The semilog plot of anodic peak current, i_p, as a function of the peak potential, E_p, shown in Fig. 12 demonstrates similar features as that described for Fig. 11, namely the anodic shift in the potentials and the steep slopes at low concentrations of expander indicating electrocrystallisation. The inhibitory effect of the expander is evidenced by the decreasing slopes for higher concentrations of expander.

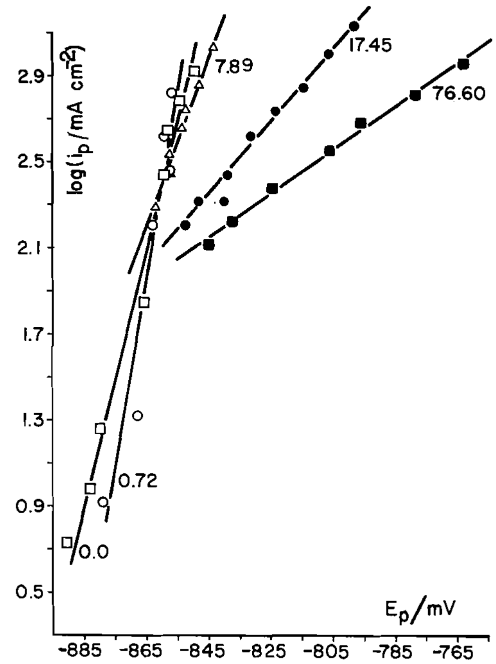

FIG. 12. A semi-log plot of the anodic peak current, i_p, as a function of peak potential, E_p. The numbers beside each line represent the expander concentrations in ppm. The steepness of the slopes at the low expander concentrations are characteristic of electrocrystallisation.

Summary

The following results were obtained in the presence of an expander at 24°C.

(*1*) The expander strongly adsorbed onto the clean amalgam surface.

(*2*) The anodic currents were increased in the presence of the expander.

(*3*) The amount of charge required for passivation was increased.

(*4*) The cathodic reduction of the $PbSO_4$ layer was inhibited.

(*5*) The resistance of the film decreased with increasing concentrations of expander, suggesting the formation of a more porous film.

(*6*) The results are consistent with the existence of an optimum concentration of expander which lies between 17.45 and 76.6 ppm.

Iodine chemistry in the +1 oxidation state. I. The electronic spectra of OI^-, HOI, and H_2OI^+ [1,2]

JEAN PAQUETTE AND BEVERLY L. FORD

Research Chemistry Branch, Atomic Energy of Canada Limited, Whiteshell Nuclear Research Establishment, Pinawa, Man., Canada R0E 1L0

Received December 4, 1984

JEAN PAQUETTE AND BEVERLY L. FORD. Can. J. Chem. **63**, 2444 (1985).

Electronic spectra are reported for the hypoiodite ion (OI^-), hypoiodous acid (HOI), and its conjugate acid (H_2OI^+) in aqueous media. Iodine in the +1 oxidation state was produced by either of the two rapid reactions

$$HOCl + I^- \rightarrow HOI + Cl^-$$

or

$$ICl(g) + H_2O \rightarrow HOI + Cl^- + H^+$$

Spectroscopic evidence of the disproportionation of $OI^-/HOI/H_2OI^+$ to iodide and iodate in basic media, and to iodine and iodate in acid media, was obtained. The results are consistent with previously reported values for the pK_a of HOI and H_2OI^+.

JEAN PAQUETTE et BEVERLY L. FORD. Can. J. Chem. **63**, 2444 (1985).

Les spectres électroniques de l'ion hypoiodite (OI^-), de l'acide hypoiodeux (HOI), et de son acide conjugué (H_2OI^+) sont décrits. L'iode dans l'état d'oxidation +1 a été obtenu en utilisant les deux réactions rapides

$$HOCl + I^- \rightarrow HOI + Cl^-$$

et

$$ICl(g) + H_2O \rightarrow HOI + Cl^- + H^+$$

La dismutation de $OI^-/HOI/H_2OI^+$ en iodure et iodate en milieu basique, et en iode et iodate en milieu acide a pu être mise en évidence. Les résultats sont en accord avec les valeurs obtenues précédemment pour le pK_a de HOI et de H_2OI^+.

Introduction

Although the iodine/water system has been studied extensively in the past (1), the aqueous chemistry of iodine in the +1 oxidation state is still not clearly understood. This is largely due to the relative instability of this oxidation state in aqueous media. The use of water-cooled nuclear reactors to produce electricity has rekindled interest in this subject, since radioactive iodine is one of the more toxic nuclear fission products. In order to design effective measures to prevent the release of volatile iodine species into the environment, a knowledge of the nature and concentration of the various iodine species in solution is essential.

In this context, the hydrolysis and disproportionation equilibrium [1] is important, since it involves the conversion of a reactive and volatile species into non-reactive, involatile species:

[1] $$3I_2 + 3H_2O \rightleftharpoons 5I^- + IO_3^- + 6H^+$$

By analogy with the other members of the halogen family, reaction [1] is thought to be, in fact, a two-step process involving the +1 oxidation state species HOI as an intermediate:

[2] $$I_2 + H_2O \rightleftharpoons HOI + I^- + H^+$$

followed by

[3] $$3HOI \rightarrow 2I^- + IO_3^- + 3H^+$$

The first step is known to be rapid (2), while the second is believed to be slower. Hypoiodous acid has not been positively identified in solution, although there is much circumstantial evidence for its existence. A positive identification of HOI is central to a full understanding of the kinetics and mechanism of reaction [1]. In this publication, we report the results of a spectrophotometric study of iodine in the +1 oxidation state in basic and acidic aqueous solutions.

The electronic spectrum of hypoiodite, OI^-, in strongly basic solutions has been described by Haimovich and Treinin (3) and by Chia (4). Although both authors agree on the general shape of the spectrum, there is disagreement on the relative intensities. Haimovich (3) obtained the OI^- spectrum by dissolving $I_2(s)$ in 4 mol dm^{-3} NaOH and Chia (4) by diluting an I_3^- solution with NaOH, or by reacting hypochlorite with an excess of iodide and extrapolating the resulting spectra to zero time. In both studies, a substantial amount of I^- would have been present, which could have distorted the spectrum below 290 nm and increased the probability of producing other iodine compounds, in particular I_3^-.

To avoid these problems and to generate iodine in the +1 oxidation state in aqueous media, we have used the following two reactions:

[4] $$HOCl + I^- \rightarrow HOI + Cl^-$$

[5] $$ICl(g) + H_2O \rightleftharpoons HOI + Cl^- + H^+$$

Reaction [4] has a rate constant of 3.3×10^8 dm^3 mol^{-1} s^{-1} at 25°C and is, thus, very rapid for pH values below 12 (5). Equilibrium [5] is rapidly established and is completely to the right at pH values greater than 2 (6).

Experimental

Materials

The sodium iodide was of ACS grade and was used without further

[1]Part of this work was funded jointly by AECL and Ontario Hydro under the CANDEV agreement.

[2]Issued as AECL-8593.

purification. The hypochlorite was obtained either as a stock solution from the Fisher Scientific Company or generated by slowly bubbling chlorine gas, from Canadian Liquid Air, into a cold 1 mol dm^{-3} NaOH solution. The iodine was resublimed ACS grade and was used as such. The iodine monochloride was obtained from the J. T. Baker Chemical Company and was used as received. Other stock solutions were prepared from ACS-grade chemicals and distilled deionized water.

The hypochlorite stock solutions were analyzed by titration with NaI in 0.01 mol dm^{-3} H_2SO_4 using an Orion iodide-specific electrode (Model 94-53) as an end-point indicator. An Orion double-junction electrode (Model 90-02) was used for reference. The OCl^- absorption band at 290 nm (ϵ = 350)[3] was also used to analyze for hypochlorite.

Apparatus and procedures

All spectra were recorded in digital form, using a double-beam diode array spectrophotometer (Hewlett-Packard Model 8450A), and stored on flexible discs. The pH measurements were made with an Orion Model 701A ionalyzer using a Microelectrodes Inc. micro-combination pH electrode.

Spectra involving I_2 in NaOH solutions were obtained by injecting an iodine solution, using a glass syringe, into an equal volume of sodium hydroxide solution contained in a spectrophotometric cell. A sodium hydroxide/sodium iodide solution was used on the reference side of the spectrophotometer to balance out the absorption due to I^-.

For reactions involving $HOCl/OCl^-$ and I^-, equal volumes of equimolar solutions in the appropriate buffer (phosphate or borate) were similarly mixed, using glass syringes, in the spectrophotometric cell, and the resulting spectra were recorded as a function of time. Sodium chloride solutions, in the appropriate buffer, were used on the reference side of the spectrophotometer. Some spectra were obtained at short reaction times by using a flow system. The two reagents were driven by a double-syringe pump into a Plexiglass mixing chamber, and then into a small-volume flow cell. A stopped-flow mixing device was also used for some experiments. The spectra were recorded with the solutions flowing and could be obtained at various reaction times by changing the flow rate.

Initial experiments with ICl were attempted by quickly adding a buffer solution to ICl crystals in a spectrophotometric cell. The results were erratic, due to the slow rate of dissolution of ICl(s), and to the production of high local concentrations, leading to the formation of undesired iodine compounds. An alternative technique was then adopted whereby the cell atmosphere was first saturated with ICl vapour. The buffer solution was then introduced and the cell shaken for a few seconds to ensure good mixing between the gaseous and aqueous phases. The total iodine concentrations in these experiments were determined at the end of the reaction by adding 1 cm^3 of an acid hydrazine solution to the cell and measuring the concentration of the resulting I^- by its absorbance at 225 nm.

An ion-exchange technique was used to remove chloride ions from low pH solutions, in order to displace equilibrium [5] to the right. The anion exchange resin (Analytical Grade Dowex 1X8, 100–200 mesh, from Bio-Rad Laboratories) was converted from the chloride to the sulfate form, by elution with a large volume of a 0.5 mol dm^{-3} Na_2SO_4 solution that had been adjusted to a pH value of 2 with H_2SO_4. The elution was continued until no precipitate could be detected in the eluate after the addition of a few drops of an $AgNO_3$ solution. Immediately after contact with ICl(g), the buffer solutions were quickly passed through 2 cm^3 of the sulfate resin contained in a plastic syringe. We verified that this procedure was capable of removing most of the chloride ions by using 10^{-3} mol dm^{-3} NaCl solutions in pH 2 sulfate buffer as test solutions, and an Ag/AgCl electrode coupled to a saturated calomel electrode as a chloride detector. We also checked that this procedure did not produce any unwanted absorbance in the 200 to 800 nm spectral region.

Results

Figure 1 shows the electronic spectrum obtained by reacting

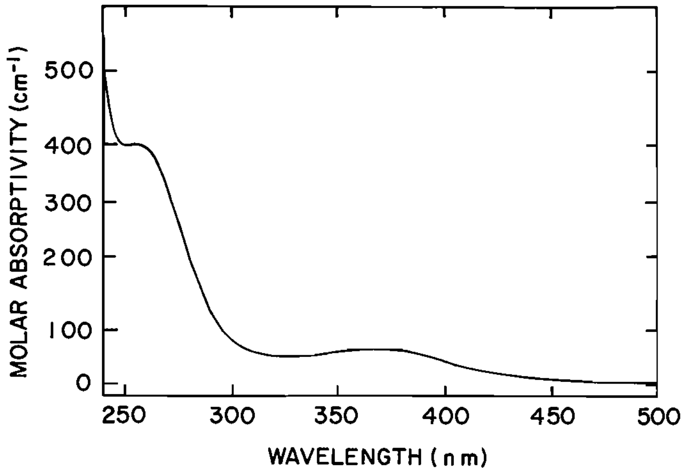

FIG. 1. The electronic spectrum for OI^- in basic solution.

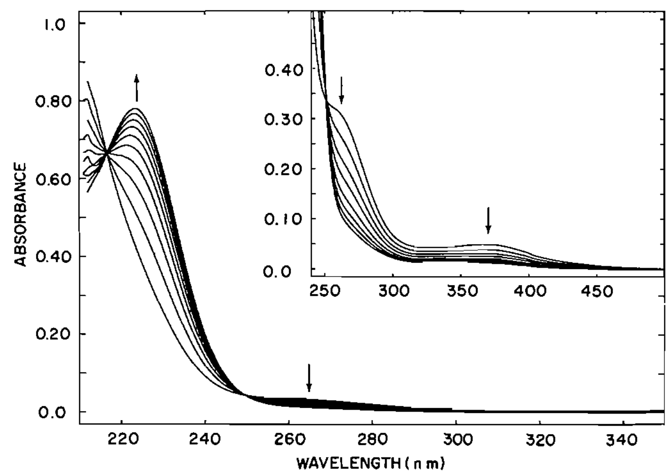

FIG. 2. Spectra as a function of time obtained after reacting ICl(g) with a borax buffer solution at a pH of 12. Arrows indicate the direction the peaks moved with time. The time between each spectrum is 200 s and the total iodine concentration is 1×10^{-4} mol dm^{-3}. The insert was obtained with a cell having a 10-cm path length.

ICl(g) with a 2 mol dm^{-3} NaOH solution (reaction [5]). An identical spectrum was obtained by diluting an I_2 solution with NaOH (reaction [2]) and using an equimolar concentration of I^- in 2 mol dm^{-3} NaOH on the reference side of the spectrophotometer, to balance out the absorption due to I^-. The spectrum is similar to those reported previously for OI^- (3, 4), but is better defined at low wavelengths. The main features of our spectrum are a weak band at 370 nm (ϵ = 60), a shoulder at 260 nm (ϵ = 400), and a sharp increase in absorbance below 260 nm. Here, ϵ is calculated in the usual manner, assuming that all of the light absorption is due to iodine in the +1 oxidation state. The spectrum changes very slowly with time at the low total concentration of iodine (5×10^{-4} mol dm^{-3}) used. Essentially identical spectra were obtained by reacting ICl(g) with 1 mol dm^{-3} and 0.1 mol dm^{-3} NaOH solutions.

Reactions [4] and [5] were used at a pH value of 12 (borax buffer) and gave identical spectra. A typical series of spectra as a function of time, obtained using reaction [5], is shown in Fig. 2. The band growing with time at 225 nm is characteristic of I^-. The spectrum obtained shortly after mixing is similar to the one obtained in 2 mol dm^{-3} NaOH and is thus attributed to OI^-. The presence of the 225 nm band and of two isobestic

[3]Throughout this paper, ϵ is the molar absorptivity, in units of mol^{-1} dm^3 cm^{-1}.

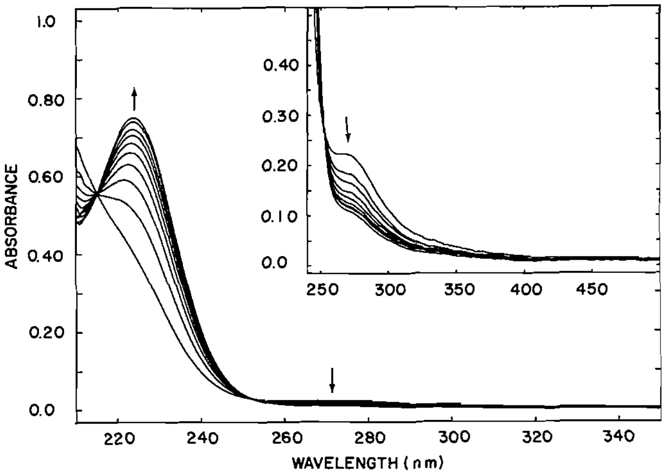

FIG. 3. Spectra as a function of time obtained after mixing equimolar solutions of I^- and OCl^- in phosphate buffer at a pH of 9. The time between each spectrum is 20 s and the total iodine concentration is 1×10^{-4} mol dm^{-3}. The insert was obtained with a cell having a 10-cm path length.

points at 215 ± 1 nm and 248 ± 1 nm is consistent with the reaction

[6] $3OI^- \rightarrow 2I^- + IO_3^-$

Figure 3 shows a series of spectra obtained as a function of time after mixing equimolar concentrations of OCl^- and I^-, at a pH value of 9, using a phosphate buffer. Identical results were obtained from reaction [5]. At this pH value, HOI would be expected to predominate over OI^- since the pK_a value for HOI is approximately 11 (4). The growing I^- band at 225 nm and the presence of two isobestic points are consistent with the occurrence of the disproportionation reaction [3].

The spectrum obtained shortly after mixing is subtly different from the spectra obtained at a pH of 12 and in NaOH solutions. The weak band previously observed at 370 nm is absent. The shoulder observed previously at 260 nm has shifted to 270 nm and the absorbance is lower at all wavelengths. Also, the two isobestic points are shifted and are now located at 210 ± 1 nm and 255 ± 1 nm.

At pH values between 8 and 7, substantial equilibrium amounts of I_2 (via reaction [2]) and I_3^- would be present, masking the spectral features of the +1 oxidation state. Therefore, this pH range was not investigated. Under more acidic conditions, the hydrolysis equilibrium [2] is very much in favour of I_2, and the following reaction sequence is expected to hold:

[4–5] $HOCl + I^-$ (or $ICl + H_2O$) $\rightarrow HOI + Cl^-$ $(+H^+)$ (fast)

[3] $3HOI \rightarrow 2I^- + IO_3^- + 3H^+$ (slow)

[2] $HOI + I^- + H^+ \rightarrow I_2 + H_2O$ (fast)

with the overall reaction being

[7] $5HOI \rightarrow 2I_2 + IO_3^- + 2H_2O + H^+$

Figure 4(a) shows spectra obtained as a function of time, at a pH of 4 (phosphate buffer). These spectra were obtained using reaction [5]; reaction [4] gave identical spectra. Two isobestic points can be observed at 260 ± 1 nm and 375 ± 1 nm. The absorbance at 285 nm decreases with time, whereas that at 460 nm increases with time. The latter band is characteristic of I_2. These observations are in agreement with the overall reaction [7]. It can be noted that some elemental iodine

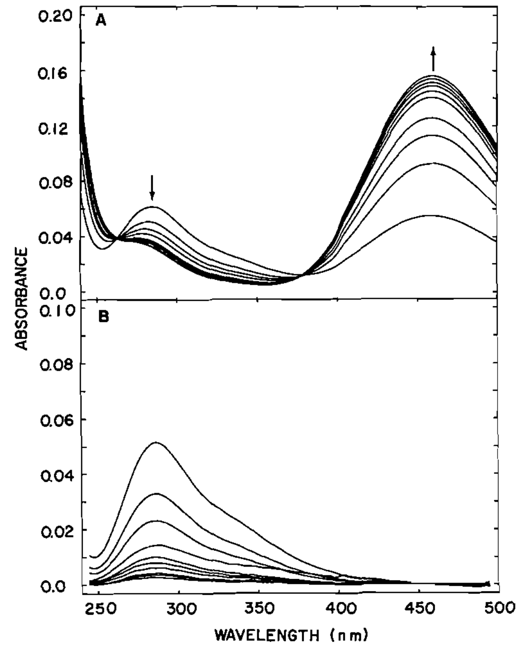

FIG. 4. (a) Spectra as a function of time obtained after reacting ICl(g) with a phosphate buffer solution at a pH of 4. The time between each spectrum is 20 s and the total iodine concentration is 5×10^{-4} mol dm^{-3}; (b) Fig. 4(a) spectra minus the ($I_2 + \frac{1}{2}IO_3^-$) spectrum scaled according to the I_2 absorbance at 460 nm.

is already present at short reaction times. In the case of reaction [5], it takes about 5 s to mix the vapour and aqueous phases. Since the subsequent disproportionation reaction is relatively rapid, some I_2 will already be present at the first measurement. For reaction [4], the reaction of HOCl with I^-, and that of HOI with I^-, have comparable rate constants (2, 5). As soon as some HOI is formed from HOCl and I^-, some reaction with the remaining I^- will occur, producing I_2. To resolve this problem, the ($I_2 + \frac{1}{2}IO_3^-$) spectrum, scaled according to the I_2 absorbance at 460 nm, was subtracted from the Fig. 4(a) spectra. The required ($I_2 + \frac{1}{2}IO_3^-$) spectrum was obtained simply by recording the spectrum at long reaction time where only I_2 and IO_3^- are present in a two-to-one ratio. The result of this subtraction process is shown in Fig. 4(b). Similar spectra were obtained at pH values of 5 and 6. These spectra are characterized by a band at 285 nm (ϵ = 200) and a weaker band at 345 nm (ϵ = 60).

Reaction [4] cannot be used at pH values below 3 due to the equilibrium formation of chlorine. To avoid this problem, only reaction [5] was used at pH values of 3 or less. Iodine monochloride is not completely hydrolyzed at low pH values and small amounts of ICl_2^- and I_2Cl^- can be formed (7). To minimize this problem, the solutions were rapidly passed through an anion exchange resin in the sulfate form to remove most of the chloride ions and displace equilibrium [5] to the right, as described in more detail in the Experimental section. Spectra obtained in this manner at pH values of 3 and 2 (sulfate buffer) were identical to the ones obtained at pH values of 4, 5, and 6.

Figure 5(a) shows a series of spectra that were obtained, as a function of time, after contacting ICl(g) with a 0.05 mol dm^{-3} H_2SO_4 solution, and passing the solutions through an anion exchange resin in the sulfate form. An isobestic point can be observed at 398 ± 1 nm. The characteristic I_2 band at 460 nm increases in intensity with time, whereas the absorbance at 310 nm decreases with time. Figure 5(b) represents the same

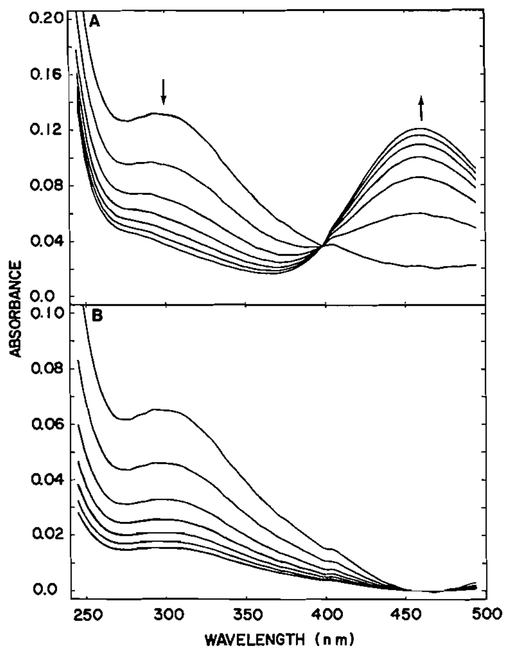

FIG. 5. (a) Spectra as a function of time obtained after reacting ICl(g) with 0.05 mol dm^{-3} H_2SO_4, and flowing the resulting solution through an anion exchange resin. The time between each spectrum is 100 s and the total iodine concentration is 5×10^{-4} mol dm^{-3}; (b) Fig. 5(a) spectra minus the ($I_2 + \frac{1}{2}IO_3^-$) spectrum scaled according to the I_2 absorbance at 460 nm.

spectra after subtraction of the ($I_2 + \frac{1}{2}IO_3^-$) spectrum, scaled according to the I_2 absorbance at 460 nm. The spectra are different from the spectra obtained at higher pH values (Fig. 4(b)), and are characterized by a single band at 310 nm (ϵ = 200). It is worth noting that spectra obtained at this acid concentration, without using the anion exchange resin, showed a conspicuous band at 335 nm, which is likely due to undissociated ICl(aq) (ref. 6, p. 574).

Discussion

We attribute the spectra obtained in NaOH solutions and at a pH of 12 to the hypoiodite ion, OI^-. Chia (4) reports a value of $(5.6 \pm 0.6) \times 10^{-3}$, based on spectrophotometric measurements, for the equilibrium quotient of the reaction

[8] $IO^- + 2I^- + H_2O \rightleftharpoons I_3^- + 2OH^-$

This value is not expected to be affected very much by the ionic strength, since the reaction is isocoulombic, and can be considered equal to the equilibrium constant. The above value, combined with the value given by Burger and Liebhafsky (8) for the equilibrium constants for reaction [2] and for the tri-iodide ion formation, leads to 10.6 ± 0.8 for the pK_a of HOI. If this value is correct, and if HOI has a spectrum markedly different from OI^-, then spectral changes would be expected to take place as the pH is lowered below 11.

This is indeed what we observed. Although there is no noticeable change in the iodine (I) spectra in solutions containing OH^- in the concentration range from 0.01 to 2 mol dm^{-3}, spectral modifications are noticeable at a pH of 9, and become very obvious at a pH of 6. From a comparison of Figs. 1, 3, and 4, the spectrum obtained at a pH of 9 is a combination of that obtained at lower pH values and that obtained in very basic solutions. We attribute the spectrum obtained at pH values between 2 to 6 to hypoiodous acid, HOI. A matrix multicomponent analysis routine was used, together with the spectra obtained in 2 mol dm^{-3} NaOH and at a pH of 4, to deconvolute the spectrum obtained at a pH of 9 into its OI^- and HOI components. An $[OI^-]/[HOI]$ ratio of 0.1 ± 0.01 was obtained. This amounts to a pK_a value of 10.0 ± 0.3 for HOI, in reasonable agreement with the value of 10.6 ± 0.8 derived from Chia's data, considering that ionic strength effects would tend to lower the pK_a. Our spectroscopic assignment is also supported by the observation of a sharp increase in the rate of decay of the spectra, as the pH is lowered below 11.

Bell and Gelles (9) determined an equilibrium constant of $(1.2 \pm 0.3) \times 10^{-11}$ at 25°C, from emf measurements, for the reaction

[9] $I_2 + H_2O \rightleftharpoons H_2OI^+ + I^-$

This value, combined with that given by Burger and Liebhafsky (8) for the equilibrium constant of reaction [2], leads to a pK_a value of 1.4 ± 0.3 for H_2OI^+. Thus, if the spectrum for H_2OI^+ is substantially different from the spectrum for HOI, spectral changes would be expected to occur as the pH is lowered below 2. This agrees well with our observations. As can be seen by comparing Figs. 4 and 5, the spectrum obtained in 0.05 mol dm^{-3} H_2SO_4 is markedly different from that obtained in the pH region from 2 to 6. We attribute the spectrum obtained in 0.05 mol dm^{-3} H_2SO_4 to protonated hypoiodous acid, H_2OI^+. This puts the pK_a for H_2OI^+ between 1 and 2, in agreement with the value of 1.4 ± 0.3 given above. This assignment is also supported by the observation of a sharp decrease in the rate of decay of the spectra as the pH is lowered below 2. It is also worth mentioning that none of the other iodine species that could be present in these solutions has an absorbance at 310 nm; ICl_2^- has a band at 345 nm (ϵ = 243) (7), I_2Cl^- has a band at 437 nm (ϵ = 1 100) (7), and ICl(aq) absorbs at 335 nm (ϵ = 250) (ref. 6, p. 574). Thus, the 310 nm band must be due to H_2OI^+.

Hypochlorite, hypobromite, and hypoiodite have low-intensity bands at 290 nm (10), 330 nm (11), and 370 nm (this work), with molar absorptivities of 350, 305, and 60, respectively. Hypochlorous, hypobromous, and hypoiodous acids have low intensity spectra that are very similar in shape. Hypochlorous acid has bands at 235 nm (ϵ = 100) and 290 nm (ϵ = 27) (10), hypobromous acid has bands at 260 nm (ϵ = 160) and 315 nm (ϵ = 35) (11), and from this work, hypoiodous acid has bands at 285 nm (ϵ = 200) and 345 nm (ϵ = 60). Thus, both the hypohalites and the hypohalous acids form remarkably regular series.

The hypohalites and the hypohalous acids have valence shells that are isoelectronic with those of the halogen molecules and of the ClF molecule. As is the case for the halogens and for ClF, the lowest energy band for the hypohalites and the hypohalous acids is likely due to the transition $^3\pi \leftarrow {}^1\Sigma^+$. For the hypohalites, the $^1\Sigma^+$ ground state correlates with $O^-(^2P)$ and $X(^2P)$, and the $^3\pi$ excited state correlates with $O(^3P)$ and $X^-(^1S)$. If the above is correct, then the potential energy curves should cross, since the electron affinity of the oxygen is smaller than that of the halogens. The dissociation products would then have high kinetic energies and, as a result, the hypohalites would be expected to decompose when irradiated in their low-intensity bands. For the hypohalous acids, the singlet ground state correlates with $OH(^2\pi)$ and $X(^2P)$. The triplet excited state may decompose to yield $OH(^2\pi)$ and $X(^2S)$. Thus, the hypohalous acids would also be expected to be photosensitive when irradiated in their low-intensity bands.

Conclusion

The use of both reaction [4] and reaction [5] has been found useful for elucidating the behaviour of iodine in the +1 oxidation state in aqueous media. The electronic spectra for OI^-, HOI, and H_2OI^+ were obtained. The results are consistent with previously reported values for the pK_a of HOI and H_2OI^+. Spectroscopic evidence of the disproportionation of iodine(I) to iodide and iodate in basic media, and to iodine and iodate in acid media, was also obtained. These reactions, coupled to uv–visible spectrophotometry, offer an ideal way of examining the kinetics of disproportionation of iodine(I). A full kinetic study will be described in a forthcoming publication.

Reçu le 4 juillet 1984[1]

MICHÈLE DAVID, JEAN SAULEAU et ARMELLE SAULEAU. Can. J. Chem. **63**, 2449 (1985).

L'ouverture d'époxydes α-éthyléniques par le phénate de sodium conduit à un mélange de composés. Les attaques nucléophiles qui entrent en compétition (composés A au niveau du carbone le moins substitué du cycle ou composés B et C au niveau du carbone β-éthylénique) peuvent être résolues par un choix judicieux des conditions opératoires (solvant, stéréochimie des époxydes). La régiosélectivité de l'attaque nucléophile est sous la dépendance d'états de transition impliquant une faible gêne stérique et une conjugaison oxiranne – double liaison.

MICHÈLE DAVID, JEAN SAULEAU, and ARMELLE SAULEAU. Can. J. Chem. **63**, 2449 (1985).

The ring cleavage reactions of α-ethylenic epoxides by sodium phenoxide afforded a mixture of products. Problems of competitive attack by this nucleophile, at the less substituted carbon (compounds A) or at the β-ethylenic carbon atom (compounds B and C), were encountered and could be resolved by judicious choice of reaction conditions (solvents, stereochemistry of the oxiranes). The regioselectivity of the attack was dependent on the transition states, implying weak steric hindrance and a conjugation oxirane – double bond.

Introduction

L'action de phénols en milieu alcalin sur des époxydes à restes saturés ou aromatiques a déjà été étudiée (1–4). Dans ce travail, nous envisageons le cas d'époxydes α-éthyléniques qui ne semble pas avoir fait l'objet d'une étude systématique, puisque les seuls exemples mentionnés dans la littérature sont ceux d'Al-bitskaya *et al.* (5) rapportés schéma 1.

Nous montrons ici que le bilan réactionnel est plus complexe; la nature, la géométrie R^*R^*,R^*S^* des époxydes insaturés, la qualité du solvant utilisé, influent en effet sur la régiosélectivité de l'attaque nucléophile par l'anion phénoxy.

Résultats

Trois composés notés A, B et C sont le plus fréquemment obtenus lors de la réaction phénol–sodium, époxydes α-insaturés (schéma 2).

Ce schéma fait ainsi apparaître une nette différence entre nos résultats et ceux d'Al'bitskaya. Si comme cet auteur, nous observons une ouverture C(1)—O époxydique (obtention de A), aucune attaque nucléophile sur le carbone-2 n'est mise en évidence. Par contre, les composés B et C formés résultent d'une attaque nucléophile sur le carbone sp_2, en β de la chaîne insaturée (cf. Discussion).

Les résultats des condensations réalisées dans le *dioxanne* (tableau 1) font apparaître les influences du degré de substitution du cycle époxydique et de sa stéréochimie.

Si les produits A sont préférentiellement formés avec les époxydes primaires–tertiaires **1***a* et **1***b*, on constate que pour **3**, la substitution du carbone-1 époxydique, sa géométrie R^*R^*, favorisent l'obtention de B et C accompagnés d'une certaine proportion de composés d'hétérocyclisation.[2] L'importance de la nature du solvant de condensation apparaît dans le tableau 1 à propos de l'époxyde **1***a* le plus facilement accessible. La compétition alcoylation O/C peut être orientée selon le solvant et l'on compare alors les taux relatifs de A, B et C.

Dans les *solvants polaires*, la régiosélectivité élevée—formation majoritaire des produits A + B d'alcoylation O—s'explique par l'accroissement de la nucléophilie de l'anion phénoxy. Avec les *solvants protiques*, les résultats corroborent ce qui est connu sur les anions ambivalents phénoxy (6, 7). La solvatation de l'oxygène époxydique et de l'anion, par interactions ion–dipole et par liaisons hydrogènes, favorise cette fois la nucléophilie du site *ortho*-carboné benzénique. Les phénols C (alcoylation C) deviennent majoritaires et ceci d'autant plus que le solvant est acide, assertion que l'on peut vérifier avec l'éthanol et le trifluoroéthanol, solvants de pK_a très différents (8).

Discussion

Pour que l'on observe une attaque nucléophile sur le carbone sp_2, en β du cycle oxiranne, l'époxyde doit pouvoir se présenter dans une conformation où le système éthylénique et le cycle oxiranne sont conjugés: coplanarité des liaisons C(1)—C(2)—C_α—C_β pour un recouvrement maximum des orbitales. Tout effet stérique empêchant ou diminuant cette conjugaison modulera alors l'attaque précitée et favorisera le site carbone-1 époxydique (formation de A).

Cas des époxydes secondaires–tertiaires 3a($R''' = H$), 3b($R''' = CH_3$) R*R* *et* R*S*

Nous envisageons deux des rotamères possibles **3′** et **3″** pour chacune des configurations R^*R^* et R^*S^* (schéma 3).

Pour les isomères R^*S^* le méthyle en C(1) et le reste éthylénique sont en position *cis*: Quand $R''' = H$, le rotamère **3′** est à exclure compte tenu de la forte gêne stérique qui implique la perte totale de la conjugaison. Seul le rotamère **3″**, moins contraint, reste à envisager; la coplanarité pouvant être atteinte, on conçoit alors la formation majoritaire de B et C de géométrie uniquement *E*. Lorsque $R''' = CH_3$, la gêne stérique dans chacun des rotamères **3′** et **3″** est telle que la conjugaison cycle – double liaison n'a pas lieu. L'attaque β est alors exclue: seul C(1) peut être attaqué (formation unique de A).

Dans les configurations R^*R^*, les conformations **3′** et **3″**, favorables à la conjugaison précitée, rendent majoritaire l'attaque du site β: obtention d'un mélange *Z*/*E* où *E* est préférentiel.

Avec le rotamère **3′** (rapprochement oxygène époxydique –

double liaison), on peut invoquer une complexation contre ion–oxygène plus facilement atteinte lorsque R‴ = H (30% de Z). Avec R‴ = CH_3, plus volumineux, 5% de Z sont obtenus. Signalons que ce type de système cyclique a été invoqué lors de la réaction époxydes β-éthyléniques – hydrures ou thiolates (9, 10). Le conformère **3″** reste cependant privilégié: le système plus étendu, permettant une meilleure délocalisation des charges lors de l'attaque nucléophile, explique le taux majoritaire en isomère *E*.

Cas des époxydes primaires–tertiaires 1 et 2 (tableau 1)

Avec les oxirannes **1**, l'absence d'encombrement du carbone-1 (contrairement à **3**) fait de ce carbone un site d'attaque préférentiel (obtention de A) par rapport au carbone β, bien que la conjugaison soit ici possible. Le taux (12%) de produits B et C obtenus pour **1***a* se justifie par une coplanarité cycle – double liaison plus facilement atteinte que dans **1***b* (aucune attaque β) où, comme nous l'avons montré par calculs théoriques et rmn ^{17}O (11), une légère gêne stérique intervient. Il ne s'agit pas d'un effet de température, puisque des essais réalisés à 150°C, pendant 3 jours, ne modifient pas les pourcentages obtenus avec **1***a*.

Le cas de leurs homologues phénylés **2** est particulier: formation préférentielle de B et C (tableau 1). Si l'on considère le modèle oxyde de styrène (4, 12, 13) où l'électrophilie du carbone-2 oxiranique favorise son attaque nucléophile, on interprète les résultats. Puisque l'ouverture C(2)—O ne peut ici se concevoir (forte gêne reste phénylé – groupe éthylénique), la délocalisation de la charge positive de ce carbone vers la double liaison explique l'attaque nucléophile en β.

Conclusion

La réaction étudiée permet l'accès à des éthers phénoliques et (ou), des phénols *ortho*-allyliques en proportions variables selon les choix du substrat, de son éventuelle géométrie et du solvant. Cette réaction est d'ailleurs généralisable puisque l'utilisation de divers phénols substitués conduit, dans le dioxanne, aux composés A, B et C, sans changement notable dans leurs pourcentages.

Partie expérimentale

Les spectres infra-rouge (solvant CCl_4) sont enregistrés sur un appareil Perkin–Elmer 377. Les spectres ($CDCl_3$) rmn ^{1}H sont réalisés sur un appareil Varian EM 360 L (60 MHz). Pour la rmn ^{13}C, on utilise un appareil Brücker 20,1 MHz à transformée de Fourier. Les valeurs des déplacements chimiques sont à ±0,05 ppm et les constantes de couplage à ±1 Hz.

Un contrôle de pureté est réalisé sur chacun des produits par chromatographie en phase vapeur (Fractovap GT Carlo Erba, colonne SE30) et (ou) par chromatographie sur gel de silice HF254 (type 60 Merck). Pour la spectrométrie de masse, un appareil Varian MAT 311 avec procédé M.I.K.E. est utilisé.

Les époxydes α-éthyléniques sont préparés selon une méthode mise au point au laboratoire (14). Les oxirannes **3***a* et **3***b*, *R*R** et *R*S** sont séparés par distillation du mélange des stéréoisomères, au moyen d'une colonne à bande tournante Perkin–Elmer (200 plateaux théoriques).

Identification spectrale de A, B et C

L'infra-rouge met en évidence les produits de type A par leur reste vinyle terminal (905 et 970 cm^{-1}).

En rmn ^{1}H, les valeurs différentes observées dans les déplacements

chimiques des restes méthylènes suffisent à différencier les trois types de produits (tableau 2). L'intégration de ces signaux, entre autre, permet de déterminer les pourcentages de chacun de ces composés dans les mélanges bruts réactionnels, ainsi que les proportions alcoylations O/C.

La rmn ^{13}C réalisée sur quelques échantillons confirme les données de rmn ^1H et permet l'attribution certaine de la géométrie *E*/*Z* de la double liaison dans B et C (tableau 3); par exemple, l'effet γ *gauche* subit par le carbone hydroxylé (pour B et C), uniquement dans les géométries *Z*, explique le blindage réciproque des carbones-1 et -4, et est en accord avec des données de la littérature (15–17) à propos d'alcools allyliques.

Enfin, la synthèse de l'éther phénolique **21**, réalisée par transposition allylique de **4** selon Babler (18), prouve sans ambiguïté la structure de la chaîne éthylénique de B et C. **21**: ϕ—O—CH_2—$C(CH_3)$ = CH—CH_2OH; rmn ^1H: 1, 70 (m, 3H), 4,00 (d, 2H, *J* =

7 Hz), 4,33 (s, 2H), 5,66 (t, 1H), 6,70–7,20 (m, 5H).

Condensation époxydes–phénol–sodium

Du phénol (0,05 mol) dissous dans 15 mL de solvant et 0,013 mol de sodium sont chauffés au reflux du solvant jusqu'à disparition du sodium. Après refroidissement puis introduction de 0,05 mol d'époxydes **1***a* ou **1***b* ou **2**, on chauffe à 120°C (bain thermostaté) jusqu'à disparition quasi complète de l'époxyde. L'avancement de la réaction est suivi en chromatographie à phase gazeuse.

Avec les époxydes **3**, le mélange réactionnel précédent est chauffé à 150°C pendant 3 jours dans un autoclave Mécabar (Prolabo, 250 mL) équipé d'un dispositif d'agitation et muni d'un régulateur de température.

Quelle que soit la technique, après retour à température ambiante, le milieu réactionnel versé sur 20 mL d'alcali de Claisen (35 g KOH en pastilles, 25 mL d'eau, quantité suffisante pour 100 mL CH_3OH absolu) atteint un pH ~13. Après extractions à l'éther éthylique, les phases éthérées alcalines sont successivement lavées par une solution de NH_4OH 2 *N* puis de NaOH 2 *N*. Après séchage et évaporation sous vide, les spectres rmn montrent qu'il s'agit des éthers de type A et B (très peu souillés de C).

La séparation de ces produits est réalisée par distillation sous pression réduite et (ou) par chromatographie sur plaque. Pour les éthers dérivés des époxydes **1** et **2**, on utilise le système benzène – acétate d'éthyle (70:30); pour ceux dérivés de l'époxyde **3**, on utilise $CHCl_3$.

La phase aqueuse alcaline est acidifiée à froid (HCl concentré) jusqu'à pH ~1. Après extraction éthérée, séchage, on isole les composés C toujours souillés de phénol résiduel; celui-ci éliminé par passage de la solution éthérée à pH ~5 (NaOH, 1 *N*). Les produits C sont distillés et isolés à l'état pur, exception faite pour **20** très facilement hétérocyclisable dont seul le spectre rmn ^1H a pu être réalisé.

La séparation des isomères géométriques *E*/*Z* des composés B et C (mis à part pour **15** et **20**) est effectuée par chromatographie sur gel de silice, avec le système de solvant benzène – acétate d'éthyle (70:30).

The synthesis of a series of 1-(2′-acetylphenyl)-3-alkyltriazenes, with electron-withdrawing α-substituents in the alkyl moiety, is described. The structure of the products from the reaction of 2-acetylbenzenediazonium ion (**1**) with methylamine has been reinvestigated using high field (360 MHz) nmr spectroscopy. The 2-acetylphenyltriazenes undergo cyclization to five- or six-membered heterocycles, depending on the substituent present in the alkyl group. Attack by N-3 of the triazene on the *ortho*-acetyl group leads to a 4-methylenetriazine, which can undergo oxidation to a benzotriazinone or acid-catalysed rearrangement to a 4-alkylaminocinnoline. The reaction of **1** with alkylamines also affords red products, which have been identified as 4-arylazomethylenetriazines and fully characterized by ^{1}H and ^{13}C nmr spectroscopy. The formation of these azo compounds is consistent with the enamine character of the 4-methylenetriazines. The introduction of a CO_2Et group at the α-position of the alkyl moiety provides a competing cyclization pathway to give a five-membered heterocycle, a 5-hydroxytriazole. In this case the cyclization pathway to the six-membered heterocycle is favoured, whereas the introduction of a CN group can lead to exclusive triazole formation. The reaction of the nitrile (**2*c***) with alumina in chloroform leads to a new heterocycle, a quinazolinotriazole; in DMSO solution, **2*c*** prefers the alternative pathway and gives only the 3-cyanomethyl-4-methylenetriazine. Introduction of a benzoyl group in the alkyl moiety gives an unstable triazene; it reacts with alumina in chloroform to give a triazole, which in turn rearranges to a novel diazoalkane.

On décrit la synthèse d'une série de (acétyl-2′ phényl)-1 alkyl-3 triazènes portant, en position α de la chaîne alkylée, des substituants électro-affinitaires. Faisant appel à la rmn à haut champ (360 MHz), on a réétudié la structure des produits obtenus par la réaction de l'ion acétyl-2 benzènediazonium (**1**) avec la méthylamine. Dépendant de la nature des substituants présents sur le groupe alkyle, les acétyl-2 phényltriazènes subissent une cyclisation conduisant à des hétérocycles à cinq ou à six chaînons. Une attaque du N-3 du triazène sur le groupe *ortho*-acétyle conduit à une méthylène-4 triazine qui peut subir soit une oxydation conduisant à une benzotriazinone soit une transposition acido-catalysée conduisant à une alkylamino-4 cinnoline. La réaction de **1** avec des alkylamines conduit aussi à des produits rouges que l'on a identifié comme étant des arylazométhylène-4 triazines et qui ont été complètement caractérisées en faisant appel à la rmn du ^{1}H et du ^{13}C. La formation de ces composés azo est en accord avec le caractère ènamine des méthylène-4 triazines. L'introduction d'un groupement CO_2Et en position α de la portion alkyle fournit une voie de réaction compétitive qui conduit à un hétérocycle à cinq chaînons, un hydroxy-5 triazole. Dans ce cas, la voie provoquant une cyclisation en un hétérocycle à six chaînons se trouve favorisée; par ailleurs, l'introduction d'un groupement CN peut conduire à la formation exclusive de triazole. La réaction du nitrile (**2*c***) avec de l'alumine dans le chloroforme conduit à la formation d'un nouvel hétérocycle, une quinazolinotriazole; en solution dans le DMSO, le composé **2*c*** suit plutôt une autre voie conduisant uniquement à la cyanométhyl-3 méthylène-4 triazine. L'introduction d'un groupement benzoyle dans la portion alkyle de la molécule conduit à un triazène instable; il réagit avec l'alumine dans le chloroforme pour donner un triazole qui, à son tour, se transpose en un nouveau diazoalkane.

[Traduit par le journal]

Introduction

1-Aryl-3-alkyltriazenes with appropriate substituents in the aryl and alkyl groups (X or Y) have been used as precursors for a variety of heterocyclic systems, Scheme 1. Interaction of a reactive *ortho*-substituent (X) in the aryl group with N-3 of the triazene chain, path (a), leads to 1,2,3-triazine derivatives, such as benzotriazinones (X = CO_2Et) (1), 4-iminobenzotriazines (X = CN) (2), 4-methylenebenzotriazines (X = $COCH_3$) (3), and 4-hydroxybenzotriazines (X = CHO or COAr) (4). Alternatively, if the alkyl group at N-3 has a reactive α-substituent (Y), then interaction with N-1 of the triazene chain, path (b), leads to 1,2,3-triazole derivatives. The latter method has successfully been applied to the synthesis

of 5-hydroxytriazoles (Y = CO_2Et) (5) and 5-aminotriazoles (Y = CN) (6).

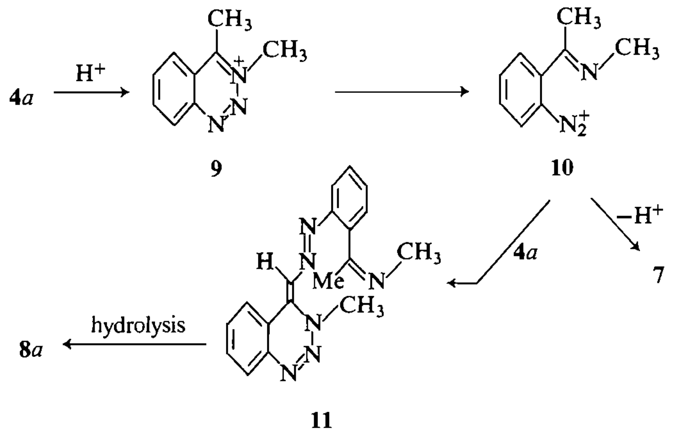
As part of our continuing interest in the applications of open-chain nitrogen compounds as precursors for heterocyclic molecules, we report here a study of the synthesis and reactions of triazenes of this type with an acetyl group at the X-position and a variety of substituents at the Y-position (H, CO_2Et, CN, COPh). In a previous study (3), the synthesis of 4-methylene-3-alkyl-3,4-dihydro-1,2,3-benzotriazines of type **4** was achieved by spontaneous cyclization of 1-(2′-acetylphenyl)-3-alkyltriazenes (e.g. **2***a*). Reaction of *o*-acetylbenzenediazonium ion (**1**) with methylamine was reported to afford a mixture of the expected triazene (**2***a*) and its cyclization products (**3***a* and **4***a*); the cyclodehydration of **2***a* → **3***a* → **4***a* was shown to be a facile process and was most conveniently carried to completion by addition of neutral alumina to a chloroform solution of the crude reaction product. The spontaneity of the dehydration step has also been observed during an alternate synthetic route to triazines of type **3** by the reaction of a methyl Grignard reagent with benzotriazinones (7), which also affords methylenetriazines (**4**).

Subsequently we have shown (4) that stable 4-hydroxytriazines of type **3** can be prepared from the coupling reaction of alkylamines with *o*-acylbenzenediazonium ions, which lack α-hydrogen atoms in the acyl group (such as —CHO and —COAr). These 4-hydroxy-3,4-dihydrobenzo-1,2,3-triazines are stable compounds since they are unable to undergo the dehydration step to the methylenetriazine; the heterocyclic structure of compounds of type **3** has been verified by X-ray crystal structure determination (8).

Results and discussion

Coupling the diazonium ion **1** with methylamine by our reported method (3) affords an unstable orange-red coloured compound, as previously observed. The Nujol ir spectrum of this product clearly shows that it is the 4-hydroxytriazine (**3***a*), the expected cyclization product of the initially formed triazene (**2***a*). In the ir spectrum, **3***a* shows a strong band at 3160 cm^{-1} for the OH group and carbonyl absorption is completely absent, eliminating the open-chain triazene structure (**2***a*) for this product, at least in the solid state. The situation is different in solution, however, since the nmr spectrum in $CDCl_3$ clearly shows that the equilibrium **2***a* ⇆ **3***a* is quickly established; the nmr also shows that the dehydration of **3***a* → **4***a* takes place as soon as the compound is in solution. Dehydration of the solid **3***a* → **4***a* was also apparent when hours-old samples of **3***a* were examined by ^{1}H nmr. These results are consistent with our previous investigation (3) at which time only 60-MHz nmr was available to us.

We have reinvestigated the structures of these compounds by high resolution (360 MHz) nmr spectroscopy, which gives a clearer picture of the identity of the three possible components and provides useful spectroscopic information for analogues reported here. The nmr of **3***a* in $CDCl_3$ shows the N-Me protons at δ 3.66, OH at δ 3.15 (broad s), and a methyl signal at δ 1.90, assigned to the methyl at C-4, which confirms the cyclic structure. The major component of the $CDCl_3$ solution is the open-chain triazene, but the chemical shift and singlet character of the *N*-methyl group (δ 3.60) and the NH signal at δ 12.60 show without question that this triazene, like others with *ortho* substituents (9), exists as the intramolecularly H-bonded tautomer **5***a*. The growing presence of the final dehydration product (**4***a*) is indicated by the signals at δ 3.59 (s, N-Me), 3.86 (d, *J* 2.56 Hz, one vinylic CH), and 4.42 (d, *J* 2.56 Hz, the other vinylic CH). The low chemical shift of the vinylic protons of **4***a* arises from increased electron density at the exocyclic carbon atom, which indicates significant enamine character in this group. Careful control of the diazonium coupling reaction of **1** with methylamine gave a product free from the dehydrated form (**4***a*). Attempts to separate the components of the mixture by chromatography resulted in complete conversion to **4***a* (3). The dehydration process (**3***a* → **4***a*) was also observed as the major reaction pathway when the triazine (**3***a*) was dissolved in methanol. A minor pathway in the methanolic dehydration is the formation of the carbinolamine ether, 4-methoxy-3,4-dimethyl-3,4-dihydro-1,2,3-benzotriazine, where the hydroxyl



SCHEME 2

group in $3a$ is replaced by methoxyl. The formation of ethers of this type in alcoholic solution is a facile general reaction of 4-hydroxy-1,2,3-benzotriazines.[3]

The alkene character of the exocyclic C═C moiety of $4a$ is evident in reaction with ozone, which affords the benzotriazinone (**6**) in low yield; it should be emphasized that this reaction has little synthetic value since benzotriazinones are readily available by other routes (1). Oxidation of $4a$ by the atmosphere occurs slowly in chloroform solution and is also evident from nmr spectra when $4a$ is stored in the solid state for long periods; samples of $4a$ used in reactions described here are freshly prepared under a nitrogen atmosphere to minimize oxidation.

The ^{13}C nmr spectrum of $4a$ unequivocally confirms the structure, particularly with respect to the enamine character. The exocyclic vinylic methylene carbon atom gives a triplet signal at δ 75.9, which is at a relatively high field for an olefinic carbon atom. This enamine character, implied by both ^1H and ^{13}C spectra, suggests that compounds of type **4** should undergo reaction with electrophilic species at the exocyclic vinylic carbon, such as protonation to give the triazinium species (**9**) (see Scheme 2); analogous reactions are known in the chemistry of 2-methylenepyridines (10) and quinolines (11). The formation of **9** should facilitate a ring-opening pathway to the diazonium ion (**10**), which could undergo a number of synthetically useful pathways such as the Dimroth rearrangement to the methylaminocinnoline (**7**).

Indeed, reaction of $4a$ with a hot mixture of acetic and sulphuric acids gave a product which was identified by spectroscopic analysis as 4-methylaminocinnoline (**7**). The ir spectrum of **7** has an NH absorption band at 3220 cm^{-1} as the only characteristic band. The ^1H nmr spectrum of **7** provides unequivocal evidence for the structure of the rearrangement product. The *N*-methyl signal at 3.15 ppm is a clear doublet, caused by coupling to the adjacent NH proton, which appears as a broad, poorly resolved quartet at 5.2 ppm. The aromatic region of the spectrum is typical of the ABCD system of an *ortho*-substituted benzene ring, with an additional one-proton singlet at δ 8.69, arising from the uncoupled proton at C-3 of the cinnoline.

Considerable effervescent decomposition can occur during this reaction, resulting in a low yield of the cinnoline. Reaction of $4a$ with acetic acid alone afforded only an intractable tar. Nevertheless, the fact that $4a$ does rearrange to the cinnoline **7** suggests that a general synthesis of 4-alkylaminocinnolines can be developed and further investigations in this direction are being pursued. Storr and co-workers (12) have shown that the conversion $4a \rightarrow 7$ can also be achieved by flash vacuum pyrolysis.

Reaction of $4a$ with dilute hydrochloric acid affords a red compound which can also be obtained, in greater yield, by reaction of **1** with 1.33 equivalents of methylamine and neutralization with sodium carbonate or by slow addition of a large excess of methylamine to the diazonium salt solution, as also described by Treppendahl and Jakobsen (13). The structure of the red product, independently identified by us and by them, is unequivocally derived by spectroscopic analysis as 3-methyl-4-(2′-acetylphenylazo)methylenebenzotriazine ($8a$). However, the reported data (13) appear to derive from a crude product, whereas in our hands the red product recrystallizes from ether to give a higher melting point product which, although sharply melting, is not a single compound, based on nmr evidence. The components of the recrystallized red product could not be separated by repeated recrystallization and did not separate on tlc plates.

The colour of this red product, which is also observed in solution, arises from an intense band in the visible region at 430 nm (CH_3CN). The mass spectrum shows a molecular ion at m/z 305, which is consistent with a structure derived from a molecule of $4a$ coupled to the diazonium ion (**1**). The ir spectrum in Nujol shows a strong carbonyl band at 1675 cm^{-1}, which is consistent with an acetyl-carbonyl group *ortho* to an sp^2-nitrogen (14). The ^1H nmr spectrum of the recrystallized red product in $CDCl_3$ shows the presence of two components; the major component (~80%) gives ^1H signals close to the reported values (13) and consistent with the azomethylenetriazine structure ($8a$). The minor component is evident from the doubling of the acetyl-Me, N-Me, and vinylic CH signals in the ^1H spectrum; the doubling of the acetyl-Me and N-Me signals is also seen in the ^{13}C spectrum. The major component has two methyl quartets at δ 32.3 (Ac-Me) and 42.4 (N-Me), compared to 32.7 and 48.1 for the minor component. Other significant features of the ^{13}C spectrum of $8a$ are (a) a carbonyl-carbon signal at 203.35 ppm; (b) splitting of the C-10 signal (117.66 ppm) in the ^1H-coupled spectrum into a quartet (J = 6.5 Hz) by three-bond coupling to the N-Me protons; (c) assignment of the signal at 124.27 ppm to the exocyclic methylene carbon, showing as it does only the doublet (J = 166.7 Hz) splitting in the coupled spectrum.

It is tempting to suggest that the additional N-Me and acetyl-Me signals in the ^1H and ^{13}C nmr spectra of $8a$ arise from the presence of a configurational isomer with almost identical physical properties. However, variable temperature nmr studies in both $CDCl_3$ and DMSO-d_6 gave no evidence to corroborate such a suggestion.

The mechanism of formation of the azo compound ($8a$) can formally be described as coupling a mole of the 2-acetylbenzenediazonium ion (**1**) to the methylenetriazine ($4a$) at the exocyclic methylene carbon; this is the anticipated behaviour of an enamine in the presence of an electrophilic diazonium ion. This route is the most likely explanation for the formation of $8a$ during the slow treatment of **1** with $MeNH_2$ (13), when the methylenetriazine is produced in the presence of unreacted diazonium ion. (If the diazonium ion is mixed rapidly with an excess of the amine, the major product is $3a$; the orange-red colour of $3a$ may be due to trace amounts of $8a$, although the

[3]H. W. Manning, R. J. LaFrance, and K. Vaughan, unpublished results (manuscript in preparation).

latter could not be detected by nmr.)

However, this simple mechanism does not explain the formation of **8***a* when **4***a* is treated with HCl, and it is likely that an alternative mechanism (Scheme 2) is involved. Protonation of **4***a* and ring opening gives the imino-diazonium ion (**10**), which then reacts with a second molecule of **4***a* to give the azo compound (**11**); hydrolysis of the imine function to the acetyl group by the aqueous acid affords the observed product (**8***a*).

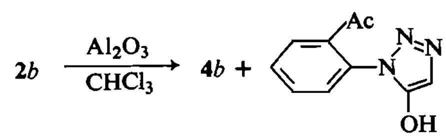
An analogous red compound is formed by the reaction of *o*-acetylbenzenediazonium chloride with ethyl glycinate hydrochloride, followed by neutralization with sodium acetate. The melting point of the crude product from this reaction is ca. 110°C, indicating that the product is the same azomethylenetriazine (**8***b*) reported (13) to have a melting point of 110–113°C. However, we have found that **8***b* can be recrystallized unchanged from ether to give red needles with mp 128–129°C.

The ir spectrum of **8***b* shows no NH or OH bands, but does have two carbonyl bands at 1750 (ester) and 1675 (ketone) cm^{-1}. The mass spectrum of **8***b* shows a molecular ion at m/z 377 consistent with structure **8***b*. The nmr analysis of **8***b* was made difficult by the instability of the compound in $CDCl_3$; decomposition in this solvent did not follow a recognizable pathway and the nmr spectra of decomposed solutions were extremely complex and unintelligible. The ^1H nmr spectrum of a fresh solution of **8***b* in $CDCl_3$ was obtained, and could be interpreted to fit structure **8***b*; however, the proton signals are broadened and doubled. The ^1H coupled ^{13}C nmr spectrum of **8***b* was assigned to a single species and gives an excellent fit to structure **8***b*; most of the signals in the spectrum of **8***b* are also found in the analogous spectrum of **8***a*. However, interpretable coupled spectra of **8***b* could not be obtained due to the decomposition taking place over the time required to record the coupled spectrum. Furthermore, **8***b* did not give measurable doubling of the methyl signals, unlike **8***a*, and **8***b* appears to be a single unstable species in $CDCl_3$.

The azomethylenetriazines **8***a* and **8***b* possess some chemical reactivity not shown by the methylenetriazines of type **4**. The visible spectra of **8***a* and **8***b* change significantly when their solutions are made acidic. Thus the strong band at 420 nm in the spectrum of **8***b* in CH_3CN shifts to 489 nm, and intensifies, when hydrochloric acid is added to the solution. The species responsible for the 489-nm band is unstable; the initial deep red colour of the HCl/CH_3CN solution fades slowly to pink and then to colourless. An analogous shift, from 430 to 477 nm, is observed when HCl is added to an ethanolic solution of **8***a*; in this case the acidified species is more stable and precipitates from the HCl/EtOH solution of **8***a* as deep-red crystals. The methylenetriazines of type **4** and the azomethylenetriazines (**8**) also differ in reactivity towards warm alcohols; triazines of type **4** are inert to reaction with alcohols, whereas those of type **8** react with alcohols under mild thermal conditions to give metastable 1:1 alcohol–triazine adducts. The structures of these adducts, and of the hydrochloride salt of **8***a*, are currently being investigated and will be reported in a later paper in this series.

The spontaneous formation of **8***b* during the coupling of ethyl glycinate with **1** indicates that the cyclodehydration **2***b* → **3***b* → **4***b* is extremely facile and also shows that the methylenetriazine (**4***b*) does indeed have a high degree of enamine reactivity as predicted (Scheme 2). When **4***b* is generated in the presence of unreacted diazonium ion, diazonium coupling to the exocyclic methylene carbon is fast and leads to the observed product (**8***b*). Isolation of the intermediate triazene (**2***b*) (or the cyclic tautomer **3***b*) was achieved by slow addition of the diazonium salt to a solution of ethyl glycinate hydrochloride with a large excess of sodium carbonate. The product of this coupling is clearly a mixture of the isomers **2***b* and **3***b*; dehydration to the methylenetriazine (**4***b*) occurs slowly in the solid and in chloroform solution. The ir spectrum of **2***b* ⇋ **3***b* shows that the material is a mixture, but also shows a minor component with a band at 2110 cm^{-1}, indicating that some of **2***b* has undergone cyclization and rearrangement, via the hydroxytriazole **12**, to an α-diazoamide (5).

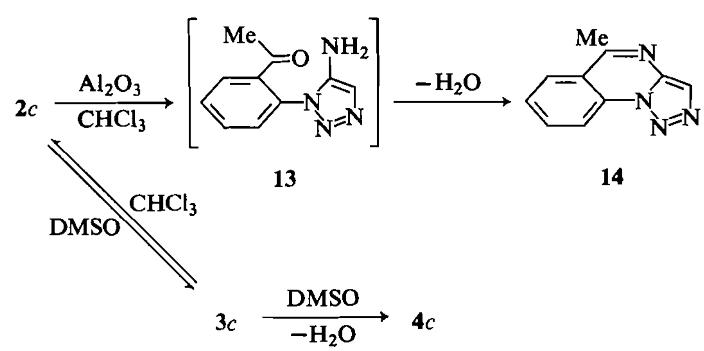
A good yield of **4***b* was obtained directly from the diazonium coupling by leaving the crude product mixture, **2***b* ⇋ **3***b*, in the aqueous mother liquor overnight. Compound **4***b* is a stable, crystalline solid which recrystallizes without decomposition; **4***b* is more stable than **4***a* and less prone to atmospheric oxidation. The ^1H and ^{13}C nmr spectra of **4***b* are entirely consistent with the methylenetriazine structure and give similar chemical shifts to **4***a*.



12

Cyclodehydration of **2***b* → **4***b* by the alumina/chloroform method (3) was not as clean as the conversion of **2***a* → **4***a*; a minor product of the alumina-catalysed cyclization of **2***b* was identified as the 5-hydroxytriazole (**12**) from its nmr spectrum. Similar cyclization of 3-ethoxycarbonylmethyltriazenes ($Ar.N{=}N.NH.CH_2.CO_2Et$) is a general reaction (5), but in this case the competing reaction to give the six-membered heterocycle (**4***b*) is the predominant one.

Extension of the coupling reaction of **1** to α-cyanomethylamine, which should lead to the cyanomethyltriazene (**2***c*), gave a product with ir and ^1H nmr spectra in DMSO-d_6 consistent with the cyclic structure (**3***c*). The Nujol ir spectrum of **3***c* shows a strong OH-band, and the DMSO-d_6 nmr spectrum shows a methyl signal at δ 1.77, consistent with the 4-methyltriazine structure; in $CDCl_3$ solution, the methyl group moves to the acetyl-methyl region, indicating a complete transformation to the open-chain triazene structure (**2***c*) in this solvent. This cyanomethyl compound is rare (13) among the compounds of this type in the extremity of the change from DMSO-d_6 to $CDCl_3$; most compounds in this series show equilibrium character in chloroform solution.



13 **14**

The ^{13}C nmr spectra of this compound in the two solvents confirm these conclusions; in $CDCl_3$, the open-chain structure is indicated by a carbonyl signal at 201.5 ppm, whereas in

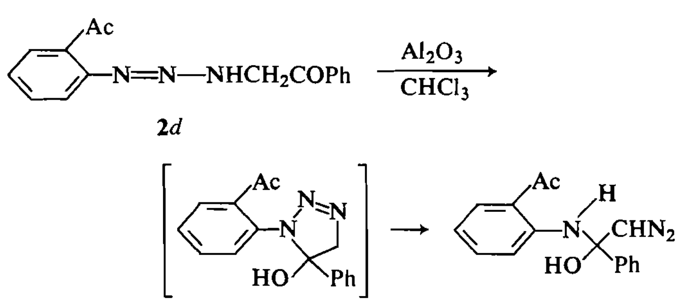
DMSO-d_6 the carbonyl signal is absent and is replaced by an sp^3-carbon signal at δ 78.0 (C-4 of **3***c*). The sharpness of the signals and the singlet character of the N-CH_2 signal in the $CDCl_3$ spectrum of **2***c* show clearly that a single, intramolecularly H-bonded tautomer (**5***c*) is the preferred tautomer of the open-chain form.

A DMSO-d_6 solution of **3***c* dehydrated completely to the methylenetriazine (**4***c*) within 3 days at room temperature. However, reaction of **2***c* with alumina in chloroform followed a different route, in which cyclization to the five-membered heterocycle is favoured to afford the triazoloquinazoline (**14**). The structure of this novel tricyclic product is established unequivocally from nmr spectra: the isolated CH group at C-4 of the triazole ring gives rise to a proton singlet at δ 8.18 and a carbon doublet at δ 126.6, with a large directly-bonded coupling constant (198 Hz). The intermediate 5-aminotriazole (**13**), the initial product of a path (b) cyclization of **2***c* (6), could not be isolated. This reaction offers a new synthesis of a novel heterocyclic system and the application of this method as a general synthesis of quinazolinotriazoles is currently being investigated.[4]

The synthesis of the 3-cyanomethyl-4-arylazomethylenetriazine (**8***c*) under a variety of conditions that afforded the analogous red compounds, **8***a* and **8***b*, could not be achieved. All attempts to prepare **8***c* afforded the 4-hydroxytriazine (**3***c*), or the cyclization product (**14**) derived from **2***c*. A logical explanation for this observation is the evident reluctance of **2***c* to undergo cyclodehydration in aqueous media to the methylenetriazine (**4***c*), which is a required intermediate for the formation of **8***c*.

Further extension of this series to the coupling reaction of **1** with α-aminoacetophenone gave a very unstable triazene (**2***d*), which decomposed within hours of preparation, even when kept desiccated under vacuum. However, reaction of the freshly made triazene with alumina in chloroform did afford a mixture of two relatively stable products, which were separated by differential solubility in ether.

The major product, an ether-soluble oil, gave a characteristic ir spectrum, with strong NH and OH bands at 3450 and 3340 cm^{-1} and an intense diazo-group band at 2100 cm^{-1}, in addition to a carbonyl band at 1645 cm^{-1}. The presence of a diazoalkane group (—CHN_2) is confirmed by a one-proton signal at δ 5.9 in the ^1H nmr spectrum and a doublet carbon signal at δ 54.0 in the ^{13}C nmr with a large directly-bonded coupling constant (198 Hz) typical of diazoalkanes (15).



2*d* **15** **16**

Full analysis of the ir, ^1H and ^{13}C nmr spectra of this product leads to the diazoalkane-carbinolamine structure (**16**). The formation of **16** arises by a type (b) cyclization to give initially the 5-hydroxytriazolidine (**15**) and rearrangement of **15** by ring-opening at the N1—N2 bond.

Experimental

Melting points were obtained on a Kofler hot-stage apparatus and are uncorrected. Infrared spectra were recorded with Nujol mulls on a Perkin Elmer 299 grating spectrophotometer. The nmr spectra were obtained with Varian CFT20 (80 MHz) and Nicolet 360NB (360 MHz) spectrometers and mass spectra were recorded with a Dupont CEC-104 medium resolution spectrometer. Ultraviolet/visible spectra were recorded on a Cary 219 (Varian) spectrophotometer. Elemental analyses were determined by the Canadian Microanalytical Service, Vancouver, B.C., Canada.

*3,4-Dimethyl-4-hydroxy-3,4-dihydrobenzo-1,2,3-triazine (3*a*)*

2-Aminoacetophenone (1.35 g), dissolved in concentrated hydrochloric acid (3 mL) and water (25 mL), was diazotized with sodium nitrite (0.80 g) in water (15 mL) at 0°C. The mixture was stirred at 0°C for 20 min, diluted with water (30 mL), and the temperature taken down to −4°C. Aqueous methylamine (40%) (5.0 g) was added rapidly to the diazonium salt solution, so that the temperature did not rise above 5°C. The mixture was cooled quickly to −4°C over a 5-min period and the resulting orange-red precipitate was filtered and dried to afford the crude triazine (**3***a*), 1.1 g (63%), mp 85−95°C (lit. (13) mp 104−107°C); $\bar{\nu}_{max}$: 3160 cm^{-1}; δ ($CDCl_3$): 1.90 (s, CH_3 at C-4 of **3***a*), 2.60 (s, acetyl-Me, **5***a*), 3.60 (s, N-Me, **5***a*), 3.66 (s, N-Me, **3***a*), 5.15 (br s, OH, **3***a*), 6.9−7.9 (m, arom., **3***a* & **5***a*), 12.60 (s, NH, **5***a*).

*4-Methylene-3,4-dihydrobenzo-1,2,3-triazine (4*a*)*

The crude triazine (**3***a*) (0.3 g) was dissolved in chloroform and neutral alumina (9.3 g) added to the solution. After stirring at room temperature for 3.5 h, the solution was filtered and evaporated to dryness *in vacuo* to afford the pure methylenetriazine, 0.27 g (quant.), mp 64−67°C (lit. (3) mp 64−66°C): ^{13}C nmr ($CDCl_3$): 40.5 (q, *J* 140 Hz, N-CH_3), 75.9 (t, *J* 161.8 Hz, exocyclic =CH_2), 119.3 (m, C-4 of triazine), 121.1 (dd, *J* 161.5 and 7.7 Hz, arom.), 127.1 (dd, *J* 164.3 and 7.4 Hz, arom.), 130.3 (dd, *J* 163.0 and 8.25 Hz, arom.), 130.6 (dd, *J* 162.8 and 8.15 Hz, arom.), 135.7 (s, arom.), and 136.7 (m, arom.) ppm.

*Ozonolysis of 4*a

The methylenetriazine (**4***a*) (0.68 g) was dissolved in a mixture of carbon tetrachloride (75 mL) and chloroform (5 mL); the solution was filtered to remove a small amount of insoluble impurity. Ozone was passed through the solution for 1.5 h. The solution was again filtered and the filtrate evaporated to dryness under reduced pressure to afford an orange residue. Recrystallization of the crude product from 50% aqueous ethanol gave 3-methyl-1,2,3-benzotriazin-4(3*H*)-one (**6**) as colourless needles, 0.1 g (15%), mp 121−123°C; $\bar{\nu}_{max}$: 1670 cm^{-1}; δ ($CDCl_3$): 4.0 (s, 3H, N-Me), 7.7−8.2 (m, 4H, arom.). The product was identical with an authentic sample (mixture mp 121−123°C and ir spectrum) (1).

4-Methylaminocinnoline (7)

The methylenetriazine (**4***a*) (0.28 g) was treated with a warm (37°C) mixture of glacial acetic acid (2.5 mL) and conc. sulphuric acid (2.5 mL) and the mixture heated at 54°C for a few minutes. Some effervescence was evident during the reaction. The mixture was poured over ice (13 g) and the resulting solution was neutralized with 6 *M* sodium hydroxide. The mixture was filtered to remove a small amount (10 mg) of an unidentified solid, and the filtrate extracted with ether. During the ether extraction, a precipitate formed in the aqueous layer. Evaporation of the dried ether extract gave a negligible yield of an oil, whereas separation of the precipitate in the aqueous layer (after 2−3 days) afforded the 4-methylaminocinnoline (**7**), 0.04−0.15 g (12−30%), mp 238−239°C (off-white prisms from dimethylsul-

[4] It has now been shown that this method has general application to the synthesis of 5-alkyl- and 5-aryl-1,2,3-triazolo[5,1-*a*]quinazolines; the parent heterocycle can also be prepared in this manner (D. L. Hooper, H. W. Manning, R. J. LaFrance, and K. Vaughan; manuscript in preparation for this journal).

foxide) (lit. (16) mp 224°C); $\bar{\nu}_{max}$: 3220 (NH), 1580 cm^{-1}; δ ($CDCl_3$): 3.15 (3H, d, J 5.1 Hz, N-CH_3), 5.2 (1H, br, NH), 7.6 (1H, dt, J 7.1 and 1.0 Hz, arom.), 7.8 (2H, m, arom.), 8.3 (1H, dd, J 8.9 and 1.3 Hz, arom.) and 8.7 (1H, s, arom. H at C-3 of pyridazine ring).

1-(2′-Acetylphenyl)-3-ethoxycarbonylmethyltriazene (2b)

A cold solution of 2-acetylbenzenediazonium chloride (0.01 mol) in water (15 mL) was added dropwise with stirring to a cold (0°C) solution of ethyl glycinate hydrochloride (0.02 mol) and sodium carbonate (0.05 mol) in water (70 mL). The colour of the solution changes from pale yellow to bright orange-red and an orange-red oil is formed. The product was immediately extracted with chloroform and the chloroform extracts were washed (H_2O), dried, and evaporated to afford the triazene (**2*b***), 2.19 g, $\bar{\nu}_{max}$: 3460(sh), 3350(br), 3240(br), 2110(w), 1750, and 1650 cm^{-1}; δ ($CDCl_3$): 1.3 (t, J 8 Hz, C-CH_3, **4*b***), 1.33 (t, J 8 Hz, C-CH_3, **2*b***), 2.67 (s, acetyl-Me of **2*b***), 3.77 (d, J 3 Hz, vinylic proton, **4*b***), 4.30 (q, J 8 Hz, O-CH_2, **2*b*** and **4*b***), 4.5 (d, J 3 Hz, vinylic proton, **4*b***), 4.60 (s, N-CH_2, **2*b***), 4.73 (s, N-CH_2, **4*b***), 7.0–7.9 (m, arom., **2*b*** and **4*b***).

The oily product was unstable and deposited crystals within 12 h. Recrystallization of the decomposed mixture from ether afforded the methylenetriazine (**4*b***), 0.78 g, mp 91–95°C.

3-(Ethoxycarbonylmethyl)-4-methylene-3,4-dihydrobenzo-1,2,3-triazine (4b)

(a) 2-Aminoacetophenone (2.7 g) was dissolved in conc. hydrochloric acid (5.2 mL), with water (20 mL), and diazotized at 0°C with sodium nitrite (1.38 g) in water (6 mL). Sodium carbonate (10.5 g) was dissolved in water (40 mL), mixed with ethyl glycinate hydrochloride (5.6 g), and the resulting slurry, which had a pH 10, cooled to 0°C. The cold diazonium salt solution was added slowly to the ethyl glycinate slurry with vigorous stirring. After stirring for 0.5 h, the mixture was observed to contain a suspension of a pale yellow precipitate and a heavy orange oil. The oil was retained in the reaction vessel after decantation of the aqueous layer; the precipitate in the aqueous layer was found to be mainly inorganic and was discarded. The oil was kept at room temperature for 24 h, during which time it solidified to give an orange-yellow solid. Recrystallization from a mixture of ether and petroleum ether gave lustrous yellow needles of the methylenetriazine (**4*b***), 2.5 g (54%), mp 94–97°C; $\bar{\nu}_{max}$: 1750 cm^{-1}; δ (DMSO-d_6): 1.2 (3H, t, J 8 Hz, CH_3), 3.83 (1H, d, J 3 Hz, vinylic), 4.20 (2H, q, J 8 Hz, O-CH_2), 4.6 (1H, d, J 3 Hz, vinylic), 4.87 (2H, s, N-CH_2), and 7.4–7.9 (4H, m, arom.); ^{13}C nmr ($CDCl_3$): 14.07 (q, J 127 Hz, CH_3), 54.5 (t, J 141 Hz, N-CH_2), 61.7 (t, J 147 Hz, O-CH_2), 76.4 (t, J 161.6 Hz, exocyclic vinylic CH_2), 119.5 (s), 121.4 (dd, J 161 and 7 Hz), 127.7 (dd, J 164 and 6.8 Hz), 130.6 (dd, J 163.6 and 7.9 Hz), 131.2 (dd, J 162 and 7.5 Hz), 134.9 (s), 136.2 (s), and 167.6 (s, C=O) ppm. *Anal.* calcd. for $C_{12}H_{13}N_3O_2$: C 62.3, H 5.7, N 18.2%; found: C 61.93, H 5.86, N 17.71%.

(b) 1-(2-Acetylphenyl)-3-ethoxycarbonylmethyltriazene (**2*b***) (0.17 g) was dissolved in chloroform (12 mL) and neutral alumina (7 g) was added. The mixture was stirred at room temperature for 16 h, filtered to remove alumina, and the filtrate evaporated to dryness to afford a mixture of two products (0.115 g). The major component (≃80%) gave ^1H nmr signals identical to those of **4*b***, described above; the second component (≃20%) was identified as 1-(2-acetylphenyl)-5-hydroxytriazole (**12**), δ ($CDCl_3$): 2.60 (s, 3H, acetyl-Me) and 6.5–7.8 (m, 6H, arom. + OH).

3-Cyanomethyl-4-hydroxy-4-methyl-3,4-dihydrobenzo-1,2,3-triazine (3c)

A cold solution of 2-acetylbenzenediazonium chloride (0.01 mol) was added dropwise to a cold solution of aminoacetonitrile bisulphate (0.02 mol) and sodium carbonate (5.24 g) in water (40 mL). An immediate orange-red precipitate was formed; after stirring for 15 min, the precipitate was filtered to afford the triazine (**3*c***), 1.49 g (74%), mp 93–95°C (from ether/chloroform); $\bar{\nu}_{max}$: 3170 (strong and broad, OH), 1640 (w) cm^{-1}; δ (DMSO-d_6): 1.77 (3H, s, CH_3), 5.03 (2H, s, CH_2), 7.05 (1H, br s, OH), and 7.5 (4H, AA′BB′, arom.); ^{13}C nmr (DMSO-d_6): 27.3 (q, J 125 Hz, CH_3), 36.9 (t, J 148 Hz, CH_2), 78.0 (s, C-4 of triazine ring), 118.1 (t, J 8 Hz, C≡N), 124.5 (dd, J 163 and 4.5 Hz), 124.8 (s), 125.2 (dd, J 163 and 6.4 Hz), 129.4 (dd, J 163 and 7.7 Hz), 130.7 (dd, J 163 and 7.5 Hz), and 135.6 (t, J 5.8 Hz) ppm. *Anal.* calcd. for $C_{10}H_{10}N_4O$: C 59.4, H 5.0, N 27.7%; found: C 59.33, H 5.13, N 27.60%.

3-(2′-Acetylphenyl)-1-cyanomethyltriazene (5c)

This triazene was observed only in solution when the 4-hydroxytriazine (**3*c***) was dissolved in chloroform; **5*c*** gave the following nmr data: δ ($CDCl_3$): 2.62 (3H, s, CH_3), 4.6 (2H, s, CH_2), and 6.9–7.9 (5H, m, arom. + NH); ^{13}C nmr ($CDCl_3$): 28.14 (q, J 128 Hz, CH_3), 47.4 (t, J 146 Hz, N-CH_2), 114.5 (d, J 159.3 Hz), 114.9 (t, J 9.52 Hz, C≡N), 118.7 (s), 121.5 (dd, J 164.9 and 8.9 Hz), 131.6 (dd, J 158.5 and 7.9 Hz), 134.9 (dd, J 159.8 and 7.9 Hz), 142.8 (t, J 4.8 Hz), and 201.5 (d, J 4.9 Hz, C=O) ppm.

3-Cyanomethyl-4-methylene-3,4-dihydrobenzo-1,2,3-triazine (4c)

A solution of the 4-hydroxytriazine (**3*c***) in DMSO-d_6 was left at room temperature for 3 days. The nmr spectrum showed that the hydroxytriazine had undergone dehydration, cleanly and quantitatively, to give the methylenetriazine (**4*c***), which gave the following nmr spectrum: δ (DMSO-d_6): 4.27 (1H, d, J 3 Hz), 4.87 (1H, d, J 3 Hz), 5.3 (2H, s), and 7.5–8.0 (4H, m).

5-Methyl-1,2,3-triazolo[1,5-a]quinazoline (14)

The 4-hydroxytriazine (**3*c***) (0.2 g) was dissolved in chloroform (12 mL) and neutral alumina (7 g) added to the solution. The mixture was stirred vigorously at room temperature for 17 h, filtered, and evaporated to dryness to afford the triazoloquinazoline (**14**), 0.18 g (99%), mp 145°C; δ ($CDCl_3$): 2.95 (3H, s, CH_3), 7.72 (1H, dt, J 7.8 and 1.1 Hz, arom.), 7.98 (1H, dt, J 7.8 and 1.2 Hz, arom.), 8.17 (1H, dd, J 8.2 and 0.67 Hz, arom.), 8.18 (1H, s, C—H at C-4 of triazole ring), and 8.70 (1H, d, J 8.3 Hz, arom.); ^{13}C nmr ($CDCl_3$): 22.7 (q, J 130 Hz, CH_3), 115.8 (dd, J 168.6 and 7.2 Hz), 118.4 (s), 126.6 (d, J 198 Hz, C-4 of triazole), 127.0 (dd, J 162 and 7.4 Hz), 127.5 (dd, J 163 and 7.6 Hz), 132.8 (s), 134.3 (dd, J 163 and 8.0 Hz), 139.9 (d, J 14 Hz), and 161.3 (quintet, J 11.8 Hz).

1-(2′-Acetylphenyl)-3-benzoylmethyltriazene (2d)

2-Aminoacetophenone (1.35 g) was dissolved in conc. hydrochloric acid (2.6 mL), with water (10 mL), and diazotized at 0°C with sodium nitrite (0.69 g) in water (3 mL), and stirred for 0.5 h. A solution of α-aminoacetophenone hydrochloride (3.43 g) in water (70 mL) was basified with sodium carbonate (5.24 g) and the resulting yellow solution was treated slowly with the diazonium salt solution. Precipitation was immediate and, after stirring for 15 min, the product was filtered and partially dried to afford the crude triazene (**2*d***), 3.7 g, mp 80–82°C. This triazene is unstable and decomposes quickly, even when stored in a vacuum desiccator. It is used immedately after partial drying for subsequent reaction.

2-(2′-Acetylphenylamino)-2-hydroxy-2-phenyldiazoethane (16)

The crude triazene (**2*d***) (1.8 g) was dissolved in chloroform (75 mL) and mixed with neutral alumina (63 g). After stirring for 14 h, the alumina was removed by filtration and the filtrate evaporated to afford an oil, 1.72 g, which solidified partially over 24 h. Crystallization of the mixture from ether/methylene chloride afforded a low yield (0.1 g) of a crystalline product, mp 198°C, which was identified by nmr as 3,6-diphenyl-2,5-dihydropyrazine (the expected dimerization product of α-aminoacetophenone). Evaporation of the filtrate afforded the diazoethane (**16**), 1.6 g, as an oil, $\bar{\nu}_{max}$: 3450(OH), 3340(NH), 2150(sh), 2100(CN_2), and 1645(C=O) cm^{-1}; δ ($CDCl_3$): 2.60 (s, 3H, acetyl-Me), 5.9 (s, 1H, CHN_2), 6.25 (br s, 1H, OH), 6.5–6.8 (m, 2H, arom.), 7.3–8.2 (m, 7.5H, arom. + NH), and 9.1 (s, 0.5H, NH); ^{13}C nmr: 27.7 (q, J 127 Hz, acetyl-Me), 54.0 (d, J 198 Hz, CHN_2), 77.1 (s), 116.4 (d, J 8 Hz), 117.0 (dd, J 8 and 158 Hz), 118.0 (s), 126.5 (dt, J 7 and 167 Hz), 128.5 (dd, J 7.6 and 169 Hz), and 131.8 (dd, J 8 and 164 Hz), 132.5 (dt, J 7.5 and 158 Hz), 134.2 (dd, J 9.1 and 146 Hz), 136.5 (t, J 7.4 Hz), 150.1 (s), 186.1 (s), and 200.5 (s).

*3-Methyl-4-(2'-acetylphenylazo)-methylene-3,4-dihydro-1,2,3-benzotriazine (8*a*)*

(a) A solution of 2-aminoacetophenone (1.35 g) in conc. hydrochloric acid (3 mL), diluted with water (25 mL), was cooled to 0°C and diazotized with sodium nitrite (0.8 g) in water (5 mL). After stirring for 10 min, a solution of 40% aqueous methylamine (1.0 g, 1.33 equiv.) in water (10 mL) was added to the diazonium salt solution. The solution darkened in colour at this point but remained clear. The solution was neutralized with saturated sodium bicarbonate, while maintaining the temperature at 0°C, and a dark red precipitate formed immediately. The product was filtered, dried, and recrystallized from ether/chloroform to afford the azomethylenetriazine (**8***a*), 0.95 g (62%), mp 157–159°C (red needles) (Note: the reported (13) mp of **8***a* is 142°C; the crude product obtained by this method had mp 142°C); $\bar{\nu}_{max}$: 1675 cm^{-1}; λ_{max} (CH_3CN): 193(ϵ 3.37 × 10^4), 231(ϵ 2.93 × 10^4), 268(ϵ 9.2 × 10^3), 304 sh(ϵ 5.3 × 10^3), and 430(ϵ 2.8 × 10^4) nm; δ ($CDCl_3$): 2.48 and 2.60 (3H, singlets, acetyl Me), 3.94 and 4.37 (3H, singlets, N-Me), 7.36 (t, *J* 7.4 Hz, arom.), 7.43 and 7.74 (1H, singlets, vinylic =C—H), 7.52 (t, *J* 7.9 Hz, arom.), 7.55 (d, *J* 6.6 Hz, arom.), 7.58 (d, *J* 8.1 Hz, arom.), 7.68 (t, *J* 5.4 Hz, arom.), 7.68 (d, *J* 7.5 Hz, arom.), 7.83–7.86 (m, arom.), 7.91 (d, *J* 7.2 Hz, arom.), and 8.93–8.96 (m, arom.); ^{13}C nmr ($CDCl_3$): 32.3 (q, *J* 128 Hz) and 32.7 (q, *J* 128 Hz), acetyl Me; 42.38 (q, *J* 141.3 Hz), and 48.12 (q, *J* 142.7 Hz), N-Me; 117.7 (q, *J* 6.5 Hz, C-4 of triazine ring), 118.0 (weak), 119.7 (dd, *J* 162 and 8.4 Hz, arom.), 124.3 (d, *J* 167 Hz, exocyclic vinylic =CH), 128.0 (dd, *J* 162 and 7.0 Hz), 128.3 (dd, *J* 164 and 7.9 Hz, 130.2 (dd, *J* 168 and 4.3 Hz), 131.3 (dd, *J* 162 and 8.4 Hz), 132.7 (dd, *J* 164 and 8.7 Hz), 133.2 (dd, *J* 162 and 7.3 Hz), 136.6 (t, *J* 6.2 Hz), 138.0 (t, *J* 1.6 Hz), 139.3 (t, *J* 3.2 Hz), 152.1 (t, *J* 7.5 Hz, arom. C adj. to azo group), and 203.35 (s, C=O) ppm; *m*/*z*: 305(M^+), 290, 289, 278, 273, 259, 232, 220, 219, 184, 120, 92. *Anal.* calcd. for $C_{17}H_{15}N_5O$: C 66.87, H 4.95, N 22.94%; found: C 66.88, H 5.06, N 22.90%.

(b) 3-Methyl-4-methylene-3,4-dihydro-1,2,3-benzotriazine (**4***a*) (0.5 g) was dissolved in 2 *M* hydrochloric acid (10 mL), which produced an immediate pink colouration. After stirring at room temperature for 15 h, the deep-red mixture was filtered and neutralized with sodium bicarbonate. The solution turned orange and a gummy oil separated. Trituration of the oil with ether afforded a solid which was filtered to afford the azomethylenetriazine (**8***a*), 0.10 g (21%); the product was identical (ir and nmr spectra) to the sample prepared in (a).

*3-Ethoxycarbonylmethyl-4-(2'-acetylphenylazo)methylene-3,4-dihydro-1,2,3-benzotriazine (8*b*)*

2-Aminoacetophenone (3.48 g) was dissolved in 2 *M* hydrochloric acid (60 mL) and diazotized at 0°C with sodium nitrite (1.8 g) in water (8 mL). The diazonium salt solution was treated in one portion with a solution of ethyl glycinate hydrochloride (4.0 g). The resulting light yellow solution was then neutralized with an aqueous slurry of sodium acetate hydrate (40 g) and an immediate orange precipitate developed. After stirring for 20 min, the product was filtered to afford the azomethylenetriazine (**8***b*), 4.8 g (97%). Recrystallization of the crude product from ether gives red needles with mp 128–129°C (Note: the reported (13) mp of this compound is 110–113°C; the *crude* product obtained by the method described here had a mp varying from 105–108°C to 112–115°C); $\bar{\nu}_{max}$: 1750 and 1675 cm^{-1}; λ_{max}: (CH_3CN): 193(ϵ 2.67 × 10^4), 230(ϵ 2.20 × 10^4), and 420(ϵ 2.78 × 10^4) nm; λ_{max}: (CH_3CN + HCl): 192(ϵ 2.0 × 10^5) and 489(unstable) nm; δ ($CDCl_3$): 1.12(t) and 1.3(br), (3H, C-CH_3); 2.46(br) and 2.65(s), (3H, acetyl Me); 4.1(q) and 4.32(br), (2H, O-CH_2); 5.08(br) and 5.6(s), (2H, N-CH_2); 7.35–8.0(m, arom.), and 8.95(br m, arom.); ^{13}C nmr: 13.9 (q, *J* 127 Hz, Me of ethyl ester), 32.9 (q, acetyl-Me); 59.53 (t, N-CH_2), 61.5 (t, O-CH_2), 116.2 (arom., C-4 of triazine), 118.1, 119.7, 121.9, 128.0, 128.2, 128.4, 130.3, 131.0, 132.7, 133.8, 136.9, 138.3, 150.9 (arom. C adj. to azo group), 166.9 (s, ester C=O), and 203.3 (s, ketone C=O). *Anal.* calcd. for $C_{20}H_{19}N_5O_3$: C 63.65, H 5.07, N 18.56%; found: C 63.70, H 5.36, N 18.40%.

On the electrical double layer between mercury and aqueous solutions of sodium citrate

S. GONZALEZ, S. V. ALVAREZ, AND A. ARÉVALO
Department of Physical Chemistry, University of La Laguna, Teneriffe, Canary Islands, Spain

Received February 3, 1984

S. GONZALEZ, S. V. ALVAREZ, and A. ARÉVALO. Can. J. Chem. **63**, 2462 (1985).

The adsorption of citrate ions at the Hg/aqueous $CitNa_3$ interface was studied, using both differential capacity and electrocapillary measurements. The results contrast with those obtained previously by Barradas *et al.* The hump of the C_d-E curve increases as the concentration of the solution increases to 0.5 *M*, to diminish beyond 1 *M*. The plots of ϕ^{M-2} vs. q^{-1} are linear and parallel to one another for the different values of *q*, which is in agreement with the results obtained by other authors for different anions. A Frumkin isotherm is also associated for the adsorption process and, finally, the parameters are obtained for the interface, using a type of isotherm proposed by Grahame.

S. GONZALEZ, S. V. ALVAREZ et A. ARÉVALO. Can. J. Chem. **63**, 2462 (1985).

Faisant appel à des mesures de capacité différentielle et d'électrocapillarité, on a étudié l'adsorption des ions citrates à l'interface Hg/Na_3Cit aqueux. Les résultats obtenus contrastent avec ceux obtenus antérieurement par Barradas et ses collaborateurs. La bosse qui existe dans la courbe C_d-E augmente avec une augmentation de la concentration de la solution jusqu'à une concentration de 0,5 *M*; cette particularité diminue au-delà d'une concentration de 1,0 *M*. Pour diverses valeurs de *q*, les courbes de ϕ^{M-2} en fonction de q^{-1} sont linéaires et parallèles l'une à l'autre; ceci est en accord avec les résultats obtenus par d'autres auteurs pour des anions différents. Une isotherme de Frumkin est aussi associée avec le processus d'adsorption et, utilisant un type d'isotherme proposé par Grahame, on a finalement obtenu les paramètres de l'interface.

[Traduit par le journal]

Introduction

A kinetic study of the Cu(II)−citrate system in its reduction at the dropping mercury electrode (dme) (1) pointed to the necessity of more detailed knowledge of the citrate−Hg interface. The only work related to the said interface in the literature is that of Barradas *et al.* (2). However, they operated with pH 8.8 which is a unit higher than the one we use.

Experimental

The citric acid and sodium hydroxide, both of Analytical grade, were supplied by Merck.

The differential capacity measurements were obtained with an alternate current impedance bridge, as described by Sluyters and coworkers (3). The C_d values, independent of the frequency between 100 and 10000 Hz, were measured at 1 kHz with an amplitude of 5 mV across the cell.

The measurements of surface tension were carried out with a capillary electrometer, calibrated using 0.1 *M* KCl, taking the values determined by Devanathan and Peries as reference (4). The capillary electrometer was controlled by a presostate designed by the Ruska firm. The measurements of the zero charge potential (E_z), were carried out with a streaming mercury electrode (5).

The dme capillary was internally treated with dimethyldichlorosilane vapour. The counterelectrode consisted of a pool of mercury connected to the exterior by way of a Pt wire. The reference electrode was the sce of the Ingold firm.

The pH was measured with a high precision pH meter, model pHM 84 by Radiometer, and a mixed glass electrode, model GK 2401 C.

The solutions were prepared starting from citric acid and adding carbonate-free NaOH to pH 7.80. The percentage of free Cit^{3-} was calculated at 99.8% at that moment, using the p*K* of citric acid determined by Petit-Ramel and Khalil (6). The concentrations studied cover the range $0.01-1.0$ *M*.

In an attempt to dispel the doubt due to the variation in the potential of union of liquids, E_j, a solution of 0.1 *M* of sodium citrate was kept permanently in contact with the reference electrode. The E_j of the second union, Na_3Cit 0.1 *M*/Na_3Cit *x M*, was calculated for each *x* by the Henderson equation, the E_r potential being determined in this manner.

All measurements were taken at 25 ± 0.1°C. Argon of 99.96% purity supplied by Oxican was used to eliminate oxygen from the solutions and as an inert atmosphere.

Results and discussion

Figure 1 shows the variation in C_d of the double layer as a function of the potential at all concentrations of sodium citrate studied, at pH 7.80.

The capacity minima at the most dilute concentrations take place at potentials slightly more negative than the point of zero charge, as is expected for highly asymmetric electrolytes.

The capacity of the hump increases when the concentration changes from 0.05 *M* to 0.5 *M*, decreasing later to 1 *M*. This behaviour is analogous to that of the majority of anions.

The C_d-E curves were integrated twice, taking the E_z and the surface tension corresponding to this potential as integral constants. The first integration gives the density of charge at the Hg, *q*, and the second the electrocapillary curves, which coincide with those obtained experimentally, as shown in Table 1 for the case of the 0.1 *M* solution of Na_3Cit. The coordinates of the electrocapillary maximum are presented in Table 2.

(a) Amount of specific adsorption, q^{-1}

In order to determine the q^{-1} charge due to specifically adsorbed Cit^{3-} anions, the Parsons function was adopted (7):

$$[1] \quad \xi^+ = \gamma + qE^+$$

The values of the E_r potential with regard to the reference electrode were converted to E^+ values by means of the well-known Frumkin relation (8):

$$[2] \quad E_r = E^+ + (RT/z_+F)\ln a_+ + \text{constant}$$

In the absence of data on ionic coefficients of medium activity of sodium citrate solutions, the coefficients determined for trisodium arsenate solutions (9) were taken provisionally.

The values obtained by the Parsons function, ξ^+, were interpolated for integer values of the charge.

The charge due to anions, q_-, was evaluated using the relation:

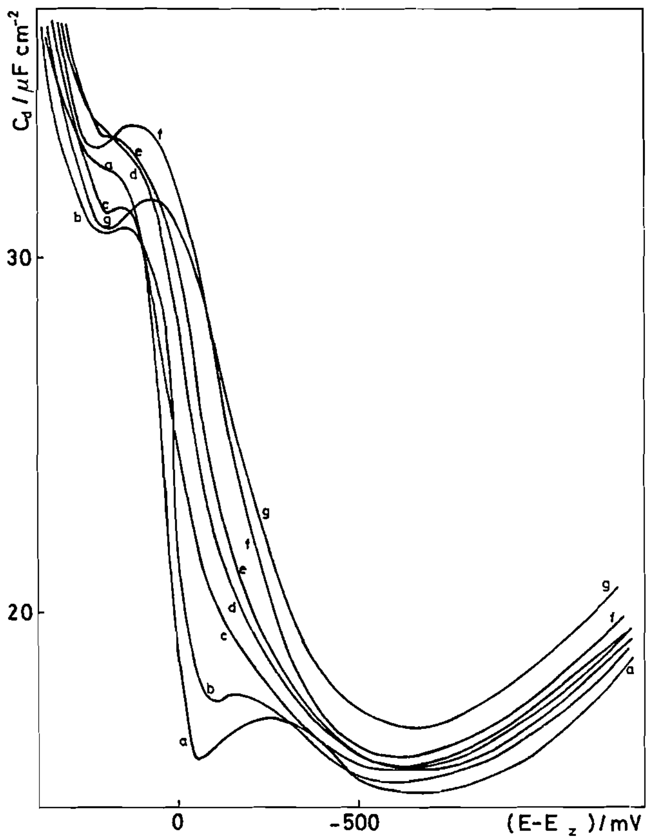

FIG. 1. Differential capacity−potential curves for Hg in aq. Na_3Cit solutions at 25°C and pH 7.80. (*a*) 0.01, (*b*) 0.02, (*c*) 0.05, (*d*) 0.1, (*e*) 0.2, (*f*) 0.5, and (*g*) 1 *M*.

$$[3] \quad q_- = -(z_- F/RT)(\partial \xi^+/\nu \partial \ln a_\pm)_q$$

The charge due to cations, q_+, was then obtained from the relation:

$$[4] \quad -q = q_s = q_+ + q_-$$

Assuming that the cation is not specifically adsorbed at all the range of potentials (i.e. $q_+ = q_+^d$), the value of ϕ_2 was calculated by means of the Gouy−Chapman theory, using the following expression resulting from the work of Grahame (10) numerically evaluated thus:

$$[5] \quad q_+^d = \frac{3RT\epsilon\epsilon_0 C}{4\pi A} \int_y^0 \frac{(3e^{-y} - 1)dy}{(3e^{-y} + e^{3y} - 4)^{1/2}}$$

where $y = F\phi_2/RT$, $A = (\epsilon\epsilon_0 RTC/2\pi)^{1/2}$, ϕ_2 is the potential at the OHP, ϵ the dielectrical constant of the solution, ϵ_0 the permittivity of the vacuum and the remaining symbols have the usual meaning.

The values of ϕ_2 were used to obtain the charge of the diffuse layer due to anions, q_-^d, evaluated from the expression by Grahame:

$$[6] \quad q_-^d = -\frac{3RT\epsilon\epsilon_0 C}{4\pi A} \int_y^0 \frac{(e^{3y} - 1)dy}{(3e^{-y} + e^{3y} - 4)^{1/2}}$$

The specifically adsorbed charge, q^{-1}, was obtained from the values of $q_-^{d'}$ and q_-, according to:

$$[7] \quad q_- = q_-^d + q^{-1}$$

Figure 2 shows the specifically adsorbed charge, q^{-1}, against the charge of the electrode at different concentrations of sodium citrate. It is evident that the curves are linear and parallel over the range of q covered. The slopes of the lines are −1, in complete agreement with the majority of anions.

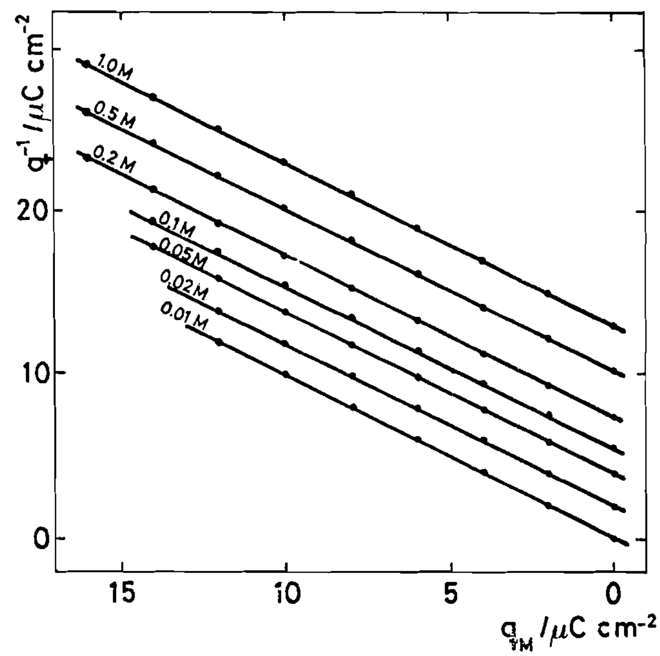

FIG. 2. Plot of charge due to specifically adsorbed citrate ions vs. electrode charge.

[a] E_z is the fem of the cell: Hg/Hg_2Cl_2 ‖ saturated KCl ‖ 0.1 *M* Na_3Cit ‖ *x M* Na_3Cit/Hg.

(b) Components of the differential capacity

The potential drop (ϕ^{M-2}) across the inner layer due to specific adsorption was calculated from the equation:

$$[8] \quad \phi^{M-2} = E_r - \phi_2 - K$$

where K is the value of ϕ^{M-2} corresponding to E_z in the absence

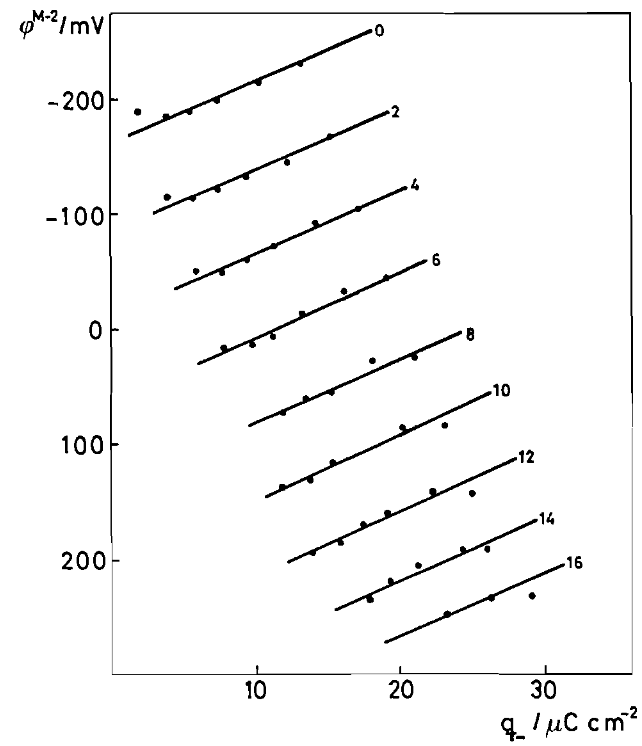

FIG. 3. Plot of potential drop across the inner layer vs charge due to specifically adsorbed citrate ions. The numbers above the lines indicate the charge on the electrode in μC cm^{-2}.

of specific adsorption.

The resulting ϕ^{M-2} values were plotted against q^{-1}, for integer values of q, as shown in Fig. 3. As observed with KCl (11), sodium benzenedisulfonate (12), and KNO_3 (13), the data determine a series of parallel straight lines. The shifts of some points is attributable to errors introduced by the graphical differentiation.

The capacity was analysed with the aid of the diffuse layer theory and the values of dq^{-1}/dq obtained by graphical differentiation of the lines in Fig. 2. The capacity of the internal region, C^i, was obtained by way of the relation:

$$[9] \quad 1/C^i = 1/C - (1/C^d)(1 + dq^{-1}/dq)$$

where C^d is the capacity of the diffuse layer, which for a 1:3 electrolyte is given by:

$$[10] \quad C^d = \frac{3AF}{2RT} \frac{e^{3y} - e^{-y}}{(e^{3y} + 3e^{-y} - 4)^{1/2}}$$

C^i was then divided into two components in accordance with:

$$[11] \quad 1/C^i = 1/{}_qC^i + (1/{}_{q^{-1}}C^i)(dq^{-1}/dq)$$

where ${}_qC^i$ is the inner layer capacity at constant specific adsorption and ${}_{q^{-1}}C^i$ the capacity at constant charge on the metal, defined respectively by:

$$[12] \quad {}_qC^i = (\partial q/\partial \phi^{M-2})_{q^{-1}}$$

and

$$[13] \quad {}_{q^{-1}}C^i = (\partial q^{-1}/\partial \phi^{M-2})_q$$

As occurs in the majority of the systems studied previously, ${}_{q^{-1}}C^i$ is independent of the amount adsorbed (in agreement with the linearity and parallelism of the plots in Fig. 3) and may therefore be substituted by the corresponding integral capacity,

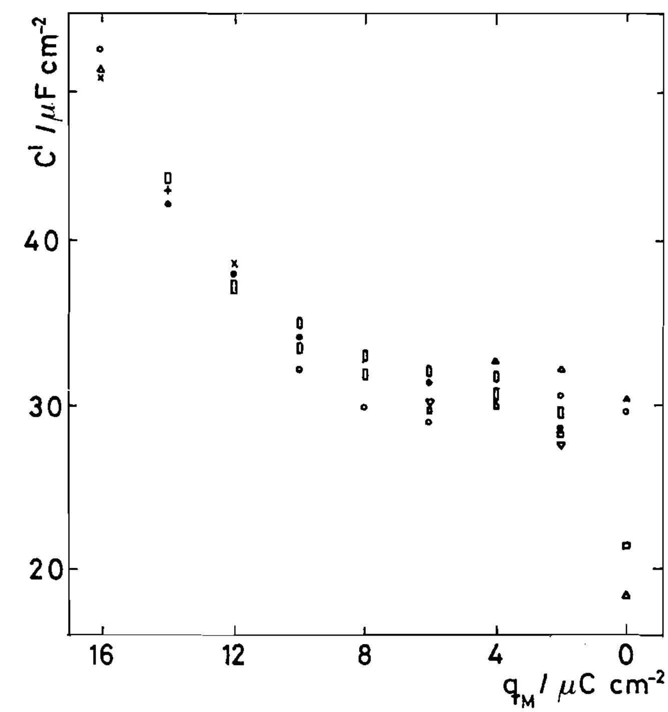

FIG. 4. Differential capacity of the inner layer of the mercury electrode in aqueous Na_3Cit as a function of the charge on the electrode and concentration of Na_3Cit: (▽) 0.01, (□) 0.02, (●) 0.05, (+) 0.1, (×) 0.2, (△) 0.5, and (○) 1 *M*.

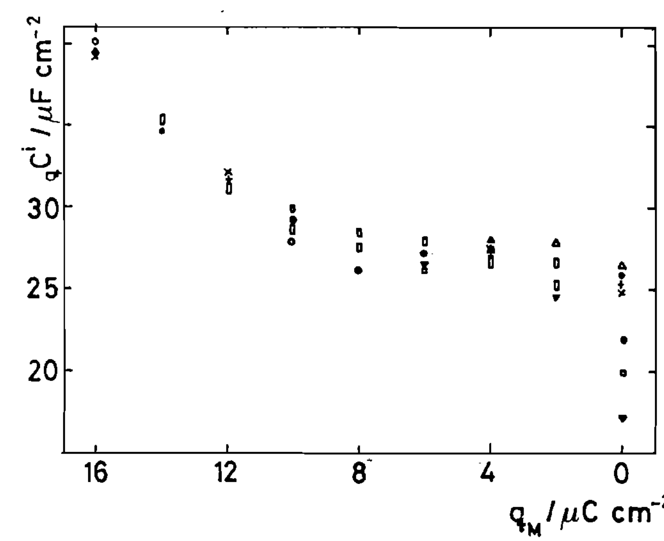

FIG. 5. Component of the capacity of the inner layer measured at constant amount adsorbed as a function of the charge on the metal and concentration of Na_3Cit: (▽) 0.01, (□) 0.02, (●) 0.05, (+) 0.1, (×) 0.2, (△) 0.5, and (○) 1 *M*.

${}_{q^{-1}}K^i$, the value of which in our system is 178 μF cm^{-2}.

The capacity of the total inner layer, C^i, and the capacity at constant charge adsorbed, ${}_qC^i$, are shown as a function of q for several concentrations of salt in Figs. 4 and 5. As can be observed, the values of both capacities depend greatly on the concentration for zero charge, but this dependence declines as the charge increases.

(c) Isotherm of adsorption

The results were fitted to a Frumkin-type isotherm as follows:

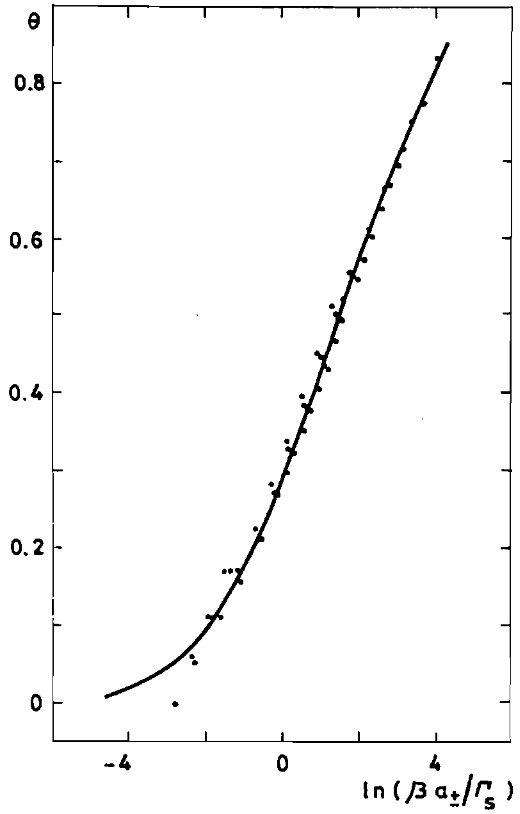

FIG. 6. Curve composed of the covering of specifically adsorbed citrate ions from solutions of Na_3Cit ($\theta = \Gamma/\Gamma_s$).

[14] $\ln [\theta/(1 - \theta)] + A\theta = \ln (\beta a_{\pm}/\Gamma_s)$

This adjustment is presented in Fig. 6, where the solid line is the theoretical curve and the values of the constants proved to be:

$A = 3$
$q_s^{-1} = 35\ \mu C\ cm^{-2}$; $\Gamma_s = 7.28 \times 10^{13}$ molecules cm^{-2}
$\ln \beta = 33.60 + 0.204q$

where A is the coefficient of lateral interaction, Γ_s the covering of saturation, q_s^{-1} equals $z_-F\Gamma_s$, and β is related with the standard free energy of adsorption at zero covering, according to:

[15] $\beta = \exp (-\Delta G^0/RT)$

The high value of the area of saturation per anion (137 Å^2/anion) suggests that the plane of the molecule is parallel to the surface of the Hg, the said orientation remaining practically constant since the results can be adjusted to a single isotherm with a constant value of the coefficient of lateral interaction, A.

In 1958, Grahame (14) proposed the use of the following adsorption isotherm:

[16] $-q^{-1} = a_{\pm} \exp (\Phi - z\phi_1 F)/RT$

where the free energy of adsorption is expressed arbitrarily as the sum of a chemical term (Φ), analogous to the potential of specific adsorption by Stern and an electrical term ($z\phi_1 F$), where ϕ_1 is the inner Helmholtz potential corresponding to the plane of the closest approach of the anion. Expression [16] was later modified by Parsons *et al.* (15) to give

[17] $(RT/z_-F) \ln (-q^{-1}/a_{\pm}) + \phi_2$
$= (\Phi/z_-F) - (q/{}_{q^{-1}}K^{i}) - (\lambda/{}_{q^{-1}}K^{i})q^{-1}$

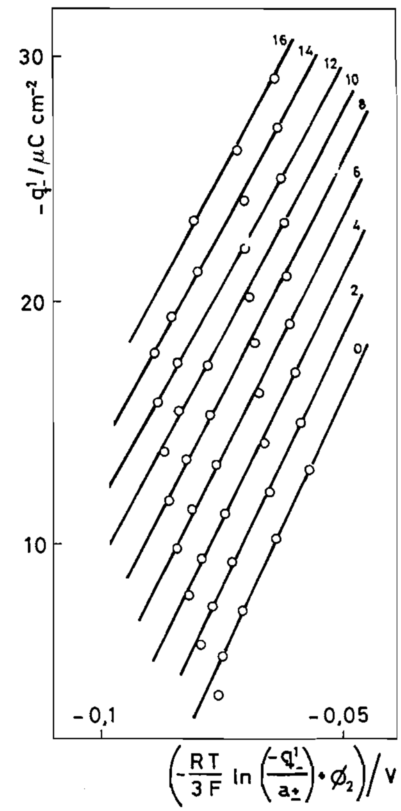

FIG. 7. Test of eq. [17] for adsorption of citrate on Hg. The numbers above the lines indicate charge on the electrode in $\mu C\ cm^{-2}$.

TABLE 3. Properties of the internal region in presence of adsorbed citrate ion

$q/\mu C\ cm^{-2}$	${}_qK/\mu C\ cm^{-2}$	$(x_2 - x_1)/x_2$	λ	g
16	29.80	0.167	0.486	0.617
14	28.50	0.160	0.495	0.601
12	27.50	0.154	0.495	0.597
10	26.91	0.151	0.474	0.614
8	26.62	0.150	0.445	0.653
6	26.27	0.148	0.445	0.651
4	25.85	0.145	0.445	0.649
2	24.61	0.138	0.445	0.644
0	23.05	0.129	0.445	0.637

where λ is defined by means of the equation:

[18] $\phi_1 - \phi_2 = [{}_q\phi^{M-2}(x_2 - x_1)/x_2] + {}_{q^{-1}}\phi^{M-2}\lambda$

The plot of the first term of eq. [17] against q^{-1} appears in Fig. 7. The adjustment of the points to straight lines supports the validity of the application of this isotherm to our system. The values of λ given in Table 3 which remain constant along the range $q = 8$ to $q = 0$, were obtained from the slopes of the lines.

The same table gives the value of $(x_2 - x_1)/x_2$, obtained by means of the expression:

[19] $(x_2 - x_1)/x_2 = {}_qK/{}_{q^{-1}}K$

together with the value of the potential of the autoatmosphere of the adsorbed ion, g, as given by:

[20] $\lambda = 1 - gx_1/x_2$

It is evident that g is smaller than the unit, as in the case of the

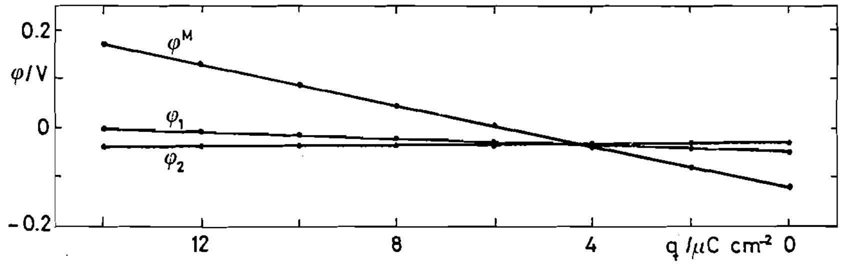

FIG. 8. Potentials in the double layer of the mercury electrode in Na_3Cit 0.1 *M* at 25°C, as a function of the charge on the electrode; ϕ^M is the part of the electrode–solution potential due to free charges, ϕ_1 is the potential of the IHP, ϕ_2 the potential of the OHP.

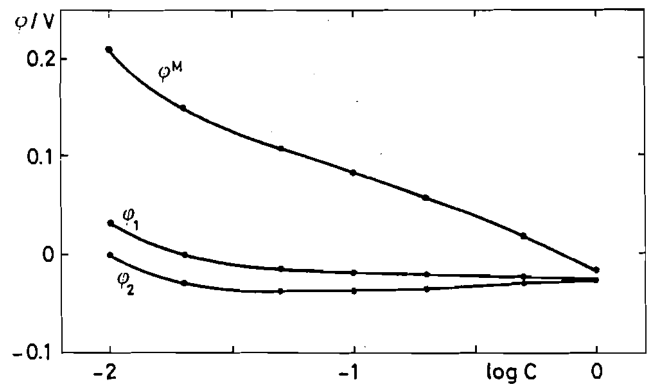

FIG. 9. Potentials in the double layer of a mercury electrode having 10 μC cm^{-2} in an aqueous solution of Na_3Cit as a function of the concentration of the solution.

azide ion (15) and the benzenedisulfonate ion (12). Given the experimental errors, g is practically independent of charge (see Table 3) supporting the prediction that the potential drop across the inner layer is additively composed of contributions from the layer on the metal and from the charge on the adsorbed layer.

The lines in Fig. 7 are parallel within the range $q = 0-16$ μC cm^{-2}. It seems reasonable therefore to conclude that the model is approximately correct in this range and that

$$g = 0.645$$
$$(x_2 - x_1)/x_2 = 0.14$$
$$\lambda = 0.445$$

The inner layer potential can be calculated from these values of the parameters by means of the equation

$$[21] \quad \phi_1 - \phi_2 = (q + \lambda q^{-1})/_{q^{-1}}K$$

The results are shown in Figs. 8 and 9; in the former they are given as a function of the charge on the mercury for a fixed concentration in the solution, while in the latter they appear as a function of the concentration for a fixed charge on the surface of the Hg. Together with ϕ_1, these figures show the external potential of Helmholtz (ϕ_2) and the part of the metal–solution potential due to free charges, ϕ^M. It should be noted that ϕ^M includes any change in potential due to the orientation of the molecules of solvent which is different from the point of zero charge.

The potential of specific adsorption, Φ, originally introduced by Stern (16), which coincides with the standard free energy of adsorption with a changed sign, can also be determined. This results in

$$\Phi = -\Delta G^0_{\text{ads}} = 20 \pm 5 \text{ kJ/mol}$$

for this system.

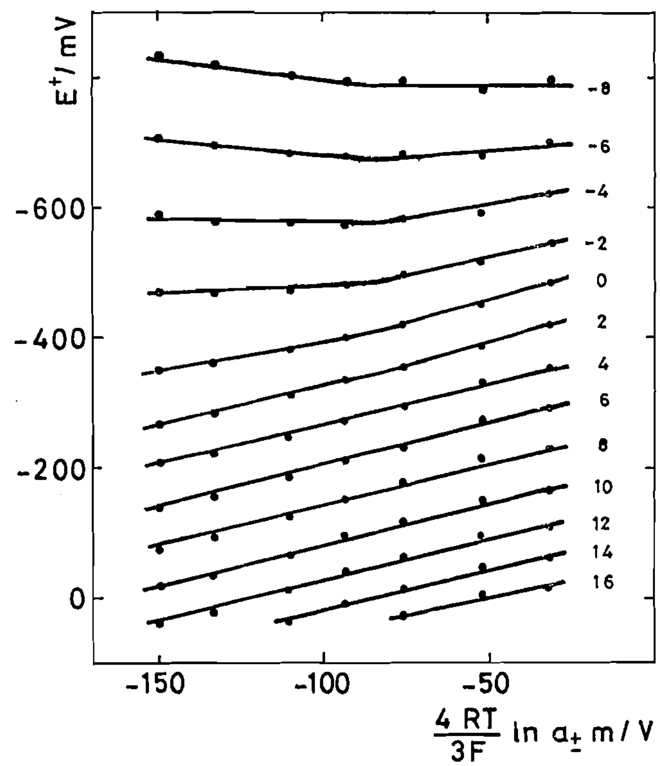

FIG. 10. Esin and Markov plots for solutions of Na_3Cit.

(d) Esin–Markov coefficient

The thermodynamic equation:

$$[22] \quad -d\xi = (4RT/3F)\Gamma_- \, d \ln a_\pm - E^+ dq$$

allows the following relation to be established:

$$[23] \quad (\partial E^+/\partial \mu)_q = -(\partial \Gamma_-/\partial q)_\mu$$

The excess of anions at the surface, Γ_-, may be separated into two contributions: that due to the specifically adsorbed charge and that due to the diffuse layer, in such a way that

$$[24] \quad z_- F(\partial E^+/\partial \mu)_q = -[(\partial q^{-1}/\partial q)_\mu + (\partial q^{\text{d}}_-/\partial q)_\mu]$$

The concentration of anions in the diffuse layer varies very little with q in the present system; the second term on the right-hand side of eq. [24] can be rejected and the Esin–Markov coefficient estimated by means of the first term.

In Fig. 10, E^+ is plotted against the chemical potential of the salt for integer values of q. The graphs are practically linear for $q > 2$ μC cm^{-2}, with slopes close to one. This is in agreement with the values obtained for $\delta q^{-1}/\delta q$ from the plots of q^{-1} vs. q (Fig. 2).

The results given above present marked differences from those obtained by other authors (2) and must be attributed to different experimental conditions.

Charge distributions and chemical effects. XXXVII. Note on tetracyclo[4.1.0.0^{2,4}.0^{3,5}]heptane

J. BRIDET, M.-T. BÉRALDIN, AND S. FLISZÁR
Département de Chimie, Université de Montréal, C.P. 6210, Succ. A, Montréal, Qué., Canada H3C 3V1

Received October 24, 1984

J. BRIDET, M.-T. BÉRALDIN, and S. FLISZÁR. Can. J. Chem. **63**, 2468 (1985).

Full geometry and ζ optimizations are a must in the study of small cycles, as in tetracyclo[4.1.0.0^{2,4}.0^{3,5}]heptane. Indeed, nonoptimized STO-3G calculations suggest the 4-carbon to be electron richer than the carbon in 3 position, whereas the reverse is shown by optimized calculations ($q_C^{\text{Mulliken}} = -150$ vs. -138 me for C-3 and C-4, respectively). The latter result is in accord with the general trends indicating that a gain in local 2s charge is accompanied by a downfield nmr shift (δ 22.1 for C-3 and −4.0 ppm for C-4, from tetramethylsilane). These charge and shift results can be directly compared to one another because the local geometries (namely, the angles) about these two carbon atoms are very similar. This, however, is not the case with other carbon atoms of 3-membered cycloalkanes, a situation restricting the validity of simple charge–shift correlations in this class of compounds because of the changes in local geometry affecting the hybridization of carbon.

J. BRIDET, M.-T. BÉRALDIN et S. FLISZÁR. Can. J. Chem. **63**, 2468 (1985).

Il est absolument nécessaire de connaître la géométrie globale ainsi que les optimisations ζ pour étudier les petits cycles, comme le tétracyclo[4.1.0.0^{2,4}.0^{3,5}]heptane. En effet, des calculs non-optimisés au niveau STO-3G suggèrent que le carbone en 4 est plus riche en électrons que le carbone en position 3; par ailleurs, des calculs optimisés ($q_C^{\text{Mulliken}} = -150$ vs. -138 me respectivement pour les carbones en positions 3 et 4) montrent le contraire. Ce dernier résultat est en accord avec les tendances générales indiquant qu'un gain de charge locale 2s est accompagné par un déplacement vers les bas champs de la rmn (δ relatif au tétraméthylsilane de 22,1 pour C-3 et de −4,0 ppm pour le C-4). On peut comparer directement ces résultats pour les charges et les déplacements les uns aux autres parce que les géométries locales (à savoir, les angles) autour de ces deux atomes de carbones sont très semblables. Ceci n'est toutefois pas le cas avec les autres atomes de carbone des cycloalkanes à trois chaînons; cette situation restreint la validité de corrélations simples charge–déplacement dans cette classe de composés à cause des changements dans la géométrie locale affectant l'hybridisation du carbone.

[Traduit par le journal]

Introduction

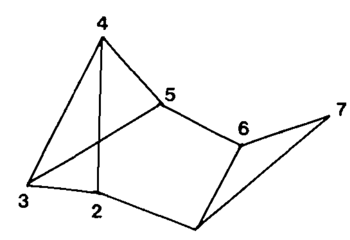
The magnetic shielding of any nucleus in a molecule depends on both local and nonlocal contributions. For heavy nuclei (e.g., ^{13}C), any change in shielding accompanying structural modifications is primarily governed by its local paramagnetic part, i.e., $\Delta\sigma_{\text{total}} \simeq \Delta\sigma^{\text{p}}_{\text{local}}$: this offers a justification for postulated correlations between nuclear magnetic resonance shifts and atomic charges which, of course, are strictly local properties (1). Indeed, a number of such correlations are known for ^{13}C, ^{17}O, and ^{15}N nuclei (2–5).[1]

A case in point is that of sp^3 hybridized carbon atoms in normal and branched paraffins and in the cyclohexane series, including polycyclic hydrocarbons constructed from chair and/or boat cyclohexane rings (2–4). Their ^{13}C nmr shifts, δ_C, are accurately described (with a standard deviation of ~0.3 ppm) by the equation

$$[1] \quad \delta_C = -237.1(\Delta q_C/q_C^0) \text{ (ppm from } C_2H_6)$$

in which q_C^0 = net atomic charge of the ethane carbon (taken as reference) and Δq_C is the difference in C net charge with respect to that of ethane.[2] Note that for these carbon atoms any increase in local electron population (more negative Δq_C) results in a downfield shift (2–4).

In contrast, a remarkable study of bicyclo[n.1.0]hydrocarbons by Christl (9) reveals an anomaly in the case of tetracyclo[4.1.0.0^{2,4}.0^{3,5}]heptane **1** at carbons 3 and 4.



Indeed, Christl's nonoptimized STO-3G calculations suggest the 4-carbon (at −4.0 ppm from tetramethylsilane) to be

TABLE 1. Selected optimized geometry parameters^a (angles in decimal degrees, distances in Å)

^{a}Additional informations available upon request.

[1]These correlations, however, are not of a universal nature: separate correlations apply, e.g., to alkane sp^3 carbons, ethylenic or benzenic sp^2 carbons, depending on the type (σ or π) of electrons involved in the structure-dependent changes of local electron populations (2, 3). Charge-nmr shift relationships are not free from conceptual difficulties and have drawbacks of their own (2, 6–8). It is, therefore, important to be aware of the limitations restricting their utilization.

[2]The proper (*ab initio*) evaluation of charges involves careful optimizations of all variational (geometry and ζ) parameters — a task which is practically feasible only in minimal basis set calculations. Now, both Δq_C and q_C^0 are basis set dependent in numerical *ab initio* calculations, the ratio $\Delta q_C/q_C^0$, however, is not: hence our choice for the fully optimized STO-3G method.

TABLE 2. Optimized STO-3G results and nmr shifts of **1**[a]

Atom (s)	ζ_K	ζ_L	$N(1s)$	$N(2s)$	$N(2p)$	q_C	δ_C
C-1, C-6	5.70465	1.72335	1.9911	1.1446	2.9086	−44.3	17.3
C-2, C-5	5.70469	1.71731	1.9913	1.1590	2.8706	−20.9	38.4

C-4	5.70341	1.70087	1.9917	1.1602	2.9862	−138.1	−4.0
C-7	5.70454	1.71940	1.9911	1.1545	2.9731	−118.7	17.6

[a]The atom numbering is indicated in text. Electron populations, N, are in electron units, net atomic charges in me (= 10^{-3} e) units. The nmr shifts (ppm, downfield from tetramethylsilane) are taken from ref. 9. The hydrogen ζ's are 1.21011 (H_1), 1.22100 (H_2), 1.21193 (H_3), 1.23992 (H_4), 1.21053 (H_7*endo*), and 1.20987 (H_7*exo*).

electron richer than the carbon in 3 position (δ 22.1 from TMS), at variance with the trend indicated by eq. [1].

Of course, carbon electrons of 3- and 6-membered cycles should not be considered on the same footing because of geometry related differences in s (vs. p) character;[3] nor is it certain that positions 3 and 4 of **1** can safely be compared to one another because their local geometries and, hence, possible differences in their s character are presently not known. The apparent reversal in charge−shift trend mentioned above could thus be ascribed to a hybridization-related "special feature" regarding carbon electrons in 3-membered cycles or/and to a possible difference in local geometry about atoms 3 and 4, affecting their hybridization. Briefly, a number of reasons can be given in the present context in order to render our ignorance less visible, but they offer no replacement for an investigation into that matter.

Computational results

A standard STO-3G calculation of **1** was performed following Pople's recipe (13). Mulliken's population analysis (14) was adopted, which is reasonable because any bias possibly resulting from the half-and-half partitioning of overlap populations (which is part of this analysis) would cancel in a comparison between carbons 3 and 4. Just as in Christl's calculation (9), C-4 appeared to be somewhat electron richer than C-3, by ~10 me (10^{-3} e units).

Next, a full geometry optimization was carried out, at the STO-3G level. From the results indicated in Table 1, it is clear that the local geometries about atoms 3 and 4 are virtually the same, thus suggesting that these positions are comparable.

Finally, all ζ parameters were carefully optimized — a point which is important because atomic charges are very sensitive to the molecular environment and, hence, to ζ optimization: the most consistent charge results are obtained when this optimization is carried out at its best for each atom (or group of equivalent atoms) of the molecule under study (2, 15, 16). Each energy minimization was carried out until stable charges were obtained, within ~0.01 me. The results are indicated in Table 2.

Discussion

With charges like those described in Table 2, it is important to be aware that they should not be taken at their face value. These are Mulliken charges, including throughout a half-and-half partitioning of overlap populations in their computation. Now, this assignment of overlap terms may carry an error in situations involving heteronuclear atom pairs (as in CH bonds in the present case) — a problem discussed earlier in detail (2, 4, 15−18). (It remains true, however, that Mulliken charges are of undisputed value provided, of course, they are used with due care, in comparisons assorted with an assessment of their validity.) For this reason, the Mulliken net charge deduced for C-7, bearing two H atoms, is not to be compared to the charges of the other C atoms, bearing only one H atom.

Next, we must examine whether the other carbon charges indicated in Table 2 can all be considered on the same footing. The answer is no. Indeed, the STO-3G populations calculated for carbons 1−6 vary in an apparently uncorrelated manner both at the $2s$ and $2p$ levels. This may well be related to the local geometries (Table 1), differing for C-1,6, C-2,5, and C-3,4, i.e., to small changes in hybridization.[3] In that event, however, a comparison encompassing the charges of carbons 1−6 could be accepted only if made using results deduced from sufficiently large basis sets (e.g. 4-31 G, or larger) after configuration interaction. This is because the contribution of excited states, and the ensuing corrections in charge results following CI, depend markedly on the state of hybridization. Minor in the case of alkanes like methane, ethane, etc. (16), they are very important in unsaturated hydrocarbons like ethylene,[4] suggesting that proper inclusion of CI is also a must before valid assessments can be made regarding charge effects accompanying changes in local geometry in highly strained systems like **1**. Briefly, the STO-3G charges obtained in this work for C-1,6 and C-2,5 should not be considered on the same footing as those deduced for C-3 and C-4.

This brings us to carbon atoms 3 and 4. Their local geometries are virtually the same, meaning that these two positions can reasonably be compared to one another, without fearing any significant bias related to geometry-dependent differences in hybridization. Their $2p$ atomic populations are also almost the same, within ~3 me. These positions differ essentially in their $2s$ populations, atom 3 being ~15 me electron richer than C-4. The situation is thus similar to that encountered with paraffins and cyclohexanic hydrocarbons obeying eq. [1]: car-

[3]Del Re and co-workers (10) were concerned with the relation of s character in hybrids to bond angles and have considered hybridization as described by local orbitals, determined by requiring that hybrids on different atoms have minimal overlap unless they participate in the same bond. Alternate approaches are provided by Wiberg (11) and by Trindle and Sinanoğlu (12). Calculated p characters are in good agreement with estimates derived from nmr coupling constants (11, 12). Evaluations of hybridization are anticipated to assist in future work on charge−shift correlations in cases suspected of presenting changes in local geometry.

[4]Current work indicates that configuration interaction affects the final carbon charge of ethylene by more than 120 me at the 4-31G level (C. Mijoule, J.-M. Leclercq, and S. Fliszár, unpublished results), as compared with a correction of ~5 me for the ethane carbon atom (16).

bons 3 and 4 are virtually in the same state of hybridization and charge variations occur at the 2*s* level. In conclusion, present optimized results are now in general accord with the trend (eq. [1]) indicating that (under otherwise similar conditions) a gain in local 2*s* charge is accompanied by a downfield ^{13}C nmr shift, whereas nonoptimized calculations would suggest the contrary.

An increased internal rotational barrier in thiophenol caused by *meta* substituents

TED SCHAEFER, JAMES D. BALEJA, AND GLENN H. PENNER
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received December 28, 1984

TED SCHAEFER, JAMES D. BALEJA, and GLENN H. PENNER. Can. J. Chem. **63**, 2471 (1985).

The twofold internal barriers to rotation about the C—S bond in 3,5-diX-thiophenols were determined in solution from long-range spin–spin coupling constants. They are 3.4, 4.8_5, 5.3, 6.4_5, and $7.2_5 \pm 10\%$ kJ/mol for X = H, CH_3, OCH_3, F, and Cl, respectively. In 3,5-dichloro-4-hydroxythiophenol, V_2 is −0.8 kJ/mol as compared to −1.9 kJ/mol in 4-methoxythiophenol. The *para* substituent here dominates. The observed barriers are in rough agreement with arguments based on perturbation molecular orbital theory and with MO calculations of changes in the barrier caused by substituents. The computed values appear as nearly pure twofold barriers with very small fourfold components.

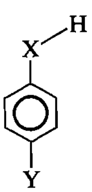
TED SCHAEFER, JAMES D. BALEJA et GLENN H. PENNER. Can. J. Chem. **63**, 2471 (1985).

Faisant appel aux constantes de couplage spin–spin à longue distance et opérant en solution, on a déterminé les barrières internes binaires à la rotation autour de la liaison C—S de di-X-3,5 thiophénols. Pour des groupes X = H, CH_3, OCH_3, F et Cl, ces valeurs sont respectivement égales à 3,4, $4{,}8_5$, 5,3, $6{,}4_5$ et $7.2_5 \pm 10\%$ kJ/mol. Dans le cas du dichloro-3,5 hydroxy-4 thiophénol, la valeur de V_2 est égale à −0,8 kJ/mol; dans le cas du méthoxy-4 thiophénol, cette valeur est égale à −1,9 kJ/mol. Dans ce cas, l'influence du substituant en *para* est prédominant. Les barrières observées sont généralement en accord avec les arguments basés sur la théorie des perturbations des orbitales moléculaires ainsi qu'avec des calculs d'OM relatifs aux changements à la barrière qui seraient causés par les substituants. Il semble que les valeurs calculées soient pratiquement des barrières binaires pures et qu'elles ne contiennent que des faibles proportions de composantes quaternaires.

[Traduit par le journal]

Introduction

It is expected and observed that the barrier to rotation about the C—X bond in **1** is increased if X is a π electron acceptor such as C═O and Y is an electron donor such as OCH_3 or F (1–3). This behaviour is easily understood in terms of the increased mobile bond order of the C—X bond. More generally, the barrier to internal rotation or its equivalent, the stability of the planar conformation, will increase if X is a π electron acceptor and Y is a donor or vice versa, whereas the barrier will decrease if X and Y are both donors or both acceptors.



1

A good illustration is provided by *para* substituted thiophenols in which S—H is a π electron donor but conjugates relatively weakly with the π electron system of the ring. The twofold barrier to internal rotation, V_2, is only 3.4 kJ/mol (4) compared to 14.9 kJ/mol in phenol (4–7). In *p*-nitrothiophenol, V_2 rises to 9 kJ/mol, and drops to 0.4 kJ/mol in *p*-fluorothiophenol (8). In the presence of a *para* amino substituent the stable conformer becomes that in which the S—H bond prefers a plane perpendicular to the benzene plane, corresponding to a negative V_2 on this energy scale.

The barriers in the *p*-X-thiophenols are derived from $^4J^{H,H}$, the spin–spin coupling constants between the sulfhydryl and *ortho* ring protons (8), on the assumption that $^4J^{H,H} = {}^4J_{90} \langle \sin^2 \theta \rangle$. $^4J_{90}$ is the coupling when the S—H bond lies in a plane perpendicular to the benzene plane and is taken as −1.10 Hz on the basis of experimental evidence (8,9). The expectation value of $\sin^2 \theta$ is then given by $^4J^{H,H}/{}^4J_{90}$ and is related to the internal barrier to rotation about the C—S bond by a hindered rotor model (10).

It is interesting that the change in barrier, ΔV_2, computed for a series of six *p*-X-phenols (X = CH_3, OH, F, NO_2, NH_2, H) by STO 3G MO methods (11, 12), is related to ΔV_2 for the corresponding thiophenol derivatives, obtained in solution by the *J* method (8), by ΔV_2^{OH} (kJ/mol) = $0.75\, \Delta V_2^{SH} - 0.01$ (the correlation coefficient, *r*, is 0.999). Again, far infrared torsion data (5) yield ΔV_2^{OH} in cyclohexane solution. For X = F, CH_3, OCH_3, NO_2, H, these numbers are related to ΔV_2^{SH} by $\Delta V_2^{OH} = 0.72\, \Delta V_2^{SH} - 0.11$ kJ/mol ($r = 0.994$). These correlations are here taken to mean that the *J* method yields reasonable V_2 values in thiophenol derivatives and, perhaps, that the less strongly conjugated SH group is more easily perturbed by a substituent than is a hydroxyl group.

Much less is known about the perturbation of internal barriers caused by *meta* substituents. Calculations at the STO 3G level of *ab initio* molecular orbital theory (12) predict an increased barrier in phenol in the presence of σ electron withdrawing groups like F, NH_2, OH, in agreement with increased double bond character of the C—O bond. The increase is expected because the rather electronegative electron withdrawing groups lower the π* (antibonding) levels in phenol and cause enhanced conjugation of the OH group (perturbation MO model). However, although the latter is also calculated to increase in the presence of *meta* CN and NO_2 groups, the barrier itself is predicted to be lower than in phenol. Furthermore, the *meta* methyl group is also calculated to increase the barrier in phenol, yet it is hardly very electronegative. But it is a π donor. In toluene, the computed π electron densities at the *ortho* and *para* positions are higher than in benzene, but are lower at the *meta* position just as in fluorobenzene, anisole, or aniline. From this viewpoint, if F, NH_2, OH, and CH_3 groups decrease the π electron density at the *meta* position, then an increased V_2 in such phenols would be expected due to enhanced conjugation of the hydroxyl group.

The available experimental data (5) appear to relate to the torsional frequencies of some *m*-X-phenols in cyclohexane

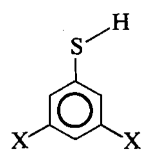
TABLE 1. The spectral parameters for a 2.6 mol% solution of 3,5-difluorothiophenol in CCl_4, containing 10 mol% of cyclohexane-d_{12} and 0.5 mol% TMS at 298 K

Parameter	Value	Parameter	Value
ν_{SH}^{a}	1039.821(1)[b]	$^4J_{26}$	1.571(2)[c]
$\nu_2 = \nu_6$	2023.992(1)	$^4J_{35}$	7.213(1)
ν_4	1969.358(1)	$^3J_{34}$	8.853(1)
^4J(H, SH)	−0.249(1)	No. of peaks, ^{1}H	72
^5J(F, SH)	±0.066(1)	Assigned peaks	72
^6J(H, SH)	−0.248(1)	Calcd. transitions	112
$^3J_{23}$	8.463(2)	Assigned transitions	101
$^4J_{24}$	2.250(1)	rms error	0.005_4
$^5J_{25}$	−1.104(1)[c]	Largest difference	0.023

[a]Shifts are given in Hz at 300.135 MHz to low field of internal TMS.
[b]The numbers in parentheses are standard deviations in the last significant figure.
[c]$^5J_{25}$ and $^4J_{35}$ correlate with −0.50, so that only their sum or difference is known with high precision.

solution, from which it apears that NO_2, F, OCH_3, and CH_3 groups all cause an increase in V_2. The changes in V_2 are *much smaller* than for the corresponding *p*-X-phenols, being only 1.7 kJ/mol at most.

Although the J method does not lend itself to the determination of the relatively large V_2 in phenol derivatives, it is suitable for the smaller barriers in thiophenol derivatives. Accordingly, we here report on the use of ^4J and ^6J (also a $\sin^2\theta$ coupling) in the determination of V_2 in some 3,5-disubstituted thiophenol derivatives, **2**. The dinitro derivative was synthesized but its intermolecular proton exchange could apparently not be stopped in solvents in which it was sufficiently soluble for nmr measurements. $^4J^{H,H}$ was also measured in 4-chloro-3-sulfhydrylthiophenol, 3,4-dichlorothiophenol, and in 3,5-dichloro-4-hydroxythiophenol.



X = F, OCH_3, CH_3, Cl

2

Experimental

The asymmetric or trisubstituted thiophenols came from Aldrich. The 3,5-dichlorothiophenol was a Fairfield product. The 3,5-difluoro-, 3,5-dimethoxy-, 3,5-dinitro, and 3,5-dimethylthiophenols were prepared from the corresponding aniline derivatives via the xanthates (13, 14). A typical synthesis went as follows. 3,5-Difluoroaniline (2.58 g, 0.02 mol, Aldrich) was suspended in 16 mL H_2O containing 3.2 mL concentrated H_2SO_4. To the cooled (4°C) solution, 1.5 g $NaNO_2$ in 8 mL of water was added dropwise over 0.5 h. The solution was stirred for 1 h and was then added dropwise to a solution (50°C) of 6 g of potassium ethylxanthate in 20 mL of water over 0.5 h. The solution was stirred for 0.5 h and allowed to reach room temperature. The reddish solution was extracted with ether. The ether layer was washed twice with water, dried over $MgSO_4$, filtered, and the ether was removed to give a clear red oil. This xanthate ester was allowed to sit for 2 days over molecular sieve and was then transferred with dry ether washings to a 50-mL round bottomed flask. A suspension of $LiAlH_4$ in ether was added to the xanthate solution until frothing ceased. A little more $LiAlH_4$ was now added and the solution was stirred for 2 h. The product was extracted into ether, washed with dilute HCl, and twice with water. The ether solution was extracted into base (20% NaOH). Neutralization with concentrated HCl, extraction with ether, washing with water, and drying over $MgSO_4$ gave the product after solvent removal. An ^{1}H nmr spectrum in CCl_4 containing 10 mol% C_6D_{12} and 0.15 mol% TMS gave a spectrum characteristic of 3,5-difluorothiophenol: a δ(SH) of 3.46 together with splittings in the ring proton region due to long-range coupling to the sulfhydryl proton.

Samples for ^{1}H and ^{19}F nmr analysis were prepared in CCl_4 containing some cyclohexane-d_{12} and TMS or in benzene-d_6 containing some TMS (for chemical shift dispersion). These solutions were dried over molecular sieve and were then transferred to 5-mm od nmr sample tubes. Degassing by the freeze−pump−thaw procedure was followed by flame-sealing. Table 1 contains details about concentrations.

The ^{1}H nmr spectra were accumulated on HA100, WH90, and AM300 nmr spectrometers, following procedures recently given in detail (15, 16).

Molecular orbital calculations were performed with the program MONSTERGAUSS (17) on an Amdahl 470/V8 system.

Results and discussion

Spectral analyses

These were performed with the computer programs LAME (18, 19) and NUMARIT (20). The results of one analysis are given in Table 1, for 3,5-difluorothiophenol. Figure 1 displays the nmr spectrum of the sulfhydryl proton, illustrating the resolution of splittings as small as 0.066 Hz. Table 2 records the long-range couplings $^4J^{H,H} \equiv {}^4J$(H, SH) and $^6J^{H,H} \equiv {}^6J$(H, SH) for 8 compounds; these are the quantities of interest in this discussion.

V_2 *derived from* ^4J*(H, SH) and* ^6J*(H, SH)*

As described in detail previously (8), ^6J(H, SH) can be written as $-0.97\ \langle\sin^2\theta\rangle$ Hz where $\langle\sin^2\theta\rangle$ is the expectation value of $\sin^2\theta$ and is related to V_2, the temperature, and the reduced moment of inertia about the C—S bond; θ is the angle by which the S—H bond twists out of the ring plane. Similarly, ^4J(H, SH) is very likely given by $-1.10\ \langle\sin^2\theta\rangle$ Hz. Accordingly, for **2** one has two sources of V_2 and these are recorded in Table 2. In view of possible intrinsic substituent perturbations of ^4J and ^6J and of experimental errors in the couplings themselves, it is probably reasonable to take the mean of the two V_2 values for each compound as a basis for discussion.

Discussion of V_2 *trends*

In 4-X-thiophenol derivatives (8), V_2 is 3.4, 2.2, −1.9, 0.4, and 3.7 kJ/mol for X = H, CH_3, OCH_3, F, and Cl respectively, with errors of perhaps 10%. The strongest π electron donor, OCH_3, causes the largest decrease in V_2, as expected from the discussion above. In the corresponding 3,5-diX-thiophenol derivatives in Table 2, V_2 increases for X = CH_3, OCH_3, F, Cl

[k]The two distinct couplings to the *ortho* protons are −0.384(5) and −0.385(5) Hz.
[l]In a 4 mol% solution in $CDCl_3$, ^4J is −0.590(7) Hz, is −0.561(2) Hz in a 4 mol% solution in CS_2, −0.541(3) Hz in 5 mol% benzene-d_6, and is −0.531(4) in a 4 mol% solution in CH_2Cl_2.
[m]A negative V_2 means that the S—H bond prefers $\theta = 90°$, that is, a plane perpendicular to the benzene plane.

FIG. 1. The ^1H nmr spectrum of the sulfhydryl proton of a 2.6 mol% solution of 3,5-difluorothiophenol in CCl_4 at 298 K and 300 MHz. The splittings of 0.066 Hz caused by coupling to the two ^{19}F nuclei are clearly visible. The couplings to the *ortho* and *para* protons are almost identical, leading to the "quartet" structure in this nearly first-order spectrum.

and is largest when X = Cl, in contrast to the smallest change caused by X = Cl in the 4-X-thiophenols. Qualitatively, the increased V_2 values increase with inherent (gas) values of σ_m (21), the latter being −0.02, 0.06, 0.27, and 0.36 for CH_3, OCH_3, F, and Cl, respectively. However, on this basis the CH_3 group should cause a decrease in V_2, contrary to observation.

In terms of PMO theory (12, 22), and taking the SH group as a electron donor, the electronegative OCH_3, F, and Cl substituents lower the energy of the (almost empty) π^* orbital, leading to increased conjugation of the SH group and therefore to a higher barrier. Furthermore, considering OCH_3 and F as π electron donors, PMO theory predicts (22) an increase in π donation by both substituents (SH and the *meta* substituent) because each substituent now donates into different π^* orbitals, whose energies have been lowered by the electronegative nature of F and OCH_3. The Cl substituent is presumably a poor π electron donor (note small change in V_2 for 4-chlorothiophenol) and the large increase in V_2 must then be attributed to the first cause above. However, the CH_3 group is not very electronegative, so that the qualitative model is not entirely consistent in its predictions. Unfortunately, our attempts at the measurement of ^4J and ^6J in 3,5-dinitrothiophenol were unsuccessful. The nitro group is a π and σ electron acceptor, unlike the substituents under consideration here.

Alternatively, a simpler qualitative model recognizes that CH_3, OCH_3, and F groups, for example, while increasing π electron densities at *ortho* and *para* positions, are calculated (12, 23) to decrease them at *meta* positions. In that event, increased conjugation of the sulfhydryl group is expected, leading to a higher barrier. However, such an interpretation hardly holds for *meta* chlorine substituents.

In this connection it is interesting that the *para* substituent in 3,5-dichloro-4-hydroxythiophenol dominates as a determinant of V_2, which is −0.8 kJ/mol. Thus, in 4-methoxythiophenol (modelling a 4-hydroxy group) V_2 is −1.9 kJ/mol and in 3,5-dichlorothiophenol V_2 becomes 7.1 kJ/mol. In other words, the *meta* substituents cause only a small change in V_2 of 4-hydroxythiophenol, but a large change in V_2 in the absence of the 4-substituent. This conclusion is consistent with the observation of a V_2 of 3.5 kJ/mol in 3,4-dichlorothiophenol, it being 3.4 in thiophenol and 3.7 in the 4-chloro derivative. In a sense, the *para* substituent causes a first-order perturbation and, *in its presence*, a *meta* substituent is a second-order perturber. Although the PMO model provides *some* insight into the substituent effects on V_2 for the thiophenol derivatives in Table 2, it does not yield quantitative data. Accordingly, geometry-optimized computations of V_2 were carried out for some of the compounds.

Table 3 contains the theoretical data on the barriers to rotation about the C—S bond for a variety of subtituents. In these computations all bond angles and bond lengths were optimized with the constraint, however, that the benzene framework re-

TABLE 3. Computed barriers to rotation about the C—S bond in some thiophenol derivatives. Geometry-optimized STO 3G MO[a]

Compound[b]	A^c (kJ mol^{-1})	B^c	Compound	A^c (kJ mol^{-1})	B^c
4-H	14.74(2)	0.20(1)	3,4-diCl	16.15(1)	0.13(1)

4-OH	11.76(1)	0.26(1)	3,5-diF	16.99(2)	0.11(2)
4-NH_2	11.9	—	3-F[d]	15.90(2)	0.41(3)
4-Cl	15.9(2)	0.17(2)	3,5-diCl-4-OH	11.99(2)	0.24(1)

[a]The benzene framework is a hexagon but all other bond angles and bond lengths are optimized.

[b]The experimental values for most of the 4-X-thiophenols are given in the text. That for X = NH_2 is -2.9 ± 0.4 kJ/mol (8).

[c]$V = A \sin^2\theta + B \sin^2 2\theta$ where θ is the angle by which the S—H bond twists out of the benzene plane. Therefore A and B represent the magnitudes of the twofold and fourfold components of the barrier, respectively.

[d]The energy difference between the *cis* and *trans* planar conformers is computed as insignificant (less than 0.05 kJ/mol).

main a regular hexagon. Computations were done at 15° intervals for θ, varying the latter between 0 and 90°. The relative energies were then fit to a $A \sin^2\theta + B \sin^2 2\theta$ curve, where A represents V_2 and B represents V_4. It became clear that V_4 is rather small, so that in the interests of economy calculations were performed only at 0° and 90° for some of the 4-X-thiophenols.

Just as for phenol (11, 12), V_2 is overestimated for thiophenol at the STO 3G level of *ab initio* MO theory. Thus, the barrier in kJ/mol is calculated as $14.74(2) \sin^2\theta + 0.20(1) \sin^2 2\theta$ at the 95% confidence level, the measured value in the gas phase being 3.4 kJ/mol (4). A significant correlation exists, however, between the computed and observed changes, ΔV_2, caused by the substituents. For the 4-X-thiophenols in Table 3, ΔV_2 (theor) = $0.20 + 0.53\, \Delta V_2$ (exp) with $r = 0.956$. If all compounds, except for 3,5-dichlorothiophenol, are included in the correlation, then ΔV_2 (theor) = $0.41 + 0.63\, \Delta V_2$ (exp) with $r = 0.952$. In view of the much better correlations presented in the introduction to this paper, it may be that the theoretical values are the less reliable.

Of course, the measured barriers may well depend somewhat on solvent. Although the 3,5-dichloro compound presents problems of chemical shift dispersion, its 4-hydroxy derivative does not. Accordingly ^4J(H, SH) for the latter was also measured in CH_2Cl_2, C_6D_6, CS_2, and $CDCl_3$ solutions (apparent decomposition occurred in CH_3CN, CH_3NO_2, $(CH_3)_2C{=}O$, and DMSO solutions), yielding $-^4J$ as 0.531(4), 0.541(3), 0.561(2), and 0.590(7) Hz, respectively. These numbers correspond to an increase of 1.2 kJ/mol in V_2 on going from CCl_4 solution (Table 2) to the rather polar CH_2Cl_2 solution. Relative to the CCl_4 solution, V_2 increases by 1 kJ/mol in C_6D_6 solution. The 3,5-dichlorothiophenol spectra were measured in C_6D_6, but it would seem that only about 1 kJ/mol of the relatively large discrepancy of 2.8 kJ/mol between the experimental value and that given by the correlation above can be accounted for in this way.

The situation is unsatisfactory, particularly because such a large discrepancy between theoretical and experimental values does not exist for 3,4-dichlorothiophenol, being less than 1 kJ/mol.

The computation for 3-fluorothiophenol implies that ΔV for *meta* substituents is additive, being 1.2 kJ/mol for the mono- and 2.3 kJ/mol for the difluoro derivatives. It would be interesting to know the microwave and far infrared data for these molecules.

Finally, the barrier to rotation for the 1-SH group in 3-mercapto-4-chlorothiophenol appears to be twofold, because the two $^4J^{H,H}$ values for this group are the same, and unchanged from its value in thiophenol. Because a 4-chloro substituent perturbs V_2 very slightly, if at all (Table 2), it follows that in its presence a 3-mercapto substituent is ineffective in altering the barrier. Parenthetically, ^5J(H, SH) for the 1-SH proton is 0.259 Hz. ^5J has been written as $0.196 \langle \sin^2\theta \rangle + 0.180$ for a twofold barrier, so that ^5J is computed as 0.248 Hz, in reasonable agreement with the observed number.

Acknowledgments

We are grateful to the University of Manitoba for some computing time and to the Natural Sciences and Engineering Research Council of Canada for financial assistance. We are grateful to Dr. S. Salman for the spectral data on 3-mercapto-4-chlorothiophenol.

Volumes molaires partiels de composés tensioactifs dans les milieux salins concentrés eau–KCl

SABAH BOUGUERRA, HAMED BAHRI ET PIERRE LETELLIER[1]

Laboratoire de Physiochimie des Solutions, Université Pierre et Marie Curie, E.N.S.C.P. 11 Rue Pierre et Marie Curie, 75231 Paris Cédex 05, France

Reçu le 7 juin 1984[2]

SABAH BOUGUERRA, HAMED BAHRI et PIERRE LETELLIER. Can. J. Chem. **63**, 2476 (1985).

Les volumes molaires apparents de quatre détergents cationiques $CH_3(CH_2)_nN(CH_3)_3Br$ pour n = 9, 11, 13 et 15 ont été déterminés dans les mélanges eau – chlorure de potassium à 298 K, pour des concentrations en électrolyte support comprises entre 0,5 et 3,5 mol L^{-1}. La très faible dépendance des volumes molaires apparents des tensioactifs, *une fois micellisés*, avec la concentration du sel de fond laisse supposer que les interactions entre les amphiphiles eux-mêmes et entre les amphiphiles et leur environnement ne sont pas fondamentalement modifiées par l'addition de sel. L'utilisation de résultats antérieurs obtenus pour ces mêmes milieux, concernant le comportement des sels d'ammonium symétriques permet d'accéder aux *volumes intrinsèques* des amphiphiles et, par conséquence, d'estimer le volume réel occupé par la phase micellaire dans la solution. Des mesures des volumes molaires apparents du bromure de dodécyltriméthylammonium et du dodécylsulfate de sodium dans les mélanges eau–NaCl permettent de confirmer les rôles dissymétriques joués par les anions et les cations en milieu salin concentré.

SABAH BOUGUERRA, HAMED BAHRI, and PIERRE LETELLIER. Can. J. Chem. **63**, 2476 (1985).

Apparent molar volumes of 4 cationic detergents $CH_3(CH_2)_nN(CH_3)_3Br$ (n = 9, 11, 13, and 15) have been determined in water – potassium chloride mixtures at 298 K over a wide range of concentrations (from 0.5 to 3.5 mol L^{-1}). The small dependence of values of apparent molar volume of micellized detergent on the salt concentration suggests the interactions between amphiphiles themselves and between amphiphiles and their surroundings are not modified by the variation of KCl concentration. Previous results lead to estimates of intrinsic volumes of micellized detergents and consequently actual volumes of the micellar phase in the solution. In addition, apparent molar volumes of dodecyltrimethylammonium bromide and sodium dodecylsulfate have been determined in water – sodium chloride mixtures. The results agree fairly well with the previous conclusions and prove the dissymmetric behaviour of the anions and cations in very highly concentrated aqueous salt solutions.

L'étude des volumes molaires partiels et apparents des composés tensioactifs est généralement entreprise dans le but de déterminer avec précision des valeurs de concentration micellaire critique (cmc) (3), le phénomène de micellisation s'accompagnant le plus souvent, dans l'eau d'une importante variation des propriétés volumiques des amphiphiles.

À ce titre, différents travaux ont été réalisés dans l'eau pure, mais également en présence de faibles quantités d'additifs moléculaires (4) ou ioniques (5) dont on a pu ainsi préciser les modes d'action dans le processus de micellisation.

Peu d'études, en revanche, s'attachent à décrire le comportement volumique des détergents en milieu salin concentré, bien que de nombreux travaux se basant sur la mesure d'autres paramètres physiques (viscosité, diffusion de la lumière . . .) (6–9) montrent que les édifices micellaires sont profondément affectés par la présence d'un électrolyte concentré.

Des travaux antérieurs (1,2) nous ayant permis de préciser les *propriétés volumiques individuelles* des anions et des cations, minéraux et organiques, *mono chargés* dans les mélanges eau–KCl pour des concentrations en chlorure de potassium comprises entre 0,5 et 3,5 mol L^{-1}, nous avons entrepris l'étude des volumes molaires partiels $\bar{V}_i$ et apparents ϕ_i de composés tensioactifs dans ces mêmes milieux.

Nous nous sommes plus particulièrement intéressés à quatre halogénures d'alkyltriméthylammonium de formule générale $CH_3(CH_2)_nN^+(CH_3)_3X^-$: les bromures de décyl (n = 9) dTA, dodécyl (n = 11) DTA, tétradécyl (n = 13) TTA, hexadécyl (n = 15) HTA triméthylammonium.

Afin de juger de l'influence de la nature de l'électrolyte support et du signe de la charge portée par l'amphiphile, les comportements du dodécylsulfate de sodium DSNa et du DTA ont été également étudiés dans les milieux eau–NaCl pour une gamme de concentrations comprise entre 0,25 et 0,75 mol L^{-1} en chlorure de sodium.

I. Conditions expérimentales

Le bromure de décyltriméthylammonium est un produit Eastman Kodak; les autres détergents cationiques sont des produits Sigma. Différents essais de reproductibilité ont montré que les résultats expérimentaux obtenus avec des produits recristallisés ne différaient pas notablement de ceux obtenus à partir des produits bruts. La purification n'a donc pas été systématiquement effectuée.

Le dodécylsulfate de sodium, d'origine Prolabo RP, ne conduit en revanche à des résultats reproductibles que recristallisé au moins deux fois dans un mélange méthanol – éther éthylique. Les chlorures de potassium et de sodium sont des produits Prolabo RP. L'eau utilisée est fraichement distillée. Sa masse volumique à 298 K a été prise égale à 0,997047 g cm^{-3}. Les mesures de masses volumiques ont été réalisées au moyen d'un "densimètre vibratomètre à flux" Sodev (modèle 03D) maintenu à la température constante de 298 ± 2 × 10^{-3} K par un thermostat Setaram. Les mesures des périodes ont été effectuées sur un fréquencemètre Hewlett Packard 5315A. Le calcul de la valeur du volume molaire apparent ϕ_i du soluté i, de masse molaire M_i, à la molalité m référée à 1000 grammes de la solution eau–KCl considérée, s'effectue à partir de la relation classique:

$$\phi_i = \frac{1000}{m}\left(\frac{1}{\rho_i} - \frac{1}{\rho_0}\right) + \frac{M_i}{\rho_i}$$

ρ_i et ρ_0 sont respectivement les masses volumiques de la solution i et du solvant eau–KCl.

II. Résultats expérimentaux

II-1. *Définition des systèmes étudiés*

L'addition d'un électrolyte à une solution de tensioactif

[1]Auteur à qui adresser la correspondance.

[2]Revision reçue le 28 janvier 1985.

TABLEAU 1. Concentrations micellaires critiques des détergents étudiés (dans l'eau à 298 K)

	Détergent				
	dTA	DTA	TTA	HTA	NaDS
cmc (mol L^{-1}) (30,31)	$6,5 \times 10^{-2}$	$1,5 \times 10^{-2}$	$3,5 \times 10^{-3}$	$9,2 \times 10^{-4}$	$8,1 \times 10^{-3}$

TABLEAU 2. Volumes molaires apparents à différentes molalités du TTA dans le mélange eau−KCl 2 *M*

Molalité (mol kg^{-1})	ρ (g cm^{-3})	ϕ (cm^3 mol^{-1})
0	1,086633	—
0,0318	1,085924	328,61
0,0499	1,085524	328,74
0,0636	1,085219	328,83
0,0731	1,085017	328,76
0,0829	1,084803	328,81
0,1450	1,083499	328,82

favorise, en règle générale, le phénomène de micellisation, ce qui se traduit par un abaissement de la valeur de la cmc (10).

La technique de détermination des volumes molaires apparents mise en oeuvre dans cette étude, nécessite l'emploi d'une concentration minimale de soluté égale à 10^{-2} mol kg^{-1} (11). À cette concentration les tensioactifs utilisés, qui possèdent déjà dans l'eau des seuils critiques micellaires relativement faibles (tableau 1), se trouvent pour la plupart partiellement ou même totalement micellisés en présence de l'électrolyte support. À titre d'exemple, les variations des volumes molaires apparents du dTA en fonction de la molalité en détergent, pour différentes teneurs de la solution en chlorure de potassium, sont reportées sur la fig. 1. On peut ainsi constater que même pour la plus faible concentration de KCl utilisée, 5×10^{-1} mol L^{-1}, le dTA à 10^{-2} mol kg^{-1} est déjà partiellement associé.

Il n'est donc pas envisageable d'étudier, au moyen de la technique de mesure précédemment décrite, le comportement des amphiphiles sous leur forme monomère dans les mélanges eau−KCl.

En revanche, l'utilisation d'une concentration suffisante en détergent permet d'obtenir des systèmes *totalement micellisés* pour lesquels les propriétés physicochimiques des amphiphiles sont parfaitement définies.

C'est dans ce cadre précis que s'inclut la présente étude.

II-2. *Volumes molaires apparents des bromures d'alkyltriméthylammonium micellisés*

II-2.1. *Variations avec la molalité du tensioactif*

Les résultats expérimentaux regroupés dans le tableau 2 et illustrés par ailleurs sur la fig. 2 montrent que *dans un milieu eau−KCl donné*, une fois le système totalement micellisé, les volumes molaires apparents des détergents, de la même manière que ceux des halogènures alcalins (1), sont indépendants de leur molalité dans la gamme de concentration utilisée ($m < 3 \times 10^{-1}$ mol kg^{-1}). On pourra donc caractériser le détergent micellisé par un volume molaire apparent ϕ_m correspondant à cette valeur constante.

II-2.2 *Variations avec la concentration en KCl*

Les valeurs moyennes des volumes molaires apparents ϕ_m pour les différents détergents étudiés, à plusieurs concentrations en chlorure de potassium sont regroupées dans le tableau 3. On remarque que ces valeurs varient très peu, pour un tensioactif donné, avec la teneur de la solution en KCl. À titre de comparaison, les variations de ϕ_m pour les quatre détergents cationiques, et celles des volumes molaires apparents à dilution infinie de deux autres électrolytes KBr et $(C_4H_9)_4NBr$ sont représentées sur la fig. 3. La différence de comportement entre ces deux derniers sels a été justifiée dans une étude précédente (2).

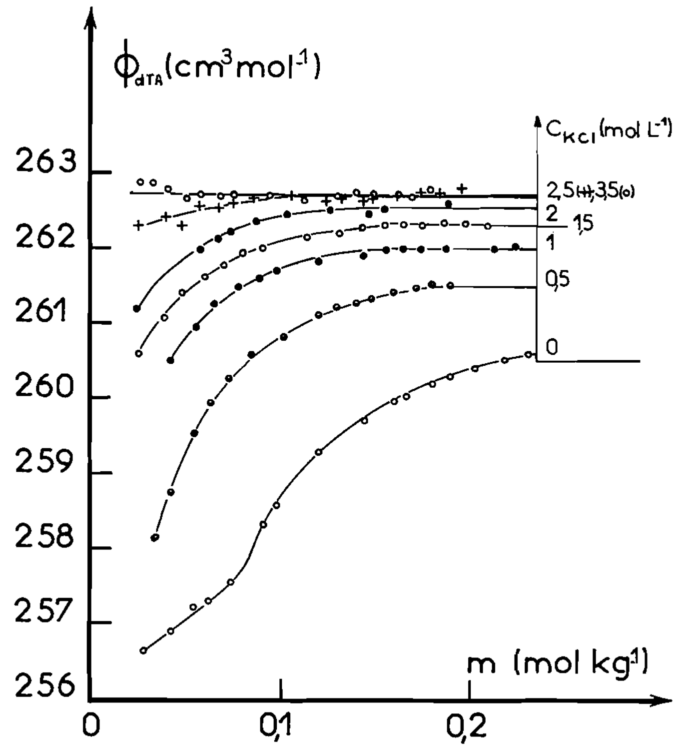

FIG. 1. Variations du volume molaire apparent du dTA avec sa molalité pour différents mélanges eau−KCl.

Les mesures réalisées avec le DSNa et le DTA dans les mélanges eau−NaCl seront évoquées ultérieurement dans le chapitre consacré à l'interprétation des résultats.

II-3. *Discussion des résultats*

La modification des propriétés structurales des systèmes micellaires, en présence de quantités variables de sel a fait l'objet de nombreux travaux et une littérature abondante existe actuellement sur ce sujet (6−9).

Nous en retiendrons les conclusions suivantes en rapport avec notre étude:

A. La création d'édifices micellaires dans l'eau pure conduit à l'apparition en solution de structures comportant un nombre élevé de charges identiques. Pour des raisons électrostatiques évidentes la majeure partie des contre-ions se trouve située dans l'environnement immédiat de la micelle.

La répartition des contre-ions s'effectue selon une loi de distribution radiale continue, partant d'une forte concentration près de la surface de la micelle qui décroit régulièrement lorsque l'on s'en éloigne (12,13).

Ce phénomène de "surconcentration" au voisinage de l'inter-

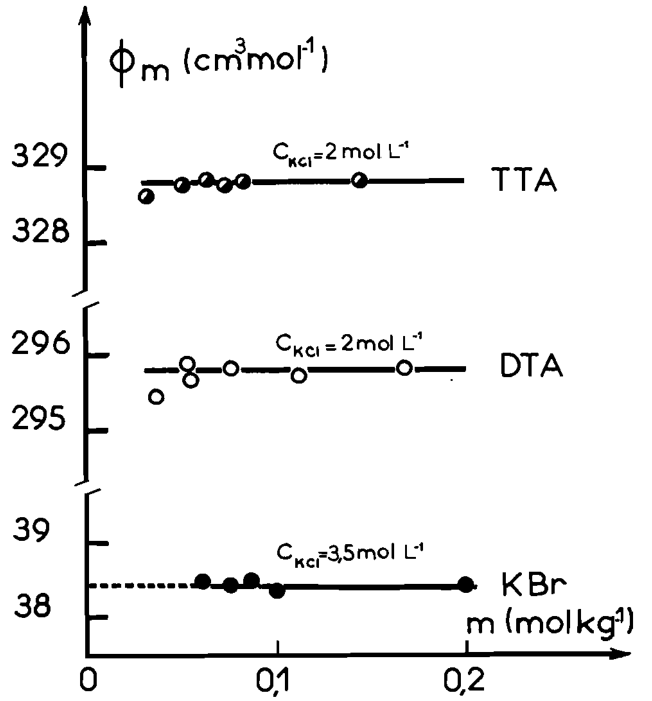

FIG. 2. Variations en fonction de leur molalité des volumes molaires apparents des détergents micellisés dans le mélange eau−KCl 2 *M* et de KBr dans le milieu 3,5 *M* en KCl.

TABLEAU 3. Valeurs des volumes molaires moyens ϕ_m des détergents micellisés dans les mélanges eau−KCl à 298 K

	Détergent			
C_{KCl} (mol L^{-1})	dTA	DTA	TTA	HTA
0	260,1	294,5	328,0	360,8
0,5	261,5	295,2	—	361,4
1	262,0	295,7	328,8	—
1,5	262,4	—	—	—
2	262,6	295,8	328,8	—
2,5	262,7	295,8	328,8	—
3	262,7	295,8	328,8	—
3,5	262,7	295,8	328,8	—

face micelle−solvant peut être traité au moyen d'un concept d'association qui suppose des contre-charges "liées" à la micelle au niveau de sa surface par l'intermédiaire d'un équilibre d'échange (14).

Cependant, la notion de "liaison" dans ce type de modèle doit être prise au sens large car elle n'implique pas l'existence de sites spécifiques sur la micelle pour le rattachement des contre-ions (15). Il en résulte que l'on ne différenciera pas au niveau de leurs propriétés thermodynamiques et en particulier de leurs volumes molaires partiels, les contre-ions qui se "fixent" sur la micelle des autres ions de la solution, cette séparation étant essentiellement formelle.

Lorsque l'on ajoute à ces solutions une quantité importante d'électrolyte, on modifie notablement la répartition des contre-ions dans l'environnement des édifices micellaires. Deux cas peuvent alors se présenter:

(a) L'électrolyte possède le même contre-ion que le détergent (ajout par exemple du sel M^+Y^- à une solution de détergent cationique T^+Y^-).

Cette opération a pour conséquence d'augmenter la concen-

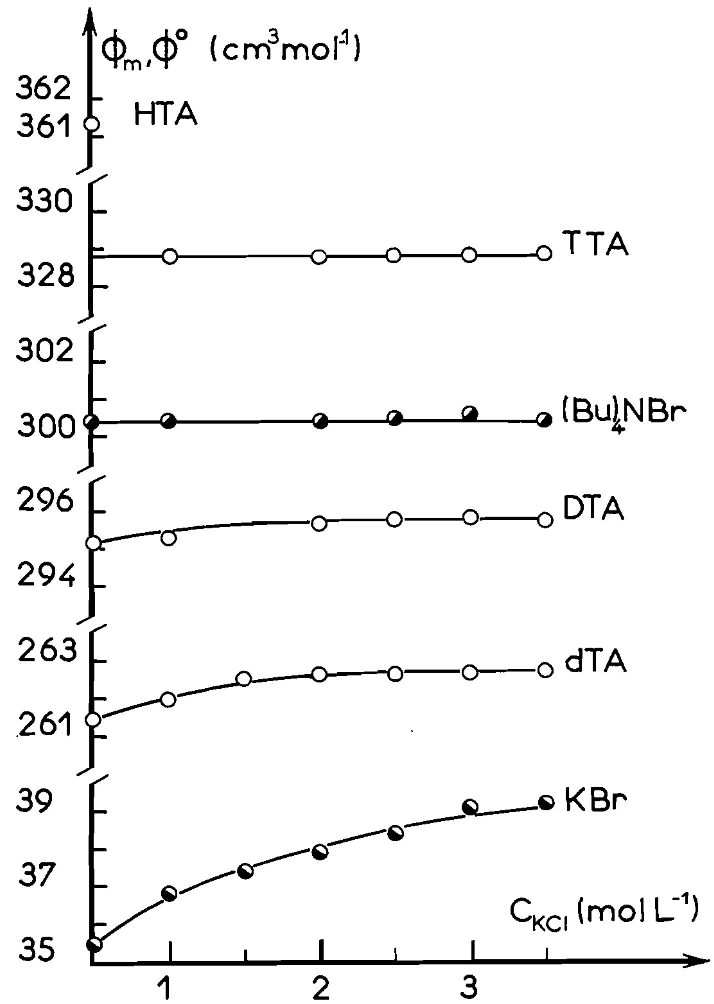

FIG. 3. Variations des volumes molaires apparents moyens ϕ_m des détergents micellisés et des volumes molaires apparents à dilution infinie ϕ^0 de KBr et $(Bu)_4NBr$ (bromure de tétrabutylammonium) dans les mélanges eau−KCl.

tration des ions Y^- dans l'environnement immédiat de la micelle. Ceci peut se traduire dans le concept de l'équilibre d'association par un déplacement de l'équilibre d'échange (contre-ions associés ⇌ contre-ions libres) vers la forme associée, ce qui correspond à une saturation en contre-ions de l'interface micelle−solvant.

Ce phénomène dont la conséquence est un affaiblissement des répulsions électrostatiques entre les "têtes" polaires des amphiphiles de la micelle est à l'origine de l'abaissement du seuil critique micellaire (16).

(b) L'électrolyte possède un contre-ion différent (par exemple l'ajout du sel M^+X^- à une solution de détergent cationique T^+Y^-).

Les ions X^- introduits tendent à participer, en concurrence avec les ions Y^-, à l'électroneutralité des édifices micellaires. Divers travaux (17−20) montrent que la répartition des ions dans le proche environnement de la micelle n'est pas controlé exclusivement par le facteur entropique, mais qu'il faut également prendre en compte la nature chimique des contre-ions.

Dans le cadre du concept de l'équilibre d'association, on considère qu'il s'établit un équilibre d'échange entre les ions X^- et Y^- plus ou moins déplacé vers l'une ou l'autre des deux formes associées (T^+,X^- et T^+,Y^-) selon la *sélectivité* relative de la micelle pour les ions X^- et Y^-.

Toutefois, en présence de fortes quantités d'électrolyte MX il se crée, par simple "effet de masse", un environnement de la micelle constitué presque exclusivement d'ions X^-.

On peut ainsi admettre que les édifices micellaires cationiques en présence de KCl à forte concentration sont associés aux ions chlorure, même si à l'origine les détergents comportaient un contre-ion différent (Br^-).

Les remarques précédentes permettent d'interpréter les propriétés des détergents cationiques dans les milieux eau−KCl et en particulier le fait que leur volume molaire apparent ϕ_m ne dépend pas de leur molalité. Ce comportement est identique à celui observé pour les halogènures alcalins mais sa justification en est différente. En effet dans le cas d'un sel minéral P^+Y^- introduit dans une solution concentrée eau−KCl, il est légitime de considérer qu'aux faibles concentrations les ions P^+ et Y^- se comportent dans le milieu comme des entités indépendantes (pas d'interactions P^+-P^+, P^+-Y^-, Y^--Y^-) (2) et en conséquence que les propriétés de ces ions peuvent être décrites par les lois des solutions diluées. La valeur du volume molaire apparent de PY est alors constante tant que la concentration du sel reste faible devant celle de l'électrolyte support. Elle s'identifie alors à sa valeur extrapolée à dilution infinie.

[1] $\phi^0_{PY} = \phi^0_{P^+} + \phi^0_{Y^-}$

Dans le cas des tensioactifs, au contraire, les cations T^+ sont agrégés sous forme d'édifices micellaires et seuls les contre-ions Y^- peuvent être supposés sans interactions réciproques tant que la concentration en détergent reste faible.

La valeur constante observée indique donc, selon toute vraisemblance, que l'intensité des interactions entre les amphiphiles T^+ eux-mêmes dans l'édifice micellaire, mais également entre T^+ et Cl^- ne varie pas lorsque la concentration du tensioactif augmente.

B. Lorsque la concentration de l'électrolyte support croit, la structure de l'édifice micellaire se modifie. La configuration initialement sphérique évolue selon la nature du détergent vers des structures de symétrie moindre (15).

Toutefois au cours des ces modifications, les interactions entre les têtes polaires des amphiphiles et les constituants du solvant ne sont pas fondamentalement modifiées, pas plus d'ailleurs que celles qui existent entre les chaînes aliphatiques regroupées au coeur de la micelle. Il faut donc s'attendre à ce que ces modifications n'entrainent pas de variations notables des volumes molaires apparents des amphiphiles micellaires.

L'indépendance des valeurs de ϕ_m, avec la concentration en KCl confirme cette hypothèse. Il a été en effet montré dans une étude précédente que les volumes molaires apparents individuels à faible concentration des halogénures Y^- s'identifiaient à leurs volumes intrinsèques ceux-ci étant eux-mêmes reliés à leurs volumes cristallins (calculés à partir des rayons de Pauling) par l'équation:

[2] $\phi_{Y^-} = V^I_{Y^-} = 1{,}92\ V^C_{Y^-}$

Les volumes molaires apparents ϕ_m des détergents T^+Y^- étant indépendants de la concentration en KCl, ϕ_{Y^-} l'étant également, il en est nécessairement de même pour les amphiphiles T^+.

Les valeurs de ϕ_m (T^+) ne varient donc pas avec la teneur de la solution en chlorure de potassium.

III. Exploitation des résultats

Une précédente étude sur le comportement des bromures de tétraalkylammonium symétriques ($(CH_3(CH_2)_x)_4NBr$) a permis

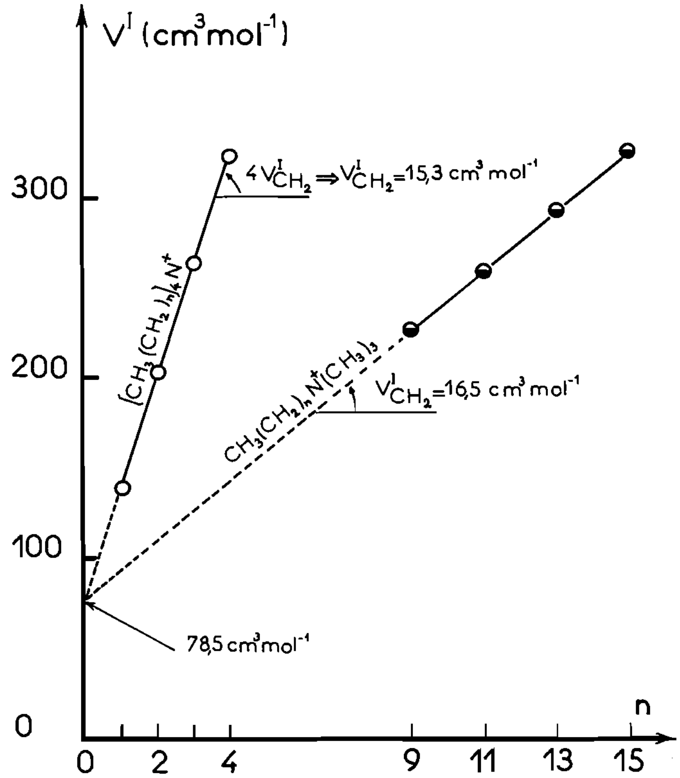

FIG. 4. Variations des volumes intrinsèques des amphiphiles micellisés $CH_3(CH_2)_nN^+(CH_3)_3$ et des volumes intrinsèques des tétra-alkylammonium $(CH_3(CH_2)_x)_4N^+$ en fonction de n ou x.

de montrer que les volumes molaires apparents des ions organiques de grande taille ($x > 2$) pouvaient être identifiés à leur volume intrinsèque en solution saline concentrée (2).

L'indépendance de ϕ_m (T^+) avec la concentration en KCl laisse supposer qu'il doit en être de même pour l'amphiphile dans l'édifice micellaire. S'il est ainsi, on peut alors écrire:

[3] $\phi_m(T^+,Br^-) = \phi_m(T^+) + \phi_{Br^-} = V^I_{T^+} + \phi_{Br^-}$

soit encore en utilisant la relation [2]:

[4] $V^I_{T^+} = \phi_m(T^+,Br^-) - 1{,}92\ V^C_{Br^-}$

Les amphiphiles étudiés appartenant à une même famille de composés $CH_3(CH_2)_nN(CH_3)_3$ (n = 9, 11, 13 et 15), il est possible de scinder leur volume intrinsèque en deux contributions: V^I_g relative au groupement polaire $(CH_3)_4N^+$, et $nV^I_{CH_2}$ relative aux n groupements CH_2 constituant la chaîne aliphatique, en supposant que chacun d'entre eux possède des propriétés voisines ($V^I_{CH_2}$).

Le volume intrinsèque de T^+ s'écrit alors:

$$V^I_{T^+} = V^I_g + n\ V^I_{CH_2}$$

soit:

[5] $V^I_{T^+} = \phi_m(T^+Br^-) - 1{,}92\ V^C_{Br^-} = V^I_g + n\ V^I_{CH_2}$

Les valeurs de $V^I_{T^+}$ ont été calculées pour les quatre détergents cationiques (tableau 4) et reportées en fonction de n sur la fig. 4. Le graphe représentatif est une droite de pente $V^I_{CH_2}$ = 16,5 cm^3 mol^{-1} et d'ordonnée à l'origine V^I_g = 78,5 cm^3 mol^{-1}.

Le volume intrinsèque de l'amphiphile $CH_3(CH_2)_nN^+(CH_3)_3$ s'écrit donc:

TABLEAU 4. Volumes intrinsèques des amphiphiles micellisés dans les milieux salins concentrés eau–KCl ($V^{I}_{Br^-}$ = 35,9 cm^3 mol^{-1})

	Détergent			
	dTA	DTA	TTA	HTA
$V^{I}_{T^+}$ (cm^3 mol^{-1})	226,8	259,9	292,9	~326

TABLEAU 5. Volumes molaires moyens de NaDS et DTA micellisés et volumes molaires apparents de NaCl et NaBr dans les mélanges eau–NaCl

	Electrolyte			
C_{NaCl} (mol L^{-1})	NaBr	NaCl	NaDS	DTA
0	23,5	16,6	249,8	294,5
0,25	25,0	17,9	250,9	295,2
0,5	25,6	18,4	251,5	295,3
0,75	26,0	19,0	252,0	295,3

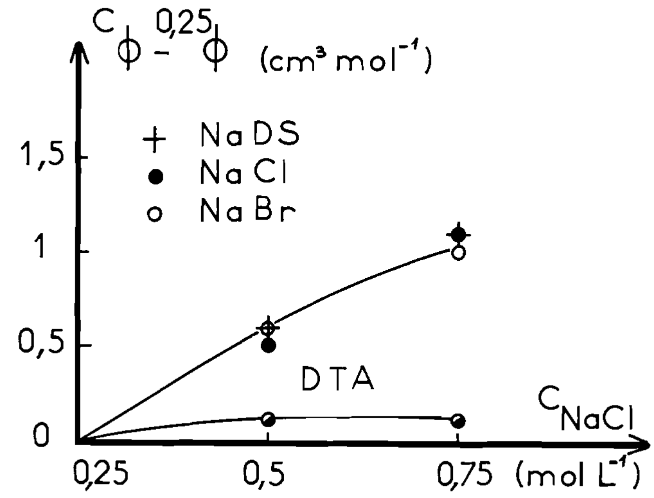

FIG. 5. Variations des volumes molaires moyens de NaDS et DTA et des volumes molaires apparents de NaCl et NaBr dans les milieux eau–NaCl à 298 K.

[6] $V^{I}_{T^+}$ (cm^3 mol^{-1}) = 78,5 + 16,5 n

La valeur trouvée pour le volume intrinsèque du groupement tétraméthylammonium (n = 0) s'identifie à celle que l'on calcule pour *l'ion tétraméthylammonium* à partir du rayon ionique proposé par Masterton *et al.* (r = 2,51 Å) (21) en appliquant la relation [2]. L'incrément de volume pour chaque CH_2 correspond à celui observé pour les alcanes purs ($8 < n < 14$) (22), laissant ainsi supposer que l'association des chaînes aliphatiques au sein de l'édifice micellaire conduit à la constitution d'un "milieu interne" dont les propriétés s'apparentent à celles des carbures saturés.

Cet incrément est nettement supérieur à celui que l'on détermine dans ce mêmes milieux pour les ions ammonium quaternaires symétriques $(CH_3(CH_2)_x)_4N^+$ pour lesquels les CH_2 possèdent un environnement aqueux (23). La représentation des variations du volume intrinsèque des cations ammonium en fonction de x conduit au tracé d'une droite de pente égale à $4V^{I}_{CH_2}$ et d'ordonnée à l'origine V^{I}_{g} relatif au même groupement tétraméthylammonium (fig. 4). On obtient:

$$V^{I}_{g} = 78{,}5 \text{ cm}^3 \text{ mol}^{-1}$$

$$V^{I}_{CH_2} = 15{,}3 \text{ cm}^3 \text{ mol}^{-1}$$

Même si l'on tient compte de la faible précision des extrapolations, il est à noter que l'on retrouve pour cette famille de composés, une valeur identique à la précédente pour le volume intrinsèque du groupement $(CH_3)_4N^+$, ce qui semble justifier les partitions des volumes telles qu'elles ont été réalisées.

La différence de volume intrinsèque observée entre les groupements —CH_2— selon qu'ils possèdent un environnement ionique aqueux ou hydrophobe est à l'origine du phénomène d'expansion lié à la micellisation qui apparaît ainsi comme une conséquence du changement d'environnement de la partie hydrophobe du détergent (24, 25).

Cas d'un détergent anionique: le dodécylsulfate de sodium

L'influence des électrolytes sur les micelles de NaDS et entre autres, les variations de la cmc avec la teneur en sel ont fait l'objet de nombreux travaux (26–29). Dans le cas du sel NaCl, il a été établi que le volume des micelles et donc leur rayon, ne varie que très faiblement (27) tant que la concentration de l'électrolyte reste inférieure à 0,45 mol L^{-1} (26,28). Au delà de cette limite la forme sphérique évolue vers une forme cylindrique (28) dont la stabilité a pu être étudiée thermodynamiquement (29). Toutefois, comme nous l'avions fait remarquer précédemment, il est probable que cette transition n'affecte pas de manière notable les volumes molaires partiels des amphiphiles et l'on pourra considérer que le volume molaire apparent de l'ion dodécylsulfate (DS^-) reste identique à son volume intrinsèque, c'est-à-dire invariant avec la teneur de la solution en électrolyte support dès que celle-ci est suffisamment importante. Il n'en sera pas de même, en revanche, pour le volume molaire apparent individuel du cation associé puisque celui-ci varie avec la teneur de la solution en électrolyte support (2). Il s'ensuit que contrairement aux détergents cationiques, il faille s'attendre à observer pour les anioniques une variation de leur volume molaire apparent avec la concentration du sel de fond.

Pour des raisons de solubilité, nous n'avons pas pu étudier le comportement de NaDS dans les mélanges eau–KCl. La vérification des hypothèses précédentes a donc été tentée dans les mélanges eau–NaCl entre 0,25 et 0,75 molaire en chlorure de sodium où nous avons étudié à titre de comparaison les volumes molaires partiels de NaDS, NaBr, NaCl, $C_{12}H_{25}N(CH_3)_3Br$.

Les résultats expérimentaux sont regroupés dans le tableau 5. Comme on peut le remarquer sur la fig. 5, le volume molaire apparent du détergent cationique est indépendant de la concentration de la solution en NaCl, alors que l'on assiste à des variations tout à fait comparables pour NaDS, NaCl et NaBr, dues essentiellement au comportement particulier de l'ion sodium.

Le volume molaire intrinsèque attribuable à l'ion dodécylsulfate est de l'ordre de 262 cm^3 mol^{-1}. Cette valeur est tout à fait comparable avec celle calculée pour le volume intrinsèque de l'amphiphile cationique, ayant même chaîne aliphatique $(CH_3(CH_2)_{11}N(CH_3)_3^+)$ qui est de l'ordre de 260 cm^3 mol^{-1}.

Ces résultats confirment les rôles dissymétriques joués par les cations et les anions dans les solutions salines concentrées.

La connaissance des valeurs des volumes intrinsèques des amphiphiles micellisés (anioniques ou cationiques) dans les mélanges eau–sel permet également d'estimer de manière précise la contribution volumique de la phase micellaire au volume total de la solution.

One-electron properties of HNO

J. ESPINOSA GARCÍA, A. LÓPEZ PIÑEIRO, AND F. J. OLIVARES DEL VALLE
Department of Physical Chemistry, University of Extremadura, Badajoz, Spain

Received May 31, 1984[1]

J. ESPINOSA GARCÍA, A. LÓPEZ PIÑEIRO, and F. J. OLIVARES DEL VALLE. Can. J. Chem. **63**, 2482 (1985).

SCF one-electron property calculations are reported for the nitroxyl molecule, using several types of Gaussian basis sets. An assessment is made of the size and type of basis set necessary to yield values for various one-electron properties that approach the best calculated or experimental results. The charge distribution is not improved by including the Gaussian lobe functions.

J. ESPINOSA GARCÍA, A. LÓPEZ PIÑEIRO et F. J. OLIVARES DEL VALLE. Can. J. Chem. **63**, 2482 (1985).

Utilisant plusieurs ensembles de base de type Gaussiens, on a effectué des calculs en champ auto-cohérent relatifs aux propriétés à un électron de la molécule de nitroxyle. On a évalué la dimension et le type d'ensemble de base nécessaire pour obtenir les valeurs de diverses propriétés à un électron qui se rapprochent le plus des résultats expérimentaux. L'inclusion des fonctions de lobe de type Gaussien n'affecte pas la distribution des charges.

[Traduit par le journal]

Introduction

The electronic structure of the nitroxyl molecule, HNO, in the ground and low-lying electronic states has been relatively well studied from an experimental (1, 2) and theoretical point of view (3). This system has been postulated as an intermediate in various photochemical and free radical reactions (2) although there is no clear evidence for the existence of free HNO. Furthermore, its structure and many of its physical and chemical properties are unknown.

Previously the study of the HNO system has been performed fundamentally on the geometry and excited states. However, the study of electronic structure and properties of the ground state has not been performed with suitable emphasis. Also, though the main characteristic of this system is its instability, HNO can form hydrogen bonded systems of an appreciable stability. In a previous work[2] this type of association has been studied.

As to the one-electron properties of HNO, very few experimental data exist (4), and no "*ab initio*" studies.

In the present paper, we report the one-electron properties for this system, analyzing the influence of the basis set. However, unfortunately it is impossible to compare our results for the HNO molecule, and we have to use a test molecule: water. Some experimental values of its one-electron properties are well determined (5), and numerous "*ab initio*" calculations have been performed. (There are several SCF computations on water. We note, among others, the ones quoted in ref. 6.)

Theoretical approach, basis set, geometry and related questions

RHF-SCF-LCAO-MO calculations were carried out using the POLYATOM V-2 (7) and GAUSSIAN 70 (8) program systems. One-electron properties were computed using the available programs as part of the POLYATOM system.

In this paper three types of Gaussian basis sets have been used: (*a*) *extended basis set* (BDZ (9, 10), DUNNING I (11), DUNNING II (12)); (*b*) *extended basis set with polarization functions*, and (*c*) *extended basis set with polarization functions and Gaussian lobe functions (13) centered off the nuclei.*

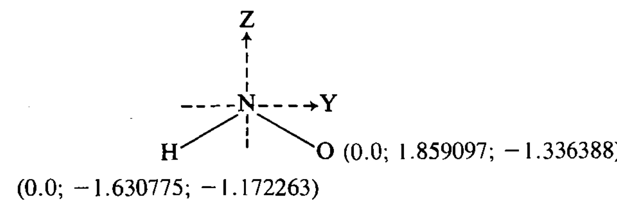

FIG. 1. Geometry and coordinates system for nitroxyl (in au).

For O and N we chose the Huzinaga and Sakai (9) basis set. This basis set includes thirteen *s*-type Gaussians and seven *p*-type Gaussians, contracted to double zeta (DZ), according to the notation {4,4,3,2;4,3}. For the hydrogen atom the basis set put forward by Basch, Robin, and Kuebler (10) has been used: four *s*-type Gaussian functions contracted to two of three and one, respectively, are used to describe the $1s$ atomic orbital (BDZ).

To study the effect of the contraction we have used the DUNNING I and II bases, which can be considered of DZ quality. Also, $3d$-type functions have been included on oxygen and nitrogen, and $2p$-type functions on hydrogen (BDZP) in order to study the effect of polarization functions.

Furthermore, the effect of the inclusion of Gaussian lobe functions, consisting of $1s$-type functions centered on the bond (BDZPL1) and the center of mass (BDZPL2) of the molecule, have also been considered.

We have used the experimental geometry for H_2O (14) and HNO (15): R(N—O) = 2.289580 au, R(N—H) = 2.008390 au and $\angle$HNO = 108.58°. See coordinate system for HNO in Fig. 1.

By convention, the multipole moments are computed relative to the center of mass of the molecule (0.0, 0.906928, − −0.727563).

Results and discussions

As numerous results exist for water (5, 6), we simply summarize, for "calibration" purposes, the values of various properties calculated with different basis sets and the corresponding experimental values in Table 1. One of the main observations that can be made is that the calculated second moments appear to agree very well with the experimental value. The results indicate that the constructed wavefunctions are remarkably successful in all cases. This is so because the second moment of the electronic distribution represents a very insensitive measure

of the details of the electronic distribution. Even assuming all electrons to be at atomic centers may give a gross agreement with experimental values (16). However, the calculation of this property for systems for which no experimental data exist may be potentially useful.

The SCF energy and some one-electron properties of HNO are shown in Table 2. The greater flexibility of the BDZP basis with respect to BDZ is reflected in the lower E_{SCF} of the former, −129.8143 au versus −129.7344 au. However, the inclusion of Gaussian lobe functions is less critical, and the energetic improvement is small. The dipole moments calculated from the double zeta basis sets are greater than the available experimental values. However, the BDZP basis set gives the smallest values. All calculated wavefunctions yielded the correct direction for the dipole moment (4).

The second moment values indicate a general increase in the size of the electronic distribution in the z direction with an increasing number of PGTF in the bases.

For the quadrupole moment of H_2O, amongst the double zeta bases the DUNNING I or DUNNING II values are better than the Huzinaga basis. We hope, that for HNO this result will be as valid as for H_2O. The effects of polarization functions provide a strong reduction in the magnitude of the dipole and quadrupole moments.

The total electric fields at nitrogen, oxygen, and hydrogen for nitroxyl are sensitive to the basis sets and to the contraction scheme. The sums of the Hellmann−Feynman forces for the DUNNING I and II bases, for example, indicate that the latter is the best from the point of view of the accuracy of the computed electric fields.

The computed components of the electric field gradient tensors at ^{14}N, ^{17}O, and at ^{2}H are collected in Table 3 for the cartesian coordinate system. Given the nuclear quadrupole moments of the nuclei the accuracy of the computed field gradient may be determined by comparing the constants (eQq/h) with the experimentally measured values. The nuclear quadrupole moment of ^{14}N was assumed to be 1.6×10^{-26} esu cm^2 (16), the nuclear quadrupole moment of ^{17}O, -2.6×10^{-26} esu cm^2 (6), and the nuclear quadrupole moment of ^{2}H, 0.28×10^{-26} esu cm^2 (6) in order to calculate the quadrupole coupling constants (Table 3). The electric field gradients for H are less sensitive to the basis set.

Finally, we have included $1s$ lobe functions in the BDZP basis set for comparing the effects which these functions produce. We observe that the values obtained for each of the one-electron properties are near to the values calculated with the BDZP basis set.

In conclusion, it seems that the calculated one-electron properties, where they can be compared with experimental results, fit in with these results quite reasonably. The inclusion of polarization functions has generally been found to lead to improvements in the one-electron properties calculated at a specific geometry.

Among the double zeta bases we can see that the contraction scheme is very important. Thus, the DUNNING I and II, with a smaller number of PGTF than the BDZ basis set of Huzinaga and Sakai, gives better results.

Although the BDZP with lobe functions (BDZPL1 and BDZPL2) are the best wavefunctions from an energetic point of view (only 0.0804 au above the Hartree–Fock limit), the charge distribution is not improved with respect to the BDZP basis set, and the time of calculation is much greater for the former.

The products of hydrolysis of cyclic orthoesters as a function of pH and the theory of stereoelectronic control[1,2]

PIERRE DESLONGCHAMPS, JEAN LESSARD, AND YVES NADEAU
Laboratoire de synthèse organique, Département de Chimie, Faculté des Sciences, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received November 23, 1984

PIERRE DESLONGCHAMPS, JEAN LESSARD, and YVES NADEAU. Can. J. Chem. **63**, 2485 (1985).

The acid hydrolysis of cyclic orthoesters **1**, **3–6** (R = Me), and **2** (R = Me and Et) as a function of pH was studied. The bicyclic orthoester **5** yields mainly the hydroxy-ester (less than 5% lactone), and this result is essentially independent of pH. For the other orthoesters, the relative percentage of products differs for each case and varies with pH. At pH $\leq$ 3, the percentage of lactone is always larger than at pH > 3. These results are explained on the basis of the stereoelectronic theory for the cleavage of tetrahedral intermediates.

PIERRE DESLONGCHAMPS, JEAN LESSARD et YVES NADEAU. Can. J. Chem. **63**, 2485 (1985).

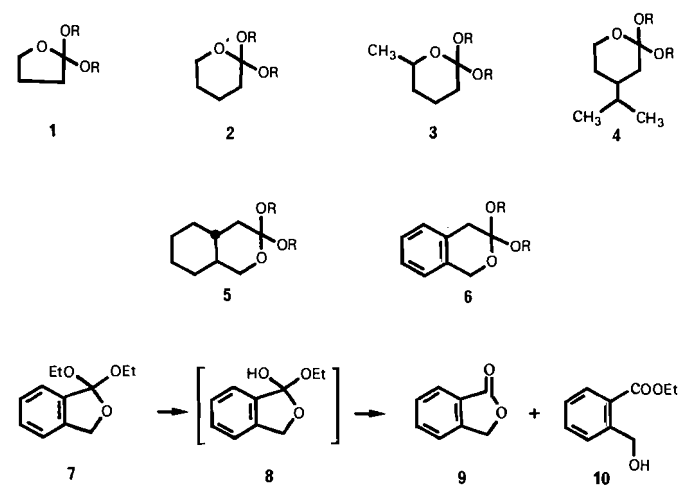
On a étudié l'hydrolyse acide des orthoesters cycliques **1**, **3–6** (R = Me) et **2** (R = Me et Et) en fonction du pH. L'orthoester bicyclique **5** donne principalement l'hydroxy-ester (moins de 5% de lactone) et ce résultat est indépendant du pH. Pour les autres orthoesters, le pourcentage relatif de produits de réaction est différent dans chaque cas et varie avec le pH. À pH $\leq$ 3, le pourcentage de lactone est toujours plus grand qu'à pH > 3. On explique ces résultats en tenant compte de la théorie du contrôle stéréoélectronique dans le bris des intermédiaires tétraédriques.

The mild acid hydrolysis under kinetically controlled conditions of the five cyclic orthoesters **1–5** (R = C_2H_5) (Scheme 1) was reported by our laboratory (3) in 1975. It was found that each orthoester gave essentially only the corresponding hydroxyester; the lactone, the other possible product of the reaction, was not observed in significant quantities.[3] These results were taken as convincing evidence in favor of the theory of stereoelectronic control in hydrolytic processes (3–7).

Capon and Grieve (8) have recently reported that part of the above results were erroneous.[4] They have studied 2,2-diethoxytetrahydropyran (**2**, R = C_2H_5) and found that under our reported conditions, 20–30% of δ-valerolactone was observed by ^{1}H and ^{13}C nmr spectroscopy. They have also investigated the mild acid hydrolysis of 2,2-dimethoxytetrahydropyran (**2**, R = CH_3) under a variety of solvents and, again, they found 30–40% of δ-valerolactone.

In the meantime, McClelland and Alibhai (9) reported (in 1981) the observation that the hydroxy-ester/lactone product ratio of **10** and **9** varies as a function of pH in the course of the acid hydrolysis of the phthalide orthoester **7**. Indeed, with this compound, a quantitative analysis of the pH-dependent product ratio reveals two pH-independent regions, corresponding to the acid and base-catalyzed breakdown of the tetrahedral hemi-orthoester intermediate **8**: at pH $\leq$ 3.5, 24% of lactone **9** is produced, but above pH 3.5, only 7% of lactone **9** (and some 93% hydroxy-ester **10**) is observed.

Due to the fact that (a) part of our results are not concordant with those of Capon and Grieve (8), and (b) product ratio varies above and below pH = 3.5 as discovered by McClelland and Alibhai (9), it became necessary to repeat our investigation, especially since in our original work the acid hydrolysis of **1–5** (R = C_2H_5) was carried out with an acidic solution having a pH of about 3 (10^{-3} *M* PTSA in water).



SCHEME 1

We wish now to report a product ratio study of the acid hydrolysis of cyclic orthoesters **1–6** (R = CH_3) and that of **2** (R = C_2H_5), as a function of pH. The results obtained are then rationalized on the basis of stereoelectronic principles.

Discussion

The results obtained are described in Table 1. All the cyclic orthoesters, except bicyclic orthoester **5**, show on hydrolysis two pH-independent regions for the product ratio, where the percentage of lactone is more important at pH $\leq$ 3 than at pH > 3. The bicyclic orthoester **5** behaved differently, yielding approximately 95% of hydroxy-ester between pH = 2 and 4.

The product ratio observed at pH = 4 and 5 in orthoester **2** (R = C_2H_5) is identical to the value that we originally obtained (3) by vpc analysis.[3] The product ratio observed at pH $\leq$ 3 for orthoesters **2** (R = CH_3 and C_2H_5) corresponds to the value observed by Capon and Grieve (8). The discrepancy between

[1] For general leading references on this subject, see refs. 1 and 2.

[2] Taken in part from the Ph.D. thesis of Y. Nadeau (December 1983).

[3] Analysis of the reaction products was carried out by two different methods: (a) ^{13}C nmr spectroscopy of the reaction mixture, which showed less than 1% of lactone, and (b) vpc analysis of the reaction mixture (after treatment with acetic anhydride and pyridine), which gave a ~5:95 ratio of lactone and the acetate derivative of the hydroxy-ester. Method (a) was believed to be more accurate, and it was concluded that the amount of lactone produced was negligible ($\leq$1%).

[4] We wish to thank Professor B. Capon who has communicated his results to us prior to publication.

TABLE 1. Product ratio of lactone (L) and hydroxy-ester (E) from the hydrolysis of cyclic orthoesters*

		pH 0.9	pH 1.9	pH 3	pH 4	pH 4.7
		L%/E%	L%/E%	L%/E%	L%/E%	L%/E%
	1	22:78	21:79	22:78	21:79	15:85
	2	19:81	21:79	26:74	6:94	4:96
	2	33:67	32:68	31:69	16:84	11:89

	3	10:90	10:90	9:91	<5:>95	<5:>95
	4	19:81	14:86	13:87	7:93	—
	5	—	6:94	<5:>95	<5:>95	—

*The pH values refer to the pH of D_2O/DCl solutions before the mixing with the solution of orthoester in hexadeuterated acetone (see Experimental).

our results (3) and those of Capon and Grieve (8) can now be explained. In our original work, the hydrolysis must have taken place at pH higher than 3. This is highly possible because the cyclic orthoesters were stored on solid anhydrous potassium carbonate to prevent decomposition. It is also possible that the 10^{-3} *M* *p*-toluenesulfonic acid solution used had a pH higher than 3. It should be pointed out that the pH of the acidic solution was not measured because it was not an important parameter at the time of the experiments. The second method of analysis which was originally used by us (^{13}C nmr)[3] indicated less than 1% of lactone, and this result was also very likely incorrect. The standard ^{13}C nmr chemical shift values that were originally used (3) for the reaction products, i.e., δ-valerolactone and the corresponding ethyl hydroxy-ester, are essentially identical to those used by Capon and Grieve (9). Therefore, the standard values used are not the source of error and we do not know why this method did not produce the correct percentage for the lactone products.

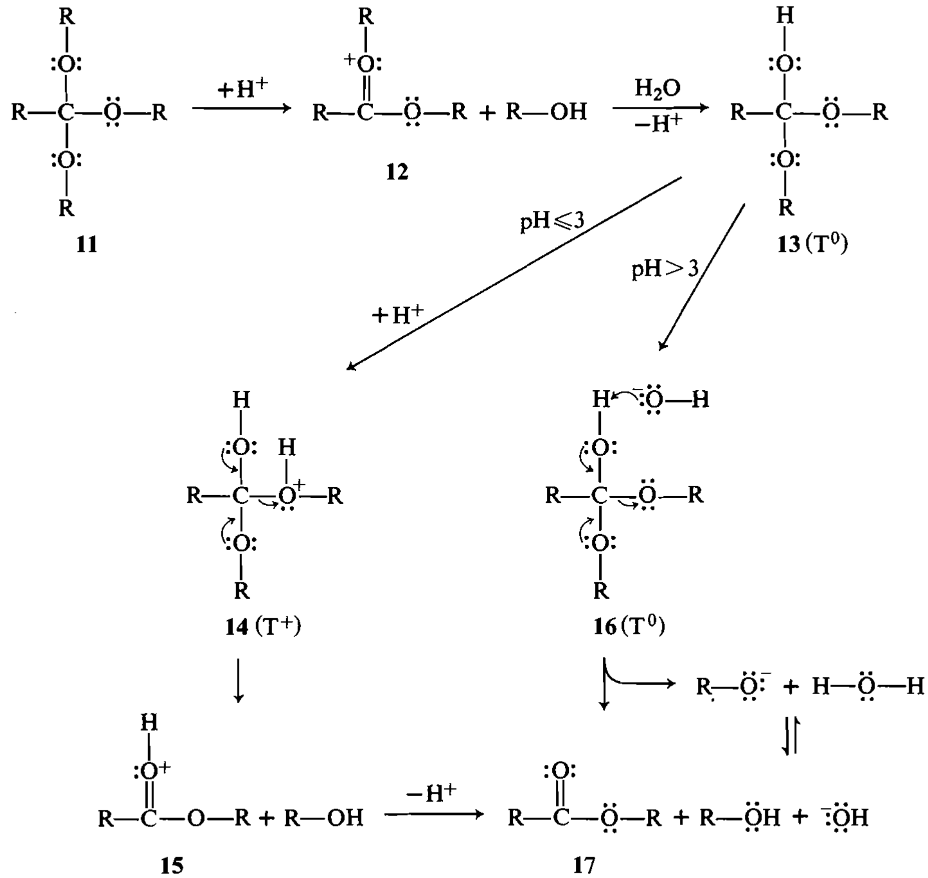
Before continuing the discussion of the results obtained with the various orthoesters, it is now appropriate to discuss the reaction mechanism of the hydrolytic process as a function of the acidity of the medium. The large difference in rates, and the variation in product ratios observed at pH $\leq$ 3 and at pH > 3, suggest a different reaction mechanism for the breakdown of the tetrahedral intermediate at high and low acid concentration. The hydrolysis of orthoesters takes place by first producing a dialkoxycarbonium ion (Scheme 2), which is then hydrated to give a hemiorthoester tetrahedral intermediate (**11** → **12** → **13**) (10). Then, following McClelland and Alibhai (9), the cleavage of the intermediate **13** at pH $\leq$ 3 would be acid catalyzed, whereas that at pH > 3 would be hydroxide catalyzed. As a result, the two mechanisms of breakdown differ in the following way: at pH $\leq$ 3, the ester (or lactone) is ejected in its protonated form, whereas at pH > 3 it is directly produced as a non-protonated neutral species. In other words, in the acid-catalyzed process, it is the T^+ ionic form of the tetrahedral intermediate which is cleaved, producing a protonated ester, whereas in the hydroxide-catalyzed process, it is the T^0 form which is cleaved, yielding a non-protonated ester. The acid and base-catalyzed processes can be expressed by the sequences **13** → **14** → **15** and **13** → **16** → **17** respectively. We would like to point out that when an intermediate or a product is protonated, the stereoelectronic effect of one electron pair has been essentially neutralized, and this factor must be taken into consideration in order to arrive at a correct understanding of the results.

