below) and the geometric requirements for an Sn_2O_2 ring of D_{2h} symmetry. The title compound is at the low end of the $d(O \cdots O')$ and OSnO′ ranges, though the point for the dioxan adduct **4** is almost cetainly too low.

Points **16** and **17** refer, not to *discrete* di-μ-oxygen bridges but to three-dimensional —Sn—O— networks containing Sn_2O_2 groups that can be regarded as local di-μ-oxygen bridges corresponding to the smallest O···O separation in the structure. In spite of this difference **16** and **17** conform to the rest of the sample.

The $d(O \cdots O')$ range in this reasonably homogeneous set is ~2.4 to 2.8 Å, and the SnOSn′ angle ranges from ~100° to ~110°, i.e. at short O···O′ distances it approaches the tetrahedral angle.

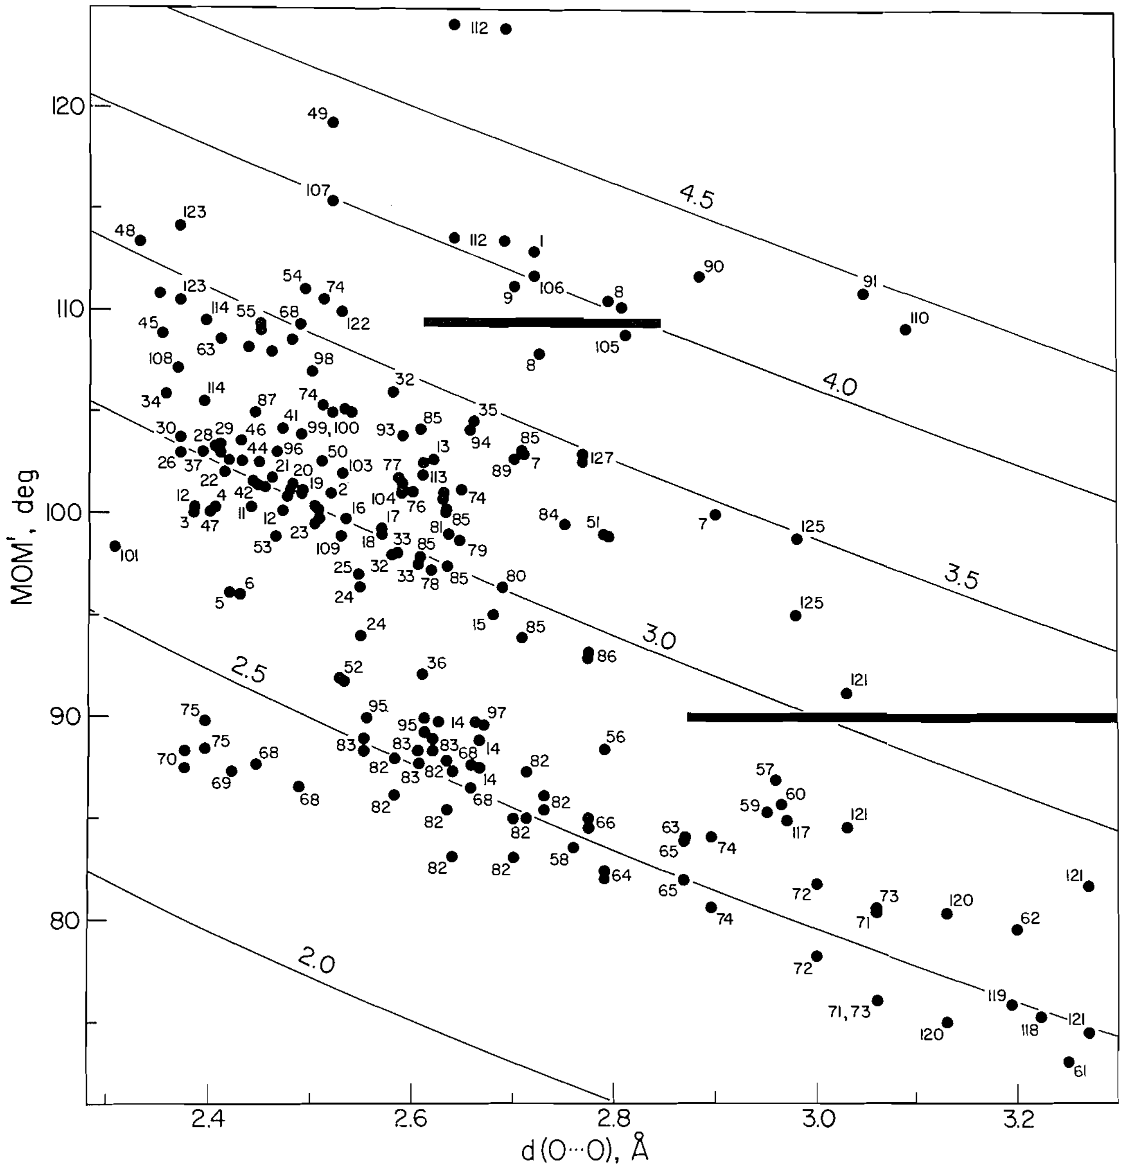

FIG. 4. Plot of the MOM' angle(s) against the O···O' distance(s) in M_2O_2 rings. To reduce crowding, 100 has been subtracted from the code numbers listed in Tables 8 and 9; even so some of the points (and all the M = Sn points) remain unlabelled. The esd's of the angles and distances are not indicated; the uncertainties in the angles may be as high as 2–3°. The heavy bars represent the d(O···O') ranges in the MO (NaCl type, **188** and **216**) and MO_2 (CaF_2, type, **110**, **192**, **202**, and **211**) oxides; the range for MO extends up to d(O···O') = 3.49 Å (PaO, **188**). The curves refer to constant d(M···M') (in Å) in M_2O_2 rings of D_{2h} symmetry.

When the set of points for Sn_2O_2 is embedded in the much larger, and presumably representative, M_2O_2 set of Fig. 4, it is seen that it covers only a small portion of the total d(O···O') and MOM' range, but the low d(O···O') end of the Sn sample comes close to the lower limit of the d(O···O') range of Fig. 4.

For a centrosymmetric MOM'O' ring with the dimensions d(M—O) ≥ d(M—O'), d(M···M'), d(O···O') and the angles MOM' and OMO' = 180° − MOM', we have

$$[1] \quad \cos \mathrm{MOM}' = -\frac{1}{2}(r + r^{-1})(R^2 - 1)/(R^2 + 1)$$

where $r = d(\mathrm{M—O})/d(\mathrm{M—O'})$ and $R = d(\mathrm{M\cdots M'})/d(\mathrm{O\cdots O'})$. The $\frac{1}{2}(r + r^{-1}) = K$ term may be regarded as an asymmetry parameter measuring the extent of distortion of the planar ring from D_{2h} ($K = 1$) to C_{2h} ($K > 1$) symmetry. When the intra-ring distances and angles for the compounds included in Fig. 4 are replotted as cos MOM' vs. R (Fig. 5), all the points corresponding to D_{2h} ring symmetry fall on the $K = 1$ straight line. Within realistic limits the effect of r on K is insignificant; it is quite unlikely that $r > 2$. If $r = 2$, $K = 1.25$, but the lines for $K = 1$ and $K = 1.25$ are so close that in practice the difference between D_{2h} and merely centrosymmetric rings is absorbed in the experimental uncertainty in MOM' and R. In compounds with points outside the two lines the MOM'O' ring is either planar but noncentrosymmetric or nonplanar.

This plot shows clearly that (a) in the majority of the compounds in our sample R is between ~1.1 and ~1.4, and MOM' is between ~95° and the tetrahedral angle; (b) R values exceeding 1.4 and MOM' angles larger than tetrahedral are observed in compounds where M is large though not necessarily having either a high C.N. or unusually bulky ligands; (c) R values smaller than unity and MOM' angles between 70° and 90° occur only in compounds containing single or multiple

*M_2O_2 rings in three-dimensionally connected —M—O— structures. For Sn compounds see Table 7.

M—M′ bonds. For M = Sn the upper limit of R appears to be ~1.4 and the SnOSn′ angles approach the tetrahedral angle.

The shortest O···O′ distance in Fig. 4, ~2.31 Å, is encountered in stishovite (**201**), the rutile-type variety of SiO_2 containing six-coordinated Si. This prompts the question of how this presumably shortest d(O···O′) separation in an M_2O_2 ring compares with the shortest observed nonbonded O···O distance, and what in fact is this distance.

What is the minimum d*(O···O) for nonbonded oxygens in general?*

The shortest nonbonded O···O contact in α-O_2 is ~3.2 Å (22), i.e. greater than twice the van der Waals radius of oxygen, 2.8 Å; this distance does not decrease appreciably with increasing pressure (23). In the ozone molecule the nonbonded O···O distance is 2.18 Å. In tetrahedral varieties of SiO_2 the corresponding distance ranges from ~2.57 to ~2.67 Å; in β-Be$(OH)_2$ it is ~2.52 (24). With the exception of stishovite the minimum nonbonded O···O distance in Si^V and Si^{VI} oxygen compounds is 2.42–2.46 Å (e.g. in SiP_2O_7 (25), $[Ca_3Si(OH)_6(H_2O)_{12}](SO_4)(CO_3)$ (26), $(Me_4N)[C_6H_5Si(O_2C_6H_4)_2]$ (27)). For distances shorter than ~2.3 Å one thus has to look among oxyanions and complexes containing oxyanions as bidentate ligands; the latter may be regarded as heteronuclear di-μ-oxo bridges.

The minimum d(O···O) in XO_3^{n-} and XO_4^{n-} ions does not appear to fall below ~2.1 Å: for example, it is 2.11 Å in $NaNO_3$ (28) and 2.14 Å in $Na_2CO_3 \cdot NaHCO_3 \cdot 2H_2O$ (29, 30). This seems to be true also of the free molecular X_mO_n species, e.g. NO_2 (2.19 Å) or the cyclic $H_2B_2O_3$ (intra-ring d(O···O) = 2.29 Å) (31).

For the nitrate ion in bidentate coordination, i.e. in MO_2N rings, the approximate range is 2.08(5)–2.16 Å (**18–23**, Table 10); the corresponding MOX angles range from ~48° to ~68°. Values lower than ~2.10 Å have so far been found only in NO_2^- ions: ~2.09 Å in $NaNO_2$ (40). The shortest nonbonded

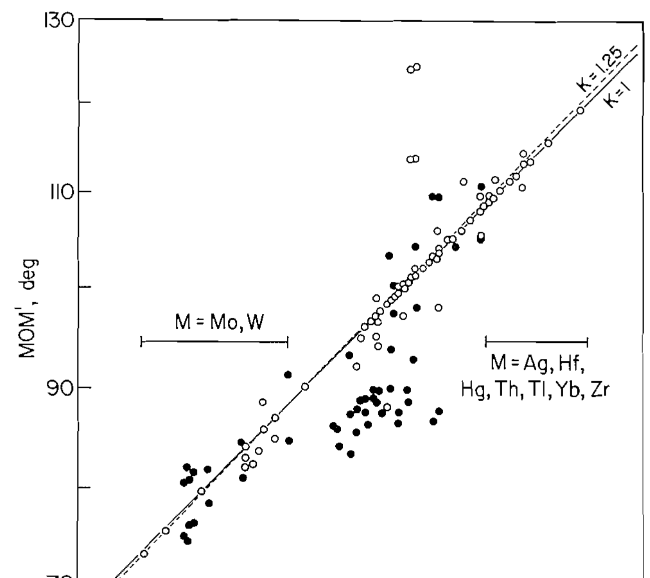

FIG. 5. Plot of MOM′ against R = d(M···M′)/d(O···O′) according to eq. [1]. The open circles refer to isolated M_2O_2 rings, the full circles to M_2O_2 rings of M_2O_3, M_3O_2, M_3O_4, and M_4O_4 bridged groupings. For the meaning of K see text. The points for R < 1 refer exclusively to Mo and W compounds; those for R greater than ~1.4 refer to compounds in which M is a large atom. The Sn compounds of Table 7 and Fig. 3 fall between R ~ 1.3 and ~1.4.

O···O distance reported to date is ~2.02 Å in the di-μ-oxo CuO_2N hetero bridge in $[Cu(bipy)_2(ONO)]NO_3$ (**25**). In contrast, in a similar bridge in Cu(bipy) $(ONO)_2$ (**24**) the distance is ~2.10 Å.

A closer comparison of the nonbonded O···O distances is

TABLE 10. The O···O bridging distance in NO_3^- and NO_2^- ions acting as bidentate ligands

No.	Compound	d(O···O), Å	Reference

25	$[Cu(bipy)_2(ONO]NO_3$	2.02	39

not warranted at present, nor are distinctions between X-ray, neutron, and spectroscopic results (i.e. between internuclear distances and separations of electron-density maxima) or between distances corrected or uncorrected for thermal motion. The accuracy quoted is rarely better than ±0.01 Å and often much poorer. Our survey of the very short O···O distances is by no means exhaustive and it does not differentiate between oxygen atoms of different types. However, it presents what must be essentially the correct picture of the situation in regard of the lower limit of O···O contacts: in M_2O_2 rings the lower d(O···O′) limit appears to be ~2.3 Å unless one of the nonoxygen atoms is B, C, or N. In that case the nonbonded O···O distance can be short as ~2.0 Å, which seems to be also the *overall* lower limit for non-σ-bonded O···O distances.

Acknowledgments

We thank Dr. M. Falk for the ir spectrum and Dr. R. A. Dunlap for the Mössbauer spectrum of the title compound. This work was supported by research grants from the Natural Sciences and Engineering Research Council of Canada to the two first-named authors.

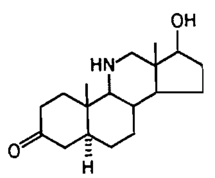
MARIA GUMULKA, IBRAHIM HALIM IBRAHIM, ZBIGNIEW BOŃCZA-TOMASZEWSKI, and CH. R. ENGEL. Can. J. Chem. **63**, 766 (1985).

An efficient synthesis from adrenosterone or 11α-hydroxytestosterone of 17β-hydroxy-11-aza-5α-androstan-3-one, the 11-aza analogue of dihydrotestosterone, is described. For the elaboration of the 11-aza structure, a pathway implying a Curtius-type rearrangement of a 9,11-seco 9-oxo 11-acid was employed.

MARIA GUMULKA, IBRAHIM HALIM IBRAHIM, ZBIGNIEW BOŃCZA-TOMASZEWSKI et CH. R. ENGEL. Can. J. Chem. **63**, 766 (1985).

On rapporte une synthèse efficace de l'hydroxy-17β aza-11 (5α)androstanone-3, l'analogue 11-aza de la dihydrotestostérone, à partir de l'adrénostérone, ou de l'hydroxy-11α testostérone. Pour l'élaboration de la structure 11-aza, une méthode impliquant une réaction du type Curtius sur un 9,11-seco 9-oxo 11-acide fut employée.

In the framework of our program on the synthesis of new steroid hormone analogues, on their biological evaluation, and on the establishment of structure–activity relationships in that field, and in particular in connection with our investigations of steroids modified in position 11, such as 11-hetero steroids, we decided to synthesize 17β-hydroxy-11-aza-5α-androstan-3-one (**1**), the 11-aza analogue of 4,5α-dihydrotestosterone. This



1

androgenically highly active testosterone metabolite is indeed regarded to be the steroid whose binding to the appropriate receptors is mainly responsible for androgenic activity. The study of the androgen agonistic or antagonistic properties of its 11-aza analogue, as well as of other biological activities this product may possess – such as its effect on spermatogenesis – should thus have considerable interest. We here report the synthesis of this new hormone analogue.

We have previously shown (2, 3) that 11-aza steroids of the 9α-series are synthetically accessible, particularly in the A/B-*trans* series, by ozonolysis of 9,11-unsaturated 12-ketones, by ammonolysis of the resulting 9,12-seco 11-nor 9-oxo 12-acids, the reduction of the 8,9-unsaturated lactams thus formed to the 8,9-unsaturated cyclic amines, and by hydrogenation of the latter, for instance via iminium salts (cf. Scheme 1) (cf. also ref. 4). This pathway suffers, however, from the fact that the ammonolysis of the keto acid has to be carried out under pressure, as well as from the low yield of the reduction of the double bond of 8,9-unsaturated 11-aza steroids (2, 4).[6] Therefore, for the synthesis of 11-azadihydrotestosterone (**1**) described here, we investigated an alternate approach implying a Curtius-type rearrangement of a 9,11-seco 9-oxo 11-acid azide, in analogy with reactions described by Lettré and Knof (5) pertaining to B-seco derivatives and which had led to 6-aza steroids.

As starting material, we chose 5α-androstane-3,11,17-trione (**3**), readily available (cf. ref. 6) by Birch reduction of adrenosterone (4-androstene-3,11,17-trione) (**2**) or of 11α-hydroxytestosterone (**2***a*), followed by Jones' oxidation (cf. Experimental). The triketone **3** was transformed in 90% yield with ethylene glycol and *p*-toluenesulfonic acid into its 3,17-diketal **4** which was reduced in 87–89% yield with lithium aluminum hydride or sodium borohydride to the 11β-hydroxy 3,17-diketal **7**. This product was dehydrated in 86% yield with thionyl chloride to 3,17-bisethylenedioxy-5α-androst-9,11-ene (**6***a*) which gave in 72% yield, upon treatment with acetone and *p*-toluenesulfonic acid, 5α-androst-9,11-ene-3,17-dione (**6**), already prepared by Shoppee (7) from 3β-acetoxy-5α-androst-9,11-en-17-one, which was obtained in turn by degradation of Reichstein's Substance A (8). Better yields (90%) in the deketalization were realized by the method of Conia and coworkers (9), consisting in reaction with silica gel, pretreated with dilute hydrochloric acid. Ozonolysis of the androstenedione **6** and oxidation with hydrogen peroxide gave in 75–81% yield the seco keto aldehyde **5**, accompanied by the diketo acid **5***a* (isolated in approximately 20% yield). The oxidation of aldehyde **5** with Jones' reagent to the diketo acid **5***a* proceeded in approximately 75% yield, but the product was unstable. In a first set of experiments it was therefore transformed without purification with oxalyl chloride (cf. ref. 10) into the acid chloride, which was converted with sodium azide to the acid azide **8** which, in turn, was subjected to a Curtius-type rearrangement, leading via the isocyanate **9** to the imine **10**; as side product, the diketo acid **5***a* was recovered. The yield of this

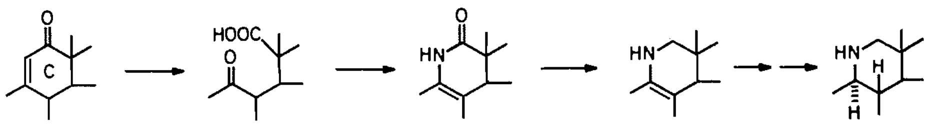
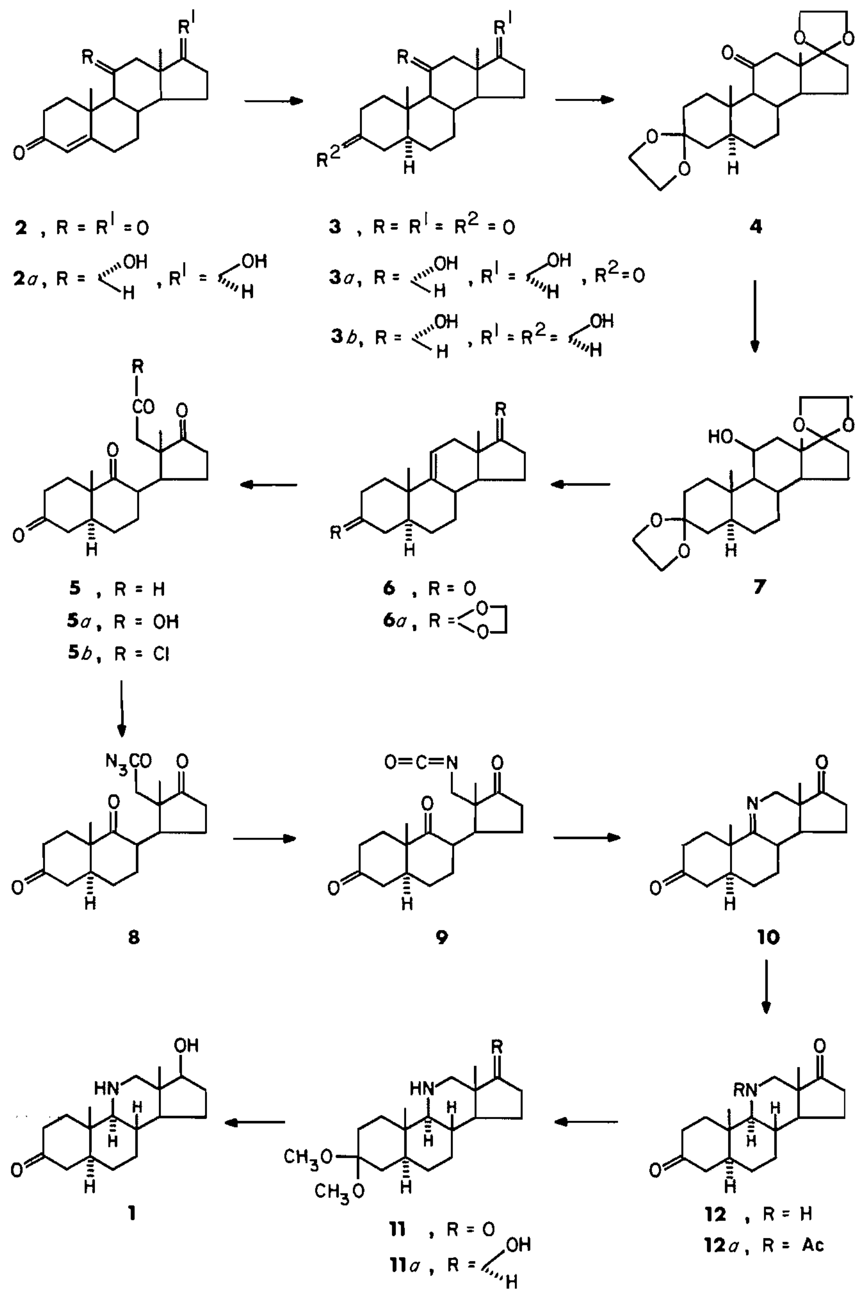
[4]The salient features of this publication were part of a paper presented at the 29th International (IUPAC) Congress of Pure and Applied Chemistry, Cologne, Federal Republic of Germany, June 5–10, 1983 (Abstracts of Papers, p. 216).
[5]Abbreviated from part of the doctoral thesis of I. H. Ibrahim, to be presented to the School of Graduate Studies, Université Laval, Quebec.
[6]Although we were able to improve the yield of this reduction which we originally reported (2), the total yield of the transformation of an 8,9-unsaturated 12-oxo 11-aza steroid into the 12-deoxygenated 8,9-saturated derivative hardly exceeded 16%. Catalytic reduction of an 8,9-unsaturated N-acylated 11-aza steroid under pressure, in the presence of perchloric acid, gave the saturated 11-aza steroid in approximately 50% yield, but under these conditions ester groups present in the molecule may be simultaneously reduced (2).



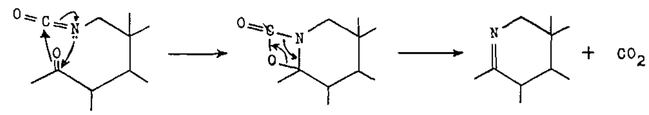
SCHEME 1



sequence of reactions depends on the conditions employed (cf. Experimental). The best results — a 68% yield, considering the recovery of acid *5a* — were obtained when the acid chloride *5b* was treated in dry benzene with activated sodium azide (11) at reflux temperature and the resulting product with concentrated hydrochloric acid. Significantly better yields (82%) in the preparation of imine **10** were realized in a second set of experiments in which the diketo acid *5a* was transformed without the intermediacy of its chloride *5b*, according to the method of Grouillier *et al.* (12), with triethylamine and ethyl chloroformate in acetone, into the isocyanate **9** which was treated with hydrochloric acid.[7]

Reduction of the imine **10** via its hydrochloride, according to the procedure of Borch *et al.* (13), and reoxidation with Jones'

[7]It is not improbable that, under the mild conditions of certain procedures employed for the conversion of the isocyanate to the imine, this product is not formed (at least not entirely) by cyclization of a 9,11-seco 9-oxo 11-amine but by a direct reaction of the isocyanate group with the keto function (cf. Scheme 2).



SCHEME 2

reagent, led in 65% yield to 11-aza-5α-androstane-3,17-dione (**12**), further characterized as the acetyl derivative **12***a*. The "natural" 9α-configuration was confirmed by the coupling constants (J = 11 Hz) of the 9α and 8β protons in the nmr spectra of compounds **12** and **12***a*. The 3-monoketal **11** was now formed in 80% yield by treatment of the amine **12** with methanol and oxalic acid, according to the method of Narwid *et al.* (14), the 17-keto function was reduced in over 90% yield with lithium aluminum hydride, and the 3-ketone liberated with acetone and *p*-toluenesulfonic acid, to afford in 69% yield the desired 11-aza analogue **1** of 4,5α-dihydrotestosterone.[8] The biological properties of the new hormone analogue will be reported elsewhere.

In summary, we report the synthesis of 11-aza-4,5α-dihydrotestosterone from readily available starting materials by an efficient and simple method, significantly superior to our previously described route to 11-aza steroids.

Experimental

Melting points were taken in evacuated capillaries and the temperatures were corrected. For elution chromatography, Davison's silica gel 923, and for thin-layer chromatography, Merck silica gel GF-254 and "DC-Alufolien Kieselgel 60" were employed. The ir spectra were recorded on a Beckman IR-12 instrument, the nmr spectra at 60 MHz on a Varian EM 360A spectrometer and at 90 MHz on a Bruker HFX-90 instrument, if not otherwise stated, in deuteriochloroform, tetramethylsilane serving as internal standard. The microanalyses and mass spectroscopies were performed by Dr. G. Schilling, Ayerst Laboratories, Montreal, to whom we express our sincere appreciation.

5α-Androstane-3,11,17-trione (3)

(a) From 4-androstene-3,11,17-trione (adrenosterone, 2)

According to the procedure of Bowers and Denot (6), 1.8 g of adrenosterone (**2**), mp 221–222°C, was transformed into 1.67 g of crude 5α-androstane-3,11,17-trione (**3**) which was absorbed on 60 g of silica gel. Elutions with benzene – ethyl acetate (8:2) afforded 1.497 g (83% yield) of pure trione **3**, mp 174–176°C; $[\alpha]_D^{26}$ +162 ($CHCl_3$) (lit. (17) mp 174.5–176°C; $[\alpha]_D^{23}$ +160 ($CHCl_3$)); ir ν_{max} (KBr): 1740 (17-ketone), 1700 (3- and 11-ketones) cm^{-1}.

(b) From 11α-hydroxytestosterone (2a)

Under stirring, a solution of 5 g of 11α-hydroxytestosterone (**2***a*), mp 175–177°C, in 100 mL of absolute tetrahydrofuran was added to a solution of 3 g of lithium wire, flattened and cut into small pieces, in 200 mL of anhydrous liquid ammonia over a period of 20 min. The mixture was stirred for another 40 min and the blue colour was discharged by addition of approximately 3 g of solid ammonium chloride; subsequently, the ammonia was allowed to evaporate in a nitrogen atmosphere. Water was added carefully to the residue, the product was extracted with methylene chloride, and the organic extract was washed with water and dried over sodium sulfate. Removal of the solvents gave 5 g of an amorphous product which upon crystallization from methanol afforded 3.963 g of *11α,17β-dihydroxy-5α-androstan-3-one* (**3***a*), mp 181–183°C. The mother liquors were subjected to flash chromatography on 100 g of silica gel, chloroform–methanol (98:2) eluting another 126 mg of the same product of the same purity (total yield: 81%). A sample was recrystallized twice from methanol; colourless prisms, mp 182–183°C (lit. (19) mp 183–185°C); $[\alpha]_D^{25}$ −2.2 (c 0.900, dioxane); ir ν_{max} (KBr): 3230 (hydroxyls), 1715 (3-ketone) cm^{-1}; nmr δ (DMSO, 90 Hz): 0.77 (s, 3H, 18-CH_3), 1.14 (s, 3H, 19-CH_3), 3.8 (m, 2H, 11β- and 17α-H). Mass (ms) calcd. for $C_{19}H_{30}O_3$: 306; found: 306.

From the above-mentioned chromatogram, the same solvent mixture eluted 511 mg of a more polar, amorphous product, representing *5α-androstane-3β,11α,17β-triol* (**3***b*). Crystallization from methanol gave 500 mg (9.7%) of crystalline triol **3***b*, mp 239–241°C. A sample was recrystallized twice from methanol; colourless prisms, mp 240–241°C (lit. (19) mp 241–243°C); $[\alpha]_D^{25}$ −8.4 (c 0.95, dioxane); ir ν_{max} (KBr): 3235 (hydroxyls) cm^{-1}; nmr δ (DMSO, 90 MHz): 0.72 (s, 3H, 18-CH_3), 0.94 (s, 3H, 19-CH_3), 3.8 (m, 3H, 3α-, 11β-, 17α-H). Mass (ms) calcd. for $C_{19}H_{32}O_3$: 308; found: 308.

To a solution of 3 g of the 11α,17β-dihydroxy-5α-androstan-3-one (**3***a*) described above, mp 181–183°C, in 100 mL of acetone, 15 mL of Jones' reagent (18) was added at 5°C, dropwise and with stirring, within 10 min. The mixture was left for another 3 h, and isopropyl alcohol (3 mL) and, subsequently, water were added. The product was extracted with dichloromethane, the organic solution was washed with water and dried over sodium sulfate, and the solvent was evaporated. Thus 2.548 g of an oily product was obtained which was chromatographed on 100 g of silica gel, benzene – ethyl acetate (8:2) eluting 2.378 g (80% yield) of authentic *5α-androstane-3,11,17-trione* (**3**), mp 174–176°C.

Under identical conditions, 500 mg of 5α-androstane-3β,11α,17β-triol (**3***b*), mp 239–241°C, was oxidized with Jones' reagent. By chromatography of the crude reaction product (421 mg) on 60 g of silica gel, 406 mg (81% yield) of pure *5α-androstane-3,11,17-trione* (**3**), mp 174–176°C, was obtained.

In another experiment, 5.5 g of 11α-hydroxytestosterone (**2***a*), mp 175–177°C, was reduced as described above to afford 5.318 g of an amorphous product. This material was oxidized directly, without separations or purifications, in 100 mL of acetone with 15 mL of Jones' reagent, as described above. Thus, 5.096 g of a crude product was obtained which was chromatographed on 150 g of silica gel to afford 4.666 g (85% yield) of pure *5α-androstane-3,11,17-trione* (**3**), mp 174–176°C.

3,17-Bisethylenedioxy-5α-androstan-11-one (4)

From a solution of 3 g of 5α-androstane-3,11,17-trione (**3**), mp 174–176°C, and 15 mL of ethylene glycol in 160 mL of dry benzene, some 50 mL was distilled off through a Dean–Stark separator and 100 mg of *p*-toluenesulfonic acid was added. The solution was refluxed with the exclusion of moisture and with a water separator for 18 h and, after cooling, the product was extracted with dichloromethane. The organic solution was washed with a saturated sodium bicarbonate solution and with water, a few drops of pyridine were added, and the mixture was dried over sodium sulfate. Removal of the solvents gave 3.619 g of a product which was crystallized from methanol to give 3.482 g (90% yield) of 3,17-bisethylenedioxy-5α-androstan-11-one (**4**), mp 164–166°C. A sample was recrystallized twice from methanol for analysis; mp 163–165°C; $[\alpha]_D^{26}$ +23 (c 0.950, $CHCl_3$);

[8]This synthesis represents a development of experiments connected with the problem of the preparation of 17-aza steroids.[9] Independently, and subsequently to the beginning of our investigations, Pivnitskiĭ and co-workers (15) used a similar approach for the formation of 11-aza-estradiol and 11-aza-19-nortestosterone derivatives (cf. also ref. 16).[10]

[9]Ch. R. Engel and N. N. Saha. Unpublished results.

[10]When using the procedure followed by Badanova and Pivinitskiĭ (15*b*) for the transformation, via the acid chloride **5***b*, of acid **5***a* into imine **10**, the yield amounted to 64%, considering the recovery of acid **5***a*; this yield is significantly lower than the one we realized (82%) when forming the isocyanate **9** without the intermediacy of acid chloride **5***b*.

ir ν_{max} (KBr): 1700 (11-ketone), 1168, 1095 (ketals) cm^{-1}; nmr δ (90 MHz): 0.77 (s, 3H) and 1.00 (s, 3H) (18- and 19-CH_3), 1.99 (d, 1H, J = 11.5 Hz, 12α-H), 2.47 (d, 1H, J = 11.5 Hz, 12β-H), 3.77 (s, 8H, 3- and 17-OCH_2CH_2O); ms m/e: 390 (M^+), 125, 112, 99 (ethylene ketal fragmentations). *Anal.* calcd. for $C_{23}H_{34}O_5$: C 70.74, H 8.78; found: C 70.43, H 8.56.

3,17-Bisethylenedioxy-5α-androstan-11β-ol (7)

(a) Under vigorous stirring, a solution of 1.2 g of 3,17-bisethylenedioxy-5α-androstan-11-one (**4**), mp 164–166°C, in 30 mL of absolute tetrahydrofuran was added dropwise, at 0°C, to a suspension of 160 mg of $LiAlH_4$ in 100 mL of absolute tetrahydrofuran. The reaction was monitored by tlc analysis; after 5 h, ethyl acetate was added and, subsequently, a saturated aqueous ammonium chloride solution. The tetrahydrofuran solution was separated, the residue was extracted with chloroform, and the extracts were dried over sodium sulfate. Evaporation of the solvents gave 1.052 g (87% yield) of crystals, mp 201–203°C. A sample was recrystallized twice from acetone–hexane for analysis; mp 195–203°C; $[\alpha]_D^{25}$ +32 (c 0.900, $CHCl_3$); ir ν_{max} (KBr): 3520 (OH), 1160, 1082 (ketals) cm^{-1}; nmr δ (90 MHz): 1.02 (s, 3H) and 1.05 (s, 3H) (18- and 19-CH_3), 3.77 (8H, 3- and 17-OCH_2CH_2O), 4.20 (m, 1H, 11α-H); ms m/e: 392 (M^+), 125, 112, 99 (ketal fragmentations). *Anal.* calcd. for $C_{23}H_{36}O_5$: C 70.37, H 9.24; found: C 70.11, H 9.07.

(b) To a solution of 1 g of the diketal **4**, mp 164–166°C, in 80 mL of methanol, 800 mg of sodium borohydride was added with stirring, at room temperature. The solution was refluxed for 3 h, cooled, and poured into 1 L of ice water. The precipitate was filtered, washed, and dried, and the resulting product (1 g, mp 197–202°C) was recrystallized from acetone–hexane to give 900 mg (89% yield) of the 11β-hydroxy diketal **7**, mp 200–203°C. The identity of the product with the one described under *(a)* was established in the usual fashion by spectral comparisons and by the determination of a mixture melting point.

3,17-Bisethylenedioxy-5α-androst-9,11-ene (6a)

A solution of 2.2 g of 3,17-bisethylenedioxy-5α-androstan-11β-ol (**7**) in 6 mL of dry pyridine was left at 0°C for 2.5 h with 20 drops of distilled $SOCl_2$. Crushed ice and water were added, the precipitate was filtered on Celite, washed with water, and dissolved in chloroform. The organic solution was dried with sodium sulfate and taken to dryness to give 2.00 g of a residue which, upon two crystallizations from ether – petroleum ether, gave 1.86 g (88.6%) of 3,17-bisethylenedioxy-5α-androst-9,11-ene (**6*a***), mp 144–147°C. A sample was recrystallized once from ether – petroleum ether for analysis; mp 145–147°C; $[\alpha]_D^{26}$ +51 (c 1.200, $CHCl_3$) ir ν_{max} (KBr): 1635 (double bond), 1170, 1100 (ketals) cm^{-1}; nmr δ (60 MHz): 0.85 (s, 3H, 18-CH_3), 0.95 (s, 3H, 19-CH_3), 3.95 (8H, bisethylene-ketal), 5.35 (d, 1H, 11-H); ms m/e: 374 (M^+), 125, 99 (ketal fragmentations). *Anal.* calcd. for $C_{23}H_{34}O_4$: C 73.76, H 9.15; found: C 73.69, H 9.06.

5α-Androst-9,11-ene-3,17-dione (6)

(a) By transketalization (ref. 20)

To a solution of 7 g of diketal **6*a*** in 150 mL of absolute acetone, 150 mg of p-toluenesulfonic acid was added and the mixture was stirred at room temperature for 4.5 h. The product was diluted with water and was extracted with dichloromethane. The organic solution was washed with a saturated sodium bicarbonate solution and with water and was dried over sodium sulfate. Evaporation of the solvent gave 5 g of a crude product which was chromatographed on silica gel, using hexane–benzene (9:1) as eluent. Thus 3.17 g (72%) of the androstenedione **6** was obtained, mp 146–148°C. A sample was recrystallized from acetone–ether–hexane for analysis; mp 146–148°C (lit. (7) mp 154°C); $[\alpha]_D^{26}$ +153 (c 0.900, $CHCl_3$) (lit. (7) $[\alpha]_D^{14}$ +156); ir ν_{max} (KBr): 1740 (17-ketone), 1715 (3-ketone), 1630 (double bond) cm^{-1}; nmr δ (60 MHz): 0.90 (s, 3H, 18-CH_3), 1.24 (s, 3H, 19-CH_3), 5.55 (br, 1H, 11-H); ms m/e: 286 (M^+), 271 (M – CH_3), 243 (M – CH_3CO), 228 (1,4-seco-2,3,19-trinorandrostra-1(10),4(5),9(11)-trien-17-one). *Anal.* calcd. for $C_{19}H_{26}O_2$: C 79.68, H 9.15; found: C 79.24, H 9.00.

From the above-described chromatogram there was also obtained 1.1 g (18%) of the 3-monoethylenedioxy derivastive of diketone **6**.

(b) By deketalization with humidified, acidic silica gel (ref. 9)

To a suspension of 18 g of silica gel (Merck 60 for column chromatography, 32–63 mesh) in 80 mL of dichloromethane, 1.8 mL of 15% sulfuric acid was added with stirring. After 2–3 min, the aqueous phase disappeared and a solution of 2 g of diketal **6*a***, mp 144–147°C, in 10 mL of dichloromethane was added and the mixture was further stirred at room temperature for 22 h. The product was neutralized with solid sodium carbonate, the mixture was filtered through a fritted glass funnel, and the solid was washed several times with dichloromethane. Evaporation of the solvent from the filtrate gave 1.5 g of an oily product which, upon crystallization from acetone–ether–hexane, gave 1.385 g (90% yield) of the androstenedione **6**, mp 146–148°C, identified by comparison of its infrared spectrum with that of the product described under *(a)* and by the determination of a mixture melting point.

3,9,17-Trioxo-9,11-seco-5α-androstan-11-al (5) and 3,9,17-trioxo-9,11-seco-5α-androstan-11-oic acid (5a) by ozonolysis of the androstenedione 6

Through a solution of 1.193 g of the androstenedione **6**, mp 146–148°C, in 60 mL of dry ethyl acetate there was passed, at –10°C, for 3 h, a stream of oxygen containing 1.75% of ozone, at a flow rate of 220 L/h. The product was treated for 18 h with 1 mL of 30% H_2O_2 and 2 mL of water. Subsequently, 150 mL of water was added and the mixture was extracted with dichloromethane. The organic phase was washed with a cold 2 N aqueous sodium hydroxide solution and with water. After drying over sodium sulfate, the solvent was evaporated to afford 1.083 g of an oily product which gave, upon crystallization from ether–hexane, 1 g (75%) of *3,9,11-trioxo-9,11-seco-5α-androstan-11-al* (**5**), mp 172–175°C. For analysis a sample was recrystallized once more from ether–hexane; mp 171–175°C; $[\alpha]_D^{26}$ +32 (c 0.900, $CHCl_3$); ir ν_{max} (KBr): 2740 (aldehyde), 1735 (17-ketone), 1720 (aldehyde), 1700 (3-ketone) cm^{-1}; nmr δ (90 MHz): 0.79 (s, 3H) and 1.36 (s, 3H) (18- and 19-CH_3), 2.78 (q-AB, 2H, J = 18 Hz, 12-H_2, superimposed on m, 1H, C8β-H), 9.60 (s, 1H, aldehyde); ms m/e: 318 (M^+), 290 (M – CO), 276 (11,12-bisnor-9,13-seco-5α-androstane-3,9,17-trione), 180 (1-methylbicyclo[4.3.0]nonane-4,9-dione$^+$), 97. *Anal.* calcd. for $C_{19}H_{26}O_4$: C 71.67, H 8.23; found: C 71.51, H 8.11.

The aqueous alkaline extract of the dichloromethane solution was acidified with sulfuric acid to the Congo blue reaction and the product was extracted with chloroform. The organic layer was washed with water to neutral, dried over sodium sulfate, and evaporated to afford 305 mg of an oily product which, upon crystallization from benzene, gave 232 mg of *3,9,17-trioxo-9,11-seco-5α-androstan-11-oic acid* (**5*a***), mp 105–106°C, identified by comparison of the infrared and nmr spectra with those of the product described below and by the determination of a mixture melting point.

3,9,17-Trioxo-9,11-seco-5α-androstan-11-oic acid (5a) from aldehyde 5

A solution of 1.2 g of aldehyde **5**, mp 172–175°C, in 60 mL of acetone was treated for 2 h (until the disappearance, on tlc, of the neutral product) with an excess (1.3 mL) of Jones' reagent (18). Isopropyl alcohol (1 mL) and 200 mL of water were added and the product was extracted with dichloromethane. The organic layer was extracted with aqueous 2 N sodium hydroxide, the alkaline extract was acidified to the Congo blue reaction with 2 N H_2SO_4, and the mixture was extracted with chloroform. The organic layer was washed with water and was dried over sodium sulfate. Removal of the solvent gave 1.087 g of crude, oily acid **5*a*** which afforded upon crystallization from benzene 955 mg (76%) of purified acid **5*a***, mp 106–111°C; $[\alpha]_D^{26}$ +22 (c 2.050, $CHCl_3$); ir ν_{max} (KBr): 3400–3000 (acid), 1740 (17-ketone), 1700 (3-ketone and acid) cm^{-1}; nmr δ (90 MHz): 0.77 (s, 3H) and 1.35 (s, 3H) (18- and 19-CH_3), 2.69 (q-AB, outer peaks ill defined, 2H, 12-H_2), 2.86 (m, 8β-H); ms m/e: 335 $(M + 1)^+$, 307, 290 (M – CO_2), 275 (M – CO_2 – CH_3), 231, 180 (8a-methyldecaline-1,6-dione).

Since acid **5***a* decomposes readily, no microanalysis could be performed and the following reactions were carried out without further purifying the product.

The neutral extract of the oxidation reaction (198 mg) was composed of a mixture which was not further investigated.

The total yield of acid **5***a* from the androstenedione **6** amounted to 78%.

11-Aza-5α-androst-9,11-ene-3,20-dione (**10**)

(*a*) *Via the acid chloride 5b, without isolation of the 3,9,17-trioxo seco acid azide 8 and the isocyanate 9*

(*i*) At 0°C, 1.5 mL of oxalyl chloride, dissolved in 10 mL of absolute benzene, was added with repeated shaking to a suspension of 1.193 g of purified acid **5***a*, mp 106–111°C, in 60 mL of absolute benzene. The mixture was allowed to warm to room temperature and was stirred for 12 h, the progress of the reaction being followed by infrared analysis of samples of the reaction mixture. The product was taken to dryness *in vacuo* at room temperature and the residue was redissolved in absolute benzene and taken again to dryness under reduced pressure. This operation was repeated another time. Thus, 1.262 g of crude, solid, *3,9,17-trioxo-9,11-seco-5α-androstan-11-oic acid chloride* (**5***b*) was obtained; ir ν_{max} (KBr): 1800 (acid chloride), 1740 (17-ketone), 1700 (3-ketone) cm^{-1}. This product was used without further purification in the following reaction.

The crude acid chloride **5***b* (1.26 g) was dissolved in 50 mL of acetone and was treated with a paste made up of 500 mg of sodium azide and 0.5 mL of water. The reaction mixture was refluxed for 30 min and a few drops of water were added until the solution became clear. Within 15 min, 50 mL of water were added and the mixture was extracted with chloroform. The organic solution was dried over sodium sulfate and the solvents were evaporated. The crude product (987 mg) did not only contain *3,9,17-trioxo-9,11-seco-5α-androstan-11-oic acid azide* (**8**) but also some rearranged product: *3,9,17-trioxo-9,12-seco-11-nor-5α-androstan-12-yl isocyanate* (**9**); ir ν_{max} (KBr): 2250 (N=C=O), 2130 (N_3), 1800, 1740, and 1700 cm^{-1}. This solid mixture was not separated but dissolved in 3 mL of acetic acid. After addition of 1.1 mL of water the product was warmed and an evolution of N_2 was observed. After the gas evolution had ceased, the mixture was cooled and an aqueous 2 *N* NaOH solution was added until it became alkaline and was then extracted with chloroform. The organic solution was extracted with 10% aqueous hydrochloric acid, the acidic extract was made alkaline with 2 *N* sodium hydroxide, and the product was again extracted with dichloromethane. The organic solution was dried over sodium sulfate and the solvent was evaporated. Thus, 302 mg of an oily product was obtained. It gave upon crystallization from ether–hexane 284 mg (28% yield) of *11-aza-5α-androst-9,11-ene-3,17-dione* (**10**), mp 173–176°C. For analysis, a sample was recrystallized twice from ether–hexane; mp 176–178°C; $[\alpha]_D^{28}$ +165.4 (*c* 1.010, $CHCl_3$); ir ν_{max} (KBr): 1740 (17-ketone), 1715 (3-ketone), 1635 (C=N) cm^{-1}; nmr δ (90 MHz): 0.83 (s, 3H) and 1.25 (s, 3H) (18- and 19-CH_3), 3.41 (d, 1H, J = 13.5 Hz) and 3.79 (d, 1H, J = 13.5 Hz) (12-H_2); ms *m/e*: 287 (M^+), 273 (M − CH_3), 260 (M − HCN), 245, 231. *Anal.* calcd. for $C_{18}H_{25}NO_2$: C 75.22, H 8.77, N 4.87; found: C 75.10, H 8.73, N 4.86.

The original aqueous alkaline solution which had been extracted with hydrochloric acid and the aqueous alkaline solution from which the imine **10** had been extracted with dichloromethane were combined and acidified with 2 *N* sulfuric acid to the Congo blue reaction. The product was extracted with dichloromethane. The organic solution was washed with water and dried over sodium sulfate. Evaporation of the solvent gave 462 mg of an oily product which afforded upon crystallization from benzene 438 mg (37%) of *3,9,17-trioxo-9,11-seco-5α-androstan-11-oic acid* (**5***a*), mp 105–110°C. Its identity was established by the comparison of its infrared spectrum with that of an authentic sample (cf. above) and by the determination of a mixture melting point. Considering the recovery of this starting material, the yield of imine **10** amounted to 44%.

(*ii*) A suspension of 232 mg of freshly activated sodium azide (11, cf. also ref. 21) in a solution in 20 mL of absolute benzene of 502 mg of acid chloride **5***b*, prepared from 500 mg of acid **5***a* as described above under (*i*), was refluxed for 20 h with exclusion of moisture. The product was cooled and filtered. To the filtrate, 5 mL of concentrated hydrochloric acid was added and the mixture was refluxed for 2.5 h. After cooling, the acid layer was separated and the benzene solution was washed with water. The acidic layer and the water washings were combined and made alkaline with 2 *N* sodium hydroxide, and the product was extracted with dichloromethane. The organic solution was washed with water and dried over sodium sulfate. Evaporation of the solvent gave 168 mg (39%) of an oily product which afforded upon crystallization from ether–hexane 146 mg (34%) of *11-aza-5α-androst-9,11-ene-3,17-dione* (**10**), mp 173–176°C. The identity of the product was established by comparison of its infrared spectrum with that of the product described under (*i*), and by the determination of a mixture melting point.

The benzene solution which had been extracted with sodium hydroxide and washed with water (cf. above) was dried over sodium sulfate and the solvent was removed. The oily residue (272 mg) gave upon crystallization from benzene 250 mg (50%) of *3,9,17-trioxo-9,11-seco-5α-androstan-11-oic acid* (**5***a*), mp 105–110°C, identified in the usual manner with an authentic sample. Considering this recovery of starting material, the yield of the imine **10** amounted to 68%.

(*b*) *Via the acid chloride 5b, with isolation of the acid azide 8 and the isocyanate 9*

(*i*) To a solution in 35 mL of acetone of 640 mg of crude acid chloride **5***b*, prepared from 680 mg of acid **5***a* as described above (*a*, *i*), a solution of a 410 mg of sodium azide in 15 mL of water was added at room temperature, with vigorous stirring. The mixture was left at room temperature for another 20 h and 200 mL of water was added. The product was extracted with dichloromethane, and the organic solution was washed with water and dried over sodium sulfate. Removal of the solvent gave 600 mg of a solid, representing crude *3,9,17-trioxo-9,11-seco-5α-androstan-11-oic acid azide* (**8**); ir ν_{max} (KBr): 2128 (C≡N), 1740 (17-ketone), 1700 (3- and 9-ketones) cm^{-1}. This product was used without further purification in the next step.

The crude azide **8** described above was dissolved in 50 mL of benzene and the solution was refluxed for 2 h, at which time gas evolution had ceased. Removal of the solvent under reduced pressure gave 580 mg of crude *3,9,17-trioxo-9,12-seco-11-nor-5α-androstan-12-yl isocyanate* (**9**); ir ν_{max} (KBr): 2250 (N=C=O), 1738 (17-ketone), 1705 (3- and 9-ketones) cm^{-1}. This product was not purified prior to the next step.

The crude isocyanate **9** described above was dissolved in 50 mL of dioxane and there was added, with vigorous stirring and dropwise, 2 mL of concentrated hydrochloric acid. The mixture was left for 20 h at room temperature and was subsequently made alkaline by the addition of 2 *N* sodium hydroxide. The product was extracted with dichloromethane, the organic layer was extracted in turn with 20% aqueous hydrochloric acid, and the acidic extract was made alkaline with 2 *N* sodium hydroxide. The resulting mixture was extracted with dichloromethane, and the organic solution was washed with water and dried over sodium sulfate. Removal of the solvent gave 320 mg of crude, amorphous, *11-aza-5α-androst-9,11-ene-3,17-dione* (**10**) which upon crystallization from ether–hexane gave 291 mg (50%) of pure *azide* **10**, mp 173–176°C, identified in the usual fashion.

The two aqueous alkaline solutions that had been extracted with dichloromethane were combined and were acidified with 2 *N* sulfuric acid to the Congo blue reaction. The mixture was extracted with dichloromethane, and the organic layer was washed with water and dried over sodium sulfate. Removal of the solvent afforded 172 mg (25%) of an oily product which gave upon crystallization from benzene 151 mg (22%) of the *trioxo seco acid* **5***a*, mp 105–110°C, identified in the usual manner. Considering this recovery of starting material, the yield of imine **10** amounted to 64%.

(*ii*) When the procedure employed by Badanova and Pivinitskii (15*b*) in the synthesis of 11-aza-estradiol was used for the transformation of 529 mg of crude acid chloride *5b*, prepared from 562 mg of acid *5a*, into *imine* **10**, 242 mg (50%) of this product, mp 173–176°C, and 120 mg (21%) of *acid* *5a*, mp 105–110°C, were obtained. Considering the recovery of starting material, the yield of imine **10** amounted to 64%.

(*c*) *Without the intermediacy of acid chloride 5b, by direct transformation of the seco acid 5a into the isocyanate 9 and thence into imine 10*

According to the procedure of Grouillier *et al.* (12), there was added, dropwise and with stirring, at −5°C, to a solution of 400 mg of purified 3,9,17-trioxo-9,11-seco-5α-androstan-11-oic acid (*5a*), mp 106–111°C, in 35 mL of acetone, a solution of 0.83 mL of triethylamine in 1 mL of acetone, subsequently a solution of 0.67 mL of ethyl chloroformate in 1 mL of acetone, and, finally, a solution of 0.78 mg of sodium azide in 3 mL of water. The mixture was stirred for 1.5 h at −5°C and then allowed to warm to room temperture, stirring being continued for another 2 h. Ice water (100 mL) was added and the product was extracted with dichloromethane. The organic solution was washed with water and was dried over sodium sulfate. Removal of the solvent gave 388 mg of solid *3,9,17-trioxo-9,12-seco-11-nor-5α-androstan-12-yl isocyanate* (**9**); ir ν_{max} (KBr): 2250 (N=C=O), 1739 (17-ketone), 1705 (3- and 9-ketones) cm^{-1}. This product was used without purification in the next step.

The crude isocyanate **9** described above was dissolved in 30 mL of dioxane and to this solution was added, dropwise and with vigorous stirring, 2 mL of concentrated hydrochloric acid. The mixture was left for 18 h at room temperature and subsequently treated with 2 *N* sodium hydroxide until it became alkaline. The product was extracted with dichloromethane, the organic layer was extracted in turn with 10% aqueous hydrochloric acid, the acidic extract was made alkaline with 2 *N* sodium hydroxide, and the product was again extracted with dichloromethane. The organic solution was washed with water and dried over sodium sulfate. Removal of the solvent gave 270 mg (79%) of an oily product which, upon crystallization from ether–hexane, gave 233 mg (68%) of *11-aza-5α-androst-9,11-ene-3,17-dione* (**10**), mp 173–176°C. The identity of the product was established by comparison of its infrared spectrum with that of an authentic sample (cf. above) and by the determination of a mixture melting point. The aqueous alkaline solutions on which dichloromethane extractions had been performed were combined and acidified with 2 *N* sulfuric acid to the Congo blue reaction. The mixture was extracted with dichloromethane, and the organic layer was washed with water and dried over sodium sulfate. Removal of the solvent afforded 87 mg of an oily product which, upon crystallization from benzene, gave 69 mg (17%) of *3,9,17-trioxo-9,11-seco-5α-androstan-11-oic acid* (**5a**), mp 106–111°C, the identity of which was established in the usual fashion. Considering this recovery of starting material, the yield of imine **10** amounted to 82%.

11-Aza-5α-androstane-3,17-dione (12)

To a solution of 200 mg of the imine **10** in 10 mL of methanol, 2 mL of a 2% HCl solution in methanol was added and, subsequently, with stirring, 100 mg of cyanosodiumborohydride. The reaction was continued for 4 h, the product was made alkaline with an aqueous 2 *N* NaOH solution, and the mixture was extracted with dichloromethane. After washing with water and drying over magnesium sulfate, the solvents were evaporated and the crude product, the keto group of which had been, according to its infrared spectrum (weak carbonyl and OH absorptions), partly reduced, was dissolved in 10 mL of acetone and reoxidized at 0°C in the usual fashion with Jones' reagent (18). After 1 h, the solution was made alkaline with 2 *N* aqueous NaOH and the product was extracted with dichloromethane. The organic solution was washed with water and was dried over magnesium sulfate, and the solvents were removed *in vacuo*. The crystalline residue (200 mg) was recrystallized from ether – petroleum ether to afford 130 mg (65%) of pure 11-aza androstanedione **12**, mp 128–132°C. For analysis a sample was recrystallized twice from ether–hexane; mp 128–132°C; $[\alpha]_D^{26}$ +132.5 (*c* 0.800, $CHCl_3$); ir ν_{max} (KBr): 3360, 3440 (NH), 1740 (17-ketone), 1710 (3-ketone) cm^{-1}; nmr δ (90 MHz): 0.99 (s, 3H) and 1.00 (s, 3H) (18- and 19-CH_3), 2.43 (d, 1H, *J* = 11 Hz) and 2.45 (d, 1H, *J* = 11 Hz) (9α- and 12α-H), 2.91 (d, 1H, *J* = 11 Hz, 12β-H); ms *m/e*: 289 (M^+), 274 (M − CH_3), 261 (M − CO), 232. *Anal.* calcd. for $C_{18}H_{27}NO_2$: C 74.70, H 9.40, N 4.84; found: C 74.78, H 9.32, N 4.81.

N-Acetyl-11-aza-5α-androstane-3,17-dione (12a)

A solution of 180 mg of the 11-aza androstanedione **12** in 0.3 mL of pyridine was heated for 5 min with 0.3 mL of acetic anhydride and subsequently the mixture was left overnight at room temperature. Methanol was added, the product was taken to dryness *in vacuo*, redissolved in benzene, and again taken to dryness; this operation was repeated once. The oily residue (186 mg) was chromatographed on silica gel with benzene–acetone (95:5) as eluent. Thus 90 mg (43% yield) of the crystalline N-acetyl derivative **12***a* was obtained. After two recrystallizations from ether – petroleum ether the product (55 mg) melted at 185–187°C. From the mother liquors, 50 mg of starting material (**12**) was isolated. Thus the effective yield of pure amide **12** corresponded to 45%. A sample of the product was recrystallized once from ether – petroleum ether for analysis; mp 185–187°C; ir ν_{max} (KBr): 1740 (17-ketone), 1710 (3-ketone), 1640 (amide); nmr δ (90 MHz): 0.91 (s, 3H) and 1.10 (s, 3H) (18- and 19-CH_3), 1.99 (s, 3H, CH_3CO), 2.82 (d, 1H, *J* = 13 Hz, 12α-H), 3.85 (d, 1H, *J* = 11 Hz, 9α-H), 4.14 (d, 1H, *J* = 13 Hz, 12β-H); ms *m/e*: 331 (M^+), 316 (M − CH_3), 288 (M − NHCO). *Anal.* calcd. for $C_{20}H_{29}NO_3$: C 72.47, H 8.82, N 4.23; found: C 72.47, H 8.79, N 4.24.

3,3-Dimethoxy-11-aza-5α-androstan-17-one (11)

A solution of 60 mg of 11-aza-5α-androstane-3,17-dione (**12**) in 10 mL of absolute methanol was kept at room temperature with 20 mg of oxalic acid and a few beads of 4A molecular sieves for 20 h. Potassium carbonate and water were added and the product was extracted with dichloromethane. The organic solution was washed with water, a few crystals of potassium carbonate were added, and the mixture was dried over magnesium sulfate. Evaporation of the solvent gave 54 mg (80%) of the crystalline ketal **11**; mp 113–115°C. For analysis the product was recrystallized four times from hexane; mp 114–115°C; $[\alpha]_D^{28}$ +26 (*c* 0.830, $CHCl_3$); ir ν_{max} (KBr): 3360 and 3440 (NH), 1735 (17-ketone), 1128, 1100, and 1049 (ketal) cm^{-1}; nmr δ (90 MHz): 0.88 (s, 3H) and 0.98 (s, 3H) (18- and 19-CH_3), 2.47 (d, 1H, *J* = 13 Hz, 12α-H), 2.91 (d, 1H, *J* = 13 Hz, 12β-H), 3.01 (s, 3H, OCH_3), 3.06 (s, 3H, OCH_3); ms *m/e*: 335 (M^+), 303 (M − CH_3OH), 289. *Anal.* calcd. for $C_{20}H_{33}NO_3$: C 71.60, H 9.92, N 4.18; found: C 71.25, H 9.74, N 4.17.

17β-Hydroxy-11-aza-5α-androstan-3-one (11-aza-4,5α-dihydrotestosterone) (1)

At 0°C, a solution of 370 mg of crude ketal **11** in 30 mL of absolute tetrahydrofuran was added dropwise and with stirring, in the course of 20 min, to a suspension of 100 mg of lithium aluminum hydride in 30 mL of absolute tetrahydrofuran. After 20 min ethyl acetate and, subsequently, a saturated aqueous ammonium chloride solution were added and the organic layer was separated. The aqueous layer was extracted with chloroform and both organic solutions were combined, washed with water, and dried over magnesium sulfate. Evaporation of the solvents gave 340 mg (92%) of crude *3,3-dimethoxy-11-aza-5α-androstan-17β-ol* (**11***a*), melting after two recrystallizations from acetone– ether at 162–164°C; ir ν_{max} (KBr): 3400–3280 (broad OH and NH band), 1114, 1100, 1046 (OCH_3) cm^{-1}; nmr δ (90 MHz): 0.83 (s, 3H) and 0.87 (s, 3H) (18- and 19-CH_3), 2.31 (d, 1H, *J* = 13 Hz, 12α-H), 2.97 (d, 1H, *J* = 13 Hz, 12β-H), 3.02 (s, 3H, OCH_3), 3.06 (s, 3H, OCH_3), 3.55 (1H, br, 17α-H). According to tlc analysis, this product contained an impurity even after purification, and was used in the crude state in the deprotection reaction of the 3-ketone. A quantity of 300 mg of crude ketal **11***a* was dissolved in 30 mL of absolute acetone and treated for 48 h at room temperature with 30 mg of *p*-toluenesulfonic acid. Subsequently, water, a few crystals of sodium hydrogen carbonate, and a few drops of an aqueous NaOH solution were added, the mixture was extracted with dichloromethane, and the organic solution was washed with water and dried over magnesium sulfate. Evaporation of the solvents gave 180 mg (69%) of *17β-hydroxy-11-aza-5α-androstan-3-one (11-aza-4,5α-dihydrotestosterone)* (**1**). The analytical sample was prepared by four recrystallizations from acetone − petroleum ether − hexane; mp 159−160°C; $[\alpha]_D^{26}$ +142 (c 0.500, $CHCl_3$); ir ν_{max} (KBr): 3400−3260 (broad band, OH, NH), 1715 (3-ketone) cm^{-1}; nmr δ (90 MHz): 0.88 (s, 3H) and 1.08 (s, 3H) (18- and 19-CH_3), 2.37 (d, 1H, J = 13 Hz, 12α-H), 3.00 (d, 1H, J = 13 Hz, 12β-H), 3.59 (t, 1H, 17α-H); ms m/e: 291 (M^+), 276 ($M - CH_3$), 166 (1-methyl-5-methylene-9-hydroxy-3-azabicyclo[4.3.0]nonane$^+$), 153 (1-methyl-9-hydroxy-3-azabicyclo-[4.3.0]non-4,5-ene). *Anal.* calcd. for $C_{18}H_{29}NO_2$: C 74.18, H 10.03, N 4.81; found: C 74.24, H 10.01, N 4.73.