The results can now be rationalized in terms of the stereoelectronic theory for the breakdown of tetrahedral intermediates,[5] which takes into account: item (a) primary and secondary (7) stereoelectronic effects, item (b) conformational change in tetrahedral intermediate prior to breakdown, and item (c) the ionic state of tetrahedral intermediates and reaction products as a function of pH.

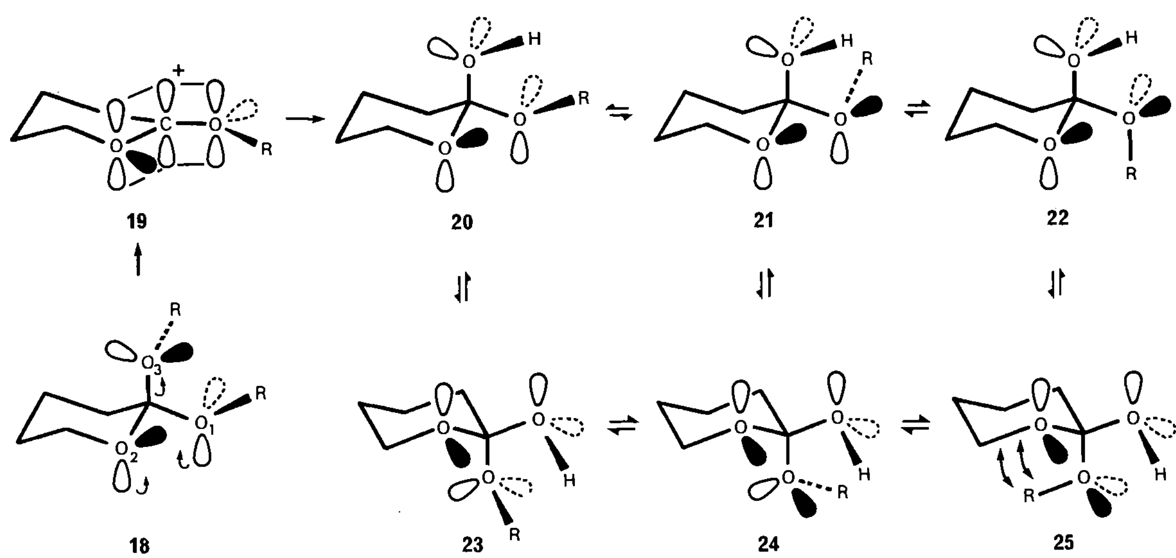
Items (a) and (b)

Primary and secondary stereoelectronic effects predict that a cyclic orthoester is best hydrolyzed via conformer **18** (conformer *A* in refs. 3 and 11; see also footnote 5) which gives first the *EZ* lactonium ion **19** followed by hydration to produce a

[5] See chapt. 3 in ref. 1 for a detailed analysis.



SCHEME 2



SCHEME 3

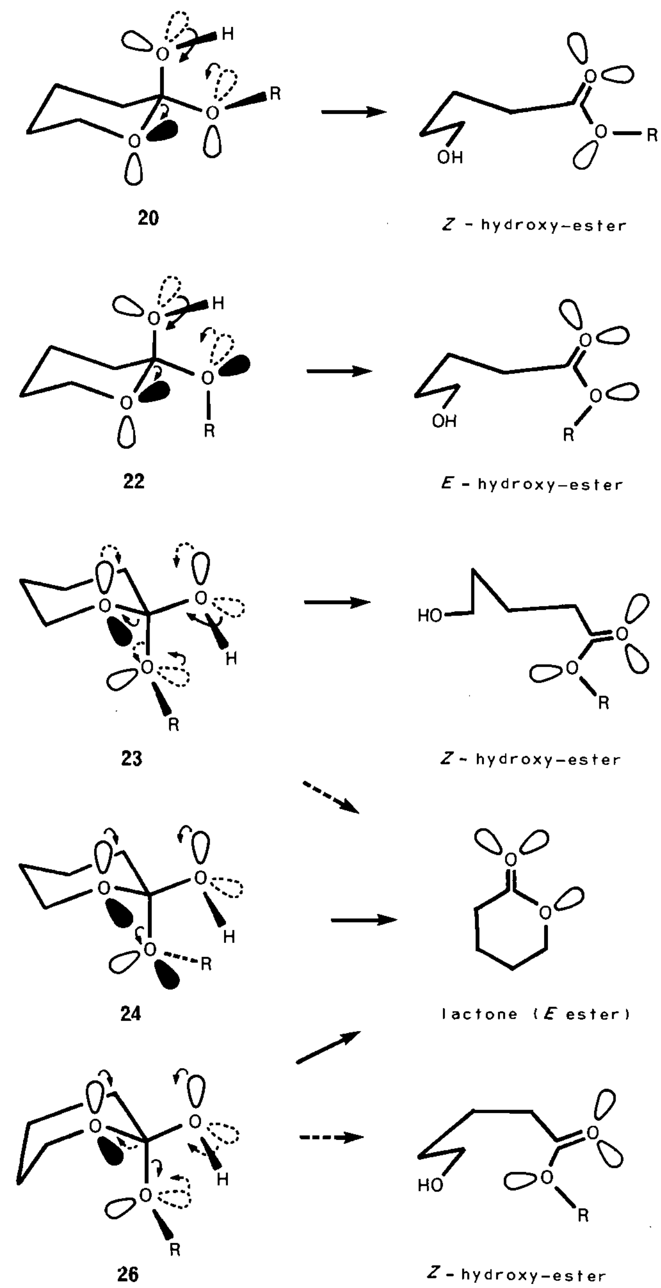
tetrahedral intermediate having conformation **20** (Scheme 3).[6] Since tetrahedral hemiorthoester intermediates have a definite lifetime under neutral or mild acid conditions (9, 12, 13), conformational equilibration then takes place to give either the three tetrahedral conformers **20**–**22** when the inversion of the chair form is not allowed or the six tetrahedral conformers **20**–**25** when chair inversion can take place with ease.

Conformer **21** cannot break down with primary stereoelectronic control (except to give back **19**), and conformer **25** is a relatively high energy conformer due to the severe steric interaction caused by the R group with the ring. These two conformers can therefore be eliminated from further consideration. The remaining four conformers **20**, **22**, **23**, and **24** can

[6] In conformation **18**, O1 and O2 each have one electron pair antiperiplanar to the axial C1—O3 bond (primary stereoelectronic effect), and O1 has one electron pair antiperiplanar to the C1—O2 bond (secondary stereoelectronic effect) (7). Thus, cleavage of the axial bond in **18** produces the *EZ* lactonium ion **19**. Following the same rule, addition of water on **19** must take place on the top face and yields a tetrahedral intermediate having the chair conformation **20**.

break down with primary stereoelectronic control. Conformers **20** and **22** can only give a hydroxy-ester, but having the *Z* and *E* configuration respectively (Scheme 4). Conformer **23** can either give the lactone or the hydroxy-ester in the *Z* conformation, whereas conformer **24** can only yield the lactone. Secondary stereoelectronic effects ease the formation of *Z* over that of an *E* ester (7). The cleavage of **20** is thus favored over that of **22**. Since lactones have the conformation of an *E* ester, formation of the hydroxy-ester in the *Z* conformation is thus electronically favored. On that basis, **23** would be more easily cleaved than **24** and would preferentially give the hydroxy-ester product. On the other hand, there is an entropy factor which favors the formation of lactone and alcohol. If this factor is as important as the secondary stereoelectronic effect, lactone formation can compete with that of the hydroxy-ester in the cleavage of **23**. On that basis, lactone formation from **24** should also be observed.[7]

Now, if we consider a cyclic orthoester (such as **2**) which can be assumed to undergo easily a conformational change via ring inversion, the following conclusion can be reached. The cation **19** will first produce **20**, which is then allowed to equilibrate to give a mixture of conformers **20**–**25**. Then, in principle, two different situations are possible. In the first one, secondary stereoelectronic effects completely overrule the entropy factor; as a result, breakdown would take place via conformers **20** and **23** yielding only the (*Z*) hydroxy-ester product. In the second situation, the secondary stereoelectronic effects cannot overrule completely the entropy factor, and breakdown could thus take place via conformers **20**, **23**, and **24**, conformer **20** yielding only the (*Z*) hydroxy-ester, conformer **23** a mixture of (*Z*) hydroxy-ester and lactone, and conformer **24** the lactone product only.[8] Thus, in the first situation, only the hydroxy-ester should be observed and, in the second, a mixture of hydroxy-ester and lactone would be expected.

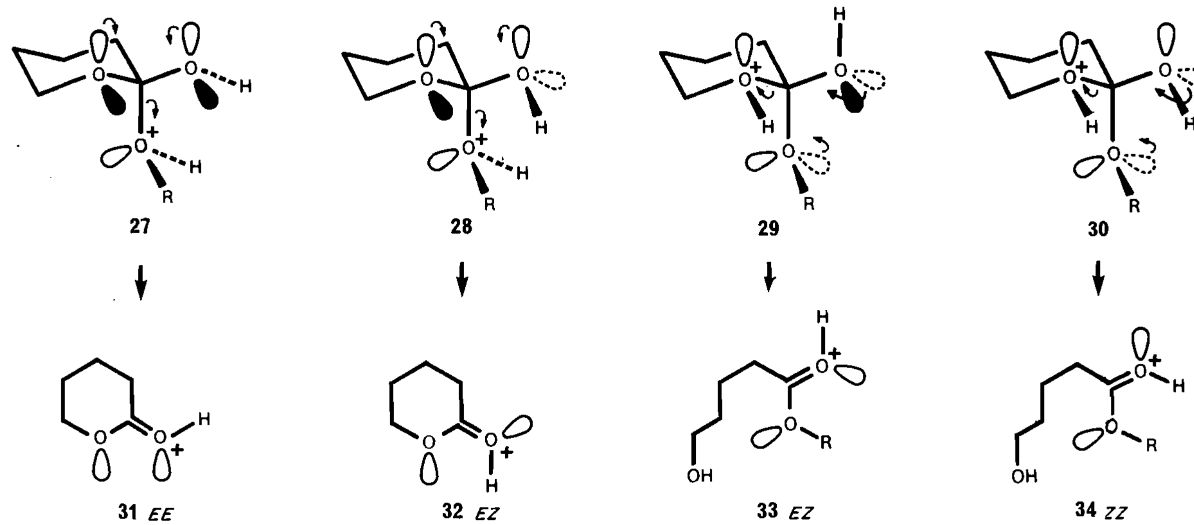


SCHEME 4

If a cyclic orthoester which cannot undergo a chair inversion (e.g. **5**) is now considered, the conclusion is the following. The cation **19** produces **20**, which is then allowed to equilibrate to give a mixture of conformers **20**–**22** only. We have already seen that with these three conformers, only **20** can break down, but to give a (*Z*) hydroxy-ester. On that basis, conformationally rigid ring orthoesters can only give the hydroxy-ester product. The only manner by which these types of orthoesters could give

[7] We have suggested (3) that the entropy release expected for a reaction involving fragmentation to give separate molecules favors the cleavage of lactone and alcohol. It was later pointed out by Kirby (see pp. 103–104 in ref. 2) that little entropy may have in fact been released by the time the transition state for C—O cleavage has been reached, and that another explanation, still based on entropy consideration, can be put forward: it involves the reversibility of ring opening in the first stage of the hydrolysis process, just before the first stable products (hydroxy-ester or lactone and alcohol) are formed. In the case of orthoesters, the first stage of the hydrolysis is the cleavage of T^+, producing (*in situ*) an R—OH group and a dialkoxycarbonium ion which are close to one another. Then two processes are possible; either the ROH group can add back on the dialkoxycarbonium ion, or the R—OH moves further away (conformational change) and becomes solvated, and concurrently the dialkoxycarbonium ion is trapped intermolecularly by water producing a hemiorthoester tetrahedral intermediate. When the ROH group is linked to the dialkoxycarbonium ion, intramolecular trapping of this ion may compete favorably with the intermolecular trapping of this ion by a molecule of solvent. With hemiorthoesters, cleavage can take place with the T^+ or the T^0 form. For the cleavage of the T^+ ionic form, the first stage is the production (nearby) of an ROH group and a protonated ester (or lactone). In the next step, either the ROH group adds back to the protonated ester or moves away and becomes solvated, and the protonated ester is concurrently deprotonated by the solvent. For the cleavage of the T^0 form, the first stage is the production (nearby) of the alkoxide ion and a non-protonated ester (or lactone). In the next step, either the alkoxide ion adds back to the ester, or moves away and becomes protonated and solvated. In both cases (T^+ or T^0), the reverse step will be more favored in an intramolecular than in an intermolecular situation. Thus, under conditions of kinetic control, i.e. when equilibration between the reaction products is not an important process, there is a factor based on entropy consideration which disfavors the formation of hydroxy-ester and favors the formation of lactone and alcohol. This effect will be referred in the text as the entropy factor.

[8] The formation of (*E*) hydroxy-ester from **22** should not be observed because this cleavage is disfavored by both the secondary stereoelectronic effects and by the entropy factor.



SCHEME 5

a mixture of hydroxy-ester and lactone, while respecting the stereoelectronic principles, is by undergoing a conformational change from a chair to a boat (or a twist-boat). For instance, conformer **20** could be transformed into the boat conformer **26** which can then break down to either a (*Z*) hydroxy-ester or the lactone (Scheme 4). In conclusion, orthoesters which cannot undergo a chair inversion are predicted to give mainly the hydroxy-ester because lactone formation can only occur via the cleavage of a tetrahedral intermediate having a boat conformation.[9]

Item (c)

The ionic state of tetrahedral intermediates and products as a function of pH must now be considered. The preceding discussion was concerned with cleavages of neutral tetrahedral intermediates yielding a non-protonated ester. This discussion and the conclusion reached can therefore be applied for cleavages occurring at pH > 3 (hydroxide-catalyzed breakdown of T^0 yielding a neutral ester product). It is, however, necessary to analyze the cleavages at pH ≤ 3 which take place on the T^+ form yielding a protonated product. This analysis can be done by examining the possible cleavages of the protonated forms of conformer **23** which can give either the hydroxy-ester or the lactone product. Appropriate conclusions then follow automatically for cleavages of the other intermediates **20**, **22**, and **24**.

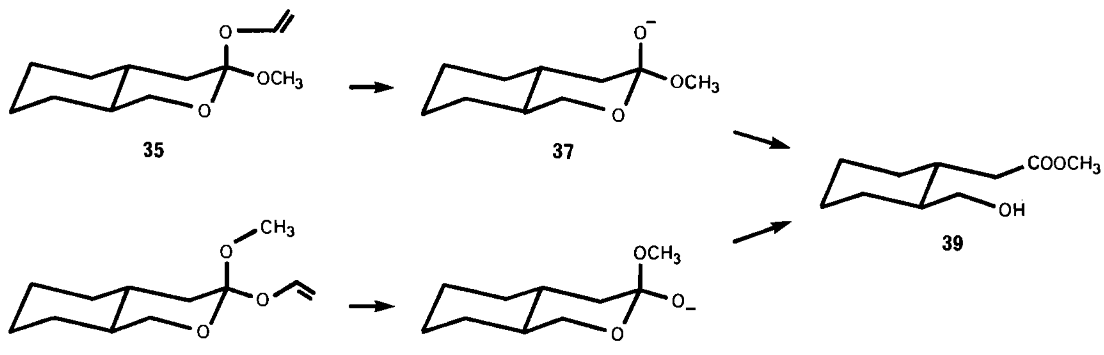
There are four different ways by which protonated conformer **23** can break down. They correspond to **27**, **28**, **29**, and **30** (Scheme 5) depending upon which oxygen is protonated[10] (axial or ring oxygen atom), and upon the orientation of the O—H bond of the equatorial oxygen atom. The first two possibilities, **27** and **28**, give the protonated lactone in the *EE* (**31**) and *EZ* (**32**) configurations respectively, whereas the other two, **29** and **30**, lead respectively to the *EZ* (**33**) and the *ZZ* (**34**) configurations of the protonated ester.

EZ Dialkoxycarbonium ions are more stable than the corresponding *EE* isomers (16). Secondary electronic effects predict the same relative stability for protonated lactones and predict also that the process **28** → **32** (*EZ*) is energetically favored over that of **27** → **31** (*EE*). Similarly, secondary stereoelectronic effects predict that in protonated esters, the *ZZ* configuration **34** is more stable than the *EZ* configuration **33**. These effects predict also that the *ZZ* configuration **34** should be preferentially formed over the *EZ* configuration **33**. However, rigorous experimental evidence on the most stable geometry for protonated esters is lacking (17). This hypothesis is, however, supported by theoretical calculation (18) and by the fact that carboxylic acids are known to preferentially exist as cyclic hydrogen-bonded dimers having the *ZZ* configuration (19). It is therefore assumed that the process **30** → **34** (*ZZ*) is more energetically favorable than that of **29** → **33** (*EZ*). Thus, at pH ≤ 3, formation of hydroxy-ester and lactone would take place via the processes **30** → **34** (*ZZ*) and **28** → **32** (*EZ*) respectively. The former process is favored by one additional secondary stereoelectronic effect. On this basis, it should take place preferentially over the other. On the other hand, the entropy factor works in the opposite direction, favoring the process **28** → **32** (*EZ*) rather than the process **30** → **34** (*ZZ*).

It is now important to compare the cleavage of T^+ with that of T^0. In both cases, the formation of hydroxy-ester is equally favored over the formation of lactone by secondary stereoelectronic effects. In both cases also, the entropy factor favors the formation of lactone and alcohol over that of hydroxy-ester. However, this factor may play a more important role in the cleavage of T^0 than in the cleavage of T^+, resulting in a relatively larger percentage of lactone and alcohol in the cleavage of T^+. This would be due to the fact that in the first stage of the hydrolysis, before formation of the final reaction products, the reverse step (i.e. the intramolecular attack of a hydroxyl group on a protonated ester to reform T^+) would take place with greater ease than the reaction of an alkoxide ion with both a non-protonated ester and a molecule of water to reproduce T^0. As a result, a larger percentage of lactone would be observed at pH ≤ 3 (breakdown of T^+) than at pH > 3 (breakdown of T^0).

[9] Cleavage via a boat conformer is expected to be a higher energy process than that of a chair conformer. It is, however, theoretically possible that the boat formation could lie on the reaction coordinate (e.g. see ref. 14), and this process could compete with the cleavage of the chair form. The experimental results show however that this is a minor process (*vide infra*, see also ref. 15).

[10] Stereochemistry of protonation of the leaving group oxygen in **27–30** could be different than the one chosen, but the conclusion would be the same.



SCHEME 6

Analysis of cyclic orthoesters ***1–6***

2,2-Diethoxytetrahydropyran (**2**, R = C_2H_5) is an orthoester which can easily undergo a chair inversion; its hydrolysis must therefore take place via the breakdown of conformers **20**, **23**, and **24**. The results at pH > 3 indicate that the major fragmentation of T^0 must take place via intermediates **20** and **23**, yielding the hydroxy-ester. The small percentage of lactone would thus be the result of a minor process resulting from the cleavage of intermediates **23** and **24**. A small proportion of lactone could also come from the fragmentation of boat conformers such as **26**. The results at pH ≤ 3 indicate that the cleavage of T^+ gives more lactone than that of T^0, in accord with the preceding discussion.

The same conclusion can be reached for 2,2-dimethoxytetrahydropyran (**2**, R = CH_3). The larger percentage of lactone observed in this case by comparison with **2** (R = C_2H_5) at various pHs, can be explained by the fact that a methoxy group is considered a better leaving group than an ethoxy group. This argument is based on the fact that methanol is a stronger acid than ethanol.

The aromatic orthoester **6** (R = CH_3) is also conformationally mobile and, as predicted, there are two different product ratios with the variation of pH. The rather large proportion of lactone observed at pH ≤ 3 can be readily explained because the CH_2OH and CH_2COOMe groupings are in a *cis* arrangement due to the benzene ring. This should favor lactone formation at the transition state level.[7]

2,2-Dimethoxytetrahydrofuran (**1**, R = CH_3) is also conformationally mobile and the results obtained are in accord with the preceding general discussion. By comparison with **2** (R = CH_3), this five-membered orthoester gives slightly more lactone at pH > 3 and less at pH ≤ 3. The differences are, however, not important enough to be discussed further.

Bicyclic orthoester **5** (R = CH_3) gave essentially the same relative proportion of lactone and hydroxy-ester at low and high acid concentration. This is expected because this orthoester cannot undergo a chair inversion, and the cleavages of both, T^0 and T^+, can take place with conformer **20** only, yielding the hydroxy-ester exclusively. The small percentage of lactone must come from the cleavage of boat conformers (as T^+ or T^0) such as **26**.

The last two cyclic orthoesters **3** and **4** (R = CH_3) can be analyzed together. In these two orthoesters, a complete chair inversion process cannot be a very important process because in one conformation, the secondary methyl or isopropyl group will be in a 1,3-diaxial orientation with one of the methoxy groups. These orthoesters can, however, take a boat or twist-boat conformation much more easily than bicyclic orthoester **5** (R = CH_3). These orthoesters have therefore a lesser degree of conformational mobility than **2** or **6** (R = CH_3), but more so than **5** (R = CH_3). The product ratios obtained are in agreement with the above analysis. Orthoester **4** (R = CH_3), which produces a larger amount of lactone, appears to be more conformationally mobile than orthoester **3** (R = CH_3). But the difference in percentage of lactone could also be explained by the fact that the leaving group would be better in **4** (a primary alcohol) than in **3** (a secondary alcohol).

Conclusion

The various product ratios observed between pH 1 and 5 with cyclic orthoesters **1–6** (R = CH_3) and **2** (R = C_2H_5) are readily rationalized on the basis of the stereoelectronic theory for the cleavage of tetrahedral intermediates, which takes into account primary and secondary stereoelectronic effects, conformational changes in tetrahedral intermediates prior to breakdown, entropic factors, and the ionic state of tetrahedral intermediates and reaction products as a function of pH.

These results put this theory on a firm basis (20) and provide new information on the cleavage of cyclic hemiorthoester tetrahedral intermediates in the T^0 and the T^+ ionic forms: (a) conformer **20**, either in the T^0 or in the T^+ ionic form, yields only the hydroxy-ester; the small percentage of lactone product (≤5%) would result from a conformational change to a boat conformer (such as **26**); (b) cleavage of **23** in the T^0 neutral form preferentially yields the hydroxy-ester (>95%), and cleavage of **24** to yield the lactone product is a minor process (<5%). The formation of lactone becomes more important when the cleavage of **23** and **24** takes place on their T^+ ionic form.

A logical deduction of the above investigation is that the cleavage of negatively charged (T^-) tetrahedral intermediate should produce a product ratio similar to that predicted for T^0, i.e. mainly hydroxy-ester. This is in agreement with the fact that permanganate oxidative cleavage, under basic conditions, of axial and equatorial vinyl orthoesters **35** and **36** (Scheme 6) yields mainly the hydroxy-ester **39** via the intermediates **37** and **38** respectively (7, 21). In accord with the above rationale, γ-butyrolactone ((22, 23), D-gluconolactone (24)) and isochromane-3-one (25) do not undergo carbonyl–oxygen exchange during their basic hydrolysis.

Experimental

The ir spectra were taken on a Perkin–Elmer 681 spectrophotometer; proton nmr spectra (δ-values) were recorded on a Bruker

WX-250 spectrometer in hexadeuteroacetone.

Lactones

γ-Butyrolactone and δ-valerolactone are commercial products. Isochromanone was prepared by Baeyer–Villiger oxidation of indanone as described in ref. 26. The preparation of 5-methyl-δ-valerolactone, 3-isopropyl-δ-valerolactone, and *trans*-octahydrocoumarin was described in ref. 3.

Orthoesters 1–6

General method of preparation (3, 27)

The lactone (2 mmol) was added to a suspension of trimethyloxonium tetrafluoroborate (2 mmol) in dichloromethane (25 mL) and the mixture stirred at room temperature overnight. The resulting solution was added to sodium methoxide (3 mmol) in methanol (25 mL) cooled to −78°C. The reaction mixture was allowed to warm up to room temperature, then washed with an aqueous solution of sodium bicarbonate (10%). The organic phase was dried over potassium carbonate and the solvent evaporated. The crude orthoester was purified by distillation under vacuum and kept over potassium carbonate.

Orthoester **1** (R = CH_3): bp 62°C/10 Torr (1 Torr = 133.3 Pa); yield 82%; ir ν_{max} (film): 1000–1200 cm^{-1}; nmr δ: 3.83 (2H, multiplet, O—CH_2—), 3.18 (6H, singlet, O—CH_3), 1.17 (4H, multiplet, methylenes at C-3 and C-4).

Orthoester **2** (R = CH_3): bp 65°C/10 Torr; yield 82%; ir ν_{max} (film): 1000–1200 cm^{-1}; nmr δ: 3.67 (2H, triplet, J = 6 Hz, O—CH_2—), 3.15 (6H, singlet, O—CH_3), 1.7 (6H, multiplet, methylenes at C-3, C-4, and C-5).

Orthoester **2** (R = C_2H_5): the preparation was described in ref. 3.

Orthoester **3** (R = CH_3): bp 60°C/100 Torr; yield 86%; ir ν_{max} (film): 1000–1200 cm^{-1}; nmr δ: 3.83–3.64 (1H, multiplet, O—CH—), 3.19 (3H, singlet, O—CH_3), 3.11 (3H, singlet, O—CH_3), 1.7–1.6 (6H, multiplet, methylenes at C-3, C-4, and C-5), 1.2 (3H, doublet, J = 6 Hz, CH_3—CH—).

Orthoester **4** (R = CH_3): bp 85°C/4 Torr; yield 86%; ir ν_{max} (film): 1000–1200 cm^{-1}; nmr δ: 3.76 (1H, doublet of doublet of doublets, J = 11 Hz, 5 Hz, 2 Hz, O—CH_aH_e—), 3.58 (1H, doublet of triplets, J = 12 Hz, 2 Hz, O—CH_aH_e—), 3.21 (3H, singlet, O—CH_3), 3.11 (3H, singlet, O—CH_3), 1.9–1.5 (7H, multiplet, methylenes at C-3, C-4, and C-5, and —$CH(CH_3)_2$), 0.9 (6H, doublet, J = 5 Hz, —$CH(CH_3)_2$).

Orthoester **5** (R = CH_3): bp 80°C/0.5 Torr; yield 81%; ir ν_{max} (film): 1000–1200 cm^{-1}; nmr δ: 3.54 (1H, doublet of doublets, J = 12 Hz, 5 Hz, O—CH_aH_e—), 3.25 (1H, triplet, J = 12 Hz, O—CH_aH_e—), 3.19 (3H, singlet, O—CH_3), 3.00 (3H, singlet, O—CH_3), 1.8–1.5 (12H, multiplet).

Orthoester **6** (R = CH_3): bp 85°C/0.5 Torr; yield 80%; ir ν_{max} (film): 1000–1200 cm^{-1}; nmr δ: 7.4–7.2 (4H, multiplet, aromatic protons), 4.83 (2H, singlet O—CH_2—), 3.26 (6H, singlet, O—CH_3), 3.00 (2H, singlet, =C—CH_2—).

Orthoester hydrolysis

General procedure

From a stock solution of the orthoesters (20–40 mg) in hexadeuteroacetone (3 mL), an aliquot (0.5 mL) was transferred into a 5-mm tube in the probe of a 250-MHz spectrometer at 25°C. A dilute solution of deuterated hydrochloric acid of a given pH (measured with a pH meter: pH values of 0.9, 1.9, 3.0, 4.0, and 4.7) was then added (0.1 mL at pH = 0.9 and 1.9; 0.25 mL at pH = 3; 0.5 mL at pH = 4 and 4.7). The reaction was followed by nmr and stopped when no more orthoester was present. Two to three runs were carried out. The relative proportion of lactone and hydroxy-ester was determined by the nmr integration of well-separated and characteristic peaks of the two products.

At pH 0.9 and pH 1.9, the reaction was usually over by the time the spectrum was recorded. Spectra were recorded for an additional 15 min to check the rate of lactonization of the hydroxy-ester. Except for the hydrolysis of orthoester **5** at pH = 0.9, there was very little change in lactone/hydroxy-ester ratio between the first spectrum and that recorded after 15 min. At pH > 3, the reaction was much slower, necessitating several hours.

In these experiments, the volume ratio D_2O/CD_3COCD_3 was not kept constant since Capon and Grieve (8) had shown that it had practically no influence on the percentage of δ-valerolactone in the hydrolysis of orthoesters **2** (R = CH_3 and C_2H_5) at pH ≤ 3.

The hydrolysis of *cis* and *trans* methoxy bicyclic and tricyclic orthoesters. Evidence for a chair–boat inversion prior to breakdown in some hemiorthoester tetrahedral intermediates

PIERRE DESLONGCHAMPS, DANIEL GUAY,[1] AND ROBERT CHÊNEVERT

Laboratoire de synthèse organique, Département de Chimie, Faculté des Sciences, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received November 23, 1984

PIERRE DESLONGCHAMPS, DANIEL GUAY, and ROBERT CHÊNEVERT. Can. J. Chem. **63**, 2493 (1985).

The acid hydrolysis of *cis* and *trans* methoxy bicyclic and tricyclic orthoesters **1–4** was studied. The *trans* isomers gave only the corresponding hydroxy-lactones (**2** → **14** and **4** → **16** + **10**) whereas the *cis* isomers gave mixtures of dihydroxy-esters and hydroxy-lactones (**1** → **13** + **14**) and **3** → **15** + **16** + **10**). These results are rationalized on the basis of the stereoelectronic theory for hydrolytic processes. The fact that hydroxy-lactone **16** is produced to a larger extent than the isomeric hydroxy-lactone **10** is taken as evidence that when a tetrahedral intermediate is not allowed (stereoelectronically) to break down in a chair conformation, it will take a boat form prior to cleavage.

PIERRE DESLONGCHAMPS, DANIEL GUAY et ROBERT CHÊNEVERT. Can. J. Chem. **63**, 2493 (1985).

On a étudié l'hydrolyse en milieu acide des orthoesters bicycliques et tricycliques (**1–4**) en séries *cis* et *trans*. Les isomères *trans* ont conduit uniquement aux hydroxy-lactones (**2** → **14** et **4** → **16** + **10**) correspondantes tandis que les isomères *cis* ont donné des mélanges d'hydroxy-esters et d'hydroxy-lactones (**1** → **13** + **14** et **3** → **15** + **16** + **10**). Ces résultats sont interprétés à la lumière de la théorie du contrôle stéréoélectronique dans les processus d'hydrolyse. La formation préférentielle de l'hydroxy-lactone **16** sur son isomère **10** constitue une évidence que, ne pouvant se briser avec contrôle stéréoélectronique dans la forme chaise, un intermédiaire tétraédrique préférera le faire sous la forme bateau.

The mild acid hydrolysis of orthoesters (1) has been used as a technique to understand better the mechanism of cleavage of tetrahedral intermediates which are occurring in hydrolytic processes (2–7). Most of this work was carried out to test the validity of the theory of stereoelectronic control (8–12). In the preceding accompanying publication (13), we have shown that the results obtained so far are readily rationalized in terms of the stereoelectronic theory when it takes into account the following elements: (a) primary (2, 3, 8, 9) and secondary (10) stereoelectronic effects, (b) conformational change in tetrahedral intermediate prior to breakdown (4, 7, 14, 15), (c) an entropy factor, and (d) the ionic state of tetrahedral intermediates and reaction products as a function of pH (4, 10, 16, 17).

This theory postulates that when a tetrahedral intermediate exists in a conformation which cannot break down with primary stereoelectronic control, the intermediate will first undergo a conformational change prior to cleavage in order to fulfill the stereoelectronic requirement. When the cyclic orthoester is a conformationally mobile six-membered ring, one of the conformational changes is a chair inversion, and studies carried out so far with various orthoesters having either a mobile or a rigid conformation support this rationalization (13). This theory also predicts that when complete ring inversion is not possible, a change from a chair to a boat (or twist-boat) conformation has to take place prior to cleavage, and experimental results have been rationalized on that basis (13).

We wish now to report a study which can be taken as the first unambiguous evidence that when a hemiorthoester tetrahedral intermediate is not allowed to break down stereoelectronically in its chair conformation, it will take a boat conformation prior to cleavage. The study undertaken is the mild acid hydrolysis of *cis* and *trans* methoxy bicyclic and tricyclic orthoesters **1**, **2**, **3**, and **4** (Scheme 1).

Synthesis

Treatment of the known bromo-lactone **5** (18) (Scheme 2) with silver tetrafluoroborate gave *in situ* the lactonium salt **6** (19), which on reaction with methanol under basic conditions gave *trans* bicyclic orthoester **2** along with a small quantity (~5%) of the *cis* isomer **1**. Isomerization of **2** under anhydrous acidic conditions gave a (~1:2) mixture of isomers **1** and **2**. Each isomer was obtained pure by column chromatography using silica gel impregnated with sodium bicarbonate. The *cis* isomer **1** is a known compound and its stereochemistry is firmly established by the first synthetic route (20).

The preparation of allylic bicyclic lactone **8** from the alkylation of bicyclic lactone **7** was recently reported (18). Following a general method (3, 21), compound **8** was converted into the allylic bicyclic orthoester **9** which, after hydroboration and acid hydrolysis, gave hydroxy-bicyclic lactone **10**. Compound **10** was then converted into the bromo-bicyclic lactone **11** via the intermediate formation of a primary mesylate. Treatment of bromo-bicyclic lactone **11** with silver tetrafluoroborate gave *in situ* the corresponding tricyclic lactonium salt **12** which, on reaction with methanol under basic conditions, gave stereospecifically the *trans*-tricyclic orthoester **4**. Acid isomerization of **4** gave a mixture of *cis* and *trans* isomers **3** and **4** in a 1:5.5 ratio. The *cis* isomer was obtained pure by chromatography with silica gel impregnated with $NaHCO_3$.

Results and discussion

The theoretical products (Scheme 1) for the hydrolysis of *cis* and *trans* methoxy bicyclic orthoesters **1** and **2** are dihydroxy-ester **13** and hydroxy-lactone **14**. Those of *cis* and *trans* methoxy tricyclic orthoesters **3** and **4** are dihydroxy-ester **15** and the isomeric hydroxy-lactones **16** and **10**.

Orthoesters **1–4** were dissolved in deuterated acetone, an hydrochloric acid solution (DCl in D_2O, pH = 2) was added, and the product distribution formed in the course of the hydrolysis experiments was analyzed by 250-MHz nmr spectroscopy. The results are shown in Table 1.

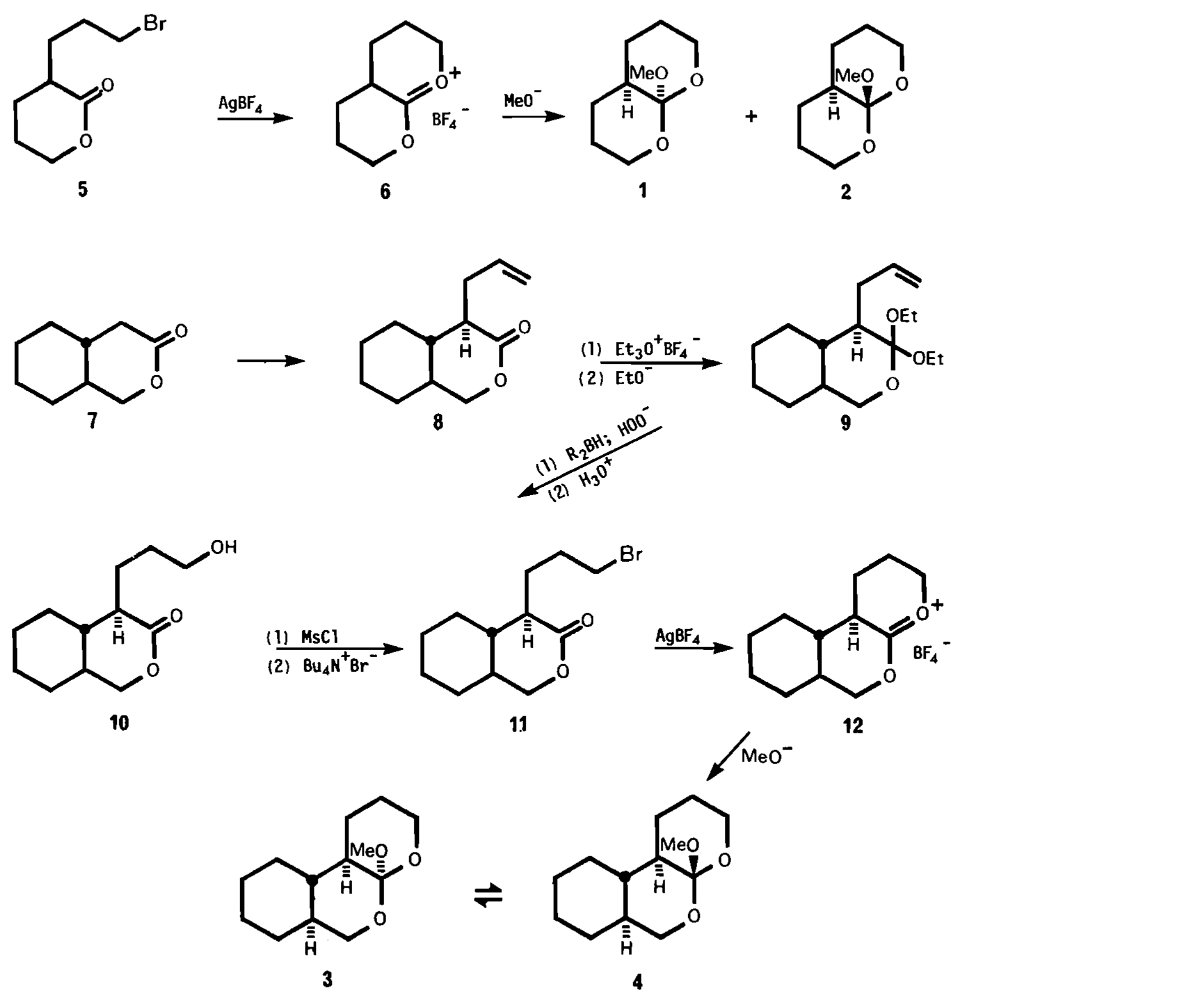
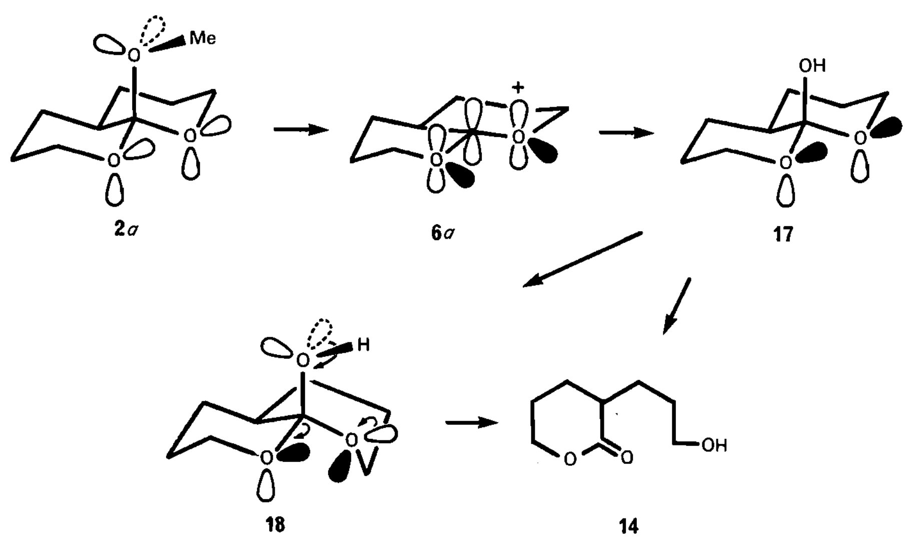
82 min	0	0	4	96



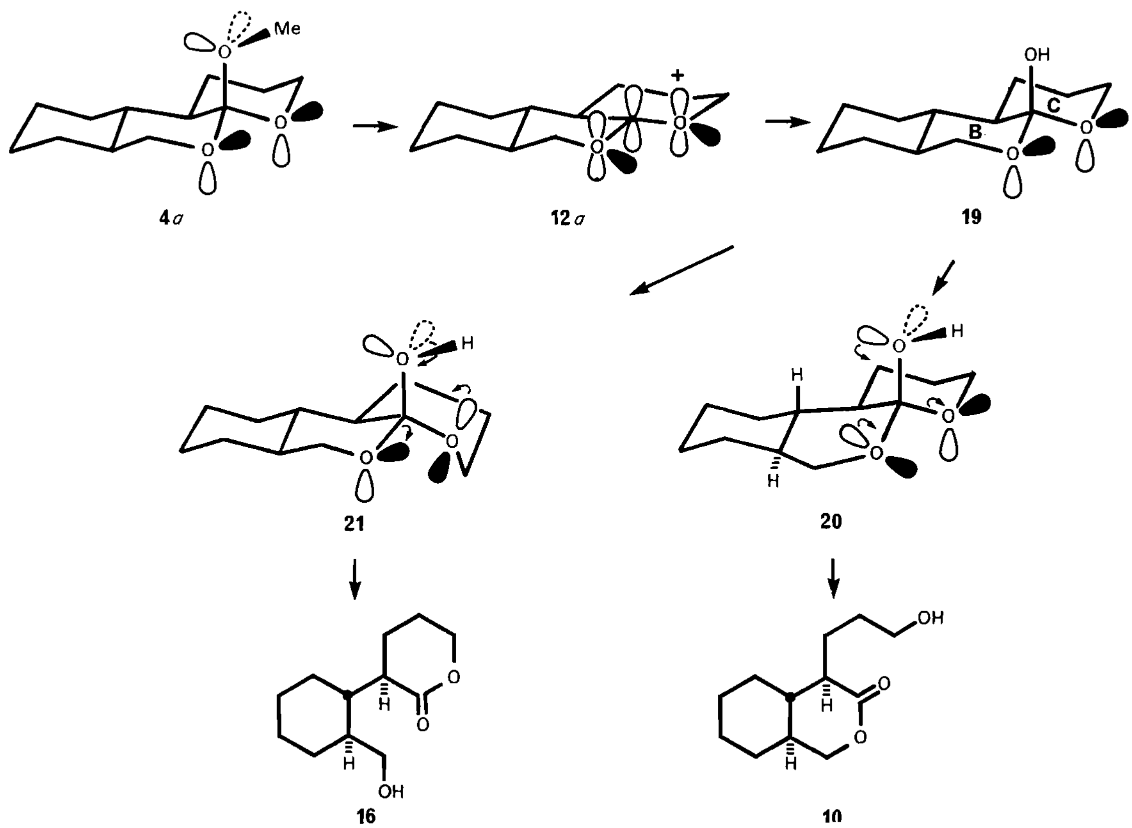
SCHEME 2



SCHEME 3

The hydrolyses of the *trans* methoxy orthoesters **2** and **4** are very fast, being complete in less than 2 min. Orthoester **2** gives only hydroxy-lactone **14**, whereas orthoester **4** produces first a mixture of hydroxy-lactones **16** and **10**, where **16** largely predominates. Hydroxy-lactone **16** is then slowly converted into the most stable hydroxy-lactone **10**. It is important to mention that the hydroxy methyl esters **13** and **15** were not observed.

The rate of hydrolysis of *cis* methoxy orthoesters **1** and **3** is slower than that of *trans* methoxy orthoesters **2** and **4**. The *cis* methoxy orthoester **1** gives a ~3:7 mixture of dihydroxy-ester **13** and hydroxy-lactone **14**. The *cis* methoxy tricyclic orthoester **3** produces first a mixture of dihydroxy-ester **15**, and hydroxy-lactones **16** and **10**. This is followed by the conversion of hydroxy-lactone **16** into the more stable isomeric hydroxy-



SCHEME 4

lactone **10**, but the conversion of dihydroxy-ester **15** into hydroxy-lactone **10** does not take place.[2]

Compounds **13**, **14**, **16**, and **10** were further characterized by preparation of their corresponding acetate derivative by reaction with acetic anhydride and pyridine.

The results obtained with *trans* methoxy bicyclic orthoester **2** are readily rationalized on the basis of the stereoelectronic theory. Orthoester **2** must exist in the conformation **2***a* (Scheme 3) which permits the ejection of the methoxy group yielding the bicyclic lactonium ion **6***a*. Hydration of **6***a* should give the intermediate **17**,[3] which can only give the hydroxy-lactone **14** on further cleavage. Since intermediate **17** cannot break down with stereoelectronic control, it is assumed that it will first take a boat form like **18** prior to cleavage (**17** → **18** → **14**).

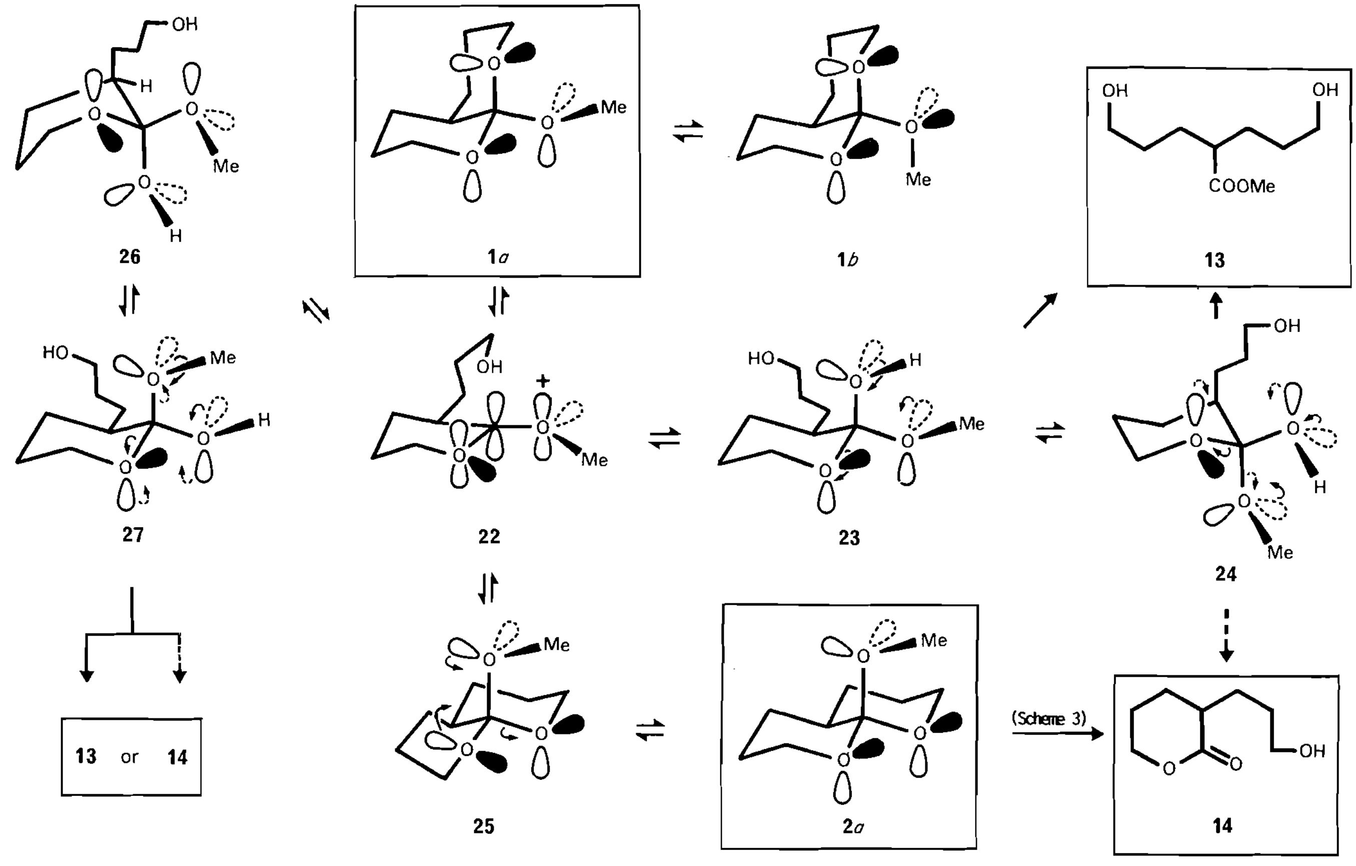
Under kinetically controlled conditions, *trans* methoxy tricyclic orthoester **4** produces no dihydroxy-ester **15**, but a mixture of the two hydroxy-lactones **16** and **10**, where the less stable isomeric lactone (**16**) predominates. Orthoester **4** must exist in conformation **4***a* (Scheme 4), which can only eject the methoxy group while respecting the principle of stereoelectronic control. This reaction produces the lactonium ion **12***a*, which on hydration should give the tetrahedral intermediate **19**. This intermediate cannot break down with stereoelectronic control and must therefore undergo a conformational change prior to breakdown. In this case, ring B or ring C can take a boat form producing **20** or **21**, which on cleavage can respectively give hydroxy-lactones **10** and **16**. The preferred formation of **16** can be explained[4] by the fact that ring C is more flexible than ring B, which is fused to ring A with a *trans* junction. The resulting consequence is that boat formation will take place much more readily in ring C (→**21**) than in ring B (→**20**), and the preferential formation of hydroxy-lactone **16** is thus readily explained on that basis. This result can therefore be taken as the first experimental evidence that cleavage must take place from a boat conformation when a tetrahedral hemiorthoester intermediate is not allowed to break down in a chair conformation with stereoelectronic control.

The *cis* methoxy orthoesters **1** and **3** differ from the *trans* methoxy orthoesters **2** and **4** in the fact that they produce the corresponding dihydroxy methyl esters (**13** and **15**) along with the hydroxy-lactones (**14**, **16**, and **10**). The next operation is to analyze the cleavage of **1** and **3** on the basis of the stereoelectronic theory. The *cis* methoxy bicyclic orthoester **1** can exist in the conformations **1***a* and **1***b* (Scheme 5). Primary stereoelectronic effects predict that conformer **1***b* cannot break down (3), and cleavage should therefore take place on conformer **1***a*, which can only give the hydroxy-lactonium ion **22**. Hydration of **22** should then occur to produce the tetrahedral intermediate **23**, which is allowed to break down in only one direction, yielding the corresponding dihydroxy-ester **13**. One possible route to producing hydroxy-lactone **14** while re-

[2] A preliminary study on the acid hydrolysis of *cis* methoxy orthoester **1** led to the incorrect conclusion that **1** gave only dihydroxy methyl ester **13** (ref. 22 and pp. 80–82 in ref. 11).

[3] Hydration of **6***a* on the opposite face would produce a tetrahedral intermediate having each ring in a boat conformation. This process is thus neglected.

[4] This result cannot be explained on the basis of entropy considerations (cf. footnote 7 in ref. 13). This factor predicts that, contrary to the experimental results, the formation of hydroxy-lactone **16** should be disfavored over that of hydroxy-lactone **10** because the CH_2OH group in **16** has a lesser degree of conformational mobility than that in **10**. As a result, this is not a determining factor in the present case.



SCHEME 5

specting the principle of stereoelectronic control, is for **23** to undergo a ring inversion to give the new conformer **24**, which is allowed to produce dihydroxy-ester **13** as well as hydroxy-lactone **14**. However, conformer **24** has an axial side chain and its proportion at equilibrium with **23** will be relatively small; consequently, the route **23** → **24** → **13** + **14** cannot be expected to become an important process. The relatively large proportion of hydroxy-lactone **14** which is formed along with dihydroxy-ester **13** is thus not explained on this basis. A very similar conclusion can be reached for the *trans* methoxy tricyclic orthoester **3**. This compound should hydrolyze via a pathway which is very similar to that of **1**, i.e. **1***a* → **22** → **23** → **13**. Indeed, in this tricyclic orthoester, the ring inversion process (**23** → **24**) is not possible. Thus, again, the rationale proposed so far does not explain correctly the experimental results.

One interesting hypothesis is to assume that the isomerization of the *cis* orthoesters **1** and **3** into their corresponding *trans* orthoesters **2** and **4** can occur at a competitive rate with that of hydrolysis; indeed, on that basis, the results are readily explained because *trans* orthoesters **2** and **4** are known to give exclusively the hydroxy-lactones.

There is a good possibility that the above assumption might become the correct explanation for the following reasons. When lactonium ion **22** is produced from **1***a*, the step which follows is the nucleophilic addition of a hydroxyl group. Theoretically, there are four possibilities. This step can take place via an intramolecular process that can either give back *cis* orthoester **1***a* or produce *trans* orthoester **2***a* via the boat conformer **25**. Hydration of **22** can also take place intermolecularly by reaction with water to produce either the chair intermediate **23** or the boat intermediate **26**. The new intermediate **26** could then give the chair intermediate **27**, which is allowed stereoelectronically to cleave to either dihydroxy methyl ester **13** or hydroxy-lactone **14**.

There is no doubt that the rate of the reclosure step **22** → **1***a* must be faster than the other three competing processes. However, the reclosure step **22** → **1***a* will not influence the product ratio, but will only slow down the overall rate of hydrolysis. This is in agreement with the fact tht the *cis* orthoesters **1** and **3** are hydrolyzed at a slower rate than the *trans* isomers **2** and **4**. The second ring closure via a boat conformation (**22** → **25**) is entropically favored but it is disfavored on steric grounds. The reverse is true for the bimolecular hydration step via the chair conformer (**22** → **23**), whereas that via the boat conformer (**22** → **26**) is both sterically and entropically disfavored. The process **22** → **26** can therefore be eliminated from further consideration. As a result, there is left the possibility that the process **22** → **25** → **2***a* can compete with the hydration step **22** → **23**. If that is the case, the experimental results are readily explained. Indeed, the formation of dihydroxy methyl ester **13** would come from intermediate **23**, whereas that of hydroxy-lactone **14** would come from *trans* orthoester (**2***a*) produced from **22** via the boat intermediate **25**.

It remains to find some evidence to show that the isomerization process **22** → **25** → **2***a* can compete with that of hydrolysis (**22** → **23** → **13**). We have submitted the *cis* methoxy orthoesters **1** and **3** to acidic conditions which are similar to those for the hydrolysis, except for the fact that water was replaced by methanol. We have found that, under these conditions, isomerization from the *cis* to the *trans* orthoesters takes place rapidly. Indeed, after 5 min, it was found in both series that more than 50% of the *cis* isomer (**1** or **3**) was already converted into the corresponding *trans* orthoester (**2** or **4**). These results strongly support the preceding rationale, which clearly explains the products observed in the hydrolysis of *cis* orthoesters **1** and **3**.

Conclusion

The products of hydrolysis of *cis* and *trans* methoxy bicyclic and tricyclic orthoesters **1–4** are readily understood on the basis of the stereoelectronic theory for the cleavage of tetrahedral intermediates. This study provides also the first experimental evidence to show that when an hemiorthoester tetrahedral intermediate is not allowed to break down in a chair conformation, it will first take a boat conformation so that the cleavage can take place with ease, i.e. while following the principle of stereoelectronic control.

Experimental

The infrared (ir) spectra were taken on a Perkin–Elmer 681 spectrophotometer. Proton nuclear magnetic resonance (nmr) spectra were recorded on a Bruker WP-60 and on a Bruker WM-250 instrument. The ^{13}C nmr spectra were recorded on a Bruker WP-80SY and on a Bruker WM-250 instrument. Mass spectral assays were obtained using a Vg Micromass ZAB-1F mass spectrometer. Vapor phase chromatographic (vpc) analysis and separation were carried out on a Varian 2800 chromatograph with thermal conductivity detector (column SE-30, 10% Chromosorb W, 60–80 mesh, 5 ft × $\frac{1}{4}$ in.). The purification of orthoesters **1–4** was carried out by column chromatography with silica gel impregnated with 1% sodium bicarbonate. SiO_2–$NaHCO_3$ was prepared by mixing a saturated solution of sodium bicarbonate in methanol with silica gel followed by evaporation of the solvent with a rotatory evaporator *under vacuo*.

trans *Methoxy bicyclic orthoester 2*

Bromolactone **5** (1.07 g, 4.84 mmol) was dissolved in dichloromethane (40 mL) and benzene (5 mL) under argon. Silver tetrafluoroborate (2.18 g, 11.2 mmol) was added and the resulting mixture stirred 20 h at room temperature in absence of light. After cooling at −78°C, a solution of methanol (48 mmol), sodium methoxide (5 mmol), and diisopropylethylamine (23 mmol) in dichloromethane (10 mL) was added via syringe. The resulting mixture was allowed to warm to room temperature and stirred for 2 h. Concentration was followed by addition of aqueous sodium bicarbonate (40 mL, 5%), and ether (50 mL). The aqueous layer was extracted with ether/pentane (75%, 2 × 100 mL). The combined organic extracts were dried over potassium carbonate, filtered, and evaporated. Filtration of the residue on silica gel (20% ethyl acetate in hexane, $SiO_2/NaHCO_3$, Et_3N) afforded *trans* methoxy bicyclic orthoester **2** (318 mg, 38%) contaminated with a small amount of *cis* isomer **1** (≃5%). On attempted distillation, isomerization of the orthoester led to a mixture of **1** and **2** in the ratio of 45:55.

cis *Methoxy bicyclic orthoester 1 and* trans *methoxy bicyclic orthoester 2*

trans Methoxy bicyclic orthoester **2** (60 mg, 0.35 mmol) was dissolved in a 1:1 mixture of methanol and dichloromethane (4 mL) containing trimethyl orthoformate (10 drops). At room temperature under an argon atmosphere, acetyl chloride (1 drop) was added. The mixture was stirred 10 min before adding triethylamine (100 μL). Evaporation *in vacuo* and flash chromatography of the residue ($SiO_2/NaHCO_3$, 1:3 ethyl acetate/hexane, Et_3N) gave *cis* methoxy bicyclic orthoester **1** (13 mg, 0.076 mmol, R_f 0.45); nmr (C_3D_6O) δ: 1.2–1.8 (9H), 3.17 (3H, singlet, OCH_3), 3.61–3.77 (4H, multiplet, two CH_2O); and *trans* methoxy bicyclic orthoester **2** (27 mg, 0.15 mmol, R_f 0.35); nmr (C_3D_6O) δ: 1.3–1.7 (9H), 3.09 (3H, singlet, OCH_3), 3.53–3.71 (4H, multiplet, two CH_2O).

Allyl bicyclic orthoester 9

Triethyloxonium tetrafluoroborate (3.59 g, 0.02 mol) was added to a solution of allyl lactone **8** (1.04 g, 0.005 mol) in anhydrous dichloromethane (30 mL) under argon. After stirring 22 h at room temperature, the mixture was cooled to −78°C. Then a solution of sodium ethoxide (2.0 g, 0.03 mol) in ethanol (10 mL) was added and the mixture was left to warm up to room temperature and stirred for 40 h. The solvents were then removed *in vacuo* and a solution (50 mL) of sodium bicarbonate (2%) was added. The aqueous phase was extracted with ether (3 × 75 mL), and the organic extract was dried with potassium carbonate, filtered, and evaporated to yield crude orthoester **9** (1.32 g, 92%) as a pale yellow oil; nmr ($CDCl_3$) δ: 1.0–2.3 (13H), 1.16 (6H, triplet, J = 7.2 Hz, two CH_3—), 3.5 (4H, diffuse quadruplet, J = 7.2 Hz, two CH_3—CH_2—O), 3.5–4.25 (2H, CH_2O of the ring), 4.8–5.2 (2H, multiplet, C=CH_2), 5.5–6.2 (1H, multiplet, —CH=).

Hydroxy-bicyclic lactone 10

Borane-methyl sulfide (732 μL, 7.3 mmol) was added to a cooled (−10°C) solution of cyclohexene (1.49 mL, 14.7 mmol) in ether (5 mL) under an atmosphere of argon. After stirring 1.5 h at 0°C, the white precipitate formed was diluted with tetrahydrofuran (20 mL). To this cooled mixture was added a solution of bicyclic orthoester **9** (1.31 g, 4.88 mmol) in tetrahydrofuran (5 mL). The reaction mixture was stirred 6 h at 0°C and was then allowed to warm up to room temperature (20 min). Aqueous sodium hydroxide (1 *N*, 15 mL) was added along with hydrogen peroxide (30%, 4 mL, 40 mmol) and the reaction mixture was stirred overnight at room temperature. The solution was acidified (pH < 2) with concentrated hydrogen chloride. Hexane (30 mL) was added, and the aqueous phase was decanted and extracted with ether (3 × 30 mL). The organic extract was dried with magnesium sulfate, filtered, and evaporated. The oily residue was purified by flash chromatography (ethyl acetate/hexane/acetone, 4:5:1) to give the hydroxy-bicyclic lactone **10** (760 mg, 74%); ir (CH_2Cl_2): 3620, 3500, and 1725 cm^{-1}; nmr (C_3D_6O) δ: 0.9–2.0 (14H), 2.15–2.23 (1H, multiplet, CH—CO—O—), 2.9 (1H, broad singlet, OH), 3.51 (2H, diffuse triplet, CH_2O of the chain, J = 5.5 Hz), 3.86 and 4.15 (2H, AB part of an ABX system, J_{AB} = 11.0 Hz, J_{BX} = 4.3 Hz, J_{AB} = 10.8 Hz, CH_2O of the ring).

Bromo-bicyclic lactone 11

Mesyl chloride (280 μL, 3.6 mmol) was slowly added to a cooled (−20°C) solution of hydroxy-bicyclic lactone **10** (421 mg, 2.0 mmol) and triethylamine (560 μL, 4.0 mmol) in dichloromethane (25 mL) under an argon atmosphere. The reaction mixture was stirred at room temperature for 14 h. Hexane (20 mL) was added and the solution was washed with hydrochloric acid (1 *N*, 2 × 15 mL), then with water (10 mL). The aqueous phases were extracted with ether (2 × 10 mL) and the combined organic layers were dried over magnesium sulfate, filtered, and evaporated to yield the crude methanesulfonate lactone (650 mg). Without further purification this crude sulfonate was dissolved in benzene (45 mL) containing tetra *n*-butylammonium bromide (2.0 g, 6 mmol) under argon. The mixture was refluxed 1.5 h and then concentrated *in vacuo*. The residue was taken into ether (30 mL) and washed with water (2 × 15 mL). The aqueous phase was extracted with ether (20 mL). The organic extracts were dried over magnesium sulfate, filtered, and evaporated. Flash chromatography (30% ethyl acetate in hexane) provided the bromo-bicyclic lactone **11** (457 mg, 83%); ir (CH_2Cl_2): 1725 cm^{-1}; nmr ($CDCl_3$) δ: 0.9–2.1 (15H), 3.4 (2H, multiplet, CH_2Br), 3.85 and 4.26 (2H, AB part of an ABX system, J_{AX} = 10.7 Hz, J_{BX} = 4.4 Hz, J_{AB} = 11.1 Hz, CH_2O); ms *m/e* (70 eV): 274 and 276 (M^+). *Exact Mass* calcd.: 276.0548; found: 276.0553.

trans *Methoxy tricyclic orthoester 4*

Silver tetrafluoroborate (435 mg, 2.2 mmol) was added to a solution of bromo-bicyclic lactone **11** (410 mg, 1.5 mmol) in benzene (5 mL) and dichloromethane (5 mL). The mixture was stirred 24 h at room temperature under argon and protected from light. Then it was cooled to −78°C. A solution of sodium methoxide in methanol (105 mg NaH, 4.5 mmol) was added, followed by triethylamine (210 μL, 1.5 mmol). The resulting mixture was allowed to warm up to room temperature before filtering through Celite. The filtrate was concentrated. Aqueous sodium bicarbonate (30 mL, 2%) was added and it was extracted with ether/hexane (2:1, 3 × 20 mL). The organic layers were dried over potassium carbonate, filtered, and evaporated. Flash chromatography of the residue (15% ethyl acetate in hexane) was effected on silica gel impregnated with sodium bicarbonate and traces of triethylamine were added in solvents and test tubes. This way, *trans* methoxy tricyclic orthoester **4** (192 mg, 57%) was obtained, along with some hydroxy-lactone **10** (46 mg, 0.22 mmol). *trans* Orthoester **4**: ir (CH_2Cl_2): 1000–1200 cm^{-1}; nmr (C_3D_6O) δ: 0.9–1.8 (15H), 3.08 (3H, singlet, OCH_3), 3.25 (1H, d of d, A part of an ABX system, $J_{AB} = J_{AX} = 11.0$ Hz, one-half CH_2O), 3.48–3.70 (3H, multiplet, one and one-half CH_2O); ^{13}C nmr ($CDCl_3$) δ: 110.7, 68.2, 63.3, 47.2, 45.5, 41.8, 40.2, 28.2, 27.4, 25.7, 25.6, 25.4, 22.0; ms *m/e* (70 eV): 226 (M^+), 194 ($M^+ - CH_3OH$). *Exact Mass* calcd.: 226.1567; found: 226.1569.

cis *Methoxy tricyclic orthoester 3*

trans Methoxy tricyclic orthoester **4** (170 mg, 0.75 mmol) was dissolved in methanol (15 mL) containing trimethyl orthoformate (15 drops) under argon. Anhydrous hydrochloric acid (0.017 mmol, prepared from acetyl chloride) in methanol (60 μL) was added. After stirring 1 h: 45 min at room temperature, triethylamine (250 μL, 1.8 mmol) was added and the solution was concentrated *in vacuo*. Flash chromatography of the oily residue (10% ethyl acetate in hexane, $SiO_2/NaHCO_3$, Et_3N) afforded *trans* orthoester **4** (132 mg, 0.58 mmol, R_f 0.35) and *cis* orthoester **3** (24 mg, 0.11 mmol, R_f 0.50); ir (CH_2Cl_2): 1000–1200 cm^{-1}; nmr (C_3D_6O) δ: 0.9–1.9 (15H), 3.18 (3H, singlet, OCH_3), 3.35–3.80 (4H, multiplet, two CH_2O); ^{13}C nmr ($CDCl_3$) δ: 68.7, 64.3, 47.1, 42.7, 40.5, 38.2, 29.1, 27.6, 26.2, 25.4, 21.0, 19.5; ms *m/e* (70 eV): 226 (M^+), 194 ($M^+ - CH_3OH$). *Exact Mass* calcd.: 226.1567; found: 226.1571.

Hydrolysis of trans *methoxy bicyclic orthoester 2*

trans Methoxy bicyclic orthoester **2** (3 mg) in deuterated acetone (1 mL) was placed in an nmr tube. The pH 2 acid solution (75 μL) was added and product distribution was checked by 250-MHz nmr spectroscopy. Hydrolysis was completed within 1.5 min (see Table 1).

Hydrolysis of cis *methoxy bicyclic orthoester 1*

cis Methoxy bicyclic orthoester **1** (2 mg) was hydrolyzed under identical conditions used for the *trans* isomer **2** (above). More than 10 min were needed for complete hydrolysis (see Table 1).

Acetate of hydroxy-lactone 14 and diacetate of dihydroxy-ester 13

The *cis* methoxy bicyclic orthoester **1** (172 mg, 1 mmol) dissolved in dichloromethane (1 mL) was vigorously stirred in the presence of aqueous *p*-toluenesulfonic acid (0.5 mL, 10^{-3} *M*) at 0°C. After 10 min, the crude mixture was taken into pyridine (10 mL) and excess acetic anhydride was added (10 mL). The resulting mixture was stirred overnight at room temperature. Methanol was added at 0°C and the solvents were evaporated *in vacuo*. The products were analyzed and separated by vapor phase chromatography.

Acetate of hydroxy-lactone 14: 52%; vpc retention time, 9.5 min (175°C); ir ($CHCl_3$): 1720 and 1240 cm^{-1}; nmr ($CDCl_3$) δ: 1.5–2.1 (8H), 2.05 (3H, singlet, CH_3COO—), 2.2–2.6 (1H, multiplet, —CH—C=O), 4.15 (2H, triplet, $J = 7.0$ Hz, CH_2OAc), 4.38 (2H, triplet, $J = 6.0$ Hz, —CH_2O of the ring); ms *m/e* (70 eV): 200 (M^+), 140 ($M^+ - CH_3COOH$).

Diacetate of dihydroxy-ester 13: 48%; vpc retention time, 15.0 min (175°C); ir ($CHCl_3$): 1715 and 1240 cm^{-1}; nmr ($CDCl_3$) δ: 1.4–2.6 (9H), 2.07 (6H, singlet, CH_3COO—), 3.75 (3H, singlet, —$COOCH_3$), 3.9–4.3 (4H, multiplet, CH_2OAc).

Hydrolysis of trans *methoxy tricyclic orthoester 4*

trans Methoxy tricyclic orthoester **4** (2.5 mg) dissolved in deuterated acetone (1 mL) was placed in an nmr tube. The pH 2 acid solution was added (100 μL) and product distribution was checked by nmr spectroscopy (250 MHz). Hydrolysis was completed within 1.5 minute (see Table 1).

Hydrolysis of cis *methoxy tricyclic orthoester 3*

The hydrolysis was performed as above for the *trans* isomer **4** (see Table 1). The following nmr data were used in calculation of hydrolysis product ratios: methanol formed: 3.23 ppm; *cis* methoxy bicyclic orthoester **1**: 3.17 ppm (3H, OCH_3); *trans* methoxy bicyclic orthoester **2**: 3.09 ppm (3H, OCH_3); hydroxy-lactone **14**: 2.45–2.60 ppm (1H, —CH—CO); dihydroxy-ester **13**: 3.60 ppm (3H, $COOCH_3$), 2.28–2.38 ppm (1H, —CH—COOMe); *cis* methoxy tricyclic orthoester **3**: 3.18 ppm (3H, OCH_3); *trans* methoxy tricyclic orthoester **4**: 3.08 ppm (3H, OCH_3); hydroxy-bicyclic lactone **10**: 2.15–2.23 ppm (1H, CH—CO), 3.86 ppm (1H, CH_2OCO); hydroxy-lactone **16**: 2.8–2.95 ppm (1H, CH—CO); dihydroxy-ester **15**: 2.68–2.77 ppm (1H, CH—COOMe), 3.58 ppm (3H, $COOCH_3$).

Acetate of hydroxy-lactone 10 and acetate of hydroxy-lactone 16

trans Methoxy tricyclic orthoester **4** (18 mg, 0.08 mmol) was dissolved in dichloromethane (750 μL) and in acetone (250 μL) under argon. At room temperature, the pH 2 acid solution (150 μL) was added. After 10 minutes, tlc analysis indicated no more starting material and pyridine (2 mL) was poured in, followed by acetic anhydride (4 mL). The reaction mixture was stirred overnight at room temperature. Hexane (5 mL) and ether (10 mL) were added. The organic phase was washed with hdyrochloric acid (1 *N*, 2 × 15 mL), sodium bicarbonate (5%, 10 mL), and brine (10 mL), then dried over magnesium sulfate and filtered. The residue was purified by column chromatography (SiO_2, 40% ethyl acetate in hexane) to give the acetate of hydroxy-lactone **10** (14 mg, 0.055 mmol, R_f 0.33); ir (CH_2Cl_2): 1730 cm^{-1}; nmr (C_3D_6O) δ: 0.9–2.0 (14H), 1.97 (3H, singlet, CH_3COO), 2.17–2.25 (1H, multiplet, CH—CO—O), 4.00 (2H, triplet, $J = 6.4$ Hz, CH_2OAc), 3.88 and 4.16 (2H, AB part of an ABX system, $J_{AX} = 11.0$ Hz, $J_{BX} = 4.4$ Hz, $J_{AB} = 10.8$ Hz, CH_2O of the ring); ms *m/e* (70 eV): 255 (MH^+), 212 ($MH^+ - CH_3CO$). *Exact Mass* calcd.: 254.1518; found: 254.1510; and the acetate of hydroxylactone **16** (6 mg, 0.024 mmol, R_f 0.25); ir (CH_2Cl_2): 1730 cm^{-1}; nmr (C_3D_6O) δ: 0.9–1.9 (14H), 1.99 (3H, singlet, CH_3COO), 2.78–2.88 (1H, multiplet, CH—CO—O of the ring), 3.91 and 4.03 (2H, AB part of and ABX system, $J_{AX} = 5.8$ Hz, $J_{BX} = 4.45$ Hz, $J_{AB} = 11.3$ Hz, CH_2OAc), 4.14–4.36 (2H, multiplet, CH_2O of the ring); ms *m/e* (70 eV): 254 (M^+), 212 ($MH^+ - CH_3CO$). *Exact Mass* calcd.: 254.1518; found: 254.1510.

High resolution mass spectroscopy confirmed the 250-MHz nmr integration in that no deuterium incorporation had occurred α to the lactone during hydrolysis.

Isomerization of cis *methoxy tricyclic orthoester 3*

cis Methoxy tricyclic orthoester **3** (16 mg) was dissolved in acetone (4 mL) at room temperature under argon. Then, 75 μL of a 10^{-2} *M* acid solution (7.1 μL acetyl chloride in 10 mL methanol) were added; tlc analysis after 5 min showed that isomerization had occurred. Triethylamine (100 μL) was added and the mixture was evaporated to dryness. Dilution with ether and filtration on silica gel gave (9 mg) crude orthoesters **3** and **4** in ratios of ≃7:3 as judged by nmr (250 MHz) spectroscopy. A third compound, believed to be an isomer (3.17 ppm), was formed (≃16%) during the reaction but could not be further characterized.

Isomerization of cis *methoxy bicyclic orthoester 1*

cis Methoxy bicyclic orthoester **1** (9 mg) was dissolved in acetone (3 mL) under argon at room temperature. Then 50 μL of a 10^{-2} *M* solution of hydrochloric acid in methanol were added; tlc analysis after 5 min indicated the presence of *trans* methoxy bicyclic orthoester **2**, as confirmed by the 250-MHz nmr spectrum of the crude mixture after triethylamine quenching (*cis* **1**/*trans* **2**, ≃1:4).

Bridged-ring steroids. III. The synthesis of bridged steroids with a bicyclo[2.2.1]heptane ring B system[1]

PETER YATES AND FRANÇOISE M. WINNIK[2]
Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received November 22, 1984

PETER YATES and FRANÇOISE M. WINNIK. Can. J. Chem. **63**, 2501 (1985).

Reaction of cholesta-5,7-dien-3β-yl 2-tetrahydropyranyl ether with bromoform and potassium *tert*-butoxide gave 3′,3′-dibromo-3′,6β-dihydrocyclopropa[5,6]-5a-cholest-7-en-3β-yl 2-tetrahydropyranyl ether (**1***c*), which on treatment with lithium aluminum hydride and water gave 5,8α-methano-5α-cholest-6-en-3β-yl 2-tetrahydropyranyl ether (**2***c*). This has been converted to 3β-acetoxy-5,8α-methano-5α-cholestan-6-one (**16***c*) and 3β-acetoxy-5,8α-methano-5α-cholestan-7-one (**17***c*). A preliminary investigation of the photochemistry of **16***c* and **17***c* has shown that the incorporation of the bicyclo[2.2.1]heptan-2-one system in the B ring of a steroid results in photoreactions of this system that are different from those observed in the case of simple bicyclo[2.2.1]heptan-2-ones.

PETER YATES et FRANÇOISE M. WINNIK. Can. J. Chem. **63**, 2501 (1985).

La réaction du tétrahydropyrannyloxy-2 cholestadiène-5,7 yle-3β avec le bromoforme et le *tert*-butylate de potassium conduit au tétrahydropyrannyloxy-2 dibromo-3,3′ dihydro-3′,6β cyclopropa[5,6] 5α-cholestène-7 yle-3β (**1***c*) qui, par traitement avec de l'hydrure double de lithium et d'aluminium et de l'eau, conduit au tétrahydropyrannyloxy-2 méthano-5,8α 5α-cholestène-6 yle-3β (**2***c*). Ce composé a été transformé en acétoxy-3β méthano-5,8α 5α-cholestanone-6 (**16***c*) et en acétoxy-3β méthano-5,8α 5α-cholestanone-7 (**17***c*). Une étude préliminaire de la photochimie des composés **16***c* et **17***c* a permis de montrer que l'incorporation du système bicyclo[2.2.1]heptanone-2 dans le cycle B d'un stéroïde fait que les photoréactions de ce système sont différentes de celles observées dans le cas des bicyclo[2.2.1]heptanones-2 simples.

[Traduit par le journal]

In connection with our interest in bridged steroids (1, 2), we have extended the work of Nazer (3), who was the only previous worker to synthesize bridged steroids with a bicyclo[2.2.1]heptane ring B system. In the earlier work ergosteryl tetrahydropyranyl ether was converted to its dibromocarbene adduct **1***a*, and this and its dihydro derivative **1***b* were converted to the bridged steroids **2***a* and **2***b*; the alcohol corresponding to **2***b* was epoxidized to **4***b* and this was converted to a mixture of diones **5***b* and **6***b*, which were not individually identified (Scheme 1). The α configuration was assigned to the one-carbon bridge of the bicyclo[2.2.1]heptane systems on spectroscopic and chemical grounds.

Our work was carried out in the cholestane rather than the ergostane series.[3] Cholesta-5,7-dien-3β-yl 2-tetrahydropyranyl ether was treated with bromoform and potassium *tert*-butoxide to give a dibromocarbene adduct. As in the ergostane series, a single adduct was formed and this is assigned structure **1***c* by analogy. We suggest that the high regio- and stereoselectivity in these additions is explicable in terms of the interpretation by Moss and Smudin of selectivity in the addition of dihalocarbenes to steroidal and related olefins (4). In the case of a steroid 5,7-diene two types of addition are possible (Fig. 1): α-axial attack, biased towards C-5, or β-axial attack biased towards C-8. Since the latter involves 1,3-diaxial interactions with the 18 and 19 CH_3 groups, H-11β, and pseudoaxial H-15β, while the former only involves 1,3-diaxial interactions with H-1α, H-3α, and H-9α, the two electronically equivalent additions are differentiated by steric control, greatly favoring α attack of the C-5 olefinic bond.

Our initial attempts to convert **1***c* to the bicyclo[2.2.1]heptane derivative **2***c* were disappointing. When a solution of the former in tetrahydrofuran was treated with lithium aluminum hydride under strictly anhydrous conditions, no rearrangement product could be detected and only starting material and some monobromo compound **8***c* (Scheme 2) were recovered. However, we discovered that the rearrangement occurred in good yield *when a 4:1 molar ratio of lithium aluminum hydride and water was used.* Moreover, optimal yields were obtained when the water was added in portions over a period of 2 days. It is possible that rearrangement of **1***a* and **1***b* occurred in the earlier experiments because of the inadvertent presence of water.

It is proposed that the conversion of **1***c* to **2***c* occurs by the route shown in Scheme 2. In the first step reductive dehalogenation (5) gives the intermediate **7***c*. This can either give **8***c* on protonation (*vide infra*) or proceed by loss of bromide ion to the carbene **9***c*; it is suggested that species formed by the interaction of lithium aluminum hydride and water act as Lewis acid catalysts for this step and account for the role of added water. Rearrangement of **9***c* to **10***c* is a vinylcyclopropylidene–cyclopentenylidene rearrangement and has ample precedent (6). Finally, addition of hydride to **10***c* and subsequent protonation gives **2***c*. Although the conversion of **1***c* to **2***c* is depicted as involving a stepwise series of reactions in Scheme 2, it is not excluded that some of these steps are concerted.

Nazer has reported that **11**, a ring A analogue of **1***c*, does not rearrange on treatment with lithium aluminum hydride, but gives **12** (3). In the hope that the addition of water would bring about rearrangement, we treated a mixture of **13** and **14** under the optimum conditions for the conversion of **1***c* to **2***c*. However, no rearrangement was observed under these conditions; compound **15** likewise failed to undergo rearrangement. These failures may reflect that interaction between the vacant *p* orbital of the putative carbene intermediate of type **9***c* and the olefinic π system is minimal in these cases; since such interaction is considered to facilitate the [1,3] sigmatropic rearrangement of the vinylcyclopropylidene species (6), reduction may then pre-

[1] For Parts I and II, see ref. 1.

empt rearrangement. In the ring B cases of type **1**, rings A and C hold ring B in a conformation where the cyclopropyl ring is nearly perpendicular to the double bond and thus in an optimum geometry for rearrangement. This difference in geometry is reflected in the unusually long wavelength of the $\pi \rightarrow \pi^*$ uv maximum of **1***c* (218 nm) relative to the corresponding maxima of **11**, **13**, and **14** (<210 nm).

Compound **2***c* was converted by acid hydrolysis and acetylation to the corresponding acetate, **3***c*. Hydroboration of **3***c* followed by sequential oxidation with alkaline hydrogen per-

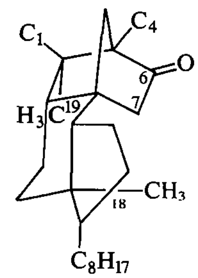
15

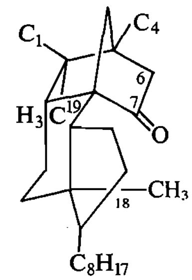
oxide and Jones reagent gave a mixture of **16***c* and **17***c* (Scheme 3). These were shown to be present in an approximately 1:1 ratio by vpc analysis, and were separated by painstaking chromatography on silica.

The structures of **16***c* and **17***c* were confirmed by elemental analytical and mass spectral data, bands in their ir spectra at 5.78 μm, maxima in their uv spectra at 289 (ε 29) and 302 nm (ε 25), and signals in their ^{13}C nmr spectra at δ 215.8 and 214.5.[4] However, these data did not allow individual structural assignments to be made. This was possible on the basis of comparison of the chemical shifts of the C-18 and C-19 signals in the ^1H nmr spectra of the two isomers. At 60 MHz one of the isomers shows these signals at δ 0.65 and 0.91, while the other shows superimposed signals at δ 0.92 (at 220 MHz this signal is resolved into two singlets at δ 0.916 and 0.925). Examination of molecular models (cf. Fig. 2) shows that this difference can readily be interpreted in terms of assignment of structure **16***c* to the former isomer and **17***c* to the latter. In **17***c* the C-18 methyl group is situated in the deshielding region of the C-7 carbonyl group, while in **16***c* it is too distant from the C-6 carbonyl group to be affected by it. Thus it is the signal of the C-18 methyl group that is shifted downfield in the second isomer relative to the first and the structural assignments are as given. This argument implies that the chemical shifts of the C-19 methyl signals are very similar in the two isomers, which is in accordance with the observation that the *endo*-methyl protons in 5,5-dimethyl- and 6,6-dimethylbicyclo[2.2.1]heptan-2-ones have closely similar chemical shifts (7).

[4] The ^{13}C nmr spectra of these and related compounds will be discussed in detail elsewhere.



16*c*

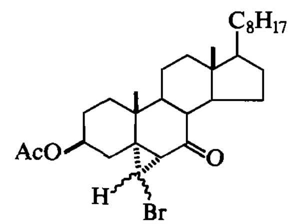


17*c*

FIG. 2

Independent chemical corroboration of the individual structural assignments was obtained as shown in Scheme 3. Treatment of the individual isomers under Haller–Bauer reaction conditions (8) gave in each case a hydroxy acid. Only one of these, that derived from **16***c*, gave on treatment with *p*-toluenesulfonic acid a γ lactone, as vouchsafed by a band at 5.66 μm in the ir spectrum of the product. Although the products were not fully characterized, it may safely be assumed that the Haller–Bauer cleavage will proceed via the more stable carbanions (8) to give the hydroxy acids **18***c* and **19***c* from **16***c* and **17***c*, respectively, and that only the former will give a γ-lactone, **20***c*, on acid treatment (Scheme 3).

In some runs for the conversion of **1***c* via **2***c* to the ketones **16***c* and **17***c* a side-product accompanied the ketones. This is considered to be the cyclopropyl ketone **21***c* on the basis of spectroscopic data (see Experimental). It must arise from **8***c* formed as a by-product in the reaction of **1***c* with lithium aluminum hydride and water (cf. Scheme 2).

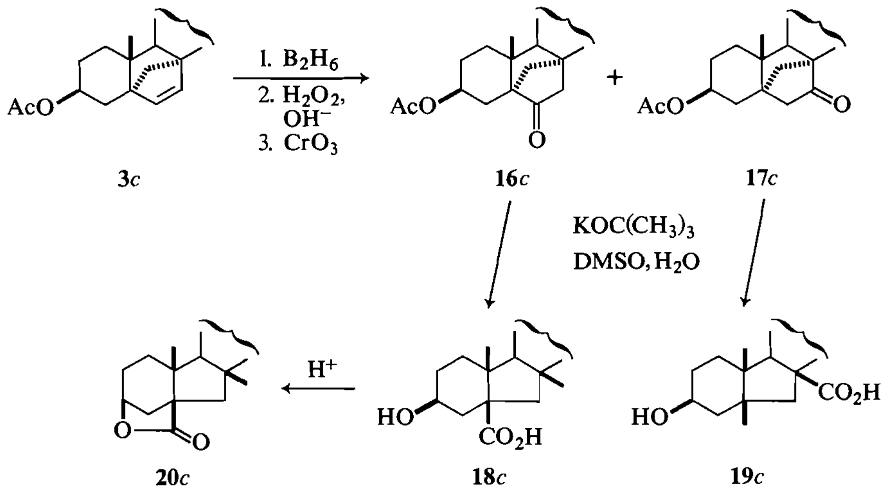


21*c*

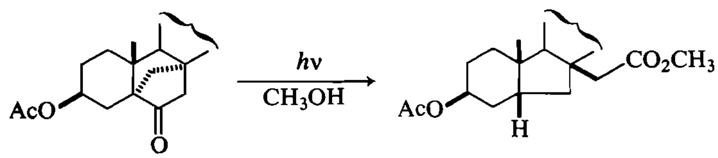
A preliminary investigation of the photochemistry of **16***c* and **17***c* revealed an interesting difference in their photoreactivities.[5] Irradiation of **16***c* in methanol gave as the major product a methyl ester, which is considered to be **22***c* (Scheme 4), formed via Norrish Type I cleavage followed by ketene formation. The ^1H nmr spectrum of the total crude photolysate showed no evidence of enal formation. The result is unusual since, in the case of simple bicyclo[2.2.1]heptan-2-ones bearing hydrogen at the *syn*-C-7 position, enal formation proceeds to the exclusion of ketene formation after Norrish Type I cleavage (9). The selective ketene formation on irradiation of **16***c* must reflect constraints imposed by rings A and C on the biradical formed upon Norrish Type I cleavage.

On the other hand, irradiation of **17***c* in methanol gave neither enal nor ketene-derived products, as shown by the ^1H nmr spectrum of the total crude photolysate. This photolysate contained no starting material as shown by vpc analysis, but attempted purification by chromatography on silica gel gave a

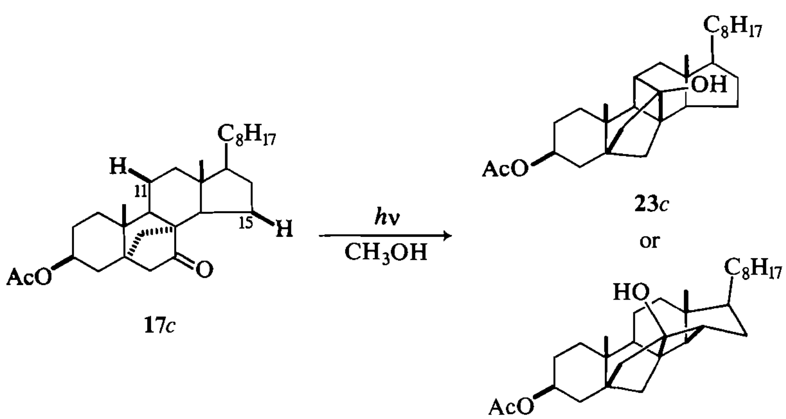
[5] For discussions of the photochemistry of bicyclo[2.2.1]heptanones, see, for example, ref. 9.



SCHEME 3



SCHEME 4



SCHEME 5

mixture whose major component was shown by vpc, tlc, and spectroscopic analysis to be **17***c*. This result can best be interpreted in terms of Norrish Type II hydrogen abstraction as the primary photochemical process followed by cyclobutanol formation (9), with the cyclobutanol reverting to the original ketone on silica gel. Examination of molecular models shows that both H-11β and H-15β, which are in the γ-relationship to the carbonyl oxygen atom, are held by the steroidal framework in very close proximity to that oxygen with a geometry that would permit ready hydrogen abstraction. We therefore postulate that the major photoproduct from **17***c* has structure **23***c* or **24***c* (Scheme 5) and that the difference in the photochemistry of **17***c* and **16***c* relates to this proximity effect.

Experimental

Melting points were determined on a Fisher–Jones apparatus and are uncorrected. Unless otherwise indicated, ir spectra were recorded in chloroform, uv spectra in cyclohexane, and ^{1}H and ^{13}C spectra in deuteriochloroform. In a standard work-up, solutions in organic solvents were washed twice with aqueous 5% sodium bicarbonate, twice with distilled water, and twice with brine, dried over anhydrous magnesium sulfate, and freed of solvent on a rotary evaporator under water aspirator pressure. Photolyses were carried out in Pyrex vessels with a Hanovia 450-W medium pressure mercury arc lamp surrounded by a quartz water-cooled jacket; photolysis solutions were flushed with dry nitrogen for 30 min immediately prior to irradiation; methanol used as solvent was boiled under reflux over magnesium and then distilled.

3′,3′-Dibromo-3′,6β-dihydrocyclopropa[5,6]-5α-cholest-7-en-3β-yl 2-tetrahydropyranyl ether (1c)

Cholesta-5,7-dien-3β-yl acetate (10) (25.0 g, 0.058 mol) was added to a solution of sodium hydroxide (5.0 g, 0.125 mol) in methanol (1 L). On heating, the solid dissolved and the solution was boiled under reflux under nitrogen for 1 h. After being kept in the refrigerator overnight, the reaction mixture was filtered to yield cholesta-5,7-dien-3β-ol (21.5 g, 96%), mp 148–150°C (lit. (11) mp 149–151°C); ir λ_{max}: 2.95 μm; ^{1}H nmr δ: 0.6–2.0 (m), 0.61 (s, 3H), 0.96 (s, 3H), 3.3–3.9 (m, 1H), 5.2–5.65 (m, 2H).

A catalytic amount of phosphorus oxychloride (20 drops) was added slowly to a stirred solution of cholesta-5,7-dien-3β-ol (21.4 g, 0.056 mol) and freshly distilled dihydropyran (22.0 mL, 0.28 mol) in dry dichloromethane (300 mL). The temperature of the solution rose from 22°C to 27°C. After 3 h the solution was diluted with diethyl ether (400 mL) and worked up in the usual manner to afford cholesta-5,7-dien-3β-yl 2-tetrahydropyranyl ether (22.4 g, 85%), recrystallized from acetone; mp 134–135°C; ir λ_{max}: 6.20 (w) μm; ^{1}H nmr δ: 0.6–2.1 (m), 0.62 (s, 3H), 0.96 (s, 3H), 3.15–4.2 (m, 3H), 4.6–4.8 (m, 1H), 5.2–5.6 (m, 2H). *Accurate Mass* calcd. for $C_{32}H_{52}O_2$ (*M*): 468.3967; found: 468.3970.

Cholest-5,7-dien-3β-yl 2-tetrahydropyranyl ether (22.3 g, 0.047 mol) was dissolved in freshly distilled, dry pentane (1 L) and the solution was poured into a 2-L three-necked round-bottomed flask fitted with a mechanical stirrer, a 100-mL addition funnel, a thermometer, and a nitrogen inlet (best yields were obtained when base-washed glassware was utilized). To the solution kept at 0°C was added potassium *tert*-butoxide (40.0 g, 0.35 mol), and then, over a period of 2 h, a solution of bromoform (35.0 g, 0.14 mol) in dry pentane (80 mL). The mixture was stirred for 2 h at room temperature and then cooled again to 0°C, and more potassium *tert*-butoxide (6.50 g, 0.058 mol) and bromoform (5.0 g, 0.019 mol) in pentane (20 mL) were added. At the end of the bromoform addition, the reaction mixture was warmed up to room temperature and filtered through alumina on a sintered-glass funnel. The solvent was evaporated to give a brown oil, which crystallized from acetone to give **1***c* as white needles (9.50 g, 31%). Recrystallization from acetone afforded **1***c* as white needles, mp 136–137°C; ir λ_{max}: 6.05 (w) μm; ^{1}H nmr δ: 0.5–2.0 (m), 0.56 (s, 3H), 1.13 (s, 3H), 3.25–4.3 (m, 3H), 5.35–5.55 (m, 1H); *m/z*: 540 (5) ($M - C_5H_{10}O_2$), 538 (10), 536 (5). *Accurate Mass* calcd. for $C_{28}H_{43}O^{81}Br$ ($C_{33}H_{52}O_2{}^{79}Br^{81}Br - C_5H_8O - H^{79}Br$ and $C_{33}H_{52}O_2{}^{81}Br_2 - C_5H_8O - H^{81}Br$), $C_{28}H_{43}O^{79}Br$ ($C_{33}H_{52}O_2{}^{79}Br^{81}Br - C_5H_8O - H^{81}Br$ and $M - C_5H_8O - H^{79}Br$): 476.2478, 474.2497; found: 476.2478, 474.2495. Chromatography or recrystallization of **1***c* led to partial hydrolysis,[6] and a satisfactory combustion analysis could not be obtained; complete hydrolysis gave the parent hydroxy compound, mp 146–148°C. *Anal.* calcd. for $C_{28}H_{44}OBr_2$: C 60.43, H 7.97, Br 28.72; found: C 60.58, H 8.07, Br 28.75.

*5,8α-Methano-5α-cholest-6-en-3β-yl acetate (3*c*)*

Compound **1***c* (11.0 g, 0.0172 mol) was dissolved in dry tetrahydrofuran (500 mL). Lithium aluminum hydride (3.1 g, 0.075 mol) was added carefully to this solution. The reaction mixture was stirred under nitrogen at room temperature for 72 h. Water (50 mg, 2.7 mmol) was added every 12 h, in five 10-μL portions. The excess hydride was destroyed by careful addition of a small amount of saturated aqueous sodium sulfate solution (3 mL). The reaction mixture was filtered, and the filtrate was diluted with diethyl ether and worked up in the usual manner. The amorphous **2***c* obtained (7.49 g, 90%) was converted into the acetate **3***c* without further purification by hydrolysis to the corresponding alcohol, followed by acetylation.

A solution of the product (7.49 g, 0.0155 mol) and concentrated aqueous hydrochloric acid (20 drops) in ethanol (75 mL) was boiled under reflux under nitrogen for 1 h. The residue after evaporation of the ethanol was taken up in diethyl ether. The usual work-up afforded the alcohol (5.89 g, 95%). A solution of the alcohol (5.89 g, 0.0148 mol) in dry pyridine (40 mL) and freshly distilled acetic anhydride (15 mL) was kept at room temperature for 16 h. The orange solution was poured over crushed ice and the mixture was neutralized with solid sodium bicarbonate. Extraction with diethyl ether, the usual work-up, and chromatography[6] on silica gel with chloroform as eluent afforded the acetate **3***c*, which was crystallized from methanol/acetone (3:1 v/v) (5.10 g, 80%); mp 92–94°C; ir λ_{max}: 5.78 μm; ^{1}H nmr δ: 0.7–2.3 (m), 0.76 (s, 3H), 0.90 (s, 3H), 2.00 (s, 3H), 4.5–5.0 (m, 1H), 5.86 and 6.31 (AB system, J = 6 Hz, 2H); *m/z*: 440 (4) (*M*). *Anal.* calcd. for $C_{30}H_{48}O_2 \cdot 0.5CH_3OH$: C 80.21, H 11.03; found: C 79.81, H 10.69. *Accurate Mass* calcd. for $C_{28}H_{44}$ ($M - C_2H_4O_2$): 380.3442; found: 380.3441.

[6] A similar observation was made in the case of **1***b* (3).

TABLE 1. Separation of compounds **16***c* and **17***c* by column chromatography

Eluent	Volume collected (mL)[a]	Weight (mg)	Composition (%)[b] 16*c*	17*c*

(98:2 v/v)	75	11	90	10
	1050	350	>99	—

[a] Rate of elution 1 mL/min; 15-mL fractions collected.
[b] Determined by vpc analysis on a 3% OV-17 on Chromosorb W-HP 80/100 column at 280°C; retention times: 10.2 (**16***c*) and 8.1 min (**17***c*).

*3β-Acetoxy-5,8α-methano-5α-cholestan-6-one (16*c*) and 3β-acetoxy-5,8α-methano-5α-cholestan-7-one (17*c*)*

To a stirred solution of **3***c* (5.10 g, 0.0116 mol) in dry diethyl ether (200 mL) kept at room temperature under nitrogen was added dropwise a solution of borane – methyl sulfide (2.0 mL, 1.60 g, 0.021 mol) in dry diethyl ether (50 mL). After completion of the addition the reaction mixture was stirred at room temperature for 1 h and then was boiled under reflux for 3 h. The excess borane was destroyed with water added slowly to the reaction mixture cooled to 0°C. Oxidation was carried out with 3 *N* aqueous sodium hydroxide (5 mL) and 28% hydrogen peroxide (10 mL) at 0°C for 15 min and at room temperature for 1 h. The usual work-up afforded a mixture of alcohols (4.42 g, 83%), which was subjected immediately to further oxidation. Jones reagent (chromium trioxide (26.67 g) and concentrated sulfuric acid (230 mL) made up to 1 L with distilled water; ~15 mL) was added dropwise to a solution of the mixture of alcohols (4.42 g, 9.6 mmol) in acetone (distilled from potassium permanganate; 150 mL) until an orange brown colour persisted. The excess oxidant was destroyed with 5% aqueous sodium bisulfite (100 mL), the acetone was evaporated, and the residue was extracted with diethyl ether. The usual work-up and chromatography on silica gel with benzene/diethyl ether (97:3 v/v) as eluent gave a mixture of the two ketones **16***c* and **17***c* (2.5 g, 57%) in an approximately 1:1 ratio. The two isomers (1.7 g) were separated by column chromatography on silica gel (120 g; column diameter: 2.5 cm) as shown in Table 1. Compound **17***c* was eluted first and was recrystallized from acetone; mp 198–199°C; ir λ_{max}: 5.78 μm; uv λ_{max} (ε): 302 (25) nm; ^{1}H nmr δ: 0.65–2.1 (m), 0.92 (s, 6H), 2.01 (s, 3H), 4.5–5.2 (m, 1H); *m/z* 456 (15) (*M*). *Anal.* calcd. for $C_{30}H_{48}O_3$: C 78.90, H 10.59; found: C 78.86, H 10.48.

The isomer **16***c* was eluted last and was crystallized from acetone; mp 158–159°C; ir λ_{max}: 5.78 μm; uv λ_{max} (ε): 289 (29) nm; ^{1}H nmr δ: 0.5–2.3 (m), 0.65 (s, 3H), 0.91 (s, 3H), 2.01 (s, 3H), 4.5–5.05 (m, 1H); *m/z* 456 (5) (*M*). *Anal.* calcd. for $C_{30}H_{48}O_3$: C 78.90, H 10.59; found: C 78.82, H 10.51.

*3β-Acetoxy-3′-bromo-3′,6β-dihydrocyclopropa[5,6]-5α-cholestan-7-one (21*c*)*

In some runs the mixture of ketones **16***c* and **17***c* obtained as above was contaminated with a small amount of **21***c*, which was separated from **16***c* and **17***c* by fractional crystallization from diethyl ether; mp 206–207°C; ir λ_{max}: 5.78 μm; uv λ_{max} (ε): 297 (54) nm; ^{1}H nmr δ: 0.6–2.1 (m), 0.66 (s, 3H), 1.08 (s, 3H), 2.01 (s, 3H), 3.85–4.1 (m, 1H), 4.6–5.2 (m, 1H); *m/z*: 536 (1), 534 (1) (*M*), 395 (100). *Accurate Mass* calcd. for $C_{28}H_{43}O$ ($M - C_2H_4BrO_2$): 395.3324; found: 395.3325.

*Haller–Bauer cleavage of 16*c *and 17*c

Potassium *tert*-butoxide (freshly sublimed at 150°C/0.25 Torr (1 Torr = 133.3 Pa); 185 mg, 1.65 mmol) and dry dimethyl sulfoxide (2 mL) were stirred at room temperature under nitrogen for 30 min. Distilled water (10.8 mg, 0.60 mmol) was added slowly followed by a solution of **16***c* (68 mg, 0.15 mmol) in dimethyl sulfoxide (3 mL). The reaction mixture was stirred at room temperature for 2 h and at 45°C for 19 h. Water (5 mL) was added dropwise and the alkaline aqueous solution was extracted three times with diethyl ether. The usual work-up gave a colorless oil (12.2 mg); ir λ_{max}: 2.80 (w), 5.74 μm. The aqueous layer was acidified with concentrated hydrochloric acid (pH 1–2) and extracted five times with diethyl ether. The combined extracts were worked up in the usual manner to yield **18***c* as an oil (29 mg, 43%); ir λ_{max}: 3.0–4.2, 5.89 μm; ^{1}H nmr δ: 0.7–2.2 (m), 0.90 (s), 3.5–4.2 (m, 1H), 5.56–6.5 (m, 2H, absent after D_2O treatment). A solution of *p*-toluenesulfonic acid (dried in benzene solution by azeotropic distillation; 2 mg, 0.01 mmol) and **18***c* (29 mg, 0.067 mmol) in dry benzene (10 mL) was heated at reflux for 15 h in a Soxhlet extractor containing activated molecular sieves. The cold reaction mixture was worked up in the usual manner to give **20***c* as an oil (10 mg, 36%); λ_{max} 5.66 μm.

Similar treatment of **17***c* gave a carboxylic acid, considered to be **19***c*, which failed to give a γ-lactone.

*Irradiation of 16*c

Irradiation of **16***c* (50 mg, 0.11 mmol) in methanol (15 mL) for 3 h afforded a mixture of three compounds in the ratio ~3:1:6 as indicated by vpc analysis. The major compound **22***c* (25 mg, 46%) was isolated by chromatography on a 1-mm silica gel preparative plate eluted with chloroform and was crystallized from methanol; mp 144–147°C; ir λ_{max}: 5.78 μm; ^{1}H nmr δ: 0.8–2.8 (m), 0.88 (s, 3H), 0.96 (s, 3H), 2.01 (s, 3H), 3.61 (s, 3H), 4.5–5.25 (m, 1H); *m/z*: 488 (4) (*M*).

*Irradiation of 17*c

Irradiation of a solution of **17***c* (84 mg, 0.18 mmol) in methanol (15 mL) for 5 h afforded one major product of 68% yield with complete consumption of starting material as indicated by vpc analysis. The usual work-up gave a mixture of at least three compounds in ~1:1:1 ratio; ir λ_{max}: 5.78 μm; ^{1}H nmr δ: 0.55–2.5 (m), 0.55 (s), 0.61 (s), 0.96 (s), 1.05 (s), 2.01 (s), 4.6–5.2 (m). Chromatography on a silica gel column eluted with chloroform gave **17***c* as the major fraction (46 mg); mp 195–198°C after crystallization from methanol.

Pronounced narrowing of the resonance signals in the 400-MHz ^{1}H nmr spectrum of cellulose triacetate in $CDCl_3$ between 25 and 50°C, as well as shielding and deshielding changes in ^{1}H chemical shifts, suggest that thermal disruption of intermolecular aggregates is accompanied by a conformational modification. Analysis of the spin–spin coupling patterns clearly evident at 50°C indicates that although there is a reversal in the chemical shifts of H-6_R and H-6_S relative to those for acetylated D-glucopyranose derivatives, the rotational conformations of the exocyclic 6-acetoxymethyl groups of the polymer and the model compounds all favor RHS and RCS rotameric forms. Supporting evidence for this conclusion is obtained from the 2-dimensional ^{1}H spectrum of a trisaccharide, *O*-β-D-glucopyranosyl-(1→3)-*O*-β-D-glucopyranosyl-(1→4)-*O*-β-D-glucopyranose undecaacetate. Computer-generated models of methyl 4,6-di-*O*-acetyl-β-glucopyranoside are examined in relation to the stereochemistry of 6-acetoxymethyl groups.

Opérant en solution dans le $CDCl_3$ et à des températures allant de 25 à 50°C, on a déterminé les spectres rmn du ^{1}H à 400 MHz du triacétate de cellulose; la finesse des bandes ainsi que les variations dans le blindage et le déblindage des déplacements chimiques du ^{1}H suggèrent que la rupture, sous l'influence de la chaleur, des aggrégats intermoléculaires s'accompagne d'une modification de conformation. L'analyse des diagrammes de couplage spin–spin, qui sont bien évidents à 50°C, indique qu'en dépit d'une inversion des déplacements chimiques de H-6_R et de H-6_S par rapport à ceux des dérivés acétylés du D-glucopyrannose, les conformations rotationnelles des groupes acétoxyméthyles-6 exocycliques du polymère et des composés types favorisent toutes les formes rotamères RHS et RCS. Les spectres rmn du ^{1}H en deux dimensions d'un trisaccharide, l'undécaacétate du *O*-β-D-glucopyrannosyl-(1→3) *O*-β-D-glucopyrannosyl-(1→4) *O*-β-D-glucopyrannose confirme cette conclusion. On examine des modèles produits par ordinateur du di-*O*-acétyl-4,6 β-glucopyrannoside de méthyle par rapport à la stéréochimie des groupes acétoxyméthyles-6.

[Traduit par le journal]

Introduction

A recent ^{1}H nmr study on a variety of *O*-acetyl derivatives of aldohexoses and disaccharides has shown (1) that chemical shift and coupling parameters observed for the 6,6′-methylene protons of those compounds are strongly dependent upon the pattern of acetylation at O-4 and O-6 and, consequently also, on linkage position. In comparing these ^{1}H nmr characteristics with those of larger carbohydrate molecules, the spectrum of cellulose triacetate (**1**) has been examined, and is described here.

Results and discussion

The signals in the 400-MHz ^{1}H nmr spectrum of cellulose triacetate in $CDCl_3$ at 25°C (Fig. 1A) are relatively broad, and hence convey little spin–spin coupling information. However, at 50°C the resolution is improved markedly throughout (Fig. 1B), as has been observed (2) for the 220-MHz spectrum at 60°C, and, whereas the resonances of H-1 and H-6 overlap in Fig. 1A, both are now clearly evident. No peaks were detected between δ 6.3 and 5.3, the region in which the α,β-anomeric protons of reducing end residues are expected (3) to resonate, indicating that the degree of polymerization of the cellulose derivative is ≥ 100.

This pronounced increase in resolution with temperature, indicative of a phase transition, may represent disruption of intermolecular aggregates that characterize (4) solutions of cellulose acetate. Another, although not necessarily independent, possibility is a change in the conformation of the macromolecule, which is suggested by the fact that the process is accompanied by substantial variations in ^{1}H chemical shift. As shown by the data of Table 1, which compares chemical shifts over the temperature range −20 to +50°C, the positions of all resonances except those of H-5 and H-6 are displaced with temperature. The most marked changes are observed for H-1, which becomes less shielded (+36 Hz) as the temperature is raised, and for H-2, which experiences an increase in shielding (−20 Hz). Other protons exhibit a diversity of lesser influences, including those of the acetoxyl groups, which likely undergo reorientation. As the anomeric proton (H-1) is the most strongly affected, an adjustment in the orientation of the (1→4) glucosidic bond may well take place as chain mobility increases with temperature.

Vicinal coupling between ring protons, close to 9 Hz throughout (Table 2), is of the magnitude expected for β-D-glucopyranosyl residues in the $^4C_1$ conformation (**1**). Another noteworthy feature of Fig. 1B concerns the resonances of the exocyclic 6-acetoxymethyl group. That is, the downfield, H-6, signal shows a smaller coupling with H-5 than does H-6′ (Table 3), which is the converse of the relationship found for the 6-acetoxymethyl group of monomeric methyl 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranoside (**2**). Although these data may imply that **1** and **2** differ widely in rotamer populations about their exocyclic C-6/C-5 bonds, recent observations (1) on the influence of *O*-acyl groups on the chemical shifts of 6-6′-methylene protons suggest otherwise.

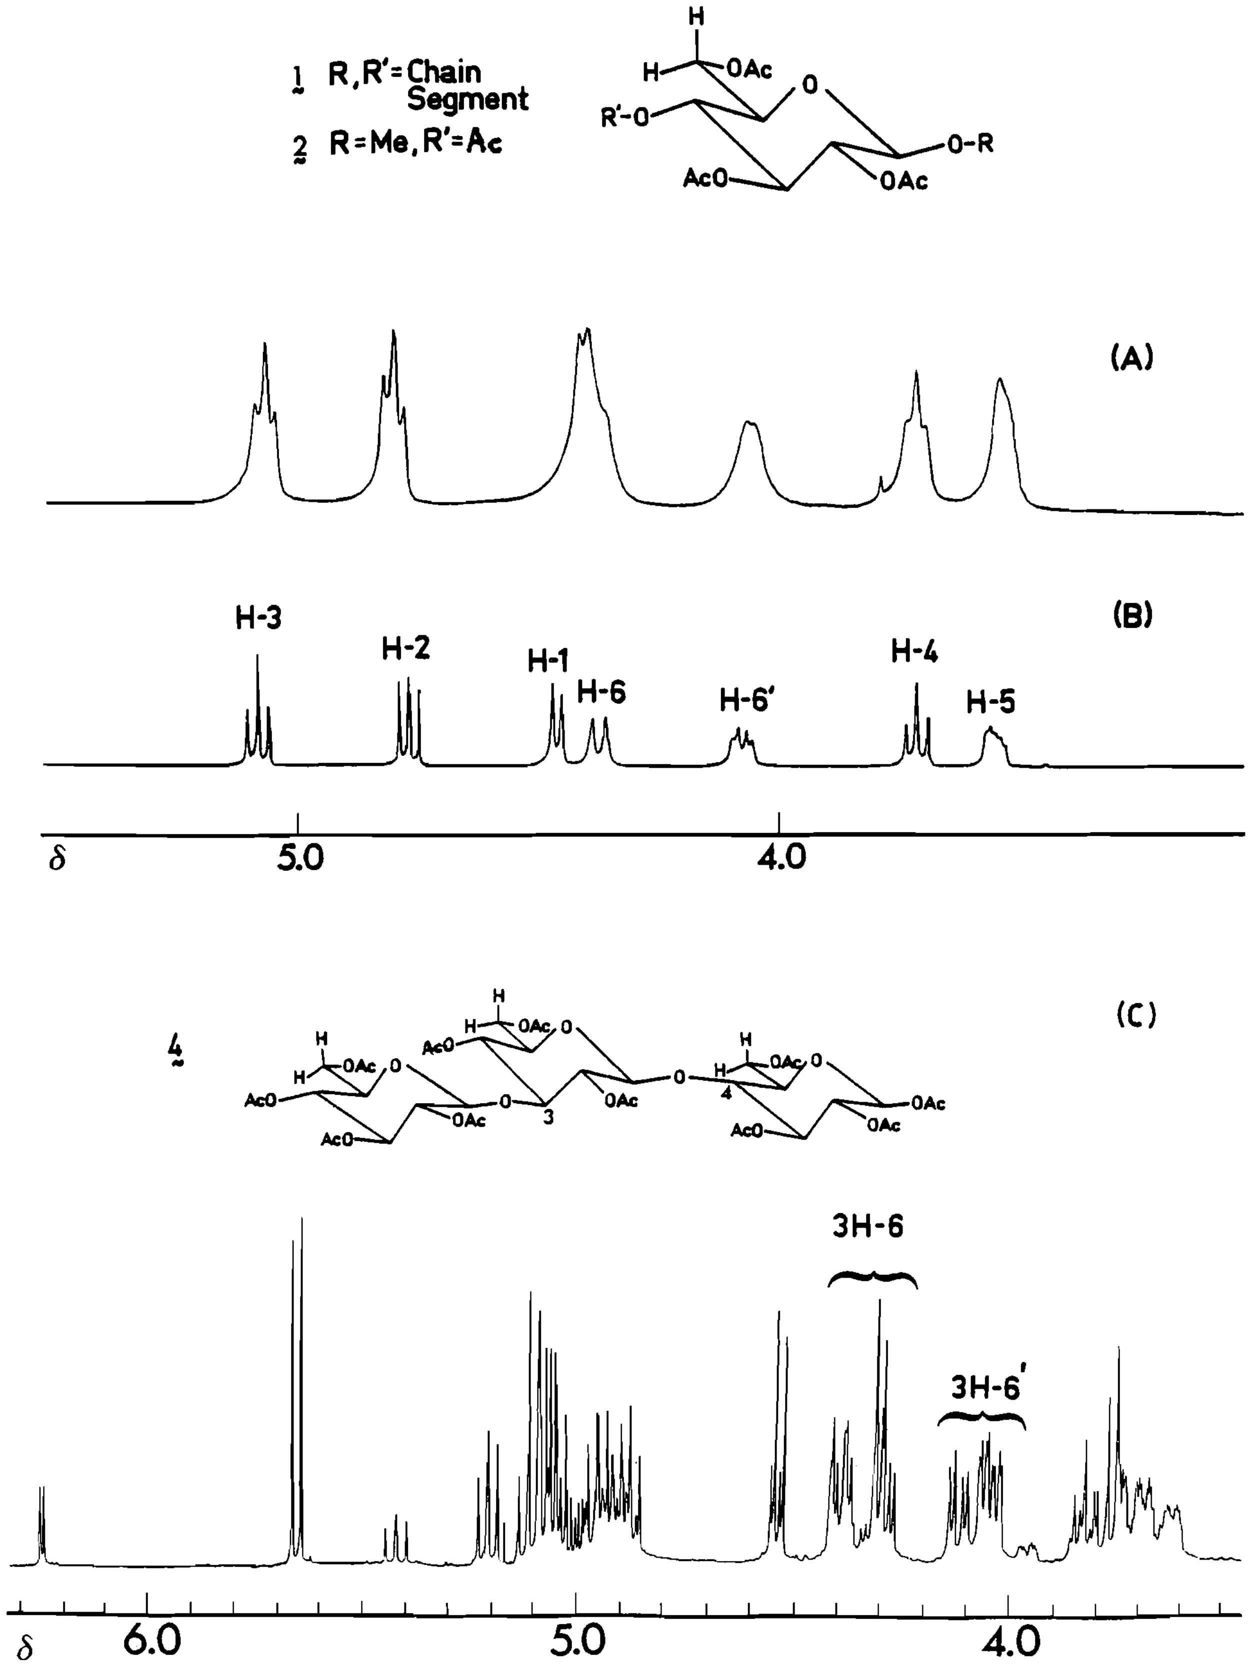

FIG. 1. The 400-MHz ^{1}H nmr spectrum of cellulose triacetate in $CDCl_3$ at (A) 25°C, (B) 50°C; signals for acetoxyl methyls are not shown (see Table 1 for chemical shift data); (C) 400-MHz ^{1}H nmr spectrum of trisaccharide derivative (4) in $CDCl_3$ at 25°C; the doublet at δ 6.25, and other minor signals, are attributable to a small proportion of the α-anomer.

TABLE 1. Effect of temperature on ^1H chemical shifts (at 400 MHz) of cellulose triacetate (**1**)

Proton	Chemical shift change (Hz)[a] 25°C	50°C
H-1	+14	+36
H-2	−10	−20
H-3	+6	+14
H-4	+10	+10
H-5	0	0
H-6	0	0
H-6′	+4	+14
OAc-2[b]	−10	−18
OAc-3[b]	−8	−12
OAc-6[b]	+4	+10

[b]At 50°C.

Conversion of an hydroxymethyl group into an acetoxymethyl group usually leads to deshielding of the 6,6′-methylene protons by about 0.3 ppm. However, for a D-glucopyranosyl moiety esterified at O-4 as well as O-6, the effects on the methylene protons are such that the relative positions of their signals become interchanged. Hence, it has been found (1) with a variety of D-glucopyranoside derivatives that when both O-4 and O-6 bear acetyl substituents, the relative positions of the 6,6′-methylene proton resonances are analogous to those of **2**, whereas the order of their chemical shifts is reversed when either O-4 or O-6 (or both) is not acylated. A proposed (1) source of this "shift reversal" is selective deshielding of H-6_R by the 6-*O*-acetyl substituent which, presumably, is oriented appropriately through a weak interaction[1] with the 4-*O*-acetyl substituent.

This proposal can be expressed in the form of stereochemical models calculated for methyl 4,6-di-*O*-acetyl-β-glucopyranoside (**3**) (Fig. 2; for convenience, the L-enantiomer is shown). For energy minimization, three different calculations were performed with the multiple option "Maximin" program (see experimental section):

[1]For effects on ^{13}C chemical shifts of intermolecular carbonyl−carbonyl interactions, and in hydrogen-bonding solvents, see ref. 6.

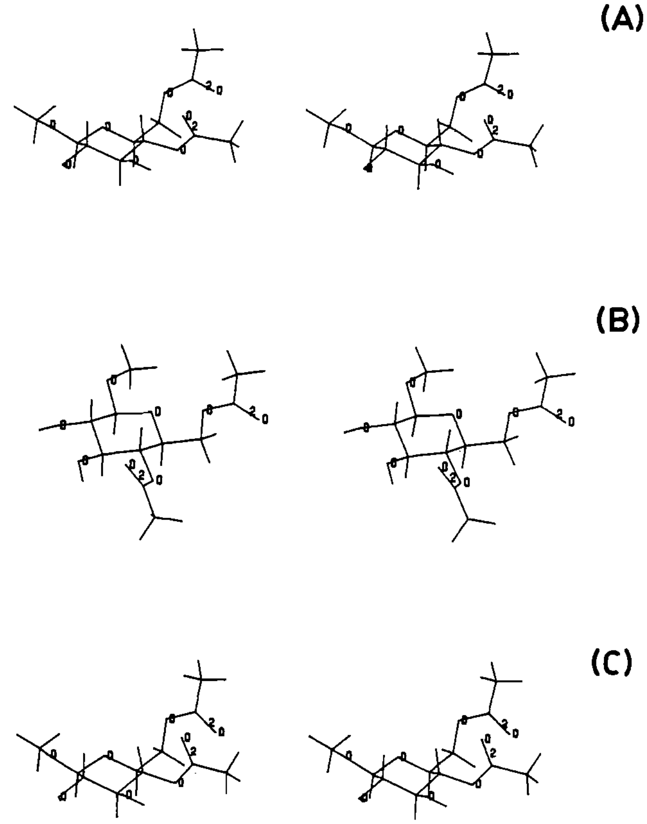

FIG. 2. Three simulated conformational models ("Maximin" minimized, 20 iterations) in *stereo* representation for methyl-4,6-di-*O*-acetyl-β-L-glucopyranoside (**3**) representing different values of E_{min}: A, −2.22 kcal/mol; B, −5.90 kcal/mol; C, 1.24 kcal/mol.

(*a*) The molecular conformation was set according to torsional angles obtained in a "search" operation, and minimization was then carried out. This procedure, which produced the structure in Fig. 2A (E_{min} = −2.22 kcal/mol), probably represents a *local*, rather than gobal, minimum energy. Altering the orientations of the individual OH groups had little or no effect on the magnitude of E_{min}.

(*b*) By allowing the five exocyclic torsional angles (see experimental section) to vary, the structure shown in Fig. 2B was obtained. Corresponding to a value of E_{min} = −5.90 kcal/mol, it is expected to represent the global minimum.

(c) A constraint was then imposed, whereby the projected angles of the two C═O groups remained fixed as in Fig. 2C during minimization, which resulted in a value of E_{min} = 1.24 kcal/mol. This increase in energy, in comparison with (b), is due mainly to a sharp rise in torsional energy, i.e, 1.97 and 7.71 kcal/mol in (b) and (c), respectively.

Energy minimization also was carried out by incorporating net atomic charges, obtained by different methods (7), for all atoms in the molecule. This treatment gave much higher total energies, attributable to the large contribution introduced by electrostatic interactions. For example, the energy (−5.90 kcal/mol) cited in (b) was raised to 1.17 kcal/mol by the incorporation of atomic charges calculated according to ref. 7(*a*), a total of 5.12 kcal/mol of this increase being due to electrostatic energy. Hence the latter accounted for most of the algebraic difference of 7.07 kcal/mol with, and without, the inclusion of atomic charges. Due to limitations in

TABLE 3. Chemical shift and spin coupling data[a] for the 6,6′-methylene protons of D-glucopyranoside peracetate residues of **1**, **2**, and **4**

	δ		^3J[b]	
	H-6	H-6′	H-6	H-6′

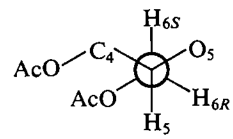
[c]Geminal coupling (^2J) is approximately −12.5 Hz, throughout.

the computer-modelling system available, it was not feasible to separate out the local dipolar interaction of specific interest between the 4- and 6-acetoxy groups of **3** from the electrostatic interactions arising from all atoms within the molecule. Consequently, the less rigorous approach represented by (b) and (c) was adopted to provide a measure of the *magnitude* of the presumed diploar interaction between the two acetoxy groups. That is, the total energy cited in (b), calculated as a function of bond stretching, angle bending, and torsional and van der Waals energy terms, was then recalculated (c) after imposing a constraint on the orientation of the 4- and 6-C═O functions, as depicted in Fig. 2c. The energy change involved would then be expected to be, at least, compensated for by the dipolar interaction between the two carbonyl groups.

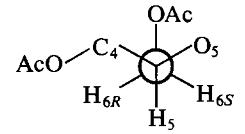
Accordingly, then, the algebraic difference in E_{min} values between (b) and (c), i.e., 7.14 kcal/mol, may be taken as an approximate measure of the stabilization energy that is entailed in the postulated dipolar attraction between the two C═O groups.

Another example in which "shift reversal" is observed is provided by a peracetylated trisaccharide, namely, *O*-β-D-glucopyranosyl-(1→3)-*O*-β-D-glucopyranosyl-(1→4)-*O*-β-D-glucopyranose undecaacetate (**4**) (8). Although the signals for the three pairs of methylene protons of **4** are not completely resolved in the 400-MHz spectrum (Fig. 1C), a full analysis was permitted by two-dimensional spectroscopy, from which the data for the ring protons and the 6,6′-methylene protons, in Tables 2 and 3, respectively, were obtained. It is seen (Table 3) that the downfield (H-6) signal of the 4-*O*-linked reducing end residue exhibits the smaller coupling with H-5 in common with cellulose triacetate. By contrast, the central, 3-*O*-linked residue and also the non-reducing end unit, both of which have O-4 and O-6 acetyl groups, are characterized by a coupling pattern closely similar to that of the glucoside (**2**). Also consistent with these findings are data reported (9) for *O*-β-D-glucopyranosyl-(1→4)-*O*-β-D-glucopyranosyl-(1→6)-*O*-β-D-glucopyranose undecaacetate: i.e., the absence of an acetyl group on O-6 of the reducing end residue, and on O-4 of the central residue, gives rise to a smaller spacing for the downfield H-6 signal in each instance, whereas the converse applies for the non-reducing end unit.

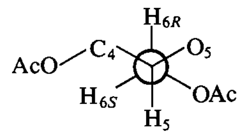
Accordingly, the fact that O-4 of cellulose triacetate is not esterified leads to the expectation that the chemical shifts of its methylenic protons should be the converse of that for **2**, which is borne out by the data of Table 3. Accepting this proposition, one may also propose assignments for the two methylene pro-



ROS



RHS



RCS

tons of the polymer, by reference to **2**, i.e., the downfield signal in Fig. 1 is due to H-6_R, and the upfield one, to H-6_S.

Based on the magnitude of coupling of H-6 and H-6′ with H-5 in D-glucopyranosides and such *O*-acetyl derivatives as **2**, it has been estimated (1) that RHS and RCS represent the major, staggered, rotamers about the C-6/C-5 bond, whereas ROS makes little or no contribution. By contrast, X-ray crystallographic studies indicate (10,11) that the 6-hydroxymethyl group of native cellulose favors the orientation represented by the ROS (tg) rotamer, and also (12) that the 6-acetoxymethyl group of solid cellulose acetate adopts principally the RHS (gg) rotameric form. However, according to the coupling data of Table 3, the RCS (gt) rotamer must contribute almost as importantly as RHS to the overall conformation of cellulose acetate in solution, as found with lower molecular weight analogs.

Experimental

Nuclear magnetic resonance spectroscopy

Proton magnetic resonance spectra were recorded with a Bruker WH-400 spectrometer, using $CDCl_3$ as solvent. Chemical shifts are reported with reference to tetramethylsilane. Analysis of the spectrum of trisaccharide peracetate **4** was facilitated by use of a two-dimensional (SECSY) technique (13).

*Molecular modelling of methyl 4,6-di-*O*-acetyl-β-glucopyranoside (**3**)*

The molecular modelling operation was performed with a "Trigraph" system, Tripos Associates, St. Louis, Mo. A model of diacetate **3** was constructed graphically from tetrahydropyran and individual atomic parameters, all of which were stored in a permanent fragment library of the system, by varying such molecular dimensions as bond length, bond angle, and torsional angle as required. The relative orientations of the exocyclic bonds (rotameric states around each rotatable bond) were adjusted according to the allowable states obtained from the "search" program, which monitors the hard-sphere van der Waals contacts between atoms. As the program contains provision for the introduction of distance constraints between atom pairs, this procedure served to screen out conformations within which the pertinent distances lay outside the regions designated. The energy minimization (14) was carried out by using the program "Maximin" (based on molecular mechanics) with multiple options, in a converging manner through optimization of molecular dimensions. It also was possible to specify molecular parts requiring optimization as a unit, e.g., the aggregate of atoms comprising the two C═O groups, as well as to preserve selected distances and angles during energy minimization. Consequently, the final energies determined are a composite of bond stretching, angle bending, and torsional and van der Waals energy terms. Negative values are obtained when there is a preponderance of residual attractive interactions (−ve) over repulsive interactions (+ve).

The search was conducted for diacetate **3** with a distance constraint range of 2.5−3.0 Å between the carbon atom of one C═O group and the oxygen atom of the other. A van der Waals factor of 0.9 and an angle increment of 15° over the range 0 to 359° were chosen for all rotatable bonds. This led to a *single* conformation with torsional

Le radical méthylènecyclopropyle: étude théorique. Chloration par *t*-BuOCl et réduction par $(n\text{Bu})_3\text{SnH}$ de dérivés cyclopropéniques

La chloration allylique par *t*-BuOCl des dialkyl-2,3 cyclopropene-2 carboxylates d'éthyle ou des alcools primaires et tertiaires analogues est régiosélective et hautement stéréosélective: on observe uniquement la formation du dérivé halogéné du méthylènecyclopropane dans lequel l'halogène et le groupement fonctionnel présentent une relation *trans* par rapport au cycle. La stéréochimie de la réduction par $(n\text{Bu})_3\text{SnH}$ des halogénures allyliques du méthylènecyclopropane et du cyclopropène est identique, cependant, on note également la formation de produits d'ouverture du cycle en C3. La migration exocyclique de la double liaison s'interprète par la formation intermédiaire du radical allylique. Une étude théorique par la méthode MNDO (UHF et RHF) montre que ces radicaux allyliques sont plans quel que soit le substituant. La réaction d'arrachement est toujours plus facile pour le carbone cyclique que pour le carbone exocyclique. De plus, elle est favorisée quand le carbone cyclique est substitué par un chlore au lieu d'un méthyle.

R. ARNAUD, S. CHOUBANI, R. SUBRA, M. VIDAL, M. VINCENS, and V. BARONE. Can. J. Chem. **63**, 2512 (1985).

The allylic chlorination of ethyl 2,3-dialkyl 2-cyclopropenecarboxylate or primary and tertiary alcohols is highly regio- and stereoselective. The halogenated methylenecyclopropane derivative only is observed. In that compound, the halogen substituent and the functional group are in a *trans* position with respect to the ring. The halogenated allylic compounds of methylenecyclopropane and of cyclopropene undergo reduction by $(n\text{Bu})_3\text{SnH}$ with the same stereochemistry. Products arising from ring opening are also observed. The exocyclic migration of the double bond can be related to the formation of a transient allylic radical. A theoretical study performed within the MNDO (UHF and RHF) framework leads to a planar allylic radical, whatever the substituent. The radical abstraction reaction which takes place during the reduction process is easier for a cyclic carbon atom than for an exocyclic one. In the former case, the faster reaction is obtained for a chlorinated carbon atom.

Introduction

Dans un travail récent nous avons rapporté l'étude théorique du cation méthylènecyclopropyle et précisé les conditions expérimentales qui permettent de réaliser en milieu acide, la migration intracyclique de la double liaison du méthylènecyclopropane (1, 2). Le but de ce mémoire est de résumer, d'une part, les résultats que nous avons obtenus au cours de la substitution radicalaire allylique en série cyclopropénique et d'approcher d'autre part, à l'aide d'une méthode semi-empirique, la structure de l'intermédiaire allylique: le radical méthylènecyclopropyle.

Ce type de radical a été en effet peu étudié (3); il nous a paru intéressant d'engendrer le radical méthylènecyclopropyle, non seulement à partir de précurseurs méthylènecyclopropaniques, mais également à partir des substrats cyclopropéniques isomères; dans ce cas, en effet, on peut espérer mettre en évidence l'interaction de l'électron célibataire et de la double liaison par l'intermédiaire des produits de transposition: les dérivés du méthylènecyclopropane.

Nous envisagerons successivement:

La chloration des dialkyl-2,3 cyclopropène-2 carboxylates d'éthyle et des alcools primaires et tertiaires correspondants par l'hypochlorite de tertiobutyle (4–8). Cette étude a donné lieu à une note préliminaire (9).

La réduction des halogénures méthylènecyclopropaniques et cyclopropéniques par l'hydrure de tributylétain (10–18).

L'étude théorique du radical allylique méthylènecyclopropyle (ou cyclopropénylméthyle) dont l'objectif essentiel est de préciser la nature de cette espèce intermédiaire en déterminant sa géométrie et sa structure électronique.

Partie expérimentale

Technique expérimentale

Les spectres, ir de composés purs (film) ont été enregistrés sur un appareil Perkin–Elmer 521 à réseau et double faisceau et les spectres rmn sur appareil Perkin–Elmer R 24 et sur appareil CAMECA fonctionnant à 250 MHz.

*Synthèse des esters et alcools cyclopropéniques dialkylés en position 2 et 3 **1–5**, du méthyl-2 bromométhyl-3 cyclopropènecarboxylate d'éthyle **18** et du chloro-2 méthylène-3 cyclopropanecarboxylate d'éthyle **6**:* voir références 19, 20, 22 et 23.

*Chloration des esters **1**, **4**, **5** et des alcools **2** et **3** par l'hypochlorite de tertiobutyle*

Cette réaction a été réalisée à 0°C, 40°C ou 60°C. On dissout 0,2 mol de dérivé cyclopropénique dans 150 mL de CCl_4 anhydre que l'on porte à la température voulue et on ajoute par petites quantités, 0,6 mol d'hypchlorite de tertiobutyle; après chaque addition, le mélange réactionnel est agité jusqu'à ce que la couleur jaune de *t*-BuOCl ait disparue. Une addition trop rapide du *t*-BuOCl provoque une élévation brusque de la température du mélange réactionnel. À la fin de la réaction, on évapore CCl_4 et la distillation sous pression réduite (par exemple $\theta_{eb}/0{,}4$ Torr $\simeq$ 27°C (1 Torr = 133.3 Pa) pour le mélange réactionnel de la chloration de **1** à 0°C) conduit aux esters ou alcools cyclopropylidéniques **6** et **9–15** et aux esters cyclopropaniques dichlorés **7** et **8**. Les rendements dans les différentes conditions sont mentionnés par ailleurs dans le texte.

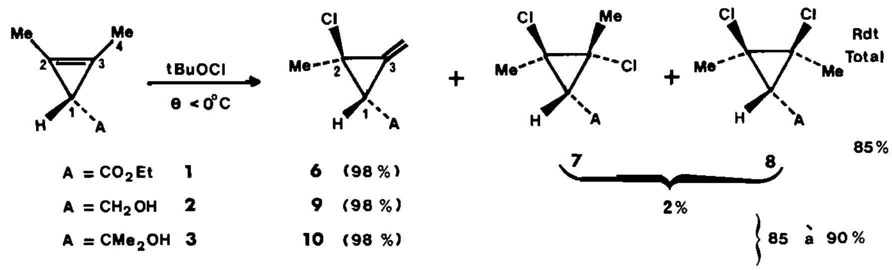
Résultats

1. *Chloration des dialkyl-2,3 cyclopropène-2 carboxylates d'éthyle **1**, **4**, **5** et des alcools primaire **2** et tertiaire **3** par l'hypochlorite de tertiobutyle*

À basse température (0°C) la chloration de l'ester **1** et des alcools **2** et **3** par *t*-BuOCl, en solution dans CCl_4, conduit avec un rendement très élevé aux dérivés du méthylènecyclopropane **6**, **9** et **10**; la H-substitution allylique présente une régiosélectivité et une stéréosélectivité très élevées: seul le carbone 2 fixe un atome de chlore d'une part et d'autre part les composés **6**, **9**, **10** ont tous la configuration relative 1*R**,2*R**; on observe également la formation de traces de dichloro-1,1 méthylène-2 cyclopropanes **7** et **8** qui résultent de l'addition du

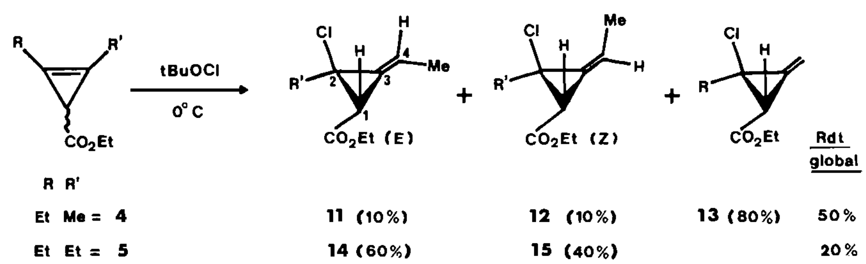


chlore sur la double liaison cyclopropénique.

À température plus élevée (65°C), le produit de H-substitution n'est plus obtenu qu'avec un rendement global de 9%, par contre la réaction d'addition du chlore sur la double liaison est nettement favorisée.

Lorsque la double liaison cyclopropénique est dissymétrique, la régiosélectivité de l'arrachement de l'hydrogène est en contradiction avec les prévisions que l'on pouvait faire à partir des réactivités comparées des liaisons C—H des carbones allyliques primaire et secondaire vis-à-vis de *t*-BuO·. À 0°C l'ester **4** conduit, en effet, préférentiellement au méthylènecyclopropane **13** avec un rendement de 40% alors que les éthylidènecyclopropanes **11** et **12** ne se forment qu'avec un rendement total de 10%; il est possible que cette inversion de la régiosélectivité soit due à une orientation défavorable des liaisons C—H du méthylène par rapport aux orbitales π. Signalons enfin que la stéréosélectivité reste, comme précédemment, très élevée et que l'addition du chlore au cycle est toujours à cette température négligeable.

L'énergie d'activation de la réaction d'arrachement du pro-

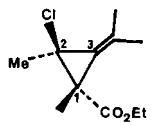


ton allylique cyclopropanique est très nettement supérieure à celle du proton allylique des substrats cyclopropéniques. Traité dans les mêmes conditions expérimentales à 0°C ou à 60°C le méthyl-2 méthylène-3 cyclopropanecarboxylate d'éthyle est retrouvé inchangé après 5 h de réaction.

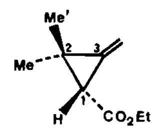
Une étude détaillée de la chloration de l'ester **1** a permis de confirmer le caractère radicalaire de cette réaction: D'une part on observe l'éxistence de périodes d'induction pour les réactions de H-substitution et d'addition du chlore, la durée de la première étant nettement supérieure à celle de la seconde. D'autre part, ces réactions sont très sensibles à l'action d'inhibiteur tel que le galvinoxyle. Lorsque l'on traite à 0°C l'ester **1** (1 mol) par *t*-BuOCl (3 mol) en solution dans CCl_4 et à l'obscurité, la chloration allylique est pratiquement terminée après 4 h de réaction alors qu'en présence de galvinoxyle (1 mol) l'ester **1** est retrouvé inchangé au bout de 15 h.

Identification (stéréochimie)

En rmn, la relation *trans* du groupe méthyle et du groupement éthoxycarbonyle dans les esters **6**, **11**, **12** est établie par l'étude des glissements induits par le tris(dipivalomethanato) europium, Eu(dpm)$_3$. Nous avons observé antérieurement que le rapport des pentes $\Delta Me_2/\Delta H_1$ des droites $\delta H = f(CEu/C^0$ substrat) permet d'établir facilement la relation *cis* ou *trans* de ce méthyle et du groupement fonctionnel (21). En particulier, dans le cas du chloro-2 méthyl-2 isopropylidènecyclopropanecarboxylate d'éthyle **16** et du diméthyl-2,2 méthylène-3 cyclopropanecarboxylate d'éthyle **17** les valeurs sont les suivantes:



16



17

$\frac{\Delta \mathrm{Me}_2}{\Delta \mathrm{H}_1} = 0,66$

$\frac{\Delta \mathrm{Me}_2}{\Delta \mathrm{H}_1} = 0,69$

$\frac{\Delta \mathrm{Me}'_2}{\Delta \mathrm{H}_1} = 0,24$

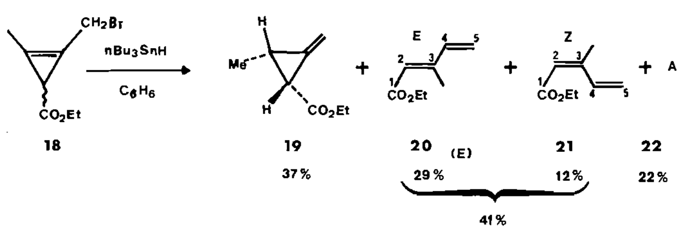
Les valeurs observées dans le cas des esters **6**, **11**, **12** qui varient de 0,64 à 0,68 permettent d'attribuer sans ambiguité la configuration relative $1R^*,2R^*$ à ces composés. Une remarque identique peut être faite dans le cas des esters **13**, **14**, **15**; la valeur du rapport $\Delta(CH_2\text{—}CH_3)/\Delta H_1$, qui varie de 0,70 à 0,80, établit de même la relation *cis* des groupes Et et —CO_2Et.

Les configurations *Z* ou *E* de **11**, **12** et **14**, **15**, se déduisent également des glissements induits des méthyles vinyliques Me_4; la valeur dans le cas de la configuration *E* ($\Delta Me_4 \simeq 8$) est, comme l'on doit s'y attendre nettement supérieure à celle de la configuration *Z* ($\Delta Me_4 \simeq 1$).

Notons enfin que l'attribution des configurations relatives aux esters dichlorés **7** et **8** est fondée sur l'équivalence magnétique des deux méthyles dans **8** et leur non-équivalence dans **7**. L'effet LIS confirme ces caractéristiques d'une part et permet d'autre part, en comparant les glissements des méthyles dans ces deux composés, d'établir la relation *cis* de ces groupes et de CO_2Et dans **8**.

2. *Réduction des halogénures allyliques méthylènecyclopropanique et cyclopropénique par l'hydrure de tri-n-butylétain*

Le méthyl-2 bromométhyl-3 cyclopropènecarboxylate d'éthyle **18** traité à 86°C par nBu$_3$SnH (2 équivalents) en solution dans le benzène subit une réduction totale en 66 h; la réaction conduit au produit de H-substitution **19**, aux produits d'ouverture **20** et **21** et à un produit non identifié **22**. La réduction, dont le rendement global reste assez faible ($\simeq$50%), est très sensible à l'addition des initiateurs tel que l'azobisisobutyronitrile.



Traité dans les mêmes conditions expérimentales l'ester chloré cyclopropylidénique **6** conduit essentiellement aux composés **19**, **20** avec un rendement global de l'ordre de 50% et dans les proportions 1:3.

En l'absence de solvant, à 76°C, l'ester **6** fournit essentiellement des polymères.

L'ester **19** est identique en ir et rmn à un échantillon authentique (23, 24).

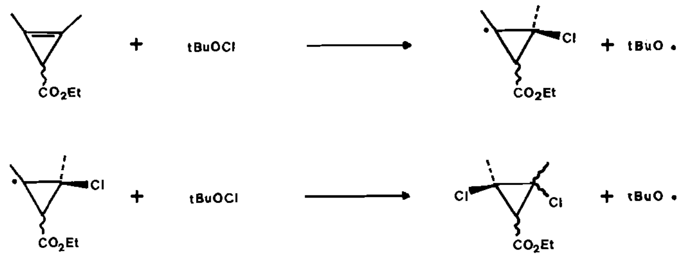
L'attribution des configurations *E* et *Z* est fondée sur l'effet anisotropique du carbonyle sur Me_3 dans **20** et sur H_4 dans **21**; le déblindage relatif de ces protons ne laisse subsister aucune incertitude quant à ces attributions. On observe en effet:

20	δ Me_3 = 2,26 ppm	**21** δ Me_3 = 1,95 ppm
	δ H_4 = 6,38 ppm	δ H_4 = 7,62 ppm

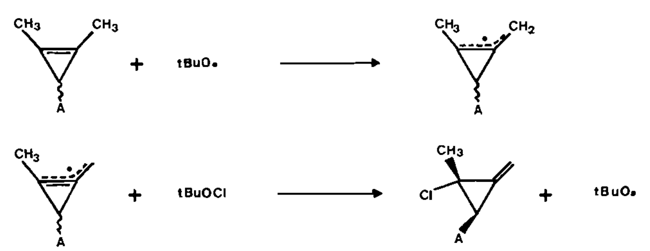
Discussion. Étude théorique

Le caractère radicalaire de la réaction de chloration des substrats cyclopropéniques par *t*-BuOCl est démontré par l'influence du galvinoxyle sur les vitesses de substitution allylique et de l'addition du chlore sur la double liaison. Le fait que la durée de la période d'induction de la chloration allylique soit supérieure à celle de l'addition sur la double liaison cyclopropénique ne peut s'interpréter que par une hypothèse analogue à celle de Walling relative aux alcynes (7) qui, compte-tenu du caractère acétylénique de la double liaison cyclopropénique n'est pas surprenante (25); notons cependant que l'attaque primaire de la double liaison peut non seulement être réalisée par *t*-BuOCl mais également par des traces de chlore moléculaire.

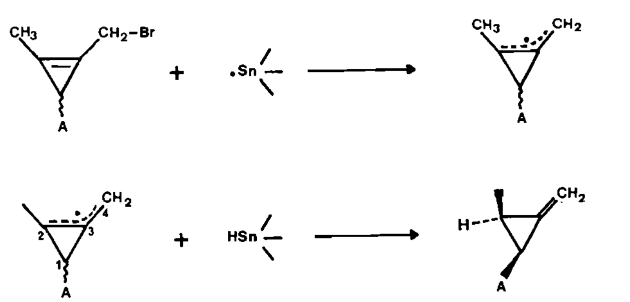
Addition du chlore:



Chloration allylique:



De même, comme nous l'avons vu, le caractère radicalaire de l'hydrogénolyse des liaisons C–halogène par les hydrures organostanniques est actuellement admis (réf. 3 et réf. citées). Comme précédemment la première étape de la réduction est la rupture d'une liaison allylique:



Qu'il s'agisse de la chloration par *t*-BuOCl ou de la réduction par Bu$_3$SnH des substrats cyclopropéniques, la première étape de la réaction conduit au radical (cyclopropène-1 yl)-1 alkyle (ou méthylènecyclopropyle). Ce radical peut subir une réaction d'ouverture ou arracher un atome de chlore (*t*-BuOCl) ou

d'hydrogène ($HSnBu_3$); dans ce cas l'attaque est régiosélective puisque seul le carbone 2 du cycle fixera l'atome de chlore ou d'hydrogène. La réaction est par ailleurs hautement stéréosélective: le réactif approche toujours du côté le moins encombré du radical intermédiaire.

Deux types de structure peuvent être envisagés pour ce radical:

Soit une structure plane caractéristique d'un radical π de type allylique. La transposition cyclopropène → cyclopropylidène que nous avons observée au cours de la chloration et de la réduction de substrats cyclopropéniques, est en faveur d'une telle hypothèse.

Soit l'électron célibataire, dans cet intermédiaire, est localisé sur C_2; le radical est tétraédrique. Cette hypothèse est étayée par la régiosélectivité très élevée observée au cours de l'attaque des réactifs par ce radical d'une part et par la stéréochimie des produits de réduction des dibromo-1,1 méthylène-2 cyclopropanes (3).

L'étude théorique qui suit porte essentiellement sur la structure des radicaux méthylènecyclopropyle diversement substitués et sur la régiosélectivité de la réaction d'arrachement d'un atome d'hydrogène par ces radicaux.

Méthode

Compte-tenu de la complexité du problème à traiter – optimisation complète de géométrie pour l'étude de structure des radicaux et "taille" des supermolécules envisagées lors des réactions d'arrachement – nous avons choisi d'utiliser une méthode semi-empirique. Parmi celles-ci la méthode MNDO (26) permet de reproduire raisonnablement les géométries et les propriétés thermodynamiques des radicaux (27, 28); de plus, parmi les méthodes SCF semi-empiriques, cette méthode est généralement bien adaptée à l'étude des chemins réactionnels (29). Deux versions pour le traitement des systèmes à couches ouvertes ont été utilisées: MNDO "half-electron" (HE) (30) et MNDO "unrestricted" (UHF) (31). Les géométries ont été totalement optimisées en utilisant l'algorithme de Davidon–Fletcher–Powell (DFP) (32).

La localisation des états de transition a été conduite de la manière suivante (33): nous avons choisi comme variable indépendante R la distance $C_iH (i = 2,4)$ entre l'atome C_i du radical et l'atome d'hydrogène du substrat (voir fig. 4); cette distance traduit le degré d'avancement de la formation de la nouvelle liaison σ; nous avons utilisé la méthode dite de coordonnée de réaction afin d'obtenir une première localisation de l'état de transition; la structure ainsi déterminée a été utilisée comme point de départ pour la localisation définitive de l'état de transition à l'aide de la méthode décrite par McIver et Komornicki (34); la matrice des constantes de force a été calculée et nous avons vérifié qu'elle possédait une seule valeur propre négative.

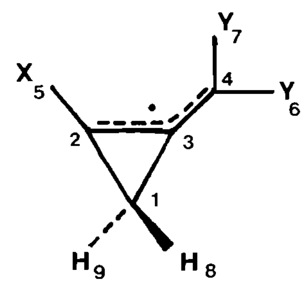

FIG. 1. Numérotation des atomes de radical méthylènecyclopropyle.

Géométries

Les principaux paramètres géométriques calculés pour les radicaux diversement substitués sont réunis dans le tableau 1; tous les radicaux sont trouvés plans (symétrie C_s); les géométries d'équilibre obtenues par les méthodes UHF et HE sont très voisines; on notera également que la présence de substituants en position 2 et 4 n'affecte que très faiblement les paramètres géométriques. Les résultats concernant les géométries d'équilibre sont en faveur d'une structure allylique: ces radicaux sont plans; les liaisons C_2—C_3 et C_3—C_4 sont intermédiaires entre une simple et une double liaison; en effet, les longueurs de ces liaisons calculées par la méthode MNDO sont comprises entre celles des hydrocarbures parents: à titre d'exemple, les liaisons C_2—C_3 et C_3—C_4 sont respectivement égales à 1,492 Å et 1,319 Å pour le méthylène-3 cyclopropane et à 1,332 Å et 1,461 Å pour le méthyl-3 cyclopropène; nous signalons que la géométrie d'équilibre calculée du méthylène-3 cyclopropane est en bon accord avec les données expérimentales (35).

On peut toutefois s'interroger sur l'aptitude de la méthode MNDO à rendre compte de l'angle de torsion α éventuel du centre radicalaire C_2. En effet, les calculs MNDO indiquent bien que les radicaux cyclopropyle (28), α-fluorocyclopropyle (α = 18,7°, déterminé dans ce travail), $\cdot CHF_2$ et $\cdot CF_3$ (27) sont pyramidaux et reproduisent correctement l'augmentation de la torsion lorsque l'on substitue les hydrogènes en α du centre

TABLEAU 2. Structure électronique et stabilité relative des radicaux méthylènecyclopropyle

Radicaux	ϵ_{SOMO} (eV)	Coefficient des OA dans la SOMO $C_{2\pi}$	$C_{4\pi}$	Indices de liaison π C_2—C_3	C_3—C_4	ΔH^* de formation (kcal mol^{-1})	Enthalpie de stabilisation* (kcal mol^{-1}) Réaction [1]	Réaction [2]

* Les valeurs entre parenthèses sont celles obtenues par la méthode MNDO (HE).

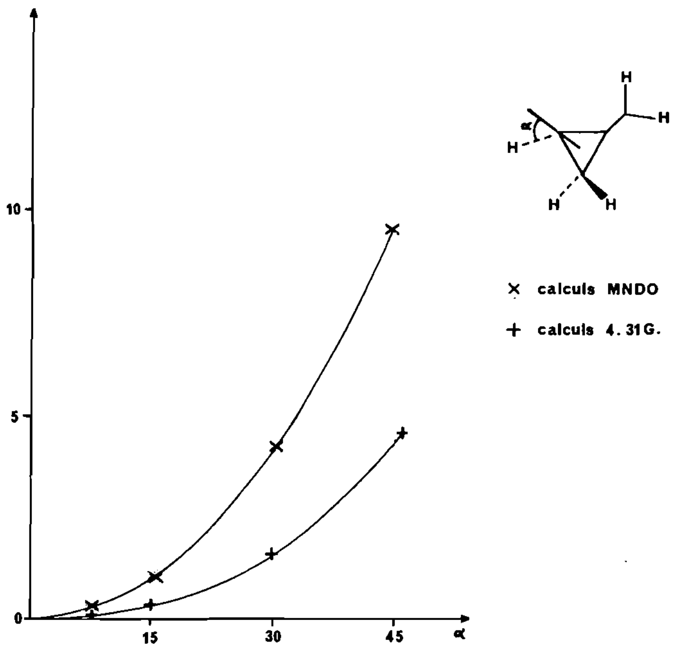

FIG. 2. Variation de l'énergie totale du radical méthylènecyclopropyle en fonction de l'angle de torsion α ($\Delta E = E_{(\alpha)} - E^0$; E^0: énergie totale du radical correspondant à α = 0°).

radicalaire par des fluors (36, 37). Cependant, les angles α ainsi obtenus semblent sous-estimés par rapport aux calculs *ab initio*: pour le cyclopropyle, α = 3° en MNDO (28) et α = 40° en *ab initio* (38); $\cdot CH_2F$, α = 0° en MNDO (27, 28) et α = 32° en *ab initio* (39). Il semble donc que la méthode sous-estime en règle générale la tendance à la pyramidalité du centre radicalaire.

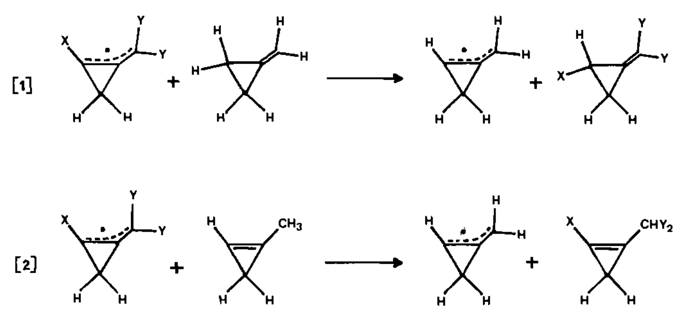
Afin de mieux affiner l'analyse conformationnelle, nous avons calculé la variation de l'énergie en fonction de l'angle α (fig. 2) pour le radical méthylènecyclopropyle non substitué à l'aide des méthodes MNDO (HE) et *ab initio* (UHF) en base 4-31G: pour chaque valeur de l'angle α, nous avons fait une optimisation complète de géométrie par la méthode MNDO et les géométries obtenues ont servi à effectuer le calcul *ab initio* correspondant.

L'accord qualitatif est bon entre les deux calculs, toutefois – et ce résultat confirme notre analyse – la méthode MNDO surestime l'énergie de torsion et de ce fait, sous-estime l'angle de torsion. Le radical non substitué est donc trouvé plan aussi bien en MNDO qu'en *ab initio* au stade SCF, alors que le radical cyclopropyle est toujours trouvé pyramidal (28, 38). On peut donc s'attendre à ce que la géométrie du centre radicalaire dans les radicaux méthylènecyclopropyle diffère notablement de celle des radicaux cyclopropyles.

Structure électronique. Effet de substituant sur la stabilité des radicaux

Nous avons réuni dans le tableau 2 les principales données caractérisant la structure électronique des radicaux méthylènecyclopropyle.

L'orbitale simplement occupée a la symétrie du radical allyle; une analyse en termes d'orbitales frontières donne le centre C_2 comme étant le plus réactif ($|C_{2\pi}| > |C_{4\pi}|$); les indices de liaison π des liaisons C_2—C_3 et C_3—C_4 confirment la structure allylique de ces radicaux. Dans les deux dernières colonnes du tableau 2, nous avons fait figurer les variations d'enthalpie des réactions isodesmiques:



Une valeur positive de la variation d'enthalpie correspond à une stabilisation du radical substitué par rapport à l'hydrocarbure correspondant (40); la géométrie de ces derniers a été totalement optimisée par la méthode MNDO.[3]

Les variations d'enthalpie de la réaction [1] montrent: qu'un groupement méthyle en position 2 stabilise le radical; que la présence de deux substituants méthyle en position 4 n'a qu'un très faible effet sur la stabilité relative du radical.

Inversement, les variations d'enthalpie de la réaction [2] montrent que seuls les groupements méthyle en position 4 augmentent de manière sensible la stabilité relative du radical correspondant.

Ces résultats peuvent être rationalisés en termes d'interaction entre orbitales moléculaires (PMO analysis) (pour une revue, voir par exemple la réf. 41); les interactions entre orbitales frontières sont illustrées sur la figure 3; dans le cas du radical, compte-tenu de la symétrie de l'orbitale moléculaire simplement occupée (SOMO), les interactions stabilisantes ① et ②[4] sont possibles à la fois lorsque le groupement méthyle est

[3] Nous tenons à la diposition des personnes intéressées les géométries totalement optimisées des produits de substitution ainsi que celles des états de transition correspondants.

[4] Les interactions du type ① peuvent devenir déstabilisantes; le caractère déstabilisant apparaît lorsque le recouvrement intermoléculaire entre les O.M qui interagissent est introduit dans l'expression de l'énergie d'interaction (42).

en position 2 *et* en position 4; on peut prévoir que la stabilisation résultante sera plus importante lorsque le méthyle est en position 2 ($|C_{2\pi}| > |C_{4\pi}|$).

Pour les hydrocarbures correspondants, l'interaction ③ entrainera une stabilisation uniquement si le groupement méthyle est en position 2; de même l'interaction ④ ne sera importante que lorsque les groupements méthyles seront en position 4.

Ainsi les données thermodynamiques de la réaction [1] traduisent l'effet stabilisant du méthyle en position 2 (ΔH ~8 kcal mol^{-1}) qui existe pour le radical et non pour l'hydrocarbure correspondant alors que l'effet stabilisant des méthyles en position 4 n'apparaît pas car il intervient à la fois pour le radical et le dérivé méthylènecyclopropanique; de même les données thermodynamiques de la réaction [2] traduisent uniquement l'effet stabilisant des deux groupements méthyles en position 4; on notera également que l'énergie de stabilisation ramenée à *un* groupement méthyle est inférieure à celle calculée dans le cas de la réaction [1] car l'énergie d'interaction est inférieure lorsque le méthyle est substitué sur le sommet 4 ($|C_{4\pi}| < |C_{2\pi}|$).

La planéité des radicaux est apparemment en contradiction avec la très grande régiosélectivité observée dans les réactions d'arrachement d'hydrogène ou de chlore. Nous allons donc examiner dans le paragraphe suivant si malgré la planéité des radicaux, les calculs peuvent rendre compte de cette sélectivité.

Étude des réactions d'arrachement par les radicaux méthylènecyclopropyle

Les réactions élémentaires présentées dans ce paragraphe concernent uniquement l'arrachement d'un atome d'hydrogène du substrat;[5] la méthode MNDO n'étant pas paramétrisée pour l'étain, nous avons choisi comme substrat SiH_4 pour représenter $HSn(nBu)_3$.

Le formalisme MNDO a été employé par Dewar et coll. lors de l'étude d'arrachement par $\dot{C}H_3$ et $\dot{C}F_3$ d'un hydrogène de l'éthane (43) et de l'arrachement par CH_3 d'un hydrogène du méthane (note 22 de la référence 43); l'enthalpie d'activation calculée pour cette dernière réaction (28,6 kcal mol^{-1}) est supérieure à l'énergie d'activation expérimentale (14,2 kcal mol^{-1}) (44) mais comparable à celle obtenue à partir d'un calcul *ab initio* 4-31G (29,9 kcal mol^{-1}) (45); on retrouve cette tendance dans le récent travail de Pudzianowski et Loew (46): l'enthalpie d'activation correspondant à l'arrachement par l'oxygène atomique d'un atome d'hydrogène de CH_4 est de 27,4 kcal mol^{-1}, l'énergie expérimentale n'étant que de 8,4 kcal mol^{-1}. Pour compléter cette étude bibliographique, nous avons également testé la méthode MNDO sur le processus élémentaire: $\dot{C}H_3 + SiH_4 \rightarrow CH_4 + \dot{S}iH_3$; les calculs reproduisent correctement la plus grande réactivité de SiH_4 par rapport à CH_4 mais les barrières d'énergie calculées sont surestimées ($\Delta H^{\neq}$ calculé: 17,8 kcal mol^{-1}, énergie d'activation expérimentale (44): 6,9 kcal mol^{-1}).

Dans ce type de réaction où une liaison est rompue, une interaction de configuration est nécessaire ce qui explique que des calculs *ab initio* au niveau SCF surestiment l'énergie d'activation; dans le cas des méthodes semi-empiriques, une partie de l'énergie de correlation est introduite du fait de la paramétrisation et l'on aurait pu espérer un meilleur accord avec l'expérience; dans le cas de la méthode MNDO, la surestimation de l'enthalpie d'activation est attribuée (43, 46) à une surestimation des répulsions dans les interactions à trois électrons répartis sur trois centres.

[5] Une étude préliminaire de la réaction d'arrachement d'un atome de chlore (substrat modèle CH_3OCl) montre que celui-ci s'arrache plus facilement qu'un atome d'hydrogène; toutefois, nous nous sommes heurtés à des problèmes de convergence qui rendent les temps de calcul prohibitifs.

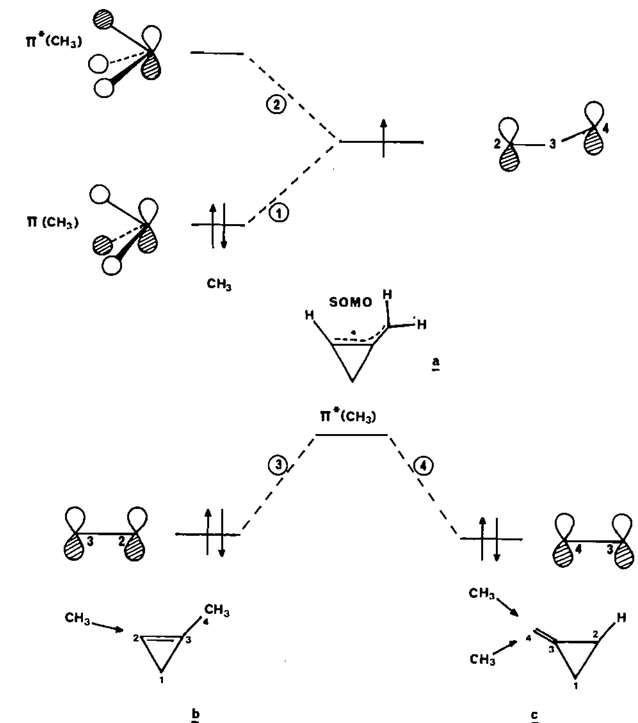


FIG. 3. Diagramme d'interaction représentant: l'interaction entre la SOMO du radical et les orbitales Π et Π* du groupement CH_3 (a); l'interaction entre la HOMO du méthyl-3 cyclopropène (b) ou la HOMO du méthylènecyclopropane (c) et l'orbitale vacante Π* (CH_3).

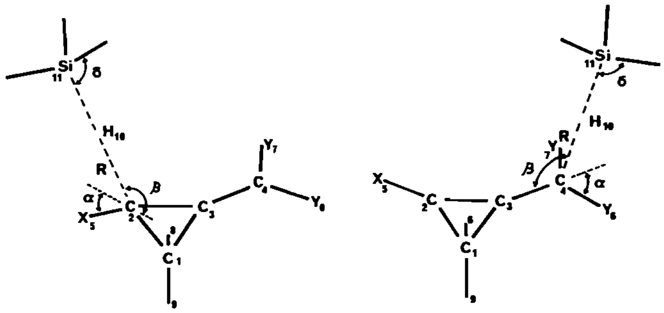
Le tableau 3 rassemble les valeurs des principaux paramètres géométriques calculés pour les états de transition (TS). La présence de substituants sur les centres réactifs C_2 et C_4 du radical n'entraîne que de très faibles modifications de la géométrie des états de transition.

Dans tous les cas, l'atome de carbone radicalaire, l'atome d'hydrogène (H_{10}) subissant l'arrachement et l'atome (numéroté 11) auquel il était lié dans le substrat restent alignés, le plan de symétrie du substrat bissectant les angles $\widehat{123}$ (fig. 4a) ou $\widehat{546}$ (fig. 4b); les géométries des substrats silylés ont été totalement optimisées au moyen de la méthode MNDO par Verwoerd (47).

Les états de transition apparaissent relativement tôt sur le chemin réactionnel, mais ils sont plus proches des réactants pour l'attaque en C_2(TS4a) que pour l'attaque en C_4(TS4b); notons également que la présence de méthyles sur les centres C_2 ou C_4 "retarde" l'état de transition: la liaison S_i—H(d_{10-11}) égale à 1,434 Å dans SiH_4 (47) est plus étirée lorsque l'attaque s'effectue sur le centre radicalaire C_4 et l'allongement de la liaison est plus important si les carbones 2(TS4a) ou 4(TS4b) portent un groupement méthyle; la liaison C_2—C_3 présente un allongement de ~0,05 Å (TS4a) tandis que la liaison C_3—C_4 s'allonge de ~0,07 Å (TS4b) par rapport aux liaisons correspondantes du radical (tableaux 1 et 3).

Les enthalpies d'activation sont réunies dans la dernière ligne du tableau 3; l'arrachement d'hydrogène se fait toujours à partir du centre C_2 du radical; la différence d'énergie d'activation entre les deux attaques, bien que surestimée, est



TS 4a TS 4b

FIG. 4. Numérotation des atomes et définition des paramètres géométriques utilisés pour décrire les états de transition.

suffisamment importante pour expliquer que le dérivé méthylènecyclopropanique soit le seul composé de substitution observé expérimentalement. La régiosélectivité de la réaction peut donc être expliquée sans qu'il soit nécessaire de postuler un radical pyramidal dont l'électron célibataire serait localisé en C_2.

Le radical chloré qui peut être considéré comme un modèle des radicaux étudiés par Bertrand et coll. (3) présente approximativement la même réactivité que le radical non substitué; par contre, l'effet stabilisant des substituants méthyles en C_2 ou en C_4 rend les radicaux correspondants beaucoup moins réactifs dans les réactions d'arrachement d'hydrogène et nos calculs prévoient la plus grande sélectivité pour le radical triméthylé qui peut être considéré comme un modèle des radicaux que nous avons étudiés. La réaction d'arrachement d'hydrogène par les radicaux méthylènecyclopropyle alkylés conduit à côté du dérivé méthylène cyclopropanique à des produits résultant de l'ouverture du radical; une étude complète du mécanisme de cette réaction devrait également envisager les problèmes relatifs à l'ouverture des radicaux et aux réactions d'arrachement par les radicaux non cycliques; de la compétition entre la réaction d'arrachement par le radical cyclique et l'ouverture de celui-ci va dépendre la nature des produits; notre travail permet cependant d'apporter un premier élément de réponse: le processus d'arrachement est défavorisé si le réactant est un radical cyclique alkylé en C_2 et en C_4, la régiosélectivité de la réaction étant conservée.

La polarité de l'état de transition n'est que très peu affectée par la présence de substituants sur le radical; notons toutefois que le chlore en α du centre radicalaire C_2 confère à celui-ci un faible caractère électrophile (SiH_4 porte une charge nette globale de $+0{,}013\ e^-$ dans l'état de transition, alors que la valeur correspondante pour le radical non substitué était de $-0{,}026\ e^-$).

Dans le tableau 4, nous avons rassemblé les grandeurs thermodynamiques calculées relatives au processus élémentaire d'arrachement d'un atome d'hydrogène du silane par les radicaux cycliques diversement substitués.

Si l'on admet que l'entropie d'activation varie peu dans la série envisagée, les variations de la réactivité d'un radical R· son données par: $\Delta E_i^{R} = \Delta H^{\neq}_{iR\cdot} - \Delta H^{\neq}_{i\,\text{référence}}$ (référence: radical cyclique non substitué; i: n° du centre radicalaire où s'effectue la réaction d'abstraction); les différences $\Delta(\Delta H_i) = \Delta H_{iR\cdot} - \Delta H_{i\,\text{référence}}$ traduisent les variations de l'énergie de la liaison C_i—H formée au cours de la réaction d'arrachement. Pour un substrat donné, la réactivité des radicaux varie comme $\Delta(\Delta H_i)$ (contrôle thermodynamique); de même la régiosélectivité de la

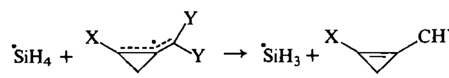
†Variation d'enthalpie calculée (kcal mol^{-1}) pour la réaction:



réaction $\Delta E^S = \Delta H_2^{\ddagger} - \Delta H_4^{\ddagger}$ est parfaitement corrélée par la différence des variations d'enthalpie $\Delta H_2 - \Delta H_4$. On peut vérifier également que l'état de transition apparaît d'autant plus tard sur le chemin réactionnel que la réaction d'arrachement est endothermique. Nos résultats sont en accord avec les règles énoncées par Tedder (48).

Une étude portant sur la pyramidalisation du centre C_4 (analogue à celle effectuée sur la torsion de la liaison C_2—H) dans le radical non substitué montre que la torsion des liaisons C_4—H d'un angle α correspondant au TS4b nécessite plus d'énergie que la torsion de la liaison C_2—H d'un même angle α dans le TS4a; la comparaison des énergies de déformation des réactants dans l'état de transition:

$$E_i^D = \Sigma E_{\text{réactants}}^{\text{TS}(i)} - \Sigma E_{\text{réactants}}^0$$

$E_{\text{réactants}}^{\text{TS}(i)}$: énergie de chaque réactant dans sa géométrie à l'état de transition; $E_{\text{réactants}}^0$: énergie de chaque réactant dans sa géométrie complètement optimisée) montre que celles-ci interviennent pour plus de 50% dans la différence des enthalpies d'activation $\Delta H_2^{\ddagger} - \Delta H_4^{\ddagger}$; ces différences traduisent à la fois la plus grande énergie nécessaire pour pyramidaliser le centre C_4 et l'apparition plus tardive sur le chemin réactionnel des TS de type 4b.

Conclusion

Cette étude de la chloration allylique des substrats cyclopropéniques et de la réduction de leurs dérivés bromés a permis de mettre en évidence sur le plan expérimental la migration exocyclique de la double liaison. Cette transposition s'interprète par la formation intermédiaire d'un radical plan de type allylique, l'électron célibataire étant essentiellement localisé sur les atomes C_2 et C_4.

L'étude théorique de la réactivité de ce radical montre que cette espèce se stabilise par fixation d'un atome sur le carbone C_2 quelle que soit la nature des substituants portés par le système allylique; ce résultat est en bon accord avec la régiosélectivité observée expérimentalement. Par ailleurs, la réaction d'arrachement se fait plus facilement lorsque l'on substitue en C_2 un méthyle par un atome de chlore.

Au terme de cette étude il nous apparaît que la méthode MNDO peut fournir un bon point de départ pour l'étude qualitative des réactions d'arrachement d'hydrogène d'un substrat donné par une série de radicaux. Elle permet entre autres de retrouver les règles proposées par Tedder.

A. Kharrat, C. Gardrat et B. Maillard. Can. J. Chem. **63**, 2522 (1985).

La thermolyse du perpentène-4 oate de *tert*-butyle **1** a été effectuée dans divers solvants ZH (acides carboxyliques, anhydrides, esters de méthyle et nitriles). Dans tous les cas, des γ-butyrolactones substituées sur le carbone 4 par le groupe ZCH_2 sont isolées, la plupart du temps avec des rendements acceptables. L'isomérisation totale des lactones **4** dérivant des acides non fonctionnels en **5** a été réalisée facilement par chauffage d'une solution tétrahydrofurannique de **4** en présence de traces d'APTS; des résultats similaires sont enregistrés à partir de solutions méthanoliques des esters lactones (**6** → **7**) en présence de traces d'APTS.

A. Kharrat, C. Gardrat, and B. Maillard. Can. J. Chem. **63**, 2522 (1985).

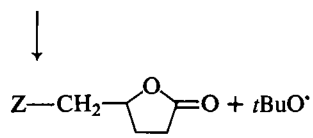
The thermolysis of *tert*-butylperpent-4-enoate in various solvents ZH (carboxylic acids, anhydrides, methyl esters, nitriles) led to γ-butyrolactones 4-substituted by the group ZCH_2 with good yields. The acidic treatment of the lactones **4** and **6** derived from non-functionalized alkanoic acids and methyl esters gave respectively the isomerized lactones **5** and **7**, increasing the synthetic interest of the studied homolytic reaction.

Introduction

Lors de l'étude de la thermolyse du perpentène-4 oate de *tert*-butyle **1** dans le cyclohexane (1) nous avons mis en évidence la présence du cyclohexyl-5 pentanolide-4 issu de la décomposition induite du perester insaturé par un radical cyclohexyle. La formation de la lactone se fait par une réaction en chaîne dont la phase de propagation se résume aux étapes suivantes:

[1] $Z^{\cdot} + CH_2{=}CH{-}(CH_2)_2{-}CO_3tBu$

1

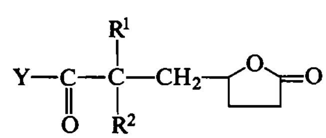


[2] $tBuO^{\cdot} + ZH \longrightarrow tBuOH + Z^{\cdot}$

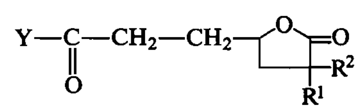
avec ZH = $c\text{-}C_6H_{12}$.

Nous avons par la suite montré que ce type de réaction n'est pas particulier aux cas des cyclanes puisqu'il intervient dans les cétones (2) et les éthers (3) permettant d'accéder facilement à des γ-butyrolactones substituées en 4 par des groupes comportant des fonctions.

Les acides et leurs dérivés sont des produits qui donnent lieu à des additions radicalaires aux composés insaturés, comme le rapporte Vogel dans une mise au point ancienne (4). Dans ces conditions la thermolyse de **1** dans un acide alcanoïque ou son substitut R^1R^2CHCOY pourrait permettre d'accéder aux olides de formule générique **2**.



2



3

Une des voies d'accès les plus simples aux γ-butyrolactones consiste en l'estérification intramoléculaire d'un γ-hydroxyacide (5). Pour obtenir des lactones **4** (**2**, Y = OH) par cette voie, il faut partir d'un γ-hydroxydiacide.

Si au moins un des substituants R^1 ou R^2 n'est pas un atome d'hydrogène, une telle synthèse peut conduire a priori à deux lactones distinctes **4** (**2**, Y = OH) et **5** (**3**, Y = OH).

A notre connaissance aucune étude de ce type n'ayant été signalée dans la littérature, nous avons décidé d'effectuer la thermolyse de **1** dans les acides alcanoïques et leurs dérivés en vue de préparer sélectivement les composés **2** et de rechercher des conditions d'isomérisation de ces derniers en **3**.

Dans une première partie, après avoir défini les conditions optimales de réaction en prenant le propionate de méthyle comme composé modèle, nous avons étendu ce travail à

[1] Auteur à qui adresser toute correspondance.

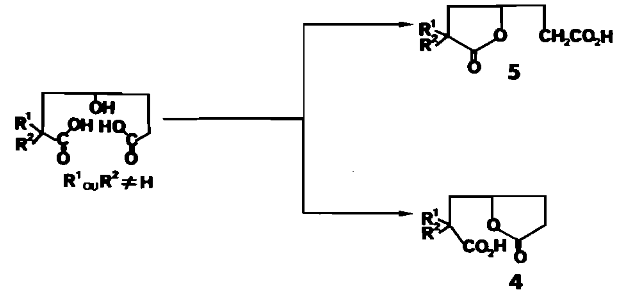


FIG. 1

d'autres esters, acides, anhydrides, amides ainsi qu'à des nitriles.[2]

Dans une deuxième partie, après avoir effectué l'étude de la lactonisation acide d'un hydroxy-4 diacide-1,7 nous avons essayé de réaliser l'isomérisation acido-catalysée de certaines γ-lactones **2** afin de voir si cela pouvait constituer une voie d'accès générale aux composés de type **3**.

Thermolyse de 1 dans les acides et leurs derivés

I. *Esters*

1. *Alcanoates de méthyle*

Les esters ont souvent été utilisés à la place des acides pour réaliser l'alkylation radicalaire de ces derniers lorsqu'il se forme des produits secondaires par réaction des acides avec les composés insaturés. Notre choix de réaliser l'étude avec les esters avant de l'entreprendre avec les acides a été dicté par une raison similaire: il semblait a priori moins facile d'avoir une isomérisation de la lactone **6** (**2**, Y = OMe) en **7** (**3**, Y = OMe) que de **4** (**2**, Y = OH) en **5** (**3**, Y = OH).[3]

Le remplacement de l'acide par un ester présente toutefois l'inconvénient d'introduire un site réactif supplémentaire: le carbone en α de l'oxygène; néanmoins, l'emploi d'un ester de méthyle limite considérablement l'attaque de la partie alcoxyle. Bien que l'acétate de méthyle soit le premier membre de la famille des esters $R^1R^2CHCO_2Me$, nous avons préféré effectuer les études préliminaires avec le propionate de méthyle afin de voir si une isomérisation de **6***b*[4] en **7***b* intervenait (dans le cas de l'acétate de méthyle, les deux formules **6***a*[4] et **7***a* correspondent au même produit).

Un essai de thermolyse de **1** dans le propionate de méthyle montre que le composé recherché **6***b* se forme. Afin de définir les conditions optimales de la réaction, nous avons effectué une étude de la décomposition de **1** dans cet ester en faisant varier la température de thermolyse, la durée et les rapports molaires.

Comme le montre le tableau 1, les conditions pour lesquelles le rendement en **6***b* est le plus élevé correspondent à un chauffage à 110°C pendant 8 h en utilisant un rapport molaire **1**/ester = 1:100.

L'étude de la thermolyse de **1** a été réalisée dans l'acétate de méthyle, le propionate de méthyle et l'isobutyrate de méthyle, ces esters possédant les différents types d'hydrogène pouvant être arrachés pour conduire à des radicaux en α du carbonyle.

[2] Les nitriles sont généralement considérés comme des dérivés d'acides. C'est pourquoi nous avons placé leur étude dans le cadre de ce travail bien qu'ils ne conduisent pas à des composés de type **2**.

[3] Les acides sont souvent transformés en esters de méthyle avant d'être analysés par cpg: cette considération a constitué un argument supplémentaire dans le choix des esters comme premiers modèles.

[4] *a*: $R^1 = R^2 = H$; *b*: $R^1 = H$, $R^2 = CH_3$; *c*: $R^1 = R^2 = CH_3$.

TABLEAU 1. Variation des rendements en **6***b* en fonction des conditions expérimentales

Rapport molaire **1**/$CH_3CH_2CO_2CH_3$	Rendement en **6***b* (%)*		
	2 h à 130°C	4 h à 120°C	8 h à 110°C
1:5	11	12	16
1:10	16	24	31
1:20	31	32	42
1:50	29	39	44
1:100	43	37	58

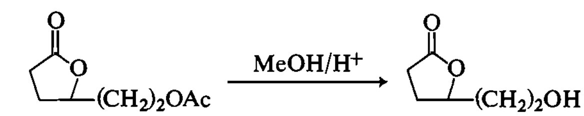
*Calculé par rapport au perester mis en jeu et déterminé par cpg.

Dans les deux derniers cas, les deux produits de substitution **6** (sur la partie acyle) et **8** (sur la partie méthoxyle) sont observés; les produits **6** ont toutefois été isolés facilement par chromatographie liquide–solide sur gel de silice permettant de préserver l'intérêt synthétique de la méthode.

A ces trois modèles, nous avons ajouté le cas particulier du formiate de méthyle dont l'addition radicalaire à un alcène permet d'effectuer une extension de chaîne d'un carbone (4).

Les différents composés décrits dans le tableau 2 ont été identifiés par rmn ainsi que par spectrométrie de masse. Les produits de référence **8** ont été synthétisés à partir de l'hydroxylactone correspondante **10**. Cette dernière a été obtenue à partir de la lactone ester préparée selon la réf. 6.

[3] $BrCH_2CO_2Et + CH_2{=}CH{-}(CH_2)_2OAc \xrightarrow[\text{benzoyle, 80°C}]{\text{peroxyde de}}$



8*a* **10**

Dans le cas de la thermolyse de **1** dans l'acétate de méthyle, nous n'avons pas réussi à séparer les deux produits possibles de substitution **6***a* et **8***a*. Une estimation des proportions relatives de ces deux composés n'a également pas pu être faite bien qu'un essai de transformation du produit réactionnel par transestérification à l'aide du méthanol en présence de traces d'APTS ait été réalisé: **8***a* devrait conduire à **10** et **6***a* ne devrait pas être affecté. Si **8***a* se forme, sa proportion relative est très faible.

Comme cela avait été signalé dans le cas particulier de l'acétonylation de l'acétate de méthyle (7), nous observons une variation des proportions relatives de **6** et **8** pour les propionate et isobutyrate de méthyle selon les rapports molaires **1**/ester utilisés (Tableau 3).

Ces résultats s'accordent fort bien avec ceux des travaux antérieurs (8) indiquant que l'attaque sur les esters par les radicaux électrophiles se fait de préférence sur le groupe alcoxyle. La compétition entre la réaction [4] et la réaction d'addition à la double liaison du perester serait responsable des résultats enregistrés.

$$[4] \quad \underset{\mathbf{A}}{R^1R^2CHCO_2\dot{C}H_2} + R^1R^2CHCO_2CH_3 \longrightarrow R^1R^2CHCO_2CH_3 + \underset{\mathbf{B}}{R^1R^2\dot{C}CO_2CH_3}$$

L'existence de rendements très éloignés de 100% montre qu'il est vain de comparer entre eux les résultats obtenus pour les deux esters. Dans le cas de l'isobutyrate de méthyle, la mise

* Dosage effectué par cpg.

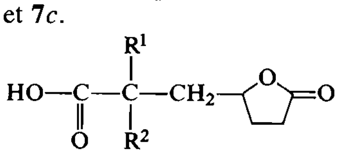
en évidence de quantités non négligeables de tétraméthyl-2,2,3,3 succinate de diméthyle montre que l'addition du radical B s'effectue difficilement.

2. *Esters fonctionnels*

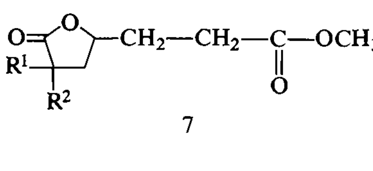
De nombreux esters fonctionnels (malonates, cyanoacétates, chloroacétates, acétylacétates, ω-diesters...) ont pu être substitués en α du carbonyle grâce aux réactions d'additions radicalaires (4). Nous avons effectué la thermolyse de **1** dans un ester de chacune de ces familles et avons isolé le produit de "pentanolidation". Les résultats obtenus sont rassemblés dans le tableau 4.

II. *Acides et anhydrides*

La thermolyse de **1** dans les acides et les anhydrides a été effectuée dans des conditions identiques à celles des esters (110°C, 8 h, rapport molaire **1**/solvant = 1 : 100). Elles ne sont peut-être pas optimales pour les acides et les anhydrides mais elles présentent l'avantage de permettre une comparaison des résultats obtenus à ceux des esters. La "pentanolidation" des acides acétique, propionique et isobutyrique s'effectue avec des rendements respectifs de 47%, 56% et 22%. Seuls les composés **4***a*, **4***b* et **4***c* sont obtenus. En effet, après méthylation au diazométhane, seuls **6***a*, **6***b* et **6***c* sont identifiés par comparaison en cpg à des échantillons de **6***a* (≡ **7***a*), **6***b* et **7***b*, **6***c* et **7***c*.



4



7

a $R^1 = R^2 = H$
b $R^1 = H$ $R^2 = CH_3$
c $R^1 = R^2 = CH_3$

Nous soulignerons que les rendements de fonctionnalisation des acides sont voisins de ceux des esters correspondants. En conséquence la thermolyse de **1** dans les monoesters de méthyle ne peut constituer la meilleure voie d'accès aux composés **6***a*, **6***b*, **6***c* puisque la méthylation au diazométhane des acides **4***a*, **4***b*, **4***c* (réaction quasi quantitative) permet d'accéder plus facilement aux composés recherchés et avec un meilleur rendement (dans le cas des esters une séparation des composés de type **6** et **8** est nécessaire). Cependant, dans le cas des esters fonctionnels correspondant à des acides instables dans les conditions de la réaction (acide acétylacétique, acide malonique) la "pentanolidation" de l'ester s'avère la meilleure voie d'autant qu'elle ne conduit qu'à un seul produit.

Remarque: Comme nous l'avons signalé dans le paragraphe précédent, l'addition radicalaire d'esters à des alcènes conduit généralement à des produits de substitution des deux carbones situés de part et d'autre du carbonyle, ce qui limite souvent l'intérêt synthétique de la méthode au cas des esters de méthyle. Les acides lactoniques **4** peuvent être le point de départ des composés de type **2** (Y étant un groupe alkyle quelconque); nous avons voulu voir si, en milieu non acide, il était possible de les estérifier sans isomérisation. La réactivité des azolides mise en évidence par Staab (9) a permis de préparer des esters en milieu neutre. Le traitement de l'acide lactonique **4***b* par le *N,N'*-carbonyldiimidazole permet d'obtenir l'azolide qui, par réaction sur le méthanol, conduit uniquement à **6***b*.

La thermolyse de **1** a été effectuée dans les anhydrides acétique et propionique (110°C, 8 h, **1**/anhydride = 1 : 100). Après hydrolyse du mélange réactionnel, les acides **4***a* et **4***b* sont isolés avec des rendements de l'ordre de 20%.

III. *Amides et nitriles*

La thermolyse de **1** dans le diméthylformamide et le diméthylacétamide (110°C, 8 h, **1**/amide = 1 : 100) n'a pas permis d'isoler la γ-butyrolactone fonctionnelle recherchée. Par contre, les réactions effectuées dans les mêmes conditions avec l'acétonitrile et le propionitrile ont conduit aux produits attendus **11***a* et **11***b* avec des rendements respectifs de 17% et 24%; avec l'isobutyronitrile, le tétraméthyl-2,2,3,3 succinodinitrile résultant du couplage des radicaux cyano-2 propyle-2 est le principal produit de la réaction comme lors des tentatives d'additions radicalaires de ce composé (10).

Isomérisation des lactones 4 et 6

Afin de situer notre méthode de préparation des lactones **4**

TABLEAU 4. Lactones isolées par thermolyse de **1** dans divers esters fonctionnels (conditions expérimentales **1**/ester = 1:100; 8 h à 110°C)

* Déterminé sur la fraction de distillation par rapport au perester **1** mis en jeu dans la réaction.

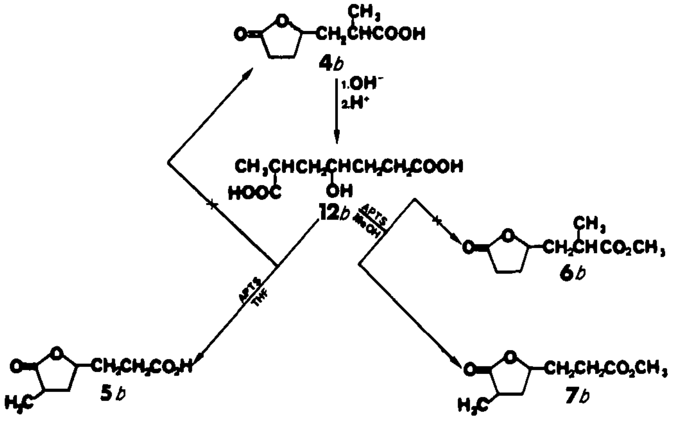

FIG. 2

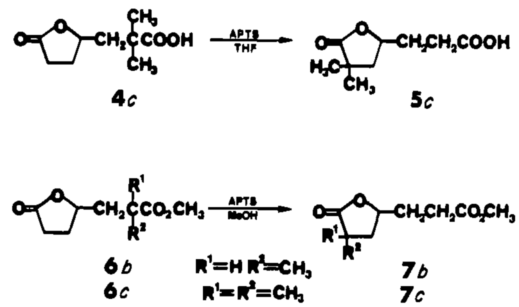

FIG. 3

relativement à la lactonisation acide à partir des hydroxydiacides, nous avons réalisé la saponification de la lactone **4***b* et isolé l'hydroxydiacide correspondant. Son traitement par l'APTS en solution dans le THF conduit à la lactone acide **5***b* isomère de **4***b*. La même réaction effectuée dans le méthanol conduit à **7***b* isomère de **6***b* (fig. 2).

Ces résultats montrent que la thermolyse de **1** dans un acide ou son ester de méthyle permet d'accéder facilement à **4** ou **6** ce qui n'est pas le cas pour la lactonisation de l'hydroxydiacide.

Il paraissait intéressant de confirmer les résultats obtenus à partir de **4***b* avec **4***c* et de voir si une isomérisation des esters **6** en composés **7** pouvait être réalisée en présence de traces d'acide dans le méthanol (fig. 3).

Le traitement de l'acide lactonique **4***c* par l'APTS dans le THF au reflux permet d'obtenir facilement l'isomère **5***c*. Les lactones **6** dérivant des monoesters conduisent à **7** (**6***b* et **6***c* donnent **7***b* et **7***c*, **6***a* et **7***a* correspondent au même composé) après un reflux de 3 h en solution méthanolique en présence de traces d'APTS.

Les composés **6***e*, **6***f*, **6***i* ne sont pas affectés même après un chauffage de 48 h. Le produit de "pentanolidation" de l'acétylacétate de méthyle **6***g* se transforme en d'autres produits que la lactone **7***g* (R^1 = H, R^2 = $COCH_3$) vraisemblablement par suite de réactions secondaires dues à la présence du carbonyle sur la chaîne latérale. La lactone **6***h* est totalement isomérisée en une autre lactone mais l'attribution de la structure de cette dernière n'a pas pu être effectuée.

Il est à noter que la thermolyse de **1** (perester brut qui contient des traces d'acide chlorhydrique) dans les monoesters et les acides conduit à un mélange de **6** et **7** ou de **4** et **5**; il est donc important que le perester soit purifié avant utilisation. La décomposition de **1** dans l'acide propionique et le propionate de méthyle en présence de faibles quantités d'APTS (2% molaire par rapport à **1**) permet d'obtenir **5***b* ou **7***b* avec des rendements équivalents à ceux obtenus sans acide pour **4***b* et **6***b*.

Conclusion

Nous retiendrons de ce travail l'intérêt synthétique de la méthode de "pentanolidation" des acides, esters de méthyle et nitriles. Dans le cas des acides et des esters de méthyle, c'est une excellente voie de préparation des lactones acides **4** et des lactones esters **6** puisque les essais de lactonisation par l'APTS de l'hydroxydiacide ont conduit uniquement aux lactones isomères **5** et **7**. La mise en évidence d'une isomérisation acidocatalysée de **4** en **5** et de **6** en **7** renforce l'aspect préparatif de la décomposition induite du perpentène-4 oate de *tert*-butyle par les radicaux dérivant des acides et des esters.

Partie expérimentale[5]

Les spectres rmn du proton ont été enregistrés sur un appareil Perkin–Elmer R 12B opérant à 60 MHz à partir de solutions à 10% dans le tétrachlorure de carbone ou le DMSO-d_6 (déplacements chimiques en δ ppm par rapport au TMS).

Les spectres rmn du ^{13}C ont été enregistrés sur un appareil Bruker WP 60 fonctionnant à 15,08 MHz équipé d'un calculateur Nicolet BNC 12 (déplacements chimiques en δ ppm par rapport au TMS) à partir de solutions dans le chloroforme deutéré.

Les spectres de masse ont été obtenus, en général, par couplage masse–cpg, sur des appareils Micromass 16 F et 70-70 sous impact électronique (70 eV). Nous n'indiquons que les pics dont l'abondance relative dépasse 10%.

L'analyse des produits par chromatographie en phase gazeuse (cpg) a été réalisée sur un appareil Intersmat IGC 112 F (ionisation de flamme; gaz vecteur: azote (débit ~30 mL/min)) équipé de colonnes en acier inox (longueur: 2 m; diamètre intérieur: 2 mm). Deux phases stationnaires ont été principalement utilisées: OV-275 (10%) sur Chromosorb WHP (80/100 mesh) et FFAP (10%) sur Chromosorb WAW (80/100 mesh). Les dosages ont été effectués par la méthode de l'étalon interne.

[5] La pureté des produits nouveaux isolés ayant été vérifiée par cpg, l'étude spectroscopique (rmn, masse) accréditant leurs structures, il ne nous a pas paru nécessaire d'effectuer leur analyse centésimale.

Les points de fusion ont été mesurés sur un appareil Mettler FP 61.

Etude des décompositions

Les études analytiques ont été réalisées en introduisant 2 cm^3 de solution dans des ampoules en Pyrex scellées placées pendant le temps adéquat dans un bain thermostaté à la température choisie (110, 120 ou 130°C).

Les études préparatives ont été effectuées sur des volumes de l'ordre de 200 cm^3 dans un autoclave de 250 cm^3 placé dans une étuve thermorégulée préalablement portée à la température souhaitée. Après élimination du solvant en excès, le produit recherché est distillé sous pression réduite puis purifié par chromatographie liquide–solide sur une colonne de gel de silice (Kieselgel 60, 35/70 mesh).

Matières premières

La préparation, la purification et le dosage du perpentène-4 oate de *tert*-butyle ont été décrits dans la réf. 1. Les esters, acides, nitriles et amides sont des produits commerciaux utilisés après distillation.

Nous avons choisi de suivre dans la partie expérimentale le même plan que pour la partie théorique.

*Thermolyse de **1** dans les acides et leurs dérivés*

1. *Alcanoates de méthyle*

Produits correspondant à l'attaque sur la partie acyle:

(Oxo-2 tétrahydrofuryl-5)-3 propionate de méthyle, **6***a*; pé 128–129°C/0,8 Torr (1 Torr = 133,3 Pa); n_D^{20} = 1,4517; rmn δ: 1,4 à 2,7 (1 massif, 8H), 3,7 (singulet, 3H), 4,1 à 4,6 (1 massif, 1H); masse m/z (abondance): 85 (100), 112 (21), 45 (16), 74 (15), 141 (14).

Méthyl-2 (oxo-2 tétrahydrofuryl-5)-3 propionate de méthyle, **6***b*; pé 128–129°C/1 Torr; n_D^{20} = 1,4562; rmn δ: 1,2 (doublet, J = 8 Hz, 3H), 1,5 à 2,9 (1 massif, 7H), 3,6 (singulet, 3H), 4,0 à 4,7 (1 massif, 1H); masse m/z (abondance): 85 (100), 88 (30), 57 (17), 56 (15), 155 (13).

Diméthyl-2,2 (oxo-2 tétrahydrofuryl-5)-3 propionate de méthyle, **6***c*; pé 130–132°C/0,8 Torr; n_D^{20} = 1,4588; rmn δ: 1,2 (singulet, 6H), 1,3 à 2,6 (1 massif, 6H), 3,6 (singulet, 3H), 4,1 à 4,7 (1 massif, 1H); masse m/z (abondance): 85 (100), 102 (38), 141 (13).

Préparation des produits correspondant à l'attaque sur la partie méthoxyle:

Le propionate d'(oxo-2 tétrahydrofuryl-5)-2 éthyle, **8***b*, a été préparé par chauffage à 80°C pendant 24 h de 65 g de bromoacétate d'éthyle et de 5 g de propionate de butène-3 yle (synthétisé à partir de chlorure de propionyle et de butène-3 ol) en présence de 0,95 g de peroxyde de benzoyle (proportions molaires respectives 10:1:0,1). Après avoir éliminé le bromoacétate d'éthyle en excès, **8***b* est obtenu pur par passage sur gel de silice (éluant: éther de pétrole – éther) avec un rendement de 55%; n_D^{20} = 1,4604; rmn δ: 1,1 (triplet, J = 6,7 Hz, 3H), 1,5 à 2,7 (1 massif, 8H), 4,0 à 4,3 (triplet, 2H), 4,4 à 4,8 (massif, 1H); masse m/z (abondance): 57 (100), 85 (74), 112 (26), 56 (16), 84 (11).

L'(oxo-2 tétrahydrofuryl-5)-2 éthanol, **10**, a été obtenu par chauffage pendant 5 h à 65°C de 1 g de lactone **8***b* dans 20 cm^3 de méthanol en présence de traces d'APTS. Après élimination du méthanol en excès et du propionate de méthyle formé, la lactone **10** est récupérée (Rdt 85%). Aucune purification n'apparaît nécessaire; n_D^{20} = 1,4705; rmn δ: 1,5 à 2,7 (1 massif, 6H), 3,6 (triplet, J = 6,7 Hz, 2H), 4,4 à 4,9 (massif, 1H), 4,7 (singulet, 1H); masse m/z (abondance): 85 (100), 43 (85), 112 (18).

Préparation de **8***a*, **8***c* et **8***d*: dans 10 cm^3 de THF anhydre on met à température ambiante 0,25 g de *N,N'*-carbonyldiimidazole puis on ajoute goutte à goutte sous agitation la quantité d'acide correspondante (0,092 g d'acide acétique, 0,135 g d'acide isobutyrique, 0,70 g d'acide formique); au bout d'une demi-heure, on additionne 0,2 g d'hydroxylactone **10** et on laisse tourner 1 h. Après élimination du THF en excès, on purifie les lactones **8***a*, **8***c* et **8***d* par chromatographie sur gel de silice.

Acétate d'(oxo-2 tétrahydrofuryl-5)-2 éthyle, **8***a*: n_D^{20} = 1,4759; rmn δ: 1,6 à 2,8 (1 massif, 6H), 2,1 (singulet, 3H), 4,15 (triplet, J = 7,3 Hz, 2H), 4,4 à 4,9 (1 massif, 1H); masse m/z (abondance): 43 (100), 85 (98), 112 (24), 84 (13).

Isobutyrate d'(oxo-2 tétrahydrofuryl-5)-2 éthyle, **8***c*: n_D^{20} = 1,4535; rmn δ: 1,15 (doublet, J = 7,3 Hz, 6H), 1,7 à 2,9 (1 massif, 7H), 4,15 (triplet, J = 7,3 Hz, 2H), 4,4 à 4,8 (1 massif, 1H); masse m/z (abondance): 71 (100), 43 (94), 85 (80), 112 (40), 72 (24), 84 (12).

Formiate d'(oxo-2 tétrahydrofuryl-5)-2 éthyle, **8***d*: n_D^{20} = 1,4768; rmn δ: 1,5 à 2,8 (1 massif, 6 H), 4,15 (triplet, J = 7,3 Hz, 2H), 4,4 à 4,9 (1 massif, 1H), 9,1 (singulet, 1H); masse m/z (abondance): 85 (100), 68 (12), 67 (10), 112 (7).

2. *Esters fonctionnels*

(Méthoxycarbonyl)-2 (oxo-2 tétrahydrofuryl-5)-3 propionate de méthyle, **6***e*: pé 144–145°C/0,8 Torr; n_D^{20} = 1,4643; rmn δ: 1,5 à 2,7 (1 massif, 6H), 3,55 (triplet, J = 8 Hz, 1H), 3,7 (singulet, 6H), 4,2 à 4,7 (1 massif, 1H); masse m/z (abondance): 85 (100), 132 (95), 55 (31), 199 (14).

Chloro-2 (oxo-2 tétrahydrofuryl-5)-3 propionate de méthyle, **6***f*: pé 112°C/0,1 Torr; n_D^{20} = 1,4763; rmn δ: 1,7 à 2,8 (1 massif, 6H), 3,6 (singulet, 3H); 3,7 (singulet, 1H); 4,1 à 4,9 (1 massif, 1H); masse m/z (abondance): 85 (100), 74 (66), 43 (27), 59 (18), 175 (14), 177 (4,5), 108 (12), 110 (4).

Acétyl-2 (oxo-2 tétrahydrofuryl-5)-3 propionate de méthyle, **6***g*: pé 145°C/1,1 Torr; n_D^{20} = 1,4672; rmn δ: 1,6 à 2,8 (1 massif, 6H), 2,2 (singulet, 3H), 3,6 à 3,9 (1 massif, 4H), 3,7 (singulet, 3H), 4,2 à 4,7 (1 massif, 1H); masse m/z (abondance): 43 (100), 85 (56), 172 (36), 116 (21).

(Méthoxycarbonyl)-3 (oxo-2 tétrahydrofuryl-5)-4 butyrate de méthyle, **6***h*: pé 146–147°C/0,6 Torr; n_D^{20} = 1,4640; rmn δ: 1,2 à 3,1 (1 massif, 9H), 3,5 (singulet, 6H), 4,1 à 4,6 (massif, 1H); masse m/z (abondance): 59 (100), 43 (85), 97 (75), 213 (71), 85 (60), 74 (40).

Cyano-2 (oxo-2 tétrahydrofuryl-5)-3 propionate de méthyle, **6***i*: pé 158–160°C/0,05 Torr; n_D^{20} = 1,4729; rmn δ: 1,7 à 2,8 (1 massif, 6H), 3,7 à 4,1 (1 massif, 1H), 3,8 (singulet, 3H), 4,4 à 5,0 (1 massif, 1H); masse m/z (abondance): 85 (100), 99 (37), 55 (28), 68 (21).

3. *Acides et anhydrides*

Acide (oxo-2 tétrahydrofuryl-5)-3 propionique, **4***a*: pé 164–166°C/0,01 Torr; F = 62,7°C; rmn δ: 1,5 à 2,7 (1 massif, 8H), 4,2 à 4,7 (1 massif, 1H); 12,1 (singulet, 1H); masse m/z (abondance): 85 (100), 56 (17), 112 (17).

Acide méthyl-2 (oxo-2 tétrahydrofuryl-5)-3 propionique, **4***b*: pé 169–172°C/0,01 Torr; n_D^{20} = 1,4687; rmn δ: 1,0 à 1,2 (doublet, J = 6,7 Hz, 3H), 1,5 à 2,7 (1 massif, 7H), 4,2 à 4,8 (1 massif, 1H), 12,3 (singulet, 1H); masse m/z (abondance): 85 (100), 41 (24), 99 (24), 55 (16), 126 (14).

Acide diméthyl-2,2 (oxo-2 tétrahydrofuryl-5)-3 propionique, **4***c*: pé 174–177°C/0,01 Torr; n_D^{20} = 1,4694; rmn δ: 1,1 (singulet, 6H), 1,6 à 2,6 (massif, 6H), 4,2 à 4,7 (massif, 1H), 11,7 (singulet, 1H); masse m/z (abondance): 85 (100), 88 (46), 55 (41), 141 (13).

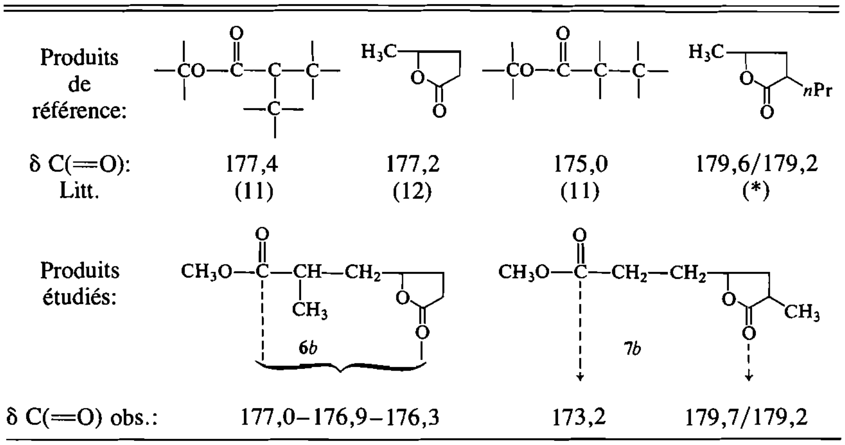
*Isomérisation des lactones **6***

Préparation des lactones **7***b* et **7***c*: les lactones **6***b* et **6***c* sont chauffées dans du méthanol au reflux pendant 2 h en présence de traces d'APTS. Après élimination du méthanol en excès, les lactones **7***b* et **7***c* sont purifiées par chromatographie sur gel de silice.

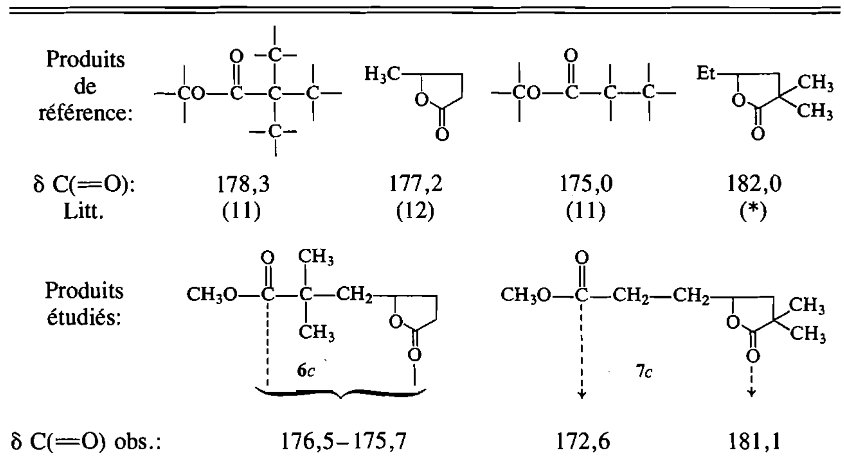
(Méthyl-3 oxo-2 tétrahydrofuryl-5)-3 propionate de méthyle, **7***b*: pé 130°C/0,8 Torr; n_D^{20} = 1,4543; rmn δ: 1,2 (doublet, J = 8 Hz, 3H), 1,5 à 2,9 (1 massif, 7H), 3,6 (singulet, 3H), 4,0 à 4,6 (1 massif, 1H); masse m/z (abondance): 99 (100), 85 (82), 74 (75), 155 (45), 126 (28).

(Diméthyl-3,3 oxo-2 tétrahydrofuryl-5)-3 propionate de méthyle, **7***c*: pé 132°C/0,8 Torr; n_D^{20} = 1,4505; rmn δ: 1,2 (singulet, 6H), 1,7 à 2,7 (1 massif, 6H), 3,7 (singulet, 3H), 4,2 à 4,7 (1 massif, 1H); masse m/z (abondance): 82 (100), 85 (65), 41 (49), 74 (23), 113 (20).

Les différences spectrales (rmn ^1H et masse) des composés **6***b* et **7***b* d'une part, **6***c* et **7***c* d'autre part ne sont pas suffisamment importantes pour confirmer leurs structures respectives. Les temps de rétention en cpg sont cependant différents. Afin de compléter l'identification de ces dérivés, nous avons effectué leur étude par rmn ^{13}C en utilisant les déplacements chimiques des différents atomes de carbone des groupes carbonyle.



* Nous avons enregistré le spectre de ce composé.



* Nous avons enregistré le spectre de ce composé.

L'étude précédente a nécessité la synthèse du diméthyl-2,2 hexanolide-4: il a été préparé à partir de 0,1 mole d'isobutyrate de méthyle et 0,1 mole d'époxyde de butène-3 yle selon la méthode générale décrite dans la réf. 14. Après acidification, extraction et distillation, la lactone est récupérée avec un rendement de 60%; pé 105–106°C/25 Torr (litt. (15) pé 89–93°C/18 Torr).

Préparation de **6*b*** à partir de **4*b***: dans 15 cm^3 de THF anhydre, on met 0,47 g de *N,N'*-carbonyldiimidazole; sous agitation et à température ambiante, on ajoute 0,5 g d'acide **4*b***. On laisse tourner une demi-heure puis on additionne lentement 0,093 g de méthanol. Une heure plus tard, on élimine le solvant, ajoute de l'eau et extrait **6*b*** à l'éther de pétrole.

Identification des produits d'addition des anhydrides: après élimination de l'anhydride en excès, on verse le résidu dans de l'eau bouillante. On laisse tourner 2 h sous agitation puis on extrait à l'éther. Après élimination du solvant, on récupère les acides **4*a*** et **4*b*** par distillation, respectivement à partir des anhydrides acétique et propionique.

4. *Nitriles*

(Cyano-2 éthyl)-5 dihydro-3,4-5*H*-furannone-2, **11*a***: pé 125–128°C/0,8 Torr; n_D^{20} = 1,4518; rmn δ: 1,5 à 2,8 (1 massif, 8H), 4,3 à 4,8 (1 massif, 1H); masse *m/z* (abondance): 85 (100), 55 (41), 41 (23), 56 (19).

(Cyano-2 propyl)-5 dihydro-3,4-5*H*-furannone-2, **11*b***: pé 131–133°C/0,8 Torr; n_D^{20} = 1,4683; rmn δ: 1,4 (doublet, *J* = 8 Hz, 3H), 1,7 à 3,1 (1 massif, 7H), 4,4 à 5,0 (1 massif, 1H); masse *m/z* (abondance): 85 (100), 55 (31), 56 (11).

Tétraméthylsuccinodinitrile: *F* = 168,5°C (litt. (13): *F* = 167–168°C).

Isomérisation des lactones 4[6]

Les lactones **4*b*** et **4*c*** (0,5 g) ont été saponifiées par chauffage en présence de potasse alcoolique (0,5 g) durant 2 h. Après extraction, acidification de la phase aqueuse, on récupère les hydroxydiacides **12*b*** et **12*c*** utilisés ensuite sans purification ultérieure (Rdt ~70%).

Acide hydroxy-4 méthyl-2 heptanedioïque, **12*b***: rmn ^{1}H: 1,85 (doublet, *J* = 8 Hz, 3H), 1,5 à 2,9 (1 massif, 7H), 4,3 à 4,8 (1 massif, 1H), 8,7 (singulet, 3H).

Acide diméthyl-2,2 hydroxy-4 heptanedioïque, **12*c***: rmn ^{1}H: 1,3 (singulet, 6H), 1,6 à 2,8 (1 massif, 6H), 4,4 à 4,9 (1 massif, 1H), 8,9 (singulet, 3H).

Les hydroxydiacides précédents (0,3 g) ont été lactonisés au reflux du THF (10 cm^3) en présence de traces d'APTS pendant 2 h. Les acides lactones **5*b*** et **5*c*** ont été obtenus après élimination du THF.