Acknowledgements

We remember with deep gratitude the late Mrs. J. Capitaine who cooperated in some of the experiments described here, and we sincerely thank Mrs. M. M. Lourdusamy for her cooperation in some other experiments, as we express our appreciation to Mrs. D. Thibeault for technical assistance. This study was performed pursuant to contract No. N01-HD-8-2815 with the National Institutes of Health, U.S. Department of Health, Education, and Welfare. We express our gratitude for this support and for the cooperation of the National Institute of Child Health and Human Development, especially to Dr. H. K. Kim. We also acknowledge with sincere thanks financial assistance and support from the National Research Council of Canada, the Natural Sciences and Engineering Research Council of Canada, the Ministère de l'Education du Québec, and Ayerst Laboratories, Montréal.

Concerning $^5J_o^{OH,CH_3}$ in 2-methylphenol and its derivatives. A proximate coupling

TED SCHAEFER, TIMOTHY A. WILDMAN, AND RUDY SEBASTIAN

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received July 6, 1984

TED SCHAEFER, TIMOTHY A. WILDMAN, and RUDY SEBASTIAN. Can. J. Chem. **63**, 773 (1985).

In 2-chloro-6-methylphenol in CCl_4 solution, $^5J_o^{OH,CH_3}$, the spin–spin coupling between the hydroxyl and methyl protons, is +68(3) mHz. In this compound, the hydroxyl group lies *trans* to the methyl group. If the coupling becomes −120 ± 60 mHz in a *cis* orientation of these two groups, then the apparent vanishing of $^5J_o^{OH,CH_3}$ in some derivatives of 2-methylphenol is understandable, as well as its presence in other derivatives. Computations of this coupling imply its proximate mechanism and can rationalize its value of −220 ± 20 mHz in 2-*tert*-butyl-6-methylphenol. Analogies are noted with $^5J_o^{OH,CF_3}$ in 2-trifluoromethyl phenol and with a coupling in styrene, which also appears to vanish in certain orientations of the vinyl group.

TED SCHAEFER, TIMOTHY A. WILDMAN et RUDY SEBASTIAN. Can. J. Chem. **63**, 773 (1985).

Dans le chloro-2-méthyl-o phénol en solution dans le CCl_4, la constante de couplage spin–spin, $^5J_o^{OH,CH_3}$, entre les protons de l'hydroxyle et du groupement méthyle est égale à +68(3) mHz. Dans ce composé, le groupement hydroxyle occupe une position *trans* par rapport au groupement méthyle. Si la valeur de ce couplage devient égale à −120 ± 60 mHz pour une orientation *cis* de ces deux groupes, on peut alors facilement comprendre l'apparente disparition du $^5J_o^{OH,CH_3}$ dans quelques dérivés du méthyl-2 phénol ainsi que sa présence dans d'autres dérivés. Des calculs de ce couplage suggèrent son mécanisme par proximité et peuvent rationaliser sa valeur de −220 ± 20 dans le *tert*-butyl-2 méthyl-6 phénol. On note un certain nombre d'analogies avec les valeurs de $^5J_o^{OH,CF_3}$ dans le trifluorométhyl-2 phénol ainsi qu'avec un couplage dans le styrène qui semble aussi disparaître avec certaines orientations du groupement vinyle.

[Traduit par le journal]

Introduction

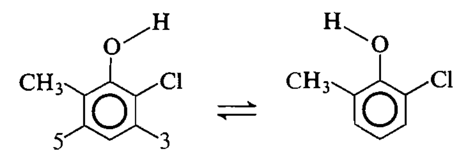
Negative proton spin–spin coupling constants over five formal bonds are usually attributable to proximate interactions involving a close approach of the bonds or atoms carrying the protons in question (1–10). An example is $^5J_o^{H,CH}$ in 2,5-dichlorostyrene (1), involving an *ortho* ring proton and that β-proton which, in a planar conformation, lies very near the ring C—H bond. Other examples are $^5J_o^{H,CH_3}$ in anisole (2, 3, 8–10) and thioanisole derivatives (5–7). The magnitude of $^5J_o^{H,CH_3}$ drops off rapidly as the OCH_3 or SCH_3 moieties move away from the benzene plane (6, 8–10). Indeed, $^5J_o^{H,CH_3}$ is a useful conformational indicator (5–10) and a detailed theoretical study for anisole indicates its mechanism and conformational dependence (10).

If the methyl group in anisole is relocated to form 2-methylphenol, then models suggest that the corresponding proximate coupling, $^5J_o^{OH,CH_3} \equiv {}^5J$, should be observable, at least in a *cis* orientation of the hydroxyl and methyl groups. Because the barrier to rotation about the Csp^2—O bond in phenol is high relative to kT at ambient temperatures, discussion in terms of *cis* and *trans* planar orientations of the hydroxyl group is adequate for 2-methylphenol (11–15).

In the following brief discussion, some peculiar observations on ^5J in 2-methylphenol and its derivatives are rationalized via an experiment on 2-chloro-6-methylphenol. $^5J_{cis} \equiv {}^5J_c$ is established as a proximate coupling, is compared with some analogous couplings in other compounds, and is used to assess the reliability of some molecular orbital calculations of the stabilities of certain conformers of 2-methylphenol.

Discussion

In a number of 2-methylphenol derivatives, ^5J sometimes but not always leads to a broadening of the hydroxyl ^1H nmr peaks. In 2-methylphenol itself in CCl_4 solution at 305 K (15), this coupling must be very small, say ≤20 mHz in magnitude, judging from the spectrum of the hydroxyl proton in ref. 15, where the linewidth at half-height is ≤70 mHz and seven peaks are cleanly resolved in a spectral range of less than 1 Hz. ^5J



a trans   *b cis*

must also be very small in 2-allyl-6-methylphenol (11). Yet it clearly exists in 2-isopropyl-6-methylphenol (16), and in 2-*tert*-butyl-6-methylphenol ^5J is −220 ± 20 mHz (17). An interpretation of this apparent inconsistency is reached as follows.

In 2-chloro-6-methylphenol, no coupling between the hydroxyl proton and H-3 is detectable (see Experimental and Table 1). As established in a variety of experiments (11–15), this observation is consistent with the virtual exclusion of the *cis* conformer, *b*, in the *a*–*b* equilibrium. A recent ranking of *ortho* substituents as hydrogen bond accepters or repellers in *ortho* substituted phenol derivatives (18) implies that 2-chloro-6-methylphenol exists as the *trans* form, *a*, to the extent of 99% in CCl_4 solution at 305 K. This internally consistent ranking for twelve *ortho* substituents implies that the free energy difference favoring *a* over *b* is 11.5 kJ/mol at 305 K. The presence of as much as 5% of *b* should have been detectable by decoupling experiments, if in no other way, because it would entail a coupling of about 30 mHz between H-3 and the hydroxyl proton. In fact, the linewidths of the peaks due to H-3 and H-5 were identical to within experimental error at ca. 0.05 Hz (at 300 MHz), fully consistent with a negligible quantity of *b*.

Another assumption used below is that nonplanar conformations of the hydroxyl group can be neglected. In the gas phase, the internal barrier to rotation in phenol is 14.6 kJ/mol (19–21), quite large compared to thermal energies of 2.5 kJ/mol at 305 K. In pentachlorophenol the internal barrier rises to 26.4 kJ/mol, no doubt due to internal hydrogen bonding (22). In form *a* the barrier to internal rotation is therefore very likely rather larger than in phenol. The presence of significant nonplanar conformations should also have been reflected in a measurable $^6J_p^{H,OH}$. Yet the peaks due to H-4 are at least as

TABLE 1. ^{1}H nuclear magnetic resonance spectral parameters for a 4.7 mol% solution of 2-chloro-6-methylphenol in CCl_4 at 100.001 MHz and 305 K

Parameter	Value	Parameter	Value
δ_{OH}	5.4672[a]	$^5J_o^{OH,CH_3}$	+0.068(3)[d]
δ_{CH_3}	2.2493	$^5J_m^{H,CH_3}$	0.322(2)
δ_3	7.0643	$^6J_p^{OH,H}$	*c*

[c]No evidence for its presence.
[d]Sign and magnitude determined at 300 MHz, see Fig. 1 and Experimental.

narrow as those arising from the other ring protons. $^6J_p^{H,OH}$ is no doubt a σ−π coupling and, as such, should vary as $\sin^2\theta$, where θ is the out-of-plane twist about the C—O bond (in thiophenol, with a low barrier to internal rotation, the analogous coupling is −0.33 Hz (23, 24)). It is also possible that the barrier in phenol is larger in solution than in the vapor, as found for anisole, for example (25). The assumption of a planar *a* appears reasonable.

Furthermore, because $^6J_p^{H,OH}$ has not been observed in any of the other phenol derivatives mentioned below, the discussion for all of them assumes *cis–trans* equilibria of planar conformations. As summarized previously (17), a variety of physical methods are all consistent with coplanar conformations of the hydroxyl group even in a highly hindered molecule like 2,6-di-*tert*-butylphenol. Again, the spin–spin coupling data on 2-isopropyl-6-methylphenol (16) are consistent with correlated conformations of the hydroxyl and isopropyl groups and no nonplanar conformations of the hydroxyl moiety were needed to interpret the experimental results.

Figure 1 shows that ^5J is +68(3) mHz. If ^5J is to be zero or very nearly zero in 2-methylphenol, then the precise coupling data (15) and the concomitant conformational deductions imply the expression $(0.65 \pm 0.01)\ ^5J_t + (0.35 \pm 0.01)\ ^5J_c = \pm 20$ mHz, assuming 20 mHz as a possible error. In this expression, 0.65 is the fraction of the *trans* form in 2-methylphenol, anologous to *a* above, ^5J_t and ^5J_c are the OH,CH_3 couplings for the *trans* and *cis* conformers, respectively. Taking ^5J_t as +68 mHz, ^5J_c follows as −126 ± 57 mHz.

Because 2-allyl-6-methylphenol has the same *cis* and *trans* populations (11) as 2-methylphenol, the apparent vanishing of ^5J in the former is also understandable.

However, in 2-isopropyl-6-methylphenol the population of the *cis* form is 62%. The expression above then yields ^5J as −52 ± 25 mHz, sufficient to account for the observed broadening (16) of the hydroxyl proton resonance. In this compound the methyl protons couple to the methine proton of the isopropyl group, as well as to the ring and hydroxyl protons, disallowing clean experiments of the kind displayed for 2-chloro-6-methylphenol in Fig. 1.

In 2-*tert*-butyl-6-methylphenol, the *cis* conformer, analogous to *b*, has a fractional population of 0.85 in CCl_4 at 305 K (17). The values for ^5J_c and ^5J_t deduced above would yield a ^5J of

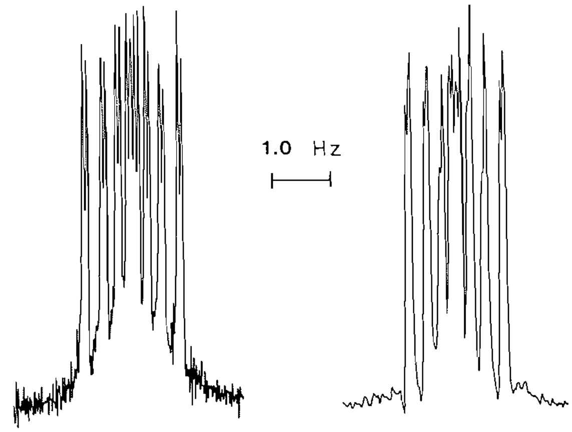

FIG. 1. The methyl group ^{1}H nmr spectrum of 2-chloro-6-methylphenol in CCl_4 at 293 K and 300.135 MHz is shown at the left. Sixteen peaks arise from spin–spin coupling to the four other protons in the molecule. The smallest splitting is 0.068(3) Hz or 68(3) mHz in magnitude. The sign of this coupling was established by double resonance experiments, in which selected peaks from H-5 were weakly irradiated. One such experiment is shown at the right, where the methyl peaks are displayed under conditions in which the H-5 peak at lowest field is being irradiated. In short, low-field peak perturbations observed in the methyl resonance established that $^5J^{OH,CH_3}$ has the same sign as $^5J_m^{OH,H-5}$. The latter is positive. In order to obtain high digital resolution, the methyl bond in the single resonance experiment was isolated using a narrow sweepwidth (100 Hz) and a data area of 8 k (zero-filled to 16 k). For double resonance experiments the sweepwidth had to be increased to include both ring and methyl resonance (1800 Hz). In order to obtain comparable digital resolution, 64 k of data area was used (zero-filled to 128 k). In both cases, 4 scans were acquired using quadrature detection.

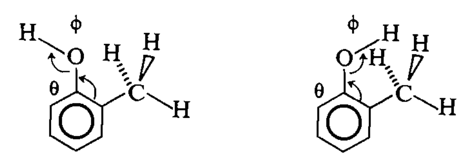
−97 ± 48 mHz. The observed value is −220 ± 20 mHz (17). This discrepancy can be rationalized. A substantial distortion of the geometry at the hydroxyl group is indicated by other spin–spin couplings in 2-*tert*-butylphenol, but must be rather less severe in 2-*tert*-butyl-6-methylphenol (17). As argued below, because ^5J_c is a proximate coupling small angle changes can lead to changes in the average distance between the C—H and O—H bonds sufficient to account for the excess magnitude of about 100 mHz in ^5J_c in this compound.

INDO MO FPT computations of $^5J_o^{H,CH_3}$ in anisole yield realistic values for this proximate coupling (10). By analogy, such computations for $^5J_o^{OH,CH_3}$ in 2-methylphenol may well

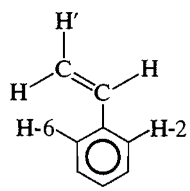


c *d*

prove enlightening. For standard geometries (26), other than the angles θ and ϕ defined in *c* and *d*, the computed ^5J_t varies between −2 and +15 mHz for $120° \le \theta \le 122°$ and $108° \le \theta \le 112°$ in the *trans* form, *c*. In phenol itself θ and ϕ are 122.1 and 108.8°, respectively (27). For the *cis* form, *d* ^5J_c is calculated as −660 mHz for θ = 120°, ϕ = 108° and as −470 mHz for θ = 122°, ϕ = 108°. Similarly, for θ = 120°, ϕ = 112°, ^5J_c becomes −520 mHz and is −370 mHz at θ = 122°, ϕ = 112°. Examination of ^5J_c for the grid of θ,ϕ angles shows that an increase of 1° in θ or 2° in ϕ causes a change of 100 mHz in the computed ^5J_c, the magnitude decreasing as the hydroxyl proton moves away from the methyl group. In other words, small geometrical changes in 2-*tert*-butyl-6-methylphenol, plausibly caused by the bulky *tert*-butyl group and leading to a small decrease in the average distance between the hydroxyl and 6-methyl groups, can lead to the observed −220 mHz for ${}^5J$ in this compound, only about 100 mHz of this value being needed as the result of geometry distortion.

The almost quantitative agreement between computed and observed ${}^5J_o^{\mathrm{H,CH_3}}$ in anisole (9, 10) is not repeated for ${}^5J_c$ in 2-methylphenol. The geometry of the latter is not known nearly as well as that of anisole, probably accounting for at least part of the discrepancy in a computed parameter so sensitive to actual geometry. Nevertheless, the computed values of ${}^5J_c$ strongly imply ${}^5J_c$ as a proximate coupling, in agreement with the available experimental data.

It may be noted that in 2-trifluoromethylphenol, ${}^5J_o^{\mathrm{OH,CF_3}}$ is -4.7 ± 0.2 Hz and ${}^5J_o^{\mathrm{OH,CF_3}}$ is +0.3 Hz (13). The former is certainly a proximate coupling (28) and the latter has the same sign as ${}^5J_t$ in 2-methylphenol.



e

The vanishing ${}^5J_o^{\mathrm{H,CH}}$ in styrene, *e* (29) and in 3,5-dibromostyrene (unpublished work in this laboratory), and its value of −150 mHz in 2,5-dichlorostyrene (1), indicate that its value is about +150 mHz in a *trans* orientation of the *ortho* C—H (H-2 in *e*) and sidechain C—H bonds. In styrene the observed coupling is the mean of the *cis* and *trans* couplings, those to H-2 and H-6. It is interesting, therefore, that ${}^5J_o^{\mathrm{H,CH'}}$ is +158 mHz in styrene and +157 mHz in 3,5-dibromostyrene. On the assumption that this coupling is a measure of the normally positive σ and (or) σ−π electron contribution to ${}^5J_o^{\mathrm{H,CH}}$, then it is cancelled by the negative proximate component to yield the approximately zero observed value of ${}^5J_o^{\mathrm{H,CH}}$ in styrene.

Finally, the present dscussion of ${}^5J^{\mathrm{OH,CH_3}}$ in 2-methylphenol and its derivatives is consistent with our previous, and the only direct, determination (15) of the $a-b$ equilibrium in 2-methylphenol. This equilibrium has been discussed extensively from various viewpoints (30−32), estimates of the *trans* population ranging from 93% to 17% near 300 K. Some MO computations (31) imply that the *trans* form, *c*, and a closely related *trans* conformer in which a C—H bond of the methyl group eclipses the C—O bond are nearly isoenergetic. Our computations of ${}^5J_t$ for the latter structure imply values as negative as −50 mHz. Comparison with the positive values computed and observed for *c*, as discussed above, suggests only minor populations of the eclipsed *trans* conformer.

Experimental

A 4.7 mol% solution of 2-chloro-6-methylphenol (Aldrich) in CCl_4 solution, containing ca. 3 mol% tetramethylsilane, was transferred to a 5-mm od nmr sample tube. The sample tube contained beads of previously dried molecular sieve from Fisher (4−8 mesh with 3 Å pore size) and the transfer took place in a dry box. The sample was degassed by eight cycles of a freeze−pump−thaw procedure and was then flame-sealed.

The ^{1}H nmr spectrum was calibrated on an HA100 nmr spectrometer at a probe temperature of 305 K by a method already described in detail (33). The peak frequencies were determined with a typical standard deviation of less than 0.015 Hz. The spectrum was analyzed with the computer program LAME (34, 35) and the spectral parameters appear in Table 1.

The assignment of H-3 and H-5 follows umambiguously from the magnitudes of their couplings to the methyl protons, ${}^4J_o^{\mathrm{H,CH_3}}$ always being larger than ${}^6J_p^{\mathrm{H,CH_3}}$ in toluene derivatives (36−38). Furthermore, ${}^3J_{34}$ is larger than ${}^3J_{45}$, as expected from known substituent effects on vicinal coupling constants in benzene derivatives (39, 40).

The crucial parameter, ${}^5J^{\mathrm{OH,CH_3}}$, could not be obtained to sufficient accuracy from the spectrum at 100 MHz. The latter was not first order and led to severe overlap in the resonance of the methyl protons. Its magnitude was 0.08 ± 0.02 Hz. However, at 300 MHz the ^{1}H nmr spectrum is essentially first order. Figure 1 displays the 16 peaks expected from the methyl protons. The smallest splitting, 0.068(3) Hz, turns out to be positive and represents ${}^5J^{\mathrm{OH,CH_3}}$. This spectrum was recorded on a Bruker AM300 spectrometer in a manner described in the caption to Fig. 1. The weak irradiation experiments for relative sign determinations (41) showed that ${}^5J^{\mathrm{OH,CH_3}}$ has the same sign as ${}^5J_m^{\mathrm{OH,H\text{-}5}}$. The latter is positive (42).

INDO MO FPT (43) computations were done on an Amdahl 470/V8 system.

Control of the orientation of the aldehyde group in 2-(alkylthio)benzaldehydes by the directional lone-pair on sulfur

TED SCHAEFER, GLENN H. PENNER, KERRY J. DAVIE, AND RUDY SEBASTIAN
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received June 14, 1984

TED SCHAEFER, GLENN H. PENNER, KERRY J. DAVIE, and RUDY SEBASTIAN. Can. J. Chem. **63**, 777 (1985).

The [1]H nmr spectral parameters for 2-alkylthio derivatives benzaldehyde (alkyl = CH_3, CH_2CH_3, $CH(CH_3)_2$, $C(CH_3)_3$) are used to show that the O-*syn* conformation of the aldehyde group decreases from 40% for the methyl to zero for the *tert*-butyl compound in CCl_4 solution at about 300 K. It appears that the alkylthio groups twist out of the benzene plane to the same extent as in the alkyl phenyl sulfides and that it is the concomitant approaches of the $3p$ lone-pairs on sulfur into the ring plane which, by repulsive interactions with the C=O bond, determine the conformations of the aldehyde group. The spectral parameters display interesting changes as the size of the alkyl group increases. For example, the chemical shift of the aldehydic proton is larger than that reported for any other benzaldehyde derivative in CCl_4 solution.

TED SCHAEFER, GLENN H. PENNER, KERRY J. DAVIE et RUDY SEBASTIAN. Can. J. Chem. **63**, 777 (1985).

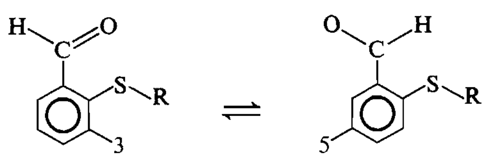
On utilise les paramètres des spectres de la rmn du [1]H d'alkylthio-2 benzaldéhydes (alkyl = CH_3, CH_2CH_3, $CH(CH_3)_2$ et $C(CH_3)_3$) pour démontrer que, en solution dans le CCl_4 et à environ 300 K, le pourcentage du groupement aldéhyde existant sous la conformation O-*syn* diminue de 40% dans le cas du méthyle à zéro pour le composé *tert*-butylé. Il semble que le taux de déplacement des groupements alkylthio hors du plan du benzène est semblable à celui que l'on observe dans les alkyl phényl sulfures et que ce soit l'approche concomitante des paires libres $3p$ du soufre dans le plan du cycle qui, par des interactions répulsives avec la liaison C=O, détermine les conformations du groupement aldéhyde. Les paramètres spectraux présentent des changements intéressants lorsque la taille des groupements alkyles augmente. Par exemple, le déplacement chimique du proton aldéhydique est plus grand que ceux rapportés pour tout autre dérivé du benzaldéhyde en solution dans le CCl_4.

[Traduit par le journal]

Introduction

A recent study of 2-(methylthio)benzaldehyde demonstrated that, contrary to previous investigations, a planar heavy-atom structure is preferred and that the O-*syn*, 1*a*, and O-*anti*, 1*b*, forms are present in similar proportions in CCl_4 solution at 305 K (1). These conclusions depended on the interpretation of the long-range spin–spin coupling constants between side-chain and ring protons and of the proton chemical shifts.

1 R = CH_3
2 R = CH_2CH_3
3 R = $CH(CH_3)_2$
4 R = $C(CH_3)_3$



a O-*syn* ⇌ *b* O-*anti*

It is interesting that the populations of *a* and *b* in **1** are not drastically different from those in 2-methylbenzaldehyde in the same solvent (2, 3), whereas 2-chloro and 2-methoxybenzaldehydes exist almost completely as the O-*anti* forms (4, 5). Perhaps favorable dipole–dipole interactions between the C=O and C—S bonds occur in 2-methylthiobenzaldehyde. It is also true that, as the size of alkyl group increases in the 2-alkylbenzaldehydes, the population of the O-*anti* conformer increases, reaching 100% in 2-*tert*-butylbenzaldehyde (3).

Now, for alkylphenylsulfides, ultraviolet, infrared, photoelectron, [13]C nmr, and [1]H nmr spectroscopies all agree that the alkyl group twists out-of-plane as the size of the alkyl group increases, perhaps reaching a twist angle of near 90° in *tert*-butylphenylsulfide (6–12). The preferred conformation of thioanisole is planar, but with a lower internal barrier than anisole, the $3p\cdots\pi$ conjugation favoring planarity being substantially weaker than the $2p\cdots\pi$ conjugation in anisole.

It is of interest whether the steric repulsions favoring nonplanar conformations for SR (R = CH_2CH_3, $CH(CH_3)_2$, $C(CH_3)_3$) dominate in the 2-(alkylthio)benzaldehydes or whether the enhanced conjugation caused by the π-electron accepting aldehyde function, together with its steric property, causes increased planar tendencies in the S-alkyl groups. Further, from the viewpoint of steric repulsions, the O-*syn* and O-*anti* populations need not change much as the size of R increases, even for perpendicular conformers; formally, the interaction between the C=O group and the thioalkyl substituent is dominated by the sulfur atom (interatomic distances). However, the occupied $3p$ orbital is twisted into the benzene plane in perpendicular conformations and therefore the $C{=}O\cdots S$ interaction should now be repulsive (Pauli), causing increased O-*anti* populations relative to the essentially planar 2-methylthiobenzaldehyde.

This paper reports on the resolution of these possibilities.

Experimental

The 2-(*tert*-butylthio)benzaldehyde, **4**, was obtained from Maybridge Chemical Co. The ethyl- and isopropylthiobenzaldehydes were prepared by alkylation of 2-mercaptobenzyl alcohol (Fairfield Chemical Co.) with the iodide, followed by oxidation to the benzaldehyde derivatives with pyridinium chlorochromate (13). Solutions in CCl_4 contained enough tetramethylsilane for an internal lock at 100 MHz, or cyclohexane-d_{12} at 90 MHz and 300 MHz. These were transferred to 5-mm od nmr sample tubes, were degassed by the freeze–pump–thaw procedure, and the tubes were then flame-sealed. The [1]H nmr spectra in the CW or FT mode were accumulated by the methods recently described in detail (14).

Results and discussion

Spectral analyses

The [1]H nmr spectra were analyzed with the computer programs LAME (15, 16) and NUMARIT (17). Table 1 contains the [1]H nmr spectral parameters. Those for 2-(methylthio)-benzaldehyde and for benzaldehyde itself are included because they are needed in the subsequent discussion. The chemical shifts are only quoted to an accuracy of 1 ppb for the sulfur

[c]5.0 mol% at 305 K and 90.024 MHz.
[d]4.5 mol% at 295 K and 300.135 MHz.
[e]4.0 mol% at 305 K and 100.00 MHz.
[f]Delta (δ) values given to a precision of 1 ppb, although they are known to higher precision.
[g]Numbers in parentheses are the standard deviations in the last significant figure for the coupling constants in Hz.
[h]No evidence for the existence of these couplings was observed in the spectra.
[i]See text and note that in C_6D_6 solution this coupling drops in magnitude.
[j]The sign could not be determined but is taken as negative in analogy to other such couplings.

compounds. They are known to considerably higher precision but, of course, are concentration dependent and therefore no purpose is served by quotation to higher precision. The footnotes to Table 1 assess the reliability of coupling constants below 0.1 Hz in magnitude. Figure 1 displays part of the ^1H nmr spectrum of H-6 in 2-(isopropylthio)benzaldehyde, demonstrating resolution of a coupling whose magnitude is 0.10 Hz.

*Populations of the O-*syn *and O-*anti *forms*

The sum of $^5J_m^{H,CHO}$ increases monotonically from 0.76 Hz in benzaldehyde to 0.91 Hz in its 2-*tert*butylthio derivative (Table 1). All available data (4, 5, 18–20) imply that $^5J_3$ in the O-*anti* form, *b*, and $^5J_5$ in the O-*syn* form, *a*, are too small to detect. In 2-fluorobenzaldehyde, the sum of the $^5J_m^{H,CHO}$ values is 0.86 Hz (19). For this compound CNDO MO FPT computations imply that $^5J_3$ in the O-*syn* form increases by 0.03 Hz relative to its computed value of 0.90 Hz in benzaldehyde and that $^5J_5$ in the O-*anti* form decreases by 0.02 Hz. This result is in disagreement with the ^5J values in Table 1, where $^5J_5$ in the O-*anti* form is largest (see the 2-*tert*butylthio derivative).

If both ^5J values increase by the same amount on substitution, then the population ratio of the O-*syn* to O-*anti* conformers is simply given by $^5J_3/^5J_5$, yielding 41:59, 23:77, 9:91, and 0:100 for R = CH_3, CH_2CH_3, $CH(CH_3)_2$, and $C(CH_3)_3$, respectively. If $^5J_3$ in the O-*syn* form remains unchanged from its value in benzaldehyde and the increase occurs in $^5J_5$ in the O-*anti* form, the populations of the former increase by 3% for R = CH_3, 4% for R = CH_2CH_3, and 2% for R = $CH(CH_3)_3$. Conversely, these increases turn into comparable decreases if the opposite perturbation of the ^5J values is assumed. It seems safe to conclude that the populations are known to a few percent.

Furthermore, the values of $^6J_p^{H,CHO}$ for these compounds imply very small deviations of the aldehyde group from the ring plane, so that discussion in terms of an *a*−*b* equilibrium is adequate. Thus, in the presence of two sizeable *ortho* substituents $^6J_p^{H,CHO}$ becomes significant in magnitude, reflecting its σ−π mechanism and an out-of-plane twist of the CHO moiety (21). Only $^6J_p^{H,CHO}$ for R = $C(CH_3)_3$ appears at first sight to be significant, being −0.06(1) Hz (Table 1). However, H-3, H-4, and H-5 are very tightly coupled at 100 MHz, the shift range being only 0.1 ppm, so that the precision of the analysis is rather poor (Table 1). Accordingly, a sample was prepared in benzene-d_6 solution. Here the shift range is 0.36 ppm and $^6J_p^{H,CHO}$ is given as −0.045(5) Hz by an analysis, much the same as for most of the other compounds in Table 1. It should be noted that no splittings due to this coupling were actually

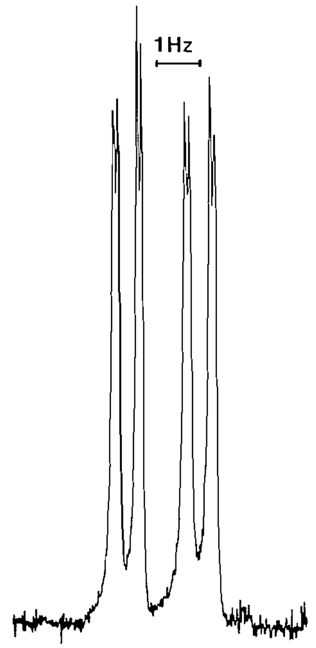

FIG. 1. Part of the ^{1}H nmr spectrum at 300 MHz and 295 K of H-6 in 2-(isopropylthio)benzaldehyde as a 4.5 mol% solution in CCl_4. The smallest splitting is 0.10 Hz and represents the coupling to the aldehyde proton, $^4J_6^{H,CHO}$

observed and that the best analysis, that at 300 MHz for R = $CH(CH_3)_2$, gave −0.009(2) Hz for $^6J_p^{H,CHO}$. Accordingly, it is concluded that, as for benzaldehyde, nonplanarity of the aldehyde group is insignificant. The barrier to rotation about the C—C bond in benzaldehyde is about 31 kJ/mol, much larger than *kT* (22).

The conformations of the —SR groups

(i) Ring proton shifts

The SCH_3 group is a π electron donor, causing an upfield shift for H-4 of about 0.21 ppm relative to benzene (23) in thioanisole. As the size of the alkyl group increases, H-4 shifts to low field, indicating a preferred perpendicular conformation for R = $C(CH_3)_3$, as does the C-4 chemical shift (6–8, 11). Now a plot of δ_5 for the 2-(alkylthio)benzaldehydes from Table 1 versus δ_4 in the alkylthiobenzenes (6) is linear within experimental error and has a slope near unity, implying that the conformation of the alkylthio group in the former is very similar to that in the latter. Note also that in 2-(*tert*-butylthio)-benzaldehyde, 7.467 for δ_5 is very close to that in benzaldehyde, 7.45; this is evidence for negligible π electron donation in the former.

The simplest explanation of these shift correlations is that the alkylthio group conformational preference is very much the same in the two sets of compounds and that the conformation of the aldehydic function is determined by repulsive forces from the directional 3*p* lone-pair of sulfur. This lone-pair lies predominantly perpendicular to the benzene plane in the SCH_3 compounds but lies mainly in the plane in the $SC(CH_3)_3$ compound. In the latter the C=O···3*p* repulsion is so large that only the O-*anti* form exists at 305 K.

δ_4 in **1** to **4** increases by 0.07 as does the corresponding δ in the alkylthiobenzenes, confirming the conclusions above. On the other hand, δ_6 in going from **1** to **4** increases by 0.19 ppm. This result may be rationalized as follows. In benzaldehyde, δ_6 consists of equal contributions from the *cis* orientations of the C=O and C—H bonds of the aldehyde group. In **4**, the C=O bond lies exclusively *cis* to H-6. Correction by 0.07 ppm for the $SC(CH_3)_3$ group (the shift change at H-4) then yields δ_6 (C=O, *cis*) as 7.86 and δ_6 (C—H, *cis*) as 7.76. In other words, the electrical and (or) the magnetic anisotropy of the C—O dipole causes only a 0.1-ppm low-field bias in δ_6 in the O-*anti* conformation. The magnitude of the bias will decrease rapidly with distance, accounting for the success of the arguments above concerning δ_4 and δ_5 in **1** to **4**.

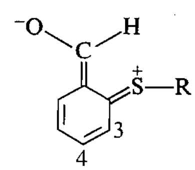
δ_3 increases to 7.565 from 7.276 in moving from **1** to **4**, being only 7.45 in benzaldehyde. Part of this excess shift to low field in the series is due to the increasing proximity of the 3*p* lone-pair, as noted previously for 2-hydroxythiophenol (24) and 2-hydroxythioanisole (25), in which the stereospecific hydroxyl hydrogen bond to the 3*p* lone-pair forces the latter into the benzene plane.

(ii) The shift of the aldehyde proton

δ_{CHO} in **4** is 10.697 relative to 9.94 in benzaldehyde itself, and is larger than that for any reported 2-substituted benzaldehydes (2, 4, 5, 19, 20, 26). In 2-chloro and 2-methoxy-benzaldehyde δ_{CHO} is 10.42 and 10.38, respectively (4, 5). The O-*anti* conformation is the only detected form in these compounds, just as in **4**. The large low-field shift in **4** is again attributed to the predominantly in-plane 3*p* orbital in **4**, leading perhaps to 1*s*,3*p* interference and therefore to a deshielding of the aldehyde proton. Of course, there is no strong argument for a linear relationship between δ_{CHO} and the O-*syn*/O-*anti* ratio in **1** to **4** because, at least for **2** and **3**, it appears that the 3*p* lone-pair takes on a conformation intermediate between planar and perpendicular. A monotonic increase of δ_{CHO} in **1** to **4** is reasonable, however, and is observed.

(iii) The ring proton coupling constants

As the S-alkyl substituent twist out-of-plane, all the couplings but $^4J_{46}$ move towards their values in benzaldehyde. $^3J_{56}$ and $^4J_{35}$ become equal to the values for benzaldehyde. The magnitude of ^3J within the ring depends somewhat on the double bond character of the intervening C—C bond (27, 28), but also on the electronegativity of the substituent (29, 30). Thus, it is tempting to attribute the decrease in $^3J_{34}$ from **1** to **4** to a decreased contribution from resonance structure **5**. The



5

double bond character of the C3−C4 bond is least in **4** and therefore $^3J_{34}$ should be smallest in **4**, as observed. A similar argument would hold for $^3J_{56}$.

It is interesting that $^4J_{35}$ in **4** becomes equal to $^4J_{35}$ in benzaldehyde, whereas $^4J_{46}$ varies relatively little between **1** and **4**.

The observed changes of the couplings within the ring are consistent with the conformational changes of the S-alkyl group discussed above. Some of the couplings for the phenylalkyl sulfides have been discussed (6).

(iv) Long-range couplings to the side-chain protons

$^5J_m^{H,CHO}$ values were used above to determine the O-*syn* and O-*anti* populations. $^4J_o^{H,CHO}$ decreases monotonically in magnitude, from 0.175 Hz in **1** to 0.05 Hz in **4**. For *para*-substituted benzaldehyde derivatives (31), the magnitude increases for

π-electron donors, presumably because the C—C bond shortens at the aldehyde group (32); see structure **5**. Consequently, the observed trend in $^4J_o^{H,CHO}$ in **1** to **4** is in agreement with decreasing π conjugation of the $3p$ orbital of sulfur as the S-alkyl group twists out of plane.

Finally, consider the long-range coupling over five formal bonds between H-3 and the alkyl protons, $^5J_3^{H,SCH}$. Its value is −0.34 Hz in 2-methylthiobenzaldehyde (Table 1) and −0.35 Hz in 2,5-dichlorothioanisole (33). This coupling is through-space and drops off rapidly in magnitude as the alkyl group twists away from the ring. The analogous coupling in anisole has been studied in detail (34−37). In the S-methyl compound the coupling to the two methyl protons in the C—H bonds nearest H-3, taking the methyl conformation as staggered about the *ortho* C—H bond, is expected to have a larger magnitude than to the other, distant methyl proton pointing away from the ring (34). Accordingly, the decrease in the magnitude of $^5J_3^{H,SCH}$ in going from the S-methyl to the S-ethyl compound is consistent with an out-of-plane twist of the latter. A further decrease in the size of the coupling occurs for the S-isopropyl derivative.

In 2-hydroxythioanisole, where the S—CH_3 group prefers a plane roughly orthogonal to the benzene plane, $^5J^{H,SCH}$ is not observed (25). By analogy to $^5J^{H,OCH}$ in anisole, the coupling is probably negligible when the twist angle, θ, reaches 60°.

A very rough estimate of the twist angle is obtainable as follows. Assume that δ_5 depends on $\sin^2\theta$ because electron densities at the *para* position are calculated by MO methods to vary in this way. Assume that θ is 90° for **4** and 0° for **1**. It follows that $\sin^2\theta$ is 0.11 for S-ethyl and 0.35 for S-isopropyl, corresponding to values of 19° and 36° for the two compounds. These numbers are to be taken as indicative only, of course, because δ_5 will depend on the expectation value of $\sin^2\theta$, the angle varying as the molecule undergoes internal torsion, and because $\langle\sin^2\theta\rangle$ is not exactly unity in **4** and zero in **1**.

However, $^5J^{H,SCH}$ in **1** to **3** is consistent with the conformational deductions based on the other spectral parameters.

No coupling over six formal bonds between methyl protons and *ortho* ring protons in **2** to **4** could be observed by careful decoupling experiments. Such a coupling is also dependent on the distance between bonds carrying the protons and is observable, for example, in 2-isopropylphenol (38) and 2-*tert*-butylphenol (39). From models it is clear that in **4**, for example, θ must be appreciable if the *tert*-butyl C—H bonds are not to approach the *ortho* C—H bonds sufficiently closely for coupling to occur.

Conclusions

All the ^{1}H nmr spectral parameters in the 2-S-alkyl (CH_3, CH_2CH_3, $CH(CH_3)_2$, $C(CH_3)_3$) derivatives of benzaldehyde are consistent with a description in which the conformation of the S-alkyl groups is approximately that of the alkylphenyl sulfide. As the S-alkyl group rotates about the benzene plane, its sulfur $3p$ orbital twists into this plane and repels the C═O bond of the aldehyde group. In consequence, the O-*anti* conformation increases from 60% to 100% as the size of the alkyl group increases from CH_3 to $C(CH_3)_3$.

The steric requirements of the $3p$ orbital on sulfur have been previously used in simple descriptions of the conformations of 2-hydroxythiophenol (24), and of some phenyl sulfides and disulfides (25). Its directional character also serves as the simplest description of the perpendicular structure of the hydrogen bonded dimer of H_2S and HF (40), but see also refs. 41 and 42.

The range of $^5J_o^{H,CH_3}$ in anisole derivatives. An indicator of torsion and compression of the methoxy group

TED SCHAEFER, SALMAN R. SALMAN,[1] TIMOTHY A. WILDMAN, AND GLENN H. PENNER
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received May 23, 1984

TED SCHAEFER, SALMAN R. SALMAN, TIMOTHY A. WILDMAN, and GLENN H. PENNER. Can. J. Chem. **63**, 782 (1985).

In a series of anisole derivatives, $^5J_o^{H,CH_3} \equiv {}^5J$, the spin–spin coupling constant between the methyl protons and the ring proton in the *ortho* position, ranges from −0.23 to −0.38 Hz when the methyl group lies *cis* to the *ortho* C—H bond. ^5J, as a proximate coupling, is sensitive to the average distance between the coupled protons. Its variation with substituent can be rationalized in terms of torsion about the Csp^2—O bond and changes in the bond angles near the methoxy moiety. The theoretical ^5J numbers can be empirically reproduced by a $\cos^4 \psi$ function, where ψ is the angle by which the methoxy group twists out of the benzene plane. In general, large *ortho* substituents cause an increase in the magnitude of ^5J (bond angle changes), strong π electron donors in the *para* position cause a decrease in the magnitude of ^5J (increased torsional freedom), and π electron acceptors do the opposite (decreased torsions).

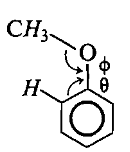
TED SCHAEFER, SALMAN R. SALMAN, TIMOTHY A. WILDMAN et GLENN H. PENNER. Can. J. Chem. **63**, 782 (1985).

Dans une série de dérivés de l'anisole dans lesquels le groupement méthyle se trouve *cis* par rapport à la liaison C—H *ortho*, la valeur de la constante de couplage spin–spin $^5J_o^{H,CH_3} \equiv {}^5J$, entre les protons du groupe méthyle et le proton situé en position *ortho* du cycle, varie entre −0,23 et −0,38 Hz. Le couplage ^5J, qui est un couplage par proximité, est sensible à la distance moyennė entre les protons qui sont couplés. Sa variation avec la nature des substituants peut être rationalisée en fonction d'une torsion autour de la liaison Csp^2—O et des changements dans les angles des liaisons près de la portion méthoxylée. On peut reproduire empiriquement les valeurs théoriques de ^5J en utilisant une fonction $\cos^4 \psi$ dans laquelle ψ est égal à l'angle de torsion du groupement méthoxy en dehors du plan du benzène. D'une façon générale, des substituants volumineux en *ortho* provoquent une augmentation dans l'amplitude de ^5J (changements dans les angles de liaisons), la présence en position *para* de groupements fortement donneurs d'électrons π provoque une diminution dans l'amplitude de ^5J (augmentation de la liberté de torsion) alors que la présence de groupements accepteurs d'électrons π provoque un effet inverse (diminution des torsions).

[Traduit par le journal]

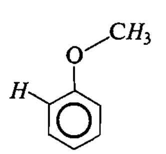
Introduction

A detailed set (1) of INDO MO FPT computations of $^5J_o^{H,CH_3} \equiv {}^5J$, the spin–spin coupling constant between methyl protons and the *ortho* ring proton in anisole, is consistent with the properties of a "through-space" or proximate coupling mechanism (1–4). As a proximate coupling, the magnitude of ^5J is calculated to decrease rapidly as the methoxy group twists out of the benzene plane, being −0.29 Hz for a planar *cis* conformation, **1**, and effectively zero as the out-of-plane twist, ψ, approaches 60°. A coupling of about 0.04 Hz is computed for ψ values between 90 and 180°.



$\psi = 0$

1



$\psi = 180°$

2

In fact, ^5J in anisole is −0.141(2) Hz (5), which could be taken to mean that ^5J is −0.28 Hz in **1** ($\psi \sim 0$) and 0.00 Hz in **2** ($\psi \sim 180°$). Or, since ^5J is calculated as −0.29 Hz at $\psi = 0$ and as −0.28 Hz at $\psi = 7.5°$, one might loosely interpret the observed value as corresponding to an expectation value of about 7° for ψ. Amusingly, the torsion about the Csp^2—O bond in a crystal of 4-nitroanisole (6) is given as 5.9(6)°. Of course, such an interpretation is best treated with circumspection, although it is true that in solution the barrier to rotation about the Csp^2—O bond in anisole is probably greater than 5 kcal/mol (1 cal ≡ 4.184 J); so that a small average torsion angle can be assumed at 305 K, usually approximated as a planar conformation. At 305 K rapid interconversion between **1** and **2** occurs, leading to the identical ^5J values for the *ortho* protons in anisole.

Early measurements of ^5J in some *ortho*-X-substituted anisoles (X = Cl, Br, I, NO_2) found a magnitude of 0.30 ± 0.03 Hz (7), the sign being determined as negative in 2,4-dibromoanisole (8). In other such compounds (X = OH, OCH_3, F) smaller magnitudes were indicated, the coupling leading to broadening only of ^{1}H nmr peaks. Later work for X = OH, OCH_3 at higher frequencies and different solvents, causing increased ring dispersion, found ^5J as −0.28(1) Hz (1, 9). In fact, for 1,2-dimethoxybenzene in benzene-d_6 solution (1) this result was taken to mean an essentially planar preferred conformation, a point of controversy (10–14). The argument for coplanarity is in agreement with ^{13}C nmr chemical shifts and spin-lattice relaxation times (12), but not with recent measurements of the temperature dependence of the dipole moment of 1,2-dimethoxybenzene, also in benzene solution (13). The conformation of the methoxy group can have important chemical and biological consequences (14, 15).

Although ^5J has been considered as proximate, some modified INDO MO FPT computations and measurements on 2,4-diaminoanisole, for example (16), have indicated substantial π electron transmitted couplings, $^6J_m^{H,CH_3}$, involving the *meta* protons in the compound. In that event, π electron contributions to ^5J can also be imagined, so that the use of ^5J as a conformational indicator would become more complicated.

Of course, if the *ortho* substituent is bulky enough, it might cause an increase in the magnitude of ^5J as steric compression gives rise to smaller average distances between the methyl protons and the *ortho* C—H bond, particularly as a proximate coupling is in principle very sensitive to the distance between

the coupled protons. If literature values of ${}^5J$ are taken at face value, ${}^5J$ varies between essentially zero and about −0.30 Hz. Accordingly, a careful set of analyses in this laboratory, accumulated over some years, was examined for regularities in ${}^5J$ and the results are reported and discussed here. Complete analyses are usually necessary because ${}^5J$ can often be obtained reliably only from the ring proton spectrum.

Experimental

All samples, at concentration indicated in the tables, were transferred to 5-mm od nmr sample tubes and were degassed by the freeze–pump–thaw procedure. All ${}^1H$ nmr spectra were recorded at 305 K, the majority on an HA100 spectrometer in the frequency sweep mode. Calibrations of spectral peak positions were done as described recently (17). Some ${}^1H$ nmr spectra were accumulated on a WH 90 FFT spectrometer, again by procedures previously described (17). The compounds came from Aldrich or were prepared from obvious starting materials.

Results and discussion

Spectral analyses

Performed with the program LAME (18, 19), the spectral data of interest are given in Table 2. Table 1 presents the results of an analysis of the ${}^1H$ nmr spectrum of 3-fluoro-4-methoxybenzaldehyde, illustrating the precision attainable. Table 2 collects some 40 values of ${}^5J_o^{H,CH_3}$ determined for anisole and a variety of its derivatives. The numbers for anisole and a few of its derivatives have been previously published and a few have been discussed in some detail, notably that for 2-methoxyanisole (1). They are included here as reference numbers and for completeness sake.

The ψ, θ, ϕ dependence of ^{5}J*; a model*

In anisole, ${}^5J$ is −0.14 Hz and the sums of the two values of ${}^5J$ in the 3-chloro, 3-bromo, and the 3-amino derivatives lie within experimental error of twice this value, at −0.29, −0.28, and −0.27 Hz, respectively. On the assumption that the barrier to rotation about the Csp^2—O bond in anisole in solution is large compared to kT (20), about 6 kcal/mol, then these numbers are consistent with ${}^5J_{cis} = -0.28$ Hz, ${}^5J_{trans} = 0.00$ Hz, and with a negligible decrease in the barrier for these three *meta* derivatives.

Two causes for a significant change in ${}^5J$ can be hypothesized. First, a substituent may increase or decrease the double bond character of the Csp^2—O bond, thereby decreasing or increasing the bond length *and* the barrier to rotation. Because ${}^5J$ is proximate and sensitive to internuclear distances, a decrease in barrier will lead to larger torsional amplitudes about the Csp^2—O bond and to smaller ${}^5J$ magnitudes. In other words, the expectation value of ψ increases from its value in anisole, causing a decrease in the magnitude of ${}^5J$. Thus, a ψ of 30° yields a calculated ${}^5J$ of −0.17 Hz in anisole, whereas at a ψ of 15° the magnitude of ^5J has dropped by only 0.03 Hz from the 0.29 Hz computed for $\theta = 0$. Second, a large *ortho* substituent may cause bond angle changes in the region of the methoxy group, leading to a smaller average distance between the methyl protons and the *ortho* protons than in anisole, and therefore to a larger magnitude of ^5J.

The computed (1) values of ^5J can be reproduced by an empirical $\cos^4 \psi$ function (see **1**) in the region of 0 to 60°.

ψ (deg)	$-^5J$ (INDO) (Hz)	$0.292 \cos^4 \psi$ (Hz)
0	0.292	0.292
7.5	0.283	0.282
15	0.257	0.254
30	0.167	0.164
45	0.064	0.073
60	0.010	0.018

Furthermore, the INDO MO FPT computations have it that a decrease of 1° in ϕ in **1** causes ^5J to decrease by 0.031 Hz, whereas a decrease of 1° in θ entails a decrease of 0.018 Hz; that is, the magnitude of ^5J increases as the geometry is compressed. Thus a decrease of only 2° in each of θ and ϕ might well lead to a decrease of 0.1 Hz in ^5J. Finally, a change of 0.01 Å in the C—O or O—C(H$_3$) bond lengths entails only a $\leq$0.005 Hz change in ^5J.

The ^5J values in Table 2 can be rationalized by intuitively sensible combinations of average $\Delta\psi$, $\Delta\theta$, $\Delta\phi$ numbers and are discussed further below.

Application of the model

In those 2-X-anisoles where X = OH, SH, SCH_3, OCH_3, CH_2OH, CH_2OCH_3, or CH_3—C=O, no significant variation in ^5J is apparent. It ranges from −0.288(1) Hz for X = OH to −0.270(10) for X = CH_2OCH_3. Apparently, these substituents do not cause appreciable geometrical distortions of the methoxy group.

Turning to 2-X-4-Y-anisoles, consider 2-fluoro-4-bromoanisole and 2-fluoro-4-carboxaldehyde-anisole. In the former, ^5J is −0.271(2) Hz in acetone-d_6 solution and is −0.281(3) Hz in CCl_4 solution, implying negligible perturbations of the conformational preferences of the methoxy groups. In the latter, ^5J is −0.299(1) Hz. It is tempting to attribute the increase of 0.02 Hz in magnitude to an enhanced barrier to torsion about the C$_1$—O bond, arising from conjugation with the CHO group in the *para* position. However, in 2,4-dinitroanisole, ^5J is −0.295(11) Hz and one might have expected somewhat larger conjugative perturbations from two nitro substituents than from a CHO group. The *ortho* nitro group, of course, may well twist out-of-plane itself to relive steric crowding, as it does in many other compounds including those with a methyl group placed *ortho* to the nitro substituent (21).

Again, in 2-methoxy-4-carboxaldehyde-anisole,[2] ^5J is −0.292(15) Hz for H-3 and −0.308(5) Hz for H-6. A tendency towards an increased magnitude of ^5J relative to its value in 2-methoxyanisole is apparent. If the *para* substituent is now replaced by a π electron donor, as in 2,4-dimethoxyanisole, the coupling to H-6 becomes −0.232(5) Hz. A larger amplitude of oscillation of the 1-methoxy group is implied by this result. The ψ dependence calculated above suggests ^5J as −0.23 Hz at $\psi = 20°$.

In a rigorous approach the observed ^5J should be related to the expectation value of ψ, that is $\langle\psi\rangle$. To find the latter, the potential function for the rotation about the Csp^2—O bond is needed. For a simple n-fold potential, and for low-amplitude oscillations (barrier large compared to kT), a classical averaging procedure (22) yields $\langle\psi^2\rangle$ as $2kT/Bn^2$, where ψ^2 is in rad^2. If $n = 2$, then $\langle\psi^2\rangle^{1/2}$ becomes about 13° for a barrier, B, of 6 kcal/mol at 305 K. If $n = 4$, then $\langle\psi^2\rangle^{1/2}$ is about 5°. The Csp^2—O barrier is apparently a mixture of twofold and fourfold components (23, 24). Accordingly, $\langle\psi^2\rangle^{1/2}$ may be about 10° for anisole in this model.

If the barrier to rotation about the Csp^2—O bond in anisole were zero, a simple average over all angles would yield ^5J as about −0.06 Hz according to the computed numbers. A decrease in the barrier from that in anisole leads to a decrease in the magnitude of ^5J, as indicated by the ^5J of −0.118(7) in 4-thiomethylanisole, that is, $^5J_{cis}$ is −0.236(14) Hz.

Now, or an *ortho* derivative of anisole, a large onefold component in the rotational potential must also be present. A naive two-site model with $\psi = 0$ and some value between 60° and 180°, for which ^5J is presumably zero, is in the spirit of numerous conformational discussions of various molecules in the literature. Such a model would have $^5J = -0.232$ Hz $= -0.292\,P(\psi = 0) - 0.00\,(1 - P)$, where P is the fractional population of the planar conformer. It would yield 80% as the population of the planar conformer of the 1-OCH_3 group in 2,4-dimethoxyanisole.

However, it is probably more satisfactory to interpret the above ψ of 20° in 2,4-dimethoxyanisole as a change in the rms amplitude of about 10° from its value in anisole. In other words, the 4-methoxy substituent, being a π donor, induces a smaller double-bond character in the Csp^2—O bond of the 1-methoxy group and therefore a larger $\langle\psi^2\rangle^{1/2}$ number. This does not happen for the 2-methoxy substituent, judging by its ^5J of −0.281(5) Hz. Unfortunately, large uncertainty in the sum of the ^5J values for the 4-methoxy group preempts discussion of its amplitude of oscillation.

However, in 2-chloro-4-methoxyanisole this sum for the 4-methoxy protons is −0.240(4) Hz, consistent with a substantially larger $\langle\psi^2\rangle^{1/2}$ than in anisole. For the other methoxy group, ^5J is −0.258(4) Hz (previously reported as −0.18 Hz (16)) compared to −0.232(5) Hz in 2,4-dimethoxyanisole. The larger magnitude is reasonably attributed to a change in θ and (or) ϕ. In 2,3,4-trichloroanisole, ^5J is −0.303(3) Hz.

Addition of a 5-nitro substituent to 2-chloro-4-methoxyanisole entails a ^5J of −0.320(1) or −0.327(1) Hz for each methoxy group (assignment uncertain). Decreased torsion amplitudes of both methoxy groups and somewhat smaller θ and ψ angles than in anisole are indicated. Interchange of the 5-nitro and 4-methoxy substituents to give 2-chloro-4-nitro-5-methoxyanisole yields the largest magnitudes of ^5J in Table 2, ^5J being −0.38 Hz for both methoxy groups. Neither of these groups now has a π electron donor as a *para* substituent and both are flanked by sizeable substituents. If the nitro group is replaced by an iodo substituent, ^5J drops to 0.35 Hz in magnitude, presumably because a π electron acceptor is no longer present. This magnitude is much the same as the 0.34 Hz in 2-iodo-5-nitroanisole. Clearly, an *ortho* substituent as large as iodine must cause decreases in θ, perhaps as large as 2°.

An apparent exception to the trends discussed above is 2,4-diaminoanisole, for which ^5J is −0.270(3) Hz, rather large in magnitude considering the ^5J of −0.232(5) Hz in 2,4-dimethoxyanisole. A possible reason is the presence of an

[2] The naming is unconventional in this discussion, but permits facile perceptions of coupling patterns.

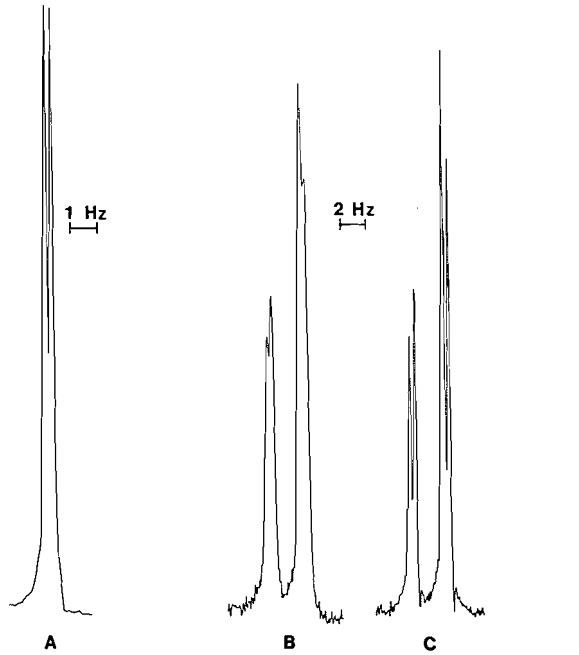

FIG. 1. In Fig. 1A the ^1H nmr spectrum of the methoxy protons in 2,4-diaminoanisole as a 2 mol% solution in acetonitrile-d_3 is displayed at 90 MHz and 305 K. $^5J_o^{H,CH_3}$ is −0.250(5) Hz. Some residual coupling to H-5 occurs, apparent here only as a slight broadening of the two peaks. In 1B the ^1H nmr peaks of H-3 are displayed. The peaks are rather broad due to unresolved coupling to the amino protons of one or two amino groups, intermolecular proton exchange being partially retarded by the presence of some basic alumina. In 1C the decoupling field, set at δ 3.68, the value for the methoxy protons, has an amplitude of 22 Hz, sufficient to decouple the amino protons with δ values of 3.88 and 3.62. Only for a large amplitude of the decoupling field do these peaks become sharp. A field amplitude sufficient to decouple the methoxy protons does not lead to such a spectrum. The line width at half height is 0.10 ± 0.01 Hz for these peaks in 1C.

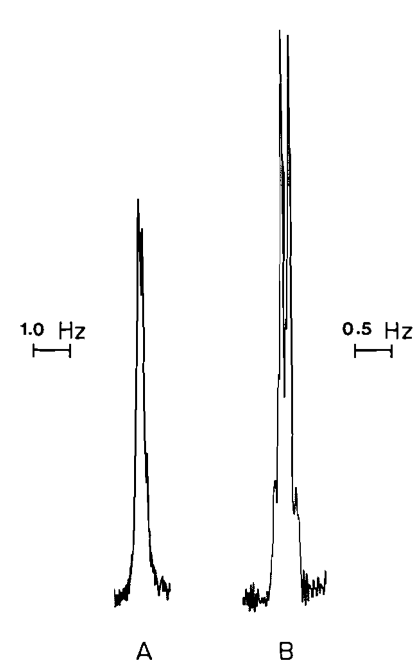

FIG. 2. In A one of the ^1H nmr bands of H-5 in 2,3,4-trichloroanisole as a 3 mol% solution in CCl_4 is displayed at 100 MHz and 305 K. The splitting represents $^6J_m^{H,OCH_3}$ and is given as 0.096(7) Hz from a LAME analysis. In B the same band is shown for a very dilute solution in acetone-d_6 at 295 K and 300.13 MHz. Considerable resolution enhancement has been applied and accounts for distortion. The splitting is 0.095(14) Hz.

N—H . . . O intramolecular hydrogen bond, which could conceivably inhibit wide excursions in ψ. The amino derivative is peculiar for another reason, as is now discussed.

Concerning ^{5}J *and* ^{6}J *in 2,4-diaminoanisole*

In a saturated benzene-d_6 solution ^5J is −0.270(3) Hz at 305 K and ^6J is 0.05(1) Hz to H-5. In view of the reported $|^6J_m^{H,CH_3}|$ values of 0.20 and 0.15 Hz to H-3 and H-5, respectively (16), the following experiments were performed on a Bruker WH90 spectrometer at 305 K. A 2 mol% solution of the compound in CD_3CN gave an ^1H nmr spectrum consistent with δ_{CH}, δ_3, δ_5, and δ_6 as 3.68172(2), 6.02880(2), 5.90970(2), and 6.55290(2), respectively. In addition, $^3J_{56}$, $^4J_{35}$, and $^5J_{36}$ were 8.405(3), 2.662(2), and 0.275(3) Hz, respectively. Figure 1 displays the doublet observed for the methyl protons; the splitting[3] of 0.250(5) Hz represents $|^5J_o^{H,CH_3}|$.

Now, the amino protons give rise to broad bands, as expected, and are centered at about 3.88 and 3.62 ppm relative to internal TMS in a solution in which intermolecular proton exchange is at least partly restricted by treatment with basic alumina. Under these conditions the ring proton peaks display a broadening which we attribute to unresolved coupling to amino protons, known to occur in aniline itself (25). Figure 1 displays the ^1H nmr spectra of H-3 for different decoupling fields centered on δ_{CH_3} at 3.68. As the amplitude of the decoupling field increases from zero to 22 Hz, the coupling from H-6 becomes clearly resolved (the small splitting). The latter decoupling amplitude, $\gamma H_2/2\pi$ = 22 Hz, is large enough at 90 MHz to decouple the amino protons at δ values of 3.9 and 3.6. Similar observations were made for H-5 and H-6. It seems possible that coupling phenomena of this kind are responsible for the literature values of $^6J_m^{H,OCH_3}$.