Acide (méthyl-3 oxo-2 tétrahydrofuryl-5)-3 propionique, **5*b***: rmn ^{1}H: 1,2 (doublet, *J* = 8 Hz, 3H), 1,5 à 2,8 (1 massif, 7H), 4,3 à 4,8 (1 massif, 1H), 11,1 (singulet, 1H).

Acide (diméthyl-3,3 oxo-2 tétrahydrofuryl-5)-3 propionique, **5*c***: rmn ^{1}H: 1,2 (singulet, 6H), 1,4 à 2,8 (1 massif, 6H), 4,3 à 4,8 (1 massif, 1H), 11,3 (singulet, 1H).

[6] L'isomérisation des lactones **6*b*** et **6*c*** a été décrite dans le paragraphe consacré aux acides et anhydrides.

Les lactones **5**b et **5**c ont été ensuite méthylées au diazométhane et identifiées aux lactones **7**b et **7**c par cpg.

On chauffe au reflux pendant 2 h en présence de traces d'APTS 0,5 g de lactone **4**c dans 10 cm^3 de THF. Après élimination du solvant, la lactone **5**c est isolée avec une conversion totale. Elle est transformée ensuite en lactone **7**c par traitement au diazométhane. **7**c est ensuite purifiée sur gel de silice.

Remerciements

Les auteurs remercient Monsieur le Professeur R. Lalande pour l'intérêt qu'il a porté à ce travail. Ils remercient également MM. Petraud et Barbe pour l'étude des spectres rmn ^{13}C ainsi que le Dr. Servens pour la fourniture d'un échantillon de propyl-2 pentanolide-4.

Enthalpies of interaction of aromatic solutes with organic solvents

W. KIRK STEPHENSON AND RICHARD FUCHS
Department of Chemistry, University of Houston, Houston, TX 77004, USA

Received August 20, 1984

W. KIRK STEPHENSON and RICHARD FUCHS. Can. J. Chem. **63**, 2529 (1985).

Heats of solution of several aromatic solutes (benzene, toluene, mesitylene, nitrobenzene, α,α,α-trifluorotoluene, anisole) and model compounds (*n*-butyl methyl ether, cyclohexane) in 17 organic solvents (*n*-heptane, cyclohexane, carbon tetrachloride, 1,2-dichloroethane, α,α,α-trifluorotoluene, triethylamine, butyl ether, ethyl acetate, dimethylformamide, dimethyl sulfoxide, benzene, toluene, mesitylene, *t*-butyl alcohol, 1-octanol, methanol, 2,2,2-trifluoroethanol) have been combined with solute heats of vaporization to give enthalpies of transfer from vapor to solvent ($\Delta H(v \rightarrow S)$). Differences between solute and model values ($\Delta\Delta H(v \rightarrow S) = \Delta H(v \rightarrow S)$ (aromatic solute) $- \Delta H(v \rightarrow S)$ (model) were used to evaluate aromatic solute−solvent polar interactions. Correlations of $\Delta\Delta H(v \rightarrow S)$ with solvent dipolarity−polarizability (Taft−Kamlet π^* parameter) have been determined.

W. KIRK STEPHENSON et RICHARD FUCHS. Can. J. Chem. **63**, 2529 (1985).

On a combiné les chaleurs de solution de plusieurs solutés aromatiques (benzène, toluène, mésitylène, nitrobenzène, α,α,α-trifluorotoluène, anisole) et de composés modèles (méthoxybutane, cyclohexane) dans 17 solvants organiques (heptane, cyclohexane, tétrachlorure de carbone, dichloro-1,2 éthane, α,α,α-trifluorotoluène, triéthylamine, éther butylique, acétate d'éthyle, diméthylformamide, diméthylsulfoxyde, benzène, toluène, mésytilène, alcool *tert*-butylique, octanol-1, méthanol, trifluoro-2,2,2 éthanol) avec les chaleurs de vaporisation des solutés pour obtenir les enthalpies de transfert de la vapeur au solvant ($\Delta H(v \rightarrow S)$). On a utilisé les différences entre les valeurs pour les modèles et pour les solutés ($\Delta\Delta H(v \rightarrow S) = \Delta H(v \rightarrow S)$ (soluté aromatique) $- \Delta H(v \rightarrow S)$ (modèle) pour évaluer les interactions polaires soluté−solvant. On a déterminé des corrélations entre les $\Delta\Delta H(v \rightarrow S)$ et le dipolarité−polarisabilité (paramètre π^* de Taft−Kamlet).

[Traduit par le journal]

Introduction

Aromatic solutes are capable of undergoing several types of interactions with organic solvents. Interactions with polar solvents are most commonly solute dipole − solvent dipole or solvent dipole − solute induced dipole interactions. In hydrogen-bond-donating (HBD) solvents, the rings of electron-rich aromatic compounds act as hydrogen-bond-acceptor (HBA) sites. Aromatic compounds also have the ability to form electron donor − acceptor (EDA) complexes (also known as charge-transfer or molecular complexes), in which an aromatic solute may serve as either acceptor or donor (1). EDA complexes between aromatic molecules are usually envisioned as being face-to-face.

Enthalpies of interaction of polar and nonpolar molecules with aromatic solvents have been reported (2) using the solvation enthalpy, or $\Delta\Delta H(v \rightarrow S)$, method. This method utilizes enthalpies of transfer from the vapor to solvent,

$$[1] \quad \Delta H(v \rightarrow S) = \Delta H_s - \Delta H_v = \Delta H_c + \Delta H_{int}$$

where ΔH_s is the enthalpy of solution of the liquid solute; ΔH_v, the solute heat to vaporization; ΔH_c, the enthalpy of cavity formation in the solvent; and ΔH_{int}, the enthalpy of solute−solvent interactions. For a polar aprotic solute A dissolved in a polar non-hydrogen-bond-donating solvent S, the ΔH_{int} term describes the sum of the solute−solvent dispersion (ΔH_d) and polar (ΔH_p) interactions,

$$[2] \quad \Delta H(v \rightarrow S)(A) = \Delta H_c + \Delta H_d + \Delta H_p$$

Subtraction of the solvation enthalpy of a suitable nonpolar model M ($\Delta H_p(M) = 0$) from eq. [2] gives:

$$[3] \quad \Delta\Delta H(v \rightarrow S)(A \text{ vs. } M) = \Delta\Delta H_c + \Delta\Delta H_d + \Delta H_p$$

where $\Delta\Delta H_c = \Delta H_c(A) - \Delta H_c(M)$ and $\Delta\Delta H_d = \Delta H_d(A) - \Delta H_d(M)$. It is presumed that the solute-model cavity and dispersion interaction mismatches are equal to zero so that $\Delta\Delta H(v \rightarrow S)(A \text{ vs. } M)$ is equal to ΔH_p.

The dependence of polar solute $\Delta\Delta H(v \rightarrow S)$ values on solvent "polarity" can be quantitatively expressed by equations of the form:

$$[4] \quad \Delta\Delta H(v \rightarrow S)(A \text{ vs. } M) = s\pi^* + y$$

where π^* is the Taft−Kamlet solvent dipolarity−polarizability parameter (3, 4); s, the π^* coefficient; and y, the calculated $\Delta\Delta H(v \rightarrow S)$ value in a solvent with $\pi^* = 0.00$ (y-intercept).

To investigate aromatic solute − organic solvent interactions, $\Delta\Delta H(v \rightarrow S)$ values of benzene, toluene, mesitylene, nitrobenzene (NO_2Ph), α,α,α-trifluorotoluene (CF_3Ph), and anisole in 17 organic solvents of varying polarity will be reported. Correlations of $\Delta\Delta H(v \rightarrow S)$ with solvent π^* will be determined.

Experimental

Solutes and solvents were commercial samples of 99% purity, with most exceeding 99.7%. All were stored over 4A molecular sieve, except for methanol and trifluoroethanol, which were dried over 3A molecular sieve. Purities were established by gas chromatography using a Shimadzu Mini 2 gc with a glass lined system, a 30 m × 0.25 mm id SE-30 silica capillary column, and a Hewlett-Packard 3390A integrator.

The calorimetric procedure and apparatus have previously been described (5). The calorimeter was immersed in a water bath at 25.00°C, with regulation to ±0.002°C. Liquid samples were introduced into 65−80 mL of solvent with 10-, 20-, or 50-μL syringes with immersed tips. Heats of solution were corrected (0.01−0.03 kcal/mol less endothermic) to allow for the heat capacity of the samples which were introduced at 21−23°C. The uncertainty intervals in ΔH_s (twice the standard deviation of the mean of three or more determinations) are 0.00−0.07 kcal/mol, except for four values with 0.09−0.15 kcal/mol uncertainty intervals. No effect of concentration on ΔH_s was observed.

Results and discussion

Heats of solution of several aromatic compounds (benzene, toluene, mesitylene, nitrobenzene (NO_2Ph), α,α,α-trifluoro-

[a]In kcal/mol.

toluene (CF_3Ph), anisole) and model compounds (n-butyl methyl ether (BuOMe), cyclohexane (c-C_6)) in 17 organic solvents (n-heptane, cyclohexane, carbon tetrachloride (CCl_4), 1,2-dichloroethane ($ClCH_2CH_2Cl$), α,α,α-trifluorotoluene, triethylamine (Et_3N), butyl ether (Bu_2O), ethyl acetate (EtOAc), dimethylformamide (DMF), dimethyl sulfoxide (DMSO), benzene, toluene, mesitylene, t-butyl alcohol (t-BuOH), 1-octanol, methanol (MeOH), 2,2,2-trifluoroethanol (CF_3CH_2OH)) are listed in Table 1. Solvent π^* values and solute heats of vaporization are also given. In Table 2 are listed and calculated $\Delta\Delta H$(v → S)(aromatic solute vs. model) values.

Benzene

To investigate aromatic ring influence on the solvation process, cyclohexane ($\pi^* = 0.00$) is chosen as a model for benzene ($\pi^* = 0.59$). $\Delta\Delta H$(v → S)(benzene vs. cyclohexane) values are given in Table 2, and show a strong dependence on solvent π^* (alcohols omitted):

[5] $\Delta\Delta H(\text{v} \rightarrow \text{S})(\text{benzene vs. } c\text{-}C_6) = -2.72\pi^* + 0.47$
$n = 13$, $r = 0.971$, see $= 0.24$ kcal/mol

where n is the number of solvents in the correlations, r denotes the correlation coefficient, and see is the standard error of the estimate. Mesitylene and toluene (as solvents) are displaced endothermically from eq. [5] by 0.36 and 0.27 kcal/mol; ethyl acetate is displaced exothermically by 0.44 kcal/mol. All alcohols are displaced endothermically, but trifluoroethanol and methanol are within the see value of eq. [5]. The hydroxyl proton of phenol has been shown to interact with the benzene π cloud (6), but H-bonding between trifluoroethanol and benzene is not observed. As in the case of ketone (7, 8) and ether (8) solutes, hydrogen bonding is anticipated because the HBA basicity of benzene is greater than that of trifluoroethanol (3, 4).

Toluene and mesitylene

The solvation enthalpy of toluene in n-heptane is more exothermic than that of benzene by 1.29 kcal/mol (Table 2), a result of additional interactions of the methylene group of toluene. The methylene increment of normal alkanes (7, 8) is −1.18 kcal/mol. Correlation of toluene and benzene solvation enthalpy differences with π^* for the aprotic solvents gives:

[6] $\Delta\Delta H(\text{v} \rightarrow \text{S})(\text{toluene vs. benzene}) = 0.374\pi^* - 1.22$
$n = 13$, $r = 0.845$, see $= 0.08$ kcal/mol

The positive s value is primarily due to the slightly smaller dipolarity–polarizability of toluene relative to benzene. Molar volume difference (MV(toluene) − MV(benzene) = 17.4 mL/mol) does not appear to significantly influence eq. [6], because the inclusion of a term in δ_H (Hildebrand solubility parameter) (9), which provides a measure of the energy of cavity formation (10), does not improve the equation. The poor correlation coefficient is due largely to the nearly horizontal slope (small s value) (11).

The difference between mesitylene and benzene solvation enthalpies in n-heptane (−3.75 kcal/mol) is roughly three times the toluene–benzene difference and reflects additional methylene group interactions. $\Delta\Delta H$(v → S)(mesitylene vs. benzene) values decrease with increasing solvent polarity (alcohols omitted):

[7] $\Delta\Delta H(\text{v} \rightarrow \text{S})(\text{mesitylene vs. benzene}) = 0.44\pi^* + 0.18\delta_H - 4.91$
$n = 13$, $r = 0.891$, see $= 0.24$ kcal/mol

(δ_H^2, rather than δ_H, may be the better indicator of ΔH_c. However, r and see are unchanged if δ_H^2 is used in the correlation.) Mesitylene and benzene molar volumes differ by 50.0 mL/mol and the δ_H term is needed to account for the solute-model cavity formation mismatch. With increasing cohesiveness of the solvent ΔH_c becomes more endothermic, and this is reflected by the positive coefficient of δ_H in eq. [7]. Exclusion of the δ_H term reduces the correlation coefficient to 0.819 and increases the see value to 0.29 kcal/mol.

α,α,α-Trifluorotoluene and nitrobenzene

Trifluoro ($\sigma_p = 0.51$) and nitro ($\sigma_p = 0.78$) groups are strongly electron withdrawing (relative to hydrogen), and the rings of CF_3Ph and NO_2Ph have lower electron densities than that of toluene, which possesses an electron-donating (σ_p =

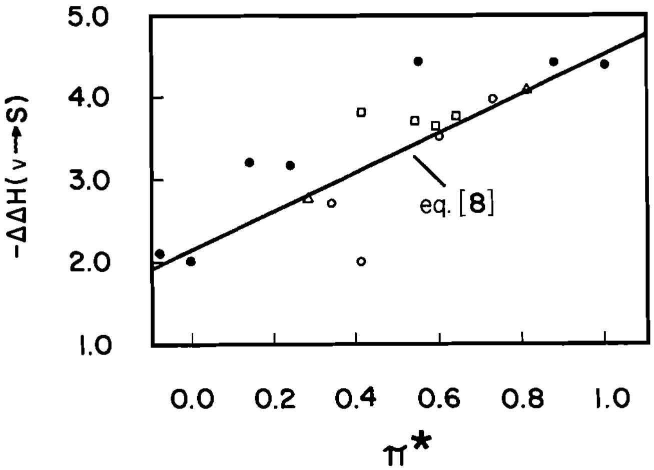

FIG. 1. Plot of $-\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})(\mathrm{NO_2Ph}$ vs. toluene) π^* versus for select (●), chloro (△), aromatic (□), and alcohol (○) solvents.

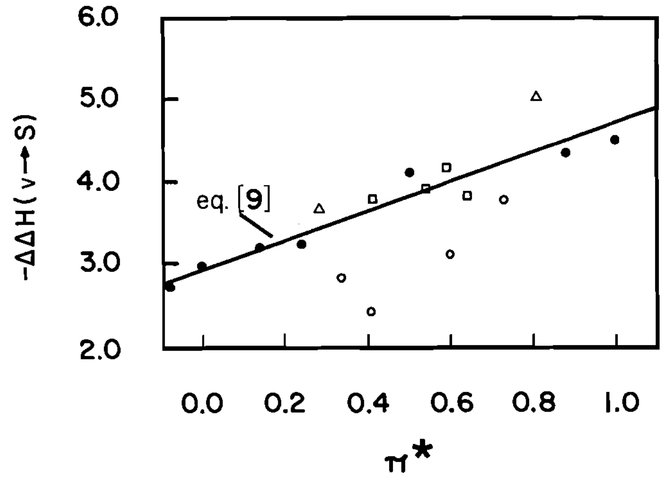

FIG. 2. Plot of $-\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})(\mathrm{NO_2Ph}$ vs. $\mathrm{CF_3Ph}$) versus π^* for select (●), chloro (△), aromatic (□), and alcohol (○) solvents.

-0.17) methyl group. The larger π^* values of nitrobenzene ($\pi^* = 1.01$, $\mu = 3.9$ D) and trifluorotoluene ($\pi^* = 0.64$, $\mu = 2.6$ D) relative to toluene ($\pi^* = 0.54$, $\mu = 0.31$ D) are due to the greater dipolarity of the first two compounds. $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})(\mathrm{CF_3Ph}$ vs. toluene) values (Table 2) incorporate $\Delta\Delta H_c$, $\Delta\Delta H_d$, $\Delta\Delta H_p$(dipole−dipole), and $\Delta\Delta H_p$(dipole − induced dipole) terms; nitrobenzene and toluene have well matched molar volumes and $\Delta\Delta H_c$ will be minimal.

A plot of $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})(\mathrm{NO_2Ph}$ vs. toluene) versus solvent π^* is shown in Fig. 1. An unusual pattern is observed for the select solvents (SS), which are polar, monofunctional aprotic, aliphatic compounds (3). $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{SS})$ values follow the order: cyclohexane < heptane < butyl ether < triethylamine < ethyl acetate > DMF > DMSO. The maximum value is observed for ethyl acetate. Rationalization of this unusual pattern is difficult because the relative abilities of solute and model to undergo dipole−dipole and dipole − induced dipole interactions with the select solvents vary drastically; nitrobenzene favors dipolar over induction interactions, whereas the opposite is true for toluene.

The low electron density of the nitrobenzene ring suggests the possibility of electron donor − acceptor (EDA) complex formation with benzene, toluene, and mesitylene solvents. EDA complexes of polynitrobenzenes with electron donor molecules are well known, as are complexes in which benzene and methylbenzenes act as electron donors (12). The electron donor ability of methylbenzenes increases with the number of methyl groups. The free energy and enthalpy of complex formation between methylbenzenes and tetracyanoethylene become linearly more exoenergetic with decreasing arene ionization potential (13). Strong EDA complexes between trinitrobenzene and hexamethylbenzene have been reported (1), and complexes between nitrobenzene and mesitylene, although weaker as acceptor and donor molecules, are reasonable.

Hooper (14) has reported that carbon tetrachloride and *p*-xylene do not complex. The assumption that 1,2-dichloroethane also fails to complex with methylbenzenes brings the number of solvents "inert" to toluene complexation to four (cyclohexane, heptane, carbon tetrachloride, and dichloroethane). Correlation of $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})$ with "inert" solvent π^* gives:

[8] $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})(\mathrm{NO_2Ph}\text{ vs. toluene}) = -2.36\pi^* - 2.14$
$n = 4$, $r = 0.992$, see $= 0.15$ kcal/mol

Displacements of benzene, toluene, and mesitylene from the line defined by these four solvents (Fig. 1) are approximately 0.1, 0.3, and 0.7 kcal/mol. These displacements provide a crude estimate of the contribution of EDA complexing to the solvation of nitrobenzene, and are in the expected order.

$\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})$(trifluorotoluene vs. toluene) values follow patterns identical to those of nitrobenzene for the select (cyclohexane < heptane < butyl ether < triethylamine < ethyl acetate > DMF > DMSO) and aromatic (benzene < toluene < mesitylene) solvents. Because of the similarity in π^* values for trifluorotoluene and toluene there would be little slope and poor correlation in a plot of $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})$ vs. solvent π^* (15).

Despite the complexity of Fig. 1, the plot of $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})(\mathrm{NO_2Ph}$ vs. $\mathrm{CF_3Ph}$) against solvent π^* (Fig. 2) is surprisingly simple. Correlation of the select solvent values with π^* gives:

[9] $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})(\mathrm{NO_2Ph}\text{ vs. }\mathrm{CF_3Ph}) = -1.78\pi^* - 2.92$
$n = 7$, $r = 0.988$, see $= 0.13$ kcal/mol

The only solvent other than the alcohols significantly out-of-line is 1,2-dichloroethane, which is displaced exothermically by 0.66 kcal/mol; other solvents are within 0.25 kcal/mol of eq. [9]. The negative slope reflects the greater dipole moment of nitrobenzene. $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{AROM})$ values are largest for benzene and smallest for mesitylene, the opposite of the trend observed with toluene as model. If EDA complexes are formed between nitrobenzene or trifluorotoluene and the methylbenzenes or benzene, the effect tends to be cancelled upon comparison of nitrobenzene with trifluorotoluene.

The well-matched molar volumes of nitrobenzene and toluene rule out a cavity formation mismatch as the source of the unusual behavior of the select solvents (SS) in Fig. 1. It is possible that $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{SS})$ values are influenced by the formation of EDA complexes in which some of the select solvents act as n donors. For example, EDA complexes of ethyl ether with tetracyanoethylene in chloroform solvent (13), diethyl ether with iodine in heptane, triethylamine with iodine in heptane, trimethylamine with sulfur dioxide in heptane, and dimethylacetamide with iodine in carbon tetrachloride (1) have been reported. However, a comparison of solvent ionization potentials suggests that nitrobenzene and trifluorotoluene do not form EDA complexes with the select solvents. For a given acceptor solute, the enthalpy of EDA complex formation is expected to increase linearly, or nearly linearly, with decreasing solvent ionization potential. The only select solvent with an ionization potential lower than those of toluene or mesitylene is triethylamine, yet butyl ether and ethyl acetate are displaced farther from the line defined by the inert solvents (Fig. 1) that is mesitylene.

Although π^* is defined as a solvent parameter, s values of $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})$(solute vs. model) versus solvent π^* correlation for a series of polar solutes have been shown to be proportional to the difference between solute and model π^* values (15):

$$[10] \quad \pi^*(\text{solute}) - \pi^*(\text{model}) = -0.20\, s - 0.01$$
$$n = 11,\ r = 0.978,\ \text{see} = 0.04$$

The y-intercept is within the see value of the origin, and the equation is consistent with the expectation that solvation enthalpy differences between solutes of equal polarity, or two nonpolar solutes, will not depend on solvent polarity.

The calculated π^* value (eq. [10]) for nitrobenzene (1.00) based on the s value of eq. [8] and the model (toluene) value of 0.54 (4) is in excellent agreement with the literature value (1.01) and the value calculated via eq. [9] (0.99). This gives credibility to eq. [8], which utilized only four solvents to define the dependency of $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})$(nitrobenzene vs. toluene) on solvent π^*.

Anisole

The π^* value of anisole (0.73) is expected to be larger than that of toluene (0.54) because of the greater dipolarity of the former ($\Delta\mu$ = 0.94 D). Differences between the solvation enthalpies (Table 2) represent, to a large extent, anisole dipolar interactions with select solvents and anisole – solvent induced dipole interactions with aromatic solvents, as well as the dispersion interaction mismatch. Solute and model molar volumes differ by only 2.3 mL/mol, and the influence of the cavity formation mismatch is minute. Correlation of the solvation enthalpy differences with solvent π^* (ethyl acetate and alcohols omitted) is given by eq. [11].

$$[11] \quad \Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})(\text{anisole vs. toluene}) = -1.12\pi^* - 1.33$$
$$n = 12,\ r = 0.969,\ \text{see} = 0.10$$

The only solvent of the 12 displaced more than 0.15 kcal/mol is benzene, which is displaced exothermically by 0.25 kcal/mol. Ethyl acetate lies 0.35 kcal/mol above the line.

Alcohol solvents exhibit behavior similar to that observed with nitrobenzene (Fig. 2) and 1-hexene (8). In each of these cases the difference between solute and model β values (Taft–Kamlet hydrogen-bond-accepting basicity parameter) (3, 4) is less than 0.30.

Evaluation of anisole induction interactions requires the use of a model with similar dipolarity, but with low polarizability. n-Butyl methyl ether has a dipole moment (μ = 1.25 D) identical to that of anisole and a molar volume which is only 9.8 mL/mol larger. The relationship of ansiole vs. n-butyl methyl ether solvation enthalpy differences with select solvent π^* is

$$[12] \quad \Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})(\text{anisole vs. } n\text{-BuOMe}) = -2.04\pi^* - 2.51$$
$$n = 7,\ r = 0.986,\ \text{see} = 0.16\ \text{kcal/mol}$$

Inclusion of the aromatic and chloro solvents reduces the correlation coefficient to 0.918. The s values of eqs. [11] and [12] suggest that anisole induction interactions contribute about 1.8 times more than anisole dipolar interactions to the solvation process.

A crude estimate of the total contribution of anisole polar interactions (induction plus dipolar) to the solvation process is obtained by adding the s value of eqs. [11] and [12]:

$$[13] \quad \Delta H_{\mathrm{p}}(\text{anisole}) = -3.16\pi^*$$

An alternative method involves the use of a nonpolar model. Cyclohexane is an excellent choice because it differs from anisole in molar volume by only 0.5 mL/mol. Correlation of $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})$(anisole vs. cyclohexane) with π^* of the select solvents gives:

$$\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})(\text{anisole vs. cyclohexane}) = -3.54\pi^* - 2.14$$

or

$$[14] \quad \Delta H_{\mathrm{p}}(\text{anisole}) = -3.54\pi^*$$

The smaller s value of eq. [13] (relative to eq. [14]) is largely due to the dipolarity of toluene (μ = 0.31 D), which cancels a portion of the anisole (μ = 1.25 D) dipolar interactions. Applying a correction of 25% (0.31/1.25) to the polarity term of eq. [11] increases the s value to −1.40, which in turn increases the s value of eq. [13] to −3.44, in fair agreement with the value from eq. [14]. Our experience in this and other studies (8) suggests that satisfactory values of π^* can be calculated from eq. [10] for most compounds other than alcohols, provided that s is obtained from a good correlation ($r >$ ~0.95). The correction is based on the assumptions that solute and model dipolarities are accurately described by the dipole moments (μ for select solvents has been shown to be directly proportional to π^* (16)), and that the coefficient s reflects differences between solute and model dipolarities (eq. [10]).

The corrected values predict that anisole induction interactions are 1.5 times greater than anisole dipolar interactions with polar select solvents.

Enthalpies of interaction of hydroxylic solutes with organic solvents

W. KIRK STEPHENSON AND RICHARD FUCHS
Department of Chemistry, University of Houston, Houston, TX 77004, U.S.A.

Received January 8, 1985

W. KIRK STEPHENSON and RICHARD FUCHS. Can. J. Chem. **63**, 2535 (1985).

Heats of solution of *m*-cresol, 1-butanol, 1-pentanol, *t*-amyl alcohol, and model compounds (toluene, ethyl ether, *n*-butyl methyl ether, *t*-butyl methyl ether) in 17 organic solvents (*n*-heptane, cyclohexane, carbon tetrachloride, 1,2-dichloroethane, α,α,α-trifluorotoluene, triethylamine, butyl ether, ethyl acetate, dimethylformamide, dimethyl sulfoxide, benzene, toluene, mesitylene, *t*-butyl alcohol, 1-octanol, methanol, 2,2,2-trifluoroethanol) have been combined with solute heats of vaporization to give solvation enthalpies ($\Delta H(\mathrm{v} \rightarrow \mathrm{S})$). Dependencies of solute vs. model solvation enthalpy differences on solvent dipolarity–polarizability and hydrogen-bond-accepting basicity were determined via correlations with Taft–Kamlet solvatochromic parameters (π^*, β, ξ).

m-Cresol is a substantially stronger H-bond donor than 1-butanol, 1-pentanol, and *t*-amyl alcohol, and H-bonds to acceptor solvents including alcohols. Cresol acts as an H-bond acceptor with the strong H-bond donor solvent trifluoroethanol.

W. KIRK STEPHENSON et RICHARD FUCHS. Can. J. Chem. **63**, 2535 (1985).

Dans le but de déterminer les enthalpies de solvatation ($\Delta H(\mathrm{v} \rightarrow \mathrm{S})$), on a combiné les chaleurs de solution du *m*-crésol, du butanol-1, du pentanol-1, de l'alcool *t*-amylique et de composés modèles (toluène, éther éthylique, méthoxy-1 butane, méthoxy-2 méthyl-2 propane) dans 17 solvants organiques (heptane, cyclohexane, tétrachlorure de carbone, dichloro-1,2 éthane, α,α,α-trifluorotoluène, triéthylamine, éther butylique, acétate d'éthyle, diméthylformamide, diméthylsulfoxyde, benzène, toluène, mésitylène, alcool *t*-butylique, octanol-1, méthanol, trifluoro-2,2,2 éthanol) avec les chaleurs de vaporisation des solutés. Utilisant des corrélations impliquant les paramètres solvatochromiques de Taft-Kamlet (π^*, β et ξ), on a déterminé les relations qui existent entre, d'une part, les différences d'enthalpie de solvatation des solutés vs. les modèles et, d'autre part, soit la polarisabilité–dipolarisabilité du solvant soit la basicité comme accepteur de liaisons hydrogènes.

Le *m*-crésol est un donneur de liaisons hydrogènes qui est substantiellement plus fort que le butanol-1, le pentanol-1 et l'alcool *t*-amylique; de plus, il forme des liaisons H avec les solvants accepteurs, y compris les alcools. Le crésol agit comme un accepteur de liaison H avec le solvant trifluoroéthanol qui est un donneur fort de liaison H.

[Traduit par le journal]

We have investigated enthalpies of interaction of ketone (1), aromatic (2), nitrogen base (3), and 1-octanol (4, 5) solutes with organic solvents of varying polarity. In this paper, several hydroxylic solutes (*m*-cresol, 1-butanol, 1-pentanol, and *t*-amyl alcohol (2-methyl-2-butanol)) will be examined. Enthalpies of interaction are determined by the solvation enthalpy, or $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})$, method. The solvation enthalpy is the enthalpy of transfer of a solute from vapor to solvent. For a solute–solvent mixture in which dispersion (d), polar (p), and hydrogen bonding (h) interactions are operative, the solvation enthalpy is

$$[1] \quad \Delta H(\mathrm{v} \rightarrow \mathrm{S}) = \Delta H_{\mathrm{s}} - \Delta H_{\mathrm{v}} = \Delta H_{\mathrm{c}} + \Delta H_{\mathrm{d}} + \Delta H_{\mathrm{p}} + \Delta H_{\mathrm{h}}$$

where s refers to the heat of solution of the liquid solute; v, the solute heat of vaporization; and c, the enthalpy of cavity formation within the solvent. ΔH_{s} and ΔH_{v} are determined experimentally. Polar and H-bonding enthalpies of interaction are presumed to be isolated by subtracting the solvation enthalpy of a suitable alkane model (M) from that of the solute (A),

$$[2] \quad \Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})(\mathrm{A\ vs.\ M}) = \Delta\Delta H_{\mathrm{c}} + \Delta\Delta H_{\mathrm{d}} + \Delta H_{\mathrm{p}} + \Delta H_{\mathrm{h}}$$

where $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})$, $\Delta\Delta H_{\mathrm{c}}$, and $\Delta\Delta H_{\mathrm{d}}$ refer to differences between solute and model. It has often been assumed that the first two terms on the right side of eq. [3] are equal to zero so that $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S}) = \Delta H_{\mathrm{p}} + \Delta H_{\mathrm{h}}$, and in the absence of H-bonding, $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S}) = \Delta H_{\mathrm{p}}$. If a model is chosen such that the solute cavity formation, dispersion, and polar interactions are cancelled, then $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S}) = \Delta H_{\mathrm{h}}$. In practice, perfect solute and model matches are rare, and solute-model cavity formation, dispersion interaction, and/or polar interaction mismatches will be encompassed in $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})$ (A vs. M) values (4, 5).

Solvation enthalpy differences can be quantitatively expressed in terms of the Taft–Kamlet solvatochromic parameters (5–7),

$$[3] \quad \Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})(\mathrm{A\ vs.\ M}) = s\pi^* + b\beta + e\xi + y$$

where π^* indicates solvent dipolarity–polarizability, β represents the solvent hydrogen-bond-accepting (HBA) basicity, and ξ is the solvent coordinate covalency parameter which allows for the "family dependent" nature of enthalpies of H-bond formation (8). Parameter coefficients are s, b, and e; y is the y-axis intercept.

$\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})$ values for *m*-cresol (vs. toluene), 1-butanol (vs. ethyl ether), 1-pentanol (vs. *n*-butyl methyl ether), and *t*-amyl alcohol (vs. *t*-butyl methyl ether) in 17 organic solvents, and correlations of the form of eq. [3], will be reported.

Experimental

Solutes and solvents were commercial samples in excess of 99% purity, with most exceeding 99.7%. Purities were established by silica capillary gas chromatography and an electronic integrator. Samples and solvents were stored over 3A or 4A molecular sieve. Triethylamine was distilled from ninhydrin to remove primary and secondary amine impurities. The calorimetric procedure and apparatus have previously been described (9).

Results and discussion

Heats of solution of *m*-cresol, 1-butanol, 1-pentanol, *t*-amyl alcohol, toluene, ethyl ether (Et_2O), *n*-butyl methyl ether (BuOMe), and *t*-butyl methyl ether (*t*-BuOMe), in organic solvents (*n*-heptane, cyclohexane, carbon tetrachloride (CCl_4), 1,2-dichloroethane ($ClCH_2CH_2Cl$), α,α,α-trifluorotoluene (CF_3Ph), triethylamine (Et_3N), butyl ether (Bu_2O), ethyl ace-

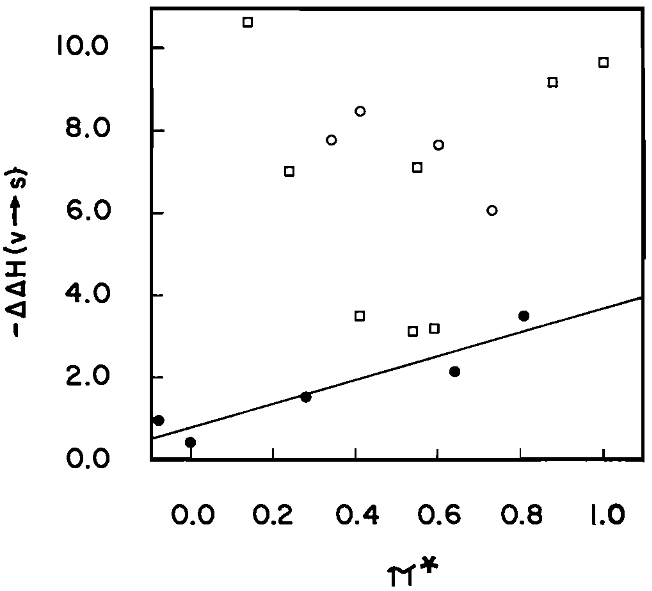

FIG. 1. Plot of $-\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})$(*m*-cresol vs. toluene) versus π^* for NHB (●), HBA (□), and HBD (○) solvents.

tate (EtOAc), dimethylformamide (DMF), dimethyl sulfoxide (DMSO), benzene, toluene, mesitylene, 1-octanol, *t*-butyl alcohol (*t*-BuOH), methanol (MeOH), and 2,2,2-trifluoroethanol (CF_3CH_2OH)) are listed in Table 1, together with solute heats of vaporization and solvent solvatochromic parameters (π^*, β, ξ, α). Differences between alcohol solute and model solvation enthalpies are listed in Table 2.

m-*Cresol in aprotic solvents*

The correlation of $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})$(*m*-cresol vs. toluene) values with π^* for the five non-hydrogen-bonding solvents (*n*-heptane, cyclohexane, CCl_4, $ClCH_2CH_2Cl$, CF_3Ph) (Fig. 1) is:

[4] $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})(\text{cresol vs. toluene}) = -2.90\pi^* - 0.78$
$n = 5$, $r = 0.942$, see $= 0.47$ kcal/mol

where n is the number of solvents, r refers to the correlation coefficient, and see is the standard error of the estimate (10). This represents the *dipolarity–polarizability* contribution to the difference in cresol vs. toluene solvation enthalpy (the non-hydrogen-bonding baseline). Displacements of the HBA solvents from eq. [4], which represent H-bonding interactions (ΔH_h(NHBB)) (4, 6) are triethylamine, −9.46 kcal/mol; butyl ether, −5.54; ethyl acetate, −4.76; DMF, −5.86; DMSO, −5.98; mesitylene, −1.55; toluene, −0.84; benzene, −0.64; octanol, −6.00; *t*-butyl alcohol, −6.51; methanol, −5.16; and trifluoroethanol, −3.18. If H-bonding between *m*-cresol and the alcohol solvents results, in part, from the alcohols acting as H-bond donor acids and cresol as HBA base, the ΔH_h(NHBB) values will be slightly smaller than the "true" values, because the model compound toluene is a weak HBA base ($\beta = 0.11$), and toluene-solvent H-bonding will cancel a small portion of the cresol-solvent H-bonding interactions. Cresol is a stronger HBA base (than toluene) because of greater π electron density on the ring, or because the oxygen atom is a still stronger HBA center. Hydrogen bonding is strongest with triethylamine. For aromatic solvents, H-bonding decreases in the order: mesitylene > toluene > benzene > trifluorotoluene, also the order of decreasing pi electron density. The dependence of ΔH_h (NHBB) on solvent HBA basicity for the nonprotic solvents is

[5] $\Delta H_h(\text{NHBB}) = -8.22\beta - 3.47\xi - 0.30$
$n = 8$, $r = 0.986$, see $= 0.62$ kcal/mol

Addition of eqs. [4] and [5] gives a total solvatochromic equation for *m*-cresol ($n = 13$):

[6] $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})(\text{cresol vs. toluene}) = -2.90\pi^* - 8.22\beta - 3.47\xi - 1.08$

Single step, multiple parameter linear regression (MPLR) gives a better correlation which is in relatively poor agreement with eq. [6]:

[7] $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})(\text{cresol vs. toluene}) = -2.29\pi^* - 9.03\beta - 2.94\xi - 1.08$
$n = 13$, $r = 0.992$, see $= 0.51$

A total solvatochromic equation determined by MPLR using anisole ($\pi^* = 0.73$, $\beta = 0.22$, $\xi = 0.20$) rather than toluene ($\pi^* = 0.54$, $\beta = 0.11$, $\xi = 0.00$) as the model, has a π^* coefficient (−1.17) smaller than that of eq. [7] (as expected from the smaller difference in π^* between cresol and anisole). The β (−8.97) and ξ (−3.00) coefficients (and see value) are quite similar, since neither model is an H-bond donor acid.

Calculated (eqs. [6], [7]) values for non-hydrogen-bonding (NHB) and HBA solvents are within 0.75 kcal/mol of the observed values. However, differences between calculated and observed $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})$ values for alcohol solvents range from 0.9 to 3.4 kcal/mol.

m-*Cresol in alcohol solvents*

Alcohol solvents have the ability to interact with cresol via type A (solvent acts as a hydrogen-bond-donating (HBD) acid) and type B hydrogen bonding (solute is HBD acid). Alcohol solvent displacements from eq. [4] decrease with decreasing HBA basicity: *t*-BuOH > octanol > MeOH > trifluoroethanol, consistent with type B hydrogen bonding. This trend is opposite that observed when triethylamine is the solute in these alcohols (3). The displacement of trifluoroethanol solvent ($\beta = 0.00$) from eq. [4] is −3.18 kcal/mol, suggesting that type A hydrogen bonding is also operative. Type A hydrogen bonding is also observed for cresol in chloroform solvent ($\pi^* = 0.58$, $\beta = 0.00$, $\alpha = 0.44$), where α is the Taft–Kamlet HBD acidity parameter (6, 7). Subtraction of the estimated solvation of *m*-cresol in chloroform from that of toluene (11) gives a $\Delta\Delta H(\mathrm{v} \rightarrow \text{chloroform})$(*m*-cresol vs. toluene) value (−3.16 kcal/mol) which is displaced −0.70 kcal/mol from eq. [4] (exothermic). ($\Delta H(\mathrm{v} \rightarrow \text{chloroform})$(*m*-cresol) was estimated to be equal to the sum of the phenol (11) and calculated (5, 12) methylene group solvation enthalpies.)

Correlation of alcohol solvent (ROH) displacements from eq. [4] (Fig. 1) with solvent HBA basicity gives:

[8] $\Delta H_h(\text{NHBB})(\text{cresol vs. toluene}) = -3.23\beta - 3.17$
$n = 4$, $r = 0.999$, see $= 0.08$ kcal/mol

The excellent correlation is obtained without regard to HBD acidity (α parameter) but leads to the false conclusion that type B hydrogen bonding varies with changing ROH solvent while type A hydrogen bonding is constant. This arises from the inverse relationship between HBA basicity and HBD acidity of the four alcohol solvents:

[9] $\alpha = -1.19\beta + 1.79$
$n = 4$, $r = 0.996$, see $= 0.16$

This makes it impossible to assess the relative contributions of type A and type B interactions to the hydrogen bonding en-

[a]In kcal/mol.

thalpy. However, the order of alcohol displacements and the zero β value of trifluoroethanol suggest that the $b\beta$ portion of eq. [8] represents the minimum possible enthalpy of type B H-bond formation, whereas the *y*-intercept represents the maximum possible type A ΔH_h. The "true" type B values for the HBA alcohols will be larger because the contribution of type A H-bonding decreases as HBD acidity decreases, rather than remaining constant at the value determined by trifluoroethanol (*y*-intercept). Finally, we note that type A H-bonding by trifluoroethanol solvent (α = 1.51) to *m*-cresol should be substantially stronger than type A H-bonding by chloroform solvent (α = 0.44), as is observed.

Aliphatic alcohols

The plot of $\Delta\Delta H$(v $\rightarrow$ S)(pentanol vs. *n*-butyl methyl ether) versus solvent π^* is shown in Fig. 2 and is very similar to analogous plots for *m*-cresol (Fig. 1) and 1-octanol (4). The same is also true for 1-butanol and *t*-amyl alcohol solutes.

The correlation of 1-pentanol $\Delta\Delta H$(v $\rightarrow$ S) values with those of the NHB solvents is

[10] $\Delta\Delta H$(v $\rightarrow$ NHB)(pentanol vs. BuOMe) = $-1.32\pi^* - 0.78$
$n = 5$, $r = 0.931$, see = 0.23 kcal/mol

The expression for the dependence of HBA solvent (ROH omitted) displacements on β and ξ is

[11] ΔH_h(NHBB)(pentanol) = $-5.47\beta - 2.24\xi - 0.15$
$n = 8$, $r = 0.996$, see = 0.21 kcal/mol

The total solvatochromic equation from eqs. [10] and [11] is

[12] $\Delta\Delta H$(v $\rightarrow$ S)(pentanol vs. BuOMe) = $-1.32\pi^* - 5.47\beta - 2.24\xi - 0.63$

MPLR gives a total solvatochromic equation in good agreement with eq. [12]:

[13] $\Delta\Delta H$(v $\rightarrow$ S)(pentanol vs. BuOMe) = $-1.22\pi^* - 5.31\beta - 2.22\xi - 0.76$
$n = 13$, $r = 0.997$, see = 0.19

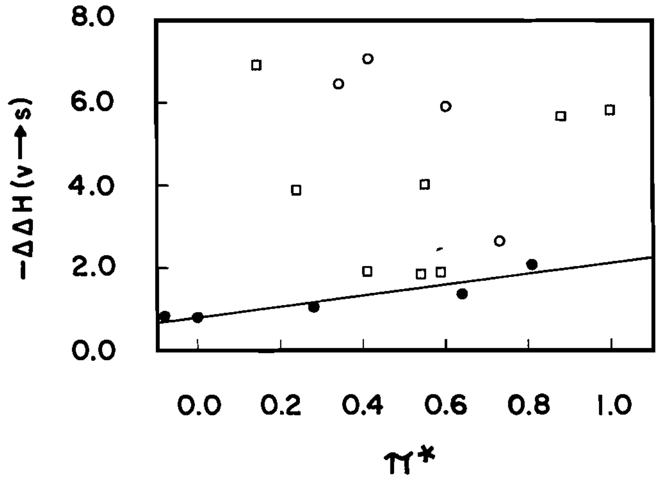

FIG. 2. Plot of $-\Delta\Delta H$(v $\rightarrow$ S)(1-pentanol vs. *n*-BuOMe) versus π^* for NHB (●), HBA (□), and HBD (○) solvents.

Total solvatochromic equations (MPLR) for 1-butanol (BuOH) and *t*-amyl alcohol are given by eqs. [14] and [15]. Alcohol solvents have been omitted.

[14] $\Delta\Delta H$(v $\rightarrow$ S)(BuOH vs. Et_2O) = $-1.07\pi^* - 5.22\beta - 2.36\xi - 0.92$
$n = 13$, $r = 0.995$, see = 0.24 kcal/mol

[15] $\Delta\Delta H$(v $\rightarrow$ S)(*t*-amyl alcohol vs. *t*-BuOMe) = $-1.12\pi^* - 4.40\beta - 1.15\xi - 0.32$
$n = 13$, $r = 0.991$, see = 0.26 kcal/mol

Based on relative β and ξ values (eqs. [13], [15]), hydrogen bonding of *t*-amyl alcohol is about 80% of that of its normal isomer. The β coefficient for *m*-cresol (eq. [6]) is almost twice as large as that of *t*-amyl alcohol, which reflects the greater HBD acidity of *monomeric* cresol (α_m) relative to monomeric alcohol solutes (Dr. Mortimer J. Kamlet, private communication).

The solvation enthalpy of *t*-amyl alcohol in *n*-heptane is less exothermic than that of 1-pentanol by 1.84 kcal/mol. The two alcohols have well matched molar volumes, and the discrepancy probably results from a dispersion interaction (rather than a cavity formation) mismatch. Approximately 0.95 kcal/mol can be attributed to the loss of quaternary carbon solvation (1, 5). The remaining 0.89 kcal/mol possibly results from a decrease in hydroxyl group solvation by dispersion interactions when hindered by an attached *t*-amyl group.

Enthalpies of interaction of nitrogen base solutes with organic solvents

W. KIRK STEPHENSON AND RICHARD FUCHS
Department of Chemistry, University of Houston, Houston, TX 77004, U.S.A.

Received September 27, 1984

W. KIRK STEPHENSON and R. FUCHS. Can. J. Chem. **63**, 2540 (1985).

Heats of solution of triethylamine, aniline, pyridine, and model compounds (3-ethylpentane, benzene) in 17 organic solvents (*n*-heptane, cyclohexane, carbon tetrachloride, 1,2-dichloroethane, α,α,α-trifluorotoluene, triethylamine, butyl ether, ethyl acetate, dimethylformamide, dimethyl sulfoxide, benzene, toluene, mesitylene, *t*-butyl alcohol, 1-octanol, methanol, 2,2,2-trifluoroethanol) have been combined with solute heats of vaporization to give enthalpies of transfer from vapor to solvent ($\Delta H(\text{v} \rightarrow \text{s})$). Differences between solute and model values ($\Delta\Delta H(\text{v} \rightarrow \text{s}) = \Delta H(\text{v} \rightarrow \text{s})$ (solute) $-$ $\Delta H(\text{v} \rightarrow \text{s})$ (model)) were used to evaluate nitrogen base solute–solvent polar interactions. Correlations of $\Delta\Delta H(\text{v} \rightarrow \text{s})$ with Taft–Kamlet solvatochromic parameters (π^*, α, β) have been determined.

Aniline was found to be a better hydrogen bond donor acid than hydrogen bond acceptor base. Nevertheless, alcohols donate H-bonds to aniline. Triethylamine and pyridine are stronger HBA bases than aniline. The π^* (dipolarity–polarizability) parameter of aniline (as a solute) is calculated to be 1.10.

W. KIRK STEPHENSON et R. FUCHS. Can. J. Chem. **63**, 2540 (1985).

On a combiné les chaleurs de solution de la triéthylamine, de l'aniline, de la pyridine et de composés types (éthyl-3 pentane, benzène) dans 17 solvants organiques (*n*-heptane, cyclohexane, tétrachlorure de carbone, dichloro-1,2 éthane, α,α,α-trifluorotoluène, triéthylamine, éther butylique, acétate d'éthyle, diméthylformamide, diméthylsulfoxyde, benzène, toluène, mésitylène, alcool *tert*-butylique, octanol-1, méthanol, trifluoro-2,2,2 éthanol) avec les chaleurs de vaporisation du soluté pour obtenir les enthalpies de transfert de la vapeur au solvant ($\Delta H(\text{v} \rightarrow \text{s})$). On a utilisé les différences entre les valeurs pour les solutés et celles pour les composés modèles ($\Delta\Delta H(\text{v} \rightarrow \text{s}) = \Delta H(\text{v} \rightarrow \text{s})$ (soluté) $-$ $\Delta H(\text{v} \rightarrow \text{s})$ (modèle)) pour évaluer les interactions polaires entre le soluté (base azotée) et le solvant. On a déterminé des corrélations existant entre le $\Delta\Delta H(\text{v} \rightarrow \text{s})$ et les paramètres solvatochromiques de Taft–Kamlet (π^*, α, β).

On a trouvé que l'aniline agit mieux comme acide donneur de liaison hydrogène que comme base qui accepte des liaisons hydrogènes. Quoiqu'il en soit, les alcools donnent des liaisons hydrogènes à l'aniline. Par rapport à l'aniline, la triéthylamine et la pyridine sont des bases acceptrices de liaisons hydrogènes plus fortes. On a calculé que le paramètre π^* (dipolarité–polarisabilité) de l'aniline est égal à 1.10.

[Traduit par le journal]

We have recently studied the enthalpies of interaction of ketone (1, 2) and aromatic (2, 3) solutes with organic solvents of varying polarity, and now extend our study to several nitrogen bases, triethylamine, pyridine, and aniline. Enthalpies of interaction are determined by the solvation enthalpy, or $\Delta\Delta H(\text{v} \rightarrow \text{s})$, method. The solvation enthalpy is the enthalpy of transfer of a solute from vapor to solvent,

$$[1] \quad \Delta H(\text{v} \rightarrow \text{s}) = \Delta H_{\text{s}} - \Delta H_{\text{v}} = \Delta H_{\text{c}} + \Delta H_{\text{int}}$$

where ΔH_{s} is the heat of solution of the liquid solute; ΔH_{v}, the solute heat of vaporization; ΔH_{c}, the enthalpy of cavity formation within the solvent; and ΔH_{int}, the enthalpy of interaction of the solute with the solvent. ΔH_{s} and ΔH_{v} are determined experimentally.

In a polar hydrogen-bond-donating (HBD) solvent, triethylamine, pyridine, and aniline are capable of dispersion (d), polar (p), and hydrogen bonding (h) interactions, and the solvation enthalpy is

$$[2] \quad \Delta H(\text{v} \rightarrow \text{s}) = \Delta H_{\text{c}} + \Delta H_{\text{d}} + \Delta H_{\text{p}} + \Delta H_{\text{h}}$$

Triethylamine and pyridine are capable of type A H-bonding (solvent acts as HBD acid) only, whereas aniline is amphiprotic and might undergo either type A or type B (solvent acts as hydrogen-bond-acceptor (HBA) base) H-bonding or both. Polar and H-bonding enthalpies of interaction can, in principle, be isolated by subtracting the solvation enthalpy of a suitable model compound (M) from that of the solute (A),

$$[3] \quad \Delta\Delta H(\text{v} \rightarrow \text{s}) = \Delta\Delta H_{\text{c}} + \Delta\Delta H_{\text{d}} + \Delta H_{\text{p}} + \Delta H_{\text{h}}$$

where $\Delta\Delta H_{\text{c}}$ and $\Delta\Delta H_{\text{d}}$ refer to the difference between solute and model cavity formation and dispersion interactions, respectively. It has often been assumed that the first two terms on the right side of eq. [3] are equal to zero, and if the model is nonpolar and non-H-bonding, $\Delta\Delta H(\text{v} \rightarrow \text{s}) = \Delta H_{\text{p}} + \Delta H_{\text{h}}$, or in the absence of solute H-bonding, $\Delta\Delta H(\text{v} \rightarrow \text{s}) = \Delta H_{\text{p}}$. If a model is chosen such that the solute cavity formation, dispersion, and polar interactions cancel, then $\Delta\Delta H(\text{v} \rightarrow \text{s}) = \Delta H_{\text{h}}$. In reality perfect model compounds are likely to be rare.

Solvation enthalpy differences can be quantitatively expressed in terms of the Taft–Kamlet solvatochromic parameters (4–6),

$$[4] \quad \Delta\Delta H(\text{v} \rightarrow \text{s}) = s\pi^* + a\alpha + b\beta + y$$

where π^* provides a measure of solvent dipolarity–polarizability; α, the solvent HBD acidity; and β, the solvent HBA basicity. Parameter coefficients are s, a, and b; y is the y-axis intercept.

In this paper, $\Delta\Delta H(\text{v} \rightarrow \text{s})$ values for triethylamine (vs. 3-ethylpentane), pyridine (vs. benzene), and aniline (vs. benzene) in 17 organic solvents will be reported. Correlations having the form of eq. [4] will also be presented. Previous correlations involving triethylamine and pyridine in non-H-bond donor solvents have examined only polar effects (π^*) (7). Some values of $\Delta H(\text{v} \rightarrow \text{s})$ for triethylamine vs. tetramethyltin have been reported (8), but correlations with solvatochromic parameters were not examined.

Experimental

Solutes and solvents were commercial samples in excess of 99% purity, with most exceeding 99.7%. Purities were established by silica capillary gas chromatography and an electronic integrator. All solutes and solvents were stored over 4A molecular sieve, except for methanol

and trifluoroethanol (3A). Triethylamine was distilled from ninhydrin to remove primary and secondary amine impurities. The calorimetric procedure and apparatus have previously been described (9).

Results and discussion

Heats of solution of triethylamine (Et_3N), pyridine, aniline (NH_2Ph), benzene, and 3-ethylpentane (Et_3CH) in 17 organic solvents (*n*-heptane, cyclohexane, carbon tetrachloride (CCl_4), 1,2-dichloroethane ($ClCH_2CH_2Cl$), α,α,α-trifluorotoluene (CF_3Ph), triethylamine (Et_3N), butyl ether (Bu_2O), ethyl acetate (EtOAc), dimethylformamide (DMF), dimethyl sulfoxide (DMSO), benzene, toluene, mesitylene, 1-octanol, *t*-butyl alcohol (*t*-BuOH), methanol (MeOH), and 2,2,2-trifluoroethanol (CF_3CH_2OH), solute heats of vaporization, and solvent solvatochromic parameters (π^*, α, β) are given in Table 1. Differences between nitrogen base and model solvation enthalpies are listed in Table 2.

Triethylamine

3-Ethylpentane (Et_3CH) is a good model for triethylamine because of the similar structural features and molar volumes ($\Delta MV = -4.4$ mL/mol). A plot of $\Delta\Delta H(v \rightarrow s)$ (triethylamine vs. 3-ethylpentane) values against solvent π^* is shown in Fig. 1. The dependence of triethylamine solvation on select solvent (4) polarity is given by eq. [5] (solvent = heptane, cyclohexane, Et_3N, Bu_2O, EtOAc, DMF, DMSO),

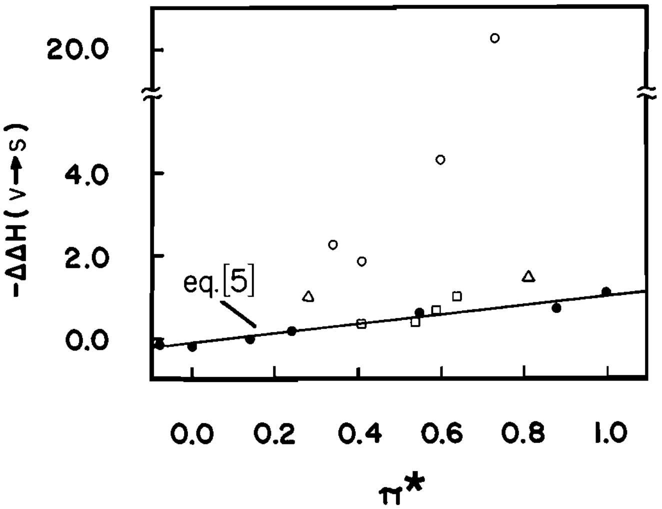

FIG. 1. Plot of $-\Delta\Delta H(\text{v} \rightarrow \text{s})(Et_3N$ vs. $Et_3CH)$ versus π^* for select (●), chloro (△), aromatic (□), and alcohol (○) solvents.

$$[5] \quad \Delta\Delta H(\text{v} \rightarrow \text{s})\ (Et_3N \text{ vs. } Et_3CH) = -1.12\pi^* + 0.11$$

$$n = 7,\ r = 0.980,\ \text{see} = 0.11 \text{ kcal/mol}$$

where n is the number of solvents, r denotes the correlation coefficient, and see refers to the standard error of the estimate (10). Mesitylene, toluene, and benzene are within 0.13 kcal/mol of eq. [5]. Trifluorotoluene is displaced exothermically by 0.39 kcal/mol, possibly due to electron donor–acceptor (charge transfer) (11) complex formation with triethylamine. Exothermic displacements of carbon tetrachloride (0.80 kcal/mol) and 1,2-dichloroethane (0.67 kcal/mol) probably result, at least partially, from a reaction with the nucleophilic amine. Reactions between amine solutes and carbon tetrachloride solvent are well documented (12).

t-Butyl alcohol, octanol, methanol, and trifluoroethanol are displaced exothermically from eq. [5] by 1.51, 2.00, 3.77, and 19.55 kcal/mol, respectively. These displacements follow the order of increasing HBD acidity:

[6] *t*-BuOH < octanol < MeOH < trifluoroethanol

and are the result of amine solute–alcohol solvent type A hydrogen bonding. $\Delta\Delta H(\text{v} \rightarrow \text{trifluoroethanol})$ is extremely large and possibly represents a proton transfer reaction in which the triethylammonium cation is formed. However, a reasonable alternative has been suggested by M. J. Kamlet (private communication). Alcohol solvents donate H-bonds to triethylamine at the expense of alcohol–alcohol H-bonds. The energy gain should depend on the HBA (β, ξ) *difference* between amine and alcohol. The difference is moderate for 1-octanol, *tert*-butyl alcohol, and methanol (vs. Et_3N), but is very large for trifluoroethanol ($\beta = 0.00$).

A total solvatochromic equation derived for the dissolution of triethylamine in select, aromatic (except trifluorotoluene), and alcohol (except trifluoroethanol) solvents using multiple parameter linear regression is

$$[7] \quad \Delta\Delta H(\text{v} \rightarrow \text{s})\ (Et_3N \text{ vs. } Et_3CH) = -1.26\pi^* - 3.19\alpha + 0.20$$

$$n = 13,\ r = 0.973,\ \text{see} = 0.32 \text{ kcal/mol}$$

The relative importance of H-bonding and polar interactions process is seen in the a/s ratio of 2.5. The π^* coefficients of eq. [5] and [7] are in fair agreement. Calculated (eq. [7]) values of $\Delta\Delta H(\text{v} \rightarrow \text{ROH})$ are more exothermic than the observed for octanol (−0.29 kcal/mol) and *t*-butyl alcohol (−0.63 kcal/mol), and more endothermic for methanol (0.65 kcal/mol). It may be that the two strongly HBA alcohols compete with solute as H-bond acceptors, whereas the weaker acceptor (methanol) does not.

TABLE 2. $\Delta\Delta H(\text{v} \rightarrow \text{s})$(nitrogen base vs. model) values[a]

Solvent	Pyridine vs. benzene	Triethylamine vs. 3-ethylpentane	Aniline vs. benzene

[a]kcal/mol.

Aniline

Aniline is a solute capable of dispersion, polar, and hydrogen bonding (HBA and HBD) interactions. The cavity formation mismatch of aniline (MV = 91.2 mL/mol) vs. benzene (MV = 88.9 mL/mol) $\Delta\Delta H(\text{v} \rightarrow \text{s})$ is minimal. The plot of $\Delta\Delta H(\text{v} \rightarrow \text{s})$ vs. solvent π^* is shown in Fig. 2. The major problem in evaluating H-bonding interactions via the non-hydrogen-bonding-baseline (NHBB) method (2, 4, 6) is that a baseline cannot be clearly defined. Carbon tetrachloride and 1,2-dichloroethane possibly react with the amine, and the line defined by the alkanes and trifluorotoluene (three data points) is suspect. However, for discussion purposes, the NHB baseline will be taken as the best fit line between the five NHB solvents:

$$[8] \quad \Delta\Delta H(\text{v} \rightarrow \text{s})\ (\text{aniline vs. benzene}) = -2.55\pi^* - 2.32$$

$$n = 5,\ r = 0.891,\ \text{see} = 0.58 \text{ kcal/mol}$$

Enthalpies of H-bond formation of aniline with aromatic and dipolar aprotic solvents, as measured by displacements from eq. [8], correlate well with solvent HBA basicity (and are essentially independent of the base family dependent term ξ):

$$[9] \quad \Delta H_h(\text{NHBB})(\text{aniline}) = -5.30\beta + 0.36$$

$$n = 8,\ r = 0.992,\ \text{see} = 0.21 \text{ kcal/mol}$$

Alcohol solvents can accept or donate a hydrogen bond, but displacements from eq. [8] follow a pattern identical to that observed with triethylamine as solute (eq. [6]). If the displacements are assumed to result from type A hydrogen bonding (solvent acts as HBD acid), then for the alcohol solvents:

$$[10] \quad \Delta H_h(\text{NHBB})(\text{aniline}) = -2.37\alpha + 0.26$$

$$n = 4,\ r = 0.957,\ \text{see} = 0.34 \text{ kcal/mol}$$

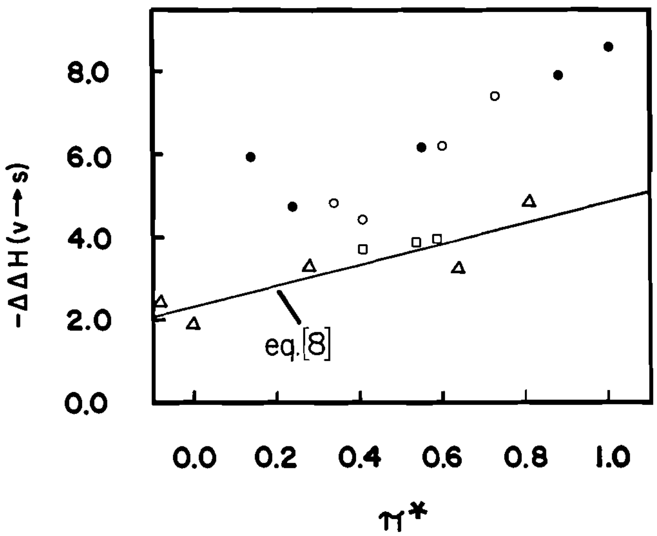

FIG. 2. Plot of $-\Delta\Delta H(v \rightarrow s)(NH_2Ph$ vs. benzene) versus π^* for H-bond acceptor (●), non-hydrogen-bonding (△), aromatic (□), and alcohol (○) solvents.

Trifluoroethanol ($\beta = 0.00$), which does not significantly undergo type B hydrogen bonding, falls well within the standard error of the estimate of eq. [10].

Addition of eq. [8]–[10] gives rise to an "all solvents" total solvatochromic equation:

$$[11] \quad \Delta\Delta H(v \rightarrow s)(\text{aniline vs. benzene}) = -2.55\pi^* -5.30\beta - 2.37\alpha - 1.70 \text{ kcal/mol}$$

where $n = 17$ and the combined see value is 0.70 kcal/mol. Multiple parameter linear regression of $\Delta\Delta H(v \rightarrow s)$ values for the same solvents gives a similar equation (β for ROH solvents assumed to be nil, i.e., aniline–alcohol solvent type B H-bonding assumed to be absent, since this would be at the expense of alcohol–alcohol H-bonding, giving no energy advantage):

$$[12] \quad \Delta\Delta H(v \rightarrow s)(\text{aniline vs. benzene}) = -2.67\pi^* -4.88\beta - 2.25\alpha - 2.16$$

$$n = 17, r = 0.985, \text{see} = 0.36 \text{ kcal/mol}$$

The dependence of aniline solvation on polar interactions is slightly larger than on type A hydrogen bonding ($s/a = 1.19$) and much smaller than type B hydrogen bonding ($s/b = 0.55$). Aniline is a considerably better hydrogen bond donor than hydrogen bond acceptor. As an acceptor aniline is considerably weaker than triethylamine (eq. [7]).

The (unreported) π^* value of aniline may be estimated from the π^* coefficients (s) in eqs. [11] and [12] as 1.09 and 1.11, based on the relationship (7) of s and the difference in π^* of solute and model.

Pyridine

Correlation of $\Delta\Delta H(v \rightarrow s)$ with π^* of the select solvents gives

$$[13] \quad \Delta\Delta H(v \rightarrow s)(\text{pyridine vs. benzene}) = -1.52\pi^* - 0.49$$

$$n = 7, r = 0.983, \text{see} = 0.13 \text{ kcal/mol}$$

Mesitylene and carbon tetrachloride are displaced exothermically by 0.30 and 0.43 kcal/mol, respectively. All other nonprotic solvents lie within 0.20 kcal/mol of eq. [13]. The negative s value is consistent with the greater polarity of pyridine ($\pi^* = 0.87$) relative to benzene ($\pi^* = 0.59$).

The four alcohol solvents are displaced exothermically from eq. [13] as a result of relatively strong type A hydrogen bonding with pyridine ($\beta = 0.64$). Displacements from eq. [13] values increase in the order octanol < MeOH < *t*-BuOH < trifluoroethanol by −1.04, −1.50, −2.55, and −6.46 kcal/mol, respectively. $\Delta\Delta H(v \rightarrow \text{ROH})$ values follow the same order and are difficult to rationalize because of the difficulty of separating the influence of ROH solvent–solvent intermolecular and pyridine–ROH solvent type A hydrogen bonding interactions. For weak HBA solutes such as 1-hexene, 1-octene, anisole, fluoro- and chlorooctane ($0.0 \leq \beta \leq 0.2$), the four alcohol solvents lie on, or endothermically displaced from, $\Delta\Delta H(v \rightarrow s)$ vs. non-HBA solvent π^* correlations (2, 3). The reason for the endothermic displacements is unknown but these possibly result from the formation of enthalpically less favorable solute – ROH solvent H-bonds at the expense of enthalpically more favorable but entropically less favorable solvent–solvent intermolecular hydrogen bonds. For slightly stronger HBA solutes (ethers, $\beta \sim 0.5$; ketones, ~ 0.5) 1-octanol, *t*-BuOH, and MeOH ($0.62 \leq \beta \leq 1.01$) lie on, or endothermically displaced from, analogous correlations; trifluoroethanol, the only ROH solvent with a β value (0.00) less than that of the solutes, is exothermically displaced. All four alcohol solvents are exothermically displaced from the triethylamine ($\beta = 0.71$), aniline, and pyridine correlations. It appears that an increase in the solute HBA basicity increases the extent to which solute–solvent H-bonding (exothermic displacements) competes with solvent–solvent intermolecular H-bonding. Because it is unknown whether enthalpies of H-bond formation with alcohol solvents are best described by displacements of $\Delta\Delta H(v \rightarrow \text{ROH})$(pyridine vs. model) values from eq. [13] or from arbitrary points endothermically displaced from eq. [13], exothermic displacements of ROH solvents (ΔH_h(NHBB)) are thought to represent minimum hydrogen bonding enthalpies. For trifluoroethanol, a weakly self-associating alcohol, the displacement from eq. [13] is probably a reasonable measure of the enthalpy of H-bond formation with pyridine.

GREGORY A. BANTA, STEVEN J. RETTIG, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **63**, 2545 (1985).

The synthesis and physical properties of two dimethylgallium citrate triester complexes are reported. Crystals of bis-[(trimethylcitrato)dimethylgallium(III)] are monoclinic, $a = 9.839(1)$, $b = 14.496(1)$, $c = 11.125(1)$ Å, $\beta = 108.31(1)°$, $Z = 2$, space group $P2_1/c$. The structure was solved by conventional heavy-atoms methods and was refined by full-matrix least-squares procedures to $R = 0.036$ and $R_w = 0.037$ for 1507 reflections with $I \geq 3\sigma(I)$. The structure consists of centrosymmetric dimers in which each citrate ligand is coordinated via the hydroxyl oxygen (bridging) and the C=O oxygen atom of the central ester group, forming five-membered chelate rings. Each Ga atom has irregular trigonal bipyramidal coordination geometry with Ga—O(eq) = 1.950(3), Ga—O(ax) = 2.103(3) and 2.395(3), and Ga—C(eq) = 1.953(5) and 1.947(5) Å.

On rapporte la synthèse et les propriétés physiques de deux complexes triesters du citrate de diméthylgallium. Les cristaux de bis[(triméthylcitrato)diméthylgallium(III)] sont monocliniques, ils appartiennent au groupe d'espace $P2_1/c$ avec a = 9,839(1), b = 14,496(1), c = 11,125(1) Å, β = 108,31(1)° et Z = 2. On a résolu la structure par des méthodes conventionnelles aux atomes lourds et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de R = 0,036 et R_w = 0,037 pour 1507 réflexions avec $I \geq 3\sigma(I)$. La structure comporte des dimères centrosymétriques dans lesquels chaque ligand citrate est coordoné par le biais de l'oxygène de l'hydroxyle (pontage) et par l'atome d'oxygène du C=O du groupement ester central pour former des cycles chélatés à cinq chaînons. La géométrie de coordination de chaque atome de Ga correspond à une bipyramide trigonale irrégulière avec Ga—O(eq) = 1,950(3), Ga—O(ax) = 2,103(3) et 2,395(3) et Ga—C(eq) = 1,953(5) et 1,947(5) Å.

[Traduit par le journal]

Introduction

The importance of gallium citrate complexes in medicinal chemistry is well documented (1), but definitive structural studies in this area are lacking. In our continuing investigations of the coordination chemistry of gallium the synthesis of two crystalline dimethylgallium citrate triester complexes has been accomplished. The mode of binding of the dimethylgallium moiety in the methyl citrate triester has been determined through an X-ray structural study.

Experimental

Air-sensitive materials were handled under oxygen-free dry nitrogen. Tetrahydrofuran (THF) was dried by refluxing over sodium/benzophenone and benzene by refluxing over molten potassium. The solvents were subsequently distilled and transferred to a glove-box for immediate use.

Starting materials

The ethyl and methyl citrate triesters were prepared by the standard acid-catalyzed esterification of citric acid with 100% ethanol and methanol, respectively, using concentrated H_2SO_4. The purity of the products was checked by correlation of their ir and nmr spectra with reference data. Trimethylgallium (2) and dimethylgallium hydroxide (3) were made by standard methods.

Synthesis of (triethylcitrato)dimethylgallium(III)

This complex was prepared by two methods:

Method A: from trimethylgallium

Ethyl citrate triester (1.24 mL, 5.10 mmol) was added via a syringe to Me_3Ga (0.584 g, 5.10 mmol) in THF (50 mL). The reaction mixture was stirred at room temperature for approximately 24 h during which time methane was evolved slowly. The solvent was then removed under vacuum and the solid product recrystallized from benzene to yield large colorless crystals of the desired complex. *Anal.* calcd. for $[Me_2Ga(C_{12}H_{19}O_7)]$: C 44.83, H 6.72; found: C 44.77, H 6.61%. ^{1}H nmr (C_6D_6): τ 9.76 s ($GaMe_2$), 9.03 t (—CH_2CH_3, $J \sim 7$ Hz), 7.07 s br (—CH_2—CO_2Et), 6.04 q, 5.92 q (—CH_2CH_3, $J \sim 7$ Hz, relative intensities 2:1) (τ values refer to $\tau(C_6H_6)$ = 2.84 ppm; s = singlet, t = triplet, q = quartet, br = broad). Ir (Nujol) ν_{CO} = 1740, 1717 cm^{-1} (ν_{CO} = 1738 cm^{-1} for ethyl citrate triester), ν_{Ga-C} = 600, 536 cm^{-1}. Mp 116–118°C.

Method B: from dimethylgallium hydroxide

$[Me_2Ga(OH)]_4$ (0.52 g, 1.11 mmol) was dissolved in benzene (50 mL). Ethyl citrate triester (1.08 mL, 4.45 mmol) was injected into the reaction vessel. The ethyl citrate which is sparingly soluble in benzene dissolves slowly as it reacts with $[Me_2Ga(OH)]_4$ to produce a clear solution of the product. The reaction mixture was stirred for approximately 24 h and then the solvent was removed under vacuum. The white solid product was pumped under vacuum for several hours to ensure removal of by-product water and it was then recrystallized from benzene to yield large colorless crystals of the ester complex. These gave identical spectra and closely similar analytical results to those obtained for the product using method A above.

Synthesis of (trimethylcitrato)dimethylgallium(III)

Me_3Ga (0.403 g, 3.51 mmol) in THF (50 mL) was reacted with methyl citrate triester (0.747 g, 3.19 mmol). The reaction mixture was stirred for approximately 24 h and then the solvent was removed under vacuum. The white solid product was recrystallized from benzene to afford well-formed colorless crystals. *Anal.* calcd. for $[Me_2Ga(C_9H_{13}O_7)]$: C 39.68, H 5.75, O 33.64; found: C 39.21, H 5.89, O 33.88. ^{1}H nmr (d_6-acetone): τ 10.37 s ($GaMe_2$), 7.07 (AB)q (—CH_2—CO_2Me), 6.31 s, 6.19 s (—CO_2Me, rel. int. 2:1) (τ values refer to $\tau(d_6$-acetone) = 7.89 ppm). Ir (Nujol): ν_{CO} = 1745, 1720 cm^{-1} (ν_{CO} = 1735 cm^{-1} for methyl citrate triester) ν_{Ga-C} = 597, 536 cm^{-1}. Mp 72–75°C. Both the complexes described above are hygroscopic.

Spectra

^{1}H nmr spectra were recorded on a Bruker WP-80 instrument using FT techniques. Ir spectra were recorded on a Perkin-Elmer 598 spectrometer.

X-ray crystallographic analysis of bis[(trimethylcitrato)-dimethylgallium(III)]

The crystal selected for the X-ray study was mounted in a capillary tube under a nitrogen atmosphere and the tube was subsequently flame-sealed. The density of the material could not be measured due

*U_{eq} = (1/3) trace U_{diag}.

to its sensitivity to air. A crystal bounded by the six faces (followed by their distances in mm from a common origin): ±(1 0 0), 0.038, ±(0 1 0), 0.225, ±(0 0 1), 0.238 was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 30−37°) measured on a diffractometer with Mo-$K\alpha$ radiation ($\lambda(K\alpha_1)$ = 0.70930, $\lambda(K\alpha_2)$ = 0.71359 Å). Crystal data at 22°C are:

$C_{22}H_{38}Ga_2O_{14}$ fw = 665.97
Monoclinic, a = 9.839(1), b = 14.496(1), c = 11.125(1) Å, β = 108.31(1)°, V = 1506.4(3) Å^3, Z = 2, ρ_c = 1.468 Mg m^{-3}, F(000) = 688, μ(Mo-$K\alpha$) = 18.4 cm^{-1}. Absent reflections: $h0l$, l odd, and $0k0$, k odd, uniquely indicate the space group $P2_1/c$ (C_{2h}^5, No. 14).

Intensities were measured with graphite-monochromated Mo-$K\alpha$ radiation on an Enraf-Nonius CAD4-F diffractometer. An ω−2θ scan at 1.55−10.06° min^{-1} over a range of (1.00 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 55°. The intensities of three check reflections, measured every 3600 s throughout the data collection, remained constant to within 1.5%. After data reduction,[1] an absorption correction was applied using the analytical method (4, 5). Transmission factors ranged from 0.481 to 0.873. Of the 3446 independent reflections measured, 1507 (43.7%) had intensities greater than or equal to 3σ(I) above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The coordinates of the Ga atom were determined from the Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference map. After full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters to R = 0.053, a difference map gave the positions of most of the hydrogen atoms. In subsequent cycles of refinement the hydrogen atoms were included as fixed contributors in idealized positions (based on the observed positions with C—H = 0.98 Å). The scattering factors of ref. 6 were used for non-hydrogen atoms and those of ref. 7 for hydrogen atoms. Anomalous scattering factors from ref. 8 were used for the Ga atoms. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix refinement of 172 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.036 and R_w = 0.037 for 1507 reflections with $I \geq 3\sigma(I)$. For all 3446 reflections R = 0.128. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

*Here and elsewhere in this report primed atoms have coordinates related to those in Table 1 by the symmetry operation (1 − x, 1 − y, 1 − z).

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.01 and 0.07σ, respectively. The mean error in an observation of unit weight was 1.285. A final difference map showed maximum fluctuations of −1.02 to +0.41 e Å^{-3} near Ga and was essentially featureless elsewhere. The final positional and thermal parameters appear in Tables 1 and 6,[2] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2] Bond distances, bond angles, and intra-annular torsion angles are given in Tables 2−4, respectively. Calculated hydrogen parameters (Table 5) and a complete listing of torsion angles (Table 7) are included as supplementary material.[2]

Results and discussion

The use of gallium citrate solutions is widespread in radiopharmaceutical procedures (1). Thus, since the discovery that ^{67}Ga localized in human soft tissue tumors (9) and also in inflammatory lesions (10, 11) it has been extensively used in diagnostic nuclear medicine (12). In addition ^{68}Ga has shown promise recently in positron emission tomography (PET) for medical diagnosis (13). Presently ^{67}Ga-citrate is the clinically applicable agent best suited to radionuclide tagging. The importance of this agent has prompted ^{1}H and ^{71}Ga nmr studies of gallium citrate complexes in aqueous solutions (14, 15), over a range of pH values, in an attempt to shed light on the structure of such complexes with a view to gaining a better understanding of the molecular mechanism of cellular binding of Ga and the inhibition of this process by citrate and other buffers. However, definitive structural data on gallium citrate complexes is lacking and in an effort to determine the mode of coordination of the gallium atoms by citrate species we have prepared two citrate triester complexes incorporating the dimethylgallium moiety. The complexes isolated, $Me_2Ga(C_{12}H_{19}O_7)$ and $Me_2Ga(C_9H_{13}O_7)$, are the first crystalline gal-

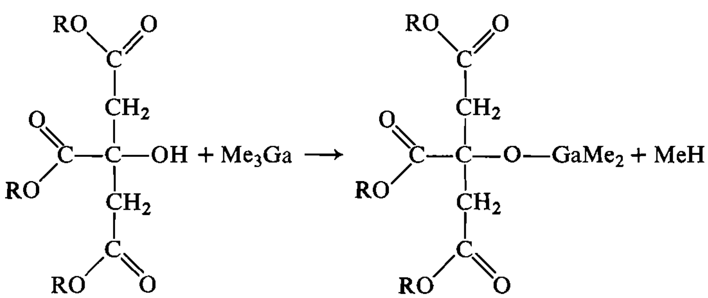
lium citrate complexes to be reported and the structural characterization of the latter (see below) represents an important contribution to our knowledge in this area. The reaction employed is one of methane elimination between the hydroxyl group of the citrate triester and trimethylgallium or elimination of water between this group and the hydroxyl group of dimethylgallium hydroxide:



It is clear from the ir and ^{1}H nmr evidence that the hydroxyl proton of the citrate triester is removed during the reaction since the original ν_{OH} (3470 cm^{-1} (Nujol) methyl citrate triester; 3480 cm^{-1} (neat liquid) ethyl citrate triester) and τ_{OH} (5.41 τ (d_6-acetone) methyl citrate triester; obscured by other signals for the ethyl citrate triester) signals are absent in spectra of the products. The ^{1}H nmr spectra of the two products (R = Me or Et) are shown in Fig. 1. In both spectra the —GaMe$_2$ group gives a sharp singlet, indicating a symmetrical structure in solution with equivalent Ga—Me groups. The presence of two different ester groups in the ratio of 2:1 is also apparent in the spectra. These observations are in agreement with the solid-state structure of the $Me_2Ga(C_9H_{13}O_7)$ (R = Me) complex (Fig. 2) in which the —GaMe$_2$ unit is symmetrically coordinated to the oxygen atom of the triester hydroxyl group and to the carbonyl oxygen atom of the central ester function, leaving equivalent outer ester groups non-involved in the bonding. In the solid state this unit exists as a centrosymmetric dimeric species, the only distance between dimers shorter than the sum of van der Waals radii being the possible weak interaction C(5)—H(5c)···O(6) ($1 + x, y, z$) (H···O = 2.54, C···O = 3.377(7) Å, C—H···O = 144°). The dimerization occurs via the formation of a central four-membered Ga_2O_2 ring, the Ga atoms attaining 5-coordination in a trigonal-bipyramidal fashion with the two coordination polyhedra sharing an axial-equatorial edge as in numerous previous examples (16). It is interesting that the outer ester groups do not chelate the gallium atoms. Such coordination would of course lead to six-membered chelate rings, rather than the five-membered chelate rings observed in the present structure.

The splitting of the single ν_{CO} vibration in the ir spectra of the original triester compounds upon forming the dimethylgallium complexes is further evidence for non-involvement of all ester functions in the coordination to gallium. The fact that one of the ester C═O groups is coordinated via oxygen to the Ga atom, albiet weakly (Ga—O = 2.395(3) Å), must lead to the observation of two ν_{CO} bands in the ir spectrum of the product. The C═O bond lengths for the outer ester functionalities (1.204(5) and 1.189(5) Å) are equal within experimental error to that observed for the coordinated central ester group (1.201(5) Å).

The central feature of the molecular structure of bis[(trimethylcitrato)dimethylgallium(III)] is the essentially planar system of three fused rings. The central four-membered ring is exactly planar, while the five-membered chelate rings are significantly non-planar (χ^2 = 166) although each of these rings, as well as the entire fused ring system, is planar to within ±0.046(6) Å. The Ga—O distances involving the bridging alkoxide O atom (1.950(3) and 2.103(3) Å, respectively, for equatorial and axial bonds) are comparable to those observed in other dimeric alkoxo-bridged species, the corresponding ranges being 1.911(3)−1.960(8) and 2.018(2)−2.078(3) Å (16). The axial Ga—O(4) distance of 2.395(3) Å is intermediate between values of 2.127(3) for an aldehyde O atom in bis[(salicylaldehydato)dimethylgallium] and 2.695(3) Å for a carboxylato C═O atom in (L-prolinato)dimethylgallium (16).

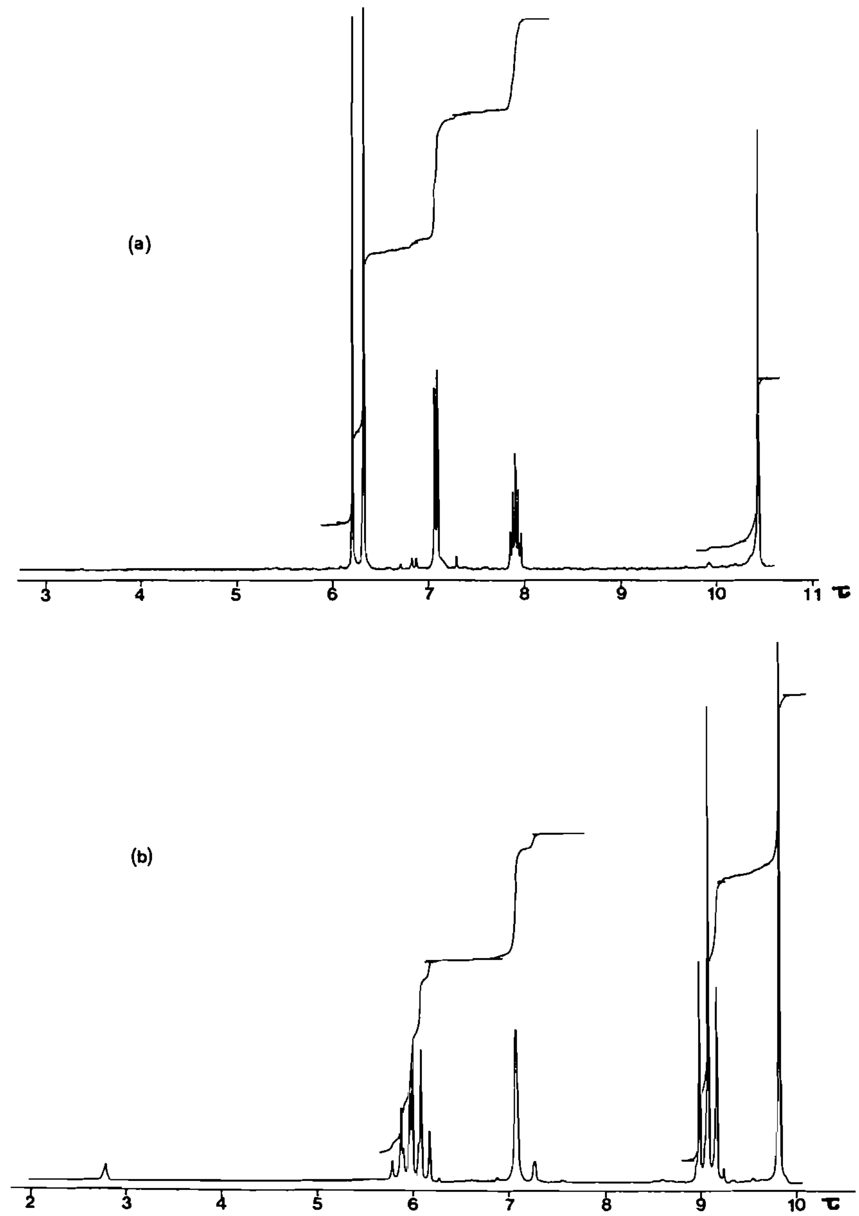


FIG. 1. 80 MHz [1]H nmr spectra of (*a*) Me_2Ga(Me citrate triester) in d_6-acetone and (*b*) Me_2Ga(Et citrate triester) in C_6D_6.

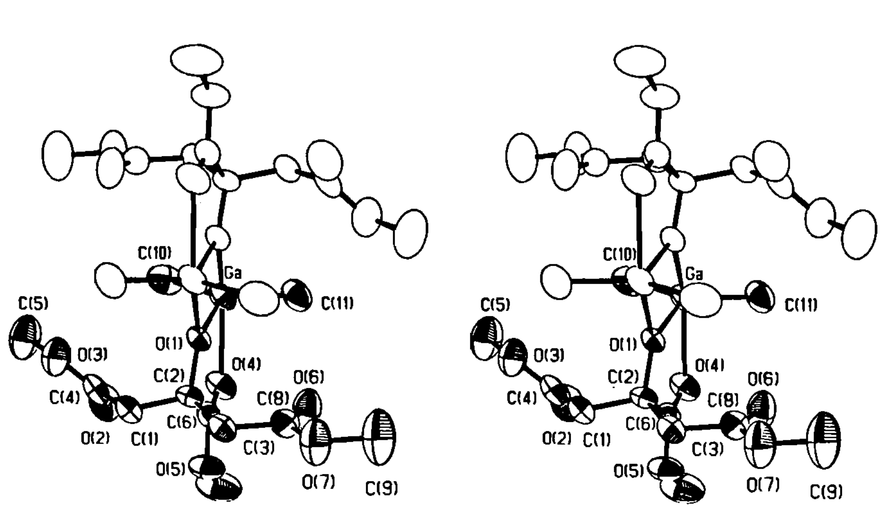

FIG. 2. Stereoscopic view of the bis[(trimethylcitrato)dimethylgallium(III)] molecule; 50% probability thermal ellipsoids are shown.

The Ga—C distances are normal as are bond lengths in the citrate moiety. Bond lengths and angles in the three ester groups are equal within experimental error, the three carboxylate groups being planar to within 0.022(5) Å with the ester methyl carbon atoms lying within 0.092(8) Å of the respective carboxylate mean planes.

Synthesis and characterization of Pt(II) complexes containing the bidentate pyrazolylgallate ligand, $[Me_2Gapz_2]^-$

SOPHIA NUSSBAUM AND ALAN STORR
Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received November 2, 1984

SOPHIA NUSSBAUM and ALAN STORR. Can. J. Chem. **63**, 2550 (1985).

The complexes $[Me_2Mpz_2]Pt(Me)L$ (where L = CO, Ph_3P, or PhC≡CPh for M = Ga; L = PhC≡CPh for M = B) have been synthesized by the direct reaction of the ligands $Na[Me_2Mpz_2]$ with Pt(Me)Cl(COD) followed by the addition of ligand L. The complexes have been shown to be fluxional in solution by variable temperature ^1H nmr methods.

SOPHIA NUSSBAUM et ALAN STORR. Can. J. Chem. **63**, 2550 (1985).

On a effectué une synthèse des complexes $[Me_2Mpz_2]Pt(Me)L$ (où L = CO, Ph_3P ou PhC≡CPh, pour M = Ga; L = PhC≡CPh pour M = B) en faisant appel à une réaction directe des ligands $Na[Me_2Mpz_2]$ avec le Pt(Me)Cl(COD), suivie d'une addition du ligand L. Faisant appel à des methodes de rmn à température variable, on a montré que les complexes en solution sont fluxionels.

[Traduit par le journal]

Introduction

As part of an on-going study of the reactions of the bidentate chelating pyrazolylgallate ligand, $[Me_2Gapz_2]^-$ (where pz = pyrazolyl, $N_2C_3H_3$) (1), the reactivity of this ligand towards the platinum compound Pt(Me)Cl(COD) (where COD = 1,5 cyclooctadiene) has been examined. This same platinum compound has been reported as being unreactive towards the pyrazolyl borate ligands $[RBpz_3]^-$ and $[R_2Bpz_2]^-$ (where R = H, Ph, Et, Bu), unless the very tightly bonded COD ligand is first activated via a halogen abstraction reaction using $AgPF_6$ (2, 3). However, our studies have revealed that the $[Me_2Gapz_2]^-$ ligand reacts smoothly with Pt(Me)Cl(COD), as does its boron analogue $[Me_2Bpz_2]^-$, without the necessity of the halogen abstraction step, and producing in moderate to high yield the desired products, $[Me_2Mpz_2]Pt(Me)L$ (where L = CO, Ph_3P or PhC≡CPh for M = Ga and L = PhC≡CPh for M = B) upon subsequent addition of ligand L.

Experimental

All reactions were performed under a dry nitrogen atmosphere, using Schlenk glassware or a glove-box. Tetrahydrofuran (THF) was dried by refluxing over sodium/benzophenone and distilled prior to use. Benzene was dried by refluxing over molten potassium. Hexane was distilled from calcium sulphate, methylene chloride from calcium hydride, and ether from lithium aluminum hydride. Pt(Me)Cl(COD) was prepared from K_2PtCl_4 by a standard route (4). Ph_3P (MCB) and PhC≡CPh (Eastman Kodak Co.) were used as supplied. MeOCOC≡CCOOMe (Aldrich) was distilled prior to use. The sodium salt of the gallium ligand $[Me_2Gapz_2]^-$ was prepared as described earlier (5) and $Na[Me_2Bpz_2]$ was prepared by a literature method (6).

Reaction of Pt(Me)Cl(COD) with $Na[Me_2Gapz_2]$

Pt(Me)Cl(COD) (0.100 g, 0.282 mmol) was dissolved in THF (~10 mL) and a solution of $Na[Me_2Gapz_2]$ in THF (3.8 mL, 0.282 mmol) was added dropwise with stirring. After the addition was complete the resultant cloudy mixture, **II**, was stirred for a further 1.5 h and then used directly in the following reactions.

(a) Reaction with Ph_3P

The solvent was removed from **II** and the colorless residue suspended in CH_2Cl_2. Ph_3P (0.074 mg, 0.282 mmol) was added with stirring. After a further period of stirring (1 h), the solvent was removed under vacuo to yield an oily residue which was washed with ether, leaving behind a white solid. The ether solution, on slow evaporation of solvent, gave the desired product $[Me_2Gapz_2]Pt(Me)(Ph_3P)$ as white crystals in ~75% yield. The compound sublimed under vacuum at 60°C and had a mp of 188°C. *Anal.* calcd. for $[Me_2Gapz_2]Pt(Me)(Ph_3P)$: C 45.91, H 4.25, N 7.93; found: C 46.09, H 4.40, N 7.96%. Mass spectrum: $(P - Me)^+$ (100%), $(P - Me - pzH)^+$ (35%), $(P - Me - 2pzH)^+$ (25%), $(P - Me - 2pzH - C_6H_6)^+$ (40%) plus signals due to Ph_3P and its fragmentation (P = parent).

The white solid remaining after extraction of the original product mixture with ether was treated with THF and the solution filtered from the insoluble NaCl. The white solid obtained on removal of THF from the filtrate was recrystallized from CH_2Cl_2/hexane to yield $[Pt(Me)(Ph_3P)(\mu\text{-pz})]_2$. Yield ~ 10%, mp 223°C. *Anal.* calcd. for $[Pt(Me)(Ph_3P)(\mu\text{-pz})]_2\cdot\frac{1}{3}C_6H_{14}$: C 49.87, H 4.22, N 5.06; found: C 50.03, H 4.31, N 5.00. ^1H nmr: ($CDCl_3$ solution) τ = 9.54 dd (Pt—Me, $J_{P-Pt-CH_3}$ = 4.4 Hz, $J_{^{195}Pt-CH_3}$ = 72 Hz), τ = 4.2 q, 3.5t (pz-^{4}H), τ = 2.23–2.75 m (Ph_3P) (pz-^{3}H, pz-^{5}H obscured by Ph_3P signals). Mass spectrum: P^+ (100%), $(P - Me - MeH)^+$ (20%), $(P - Me - MeH - pzH)^+$ (61%), $(P - Me - MeH - 2pzH)^+$ (23%), $(P - Me - MeH - 2pzH - C_6H_6)^+$ (33%) plus signals due to Ph_3P and its fragmentation.

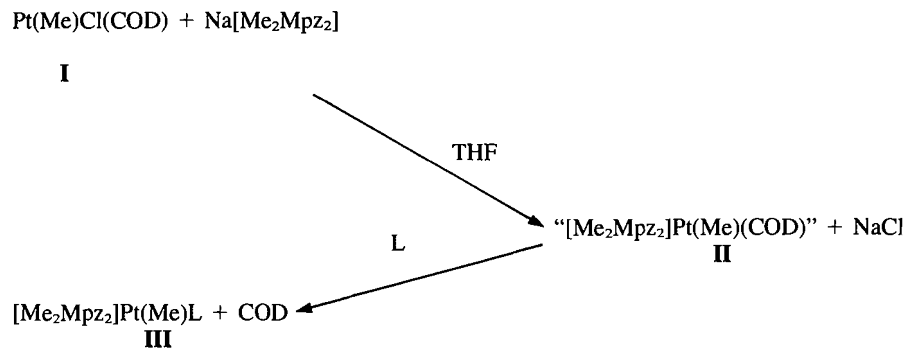
(b) Reaction with PhC≡CPh

To the stirred mixture **II** was added an equimolar amount of PhC≡CPh (0.05 mg, 0.282 mmol). The resultant solution was stirred for a further 1.5 h and the solvent then removed under vacuo. The resultant oily product mixture was then pumped for an additional 0.5 h at 40°C to remove cyclooctadiene. The remaining oil was then treated with ether and filtered. The filtrate yielded a pale yellow oil, on removal of ether solvent, which after repeated washings with hexane gave a yellow powder.[1] *Anal.* calcd. for $[Me_2Gapz_2]$Pt-(Me)(PhC≡CPh): C 44.38, H 4.02, N 9.01; found: C 41.22, H 4.16, N 8.31. Yield 89% ir (Nujol) $\nu_{C\equiv C}$ = *2069 cm^{-1}*. Mass spectrum: $(P - Me)^+$ (100%), $(P - Me - pzH)^+$ (57%), $(P - Me - 2pzH)^+$ (18%), $(P - Me - (PHC{\equiv}CPh))^+$ (40%), $(P - Me - pzH - (PhC{\equiv}CPh))^+$ (37%) plus signals due to PhC≡CPh and its fragmentation.

(c) Reaction with CO

Carbon monoxide was bubbled through the stirred mixture **II** for 1.5 h and the solvent then removed under vacuo. The oily residue was pumped on for a further 0.5 h. The oily product was then treated with CH_2Cl_2 and the mixture filtered. The CH_2Cl_2 was removed from the filtrate to yield the product as a colorless oil in approx. 40% yield. *Anal.* calcd. for $[Me_2Gapz_2]Pt(Me)(CO)$: C 25.43, H 3.18, N 11.87; found: C 25.70, H 3.29, N 11.90. Ir (CH_2Cl_2) ν_{CO} = 2085 cm^{-1}. Mass spectrum: $(P - Me)^+$ (100%), $(P - Me - CO)^+$ (35%), $(P - 2Me - CO)^+$ (8%).

[1]The product probably contains some free Pt as found by Clark *et al.* (2) in the material from the similar reaction involving the $[Et_2Bpz_2]^-$ ligand. Unfortunately, attempts to purify our product by sublimation or chromatography were unsuccessful.



M = Ga or B; L = Ph_3P, CO, PhC≡CPh, MeOCOC≡CCOOMe

SCHEME 1

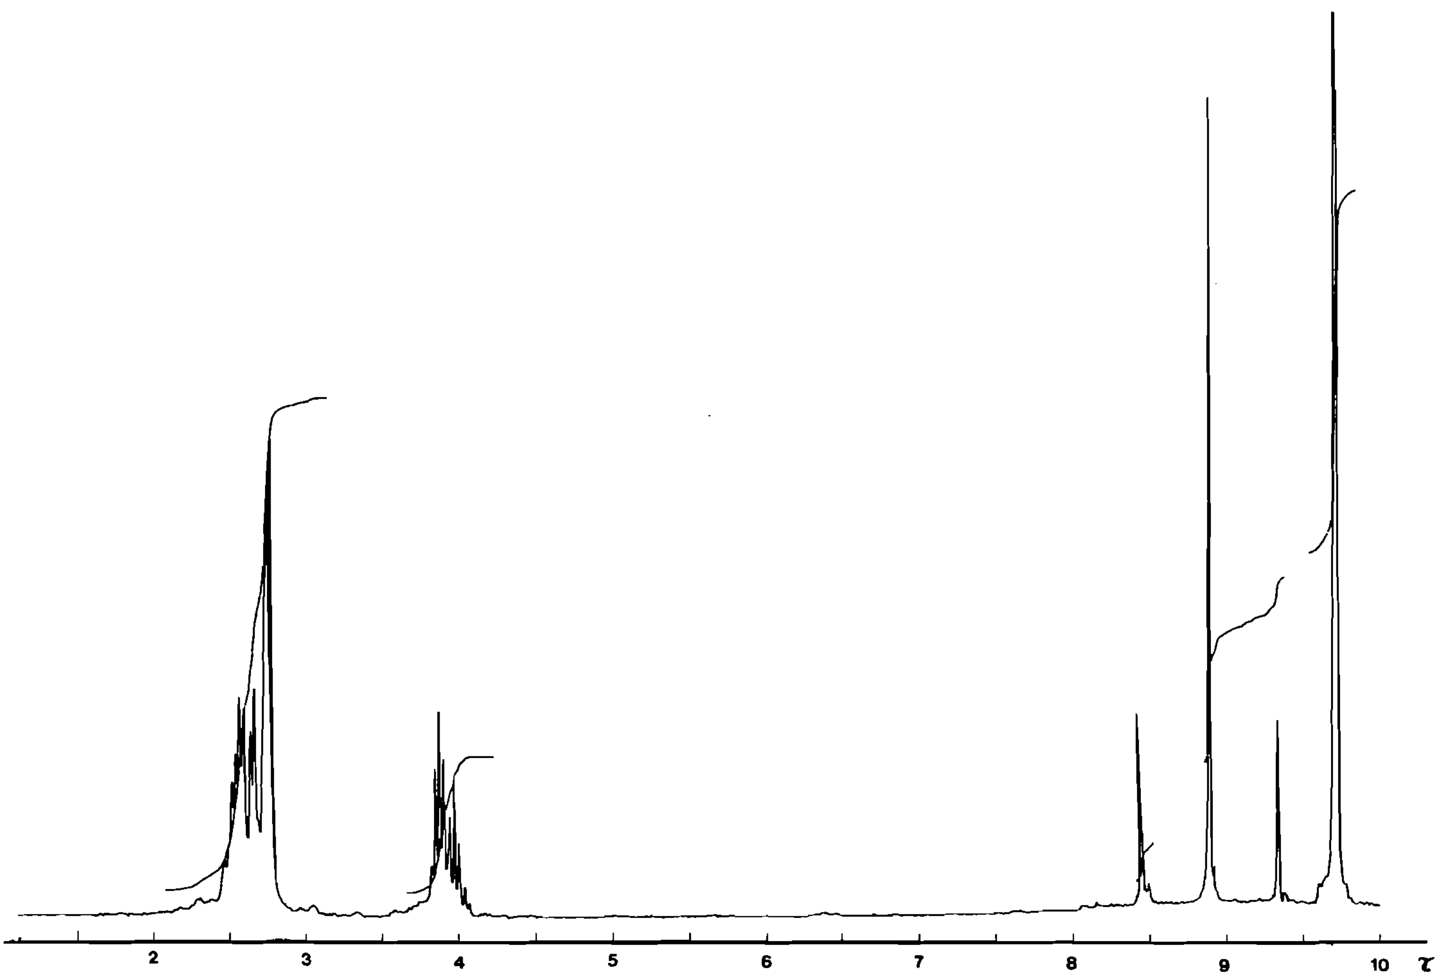


FIG. 1. Room temperature 80 MHz ^{1}H nmr spectrum of $[Me_2Gapz_2]Pt(Me)(CO)$ in C_6D_6 solution.

(d) Reaction with MeOCOC≡CCOOMe

The stirred mixture **II** was treated with an equimolar amount of MeOCOC≡CCOOMe (0.040 mg, 0.282 mmol). The reaction mixture became yellow and the color darkened slightly during the subsequent 1.5 h of stirring. The yellow oil obtained on evaporation of the solvent darkened under vacuo at ~30°C. It was then treated with CH_2Cl_2 and the mixture filtered. The yellow oil obtained on evaporation of the CH_2Cl_2 from the filtrate yielded a yellow powder on repeated washing with hexane. The characterization of this material has met with little success. Its ^{1}H nmr was very complicated although this did simplify slightly on heating the C_6D_6 solution to 70°C. Ir (CH_2Cl_2) ν_{CO} 1712, 1564 cm^{-1}, $\nu_{C=C}$ 1615 cm^{-1}.

Attempted insertion of PhC≡CPh into Pt—Me bond

(*i*) A solution of $[Me_2Gapz_2]Pt(Me)(PhC{\equiv}CPh)$ in C_6D_6 was heated to 80°C for 3 h. Some black precipitate was formed during the heating but the ^{1}H nmr spectrum of the solution remained virtually unchanged.

(*ii*) Carbon monoxide was bubbled through a solution of $[Me_2Gapz_2]Pt(Me)(PhC{\equiv}CPh)$ in benzene. The solvent was then removed under vacuum and the residue washed with hexane. $[Me_2Gapz_2]Pt(Me)(CO)$ was the only Pt-containing product formed.

Reaction of Pt(Me)Cl(COD) with Na[Me₂Bpz₂] and PhC≡CPh

Pt(Me)Cl(COD) (0.050 g, 0.14 mmol) was dissolved in 5 mL THF and a solution of $Na[Me_2Bpz_2]$ (0.028 g, 0.14 mmol) in 5 mL THF added dropwise with stirring. The mixture became cloudy immediately and was stirred for about 1.5 h. An equimolar amount of PhC≡CPh (0.025 g, 0.14 mmol) was then added and stirring was continued for a further 1.5 h. A pale yellow mixture resulted. The THF was removed to yield an oily residue which was pumped under vacuo for 1.5 h at 40°C. The residue was then extracted with CH_2Cl_2 and the mixture filtered. Addition of pentane to the filtrate and cooling to −23°C produced no crystallization of the product. The solvents were removed to yield initially a yellow oil, which transformed to a fluffy yellow solid product on brief pumping under vacuum. *Anal.* calcd. for $[Me_2Bpz_2]Pt(Me)(PhC{\equiv}CPh)$: C 49.03, H 4.44, N 9.95; found: C 49.21, H 4.52, N 9.54. Yield 83%, mp 50°C. Ir (CH_2Cl_2) $\nu_{C\equiv C}$ 1970 cm^{-1}.

Results and discussion

There have been a number of reports in the literature dealing with platinum complexes containing polypyrazolyl borate ligands (2, 3, 7−11). The reactivity of the Pt(Me)Cl(COD) complex towards such ligands has been reported to be restricted by the tightly bound COD ligand, and it was found necessary to activate the platinum complex by removal of the chloride ion using the silver salt of a non-coordinating anion (e.g. $AgPF_6$) in acetone or THF. In the resultant $[Pt(Me)(COD)(solvent)]^+$ species the COD ligand was quite labile and easily displaced (2, 3). In our studies we have examined the reactions of the $Na[Me_2Mpz_2]$ ligands (where M = Ga or B), with the Pt(Me)Cl(COD) complex and have found that the displacement of the COD ligand is quite facile without prior activation via a halide abstraction process. The synthetic route employed in the preparation of a series of platinum compounds is outlined in Scheme 1.

On addition of the pyrazolyl ligand to a solution of Pt(Me)-Cl(COD) in THF, a cloudiness occurred immediately. The resulting mixture **II** was not analyzed but, rather, used directly or after a change of solvent to CH_2Cl_2. The ligands, L, reacted smoothly with **II**, producing the complexes **III** in moderate to high yields. These were characterized by elemental analyses, mass spectra, ir, and ^1H nmr data. The ^1H nmr results are collected in Table 1 and clearly indicate the non-equivalence of the bridging pyrazolyl groups, as expected. The ^3H and ^5H proton signals appear as doublets, the ^4H proton signals as triplets. By analogy with the assignments made for the analogous complexes, $[R_2Bpz_2]Pt(Me)L$ (where R = Et or Ph; L = tertiaryphosphine, isocyanide or acetylene) (2), we assign the higher field signals to the ^4H protons on the ring *trans* to the Me group on Pt. These protons also exhibit a smaller coupling to the ^{195}Pt atoms, possibly due to the higher *trans* influence of the Me group compared to L (2).

Bimetallic species involving two bridging pyrazolyl groups usually exhibit a boat conformation for the central six-membered ring involving the two metals and the four nitrogens of the pyrazolyl rings. This arrangement has been established recently for a number of *bis* pyrazolylgallate complexes of Rh (12, 13), Re (14), Ir (15), and earlier for complexes of Mn, Mo (16), Ni (17, 18), and Cu (19). Thus the observation of a singlet for the Me_2M protons in the solution ^1H spectra at room temperature of the platinum complexes **III** led us to suspect a fluxional process for the species in solution rather than the alternate explanation of a planar M(—N—N—)$_2$Pt six-membered ring in the complexes. A representative room temperature ^1H nmr spectrum, for the complex $[Me_2Gapz_2]$-Pt(Me)(CO), is shown in Fig. 1. To confirm our prediction of a fluxional process in solution at room temperature a variable

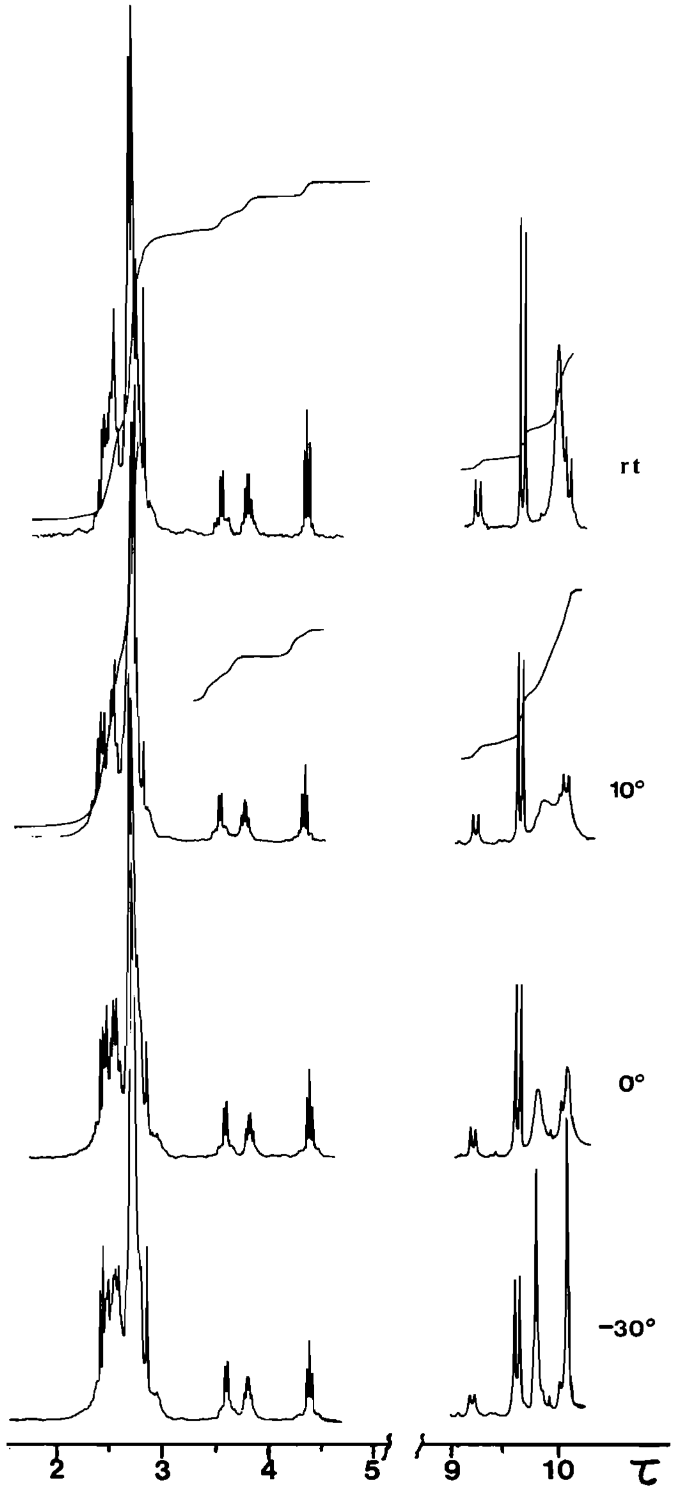

FIG. 2. Low temperature ^1H nmr spectra of $[Me_2Gapz_2]Pt(Me)$-(PPh_3) in $CDCl_3$ solution.

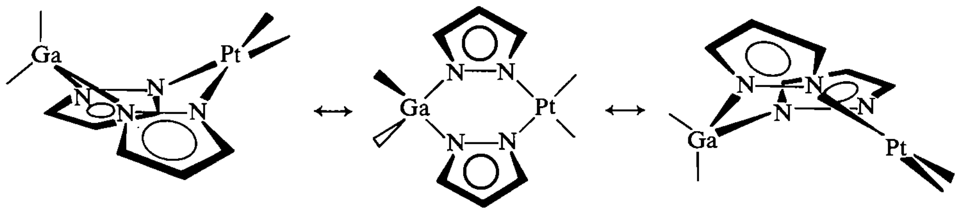
temperature ^1H nmr study was undertaken on the complex $[Me_2Gapz_2]Pt(Me)(PPh_3)$. This complex was chosen since the Me_2Ga singlet at room temperature was already quite broad (Fig. 2) suggesting a sluggish fluxional process even at this temperature. On cooling the solution, this signal broadened still further and eventually split into two separate signals which became quite sharp at −30°C. A fluxional process which can account for these results is shown below:

TABLE 1. ^{1}H nmr data for the complexes

			τ (ppm)*					
M	L	Solvent	M—Me	^4H_A	^4H_B	^3H, ^5H	Pt—Me	$J_{^{195}Pt—CH_3}$
Ga	Ph_3P	$CDCl_3$	9.96s	4.37t	3.81t	3.55d + signals obscured by Ph_3P	9.63d $J_{P—Pt—CH_3}$ = 4 Hz	70
Ga	PhC≡CPh	C_6D_6	9.76s	4.11t	3.91t	2.24d, 2.56d + signals obscured by PhC≡CPh	8.94s	72
Ga	CO	C_6D_6	9.72s	3.97t	3.87t	2.52–2.70 overlapping doublets	8.90s	70
B	PhC≡CPh	C_6D_6	9.12s	4.22t	4.04t	2.30d, 2.79d + signals obscured by PhC≡CPh	8.97s	74

*τ values refer to $\tau_{C_6D_6}$ = 2.84 ppm, τ_{CHCl_3} = 2.84 ppm; J_{HCCH} ≈ 2 Hz for pz protons. H_A ring *trans* to Pt—Me, H_B ring *cis* to Pt—Me; s = singlet, d = doublet, t = triplet.



In this process the room temperature spectra result from a rapid interconversion of the extreme boat conformations via a planar intermediate. At lower temperatures the axial and equatorial Ga—Me groups become distinguishable as the fluxional process becomes slow on the nmr time scale.

In the ^{1}H nmr of all the complexes **III** the Pt—Me signal appears at ~9τ with a $J_{^{195}Pt—CH_3}$ of approximately 70 Hz, a value normally found for planar Pt(II) species. In the complex where L = Ph_3P the Pt—Me signals are split into doublets with a $J_{P—Pt—CH_3}$ of approximately 4 Hz (see Fig. 2).

Attempts to promote insertion of the PhC≡CPh ligand into the Pt—Me bond in the complex $[Me_2Gapz_2]Pt(Me)$-(PhC≡CPh) were unsuccessful. Thus prolonged refluxing of a solution of this compound in C_6D_6 caused no change in its nmr spectrum although some black precipitate suggested some decomposition. Passing carbon monoxide through a solution of the complex resulted only in displacement of the alkyne by CO and no evidence of an insertion reaction was observed. A similar reluctance to undergo insertion reactions has been observed for the related $[R_2Bpz_2]Pt(Me)$(PhC≡CPh) (where R = Et or Ph) complexes (2).

Although the reaction of **II** with the alkyne MeOCOC≡CCOOMe was complicated and gave inconclusive results it was evident that a rapid reaction had occurred, as evidenced by the immediate color change on mixing the reactants and the absence of signals due to free acetylene in the ^{1}H nmr and ir spectra of the product mixture. The ir of the product mixture exhibits a very strong band due to an uncoordinated CO group (1715 cm^{-1}) and a weaker band possibly due to a coordinated CO group (1564 cm^{-1}). A band at 1615 cm^{-1} may be due to a C=C grouping and the spectrum was blank in the region where $\nu_{C\equiv C}$ bands usually appear. Thus it appears likely that, following alkyne coordination to the Pt centre, a facile insertion of this group into the Pt—Me band may occur. A similar facile insertion has been established for the $[R_2Bpz_2]Pt(Me)$-(MeOCOC≡CCOOMe) complexes described earlier (2).

The $[Me_2Mpz_2]Pt(Me)L$ complexes, **III**, were the only Pt-containing products in all the reactions (see Scheme 1) with the exception of L = Ph_3P where **III** was formed along with a smaller amount (~10%) of the pyrazolyl-bridged platinum dimer $[Pt(Me)(Ph_3P)(\mu\text{-}pz)]_2$. (The concurrent formation of the $[Me_2Gapz_2]$ dimer was indicated in ^{1}H nmr spectra but this previously characterized compound (20, 21) was not isolated.) Both the $[Me_2Mpz_2]^-$ ligands reacted with equal facility with the Pt(Me)Cl(COD) starting material and both reaction sequences led to moderate to high yields of the final products after introduction of the ligand L. Thus it appears that the halogen abstraction step using $AgPF_6$ (2, 3) is unnecessary with these two bidentate ligand systems and perhaps by extrapolation with the $[R_2Bpz_2]^-$ ligands in general.

ALAN SHAVER, RABIN D. LAI, PETER H. BIRD, and WASANTHA WICKRAMASINGHE. Can. J. Chem. **63**, 2555 (1985).

Attempts to prepare the complexes *cis*-$L_2Pt(SH)_2$, where L = PPh_3, $PMePh_2$, and PMePh by treatment of the appropriate dichloro complexes with NaSH in the presence of CH_2Cl_2 have resulted in the isolation of the complexes $L_2Pt(S_2CH_2)$. The X-ray structure determination of the compound for which L = PMe_2Ph confirms the presence of the $CH_2S_2^{2-}$ ligand.

ALAN SHAVER, RABIN D. LAI, PETER H. BIRD et WASANTHA WICKRAMASINGHE. Can. J. Chem. **63**, 2555 (1985).

Des essais réalisés dans le but de préparer les complexes $L_2Pt(SH)_2$-*cis*, dans lesquels L = PPh_3, $PMePh_2$ et PMe_2Ph, par la réaction des complexes dichlorés appropriés avec du NaSH en présence de CH_2Cl_2 n'ont conduit qu'à la formation de complexes $L_2Pt(S_2CH_2)$. Une détermination de la structure du composé dans lequel L = PMe_2Ph, en faisant appel à la diffraction des rayons-X, permet de confirmer la présence du ligand $CH_2S_2^{2-}$.

[Traduit par le journal]

Introduction

Compounds containing the SH^- ligand have been shown to be good precursors to complexes of catenated polysulfur ligands. Thus, $CpW(CO)_3SH$ reacts with sulfur transfer reagents of the type R—S_x—Imidyl, where x = 1, 2 and Imidyl = pthalimide, to give $CpW(CO)_3S_xR$ (1). The bisthiolo complex $Cp_2Ti(SH)_2$ reacts with the difunctional sulfur transfer reagents Imidyl—S_x—Imidyl, where x = 1, 2 to give Cp_2TiS_5, containing the cyclic S_5 ligand (2) and with R—S—Imidyl to give $Cp_2Ti(SSR)_2$, when R = alkyl and $Cp_2Ti(SR)(SSSR)$ when R = aryl (3). Thus, the reports (4–6) of the complex *cis*-$(PPh_3)_2Pt(SH)_2$, **1**, were of particular interest to us. However, despite the fact that three different preparative routes to this complex have been reported, we found it to be somewhat elusive. In this paper, we report our attempts to prepare this complex during which we have observed a novel reaction between CH_2Cl_2 and the reactants *cis*-L_2PtCl_2/NaSH, where L = PPh_3, $PMePh_2$, and PMe_2Ph, to give the complexes $L_2Pt(S_2CH_2)$, **2**–**4**. These contain the chelating ligand $CH_2S_2^{2-}$ as confirmed by the X-ray structure of complex 4.

Experimental

The general techniques used to prepare and characterize the complexes were similar to those already described (7). All solvents were of spectrograde quality. Melting points were determined in air on a Thomas-Hoover Uni-melt apparatus and are uncorrected. Proton nmr spectra were obtained on a Varian T-60 spectrometer, using $CDCl_3$ (Merck, Sharpe and Dohme of Montreal) as solvent and TMS as internal standard. Phosphorus nmr spectra were recorded using a Bruker WH-90 instrument operating in the pulsed Fourier Transform mode. The ^{31}P chemical shifts of the samples in $CDCl_3$ solution are reported in ppm upfield (negative) from 85% H_3PO_4 as external standard, using D_2O as the lock signal. Elemental analyses were performed by Midwest Microlab Ltd., Indianapolis, IN. Molecular weights were obtained in benzene or $CHCl_3$ by Spang Microanalytical Laboratory, Eagle Harbor, MI. The reactions were conducted under N_2 atmosphere with workup of the products carried out in air. The starting materials $(PPh_3)_2PtO_2$ (8) and *cis*-bis(phosphine)$PtCl_2$ (9–11) were prepared by literature methods. Technical grade (≥98.5%) dihydrogen sulfide gas (Linde) was passed through a column of "Drierite" (Anachemia) before use. Sodium hydrogen sulfide was prepared by the standard procedure (12).

A. cis-*Bis(thiolo)bis(triphenylphosphine)platinum(II),* cis-*$(PPh_3)_2Pt(SH)_2$,* ***1***

H_2S was bubbled through a THF suspension (40 mL) of $(PPh_3)PtO_2$ (0.52 g, 0.7 mmol) for 15 min. The white precipitate which formed was filtered, washed with THF and hexane, and pumped on (0.35 g, 64%).

Methanedithiolato complexes

The complexes $L_2Pt(S_2CH_2)$, where L = PPh_3, **2**; $PMePh_2$, **3**; PMe_2Ph, **4**, could be prepared by a number of similar routes as outlined in the Results section. The preparation of **4** is given as a typical example.

B. Methanedithiolatobis(dimethylphenylphosphine)platinum(II), $(PMe_2Ph)_2Pt(S_2CH_2)$, ***4***

The complex *cis*-$(PMe_2Ph)_2PtCl_2$ (0.88 g, 1.6 mmol) and NaSH (0.25 g, 45 mmol) were refluxed under nitrogen in a mixture of toluene (10 mL) and ethanol (25 mL) for 5 h. The reaction mixture was filtered in air, the filtrate evaporated in *vacuo* to a yellow oil which was extracted with a minimum amount of CH_2Cl_2, washed with 2 × 100 mL of H_2O, and dried over anhydrous $MgSO_4$. Addition of ether to the CH_2Cl_2 solution and cooling at −12°C gave **4** as yellow crystals which were collected, washed with CH_2Cl_2/Et_2O, and Et_2O, dried in a stream of N_2, and pumped on for 24 h (0.32 g, 37%).

X-ray structure determination

Crystal data:
$C_{17}H_{24}P_2PtS_2$ fw = 549.56
Monoclinic, $P2_1/c$, a = 9.555(6), b = 16.478(9), c = 13.485(8), β = 112.67(5) Å, V = 1959.1 Å^3, Z = 4, ρ_o = 1.88(2), ρ_c = 1.863 g cm^{-3}, ($MoK_\alpha\lambda$ = 0.71069 Å, 20°C, μ = 75.98 cm^{-1}).

The crystal used in the structure determination was grown from a mixture of methylene chloride and hexanes. It was a small irregularly shaped fragment with no dimension exceeding 0.1 mm. Preliminary photographic data unambiguously established the space group as monoclinic, $P2_1/c$. The unit cell was measured by accurately aligning

30 reflections on a Picker Nuclear FACS-1 fully automated diffractometer, and then performing a least-squares calculation. The data were collected using a θ−2θ scan and profile analysis (13). The scan speed was 2.0 deg min^{-1}. A unique quadrant of data was collected in the region $\pm h$, $+k$, $+l$, with three standards re-measured every 50 measurement cycles. The intensity of these standards varied randomly by less than 1%. The data were corrected for Lorentz and polarization effects, but due to the small size and poorly definable shape of the crystal no absorption correction was attempted. After data processing of 2561 measured reflections, 1883 having $I > \sigma(I)$ were retained for the structure solution. The following formulae were used for data reduction:

$$I = [N - B \cdot t_s/t_b]$$
$$\sigma(I) = [N + B(t_s/t_b)^2 + (0.02N)^2]^{1/2}$$
$$(Lp)^{-1} = \sin 2\theta_s(\cos^2 2\theta_n + 1)/(\cos^2 2\theta_m + \cos^2 2\theta_s)$$

where I is the net intensity derived from N, the measured count during the scan of duration t_s; B is the background count estimated from the peak profile analysis (13) during a time t_b; Lp is the Lorentz-polarization correction calculated using $2\theta_m$ and $2\theta_s$, the diffraction angles at the monochromator and the sample crystals, respectively.

made to find or refine hydrogen atoms. Calculated parameters shifts were multiplied by 0.6 after each cycle and anisotropic refinement was terminated when the largest shift was less than 1/10th of the corresponding standard deviation. A final difference Fourier synthesis showed no features above 0.4 e/Å^3. The final discrepancy indices were $R_f = 0.056$, $R_{wf} = 0.077$, and the "goodness-of-fit" = 1.30. The final atomic parameters are listed in Table 1.[3] The function minimized in the least-squares refinement was: $[\Sigma w(|F_o| - |F_c|)^2]$, where $w = [(\sigma(F)^2 + 0.03\ F^2]^{-1}$. The conventional discrepancy indices are $R_f = \Sigma(||F_o| - |F_c||)/\Sigma|F_o|$, $R_{wf} = [\Sigma_w(|F_o| - |F_c|)^2/\Sigma_w|F_o|^2]^{1/2}$ and the "goodness-of-fit" is $[\Sigma_w(|F_o| - |F_c|)^2/(m - n)]^{1/2}$.

The program to control the diffractometer and the programs used for the data processing, solution and refinement of the structure were parts of the N.R.C. Package of programs wirtten for the PDP-8a minicomputer by Larson and Gabe (14).

Results

The analytical and physical data of complexes **1**−**4** are given in Table 1. The nmr data of these complexes and the data reported for some other platinum thiolo complexes are given and compared in Table 2. The preparation of **1** was a modification of a literature method (5). The use of chlorinated solvents, recommended by other reports, was found to lead to decomposition. Complex **1** reacts with CH_2Cl_2 in the presence of K_2CO_3 but the product(s) could not be identified. The routes to *cis*-$(PPh_3)_2Pt(SH)_2$ described by Schmidt and Hoffmann (6, 15) did not work in our hands. Treatment of *cis*-$(PPh_3)_2PtCl_2$ with H_2S/K_2CO_3 or with NaSH in CH_2Cl_2 gave mostly starting material plus some **2**. While it might be tempting to assign complex **1** to be *cis*-$(PPh_3)_2Pt(SH_2)$, the elemental analysis of **1**, while close to that required, was not satisfactory. The chemical shift of the S—H protons compares well to that of several other Pt—SH species but does not agree with any of the three different values reported for *cis*-$(PPh_3)Pt(SH)_2$ (5, 6, 15, 16). The values of the coupling constants between the S—H protons and the platinum and phosphorus atoms are in the range reported in the literature. However, it must be noted that **1** was quite insoluble and the nmr data may be of material extracted from the bulk and thus not representative. The infrared spectrum of **1** was not informative being similar to other platinum−sulfur systems (7, 9). Bands due to the S—H stretching vibration are often weak and difficult to detect. Reaction of **1** with sulfur transfer reagents led to intractable brown tars.

Treatment of L_2PtCl_2 with NaSH in the presence of CH_2Cl_2 led to the isolation of complexes **2**−**4**. The characterization of these complexes (Tables 1 and 2) is consistent with their formulation as compounds of the simple methanedithiolato ligand. The complexes were formed in varying yields from treatment of the dichloride with: NaSH in CH_2Cl_2, or H_2S and pulverized K_2CO_3 in CH_2Cl_2 or NaSH in toluene/ethanol followed by extraction of the dried residue with CH_2Cl_2. The latter method appears to work best. A large excess of NaSH was used since it has been found that this promotes the preparation of other MSH species. The methylene is strongly bonded to the sulfur atoms. No reaction occurred when **3** was refluxed under N_2 with lithium metal in THF for 2 h. However, benzyl chloride reacted with **3** to give the dichloride complex and presumably $PhCH_2SCH_2SCH_2Ph$; however, the latter was not isolated.

The structure of **4** consists of a square planar arrangement of two phosphine ligands and the chelating $CH_2S_2^{2-}$ ligand (Fig. 1). The final positional parameters are listed in Table 3 and the listing of the bond lengths and angles appears in Table 4. The P_2PtS_2C grouping of atom is remarkably flat, deviations from planarity being less than 0.003 Å. The phenyl rings are disposed in an *anti* fashion. Comparison of the bond lengths and angles about the coordinated atoms of **4** with those of the complex $(PPh_3)Pt(SCH_2CH_2S)$, **5** (21), which has a two carbon atom bridge between the two sulfur atoms, reveals the effect of

[3] Table 6 (temperature factors for *cis*-$(PMe_2Ph)_2Pt(S_2CH_2)$) and Table 7 (observed and calculated structure amplitudes *cis*-$(PMe_2Ph)_2Pt(S_2CH_2)$) may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

TABLE 5. Comparison of selected average bond lengths and angles in $(PMe_2PH)_2Pt(S_2CH_2)$ and $(PPh_3)_2Pt(SCH_2CH_2S)$

Parameter	Value	
	S_2CH_2	SCH_2CH_2S[a]

[a]Reference 21.

the $CH_2S_2^{2-}$ ligand (Table 5). As expected the S—Pt—S and Pt—S—C angles are reduced in **4**. Interestingly the average Pt—P and Pt—S bond distances are also slightly shorter in **4**. The S—C—S angle in **4** (102.1) is intermediate between those for $Fe(CO)_6(S_2CH_2)$ (94.55 (22)) and $[Os_3H(CO)_{10}]_2(\mu\text{-}S_2CH_2)$ (105.3 (23)). The $CH_2S_2^{2-}$ ligand in the Osmium complex is not chelating. The S—S distance in **4** is 2.841(5) Å, which is longer than that in $Fe_2(CO)_6(S_2CH_2)$ (2.673(2)) and much longer than that in $Fe_2(CO)_6S_2$ (2.007(5)) where a S—S bond exists (24).[3]

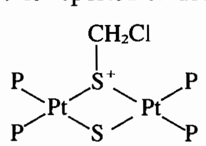
Discussion

Since CH_2Cl_2 can, under certain circumstances, couple two thiol molecules to give a dithioacetal (25), it is tempting to suggest that complexes **2**–**4** were formed by the reaction of

$$2RSH + CH_2Cl_2 \rightarrow RS—CH_2—SR + 2HCl$$

CH_2Cl_2 with the appropriate *cis*-$L_2Pt(SH)_2$ complex. The latter, however, were not isolated except for L = PPh_3, **1**, and there remains some doubt about its characterization. Complex **1** reacts with CH_2Cl_2 but the products could not be identified. The odor of H_2S was detected during the preparations of **2**–**4** which is consistent with the reaction of the excess NaSH present with HCl produced by the reaction of CH_2Cl_2.

An alternative possibility involves the recognition (26) of the strong nucleophility of the sulfur atoms in $[Pt(\mu\text{-}S)(PPh_3)_2]_n$, **6**. This complex reacts with CH_2Cl_2 to give $[Pt_2(\mu\text{-}S)(\mu\text{-}SCH_2Cl)(PPh_3)_4]\cdot Cl$ a cation with a bridging CH_2SCl^- ligand, **7**. Complex **7** is reported to decompose in CH_2Cl_2.



7

Complex **6** has been reported as the product upon treatment of **1** with NaOEt (15). It is possible that **1** could dimerize (7) to give **6** via elimination of H_2S. This type of reaction has been observed for $Cp_2Zr(SH)_2$ leading to $[Cp_2Zr(\mu\text{-}S)]_2$ (2). Conversion of **7** to **2** can be envisioned via internal alkylation of the bridging sulfide ligand (26).

Use of peak height for quantification in solvent extraction/flow injection analysis

JAMAL A. SWEILEH AND FREDERICK F. CANTWELL[1]
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received December 5, 1984

JAMAL A. SWEILEH and FREDERICK F. CANTWELL. Can. J. Chem. **63**, 2559 (1985).

The following equation is derived which expresses peak height (P.H.) in terms of sample concentration injected (C_{SAMP}), detector sensitivity (S_F), dilution due to band dispersion (R_v), fraction extracted (ϕ), flow rates of carrier ($F_{Carrier}$), organic phase (F_o), and compensating solvent (F_c), and flow rate of organic extract through the membrane phase separator (F_M):

$$\text{P.H.} = C_{SAMP} \cdot S_F \cdot R_v \cdot \frac{F_{Carrier}}{F_o} \cdot \phi \cdot \frac{F_M}{F_M + F_c}$$

Each term in the equation is evaluated experimentally to validate the equation.

JAMAL A. SWEILEH et FREDERICK F. CANTWELL. Can. J. Chem. **63**, 2559 (1985).

On a dérivé l'équation suivante, qui exprime la hauteur des pics (H.P.) en fonction de la concentration des échantillons injectés (C_{ECHANT}), de la sensibilité du détecteur (S_F), de la dilution due à la dispersion de la bande (R_v), de la fraction extraite (ϕ), des vitesses d'écoulement du porteur ($F_{Porteur}$), de la phase organique (F_o), de la compensation par un solvant (F_c) et des vitesses d'écoulement des composés organiques à travers la membrane qui sépare les phases (F_M):

$$\text{H.P.} = C_{ECHANT} \cdot S_F \cdot R_v \cdot \frac{F_{Porteur}}{F_o} \cdot \phi \cdot \frac{F_M}{F_M + F_c}$$

On a évalué expérimentalement chacun des termes de cette équation afin de la valider.

[Traduit par le journal]

The performance of automated solvent extraction in the flow injection analysis (FIA) mode has been studied both in terms of its principles of operation and its application to quantitative determinations (refs. 1−4 and references therein). Quantification in solvent extraction/FIA is based on either peak height or peak area. In a previous paper from this laboratory the quantitative relationship between *peak area* and various system parameters was derived and experimentally verified for systems employing a concentration sensitive detector (1). The present paper deals with the quantitative relationship between *peak height* and such system parameters as detector sensitivity, peak dispersion, flow rates of aqueous and organic streams, and sample distribution coefficient.

Some types of detectors, such as molecular absorption spectrophotometers, can simply be attached to the organic extract line exiting the phase separator (1), while other detectors, such as atomic absorption spectrophotometers (AAS), may require additional plumbing to provide flow compensation to the extract entering the nebulizer (3). Furthermore, while the detector sensitivity is independent of flow rate with molecular absorption spectrophotometers, it exhibits a complex flow-rate dependence with AAS detectors (3, 5). Both situations are included in the equation which is derived and experimentally verified in the present report.

Experimental

Apparatus

Two versions of the extraction/FIA instrument are considered, one with an AAS detector and the other with a molecular absorption spectrophotometric detector. The former, which has been used in the atomic absorption determination of zinc following solvent extraction of $Zn(SCN)_2$ (3), is shown in Fig. 1. It will be referred to as Version I of the instrument. The aqueous carrier is 0.10 M HCl, the aqueous reagent is 0.50 M KSCN in 0.10 M HCl and the immiscible organic solvent is methylisobutylketone (MIBK). Carrier and reagent streams merge at the first tee junction (T_1) and the resulting combined aqueous stream merges with MIBK in the phase segmentor tee (T_2). After passing through the 3-m long Teflon extraction coil the segmented flow stream enters the membrane phase separator M from which a portion of the MIBK exits to the tee junction T_3, where it is merged with the flow of MIBK from the compensating flask. The resulting MIBK solution enters the nebulizer of the AAS detector. Carrier, reagent, and organic solvents are pumped with nitrogen pressurized constant pressure pumps (1, 3).

Samples consist of dilute solutions of Zn(II) in 0.1 M HCl which are injected via a sample injection valve V_3. During passage of the segmented aqueous−organic flow stream through the extraction coil the complex $Zn(SCN)_2$ is quantitatively extracted into MIBK. The AA signal peak is due to Zn. AA peaks are displayed on a strip chart recorder R. Details of the instrument and operation of the phase segmentor are described elsewhere (3, 4).

The aqueous flow rate F_a is the sum of carrier flow rate $F_{Carrier}$ and reagent flow rate $F_{Reagent}$; the total flow rate F_T is equal to F_a plus the MIBK flow rate F_o; flow rate of MIBK phase passing through the membrane phase separator is F_M and compensating flow rate of MIBK from the flask is F_c. It was found that use of the flow compensator resulted in the total flow rate of MIBK entering the nebulizer ($F_M + F_c$) remaining constant for a given nebulizer setting, even when F_M was purposely varied during experiments. The value of ($F_M + F_c$) is governed by the "natural" aspiration rate demanded by the particular nebulizer setting as demonstrated in this study.

The second version of the extraction/FIA instrument, called Version II, was used in studies where some flow rates were varied while others were kept constant and where it was desired to use a detector whose sensitivity is flow-rate independent. The design was similar to that in Fig. 1 except for the following changes; (*i*) the constant pressure pumps were replaced by three constant flow rate liquid chromatography pumps (Model 6000A, Waters Assoc. and Model 396 Minipump, Laboratory Data Control); (*ii*) methanol was used, instead of acetone as a flushing solvent; (*iii*) T_3 and the compensating solvent were absent; (*iv*) a uv absorbance detector (Model 770, Schoeffel Instr. Corp.) was used at 410 nm, in place of the AAS; (*v*) a peristaltic pump (Minipuls 2, Gilson Instruments) was placed in the outlet line from the detector flow cell in order to gate the flow F_M, as described previously (1); (*vi*) carrier was water, reagent was phosphate buffer,

[1]To whom all correspondence should be addressed.

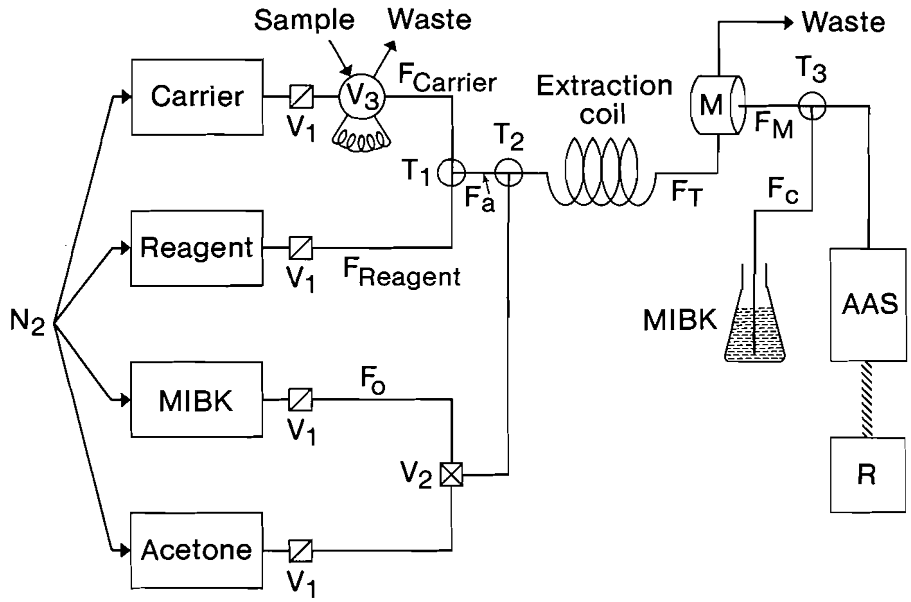

FIG. 1. Diagram of the solvent extraction/FIA instrument employing constant pressure pumping, an atomic absorption detector, and flow compensation.

organic solvent was $CHCl_3$, and the sample solution was *o*-nitroaniline in water.

In both versions of the instrument flow rates were measured by collecting the liquids in burets at the outlet end of the system. Therefore, reported values of F_{Carrier}, F_{Reagent}, F_o, F_a, and F_M are for mutually saturated phases. Also, the extraction coil was sufficiently long that extraction equilibrium was always achieved for both $Zn(SCN)_2$ and *o*-nitroaniline.

Reagents and chemicals

Ortho-nitroaniline stock solution (5.0×10^{-3} *M*) was prepared in water from the reagent grade chemical (BDH, Montreal). The sample solution (4×10^{-5} *M*) was prepared by dilution of the above stock. Phosphate buffer (0.01 *M*, pH = 7.0) was prepared in water by titrating a solution of KH_2PO_4 (McArthur Chemical Co., Montreal) to pH = 7.0 with NaOH and diluting to 2 L. Reagent grades of $CHCl_3$ (Mallinckrodt) and MIBK (Fisher Scientific Co.) were used without further purification. Other reagents and chemicals were reagent grade and have been described elsewhere (3).

Sensitivity curve

This was measured by pumping a solution of $Zn(SCN)_2$ in MIBK into the nebulizer. The "natural" aspiration rate of the nebulizer was set at 2.5 mL/min by suitable adjustment of the position of the nebulizer tip. The $Zn(SCN)_2$ solution was pumped from a constant pressure pump directly and continuously into the nebulizer — no solvent extraction or FIA was involved. $Zn(SCN)_2$ concentrations of 0.40 μg/mL and 0.70 μg/mL were used.

Effect of F_c

Variation of peak height with flow rate of compensating solvent was studied by pumping 0.4 μg/mL $Zn(SCN)_2$ solution in MIBK from a constant pressure pump through a tee junction, where it merged with the compensating flow of MIBK, and then into the nebulizer. No solvent extraction or FIA was involved in this study. The "natural" aspiration rate of the nebulizer was set at about 5 mL/min. A baseline for the AA signal was obtained by shutting off the flow of $Zn(SCN)_2$ solution so that the nebulizer aspirated only MIBK compensating solvent. The flow rate of $ZN(SCN)_2$ solution was then set, in turn, at several values by varying the nitrogen pressure in the pumps. Flow rate of the $Zn(SCN)_2$ solution from the pump was measured for each run by switching a three-way valve (No. CAV 3031, LCD) located between the pump and compensating tee so that the $Zn(SCN)_2$ solution was diverted to a measuring buret. The flow rate of compensating solvent during each run was measured as the rate of reduction in liquid level in the compensating solvent container.

Results and discussion

The derivation of an equation relating peak height to various system parameters in solvent extraction/FIA is first presented and then each of the terms in the equation is examined experimentally.

Derivation

Peak height (P.H.) is related to the maximum concentration in the sample zone (peak) entering the detector, C_{Pk}, by the expression:

$$[1] \quad \mathrm{P.H.} = S_F \cdot C_{\mathrm{Pk}}$$

in which S_F is the sensitivity of the detector in units of height per unit concentration of sample component. Depending on the detector used S_F may depend on (3, 5), or be independent of (1, 2), flow rate into the detector. The peak concentration C_{Pk} can be calculated from the concentration of sample component in the sample solution injected, C_{SAMP}, by taking into account the dilution steps, the extraction efficiency and the dilution resulting from band dispersion. These are considered here for the instrument shown in Fig. 1. Dilution resulting from merging of carrier stream with reagent stream is given by $(F_{\mathrm{Carrier}}/F_a)$. Dilution resulting from extraction into the organic phase is given by the product of the ratio F_a/F_o times the fraction of sample component extracted, ϕ. The fraction extracted can be calculated from the distribution ratio, D, and the phase ratio (1, 2):

$$[2] \quad \phi = \frac{D \cdot (F_o/F_a)}{1 + D \cdot (F_o/F_a)}$$

Dilution caused by band dispersion through the system is the result of laminar flow in connecting tubing and mixing chamber effects in the phase separator and detector (6). The relative dilution, R_v, of the sample due to dispersion is measured experimentally from a plot of peak height versus volume of sample solution injected as described below.

In flow sensitive detectors, such as an AAS, a compensating flow, F_c, merges with the flow of organic extract from the phase separator, F_M, before it enters the detector (3). Dilution of sample component concentration from this source is given by $(F_M/(F_M + F_c))$.

Combining all of the above factors accounting for dilution of the sample component allows C_{Pk} to be calculated:

$$[3] \quad C_{Pk} = C_{SAMP} \cdot R_v \cdot \frac{F_{Carrier}}{F_a} \cdot \frac{F_a}{F_o} \cdot \phi \cdot \frac{F_M}{F_M + F_c}$$

Simplifying this expression and substituting into eq. [1] gives:

$$[4] \quad \text{P.H.} = C_{SAMP} \cdot S_F \cdot R_v \cdot \frac{F_{Carrier}}{F_o} \cdot \phi \cdot \frac{F_M}{F_M + F_c}$$

The quantity ϕ depends on F_a and F_o (eq. [2]), but in the usual situation in which D is large $\phi \approx 1$ so that both ϕ and P.H. become independent of F_a. It should also be noted that with flow-rate sensitive detectors S_F depends on $(F_M + F_c)$ but, as mentioned above, when flow compensation is used with the AAS detector, $(F_M + F_c)$ remains essentially constant and equal to the "natural" aspiration rate of the nebulizer even when F_M is varied. Thus the appropriate value of S_F is read from the sensitivity curve (see below) at a flow rate equal to the nebulizer aspiration rate.

Calibration curve

Using Version I of the instrument in which an atomic absorption detector is employed, a calibration plot of peak height versus zinc concentration injected, C_{SAMP}, was found to be linear with zero intercept and a correlation coefficient of 0.9996 up to peak heights corresponding to an absorbance of about 0.5. The negative deviation observed above this absorbance is found also when samples of Zn^{2+} are aspirated directly into the flame in the normal, non-FIA manner of performing atomic absorption. This, therefore, arises from a negative deviation from Beer's Law at higher absorbances which is a well known phenomenon in atomic absorption spectroscopy. The linearity of P.H. vs. C_{SAMP} observed in the linear absorbance range of the spectrophotometer confirms the prediction of eq. [4].

Sensitivity curve

In Fig. 2 are presented plots of detector sensitivity versus flow rate into the nebulizer. The experiment was performed by pumping MIBK solutions containing two different concentrations of $Zn(SCN)_2$ directly and continuously into the nebulizer. It is seen that S_F, which is the AA signal divided by $Zn(SCN)_2$ concentration, is essentially independent of sample concentration. The general shape of this type of curve has previously been discussed (5). It clearly demonstrates the flow rate dependence of S_F for an AAS detector. Presumably, the leveling-off of the value of S_F at higher flow rates derives from the decreasing efficiency of the nebulizer at producing a fine aerosol from the aspirated liquid. The appropriate value of S_F for use in eq. [4] is read from the curve at a flow rate equal to the value of $(F_M + F_c)$ being used (i.e. at the nebulizer aspiration rate).

Relative dilution, R_v

Band dispersion resulting from flow of the sample zone through the system causes a broadening and decrease in height of the peak. In addition, as the volume of sample injected is made larger it too contributes to the width of the peak (1). To study this phenomenon both Version I and Version II instruments were used. Relative dilution R_v is evaluated from the dependence of peak height on sample volume injected. A plot of this type, for measurements made on the Version I instrument has been published (3). Three plots of this type for measurements made on the Version II instrument are presented in Fig. 3. All plots have the same general shape. The evaluation of R_v is done as follows: consider first curve A in Fig. 3. The limiting plateau seen in this curve at large injection volumes exists because the "slug" of injected sample is sufficiently long that dilution due to band dispersion does not reach the centre of the zone (1). Hence, there is no dilution due to dispersion on this plateau. For a system in which $F_o/F_a = 2.3$ the value of R_v corresponding to any injection volume is calculated as the ratio of the peak height seen in Fig. 3 at the corresponding injection volume divided by the peak height on the limiting plateau. Defined in this way R_v is the reciprocal of the "dispersion", D, used by some workers in FIA (7). The term relative dilution has been used instead of dispersion because the latter term has long been used by chromatographers to refer to bandbroadening as expressed by the standard deviation, the variance or the second central moment of the band, rather than to refer to the decrease in peak height resulting from bandbroadening.

Comparison of curves A, B, and C in Fig. 3, each of which was obtained at a different value of F_o/F_a, shows that R_v is somewhat sensitive to large changes in F_o/F_a. This is not surprising in view of the processes giving rise to band dispersion. It means, in a practical sense, that the curve used to calculate the value of R_v to be used in a given extraction/FIA determination should have been obtained under similar experimental conditions to those used in the determination. The increase in the plateau peak height seen on going from curve A to curve C is a consequence of the increase in $(F_{Carrier}/F_o)$ as seen in eq. [4] and as discussed below. (Note change in de-

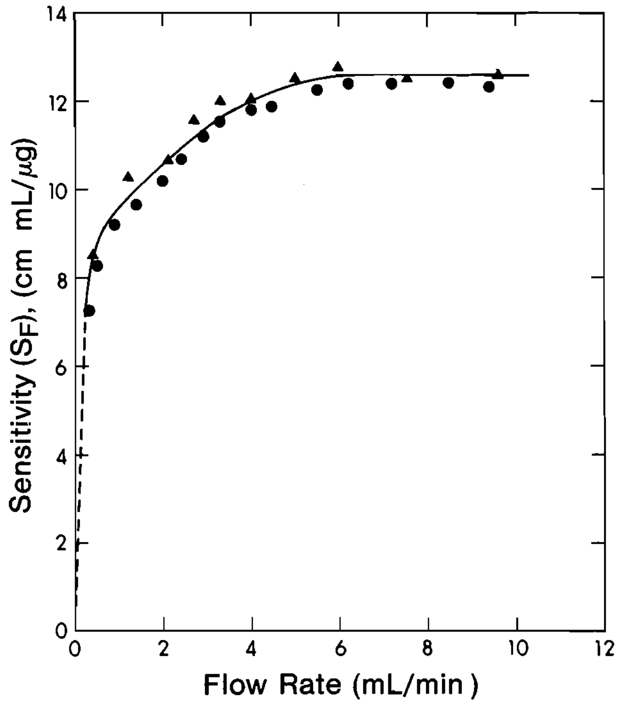

FIG. 2. Sensitivity curve for Zn obtained by pumping 0.7 μg/mL (▲) and 0.4 μg/mL (●) of $Zn(SCN)_2$ in MIBK directly into the nebulizer of the AAS. Nebulizer "natural" aspiration rate was fixed at 2.5 mL/min.

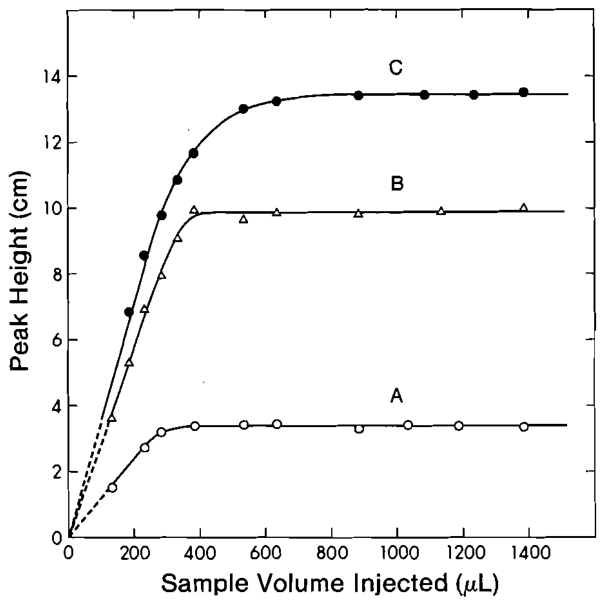

FIG. 3. Effect of sample volume injected on peak height for a sample containing 4×10^{-5} *M* *o*-nitroaniline. Version II instrument. Flow rates in mL/min are: curve *A*, $F_o = 3.0_0$, $F_{Carrier} = 0.9_0$, $F_{Reagent} = 0.4_0$, $F_M = 1.2_0$, $F_o/F_a = 2.3_1$, detector AUFS = 0.01; curve *B*, $F_o = 3.0_0$, $F_{Carrier} = 2.0_0$, $F_{Reagent} = 2.0$, $F_M = 1.1_0$, $F_o/F_a = 0.75$, detector AUFS = 0.02; curve *C*, $F_o = 1.5_0$, $F_{Carrier} = 2.0_0$, $F_{Reagent} = 2.0_0$, $F_M = 0.9_0$, $F_o/F_a = 0.37_5$, detector AUFS = 0.02.

tector sensitivity given in figure caption.) It will be recalled that, since R_v is a ratio of peak heights, it is the shapes of curves $A-C$ that relate to R_v and not the absolute values of peak heights.

Effect of $F_{Carrier}$ *on P.H.*

Equation [4] predicts a linear dependence of P.H. on $F_{Carrier}$ provided that S_F, R_v, ϕ, F_o, F_M and $(F_M + F_c)$ remain constant. This was studied using the Version II instrument. For this instrument S_F is constant, independent of flow rate. Since no compensating flow is used the last term in eq. [4] reduces to 1 and F_M is eliminated from the equation. For the sample compound *o*-nitroaniline $\phi \approx 1$ because K_D is large (8). In this experiment F_o was fixed at 3.0_0 mL/min, $F_{Reagent}$ at 0.50 mL/min and F_M at 1.0_0 mL/min while $F_{Carrier}$ was varied between 0.10 mL/min and 2.5_0 mL/min. An injection volume of 385 μL was used. Under these conditions F_o/F_a varies between 1 and 5 over the range of $F_{Carrier}$ used. Examination of Fig. 3 shows that for $F_o/F_a > 0.75$ an injection volume of 385 μL falls on the plateau so that $R_v \simeq 1$ for all values of $F_{Carrier}$ used. Thus S_F, R_v, ϕ, and F_o are constants and F_M is eliminated from eq. [4]. A plot of P.H. vs. $F_{Carrier}$ is expected to be linear. The experimentally measured plot was linear (slope = $8.3_5 \pm 0.1_2$ at 95% C.L.) with zero intercept (intercept = 0.024 ± 0.368 at 95% C.L.) and a correlation coefficient of 0.9995.

Effect of $F_{Reagent}$ *on P.H.*

According to eq. [4], P.H. should be independent of $F_{Reagent}$. The Version II instrument was used. $F_{Carrier}$ was held at 1.0_0 mL/min, F_o at 3.00 mL/min, and F_M at 1.4_5 mL/min while $F_{Reagent}$ was varied from 0.50 to 2.50 mL/min. Injection volume of *o*-nitroaniline sample solution was 385 μL. Peak height was found to be constant, independent of $F_{Reagent}$. The slope and its 95% C.L. of a plot of pH vs. $F_{Reagent}$ were 0.06 ± 0.05.

TABLE 1. Effect of compensating flow rate on signal and constancy of $(F_M + F_c)$

F_M (mL/min)	F_c (mL/min)	$(F_M + F_c)$ (mL/min)	$\frac{F_M}{(F_M + F_c)}$	AA signal (cm)
1.6_0	4.9_0	6.5_0	0.24_6	1.25
2.3_0	4.2_0	6.5_0	0.35_4	1.85
2.9_0	3.6_0	6.5_0	0.44_6	2.30
3.2_5	3.2_0	6.4_5	0.50_4	2.75
4.0_0	2.5_0	6.5_0	0.61_5	3.25
4.6_0	1.9_0	6.5_0	0.70_8	3.80
5.2_0	1.3_0	6.5_0	0.80_0	4.25
6.0_0	0.5_0	6.5_0	0.92_3	4.65
6.5_0	0.0_0	6.5_0	1.00	5.25

It should be realized that eq. [4] takes no account of the chemistry or stoichiometry of the reaction upon which an extraction/FIA determination may be based. Thus if the amount of product formed by the reaction between the sample component and the reagent is changed as a result of a change in $F_{Reagent}$, the peak height would of course change — but this effect is unrelated to the flow dependencies to which eq. [4] relates.

Effect of F_o *on P.H.*

Using the Version II instrument, $F_{Carrier}$ was fixed at 1.0_0 mL/min, $F_{Reagent}$ at 0.50 mL/min, and F_M at 1.4_5 mL/min while F_o was varied from 1.8_0 to 3.0_0 mL/min. Injection volume of *o*-nitroaniline solution was 385 μL. Since all other variables on the right-hand-side of eq. [4] are constant and F_M is eliminated as discussed earlier, a plot of P.H. vs. $1/F_o$ is expected to be linear. The experimental plot was linear (slope = 25.2 ± 1.3 at 95% C.L.) with zero intercept (intercept = 0.12 ± 1.8 at 95% C.L.) and a correlation coefficient of 0.996.

Effect of F_C *on P.H.*

Variation of peak height with the flow rate of compensating solvent was studied as described in the Experimental section. In this experiment the flow rate of $Zn(SCN)_2$ from the pump is analogous to F_M in the extraction/FIA experiment, while the flow of MIBK from the compensating flask is F_c. The results of this experiment are summarized in Table 1. It can be seen from the first three columns that, at a fixed nebulizer "natural" aspiration rate, $(F_M + F_c)$ remains constant as F_M is changed. From eq. [4] it is expected that a plot of AA signal vs $F_M/(F_M + F_c)$ should be linear. Using the data in Table 1 a plot of AA signal vs. $F_M/(F_M + F_c)$ is linear (slope = 5.17 ± 0.12 at 95% C.L.) with zero intercept (intercept = 0.05 ± 0.19 at 95% C.L.) and a correlation coefficient of 0.998.

Other studies

Several reports on the effect of flow rates on peak height in solvent extraction/FIA have previously appeared (9–12). These studies were performed as part of the optimization procedure in the development of extraction/FIA determinations. As such they were not meant to include the effects of all system parameters and, for the most part, no effort was made to keep all other system variables constant while studying the effect of one. Taking this into account, the data obtained in these studies is consistent with the predictions of eq. [4]. For example, data presented in refs. 9 and 11 give a linear plot of P.H. vs $1/F_o$

in the higher end of the range of F_0 studied, though the plots are non-linear at lower F_0. Also data in ref. 12 show that P.H. increases with an increase in aqueous phase flow rate.

Height versus area

Equation [4] is generally applicable to any detection scheme in solvent extraction/FIA in which peak height is used as the basis for quantification. Some detectors, such as an inductively coupled plasma spectrometer and amperometric detectors, exhibit a sensitivity S_F which depends on flow rate of solution into the detector, as does the atomic absorption spectrophotometer. Other detectors, such as those employing fluorescence, refractive index, or potentiometric measurements, exhibit a sensitivity that is independent of flow rate, as does the uv absorbance detector.

In several previous studies from this laboratory peak area was studied as a means of quantification in solvent extraction/FIA (1, 2, 13). On the basis of these studies and the present one it is possible to make a few observations regarding the relative advantages and disadvantages of quantification by heights and by areas. In general, under experimentally achievable optimum conditions, both area and height measurements yield a precision and accuracy of about 1%. Area measurements have the disadvantage of requiring a relatively expensive digital integration. On the other hand, area measurements are more robust than height measurements. For example, assuming that the distribution ratio is made very large so that extraction is quantitative, peak area measured in the organic phase is independent of flow rate of the aqueous phase (eq. [5], ref. 1) but peak height depends on flow rate of the aqueous carrier ($F_{Carrier}$). Thus precise control of $F_{Carrier}$ is more critical with height measurements. Another example of the robustness of area measurements is their relative independence of refractive index effects (13). The positive and negative portions of the refractive index "peak" cancel out when measurements are made over the whole peak width. In a similar way area measurements are relatively independent of the precise way in which a given volume of sample is injected (e.g. slowly or rapidly switching the injection valve).

Tetrakis(μ-3-chloropropanoato)bis(triphenylphosphine oxide)dicopper(II) is formed by the reaction of the phosphine oxide on the parent copper carboxylate. It belongs to the triclinic space group $P\bar{1}$, with a = 8.603(6), b = 12.605(4), c = 12.624(5) Å, α = 76.94(3), β = 71.74(4), and γ = 74.42(4)°. The complex has the copper acetate dimer structure, in which two Cu atoms separated by 2.649(1) Å are bridged by four bidentate carboxylate groups (mean Cu—O = 1.969 Å). The Cu—O apical bond to triphenylphosphine oxide is relatively short (2.097(2) Å). The epr spectra of the solid are interpreted in terms of a dimeric species with a paramagnetic triplet state. The same signals are found in the spectra of frozen ethanol solutions, indicating that the dimer structure is retained. Magnetic susceptibility was determined in the range 81–293 K and the energy separation $-2J$ = 328(4) cm^{-1} was found between the two spin states. The phosphine oxide adduct is toxic to *Escherichia coli* with ID_{50} values near 100 μg/mL.

Le tétrakis(μ-3-chloropropanoato)bis(oxyde de triphénylphosphine)dicuivre(II) est produit par addition de l'oxyde de phosphine sur le sel cuivrique de l'acide 3-chloropropanoïque. La maille cristalline est triclinique, groupe spatial $P\bar{1}$, a = 8,603(6), b = 12,605(4), c = 12,624(5) Å, α = 76,94(3), β = 71,74(4) et γ = 74,42(4)°. Le complexe possède la structure dimère de l'acétate de cuivre, dans laquelle deux atomes de Cu à 2,649(1) Å l'un de l'autre sont pontés par quatre groupes carboxylate bidentates (Cu—O moyenne = 1,969 Å). La liaison Cu—O apicale avec l'oxyde de triphénylphosphine est relativement courte (2,097(2) Å). Les spectres RPE correspondent à un complexe dimère à l'état solide avec des interactions magnétiques conduisant à un état triplet paramagnétique. On retrouve les mêmes signaux dans les solutions éthanoliques gelées, ce qui indique que le dimère persiste dans ces conditions. La susceptibilité magnétique a été déterminée dans le domaine 81–293 K et une valeur $-2J$ = 328(4) cm^{-1} en a été tirée pour la différence d'énergie entre les deux états de spin. Le composé d'addition avec l'oxyde de phosphine est bactéricide envers *Escherichia coli* à des doses de 100 μg/mL.

Introduction

The spectroscopic and magnetic properties of Cu(II) carboxylates have attracted considerable attention over the years. By forming monomeric, dimeric, and polymeric structural arrangements (1–3), this class of compounds provided a variety of systems from which much of our understanding of magnetic exchange phenomena was derived.

In the past few years, we have become interested in the bactericide and fungicide properties of Cu(II) carboxylates. With a recent series of experiments (4), we have shown that antibacterial and antifungal efficiency was significantly enhanced by the presence of halogen substituents on the chain of aliphatic carboxylates. In order to extend this initial study, a broader sample of variously halogenated carboxylates is currently being investigated, and the influence of a second ligand is being examined. The triphenylphosphine oxide complex of copper(II) 3-chloropropanoate described in the present paper was isolated as part of this study. The epr spectrum of this compound in frozen ethanol solution showed signals characteristic of a carboxylate-bridged dimer. Addition of excess Ph_3PO enhanced this signal, in contrast with most similar systems, for which excess ligand results in dimer disruption (5). We therefore decided to determine the structure of this compound, since the Cu(II)–carboxylate complexes examined so far by X-ray diffraction (6–9) do not contain in apical positions bulky ligands which could distort the dimer cage (10). In addition, the compound was characterized by spectroscopic and magnetic techniques, and its antibacterial activity was measured.

Experimental section

Preparation

Copper(II) 3-chloropropanoate monohydrate was prepared from basic copper(II) carbonate and 3-chloropropanoic acid by the previously described method (11). $Cu(ClCH_2CH_2COO)_2 \cdot OPPh_3$ was prepared by combining a warm methanol solution of copper(II) 3-chloropropanoate monohydrate (together with a small amount of the corresponding free acid) and triphenylphosphine oxide Ph_3PO in a molar ratio of 1 : 1. The reaction was left to stand at room temperature. The final green product which precipitated after a few hours was filtered off, washed with cold methanol, and dried in ambient atmosphere. The compound was purified by recrystallization from methanol.

C, H, and P analyses were done by the microanalysis service of the Chemistry Department, York University, Downsview. Copper

was determined volumetrically with EDTA. *Anal.* calcd. for $C_{24}H_{23}Cl_2CuPO_5$: Cu 11.41, C 51.76, H 4.16, P. 5.56; found: Cu 11.30, C 51.82, H 4.19, P 5.71.

Spectral studies

An infrared spectrum (Nujol mull) in the region 4000−400 cm^{-1} was recorded with a Perkin Elmer 621 grating infrared spectrophotometer. An electronic spectrum (Nujol mull) in the region 1.0−2.8 μm^{-1} was recorded with a Cary 14 spectrophotometer. Electron paramagnetic resonance spectra of polycrystalline samples as well as frozen solutions were recorded on a Varian model E9 spectrometer.

Magnetic measurements

Variable-temperature magnetic susceptibility measurements in the 81−293 K range were made using Gouy equipment. Magnetic susceptibility was corrected for the diamagnetism of all atoms (327×10^{-6} cm^{-3} mol^{-1}) and the temperature-independent paramagnetism of Cu(II) (60×10^{-6} cm^3 mol^{-1}) (12). The effective magnetic moment was calculated from the equation

$$\mu_{eff} = 2.82\,(\chi_M^{corr} \times T)^{1/2}.$$

Bacterial cultures

The nutrient broth used for the cultures was prepared at 8 g/L concentrations using Difco products (8 g bacto beef extract for 5 g bacto peptone). Difco bacto nutrient agar and bacto potato dextrose agar were used in colony-counting. Freeze-dried microlife cultures were from Carolina Biologicals and included *Bacillus subtilis* (no. 15-4921A) and *Escherichia coli* (no. 15-5065A). Stock cultures were prepared and renewed weekly, from which 100 μL samples were drawn for injection into 2 mL of nutrient broth contained in plastic optical cells of 1 cm optical length from Markson Science. These cultures were placed in scintillation containers and thermostated to 37°C in a Heto water-bath and shaker. Optical density was measured on a Beckman DB-G grating spectrophotometer with the wavelength set at 500 nm. Sample cells were vibrated before absorbance measurements. Calibration experiments showed successive dilutions caused linear decreases in absorbance. Agar-plating showed 1×10^6 to 4.5×10^7 colony-forming units/mL for absorbances of 0.1 to 1.0. Small samples of the compounds to be tested (100 μL) were micropipeted directly into the culture media after the lag phase, during the growth cycle of the bacteria. This had no immediate effect on the turbidimetry at the concentrations used.

Crystal data

$[Cu(ClCH_2CH_2CO_2)_2OP(C_6H_5)_3]_2$, ($C_{48}H_{46}Cl_4Cu_2P_2O_{10}$) fw = 1113.8 Triclinic, space group $P\bar{1}$, a = 8.603(6), b = 12.605(4), c = 12.624(5) Å, α = 76.94(3), β = 71,74(4), γ = 74.42(4)°, V = 1237.1 $Å^3$, Z = 1, D_c = 1.494 g cm^{-3}, F(000) = 570, λ(CuK$\bar{\alpha}$) = 1.54178 Å (graphite monochromator), t = 23°C, μ(CuK$\bar{\alpha}$) = 41.6 cm^{-1}. Crystal dimensions: 0.045 mm (between 011 and $0\bar{1}\bar{1}$) × 0.090 mm ($0\bar{1}0$ and 010) × 0.225 mm (210 and $\bar{2}\bar{1}0$).

Crystallographic measurements

The crystal was mounted on an Enraf-Nonius CAD4 diffractometer and a set of 25 reflections randomly distributed in the Laue sphere was created by the automatic search procedure. These reflections were centered and indexing yielded the above reduced triclinic cell. This cell was checked by taking along each crystallographic axis an oscillation photograph, which showed the expected layer-line spacing. The Niggli parameters clearly indicated that the lattice cannot be described within a cell of higher symmetry. The accurate cell dimensions were derived from least-squares refinement on the setting angles for the set of 25 reflections.

A total of 4665 independent CuKα reflections (hkl, $hk\bar{l}$, $h\bar{k}\bar{l}$, and $\bar{h}\bar{k}l$) within a sphere limited by 2θ = 140° were collected as described elsewhere (13). A set of 3829 reflections satisfying the criterion $I \geq 3.0\sigma(I)$ was retained for structure determination, and refinement. The intensities of three reference reflections measured every hour were used as a check on instrument and crystal stability. They showed fluctuations with 3% about respective means. The data were corrected for the Lorentz effect, polarization, and absorption (Gaussian integration, grid 10 × 10 × 10, transmission range = 0.38−0.73).

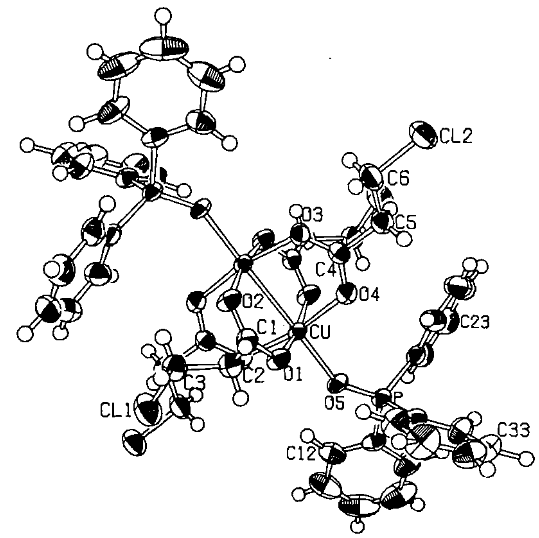

FIG. 1. ORTEP drawing of the dimeric molecule.The ellipsoids correspond to 50% probability. Phenyl ring atoms are represented by a two-digit symbol: the first digit corresponds to ring number, the second to sequential numbering around the ring, position 1 corresponding to the P-bonded carbon atom.

Resolution of the structure

The structure was solved by the heavy-atom method. The Cu and Cl atoms were located from a Patterson synthesis and the light atoms were positioned from subsequent difference Fourier (ΔF) map. Isotropic refinement of all non-hydrogen atoms by full-matrix least-squares converged to $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.135$. The block-diagonal approximation was used for anisotropic refinement and the R factor reduced to 0.077. All H atoms were then located and isotopically refined. In the last cycles, individual weights w based on counting statics were applied to each reflection and a secondary extinction parameter was refined ($1.9(2) \times 10^3$). The final R factor was 0.047, whereas the weighted residual $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$ was 0.056, for 391 parameters refined. The goodness-of-fit ratio was 2.13. The final ΔF map showed four peaks of 0.6−1.3 e/$Å^3$ within 1.2 Å from Cu. The general background was lower than ±0.7 e/$Å^3$.

The form factors and the contributions to anomalous dispersion of Cu, Cl, and P were from standard sources (14). The programs used are listed elsewhere (15). The final coordinates and equivalent temperature factors are given in Table 1.[4]

Results and discussion

Unlike the analogous chromium(II) carboxylates, copper(II) carboxylates are not known to form adducts with phosphines. However, triphenylphosphine oxide is less sterically demanding and it reacts readily with cupric 3-chloropropanoate. No excess ligand is needed to prepare the 1 : 1 adduct.

Crystal structure

The crystal consists of dimers (Fig. 1) containing the tetrakis (μ-chloropropanoato)dimetal "windmill" cage commonly

[4]The supplementary material includes a list of observed and calculated structure factor amplitudes, the anisotropic temperature factors, the torsion angles in the carboxylate, details on least-squares plane calculations, and a table of distances and angles involving the hydrogen atoms. Complete set of data may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[a]Hydrogens isotropically refined.

found for carboxylates of Cr(II), Cu(II), Mo(II), and Rh(II) (6). Each end of the Cu—Cu axis is occupied by the oxygen atom of a triphenylphosphine oxide ligand. The molecule possesses a crystallographic inversion center on the middle of the Cu—Cu axis. Selected interatomic distances and bond angles are listed in Table 2.

This molecule follows the trends already noted for this type of dimers. The Cu—Cu separation (2.649(1) Å) is similar to those observed in other Cu acetate or propanoate compounds (6, 16). Correlations between metal−metal separation and bond lengths or angles in the Cu—Cu—O—C—O rings have been discussed (1, 6). The Cu—Cu—O angle has been found to be the most sensitive to a change in the Cu—Cu distance. From the equation derived by Koh and Christoph (6), the distance observed here should correspond to a Cu—Cu—O angle of 84.0°, which is exactly the observed average value. Our results for other parameters compare well with those found for complexes with similar Cu—Cu separations: (averages) Cu—O, 1.969 Å; C—O, 1.256 Å; Cu—O—C, 122.9°; O—C—O, 125.9°. There exists a relation between the displacement of the copper(II) atom from the basal plane toward the apical ligand, and the increase of the copper−copper distance (1). The Cu(II) atom in the present compound is displaced 0.2063(4) Å, toward the apical oxygen atom, from the least-squares plane defined by the basal atoms, in agreement with this trend.

The cage should ideally have a four-fold axis along the Cu—Cu direction. Departure from this symmetry is significant, but not very large. The dihedral angles between adjacent Cu—Cu—O—C—O rings deviate by only 1.8° from the ideal 90° value. Some steric effect of the phenyl rings of Ph_3PO introduces small distortions. For instance, the oxygen O(5) belonging to phosphine oxide does not lie exactly along the Cu—Cu axis, the Cu—Cu—O(5) angle being 174.3(1)°. The fact that the Cu—O(3)—C(4) and Cu—O(2)—C(1) angles are ~4° greater than Cu—O(1)—C(1) and Cu—O(4)—C(4) undoubtedly results from repulsions with the nearby phosphine oxide molecule, since the O(1)···H(36) and O(4)···H(26) intramolecular contacts (2.88(4) and 2.74(3) Å, respectively) are both close to the sum of the van der Waals radii.

The Cu—O(5) bond to the apical triphenylphosphine oxide (2.097(2) Å) is noticeably shorter than the average distance of dimeric copper(II) carboxylate adducts with CuO_5 chromophores (2.16 Å) (1). Only in two examples, $Cu(2\text{-}HOC_6H_4COO)_2(C_4H_8O_2)\cdot H_2O$ (Cu—Cu = 2.64 Å) (17) and $Cu(CH_3COO)_2$ urea·H_2O (Cu—Cu = 2.637 Å) (18) is the Cu—O(apical) bond shorter than in the present case. The Cu—O(apical) distance of 1.95 Å found in $Cu(Cl_3CCOO)_2$ (2,2,6,6-tetramethylpiperidinyl-1-oxy) (8) is far shorter, but on the other hand the Cu—Cu distance (3.256(2) Å) is far longer than in any other similar dimer (1, 6). On the other hand, the Cu—O(5) distance in the present case is noticeably longer than observed in other copper(II) triphenylphosphine oxide compounds of different structural types where the metal is more accessible (19). The Cu—O(5)—P angle (149.0(2)°) lies within the wide range (140−180°) of reported metal—O—P angles (20). In all other respects, the geometry of coordinated phosphine oxide does not differ appreciably from that of the free ligand (21): P—C = 1.797 Å (av.), O—P—C = 111.6° (av.), C—P—C = 107.3° (av.). The phenyl rings are planar within 2σ (0.009 Å), with average bond lengths of 1.380 Å.

The geometry of the chloropropanoate ligand shows no unusual features. The two nonequivalent ligands present different chain conformations. In carboxylates, one of the α substituents is commonly close to an eclipsed orientation with respect to a carboxylate oxygen. In one of the ligands, O(1) is nearly eclipsed with H(1), but in the other, O(3) is eclipsed with C(6).

[a]$1 - x, -y, -z$.

The chloro substituents also adopt different orientations, the C—C—C—Cl angles being 72° for ligand 1 and 169° for ligand 2.

A stereoview of the unit cell is given in the supplementary material.[4] The molecules interact through normal van der Waals contacts.

Spectroscopic results

The ir spectrum of $Cu(ClCH_2CH_2COO)_2 \cdot OPPh_3$ shows a strong absorption band at 1188 cm^{-1} which includes the P—O stretching mode of coordinated $OPPh_3$ and an in-plane bending vibration. The shift of ν(P—O) to lower wavenumber compared with the corresponding band of free $OPPh_3$ (ν(PO) = 1193 cm^{-1}) (22) is due to the transfer of electron density from oxygen to the metal in agreement with coordination of $OPPh_3$ to copper(II) through the oxygen atom. The carboxylate stretching frequencies, $\nu_{as}(COO^-)$ at ~1630 cm^{-1} and $\nu_s(COO^-)$ at ~1415 cm^{-1}, occur at energies very similar to those reported for other copper(II) carboxylates having the dimeric copper(II) acetate structure (2, 23).

FIG. 2. Electron paramagnetic resonance spectra of the title compound. (a) Room temperature powder spectrum (b) Same sample at $\simeq$ 130 K. The inset at the right is the expanded H_{z2} signal. Microwave frequency $\nu = 9.123$ GHz. (c) Frozen ethanol solution of the complex at microwave frequency $\nu = 9.117$ GHz. The spectra are first derivative presentations of the absorptions.

The electronic absorption spectrum of the compound shows a ligand field band with a maximum at ~1.35 μm^{-1} and a shoulder at ~2.70 μm^{-1}, which is typical of bridging systems with antiferromagnetic interactions (2, 24). The position of the visible absorption band occurs at any energy slightly lower than the corresponding one found in copper(II) 3-chloropropanoate monohydrate, 1.48 μm^{-1} (11).

The epr spectra obtained for the triphenylphosphine oxide adduct are presented in Fig. 2. The absorption features of the powder at room temperature (Fig. 2a) are similar to those previously reported for dimeric copper(II) carboxylates (2, 25–27). The paramagnetic triplet state yields the absorptions at low and high field (H_{z1} and H_{z2}, respectively) and the asymmetric absorption near 4.5 kG ($H_{\perp 2}$). One absorption is missing ($H_{\perp 1}$) because $D > h\nu$ at the X-band frequency used. The spectra can be interpreted using a spin Hamiltonian for axial symmetry, where S = 1 for the thermally accessible triplet state and

$$H = g_{\|}\beta H_z S_z + g_{\perp}\beta(H_x S_x + H_y S_y) + D(S_z^2 - 2/3)$$

the other symbols have their usual meaning. We notice that a monomer signal is also present at 3.1 kG ($g_0 = 2.18$), which corresponds to a spin $S = \frac{1}{2}$ species, despite repeated purification of the complex. Bulk magnetic susceptibility indicates that this monomer "impurity" corresponds to ~0.15% of the copper present. Monomer signals are commonly found for dimeric cupric carboxylates (3, 26–28) and they may arise from defects particularly on the crystal surfaces, which are very large for the powders used in epr studies.

The low temperature powder spectrum (Fig. 2b) shows better resolution with some copper hyperfine appearing on H_{z2} and a clearly resolved seven-line pattern on H_{z1}. The observed hyperfine is consistent with coupling to two copper nuclei of spin $I = \frac{3}{2}$. The improved resolution can be attributed decreased molecular vibrations at low temperature and/or to increasing population of the diamagnetic spin-paired state at lower temperatures due to antiferromagnetic interactions.

Figure 2c presents the first frozen ethanol solution spectrum of a cupric carboxylate which shows triplet state features. The absence of $S = 1$ absorptions in liquid solution has been ascribed to the magnitude of the anisotropic zero-field parameter D (29). The frozen solution spectrum reported here demonstrates that in ethanol the complex retains the dimer structure. Furthermore, it can be seen that the width of the absorption corresponding to H_{z1} and containing unresolved hyperfine structure is similar in the frozen solution to that found at room temperature for the solid. Interdimer magnetic interactions can safely be discarded as a mechanism causing the observed line broadening in the frozen solution case.

The spin Hamiltonian parameters are classical ($g_{\perp} = 2.091$, $g_{\|} = 2.368$, $\bar{g} = 2.183$, and $A_{\|} = 125$ G) for the anisotropic frozen ethanol $S = \frac{1}{2}$ signal. The liquid solution spectrum in the same solvent is broad, with $g_0 \approx 2.20$ and $A_0 \approx 44$ G. We note that added triphenylphosphine oxide reduces the intensity of the $S = \frac{1}{2}$ signal in ethanol (at room or low temperature). From this we conclude excess ligand stabilizes the dimer structure and does not, like strong nitrogen bases, lead to monomer adducts. However, we find that water causes a dramatic increase in the $S = \frac{1}{2}$ signal intensity, pointing to water promoted dissociation of the complex. For the triplet state spectra, we find $g_{\perp} = 2.093$, $g_{\|} = 2.382$, $\bar{g} = 2.193$, and $D = 0.346$ cm^{-1}. The solid and frozen solution spectra yield identical results within experimental error. The epr parameters for the $S = 1$ and $S = \frac{1}{2}$ species are thus very similar. The hyperfine structure along H_{z1} is $A_{\|} = 60$ G, approximately half the value along $g_{\|}$ ($A_{\|} = 125$ G), in agreement with coupling to two copper atoms. Additional features include a weak half-field absorption near 1.8 kG in the frozen solution and an unexpected weak absorption on the high-field side of $H_{\perp 2}$ for the solid state spectra.

Magnetic susceptibility

The effective magnetic moment per Cu(3-chloropropanoate)$_2\cdot$OPPh$_3$ unit was measured over the range 81–293 K. It was found to decrease systematically by lowering the temperature, from 1.37 BM at 293 K to 0.23 BM at 81 K. The corresponding variation of the magnetic susceptibility, from 810×10^{-6} cm^3 mol^{-1} to 80×10^{-6} cm^3 mol^{-1} is represented in Fig. 3.

The magnetic susceptibility data of Fig. 3 were fitted to the modified Bleaney–Bowers equation (30) by a non-linear least-squares procedure:

$$\chi_M^{corr} = \frac{g_d^2 N\beta^2}{3kT}\left[1 + \frac{1}{3}\exp(-2J/kt)\right]^{-1}(1 - x) + \frac{g_m^2 N\beta^2}{4kT}x$$

In this equation, J is the exchange integral in the Heisenberg – Dirac – Van Vleck Hamiltonian ($H = -2J\hat{S}_1\cdot\hat{S}_2$), g_m and g_d are the Lande factors for the monomer and dimer, respectively, x is the molar percentage of mononuclear form, and the other symbols have their usual meanings. An epr derived Lande

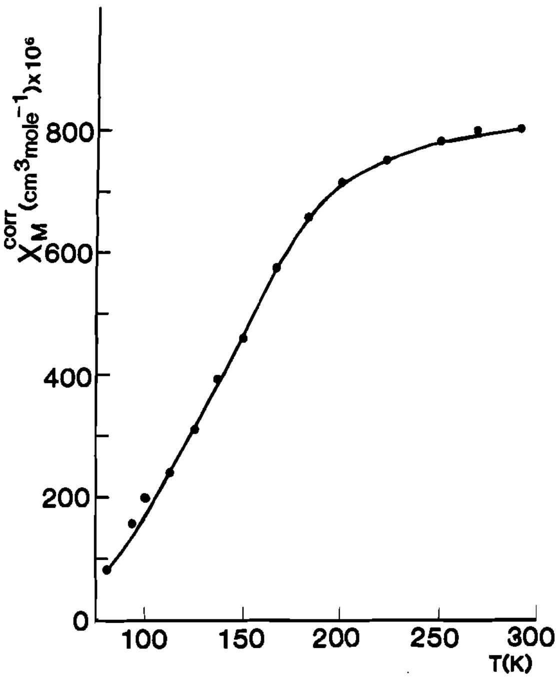

FIG. 3. Theoretical and experimental magnetic susceptibilities for the title compound. The solid line was calculated with $-2J = 328(4)$ cm^{-1} and $x = 0.15\%$.

parameter $\bar{g} = 2.19$ was used in the refinement of J and x.

The energy separation between the two spin states of the compound ($-2J = 328(4)$ cm^{-1}) indicates for this dimer an antiferromagnetic super-exchange interaction comparable with those commonly found for Cu(II) carboxylates (1−3, 26).

The magnetic data also indicate the presence of a small amount (~0.15%) of a mononuclear species in the compound. This mononuclear species produced a line at ~3.1 kG in the epr spectrum of the compound. Small amounts of monomeric "impurities" are commonly found in analytically pure Cu(II) carboxylates (3, 27−29).

Biological properties

Turbidimetric measurements carried over a 72 h period show that cupric complexes of 3-chloropropanoic acid have mild bactericidal properties. Increasing concentrations of complex lead to stronger inhibition of growth of *Escherichia coli* or *Bacillus subtilis*. The optical densities of bacterial suspensions are related to the total biomass present and the concentration needed to obtain 50% inhibition of bacterial growth can be evaluated from the reduction in absorbance resulting in the suspensions treated with bactericides (31). The dose needed for 50% inhibition of growth following a 24 h period is defined as ID_{50}^{24}.

No bactericidal effect was noted on *Bacillus subtilis*, but inhibition of growth occurs for *Escherichia coli*. The parent bis(propanoato)copper(II) monohydrate has an ID_{50}^{24} value of 50 μg/mL with an estimated error of 15% in part due to reproducibility difficulties in the age of the starting inoculum. We find that bis(3-chloropropanoato)copper(II) monohydrate is slightly more potent with $ID_{50}^{24} = 40$ μg/mL. However, the triphenylphosphine oxide adduct is much less toxic to the bacteria with $ID_{50}^{24} > 100$ μg/mL. The highest dose we used (100 μg/mL) resulted in 48% inhibition after 24 h, 66% inhibition after 48 h, and 59% after 72 h.

It may be argued that the increased molecular weight of the triphenyl phosphine oxide adduct decreases the percentage of copper in the compound, thus effectively reducing its bactericidal power. This would assume that cupric ions are the sole toxic species liberated by dissociation of the complex in water. However, we found that bis(3-chloropropanoato)copper(II) forms adducts with 4-acetylpyridine-*N*-oxide and also caffeine, with respective ID_{50}^{24} values of 50 and 75 μg/mL. Therefore, synergistic or antagonist effects between copper(II), 3-chloropropanoic acid, and added ligands may play a role in defining the biological activities of these complexes. We will report elsewhere the results obtained with similar fluoro-, bromo-, and iodocarboxylates (32).

Conclusion

X-ray diffraction shows that the 1:1 complex of triphenylphosphine oxide with $Cu(3\text{-chlopropanoate})_2$ has the copper acetate dimeric structure. The apical Ph_3PO ligands, despite their three phenyl rings, do not introduce severe distortions in the tetracarboxylate−dimetal framework. The presence of oxygen between Cu and P makes the oxide much less sterically demanding than the corresponding phosphine in the coordination sphere. However, the bulky phenyl rings may help in stabilizing the dimer by efficiently shielding the apical sites of the dimer, thereby opposing the propensity of these dimers to break into monomeric species with excess ligand. Magnetic susceptibility and epr spectra are consistent with the dimer structure in the solid, and the epr spectra indicate that the same structure is retained in frozen ethanol solution. Nevertheless, addition of water drastically changes the epr spectra, leading to features characteristic of a monomeric Cu(II) complex in solution. Therefore, the species actually responsible for the antibacterial activity is probably not the dimer originally present in the solid but some monomeric species derived therefrom.

SHINICHI YAMABE, TSUTOMU MINATO, MAKINO SAKAMOTO, and KIMIHIKO HIRAO. Can. J. Chem. **63**, 2571 (1985).

An *ab initio* MO calculation is made on the $H_3S^+(H_2S)_n$ cluster ($n = 0-5$). For $n = 1$, full thermodynamic data are reproduced theoretically, and for $n = 1$, 2, and 3 the effect of *d* functions on the structure and energies is investigated. On the basis of the present results, the accuracy of two conflicting experimental data is examined.

SHINICHI YAMABE, TSUTOMU MINATO, MAKINO SAKAMOTO et KIMIHIKO HIRAO. Can. J. Chem. **63**, 2571 (1985).

On a réalisé des calculs d'OM *ab initio* sur l'aggrégat $H_3S^+(H_2S)_n$ ($n = 0-5$). Pour $n = 1$, on a pu reproduire sur une base théorique l'ensemble des données thermodynamiques; pour $n = 1$, 2 et 3, on a étudié l'effet des fonctions *d* sur la structure et les énergies. Sur la base des résultats obtenus dans présent travail, on évalue l'exactitude de deux ensembles contradictoires de données expérimentales.

[Traduit par le journal]

Introduction

The temperature dependence of the gas-phase equilibria $H_3S^+(H_2S)_{n-1} + H_2S \rightleftarrows H_3S^+(H_2S)_n$ was measured by pulsed high-pressure mass spectroscopy. Two independent thermochemical data were reported almost at the same time (1, 2). The data from the two studies, the enthalpy change ($\Delta H^0_{n-1,n}$) and the entropy change ($\Delta S^0_{n-1,n}$), are appreciably different. The $H_3O^+(H_2O)_n$ cluster has been well investigated both by experiments (3) and by theoretical calculations (4). Its geometry and energetics are now established. However, the $H_3S^+(H_2S)_n$ cluster has not yet been analyzed theoretically. One reason for this unexplored subject is the need of the large computational time, in particular, when *d* functions on the sulfur atom are included.

Since the two experimental results are somewhat conflicting (1, 2), a theoretical judgement on which data is more reliable should be informative. Also, it is of mechanistic interest to see the similarity or the difference between $H_3O^+(H_2O)_n$ and $H_3S^+(H_2S)_n$. In the present work, we carry out *ab initio* MO and CI calculations for $H_3S^+(H_2S)_n$ ($n = 1-5$).

Computational method

The GAUSSIAN 80 program (5) is used for the *ab initio* MO calculation. The 4-31G and 4-31G(*) basis sets are adopted, where in the latter the *d* orbital (exponent = 0.65) is augmented onto the sulfur atom (6). A valence-shell SD-CI calculation is performed to estimate the electron correlation effect on the $n = 1$ cluster.

To obtain the zero-point energy and the vibrational term in the entropy, vibrational analyses on the optimized geometries are made numerically. The analytical first derivatives of total energies are obtainable in the program. The second derivatives may be obtained by differentiating them numerically. They are calculated by 0.01 au displacements relative to the equilibrium points.

Results and discussion

First, the proton affinity (PA) of hydrogen sulfide is obtained. PA(4-31G) = 161 kcal/mol and PA(4-31G(*)) = 176, whereas PA(exptl) = 172 (7). In the formation of the smallest cluster $H_3S^+(H_2S)$ (i.e., $n = 0 \rightarrow 1$), ΔH^0 and ΔS^0 are evaluated at the full thermodynamic level. They are displayed in Table 1 together with their components. There is a large difference of $\Delta H^0_{0,1}$ between 4-31G and 4-31G(*) (−18.0 vs. −13.9). This comes mainly from that of the electronic binding energy $\Delta E_{0,1}$ and slightly from that of vibration energy ΔE_{vib}. Correlation corrections are about 2 kcal/mol for $H_3S^+ \cdots H_2S$. As for the entropy change, however, complete agreement is found (−27.0).

The huge difference of $\Delta H^0_{0,1}$ between $H_3O^+(H_2O)$ and $H_3S^+(H_2S)$ is ascribed solely to that of $\Delta E_{0,1}$ (−32.6 vs. −16.8). It is interesting to note that $\Delta S^0_{0,1}$ values of $H_3O^+(H_2O)$ and $H_3S^+(H_2S)$ are similar in spite of the remarkable difference in $\Delta E_{0,1}$.

At the right side of Table 2, the 4-31G $\Delta E_{n-1,n}$ obtained in the present work is exhibited. The 4-31G(*) values are in parentheses. The use of $\Delta E_{n-1,n}$ instead of $\Delta H^0_{n-1,n}$ is rationalized by the similar values of $\Delta H^0_{0,1}$ and $\Delta E_{0,1}$ in Table 1. As n increases, $-\Delta E_{n-1,n}$ decreases and so does $-\Delta H^0_{n-1,n}$. A large gap between $\Delta E_{2,3}$ and $\Delta E_{3,4}$ (−10.6 vs. −5.4) is found. The former corresponds to the completion of the inner solvation shell $H_3S^+(H_2S)_3$, and the latter to the attachment of an H_2S molecule at the terminal site of the shell. Such a critical gap between (2,3) and (3,4) is also shown by the $H_3O^+(H_2O)_n$ cluster. The binding energy $\Delta E_{n-1,n}$ as well as $\Delta H^0_{n-1,n}$ of $H_3O^+(H_2O)_n$ is nearly twice as large as that of $H_3S^+(H_2S)_n$. This reflects the difference of the permanent dipoles of H_2O and H_2S. μ_{H2S} = 1.78 debye(4-31G), 1.33(4-31G(*)), and 1.1(exptl). μ_{H2O} = 2.19(DZ + p) and 1.8(exptl).

The accuracy of the two experimental data $\Delta H^0_{n-1,n}$(MF) and $\Delta H^0_{n-1,n}$(HK) and two theoretical energies is examined. For (0,1) and (1,2), the 4-31G overestimates $-\Delta E_{n-1,n}$ by a few kcal/mol relative to that of 4-31G(*). This noticeable dis-

crepancy is related to the following trend. The localization of the protonic nature involved in the small species would tend to increase the 4-31G/4-31G(*) discrepancy. As another case, the charge-free system of the dimer of hydrogen sulfide $(H_2S)_2$ is considered. Its hydrogen-bond energies are calculated to be −1.9 kcal/mol (4-31G) and −1.7 (4-31G(*)). These compare favorably to −1.7 ± 0.3 by an infrared intensity measurement (8). As the cluster size becomes larger, therefore, the positive charge is dispersed and the overestimate of 4-31G gets smaller. In (2,3), the 4-31G/4-31G(*) discrepancy is only 1.3 kcal/mol. Thus, the agreement between $\Delta H^0_{n-1,n}$(HK) and the 4-31G $\Delta E_{n-1,n}$ for $n \geqq 3$ is reasonable, and overall our computational data support $\Delta H^0_{n-1,n}$(HK) rather than $\Delta H^0_{n-1,n}$ (MF). However, in $\Delta H^0_{n-1,n}$(HK), the gap between (2,3) and (3,4) appears to be slightly small (−8.4 vs. −6.7). The completion of the inner solvation shell and the soft attachment of the outer solvent would give more energetic distinction.

Figure 1 gives the optimized structures and the electron distribution of H_2S and $H_3{}^+S$. When H_2S is protonated, the positive charge is delocalized both on the three hydrogens and on the sulfur atom of H_3S^+. This is in contrast to the change of the electron density in $H_2O + H^+ \rightarrow H_3O^+$. The protonic nature is attributed to the decrease of the charge on the three hydro-

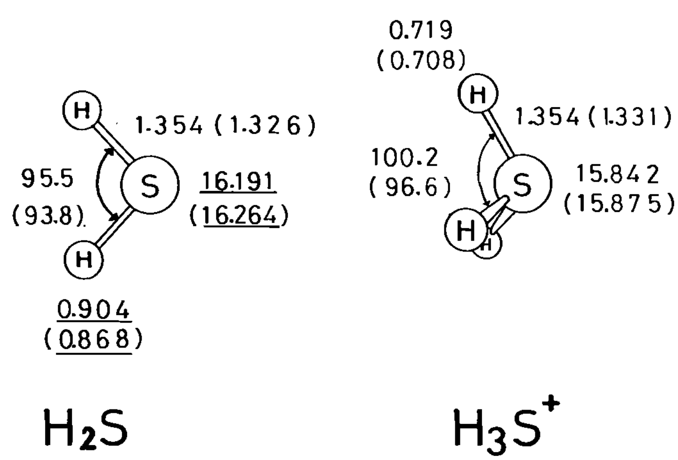

FIG. 1. The 4-31G optimized geometries of hydrogen sulfide and its protonated species. The values in parentheses are those obtained by the 4-31G(*) basis set. The bond distance is in Å and the angle in degree. Underlined numbers denote the Mulliken atom populations.

gens of H_3O^+. The small polarity of H_3S^+ as well as of H_2S is reflected in the weak strength of the hydrogen bonds in Fig. 2. In fact, the ratio of bond distances (S···H/S—H), 1.38, is

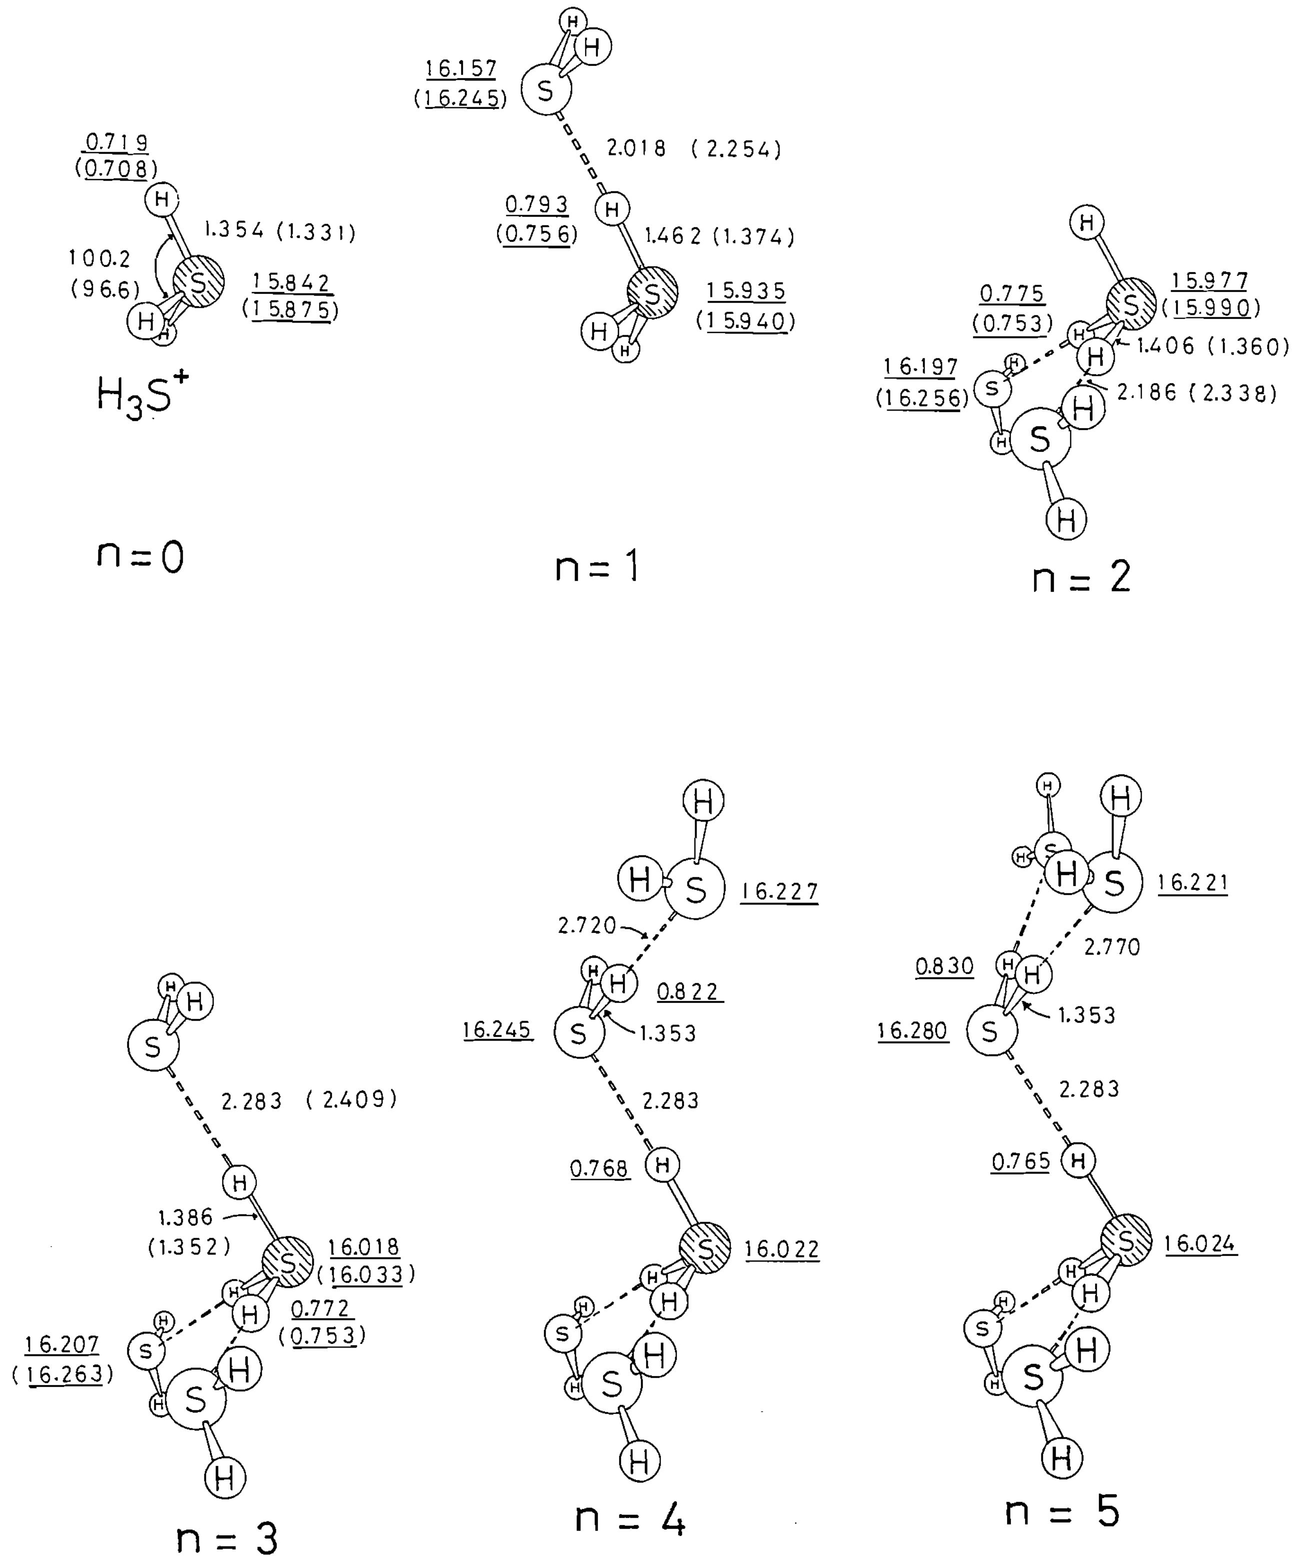

FIG. 2. The 4-31G optimized geometries of the $H_3S^+(H_2S)_n$ cluster. The structures of n = 4 and 5 are obtained by the partial optimization, where, the shell part (i.e., the n = 3 cluster) is kept constant during the optimization.

larger than that of (O···H/O—H), 1.26 (4*b*). As the cluster size grows larger, the positive (cationic) charge is dispersed and the intermolecular S···H bond becomes longer. At n = 3 and inner solvation shell completion, the electron density of the terminal hydrogen is more protonic (0.841) than that of the free H_2S molecule (0.904). Thus, $H_3S^+(H_2S)_3\cdots SH_2$ is more tightly bound than $H_2S\cdots HSH$. Even if the polarity of each species is small, the positive charge is transmitted smoothly up to terminal hydrogens in the cluster.

The effect of the *d* orbital is examined. The S—H bond of H_2S and H_3S^+ has a slightly larger polarity with 4-31G(*) than that with 4-31G. This covalent bond of 4-31G(*) is shorter than that of 4-31G. But, the intermolecular $H_2S\cdots HSH_2^+$ bond in $n = 1$ gives the opposite trend (2.254 Å by 4-31G(*) vs. 2.018 by 4-31G). This is because the intermolecular bond is composed of two bonding forces, electrostatic (ES) and charge-transfer (CT). The inclusion of the *d* orbital gives the polarization of S—H covalent bonds and enhances ES. On the other hand, it decreases CT and this is more crucial. As a net effect of these two, 4-31G(*) gives the larger intermolecular distance and smaller $-\Delta H^0_{0,1}$ (in Table 1) than 4-31G. It is well documented that the 4-31G basis set overestimates the intermolecular binding energy by a few kcal/mol due to the basis set superposition error (BSSE) (9). Generally, BSSE is recognizable in the supermolecule calculation with the basis sets of the double zeta or poorer levels. An addition of polarization functions to them diminishes the physically meaningless effect. Thus, the decrease of CT by 4-31G → 4-31G(*) may be partly ascribed to that of BSSE.

Concluding remarks

In this study, the structures and stabilities of the $H_3S^+(H_2S)_n$ clusters have been examined theoretically. Two basis sets, 4-31G and 4-31G(*), are adopted for the MO calculation. In the comparison of $\Delta H^0_{0,1}$ and $\Delta S^0_{0,1}$, the 4-31G/4-31G(*) discrepancy of the former is noticeable, but the latter term is the same. The *d* orbital on the sulfur atom enhances the polarity of H_3S^+ and H_2S, and more significantly diminishes the BSSE. As *n* increases, however, the discrepancy gets small and the use of the 4-31G basis set may be rationalized for the larger clusters.

The two conflicting experimental data are examined critically on the basis of the present results. The calculated data support $\Delta H^0_{n-1,n}$(HK) rather than $\Delta H^0_{n-1,n}$(MF). One point emerges from the former data. There would be a larger gap between $\Delta H^0_{2,3}$ and $\Delta H^0_{3,4}$ to reflect the structural differences (the inner solvation shell completion vs. the soft attachment of the H_2S).

Acknowledgments

The authors thank the Institute for Molecular Science for an allotment of CPU time on the HITAC M-200H computer. The program for the vibrational analysis has been coded by Dr. K. Yamashita, to whom they are grateful.

Received September 17, 1984

ERWIN BUNCEL, RAJESH KUMAR, ALBERT R. NORRIS, and ANDRÉ L. BEAUCHAMP. Can. J. Chem. **63**, 2575 (1985).

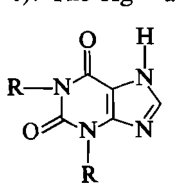
The synthesis, ^{1}H and ^{13}C nmr and infrared spectra of the complex bis(theophyllinato)tetraaquocadmium(II), [$CdC_{14}H_{22}N_4O_5$], and its *N,N*-dimethylformamide solvates are reported. The crystals containing two molecules of *N,N*-dimethylformamide per complex belong to the monoclinic space group $P2_1/c$ with a = 10.891(3), b = 13.696(7), c = 10.110(2) Å, β = 109.03(4)°, ρ_c = 1.595 g cm^{-3}, and Z = 2. Least-squares refinement of the structure has led to a final value of the conventional R factor of 0.044 for 261 variables, using 1299 nonzero MoKα reflections. The complex consists of monomeric [$CdTh_2(H_2O)_4$] units. The cadmium lies on an inversion center. The geometry of the atoms bonded to cadmium is roughly octahedral with the two theophyllinate ions *trans* to each other and coordinated through N(7). The Cd—N(7), Cd—O(13), and Cd—O(14) distances of 2.300(5) Å, 2.346(5) Å, and 2.336(5) Å, respectively, are normal. The hydrogen bonding in the crystals is complex, with all the ligand donor and acceptor atoms participating. *N,N*-Dimethylformamide is not coordinated to cadmium, but participates in the hydrogen bonding system. The nmr spectra are consistent with theophyllinate ion being similarly bonded to cadmium in dimethyl sulfoxide solution.

ERWIN BUNCEL, RAJESH KUMAR, ALBERT R. NORRIS et ANDRÉ L. BEAUCHAMP. Can. J. Chem. **63**, 2575 (1985).

On rapporte la synthèse, les spectres rmn ^{1}H et ^{13}C et les spectres infrarouges du complexe bis(théophyllinato)tetraaquocadmium(II), [$CdC_{14}H_{22}N_4O_5$], et de ses composés solvatés avec la *N,N*-diméthylformamide. Le cristal comportant deux molécules de *N,N*-diméthylformamide par complexe appartient au groupe spatial monoclinique $P2_1/c$: a = 10,819(3), b = 13,696(7), c = 10,110(2) Å, β = 109.03(4)°, ρ_c = 1.595 g cm^{-3} et Z = 2. L'affinement par moindres carrés au moyen de 1299 réflexions MoKα significativement observées a convergé à une valeur finale de R de 0,044 pour 261 paramètres variés. Le composé est constitué de molécules monomères [$CdTh_2(H_2O)_4$]. Le cadmium se situe sur un centre de symétrie. Les atomes liés au cadmium décrivent une géométrie à peu près octaédrique, deux ions théophyllinate coordonnés par l'intermédiaire de N(7) occupant des positions *trans* l'un par rapport à l'autre. Les distances Cd—N(7), Cd—O(13) et Cd—O(14), respectivement égales à 2,300(5) Å, 2,346(5) Å et 2,336(5) Å, sont normales. Les liaisons hydrogène dans le cristal constituent un ensemble complexe auquel participent tous les atomes donneurs et accepteurs des coordinats. La *N,N*-diméthylformamide n'est pas coordonnée au cadmium, mais elle participe au réseau de liaisons hydrogène. Les spectres rmn sont en accord avec la présence d'un ion théophyllinate semblablement lié au cadmium dans la solution de diméthylsulfoxyde.

Introduction

The N(7)/O(6) portion of guanine is the region of DNA which has been the most thoroughly discussed in reference to heavy metal – DNA interactions. It is generally recognized that N(7) is the primary site of attachment of platinum antitumor drugs. Subsequent chelate formation by metal–O(6) binding has been suggested, but definitive evidence for this type of interaction is lacking (1). During the last several years, our laboratories have been actively investigating the reactions of soft mercury(II) species with nucleobases (2–4). We have recently described a number of complexes obtained with theophylline (**1**), a purine base having the same N(7)/O(6) arrangement as guanine (5, 6). The Hg^{2+} and CH_3Hg^+ cations have



1 (R = CH_3)

been shown to bind to N(7) in all these compounds, but there was no evidence for interactions with O(6). Since Cd^{2+}, a cation noticeably harder than Hg^{2+} (7), should give rise to stronger metal–oxygen interactions, complex formation between theophylline and Cd^{2+} was examined. Our interest in this system was also stimulated by the fact that cadmium is known to be an environmental pollutant and to participate in various biological processes (8).