Other estimates of torsional amplitudes

A harmonic model has been employed in the estimation of force constants for the torsional motions in crystals of a variety of molecules, including anisole derivatives (22). The force constants given for the latter translate into $\langle\psi^2\rangle^{1/2}$ values ranging from 6° to 17°. Of course, intermolecular perturbations of the librational motions will be somewhat larger in the solid than in the solutions studied here. Nevertheless, the torsional amplitudes indicated by ^5J appear reasonable when compared to those implied by atomic vibration tensors obtained from X-ray or neutron diffraction data (22).

Concerning $^6J_m^{H,OCH_3} \equiv {}^6J$

This coupling, when observed, occurs for the *meta* proton in a *cis* arrangement to the methoxy group. Its existence was first reported for 2,4-dibromoanisole (8), and was determined as +0.06(1) Hz in 2-methoxyanisole (1). For the compounds in Table 2, ^6J ranges from 0.02 to 0.09 Hz. Splittings due to ^6J were not always resolved and were then estimated by simulations of ring proton spectra in the presence and absence of decoupling fields applied to the methyl proton peaks. Figure 2 displays splittings arising from ^6J, the analytical value at 100 MHz being confirmed at 300 MHz.

[3]This value is slightly smaller than in benzene-d_6, consistent with a smaller degree of N—H . . . O interaction in CD_3CN.

Conclusion

${}^5J_o^{H,CH_3}$ (*cis*) in anisole and its derivatives can vary from about −0.23 Hz to −0.38 Hz. A value of −0.28 Hz is typical of anisole and those of its 2-X derivatives in which X is not larger than chlorine or is a substituent presenting a similar size to the methoxy moiety. An electron donor, particularly when placed *para* to the methoxy group, reduces the magnitude of ${}^5J_o^{H,CH_3}$, probably because an increased torsional amplitude about the Csp^2—O bond leads to a larger average distance between the *ortho* C—H bond and the methoxyl protons. Large *ortho* substituents cause steric compression of the geometry of the methoxy group, thereby causing an increase in the magnitude of ${}^5J_o^{H,CH_3}$. This increase can be further enhanced in the presence of π electron withdrawing substituents.

${}^6J_m^{H,CH_3}$ is less than +0.1 Hz and appears for the C_m—H bond arranged *cis* to the methoxy group.

It appears that changes in the length of the Csp^2—O bond are a minor cause of changes in ${}^5J$ because an STO 3G optimization computes a decrease of only 0.007 Å in 4-nitroanisole, and the computed ${}^5J$ changes by rather less than 0.005 Hz for such a perturbation. Excursions in the torsion and bond angles are the important determinants of the observed ${}^5J$ in the present model.

The distribution of branched octanols between dodecane and water[1]

NORMAN H. SAGERT AND DANNY W. P. LAU

Research Chemistry Branch, Atomic Energy of Canada Limited, Whiteshell Nuclear Research Establishment, Pinawa, Man., Canada R0E 1L0

Received July 19, 1984

NORMAN H. SAGERT and DANNY W. P. LAU. Can. J. Chem. **63**, 789 (1985).

The distribution of four branched chain octanols, 3-ethyl-3-hexanol, 4-ethyl-3-hexanol, 2-ethyl-4-methylpentanol, and 4-octanol, has been measured between dodecane and water. Measurements were made at alcohol concentrations in the dodecane of less than 0.1 mol/dm^3, and as a function of temperature from 10°C to 35°C. From these distribution data, standard thermodynamic functions for transfer were calculated. Standard Gibbs energies of transfer from water to dodecane at 25°C were in the range −14.1 to −15.1 kJ/mol, whereas the standard enthalpies of transfer at 25°C varied from 29 to 39 kJ/mol. Thus, the change in the standard enthalpy tends to inhibit transfer, but a large standard entropy of transfer results in dodecane being the favoured phase.

NORMAN H. SAGERT et DANNY W. P. LAU. Can. J. Chem. **63**, 789 (1985).

On a mesuré la distribution de quatre octanols ramifiés (éthyl-3 hexanol-3 éthyl-4 hexanol-3, éthyl-2 méthyl-4 pentanol et octanol-4) entre le dodécane et l'eau. On a effectué les mesures à des concentrations en alcools dans le dodécane qui étaient inférieures à 0,1 mol/dm^3 et à des températures allant de 10 à 35°C. A l'aide de ces données sur la distribution, on a pu calculer les fonctions thermodynamiques standards pour le transfert. A 25°C, les énergies standards de Gibbs pour le transfert de l'eau au dodécane varient de −14,1 à −15,1 kJ/mol alors que, à 25°C, les enthalpies standards de transfert varient de 29 à 39 kJ/mol. Donc, alors que la variation dans l'enthalpie standard a pour effet d'inhiber le transfert, l'existence d'une entropie standard de transfert élevée fait que le dodécane est la phase favorisée.

[Traduit par le journal]

Introduction

We are presently engaged in a program to study interfacial properties relevant to the solvent extraction systems used in the nuclear industry (1, 2). As an adjunct to that program, we have measured the adsorption of the branched chain octanols, 3-ethyl-3-hexanol and 4-octanol, at the dodecane−water interface. These alcohols were chosen because of their different shapes. To interpret this adsorption data, the thermodynamics of the complete transfer of the alcohol from water to dodecane must be known. The transfer of branched alcohols from water to dodecane is also of interest in the study of lipid membranes (3), and in studies of the microemulsions used in tertiary oil recovery (4).

Standard thermodynamic functions for transfer are often calculated from the thermodynamics of solution of the solute in each of the two solvents (5, 6). The thermodynamics of solution of lower alcohols in alkanes and water are reasonably well known (5, 6). However, octanols are only sparingly soluble in water, so accurate calorimetric data on their heats of solution in water are not available. Recently, Goffredi and co-workers (7−9) have used a direct calorimetric method to obtain the thermodynamics of transfer of smaller alcohols from water to octane. However, they did not report data for octanols.

This work is a short study of the distribution of four branched-chain octanols between water and dodecane, carried out at low solute concentrations so that standard Gibbs energies of transfer at infinite dilution can be obtained. These alcohols, 3-ethyl-3-hexanol, 4-octanol, 4-ethyl-3-hexanol, and 2-ethyl-4-methylpentanol, represent a range of shapes and are available commercially. From the temperature dependence of these standard Gibbs energies of transfer, standard enthalpies of transfer are calculated, although they are less precise than those obtained calorimetrically. The data also give some information about the aggregation of these alcohols at low concentrations in dodecane.

[1]Issued as AECL-8435.

Experimental

The general procedures have been described previously (10). Analyses of alcohol concentrations were done, as previously, using gas chromatography, but the column used was 3% OV-1 on Chromosorb W at a temperature of 120°C.

The 3-ethyl-3-hexanol was obtained from ICN Pharmaceuticals, and the other alcohols from Pfaltz and Bauer. The alcohols were passed through an activated silica gel column until their purity was better than 99%, as determined by gas chromatography. The sources and purification of the water and dodecane have been described previously (11).

Results and discussion

The distribution of 4-octanol, 3-ethyl-3-hexanol, 4-ethyl-3-hexanol, and 2-ethyl-4-methylpentanol between dodecane and water was measured at concentrations up to 0.1 mol/dm^3 in the dodecane and at temperatures from 10°C to 35°C. In some cases a slightly wider temperature range was used. Figure 1 shows the results[2] for 2-ethyl-4-methylpentanol, where D, the distribution ratio, is defined as the concentration of alcohol in the dodecane divided by that in the water. Distribution ratios for this alcohol do increase as the concentration of alcohol increases, at least at lower temperatures, but the ratios are easily extrapolated to zero concentration to give the infinite dilution distribution coefficients, K_D. For reasons that will be discussed later, we actually used a plot of D against the cube of the alcohol concentration in the aqueous phase as the appropriate extrapolation procedure.

Table 1 shows the measured infinite dilution distribution coefficients, K_D. Since the errors in the individual distribution ratios are of the order of ±15%, the errors in the distribution coefficients are likely of the same order. Table 1 also gives the distribution coefficients calculated on a mole-fraction basis, K_D^X. Traditionally (12, 13), mole-fraction standard states have

[2]All the measured distribution ratios are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

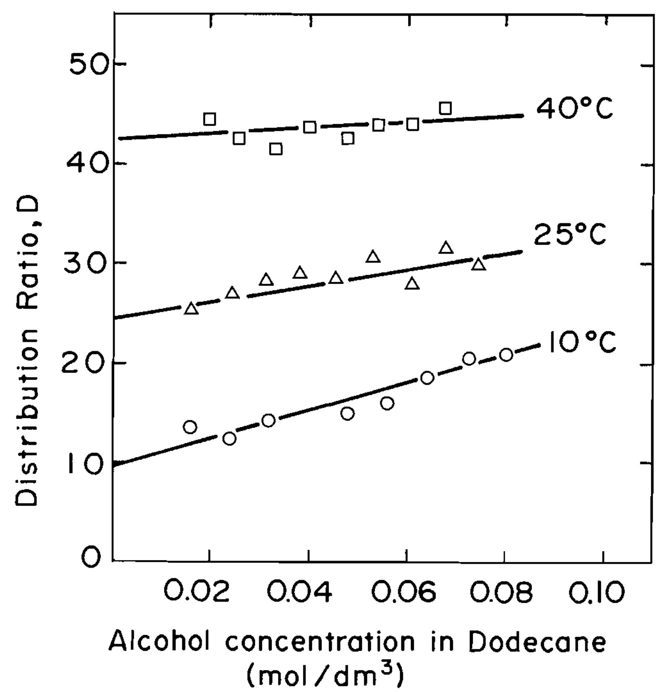

FIG. 1. Distribution ratios, D, for 2-ethyl-4-methylhexanol as a function of 2-ethyl-4-methylhexanol concentration in dodecane at three temperatures.

been used for calculating the thermodynamics of transfer, and we will use them here. Such standard states have the advantage that the reference states are temperature independent. Since both K_D and K_D^X refer to infinite dilution, their ratio is simply given by the ratio of the molar volumes of the two solvents (10, 14).

The standard Gibbs energies of transfer of alcohols from water to dodecane at infinite dilution, $\Delta_\alpha^\beta \bar{G}_1^\theta$, are calculated in the usual way (10, 14) using eq. [1]:

$$[1] \quad \Delta_\alpha^\beta \bar{G}_1^\theta = -RT \ln K_D^X$$

The alcohol is designated component 1, while the α phase is water and the β phase is dodecane. The standard states are the hypothetical standard states of ideal unit solute mole fraction. Thus, the activity coefficients implied are those that approach unity as the mole fraction of the solute approaches zero.

When standard Gibbs energies of transfer are known as a function of temperature, standard enthalpies of transfer can be calculated from eq. [2]:

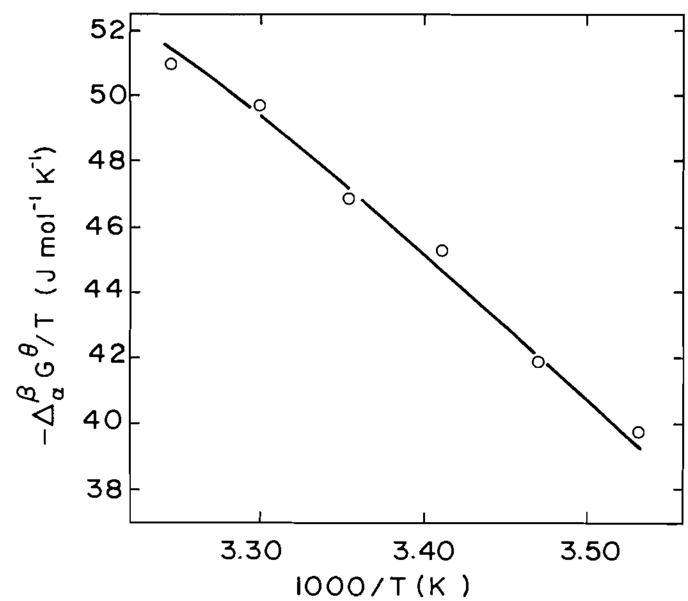

FIG. 2. Enthalpy of transfer plot of the standard Gibbs energy of transfer divided by the temperature plotted against reciprocal temperature. This plot is for 3-ethyl-3-hexanol.

$$[2] \quad \Delta_\alpha^\beta H_1^\theta = \partial(\Delta_\alpha^\beta \bar{G}_1^\theta/T)/\partial(1/T)$$

A plot of the standard Gibbs energy of transfer divided by the temperature, as a function of the reciprocal of the temperature, is shown in Fig. 2 for 3-ethyl-3-hexanol. Even over the small temperature range used, a slight curvature was noted. Thus, the standard enthalpy of transfer varies with temperature, and there is a measurable standard heat capacity of transfer:

$$[3] \quad \Delta_\alpha^\beta C_p^\theta = \partial \Delta_\alpha^\beta H_1^\theta/\partial T$$

Values of the standard Gibbs energies, enthalpies, entropies, and heat capacities of transfer, all of 25°C, are given in Table 2. The errors in the standard functions shown represent 90% confidence limits.

The standard Gibbs energies of transfer are, as expected, a little less than the value for 1-octanol obtained by extrapolating the data of Goffredi and Liveri (8) for lower alcohols up to octanol, and closer to their value for 2-octanol (9). Their data, with concentrations expressed as mole fractions, give values of −15.4 kJ/mol and −14.3 kJ/mol for transfer of 1-octanol and 2-octanol, respectively, from water to n-octanol at 25°C. Aveyard and Mitchell (14) have shown that the mole-fraction distribution coefficients do not change drastically as the solvent

Solute	$-\Delta_\alpha^\beta G_1^0$ (kJ/mol)	$\Delta_\alpha^\beta H_1^0$ (kJ/mol)	$\Delta_\alpha^\beta S_1^0$ (J K^{-1} mol^{-1})	$-\Delta_\alpha^\beta C_p^0$ (J K^{-1} mol^{-1})
3-Ethyl-3-hexanol	13.99±0.20	39.1±2.0	178±7	600±700
4-Ethyl-3-hexanol	14.10±0.04	29.4±2.0	146±3	730±140
4-Octanol	15.12±0.07	34.4±2.0	166±7	1200±200
4-Ethyl-2-methylpentanol	14.47±0.04	35.8±2.0	158±4	900±150

alkane changes, although in going from n-octanol to dodecane they become ~500 J/mol more negative for hexanol and heptanol. Thus, the Gibbs energies of transfer of Goffredi and Liveri should be approximately valid for transfer to dodecane as well, although it is possible that for transfer to dodecane they could be 400 to 600 J/mol more negative. Our standard Gibbs energies of transfer for the branched chain octanols examined here are in the range −15.1 to −14.1 kJ/mol. Unfortunately, the transfer of 1-octanol and 2-octanol proved difficult to measure accurately using our techniques, because the solubility in water at suitable concentrations in dodecane was lower than we could measure accurately. However, our results seem to bear out Goffredi and Liveri's conclusion that the more branched alcohols have a less negative standard Gibbs energy of transfer than the normal alcohols. Earlier data by Aveyard and Mitchell (14) on the transfer of lower normal alcohols is in good agreement with that of Goffredi and Liveri (8). When the data of Aveyard and Mitchell are extrapolated to 1-octanol at 25°C, one obtains a standard Gibbs energy of transfer of −15.0 kJ/mol, which is still more negative than those of the branched chain alcohols examined here, with the exception of 4-octanol.

The standard enthalpies of transfer of the alcohols from water to dodecane are all positive, so the transfer is opposed enthalpically and only takes place because of the large standard entropy of transfer. The standard enthalpy change at 25°C is, perhaps, equivalent to the breaking of about one or two hydrogen bonds, although the actual processes are unlikely to be that simple, since enthalpy changes in the hydration of the hydrocarbon chain must be considered. It is possible, in principle, to compare the standard enthalpies of transfer obtained here with those calculated from calorimetric data, since the enthalpy of transfer is simply the difference between the enthalpies of solution in the two phases. Standard enthalpies of solution and transfer of smaller linear and branched chain alcohols have been reviewed recently by Kertes and Lai (5). Standard enthalpies of solution in aliphatic hydrocarbons are endothermic and quite constant, at 23 to 24 kJ/mol (5, 15). On the other hand, standard enthalpies of solution in water are exothermic and variable (5, 6). They range from −4.6 kJ/mol for 1-hexanol (16) to −18.3 kJ/mol for 2-methyl-2-butanol (6, 17). The least negative enthalpies are for the longer, straight chain alcohols, and they become more negative as the chain length shortens. Branched chain alcohols, and especially tertiary alcohols, have very negative standard enthalpies of solution; strong hydrogen bonding with water is thought to play a role (18), but differences in the hydration of the hydrocarbon chains are also likely to be quite important here. This hydration seems to be stronger (i.e. more negative) for the branched alcohols.

Thus, standard enthalpies of transfer from water to dodecane measured calorimetrically vary from 28 kJ/mol for 1-hexanol to 41.6 kJ/mol for 2-methyl-2-butanol. Primary alcohols have smaller standard enthalpies of transfer, as a result of their less negative standard enthalpies of solution in water, as discussed above. The standard enthalpies of transfer observed with the octanols studied here are consistent with those observed for smaller branched chain alcohols, with the exception of 4-ethyl-3-hexanol, which is rather low. Also to be noted is that the standard enthalpy of transfer for 2-ethyl-4-methylpentanol is fairly large even though it is, stricty speaking, a primary alcohol.

Our measurements of standard heat capacities of transfer are very crude, being based on the curvature of plots like Fig. 2. The values obtained were compared with the apparent molal heat capacity of the alcohols in water, calculated from the additivity relationships of Jolicoeur and Lacroix (19). If the molal heat capacities of the alcohols in dodecane are small, then our standard heat capacities of transfer should be the negative of the heat capacities in water. The calculated values are in the range 750−780 J K^{-1} mol^{-1}. Our observed value for 3-ethyl-3-hexanol is less negative than predicted and our values for 2-ethyl-4-methylpentanol and 4-octanol are somewhat more negative than predicted. However, our values are subject to large errors and are consistent with the relationships of Jolicoeur and Lacroix (19), with the possible exception of 4-octanol. Thus, the standard heat capacities of transfer can be accounted for by the loss in hydrational heat capacity as the hydrocarbon chains are transferred from water to dodecane.

Finally, with respect to all comparisons with calorimetric data, it must be noted that thermodynamic functions of solution are measured for solution in pure solvents, whereas, when measuring transfer directly, we are dealing with mutually saturated phases. The small solubility of dodecane in water is unlikely to be a problem, but there is evidence that alcohols take complexed water with them into the dodecane (20).

Attempts were made to predict the standard Gibbs energies and enthalpies of transfer from scaled particle theory, using equations developed by Pierotti (21). Molecular parameters for dodecane were taken from the work of Wilhelm and Battino (22). However, all reasonable values of the molecular parameters of the alcohols gave standard Gibbs energies of transfer that were much too positive and standard enthalpies of transfer that were too large.

The concentration dependence of our distribution ratios gives some information about the aggregation of these alcohols in dodecane. From Wooley *et al.* (23) a general association can be written for the alcohols in dodecane:

$$[4] \quad nA \overset{K_n}{\rightleftharpoons} A_n$$

provided that the monomer is assumed to be the predominant species in the aqueous phase. The distribution ratio, D (Fig. 1), is the total alcohol concentration in the dodecane divided by that in the water. At infinite dilution, where by definition D becomes K_D, only monomers would be present in the dodecane as well. Thus, K_D gives the ratio of alcohol monomers in the dodecane to the total alcohol (largely monomers) in the aqueous phase. Branched chain alcohols are thought to associate in alkane phases primarily as the tetramer (24). Any change in the chemical potential of the alcohol monomers due to solute–solute interaction is ignored. Thus, following Woolley *et al* (23), we obtain:

$$[5] \quad D = K_D + 4K_4K_D^4[\text{alcohol}]_{aq}^3$$

Both ethylhexanols showed essentially no variation of D with alcohol concentration. Thus, in the low concentration range used here, these alcohols did not aggregate measurably in the dodecane. With 2-ethyl-4-methylpentanol and 4-octanol, appreciable slopes were noted, although only at lower temperatures for the former. At 25°C, K_4 values were 280 ± 100 and 900 ± 200 dm^9/mol^3, respectively. These can be compared with 230 dm^9/mol^3 obtained by Rytting *et al.* (24) for 2-methylpropanol-2 at 25°C by vapor-pressure methods. When the logarithm of these association constants was plotted against reciprocal temperature, association enthalpies of 85 ± 20 and 65 ± 15 kJ/mol, respectively, were obtained. These enthalpies correspond roughly to the enthalpies required to form the four hydrogen bonds of a tetramer. Thus, our association constants are consistent with those reported in the literature. As these experiments were not designed primarily to measure association, that is probably as much as should be said.

The reaction of the hexacyanoferrate(III) ion with hydrogen peroxide

DONALD R. EATON[1] AND MARIANNE PANKRATZ
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received June 19, 1984

DONALD R. EATON and MARIANNE PANKRATZ. Can. J. Chem. **63**, 793 (1985).

In basic solution hydrogen peroxide reduces the hexacyanoferrate(III) ion to the Fe(II) complex. The stoichiometry and kinetics of this reaction have been examined. Both a stoichiometric reduction and a catalytic reaction leading to decomposition of the hydrogen peroxide occur. The latter is largely, but not completely, photochemical in origin. The data are consistent with the involvement of a common intermediate for the stoichiometric and the thermal catalytic reactions. It is suggested that this intermediate is formed by nucleophilic attack of the hydroperoxide ion or the superoxide radical on the carbon of a cyanide ligand.

DONALD R. EATON et MARIANNE PANKRATZ. Can. J. Chem. **63**, 793 (1985).

En solution basique, le peroxyde d'hydrogène réduit l'ion hexacyanoferrate(III) en un complexe de Fe(II). On a étudié la stoïchiométrie et la cinétique de cette réaction. Il se produit une réduction stoïchiométrique et une réaction catalytique conduisant à une décomposition du peroxyde d'hydrogène. Cette dernière réaction serait principalement, mais non exclusivement, d'origine photochimique. Les données sont en accord avec l'implication d'un intermédiaire commun pour les réactions stoïchiométriques ainsi que catalytiques thermiques. On suggère que cet intermédiaire se forme par une attaque nucléophile de l'ion hydroperoxyde ou du radical hydroperoxyde sur le carbone d'un ligand cyanure.

Introduction

Hydrogen peroxide represents an oxidation state of oxygen intermediate between water and molecular oxygen. As such it can behave either as an oxidising agent or a reducing agent. A well known example of this dual behaviour is the observation that in acid solution hydrogen peroxide will oxidise the ferrocyanide ion to ferricyanide, but in basic solution ferricyanide is reduced to ferrocyanide. This reversal is associated with the pH dependence of the oxidising properties of hydrogen peroxide. Thus O'M. Bockris and Oldfield (1) have measured the potential (E) of hydrogen peroxide at a platinum electrode as a function of pH and find

$$E = 0.84 - 0.0509 \text{ pH Volts}$$

This variation suffices to change the direction of the ferricyanide/ferrocyanide reaction (standard oxidation potential 0.36 V) over the range pH 7 to pH 9. These authors also consider the possible oxidation/reduction and protonation reactions occurring at the electrode. The superoxide ion and its protonation product can both result from the one electron oxidation of peroxide. These electrode reactions have been discussed more recently by Morrison *et al.* (2). The mechanism of the oxidation of ferrocyanide to ferricyanide by hydrogen peroxide is reasonably well understood. It is of the inner sphere type and replacement of a cyanide ligand by a water molecule, either by photolysis or thermolysis, is a necessary first step. The thermal reaction is quite slow. Earlier studies have been reviewed by Baxendale (3) and Davies and Garafalo (4) have examined the mechanism of the reaction of the pentacyanoquo complex with hydrogen peroxide in some detail. The reduction of ferricyanide to ferrocyanide is less well understood. It is a relatively rapid reaction. To our knowledge there have been two reports of kinetic studies of the reduction of ferricyanide by peroxide. Sobkowski (5) describes the reaction in 0.1 M NaOH as being first order in peroxide and first order in ferricyanide and suggests that "one of the rate determining steps is the displacement of cyanide ion by hydroxide ion in the ferricyanide complex". Girdhar (6) agrees on the order of the reaction, but postulates an outer sphere one electron transfer rate determining step to give superoxide radicals.

There are two complications. Ferricyanide may act as a catalyst for the decomposition of hydrogen peroxide. There are many precedents for the catalysis of this reaction by Fe(III) complexes (7–9). Girdhar and Jain (10) indeed report catalysis by the ferricyanide ion. Secondly, photochemical reactions are possible. The photochemistry of complex cyanides has been studied by Asperger (11) and by MacDiarmid and Hall (12). Both ferrocyanide and ferricyanide are photoaquated relatively rapidly in light of moderate intensity. The resultant aquo compounds are considerably more reactive than the parent hexacyanides. It is clear (10) that catalysis of the decomposition of hydrogen peroxide in the presence of hexacyanoferrates occurs by a photochemical reaction. Thermal catalysis is less well established.

There are objections to both mechanisms suggested for the reduction of ferricyanide ions by hydrogen peroxide. An inner sphere mechanism requires prior dissociation of cyanide ligand. The exchange of cyanide ligands has been studied by radiochemical methods and found to be very slow. Thus Adamson, Welker, and Volpe (13) reported that in the absence of light only 12% of the ligands of ferricyanide ion had exchanged after 115 h at high pH. MacDiarmid and Hall (14) found no exchange in the dark at pH 10. These results clearly rule out an inner sphere mechanism for the relatively rapid thermal reduction process. The outer sphere electron transfer mechanism is less easy to eliminate. On this mechanism ferricyanide and peroxide react to give ferrocyanide and superoxide. The superoxide must then react rapidly with a further molecule of ferricyanide to complete the reaction. Brown and Higginson (15) have discussed mechanisms for the reduction of metal complexes involving free radical intermediates and have concluded that they are energetically unfavourable if the metal complex is a weak oxidant. Bennett (16) has discussed the oxidation/reduction potentials in the molecular oxygen/peroxide/water system and has pointed out the advantages of two electron reductions of molecular oxygen in avoiding superoxide intermediates. Similar considerations apply to the two electron oxidation of peroxide to molecular

[1]To whom all correspondence should be addressed.

oxygen. Considerations of this type have been used to explain the catalysis of hemoglobin (17) and myoglobin (18) autoxidations by reducing agents.

The present paper reports a kinetic study of the reaction between ferricyanide and hydrogen peroxide in the pH range 11–12. At these pH's reduction to ferrocyanide is complete.

Experimental

BDH Analar $K_3Fe(CN)_6$ and Anachemia 30% H_2O_2 were used in all experiments. Three types of experiment are reported.

In the first type, progress of the reaction was monitored by measuring the evolution of oxygen. The oxygen given off was measured by displacing water in a gas burette. Solutions of $K_3Fe(CN)_6$ in 0.1 *M* NaOH were placed in a three-necked flask equipped with a serum cap and outlet to the gas burette. H_2O_2 (30%) was added by syringe in quantities sufficient to give the desired concentration of peroxide and the O_2 collected was measured at timed intervals. The pH of the solution was greater than 12 and did not change during the reaction. Blank runs of H_2O_2 in 0.1 *N* NaOH were used to correct for H_2O_2 decomposition due to other factors. Dark reactions were run with aluminum foil around the reaction flask. The objectives of these experiments were to establish the stoichiometry of the reaction and to assess the importance of the photochemical and catalytic reactions.

The reaction was examined spectroscopically using a Tracor Northern spectrophotometer equipped with a photo-diode array detector. It was possible to obtain a spectrum of the reacting mixture 2 to 3 s after mixing the reactants. It was hoped that in this way an intermediate of the type reported by Lancaster and Murray (19, 28) for the sulphite/ferricyanide reaction could be detected. The spectrum obtained in this manner was, however, identical to that of the final ferrocyanide product. We infer that the intermediate, if it exists, is much shorter-lived than that observed in the sulphite reaction.

Stopped-flow experiments were run in a Durrum D110 spectrophotometer equipped with a Nicolet 1170 signal averager. All solutions were made up in phosphate buffer (Na_2HPO_4), with ionic strength corrected to 1.0 *M* with NaCl. Concentrations of dilute H_2O_2 solutions were determined by titration with $KMnO_4$ solution, which had been standardized with sodium oxalate. Temperature was controlled by a water bath maintained at 25 ± 0.2°C. The disappearance of ferricyanide was monitored at 420 nm. The concentrations of hydrogen peroxide used in the present experiments are approximately one order of magnitude greater than those used by Girdhar (6) or by Sobkowski (5). This was partly due to the desire to maintain pseudo first order conditions in the stopped flow experiments and partly with the intent of testing for first order dependence of the rate at higher peroxide concentrations, since the theory predicts that the dependence will become zero order at high peroxide concentrations if the catalytic reaction is important. These experiments have also been carried out at pH values much higher than those reported by Girdhar (6) to ensure that the reaction proceeded to completion and to investigate the pH dependence of the rate in the sensitive region close to the pK_a of hydrogen peroxide. As a result of this choice of conditions the rate of evolution of oxygen is quite rapid and bubbles in the stopped flow observation cuvette limit the accuracy of the data. This is especially true at the higher peroxide concentrations.

Results

In agreement with the previous reports we find that at pH's greater than 11 ferricyanide is completely reduced to ferrocyanide by any amount of hydrogen peroxide equal to or greater than that required by the equation:

$$2Fe(CN)_6^{3-} + H_2O_2 = 2Fe(CN)_6^{4-} + O_2 + 2H^+$$

The results of the oxygen evolution experiments are illustrated in Figs. 1 and 2. Figure 1 shows results obtained for the dark reaction and Fig. 2 for the reaction in laboratory light. It is clear from a comparison of the two figures that a photolytic reaction is occurring. In these experiments the concentration of ferricyanide was 0.022 *M* and that of hydrogen peroxide varied from 0.004 *M* to 0.34 *M*. If the reaction is stoichiometric, the maximum value of the ratio moles O_2/moles $Fe(CN)_6^{3-}$ plotted in Figs. 1 and 2 should be 0.5 if the concentration of peroxide is greater than 0.011 *M*. If the concentration of peroxide is less than 0.011 *M* the ratio should be peroxide concentration/0.022. Ratios greater than these demonstrate a catalytic

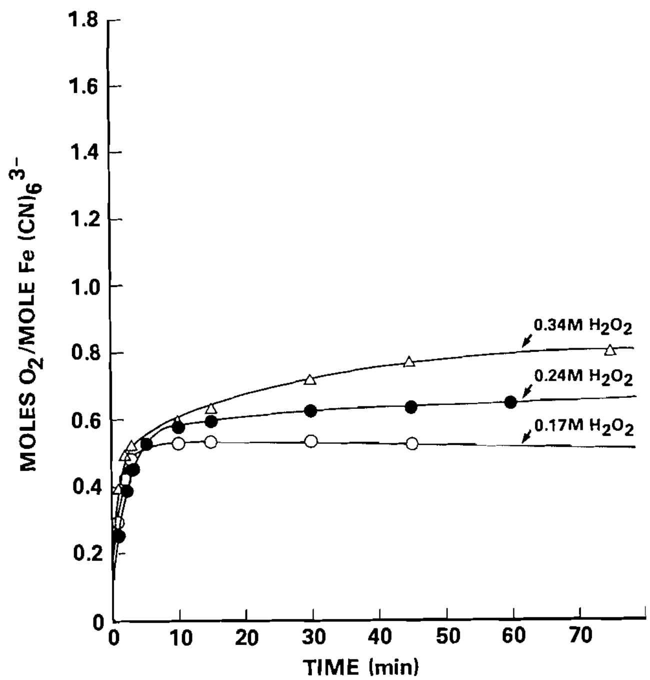

FIG. 1. Oxygen evolution in the dark reaction between $Fe(CN)_6^{3-}$ and H_2O_2. The concentration of $Fe(CN)_6^{3-}$ is 0.022 *M* throughout. The stoichiometric reaction leads to production of 0.5 mol of oxygen per mol of $Fe(CN)_6^{3-}$.