Crystal structure analyses on cadmium–nucleobase complexes have shown that the metal ion generally binds to the nitrogen lone pair of N(7) in purines or N(3) in pyrimidines (9–16). When a carbonyl oxygen is adjacent to these sites, it often participates in "indirect chelation" by forming hydrogen bonds with other ligands in the coordination sphere (13, 14). However, in some instances, "direct" cadmium–carbonyl interaction has been found to take place (15, 16).

In the solid state, the weakly acidic proton of neutral theophylline is bound to N(7) (17, 18). However, the comparable basicities of the imidazole N(7) and N(9) sites in purines commonly lead to a tautomeric equilibrium between the N(7)—H and N(9)—H forms. This duality manifests itself in the existence of two types of complexes with formally neutral theophylline: the metal can be bound via N(9) to the N(7)—H tautomer (19, 20), or via N(7) to the N(9)—H tautomer (21). The theophyllinium (ThH_2)$^+$ ion, in which both N(7) and N(9) bear a hydrogen atom (21, 22), has only carbonyl oxygens available for coordination and shows no pronounced affinity

[1]Correspondence to be addressed to one of these authors.

for binding to metal ions. The theophyllinate anion (Th^{-1}) derived from theophylline could, in principle, react either through N(7) or N(9), but in all the crystal structures reported so far (23–29), it was found to be bound to the metal via N(7).

As a part of our program dealing with the interactions of metal ions with nucleic acid constituents (4), we have isolated and characterized by microanalytical data, ^{1}H and ^{13}C nmr and ir spectroscopy, the novel cadmium complex bis(theophyllinato)tetraaquocadmium(II). However, the structure of this complex could not be established unambiguously by standard spectroscopic techniques, and hence, an X-ray diffraction study of the complex, crystallized from *N*,*N*-dimethylformamide/pyridine, was undertaken. The combined synthetic and structural studies are reported herein.

Experimental

^{1}H nmr spectra were measured in $(CD_3)_2SO$ on a Bruker HX-60 instrument operating at 60 MHz in the Fourier transform mode, using $(CH_3)_4Si$ (TMS) as internal standard. ^{13}C nmr spectra were recorded on a Bruker CXP-200 instrument operating at 50.307 MHz and were also referenced to internal TMS. All spectra were recorded at room temperature (25 ± 2°C). Infrared spectra were recorded as 1% KBr discs on a Perkin-Elmer 598 spectrometer. Microanalyses were performed by Guelph Chemical Laboratories Limited.

Commercially available theophylline (Sigma) and cadmium acetate dihydrate (BDH) were used as received.

Preparation of compounds

To a hot solution of theophylline (0.50 g, 2.77 mmol) in 50 mL of deionized water was added dropwise a solution of cadmium acetate dihydrate (0.37 g, 1.39 mmol) in 5 mL of deionized water. Immediate formation of a white precipitate resulted. After stirring the reaction mixture for 15 min at 80°C, the white solid was collected by filtration, washed with 100 mL of hot water, and dried to constant weight in a vacuum desiccator. It was crystallized once from methanol and then from a 1:5 pyridine/*N*,*N*-dimethylformamide (DMF) mixture to yield colourless crystals in 17% yield.

The analysis of the white precipitate corresponds to $[CdTh_2(H_2O)_4]$. *Anal.* calcd. for $CdC_{14}H_{22}N_8O_8$: C 30.98, H 4.09, N 20.64; found: C 31.00, H 4.36, N 20.67.

A sample of the colourless crystalline material recovered from DMF/pyridine was also submitted for elemental analysis and the results indicated a monosolvate $[CdTh_2(H_2O)_4]$.DMF. *Anal.* calcd. for $CdC_{17}H_{29}N_9O_9$: C 33.15, H 4.75, N 20.47; found: C 33.18, H 5.04, N 20.09. Single crystals taken from this sample were found to be the disolvate $[CdTh_2(H_2O)_4]$.2DMF (see below). Since the crystals deteriorate when exposed to the atmosphere for a few hours, it is likely that the material analysed had lost some DMF to give the monosolvate.

^{1}H chemical shift data

Literature values for the uncomplexed theophylline ligand are given in parentheses (5).

(*a*) For the white precipitate, $CdC_{14}H_{22}N_8O_8$: N(1)—CH_3 = 3.23 (3.26), N(3)—CH_3 = 3.45 (3.47), C(8)—H = 7.52 (8.06), N(7)—H = (13.53), H_2O = 3.52.

(*b*) For the colourless crystalline material, $CdC_{17}H_{29}N_9O_9$: N(1)—CH_3 = 3.23 (3.26), N(3)—CH_3 = 3.45 (3.47), C(8)—H = 7.52 (8.06), N(7)—H = (13.53), H_2O = 3.52, $(CH_3)_2N$— = 2.89, 2.73, —C(O)—H = 7.95.

^{13}C chemical shift data

(*a*) For the white precipitate, $CdC_{14}H_{22}N_8O_8$: N(1)—CH_3 = 27.71 (27.37), N(3)—CH_3 = 30.19 (29.36), C(2) = 151.56 (151.03), C(4) = 148.65 (147.63), C(5) = 113.56 (106.28), C(6) = 157.87 (154.18), C(8) = 147.68 (139.96).

(*b*) For the colourless crystalline material, $CdC_{17}H_{29}N_9O_9$: N(1)—CH_3 = 27.27 (27.37), N(3)—CH_3 = 29.70 (29.36), C(2) = 151.37 (151.03), C(4) = 148.60 (147.63), C(5) = 113.17 (106.28), C(6) = 157.39 (154.18), C(8) = 147.15 (139.96), $(CH_3)_2N$— = 35.62, 30.67, —C(O)—H = not observed.

Infrared absorption data:

For the white precipitate: ν(C=O) + $\delta(H_2O)$ = 1645(s); ν(C=C) + ν(C=N) = 1602(s), 1520(m). Free theophylline: 1720(s), 1680(s), 1610(w), 1560(m) (5).

Crystal data

$[CdTh_2(H_2O)_4]$.2DMF ($CdC_{14}H_{22}N_8O_8.2C_3H_7NO$) fw = 684.9

Monoclinic, $P2_1/c$, a = 10.891(3), b = 13.696(7), c = 10.110(2) Å, β = 109.03(4)°, V = 1425.6 Å^3, Z = 2, D_c = 1.595 g cm^{-3}, μ(MoKα) = 8.3 cm^{-1}, λ(MoK$\bar{\alpha}$) = 0.71069 Å (graphite monochromator), T = 23°C. Crystal dimensions: 0.12 mm × 0.14 mm × 0.15 mm.

Crystallographic measurement

The compound precipitated as colourless transparent crystals from a pyridine–DMF mixture, but these became opaque after exposure to the atmosphere for a few hours. This deterioration, which is probably due to the loss of DMF, was slowed considerably by sealing the crystal in a Lindemann capillary. Precession and cone axis photographs showed $2/m$ Laue symmetry and the systematic absences ($h0l$, $l \neq 2n$ and $0k0$, $k \neq 2n$) unambiguously defined space group $P2_1/c$.

The crystal was mounted on an Enraf-Nonius CAD-4 diffractometer. The cell parameters reported above were obtained by least-

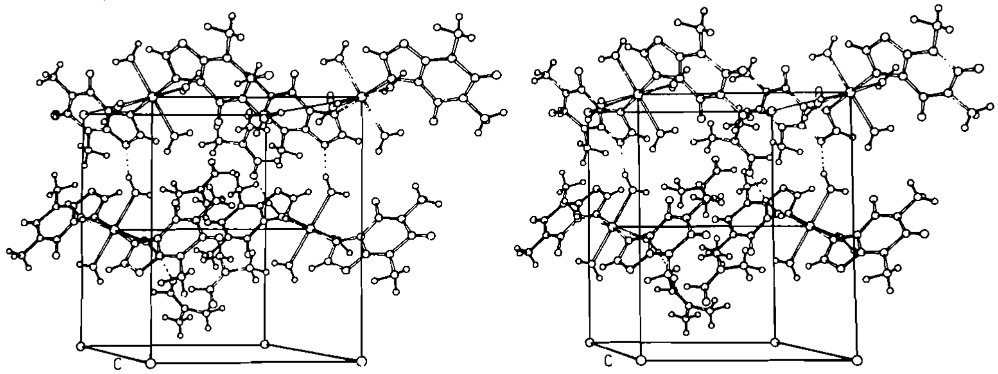

FIG. 1. Stereo view of the unit cell. The atoms are represented by spheres of arbitrary sizes. Dashed lines correspond to hydrogen bonds.

squares refinement on the setting angles of 25 reflections randomly distributed in the Laue sphere. The intensity data were collected as described elsewhere (30). The intensities of the three standard reflections decreased slowly, at the same rate, during data collection. At the end, 24% of the original intensity had been lost. The intensities were corrected accordingly at the data reduction stage. A total of 1865 *hkl* and $h\bar{k}l$ reflections were measured in the sphere limited by $2\theta \leq 45°$ (MoKα). A set of 1299 reflections with intensities $I > 3\sigma(I)$ was used to solve and refine the structure. These data were corrected for the Lorentz effect and polarization. A sample calculation showed that the transmission factor varied in the very narrow 0.85–0.89 range. Therefore, an absorption correction was deemed unnecessary.

Resolution of the structure

The structure was solved by the heavy-atom method and refined by full-matrix least-squares. The Cd atoms were positioned on equipoint 2*a* on the basis of a three-dimensional Patterson synthesis. A portion of the five-membered ring of theophylline could also be extracted from this map. These light atoms, together with Cd, were used as the initial phasing model. The remaining nonhydrogen atoms were located from subsequent structure factor and difference Fourier (ΔF) calculations. Isotropic refinement of all nonhydrogen atoms converged to $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.086$ and $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.097$. An individual weight $w = 1/\sigma^2(F)$ based on counting statistics (30) was applied to each reflection. The positions of all the hydrogen atoms were determined from the ΔF map calculated at this stage. The atoms were then anisotropically refined, except for hydrogens, which were isotropically refined. Convergence was reached for $R = 0.044$ and $R_w = 0.052$. The goodness-of-fit ratio was 1.87. The final ΔF map was essentially featureless: the general background was within $\pm$ 0.55 e Å^{-3}, but a few peaks of $\pm \sim 1$ e Å^{-3} were found near Cd.

The scattering curves were from standard sources (31). The f' and f'' contributions of Cd to anomalous dispersion were taken into account (32).

The refined coordinates are listed in Table 1. The lists of temperature factor and structure factor amplitudes are part of the supplementary material.[2]

Results and discussion

Theophylline contains four potential binding sites since the methyl groups at N(1) and N(3) effectively render these sites non coordinating. Three of these sites, i.e. C(6)═O, C(2)═O, and N(9) possess one or more lone pairs of electrons in the undissociated ligand. The N(7) atom can become a reactive site as a result of the formation of Th^{-1} via displacement of the weakly acidic N(7)—H proton (pK_a = 8.5) (33).

The solid DMF-free compound was obtained by reacting equimolar amounts of theophylline and cadmium acetate dihydrate in aqueous solution at pH 5 according to the following net reaction:

$$[1] \quad 2ThH + Cd(CH_3CO_2)_2.2H_2O \xrightarrow{H_2O} [CdTh_2(H_2O)_4] + 2CH_3COOH$$

Recrystallization of $[CdTh_2(H_2O)_4]$ from a pyridine/DMF mixture (1:5) yielded a crystalline solid whose elemental analysis was consistent with a complex containing cadmium(II), DMF, water, and theophyllinate ions. However, while the results of standard spectroscopic techniques (see below) clearly indicated that DMF was not a component of the inner coordination sphere, they were less successful in establishing unambiguously the geometrical arrangements of water and theophyllinate ions in the inner coordination sphere, the site utilized by Th^{-1} in its binding to cadmium, the state of aggregation of the complex (e.g. monomeric or dimeric), the structure of the complex and the extent (if any) of the involvement of the C(6)═O in bonding to cadmium. In order to shed some light on these problems, we undertook the X-ray crystal structure determination, the results of which are reported below.

Crystal structure of [CdTh$_2$(H$_2$O)$_4$].2DMF

Figure 1 shows an ORTEP drawing of the complex. The interatomic distances and bond angles are listed in Table 2. The structure consists of monomeric, six-coordinate molecules, $[CdTh_2(H_2O)_4]$, in which the two Th^{-1} anions are in the *trans*-positions and bound to cadmium via their N(7) nitrogens. Cadmium occupies a crystallographic inversion centre and its coordination is roughly *trans*-octahedral. Opposite Cd–ligand bonds are exactly 180° apart by symmetry. The N—Cd—O angles range from 88.4(2) to 91.6(2)°. Departure from the ideal 90° value is greater for the O—Cd—O angles (83.5(2), 96.5(2)°). The Cd—O distances of 2.346(5) and 2.336(5) Å compare well with those found in other aquo complexes (11–14). The Cd—N(7) distance (2.300(5) Å) is similar to those reported for complexes with related ligands (9–16).

N,*N*-Dimethylformamide is clearly not a constituent of the inner coordination sphere of cadmium, but rather is present in well defined lattice sites as a solvent of crystallization (Fig. 2).

As mentioned earlier, both the N(1) and N(3) sites in the theophylline are blocked by a methyl group, so coordination occurs either through N(7) or N(9) (or, perhaps, via C(6)═O or C(2)═O). In view of the observation that in neutral theophylline, the imidazole proton is bound at N(7) (17, 18), it is not surprising that, in the majority of the complexes containing

[2]Lists of anisotropic temperature factors (Table 4), weighted least-squares planes (Table 5), and observed and calculated structure factor amplitudes (Table 6) may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

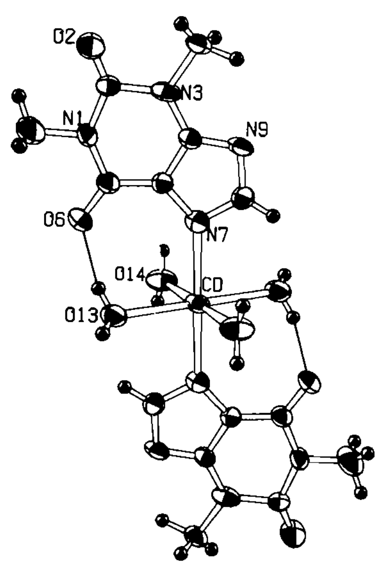

FIG. 2. ORTEP drawing of the $Cd(H_2O)_4(C_7H_7N_4O_2)_2$ molecule. The ellipsoids correspond to 50% probability, except for hydrogens, which are shown as spheres of arbitrary size. The dashed lines correspond to hydrogen bonds. The cadmium atom occupies a crystallographic inversion centre.

the theophyllinate anion, the coordination of $(Th)^{-1}$ is through N(7). Kistenmacher, Marzilli, and co-workers (23–29) reported the structures of a number of complexes with the theophyllinate anion and they invariably found the metal to be bound to N(7) rather than N(9). They also pointed out that O(6) is consistently involved in stabilizing interactions, either by weak coordination with the metal (in copper complexes), or through hydrogen bonding with other coordinated ligands. The present complex clearly belongs to the latter class. The intramolecular O(13)—H···O(6) bond is strong, with an O(13)—O(6) separation of 2.689(8) Å lying on the low side of the range (2.65–2.93 Å) proposed by Stout and Jensen for this type of H-bond (34). The hydrogen lies close to the O(13)—O(6) direction and all the angles are favorable (Table 3). On the other hand, binding via N(9) would replace this stabilizing interaction by a repulsion between water and the hydrophobic N(3)—CH_3 portion of theophylline. The so-called "indirect chelation" of O(6) appears to introduce a stabilization large enough to favor bonding to N(7) in azahypoxanthine, a ligand very similar to theophylline, in spite of the fact that N(8) and N(9) are believed to be more basic that N(7) (14). Indirect chelation also exists in the cadmium complexes of inosine monophosphate and guanosine monophosphate (13). Therefore, whenever such extra stabilization is possible, the acceptor ability of N(7) is enhanced, and both factors have to be considered when discussing the relative affinities of N(7) and N(9) in such systems.

The theophylline unit consists of two individual rings, both planar within 1.7σ (0.012 Å). The angle between the rings is 2.0° (Table 4, supplementary material). The substituents are displaced slightly, although significantly, from their respective planes: O(6), 0.047(5) Å; C(1), 0.034(9) Å; Cd, −0.137 Å. The DMF molecule (excluding the methyl hydrogens) is planar within 2σ (0.019 Å).

The hydrogen bonding in $[Th_2Cd(H_2O)_4]$.2DMF is extensive due to the presence of a number of donor and acceptor sites in the theophyllinate anion and DMF molecule. The four water molecules on the cadmium atom provide additional donor sites. The distances and angles associated with these possible hydrogen bonds are listed in Table 3. The pair of symmetry-equivalent intramolecular O(13)—H(13)···O(6) hydrogen bonds has been discussed above. The packing pattern (Fig. 2) shows some intermolecular hydrogen bonds. O(2) is involved in an intermolecular hydrogen bond with the hydrogen of an O(14) water molecule: the O(14)···O(2) distance is 2.799(6) Å, and the O(14)—H(142)—O(2) angle is 175(6)°. The theophyllinate ligands are linked together by intermolecular O(13)—H(132)···N(9) hydrogen bonds, with an O(13)—N(9) distance of 2.828(7) Å and O(13)—H(132)—N(9) angle of 162(8)°. The oxygen atom of DMF is also involved in hydrogen bonding to water molecules attached to the central metal atom.

^1H and ^{13}C nmr and ir spectroscopic analysis of the compounds

^1H and ^{13}C nmr and ir spectra of the complexes, together with comparable data for the parent theophylline, are given in the experimental section. The ^1H nmr spectrum exhibits upfield shifts of the N(1)—CH_3, N(3)—CH_3, and C(8)—H resonances, with the resonance due to N(7)—H being absent. This is consistent with theophyllinate binding via N(7) with concomitant proton displacement. The trends of the chemical shifts of the N(1)—CH_3, N(3)—CH_3, and C(8)—H are parallel to those observed in the [(CH_3Hg)Th].H_2O and [Th_2Hg].H_2O complexes, in which N(7)—Hg binding is known to occur (5). In a solution of the crystalline sample, the ^1H resonances associated with DMF are at $\delta = 2.89$ and 2.73 ppm ($N(CH_3)_2$) and $\delta = 7.95$ ppm (—C(O)—H). The water and purine resonances of the DMF solvate are relatively unchanged as compared to corresponding resonances of the noncrystalline sample. Natural abundance proton decoupled ^{13}C nmr spectra were also obtained. Signals of most interest are those which are close to the site of metallation. The resonances due to C(5) and C(8) show downfield shifts of 7.28 and 7.72 ppm together with a downfield shift of the C(6) resonance of 3.69 ppm. The other resonances are relatively unaffected in comparison to those of theophylline itself. The trend is in the same order as is observed with [(CH_3Hg)Th].H_2O and [Th_2Hg].H_2O (5). These changes in the chemical shifts of C(5) and C(8) resonances can be attributed to the transfer of charge from N(7) to the ring systems on removal of the proton (35). The change in chemical shift of the C(6) resonance could be, in part, due to the involvement of C(6)═O group in hydrogen bonding to the water groups attached to the central metal atom (see X-ray structure).

The ir spectra of the complexes show a strong multicomponent absorption at 1645 cm^{-1}. Similar strong bands, attributed to the $\delta(H_2O)$ mode and the two C═O stretching vibrations found at ~1685 and ~1635 cm^{-1}, have been found in a number of complexes containing the theophyllinate ion (5, 36). Free theophylline has corresponding absorptions at 1720 and 1680 cm^{-1}. Shifts of this magnitude in the C═O stretching modes are sometimes cited as evidence for N(7)—O(6) chelation. However, based on the X-ray results obtained in the present study and with [(CH_3Hg)Th].H_2O (5, 6), this lowering in the stretching mode is more likely a consequence of the deprotonation of the imidazole ring, with a possible contribution resulting from the involvement of the C(6)═O oxygen atom in the formation of strong hydrogen bonds with the hydrogen atom of the water molecule attached to the central metal atom.

Acknowledgments

We wish to thank M. J. Olivier for collecting the X-ray data and the Natural Sciences and Engineering Research Council of Canada for financial support.

COMMUNICATION

Facile H–D exchange of the bridgehead methyls of bicyclo[2.2.2]octan-2,5-diones. Evidence for a carbon analogue of the acyloin rearrangement

NICK HENRY WERSTIUK, GWEN IRENE WADE,[1] AND PETER JOHN JOSEPH MARTIN[2]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received May 10, 1985

NICK HENRY WERSTIUK, GWEN IRENE WADE, and PETER JOHN JOSEPH MARTIN. Can. J. Chem. **63**, 2582 (1985).

Hexamethyltwistyl-2,5-dione **4** has been synthesized and its H–D exchange studied in *t*-BuOK/*t*-BuOD at 125°C. We find that the bridgehead methyl at C-3 undergoes exchange 7×10^5 times faster than the bridgehead methyl of bicyclo[2.2.1]heptan-2-one (fenchone). This result, along with a previous study, establishes the first examples of the carbon analogue of the acyloin rearrangement of alicyclic systems.

NICK HENRY WERSTIUK, GWEN IRENE WADE et PETER JOHN JOSEPH MARTIN. Can. J. Chem. **63**, 2582 (1985).

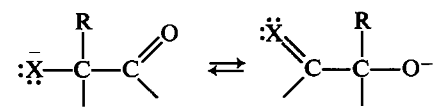
On a synthétisé l'hexaméthyltwistyldione-2,5 (**4**) et on a étudié son échange H–D sous l'influence du *tert*-BuOK/*tert*-BuOD, à 125°C. On trouve que la vitesse d'échange du groupement méthyle en tête de pont, en C-3, est 7×10^5 fois plus rapide que celle du groupement méthyle en tête de pont de la triméthyl-1,3,3 bicyclo[2.2.1] heptanone-2 (fenchone). Ce résultat, de même que ceux obtenus au cours d'une étude antérieure, permet d'établir les premiers exemples d'analogues carbonés d'une transposition aux acyloïnes dans des systèmes alicycliques.

[Traduit par le journal]

Numerous examples of the base-catalyzed rearrangement of α-ketols (acyloins) (Scheme 1) have been documented in the literature. The rearrangements occur readily in acyclic, monocyclic, bicylic, and polycyclic substrates (1–10).[3] The nitrogen analogue of the acyloin rearrangement has been observed in the conversion of α-lactams to α-hydroxyimines by alkyllithiums (11–13). Prior to this report, which documents the first examples of the carbon analogue of the acyloin rearrangement in alicyclic systems, Miller and Bhattacharya (14)[4] established that the anion of dienone **1** undergoes a concerted 1,2 shift of a methyl group at −10°C to yield anthrone **2** (Scheme 2).

From our studies on the homoenolization of bicyclic diones (15, 16) it was established that dione **3** undergoes facile H–D exchange of the bridgehead methyl (Table 1) at 100°C. From the unusual sequence of the deuterium incorporation we deduced that H–D exchange was not rate determining and considered a possible mechanism for the exchange based on a β-enolization.

To establish the generality of the facile exchange of the bridgehead methyl, we have synthesized hexamethyltwistyl-2,5-dione **4** and studied its H–D exchange in 1 *M* *t*-BuOK/*t*-BuOD at 125°C. It was found that the bridgehead methyl at C-3 undergoes exchange approximately 7×10^5 times faster than the bridgehead methyl of fenchone (17).[5] We propose that the exchange of the methyls of **3** and **4** does not occur via a β-enolization, but rather is a consequence of the involvement of a carbon analogue of the acyloin rearrangement (CAAR) of α-enolate **4**-*E* that locates a methyl group at the terminus of an enone (Scheme 3). Our work represents the first examples of



X = O, N, C
: = lone pairs or σ bonds

SCHEME 1

TABLE 1. Base-catalyzed H–D exchange of diones in *t*-BuOK/*t*-BuOD

Dione[a]	Temperature (±3°)	Time (h)	Excess D per molecule (D in methyl)[b]
3	100°C	25	2.01(0.51)
4	125	24	3.78(2.53)
4	125	44	4.35(2.40)[c]

[a] Ketone concentrations ranged between 0.1 and 0.15 *M* and the base concentrations were in the range of 1.0–1.2 *M*. The diones were recovered in 70–80% yield.
[b] Determined mass spectrometrically at low voltage.
[c] Small amounts of d_5 and d_6 species were present.

SCHEME 2

[5] Based on the fact that fenchone (1,3,3-trimethylbicyclo[2.2.1]-heptan-2-one) undergoes 7.3% exchange of the bridgehead methyl after 300 h at 220°C (17). We previously reported that the methyl of **3** exchanges 5×10^3 faster than the bridgehead methyl of fenchone. The apparent increase in the rate of exchange of **4** is predominantly due to the fact that a better estimate of the rate of exchange of the bridgehead methyl of fenchone is now available.

SCHEME 3

CAAR in systems lacking the driving force of a concurrent aromatization.

Dione **4** was prepared from tricyclic hydroxyenone **5** that was described previously by Scheffer and Dzakpasu (18). To avoid the possibility of ring-opening of the Δ^9-analogue of **4** during exchange, hydroxyenone **5** was converted into **6** by catalytic hydrogenation on Pd/charcoal, and **6** was rearranged to **4** by KH/THF (19).[6] The stereochemistries at C-4 and C-9 of **4** are those expected on the basis of the stereoelectronic control of protonation of the α-enolate and the steric control of the reduction, respectively. The *W*-coupling of 2 Hz between the *exo* protons at C-8 and C-10 of **6** confirms the latter expectation (in **4** the *W*-coupling between the *exo* proton at C-7 and the proton at C-9 is also clearly visible and is 1 Hz).

The ^{2}Hmr spectrum of deuterated **4** showed signals only at δ 2.2 and δ 1.1 in a ratio of 1:3. Based on the ^{1}Hmr spectrum, the resonance at δ 2.2 corresponds to the deuteron α to the carbonyl group. That the resonance at δ 1.1 corresponds to the bridgehead methyl at C-1 was established by selectively labelling the methyl group at the terminus of the enone system of **5** in NaOD/D_2O/dioxane. Trideutero-**5** was reduced to deuterated **6**, and **6** was rearranged to **4**, which exhibited a resonance at δ 1.1 in the ^{2}Hmr spectrum. In our view, the facile exchange of **4** (and **3**) can only be accounted for by invoking a rearrangement of the α-enolate **4**-*E* to **6**-*O*, the oxyanion of **6**. Base-catalyzed exchange of **6**-*O* or **6**, followed by rearrangement of **6**-*O* to deuterated **4** via a vinylogous acyloin rearrangement, can account for the experimental results. The vinylogous acyloin rearrangement, examples of which are documented in the literature (19–23), and the carbon analogue of the acyloin rearrangement are related in that the latter is the reverse of the former. Under certain circumstances the CAAR occurs at a reasonable rate but, in cases where the dione is significantly more stable than the hydroxyenone, the CAAR can only be detected by hydrogen-isotope exchange. That the α-enolates of **3** and **4** rearrange at 100–125°C and the anion of **1***a* rearranges at −10°C is a consequence of the aromatization of ring a of **1***a*. It is interesting to note that, although methyl substitution α to the carbonyl group (compare **3** and **4**) does not appear to affect the rate of rearrangement in the alicylic systems, Miller and Bhattacharya reported that dienedione **1***b* does not undergo the 1,2-methyl shift (14).

[6] The spectroscopic data for **4** and **6** were consistent with the proposed structures.

The indirect determination of trace reactive silicon in waters by neutron activation analysis

PHILLIP OLTMANN AND DOUGLAS E. RYAN[1]

Trace Analysis Research Centre, Chemistry Department, Dalhousie University, Halifax, N.S., Canada B3H 4J1

Received December 3, 1984

PHILLIP OLTMANN and DOUGLAS E. RYAN. Can. J. Chem. **63**, 2585 (1985).

Reactive silicon in waters was determined indirectly by counting ^{101}Tc after neutron activation of molybdosilicic acid (MSA) extracted with methyl isobutyl ketone (MIBK). The detection limit (defined as twice the standard deviation for the blank) was 0.2 ng mL^{-1}. The relative standard deviation was 3% at the 10 ng mL^{-1} level and 30% at the 1 ng mL^{-1} level. Phosphate, arsenate, and ferric ions did not interfere by themselves. Interference from the reduction of molybdophosphoric acid by tannic acid was eliminated through the use of dichromate. The salt effect normally encountered in the analysis of sea water was examined with particular reference to silicate content of reagent salts used in preparing synthetic sea water.

PHILLIP OLTMANN et DOUGLAS E. RYAN. Can. J. Chem. **63**, 2585 (1985).

On a déterminé les niveaux de silicium réactif présents dans des eaux en faisant appel à une méthode indirecte impliquant le comptage du ^{101}Tc après une activation neutronique de l'acide molybdisilicique (AMS) qui est extrait par de la méthyl isobutyl cétone (MIBC). La limite de détection (qui est définie comme étant le double de la déviation standard d'un blanc) est égale à 0,2 ng mL^{-1}. La déviation relative standard est égale à 3% à des concentrations de 10 ng mL^{-1} et de 30% à un niveau de 1 ng mL^{-1}. Les ions phosphate, arsénate et ferrique n'interfèrent pas directement. L'interférence provenant de la réduction de l'acide molybdophosphorique par l'acide tannique a été éliminée en utilisant du bichromate. On a étudié l'effet de sel que l'on rencontre lors de l'analyse de l'eau de mer et particulièrement en ce qui a trait au contenu en silicate des réactifs qui sont utilisés pour préparer de l'eau de mer synthétique.

[Traduit par le journal]

Introduction

Silicon is second in abundance to oxygen in the geosphere and therefore is present in other spheres including natural waters. The concentration may be high in deep sea water or undetectable in some surface waters (1, 2). Silicon in waters is essential to diatoms and planktons, the basis of the aquatic food chain (1, 3, 4). It is present in waters as silicate ions (which may be polymerized), as colloidal silicon dioxide and clays, or in plant life. Silicon is also deleterious to industrial processes (5–7) leaving hard deposits on turbine blades and piping of steam power generators resulting in reduced heat transfer and turbine efficiency; demineralization processes must reduce concentrations to less than 50 ng mL^{-1}. Chemicals such as phosphates, tannic and oxalic acids are used in piping waters to reduce corrosion and minimize deposits, and these vary with generator manufacturer. Natural waters may also contain copious amounts of phosphate, sodium chloride, or biological decay products. Methods for silicon determinations, therefore, must be selective and sensitive.

A recent paper (8) reports on the determination of silicon in waters used for washing modern integrated circuits. ASTM recommends that silicic acid concentrations be below 5 ng mL^{-1} for this application, a restraint that renders conventional analysis methods obsolete. The determination of silicon in waters is usually accomplished spectrophotometrically after reduction of molybdosilicic acid (MSA). MSA has also been applied in a flow injection system (9), in a voltammetric finish (7, 10), in a kinetic method (11), and a radioreagent method (12). Only α-MSA is formed over the pH range 3.8–4.8 in solutions 0.005 – 0.1 *M* in molybdate and only β-MSA at pH's 1.0–1.8 at the same molybdate concentrations (13). A short review of MSA production has recently been published (14).

"Reactive silica" denotes silicon species that readily react producing MSA (<20 min); these are orthosilicate and its dimer. Longer chains and colloidal silica react slowly over a period of hours or days reflecting their dissociation and dissolution. Phosphorus(V), arsenic(V), and germanium(IV) also form heteropoly acids under the β-MSA formation conditions and can produce a positive interference in spectrophotometric determinations while fluoride and tannic and humic acids (biological decay products) can produce negative interferences by inhibiting the formation of MSA. Tannic acid can produce a positive interference when present with phosphate by reducing molybdophosphoric acid.

This paper reports on the determination of reactive silicon by neutron activation of extracted MSA. The production of MSA is well defined and its separation from excess molybdate, by extraction, is readily accomplished. The SLOWPOKE reactor is particularly advantageous since direct irradiation of liquids can be done.

Experimental

Reagents and instrumentation

The following reagents were used: ammonium molybdate (Fisher certified), silicon dioxide (INC 99.999%), soidum carbonate (Thorn Smith 99.98%), sulfuric acid (Fisher 96%), MIBK (Aldrich reagent grade), and potassium hydroxide (BDH ACS grade). Ultrapure water, used to dilute reagents, was prepared by sub-boiling distillation of distilled water from a 20 L pyrex flask heated with an ir lamp. A 5 L nalgene flask cooled with ice was used for collection and the water was stored in a similar 20 L container. Teflon separatory funnels were dismantled and soaked in 50% KOH between uses to eliminate possible memory effects. A Tracor Northern TN 1700 multichannel analyzer connected to a Ge(Li) detector was employed to monitor the 307 keV photopeak of ^{101}Tc, the daughter of ^{101}Mo produced upon irradiation.

Procedure

To 50 mL water samples in 125 mL Teflon separatory funnels were added 1 mL of a freshly prepared 10% ammonium molybdate solution and 1 mL 1:5 H_2SO_4:H_2O to produce a pH of 1.2–1.4. After 20 min, any isopoly acids, molybdosphosphoric acid (MPA), and molybdoarsenic acid (MAA) present were destroyed by the addition of 20 mL of 1:1 H_2SO_4 and the MSA extracted with 2 mL MIBK. The

[1]To whom all correspondence should be addressed.

organic phase was washed once with 10 mL 1:5 H_2SO_4 and transferred to a polyvial. The vial was doubly sealed before irradiation in the SLOWPOKE II research reactor; irradiation (t_i), decay (t_d), and counting times (t_c) were 30 min, 1 min, and 30 min, respectively, at a neutron flux of 5×10^{11} n cm^{-1} s^{-1}. Quantitation was achieved by reference to an analytical curve prepared from data obtained for 0−1 μg Si added to 50 mL of ultrapure water. Sea water standards (Wako Pure Chemicals) were analyzed by using a 1 mL aliquot with 50 mL of ultrapure water. The amount of sulfuric acid needed to give the proper pH was determined in a separate experiment.

Interference study

Chemicals present in natural and industrial waters were examined for interferences on the production of MSA, for silicate content and for complexation/extraction of molybdate. The chemicals studied were ferric ammonium sulfate (McArthur Chem. Co. reagent grade), sodium chloride (BDH ACS grade), citric acid (Fisher ACS), tartaric acid (Eastman), oxalic acid (Fisher ACS), tannic acid (J. T. Baker), humic acid (Aldrich), ammonium fluoride (Analar AR grade), ammonium phosphate monobasic (B & A), phosphorous and arsenic AA standards 1000 ppm (Aldrich), sodium arsenate (Analar AR grade), and germanium dioxide (Fisher 99.99%), the latter fused as for silicon dioxide.

Possible interferences were studied under three separate reaction conditions: (*A*) molybdate was added to test ion solutions after the addition of 20 mL 1:1 H_2SO_4; (*B*) all reagents were reacted at pH 1.4 without a silicate standard; (*C*) same as (*B*) but with a silicate standard. Ions were studied further by using ^{76}As and ^{32}P labelled salts in similar experiments. The organic phases were counted for β^- emissions using a Triton X-100 cocktail (15). Equal activities of ^{76}As and ^{32}P were added directly to the cocktail and counted as a reference. Labelled salts were prepared by irradiation of ammonium arsenate and ammonium phosphate in the SLOWPOKE II reactor.

Results and discussion

The sensitivity of the method was 85.7 ± 2.1 counts per nanogram of silicon; the blank value was 1800 ± 550 counts as calculated using a least-squares analysis on 26 data points over the range 0−1 μg of silicon added. The data were obtained using two separate silicon standards and four separate molybdate preparations over a period of four days. The standard deviations listed, therefore, represent the sum of all weighing, measuring, and counting variances with the latter making the largest contribution. The blank value, equivalent to 20 ng Si, represents reactive silicon contamination in molybdate sources since the blank increased with molybdate concentration. There was also a contamination by unreactive forms of silicate since the blank value tripled when a one week old solution of molybdate was used; the blank value for Aldrich Gold Label ammonium molybdate was similar to that for the cheaper Fisher certified reagent.

The detection limit was defined as twice the standard deviation of the blank (13 ng Si). Thus for a 50 mL aliquot, the detection limit was 0.2 ng mL^{-1} (or 0.007 μg-at L^{-1} in the units used by oceanographers where 1 μg-at = 1 μmol). This detection limit is comparable to that of the most recent papers published (8, 16) and is significantly lower than a reported radioreagent method (12). The proposed method has the advantage over the latter in that one does not handle radioactive solutions, and irradiated samples can be disposed of safely without a long waiting period.

The upper limit was taken to be 1000 ng (20 ng mL^{-1}) above which the 307 keV photopeak broadened and accuracy decreased. The unsymmetrical broadening was a function of the redrifted detector and the counting system available. This upper limit can be extended by dilution of the sample with ultrapure water. Reducing the sample size, increasing the volume of MIBK used for extraction, reducing irradiation and count times or placing the sample farther from the detector also increases the upper limit but a new analytical curve must be prepared for these conditions.

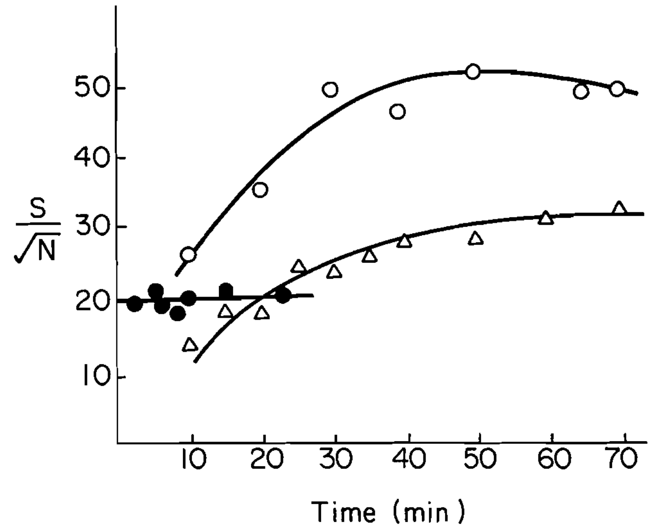

FIG. 1. Optimization curves obtained by plotting the signal to square root of noise ratio ($S/\sqrt{N}$) vs. time. ○ t_d, t_c = 1 m, 30 m, time = irradiation time; △ t_i, t_d = 15 m, 1 m, time = counting time; ● t_c = t_c = 15 m, time = decay time. N = background reading.

Figure 1 shows the data for optimizing irradiation, decay, and counting times. This was necessary because of the Compton background at 307 keV due to ^{41}Ar and ^{38}Cl; argon was present in the vial headspace and dissolved in MIBK while chlorine was present as a contaminant in the irradiation vials. The major contribution was ^{38}Cl and removal of ^{41}Ar by flushing with nitrogen was not particularly advantageous. Short variations in decay time had little affect on $S/\sqrt{N}$; this reached a maximum at an irradiation time of 30 minutes. The greatest increase in $S/\sqrt{N}$ vs. counting time is over the time interval of 0−30 min. At more than 30 min count time, little rise in $S/\sqrt{N}$ is observed. Time economy and a detectable reagent blank lead to the optimum conditions $t_i = t_c = 30$ m and $t_d = 1$ m.

Table 1 shows the results of possible interferences. Under condition *A*, heteropoly acids do not form at the acidity used. Therefore, an apparent signal indicates that a molybdenum complex, other than a heteropoly acid, was extracted. This was observed for tannic acid and high concentrations of fluoride and chloride. The positive interference of tannic acid was eliminated with dichromate. Interference by fluoride can be neglected for natural water samples since such high concentrations are not observed in nature. The interference from chloride was linear and was equivalent to 42.6 ng Si/1% NaCl. This value was used as a correction for the molybdenum chloride interaction in seawater analysis.

Reaction under condition *B* (pH 1.4) yields heteropoly acids including any MSA formed from silicate present in the salts used. All chemicals tested showed silicate contamination. Molybdogermanic acid is stable under the conditions used, but effects from germanium can normally be neglected due to its very low occurrence (17). The evidence under condition *B* was not, *on its own*, sufficiently conclusive to say that the data for phosphate and arsenate were the consequence of silicate but the

2.5	2.4	0.3
1.9	1.8	0.3
1.2	1.4	0.3
0.6	0.8	0.3
0.2	0.4	0.3
0.1	<0.2	0.3

results from two different sources of these ions show that there must be varying amounts of silicate present. Table 2 shows, when ^{32}P and ^{76}As are used as tracers, that <0.007% of phosphate and 0.03% arsenate are extracted and proves that the results obtained under conditions *B* for these ions must be the result of silicate contamination.

Chemicals contain silicon in both reactive and unreactive forms. The blank increased for solutions of molybdate on standing and higher values were observed for old solutions of test ions.

Low-level silicate contamination is deleterious especially when reagents contribute the same amount or more than samples. The accuracy of determinations in the interference study was therefore reduced as can be seen by comparison of values for conditions *B* and *C*; the quantity of silicon found was, of course, the difference.

Table 3 shows the accuracy of the method for the determination of silicon in standard water samples prepared in this laboratory. The lowest value (0.1 ng mL^{-1}) was below the detection limit ($2\sigma_b$, b = blank value) and at about the detection limit (0.2 ng mL^{-1}) a large error was observed and expected since meaningful data cannot be achieved below the quantitation limit ($4\sigma_b$, or 0.4 ng mL^{-1}).

Table 4 shows the applicability of the procedure to seawater analysis. The data are the mean of three replicate determinations. Values were consistently high indicating that the silicate content of the salts used in standard preparation may have been neglected by the manufacturer. The neglect of silicate contamination of salts used in preparing an analytical curve for seawater analysis has the net effect of producing slightly lower results for real samples. The methodology used here eliminates this problem.

Deionized water (Fisher high purity column), distilled water (Corning borosilicate still), and tap water were analyzed giving silicon concentrations of 1.1 ng mL^{-1}, 4.6 ng mL^{-1}, and 1.2 μg mL^{-1}, respectively. Unfortunately no standard reference ma-

terials were available for further testing.

The $^{101}Mo-^{101}Tc$ decay scheme was chosen over the $^{99}Mo-^{99m}Tc$ parent daughter relationship because the latter necessitates long irradiations and, therefore, the use of dry samples. Attempts to dry organic phases resulted in solvent creep and irregular deposition of the analyte on vial walls. Use of short-lived species permitted a much shorter analysis time. In addition the reagent blank determined the detection limit, not the ability to detect molybdenum and there was no advantage in using the more sensitive, but longer lived $^{99}Mo-^{99m}Tc$ parent daughter relationship.

Conclusions

The method described is applicable to water with extremely low silicon content (20−0.2 ng mL^{-1}), and is not affected by large amounts of tannic acid, arsenate, phosphate, and ferric ions or combinations of these. It is advantageous for colored samples and can determine silicate in reagent salts. Samples can be stored for long periods of time once encapsulated, since the NAA experiment does not depend on subsequent speciation changes. The detection limit could be lowered if methods of purifying molybdate sources improve.

The low operating temperature of the SLOWPOKE II reactor permits irradiation of liquids for periods up to 3 h so that samples need not be dried and short analysis times are possible.

Received October 2, 1984

J. W. ApSimon, L. W. Herman, and C. Huber. Can. J. Chem. **63**, 2589 (1985).

The synthesis of 2,2-dimethyl-5-hydroxychromene (**1***d*) is described. The synthesis of the analogous 5,7-dihydroxy derivatives, using similar conditions, yields the adduct **9** derived via a Bucherer type reaction. X-ray analysis of **9** demonstrated that a pyrrolidine group was in the 7-position, and that the 5-hydroxyl group was involved in a strong intramolecular hydrogen bond to the 4-keto oxygen atom.

J. W. ApSimon, L. W. Herman et C. Huber. Can. J. Chem. **63**, 2589 (1985).

On décrit une synthèse du diméthyl-2,2 hydroxy-5 chromène (**1***d*). Une synthèse des dérivés dihydroxy-5,7 analogues qui fait appel à des conditions semblables ne conduit qu'à l'adduit **9** qui provient d'une réaction du type de Bucherer. Par diffraction des rayons-X on peut démontrer que, dans le composé **9**, le groupement pyrrolidine est en position 7 et que le groupement hydroxyle en position 5 est impliqué dans une forte liaison hydrogène intramoléculaire qui le lie à l'atome d'oxygène de la cétone en position 4.

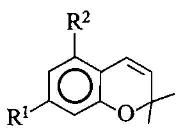
Introduction

In 1976, Bowers *et al.* (1) isolated two compounds from the plant *Ageratum houstanianum* which caused precocious metamorphosis, prevented ovarian development, and induced diapause in locusts and certain beetles. These natural anti-juvenile hormones, now known as Precocene I (**1***a*) and II (**1***b*),



1*a* R^1 = OMe, R^2 = H
1*b* R^1 = R^2 = OMe
1*c* R^1 = R^2 = H
1*d* R^1 = H, R^2 = OH
1*e* R^1 = OTs, R^2 = H
1*f* R^1 = H, R^2 = OBn
1*g* R^1 = H, R^2 = OPhenacyl

were already named 6-demethoxy ageratochromene (2) and ageratochromene (3) by the groups who first characterized them. This family of compounds shows great promise as a new generation of insecticides: while they are deadly to the insect targets, they are non-toxic to mammals probably because of their mechanism of action, which is believed (4–7) to require in vivo activation to a reactive epoxide which easily alkylates nucleophiles (7, 8), a route that is probably responsible for the destruction of the *corpora allata*, the insect organ responsible for juvenile hormone production.

The synthesis of 2,2-dimethyl chromenes (**1***c*) may be approached either by the preparation of another related ring system with subsequent variation of functionality, or by alkylation of a free phenol followed by cyclization onto the aromatic ring. Among the former approaches, the earliest was the alkylation of a coumarin with a Grignard reagent (9). In 1962, Iwai and Ide (10) first reported the synthesis of chromenes from the Claisen rearrangement of propargyl aryl ethers, an approach later used by Hlubecek *et al.* (11) who synthesized Precocenes I and II by the O-alkylation of 3-methoxy or 3,4-dimethoxy phenol with 3-chloro-3-methyl-1-butyne, followed by cyclization in *N,N*-diethylaniline.

Chromenes may also be obtained via the corresponding chroman by dehydrogenation with DDQ (12–14, 16, 17) or halogenation–dehydrohalogenation (16). Prenylated aromatic compounds may be formed under acidic conditions, with 2-methylbut-3-en-2-ol in the presence of BF_3 etherate (16), or under basic conditions with n-BuLi and dimethallyl bromide (17). Camps *et al.* (18) used $Ni(AcAc)_2$ as a catalyst to condense phenols with 1,3-dichloro-3-methylbutane to give the chroman system. Alternatively, *ortho* prenylated phenols may be directly cyclized to chromenes using potassium dichromate in benzene in the presence of Adogen 464 ("orange benzene") (19), DDQ in ether (19), or *N*-iodosuccinimide (20).

Sartori *et al.* (21) reacted metal phenolates with α,β-unsaturated aldehydes in toluene and obtained good yields of chromenes. Titanium, magnesium, tin, and aluminum phenolates were all found to be reactive, but highly coordinating solvents (e.g. DMF, glyme, HMPA, TMEDA) caused the reaction to fail. Crombie and co-workers (22) used a masked enone synthon, 3-hydroxy-3-methyl-1,1-dimethoxybutane, to give chromenes directly from phenols. This method was used primarily on aromatic compounds with an acetyl group *para* to the free phenol.

Another straightforward route to 2,2-dimethyl chromenes is via the corresponding chromanone derivative, followed by hydride reduction and dehydration. Chromanones are formed by the condensation of a phenol with 3,3-dimethyl acrylic acid in the presence of an acid catalyst such as HF (23), zinc chloride – phosphoryl chloride (24), polyphosphoric acid (25), BF_3 etherate (26), or methanesulphonic acid (27) (which is now the reagent of choice). Alternately, pyrrolidine catalysed condensation of an *ortho*-hydroxy acetophenone with ketones also affords chromanones in high yields (28).

In a series of studies, various chromenes related to naturally occurring compounds possessing insecticidal activity were synthesized in an attempt to discover materials of greater biological activity.

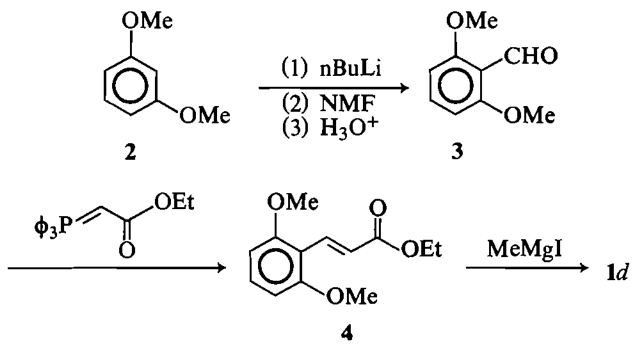


SCHEME 1

Results and discussion

Based on a report by Mechoulam and Gaoni (29) that a cannabinoid precursor was demethylated and alkylated to the corresponding phenoxy pyran, the synthesis outlined in Scheme 1 was performed. Aromatic formylation may occur in higher yields by using DMF in place of *N*-methyl formanilide. Reaction of aldehyde **3** with the stable Wittig reagent methylenecarboethoxytriphenylphosphorane occurred cleanly in high yield (85%), but the one-pot Grignard fusion methylation–dealkylation gave only ~30% of the desired product, **1***d*, along with a large amount of polymeric material.

An alternate route was followed when the synthesis of the 7-OH isomer of the desired chromene was attempted. Formation of chromanone **5***a* was achieved by the condensation of resorcinol and 3,3-dimethyl acrylic acid in the presence of $POCl_3/ZnCl_2$ (24) and, upon isolation, pure crystalline **5***a* was obtained in 67% yield. Protection of the free phenol as the *p*-toluene sulphonate followed by reduction of the carbonyl provided the desired alcohol **6***a* in 75% yield (some cleavage

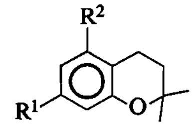
5*a* R' = OH, R² = H
5*b* R' = H, R² = OH
5*c* R' = H, R² = OBn
5*d* R' = R² = OH
5*e* R' = OTs, R² = H
5*f* R' = H, R² = OTs
5*g* R' = H, R² = OAc

6*a* R' = OTs, R² = H
6*b* R' = H, R² = OBn
6*c* R' = H, R² = OH
6*d* R' = H, R² = OPhenacyl

of the tosyl group was observed). Dehydration of this alcohol using toluene sulphonic acid in refluxing toluene was quantitative; however, deprotection of the phenol with KOH/MeOH met with unexpected failure when only polymeric material was isolated. Photochemical cleavage was also ineffective. The lability of **1***e* to base, along with the total stability of **6***a* to TsOH, is unusual considering the reported compatibility of chromenes with base (15, 23) and their reactivity with respect to acids (30–32).

Several simple syntheses were next attempted in the absence of a phenol protecting group. Chroman **7***a* was synthesized as reported (15); however, treatment with DDQ gave only intractable tars. Crombie's 3-hydroxy-3-methyl-butanal dimethyl acetal (22), which reacts with some phenols to give hydroxychromenes, did not react with resorcinol.

In order to synthesize 5-OH chromanones in a regiospecific way, the method developed by Kabbe (28) was employed.



7*a* R' = OH, R² = H
7*b* R' = H, R² = OH

2,6-Dihydroxyacetophenone, synthesized via the appropriately substituted coumarin (33), was condensed with acetone, giving chromanone **5***b* in 75% yield. Because of the strong chelating effect shown by *ortho*-hydroxy aromatic ketones, the phenol could not be acylated under standard conditions (e.g. K_2CO_3/acetone/TsCl). Using conditions of anhydrous phase transfer catalysis (34), however, the *p*-toluene sulphonate and acetate esters could be formed, but reduction of these esters with a variety of hydride reagents resulted only in cleavage of the esters or re-isolation of starting materials. Chromanone **5***b* was benzylated using benzyl bromide/K_2CO_3/acetone and reduction of **5***c* with $NaBH_4$ occurred readily (30), as did the subsequent dehydration with TsOH. Unfortunately, the benzylated chromene **1***f* was not a suitable synthetic intermediate. Catalytic hydrogenation with absorption of one equivalent of hydrogen yielded only the deprotected chroman **7***b* and unreacted starting material. Subsequent attempts at dealkylation using a wide variety of reagents noted for their mildness all failed (35–39), yielding only intractable tars.

The phenacyl group (40) proved to be suitable protecting group for the desired synthesis. Reaction of chromanone **5***b* with 2-bromoacetophenone in K_2CO_3/acetone or under phase transfer conditions both failed but, after reduction of **5***b* with LAH, the corresponding chromanol **6***c* was O-alkylated with phenacyl bromide only at the phenolic site (**6***d*). This was then dehydrated with TsOH to give **1***g*, and the deprotection of the phenol effected with Zn in acetic acid. In this manner chromene **1***d* was isolated in high yield with no evidence of polymerization.

While the dehydration of unprotected chromanol **6***c* with TsOH gives only tarry material, reaction with Zn/AcOH gives the 5-OH chroman **7***b* in 67% yield.

The synthesis of 5,7-dihydroxychromenes was next investigated. Although 5,7-dihydroxy chromanones are readily available (26) by the condensation of phloroglucinol and 3,3-dimethylacrylic acid in BF_3 etherate, the applicability of the pyrrolidine catalysed route was examined.

Phloroglucinol was acetylated in good yield with acetonitrile in the presence of HCl and $ZnCl_2$ (41). Treatment of phloroacetophenone (**8**) with pyrrolidine and acetone resulted in a product **9**. This adduct probably arises as a result of initial substitution of a phenolic hydroxyl by pyrrolidine (as in the classical Bucherer reaction (42)), followed by cyclization. This was demonstrated by the sequential reaction of **8** with pyrrolidine, giving adduct **10**, followed by treatment with pyrrolidine/acetone to give chromanone **9**. Chromanone **5***d*, synthesized by another route (27), does not react with pyrrolidine in a Bucherer sense.

X-ray structural analysis was performed on a sample of **9**. Final fractional coordinates for the non-hydrogen atoms are listed in Table 1, and thermal vibration parameters have been deposited.[3] A perspective view of the molecule is shown in Fig.

[3]Tables of observed and calculated structural factors, of final parameters for the hydrogen atoms, of anisotropic thermal vibration parameters for the non-hydrogen atoms, and of bond lengths and bond angles involving hydrogen atoms may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

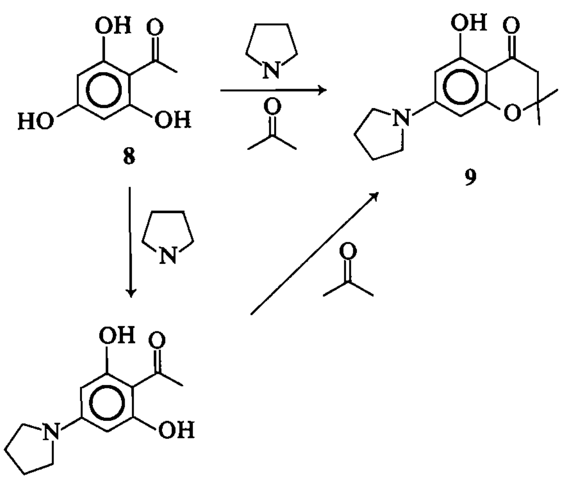
$$B_{eq} = \frac{8}{3}\pi^2 \sum_i \sum_j U_{ij} a_i^* a_j^* \mathbf{a}_i \cdot \mathbf{a}_j.$$



1, and the crystallographic numbering scheme and bond lengths are given in Fig. 2. The C—H bond lengths, which are not shown, vary from 0.90 to 0.99 Å, with a mean value of 0.95 Å. Bond angles are presented in Fig. 3.

With the exception of the C(12) atom, representing an axial methyl group, all the non-hydrogen atoms in the molecule are within 0.5 Å of planarity, but there are statistically significant deviations from each of the constituent mean planes mentioned below. The pyrrolidine ring has an envelope conformation with the C(14) atom displaced 0.395(6) Å from the mean plane through the other four atoms. This plane makes an angle of 6.57° with the mean plane through the benzopyrone system. The aromatic ring is nearly planar, with maximum deviations of 0.008(3) Å, while the dihydropyran ring is in the 1,2-diplanar conformation, with C(2) displaced by 0.606(3) Å from the mean plane through the other five atoms. Endocyclic torsional angles are listed in Table 2.

The bond lengths and angles in the benzopyrone moiety are generally similar to the equivalent values in 3-bromo-2,3-di-

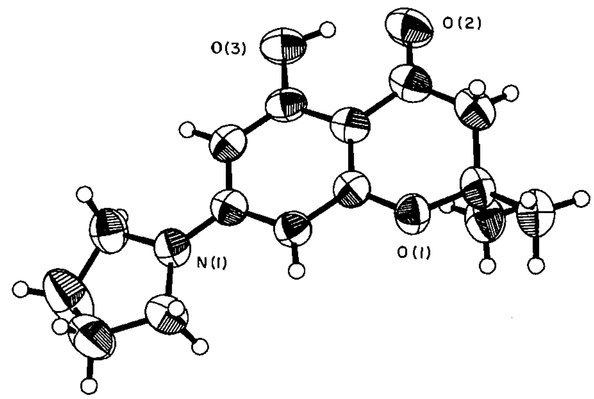


FIG. 1. A perspective view of the molecule. The thermal ellipsoids enclose 50% probability, while hydrogen atoms are shown as arbitrarily small spheres.

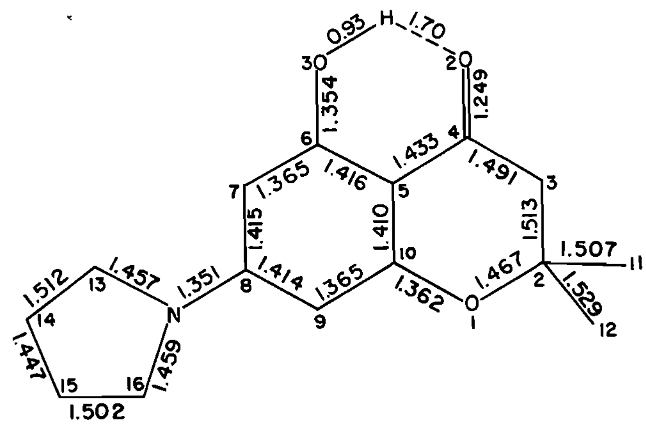

FIG. 2. Crystallographic numbering scheme and bond lengths (Å). The estimated standard deivations are 0.003–0.006 Å.

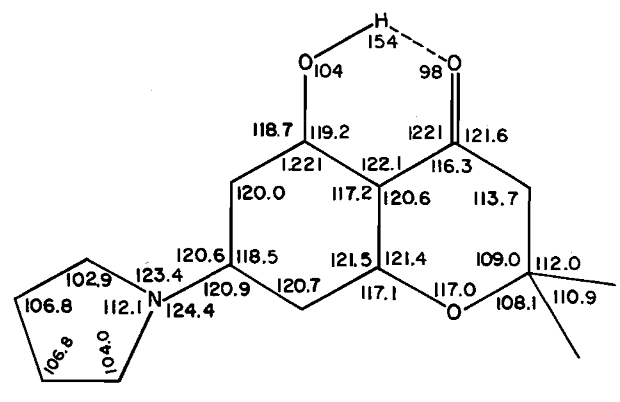

FIG. 3. Bond angles (°). The estimated standard deviations are 0.2–0.4°.

hydro-2-phenyl-4*H*-benzopyran-4-one (43), 4′-bromoflavanone (44), and (−)-2*R*-(2,3-dihydro-2*R*-isopropyl-4-oxo-4*H*-1-benzopyran-6-yl)-*N*-(1*R*-phenylethyl) propionamide (45), see Table 5. However, in the present structure the C(4)=O(2) bond is longer and the adjacent C(4)—C(5) bond is shorter than the equivalent bonds in the other structures. The aromatic ring here shows pronounced quinonoid character, with C(6)—C(7) and C(9)—C(10) significantly shorter than the other four bonds and C(6)—C(5)—C(10) and C(7)—C(8)—C(9) smaller than the other four endocyclic angles. The C(8)—N(1) bond also appears to be shorter than

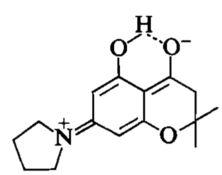
expected for a C_{sp^2}—N_{sp^2} single bond. These observations suggest that some electron polarization is occurring as indicated in **11**, an effect which would be favoured by the strong intramolecular hydrogen bond.



11

The C(14)—C(15) bond in the pyrrolidine group (1.447(4) Å) is very much shortened from the usual single bond length. Such an effect has been observed before in other structures; in sodium 1-pyrrolidine carbodithioate (SPCT) (46), the shortening (to 1.419 Å) is more extreme even at 150 K, while in the structure of sulpiride (47), the equivalent bond is shortened only to 1.483(10) Å. In the present structure the C(14) and C(15) atoms both have very large thermal vibration parameters, indicating that there may be some time-averaged conformational reorientation here, as in SPCT (46).

There are no intermolecular distances shorter than normal van der Waals contacts.

Experimental

Melting points were determined on a Fisher melting point block or a Mettler FP1 melting point apparatus; all melting points are expressed in degrees Celsius, and are uncorrected. The ^{1}H nmr spectra were obtained on Varian EM-360A or Varian T-60A 60-MHz spectrometers using $CDCl_3$ as solvent and tetramethylsilane (TMS) as the internal standard; shifts are expressed in the δ scale and the following abbreviations used: s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet. Infrared (ir) spectra were obtained on a Perkin–Elmer 237B grating spectrophotometer using polystyrene film as a standard; absorbances are expressed in units of cm^{-1}. Mass spectra were determined with an A.E.I. M.S. 12 instrument at Trent University; values are expressed as *m/e* (relative intensity). Combustion analyses were performed by Canadian Microanalytic Laboratories at Guelph, Ontario.

Thin layer chromatographic plates were obtained from E. Merck Reagents (silica gel F-254, 0.25 mm layer thickness); preparative thick layer chromatography was performed on similar plates but with a 2-mm layer of silica gel. Products were detected by viewing under an uv source, or by spraying the plate with 1% ceric ammonium nitrate in 50% aqueous sulphuric acid followed by gentle heating. All ethereal reaction solvents (except for diethyl ether) were dried by refluxing over Na in the presence of benzophenone until a dark blue colour persisted, and then distilled. Anhydrous diethyl ether was purchased from Mallinckrodt and used directly. Spectral grade solvents were used for all other reactions where dryness was not critical.

Carbon-13 spectra were taken on a Bruker WP-80 spectrometer at the National Research Council of Canada, Ottawa, Ontario, or on a Varian CFT-20 at the University of Ottawa, Ottawa, Ontario.

Ethyl-2,6-dimethoxy-cinnamate (4) from 3

Based on a method by Mali and Yadev (48), aldehyde **3** (0.70 g, 4.4 mmol) (49) and methylenecarboethoxytriphenylphosphorane (2.3 g, 6.6 mmol) (50) were refluxed for 1 day in toluene (15 mL) under Ar. The mixture was cooled, washed with two 10-mL portions of 2 *M* HCl, passed through Florisil, and eluted with CH_2Cl_2 (75 mL). Removal of the solvent afforded 0.90 g (3.8 mmol) of cinnamate **4**, essentially pure by tlc (86% yield). The oil solidified upon standing, mp 78–80°C; ir: 1695 (α,β-unsaturated ester); nmr: 1.30 (t, 3H, J = 7 Hz, —OCH_2CH_3), 3.85 (s, 6H, —OCH_3), 4.27 (q, 2H, J = 7 Hz, —OCH_2CH_3), 6.53 (d, 2H, J = 7 Hz, H-3 and H-5), 6.87 (d, 1H, J = 16 Hz, —H), 7.25 (t, 1H, J = 7 Hz, H-4), 7.80 (d, 1H, J = 16 Hz, —H); ms: 236 (100), 205 (96), 191 (96), 177 (95), 161 (19), 148 (45), 133 (26), 105 (18), 91 (20), 77 (18). *Mol. Wt.* (high resolution ms) calcd. for $C_{13}H_{16}O_4$: 236.1098; found: 236.1073.

2,2-Dimethyl-4-keto-7-tosyloxy-benzopyran (5e) from 5d

Chromanone **5*a*** (9.7 g, 50 mmol) (38), K_2CO_3 (50 g), and *p*-toluene sulphonyl chloride (9.5 g, 50 mmol) were refluxed in acetone (100 mL) for 3 h. After cooling, the mixture was filtered and the solvent removed on a rotoevaporator. The residue was recrystallized from MeOH–H_2O, affording pure crystalline **5*e*** (14.9 g, 43 mmol, 86% yield), mp 79–80°C; ir: 1695 (C=O) cm^{-1}; nmr: 1.42 (s, 6H, C-2 *gem* dimethyls), 2.43 (s, 3H, tosyl CH_3), 2.70 (s, 2H, H-3), 6.70 (bs, 2H, H-6 and H-8), 7.35 (bd, 2H, J = 8 Hz, tosyl Ar-H's *ortho* to sulphone), 7.78 (bd, 3H, J = 8 Hz, tosyl Ar-H's *ortho* to methyl and H-5); ms: 347 (14), 346 (56), 332 (21), 331 (94), 291 (35), 155 (50), 91 (100), *m** 317.

2,2-Dimethyl-4-hydroxy-7-tosyloxy-benzopyran (6a) from 5e

To a suspension of $LiAlH_4$ (41.0 g, 10.8 mmol) in ether (50 mL) under argon at 0°C was added, dropwise, chromanone **5*e*** (5.0 g, 14.4 mmol) in dry ether (50 mL). After stirring for 4 h, the reaction was quenched with 20% (v/v) aqueous acetic acid (20 mL). The mixture was stirred until most of the solids had dissolved (about 1 h), ether (100 mL) added, and the mixture was filtered. The aqueous layer was removed, and the organic layer washed with two 100-mL portions of saturated aqueous $NaHCO_3$ solution. Evaporation followed by recrystallization from MeOH–H_2O gave 3.7 g (10.8 mmol, 75%) of pure crystalline **6*a***, mp 107°C; ir ($CHCl_3$): 3350 (phenolic OH) cm^{-1}; nmr: 1.30 (d, 6H, J = 7 Hz, C-2 *gem* dimethyls), 2.43 (s, 3H, tosyl CH_3), 4.80 (d of d, 1H, J = 6.8 Hz, H-4), 6.53 (s, 1H, H-8), 6.58 (d, 1H, J = 4 Hz, H-6), 7.36 (bd, 3H, J = 6 Hz, tosyl Ar-H's *ortho* to sulphone, H-5), 7.76 (d, 2H, J = 8 Hz, tosyl Ar-H's *ortho* to methyl); ms: 348 (52), 315 (35), 293 (36), 155 (100), 91 (87). *Mol. Wt.* (high resolution ms) calcd. for $C_{18}H_{20}O_5S$: 348.1058; found: 348.1044.

Δ^3-2,2-Dimethyl-7-tosyloxy-benzopyran (1e) from 6a

Chromanol **6*a*** (1.00 g, 2.86 mmol) and *p*-toluene sulphonic acid (20 mg) were refluxed in toluene (50 mL) for 15 min. The slightly pink solution was cooled, washed with saturated $NaHCO_3$ solution, the solvent removed, and the residue recrystallized from MeOH–H_2O. Chromene **1*e*** (0.90 g, 2.70 mmol, 94% yield) was obtained as light pink crystals, mp 102°C; nmr: 1.73 (s, 6H, C-2 *gem*-dimethyls), 2.80 (s, 3H, tosyl Ar-CH_3), 5.63 (d, 1H, J = 10 Hz, H-3), 6.40 (d, 1H,

J = 10 Hz, H-4), 6.55 (s, 1H, H-8), 6.62 (d, 1H, J = 4 Hz, H-6), 7.45 (bd, 2H, J = 6 Hz, tosyl Ar-H's *ortho* to sulphone), 7.90 (bd, 24, J = 6 Hz, tosyl Ar-H's *ortho* to methyl); ms: 330 (16), 315 (100), 160 (29), 132 (14), 91 (18); m^* 301. *Mol. Wt.* (high resolution ms) calcd. for $C_{18}H_{18}O_4S$: 330.0935; found: 330.0930.

*2,2-Dimethyl-5-hydroxy-4-keto-benzopyran (5*b*)*

Based on a procedure by Kabbe (28), 2,6-dihydroxy acetophenone (14.4 g, 98.6 mmol), pyrrolidine (12.2 g, 172 mmol), acetone (6.0 g, 103.5 mmol), and toluene (100 mL) were stirred for 4 days under Ar. The mixture was acidified with 2 *N* HCl (100 mL), the organic layer separated and washed with three 50-mL portions of saturated aqueous NaCl, and the solvent removed. The residue was dissolved in CH_2Cl_2 (50 mL), passed through Florisil, and eluted with CH_2Cl_2 (200 mL). After removal of the solvent, the residue was recrystallized from ethanol–water to give **5*b*** as yellow needles (14.0 g, 72.5 mmol, 74% yield), mp 66°C; ir: 3100 (b, w, hydrogen bonded OH), 1565 (hydrogen bonded C=O) cm^{-1}; nmr: 1.47 (s, 6H, C-2, *gem*-dimethyls), 2.75 (s, 2H, H-3), 6.43 (d, 1H, J = 8 Hz, H-6), 6.52 (d, 1H, J = 8 Hz, H-8), 7.40 (t, 1H, J = 8 Hz, H-7); ms: 192 (59), 177 (100), 137 (65), 136 (43), 108 (28). *Mol. Wt.* (high resolution ms) calcd. for $C_{11}H_{12}O_3$: 192.0840; found: 192.0813.

*2,2-Dimethyl-4-keto-5-tosyloxy-benzopyran (5*f*) from 5*b

Chromanone **5*f*** (1.0 g, 5.2 mmol), *p*-toluenesulphonyl chloride (1.1 g, 5.7 mmol), NaOH (1.0 g, 25 mmol), and TEBAC (0.13 g, 0.52 mmol) were stirred in CH_2Cl_2 (25 mL) under Ar for 6 h. The mixture was passed through Florisil, eluted with 100 mL CH_2Cl_2, the solvent removed, and the residue purified by column chromatography (silica gel) to give **5*f*** as a clear oil (1.3 g, 3.7 mmol, 72% yield); ir: 1700 (C=O) cm^{-1}; nmr: 1.33 (s, 6H, C-2 *gem* dimethyls), 2.40 (s, 3H, tosyl CH_3), 2.57 (s, 2H, H-3), 6.70–6.97 (m, 2H, H-6 and H-8), 7.33 (d, 2H, J = 8 Hz, tosyl Ar-H's *ortho* to sulphone), 7.85 (d, 2H, J = 8 Hz, tosyl Ar-H's *ortho* to methyl); ms: 346 (45), 331 (25), 291 (28), 155 (100), 91 (80). *Mol. Wt.* (high resolution ms) calcd. for $C_{18}H_{20}O_5S$: 346.0947; found: 346.0911.

*5-Acetoxy-2,2-dimethyl-4-keto-benzopyran (5*g*) from 5*b

Chromanone **5*b*** (0.10 g, 0.52 mmol), powdered NaOH (0.10 g, 2.5 mmol), and triethyl benzyl ammonium chloride (TEBAC) (0.025 g, 0.12 mmol) were stirred under Ar in dry CH_2Cl_2 (5 mL). Acetyl chloride (2 mL) was added dropwise by syringe and the mixture was stirred for 20 min. Dichloromethane (20 mL) was then added, and the mixture passed through Florisil and eluted with 50 mL CH_2Cl_2. The solvent was removed and the residue purified by thick layer chromatography to give **5*g*** (0.11 g, 0.47 mmol, 90% yield); ir: 1770 (acetate C=O), 1690 (C-4 C=O) cm^{-1}; nmr: 1.43 (s, 6H, C-2 *gem* dimethyls), 2.33 (s, 3H, acetate CH_3), 2.63 (s, 2H, H-3), 6.60 (d, 1H, J = 8 Hz, H-6), 6.83 (d, 1H, J = 8 Hz, H-8), 7.43 (t, 1H, J = 8 Hz, H-7); ms: 234 (17), 192 (72), 177 (100), 137 (57), 136 (39), 108 (27). *Mol. Wt.* (high resolution ms) calcd. for $C_{13}H_{14}O_4$: 234.0930; found: 234.0911.

*5-Benzyloxy-2,2-dimethyl-4-keto-benzopyran (5*c*) from 5*b

Chromanone **5*b*** (0.10 g, 0.52 mmol), benzyl bromide (0.10 g, 0.58 mmol), and K_2CO_3 (0.5 g) were refluxed in acetone (20 mL) for 3 days. The mixture was filtered, the solvent removed, and the residue taken up in 50 mL of ether. After washing with 2 *N* NaOH (30 mL) followed by H_2O (30 mL), the solvent was evaporated. Recrystallization from ether–hexane gave **5*c*** (0.12 g, 0.43 mmol, 83%) as white crystals, mp 128°C; ir: 1685 (C=O) cm^{-1}; nmr: 1.45 (s, 6H, C-2 *gem* dimethyls), 2.70 (s, 2H, H-3), 5.20 (s, 2H, benzylic CH_2), 6.55 (d, 2H, J = 8 Hz, H-6 and H-8), 7.20–7.73 (m, 6H, aromatic H); ms: 282 (11), 91 (100).

*5-Benzyloxy-2,2-dimethyl-4-hydroxy-benzopyran (6*b*) from 5*c

Chromanone **5*c*** (1.8 g, 6.3 mmol) in methanol (10 mL) was added dropwise to $NaBH_4$ (0.34 g, 9.2 mmol) in methanol (30 mL). After stirring overnight under Ar, the excess $NaBH_4$ was destroyed by careful dropwise addition of 2 *N* HCl (30 mL). The resulting solution was diluted with ether (100 mL) and water, and the organic layer separated and washed with a saturated sodium bicarbonate solution (2 × 50 mL). After removal of the solvent, the oily residue (1.7 g, 6.0 mmol, 95% yield) was found to be pure enough (by tlc) to proceed to the dehydration step. A small sample was purified by thick layer chromatography for analysis, confirming its identity as **6*b***; ir: 3450 (benzylic OH) cm^{-1}; nmr: 1.32 (s, 3H, C-2 methyl), 1.42 (s, 3H, C-2 methyl), 2.03 (d, 2H, J = 6 Hz, H-3), 3.37 (bs, 1H, C-4 OH), 5.10 (t, 1H, J = 6 Hz, H-4), 5.13 (s, 2H, benzyl CH_2), 6.57 (d, 2H, J = 7 Hz, H-6, and H-8), 7.30 (t, 1H, J = 7 Hz, H-7), 7.47 (s, 5H, benzyl Ar-H).

*Δ^3-5-Benzyloxy-2,2-dimethyl-benzopyran (1*g*) from 6*b

Chromanol **6*b*** (1.6 g, 5.6 mmol) was dissolved in dry toluene (50 mL). The solution was brought to reflux under Ar, and *p*-toluene sulphonic acid (50 mg, 0.29 mmol) was added in one portion. After refluxing for 15 min, the solution was allowed to cool and washed with two 10-mL portions of 2 *N* NaOH, followed by one 50-mL portion of distilled water. The organic layer was passed through Florisil, eluted with CH_2Cl_2 (100 mL), and the solvent removed to give chromene **1*g*** (1.4 g, 5.2 mmol, 93%) as a slightly yellow oil, essentially pure by tlc. A small sample was purified further by thick layer chromatography; nmr: 1.47 (s, 6H, C-2 *gem* dimethyls), 5.13 (s, 2H, benzyl CH_2), 5.60 (d, 1H, J = 10 Hz, H-3), 6.53 (d, 1H, J = 8 Hz, H-8), 6.51 (d, 1H, J = 8 Hz, H-6), 6.82 (d, 1H, J = 10 Hz, H-4), 7.47 (s, 5Hz, benzyl Ar-H); ms: 266 (35), 251 (99), 160 (41), 91 (100), 65 (26). *Mol. Wt.* (high resolution ms) calcd. for $C_{18}H_{18}O_2$: 266.1347; found: 266.1327.

*5-Hydroxy-2,2-dimethyl-benzopyran (7*b*) from 1*g

Chromene **1*g*** (0.10 g, 0.37 mmol), Pd/C (0.1 g), and dry ethanol (5 mL) were stirred under a hydrogen atmosphere. When 8 mL of hydrogen were consumed, the reaction vessel was removed, the solution filtered, and the solvent removed. After separation by thick layer chromatography, 43 mg of starting material was recovered along with **7*b*** (32 mg, 0.18 mmol, 86% yield based on recovered starting material); ir: 3350 (b, phenolic O—H) cm^{-1}; nmr: 1.30 (s, 6H, C-2 *gem* dimethyls), 1.78 (t, 2H, J = 6 Hz, H-3), 2.67 (t, 2H, J = 6 Hz, H-4), 5.10 (bs, 1H, phenolic O—H), 6.33 (d, 1H, J = 8 Hz, H-6), 6.45 (d, 1H, J = 8 Hz, H-8), 7.00 (t, 1H, J = 8 Hz, H-7); ms: 178 (60), 163 (22), 123 (100), 94 (17). *Mol. Wt.* (high resolution ms) calcd. for $C_{11}H_{14}O_2$: 178.1028; found: 178.1011.

*4,5-Dihydroxy-2,2-dimethyl-benzopyran (6*c*) from 5*b

To a suspension of $LiAlH_4$ (0.1 g, 26.3 mmol) in anhydrous ether (50 mL) under Ar was added, dropwise, **5*b*** (504 mg, 2.23 mmol) in

$T = \exp\left[-2\pi^2\left(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{23}klb^*c^* + 2U_{13}hla^*c^* + 2U_{12}hka^*b^*\right)\right]$.

anhydrous ether (20 mL) and stirring continued overnight. After cooling to 0°C, 1 mL of water, then 1 mL of 3 *N* NaOH, and finally 3 mL of water were added sequentially and dropwise to the reaction mixture. The solids were filtered by suction, washed with ether, and the solvent removed to give **6***c* (451 mg, 2.32 mmol, 88%) as a clear oil. Purification was unnecessary; ir: 3300 (phenolic OH, benzylic OH) cm^{-1}; nmr: 1.27 (s, 3H, C-2 methyl), 1.37 (s, 3H, C-2 methyl), 2.03 (d, 2H, J = 6 Hz, H-3), 3.77 (m, 1H, C-4 OH), 5.12 (t, 2H, J = 6 Hz, H-4), 6.42 (d, 2H, J = 8 Hz, H-6 and H-8), 7.08 (t, 1H, J = 8 Hz, H-7).

*2,2-Dimethyl-5-hydroxy-benzopyran (7*b*) from 6*c

Chromanol **6***c* (1.0 g, 5.2 mmol), Zn dust (2.0 g), and acetic acid (20 mL) were stirred overnight. After addition of methanol (100 mL), solid $NaHCO_3$ was added with vigorous stirring until no further CO_2 evolution was noted. The mixture was filtered and the solvent removed to afford 0.63 g of chroman **7***a* (3.5 mmol, 67% yield), essentially pure by tlc.

*2,2-Dimethyl-4-hydroxy-5-phenancyloxy-benzopyran (6*d*) from 6*c

Compound **6***c* (100 mg, 0.51 mmol), K_2CO_3 (1 g), and phenacyl bromide (110 mg, 0.55 mmol) were refluxed in acetone (20 mL) under Ar for 3 h. The orange solution was filtered, the solvent removed, and the residue purified by thick layer chromatography to give **6***d* (128 mg, 0.41 mmol, 81%) as a yellow oil; ir: 3450 (benzylic OH), 1700 (phenacyl C=O) cm^{-1}; nmr: 1.34 (s, 3H, C-2 methyl), 1.43 (s, 3H, C-2 methyl), 2.08 (d, 2H, J = 6 Hz, H-3), 5.13 (t, 1H, J = 6 Hz, H-4), 5.39 (5.24, benzyl CH_2), 6.41 (d, 2H, J = 8 Hz, H-6 and H-8), 6.90 (t, 1H, J = 8 Hz, H-7), 7.30–8.10 (m, 6H, phenacyl Ar-H); ms: 312 (4), 295 (100), 177 (12), 149 (85).

*Δ^3-2,2-Dimethyl-5-phenacyloxy-benzopyran (1g) from 6*d

Compound **6***d* (100 mg, 0.32 mmol) was dissolved in toluene (10 mL) and brought to reflux under Ar. *p*-Toluene sulphonic acid (1 mg) was added, and reflux was continued for 15 min. After allowing the solution to cool, it was washed with 2 *N* NaOH (20 mL), passed through Florisil, and eluted with CH_2Cl_2 (50 mL). Removal of the solvent gave chromene **1***g* (89 mg, 0.30 mmol, 93% yield), essentially pure by tlc; ir: 1700 (C=O) cm^{-1}; nmr: 1.42 (s, 6H, C-2 *gem* dimethyls), 5.25 (s, 2H, phenacyl CH_2), 5.57 (d, 1H, J = 10 Hz, H-3), 6.32 (d, 1H, J = 8 Hz, H-8), 6.34 (d, 1H, J = 8 Hz, H-6); ms: 295 (100), 294 (24), 279 (44), 223 (21), 161 (19), 105 (26).

*Δ^3-2,2-Dimethyl-5-hydroxy-benzopyran (1*d*) from 1g*

Chromene **1***g* (140 mg, 0.48 mmol) was dissolved in a mixture of H_2O (5 mL) and glacial acetic acid (15 mL). After adding zinc dust (0.13 g, 2.0 mmol) the solution was stirred under Ar overnight. The mixture was filtered, diluted with methanol (50 mL), and neutralized with solid $NaHCO_3$ under vigorous stirring until no CO_2 evolution was apparent. The mixture was again filtered, and the solvent removed. Pure **1***d* was obtained by thick layer chromatography (62 mg, 0.35 mmol, 74%) as pale white flakes. All physical and spectral data was identical to an authentic sample of **1***d*.

2,2-Dimethyl-5-hydroxy-4-keto-7-pyrrolidinyl-benzopyran (9) from 8

A mixture of acetophenone **8** (3.1 g, 19.1 mmol) (30), pyrrolidine (3.2 mL, 2.7 g, 38.0 mmol), and acetone (1.6 g, 33.3 mmol) were heated in toluene (75 mL) until all of the solids were dissolved (~40°C), under Ar. Stirring was continued for 3 days, after which the reaction was cooled, washed with 2 *N* HCl, and the solvent removed. The residue was dissolved in CH_2Cl_2, passed through Florisil, and eluted with CH_2Cl_2. After removal of the solvent, the remaining material was recrystallized from MeOH–H_2O to give pure **9** (1.9 g, 7.2 mmol, 38% yield), mp 143–144°C; ir (KBr pellet): 3450 (phenolic OH), 1665 (aromatic hydrogen bonded C=O) cm^{-1}; nmr: 1.45 (s, 6H, C-2 *gem* dimethyls), 2.00 (m, 4H, pyrrolidinyl H3 and H4), 2.63 (s, 2H, H-3), 3.35 (t, 4H, J = 6 Hz, pyrrolidinyl H2 and H5), 5.63 (bs, 2H, H-6 and H-8); ^{13}C nmr: 25.35 (9, C-2 *gem* dimethyls), 26.92 (t, pyrrolidinyl C-3 and C-4), 47.45 (t, C-3), 47.70 (9, pyrrolidinyl C-1 and C-5), 91.28 (d, C-8), 91.39 (d, C-6), 99.10 (s, C-10), 154.78 (s, C-7), 160.83 (s, C-5), 160.83 (s, C-5), 163.56 (s, C-9), 193.47 (s, C-4); ms: 262 (18), 261 (100), 246 (53), 206 (47). *Anal.* calcd.: C 68.67, H 7.70, N 5.34; found: C 68.81, H 7.44, N 5.38.

2,6-Dihydroxy-4-pyrrolidinyl-acetophenone (10) from 8

A mixture of acetophenone **8** (100 mg, 0.617 mmol) and pyrrolidine (1 mL) was stirred at 40°C under Ar for 3 days in toluene (10 mL). After cooling, the solvent was removed on the rotoevaporator and the residue dissolved in CH_2Cl_2, passed through Florisil, and eluted with more CH_2Cl_2. After removal of the solvent, purification by thick layer chromatography gave **10** as an oil (41 mg, 0.19 mmol, 31%); ir: 3300 (b, phenolic OH), 1635 (aromatic hydrogen bonded C=O) cm^{-1}; nmr: 1.80–2.16 (m, 44, pyrrolidinyl H-3 and H-4), 2.58 (s, 3H, $COCH_3$), 3.10–3.47 (m, 4H, pyrrolidinyl H-1 and H-5), 5.67 (s, 2H, H-3 and H-5); ms: 221 (52), 207 (12), 206 (100); *m** 192.

Compound **9** crystallized from ethanol as colourless translucent prisms. The specimen picked for X-ray study had dimensions 0.2 × 0.4 × 0.5 mm. It was mounted with its elongation direction parallel to the ϕ axis on an Enraf–Nonius CAD-4F diffractometer and the following data were obtained.

$C_{15}H_{19}NO_3$ f.w. 261.32

Monoclinic, $P2_1/c$, a = 11.319(1), b = 6.376(1), c = 19.563(2) Å, β = 104.59(1)°, V = 1366.3 Å^3, Z = 4, ρ_c = 1.270 g cm^{-3}, μ(MoKα) = 0.95 cm^{-1}, F(000) = 560.

Cell dimensions were measured with Ni-filtered Cu radiation ($\lambda(K\alpha_1)$ = 1.54056, $\lambda(K\alpha_2)$ = 1.54439 Å) using the θ values of 25 carefully centered reflections. The relative intensity measurements were made with monochromatized Mo radiation ($\lambda(K\bar{\alpha})$ = 0.7107 Å), using $\omega-2\theta$ scans over ω ranges of $(1.2 + 0.4 \tan\theta)°$, extended by 25% at each end for the backgrounds, at scan speeds of 0.63 to 5.03 min^{-1} in ω. A total of 2401 independent reflections in the hkl and hKl octants, $\theta \le 25°$, were measured and 1498 of these, with $I \ge \sigma(I)$, were considered observed. Two standard reflections were monitored at intervals of 100 min exposure time, and their intensities showed random fluctuations of ±2% and ±2.3%. The net intensities were corrected for Lorentz and polarization effects; no absorption correction was applied.

The structure was determined by direct methods, and refined by block-diagonal least-squares calculations, minimizing $\Sigma w(|F_o| - |F_c|)^2$. All hydrogen atoms were located on a difference map, and refined with isotropic thermal parameters, Table 3, while non-hydrogen atoms were refined anisotropically (Tables 4 and 5). However, the hydrogen atom parameters associated with the pyrrolidine group did not converge satisfactorily, and ultimately were held constant. The weighting scheme used for the final stages of refinement was: $\sqrt{w}$ = 1 if $|F_o| \le 25.0$, $\sqrt{w} = 25.0/|F_o|$ if $|F_o| > 25.0$, and $\sqrt{w} = \sqrt{w} \times \sin^2 0.0536$ if $\sin^2\theta < 0.0536$. This scheme made $\langle w(F_o - F_c)^2\rangle$ values essentially independent of $|F_o|$ and of $\sin^2\theta$. In the final least-squares cycle, the mean (shift/estimated standard deviation) was 0.03, and all shifts were less than 0.20 σ. The final R value was 0.0466 for all observed reflections, and R_w was 0.054. A difference map calculated from the final structure factors contained random densities between 0.25 and −0.19 e/Å^3. Scattering factor values for C, N, and O were taken from International Tables for X-ray Crystallography, Vol. IV (51), and values for H were taken from Stewart, Davidson, and Simpson (52).

The systematic absences are ($h0l$) if l is odd, ($0k0$) if k is odd, these specify space group $P2_1/c$ uniquely. No violations were noticed in the preliminary experimental work: for the main intensity measurement process the systematic absence conditions were incorporated into the data collection parameters.

^1H nuclear magnetic resonance spectral parameters of toluene. Implications for conformational analysis and isotope shifts

TED SCHAEFER, RUDY SEBASTIAN, AND GLENN H. PENNER
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received December 19, 1984

TED SCHAEFER, RUDY SEBASTIAN, and GLENN H. PENNER. Can. J. Chem. **63**, 2597 (1985).

A precise analysis of the ^1H nmr spectrum of toluene as a dilute solution in carbon disulfide yields a revised set of spectral parameters. The chemical shift of the *para* proton lies 12.6 ppb to low frequency of that of the *ortho* protons at 300 K. The ring proton chemical shifts are discussed and compared with ^1H and ^3H shifts observed in carbon tetrachloride. The long-range couplings between methyl and ring protons can be said to be quantitatively understood in terms of σ and $\sigma-\pi$ electron transmitted mechanisms. The changes observed in these three couplings in phenylacetaldehyde can be quantitatively reproduced in terms of these mechanisms and also illustrate how these changes are direct measures of the conformational preferences in this molecule.

TED SCHAEFER, RUDY SEBASTIAN et GLENN H. PENNER. Can. J. Chem. **63**, 2597 (1985).

Une analyse précise des spectres rmn du ^1H du toluène, en solution diluée dans le disulfure de carbone, a permis d'obtenir un nouvel ensemble de paramètres spectraux. À 300 K, le déplacement chimique du proton *para* se situe à une fréquence de 12,6 ppb plus basse que celle des protons *ortho*. On discute des déplacements chimiques des protons du cycle et on les compare avec les déplacements des ^1H et ^3H qui ont été déterminés en solution dans le tétrachlorure de carbone. On peut dire que l'on peut expliquer quantitativement les couplages à longue distance entre les protons du cycle et ceux du groupement méthyle en faisant appel à des mécanismes impliquant que les électrons sont transmis par les liaisons σ et $\sigma-\pi$. On peut reproduire quantitativement les changements observés dans ces trois couplages du phénylacétaldéhyde en faisant appel à ces mécanismes; de plus, on peut illustrer comment ces changements sont des mesures directes des préférences conformationnelles dans cette molécule.

[Traduit par le journal]

Introduction

A remarkable early analysis of the tightly coupled ^1H nmr spectrum (1) of neat toluene yielded spectral parameters of interest in a variety of applications. The order of the chemical shifts of the ring protons is solvent dependent and is of interest from the viewpoint of the methyl group as an electron donor (2) and in the use of ^3H nmr spectroscopy (3). The coupling constants are of use in, for example, the analysis of ^{13}C nmr spectra (4–6) and in the theory of spin–spin coupling mechanisms (7–9). In particular, the long-range couplings over four, five, and six formal bonds between the methyl and ring protons, $^4J(H,CH_3)$, $^5J(H,CH_3)$, and $^6J(H,CH_3)$, constitute the reference points for theoretical computations of $\sigma-\pi$ and other coupling mechanisms (7) and for the use of these couplings as detailed conformational indicators (8–10).

With modern nmr instrumentation, the precision of calibration procedures and the chemical shift dispersion have improved significantly. It becomes desirable to provide somewhat more precise spectral parameters for toluene than could be obtained with older instruments.

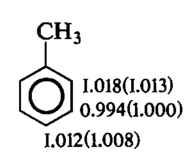
Results and discussion

In Table 1 the ^1H nmr spectral parameters are given for toluene as a dilute solution in a CS_2/C_6D_{12}/TMS mixture. The precision of the parameters is understandably rather higher than that of previous analyses at lower spectrometer frequencies and some of their values differ significantly from those in the literature (1, 2, 11). Figure 1 illustrates the computed and observed ^1H nmr spectra of the methyl protons.

The chemical shifts

Solvent effects (12–14) on chemical shifts are well known, of course, particularly the large differential solvent shifts caused by aromatic solvents (12–18). The latter no doubt account for the fact that in neat toluene the *ortho* protons resonate to high field of the *para* proton, whereas in other solvents, including that in Table 1, the *para* protons are most shielded (2, 3).

The ring proton shifts, measured at 100 MHz in CCl_4, were extrapolated to infinite dilution (2), as were the ^3H nmr shifts (3). From these results it is clear that measurement at 2.0 mol% as in Table 1 yields a maximum difference of less than 0.002 ppm between these shifts and those at infinite dilution. In Table 2 are given the high field shifts, Δ, relative to benzene, caused by the methyl substituent in toluene. In CS_2 solution, Δ_P is 0.212 ppm, which may be compared with an INDO calculation (19) of 0.28 ppm. Qualitatively, the positive Δ_P is expected because the methyl group is a π electron donor. However, all the ring proton resonances shift to high field in the presence of the methyl substituent whereas the MO theories (20, 21) imply that the electron density decreases at the *meta* position relative to benzene. Furthermore, the computed π electron densities in **1** at the *para* position are too small to account for the upfield shift of 0.21 ppm, if the common proportionality (22) of about 11 ppm/electron is accepted (of course, the π electron densities at the *meta* position of common π electron donors like NH_2 or OCH_3 are also calculated to be less than in benzene, yet the *meta* proton shifts in aniline and anisole lie upfield from benzene (23)). Solvent effects are not likely the source of such discrepancies. Thus, the π charge distribution for toluene in CS_2 solution, determined from absolute infrared band intensities (25) and given in parentheses in **1**, also disagrees with a simple model of this kind. These matters have been discussed



1

TABLE 1. ^{1}H nuclear magnetic resonance spectral parameters for a 2.0 mol% solution in CS_2[a] at 300 K

Parameter	Value	Parameter	Value
ν_{CH_3}	688.561(1)[b,c]	$^5J_{25}$	0.610(1)
ν_o	2106.558(1)[d]	$^4J(H,CH_3)$	−0.702(1)
ν_m	2130.281(1)	$^5J(H,CH_3)$	0.329(1)
ν_p	2102.784(2)	$^6J(H,CH_3)$	−0.602(2)
$^3J_{23}$	7.655(2)[e]	Transitions calcd.	566
$^3J_{34}$	7.417(2)	Transitions assigned	408
$^4J_{26}$	1.902(3)	Peaks observed	147
$^4J_{35}$	1.442(2)	Largest difference	0.032
$^4J_{24}$	1.273(3)	Root mean square deviation	0.013

[a]Containing also 10 mol% of C_6D_{12} and 0.5 mol% TMS.
[b]In Hz at 300.135 MHz to low field of TMS.
[c]Numbers in parentheses are standard deviations in the last significant figure.
[d]At the same concentration in this solvent, $\nu_{C_6H_6}$ is 2166.440 Hz.
[e]The largest correlations among the parameters are: ν_m/ν_p 0.19, $\nu_o/^4J_{26}$ −0.22, $\nu_p/^4J_{26}$ 0.16, $\nu_p/^3J_{34}$ 0.27, $^3J_{23}/^4J_{35}$ −0.16, $^3J_{23}/^4J_{26}$ −0.20.

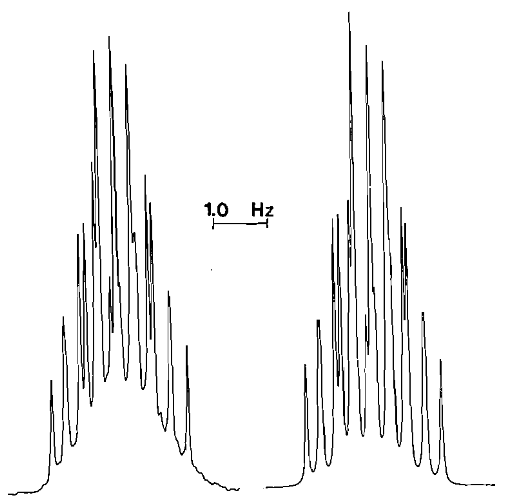


FIG. 1. The ^{1}H nmr spectrum of the methyl protons in toluene in 300 K as a 2.0 mol% solution in CS_2 and containing 10.0 mol% cyclohexane-d_{12} and 0.5 mol% tetramethylsilane. The computed spectrum assumes the spectral parameters in Table 1. The computed spectrum has lorentzian line shapes whereas the observed spectrum contains a small amount of gaussian character. In addition, the baseline of the observed spectrum is not identical to that of the computed spectrum. The discrepancies between the two spectra are only apparent in the sense that peak frequencies, on which the analysis is based, are in satisfactory agreement. The spectra were recorded on a scale of 0.5 Hz/cm.

(24) and it is shown that ^{1}H shifts at the *meta* and *para* positions can be roughly related to computed σ-electron populations at hydrogen if certain correction terms are included.

Based on somewhat complex referencing procedures (3, 26), it was concluded that aromatic tritons resonate *downfield* from aromatic protons. The Δ values in Table 2 appear to confirm this conclusion because the ^{1}H nmr shift of benzene in the appropriate solvent is used to calculate the Δ values (the shift of ^{3}H in [^{3}H]-benzene relative to the shift of ^{1}H in benzene is apparently unavailable). This isotope effect amounts to 0.04_3 ppm at each position in toluene if the data in rows 2 and 3 of Table 2 are considered to be most reliable. Note that

TABLE 2. Ring proton chemical shift changes caused by the methyl group in toluene

Solvent	Δ_o[d]	Δ_m[d]	Δ_p[d]	$\Delta_p - \Delta_o$	$\Delta_o - \Delta_m$	$\Delta_p - \Delta_m$
CCl_4[a]	0.201	0.124	0.220	0.019	0.077	0.076
CS_2[b]	0.199_5	0.120_5	0.212	0.013	0.079	0.093
CCl_4[c]	0.156	0.077	0.171	0.015	0.079	0.094

[a]Analyses at 100 MHz and extrapolation to infinite dilution, $\delta_{C_6H_6}$ is 7.262 ppm.
[b]Present results, $\delta_{C_6H_6}$ is 7.218 ppm.
[c]From ^{3}H nmr shifts, taking $\delta_{C_6H_6}$ as 7.262 ppm.
[d]A positive Δ implies a high-field shift relative to benzene.

the *differences* between the Δ values for these two rows agree rather well.

However, these results should not be taken as proof that tritons are less shielded than protons in the same position (primary isotope effect). Because the change in shielding caused by bond lengthening is negative (27), it is most likely that the aromatic tritons are more shielded than aromatic protons. Accordingly, the apparent negative isotope shift in Table 2 is a consequence of the reference procedure using tetramethylsilane and singly tritiated tetramethylsilane (26).

The long-range couplings to methyl protons

$^4J(H,CH_3) \equiv {}^4J$, sometimes called an *ortho* benzylic coupling, was originally found to be −0.75 Hz (1). Its value in Table 2 is −0.702(1) Hz. In a recent (8) detailed investigation of ^4J and its conformational dependence in aromatic systems, it was written as

$$[1] \quad {}^4J\ (\mathrm{Hz}) = 6.90\ \pi \sin^2\theta - 0.32 \cos^2\theta$$

where π is the mutual atom−atom polarizability and θ is the angle by which the α C—H bond twists out of the benzene plane. For toluene π is −0.157 and we rewrite eq. [1] as eq. [2],

$$[2] \quad {}^4J\ (\mathrm{Hz}) = -1.08\langle\sin^2\theta\rangle - 0.32\langle\cos^2\theta\rangle$$

where angular brackets indicate expectation values. The latter are 0.5 for toluene, whether or not the methyl group rotates rapidly, so that ^4J is calculated as −0.70 Hz, exactly as given in Table 1.

The INDO MO FPT computations (7) of ^4J are reproduced by eq. [3], where the indicated errors come from the 95%

$$[3] \quad {}^4J\ (\mathrm{Hz}) = -0.342(5) - 1.005(6)\sin^2\theta - 0.230(5)\sin^2(\theta/2)$$

confidence level. This equation predicts ^4J as −0.96 Hz, clearly an overestimate of its magnitude. An empirical adjustment might proceed as follows. The expectation value of $\sin^2(\theta/2)$ is again 0.5, so that eq. [3] becomes ^4J (Hz) = −0.457 − 1.005 $\sin^2\theta$. If the numbers are scaled by 0.70/0.96, one has ^4J (Hz) = −0.33 − 0.73 $\sin^2\theta$ or a value of -0.69_5 Hz. Of course, eq. [2] may also be written as ^4J (Hz) = −0.32 − 0.76 $\sin^2\theta$ for toluene (high symmetry). The angle independent term in eq. [3] does seem unsatisfactory, however.

The ring-substituent dependence of ^4J can be large because of changes in the atom−atom polarizability (8). However, in 3-fluorotoluene the ^4J values are −0.693(2) Hz for H-3 and −0.701(2) Hz for H-6, while in 2-chloro-5-fluorotoluene ^4J is −0.700(3) Hz (28). On the other hand, ^4J is −0.779(2) Hz in 2-fluorotoluene (29) and −0.714(3) Hz in 4-fluorotoluene (30). All these numbers are for CS_2 solutions.

TABLE 3. The ^{1}H spectral parameters for a 3 mol% solution of phenylacetaldehyde in benzene-d_6 at 294 K and 300.135 MHz

Parameter	Value	Parameter	Value
ν(COH)[a]	2877.281(1)[b]	^4J(H,CH$_2$)	−0.564(1)
ν(CH$_2$)	911.543(1)	$^5J_{25}$	0.606(1)
$\nu_2 = \nu_6$	2044.701(1)	^5J(H,CH$_2$)	0.282(1)
$\nu_3 = \nu_5$	2118.595(1)	^5J(H,CHO)	0.000(1)[c]
ν_4	2206.749(2)	^6J(H,CH$_2$)	−0.399(2)
^3J(H,CH$_2$)	2.357(1)	^6J(H,CHO)	0.000(1)[c]
$^3J_{23}$	7.683(1)	^7J(H,CHO)	(−)0.001(2)[c]
$^3J_{34}$	7.497(2)	Calcd. transitions	776
$^4J_{24}$	1.253(2)	Assigned transitions	403
$^4J_{26}$	1.937(2)	Largest difference	0.032
$^4J_{35}$	1.474(1)	Root mean square deviation	0.010

[a]In Hz at 300.135 MHz to low field of internal tetramethylsilane.
[b]Numbers in parentheses are the standard deviations in the last significant figure.
[c]No evidence for finite magnitudes of these couplings existed in the spectrum, but the couplings were allowed to vary in the iterations.

Turning to $^5J(\mathrm{H,CH_3}) \equiv {}^5J$, it has been proposed (9) that ^5J is given by eq. [4].

$$[4] \quad {}^5J = {}^5J^{\pi} \sin^2\theta + {}^5J^{\sigma} \sin^2(\theta/2)$$

In eq. [4] the $\sigma-\pi$ electron contribution is given by 0.336 Hz (9). Then $^5J^{\sigma}$, the σ-electron component, is 0.322 Hz because ^5J in toluene is 0.329(1) Hz in Table 1. Hence eq. [4] becomes eq. [5].

$$[5] \quad {}^5J\ (\mathrm{Hz}) = 0.336\langle\sin^2\theta\rangle + 0.322\langle\sin^2(\theta/2)\rangle$$

The observed ring substituent dependence of ^5J is relatively large (9). ^5J is 0.300(1) Hz in 3-fluorotoluene and is as large as 0.438(2) Hz in 2,6-difluorotoluene.

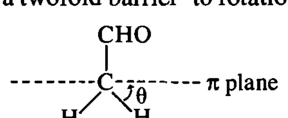
Unlike ^5J, the coupling over six bonds, $^6J(\mathrm{H,CH_3}) \equiv {}^6J$ is insensitive to ring substitution. ^6J in toluene is −0.602(2) Hz (Table 1) and varies from −0.584(2) Hz in 2-fluoro-6-aminotoluene to −0.622(1) Hz in 2,3,5,6-tetrafluorotoluene (29). Experimentally and theoretically it appears that eq. [6] holds for ^6J, where

$$[6] \quad {}^6J = {}^6J_{90} \sin^2\theta$$

$^6J_{90}$ is its value when the α C—H bond lies in a plane perpendicular to the benzene plane (7, 10). It appears that $^6J_{90}$ is −1.20 Hz.

A test of equations [2], [5], and [6]

For a 3 mol% solution of phenylacetaldehyde in benzene-d_6, we find ^4J, ^5J, and ^6J as −0.564(1), 0.282(1), and −0.399(2) Hz, respectively (precise analyses of benzyl compounds are scarce and therefore the spectral parameters are given in Table 3). The value of ^6J implies that **2** is the preferred conformation and that $\langle\sin^2\theta\rangle$ is −0.339/−1.20 or 0.332. With the assumption of a twofold barrier[1] to rotation about the C—C



$\theta = 30°$

2

[1]An STO 3G MO computation (see Experimental) suggests that **2** is 8 kJ/mol more stable than a conformer with $\theta = 60°$ (aldehyde function in-plane).

bond to the phenyl group (10), this value of $\langle\sin^2\theta\rangle$ corresponds to 9.7 kJ/mol. It also follows that $\langle\cos^2\theta\rangle$ is 0.668 and therefore, from eq. [2], that ^4J should be −0.572 Hz. The observed value is −0.564(1) Hz. Again, from eq. [5], one has ^5J as 0.273 Hz because for a twofold barrier (31) $\langle\sin^2(\theta/2)\rangle$ is 0.5. The measured value is 0.282(1) Hz. The consistency among calculated and observed numbers is taken as adequate. The utility of these long-range couplings and its reliance on the precise values in Table 1 are thereby shown. It remains to be investigated just how sensitive the couplings are to the electronic nature of the atom attached to the methylene group.

Experimental

A 2.0 mol% solution of toluene in CS$_2$, containing 10 mol% cyclohexane-d_{12} and 0.5 mol% tetramethylsilane, was transferred to a 5-mm od nmr tube. The solution was degassed by the freeze−pump−thaw procedure and the sample tube was flame sealed. The ^{1}H nmr spectrum was accumulated at a probe temperature of 300 K on a Bruker AM300 spectrometer. A 3.0 mol% solution of phenylacetaldehyde in benzene-d_6 solution was treated similarly, except that the probe temperature was 294 K.

A wide sweepwidth survey spectrum was obtained in order to reference the spectrum with respect to TMS, and to obtain the locations of the aromatic and sidechain regions. Each region was examined in detail, with sweepwidth and data region adjusted to given acquisition times of approximately 40 s. Four to sixteen scans were acquired. Zero filling to twice the original data region was done before transforming the FIDs using a small amount of gaussian multiplication. Linewidths at half height were approximately 0.08 Hz after this resolution enhancement.

The ^{1}H nmr spectrum was analyzed with the computer program NUMARIT (32), extensively modified by R.S.

The STO 3G MO computations employed the program MONSTERGAUSS (33) and were performed on an Amdahl V8 system. Geometry optimization of all bond angles and bond lengths was done at $\theta = 0°$ and 90°. However, the phenyl framework was constrained to remain a regular hexagon.

Acknowledgments

We are grateful to the Natural Sciences and Engineering Research Council of Canada for financial assistance and to a referee for very instructive comments.

Réactivité du nucléophile azoture vis-à-vis de cations hétérocycliques aromatiques. VIII. Réarrangement de β-tétrazolo-*trans*-benzalacétophénones

JEAN-CLAUDE CHERTON, MARC BAZINET, MARIE-MADELEINE BOLZE, MARC LANSON ET PAUL-LOUIS DESBENE
Laboratoire de chimie organique structurale, Université de Paris VI, 8, rue Cuvier, 75230 Paris Cédex, France

Reçu le 13 novembre 1984

JEAN-CLAUDE CHERTON, MARC BAZINET, MARIE-MADELEINE BOLZE, MARC LANSON et PAUL-LOUIS DESBENE. Can. J. Chem. **63**, 2601 (1985).

Les β-tétrazolo-*trans*-benzalacétophénones (T) s'isomérisent au chauffage en iminoazides (I.A.) correspondants. Ces derniers, non isolables, subissent selon les conditions du milieu diverses évolutions. Ils peuvent être interceptés par les bases organiques comme la triphénylphosphine et la pyridine. En solvants aromatiques, ils évoluent avec perte d'azote par l'intermédiaire de diazirines et d'oxadiazépines vers des hétérocycles diazotés à cinq chaînons: pyrazoles et imidazoles *N*-benzoylés. L'emploi d'un solvant protique favorise l'isomérisation des tétrazoles en iminoazides. On observe alors la solvolyse des formes azidooxazines et même oxazinium résultant de la suite d'équilibres et réaction:

(T) $\leftrightarrows$ (I.A.) $\leftrightarrows$ azidooxazine $\rightarrow$ oxazinium.

JEAN-CLAUDE CHERTON, MARC BAZINET, MARIE-MADELEINE BOLZE, MARC LANSON, and PAUL-LOUIS DESBENE. Can. J. Chem. **63**, 2601 (1985).

β-Tetrazolyl-*trans*-benzalacetophenones (T) isomerize upon heating into the corresponding azido-azomethines (A). These non-isolable products undergo various transformations depending on the reaction conditions. With organic bases such as triphenylphosphine or pyridine, their interception can occur. In aromatic solvents, a rearrangement involving loss of nitrogen leads to five-membered diazoted heterocycles: *N*-benzoyl imidazoles and pyrazoles, via intermediate diazirines and oxazepines. Protic solvents have been found to facilitate the isomerisation of tetrazoles into azidoazomethines. Solvolysis of the azido-oxazine and in some cases of the oxazinium species resulting from the equilibrium and reaction:

(T) $\leftrightarrows$ (A) $\leftrightarrows$ azidooxazine $\rightarrow$ oxazinium

are then observed.

Dans un précédent article, nous avons décrit le comportement de cations oxaziniums-1,3 **1** (1) vis-à-vis du nucléophile azoture. Nous avons montré que la formation des β-tétrazolo-*trans*-benzalacétophénones **2** (notées plus rapidement "tétrazoles") résultait selon toute vraisemblance d'une attaque de N_3^- sur le pôle C2 du cation hétéroaromatique conduisant transitoirement aux azido-2 2*H*-oxazines-1,3 **3** correspondantes. La filiation azide **3** → tétrazole **2** était interprétée comme résultant de la superposition de deux tautoméries de type cycle–chaîne autour de l'iminoazide **4** (cf. schéma 1).

L'obtention des tétrazoles **2** constitue une dérivation au schéma réactionnel qu'on pouvait escompter en se fondant sur le comportement des pyryliums (2–4) puisqu'elle inhibe la formation des hétérocycles heptaatomiques.

Cation hétéroaromatique $\xrightarrow{N_3^-}$ azide hétérocyclique $\xrightarrow{-N_2,\,\Delta}$ hétérocycle azoté heptaatomique

Néanmoins, le mécanisme que nous proposons pour la formation des tétrazoles (cf. schéma 1) laisse entrevoir la possibilité d'un retour vers les formes azides **4** et même **3** en intervenant sur les conditions des deux tautoméries.

Le travail présenté concerne l'étude de la tautomérie iminoazide $\rightleftharpoons$ tétrazole pour le couple **4**/**2**, entreprise comme une tentative d'aboutir à un réarrangement des formes azides **4** ou **3** en hétérocycles diazotés heptaatomiques.

De telles isomérisations peuvent s'envisager soit comme des réactions électrocycliques (5) soit comme des cycloadditions dipolaires-1,5 (6) soit encore comme des cycloadditions-1,3 au cours de l'attaque d'un azide sur une imine (7). Un calcul effectué par la méthode LCAO–SCF sur le modèle le plus simple ($R^1 = R^2 = H$, cf. schéma 2) montre que dans l'isomérisation iminoazide (I.A.) $\leftrightarrows$ tétrazole (T), l'état de transition s'apparente plutôt au réactif (I.A.) (quoique plus polarisé) qu'au produit (T) (7).

Ce résultat théorique s'accorde aussi bien avec le postulat de Hammond (prédiction d'états de transition "reactant-like" pour les systèmes réactifs) qu'avec de nombreux résultats de la littérature (ainsi qu'avec nos observations) qui montrent en général une plus grande stabilité pour la forme tétrazole (7, 8).

L'examen des données de la littérature permet de distinguer deux types de facteurs jouant sur l'équilibre (I.A.) $\leftrightarrows$ (T): des facteurs structuraux (nature de R^1, R^2) et des facteurs de milieu (température, polarité et proticité du solvant).

Facteurs structuraux

La cyclisation implique une configuration *cis* entre la paire libre de l'atome imino et le reste azido. Pour les iminoazides linéaires (R^1 et R^2 non liés) cette condition implique que l'isomérisation *syn* $\leftrightarrows$ *anti* de la double liaison C=N soit possible. Une telle inversion est très rapide si R^1 est un groupe alkyle ou aryle, la forme tétrazole est alors généralement observée (9). En revanche, si R^1 est électro-donneur ($\ddot{O}R$, $\ddot{O}H$, $\ddot{S}R$, $\ddot{N}R$) l'inversion est considérablement ralentie et l'(I.A.) est la forme tautomère prépondérante (9), voire unique comme dans le cas des azidoximes (10).

Facteurs de milieu

L'emploi de solvants polaires, donc de solvants stabilisant mieux l'état de transition polarisé que la forme (I.A.) doit en principe favoriser la cyclisation en tétrazole (7), cette prévision s'accorde avec un ensemble d'observations (9).

Lorsque le groupe R^1 est susceptible de se protoner l'emploi de solvants protiques déplace par contre l'équilibre vers les formes (I.A.) (9). Enfin, bien que cette règle ne soit pas d'une généralité absolue, la formation des iminoazides est souvent endothermique (11).

SCHÉMA 2

Résultats et discussion

Dans le cas des couples (I.A.)/(T) **4**/**2** les formes (I.A.) sont des formes acycliques dont le groupe R^1 n'est pas électrodonneur, il est donc normal que la forme tétrazole **2** soit la plus stable à température ambiante. Aussi n'avons nous pas tenté d'intervenir sur les facteurs de structure mais sur les facteurs de milieu, d'exploitation plus immédiate.

1. *Effets de solvant à température ordinaire*

Nous avons choisi l'infra-rouge comme méthode d'étude de l'equilibre en solution et procédé à l'enregistrement des solutions du tétrazole triphénylé **2***a* (cf. schéma 1) dans CCl_4, CH_3CN et CF_3COOH. Dans ces conditions nous n'avons décelé aucune trace d'absorption dans la région caractéristique des vibrations d'élongation asymétrique du groupe N_3 des iminoazides (2160–2120 cm^{-1}) (12).

Le facteur solvant est donc à lui seul insuffisant pour déplacer à température ambiante l'équilibre (T) $\leftrightharpoons$ (I.A.) vers les formes (I.A.).

2. *Utilisation du facteur température: thermolyse des tétrazoles 2*

On pouvait envisager pour les tétrazoles **2** une isomérisation endothermique en les iminoazides **4** correspondants. Nous avons donc procédé à une étude de la thermolyse des tétrazoles **2** dans diverses conditions (solvant, catalyseur...).

Le chauffage des tétrazoles **2** n'a pas permis d'isoler les iminoazides **4** correspondants; on observe selon la nature du solvant, aromatique ou protique, deux comportements bien typés des tétrazoles.

(a). Réarrangements thermiques en solvant aromatique

Ils conduisent par perte d'azote (~100%) à des mélanges essentiellement constitués d'hétérocycles à cinq chaînons: les pyrazoles **5** et **6** et les imidazoles **7** et **8** (schéma 3).

La transformation totale du tétrazole **2***a* nécessite un chauffage à 160°C pendant 6 h. Elle conduit à un mélange complexe d'une vingtaine de composés dont on a pu identifier ou isoler les six constituants prépondérants représentant environ 70% du bilan (cf. tableau 1 et partie expérimentale).

Le *N*-benzoyldiphényl-3,5 pyrazole **5***a* et le *N*-benzoyldiphényl-2,4 imidazole **7***a*, composés majoritaires, semblent être des produits primaires de la réaction. En revanche, le diphényl-3,5 pyrazole **6** (13) et le *N*-benzoyl-diphényl-2,5 imidazole **8** sont des produits secondaires résultants de transformations ultérieures des produits majoritaires **5** et **7** respectifs dans les conditions de la thermolyse (cf. tableau 2).

On note également la présence de traces de β-benzamido-*trans*-benzalacétophénone **9***a* "pseudo base" de l'oxazinium **1***a* (1, 14) ainsi que d'un composé **10***a* (il s'agit comme on le verra d'un photoisomère de **2***a*).

(b). Réarrangement thermique des tétrazoles en solvant protique

Le tétrazole **2***a* ne subit pratiquement aucune modification au cours d'un chauffage au reflux dans l'éthanol absolu. En revanche il se réarrange par chauffage dans l'éthanol à 95%, l'acide acétique ou l'acide trifluoroacétique. On obtient, non plus des hétérocycles azotés à cinq chaînons et de l'azote moléculaire, mais la β-benzamido-*trans*-benzalacétophénone **9***a*. Comparativement aux réarrangements en solvants aromatiques, ces réarrangements en solvants protiques sont plus rapides et s'effectuent à température modérée.

Il est à noter que lors du chauffage du tétrazole **2***a* en solution dans l'acide trifluoroacétique se développe une coloration jaune vif qui a pu être attribuée à la présence du cation oxazinium, le trifluoroacétate d'oxazinium (cf. partie expérimentale).

(c). Chauffage du tétrazole 2a en présence de réactifs spécifiques des azides organiques

L'emploi du cuivre comme éventuel catalyseur de décomposition du tétrazole **2***a* (15) diminue effectivement la température du réarrangement, mais il en modifie aussi le cours (cf. tableaux 1 et 2) puisqu'il catalyse également la débenzoylation du *N*-benzoyl-pyrazole **5** et qu'il dégrade le *N*-benzoylimidazole **7**. Ce catalyseur n'apporte donc pas d'amélioration aux réarrangements thermiques.

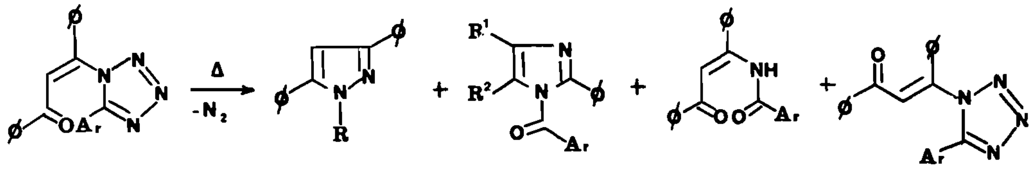
Nous avons également tenté de mettre en évidence le retour vers des formes azides par chauffage du tétrazole **2***a*, en opérant en présence de réactifs spécifiques d'azides organiques comme la triphénylphosphine $P(Ph)_3$ (16*a*, *b*) ou les amines aromatiques.

La triphénylphosphine est bien connue pour intercepter les azides organiques en conduisant à des adduits 1:1 plus ou moins stables à température ambiante. On constate que son emploi lors du chauffage du tétrazole **2***a* modifie le cours

$$P(Ph)_3 + R'N_3 \rightleftharpoons \left|\overset{+}{P}(Ph)_3\text{—}\overset{-}{N}\text{—}N\text{=}N\text{—}R'\right| \xrightarrow{-N_2} \overset{+}{P}(Ph)_3\text{—}\overset{-}{N}\text{—}R' \updownarrow P(Ph)_3\text{=}N\text{—}R'$$

phosphoimine

habituel des réarrangements thermiques. Ainsi, dans l'orthodichlorobenzène (ODCB) aussi bien que dans l'éthanol à 95% on observe une diminution des rendements en produits habituels, respectivement hétérocycles azotés majoritaires **5***a* et **7***a* et pseudo-base **9***a*. On note en revanche la formation de nouveaux



2 5 R = ArCO 6 R = H 7 R¹ = ϕ, R² = H 8 R¹ = H R² = ϕ 9 10

produits: oxyde de triphénylphosphine et triphényl-2,4,6 pyrimidine **11**. Enfin, l'utilisation de la pyridine comme solvant de thermolyse de **2***a* modifie également le comportement habituel; comme précédemment, on obtient de la triphényl-2,4,6 pyrimidine **11** à côté d'un composé supplémentaire: le diphényl-3,5 isoxazole **12** (17).

3. *Activation photochimique des tétrazoles*

Nous avons également envisagé d'intervenir sur l'équilibre (T) ⇆ (I.A.) par une décomposition photochimique de l'azide (2, 18).

L'irradiation donne lieu à deux types de transformations: (*i*) une activation de courte durée et peu énergétique provoque une

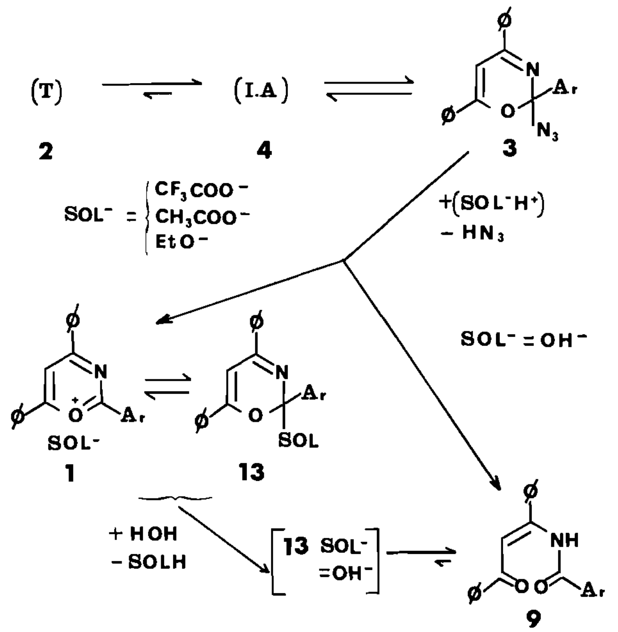

SCHÉMA 4

photoisomérisation du système énonique avec préservation du noyau tétrazole. Cette photoisomérisation **2***a* ⇆ **10***a* s'apparente à la photoisomérisation *trans* ⇆ *cis* de la benzalacétophénone (19) et, comme celle-ci, peut se produire à la lumière solaire. (*ii*) Une irradiation prolongée à plus courte longueur d'onde provoque, outre la photoisomérisation précédente, un réarrangement du motif tétrazole des deux isomères **2***a* et **10***a*. On aboutit rapidement à un mélange réactionnel beaucoup plus complexe que celui des thermolyses, les divers produits primaires pyrazoles et imidazoles devant vraisemblablement subir eux-mêmes des réarrangements photochimiques (20).

Ce mode d'activation n'a donc pas été retenu pour le réarrangement des tétrazoles.

Le noyau tétrazole est un cycle relativement stable en l'absence de substituants le rendant sensible à la chaleur (21). Ainsi, les diaryl-1,5 tétrazoles se décomposent-ils par chauffage au dessus de leurs points de fusion (220–250°C) avec perte d'azote et formation de mélange de carbodiimides et de benzimidazoles (22).

La décomposition des tétrazoles **2** semble suivre un cours différent: elle se produit à plus basse température, 160°C dans l'ODCB et même 78°C dans l'éthanol à 95%, et ne fournit pas de carbodiimide (absence de bande d'absorption N═C═N vers 2160 cm^{-1} en spectroscopie infra-rouge).

Ceci conduit à envisager pour les β-tétrazolo-*trans*-benzalacétophénones **2** plutôt qu'un réarrangement "classique" de la forme tétrazole, un réarrangement des formes azides correspondantes: (I.A.) **4** voire azido oxazine **3**. Nous proposons donc un mécanisme impliquant dans un *premier temps* la conversion des tétrazoles **2** en (I.A.) **4** correspondants,[1] ces derniers subissant dans un *deuxième temps* diverses évolutions selon les conditions de milieu.

[1] Comparativement aux diaryl-1,5 tétrazoles on peut concevoir que cette thermolyse soit favorisée par la présence d'un groupe R[1] *trans*-chalcone plus électroattracteur qu'un groupe aryle (cf. schéma 2). Il y aurait déstabilisation du noyau tétrazole réputé électroattracteur (23) et stabilisation de la forme azide électrodonneur (24).

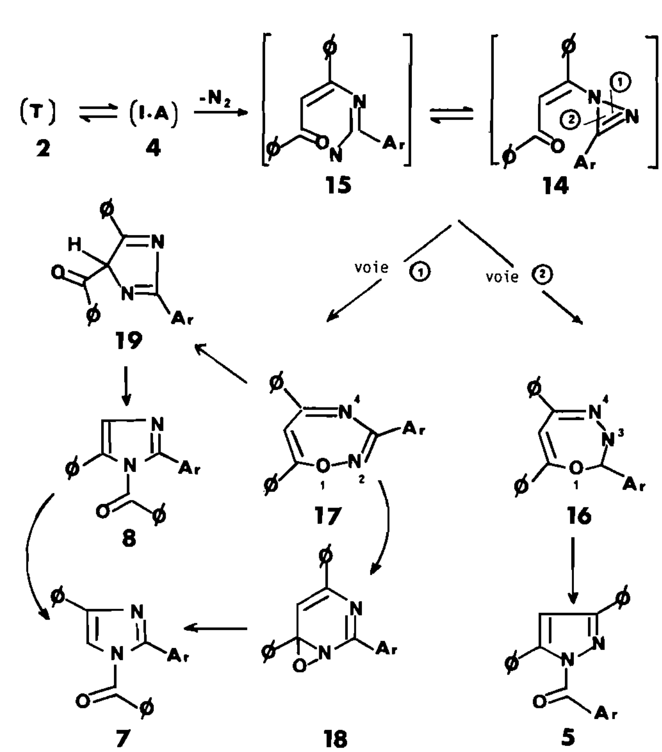

SCHÉMA 5

En solvant protique

L'obtention des pseudo-bases **9** s'interprète en admettant la solvolyse des azido-oxazines **3**. Les 2*H*-oxazines **13** résultantes peuvent même selon les cas ($sol^- = CF_3COO^-$ ou CH_3COO^-) évoluer selon une troisième dissociation d'un type nouveau (25) oxazine → oxazinium-1,3. Cette hypothèse d'une dissociation des oxazines en paires d'ions plus ou moins intimes selon la nature du solvant est confirmée par l'observation du cation oxazinium dans le cas où le solvant est CF_3COOH.

En solvant aromatique neutre

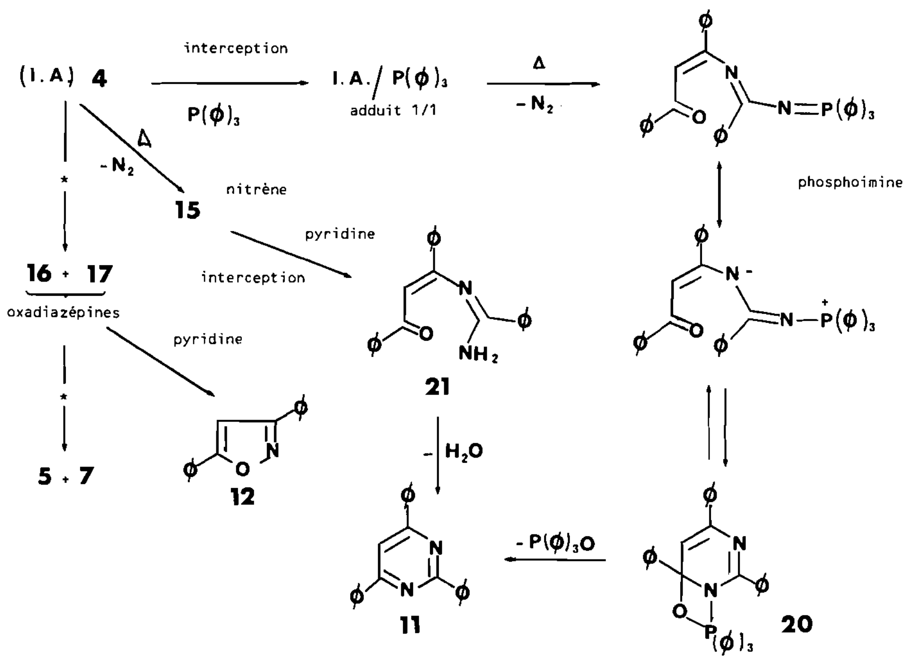
La conversion (I.A.) → (T) ne bénéficiant plus du facteur favorable de la proticité exige un chauffage plus important. En ce qui concerne le deuxième équilibre (I.A.) → azidooxazine, il est vraisemblable que c'est la forme (I.A.) qui prédomine (en raison de l'absence de solvolyse, et car c'est vraisemblablement la forme la plus stable si l'on se rapporte au système α-pyranne – diénone (26)).

Nous proposons donc de rationaliser les thermolyses en solvant aromatique à partir de la forme (I.A.) **4** avec comme étapes clés la formation d'intermédiaires tels que la diazirine[2] **14** et les oxadiazepines **16** et **17**.

La thermolyse des azides vinyliques fait intervenir des azirines formées par addition des nitrènes intermédiaires sur la double liaison (27, 28). De façon analogue on peut concevoir le passage (I.A.) **4** → cétodiazirine **14** via le nitrène **15**.

Deux évolutions vers les oxadiazépines **16** et **17** sont possibles pour cette cétodiazirine **14**, par attaque du dipôle-1,3 qu'elle constitue sur le carbonyle du système énonique (2, 4). (voies 1 et 2). Enfin, (*i*) le passage oxadiazépine-1,3,4 **16** → pyrazole **5** s'effectuerait par transposition sigmatropique d'ordre 1,3 (cf. la réf. 31 dans le cas voisin des benz(*d*)oxazépines-1,3); (*ii*) alors que l'oxadiazépine-1,2,4 **17** conduirait à l'imidazole **7** par des transpositions faisant jouer

[2] Ce type d'intermédiaire a déjà été postulé pour rendre compte de la photodécarboxylation de diverses sydnones (29, 30).



*évolution habituelle

SCHÉMA 6

l'oxirane **18** (32) ou l'imidazole *C*-benzoylé **19**.

En présence de $P(Ph)_3$ ou de pyridine

La thermolyse du tétrazole **2***a* en présence de $P(Ph)_3$ conduit aux mêmes produits $P(Ph)_3O$ et pyrimidine **11** que lors d'une attaque de NaN_3 sur l'oxazinium **1***a* effectuée en présence de $P(Ph)_3$ (1). Ceci suggère une interception du même azide: azidooxazine **3***a* ou plus vraisemblablement iminoazide **4***a*. Dans la dernière hypothèse, il s'agirait en fait d'une réaction "Wittig-like" intramoléculaire dont on connaît un précédent (33).

L'emploi de pyridine comme solvant conduit également à la formation de la pyrimidine **11**. Il s'agit vraisemblablement de l'interception de l'imidonitrène **15** avec formation de l'énamine intermédiaire **21**. Un deuxième effet de la pyridine est de limiter[3] les réarrangements des oxadiazépines **16** et **17** en pyrazoles **5** et imidazoles **7** au profit d'une autre évolution conduisant au diphényl-3,5 isoxazole **12** par perte de benzonitrile (cf. schéma 6).

Conclusion

L'étude de la tautomérie tétrazole **2** → (I.A.) **4** a montré que conformément aux prévisions la formation des (I.A.) est endothermique. En solvant aromatique, les (I.A.) évoluent comme attendu avec perte d'azote vers des hétérocycles à 7 chaînons: les oxadiazépines. Ces composés sont malheureusement instables et s'isomérisent thermiquement en pyrazoles et imidazoles *N*-benzoylés. Si l'emploi de solvants protiques favorise l'isomérisation (T) → (I.A.) il ne permet pas davantage l'isolement des oxadiazépines. En effet surviennent alors exclusivement des réactions de solvolyse de l'azidooxazine **3** résultant de l'équilibre (I.A.) $\rightleftharpoons$ **3**. S'il a été observé que l'introduction d'un groupe électroattracteur comme un *p*-nitrophényl sur le carbone du noyau tétrazolique joue dans un sens favorable à l'isomérisation (T) $\leftrightarrows$ (I.A.), l'exploitation des facteurs structuraux reste encore à approfondir. Enfin, dans le but d'éviter tout chauffage en vue d'isoler éventuellement les oxadiazépines, nous envisageons de faire appel à des azapyryliums, comme les oxaziniums-1,2 ou oxaziniums-1,4, tels que la formation de tétrazoles soit d'emblée impossible.

[3]On connaît en effet des réarrangements d'oxazépines-1,3 en *N*-benzoylpyrroles catalysés par les acides (34).

Partie expérimentale

Les spectres d'absorption ultraviolet–visible et infra-rouge ont été respectivement enregistrés sur des appareils Hewlett–Packard 8450 A ou Philips SP8-250 et Philips SP3-200. Les spectres de rmn ^1H et rmn ^{13}C ont été enregistrés sur appareil EM 360 Varian ou Bruker WP 80 et WM 250. Les spectres de masse ont été effectués par Mesdemoiselles J. Mercier et C. Lange que nous remercions, respectivement au centre de Mesures Physiques de Paris sur un spectromètre AEI MS 50 et au laboratoire sur un spectrographe quadrupôlaire Nermag R10-10C. Les analyses élémentaires ont été effectuées par le centre de Microanalyse du CNRS ou au laboratoire de Microanalyse de l'Université Pierre et Marie Curie. Les points de fusion non corrigés ont été déterminés de façon instantanée au banc de Köfler.

Le chromatographe liquide utilisé est constitué de: 2 pompes Waters modèle 6000 A pilotées par le moniteur de gradient Waters modèle 660; un injecteur universel U6 K; un détecteur uv–visible à filtres interférentiels Waters M 440.

I. *Effets de température et de solvants sur l'équilibre iminoazide $\rightleftharpoons$ tétrazole*

Les thermolyses des tétrazoles **2***a*, *b*, *c* ont été effectuées à l'abri de la lumière dans diverses conditions de température, de solvant ou de réactifs spécifiques d'azides organiques. L'évolution des réactions est suivie par chromatographie sur couche mince de silice (ccm) jusqu'à cessation du dégagement d'azote.

Thermolyse du tétrazole 2a *dans l'ODCB. Manipulation 1*

Une solution de 100 mg de tétrazole **2***a* dans 2 cm^3 d'ODCB anhydre est chauffée à 160°C pendant 6 h. La solution est concentrée puis analysée par ccm préparative sur silice (Merck) (cf. tableau 1). Une analyse qualitative par chromatographie liquide hautes performances (clhp) révèle la présence d'une vingtaine de composés. Nous avons pu procéder à la quantification de six composés majoritaires au moyen d'échantillons standards indépendamment obtenus en conjuguant la clhp *semi-préparative et la ccm.*

Conditions d'analyse clhp: *colonne*: 2 (33 × 0,46 cm) μ porasil 10μ; *solvant*: gradient n° 6 entre n-heptane et n-heptane/[CH_2Cl_2/AcOEt] (95:5) en 15 min jusqu'au mélange n-heptane/[CH_2Cl_2/AcOEt] (75:25); *débit*: 2 mL/min; détection uv à 254 nm; température ambiante.

Thermolyse des tétrazoles 2b *et* 2c *dans l'ODCB. Manipulations 2 et 3*

On opère comme précédemment. Les pyrazoles **5***b* et **5***c* sont isolés par ccm sans difficulté, par contre, les imidazoles **7***b* et **7***c* n'ont pu être suffisamment purifiés pour donner une analyse centésimale satisfaisante. Ceci est dû à la présence de produits de polarités voisines tels que pseudo-bases **9***b*, *c* et pyrazoles bases **6***b*, *c* (cf. tableau 1). La structure des produits majoritaires pyrazoles **5**, **6**, imidazoles **7**, **8** sera discutée dans le paragraphe suivant.

Thermolyse des tétrazoles dans le benzène. Manipulations 4 et 5

Le chauffage *de 100 mg de tétrazole* **2***a* (ou **2***b*) dans 2 cm^3 de benzène anhydre ne produit aucune modification en 48 h. Par contre, dans les mêmes conditions, le tétrazole **2***c* se réarrange en partie: la ccm permet d'isoler 20% de pyrazole **5***c* (19,5 mg), 10% de pseudo-base **9***c* (9,5 mg), et 40 mg de tétrazole inchangé.

Thermolyse du tétrazole 2a *en solvant protique. Manipulations 6 à 9*

On chauffe les solutions de **2***a* dans divers solvants protiques au reflux. Après traitement: lavage à l'eau, extraction à l'éther ou simplement évaporation du solvant dans le cas de l'éthanol, on purifie la pseudo-base **9***a* par ccm. Dans le cas du chauffage dans CF_3COOH, la coloration jaune vif fluorescente a été attribuée à la formation du cation oxazinium-1,3 **1***a* par spectroscopie uv–visible.

Thermolyses du tétrazole 2a *dans l'ODCB en présence de P(Ph)₃. Manipulation 11*

Le tétrazole **2***a* (186 mg, 0,5 mmol) est chauffé dans 2 cm^3 d'ODCB anhydre à 160°C pendant 6 h en présence de 131 mg (0,5 mmol) de $P(Ph)_3$. Le traitement habituel conduit à un mélange de pyrazole **5***a* (18%, 30 mg), d'imidazole **7***a* (13%, 21 mg), de pseudo-base **9***a* (2%, 2,5 mg), de triphényl-2,4,6 pyrimidine **11** (1) (20%, 31 mg) et de l'oxyde de triphénylphosphine (20%, 25 mg). On obtient le même genre de produits en opérant au reflux de l'éthanol (*manipulation 12*).

Thermolyse du tétrazole 2a *dans la pyridine. Manipulation 13*

Le tétrazole **2***a* (30 mg, 0,08 mmol) est chauffé 48 h dans 2 cm^3 de pyridine anhydre à 115°C. On obtient après traitement: de la triphénylpyrimidine **11** (11%, 3 mg), du diphényl-3,5 isoxazole **12** (17) (15%, 3,5 mg, Fi 140°C) ainsi que de la pseudo-base **10***a* (40%, 11,5 mg).

Thermostabilité du pyrazole 5a *(cf. tableau 2)*

La manipulation 14 montre que le pyrazole **5***a* n'est pas stable dans les conditions où il est produit par dégradation du tétrazole **2***a*. Il se décompose en mélange de composés dont le seul qui puisse être identifié est le pyrazole base **6***a* (4%). Cette décomposition est beaucoup plus propre et plus rapide en présence de cuivre (*manipulation 15*).

Thermostabilité de l'imidazole 7a *(cf. tableau 2)*

La manipulation 16 montre que l'imidazole **7***a* subit une dégradation importante au chauffage, le seul produit isolable étant son isomère **8***a* en faible quantité. La dégradation de **7***a* est complète en présence de cuivre même pour un chauffage de courte durée (*exp. 17 et 18*).

II. *Structure des produits issus des thermolyses*

Les pseudo bases **9***a*–*c* obtenues par chauffage des tétrazoles en solvant protique ont fait l'objet d'une étude spectroscopique dans un précédent article (1). La triphényl-2,4,6 pyrimidine **11** déjà connue (34) a été identifiée (Fi, ir) à un échantillon authentique, de même que le diphényl-3,5 isoxazole **12***a* (17).

1. *Structure des pyrazoles* **5** *et* **6**

Seul le diphényl-3,5 pyrazole **6***a* était connu, nous l'avons identifié à un échantillon obtenu par action de l'hydrazine sur l'oxazinium **1***a* (35).

(a) *Benzoyl-1 diphényl-3,5 pyrazole* 5a: À une solution de 76 mg (0,34 mmol) de pyrazole **6***a* dans 5 cm^3 d'éther anhydre, on ajoute lentement 20 μL de chlorure de benzoyle. Après lavage à l'eau jusqu'à neutralité le mélange réactionnel chromatographié (ccm sur silice) fournit 56 mg (40%) de **5***a* pur, Fi 128°C (éther); ir cm^{-1} (KBr): 1700, 1600, 1580, 900; uv ν_{max} (log ϵ_{max}) (éther): 242 (4, 53), 275 (4, 17); rmn ^1H ($CDCl_3$) δ ppm/TMS: 8,3–8,05 (m, 2H), 8,7–7,5 (m, 2H), 7,7–7,2 (m, 11H), 6,8 (s, 1H, H4); masse *m/e*: M^+ 324 (25), 296 (12), 295 (17), 220 (35), 191 (11), 165 (3), *105* (100), 77 (39); *Anal.* calc. pour $C_{22}H_{16}N_2O$: C 81,46, H 4,97, N 8,64; tr: C 81,42, H 5,01, N 8,69.

La structure des autres N*-aroyl-pyrazoles* 5b *et* 5c se fonde sur la comparaison de leurs propriétés spectroscopiques avec celles de **5***a*. En infra-rouge, la présence d'une bande d'absorption située vers 1710 cm^{-1} écarte l'hypothèse d'une structure de *C*-aroyl-pyrazole pour laquelle le carbonyle se situerait vers 1660–1665 cm^{-1} (36). Elle s'accorde en revanche avec la structure proposée de *N*-aroyl-pyrazole (37). En rmn ^1H, on constate que le déplacement chimique du proton noté H4 est pratiquement constant pour les pyrazoles **5***a*–*c*. Ce résultat établit que le groupe aryle substitué est situé dans le motif aroyle (qu'il influence d'ailleurs en ir au niveau de ν(C=O)) et non pas sur les sommets C3 ou C5. L'utilisation de la relation empirique de Tensmeyer et Ainsworth (38) donnée pour les pyrazoles-1,3,5 trisubstitués confirme nettement dans le cas de **5***a* la structure de *N*-benzoyl-diphényl-3,5 pyrazole:

δ H4	$CDCl_3$	observé 6,85	calculé 6,86
	CCl_4	observé 6,80	calculé 6,75

(b) p-*Méthoxybenzoyl-1 diphényl-3,5 pyrazole* 5b: Fi 80–82°C (éther); ir cm^{-1} (KBr): 2860, 1705, 1600, 1580, 900; rmn ^1H ($CDCl_3$) δ ppm/TMS: 8,25–7,05 (sys. AA′BB′, 4H), 8,1–7,3 (m, 10H), 6,9 (s, 1H, H4), 3,9 (s, 3H); masse *m/e*: M^+ 354 (35), 220 (80), 191 (20), 189 (12), *135* (100), 105 (5), 77 (40).

(c) p-*Nitrobenzoyl-1 diphényl-3,5 pyrazole* 5c: Fi 150–152°C (éther); ir cm^{-1} (KBr): 1715, 1600, 1575, 1350, 920; rmn ^1H ($CDCl_3$) δ ppm/TMS: 8,5–8,2 (m, 4H), 8,05–7,7 (m, 4H), 7,7–7,3 (m, 6H), 6,89 (s, 1H, H4); masse *m/e*: M^+ 369 (10), 341 (8), *220* (100), 191 (40), 189 (30), 165 (10), 150 (25), 105 (8), 77 (42). *Anal.* calc. pour $C_{22}H_{15}N_3O_3$: C 71,53, H 4,09, N 11,38; tr: C 71,68, H 4,18, N 11,55.

2. *Structure des imidazoles* 7a *et* 7b

Les preuves structurales reposent essentiellement sur des arguments chimiques. Ainsi l'hydrolyse (39) du diphényl-2,4 *N*-benzoyl-imidazole **7***a* (*F* 141°C), conduit-elle à la "base de Minovici": le diphényl-2,5 imidazole via la "base de Kunckell" (40): le diphényl-2,4 imidazole instable dans les conditions de l'hydrolyse. La benzoylation de cette dernière "base" selon la réf. 41 conduit au *N*-benzoyl-diphényl-2,5 imidazole identifié au composé **8***a* (*F* 120–121°C) obtenu lors de la thermolyse du tétrazole **2***a*.

(a) N-*Benzoyldiphényl-2,4 imidazole* 7a, obtenu par thermolyse du tétrazole **2***a* après ccm (silice): Fi 141°C (éther); ir cm^{-1} (KBr): 1715, 1600, 1580, 900; uv (éther) ν_{max} nm (log ϵ_{max}): 257 (4, 33), 2,84 (4, 34); rmn ^1H ($CDCl_3$) δ ppm/TMS: 8,0–7,1 (m); masse *m/e*: M^+ 324 (16), 220 (5), 165 (1), 106 (10), *105* (100), 77 (10). *Anal.* calc. pour $C_{22}H_{16}N_2O$: C 81,46, H 4,97, N 8,64; tr: C 81,42, H 4,91, N 8,52.

(b) *Hydrolyse du benzoyl-1 diphényl-2,4 imidazole* 7a: 23 mg de l'imidazole **7***a* sont hydrolysés selon la méthode de M. Weiss (39) en présence d'acétate d'ammonium (50 mg) et d'acide acétique (250 μL). Au cours de la réaction suivie par ccm, on constate la transformation du produit primaire d'hydrolyse **7***a* en base de Minovici **8***a* de polarité supérieure. On isole après traitement 11 mg (72%) de **8***a*, Fi 141°C, identifié à un échantillon authentique préparé indépendamment (41).

(c) *Benzoyl-1 diphényl-2,5 imidazole* 8a: 14 mg de **8***d* sont chauffés 20 min à 130°C dans 200 μL de Φ-COCl. Après refroidissement et agitation 30 min dans une solution éthanolique d'ammoniaque à 10%, on lave à l'eau et extrait à l'éther jusqu'à neutralité. On obtient après ccm sur silice 8 mg (40%) d'imidazole **8***a*, Fi 120–121°C.

Ce composé est identique à l'imidazole obtenu (7%) par thermolyse du tétrazole **2***a* dans l'ODCB ou par réarrangement thermique de l'imidazole **7***a* (cf. tableau 2); ir cm^{-1} (KBr): 1730, 1710, 1600, 1580, 900; masse *m*/*e*: M^+ 324 (10), 220 (4), 165 (1), 106 (11), *105* (100), 77 (45).

III. *Irradiation du tétrazole* **2**a

Irradiation de courte durée à $\lambda > 300$ *nm ou irradiation à la lumière solaire. Obtention du tétrazole* **10**a

La tétrazole **2***a* s'isomérise lentement à l'état solide ou en solution à la lumière du laboratoire en tétrazole **10***a* (cf tableau 1).

Une solution de 200 mg (0,57 mmol) de tétrazole **2***a* dans 100 cm^3 d'un mélange de cyclohexane–benzène (60:40) est préalablement dégazée pendant 15 min par barbotage d'azote. L'irradiation est réalisée au moyen d'une lampe de type SP 500 Philips au travers d'un filtre Pyrex ($\lambda > 300$ nm). Il semble que la réaction, suivie par ccm, donne lieu à un photoéquilibre. Au bout d'1 h on évapore le solvant et obtient après purification par ccm (silice) 150 mg (75%) de tétrazole **10***a*, Fi 116°C (éther); ir[4] cm^{-1} (KBr): 1670, 1620, 1595; uv (éther) ν_{max} nm (log ϵ_{max}): 238 (4, 38), 290 (3, 94); rmn ^1H ($CDCl_3$) δ ppm/TMS: 8,1–7,6 (m, 4H), 7,55–7,20 (m, 11H), 7,15[5] (s, 1H); rmn ^1H (C_6D_6) δ ppm/TMS: 7,9–7,7 (m, 4H), 7,2–6,65 (m, 11H), 6,6[5] (s, 1H, H5); rmn ^{13}C ($CDCl_3$) δ ppm/TMS: carbones quaternaires 191,2, 155,2, 141,8, 137,3, 133,3, 131,3, 124,6; carbones tertiaires 134,7, 132,4; masse *m*/*e*: M^+ 324 (221), 310 (9), 247 (7), *105* (100), 77 (45). *Anal.* calc. pour $C_{22}H_{16}N_4O$: C 74,98, H 4,58, N 15,90; tr: C 74,69, H 4,70, N 15,63.

[4] On note entre 1340 et 690 cm^{-1} la présence d'un ensemble de bandes caractéristiques du noyau tétrazolique (1).

[5] Le recours à un réactif de déplacement chimique induisant des déplacements à champ fort $Pr(fod)_3$ a permis de localiser le proton H5 à la limite du massif aromatique vers les champs forts. Cette attribution est également confirmée par la rmn à haut champ (250 MHz).

The gas phase reactions of the trichloromethylium ion with alkyl aromatics, studied by high pressure mass spectrometry

JOHN ALFRED STONE, NANCY JOAN MOOTE, AND ANASTASIA C. M. WOJTYNIAK
Chemistry Department, Queen's University, Kingston, Ont., Canada K7L 3N6

Received August 17, 1984[1]

JOHN ALFRED STONE, NANCY JOAN MOOTE, and ANASTASIA C. M. WOJTYNIAK. Can. J. Chem. **63**, 2608 (1985).

The reactions of trichloromethylium (CCl_3^+) with benzene and the lower alkyl aromatics (ArH) have been studied by high pressure mass spectrometry at pressures in the range 2–4 Torr and temperatures from 300 to 560 K. The only two primary products are the adduct $ArHCCl_3^+$ and $ArCCl_2^+$, which is formed by loss of HCl from the adduct. The relative yields of adduct increase with increasing number of methyl substituents on the aromatic ring (benzene → mesitylene). The disappearance of CCl_3^+ is kinetically second order with specific rate constants increasing from benzene to mesitylene, the latter reacting essentially at every ion–molecule collision. All rate constants are fairly large ($>10^{10}$ cc molecule^{-1} s^{-1}) and show negative temperature coefficients. $ArCCl_2^+$ is unreactive but $ArHCCl_3^+$ reacts further by proton transfer to ArH.

JOHN ALFRED STONE, NANCY JOAN MOOTE et ANASTASIA C. M. WOJTYNIAK. Can. J. Chem. **63**, 2608 (1985).

Opérant à des pressions allant de 2 à 4 Torr et à des températures allant de 300 à 560 K et faisant appel à la spectrométrie de masse à haute pression, on a étudié les réactions de l'ion trichlorométhylium (CCl_3^+) avec le benzène et les alkylbenzènes légers (ArH). Les deux seuls produits primaires sont l'adduit $ArHCCl_3^+$ et le $ArCCl_2^+$ qui se forme à partir de l'adduit par la perte de HCl. Les rendements relatifs de l'adduit augmentent avec une augmentation du nombre de substituants méthyles sur le noyau aromatique (benzène → mésitylène). La disparition du CCl_3^+ est cinétiquement du deuxième ordre et les constantes spécifiques de vitesse augmentent lorsqu'on passe du benzène au mésitylène; ce dernier réagit essentiellement à chaque collision ion–molécule. Toutes les constantes de vitesse sont assez élevées ($>10^{10}$ cc molécule^{-1} s^{-1}) et elles présentent toutes des coefficients de température qui sont négatifs. Alors que le $ArCCl_2^+$ n'est pas réactif, le $ArHCCl_3^+$ est susceptible de donner d'autres réactions par transfert de proton vers les ArH.

[Traduit par le journal]

Introduction

The reactions of trichloromethylium, CCl_3^+, with aromatic hydrocarbons have been previously studied by mass spectrometry at low pressures (~10^{-4} Torr; 1 Torr = 133.3 Pa). Theard and Hamill (1) identified the main reaction between CCl_3^+ and benzene, in CCl_4/C_6H_6 mixtures, as

[1] $CCl_3^+ + C_6H_6 \rightarrow C_7H_5Cl_2^+ + HCl$

Virin *et al.* confirmed the occurrence of this reaction in the same system (2) and also found the analogous reactions with toluene (3) and ethylbenzene (4). The stabilized $C_6H_6CCl_3^+$ adduct was not observed. Theard and Hamill did observe several other chlorinated and non-chlorinated secondary ions, which can be ascribed to the presence of either epithermal ions caused by the ion repeller fields used or primary ions other than CCl_3^+.

Many ion–molecule reactions observed mass spectrometrically can often also be identified in radiolytic systems (5). It is therefore surprising that no chlorinated aromatic products are ascribed to the reactions of CCl_3^+ in γ-irradiated CCl_4/aromatic (100:2) mixtures at total pressures from 100 to 760 Torr and ambient temperature (6, 7). The reported yields of chlorinated benzene and toluene products are very low, the sum of *G* values (molecules of product formed per 100 eV of energy absorbed by the system) being in no system greater than 1, whereas *G* (ions) in gases is ~4 (8). The few products observed were shown to probably have free radicals (CCl_3 and Cl) as precursors. Since CCl_3^+ is the dominant ion in the low pressure mass spectrum of CCl_4 and since it is unreactive towards the parent molecule (9), much ion chemistry in dilute aromatic/CCl_4 mixtures must originate with CCl_3^+ even though none was identified.

[1]Revision received March 18, 1985.

In order to gain some insight into the radiolysis results and to obtain more information on the reactions of CCl_3^+ with aromatic compounds we have studied the behaviour of CCl_4/aromatic hydrocarbon mixtures in a high pressure (2–4 Torr) mass spectrometer ion source operated under field free conditions. Our pressure regime is between that of the earlier low pressure mass spectrometric work and the much higher pressure used in the radiolysis study.

Experimental

Materials

Methane (Matheson Ultra-high Purity) had a stated purity exceeding 99.99%; carbon tetrachloride (Fisher Spectrograde) was used as received; all aromatics were of the highest purities available. In no case were impurities, or ions attributable to impurities, observed in any of the mass spectra.

Procedure

The mass spectrometer, equipped with field free, high pressure ion source has been described previously (10). The pressure range over which the instrument gave adequate signal was 2–4 Torr. Products of ion–molecule reactions were identified in conventional chemical ionization spectra when the source was operated in a standard, continuous ionization mode. Reaction sequences were determined by pulsing the electron beam (11). After a 50-μs pulse of 2-keV electrons the temporal profile of the intensity of a selected ion was followed for up to 10 ms using an ion multiplier, ion counting equipment, and a multiscalar. Data for $1-8\times10^3$ pulses were summed. Such data for every ion observed in the CI spectrum were normalized and plotted as normalized ion intensities vs. residence time in the ion source.

Results and discussion

The formation of CCl_3^+

In order to obtain unambiguous results it was essential that CCl_3^+ ions be generated in a bath gas towards which they exhibit no reactivity. It would have been preferable to use pure

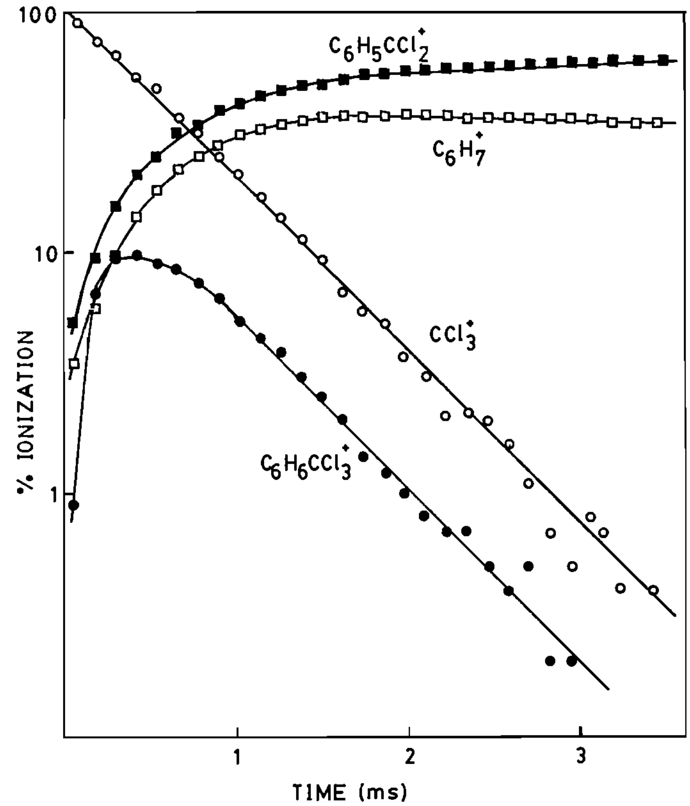

FIG. 1. Normalized ion intensities as functions of time, observed in 3.8 Torr of methane containing 3.5×10^{-4} Torr benzene and 1.0×10^{-3} Torr carbon tetrachloride at 435 K.

CCl_4 since it has been shown that CCl_3^+ generated from CCl_4 by electron impact is unreactive towards the parent molecule (9). High pressures of CCl_4 were found to inhibit the operation of the field free source. After a short time of operation, ions no longer emerged from the ion exit slit without the assistance of a repeller field. Such effects have been attributed to the formation of a semiconducting film on the edges of the slit (12). Ions were transmitted again when the source was heated to ~600 K and then cooled to the appropriate temperature but the use of pure CCl_4 again led to the disappearance of the ion beam.

CCl_3^+ was readily formed in mixtures of ~0.3 mol% CCl_4 in CH_4 and it was the only ion present 100 μs or so after a pulse of ionizing electrons at pressures above 2 Torr. The major ions present in methane alone at long reaction times are CH_5^+ and $C_2H_5^+$ (13). Both these ions react with CCl_4 to produce CCl_3^+. In addition, i-$C_3H_7^+$ produced in a CH_4/C_3H_8 mixture (20:1) also reacts with CCl_4 to produce CCl_3^+. However, neither i-$C_4H_9^+$ formed in CH_4/n-C_4H_{10} nor *t*-$C_4H_9^+$ formed in CH_4/i-C_4H_{10} mixtures was observed to react with CCl_4. These findings are in accord with those obtained using ion cyclotron resonance and substantiate the range 191–203 kcal mol^{-1} placed on $\Delta H_f^0(CCl_3^+)$ (14).

The reactions of CCl_3^+ with aromatic hydrocarbons

CCl_3^+ was found to react with benzene, toluene, the xylenes, and mesitylene. Only two initial product ions were observed with each aromatic (ArH), the adduct ion, $ArHCCl_3^+$, and the ion $ArCCl_2^+$ formed by loss of HCl from the adduct. Typical results are shown in Figs. 1–3.

Benzene + CCl_3^+

The adduct formed between C_6H_6 and CCl_3^+, $C_6H_6CCl_3^+$, is

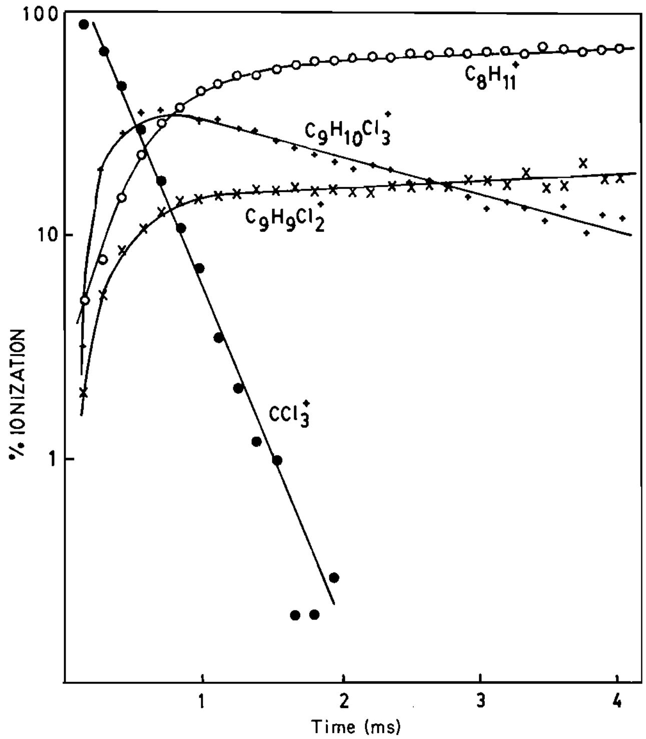

FIG. 2. Normalized ion intensities as functions of time, observed in 3.9 Torr of methane containing 1.8×10^{-4} Torr *m*-xylene and 1.0×10^{-3} Torr carbon tetrachloride at 460 K.

a major product ion only at low temperatures and, even then, only at short reaction times (Fig. 1). It is absent from the spectrum at temperatures above 500 K when $C_6H_5CCl_2^+$ is the sole product ion observed. This latter ion is always the major product at long reaction times at temperatures from 300 to 560 K. It is always the major ion in the mass spectrum.

At low temperatures, when $C_6H_6CCl_3^+$ is present, its yield maximizes after a few hundred microseconds and then decreases rapidly. $C_6H_6CCl_3^+$ is identified as an arenium ion since it transfers a proton to neutral benzene in a second-order reaction. Proton transfer to bases of higher basicity than benzene is also observed.

[2]  (I)

[3] 
The *ipso*-protonated ion, **I**, probably rearranges rapidly by H^+ migration to more basic sites on other ring carbons prior to the occurrence of reaction [2]. The electron-withdrawing properties of the CCl_3 group will increase the acidity of the proton in **I** and its isomers to a value greater than that of protonated benzene, which explains the facile proton transfer, reaction [3].

$C_6H_5CCl_2^+$ is presumably a benzyl cation, which is the same as that observed at low pressure (1, 2) and is formed by loss of HCl from the adduct. It is not observed to react further.

[4] 

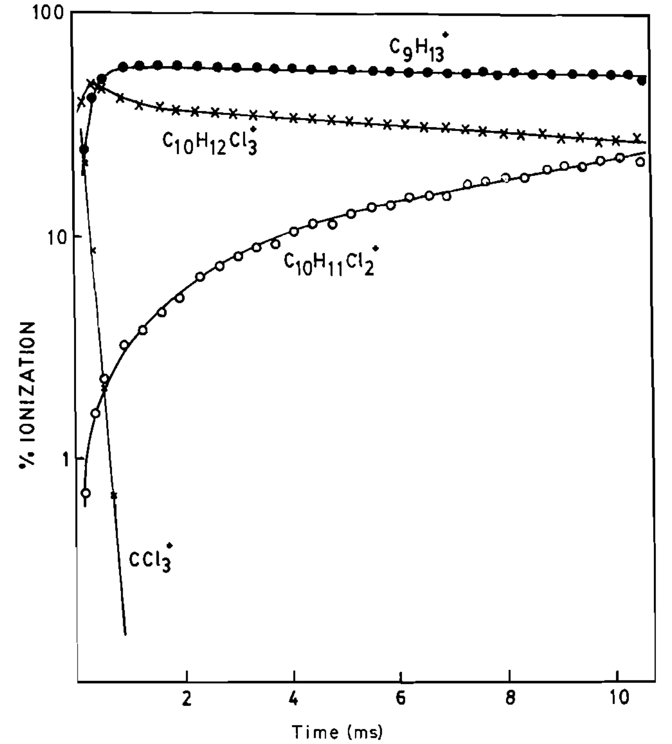

FIG. 3. Normalized ion intensities as functions of time, observed in 3.9 Torr of methane containing 1.4×10^{-4} Torr mesitylene and 1.6×10^{-3} Torr carbon tetrachloride at 300 K.

If reactions [2] and [3] were the only fate of $C_6H_6CCl_3^+$, then the ratio ($[C_6H_7^+] + [C_6H_6CCl_3^+])/[C_6H_5CCl_2^+]$ should remain constant at all times. The ratio actually declines slowly from a value of 1.2 at short reaction time to 0.53 at the longest time. At very long reaction time $C_6H_7^+$ is decreasing very slowly, while $C_6H_5CCl_2^+$ is still increasing (Fig. 1) even though CCl_3^+ and $C_6H_6CCl_3^+$ have essentially disappeared. This suggests that $C_6H_7^+$ is reacting to form $C_6H_5CCl_2^+$, presumably by reaction with CCl_4. Two possible mechanisms may be written, (a) a dissociative proton transfer (reaction [5]) generating CCl_3^+ which then reacts with C_6H_6 via reactions [2] and [4] to give $C_6H_5CCl_2^+$:

[5] $C_6H_7^+ + CCl_4 \rightarrow C_6H_6 + HCl + CCl_3^+$

and (b) a concerted reaction whereby $C_6H_6CCl_3^+$ is formed as a primary product and again decomposes to $C_6H_5CCl_2^+$:

[6] $C_6H_7^+ + CCl_4 \rightarrow C_6H_6CCl_3^+ + HCl$

With ΔH_f^0 (CCl_3^+) in the range 192–203 kcal mol^{-1}, reaction [5] is endothermic by 13–25 kcal mol^{-1} and will not be observed. Reaction [6] is less endothermic than reaction [5] by the binding energy of CCl_3^+ to C_6H_6. The latter value is not known but, considering that the methyl cation affinity of benzene calculated from the dissociation of protonated toluene is 95 kcal mol^{-1},[2] the binding energy of CCl_3^+ to C_6H_6, although less than that of CH_3^+, will be sufficiently great to make reaction [6] exothermic. The slowness of the energetically allowed reaction may be attributed to competitive dissociation of an initially formed ion–molecule complex. Entropy favours return to reactants rather than formation of products via a tight transition state.

It was not possible to experimentally ascertain whether reaction [6] occurs. A very slow ($k = 7 \times 10^{-13}$ cc molecule^{-1} s^{-1} at 468 K) disappearance of $C_6H_7^+$ was observed in a 4:1 CCl_4/C_6H_6 mixture in CH_4. A small accompanying increase in the yield of $C_6H_5CCl_2^+$ was observed at the same time but this increase was only about one-half the expected value. Some unidentified products (*m/z* 119 and 121) made up the difference. No such reaction was observed with any of the other aromatics. Such a slow reaction is at the lower limit of what can be studied by high pressure mass spectrometry. The study is doubly difficult since the product, $C_6H_5CCl_2^+$, is also formed in other reactions. Confirmation of the occurrence of reaction [6] will require a different experimental technique.

Reaction [6] is obviously too slow to account for all the large change with time of the ratio ($[C_6H_7^+] + [C_6H_6CCl_3^+])/[C_6H_5CCl_2^+]$. A slow thermal decomposition of stabilized $C_6H_6CCl_3^+$ must also be occurring. Such a reaction was found to occur with xylene and mesitylene (see later).

The $C_7H_6Cl_3^+$ formed in reaction [2] will be in an excited state and will require third body stabilization in order to be observed by the ion detection system. Prior to this stabilization it may be possible for decomposition to occur by loss of HCl, yielding $C_6H_5CCl_2^+$ (reaction [4]). It is impossible to quantitatively determine the branching ratio of decomposition to stabilization since, as discussed above, $C_6H_5CCl_2^+$ is formed in several ways. If the assumption is made that all the $C_6H_7^+$ observed has $C_7H_6Cl_3^+$ as precursor, then the following generalization may be made regarding the effects of temperature and pressure on the branching ratio. At high temperature (>500 K) and any pressure in the range 1.0–4.5 Torr the yield of $C_6H_5CCl_2^+$ constitutes more than 99% of the detected products. At 298 K and 4.0 Torr, $C_7H_6Cl_3^+ + C_6H_7^+$ account for 90% of the products observed at the shortest reaction time; at the same temperature and a pressure of 1.2 Torr the value is reduced to 75%. These percentages are only a lower limit for stabilization and it is probable that at 298 K and 2–4 Torr essentially all encounters between CCl_3^+ and C_6H_6 lead to a stabilized $C_7H_6Cl_3^+$ that either thermally decomposes or reacts by proton transfer. As the temperature is increased decomposition may occur before stabilization but, since the lifetime of the stabilized complex with respect to thermal decomposition will decrease, the two effects are inseparable.

An attempt was made to produce the adduct $C_6H_6CCl_3^+$ by protonation of α,α,α-trichlorotoluene. The only observed product of protonation by CH_5^+ and $C_2H_5^+$ was $C_6H_5CCl_2^+$. Protonation must be on chlorine rather than on the ring. α,α,α-Trichlorotoluene is formed in reaction [2] and it is at first sight surprising that this product was not observed in good yield in the γ-radiolysis of CCl_4/C_6H_6 gaseous mixtures (7). We found, however, that the following slow reaction occurs.

[7] 
At the high total dose of 4.8 Mrad employed in the radiolysis it is possible that much of the initially formed α,α,α-trichlorotoluene is scavenged. The fate of the resulting α,α-dichlorobenzyl cation is unknown. Neutralization by a negative ion to give products that were not discovered or further reaction with

[2]Thermochemical data for neutral molecules are taken from ref. 15. Proton affinities are from ref. 16. ΔH_f^0 (CH_3^+) = 261.8 kcal mol^{-1} (ref. 24). The proton affinity values have been decreased by 2 kcal mol^{-1}, in line with the change in the accepted value of the proton affinity of ammonia from 205 to 203 kcal mol^{-1}.

benzene to give undetected high molecular weight products are possibilities.

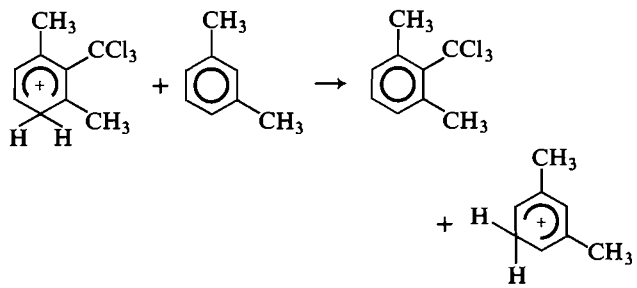
Toluene + CCl_3^+

The reaction of toluene with CCl_3^+ was qualitatively the same as that of benzene. The $C_7H_8CCl_3^+$ adduct was a little more stable than that of benzene and a very small signal due to this ion was present (<1% total ionization) even at the elevated temperature of 560 K.

Xylenes + CCl_3^+

All the xylenes behaved in the same manner, the example of *m*-xylene shown in Fig. 2 being typical. The CCl_3^+ adducts are much more stable than those of either toluene or benzene but, again, further reaction occurs by proton transfer to yield protonated xylenes, e.g.

[8]

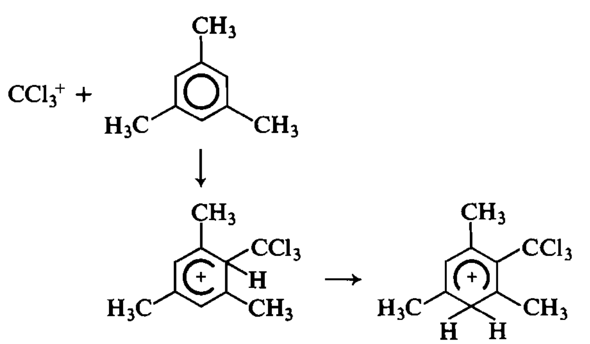


Loss of HCl from $C_9H_{10}Cl_3^+$ leads to $C_9H_9Cl_2^+$. Figure 2 shows that the yield of the latter ion reaches a maximum value of only 15% total ionization. The yield increases rapidly at short times when CCl_3^+ is still present, implying decomposition of the nascent *m*-xylene CCl_3^+ complexes. At long reaction times the $C_9H_9Cl_2^+$ curve increases slowly, even though CCl_3^+ has disappeared. This increase must be due to the thermal decomposition of the thermally stabilized complex, a reaction which is in competition with proton transfer to neutral *m*-xylene.

Mesitylene + CCl_3^+

Mesitylene yields the most stable adduct with CCl_3^+. Even at 560 K the adduct constituted about 50% of the product ions in a mass spectrum taken at 3.0 Torr for a 0.03:0.0003:1, CCl_4/mesitylene/CH_4 mixture.

[9]



(II) (III)

The three methyl groups confer stability on $C_{10}H_{12}Cl_3^+$. Two of the methyl groups will always be *ortho* and one will be *para* to the protonated tetrahedral site even if, as is probable, rearrangement occurs from an initial *ipso* form (**II**) to a more stable structure (**III**).

The stabilization afforded by the methyl group of toluene protonated at different ring positions relative to protonated benzene has been estimated (17). The values are (kcal mol^{-1})

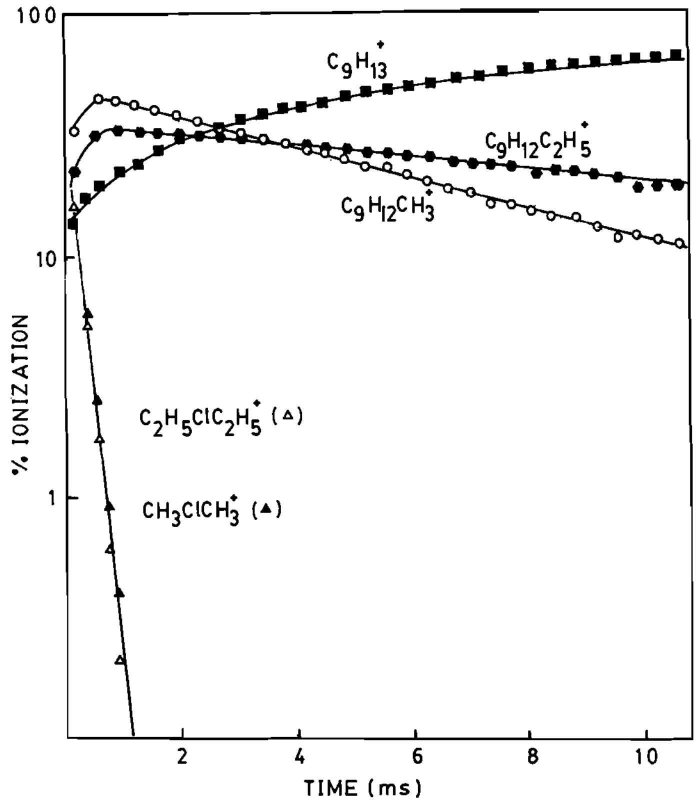


FIG. 4. Normalized ion intensities as functions of time, observed in 3.5 Torr methane containing 0.26 Torr methylchloride and 1.4 × 10^{-4} Torr mesitylene at 300 K.

ipso 0.3, *ortho* 6.5, *meta* 2.0, and *para* 8.5. On the assumption that the effects of methyl groups are additive, the calculated proton affinity of mesitylene with two methyls *ortho* and one methyl *para* to the protonation site is +21.5 kcal mol^{-1} relative to that of benzene. Experimentally the value is +17.0 kcal mol^{-1}, consistent with the estimate (17).

The most stable form of the mesitylene CCl_3^+ adduct should therefore be **III**, with the electron-withdrawing CCl_3 group *meta* to the proton site. Although its effect on proton binding energy will be least in this position, the CCl_3 group should still be destabilizing. We therefore expected a facile proton transfer to mesitylene, analogous to the reactions observed in the systems containing benzene, toluene, and the xylenes.

Figure 3 shows that at 300 K $C_{10}H_{12}Cl_3^+$ transfers a proton to mesitylene, yielding $C_9H_{13}^+$ only at relatively short reaction times when CCl_3^+ is still present. After this time the yield of $C_9H_{13}^+$ remains constant and no further reaction of this ion was observed. This was found to be the case for a variety of reagent concentrations and total pressures. The implication is that at this temperature only nascent, i.e. not fully thermalized, arenium ions are capable of protonating mesitylene. For the thermalized arenium ion, therefore, a CCl_3 substituent appears actually to decrease the acidity of protonated mesitylene.

The above observation is in contrast to that of Buttrill and co-workers (18) who found that the arenium ion resulting from the addition of mesitylene$^+$ to NO_2, $C_9H_{12}NO_2^+$, transfers a proton "very rapidly" to mesitylene. If the arenium ion has a structure analogous to **III**, with NO_2 *meta* to the site of the proton, then its destabilizing influence should not be too much greater than that of CCl_3 since at this site only the inductive effect is operative (19).

TABLE 1. Rate constants for the reaction CCl_3^+ + ArH → products

ArH	Temperature (K)	k (cc molecule^{-1} s^{-1} × 10^{10})	Reaction efficiency[a]
Benzene	560	1.0	0.09
Toluene	560	4.4	0.38
o-Xylene	560	6.5	0.55
m-Xylene	560	8.9	0.75
p-Xylene	560	6.6	0.56
Mesitylene	560	8.8	0.72
Mesitylene	298	12.7	1.04
p-Fluorotoluene	432	2.9	—

[a]Reaction efficiency = $P = k_{\text{exptl}}/k_{\text{ADO}}$.

We have previously reported (20) that when CH_3^+ or $C_2H_5^+$ adds to mesitylene, the resulting arenium ion does transfer a proton, albeit slowly, to mesitylene. We have repeated that experiment with the results shown in Fig. 4. The decays of the two arenium ions by proton transfer to mesitylene at 300 K are second order, with the very low rate constants of 1×10^{-11} (C_2H_5) and 3×10^{-11} (CH_3) cc molecule^{-1} s^{-1}. These alkyl groups *meta* to the CH_2 group will stabilize the ion by ~2 kcal mol^{-1} (17), the ethyl group being slightly more effective than the methyl. Proton transfer to mesitylene will therefore be endothermic by this amount and hence the reaction will be quite slow (21), as is observed. Comparison of the results in Figs. 3 and 4 suggests that a CCl_3 substituent is more stabilizing than either CH_3 or C_2H_5, but the effect must therefore be kinetic rather than thermodynamic.

At 468 K the mesitylene-CCl_3^+ adduct did transfer a proton to mesitylene ($k = 7 \times 10^{-11}$ cc molecule^{-1} s^{-1}), consistent with the reaction being endothermic and therefore having a positive activation energy. It is interesting that proton transfer from the $C_2H_5^+$ and CH_3^+ mesitylene adducts to mesitylene at the same and higher temperatures did not show the expected increases in rate. At 468 K the methyl and ethyl adducts had rate constants of 1.6 and 0.8×10^{-11} cc molecule^{-1} s^{-1} respectively and the values decreased further at higher temperatures. It was confirmed by equilibrium measurements that the proton affinity of 1,2,3,5-tetramethylbenzene is higher than that of mesitylene, the difference being 2.2 kcal mol^{-1}. These results suggest that the adducts formed by alkyl ions and aromatics may not be the commonly accepted arenium ions. This point is under further investigation.

Figure 3 shows that although $C_{10}H_{11}Cl_2^+$ has the mesitylene-CCl_3^+ adduct $C_{10}H_{12}Cl_3^+$ as precursor its rate of formation is very low and that it must arise from thermalized $C_{10}H_{12}Cl_3^+$. There is no dependence of yield on mesitylene concentration and a second-order transfer of CCl_3^+ to mesitylene with accompanying loss of HCl may be ruled out. Thermal decomposition of the adduct, as suggested for benzene, toluene, and the xylenes, must occur. In support of this contention, the yield of $C_{10}H_{11}Cl_2^+$ was negligibly small at 298 K. No experimental evidence was found for a reaction between protonated mesitylene and CCl_4 analogous to that suggested for benzene.

Specific rate constants for the disappearance of CCl_3^+

The reaction of CCl_3^+ with an aromatic molecule to form a stabilized adduct may be written

$$[11] \quad CCl_3^+ + ArH \underset{k_b}{\overset{k_a}{\rightleftharpoons}} (ArHCCl_3^+)^*$$

$$[12] \quad (ArHCCl_3^+)^* + M \underset{k_d}{\overset{k_c}{\rightleftharpoons}} ArHCCl_3^+ + M$$

With the usual assumptions that the excited intermediate complex achieves a steady state concentration and that k_d is negligible compared with k_c, the overall forward rate constant is given by

$$[13] \quad k_f = \frac{k_a k_c[M]}{k_b + k_c[M]}$$

When $k_b \gg k_c[M]$ the reaction is kinetically third order, whereas at higher total pressure, when $k_c[M] \gg k_b$, second-order kinetics will be observed. The disappearance of CCl_3^+ was always pseudo first order (see Figs. 1–3). Second-order rate constants were obtained from the measured slopes using the equation

$$[14] \quad \ln \frac{[CCl_3^+]_t}{[CCl_3^+]_0} = \ln \frac{i_t}{i_0} = k_f[ArH]_t$$

where i_t is the normalized CCl_3^+ ion current at time t. There was no significant change in the value of any measured second-order rate constant with pressure over the limited experimental range of 2–4 Torr. Meot-Ner has discussed in detail the available data on pressure and temperature dependences of ion–molecule association reactions (22). Although third-order behaviour has been observed for many of these reactions at pressure below 1 Torr, intermediate or second-order behaviour is often observed at higher pressure especially for more complex molecules. It is not surprising that only second-order behaviour is observed in our systems, which contain relatively large participating molecules with many degrees of freedom in their internal motions.

Second-order rate constants, obtained mainly at 560 K, are presented in Table 1. Reproducibility of a given value from day to day was better than ±15%. Also shown is the efficiency of reaction per collision, $P = k_{\text{exptl}}/k_{\text{ADO}}$, where k_{ADO} is the rate constant for ion–molecule collision calculated by the averaged dipole orientation theory (23).

The efficiency of reaction is high for all the aromatics studied and is close to unity for mesitylene at all temperatures. The efficiency of reaction increases as the number of methyl groups on the aromatic increases (benzene → mesitylene), presumably due to the stability of the arenium ion formed, i.e. there is a correlation between reaction exothermicity and reaction rate.

Figure 5 shows the effect of temperature on the specific rate constants for benzene, toluene, *m*-xylene, and mesitylene. The data points for benzene show some scatter but do encompass results for a range of benzene concentrations differing by a factor of 20 and for carbon tetrachloride by a factor of more than 100. The plot for benzene shows that the temperature dependence of the specific reaction rate constant is of the form $k \propto T^n$ with $n = -2$. *m*-Xylene and mesitylene have specific rate constants close to the collisional limit at all but the highest temperatures, when the values fall off somewhat, so that in this region again each shows a negative temperature dependence. The rate constants for toluene are between those of benzene and *m*-xylene, with a negative temperature coefficient ($n \approx -1$). It was not experimentally possible to obtain data at temperatures below 298 K.

There is therefore no energy barrier to the formation of the trichloromethylarenium ions but there are insufficient data to

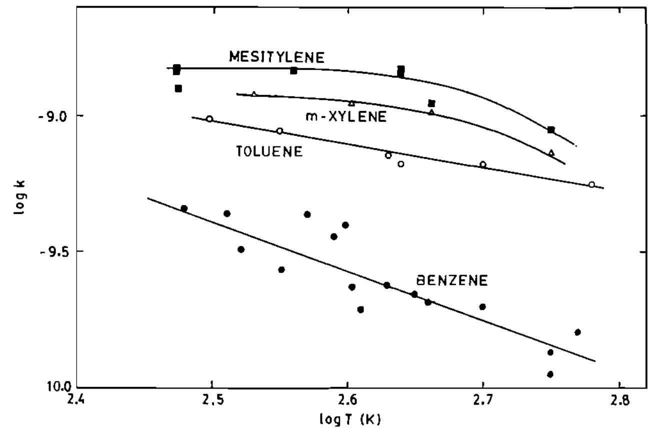

FIG. 5. The variations with temperature of the specific rate constants for the reactions of CCl_3^+ with benzene, toluene, *m*-xylene, and mesitylene. Ion source pressures 2–4.5 Torr. For *m*-xylene and mesitylene the points encompass results obtained with carbon tetrachloride in the concentration range 0.1–0.3 mol% and 4×10^{-3} mol% aromatic. For benzene and toluene the range of carbon tetrachloride concentrations is 5×10^{-3} to 0.1 mol% and aromatic 1×10^{-3} to 2×10^{-2} mol%. There are no significant trends with concentration variations.

speculate on the significance of the slopes of the plots shown in Fig. 5; suffice to say that the nature of the plots is consistent with the association mechanism postulated.

At 298 K benzene reacts with CCl_3^+ with an efficiency $P = 0.4$. This least reactive of the aromatics therefore reacts at this temperature once in every 2.5 collisions. In order to study in depth the temperature coefficients of the reactions of CCl_3^+ with aromatics it will be necessary to work with compounds of lower reactivity than benzene. The halogenated benzenes would be suitable candidates, although in this context it is interesting that no reaction was observed between CCl_3^+ and hexafluorobenzene at 463 K.

The conformational analysis of piriprost, an inhibitor of leukotriene synthesis, based on high-field nuclear magnetic resonance studies[1]

GEORGE KOTOVYCH, HELMUT BEIERBECK, AND DAVID SALMON
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received October 22, 1984

GEORGE KOTOVYCH, HELMUT BEIERBECK, and DAVID SALMON. Can. J. Chem. **63**, 2614 (1985).

The analysis of proton nuclear Overhauser effect data for piriprost, (6,9-deepoxy)-6,9-(phenylimino)-$\Delta^{6,8}$ prostaglandin I_1, indicates that the cyclopentene ring has the ^{11}E conformation. A long-range nOe effect indicates that the α-chain is folded near the pyrrole and the phenyl rings.

GEORGE KOTOVYCH, HELMUT BEIERBECK et DAVID SALMON. Can. J. Chem. **63**, 2614 (1985).

Une analyse des données relatives à l'effet Overhauser nucléaire du proton pour le piriprost, déépoxy-6,9 phénylimino-6,9 $\Delta^{6,8}$-prostaglandine I_1, indique que le noyau cyclopentène existe dans la conformation ^{11}E. Un effet eOn à longue distance indique que la chaîne α est repliée près des noyaux pyrrole ainsi que phényle.

[Traduit par le journal]

The leukotrienes are the products of the metabolism of arachidonic acid, which proceeds via two enzymatic processes. Cyclooxygenase transforms arachidonic acid to the prostaglandins, the thromboxanes, and prostacyclin, whereas lipoxygenases give rise to the leukotrienes. The properties and syntheses of the leukotrienes have been well reviewed (1, 2). The leukotrienes may be separated into two categories. The first series consists of leukotrienes C_4, D_4, and E_4, which collectively account for the biological activity ascribed to Slow Reacting Substances of Anaphylaxis. These compounds may therefore be important mediators of human diseases such as bronchial asthma. The second series consists of 5,12-dihydroxyeicosatetraenoic acids and one of these is leukotriene B_4, which is a potent stimulator of the movement of the leucocytes in vitro.

Over the last few years, we have been interested in the conformational analysis of the prostaglandins and leukotrienes (3, 4) as well as in quantitative nuclear Overhauser effect (nOe) studies as applied to flexible systems. In the course of these studies, we have analyzed nuclear Overhauser effect data for piriprost (6,9-deepoxy)-6,9-(phenylimino)-$\Delta^{6,8}$ prostaglandin I_1 (5), an inhibitor of leukotriene synthesis (Fig. 1). The quantitative analysis of the nOe data indicates the presence of a long-range interaction between the H-2 protons of the α chain and the pyrrole as well as the phenyl protons. These results will lead to a better understanding of structure–activity relationships.

Experimental

Piriprost was a gift from the Upjohn Company, in Kalamazoo, Michigan. The sample was prepared in glycine-d_6 buffer in D_2O, pH 9.95. The sample was frozen on the vacuum rack, the D_2O was removed, and fresh 100% D_2O was vacuum distilled into the nmr tube. The sample was then degassed, using the freeze–pump–thaw technique, and sealed. The solution concentration was ~0.005 *M* to minimize intermolecular association. About 5% EDTA was added to the solution. All glassware was cleaned extensively, including a nitric acid wash, to eliminate paramagnetic impurities.

All nmr measurements were carried out on a Bruker WH-400 FT nmr spectrometer equipped with an Aspect 2000 data system, using 16K, 32K, or 64K of memory, as required. The solvent deuterium resonances served as lock signal.

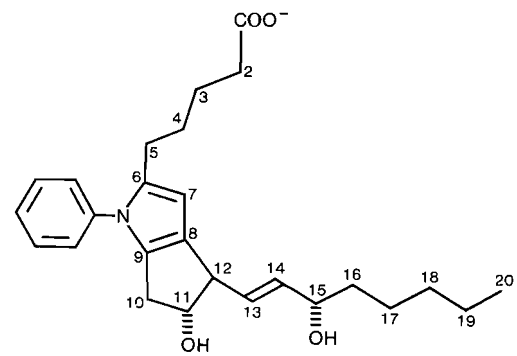

FIG. 1. The structure of piriprost.

For the determination of nonselective longitudinal ^{1}H relaxation times the $180°-t-90°$ pulse sequence was employed. Usually three M_∞ and twelve M_t measurements were taken, with $t \leq T_1$. The M_∞ and M_t represent sums of peak heights for each multiplet. Relaxation times were derived by a ln $(M_\infty - M_t)$ vs. t least-squares linear fit as well as a nonlinear least-squares fit using the Bruker DISNMR program, with good agreement. The T_1 data are averages of three determinations.

In the nOe experiments the decoupler was set to the first of three or four multiplets and four transients recorded (quadrature detection), the decoupler moved to the next multiplet, and finally far off resonance. Each multiplet was irradiated for a time $t \geq 5T_1$ with sufficient power to just saturate that signal. Each quoted nOe value is the average of three to five determinations. The quantitative nOe's were evaluated as follows. The normal and saturated spectra were simultaneously displayed on the screen and then subtracted. The difference spectrum was plotted and then the integration was performed. The intensity of the proton being saturated was used as the reference and nOe's are measured with respect to this peak.

Nuclear Overhauser effects

For the case of isotropic motion and dipole–dipole relaxation the fractional enhancement $f_d(s)$ at nucleus d on saturating signal s is given by (6)

$$[1] \quad f_d(s) = A\left[\sum_s g_d(s) - \sum_{i \neq d,s} f_i(s) g_d(i)\right] = -A \sum_{i \neq d} f_i(s) g_d(i), \qquad f_s(s) = -1$$

where $g_d(i)$ = the geometric term = $N_i\langle r_{di}^{-6}\rangle / \Sigma N_j \langle r_{dj}^{-6}\rangle$; N_j = number of magnetically equivalent nuclei j; r_{dj} = distance between protons d and j; and

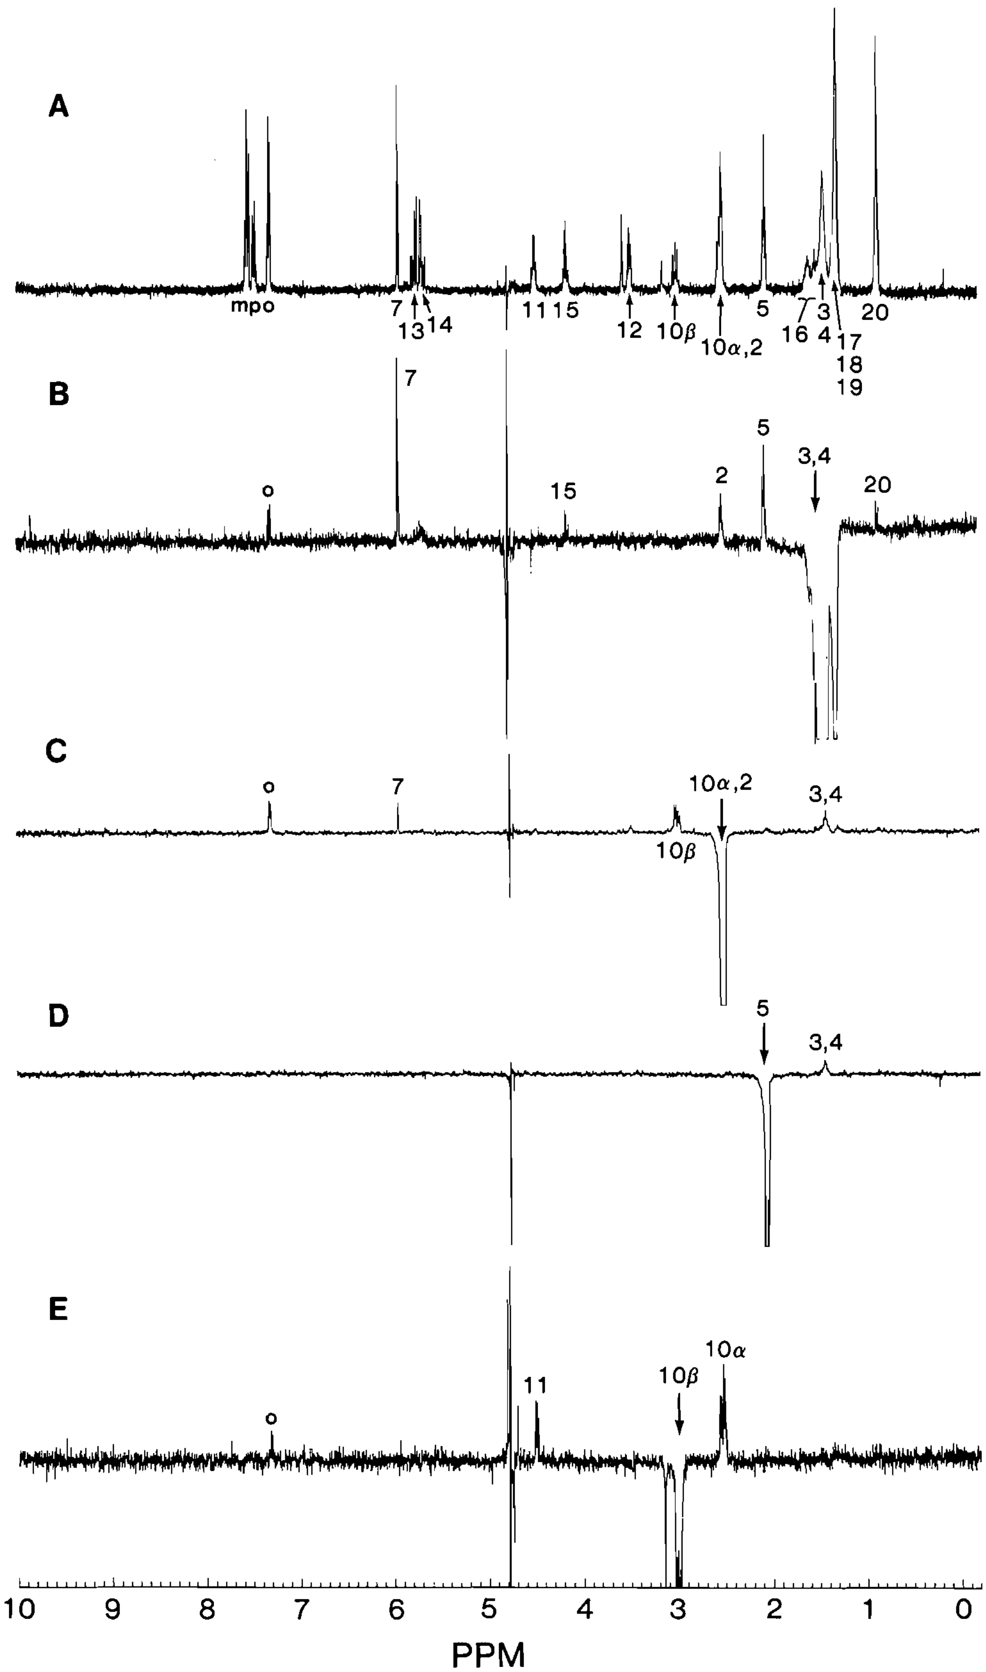

FIG. 2. The nmr spectra observed for piriprost. (A) the normal spectrum including solvent suppression, (B) saturation of the H3,4 multiplet, (C) saturation of the H10α and H2 multiplets, (D) saturation of H5, and (E) saturation of H10β.

TABLE 1. Chemical shifts (ppm) and coupling constants (Hz) for piriprost in glycine buffer, pH 9.85[a]

Protons	δ	Protons	J
2 (10α)	2.528	H2–H3	7.0
3	1.425		
4	1.432	H4–H5	7.2
5	2.060		
7	5.944		
10α (2)	2.528	H10α–H10β	15.25
10β	3.004	H10β–H11	7.2
11	4.498	H10α–H11	5.7
12	3.485		
13	5.774	H11–H12	5.5
14	5.682	H12–H13	7.1
15	4.159	H13–H14	15.3
16, 16*	~1.57	H14–H15	7.2
17–19	1.308	H15–H16	6.9
20	0.870	H19–H20	6.9

[a]The reference for the chemical shifts was internal DSS that was added after all the nOe and T_1 measurements were completed.

A = the correlation term

$$= [6\tau_c/(1 + 4\omega^2\tau_c^2) - \tau_c]/[\tau_c + 3\tau_c/(1 + \omega^2\tau_c^2) + 6\tau_c/(1 + 4\omega^2\tau_c^2)]$$

The brackets in $\langle r_{dj}^{-6}\rangle$ indicate conformational averages (7), where appropriate. The $f_d(s)$ were derived by an iterative least-squares fit of eq. [1] to the observed nOe's, treating A as an adjustable parameter.

Relaxation times

Nonselective ^{1}H relaxation times were calculated by a least-squares fit of eq. [2] (6) to the observed values, treating B as variable

$$[2] \quad T_{1i} = B/\left[\sum_{j\neq i} N_j\langle r_{ij}^{-6}\rangle + (N_i - 1)r_{ii}^{-6}\right]$$

where

$$B = 10/\{\hbar^2\gamma_H^4 \times [3\tau_c/(1 + \omega^2\tau_c^2) + 12\tau_c/(1 + 4\omega^2\tau_c^2)]\}$$

Ring conformations

The ring coordinates were based on the microwave structure of pyrrole (8) coupled with the force-field structure for cyclopentene (9).

The cyclopentene ring can only adopt the ^{11}E or $_{11}E$ conformations and the nOe data support the ^{11}E conformation. This places the ω chain as well as the C-11 OH group pseudoequatorial. The phenyl group must be nearly perpendicular to the pyrrole ring due to steric interactions from the protons at C5 and C10. In this conformation H10β is closer to the phenyl protons than H10α. X-ray data of related systems indicate that in 2,6-disubstituted biphenyl analogs the angle between the planes is either 73.9° (10) or 91.8° (11).

Side chain conformations

Coordinates and conformer populations for segment C2–C15 were needed. The conformations of the α- and ω-chains were built with C—C and C═C bond lengths of 0.154 and 0.134 nm, trigonal bond angles, and eclipsed C(sp^2)—C(sp^3) and staggered C(sp^3)—C(sp^3) rotamers. The N—C6—C5 bond angle was taken to be 120° and the C6—C5—C4 and C5—C4—C3 bond angles 112°.

Results and discussion

The 400-MHz nmr spectrum of piriprost is shown in Fig. 2 together with the multiplet assignments. These are based on decoupling experiments. Representative nOe experiments are also presented in Fig. 2. The chemical shifts and coupling constants are shown in Table 1. For the cyclopentene ring, only three vicinal coupling constants are available. On this basis, it

[a]The error limits on the observed nOe's are estimated to be one unit.
[b]A correlation time of 0.25 ns was used in the calculations.
[c]The 2 and 10α protons overlap but the appropriate nOe's are assigned as shown.
[d]The calculated nOe is due to the saturation of H10α.

was difficult to confirm the ring conformation. The nOe data proved most useful in showing that this ring has the ^{11}E conformation (Table 2). The nOe expression [1] is applicable to the rigid portion of the molecule, from C6 to C15, as is the case for prostacyclin and its analogs (12, 13).

Excellent agreement is observed between the observed and calculated nOe's between the ring protons, namely, H10α, H10β, 11, and 12 (Table 2) for the ^{11}E conformation of the cyclopentene ring. The phenyl group is oriented almost perpendicular to the plane of the pyrrole ring. This is supported by the fact that an nOe is not observed to the *ortho* protons on saturating H5. An nOe is not observed to H5, H10α, nor H10β on saturating the *ortho* protons. Saturation of H10β results in a small nOe (1.6%) to the *ortho* protons. Saturation of the overlapping H2 and H10α multiplet results in a 6.1% nOe to the *ortho* protons. In both cases the calculated nOe is 1%. The difference is due to the interaction between the H2 and the *ortho* protons. A wide range of calculations were carried out in which the phenyl group was placed at different positions with respect to the pyrrole ring, but the best agreement between the observed and calculated nOe values was for the perpendicular phenyl ring conformation.

The data in Table 2 show that the large long-range nOe from H2 to H7 is about 4.5%. This nOe cannot arise from saturation of H10α (which overlaps H2) because the internuclear distance across the ring is too large. Finally, saturation of the *ortho* protons results in a very small nOe to H2.

The calculated and observed T_1 data are presented in Table 3. Good agreement is observed for protons H7, H10β, H11, and H12 as well as the *meta* protons. The long T_1 for the phenyl *ortho* protons becomes 1.43 s when the phenyl ring is

para	2.05	1.63

[a]A correlation time of 0.10 ns was used to calculate the T_1 data. The error limits on the T_1 measurements are ±5%.

twisted 30° out of the perpendicular orientation, and then is in good agreement with the observed T_1 of 1.53 s. The longer observed T_1 for H_p is a special case because it is on an axis of rotation and hence may have a shorter correlation time. Hence these data suggest some flexibility in the conformation of the phenyl ring. Finally, the calculated T_1's are based on a correlation time of 0.10 ns, which is slightly shorter than the 0.25-ns correlation time that gives the best fit to the nOe data (Table 2). The reason for this discrepancy is not known, but was observed previously in the PGI series (13).

The ω-chain conformations are determined by the fact that acyclic C(sp^2)—C(sp^3) bonds such as C12—C13 and C14—C15 are known to prefer rotational states in which the double bond eclipses the single bond (14, 15). In this situation the C12—H and C15—H bonds would be more or less coplanar with C13—C14. The vicinal coupling constants (J(H12−H13) = 7.1 Hz and J(H14−H15) = 7.2 Hz) do not agree with an exclusive antiperiplanar conformation, for which Garbisch's equation (16) estimates a value of 11.6 Hz. Consequently, other eclipsed rotamers are significantly populated. Ideally, the nOe experiment should allow the estimation of rotamer populations. Unfortunately H13 and H14 form an AB system and only the f_i{13,14} are available. Consequently, the nOe's and T_1's in Tables 2 and 3 were calculated with the population of the preferred rotamer to be 50%, as was done with the PGI series (13). In the minor rotamers H14 comes very close to H11 and a large nOe (10.4%) is calculated for f_{11}{13,14}. The observed nOe is 4.1%. In the absence of a molecular mechanics calculation for this molecule, a computer fit to the T_1 and nOe data was not pursued beyond C14 because the range of conformers about C12—C13 could be varied, or C12—C13 may be in rotational states with an H12—H13 dihedral angle close to 150° (3).

The mobility of the α-chain, and the close approach of H2 to the *ortho* protons as well as H7 is most interesting. As there is no nOe from H5 to H7, this indicates that H5 must be as far away as possible from H7. Similarly, there is no nOe to the *ortho* protons on saturating H5. This is consistent with the nearly perpendicular orientation of the phenyl ring. However, rotation about C5—C6 is necessary. The C4—C5—C6—C7 dihedral angle of zero will explain the lack of an nOe from H5 to H7, but it will exclude an nOe from H2 to the *ortho* protons. What was done, therefore, in our calculations was to take this angle as zero and C3—C4—C5—C6, C2—C3—C4—C5, and C1—C2—C3—C4 dihedral angles all *trans*. This does not bring the H2 protons near the *ortho* nor the H7 protons to which an nOe is observed. But because of the wide range of conformations that can be adopted by this chain, coupled with the fact that the α-chain will have a shortening of the correlation times as the segmental motion increases, the above model was used in the calculations.

In Table 2, the calculated contributions to the nOe's arising from the α-chain are therefore not reported, i.e. from H2 to H7 and to the *ortho* protons, from H3,4 to H7, nor from H7 to H3,4.

In summary, a long-range nOe is observed from H2 to the *ortho* protons and the pyrrole H7 proton. In all of our previous work involving the prostaglandins, this long-range nOe was not observed, either because of multiplet overlap or due to the fact that for the prostacyclin analogs there are two geminal H7 protons. As these protons relax each other, it would be difficult to observe long-range nOe's. The ring adopts an ^{11}E conformation, which is supported specifically by the nOe data, more so than the limited coupling constant data. The phenyl ring is almost perpendicular to the plane of the rings as determined by the small nOe's between the H10 and H5 protons and the aromatic ring protons, while the T_1 data suggest some flexibility in this ring. Finally, the ω-chain conformations are similar to those observed in the prostacyclin series of compounds because the coupling constants are similar.

Nitro-olefin bicycloannulation: one-step synthesis of tricyclo[3.2.1.$0^{2,7}$]octan-6-ones from cyclohexenones and of tricyclo[2.2.1.$0^{2,6}$]heptan-3-ones from cyclopentenones

Nitro-olefins bicycloannulate the α′-enolates of α-cyclohexenones and α-cyclopentenones by initial addition at −78°C, followed by further reaction *in situ* in the presence of hexamethylphosphoramide in refluxing tetrahydrofuran to give tricyclo-[3.2.1.$0^{2,7}$]octan-6-ones and tricyclo[2.2.1.$0^{2,6}$]heptan-3-ones in a single synthetic step. The reactions with 1-nitropropene and with a nitro-olefin having a more complex β-substituent are stereoselective, forming predominantly the tricyclic diastereomer in which the group derived from the β-substituent of the nitro-olefin is *syn* to the carbonyl bridge. Based on the isolation of intermediates and side products, the mechanism of the bicycloannulation is shown to proceed via sequential kinetically controlled conjugate addition of the enolate to the nitro-olefin at low temperatures, thermodynamically controlled intramolecular Michael addition at higher temperatures to give a bicyclo[2.2.2]octanone intermediate, and hexamethylphosphoramide-assisted expulsion of the nitro group as nitrite ion with formation of the cyclopropane ring. For the first time this type of bicycloannulation has been applied to cyclopentenones, and a one-step synthesis of tricyclenone has been carried out to demonstrate the synthetic utility of this new reaction.

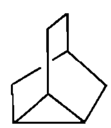
ROBERT M. CORY, PAUL C. ANDERSON, MURRAY D. BAILEY, FRED R. MCLAREN, RICHARD M. RENNEBOOG et BRIAN R. YAMAMOTO. Can. J. Chem. **63**, 2618 (1985).

À −78°C, les nitro-oléfines s'additionnent sur les α′-énolates des α-cyclohexénones et des α-cyclopenténones; par réaction *in situ* en présence d'hexaméthylphosphoramide dans le tétrahydrofuranne au reflux, les produits ainsi obtenus conduisent en une seule étape à une bicycloannellation qui fournit les tricyclo[3.2.1.$0^{2,7}$]octanones-6 et les tricyclo[2.2.1.$0^{2,6}$]heptanones-3. Le nitro-1 propène et les nitro-oléfines ayant des substituants plus complexes en positions β réagissent d'une façon stéréosélective pour conduire à la formation prépondérante du diastéréoisomère tricyclique dans lequel le groupe provenant du substituant en position β de la nitro-oléfine est en position *syn* par rapport au pont carbonyle. En se basant sur la nature des intermédiaires et des produits secondaires qu'on a pu isoler, on montre que la bicycloannellation s'effectue par l'intermédiaire d'une série d'additions conjuguées sous contrôle cinétique de l'énolate sur la nitro-oléfine à basses températures et d'additions de Michael intramoléculaires à haute température sous contrôle thermodynamique qui conduisent à la bicyclo[2.2.2]octanone intermédiaire et à l'expulsion du groupe nitro sous forme de cyclopropane. On a appliqué pour la première fois ce type de bicycloannellation aux cyclopenténones et, pour démontrer l'utilité de cette nouvelle réaction, on a réalisé en une seule étape la synthèse de la tricyclénone.

[Traduit par le journal]

Introduction

The development of new methodology for the efficient construction of polycyclic systems has long been a major emphasis of research in organic synthesis. Our own contributions to this work have focussed on the discovery of new bicycloannulation reactions, in which tricyclic structures are formed in a single synthetic operation from monocyclic precursors.[2] In particular, we have reported a series of methods for the bicycloannulation of cyclohexenes (1*b*, 2) and cyclohexenones (1*a*, 3) to give tricyclo[3.2.1.$0^{2,7}$]octanes (**1**). This tricyclic system is a salient



1

feature of four terpene families, including the ishwarane (4) and cycloseychellene (5) sesquiterpenes and the trachylobane (6) and helifulvane (7) diterpenes, and we have applied two of our bicycloannulation reactions to the total synthesis of ishwarane (1*b*, 2*b*) and trachyloban-19-oic acid (3*c*, *d*).

[1]Author to whom correspondence should be addressed.

[2]For the most recent previous papers in the series Bicycloannulation see ref. 1.

While recent work elsewhere has involved the construction of this tricyclo-octane system using multi-step procedures terminated by carbene insertion reactions (8),[3] our cyclohexenone bicycloannulations (Scheme 1) follow a series of three mechanistic steps, none of which involve carbenes. The α′ (kinetic) enolate (**2**) of the enone undergoes an initial conjugate addition to an activated olefin (**3**), in which Z has dual character, acting first as an electron-withdrawing group and then as a leaving group, displacement of which forms the cyclopropane ring of the tricyclo-octanone (**4**).[4] We have demonstrated that this type of bicycloannulation is successful with vinyl phosphonium salts (3*c*−*e*), vinyl sulfones (1*a*, 3*b*), and nitro-olefins (3*a*), and Hagiwara *et al.* have reported an analogous reaction of α-bromoacrylic esters, which they have used as the key step in a synthesis of ishwarane (12). Nitro-olefins, in particular, have become increasingly useful in synthesis in recent years (13−15), and we present herein a full description of our own work with these versatile reagents.

[3]We have also used a carbene strategy for a total synthesis of ishwarone (1*b*, 9). The first total synthesis of ishwarone employed a fundamentally different approach, in which the cyclopropane ring was generated by carbene addition in the *first* step of the construction of the tricyclo-octane system from a cyclohexene (10).

[4]The cyclopropane ring of this tricyclo-octanone system has also been formed by intramolecular enolate displacement of *conventional* leaving groups (11).

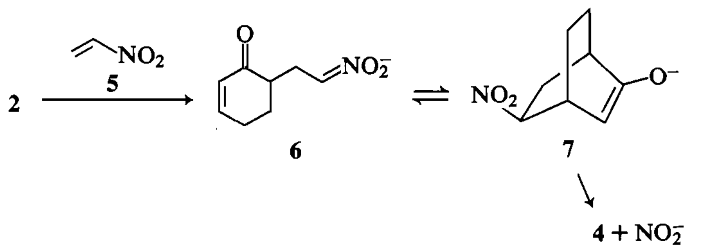
SCHEME 1. Bicycloannulation of cyclohexenone.



SCHEME 2. Nitro-olefin bicycloannulation.

The proposed mechanism of our bicycloannulation with nitroethylene (**5**) is shown in Scheme 2, in which the initial intermediate, nitronate **6**, closes to a bicyclo[2.2.2]octane system (**7**), followed by expulsion of nitrite ion. Conjugate addition of ketone enolates to nitro-olefins has found recent synthetic utility (13, 15*a*, *b*, *c*, *h*), and Michael addition of nitronate ions to α,β-unsaturated ketones has long been a useful tool (13, 16). The displacement of the nitro group from sp^3 carbon has received little attention (17), but a cyclopropanation method involving base-catalyzed addition of nitromethane and nitroethane to alkylidene malononitriles and malononitrile esters followed by intramolecular displacement of the nitro group has been reported (18). However, although each of the three steps in the bicycloannulation had precedent in previous studies, their combination had not been reported prior to our investigation.

Results and discussion

As in our studies of vinyl sulfones, in our initial experiments with nitro-olefins the procedure effective in bicycloannulations with vinyl phosphonium salts (3*c*) failed to provide volatile products, even with long reflux periods in tetrahydrofuran (THF). However, addition of hexamethylphosphoramide (HMPA) after addition of the nitro-olefin to the enolate, followed by a period of reflux, caused the formation of low to moderate yields of tricyclo-octanones. Polymerization of the nitro-olefin was minimized by adding it at −78°C. Thus, for example, when a solution of 1-nitropropene (**10**) in THF was added to a solution of the lithium α′-enolate (**9**) of isophorone (**8**) in THF at −78°C followed by addition of HMPA at room temperature and reflux for 16 h, there was obtained a 63% combined yield of two diastereomeric tricyclo-octanones: 58% of isomer **11**, having the 8-methyl group *syn* to the carbonyl bridge, and 5% of isomer **12**, having the 8-methyl *anti*. In addition, the nitro-bicyclo-octanone **13** was isolated in 4% yield (see entry 1, Table 1).

The stereochemistry of the major product was evident from the fact that the C-8 proton was coupled only with the 8-methyl protons in ^{1}H nmr, giving rise to a quartet at δ 2.36 with a coupling constant of 6.5 Hz. The lack of coupling of the *anti* 8-H with the bridgehead protons vicinal to it at C-1 and C-5 had been established in earlier work (3*c*). In contrast, the absorption due to the C-8 proton of epimer **12** appeared as a quartet

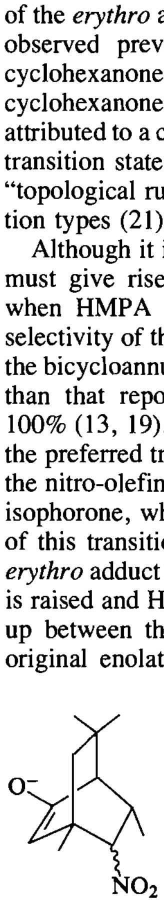
16 17

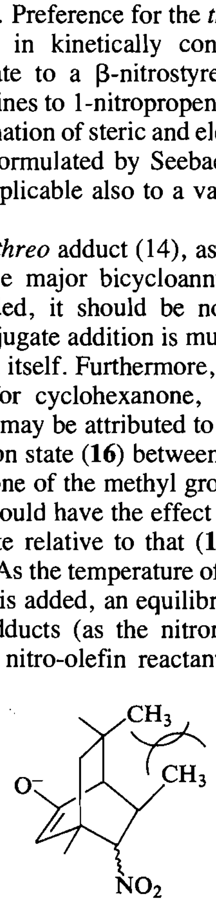
of doublets of doublets at δ 2.43, in which coupling constants of 7, 5, and 3 Hz were established by decoupling experiments to be due to coupling with the 8-methyl, C-5, and C-3 protons, respectively. These assignments were confirmed by LIS (lanthanide-induced shifts) studies, which found the ratio of Eu(fod)$_3$-induced shifts of the 8-methyl relative to the 8-H absorptions to be 1.2 for the *syn* isomer (**11**) vs. 0.42 for the *anti* isomer (**12**). For the adduct, **13**, decoupling showed the proton at C-6 (δ 2.68) to be coupled with the bridgehead proton at C-1, but with a coupling constant near zero, and also demonstrated coupling of 6-H with the proton at C-5 (δ 4.47) with J = 9 Hz. The C-5 proton also showed long range (*W*) coupling of 1 Hz with the proton at C-3 *anti* to the nitro group. These data are consistent only with the *syn-syn* stereochemistry proposed for this product.

When the reaction was quenched with acetic acid 30 min after adding the nitropropene at −78°C, two diastereomeric adducts were isolated in a combined yield of 74%. The major product (46%) was assigned to the *threo* adduct (**14**) based on the similarity of the AB pattern (part of an ABX system) in the ^{1}H nmr, due to the CH_2NO_2 protons, to that of the corresponding adduct with carvone (*vide infra*), the structure of which was unambiguously determined. These AB absorptions for **14** appeared at δ 4.60 and 4.28 with vicinal couplings of 10 and 3 Hz, respectively, and a geminal coupling constant of 13 Hz. By default the minor diastereomer (28%) was the *erythro* adduct, **15**, in the nmr of which the corresponding AB pattern at δ 4.62 and 4.36 showed vicinal couplings of 7 and 7.5 Hz, respectively, and the same geminal coupling of 13 Hz. In addition, the side-chain methyl doublet appeared at δ 1.25 in the spectrum of the *threo* diastereomer but at δ 1.00 in the case of the *erythro* adduct. Preference for the *threo* adduct has been observed previously in kinetically controlled additions of cyclohexanone enolate to a β-nitrostyrene (13, 19) and of cyclohexanone enamines to 1-nitropropene (20). This has been attributed to a combination of steric and electronic effects in the transition state and formulated by Seebach and Golinski as a "topological rule" applicable also to a variety of related reaction types (21).

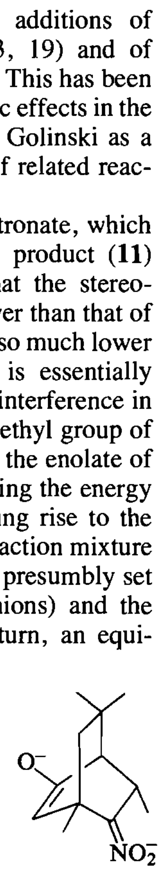
Although it is the *threo* adduct (14), as the nitronate, which must give rise to the major bicycloannulation product (**11**) when HMPA is added, it should be noted that the stereoselectivity of the conjugate addition is much lower than that of the bicycloannulation itself. Furthermore, it is also much lower than that reported for cyclohexanone, which is essentially 100% (13, 19). This may be attributed to steric interference in the preferred transition state (**16**) between the methyl group of the nitro-olefin and one of the methyl groups of the enolate of isophorone, which would have the effect of raising the energy of this transition state relative to that (**17**) giving rise to the *erythro* adduct (**15**). As the temperature of the reaction mixture is raised and HMPA is added, an equilibrium is presumably set up between these adducts (as the nitronate anions) and the original enolate and nitro-olefin reactants. In turn, an equilibrium concentration of each of the bicyclo-octanes (**18** and **19**) resulting from intramolecular Michael addition of **14** and **15**, respectively, should also be established. This time it is adduct **19** in which unfavorable steric interaction between the two offending methyl groups is present. Thus, preference for the *syn* tricyclo-octanone **14** can be ascribed to an unfavorable equilibrium concentration of the *anti* adduct, **19**, relative to that of the *syn* adduct, **18**.



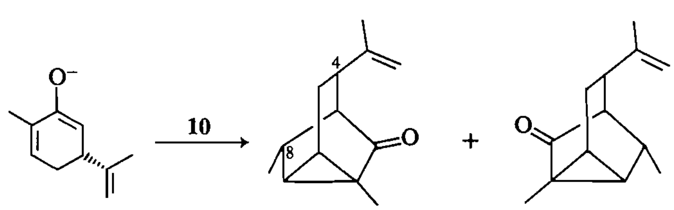
18



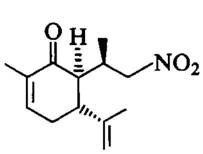
19



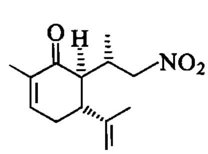
20



21 **22** **23**



24



25

The formation of the annulation product, **13**, as a by-product of the bicycloannulation is understandable if one assumes that the excess LDA can remove a proton from intermediate **18** to give dianion **20**, thus removing some of **18** from the pathway leading to tricyclo-octanone **11** by preventing the final step, displacement of the nitro group, from taking place. During work-up, protonation of **20** would be expected to occur from the side of the nitronate moiety *anti* to the adjacent methyl group at C-6, thus providing the observed stereochemistry in adduct **13**. Whatever the explanation, the presence of **13** at least proves the presence of intermediate **18** in the reaction mixture and lends support to the proposed mechanism for the bicycloannulation.[5]

In our studies of vinyl phosphonium bicycloannulation a substrate providing some of the highest yields was carvone, although these were only on the order of 30−45% (3*c*). In the bicycloannulation of the same substrate with phenyl vinyl sulfone, however, only a 5% yield of tricyclo-octanone was obtained (1*a*, 3*a*). It was thus of great interest to determine if the relatively high yield obtained from the bicycloannulation of isophorone with 1-nitropropene extended also to carvone. Unfortunately, the results were even less encouraging than in the case of the vinyl sulfone. Reaction of the α-enolate (**21**) of *l*-carvone with 1-nitropropene under the same conditions as for isophorone, followed by addition of HMPA and reflux, gave only a 3% yield of the expected tricyclo-octanone, **22**, formed by attack of the nitro-olefin from the less hindered side of the enolate, and a 1% yield of tricyclo-octanone **23**, formed by attack on the *more* hindered side of the enolate. Interestingly, none of the two possible diastereomers with an *anti* 8-methyl group was detected, but in view of the low yields it is quite possible that minor amounts of other diastereomers were formed but in less than detectable quantities.

As was the case for the major product (**11**) from bicycloannulation of isophorone, the C-8 proton of *both* of the carvone-derived tricyclo-octanones gave rise to a quartet with J = 6.5 Hz in each of their nmr spectra (δ 2.11 for **22** and 2.18 for **23**), showing that the 8-methyl group in each of these diastereomers is *syn* to the carbonyl bridge. Again this assignment was confirmed by LIS, with a ratio of 0.9 for 8-methyl to 8-H for **22** and a ratio of 1.0 for **23**. Inter-compound LIS ratios for the isopropenyl groups were 2.3 for the methyl shift of **22** to that of **23**, 1.3 for the vinyl protons *trans* to the tricyclic system, and 3.2 for the *cis* vinyl protons, indicating *opposite* stereochemistry at C-4, the *syn* diastereomer being the major product, **22**. A detailed analysis of the ^{13}C nmr spectra (see Experimental) of the two tricyclo-octanones was also consistent with this stereochemical assignment.

[5]We have no evidence which would indicate the mechanism by which the nitro group is actually displaced, but the involvement of single electron transfer (SET) in this step would enable displacement even when the nitro group is *syn*, as in adduct **13**. Although an internal S_N2 type of mechanism has been proposed for cyclopropane ring formation of this type (18), a SET mechanism is preferred for most displacements of nitro groups from sp^3 carbon (17).

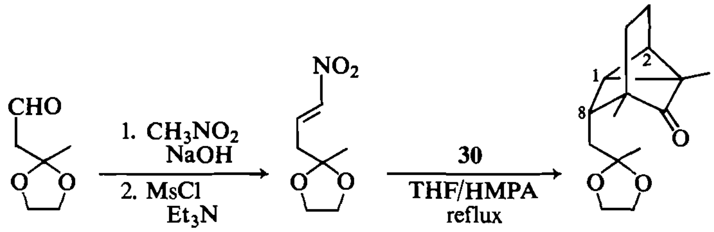
SCHEME 3. Retro-synthetic analysis.

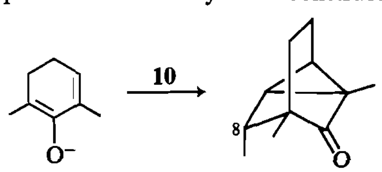


32 33 34

SCHEME 4. Synthesis of a "cycloseychellene" precursor.

In spite of the low yield of the bicycloannulation of carvone, quenching with acetic acid at −78°C gave a 4 : 1 mixture of two diastereomeric adducts from which the major one could be isolated by recrystallization from ethanol in 75% yield. A single crystal X-ray structure determination (22) proved that this adduct (**24**) had the *threo* stereochemistry with respect to the new carbon−carbon single bond, as predicted by the *topological rule*, and that addition of the nitro-olefin had occurred from the side of the enolate opposite to the isopropenyl group, as expected on steric grounds. The minor adduct (**25**) was separated from the mother liquor with difficulty by thick-layer chromatography in 7% yield. That this diastereomer had the *erythro* stereochemistry was indicated by the fact that the nmr absorption due to the CH_2NO_2 protons was an AB portion of an ABX pattern almost superimposable on that of the minor adduct (**15**) from isophorone (δ 4.91 and 4.62; J_{gem} = 13 Hz and J_{vic} = 7 and 6.5 Hz, respectively). Similarly, the AB pattern at δ 4.58 and 4.32 for the *threo* adduct (**24**) showed a geminal coupling constant of 12 Hz and vicinal ones of 9 and 4 Hz, respectively, very close to the values observed for the major isophorone adduct and thus supporting the stereochemical assignment of the latter. As with the isophorone adducts, the doublet for the methyl group of the side chain appeared at δ 1.29 and 1.00 for the *threo* and *erythro* adducts, respectively. Thus, low temperature addition of 1-nitropropene to carvone occurs exclusively from the less hindered side of the enolate, in spite of the observation that at higher temperatures and in the presence of HMPA tricyclo-octanone **23** is formed and must be derived from initial attack of the nitro-olefin from the *more* hindered side. Again, this seeming discrepancy may be attributed to kinetic control at −78°C in the absence of HMPA vs. thermodynamic control at reflux in the presence of HMPA. The greater stereoselectivity observed for addition to carvone at low temperature as compared with that for the corresponding addition to isophorone is consistent with the lack, in the transition state for carvone, of any adverse methyl−methyl steric interaction as depicted in structure **16**.

The relatively high degree of stereoselectivity found in the bicycloannulation of isophorone was attractive from the point of view of natural product synthesis, and one possibility investigated was a total synthesis of a structure (**26**) proposed for cycloseychellene, a tetracyclic patchouli oil sesquiterpene, in 1973 (23). The retro-synthetic strategy, shown in Scheme 3, involved disconnection of the two bonds indicated, giving tricyclo-octanone **27** after functionalization, where R would contain appropriate functionality for construction of the missing ring. Based on our results for nitro-olefin bicycloannulation of isophorone and carvone, this intermediate should be preparable stereoselectively from nitro-olefin **28** and cyclohexenone **29**. There were, however, two potential stumbling blocks in the path of this scheme. First, although the reasons for the low yield of the bicycloannulation of carvone are unknown, it is related to **29** in that both enones have a methyl group at the α position, as opposed to the β-methyl of the high yielding substrate, isophorone. Second, it was not known to what extent the methyl−methyl steric interaction depicted in intermediate **19** was responsible for the high stereoselectivity in the bicycloannulation of isophorone, an effect which would be absent in the addition of **28** to **29**.



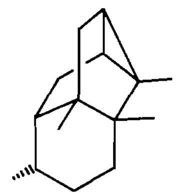
30 31

Therefore, a model study was carried out using 1-nitropropene as the bicycloannulation reagent and cyclohexenone **29** (1*b*) as the substrate. When the α'-enolate (**30**) of this ketone was treated with 1-nitropropene under the same conditions as for the other two substrates, we were gratified to discover that the desired tricyclo-octanone, **31**, was produced, apparently *with complete stereoselectivity*, in a yield of 42%! As before, the stereochemistry of the product was evident from ^{1}H nmr, in which the 8-H absorption appeared as a quartet (J = 7 Hz) at δ 2.02, and the LIS ratio of 8-methyl to 8-H was 1.0.

Whatever the reasons for this unexpected success, the stage was now set for cycloseychellene itself. The translation of a portion of the strategy implied in Scheme 3 into chemical reality was accomplished by choosing a masked acetonyl group to represent R. The conversion of tricyclo-octanone **27** into the natural product might be carried out by transforming the keto group of **27** into an acceptor containing a latent methyl group, ring closure by intramolecular attack of the enolate of the acetonyl group on this acceptor group, and methylation. Accordingly, the protected keto-nitro-olefin, **33**, was prepared by base-catalyzed nitro-aldol condensation[6] of nitromethane with keto-aldehyde, **32**, previously reported by Kelly and Tsang (25), followed by dehydration employing a modification of the method of McMurry and Melton (26) (Scheme 4). When this nitro-olefin was condensed with enolate **30** under the standard bicycloannulation protocol, the desired tricyclo-octanone, **34**, was isolated in 25% yield, none of the *anti* diastereomer being detected. The stereochemistry of this product was indicated by the presence of a sharp doublet in the nmr at δ 2.36 (J = 7.5 Hz), which could only be due to the bridgehead cyclopropyl proton at C-1 coupled with its vicinal partner at C-2 (3*c*). The lack of coupling of the 1-H with the proton at C-8 shows, as for the simpler tricyclo-octanones, that the side chain must have the *syn* configuration, as required for the total

[6]The more recent method of Wollenberg and Miller (24), employing potassium fluoride as the catalyst, proved to be capricious in this case.

synthesis. Unfortunately, it was at this point that a report by Welch and co-workers appeared, demonstrating that structure **26** was *not* the correct one for cycloseychellene and proving that the actual structure of the natural product is **35**, in which the only difference is the placement of the cyclopropane ring (5, 8*c*).[7] From a synthetic standpoint, of course, this is not a trivial change, and the course of our proposed total synthesis had to be altered completely and started over again. Our revised synthesis, which does not involve nitro-olefin bicycloannulation, is now in the final stages and will be reported separately.



35

With the synthetic power of bicycloannulation with β-substituted nitro-olefins **10** and **33** well established, it was of interest to test the possibility that nitroethylene itself (**5**), the instability of which toward polymerization places it just within the borders of synthetic utility (14*f*, *l*), could also be used for the bicycloannulation of cyclohexenones. This would not only extend the scope of the nitro-olefin method, but would, in addition, allow an accurate comparison between the three bicycloannulation methods we have developed for cyclohexenones. We have found that *l*-carvone can readily be methylated at the α′ position (1*a*, 3*b*), and the resulting 2,6-dimethyl substituted cyclohexenone, **36**, as a mixture of diastereomers, could be converted to its α′-enolate, **37**, by reaction with LDA as usual. Treatment of this enolate with nitroethylene in the presence of HMPA using the standard bicycloannulation conditions produced a disappointingly low yield (13%) of tricyclo-octanone **38**, but in this case the reaction appeared to be completely stereoselective, only the product resulting from attack of the reagent from the less hindered side of the enolate being detected. Bicycloannulation of 3-methylcyclohexenone **39** with nitroethylene gave the annulation adduct, bicyclo-octanone **41**, as the major product, but in only 7% yield, the tricyclo-octanone (**40**) being isolated in only 3% yield. Similarly, bicycloannulation of isophorone (**8**) with the same reagent gave only a 2% yield of the desired tricyclo-octanone (**42**), the major product again being the bicyclic nitro-ketone (**43**), formed in a yield of 19%.

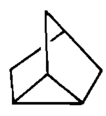
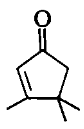
[a]Ar = *p*-chlorophenyl.

The bicycloannulation yields for nitroethylene are summarized in Table 2 along with the corresponding data for phenyl vinyl sulfone (1*a*) and vinyltriphenylphosphonium bromide (3*c*). It is quite clear that bicycloannulation with the parent nitro-olefin, at least, does not compare favorably with the other two methods. However, it must be borne in mind that nitroethylene possesses an exceptional tendency to polymerize, so that this comparison cannot be generalized to all nitro-olefins. Unfortunately, we have no information on the abilities of *propenyl* sulfones and phosphonium salts to undergo the bicycloannulation reaction, so no comparison can be made with 1-nitropropene.

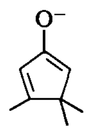
Although it would be desirable to extend these bicycloannulation methods to substrates other than cyclohexenones, our efforts toward this end were uniformly unsuccessful in the cases of the vinyl sulfones and vinyl phosphonium salts. Even cyclopentenones were uncooperative with the latter two reagents, but there still remained the possibility of success with the nitro-olefin method. In view of the variety of terpenes having the tricyclo[2.2.1.0^{2,6}]heptane ring system (**44**), including the sesquiterpenes α-santalol, α-santalene, longicyclene, cyclosativene, and cyclocopacamphene, the extension of nitro-olefin bicycloannulation to cyclopentenones would be of potential importance for the total synthesis of these natural products. Since isophorone had given the highest yields of the cyclohexenone substrates, a cyclopentenone (**45**) was chosen such that its structure approximated most closely that of isophorone. In the event, when its α'-enolate, **46**, generated in the usual way, was treated with 1-nitropropene and HMPA at reflux, a 39% yield of the desired tricyclo-heptanone (**47**) was obtained stereoselectively. The overall structure was indicated by the presence of three methyl singlets, a methyl doublet at δ 1.00, and the lack of vinyl proton absorption in the nmr, by a strong carbonyl ir absorption at 1757 cm^{-1}, and by comparison of the ^{13}C nmr data with that for related compounds (28, 29). An LIS ratio of 1.3 for 5-methyl to 5-H demonstrated the expected *syn* stereochemistry, while the latter proton gave rise to an nmr absorption which appeared to be a quartet of triplets, J = 6.5 and 1.5 Hz at δ 2.50, showing small coupling with the C-4 and C-6 protons vicinal to it.



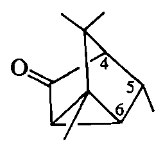
44



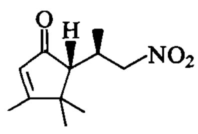
45



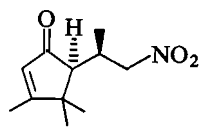
46



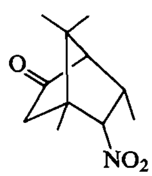
47



48



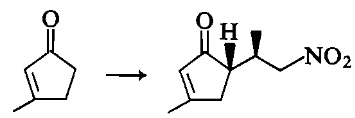
49



50

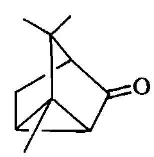
A low temperature quench with acetic acid after addition of the nitro-olefin gave unexpected results, the predominant adduct having the *erythro* stereochemistry (**48**), based again on ^{1}H nmr, and the minor product being the *threo* diastereomer (**49**), formed in yields of 50% and 37%, respectively. Although this stereochemistry is opposite to that observed for the cyclohexenone adducts, when it is compared with that of the adducts from isophorone, in which the corresponding yields were 28% and 46%, respectively, it can be seen that neither the selectivities nor the differences between them are very significant. Presumably, similar factors are responsible for the large proportion of *erythro* product in each case (*vide supra*). Interestingly, when the reaction was allowed to proceed at reflux, but in the *absence* of HMPA, the proportion of **48** and **49** was observed to slowly decrease at the expense of a new product. Work-up provided *none* of the tricyclo-heptanone (**47**) observed to form under the influence of HMPA, but gave a 3% yield of **49**, 6% of **48**, and 6% of what is believed to be the cyclized adduct, **50**, by analogy with adduct **13** from isophorone. The ^{1}H nmr data for the latter product were consistent with this stereochemical assignment, showing absorptions due to the C-5 proton at δ 4.76 as a doublet of doublets coupled with the vicinal 6-H (J = 6.5 Hz) and long-range (W) with the *exo* 3-H (J = 1 Hz), to the C-6 proton at δ 2.80 as a quintet coupled with both the 6-methyl and H-5 with a coupling constant of about 7 Hz, and to the C-1 bridgehead proton as a singlet at δ 2.13, $J_{1,6}$ being zero. The formation of this product only in the *absence* of HMPA and the isolation of the tricyclo-heptanone (**47**) only in the *presence* of HMPA would seem to argue for a predominant role in the *final* step of the mechanism, the displacement of the nitro group, for the facilitating effects of this cosolvent in the bicycloannulation reactions.

Although we were unsuccessful in isolating any volatile products from an attempted bicycloannulation of 3-methylcyclopentenone (**51**) with 1-nitropropene, a low temperature quench gave a 57% yield of an adduct which could not be completely purified, but the ^{1}H nmr of which was consistent with the *erythro* structure, **52**. If this assignment is correct, and we have no additional confirmation of it, it indicates that more work must be done before a firm understanding of the factors determining the stereochemistry of these adducts is at hand.

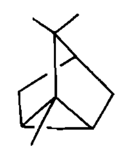


51 **52**

The success of the bicycloannulation of cyclopentenone **45** with 1-nitropropene led us to attempt a one-step synthesis of racemic tricyclenone (**53**) (30) from the same ketone. In the event, when the α'-enolate of cyclopentenone **45** was treated with nitroethylene in the presence of HMPA, the reaction required 187 h to force it to completion, but in the end a 22% yield of crystalline tricyclenone was isolated. Since tricyclenone has been converted by Wolff–Kishner reduction to tricyclene (**54**) by Nametkin and Zabrodina (31), our synthesis represents a formal two-step synthesis of this monoterpene,



53



54

which occurs naturally in *Picea abies* (L.) Karsten (= *P. excelsa* Link) (32), *Picea mariana* (Mill.) (the black spruce) (33), and *Abies balsamea* (L.) Mill. (the balsam fir) (34).

In summary, although the nitro-olefin bicycloannulation method described here often gives inferior yields to those obtained by vinyl sulfone and vinyl phosphonium salts, in many cases the yields are quite acceptable, and in one specific example, the conversion of isophorone to tricyclo-octanone **11**, the yield is among the highest ever obtained for this type of reaction. Furthermore, the high degree of *syn* stereoselectivity observed when 1-nitropropene is used as the reagent is a characteristic of this method which promises to be useful in the total synthesis of natural products. The relatively inexpensive and convenient preparation of this stable nitro-olefin from cheap and readily available materials makes it all the more attractive. Finally, for the first time it is now possible to synthesize tricyclo-heptanones in a single synthetic step from cyclopentenones, although it remains to be seen how general this method will be for this purpose. Even nitroethylene gave a fairly good yield of tricyclenone, considering that the yield of this one-step procedure was higher than the overall yield of the previously reported highest-yielding multi-step one (30). The availability of these new synthetic tools greatly expands the pool of tricyclic products and intermediates within our reach, and those that we have described, as well as (by implication) a variety of related compounds, are now only a step away.

Experimental

General

All reactions were conducted under a positive pressure of argon. Ethyl ether (when used as a reaction solvent) and tetrahydrofuran were freshly distilled from sodium benzophenone ketyl, diisopropylamine was distilled from calcium hydride and stored over 4-A molecular sieves, and hexamethylphosphoramide was distilled from 13X molecular sieves. Butyllithium (in hexane) was obtained from Ventron and was titrated with 2-butanol in xylene (bipyridyl indicator) before use.

Preparative thick-layer chromatography was performed on precoated E. Merck silica gel GF (2 mm) on glass plates. Ethyl acetate was used to extract the separated components from the silica gel.

Nuclear magnetic resonance spectra were recorded on Varian Model XL-100 and XL-200 spectrometers, and ^1H and ^{13}C chemical shifts are reported in ppm (δ) downfield from internal tetramethylsilane. Infrared spectra were obtained on a Beckman Model 4250 spectrophotometer, and mass spectra were determined by electron impact on a Varian MAT Model 311A spectrometer employing an ionizing voltage of 70 eV unless stated otherwise. Melting and boiling points are uncorrected.

*Bicycloannulation procedure. 2,4,4,8(*syn*)-Tetramethyltricyclo-[3.2.1.0^{2,7}]octan-6-one (11) and 2,4,4,8(*anti*)-tetramethyltricyclo[3.2.1.0^{2,7}]octan-6-one (12)*

To a solution of 0.62 mL (0.45 g, 4.4 mmol) of diisopropylamine and 3 mg of 2,2′-bipyridyl in 4 mL of tetrahydrofuran at 0°C was added dropwise, with stirring, 2.5 mL (4.0 mmol) of 1.6 *M* *n*-butyllithium over 10 min. The resulting crimson solution was stirred at 0°C for 15 min, and a solution of 0.46 g (3.3 mmol) of isophorone (**8**) in 4 mL of tetrahydrofuran was then added dropwise, with stirring, over 45 min. After the mixture had been cooled to −78°C, a solution of 0.35 g (4.0 mmol) of 1-nitropropene[8] in 12 mL of tetrahydrofuran was added dropwise, with stirring, over 1.75 h, and the resulting yellow solution was stirred at −78°C for an additional 30 min. After the mixture had been allowed to warm to room temperature, 5 mL of hexamethylphosphoramide was added, and the mixture was then refluxed for 16 h. The cooled mixture was poured into 50 mL of saturated aqueous sodium bicarbonate, and the aqueous phase was extracted with 3 × 50 mL of petroleum ether (boiling range 30−60°C). The combined extracts were washed with 2 × 40 mL of water and 40 mL of brine and dried over anhydrous sodium sulfate. The solvent was distilled through a Vigreux column, and the residual concentrate was subjected to preparative gas chromatography[9] (140°C for 45 min; heat to 230°C at 40°C min^{-1}; 230°C) to give the following three products (yields determined by analytical gas chromatography[10] at 210°C using *n*-hexadecane as internal standard): (a) tricyclo-octanone **11**; 58%; colorless oil; gas chromatography[9] t_r = 28 min; ir ($CHCl_3$): 1720 cm^{-1}; ^1H nmr (100 MHz, $CDCl_3$) δ: [relative lanthanide-induced shifts (LIS) with added Eu(fod)$_3$ in brackets] 2.86 (d, 1H, *J* = 14 Hz), 2.83 (d, 1H, *J* = 5 Hz), 2.61 (d, 1 H, *J* = 14 Hz), 2.51 (d, 1H, *J* = 5 Hz), 2.36 [1.0] (q, 1H, *J* = 6.5 Hz), 1.26 (bs, 1H), 1.08 (s, 3H), 1.05 (s, 3H), 1.02 [1.2] (d, 3H, *J* = 6.5 Hz), 0.90 (s, 3H); mass spectrum, *m/z* (relative intensity): 178 (M$^+$, 22), 163 (7), 150 (9), 135 (19), 121 (20), 107 (41), 83 (100), 54 (22); high resolution mass spectrum, *m/z* calcd. for $C_{12}H_{18}O$: 178.1358; found: 178.1359; (*b*) tricyclo-octanone **12**; 5%; colorless oil; gas chromatography[9] t_r = 42 min; ir ($CHCl_3$): 1720 cm^{-1}; ^1H nmr (100 MHz, $CDCl_3$) δ: [relative LIS (with added Eu(fod)$_3$) in brackets] 2.43 [1.0] (qdd, 1H, *J* = 7, 5, 3 Hz), 2.04 (d, 1H, *J* = 14 Hz), 1.89 (dd, 1H, *J* = 5, 3 Hz), 1.61 (d, 1H, *J* = 5 Hz), 1.60 (d, 1H, *J* = 14 Hz), 1.51 (d, 1H, *J* = 5 Hz), 1.30 [0.42] (d, 3H, *J* = 7 Hz), 1.11 (s, 3H), 1.10 (s, 3H), 0.86 (s, 3H); mass spectrum, *m/z* (relative intensity): 178 (M$^+$, 18), 163 (6), 150 (15), 135 (21), 121 (32), 107 (43), 95 (22), 83 (100), 53 (28); high resolution mass spectrum, *m/z* calcd. for $C_{12}H_{18}O$: 178.1358; found: 178.1361; (c) 4,6(*syn*), 7,7-tetramethyl-5(*syn*)-nitrobicyclo-[2.2.2]octan-2-one (**13**); 4%; yellow oil; gas chromatography[9] t_r = 55 min; ir ($CHCl_3$): 1710, 1550 cm^{-1}; ^1H nmr (100 MHz, $CDCl_3$) δ: 4.47 (dd, 1H, *J* = 9, 1 Hz), 2.87 (bd, 1H, *J* = 19 Hz), 2.68 (bq, 1H, *J* = 8 Hz), 2.00 (bs, 1H), 1.85 (dd, 1H, *J* = 19, 1 Hz), 1.58 (d, 1H, *J* = 14 Hz), 1.41 (d, 1H, *J* = 14 Hz), 1.34 (d, 1H, *J* = 7 Hz), 1.22 (s, 3H), 1.02 (s, 3H), 0.97 (s, 3H); mass spectrum, *m/z* (relative intensity): 225 (M$^+$, 10), 178 (7), 153 (7), 135 (100), 121 (52), 109 (62), 95 (74), 83 (48), 69 (55), 55 (74); high resolution mass spectrum, *m/z* calcd. for $C_{12}H_{19}NO_3$: 225.1365; found: 225.1368.

Michael addition procedure. threo-*3,5,5-Trimethyl-6-(1-methyl-2-nitroethyl)cyclohex-2-en-1-one (14) and* erythro-*3,5,5-trimethyl-6-(1-methyl-2-nitroethyl)cyclohex-2-en-1-one (15)*

To a solution of 0.62 mL (0.45 g, 4.4 mmol) of diisopropylamine and 3 mg of 2,2′-bipyridyl in 4 mL of tetrahydrofuran at 0°C was added dropwise, with stirring, 2.5 mL (4.0 mmol) of 1.6 *M* *n*-butyllithium over 10 min. The resulting crimson solution was stirred at 0°C for 15 min, and a solution of 0.46 g (3.3 mmol) of isophorone (**8**) in 4 mL of tetrahydrofuran was then added dropwise, with stirring, over 45 min. After the mixture had been cooled to −78°C, a solution of 0.35 g (4.0 mmol) of 1-nitropropene[8] in 12 mL of tetrahydrofuran was added dropwise, with stirring, over 1.75 h. The resulting yellow solution was stirred at −78°C for an additional 30 min, after which 0.23 mL (0.24 g, 4.0 mmol) of glacial acetic acid was added rapidly, with stirring. The mixture was allowed to warm to room temperature and poured into 50 mL of water, and the aqueous phase was extracted with 3 × 50 mL of ethyl ether. The combined extracts were washed with 2 × 25 mL of water and 25 mL of brine and dried over anhydrous sodium sulfate. The solvent was evaporated under reduced pressure to give 0.83 g of crude product, of which 0.20 g was subjected to preparative thick-layer chromatography (eluting 4× with 9:1 methylene chloride/cyclohexane). Although the products were not completely separated from each other, careful dissection of the adsorbent layer provided samples enriched in each of the two major products, and integration of the nmr spectra gave approximate relative amounts from which the yields could be calculated: (a) *threo* adduct **14**; 0.34 g (46%); yellow oil; ir ($CHCl_3$): 1675, 1550 cm^{-1}; ^1H nmr (100 MHz, $CDCl_3$) δ: 5.85 (bs, 1H), 4.60 (dd, 1H, *J* = 13, 10 Hz), 4.28 (dd, 1H, *J* = 13, 3 Hz), 2.76 (m, 1H), 2.2 (m, 3H), 1.94 (bs, 3H), 1.25 (d, 3H, *J* = 7 Hz), 1.17 (s, 3H), 1.09 (s, 3H); mass spectrum (25 eV), *m/z* (relative intensity): 225 (M$^+$, 3), 191 (3), 178 (33), 162 (27), 149 (15), 136 (34), 123 (45), 97 (20), 82 (100); high resolution mass spectrum, *m/z* calcd. for $C_{12}H_{19}NO_3$: 225.1365; found: 225.1361; (*b*) *erythro* adduct **15**; 0.21 g (28%); yellow oil; ir ($CHCl_3$): 1675, 1550 cm^{-1}; ^1H nmr (100 MHz, $CDCl_3$) δ: 5.91 (bs, 1H), 4.62 (dd, 1H, *J* = 13, 7 Hz), 4.36 (dd, 1H, *J* = 13, 7.5 Hz), 2.84 (sextet of d, 1H, *J* = 7, 2.5 Hz), 2.22 (bs, 1H), 2.04 (d, 1H, *J* = 2.5 Hz), 1.94 (bs, 3H), 1.12 (s, 3H), 1.09 (s, 3H), 1.00 (d, 3H, *J* = 7 Hz; mass spectrum, *m/z* (relative intensity): 225 (M$^+$, 5), 178 (5), 163 (9), 149 (8), 123 (30), 97 (9), 82 (100), 54 (14); high resolution mass spectrum, *m/z* calcd. for $C_{12}H_{19}NO_3$: 225.1365; found: 225.1368. In addition, a small amount of an impurity (ca. 10%), tentatively assigned to 4,6(*syn*),7,7-tetramethyl-5(*anti*)-nitrobicyclo[2.2.2]octan-2-one, could be discerned in the nmr spectrum of **14**: 4.06 (bd, 1H, *J* = 6 Hz), 2.99 (b, quintet, 1H, *J* = 7 Hz), 1.01 (s, 3H), 0.97 (s, 3H).

[8] 1-Nitropropene was prepared in 36% overall yield from acetaldehyde and nitromethane using an improved procedure for the nitroaldol condensation (Henry reaction) (24). The dehydration of the nitro-alcohol (without purification of this intermediate) was carried out according to a long-standing recipe (35), which has since been optimized (36).

[9] A 0.2 in. × 10 ft copper column packed with 10% SE-30 on Diatoport S was employed with a helium flow rate of 60 mL min^{-1}.

[10] A 0.2 in. × 6 ft stainless-steel column packed with 10% Silar-5CP (Applied Science silicone ASI 50 phenyl/50 cyanopropyl) on Gas-Chrom Q (100/120 mesh) was employed with a helium flow rate of 60 mL min^{-1}.

4(syn)-Isopropenyl-7,8(syn)-dimethyltricyclo[3.2.1.0^{2,7}]octan-6-one (22) and 4(anti)-isopropenyl-7,8(syn)-dimethyltricyclo-[3.2.1.0^{2,7}]octan-6-one (23)

By the standard bicycloannulation procedure, 0.50 g (3.3 mmol) of *l*-carvone and 0.35 g (4.0 mmol) of 1-nitropropene[8] gave (gas chromatography[9] program: 170°C for 24 min; heat to 230°C at 40°C min^{-1}; 230°C) tricyclo-octanone **22**; 3%; colorless oil; gas chromatography t_r = 19.5 min; ir ($CHCl_3$): 1722, 1645 cm^{-1}; ^{1}H nmr (100 MHz, $CDCl_3$) δ: [relative LIS with added $Eu(fod)_3$ in brackets] 4.78 [0.4 and 1.6] (bs, 2H), 2.66 [1.1] (ddd, 1H, *J* = 10, 6, 2 Hz), 2.29 (ddd, 1H, *J* = 14, 10, 2.5 Hz), 2.11 [1.0] (q, 1H, *J* = 6.5 Hz), 2.08 (ddd, 1H, *J* = 14, 6, 2.5 Hz), 1.91 [2.7] (d, 1H, *J* = 2 Hz), 1.87 (d, 1H, *J* = 7 Hz), 1.68 [0.7] (bs, 3H), 1.67 (dt, 1H, *J* = 7, 2.5 Hz), 1.21 [1.2] (s, 3H), 1.04 [0.9] (d, 3H, *J* = 6.5 Hz); ^{13}C nmr (25.2 MHz, $CDCl_3$) δ: 213.4 (s), 147.3 (s), 110.4 (t), 53.3 (d), 49.3 (d), 39.4 (d), 36.7 (d), 34.5 (d), 33.2 (s), 23.9 (t), 21.3 (q), 19.9 (q), 12.9 (q) (cf. ref. 28); mass spectrum, *m/z* (relative intensity): 190 (M^+, 17), 175 (10), 147 (8), 135 (10), 122 (100), 106 (28), 94 (34), 80 (30), 67 (43); high resolution mass spectrum, *m/z* calcd. for $C_{13}H_{18}O$: 190.1358; found: 190.1356; and tricyclo-octanone **23**; 1%; colorless oil; gas chromatography t_r = 21.5 min; ir ($CHCl_3$): 1727 cm^{-1}; ^{1}H nmr (100 MHz, $CDCl_3$) δ: [relative LIS with added $Eu(fod)_3$ in brackets] 4.72 [0.3] (bs, 1H), 4.63 [0.5] (bs, 1H), 2.54 [1.8] (bt, 1H, *J* = 9 Hz), 2.18 [1.0] (q, 1H, *J* = 6.5 Hz), 1.84 [2.7] (bs, 1H), 1.7–2.3 (m, 4H), 1.61 [0.3] (bs, 3H), 1.15 [1.7] (s, 3H), 0.94 [1.0] (d, 3H, *J* = 6.5 Hz); ^{13}C nmr (25.2 MHz, $CDCl_3$) δ: 212.9 (s), 146.2 (s), 109.3 (t), 52.7 (d), 47.3 (d), 38.9 (d), 34.6 (d), 32.4 (s), 28.7 (d), 22.4 (t), 22.1 (q), 20.1 (q), 12.9 (q) (cf. ref. 28); mass spectrum, *m/z* (relative intensity): 190 (M^+, 11), 175 (6), 147 (4), 135 (8), 122 (100), 105 (20), 91 (18), 79 (17), 67 (22); high resolution mass spectrum, *m/z* calcd. for $C_{13}H_{18}O$: 190.1358; found: 190.1360.

(1′R, 5R, 6R)-5-Isopropenyl-2-methyl-6-(1′-methyl-2′-nitroethyl)-cyclohex-2-en-1-one (24) and (1′S, 5R, 6R)-5-isopropenyl-2-methyl-6-(1′-methyl-2′-nitroethyl)cyclohex-2-en-1-one (25)

By the standard Michael addition procedure, 0.50 g (3.3 mmol) of *l*-carvone and 0.35 g (4.0 mmol) of 1-nitropropene[8] gave, after recrystallization of the crude product (nmr indicated a 4:1 ratio of **24** to **25**), adduct **24**; 0.5 g (75%); colorless needles; mp 106.5–107°C (ethanol); ir ($CHCl_3$): 1670, 1550 cm^{-1}; ^{1}H nmr (100 MHz, $CDCl_3$) δ: 6.71 (bs, 1H), 4.94 (bs, 2H), 4.58 (dd, 1H, *J* = 12, 9 Hz), 4.32 (dd, 1H, *J* = 12, 4 Hz), 2.2–3.0 (m, 5H), 1.76 (bs, 6H), 1.29 (d, 1H, *J* = 7 Hz); mass spectrum, *m/z* (relative intensity): 237 (M^+, 2), 220 (2), 191 (3), 161 (2), 149 (12), 110 (9), 94 (10), 83 (100), 50 (20); high resolution mass spectrum, *m/z* calcd. for $C_{13}H_{19}NO_3$: 237.1365; found: 237.1369; single crystal X-ray structure determination (22). The mother liquor was evaporated under reduced pressure, and the residue was subjected to preparative thick-layer chromatography (eluting 2× with 9:1 methylene chloride/cyclohexane). Although the products were not completely separated from each other, careful dissection of the adsorbent layer provided a sample consisting of ca. 10% adduct **24** and ca. 90% adduct **25**; 53 mg (7%); yellow oil; ir ($CHCl_3$): 1670, 1550 cm^{-1}; ^{1}H nmr (100 MHz, $CDCl_3$) δ: 6.73 (bs, 1H), 4.91 (dd, 1H, *J* = 13, 7 Hz), 4.90 (bs, 2H), 4.62 (dd, 1H, *J* = 13, 6.5 Hz), 2.3–3.1 (m, 5H), 1.73 (bs, 6H), 1.00 (d, 3H, *J* = 7 Hz); mass spectrum (25 eV), *m/z* (relative intensity): 237 (M^+, 2), 220 (2), 204 (2), 189 (11), 175 (10), 161 (13), 149 (58), 135 (14), 121 (21), 110 (23), 83 (100).

5,7,8(syn)-Trimethyltricyclo[3.2.1.0^{2,7}]octan-6-one (31)

By the standard bicycloannulation procedure, 0.41 g (3.3 mmol) of 2,6-dimethylcyclohex-2-en-1-one (**29**) (1*b*) and 0.35 g (4.0 mmol) of 1-nitropropene[8] gave (gas chromatography[10] 210°C) tricyclo-octanone **31**; 42% (*n*-hexadecane internal standard); colorless oil; ir: 1730 cm^{-1}; ^{1}H nmr (100 MHz, $CDCl_3$) δ: [relative LIS with added $Eu(fod)_3$ in brackets] 2.02 [1.0] (bq, 1H, *J* = 7 Hz), 1.5–1.9 (m, 7H), 1.22 [1.5] (s, 3H), 0.93 [1.0] (d, 3H, *J* = 7 Hz), 0.83 [1.7] (s, 3H); ^{13}C nmr (50.4 MHz, $CDCl_3$) δ: 217.7 (s), 47.0 (s), 38.5 (t), 38.1 (d), 37.9 (d), 36.6 (d), 33.3 (s), 18.0 (q), 17.2 (t), 15.7 (q), 13.4 (q); mass spectrum, *m/z* (relative intensity): 164 (M^+, 53), 149 (15), 136 (17), 122 (33), 107 (44), 95 (100), 91 (46), 82 (84), 67 (72); high resolution mass spectrum, *m/z* calcd. for $C_{11}H_{16}O$: 164.1201; found: 164.1200.

2-Methyl-2-(3-nitro-allyl)-1,3-dioxolane (33)

To a solution of 1.0 mL (14.4 mmol) of nitromethane in 14 mL of 95% ethanol was added dropwise, with stirring, 1.5 mL of 10% aqueous NaOH. To the resulting yellow solution was added dropwise, with stirring, 1.79 g (13.8 mmol) of 2-methyl-1,3-dioxolane-2-acetaldehyde (**32**) over 15 min. After the mixture had been stirred for 24 h, 50 mL of water was added, and the aqueous phase was extracted with methylene chloride (3 × 50 mL). The combined extracts were dried over anhydrous sodium sulfate, and the solvent was evaporated under reduced pressure to give the ketal-nitro-aldol, 2-(2-hydroxy-3-nitropropyl)-2-methyl-1,3-dioxolane; 1.82 g (69%); yellow oil (from which an analytical sample was obtained by bulb-to-bulb distillation); bp 92–95°C/0.5 Torr (1 Torr = 133.32 Pa); ir: 3435, 1555 cm^{-1}; ^{1}H nmr (200 MHz, $CDCl_3$) δ: 4.63 (m, 1H), 4.45 (d, 2H, *J* = 7 Hz), 4.02 (s, 4H), 3.81 (bs, 1H), 1.95 (d, 2H, *J* = 6 Hz), 1.40 (s, 3H); mass spectrum (25 eV), *m/z* (relative intensity): 176 (20), 158 (2), 115 (3), 112 (6), 89 (5), 88 (100), 57 (3).

To a solution of 0.18 g (0.96 mmol) of the crude ketal-nitro-aldol and 0.53 mL (3.8 mmol) of triethylamine in 6 mL of methylene chloride at 0°C was added dropwise, with stirring, 0.10 mL (1.3 mmol) of methanesulfonyl chloride. After the mixture had been stirred for 30 min at 0°C, it was washed with water (2 × 50 mL) and 50 mL of brine and dried over anhydrous sodium sulfate. The solvent was evaporated under reduced pressure, and the residual oil was subjected to open-column liquid chromatography on silica gel, eluting with 1:1 cyclohexane/ethyl acetate, to give ketal-nitro-olefin **33**; 0.10 g (61%); yellow oil; ir: 1660, 1520 cm^{-1}; ^{1}H nmr (100 MHz, $CDCl_3$) δ: 7.28 (dt, 1H, *J* = 13, 7 Hz), 6.99 (d, 1H, *J* = 13 Hz), 3.97 (s, 4H), 2.59 (d, 2H, *J* = 7 Hz), 1.38 (s, 3H); mass spectrum (25 eV), *m/z*: 158, 127, 87, 43.

5,7-Dimethyl-8(syn)-(2-methyldioxol-2-ylmethyl)tricyclo-[3.2.1.0^{2,7}]octan-6-one (34)

By the standard bicycloannulation procedure (66 h reflux), 0.52 g (4.2 mmol) of 2,6-dimethylcyclohex-2-en-1-one (**29**) (1*b*) and 0.63 g (3.7 mmol) of ketal-nitro-olefin **33** gave a crude orange oil which was subjected to open-column liquid chromatography on silica gel. Elution with cyclohexane gave ketal-tricyclo-octanone **34**; 0.23 g (25%); yellow oil; ir: 1715 cm^{-1}; ^{1}H nmr (100 MHz, $CDCl_3$) δ: 3.94 (s, 4H), 2.36 (d, 1H, *J* = 7.5 Hz), 1.5–2.2 (m, 8H), 1.37 (s, 3H), 1.22 (s, 3H), 0.83 (s, 3H); mass spectrum (25 eV), *m/z* (relative intensity): 250 (M^+, 1), 235 (2), 179 (2), 149 (1), 135 (3), 124 (2), 87 (100); high resolution mass spectrum, *m/z* calcd. for $C_{15}H_{22}O_3$: 250.1569; found: 250.1574.

4(syn)-Isopropenyl-5,7-dimethyltricyclo[3.2.1.0^{2,7}]octan-6-one (38)

By the standard bicycloannulation procedure, 0.94 g (5.6 mmol) of (5*R*)-2,6-dimethyl-5-isopropenylcyclohex-2-en-1-one (**36**) (1*a*) and 1.8 mL (5.6 mmol) of 3.1 *M* nitroethylene in benzene (14*l*) gave (gas chromatography[11] 170°C) tricyclo-octanone **38**; 13%; colorless oil; ^{1}H nmr (200 MHz, $CDCl_3$) δ: 4.67 (nm, 1H), 4.60 (nm, 1H), 2.59 (dd, 1H, *J* = 10, 6 Hz), 2.31 (ddd, 1H, *J* = 15, 10, 2 Hz), 1.6–2.0 (m, 5H), 1.52 (nm, 3H), 1.24 (s, 3H), 0.87 (s, 3H; other spectral data as reported earlier (1*a*).

2-Methyltricyclo[3.2.1.0^{2,7}]octan-6-one (40)

By the standard bicycloannulation procedure, 0.25 g (2.3 mmol) of 3-methylcyclohex-2-en-1-one (**39**) and 4.3 mL (3.0 mmol) of 5% nitroethylene in benzene (14*l*) gave (gas chromatography[11] 170°C), in addition to a 12% recovery of **39**, tricyclo-octanone **40**; 2 mg (3%); colorless oil; spectral data as previously reported (1*a*); and 4-methyl-5(*syn*)-nitrobicyclo[2.2.2]octan-2-one (**41**); 30 mg (7%); yellow oil; ir: 1726, 1545 cm^{-1}; ^{1}H nmr (100 MHz, $CDCl_3$) δ: 4.42

[11] A 0.2 in. × 6 ft stainless-steel column packed with 10% OV-225 on Chromosorb W (80/100 mesh) was employed with a helium flow rate of 60 mL min^{-1}.

(m, 1H), 1.02 (s, 3H); mass spectrum, *m/z*: 183 (M^+), 164, 145, 136, 121, 109, 93, 84, 67, 55, 41; high resolution mass spectrum, *m/z* calcd. for $C_9H_{13}NO_3$: 183.0900; found: 183.0893.

*2,4,4-Trimethyltricyclo[3.2.1.0^{2,7}]octan-6-one (**42**)*

By the standard bicycloannulation procedure, 0.25 g (1.8 mmol) of isophorone (**8**) and 4.7 mL (3.2 mmol) of 5% nitroethylene in benzene (14*l*) gave (gas chromatography[11] 170°C), in addition to a 20% recovery of **8**, tricyclo-octanone **42**; 5 mg (2%); colorless oil; spectral data as previously reported (3*c*); and 4,7,7-trimethyl-5-(*syn*)-nitrobicyclo[2.2.2]octan-2-one (**43**); 72 mg (19%); yellow oil; ir: 1725, 1546 cm^{-1}; ^{1}H nmr (100 MHz, $CDCl_3$) δ: 4.57 (bdd, 1H, J = 9, 6 Hz), 1.12 (s, 3H), 1.05 (s, 3H), 1.00 (s, 3H); mass spectrum, *m/z* (relative intensity): 211 (M^+, 27), 180 (22), 165 (38), 137 (22), 121 (100), 95 (68), 81 (62), 69 (92), 55 (47), 41 (53); high resolution mass spectrum, *m/z* calcd. for $C_{11}H_{17}NO_3$: 211.1210; found: 211.1211.

*1,5(*syn*),7,7-tetramethyltricyclo[2.2.1.0^{2,6}]heptan-3-one (**47**)*

By the standard bicycloannulation procedure, 0.54 g (4.4 mmol) of 3,4,4-trimethylcyclopent-2-en-1-one (**45**) (37) and 0.43 g (4.9 mmol) of 1-nitropropene[8] gave (gas chromatography[9] program: 150°C for 3 min; heat to 210°C at 30°C min^{-1}; 210°C) tricyclo-heptanone **47**; 39% (biphenyl internal standard); colorless oil; ir: 1757 cm^{-1}; ^{1}H nmr (100 MHz, $CDCl_3$) δ: [relative LIS with added $Eu(fod)_3$ in brackets] 2.50 [1.0] (qt, 1H, J = 6.5, 1.5 Hz), 1.89 [1.0] (bd, 1H, J = 5 Hz), 1.33 [3.2] (bs, 1H), 1.20 [0.5] (s, 3H), 1.17 [1.8] (d, 1H, J = 5 Hz), 1.05 [0.8] (s, 3H), 1.03 [1.5] (s, 3H), 1.00 [1.3] (d, 3H, J = 6.5 Hz); ^{13}C nmr (25.2 MHz, $CDCl_3$) δ: 213.5 (s), 58.0 (d), 44.5 (s), 40.0 (s), 36.6 (d), 35.5 (d), 26.8 (d), 21.6 (q), 19.6 (q), 14.8 (q), 10.4 (q); mass spectrum, *m/z* (relative intensity): 164 (M^+, 18), 149 (8), 136 (12), 121 (100), 105 (29), 91 (18), 79 (21), 67 (6), 53 (9); high resolution mass spectrum, *m/z* calcd. for $C_{11}H_{16}O$: 164.1201; found: 164.1205.

threo-*3,4,4-Trimethyl-5-(1-methyl-2-nitroethyl)cyclopent-2-en-1-one (**49**) and* erythro-*3,4,4-trimethyl-5-(1-methyl-2-nitroethyl)-cyclopent-2-en-1-one (**48**)*

By the standard Michael addition procedure, 0.50 g (4.1 mmol) of 3,4,4-trimethylcyclopent-2-en-1-one (**45**) (37) and 0.44 g (5.1 mmol) of 1-nitropropene[8] gave (preparative gas chromatography[9] program: 200°C for 5 min; heat at 6°C min^{-1} to 230°C; 230°C) *threo* adduct **49**; 0.32 g (37%); yellow oil; gas chromatography t_r = 16.9 min; ir (CCl_4): 1705, 1625, 1555 cm^{-1}; ^{1}H nmr (100 MHz, $CDCl_3$) δ: 5.83 (bs, 1H), 4.91 (dd, 1H, J = 13, 4 Hz), 4.53 (dd, 1H, J = 13, 9 Hz), 2.70 (m, 1H), 2.14 (d, 1H, J = 7 Hz), 2.06 (d, 3H, J = 1 Hz), 1.29 (s, 3H), 1.26 (d, 3H, J = 7 Hz), 1.23 (s, 3H); mass spectrum (25 eV), *m/z* (relative intensity): 211 (M^+, 2), 196 (3), 180 (7), 164 (79), 150 (12), 135 (11), 124 (100), 109 (15), 85 (10), 72 (12); high resolution mass spectrum, *m/z* calcd. for $C_{11}H_{17}NO_3$: 211.1204; found: 211.1207; and *erythro* adduct **48**; 0.4 g (50%); yellow oil; gas chromatography t_r = 15.5 min; ir (CCl_4); 1707, 1627, 1554 cm^{-1}; ^{1}H nmr (100 MHz, $CDCl_3$) δ: 5.82 (bs, 1H), 4.72 (dd, 1H, J = 12.5, 7.5 Hz), 4.51 (dd, 1H, J = 12.5, 7 Hz), 2.75 (m, 1H), 2.05 (d, 3H, J = 1 Hz), 1.22 (s, 6H), 0.93 (d, 1H, J = 7 Hz); mass spectrum (25 eV), *m/z* (relative intensity): 211 (M^+, 2), 196 (4), 181 (8), 164 (20), 149 (9), 135 (9), 124 (100), 109 (30), 95 (16), 84 (14), 48 (22); high resolution mass spectrum, *m/z* calcd. for $C_{11}H_{17}NO_3$; 211.1204; found: 211.1198.

*4,6(*endo*),7,7-Tetramethyl-5(*endo*)-nitrobicyclo[2.2.1]heptan-2-one (**50**)*

To a solution of 0.85 mL (6.1 mmol) of diisopropylamine and 3 mg of 2,2′-bipyridyl in 4 mL of tetrahydrofuran at 0°C was added dropwise, with stirring, 3.7 mL (5.3 mmol) of 1.4 *M* *n*-butyllithium over 10 min. The resulting crimson solution was stirred at 0°C for 15 min, and a solution of 0.55 g (4.5 mmol) of 3,4,4-trimethylcyclopent-2-en-1-one (**45**) (37) in 8 mL of tetrahydrofuran was then added dropwise, with stirring, over 45 min. After the mixture had been cooled to −78°C, a solution of 0.50 g (5.7 mmol) of 1-nitropropene in 9 mL of tetrahydrofuran was added dropwise, with stirring, over 2.5 h, and the resulting yellow solution was stirred at −78°C for an additional 30 min. After the mixture had been allowed to warm to room temperature, it was refluxed for 20 h. The progress of the reaction was followed by gas chromatography, which indicated the presence of Michael adducts **49** and **48** plus only a relatively small amount of bicycloheptanone **50** just prior to reflux, followed by a gradual increase in the amount of **50** at the expense of the other two products during reflux. The cooled mixture was poured into 50 mL of saturated aqueous sodium bicarbonate, and the aqueous phase was extracted with 3 × 50 mL of ethyl ether. The combined extracts were washed with 50 mL of brine and dried over anhydrous sodium sulfate. The solvent was distilled through a Vigreux column, and the residual concentrate was subjected to preparative gas chromatography[9] (program: 200°C for 5 min; heat at 6°C min^{-1} to 230°C; 230°C) to give the following three major products: (a) Michael adduct **49**; 28 mg (3%); gas chromatography and spectral data as above; (b) Michael adduct **48**; 59 mg (6%); gas chromatography and spectral data as above; (c) bicycloheptanone **50**; 55 mg (6%); yellow oil; gas chromatography t_r = 13.0 min; ir (CCl_4): 1767, 1550 cm^{-1}; ^{1}H nmr (100 MHz, $CDCl_3$) δ: 4.76 (dd, 1H, J = 6.5, 1 Hz), 2.80 (quintet, 1H, J = 7 Hz), 2.31 (d, 1H, J = 19 Hz), 2.13 (s, 1H), 2.05 (d, 1H, J = 19 Hz), 1.38 (d, 3H, J = 7 Hz), 1.25 (s, 3H), 1.20 (s, 3H), 1.00 (s, 3H); mass spectrum, *m/z* (relative intensity): 211 (M^+, 5), 180 (1), 165 (4), 150 (5), 135 (23), 121 (45), 108 (31), 95 (53), 83 (100), 67 (43), 54 (61); high resolution mass spectrum, *m/z* calcd. for $C_{11}H_{17}NO_3$: 211.1204; found: 211.1206.

erythro-*3-Methyl-5-(1-methyl-2-nitroethyl)cyclopent-2-en-1-one (**52**)*

To a solution of 0.71 mL (5.1 mmol) of diisopropylamine and 3 mg of 2,2′-bipyridyl in 4 mL of tetrahydrofuran at 0°C was added dropwise, with stirring, 3.1 mL (4.4 mmol) of 1.4 *M* *n*-butyllithium over 10 min. The resulting crimson solution was cooled to −78°C and 0.59 mL (3.3 mmol) of hexamethylphosphoramide was added, resulting in a deep purple solution. After this solution had been stirred at −78°C for 15 min, a solution of 0.32 g (3.3 mmol) of 3-methylcyclopent-2-en-1-one (**51**) in 4 mL of tetrahydrofuran was then added dropwise, with stirring, over 45 min. After the mixture had been stirred at −78°C for an additional 30 min, a solution of 0.39 g (4.1 mmol) of 1-nitropropene[8] in 8 mL of tetrahydrofuran was added dropwise, with stirring, over 2.5 h. The resulting yellow solution was stirred at −78°C for an additional 30 min, after which 0.29 mL of glacial acetic acid was added rapidly, with stirring. The mixture was allowed to warm to room temperature and poured into 50 mL of ethyl ether and 50 mL of saturated aqueous sodium bicarbonate, and the aqueous phase was extracted with 2 × 50 mL of ethyl ether. The combined extracts were washed with 50 mL of brine and dried over anhydrous sodium sulfate. The solution was concentrated by distillation through a Vigreux column, and the concentrate was subjected to preparative thick-layer chromatography (eluting 2× with $CHCl_3$) to give impure adduct **52**; 0.36 g (57%); ^{1}H nmr (100 MHz, $CDCl_3$) δ: 5.59 (bs, 1H), 4.81 (dd, 1H, J = 12.5, 6.5 Hz), 4.53 (dd, 1H, J = 12.5, 7.5 Hz), 2.5−3.2 (m, 4H), 2.35 (bs, 3H), 1.08 (d, 3H, J = 7 Hz).

*Tricyclenone (**53**)*

By the standard bicycloannulation procedure (but with a 187-h reflux period, during the first 130 h of which the product gas chromatography peak was observed to increase gradually) 0.51 g (4.1 mmol) of 3,4,4-trimethylcyclopent-2-en-1-one (**45**) (37) and 2.3 mL (5.2 mmol) of 2.3 *M* nitroethylene in benzene (14*l*) gave (gas chromatography[9] 180°C) tricyclenone (**53**); 22% (diphenylmethane internal standard); colorless crystals; mp 100−106°C (lit. (38) mp 97.5−100°C); ir (CCl_4): 1758 cm^{-1} (the spectrum was superimposable on that of an authentic sample);[12] ^{1}H nmr (100 MHz, $CDCl_3$) δ: 2.06 (dt, 1H, J = 11, 1.5 Hz), 1.97 (bd, 1H, J = 5 Hz), 1.84 (bd, 1H, J = 11 Hz), 1.52 (bs, 1H), 1.23 (s, 3H), 1.19 (bd, 1H, J = 5 Hz), 1.05 (s, 3H), 1.02 (s, 3H); ^{13}C nmr (25.2 MHz, $CDCl_3$) δ: 213.6 (s), 51.5 (d), 43.9 (s), 38.7 (s), 29.4 (t), 29.3 (d), 27.9 (d), 21.3 (q), 19.3 (q), 10.2 (q).

[12]We are grateful to Professor J. K. Crandall for copies of ir and nmr spectra of tricyclenone.

A magnetically aligning lyotropic mesophase with a clay inclusion

M. A. DESANDO AND L. W. REEVES
Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received July 3, 1984[1]

M. A. DESANDO and L. W. REEVES. Can. J. Chem. **63**, 2628 (1985).

The inclusion of clay (bentonite) (ca. 0.08–0.64 wt.%) in the lyotropic mesophase formed by potassium dodecanoate + KCl + ^2H_2O has been observed by ^2H nmr not to alter the type I CM character of the phase. Relaxation of the mesophase director has been analyzed in terms of two processes over a range of ^2H_2O concentrations. A slow process with rate constants of ca. $2 \times 10^{-4} - 8 \times 10^{-4}$ s^{-1} exists for the phase with clay over ^2H_2O concentrations of 63.9–65.9 wt.%. A tenfold increase in the rate constant with an increase in the ^2H_2O content from 62.5 to 65.5% was observed for the ternary phase at 302 K.

M. A. DESANDO et L. W. REEVES. Can. J. Chem. **63**, 2628 (1985).

Faisant appel à la rmn du ^2H, on a observé que l'inclusion d'argile (bentonite) (environ 0,08–0,64% en poids) dans la mésophase lyotrope formée par du dodécanoate de potassium + KCl + ^2H_2O n'altère pas le caractère de type I CM de la phase. Pour diverses concentrations de ^2H_2O, on a analysé la relaxation du directeur de la mésophase en fonction de deux processus. Pour la phase avec de l'argile et à des concentrations de ^2H_2O allant de 63,9 à 65,9% en poids, il existe un processus lent avec des constantes de vitesse d'environ 2×10^{-4} à 8×10^{-4} s^{-1}. Dans la phase ternaire à 302 K, la constante de vitesse est multipliée par 10 lorsque la teneur en ^2H_2O augmente de 62,5 à 65,5%.

[Traduit par le journal]

Introduction

Lyotropic mesophases which align in magnetic fields have been reported (1–6), in which the components of the micelles are of molecular dimensions, e.g., surfactants, aliphatic alcohols, and inorganic electrolytes. A novel situation exists when the size of an inclusion is larger than that of the micelles—in this work, clay particles. Intermicellar forces contribute largely to the generation of nematic order in the mesophase; thus the presence of large particles in suspension will no doubt change the order in the system, and consequently the alignment properties in a magnetic field.

A key factor in the preparation of a mesophase with large inclusion particles is the formation of a stable suspension. Clays are good examples of materials which display colloidal properties (7). The study of clay–surfactant interactions, particularly in the mesophase condition, offers interesting prospects in areas such as enhanced oil recovery, mineral processing, chemical evolution (protobiogenesis), and membrane phenomena. The dispersion of clays in a mesophase matrix not only affords information on mesophase phenomena, but also provides a novel approach to the study of clays, per se. In addition, clays are flexible chemical systems; for instance, they may be intercalated with different types of compounds, and may undergo ion-exchange reactions (7, 8).

Experimental

Bentonite (Fisher) was ground and dried in an oven at ~200°C for several days. The clay was mixed with isotopically pure deuterium oxide (^2H_2O) (99.7 at.%; Merck, Sharp and Dohme) to form a slurry which was centrifuged on an Adams Analytical centrifuge for various intervals of time to produce suspensions with clay concentrations in the range 0.09–0.98 weight percent. In each case the supernatant liquid showed a strong Tyndall effect in He–Ne laser light. The quantity of bentonite in suspension was determined gravimetrically from evaporation of the ^2H_2O.

Potassium dodecanoate was prepared by reacting equimolar quantities of dodecanoic acid and potassium hydroxide in absolute ethanol followed by several recrystallizations from ethanol. Surfactant from laboratory stock (3) was recrystallized from absolute ethanol and then dried *in vacuo*. The purity of the surfactant was checked from its proton nmr spectrum.

Mesophases were prepared with compositions, in weight percent, of potassium dodecanoate/KCl/^2H_2O, and potassium dodecanoate/KCl/^2H_2O/bentonite as listed in Tables 1 and 2. The amounts of ^2H_2O and bentonite in the phases were varied while the ratio of wt.% surfactant to electrolyte was maintained around 11.03. Experiments were performed on many different mesophases, each prepared separately by weight. Some mesophases were made of similar concentrations and some repeat experiments were carried out on the same samples in order to verify the observed alignment rate constants. All glassware were cleaned by the same procedure, that is, they were first washed with a commercial detergent solution, then rigorously rinsed with deionized water, and finally dried *in vacuo*.

The ^2H nmr spectra were recorded on a Bruker WP-80 Fourier transform spectrometer operating at 12.24 MHz with a magnetic field strength of 1.88 T. The temperature was maintained within ±1 K with a calibrated B-ST 100/700 temperature controller. Samples in 10-mm

od thin-wall precision nmr tubes (Wilmad) were placed in a multinuclear probehead equipped with an external deuterium lock. Mesophases were allowed to align (usually overnight) in the magnetic field until a constant deuterium nuclear quadrupole splitting was observed. Each sample was subjected to an angular displacement, in the range ca. 20–35° away from the aligned position, around the long axis of the nmr tube. A Bruker Aspect 2000 computer program was used to accumulate, transform, and store deuterium nmr spectra at various intervals of time during the course of the mesophase realignment.

References 5, 9, and 10 outline in additional detail the procedure used in the measurements of the alignment rates.

Mesophases were viewed between crossed light polarizing film (Bausch & Lomb; catalogue no. 31-52-62-26) after they were allowed to align in the 1.88-T field of a Bruker magnet and also in the 2.31-T field of a Varian magnet.

Results

Alignment of the mesophase director in a steady-state externally applied magnetic field can be followed by measuring the nuclear quadrupole splitting ($\Delta\nu$) as a function of time (9, 10). The angle (Ω) between the mesophase director (uniaxis of symmetry) and the applied field can be expressed as:

$$\Omega = \cos^{-1}\{[(2\Delta\nu)/(3\Delta\nu_0)] + (1/3)\}^{1/2}$$

where $\Delta\nu_0$ is the value of the nuclear quadrupole splitting for the mesophase director aligned parallel to the direction of the external magnetic field.

A kinetic rate expression, based on the continuum theory, may be derived to describe the discrete relaxation of the mesophase director with time (t) from its initial angular displacement (Ω_0) relative to the $\Omega = 0$ position (aligned parallel to the applied field) (10).

$$-\ln(\tan\Omega) = kt - \ln(\tan\Omega_0)$$

The continuum theory, however, neglects surface effects such as those generated by solid/liquid interfaces, e.g., glass walls and solid particulates (11–13). Other solutions of the continuum equations are therefore necessary if the alignment process involves a nonuniform distribution of micelle directors and more than one relaxation process, resulting in a nonlinear function of $-\ln(\tan\Omega)$ with time.

Rate constants were determined from linear regression analyses of the lines of best fit to the plots of $-\ln(\tan\Omega)$ versus t (see Figs. 2 and 3 for sample plots). Where nonlinear variation of $-\ln(\tan\Omega)$ with time was dominant, two rate constants were determined from the limiting slopes of the curve (see Fig. 3). The uncertainty in the rate constant within the error limits of $\Delta\nu$ and the reproducibility is ca. $\pm 0.5 \times 10^{-4}$ s^{-1}.

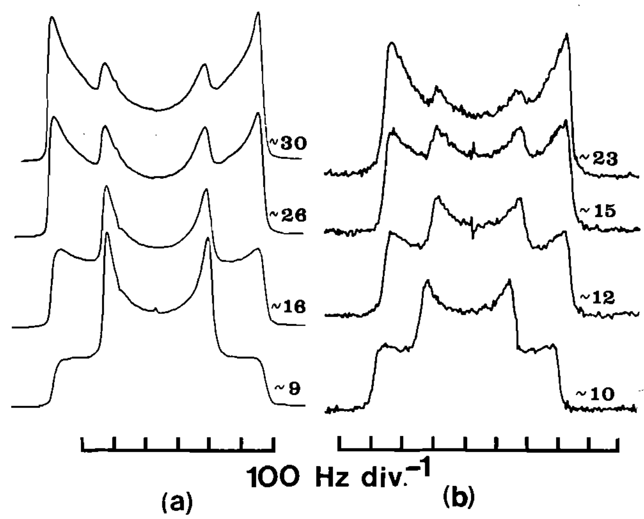

FIG. 1. Evolution of the ^2H nmr powder pattern spectra of ^2H_2O as a function of time (in min) elapsed after placement of the type I CM lyotropic mesophase in the applied magnetic field; (a) potassium dodecanoate/KCl/^2H_2O (33.40:3.11:63.49 wt.%); (b) potassium dodecanoate/KCl/bentonite/^2H_2O (32.50:2.93:0.63:63.94 wt.%).

Discussion

Analysis of the deuterium nmr signal from ^2H_2O in an aligning lyotropic mesophase allows for the characterization of the type of phase with respect to the sign of the diamagnetic susceptibility anisotropy ($\Delta\chi$) (2, 4–6). For example, the powder pattern spectra in Fig. 1 can be ascribed to type I CM (cylindrical micelle) lyomesophases, that is, liquid crystals composed of cylindrical type micelles with a positive $\Delta\chi$, i.e., with the director aligned in the direction of the applied field. This feature is a remarkable one, for mesophases may be quite sensitive to alterations in their physical and chemical constitutions. Even more interesting are the comparisons of the rate constants for alignment of the director of the mesophase with clay to those of the same phase without the clay (see Tables 1 and 2, and Figs. 2, 3, and 5).

The rate constants ($1.1 \times 10^{-4} - 11.4 \times 10^{-4}$ s^{-1} at 302 K) for the ternary phase are of the same order of magnitude as

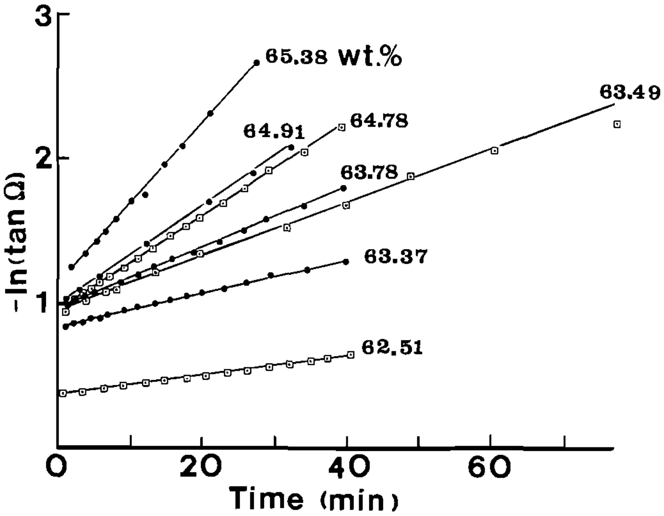

FIG. 2. Time dependence of the angular displacement (Ω) between the mesophase director and the applied magnetic field after an initial rotation of the aligned mesophase director away from the direction of the applied magnetic field, for potassium dodecanoate + KCl + ^2H_2O at different ^2H_2O concentrations (wt.%).

those measured by Fujiwara and Reeves (10) at 1.44 T. The presence of the bentonite particles, which typically are disk-shaped (14) (diameter of ~2 500 to 7 000 Å) (14, 15), must perturb the order of the cylindrical micelles (length ≥ 500 Å) (16) in the mesophase, the intermicellar interactions, and consequently the order of the ^2H_2O molecules. These effects influence the pattern of flow dislocations in the mesophase, which may account for the weaker less apparent optical diffraction pattern ("schlieren" texture) (17) when the mesophase with clay (in the nmr tubes) was viewed between crossed Polaroids. This behaviour is in contrast to the ternary phase, which exhibited a clear diffraction pattern. The diffraction pattern of the former phase was observed to be far more sensitive to mechanical disturbances than the phase without the clay.

An average spatial angular distribution of the clay particles that is different from that of the surfactant micelles induces localized reordering around the inclusion particles, which in turn leads to a distribution of the diamagnetic susceptibility anisotropy in the sample ($\Delta\chi = \sum_i X_i \Delta\chi_i$; the summation is over the $\Delta\chi$ associated with mole fractions X_i of the species which are present, e.g., surfactant micelles, clay particles, hemimicelles, etc.). A consequence of the foregoing effect may be a change in the rate of alignment of the mesophase director, for $k = -\Delta\chi B^2/\lambda$ (B is the strength of the applied magnetic field and λ is a parameter related to the twist viscosity of the medium (10)). Also, an increase in λ owing to changes in the structure of the mesophase, from the bentonite, would decrease the alignment rate of the mesophase director.

A measure of local order in the system may be gained from the value of the quadrupole splitting ($\Delta\nu$)

$$\Delta\nu = (3/4)QS_a\langle(3\cos^2\Omega - 1)\rangle$$

which is related to the degree of order parameter (S_a) (2, 10, 18).

$$S_a = (1/2)\langle(3\cos^2\theta - 1)\rangle$$

In the case of the ^{2}H nmr signal of ^2H_2O, the S_a is associated with the average angle of alignment (θ) of the O—^{2}H bonds to the mesophase director. It is evident from Fig. 4 that $\Delta\nu$ decreases nearly linearly with an increase in the weight percent (W) of ^2H_2O from ca. 62.5% to 65.5% ($\Delta\nu$(Hz) = $-68.4W$ + 4990.2 for the ternary phase) and is in line with a decrease in nematic order as the isotropic micellar domain is approached at ~66 wt.% ^2H_2O.

Observations of the temporal dependence of the deuterium nuclear quadrupole splitting reveal, for the mesophases with clay, a dispersion of the alignment rate process (see Table 2 and Fig. 3). One interesting feature of the $-\ln(\tan\Omega)$ versus time plots is that there is no appreciable dispersion of the mesophase director for the ternary phase (Fig. 2).

Although the dispersion of the mesophase alignment into more than one rate process has been previously reported (10, 19) for nematic lyotropes, the nature of the relaxations is not well understood. There is evidence from the work of Fujiwara and Reeves (10) that wall effects play a role in the alignment process. Results from the present study also favour the fact that solid surfaces, e.g., clay particles, influence the relaxation of the mesophase director.

Magnetohydrodynamic relaxation of the potassium dodecanoate/KCl/^2H_2O mesophase shows a strong correlation to the amount of solvent. Notice from Fig. 5 how the rate constant (k) increases from ca. 10^{-4} to ca. 10^{-3} s^{-1} over the cylindrical micelle (CM) domain of the mesophase. Furthermore, note that the k value appears to vary nonlinearly, especially around the limits of the CM domain. A curve corresponding to the equation, $k = \exp(0.697\,W - 52.534)$, from the plot of ln k versus wt.% ^2H_2O, has been fitted to the data in Fig. 5. Even though the curve is for the rate constant (k) associated with a single process, i.e., no dispersion, nearly all of the k_1 values for the quaternary phase are on or above the curve. However, the k_2 values when clay is added to the system lie below the curve and suggest that the bentonite particles induce a slower relaxation process for the alignment of the mesophase director. Note, for example (Table 2), how the ratio of the alignment rate for the fast and slow processes (k_1/k_2) is, in most cases, around 1.5–2.0 when clay is present.

Clay particles are known to align in electric and in magnetic fields. Shah *et al.* (14, 15) have demonstrated how aqueous bentonite suspensions undergo a reversal of electro-optical birefringence with increasing electric field strength owing to the presence of permanent and induced dipole moments. In strong electric fields the bentonite particles align with the normal to the plate face perpendicular to the direction of the applied field (14, 15). The research of J. V. Champion *et al.* (20) on kaolinite, containing iron impurities, has shown that the particles possess a permanent magnetic moment susceptibility. Aqueous suspensions of bentonite are also known to exhibit magneto-optical birefringence (21).

Other important properties of clays which should be noted are their ability to (*i*) self-associate (22); (*ii*) intercalate long-chain polar molecules (23–25) and electrolytes (7, 8, 24), and (*iii*) form bilayer, multilayer, or hemimicelle clay particles (26). The physico-chemical properties of the clay, no doubt, are responsible in large part for the intriguing alignment properties of the mesophase.

Conclusion

A low concentration (ca. 0.08–0.64 wt.%) of clay (bentonite)[2] in the nematic lyomesophase formed by potassium dodecanoate/KCl/^2H_2O does not destroy the type I CM character of the phase. In the case of the ternary potassium dodecanoate/KCl/^2H_2O mesophase, the alignment rate for the mesophase director increases by about an order of magnitude from ca. 10^{-4} to 10^{-3} s^{-1} with an increase in ^2H_2O concentration from ca. 62.5 to ca. 65.5 wt.% at 302 K in a 1.88-T magnetic field.

Relaxation of the director of the aligned clay-containing mesophase has been analyzed in terms of two rate constants. The results suggest that the inclusion of the clay particles may induce a slower relaxation of the mesophase director.

Inclusions of particles of colloidal dimension, e.g., clay, in a nematic lyotropic mesophase offer a unique method for the study of clay–micelle interactions and the magnetic properties of clays.

Quantitative studies of the autoxidation of linoleate monomers sequestered in phosphatidylcholine bilayers. Absolute rate constants in bilayers

LAWRENCE ROSS COATES BARCLAY,[1] STEVEN JEFFREY LOCKE, JOSEPH MARK MACNEIL, AND JOANN VANKESSEL
Department of Chemistry, Mount Allison University, Sackville, N.B., Canada E0A 3C0

Received December 19, 1984

LAWRENCE ROSS COATES BARCLAY, STEVEN JEFFREY LOCKE, JOSEPH MARK MACNEIL, and JOANN VANKESSEL. Can. J. Chem. **63**, 2633 (1985).

The kinetics of autoxidation of linoleic acid in dimyristoylphosphatidylcholine (DMPC) bilayers were studied at 30°C and pH 7 under 760 Torr O_2. Reactions were initiated using either the lipid-soluble di-*tert*-butylhyponitrite (DBHN) or water-soluble azobis(2-amidinopropane)·HCl (ABAP). Rates of chain initiation, R_i, were measured with a lipid-soluble antioxidant, α-tocopherol, or a water-soluble one, 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylate (Trolox). The slightly higher oxidizability obtained ($k_p/2k_t^{\frac{1}{2}} = 2.76 \times 10^{-2}\ M^{-\frac{1}{2}}\ s^{-\frac{1}{2}}$) compared to methyl linoleate in chlorobenzene ($k_p/2k_t^{\frac{1}{2}} = 2.18 \times 10^{-2}\ M^{-\frac{1}{2}}\ s^{-\frac{1}{2}}$) is attributed to a moderate polar solvent effect on ionized linoleate near the bilayer surface. A low initiator efficiency, $e = 0.0895$ for DBHN in DMPC, is attributed to the cage effect in the bilayer of high microviscosity. Similar autoxidation experiments on methyl linoleate in DMPC bilayers gave a lower oxidizability ($k_p/2k_t^{\frac{1}{2}} = 1.79 \times 10^{-2}\ M^{-\frac{1}{2}}\ s^{-\frac{1}{2}}$), indicating that the ester is sequestered deeper in the hydrophobic region of DMPC than is ionized linoleate. Some absolute rate constants are determined using the rotating sector technique for linoleic acid in 0.50 *M* SDS micelles, and egg lecithin and dilinoleoylphosphatidylcholine (DLPC) bilayers. A hundredfold decrease in the termination rate constant, $2k_t$, for DLPC bilayer compared to homogeneous solution is attributed to chain termination in a bilayer region of high polarity. A concomitant reduction (up to tenfold) in the propagation rate constant, k_p, is attributed to diffusion of polar peroxyl radicals away from the oxidizable region of the bilayer.

LAWRENCE ROSS COATES BARCLAY, STEVEN JEFFREY LOCKE, JOSEPH MARK MACNEIL et JOANN VANKESSEL. Can. J. Chem. **63**, 2633 (1985).

Opérant à 30°C, à un pH de 7 et sous une pression de 760 Torr d'O_2, on a étudié la cinétique de l'auto-oxydation de l'acide linoléique dans des couches doubles de dimyristoylphosphatidylcholine (DMPC). On a initié les réactions à l'aide soit de l'hyponitrite du di-*tert*-butyle (HNDB) qui est soluble dans les lipides soit le chlorhydrate de l'azo bis(amidino-2 propane) (ABAP) qui est soluble dans l'eau. On a mesuré les vitesses d'initiation de chaînes, R_i, en présence d'un antioxydant soluble dans l'eau, l'α-tocophérol, ainsi que d'un antioxydant soluble dans l'eau, l'hydroxy-6 tétraméthyl-2,5,7,8 chromanecarboxylate-2 (Trolox). L'oxydabilité est légèrement supérieure ($k_p/2k_t^{\frac{1}{2}} = 2{,}76 \times 10^{-2}\ M^{-\frac{1}{2}}\ s^{-\frac{1}{2}}$) à celle du linoléate de méthyle ($k_p/2k_t^{\frac{1}{2}} = 2{,}18 \times 10^{-2}\ M^{-\frac{1}{2}}\ s^{-\frac{1}{2}}$); on attribue ce résultat à une influence modérée du solvant polaire sur le linoléate ionisé près de la surface à couche double. On attribue la faible efficacité comme initiateur, $e = 0{,}0895$, du HNDB dans le DMPC à un effet de cage dans la double couche qui aurait une microviscosité élevée. Des expériences semblables d'auto-oxydation sur le linoléate de méthyle dans des doubles couches de DMPC donnent lieu à des oxydabilités plus faibles ($k_p/2k_t^{\frac{1}{2}} = 1{,}79 \times 10^{-2}\ M^{-\frac{1}{2}}\ s^{-\frac{1}{2}}$); ce résultat indiquerait que l'ester est plus séquestré dans la région hydrophobe du DMPC que les ions linoléates. Faisant appel à la technique des secteurs rotatifs, on a déterminé quelques constantes absolues de vitesse pour l'acide linoléique à 0,5 *M* dans des micelles de SDS et dans des doubles couches de lécithines d'oeuf et de dilinoléoylphosphatidylcholine (DLPC). On a observé que, par comparaison avec les valeurs obtenues en solutions homogènes, les constantes de vitesse de terminaison, $2k_t$, dans des doubles couches de DLPC sont cent fois moins grandes; on attribue ce résultat à des terminaisons de chaînes dans une région de la double couche de haute polarité. Une réduction concomitante (facteur allant jusqu'à dix) dans la constante de vitesse de propagation, k_p, est attribuée à la diffusion des radicaux polaires peroxyles de la région oxydable de la double couche.

[Traduit par le journal]

Introduction

Renewed interest in the autoxidation of polyunsaturated fatty acids and esters has developed because of the susceptibility of unsaturated carbon chains to peroxidation when they are incorporated into phospholipid biomembranes and the relevance of such peroxidation to various cell-damaging pathological events, including aging (1, 2), heart disease (3), and cancer (4).

We are applying *quantitative* kinetic methods to study the autoxidation of biological molecules in microenvironments such as bilayers and micelles (5–8). Autoxidation in these systems is a free-radical chain process which appears to follow the same classical rate law as in homogeneous solution (5, 8) whereby the oxygen uptake is given by eq. [1]:

$$[1]\quad -\frac{d[O_2]}{dt} = \frac{k_p}{2k_t^{\frac{1}{2}}}[RH]R_i^{\frac{1}{2}}$$

where RH is the substrate, R_i the rate of chain initiation, k_p the propagation rate constant, and $2k_t$ the chain termination rate constant. In these kinetic studies, the rate of chain initiation, R_i, is controlled by using an initiator with a known rate constant for decomposition, k_i. Not all of the radicals escape the solvent cage where they are formed; therefore the actual R_i must be measured, for example, by the inhibitor method (9) using a phenolic antioxidant such as α-tocopherol (α-T) known to trap two peroxyl radicals (10), so that R_i is given by eq. [2], where τ is the inhibition time.

$$[2]\quad R_i = 2[ArOH]/\tau$$

The efficiency of chain initiation is expressed as $e = R_i/2k_i[In]$

[1]Author to whom correspondence may be addressed.

and the radical chain length as $\nu = d[O_2]/dt/R_i$. Under such controlled conditions, the ratio of rate constants $k_p/(2k_t)^{\frac{1}{2}}$ known as the "oxidizability" of the substrate can be measured (eq. [3]):

$$[3] \quad \frac{k_p}{(2k_t)^{\frac{1}{2}}} = \frac{-d[O_2]/dt}{[RH]R_i^{\frac{1}{2}}}$$

Bilayers provide a medium for transport and solubilization of various solutes (11), including relatively large proportions of biologically important intermediates such as cholesterol (12) and fatty acids (13). Bilayer vesicles are also important as drug carriers and media for reactivity control (14) and such bilayers as the phosphatidyl cholines have important effects on free radical dynamics (15–17). It is desirable, therefore, to know what effect a bilayer might have on the chemical behavior of a substance solubilized in it. The fundamental question we address here is: *What is the effect on the oxidizability of a polyunsaturated fatty acid (or ester) when it is sequestered in a phosphatidyl choline bilayer?* We selected linoleate as the unsaturated acid/ester substrate for this kinetic study. The kinetics of autoxidation of linoleate have recently been studied in homogeneous solution (18, 19) and in micelles (5–8, 20), and Weener and Porter have reported on product studies from the cooxidation of polyunsaturated lecithins with linoleic acid (21). However, we are not aware of a quantitative kinetic study of an unsaturated fatty acid in a bilayer. In addition, we report on some *preliminary* studies of the absolute rate constants for propagation, k_p, and termination, $2k_t$, for autoxidation of linoleate in various media, and of unsaturated lecithins in bilayers using the rotating sector technique.

Experimental

1. *Materials and preparations*

Solvents

Chlorobenzene and *ortho*-dichlorobenzene, reagent grades, were dried over calcium chloride and distilled before use.

Phosphate buffer

Solutions were prepared from 0.05 *M* of each of NaH_2PO_4 and $NaHPO_4$ in glass-distilled water containing 1×10^{-4} *M* EDTA.

Tetralin

Tetralin, Fisher Purified, was distilled "*in vacuo*" under nitrogen and passed through a column of alumina to remove traces of hydroperoxides immediately before use.

Linoleic acid and *methyl linoleate* were obtained from Nu-Chek-Prep, >99% purity).

Sodium dodecyl sulfate

The SDS was electrophoresis purity grade (Bio–Rad).

Initiators

Initiators were stored at −30°C and solutions were then prepared immediately before use. Di-*tert*-butylhyponitrite (DBHN) (5) was purified by recrystallization from cold methanol. Azobis(2-amidinopropane)hydrochloride (ABAP), azobisisobutyronitrile (AIBN), azobiscyclohexylnitrile (ACHN), and 2,2′-azobis(2,4-dimethylvaleronitrile) (ADVN) were obtained from Polysciences, Inc. The latter three were recrystallized from methanol before use. The 4,4′-azobis(4-cyanovaleric acid) (ABVA) was obtained from Aldrich. The azobis(2-*n*-butylcarboxylpropane) (ABCP) was synthesized as described (15).

Phospholipids

The egg lecithin phosphatidylcholine (ELPC), dilinoleoyl phosphatidylcholine (DLPC), dipalmitoyl phosphatidylcholine (DPPC), and dimyristoyl phosphatidylcholine (DMPC) were obtained from Avanti Polar Lipids. They were stored in sealed vials at −30°C.

Inhibitors

α-Tocopherol (α-T) (Eastman–Kodak) was stored in known concentrations in hexane under argon at −30°C. The water-soluble Trolox, a gift from Hoffmann–LaRoche, Nutley, New Jersey, was used as freshly prepared solutions in phosphate buffer (pH 7.0).

Bilayers

The bilayer dispersions were prepared by vortex stirring in phosphate buffer (pH 7) containing EDTA of films of the phospholipids from evaporation of a solution in methylene chloride as described (5). Lipid-soluble initiators (DBHN, ABCP, ACHN, and ADVN) were dissolved in the bilayers by adding them to the organic solvent – phospholipid phase before evaporation to a film. Sonication of the bilayers was carried out under argon in a Bransonic 220 ultrasonic bath.

2. *Analyses*

The concentration of DBHN remaining in the bilayer was measured by hlpc analysis because of the loss of this initiator due to its volatility (5) during the bilayer preparation. An aliquot of the bilayer dispersion containing DBHN was added to three times its volume of methanol to break up the bilayer. An internal standard solution of acetanilide was then added and the DBHN concentration measured on a SP-8000 hplc using a Brownlee RP-8 column eluted with 60:40 methanol/water at 2.0 mL/min.

The particle sizes of the vesicles in the aqueous dispersions were determined by Dr. G. F. Barclay on a difference interference contrast microscope (Zeiss Nomarski) at 1250× magnification.

3. *Autoxidation procedures*

The autoxidation procedure described previously (5) was followed. In autoxidation using water-soluble initiators (ABAP, ABVA) and inhibitor (Trolox), the reaction was initiated by adding a solution of known concentration of the initiator in phosphate buffer. The rate of oxygen uptake was measured, followed by injection of a known concentration of Trolox in buffer to the same reaction to measure the R_i by the induction period method.

The rotating sector method to measure absolute rate constants has been reviewed in terms of the theory (22) and applications (23). Our procedure to obtain k_p and $2k_t$ for autoxidation was similar to that of Howard and Ingold (24). The method is based upon measurement of the lifetime of the reaction chains. For this measurement the reaction is initiated by photochemical decomposition of the initiator with a rotating sectored disc of known dimensions between the light source (in this case a focused 200-W super pressure mercury arc light filtered through Pyrex) and the reaction flask. Rates of oxygen uptake are measured at various sector speeds and the $2k_t$ calculated as described (24). The k_p is then calculated from the rate at steady illumination from eq. [1] by substituting for the measured $2k_t$ and the R_i. The variations in rates with light intensity were measured at full light and 10%, 25%, and 50% light by inserting neutral density filters into the light beam. In all cases the thermal (dark) rate remained low (less than 10%) compared to the photochemical rate on the same sample.

Results and discussion

1. *The oxidizability of methyl linoleate in homogeneous solution*

The kinetics of autoxidation of methyl linoleate initiated by azobisisobutyryl nitrile (AIBN) were studied at three concentrations in chlorobenzene and the results are shown in Table 1. The oxidizability result ($k_p/2k_t = 2.18 \pm 0.09 \times 10^{-2} M^{-\frac{1}{2}} s^{-\frac{1}{2}}$) is in good agreement with the published value of 2.10×10^{-2} $M^{-\frac{1}{2}} s^{-\frac{1}{2}}$ (25). The considerably higher oxidizability in *ortho*-dichlorobenzene ($4.08 \times 10^{-2} M^{-\frac{1}{2}} s^{-\frac{1}{2}}$) is attributed to a solvent effect since an increase in solvent polarity[2] is known to increase

[2]The dielectric constants of the solvents are C_6H_5Cl, 5.62, and o-$C_6H_4Cl_2$, 9.93 at 25°C (26).

[a]1.29×10^{-5} mol, 4.0×10^{-6} L of linoleic acid and 2.12×10^{-5} L of bilayer were used in each run. The combined volume was used for the reaction volume in calculations. Reactions were carried out in 2.00 mL of phosphate buffer (pH 7.0) at 30°C.
[b]DMPC, dimyristoyl phosphatidylcholine; DPPC, dipalmitoyl phosphatidylcholine.
[c]DBHN, di-*tert*-butylhyponitrite (the amount in the bilayers determined by RP hplc analyses); ABAP, azobis(2-amidinopropane hydrochloride), $k_i = 3.82 \times 10^{-7}\ s^{-1}$ (ref. 6).
[d]The value of 0.026 was used to calculate the R_i.
[e]The bilayers were prepared by vortex stirring, giving mixtures of particle sizes up to approximately 6 μm in size.
[f]The bilayer was prepared by sonication (2 h).
[g]The bilayer was sonicated at 50°C until a nearly clear dispersion formed ($9\frac{1}{2}$ h). The particles were less than 0.2 μm in size.
[h]The same as footnote *d*, Table 1.

the oxidizability of a substrate (27−29). The results in these similar nonprotic solvents of different polarity provide a basis for comparison with the autoxidation of linoleate in micelles and bilayers.

2. *Autoxidation of linoleate in PPC bilayers*

(*a*) *The oxidizability of linoleic acid in DMPC and DPPC bilayers using lipid-soluble and water-soluble initiators and inhibitors*

We have recently shown (6) that various combinations of *lipid-soluble* and *water-soluble* initiators and inhibitors can be used for quantitative kinetic studies in micelles and bilayers whereby the same oxidizability of a substrate was obtained with the initiator or inhibitor in either the aqueous phase or the micellar or bilayer phase. The present results from the autoxidation of linoleic acid in bilayers outlined in Table 2 provide an important application of the earlier findings. Thus the oxidizability of linoleic acid in dimyristoyl phosphatidyl choline (DMPC) bilayers is the same, within experimental error, whether one uses a combination of a lipid-soluble initiator, di-*tert*-butylhyponitrite (DBHN), with a lipid-soluble inhibitor, α-tocopherol (α-T), or a water-soluble inhibitor, 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylate (Trolox). Furthermore, similar results were obtained for the oxidizability of linoleic acid in DMPC when one initiates with a water-soluble initiator azobisamidinopropane·HCl (ABAP) and uses water-soluble Trolox to measure the R_i (Table 2). Other workers (13) report that linoleic acid readily partitions into PPC bilayers, and the fact that we obtain the same oxidizability of linoleic acid whether the initiators and inhibitors are located in the water or the bilayer is consistent with solubilization into the bilayer region.

The *magnitude* of the oxidizability of a *given* substrate is known to be increased by the polarity of the medium (27−29). This solvent effect could be exerted on a dipolar transition state of the type

$$\text{R—O—O}\cdot + \text{H—R} \xrightarrow{k_p} [\text{R—O—O}^{-}\cdot\text{H}\cdot\overset{+}{\text{R}}]$$

resulting in an increase in the propagation rate constant. However, actual measurements of propagation (k_p) and termination (k_t) rate constants for hydrocarbons in various solvents demonstrated that the solvent polarity effect is mainly on the rate of *termination* (28), which is decreased due to the fact that the polarity of peroxyl radicals (30) is destroyed in the termination step. The termination rate constants for radical recombinations

in bilayers could similarly be suppressed if peroxyl radicals diffuse to the polar region as suggested earlier (5).

The value for the oxidizability of linoleic acid in DMPC bilayers ($2.76 \pm 0.42 \times 10^{-2}\,M^{-\frac{1}{2}}\,s^{-\frac{1}{2}}$) is somewhat higher than that found for methyl linoleate in solution in chlorobenzene. This difference could be due to the position of the linoleate chain in the bilayer. An ionized carboxylate head group in this case would tend to pull the chain out towards the aqueous surface where the dielectric constant is expected to be higher, resulting in a moderate "solvent effect". The higher oxidizability of linoleic acid in highly sonicated vesicles ($3.49 \times 10^{-2}\,M^{-\frac{1}{2}}\,s^{-\frac{1}{2}}$) appears to be due to the effect of particle size on the absolute rate constants (*vide infra*).

The rather low initiator efficiency, *e*, for the bilayer-soluble initiator, DBHN ($8.95 \pm 1.15\%$), is consistent with chain initiation in the bilayer region where the microviscosity is high. This results in a high proportion of cage recombination. Similar results were found for initiation of bilayer autoxidation in egg lecithin by DBHN, where *e* was found to be 9.1% (5).

A few autoxidation runs were carried out on linoleic acid in a bilayer below the phase transition temperature by using dipalmitoylphosphatidyl choline (DPPC, phase transition 41°C) at 30°C and typical results are included in Table 2. In this case the initiator efficiency of DBHN is even lower (2.6%), presumably due to a higher microviscosity of a bilayer below its phase transition temperature.

(b) The oxidizability of methyl linoleate in DMPC bilayers

The autoxidation of methyl linoleate was initiated in DMPC bilayers by using water-soluble initiators ABAP and 4,4′-azobis(4-cyanovaleric acid) (ABVA). The R_i was measured using either the lipid-soluble inhibitor, α-T, or water-soluble Trolox. The results of these experiments are summarized in Table 3. The oxidizability of this *neutral* linoleate chain ($1.79 \pm 0.07 \times 10^{-2}\,M^{-\frac{1}{2}}\,s^{-\frac{1}{2}}$) is only measurably lower than observed in chlorobenzene solution but it is significantly lower than that found for ionized linoleate in DMPC ($2.76 \times 10^{-2}\,M^{-\frac{1}{2}}\,s^{-\frac{1}{2}}$). We suggest that this indicates that methyl linoleate is sequestered deep in the relatively nonpolar, more fluid region (31) of DMPC where it undergoes autoxidation.

Our results outlined in Tables 2 and 3 provide interesting applications of various combinations of lipid-soluble and water-soluble initiators and inhibitors for quantitative kinetic studies in bilayers (i.e. DBHN with either α-T or Trolox, ABAP with Trolox, ABAP with α-T or Trolox[3]). This raises important questions as to how both water-soluble and lipid-soluble initiators and inhibitors exhibit the same effectiveness in initiating autoxidation and trapping radicals in bilayer autoxidation. The radical trapping effectiveness of water-soluble Trolox for radicals formed in the lipid phase is understood on the basis of our earlier postulate (5) that polar peroxyl radicals formed in the nonpolar hydrocarbon phase of a bilayer will diffuse into the more polar aqueous–lipid interfacial region. The effective radical trapping ability of Trolox for peroxyls initially formed in the bilayer from lipid-soluble DBHN confirms this postulate. Trolox in the water is expected to trap these radicals at the water–bilayer interface. It is also remarkable to find that a charged water-soluble initiator (ABAP, ABVA) and inhibitor appear to have access to the various layers of the multilamellar liposomes used, suggesting a rather fluid overall system. We are studying these phenomena in more detail by comparing the behavior of multilamellar and unilamellar systems.

3. *Absolute rate constants for propagation,* k_p, *and termination,* $2k_t$

Some exploratory experiments were conducted to (1) determine if the rotating sector technique (22), widely used to study photoinitiated reactions in homogeneous solution (33, 34) can be applied to determine absolute rate constants, k_p and $2k_t$, in microenvironments such as bilayers and micelles, and (2) to determine the applicability of water-soluble initiators and inhibitors (6) to this technique. Trial experiments carried out in homogeneous media, Table 4, Nos. 1–4, gave good agreement of the k_p and $2k_t$ for tetralin (lit. values (33) are $k_p = 6.4\,M^{-1}\,s^{-1}$ and $2k_t = 7.6 \times 10^6\,M^{-1}\,s^{-1}$) and reasonable agreement for methyl linoleate in chlorobenzene (lit. values (34) are $k_p = 62\,M^{-1}\,s^{-1}$ and $2k_t = 8.8 \times 10^6\,M^{-1}\,s^{-1}$), considering the large errors that occur in the determinations of k_p and $2k_t$ (24). For eq. [1] (Introduction) to be followed exactly, chain termination must be bimolecular and the oxidation rate must be proportional to $R_i^{\frac{1}{2}}$. This is tested by using initiators of relatively high thermal stability (Table 4) and measuring the reaction rate order, which should be half order, with respect to the light intensity. The somewhat higher order (0.57) with methyl linoleate is attributed to some first-order chain termination in addition to bimolecular chain termination.

Preliminary experiments in SDS micelles and bilayers (Table 4, Nos. 6–12) indicate that photodecomposition of azo-initiators occurs so that the rotating sector method to estimate absolute rate constants is applicable to these systems. Although bilayers are typically opaque milky dispersions, continuous shaking of the sample exposes a fresh layer to the light and permits effective photocatalytic decomposition of the initiator.

[3]ABAP has recently been reported to initiate oxidation of lecithin bilayers (32).

Furthermore, the order in light intensity is one-half, within experimental error, as required for bimolecular termination. The use of water-soluble initiators and inhibitors also makes it possible to prepare the bilayers by various techniques (vortex stirring, sonication, dialysis) *prior* to the initiation of autoxidation. The latter two procedures result in decomposition or loss of lipid-soluble initiators and inhibitors which must be inserted prior to preparation of a bilayer (5), and this decomposition makes it difficult to study unilamellar bilayer vesicles by controlled autoxidation.

The data outlined in Nos. 6–13 provide the first published evidence of absolute autoxidation rate constants in microenvironments. Although our results for the absolute rate constants are somewhat preliminary and a detailed analysis requires more data, a few interesting trends can be noted. There is a notable decrease in the termination rate constant ($2k_t$) for autoxidation of a phospholipid in bilayers compared to that in homogeneous solution (Compare Nos. 7–11 with DLPC in *tert*-butyl alcohol), and this reduction could be as much as a hundredfold for DLPC in bilayers compared to homogeneous solution. We suggest that this reduction in $2k_t$ is probably a consequence of the termination of peroxyls in the polar region of the bilayer.[4] Nevertheless the oxidizability, $k_p/2k_t^{\frac{1}{2}}$, of a bilayer remains about the same as that in homogeneous solution (compare DLPC in *tert*-butyl alcohol and in a bilayer, Nos. 5 and 9). This results from a significant *reduction* in the k_p, by as much as tenfold, as well as the noted decrease in $2k_t$. A reduction in k_p was anticipated earlier (5) when we hypothesized that polar peroxyl radicals (30) would diffuse away from the nonpolar hydrocarbon-like environment. As a result they would not readily abstract the labile CH_2 groups which are deeper in the bilayer. It also appears that the oxidizability of a substrate depends somewhat on the nature of the PPC particles employed. Thus DLPC in sonicated vesicles has about double the $k_p/2k_t^{\frac{1}{2}}$ (Nos. 10, 11) compared to multilamellar bilayers (No. 9), and methyl linoleate in highly sonicated DMPC vesicles has a significantly higher $k_p/2k_t^{\frac{1}{2}}$ value compared to that in multilamellar bilayers (Table 3). The reason for this is not entirely obvious, although it appears to result mainly from an increase in the k_p term.

Acknowledgements

We are indebted to Drs. G. W. Burton and K. U. Ingold of N.R.C.C. for their assistance with the rotating sector experiments, and to Dr. G. F. Barclay of our Biology Department for the microscopic examination of the vesicles. [4]If the peroxyl radicals terminate in the aqueous-lipid interface as proposed (*vide infra*), the reduction in $2k_t$ could be due to stabilization of the polar peroxyl radicals by the polar aqueous buffer and by hydrogen bonding (29):

$$R-\ddot{\underset{..}{O}}-\dot{\underset{..}{O}} \leftrightarrow R-\overset{+}{\dot{\underset{..}{O}}}-\overset{-}{\ddot{\underset{..}{O}}}:\text{---}\underset{H}{HO}$$

Interactions entre les cations et les sucres. I. Évaluation de l'enthalpie libre d'interaction Ca^{2+} − D-(−)-ribose dans l'eau à 25°C

JEAN-PIERRE MOREL[1] ET CLAUDE LHERMET
Laboratoire d'Étude des Interactions Solutés–Solvants, U.A. au C.N.R.S. n° 434, Université de Clermont 2, 63170 Aubière, France

Reçu le 17 décembre 1984

JEAN-PIERRE MOREL et CLAUDE LHERMET. Can. J. Chem. **63**, 2639 (1985).

L'interaction des deux pentoses isomères D-(−)-ribose et D-(−)-arabinose avec l'ion Ca^{2+} en solution aqueuse est étudiée à l'aide de deux types de cellules électrochimiques (avec et sans jonction) comportant une électrode à membrane liquide sélective à Ca^{2+}. Certains isomères du D-(−)-ribose possèdent une séquence d'hydroxyles susceptible d'interagir spécifiquement avec le cation. La mesure de l'enthalpie libre de transfert de l'ion Ca^{2+} entre l'eau et les solutions sucrées permet de calculer un paramètre d'interaction par paire caractéristique. D'autre part, cette interaction spécifique est également caractérisée par sa constante d'association: β_1 = 0,93. Les deux approches sont étudiées et leur cohérence est démontrée.

JEAN-PIERRE MOREL and CLAUDE LHERMET. Can. J. Chem. **63**, 2639 (1985).

The interaction of the two isomeric pentoses D-(−)-ribose and D-(−)-arabinose with the Ca^{2+} ion in aqueous solution is studied with the help of two types of electrochemical cells (with and without liquid junction) including a liquid-membrane Ca^{2+}-selective electrode. Some of the D-(−)-ribose isomers contain a sequence of hydroxyl groups which can interact specifically with the cation. The measurement of the Gibbs free energy of transfer of Ca^{2+} between water and the sugar solutions allows one to calculate a characteristic pair-interaction parameter. This specific interaction can also be characterized by its association constant: β_1 = 0.93. The two approaches are studied and their coherence is shown.

Introduction

Les interactions en solution aqueuse entre les cations métalliques et les saccharides, malgré leur relative faiblesse, sont d'une grande importance pour la chimie et la biochimie des sucres. Elles intéressent également des domaines de la biologie tels que le stockage du calcium ou l'adhésion des cellules.

Les travaux de S. J. Angyal (1, 2) ont d'abord montré le rôle joué par la présence des séquences d'hydroxyles *axial–équatorial–axial* dans les cycles à 6 atomes, et *cis–cis–cis* dans les cycles à 5 atomes des molécules de sucres, de leurs dérivés ou des composés cycliques polyhydroxylés. Des études quantitatives ont permis de préciser l'ordre de grandeur des constantes d'association entre certaines cations et certains sucres. Le D-(−)-ribose, en particulier, a fait l'objet de plusieurs études; il s'agit en effet d'un des rares sucres simples qui présente des structures favorables à la complexation: les deux conformères $^4C_1$ et $^1C_4$ de la forme α-pyranose et le conformère $^1C_4$ du β-pyranose présentent une séquence *ax–eq–ax* alors que la forme α-furanose présente une séquence *cis–cis–cis* d'hydroxyles. Les études en rmn de Lenkinski et Reuben (3) et de Symons *et al.* (4) ont permis de proposer des valeurs de constante d'association pour les différentes formes ci-dessus avec l'ion Ca^{2+}. Des méthodes potentiométriques ont également été appliquées à l'étude de ce couple (5, 6).

Si la rmn est une méthode de choix qui permet de distinguer les différents isomères présents à l'équilibre, elle nécessite l'étude de solutions où le sucre est souvent présent à des concentrations de l'ordre de 1 *M* alors que la concentration du sel de calcium peut varier jusqu'à 2 *M*. Dans ces conditions, les constantes obtenues sont apparentes et comparatives mais sans nul doute assez éloignées des valeurs thermodynamiques; de plus, aux fortes concentrations en sel, l'effet des anions peut fausser notablement l'interprétation des résultats.

L'étude thermodynamique des interactions sucre–cation n'a pas été réalisée de façon approfondie. Si la première étape d'une telle étude est logiquement la détermination des paramètres d'enthalpie libre, on peut penser que la connaissance d'autres grandeurs thermodynamiques (en particulier l'enthalpie et l'entropie d'interaction) seraient également très utile à la compréhension du phénomène. Nous nous proposons d'aborder ces problèmes par une interprétation de résultats expérimentaux obtenus en potentiométrie. Les électrodes à membrane liquide sélectives à l'ion Ca^{2+} permettent des mesures très précises de l'activité de cet ion en solution aqueuse. Dans les cellules galvaniques mettant en oeuvre une telle électrode, le D-(−)-ribose sera comparé au D-(−)-arabinose, pentose isomère dont les formes pyraniques présentes à l'équilibre ne comportent aucune séquence d'hydroxyle favorable à la complexation.

[1]Auteur à qui adresser toute correspondance.

Théorie

La première cellule galvanique étudiée est:

[1] Electrode à Ca $|CaCl_2(m)$, sucre $(m_s)|AgCl|Ag$

où m est la molalité de $CaCl_2$ et m_s celle du sucre, ribose (m_R) ou arabinose (m_A). La réaction de cellule s'écrit:

[2] $Ca \text{ (électrode)} + 2\ AgCl = Ca^{2+} + 2Cl^- + Ag$

Une étude préliminaire, pour laquelle $m_s = 0$, nous permet de vérifier la réversibilité de cette cellule dont la tension s'écrit, à T et P constantes,

[3] $U(m) = U^{\ominus} + 3k/2 \log m\gamma_{\pm}$

où $U^{\ominus}$ est la tension standard dans l'échelle des molalités,

$$k = \ln 10\ RT/F = 0{,}05916 \text{ V à } 25°\text{C}$$

En utilisant les valeurs de $\gamma_{\pm}$ ($CaCl_2$) données par Robinson et Stokes (7) et les valeurs expérimentales de U, on peut calculer une pente de 88,8 mV en excellent accord avec la valeur thermodynamique.

Le principe de la mesure consiste à ajouter une solution concentrée de sucre contenant $CaCl_2$ à la molalité m par rapport au solvant (eau + sucre) dans une solution aqueuse initiale de même molalité m en $CaCl_2$ contenue dans la cellule (8). On explore ainsi une gamme de concentration en sucre variant par exemple de $m_s = 0$ à $m_s = 0{,}4$ en maintenant m constant. Les tensions de cellule s'expriment en utilisant l'état standard correspondant à $CaCl_2$ infiniment dilué dans l'eau d'une part et dans la solution sucrée d'autre part.

$$[4] \quad U(m) = U^{\ominus} + 3k/2 \log m\, \gamma_{\pm}(m)$$

$$[5] \quad U(m, m_s) = U^{\ominus}(m_s) + 3k/2 \log m\, \gamma_{\pm}(m, m_s)$$

où les $\gamma_{\pm}$ tendent vers 1 dans les deux cas lorsque $m \rightarrow 0$. On voit que:

$$U(m, m_s) - U(m) = [U^{\ominus}(m_s) - U^{\ominus}] + 3k/2 \log \frac{\gamma_{\pm}(m, m_s)}{\gamma_{\pm}(m)}$$

et lorsque $m \rightarrow 0$

$$[U(m, m_s) - U(m)] \rightarrow [U^{\ominus}(m_s) - U^{\ominus}]$$

L'expérience montre que pour des concentrations en $CaCl_2$ $m = 5 \times 10^{-3}$ et $m = 1 \times 10^{-1}$, la différence des tensions ne dépend que de m_s et représente la différence des tensions standard, c'est-à-dire qu'on peut considérer que

$$\gamma(m, m_s)/\gamma(m) \sim 1$$

Cette expérience permet donc d'accéder à l'enthalpie libre standard de transfert de l'électrolyte $CaCl_2$ de l'eau pure à la solution sucrée de molalité m_s (8).

$$[6] \quad \Delta G_t^{\ominus} = 2\, F[U^{\ominus}(m_s) - U^{\ominus}]$$

où F est le Faraday. Cette grandeur standard de transfert peut s'interpréter en terme de paramètre d'interaction par paires, triplets etc ... (9) sous la forme

$$[7] \quad \Delta G_t^{\ominus} = 2\nu\, g_{ES}\, m_s + 3\, \nu\, g_{ESS}\, m_s^2 + \ldots$$

où ν est le nombre d'ions de l'électrolyte E, c'est-à-dire, ici, $\nu = 3$ pour $CaCl_2$. Ce formalisme fait apparaître le paramètre d'enthalpie libre de la paire électrolyte–sucre, g_{ES}, qui est la moyenne des paramètres d'interaction des paires cation–sucre et anion–sucre de telle façon que

$$[8] \quad g_{ES} = (g_{Ca^{2+}s} + 2\, g_{Cl^-s})/3$$

Dans cette étude, le sucre étudié sera successivement le D-(−)-ribose et le D-(−)-arabinose. Si l'on admet que les interactions non spécifiques de ces deux sucres avec les cations et anions sont identiques, la différence $g_{ER} - g_{EA}$ sera caractéristique de l'interaction spécifique entre le D-(−)-ribose et le cation Ca^{2+} par l'intermédiaire des séquences d'hydroxyles favorables à la complexation.

Une deuxième interprétation des résultats expérimentaux donnés par cette cellule consiste à exprimer une constante d'association spécifique entre le ribose et Ca^{2+}. On utilise, dans ce cas, une expression de la tension de cellule qui se réfère à l'état infiniment dilué dans l'eau pour $CaCl_2$ et pour le sucre.

$$[9] \quad U(m, m_R) = U^{\ominus} + k/2 \log [Ca]_R\, m_{Cl}^2\, \gamma_{\pm}^3(m, m_R)$$

$$[10] \quad U(m, m_A) = U^{\ominus} + k/2 \log m_{Ca}\, m_{Cl}^2\, \gamma_{\pm}^3(m, m_A)$$

pour respectivement le ribose et l'arabinose. Si dans l'expression [10], m_{Ca} est toujours la molalité analytique en Ca^{2+}, dans [9], la concentration en ions libres est $[Ca]_R$, une fraction de ceux-ci étant associée avec le ribose. En faisant l'hypothèse que pour $m_A = m_R$, $\gamma_{\pm}(m, m_A) = \gamma_{\pm}(m, m_R)$, on tire

$$[11] \quad U(m, m_R) - U(m, m_A) = k/2 \log \frac{[Ca]_R}{m}$$

Comme nous l'avons dit plus haut, cette différence ne dépend pratiquement pas de m. La méthode de Leden (10) nous permet d'écrire la fonction

$$[12] \quad F(R) = \frac{m - [Ca]_R}{[Ca]_R[R]} = \beta_1 + \beta_2\, [R]$$

où

$$[13] \quad \beta_1 = \frac{[CaR]}{[Ca][R]} \qquad \beta_2 = \frac{[CaR_2]}{[Ca][R]^2}$$

Puisque nous opérons avec un excès de ribose et que le taux d'association est faible, il est normal d'observer que

$$[14] \quad \frac{m}{[Ca]_R} = 1 + \beta_1[R] + \beta_2[R]^2 \sim \text{constante}$$

quel que soit m si $[R] \sim m_R$. De toute façon, cette méthode consistera à calculer $F(R)$ connaissant $m/[Ca]_R$, c'est-à-dire

$$[Ca]_R \text{ et } [R] = m_R - m + [Ca]_R$$

L'étude d'une deuxième cellule galvanique comportant une jonction liquide va nous permettre d'accéder aux mêmes grandeurs que ci-dessus moyennant des hypothèses différentes. La cohérence des résultats obtenus par les deux méthodes pourra être considérée comme un critère de leurs validités respectives. La cellule

$$[15] \quad \text{Electrode à Ca}|CaCl_2(m), \text{ sucre } (m_s) \left\| \begin{matrix} KNO_3 \\ \text{Sat.} \end{matrix} \right\| \begin{matrix} KCl \\ \text{Sat.} \end{matrix} \left| Hg_2Cl_2 \right| Hg$$

possède une double jonction liquide qui permet d'éviter la jonction directe de la solution étudiée avec l'électrode au calomel (l'expérience montre, dans ce cas, une grande instabilité des tensions mesurées due probablement à la présence des ions mercureux). Avec ce montage, les tensions sont parfaitement stables et reproductibles. La tension de cette cellule s'écrit:

$$[16] \quad U(m, m_s) = (U_{Ca}^{\ominus} - U_R) + U_j(m, m_s) + k/2 \log m\, \gamma_{Ca}(m, m_s)$$

où $U_{Ca}^{\ominus}$ est la tension standard de l'électrode à calcium, U_R la tension de l'électrode de référence et U_j la tension de la première jonction liquide. Les hypothèses de travail sont ici

$$U_j(m, m_A) = U_j(m, m_R) \text{ si } m_A = m_R$$

c'est-à-dire que la valeur de la tension de jonction ne dépend pas de la nature du sucre. De plus, comme plus haut,

$$\gamma_{Ca}(m, m_A) = \gamma_{Ca}(m, m_R)$$

Expérimentalement, on constate que la différence $U(m, m_s) - U(m)$dépend de la concentration m en électrolyte, contrairement à ce que nous avions constaté avec la cellule sans jonction (ceci traduit très probablement la variation de U_j avec m). Par contre, la différence $U(m, m_R) - U(m, m_A)$ est sensiblement indépendante de m. On pourra donc, comme plus haut, accéder à la grandeur $m/[Ca]_R$ et calculer la constante d'association spécifique Ca^{2+}–ribose.

Partie expérimentale

L'électrode sélective aux ions Ca^{2+} est une Orion 93-20, l'électrode AgCl|Ag une Tacussel et l'électrode au calomel à double jonction une Tacussel RDJ 17. Le millivoltmètre électronique Tacussel ISIS 20000

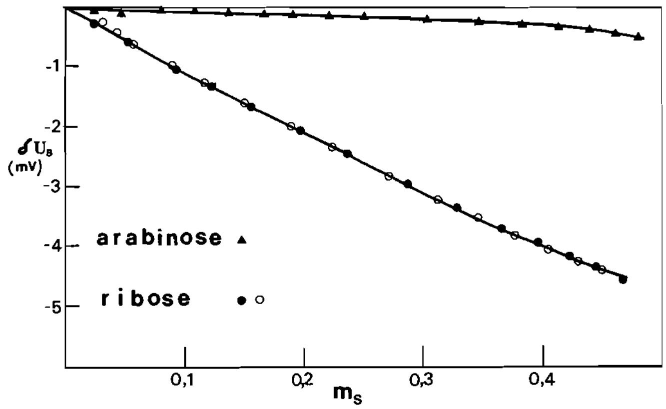

FIG. 1. Variation de tension δU_s de la cellule électrochimique [1] avec la molalité en sucre m_s. ●▲ m_{CaCl_2} = 0,1; ○ m_{CaCl_2} = 5×10^{-3} (molalités en Ca^{2+} par rapport à l'eau).

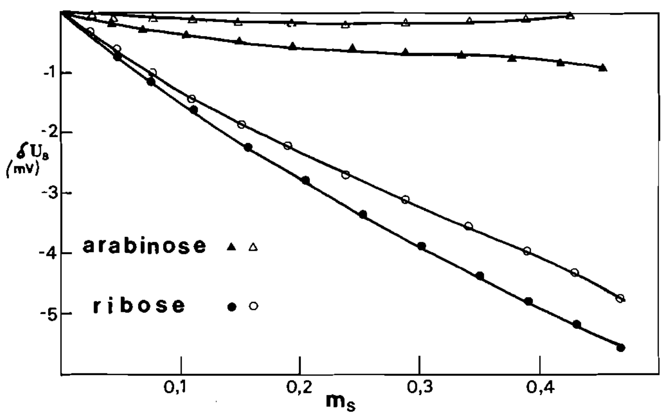

FIG. 2. Variation de tension δU_s de la cellule électrochimique [15] avec la molalité en sucre m_s. ○△ $m_{CaCl_2} = 5 \times 10^{-3}$; ●▲ m_{CaCl_2} = 2×10^{-2} (molalités en Ca^{2+} par rapport à l'eau).

permet de lire le 1/100^e de mV.

L'eau est tridistillée et dégazée avant usage.

Les sucres sont des produits Fluka Puriss pour analyse utilisés comme tel; le chlorure de calcium un produit Merck Pro Analysi.

Toutes les solutions sont réalisées par pesée et l'addition de la solution concentrée en sucre se fait à l'aide d'une burette gravimètrique Mettler P 160 N. La cellule de mesure est thermorégulée par circulation d'eau, la stabilité en température étant de l'ordre de 1/100^e de degré.

Résultats

Les figures 1 et 2 montrent, respectivement, les variations de la tension des deux cellules galvaniques étudiées, soit $\delta U_s = U(m, m_s) - U(m)$ en fonction de la concentration en sucre de la solution. Notons que malgré le faible domaine de variation des tensions mesurées (au maximum 5 mV), celles-ci sont connues avec une précision remarquable (la reproductibilité des mesures et de l'ordre de ±0,02 mV). Pour la cellule [1] (fig. 1), on voit que δU_s est identique pour $m = 5 \times 10^{-3}$ et $m = 1 \times 10^{-1}$ en $CaCl_2$, ce qui justifie notre précédente hypothèse. Au contraire, pour la cellule à jonction liquide [15] (fig. 2), δU_s dépend de la concentration en $CaCl_2$.

Les résultats des calculs sont regroupés dans le tableau 1. Les enthalpies libres standard de transfert de $CaCl_2$ de l'eau aux solutions de ribose ($\Delta G^{\ominus}_{tR}$) et aux solutions d'arabinose ($\Delta G^{\ominus}_{tA}$) sont calculées grâce à la relation [6]. En portant $\Delta G^{\ominus}_t/m_s$ en fonction de m_s (relation [7]), une extrapolation linéaire permet d'obtenir les paramètres d'interaction. Un tel traitement graphique donne ici:

$$2\nu g_{ER} = -1160 \text{ J mol}^{-2} \text{ kg} \quad 3\nu g_{ERR} = +750 \text{ J mol}^{-3} \text{ kg}^2$$

$$2\nu g_{EA} = +950 \text{ J mol}^{-2} \text{ kg} \quad 3\nu g_{EAA} = -100 \text{ J mol}^{-3} \text{ kg}^2$$

Les valeurs de $\Delta U(R - A) = \delta U_R - \delta U_A$ permettent de calculer (relations [11] et [12]) la fonction de Leden $F(R)$. Pour la cellule [1], les valeurs de ΔU correspondent aux interpolations effectuées sur la courbe moyenne de 3 essais à des molalités différentes en $CaCl_2$ (0,005, 0,02, 0,1). La fonction $F(R)$ décroit de façon significative quand m_s croît; cette variation ne met donc pas en évidence la formation du complexe CaR_2, puisque la pente β_2 devrait alors être positive. L'extrapolation à concentration nulle en sucre conduit à $\beta_1 = 0,89 \pm 0,10$ environ. Pour la cellule [15], les calculs de $F(R)$ sont effectués pour deux concentrations en $CaCl_2$ (m = 0,005 et 0,02) et l'on voit que ΔU dépend peu de cette concentration. Les valeurs de $F(R)$ sont pratiquement indépendantes de m_s, concentration en sucre, et le complexe CaR_2 n'est pas mis en évidence dans le domaine étudié; on admettra donc que $F(R) = \beta_1$. Pour m = 0,005 on trouve une valeur moyenne $\beta_1 = 0,93 \pm 0,07$ et pour m = 0,02, $\beta_1 = 0,93 \pm 0,16$.

Discussion

L'enthalpie libre standard de transfert de $CaCl_2$ de l'eau aux solutions de ribose est négative alors que la grandeur de transfert de l'eau aux solutions d'arabinose est positive. C'est la manifestation immédiate de l'interaction spécifique du premier de ces deux pentoses isomères avec l'ion Ca^{2+}. Quantitativement, cette interaction spécifique est caractérisée par la différence

$$2\nu(g_{ER} - g_{EA}) = 2g_{CaR} = -2110 \text{ J mol}^{-1} \text{ (voir relation [8])}$$

si l'on fait l'hypothèse de l'identité des interactions non spécifiques entre $CaCl_2$ d'une part, et ribose ou arabinose d'autre part. Nous n'interpréterons pas ici les paramètres g relatifs aux triplets, mais remarquons cependant que g_{ERR} est positif, ce qui ne plaide pas pour l'existence du complexe CaR_2.

Les calculs de la constante d'association conduisent à β_1 = 0,89 avec la cellule [1] et β_1 = 0,93 avec la cellule [15]. Compte tenu des incertitudes évaluées, la bonne concordance de ces deux résultats montre que les hypothèses formulées sont satisfaisantes en première approximation. Ces calculs ne conduisent pas, eux non plus, à la prise en compte d'un complexe du type CaR_2.

Les résultats obtenus précédemment par des méthodes potentiométriques sont: d'une part (5), β_1 = 1,6 par une méthode de compétition entre Ca^{2+} et Pb^{2+} en présence de $NaClO_4$ 1 M, la concentration en ribose étant 0,1 M et celle en ion Ca^{2+} variant jusqu'à 0,15 M; d'autre part (6), β_1 = 1,1 et β_2 = 8,5 avec une solution 0,1 M en ribose et des concentrations en Ca^{2+} allant jusqu'à 0,16 M. Au contraire des expériences réalisées ci-dessus, les méthodes que nous présentons consistent à faire varier la concentration en sucre alors que celle de $CaCl_2$ reste constante. Compte tenu de l'importance des facteurs d'activité dans l'expression de la constante thermodynamique d'équilibre, il est important de prouver, comme nous l'avons fait, que les résultats obtenus ne dépendent pas de la concentration en $CaCl_2$. On s'affranchit également de la présence de tout sel de fond dont on ne peut, à priori, négliger les interactions des ions avec la molécule de sucre.

La valeur que nous obtenons pour β_1, soit environ 0,9, est en

TABLEAU 1. Enthalpies libres standard de transfert de $CaCl_2$ de l'eau aux solutions d'arabinose et de ribose de molalité m_s (cellule [1]) et fonctions de Leden F(R) de la complexation du calcium par le ribose (cellule [1] et cellule [15])

accord passable avec la moyenne que l'on peut calculer en considérant, qu'à l'équilibre, la solution de ribose contient environ: 35% (soit 60% de 59%) de β-pyranose $^1C_4$ (β = 0,8), 21% de α-pyranose (β = 3,4) et 6,5% de α-furanose (β = 5,3) (1). Avec ces valeurs données à 31°C par Angyal, le calcul conduit en effet à une valeur moyenne pour β_1 égale à 1,3. Les deux expressions de l'enthalpie libre d'interaction spécifique entre le calcium et le ribose, d'une part g_{CaR} et d'autre part β_1, sont naturellement reliées. La relation qui existe entre deuxième coefficient du viriel et constante d'association en phase gazeuse peut être établie de façon très simple (11). Pour ce qui concerne la thermodynamique statistique des solutions, Wood *et al.* (12) ont comparé les développements possibles du coefficient osmotique d'une solution, ϕ_{MM}, exprimé dans les conditions de McMillan-Mayer (T, π, c): d'une part le développement en série des activités où interviennent les constantes de "Sociation", d'autre part le développement en série des concentrations molaires avec les coefficients du viriel. On peut montrer que les coefficients d'interaction par paires de type g_{ij} de la relation [7] interviennent dans le développement du coefficient osmotique ϕ_{LR} (conditions de Lewis et Randall qui sont celles de nos mesures, soit T, P, m) sous la forme

$$[17] \quad \phi_{LR} = 1 + B_{LR}m = 1 + \frac{g_{ij}}{RT}m$$

si on se limite au coefficient d'interaction par paires d'espèces différentes dans le cas $m_i = m_j = m$, pour simplifier la présentation. Dans les conditions de McMillan-Mayer, le développement du coefficient osmotique s'écrit

$$[18] \quad \phi_{MM} = 1 + B_{MM}\, c$$

et l'on peut montrer (13) que

$$[19] \quad B_{MM} = B_{LR}/\rho^0 + \frac{1}{2}\bar{V}_i^{\ominus} + \frac{1}{2}\bar{V}_j^{\ominus} - \frac{1}{2}RT\beta^0$$

où ρ^0 est la masse volumique et β^0 le coefficient de compressibilité isotherme du solvant, $\bar{V}_i^{\ominus}$ et $\bar{V}_j^{\ominus}$ les volumes molaires partiels à dilution infinie des espèces i et j en interaction. Ici, $\bar{V}_R^{\ominus}$ = 0,095 L mol^{-1} (14) et $\bar{V}_{Ca^{2+}}^{\ominus}$ = −0,029 L mol^{-1} (15). Le dernier terme de [19] étant négligeable, on trouve

$$B_{MM} = -0{,}41 \text{ L mol}^{-1}$$

Compte tenu de la forme des développements en fonction des concentrations que nous avons utilisés ici, on peut montrer que la relation fondamentale évoquée plus haut s'écrit

$$[20] \quad \beta_1 = -2\, B_{MM}$$

où, en toute rigueur, β_1 est la constante thermodynamique d'association dans l'échelle des molarités. Celle-ci, dans l'eau, est naturellement très voisine de celle que nous avons calculée plus haut dans l'échelle des molalités. Comme on voit, cette relation est vérifiée de façon très satisfaisante dans le cas que nous venons d'examiner. Notons que la relation [20] peut s'écrire avec une approximation en général acceptable

$$[21] \quad \beta_1 = -2g_{ij}/RT$$

Cet exemple nous permet d'apprécier la cohérence des deux différents langages utilisés pour exprimer l'interaction entre deux espèces en solution. En thermodynamique statistique, c'est B_{MM}, grandeur directement liée au potentiel de force moyenne (12), qui caractérise fondamentalement cette interaction.

On peut s'interroger sur les causes de la petite différence observée sur les valeurs de β_1 obtenues respectivement avec les cellules [1] et [15], soit 0,89 et 0,93. La première cellule fait intervenir les interactions des anions chlorures avec le sucre, interactions qui sont éliminées en supposant que

$$g_{Cl^-R} = g_{Cl^-A}$$

Si l'on considère les valeurs des termes triplet g_{ERR} et g_{EAA}, on voit qu'elles sont de signes opposés; on peut en conclure que les interactions non spécifiques avec les deux pentoses isomères peuvent être notoirement différentes.

Il est tout à fait probable que les interactions impliquant les ions Cl^- contribuent à cette différence et que l'hypothèse ci-dessus n'est pas rigoureusement exacte. Ainsi, les résultats obtenus en étudiant la cellule [15], et dont on a vérifié qu'ils ne dépendaient pas de la concentration en $CaCl_2$, peuvent être considérés comme plus satisfaisants.

Conclusion

Nous avons utilisé et discuté deux méthodes potentiométriques qui permettent de mesurer de façon satisfaisante l'interaction spécifique entre le cation Ca^{2+} et les séquences d'hydroxyles favorables à la "complexation" d'un sucre. Ces méthodes consistent à comparer le sucre en question avec un isomère dont la structure ne permet pas d'interaction spécifique avec le cation.

Nous proposons pour l'interaction spécifique Ca^{2+} – D-(–)-ribose dans l'eau, à 25°C, une valeur de la constante d'association égale à 0,93. Le complexe comportant deux sucres pour un calcium n'a pas été mis en évidence.

Cette étude nous a permis de comparer les deux langages possibles pour caractériser le phénomène de "complexation", celui de l'interaction par paire et celui de la constante d'association.

Using a radioimmunoassay to measure the relative potencies as inhibitors of a wide number of chemically modified structures related to the Lewis b human blood group determinant, it was found that derivatives of the Lewis b (αLFuc(1→2)βDGal(1→3)[αLFuc(1→4)]βDGlcNAc) and the Y (αLFuc(1→2)βDGal(1→4)[αLFuc(1→3)]βDGlcNAc) determinants are complexed by the lectin IV of *Griffonia simplicifolia* through the recognition of a topographical feature that is common to both the tetrasaccharides. This surface provides a nonpolar region formed by the two methyl groups of the fucose units and extends along the C-1—O-5—C-5 side of the αLFuc(1→2) unit and terminates at one end by a polar grouping which is formed by OH-3 and OH-4 of the βDGal unit and OH-4 of the αLFuc(1→4) unit. Association constants were determined from changes in ultraviolet absorption that occur as the result of complex formation. For the reaction of the Lewis b-OCH_3 tetrasaccharide, the thermodynamic parameters were found to be $\Delta H = -13$ kcal/mol and $\Delta S = -22$ cal/mol/K. The inhibition data for the relevant monodeoxy derivatives indicated that OH-2 and OH-3 of both of the αLFuc units are not directly involved in the binding reaction. The basis for drawing these conclusions was strengthened by finding that the reaction of the simple Lewis b analog, methoxymethyl (1→2)βDGal(1→3)[αLFuc(1→4)]βDGlcNAcOCH_3 displayed very similar thermodynamic values; namely, $\Delta H = -14$ kcal/mol and $\Delta S = -26$ cal/mol/K, to those mentioned above for the Le^b-OCH_3 tetrasaccharide. The OH-4 of the αLFuc(1→2) unit may be bound in an intramolecularly hydrogen bonded form.

ULRIKE SPOHR, OLE HINDSGAUL et RAYMOND U. LEMIEUX. Can. J. Chem. **63**, 2644 (1985).

Utilisant un essai radioimmunologique pour mesurer les pouvoirs inhibiteurs relatifs d'un grand nombre de structures modifiées chimiquement et qui sont reliées au déterminant du groupe sanguin humain de type Lewis b, on a trouvé que les dérivés des déterminants du type Lewis b (αLFuc(1→2)βDGal(1→3)[αLFuc(1→4)]βDGlcNAc) et Y (αLFuc(1→2)βDGal(1→4)[αLFuc(1→3)]βDGlcNAc) sont complexés par la lectine IV de la *Griffonia simplicifolia* par le biais d'une reconnaissance d'une caractéristique topographique qui est commune aux deux tétrasaccharides. Cette surface fournit une région non polaire formée par les deux groupes méthyles des unités fucose; elle s'étend le long du côté C-1—O-5—C-5 de l'unité αLFuc(1→2) et se termine à l'une des extrémités par un groupement polaire qui est formé par les OH-3 et OH-4 de l'unité βDGal et par le OH-4 de l'unité αLFuc(1→4). On a déterminé les constantes d'association à partir des changements d'absorption dans l'ultraviolet qui sont associés à la formation du complexe. Pour la réaction du tétrasaccharide-OCH_3 du type Lewis-b, on a trouvé que les paramètres thermodynamiques sont les suivants: $\Delta H = -13$ kcal/mol et $\Delta S = -22$ cal/mol/K. Les données relatives au pouvoir inhibiteur des dérivés monodéoxy correspondants indiquent que les fonctions OH-2 et OH-3 des deux unités αLFuc ne sont pas directement impliquées dans la réaction de liaison. Ces conclusions sont confirmées par le fait que les valeurs thermodynamiques de la réaction de l'analogue simple de type Lewis b, le méthoxyméthyl (1→2)βDGal(1→3)[αLFuc(1→4)]βDGlcNAcOCH_3, soit un $\Delta H = -14$ kcal/mol et un $\Delta S = -26$ cal/mol/K, sont très semblables à celles mentionnées plus haut pour le tétrasaccharide Lewis-b-OCH_3. Le groupe OH-4 de l'unité αLFuc(1→2) pourrait être lié par des liaisons hydrogènes intramoléculaires.

Introduction

The [1]H nmr investigation (1) of the synthetic Y hapten (αLFuc(1→2)βDGal(1→4)[αLFuc(1→3)]βDGlcNAcO$(CH_2)_8$-$COOCH_3$) (**5**) (2) required that this compound possess a topography about the fucose units and the terminal end of the galactose virtually identical to that present in the Lewis b (Le^b) blood group determinant (αLFuc(1→2)βDGal(1→3)[αLFuc-(1→4)]βDGlcNAcO$(CH_2)_8COOCH_3$) (**2**) (3). It was therefore considered (4) that a polyclonal population of anti-Le^b antibodies raised in rabbits and collected by affinity chromatography on a commercial Le^b-immunoadsorbent (Synsorb Le^b) (5) might contain antibodies that would cross-react with the Y determinant. In fact, an immunoadsorbent prepared from **5** was found (4) to bind nearly half the antibodies present in the anti-Le^b antibody preparation. In view of this observation, Dr. D. A. Baker (Chembiomed Ltd.) examined whether or not the then recently isolated fourth lectin of *Griffonia simplicifolia* seeds (6) which was known to be Le^b active would also be Y active. Indeed, the lectin was found to recognize both the Le^b and Y determinants (6).

A wide range of Le^b-related structures have now been synthesized (7) to serve as inhibitors in a systematic probing of the combining site of the lectin. It is recognized that differences in the amounts of inhibitors that provide 50% inhibition at a given temperature are only related to the differences of the binding free energies ($\Delta\Delta G^0 = -RT \ln K$). Since these $\Delta\Delta G^0$ values may arise, as demonstrated by Neurohr *et al.* (8), from major differences in both the enthalpies and entropies for the various complexation reactions, interpretations of 50% inhibition data may be misleading in the sense that structurally quite different complexes may exhibit the same thermodynamic stabilities. Nevertheless, we suggest that serious misconceptions in this regard are not likely to arise in the context of the present study, which involves measuring relative 50% inhibitions for a wide range of structures that represent the reference oligosaccharide with, in each case, only a minor change in structure. This

opinion is supported by the discovery that all of the data obtained to date have consistently allowed appraisals of the combining sites of lectins (10) and antibodies (9, 11, 12) based on sound chemical principles. The first paper in this series (9) demonstrated that the monoclonal anti-I Ma antibody interacts with a large weakly polar and wedge-shaped portion of the trisaccharide βDGal(1→4)βDGlcNAc(1→6)α,βDGal and that only OH-4 and OH-6 of the terminal βDGal unit are involved in a strong polar interaction with the protein. The arguments, based on inhibition data, to reach this conclusion are strongly supported by results obtained in this present study.

The following discussion of results employs a number of widely used terms which, however, require special definition in the context of this presentation. For example, the term "amphiphilic" normally is used to refer to a molecule or ion which has a polar (hydrophilic) end attached to a hydrocarbon-like (hydrophobic) end. In this paper, amphiphilic is used in the same way but with reference to only a portion of the surface of a molecule. The term "polar interaction" means an interaction between two polar groupings. Since these interactions are directional in nature, the result can be either attractive or repulsive. In this paper, all considerations of polar interactions are necessarily restricted to intermolecular hydrogen bonding. The term "lipophilic" will mean a structure (surface) that is either nonpolar (hydrocarbon-like) or weakly polar.

Reference will be made to "nonpolar interactions". The strengths of these interactions (dispersion forces of attraction) are distance dependent, are always attractive, and occur between all types of surfaces. Salem (13) has pointed out that these forces can cause large forces of attraction between large molecules if the complex involves a substantial number of appropriate distances between atoms in both molecules. Being nondirectional in character, nonpolar interactions increase in strength with increasing complementarity between the interacting surfaces.

It is to be expected, when water is the solvent, that the nonpolar interactions will be less effective in keeping polar and nonpolar surfaces together than in keeping two nonpolar surfaces together. The contribution of the nonpolar interactions to the stability of the complex will, of course, increase as one or both of the surfaces become less polar in character and, therefore, interact more weakly with the surrounding water molecules. An outstanding feature of the results obtained in this and related investigations is that, in all likelihood, nonpolar interactions between polar and nonpolar groups contribute importantly to the stability of certain of the complexes formed between oligosaccharides and antibodies or lectins. A strongly polar group such as a free hydroxyl group is not expected to be sufficiently compatible with a hydrophobic environment to become importantly involved in a totally nonpolar interaction. However, it is well known that the involvement of a hydroxyl group in intramolecular hydrogen bond formation can increase the lipophilicity of the grouping and thereby render it more acceptable for nonpolar interaction. Intramolecular hydrogen bonding effects on the binding of a saccharide by antibodies were discussed in a paper (14) in which a number of concepts related to molecular recognition were reviewed. In this present paper, intramolecular hydrogen bonding will be invoked only when the steric relationship between the proton donor and proton acceptor atoms is known to be appropriate.

The use of the terms "specific" and "nonspecific" can also be troublesome. A specific interaction will mean an interaction between an inhibitor and a protein binding site of the limited

size defined by the reference oligosaccharide. Fortuitous interactions of the inhibitor with protein structure outside this recognition site are described as nonspecific. Differences of binding free energies ($\Delta\Delta G^0$ values) are calculated from the inhibition data and possible reasons for the occurrence of these differences are offered. These conclusions, especially when the $\Delta\Delta G^0$ values are small, are, of course, tentative and presented primarily for heuristic purposes. It is to be noted that the inhibition data presented in this and the following papers are interpreted in terms of the binding of the minimum energy conformer, as derived by HSEA calculation (1) and supported by nmr evidence.

Results and discussion

The inhibition data for the various structures listed in Tables 1–3 and 5, 6 were obtained using a previously reported solid-phase radioimmunoassay (15). In this present study, the reaction between a ^{125}I-labelled (Le^{b})$_{19}$-BSA artificial antigen and the immobilized lectin was examined. Throughout the tables, the amount of the Le^{b}-OCH_3 compound (**1**) in μmol/L required to provide 50% inhibition, under standardized experimental conditions, was used to calculate relative inhibition potencies. The 50% inhibitions were reproducible to within ±5% of the amounts reported. Typical inhibition curves are presented in Fig. 1. A compound was declared inactive when it became apparent that 50% inhibition would not be reached using 50 times the amount of the reference inhibitor (**1**) that provided 50% inhibition under the same experimental conditions. The phosphate buffer used in the radioimmunoassay contained calcium and manganese ions. An attempt to establish that the binding is dependent on these ions failed, in the sense that no detectable amount of activity was lost when the lectin was dialyzed, first against salt-free water, then against phosphate buffer 0.01 M in ethylenediamine tetraacetate, and finally with

calcium-free (Chelex 100 (Bio-Rad) treated) phosphate buffer. Thus, the lectin may be neither calcium nor manganese ion dependent. Nevertheless, these ions were added to the buffered solution of the lectin that was used to coat the tubes and in the binding studies based on ultraviolet absorption.

Shibata *et al.* (6) reported that the Le^b-$O(CH_2)_8COOCH_3$ hapten (**2**) was somewhat less strongly bound ($\Delta\Delta G^0 = 0.3$ kcal/mol) by the lectin than was the hexasaccharide Le^b(1→3)βDGal(1→4)DGlc. This increase in binding must arise from nonspecific interactions since our inhibition data (Table 1) infer noninvolvement of the βDGlcNAc unit in the binding reaction. This condition, presumably, would extend to include the aglycon. In fact, as seen in Table 1, change of the aglycon from CH_3 (**1**) to $(CH_2)_8COOCH_3$ (**2**) provided an insignificant change in the inhibitor potency. De-*N*-acetylation of **2** and **5** to form **3** and **6** also produced only minor effects on the inhibitor potencies, as did deoxygenation at the 6-position of the βDGlcNAc residue of **1** to form **4**. These findings are in accord with the expectation, based on molecular modelling of the ^1H nmr conformers for the Le^b and Y structures (1, 16), that the binding of these structures by the lectin should occur on the other end of the molecule where a topography common to both the Le^b and Y structures can be recognized (4).

Involvement of the fucosyl units in the binding reaction was established by the inhibition studies reported by Shibata *et al.* (6). The inhibitions (Table 2) provided by compounds **7**, **8**, **9**, and **10** substantiate these observations and, furthermore, confirm that the αLFuc(1→4) unit (unit c[5]) present in compounds **8** and **10** is more importantly involved in the binding reaction than is the αLFuc(1→2) unit (unit d) which is present in the virtually inactive compounds **7** and **9**. As will be seen below, the αLFuc(1→4) unit provides one of the hydroxyl groups (OH-4^c) to the key polar grouping which is presented to the lectin by both the Le^b and Y tetrasaccharides. The inactivities of **7** and **9**, therefore, result from the absence of this specific grouping in these compounds. In contrast, the complete "key" polar grouping is presented by the trisaccharides **8** and **10**, and these compounds do show residual activities.

As seen from the data presented in Table 2, replacement of the αLFuc(1→2) unit of **1** by hydrogen to form **10** decreased the stability of the complex by 1.7 kcal/mol, and a greater decrease (by 2.1 kcal/mol) occurred when the substitution was by a methyl group to form **11**. Thus it was tempting to surmise that the binding of the αLFuc(1→2) unit was polar in character. However, it is seen that replacement of this group by the *n*-propyl group to form **12** led to a decrease in the stability of the complex of only 1.2 kcal/mol. This observation is made primarily to underline the hazards involved in drawing conclusions from limited data.

A change in the structure of a hapten must be expected to cause a change in the total energy (enthalpy) of the system since the chemical change is bound to influence the hydration of both the free oligosaccharide and the complex that is formed. Thus, even the replacement of an hydroxyl group that is not involved in the complexing reaction by hydrogen may somewhat influence the energetics of the reaction. In order to assess this situation, the 2^b-alkoxymethyl derivatives **13**, **14**, and **15** were examined. It was expected for reasons of the anomeric effect that these substituents would better imitate the αLFuc(1→2) unit of the Le^b structure than would the *n*-propyl group present in **12**. Indeed, as seen in Table 2, the three alkoxymethyl compounds were better inhibitors than the *n*-propyl derivative **12**, but only barely so for the ethoxymethyl (**14**) and isopropoxymethyl (**15**) analogs. On the other hand, the simple methoxymethyl derivative **13** was half as strong an inhibitor as the reference Le^b compound (**1**). This result strongly suggested that the hydroxyl groups of the αLFuc(1→2) unit of **1** are not involved in polar interactions within the complex. That this is, in fact, the case for OH-2^d and OH-3^d, as will be discussed below, is supported by the inhibition data presented in Table 3 for the deoxy compounds **19** and **20**. The relatively lower activities displayed by the ethoxy (**14**) and isopropoxy

[5] As previously done (3), the βDGlcNAc, βDGal, αLFuc(1→4), and αLFuc(1→2) units of the Le^b determinant are designated as the a, b, c, and d units, respectively.

(**15**) compounds as compared to **13** can be attributed to steric hindrance to these groups adopting the required orientation for the presentation of a surface similar to that presented by the CH-1^d—O-5^d—CH-6^d region of the Le^b tetrasaccharide.

The inhibition data provided by the βDAra(1→2) compound **16** (Table 3) indicate that the CH_3-6 group of the αLFuc(1→2) unit is only marginally involved in the binding reaction. This result is in accord with the high activity possessed by the methoxymethyl compound **13**, especially when it is considered that the methoxymethyl group is conformationally labile whereas the ^{1}H nmr evidence requires the αLFuc(1→2) unit to be held rigidly in place (3). In contrast, replacement of the CH_3-6 group of the αLFuc(1→4) unit by hydrogen to form the βDAra(1→4) compound (**17**) provided a much weaker inhibitor, with the stability of the complex decreasing by 1.0 kcal/mol. The effect of replacing both the CH_3-6 methyl groups by hydrogen produced a compound (**18**) with a potency in line with the potencies displayed by **16** and **17**. Thus, these data indicate that the binding of the Le^b tetrasaccharide involves strong interaction with H-1 and O-5 of the αLFuc(1→2) unit, the CH_3-6 group of the αLFuc(1→4) unit, and likely H-2 of the αLFuc(1→2) unit as well, because of its close proximity to the H-1 and O-5 atoms of the same unit. The possibility of marginal involvement of the CH_3-6^d group suggests that OH-4^d of the αLFuc(1→2) unit may also be involved since it is very close to the O-5^d and H-2^d atoms of the same unit which, as

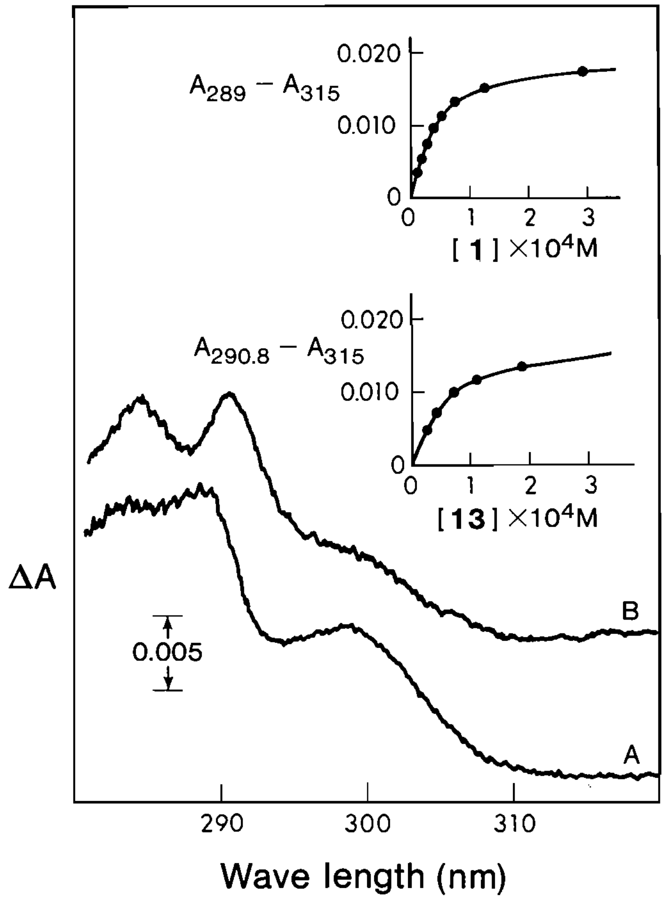

FIG. 2. Ultraviolet difference spectra of the lectin IV of *Griffonia simplicifolia*, at 25°C, complexed with αLFuc(1→2)βDGal(1→3)[αLFuc(1→4)]βDGlcNAc-OCH_3 (**1**, spectrum A) and methoxymethyl(1→2)βDGal(1→3)[αLFuc(1→4)]βDGlcNAc-OCH_3 (**13**, spectrum B). The insets show the variation of the maximum absorbance change as a function of the concentration of both **1** and **13**. The concentration of lectin binding sites was near 2×10^{-5} *M*.

discussed above, appear to be involved in the complexation. This possibility was tested by synthesis of the 4-deoxy compound **21**. In fact, **21** proved to be slightly superior to **1** as an inhibitor. This enhancement suggests that if OH-4^d is indeed involved it is by way of a nonpolar interaction. This must surely be the case since the 4^d-deoxy-4^d-fluoro derivative of **1**, namely, **22**, proved to be twice as potent an inhibitor as is **1**. Therefore, the Le^b tetrasaccharide appears to be accepted by the lectin with OH-4^d hydrogen bonded either to the neighboring *cis*-OH-3^d (or *cis*-O-5^d) or to water but, in whatever the manner, to become engaged in the formation of the complex by way of a nonpolar interaction. It is unlikely that the fluorine atom of **22** acts as a proton acceptor in the complex formation since the 4^d-deoxy compound **21** would then surely have been a much poorer inhibitor.

As seen in Table 3, replacement of either OH-2^d or OH-3^d of the αLFuc(1→2) unit to produce structures **19** and **20**, respectively, led to inhibitors with about one-third the potency of **1**. As mentioned above with reference to **13**, these hydroxyl groups are not required for the formation of a highly stable complex and, therefore, do not appear to be directly involved in the complexation reaction. However, as mentioned above, the deoxygenation of an oligosaccharide must have an influence on the hydration shell of the compound and thereby,

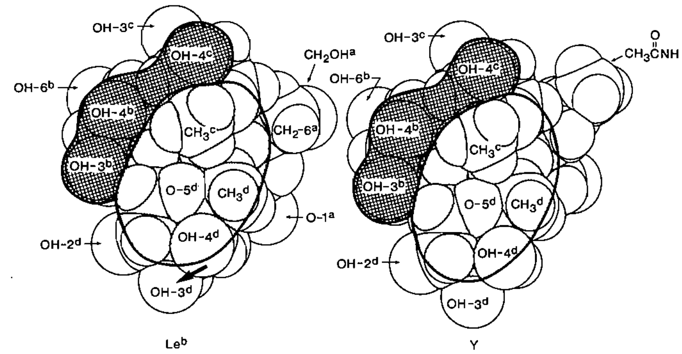

FIG. 3. Computer drawn projections (HSEA calculation) of CPK models for the Lewis b (Le^b) and Y determinants in their preferred conformations. The a, b, c, and d superscripts refer to atoms on the βDGlcNAc, βDGal, αLFuc(1→4), and αLFuc(1→2) units, respectively. The shaded areas represent regions that are bound by the lectin IV of *Griffonia simplicifolia*. Note that these surfaces are present in both the structures, which react almost equally well with the lectin. The heavily shaded surface represents the cluster of hydroxyl groups that become involved in the key polar interaction. The lightly shaded area displays the surface that becomes engaged in nonpolar interactions. It is possible that hydrogen atoms on the β-side of the βDGal unit also become involved through nonpolar interactions that stabilize the complex. These atoms are not shown but reside just below the OH-4^b and OH-3^b groups.

indirectly, on the stability of the complex that is formed. On the other hand, it seems reasonable to expect that such a change may not affect the thermodynamics of the reaction in a dramatic fashion since the change in structure that results from a simple monodeoxy substitution is very small. To test this hypothesis, the thermodynamic parameters for the methoxymethyl(1→2)βDGal(1→3)[αLFuc(1→4)]βDGlcNAcOCH$_3$ (**13**) analog of Le^b-OCH_3 (**1**) were determined. These data were obtained by measuring the effect of temperature on the association constants as determined by ultraviolet difference spectroscopy (Fig. 3). As seen from Fig. 2, the difference spectra are not the same. The complex formed with **1** showed a maximum absorbance at 289 nm in comparison to a maximum absorbance at 290.8 nm for **13**. Also, the shapes of the difference absorption spectra are different. This difference need not be taken as evidence that the conformation of the protein is importantly different for the complexes that are formed, since the difference in the structures complexed involves a change in the hydrophobicity of a major substituent. Indeed, taken together with the thermodynamic data presented in Table 4, this difference in spectral change suggests that the ultraviolet absorption involves amino acid residues that are directly involved in forming the combining site. As seen from Table 4, the ΔH and ΔS terms for the binding of **13**, where the αLFuc(1→2) unit of **1** has been replaced by the simple CH_3OCH_2 group, are very similar to those measured for **1**. Therefore it seems reasonable to conclude that the structures of the complexes are very similar and that these results lend support to our contention that the influences on complex stability of 0.6–0.7 kcal/mol observed on deoxygenation at positions 2^d or 3^d to form **19** and **20** (structural changes that are smaller than that between **1** and **13**) result only from indirect effects, and that OH-2^d and OH-3^d remain in contact with water. Therefore, in the interpretation of the effect of a deoxygenation on binding, we tentatively assign influences on the $\Delta\Delta G^0$ value of 0.4 ± 0.4 kcal/mol to indirect marginal effects on complex stability. As discussed above with reference

† By extrapolation.

to **7** and **9** (Table 2), a deoxygenation which results in an essentially inactive compound ($\Delta\Delta G^0 > 2.3$ kcal/mol compared with the parent tetrasaccharide) is interpreted as meaning that the hydroxyl group which was replaced becomes directly involved in a key polar interaction for complex formation. Deoxygenations which provide compounds with $\Delta\Delta G^0$ values in the range 0.8–2.3 kcal/mol are then interpreted as being engaged in the complexation reaction through polar interactions that are not of crucial importance to the formation of a complex.

In certain cases, deoxygenation leads to a superior inhibitor. This has been demonstrated for the lectin I of *Ulex europaeus* (2, 10) and the monoclonal anti-I Ma antibody (9), and now observed for **21**. In such cases, the hydroxyl group that was replaced by hydrogen must become involved in nonpolar interactions with its environment in the complex. In the case of the binding by the anti-I Ma antibody (9), the trisaccharide is undoubtedly accepted with the hydroxyl group at the 3-position of the βDGlcNAc unit intramolecularly hydrogen bonded. In the case of the *Ulex* lectin, the circumstantial evidence for intramolecular hydrogen bonding appears convincing. Therefore, whenever enhancements in binding are observed as the result of a specific monodeoxygenation of an oligosaccharide, it is expected that the hydroxyl group acts as a proton donor to hydrogen bond formation either with the aqueous environment for the resulting complex or intramolecularly with a suitable proton acceptor but not with a proton acceptor that is provided by the protein. To date, whenever such enhancements have been observed, the hydroxyl group has been either sterically well disposed for intramolecular hydrogen bonding with a neighboring atom that can serve as a proton acceptor or can assume an orientation that provides the necessary (about 2.7–3.0 Å) oxygen-to-oxygen internuclear distance by way of a low-energy conformational change (11). Whether or not intramolecular hydrogen bond formation actually occurs may be tested in a number of ways. In the instance of a rigidly held *cis*-glycol grouping, replacement by hydrogen of the hydroxyl group that serves as the proton acceptor should have a deleterious effect on binding and this has been observed (11). In contrast, replacement by fluorine should have little if any effect but this remains to be examined. On the other hand, both the replacement of the hydroxyl group that serves as proton donor by hydrogen or fluorine should lead to a relatively stronger inhibition and this has been observed not only for compounds **21** and **22** but also in another similar situation (11). A consideration of a situation wherein intramolecular hydrogen bond formation appears to involve important conformational changes is reserved for the discussion of the binding of the Le[b] tetrasaccharide (**1**) by a monoclonal anti-Lewis b antibody (11).

The effects of changes in the structure of the αLFuc(1→4) unit of **1** are presented in Table 5. The evidence for important involvement of the CH_3-6 group was presented in connection with Table 3. The hydroxyl groups at positions 2 and 3 appear

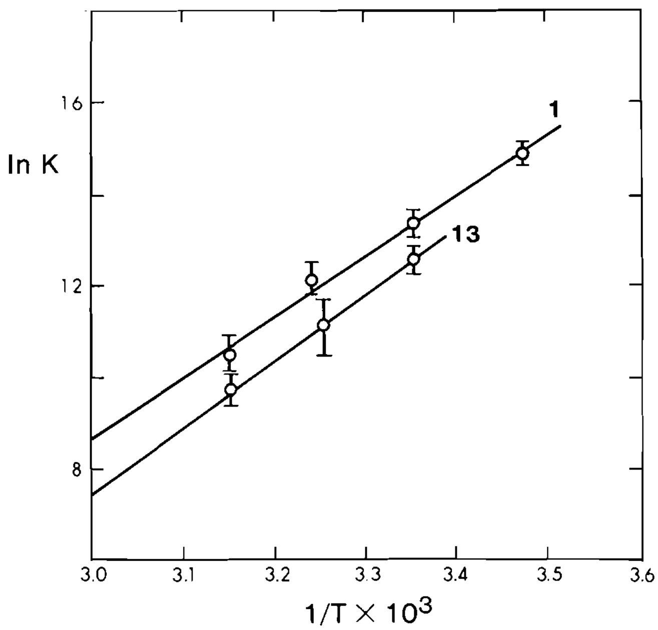

FIG. 4. The van't Hoff plot of the effect of temperature on the association constants for the binding by the lectin IV of *Griffonia simplicifolia* with αLFuc(1→2)βDGal(1→3)[αLFuc(1→4)]βDGlcNAc-OMe (**1**) and methoxymethyl(1→2)βDGal(1→3)[αLFuc(1→4)]-βDGlcNAc-OMe (**13**). The equilibria were determined at near 25°C, 35°C, and 45°C for both compounds and also at 15°C for **1**.

not to be directly involved in the binding reaction since their replacement by hydrogen to form **23** and **24** provided compounds that still retained a third of the inhibitory potency of **1**. In contrast, replacement of OH-4[c] by hydrogen led to the virtually inactive compound **25**. Therefore, OH-4[c] is considered to be involved in a key polar interaction. This involvement may be as a proton donor to complex formation since the 4[c]-deoxy-4[c]-fluoro compound **26** is also essentially inactive. Thus, the data indicate that only the CHOH-4[c] – CH_3-6[c] portion of the αLFuc(1→4) unit of **1** becomes directly involved in the binding reaction.

The manner in which the βDGal unit of **1** becomes involved in the complex is at once apparent from the data presented in Table 6. Obviously, both OH-3[b] and OH-4[b] contribute to the key polar interaction since both **27** and **28** are inactive. In contrast, replacement of the OH-6[b] group by hydrogen to form **29** had little influence on the stability of the complex and, therefore, this hydroxyl group appears to remain in contact with the aqueous phase.

The conclusions reached in this study are summarized in Fig. 4, where the 3-dimensional models for the Le[b] and Y tetrasaccharides are projected. Our nmr studies (1, 3, 16) require that these structures be rigidly held in the conformations shown, which were produced by HSEA calculation (1). It is seen that the topography of the Le[b] determinant, which our interpretation of the inhibition data indicates to be directly involved in interaction with the protein to stabilize the complex, is also present in the Y determinant. This correspondence lends strong support to the interpretations of the inhibition data that led to these conclusions.

It is to be noted that the topography that is recognized by the lectin is amphiphilic in character in that it possesses a polar cluster formed by OH-3[b], OH-4[b], and OH-4[c] adjacent to a relatively large lipophilic surface that is essentially nonpolar except for OH-4[d]. However, OH-4[d] was found to become engaged with the protein by way of a nonpolar interaction and perhaps intramolecularly hydrogen bonded to OH-3[d] (or O-5[d]). Thus, it appears that the Le[b] determinant is accepted by a shallow amphiphilic combining site at the surface of the lectin. Judging from the large decrease in entropy (Table 4) which occurs, considerable organization of the system is required to form the complex. The freeing of water from the nonpolar regions of the amphiphilic surfaces that interact to form the complex should lead to an increase, not a decrease, in entropy. Perhaps the organization of a conformationally highly labile protein into a specific conformer may be all that is needed to account for most of the decreases in entropy that are observed in these complexation reactions (10). It is important to note in this regard that complex formation results in response to a demand made on the system by an essentially rigid oligosaccharide.

The relative contributions to the stability of the complex made by the polar and nonpolar interactions are not known although there can be no doubt that the nonpolar contribution is most important (10). Nevertheless, it seems definitely established (9–12) that the integrity of the polar interaction is of crucial importance to complex formation. This situation need not mean that the polar interaction contributes importantly to the stability of the complex. Indeed, it would be exceedingly surprising if it did, unless both prior to and after binding the polar grouping provided by the protein was imbedded in a hydrophobic well at the surface of the protein (17). However, this does not appear to be the case since neighboring hydroxyl groups (OH-6^b, OH-2^d, and OH-3^c) appear to remain in contact with the aqueous phase after the complex has formed. On the other hand, the polar complex after it has formed could be inside a *narrow* hydrophobic cleft presented by the protein should the nonpolar β-side of the βDGal unit also become involved in the formation of the complex. Compounds designed to test this possibility were not synthesized. Nevertheless, this possibility does not appear attractive, primarily because the bringing of the polar complex into a hydrophobic pocket must be expected to be highly demanding in energy and this energy would have to be compensated by the additional nonpolar interactions gained through interaction with the relatively small nonpolar surface that is present on the β-side of the βDGal unit. As previously suggested (2, 14, 16), it is considered that the main source of the stability of the complex derives from changes in dispersion forces of attraction. The "hydrated polar group gate effect" (18) proposes that the sum of these forces of attraction between the complementary surfaces that interact to form the complex is greater than the sum of the dispersion forces between the separated surfaces and the surrounding water molecules. This condition is expected to arise from water seeking its own structure when interacting with amphiphilic surfaces (19).

Experimental

The syntheses and characterization of the compounds used in the inhibition studies will be reported separately (7).

Buffers

All at pH 7.2 adjusted either with HCl or NaOH.

I. 0.08 *M* in Na_2HPO_4, 0.02 *M* in KH_2PO_4, 0.15 *M* in NaCl, 0.015 *M* in NaN_3, 0.5 m*M* in $Na_2S_2O_4$, and 0.14 m*M* in $CaCl_2$.

II. 0.072 *M* in Na_2HPO_4, 0.028 *M* in NaH_2PO_4, 0.15 *M* in NaCl, 3 m*M* in NaN_3, 0.1 m*M* in $CaCl_2$, and 0.1 m*M* in $MnCl_2$.

III. 7.8 m*M* in Na_2HPO_4, 2.2 m*M* in KH_2PO_4, 15 m*M* in NaN_3, and 0.15 *M* in NaCl.

Lectin IV of Griffonia simplicifolia

The lectin was prepared in a manner closely analogous to that reported by Shibata *et al.* (6). Finely ground seeds (500 g) were stirred at room temperature for 15 min with 1 L of methanol and recovered by filtration. This extraction was repeated 6 times and then the residue was extracted 3 times with dichloromethane (3 × 1 L). After drying, the grey meal (280 g) was stirred for 2 h at 4°C with 2 L of buffer I solution. The solids were collected by centrifugation and extracted a second time under the same conditions with buffer I (1.5 L). The aqueous extracts were combined and 170 g/L of solid $(NH_4)_2SO_4$ were added, always keeping the solution at 4°C. The solids that precipitated were removed by centrifugation and more solid $(NH_4)_2SO_4$ (130 g/L) was added. After standing at 4°C for 16 h, the precipitate which had formed was collected by centrifugation, dissolved in buffer I (70 mL), and this solution was dialyzed against two changes of the buffer (4 L) each for 24 h using dialysis tubing (Fisher Scientific seamless cellulose with a 12 000 m.wt. cutoff). The resulting solution (225 mL) was then absorbed using Synsorb-Le^b (Chembiomed Ltd., University of Alberta) in the following manner. Always at 4°C in the cold room, an aliquot (50 mL) was passed down a column of the immunoadsorbent (25 g) in 1 h and the column was washed with 1.4 L of buffer I. At this point the eluate showed an absorbance at 280 nm of less than 0.03. A solution 0.1 *N* in acetic acid and 0.015 *N* in NaCl was then passed down the column while collecting 13-mL fractions of the eluate. The fractions which showed absorbance at 280 nm greater than 0.1 were combined and brought to pH 7.0 using 1 *N* NaOH. The solutions from the various chromatograms were combined (750 mL) and dialyzed using an ultrafiltration membrane (Diaflo PM10, Amicon) against phosphate buffer II to provide 400 mL of a solution which showed absorbance of 1.15 at 280 nm. The solution was then passed through a column of Synsorb A (30 g) followed by a column of Synsorb B (30 g) using buffer II as eluent. The protein-containing fraction was then concentrated by ultrafiltration to an absorbance of 2.0 (175 mL). The behavior of the protein on polyacrylamide gel electrophoresis was identical to that published (6) for the lectin IV of *Griffonia simplicifolia* and showed no evidence of other proteins.

Solid-phase radioimmunoassay

The procedure was essentially that briefly reported by Young *et al.* (15). The 2-mL polystyrene vials (Simport Plastics, Montreal) were coated using 0.15 milliliters per tube of a solution of the lectin in buffer II, which showed an absorbance of 0.1 at 280 nm and which corresponds to about 60 μg/mL of the lectin. The incubation was overnight at 4°C. The coating of the tubes was then completed by incubation at room temperature for 2 h with 0.2 mL of a 15% solution of BSA in buffer II. The tubes were then washed by the addition of a 1% solution of BSA in the same buffer, followed by aspiration, and air dried for 30 min prior to use. The ^{125}I-labelled $(Le^b)_{19}$-BSA artificial antigen (54 ng/mL in buffer III prepared by the iodogen procedure (20)) was purchased from Chembiomed Ltd. and usually produced near 200 000 cpm/100 μL. It was not used after the radioactivity had diminished to less than 160 000 cpm. The radioactivity of a coated tube after incubation at room temperature (23°C) and washing with buffer II was about 120 000 cpm. The solution of the inhibitor in buffer II (50 μL) was added to the tube and this was immediately followed by addition of 100 μL of the labelled antigen. All runs were done in triplicate and the measured radioactivities (Beckman 4400 gamma counter) were averaged for calculation of the % inhibition obtained in a given run. The 50% inhibitions were estimated using plots as shown in Fig. 1. Whenever 50% inhibition was achieved, the value obtained was checked in at least one separate similar run using concentrations of the inhibitor near the amounts required for 50% inhibition. In the case of separate runs, the amount of the reference inhibitor required to provide 50% inhibition was divided by the amount of the inhibitor that also provided 50% inhibition in order to obtain the relative potency under the prevailing experimental conditions. These relative potencies agreed well from run to run, as can be gauged from the data plotted in Fig. 1. To arrive at the points marked with an asterisk, the amounts of **1** required to reach 50% inhibition in separate runs were brought to a common value. It is noteworthy that the $\Delta\Delta G^0$ value of 0.4 kcal/mol calculated for the 50% inhibition data for compounds **1** and **13** (Table 2) is in good agreement with the value of 0.2 kcal/mol determined in the solution binding studies at 25°C (Table 4).

Ultraviolet difference spectroscopy (ref. 21)

The spectra were recorded on a Cary-210 spectrophotometer with both the sample and the reference base thermostated by circulating water. A solution of the lectin (750 μL in buffer II) having A_{280} near 1.0 was placed in both sample and reference semi-micro cells and a baseline was recorded into the instrument memory for automatic digital subtraction from subsequent spectra. The experiment was then initiated by addition of an aliquot (1–16 μL) of a solution of the oligosaccharide (5 × 10^{-3} *M* in buffer II) to the sample cell and the addition of an identical volume of buffer to the reference cell. The contents of the cells were then briefly mixed with a Teflon rod and the solutions were allowed to equilibriate until a stable difference spectrum was obtained, usually within 20–30 min. Spectra were then recorded at a scan rate of 3 nm/min. In a typical titration experiment, sequential additions of 1, 1, 2, 4, 8, and 16 μL of the oligosaccharide solution were made with the oligosaccharide concentrations, and addition volumes, selected to provide difference spectra where the percentage of the lectin bound ranged from 20% to 80%. The temperature was recorded at several places along the titration curve using a thermistor probe inserted directly into the sample cell and was found to be constant to within ±0.1°C. The difference spectra obtained in the above experiments were corrected for absorption due to the oligosaccharide alone, values which were determined in separate experiments and which, in all cases, amounted to less than 10% of the observed difference spectrum. Each titration experiment was repeated at least once.

The difference spectra were positive (Fig. 2) with the maximum absorbance changes occurring at 289.0 nm for binding with the Le^b tetrasaccharide (**1**) ($\epsilon = 1800\ M^{-1}\ cm^{-1}$) and 290.8 nm for its analog (**13**) ($\epsilon = 1680\ M^{-1}\ cm^{-1}$). The values of the equilibrium binding constants were determined from the slope and intercept of a Scatchard plot (22) and based on the assumption that the two lectin subunits bind independently. Since the Scatchard plots were linear, this assumption seems justified.

The extinction coefficient of the lectin was estimated by weighing a lyophilized sample of the affinity purified protein, which had been exhaustively dialyzed against distilled water. This method gave $E^{1\%}_{280} = 17$, which corresponds, based on a molecular weight of 58 000 for the lectin (6), to $\epsilon^{280} = 1 \times 10^5\ M^{-1}\ cm^{-1}$.

Using a radioimmunoassay to measure the relative potencies of a wide range of chemically modified structures related to the H-type 2 human blood group determinant, evidence was accumulated that the binding of αLFuc(1→2)βDGal(1→4)-βDGlcNAc-OMe by the lectin I of *Ulex europaeus* involves a wedge-shaped amphiphilic surface which extends on one side of the molecule from the methoxy aglycon to OH-3 of the βDGal unit. A cluster which involves OH-3, OH-4, and OH-2 of the αLFuc unit along with OH-3 of the βDGal unit provides the polar interactions with the lectin. However, only OH-3 and OH-4 of the αLFuc are indispensable to complex formation and are regarded as providing the key polar interaction. The binding reaction involves both a decrease in enthalpy of 29 kcal/mol and a decrease of 68 cal/mol/K in entropy. It is submitted that the main source of the decrease in enthalpy is the establishment of nonpolar interactions that extend from the aglycon over the nonpolar portion of the β-side of the βDGlcNAc unit and on to include a major portion of the α-side of the αLFuc unit. The binding of the βDGlcNAc unit includes OH-6 intramolecularly hydrogen bonded to O-5 in order to extend the nonpolar interactions to the α-side of this unit and perhaps beyond. The decreases in enthalpy (6.0 kcal/mol) and entropy (2.7 cal/mol/K) which occur on the binding of methyl α-L-fucopyranoside are much smaller than for the H-type 2 trisaccharide and are compatible with the much smaller surface that interacts to form the complex. The inhibition data obtained using a range of structures related to methyl α-L-fucopyranoside are in general accord with expectations based on the results obtained with the more complex structures.

OLE HINDSGAUL, DEVESHWARI P. KHARE, MIMI BACH et RAYMOND U. LEMIEUX. Can. J. Chem. **63**, 2653 (1985).

Utilisant un essai radioimmunologique pour mesurer la puissance relative d'un grand nombre de composés chimiquement modifiés et apparentés au déterminant du groupe sanguin humain de type H-2, on a accumulé des données suggérant que la liaison du αLFuc(1→2)βDGal(1→4)βDGlcNAc-OMe avec la lectine I de l'*Ulex europaeus* implique une surface amphiphile en forme de coin qui s'étend sur un côté de la molécule du groupement méthoxyle de l'aglycone jusqu'au groupement OH-3 de l'unité βDGal. Un aggrégat impliquant les groupements OH-3, OH-4 et OH-2 de l'unité αLFuc ainsi que le groupement OH-3 de l'unité βDGal est responsable des interactions polaires avec la lectine. Toutefois, seuls les groupements OH-3 et OH-4 de l'unité αLFuc sont indispensables à la formation d'un complexe et on les considère comme les éléments clés des interactions polaires. La réaction de liaison implique à la fois une diminution d'enthalpie de 29 kcal/mol et une diminution d'entropie de 68 cal/mol/K. On pense que la diminution d'enthalpie est due principalement à l'existence d'interactions non polaires qui vont de l'aglycone qui se trouve au-dessus de la portion non polaire de la face β de l'unité βDGlcNAc et qui incluent aussi une partie importante de la face α de l'unité αLFuc. La liaison de l'unité βDGlcNAc comprend le groupement OH-6 qui est lié par des liaisons hydrogènes intramoléculaires au O-5 de façon à étendre les interactions non polaires à la face α de cette unité et peut être même au-delà. Les diminutions d'enthalpie (6 kcal/mol) et d'entropie (2,7 cal/mol/K) qui sont observées lorsqu'il se produit une liaison de l'α-L-fucopyrannoside de méthyle sont plus faibles que celles qui sont observées avec le trisaccharide de type H-2; ces valeurs sont compatibles avec le fait que la surface impliquée pour former des complexes est beaucoup plus petite. Les données concernant le pouvoir inhibiteur qui ont été obtenues en utilisant une grande variété de structures apparentées au α-L-fucopyrannoside de méthyle sont en général en accord avec les hypothèses fondées sur les résultats obtenus avec des structures plus complexes.

Introduction

The lectin I of *Ulex europaeus* (common gorse) was found (1) to agglutinate O human red cells and proved to be a useful reagent for the classification of people of the O blood group as secretors or nonsecretors (2). This proved to be a fortunate circumstance, which is now known to arise because the lectin has a strong affinity for the H-type 2 determinant (αLFuc(1→2)βDGal(1→4)βDGlcNAc--) but does not recognize the H-type 1 determinant (αLFuc(1→2)βDGal(1→3)βDGlcNAc--) (3). The lectin is available commercially and its binding characteristics have received major previous attention (4). Our recent studies (5–7) of the binding of oligosaccharides by lectins and antibodies have shown that complex formation may require a polar interaction involving hydroxyl groups that are present in different sugar units. In such cases, the protein binds neither the simple sugars that make up the oligosaccharides nor their methyl glycosides. Thus, binding of the H-type 2 determinant by the lectin I of *Ulex europaeus* was of special interest since it was known (4) that both fucose and methyl α-L-fucopyranoside are effective as inhibitors of the agglutination of O red cells by the lectin.

Recently, we reported on the ability of a number of modified H-type 2 structures to inhibit the agglutination of O red cells (8). This study confirmed that the acetamido group is not involved in the binding reaction (4). Also, it became apparent that neither OH-3 of the βDGlcNAc unit nor OH-4 of the βDGal unit interact with the protein. Structural changes involving the αLFuc were not extended beyond replacement of its CH_3-6 group by hydrogen. It was concluded that the binding involves the recognition by the lectin of a wedge-shaped lipophilic surface which includes OH-6 of the βDGlcNAc unit intramolecularly hydrogen bonded to O-5. We now wish to report

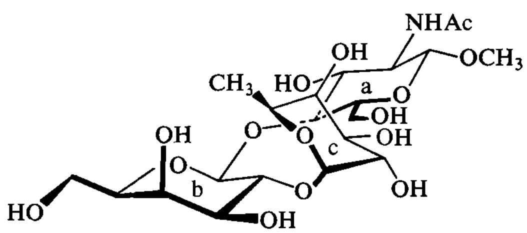
a continuation of these studies but using a solid-phase radioimmunoassay to determine relative inhibition potencies. This paper includes the examination of the eight possible monodeoxy derivatives of the H-type 2 determinant αLFuc(1→2)-βDGal(1→4)βDGlcNAc (9). Also, a wide number of derivatives of methyl α-L-fucopyranoside were examined.

In our previous study (8), the inhibitors were synthesized with $(CH_2)_8COOCH_3$ as aglycon. A number of these compounds were used in this investigation but most of the structures are new (9) and contain the simple methyl group as aglycon. In Tables 2 and 3, the reference inhibitor for the expression of relative potencies is the methyl glycoside (**1**) of the H-type 2 trisaccharide and the sugar units are labelled a, b, and c, as shown. The formula for **1** is drawn as a projection that



1

imitates the conformational preference suggested by HSEA calculation and supported by ^{1}H nmr (10, 11). It is noteworthy in this regard that the lectin IV of *Griffonia simplicifolia* binds the Lewis b and Y determinants nearly equally well and that this finding is in agreement with the conformational analyses, based on ^{1}H nmr, for these two structures (5). We therefore have confidence that the conformer for **1** with ϕ^b/ψ^b = 55°/0° and ϕ^c/ψ^c = 50°/15° (11) well represents the compound in aqueous solution. Furthermore, the ^{1}H and ^{13}C nmr parameters found (9) for the various modifications of **1** used in this study indicate that this conformational preference is maintained. The specific deshielding of H-5 of the αLFuc unit by O-4 of the βDGlcNAc unit (8, 11) supports our contention that these are rigidly held conformers.

Results and discussion

The radioimmunoassay used to determine the inhibition data presented in Tables 1–4 was described in detail in paper II of this series (5) and the 50% inhibitions proved reproducible to within ±5% of the values listed.

The results presented in Table 1 confirm the conclusions reached in our previous publication (8). Previously, the activity of the Y determinant (**5**) was taken as evidence that OH-3^a is not involved in the binding reaction. On the basis of the criteria set for noninvolvement of a hydroxyl group (5), this conclusion is now confirmed by the high potency displayed by the 3^a-deoxy derivative **4**. The fact that **2** is only slightly more active than **1** suggests that binding of the aglycon does not extend importantly beyond the aglyconic carbon grouping, as was found, for example, for the anti-I Ma antibody (12). In contrast, in the case of a monoclonal anti-Lewis b antibody (6), the change in aglycon from CH_3 to $(CH_2)_8COOCH_3$ increased the potency by a factor of 6.5. As previously reported (8), deoxygenation of the CH_2OH^a group importantly increased the potency. On the basis of the presently used radioimmunoassay, elimination of the requirement of OH-6^a to become intramolecularly hydrogen bonded to O-5^a increases the potency by a factor of 3.5 and, therefore, appears to increase the driving force for reaction by about 0.75 kcal/mol. Replacement of the βDGlcNAc-O$(CH_2)_8COOCH_3$ portion of **2** by the $O(CH_2)_8$-$COOCH_3$ group led to the much less potent inhibitor **7**. However, replacement by an hydroxyl group provided an even weaker inhibitor (**8**). These results were not surprising since it had become evident that binding about the aglycon of the βDGal unit of **1** is extensive and nonpolar in nature (8). Evidently, the $(CH_2)_8COOCH_3$ group of **7** does not well provide a conformation that is complementary to the hydrophobic cleft of the lectin which binds the βDGlcNAc unit of **1**.

As seen from Table 2 and as previously noted (8), the 4^b-epimer of **2**, namely, **10**, is only about twice less active than **2**. This observation was interpreted as noninvolvement of OH-4^b and, therefore, probably also OH-6^b. This latter prediction is now confirmed by the high potency displayed by the 6^b-deoxy

compound (**11**). On the other hand, deoxygenation of the OH-3^b position of **1** to form **9** decreased the potency by a factor of 40. Thus, OH-3^b is importantly involved in a polar interaction with the combining site. For reasons previously discussed (5), a polar interaction that is not essential to complex formation is not included in the so-called key polar interaction. As will be seen below, OH-2^c, which projects in space close to OH-3^b, is also involved in an important but not essential interaction with the lectin.

The effects on binding that arose from modifications of the αLFuc unit are reported in Table 3. It is seen at once that all three hydroxyl groups become involved in polar interactions with the lectin. However, only deoxygenation at positions 3^c and 4^c yielded essentially inactive compounds, namely, **13** and **14**. In contrast, replacement of OH-2^c of **1** by hydrogen to produce **12** caused a marked decrease in potency but the compound retained an activity near that of methyl α-L-fucopyranoside (**16**). Judging from the $\Delta\Delta G^0$ values, this complex is nearly 3 kcal/mol less stable than that formed from **1**. As will be discussed in more detail below, OH-2^c projects close to OH-3^b and these two hydroxyl groups appear to form a polar grouping adjacent to the key polar grouping provided by OH-3^c and OH-4^c. Important involvement of the CH_3-6^c group is indicated by the large decrease in potency that results from the replacement of this group in the inhibitor **2** (Table 1) by hydrogen to form **15**. This observation is confirmed by the large difference in the inhibitions provided by methyl α-L-fucopyranoside (**16**) and methyl β-D-arabinopyranoside (**17**), the latter compound being essentially inactive.

The results obtained using a variety of derivatives of methyl α-L-fucopyranoside (**16**) are reported in Table 4. As was to be expected from the results obtained using the 3^c- and 4^c-deoxy

derivatives of **1**, namely, **13** and **14** (Table 3), the 3-deoxy (**19**) and 4-deoxy (**21**) derivatives of **16** proved inactive. In the case of the 2-deoxy derivative (**18**) of **16**, substantial residual activity (13% of **16**) was found. This decrease in activity is much less than that observed on deoxygenation of **1** to form the 2^c-deoxy derivative **12** where the decrease in potency was to less than 1% that of **1**. It appears, therefore, that the combining site formed to accept **1** with the establishment of a polar interaction with the OH-3^b–OH-2^c grouping is not completed for the acceptance of the simple methyl α-L-fucopyranoside (**16**). In fact, the thermodynamic data presented in Table 5 strongly support this indication that the extent of the organization of the lectin to accept **1** is much greater than that for the acceptance of **16**. It is seen that the decrease in entropy to form the complex with the trisaccharide **1** involves 68 entropy units in contrast to only 2.7 entropy units for the simple methyl α-L-fucopyranoside. These thermodynamic parameters were determined by measuring the change in ultraviolet absorption (A_{286}–A_{290} nm) under the same experimental conditions described in our study of the lectin IV of *Griffonia simplicifolia* (5). In contrast to the experience with this lectin, the difference ultraviolet spectra for the binding of **1** and **16** by the *Ulex* lectin were very similar. Experimental details and the discussion of the results obtained using **1**, **16**, and a number of other structures that are bound by *Ulex* are reserved for a separate communication (13).

It is considered interesting to note that the thermodynamic parameters for the binding of oligosaccharides by a variety of lectins have recently appeared in the literature. Some of the findings are summarized in Fig. 1 where it is seen that a fairly linear relationship exists between the ΔH and $T\Delta S$ terms. It appears, therefore, that any gain in complex stability resulting from a decrease in enthalpy is always accompanied by some cancelling from a decrease in entropy. Thus, it can be expected that the larger the combining site, the greater the effort may be for organization as reflected by a greater decrease in entropy. The thermodynamic parameters reported herein for the *Ulex* lectin and those previously reported (5) for the lectin IV of *Griffonia simplicifolia* appear in accord with this observation. The findings for **1** (Table 5) are the highest values reported to date ($\Delta H = -29$ and $T\Delta S = -20$ kcal/mol at 25°C).

Returning to Table 4, it is seen that replacement of either OH-3 or OH-4 of **16** by fluorine, to form **20** and **22**, led to essentially inactive compounds. It is likely, therefore, that these key hydroxyl groups act as proton donors in the complex formation.

As previously mentioned (8), the α-side of an α-L-fucopyranosyl group presents substantial nonpolar surface to its environment. As noted above, the CH_3-6 group of both **1** and **16** appears involved in the binding reaction and this result would be in keeping with the *Ulex* lectin recognizing the nonpolar α-side of the αLFuc unit. That this is the case is supported by the fact (Table 4) that αLFuc-OCH_3 (**16**) is much more strongly bound than its β-anomer (**24**). In fact, even free L-fucose (**25**) is more strongly bound than is **24**. Evidently O-1 of L-fucose becomes involved in the binding reaction but this must surely be by way of a nonpolar interaction since **16** is about 5 times more potent than **25** as an inhibitor. It is apparent, therefore, that the binding of **16** involves a polar interaction between OH-3 and OH-4 with a polar grouping provided by the lectin and which allows the establishment of nonpolar interactions between a complementary surface provided by the protein and the surface of **16** defined by H-3, H-4, H-5, CH_3-6, O-1, and the methyl aglycon. In order to test this hypothesis,

the 4-*C*-methyl derivative of **16**, namely, **23**, was synthesized.[4] It is seen that the simple substitution of H-4 by CH_3 led to an inactive compound. It is possible that the substitution interferes with the polar interaction and that this is the main reason why **23** is inactive. On the other hand, this inactivity could result from the methyl group preventing the establishment of a proper interfacing of complementary nonpolar surfaces. We submit that the latter is the case since the small decrease in entropy (2.7 entropy units) that accompanies the binding of **16** suggests that the combining site is virtually already present in the lectin. Thus, the formation of the complex must be highly dependent on the complementarity of the interacting surfaces. Only a slight change in the topography of one of these surfaces may so weaken a complex, which is formed through a decrease in enthalpy of only 6 kcal/mol, that complex formation is not observed.

The results of this study are summarized in Fig. 2 where the H-type 2-OCH_3 compound (**1**) is presented in the conformer indicated by ^1H nmr (11) and produced by HSEA calculation. It is seen that the polar interactions involve OH-4^c, OH-3^c, OH-2^c, and OH-3^b and that these groups form a polar cluster at one end of the molecule. The OH-4^c and OH-3^c groups provide the key polar interaction which is indispensible to complex formation. In contrast, the OH-2^c and OH-3^b region, while providing important stability to the complex, are not essential. The lightly shaded area, part of which is expected to extend behind the CH_3-6^c group, represents the lipophilic surface which appears to make the major contribution to the stability of the complex. This surface may well extend to include more of the β-side of the βDGlcNAc unit and the α-side of the βDGal unit than is indicated. In order to extend the nonpolar interactions to this side of the structure, OH-6^a forms an intramolecular hydrogen bond with O-5^a. Although not reexamined in this present study, it was previously established (8) that the H-type 1 determinant (αLFuc(1→2)βDGal(1→3)βDGlcNAc-$O(CH_2)_8COOH$) is not bound but that the free amine form (αLFuc(1→2)βDGal(1→3)βDGlcNH$_2$-$O(CH_2)_8COOH$) interacts quite strongly with the lectin. This observation was taken as evidence that the de-*N*-acetylation exposed the α-side of the αLFuc unit for binding by the lectin while providing a lipophilic surface very similar in topography to that provided by **2**. Thus, the evidence appears convincing that the surface of **1** that is recognized by the lectin is amphiphilic in character, as represented in Fig. 2. There can be no doubt that the NHAc-2^a, OH-3^a, OH-4^b, and OH-6^b groups remain in contact with the aqueous phase. The nonpolar interactions may involve a greater surface than that shown but no evidence in this regard was obtained in this present study.

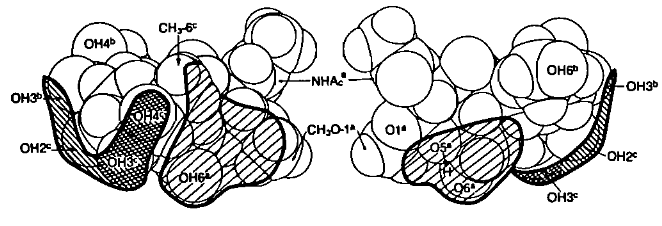

FIG. 2. The HSEA molecular model for αLFuc(1→2)βDGal(1→4)βDGlcNAc-OMe (**1**) (H-type 2). Opposite sides of the model are shown and the hatched areas display the surface which comes into interaction for complex formation with the lectin I of *Ulex europaeus*. The cross-hatched key polar interaction involving OH-4^c and OH-3^c of the fucose unit is seen to occur adjacent to the lipophilic region (lightly hatched). The OH-3^b and OH-2^c groups are seen to be adjacent to the key polar group. These hydroxyl groups also become involved in important polar interactions with the lectin but this involvement appears to arise from a conformative response that is not essential for the formation of a complex.

Experimental

Inhibitors

The various compounds used as inhibitors were synthesized following well-established procedures (8, 9). The structures and their purity were confirmed by appropriate ^1H nmr (400 MHz) and ^{13}C nmr (100 MHz) studies.

Lectin I of Ulex europaeus was purchased from Sigma Chemical Company.

Radioimmunoassay

The procedure followed was that previously reported (5) using an ^{125}I-labelled (αLFuc(1→2)βDGal(1→4)βDGlcNAc-$O(CH_2)_8CO$-$NH)_{11}$BSA antigen purchased from Chembiomed Ltd. (University of Alberta, Edmonton, Alberta, T6G 2G2). The solution provided nearly 200 000 cpm/100 μL and the tubes were incubated at room temperature (23°C). In the absence of the inhibition, about 65% of the radioactivity was bound.

A commercial hybridoma monoclonal anti-Lewis b antibody appears to accept the Lewis b human blood group determinant (αLFuc(1→2)βDGal(1→3)[αLFuc(1→4)]βDGlcNAc--) by involving OH-3 of the βDGal unit and OH-2 of the αLFuc(1→2) unit in a key polar interaction at the periphery of a large wedge-shaped lipophilic surface that extends about the tetrasaccharide and essentially leaves 5 of the 8 other hydroxyl groups in contact with the aqueous phase. It is proposed that the three remaining hydroxyl groups, namely, OH-4 of the βDGal unit, OH-3 of the αLFuc(1→4) unit, and OH-4 of the αLFuc(1→2) unit, become intramolecularly hydrogen bonded for acceptance into a hydrophobic environment. The results are taken as further circumstantial evidence that the stability of the complex is mainly related to the establishment of dispersion forces of attraction between complementary lipophilic surfaces provided by the oligosaccharide and the protein. These forces are expected to be stronger than those prior to binding between the amphiphilic surfaces that are involved and water.

ULRIKE SPOHR, NAOHIKO MORISHIMA, OLE HINDSGAUL et RAYMOND U. LEMIEUX. Can. J. Chem. **63**, 2659 (1985).

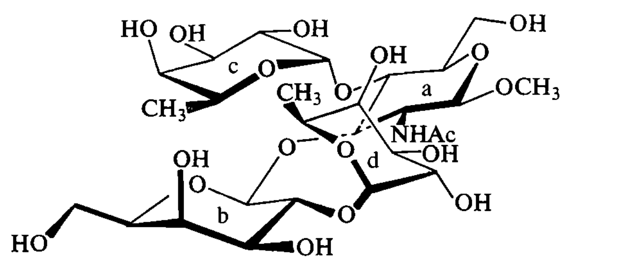
Un anticorps monoclonal hybride, de type anti-Lewis b et disponible commercialement, semble accepter le déterminant du groupe sanguin humain de type Lewis b, le (αLFuc(1→2)βDGal(1→3)[αLFuc(1→4)]βDGlcNAc--), en faisant intervenir le groupe OH-3 de l'unité βDGal et le groupe OH-2 de l'unité αLFuc(1→2) dans une interaction polaire clé à la périphérie d'une grande surface lipophile en forme de coin qui s'étend autour de tétrasaccharide et qui laisse essentiellement 5 des 8 autres groupes hydroxyles en contact avec la phase aqueuse. On propose que ce sont les trois groupes hydroxyles qui restent, soit le OH-4 de l'unité βDGal, le OH-3 de l'unité αLFuc(1→4) et le OH-4 de l'unité αLFuc(1→2), qui établissent des liaisons hydrogènes intramoléculaires qui permettent d'être accepté dans un environnement hydrophobe. On considère que les résultats fournissent une preuve circonstancielle additionnelle du fait que la stabilité du complexe est liée principalement à l'existence de forces de dispersion et d'attraction entre les surfaces lipophiles complémentaires fournies par l'oligosaccharide et la protéine. On s'attend à ce que ces forces soient supérieures à celles qui existeraient avant la liaision entre les surfaces amphiphiles impliqués et l'eau.

[Traduit par le journal]

Introduction

The Lewis b (Le^b) human blood group determinant is characteristic of the epithelial cells of nearly 70% of individuals (1, 2). The purpose of this communication is to report the results obtained in a systematic probing of the combining site of a commercial (Chembiomed Ltd., Department of Chemistry, University of Alberta, Edmonton T6G 2G2) hybridoma monoclonal anti-Le^b antibody using a wide range of synthetic analogs to inhibit the reaction of the antibody with an artificial Le^b-BSA antigen (2). The experimental data obtained by way of a solid-phase radioimmunoassay (3) are in accord with the general characteristics established for protein–oligosaccharide binding reactions involving monoclonal anti-I Ma (4) and anti-B antibodies (5), the lectin I of *Ulex europaeus* (6), and the lectin IV of *Griffonia simplicifolia* (3). The outstanding feature of this communication is that the binding of the Le^b determinant appears to involve its acceptance by the antibody in the extensively intramolecularly hydrogen bonded form presented in the various tables. As previously done (3, 7), and as specified in **1**, the sugar units will be designated as units a (βDGlcNAc), b (βDGal), c (αLFuc(1→4^a), and d (αLFuc(1→2^b).

Experimental evidence now exists that intramolecular hydrogen bonds form in aqueous solution only when an appropriate internuclear distance (2.7–3.0 Å) between the proton donor



1

and the proton acceptor is enforced by the steric and stereoelectronic demands that govern the conformational preference of the oligosaccharide (8–10). Consequently, in the absence of such intramolecular enforcement, energy must be expended for the formation of intramolecular hydrogen bonds by an oligosaccharide in order that it can become bound by a protein. Since the formation of an intramolecular hydrogen bond is expected to render a polar molecule more compatible for a nonpolar interaction and since energy is required for its formation, the conclusion appears unavoidable that the stability of the complex has its origins in strong dispersion forces of attraction between the oligosaccharide and a hydrophobic binding site on the protein (11, 12).

Results and discussion

As seen from Table 1, both the αLFuc units of the Le^b determinant are involved in the binding reaction, as both the Le^d (H-type 1, **3**) and the Le^a (**4**) trisaccharides are poor inhibitors. Because **4** is essentially inactive, the compound appears not to contain intact the key polar grouping that is essen-

tial for binding (3). However, **3**, as a weak but still active inhibitor, is expected to possess this grouping and, in view of the inactivity of **4**, the αLFuc(1→2[b]) unit is expected to contribute to this grouping. In fact, as will be seen below (Table 5), the key polar grouping does involve OH-2[d] of **3**. This situation is in contrast to the binding of the Le[b] tetrasaccharide by the lectin IV of *Griffonia simplicifolia* (3), where it is the αLFuc(1→4[a]) residue which provides an hydroxyl group to the key polar interaction. Not surprisingly, therefore, replacement of the d-fucosyl group by a methoxymethyl group to simulate (3) the αLFuc(1→2[b]) anomeric linkage produced an inactive compound (**5**). It may be noted at this point that the substantially greater activity of **2** as compared to the simple methyl glycoside (**1**) requires that binding occurs about the aglycon (R_1^a) (Table 1) and that this region of the combining site is hydrophobic in nature. Also, it should be noted that the formulas presented in Tables 1–5 describe, in each case, the intramolecular hydrogen bonds that are present in the Le[b] determinant *after* it was bound by the antibody. These intramolecular hydrogen bonds are not expected to be abundant prior to the formation of the complex.

That the βDGlcNAc residue is involved in the binding reaction became apparent when the Y determinant (**6**) was found to be inactive (Table 2). In fact, involvement of the acetamido group is indicated by the low activity demonstrated by the amino acid (**7**). The hydroxymethyl group of the βDGlcNAc residue is definitely not involved in a polar interaction with the combining site since the 6[a]-deoxy derivative (**8**) is slightly more active than the parent structure (**1**). Possible involvement of this hydroxymethyl group must then be limited to a hydrophobic interaction, perhaps while hydrogen bonded to the ring oxygen (6). An involvement of this group may importantly contribute to the stability of the complex as, for example, does the hydroxymethyl group of the αDGal unit of the human B determinant when bound by monoclonal anti-B antibodies (5). As will be seen with reference to Fig. 1, the CH_2OH^a group is

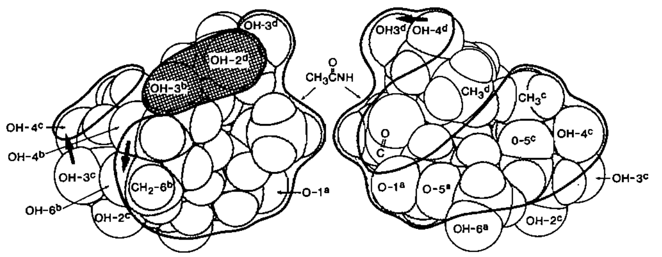

FIG. 1. The HSEA molecular model for αLFuc(1→2)βDGal(1→3)-[αLFuc(1→4)]βDGlcNAc-OMe. Opposite sides of the model are shown and the hatched areas display the surface which was identified as that which comes into interaction for complex formation with a hybridoma monoclonal anti-Lewis b antibody. The cross-hatched region involving the OH-3[b] and OH-2[d] provides the key polar interaction. The arrows indicate the location of the three intramolecular hydrogen bonds that are postulated to form in the course of complex formation. It is noteworthy that the most hydrophobic region is adjacent to the key polar grouping.

included in the topography that is bound in order to extend the lipophilic surface to both sides of the molecule. The high activity of **8** supports this contention.

The results presented in Table 3 with regard to involvement of the βDGal unit are particularly interesting. First of all, replacement of OH-3[b] by hydrogen provided an inactive product (**9**) but deoxygenation at position 4[b] to produce **10** left an active compound. Thus, OH-3[b] and OH-2[d] form the polar key and, as seen in Fig. 1, these are located in close proximity to each other. Replacement of OH-6[b] by hydrogen provided an inhibitor (**11**) that is 18 times more potent than the parent Le[b] tetrasaccharide (**1**). This truly remarkable event amounts to an increase in the stability of the complex by 1.7 kcal/mol. Angyal and McHugh (13) estimated the nonbonded interaction between *syn*-axial hydroxyl groups to be 1.8 kcal/mol. Also, the nonbonded interaction between *syn*-axial acetoxy groups was estimated to be approximately 2.1 kcal/mol (14, 15). We therefore propose that replacement of OH-6[b] by hydrogen relieves the system of the energy required to bring OH-6[b] in *syn*-axial-like relationship with OH-4[b]. In this orientation, an intramolecular hydrogen bond between OH-6[b] and O-4[b] should be enforced and it is for this reason that this bond is displayed in the formula for **1** in Table 2. The reason for the enforcement of this unfavorable orientation for OH-6[b] is clearly apparent from a consideration of Fig. 1 where it is seen that, as the result of losing the energy required to orient OH-6[b], a larger hydrophobic area is gained, stretching from the CH_2-6[b] methylene group to the methyl of the acetamido group. In the normal orientation, OH-6[b] would project largely *syn*-axial-like to H-4[b] (8, 9) and thereby disrupt the continuity of the weakly polar–nonpolar wedge-shaped topography indicated in Fig. 1 and which is expected to be complementary to the hydrophobic cleft defined by the combining site. As mentioned above, replacement of OH-4[b] by hydrogen provided a weak inhibitor. On the basis of the proposal for binding presented in Fig. 1, this result is not surprising. First of all, at least marginal involvement of OH-4[b] in the polar interaction provided by the neighboring OH-3[b] must be anticipated. Secondly, in the absence of OH-4[b], OH-6[b] must adopt the energetically less favorable orientation wherein it is *anti*-periplanar to H-5[b] in order to form a bond with O-5[b]. This latter hydrogen bond should be weaker than that when O-4[b] was available as the proton acceptor since OH-4[b] must be a proton donor (most likely to water) in the complex. The cooperativity of hydrogen bonds (16), when first observed (17), was termed hydrogen-bond conjugation.

Further rather convincing evidence for the formation of intramolecular hydrogen bonds in the course of the binding of **1** by the antibody is presented in Table 4. First of all, replacement of OH-2[c] by hydrogen to form **12** had no effect on the extent of binding and it is therefore concluded that this hydroxyl group remains in contact with water. However, replacement of OH-4[c] by hydrogen to form **14** led to a nearly two-fold increase in potency. Thus, OH-4[c] appears to become involved, through intramolecular hydrogen bonding, in a nonpolar interaction with the protein. This conclusion is supported by the fact that replacement of OH-4[c] by fluorine to provide **15** led to a nearly five-fold increase in potency. This is in accord with expectation since the engagement of a polar fluorine atom in a nonpolar interaction can be expected to resemble that of an hydroxyl group involved as the proton donor to an intramolecular hydrogen bond. On the basis that **1** is accepted with OH-4[c] hydrogen bonded to O-3[c], it is to be expected that replacement of OH-3[c] by hydrogen to form **13** would provide a weaker inhibitor. In fact, as seen in Table 4, its potency is about five times less than that of **1**. That it is not an even less active compound is not surprising, since OH-4[c] can still form an intramolecular hydrogen bond with O-5[c]. Finally, should

OH-4[c] become involved in a nonpolar interaction within the complex, it would be surprising indeed if the neighboring nonpolar CH_3-6[c] group was not similarly involved. In fact, as seen in Table 4, replacement of CH_3-6[c] by hydrogen to form **16** led to a nearly eight-fold reduction in potency, which amounts to a near 1.3 kcal/mol reduction in the stability of the complex. On the other hand, as seen in Table 5, replacement of CH_3^d by hydrogen to form **17** had little effect on the binding reaction. In the case of compound **18**, both the CH_3^c and CH_3^d groups of **1** are replaced by hydrogen. As expected from the potencies of **16** and **17**, **18** is only slightly less potent than **16**.

As was mentioned above, the activity displayed by the Le[d] determinant (**3**) suggested that the αLFuc(1→2[b]) unit provides an hydroxyl group to the key polar interaction. Indeed, as seen in Table 5, the 2[d]-deoxy derivative (**19**) of **1** proved to be inactive. The superiority of the 3[d]-deoxy compound (**20**) as an inhibitor suggests that OH-3[d] of **1** becomes involved, hydrogen bonded to O-4[d], as displayed in the formula for Table 4. On this basis, deoxygenation at position 4[d] should provide an inferior inhibitor. In fact, this is the case and compound **21** is only about a fifth as active as **1**. The requirement for OH-3[d] to form an intramolecular hydrogen bond should be fulfilled, although not as effectively, by a fluorine atom at position 4[d]. In fact, replacement of OH-4[d] by fluorine to provide **22** resulted in a compound that proved to be about half as potent as **1**. As to involvement of OH-4[d], it is possible that, in the complex, this hydroxyl becomes intramolecularly hydrogen bonded to O-5[d], as is displayed in Table 4. However, as seen in Fig. 1, this hydroxyl group is also well disposed for interaction with water. It is shown bonded to O-5[d] only to indicate that this possibility exists and that the lipophilic surface that becomes involved in the complexation reaction may be even more extensive than is indicated in Fig. 1.

In summary, compound **1** appears to be recognized by this particular monoclonal anti-Le[b] antibody through interaction with the wedge-shaped amphiphilic surface depicted in Fig. 1 for the tetrasaccharide in its energetically favored conformation in aqueous solution (7). In order to present this surface to the antibody, three and perhaps four intramolecular hydrogen bonds are formed. In view of the involvement of such hydrogen bonds, the surface is not strictly hydrophobic in nature. Instead, it can only, because of the intramolecular hydrogen bonds, become energetically more compatible for interaction with a nonpolar complementary surface provided by the protein. Most likely the engagement of these groupings is enforced in order for the protein to gain access to the adjacent nonpolar groupings. It seems unlikely that the intramolecularly hydrogen bonded hydroxyl groups become involved in polar interactions within the complex, since in each case the deoxygenation produced a superior inhibitor.