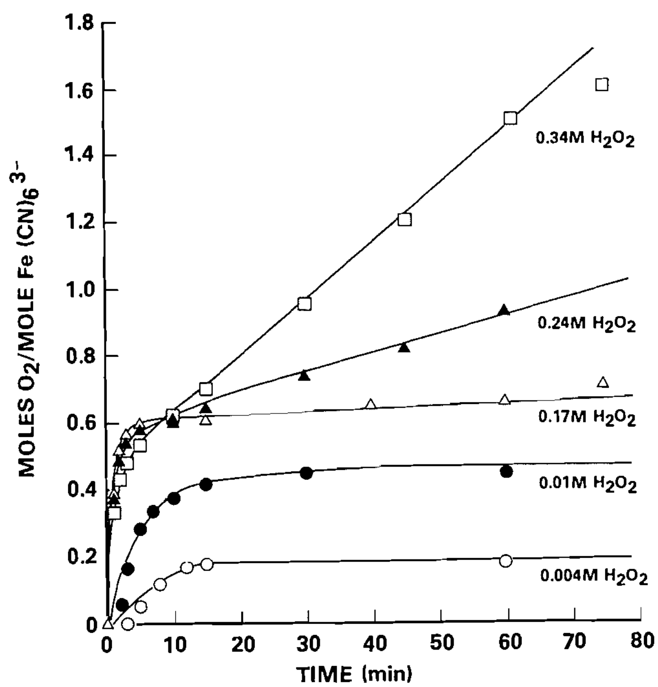

FIG. 2. Oxygen evolution in the reaction between $Fe(CN)_6^{3-}$ and H_2O_2 carried out in laboratory light. Conditions the same as Fig. 1.

reaction. It is apparent that at low concentrations of hydrogen peroxide the reaction is predominantly stoichiometric but at higher concentrations the catalytic reaction becomes more important. The initial parts of the curves of Figs. 1 and 2 are very similar, terminating at a ratio close to that expected for the stoichiometric reaction. This indicates that the latter reaction is thermal rather than photochemical and is rapid compared to the subsequent reaction. The stopped-flow results reported below therefore reflect only the thermal reaction. Comparison of Figs. 1 and 2 shows that the slower catalytic reaction is predominantly, but not exclusively, photochemical. Even in the dark more oxygen is produced at high peroxide concentrations than can be accounted for by a purely stoichiometric reaction.

The earlier portion of the reaction can be monitored by using stopped-flow spectrophotometry. Reactions were carried out under pseudo first order conditions with hydrogen peroxide in excess. These experiments were carried out in the pH range 11–12. In each case good exponential decays were observed indicating that the reaction is first order in ferricyanide. Table 1 presents the kinetic data obtained in these experiments. The accuracy of the data is limited by the experimental problems caused by oxygen bubbles, but the increase in rate with pH is quite clear. This increase is consistent with the suggestion of Girdhar (6) that HO_2^- is the reacting species. The present data do not indicate that the reaction is first order in hydrogen peroxide. This is shown by the variability of the calculated second order rate constants given in Table 1. Some of this variation could result from the rather poor quality of the data at high peroxide concentrations but the trend to less than first order dependence is consistent and statistically meaningful. The data of Girdhar (6) also show some decrease in apparent second order rate constants at higher peroxide concentrations. Sobkowski (5) did not investigate the peroxide dependence of the rate. A few experiments to investigate the effect of ionic strength on the rate were also carried out and these results are included in Table 1.

Discussion

The results described above have demonstrated the following features of the ferricyanide/hydrogen peroxide reaction. (*1*) Both thermal and photolytic reactions are important. The photolytic reaction leads to the catalytic decomposition of the peroxide and, at least under conditions of normal illumination, is much slower than the thermal stoichiometric reaction. The latter results in the reduction of ferricyanide to ferrocyanide. It seems reasonable to suppose that the photolytic reaction proceeds via a pentacyano-aquo species. Since ferrocyanide is present as the product of the stoichiometric reaction photochemical catalytic decomposition is to be expected (4). (*2*) The thermal reaction is predominantly stoichiometric at low concentrations of hydrogen peroxide but becomes partly catalytic at higher concentrations. (*3*) We were unable to detect an intermediate of the type reported by Lancaster and Murray (19) for the ferricyanide/sulphite reaction. This does not imply that such an intermediate does not exist but places an upper limit of 1–2 s on its lifetime. (*4*) The rate of the thermal reaction is first order in ferricyanide but less than first order in peroxide. (*5*) The rate of the reaction increases with pH. The increase is consistent with the hydroperoxide ion being the reactive species. Since the order of the reaction with respect to peroxide is not well defined it is a little difficult to quantify the pH dependence. However, if the average first order rate constant at a given pH is plotted against the fractional concentration of hydroperoxide ion (calculated assuming a value of 11.62 for the pK_a of hydrogen peroxide) the straight line 0.19 + $1.164[HO_2^-]$ is obtained with a correlation coefficient of 0.996. Although some reactivity for the neutral peroxide molecule is not ruled out, this result clearly indicates that the hydroperoxide ion is the principal reacting species.

Any mechanism for the reaction must be consistent with these observations. The reports that cyanide ligand exchange is very slow (13, 14) would seem to preclude an inner sphere mechanism for the thermal reduction of ferricyanide. For such a mechanism the overall rate could not be greater than the rate of dissociation of cyanide ligands and this rate is clearly insufficient to account for the stopped-flow data. We note that for the ferricyanide/sulphite reaction Wiberg *et al.* (20) have eliminated the inner sphere mechanism by a direct radiochemical exchange experiment. An inner sphere mechanism remains a very plausible path for the photochemical reaction since photodissociation of cyanide is well established.

The mechanism suggested by Girdhar (6), namely,

$$Fe(CN)_6^{3-} + HO_2^- \rightarrow Fe(CN)_6^{4-} + HO_2 \text{ (rate determining)}$$

$$Fe(CN)_6^{3-} + HO_2 \rightarrow Fe(CN)_6^{4-} + O_2 + H^+ \text{ (fast)}$$

does not readily account for the low order dependence of the rate on peroxide at high peroxide concentrations.

We would like to suggest an alternative mechanism based on the interpretation of the ferricyanide/sulphite reaction proposed by Lancaster and Murray (19, 21). These authors demonstrated the existence of an intermediate and originally postulated $Fe(CN)_5(CNSO_3)^{5-}$ formed by nucleophilic attack of sulphite on the carbon of a cyanide group. They subsequently concluded (28) that the intermediate was correctly formulated as $[Fe(CN)_5(CNSO_3)]^{4-}$ and was formed by the nucleophilic attack of a sulphite radical on a ferricyanide ion. This type of reaction is well documented in nitroprusside chemistry (22, 23). An intermediate of this kind could well play a part in the peroxide chemistry. The simplest scheme, based on Lancaster and Murray's original formulation of the intermediate, would be:

$$[1]\quad Fe(CN)_6^{3-} + HO_2^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Fe(CN)_5(CNO_2H)^{4-}$$

$$[2]\quad Fe(CN)_5(CNO_2H)^{4-} + Fe(CN)_6^{3-} \xrightarrow{k_2} 2Fe(CN)_6^{4-} + O_2 + H^+$$

$$[3]\quad Fe(CN)_5(CNO_2H)^{4-} + H_2O_2 \xrightarrow{k_3} Fe(CN)_6^{3-} + O_2 + OH^-$$

With the condition that $k_{-1} \ll k_2[Fe(CN)_6^{3-}]$ this scheme leads to the rate equation:

$$\frac{-d[FE(CN)_6^{3-}]}{dt} = \frac{2k_1k_2[FE(CN)_6^{3-}]^2[HO_2^-]}{k_2[Fe(CN)_6^{3-}] + k_3[H_2O_2]}$$

This equation correctly predicts that the catalytic reactions [3] will become more important at high peroxide concentrations and that under these conditions the rate tends to zero order in peroxide. However, it also predicts that at high peroxide concentrations the rate will become second order in ferricyanide and a careful inspection of the stopped-flow traces does not confirm this prediction. A modification of the reaction scheme is to replace reactions [2] and [3] with [4], [5], and [6].

$$[4]\quad Fe(CN)_5(CNO_2H)^{4-} + Fe(CN)_6^{3-} \xrightarrow{k_2}$$

$$[(CN)_5Fe\overset{\overset{\textstyle N}{\|}}{C}{-}OOH\cdots NCFe(CN)_5]^{7-}$$

Int 2

$$[5]\quad \text{Int 2} \xrightarrow{k_3} 2Fe(CN)_6^{4-} + O_2 + H^+$$

$$[6]\quad \text{Int 2} + H_2O_2 \xrightarrow{k_4} 2Fe(CN)_6^{4-} + O_2 + H_2O + OH^-$$

In this modified scheme a further intermediate is formed by reaction with the second ferricyanide molecule and this can either decompose to give the stoichiometric reaction products or react with more peroxide to give the catalytic reaction. This type of intermediate can equally well be formed by the sequence

$$Fe(CN)_6^{3-} + HO_2^- \xrightarrow{k_1} Fe(CN)_6^{4-} + HO_2$$

$$Fe(CN)_6^{4-} + HO_2 + Fe(CN)_6^{3-} \xrightarrow{k_2}$$

$$[(CN)_5Fe\overset{\overset{\textstyle N}{\|}}{C}{-}OOH\cdots NCFe(CN)_5]^{7-}$$

which corresponds to Murray's second suggestion for the intermediate, namely attack of the radical on ferricyanide. The two routes are kinetically indistinguishable. In the first case k_1 is the rate of nucleophilic attack on the cyanide ligand and in the second case it corresponds to an outer sphere electron transfer reaction. They lead to the rate equation

$$\frac{-d[Fe(CN)_6^{3-}]}{dt} = \frac{2k_1k_2k_3[Fe(CN)_6^{3-}]^2[HO_2^-]}{(k_{-1} + k_2[Fe(CN)_6^{3-}])(k_3 + k_4[H_2O_2])}$$

which further simplifies to

$$\frac{-d[Fe(CN)_6^{3-}]}{dt} = \frac{2k_1k_3[Fe(CN)_6^{3-}][HO_2^-]}{k_3 + k_4[H_2O_2]}$$

if $k_{-1} \ll k_2[Fe(CN)_6^{3-}]$. This rate equation is compatible with all the experimental data. A little rearrangement gives

$$\frac{K}{k_{obs}([H^+] + K)} = \frac{k_4}{2k_1k_3} + \frac{1}{2k_1[H_2O_2]}$$

where K is the acid dissociation constant of hydrogen peroxide (taken as 2.4×10^{-12}). Plots of the left-hand side of this equation versus $1/[H_2O_2]$ show a great deal of scatter, which we attribute to the relatively poor quality of the data caused by oxygen bubble problems, but yield values of 58 M^{-1} s^{-1} for k_1 and 0.016 for the ratio k_4/k_3. The former value agrees reasonably well with the value of 99 M^{-1} s^{-1} for the second order rate constant obtained by Girdhar (6) for the rate-determining step of the stoichiometric reaction at much lower concentrations of peroxide and lower pH's. The data of Sobkowski (5) give a second order rate constant approximately one order of magnitude lower than that found above (average 5.2 M^{-1} s^{-1}) but it is difficult to evaluate this data since no peroxide concentration or ionic strength dependence is reported. These literature data are given at the end of Table 1. The value obtained for the ratio k_4/k_3 clearly indicates that the stoichiometric reaction will predominate except at high peroxide concentrations. The results displayed in Fig. 1 show that this is indeed the case. Also included in Table 1 are some data showing the variation of rate with ionic strength. Swinehart (24) and others have reported large variations of rate with alkali metal ion concentration for reactions of this type. This is clearly true for the present reaction with the rate diminishing with increasing metal ion concentration. This effect might perhaps arise from ion pairing with the hydroperoxide ion.

To summarize, the present results show that the reducing agent in the ferricyanide/hydrogen peroxide reaction is the hydroperoxide ion. At low peroxide concentrations the reaction is predominantly stoichiometric. At higher concentrations a catalytic component is apparent. It is suggested that the key intermediate in both the stoichiometric and the catalytic reactions is formed by nucleophilic attack of the hydroperoxide ion or radical on the carbon of a cyanide ligand. We prefer the former mechanism since HO_2^- will certainly be a better nucleophile than HO_2 but the second mechanism cannot be eliminated on kinetic grounds. There is evidence for a similar mechanism in the reduction of met-myoglobin cyanide by dithionite (25, 26). This occurs by attack of the SO_2^- ion without dissociation of the cyanide ligand. A very similar mechanism has been suggested for the reduction of imidazole derivatives of met-myoglobin by dithionite (27). In this case the nucleophilic attack occurs at the 2 position of the imidazole ligand and the electron is then transferred through the ligand π system. This type of mechanism avoids the energetic problems pointed out by Brown and Higginson (15) for outer sphere reactions in which an unstable free radical is formed by a weak oxidizing agent. Either no free radical is formed or if one is formed in an initial electron transfer reaction it is stabilized by complexation.

Free energies and entropies of transfer of hydrogen halides from water to aqueous 2-methoxy ethanol and structuredness of the solvents

PRABIR K. GUHA[1] AND KIRON K. KUNDU[2]
Physical Chemistry Laboratories, Jadavpur University, Calcutta — 700 032, India

Received April 6, 1984

PRABIR K. GUHA and KIRON K. KUNDU. Can. J. Chem. **63**, 798 (1985).

Standard free energies (ΔG_t^0) and entropies (ΔS_t^0) of transfer of HBr and HI from water to some aqueous solutions of 2-methoxy ethanol (ME) have been determined from emf measurements of the cells: Pt, H_2 (g, 1 atm)/HBr (m), solvent/AgBr−Ag and Pt, H_2 (g, 1 atm)/KOH (m_1), KI (m_2), solvent/AgI−Ag, respectively, at seven equidistant temperatures ranging from 15 to 45°C. ΔG_t^0 values of HBr and HI as well as of HCl obtained from literature, and particularly that of the individual ions obtained by tetraphenylarsonium tetraphenylboron (TATB) assumption, suggest that while H^+ is increasingly stabilized by cosolvent-induced larger "basicity", halide ions (X^-) are increasingly destabilized by cosolvent-induced decreased "acidity" and the dielectric constant of the mixed solvents compared to that of water. Analysis of the variation of the observed $T\Delta S_t^0$(HX) and particularly of ΔY (= $T\Delta S_t^0(H^+) + T\Delta S_{t,ch}^0(X^-)$), with composition, in the light of Kundu *et al's* semi-quantitative theory reveals that ME induces breakdown of three dimensional (3D) tetrahedral structures of water at water-rich compositions. This is being followed by an ordered region due to possible H-bonded cosolvent−water complexation and then the usual disordered region due to packing imbalance. Comparison of ΔY(HI)−composition profiles for aqueous mixtures of t-butanol (Bu^{t}OH), ethylene glycol (EG), and 1,2-dimethoxy ethane (DME) also demonstrates that the remarkable enhancement of 3D water structures by the well known structure promoter Bu^{t}OH gets succintly diminished when cosolvent Bu^{t}OH is replaced by EG, ME, and DME, as is expected from structural and electronic considerations of the cosolvents.

PRABIR K. GUHA et KIRON K. KUNDU. Can. J. Chem. **63**, 798 (1985).

Opérant à sept températures équidistantes échelonnées de 15 à 45°C et faisant appel à des mesures de f.é.m. obtenues respectivement à l'aide des cellules Pt, H_2 (g, 1 atm)/HBr (m), solvant/AgBr−Ag et Pt, H_2 (g, 1 atm)/KOH (m_1), KI (m_2), solvant/AgI−Ag, on a déterminé les énergies (ΔG_t^0) et les entropies (ΔS_t^0) libres standards pour les transferts de HBr et de HI de l'eau vers des solutions aqueuses de méthoxy-2-éthanol (ME). Les valeurs de ΔG_t^0 déterminées pour HBr et HI ainsi que les valeurs équivalentes obtenues dans la littérature pour HCl et, en particulier, les valeurs obtenues pour les ions individuels en faisant l'hypothèse du tétraphénylarsonium tétraphénylbore (TATB), suggèrent que, alors que les ions H^+ sont de plus en plus stabilisés par des "basicités" de plus en plus élevées induites par le cosolvant, les ions halogénures (X^-) sont de plus en plus déstabilisés par des diminutions d'"acidité" induites par le cosolvant et par la constante diélectrique des solvants mixtes comparée à celle de l'eau. Si l'on effectue, à la lumière de la théorie semi-quantitative de Kundu et de ses collaborateurs, une analyse de la variation, en fonction de la composition, des valeurs observés pour $T\Delta S_t^0$(HX) et en particulier pour ΔY (= $T\Delta S_t^0(H^+) + T\Delta S_{t,ch}^0(X^-)$), on en conclut que le ME induit des ruptures dans les structures tétraédriques tridimensionnelles (3D) des compositions d'eau ou riches en eau. Ceci est suivi par une région ordonnée qui est peut être due à une complexation eau-cosolvant provenant d'une liaison hydrogène possible et finalement par la région désordonnée habituelle qui est due à une mauvaise balance dans l'entassement. Une comparaison des profils reliant le ΔY (HI) et la composition, pour des mélanges aqueux de t-butanol (t-BuOH), d'éthylène glycol (EG) et de diméthoxy-1,2 éthane (DME), permet aussi de démontrer que les structures tridimensionnelles de l'eau sont rehaussées d'une façon remarquable par le t-BuOH, qui est bien connu pour promouvoir des structures, alors qu'elles sont fortement diminuées lorsque le t-BuOH est remplacé par l'EG, le ME ou le DME; ces constatations correspondent à ce que l'on peut prévoir sur la base de considérations structurales et électroniques des cosolvants.

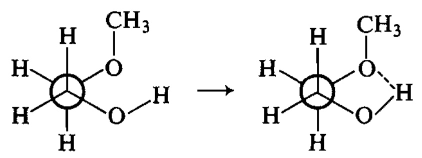
Introduction

2-Methoxy ethanol (ME), variously known as methyl cellosolve, is a widely used organic solvent for various industrial processes because of its unique solvating properties associated with its quasi-aprotic character. In fact, being a hydroxyether it has partly protic and partly aprotic characters. Besides, by virtue of its unique structural characteristics it is also likely to have enhanced aprotic character, as is expected from the possible formation of intramolecular hydrogen-bonded aprotic form **B**



A **B**

Moreover, being a mono-methyl ether of ethylene glycol (EG), it is also likely to show some physico-chemical characteristics which would lie intermediate to protic EG and its dimethyl ether, i.e., aprotic 1,2-dimethoxy ethane (DME). Because of these reasons it should be very useful and interesting to evolve the knowledge of solvating and structural characteristics of the aqueous mixtures of these closely related cosolvents.

With that end in view we have recently undertaken comprehensive studies (1−4) on ion−solvent interactions of a series of ions like alkali metal ions (M^+), halide ions (X^-), H^+, OH^- etc. in the aqueous mixtures of these closely related cosolvents, as determined from emf measurements of suitable galvanic cells and by the use of widely used tetraphenylarsonium tetraphenylboron (TATB) reference electrolyte assumption (5):

$$\Delta G_t^0(Ph_4B^-) = \Delta G_t^0(Ph_4As^+) = \frac{1}{2}\,\Delta G_t^0(Ph_4AsPH_4B)$$

where Ph = phenyl and ΔG_t^0(i) denotes transfer free energies of the ion from the reference solvent water to the mixed solvents. These studies helped derive important reflections about

[1]Holder of a Junior Research Fellowship under University Grants Commission, New Delhi.

[2]To whom all correspondence should be addressed.

the solvating characteristics of these cosolvents, which conform fairly well with the structural and electronic considerations of these cosolvent molecules. Moreover, as part of gleaning three dimensional (3D) ice-like tetrahedral structures of water in aqueous mixtures of these cosolvents we have recently reported the standard electrode potentials (E^0) of Ag−AgX electrodes and the related transfer free energies ΔG_t^0(HX) and entropies ΔS_t^0(HX) of hydrogen halides (HX) for aqueous solutions of EG (1) and DME (4*a*) as the latter quantities have recently been shown (6) to be a useful probe for the relative 3D tetrahedral structures of water in various aquo-organic solvents. But although E^0 values of the Ag−AgCl electrode at different temperatures — the basis of ΔS_t^0(HCl) in aqueous ME solutions are already reported by Sadek *et al.* (7) those for the Ag−AgBr and Ag−AgI electrodes are yet to be determined. It should therefore be of particular interest to extend such studies for other two hydrogen halides namely HBr and HI.

In this paper we report E^0 values of the Ag−AgBr and Ag−AgI electrodes at different temperatures and the related transfer energetics of HBr and HI in this solvent system. E^0 values of the Ag−AgBr electrode have been determined by emf measurements of cell [C]

[C] Pt, H_2 (g, 1 atm)/HBr (*m*), solvent/AgBr−Ag

But owing to the gradual oxidation of I^- at low pH even when freshly distilled HI and freshly purified and also deoxygenated solvent ME were used, it was not possible to use the cell of the type [C] for the Ag−AgI electrode. Instead, as in aqueous like DME, THF, and dioxane (D), cell [D]

[D] Pt, H_2 (g, 1 atm)/KOH (m_1), KI (m_2), solvent/AgI−Ag

was found suitable for this solvent system as well. The required ionization constant (K_s) values of the solvents were known from a parallel study using a cell of the type [D] with KBr and AgBr−Ag electrode in place of KI and AgI−Ag electrode, respectively, which are reported in the following paper (8). In all the above cases the compositions of the solvent mixtures are 10, 30, 50, and 70 wt% ME and the temperatures are in the range of 15−45°C at 5° interval.

Experimental

2-Methoxy ethanol (Merck) was purified by refluxing and distilling successively over pieces of sodium for about 5 h and over $LiAlH_4$ for about 5 h. The distillate was stored in a desiccator and redistilled every time before use after refluxing with $LiAlH_4$ for about 5 h. The bp and density compared fairly well with literature values (3*a*, 7). Water used was triply distilled. HBr (Riedel) was purified just before use by digesting the acid with red phosphorous and then distilling in an all glass apparatus under oxygen free N_2 atmosphere (9*a*). Before collecting the distilled HBr the solvent was freed from dissolved air by passing purified H_2 gas through it, so as to avoid the possible oxidation of HBr in the solvent. KI (E. Merck, G.R.) was used after drying at about 150°C and then over a vacuum desiccator for about 2−3 days. The Ag−AgBr and Ag−AgI electrodes were of thermal type and prepared by the methods described by Ives and Janz (10). Other experimental details including the preparation of solvents, solutions, platinization of Pt-foil H_2 electrodes and also the procedure of measurements, were discussed earlier (6). The behaviour of the electrodes, the time for the attainment of equilibrium, and the criteria of equilibrium of the cells were essentially similar to that described earlier (6).

Results

The observed emf (corrected to pH_2 = 1 atm) for both the cells [C] and [D] at different temperatures for the corresponding molalities of HBr (cell [C]) and of KOH and KI (cell [D]) have been tabulated elsewhere.[3] The standard potential E_m^0 (molal scale) of the Ag−AgBr electrode at any temperature for any solvent was determined by extrapolating the observed linear plot of the usual extrapolation function $E^{0\prime}$ defined by relation [1] (11),

$$[1] \quad E^{0\prime} = E + 2k' \ln m - 2k'A_0B_0m^{1/2}(1 + a_0B_0m^{1/2})^{-1} - 2k' \ln(1 + 0.002\, M_s m) = E_m^0 - 2k'\beta m$$

against the molality m of HBr to $m = 0$. In eq. [1] E is the observed equilibrium emf value (corrected to pH_2 = 1) for the particular molality m of HBr, M_s the mean molar mass of the mixed solvents, $k' = RT/F$, A_0B_0 and B_0 are Debye−Hückel constants as given by

$$A_0B_0 = 1.8246 \times 10^6 (\ln 10)\, d_s^{1/2} (\epsilon_s T)^{-3/2} \text{ mol}^{-1/2} \text{ kg}^{1/2}$$

$$B_0 = 50.29 \times 10^{10}\, d_s^{1/2} (\epsilon_s T)^{-1/2}\, m^{-1} \text{ mol}^{-1/2} \text{ kg}^{1/2}$$

and β is an empirical constant for a given pair of solute and solvent but depending upon the adjustable ion-size parameter a_0. The required densities (d_s), the vapour pressure, and the dielectric constant (ϵ_s) of the solvents are taken from Sadek *et al*'s paper (7) and by interpolation where necessary. The dielectric constant data at 15 and 20°C were obtained by extrapolation of the observed linear plots of log ϵ_s vs. T^{-1} for each of the solvent mixtures. As earlier (6, 11), the value of a_0 was taken as zero, since this gave a good linear plot in each case and reasonable variation of a_0 had no significant influence of E_m^0 values.

The standard potential (E_m^0) of the Ag−AgI electrode at any temperature for any solvent mixture was obtained by extrapolating the observed linear plot of the usual extrapolation function $E^{0\prime}$ defined by [2] (4*b*)

$$[2] \quad E^{0\prime} = E + k \log m_{I^-}/m_{S^-} + k \log K_s = E^0 - k \log a_{SH}\gamma_{I^-}/\gamma_{S^-} = E_m^0 + f(\mu)$$

against the ionic strength μ to $\mu = 0$. In eq. [2] E is the observed equilibrium value (corrected to pH_2 = 1 atm) of cell [B],[3] K_s the autoinization constant of the mixed solvent (SH), as defined by $K_s = a_{H^+}\, a_{S^-}/a_{SH}$ (4*b*), where S^- stands for all the lyate ions (including OH^- and 2-methoxy ethylate ion) and H^+ counts all the H^+ (solvated) (including H_3O^+ and 2-methoxy ethoxonium ion ($Me - H^+$) and the other terms have usual significance.

As in the previous cases (4, 12) standard states are so chosen that at infinite dilution in each solvent mixture the activity coefficients (γ_i) of the ions concerned as well as the activity of the mixed solvent SH are unity. Also, as the term by $a_{SH}\, \gamma_{I^-}/\gamma_{S^-}$ in dilute solution in each solvent is as before (4*b*, 12) likely to be proportionate to μ, extrapolation of the function $E^{0\prime}$ [2] to $\mu = 0$ yielded E_m^0. Assuming that the electrolytes KOH and KI are completely dissociated in these mixed solvents m_{S^-} and m_{I^-} are taken as equal to m_1 and m_2, respectively, and $\mu = (m_1 + m_2)d_s$. The required values of K_s for computing $E^{0\prime}$ are obtained from the following paper (8). The values of E_m^0 for both Ag−AgBr and Ag−AgI electrodes are given in Table 1. The uncertainties in the values of E_m^0 for the Ag−AgBr elec-

[3]A complete set of the data referred to above is available, at a nominal charge, from the depository of Unpublished Data (CISTI), National Research Council of Canada, Ottawa, Ont., K1A 0S2.

[b]Modified data from ref. 3*a* as the original data were wrong due to computational error. Values in parentheses at 70 wt.% ME are extrapolated data as computed from the data in ref. 7, see text.

trode lie within ±0.3 mV, while those for the Ag–AgI electrode are within ±0.5 mV.

The E^0_m values for both the electrodes at different temperatures for each solvent mixture were then fitted by the method of least squares to eq [3]

$$[3] \quad E^0_m = a + b(t - 30) + c(t - 30)^2$$

where t is the temperature in °C. The coefficients a, b, and c for the two electrodes for each of the solvent mixtures are listed in Table 2. The coefficients of eq. [3] for water have been obtained by use of the data of Bates and co-workers (9) for the two electrodes, and are also included in Table 2.

The free energy changes, ΔG^0_t, accompanying the transfer of 1 mol HX (X = Br, I) from the standard state in water (w) so that in each of the mixed solvents (s), i.e., of the process HX (w) → HX (s), have been computed on the mole fraction scale at 25°C, using the relation

$$[4] \quad \Delta G^0_t(\mathrm{HX}) = -F\,[(E^0_m)_s - (E^0_m)_w] - 2\,RT \ln M_s/M_w$$

and the corresponding entropy changes, ΔS^0_t, at 25°C have been obtained by use of eq. [5]

$$[5] \quad \Delta S^0_t(\mathrm{HX}) = F\,[(b_s - b_w) - 10\,(c_s - c_w)] + 2\,R \ln M_s/M_w$$

where M_s and M_w are the average and pure molar mass of the mixed solvent and water, respectively, and T = 298.15 K. The values for ΔG^0_t and $T\Delta S^0_t$ so obtained for HBr and HI for all these solvents are presented in Table 3. The average estimated uncertainties in ΔG^0_t and ΔS^0_t are as before (16) ± 0.03 kJ mol^{-1} and ±1. J K^{-1} mol^{-1}, respectively.

For the sake of comparison, the corresponding values for HCl have also been computed in a similar manner, i.e., the reported E^0_m values in water (13) and in 10, 30, and 50 wt % ME (7) were first fitted into eq. [6]

$$[6] \quad E^0_m = a + b(t - 35) + c(t - 35)^2$$

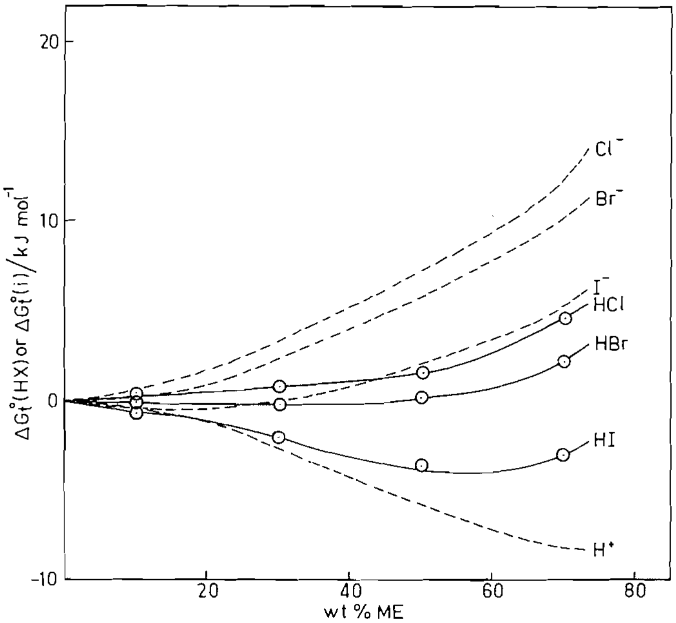

FIG. 1. Variation of ΔG_t^0(HX) (solid lines) and ΔG_t^0(i) for some ions (H^+, Cl^-, Br^-, I^-) (broken lines) with wt.% ME at 25°C.

and the coefficients so obtained were used to compute ΔG_t^0(HCl) and ΔS_t^0(HCl) values at 25°C by relations [7] and [8], respectively

$$[7]\quad \Delta G_t^0(\mathrm{HCl}) = -F\,[(a_s - a_w) - 10(b_s - b_w)] + 100\,(c_s - c_w) - 2RT \ln M_s/M_w$$

$$[8]\quad \Delta S_t^0(\mathrm{HCl}) = F\,[(b_s - b_w) - 20(c_s - c_w)] + 2R \ln M_s/M_w$$

ΔG_t^0 and $T\,\Delta S_t^0$ values of HCl so obtained at 25°C are also listed in Table 3. Since the E_m^0 values for 70 wt% ME are not available in Sadek *et al*'s paper the thermodynamic parameters for HCl in the corresponding solvent composition were not compared with our values.