These observations justify the idea presented in 1978, "that carbohydrates (depending on their structure and configuration) through intramolecular hydrogen bonding can assume (depending on demand by the environment and by way of a low energy process) either hydrophilic or hydrophobic properties. . ." (11). In this context, the oligosaccharides comprise a wide range of conformationally well-defined non-surface-active structures which, because of their polar groups, are compatible with water and can serve to extend amphiphilic surfaces into the aqueous phase where these can seek receptor sites for the guidance of biological processes. To date (3–6), our experimental data indicate that these interactions comprise sterically well-directed and coordinated polar and nonpolar interactions between complementary surfaces, with the greater the complementarity presented for lipophilic interaction, the greater the stability of the complex. However, whether or not a complex is formed appears to depend on the integrity of the polar interaction. This interaction could correspond to the first step proposed by Neurohr *et al.* (18) for the binding of methyl α-D-galactopyranoside by peanut agglutinin. This step could not be followed but was considered to occur with a low equilibrium constant and probably diffusion controlled or nearly so. There then follows a mutual fitting of site and sugar which is much slower than expected for a diffusion-controlled process and which is associated with a negative entropy of activation (6). We propose that the polar interaction provides the key to the complexation reaction in that it allows the mutual fitting to begin and that its main function is to bring a nonpolar portion of the oligosaccharide into a position suitable for it to interact with the protein. On this basis, the polar grouping of the oligosaccharide serves as a key that opens a "hydrated polar gate" (12) provided by the protein which, like the key polar group, is adjacent to a nonpolar region which is complementary to the nonpolar surface of the oligosaccharide. Low energy conformational changes by the protein toward completion of the complex then occur. These changes involve both a decrease in enthalpy and decrease in entropy. On this basis, the specificity of the reaction depends on an ability of the nonpolar interaction to become established in accord with the stereochemical requirements of the key polar interaction. Important cross reactions (that is, different inhibitor potencies) occur when the requirements of the key polar interaction are met, but the extent to which complementary lipophilic surfaces can be established differs. This coordination of effort is probably basic to all *specific* processes for molecular recognition, including the organization of macromolecules and the binding of substrates by enzymes (19). It has been suggested that the main driving force for the "fitting" of a protein to an oligosaccharide is the filling of voids along amphiphilic surfaces (12).

Experimental

Inhibitors

The structures and purity of the various compounds used as inhibitors were established by appropriate ^{1}H (400 MHz) and ^{13}C (100 MHz) nuclear magnetic resonance studies (20).

Radioimmunoassay

These assays were conducted following the procedure described in the study of the lectin IV of *Griffonia simplicifolia* (3). The results were similar in quality. It was found that an antigen of the composition $(Le^{b})_{19}$-BSA-^{125}I was so strongly absorbed that prohibitively high concentrations of **1** were required to reach 50% inhibition. This problem was solved by using an antigen with a lower degree of substitution, namely, $(Le^{b})_{1-2}$-BSA-^{125}I. In the absence of an inhibitor, about 85 000 cpm (50% of that added) were bound by an antibody-coated tube. The IgM antibody (clone 96FR 2.10) can be purchased from Chembiomed Ltd. in the form of a reagent suitable for blood typing.

A systematic study was made of the effect of changes in the structure of αLFuc(1→2)[αDGal(1→3)]βDGal-OMe (**1**) on the inhibition of the binding of an artificial antigen by two monoclonal anti-B antibodies. Both OH-4 of the βDGal unit and OH-2 of the αDGal unit are essential for binding by one of the antibodies. For the other antibody, OH-3 of the αDGal unit also forms part of the key polar grouping. Both the antibodies recognize a large lipophilic surface extending from the CH_3-6 group of the αLFuc unit along the α-sides of this group and the βDGal unit to include its CH_2OH-6 group, most likely intramolecularly hydrogen bonded to the neighboring O-5. The lipophilic surface then extends to include the CH_2OH-6 group of the αDGal unit intramolecularly hydrogen bonded to the O-5 atom. The stability of the complex is attributed to nonpolar interaction of this surface within a hydrophobic cleft-like combining site which offers a polar grouping at its periphery for interaction with the key polar grouping of the trisaccharide. The solution conformer for **1**, as determined by ^1H nmr, is present in its crystal structure.

RAYMOND U. LEMIEUX, ANDRÉ P. VENOT, ULRIKE SPOHR, PAUL BIRD, GAURHARI MANDAL, NAOHIKO MORISHIMA, OLE HINDSGAUL et DAVID R. BUNDLE. Can. J. Chem. **63**, 2664 (1985).

On a effectué une étude systématique sur l'effet des changements dans la structure du trisaccharide αLFuc(1→2)-[αDGal(1→3)]βDGal-OMe (**1**) sur l'inhibition de la liaison d'un antigène artificiel par deux anticorps anti-B monoclonaux. La présence tant du OH-4 de l'unité βDGal que du OH-2 de l'unité αDGal est essentielle pour qu'il se produise une liaison avec l'un des anticorps. Dans le cas de l'autre anticorps, le OH-3 de l'unité αDGal fait également partie du groupment polaire clé. Chacun des deux anticorps reconnaît une grande surface lipophile qui comprend le groupement CH_3-6 de la portion αLFuc, situé le long du côté α de cette portion, la portion βDGal ainsi que le groupement CH_2OH-6 de cette dernière qui est probablement lié à l'atome O-5 voisin par une liaison hydrogène intramoléculaire. La surface lipophile s'étend alors de façon à inclure le groupement CH_2OH-6 de l'unité αDGal qui est liée à l'atome O-5 par une liaison hydrogène intramoléculaire. On attribue la stabilité de ce complexe à une interaction non polaire de cette surface à l'intérieur d'un site de liaison hydrophobe ressemblant à une crevasse qui présente, à sa périphérie, un groupement polaire qui permet d'effectuer une interaction avec le groupe polaire principal du trisaccharide. Le conformère du composé **1** qui, d'après la rmn du ^1H, existerait en solution serait aussi présent dans la structure cristalline.

Introduction

Bundle, Rahman, and co-workers (1) produced hybridoma monoclonal antibodies in mice against an artificial antigen prepared by acylation of human O red cells with the synthetic B human blood group related structure αLFuc(1→2)[αDGal-(1→3)]βDGal-$O(CH_2)_8CON_3$ (2–4). We report herein how the combining sites of the two IgM monoclonal, affinity purified, anti-B antibodies (I and II, obtained from clones 3E-7 and 1A-12, respectively) (1) recognize this trisaccharide.

The procedure, based on a solid-phase radioimmunoassay, was that used for the probing of the combining sites of the lectin IV of *Griffonia simplicifolia* (5), the lectin I of *Ulex europaeus* (6), and a hybridoma anti-Lewis b antibody (7). The conclusions are similar in kind to those reached in these previous studies in that the recognition involves an interaction of the antibody with an amphiphilic surface, a situation which was also found for the binding by the monoclonal anti-I Ma antibody where the inhibitions were determined using a quantitative precipitin assay (8).

Results and discussion

The combining sites were probed using synthetic oligosaccharides, listed in Tables 1–3, prepared, in the most part, following established procedures (2) and thoroughly characterized by high field ^1H and ^{13}C nmr studies (9). The 50% inhibitions were determined using a previously reported solid-phase radioimmunoassay (5, 10). The differences in binding free energies ($\Delta\Delta G^0$ values at 23°C) provide an assessment of how much structural changes influence the stabilities of the complexes formed as compared to that for the reference inhibitor (**1**).

In order to discover the extents of involvement of the hydroxyl groups in the binding of the reference inhibitor (**1**), the nine possible monodeoxy derivatives (**2–10**) were synthesized (11, 12) and their performances as inhibitors are reported in

‡By extrapolation.

Table 1. The similarity of the results obtained for both antibodies is remarkable. These results require direct involvement of OH-4^a and OH-2^c in the binding with both the antibodies, since their removal to produce **8** and **9** resulted in complete abolishment of activity. The data for compound **10** indicate a stronger requirement of OH-3^c for antibody II than for I but important involvement occurs in both cases. In accordance with the previous proposals (5) for describing specific polar regions that are essential for binding by lectins and antibodies, OH-4^a and OH-2^c form the key polar grouping for antibody I. In the case of antibody II, this grouping also includes OH-3^c, because for this antibody compound **10** is inactive. The reduced activities that result from deoxygenation at C-4^c to form **7** may arise from changes in hydration near the strongly polar involvements of the neighboring OH-3^c. In view of these results, it was not surprising that epimerization of C-4^c to convert the αDGal unit to αDGlc provided an inactive product. These findings are in accord with the recent report by Rahuel *et al.* (13) that the 3^c-deoxy and 3^c,4^c-dideoxy derivatives of the B-trisaccharide are inactive as inhibitors of the agglutination of human B red cells. The low but detectable activity displayed by the amine **11**, as compared to the inactivity shown by the A determinant **12**, is in accord with their findings on acquired B antigens.

Change of the methyl aglycon of **1** to $(CH_2)_8COOCH_3$ to form **17** increased the binding strength by about 0.37 and 0.65 kcal/mol for antibodies I and II, respectively (Table 2). The involvement of the linking arm was not surprising (14). Indeed, antibodies from other clones showed much greater involvement of the linking arm in the immune response to the artificial antigenic determinant derived from **17** (1). The relatively low activities exhibited by the tetrasaccharide type 1 (**18**) and type 2 (**19**) B haptens are therefore understandable and establish the binding of the methoxy group of **1** in both the antibody reactions. In fact, inversion of C-1^a of **1** to form the α-anomer **13** led to substantial loss in potency. These decreases in complex stability are attributed to losses of complementarity involving both the methoxy group and the weakly polar α-side of the βDGal unit (15).

It is established (16, 17) that the preferred orientation of OH-6 of a galactopyranoside has this group *anti*-periplanar to O-5. The data in Table 1 require that neither OH-6^a nor OH-6^c are involved in polar interactions within the combining sites, since the replacement of these hydroxyls by hydrogen provided highly active compounds (**5** and **6**). Because the 6^c-deoxy derivative (**6**) is a superior inhibitor, it is anticipated that **1** is bound with OH-6^c intramolecularly hydrogen bonded to O-5^c, as is present in the crystal structure (18), a situation that was observed both for the binding of the H-type 2 determinant of *Ulex europaeus* (6, 19) and the Lewis b determinant by a hybridoma monoclonal anti-Le^b antibody (7). That binding occurs about the C-6^c grouping is required by the low activity of the βL Ara compound **24**. Since the 6^a-deoxy compound **5** is slightly less active than **1**, the evidence that OH-6^a becomes intramolecularly hydrogen bonded to O-5^a, as displayed in Table 1, is not as convincing as for the bonding of OH-6^c to O-5^c. The hydrogen bond is suggested in view of the high activity displayed by **5**, together with the fact that the L-6^a-C-methyl compound **21** is much more active than its D-isomer (**20**). In the case of **21**, OH-6^a in its preferred orientation (15) can form a hydrogen bond with O-5^a, but OH-6^a of **20** cannot.

The conformation of the trisaccharide portion of **17** in aqueous solution (9) was found to be that present in the crystal

structure (18) of **1** and presented in Fig. 1. In view of the inhibition data presented in Tables 1−3 and the evidence that **1** is a conformationally rigid structure (9), we conclude that the binding reaction involves a highly directional polar interaction with the cluster of hydroxyl groups defined by OH-4^a and OH-2^c in the case of antibody I and by OH-4^a, OH-2^c, and OH-3^c in the case of antibody II. It appears that the polar interactions involving OH-3^c and OH-4^c for antibody I and that involving OH-4^c for antibody II are less demanding in terms of the structures of the complexes that are formed. For antibody II, the three hydroxyl groups of the fucosyl unit and the polar side of **1** occupied by O-5^a, O-1^a, and O-5^b appear to remain in contact with water. It is possible that OH-4^b becomes intramolecularly hydrogen bonded to OH-3^b for involvement in a nonpolar interaction with antibody I, since deoxygenation at the 4^b-position to produce **4** (Table 1) provided a superior inhibitor. Similar situations were found for the binding by the lectin IV of *Griffonia simplicifolia* (5) and a monoclonal anti-Lewis b antibody (7).

As is displayed in Fig. 1, a large lipophilic region appears to

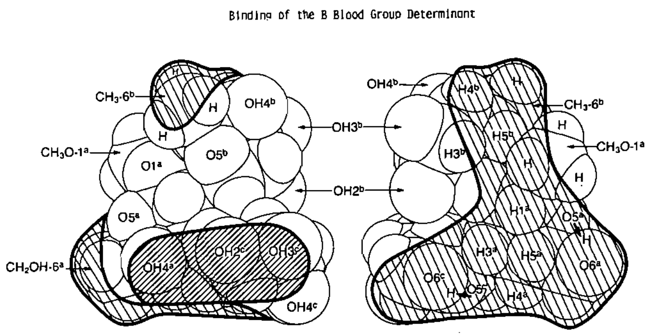

FIG. 1. Schematic representation of the combining sites for the monoclonal anti-B antibodies (I and II) to illustrate the regions of αLFuc(1→2)[αDGal(1→3)]βDGal-OMe (**1**, CPK representation of its crystal structure) that are bound. Note that the polar regions O-1^a, O-5^a, O-5^b, as well as OH-2^b and OH-3^b remain in contact with water. This condition also applies to OH-4^b in the case of antibody II. For antibody I, the lipophilic surface (lightly hatched) may extend to include OH-4^b intramolecularly hydrogen bonded to OH-3^b. The key polar grouping shown is for antibody II. For antibody I, this grouping is limited to OH-4^a and OH-2^c.

be involved, which extends from the CH_3-6^b group of the fucosyl unit to include the two hydroxymethyl groups intramolecularly hydrogen bonded to the neighboring ring oxygens (O-5^a and O-5^c). The conformation of **1** places the key polar grouping adjacent to this lipophilic surface. As in all cases so far studied (5–8), this polar grouping is well positioned to interact with a polar grouping at the periphery of the combining site and termed the polar gate (20). Prior to binding, both the polar groupings (i.e., the key and the gate) likely are strongly hydrated and their interaction may not contribute importantly to the stability of the complex. The possibility that the polar grouping provided to the complex was shielded from hydration prior to binding does not appear to be relevant. Judging from the shapes of the topographies provided by the oligosaccharide to the complex, the polar interactions within the complex occur at the interface with the aqueous environment. This matter was previously discussed in relation to the binding of the H-type 2 determinant by the lectin I of *Ulex europaeus* (6). Definitely, the interaction between the nonpolar complementary surfaces contributes importantly and, indeed, appears to be the dominating factor for complex stability (6). Considering that the polar interactions, which are directional in character, must be compatible with the required orientations for the complementary lipophilic surfaces to interact, it is evident that these interactions provide the main contribution to the specificity of the overall binding reaction. This finding is of major importance to efforts aimed at the detection of lectin and antibody specificities using partial structures as potential inhibitors (5, 7). The failure of the simple alkyl glycosides and **14** (Table 2) to display appreciable levels of activity is noteworthy in this regard. In the case of the binding of the H-type 2 determinant (αLFuc(1→2)βDGal(1→4)βDGlcNAc) by the lectin 1 of *Ulex europaeus*, the key polar grouping is provided by the 3- and 4-hydroxyl groups of the fucosyl unit and this lectin also binds methyl α-L-fucopyranoside.

The conclusions reached in this investigation regarding the nature of the combining sites for antibodies I and II are similar in kind to those reached in the case of the anti-I Ma antibody (8) and the lectin 1 of *Ulex europaeus* (6), the lectin IV of *Griffonia simplicifolia* (5), and a monoclonal anti-Lewis b antibody (7). The common feature is for the oligosaccharide to offer substantial surface which is compatible for binding by a complementary hydrophobic cleft at the surface of the antibody. In all cases, this surface terminates with a relatively much smaller cluster of hydroxyl groups that is well positioned to react with a polar grouping at a region along the periphery of the combining site. As previously noted (6, 7), the stability of the complex appears mainly derived from the extent that nonpolar interactions can be established between complementary lipophilic surfaces.

Experimental

Antibodies I and II

Commercially available (Chembiomed Ltd.) mouse hybridoma monoclonal antibody I (clone 3E-7) (ref. 1) was affinity purified by absorption on commercial B Synsorb, washing with phosphate buffer, and then isolated by desorption using 0.1 *M* aqueous acetic acid that was 0.15 *M* in sodium chloride. The solvent was then rapidly exchanged to phosphate buffer (pH 7.5) in the usual manner (14). Antibody II (clone 1A-12) (ref. 1) was similarly purified prior to use in the radioimmunoassay.

Inhibitors

The various inhibitors were obtained by chemical synthesis (11, 12) and shown to be of high purity by appropriate ^{1}H (400 MHz) and ^{13}C (100 MHz) nuclear magnetic studies.

Radioimmunoassay

The assay (5) employed a solution of (αLFuc(1→2)[αDGal(1→3)]-βDGal)$_{15}$-BSA-^{125}I which provided about 290 000 cpm/100 μL. In the absence of inhibitor, the antibody-coated tubes bound nearly 50% of these counts. The tubes were coated using solutions of antibody I (12.5 μg/mL) and antibody II (6 μg/mL) in 0.05 *N* sodium phosphate buffer (pH 7.5).

The electroreduction of halogenated thiophenes

RICHARD NEVILLE GEDYE, YOGINDER NATH SADANA, AND RAYMOND LEGER
Department of Chemistry, Laurentian University, Sudbury, Ont., Canada P3E 2C6

Received June 7, 1984[1]

RICHARD NEVILLE GEDYE, YOGINDER NATH SADANA, and RAYMOND LEGER. Can. J. Chem. **63**, 2669 (1985).

Electroreduction of polyhalothiophenes results in the preferential reduction of the α-halogen atoms. Preparative electrochemical reduction of these compounds at controlled potential can be used to synthesize 2,3,4-trihalo, 3,4-dihalo, and 3-halothiophenes. Experimental conditions were developed under which these reductions could be done selectively, giving good yields of the desired products. Electroreduction of tetrabromothiophene can also lead to the formation of a polybromodithienyl mercury compound.

RICHARD NEVILLE GEDYE, YOGINDER NATH SADANA et RAYMOND LEGER. Can. J. Chem. **63**, 2669 (1985).

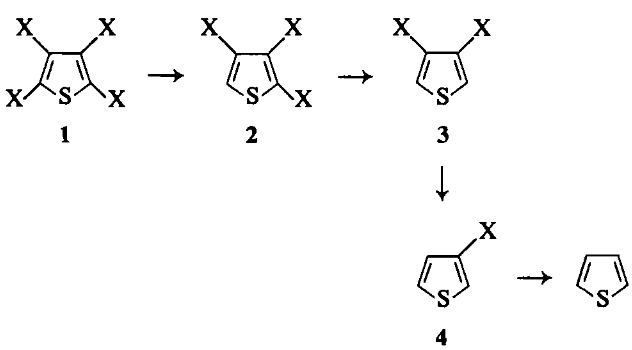
L'électroréduction de polyhalothiophènes conduit à la réduction des atomes d'halogènes en α. Opérant à des potentiels controlés, on peut utiliser la réduction électrochimique préparative de ces composés pour réaliser la synthèse des trihalo-2,3,4, des dihalo-3,4 et des halo-3 thiophènes. On a développé des conditions expérimentales qui permettent de réaliser de telles réduction d'une façon sélective et avec de bons rendements en produits désirés. L'électroréduction du tétrabromothiophène peut aussi conduire à la formation d'un composé polybromodithiényle mercure.

[Traduit par le journal]

Introduction

Electrophilic substitution of thiophenes occurs more rapidly in the α (2 and 5) positions than the β (3 and 4) positions. For this reason the direct synthesis of 3-halo and 3,4-dihalo derivatives from the parent heterocycles cannot be achieved. 3-Bromothiophene can be prepared by the bromination of thiophene to 2,3,5-tribromothiophene followed by reduction with zinc in acetic acid (1). This reduction results in preferential dehalogenation in the α-positions but requires a large excess of zinc and leads to large volumes of effluent containing zinc ions (2).

The electroreduction of polyhalogenated heterocycles was considered to be an attractive alternative to chemical reduction. Polarographic studies on tetrabromothiophene **1***a* (3) and tetraiodothiophene **1***b* (4) have shown that the α-halogens are reduced at a lower potential than the β-halogens and that stepwise reduction of the four halogens occurs, giving four distinct waves.



a, X = Br; *b*, X = I

Feldmann and Koberstein (5) have investigated the reduction of 2,3,5-tribromothiophene by cyclic voltammetry and confirmed the proposed pathway by preparative electrochemical reduction. Constant potential reductions at −1.2, −1.45, and −1.75 V gave 2,3-dibromothiophene, 3-bromothiophene, and thiophene, respectively. Recently the electrochemical reduction of 2,3,5-tribromothiophene to **4***a* using a lead, mercury, or graphite cathode in 70% dioxane/30% water has been reported (2). The yields, estimated by glc, were generally high at potentials (−1.5 to −1.7 V) just positive to the potential of hydrogen evolution.

This paper describes the controlled potential reduction of tetrahalothiophenes **1***a* and **1***b*, the trihalothiophene **2***a*, and the dihalothiophene **3***a*. The potentials used in these reductions were determined by polarography.

Experimental

Apparatus

Polarography was performed using a Princeton Applied Research Model 174-A polarograph, with its associated drop timer and cell, along with a Houston Instruments Omnigraph 2000 $x-y$ recorder. A 15 cm long, 0.1-mm internal diameter capillary was used and potential measurements were relative to a saturated calomel reference electrode. This calomel electrode was connected to the cell by means of a salt bridge containing a Luggin capillary tip packed tight with glass fibres. The salt bridge was filled with the same solvent and supporting electrolyte as used in the cell. When other metals were used as the working electrode, a thin polished wire of the metal was placed in the cell at a depth of about 1 mm into the solution.

Cyclic voltammetry was carried out using the same polarograph and a Princeton Applied Research Model 175 universal programmer. The results were viewed on a Tektronics model 564B storage polarograph and recorded by the same recorder used in the polarography. The x-axis signal from the polarograph was amplified using a Hewlett–Packard Harrison Model 6824A power supply/amplifier used in the amplifier mode.

A Wenking Model 66-TS10 potentiostat was used in the preparative electrolyses. Undivided cell electrolyses were carried out in a modified 400-mL beaker, the centre of the bottom of which was depressed about 5 mm to contain the mercury pool. The connection to the mercury pool was made using a short piece of platinum wire sealed into the bottom of the beaker. The beaker was covered with a rubber stopper containing holes for insertion of the salt bridge, stirrer, and anode wire, and for the introduction and removal of samples. When a solid metal electrode was used, a strip of it was suspended vertically on one side of the cell and the anode wire looped vertically on the other side.

In the divided cell electrolyses, the cathode compartment was the same beaker as described above. The anode compartment was a 12 cm long, 4.3-cm diameter glass tube containing a medium porosity glass sinter at the base. A rubber stopper covered the top of the cathode cell and held the anode compartment in place. The stopper also contained holes for the salt bridge and sample introduction/removal. The anode

compartment was also covered with a rubber stopper that contained holes and stirrer and the anode wire. The catholyte was stirred using a small magnetic stirrer placed to one side of the mercury pool. In both types of electrolysis the anode consisted of a looped 1.1-mm diameter steel wire and the salt bridge and calomel electrode were similar to those used for polarography.

Analysis

The nmr spectra were recorded with a Varian T-60 nmr spectrometer and ir spectra with a Beckmann Acculab 1 or a Perkin–Elmer 735B spectrophotometer. Gas chromatography was performed using a Varian Aerograph 90-P gas chromatograph with a thermal conductivity detector and a 10 ft × 0.25 ft aluminum column containing 10% SE-30 on Chromosorb W. Microanalysis and mass spectrometry were carried out at the University of Alberta, Edmonton. Fast atom bombardment spectra were run on an AE1 MS9 mass spectrometer in the negative ionization mode, using a glycerol/sulfolane matrix or a pure sulfolane matrix chilled in liquid nitrogen. Chemical ionization spectra were run on an AE1 mass spectrometer in the positive ionization mode using ammonia reagent gas.

Solvents and supporting electrolytes

Dimethylformamide (DMF) and dimethylsulfoxide (DMSO) from BDH were dried by refluxing over calcium hydride and distilling at reduced pressure. Acetonitrile (Aldrich) was refluxed over P_2O_5 and distilled at atmospheric pressure. Tetraethylammonium bromide (Aldrich) was recrystallized from ethanol–ether and tetrabutylammonium iodide (Baker) from ethyl acetate. Both quaternary ammonium salts were dried *in vacuo* before use.

Electrolysis substrates

Tetrachlorothiophene (6), tetrabromothiophene (7), and tetraiodothiophene (8*a*) were prepared and purified by literature methods.

Electrolysis procedure

(a) *Undivided cell*

DMF (200 mL), which was 0.1 *M* in tetraethylammonium bromide (TEAB), was poured into the cell. This solution was pre-electrolyzed at the same potential to be used for the substrate, for about 10 min, in order to destroy trace amounts of electroactive substances and to measure the background current at that potential. The substrate (5 g) was added along with an additive to absorb bromine (approx. 2 equivalents) and a few drops of 40% HBr solution. The solution was electrolyzed until the current had decreased to a value close to the pre-electrolysis background current or when glc analysis showed that the substrate was no longer detectable. The reaction mixture was poured into cold water (1.5 L) and extracted with ether. After drying ($MgSO_4$), the ether was evaporated and the residue distilled, usually at reduced pressure. The products were identified by glc, nmr, and ir by comparing with literature data and (or) authentic samples. The results are summarized in Table 1.

(b) *Divided cell*

The sinter, dividing the cathode and anode compartments, was first impregnated with a gel of methyl cellulose. Methyl cellulose (5 g) was added to hot DMF (25 mL), which was 0.1 *M* in TEAB. The hot viscous solution was drawn through the sinter using a vacuum and then forced back using air pressure. This procedure was repeated a few times in order to remove air bubbles from the sinter. After cooling, the excess gel was scraped off the sinter.

DMF (140 mL), which was 0.1 *M* in TEAB, was introduced into the cathode compartment. Generally, 60 mL of the same solution was introduced into the anode compartment, although in one electrolysis an aqueous solution of the electrolyte (0.1 *M*) was used.[2] A slight excess of hydrazine was dissolved in the anode solution. After a pre-electrolysis, the substrate (5 g) was added to the catholyte together with a few drops of 40% HBr and the solution electrolyzed at constant potential. It was noted that the anode solution became acidic during the course of the electrolysis and was neutralized occasionally by the addition of KOH. When the electrolysis was judged over (glc analysis and (or) current monitoring), the cathode solution was worked up in the same manner as the undivided cell electrolysis. The results are given in Table 2.

3,4,5-Tribromo-2-thiophene carboxylic acid

A divided cell electrolysis was carried out as above, but in the presence of a stream of CO_2. The product was poured into water, acidified, and extracted with ether. The ether solution was extracted with aqueous NaOH and the aqueous layer acidified with HCl, giving a white precipitate of 3,4,5-tribromo-2-thiophene carboxylic acid (1.1 g, 35%), mp 258–260°C, (lit. (8*b*) mp 258–259°C; ir: 1700 (s, C═O *str*) cm^{-1}.

Di-3,4,5-tribromo-2-thienylmercury

A divided cell electrolysis of tetrabromothiophene (5 g) was carried out at −0.95 V without the addition of acid to the catholyte solution. After a few minutes the current dropped to a background level and the electrolysis was allowed to run for 3 days. On pouring the product into water a cream coloured solid, which was insoluble in ether, separated. Filtration, followed by washing with ethanol and ether, gave the crude product (1.0 g). Extraction of the filtrate with the ether gave a solid which was shown by glc to be mostly the starting material. The crude product was crystallized from DMF/ethanol giving a cream powdery solid (0.6 g, 11%), mp 295–301°C (lit. (8*c*) mp 291°C); ir (KBr):

[2]In one electrolysis water was used in the anode compartment.

Results and discussion

Polarographic studies were carried out on the tetrahalothiophenes in DMF, DMSO, and acetonitrile, using TEAB as supporting electrolyte. It was noted that the polarograms of each substrate were virtually identical in the three solvents and only small differences were observed in the half-wave potentials ($E_{\frac{1}{2}}$ values) and diffusion currents (i_d). The $E_{\frac{1}{2}}$ values are listed in Table 3.

In agreement with previous polarographic studies (3, 4), both tetrabromo- **1***a* and tetraiodothiophene **1***b* showed four waves, corresponding to the successive reduction of each halogen in the molecule. Tetrachlorothiophene also showed four waves in DMF but the highest potential waves in DMSO and CH_3CN were masked by solvent decomposition. As expected, the ease of reduction for the tetrahalothiophenes was in the order I > Br > Cl.

With DMF as solvent, the effect of the presence of water and aqueous acid or base on the half-wave potentials was investigated. Up to the concentration at which their reduction waves swamped the polarograms, water, acid, and base had little or no effect on the $E_{\frac{1}{2}}$ values. It was concluded that the reduction potentials were not pH dependent.

The effect of the electrode material on the reduction potentials in DMF was investigated, with a view to the use of solid electrodes in preparative electroreductions. The results are listed in Table 4. Using solid electrodes, it was generally not found possible to obtain all four waves. It was also noted that the reduction potentials were higher and closer together than those obtained with mercury. It was confirmed later by preparative electrolyses that selective reductions were more difficult to achieve using copper and lead cathodes than with a mercury cathode.

Polarographic (3) and cyclovoltammetric studies (5) on bromothiophenes indicate that they reduce by an irreversible mechanism in which two electrons are required for reduction of each halogen atom. The resulting anion is then protonated by the autoprotolysis of DMF and (or) by water. The source of protons in aqueous media is water and it has been reported (9) that, even in reductions in DMF, water is the usual proton source since the removal of small amounts of water from the solvent using conventional drying agents is difficult.

$$RBr \xrightarrow{2e^-} R^- + Br^-$$

$$R^- \xrightarrow{SH \text{ or } H_2O} RH$$

The electroreductions of **1***a* (3) and **1***b* (4) have also been reported to be diffusion controlled.

The irreversibility of the reductions was confirmed by cyclic voltammetry of the substrates in DMF, which was 0.1 *M* in tetrabutylammonium perchlorate. The cathodic peaks in the cyclic voltammograms obtained correspond to the polarographic reduction waves of these compounds and there were no appreciable oxidation peaks associated with any of these reduction waves. Although some small anodic peaks were found in the −0.8 to +0.5-V range, these occurred in all the voltammograms and were attributed to the oxidation of the solvent decomposition products created by the high potentials used in the cathodic scans.

In our initial preparative electrolyses, **1***a* was electrolyzed in an undivided cell at a mercury electrode, using DMF as solvent and TEAB as supporting electrolyte at a potential corresponding to the $E_{\frac{1}{2}}$ value of the appropriate polarographic wave. It was found, however, that the current increased until the current limit of the potentiostat (1 amp) was reached. At this limit the cathode potential would start to decrease, preventing further reduction from occurring. Since it was believed that this problem was caused by the generation of bromine, which may react with DMF (10) or brominate the reduced bromothiophene, the effect of addition of various compounds which might trap the bromine was investigated. The most effective of these additives were found to be alkenes (such as 1-hexene, 1-heptene, and 1-decene), dimethylaniline (DMA), and phenol. It was also found necessary to add a small amount of mineral acid (HBr) in order for the electrolysis to proceed normally. In the absence of acid, it was generally observed that the currents, initially about 100 mA, decreased within minutes to a background level of about 5 mA. Acidification of the solution caused the current to increase to approximately its initial value. The addition of weaker proton donors such as acetic acid, ethanol, and water had little or no effect on the current when at the background level.

The results of these electrolyses are summarized in Table 1. In some cases good yields of the desired reduction products were obtained, but in others problems arose because of the difficulty in separating the additive or brominated additive from the product by distillation.

Preparative electrolyses were also performed using copper and lead cathodes at the potentials determined by polarography at these electrodes. The reaction products and yields are also given in Table 1. The reductions at these electrodes were not as selective as those at the mercury electrode and mixtures of reduction products were obtained.

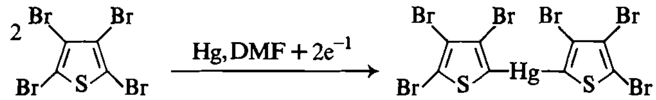
Constant potential electrolysis using a divided cell was found to give generally good yields of the desired products and avoided the necessity for using additives to remove the bromine. Initially, satisfactory results were not obtained due to diffusion of the substrate through the sinter to the anode compartment. This problem was overcome by impregnating the sinter with a gel of methyl cellulose. The cathode compartment, in these electrolyses, contained a 0.1 *M* solution of TEAB in DMF to which the substrate was added after a short pre-electrolysis. In most experiments the same solution was used in the anode compartment, together with hydrazine as an anodic depolarizer. One preparative electrolysis was carried out using water as the anode cell solvent containing 0.1 *M* TEAB, and gave satisfactory results.

As with the undivided cell electrolysis, it was found necessary to add a small amount of acid to prevent the current dropping rapidly in the initial stages of the electrolysis. After some time the acid was depleted, causing the current to decease again even through the catholyte contained much unreacted substrate. The addition of more acid at this point restored the current to its normal value. At the end of the electrolysis, glc analysis showed that the product was present only in the catholyte. No trace of the substrate or product was found in the anolyte.

The results of the divided cell electrolyses are given in Table 2. It was observed that the electrolysis of tetrabromothiophene **1***a* at its lowest reduction potential (−0.90 V) results in the formation of **2***a*. Reduction of both **1***a* and **2***a* at the second potential (−1.20 V) yields **3***a*. Reduction of **1***a*, **2***a*, and **3***a* at the third potential (−1.70 V) yields **4***a*. Similarly, tetraiodothiophene **1***b* was reduced to **3***b* at −0.93 V and to **4***b* at −1.20 V. These results support the interpretation made by previous workers (3, 4) of their polarographic data and clearly show that each polarographic wave corresponds to the reduction of one halogen atom, and that the α-halogens of tetrahalothiophenes are reduced at lower potentials than the β-halogens.

Preliminary work on the preparative electroreductions of tetrachlorothiophene has shown that selective reductions are more difficult to achieve. It should also be noted that the pure starting material is more difficult to prepare than the tetrabromo and tetraiodo analogues.

When the electrolysis of **1***a* was allowed to run for a few days without strong acid in the catholyte solution, an organo-mercury compound identified as di-3,4,5-tribromo-2-thienylmercury, **5**, was obtained in low yield together with some unreacted starting material. This was in contrast to the stepwise replacement of bromine by hydrogen observed in the presence of acid.



1*a* **5**

The organo-mercury compound **5** proved to be difficult to purify because of its low solubility in organic solvents. Its ir spectrum was rather similar to those of **1***a* and **2***a*, and polarography yielded three waves at essentially the same potentials as **2***a*. However, the substance had a much higher melting point than either **1***a* or **2***a* and mass spectrometry (chemical ionization and fast ion bambardment) showed a large multiple peak centred at 840 amu, which would correspond to the mass of the molecular ion of **5**. Some peaks at even higher mass numbers in the FAB spectrum indicated the presence of impurities, and multiple isotope peaks were also observed at 761 (M − Br) and 583 (M − 2Br). Computer generated isotope patterns for the peaks at 840, 761, and 583, assuming structure **5**, were in close agreement with those observed in the mass spectra. The microanalytical results for determination of C, Br, and S in the compound were consistent with structure **5** and slight differences from the calculated values could be attributed to small amounts of impurity.

It would appear that the organo-mercury compound is formed via chemisorbed radicals on the cathode surface.

$$RX + e^{-1} \rightarrow R^0 + X^-$$

$$R^0 + Hg \rightarrow RHg^0\ (\text{ads})$$

$$2RHg\ (\text{ads}) \rightarrow R_2Hg + Hg$$

In our preparative electrolyses it was observed that, in the absence of added mineral acid, the current would fall within minutes to a background level. A similar observation was made by Brown and Taylor (11) in the synthesis of mercury dialkyls from alkyl halides. These authors attributed this behaviour to the intermediate formation of adsorbed radicals, which are then converted to the product on the surface of the mercury.

Received February 8, 1985

ROBERT A. MCCLELLAND and CLAUDE MOREAU. Can. J. Chem. **63**, 2673 (1985).

Hydrolysis kinetics are reported for four spiro ortho esters: 3,4-dihydro-6-methoxy-1*H*-2-benzopyran-1-spiro-2′-1′,3′-dioxolane (**13**), its 1′,3′-dioxane analog (**14**), and the 6-unsubstituted versions of each (**11** and **12**). For comparison, also included are the diethoxy analogs: 1,1-diethoxy-3,4-dihydro-6-methoxy-1*H*-2-benzopyran (**10**) and the 6-unsubstituted compound (**9**). Product analysis implicates an initial opening of the dioxolane or dioxane ring in the spiro ortho esters, as expected on the basis of stereoelectronic considerations. The intermediate dialkoxycarbocations can be observed in HCl solutions. A detailed analysis has been carried out for the 6-methoxy systems to provide the rate constants k_1, the second-order rate constant for H^+-catalyzed formation of the cation from the ortho ester, k_2, the first-order rate constant for water addition to the cation, and k_{-1}, the first-order rate constant for ring closing of the cation to reform the ortho ester. The two spiro ortho esters are shown in this analysis to undergo reversible ring opening in their hydrolysis, in that values of k_{-1} are greater than k_2. The differences, however, are not large, k_{-1}/k_2 being 1.2 (dioxolane, **13**) and 3.8 (dioxane, **14**). Comparison with the diethoxy ortho ester also reveals that the ring opening process (k_1 rate constants) is inherently more difficult with the dioxolane, although not with the dioxane. An argument involving lone pair orientation is advanced to explain this.

ROBERT A. MCCLELLAND et CLAUDE MOREAU. Can. J. Chem. **63**, 2673 (1985).

On rapporte les données cinétiques relatives à l'hydrolyse que quatre spiro ortho esters: le dihydro-3,4 méthoxy-6 1*H*-benzo-2 pyrannespiro-1 dioxolane-2′-1′,3′ (**13**), son analogue dioxanne-1′,3′ (**14**) ainsi que les homologues non substitués en position 6 (**11** et **12**). Pour fins de comparaisons, on a également inclus les analogues diéthoxylés: le diéthoxy-1,1 dihydro-3,4 méthoxy-6 1*H*-benzo-2 pyranne (**10**) et le composé qui n'est pas substitué en position 6 (**9**). L'analyse des produits implique que l'ouverture initiale se fait au niveau des cycles dioxolane ou dioxanne des ortho esters spiro et ce conformément à ce que laissent prévoir les facteurs stéréoélectroniques. On peut observer les dialkoxycarbocations intermédiaires dans des solutions de HCl. On a effectué une analyse détaillée des systèmes méthoxy-6 dans le but d'obtenir: (a) les constantes de vitesse k_1, (b) la constante de vitesse d'ordre deux, k_2, relative à la formation, catalysée par H^+, du cation à partir de l'ortho ester, (c) la constante de vitesse d'ordre un relative à l'addition d'eau sur le cation et (d) k_{-1}, la constante de vitesse d'ordre un pour la cyclisation du cation qui ramène à l'ortho ester. Grâce à cette analyse on démontre que, au cours de leur hydrolyse, les deux spiro ortho esters subissent une ouverture réversible de cycle qui se traduit par le fait que la valeur de k_{-1} est supérieure à k_2. Cependant, la différence n'est pas très grande; k_{-1}/k_2 est égal à 1,2 pour le dioxolane **13** et à 3,8 pour le dioxanne **14**. Une comparaison de ces résultats avec ceux obtenus avec les diéthoxy ortho esters révèle également que l'ouverture de cycle (constante de vitesse k_1) est plus difficile dans le cas du dioxolane même si ce n'est pas le cas avec le dioxanne. On fait intervenir l'orientation du doublet libre pour expliquer ces résultats.

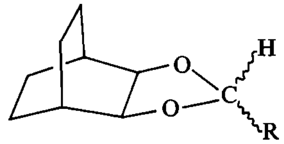
[Traduit par le journal]

A three-stage reaction mechanism is now commonly accepted for the hydrolysis of acetals and ortho esters (1–3): (*i*) acid-catalyzed formation of an oxocarbocation, (*ii*) hydration of this cation to produce a hemiacetal or hemiorthoester, and (*iii*) decomposition of this intermediate to products. Under the conditions normally employed for kinetic studies, namely dilute substrate in aqueous solvent, the first stage is essentially irreversible. The small amount of alcohol which is being released during the hydrolysis cannot compete with the solvent, so that the oxocarbocation once formed must go on to products. With cyclic systems where the first stage involves ring opening, reversibility is, however, a factor. Now the reverse reaction is intramolecular, and in principle it can compete even when there is a large excess of water. Cyclic acetals do undergo hydrolysis at a slower rate than their acyclic analogs, and this observation has been explained by reversibility in the cyclic cases (4). Reversibility, however, is difficult to demonstrate

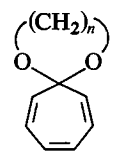
[1] 
[2] 
[3] 
[4] 
unambiguously, since the observed kinetic expression is the same regardless of the relative magnitudes of k_{-1} and k_2 (eq. [5]). Reversibility has been demonstrated unequivocally with

$$[5] \quad \text{Rate} = k_H(\text{obs})\,[\text{acetal}]\,[H^+] = \frac{k_1 k_2}{k_{-1} + k_2}\,[\text{acetal}]\,[H^+]$$

two cyclic acetals—with derivatives of *exo,exo*-norbornane-2,3-diol (**1**) where epimerization at the pro-acyl carbon is observed during hydrolysis (5), and with **2** and **3** which are

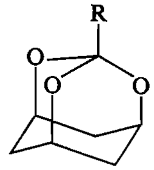


1

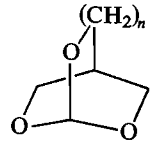


2 $n = 2$
3 $n = 3$

derivatives of tropone (6). With the latter acetals the relatively stable oxytropylium ion intermediates are observed during the hydrolysis. The kinetic behavior therefore becomes more complex than that described in eq. [5], and a kinetic analysis can furnish the exact values of the three rate constants k_1, k_{-1}, and k_2. A similar approach (7, 8) has been employed at the ortho level with trioxaadamantanes **4**, which are highly reversible in their initial ring opening (9). Results with the bicyclic ortho esters **5** (10) and **6** (11), on the other hand, are best interpreted

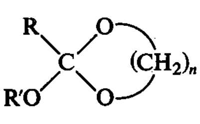


4

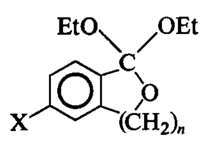


5 $n = 0$
6 $n = 1$

in terms of irreversibility. In the trioxaadamantane system the departing hydroxyl group remains directly in the face of the oxocarbocation. With **5** and **6** it appears as if strain energy in the ortho ester retards the ring closing. The ortho esters **7** (2, 11–13), **8** (14), **9** (15), and **10** (15) have a choice of endocyclic



7 $n = 2$ or 3



8 $n = 1$, X = H
9 $n = 2$, X = H
10 $n = 2$, X = OMe

or exocyclic bond cleavage for their oxocarbocation-forming stage, and show a strong preference for the latter. In the ortho esters **7** where the oxocarbocation can be stabilized by an adjacent phenyl (R = Ar) this tendency can be explained in terms of cation stability (16–18). This preference is also seen with **7**, R = alkyl (13, 18), where the cations derived from the two initial cleavages are expected to have similar stability. This suggests that there is an inherent difficulty in the endocyclic process.

In this paper we address the question of reversibility with the spiro ortho esters **11–14**. These combine features of both **7** and **9** or **10**, with the obvious difference that a ring must open in the first stage of the hydrolysis. We anticipated on the basis of previous results with **8** (14) that the oxocarbocation intermediate would be observed as a transient species, and that this would permit a detailed kinetic analysis similar to that carried out with the tropone acetals (6). This indeed proved to be the case.

Experimental

Materials

1,1-Diethoxy-3,4-dihydro-1*H*-2-benzopyran (**9**) and 1,1-diethoxy-3,4-dihydro-6-methoxy-1*H*-2-benzopyran (**10**) were from a previous study (15). Spiro ortho esters were prepared from these by ortho ester interchange. The diethoxy ortho ester and appropriate diol were mixed in equal amounts and a crystal of 4-toluenesulfonic acid added. The flask was evacuated to 1 Torr (133.3 Pa) at room temperature to remove the ethanol product of the exchange. After complete removal of the ethanol, a small amount of triethylamine was added to neutralize the acid. The ortho ester product was then obtained by distillation under reduced pressure.

*6-Methoxy-3,4-dihydro-1*H*-2-benzopyran-1-spiro-2′-1′,3′-dioxolane* (**13**) had bp 90°C, 0.1 Torr, turning to a waxy solid on standing; ^{1}H nmr ($CDCl_3$, 200 MHz), δ: 6.97 (1H, d, J = 9 Hz, H8), 6.79 (1H, dd, J = 9 Hz and J = 3 Hz, H7), 6.66 (1H, d, J = 3 Hz, H5), 4.18 (4H, bs, H4′ and H5′), 4.07 (2H, t, J = 6 Hz, H3), 3.81 (3H, s, 6-OCH_3), 2.82 (2H, t, J = 6 Hz, H4). *Anal.* calcd. for $C_{12}H_{14}O_4$: C 64.85, H 6.35; found: C 65.03, H 6.42.

Kinetic methods

Conventional uv kinetic measurements for the hydrolysis in solutions with pH > 5 were carried out on a Unicam SP 1800 spectrophotometer. A solution of approximately 0.1 *M* concentration of the ortho ester in dry acetonitrile was prepared; 2–3 μL of this solution were added directly to the uv cuvette containing 2–3 mL of the appropriate aqueous buffer. This cuvette and solution had been previously thermostatted at 25.0°C in the uv instrument. A wavelength of 230 nm was employed for **9**, **11**, and **12** and a wavelength of 255 nm for **10**, **13**, and **14**. Kinetic plots of ln ($A_\infty - A$) versus time were excellently linear and the observed first-order rate constants were calculated as their slopes.

Stopped-flow kinetic measurements for the hydrolysis in solutions with pH < 3 were carried out with a Durrum–Gibson stopped-flow spectrophotometer thermostatted at 25.0°C. The ortho ester was dissolved in 0.002 *M* NaOH to give solutions of approximately 10^{-4} *M* and this solution mixed with excess HCl solutions. A wavelength of 300 nm (for **10**, **13**, and **14**) was chosen. The photomultiplier output of this instrument was digitized to provide 118 absorbance readings for each kinetic run. The absorbance–time values were transferred to a

Tektronix 4051 microcomputer for the analysis described in the next section.

Product analysis

The pure ortho esters were injected via syringe into 0.01 M DCl in D_2O to give a solution of 0.01 M in ortho ester. The ^1H nmr spectra of these solutions were recorded on a 200-Mz nmr spectrophotometer.

Results and discussion

As summarized in eq. [6] there are two possible initial modes of cleavage producing two different dialkoxycarbocations **15** and **18**, and there are two possible types of products, the lactone **16**, which will be accompanied by diol, and the benzoate ester **19**. Products were determined in 0.01 M DCl by directly recording the nmr spectra of hydrolyzed solutions. For all four ortho esters a predominance (85–95%) of lactone plus diol is observed. The ester **19** can cyclize to the lactone but this process is slow compared to the ortho ester hydrolysis (14, 15). The nmr spectra were recorded sufficiently quickly to provide the products of kinetic control.

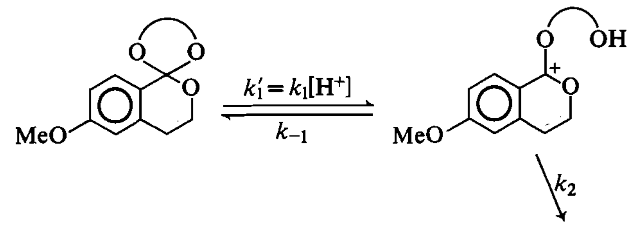
The lactone plus diol products obviously must arise from the cation **15**. We feel that the small amount of ester also comes from this cation. Under similar conditions the ortho ester **10** gives 85% lactone (15). This ortho ester undergoes only cleavage of the exocyclic ethoxy group (15) to produce a cation analogous to **15**. Production of the cation **15** is also expected on stereoelectronic grounds. As shown in the transition state structure **17**, the alternative cleavage to the cation **18** must proceed with the phenyl ring at right angles to the developing π system of the dialkoxycarbocation. Thus no initial stabilization associated with the aromatic ring is possible. That this conjugation is important can be seen in the faster rate of hydrolysis of 2-phenyl-2-methoxy-1,3-dioxolane compared to that of trimethyl orthobenzoate (16). Kresge and co-workers have explained this difference by a steric effect associated with the latter which prevents the phenyl ring from becoming fully conjugated with the cation center (16–18). The argument with the present system is essentially an extension of Deslongchamps antiperiplanar lone pair hypothesis (19, 20). For an efficient reaction, not only must the two remaining oxygen atoms have lone pairs antiperiplanar to the bond being broken, but also the aromatic ring should be set up with the correct orientation. The reaction forming **15** satisfies both requirements; the reaction forming **18** fails on the latter.

First-order rate constants were measured for the spiro ortho esters as well as for their diethoxy analogs in phosphate buffers of pH 5.5–7.5, following the appearance of the lactone plus benzoate ester products in the uv spectrum. As expected, these observed rate coefficients, after correction for a small contribution from the buffer by extrapolation to zero buffer concentration, are linear in H^+ concentration. Values of the H^+ catalytic coefficients are listed as k_H(obs) in Table 1. The spiro ortho esters do hydrolyze significantly more slowly than their diethoxy analogs, the difference being a factor of 60–80 for the dioxolane systems and 6 for the dioxanes.

In HCl solutions kinetic experiments were conducted using stopped-flow spectroscopy, and with all six ortho esters a transient absorbance was observed attributable to the oxocarbocation intermediate. For detailed analysis we have concentrated on the 6-methoxy compounds **10**, **13**, and **14**, where the cations are longer lived. The intermediates with these systems have uv absorbance with λ_{max} at 300 nm typical of p-methoxyphenyl dialkoxycarbocations (2, 21, 22). As shown in Fig. 1, the monitoring of this wavelength produces a rapid rise and fall in absorbance as the cation is formed and subsequently decays. The absorbance in fact starts at zero and finishes at zero since neither the ortho ester nor the product have significant extinction coefficients at this wavelength. It can also be seen from Fig. 1 that the maximum amount of the cation which is produced increases with increasing acid concentration.

For the spiro ortho esters the kinetic system has the form:

[7]



products

where k_1' is the pseudo-first-order rate constant for the ring-opening reaction at constant pH. The fraction of cation formed as a function of time is given by eq. [8] (23),

$$[8] \quad \frac{[\text{Cation}]}{A_0} = C(e^{-\lambda_2 t} - e^{-\lambda_1 t})$$

where A_0 = initial concentration of ortho ester (or total concentration of ortho ester, cation, and product), $C = k_1'/(\lambda_1 - \lambda_2)$, and $\lambda_1, \lambda_2 = (1/2)\,((k_1' + k_2 + k_{-1}) \pm ((k_1' + k_2 + k_{-1})^2 - 4k_1'k_2)^{1/2})$. In terms of absorbance this equation can be rewritten

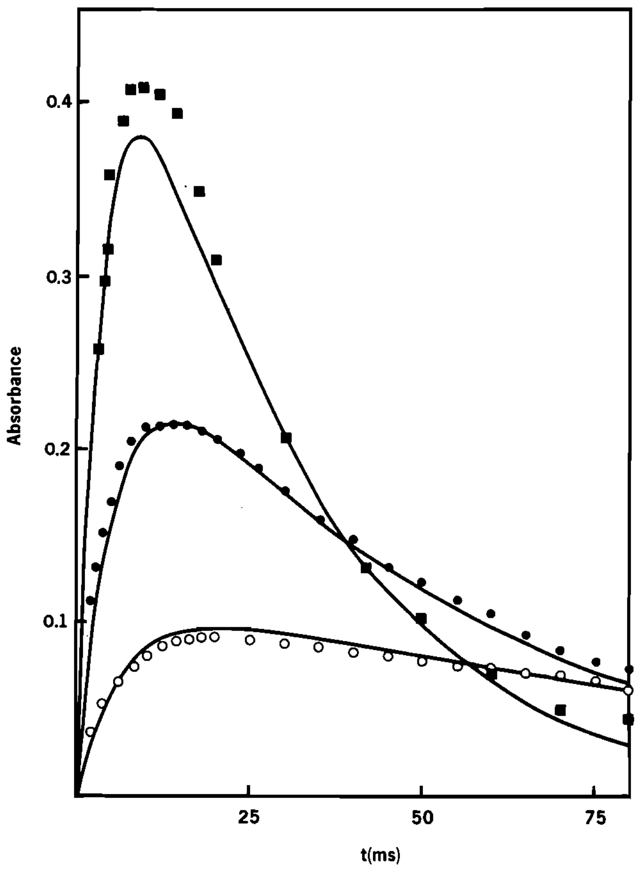

FIG. 1. Absorbance at 300 nm for the ortho ester **13** (3.5×10^{-5} M) in 0.028 M HCl (○), 0.078 M HCl (●), and 0.198 M HCl (■). The points are experimental. The curves are calculated using eq. [9] and the values of k_1, k_{-1}, and k_2 listed in Table 1. The curves have been normalized by having the maximum observed absorbance in 0.078 M HCl coincide with the calculated maximum in that acid (see text for explanation).

as follows,

$$[9] \quad \text{Absorbance} = \frac{A_0C}{\epsilon l}(e^{-\lambda_2 t} - e^{-\lambda_1 t})$$

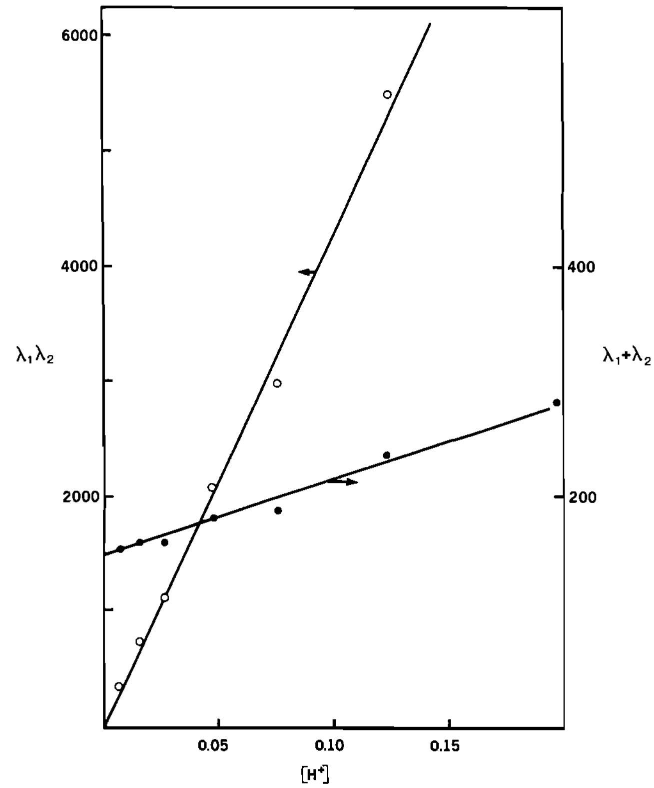

FIG. 2. Plots of the product of the relaxation coefficients $\lambda_1\lambda_2$ (○) and the sum $\lambda_1 + \lambda_2$ (●) obtained for the ortho ester **13** as a function of H^+ concentration.

where ϵ = extinction coefficient of the cation, and l = pathlength of the uv cuvette (2 cm). The stopped-flow instrument is linked to a digitization device which provides 118 absorbance–time readings per kinetic run. Using nonlinear least squares we have fit these data to eq. [9] to obtain values of λ_1 and λ_2 as a function of acidity. These are the relaxation constants (23) for this kinetic system (although this is not a relaxation process since amplitudes are large). A third parameter, $A_0C/\epsilon l$ is also provided by the curve fitting, but we have ignored these values in further calculations since the value of ϵ is unknown.

As a function of H^+ concentration the following relationships can be written for λ_1, λ_2

$$[10] \quad \lambda_1 + \lambda_2 = k_1[H^+] + (k_{-1} + k_2)$$

$$[11] \quad \lambda_1\lambda_2 = k_1k_2[H^+]$$

Both the quantities $\lambda_1 + \lambda_2$ and $\lambda_1\lambda_2$ are predicted to be linear in H^+ concentration, the latter with a zero intercept. Using data obtained with the ortho ester **13**, such plots are shown in Fig. 2, and the predicted forms are obviously obtained. The slopes and intercepts of these plots then provide the rate constants k_1, k_{-1}, and k_2. We illustrate these calculations in detail for **13** to indicate the magnitudes of the errors. The slope of the $\lambda_1 + \lambda_2$ plot gives k_1 directly, a value of $(6.6 \pm 0.6) \times 10^2 M^{-1} s^{-1}$. The slope of the $\lambda_1\lambda_2$ plot is equal to $(4.3 \pm 0.3) \times 10^4$, regardless of whether a zero intercept is enforced. This slope is equal to k_1k_2, so that by using the above value of k_1, k_2 can be calculated as 65 ± 10. The intercept in the $\lambda_1 + \lambda_2$ plot is 150 ± 10 and this is equal to $k_{-1} + k_2$. Since k_2 is now known, the value of k_{-1} can be calculated as 85 ± 14. A summary of these values along with those obtained for **14** is given in Table 1.

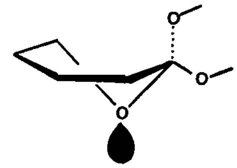
This analysis indicates that with both spiro ortho esters ring opening is reversible in that k_{-1} is greater than k_2. Evidence of the consistency in the analysis can be seen in Fig. 1 from the reasonable agreement between the experimental data and curves calculated on the basis of eq. [9] and the derived rate constants. One additional parameter is required in this calculation, the extinction coefficient of the cation. This has been calculated as 1.4×10^4 by forcing the maximum calculated absorbance in 0.078 M HCl to coincide with the maximum observed absorbance in that acid. All the other points in that particular curve and the two other curves then follow automatically. A second point of agreement can be seen between values of $k_1k_2/(k_{-1} + k_2)$ calculated on the basis of the HCl data and the experimental values of k_H(obs) determined at higher pH: 2.9×10^2 (calcd.) versus 3.5×10^2 for **13** and 5.5×10^3 (calcd.) versus 5.0×10^3 for **14**.

With the diethoxy ortho ester **10**, the k_{-1} process of eq. [7] can be ignored. A rise and fall in absorbance at 300 nm is observed. The rising portion of the curve can be analyzed to give a value of k_1 of 3.4×10^4 M^{-1} s^{-1}, in reasonable agreement with the k_H(obs) of 2.9×10^4 M^{-1} s^{-1} measured in phosphate buffer. The decay portion of the curves gives a value of k_2 of 23 s^{-1} for cation hydrolysis. (It can be noted that in acids more concentrated than 0.02 M HCl only the decay curve is seen, since cation formation is complete within the dead-time of the stopped-flow instrument.)

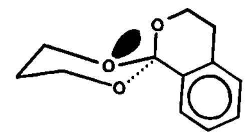
A trend can be noted in the k_2 values, namely $k_2(OCH_2CH_3) < k_2(OCH_2CH_2CH_2OH) < k_2(OCH_2CH_2OH)$. This same trend was previously observed with the tropone systems (see also Table 1). It can be explained by an electron-withdrawing inductive effect associated with the OH groups in the ring-opened cations. This destabilizes these cations, making them more reactive towards hydrolysis. The effect is more important with the ethylene compound where the hydroxyl group is closer to the cationic center, so that this is the most reactive.

With the diethoxy compound **10** as model, the decreased reactivity of the cyclic systems observed at higher pH (k_H(obs) values) can be dissected into a reversibility factor and an inherent difficulty in ring opening (see eq. [5]). The latter comes simply from a comparison of the k_1 values in the cyclic and acyclic systems. The former is measured by the extent to which $k_2/(k_{-1} + k_2)$ is less than unity. For the dioxolane system **13** the 80-fold decrease in k_H(obs) compared to **10** can be divided into a 40-fold decrease associated with k_1 and only a 2-fold decrease associated with reversibility. Thus in this system ring opening to the cation is inherently more difficult. With the dioxane system **14**, however, there is only a 6-fold decrease in reactivity compared to **10** and this is almost entirely due to reversibility since the value for k_1 for **14** is only slightly smaller than that for **10**.

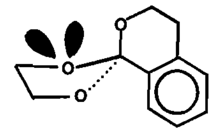
It is not immediately obvious why there should be a difference between the two cyclic systems. One possible interpretation involves lone pair orientation (19). (Although this principle has been challenged recently (24), it is probably applicable to ortho esters where transition states are not well advanced towards the oxocarbocation.) As shown in structure **20**, with both spiro ortho esters a lone pair on the oxygen of the dihydrobenzopyran ring can be placed in an orientation approximately antiperiplanar to an oxygen in the dioxolane ring or dioxane ring (dashed line). In the dioxane system, there is also a lone pair on the other oxygen in the dioxane ring that is an antiperiplanar arrangement (structure **21**), so that this system is well set up for bond breaking. With the dioxolane, on the other



20



21



22

hand, there is distortion caused by imposing the proper ring geometry (structure **22**). In the transition state for bond breaking this may prevent 100% conjugation with the other oxygen in the dioxolane ring, making this system inherently less reactive. This argument is tantamount to a Baldwin's rule (25) application. The ring opening in the dioxolane is a disfavored 5-*endo* trig reaction with respect to the dioxolane ring.

Interestingly, the difference in ring opening reactivity between the 5-cycle and 6-cycle is not seen in the tropone system. Here the k_1 values for the two are approximately the same, each being about 10-fold smaller than the value for the diethoxy compound (see Table 1). This may be related to different geometrical features in this system where the spiro junction involves a planar 1,3,5-cycloheptatriene. This can also be looked at in terms of an argument that in the tropone system the majority of the stabilization in the cations is associated with their being tropylium ions. Although the other ring oxygen results in some additional stabilization, the effect is small so that lone pair orientation is not so important.

In summary, both the dihydrobenzopyran ortho esters and the tropone acetals exhibit the same general behavior. Ring opening is reversible. There is not a significant difference between the dioxolane (ethylene bridge) and dioxane (trimethylene bridge) with respect to relative rates of cyclization versus water addition. In no case is there an overwhelming preference for ring closure; values of k_{-1}/k_2 have now been obtained which range from 1.2 to 4.2.

Evaluation of homogeneity of marine biological tissues for lead and cadmium by GFAAS

BYRON KRATOCHVIL, RAM S. THAPA, AND NORINE MOTKOSKY
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received February 26, 1985

BYRON KRATOCHVIL, RAM S. THAPA, and NORINE MOTKOSKY. Can. J. Chem. **63**, 2679 (1985).

Several marine biological tissues were tested for homogeneity with respect to lead and cadmium. The variance for the certified reference material TORT-1 is approximately 1 μg/g for each metal. This is of the same order as the heterogeneity of spray-dried dogfish and swordfish tissue. Scallop adductor muscle was of the same level of heterogeneity for cadmium; the lead content was below the limit of detection of the procedure used.

BYRON KRATOCHVIL, RAM S. THAPA et NORINE MOTKOSKY. Can. J. Chem. **63**, 2679 (1985).

On a fait des essais sur plusieurs types de tissus biologiques marins dans le but de déterminer leur homogénéité en plomb et en cadmium. Pour chacun des métaux présent dans l'échantillon de référence TORT-1, l'écart est d'environ 1 μg/g. Cet écart est du même ordre que l'hétérogénéité de tissus de la roussette ou de l'espadon séchés. Vis-à-vis du cadmium, le muscle de la coquille St-Jacques est du même ordre d'hétérogénéité; pour ce qui est du contenu en plomb, il est inférieur à la limite de détection de la méthode.

[Traduit par le journal]

The toxicity of heavy metals makes their determination in foodstuffs of major interest. Contamination of sea water by anthropogenic activity can cause bioaccumulations of heavy metals in marine life, particularly in economically important food species such as fish, lobster, clams, and mussels. For this reason, the accurate and precise determination of toxic elements in marine biological materials is important. To assist in the development and testing of analytical procedures for such elements a reference material, TORT-1, has been issued by the National Research Council of Canada through the Marine Analytical Chemistry Standards Program. This material was prepared from edible grade lobster tomalley (hepatopancreas) that had been spray dried and acetone extracted. The acetone extraction was performed to remove lipid components that affect stability on storage. Removal of the large amounts of lipids results in a concentration of trace elements in the material. The form in which heavy metals are present in this material is not known, but if more than one form is present distributions of the metals in the material may be affected (1). For this reason, and because many new analytical techniques require only small amounts of sample, the homogeneity of such a reference material is of interest. The concentration of lead in TORT-1 is reported to be 10.4 ± 2.0 μg/g, and that of cadmium 26.3 ± 2.0 μg/g, the uncertainties representing 95% tolerance limits for an individual subsample of 500 mg or greater. We were interested in determining the between-bottle homogeneity for lead and cadmium in samples below 50 mg (2). Single bottles of three additional spray dried marine biological materials, dogfish tissue, scallop adductor muscle, and swordfish tissue, obtained from the National Research Council of Canada, were also tested for homogeneity of lead and cadmium. The method chosen for this study was graphite furnace (electrothermal) atomic absorption spectroscopy with standard additions (3). This technique, with background correction and a L'vov platform, provides the sensitivity and selectivity required for determination of low levels of lead and cadmium in these materials.

Use of the L'vov platform (4−8) reduces matrix effects by allowing the analyte to vaporize into an atmosphere of higher temperature that favors quantitative atom formation. Addition of matrix modifiers such as $NH_4H_2PO_4$ (8) or Triton X-100 (9, 10) to digested solid samples may also reduce matrix effects by stabilizing the analyte or converting interfering sample components to volatile compounds that are removed during the ashing step.

Treatment of tissue samples before analysis ranges widely. Direct injection of freeze-dried (11), powdered (12), or untreated samples (8) has been used but problems with weighing of microgram test portions and with the ashing step make the procedure imprecise. Some of the weighing difficulties may be circumvented by injection of microliter volumes of slurries (13). Digestion of samples has been accomplished with enzymes (14), concentrated acids (7, 15−17) or dry ashing followed by dissolution in acid (18). A solvent extraction technique consisting of acid digestion followed by extraction of cadmium as dithizone complexes into an organic layer has been investigated (19). Still another separation technique involves vaporization of the sample followed by separation on a column (20). Most of these procedures give a precision for lead and cadmium of better than 10%.

For the work reported here digestion with nitric acid followed by a standard additions procedure and vaporization on a L'vov platform were found to give satisfactory results. Use of graphite furnace atomic absorption spectroscopy for the determination of lead or cadmium requires attention to numerous aspects of sample handling and furnace operation. Potential problems include memory effects in the graphite tube and platform and loss of lead or cadmium by adsorption from solution onto container walls with time or during the furnace charring step. Volatilization of lead during charring is reduced considerably by the presence of phosphate in the solution (21−24).

Experimental

Apparatus

The atomic absorption measurements were made on a Model 5000 spectrophotometer (Perkin-Elmer, Norwalk, CT) with background correction, an HGA 2200 furnace, and an AS-1 autosampler. Injected volumes were 20 μL. Pyrolytic graphite tubes with platforms (Perkin-Elmer Part No. B012-1091) were used (25). Operating conditions are given in Table 1. The argon purge gas flow was stopped during the atomization of lead, but was continued using the normal (40 cm^3/min) setting for the first 3 s during the atomization of cadmium. Peak areas were recorded on a Perkin-Elmer PRS-10 printer sequencer. Working curves were linear over the range 0 to 7.2×10^{-8} *M* lead (0 to 0.3 ng Pb per measurement) and 0 to 1.8×10^{-8} *M* cadmium (0 to 0.04 ng Cd per measurement). Blanks, carried through the same procedure as

the samples, were run on the instrument after every few sample measurements and the absorbance for the appropriate blank subtracted from the sample absorbances to correct for drift and furnace deterioration. Each solution was injected at least two, and generally three, times.

Reagents

Distilled water was further purified by passage through a column of mixed strong acid and strong base ion exchange resins (Amberlite MB-3, Rohm and Haas Co.). The nitric acid for sample dissolution was either Aristar (British Drug House) or Seastar (Seastar Chemicals, Sidney, B.C. Canada). All other chemicals were either analytical or reagent grade. Certified standard solutions of lead (Fisher Scientific) and cadmium (Spex Industries) were used to prepare calibration curves and for the standard additions.

For comparison and checking purposes, a standard reference material from the U.S. National Bureau of Standards, Oyster Tissue 1566, was analyzed for lead and cadmium, and a second material, Bovine Liver 1577a, was analyzed for cadmium.

Sample preparation

Six bottles of TORT-1, obtained from Marine Standards Analytical Program, Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R9, were tumbled end-over-end for 2 h. Approximately 5-g portions from each were then removed and dried in glass weighing bottles for 24 h at room temperature (23−24°C) in a vacuum oven (National Appliance Co. Model 5851-6) at approximately 0.06 mm Hg. The vacuum was produced with a pump (Welch Co.) separated from the oven by a dry ice − acetone cold trap. Previous studies had shown these drying conditions to be optimum. The dried samples were stored in closed weighing bottles in a desiccator over magnesium perchlorate.

Single bottles of spray dried scallops adductor muscle and swordfish tissue, also obtained from the National Research Council of Canada, Ottawa, were treated in the same way except that 48 h were required to bring the materials to constant weight. Dogfish tissue, obtained from the same source, was difficult to dry because the surface of the material tended to form a crust that slowed further drying. The procedure finally adopted involved recrushing of the clumps with a spatula every 6 to 8 h during the drying period. Even with intermittent crushing a total of 120 h was required to bring the material to constant weight. The total weight loss was of the order of 5%.

For the TORT-1 lead and cadmium analyses approximately 25-mg portions of the material were weighed to ±0.01 mg on a Mettler H-51 semimicro balance into 125-mL wide mouth FEB Teflon bottles (Nalgene 2100-0004). About 5 mL of 15.8 *M* nitric acid was added to each bottle, the bottle capped loosely with Tefzel closures, and the contents refluxed gently by placing the bottle in a sand bath at 130°C until dissolution was complete.

For the dogfish, sample sizes were about 0.05 g for the lead and 0.8 g for the cadmium determinations. Corresponding sample sizes were 0.8 g and 0.25 g for the swordfish, and 1.5 g and 0.125 g for the scallops. The dissolution procedure was the same as for TORT-1, except that the volume of nitric acid used for the dissolution had to be increased to as much as 15 mL for the largest samples. Other methods of sample dissolution were investigated and found to be less satisfactory (26). These included digestion at lower concentrations of nitric acid at ~180°C and digestion with various concentrations of nitric acid in a pressure cooker (27).

The digested solution was transferred to a 10-mL volumetric flask and diluted to volume. For the determination of lead, solutions for the standard additions procedure were prepared by pipetting from 0.6 to 2 mL of the sample solution, depending on the lead concentration, into each of four or five 10-mL volumetric flasks and adding from 0 to 0.15 mL of a solution containing 1 μg lead per mL with a variable micropipet (Soccorex 5-25 μL, Cat. No. 841). Next, 0.5 mL of ammonium dihydrogen orthophosphate (0.1% in 1% HNO_3) was added to each flask and the volume was made to the mark with 1% HNO_3. These solutions were then run immediately on the atomic absorption spectrophotometer. Solutions that were allowed to stand for several hours or overnight gave low and erratic results. A plot of absorbance against added lead was then drawn and the intercept on the horizontal axis used to calculate the lead present in the sample solution (28). The value of the intercept was obtained both graphically and by calculation of the least-squares intercept.

The same method was followed for cadmium except that sample volumes ranged from 0.1 to 2 mL, and the volumes of standard cadmium solution (1 μg Cd per mL) added ranged from 0 to 20 μL. Also, the addition of ammonium dihydrogen orthophosphate was omitted because its use did not improve precision or accuracy.

Results and discussion

Results for the lead study are summarized in Table 2 and those for cadmium in Table 3. The uncertainty in the measurement step can be estimated from the variance in the intercept as calculated by least squares. The overall uncertainty, which includes both the measurement and subsampling variances, can be obtained from the variance of the results for a set of measurements on individual subsamples. The difference between these two values is the subsampling variance. From the precision of the values obtained for TORT-1 on replicates from single test portions by least-squares calculations on standard additions it can be concluded that random errors in the measurement operations are sufficiently smaller than the subsampling uncertainty that the variation observed between individual test portions can be ascribed to sample variability. Results on duplicate test portions from individual bottles for TORT-1 (all bottles for Cd, one for Pb) show variations of the same magnitude as between bottles. Although more analyses would be required to establish with a high level of confidence the extent of the within-bottle variance, on the basis of results observed in studies of other elements it is likely to be of the same order as the between-bottle variance. A further conclusion is that the 95% tolerance limits (29), 4.1 μg for lead and 6.1 μg for cadmium, for individual subsamples of 30 mg are no more than two and one half times greater than those provided by NRC for 500-mg subsamples. Accordingly, for the determination of lead and cadmium in TORT-1 a subsample

size of up to a factor of 10 less than 500 mg can be taken with reasonable probability that the subsampling error will not exceed the specified tolerance limits of ±2 µg/g.

From the precision of the least-square values obtained for cadmium on individual subsamples of dogfish, scallops, and swordfish, it can be concluded that the subsampling uncertainty for these materials is of the same order or less than the measurement uncertainty. The heterogeneity of the material, therefore, does not contribute significantly to the overall analytical uncertainty. The variability in the dogfish tissue was somewhat higher for cadmium but about the same for lead as for the other materials. The dogfish tissue, unlike the finely powdered lobster, scallops, and swordfish material, contained many small clumps and some stringy material. This heterogeneity in physical properties might be expected to lead to greater variability in composition at the trace level, but evidence for this was not strong.

No lead was detected in the scallops muscle, even in samples of 1.5 g. The limit of detection for lead by the procedure used is estimated to be of the order of 0.2 ng per mL; therefore the lead content is less than 0.01 µg/g.

Acknowledgements

The assistance of E. Stubley with data treatment is gratefully acknowledged. Also, we thank S. Hrudey and W. George of the Department of Civil Engineering, University of Alberta, for the use of the atomic absorption spectrophotometer and furnace.

Correlations between carbon-13 nuclear magnetic resonance and X-ray crystallography for pyrroles containing electron-withdrawing groups

J. B. PAINE III, D. DOLPHIN, J. TROTTER, AND T. J. GREENHOUGH
The Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received July 24, 1984

J. B. PAINE III, D. DOLPHIN, J. TROTTER, and T. J. GREENHOUGH. Can. J. Chem. **63**, 2683 (1985).

The ^{13}C nmr chemical shifts of benzyl 4-ethyl-3,5-dimethylpyrrole-2-carboxylate (**1**), methyl *E*-3-(3-ethyl-4,5-dimethylpyrrol-2-yl)-2-cyanopropenoate (**2**), and methyl *E*-3-(5-(benzyloxy)carbonyl-3-ethyl-4-methylpyrrol-2-yl)-2-cyanopropenoate (**3**) have been compared to their X-ray crystallographic structures. The ^{13}C nmr chemical shifts were determined by direct comparison of a series of closely related homologs.

Crystal data for **1**, **2**, and **3** are as follows: **1**, monoclinic, $P2_1/c$, a = 14.934(2), b = 6.674(2), c = 15.269(2) Å, β = 101.96(1)°, Z = 4; **2**, monoclinic, $P2_1/n$, a = 7.3030(3), b = 13.478(1), c = 12.985(1) Å, β = 97.48(1)°, Z = 4; **3**, monoclinic, $P2_1/c$, a = 11.157(2), b = 13.109(2), c = 14.068(1) Å, β = 115.47(1)°, Z = 4. The structures were determined with diffractometer data by direct methods, and refined by full-matrix least-squares techniques to R = 0.052, 0.040, 0.038 for 862, 2032, 1483 reflexions, respectively. The molecules are approximately planar, except for deviations of the phenyl rings and of the terminal carbon atoms of the C_3-ethyl groups from the molecular planes. The bond lengths in the pyrrole rings differ from those in pyrrole itself, as a result of the presence of the strongly electron-withdrawing sustituents; exocyclic bond lengths also exhibit differences from normal values.

The competitive effects of the various electron withdrawing groups have been correlated to change in bond lengths, ^{13}C chemical shifts, and the chemical reactions of the pyrrolic nucleus.

J. B. PAINE III, D. DOLPHIN, J. TROTTER et T. J. GREENHOUGH. Can. J. Chem. **63**, 2683 (1985).

On a comparé les déplacements chimiques en rmn du ^{13}C de l'éthyl-4 diméthyl-3,5 pyrrolecarboxylate-2 de benzyle (**1**), de l'(éthyl-3 diméthyl-4,5 pyrrolyl-2)-3*E* cyano-2 propèonate de méthyle (**2**) et du ((benzyloxy)carbonyl-5 éthyl-3 méthyl-4 pyrrolyl-2)-3*E* cyano-2 propèonate de méthyle (**3**) avec leurs structures déterminées par cristallographie de rayons x. On a déterminé les déplacements chimiques de ces composés en rmn du ^{13}C en se basant sur une comparaison directe avec une série d'homologues très voisins.

Le composé **1** est monoclinique et il appartient au groupe d'espace $P2_1/c$ avec a = 14,934(2), b = 6,674(2), c = 15,269(2) Å, β =101,96(1)°, Z = 4; le composé **2** est monoclinique et il appartient au groupe d'espace $P2_1/n$, avec a = 7,3030(3), b = 13,478(1), c = 12,985(1) Å, β = 97,48(1)°, Z = 4; le composé **3** est monoclinique et il appartient au groupe d'espace $P2_1/c$, avec a = 11,157(2), b = 13,109(2), c = 14,068(1) Å, β = 115,47(1)°, Z = 4. On a déterminé les structures par des méthodes directes et on les a affinées par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs respectives de R de 0,052, 0,040, 0,038 pour 862, 2032 et 1483 réflexions. Les molécules sont approximativement planes à l'exception des déviations, par rapport aux plans moléculaires, des cycles phényles et des atomes de carbone terminaux des groupes éthyles C_3. Les longueurs de liaison dans le cycle du pyrrole diffèrent de celles du pyrrole lui-même en raison de la présence de substituants fortement électroattracteurs. Les longueurs des liaisons exocycliques diffèrent également des valeurs normales.

On a établi une corrélation entre les effets concurrents de divers groupes électroattracteurs et les variations des longueurs de liaison, les déplacements chimiques en rmn du ^{13}C et les réactions chimiques du noyau pyrrole.

[Traduit par le journal]

Introduction

There have been few reports on the ^{13}C nmr of pyrroles even though this spectroscopic technique has been skilfully used to elucidate the biosynthesis of tetrapyrrolic macrocycles (1, 2). Lauterbur (3) was the first to show that non-alternant hydrocarbons exhibit much larger ^{13}C shieldings than alternant hydrocarbons and Grant and his colleagues (4, 5) have examined substituted and charged five-membered aromatic heterocycles. As with many homologous series a variety of empirical correlations between ^{13}C chemical shifts and substitution patterns has been made. Abraham *et al.* (6) have assigned the ^{13}C nmr of 55 variously substituted pyrroles which allowed them to describe specific substituent chemical shift effects (SCS). However, they found that the additivity of SCS effects frequently gave discrepancies of ~5 ppm. Additional allowances for steric compression shifts (7) improved their correlations. However, compounds with carbonyl groups directly attached to the pyrrolic nucleus did not give good agreement between "calculated" and observed chemical shifts. Carbonyl groups are, of course, electron-withdrawing and their anomalous behaviour coupled with the greater effects of α- compared to β-substituents led to the suggestion that resonance was involved. These authors (6) speculated as to whether this effect resulted from changes in electron densities or ring geometries. π-Charge densities were calculated using the INDO approximation, but since this assumes a fixed geometry the question as to changes in ring geometry with substitution pattern remained unanswered.

We report here the X-ray crystallographic structures of the pyrroles **1**–**3** which bear electron-withdrawing groups. Their ^{13}C nmr spectra have been assigned and correlations between ^{13}C chemical shifts, molecular structure, and chemical reactivity are presented.

Experimental methods

Benzyl 4-ethyl-3,5-dimethylpyrrole-2-carboxylate (8) (1)

Compound (**1**) was prepared by an *in-situ* diborane reduction of benzyl 4-acetyl-3,5-dimethylpyrrole-2-carboxylate (9), effected in a manner similar to the procedure of Whitlock and Hanauer (10), or via a high temperature modification (11) of the base-catalyzed transesterification (8) of ethyl 3-ethyl-4,5-dimethylpyrrole-2-carboxylate. The product crystallized from methanol as yellow plates.

mmol) and methyl cyanoacetate (2.52 g, 25.5 mmol) were heated (steambath) in toluene (50 mL) with triethylamine (2 mL) and acetic acid (1 mL) until tlc (CH_2Cl_2, silica) showed the reaction to be nearly complete (5 h). The solvent was removed *in vacuo*, and chased with methanol. The product was stirred in methanol, filtered, washed with methanol then ether, to give after air drying 2.96 g (60%). On standing the filtrates deposited magnificent transparent golden diamonds which were used for the X-ray analysis. Mp 135.5−138.5°C. *Anal.* calcd. for $C_{13}H_{16}N_2O_2$: C 67.22, H 6.94, N 12.06; found: C 67.34, H 6.98, N 12.12.

Methyl E-*3-(5-(benzyloxy)carbonyl-3-ethyl-4-methylpyrrol-2-yl)-2-cyanopropenoate (3)*

5-Benzyloxycarbonyl-3-ethyl-4-methylpyrrole-2-carboxaldehyde (13) (20 g) in toluene (50 mL) was heated (steambath) with triethylamine (1 mL) for 1 h. The solvent was removed *in vacuo*, and the product crystallized, as golden chunks, from methanol to give, after air drying 21 g (87%). Mp 124.5−125.1°C. *Anal.* calcd. for $C_{20}H_{20}N_2O_4$: C 68.17, H 5.72, N 7.95; found: C 68.24, H 5.78, N 7.91.

X-Ray crystal analysis of ***1**, **2**, **3***

Data were measured in an Enraf-Nonius CAD4-F diffractometer, as outlined in Table 1. Additional data for all three compounds are $\sigma^2(I) = S + B + (0.05S)^2$, S = scan count, and B = normalized background count; LP but no absorption corrections. Structures were determined by direct methods, and refined by full-matrix least-squares techniques,[1] with minimization of $\Sigma w(F_o - F_c)^2$; $R = \Sigma(F_o - F_c)/\Sigma F_o$, $R_w = [\Sigma(F_o - F_c)^2/\Sigma F_o^2]^{1/2}$. Scattering factors are from refs. 14 and 15; and extinction correction as in refs. 16 and 17. Atomic positional parameters are listed in Table 2, and other material has been placed in the Depository of Unpublished Data.[2] Due to poorer crystal quality, the intensity data for **1** are less extensive than and the structural results not as accurate as for **2** and **3**, as reflected in the higher standard deviations for the parameters of **1**; comparisons involving **1** are therefore of less statistical significance.

Carbon-13 nmr spectral data were recorded on a Varian CFT-20, using saturated solutions in $CDCl_3$ and 10 mm diameter sample tubes with TMS as an internal standard.

[1]The computer programs used include locally written programs for data processing and locally modified versions of the following: MULTAN 78, direct methods by P. Main, S. E. Hull, L. Lessinger, G. Germain, J. P. Declercq, and M. M. Wolfson; TANS, direct methods by M. G. B. Drew, D. H. Templeton, and A. Zalkin; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin, and H. A. Levy; FORDAP, Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

[2]Anisotropic thermal parameters, hydrogen positional and isotropic thermal parameters, bond lengths and angles, mean planes, and structure factors may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

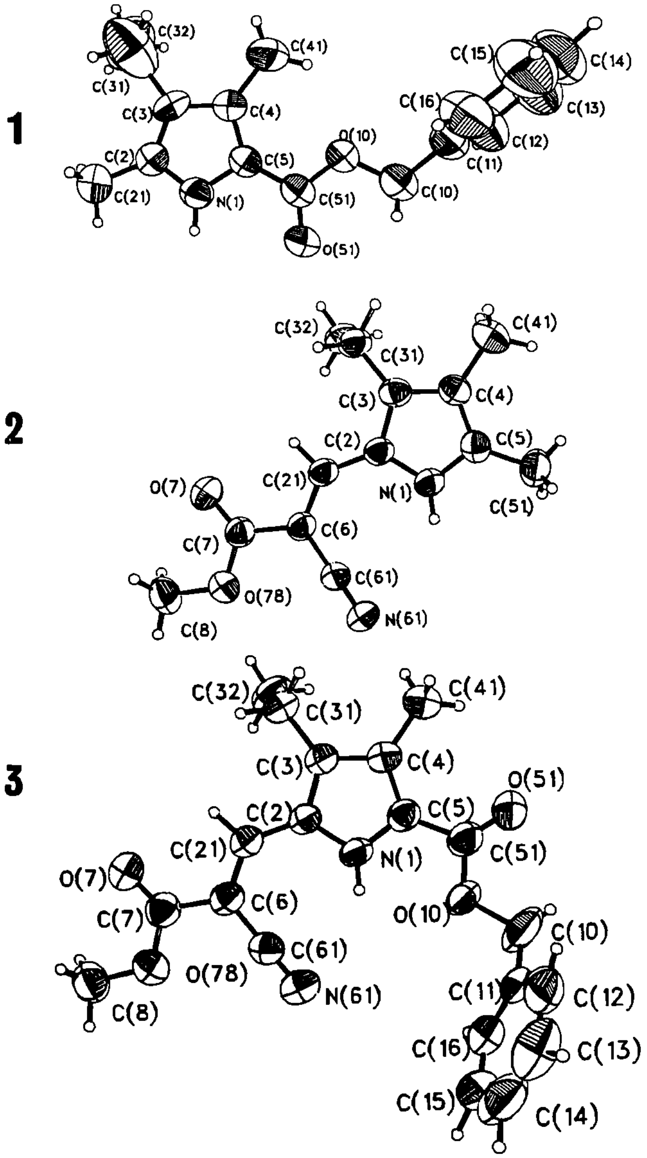

FIG. 1. ORTEP drawings of **1**, **2**, and **3**.

Results and discussion

The molecules of **1**, **2**, and **3** (Fig. 1) are approximately planar, except for the phenyl rings of the benzyloxycarbonyl substituents, which make angles of about 70° with the planes of the remainder of the molecules, and the terminal carbon atoms of the C_3-ethyl groups which are displaced by the order of 1 Å from the molecular planes. In more detail:[2] in **1** and **3** the $C—CO_2—CH_2$ planes make angles of 5.0 and 4.6°, respectively, with the planes of the pyrrole rings, and 68.4 and 74.3° with the phenyl planes; in **2** and **3**, the methoxycarbonyl groups make angles of 2.3 and 3.1°, respectively, with the pyrrole planes. The terminal ethyl C(32) atoms are displaced from the pyrrole planes by 1.0, 1.4, and 1.4 Å in **1**, **2**, and **3**, respectively.

The cyano(methoxycarbonyl)vinyl substituents in **2** and **3** are similarly oriented (Fig. 1). The cyano group is *cis* and the methoxycarbonyl group is *trans* to the pyrrole ring (with respect to the vinyl C=C bond); the vinyl C=C bond and the C(2)—N pyrrole ring bond have a *syn* conformation about C(2)—C(21), possibly because of the favourable *anti* arrange-

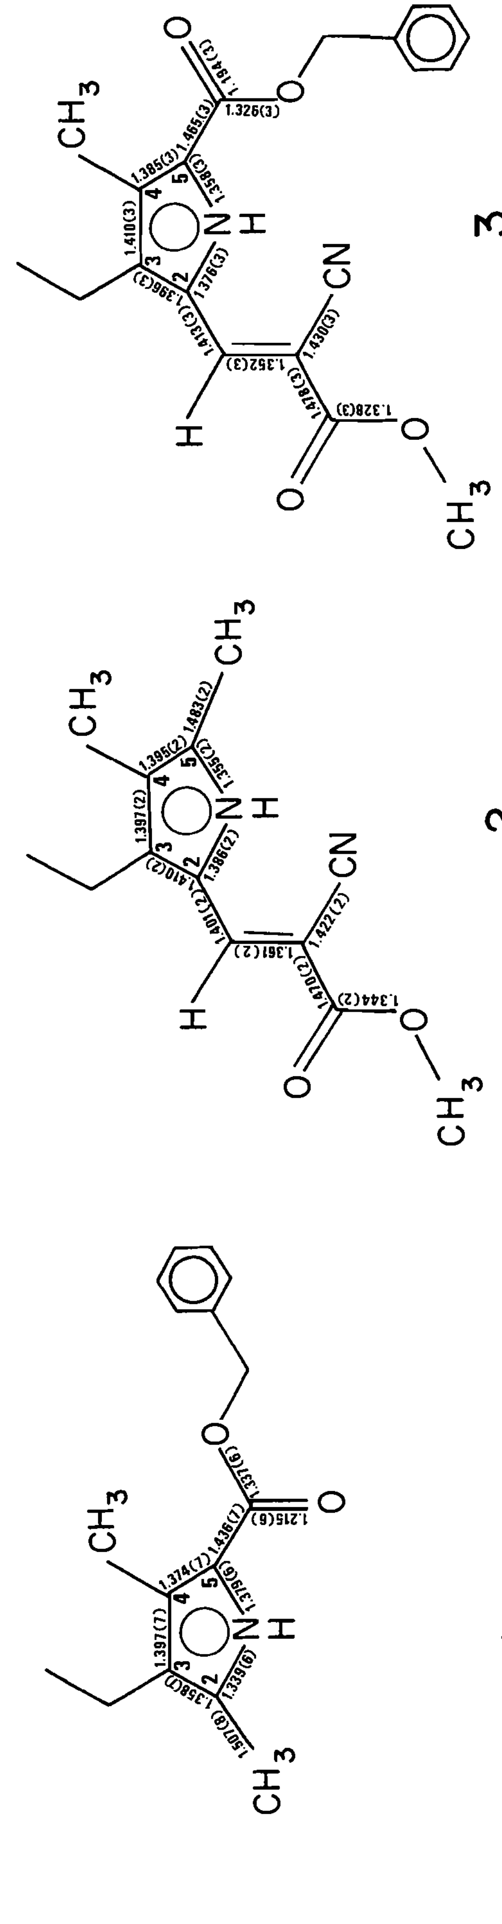

FIG. 2. Principal bond lengths for compounds **1**, **2**, and **3**.

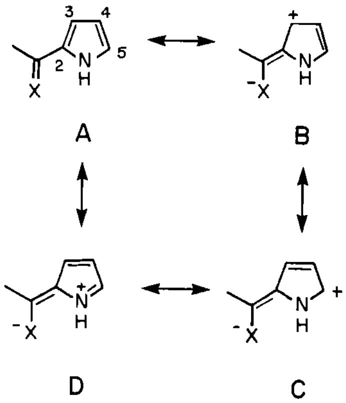

FIG. 3. Principal canonical forms for a pyrrole bearing an electron-withdrawing group in the α-position.

ment of C(21)=C(6) and C(2)=C(3). Such a conformation also minimizes steric interaction with the ethyl substituent. The benzyloxycarbonyl substituents in **1** and **3** have *different* conformational arrangements (Fig. 1); in **1** the C=O bond is *syn* to C(5)—N about C(5)—C(51). In **3** the whole group is rotated 180° about C(5)—C(51) to give an *anti* C=O/C(5)—N conformation; this may result from electrostatic repulsion between the two polar C=O and C≡N groups which would occur in a *syn* arrangement.

The chemically-interesting bond distances are illustrated in Fig. 2, and a full listing of distances and angles is given in the supplementary material.[2] The bond lengths in the pyrrole rings differ significantly from those in pyrrole itself (18), as a result of the presence of the strongly electron-withdrawing substituents. Four principal canonical structures (*A–D*, Fig. 3) may be drawn for a pyrrole α-substituted by an electron-withdrawing group capable of mesomeric interaction; these lead to an expectation of a decrease, relative to pyrrole, of the length of the C—N bond remote from the electron-withdrawing substituent, i.e., C(5)—N if the substituent is at C(2); C(2)—N should probably increase as a result of overall removal of electron-density from the ring. C(2)—C(3) should show a marked increase in length relative to pyrrole (resonance forms *B*, *C*, *D*), C(3)—C(4) a decrease (*D*, *C*), and C(4)—C(5) a smaller increase (*D*, *C*).

These differences are clearly observed in the structure of **2**. Comparison can be made with pyrrole itself whose structure has been determined by microwave spectroscopy in the gas phase (18*a*). These microwave data are quite accurate, but may suffer from vibration–rotation erros of up to 0.005 Å; taking this error estimate as 2–3σ, the N—C(2), C(2)—C(3), C(3)—C(4) distances in gaseous pyrrole are 1.370, 1.382, 1.417 (σ ~ 0.002) Å. Since spectroscopically-determined bond lengths may differ from those measured by diffraction methods in the solid state, comparison with bond lengths measured in the solid would be more appropriate. However, it is difficult to find accurate data for unsubstituted pyrrole; data for molecules in which substituents have no mesomeric interactions (18*b*, *c*) suggest lengths of 1.38, 1.37, 1.41 (σ ~ 0.003) Å for the three bonds, although these values may be slightly affected by inductive effects (18*b*).

The C(5)—N bond of 1.370 Å is gaseous pyrrole (or 1.38 Å in solid pyrroles) is shortened by 5σ (or 7σ) to 1.355(2) Å in **2**, and C(2)—N is lengthened by 6σ (or only 1.7σ) to 1.386(2) Å; the C(2)—C(3), C(3)—C(4), C(4)—C(5) distances in **2** are 1.410(2), 1.397(2), 1.395(2) Å, i.e. changes of +10, −7, +5σ, respectively, from the gaseous pyrrole distances (+11, −4, +7σ relative to solid pyrroles). Similar trends are found in **1**, although the poorer accuracy makes the differences less significant. The C—N bond remote from the benzyloxycarbonyl group (labelled C(2)—N here, since the group has been placed at position 5 to facilitate comparison with compound **3**) is shortened by 5σ (or 6σ) to 1.339(6) Å; the adjacent C—N bond at 1.379(6) Å does not differ significantly from that in pyrrole. The pyrrole C—C bond lengths in **1** are in the expected relative order, with the bond opposite the benzyloxycarbonyl substituent shorter at 1.358(7) Å than the adjacent C—C bond of 1.374(7) Å, although the difference is not statistically significant. The C(3)—C(4) bond of 1.397(7) Å is again shorter than the 1.417 (1.41) Å of pyrrole as expected, but the difference is again only 1.8σ (1.7σ).

The exocyclic bond distances add supportive evidence for contributions from canonical forms *B*, *C*, and *D* not only when compared with "normal" bond lengths, but also between themselves. In **2** the C(2)—C(21) distance is 1.401(2) Å, considerably shortened from the normal C(sp^2)—C(sp^2) single bond distance of 1.474 Å (19); the vinyl C=C bond of 1.361(2) Å shows an increase from the normal ethylenic bond distance of 1.335 Å, and the C—CN distance of 1.422(2) Å a decrease from the corresponding length of 1.46 Å in alkyl cyanides (20). In the less accurately determined **1**, the exocyclic C—C bond is again shortened, to 1.436(7) Å.

Many of these bond length variations have been observed in a few other pyrrole derivatives (21). Bond angles[2] show only minor variations from those in pyrrole.

When two electron-withdrawing groups are introduced in the C(2) and C(5) positions, as in **3**, the changes in structural effects are not additive, nor are the changes in the ^{13}C nmr parameters (see below). The electron-withdrawing power of one such group is diminished by the presence of the other, which is competing for available electron-density. As expected, the more-powerful cyano(methoxycarbonyl)vinyl group dominates, with the C(5)—N bond remote from this group shortened to 1.358(3) Å relative to pyrrole, 1.370 (1.38) Å, and to the C(2)—N bond in **3**, 1.376(3) Å; similarly the C(2)—C(3) bond adjacent to the more powerful group is lengthened, 1.396(3) Å, compared to pyrrole, 1.382 (1.37) Å, or to the C(4)—C(5) bond 1.385(3) Å. The sequence of bonds C(2)—C(3), C(3)—C(4), C(4)—C(5) at 1.396(3), 1.410(3), 1.385(3) Å, varies less from the values in pyrrole, than does the corresponding sequence in the compounds with only one electron-withdrawing substituent, **1** and **2**.

The exocyclic bond lengths in **3** are also in accord with reduced electron-withdrawing as a result of competition between the two groups. For the cyanomethoxycarbonylvinyl group, C(2)—C and C=C at 1.413(3), 1.352(3) Å show less extreme differences from normal values (1.474, 1.335 Å) than do the corresponding bonds in **2** (1.401(2), 1.361(2) Å). For the benzyloxycarbonyl group, C(5)—C at 1.465(3) Å is again much closer to 1.474 Å than the bond in **1**, 1.436(7) Å; the C=O bond of this group in **3** is situated *anti* to the C(5)—N bond and is the shortest C=O bond in all the molecules at 1.194(3) Å, again indicative of reduced electron-withdrawing properties.

Other bond lengths and angles in all the substituent groups[2] are close to normal values.

The crystal structures of **1** and **2** contain pairs of molecules joined around centres of symmetry by intermolecular hydrogen bonds. In **2** the hydrogen bonding is of the type N(pyrrole)—

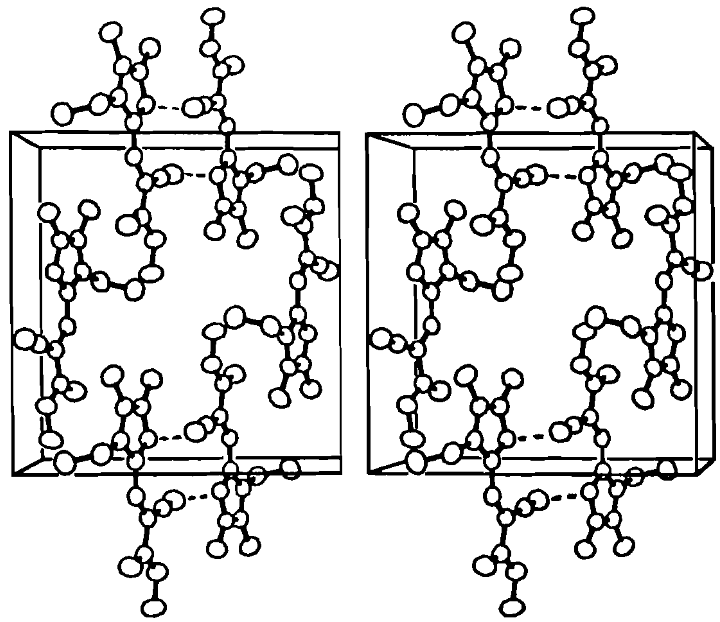

FIG. 4. Hydrogen bonding scheme for **2**; origin at upper left, x towards viewer, y down, z across.

H···N(cyano) (Fig. 4). The parameters are N···N($2 - x$, $1 - y$, $-z$) = 3.065(2), N—H = 0.85(3), H···N = 2.27(3) Å, N—H···N = 156(2)°. The N(cyano)···N(cyano) distance between two molecules is 2.960(2) Å and the intramolecular N(cyano)···H separation is 2.85(2) Å; this might indicate a very weak bifurcation of the hydrogen bond, although the distances correspond to van der Waals interactions. Other intermolecular distances in **2** are normal. The crystal of **1** contains pairs of molecules with N(pyrrole)—H···O=C type hydrogen bonds, N···O($2 - x$, $-y$, $1 - z$) = 2.868(6), N—H = 0.90(5), H···O = 1.99(5) Å, N—H···O = 164(4)°.

In **3** there is no intermolecular hydrogen bonding, forces between molecules being of van der Waals type. The disposition of the substituents results in intramolecular N(pyrrole)···N(cyano) and N(pyrrole)···O(benzyloxy) distances of 3.279(3) and 2.615(2) Å, respectively; the corresponding H(N-pyrrole)···N(cyano) and H(N-pyrrole)···O(benzyloxy) distances are 2.48(2) and 2.34(2) Å, so that weak bifurcated intramolecular hydrogen bonding is possibly present.

The assigned ^{13}C nmr chemical shifts reported for compounds **1–3** (Table 3) were determined by direct comparison of a series of closely related homologues (Table 3). Replacement of a methyl by an ethyl group, for example, deshields the pyrrolic point of attachment by ~6–7 ppm (a β-effect) and shields *adjacent* pyrrolic positions by ~0.6 ppm (a γ-effect). A judicious choice of substituents allowed all resonances for the compounds in Table 3, including compounds **1–3**, to be unambiguously assigned. Changes in shielding may result from a variety of factors including the electronegativity of substituents, field effects and strain (associated with hybridization). To a first approximation ^{13}C chemical shifts vary linearly with electron density at the carbon atom and thus this spectroscopic technique can be used to examine the nature of bonding and electronic distribution within molecules. While both inductive and mesomeric effects can affect chemical shifts the mesomeric effects are frequently more important in aromatic systems even though α-effects are larger in unsaturated compared to saturated systems.

Carbon nuclei π-conjugated to an electron-withdrawing group suffer significant deshielding by mesomeric interactions. Dipolar resonance canonical forms readily indicate which carbon atoms can be expected to experience enhanced shielding. Interacting bonds may also suffer a change in bond order as a consequence of increasing contributions from *certain canonical forms*. It is thus reasonable to expect that correlations may exist between the magnitudes of deshielding (as measured by the ^{13}C chemical shift) and the importance of such canonical forms. These will show up as changes in bond order which can be measured by changes in bond length as measured by X-ray crystallography.

In the pyrroles under discussion (**1–3**) we have chosen to examine the effects of the benzyloxycarbonyl ($-\overset{\overset{\displaystyle O}{\|}}{C}-O-CH_2OC_6H_5$) and cyano(methoxycarbonyl)vinyl ($-CH{=}C(CN)CO_2CH_3$) groups attached to the pyrrolic nucleus. It has been observed experimentally, and it is of considerable synthetic importance (22) that the latter substituent is especially strongly electron-withdrawing which affects the ease of electrophilic aromatic substitution on the pyrrolic nucleus.

From the crystallographic results it is clear that the cyano(methoxycarbonyl)vinyl group is more electron-withdrawing than a simple ester function and this is reflected in the ^{13}C nmr spectra. An electronegative substituent at C_2 acting primarily through the π-system will affect the greatest deshielding at C_3 and C_5 (canonical forms *B* and *C*). The effect at C_2 has a component of both σ- and π-withdrawal, plus an unknown and unresolvable "substituent effect." Effects at C_4 reflect a "general" deshielding of the π-system, which is appreciable, but considerably less than that at the conjugated positions. It can be seen from Table 3 that the cyano(methoxycarbonyl)vinyl group effects nearly twice as much deshielding at C_3, C_4, and C_5 than the ester, and that for a specific compound C_3 is somewhat more affected than C_5. When compounds bearing both electron withdrawing groups are compared to those bearing only one (Table 4) the cyano(methoxycarbonyl)vinyl group dominates the ^{13}C nmr just as it dominates the structural features. However, the mutual interference noted above between

this and an ester group results in considerably smaller effects at C_2 and C_5 than at C_3 and C_4 as the charge-repulsion from the dipolar substituents removes the positive charge from the "ipso" position. Thus the marginal effect of introducing a second α-electron-withdrawing group falls mainly on the adjacent β-position. As can be seen from Table 3, addition of an ester has essentially no effect at C_4 or C_5 and is of opposite sign — slightly deshielding at C_5 and slightly shielding at C_4.

This electronic distribution is reflected not only in the pyrrole core, but in the substituents themselves. In the difunctional compound **3**, the benzyl ester carbonyl is *less* polarized, and occurs 2.26 ppm upfield from the mono-ester **1**. With the benzyl ester in opposition, the nitrile carbon occurs 2.35 ppm upfield, and the carbonyl 1.86 ppm upfield of the corresponding carbons in the mono-functional analogues. The effect is largest on the vinyl double bond itself; in the mono-substituted compound, where the cyanovinyl group has the sole access to the pyrrolic electron density, this bond is most polarized, with the negative charge shifting the 2-carbon 9.63 ppm upfield of the difunctional analog.

The competitive effects of the electron-withdrawing groups is reflected in the chemical reactivity of pyrroles bearing such groups. For example, in the synthesis of cyano(methoxycarbonyl)vinyl adducts from 2-formylpyrroles and methyl cyanoacrylate, the presence of an ester at C_5 greatly accelerates the rate of the reaction since with less electron-density available to it from the pyrrole ring, the formyl group becomes more electrophilic (22).

Hydrodynamic studies on micellar solutions of styrene–butadiene block copolymers in selective solvents

LEVENT ORANLI, PRATAP BAHADUR,[1] AND GÉRARD RIESS
Ecole Nationale Supérieure de Chimie de Mulhouse, France

Received March 28, 1984

LEVENT ORANLI, PRATAP BAHADUR, and GÉRARD RIESS. Can. J. Chem. **63**, 2691 (1985).

Hydrodynamic radius of micelles of several block copolymers in different selective solvents (for both types of blocks) was determined from photon correlation spectroscopy. The boundaries of micellar solutions in heptane (good solvent for polybutadiene block) and dimethylformamide (good solvent for polystyrene block) were established for polymers in terms of their molecular mass and block composition. The photon correlation spectroscopy data in combination with intrinsic viscosities of block copolymers in selective solvents were used to determine micellar molecular mass and aggregation number. The influence of temperature on the micelle size was examined. The block copolymer micelles could solubilize a certain amount of insoluble homopolymer within their insoluble core. ^{1}H nmr spectra were examined to study the influence of temperature on micellar systems.

LEVENT ORANLI, PRATAP BAHADUR et GÉRARD RIESS. Can. J. Chem. **63**, 2691 (1985).

Le rayon hydrodynamique des micelles de copolymères blocs formés dans différents solvants sélectifs de l'une ou de l'autre séquence a été déterminé par spectroscopie de photocorrélation. Pour ces copolymères du type polystyrène-*block*-polybutadiène on a défini le domaine d'existence des solutions micellaires dans l'heptane (solvant sélectif de la séquence polybutadiène) et dans le diméthylformamide (solvant sélectif de la séquence polystyrène) en fonction de la masse moléculaire et de la composition. La masse moléculaire des micelles et le nombre d'agrégation ont été déterminés sur la base de la viscosité intrinsèque des copolymères et des résultats de spectroscopie de photocorrélation. On a examiné par ailleurs l'influence de la température sur la taille des micelles et la solubilisation d'homopolymères dans le coeur de celles-ci. Les caractéristiques micellaires du système ont été étudiées par spectroscopie rmn du proton à différentes températures.

Introduction

Dilute solutions of block copolymers in selective solvent (a good solvent for one sequence but a poor solvent for the other) show the existence of micelles formed through a reversible closed association process in analogy to low molecular weight surfactants (1–3). Styrene–diene block copolymers have received much attention in the study of such polymeric micelles. The micelle formation in selective solvents (pure and mixed solvents) for each block has been studied using several techniques viz. light scattering (4–14), viscosity (4, 7, 9, 13–15), osmometry (12, 15, 16), ultramicroscopy (19), electron microscopy (19–21), gel permeation chromatography (20), nmr (22, 23), small angle X-ray scattering (17, 18, 24, 25), photon correlation spectroscopy (19, 26), and sedimentation measurements (10, 15).

In most cases block copolymers in solution showed the presence of spherical micelles over a wide concentration and temperature range which had narrow size distribution and were stable for long time. However, a few studies report the formation of unusually large particles which were examined to be polydispersed and unstable.

It is realised that the micellar behaviour of block copolymers largely depends upon their molecular characteristics (type, molecular mass, and block composition), the selectivity of solvent, temperature and concentration range studied. Despite several works cited above, the authors feel scarsity of systematic data describing the domains of micellar solutions formed by different block copolymers with varying molecular characteristics in different solvents and the influence of block copolymer characteristics, nature of solvent, temperature on the micellar characteristics (size, aggregation number, critical micelle concentration, etc...).

Generally, studies on styrene–butadiene block copolymers have been carried out in solvents selectively bad for polystyrene block (e.g. *n*-alkanes). Although Tuzar and Kratochvil (1) have studied micelles with polybutadiene core but these authors have always used a mixed solvent which may cause some complexities due to preferential adsorption. In this paper, both type of solvents are used to study micelles. Further, a large number of copolymers differing in molecular weight and block composition are used to observe the domains of molecularly dissolved solutions (perhaps unimolecular micelles), true micelles (multimolecular with narrow distribution, stable over a prolonged period), and aggregates of insoluble particles in the form of coarse and unstable suspension with wide distribution. Some tapered block copolymers are also considered in order to compare tapered and pure block composition on the micelle size and aggregation number. Micellar solutions prepared using tetrahydrofuran (good solvent for both the block) to dissolve the copolymer, adding the selective solvent and subsequently removing tetrahydrofuran resulted to real micelles and the technique has proved to be better than making micellar solutions of block copolymers directly in selective solvent by simple heating, particularly with relatively high molecular mass and high percentage composition of insoluble block when it was too difficult to dissolve the block copolymer even on heating for several hours.

Micellar size and aggregation number have been estimated from the hydrodynamic properties of micellar solutions as observed from photon correlation spectroscopy, a relatively new technique for studying micellar solutions, and viscosity. Influence of temperature and solubilization of insoluble homopolymers within the cores of micelles has been examined. The temperature effect on micellar solutions affecting monomer–micelle equilibrium has also been investigated using ^{1}H nmr.

Experimental

Several two block styrene–butadiene copolymers synthesised anionically were used. Some of them were prepared in the laboratory while others were of commercial origin. All these block copolymers

were characterised by gpc and nmr. The detailed specifications of the copolymers are shown in Table 1.

n-Alkanes (heptane, octane, decane, and dodecane), *N,N'*-dimethylformamide, *N,N'*-dimethylacetamide, and methyl ethyl ketone used as selective solvents for the block copolymers were of AnalaR grade.

The micellar solutions were prepared by using tetrahydrofuran unless stated otherwise. The block copolymers were first dissolved in small amounts of tetrahydrofuran to which the selective solvent was subsequently added. Tetrahydrofuran was then removed from the solution by distillation at 60°C. Enough care was taken in the removal of tetrahydrofuran which in turn may affect micellar characteristics of the block copolymers in selective solvents.

Stock solutions (1.5–2% by weight) of block copolymers, bluish transparent to milky opalescence in appearance (characteristics of micelles) and stable for several weeks were prepared. Dilutions were made from the stock solutions and each solution was filtered before measurements.

Photon correlation spectroscopy studies on micellar solutions of block copolymers were carried out using Coulter model N 4 to give the hydrodynamic radius of micelles.

The scattering angle was always 90°. Z-average diffusion coefficient of micelles, $\bar{D}_Z$, was calculated from the mean decay constant, $\bar{Q}$, of autocorrelation functions using the relationship

$$[1] \quad \bar{D}_Z = \frac{\bar{Q}}{2K^2}$$

where $K = (4\pi\, n \sin \theta/2)/\lambda$ is the scattering vector, θ is the scattering angle, n the refractive index of the medium, and λ the wavelength of light *in vacuo*.

The equivalent spherical hydrodynamic radius of the micelle, $R_{h,D}$ is then calculated, assuming the applicability of Stokes–Einstein equation,

$$[2] \quad R_{h,D} = kT/6\pi\eta\bar{D}_Z$$

where k is the Boltzmann constant, T, the absolute temperature, and η, the viscosity of solvent.

Measurements were generally made at 25°C at various concentrations between 0.1–1.5%. The diffusion coefficient (and thus the hydrodynamic radius) was determined by extrapolation to infinite dilution.

The viscosities were measured using Ubbelhode-type viscometer with electronic time registration. Essentially solutions were diluted till the solutions had bluish appearance. The intrinsic viscosities were calculated by extrapolating specific viscosities to zero concentrations.

The following equation relates hydrodynamic radius to the micellar weight

$$[3] \quad R^3_{h,\eta} = \frac{3[\eta]M^m}{10\pi N}$$

where M^m is the micellar weight, $[\eta]$ the intrinsic viscosity, N_A the Avogadro number, and $R_{h,\eta}$ the hydrodynamic radius of micelle obtained from viscosity.

Almost same values of hydrodynamic radii of micelles obtained from diffusion coefficient and viscosity data have been observed by various workers (27–29). We have therefore used $R_{h,D}$ instead of $R_{h,\eta}$ in eq. [3] to calculate the micellar weight and to estimate the aggregation number.

The ^{1}H nmr spectra of copolymer in heptane at various temperatures were recorded using a Bruker WP 80 CW instrument working at 80 MHz and attached to a temperature control unit (Bruker B-ST 100/700C). Enough time was provided for attaining the equilibrium of micellar solutions at different temperatures.

Results and discussion

Solutions of block copolymers in both the types of selective solvents behave in a quite peculiar way. Molecularly dispersed solutions, micellar solutions or unstable suspensions of block copolymers can be obtained depending upon the concentration and the molecular characteristics of block copolymer, solubility parameters of solvent with respect to the two blocks of the copolymer, and temperature. In general, increasing copolymer concentration, its total molecular weight, and the composition of the insoluble block favour the formation of micelles from truly molecularly dissolved solutions. Decrease in temperature and increase in precipitant nature of solvent shift the unimer $\rightleftharpoons$ micelle equilibrium to micelle side.

Micelles in each case were multimolecular, spherical in shape, and had low polydispersity. In *n*-alkanes the block copolymer micelles consisted of insoluble polystyrene core surrounded by the soluble fringes of polybutadiene. A reverse structure was observed in the other type of selective solvent. e.g., in DMF, DMA, and MEK.

(1) Micelles in various selective solvents

Micellar solutions of a few block copolymers were obtained by dissolution of the copolymers in both kinds of solvent (selectively good solvents for polybutadiene, viz. *n*-heptane, *n*-octane, *n*-decane, and *n*-dodecane as well as selectively good solvent for polystyrene viz. DMF, DMA, and MEK). Generally 1 g or less of the copolymer was dissolved in 100 mL of solvent by heating the copolymer–solvent mixture in closed tubes in a water thermostat at about ~60°C. For block copolymers in MEK the micellar solutions were obtained by heating at ~50°C.

As mentioned above, only a few copolymers formed micelles (characterised by bluish transparent tinge) whereas others were insoluble in the solvent (these showed phase separation or unstable suspension of the insoluble particles). Generally, dissolution of block copolymer above a certain critical value of insoluble block composition (which of course depends on total molecular weight and solubility parameter of the solvents) becomes difficult and results to the macro phase separation.

The size of these block copolymer micelles is shown in Table 2. Since the measurements of micelle size were carried out using photon correlation spectroscopy, the value expressed as hydrodynamic radius takes into account both the insoluble core (which depends upon the aggregation number) and soluble shell (which mainly depends upon the solubility of the soluble block in the solvent). For this reason, it is in fact usual to get different trend in R_h and N.

TABLE 2. Hydrodynamic radius, intrinsic viscosity, and aggregation number of block copolymer micelles in various selective solvents (the micellar solutions were prepared by dissolving the copolymer at ~60°C)*

	SB-7			Rh (nm)

MEK	—	—	—	i	34.5	55.0	38.0

*i = insoluble.

An examination of the data on R_h for copolymers in n-alkanes, it appears that the size of micelle does not differ much. The greater size for n-dodecane may be explained on account of the fact that the soluble chain is very much extended in spite of the fact that the micelle has least aggregation number. The decreasing trend in the aggregation number of micelles of styrene–butadiene block copolymers with increasing carbon chain length in n-alkane was observed by Stacy and Kraus (5).

The hydrodynamic radius of block copolymers in DMF, DMA, and MEK are also shown in Table 2. A comparison of size of various copolymers in these three solvents shows that the values for DMF and MEK are not much different. Higher values of micelle size in DMA were observed. The high hydrodynamic radius of micelles in DMA as compared to in DMF is explained due to the higher aggregation number (which increases the core size) and more extended soluble shell (due to the difference in solubility parameter). The hydrodynamic radius of micelles in MEK, where the soluble chain seems to be most extended may result from its very low aggregation number. However, this could not be verified in case of copolymer SB-7 which at concentrations studied (even up to ~3%) contains more of unimers and such solutions were more or less clear with very faint bluish appearance.

It was observed that the size and aggregation number has no influence on heating at temperature above 60°C. Even the micellar solutions of block copolymers formed by the dissolution of copolymer at temperature just below the boiling point of the respective solvent on cooling to the measuring temperature resulted the same size. Further, that repeated heating and cooling did not affect the micelle size and aggregation number. Of course, it is to be mentioned here that enough time was given for the equilibrium of the micellar solution at the measuring temperature. The micellar solutions were generally kept for 1–2 h at the measuring temperature before the measurement.

Further studies were confined to n-heptane and DMF taken as representatives of the two types.

(2) Micelles in n*-heptane and DMF (comparison of dissolution and THF technique)*

In Table 3 are compared the hydrodynamic radii of block copolymer micelles prepared in solution by simple dissolution of the copolymer at ~60°C or using small amounts of THF as the supporting solvent, added to dissolve the copolymer and was subsequently removed. It appears that for SB-7 and SB-1205 micelles in n-heptane, the size is practically the same. Increased size for ANIC C micelles in solution prepared from simple dissolution technique may be due to large proportion of bigger particles and broader distribution in micelle size. It may be said that increasing content of insoluble block and increase in total molecular weight may result in micellar solutions (obtained by simple dissolution) which are not perfectly homogeneous and the size of the micelles is greater than that in solution prepared using THF technique.

TABLE 3. Hydrodynamic radius of block copolymer micelles in n-heptane and DMF at 25°C (micellar solutions were obtained by the dissolution of copolymer at ~60°C or using THF technique)

		Rh (nm)	
Copolymer	Solvent	Dissolution technique	THF technique
SB-7	n-Heptane	30.5	32.5
ANIC C	n-Heptane	63.6	52.5
SB-1205	n-Heptane	41.5	41.5
SB-7	DMF	21.0	14.5
AN 28	DMF	55.8	29.0
AN 29	DMF	42.0	23.0

Larger difference in the micelle size of copolymers in DMF was seen in the solutions prepared using the dissolution technique or the THF technique. This probably accounts for a rather poor solvent nature for DMF.

As a general rule, it may be said that the two techniques may result in the micellar solutions of the same size when the insoluble block % is fairly low (<30%) and total molecular weight is not too high (~50 000). The advantage of the THF technique lies in the fact that for block copolymers with high content of insoluble block and high molecular weight, micelles of lower size than obtained by simple dissolution on heating can be obtained. In addition, the critical limit of insoluble block can be extended by using the THF technique and micellar solutions of block copolymers could be prepared which were otherwise not possible by the dissolution technique where the macro phase separation resulted. However, using the THF technique also it was possible to obtain micelles of block copolymers in both the solvents up to 60 wt.% of insoluble block for copolymers with molecular mass of about 100 000.

(3) Micelles in n*-heptane and DMF (THF technique)*

Table 4 shows the hydrodynamic radius, intrinsic viscosity, micellar weight, and aggregation number of several block copolymer micelles in n-heptane and DMF. A general observable feature is that micelle size and aggregation number increase

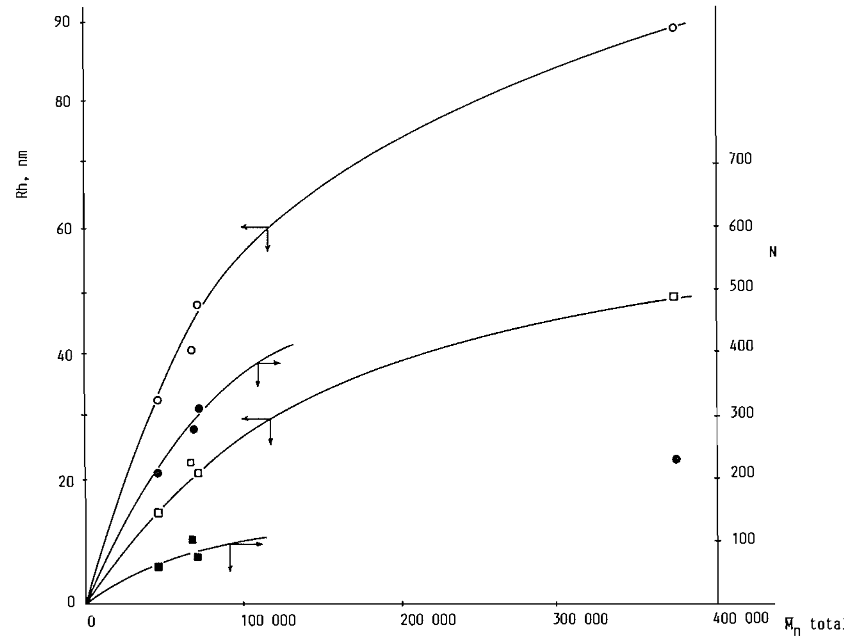

FIG. 1. Hydrodynamic radius and aggregation number of block copolymer (~50% PS) in n-heptane and DMF; ○ Rh in heptane, □ Rh in DMF, ● N in heptane, ■ N in DMF.

with increase in % insoluble block and increase in total molecular weight of copolymers. However, an additional feature is that the micelle radius as high as ~100 nm could be obtained and the aggregation number as high as ~312 was seen. Usually, the micelle size and aggregation number for the same block copolymer in n-heptane was higher compared to those in DMF. We could not observe very high micelle size and aggregation number for TX 006 (% PS 48, $\bar{M}_n$ total 375 000) in heptane as observed by Stacy and Kraus (5) and as predicted from the theoretical results of Noolandi and Hong (24). We have checked this point and results from solution of copolymers prepared at different times gave the same value.

Further experiments are necessary to check the micelle size and the aggregation number of more copolymers with high molecular weights.

Figure 1 shows R_h and N values for copolymers (~50% each of the blocks) micelles in n-heptane and DMF as a function of total molecular weight of the copolymer. A reasonably good trend in R_h and N values for the micelles in both solvents can be observed in this figure.

(4) Influence of temperature on micelles

The influence of temperature on the hydrodynamic radii of block copolymer micelles in n-heptane and DMF can be seen from Fig. 2. In both solvents, the hydrodynamic radius of micelles decreases. This decrease may be accounted for by the decrease in micellar weight or aggregation number. Similar decrease for styrene–butadiene block copolymer micelles in n-heptane has been observed by Plestil and Baldrian (17) and in tetrahydrofuran + allyl alcohol (where the micelle structure is similar to that in DMF) by Tuzar and Kratochvil (1). Of course, the relative proportion of unimers in the micellar solution increases with increasing temperature.

It was also interesting to examine the influence of temperature on ^{1}H nmr spectrum of block copolymer micelles. Spectra for SB-7 in n-heptane were recorded at different temperatures (Fig. 3). It is evident from Fig. 3 that no aromatic protons of polystyrene could be detected up to ~65°C. The

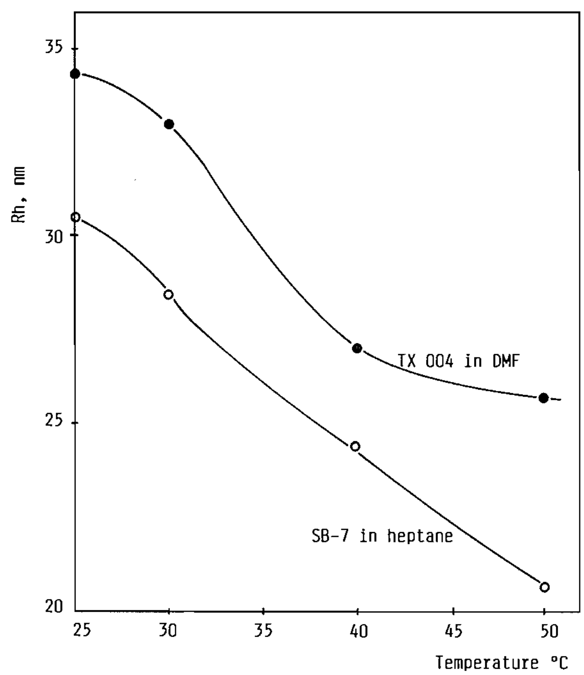

FIG. 2. Hydrodynamic radius of block copolymer micelles in heptane and DMF; ● TX 004 in DMF, ○ SB-7 in heptane.

undetectable polystyrene due to restricted motion of styrene units may account for the fact that at this temperature most of the block copolymer is in the micellar form. The small amount of unimers present may acquire the conformation similar to the so-called "unimolecular micelles", thus shielding the motion of styrene units. At the highest temperature studied i.e. 95°C, distinct peaks corresponding to polybutadiene and polystyrene were observed and calculation from integrated intensity gave the percentage composition of the two block as the actual value for the copolymer SB-7 (51% PS).

This indicates that at this temperature almost all of the co-

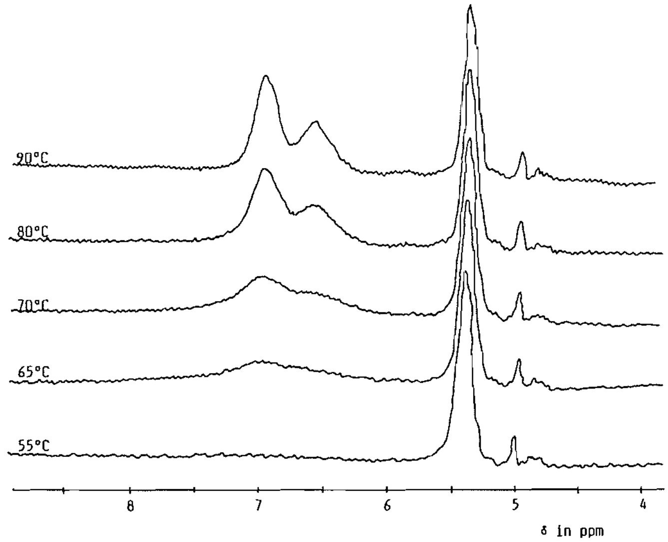

FIG. 3. ^{1}H nmr spectra of block copolymer SB-7 (concentration 5 g dL^{-1}) at different temperatures in *n*-heptane.

polymer is unimolecularly dissolved with free motion of styrene units of the polystyrene block. The nature of spectra in the intermediate temperature range is quite peculiar. On going above the temperature 65°C, broad peak of aromatic styrenic protons begins to appear, and becomes higher and narrower with a gradual increase in temperature. Several factors seem to be important here which may lead to the growth of mobility of styrene units with increase in temperature. These may be, for example, the disintegration of actual (polymolecular) micelles to unimers, the swelling of cores of micelles (both polymolecular and unimolecular), change in conformation of unimolecular micelles leading to free unimers, and the polydispersity effect in molecular weight and composition of copolymer. Different effects may be predominant in various temperature range till 95°C where the actual composition of copolymer was seen. A similar behaviour in ^{1}H nmr spectra for copolymer micelles as affected by temperature was observed by Spevacek (23).

(5) Solubilization of homopolymers

Homopolymers could be solubilized within the core of micelles of block copolymers. However, the extent of solubilization largely depended upon the molecular mass of homopolymer and of block copolymer sequence forming the insoluble core. It was only possible to solubilize homopolymer if its molecular mass did not exceed that of corresponding sequence of block copolymer. In general, lower molecular mass homopolymer enhanced the extent of solubilization. Also, it was observed that an homopolymer under certain conditions could be solubilized up to 50 wt.% of the copolymer. All the solubilized solutions had stability comparable to those of micellar solutions without any solubilized homopolymer.

Table 5 reveals some results on solubilization of polystyrene

TABLE 5. Solubilization of homopolymers within the core of micelles of block copolymers

homopolymer in block copolymer micelles in *n*-heptane and polybutadiene homopolymers in block copolymer micelles in DMF. An examination of the data clearly reveals that the micelle size increases (or in fact the core size) with increased amount of homopolymer solubilized and its molecular weight. More amount of homopolymer with low molecular weight could be solubilized than of high molecular weight. The increased size in the solubilized micelles seems to be quite reasonable. More experiments on solubilized micelles are in progress and will be published later.

Acknowledgements

The authors wish to acknowledge their thanks to P. Gaillard, CdF Chimie, for supplying some of the block copolymer samples, and to H. Strub for taking the ^{1}H nmr spectra.

MOHAMMED A. E. SALLAM, ROY L. WHISTLER, and JOHN M. CASSADY. Can. J. Chem. **63**, 2697 (1985).

Catalytic hydrogenolysis of daunomycinone (**4**) over palladium–carbon or palladium – barium sulfate afforded a mixture of 7-deoxydaunomycinone (**5**) and 7,11-dideoxydaunomycinone (**6**). 7-Deoxy-7-thioacetyldaunomycinone (**8**) and its 7-epimer (**9**) were prepared from **5** via the intermediate 7-deoxy-7-bromo derivative **7** in 33% yield. Compound **8** was prepared from **4** in a one-step reaction by treatment with thioacetic acid (THAA) and trifluoroacetic acid (TFAA), in 13% yield. Refluxing **4** in a mixture of THAA and glacial acetic acid (GAA) increased the yield of **8** and **9** to 83%. Epimerization of **9** with TFAA afforded **8**. Hydrolysis of **8** gave a mixture of thiodaunomycinone (**10**), **5**, and bisanhydrodaunomycinone (**11**). Compound **10** converts partially into its dimeric form (**12**) on standing.

MOHAMMED A. E. SALLAM, ROY L. WHISTLER et JOHN M. CASSADY. Can. J. Chem. **63**, 2697 (1985).

L'hydrogénolyse catalytique de la daunomycinone (**4**) sur des catalyseurs de palladium/charbon ou de palladium/sulfate de baryum conduit à un mélange de déoxy-7 daunomycinone (**5**) et didéoxy-7,11 daunomycinone (**6**). On a aussi préparé la déoxy-7 thioacétyl-7 daunomycinone (**8**) et son épimère en position 7 (**9**) avec un rendement de 33% en utilisant **5** comme produit de départ et en procédant par l'intermédiaire du dérivé déoxy-7 bromo-7 (**7**). Le traitement de **4** par de l'acide thioacétique (ATHA) et de l'acide trifluoroacétique (ATFA) conduit en une étape au composé **8**, avec un rendement de 13%. Si l'on porte le composé **4** au reflux dans un mélange d'ATHA et d'acide acétique glacial (AAG), on augmente le rendement de **8** et de **9** à 83%. L'épimérisation de **9** par de l'ATFA conduit à **8**. L'hydrolyse de **8** conduit à un mélange de thiodaunomycinone (**10**), de **5** et de bisanhydrodaunomycinone (**11**). Si on le laisse à la température ambiante, le composé **10** se transforme partiellement en sa forme dimère **12**.

[Traduit par le journal]

The anthracycline antibiotics, daunorubicin (**1**, $R^1 = CH_3$, $R^2 = H$) (2, 3), doxorubicin (adriamycin; **1**, $R^1 = CH_3$, $R^2 = OH$) (3, 4), and carminomycin (**1**, $R^1 = R^2 = H$) (5) are potent and clinically useful antitumor agents, with adriamycin having an especially broad spectrum of activity, extending to certain solid tumors that are normally resistant to most modes of chemotherapy. However, the clinical use of these drugs is hampered by a number of undesirable side effects, common to many antitumor drugs, such as severe alopecia, and dose-limiting and irreversible cardiotoxicity (6) (congestive heart failure), which have limited their optimum utilization in chemotherapy. The possible covalent bindings between C-7 and various biological nucleophiles have been suggested (7) as a basis for the toxic side effects of daunorubicin and adriamycin. Major efforts have been made to modify the anthracycline molecule with the objective of developing analogs with a wider spectrum of activity and reduced toxicity (8, 9). The synthesis of anthracycline analogs with various leaving groups (10) at C-7, and displacement of the 7-OH with O- and S-nucleophiles (11), have been described.

Rapid deactivation of these useful anticancer drugs takes place by hydrolytic or reductive cleavage of the glycosidic oxygen at position 7. The *C*-glycosyl analog **2**, in which the glycosidic oxygen atom is replaced by CH_2, was suggested to be more resistant (12) to rapid metabolic deactivation than the glycosidic oxygen-linked analog **1**. It might be incapable of generating alkylating activity at the 7-position, one mechanism of action proposed (10) as following ejection of the sugar from **1**. On the other hand, **2** should retain the DNA-binding properties (13) of the anthracyclines and the free-radical generating properties from cyclic reduction and reoxidation of the quinone (14, 15). The *C*-glycosyl analog **2** might also show favored biological effect upon testing and is expected to be a superior drug. *C*-Daunosaminyl intermediates required for the elaboration of the carbon-bridged anthracyclines have been reported (12).

The sulfur-bridged glycoside **3** is also expected to be considerably more stable (16) to reductive cleavage and hydrolysis in vivo than the glycosidic oxygen bond in **1**. In addition, replacement of the glycosidic oxygen by sulfur might possibly display or exhibit biological properties markedly different from the glycosidic oxygen analog, as expected for the carbon bridged analog **2**. In this work, replacement of the oxygen atom at C-7 of daunomycinone **4** by sulfur was explored to provide the aglycon part required for the elaboration of the sulfur-bridged analog **3**.

Catalytic hydrogenolysis of daunomycinone **4** with hydrogen over palladium – barium sulfate afforded a mixture of 7-deoxydaunomycinone (**5**) and 7,11-dideoxydaunomycinone (**6**) (Scheme 1). Reported (17) catalytic hydrogenolysis of the glycoside daunomycin or the aglycone **4** afforded only com-

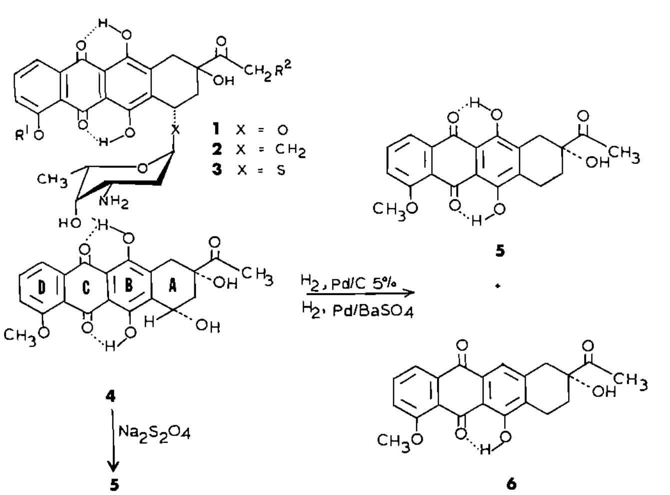
[a] Spectra recorded at 470 MHz in chloroform-*d*. Spin couplings (Hz) are given in parentheses. Signal multiplicities: b, broadened; d, doublet; m, multiplet; s, singlet; sbs, split broad singlet; t, triplet.



SCHEME 1

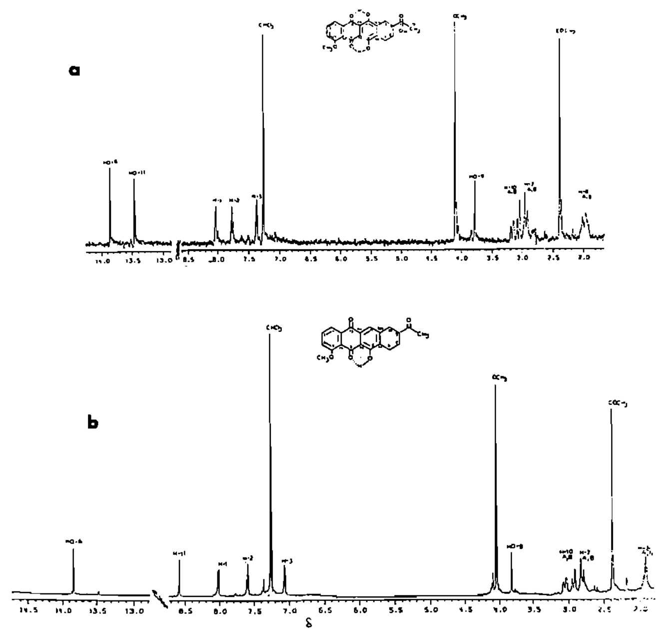


FIG. 1. The 470-MHz nmr spectra of (a) 7-deoxydaunomycinone **5** and (b) 7,11-dideoxydaunomycinone **6**.

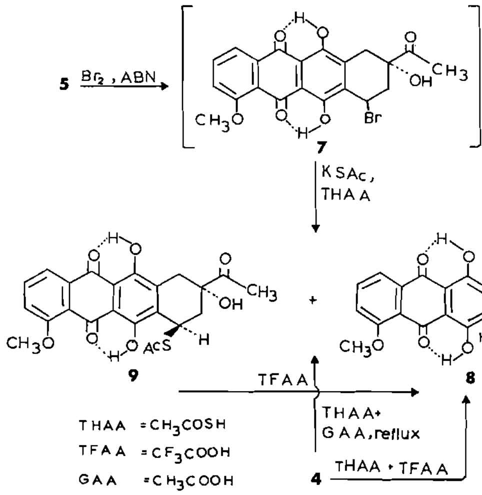
pound **5**. The nmr spectrum of compound **6** (Fig. 1) showed the absence of the singlet corresponding to the chelated phenolic 11-OH which is present at δ 13.449 for compound **5**, and the appearance of a down-field singlet corresponding to the aromatic H-11 at δ 8.580, instead (Table 1). The further downfield shift for the chelated phenolic 6-OH at δ 13.844 and δ 13.827 for compounds **5** and **6**, respectively, can be rationalized based on extended resonance (18) with the C-4 methoxy that can occur only for the 6-OH. The nmr spectral data for compound **6** are similar to those reported for the compound obtained by catalytic hydrogenolysis of the biologically active 11-deoxydaunoribicin or 11-deoxydaunomycinone (19). Chemical reduction of compound **4** with sodium dithionite (19–21) gives compound **5**.

Several attempts were made to introduce sulfur as a thioacetyl group at the 7-position of 7-deoxydaunomycinone in a reasonable yield. Treatment of compound **5** with bromine and a catalytic amount of 2,2′-azobisisobutyronitrile (ABN) in refluxing CCl_4 gave the unstable intermediate 7-bromo-



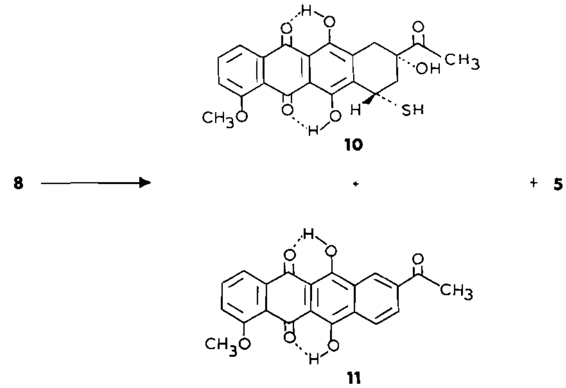
SCHEME 2

daunomycinone **7**. Wong *et al.* (22) postulated that steric hindrance about the 10-position allowed benzylic bromination to proceed regiospecifically at the 7-position. The bromine derivative **7** was treated with potassium thioacetate in a solution of thioacetic acid, giving a mixture of 7-thioacetyldaunomycinone **8** and 7-epithioacetyldaunomycinone **9** in 33% yield (Scheme 2).

In a one-step reaction, the 7-thioacetate **8** was prepared in 13% yield from **4**, by treatment with a mixture of thioacetic acid (THAA) and trifluoroacetic acid (TFAA) in the ratio of 5:2 at room temperature. This reaction mixture favors the formation of compound **8** with the stereochemistry of the natural 7,9-*cis* configuration at C-7. Replacement of TFAA with glacial acetic acid (GAA) and refluxing, gave a mixture of the thioacetate **8** and its epimer **9** in a ratio of 5:1 and in a total yield of 83%. The major isomer **8** was purified by recrystallization, and the minor isomer was separated from the mother liquor by chromatography. The reaction is assisted by the unusual reactivity of the benzylic hydroxyl group at the 7-position, which undergoes nucleophilic substitution by the thioacetate anion. The formation of two isomeric thioacetates can be explained by racemization through the formation of the carbocation at C-7 and subsequent attack of the thioacetate anion, rather than an S_N2 process which would produce the epimer. An identical benzylic carbocation was postulated (23).

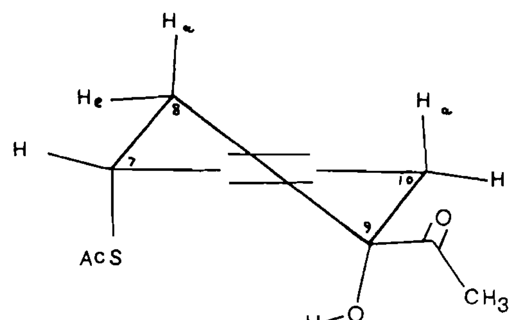
The nmr spectrum of compound **8** showed two signals at δ 2.388 and δ 2.368, each of three-proton intensity corresponding to the 9-acetyl and 7-thioacetyl groups, respectively. The 7*S* configuration of **8** was determined according to a previous method of assignment (20, 21, 24–27) based on the peak widths ($\nu_{1/2}$) for the benzylic proton (H-7). Compound **8** showed H-7 as a doublet at δ 5.447 having a coupling constant of 4.7 Hz, thus assigning the natural 7*S* configuration to **8** (see Table 1).

The nmr spectrum of compound **9** also showed the three-proton signals at δ 2.406 and 2.341, characteristic for the acetyl groups. The 7*R* configuration of **9** was determined from the benzylic proton (H-7) which was shown as a multiplet at δ 5.077 having $\nu_{1/2}$ 15.9 Hz, in agreement with an axial orientation of H-7. The stereochemistry at position 7 for compounds **8** and **9** can be ascertained on the basis of the chemical shifts in pyranoid rings (28–30); equatorial protons resonate at lower field than constitutionally similar axial protons. The benzylic proton H-7 for compound **8** was shown at relatively lower field

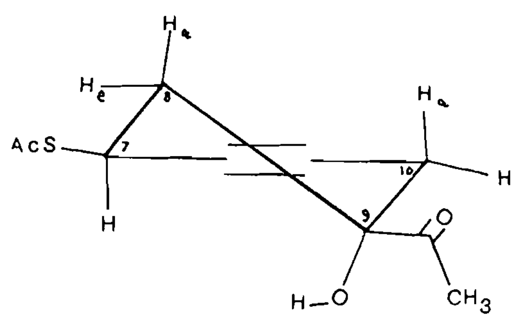


SCHEME 3

(δ 5.447) than that for compound **9** (δ 5.077). In addition, the protons associated with the methyl groups in axial acetoxy groups resonate at lower field than the corresponding protons in equatorial acetoxy groups (29). However, the appearance of the 7-thioacetyl signal at relatively lower field (δ 2.368) for compound **8** than that for compound **9** (δ 2.341) is in agreement with the axial orientation of the 7-thioacetyl group for compound **8** and the equatorial orientation for compound **9**.



8



9

Half-chair conformation of ring A for compounds **8** and **9**

The mass spectrum of compound **8** showed a weak molecular ion at *m/z* 456, and a base peak at *m/z* 43 corresponding to the CH_3CO group. The mass spectrum of compound **9** did not show a molecular ion; however, its C.I. mass spectrum showed the protonated molecular ion at *m/z* 457. It showed a fragmentation pattern identical to that of compound **8**.

Anthracyclines having an axial proton at C-7 have been

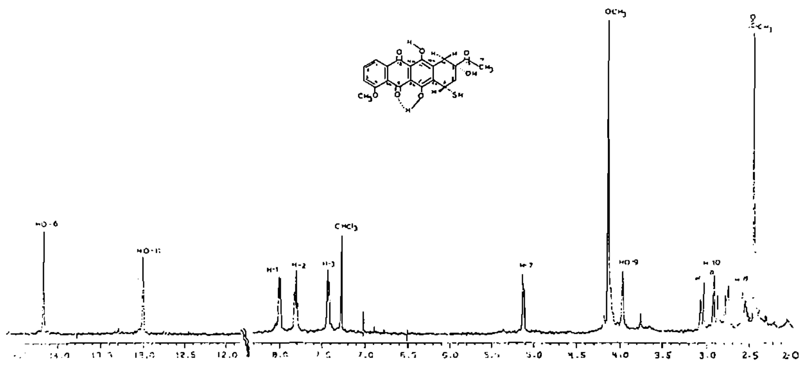


FIG. 2. The 470-MHz nmr spectrum of thiodaunomycinone **10**.

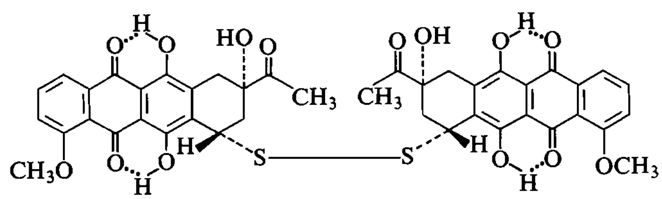
epimerized with acid (24). Treatment of compound **9** with TFAA afforded compound **8**.

Hydrolysis of compound **8** with sodium methoxide or potassium carbonate (Scheme 3) afforded a mixture of 7-deoxy-7-thiodaunomycinone **10**, **5**, and bisanhydrodaunomycinone **11** (31). The yield of **10** was low (37%) because of the concomitant formation of compound **5**, by ring-sulfur cleavage, and compound **11** by aromatization of ring A. Numerous repetitions and variation of the reaction conditions failed to give only one product. Compounds **5** and **10** were separated on preparative tlc and identified. Further purification of **11** by multiple development chromatography produced resolution into two components having very close R_f values, by partial dimerization of compound **10** into the dimer **12**.



12

The nmr spectrum of compound **10** (Fig. 2) showed a singlet of three-proton intensity at δ 2.355 corresponding to the 9-acetyl group, with the disappearance of the singlet corresponding to the thioacetyl group. The signal corresponding to the 9-hydroxyl group for compound **10** was shown as a singlet shifted to lower field (δ 3.897) than that for daunomycinone (δ 3.776). In addition, the peaks corresponding to the 8-CH_2 group were shifted to lower field than that for daunomycinone (Table 1). The benzylic proton for compound **10** was shown as a broad singlet at δ 5.057, shifted to higher field than that for compound **8** (δ 5.447) due to the removal of the acetyl group, and shifted to higher field than that for compound **4** (δ 5.306) because of the shielding effect of the sulfur compared to oxygen. The shielding of the benzylic proton of **10** compared to that of **8** and **4**, confirms the substitution at position 7.

The stereochemistry at the 7-position of anthracyclines is important for the expression of biological activity (32) and of DNA binding properties (33). The signal corresponding to H-7 for compound **10** showed $\nu_{1/2}$ ($J_{7,8a} + J_{7,8e}$) = 5 Hz, indicating (20, 21, 24–27) a quasiequatorial orientation for this proton. The new substituent at C-7 for compound **10** therefore has the same 7*S* configuration as the precursor acetate **8** and the natural daunomycinone, i.e., the quasiaxial configuration.

Compound **10** was further identified by mass spectroscopy. Its C.I. or E.I. mass spectrum did not show a molecular ion. The C.I. mass spectrum showed the highest mass peak at m/z 383 corresponding to the ion ($M + 1 - S$). The base peak was shown at m/z 363 corresponding to the ion ($M + 1 - H_2S - H_2O$). The E.I. mass spectrum showed the highest mass fragment at m/z 396 corresponding to the ion ($M - H_2O$), which was followed at the lower masses by the peaks at m/z 382 corresponding to ($M - S$), and m/z 362 corresponding to the ion ($M - H_2S - H_2O$). The base peak was shown at m/z 43 corresponding to the CH_3CO group. However, the field desorption mass spectrum of compound **10** showed the molecular ion peak (M) as the most intense peak at m/z 414, followed at the lower masses by the fragments at m/z 380 ($M - H_2S$), 362 ($M - H_2S - H_2O$), and 337 ($M - H_2S - CH_3CO$). Partial dimerization of **10** into **12** was shown by the peak at m/z 826 corresponding to $M_2 - 2H$ at the high mass spectrum region.

This synthetic route represents the method for replacement of the benzylic oxygen atom of daunomycinone by a sulfur atom. The synthetic availability of the 7-thioanalog **10** provides the versatile aglycon portion required for further elaboration of the sulfur-bridged anthracyclines **3**.

Experimental

Melting points are uncorrected, infrared spectra (ir) were recorded with a Perkin Elmer 467 grating spectrometer. The ^1H nmr spectra were recorded with a Nicolet 470-MHz instrument, using internal tetramethylsilane as the reference. Mass spectra were recorded with a Finnigan 6100 Data System gas chromatograph/E.I.–C.I. spectrometer. Combustion analyses were performed in the Department of Chemistry, Purdue University.

Thin-layer chromatograms (tlc) were obtained on 200 μm silica gel G plates. Preparative layer chromatograms (plc) were obtained on 20 × 20 × 0.2 silica gel 60 F plates (E. Merck) with solvent A, 9:1 benzene–acetone and solvent B, 97:2 methylene chloride – methanol.

Reduction of daunomycinone

(a) *With hydrogen over palladium–carbon 5%*

Daunomycinone (**4**, 200 mg) was dissolved in ethanol (300 mL), and shaken under hydrogen atmosphere with palladium–carbon 5% for 3 h. Thin-layer chromatography indicated the disappearance of the starting material and formation of two more mobile spots in the ratio of 1:1; R_f 0.36 and 0.29 (solvent A). The solution was filtered off and the catalyst washed with ethanol. The filtrate and washings were combined and evaporated to dryness, yield 160 mg (83%). The solution was green in color and turned pink upon exposure to the air. The two components were separated by plc (solvent A) and recrystallized from benzene. The slower-migrating spot (orange), R_f 0.29, showed mp 234–235°C, identical to that of 7-deoxydaunomycinone **5** (lit. (17) mp 229–231°C); ir: 3480 (OH), 1720 (C═O), 1610, 1575 (H-bonded quinone) cm^{-1}; mass spectral data (E.I., selected ions): m/z 384 (1, M + 2), 383 (4, M + 1), 382 (16, M), 364 (7, M − H_2O), 340 (22), and 339 (100, M − CH_3CO). For nmr spectral data see Table 1.

The faster-migrating spot (pink), R_f 0.36, mp 190–192°C, (lit. (19) mp for 7,11-dideoxydaunomycinone **6**, 186–189°C); E.I. mass spectral data (selected ions): m/z 368 (1, M + 2), 367 (7, M + 1), 366 (28, M), 348 (23, M − H_2O), 339 (3), 324 (21), and 323 (100, M − CH_3CO). For nmr spectral data see Table 1. *Anal.* calcd. for $C_{21}H_{18}O_6$: C 68.85, H 4.95; found: C 68.66, H 5.16.

(b) *Reduction with hydrogen over palladium – barium sulfate*

Compound **4** (50 mg) was dissolved in ethanol (200 mL), treated with a catalytic amount of palladium – barium sulfate (20 mg), and shaken under hydrogen atmosphere for 2 h, and treated as above. Thin-layer chromatography indicated the disappearance of the starting material and formation of two more mobile spots at the same R_f as those of **5** and **6** (solvents A and B).

(c) *Reduction with sodium dithionite*

Compound **4** (100 mg) was dissolved in THF (50 mL), the solution was blanketed with nitrogen, and treated with dropwise addition of sodium dithionite (200 mg) in water (25 mL). After complete addition (15 min), the solution was stirred at room temperature for a further 2 h, evaporated to dryness, the residue extracted with chloroform, and the extract washed with water, dried over anhydrous sodium sulfate, filtered, and evaporated to dryness, yield 75 mg. It was recrystallized from benzene to give chromatographically (tlc) pure red needles, mp and mixture mp (with **5**) 232–233°C, having the same R_f values on tlc (solvents A and B).

7-Thioacetyldaunomycinone (8)

A solution of compound **5** (50 mg) in CCl_4 was refluxed under N_2 for 1 h. Br_2 (3 mL of 0.125 M solution in CCl_4) and ABN (4 mg) were added and refluxed for 2 h. The solvent was removed and the residue was dissolved in THAA (10 mL), then CH_3COSK (100 mg) was added and the mixture stirred under N_2 for 17 h. The mixture was evaporated to dryness, the residue extracted with $CHCl_3$, and the organic layer was then washed with water, dried over anhydrous sodium sulfate, and evaporated. The residue was recrystallized from benzene–hexane giving a red amorphous precipitate. Thin-layer chromatography (solvent B) showed two spots, R_f 0.31 and 0.21. Fractional recrystallization of the mixture from benzene gave compound **8** as orange-red needles, yield 18 mg, mp 230–232°C; R_f 0.31, solvent A; ir: 3420 (OH), 1705 (C═O), 1690 (SAc), 1610 and 1580 (chelated quinone) cm^{-1}; mass spectral data (C.I.): m/z 459 (7, M + 3), 458 (16, M + 2), 457 (83, M + 1), 425 (9), 383 (41), 363 (52), 321 (22), and 77 (100); (E.I.): m/z 456 (1, M), 438 (1, M − H_2O), 413 (1, M − CH_3CO), 382 (1, M − CH_3COSH), 362 (M − CH_3COSH − H_2O), 338 (1), 77 (2, Ph), 76 (2, CH_3COSH), 75 (1, CH_3COS), and 43 (100, CH_3CO); for nmr spectral data see Table 1. *Anal.* calcd. for $C_{23}H_{20}O_8S$: C 60.39, H 4.63, S 7.01; found: C 60.45, H 4.81, S 6.81.

7-Epithioacetyldaunomycinone (9)

The mother liquor of **8** showed two spots on tlc which were separated by plc (solvent A) and the slow migrating spot, R_f 0.21, was recrystallized from methanol giving red needles, mp 207–209°C; ir: 3440 (OH), 1705 (C═O), 1690 (SAc), 1610 and 1580 (chelated quinone) cm^{-1}; mass spectral data (C.I.): m/z 457 (1, M + 1), 385 (3), 383 (39), 363 (17), 91 (29), 85 (42), and 76 (100); (E.I.): m/z 362 (10, M − CH_3COSH − H_2O), 339 (9, M − CH_3COSH − CH_3CO), 337 (13), and 43 (100, CH_3CO). For nmr spectral data see Table 1. *Anal.* calcd. for $C_{23}H_{20}O_8S$: C 60.39, H 4.63, S 7.01; found: C 60.14, H 4.84, S 6.94.

Conversion of daunomycinone into 7-thioacetyldaunomycinone

Method "A", by treatment of 4 with a mixture of THAA and TFAA

Compound **4** (50 mg) was treated with THAA (5 mL) and TFAA (2 mL) and kept at room temperature for 6 h. Thin-layer chromatography indicated the disappearance of the starting material and formation of three spots; the slow migrating one was shown at the same R_f value as for compound **8**. It was isolated by plc and recrystallized from benzene, yield 6.5 mg, mp and mixture mp 232–234°C. Its nmr spectrum was identical to that of **8**. No spot corresponding to compound **9** was detected by tlc.

Method "B", by refluxing compound 4 with THAA and GAA

Compound **4** (100 mg) was treated with THAA (10 mL) and GAA (4 mL) and the mixture refluxed for 21 h. Monitoring of the reaction by tlc indicated disappearance of the starting material and formation of two more mobile spots at the R_f values for compounds **8** and **9**. The reaction was complete after 21 h. The mixture was evaporated to dryness and traces of acids were removed by repeated evaporation with CH_2Cl_2. The dry residue was recrystallized from benzene giving orange red needles of compound **8**, mp and mixture mp 228–230°C. The mother liquor, containing **8** and **9**, was separated with plc (solvent B); yield of **8**, 80 mg, and **9**, 15 mg; total yield 83% from **4**.

Epimerization of compound 9 into 8

Compound **9** (5 mg) was treated with TFAA (1 mL) and kept for 20 h at 20°C. The acid was removed by repeated evaporation with CH_2Cl_2. Thin-layer chromatography indicated complete conversion of **9** into **8**. Similar treatment of **8** with TFAA did not give **9** by epimerization under the same conditions.

Hydrolysis of 7-thioacetyldaunomycinone

Method "i", with 0.01 N *sodium methoxide solution*

A solution of **8** (30 mg) in THF (4 mL) was blanketed with argon and a solution of 0.01 N sodium methoxide (2 mL) was added with stirring; the blue-colored solution obtained was stirred at 20°C for 5 h. It was neutralized with glacial acetic acid which turned the solution red. Thin-layer chromatography (solvent B) showed the formation of three spots which were isolated by plc and identified. The slow migrating spot, R_f 0.47 (solvent B), was isolated, dissolved in benzene, and precipitated by hexane as an amorphous powder of thiodaunomycinone **10**; yield 10 mg, mp 195–198°C. Further purification on analytical tlc plates (solvent B) showed splitting into two non-resolvable spots, having close R_f values, probably by air oxidation and formation of the dimer **12**; ir: 3430 (OH), 1705 (C═O), and 1615 and 1580 (hydrogen bonded quinone) cm^{-1}. Mass spectral data (C.I.): m/z 383 (9, M + 1 − S), 363 (100, M + 1 − H_2S − H_2O); (E.I., selected ions): m/z 396 (1, M − H_2O), 382 (3, M − S), 362 (M − H_2S − H_2O), 344 (17), 339 (16), 337 (9, M − H_2S − CH_3CO), and 43 (100, CH_3CO). Field desorption mass spectrum (F.D.): 826 (31, M_2 − 2H), 414 (91, M), 380 (77, M − H_2S), 362 (18, M − H_2S − H_2O), 337 (18, M − H_2S − $COCH_3$). For nmr spectral data see Table 1. *Anal.* calcd. for $C_{21}H_{18}O_7S$: C 60.86, H 4.38, S 7.74; found: C 60.64, H 4.62, S 7.45.

The second hydrolysis product (orange color), R_f 0.59 (solvent B) was isolated by plc and recrystallized from benzene, mp and mixture mp (with **5**) 233–235°C (lit. (20) mp 230–232°C). The faster moving spot (violet color), R_f 0.67 (solvent B), was isolated by plc and recrystallized from benzene–methanol as brown-violet needles, yield 5 mg; mp 229–232°C (lit. (31) mp for bisanhydrodaunomycinone, 225–230°C); mass spectral data (C.I.): m/z 363 (100, M + 1), 361 (36, M + 1); (E.I., selected ions): m/z 364 (9, M + 2), 363 (40, M + 1), 361 (96, M + 1), 345 (52), 343 (38), 319 (5, M − CH_3CO), and 43 (100, CH_3CO).

Method "ii". Hydrolysis of 8 with saturated solution of potassium carbonate

A solution of compound **8** (30 mg) in THF (5 mL) was blanketed with argon, then a solution of saturated potassium carbonate (0.2 mL) was added with stirring. The solution, which turned blue, was stirred at 20°C for 2 h, then acidified with 5% oxalic acid solution which converted it into a red color; the mixture was then partitioned between water and chloroform, and the organic layer washed with water and dried. The chloroform was removed and tlc (solvent B) of the residue showed three spots at the same R_f values, for compounds **5**, **10**, and **11**, that were obtained by method i.

Acknowledgments

This work was partly supported by Adria Laboratories Inc., Columbus, Ohio, and the authors thank Dr. D. Lednicer for providing a sample of daunomycinone. The authors thank the Purdue University Biochemical Magnetic Resonance Laboratory for the 470-MHz spectral measurements, which were supported by NIH grant No. RR 01077. Thanks are also due Dr. J. L. Markley, the director of the facility, and Dr. D. Croll, Dr. R. Virudachalam, and Patricia Hoyos for recording the spectra. Finally, thanks to Dr. John L. Occolowitz, Lilly Research Laboratories, for field desorption mass spectral measurements.

Reçu le 6 novembre 1984

G. FOLCHER, J. PARIS et F. CHAUVEAU. Can. J. Chem. **63**, 2703 (1985).

Une cellule photogalvanique est réalisée avec une solution de décatungstate ($W_{10}O_{34}^{4-}$) de tétrabutylammonium dans l'acétonitrile à la concentration 0,2 *M* en atome-gramme de tungstène. Le dispositif utilisé comporte une électrode de platine éclairée et une électrode de graphite dans l'obscurité. Les conditions d'utilisation de la pile pour obtenir le meilleur rendement électrique sont déterminées. Un mécanisme global est proposé: le décatungstate excité par la lumière est réduit reversiblement, un donneur d'électron ou l'eau est oxydée pendant la réaction. Nous montrons que le mécanisme fait vraisemblablement intervenir deux photons. La fem développée est de 650 mV et le rendement expérimental (puissance de la pile/énergie lumineuse) est voisin de 1%.

G. FOLCHER, J. PARIS, and F. CHAUVEAU. Can. J. Chem. **63**, 2703 (1985).

A photogalvanic cell which functions with an acetronitrile solution of tetrabutylammonium decatungstate ($W_{10}O_{34}^{4-}$) (0.2 *M* in gram-atoms of tungsten) has been realized. This cell utilizes an irradiated platinum electrode with a non-illuminated graphite electrode. The conditions giving the best conversion of light to electric power have been determined. An overall mechanism has been proposed. The decatungstate photooxidizes an electron donor like water. The involvement of a two-photon process has been demonstrated. The emf produced is about 650 mV, and the experimental yield is in the neighborhood of 1%.

La recherche des réactions de transfert d'électrons capables de stocker l'énergie solaire s'oriente vers des systèmes microhétérogènes (10), micelles et colloïdes. Les polyanions peuvent constituer une alternative intéressante (9): la structure déterminée à l'état solide est conservée en solution (1) et on peut faire varier dans une certaine mesure la taille et la forme des arrangements moléculaires. Ceux-ci présentent des propriétés bien spécifiques comme le montre la chimie des polytungstates (2).

Le tungstène VI engagé dans le polyanion est photosensible et joue le rôle de capteur d'électron (3). C'est précisément ce qui est observé dans le cas du décatungstate $W_{10}O_{32}^{4-}$. Celui-ci a la structure présentée sur la figure 1 (4). Une bande de transfert de charge centrée à 325 nm mais étendue dans le domaine visible peut être utilisée pour accroître son affinité électronique.

Dans le cas de l'uranium hexavalent, nous avons pu utiliser les propriétés oxydantes de l'uranyle excité pour créer un effet photogalvanique, c'est-à-dire l'apparition d'une différence de potentiel entre deux électrodes plongées dans une solution d'uranyle quand l'une d'entre elle est éclairée (5).

Le montage utilisé dans cette expérience a pu être reconduit dans le cas des solutions de polytungstates. Les premiers résultats obtenus nous ont amené à étudier ce phénomène en détail.

Partie expérimentale

Le montage de la cellule a été décrit par ailleurs (5). Nous rappelons que la lumière éclaire une électrode de platine tandis qu'une électrode de graphite reste non irradiée. La principale difficulté réside dans le réglage de la distance optimale entre la fenêtre et l'électrode. L'utilisation d'une électrode circulaire appliquée sur la paroi éclairée permet de pallier cet inconvénient (fig. 2).

Le décatungstate de tétrabutylammonium est préparé par acidification convenable d'une solution de tungstate de sodium suivant les modes opératoires déjà décrits (7, 8) (16,5 g de $WO_4Na_2 \cdot 2H_2O$ dissous à ébullition dans 100 mL d'eau, acidifiée par 90 mL de HCl normal également à la même température. La solution rapidement refroidie est précipitée par 7 g de bromure de tétrabutylammonium).

Le produit précipité est lavé successivement à l'eau, l'alcool et à l'acétone. Une fois séché, il est recristallisé dans l'acétonitrile. *Anal.* calc.: W 55,37, C 23,26, N 1,69, H 4,37%; tr.: W 55,25, C 23,1, N 2,68, H 4,33%.

La concentration adoptée dans les expériences décrites est de 0,2 *M* en atome-gramme de tungstène, 0,2 mol^{-1} dans l'acétonitrile Merck.

L'irradiation est réalisée par une lampe xénon 900 W, filtrée par une cellule de 10 cm d'une solution aqueuse de sulfate de cuivre.

Pour les mesures de rendement quantique on opère de la façon suivante:

La lumière émise par une lampe xénon est mesurée par un joulemètre, après passage dans un monochromateur, sur toute l'étendue du spectre. Le faisceau est ensuite envoyé sur une électrode de taille inférieure au diamètre du faisceau. On suppose que toute la lumière est absorbée et on mesure la puissance de la pile.

Résultats

Électrochimie

Les potentiels d'oxydoréduction de $W_{10}O_{32}^{4-}$ dans l'acétonitrile ont été déterminés en présence de perchlorate de tétrabutylammonium 0,1 *M*. On observe alors deux vagues de réduction réversibles sur le mercure (l'électrode de référence est une électrode au calomel saturé à double jonction). On sait que dans ces conditions les $E_{1/2}$ sont assimilables aux potentiels normaux d'oxydoréduction. Les deux vagues observées correspondent respectivement à 1 et 2 électrons par mole. Elles sont analogues à celles que Termes et Pope ont observées dans le carbonate de propylène (6). Les potentiels sont respectivement de $-0{,}61$ et $-1{,}08$ V par rapport à H_2 normal (6).

Dans les conditions de fonctionnement de la pile, des phénomènes différents dus aux électrodes peuvent se manifester.

Nous avons mesuré par voltamétrie cyclique sur électrodes de platine poli les potentiels de réduction d'une solution de $W_{10}O_{32}^{4-}$ dans CH_3CN, dans des conditions voisines de celles du

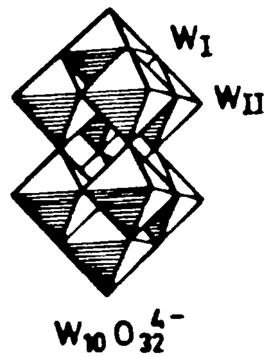

FIG. 1. Représentation polyédrique de la structure de $W_{10}O_{32}^{4-}$. Les atomes de tungstène W_I et W_{II} occupent approximativement le centre des octaèdres.

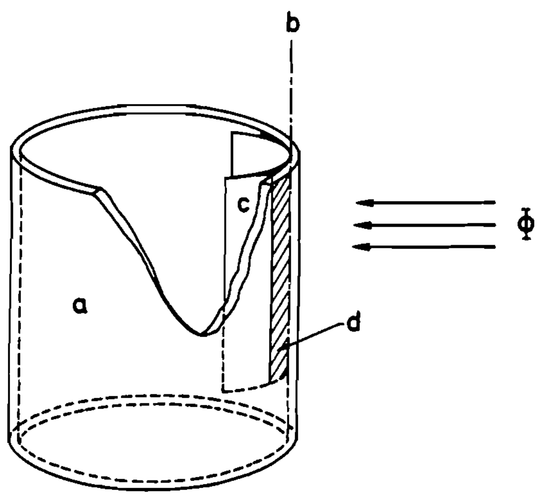

FIG. 2. Coupe schématique de la cuve avec son électrode de platine; (a) cuve en Pyrex; (b) génératrice de contact entre le platine et le verre; (c) électrode de platine; (d) localisation des espèces bleues en fonctionnement.

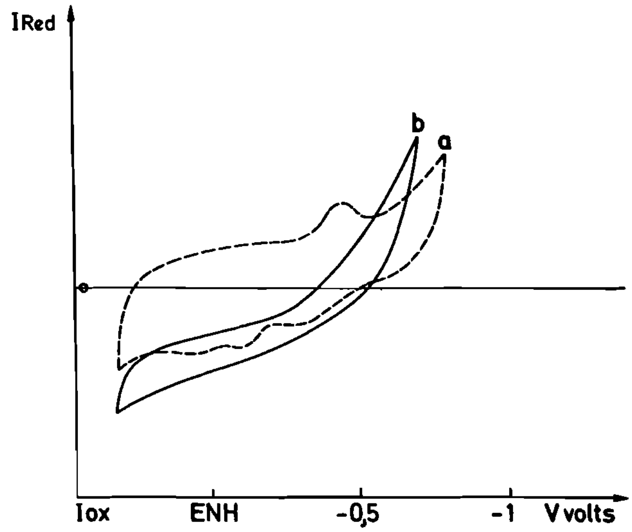

FIG. 3. Diagramme de voltamétrie cyclique obtenue dans CH_3CN, sans électrolyte support et sur électrode de platine. Vitesse de balayage 1 V/nm. L'électrode de référence est une électrode de Pleskov; (a) obscurité; (b) lumière.

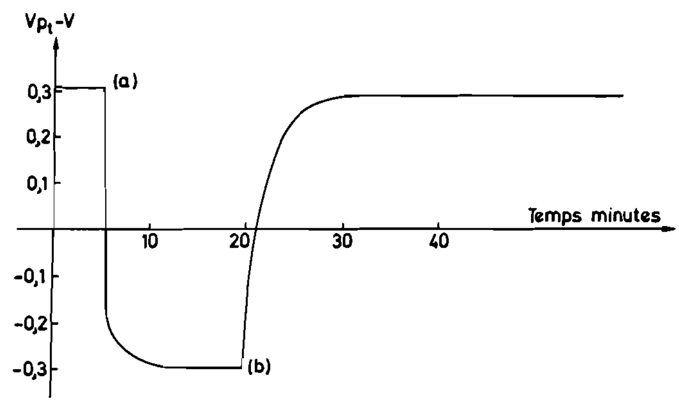

FIG. 4. Potentiel obtenu sur le platine; (a) éclairement; (b) obscurité.

fonctionnement de la pile en utilisant une électrode de Pleskov comme référence. La figure 3 présente le premier balayage qui met en évidence une réduction à −0,55 V par rapport à l'électrode de Pleskov. Pour des valeurs plus négatives, il y a formation d'un dépôt sur l'électrode qui modifie sensiblement le comportement du système. Vers les potentiels positifs, un système apparaît vers +0,20 V qui n'est pas dû à l'oxydation du solvant, observé dans ces conditions à +0,40 V. Ce système apparaît aussi comme instable dans le temps.

En présence de lumière, le voltamogramme est différent: il présente un accroissement considérable des courants d'oxydation sur le platine avant −0,5 V et une vague très intense pour les potentiels plus négatifs.

Il apparaît donc que la lumière crée des espèces réduites de polytungstate qui peuvent donc être réduites dans un deuxième temps à des potentiels inférieurs à −0,5 V.

Photochimie

Nous utilisons le montage photogalvanique (fig. 2). La différence de potentiel mesurée en circuit ouvert entre l'électrode de platine éclairée et l'électrode de graphite est de 650 mV, le platine constituant la cathode.

La coupure de l'éclairement conduit à l'annulation rapide de cette différence de potentiel. De même, en rallumant la lampe la valeur de 650 mV est atteinte en quelques secondes (fig. 4).

La figure 5 présente la courbe de la puissance fournie dans les conditions expérimentales précédentes, en fonction du potentiel entre les électrodes. Elle est obtenue en faisant varier la résistance introduite sur le circuit. En se plaçant au maximum de cette courbe, on peut faire débiter la pile pendant plusieurs heures sans observer une variation notable des constituants de la solution ni de variation importante des performances.

En fonctionnement on voit apparaître sur l'électrode éclairée deux bandes colorées en bleu, le long des génératrices du cylindre, symétriques par rapport à la génératrice de contact, entre l'électrode et la paroi (fig. 2). Nous verrons que cette coloration est due à une espèce réduite de tungstène qui est formée par action de la lumière et d'un réducteur. Cette espèce qui est réoxydée au contact du platine est donc visible en concentration stationnaire. Elle illustre le rôle critique joué par l'épaisseur de la couche de liquide entre la fenêtre d'entrée et l'électrode. En se plaçant au maximum de la courbe de la figure 5, nous avons étudié la variation de la puissance émise en fonction de la longueur d'onde. Nous interposons entre la lampe et la cellule un monochromateur dont nous ouvrons largement la fente. Le rendement est porté en fonction de la longueur d'onde (fig. 6). On constate que la courbe ne coïncide pas avec la courbe d'absorption mais est décalée vers le rouge.

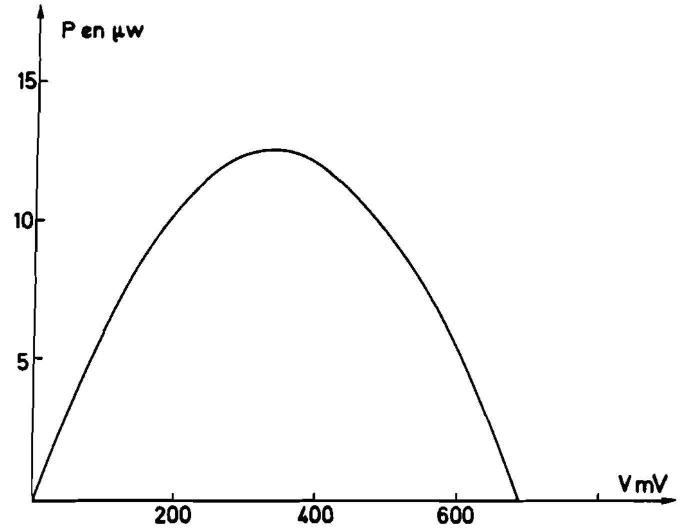

FIG. 5. Puissance électrique fournie en fonction de la tension disponible.

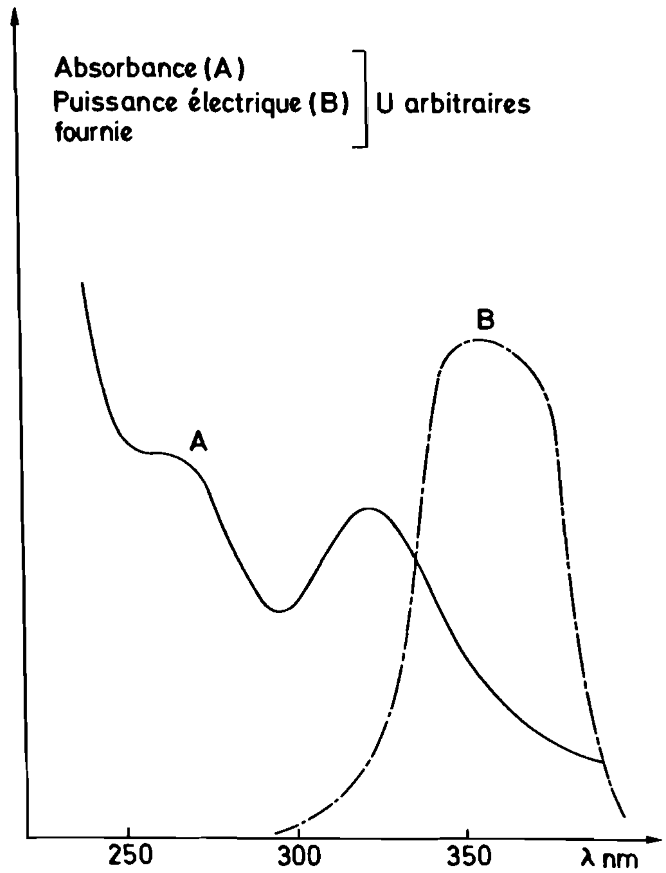

FIG. 6. (A) Spectre d'absorption électronique en fonction de la longueur d'onde. (B) Puissance électrique fournie en fonction de la longueur d'onde.

Plusieurs interprétations peuvent être données de ce phénomène parmi lesquelles un processus faisant intervenir un deuxième photon absorbé par l'espèce formée par le premier.

Si l'on porte maintenant (fig. 7) le rendement en fonction du flux lumineux, on note qu'une valeur constante n'est atteinte qu'à partir d'une valeur élevée de l'intensité incidente. Dans le cas simple de l'utilisation d'un seul photon on devrait observer

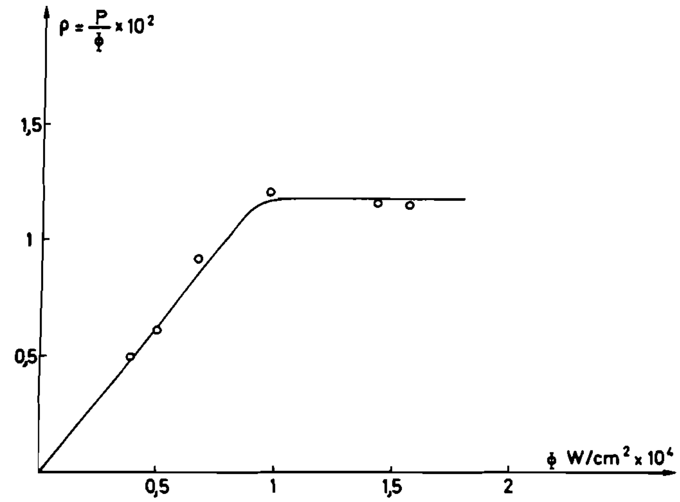

FIG. 7. Rendement en fonction du flux lumineux.

un rendement indépendant du flux lumineux au moins aussi longtemps que l'on n'a pas atteint la saturation.

Discussion

D'après les spectres uv–visibles réalisés dans l'acétonitrile la structure en solution est celle de l'état solide (fig. 1).

La molécule comporte deux entités compactes constituées de 5 octaèdres WO_6, dont le tungstène occupe le centre, et reliés entre eux par une mise en commun d'arêtes. Les deux moitiés de la molécule sont reliées entre elles par une mise en commun de sommets. Il en résulte deux variétés de tungstène W_I et W_{II} et deux types de points W_IOW_{II} et $W_{II}OW_{II}$, les derniers étant quasiment linéaires (175°) (6).

La bande à 325 nm que nous irradions serait liée à l'existence des ponts (6) et suggère que seul un type de liaison participe aux transferts de charge responsable de la photochimie.

Dans l'acétonitrile, les mesures de conductibilité ont montré que les sels du polyanion sont entièrement dissociés. Les expériences de rmn en cours confirment la présence de deux types de tungstène.

Aucune détermination des potentiels d'oxydoréduction des polyanions de tungstène n'avait été réalisée dans CH_3CN mais les travaux de Pope (2) avaient montré que la réduction électrochimique à 1 et 2 électrons était réalisée réversiblement. Nous avons pu voir dans nos conditions: CH_3CN et électrode de platine, une première réduction réversible à l'électron à 0,55 V par rapport à l'électrode de Pleskov (soit sensiblement à 0,40 V par rapport à l'électrode hydrogène. À lumière de la mise au point récente (1) sur les propriétés photochimiques des polytungstates on peut penser que l'espèce bleue dont la concentration stationnaire peut être observée au contact de l'électrode est l'espèce réduite à un électron $W_{10}O_{32}^{5-}$. Elle sera réoxydée sur le platine à un potentiel de 0,35 V en circuit ouvert. C'est l'espèce dont la quantité augmente lors de l'irradiation de la solution mais elle peut être limitée par la réaction de dismutation

$$2W^{V}W_9O_{32}^{5-} \leftrightarrows (W_2^{V}W_8^{VI}O_{32})^{6-} + (W_{10}O_{32})^{4-}$$

La réaction sur le graphite est plus difficile à caractériser. Son potentiel mesuré à +300 mV en circuit ouvert lors de l'irradiation de la solution, est aussi celui où se trouvent les deux électrodes en l'absence de lumière. Il correspond bien à la vague d'oxydation observée sur la solution de polytungstate sans que l'on puisse en définir la nature avec précision. Chemseddine *et al.* (11) ont montré que l'espèce réduite à un électron $(W_{10}O_{32})^{5-}$ présente une bande d'absorption intense à 370 nm. Il est donc possible de rendre compte du décalage vers le rouge de la courbe de rendement dont le maximum est à 350 nm en supposant qu'un deuxième photon est absorbé par l'espèce donnée par réduction à 1 électron dès sa formation. On obtiendrait alors en régime stationnaire l'espèce doublement réduite.

Nous pouvons proposer le schéma suivant:

$$(W^{VI}_{10}O_{32})^{4-} \xrightarrow{h\nu_1 = 320 \text{ nm}} (W^{VI}_{10}O_{32})^{4-*}$$

$$(W^{VI}_{10}O_{32})^{4-*} + D \rightarrow (W^{VI}_9W^{V}O_{32})^{5-} + D^+$$

$$(W^{VI}_9W^{V}O_{32})^{5-} \xrightarrow{h\nu_2 = 370 \text{ nm}} (W^{VI}_9W^{V}O_{32})^{5-*}$$

$$(W^{VI}_9W^{V}O_{32})^{5-} + (W^{VI}_9W^{V}O_{32})^{5-} \rightarrow (W^{VI}_8W^{V}_2O_{32})^{6-} + (W_{10}O_{32})^{4-}$$

$$(W^{VI}_9W^{V}O_{32})^{5-*} + D \rightarrow (W^{VI}_8W^{V}_2O_{32})^{6-} + D^+$$

et finalement

$$(W^{VI}_8W^{V}_2O_{32})^{6-} \xrightarrow{Pt} (W^{VI}_{10}O_{32})^{4-} + 2\,e^-$$

$$2\,D^+ + 2e^- \xrightarrow{\text{Graphite}} 2\,D$$

où nous appelons D l'espèce oxydable. D doit réaliser plusieurs conditions. Cette espèce doit être présente au voisinage de l'ion excité et sa forme oxydée devra pouvoir se mettre sous une forme stable qui sera réduite sur le graphite.

La cation tétrabutylammonium ne pourra pas jouer ce rôle: son potentiel d'oxydation est très élevé et nous n'avons pas mis en évidence de produits de réactions tels que le butène. On peut aussi penser à l'acétonitrile plus facilement oxydable.

On sait (12) que l'acétonitrile est oxydé en CH_2CN et que le produit final est généralement le succinonitrile en absence d'oxygène. Sinon il réagit sur l'oxygène pour donner le peroxyde O_2CH_2CN (13). Il paraît peu probable que ces produits puissent être réduits sur le graphite avec un potentiel convenable.

Yamase a montré dans le cas de polytungstate par méthode de capteur de spin que W^{VI*} était capable d'arracher un hydrogène de l'eau pour donner le radical $OH^{\bullet}$ (3). On peut donc supposer comme dans le cas de l'uranyle que ces radicaux se recombinent pour produire H_2O_2 qui serait réduit sur le graphite. Le rôle de l'électrode de platine peut être invoqué pour favoriser la réaction bimoléculaire de recombinaison des radicaux hydroxyles.

Comme dans le cas de l'uranyle, nous pensons que l'eau joue le rôle de donneur. Nous avons observé que l'addition d'une petite quantité d'eau à la solution provoquait une petite amélioration de l'effet photogalvanique.

Cependant en mesurant directement le potentiel du couple OH^-/H_2O_2 sur du platine ou du graphite on obtient une valeur voisine de 0,6 V qui ne rend pas compte des résultats obtenus dans le fonctionnement de la pile. Il est probable que le schéma proposé est approximatif.

Au plan de l'intérêt pratique du système nous soulignons le rendement relativement élevé qui a été obtenu dans des conditions non optimisées. La valeur du rendement maximale obtenue comme le rapport de la puissance de la pile à l'énergie lumineuse monochromatique incidente est de l'ordre de 1%. Cette valeur est affectée de la mauvaise utilisation de la surface de l'électrode éclairée et devrait être améliorée par un montage où l'épaisseur optimale serait réalisée sur l'ensemble de la surface éclairée. Enfin le système présente une bonne stabilité dans le temps en accord avec les hypothèses de mécanisme proposées où aucune espèce chimique n'est consommée.

Remerciement

Biosynthesis of the lupine alkaloids. I. Lupinine

W. MAREK GOLEBIEWSKI[1] AND IAN D. SPENSER
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received February 5, 1985

W. MAREK GOLEBIEWSKI and IAN D. SPENSER. Can. J. Chem. **63**, 2707 (1985).

The mode of incorporation into lupinine of cadaverine, intramolecularly doubly labelled with ^{15}N and with ^{13}C at the C-atom adjacent to ^{15}N, i.e., $^{13}C,^{15}N$-"bond-labelled", was determined by ^{13}C nmr spectroscopy; lupinine is generated from two cadaverine-derived C_5-units by a route which excludes a "dimeric" intermediate with C_{2v} symmetry. The mode of incorporation of ^2H from L-(2-^{2}H)lysine, from (*R*)- and (*S*)-(1-^{2}H)cadaverine, and from (2-^{2}H)-Δ^1-piperideine into lupinine was determined by ^2H nmr spectroscopy. The results corroborate the conclusions from the $^{13}C,^{15}N$ experiment and they establish the stereochemistry of six of the steps in the biosynthetic conversion of L-lysine into lupinine.

W. MAREK GOLEBIEWSKI et IAN D. SPENSER. Can. J. Chem. **63**, 2707 (1985).

Faisant appel à la spectroscopie rmn du ^{13}C et utilisant de la cadavérine doublement marquée d'une façon intramoléculaire par du ^{15}N et du ^{13}C sur le carbone voisin du ^{15}N (liaison $^{13}C,^{15}N$ marquée), on a étudié le mode d'incorporation de la cadavérine à la lupinine. Les résultats obtenus suggèrent que la lupinine se forme à partir de deux unités en C_5 dérivées de la cadavérine par le biais d'une voie réactionnelle qui exclut la formation d'un intermédiaire "dimère" possédant une symétrie C_{2v}. Faisant appel à la rmn du ^2H, on a déterminé le mode d'incorporation du ^2H de la L-(^{2}H-2) lysine, des (^{2}H-2) cadavérines-(*R*) et -(*S*) et de la (^{2}H-2)-Δ^1-pipéridine à la lupinine. Les résultats confirment les conclusions tirées sur la base des expériences conduites avec le ^{13}C et le ^{15}N; de plus, elles permettent d'établir la stéréochimie de six des étapes conduisant à la transformation biosynthétique de la L-lysine en lupinine.

[Traduit par le journal]

Introduction

Speculations concerning the biosynthesis of the lupine alkaloids go back more than 50 years. In 1931 Schöpf suggested (1, 2) that the ring skeleton of lupinine (**20**) might be generated by condensation of two lysine (**1**) derived fragments, 5-aminopentanal (**3**) ($\rightleftharpoons$ Δ^1-piperideine (**4**) (3, 4)) and glutardialdehyde (**5**), followed by reduction (Scheme 1Bd). Schöpf later abandoned this notion in favour of the idea (3) that the iminodialdehyde (**7**) might be the intermediate between lysine and lupinine (Schemes 1Ba and 1Bb). This intermediate was favoured also by Robert Robinson (4). In a further variation of this theme it was suggested (5, 6) that lupinine arose by rearrangement of tetrahydroanabasine (**14**), a dimer of Δ^1-piperideine (**4**) (3, 5) (Scheme 1Be).

The first tracer experiments to test these ideas were carried out twenty-five years ago. Radioactivity from DL-[2-^{14}C]lysine (7) and from its decarboxylation product, [1-^{14}C]cadaverine (6, 8), was indeed incorporated into lupinine. With either substrate, approximately one quarter of the total activity of the alkaloid was present within the hydroxymethyl carbon, C-11, of lupinine. Also, the two methylene carbon atoms, C-4 and C-6, together, accounted for one half of the total alkaloid activity (7, 8). If the assumption is made that this activity is distributed equally over C-4 and C-6, and that each of these two C atoms contains one quarter of the label,[2] it follows that four sites within lupinine, C-11, C-4, C-6, and, presumably, C-10, each account for one quarter of the label of the intact alkaloid (**20**). This conclusion was substantiated by the results of a recent feeding experiment (9) with DL-(4,5-$^{13}C_2$)lysine. Enrichment was detected at four pairs of neighbouring carbon atoms of lupinine, C-1,-2, C-2,-3, C-7,-8, and C-8,-9. This labelling pattern serves as evidence that the carbon skeleton of lupinine is generated from two lysine-derived C_5-units, via an intermediate with C_{2v} symmetry (e.g., either cadaverine (**2**) or the iminodialdehyde (**7**), or both). However, since the distribution of label observed in all these experiments is that which is predicted by every one of the five hypothetical routes (Schemes 1Ba–1Be) that have been advanced to account for the derivation of lupinine from lysine, available tracer evidence cannot serve to discriminate among the biogenetic proposals.

Nor is it certain that cadaverine (**2**) is an intermediate between lysine (**1**) and lupinine (**20**): Neither the observation that incorporation of the two substrates, DL-[2-^{14}C]lysine and [1-^{14}C]cadaverine, leads to the same distribution of label within lupinine, nor the labelling pattern from DL-(4,5-$^{13}C_2$)lysine constitute conclusive evidence for the obligatory intermediacy of cadaverine. Other interpretations are possible which account for such a distribution of label (cf. ref. 10).

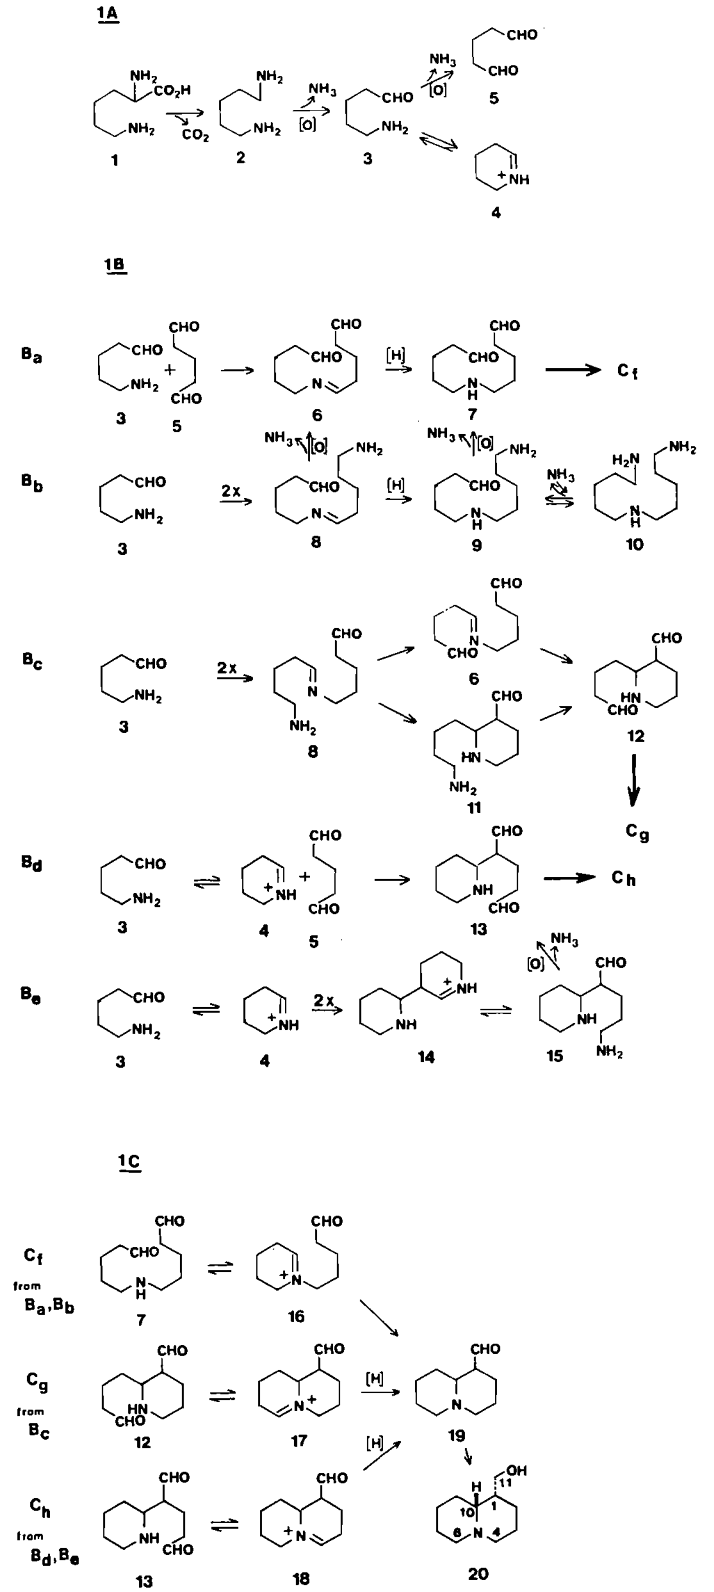
The tracer experiments with doubly $^{13}C,^{15}N$- and with ^2H-labelled substrates which are here reported serve as critical tests of the hypotheses that have been advanced to account for the origin of lupinine. The results, which controvert all but one of the hypothetical sequences, provide support for the tetrahydroanabasine route (Scheme 1Be). Furthermore, the results of the tracer experiments with ^2H-labelled substrates clarify stereochemical aspects of this route. Preliminary accounts of parts of this work have appeared (11, 12).

Methods and results

In six tracer experiments, compounds, specifically labelled with stable (Experiments 1–5) and with radioactive isotopes (Experiment 6), were administered by the wick method to intact plants of *Lupinus luteus* (yellow lupine) over a period of 3–6 days. Details of the experiments are summarized in Table 1.

[1] On leave from the Department of Chemistry, University of Warsaw, 02-093 Warsaw, Poland.

[2] Another possible interpretation of these results is that one of the two centres, C-4 or C-6, accounts for 50% of the activity of the intact lupinine, while the other centre is free of activity.



SCHEME 1. Five alternative hypothetical schemes of the biogenesis of lupinine. A. The initial steps. B_a–B_e. Variants of the intermediate steps. C_f–C_h. Variants of the final steps.

The sample of cadaverine, intramolecularly doubly labelled ("bond-labelled") with ^{13}C and ^{15}N (Experiment 5) was prepared in three steps from sodium (^{13}C,^{15}N)cyanide and 1-bromo-4-phthalimidobutane by the reaction sequence shown in Scheme 2, in analogy with the preparation of a similarly labelled sample of putrescine (10).

The samples of DL-(2-^2H)lysine (Experiment 3), (2-^2H)-Δ^1-piperideine (Experiment 4), (*S*)-(+)-(1-^2H)cadaverine dihydrochloride (Experiment 2), and (*R*)-(−)-(1-^2H)cadaverine dihydrochloride (Experiment 1) were prepared by chemical and enzymic methods, respectively, which we have previously described (13). The samples of L-[4-^3H]lysine monohydrochloride and DL-[6-^{14}C]lysine monohydrochloride (Experiment 6) were commercial products.

When the administration of tracer was complete, the plants to which labelled substrates had been administered were macerated with cold methanol in a Waring blendor and the alkaloids were isolated by methanol extraction. Lupinine and sparteine were separated by chromatography on silica gel, lupinine was converted into the hydrochloride, sparteine into the sulfate.

The present paper presents a discussion of the results obtained with lupinine. The sparteine results will be dealt with in the second paper of this series.

Lupinine hydrochloride consists of a 1.7:1 mixture of the *trans* and *cis* ring fused stereoisomers, as shown by the natural abundance ^{13}C nmr spectrum (Fig. 1B). The ^{13}C nmr spectrum (Fig. 1A) of the sample of lupinine hydrochloride from Experiment 5, in which (1-^{13}C,^{15}N)cadaverine in admixture with [1-^{14}C]cadaverine had been administered (Experiment 5), shows that four of the ten C-atoms, C-4, -6, -10, and -11, were enriched in ^{13}C, to an equal extent. The enrichment, above natural abundance, calculated for each of these four carbon atoms (Tables 2 and 3) is in agreement with the specific incorporation of ^{14}C (Table 1).

The signals in the proton noise decoupled ^{13}C nmr spectrum due to two of the ^{13}C-enriched carbon atoms, C-10 and C-11, appear as singlets, the signals due to the two others, C-6 and C-4, as multiplets (Fig. 1A). The coupling constants of the doublet component of the multiplets are different from one another ($J_{^{13}C\text{-}4,^{15}N}$: *trans* isomer 4.1 Hz, *cis* isomer 4.1 Hz; $J_{^{13}C\text{-}6,^{15}N}$: *trans* isomer 7.0 Hz, *cis* isomer 6.4 Hz; isotope shift C-4, *cis* +0.02, *trans* +0.02; C-6, *cis* −0.04, *trans*, −0.04). Each of the two sets of multiplets consists of a doublet superimposed on a singlet. The doublet (87 ± 11%) (^{13}C-6,^{15}N) in the signals due to C-6 (*trans*, δ 55.7, *cis*, δ 52.9 ppm) is much more intense than the singlet (13 ± 2%) (^{13}C-6,^{14}N) (Tables 2 and 3), so that the latter is not apparent in the unexpanded spectrum. In the signals due to C-4 (*trans*, δ 54.8, *cis*, δ 44.6 ppm) the doublet (36 ± 5% of signal area, Tables 2 and 3) (^{13}C-4,^{15}N) appears as a shoulder straddling the singlet (64 ± 8%) (^{13}C-4,^{14}N). The doublet/singlet ratios at C-6 ((87 ± 11)/(13 ± 2) = 6.7 ± 1.3) and at C-4 ((36 ± 5)/(64 ± 8) = 0.6 ± 0.1) thus differ from one another by an order of magnitude (Tables 2 and 3).

Lupinine hydrochloride obtained from the feeding experiment with [L-4-^3H/DL-6-^{14}C]lysine (Experiment 6) was converted into the methiodide and crystallized to constant radioactivity and constant tritium/^{14}C ratio. The $^3H/^{14}C$ ratio of the purified lupinine methiodide was 8.4 ± 0.1, approximately double that of the intermolecularly doubly $^3H/^{14}C$ labelled lysine that had served as the substrate ($^3H/^{14}C$ of lysine, 4.1 ± 0.1 (Table 1)).

The deuterium nmr spectra of the samples of lupinine (free base) from the experiments with deuterium labelled substrates (Experiments 1–4, Table 1) are shown in Fig. 2. The deuterium chemical shifts observed in the spectra of these four

[c]Peak areas are normalized relative to C-8 = 100%. Estimated standard deviation ±8% for singlet signals, ±10% for composite signals.
[d]The ratio A_E/A_{NA} is normalized so that the average value for carbon atoms 1, 2, 3, 7, 8, and 9 equals 1.0.
[e]$((1.08\ A_E/A_{NA}) - 1) \times 1.1\%$ for singlets; $(1.08\ A_E/A_{NA}) \times 1.1\%$ for doublets.
[f]The average specific incorporation per C_5 unit = $1/4(12.7(\pm1.3) + 12.1(\pm1.5) + 15.1(\pm1.8) + 9.9(\pm1.2))/(99/2) \times 100\% = 25 \pm 2\%$.

lupinine samples are summarized in Table 4 and are compared with the corresponding proton chemical shifts (Table 5). The ^{2}H nmr spectra of two lupinine samples, that derived from (*S*)-(1-^{2}H)cadaverine (Experiment 2) and that derived from the L-component of DL-(2-^{2}H)lysine (Experiment 3), were identical, each showing two signals, at δ 1.72 (±0.01) and 1.54 ppm. The chemical shifts of the two signals (δ 4.11 and 1.80 ppm) in the spectrum of the sample derived from (2-^{2}H)-Δ^1-piperideine (Experiment 4) corresponded to those of two of the signals (δ 4.14 and 1.77) in the spectrum of the sample from (*R*)-(1-^{2}H)cadaverine (Experiment 1). The latter spectrum showed an additional signal at δ 2.50 ppm. The assignment of these spectra will be discussed in the appropriate context of the next section.

Discussion

The results of the tracer experiments with ^{14}C-labelled lysine (7) and cadaverine (6, 8) and with DL-(4,5-$^{13}C_2$)lysine (9) do not discriminate among the various biogenetic hypotheses that have been advanced to account for the biosynthesis of lupinine (**20**) (Scheme 1A, B, C). The first task in a reexamination of the problem was to devise experiments capable of narrowing down the possibilities.

All the hypotheses that have been advanced (Scheme 1) share a common initial phase, decarboxylation of lysine (**1**) to cadaverine (**2**), followed by oxidative deamination of the latter

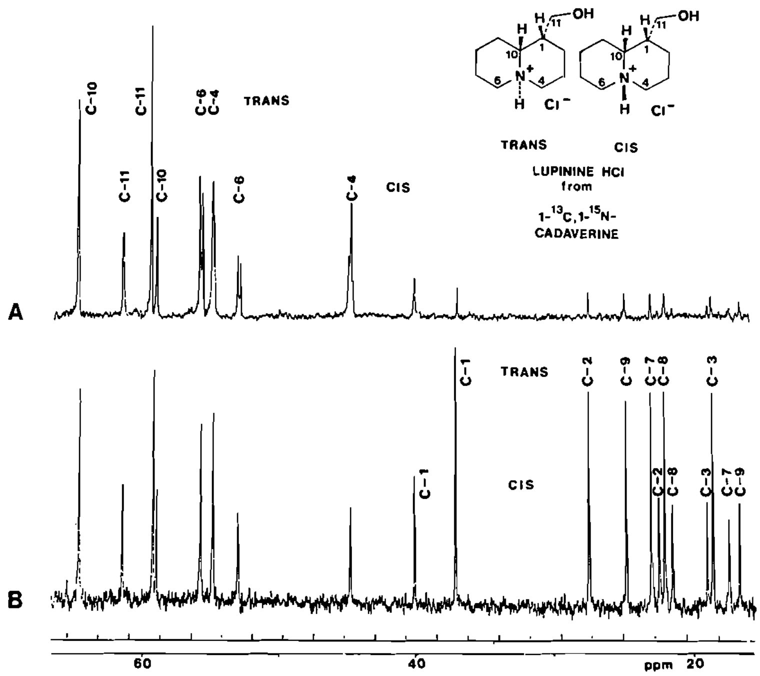

FIG. 1. ^{13}C nmr spectra (20.15 MHz) of lupinine hydrochloride. The spectra were recorded in the Fourier mode on a Bruker WP 80 spectrometer, in 2-mm tubes, with the natural abundance methyl signal of acetone (29.8 ppm) as internal reference. The acquisition time was 3.41 s. For further details see Tables 2 and 3. Top: Fig. 1A. Proton-noise decoupled (P.N.D.) spectrum (20 000 scans) of the $^{13}C,^{15}N$-enriched sample of lupinine hydrochloride (10 mg in 10 μL ^2H_2O) derived from (1-^{13}C,1-^{15}N)cadaverine (Experiment 5). Bottom: Fig. 1B. P.N.D. Spectrum (18 112 scans) of a natural abundance sample of lupinine hydrochloride (17 mg in 20 μL ^2H_2O).

[a]The ^1H nmr spectrum. Recorded in C_6D_6 at 250 MHz and 400 MHz in the Fourier mode on a Bruker WM 250 and WH 400 spectrometer, respectively. For full assignment of the proton spectrum, see Table 5.
[b]The ^2H nmr spectra. Recorded in C_6H_6 at 38.40 MHz in the Fourier mode on a Bruker WM 250 spectrometer, in 10-mm tubes with natural abundance C_6DH_5 (7.19 ppm) as internal reference. Acquisition time 2.048 s.

to 5-aminopentanal (**3**), an aminoaldehyde in equilibrium with its intramolecular Schiff base, Δ^1-piperideine (**4**) (Scheme 1A). The hypotheses also agree on the final step in the biogenetic process, reduction of lupinal (**19**) to lupinine (**20**) (Scheme 1C). The hypotheses differ in the proposed routes leading from 5-aminopentanal (**3**) ($\rightleftharpoons$ Δ^1-piperideine (**4**)) to lupinal (**19**) (Schemes 1B, 1C).

What was required for a critical examination of the biogenetic process was a method which could distinguish the different paths between 5-aminopentanal (**3**), the last early intermediate common to all the biogenetic proposals, and lupinal (**19**), the common intermediate of the final stage. One way of differentiating among the routes would be by an experiment capable of tracing the fate of the intact C—N bond of 5-aminopentanal (**3**) into the product.

A successful experiment, leading to incorporation of such a C—N bond into lupinine, can have one of three different outcomes. Two of the routes (Schemes 1Bd and 1Be) lead from **3** into **19**, via the bicyclic compound (**18**) and other intermediates, in such a way that the intact C—N bond of **3** is destined to become the C-6,N bond of lupinine (Scheme 3C). A third route (Scheme 1Bc) leads from **3** into **19**, via the bicyclic compound (**17**) and other intermediates, in such a way that the intact C—N bond of **3** is destined to become the C-4,N bond of lupinine (Scheme 3B). It can be predicted that each of these routes leads to a sample of lupinine in which only one of the three C—N bonds of the product is derived from the intact C—N bond of **3**.

The other two routes (Schemes 1Ba and 1Bb) differ from the above in that they give rise to a sample of lupinine which

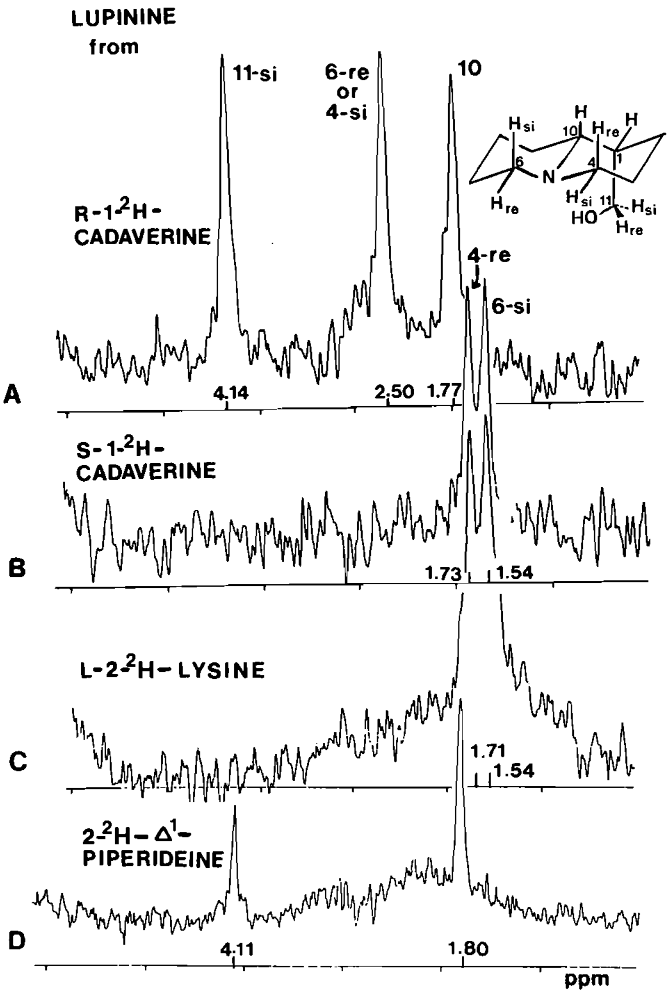

FIG. 2. ^{2}H nmr spectra (38.40 MHz) of deuterium-enriched samples of lupinine derived from deuterium labelled substrates (Experiments 1–4). The spectra were recorded in the Fourier mode on a Bruker WM 250 spectrometer, in 10-mm tubes, with natural abundance C_6DH_5 (7.19 ppm) as internal reference. The acquisition time was 2.048 s (see Table 4). 2A. Lupinine from (*R*)-(1-^{2}H)cadaverine (Experiment 1). 2B. Lupinine from (*S*)-(1-^{2}H)cadaverine (Experiment 2). 2C. Lupinine from the L-component of DL-(2-^{2}H)lysine (Experiment 3). 2D. Lupinine from (2-^{2}H)-Δ^1-piperideine (Experiment 4).

contains an equimolar mixture of two species, one of which contains the intact C—N bond of **3** at C-4,N while the other contains it at C-6,N. This is the consequence of the postulated intermediacy of the dialdehydeimine (**7**). This compound contains two C—N bonds, but only one of these is derived intact from **3**. However, the compound possesses C_{2v} symmetry. Ring closure of **7** by an intramolecular Mannich reaction to yield lupinal (**19**) can take place in two equivalent ways. The C—N bond that is derived intact from **3** has an equal chance of becoming either C-4,N or C-6,N within the product. The product will then comprise an equimolar mixture of two chemically indistinguishable species, which differ solely in the origin of the two C—N bonds, C-4,N and C-6,N (Scheme 3A).

The origin of the two C—N bonds of lupinine, C-4,N and C-6,N, can be determined by a tracer experiment with C—N "bond-labelled" 5-aminopentanal (**3**) or one of its precursors, lysine (**1**) or cadaverine (**2**). A sample of the latter, intramolecularly doubly ^{13}C,^{15}N labelled (NH_2—CH_2—CH_2—CH_2—CH_2—$^{13}CH_2$—$^{15}NH_2$), was employed to probe the incorporation of an intact C—N bond into lupinine (Experiment 5) (11). A similar experiment, with essentially identical results and conclusions, was reported in an independent investigation (14). Entry of this bond-labelled cadaverine, via 5-aminopentanal, by route Bd or Be (Scheme 1), should yield a single species of intramolecularly ^{13}C,^{15}N doubly labelled product in which the ^{13}C,^{15}N moiety is located at the C-6,N position of lupinine. Entry by Route Bc (Scheme 1) should similarly yield lupinine enriched at C-4,N. Entry via the nondissymmetric intermediate **7** (Routes Ba, Bb, Scheme 1) must yield an *equimolar mixture* of the above two enriched species (Scheme 3A). Non-equimolar enrichment at the two sites, C-4,N and C-6,N, is not consistent with the intermediacy of a "dimeric" compound with C_{2v} symmetry, such as **7**.

TABLE 5. The ^{13}C and ^{1}H nmr spectra of *trans*-lupinine (free base)

Carbon	^{13}C nmr[a] chemical shifts (ppm)[c,d]	^{1}H nmr[b] chemical shifts (ppm)[c] axial protons	equatorial protons

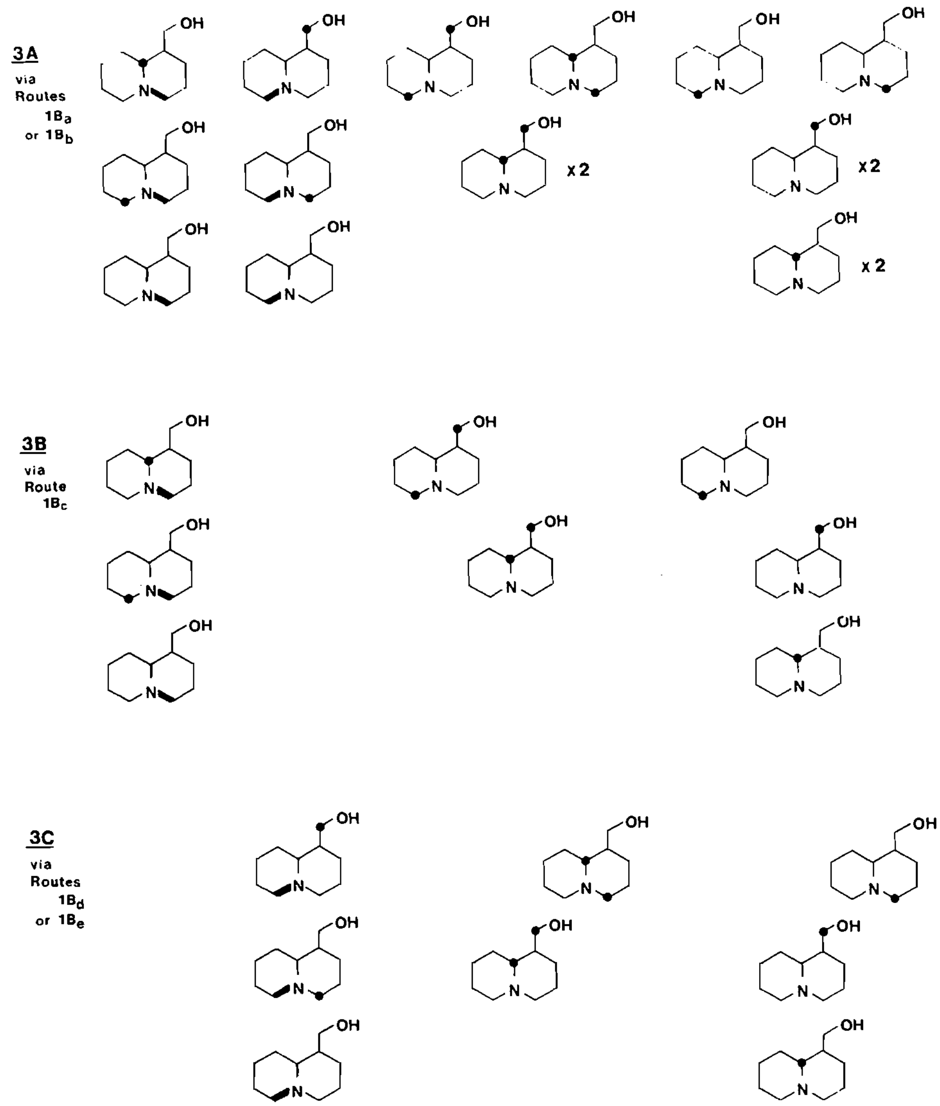
The proton noise decoupled ^{13}C nmr spectrum of the sample of lupinine hydrochloride (a mixture of the *trans* and the *cis* isomers, in the ratio 1.7:1) isolated from plants to which (1-^{13}C,1-^{15}N)cadaverine dihydrochloride had been administered in admixture with [1-^{14}C]cadaverine dihydrochloride (Experiment 5, Table 1) is shown in Fig. 1A.

Lupinine hydrochloride rather than the free base was chosen as the compound for ^{13}C nmr analysis since, even though the salt consists of a mixture of the *trans* and *cis* ring fused isomers, in the ^{13}C nmr spectrum of the *cis* isomer in D_2O the signals due to C-4, -6, -10, and -11, the carbon atoms crucial for the interpretation of the biosynthetic experiment, are well resolved (15) (Δδ C-4,-6: 8.3; C-10,-11: 2.4 ppm) (Table 3). The free base, on the other hand, is *trans* ring fused, and the corresponding signals in the spectrum of the free base show poor resolution (Δδ C-4,-6: 0 (15.1 MHz (15, 16), 5.0 MHz (17)), 0.1 (22.5 MHz (18)) in $CDCl_3$; 0.1 (50.3 MHz (14)) in C_6D_6; Δδ C-10,-11: 0 (16), 0.4 (15) (15.1 MHz), 0.3 (5.0 MHz (17)), 0.9 (22.5 MHz (18)) in $CDCl_3$; 0.3 (50.3 MHz (14)) in C_6D_6).

Spectral assignments of the crucial carbon atoms, C-4, -6, -10, and -11, were made as follows: The natural abundance proton noise decoupled ^{13}C spectrum of lupinine hydrochloride (Fig. 1B) shows two sets of 10 signals, corresponding to two stereoisomers of lupinine hydrochloride that differ in the stereochemistry of the ring fusion. Since the two sets of signals show different signal areas, the two isomers are present in



SCHEME 3. Incorporation of (1-^{13}C,1-^{15}N)cadaverine into lupinine. Labelling patterns predicted from the five biogenetic schemes outlined in Scheme 1. A. Via routes B_a or B_b, Scheme 1. B. Via route B_c, Scheme 1. C. Via routes B_d or B_e, Scheme 1. Left columns: ^{13}C,^{15}N bond-labelled species. Central columns: Doubly ^{13}C-labelled species. Right columns: Singly ^{13}C-labelled species. ● = ^{13}C; ■ = ^{13}C—^{15}N.

unequal amounts (1.7:1). The less intense set of signals shows two signals at δ 40.0 and 44.6 ppm. Signals in this spectral region are absent from the spectra of the *trans* fused free base (14–18) or the *trans* fused salt (15) but are present in the *cis* fused salt (15). The signal set of lower intensity is thus due to the *cis* fused salt, which is the less abundant (ca. 37%), and the signals at δ 40.0 and 44.6 ppm must be assigned (19) to C-1 and C-4, respectively, of this isomer. This assignment is confirmed by the off-resonance spectrum in which the signal at δ 40.0 appears as a doublet and the signal at δ 44.6 ppm as a triplet. A second signal, which in the low intensity set appears as a doublet, is that at δ 58.9 ppm, which must therefore be assigned to C-10. This leaves the downfield signal at δ 61.3 ppm to be assigned to the hydroxymethyl carbon, C-11, and the signal at δ 52.9 ppm to C-6. The corresponding resonances in the more intense signal set, due to the *trans* fused stereoisomer, which appear as doublets in the off-resonance spectrum, are those at δ 36.8 ppm (C-1) and at δ 64.7 ppm (C-10). The signal at δ 59.4 must then be assigned to C-11 and those at δ 54.8 and 55.7 ppm to the aminomethyl carbons, C-4 and C-6. Since in the spectrum of the enriched sample of lupinine hydrochloride (Fig. 1A) the high intensity signal at δ 55.7 appears as a doublet and shows a similar doublet/singlet area (1252/194 = 6.4, Table 2) as the low intensity doublet due to C-6 at δ 52.9 ppm (1039/156 = 6.7, Table 3), the signal at δ 55.7 must also be due to C-6. Similarly, the signal at δ 54.8 ppm in the high intensity set corresponds in doublet/singlet area (534/941 = 0.6, Table 2) to that at δ 44.6 ppm (434/786 = 0.6, Table 3) in the low intensity set, due to C-4.

The distribution of label within the ^{13}C,^{15}N enriched alkaloid is evident from the spectrum (Fig. 1A). As expected, only four of the ten C-atoms (C-4, C-6, C-10, C-11) are enriched in ^{13}C, to an equal extent, within experimental error (Tables 2 and 3).

The average specific incorporation of label per C_5 unit (C_5 unit A: C-6, -7, -8, -9, -10, ^{13}C enrichment in either C-6 or C-10 but not in both within the same molecule; C_5 unit B: C-11, -1, -2, -3, -4, ^{13}C enrichment in either C-11 or in C-4, but not in both), based on the ^{13}C nmr data (Tables 2 and 3), was ca. 30 at.% ^{13}C. This corresponds to an incorporation of 30/99 × 100 = 30% of cadaverine per C_5 unit, a value which is in good agreement with that obtained from ^{14}C measurements ((3.0 × 10^7)/(5.3 × 10^7)) × 100 × 1/2 = 28%, Table 1.

The signals due to C-6 and C-4 appear as multiplets. Since the coupling constants of the doublet component of these multiplets differ from one another, the multiplets do not arise from ^{13}C-6,^{13}C-4 coupling, but are due to ^{13}C,^{15}N coupling.

The intense ^{13}C-6,^{15}N doublet indicates intact incorporation of the ^{13}C—^{15}N unit of the administered cadaverine into C-6,N of lupinine. The low intensity doublet due to ^{13}C-4,^{15}N arises as a consequence of the remarkably high efficiency of incorporation, into the alkaloid, of the administered (1-^{13}C,1-^{15}N)-cadaverine. It can be calculated from the ^{13}C nmr data (Tables 2 and 3) that the enriched lupinine which was biosynthesized in the course of the experiment was diluted by natural abundance lupinine present in the plants prior to the experiment by approximately 68%. It can also be calculated that the administered doubly enriched cadaverine was diluted by no more than 25% of endogenous natural abundance cadaverine, prior to conversion into lupinine. The intensity of the ^{13}C-4,^{15}N doublet is fully accounted for by intermolecular ^{13}C,^{15}N coupling between two monomer units, derived from this highly enriched cadaverine, which are incorporated into lupinine after dimerization.

The observed difference in the doublet/singlet ratios of the signals due to C-6 and due to C-4 serves as evidence that an intermediate with C_{2v} symmetry, such as **7**, cannot be implicated in lupinine biosynthesis. The biogenetic proposals shown in Schemes 1Ba and 1Bb are thus eliminated.

Furthermore, since the intact ^{13}C—^{15}N unit of the administered cadaverine is maintained at C-6,N and not at C-4,N of lupinine, the sequence shown in Scheme 1Bc, according to which the precursor C—N bond enters C-4,N of lupinine, is no longer in contention.

The biogenetic schemes which need to be examined further are those shown in Schemes 1Bd and 1Be. These two schemes differ in the timing of the loss of the nitrogen atom of one of the two cadaverine-derived aminopentanal units. Scheme 1Bd postulates that this nitrogen atom is lost at an early stage, so that the aminopentanal-derived intermediate which serves as the precursor of the C_5 chain, C-4, -3, -2, -1, -11, of lupinine is glutardialdehyde (**5**), a compound wih C_{2v} symmetry. Scheme 1Be, on the other hand, postulates that this nitrogen atom is eliminated at a late stage of biosynthesis, following formation of the C_1 dimers, **14** and **15**.

An experiment with 5-aminopentanal or Δ^1-piperideine, labelled at the sp^2 carbon atoms with ^{13}C or ^{14}C, would serve as a critical test of these two suggested routes. In one instance (Scheme 1Bd), three of the carbon atoms of lupinine, C-10, C-11, and C-4, should carry label. In the other instance (Scheme 1Be), label should be present at two of these carbons, C-10 and C-11, but not at the third, C-4. Similarly, an experiment with 5-aminopentanal or Δ^1-piperideine labelled with deuterium at the sp^2 carbon atom would distinguish these two routes, provided that it can be demonstrated that the integrity of the C—D bond is maintained in the course of the biogenetic process. The results of an experiment with (2-^{2}H)-Δ^1-piperideine (Experiment 4) that fulfils this condition will be discussed later. On the basis of this experiment and of other experiments with deuteriated substrates (Experiments 1–3) (see later) the hypothesis based on the intermediacy of glutardialdehyde (Scheme 1Bd) can be discounted.

The biogenetic sequence shown in Scheme 1Be remains. It is consistent with all available experimental evidence.

The initial step in the biosynthetic process leading to lupinine from primary metabolites is the decarboxylation of lysine (**1**) to yield cadaverine (**2**). Two stereochemical questions concerning this step must be answered. First, it must be established whether L-(i.e., (*S*)-)lysine or D-(i.e., (*R*)-)lysine serves as the substrate. Secondly, it must be established whether the decarboxylation process which converts this lysine into cadaverine takes place with net retention of configuration or with net inversion of configuration. We have answered both these questions.

The result of the experiment with intermolecularly doubly labelled [L-^{3}H/DL-^{14}C]lysine (Experiment 6) demonstrates that L-lysine, rather than D-lysine or DL-lysine, serves as the precursor of lupinine in *L. luteus*. The ^{3}H/^{14}C ratio of the doubly labelled lysine that was administered to the plants was 4.1 ± 0.1. The ^{3}H/^{14}C ratio of the lupinine methiodide that was obtained was 8.4 ± 0.1 (Table 1). From these results it can be calculated that, within experimental error, lupinine is derived entirely (102 ± 3%) from L-lysine (% of product derived from L-substrate = 50 (^{3}H/^{14}C ratio of product)/(^{3}H/^{14}C ratio of substrate)) (20).

Demonstration that the decarboxylation of L-lysine to cadaverine takes place with net retention of configuration comes from two of the experiments with deuteriated substrates.

These experiments (Experiments 1–4), which solved not only this stereochemical problem, but which also answered all other stereochemical questions concerning the biosynthetic steps of the route from lysine into lupinine that involve transformations at those carbon atoms of lupinine which originate from the terminal carbon atoms of cadaverine, will now be discussed.

In the first two of these experiments, samples of cadaverine, chirally deuteriated at C-1, were used as substrates. The samples of lupinine obtained from these experiments were examined by ^{2}H nmr. The ^{2}H nmr spectra are shown in Figs. 2A and 2B. Chemical shifts were assigned by comparison with the corresponding ^{1}H nmr chemical shifts (Table 4).

Unambiguous assignment of the resonances due to the 19 protons of lupinine was not possible with one-dimensional nmr spectroscopy, even at 400 MHz, because of substantial overlap of some of the signals. Homo- and heteroscalar correlated two-dimensional ^{1}H and ^{1}H,^{13}C nmr spectroscopy (COSY) and *J*-resolved 2D ^{1}H nmr spectroscopy were employed for a complete assignment of the spectrum. Assignment of the downfield signals, due to the 11-*re* and 11-*si* protons, had been reported (21). A full discussion of the ^{1}H nmr spectrum of lupinine will appear elsewhere (19). Assignments of the signals due to the protons of importance in this study are given in Table 4. These assignments were originally made on the basis of a spectrum determined at 250 MHz and subsequently confirmed on the basis of 400-MHz two-dimensional spectra (Table 5). But even at this frequency the signals for two pairs of protons, 4α and 6α, and 4β and 10β, which appeared as two unresolved signals at 250 MHz, were insufficiently separated for unequivocal assignment of the deuterium signals at chemical shifts corresponding to these positions: 4α (eq) 2.57, 6α (eq) 2.51; 4β (ax) 1.75, 10β (ax) 1.78 ppm. Assignment of the other three protons of interest, 6β (ax), 1.57; 11-*re*, 3.75; 11-*si*, 4.16 ppm, did not pose a problem.

On the basis of the proton resonances, the deuterium signals in the spectrum of lupinine derived from (*R*)-(1-^{2}H)cadaverine (Fig. 2A) can be assigned as follows: δ 4.14, H-11-*si* (corresponding to the signal at δ 4.16 ppm in the ^{1}H spectrum); δ 2.50, either H-6α (2.51) or H-4α (2.57); δ 1.77, either H-4β (1.75) or H-10β (1.78 ppm). Similarly, the signals in the spectrum of lupinine from (*S*)-(1-^{2}H)cadaverine (Fig. 2B) are due to the following protons: δ 1.73, either H-4β (1.75) or H-10β (1.78); 1.54, H-6β (1.57 ppm).

These spectral assignments lead to four possible sets of deuteriated positions in the sample of lupinine from (*R*)-(1-^{2}H)-cadaverine, and to two possible sets in the sample of lupinine from (*S*)-(1-^{2}H)cadaverine, a total of eight possible combinations for the assignment of the two spectra:

	Spectrum 2A: lupinine from (*R*)-(1-^{2}H)cadaverine				Spectrum 2B: lupinine from (*S*)-(1-^{2}H)cadaverine	
	δ 4.14	δ 2.50	δ 1.77		δ 1.54	δ 1.73
1.	H-11 *si*	H-6α	H-4β	a.	H-6β	H-4β
2.	H-11 *si*	H-6α	H-10β	b.	H-6β	H-10β
3.	H-11 *si*	H-4α	H-4β			
4.	H-11 *si*	H-4α	H-10β			

A number of these combinations of assignments can be eliminated on the basis of considerations which follow from the fact that the samples of lupinine from (*R*)- and from (*S*)-(1-^{2}H)cadaverine give different ^{2}H nmr spectra and that incorporation is thus stereospecific.

Firstly, it can be assumed that, since incorporation is stereospecific, the α and β protons at any one carbon atom cannot both be deuteriated in a given lupinine sample. Thus, assignment 3 for spectrum 2A, in which H-4α and H-4β both carry deuterium, can be discounted.

Secondly, it can be assumed that since incorporation is stereospecific, the two samples of lupinine derived from the two enantiomers of (1-^{2}H)cadaverine cannot both bear deuterium at the same site. Thus, the pair (1 + a) for the assignment of the spectra of the lupinine samples derived from (*R*)- and (*S*)-(1-^{2}H)cadaverine, respectively, can be discounted, since assignment 1 and assignment a both have a resonance assigned to H-4β. Similarly, the pairs (2 + b) and (4 + b) are eliminated, since in each pair both assignments have a resonance due to H-10β.

A further restriction follows from the mode of incorporation of ^{13}C- and ^{14}C-labelled substrates into cadaverine. From these experiments it was concluded that the two C_5 chains of lupinine, C-6, -7, -8, -9, -10 and C-4, -3, -2, -1, -11, ultimately originate from one and the same C_5 precursor. The observed localization of label in all experiments with ^{14}C-labelled tracers was consistent with equimolar distribution of radioactivity between the two C_5 chains, and the mode of incorporation of ^{13}C from (1-^{13}C,1-^{15}N)cadaverine, as demonstrated by ^{13}C nmr, proved this equimolar distribution (*vide supra*). It is quite unlikely, therefore, that a sample of lupinine formed biosynthetically from a specifically deuteriated C_5-substrate would contain two deuteriated sites in one of the two C_5 units, while the other C_5 unit is free of deuterium. Yet this is the situation presented by assignment b for spectrum 2B. According to this assignment, both deuterium sites are located on the C_5-unit, C-6, -7, -8, -9, -10, while the other C_5-unit, C-4, -3, -2, -1, -11, is devoid of deuterium. In the light of the results of earlier biosynthetic experiments such a distribution is improbable.

With these restrictions, the assignment of spectrum 2B is unambiguous. The signals at δ 1.73 and 1.54 ppm can be assigned to deuterium at H-4β and H-6β, respectively. Two possible assignments remain for spectrum 2A. While the signals at δ 4.14 and 1.77 ppm can be unequivocally assigned to deuterium at H-11-*si* and H-10β, respectively, the signal at δ 2.50 ppm is due either to H-6α or to H-4α.

Notwithstanding this remaining ambiguity in the assignment of one of the ^{2}H nmr spectra of the ^{2}H-labelled samples of lupinine, the stereochemistry of every step of the biosynthetic process from cadaverine into lupinine can now be deduced from the available evidence.

As shown by the ^{13}C nmr spectrum (Fig. 1A) of lupinine derived from (1-^{13}C,1-^{15}N)cadaverine (Experiment 5), four carbon atoms of lupinine, C-6 and C-10 of one of the C_5 units and C-4 and C-11 of the other, are derived from an α-carbon atom of cadaverine. As shown further by this spectrum, only one of the three C—N bonds of lupinine, N,C-6, represents an intact C—N bond of cadaverine, whereas the three carbon atoms, C-4, C-10, and C-11, of lupinine represent cadaverine carbon atoms from which a nitrogen atom had been detached in the course of the biosynthetic process.

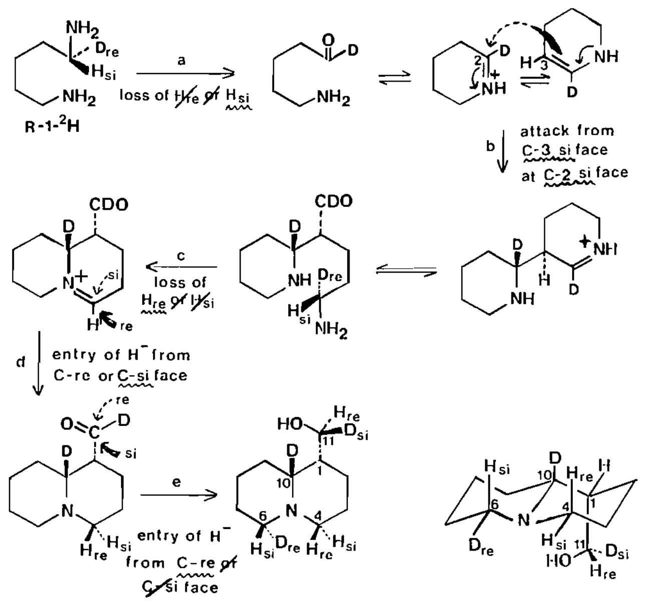
Biochemical separation of a primary amino group from a carbon atom is invariably accompanied by loss of hydrogen atom from the α-carbon, either by oxidation (catalyzed by a dehydrogenase, E.C.1.4.1., or by an oxidase, E.C.1.4.3.) or by transamination (catalyzed by an aminotransferase, e.g., E.C.2.6.1.). These processes are stereospecific, i.e., the α-hydrogen atom must be in the "correct" steric environment in order to be removed.

If, in the course of lupinine biosynthesis, removal of a hydrogen atom from the cadaverine carbon that is destined to become C-4, C-10, and C-11 of lupinine indeed takes place stereospecifically, then only one or the other, but not both, of the samples of lupinine derived from the two enantiomers of (1-^{2}H)cadaverine should carry deuterium at these positions. The carbon atom destined to become C-6 of lupinine, on the other hand, is shown by the experiment with ^{13}C,^{15}N-labelled cadaverine to remain attached to the original nitrogen atom throughout the biosynthetic process. Deuterium should then be found at C-6 in both samples of lupinine. It follows that the signal at δ 2.50 ppm in the spectrum of the sample of lupinine derived from (*S*)-(1-^{2}H)cadaverine (the "*S*-lupinine") is due to a 6 proton rather than to a 4 proton.

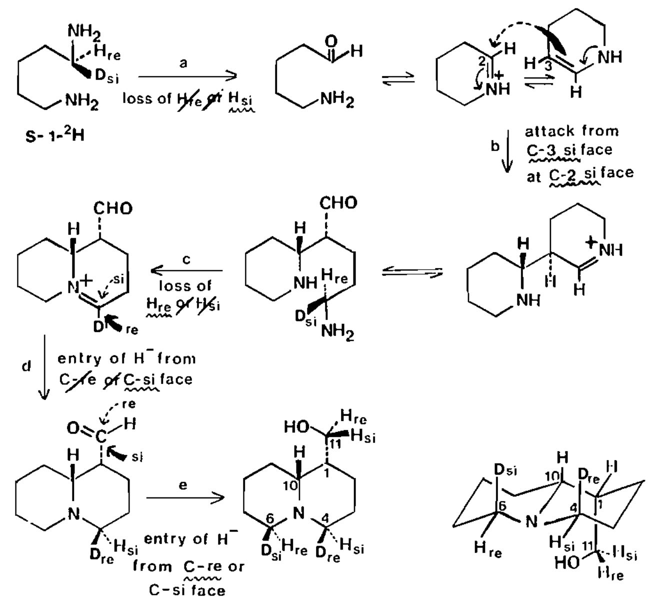
The stereospecificity of incorporation of deuterium from (*R*)- and from (*S*)-(1-^{2}H)cadaverine into the two proton sites at C-6 of lupinine serves as clear evidence that the integrity of the C—D bond of cadaverine is maintained on route into lupinine. Deuterium from (*R*)-(1-^{2}H)cadaverine enters the *re*-site (α) at C-6, whereas deuterium from (*S*)-(1-^{2}H)cadaverine enters the *si*-site (β).

With the complete assignment of the signals in the ^{2}H nmr spectra of the deuterated samples of lupinine (Figs. 2A and B), the stereochemical course of the biosynthetic steps from cadaverine into lupinine becomes clear.

The carbon atoms destined to become C-10 and C-11 of lupinine are derived, according to Schemes 1Bd and 1Be (and also 1Bc), from the aldehyde group of the intermediate 5-aminopentanal (**3**), a compound that is formed, early in the biosynthetic sequence, directly from cadaverine by loss of an amino group. Deuterium is present at C-10 and C-11 in the lupinine sample derived from (*R*)-(1-^{2}H)cadaverine ("*R*-lupinine") (Scheme 4) but not in that derived from (*S*)-(1-^{2}H)cadaverine ("*S*-lupinine") (Scheme 5). It follows that removal of the amino group in the course of conversion of cadaverine (**2**) into 5-aminopentanal (**3**) is accompanied by stereospecific loss of the *si*-proton from the α-carbon atom of cadaverine (step a, Schemes 4 and 5).



SCHEME 4. The biosynthetic route from cadaverine into lupinine and its stereochemistry: incorporation of (R)-(1-^{2}H)cadaverine.



SCHEME 5. The biosynthetic route from cadaverine into lupinine and its stereochemistry: incorporation of (S)-(1-^{2}H)cadaverine.

The observation that a signal due to deuterium at C-4 is found in the spectrum of "S-lupinine" (Fig. 2B) but not in that of "R-lupinine" (Fig. 2A) proves that glutardialdehyde (**5**) (Scheme 1Bd) cannot be implicated in the biosynthetic process: Loss of the amino group of **3** to yield **5** can, in principle, be accompanied by loss of the *si* proton or the *re* proton from the carbon α to nitrogen. If the *si* proton were lost, then the sample of "S-lupinine" should show only one deuterium signal, due to deuterium at carbon-6, while the sample of "R-lupinine" should show four signals, due to deuterium at carbons 6, 10, 4, and 11. If the *re*-proton were lost then, as a consequence of the C_{2v} symmetry of glutardialdehyde, the sample of "S-lupinine" should show signals due to deuterium at carbons 6, 4, and 11, in the ratio 2:1:1, while the sample of "R-lupinine" should show signals due to deuterium at carbons 6, 10, 4, and 11, in the ratio 2:2:1:1. This is not observed. Scheme 1Bd is thereby disproven. The amino group is thus shed at a later stage of the biosynthetic process (step c, Schemes 4 and 5). Since deuterium at C-4 is preserved in "S-lupinine" (Scheme 5) and not in "R-lupinine" (Scheme 4), it is the *re*-proton which is lost, together with the amino group, in this step.

Since the deuterium at C-4 of the "S-lupinine" is found in the *re* position, reduction of the iminium bond (step d, Scheme 5) must take place by entry of the reducing hydride ion from the *si*-face at C-4. Finally, since deuterium at C-11 of the "R-lupinine" is found in the *si* position, reduction of the carbonyl carbon (step e, Scheme 4), must take place by entry of the hydride ion from the *re*-face. The two experiments with enantiotopically deuteriated (1-^{2}H)cadaverine thus clarify the hidden stereochemistry of four steps in the biosynthetic sequence. The overt stereochemistry at C-1 and C-10 of lupinine is determined in the dimerization step (step b, Schemes 4 and 5) that leads from Δ^1-piperideine (**4**) into tetrahydroanabasine (**14**).

The proposed reaction sequence (Schemes 1Be, 4, and 5) postulates that Δ^1-piperideine serves as an intermediate between cadaverine and lupinine. The validity of the proposed sequence and its stereochemistry can be further tested by means of an experiment with deuterium-labelled Δ^1-piperideine (Experiment 4). If the conclusions drawn from the experiments with chirally deuteriated cadaverine (Experiments 1 and 2) are correct, it can be predicted that deuterium from (2-^{2}H)-Δ^1-piperideine must enter at C-10 and at C-11-*si* of lupinine. The ^{2}H nmr spectrum of a sample of lupinine derived from (2-^{2}H)-Δ^1-piperideine is shown in Fig. 2D. The predictions are fully substantiated.

The final stereochemical question that was answered in this investigation concerns the prochirality of the decarboxylation of lysine in *L. luteus*. The evidence which shows that L-lysine is the precursor of lupinine in *L. luteus* (Experiment 6) has already been discussed (*vide supra*). Decarboxylation of L-lysine yields cadaverine. In principle, this decarboxylation can take place either with net retention or with net inversion of configuration. Decarboxylation of L-(i.e., (S)-)(2-^{2}H)lysine with net retention of configuration yields (S)-(1-^{2}H)cadaverine, whereas decarboxylation with net inversion yields (R)-(1-^{2}H)cadaverine. Incorporation into lupinine of the L-component of DL-(2-^{2}H)lysine yields a sample of lupinine whose ^{2}H nmr spectrum (Fig. 2C) is identical with that of the lupinine sample obtained when (S)-(1-^{2}H)cadaverine served as the substrate (Fig. 2B).

It follows that, en route to lupinine, L-(2-^{2}H)lysine is converted into (S)-(1-^{2}H)cadaverine, i.e., in the process leading from L-lysine to cadaverine the carboxyl group of lysine is replaced by a proton with net retention of configuration. This stereochemical course is consistent with the prochirality of the reactions catalyzed by other L-amino acid decarboxylases (22) (E.C.4.1.1.).

The experimental evidence here presented serves as a critical test of the biogenetic hypotheses of lupinine biosynthesis that have been proposed. All but one of the hypotheses are disproven on the basis of the results of the six biosynthetic experiments which are here reported. The remaining hypothesis (Scheme 1Be) which is presented in full detail in Schemes 4 and 5, is entirely consistent with all the experimental evidence. This evidence throws light on the steps from lysine into lupinine and on the stereochemistry of several of these steps.

Experimental

Extraction of lupinine and sparteine from Lupinus luteus

The fresh plant material was immediately ground in a blendor with methanol and extracted in a Soxhlet apparatus for 8 h. The extract was concentrated *in vacuo* and sulfuric acid (1 *M*, 1 mL) was added to the residue. The mixture was extracted with ether (4 × 10 mL) and the aqueous phase filtered through Celite and extracted with chloroform (3 × 10 mL). The aqueous phase was neutralized with solid potassium carbonate, basified with potassium hydroxide (50% w/v, 2 mL), and extracted with methylene chloride (4 × 15 mL). The solvent was evaporated *in vacuo* and the residue once again taken through an acid/base cycle (sulfuric acid, potassium hydroxide, as above), yielding a basic fraction (25 mg) which contained lupinine (**20**) and sparteine as the major components.

The alkaloid fraction (25 mg) was applied to a silica gel column (10 × 185 mm, 4 g, 230–400 mesh, BDH). The column was washed, in turn, with methylene chloride (10 mL), 3% methanol in methylene chloride/0.880 ammonia, 500:1 (20 mL) and 5% methanol in methylene chloride/0.880 ammonia, 333:1 (40 mL). The lupinine fraction was eluted with 8% methanol in methylene chloride/0.880 ammonia, 166:1 (120 mL), the sparteine fraction with 12% methanol in methylene chloride/0.880 ammonia, 100:1 (80 mL). Yield of crude alkaloids: lupinine, 10 mg; sparteine, 4.5 mg. Lupinine was dissolved in hydrochloric acid (0.1 *M*, 0.7 mL), water and excess of acid were removed *in vacuo*, and the residue dried *in vacuo*. Recrystallization from a mixture of methanol–acetone gave lupinine hydrochloride, mp 208–209°C (lit. (23) mp 207–209°C). A small sample of lupinine was converted into lupinine methiodide, lit. (23) mp 295–296°C.

Sparteine was dissolved in acetone (2 drops) and a solution of sulfuric acid in absolute ethanol (1 *M*, 60 μL freshly prepared) was added. Crystals of the sulfate derivative formed immediately, were filtered off, and washed with a mixture of acetone and absolute ethanol (3:1, 3 drops), mp 265–266°C (dec.) (lit. (24) mp 264.5–265.5°C).

Radioactive materials

DL-[6-^{14}C]Lysine and L-[4-^{3}H]lysine were obtained from commercial sources (see Table 1).

Administration of radioactive tracers to L. luteus

Plants were grown from seed and used for tracer experiments 6 weeks after germination. The experiment was carried out in the growth chambers (Experiment 6). Tracer solution was administered to 36 plants by wick in a single dose. The plants were allowed to grow 3 days in contact with tracer.

Materials labelled with stable isotopes

(1-^{13}C,1-^{15}N)Cadaverine dihydrochloride (24)

5-Phthalimidopentano(1-^{13}C,1-^{15}N)nitrile (22)

A solution of 1-bromo-4-phthalimidobutane (**21**) (0.85 g) in dimethyl sulfoxide (1.6 mL) was added dropwise over 2 min to a stirred solution of sodium (^{13}C,^{15}N)cyanide (99 at.% ^{13}C, 99 at.% ^{15}N, MSD Isotopes, Montreal) (0.15 g) in aqueous dimethyl sulfoxide (1.6 mL DMSO, 0.2 mL H_2O). The solution was stirred 4 h at 65°C and left overnight at room temperature. Water (12 mL) was added and the mixture extracted with benzene (4 × 5 mL). The benzene extract was reextracted with water, dried, and evaporated to dryness *in vacuo*, yielding crystalline product (680 mg). A small sample was recrystallized from absolute ethanol, mp 69–70°C; ^{1}H nmr ($CDCl_3$) δ: 8.13–7.87 (4H, m), 3.83 (2H, t, *J* 6 Hz, H-5) 2.65–2.35 (2H, m, H-4), 2.1–1.9 (4H, m); ^{13}C nmr ($CDCl_3$) δ: 119.2 (d, $J_{^{13}C,^{15}N}$ 16.7 Hz), 36.7 (C-5), 27.6 (C-4), 22.7 (C-3), 16.6 (d, *J* 55.2 (Hz, C-2); ms *m/z*: 230 (6.5%), 188 (31, M − (CH_2–$^{13}C^{15}N$)), 160 (100, M − (C_3H_5–$^{13}C^{15}N$)), 149 (21), 104 (98), 77 (12), 76 (13).

*1-*N*-Acetyl-5-*N*-phthaloyl-1,5-diamino(1-^{13}C,1-^{15}N) pentane (23)*

Crude 5-phthalimidopentano(1-^{13}C,1-^{15}N)nitrile (**22**) (0.67 g) in acetic anhydride (3 mL) was added to a suspension of freshly prepared Raney nickel catalyst (0.5 g) in acetic anhydride (7 mL). (The catalyst had been freshly prepared immediately before use by gradual addition of sodium hydroxide pellets to a suspension of nickel aluminum alloy (1:1 w/w, BDH) in water, without cooling. This mixture was left for 30 min and heated on the steam bath for 1 h. The solid was then washed with water, 95% alcohol, absolute alcohol, and acetic anhydride.) Hydrogenation was carried out at 80–90°C and 1 atm for 3 h. The mixture was centrifuged, the supernatant solution was decanted, and the metallic residue washed with acetic anhydride. The solvent was evaporated *in vacuo* to yield the acetyl derivative as a solid (yield 0.8 g, mp 134–136°C, after recrystallization from absolute ethanol); ^{1}H nmr ($CDCl_3$) δ: 7.9–7.7 (4H, m), 6.0 (1H, dtd, $J_{^{15}N,H}$ 89.5 Hz, $J_{CH_2\text{-}1,NH}$ 11.2 Hz, $J_{^{13}C,NH}$ 2.8 Hz), 3.67 (2H, t, *J* 6.6 Hz, H-5), 3.23 (2H, dm, $J_{^{13}C,H\text{-}1}$ 139 Hz), 1.94 (3H, d, *J* 12 Hz), 1.8–1.3 (6H, m); ^{13}C nmr ($CDCl_3$) δ: 170.2 (^{15}NCO–), 168.6 (NCO–), 134.1 (C-3′,-4′), 132.3 (C-1′,-6′), 123.3 (C-2′,-5′), 39.5 (d, $J_{^{13}C\text{-}1,^{15}N}$ 10.2 Hz, C-1), 37.7 (C-5), 29.0 (d, *J* 33 Hz, C-2), 28.2 (d, *J* 7.1 Hz, C-4), 24.1 (CH_3), 23.3 (d, *J* 8.5 Hz, C-3).

(1-^{13}C,1-^{15}N)Cadaverine dihydrochloride (24)

Hydrochloric acid (6 *M*, 14 mL) was added to the crude acetyl derivative (**23**) and the mixture was stirred for 18 h at 100°C. Crystallization of phthalic acid started on cooling and was complete after 1 h at 0°C. The phthalic acid was removed by centrifugation and the supernatant solution was extracted with ethyl acetate (3 × 10 mL). The aqueous layer was evaporated *in vacuo*. The residue was dried (0.45 g) and recrystallized from 95% ethanol. After the first crop of crystals (0.17 g), mp 255–257°C, was filtered off, the mother liquors were chromatographed on an ion exchange column (Dowex 50-X4, H^+ form, 2.1 mequiv./mL, 1.3 × 11 cm). The column was washed with water (20 mL) and the product was eluted with hydrochloric acid (1.5 *M*, 200 mL), yielding a further crop (0.13 g) of (1-^{13}C,1-^{15}N)cadaverine dihydrochloride. Total yield 57% (relative to Na^{13}C^{15}N); ^{1}H nmr (D_2O) δ: 3.76 (1H, t, *J* 7.2 Hz), 2.97 (2H, t, *J* 7.2 Hz), 2.18 (1H, t, *J* 7.2 Hz), 1.45–1.75 (6H, m); $J_{^{13}C,H\text{-}1}$ 144 Hz; the signals at δ 3.76 and 2.18 ppm are doublets of triplets, due to ^{13}C,H-1 coupling of the 1-$^{13}CH_2$ group. The signal at δ 2.97 ppm is due to the 5-CH_2 group; ^{13}C nmr (D_2O) δ: 40.0 (d, $J_{^{13}C\text{-}1,^{15}N}$ 4.4 Hz), 27.0 (s, d, $J_{^{13}C\text{-}2,^{13}C\text{-}1}$ 35.4 Hz[3]), 23.4 (s, C-3).

DL-(2-^{2}H)Lysine monohydrochloride was prepared (13) in two steps from diethyl 2-acetamidomalonate and 1-bromo-4-phthalimidobutane (**21**). Condensation yielded diethyl 2-acetamido-2-(4-phthalimidobutyl)malonate, whose hydrolysis in DCl/D_2O yielded the desired product. DL-(2-^{2}H)Lysine monohydrochloride: ^{1}H nmr (D_2O) δ: 3.7 (ca. 0.05 H, H-2), 3.05 (2H, t, *J* 7.2 Hz, H-6), 1.3–2.0 (m, 6H).

(2-^{2}H)-Δ^1-Piperideine and (*S*)-(+)-(1-^{2}H)cadaverine hydrochloride were prepared from the above DL-(2-^{2}H)lysine (*vide infra*).

(2-^{2}H)-Δ^1-Piperideine (cf. ref. 13)

Freshly crystallized *N*-bromosuccinimide (0.32 g) was added to a solution of DL-(2-^{2}H)lysine monohydrochloride (0.64 g) in water (90 mL) and the solution was heated at 50°C in a nitrogen atmosphere on a rotary evaporator under mild suction until colorless. Three more portions of *N*-bromosuccinimide (3 × 0.32 g) were added and reaction continued in the same way. The total reaction time was 55 min. The solution was used for feeding without further purification.

A small portion of the solution was concentrated and the ^{1}H and ^{2}H nmr spectra of the mixture were determined; ^{1}H nmr δ: 7.5 (s), 6.9 (s), 6.3 (s), 4.5 (H_2O), 3.5 (bm), 3.2 (s), 3.0 (m), 2.6 (s), (CH_2–$CO)_2$NH, succinimide); ^{2}H nmr δ: 8.7 (rel. area 1), 4.9 (rel. area 2.4), 4.5 (DHO, natural abundance) ppm. When the solution was evaporated and redissolved in water, the ^{2}H nmr spectrum changed considerably: ^{2}H nmr δ: 8.3 (rel. area 5.7), 8.1 (1.3), 6.7 (1.0), 4.9 (1.8), 3.8 (4.3). When the solution was basified (K_2CO_3) and extracted six times with chloroform, the chloroform evaporated, and the residue redissolved in water, a further spectral change was observed: ^{2}H nmr δ: 7.9 (rel. area 0.1), 3.1 (0.9).

(R)-(−)- and (S)-(+)-(1-^{2}H)Cadaverine hydrochloride

(R)-(−)-(1-^{2}H)Cadaverine hydrochloride was prepared by decar-

[3]The value, 18.4 Hz, for $J_{^{13}C\text{-}2,^{13}C\text{-}1}$ that was reported in our preliminary communication (11) was in error. We thank Dr. E. Leete for pointing out this mistake.

boxylation of the L-component of DL-lysine in deuterium oxide, catalyzed by L-lysine decarboxylase (13). ^{1}H nmr (D_2O) δ: 2.95 (3.01 H, t, *J* 7.2 Hz, H-1,5) 1.45–1.75 (m, 6H); ca. 1% nondeuteriated product; ms *m/z*: 89 (M' + 1, 9%) 88 (M', 100 $^+NH_3CHD(CH_2)_4$), 87 (M' − 1, 14).

(S)-(+)-(1-^{2}H)Cadaverine hydrochloride was obtained (13) by decarboxylation, catalyzed by L-lysine decarboxylase, of the L-component of DL-(2-^{2}H)lysine (95 at.% 2-^{2}H). (*S*)-(+)-(1-^{2}H)-Cadaverine dihydrochloride (93 at.% 1-^{2}H): ^{1}H nmr (D_2O) similar to that of (*R*)-(−)-(1-^{2}H)cadaverine hydrochloride, above; ms *m/z*: 89 (M' + 1, 10.6%), 88 (M', 100), 87 (M' − 1, 16), 7% non-deuteriated product, based on computer assisted peak height analysis.

Administration of enriched substrates to L. luteus

The plants used in these experiments were grown from seed and were used in feeding experiments 3–6 weeks after germination. The feeding experiments were carried out in the greenhouse (summer months, Experiments 3, 5) or in the growth chambers (winter months, Experiments 1, 2, 4). Tracer solution was administered by wick over a period of 5–6 days; the plants were then grown for a further period of 3–4 days before being harvested.

Acknowledgements

We are grateful to Professor Dr. M. Wiewiórowski, University of Poznan, for a gift of seeds of *Lupinus luteus*, to Thelma Leech, Greenhouse Supervisor, McMaster University, for providing facilities for our experiments, and to J. Ian A. Thompson and Brian G. Sayer, Department of Chemistry, for recording nmr spectra. We are greatly indebted to Dr. R. E. Lenkinski, South Western Ontario NMR Facility, University of Guelph, for determining COSY and 2-D *J* resolved spectra. This investigation was supported by a grant from the Natural Sciences and Engineering Research Council of Canada.

P. C. GOSWAMI, PAUL DE MAYO, N. RAMNATH, G. BERNARD, N. OMKARAM, JOHN R. SCHEFFER, and Y-F. WONG. Can. J. Chem. **63**, 2719 (1985).

Dianin's compound (4-*p*-hydroxyphenyl-2,2,4-trimethylchroman) serves as host in a series of well-defined clathrate inclusion complexes with eleven linear, as well as branched chain, phenyl alkyl ketone guest molecules, chosen for their ability to undergo the Norrish type I and type II photochemical reactions in solution. The photochemical reactivity of the guest ketones within the clathrate cavity was determined by irradiation of the inclusion complexes in the solid state. The results were compared to the photoreactivity of the ketones in polar as well as nonpolar liquid media. In general, the inclusion complex medium brings about an enhancement of type I over type II reactivity and causes an increase in type II fragmentation compared to type II cyclization. This change in reactivity is interpreted as resulting from the relatively restricted environment of the clathrate cavity coupled with the greater motion required for the type II process (γ-hydrogen abstraction) compared to the type I reaction (α-cleavage), as well as from the greater steric requirements for type II cyclization (cyclobutanol formation) as compared to type II cleavage (1,4-hydroxybiradical scission).

P. C. GOSWAMI, PAUL DE MAYO, N. RAMNATH, G. BERNARD, N. OMKARAM, JOHN R. SCHEFFER et Y-F. WONG. Can. J. Chem. **63**, 2719 (1985).

Il se forme des complexes d'inclusion bien définis à l'intérieur de clathrates du composé de Dianin, le *p*-hydroxyphényl-4 triméthyl-2,2,4 chromane, avec des phényl alkyl cétones, incluant tant des composés aliphatiques en chaînes droites ou ramifiées, choisies pour leur facilité de subir des réactions photochimiques de Norrish des types I et II, en solution. On a déterminé la réactivité photochimique des molécules hôtes à l'intérieur de la cavité en procédant à l'irradiation des complexes d'inclusion à l'état solide. On compare les résultats obtenus avec les photoréactivités des cétones tant dans des milieux polaires que dans des milieux liquides non polaires. D'une façon générale, les complexes d'inclusion augmentent la réactivité du type I par rapport au type II et provoquent une augmentation de la fragmentation du type II par rapport à la cyclisation du type II. On suggère que ce changement dans la réactivité provient d'un effet combiné de l'environnement relativement restreint qui existe dans la cavité du clathrate avec le fait que, par rapport à la réaction de type I (coupure en α), le processus de type II (enlèvement d'un hydrogène en γ) nécessite de plus grands déplacements; de plus, les besoins stériques des cyclisations de type II (formation du cyclobutanol) sont plus importants que ceux requis pour les scissions du type II (scission en hydroxybiradical-1,4).

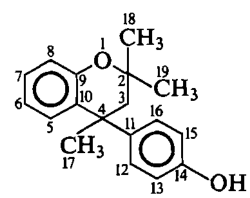
Introduction

The use of organized media to modify photochemical reactivity, as compared to that observed in isotropic liquids, is a subject of considerable current interest. Media which have been investigated include crystals (1−9), liquid crystals (10−12), monolayers (13, 14), micelles (14−25), and surfaces (26−29). A major goal of such studies is to utilize the order of the medium so as to increase the rate and selectivity of the photochemical processes involved in much the same way that enzymes modify the reactivity of the substrates to which they are bound.

An additional technique which holds great promise in this regard is the use of molecular inclusion complexes. Inclusion complexes may be divided into several categories. These include the channel type (e.g., urea), the layer or intercalation type (e.g., graphite), and the true clathrate type in which the guest molecules are located in discrete closed cavities or cages of the host molecule. Examples of this last type are the cyclodextrins (30) as well as the molecule which is the subject of this paper, Dianin's compound (4-*p*-hydroxyphenyl-2,2,4-trimethylchroman), **1** (31).



1

Compound **1** was first synthesized and its ability to retain organic solvents first noted by Dianin in 1914 (32). Subsequent work has shown that Dianin's compound is capable of including a wide variety of organic molecules, including ketones (33). X-ray crystallography (34, 35) reveals that six molecules of compound **1** form a cage and that the cages are hourglass shaped with a length of approximately 11 Å, a mid-point width of 4.2 Å, and a maximum upper and lower width of 6.3 Å. The ends of each cage have a width of 2.8 Å and are formed by six hydrogen-bonded hydroxyl groups (Fig. 1). The cages may hold two small molecules in the wide parts or one larger guest.

Some inclusion complexes, such as those formed between organic molecules and the cyclodextrins, are stable in solution, particularly in aqueous solution where the hydrophobic guest molecule seeks the cavity so as to escape from the aqueous

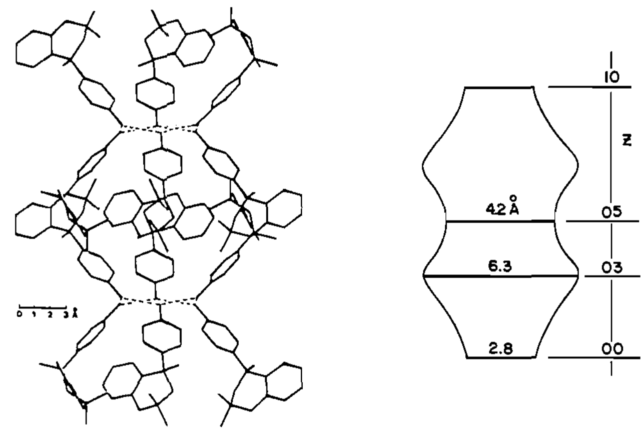

FIG. 1. The left figure is a view normal to the c-axis of unsolvated Dianin's compound (taken from ref. 31). The right figure represents the shape and size of the largest figure of revolution which can fit into the cage. The height is 11 Å (taken from ref. 34).

environment; complexes such as these are most conveniently studied in solution. On the other hand, inclusion complexes with Dianin's compound dissociate upon dissolving in organic solvents and, therefore, must be studied in the solid state. Recently there have been several reports of photochemical reactions of guest molecules in crystalline inclusion complexes of various types. These include stilbene photoisomerization in a tri-*o*-thymotide complex (36), the reactions of dialkyl and aralkyl ketones in deoxycholic acid (37−41), the photoisomerization of α-oxoamides, also in deoxycholic acid (42), the [2+2] photocycloaddition of chalcone derivatives in 1,1,6,6-tetraphenyl-2,4-hexadiyn-1,6-diol (43), the photodecomposition of alkanones in urea inclusion compounds (44), and the photochemistry of di-tert-butyl thioketone in deoxycholic acid (45). In this paper we report an investigation of the Norrish type I and type II photochemical reactions of guest aryl alkyl ketones included in Dianin's compound. These reactions were chosen because the solution state photochemistry of a wide variety of aralkyl ketones has been well established and shown to be sensitive to changes in the irradiation medium (46−51). They should, therefore, provide a sensitive probe of the environment of the Dianin complex cavity. Very recently, Turro and Wan have reported an investigation of the type I and type II reactions of aralkyl ketones adsorbed on zeolite molecular sieves (52). A comparison of our results with theirs is a further point of interest in this study.

Results

Inclusion complexes

The aryl alkyl ketones **2**−**12** (Table 1) were chosen for study. Differing only in the nature of the alkyl chain, they range from simple linear systems to moderately complex branched chain compounds. Their selection was based in part on a desire to test the limits of the size of the molecules which can be accommodated within the cavity. The solution phase photochemistry of most of these molecules has been investigated previously in some detail (53−56).

The complexes were prepared by slow crystallization from solutions of "empty" Dianin's compound dissolved in excess liquid ketone. After filtration, the crystalline complexes were dried (50−55°C, 0.05 Torr; 1 Torr = 133.3 Pa) to constant weight. The host/guest ratio in each case was determined in one or more of three ways: nmr spectroscopy, uv spectroscopy, or gas chromatography (see experimental section for details).

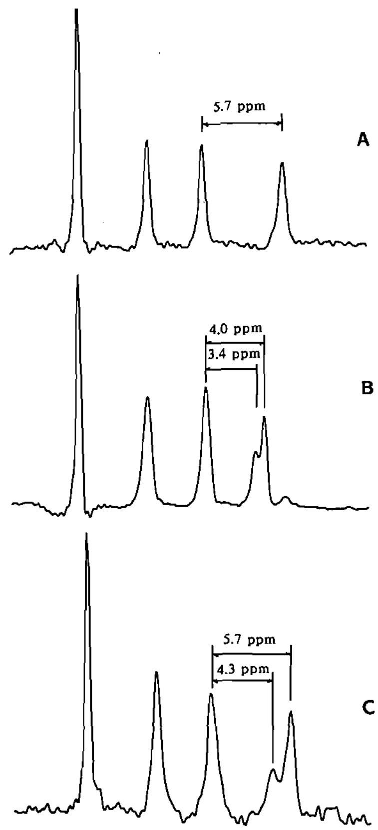

FIG. 2. Partial ^{13}C CPMAS solid state nmr spectra of Dianin's compound (A) and its inclusion complexes with ketones **7** (B) and **3** (C).

The results are summarized in Table 1. In general it was found that the host/guest ratio increased with increasing alkyl chain length and (or) methyl substitution at the α-position. Methyl substitution at the β-position (ketone **6**) also caused an increase in the host/guest ratio, but when the β-substituent is "tied back" as part of a cycloalkane ring (ketones **7** and **8**), the host/guest ratio is once again in the normal 6−9 range.

In the case of three of the complexes (those with butyrophenone (**2**), valerophenone (**3**), and α-cyclohexylacetophenone (**7**)), solid state magic angle spinning ^{13}C nmr was used to determine whether or not the guest molecules were properly included within the host cavity. These experiments were based on work by Ripmeester (57), who showed that the formation of Dianin's complexes causes certain characteristic chemical shift changes in the host spectrum compared to the uncomplexed spectrum. Specifically, the chemical shift difference between the C18 and C19 *gem*-dimethyl groups of Dianin's compound was found to decrease from 5.7 ppm in the uncomplexed form to 3.3−4.7 ppm in the complexed form, depending on the nature of the guest molecule. Figure 2 shows the spectral region in question for empty Dianin's compound as well as for its complexes with ketones **3** and **7**. We note that for both complexes there are *two* upfield methyl signals. We interpret this as indicating two nonequivalent sites for complexation. In the case of the complex with ketone **7**, the chemical shift differences are 4.0 (major) and 3.4 (minor) ppm, both consistent with full complexation. For the complex with valerophenone (**3**), the chemical shift differences are 5.7 (major) and 4.3 (minor) ppm. The closeness of the 5.7-ppm chemical shift difference to that for the unoccupied Dianin's compound may indicate that the major part of the valero-

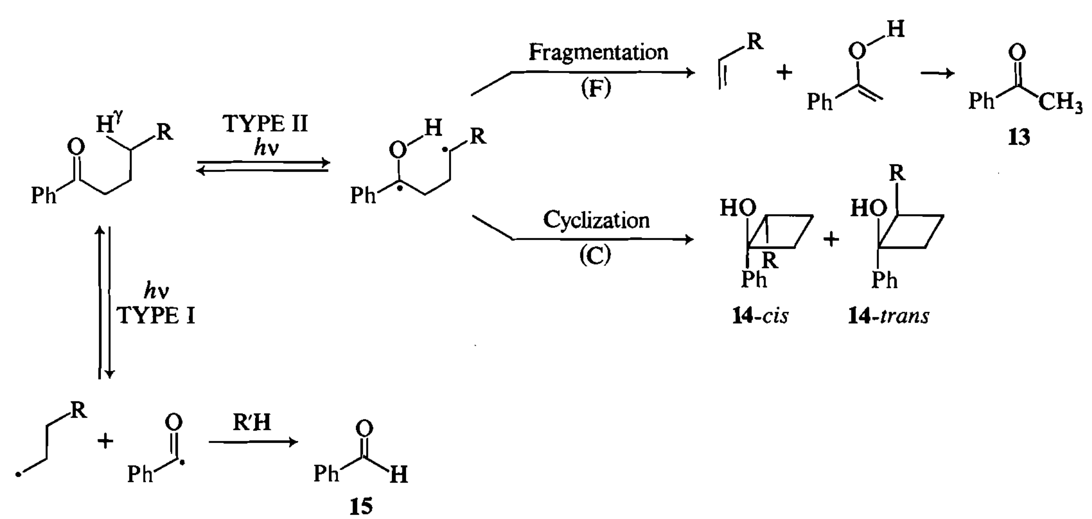
[a] Conversions were generally kept below 20%. All irradiations were conducted using a 450-W Hanovia medium pressure mercury lamp except those involving ketones **7** and **8**, which utilized a pulsed nitrogen laser. The estimated error in the photoproduct ratios is 10% of the quoted values.
[b] Ratio of Dianin's compound **1** to ketone as determined by uv, nmr and (or) gc. See experimental section for details.
[c] Ratio of acetophenone **13** to cyclobutanols **14**.
[d] *trans*-Cyclobutanol to *cis*-cyclobutanol ratio.
[e] Ratio of benzaldehyde to total type II photoproducts. No entry indicates no observable benzaldehyde.
[f] Reported to give only cleavage upon irradiation in pentane or ethanol (56).
[g] Cyclobutanol photoproduct formed in trace amounts only.
[h] Not determined due to poor gc separation and small amounts.
[i] Not previously photolyzed.



SCHEME 1

phenone is only weakly complexed. As we shall see, this may be the reason that the photochemical results with the valerophenone complex more closely resemble the solution results, whereas irradiation of the crystalline complex of ketone **7** leads to results which are more solid state-like. The solid state nmr (and photochemical) results with the butyrophenone (**2**) complex were qualitatively similar to those with the valerophenone complex, although the spectra were not as well resolved.

Photochemistry

Even though the solution phase photochemistry of most of the ketones listed in Table 1 has been reported previously (53–56), for the sake of direct comparison under a common set of reaction conditions each was re-irradiated in a nonpolar solvent (benzene) as well as in polar solution (*tert*-butyl alcohol or acetonitrile). The ketone concentration was 0.1 *M*, and the light source was a 450-W Hanovia medium pressure mercury lamp fitted with a Pyrex filter sleeve. Only in the case of ketones **7** and **8** was the light source different, consisting of the output from a Molectron UV 22 pulsed nitrogen laser (wavelength 337 nm). Irradiation of the crystalline inclusion complexes was conducted using the same light sources in sealed Pyrex sample tubes, which had been degassed by several evacuation/nitrogen purge cycles. All product ratios were determined by gas chromatography using the appropriate internal standards.

Three product ratios were determined for each compound and medium investigated. (1) F/C, the type II fragmentation to cyclization ratio. Following γ-hydrogen abstraction, the intermediate 1,4-hydroxybiradical can return to starting material, fragment to give the enol of acetophenone, or cyclize to cyclobutanol (Scheme 1) (46–51). The F/C ratio is defined as the yield of acetophenone divided by the total cyclobutanol yield, i.e., **13**/**14**. (2) *t*/*c*, the *trans*-cyclobutanol to *cis*-cyclobutanol ratio. The *trans* isomer is defined as the epimer having the phenyl and R groups *trans* to one another. (3) Type I/Type II, the ratio in which the excited ketones partition themselves between Norrish type I (α-cleavage) and Norrish type II reactivity. For the ketones **2**–**12**, type I reactivity is characterized by formation of benzaldehyde (Scheme 1), and the type I/type II ratio is defined as the yield of benzaldehyde **15** divided by the total yield of the type II products acetophenone and *cis* and *trans* cyclobutanols.

The following generalizations appear to be justified on the basis of the data collected in Table 1. (1) F/C ratio: For ketones **2**–**8**, the fragmentation/cyclization ratios obtained in the crystalline complex differ relatively little from the solution phase ratios and are closer to the benzene values than the *tert*-butyl alcohol values. An exception to this generalization is ketone **5** for which the solid state F/C ratio is some four times greater than the benzene value and approximately twice the *tert*-butyl alcohol ratio. Ketones **7** and **8** also show enhanced F/C ratios in the solid complex. For the dimethyl substituted ketones **9**–**12**, the F/C ratio is consistently higher in the complex than in solution by factors of up to 10. (2) *t*/*c* ratio: This ratio does not appear to be particularly sensitive to medium effects and consistently ranges between 1.1 and 3.4 for all ketones and media studied. A notable exception is ketone **12** with a *t*/*c* ratio in *tert*-butyl alcohol of 14.1. As was the case with the F/C ratios, the *t*/*c* ratios obtained in the solid complex more closely resemble the results found in benzene than those in *tert*-butyl alcohol or acetonitrile (3) Type I/Type II ratio: Only those ketones having *gem*-dimethyl substitution at the α-carbon atom (compounds **9**–**12**) undergo detectable Norrish type I reaction, regardless of medium. For these ketones, type I photoreaction is considerably enhanced in the solid complex compared to solution media. The exception to this rule is ketone **9** for which type I reactivity is seen to decrease somewhat in the solid complex. The type I/type II ratio in the case of ketone **9** is also noticeably greater than for ketones **10**–**12**.

Discussion

Two pieces of evidence point to the conclusion that the environment of an included guest molecule in Dianin's complex is essentially nonpolar in character. The first of these is derived from the similarity of the F/C ratios in benzene and the solid complex for ketones **2**, **3**, **4**, and **6**, and the second is based on the similarity of the *t*/*c* ratios in the same two media for ketones **4**, **7**, **10**, **11**, and **12**. This conclusion is consistent with the X-ray crystal structures of Dianin's compound and its complexes (34, 35), which show that the major portion of the cavity is bounded by hydrocarbon groups, particularly the central "hourglass" constriction which is attributable to the *gem*-dimethyl group at carbon 2. Aside from the puzzling large increase in the *trans* to *cis* cyclobutanol ratio for ketone **12** in *tert*-butyl alcohol, the relative insensitivity of the F/C and t/c ratios to changes in medium for the ketones mentioned above brings out a second conclusion from this work, which is, that, in general, inclusion of guest ketones in the host cavity of Dianin's compound does not greatly alter the chemical reactivity of the excited state and biradical intermediates produced by photolysis. Nevertheless, certain trends of a more modest nature are evident. For example, for ketones **5**, **7**, **8**, **9**, **10**, and **12**, the F/C ratio shows a definite increase in going from solution media to the environment of the solid inclusion complex. This is reasonable if we assume that the inclusion complex affords a relatively restricted environment and that cyclization is a sterically more demanding, "greater motion" process as compared to fragmentation. A similar explanation was used by one of us (58) in interpreting the increased F/C ratio that results from the irradiation of pure crystalline *p*-substituted derivatives of ketone **7** (ketone **7** itself is a liquid at room temperature). In their work on the type II photochemistry of ketones adsorbed on zeolites, Turro and Wan (52) also assumed that cyclization involves greater atomic and molecular motion than fragmentation, and used this idea to explain the greatly increased F/C ratio (>50) observed in the case of the 6 Å Silicalite molecular sieve. However, of the five zeolites tested (52), only the 6 Å pore size material gave results which differed significantly from those in solution. This was attributed to the fact that this pore size is just sufficient to accommodate the benzene ring of the aralkyl ketones investigated. Thus a "tight fit" of the guest molecule in the host cavity appears to be required to bring about increased reaction selectivity in host–guest assemblies. In analogy, it seems reasonable to suggest that those ketones which exhibit increased F/C ratios in Dianin's complex fit more snugly into the host cavity than those ketones for which the F/C ratio is medium independent. Molecular volume calculations and modeling studies may be useful in testing this idea.

With regard to the type I/type II ratios, only ketones **9–12** gave both types of reactivity, attributable of course, to the greater stability of the tertiary alkyl radicals produced by acyl–alkyl cleavage as compared to the primary alkyl radicals which would be formed in the case of ketones **2–8**. The greater type I/type II ratio in the case of ketone **9** compared to ketone **10** was shown (54) to be the result of the slower rate of primary hydrogen atom abstraction in **9** as opposed to secondary hydrogen atom abstraction in **10**. Similar low type I/type II ratios are seen for ketones **11** and **12**, which also bear secondary γ-hydrogen atoms. In three of the four cases studied, the type I/type II ratio increases significantly in proceeding from liquid media to the environment of the solid Dianin's complex. Turro and Wan (52) observed qualitatively similar, but more dramatic (type I/type II > 50) results for ketone **10** adsorbed on 6 Å Silicalite molecular sieves. An explanation similar to that used to rationalize the medium dependence of the fragmentation to cyclization ratios (above) appears reasonable, namely, that the clathrate cavity restricts the movement of its guests and that type I cleavage requires less atomic and molecular motion than the type II reaction for these compounds (γ-hydrogen abstraction).

The question arises as to the meaning of the higher host/guest ratios observed for the more substituted ketones. We presume that the host cavities are flexible and that the larger guests can occasionally be accommodated, but only at the expense of contiguous assemblies. The process then resembles the insertion of a Champagne bottle into a Bordeaux case rather than that of an egg into an egg carton. The ratio is then a measure of how much distortion can be made while maintaining a crystalline structure.

To date there have been four studies (including this one) which report the influence that immobilization within the solid state or inclusion complexes has on the Norrish type II process. These are Dianin's complexes (this study), urea inclusion complexes (44), the pure crystalline state (58), and zeolite molecular sieves (52). Of these, the zeolite environment has the greatest effect on the photoproduct ratios, but only one of the five zeolites studied, the 6 Å pore size Silicalite, was effective. In the pure, crystalline state, the F/C ratios were observed to increase by factors of 2–3 over the ratios in acetonitrile. However, the stereoselectivity of cyclobutanol formation (t/c) remained essentially constant (58). Finally, for the urea inclusion complex of 5-nonanone, the F/C ratio was actually found to decrease by a factor of 2 in going from solution (methanol) to the solid complex (44). Fascinatingly, however, only a single cyclobutanol stereoisomer (believed to be the *cis* isomer) was obtained. It is thus apparent that the ultimate goal of research of this type, to be able to direct photochemical systems completely (and in synthetically useful quantities) toward specific reaction pathways depending on the medium employed, is yet to be realized. Efforts along these lines are continuing in both our laboratories.

Experimental

Apparatus

Ultraviolet spectra were recorded on a Varian Cary 219 spectrophotometer. Proton nmr spectra were recorded on a Varian XL-200 (200 MHz) spectrophotometer using tetramethylsilane as internal standard in deuteriated methanol as solvent. The solid state ^{13}C nmr spectra were run at U.B.C. on a Bruker FT CXP-200 instrument. The ^{13}C signal of liquid benzene, lying 128.5 ppm downfield from tetramethylsilane, was used as an external reference to determine chemical shift values. Gas chromatography was carried out on Varian 3700 (5 ft × 2 mm glass column packed with 15% FFAP on 45/60 mesh Chromosorb W) and Hewlett–Packard 5890 A (12-m fused silica Carbowax 20M capillary column) instruments fitted with flame ionization detectors. Irradiations were carried out with either a 450-W Hanovia medium pressure mercury lamp housed in a Pyrex sleeve or a Molectron UV 22 pulsed nitrogen laser operating at 337 nm with an average power of 330 mW.

Materials

Baker analyzed spectrograde solvents were used for solution irradiations. Ketones **2** and **4** were obtained commercially (Aldrich). Ketones **3**, **5**, and **6** were prepared by Friedel–Crafts acylation of benzene using the appropriate acyl chloride (59). Ketones **7** and **8** were prepared according to the procedure of Wamser and Wagner (56). Ketones **9–12** were prepared from isobutyrophenone with sodium amide and the corresponding alkyl bromide (60). All ketones were purified by column chromatography and (or) vacuum distillation prior to use. Dianin's compound (**1**) was prepared and purified by the method of Baker *et al.* (33). Unsolvated Dianin's compound was obtained by sublimation of the ethanol complex at 140°C and 1 Torr (mp 166–167°C).

Preparation of inclusion complexes

The ketone inclusion complexes with Dianin's compound were prepared by slow crystallization of unsolvated Dianin's compound from the appropriate liquid ketone after dissolution at 80°C. The complexes were dried *in vacuo* (50–55°C/0.05 Torr) to constant weight. Drying was terminated when weight losses of less than 10^{-5} g/h were observed. The host/guest ratio was determined in one or more of three ways. (1) Ultraviolet spectrophotometry: methanol solutions of known concentration were made up for each complex and monitored at 330 nm. The amount of ketone incorporated was calculated by assuming that the absorption at 330 nm due to the ketone in the presence of Dianin's compound is identical to that in its absence. (2) Proton nmr spectroscopy: this method was used for ketones **2**–**6** only. The host/guest ratio was determined as the ratio of the integrated peak heights of the C3 methylene protons of Dianin's compound and the α-methylene protons of the guest ketones. (3) Gas chromatography: the amount of ketone present in a weighed sample of complex was determined by gas chromatographic integration of the ketone peak compared to that of a known amount of internal standard (heptadecane, hexadecane, or octadecane, as appropriate). Alternatively, capillary gas chromatography allowed direct integration of the peaks due to ketone and Dianin's compound. In general, agreement among the three methods was satisfactory.

Solution photolyses

Solution photolyses were carried out in Pyrex sample tubes at a concentration of 0.1 *M*. The solutions were degassed prior to irradiation by purging with nitrogen. The identity of the non-cyclobutanol-containing photoproducts was verified using authentic samples, and the product ratios were determined by gas chromatography employing the appropriate internal standards.

Photolysis of inclusion complexes

Weighed samples (10–20 mg) of the inclusion complexes (conglomerates of fibrous needles) in Pyrex sample tubes were repeatedly evacuated and purged with nitrogen before sealing the tubes under 0.05 Torr vacuum. The tubes were rotated during irradiation and, after photolysis was complete, the samples were dissolved in a methanolic solution of the appropriate internal standard of known concentration and analyzed by gas chromatography as before.

SEEMA KOTHARI and KALYAN KUMAR BANERJI. Can. J. Chem. **63**, 2726 (1985).

The oxidation of substituted benzyl alcohols by sodium *N*-bromobenzenesulfonamide (BAB) in acid solution results in the formation of the corresponding benzaldehydes. The reaction is first order with respect to BAB, the alcohol, and hydrogen ions. The reaction exhibits a primary kinetic isotope effect ($k_H/k_D = 5.26$). The value of the solvent isotope effect, $k(H_2O)/k(D_2O)$, equals 0.43 at 298 K. Addition of benzenesulfonamide has no effect on the rate. Increase in amount of acetic acid in the solvent increases the rate. The reaction rate has been determined at five different temperatures and the activation parameters have been calculated. $(PhSO_2NH_2Br)^+$ has been postulated as the reactive oxidizing species. The rates of oxidation of substituted benzyl alcohols correlate very well with Brown's σ^+ constants. The value of the reaction constant is −2.84 at 298 K. A hydride transfer from the alcohol to the oxidant, in the rate-determining step, has been proposed.

SEEMA KOTHARI et KALYAN KUMAR BANERJI. Can. J. Chem. **63**, 2726 (1985).

L'oxydation d'alcools benzyliques substitués par du *N*-bromobenzènesulfonamide de sodium (BAB) en milieu acide conduit à la formation des benzaldéhydes correspondants. La réaction est du premier ordre par rapport à la concentration du BAB, de l'alcool et des ions hydrogènes. La réaction présente un effet isotopique cinétique primaire ($k_H/k_D = 5,26$). À 298 K, l'effet isotopique du solvant $k(H_2O)/k(D_2O) = 0,43$. L'addition de benzènesulfonamide n'a pas d'effet sur la vitesse. L'addition d'acide acétique dans le solvant augmente la vitesse. On a déterminé les vitesses de réactions à cinq températures différentes et on a calculé les paramètres d'activation. Il est suggéré que le $(PhSO_2NH_2Br)^+$ serait l'espèce oxydante réactive. On peut établir une bonne corrélation entre les vitesses d'oxydation des alcools benzyliques substitués et les constantes σ^+ de Brown. À 298 K, la valeur de la constante de réaction est égale à −2,84. On suggère que l'étape déterminante de la réaction impliquerait le transfert d'un hydrure de l'alcool à l'oxydant.

[Traduit par le journal]

Introduction

Recently Gunasekaran and Venkatasubramanian have reported the oxidation of diphenylmethanols (1) and fluoren-9-ols (2) by bromamine-T (BAT). Though the rate laws of oxidation of the two series of alcohols are similar, the kinetic isotope effects are different. Moreover, the authors (1) have suggested many possible mechanisms and the available data do not enable one to distinguish between them. In view of this, we have undertaken this investigation. We report in this article the kinetics of the oxidation of several monosubstituted benzyl alcohols by sodium-*N*-bromobenzenesulfonamide (bromamine-B or BAB) in aqueous acetic acid, in the presence of perchloric acid.

Experimental

The preparation and characterization of the alcohols have been described earlier (3). BAB was prepared by the bromination of benzenesulfonamide (BS) in an alkaline solution (4). It was recrystallized from hot water and the purity of the compound was found to be 99% by iodometric determination. Deuterium oxide (99.4%) was supplied by BARC, Bombay. Perchloric acid (E. Merck) was used as a source of hydrogen ions. Acetic acid (Sarabhai M) was refluxed with chromium trioxide and acetic anhydride for 3 h and then fractionated. All other chemicals were of analysed reagent grade. Double distilled water was used throughout.

Product analysis

Product analyses were carried out under kinetic conditions, i.e. with an excess of the alcohol over BAB.

In a typical experiment, benzyl alcohol (4.9 g, 0.05 mol) and BAB (2.8 g, 0.01 mol) were dissolved in 100 mL of 1:1 (v/v) acetic acid − water, in the presence of 1.0 *M* perchloric acid. The mixture was kept in the dark for ca. 10 h to ensure completion of the reaction. It was then treated overnight with an excess (250 mL) of a saturated solution of 2,4-dinitrophenylhydrazine in 2 *M* HCl. The precipitated 2,4-dinitrophenylhydrazone (DNP) was filtered off, dried, weighed, recrystallized from ethanol, and weighed again. The identity of the DNP was established by determining its mp and mixture mp with an authentic sample of DNP of benzaldehyde. The yield of DNP was 2.6 g (91%) and 2.4 g (84%) before and after recrystallization, respectively. In similar experiments with substituted benzyl alcohols, the yield of DNP, after recrystallization, was 78 to 84%.

Stoichiometry

Benzyl alcohol (1.96 g, 0.02 mol) and BAB (1.42 g, 0.005 mol) were dissolved in 100 mL of 1:1 (v/v) acetic acid − water in the presence of 0.5 *M* perchloric acid. When the reaction was complete, the reaction mixture was neutralized by Na_2CO_3 and extracted with ether (3 × 100 mL). The ether solution was dried over anhydrous magnesium sulfate and the solvent was allowed to evaporate. The residue was taken up in 3:2 (v/v) acetonitrile−water and was analysed by hplc on equipment supplied by Bioanalytical Systems, U.S.A. (LC-153), fitted with a RP-8 column and an uv detector (254 nm). The flow rate of solvent was 1.0 mL/min and operating temperature was 30°C. The concentration of residual benzyl alcohol was read from a calibration curve.

The analysis indicated a 1:1 stoichiometry for the reaction.

Kinetic measurements

The reactions were arranged to be under pseudo-first-order conditions by keeping a large excess (10-fold or greater) of the alcohol over BAB. The reactions were carried out in flasks blackened from the outside to prevent any photochemical reaction. The temperature was kept constant to ±0.1 K. The reactions were followed iodometrically for over 70% of the reaction. The pseudo-first-order rate constant, k_1, was calculated from the linear ($r > 0.98$) plots of log [BAB] against time. The specific order rate constant, k, was obtained by the relation $k = k_1/[\text{Alcohol}][H^+]$. Duplicate kinetic runs showed that the rates were reproducible to within ±4%. The solvent was 1:1 (v/v) acetic acid − water unless mentioned otherwise. Preliminary experiments showed that the reaction is not very sensitive to ionic strength, hence no attempt was made to keep it constant.

Results

The rate laws and other experimental data were obtained for all the alcohols investigated. Since results are similar, only representative data are given here.

The analysis of product formed and determination of stoichiometry indicate the overall reaction [1].

[1] $PhCH_2OH + PhSO_2NBr^- \rightarrow PhCHO + PhSO_2NH_2 + Br^-$

Rate laws

The oxidation of benzyl alcohols by BAB is found to be clearly first order with respect to BAB both regarding time (as evidenced by good fits of log [BAB] versus time plots) and concentration (as shown by the time order rate coefficient being independent of initial [BAB]). The effect of variation in the concentration of alcohol shows a first-order dependence on the concentration of alcohol. The reaction rate increases linearly with an increase in the concentration of perchloric acid (Table 1).

Isotope effects

To ascertain the importance of the cleavage of the α-C—H bond in the rate-determining step, the oxidation of α,α-dideuteriobenzyl alcohol was studied. The results show that the primary kinetic isotope effect, k_H/k_D equals 5.26 ± 0.07 at 298 K (Table 2). This is in contrast to the absence of the kinetic isotope effect in the oxidation of diphenylmethanol (1) and the low value observed in the oxidation of fluoren-9-ol by BAT (2). This is, however, in agreement with the earlier observations of the oxidations by molecular halogens (5, 6) and other sodium N-halogeno compounds (7, 8).

The oxidation of benzyl alcohol was studied in 95% deuterium oxide. The values of rate constants at 298 K in H_2O and D_2O are $10^4 k = 1.30$ and $3.00\ L^2\ mol^{-2}\ s^{-2}$ respectively. The solvent isotope effect, $k(H_2O)/k(D_2O) = 0.43$ at 298 K. This set of experiments was carried out in the absence of acetic acid.

$10^5 k_1$ (s^{-1})	2.60	3.70	5.20	10.5	20.0	50.2

Effect of BS

Addition of BS does not affect the rate of oxidation (Table 3).

Induced polymerization of acrylonitrile

In an atmosphere of nitrogen, the oxidation of benzyl alcohol failed to induce polymerization of acrylonitrile. Thus a radical mechanism is highly unlikely.

Effect of solvent composition

The rates of oxidation were obtained in binary solvent mixtures of acetic acid and water. The rate increases with an increase in the proportion of acetic acid in the solvent mixture (Table 4).

Effect of temperature

The rates of oxidation of eight monosubstituted benzyl alcohols were determined at five different temperatures between 298 K and 318 K (Table 5) and the activation parameters were evaluated (Table 6). The average errors in the values of ΔH^*, ΔS^*, and ΔG^* (at 298 K) are ± 2 kJ mol^{-1}, ± 5 J mol^{-1} K^{-1}, and ± 3 kJ mol^{-1} respectively.

Discussion

The enthalpy and entropy of activation of the oxidation of eight monosubstituted benzyl alcohols are linearly related (r = 0.9988, β = 508 K). The correlation was tested and found genuine by applying Exner's criterion (9). The value of isokinetic temperature, determined by Exner's method, is 509 K. Current views do not attach much physical significance to the value of isokinetic temperature (10), though a linear correlation is usually a necessary condition for the validity of linear free energy relationships. It also implies that all the alcohols are oxidized by the same mechanism and the change in rate is governed by both enthalpy and entropy of activation (11).

In an acidified solution of BAB, in aqueous acetic acid, the probable oxidizing species are BAB itself, $PhSO_2NBr_2$, Br_2, $PhSO_2NHBr$, HOBr, AcOBr, and their protonated forms.

However, no effect of BS on the reaction rate precludes a pre-equilibrium in which BS is one of the products. This in effect rules out HOBr, AcOBr, Br_2, $PhSO_2NBr_2$, and their protonated forms as reactive oxidizing species. It also rules out the formation of a hypobromite ester as an intermediate in the oxidation process. $PhSO_2NBr_2$ and molecular bromine can also be ruled out in view of the strict first-order dependence of the reaction rate on BAB. This leaves $PhSO_2NHBr$ or *N*-bromobenzenesulfonamide as the most likely oxidizing species. Gunasekaran and Venkatasubramanian (1, 2) also suggested that in the oxidation by BAT, the corresponding *N*-bromosulfonamide is the reactive species. They explained the linear dependence of rate on acidity, obtained in the oxidations by BAT, on the basis of the following equilibrium [2].

[2] $p\text{-}MeC_6H_4SO_2NBr^- + H_3O^+ \rightleftharpoons p\text{-}MeC_6H_4SO_2NHBr + H_2O$

N-Bromosulfonamides are, however, weak acids. The p*K* for $PhSO_2NHBr$ is 4.95 at 298 K in aqueous solution (12). Thus in the presence of even 0.1 *M* $HClO_4$, almost all of the BAB will be in the form of $PhSO_2NHBr$ and a further increase in the acidity of the solution will not cause any significant increase in concentration of $PhSO_2NHBr$. Therefore, the postulation of Gunasekaran and Venkatasubramanian (1, 2) and our own earlier proposal (8) that the neutral halosulfonamide is the reactive oxidizing species are in error. The linear increase in reaction rate on increasing hydrogen ion concentration can be explained by assuming a further protonation of the bromosulfonamide to give a stronger electrophile and oxidant.

[3] $PhSO_2NHBr + H_3O^+ \rightleftharpoons (PhSO_2NH_2Br)^+ + H_2O$

The rate of oxidation increases with a decrease in the polarity of the solvent. The dielectric constants of acetic acid − water mixtures have been estimated earlier (13). It is observed that a plot of log (rate) against the inverse of the dielectric constant of the solvent is linear (r = 0.9980) with a positive slope. This indicates an interaction between a dipolar molecule and a positive ion in the rate-determining step (14). This further supports the idea that the oxidizing species in this reaction is $(PhSO_2NH_2Br)^+$.

The oxidation rates of the monosubstituted benzyl alcohols correlate very well with Brown's σ^+ substituent constants (15), with large negative reaction constants (Table 7). This indicates an electron-deficient carbon centre in the rate-determining step.

D_3O^+ is a stronger acid than H_3O^+ and the rate of an acid-catalysed reaction is expected (16) to be faster in D_2O than in H_2O. Active hydrogen atoms, like those in —OH groups, undergo rapid exchange in D_2O, and if the hydroxyl group is involved in the rate-determining step or in the pre-equilibria, the k_{OH}/k_{OD} isotope effect comes into play and cancels the rate-enhancement due to D_3O^+. The oxidation of benzyl alcohol by BAB exhibits a "normal" solvent isotope effect. This makes the formation of a hypobromite ester, as suggested in the oxidation of diphenylmethanol (1), highly unlikely.

The presence of a substantial primary kinetic isotope effect confirms that the C—H bond, from the carbinol carbon, is cleaved in the rate-determining step. The deuterium isotope effect is also rather large for the non-symmetrical transition state implied in the ester mechanism.

The large negative reaction constant and the high value of the deuterium isotope effect suggest a considerable carbonium ion character in the transition state. This is in accord with the excellent correlation obtained with Brown's σ^+ values. Thus an intermolecular hydride ion transfer from the alcohol to the oxidant is strongly indicated.

[4] 
[5] $Ph\overset{+}{C}HOH \xrightarrow{\text{fast}} PhCHO + H^+$

The negative entropy of activation also supports the above mechanism. The reactions in which two molecules combine to form a single activated complex show a decrease in the entropy (17).

In the oxidation of fluoren-9-ols by BAT, Gunasekaren and Venkatasubramanian (2) have suggested synchronous removal of a hydride ion from the C—H bond, and a proton from the hydroxyl group, to account for the low value of the deuterium isotope effect (k_H/k_D = 2.2) obtained by them. Their mech-

TABLE 7. Temperature dependence of the reaction constant

Temperature (K)	298	303	308	313	318
ρ^+	−2.84	−2.71	−2.60	−2.51	−2.39
Regression coefficient	0.9976	0.9985	0.9991	0.9968	0.9993

anism is, however, inconsistent with the high magnitude of the reaction constant ($\rho = -2.8$) exhibited in the oxidation of fluoren-9-ols. In a completely synchronous process, the reaction constant is nearly zero. The oxidation of fluoren-9-ols may involve the prior formation of a hypobromite ester and its subsequent decomposition in the rate-determining step. Thus it seems that different mechanisms operate in the oxidation of fluoren-9-ol and benzyl alcohol. Many fluorene derivatives are reported to react differently from the corresponding aromatic and aliphatic compounds. For example, fluorene-9-carboxylic esters (18) are hydrolysed, in alkaline solution, by a mechanism quite different from that operative for other esters (19). This may be due to the special structural features of fluorene in which a secondary carbon is linked to two benzene rings.

$Ni(H_2O)_2(3\text{-}CH_3C_5H_4N)_6(PF_6)_2$: a revision of the crystal data

RAYMOND M. MORRISON, ROBERT C. THOMPSON, STEPHEN V. EVANS, AND JAMES TROTTER
Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received October 23, 1984

RAYMOND M. MORRISON, ROBERT C. THOMPSON, STEPHEN V. EVANS, and JAMES TROTTER. Can. J. Chem. **63**, 2730 (1985).

The crystal structure of the title compound is revised and described in the orthorhombic space group *F2dd*, rather than in monoclinic *Cc*. Chemical conclusions are unchanged.

RAYMOND M. MORRISON, ROBERT C. THOMPSON, STEPHEN V. EVANS et JAMES TROTTER. Can. J. Chem. **63**, 2730 (1985).

On propose une revision de la structure cristalline du composé mentionné dans le titre et on le décrit dans le groupe d'espace orthorhombique *F2dd*, plutôt que dans le groupe monoclinique *Cc*. Les conclusions chimiques demeurent inchangées.

[Traduit par le journal]

A (100/010/102) transformation (1) of the *Cc* cell (2) and a detailed examination of the intensity data indicate that the true symmetry is orthorhombic. The revised crystal data are: Orthorhombic, *F2dd*, a = 10.497(1), b = 20.074(3), c = 42.388(10) Å, V = 8932 Å^3, Z = 8, μ(Mo) = 5.9 cm^{-1}, molecular symmetry exactly C_2 (rather than approximately (2)).

Transformation of atomic parameters [(1 0 −0.5/0 1 0/0 0 0.5) − (3/8, 1/8, 1/8)] reveals only small differences between the positions of symmetry-equivalent atoms (maximum 0.03 Å, Table 1), and averaged parameters give a reliable description of the structure, since the previous refinement (2) is still reasonably appropriate (3). The intensity data were averaged (most of the measured data are Friedel pairs, which were not averaged) and the refinement was repeated in *F2dd*; final R = 0.048 for 2483 reflections ($\geq 3\sigma(I)$, of a total

TABLE 1. Positional parameters in space group *F2dd* (the final column gives the distance in the original *Cc* determination (2) between an atom in column 1 and an atom in column 2 with transformation x, $\bar{y}$, $\bar{z}$)

Cyclic voltammetric study of acid hydrolysis of tris(bipyridine) chromium(II): a critical appraisal of CV determination of kinetic parameters[1]

SHACHAR D. NADLER, JAMES G. DICK, AND COOPER H. LANGFORD
Department of Chemistry, Concordia University, Montreal, Que., Canada H3G 1M8

Received November 13, 1984

SHACHAR D. NADLER, JAMES G. DICK, and COOPER H. LANGFORD. Can. J. Chem. **63**, 2732 (1985).

Cyclic voltammetry has been exploited to reinvestigate discrepancies in the reported rate constant for the reaction:

$$Cr(bipy)_3^{2+} + 2H_2O \xrightarrow{k_f} Cr(bipy)_2(H_2O)_2^{2+} + bipy$$

which follows electrode reduction of the substitution inert $Cr(bipy)_3^{3+}$. It is shown that the problems arise from oversimplified treatment of residual currents when estimating the anodic peak current, i_a. A "two scan" procedure for estimating the background currents is introduced which appears to resolve discrepancies. The kinetic studies were extended to a methyl-substituted bipyridine. Since ring methylation has very little effect on k_f, it appears that the aquation reaction is initiated by a rate-determining step which requires a minimum of bipyridine rearrangement.

SHACHAR D. NADLER, JAMES G. DICK et COOPER H. LANGFORD. Can. J. Chem. **63**, 2732 (1985).

Utilisant la voltamétrie cyclique, on a réexaminé les divergences rapportées au sujet de la vitesse de la réaction:

$$Cr(bipy)_3^{2+} + 2H_2O \xrightarrow{k_f} Cr(bipy)_2(H_2O)_2^{2+} + bipy$$

Cette méthode permet de suivre l'évolution de la réduction à l'électrode du $Cr(bipy)_3^{3+}$ qui est inerte à la substitution. On démontre que les problèmes proviennent d'une trop grande simplification des courants résiduels lorsqu'on évalue le courant anodique maximal, i_a. On introduit une méthode à double balayage pour évaluer les courants résiduels et cette méthode semble éliminer les irrégularités. On a étendu les études cinétiques à une bipyridine substituée par un méthyle. Puisque la méthylation du cycle n'a qu'un minime effet sur k_f, il semble que la réaction représentée par l'équation est initiée par une étape déterminant la vitesse qui nécessite un minimum de transposition de la part de la bipyridine.

Introduction

The behaviour of the *tris*-(2,2-bipyridine) chromium(III) has been the subject of several electrochemical studies which have challenged the capacity of various electrochemical techniques to extract chemical kinetic information. The system has been reinvestigated in order to resolve discrepancies and refine the procedures for accurate extraction of kinetic parameters. Sato and Tanaka (1) have demonstrated that in aprotic solvents, $[Cr(bipy)_3]^{3+}$ is reduced in four, one electron steps to the $[Cr(bipy)_3]^{1-}$ anion. The aqueous behaviour of this chromium complex has been shown to be somewhat more complicated, notably because of solvolytic ligand exchange. Using conventional polarographic techniques, Tucker *et al.* (2) and Baker and Metha (3) obtained four polarographic waves for the reduction of aqueous $[Cr(bipy)_3]^{3+}$. They observed that the nature of these waves (size and shape) was a function of pH and temperature. From the behaviour of the first two polarographic waves Baker suggested the following reactions:

[1] $[Cr(bipy)_3]^{3+} + e^- \rightleftharpoons [Cr(bipy)_3]^{2+}$ $\qquad E_{1/2} = -0.89$ V

[2] $[Cr(bipy)_3]^{2+} + 2H_2O \underset{k_2}{\overset{k_1}{\rightleftharpoons}} [Cr(bipy)_2(H_2O)_2]^{2+} + bipy$

[3] $[Cr(bipy)_3]^{3+} + [Cr(bipy)_2(H_2O)_2]^{2+} \rightleftharpoons [Cr(bipy)_3]^{2+} + [Cr(bipy)_2(H_2O)_2]^{3+}$

[4] $[Cr(bipy)_2(H_2O)_2]^{3+} + e^- \rightleftharpoons [Cr(bipy)_2(H_2O)_2]^{2+}$ $\qquad E_{1/2} = -0.72$ V

In a later study, Soignet and Hargis (4, 5) suggested that the chromium(II) species undergoes further reduction and completed the cycle as shown below:

[4] $[Cr(bipy)_2(H_2O)_2]^{3+} + e^- \rightleftharpoons [Cr(bipy)_2(H_2O)_2]^{2+}$ $\qquad E_{1/2} = -0.72$ V

[5] $[Cr(bipy)_2(H_2O)_2]^{2+} + 2H_2O \rightleftharpoons [Cr(bipy)(H_2O)_4]^{2+} + bipy$

[6] $[Cr(bipy)_2(H_2O)_2]^{2+} + bipy \underset{k_1}{\overset{k_2}{\rightleftharpoons}} [Cr(bipy)_3]^{2+} + 2H_2O$

The ligand exchange in reaction [2] does not affect the electron transfer in reaction [1]. Hence, the reactions described by [1] and [2] are by themselves reversible. However, when a rapid scan technique such as cyclic voltammetry is employed, it becomes evident that in the presence of $[Cr(bipy)_3]^{3+}$ the diaquo complex formed in reaction [2] is rapidly removed in a manner described in reaction [3]. Under these conditions reactions [1] and [2] describe an electron exchange followed by an irreversible chemical reaction following the well known pattern

[7] $O + e \rightleftharpoons R$

[8] $R \xrightarrow{k_f} Z$

Hence, the rate of reaction/dissociation of the complex, K_f, can be evaluated electrochemically.

In their classical paper on stationary electrode kinetics, Nicholson and Shain (6) described a technique for cyclic voltammetry (CV) by which K_f may be evaluated from a working curve from i_a/i_c versus $K_f\tau$, where i_a/i_c is the ratio of the anodic and cathodic waves obtained by CV for reaction [7] and τ is the elapsed time between the potential at which the scan is reversed (E_{sw}) and the $E_{1/2}$ of the cathodic wave.

The only difficulty with this technique lies in the evaluation of i_a/i_c. While i_c can be easily measured from a well-defined base line (the residual current), the anodic peak i_a is quite difficult to measure since the voltammograms do not show a base line at all for the oxidation portion of the scan. In order to obtain a clear (horizontal) base line, one would have to scan

[1]We thank NSERC, Canada, and FCAC, Québec, for financial support for part of this work.

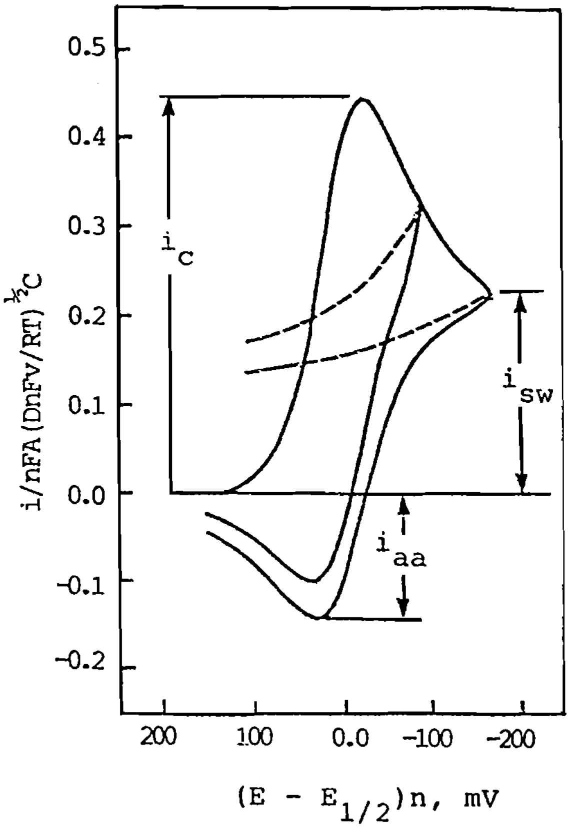

FIG. 1. Nicholson's easy-to-measure parameters from cyclic voltammograms.

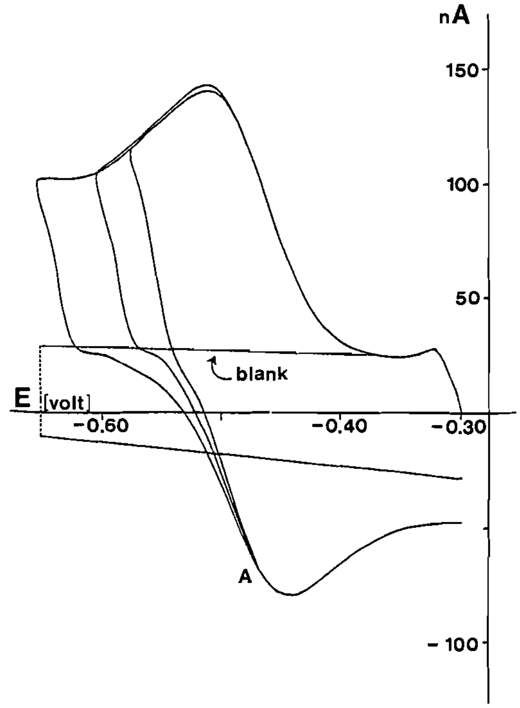

FIG. 2. Aqueous $Cr(bipy)_3$; three polarograms having different switching potentials. From these polarograms it can be seen that E_{switch} does not affect the anodic peak "A". Conditions: 5.5×10^{-5} *M* $[Cr(bipy)_3]^{3+}$ in 0.1 *M* KCl, pH 3.5, 25°C; WE: HMDE $r =$ 0.265 mm; Ref.: SCE (saturated KCl); AUX: Pt; CV: 0.10 V/s.

well past the cathodic peak. However, due to the nature of the chemical process, this will allow reaction [8] to dominate, resulting in an excellent base line but a poor anodic peak. To overcome this problem, Nicholson (7) has developed a semi-empirical procedure which permits the computation of the i_a/i_c ratio from a single-cycle voltammogram. The technique involves three easy-to-measure quantities; the cathodic current (i_c), the apparent anodic current, i_{aa}, and the current at the switching potential, i_{sw}, all measured from the cathodic base line as can be seen in Fig. 1. Using these parameters the true peak ratio was found to be:

$$\frac{i_a}{i_c} = \frac{i_{aa}}{i_c} + \frac{0.485 i_{sw}}{i_c} + 0.086$$

A striking feature of this technique is that the ratio of peak height is independent of such experimental parameters as diffusion coefficients and electrode size and surface area.

From initial CV scans on the chromium complexes it became evident, however, that Nicholson's method could not be applied in a simple fashion. The resulting voltammograms suggested the presence of multiple complicating factors, of which the most outstanding was a large residual current (capacitance). This made it impossible to measure i_{sw} and i_{aa}. Hence a different method had to be developed. The technique involves two CV runs: one of which is stopped at the switching potential and consequently provides an electrochemical equilibrium point from which the anodic current i_a is measured in the second run. Since the problems encountered with Nicholson's technique are not unique to $[Cr(bipy)_3]^{3+}$ systems, the modifications developed for the present problem may be of more general use.

Experimental

Apparatus

Electrochemical measurements were made with a Metrohm Model E-612 VA-Scanner function generator.

The cell used in the CV study consisted of 50 mL water jacketed sealed beaker fitted to hold three electrodes and fitted with an inlet and outlet for purge gas. All currents were measured at the hanging-mercury-drop-electrode (HMDE) using the Metrohm EA-290 capillary equipped with a micrometer drum allowing manual selection of drop size. Unless otherwise specified, all potentials were recorded versus a standard calomel (saturated KCl) electrode. A platinum microelectrode was used as auxiliary. Prepurified nitrogen was used for deoxygenation and subsequently blanketing the solution under studies.

All chemicals used were reagent grade. The pH was adjusted using ultrapure HCl and NaOH. All solutions of $[Cr(2,2'\text{-bipyridine})_3](ClO_4)_3 \cdot H_2O$ and $[Cr(4,4'\text{-}Me_2\text{-}2,2'\text{-bipyridine})_3](ClO_4)_3 \cdot H_2O$ were prepared to yield 5.5×10^{-5} *M* complex in 0.1 *M* KCl adjusted to pH 3.5. Measurements were taken at an ambient temperature of 24 ± 1°C or, when needed, at elevated temperature of up to 35°C, controlled by passing hot water through the built-in glass jacket of the cell.

The samples of the two complexes were a gift from Drs. N. Serpone and M. A. Jamieson. Their preparation has been described (3, 11).

Results and discussion

Initial cyclic voltammograms of $[Cr(bipy)_3]^{3+}$ indicated that in order to proceed with the determination of K_f, two major complicating factors had to be minimized. These were the size of the charging current and the presence of intermediate species at the outset. The latter caused ill-defined anodic cathodic peaks occurring at potentials significantly more anodic than those reported in the literature.

TABLE 1. Computed rate of reaction (K_f) using different scan rates for $Cr(bipy)_3$ at 23 and 25°C

*Measured vs. SCE saturated KCl.

The effect of the charging current was greatly reduced by decreasing the size of the HMDE, from 0.423 to 0.265 mm in radius. This action was decided upon after it was observed that the size of the working electrode had a greater effect on the charging current than on the faradaic current.

The second problem was solved by the use of prolonged electrolysis at the HMDE. This technique involved multicycle scanning between 0 and +0.3 V vs. SCE. The positive potential electrolysis insured that most of the analyte was in primary form, $[Cr(bipy)_3]^{3+}$.

Although the electrolyzed sample gave large and well-defined peaks, the residual currents were not completely eliminated, and their effect was noted both at the beginning of the cycle and more importantly at the switching point (E_{sw}). Figure 2 shows that the potential at which the scan was reversed had little or no effect on the anodic peak. Hence, a technique was developed to create a proper base line from which the true anodic peak current (i_a) can be measured.

Earlier techniques for the establishment of anodic base lines in CV (8, 9) involved stopping the scan for several minutes upon completion of the cathodic portion and allowing the current to decay to a point of electrochemical equilibrium at the switching potential. A horizontal line passing through this point becomes the anodic base line. However, in complex reaction systems, as in the case of $[Cr(bipy)_3]^{3+}$, this technique cannot be applied directly. Stopping the scan will permit the irreversible process (reaction [8]) to dominate and consequently distort the size and shape of the anodic peak. This, however, does not affect the current equilibrium at the switching potential, since reaction [8] does not involve electron transfer (i.e. the catalytic reaction is not detected by the electrode system). Consequently the following procedure was adopted. Each determination involved two scans. The first produced the full redox cycle, and the second scan was carried out only cathodically and yielded the equilibrium point which was used in the measurement of the true anodic peak. The procedure can be seen in Fig. 3.

The results obtained from duplicate samples of $Cr(bipy)_3$ at 23 and 25°C are summarized in Table 1. The K_f values tabulated at each scan rate are averages obtained from a minimum of four determinations. Averaging all reaction rates (K_f) at all the scan rates yielded the final values for $Cr(bipy)_3$:

$$K_f = 0.293 \pm 0.022\ s^{-1} \text{ at } 23°C$$

$$K_f = 0.343 \pm 0.028\ s^{-1} \text{ at } 25°C$$

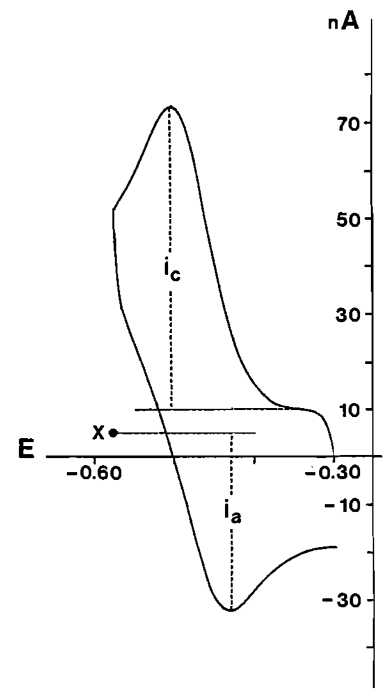

FIG. 3. Peak magnitude determinations. Reduction peak (i_c) is measured from the residual current. Oxidation peak (i_a) is measured from a point of current equilibrium (X) at half cycle. Conditions: $5.5 \times 10^{-5}\,M\,[Cr(bipy)]_3^{3+}$ in 0.1 *M* KCl, pH 3.5, 23°C; WE: HMDE, r = 0.265 mm; Ref: SCE, saturated KCl; AUX: Pt; CV: 0.05 V/s.

The results obtained at 25°C, pH 3.5, are in reasonable agreement with reported results, $K_f = 0.38\ s^{-1}$, obtained by other polarographic techniques and by direct chemical methods (3, 10). On the other hand, the value of 0.293 s^{-1} obtained at 23°C and pH 3.5 was in disagreement with 0.108 s^{-1} at pH 5 reported by Soignet and Hargis (4) and obtained by CV technique. The large difference in K_f values could not be attributed to differences in pH since K_f is pH independent in acid solutions (3). Part of the difference could be attributed to the choice of approximation for the $E_{1/2}$ value. In CV the dynamic $E_{1/2}$ occurs at a point 85.17% up the cathodic slope (5). Hence, one should not estimate $E_{1/2}$ simply by multiplying the peak potential by 0.8517 (85.17%) since this yields good results only when the cathodic slope begins at 0.00 volts.

The balance of the difference in the K_f values is probably due

TABLE 2. Computed rate of reaction (K_f) using different scan rates for $Cr(Me_2\text{-bipy})_3$ at 25°C

Scan rate (V/s)	E_{start} (V)	E_{switch} (V)	Cathodic peak (V)	$E_{1/2}$* (V)	i_a/i_c	$K_f\tau$	τ (s)	$K_f \pm \sigma$ (s^{-1})
0.040	−0.450	−0.745	−0.665	−0.645	0.533	0.846±0.040	2.50	0.339±0.015

*Measured vs. SCE saturated KCl.

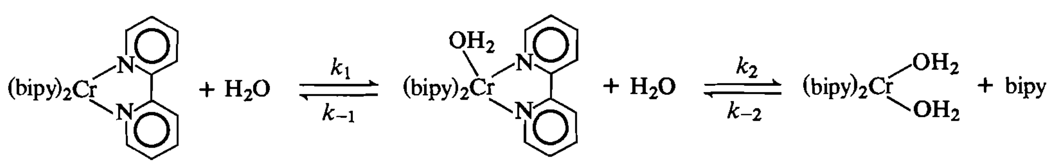
to the different treatment given to the residual currents. This disagreement gives a clear indication of the impact of the data treatment recommended here.

The aqueous behaviour of $[Cr(Me_2\text{-bipy})_3]^{3+}$ is similar to that of $[Cr(bipy)_3]^{3+}$ as described above. The results obtained from duplicate samples of this complex are presented in Table 2. Averaging the K_f values obtained at all scan rates yielded for 5.5×10^{-5} *M* $Cr(Me_2\text{-bipy})_3$ in 0.1 *M* KCl:

$$K_f = 0.353 \pm 0.032\ s^{-1} \text{ at 25°C, pH 3.5}$$

The present kinetic results can perhaps also add a little to the understanding of the mechanism of acid hydrolysis of $Cr(bipy)_3^{2+}$ to form $Cr(bipy)_2(H_2O)_2^{2+}$. Since the work of Baker and Metha (3) established the pH independence of this reaction between pH 1 and 9, an important contribution to understanding related mechanisms has been made by Serpone and his colleagues in a series of studies as hydrolysis of $Cr(bipy)_3^{3+}$ (11, 12). For the slower reaction of this tripositive ion, they showed pH independence in acid solution giving over to rate increasing with pH at higher pH. The interpretation suggested that acid hydrolysis is readily reversible *unless* deprotonation of a coordinated water molecule leads to coordinated —OH. The hydroxo ligand (which takes us out of the realm of acid hydrolysis) renders hydrolysis irreversible. Extending the Serpone mechanism to the Cr(II) complex explains the otherwise puzzling pH independence since a water molecule coordinated to Cr(II) will be distinctly less acidic than are coordinated to Cr(III). The low rate of the overall reaction compared to the high lability of Cr(II) complexes of monodentate ligands implies that reversal of the initial hydrolytic step is quite fast and efficient, as the Serpone mechanism suggests it would be expected to be.

The associative version of the Serpone *et al.* mechanism is shown in Scheme 1 below.



SCHEME 1

The rate-determining step for such a path is most probably k_2. The modest increase in rate for the dimethyl ligand is to be understood according to this mechanism as a consequence of the same factors which lead dimethyl bipyridine complexes of Cr(III) to exhibit longer doublet phosphorescence lifetime (II), namely, increasing rigidity. The attack by H_2O presumably goes via the "pockets" found between the ligands by X-ray (13). These appear to be rendered more accessible by the more rigid ligand, favouring attack.

Organic reactions in liquid crystalline solvents. 2. An investigation into the use of liquid crystalline solvents to effect stereochemical control in the Diels–Alder reaction

WILLIAM J. LEIGH[1]

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received February 26, 1985

WILLIAM J. LEIGH. Can. J. Chem. **63**, 2736 (1985).

The possibility of using liquid crystalline solvents to control the stereospecificity of bimolecular reactions as a result of differences in liquid crystalline solvation of the various possible transition states has been examined. The Diels–Alder reactions of 2,5-dimethyl-3,4-diphenylcyclopentadienone with four dienophiles of varying steric size (cyclopentene, cycloheptene, indene, and acenaphthylene) have been carried out in benzene, cholesteryl nonanoate (isotropic), cholesteryl propionate (cholesteric), and 4-ethyl-4′-(4-pentylcyclohexyl)biphenyl (smectic) at 105°C. In spite of very large differences in steric solvation requirements for the *endo*- (globular in shape) and *exo*- (plate-like in shape) transition states in these reactions, no variation in product ratio with solvent phase is observed in any case.

The inability of the ordered liquid crystalline phases to differentiate between *endo*- and *exo*-transition states in the Diels–Alder reactions investigated is rationalized as being the possible result of several factors. The most important of these are believed to be free volume effects, owing to both inefficient steric solvation of the bulky diene and volume contraction in the transition states for cycloaddition.

WILLIAM J. LEIGH. Can. J. Chem. **63**, 2736 (1985).

On a étudié la possibilité d'utiliser des cristaux liquides comme solvants pour obtenir un contrôle sur la stéreospécificité de réactions bimoléculaires qui résulterait de différences de solvatation des divers états de transition possibles par les cristaux liquides. Opérant à 105°C et dans divers solvants comme le benzène, le nanoate de cholestéryle, (isotrope), le propionate de cholestéryle (cholestérique) et l'éthyl-4 (pentyl-4 cyclohexyl)-4′ biphényle (smétique), on a effectué une réaction de Diels–Alder entre la diméthyl-2,5 diphényl-3,4 cyclopentadiénone et quatre diénophiles de comportements stériques différents comme le cyclopentène, le cycloheptène, l'indène et l'acétylnaphtène). Malgré de très grandes différences dans les demandes stériques de solvatations qui proviennent d'encombrements stériques différents pour les formes *endo* (forme globulaire) et *exo* (en forme de plateau) des états de transition de ces réactions, on n'a dans aucun cas observé de variations dans les rapports de produits dans la phase solvant.

On attribue à différents facteurs cette incapacité des phases cristallines liquides ordonnées de différencier les états de transition *endo* et *exo* des réactions de Diels–Alder étudiées. On croit que les effets de volume libre sont les facteurs les plus importants et que ceci résulté à la fois d'une solvatation stérique inefficace du diène encombré et d'une contraction de volume dans les états de transition des cycloadditions.

Introduction

The ability of liquid crystals to affect the rates and energetics of thermal and photochemical organic reactions is of considerable interest (1–14), both because of their considerable technological importance, as well as similarities in the microstructure of these materials to that in biological systems such as cell membranes (for comprehensive descriptions of the structure and properties of liquid crystals, see ref. 15). Their effects on chemical reactivity have been investigated primarily from the point of view of orientational effects, since it is well known that liquid crystals are able to orient dissolved solute molecules in a manner which depends primarily on steric factors, i.e., structural similarities between solute and solvent molecules (16). A rod-shaped solute is oriented in a liquid crystal so that its long molecular axis is parallel to those of the surrounding solvent molecules, and the effects of the liquid crystal on its reactivity are then the result of the solvent's ability to control this orientation. While unimolecular reactions (e.g. cyclizations) may be restricted owing to solvent-induced inhibition to achieving the optimum molecular geometry for reaction (3, 12, 17), bimolecular reactions may be inhibited or promoted depending on the relative orientation of two reactive solutes and the solvent's ability to define and hold this relative orientation (4–6, 8, 18). It would appear that there are two factors which are primarily responsible for affecting the reactivity of solutes ordered in liquid crystals: the efficiency with which the solute(s) are solvated by the liquid crystal (or, the "tightness" of the solvation shell), and the degree of distortion which the reacting system must undergo in proceeding through the transition state (19).

We have an interest in probing the possible effects of liquid crystalline solvents on the reactivity of solutes which are perhaps not highly oriented by the ordered solvent, but which undergo very large changes in molecular shape as the transition state is approached. To illustrate, consider a planar, disc-shaped solute molecule which reacts via a bulky, globular transition state in proceeding to product (Scheme 1). Such a reactant will be solvated in a liquid crystal so that its molecular plane is oriented parallel to the long axes of the surrounding solvent molecules (20). To the extent that the solute's solvation shell retains some degree of liquid crystalline order, then such a process is expected to be affected as a result of the disruption of local solvent order which may accompany formation of the globular transition state. The effect on reaction rate will then be the result of synergistic effects on the activation energy (rate retardation) and entropy (rate enhancement). That liquid crystals are indeed capable of affecting the dynamics of unimolecular reactions of this type has been demonstrated (12, 19).

If liquid crystalline solvents are capable of affecting reactivity in systems such as that depicted in Scheme 1, then it may be possible to exploit this capability to control reactivity in

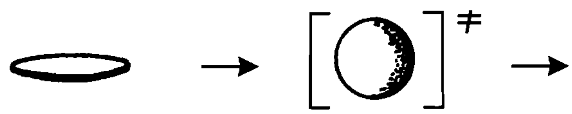
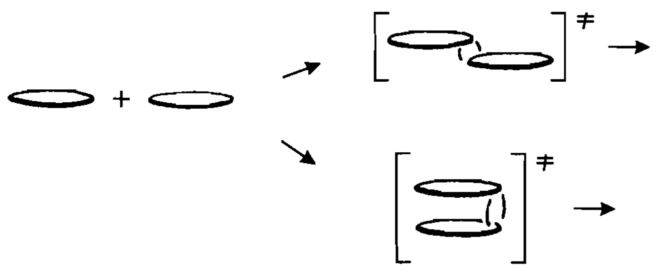


SCHEME 1



SCHEME 2

systems which normally react via a number of possible pathways through transition states which disrupt solvent order to varying extents. For example, consider two planar reactants which normally react to give two products through transition states such as those depicted in Scheme 2. By analogy with the known behaviour of liquid crystalline media with respect to the effectiveness with which they solvate planar versus globular solutes (16), it might be expected that solvent order would be more severely disrupted by the globular transition state than by the more planar one. To the extent that this difference in the solvation requirements of the two transition states is reflected in different effects on the activation parameters for the two processes, then an alteration in the product ratio may be observed in liquid crystalline solvents relative to the value in isotropic solvents.

An attractive system with which to test this hypothesis is the Diels–Alder reaction, since it proceeds to yield two adducts through transition states which differ considerably in steric shape. In choosing a substrate pair for investigation, we kept several factors in mind. For example, we endeavoured to keep the diene and dienophile as large as possible in order to maximize the difference between the shapes of the *endo*- and *exo*-transition states, without deviating too much from planarity in order to ensure that the reactants are reasonably well-solvated in a liquid crystalline solvent. Furthermore, we looked for a probe system which is known to yield both *exo*- and *endo*-adducts under ordinary conditions; when this is the case, then even small (< ca. 0.3 kcal/mol) solvent order-induced differences in the transition state energies will result in a measurable effect on the product ratio for the reaction (>20%). The Diels–Alder reaction of 2,5-dimethyl-3,4-diphenyl-cyclopentadienone (**1**) with cyclopentene (21) (reaction [1]) appeared to us to come closest to satisfying these requirements; furthermore, since dienones such as **1** are well-recognized to be rather potent dienes toward Diels–Alder addition (22), it seemed likely that other dienophiles might be used in addition to cyclopentene in order to broaden the scope of the investigation.

We wish to report the results of our investigation of the reaction of **1** with cyclopentene, cycloheptene,[2] indene, and acenaphthylene in isotropic solvents and cholesteric and smectic liquid crystalline solvents. Our results indicate that in the present cases at least, liquid crystalline solvents are incapable of distinguishing between transition states which differ in their bulk steric shape. While several possible reasons for this can be advanced, it is suggested that liquid crystalline effects of the type proposed can only be expected to occur under very special circumstances.

[2] While the reaction of **1** with cycloheptene has been reported to yield a mixture of adducts (21), their yields and characterization have apparently not been published.

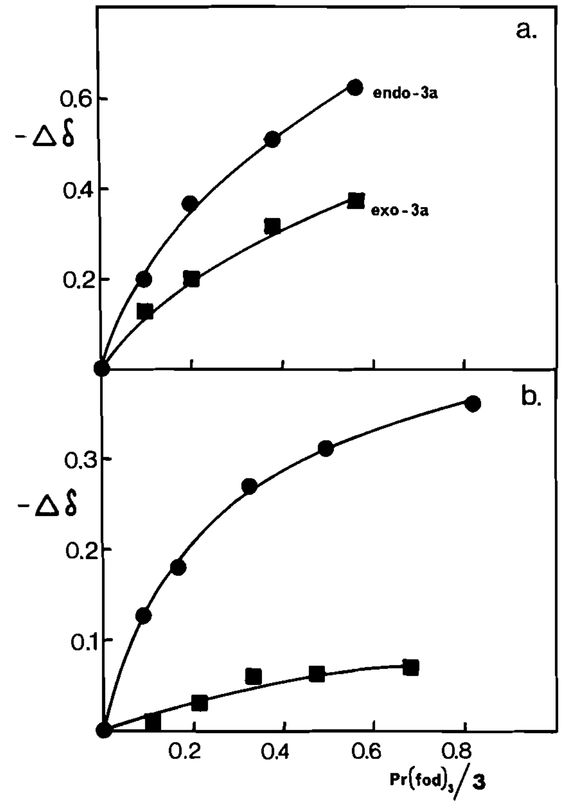


FIG. 1. Plots showing the variation in chemical shift of the 0-bridge protons versus added $Pr(fod)_3$-d_{30} for (*a*) *endo*- and *exo*-**3***a* and (*b*) *endo*- and *exo*-**3***d* in deuterochloroform solution.

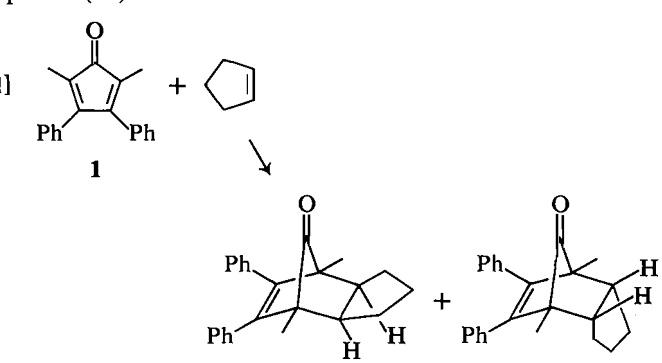
Results

Reaction of 2,5-dimethyl-3,4-diphenylcyclopentadienone (**1**) with cyclopentene (**2***a*), cycloheptene (**2***b*), indene (**2***c*), and acenaphthylene (**2***d*) in benzene solution at 105°C yields mixtures of two adducts in each case (reaction [2]). The identities of *endo*- and *exo*-**3***a* were established on the basis of comparisons of their ^{1}H nmr spectra with those previously reported (21).

[1]



Nuclear magnetic resonance shift reagent studies, using $Pr(fod)_3$-d_{30}, were employed to assign the structures of the *endo*- and *exo*-isomers of **3***b*–*d*. While the ^{1}H nmr spectrum of

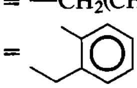
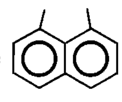
c, X =



d, X =



the Diels–Alder adduct of tetraphenylcyclopentadienone and styrene has been reported to be unaffected by the addition of europium shift reagents (23) we find that addition of either Eu(fod)$_3$-d_{30} or Pr(fod)$_3$-d_{30} to deuterochloroform solutions of the isomeric adducts of the comparatively less sterically hindered **1** with **2***a*–*d* results in distinct, although small, changes in the chemical shifts of the ring-juncture protons (at the 0-bridge) in each case. Plots of the change in the chemical shifts of these protons versus concentration of added shift reagent are shown in Fig. 1*a* for *endo*- and *exo*-**3***a*. As expected, the magnitude of the lanthanide-induced shift is clearly larger for *endo*-**3***a* than for the *exo*-isomer. Similar experiments conducted with the isomeric adducts **3***b*–*d* yielded similar results, and allowed structural assignments to be made. Figure 1*b* shows the plots obtained for the dienone–acenaphthylene adducts **3***d*.

That the product ratios observed for reaction of **1** and **2***a*–*d* at 105°C represent the true kinetic product ratios and not the equilibrium ratios was verified by heating samples of pure *endo*-**3***a* and *endo*-**3***d* at 105°C in benzene solution for extended periods of time. No isomerization of either adduct was apparent at this temperature under these conditions. While *endo*-**3***d* was similarly unreactive at 140°C, heating the sample of *endo*-**3***a* at this temperature did result in slow isomerization to the *exo*-isomer. At 180°C, *endo*-**3***d* was found to undergo primarily decomposition, presumably via decarbonylation (22), with minor isomerization to the *exo*-isomer.

Cholesteryl propionate (ChP) exhibits an enantiotropic cholesteric phase over the temperature range 94°C to 114.5°C (lit. 96–112°C (24)). Addition of 0.8 wt% **1** (as the Diels–Alder dimer (25)) results in a 3.5° depression in the optically-detected cholesteric-isotropic transition temperature of this compound. A similar depression (3°) is observed in the smectic–nematic transition temperature of 4-ethyl-4′-(4-pentylcyclohexyl)-biphenyl (EPCB) upon addition of 0.4 wt% **1**. Undoped EPCB exhibits an enantiotropic smectic B phase from 34–146°C, and a nematic phase from 146–164°C (8*b*, 26). Addition of 0.4 wt% **1** has no discernible effect on the nematic–isotropic transition temperature of this compound. The Diels–Alder dimer of **1** is known to be largely dissociated at 80°C (25).

TABLE 1. *Endo-/exo-* product ratios for the Diels–Alder reactions of 2,5-dimethyl-3,4-diphenylcyclopentadienone (**1**) and **2***a*–*d* in isotropic and liquid crystalline solvents at 105°C[a]

Solvent	**2***a*	**2***b*	**2***c*	**2***d*
Benzene	0.91	2.6	4.5	8.3
ChN (isotropic)	0.93	2.6	4.5	8.5
ChP (cholesteric)	0.90	2.5	4.3	7.8
EPCB (smectic)	—	—	4.6	—

[a] Average of at least two determinations. Error is estimated as ±10%.

The reactions of **1** with **2***a*–*d* were carried out in benzene, cholesteryl nonanoate (ChN, isotropic), and ChP (cholesteric), at 105°C. The reactions with **2***a*, *b* were qualitatively much slower in the steroidal solvents than was found to be the case in benzene solution. This is presumably a concentration effect, relating to the very much lower vapour pressures of the steroids compared to benzene, and hence to the fact that a considerably larger portion of available dienophile will reside in the vapour phase for the steroidal solutions relative to the benzene solutions. Regardless of differences in the absolute rates of reaction, no new products in addition to the isomeric Diels–Alder adducts **3***a*–*d* were observed in any case when the reactions were carried out in the cholesteric ester solvents. The reaction of **1** with **2***c* was also examined in the smectic phase of EPCB at 105°C. Yields of the isomeric adducts, obtained by hplc analysis of the mixtures obtained from reaction of **1** and **2***a*–*d* in these four solvents at 105°C are collected in Table 1.

Discussion

The molecular order in thermotropic liquid crystals is such that the long molecular axes of the component molecules are arranged, on the average, parallel to one another (15). In nematic phases, there is no further molecular ordering present, and these are the most fluid of liquid crystalline phases. Cholesterics are optically active nematic phases, and are characterized by a gradual twist in orientational alignment as one proceeds through the bulk of the sample. Apart from this macroscopic optical activity, there are no further differences in the bulk physical properties of nematics and cholesterics, and they are considered to belong to the same class of liquid crystalline phases (15). Smectic liquid crystals are further arranged in layers, with the long axes of the component molecules parallel to one another and perpendicular (or at some angle close to perpendicular) to the plane of the layers. As a result of this additional molecular ordering, smectics are more nearly crystalline in their appearance and bulk physical properties (15).

In liquid crystals, solutes are incorporated in the best packing arrangement based on steric factors (15, 16, 20). The structures of the reactants employed in the present study are such that they are expected to be, on the average, oriented in a liquid crystalline phase with their molecular planes held parallel to the long molecular axes of the surrounding solvent molecules (20). Indene (**2***c*) and acenaphthylene (**2***d*) are slightly elongated molecules, so there will be some preference for these two to be further oriented with their long axes parallel to those of the solvent (20). On the other hand, since the breadths of **1**, **2***a*, and **2***b* across two of their molecular axes are in each case roughly equal, their orientations within their molecular planes is expected to be random. Thus, consideration of the manner in which **1** and **2***a*–*d* will be oriented in a liquid crystal leads to the prediction that in each case, there should be an equal probability that the two reactants will approach each other in orientations favouring *endo*-product formation as those favouring *exo*-product formation. Depending on how tightly the reactants are solvated in the liquid crystalline matrix, approach to the transition states as reaction proceeds should result in some degree of disruption of local solvent order as the solvation shell reorganizes to accommodate it. If the degree of disruption is greater for one reactive pathway than the other, then that pathway should be inhibited in a liquid crystalline solvent in favour of the less disruptive one. By analogy with the solvation behaviour of liquid crystals towards differently shaped solutes (16), it is expected that a globular transition state should result in more disruption of the liquid crystalline lattice than a planar or rod-like one. These considerations lead to the prediction that the effect of a liquid crystalline phase on the Diels–Alder reaction will be to inhibit the formation of the more globular *endo*-adduct in favour of the *exo*-adduct. Furthermore, consideration of the relative sizes of **2***a*–*d* leads to the prediction that differentiation between the two transition states on the basis of their sizes and shapes should increase throughout the series **2***a* < **2***b* < **2***c* < **2***d*.

Clearly, the data in Table 1 indicate that neither cholesteric nor the more tightly ordered smectic liquid crystals are capable of distinguishing between *endo*- and *exo*-transition states in any of the Diels–Alder reactions investigated, in spite of the large differences in steric shape of the two transition states. The product ratios observed in all four of these reactions in isotropic media correspond to differences in transition state energies (*exo* relative to *endo*) of 0.2–1.3 kcal/mol, assuming identical pre-exponential factors for the two pathways. Allowing for an error of ca. 10% in our determination of product ratios, then a solvent effect of as little as 0.2 kcal/mol on the relative *exo*–*endo* transition state energies would result in a significant change in product ratio, in the absence of entropy effects. Thus, our data indicate that either there is no liquid crystalline effect on the relative energies of the *endo*- and *exo*-transition states in the systems examined, or that the effect on relative transition state energies is exactly offset by entropy effects.

The failure of liquid crystalline solvents to exert an effect on the product distributions in the Diels–Alder reactions investigated may bear some analogy to the reported effects of liquid crystalline solvents on the triplet state photodimerization of acenaphthylene (6). While the presence of cholesteric order was found to have marked effects on the overall efficiency of this process, no alteration in the *syn*-/*anti*- product ratio was observed in liquid crystalline media relative to the value in isotropic solvents. Clearly, the differences in bulk steric shape of the acenaphthylene photodimers are almost as pronounced as those of the *exo*-/*endo*- adducts in the present cases. However, the potential ability of liquid crystalline solvents to differentiate between transition states of differing steric bulk is expected to depend in large part on the degree of product character which is developed in the transition states, and this is expected to be small for fast, low activation energy processes such as triplet state olefin dimerizations. To the extent that the transition states for the present thermal cycloadditions are expected to be much more product-like in character, they should be considerably more susceptible to solvent order-induced perturbations of their relative energies.

Several factors may be contributing to the failure of these solvents toward discriminating between transition states of such grossly differing shapes. First, although the transition temperatures (as well as visual inspection) of samples of ChP and EPCB doped with **1** indicate that bulk liquid crystalline order is retained in these mixtures at the reaction temperature, it is important to note that macroscopically determined transition temperatures of solute-doped liquid crystals do not necessarily offer any indication of the effect of that solute on *local* solvent order (2*b*, *c*) (i.e., in the immediate vicinity of the solute). However, since the Ch → I and Sm → N transition temperatures of ChP and EPCB, respectively, are both substantially affected by incorporation of relatively small amounts (0.4–0.8 wt%) of **1**, it appears safe to conclude that local solvent order is probably severely disrupted. Indeed, doping of ChP at a level of 1.5 wt% **1** results in complete destruction of the bulk cholesteric phase at temperatures greater than 90°C. It may be that this solute in fact resides in an isotropic environment in at least its primary solvation shell, with the result that the disruptive effects of a bulky transition state on solvent order will be truncated (2, 19).

Second, space-filling molecular models indicate that **1** is in fact a fairly bulky, non-planar molecule, the phenyl groups being unable to achieve a coplanar arrangement owing to steric interactions. The bulkiness of this reactant is undoubtedly the cause of the large effects on the transition temperatures of ChP and EPCB discussed above, and presumably also acts to further truncate any differential solvation of the two possible transition states, especially with the relatively small dienophile **2***a*.

Third, it is well known that cycloadditions such as the Diels–Alder reaction are characterized by a substantial volume contraction in the transition states for both *endo*- and *exo*-addition (27). The occurrence of this volume contraction as the transition states are approached will further reduce the ability of an ordered environment to distinguish between the two on the basis of their sizes and shapes, since solvent reorganization in these relatively viscous media is expected to be too slow to keep up with the contracting reactive complexes.

Finally, more detailed consideration of how the reactants are expected to be oriented relative to one another in these liquid crystalline phases makes it clear that in at least some of these cases, the products may be formed in orientations which are not the favoured ones in a liquid crystalline environment, if at least one of the reactants is itself reasonably well-oriented. The best illustration of this is the reaction of **1** with **2***d*. Acenaphthylene is oriented in a cholesteric phase with its long axis preferentially parallel to those of the surrounding solvent molecules (6, 20). When reaction of **1** occurs with a **2***d* molecule which is in this solvent-preferred orientation, the product is formed in an orientation such that its long molecular axis is *perpendicular* to those of the solvent. In such a case, the reaction itself provokes additional disruption of solvent order in that the products are formed in energetically unfavourable orientations. If the extent of this disruption is similar for the two reaction pathways, then a lesser degree of discrimination between transition states can be expected. The structure and expected orientation of **2***c* indicate that products from this dienophile should be formed in their solvent-preferred orientations, while for the symmetric **2***a* and **2***b* there should be an equal probability that they will approach **1** in such orientations as to lead to products whose orientations are parallel and perpendicular to the preferred solvent alignment.

It is difficult to predict which of the above factors might be most critical in the present case, or whether they are all playing a role. Nevertheless, our observation that the stereochemical distribution of products from the Diels–Alder reaction of **1** with the four dienophiles examined in the present study is unaffected by the presence of cholesteric or smectic solvent order allows several important conclusions to be derived. It is clear that liquid crystals are not *generally* useful as solvents to affect stereochemical control on reactions in the absence of careful consideration of specific details regarding the structures of reactants, products, and transition states, their preferred orientations in a liquid crystalline environment, and the disruptive effects that each has on solvent order. Control over these factors is expected to be even more critical when the reaction in question involves overall volume contraction in the transition state, since this process will occur on a time scale which must be several orders of magnitude faster than that of solvent reorganization. It may be that effects such as that investigated here are more likely to be observed when the reactants are smaller, and hence incorporated much more efficiently in a liquid crystalline matrix. Further work in this area is in progress and will be reported in the near future.

Experimental

Melting points and transition temperatures were measured on a Reichert micro-hot stage microscope with polarizing lenses and are corrected. ^{1}H nmr spectra were recorded in deuterochloroform solution on a Varian EM390 nmr spectrometer, and are reported in parts per million downfield from TMS. Infrared spectra were recorded on a Perkin-Elmer Model 283 infrared spectrometer, and are reported in wavenumbers, calibrated against the 1601.8 cm^{-1} polystyrene absorption. Elemental analyses were performed by Guelph Chemical Laboratories, Guelph, Ontario. A Jumo-MS D.B.P. mercury thermoregulator, a Fisher Model 32 Transistor Relay, and an insulated silicon oil (Dow Corning 710) bath were used for temperature control in small scale reactions in benzene and the mesogenic solvents. Temperatures were recorded with a Leeds & Northrup Model 8692 Temperature Potentiometer and a copper–constantan thermocouple, and are considered accurate to ± 1°C.

Analyses of product mixtures were performed using a Gilson isocratic hplc system, consisting of a Model 302 pump (fitted with a 5 mL head), Model 802B manometric module, Holochrome variable wavelength detector, a Rheodyne Model 7125 loop injection valve, and a Varian Model A-6 strip chart recorder, in conjunction with a 25 $\times$ 0.46 cm Merck Hibar Si60 (10 μm) analytical column. Hexane(50%)/dichloromethane was used as eluant, with a flow rate of 0.8–1 mL/min, and an analytical wavelength of 280 nm was used for all analyses. Preparative lc was performed using the same system (50 mL pump head), in conjunction with 24 $\times$ 1.1 cm or 31 $\times$ 2.5 cm Merck Lobar Si60 (40–63 μm) glass columns, hexane(60%)/dichloromethane as eluant, and flow rates of 3.5 and 12 mL/min, respectively. For quantitative hplc analyses, the detector was interfaced to a Unitron microcomputer via an Adalab data acquisition/control card (Interactive Microware, Inc.), after amplification of the 0–10 mV signal to 0–1V with an Adaamp analog amplifier. Chromatogram acquisition, storage, and integration was performed using the Chromatochart (Interactive Microware, Inc.) software. Apparent product ratios for each product mixture so obtained were then converted to true values with working curves, constructed for each isomeric adduct pair with a few standard solutions of accurately weighed mixtures of the authentic adducts.

Benzene (BDH Reagent) was purified by repeated extraction with concentrated sulphuric acid, followed by several washings with water and saturated aqueous bicarbonate. It was dried over calcium chloride, refluxed over calcium hydride, and distilled. Dichloromethane was Caledon HPLC grade and was used as received. Hexanes (BDH Reagent) were distilled before use. Cholesteryl propionate (Sigma) was recrystallized once from *n*-pentanol (28), washed several times with aqueous ethanol, and dried in a vacuum desiccator. Cholesteryl nonanoate (Aldrich) was recrystallized once from 95% ethanol. Transition temperatures for these two compounds agreed well with published values (24). 4-Ethyl-4′-(*trans*-4-pentylcyclohexyl)biphenyl (EPCB; EM Licristal) was used as received from BDH Chemicals, Ltd. Acenaphthylene (Aldrich) was sublimed *in vacuo* and recrystallized from 95% ethanol. Indene (Aldrich) was vacuum distilled. Cyclopentene and cycloheptene were used as received from Aldrich Chemical Co. $Pr(fod)_3$-d_{30} and $Eu(fod)_3$-d_{30} were used as received from Alfa Products, Inc. The Diels–Alder dimer of 2,5-dimethyl-3,4-diphenylcyclopentadienone (**1**) was prepared according to the published procedure (26), and was purified by recrystallization from 95% ethanol to yield colourless needles (mp 185–187°C; lit. (26) 196°C). The ^{1}H nmr spectrum of this compound was consistent with its proposed structure (δ (ppm): 0.60 (s, 3H), 1.28 (s, 3H), 1.64 (s, 3H), 2.24 (s, 3H), 6.6–7.4 (cplx. mult., 20H).

*Preparation and identification of Diels–Alder adducts 3*a–d

*3*a. *Adducts of 1 and cyclopentene (2*a)

1 (0.78 g, 3 mmol) and cyclopentene (1.75 mL, 20 mmol) were dissolved in benzene (9 mL), placed in a 16 mm medium-walled Pyrex tube, degassed (3 freeze–pump–thaw cycles), and sealed. The solution was heated at 100°C for 24 h, at which time the characteristic red colour of the dissociated dienone had dissipated. The tube was opened and the solvent evaporated on the rotary evaporatory, yielding a yellow oil which solidified. Preparative lc afforded two products, which were recrystallized from ethanol. The isomer which eluted first from the column was identified as *exo-3a* (0.46 g, 47%; mp 182–182.5°C; lit. (21) 180–180.5°C. ^{1}H nmr: 1.12 (s, 6H), 1.06–1.35 (m, 2H), 1.73 (m, 4H), 2.64 (m, 2H), 7.00–7.25 (m, 10H). Ir (CCl_4): 3091 (w), 3068 (w), 3020 (w), 2960 (s), 2940 (s), 2875 (m), 1775 (s), 1499 (m), 1491 (m), 1452 (s), 1384 (m), 1174 (w), 1070 (w), 950 (w), 904 (w), 689 (s).

The second isomer to elute from the column was identified as *endo-3a* (0.43 g, 44%; mp 109–110°C; lit. (21) 109.5–110°C). ^{1}H nmr: 1.32 (s, 6H), 1.30–1.52 (m, 2H), 1.70–2.05 (m, 4H), 2.48 (m, 2H), 6.97–7.30 (m, 10H). Ir (CCl_4): 3091 (w), 3068 (w), 3020 (w), 2960 (s), 2940 (s), 2912 (m), 2878 (m), 1775 (s), 1499 (m), 1490 (m), 1450 (s), 1381 (m), 1074 (m), 957 (m), 908 (m), 690 (s).

*3*b. *Adducts of 1 and cycloheptene (2*b)

1 (0.26 g, 1 mmol) and cycloheptene (0.8 mL, 9 mmol) were dissolved in benzene (7 mL) and sealed in a 16 mm tube as described above. The solution was heated for 24 h, the tube was opened, and the solvent evaporated, yielding a colourless solid. Preparative lc afforded two products, the first of which to elute was recrystallized from ethanol, yielding colourless needles (mp 179–179.5°C), and identified as *exo-3b* (0.030 g, 10%) on the basis of nmr shift reagent studies, and comparisons of its ^{1}H nmr spectrum and hplc retention time to that of *exo-3a*. ^{1}H nmr: 1.09 (s, 6H), 0.95–1.35 (m, 4H), 1.58–2.15 (m, 6H), 2.26 (m, 2H), 7.02–7.34 (m, 10H). Ir (CCl_4): 3062 (w), 2980 (m), 2935 (s), 2860 (m), 1776 (s), 1455 (m), 1382 (w), 925 (w), 907 (w). *Anal.* calcd. for $C_{26}H_{28}O$: C 87.60, H 7.92; found: C 87.43, H 8.25.

The second isomer to elute from the column was recrystallized from ethanol to yield colourless needles (mp 173–174°C) which were identified as *endo-3b* (0.180 g, 70%). ^{1}H nmr: 1.06–1.43 (m, 4H), 1.27 (s, 6H), 1.70–2.10 (m, 6H), 2.21 (m, 2H), 7.00–7.31 (m, 10H). Ir (CCl_4): 3065 (w), 2980 (m), 2938 (s), 2862 (s), 1778 (s), 1462 (m), 1454 (m), 1443 (m), 1383 (m), 690 (s). *Anal.* calcd. for $C_{26}H_{28}O$: C 87.60, H 7.92; found: C 87.38, H 8.20.

*3*c. *Adducts of 1 and indene (2*c)

A solution of **1** (0.505 g, 1.94 mmol) and indene (0.34 mL, 3 mmol) in benzene (9 mL) were sealed in a 16 mm tube and heated at 100°C for 17 h. The tube was opened and the solvent evaporated to yield a slightly yellow oil. This was chromatographed as described above to yield two products. The first to elute was recrystallized from 95% ethanol to yield colourless needles (0.070 g, 10%, mp 209–211°C) which were identified as *exo-3c* on the basis of nmr shift reagent studies. ^{1}H nmr: 1.27 (s, 3H), 1.37 (s, 3H), 2.93–3.49 (cplx. m, 3H), 3.76 (cplx. d, 1H), 7.07–7.41 (m, 14H). Ir (CCl_4): 3080 (m), 3060 (m), 3035 (m), 2975 (m), 2935 (m), 1775 (s), 1485 (m), 1447 (m), 1384 (m), 1072 (w), 941 (w), 907 (w), 688 (s). *Anal.* calcd. for

$C_{28}H_{24}O$: C 89.33, H 6.43; found: C 89.75, H 6.57.

The second isomer to elute was recrystallized from 95% ethanol to yield colourless needles (0.49 g, 67%, mp 147–148°C), identified as *endo*-**3c** on the basis of nmr shift reagent studies. ^{1}H nmr: 1.44 (s, 6H), 3.08 (m, 3H), 3.82 (m, 1H), 6.31 (m, 2H), 6.92–7.40 (cplx. m, 12H). Ir (CCl_4): 3080 (w), 3032 (w), 2975 (m), 2935 (m), 1778 (s), 1481 (w), 1445 (w), 1379 (w), 690 (s). *Anal.* calcd. for $C_{28}H_{24}O$: C 89.33, H 6.43; found: C 89.17, H 6.60.

*3*d. *Adducts of 1 and acenaphthylene (2*d*)*

A solution of **1** (0.52 g, 2 mmol) and acenaphthylene (0.3 g, 2 mmol) in benzene (7 mL) were sealed and heated in a 16 mm tube for 5 h at 110°C. The tube was opened and the solvent evaporated to yield a slightly yellow solid which was chromatographed as described above. The first isomer to elute from the column was recrystallized from chloroform/ethanol to yield colourless needles (0.030 g, 4%, mp 225–227°C), which were identified as *exo*-**3d** on the basis of nmr shift reagent studies. ^{1}H nmr: 1.34 (s, 6H), 4.20 (s, 2H), 7.25 (m, 10H), 7.25–7.75 (m, 6H). Ir (KBr): 3050 (m), 2970 (w), 2930 (w), 1776 (s), 1600 (m), 1490 (m), 1450 (m, br), 1385 (m), 905 (m), 802 (s), 795 (s), 778 (s), 768 (m), 759 (m), 721 (w), 698 (s). *Anal.* calcd. for $C_{31}H_{24}O$: C 90.26, H 5.86; found: C 90.25, H 6.04.

The second isomer to elute yielded colourless plates upon recrystallization from chloroform/ethanol (0.40 g, 49%, mp 195–197°C), which were identified as *endo*-**3d** on the basis of nmr shift reagent studies. ^{1}H nmr: 1.60 (s, 6H), 4.12 (s, 2H), 6.06 (m, 4H), 6.93 (m, 6H), 7.30–7.80 (m, 6H). Ir (KBr): 3050 (m), 2976 (w), 2938 (w), 1770 (s), 1602 (w), 1500 (m), 1445 (m), 1382 (m), 964 (m), 797 (s), 780 (s), 760 (m), 742 (s), 704 (s), 696 (s). *Anal.* calcd. for $C_{31}H_{24}O$: C 90.26, H 5.86; found: C 90.31, H 6.30.

*Reaction of 1 with 2*a–d *in liquid crystalline solvents*

Stock solutions of **1** in ChP, ChN, and EPCB were prepared by dissolving 0.004 or 0.008 g of **1** and 1.00 g of the mesogen in 10 mL dichloromethane, distilling off the solvent on the rotary evaporator, and pumping on the resulting solids for 2–8 h under high vacuum. Accurately weighed 100 mg portions of these solutions were placed in clean 100 × 7 mm Pyrex tubes, and a slight (10%) excess of the dienophile was added using a 1-μL syringe. For **2*d*** the dienophile was added as a benzene solution to a portion of the stock dienone solution, the whole was dissolved in dichloromethane, and the volatile solvents removed as before. The tubes were degassed (two freeze–pump–thaw cycles) and sealed at 10^{-3} Torr, then placed in the insulated oil bath and heated for 12–40 h at 105°C. The tubes were then opened, and the contents were dissolved in dichloromethane and analysed by hplc; product yields are collected in Table 1.

Acknowledgments

We wish to thank Dr. H. J. Ladendorff, BDH Chemicals Canada Ltd., for a sample of EPCB. We acknowledge the Natural Sciences and Engineering Research Council of Canada for its generous financial support of this work.

Monolayers of mono- and dioxyethylene dodecyl ethers at air–water and alkane–water interfaces

ROBERT AVEYARD,[1] NEIL CARR,[2] AND HELEN SLEZOK
Department of Chemistry, The University of Hull, Hull, England HU6 7RX

Received January 14, 1985

ROBERT AVEYARD, NEIL CARR, and HELEN SLEZOK. Can. J. Chem. **63**, 2742 (1985).

Surface pressure–area isotherms have been obtained for mono- and dioxyethylene dodecyl ethers both spread at the air–water surface and adsorbed at the heptane–water interface and results are compared with those for straight chain alkanols. At the heptane–water interface it appears that the ethyleneoxy groups are disposed parallel to the interface in fairly dilute films. The dual hydrophilic/hydrophobic nature of isolated CH_2CH_2O groups is demonstrated by showing that they give a negative contribution to the standard free energy of adsorption from both water and heptane to the heptane–water interface.

ROBERT AVEYARD, NEIL CARR et HELEN SLEZOK. Can. J. Chem. **63**, 2742 (1985).

On a déterminé les isothermes de pression/surface des mono- et dioxyéthylènoxydodécanes qui ont chacun été répandus à la surface air/eau et adsorbés à la surface heptane/eau et l'on a comparé les résultats avec ceux obtenus avec des alcanols en chaînes droites. A l'interface eau/heptane et lorsque les films sont assez dilués, il semble que les groupements éthylèneoxy soient disposés parallèlement à l'interface. On démontre la nature double hydrophile/hydrophobe des groupements CH_2CH_2O isolés en se basant sur le fait que leur contribution à l'énergie libre standard d'adsorption soit de l'eau ou de l'heptane à soit l'heptane ou à l'interface heptane/eau est négative.

[Traduit par le journal]

Introduction

There has been a considerable interest over the years in the surface and micellar properties of surfactants of the type RE_n (where R is a hydrophobic moiety such as an alkyl or alkylbenzene group and E is the ethyleneoxy group CH_2CH_2O) both for mixtures with a range of n values, usually for large average n, and for pure materials with n up to about 8 (1–6). Thermodynamic studies have thrown some light onto the dual hydrophilic/hydrophobic nature of E_n groups (4–6). For example, thermodynamic parameters of micellisation have been reported, as have those for adsorption from aqueous solution to films at both high and low concentration at the air–water surface. However, the environment (and hence values of thermodynamic parameters) of individual E groups depends not only on the size of the E_n group, which is likely to become progressively more coiled as n increases, but on the environment of the E_n group as a whole. The latter can be close-packed, as at a micelle surface or in a saturated monolayer, or they may be essentially isolated in dilute solution or in a dilute monolayer.

Here we report surface pressure–area (π,A) isotherms for air–water and oil–water interfaces, and standard free energies of adsorption of mono- and dioxyethylene dodecyl ethers ($C_{12}H_{25}(OCH_2CH_2)_nOH$, denoted $C_{12}E_1$ and $C_{12}E_2$ for $n = 1$ and 2, respectively) from heptane to dilute films at the heptane–water interface. From these we have derived a free energy contribution of an E group to the adsorption of $C_{12}E_1$ and $C_{12}E_2$ from both oil and water to the oil–water interface. Since $n = 1$ or 2 we may suppose the E groups interact only with water and/or alkane in bulk and at the interface, and not with other E groups in the same E_n moiety.

Experimental

Materials

Samples of $C_{12}E_1$ and $C_{12}E_2$ were pure homogeneous samples supplied by the Nikko Chemicals Co. (Japan) and were used without further treatment. Dodecanol and octadecanol were "puriss" samples from Fluka, and pentadecanol was "purum" grade, also from Fluka. These had estimated purities (determined by glc in this laboratory) of >99.5% for "puriss" and >98.5% for "purum" samples and were used untreated. Heptane (Fisons, England) was HPLC grade and was shown by glc to be >99% pure. It was passed through chromatographic alumina immediately prior to use. It had an interfacial tension against water at 25°C of 50.78 mN m^{-1} in excellent agreement with a previous value of 50.77 mN m^{-1} obtained using a highly pure heptane sample (7). Water was distilled once, passed through an Elgastat ion exchange column and then through a Milli-Q Reagent Water System.

Techniques

Interfacial tensions between solutions of $C_{12}E_1$ and $C_{12}E_2$ and water were determined by the drop-volume technique (7). The tensions were highly reproducible (±0.05 mN m^{-1}) and showed no tendency to ageing (unlike those for aqueous solutions against air).

The π,A isotherms for materials spread from solution in heptane at the air–water surface were obtained using a Joyce-Loebl (Gateshead, England) automated recording Langmuir trough. The barrier was a constant perimeter Teflon tape, and the surface pressure was measured using the Wilhelmy plate technique. It was found that the use of filter paper as the "plate" gave very reproducible results which, in the case of octadecanol and pentadecanol were in good agreement with literature data (8). The isotherms reported here, which were very reproducible, were all obtained by compressing the film over a period of 2 min but were indistinguishable from those obtained over a 4 min period. Low temperature isotherms were obtained by circulating cold water through glass tubing immersed in the trough.

Results and discussion

Interfacial tensions γ between dilute solutions of $C_{12}E_1$ and $C_{12}E_2$ in heptane, and water are shown in Fig. 1. At the concentrations used the surfactants reside almost entirely in the alkane phase as may be deduced from the distribution data reported by Manabe *et al.* (9) As expected $C_{12}E_2$ in heptane is more surface active than $C_{12}E_1$. The tensions have been fitted to cubics in surfactant mole fraction x in overlapping concentration ranges. The fitting constants of the equations

$$[1] \quad \gamma = a + bx + cx^2 + dx^3$$

are given in Table 1. We may assume that at the high dilutions

TABLE 1. Constants from eq. [1] for $C_{12}E_1$ and $C_{12}E_2$ adsorbed at the heptane–water interface at 25°C

(*a*) $C_{12}E_1$

a	$-10^{-4}\,b$	$10^{-7}\,c$	$-10^{-10}\,d$	Range of x	Number of points
50.80	5.23539	21.77382	51.03840	$0 - 15 \times 10^{-5}$	12
50.00	3.14254	4.17710	2.49578	$8 \times 10^{-5} - 51 \times 10^{-5}$	11

(*b*) $C_{12}E_2$

a	$-10^{-5}\,b$	$10^{-10}\,c$	$-10^{-14}\,d$	Range of x	Number of points
50.74	4.74867	2.17301	4.76578	$0 - 2 \times 10^{-5}$	15
50.03	2.63606	0.38145	0.19527	$0.5 \times 10^{-5} - 3.6 \times 10^{-5}$	14

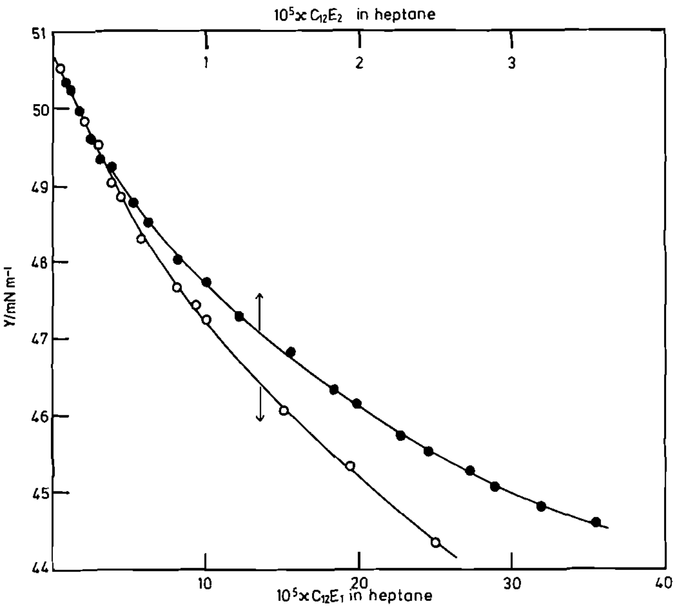

FIG. 1. Interfacial tensions between solutions of $C_{12}E_1$ and $C_{12}E_2$ in heptane and water at 25°C. Six further high concentration points ($x > 25 \times 10^{-5}$) were obtained for $C_{12}E_1$. They are not shown here but were included in the fit of data (see text).

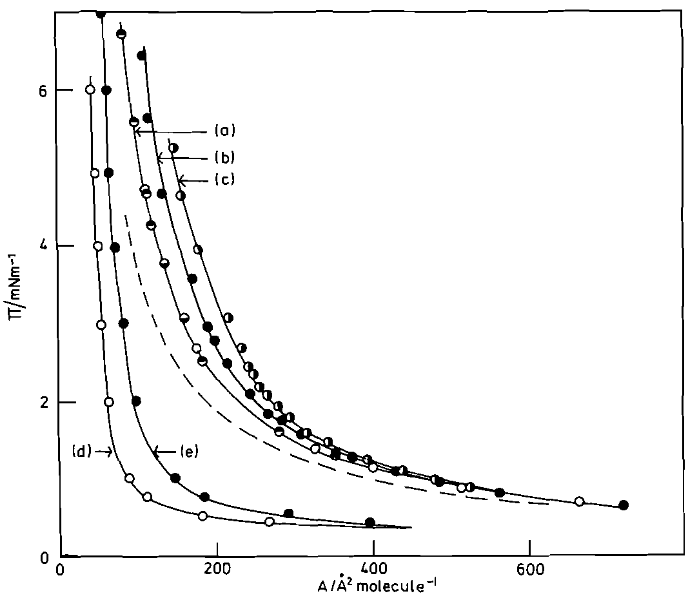

FIG. 2. π,A-isotherms at 25°C. Curves (*a*), (*b*), and (*c*) relate to alkane–water interfaces and are for, respectively, alkanols (octanol, decanol, and dodecanol — see text), $C_{12}E_1$, and $C_{12}E_2$. Curves (*d*) and (*e*) are for $C_{12}E_1$ and $C_{12}E_2$, respectively, at air–water surface.

employed ($x < 5 \times 10^{-4}$ for $C_{12}E_1$ and $x < 4 \times 10^{-5}$ for $C_{12}E_2$) surfactant activity coefficients are unity and activity may be expressed by x.

The Gibbs adsorption equation in general form is, for constant temperature,

$$[2] \quad -d\gamma = \sum_i \Gamma_i d\mu_i$$

where Γ_i are surface concentrations of species i and μ_i are chemical potentials. For low surfactant concentrations $d\mu$ for the heptane and the water may reasonably be set at zero so that from eqs. [1] and [2]

$$[3] \quad \Gamma = A^{-1} = -(x/kT)\,(b + 2cx + 3dx^2)$$

where Γ is the surface concentration of surfactant (molecules per unit area) and A is the area available per surfactant molecule in the film. We denote the surface pressure of a film, which is the lowering in γ caused by adsorption, π. The quantities π and A are related through a surface equation of state.

In addition to the study of films at the oil–water interface we have also obtained π,A data for films at the air–water surface. Adsorption of nonionic surfactants from water is not easy to study since it is time dependent and γ can change markedly over long periods of time (2). However $C_{12}E_1$ and $C_{12}E_2$ are sufficiently insoluble in water (as judged by the reproducibility of the π,A curves obtained at different rates of compression) for monolayers to be studied using the Langmuir trough.

In Fig. 2 we present (π,A) data (for π up to 6 mN m^{-1}) for $C_{12}E_1$ and $C_{12}E_2$ at both the air–water and heptane–water interfaces. Also included are data for octanol, decanol, and dodecanol adsorbed at the alkane–water interface (10). For the oil–water interface both $C_{12}E_1$ and $C_{12}E_2$ films are more expanded than the alkanol films, for which the π,A values fall on a common curve. The similarity of the π,A data for all alkanols implies that chain–chain interactions are unimportant at the oil–water interface and that the alkanol chains are oriented normal to the interface (11). It follows that the larger π (for a given A) exerted by $C_{12}E_1$ and $C_{12}E_2$ arise from the larger effective cross-sectional areas of these molecules at the interface, a point we return to shortly.

The π,A curves for the surfactants at the air–water surface fall well below those for the oil–water interface, and below the ideal curve for which $\pi A = kT$; this is a result of the lateral attractions between the hydrocarbon chains in the surface. As

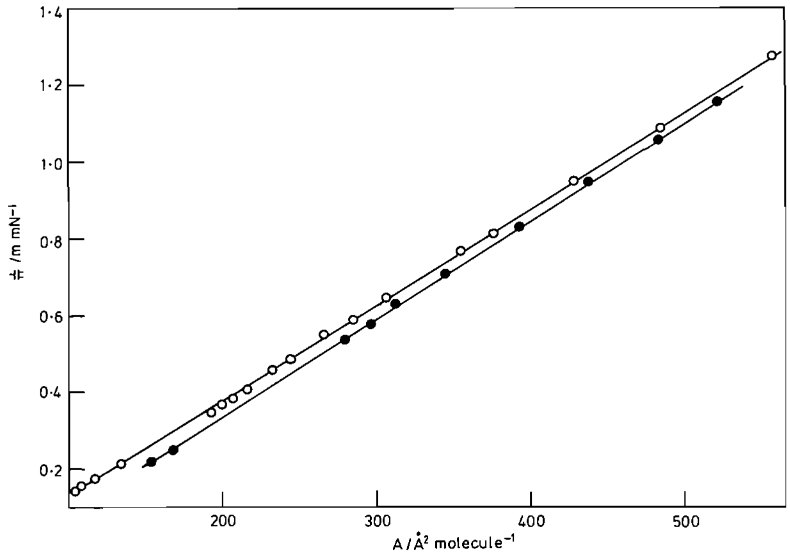

FIG. 3. Plots according to eq. [5] for $C_{12}E_1$ (upper line) and $C_{12}E_2$ at the heptane–water interface at 25°C.

for the oil–water interface, the $C_{12}E_2$ film is more expanded than that for $C_{12}E_1$ presumably due again to the greater cross-sectional area of $C_{12}E_2$. The π,A curves for $C_{12}E_1$ and $C_{12}E_2$ both at the air–water and oil–water interfaces converge at areas between 400 and 500 Å^2 molecule^{-1}.

Surface equations of state

Consideration of surface equations of state can give useful indications concerning interactions and orientations within monolayers. It is known (10) that alkanol behaviour at oil–water interfaces is well described by the Volmer equation

[4] $\quad \pi(A - A_0) = kT$ per molecule

The quantity A_0 is the molecular co-area of the adsorbate and although it is twice the area defined by closest approach of the molecules at the surface, it may be regarded as a good measure of the effective cross sectional area of the molecules (12, 13). For a series of alkanols $A_0 \simeq 27$ Å^2 molecule^{-1} (10).

In linear form eq. [4] is

[5] $\quad 1/\pi = A/kT - A_0/kT$

and plots according to this equation for $C_{12}E_1$ and $C_{12}E_2$ at the heptane–water interface are shown in Fig. 3. The plots are very linear and the values of A_0 obtained from the intercept on the A-axis are 49 and 68 Å^2 molecule^{-1} for $C_{12}E_1$ and $C_{12}E_2$, respectively. The full lines shown in Fig. 2 are those generated by eq. [4] using these A_0 values. If we suppose that the CH_2 group covers 6.5 Å^2 of surface (14) and that the CH_2 and O groups are the same size, the CH_2CH_2O is expected to cover about 20 Å^2 if disposed along the interface. Given that alkanols have $A_0 = 27$ Å molecule^{-1} we expect A_0 for $C_{12}E_1$ and $C_{12}E_2$ to be 47 and 67 Å^2 molecule^{-1} if the E groups are flat along the interfaces. The values are remarkably close to the A_0 values quoted above, and it therefore appears that both CH_2 groups and O are *at* the interface and that the E group has both hydrophilic and hydrophobic properties, a point considered further shortly.

Repulsive interactions resulting from finite size account for deviations from ideality for oil–water films as seen. Repulsive interactions also obviously occur in films at the air–water surface but here π values fall below those expected for ideal films. The difference in π (for a given A) for a film at the oil–water and the air–water surface has often been referred to as the "cohesive pressure" π_c within the air–water film and taken to be a measure of interchain cohesion (15). However, this is not a satisfactory estimate of attractive interactions between chains. At an oil–water interface the alkyl chains of adsorbate molecules are roughly normal to the surface as mentioned. At the higher area represented in Fig. 2, however, alkyl chains at an air–water surface are likely to lie along the surface in order to interact with the underlying water molecules (13). Hence at these areas, the effective A_0 will be larger than those appropriate for the oil–water interface. As the film becomes more concentrated, the alkyl chains assume more nearly vertical orientations and so A_0 changes. The cohesive pressure as defined above therefore contains (changing) repulsive contributions as well as the attractive contributions.

Data for air–water films of $C_{12}E_1$ and $C_{12}E_2$ at high surface pressures are shown in Fig. 4 where results for pentadecanol ($C_{15}OH$) are also given. The π,A curve of $C_{15}OH$ is very similar to that obtained for octadecanol ($C_{18}OH$, not shown), and these two alkanols were investigated since they have similar overall size (i.e. extended chain length) to the surfactants. Some results are also shown for dodecanol (formally $C_{12}E_0$) but these are considered to be less reliable than the others as a result of the higher solubility in water. At 25°C the films of dodecanol, $C_{12}E_1$, and $C_{12}E_2$ are all expanded up to high pressures, whereas monolayers of $C_{15}OH$ and $C_{18}OH$ are readily condensed. In the case of $C_{12}E_1$ and $C_{12}E_2$, areas are attained which are considerably less than the A_0 values obtained at the heptane–water interface and so the E groups are presumably forced out of the interface into the aqueous phase. This effect can be expected to militate against the formation of condensed films. It is interesting though that films of $C_{12}E_1$ at temperatures below 25°C do eventually become condensed at higher pressures and exhibit quite extensive expanded-condensed transition regions. Possible origins of such transition regions are discussed by Gaines (8).

Standard free energies of adsorption

We have suggested, from a consideration of an equation of state, that the E groups in $C_{12}E_1$ and $C_{12}E_2$ are disposed parallel to the oil–water interface and that they have both hydrophilic and hydrophobic character at the interface. These ideas can be

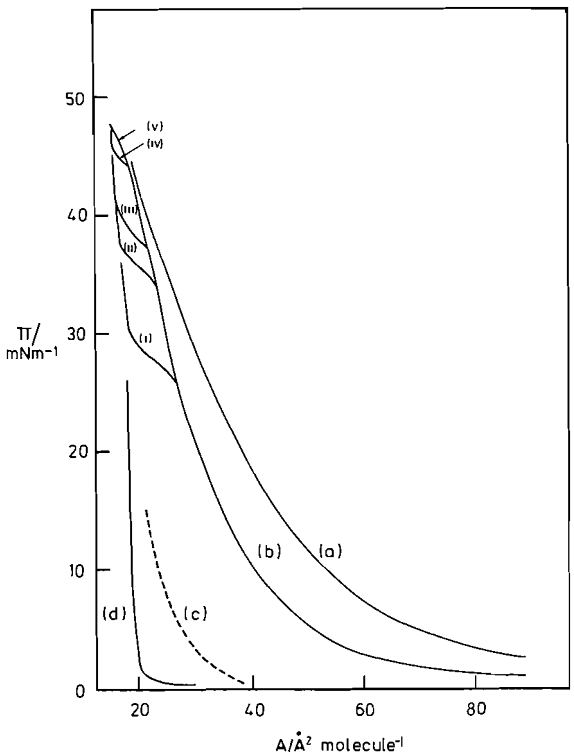

FIG. 4. π,A-isotherm for films at the air–water surface (*a*) $C_{12}E_2$ at 25°C; (*b*) $C_{12}E_1$ at (*i*) 4.6°C, (*ii*) 11.9°C; (*iii*) 15.8°C; (*iv*) 21.0°C; (*v*) 25.0°C; (*c*) dodecanol at 25°C; (*d*) pentadecanol at 25°C.

quantified in terms of standard free energies of adsorption and of transfer between aqueous and oil phases. We first consider the significance of various "adsorption free energies" which have been reported in the literature.

The adsorption isotherm equation, which contains a standard free energy of adsorption, is obtained by equating the chemical potentials of the surfactant in surface (μ^s) and bulk (μ^l) at adsorption equilibrium. For an infinitely dilute film we may write

[6] $\mu^s = \mu_\pi^{\ominus,s} + RT \ln(\pi/\pi_{st})$

[7] $\quad = \mu_\Gamma^{\ominus,s} + RT \ln(\Gamma/\Gamma_{st})$

where $\pi = \Gamma RT$, $\mu_\pi^{\ominus,s}$ and $\mu_\Gamma^{\ominus,s}$ are standard chemical potentials, and π_{st} and Γ_{st} are the standard surface pressure and standard surface concentration respectively. If, for a given temperatue, π_{st} is chosen as being equal to $\Gamma_{st}RT$ then $\mu_\pi^{\ominus,s} = \mu_\Gamma^{\ominus,s}$ for that temperature. Further, for an ideal dilute solution

[8] $\mu^l = \mu^{\ominus,l} + RT \ln(c/c_{st})$

where c_{st} is the standard concentration. It follows that for adsorption into an infinitely dilute film

[9] $\mu_\pi^{\ominus,s} - \mu^{\ominus,l} = \Delta_a\mu_\pi^\ominus = -RT \ln(\pi c_{st}/c\pi_{st})_0$

and

[10] $\mu_\Gamma^{\ominus,s} - \mu^{\ominus,l} = \Delta_a\mu_\Gamma^\ominus = -RT \ln(\Gamma c_{st}/c\Gamma_{st})_0$

where the subscript 0 denotes that the quantity in brackets is taken at infinite dilution. If we choose the same c_{st} and if $\pi_{st} = \Gamma_{st}RT$ at the given temperature T, $\Delta_a\mu_\pi^\ominus$ and $\Delta_a\mu_\Gamma^\ominus$ are equal at that temperature. If however we choose, for example, a temperature independent standard surface pressure the correspond-

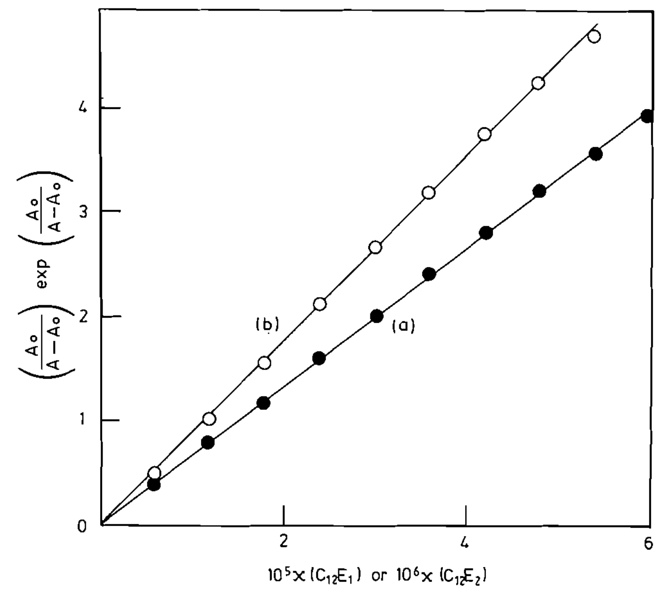

FIG. 5. Plots according to eq. [11] for (*a*) $C_{12}E_1$ and (*b*) $C_{12}E_2$ adsorbed at the heptane–water interface at 25°C.

ing Γ_{st} ($= \pi_{st}/RT$) varies with T and so the standard enthalpies and entropies obtained from the temperature variation of the two free energies will differ.

For films which are not ideally dilute, expressions [6] and [7] are no longer true, and for a film obeying the Volmer equation (eq. [4]) it can be shown that (16)

$$\Delta_a\mu_v^\ominus = RT(\ln K + 1)$$

where

[11] $K = \left\{c\Big/\left(\frac{A_0}{A - A_0}\exp\frac{A_0}{A - A_0}\right)\right\}$

and the standard state for the surface is taken as $A_{st} = 2A_0$. It can be shown that

[12] $\Delta_a\mu_v^\ominus = \Delta_a\mu_\pi^\ominus - RT\{\ln(A_0/kT) - 1\}$

where the standard state $\pi_{st} = 1$ is chosen for $\Delta_a\mu_\pi^\ominus$. We have data from which we can obtain $\Delta_a\mu_v^\ominus$ and we will wish to obtain $\Delta_a\mu_\pi^\ominus$ using eqs. [11] and [12].

Sokolowski and Burczyk (6) have obtained values of $\Delta_a\mu_\pi^\ominus$ for the adsorption of R_nE_m (where R is an alkyl group with n = 4 to 8, and m = 1 to 5) from water to the air–water surface. We will therefore be able to use their data in conjunction with our own. On the other hand, Barry and El Eini (4) and Guveli *et al.* (5) employ a free energy of adsorption defined by

[13] $\Delta_a\mu^\ominus = -RT \ln\{(\Gamma/c_0^{2/3})10^2N^{1/3}\}$

where Γ is the saturation adsorption at the cmc (c_0). The significance of $\Delta_a\mu^\ominus$ is not clear. Equation [13] implies that we may write

[14] $\mu^l = \mu^\ominus + RT \ln c^{2/3}$

Comparison of eqs. [8] and [14] (for $c_{st} = 1$) shows that $\mu^\ominus = \mu^{\ominus,l} + RT \ln c^{1/3}$ so that $\mu^\ominus$ changes with concentration. Equation [13] further implies that eq. [7] holds for a concentrated film, which it does not. This must also throw doubt upon the significance of the enthalpies and entropies obtained from $\Delta_a\mu^\ominus$.

In Fig. 5 are shown plots of $\{A_0/(A - A_0)\}\exp\{A_0/(A - A_0)\}$

TABLE 2. Standard free energies of adsorption and values of A_0

$-\Delta_a\mu_\pi^\ominus$/kJ mol^{-1}	23.64	27.10	32.70
A_0/Å^2 molecule^{-1}	26	49	68

*Values for dodecanol taken from ref. 10.

($= f(A)$) against c (in mole fraction x) for $C_{12}E_1$ and $C_{12}E_2$ in the heptane–water system. Values of $f(A)$ were obtained at equal intervals of x using the constants in Table 1. The plots are very linear and values of $\Delta_a\mu_v^\ominus$ have been obtained from the slopes using eq. [11]. Since A_0 is different for $C_{12}E_1$ and $C_{12}E_2$, so are the standard states for the surface. We have therefore converted $\Delta_a\mu_v^\ominus$ to $\Delta_a\mu_\pi^\ominus$ using eq. [12] and the various free energies are given in Table 2.

For $C_{12}E_1$ and $C_{12}E_2$ in dilute solution and in dilute monolayers the E groups are probably in contact only with one or, at the interface, both of the solvents, but not in mutual contact. Manabe *et al.* (9) have shown that the standard free energy of transfer of R_nE_m (m = 1 to 4) from dilute aqueous solution to dodecane varies linearly with m (suggesting the equivalence of all E groups up to E_4), the E group contribution being within experimental error the same for n between 2 and 5. The mean standard free energy of transfer of the E group was found to be +2.74 kJ mol^{-1}. From our results, the change in $\Delta_a\mu_\pi^\ominus$ per E group (for E_1 to E_2) is −5.60 kJ mol^{-1}; in view of the transfer data we may reasonably suppose this increment holds up to E_4. It follows that the standard free energy of adsorption of the E group from water to the oil–water interface is −2.86 kJ mol^{-1}. It is seen then that the E group is surface active (i.e. has a negative standard free energy of adsorption) both from water and from alkane, but more strongly so from alkane.

Sokolowski and Burczyk (6) obtain a value for the standard free energy of adsorption of the E group from aqueous solution to infinite dilution at the air–water surface of −1.86 kJ mol^{-1}. For straight chain alkanols, the difference in $\Delta_a\mu_\pi^\ominus$ per CH_2 group for adsorption from aqueous solution to the oil–water and the air–water interfaces is 0.5 kJ mol^{-1} (16). This difference for CH_2CH_2 is thus 1.0 kJ mol^{-1}, which is the same as for the two CH_2 groups in CH_2CH_2O. Clearly, the methylene groups of the E moiety are unlikely to extend deep into the alkane phase at an alkane–water interface as do the CH_2 groups of a long chain alkanol, but it has been argued elsewhere (10, 13) that the free energy of interaction of methylene groups with interfacial water is similar to that for the corresponding interaction with alkane and that the free energies of CH_2 groups in chains normal to and parallel to the oil–water interface are essentially equal.

Included in Table 2 is a value for the standard free energy of adsorption of dodecanol from octane to the octane–water interface. The value is more negative than expected if the alcoholic OH were the same as the OH in $C_{12}E_1$ and $C_{12}E_2$. This is in accord with the findings of Manabe *et al.* (9) concerning transfer free energies.

High field ^{13}C nmr has been utilized for the analysis of new conformational equilibria in each of the title crown ethers at low temperature. Evidence indicates that these equilibria arise from restricted rotation in the macrocyclic portions of these molecules. The conformational free energy differences between the isomers are small (0.1–0.3 kcal/mol) while barriers to their interconversion are of the order of 8.5–9.0 kcal/mol. Comparisons are made with the degenerate equilibria involving inversion of the cyclohexane rings.

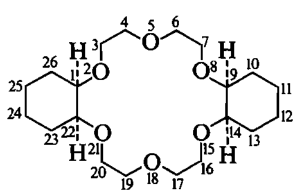
G. W. BUCHANAN, K. BOURQUE, J. W. BOVENKAMP et A. RODRIGUE. Can. J. Chem. **63**, 2747 (1985).

On a fait appel à la rmn du ^{13}C à haut champ pour analyser de nouveaux équilibres conformationnels, à basse température, dans chacun des éthers couronnes mentionnés dans le titre. Les données indiquent que ces équilibres proviennent de rotations empêchées dans les portions macrocycliques de ces molécules. Les différences d'énergie libre conformationnelle entre les isomères sont petites (entre 0,1 et 0,3 kcal/mol) alors que les barrières à leur interconversion sont de l'ordre de 8,5 à 9,0 kcal/mol. On a fait des comparaisons avec les équilibres dégénérés impliquant l'inversion de cycle dans le cyclohexane.

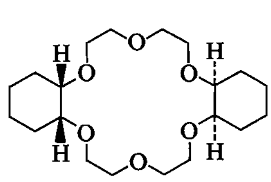
[Traduit par le journal]

Introduction

Both the *cis-syn-cis* (**1**) and *cis-anti-cis* (**2**) isomers of dicyclohexano-18-crown-6 (below) are expected to undergo degenerate inversions of their 18-membered rings, which necessarily involve inversion of their cyclohexane rings (1).



1



2

Recently (2) we reported determination of the ring inversion barriers for **1** and **2**, as well as their 1:1 complexes with potassium phenoxide using 50.3-MHz ^{13}C nmr at low temperature. For **1** and **2**, the magnitudes of these barriers (ca. 10.2 kcal/mol) are similar to those previously measured for *cis*-1,2-disubstituted cyclohexanes (3). Minor increases (ca. 1 kcal/mol) were observed in the barriers for the complexes with potassium phenoxide relative to the free crown ethers.

In our communication (2) it was noted that 50.3-MHz ^{13}C spectra of pure **1** and **2**, but *not* the potassium complexes, showed evidence of additional spectral features at very low temperatures. The inherent sensitivity of the instrument used, however, did not permit a clear definition of the phenomena involved.

Presently, we report the results of 100.6-MHz ^{13}C spectra of **1** and **2** at 173 K. The increased sensitivity and dispersion of these spectra have permitted the clear identification of a second conformational isomer for each of the pure crown ethers **1** and **2**. From relative intensities of the ^{13}C resonances at 173 K the conformational free energy difference between these conformers has been calculated.

Results and discussion

(i) Spectra

The ^{13}C chemical shifts for **1** and **2** in two solvent media at 298 K are presented in Table 1. Assignments are consistent with those reported earlier (4). For each compound only 5 resonances appear, due to rapid ring inversion on the nmr time scale at this temperature.

As a typical example of the spectral behaviour of these materials as a function of temperature, Fig. 1 shows the 100.6-MHz ^{13}C spectra of **2** in CD_2Cl_2 between 173 and 293 K. Clearly, decoalescence phenomena are first observed for the C-1,9,14,22 site, centered at δ_C = 77.44, and the C-11,12,24,25 site at δ_C = 22.48. A slow exchange spectrum results at 198 K, where it appears that there is a simple 1:1 exchange process. The chemical shift differences at the remaining three sites appear to be too small to allow observation of resonances for separate conformers. Spectra such as this were observed at 50.3 MHz (2) and were employed in the earlier barrier calculations for pure **1** and **2**, for degenerate ring inversion.

As is evident from Fig. 1, however, further cooling to 173 K results in additional fine structure being observable at 100.6 MHz. Resolution enhanced 100.6-MHz ^{13}C spectra for the 15–30 ppm and 65–82 ppm ranges of **2** in CD_2Cl_2 are depicted in Figs. 2 and 3 respectively.

In the 15–30 ppm region (Fig. 2), the initial two resonances at 293 K have, at 173 K, split into eight resonances. These eight lines can be divided into four pairs, arising from individual non-oxygenated carbons of major and minor conformers of **2**.

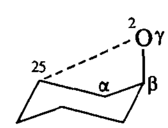
carbons due to their *gauche* γ−relationship to the axial oxygen atoms at sites 15 and 2 respectively (5). The C-11,24 pair of carbons are deshielded by ca. 5 ppm relative to C-12,25, an observation consistent with the γ−*trans* relationship of C-11,24 to the oxygen atoms at positions 8 and 21 respectively.



The resonance for C-10,13, 23,26 shows little broadening even at 198 K, but finally splits into 4 lines in the range of 26.30 to 27.74 ppm. Tentative signal assignments can be made from additivity using the known β and γ ^{13}C substituent effects for axial and equatorial OR groups in monosubstituted cyclohexanes at low temperature (6). This leads to the expectation that the C-10,23 site will resonate ca. 1–2 ppm upfield from the resonance for C-13,26. The observed difference is

†Peak overlap.

0.75 ppm for the major conformations. Interestingly, in the minor conformers this difference decreases, to only 0.16 ppm.

Figure 3 shows the oxygenated carbon resonances for **2** in CD_2Cl_2 at 173 K. The lowest field pair of signals in the range 79–80 ppm arises from the C-9,22 sites of **2** in its major and minor conformations. These carbons, bearing equatorial oxygens, are expected, by analogy with cyclohexanol derivatives (7), to be substantially deshielded relative to their counterparts C-1,14 which bear axial oxygen atoms. For both the major and minor conformation, the difference is ca. 7.2 ppm.

From Fig. 3, it is evident that considerable peak overlap persists in the resonances for the C-4,6,17,19 sites of **2**, even at 100.6 MHz. Thus, instead of the 4 lines expected here, just 2 are observed. The resonance at δ_C = 70.11 represents a composite of several (probably three) signals while the intensity of the remaining signal at δ_C = 70.74 suggests that it arises from the minor conformation.

The remaining four signals are due to the C-3,16 and C-7,20 sites, as depicted in Fig. 3. Carbons directly bonded to axial oxygens (i.e. C-3,16) were found to be substantially deshielded relative to their C-7,20 counterparts, which are linked to equatorial oxygens. The result is consistent with our recent findings (8) in which axial OCH_3 carbons in vicinally di- and tri-substituted cyclohexanes are always deshielded (by ca. 0.5–1.0 ppm) relative to equatorial OCH_3 functions.

In general, similar trends were noted for **2** in CD_3OD solution, although more accidental resonance overlap was observed. Chemical shift data for individual conformers of **2** in CD_2Cl_2 and CD_3OD at 173 K are presented in Table 3.

In the case of isomer **1**, there is also clear evidence for the presence of a second conformation at 173 K. There is, however, more accidental overlap of resonances for major and minor conformers, especially in CD_2Cl_2 solution. Accordingly, only low temperature data for **1** in CD_3OD solutions are listed in Table 2.

(ii) Conformations

A considerable amount of X-ray data is available for complexes of **1** and **2** (9–11). In these cases, it is generally true that the crown ethers assume conformations in which the oxygen atoms are displaced alternately above and below the mean plane of the 18-membered ring. These conformations are referred to as the "all *gauche*-O—CH_2—CH_2—O—" or "ideal" conformations for complexation.

For the crown ethers themselves in the solid phase, however, X-ray data (12) indicate some changes from the above "ideal" complexation geometries. In fact, the results for **1** and **2** suggest that all six oxygen atoms lie approximately in a plane, with the central cavity being elliptical in shape. Of course the conformations of these molecules in solution may vary substantially from those in the crystal, but the solid state geometries can be used as a starting point for discussion.

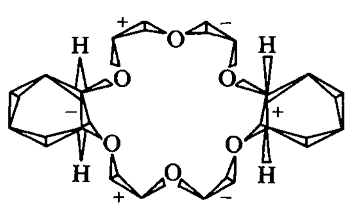
It is important to note that the ^{13}C chemical shifts of both major and minor conformations of **1** and **2** at 173 K are, on the average, within 1 ppm of those for the potassium phenoxide complexes at comparable temperatures (2). This suggests that there are no *major* structural perturbations from the "all *gauche*-O—CH_2—CH_2—O" geometry in *either* of the conformations of free **1** and **2**. As was noted in the introduction, the ^{13}C spectra of potassium phenoxide complexes of **1** and **2** show *no* evidence of the presence of minor crown ether conformers (2) at low temperature. Presumably electrostatic interactions between the oxygen lone pairs and the cation in the cavity will stabilize the "all *gauche*-O—CH_2—CH_2—O" conformation in the complex relative to the situation for free **1** and **2**.

It has been shown (13) that for the network —O—CH_2—CH_2—O—, the conformation in which the oxygens are *gauche* is ca. 0.4 kcal/mol more stable than the conformer having *trans* oxygen atoms. With this information and the ^{13}C chemical shifts in hand, one can now speculate regarding the nature of the major and minor conformations for **1** and **2** respectively.

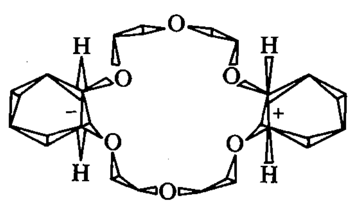
From relative ^{13}C peak areas at 173 K, and use of the equation $-\Delta G^0 = RT \ln K_{eq}$, the conformational free energies were determined to be as follows: for **1** in CD_3OD, 0.10 ± 0.04 kcal/mol; for **2** in CD_2Cl_2, 0.31 ± 0.05 kcal/mol; and for **2** in CD_3OD, 0.10 ± 0.04 kcal/mol.

It is of interest to note that the ^{13}C chemical shifts for minor conformers are all *downfield* relative to those for the corresponding carbons of the major isomers. In this context it is useful to recall that ^{13}C shifts for carbons involved in "γ–*gauche*" interactions are normally upfield from those for carbons experiencing more transoid-type γ steric situations (5). From Tables 2 and 3 it is also evident that the largest chemical shift differences between conformers occur at carbons in the central 18-membered ring. The smallest differences in ^{13}C shieldings between conformers are noted at the C-11,12,24,25 sites, which are the most remote from the macrocyclic cavity.

Based on the points in the preceding paragraph, we conclude that the presence of the second conformational isomer in free crown ethers **1** and **2** is a consequence of rotational isomerism in the macrocyclic ring. The more populated form, we suggest, is the one having all *gauche*-O—CH_2—CH_2—O" networks in the macrocyclic ring as depicted for **2***A* (below), with alternating g_+ and g_- arrangements. For **2***B*, the minor form, we postulate that there is ring deformation in the central region of the macrocycle leading to more transoid character in the —O—CH_2—CH_2—O networks.



2*A*



2*B*

As our results show, however, there is only a small difference in the stability of the conformational isomers, since the largest $-\Delta G^0$ value is 0.31 ± 0.05 kcal/mol for **2** in CD_2Cl_2.

The fact that the barriers to rotation in the macrocyclic rings are large enough to permit detection of conformational isomers by nmr is perhaps not surprising, in view of recent results (14) regarding rotational barriers in substituted ethane units containing vicinal heteroatoms.

The present ^{13}C data can be used to calculate $\Delta G^{\neq}$, the free energy of activation for the conformational interconversion in the macrocycle at the coalescence temperature. A modified (for unequally populated two-site exchange processes) Gutowsky–Holm equation and the Eyring equation are used. The rate constant k is calculated from the equation (15)[2]

$$K = \frac{\pi \Delta \nu}{\sqrt{2}\rho_\beta}$$

where ρ_β is the site population ratio (larger to smaller area). For **1** and **2** this calculation leads to barriers in the range of 8.5–9.0 kcal/mol. These barriers are ca. 1.5 kcal/mol lower than those for the overall ring inversion process (2) for **1** and **2**, in which cyclohexane ring inversion is necessarily involved.

An X-ray crystallographic study on complexes **1** and **2** with sodium and potassium salts involving unusual host/guest ratios has been completed recently (17). Of relevance to the present work is the finding that the macrocyclic ring of the solid complex of **1** with sodium phenoxide is in a "non-ideal" conformation, similar in nature to those postulated here for the minor isomers of **1** and **2** in solution.

Finally, it should be noted that the nature of the solvent undoubtedly plays an important role in affecting the observed conformations of the macrocyclic rings of **1** and **2**. Recently Popov and co-workers (18) have demonstrated the influence of solvent association on the ligand conformation in the cryptand C221. They classify both solvents used here, i.e. CD_2Cl_2 and methanol, as "A-class" solvents which are expected to interact with crown ethers via hydrogen bonding. We have also examined the low temperature ^{13}C spectra of **1** and **2** in a "B-class" solvent, namely toluene-d_8. In these experiments, there was again evidence for additional conformations of **1** and **2**; however, extensive peak overlap precludes a detailed discussion of results.

Experimental

(a) *Materials*

The commercial mixture of **1** and **2** was separated by published methods (16). For **1**, mp = 61–63°C and for **2**, mp = 69–70°C.

(b) *Spectra*

^{13}C Spectra were recorded at the Univesity of Guelph using a Bruker WH-400 spectrometer at 100.6 MHz. Suppressed nOe. ^1H decoupling was used. Samples were 0.4 *M*, contained in 5-mm tubes. Typical sweep width was 31 250 Hz, acquisition time 0.262 s with 56 K data points. Pulse repetition rate was 2.0 s, with 45° observe pulses. Normally 200 spectral accumulations were obtained. Temperatures are accurate to ±2.0 K. Chemical shifts are relative to internal TMS.

The crystal and molecular structures of methyl β-carboline-3-carboxylate, $C_{13}H_{10}N_2O$, a high-affinity ligand for the benzodiazepine receptor, are reported. This candidate for the endogenous ligand for the receptor produces a biological response that is opposite to the anxiety-reducing effect of the usual agonists of the receptor and is, therefore, classified as an inverse-agonist. The space group is $P2_1/c$ with a = 11.4866(9), b = 5.8091(3), c = 32.417(3) Å, β = 97.111(3)°, Z = 8. In both of the unique molecules, the ester side chain has an extended conformation and is coplanar with the β-carboline moiety. The carbonyl oxygen atom and the aromatic nitrogen atom are *cis* and form a three-centre hydrogen bond to the amine nitrogen atom of the other molecule in the asymmetric unit.

ALASTAIR K. S. MUIR et PENELOPE W. CODDING. Can. J. Chem. **63**, 2752 (1985).

On rapporte les structures cristalline et moléculaire du β-carbolinecarboxylate-3 de méthyle, un ligand de grande affinité pour le récepteur benzodiazépine. Ce candidat pour le ligand endogène pour le récepteur produit une réponse biologique qui est opposée à l'effet de réduction d'anxiété des agonistes usuels du récepteur; on peut donc le classifier comme agoniste inverse. Le composé cristallise dans le groupe d'espace $P2_1/c$ avec a = 11,4866(9), b = 5,8091(3), c = 32,417(3)Å, β = 97,111(3)° et Z = 8. Dans chacune des deux molécules distinctes, la chaîne latérale de l'ester existe dans une conformation allongée et elle est coplanaire avec la β-carboline. L'atome d'oxygène du groupement carbonyle et l'atome d'azote aromatique sont *cis* et ils forment une liaison hydrogène à trois centres avec l'atome d'azote de l'amine de l'autre molécule de l'unité asymétrique.

[Traduit par le journal]

Methyl β-carboline-3-carboxylate (hereinafter CCM) is one of several β-carboline derivatives that have been studied as possible endogenous ligands for the benzodiazepine receptor (1). The identity of the natural ligand for the benzodiazepine receptor is not certain, as the isolation procedures from rat brain and from urine have been shown to chemically modify the naturally occurring β-carboline isolate to the ethyl ester. CCM binds with high affinity (2–4) to the receptor and displaces diazepam, an agonist. The β-carbolines produce three different responses when bound to the benzodiazepine receptor; the methyl ester is a convulsant (opposite to the agonists and hence labeled an inverse-agonist), the ethyl ester is a proconvulsant (potentiates the onset of convulsions), and the propyl ester acts as a weak agonist (anticonvulsant). Braestrup *et al.* (5) report that the binding of the β-carbolines and, hence, their effects are mediated by the inhibitory neurotransmitter, γ-aminobutyric acid (GABA). The sensitivity of the binding of benzodiazepine receptor ligands to the presence of GABA has suggested an allosteric regulation of the GABA receptor by benzodiazepines (6). Recent models for this mechanism propose a multiconformation receptor; the different conformations are induced by the binding of ligands of different biological effect (6, 7).

These observations indicate the importance of the β-carbolines in the development of an understanding of the benzodiazepine receptor. The shapes and receptor binding characteristics of these molecules play an integral role in the biological response that they produce. The methyl ester has the highest affinity for the receptor of any of the β-carbolines that have been structurally characterized. The X-ray structure determination of CCM is part of an ongoing study of the ligands for this receptor (8).[3]

[3]As this paper was being reviewed, a communication of this structure appeared; see ref. 29.

Experimental

A sample of CCM was provided by Drs. R. Coutts and R. Micetish of the Faculty of Pharmacy, University of Alberta. CCM was recrystallized from a 3:1 ethanol–water mixture. A colourless, rectangular crystal (0.20 × 0.20 × 0.25 mm) was cut from the end of a long needle and mounted along its axis for data collection on an Enraf–Nonius CAD4F automated diffractometer.

Crystal data

Monoclinic, systematic absences ($h0l$); $l = 2n + 1$ and ($0k0$); $k = 2n + 1$, space group $P2_1/c$, a = 11.4866(9), b = 5.8091(3), c = 32.417(3) Å, β = 97.111(3)°, V = 2146.4(3)Å^3, Z = 8, D_C = 1.400 g cm^{-3}, T = 20°C, CuK_α, Ni filter, λ = 1.5418 Å, ω/2θ scan, $D_w = 1.5(0.53 + 0.14 \tan\theta)$, θ_{max} = 70°, 4043 unique reflections collected, 3290 observed ($I \geq 2.5\sigma(I)$), μ = 4.07 cm^{-1}. Three intensity standards were measured every 1800 s and showed no deterioration. Lorentz and polarization corrections were applied. E values were calculated by applying K curve.

The structure was solved using MULTAN 78 (9); all non-hydrogen atoms in the two molecules in the asymmetric unit were identified in the first E synthesis. All calculations (other than MULTAN) were done using the XRAY 76 system of programs (10) implemented on a Honeywell computer. X-ray scattering factors were those of Cromer and Mann (11) except that the scattering factor of Stewart *et al.* (12) was used for the hydrogen atom. Hydrogen atom positions were located in difference Fourier syntheses. The least-squares refinement was blocked with the anisotropic thermal parameters for the nonhydrogen atoms, the isotropic thermal parameters of the hydrogen atoms, and the positional parameters of all atoms of one unique molecule in each block. The final R value is 0.049, $R_w = ((\Sigma w|F_o| - |F_C|)^2/\Sigma w(F_o)^2)^{1/2} = 0.069$, standard deviation of an observation of unit weight is 1.36, the average shift/error = 0.10, and the maximum shift/error = 0.82. The function minimized was $w(|F_o| - |F_C|)^2$ where the weight, w, is defined as $((\sigma(F_o))^2 + 0.0015F_o^2)^{-1}$. The 3700 reflections used in the refinement were the 3290 observed reflections and only those unobserved reflections (410 data) that had $F_C^2 > 2.5\sigma(I_o)$. An isotropic extinction correction was applied (13) and refined to a value of $g = 21.9(6) \times 10^{-3}$. The peaks in the final difference Fourier synthesis had maximum/minimum values of +/− 0.33 e Å^{-3} and were associated with the C(10)—C(11) bond.

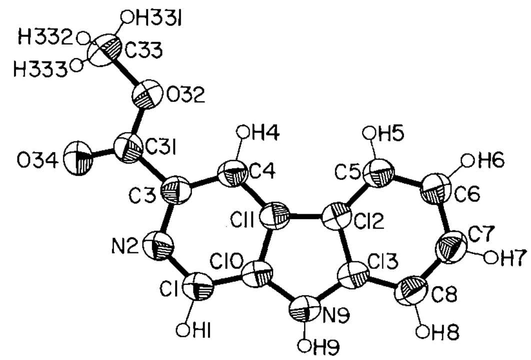

FIG. 1. The molecular conformation and the atomic labeling scheme for one of the two unique molecules of CCM. The conformation of the other unique molecule is nearly identical and the atom labels are distinguished by primes (′). The drawing was made with the program ORTEP (27).

The atomic coordinates are given in Table 1 with the atoms labeled as in Fig. 1.[4] The second molecule of the asymmetric unit is distinguished by a prime (′). The bond lengths and angles are shown in Table 2.

Discussion

The important features of this structure are the conformation of the ester side chain and the intermolecular interactions in the crystal environment. The side chain in each of the unique molecules has approximately the same orientation; the torsion angle, N(2)—C(3)—C(31)═O(34), is 3.2(1)° in one molecule and −5.3(2)° in the other. This orientation places the nitrogen atom of the pyridine fragment of the β-carboline and the carbonyl oxygen atom of the ester side chain in a *cis* configuration and is opposite to the side chain conformation observed in the carboxyamide derivative of β-carboline (8). In the carboxyamide case, all published examples of that side chain and a similar aromatic N atom were found in the *trans* configuration. Lawson *et al.* (14) have determined through structure−activity studies of β-carbolines that, for high affinity, the C(3) substituent interacts with specific sites rather than through a general electrostatic interaction. Since the methyl ester derivative has a higher affinity for the benzodiazepine receptor (1.5−19 n*M* (15, 16)) than the carboxyamide derivative (250 n*M* (17)) and has a different configuration of the side chain, the relative populations of the possible orientations of the ester group are important to the determination of the position and number of specific sites.

The Cambridge Structural Database[5] was searched for examples of the ester side chain attached to a fragment similar to the β-carboline pyridine ring; three populations of side chain orientation were found. In the cases that had a bulky substituent on the carbon atom (C(4) in this numbering scheme) that is on the opposite side of the ester bearing atom (C(3)) from the nitrogen atom (N(2)), the torsion angles (N—C—C═O) were in the range 55−127°. There were 7 examples of this steric crowding. The *trans* configuration (torsion angles from 140−180°) was observed in 8 cases. Four of these cases came from two crystal

[4]The anisotropic thermal parameters, the observed and calculated structure factors, and the REFCODES for the Database search may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada, K1A 0S2.

[5]Tables of torsion angles, ref. codes, and references are available from the authors.

*The atoms of molecules A and B have the same number except that those of molecule B are primed (see Table 1).

structures of the pyrromethane moiety; in one case the *trans* form is stabilized by an intramolecular N—H···N hydrogen bond and in the other by ion pairing with a Br^- ion. Thus these four observations are not directly comparable to the fragment contained in CCM. The *cis* configuration (torsion angles from 1–43°) was observed 10 times; in only three cases were H bonds reported. In two of these cases a three-centre H-bond involving the two *cis* electronegative atoms could be observed; in the other case the N atom is protonated and forms a hydrogen bond with a Cl^- ion. In general, these structures had few H atom donors so that the effect of stable H-bond formation on the relative populations of the configurations could not be fully assessed.

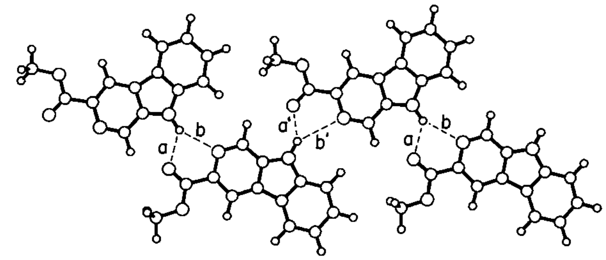

FIG. 2. A detail of the crystal packing of CCM showing the three-centre intermolecular hydrogen bonds. The labeled distances are a = 2.27(2), b = 2.54(2), a' = 2.04(2), and b' = 2.91(2) Å. The drawing was made with the computer program PLUTO (28).

The data base searches on the carboxyamide (8) and ester side chains of fragments similar to the β-carboline moiety indicate that the conformation of the side chain is dictated by π interactions that keep the side chain coplanar with the ring and by interactions with the aromatic nitrogen atom. These forces can be overcome by steric effects if there are substituents vicinal to the side chain and opposite the nitrogen atom. Bulky side chains in this position cause the rotation of the ester fragment to a position ca. 55° out of the plane.

Intermolecular contacts observed in crystals have been used as models for the types of interactions in receptor–ligand interactions (18, 19). The crystalline environment in this structure has a three-centre intermolecular hydrogen bond (see Fig. 2) formed by the interaction between the *cis* configuration of the aromatic nitrogen atom and carbonyl oxygen atom as the acceptors and the amine nitrogen atom, N(9), as the donor. The parameters describing these bonds are given in Table 3. The hydrogen-bonding distances are slightly different in the two unique interactions; the differences arise from a slip of one molecule past the other in the hydrogen-bonding plane. The distance between the two N atoms involved in the three-centre bonds is greater than the sum of the van der Waals radii for these atoms. Hamilton and Ibers (20) have noted that such a discrepancy occurs in weak hydrogen bonds and have stated that a more restrictive criterion is the separation between the H atom and the acceptor atom. To apply this criterion involving the position of the H atom, the systematic errors in X-ray determinations of bond distances involving hydrogen have to be overcome. The simplest method (21) for correcting for this error is to "normalize" the hydrogen atom position by moving the H atom along the N—H line to the average neutron-determined distance, which for N—H is 1.03 Å (22). This correction was applied; the "normalized" parameters for the hydrogen bonds are given in Table 3. All but one of the "normalized" H atom to acceptor atom distances meet the restrictive criterion of Hamilton and Ibers. The H(9)···N(2) separation is 0.2 Å longer than the sum of the van der Waals radii for the atoms; even so, this contact is still a close one and can be considered to be weakly attractive. Thus, each of the unique molecules acts as both a donor and an acceptor for these three-centre bonds.

Three-centre hydrogen bonds including the N—H···O=C functionality have been the subject of a recent analysis (22). Of 1509 hydrogen bonds with this functionality, 304 were defined as three-centre bonds. It was found that the nonbonded re-

TABLE 3. Intramolecular hydrogen bond distances and angles. The values in square brackets were obtained after the N—H distances were normalized following ref. 22

Atoms	D···A in Å	D—H in Å	H···A in Å	∠D—H···A in °
N(9)′—H(9)′···O(34)	2.819(4)	0.86(2) [1.03]	2.04(2) [1.91]	150(2) [146]
N(9)′—H(9)′···N(2)	3.637(5)	0.86(2) [1.03]	2.91(2) [2.75]	144(2) [144]
N(9)—H(9)···O(34)′	2.919(4)	0.85(2) [1.03]	2.27(2) [2.14]	134(2) [131]
N(9)—H(9)···N(2)′	3.317(3)	0.85(2) [1.03]	2.54(2) [2.38]	154(2) [151]

pulsion between the two acceptor atoms caused the hydrogen bonds to deviate considerably from linearity and made short H···O distances unfavorable. The parameters for the hydrogen bonds found in the crystal lattice of CCM are in agreement with these conclusions. In addition to the hydrogen bonds found in CCM, two examples of three-centre bonding were found in the specific Database search mentioned above. The first example has a water molecule as the donor of the shared hydrogen atom; this hydrogen bond determines the conformation of the ethyl side chain in the thiazole (23). The second example has an intramolecular three-centre bond wherein the nitrogen atom nearest the ester linkage is protonated and donates to both the carbonyl oxygen atom and a morpholino nitrogen atom (24). Together, these findings suggest that the three-centre bond is stable and can be a part of the chemistry of this molecular fragment.

Theoretical calculations (25) of the low energy conformations of the side chains in β-carbolines confirm the crystallographic observation of two equivalent conformations for the ester side chain (*cis* and *trans*) and one low energy conformation for the carboxyamide side chain (*trans*). In these calculations, the binding sites for the side chains were modeled with cationic sites on the receptor. A single cationic site would bind to the *cis* conformer of the ester side chain and another active derivative with a cyano side chain, but would not bind to the *trans* conformer of the ester or to the carboxyamide, which only exists in the *trans* conformation. Thus a single site is consistent with the high affinity of the ester and the cyano derivatives and the low affinity of the carboxyamide compound. The three-centre hydrogen bond observed in this crystal structure exemplifies the type of interaction possible with such a cationic site.

In addition, the consistent participation of the amine nitrogen atom, N(9), in hydrogen bonds in the crystal structures of β-carbolines (ref. 8 and this work) and in the naturally occurring harmaline (26) is indicative of the acidity of this atom and suggests that this interaction is also part of the receptor binding features of β-carbolines.

In summary, the crystal structures of β-carboline ligands of the benzodiazepine receptor (refs. 8, 26, and this work) have identified some possible features of their receptor site interactions. These include the formation of a three-centre hydrogen bond involving a *cis* conformation of the side chain and the participation of the acidic nitrogen atom, N(9), in a separate hydrogen bond.

Synthesis and equilibration of conformationally rigid *cis* and *trans* tricyclic mono and dithioacetals. An evaluation of stereoelectronic (anomeric) effects in thioacetals[1]

PIERRE DESLONGCHAMPS AND DANIEL GUAY[2]

Laboratoire de synthèse organique, Département de Chimie, Faculté des Sciences, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received December 10, 1984

PIERRE DESLONGCHAMPS and DANIEL GUAY. Can. J. Chem. **63**, 2757 (1985).

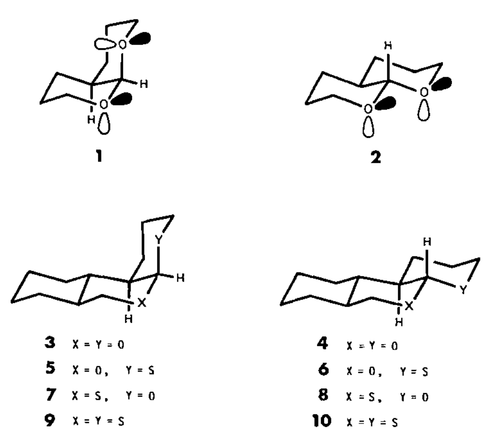
The synthesis of *cis* and *trans* tricyclic monothioacetals **5–8** and dithioacetals **9** and **10** is reported (Schemes 1 and 2). The *cis* isomers **5**, **7**, and **9** are the kinetic products of cyclization, a result which is explained on the basis of stereoelectronic principles. Equilibration studies (Table 1) led to an evaluation of the anomeric effect for sulfur; it was found to be of the same order as that for oxygen.

PIERRE DESLONGCHAMPS et DANIEL GUAY. Can. J. Chem. **63**, 2757 (1985).

La synthèse des monothioacétals **5–8** et dithioacétals tricycliques **9** et **10** est décrite (Schémas 1 et 2). Les produits cinétiques de cyclisation sont les isomères *cis* **5**, **7** et **9** tel que prédit par les principes du contrôle stéréoélectronique. Des études d'équilibration ont permis d'évaluer que l'effet anomère du soufre est du même ordre de grandeur que celui de l'oxygène.

The acetal function can take six different *gauche* conformations (3) and the relative stability of these conformers depends on stereoelectronic (anomeric (4) and *exo*-anomeric (5)) effects and standard steric interactions (1). A valuable experimental method for the determination of the relative stability of these conformers and for the evaluation of stereoelectronic effects is to construct and equilibrate stereochemical isomers which exist in different but rigid conformations.

Using this approach, Descotes *et al.* (6) carried out the acid equilibration of *cis* and *trans* bicyclic acetals **1** and **2** (Scheme 1) at 80°C and found, at equilibrium, a mixture of 57% *cis* and 43% *trans*. Since the *cis* isomer **1** has one anomeric effect (i.e., one oxygen electron pair antiperiplanar to a C—O bond) and the *trans* isomer has none, and taking into consideration steric[3] and entropic[4] factors, these authors arrived at a value of 1.4 kcal/mol for the anomeric effect in structure



1 **2**

3 X = Y = O
5 X = O, Y = S
7 X = S, Y = O

1. More recently, the equilibration of conformationally rigid *cis* and *trans* tricyclic acetals **3** and **4** was reported by our laboratory (7). The *cis* isomer **3** was found less stable (45% at equilibrium) than the *trans* isomer **4** by 0.14 kcal/mol. As a result, after taking into consideration the steric interaction of the *cis* isomer **3** (the same as in **1**, 1.65 kcal/mol),[3] the anomeric effect in structure **3** was estimated to be 1.5 kcal/mol, confirming the value of Descotes.

We wish now to report the synthesis and the acid equilibration of three pairs of *cis* and *trans* tricyclic thioacetals, namely, monothioacetals **5** and **6**, monothioacetals **7** and **8**, and dithioacetals **9** and **10**. Analysis of these results allows an evaluation of the anomeric effects of the sulfur and the oxygen atoms in the mono and the dithioacetal functions.[5]

Synthesis and equilibration studies

The syntheses of *cis* and *trans* tricyclic monothioacetals **5**, **6**, **7**, **8** and dithioacetals **9** and **10** are summarized in Scheme 2. The known bicyclic allyl lactone **12** was prepared from

[1]For general leading references on this subject, see pp. 21–26 in ref. 1 and pp. 23–26 in ref. 2.

[2]N.S.E.R.C.C. (Ottawa) and F.C.A.C. (Quebec) predoctoral fellowships 1982–1985.

[3]*Cis* isomer **1** is sterically less stable than *trans* isomer **2** by ~1.65 kcal/mol: one *gauche* form of *n*-butane, 0.85 kcal/mol and an oxygen axial to cyclohexane, 0.8 kcal/mol.

[4]Isomer **1** is a *cis* decalin which is conformationally mobile; on that basis, isomer **1** is more stable than the conformationally rigid *trans* isomer **2** by 0.42 kcal/mol at 80°C.

[5]The 1,7-dioxaspiro[5.5]undecane system and the corresponding sulfur analogs have also been extensively studied. This spiro system can theoretically take three different conformations having respectively two, one, and zero anomeric effects. This work has led to an evaluation of the anomeric and *exo*-anomeric effects in ketals, and in mono and dithioketals (8). For previous studies on 2-substituted thianes, see refs. 9 and 10.

bicyclic lactone **11** following a published procedure (7), and converted into thioacetate bicyclic lactone **13** in 91% yield via the addition of thioacetic acid (11). Reduction of **13** with diisobutylaluminium hydride (DIBAH) gave the intermediate thiol hemiacetal **14**, which on treatment with benzene containing a catalytic amount of *p*-toluenesulfonic acid (PTSA) gave a 9:1 crystalline mixture of *cis* and *trans* tricyclic monothioacetals **5** and **6** in 80% yield. A *trans* enriched mixture (ratio 85:15) was obtained after equilibration and chromatography. The complete separation of the *cis* and the *trans* isomers was not successful.

Reaction of bicyclic lactone **11** with trimethylsilyl iodide (12) gave iodo carboxylic acid **15** (97% yield), which was then converted into iodo acid chloride **16** by reaction with oxalyl chloride. The iodo acid chloride **16** was then transformed into bicyclic thiolactone **17** (87% yield) by reaction with hydrogen sulfide in dichloromethane in the presence of triethylamine. Alkylation (13) of bicyclic thiolactone **17** (LDA, THF–HMPA, −78°C) with allyl bromide gave pure allyl bicyclic thiolactone **18** in 85% yield after chromatography. Reduction of allyl bicyclic thiolactone **18** with DIBAH followed by a reflux in benzene containing PTSA gave pure allyl bicyclic thioenolether **19** in 87% yield after chromatography. Selective hydroboration–oxidation (14) (Me_2S/BH_3, cyclohexene, THF; H_2O_2, NaOH) of the terminal olefin of **19** yielded hydroxy bicyclic thioenolether **20** (82% yield), which on treatment with a mixture of benzene, methanol, trimethyl orthoformate, and PTSA at room temperature gave a 85:15 mixture of *cis* and *trans* tricyclic thioacetals **7** and **8** (88% yield). Both isomers could be obtained pure by chromatography.