Discussion

Free energies of transfer

ΔG_t^0(HX)−composition profiles (Fig. 1) for the hydrogen halides in this solvent system are found to be more or less typical of what have been observed in similar other aquo-organic solvents including aliphatic alcohols (14), EG (15), glycerol (GL) (16), or ethers like D (4*a*), THF (4*a*), and DME (4*a*). Thus, as in other aquo-organic solvents the observed gradual increase in ΔG_t^0(HCl) and ΔG_t^0(HBr) and the initial downward trends of ΔG_t^0(HI) followed by the upward trend at higher compositions and for a given composition the observed order: ΔG_t^0(HCl) > ΔG_t^0(HBr) > ΔG_t^0(HI) are the result of opposing behaviour of the individual ions like H^+ and X^- ions, which are likely to be guided by the acidity, basicity, and dielectric constant of the solvents. This is also evident from the corresponding profiles of the ions in the system as have been obtained by use of the widely used tetraphenylarsonium tetraphenylboron (TATB) reference electrolyte assumption (5) studied previously for this solvent system (3*a*). As can be seen from these profiles, while $\Delta G_t^0(H^+)$ values become increasingly negative, $\Delta G_t^0(X^-)$ values become increasingly positive. The increased solvation of H^+, as indicated earlier

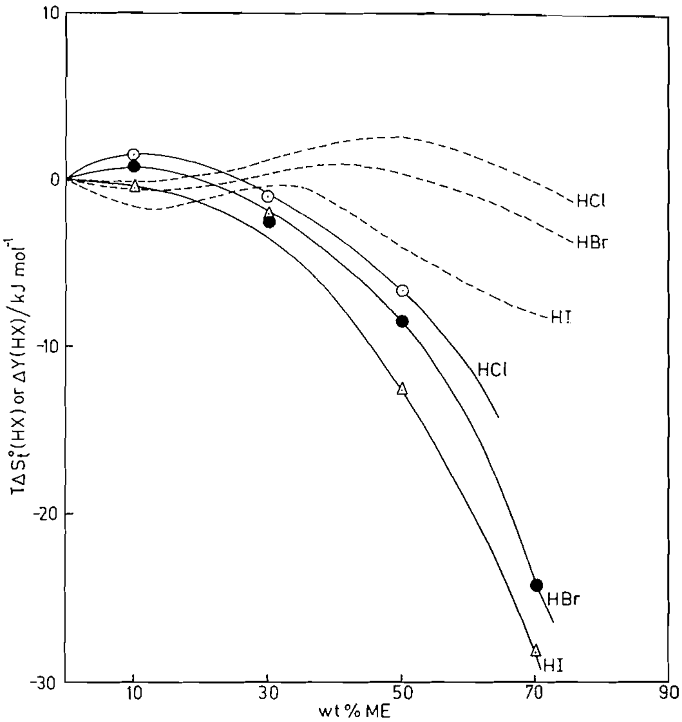

FIG. 2. Variation of $T\Delta S_t^0$(HX) (solid lines) and ΔY(HX) (broken lines) with wt.% ME at 25°C.

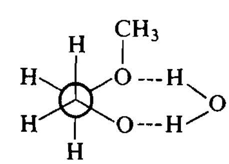
(3*a*), can be attributed to the cosolvent-induced larger basicity (17, 18) of the mixed solvents and their "cation—O—centre" type "acid−base" interactions (17, 18) with H^+. Similarly, the decreased solvation of X^- is attributable to the combined effects of cosolvent-induced decreased "acidity" or "anion−H−centre" type "acid−base" interactions (17, 18) with X^- ions, and the decreased dielectric constant causing increased Born-type electrostatic contribution in the mixed solvents compared to that in water. Moreover, the relative order of destabilization of the halide ions is the combined effect of the decreasing strength of "anion−H−centre" type interactions and the possible increasing strength of "soft−soft" interactions (19) between the increasingly polarizable anions and the softer cosolvent molecules or H-bonded aquo-cosolvent bases compared to that in water. Notably, the observed trend of relatively less destabilization of I^- compared to Cl^- and Br^- at higher cosolvent compositions in particular, is indicative of the possible enhanced "soft−soft" interactions due to enhanced softness of the possible aprotic form **B** of the cosolvent molecules or of the H-bonded aquo-cosolvent complexes of the type **E**:



E

Entropies of transfer

The observed $T\Delta S_t^0$(HX)−composition profiles (Fig. 2) unlike in aqueous alcohols (6), glycol (6), glycerol (16), and THF (4*a*) but like in aqueous DME (4) pass through a slight hump around 10 wt. % ME and then move sharply downward at higher compositions and at any composition their relative order is HCl > HBr > HI. The observed slight hump is possibly the superimposed effect of dielectric constant on $\Delta S_t^0(HX)$, as have been observed in the case of aqueous DME (4*a*). That this is particularly true becomes all the more evident when we consider the partly rationalized quantities ΔY ($= T\Delta S_t^0(H^+) + T\Delta S_{t,ch}^0(X^-)$) as illustrated in Fig. 2. These ΔY values have been obtained by subtracting $T\Delta S_{t,ch}^0(X^-)$ values from the observed $T\Delta S_t^0(HX)$ values, the former values being tentatively computed as before (6) by use of Born equation (14, 20). The required $\theta_s(= -d \ln \epsilon_s/dT)$ values were taken from ref. 7 and obtained where necessary from the observed linear plots of ln ϵ_s vs T. As could be seen from Fig. 2, ΔY–composition profiles instead of retaining the characteristic maximum as in aqueous EG (6), or exhibiting a sharply downward trend as in DME (4*a*), exhibits a wavy or "roller-coaster" type behaviour (20, 21) at initial compositions, reflecting the effects of possible structural changes of aqueous ME.

The real implications of the observed $T\Delta S_t^0(HX)$– and especially ΔY–composition profiles, can be visualized in the light of our aforesaid semi-quantitative theory on $\Delta S_t^0(HX)$, which is essentially based on Frank and Wen's model (22) of ion-solvation and fairly well recognized (23) four-step transfer process (6, 24). According to this theory

(*a*) when 3D tetrahedral structuredness of aquo-organic solvent > 3D structuredness of pure water

$$\Delta Y > 0, \text{ and } \Delta Y(X = I) > \Delta Y(X = Br) > \Delta Y(X = Cl)$$

(*b*) when solvent structure < pure water structure

$$\Delta Y < 0, \text{ and } \Delta Y(X = I) < \Delta Y(X = Br) < \Delta Y(X = Cl)$$

The observed characteristic maxima of ΔY and their relative order: HI > HBr > HCl in water-rich compositions of aqueous mono-ols (6) and the sharply downward trends and the reverse order: HCl > HBr > HI at higher cosolvent compositions also substantiated the theory as the mono-ols are well known promoters of 3D structures at water-rich compositions and 3D structure breakers at higher compositions (25, 26). Moreover, the important conclusions regarding structural features of aqueous EG (6), GL (16), and of ethers like D, THF, and DME (4*a*) derived in the light of the above-noted tenets are also in fair agreement with those derived from various other studies in the respective solvents.

In the present ME–water system the observed roller-coaster type behaviour of $\Delta Y(HX)$ instead of the characteristic maxima as observed in aqueous mono-ols, followed by the usual downward trends at higher compositions and particularly the relative order: $\Delta Y(HCl) > \Delta Y(HBr) > \Delta Y(HI)$ observed all through suggest that unlike mono-ols but like D and DME, ME possibly causes break down of 3D structures of water right from the initial composition. The observed upward trend after the initial downward trend imparting roller-coaster type behaviour is seemingly the result of possible hydrogen bonded intercomponent complexation of the type **E**, making the solvents at these compositions somewhat more ordered. Such type of intercomponent complexes were attributed to similar upward trends observed in $\Delta Y(HX)$–composition profiles (6) or ΔS_t^0-composition profiles for *p*-nitroaniline (27) or benzoic acid (28) especially in aqueous mono-ols at higher compositions.

Referring to Fig. 3 where we have illustrated the ΔY–composition profiles for HI in aqueous mixtures of the closely related cosolvents like EG, ME, and DME, as well as for Bu^{t}OH, we find that the effect of remarkable enhancement of 3D water structures by the well known structure promoter — Bu^{t}OH (29) gets succintly diminished when cosolvent Bu^{t}OH is replaced by EG, ME, and DME. This diminution is so much that ME and DME are effectively weak and strong structure breakers respectively. Seemingly, the inductive effect of two (—CH_3) groups attached to the two flexible etherial O-atoms of the DME molecule makes it more hydrophilic than ME molecule containing one (—CH_3) group attached to one flexible etherial O-atom, which is again relatively more hydrophilic than EG. As structuring or destructuring ability of a cosolvent depends upon the ratio of hydrophobic to hydrophilic effects of the cosolvents (30) the observed slight structure making propensity of EG skeletal exceeds the hydrophilicity of two —OH groups attached to it. But on passing from EG to DME via ME by successive replacement of hydroxy H-atoms by electron donating —CH_3 groups enhances hydrophilic character of the cosolvents, which in turn imparts increasingly 3D structure breaking propensities of these cosolvents.

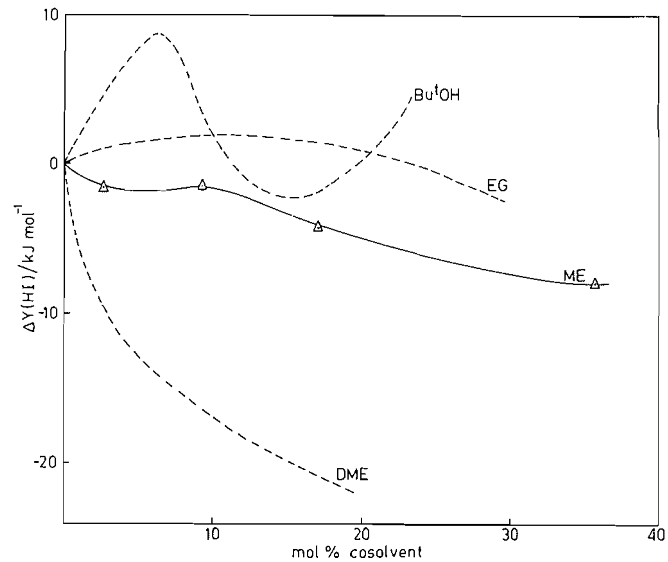


FIG. 3. Variation of ΔY(HI) in aqueous Bu^{t}OH, ME, DME, and EG.

Standard free energies (ΔG^0) and entropies (ΔS^0) of autoionization of aqueous mixtures of 10, 30, 50, and 70 wt.% of 2-methoxy ethanol (ME) have been evaluated from the autoionization constants (K_s) of the solvents as determined from emf measurements of the cell Pt, H_2 (g, 1 atm)/KOH (m_1), KBr (m_2), solvent/AgBr–Ag at seven equidistant temperatures ranging from 15 to 45°C. The observed increase in pK_s and the related $\delta(\Delta G^0)$ (= ${}_s\Delta G^0 - {}_w\Delta G^0$) has been ascribed to be the effect of decreased dielectric constant, increased basicity and decreased acidity of the mixed solvents compared to that of water. Analysis of relative entropic contributions of autoionization, $T\delta(\Delta S^0)$ (= $T({}_s\Delta S^0 - {}_w\Delta S^0)$) and their chemical part, $T\delta(\Delta S^0)_{ch}$ in the aqueous mixtures of ME as well as the closely related cosolvents like ethylene glycol (EG) and 1,2-dimethoxy ethane (DME), appears to suggest that unlike EG but like DME, ME has an overall structure breaking propensity of three dimensional (3D) tetrahedral structures of water. But the transfer entropies of water $\Delta S_t^0(H_2O)$ derived thereof, for these cosolvents suggest that while the structural changes induced by protic EG are seemingly obscured due to the involved multiple acid-base equilibria with water, and that by aprotic DME are disturbed by the formation of strong hydrogen-bonded DME–H_2O complexes around 4–14 mol% DME, quasi-aprotic ME appears to induce some order due to the possible formation of H-bonded ME–water complexes around 10–15 mol% ME.

PRABIR K. GUHA et KIRON K. KUNDU. Can. J. Chem. **63**, 804 (1985).

Opérant à sept températures équidistantes entre 15 et 45°C et utilisant des f.é.m. mesurées à l'aide de la cellule Pt, H_2 (g, 1 atm)/KOH (m_1), KBr (m_2), solvant/AgBr–Ag, on a évalué les constantes d'autoionisation (K_s) des solvants et puis les énergies libres (ΔG^0) ainsi que les entropies standards (ΔS^0) d'autoionisation de mélanges aqueux à 10, 20, 30, 50 et 70% en poids de méthoxy-2 éthanol (ME). On a observé une augmentation du pK_s ainsi que de la valeur apparentée $\delta(\Delta G^0)$ (= ${}_s\Delta G^0 - {}_w\Delta G^0$) et on attribue ces observations aux effets combinés d'une diminution de la constante diélectrique, d'une augmentation de la basicité et d'une diminution de l'acidité des solvants mixtes par rapport à celles de l'eau. L'analyse des contributions relatives de l'entropie d'autoionisation, $T\delta(\Delta S^0)$ (= $T({}_s\Delta S^0 - {}_w\Delta S^0)$) ainsi que de leur partie chimique $T\delta(\Delta S^0)_{ch}$ dans les mélanges aqueux de ME ainsi que dans des cosolvants très voisins comme l'éthylèneglycol (EG) et le diméthoxy-1,2 éthane (DME) semble suggérer que contrairement à ce que l'on observe avec l'EG mais d'une façon similaire à ce que l'on observe avec le DME, le ME possède une propension globale à briser les structures tridimentionnelles (3D) tétraédriques de l'eau. Toutefois, un examen des entropies de transfert de l'eau $\Delta S_t^0(H_2O)$ qui en dérivent pour ces cosolvants suggère qu'alors que les changements structuraux induits par l'EG protique semblent être masqués par des équilibres acide–base multiples et complexes avec l'eau et que les changements induits par le DME aprotique sont perturbés par la formation de complexes DME–H_2O qui, autour de compositions contenant de 4 à 14% de DME, sont liés par de fortes liaisons hydrogènes, le ME qui est quasi aprotique semble induire un certain ordre à cause de la formation possible de complexes ME–eau, qui à des concentrations de 10–15 mol% de ME, sont liés par des liaisons hydrogènes.

[Traduit par le journal]

Introduction

As part of our comprehensive studies (1–5) on acid–base properties, ion–solvent interactions, and solvent structures in the aqueous binaries of the closely related cosolvents like protic ethylene glycol (EG), quasi-aprotic 2-methoxy ethanol (ME) and aprotic 1,2-dimethoxy ethane (DME), we have reported in the previous paper (1) the transfer energies of hydrogen halides (HX) and derived important reflections on acid–base as well as the structural aspects of the aqueous mixtures of ME. But as previous studies by Kundu and co-workers (4*b*, 5) have shown, the autoionization constant (K_s) of different aquo-organic solvents at different temperatures and the related thermodynamic parameters are likely to reflect not only the acidity and basicity of the solvents, but also their structural features. So, it should be of particular interest to extend such studies to this solvent system as well. Previously, autoionization constants of this solvent system have been reported by Woolley *et al.* (6) but by use of glass–Ag–AgCl electrodes, while that by Bhattacharya *et al.* (3*c*) though by use of H_2– and Ag–AgCl electrodes, but at 25°C only.

In the aqueous mixtures of ME autoionization of the solvents can be represented by general eq. [1]

$$[1] \quad SH(s) + SH(s) = SH_2^+(s) + S^-(s)$$

where SH represents a solvent molecule in the mixed solvents, being either water or ME and SH_2^+ and S^- are lyonium and lyate ions and (s) essentially denotes that the species are in their standard state in the respective mixed solvents. But when ME acts as an intramolecularly H-bonded aprotic solvent (1), SH molecule essentially represents H_2O and SH_2^+ and S^- are respectively H_3O^+ and OH^- and the autoionization [1] will in effect stand for the ionization of water in the mixed solvents, as in the case of DME (4*b*). As in previous studies (4*b*, 5*c*), the thermodynamics of autoionization of these mixed solvents have been determined from the autoionization constant (K_s) of these solvents as obtained from emf measurements of cell [A]

$$[A] \quad \text{Pt, } H_2 \text{ (g, 1 atm)/KOH } (m_1), \text{ KBr } (m_2), \text{ solvent/AgBr–Ag}$$

at seven equidistant temperatures ranging from 15 to 45°C. The compositions studied are 10, 30, 50, and 70 wt.% ME.

[a]Computed from the data reported in refs. 10 and 18.

Experimental

The quality and the method of purification of ME have been described earlier (1). Water used was triply distilled. KBr (E. Merck, G.R.) was used after drying at about 250°C and cooling in a vacuum desiccator for 3–5 days. Other experimental details including the preparation of solvents, solutions, Ag–AgBr and platinized Pt electrodes and also the methods of emf measurements were exactly similar as described in the preceding papers (1, 4*b*, 5*c*).

Results

The pK_s values (molal scale) in these mixed solvents were obtained by extrapolating the observed linear plots of function [2]

$$[2] \quad pK_s' = \frac{F[E - (E^0_m)_{Ag-AgBr}]}{2.303\,RT} + \log \frac{m_{Br}}{m_{S^-}}$$

$$= pK_s - \log a_{SH}\, \gamma_{Br^-}/\gamma_{S^-} = pK_a + f(\mu)$$

against the ionic strength μ to $\mu = 0$. Here the terms have exactly the same significance as described in the preceding paper. The required $(E^0_m)_{Ag-AgBr}$ values in the solvents were obtained from the said paper.

The emf data of cell [A] at different temperatures and the corresponding molalities of KOH and KBr for each of the solvent mixtures are given elsewhere.[3] The pK_s values at different temperatures for all the compositions of the mixed solvents are listed in Table 1. The estimated uncertainties in pK_s values is of the order of ±0.005 unit. Notably, pK_s values at 25°C compare fairly well with Bhattacharya *et al.*'s data (3*c*) at lower compositions but differ by 0.13 and 0.16 unit at 50 and 70 wt.% cosolvent, respectively. The present values, however, compare tolerably well with those of Woolley *et al.*'s data (6) except at 30 wt.% ME where deviation is about 0.10 unit. Evidently, our earlier doubts about the untoward behaviour of glass electrode at higher compositions in this solvent system seem unfounded. The discrepancies between our present and earlier data may result from the possible uncertainty in the involved $E^0_{Ag-AgCl}$ values of Sadek *et al.* (7), as these values yielded ΔG^0_t(HCl) values in these solvents, which are somewhat different from those by Smits *et al.* (8).

The pK_s values at different temperatures for each of the cosolvent compositions were fitted as before (1, 4*b*) into the Harned–Robinson expression [3] (9)

$$[3] \quad pK_s = A/T + B + CT$$

by the method of least squares. The values of the coefficients A, B, and C for each of the compositions of these mixed solvents are given in Table 2. These coefficients reproduce pK_s values to within ±0.005 unit of the experimental data.

The thermodynamic quantities, namely ΔG^0, ΔS^0, and ΔH^0 accompany the autoionization of 1 mol of the mixed solvents were evaluated at 25°C by using the standard relations (10) comprising the coefficients of eq. [3]. These values (molal scale) are presented in Table 2.

[a] The values of $\Delta G^0_t(H^+)$ and $\Delta G^0_{cell\text{-}A}$ were obtained after due correction of this data reported in ref. 3*c*, which were wrong due to the involved computational error. Also, the values of $\Delta G^0_t(OH^-)'_{app}$ ($= \Delta G^0_{cell\text{-}A} - 2\,\Delta G^0_t(K^+)$, see ref. 3*c*) and of $\Delta G^0_t(OH^-)$ ($= \Delta G^0_t(OH^-)'_{app} - \Delta G^0_t(OH^-)_{app}$, vide ref. 3*c*) after due correction.

The standard free energy changes accompanying the autoprotolytic reaction [1] in the mixed solvent ${}_s\Delta G^0_N$, relative to that in pure water, ${}_w\Delta G^0_N$, have been computed on the mole function scale at 25°C using [4]

$$[4]\quad \delta(\Delta G^0_N) = {}_s\Delta G^0_N - {}_w\Delta G^0_N = 2.303RT[p({}_sK_s)_N - p({}_wK_s)_N]$$
$$= 2.303RT[p_sK_s + 2\log 1000/M_s] - [p_wK_s + 2\log 1000/M_w]$$

Similarly, those for entropy changes $\delta(\Delta S^0_N)$ were computed by use of eq. [5]

$$[5]\quad \delta(\Delta S^0_N) = {}_s\Delta S^0_N - {}_w\Delta S^0_N = 2.303R(B_w - B_s) + 4.606RT(C_w - C_s) + 2R\ln M_s/M_w$$

The subscripts s, w, N, M_w, and M_s have their usual significance as described in ref. 1. The values of (ΔG^0_N) and (ΔS^0_N) are listed in Table 3.

From the results in Table 1 it appears that the pK_s values of ME–water mixtures are increasingly greater than that of pure water. As is well known, autoprotolysis constant of an amphiprotic solvent is a composite function of the intrinsic acidity and basicity as well as dielectric constant of the solvent medium. In our preceding paper (1) it has been shown that ME is more basic and less acidic than water and also with increasing ME, dielectric constant decreases (7). Obviously, the observed pK_s values conform to the combined result of these three effects (2, 3*c*, 4*b*).

Moreover, as shown in our earlier paper on this aspect at 25°C (3*c*), the standard free energy change $\delta(\Delta G^0_N)$ accompanying the autoprotolysis of the mixed solvents relative to that of water is given by

$$[6]\quad \delta(\Delta G^0_N) = \Delta G^0_t(H^+) + \Delta G^0_t(OH^-)_{app}$$

where $\Delta G^0_t(H^+)$ and $\Delta G^0_t(OH^-)_{app}$ stand for the free energy changes for the processes [7] and [8], respectively

$$[7]\quad H_3O^+(w) + SH(s) = H_2O(w) + SH_2^+(s)$$

$$[8]\quad SH(s) + OH^-(w) = S^-(s) + H_2O(w)$$

Using the values of H^+ based on TATB method studied earlier for this solvent system (3*a*) $\Delta G^0_t(OH^-)_{app}$ could be computed by use of eq. [6]. Notably however, $\Delta G^0_t(H^+)$ values reported earlier (3*c*) involved some computational error. So also are the values $-\Delta G^0_{cell\text{-}A}$, $\Delta G^0_t(OH^-)'_{app}$, $\Delta G^0_t(OH^-)_{app}$, and $\Delta G^0_t(OH^-)$ reported in that paper (3*c*). Moreover, the present $\delta(\Delta G^0)$ values are also slightly different from the data reported in ref. 3*c*. So, the correct values for all the quantities including $\Delta G^0_t(OH^-)'_{app}$ as well as $\Delta G^0_t(OH^-)$, are given in Table 2. Notably of course, the new values hardly affect our earlier contention.

Besides, if Born-type electrostatic contributions $\Delta G^0_{t,el}(i)$ (12) for H^+ and OH^- be computed tentatively by using $r_{H_3O^+} = 0.276$ nm (13) and $r_{OH^-} = 0.156$ nm (14) and be subtracted from the values of $\Delta G^0_t(H^+)$ and $\Delta G^0_t(OH^-)$, respectively, the resulting $\Delta G^0_{t,ch}(H^+)$ and $\Delta G^0_{t,ch}(OH^-)$ values (see Table 3) suggest that the "chemical" basicity of the mixed solvents exceeds the "chemical" acidity of the corresponding compositions of the mixed solvents relative to that of water. The acidity constant of ME, ($pK_H = 15.2 \pm 0.5$) determined by Woolley and George (6) also partly substantiates this observation. This is possibly indicative of the partial quasi-aprotic character of ME as indicated in the previous paper (1).

Entropy of autoprotolysis

As is well recognized, entropy changes rather than enthalpy changes, are more informative about structural implications of the solvents (4, 5*b*, 5*c*, 15) accompanying a process in any aquo-organic solvents. So, as before (4*b*), analysis of the entropy changes of the autoprotolysis should be rewarding. The variation of $T\delta(\Delta S^0_N)$ ($= T({}_s\Delta S^0_N - {}_w\Delta S^0_N)$) with mol% of the cosolvent is shown in Fig. 1. For the sake of comparison those for the aqueous mixtures of the closely related cosolvents like EG and DME, taken from literature (4*b*, 16), are also illustrated in Fig. 1. Since the depolymerization of water molecules prior to self-protolysis contributes positive entropy changes to the overall entropy of autoionization, the larger is the extent of 3D tetrahedral water structures in the aquo-organic solvents, the larger is this contribution (5*c*). Consequently, the appearance of a maximum in $T\delta(\Delta S^0_N)$–composition profile would imply that the mixed solvents are more structured than pure water and a downward trend would imply less structured (4*b*, 5*b*). Apparently, the observed $T\delta(\Delta S^0_N)$–composition profiles (Fig. 1) suggest that all the cosolvents break down 3D structures of water. But at any composition the observed relative order of $T\delta(\Delta S^0_N)$: DME > EG > ME is indeed highly intriguing. In view of the fact that autoionization is a charge separation process, the relative variations of ϵ_s and θ_s ($= -d\ln \epsilon_s/dT$) dictating the Born-type electrostatic contribution $\delta(\Delta S^0)_{el}$ (11), are likely to contribute significantly to the observed order. To see the structural contributions free of this electrostatic effect, $\delta(\Delta S^0)_{el}$ values have been computed, tentatively though, by use of simple Born equation (11):

$$[10]\quad \delta(\Delta S^0)_{el} = \frac{Ne^2}{2}[(\epsilon_s\theta_s)^{-1} - (\epsilon_w\theta_w)^{-1}]$$

assuming that $r_{SH_2^+} \approx r_{H_3O^+} = 0.276$ nm (12) and $r_{S^-} \approx r_{OH^-} = 0.156$ nm (13) and obtaining the values of ϵ_s and θ_s from ref. 7 and ϵ_w and θ_w from ref. 10. On subtracting these from $\delta(\Delta S^0_N)$

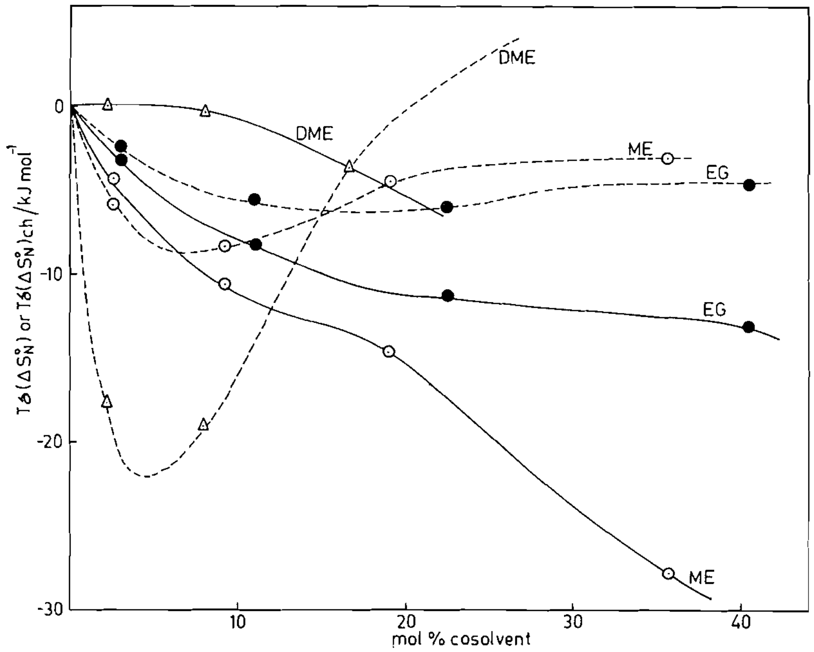

FIG. 1. Variation of $T\delta(\Delta S^0_N)$ (solid lines) and $T\delta(\Delta S^0_N)_{ch}$ (broken lines) accompanying the autoionization of aqueous mixtures of ME, DME, and EG.

values are obtained the "non-Born" or "chemical" contribution $\delta(\Delta S^0_N)_{ch}$ which are plotted against cosolvent compositions by dotted curves in Fig. 1. Interestingly enough, the observed plots apparently indicate that at water-rich compositions $|-T\delta(\Delta S^0)_{ch}|$ are in the order DME > ME > EG implying that the structure breaking propensities of the cosolvents are also in the same order conforming to what has been observed in the previous paper (1). But the observed upward trend and the reverse order of $\delta(\Delta S^0_N)_{ch}$–composition profiles at higher compositions are again apparently intriguing. This is because the effects of $\Delta S^0_t(H_2O)$ involved in $\delta(\Delta S^0_N)$ (loc. cit. eq. [11]) and the structural changes due to the packing imbalance with increased addition of cosolvents are likely to confuse the issue. So, consideration of the structural implications of $\delta(\Delta S^0_N)$ from another angle is in order.

If we assume that ME acts predominantly as quasi-aprotic (1) and that the autoionization of the ME–water mixed solvents is mainly dictated by autoionization of water, $T\delta(\Delta S^0_N)$ is likely to be involved by having a contribution of $\Delta S^0_t(H_2O)$ as has been indicated in DME–water mixtures (*4b*). Thus, since

$$[11] \quad \delta(\Delta S^0_N) = {}_s\Delta S^0_N - {}_w\Delta S^0_N = \Delta S^0_t(H^+) + \Delta S^0_t(OH^-) - \Delta S^0_t(H_2O)$$

and the contributions of $\Delta S^0_t(H^+) + \Delta S^0_t(OH^-)$ could be tentatively obtained from another source which is free from a_{H_2O}, it would be possible to estimate $\Delta S^0_t(H_2O)$ by subtracting the contributions of the sum: $(\Delta S^0_t(H^+) + \Delta S^0_t(OH^-))$ from $\delta(\Delta S^0_N)$. The tentative values of $(\Delta S^0_t(H^+) + \Delta S^0_t(OH^-))$ for different compositions of this solvent system have been obtained by plotting $(\Delta S^0_t(H^+) + \Delta S^0_t(X^-))$ where X = Cl^-, Br^-, and I^- against $(r_{X^-})^{-1}$ using $r_{Cl^-} = 0.181$ nm, $r_{Br^-} = 0.195$ nm and $r_{I^-} = 0.217$ nm (10) and reading out the values corresponding to $r_{OH^-} = 0.156$ nm (13). The required values of $\Delta S^0_t(H^+) + \Delta S^0_t(X^-)$ in ME–water mixtures for $X^- = Cl^-$ have been taken from ref. 7 and those for X = Br^- and I^- from our preceding paper (1). The $\Delta S^0_t(H_2O)$ values so obtained in ME–water mixtures are listed in Table 2 and the variation of

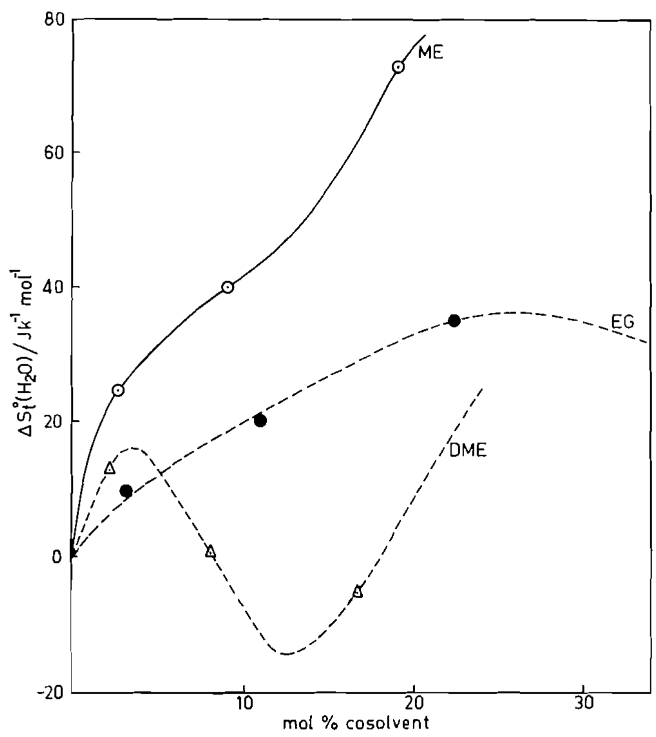

FIG. 2. Variation of $\Delta S^0_t(H_2O)$ in aqueous ME, DME, and EG.

$\Delta S^0_t(H_2O)$ at 25°C with mol% ME is shown in Fig. 2. For the sake of comparison, $\Delta S^0_t(H_2O)$ values in DME–water mixtures have been taken from the ref. *4b*. Also, assuming tentatively that in EG–water mixtures as well autoionization might be chiefly guided by ionization of water at least in water-rich compositions, $\Delta S^0_t(H_2O)$ values have been similarly computed from the reported values of $\delta(\Delta S^0_N)$ (15) and $\Delta S^0_t(HX)$ (*2a*) for that solvent system. The $\Delta S^0_t(H_2O)$–composition profiles for both DME–water mixtures and EG–water mixtures are illustrated in Fig. 2.

Now simple consideration of order–disorder phenomena indicates that the negative trend of the $\Delta S_t^0(H_2O)$–composition profile would imply more order and hence more "structure or cluster" in the mixed solvents than in water. But when the $\Delta S_t^0(H_2O)$–composition profile has a positive trend the reverse is true. The nature of the curves in Fig. 2 therefore suggests that addition of EG apparently induces breaking down of 3D water structures right from the beginning, contrary to the contentions expressed in our preceding paper (1, 16). But in the case of DME–water system as discussed earlier (4*b*) the observed sharp increases of $\Delta S_t^0(H_2O)$ at the initial compositions are indicative of the effect of the predominant structure breaking and the downward trend thereafter around 4–14 mol% DME is the result of increased order accompanying the possible formation of stable H-bonded bidentate DME–water complex (3*b*, 17). Similarly, in the case of ME–water system the observed sharp increases of $\Delta S_t^0(H_2O)$ with the addition of ME are indicative of the effect of structure breaking propensity of ME and then the observed downward trend resulting in a hump onward 10–15 mol% ME is possibly the result of the formation of H-bonded ME–water complexes referred to earlier (1). Lastly, the observed upward trends at still higher compositions in the cases of both ME and DME are the reflection of increased disorder due to the packing imbalance common to all other cosolvents.

Notably of course the observed anomalous order and features of $\Delta S_t^0(H_2O)$–composition profile for EG–water system is possibly indicative of the fact that the cosolvent EG being exclusively protic in nature, is possibly undergoing acid–base equilibria among themselves as well as with water molecules and thus obscuring the effect of ionization of water on which $\Delta S_t^0(H_2O)$ values are based.

Thus, the contentions of the present study are in fair agreement with those drawn from behaviour of $T\Delta S_t^0(HX)$ or $\Delta Y(HX)$ discussed in the preceding paper (1). Notably, however, that the structural information obtained from the observed hump of $\Delta S_t^0(H_2O)$ referred to in this paper is not exactly reflected in the behaviour of $T\Delta S_t^0(HX)$, $\Delta Y(HX)$, or $T\delta(\Delta S_N^0)$ values. Evidently, the behaviour of $\Delta S_t^0(H_2O)$ values, if free from uncertainties, is likely to be more informative than any of the other quantities, which after all, contain the Born-type electrostatic contributions.

Received July 17, 1984

This paper is dedicated to Professor C. Sandorfy on the occasion of his 65th birthday

ALFRED KARPFEN and PETER SCHUSTER. Can. J. Chem. **63**, 809 (1985).

Infinitely extended, periodic, bent chains of methanol and water molecules have been investigated with the aid of the *ab initio* crystal orbital method. Results on equilibrium geometries, stabilization energies, and other ground state properties are compared with the corresponding data obtained on monomers and homodimers. We also confront our computed results with experimental vapor phase and solid state data. Deviations from additivity of intermolecular interactions and the change of molecular properties from vapor phase monomer to molecules embedded in a periodic lattice are pointed out and compared to analogous effects as observed in other hydrogen bonded polymers. A few remarks on the evaluation of effective molecular dipole moments in molecular crystals are included as well.

ALFRED KARPFEN et PETER SCHUSTER. Can. J. Chem. **63**, 809 (1985).

Utilisant la méthode *ab initio* des orbitales cristallines, on a étudié des chaînes recourbées, périodiques et infiniment étendues de molécules de méthanol et d'eau. On compare les résultats obtenus relativement aux géométries d'équilibre, aux énergies de stabilisation et à d'autres propriétés de l'état fondamental avec des données correspondantes obtenues à l'aide de monomères et d'homodimères. On a aussi confronté nos résultats de calculs avec les données expérimentales obtenues tant en phase gazeuse qu'à l'état solide. On identifie les déviations par rapport à l'additivité des interactions intermoléculaires et le changement des propriétés moléculaires qui accompagne un changement du monomère en phase gazeuse en molécules imbriquées dans un réseau périodique et on les compare aux effets analogues observés dans d'autres polymères liés par des pont hydrogènes. On inclut aussi quelques remarques sur l'évaluation des moments dipolaires moléculaires effectifs dans des cristaux moléculaires.

[Traduit par le journal]

1. Introduction

Formation of hydrogen bonded chains is an often encountered structural feature in molecular crystals. Molecules which simultaneously can play the role of proton donors and acceptors such as hydrogen halides, simple alcohols and carboxylic acids, hydrogen cyanide, imidazole and many others preferentially crystallize in highly anisotropic structures containing sequentially aligned hydrogen bonds. Because of the large anisotropy in these systems many characteristic solid state properties may be reasonably well described by a treatment of the isolated hydrogen bonded chains.

In this series of papers the ground state properties of periodic, hydrogen bonded chains formed by hydrogen fluoride (1, 2), hydrogen cyanide (3), and formic acid molecules (4) have been investigated within the framework of the Hartree–Fock approximation. Here we wish to report results of similar *ab initio* studies on infinite chains of methanol and water molecules, respectively. To our best knowledge these are the first *ab initio* studies on these systems. Whereas the infinite chain of methanol molecules closely resembles the actual crystal structure of solid methanol, we regard the corresponding calculations on H_2O polymers mainly as a model study and as a first step towards a fully quantum chemical description of the various ice modifications.

Methanol adopts a polymeric, chain-like structure in the solid state (5). Various phase transitions have been detected in solid methanol (6–8). Structural differences between these phases consist mainly of varying degrees of puckering in the O—H---O chain. Moreover, the relative orientation and order of methyl groups changes as well. An elucidation of the relative stability of different periodic patterns in $(CH_3OH)_\infty$ goes far beyond the scope of this work, we note, however, that the chain structure persists in all solid phases of methanol. Detailed analysis of vibrational spectra of solid methanol substantiated the structural results (9–14).

The structure of the isolated methanol molecule in the vapor phase is well known (15–17). Corresponding detailed information on the preferred geometries of methanol dimers in the vapor phase is not available yet although the existence of vapor phase dimers and higher oligomers is well established (18–22). Experimental data on methanol dimer have been obtained by infrared spectroscopy in inert matrices (23–25) and by infrared photodissociation (26). Several *ab initio* studies on methanol dimers (21, 27–32) and trimers (27–29) have been reported. Higher oligomers are only dealt with in a single *ab initio* study (29) performed at a minimal basis set level.

Because of their overwhelming importance in nature vapor phase and particularly condensed phases of H_2O have been studied in great detail (33–35). The ability of H_2O to form four hydrogen bonds with surrounding water molecules leads to crystallization in essentially three-dimensional structures. Nevertheless, for various purposes, an isolated chain of water molecules has often been used as a model system in the past. Either it may be viewed as part of the ice lattice and constitutes therefore a simple model to study the influence of cooperative effects in a hydrogen bonded lattice, or, alternatively, a chain of water molecules has often served as the most primitive model for proton pumps (36–40).

As with the experimental work the number of quantum chemical studies on H_2O dimers and clusters is too numerous to be discussed here. For a recent review of experimental data and quantum chemical studies on $(H_2O)_n$ we refer to ref. 41 and also to newer *ab initio* calculations on H_2O clusters (42–44).

In this work, we aim towards a detailed and systematic description of a number of ground state properties of infinitely extended, periodic chains of methanol and water molecules, respectively. Nearly complete geometry optimization has been performed for both periodic structures. In case of the methanol polymer double ζ quality calculations have been performed only, whereas the H_2O chain has been treated by applying the same double ζ basis and additionally a more extended basis set containing a set of polarization functions on all atoms. In order to furnish an appropriate comparison monomers and homodimers of CH_3OH and H_2O have been treated at the same level. We report equilibrium geometries, stabilization energies, O—H stretching force constants and dipole moments. We also discuss some problems in the evaluation of effective dipole moments in molecular crystals or polymers. Finally we compare some aspects of the cooperative nature of hydrogen bonding in $(CH_3OH)_\infty$ and $(H_2O)_\infty$ with the behavior observed in related hydrogen bonded polymers.

2. Method of calculation

Ab initio Hartree–Fock calculations on one-dimensional, infinitely extended, periodic systems may nowadays be performed quite routinely. Explicit use of translational symmetry via the crystal orbital technique (45–47) offers considerable advantages over conventional cluster type approaches combined with subsequent attempts to extrapolate certain properties of interest to infinite chain length. Proper convergence is easily guaranteed and uncertainties in the extrapolation of quantities like total energies and geometrical parameters or conceptual difficulties connected with the evaluation of effective electrostatic moments in particular dipole moments per molecule are easily avoided. Moreover, full geometry optimization is easier since under the constraint of translational symmetry the number of internal degrees of freedom is much less than in open chain clusters. Recent methodical advances in *ab initio* crystal orbital calculations and several reviews dealing with applications in different fields of polymer physics may be found in ref. 48.

Computational techniques of our crystal orbital calculations have already been described in the previous papers of this series (1–4). We mention therefore only that all calculations on H_2O- and CH_3OH-polymers were performed in third neighbors' approximation. Remaining interaction terms could be treated with the aid of electrostatic approximations (49) without causing a significant loss in accuracy. Total energies per molecule obtained in this way are sufficiently converged (better than five digits) to ensure a reliable computation of potential energy surfaces and a meaningful comparison to monomer and dimer energies.

In a first step the equilibrium geometries of zig-zag H_2O- and CH_3OH-polymers were determined (see Fig. 1). In the case of $(CH_3OH)_\infty$ two geometric restrictions have been applied. Carbon atoms and the O—H---O backbone were confined to the same plane and methyl groups were oriented in a way to preserve a plane of symmetry. All remaining internal coordinates have been optimized. The dimer $(CH_3OH)_2$ has been treated under identical geometrical constraints. In case of $(H_2O)_\infty$ only planarity of the O—H---O backbone was required whereas hydrogen atoms not involved in hydrogen bonding point alternately above and below the O—H---O plane. Explicit use of an S_2 screw axis reduced the problem to a single molecule per primitive unit cell in $(H_2O)_\infty$ as well as in $(CH_3OH)_\infty$.

Both for $(H_2O)_\infty$ and $(CH_3OH)_\infty$ a double ζ type $7s3p/3s$ basis (50, 51) contracted to $4s2p/2s$ was applied. The choice of this comparatively small basis set was largely dictated by a compromise between desired flexibility and limitations in computing resources. Because of the presence of methyl groups large basis sets could not be applied for methanol chains. The only cluster calculations on larger methanol oligomers reported up to now in the literature have been performed with the minimal STO-3G basis applying additionally a frozen molecule approximation (29). STO-3G calculations usually grossly underestimate intermolecular distances. This tendency together with the well established correlation between X---Y bond lengths and X—H bond lengths often leads to an artificial stabilization of symmetric hydrogen bonds in polymers. An artefact of this type is e.g. obtained for hydrogen fluoride polymers in case the STO-3G basis is applied (52). We therefore decided to use at least a double ζ quality description for our calculations. The main drawback at this level of approximation is a large basis set superposition error resulting in a substantial overestimation of stabilization energies. Intermolecular distances are already quite reasonably described at this level although they turn out to be somewhat underestimated.

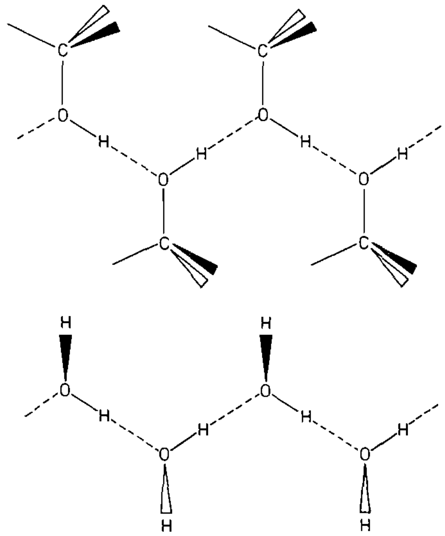

FIG. 1. Structure of $(CH_3OH)_\infty$ and $(H_2O)_\infty$.

In order to investigate the influence of basis set extension a $9s5p1d/5s1p \rightarrow [5,3,1/3,1]$ basis was additionally applied in case of $(H_2O)_\infty$. s and p basis sets were again taken from refs. 50, and 51. Exponents of polarization functions were 1.3 for d-functions on oxygen and 0.75 for p-functions on hydrogen atoms. Geometry optimizations have been performed under identical constraints as described for the smaller basis set.

3. Results and discussion

3.1. $(CH_3OH)_\infty$

Computed equilibrium structures of methanol monomer, dimer, and polymer are shown in Fig. 2. Although equilibrium geometries of monomer and dimer have been obtained via gradient optimization techniques and the polymer geometry has been found by a pointwise search on the energy surface we find satisfactory agreement in those geometrical parameters (methyl group geometry) not involved in hydrogen bonding. For future calculations it seems therefore a legitimate approximation to freeze the geometrical parameters of the methyl-group at the monomer value. Total energies, stabilization energies and other quantities which change substantially upon polymer formation, namely $r_{O\cdots O}$, r_{O-H}, f_{OH} and the dipole moment are displayed in Table 1.

As already mentioned before the main weakness of the current calculations is the strong overestimation of hydrogen bond — or stabilization energies. Dimer stabilization energies as obtained with STO-3G, 4-31G and 6-31G* basis sets are −5.57, −8.06, and −5.66 kcal/mol, respectively (32). We obtain −9.0 kcal/mol indicating that within the $7s3p/3s$ basis

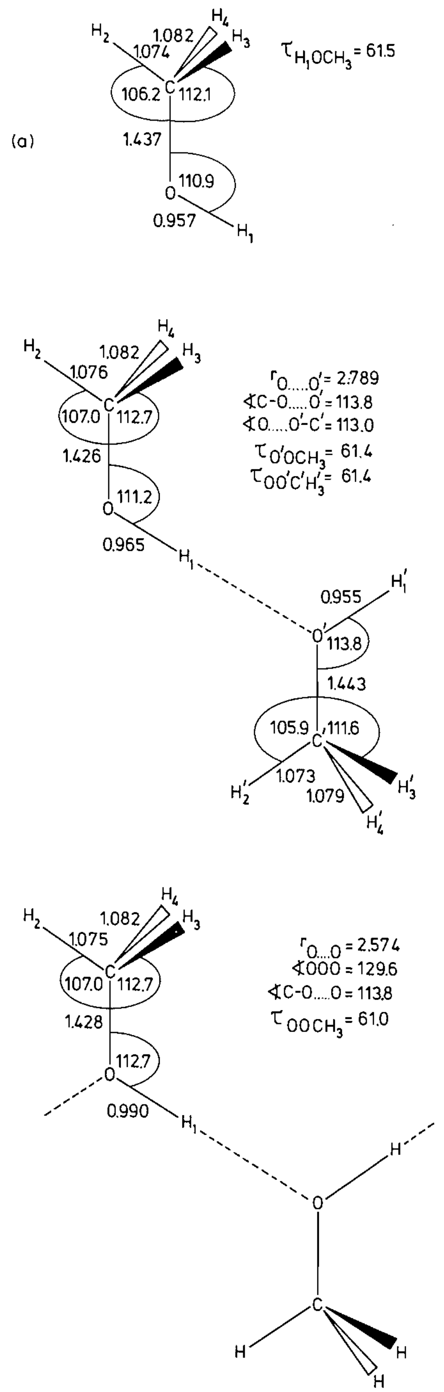

FIG. 2. Equilibrium geometries of monomer (*a*), dimer (*b*), and polymer (*c*) of methanol as obtained with the $7s3p/3s$ basis. Distances in Å, angles in deg.

the superposition error is even slightly larger than the one obtained with 4-31G. From previous experience (1–4), however, we are confident that relative changes occurring upon polymer formation are reasonably described. We observe an increase of the stabilization energy from −9.0 kcal/mol in the dimer to −13.4 kcal/mol in the polymer. Equally the intermolecular distance is substantially smaller in the polymer than in the dimer. In the solid state of methanol an O - - - O distance of 2.66 Å is observed, slightly larger than our computed value of 2.57 Å and consistent with the known tendency to underestimate intermolecular distances at the double ζ level.

TABLE 1. Selected ground state properties of methanol monomer, dimer, and polymer as obtained with the $7s3p/3s$

	Value		
Parameter	CH_3OH	$(CH_3OH)_2$	$(CH_3OH)_\infty$
Total energies (hartree)	−114.86109	−229.73653	−114.88251
ΔE (kcal/mol)	—	−9.0	−13.4
$r_{O\cdots O}$ (Å)	—	2.79	2.57
$r_{O—H}$ (Å)	0.957	0.965	0.990
$f_{O—H}$ (mdyn/Å)	8.19	7.55	5.29
μ (Debye)	2.151	4.163	2.331

Significant changes are also observed in O—H bond lengths and particularly in the corresponding force constant f_{OH}. We have not performed a full vibrational analysis and therefore the computation of the O—H frequency on the basis of f_{OH} alone would be premature. We note, however, that the vapor phase frequency of ν_{OH} is 3682 cm^{-1} (53). Matrix isolation of $(CH_3OH)_2$ yielded values of 3490–3528 cm^{-1} dependent on the type of matrix used (24) whereas the lowest OH-frequency in the solid is 3187 cm^{-1} (9). Vibrational frequencies in liquid methanol lie between the matrix and solid state data (54) indicating substantial self-association and polymer formation in the liquid. Our results therefore reproduce quite nicely the experimental trends.

3.2. $(H_2O)_\infty$

Equilibrium geometries of H_2O, $(H_2O)_2$, and $(H_2O)_\infty$ as obtained with the $7s3p/3s$ and the $9s5p1d/5s1p$ basis are shown in Fig. 3. Contrary to the case of $(CH_3OH)_2$ the water dimer has been treated in a configuration corresponding to the most stable dimer. This geometry differs from the $(H_2O)_\infty$ chain by a change in the torsional angle around O—O bonds. Whereas periodicity dictates that a screw axis remains as symmetry element in the polymer the corresponding symmetry is lacking in the case of the open chain dimer. The most important data obtained on H_2O, $(H_2O)_2$, and $(H_2O)_\infty$ are collected in Table 2. All of the changes observed to occur in the course of polymer formation of methanol are found to occur in H_2O polymers as well. Comparison to experimental data on ice is, however, less straightforward. The inherently three-dimensional structure of ice and the lack of anisotropy certainly causes substantial deviations from an idealized one-dimensional aggregate. From detailed studies of the amount of non-additive interactions in different types of H_2O-trimers (55) one may conclude that most of the attractive part of the non-additive interactions are already contained in our model polymer because it consists exclusively of a superposition of DA (donor–acceptor) trimers. DA-trimers are significantly more stable than either DD or AA trimers. Moreover, two thirds of the possible trimers in either ice I_h or ice I_c correspond to sequential trimers of the DA type.

With the above reservations in mind we observe experimentally a reduction of $r_{O\cdots O}$ from 2.98 Å in the vapor phase dimer (56) to 2.74 Å in ice I_c (33). The larger basis set calculations yield a corresponding reduction from 2.98 to 2.84 Å. From a comparison with our earlier calculation on $(HF)_\infty$ we estimate that a small fraction (about 10%) of the observed discrepancy is still due to basis set deficiencies in our calculations on one-dimensional H_2O chains. At the double ζ level we obtain a reduction of the intermolecular distance from 2.85 to 2.60 Å on going from the dimer to the polymer. 4-31G calculations, comparable in quality to our double zeta calcu-

μ (Debye)	2.42	2.16	3.66	3.46	2.50	2.37

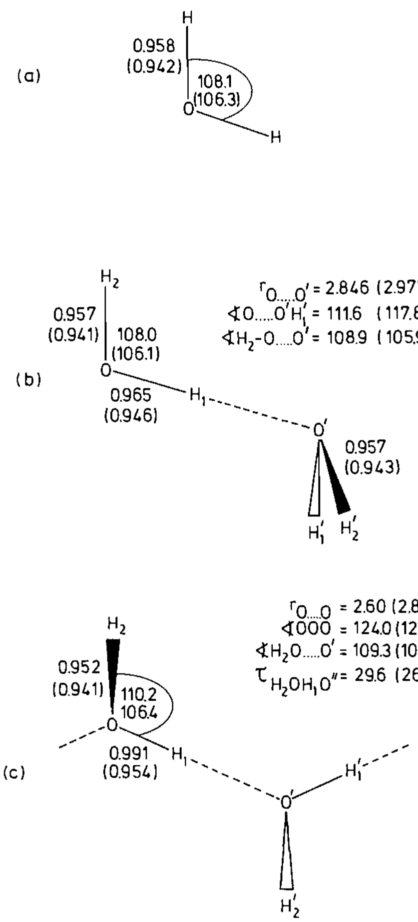

FIG. 3. Equilibrium geometries of monomer (*a*), dimer (*b*), and polymer (*c*) of H_2O as obtained with the $7s3p/3s$ and the $9s5p1d/5s1p$ basis. The latter values are given in parentheses. Distances in Å, angles in deg.

lations, by Tse *et al.* (32) on $(H_2O)_2$ and by Newton (44) on $(H_2O)_3$, $(H_2O)_5$, and $(H_2O)_6$ gave O---O distances of 2.85, 2.77, and 2.71 Å for dimer, DA-trimer and cyclic hexamer, respectively, whereas the dimer distance was recovered for a pentamer in which the molecule was tetrahedrally surrounded by four others.

3.3. *A note on dipole moments of molecules embedded in a periodic medium*

Recently Scheiner and Nagle (42) reported *ab initio* calculations on the charge partitioning between Bjerrum and ionic defects in ice. To this end they performed calculations on linear clusters of water molecules. For a more detailed discussion of this problem we refer to their work (42). For the following it is only important that they had to evaluate the *z*-component of the dipole moment of an H_2O molecule embedded in a linear H_2O polymer, where *z* is the direction in which the polymer extends. Their procedure was to evaluate μ_z for clusters of increasing chain length and then to divide by the number of molecules in the cluster. We shall demonstrate here that the above procedure, although valid, e.g., for the extrapolation of total energies per molecule, leads to effective dipole moments which always contain significant contributions from edge effects. For this purpose we performed model calculations on strictly linear hydrogen fluoride clusters containing 1, 3, 5, 7, and 9 HF molecules, respectively, and compared these to corresponding crystal orbital calculations. Results are given in Table 3.

In case a cluster is uncharged the total dipole moment is independent of the choice of the origin. This total dipole moment may now be partitioned into dipole moments of individual molecules in an infinite number of ways. For a short discussion of sources of arbitrariness see ref. 3 and references therein. Here we chose to partition the electron density in the same way as it is done in a Mulliken population analysis in close analogy to the evaluation of dipole moments via the crystal orbital approach (41, 49). Since molecules in the periodic, infinite chain are all identical and *neutral*, their dipole moment is independent of the choice of the origin. The same is asymptotically true for the innermost molecules of large clusters. Because of charge transfer molecules at the edge of the cluster are *charged*. Their dipole moments are consequently a function of the position of the origin. Because the amount of charge accumulated at the edge molecules converges as well with increasing cluster size, μ_{total}/n, converges too. However, invariably much too large values of the dipole moment are obtained in this way. This behavior is nicely reflected in our model calculations (see Table 3) and needs no further discussion.

In Table 4 we show dipole moment components of isolated H_2O molecules and those resulting from H_2O molecules embedded in the infinite chain as obtained with the $9s5p1d/5s1p$ basis. In order to obtain a comparison with the results of Scheiner and Nagle a single calculation on $(H_2O)_\infty$ in the ice geometry ($r_{O\cdots O}$ = 2.76 Å, r_{O-H} = 0.97 Å, all bond angles tetrahedral) has been performed as well. We obtain an increase of μ_z by 14 and 16% at the equilibrium geometry and at the ice configuration, respectively. As a consequence of the one-dimensional model, total dipole moments are increased by 9.8 and 8.7%. Scheiner and Nagle report increases of μ_z by 44 and 59%, respectively, dependent on the type of basis set used. In view of the above discussion we attribute their findings to an

inadequate extrapolation procedure which yields results that depend on the detailed surface structure of the cluster. For other attempts in the literature to compute the induced moments of an H_2O molecule in the ice lattice we refer the reader to (57, 58).

Clearly within our one-dimensional model chain we cannot hope to obtain the dipole moment of H_2O in the ice modifications. The additional induced dipole moments strongly depend on the lattice type as, e.g., discussed recently by Johari (57).

4. Comparison to other hydrogen bonded polymers

In Table 5 we confront our results on H_2O and CH_3OH polymers with recent *ab initio* studies on similar hydrogen bonded polymers emphasizing the differences between properties of vapor phase dimers and infinite chains. We consider the extra stabilization energy per molecule ΔE over the dimer value gained by polymer formation, the reduction of intermolecular distances $\Delta r_{X\cdots Y}$, the elongations of X—H bond lengths and the corresponding reductions of X—H force constants, and finally the change of molecular dipole moments.

Turning first to a discussion of stabilization energies we observe in all cases a substantial enhancement of "hydrogen bond" energies in the polymers. A simple analysis of a strictly linear chain of dipoles (41) yielded an increase of 28% of the dimer stabilization solely on the basis of pairwise additive forces. From the species considered in Table 5 $(HCN)_\infty$ and $(HF)_\infty$ most closely approach this model system. Comparison of infinite chain and dimer properties is also easier in these systems because the equilibrium geometry of the vapor phase dimers closely resemble the polymer structure with respect to the relative orientation of neighboring molecules.

Non-additive contributions to intermolecular interactions are small in the case of $(HCN)_\infty$ which essentially behaves like a simple dipole system. Much larger cooperative contributions are found in $(HF)_\infty$. In case of the other polymers $(H_2O)_\infty$, $(CH_3OH)_\infty$, and $(HCOOH)_\infty$ a quantitative assessment of the degree of nonadditivity cannot be given by comparison to a simple linear chain of dipoles. Additional calculations on more detailed models would be necessary in order to define the appropriate reference system.

Of particular importance is the substantial reduction of intermolecular distances and the elongation of X—H bond lengths taking place upon polymer information. The size of these effects provides an estimate of the inherent failures of Monte-Carlo or molecular dynamics studies of condensed phases, liquid or solid, of hydrogen bonded molecules working with pair potentials derived from the vapor phase and relying consequently also on a frozen molecule approximation.

This deviation from the frozen molecule assumption is essential for a proper consideration of the lattice dynamical aspects of hydrogen bonded solids (2). The strong decrease of X—H force constants in the polymers causes large shifts in the corresponding vibrational frequencies, the most characteristic feature of hydrogen bonds from the experimental point of view. As already discussed before the detailed changes of effective dipole moments in the polymers is not easy to systematize unless the consequences of the specific structure of a given polymer are analysed on their own. Monomer dipole moments are, however, always modified considerably. The same clearly applies to higher moments as well.

Conclusions

Crystal orbital calculations on hydrogen bonded polymers offer a convenient way to study the influence of periodic environments on various molecular properties. Because of the explicit use of translational symmetry and the possibility to perform lattice summations in a numerically satisfactory way, truncation errors and uncertainties in extrapolation procedures from small clusters to periodic systems arising in conventional cluster calculations are completely avoided. Advantages of this kind of approach will be even more pronounced in three-

TABLE 5. Survey of the modifications of selected monomer and dimer properties occurring upon polymer formation in hydrogen bonded systems, all values in %

				Δr_{X-H}[c]		$-\Delta f_{X-H}$[c]			
Species	Basis set	$-\Delta E$[a]	$-\Delta r_{X\cdots Y}$[b]	Dimer	Polymer	Dimer	Polymer	$\Delta\mu$[c]	*Reference*

	(10,6,1/6,1)	39.8	4.1	—	0.4	—	6.9	14.8	

[a] Increase over the dimer stabilization.
[b] Reduction of the dimer distance.
[c] Relative to monomer.

dimensional systems. With the advent of faster computers fully quantum chemical studies of hydrogen bonded solids will soon come into reach and will allow a more reliable discussion of condensed phase properties than models based on pairwise additive potentials.