Addition of thioacetic acid (11) on allyl bicyclic thiolactone **18** gave thioacetate bicyclic thiolactone **21** in 95% yield. Reduction of **21** with DIBAH followed by a reflux with PTSA in benzene gave a 95:5 mixture of *cis* and *trans* tricyclic thioacetals **9** and **10** in 93% yield. Both isomers could be separated by chromatography.

Equilibration of an 85:15 mixture of *cis* and *trans* tricyclic monothioacetals **5** and **6** (benzene, PTSA catalytic, reflux, 6 h) gave a *cis*/*trans* ratio of 47:53. Equilibration of an 88:12 mixture of *cis* and *trans* tricyclic monothioacetals **7** and **8** (methanol, benzene, trimethylorthoformate, PTSA (1 mol-equiv.), reflux, >2.5 h) gave a *cis*/*trans* ratio of 57:43. Finally, equilibration of a 95:5 mixture of *cis* and *trans* tricyclic dithioacetals **9** and **10** (PTSA (1 mol-equiv.), benzene, ≥3 days) produced a *cis*/*trans* ratio of 62:38.[6]

The following observations were also made. When the cyclization of thiol hemiacetal **14** was carried out under milder acid conditions and for a shorter time, the reaction was not completed (30–50%) but a 97:3 mixture of *cis* and *trans* tricyclic monothioacetals **5** and **6** was produced. When the cyclization reaction of **20** was quenched prior to completion, a 98:2 mixture of *cis* and *trans* tricyclic monothio acetals **7** and **8** was formed. Taking these results along with the equilibration studies just described, it appears clear that the kinetic products of the cyclization of **14**, **20**, and **22** are the *cis* isomers **5**, **7**, and **9**, respectively.

The stereochemical assignment of *cis* and *trans* tricyclic compounds **5**–**10** was made by 250-MHz nmr spectroscopy and by comparison with spectral data obtained from the *cis* and

[6]Formation of secondary products (≤20% by weight) was observed in the course of these equilibration experiments, especially under the vigorous acidic conditions.

trans bicyclic and tricyclic acetals **1**–**4**. In the *cis* series, the anomeric hydrogen appears either as a broad singlet or as a doublet ($J \cong 3$ Hz) whereas in the *trans* series, the same hydrogen shows a doublet ($J \cong 9.5$ Hz).

Discussion

The preferential formation of the *cis* tricyclic acetal **3** over the *trans* isomer **4** under kinetically controlled conditions was previously reported (7) and this selectivity was explained by a combination of steric and stereoelectronic effects which control the formation of a cyclic acetal. The preferential formation of the *cis* isomers **5**, **7**, and **9** that is similarly observed can be explained on the same basis. Indeed, between the two processes **23** → **24** and **23** → **25** → **26** (X = O or S, Y = OH or SH), which lead respectively to the *cis* and the *trans* isomer (Scheme 3), the former process, which takes place via a chair intermediate (**24**), is favored energetically over the latter, which can only occur via an intermediate having a boat conformation (**25**) because of stereoelectronic reasons. Consequently, these results demonstrate that in the cyclization of **23**, stereoelectronic effects are operative when the incoming nucleophile is either an OH or an SH group, and more interestingly, even when the heteroatom of ring B is a sulfur atom.

The equilibration study of *cis* and *trans* isomeric compounds **3**–**10** is summarized in Table 1. It can be seen that there is a small increase of the *cis* isomer when ring C contains a sulfur atom. This study also shows that the proportion of the *cis* isomer is higher when the ring B heteroatom is sulfur rather than oxygen.

The *cis* isomeric series (cf. **24**) possesses one electron pair on atom X, which is antiperiplanar to the polar C—Y bond. Such a situation is not found in the *trans* series (cf. **26**); as a result, the *cis* series should be stabilized by one anomeric effect, in contrast to the *trans* series. On the other hand, the *trans* series, by comparison with the *cis* series, is free from steric interactions. Since the difference in energy between the *cis* and the *trans* series can be established experimentally by equilibration, the stereoelectronic effects found in the *cis* series can be estimated correctly provided that the steric effects of the *cis* isomers are properly evaluated.

The *cis* isomeric series (cf. **24**) contains one *gauche* form of butane (C4—C5—C6—C7) and the two *gauche* forms of segments Y—C1—X—C13 and Y—C1—C6—C7. The *gauche* steric interactions of S—CH_2—CH_2—CH_2 and O—CH_2—CH_2—CH_2 segments can be estimated to be about 0.4 kcal/mol on the basis that steric effects due to an axial OR (15) or SR (16, 17) group in cyclohexane are approximately the same (~0.8 kcal/mol). If the assumption is made that the steric interactions of the *gauche* segment Y—C1—X—C13 will be approximately the same as those of Y—C1—C6—C7, i.e. they are of the same order (~0.4 kcal/mol), the anomeric effect for the oxygen atom of ring B in the *cis* isomer **5** must correspond to a value of 1.6 kcal/mol, whereas that for the sulfur atom in the *cis* isomers **7** and **9** must correspond to 1.8 and 2.0 kcal/mol respectively.

The first conclusion which can be reached from this analysis is that the anomeric effect of the sulfur atom is of the same order as that for the oxygen atom (Table 1). A similar conclusion was reached in our study of mono and dithio spiroketals (8–10).[5]

A second conclusion which may be reached from this analysis is that the anomeric effect of the sulfur atom in ring B would be larger than that for an oxygen, and that this stereoelectronic effect would be even larger when ring C contains a sulfur atom. We think, however, that this a priori unexpected conclusion[7] is very likely incorrect because the value taken for the steric interactions must be smaller when the heteroatom is sulfur (18–20). Indeed, with a sulfur atom, the C—X and the C—Y bonds are longer and this should lead to fewer steric interactions and, if smaller values are taken for the steric effects, the value for the anomeric effect will be diminished accordingly.[8]

It is also interesting to mention that the equilibration of the *cis* and *trans* isomers **5** and **6** requires only a catalytic amount of PTSA, whereas that of the other two series (**7**, **8**, and **9**, **10**) requires one mol of PTSA per mol of thioacetal. Furthermore, the equilibration of isomers **9** and **10** is much slower (>24 h) than that of **7** and **8** (a few hours). This order of ease of reaction (**5**, **6** > **7**, **8** > **9**, **10**) might be a reflexion of two distinct effects. First, the double bond in intermediate **23** might be more readily formed when X is an oxygen atom (22). Second, and less important, is the fact that sulfur is harder to protonate than oxygen (23). Further experimentation is, however, necessary to ascertain the rationalization of these observations.

Conclusion

The *cis* tricyclic monothio and dithioacetals **5**, **7**, and **9** are the kinetic products of cyclization and these results can be readily explained on the basis of the stereoelectronic theory. Equilibration studies carried out on the *cis* and *trans* monothio and dithioacetals **5–10** lead to an evaluation of the anomeric effect. The value obtained is of the same order of magnitude for the oxygen and the sulfur atoms (~1.5 kcal/mol). A more precise conclusion cannot be reached because of the uncertainty in the evaluation of the steric interactions.

Experimental

All reactions were conducted under an argon atmosphere. Triethylamine, methylene chloride, and benzene were distilled over calcium hydride whereas ether and tetrahydrofuran were dried by distilling over sodium benzophenone. Melting points were determined on a Büchi M-50 apparatus, and are uncorrected. Infrared (ir) spectra were taken on a Perkin–Elmer 681 spectrophotometer. Proton nuclear magnetic resonance spectra (^{1}H nmr) were recorded on a Bruker WP-60 and a Bruker WM-250 instrument. Carbon nuclear magnetic resonance spectra (^{13}C nmr) were recorded on a Bruker WM-250 instrument. Mass spectral assays and peak matching were obtained using a VG Micromass ZAB-1F spectrometer. Vapor phase chromatographic (vpc) analysis was carried out on a Hewlett–Packard 5710A gas chromatograph with a flame ionization detector (capillary column OV-101, 25 meter). For flash chromatography, Merck Kiesel gel 60 (230–400 mesh A.S.T.M.) was used.

Thioacetate bicyclic lactone 13

Allyl bicyclic lactone **12** (503 mg, 2.59 mmol) was dissolved in cyclohexane. Thiolacetic acid (5.2 mmol) was added, followed by some azobisisobutyronitrile, and the solution heated to reflux. After 30 min, the solution was cooled, diluted with ether (10 mL), and washed with saturated aqueous sodium bicarbonate (2 × 20 mL) and with brine (10 mL). The organic phase was dried over magnesium sulfate, filtered, and concentrated *in vacuo*. Flash chromatography of the crude product (35% ethyl acetate in hexane) afforded pure thioacetate lactone **13** (637 mg, 91%). An analytical sample was prepared by recrystallization from ether–pentane; mp 40–41°C; ir ($CHCl_3$): 1720, 1685, and 1170 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 0.9–2.0 (14H), 2.17 (1H, multiplet, —CH—CO), 2.32 (3H, singlet, CH_3COS), 2.87 (2H, triplet, J = 7.1 Hz, CH_2S—), 3.85 and 4.22 (2H, AB part of an ABX system, J_{AB} = 10.9 Hz, J_{AX} = 4.4 Hz, J_{BX} = 11.1 Hz, CH_2O); ms *m/e* (70 eV): 270 (M^+). *Exact Mass* calcd.: 270.1289; found: 270.1281.

Cis *and* trans *tricyclic thioacetals 5 and 6*

To a cooled (−78°C) solution of thioacetate lactone **13** (600 mg, 2.2 mmol) in dichloromethane (20 mL) was slowly added diisobutylaluminium hydride (4.6 mmol, 1 *M* in hexane). After stirring $2\frac{1}{2}$ h at −78°C, the reaction was quenched with saturated sodium sulfate (10 mL) and dilute sulfuric acid (5%, 5 mL). The aqueous layer was decanted and extracted with dichloromethane (3 × 20 mL). The combined organic extracts were dried over magnesium sulfate, concentrated, and filtered through a pad of silica. Evaporation gave an oil (515 mg), which was dissolved in benzene (25 mL). A catalytic amount of *p*-toluenesulfonic acid monohydrate was added and the solution was refluxed with azeotropic removal of water for 1 h. Methylene chloride (15 mL) was added and the solution was washed with saturated sodium bicarbonate (5 mL). The organic phase was dried ($MgSO_4$) and evaporation of the solvents gave crude acetals (457 mg). Flash chromatography (7% ethyl acetate in hexane) afforded tricyclic thioacetals **5** and **6** (380 mg, 80%) as a mixture of *cis* and *trans* (≈9:1) isomers inseparable by chromatography. When the cyclization was conducted under milder conditions (50–60°C, trace of acid, 30 min) lower yields (30–50%) of *cis* tricyclic thioacetals could be obtained, containing only a trace (≈3%) of the *trans* isomer. On one occasion, when an equilibrated mixture (≈1:1) of isomers was chromatographed (preparative tlc, twice) a *trans* enriched mixture (≈85:15) was obtained.

Cis *tricyclic thioacetal 5*: mp (9:1): 54–55°C; ir (9:1, $CHCl_3$): 1145, 1105, and 1080 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 0.8–2.2 (15H), 3.7 (2H, multiplet, CH_2S), 3.51 and 3.63 (2H, AB part of an ABX

[7]Recent *ab initio* calculation (STO-3G) on thiomethanol, methanedithiol, and methanediol suggests that there is a relative decrease in the anomeric effect on changing from oxygen to sulfur (21).

[8]Sources of steric energy other than the *gauche* interactions have also been neglected in our study because they are not available. More precise information on these effects is necessary to evaluate further the importance of the anomeric effect in mono and dithioacetals. Since compounds **5**, **6**, **8–10** are crystalline, X-ray structures and molecular modeling could be used to evaluate further those effects which would lead to a more precise evaluation of the anomeric effect for these compounds.

system, J_{AB} = J_{AX} = 11.1 Hz, J_{BX} = 4.6 Hz, CH_2O), 5.28 (1H, doublet, J = 3.6 Hz, O—CH—S); ^{13}C nmr ($CDCl_3$) δ: 80.6, 67.4, 42.1, 41.6, 35.1, 29.5, 27.8, 27.4, 26.5, 26.0, 25.4, 20.4; ms m/e (70 eV); 212 (M^+). *Exact Mass* calcd.: 212.1235; found: 212.1232. vpc, rt: 7.2 min (160°C).

Trans *tricyclic thioacetal* **6**: mp (4:1): 64.5–65.5°C; ir (4:1, $CHCl_3$): 1145, 1110, and 1080 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.8–2.15 (15H), 2.7 (2H, multiplet, CH_2S), 3.20 and 3.84 (2H, AB part of an ABX system, J_{AB} = 11.1 Hz, J_{AX} = 4.1 Hz, J_{BX} = 11.0 Hz, CH_2O), 4.26 (1H, doublet, J = 9.2 Hz, O—CH—S); ^{13}C nmr ($CDCl_3$) δ: 83.9, 74.0, 48.4, 45.6, 41.8, 29.8, 28.1 (2), 27.8, 27.5, 26.1, 25.4; ms m/e (70 eV): 212 (M^+). *Exact Mass* calcd.: 212.1235; found: 212.1232; vpc, rt: 7.7 min (160°C).

Equilibration of cis *and* trans *tricyclic thioacetals 5 and 6*

A mixture of *cis* and *trans* tricyclic thioacetals **5** and **6** (310 mg, 1.46 mmol, 85:15 *cis/trans*) was dissolved in benzene (25 mL) and a few crystals of *p*-toluenesulfonic acid were added. The solution was refluxed for 6 h. Concentration and dilution with hexane was followed by filtration through silica gel and solvent evaporation. Proton nmr spectroscopy and vpc analysis of the oily residue indicated a *cis/trans* ratio of 47:53. The equilibration was repeated with the product of the first equilibration and the *cis/trans* ratio found was 48:52, indicating thermodynamic populations.

Iodo acid 15

Iodotrimethylsilane (26 mmol) was added to a solution of bicyclic lactone **11** (3.84 g, 24.9 mmol) in methylene chloride (25 mL). The reaction mixture was stirred for 5 days at room temperature. Water (20 mL) was added, the organic layer decanted, and the aqueous phase extracted with methylene chloride (4 × 10 mL). The organic extracts were washed with aqueous sodium thiosulfate (10%, 20 mL), dried over sodium sulfate, and filtered. Evaporation of the solvents afforded crude iodo acid **15** (6.82 g, 97%), which was used without further purification; ^1H nmr ($CDCl_3$) δ: 0.9–1.9 (10H), 2.15 and 2.51 (2H, AB part of an ABX system, J_{AB} = 14.4 Hz, J_{AX} = 3.6 Hz, J_{BX} = 7.0 Hz, CH_2—COO), 3.3 (2H, multiplet, CH_2I), 10.6 (1H, br singlet, COOH).

Bicyclic thiolactone 17

Oxalyl chloride (33 mmol) was added to a solution of iodo acid **15** (2.33 g, 8.27 mmol) in benzene (30 mL) and the resulting mixture was stirred at room temperature for 1 day. Evaporation to dryness afforded the crude acid chloride **16**, which could be characterized (ir (CH_2Cl_2): 1795 cm^{-1}; nmr ($CDCl_3$) δ: 0.9–2.0 (10H), 2.77 and 3.10 (2H, CH_2COCl), 3.25 (2H, CH_2I)) but was best used directly for the next step. Dissolution of this acid chloride in methylene chloride (40 mL) was followed by hydrogen sulfide bubbling. Triethylamine (25 mmol) was immediately added while continuing bubbling for 5 min. Saturated ammonium chloride (40 mL) was added. The organic layer was decanted and the aqueous layer was extracted with methylene chloride (2 × 20 mL). The combined organic extracts were dried with magnesium sulfate. Filtration, concentration, and flash chromatography (10% acetone in hexane) of the residue gave pure bicyclic thiolactone **17** (1.22 g, 87%) as an oil; ir (CH_2Cl_2): 1660, 1110 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.95–1.9 (10H), 2.22 and 2.63 (2H, AB part of an ABX system, J_{AB} = 17.6 Hz, J_{AX} = 3.6 Hz, J_{BX} = 11.6 Hz, CH_2CO), 2.92 (2H, multiplet, CH_2S); ^{13}C nmr ($CDCl_3$) δ: 200.4, 48.7, 38.7, 38.5, 35.9, 33.8, 32.7, 25.8, 25.0; ms m/e (70 eV): 170 (M^+), 142 (M^+ – CO). *Exact Mass* calcd.: 170.0765; found: 170.0765.

Allyl bicyclic thiolactone 18

n-Butyllithium (7.8 mmol, 1.55 *M* in hexane) was added at −78°C to diisopropylamine (8.1 mmol). The resulting slurry was warmed to 0°C for 15 min. After cooling to −78°C, tetrahydrofuran (20 mL) was added, followed by bicyclic thiolactone **17** (1.26 g, 7.4 mmol) dissolved in tetrahydrofuran (10 mL). The solution was stirred $1\frac{1}{2}$ h before adding hexamethylphosphoramide (7.4 mmol) and allyl bromide (74 mmol) slowly via syringe. After 7 h at −78°C, the solution was stirred at −45°C for $1\frac{1}{2}$ h. Saturated ammonium chloride (5 mL) was added and the resulting mixture concentrated. Hexane (30 mL) and ether (15 mL) were added. The organic phase was washed with water (3 × 15 mL) and aqueous lithium chloride (14%, 15 mL), and the aqueous phases extracted with ether/hexane (1:5, 2 × 20 mL). The combined organic extracts were dried over magnesium sulfate, filtered, and evaporated *in vacuo*. Flash chromatography (10 to 20% ethyl acetate in hexane) gave pure allyl bicyclic thiolactone **18** (1.32 g, 85%) as an oil; ir (CH_2Cl_2): 1650 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.9–2.0 (12H), 2.25 (1H, multiplet, CH—CO), 2.76 and 2.94 (2H, AB part of an ABX system, J_{AB} = 12.4 Hz, J_{AX} = 11.0 Hz, J_{BX} = 3.4 Hz, CH_2S), 5.1 (2H, multiplet, CH_2=C), 5.7 (1H, multiplet, —CH=C); ^{13}C nmr ($CDCl_3$) δ: 203.0, 134.2, 117.6, 56.4, 41.8, 38.8, 35.2, 33.8, 33.4, 32.2, 25.4, 25.1; ms m/e (70 eV): 210 (M^+), 182 (M^+ – CO). *Exact Mass* calcd.: 210.1079; found: 210.1076.

Allyl bicyclic thioenolether 19

Diisobutylaluminium hydride (4.4 mmol, 1 *M* in cyclohexane) was slowly added to a cooled (−78°C) solution of allyl bicyclic thiolactone **18** (850 mg, 4 mmol) in methylene chloride (30 mL). The resulting mixture was stirred 2 h at −78°C before being quenched with hydrochloric acid (10 mL, 1 *N*). The organic layer was decanted, and the aqueous phase was saturated with ammonium chloride and extracted with 1:1 ether–hexane (3 × 20 mL). The organic extracts were dried with magnesium sulfate, filtered, and concentrated. The crude residue was taken into benzene (20 mL) and refluxed 2 h with *p*-toluenesulfonic acid (0.5 mol) for azeotropic removal of water. Then the solution was evaporated to dryness and the residue purified by flash chromatography (5% ethyl acetate in hexane) to give pure allyl bicyclic thioenolether **19** as an oil (684 mg, 87%); ir (CH_2Cl_2): 1640 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.8–2.2 (10H), 2.55 and 2.76 (4H, multiplets, CH_2S and =C—CH_2—C=), 5.03 (2H, multiplet, CH_2=C), 5.8 (1H, multiplet, CH=C), 5.75 (1H, broad singlet, =CH—S); ms m/e (70 eV): 194 (M^+). *Exact Mass* calcd.: 194.1129; found: 194.1131.

Hydroxy bicyclic thioenolether 20

Cyclohexene (11.3 mmol) was dissolved in ether (5 mL). The solution was cooled (−10°C) and borane/methyl sulfide complex (5.5 mmol) was added via syringe. On stirring 2 h at 0°C a white precipitate formed. The ether was partially removed by an argon stream, tetrahydrofuran (20 mL) was added, and the resulting solution cooled to −50°C. Allyl bicyclic thioenolether **19** (665 mg, 3.4 mmol) in tetrahydrofuran (5 mL) was added to the reaction mixture and the temperature was allowed to slowly (4 h) rise to 25°C. Aqueous sodium hydroxide (1 *N*, 31 mmol) and hydrogen peroxide (30%, 18 mmol) were added and the resulting mixture was vigorously stirred for 3 h. Hexane (30 mL) was added. The aqueous phase was acidified to pH 2 with dilute sulfuric acid and extracted with ether/hexane (1:1, 3 × 20 mL). The combined organic extracts were washed with brine (20 mL) and dried over magnesium sulfate, filtered, and evaporated. Flash chromatography (30% ethyl acetate in hexane) gave hydroxy bicyclic thioenolether **20** (590 mg, 82%) as an oil; ir (CH_2Cl_2): 3610, 3450, and 1060 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.9–2.3 (15H), 2.46 (1H, split doublet, J_{AB} = 12.3 Hz, J_{BX} = 2.2 Hz, J_W = 2.2 Hz, one hydrogen of CH_2S), 2.68 (1H, A part of an ABX system, J_{AB} = 12.3 Hz, J_{AX} = 11.3 Hz, the other hydrogen of CH_2S), 3.65 (2H, doublet of triplet, J = 2 Hz, J = 6.4 Hz, CH_2O), 5.75 (1H, singlet, =CH—S); ^{13}C nmr ($CDCl_3$) δ: 134.5, 112.6, 62.3, 42.2, 40.7, 34.5, 31.9, 31.4, 30.9, 29.6, 26.9, 26.3; ms m/e (70 eV): 212 (M^+). *Exact Mass* calcd.: 212.1235; found: 212.1240.

Cis *and* trans *tricyclic thioacetals 7 and 8*

Hydroxy bicyclic thioenolether **20** (190 mg, 0.9 mmol) was dissolved in a mixture of benzene (15 mL), methanol (0.5 mL), and trimethyl orthoformate (0.2 mL). Then, *p*-toluenesulfonic acid monohydrate (1.1 mmol) was added and the solution stirred 48 h at room temperature. Ether (10 mL) and saturated sodium bicarbonate (25 mL) were added. The aqueous phase was decanted and extracted with ether (20 mL). The organic extracts were dried over magnesium sulfate, filtered, and evaporated to give crude tricyclic thioacetals **7** and **8** (167 mg, 88%) as a mixture of *cis* and *trans* isomers (85:15, nmr and vpc analysis). The *cis* isomer was most conveniently obtained by flash chromatography (10% ethyl acetate in hexane) of a reaction mixture quenched before completion, since it is the kinetic product (*cis*/*trans* ratio ≃ 98:2). Pure *trans* isomer was obtained by flash chromatography (10% ethyl acetate in hexane) of an equilibrated mixture.

Cis *tricyclic thioacetal* **7**: ir ($CHCl_3$): 1035 and 1080 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.8–2.2 (16H), 2.75 (1H, A part of an ABX system, J_{AB} = 13.2 Hz, J_{AX} = 11.4 Hz, axial hydrogen of CH_2S), 3.59 (1H, B part of an AA'BB' system, J_{AB} = 12.0 Hz, $J_{A'B}$ = 11.5 Hz, $J_{BB'}$ = 2.6 Hz, axial hydrogen of CH_2O), 4.08 (1H, complex doublet, equatorial hydrogen of CH_2O), 4.38 (1H, br singlet, S—CH—O); ^{13}C nmr ($CDCl_3$) δ: 79.8, 70.6, 43.2, 43.0, 36.8, 33.9, 30.1, 29.3, 26.9, 26.3, 26.0, 20.1; ms *m*/*e* (70 eV): 212 (M^+). *Exact Mass* calcd.: 212.1235; found: 212.1240; vpc, rt: 9.1 min (T_1 = 140°C for 4 min, rate = 4°C/min, T_2 = 200°C).

Trans *tricyclic thioacetal* **8**: mp: 70.5–71.5°C; ir ($CHCl_3$): 1085 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.75–2.1 (15H), 2.43 and 2.52 (2H, AB part of an ABX system, J_{AB} = 13.6 Hz, J_{AX} = 10.5 Hz, J_{BX} = 3.9 Hz, CH_2S), 3.46 (1H, B part of an AA'BB' system, J_{AB} = 11.3 Hz, $J_{A'B}$ = 11.7 Hz, $J_{BB'}$ = 3.0 Hz, axial hydrogen of CH_2O), 4.03 (1H, complex doublet, equatorial hydrogen of CH_2O), 4.26 (1H, doublet, *J* = 9.2 Hz, S—CH—O); ^{13}C nmr ($CDCl_3$) δ: 83.9, 69.1, 48.3, 45.8, 43.4, 34.8, 33.6, 28.8, 27.1, 26.2, 26.0, 25.8; ms *m*/*e* (70 eV): 212 (M^+). *Exact Mass* calcd.: 212.1235; found: 212.1240; vpc, rt: 9.9 min (T_1 = 140°C for 4 min, rate = 4°C/min, T_2 = 200°C).

Equilibration of cis *and* trans *tricyclic thioacetals 7 and 8*

A mixture of *cis* and *trans* tricyclic thioacetals **7** and **8** (150 mg, 0.71 mmol, 88:12 *cis*/*trans*) was dissolved in benzene (10 mL) containing methanol (0.5 mL) and trimethyl orthoformate (0.2 mL). The *p*-toluenesulfonic acid monohydrate (0.8 mmol) was added and the solution refluxed 1 h. Ether (10 mL) was added and the solution washed with saturated sodium bicarbonate (2 × 5 mL). Extraction of the aqueous layer with ether (10 mL) was followed by magnesium sulfate drying of the organic extracts. Concentration gave crude tricyclic thioacetals **7** and **8** (145 mg, 96%). Proton nmr spectroscopy and vpc analysis indicated a *cis*/*trans* ratio of 74:26. Further equilibrations of this crude mixture under analogous conditions (~2 h, reflux) gave a ratio of 58:42. A third equilibration gave a *cis*/*trans* ratio of 57:43.

Thioacetate bicyclic thiolactone 21

Thiolacetic acid (3.8 mmol) was added to a solution of allyl bicyclic thiolactone **18** (397 mg, 1.9 mmol) in cyclohexane (15 mL) containing some azobiisobutyronitrile. The resulting mixture was refluxed 15 min, cooled, and diluted with ether (15 mL). The solution was washed with saturated sodium bicarbonate (2 × 25 mL) and brine (10 mL) before drying with magnesium sulfate. Filtration and evaporation, followed by flash chromatography (20%, ethyl acetate in hexane) of the residue, gave the oily thioacetate bicyclic thiolactone **21** (514 mg, 95%); ir (CH_2Cl_2): 1687, 1650, 1135, and 1110 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.9–2.05 (14H), 2.21 (1H, multiplet, CH—CO), 2.32 (3H, singlet, CH_3COS), 2.78 and 2.95 (2H, AB part of an ABX system, J_{AB} = 12.4 Hz, J_{AX} = 11.1 Hz, J_{BX} = 3.5 Hz, CH_2S of the ring), 2.85 (2H, triplet, *J* = 7.1 Hz, CH_2S of the side chain); ms *m*/*e* (70 eV): 286 (M^+), 244 (MH^+ − CH_3CO). *Exact Mass* calcd.: 286.1061; found: 286.1075.

Cis *and* trans *tricyclic dithioacetals 9 and 10*

Diisobutylaluminium hydride (3.9 mmol, 1 *M* in hexane) was slowly added to a cooled (−78°C) solution of thioacetate bicyclic thiolactone **21** (530 mg, 1.85 mmol) in methylene chloride (15 mL). After 2 h at −78°C, saturated sodium sulfate (10 mL) and dilute sulfuric acid (5%, 5 mL) were added, the organic layer decanted, and the aqueous phase was extracted with methylene chloride (3 × 20 mL). The combined organic extracts were dried over magnesium sulfate, filtered, and concentrated *in vacuo*. The oily residue was taken into benzene (20 mL). A few crystals of *p*-toluenesulfonic acid were added and the solution was refluxed 45 min with azeotropic removal of water. The resulting mixture was concentrated, diluted with methylene chloride (15 mL), and washed with saturated sodium bicarbonate (10 mL). Extraction of the aqueous phase with methylene chloride (2 × 20 mL) and magnesium sulfate drying of the organic extracts gave crude acetals. Filtration on silica gel afforded tricyclic dithioacetals **9** and **10** (393 mg, 93%) as a 95:5 *cis*/*trans* mixture of isomers (nmr and vpc analysis).

Both isomers could be separated by flash chromatography (8% ethyl acetate in hexane).

Cis *tricyclic dithioacetal* **9**: mp 125.5–127°C; ir ($CHCl_3$): 1100–1200 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.85–2.2 (16H), 2.58 and 2.86 (3H, multiplets, three hydrogens of the two CH_2S), 4.03 (1H, doublet, *J* = 2.7 Hz, S—CH—S); ^{13}C nmr ($CDCl_3$) δ: 45.4, 44.0, 43.6, 36.5, 33.9, 31.9, 30.7, 30.1, 28.8, 26.6, 26.1, 19.6; ms *m*/*e* (70 eV): 228 (M^+). *Exact Mass* calcd.: 228.1006; found: 228.1008; vpc, rt: 9.6 min (170°C).

Trans *tricyclic dithioacetal* **10**: mp 84–85°C; ir ($CHCl_3$): 1100–1200 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.8–2.25 (15H), 2.38 (1H, B part of an ABX system, J_{AB} = 13.3 Hz, = 3.2 Hz, equatorial hydrogen of CH_2S middle ring), 2.55 (2H, multiplet, other hydrogens of the two CH_2S), 2.79 (1H, A part of an AA'BB' system, $J_{AA'}$ = J_{AB} = 13 Hz, $J_{AB'}$ = 2.7 Hz, axial hydrogen of CH_2S outer ring), 3.74 (1H, doublet, *J* = 9.7 Hz, S—CH—S); ^{13}C nmr ($CDCl_3$) δ: 49.4, 48.0, 47.3, 44.0, 36.1, 34.4, 30.6, 29.7, 29.1, 28.3, 26.5, 25.8; ms *m*/*e* (70 eV): 228 (M^+). *Exact Mass* calcd.: 228.1006; found: 228.1008; vpc, rt: 10.9 min (170°C).

Equilibration of cis *and* trans *tricyclic dithioacetals 9 and 10*

A mixture of *cis* and *trans* tricyclic dithioacetals **9** and **10** (384 mg, 1.68 mmol, 95:5 *cis*/*trans*) was dissolved in benzene (25 mL) containing *p*-toluenesulfonic acid (1.5 mmol). The solution was refluxed 18 h and then cooled to room temperature. Ether was added (20 mL) and the solution was washed with saturated sodium bicarbonate (2 × 5 mL). The aqueous phases were extracted with ether (2 × 15 mL). The combined organic extracts were dried over magnesium sulfate, filtered, and concentrated *in vacuo*. The crude product (343 mg) was filtered through silica gel. Proton nmr spectroscopy and vpc analysis indicated a *cis*/*trans* ratio of 85:15. This crude mixture was equilibrated by refluxing 48 h with one equivalent of acid. The *cis*/*trans* ratio then obtained was 62:38. Further treatment with acid (1 equiv., 24 h) gave the same *cis*/*trans* ratio (62:38), thus determining thermodynamic populations.

The isomeric 5,6α- and 5,6β-epoxycholestanes, in addition to an analogous series of compounds substituted at C-3 with hydroxy (α or β stereochemistry) or ethylene ketal groups, have been treated with aluminum isopropoxide or *tert*-butoxide. The latter series of reactions did not give identifiable material, but aluminum isopropoxide gave products derived from epoxide opening and rearrangement in all cases. With epoxides unsubstituted at C-3, aluminum isopropoxide functioned as a Lewis acid in promoting epoxide rearrangements. In the presence of a C-3 alcohol function, additional products were obtained arising from fragmentation of the C-4,C-5 bond, or from β-elimination of the epoxide involving the loss of a C-7 hydrogen. Meerwein–Pondorff reduction of product carbonyl groups was also observed. C-3 ketal substituted epoxides were rearranged cleanly to 6-hydroxy-Δ^4-3-ketones. Cyclohexene oxide reacted with aluminum isopropoxide (but not with *tert*-butoxide) to give two products arising from epoxide addition reactions. Structures for these products are proposed based on their ^{13}C nmr spectra, and a possible route for their formation is presented. None of the epoxides examined in this study reacted with magnesium methoxide.

Herbert L. Holland et Saeed R. Khan. Can. J. Chem. **63**, 2763 (1985).

On a fait réagir les époxy-5,6α et -5,6β cholestanes ainsi qu'une série de composés analogues substitués en C-3 par un groupement hydroxyle (de stéréochimie α ou β) ou par un groupement éthylène cétal avec l'isopropylate ou le *tert*-butylate d'aluminium. Les réactions avec le *tert*-butylate ne donnent pas de produits identifiables; toutefois, lors des réactions avec l'isopropylate d'aluminium, on obtient dans tous les cas des produits qui résultent d'une ouverture de l'époxyde suivie d'une transposition. Dans les cas des époxydes qui ne sont pas substitués en C-3, l'isopropylate d'aluminium agit comme un acide de Lewis qui favorise les transpositions de l'époxyde. En présence d'une fonction alcool en C-3, on obtient des produits additionnels provenant soit d'une fragmentation de la liaison C-4, C-5 soit d'une élimination β de l'époxyde qui implique une perte d'hydrogène en C-7. On a également observé une réduction de Meerwein–Pondorff des groupements carbonyls. Les époxydes ayant un substituant cétal en position C-3 se transposent proprement en hydroxy-6 Δ^4 cétones-3. L'époxyde du cyclohexène réagit avec l'isopropylate d'aluminium (mais non avec le *tert*-butylate) pour donner des produits découlant de réactions d'addition sur l'époxyde. À partir des spectres de rmn du ^{13}C, on propose des structures pour ces produits et l'on propose une voie possible pour leur formation. Aucun des époxydes étudiés dans ce travail ne réagit avec le méthylate de magnésium.

[Traduit par le journal]

The stereochemical control of product formation inherent in the epoxide opening reaction has ensured place for the latter in modern asymmetric synthesis (e.g. ref. 1). The opening of epoxides by nucleophiles may be assisted by Lewis acids (2); the latter reagents alone catalyse epoxide rearrangements efficiently, a reaction which has been thoroughly studied in steroidal examples (3–6). Strong Brönsted bases react with epoxides by abstracting a β-hydrogen to produce allylic alcohols (ref. 7, and references therein).

We have now studied reactions of the latter type using a reagent, aluminum isopropoxide, in which Brönsted base capability is combined with a source of potential Lewis acid activation. This reaction has been used catalytically to carry out the β-elimination reaction on several terpene epoxides (8, 9). We have now examined the reactions under both catalytic and equimolar conditions between a series of steroidal 5,6-epoxides and aluminum isopropoxide or *tert*-butoxide, in addition to magnesium methoxide. The latter reagent has proven effective in certain intramolecular fragmentations of steroidal epoxides (10).

The epoxides used in the present study, **1** and **2**, were prepared as previously outlined (7); their ^{13}C nmr spectra have been presented in an earlier publication (7). Magnesium methoxide was found not to react with the range of epoxides investigated. Reactions with aluminum alkoxides were performed in dry toluene, the choice of solvent being based on earlier studies (7, 8, 11): aluminum *tert*-butoxide gave complex, intractable reaction mixtures, and aluminum isopropoxide in catalytic amount did not promote reactions with

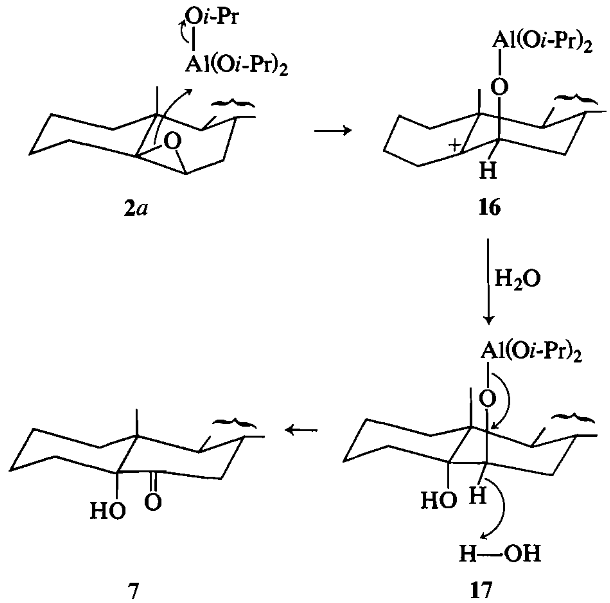
[c]In $CDCl_3$/DMSO-d_6 solvent.

any of the epoxides studied. However, the latter reagent in equimolar or greater ratios gave, with one exception (reaction with **2***c*), products which were readily separated and identified.

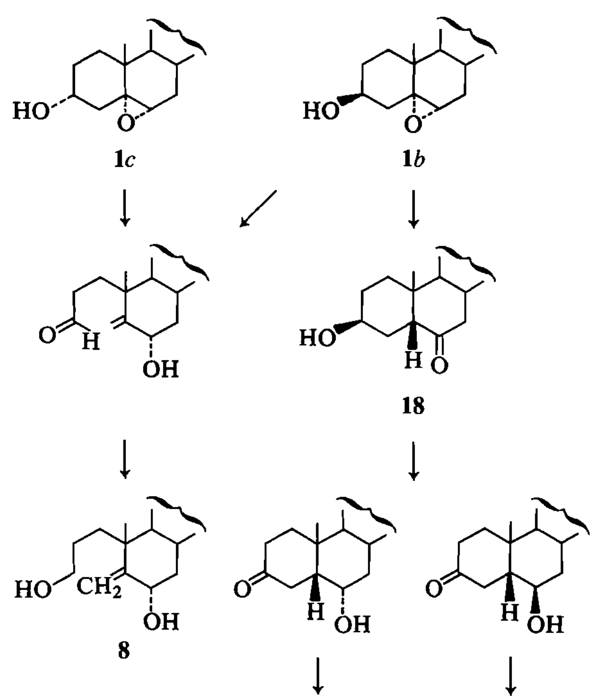
The results of the reactions with aluminum isopropoxide are summarized in Table 1. Product identification relied heavily on ^{13}C nmr spectral data, and assignments which are hitherto unreported are listed in Table 2. The unsubstituted epoxides **1***a* and **2***a* both gave mixtures of $\Delta^{3,5}$- and $\Delta^{4,6}$-cholestadienes (**3** and **4**), which could not be separated by the chromatographic means at our disposal. The olefins **3** and **4** may be formed via β-elimination of the epoxide from C-4 or C-7, followed by dehydration. Similar reactions have been reported to occur between terpene epoxides and aluminum isopropoxide (8, 11).

Also obtained from both **1***a* and **2***a* was the 5α,6β-diol **5**. This product was produced during the hydrolytic work-up of the reaction, evidenced by its absence during the monitoring of the progress of the reaction by tlc.

In addition, the α-epoxide **1***a* gave the 5β-6-ketone **6**, one of the products of Lewis acid catalysed rearrangement (3–6), and the β-epoxide **2***a* afforded the 5α-hydroxy-6-ketone (**7**). Formation of the latter product may be rationalized as outlined in Scheme 1. Coordination of the reagent to the epoxide **2***a* can lead to formation of the 5-cation **16**; the latter cannot rearrange by transfer of the C-6 hydrogen to C-5, as happens in Lewis acid catalysed rearrangements of 5,6α-epoxides (3–6) because of the location of the hydrogen orthogonal to the empty *p* orbital on C-5. A similar phenomenon leading to abnormal rearrangement products has been reported to control the



SCHEME 1. Conversion of 5,6β-epoxycholestane to 5α-hydroxycholestan-6-one by aluminum isopropoxide.

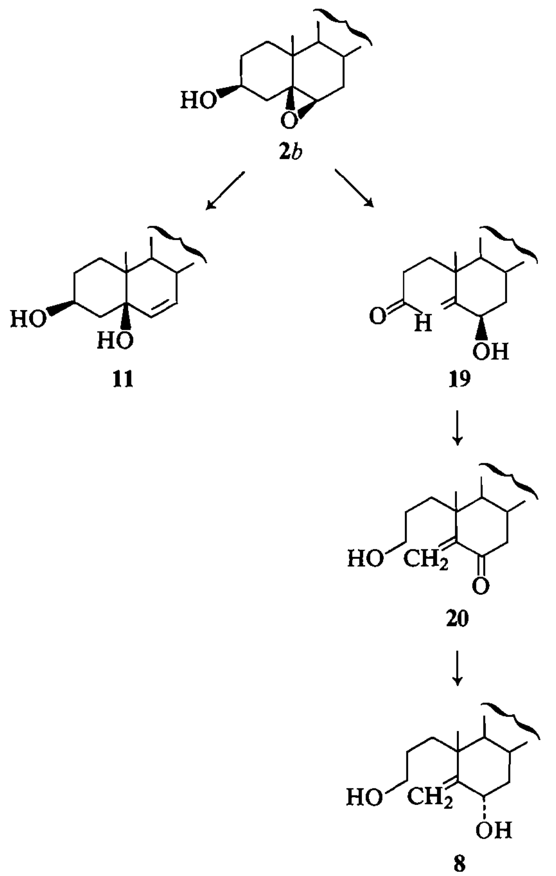


SCHEME 2. Reactions of 5,6α-epoxy-3-hydroxycholestanes with aluminum isopropoxide.

reactions of other 5,6β-epoxy cholestanes with BF_3 (12).

Capture of **16** by water (perhaps that produced by the dehydration reactions leading to **3** and **4**) can lead to **17**. The relief of strain afforded by the formation of the steroidal ketone may then lead to **7** by hydride transfer, a process analogous in mechanism to the Oppenauer oxidation. The nature of the hydride acceptor is not clear, but a possible candidate is water. The absence of **7** during the reaction (as monitored by tlc) supports its formation during the work-up.

The C-3 alcohol-substituted 5,6α-epoxides **1***b* and **1***c* both reacted with aluminum isopropoxide. The 3α-alcohol **1***c* gave

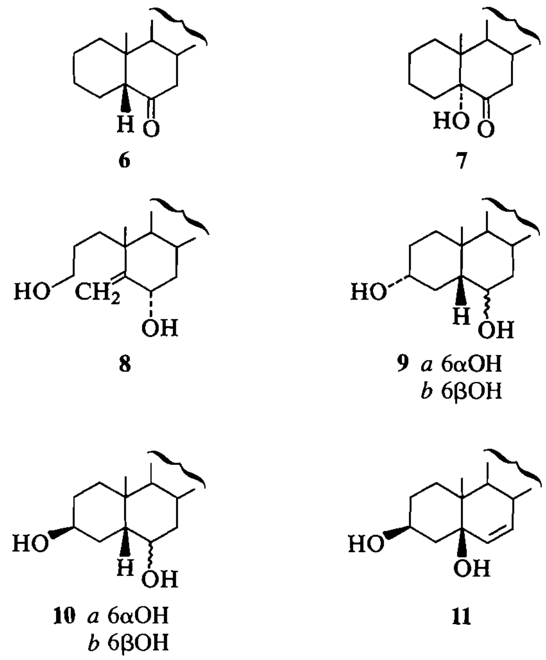


SCHEME 3. Reactions of 5,6β-epoxy-3β-hydroxycholestane with aluminum isopropoxide.

the seco-diol **8**, identified by ^{13}C nmr (Table 2) and other spectral data. The presence of the *exo*-methylene group and primary alcohol are clearly evident in the ^{13}C nmr spectrum, while the stereochemistry of substitution at C-6 follows from the resonance positions assigned to C-6 and C-8, the latter being characteristic of the stereochemistry of hydroxyl at C-6 (13). The formation of **8** is readily rationalized in terms of fragmentation followed by Meerwein–Pondorff reduction of the intermediate aldehyde (Scheme 2).

The reaction of the 3β-hydroxy-5,6α-epoxide **1***b* was complex. In addition to **8**, which can be produced as outlined above, all four isomers of 5β-cholestane-3,6-diol (**9** and **10**) were formed. These presumably arise via the 6-ketone **18** (Scheme 2) and its subsequent reduction at C-6, and oxidation and reduction at C-3. The redox reactions, the order of which is not necessarily implied in Scheme 2, may all be brought about by the metal alkoxide reagent. The structures of **9** and **10** follow from their ^{13}C nmr spectra (Table 2). Chemical shifts diagnostic of stereochemistry are those of C-19 (for 5β steroids), C-1 and C-5 (for C-3 alcohols), and C-4 and C-8 (for C-6 alcohols) (13). The ^1H nmr spectra of **9** and **10** (see Experimental), in particular the multiplicity of the signal assigned to the C-6 hydrogen, support the structural assignments.

The 5,6-epoxides **2***b* and **2***c* also reacted with aluminum isopropoxide. The C-3α alcohol epoxide **2***c* gave a complex intractable mixture: derivatives of this epoxide are prone to undergo intramolecular reactions (14), which may contribute to the complexity of the present reaction. The 3β isomer **2***b*, however, reacted cleanly to give two products. The minor product, **11**, was the result of base promoted epoxide opening



from C-7; this reaction parallels that observed with **2***b* in our earlier study (7). The major product was, surprisingly, **8**, identical with the secosteroid derived from the α epoxides **1***b* and **1***c*. This may be rationalized by the proposal of Scheme 3, in which the intermediate 6β-alcohol **19** must undergo reversible oxidation and reduction at C-6 together with reduction at C-3 (not necessarily in that order). The stereochemistry of substitution at C-6 in the product **8** appears to reflect a degree of product development control during the reaction unusual for the Meerwein–Pondorff reduction (15). However, the absence of the steric restraining influence of ring A and the presence of the sp_2 centre at C-5 in **20** contribute unknown steric influences in this particular case. The formation of **8** from **2***b* raises the possibility that undetected oxidation and reduction at C-6 may occur during the conversion of the 5,6α-epoxides **1***b* and **1***c* to **8**.

In parallel with our earlier results using LDEA as base (7), the ketal epoxides **1***d* and **2***d* react cleanly with aluminum isopropoxide to yield, following aqueous acid work-up, the corresponding Δ^4-3-keto-6-alcohols **12***a* and **12***b*. The stereochemical integrity at C-6 is maintained in these reactions as a consequence of the absence (until work-up) of a carbonyl or any other functionality in the reaction mixture capable of acting as a hydride acceptor and therefore providing the oxidizing equivalents necessary for alcohol–keto interconversion.

In view of the complexity of the reactions observed between the steroidal epoxides and aluminum isopropoxide, we decided to investigate reaction of the latter with the simple epoxide, cyclohexene oxide (**13**). Two products were isolated and identified by their spectral characteristics as isomers of a substituted dicyclohexyl ether. The ^1H nmr spectra clearly showed the presence of an isopropyl ether function and four additional protons geminal to oxygen; the ^{13}C nmr spectra confirmed these observations, and suggest the relative stereochemistry. The latter follows from a comparison of the ^{13}C nmr chemical shifts assigned to C-1, -2, -1′, and -2′ with those calculated for the possible isomeric series **14**, **15**, **21**, and **22** (Table 3).

The calculated values of Table 3 were arrived at as follows: a comparison of the spectra of isopropanol and di-isopropyl ether enable the spectrum of dicyclohexyl ether to be calculated

TABLE 3. ^{13}C nuclear magnetic resonance spectra of dicyclohexyl ethers **14**, **15**, **21**, and **22**

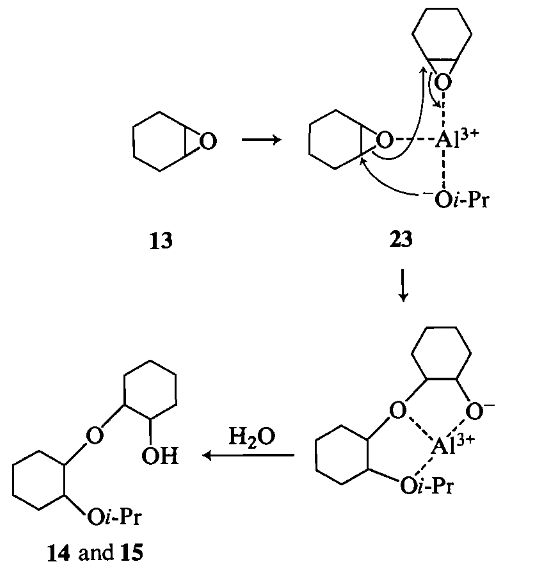
from that of cyclohexanol to be C-1, 75.2 ppm; C-2, 33.6 ppm. The shift parameters for axial and equatorial hydroxyl (ref. 13, and references therein) can then be applied to the calculated spectrum of dicyclohexyl ether to generate predicted spectra for diols corresponding to structures **14**, **15**, **21**, and **22**. The modification of these values by the parameters for the addition of one isopropyl ether (as above) then produces the values listed in the table.

It is clear from these values that the reaction products correspond most closely to the *trans,trans* structures **14** (major product) and the *cis,cis* structures **15** (minor product). In particular, the resonance at δ 72.5 ppm in the minor product can only belong to an axial hydroxyl-substituted carbon (possible structures **15** or **21**). The absence of a series of low field resonances such as those predicted (82.0 to 82.8 ppm) for **21** now suggests structures **15***a* or **15***b* for the reaction product. The ^{13}C nmr spectrum of the major product accords most closely with that predicted for structures **14** in which the two lowest field resonances are assigned to C-1 and C-1′. An alternative calculation of the chemical shifts for **14**, **15**, **21**, and **22**, using *cis* and *trans* cyclohexane-1,2-diols as the base structures, leads to predicted chemical shifts whose relative magnitudes are identical with those listed in Table 1.



SCHEME 4. Reaction of cyclohexene oxide with aluminum isopropoxide.

A possible route for the formation of **14** and **15** is given in Scheme 4. The formation of a *trans,trans* isomer **14** as major product from a complex such as **23** accords with the expectations of sterochemistry normally associated with epoxide openings. The alumina-catalysed alcohol addition to epoxides proceeds similarly with *trans* ring opening (16). The ratio of **14** to **15** was changed from 1.6:1 to 4:1 by carrying out the reaction with 15-fold reduction in the concentration of aluminum isopropoxide relative to that of cyclohexene oxide, suggesting that the formation of a *cis,cis* isomer **15** may be due, at least in part, to an intermolecular isopropoxide transfer as opposed to the intramolecular process illustrated in Scheme 4. Alternatively, compound **15** may arise from a single complex such as **23** in which Lewis acid catalysed carbon–oxygen bond cleavage of the epoxide precedes attack by the RO^- nucleophile to such an extent that the latter reaction becomes non-stereospecific.

In either event, it is not clear why only two of the eight possible diastereomeric products are formed. An analogous result has been reported for the dimerization of **13** by activated alumina, but without elaboration of the stereochemistry involved (17). One possibility is that as the intermediate complex **23** proceeds towards a transition state, the necessity of having the three oxygens coordinated simultaneously to a single metal ion selects two of the possible geometrical combinations as belonging to pathways of lower energy. The failure of any of the steroid epoxides studied herein to react in a similar way is readily explained by their relative bulk. The formation of a complex such as **23** from steroidal epoxides would be sterically difficult.

In conclusion, the reactions between the epoxides studied and aluminum isopropoxide encompass all the possibilities of Lewis acid catalysis base catalysed fragmentation, Meerwein–Pondorff oxidation/reduction, and nucleophilic epoxide opening. Selection of the desired activities from among this range should now be possible by choosing an appropriate aluminum based reagent.

Experimental

Apparatus, materials, and methods

Melting points were determined on a Kofler heating stage and are uncorrected. Infrared spectra were recorded with an Analect 6260FX Fourier transform ir spectrometer. Proton nmr spectra were recorded at 80 MHz with a Bruker WP80CW or at 250 MHz with a WM250 spectrometer (at McMaster University), and carbon nmr spectra on a Bruker WP60 (Brock), WM250 (McMaster), or WH400 instrument (Southwestern Ontario NMR centre, University of Guelph), using $CDCl_3$ as solvent (unless otherwise stated) and TMS as internal standard. Mass spectra were obtained with an AE1 MS30 spectrometer fitted with a Kratos DS-55 data system. Thin-layer chromatography was performed on Merck silica gel 60 F-254, and column chromatography on silica gel (230–400 mesh).

Elemental analyses were performed by Guelph Chemical Laboratories, Guelph, Ontario.

Preparation of epoxides

The epoxides used in this study were all prepared as outlined earlier (5) and characterized by spectral and physical properties.

Reactions with magnesium methoxide

Magnesium methoxide solution (3.3 mL, 0.4 *M* in methanol) was added to a solution of epoxide (100 mg) in dry toluene (25 mL) and the resulting mixture refluxed for 72 h, being monitored (tlc) daily for product formation. The mixture was then cooled, diluted with water (100 mL), and neutralized (dilute HCl) prior to extraction with ether. The ether extract was dried and evaporated, yielding only starting material.

Reactions with aluminum tert*-butoxide*

Reactions of epoxides (100 mg) in dry toluene (25 mL) with aluminum *tert*-butoxide (5 molar equivalents) were monitored by tlc during treatment under reflux. The development of streaking on the plate heralded the formation of intractable products, which was confirmed by work-up as outlined above.

Reactions with aluminum isopropoxide

*5,6α-Epoxycholestane (1*a*)*

The typical reaction procedure is described as follows. A solution of aluminum isopropoxide (freshly distilled, 1.35 g) in dry toluene (25 mL) was added by syringe to a stirred solution of 5,6α-epoxycholestane (0.5 g) in dry toluene (25 mL) under a nitrogen atmosphere. The resulting mixture was refluxed for 72 h, then cooled, added to dilute HCl (100 mL, 1 *M*), and extracted with ether. The organic extract was washed with water, dried over sodium sulphate, and evaporated. The residue was chromatographed using benzene to ether elution (10% step gradient) to give, in order of elution, a mixture of cholesta-3,5-diene (**3**) and cholesta-4,6-diene (**4**) (0.145 g), mp 78–80°C, identified by ^1H and ^{13}C nmr comparison with the spectra of the authentic separated isomers (10); cholestane-5α,6β-diol (**5**) (0.135 g), mp 121–124°C (lit. (18) mp 126–128°C); ^1H nmr included signals at δ 3.45 ppm (C-6α H); ^{13}C nmr, see Table 2; ms *m/z*: 386 (67), 371 (33), 368 (29), 353 (24) relative to 55 (100); and 5β-cholestane-6-one (**6**) (0.08 g), mp 128–130°C (lit. (3) mp 131–132°C); ^{13}C nmr spectrum identical with that reported (19).

*5,6α-Epoxycholestan-3β-ol (1*b*)*

Treatment of **1***b* (0.2 g) with aluminum isopropoxide (0.52 g) as described above gave 3,4-secocholest-4-ene-3,6α-diol (**8**) (0.06 g), mp 182–183°C; ^1H nmr included signals at δ 3.45–3.70 (2H, br s, C-3 H), 4.1–4.4 (1H, dd, *J* = 4, 12 Hz, C-6β H), and 4.76 and 5.08 (each 1H, br s, C-4 H's) ppm; ^{13}C nmr, see Table 2; ms *m/z*: 404 (0.5), 386 (6), 384 (2), 371 (5), 368 (5) relative to 55 (100). *Anal.* calcd. for $C_{27}H_{48}O_2$: C 80.14, H 11.95%; found: C 80.25, H 11.62%; 5β-cholestane-3β,6β-diol (**10***b*) (0.02 g), mp 195–197°C (lit. (20) mp 198–200°C (corrected)); ^1H nmr included signals at δ 3.4–3.75 (1H, br m, C-3α H) and 3.75 (1H, br s, $W_{1/2}$ = 5 Hz, C-6α H) ppm; ^{13}C nmr, see Table 2; 5β-cholestane-3α,6β-diol (**9***b*) (0.03 g), mp 148–150°C (lit. (21) mp 142–143.5°C), ^1H nmr included signals at δ 3.4–3.85 (1H, br m, C-3β H) and 3.75 (1H, br s, $W_{1/2}$ = 5 Hz, C-6α H) ppm; ^{13}C nmr, see Table 2; 5β-cholestane-3β,6α-diol (**10***a*) (0.016 g), mp 212–215°C; ^1H nmr included signals at δ 3.35–3.75 (1H, br m, C-3α H) and 4.10 (1H, br s, $W_{1/2}$ = 12 Hz, C-6β H); ^{13}C nmr, see Table 2. *Anal.* calcd. for $C_{27}H_{48}O_2$: C 80.14, H 11.95%; found: C 80.04, H 11.74%; and 5β-cholestane-3α,6α-diol (**9***a*) (0.024 g), mp 167–170°C; ^1H nmr included signals at δ 3.4–3.9 (1H, br m, C-3β H) and 3.95 and 4.08 (1H, dd, *J* = 4, 9 Hz, C-6β H) ppm; ^{13}C nmr, see Table 2. *Anal.* calcd. for $C_{27}H_{48}O_2$: C 80.14, H 11.95%; found: C 80.17, H 11.73%.

*5,6α-Epoxycholestan-3α-ol (1*c*)*

Treatment of **1***c* (0.15 g) with aluminum isopropoxide (0.5 g) as described above gave only 3,4-secocholest-4-ene-3,6α-diol (**8**) (0.05 g), identical in all respects with the sample described above.

*5,6α-Epoxycholestan-3-one, 3-cyclic ethylene ketal (1*d*)*

Treatment of **1***d* (0.1 g) with aluminum isopropoxide (0.24 g) as described above gave cholest-4-en-6α-ol-3-one (**12***a*) (0.055 g), mp 152–153°C, identical in all respects with an authentic sample of **12***a*.

*5,6β-Epoxycholestane (2*a*)*

Treatment of **2***a* (0.1 g) with aluminum isopropoxide (0.27 g) as described above and chromatography using benzene – ethyl acetate gave a mixture of cholesta-3,5-diene (**3**) and cholesta-4,6-diene (**4**) in equal amounts (total 0.028 g) identified as described above; cholestan-5α-ol-6-one (**7**) (0.035 g), mp 150–151°C (lit. (18) mp 150–150.5°C); ^{13}C nmr, see Table 2, ms *m/z*: 402 (60), 384 (35), 369 (19), 356 (11), 341 (10), 318 (48) relative to 55 (100); and cholestane-5α,6β-diol (**5**) (0.025 g), mp 122–124°C, identical in all respects with the sample described above.

*5,6β-Epoxycholestan-3β-ol (2*b*)*

Treatment of **2***b* (0.2 g) with aluminum isopropoxide (0.52 g) gave 3,5-secocholest-4-ene-3,6α-diol (**8**) (0.06 g), identical in all respects with the samples of **8** described above; and cholest-6-ene-3β,5β-diol (**11**) (0.025 g), mp 138–140°C (lit. (22) mp 139–140°C); ^1H nmr included signals at δ 3.8–4.2 (1H, br s, C-3α H) and 5.40 (2H, s, C-6 and -7 H's) ppm; ^{13}C nmr, see ref. 5.

*5,6β-Epoxycholestan-3α-ol (2*c*)*

Treatment of **2***d* (0.1 g) with aluminum isopropoxide (0.24 g) as described above gave only an intractable mixture of products.

*5,6β-Epoxycholestan-3-one, 3-cyclic ethylene ketal (2*d*)*

Treatment of **2***d* (0.1 g) with aluminum isopropoxide (0.24 g) as described above gave, following chromatography using benzene – ethyl acetate, cholest-4-en-6β-ol-3-one (**12***b*) (0.056 g), mp 194–196°C, identical in all respects with an authentic sample.

Cyclohexene oxide

Treatment of cyclohexene oxide (0.52 g) with aluminum isopropoxide (0.55 g) as described above gave *cis,cis*-2-oxypropyl-2′-hydroxydicyclohexyl ether (**14**) (0.296 g) as an oil; ^1H nmr included signals at δ 1.18 (d, *J* = 6 Hz, isopropyl methyls), 2.8–3.6 (3H, m, C-1, -1′, and -2′ H's), and 3.75 (1H, septet, *J* = 6 Hz, isopropyl CH) ppm; ^{13}C nmr, see Table 2; ms *m/z*: 238 (M – H_2O, 0.7), 196 (0.7), 175 (1), 99 (88), 81 (100). *Anal.* calcd. for $C_{15}H_{28}O_3$: C 70.27, H 11.01%; found: C 70.41, H 11.00%; and *trans,trans*-2-oxypropyl-2′-hydroxydicyclohexyl ether (**15**) (0.186 g) as an oil; ^1H nmr included signals at δ 1.20 (d, *J* = 6 Hz, isopropyl methyls), 3.0–3.6 (3H, m, C-1, -1′, and -2′ H's) and 3.80 (1H, septet, *J* = 6 Hz, isopropyl CH) ppm; ^{13}C nmr, see Table 2; ms *m/z*: 196 (1), 175 (2.5), 99 (85), 81 (100). *Anal.* calcd. for $C_{15}H_{28}O_3$: C 70.27, H 11.01%; found: C 70.40, H 11.04%. Repetition of the reaction with 0.11 g of aluminum isopropoxide afforded only **14** and **15** in the ratio 1.5:1; repetition with 0.04 g of aluminum isopropoxide gave a 4:1 ratio of **14** to **15**.

Acknowledgements

We are grateful to Mr. T. Jones (Brock) and Mr. B. Sayer (McMaster) for their assistance in obtaining spectra, and to the Southwestern Ontario NMR Centre, Guelph, for their services. Financial support was provided by the Natural Sciences and Engineering Research Council of Canada.

Synthesis of coleon C tri-*O*-methyl ether

ROBERT H. BURNELL, ANDRÉ ANDERSEN, MARTINE NÉRON, AND SYLVAIN SAVARD
Chemistry Department, Université Laval, Québec (Qué.), Canada G1K 7P4

Received February 20, 1985

ROBERT H. BURNELL, ANDRÉ ANDERSEN, MARTINE NÉRON, and SYLVAIN SAVARD. Can. J. Chem. **63**, 2769 (1985).

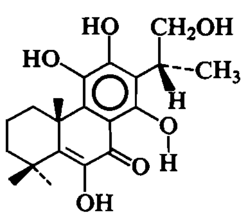
Starting from podocarpic acid, two model preparations are described leading to *p*-quinones suitably functionalized as intermediates in the synthesis of coleon C. The proper *p*-quinone was obtained by a regio- and stereo-selective route and, following steps previously found effective for the preparation of coleon U, a synthesis of tri-*O*-methyl coleon C has been achieved. Some of the by-products encountered have also been identified.

ROBERT H. BURNELL, ANDRÉ ANDERSEN, MARTINE NÉRON et SYLVAIN SAVARD. Can. J. Chem. **63**, 2769 (1985).

À partir de l'acide podocarpique, nous avons réalisé selon deux méthodes différentes, la préparation de modèles de *p*-quinones semblables aux intermédiaires de synthèse de la coléone C. Ensuite nous avons préparé, par une voie régio- et stéréo-sélective, une *p*-quinone possédant toutes les fonctions necessaires. Elle fut transformée en dérivés de la coléone C par une séquence réactionnelle antérieurement élaborée, lors de la synthèse de la coléone U.

The yellow pigment coleon C was isolated from *Coleus aquaticus* Gürcke by Eugster and his co-workers (1) who assigned to it the structure **1**. In unambiguous fashion they later defined the relative and absolute stereochemistry of the two chiral centres (C-10 and C-15) by X-ray diffraction (2). From the synthetic viewpoint the molecule presents the normal skeletal challenge and also the problem of obtaining selectively the *R* configuration in the side chain. Our previously reported method for elaborating the properly functionalized cyclic system (3) (such as found in coleon U) should lend itself to the synthesis of coleon C but first it would be necessary to obtain the key quinone intermediate **6***b*.

To determine the best preparation of the quinone, we chose to experiment with ester-containing analogues because these are more immediately available from podocarpic acid, allowing the saving of both time and material. Two avenues were investigated. The first started from the benzofuran **3***c* described by Cambie *et al.* (4), whose preparation involved cyclization of the acid derivative **2***b*, which was prepared from the corresponding ester **2***c*. We felt that this procedure could be streamlined in that the cyclization of the ester **2***c* could be effected during its formation, leading directly to the furan-ester **3***a*. Such was the case. In fact, we obtained both the benzofuran **3***c* and the furan-ester **3***a* which, by subsequent hydrolysis to the



1

	R^1	R^2	X
2*a*	R^1 = COOMe,	R^2 = H	X = H, H
2*b*	COOMe	CH_2COOH	H, H
2*c*	COOMe	CH_2COOEt	H, H
2*d*	CH_3	H	=O

acid **3***b* and decarboxylation, gave more of the desired furan **3***c* but in unoptimized yields that fell short of Cambie's procedure. The furan double bond was then reduced catalytically to give a 4:1 mixture of C-15 epimers **4***a* (as reflected by the nmr). From examination of molecular models, it is clear that hydrogenation must be from the convex β face of the furan **3***c*, enabling us to affirm that the C-15 methyl group is α in the major product. We were unable to separate the epimers efficiently at this stage. Hence the C-7 position was oxidized to afford the epimeric ketones **5***a*. Treatment of the latter with peracetic acid (prepared *in situ*) gave two quinones **6***a* and **6***c* but in subsequent oxidations in similar ketones we were able to avoid the hydrolysis of the *O*-acetyl residue. The highly polar **6***c* was tiresome to manipulate. It was only after we had handled the epimeric quinone **10***a*, as the result of the method to be described shortly, that we were able to isolate it from the mother liquors of this reaction, thus confirming that the dihydrofuran **4***a* did contain both epimers. In a previously conceived strategy, which was abandoned after the utility of the peracid oxidation became apparent, we had reduced the ketone **5***a* to the alcohol **4***b*, which was dehydrated to the olefin **4***c*.

In our second trial quinone synthesis, the known isopropenyl derivative **7***a*, prepared by Cambie's method (5), was subjected to hydroboration/oxidation to afford the primary alcohol **8***a* in which the stereochemistry at C-15 is established. No important stereo-induction can be invoked, so the reaction must give rise to about equal amounts of the C-15 epimers. The alcohol was protected by conversion to the acetate **8***b*, which was oxidized at the benzylic position (C-7) affording the ketone **9***a*. When subjected to peracetic acid oxidation, the latter underwent, first, rupture of the C-7—C-8 bond, followed by further hydrolysis/oxidation to give the two *para*-quinones **6***a* and **10***a*. The ^{1}H nmr spectrum confirmed that the mixture contained equal quantities of the epimers. Isolation of one isomer (**6***a*) in high yield was easy, while the other proved more elusive. We felt that by using chiral boranes, this preparation could have given us the C-15 epimer of our choice.

The appropriate quinone for the coleon C synthesis, with geminal methyl groups at C-4, was prepared by both of the model sequences described. Only the more successful is detailed in the Experimental. The ^{13}C nmr data for the compounds encountered in the other approach (**7***b*, **8***c*, **8***d*, and **9***b*) are included in Table 1. The more rewarding stereoselective route involving the benzofuran afforded a 4:1 preference for the

10b CH_3

C-15(*R*) epimer, which again was the easier one to isolate. In another context (3), we had already prepared the ketone **5*b*** by oxidation of the dihydrobenzofuran **4*d***. In repeating this work we were surprised to find that the oxidation affords not only the ketone **5*b*** but also the hydroxy-acetophenone **2*d***, which we had previously isolated in small quantities and assumed to be an impurity in the starting material. As had been noticed with the ester analogs (**6*a*** and **10*a***), the two quinones **6*b*** and **10*b*** were similar in many of their physical properties but they showed marked differences in their ^{1}H nmr spectra. One peculiarity of the nmr of **10*b*** was that significant changes were noted in the spectrum on varying the concentration in $CDCl_3$. The protons in the side chain were particularly sensitive. Many of the transformations described in the following paragraphs were actually performed on both C-15 epimers, but in the text and in the drawings only the C-15(*R*) isomer will be portrayed. To not overburden the experimental section, only the C-15(*R*) experiments are described. The results for the C-15(*S*) compounds are available elsewhere (6). We should point out that at the time we were completing this synthesis, the "natural" coleon C was reputedly the C-15(*R*) epimer but, from the published nmr spectrum, we felt that it contained the C-15(*S*) isomer also (*two* methyl doublets). This turned out to be true, as Eugster and co-workers have pointed out in a recent paper (7).

The subsequent steps needed to transform the quinone **6*b*** to the coleon C derivative (**24*a***) followed methods elaborated on models and used to synthesize coleon U (3). In all previous cases, the side chain on the aromatic ring was an isopropyl residue and the steps involved were highly regioselective. In the present synthesis, however, we isolated several minor products from some of the reactions, indicating that the more substantial side chain competes more effectively with the other substituent (ring A and its appendages). In the addition of bromine to the quinone **6*b*** the major product was the dibromo derivative **12**, which almost spontaneously eliminated hydrogen bromide to afford the bromoquinone **16**. Rather than manipulate the fragile dibromo compound, we treated the crude mixture with diethylamine and in the subsequent purification we obtained the required bromoquinone **16** and only trace amounts of the isomeric bromoquinone **17**. Thus the bromination had given rise to little of the alternate dibromo derivative **13**. It is likely that the tetrabromo compound **14** was also formed and, while we could never isolate it, we did obtain substantial amounts of the dibromolactone **18** that must arise from the displacement of the relevant bromo substituent in **13**, or its equivalent, by the carboxylic function.

To replace the bromo substituent in the bromoquinone **16**, it was treated with mild aqueous base containing sufficient methanol to render the substrate soluble. The resulting hydroxyquinone **15*a*** was accompanied by minor quantities of the methoxyquinone **15*b***. The ^{13}C nmr spectra leave no doubt as to the identity of these compounds. Both quinones (**15*a*** and **15*b***) were catalytically reduced to the corresponding hydroquinones and these were *O*-methylated, while still in the hydrogenation apparatus, to avoid their re-oxidation by air during the work-up. The product was mostly the ester **19*a*** (55%) but some incompletely methylated compounds were also obtained. By further methylation of the relevant fractions, an additional quantity (22%) of the ester **19*a*** was made available to continue the synthesis. The major partially methylated intermediate, and the only one obtained pure enough to ascertain the structure, was the phenol **20** (see ^{13}C nmr, Table 1).

Some of the products from the original methylation could not be easily reintegrated into the synthesis. One compound, for instance, contained an additional *O*-methyl residue and from spectral evidence must be the product **21*a*** in which the primary alcohol function has also suffered alkylation. The final unexpected methylation by-product displayed (as seen from the nmr and other spectra) two phenolic methoxyls and the methyl ester but no primary hydroxyl nor phenol residues. The great similarity of the ^{1}H nmr spectrum to that of dihydrobenzofurans such as **4*a*** and **4*d*** showed that the product must have cyclized during the reaction. Compound **22*a***, in which the two remaining methoxyl groups were adjacent, seemed the more likely of the two possible structures, an assumption that was confirmed later.

The ester **19*a*** was hydrolysed to the corresponding acid **19*b***.

15a R = H
15b R = Me
16 17 18

The latter cyclized readily in trifluoroacetic anhydride at room temperature to the aromatic ketone **23**a. As in our previous syntheses in this field, the final oxygen was introduced by stirring the ketone **23**a in anhydrous strong base in the presence of oxygen, which afforded the coleon C tri-*O*-methyl ether **24**a in modest yield (49%). This particular derivative is not described in the literature, since in the characterization of coleon C the strongly hydrogen-bonded C-14 hydroxyl group resists methylation. Our ether was identical with the trimethyl ether obtained via coleon D, as shown by thin-layer chromatography using several different solvent systems (we are grateful to Professor C. H. Eugster, Zürich, for the sample of coleon D). The tetra-*O*-methyl coleon C derivative was also prepared. There was a second product in the oxygenation reaction, which proved to be the enolized diketone **25** that we prepared later from the cyclized ester **22**a. Repeating this part of the synthesis on a larger scale, as described in the Experimental, we were surprised that our rigorously pure ester **19**a gave rise to a significant quantity (26%) of this tetracyclic diosphenol **25**. The five-membered ring must be closed during the oxygenation in strong base.

Both of the fortuitously isolated esters, **21**a and **22**a, were hydrolysed to the acids **21**b and **22**b, respectively, and these were cyclized to the aromatic ketones **23**b and **26**. Oxygenation of the tetracyclic ketone **26** in *tert*-butanol containing potassium *tert*-butoxide gave the diosphenol **25** that had previously been isolated from the oxidation of ketone **23**a. Had the cyclization of the five-membered ring involved the C-12 hydroxyl (or methoxyl) rather than the C-14 position, the product would have been a derivative of the naturally occurring lycoxanthol (8).

During this work we found the ^{13}C nmr spectra to be of great importance in the assigning of structures to the synthetic products. These data are grouped in Table 1. The resonances were assigned by using Enzell's listing of certain diterpenoid spectra (9) and adding our own accumulated experience arising from our synthetic projects in this field (10a–c).

Experimental

Unless otherwise stated, the conditions and instruments used to characterize the products were melting points, Electrothermal, uncorrected; ultraviolet spectra, ethanol solutions (log ϵ in parentheses), Hewlett Packard 8450A; infrared spectra, solids as KBr pellets, others as carbon tetrachloride solutions, Beckman 4250 and Perkin Elmer 457; proton magnetic resonance spectra, deuteriochloroform solutions, TMS internal standard, (multiplicity, integrated peak areas—where important, coupling constants and assignments in parentheses: D_2O infers that resonances were no longer detectable after shaking the solution for a few minutes with deuterium oxide), Bruker HX 90; carbon-13 magnetic resonance spectra, deuteriochloroform solutions, TMS internal standards, Bruker WP 80; mass spectra, Hewlett Packard 5992; high resolution mass spectra were recorded on an AEI MS30. Elemental analyses were by Galbraith Laboratories, Knoxville, Tenn.

Dry column chromatography (abbreviated dry col chrom) implies that use of Merck Kieselgel 60F (70–230 mesh) in nylon foil tubing and development with either hexane – ethyl acetate or carbon tetrachloride – ethyl acetate (proportions determined by prior thin-layer chromatography using Machery–Nagel pre-coated plastic sheets).

*Benzofuran 3*c *and furan-ester 3*a

The hydroxy-acetophenone **2**a (28.3 g, prepared following Cambie *et al.* (4)) was dissolved in acetone (700 mL) to which was then added ethyl bromoacetate (43.6 mL) and anhydrous potassium carbonate (88.6 g). After 24 h the reaction appeared very slow (tlc), so the acetone was slowly distilled and the residue then heated to 140°C in an oil bath for 24 h. The mixture was then taken up in ether, which was well washed, and the residue, after drying and evaporation, was filtered through a short column of alumina (act. III) that removed much of the color, and was then chromatographed over silica gel (dry col). The benzene eluate contained the furan-ester **3**a (5.16 g: 15%), which crystallized, and the benzofuran **3**c (6.21 g: 22%) from the mother liquors. *7(β)-Methoxycarbonyl-3,7(α),10a(β)-trimethyl-5,6,6a,7,8,9,10,10a-octahydrophenanthro[3,2-*b*]furan* **3**c, mp 130–131°C (from hexane); ir: 1722, 1635, and 1580 cm^{-1}; ^{1}H nmr δ: 1.06 and 1.26 (2s, Me-C), 2.16 (d, J = 1 Hz, Me-arom), 3.64 (s, COOMe), 7.17 and 7.36 (2s, arom H), and 7.30 (d, J = 1 Hz, furan H); ^{13}Cmr, see Table 1. *Anal.* calcd. for $C_{21}H_{26}O_3$: C 77.28, H 8.03; found: C 77.28, H 8.04. *2-Ethoxycarbonyl-7(β)-methoxycarbonyl-3,7(α),10a(β)-trimethyl-5,6,6a,7,8,9,10,10a-octahydrophenanthro[3,2-*b*]furan* **3**a, mp 161–163°C (from methanol); ir: 1723, 1638, and 1600 cm^{-1}; ^{1}H nmr δ: 1.07 and 1.30 (2s, Me-C), 1.43 (t, J = 7 Hz, Me-CH_2), 2.54 (s, Me-arom), 3.67 (s, COOMe), 4.43 (q, J = 7 Hz, CH_3CH_2O—), 6.93 and 7.14 (2s, arom H); ^{13}Cmr, see Table 1. *Anal.* calcd. for $C_{24}H_{30}O_5$: C 72.33, H 7.59; found: C 72.30, H 7.80.

*Hydrolysis of the furan-ester 3*a *to the acid 3*b

To a solution of the ester **3***a* (0.475 g) in ethanol (15 mL) was added aqueous sodium hydroxide (3 mL of 10%). After refluxing for 1 h, the cooled solution was acidified (dilute hydrochloric acid) and the white precipitate was filtered, dried, and crystallized from methanol affording the *2-carboxy-7(β)-methoxycarbonyl-3,7(α),10a(β)-trimethyl-5,6,6a,7,8,9,10,10a-octahydrophenanthro[3,2-*b*]furan* **3***b*, mp 228–231°C (0.425 g: 96%); ir: 3300 (br), 1735, 1720, and 1675 cm^{-1}; ^{1}H nmr δ: 1.07, 1.30, and 2.57 (3s, Me-C), 3.68 (s, COOMe), 7.27 and 7.53 (2s, arom H), and 11.04 (br s, COOH, D_2O); ^{13}Cmr, see Table 1; mass spectra *m/e*: 370 (M^+), 355, and 327. *Anal.* calcd. for $C_{22}H_{26}O_5$: C 71.33, H 7.08; found: C 71.49, H 7.08.

*Decarboxylation of the acid 3*b

Copper powder (5 mg) was added to the acid **3***b* (112 mg) dissolved in quinoline (2 mL). The mixture was stirred for 2.5 h while the temperature was increased from 145 to 205°C. The cooled solution was treated with ice (25 g) and concentrated hydrochloric acid (20 mL) and then extracted with ether. The dark oil so obtained was chromatographed over alumina (act. III). The benzene eluate afforded the benzofuran **3***c* (70 mg: 72%), identical with that obtained earlier.

*Catalytic hydrogenation of the benzofuran 3*c

The benzofuran **3***c* (8.0 g) was dissolved in glacial acetic acid (400 mL) and 10% palladium on carbon (4.0 g) was introduced. The mixture was shaken under 3 atmospheres (1 atm = 101.3 kPa) of hydrogen for 4 h and the catalyst then filtered over Celite. The solvent was removed under vacuum and the white residue crystallized from hexane to give the dihydrofuran **4***a* (7.78 g: 97%; *7(β)-methoxycarbonyl-3,7(α),10a(β)-trimethyl-2,3,5,6,6a,7,8,9,10,10a-decahy-*

*drophenanthro[3,2-*b*]furan*), mp 149–150°C; ir: 1720 cm^{-1}; ^{1}H nmr δ: 1.01 and 1.24 (2s, Me-C), 1.28 (d, J = 8 Hz, Me-CH), 3.46 (m, 1H, C15-H), 3.63 (s, COOMe), 4.00 (dd, J = 8 and 9 Hz) and 4.62 (dd, J = 9 and 9 Hz, —CH_2O—), 6.68 and 6.81 (2s, arom H); ^{13}Cmr, see Table 1; mass spectra *m/e*: 328 (M^+), 313, 269, and 253. *Anal.* calcd. for $C_{21}H_{28}O_3$: C 76.79, H 8.59; found: C 76.98, H 8.76.

*Oxidation to the ketone 5*a

The dihydrofuran **4*a*** (656 mg) in glacial acetic acid (20 mL) was treated drop by drop with a solution of chromium trioxide (400 mg) in acetic acid (4 mL of 80%). After 45 min at room temperature, the solution was poured onto ice and the product obtained by ether extraction. The oil was chromatographed over alumina (act. III) affording the ketone **5*a*** as an oil which crystallized on contact with hexane (506 mg: 73%; *7(β)-methoxycarbonyl-5-oxo-3,7(α),10a(β)-trimethyl-2,3,5,6,6a,7,8,9,10,10a-decahydrophenanthro[3,2-*b*]furan*), mp 142–144°C; ir: 1720 and 1675 cm^{-1}; ^{1}H nmr δ: 1.10 and 1.27 (2s, Me-C), 1.35 (d, J = 8 Hz, Me-CH), 3.54 (m, C15-H), 3.71 (s, COOMe), 4.13 (dd, J = 8 and 9 Hz) and 4.76 (dd, J = 9 and 9 Hz, —CH_2O—), 6.78 and 7.91 (arom H at C11 and C14 resp.); ^{13}Cmr, see Table 1; mass spectra *m/e*: 342 (M^+), 327, 282, and 266. *Anal.* calcd. for $C_{21}H_{26}O_4$: C 73.66, H 7.66; found: C 73.35, H 7.36.

*Sodium borohydride reduction of ketone 5*a

To the refluxing solution of the ketone **5*a*** (0.7 g) in aqueous methanol (70 mL of 75%) containing sodium hydroxide (0.53 g) was added sodium borohydride (0.25 g) in 1 *N* aqueous sodium hydroxide (21 mL). After refluxing for 2.5 h, the cooled solution was neutralized with dilute acetic acid and the white solid alcohol **4*b*** was collected by filtration and crystallized from methanol (0.65 g: 92%; *7(β)-methoxycarbonyl-5(β)-hydroxy-3,7(α),10a(β)-trimethyl-2,3,5,6,6a,7,8,-9,10,10a-decahydrophenanthro[3,2-*b*]furan*), mp 186–190°C; ir: 3450 and 1708 cm^{-1}; ^{1}H nmr δ: 1.06 and 1.26 (2s, Me-C), 1.30 (d, J = 8 Hz, Me-CH), 2.20 (s, 1H, OH, D_2O), 3.50 (m, C15-H), 3.64 (s, COOMe), 4.02 (dd, J = 9 and 9 Hz) and 4.65 (dd, J = 9 and 9 Hz, —CH_2O—), 4.67 (dd, J = 10 and 6 Hz, *C*H—OH), 6.67 and 7.50 (2s, arom H); ^{13}Cmr, see Table 1; mass spectra *m/e*: 344 (M^+), 329, 326, 267, and 251. *Anal.* calcd. for $C_{21}H_{28}O_4$: C 73.22, H 8.19; found: C 73.47, H 8.28.

*Dehydration of alcohol 4*b

This is essentially Wenkert's method (11). The alcohol **4*b*** (250 mg) was heated to 50°C for 30 min in benzene (25 mL) containing *p*-toluene sulfonic acid monohydrate (90 mg) and anhydrous calcium chloride (150 mg). The mixture was then washed with aqueous sodium bicarbonate, dried, and evaporated. The solid was purified by dry col chrom to give the tetraene **4*c*** (220 mg: 91%; *7(β)-methoxycarbonyl-3,7(α),10a(β)-trimethyl-2,3,6a,7,8,9,10,10a-octahydrophenanthro-[3,2-*b*]furan*), mp 138–140°C (from hexane); ir: 3040 and 1720 cm^{-1}; ^{1}H nmr δ: 0.85 and 1.30 (2s, Me-C), 1.32 (d, J = 8 Hz, Me-CH), 3.48 (m, C15-H), 3.68 (s, COOMe), 4.04 (dd, J = 9 and 8 Hz) and 4.67 (dd, J = 9 and 9 Hz, —CH_2O—), 6.37 (m, 2H, C6 and C7 olefinic H), 6.71 and 6.86 (2s, arom H); ^{13}Cmr, see Table 1. *Anal.* calcd. for $C_{21}H_{26}O_3$: C 77.27, H 8.03; found: C 77.17, H 8.18.

*Peracid oxidation of ketone 5*a *(formation of quinones 6*a *and 6*c*)*

The reagent is prepared by adding hydrogen peroxide (10 mL of 30%) dropwise to a cooled solution of concentrated sulfuric acid (0.2 mL) in acetic anhydride (23 mL). After standing overnight, the peracid is slowly added to the cooled solution of the ketone **5*a*** (1.0 g) in acetic anhydride (20 mL). The mixture was allowed to warm to room temperature and stirring was continued for 7 h; it was then poured onto ice and stirred for 12 h, during which time a yellow solid precipitated. The latter was filtered and chromatographed to give the quinone **6*a*** (293 mg: 23%; *2-{2-[4-(2-acetoxy-1-methylethyl)-2,5-benzoquinone]-yl-6-methoxycarbonyl-2,6-dimethylcyclohexyl}ethanoic acid*), mp 140–141°C (from methanol): $[\alpha]_D^{20}$ −10° ($CHCl_3$); ir: 3200 (br), 1730, 1712, 1660, 1640, and 1605 cm^{-1}; ^{1}H nmr δ: 1.06 and 1.27 (2s, Me-C), 1.23 (d, J = 7 Hz, Me-CH), 2.09 (s, Me—CO—), 3.21 (m, C15-H), 3.69 (s, COOMe), 3.84 (dd, J = 11 and 4 Hz) and 4.79 (dd, J = 11 and 4 Hz, —CH_2O—Ac), 6.43 and 6.61 (2s, olefinic H), and 8.66 (br s, COOH, D_2O); ^{13}Cmr, see Table 1; mass spectra *m/e*: 434 (M^+), 374, and 330. *Anal.* calcd. for $C_{23}H_{30}O_8$: C 63.58, H 6.96; found: C 63.71, H 6.92.

The filtrate from above was extracted with methylene chloride which, after washing and drying, was evaporated to give a yellow oil (740 mg). Dry col chrom of the latter afforded more of the quinone acetate **6***a* (35 mg) and then the primary alcohol **6***c* (380 mg: 30% after recrystallization from ethyl acetate; *2-{2-[4-(2-hydroxy-1-methylethyl)-2,5-benzoquinone]yl-6-methoxycarbonyl-2,6-dimethylcyclohexyl}-ethanoic acid*), mp 191–193°C (orange needles); ir: 3300 (br), 1720, 1650, and 1595 cm^{-1}; ^{1}H nmr (DMSO-d_6) δ: 0.99 and 1.14 (2s, Me-C), 1.07 (d, J = 8 Hz, Me-CH), 3.44 (m, 3H, C15-H and —CH_2O—), 3.63 (s, COOMe), 6.49 and 6.60 (2s, olefinic H); mass spectra m/e: 392 (M$^+$), 376, 362, 348, 330, and 316. *Anal.* calcd. for $C_{21}H_{28}O_7$: C 64.27, H 7.19; found: C 64.02, H 7.11.

The alcohol **6***c* was readily acetylated by acetic anhydride/pyridine at room temperature, affording the acetoxy-quinone **6***a*.

Hydroboration/oxidation of the isopropenyl derivative **7**a

The isopropenyl compound **7***a* (3.47 g: prepared following the method of Cambie *et al.* (5)) was dissolved in THF (6 mL) and cooled to 0°C. Borane – methyl sulfide (0.97 mL of 2 *M* in THF) was added slowly and the solution then stirred at room temperature for 2 h. Aqueous sodium hydroxide (3.4 mL of 3 *N*) was introduced, followed by hydrogen peroxide (1.3 mL of 30%), which was added slowly with cooling. After 1 h at room temperature, the mixture was refluxed for 1 h and then poured into water. Ether extraction gave **8***a* as a yellowish foam that crystallized from ether–hexane as colorless prisms, mp 113–114°C (3.50 g: 96%; *methyl 12-*O*-methyl-13-(2-hydroxy-1-methylethyl)podocarpate*); ir: 1730 cm^{-1}; ^{1}H nmr δ: 1.02 and 1.25 (2s, Me-C), 1.21 (d, J = 7 Hz, Me-CH), 3.36 (m, C15-H), 3.60 (m, 2H, CH_2OH), 3.60 (s, COOMe), 3.71 (s, MeO-Ar), 6.70 and 6.79 (2s, arom H); ^{13}Cmr, see Table 1. *Anal.* calcd. for $C_{22}H_{32}O_4$: C 73.30, H 8.95; found: C 73.32, H 8.91.

Acetylation of **8**a *and oxidation of the acetate* **8**b

The primary alcohol **8***a* (3.50 g) was treated with pyridine (7 mL) and acetic anhydride (7 mL) for 40 h at room temperature. The solution was then poured into ice-water and the product obtained by ether extraction. Dry col chrom gave the acetate **8***b* as an oil which could not be crystallized (3.12 g: 92%; ir: 1735 cm^{-1}; ^{1}H nmr δ: 2.03 s, Me—CO—) and was used as such for the oxidation.

To a solution of the acetate **8***b* (3.62 g) in acetic acid (65 mL) cooled in an ice bath was added, dropwise, chromium trioxide (2.2 g) dissolved in 80% aqueous acetic acid (15 mL). Stirring was continued for 3 h and the mixture was then poured into ice-water, and the product extracted into ether and then crystallized from ether (2.62 g: 70%; *methyl 12-*O*-methyl-13-(2-acetoxy-1-methylethyl)-7-oxo-podocarpate* **9***a*), mp 145–146°C; uv: 228 (4.13) and 276 (4.06) nm; ir: 1725 and 1665 cm^{-1}; ^{1}H nmr δ: 1.12 and 1.24 (2s, Me-C), 1.27 (d, J = 7 Hz, Me-CH), 3.42 (m, C15-H), 3.65 (s, COOMe), 3.85 (s, MeO—Ar), 4.09 (dd, 2H, CH_2O—Ac), 6.74 and 7.80 (2s, arom H at C11 and C14 resp.); ^{13}Cmr, see Table 1. *Anal.* calcd. for $C_{24}H_{32}O_6$: C 69.21, H 7.74; found: C 69.33, H 7.79.

Oxidation of ketone **9**a *to quinones* **6**a *and* **10**a

The reagent was prepared by adding, slowly, hydrogen peroxide (22 mL of 30%) to acetic anhydride (51 mL) containing concentrated sulfuric acid (0.05 mL) maintained at 0°C. Stirring was continued for 24 h and the solution was then added to the cooled solution of the ketone **9***a* (2.57 g) in acetic anhydride (44 mL) over a period of 30 min. After stirring at room temperature for 20 h, the solution was poured onto ice (500 g) and one hour later the product was obtained by ether extraction as a viscous yellow oil (2.24 g). The separation of the two isomers was tedious and involved three successive silica gel columns. In this way, fractions were obtained that contained the pure quinone **6***a* (0.57 g: 19%), identical with that described earlier. The C15(*S*) epimer **10***a* (0.51 g: somewhat slower on the columns: 18%) was also isolated, mp 146–148°C (from methanol); $[\alpha]_D^{20}$ +52° ($CHCl_3$); ir: 3200 (br), 1735, and 1655 cm^{-1}; ^{1}H nmr δ: 1.04 and 1.26 (2s, Me-C), 1.21 and 1.24 (2d, J = 7 Hz, Me-CH), 2.03 (s, Me—CO—), 3.03 (m, C15-H), 3.67 (s, COOMe), 4.07 (dd, J = 11 and 6 Hz) and 4.27 (dd, J = 11 and 5 Hz, CH_2O—Ac), 6.51 and 6.56 (2s, olefinic H), and 10.1 (COOH, D_2O). *Anal.* calcd. for $C_{23}H_{30}O_8$: C 63.58, H 6.96; found: C 63.45, H 6.95.

Formation of ketone **5**b

The ketone **5***b*, prepared as described earlier (3), was identical with that obtained previously (yield 80%) but this time we were able to confirm the identity of a second product **2***d*, *7-oxo-13-acetyl-12-hydroxypodocarpa-8,11,13-triene* in 13% yield, mp 142–143°C (from hexane); uv: 248 (4.46), 279 (4.05), and 324 (3.55) nm; ir: 3400–2600 (broad OH), 1680, and 1650 cm^{-1}; ^{1}H nmr δ: 0.96, 1.01, and 1.24 (3s, Me-C), 1.82 (dd, 1H, J = 11 and 7 Hz, C5-H), 2.56 (dd, 1H, J = 18 and 11 Hz, C6-Hβ), 2.67 (s, Me—CO—), 2.79 (dd, 1H, J = 18 and 7 Hz, C6-Hα), 6.91 (s, C11-H), 8.48 (s, C14-H), and 12.36 (s, OH, D_2O); ^{13}Cmr, see Table 1; mass spectra m/e: 300 (M$^+$), 286, 285, and 217. *Anal.* calcd. for $C_{19}H_{24}O_3$: C 75.97, H 8.05; found: C 75.79, H 8.19.

Quinones **6**b *and* **10**b

A solution of peracid was prepared from hydrogen peroxide (40 mL of 30%), acetic anhydride (92 mL), and concentrated sulfuric acid (0.8 mL) as described above. This solution was stirred at room temperature for 24 h and then cautiously added dropwise to the cooled solution of the ketone **5***b* (7.5 g) in acetic anhydride (90 mL). The temperature was allowed to rise to ambiant while stirring was continued for 20 h. The mixture was poured into ice-water and, after stirring for several hours, the product was obtained by ether extraction (8 g, yellow solid) and chromatographed (silica gel, hexane – ethyl acetate, 7:3) affording some starting material **5***b* (0.51 g), the mixture of quinones **6***b* and **10***b* (5.13 g), and a mixture of the two quinones in which the primary acetate had been hydrolysed (1.63 g). The latter mixture was acetylated by dissolving in pyridine (15 mL), adding acetic anhydride (20 mL), and stirring at room temperature overnight. A normal work-up afforded the mixture of **6***b* and **10***b* (1.61 g), which was combined with the previous amount and chromatographed again to give first the major *R* component **6***b* (4.3 g: 47%), the *S* isomer **10***b* (1.5 g: 17%), and some mixed *R/S* fractions (0.9 g). Quinone **6***b* (*2-{2-[4-(2-acetoxy-1(*R*)-methylethyl)-benzoquinone-2,5]yl-2,6,6-trimethylcyclohexyl}ethanoic acid*), mp 143–145°C (from ethanol); $[\alpha]_D^{25}$ −50° ($CHCl_3$); uv: 258 (4.14) nm; ir: 3400–2400 (br OH, COOH), 1725, and 1655 cm^{-1}; ^{1}H nmr δ: 0.92, 0.98, and 1.26 (3s, Me-C), 1.21 (d, J = 7 Hz, Me-CH), 2.06 (s, Me—CO—), 2.08 (dd, 1H, J = 16 and 4.5 Hz, C6-H), 2.28 (dd, 1H, J = 16 and 8.5 Hz, C6-H), 2.73 (dd, 1H, J = 8.5 and 4.5 Hz, C5-H), 2.97–3.33 (m, C15-H), 3.79 (dd, 1H, J = 11 and 4 Hz, C16-H), 4.77 (dd, 1H, J = 11 and 3 Hz, C16-H), 6.35 (d, 1H, J = 1.5 Hz, C14-H), 6.58 (s, C11-H), and 8.94 (COOH, D_2O); ^{13}Cmr, see Table 1; mass spectra m/e: 390 (M$^+$), 374, 355, 347, 329, 313, and 285. *Anal.* calcd. for $C_{22}H_{30}O_6$: C 67.67, H 7.74; found: C 67.78, H 7.60. Quinone **10***b* (*2-{2-[4-(2-acetoxy-1(*S*)-methylethyl)-benzoquinone-2,5]yl-2,6,6-trimethylcyclohexyl}ethanoic acid*), mp 119–120°C (from ethanol); $[\alpha]_D^{25}$ −19° ($CHCl_3$); uv: 258 (4.14) nm; ir: 3400–2500 (br OH, COOH), 1730, 1705, and 1655 cm^{-1}; ^{1}H nmr (0.22 *M* in $CDCl_3$) δ: 0.89, 0.91, and 1.18 (3s, Me-C), 1.17 (d, J = 6.5 Hz, Me-CH), 1.97 (s, Me—CO—), 1.99 (dd, J = 16 and 8 Hz, C6-H), 2.28 (dd, J = 16 and 4 Hz, C6-H), 2.64 (dd, J = 8 and 4 Hz, C5-H), 2.96 (m, C15-H), 3.83 (dd, J = 11 and 5 Hz, C16-H), 4.32 (dd, J = 11 and 7 Hz, C16-H), 6.24 and 6.35 (2s, C14 and C11-H resp.); ^{13}Cmr, see Table 1; mass spectra m/e: 390 (M$^+$), 348, 330, 317, and 315. *Anal.* calcd. for $C_{22}H_{30}O_6$: C 67.67, H 7.74; found: C 67.58, H 7.78.

Bromo-quinone ***16***

This procedure is based on that described by Moore *et al.* (12). To the quinone **6***b* (3.90 g) in glacial acetic acid (50 mL) was added bromine (0.80 mL), and the mixture was stirred for 3 h and then poured into water (500 mL). The orange precipitate was filtered and well washed to afford an unstable crude product (5.03 g, after drying), which was used immediately for the next step.

The crude bromo compound was dissolved in ether and cooled to 10°C and then diethylamine (1.0 mL) in ether (10 mL) was added dropwise. After stirring for 3 h at room temperature, the mixture was poured into water and the product obtained by ether extraction. Chromatography over silica gel (hexane − ethyl acetate 4:1) afforded the *bromoquinone* **16** (3.70 g: 79%), orange solid, mp 151−153°C (dec., from ethanol); uv: 275 (3.97) and 358 (2.87) nm; ir: 1725, 1700, 1670, and 1650 cm^{-1}; ^{1}H nmr δ: 0.89 (s, 6H, 2 Me-C), 1.16 (s, Me-C), 1.19 (d, J = 7 Hz, Me-CH), 1.92 (s, Me—CO—), 1.93 (dd, J = 17 and 7 Hz, C6-H), 2.24 (dd, J = 17 and 4 Hz, C6-H), 2.60 (dd, J = 7 and 4 Hz, C5-H), 3.44 (m, C15-H), 4.21 (d, 2H, C(16)H_2—OAc), 6.31 (s, C8-H), and 9.92 (COOH, D_2O); ^{13}Cmr, see Table 1; mass spectra m/e: 470 (M^+ + 2), 468 (M^+), 454, 452, 428, 426, 410, 408, 394, and 392. *Anal.* calcd. for $C_{22}H_{29}O_6Br$: C 56.29, H 6.23, Br 17.08; found: C 56.45, H 6.43, Br 17.21.

From the mother liquors (above) a second product was obtained. Dry col chrom gave the pure *dibromo-lactone* **18** (0.45 g: 8%), mp 163−165°C (from ether); $[\alpha]_D^{25}$ −44° ($CHCl_3$); uv: 291 (3.81) and 365 (2.66) nm; ir: 1750 (br) and 1695 cm^{-1}; ^{1}H nmr δ: 0.82, 0.90, and 1.20 (3s, Me-C), 1.21 (d, J = 6.5 Hz, Me-CH), 1.91 (s, Me—CO—), 2.32 (dd, J = 16 and 10.5 Hz, C6-H), 2.69 (dd, J = 16 and 6 Hz, C6-H), 3.56 (m, C15-H), 4.22 (dd, J = 13 and 7 Hz, C16-H), 4.33 (dd, J = 13 and 7 Hz, C16-H), and 4.78 (s, CH-Br); ^{13}Cmr, see Table 1; mass spectra m/e: 550, 548, 546 (M^+), 471, 469, 467, 453, 451, 409, 407, 393, 391, and 389. *Anal.* calcd. for $C_{22}H_{28}O_6Br_2$: C 48.19, H 5.15, Br 29.15; found: C 47.95, H 5.24, Br 28.87.

Formation of the hydroxy-quinone **15**a *and the methoxy-quinone* **15**b

To a solution of the bromo-quinone **16** (2.8 g) in methanol (30 mL) was added aqueous sodium hydroxide (30 mL of 20%) and the mixture was stirred at room temperature for 15 min, after which the dark violet solution was diluted with water, acidified with 5% aqueous hydrochloric acid, and then extracted with ether. The two products (as seen by tlc) were separated by chromatography over silica gel (hexane − ethyl acetate 1:1) affording *hydroxy-quinone* **15***a* (1.41 g: 64%; *2-{2-[3-hydroxy-4-(2-hydroxy-1-methylethyl)-benzoquinone-2,5]yl-2,6,6-trimethylcyclohexyl}ethanoic acid*), orange needles, mp 168−170°C (from ethanol); uv: 273 (3.95) and 400 (2.96) nm; ir: 3600−2400 (br COOH), 3360 (OH), 1710, 1665, and 1635 cm^{-1}; ^{1}H nmr δ: 0.93, 0.98, and 1.24 (3s, Me-C), 1.13 (d, J = 7 Hz, Me-CH), 2.08 (dd, J = 16 and 9 Hz, C6-H), 2.34 (dd, J = 16 and 3.5 Hz, C6-H), 2.63 (dd, J = 9 and 3.5 Hz, C5-H), 3.10−3.44 (m, C15-H), 3.56−3.99 (m, 2H, C(16)H_2—O), 6.49 (s, C11-H), and 7.59 (m, 3H, COO*H*, CH_2O*H* and O*H*, D_2O); ^{13}Cmr, see Table 1. *Anal.* calcd. for $C_{20}H_{28}O_6$: C 65.91, H 7.74; found: 65.76, H 7.61.

The more mobile product was the *methoxy-quinone* **15***b* (0.61 g: 27%; red glass); ^{1}H nmr δ: 0.93, 0.98, and 1.24 (3s, Me-C), 1.07 (d, J = 7 Hz, Me-CH), 4.03 (s, MeO—), 6.48 (s, C11-H), and 7.76 (m, 2H, COO*H* and CH_2O*H*, D_2O); ^{13}Cmr, see Table 1; mass spectra m/e: 378 (M^+), 259, and 245.

Reduction and methylation of the hydroxy-quinone **15**a

This procedure was inspired by that of Edwards *et al.* (13). Adams' catalyst (100 mg) was hydrogenated in methanol (10 mL) at atmospheric pressure. The hydroxy-quinone **15***a* (1.80 g) was introduced dissolved in methanol (38 mL) and the mixture was stirred under hydrogen for 2 h, by which time the solution had become colorless. Then, every hour, aqueous sodium hydroxide (1.5 mL of 30%) and dimethyl sulfate (1 mL) were added, up to a total of 16.5 and 11 mL, respectively. The catalyst was removed by filtration with Celite, the solution was diluted with water (70 mL), and the bulk of the methanol was removed under vacuum. Ether extraction afforded an oily mixture which was separated by chromatography (silica gel; hexane − ethyl acetate 4:1) which gave the following.

Trimethyl ether **19***a* (1.03 g: 48%; pale oil: *methyl 2-[2,3,5-trimethoxy-4-(2-hydroxy-1(*R*)-methylethyl)-phenyl-2,6,6-trimethylcyclohexyl]ethanoate*); ir: 3500, 1730, and 1605 cm^{-1}; ^{1}H nmr δ: 0.92, 0.99, and 1.35 (3s, Me-C), 1.28 (d, J = 7 Hz, Me-CH), 2.08 (dd, J = 16 and 6 Hz, C6-H), 2.32 (dd, J = 16 and 5 Hz, C6-H), 2.48 (br s, CH_2O*H*, D_2O), 2.83 (dd, J = 6 and 5 Hz, C5-H), 3.33 (s, COOMe), 3.54 (m, C15-H), 3.61−3.89 (m, C*H*$_2$OH), 3.79 (s, 6H, OMe at C12 and C14), 3.95 (s, OMe at C11), and 6.59 (s, C8-H); ^{13}Cmr, see Table 1.

Tetramethyl ether **21***a* (352 mg: 16%; pale yellow oil); ir: 1735 cm^{-1}; ^{1}H nmr δ: 0.91, 0.97, and 1.33 (3s, Me-C), 1.29 (d, J = 7 Hz, Me-CH), 2.05 (dd, J = 15.5 and 5 Hz, C6-H), 2.28 (dd, J = 15.5 and 5 Hz, C6-H), 2.95 (dd, J = 5 and 5 Hz, C5-H), 3.29 (s, 6H, COOMe and CH_2OMe), 3.74 (s, 6H, OMe at C12 and C14), 3.91 (s, OMe at C11), and 6.55 (s, C8-H); ^{13}Cmr, see Table 1.

Dimethyl ether **20** (298 mg: 15%; pale yellow oil); ir: 3450 and 1730 cm^{-1}; ^{1}H nmr δ: 0.93, 0.97, and 1.37 (3s, Me-C), 1.31 (d, J = 7 Hz, Me-CH), 2.03 (dd, J = 15 and 6 Hz, C6-H), 2.31 (dd, J = 15 and 6 Hz, C6-H), 3.14 (dd, J = 6 and 6 Hz, C5-H), 3.28 (s, COOMe), 3.44−3.89 (m, 3H, C15-H and C*H*$_2$OH), 3.75 and 3.78 (2s, OMe at C14 and C12), 6.07 (phenolic OH, D_2O), and 6.60 (s, arom H); ^{13}Cmr, see Table 1. Further methylation of this dimethyl ether (dimethyl sulfate/sodium hydroxide) afforded the trimethyl ether **19***a* in excellent yield.

Reduction and methylation of hydroxy-quinone **15**a *(second procedure)*

The quinone **15***a* (2.02 g) in methanol (20 mL) was hydrogenated as described above (70 mg of PtO_2 in methanol). The colorless solution was then treated with aqueous sodium hydroxide (1 mL of 30%) and dimethyl sulfate (1 mL) every hour, up to a total of 12 mL of each reagent, and stirring was continued for 40 more hours. The solution had become acid during this time. Following the same work-up as in the earlier procedure afforded, as the major product, the trimethyl ether **19***a* (1.09 g: 47% after dry col chrom) but the minor product was the cyclized compound **22***a* (302 mg: 14%; colorless oil: *methyl 2-[2-(4,5-dimethoxy-3(*R*)-methyl-2,3-dihydrobenzofuran-6)yl-2,6,6-trimethyl cyclohexyl]ethanoate*); ir: 1730 cm^{-1}; ^{1}H nmr δ: 0.89, 0.97, and 1.27 (3s, Me-C), 1.34 (d, J = 6.5 Hz, Me-CH), 2.02 (dd, J = 15.5 and 5.5 Hz, C5-H), 3.38 (s, COOMe), 3.61 (m, C15-H), 3.84 and 3.94 (2s, OMe), 4.04 (dd, J = 8.5 and 6 Hz, C16-H), 4.58 (dd, J = 8.5 and 8.5 Hz, C16-H), and 6.48 (s, arom H). *Anal.* calcd. for $C_{23}H_{34}O_5$: C 70.74, H 8.78; found: C 70.48, H 8.49.

Hydrolysis of ester **19**a

Sodium hydroxide solution (40 mL of 10% aqueous) was added to the ester (1.0 g) in methanol (40 mL) and the mixture was refluxed for 20 h. After adding more water, the methanol was removed under vacuum and the product then obtained by ether extraction. The yellow oil (850 mg) was chromatographed (silica gel; hexane − ethyl acetate 7:3) to give the acid **19***b* (802 mg: 83%; *2-[2,3,5-trimethoxy-4-(2-hydroxy-1(*R*)-methylethyl)phenyl-2,6,6-trimethylcyclohexyl]ethanoic acid*), pale yellow oil; uv: 229 (sh 3.90) and 286 (3.41) nm; ir: 3600−2400 (br COOH), 3400 (OH), and 1710 cm^{-1}; ^{1}H nmr δ: 0.91, 0.98, and 1.33 (3s, Me-C), 1.23 (d, J = 7 Hz, Me-CH), 2.03 (dd, J = 16 and 5 Hz, C6-H), 2.28 (dd, J = 16 and 6 Hz, C6-H), 2.77 (dd, J = 6 and 5 Hz, C5-H), 3.51 (m, C15-H), 3.74 (s, 6H, OMe at C12 and C14), 3.89 (s, OMe at C11), 6.57 (s, arom H) and 6.67 (m, 2H, COOH and OH, D_2O); ^{13}Cmr, see Table 1; mass spectra m/e: 408 (M^+), 378, 377, 359, 235, 221, and 195. *Anal.* calcd. for $C_{23}H_{36}O_6$: C 66.62, H 8.88; found: C 66.93, H 8.67.

Cyclization of acid **19**b *(to give ketone* **23**a*)*

Following Pelletier and Ohtsuka's method (14), the acid **19***b* (850 mg) was stirred at room temperature in trifluoroacetic anhydride (7 mL) for 20 h. After pouring into water, the product was obtained by ether extraction and repeated washing. The actual product at this stage was the enol trifluoroacetate (ir 1805 cm^{-1}) but this was hydrolysed immediately by stirring in methanol (50 mL) and aqueous sodium hydroxide solution (10 mL of 10%) for 40 min. Chromatography over silica gel (hexane − ethyl acetate 7:3) of the oil obtained by extraction afforded the cyclized ketone **23***a* (820 mg: 89%; *7-oxo-11,12,14-trimethoxy-13-(2-hydroxy-1(*R*)-methylethyl)-podocarpa-8,11,13-triene*), mp 108−111°C (from ether−hexane); $[\alpha]_D^{26}$ +209° ($CHCl_3$): uv: 274 (3.92) and 314 (3.46) nm; ir: 3500 and 1680 cm^{-1}; ^{1}H nmr δ: 0.94, 0.98, and 1.33 (3s, Me-C), 1.28 (d, J = 7 Hz, Me-CH), 1.82 (dd, J = 11 and 7 Hz, C5-H), 2.32 (m, 1H, CH_2O*H*, D_2O), 2.48 (dd, J = 18 and 11 Hz, C6-H), 2.71 (dd, J = 18 and 7 Hz, C6-H), 3.56 (m, C15-H), 3.67−3.94 (m, 2H, C*H*$_2$OH), 3.75, 3.78, and 3.84 (3s, OMe at C14, 12, and 11 resp.); ^{13}Cmr, see Table 1; mass spectra m/e: 390 (M^+, very weak), 357, and 342. The molecular ion was too weak for an *Exact Mass* determination.

Oxidation to the enolic α-diketone **24**a *(coleon C trimethyl ether)*

The ketone **23***a* (400 mg) in *tert*-butanol (20 mL) was added to the solution obtained by dissolving potassium (1.5 g) in *tert*-butanol (40 mL). The mixture was stirred vigorously at room temperature in an atmosphere of oxygen for 2 h, after which water (50 mL) containing concentrated hydrochloric acid (4 mL) was added and the product extracted into chloroform. Silica gel chromatography using hexane – ethyl acetate 7:3 as eluant afforded first the enolic α-diketone **25** (130 mg: 26%; *4-oxo-5-hydroxy-1(*R*),6,6,9a(*S*)-tetramethyl-1,2,4,-6,7,8,9,9a-octahydrophenanthro[1,2-*b*]furan*), pale yellow needles, mp 180–183°C (from hexane); $[\alpha]_D^{22}$ +51° ($CHCl_3$); uv: 320 (sh 4.03), 254 (4.08), 277 (3.91), 309 (3.71), and 362 (4.00) nm; ir: 3300, 1615, and 1585 cm^{-1}; ^{1}H nmr δ: 1.35 (d, J = 7 Hz, Me-CH), 1.45 (s, 6H, Me-C at C4), 1.64 (s, Me-C at C10), 2.63–3.08 (m, 2H, C1-H), 3.66 (m, C15-H), 3.87 and 3.94 (2s, OMe), 4.34 (dd, J = 9 and 6 Hz, C16-H), 4.86 (dd, J = 9 and 8.5 Hz, C16-H), and 7.33 (OH, D_2O); ^{13}Cmr, see Table 1; mass spectra *m/e*: 372 (M^+), 357, 341, 329, and 303. *Anal.* calcd. for $C_{22}H_{28}O_5$: C 70.94, H 7.58; found: C 70.98, H 7.60. The second product was the major component, enolic α-diketone **24***a* (203 mg: 49%; *7-oxo-11,12,14-trimethoxy-6-hydroxy-13-(2-hydroxy-1(*R*)-methylethyl)podocarpa-5,8,11,13-tetraene*), pale yellow needles, mp 145–148°C (from hexane); $[\alpha]_D^{26}$ +79° ($CHCl_3$); uv: 247 (3.82), 278 (3.80), and 334 (3.79) nm; ir: 3500, 3380, 1630, and 1575 cm^{-1}; ^{1}H nmr δ: 1.32 (d, J = 7 Hz, Me-CH), 1.44, 1.47, and 1.64 (3s, Me-C), 2.67–3.06 (m, 2H, C1-H), 3.57 (m, C15-H), 3.67–4.01 (m, 2H, C*H*$_2$OH), 3.78 (s, OMe at C14), 3.88 (s, 6H, OMe at C11 and C12), and 7.42 (s, OH, D_2O); ^{13}Cmr, see Table 1; mass spectra *m/e*: 404 (M^+), 389, 374, 372, 361, 357, and 341. *Anal.* calcd. for $C_{23}H_{32}O_6$: C 68.29, H 7.97, O 23.74; found: C 67.90, H 8.11, O 24.08.

Coleon C tetramethyl ether (methylation of **24**a*)*

To the enol **24***a* (90 mg) in ethanol (15 mL) and water (15 mL) was added aqueous sodium hydroxide (10 mL of 30%). After stirring for 30 min at room temperature, dimethyl sulfate (6 mL) was introduced and the mixture was stirred for 36 h. After diluting with water and extraction, the crude material was chromatographed (silica gel; hexane – ethyl acetate 7:3) affording the crystalline tetramethyl ether **24***b* (65 mg: 70%; *7-oxo-6,11,12,14-tetramethoxy-13-(2-hydroxy-1(*R*)-methylethyl)podocarpa-5,8,11,13-tetraene*), colorless needles, mp 162–164°C (from hexane); uv: 248 (sh 3.82), 274 (3.78), 300 (3.74), and 331 (3.59) nm; ir: 3440, 1658, and 1620 cm^{-1}; ^{1}H nmr δ: 1.33 (d, J = 7 Hz, Me-CH), 1.42 (s, 6H, Me-C both at C4), 1.63 (s, Me-C at C10), 1.95 (br s, OH, D_2O), 2.61–3.01 (m, 2H, C1-H), 3.51 (m, C15-H), 3.67–3.94 (m, 2H, C*H*$_2$OH), 3.71, 3.72, 3.78, and 3.79 (4s, OMe at C6, 14, 12, and 11 resp.); mass spectra *m/e*: 418 (M^+), 404, 403, 386, 371, 355, 343, and 317. *Anal.* calcd. for $C_{24}H_{34}O_6$: C 68.87, H 8.19; found: C 69.01, H 8.14.

Ketone **23**b *(hydrolysis of ester* **21**a *and cyclization of acid* **21**b*)*

To the ester **21***a* (350 mg) in methanol (10 mL) was added aqueous sodium hydroxide (10 mL of 10%) and the mixture was refluxed for 24 h. Normal extractive isolation afforded an acid fraction (340 mg) which was chromatographed (silica gel; hexane – ethyl acetate 7:3) to give the acid **21***b* (304 mg: 89%); ir: broad acid trough, 1710 cm^{-1}; ^{1}H nmr δ: 0.89, 0.98, and 1.31 (3s, Me-C), 1.29 (d, J = 7 Hz, Me-CH), 2.03, 2.27, and 2.83 (3dd, similar to ester **21***a*, C5-H and C6-H), 3.33, 3.72 (6H), and 3.89 (3s, four OMe), 6.55 (s, arom H), and 10.03 (COOH, D_2O); ^{13}Cmr, see Table 1.

The acid **21***b* (200 mg from above without further purification) was taken up in trifluoroacetic anhydride (5 mL) and stirred at room temperature for 20 h. The enol trifluoroacetate intermediate was dissolved in methanol (40 mL) and hydrolysed by stirring for 1 h at room temperature after adding aqueous potassium hydroxide (4 mL of 10%). Dry col chrom of the extracted neutral fraction gave the ketone **23***b* (145 mg: 70%; *7-oxo-11,12,14-trimethoxy-13-(2-methoxy-1(*R*)-methylethyl)podocarpa-8,11,13-triene*), mp 72–75°C (from hexane), $[\alpha]_D^{25}$ +193° ($CHCl_3$); uv: 215 (4.25), 274 (3.91), and 314 (3.47) nm; ir: 1680 cm^{-1}; ^{1}H nmr δ: 0.93, 0.97, and 1.32 (3s, Me-C), 1.28 (d, J = 7 Hz, Me-CH), 1.81 (dd, J = 11 and 7 Hz, C5-H), 2.47 (dd, J = 18 and 11 Hz, C6-H), 2.69 (dd, J = 18 and 7 Hz, C6-H), 3.32, 3.75, 3.76, and 3.82 (4s, OMe at C16, 14, 12, and 11 resp.); ^{13}Cmr, see Table 1; mass spectra *m/e*: 404, 389, 373, 373, 359, and 344. *Exact Mass* (M^+) calcd. for $C_{24}H_{36}O_5$: 404.2564; found (high resolution ms): 404.2572.

Ketone **26** *(hydrolysis of ester* **22**a *and cyclization of acid* **22**b*)*

The ester **22***a* (70 mg) was hydrolysed by refluxing in methanol (10 mL) containing aqueous sodium hydroxide (10 mL of 10%) for 20 h. Most of the methanol was evaporated and the acid fraction obtained by extraction was purified by dry col chrom. The acid **22***b* (^{1}H nmr δ: 0.87, 0.97, and 1.24 (3s, Me-C), 1.31 (d, J = 7 Hz, Me-CH), 1.98 (dd, J = 17 and 5.5 Hz, C6-H), 2.24 (dd, J = 17 and 7 Hz, C6-H), 2.89 (dd, J = 7 and 5.5 Hz, C5-H), 3.59 (m, C15-H), 3.79 and 3.89 (2s, OMe), 4.01 (dd, J = 8.5 and 6.5 Hz, C16-H), 4.57 (dd, J = 9 and 8.5 Hz, C16-H), 6.47 (s, arom H), and 10.14 (COOH, D_2O)) was used as such for the cyclization, accomplished by stirring in trifluoroacetic anhydride (4.0 mL) for 20 h. The initial product was then hydrolysed (40 mL methanol, 4 mL aqueous potassium hydroxide 10%, 1 h) and the extracted neutral fraction was then chromatographed over silica gel (hexane – ethyl acetate 7:3) affording the glassy ketone **26** (36 mg: 54%; *4-oxo-10,11-dimethoxy-1(*R*),6,6,9a(*S*)-tetramethyl-1,2,4,5,5a(*R*),6,7,8,9,9a-decahydrophenanthro[1,2-*b*]furan*); uv: 226 (4.09), 235 (sh 4.09), 270 (3.85), and 335 (3.57) nm; ir: 1675 cm^{-1}; ^{1}H nmr δ: 0.92, 0.96, and 1.26 (3s, Me-C), 1.32 (d, J = 6.5 Hz, Me-CH), 1.79 (dd, J = 10.5 and 6.5 Hz, C5-H), 2.46 (dd, J = 17 and 10.5 Hz, C6-H), 2.67 (dd, J = 17 and 6.5 Hz, C6-H), 3.59 (m, C15-H), 3.75 and 3.90 (2s, OMe at C12 and C11 resp.), 4.24 (dd, J = 9 and 6 Hz, C16-H), and 4.79 (dd, J = 9 and 9 Hz, C16-H); mass spectra *m/e*: 358, 342, 301, 273, 261, and 247. *Exact Mass* (M^+) calcd. for $C_{22}H_{30}O_4$: 358.2145; found (high resolution ms): 358.2124.

Received November 24, 1984

JAY E. TAYLOR and RENÉE GREEN. Can. J. Chem. **63**, 2777 (1985).

Good yields of *cis*-1,2-cyclohexanediol were formed by the reaction of cyclohexene and aqueous potassium permanganate under turbulent stirring conditions only in the presence of low concentrations of sodium hydroxide. Larger amounts had no further benefit or were deleterious. The lack of sensitivity to low concentrations of hydroxide ion indicated that its benefit is to inhibit acid promoted oxidations. There was no indication of its participation in the mechanism of glycol formation. The addition of the neutral salts, sodium sulfate or sodium nitrate, caused a decrease in glycol yields presumably due to a positive salt effect on a secondary negative ion − negative ion reaction, which formed other oxidation products. Stoichiometric amounts of hydroxide and potassium ions were not isolated as reaction products due to interaction with the hydrated manganese dioxide in a 1:2 ratio. The mechanisms in acidic and basic solutions appear to be quite different. A mechanism for basic solutions is suggested.

JAY E. TAYLOR et RENÉE GREEN. Can. J. Chem. **63**, 2777 (1985).

Il se forme de bons rendements de cyclohexanediol-1,2-*cis* lors de la réaction du cyclohexène et du permanganate de potassium, soumis à une agitation tumultueuse et seulement en présence de faibles concentrations d'hydroxyde de sodium. Des concentrations plus fortes d'hydroxyde n'améliorent pas la réaction; elles peuvent même avoir un effet contraire. Le manque de sensibilité à la présence de faibles concentrations d'ions hydroxydes indique que ces derniers inhibent les oxydations favorisées par les milieux acides. On n'a aucune preuve de leur participtation au mécanisme de formation du glycol. L'addition de sels neutres, comme le sulfate de sodium ou le nitrate de sodium, provoque une diminution du rendement en glycol et cet effet est probablement causé par un effet de sel positif sur une réaction secondaire entre ions négatifs qui forme d'autres produits d'oxydation. À cause de l'interaction avec le dioxyde de manganèse hydraté, dans un rapport de 1:2, on n'a pas isolé des produits de la réaction des quantités stoechiométriques d'ions potassium et hydroxyde. Les mécanismes de réaction en solutions acide et basique semblent être très différents. On suggère un mécanisme pour les réactions en solutions basiques.

[Traduit par le journal]

Introduction

Aqueous potassium permanganate reacts with cyclohexene to form a variety of products including *cis*-1,2-cyclohexanediol. The yield of the latter product is markedly enhanced by turbulent stirring (1). A study has been made of conditions which influence this reaction (2). This study is continued in this paper.

Experimental

Procedure I

Potassium permanganate, 7.780 g (0.0492 *m*), was dissolved in 450 mL water, and this solution was added concurrently with 50 mL methanol over a period of 1 h to a turbulently stirred slurry (2) of 5.00 mL (0.0492 *m*) cyclohexene at 20°C, 180 mL of dilute sodium or potassium hydroxide, as indicated, and 20 mL methanol. After treatment with sulfur dioxide to remove the manganese dioxide and sodium bicarbonate (~pH 8), the glycol was extracted continuously with dichloromethane[1] for 2−3 days. This solution was concentrated to ~6 mL/g glycol and then was allowed to crystallize in an ice chest, giving the primary glycol yield. A secondary crop of crystals of lower purity was obtained by concentrating this solution. The apparatus and product isolation techniques employed have been previously described (2) as procedure A.

Procedure II

The procedure was the same as the above except that the sodium hydroxide was included with the permanganate solution instead of with the cyclohexene.

[1]After working intermittently with this solvent for several years, the major author developed, quite suddenly, a highly specific pulmonary sensitivity to the vapor of dichloromethane. No other complications have been observed. Due care in handling this solvent is therefore strongly recommended.

Hydroxide ion determination

After addition of potassium permanganate as described, the total reaction mixture was treated with Celite filter aid, filtered twice, and then titrated with 1.101 *N* sulfuric acid, phenolphthalein indicator.

Potassium ion determination

The above solution was diluted to 1 L and made slightly acidic with sulfuric acid. A 20.0-mL aliquot was removed and an excess of ammonium hydroxide added. The potassium ion was determined as potassium sulfate (3).

Manganese dioxide determination

For each determination the indicated amount of standardized potassium permanganate was added, as in Procedure I. This was followed by a weighed excess of ferrous ammonium sulfate, 10 mL of phosphoric acid, and 45 mL of 10% sulfuric acid. The excess ferrous ion was titrated with 0.1 *N* $K_2Cr_2O_7$ using barium diphenylamine sulfonate indicator. Both the $KMnO_4$ and $K_2Cr_2O_7$ solutions were standardized against the ferrous ammonium sulfate.

Results and discussion

The effects of varying hydroxide ion and inert salt concentrations upon *cis*-glycol yields have been determined for the turbulently stirred reaction of cyclohexene with potassium permanganate. Also, a disappearance of potassium and hydroxide ions from solution has been noted.

Effect of added hydroxide ion

That hydroxide ion is essential to the formation of the *cis*-glycol has been clearly demonstrated (1), and further evidence is seen in comparing experiment 1, Table 1, with the remainder of the table. Essentially no product glycol was isolated under slightly acid conditions, and it seems unlikely that it was first formed and then further oxidized since the rate of oxidation of the *cis*-glycol by permanganate is low in mildly acid solutions.

TABLE 1. Effects of varied hydroxide ion concentrations on yields of *cis*-1,2-cyclohexanediol

1.5 m/L			0.453	85–88	

[a]Procedure I was followed in all experiments. The indicated molarity of salt was maintained during the reaction by adding the appropriate amount of specified salt to both the permanganate solution and cyclohexene slurry. The methanol was included as part of the total volume. Sodium hydroxide, 0.01 m, was added in each case.

[b]The dual entries are the primary and secondary glycol yields whose relative purities are indicated by the corresponding melting points. The major impurity appeared to be *trans*-1,2-cyclohexanediol.

The effects of adding varying amounts of hydroxide ion are shown in Table 1. As seen in comparing experiments 3 with 4 or 7 with 8, doubling the hydroxide ion concentration had no significant effect on glycol yields. Even with no added hydroxide, experiment 2, the hydroxide ion which formed as a reaction product provided the needed basicity except at the start of the reaction, and, as a result, the overall yields were but slightly lowered.

For those experiments in which the sodium or potassium hydroxide was added with the potassium permanganate by Procedure II, roughly the same yields were obtained with 0, 0.005 m, or 0.010 m of hydroxide, and these yields were lower than those with 0.005 m or 0.010 m added as in Procedure I. See experiments 2, 7, 8, Table 1, and compare with experiments 3 and 4. These lowered yields again resulted from low hydroxide concentrations at the outset of the reactions.

From these observations, it is concluded that the function of added hydroxide ion was to provide a basic medium to minimize any acid promoted reactions, and that the hydroxide ion had no function in the mechanism of glycol formation, in contrast to a previous suggestion (4). Wiberg and Geer (5) had noted much earlier that these reactions are independent of concentration of base.

A large excess of hydroxide ion was deleterious to glycol formation, as seen in experiments 5 and 6, Table 1, where the yields were lowered to 72 and 56% by the presence of 0.05 m and 0.10 m, respectively, of sodium hydroxide in the reaction flask. Adding the same amount of sodium hydroxide to the potassium permanganate solution had a lesser effect since the basicity was more gradually introduced into the reaction. Compare experiments 4 and 5 with 9 and 10. The stronger base caused a decrease in yields, it appears, as a result of base promotion of the reaction, $Q^- + MnO_4^-$ or glycol + MnO_4^-. In support of the latter, it has been observed that the *cis*-glycol is more rapidly oxidized by permanganate ion in the presence of the higher hydroxide ion concentrations.

Inert salt effect

The following mechanism has been proposed for glycol formation (2):

[1] $C_6H_{10} + MnO_4^- \rightarrow Q^-$

[2] $Q^- + H_2O \rightarrow C_6H_{10}(OH)_2 + MnO_3^-$

In the presence of localized excesses of permanganate ion, adipic acid and other oxidation products may be formed.

[3] $Q^- + MnO_4^- \rightarrow$ various oxidation products $+ MnO_2$

Reaction [3] is clearly a negative ion – negative ion reaction and should show a rate increase in the presence of neutral salts, as predicted by the Bronsted, Bjerrum, Christiansen, Scatchard relationship (6). If mechanism [1]–[3] is operative, addition of inert salts should enhance reaction [3] at the expense of reaction [2] since the latter is an ion–dipole reaction with a rather small salt effect. Added salts should then cause a decrease in glycol yields. As seen in Table 2, this was definitely found to be the case, and these data thereby provide support for the above proposal. The salt effect data were repeated under the condi-

TABLE 3. Demonstration of the constancy of potassium and hydroxide ion absorption with varied potassium hydroxide additions

[a]Procedure I.
[b]Procedure II.
[c]$KMnO_4 = C_6H_{10} = 0.0492$ m, 10% methanol, no sulfur dioxide was added, K^+ and OH^- analyses were done as described.
[d]The molarity of added KOH is subtracted from both the total K^+ and total OH^- concentrations as determined by analysis.
[e]The values in column 2 are subtracted from the predicted value of OH^- = 0.328 m.
[f]The values in column 3 are subtracted from the predicted value of K^+ = 0.0492 m.

tions 0.0492 and 0.0985 m of added permanganate using equal amounts of cyclohexene, and with 10 and 25% methanol.

It is emphasized that these salt effect studies are not an absolute proof of the existence of the mechanism because of the inherent complexity of the system. The potassium permanganate solution was added dropwise and reacted very rapidly; therefore, excess amounts of permanganate ion exist only momentarily and in localized areas. The concentration of the intermediate Q^- must have been similarly highly variant. Under turbulent stirring conditions it was obvious that reaction [2] strongly predominated over reaction [3]. Thus, a large increase in rate of reaction [3] would have had but a modest effect on the observed yields. Accordingly, the salt effect data can be interpreted only qualitatively.

Manganese dioxide analysis

Although it has been commonly assumed from earlier evidence that manganese dioxide was the final reduction product of the permanganate ion, it was decided to verify that assumption for this particular reaction. This was accomplished by titrating the total manganese oxide residue resulting from the reduction of a given volume of standardized potassium permanganate. Several methods of assay were tried. The first was sulfur dioxide using a gas buret and an oxygen-free atmosphere. The advantage was rapidity of reaction in a low acid medium. Since two products of oxidation, SO_4^{2-} and $S_2O_6^{2-}$, were formed indiscriminately, the procedure was unduly complicated and therefore rejected. Better success was obtained using the ferrous ammonium sulfate – potassium chromate procedure in the absence of methanol. An equivalent result was also obtained with an arsenic trioxide – potassium iodide procedure (not described) which was usable in the presence of methanol.

Titrations of 0.00525 m, 0.0105 m, 0.01575 m, 0.01969 m of $KMnO_4$ which had reacted in each case with 0.0263 m cyclohexene, gave respectively MnO_x analyses where x = 1.97, 1.98, 1.98, 1.99. These runs were made without added methanol using aliquot volumes of 0.0525 m/L $KMnO_4$ solution added to 200-mL volume slurries of the cyclohexene. A corresponding experiment with 0.00525 m $KMnO_4$ and 25% methanol gave x = 1.98. Thus the MnO_2 end product was substantiated with small deviations. The significance of the 0.01–0.03 unit variance from MnO_2 is not known. Note, however, that lower values were obtained with the greater C_6H_{10}/MnO_4^- ratios. The analytical procedure was accurate to ±0.2% or better. Narita and Okabe (7) have noted a similar variation in manganese dioxide analyses at pH ≥ 8.

Hydroxide ion product

The stoichiometric equations for the formation of the glycol and adipic acid are as follows.

$$[4] \quad 3C_6H_{10} + 2MnO_4^- + 4H_2O \rightarrow 2MnO_2 + 3C_6H_{10}(OH)_2 + 2OH^-$$

$$[5] \quad 3C_6H_{10} + 8MnO_4^- \rightarrow 8MnO_2 + 3C_4H_8(CO_2)_2^{2-} + 2OH^- + 2H_2O$$

Thus hydroxide ion is formed in equimolar amounts from permanganate ion with eq. [4]. In eq. [5] there is hydroxide ion formation equivalent to glycol formation (as in eq. [4]), but, beyond this, carboxyl ion is formed in place of hydroxyl ion. Along with adipic acid by eq. [5], a variety of unidentified products of intermediate oxidation states were formed, thereby complicating interpretation of the mechanism.

Let us assume a typical yield of 83% glycol. By eqs. [4] and [5], 2 m OH^- result from 3 m cyclohexene. Thus upon assuming 100% consumption of the cyclohexene with adipic acid as the exclusive by-product, $2/3 \times 0.0492 = 0.0328$ m OH^- formed. Referring to Table 3 it is seen that only about one-fourth of this amount of hydroxide ion is titrable in a filtered solution. The decrease of the hydroxide ion prompted the analyses for potassium ion. The presence or absence of potassium ion would indicate if the hydroxide was not formed or if it was initially formed and removed from solution. The potassium ion added for each experiment in Table 3 was 0.0492 m, but it is seen that only about one-half this amount is in evidence. Thus the hydroxide ions were formed and then removed along with potassium ions.

Since ideally 0.0328 m OH^- and 0.0492 m K^+ should be products, the difference is 0.0164 m. Fortuitously, this same value is approximated upon subtracting column 2 from column 3, Table 3. However, an analysis was made for adipic acid in a high yield reaction. The aqueous solution was acidified after extraction of the glycol, and this solution was extracted with ether. The adipic acid was indicated to be in the range of 6–7%. This is reasonable since other nonionic products were formed. With the low adipic acid analysis (compared to that projected above) there should be a correspondingly greater hydroxide ion analysis. That this was not the case may be attributed to incomplete reaction of the cyclohexene and formation of not otherwise identified acidic products, e.g., carbon dioxide from methanol, etc.

The disappearance of the potassium hydroxide requires special consideration. The only substance with which it can react is the hydrated manganese dioxide. The data in Table 3 show a very interesting consistency. In columns 3 and 4, Table 3, the amounts of OH^- and K^+ absorbed are listed. Allowing for experimental error and uncertainty in the 0.0328 m value projected for the hydroxide ion, the values of OH^- and K^+ absorbed are closely equal and, of even greater significance, are roughly one-half the final concentration (0.0492 m) of hydrated manganese dioxide. This 2:1 relationship holds even in the presence of excess potassium hydroxide. See experiments 2–5 as compared with 1.

An attempt was made to estimate the amount of absorbed hydroxide ion, by titrating the unfiltered slurry of product manganese dioxide with 1 *N* sulfuric acid. There was only a slight increase in titre over the filtered solution, and the pH-meter end point drifted very slowly. Thus the KOH appeared to be tightly bound.

Based on these evidences, the following is suggested.

[6] $KOH \cdot 2MnO_2 \cdot xH_2O$

The existence of a potassium manganite has been long recognized (8). A very careful structural study of the $KOH-MnO_2$ interaction has been made by Narita and Okabe (7) who have noted that at pH ≥ 8 amorphous ternary compounds of Mn(IV) oxide with an approximate composition of $K_2O \cdot 4MnO_x \cdot 4H_2O$ (x = 1.97–2.00) were formed by reduction of MnO_4^- or MnO_4^{2-}. The results in Table 3 and the manganese dioxide analyses thereby completely support the earlier conclusions of Narita and Okabe. Assuming the four H_2O molecules of their formula are chemically bound, a linear four-Mn unit is suggested. Such a structure is difficult to rationalize. With small variations in the numbers of bound water the structure could be represented with only two Mn per unit or alternatively, as more complex polymeric or cyclic units. In view of these uncertainties, formula [6] is used in the discussion to follow.

Proposed mechanism

Based on the above and earlier observations, a summarizing mechanism is proposed for the oxidation of cyclohexene by potassium permanganate.

Quite clearly, the acid and basic (OH^-) mechanisms for this reaction are quite different. There may be the common factor of an intermediate complex (4) but, beyond this stage, there appears to be no mechanistic similarity between an acidic or basic environment.

For the following mechanism, manganese dioxide is written as the potassium hydroxide adduct and 1,2-cyclohexanedione is suggested as a secondary oxidation intermediate. It has been observed that upon acidifying the post-glycol extraction solution, permanganate oxidizable substances (other than sulfur dioxide) are present in small amounts. Also the dione is base sensitive and a reaction with OH^- may account for the small amounts of unidentified neutral residues which invariably form.

The following proposal applies only in a basic medium.

[7] 
[8] 
[9] $3MnO_3^- + K^+ + (x + 1)H_2O \rightarrow MnO_4^- + KOH \cdot 2MnO_2 \cdot xH_2O + OH^-$

FRANCIS MICHON, JEAN ROBERT BRISSON, RENÉ ROY, HAROLD J. JENNINGS, and FRASER E. ASHTON. Can. J. Chem. **63**, 2781 (1985).

The capsular polysaccharide antigen of *Neisseria meningitidis* group K was isolated by Cetavlon precipitation and purified by ion-exchange chromatography. The structure of the K polysaccharide was determined to a large extent by comprehensive proton and carbon-13 nuclear magnetic resonance (nmr) studies. In these studies one-dimensional and two-dimensional experiments were carried out directly on the K polysaccharide. The K polysaccharide is composed of the following repeating unit: -4)β-D-Man*p*NAcA(1→3) [4-OAc]β-D-Man*p*NAcA(1→. Except for the one-bond couplings between their anomeric carbons and protons ($^1J_{^{13}\mathrm{C,H}}$), all the nmr spectroscopic evidence was consistent with both 2-acetamido-2-deoxy-D-mannopyranosyluronic acid residues adopting the $^4C_1$ (D) conformation and having the β-D-configuration. This ambiguity in $^1J_{^{13}\mathrm{C,H}}$ is probably due to through-space electronic effects generated by the presence of contiguous carboxylated sugar residues in the K polysaccharide. The *O*-acetyl substituents of the K polysaccharide are essential for its antigenicity to group K polysaccharide-specific antibodies.

FRANCIS MICHON, JEAN ROBERT BRISSON, RENÉ ROY, HAROLD J. JENNINGS et FRASER E. ASHTON. Can. J. Chem. **63**, 2781 (1985).

Faisant appel à une précipitation de Cétavlon, on a isolé le polysaccharide capsulaire antigène du groupe K du *Neisseria meningitidis* et on l'a purifié par passage sur une colonne échangeuse d'ions. En se basant principalement sur des études de rmn du ^{1}H et du ^{13}C, on a déterminé la structure du polysaccharide K. Au cours de ces études, on a réalisé des expériences en une et en deux dimensions directement sur le polysaccharide K. L'unité de base du polysaccharide K est la suivante: -4)β-D-Man*p*NAcA(1→3) [OAc-4]β-D-Man*p*NAcA(1→. À l'exception de couplages à travers une liaison entre les carbones et les protons anomères ($^1J_{^{13}\mathrm{C,H}}$), toutes les données spectroscopiques sont en accord avec le fait que les deux résidus d'acide acétamido-2 déoxy-2 D-mannopyrannosyluronique adoptent la conformation $^4C_1$ (D) et ont une configuration β-D. Cette ambiguité relative à la constante de couplage $^1J_{^{13}\mathrm{C,H}}$ est due probablement à des effets électroniques, à travers l'espace, engendrés par la présence contigue de résidus de sucres carboxylés dans le polysaccharide K. Les substituants *O*-acétylés du polysaccharide K sont indispensables pour assurer son comportement antigène envers les anticorps spécifiques du polysaccharide K.

[Traduit par le journal]

Introduction

Neisseria meningitidis is a Gram-negative organism that has been classified serologically (1–3) into groups A, B, C, D, 29E, L, W-135, X, Y, and Z. Except for group D, each group produces a unique capsular polysaccharide that is the antigen responsible for group specificity (1–3), and the structures of all the polysaccharides have been determined (2, 4). In 1981 Ding *et al.* (5) described three new meningococcal groups and designated them groups H, I, and K. The structure of the H polysaccharide has been recently reported (6, 7). As a continuation of our structural studies on the meningococcal polysaccharides we now report the structure of the K polysaccharide. The structure of the I polysaccharide has been reported elsewhere (8).

Nuclear magnetic resonance spectroscopy has played an increasingly important role in the structural elucidation of the meningococcal polysaccharides (2, 3, 6, 7), and the utility of this technique has been further demonstrated in the structural elucidation of the I (8) and K polysaccharides, where a number of one-dimensional, two-dimensional, and nuclear Overhauser enhancement (nOe) techniques were employed. Although two-dimensional techniques (9) have been used frequently on oligosaccharides since their introduction in 1982 (10–12), examples of the direct application of these techniques to polysaccharides are few (13).

Unlike the other meningococcal polysaccharides, the I (8) and K polysaccharides cross-react serologically to a certain extent. This cross-reaction is probably associated with their common 4-*O*-acetyl-2-acetamido-2-deoxy-β-D-mannopyranosyluronic acid residue.

Experimental

Materials

The *Neisseria meningitidis* strain 1811 (K) was obtained from Dr. Shao-quing Ding, National Institute for the Control of Pharmaceutical and Biological Products, Beijing, China, and was grown in a chemically defined medium (14). The capsular polysaccharide was isolated and partially purified as previously described (14) using an initial Cetavlon precipitation to obtain the crude polysaccharide. Purification of the K polysaccharide was achieved by its application to a column of DEAE-Sephadex A-25 (Cl-form, Pharmacia Fine Chemicals) in 0.01 *M* Tris–HCl buffer at pH 7.4 and the development of the column with a linear gradient of NaCl to 0.5 *M*. The polysaccharide was detected by Ouchterlony immunodiffusion using antisera to the K polysaccharide that were prepared by injecting whole group K organisms in rabbits as previously described (15). Using this assay it was shown that the K polysaccharide eluted as a single peak with approximately 0.3 *M* NaCl. The K polysaccharide had $[\alpha]_D$ −68° (*c* 0.25, in water).

[1] NRCC No. 24632.

The de-*O*-acetylated K polysaccharide was obtained by treatment of the native K polysaccharide with 0.1 *M* NaOH solution at 25°C for 16 h with subsequent neutralization, dialysis, and lyophilization of the solution. Carboxyl-reduced K polysaccharide was obtained using the method of Taylor and Conrad (16), in which sodium borohydride was added to its carbodiimide complex at pH 7.0. Two treatments were necessary in order to achieve complete reduction.

Instrumental methods

Solutions were concentrated in a rotary evaporator under reduced pressure below 40°C. Optical rotations were determined on a Perkin–Elmer 243 instrument with 1-dm semi-micro cells at 23 ± 1°C.

Gas–liquid chromatography (glc) was performed on a Hewlett–Packard 5710A instrument equipped with a flame ionization detector and a model 3380A electronic integrator using the following columns: (i) glass column (180 × 0.15 cm) containing 3% SP2340 on Supelcoport (80–100 mesh) operated at 180°C (delay 2 min) to 240°C at 4°C/min; and (ii) fused silica capillary column (0.32 mm × 25 m) containing 3% OV17 operated at 180°C to 230°C at 2°C/min and held for 10 min at 230°C. Combined gas–liquid chromatography – mass spectrometry (glc–ms) was performed on a Hewlett–Packard 5985B instrument using the above columns and an ionization potential of 70 eV.

The ^{13}C and ^{1}H nmr spectra were recorded on a Bruker AM-500 spectrometer. Acetone was used as the internal chemical shift reference for ^{1}H nmr (2.225 ppm) and dioxan was used as the external chemical shift reference for ^{13}C nmr (67.4 ppm). Polysaccharides were exchanged twice with D_2O and then run in 0.4 mL D_2O (5-mm tubes) at a concentration of 60 mg/mL.

Proton homonuclear shift correlated 2-D nmr experiments (H, H COSY) and proton dipolar correlation 2-D nmr experiments (NOESY) were performed using the standard 90–t_1–90 pulse sequence and the 90–t_1–90–τ–90 pulse sequence, respectively; a mixing time of 100 ms was used. Quadrature detection in both dimensions was employed. All phase cyclings were according to the standard software provided by Bruker (DISNMRP 840301.1). The initial (t_1, t_2) matrices were 64 × 512 data points with 4 Hz/pt digital resolution in the second domain. Data points in both dimensions were weighted by unshifted sine bell functions prior to Fourier transformation. The final (f_1, f_2) matrix was zero filled to 512 × 512 points. Magnitude spectra, which are symmetrized about the diagonal, were used to represent the data.

The ^{13}C–H shift correlation with proton decoupling in the F_1 domain was done according to Bax (17). The initial ($\mathbf{t}_1$, $\mathbf{t}_2$) matrix of 64 × 1024 points was Fourier transformed to a final matrix of 256 × 1024 points corresponding to a digital resolution of 23 Hz/pt in the F_2 domain and 15 Hz/pt in the F_1 domain. Gaussian weighting functions were used in both domains and a power spectra representation of the data points was used.

Analytical methods

Paper chromatography was carried out by the descending method using ethyl acetate – pyridine–water (5:2:5, v/v top layer) and *n*-butanol – pyridine–water (6:4:3, v/v) as eluants. Thin-layer chromatography (tlc) was performed on precoated tlc plates using ethyl acetate – pyridine – acetic acid – water (5:5:1:3, v/v) as ascending eluants. Compounds were visualized after spraying the plates with ninhydrin (amino sugars) or alkaline silver nitrate and *p*-anisidine reagents (pentoses).

Mannosamine was detected in the hydrolyzates of the carboxyl-reduced K polysaccharide either directly using a Technicon autoanalyzer, or by the identification of the products of its deamination (18) or ninhydrin degradation (19). For the purpose of deamination the K polysaccharide was first carboxyl-reduced, using sodium borodeuteride, before being hydrolyzed (2 *N* HCl for 90 min at 100°C), until complete de-*N*-acetylation had occurred. Following deamination and conversion to alditol acetates (20) the sugars were identified by glc–ms using column (i).

In preparation for ninhydrin degradation, the carboxyl-reduced K polysaccharide was first depolymerized with anhydrous HF for 16 h at 25°C and the free hexosamine generated by treating the depolymerized product with 1 *N* HCl at 100°C for 3 h. Following ninhydrin degradation of the hexosamine the derived pentose was identified by paper chromatography, and by glc–ms of its alditol acetate derivative using column (i).

Methylation analysis

The carboxyl-reduced K polysaccharide was methylated with methyl iodide in the presence of methyl sulfinyl anion according to the method of Hakomori (21). The methylated product was then purified on a small LH-20 column (10 cm × 0.5 cm) using chloroform as the eluant. The fractions were monitored by spotting the eluant on silica gel tlc plates, spraying the plates with 10% H_2SO_4 in ethanol, and charring the plates in an oven for 5 min at 130°C. The methylated polysaccharide was then hydrolyzed with 1 *M* trifluoroacetic acid for 16 h at 105°C and, following evaporation of the acid, the partially methylated monomers were reduced with $NaBH_4$, acetylated, and the products analyzed by glc–ms (22) using column (ii).

Quantitative microprecipitin experiments

Quantitative microprecipitin experiments were carried out by the method of Kabat and Mayer (23) using 0.1 mL rabbit antisera to the K polysaccharide (diluted twice in PBS at pH 7.0) and 0.1 mL of antigen solution containing from 1 to 100 μg of polysaccharide. Precipitates were dissolved in 0.1 mL of 0.1 *M* sodium hydroxide and the protein content was determined by the method of Lowry *et al.* (24).

Results and discussion

Characterization of 2-acetamido-2-deoxy-D-mannuronic acid

The presence of 2-acetamido-2-deoxy-D-mannuronic acid as a constituent of the K polysaccharide was established when 2-amino-2-deoxy-mannose was identified, by amino acid analyzer, in the hydrolyzate of the carboxyl-reduced K polysaccharide. This evidence was also consistent with the identification of arabinose, the anticipated product of the ninhydrin degradation of 2-amino-2-deoxy-mannose (19), in the ninhydrin-treated hydrolyzate. Further evidence was obtained when glucose was found to be the major product of the deamination of the de-*N*-acetylated (hydrolyzed) carboxyl-reduced K polysaccharide. The identification of glucose in the above reaction and not in the hydrolyzate of the original carboxyl-reduced K polysaccharide is indicative of its precursor being 2-amino-2-deoxy-mannose residues (25).

All the above evidence indicated that 2-acetamido-2-deoxy-mannuronic acid was probably the only sugar constituent of the K polysaccharide, and this was confirmed by treatment of the K polysaccharide with anhydrous hydrogen fluoride. Evaporation of the hydrogen fluoride yielded only 2-acetamido-2-deoxy-α- and β-D-mannofuranurono-6,3-lactone, a compound readily formed from 2-acetamido-2-deoxy-D-mannuronic acid (26). In the ^{13}C nmr spectrum of the crude depolymerization product only the signals of the lactone (26) were identified. The lactone had $[\alpha]_D$ +106° (*c* 0.35, in water), close to that reported (26) for the authentic equilibrated D-form of the lactone, which again confirmed the D-configuration of the 2-acetamido-2-deoxy-mannuronic acid residues of the K polysaccharide.

Structure of the K polysaccharide

A preliminary analysis of the ^{13}C nmr spectrum of the K polysaccharide is consistent with it being composed of a mono-*O*-acetylated disaccharide repeating unit containing only *N*-acetyl hexuronic acid residues, these residues having been previously identified as 2-acetamido-2-deoxy-D-mannuronic acid, and the structure of the repeating unit is shown in Fig. 1a. In the ^{13}C nmr spectrum of the K polysaccharide two distinct anomeric carbons at 99.20 and 96.82 ppm were observed,

which were strongly indicative of a disaccharide repeating unit, and this was substantiated by the presence of only two anomeric proton signals at δ 4.91 and 4.70 in its ^1H nmr spectrum (Fig. 2). The presence of two *N*-acetyl groups could be deduced by the observation of two signals in the ^{13}C nmr spectrum of the K polysaccharide characteristic of this group at 53.50 and 51.04 ppm (C—N) and at 22.81 and 22.70 ppm (acetamido methyl groups). The signal at 21.50 ppm, which disappeared following base treatment of the K polysaccharide, could be readily assigned to the *O*-acetyl methyl groups. Consistent with the proposed repeating unit, no signals were observed in the hydroxymethyl region of the ^{13}C nmr spectrum of the K polysaccharide until, as expected, two signals at 61.4 and 61.0 ppm appeared in the ^{13}C nmr spectrum of the carboxyl-reduced K polysaccharide (Fig. 1c).

Although no monomeric *N*-acetyl-mannuronic acid units were available to assist in the assignment of the signals in the ^{13}C nmr spectrum of the de-*O*-acetylated K polysaccharide (Fig. 1b) it was possible to make an empirical assignment of the carboxyl-reduced K polysaccharide using the previously assigned (27) signals of 2-acetamido-2-deoxy-α- and β-D-mannopyranose for reference. However, due to the mixed linkages in the polysaccharide this proved to be unsatisfactory, resulting in potentially ambiguous assignments. Because these assignments were crucial to the structural elucidation of the K polysaccharide, they were made unambiguously without model compounds using a number of two-dimensional nmr techniques. This type of analysis is now routinely used for the assignment of oligosaccharide nmr signals, but only one report of its direct application to polysaccharides has so far been described (13). The method chosen was to correlate the carbon spectrum of the de-*O*-acetylated K polysaccharide with its assigned proton spectrum, thus assigning the carbon spectrum indirectly.

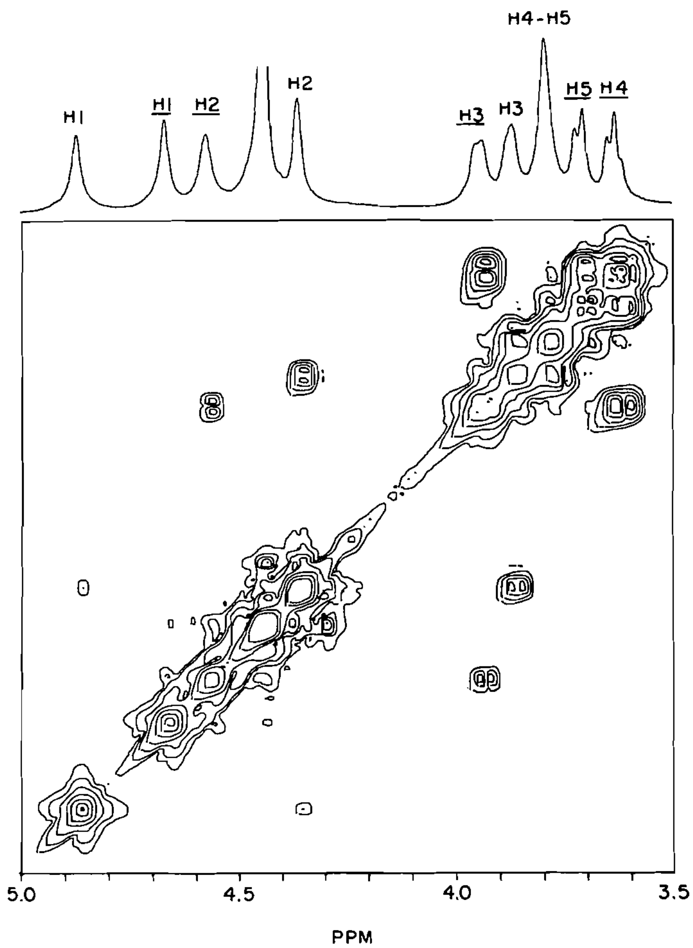

FIG. 2. Homonuclear 2-D shift correlated (H, H COSY) spectrum of the de-*O*-acetylated K polysaccharide in D_2O (330 K) with the 1-D spectrum above. The corresponding assignments for residue A and residue B (underlined) are also shown.

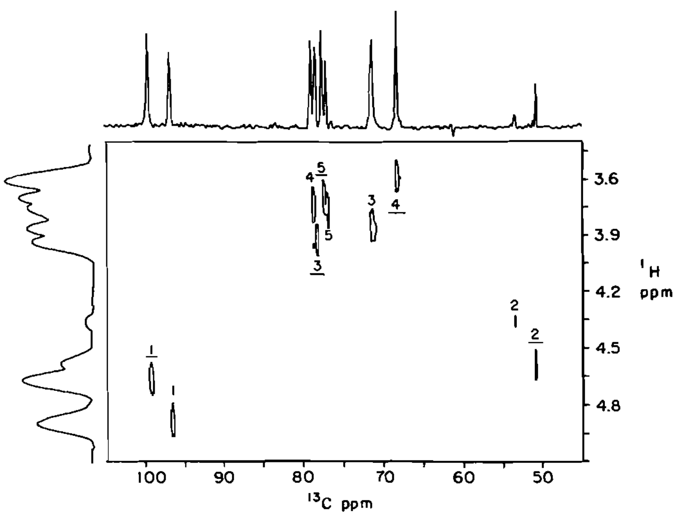

FIG. 3. Heteronuclear 2-D shift correlated (^{13}C, H COSY) spectrum of the de-*O*-acetylated K polysaccharide in D_2O (310 K) along with the f_1 and f_2 projections. The resulting assignments of the C–H correlations for residue A and residue B (underlined) are shown.

The ^{1}H nmr spectrum of the de-*O*-acetylated K polysaccharide shown in Fig. 2 was difficult to assign directly due to its complexity. Therefore a proton homonuclear shift correlated 2-D nmr (H, H COSY) experiment was performed and the spectrum is also shown in Fig. 2. As a result of this experiment it was possible to assign all the protons of both the 2-acetamido-2-deoxy-mannuronopyranosyl residues (A and B) of the repeating unit of the de-*O*-acetylated K polysaccharide (Fig. 1b). These assignments, together with some measurable coupling constants, are listed in Table 1. Using these data a heteronuclear shift correlated 2-D nmr (^{13}C, H COSY) experiment was performed and the ^{13}C–H correlation contour map is shown in Fig. 3. This experiment enabled the unambiguous assignment of all the carbons in the repeating unit of the de-*O*-acetylated K polysaccharide (Fig. 1b) to be made and they are listed in Table 2. Because of the importance of ^{13}C chemical shift data for making linkage and configurational assignments (28) on the K polysaccharide, and the lack of a suitable monomer model, the above two-dimensional experiments were also performed on the carboxyl-reduced K polysaccharide. This enabled 2-acetamido-2-deoxy-α- and β-D-mannopyranose (27) to be used as a satisfactory model for these assignments. The chemical shift data from the two-dimensional experiments are listed in Tables 1 and 2.

By studying patterns of chemical shift differences between 2-acetamido-2-deoxy-α- and β-D-mannopyranose and residues A and B of the repeating unit of the carboxyl-reduced K polysaccharide (Fig. 1c) it can be seen that regardless of anomeric configuration, although both A and B were later unambiguously assigned the β-D-configuration (*vide infra*), A is linked at *O*-4 and B at *O*-3. This is consistent with characteristic downfield displacements on C-4 of A (9.5 ppm) and C-3 of B (5.28 ppm), plus an upfield displacement on C-2 of B (4.5 ppm) (β effect), in comparison with the chemical shifts of the same carbons in the β-D-anomer of the model compound. Consistent with the above linkage assignment, both 3,6- and 4,6-di-*O*-methyl-2(*N*-methylacetamido)-2-deoxy-mannose together with their *N*-acetamido derivatives were detected (glc–ms using column (ii)) in the hydrolyzate of the methylated carboxyl-reduced K polysaccharide (Fig. 1c).

On the basis of the above chemical shift comparison it was also possible to make an assignment of the β-D-configuration to residues A and B of the carboxyl-reduced K polysaccharide (Fig. 1c), although further problems were encountered in this analysis due to substituent effects on the anomerically sensitive C5 signal of A caused by the vicinal linkage at *O*-4. However, allowing for the direction and magnitude of this effect, experience (28, 29) would indicate an approximate upfield shift of 2 ppm as a reasonable estimate, an assignment was possible. The chemical shifts of C5 of A (78.5 ppm) and B (75.8 + 2 ppm = 77.8 ppm) are more comparable to the equivalent C5 signal of 2-acetamido-2-deoxy-β-D-mannopyranose than to C5 of its α-D-anomer. The above configurational assignment was not definitive, however, as conflicting evidence was obtained using ^{1}H nmr spectroscopy.

Because residues A and B (Fig. 1a–c) are in the D-*manno* form, their anomeric configurations could not be determined with any degree of accuracy by the magnitude of their three-bond H1–H2 coupling constants (${}^3J_{H1,H2}$) (Table 1). However, in this circumstance it is common practice to use the anomeric one-bond ^{13}C–^{1}H coupling constants (${}^1J_{^{13}C,H}$) for this purpose, which have been demonstrated to be diagnostic of anomeric configuration (30–32). For example, in the case of D-glucopyranose (${}^4C_1$ (D) conformation) the α-D-anomer (equatorial H1) has ${}^1J_{^{13}C,H}$ = 169 Hz while the β-D-anomer (axial H1) has

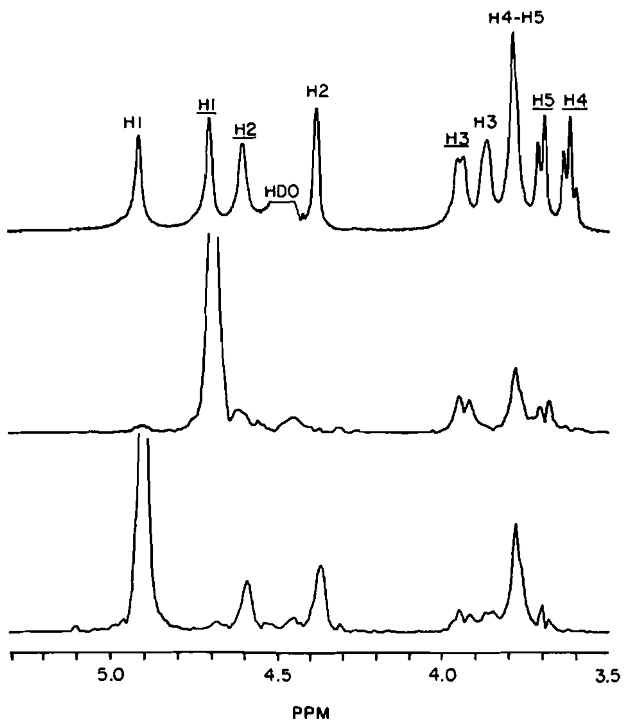

FIG. 4. The ^{1}H nmr spectrum (top) of the de-*O*-acetylated K polysaccharide in D_2O (330 K) with the assignments for residue A and residue B (underlined). Cross-sections of the 2-D NOESY contour map showing the nOe's for H1 of residue B (middle) and H1 of residue A (bottom).

$^1J_{^{13}C,H}$ = 161 Hz (31). These coupling constants and the 8–10 Hz difference between them have been found consistently in a large number of anomeric pairs of hexopyranoses (30–32) and hexopyranosyl residues in oligosaccharides and polysaccharides (33). The values of $^1J_{^{13}C,H}$ for A and B were 168.8 and 171.0 Hz, respectively, from which one could clearly deduce on the basis of the above accumulated evidence that they were both in the α-D-configuration. However, the values of $^1J_{^{13}C,H}$ for A and B of the carboxyl-reduced K polysaccharide (162.7 and 162.5 Hz) provide contradictory evidence, albeit consistent with the ^{13}C chemical shift data, that A and B of the K polysaccharide had the β-D-configuration. This latter assignment was later confirmed by nuclear Overhauser enhancement experiments (*vide infra*).

Two possible explanations for the anomalous values of $^1J_{^{13}C,H}$ for residues A and B of the K polysaccharide are that either they have equatorial anomeric protons due to their being in the $^4C_1$ (D) or twist boat conformation, or that this anomaly is associated with structural features peculiar to the K polysaccharide. In fact the latter explanation proved to be the relevant one because unambiguous assignments of the anomeric configuration (β-D) and conformation ($^4C_1$ (D)) of residues A and B of the K polysaccharide were obtained by 2-D nuclear Overhauser experiments carried out directly on the de-*O*-acetylated K polysaccharide. A number of nuclear Overhauser enhancements were observed on the resonances of protons in close proximity to the anomeric protons of residues A and B (Fig. 4). Critical to the above assignments are the intra-residue enhancements observed between H1–H3, H1–H5 of ring A and *H1–H3*, *H1–H5* of ring B which indicated that H3, H5 and *H3*, *H5* were both *cis* and 1,3-diaxially disposed to their respective anomeric protons.

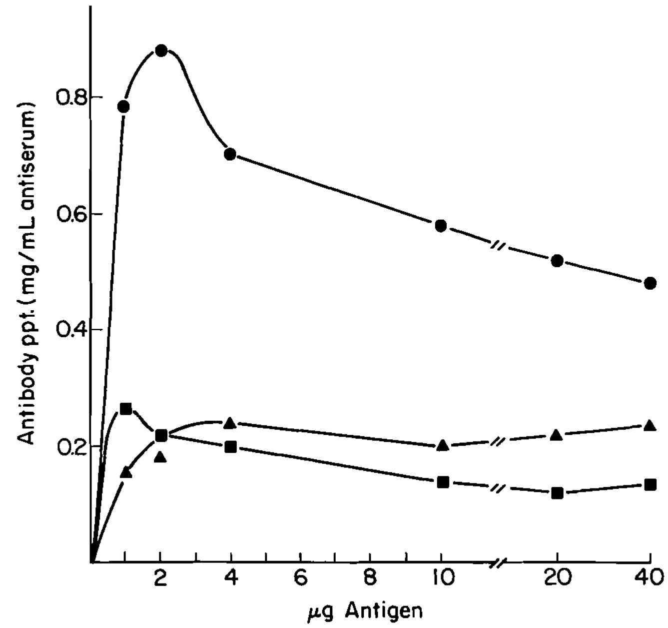

FIG. 5. Quantitative precipitin curves of the K polysaccharide (●-●), the de-*O*-acetylated K polysaccharide (■-■), and the group I meningococcal polysaccharide (△-△).

Inter-residue enhancements between H1 and H4–H5 (strongly coupled) were consistent with a β 1→4-linkage between residues B and A that would place H4 in close proximity (<2.5 Å) to *H1*. Similarly inter-residue enhancements between H1 and *H3* and between H1 and *H2* are a consequence of the β 1→3-linkage between residues A and B. Since inter-residue nOe's are dependent on the linkage conformation, the magnitude of these enhancements reflects the relative orientation of these residues with respect to each other.

The most probable explanation of the anomalous values of $^1J_{^{13}C,H}$ of residues A and B in the K polysaccharide is that they are due to electronic effects. Although this type of effect has been observed for hexopyranosyl derivatives having electronegative substituents at the anomeric center (32), no such effect has so far been observed in monomers with carboxylate groups in positions remote from the anomeric center. In fact residue B is also a constituent of the type e *H. influenzae* capsular polysaccharide and in this environment has $^1J_{^{13}C,H}$ = 164 Hz (34), a value more compatible with its β-D-configuration. Unlike the K polysaccharide, in this polysaccharide the carboxylated B residues are separated by uncharged sugar residues, which would strongly indicate that the anomalous $^1J_{^{13}C,H}$ values of the K polysaccharide are due to inter-residue through-space effects associated with the presence of contiguous carboxylated residues. This hypothesis is supported by the fact that residue B (Fig. 1b), also a constituent of the meningococcal group I polysaccharide, exhibits a similar and anomalous $^1J_{^{13}C,H}$ in this environment, where residue B alternates with a 1→4-linked 2-acetamido-2-deoxy-α-L-guluronopyranosyl residue (8). Interestingly, these latter residues (8) together with contiguous hexuronosyl residues of other glycuronans (35, 36) have been shown to have conventional values of $^1J_{^{13}C,H}$, indicating that the above phenomenon is not general.

The simple pattern of chemical shift displacement observed by comparing the ^{13}C nmr signals of the de-*O*-acetylated (Fig. 1b) with the native K polysaccharide (Fig. 1a) (Table 2) indicated that the repeating unit of the latter is specifically monosubstituted by *O*-acetyl at *O*-4 of residue B (Fig. 1a). Consistent with the above assignment, only three significant displacements were observed in the signals of the K polysaccharide: a rather small downfield displacement of 0.75 ppm on C4 of B with concomitant upfield displacements on the vicinal C3 and C5 signals of the same residue (2.29 and 2.55 ppm respectively). This assignment was also confirmed by comparing the ^{1}H nmr spectra of the de-*O*-acetylated (Fig. 1b) and native K (Fig. 1a) polysaccharide (Table 1). The only proton signal of the K polysaccharide to undergo a substantial downfield displacement, indicative of *O*-acetyl substitution, was H4 of residue B which was displaced by 1.34 ppm.

Immunological properties of the K polysaccharide

Quantitative serological precipitation experiments using the native (Fig. 1a) and de-*O*-acetylated (Fig. 1b) K polysaccharide with a meningococcal group K specific antiserum are shown in Fig. 5. These experiments demonstrate that the *O*-acetyl group is essential to the formation of the group-specific determinant. While the native K polysaccharide precipitated close to 0.9 mg of antibody from 1 mL of antiserum, the de-*O*-acetylated K polysaccharide precipitated only 0.25 mg of antibody from the same volume of antiserum. Probably due to their common 3-linked 4-*O*-acetyl 2-acetamido-2-deoxy-β-D-mannouronopyranosyl residues the meningococcal group I polysaccharide cross-reacts with the K polysaccharide-specific antiserum, although this cross-reaction is very weak.

LUCJAN J. J. HRONOWSKI and WALTER A. SZAREK. Can. J. Chem. **63**, 2787 (1985).

Aminohydroxycyclopentanemethanols are important precursors for the synthesis of cyclopentane analogs of purine and pyrimidine nucleosides. The regiospecific synthesis of two new aminohydroxycyclopentanemethanols, **17** and **22**, is described. In these syntheses the desired configuration in the cyclopentane ring is obtained by opening the *cis*-acetoxy-1,3-cyclopentanedicarboxylic acid anhydride **3** with either ammonia or methanol. The attack by each nucleophile occurs at the carbonyl carbon farthest away from the acetoxy group to give a carbamoyl or an ester function at this position. Since the ester function is destined to become the hydroxymethyl substituent and the carbamoyl function the amino substituent, the type of nucleophile used to open the anhydride determines whether the 2-deoxy or the 3-deoxy isomer is obtained. Coupling of the aminohydroxycyclopentanemethanols with 3-ethoxypropenoyl isocyanate followed by cyclization of the acyl ureas in 2 *N* H_2SO_4 gave two new cyclopentane analogs of uracil nucleosides. Coupling of the aminohydroxycyclopentanemethanols with 3-ethoxypropenoyl isothiocyanate followed by cyclization of the acyl thioureas in 15 *N* aqueous ammonia gave two new cyclopentane analogs of 2-thiouracil nucleosides.

LUCJAN J. J. HRONOWSKI et WALTER A. SZAREK. Can. J. Chem. **63**, 2787 (1985).

Les aminohydroxycyclopentaneméthanols sont des précurseurs importants dans la synthèse des analogues cyclopentaniques des nucléosides de la pyrimidine ainsi que de la purine. On décrit des synthèses régiospécifiques des deux nouveaux aminohydroxycyclopentaneméthanols **17** et **22**. Dans ces synthèses, on obtient la configuration désirée du cyclopentane en procédant à l'ouverture de l'anhydride de l'acide acétoxy cyclopentanedicarboxylique-1,3-*cis*, **3**, à l'aide d'ammoniac ou de méthanol. Chaque nucléophile attaque le carbone du carbonyle le plus éloigné du groupe acétoxy; cette réaction donne naissance à une fonction carbamoyle ou à une fonction ester dans cette position. Puisque la fonction ester est destinée à devenir le substituant hydroxyméthyle alors que la fonction carbamoyle est destinée à devenir le substituant amino, le type de nucléophile utilisé pour ouvrir l'anhydride détermine la nature de l'isomère déoxy-2 ou déoxy-3 qui sera obtenu. Le couplage des aminohydroxycyclopentaneméthanols avec de l'isocyanate d'éthoxy-3 propénoyle, suivi d'une cyclisation des acylurées en présence de H_2SO_4 2 *N*, conduit à deux nouveaux analogues cyclopentaniques des nucléosides de l'uracile. Le couplage des aminohydroxycyclopentaneméthanols avec de l'isothioocyanate d'éthoxy-3 propénoyle, suivi d'une cyclisation des acylthiourées en présence d'ammoniaque 15 *N*, conduit à deux nouveaux analogues cyclopentaniques des nucléosides du thio-2 uracile.

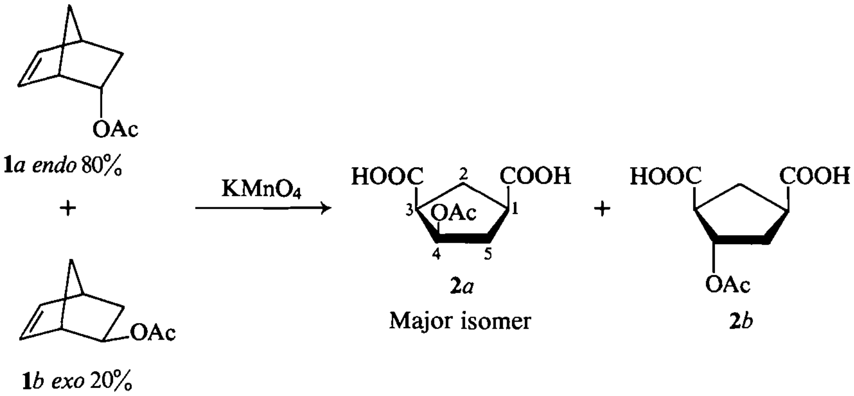
[Traduit par le journal]

Introduction

The replacement of the furanose-ring oxygen by a methylene group can have a profound effect on a nucleoside's biochemical and biological activity. Guranowski *et al.* (1) showed that the cyclopentane analog of adenosine was several orders of magnitude less effective as a substrate for the beef liver enzyme *S*-adenosylhomocysteine hydrolase than adenosine and also that it is the most potent inhibitor of this enzyme with a K_i of $5 \times 10^{-9}\,M$, results which indicated the necessity of the oxygen of the ribofuranose ring for the enzymatic reaction but not for binding to the active site. A large number of cyclopentane analogs of both purine and pyrimidine nucleosides have been synthesized and many have shown antiviral and (or) anticancer activity (see, for example, refs. 2–7).

Virtually all of the syntheses of cyclopentane analogs of nucleosides described to date involve the prior preparation of an appropriately functionalized cyclopentylamine followed by the coupling of this amine with an appropriate base precursor. The central problem, therefore, in the synthesis of the cyclopentane analogs is the synthesis of a cyclopentane ring with the different substituents having the required configurations. Shealy *et al.* (8) have synthesized cyclopentane analogs of nucleosides having the "deoxy*ribo*" (8*a*) and *ribo* (8*b*) configurations by the oxidation of *exo*-5-norbornen-2-yl acetate and *exo-cis*-norbornen-2,3-diyl diacetate, respectively, with sodium permanganate. More recently, cyclopentylamines having the *ribo* (9, 10), *lyxo* (10), and *arabino* (11) configurations have been prepared from the readily available 2-azabicyclo-[2.2.1]hept-5-en-3-one (12), which is structurally analogous to norbornene. Holý (13) reported the preparation of the cyclopentane analog having the *ribo* configuration by catalytic hydrogenation of diethyl cyclopentane-2,3-dione-1,4-dicarboxylate. In the preparation of cyclopentane analogs of *C*-nucleosides, bin Sadikun *et al.* (4) achieved the *lyxo* configuration using norborn-5-ene-2-*endo*,3-*endo*-dicarboxylic acid anhydride. Just *et al.* achieved the *arabino* configuration using 5-carbomethoxy-2-*exo*,3-*endo*-dipivaloyoxybicyclo-[2.2.1]hept-5-ene (14) and the "2-deoxy*ribo*" configuration using 2-carbomethoxy-*exo*-5-*p*-nitrobenzoyloxybicyclo-[2.2.1]hept-2-ene (15). Paulsen and Maass (16) prepared cyclopentane rings having substituents in various orientations by allylhydroxylation of epoxides of cyclopentanemethanols using phenyl selenide. Shealy and O'Dell (7) obtained the cyclopentane analog of Ara-C from the cyclopentane analog of cytidine by way of the 2,2′-anhydro derivative.

In most of the above-mentioned syntheses (2–6, 8–11, 14, 15) the configurations of the cyclopentane rings are determined by the intermediacy of a bicyclo[2.2.1] derivative. The methods of Paulsen and Maass (16) and Holý (13), which do not utilize such a bicyclo[2.2.1] intermediate, give mixtures of isomers which must be resolved. Some of the methods (8*a*, 11) which utilize a bicyclo[2.2.1] intermediate also produce mixtures of isomers. The present article describes the synthesis of new aminohydroxycyclopentanemethanols, **17** and **22**,



SCHEME 1

by regiospecific routes from the common precursor (±)-(1β,3β,4β)-4-acetoxy-1,3-cyclopentanedicarboxylic acid anhydride (**3**), and the conversion of each of them into uracil and 2-thiouracil nucleosides.

Results and discussion

The starting material for the synthesis of (±)-(1β,3β,-4β)-4-amino-3-hydroxycyclopentanemethanol (**17**) and (±)-(1β,2β,4β)-4-amino-2-hydroxycyclopentanemethanol (**22**) was a commercial sample (see experimental section) of 5-norbornen-2-yl acetate, which was shown to contain 80% of the *endo* (**1***a*) and 20% of the *exo* (**1***b*) isomers. An efficient method has been described by Birch *et al.* (17) for the oxidation of norbornene using $NaMnO_4$ to give cyclopentane-*cis*-1,3-dicarboxylic acid in 95% yield, and the method has been adapted for the preparation of *cis*-diacids from *exo*-5-norbornen-2-yl acetate and the *exo-cis*- and *endo-cis*-5-norbornen-2,3-diyl diacetates by Shealy *et al.* (8). In the present work the methods of the above workers (8, 17) have been utilized; however, instead of using $NaMnO_4$ as the oxidant, the more readily available $KMnO_4$ has been used to give the described diacid **2***a*[1] (Scheme 1) in 77% yield after recrystallization and a crude sample of **2** in 93%. This high yield has been consistently obtained in experiments in which the reaction temperature was maintained below 12°C; however, when the reaction temperature was allowed to rise above 40°C the yield of the desired diacid was greatly reduced.

The *cis* (**2***a*) and the *trans* (**2***b*) isomers were observed to have significantly different [1]Hmr spectra using a 200-MHz spectrometer; however, two spectral features which allow one to easily distinguish these isomers even on a 60-MHz instrument are the significantly different chemical shifts of the acetoxy methyls, which resonate at δ 1.90 in the case of the *cis* isomer (**2***a*) and at δ 2.00 in the case of the *trans* isomer (**2***b*). In addition, although the chemical shifts of the H-4 protons in the two isomers are identical at δ 5.20, the coupling patterns are quite distinct. In the *cis* isomer this proton couples with two *cis* vicinal protons and one *trans* vicinal proton to give a triplet-of-doublets coupling pattern, whereas in the *trans* isomer this proton couples with two *trans* vicinal protons and one *cis* vicinal proton to give a coupling pattern approximating an overlapping doublet of triplets.

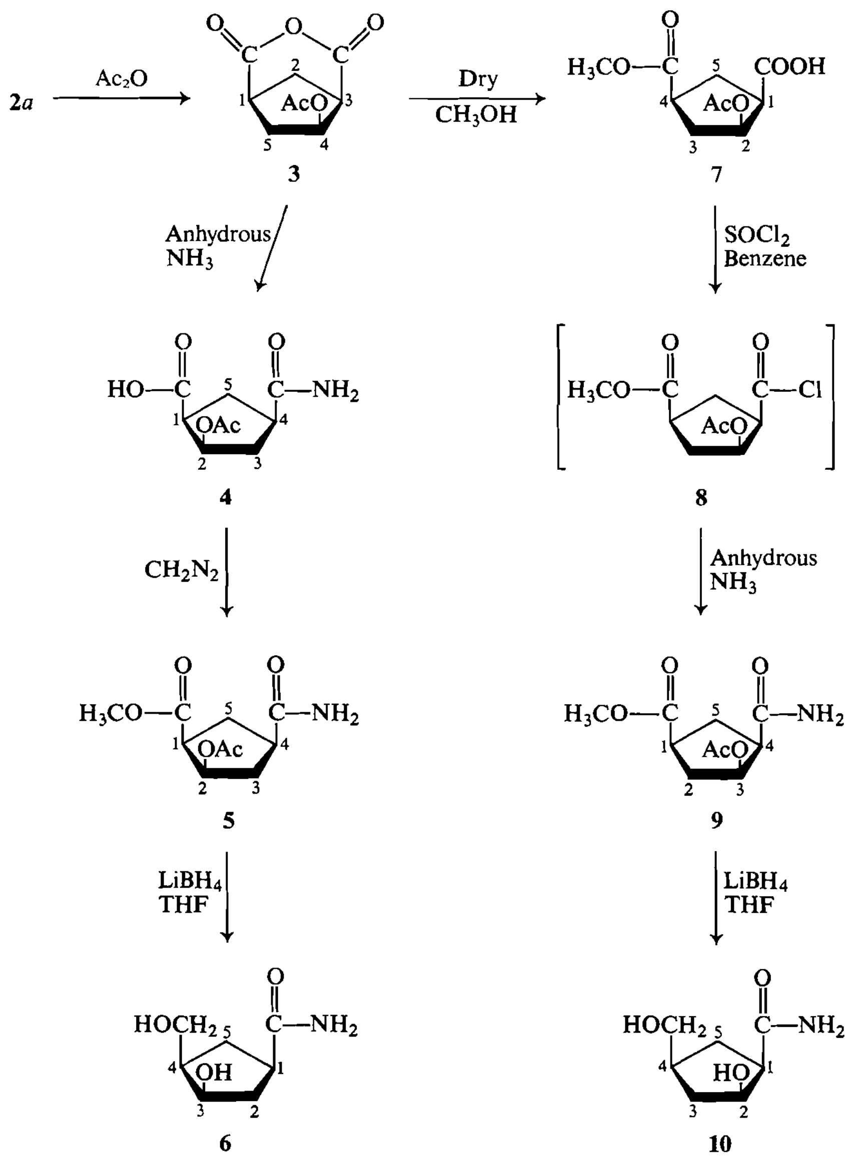
Regiospecific opening of anhydride 3

The opening of the anhydride **3** (see Scheme 2) with anhydrous methanol followed by conversion of the carboxylic acid group into the carbamoyl function produced a single regioisomer **9**. Analysis of the [1]Hmr spectra of both the crude oily product (see experimental section) and the components separated by column chromatography on silica gel failed to reveal signals attributable to **5**. Similarily, the [1]Hmr spectrum of **4**, a compound which was produced by opening of the anhydride **3** with anhydrous ammonia, did not reveal any traces of a second regioisomer. In this second case, however, only the crystalline solid that represented a 91.3% yield was analyzed, and thus the possibility of the presence of a small amount of the other regioisomer, which may have been present in the crude mother liquor, was not eliminated. In both cases, however, the nucleophile attacks the carbonyl carbon farthest away from the acetoxy group. Compound **4** was esterified using diazomethane to give compound **5**. Therefore, since the carbamoyl function is destined to become N-1 in the pyrimidine nucleoside and the ester function the hydroxymethyl group at C-4′ in the nucleoside, it is possible to obtain the "2-deoxy*lyxo*" or the "3-deoxy*lyxo*" configuration selectively (as shown in Scheme 2). In contrast, in the case of (±)-(1β,3β,4α)-4-acetoxy-1,3-cyclopentanedicarboxylic acid anhydride, in which the acetoxy group has the *trans* configuration, Shealy and O'Dell (8*a*) obtained the two regioisomers having the 2-deoxy*ribo* and "3-deoxy*ribo*" configurations in approximately equal amounts, thus requiring the separation of the two regioisomers by column chromatography. From these observations and a consideration of a model of anhydride **3** it seems likely that the large *cis*-acetoxy group prevents facile attack by nucleophiles on the nearby carbonyl carbon by steric interactions.

The ester functions of compounds **5** and **9** were reduced using $LiBH_4$. In the case of **5** it was observed that the percentage yield of the product **6** was greatly dependent on the time of reflux during the reduction, ranging from 29% after 2 h to 81% when the time of reflux was only 20 min.

The configurations of compounds **4**–**10** (Scheme 2) have been assigned with the aid of [1]Hmr decoupling experiments. The chemical shifts of the methylene protons of the hydroxymethyl substituent in compounds **6** and **10** are of particular interest. In compound **10** these two protons are equivalent and give rise to a single multiplet (doublet of doublet due to coupling with O*H* and H-4) at δ 3.33; however, in the case of

[1] Structures **1**–**10** and **17**–**30** depict only one enantiomer of racemic mixtures. The relative configurations of substituent groups on the cyclopentane ring are specified by the α,β system used for steroids (31). Substituents which are written below the plane of the cyclopentane ring are designated α and those above the plane of the ring as β.



SCHEME 2

compound **6** two separate multiplets are observed for these two methylene protons, at δ 3.35 and 3.59. This non-equivalence of the hydroxymethyl methylene protons indicates that rotation of the hydroxymethyl substituent in compound **6** is restricted.

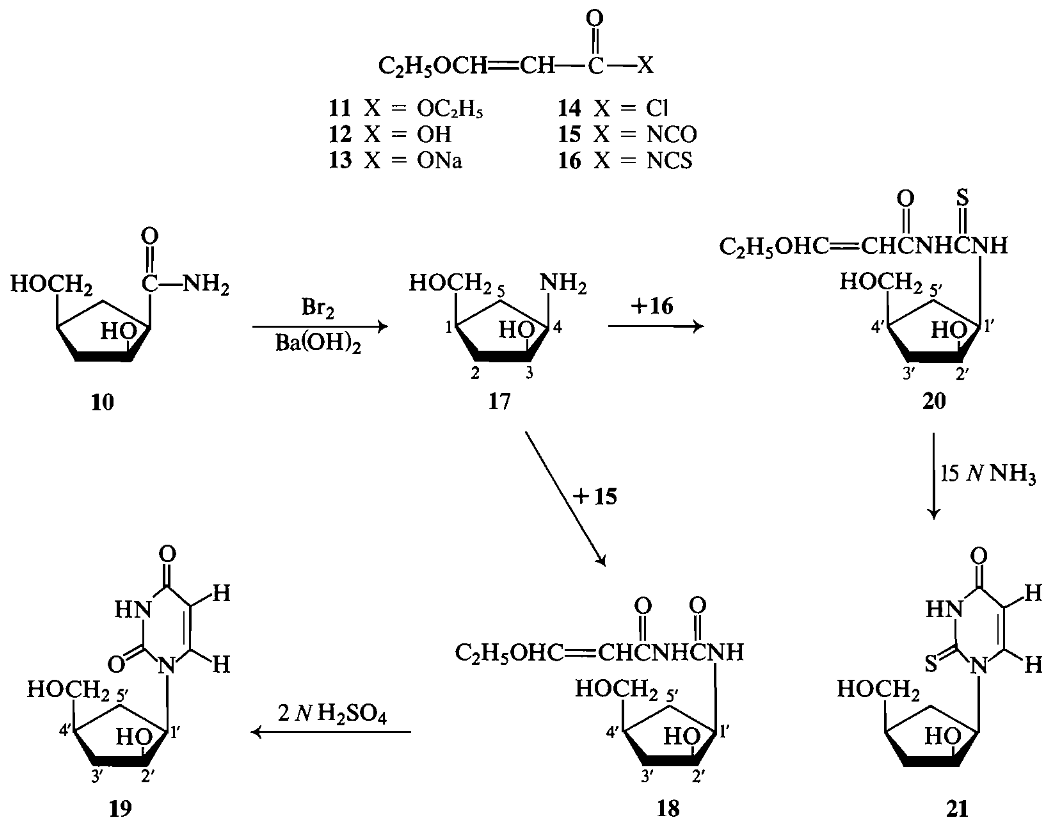
*Synthesis of the carbocyclic analogs (19 and 21) of 3-deoxy-*threo*-pentofuranosyl nucleosides*

The carbamoyl substituent in **10** was converted into the amino substituent in **17** (see Scheme 3) by the Hofmann reaction (18) using the procedure described by O'Dell and Shealy (19) for the preparation of aminohydroxycyclopentanemethanols having the "deoxy*ribo*" configurations. The amine **17** was coupled then with 3-ethoxypropenoyl isocyanate (**15**), which was prepared by previously described methods (20–23), to give compound **18**. Nucleoside analog **19** was prepared by heating **18** in 2 *N* H_2SO_4 at reflux temperature for 30 min. The ^{1}Hmr spectrum of compound **19** is very complex; however, it is different from that of the nucleoside analog having the "3-deoxy*ribo*" configuration, a sample of which had been prepared by previously described methods (22). The ^{1}Hmr signals in the spectra of these nucleosides have been assigned with the aid of spin–spin decoupling experiments.

Compound **20** was prepared by coupling **17** with 3-ethoxypropenoyl isothiocyanate (**16**) (see Scheme 3), which was prepared as described by Shaw and Warrener (21). Nucleoside analog **21** was obtained by heating **20** in 15 *N* aqueous ammonia at 100°C for 20 min. The multiplet patterns of the ^{1}Hmr spectra of nucleoside analogs **19** and **21** were observed to be very similar using a 200-MHz spectrometer; however, in general, the signals of protons in nucleoside analog **21** are found farther downfield than the signals of corresponding protons in nucleoside analog **19**. For example, the signal of H-1′ resonates at δ 4.49 in the case of **19** and at δ 5.41 in the case of **21**. The coupling constants found in the H-1′ multiplet are virtually identical for both nucleoside analogs. The largest difference in chemical shifts occurs for the H-3 proton, which in the case of **19** resonates at δ 11.20 while in the case of **21** it resonates at δ 12.59. In both of these analogs H-5 has a long-range coupling constant of 1.7–1.9 Hz to H-3 in addition to the vicinal coupling constant of 7.8–8.1 Hz to H-6.

*Synthesis of the carbocyclic analogs (24 and 26) of 2-deoxy-*threo*-pentofuranosyl nucleosides*

Two approaches have been utilized for the conversion of the



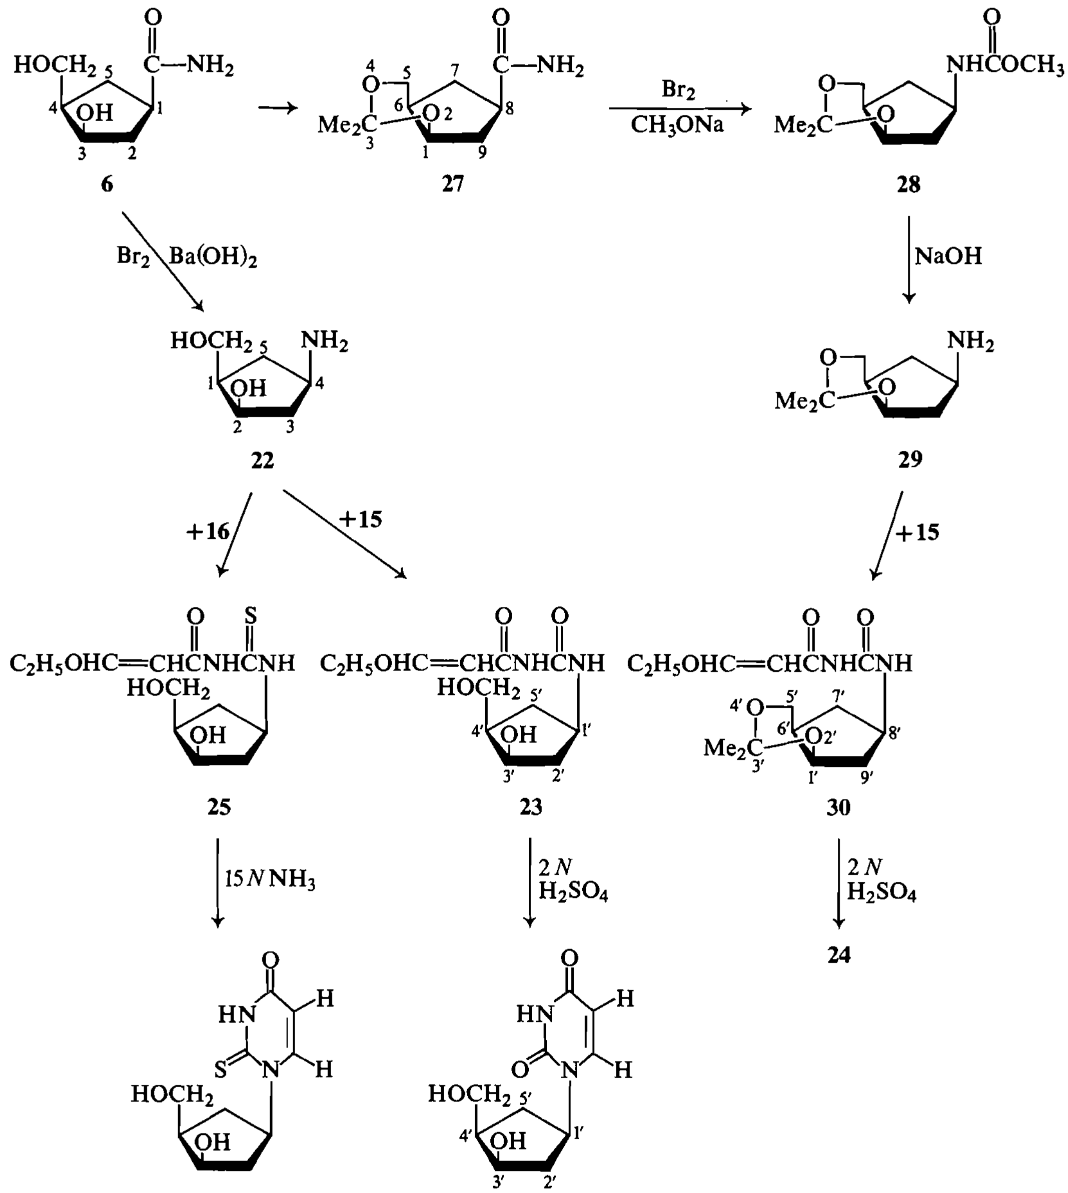
SCHEME 3

carbamoyl substituent in compound **6** to the amino substituent (see Scheme 4). In the first approach the Hofmann reaction was performed directly on **6**, which gave the amine **22** after purification on a cation-exchange resin in 27% yield. In the second approach the hydroxyls in compound **6** were protected by an isopropylidene group and the Hofmann reaction (18) was performed on **27** in methanol using sodium methoxide as the base to give the carbamate **28**. Hydrolysis of the carbamate with sodium hydroxide gave the amine **29** in 54% yield from **6**. The advantages of this latter route, despite the fact that it involves three steps instead of one, are not only the much greater overall yield but also the fact that the work-up in this latter approach is greatly simplified. In addition, the protected compound **29** gives significantly better yields in the subsequent steps leading to nucleoside analog **24** (see Scheme 4). Thus, **24** has been prepared in 26.4% yield from **6** by the latter route compared to 7.5% yield by the first route, a 3.5-fold improvement. Nucleoside analog **26** has been obtained by coupling the unprotected compound **22** with **16** to give **25**, followed by heating at 100°C in 15 *N* aqueous ammonia.

An attempt was made also to synthesize the amine **22** by first converting the carbamoyl substituent of compound **4** to an amino group by a Hofmann hypobromite reaction; however, the conditions lead to the elimination of acetic acid as shown in Scheme 5.

As was observed in the cases of the nucleoside analogs **19** and **21**, the multiplet patterns of the ^{1}Hmr spectra of analogs **24** and **26** are very similar also, with the multiplets of the 2-thiouracil-containing analog **26** occurring farther downfield than the multiplets of corresponding protons in the uracil-containing analog **24**. This difference in chemical shifts between corresponding protons in the uracil- and 2-thiouracil-containing nucleosides decreases with distance from the thio group such that the protons in the hydroxymethyl substituent resonate at virtually the same chemical shifts in the cases of both nucleoside analogs (**24** and **26**). Also, as previously observed for compound **6**, the ^{1}Hmr spectra of compounds **22**–**26** (Scheme 4) each show two well-separated multiplets for the methylene protons of the hydroxymethyl substituent. In contrast, only a single multiplet was observed for these protons in the spectra of compounds **10** and **17**–**21** (Scheme 3). The chemical shifts and the coupling constants of one of the methylene multiplets are very similar in the cases of compounds **6** and **22**–**26**; in the cases of all of these compounds this multiplet occurs in the δ 3.58–3.60 region. In the spectrum of compound **22** coupling to the hydroxyl proton is not observed. The chemical shift of the other multiplet varies over a greater range between the different compounds (**6**, **22**–**26**); in compound **6** it occurs at δ 3.35, in **22** at δ 3.37, in **23** and **25** at δ 3.40, and in the nucleoside analogs **24** and **26** at δ 3.43 and 3.44, respectively. The non-equivalence of the two methylene hydrogens in the hydroxymethyl substituent may be in part due to intramolecular hydrogen bonding between the hydroxyls. That hydrogen bonding alone may not account for these observations is indicated by the fact that, when the two hydroxyls in each of compounds **6**, **19**, and **24** are acetylated, non-equivalence is still observed to the extent of approximately 0.10 ppm for the corresponding methylene protons in the acetates of **6** and **24**, and also in the acetate of **19**; however, in this last acetate the difference in chemical shifts between these methylene protons is much smaller than in the first two.

In the ^{1}Hmr spectra of compounds **27**–**30**, in which these methylene protons are part of a heterocyclic six-membered ring, the multiplets arising from these protons are also well separated but appear farther downfield. The chemical shifts of one of the multiplets are in the δ 3.50–3.54 region and those



SCHEME 4

of the other in the δ 3.96–4.03 region.

Ultraviolet spectra of the nucleoside analogs

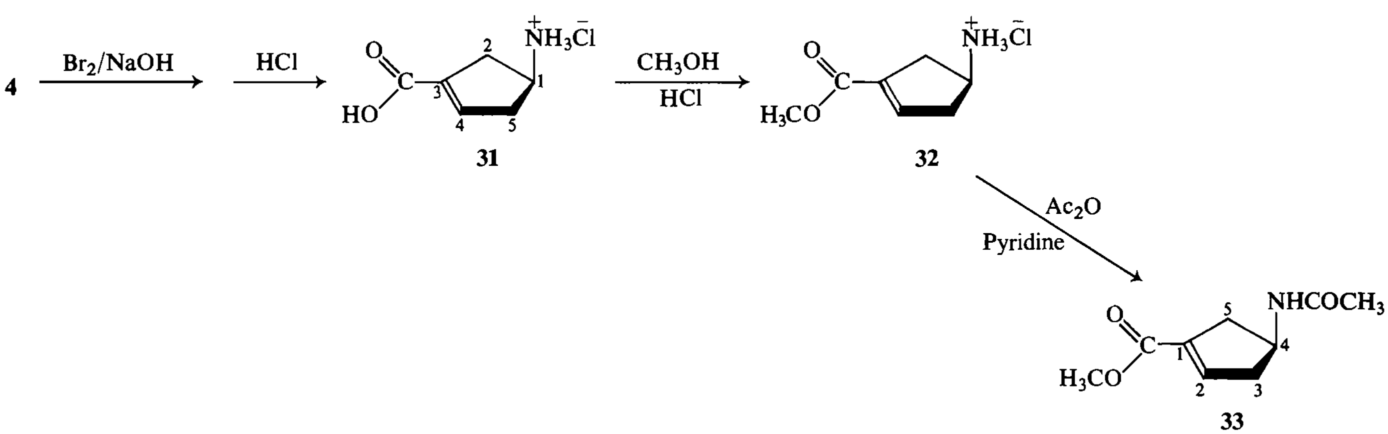
The ultraviolet spectra of the uracil-nucleoside analogs **19** and **24** exhibit virtually identical absorption maxima in both acidic and alkaline ethanol and they closely resemble the spectra of 1-methyluracil (24) at the corresponding pH's. The spectra of the 2-thiouracil-nucleoside analogs **21** and **26** are also similar in both acidic and alkaline ethanol, although quite different from those of **19** and **24**. The absorption maxima in the spectra of **21** and **26** occur at longer wavelengths and the spectra have a shoulder at approximately 290 nm in acidic and neutral ethanol. The molar absorptivities at the absorption maxima are also much greater in the cases of the 2-thiouracil-nucleoside analogs, especially in alkaline ethanol in which they are more than 2-fold greater. The ultraviolet spectra of the 2-thiouracil-nucleoside analogs **21** and **26** closely resemble those of 1-methyl-2-thiouracil (24) at the corresponding pH's.

Conclusions

Two new cyclopentane analogs of uracil nucleosides having the "2-deoxy*lyxo*" and "3-deoxy*lyxo*" configurations have been synthesized regiospecifically. In addition, the corresponding analogs of 2-thiouracil nucleosides have been synthesized; this work represents the first reported synthesis of cyclopentane analogs of nucleosides having the 2-thiouracil base. The synthetic routes also provide the possibility of regiospecific synthesis of cyclopentane analogs of nucleosides having the "deoxy*ribo*" configurations, by an inversion of configuration at C-2′ or C-3′ in the corresponding "deoxy*lyxo*" analogs. Analogs having the "2-deoxy*ribo*" configuration have been found to be biologically active in a variety of systems (2, 25).

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. The ^{1}Hmr spectra were recorded on a Bruker CXP-



SCHEME 5

200 spectrometer at 200 MHz. Chemical shifts (δ) are given downfield from the signal of Me_4Si. Assignments of chemical shifts and coupling constants were made with the aid of spin-decoupling experiments. The following abbreviations are used in describing [1]Hmr signals: singlet (s), doublet (d), triplet (t), quartet (q), quintuplet (qu), sextuplet (se), multiplet (m), and broadened (br). Ultraviolet spectra were recorded on a Perkin–Elmer 552 spectrophotometer. Thin-layer chromatography (tlc) was performed using silica gel 60 F-254. The developed plates were dried and sprayed with a solution of ceric sulfate (1%) and molybdic acid (1.5%) in 10% aqueous sulfuric acid, and heated at ~150°C.

(±)-(1β,3β,4β)-4-Acetoxy-1,3-cyclopentanedicarboxylic acid (2a) and (±)-(1β,3β,4α)-4-acetoxy-1,3-cyclopentanedicarboxylic acid (2b)

5-Norbornen-2-yl acetate[2] (98 g, 0.64 mol) in 2,2,4-trimethylpentane (500 mL) was added to water (4 L) and the mixture was cooled to 10°C. To the stirred mixture $KMnO_4$ (325 g, 2.06 mol) in water (6 L) was added over a period of 3.5 h. During the addition of $KMnO_4$ a steady stream of CO_2 was passed through the reaction mixture and the temperature was maintained between 10 and 12°C using an ice bath. After the $KMnO_4$ had been added, SO_2 was passed through the reaction mixture until it became clear, with the temperature being maintained below 20°C. The volume of the reaction mixture was reduced to 1.6 L, and the mixture was cooled to 5°C and acidified with concentrated HCl (100 mL). It was extracted then with diethyl ether (5 × 400 mL); evaporation of the ether afforded a white solid (115.3 g). The reaction solution was reduced further to 900 mL, the solution was cooled to 5°C, and additional concentrated HCl (20 mL) was added; extraction again with ether (4 × 225 mL) gave an additional 14.3 g of solid, for a total yield of crude product of 129.6 g. The crude solid was recrystallized from ethyl acetate – hexanes and gave, in several crops, 81.3 g of a crystalline solid having mp 131–132°C and 4.0 g having mp 128–131°C, for a total yield of 85.3 g (77%) of **2***a*; [1]Hmr (200 MHz, Me_2SO-d_6) δ: 1.90 (3H, s, OAc), 1.95 (1H, m, J_{gem} = 14.7, $^3J_{5,1}$ = 6.1, $^3J_{5,4}$ = 2.7 Hz, H-5), 2.0–2.2 (2H, m, H-2 and H-2′), 2.20 (1H, m, J_{gem} = 14.7, $^3J_{5',1}$ = 10.1, $^3J_{5',4}$ = 5.2 Hz, H-5′), 2.83 (1H, m, H-1), 2.99 (1H, m, $^3J_{3,2}$ = 10.8, $^3J_{3,2'}$ = 8.4, $^3J_{3,4}$ = 5.4 Hz, H-3), 5.20 (1H, t of d, ^3J = 5.3, $^3J_{4,5}$ = 2.7 Hz, H-4), 12.31 (2H, br s, CO_2H at positions 1 and 3); spin–spin decoupled at H-4.

Two additional crops from the mother liquor of **2***a* gave 22.4 g of a white solid, mp 85–111°C, which was shown by [1]Hmr to consist primarily of **2***b*. Compound **2***b* was prepared also from *exo*-5-norbornen-2-yl acetate (**1***b*) (8*a*, 29) by the above oxidation method; mp 114–115°C (lit. (8*a*) mp 116–117°C); [1]Hmr (200 MHz, Me_2SO-d_6) δ: 1.79–1.95 (2H, m, H-2 and H-5), 2.00 (3H, s, OAc), 2.09 (1H, m, J_{gem} = 14.1, $^3J_{5',1}$ = 9.0, $^3J_{5',4}$ = 6.6 Hz, H-5′), 2.30 (1H, m, J_{gem} = 13.3, $^3J_{2',1}$ = 9.2, $^3J_{2',3}$ = 8.6 Hz, H-2′), 2.82 (1H, t of d, ^3J = 8.6, $^3J_{3,4}$ = 4.6 Hz, H-3), 2.92 (1H, qu, ^3J = 8.6 Hz, H-1), 5.20 (1H, d of t, $^3J_{4,5'}$ = 6.6, ^3J = 3.9 Hz, H-4), 12.46 (2H, br s, CO_2H at positions 1 and 3); spin–spin decoupled at H-4.

(±)-(1β,3β,4β)-4-Acetoxy-1,3-cyclopentanedicarboxylic acid anhydride (3)

A stirred mixture of **2***a* (85.1 g, 0.394 mol) in acetic anhydride (1 L) was heated at reflux temperature gently for 45 min. The reaction solution was cooled to room temperature and the solvent was removed under reduced pressure. The residual oil was shaken in the presence of diethyl ether (500 mL) and several seed crystals. The resulting white crystalline solid was collected by filtration and washed with diethyl ether to give **3** (54.6 g) having an initial mp 77–78°C which dropped to a sharp mp of 70°C overnight. The volume of the mother liquor was reduced to 200 mL and cooled in an ice bath to give an additional 4.75 g of a white crystalline solid having mp 70°C. The mother liquor was then evaporated to an oil which was heated at reflux temperature in acetic anhydride (200 mL) for 15 min to give a crystalline grey-brown solid (11.91 g), mp 69°C, for a total yield of 71.2 g (91.3%); [1]Hmr (200 MHz, $CDCl_3$) δ: 1.94 (1H, d of t, J_{gem} = 13.1, ^3J = 4.0 Hz, H-2), 2.00 (1H, m, J_{gem} = 15.3, $^3J_{5,4}$ = 3.7, $^4J_{5,2'}$ = 2.7 Hz, H-5), 2.07 (3H, s, OAc), 2.36 (1H, m, J_{gem} = 13.1, $^4J_{2',5}$ = 2.7 Hz, H-2′), 2.65 (1H, d of d of d, J_{gem} = 15.3, $^3J_{5',4}$ = 9.8, $^3J_{5',1}$ = 7.0 Hz, H-5′), 3.26 (1H, m, $^3J_{1,5'}$ = 7.0, $^3J_{1,2}$ = 4.0, $^4J_{1,3}$ = 1.5 Hz, H-1), 3.66 (1H, m, $^3J_{3,4}$ = 6.4, $^3J_{3,2}$ = 4.0, $^4J_{3,1}$ = 1.5 Hz, H-3), 5.44 (1H, d of d of d, $^3J_{4,5'}$ = 9.8, $^3J_{4,3}$ = 6.4, $^3J_{4,5}$ = 3.7 Hz, H-4). Spin–spin decoupling was performed at each of the protons. *Anal.* calcd. for $C_9H_{10}O_5$: C 54.55, H 5.09; found: C 54.22, H 5.22.

(±)-(1β,2β,4β)-2-Acetoxy-4-carbamoylcyclopentanecarboxylic acid (4)

Dry ammonia was bubbled through a stirred solution of **3** (71.2 g, 0.359 mol) in tetrahydrofuran (450 mL) which had been cooled to 5°C. The bubbling of ammonia was continued for 30 min at a rate which allowed the reaction temperature to be maintained between 10 and 12°C with an ice bath. The reaction mixture was flushed then with N_2 for 30 min. The solid was collected by filtration and dissolved in water (500 mL). The solution was then cooled to ice-bath temperature, acidified with concentrated HCl (35 mL), and left in the ice bath to crystallize. The crystalline product was collected by filtration and washed with a small amount of cold water to give a solid (57.7 g), mp 161–163°C. The volume of the mother liquor was reduced to 100 mL to give an additional 12.9 g of a light grey-brown solid, mp

[2] 5-Norbornen-2-yl acetate (bp 73–76°C/14 Torr; 1 Torr = 133.3 Pa) was purchased from the Aldrich Chemical Company and was shown to contain 80% of the *endo* (**1***a*) and 20% of the *exo* (**1***b*) isomers by integration of the well-resolved C-2 proton signals in the [1]Hmr spectrum (26). This determination is in good agreement with previous estimates of isomer composition in 5-norbornen-2-yl acetate samples prepared by the Diels–Alder reaction between vinyl acetate and cyclopentadiene (27, 28) which showed the *exo* isomer to comprise about 19% (28).

161–163°C, for a combined yield of 70.6 g (91.3%). An analytical sample was prepared by recrystallization twice from water; mp 164–165°C; [1]Hmr (200 MHz, Me_2SO-d_6) δ: 1.82 (1H, d of d of d, J_{gem} = 14.4, $^3J_{3,4}$ = 7.7, $^3J_{3,2}$ = 3.1 Hz, H-3), 1.91 (3H, s, OAc), 1.93–2.14 (2H, m, H-5 and H-5′), 2.19 (1H, m, J_{gem} = 14.4, $^3J_{3',4}$ = 9.7, $^3J_{3',2}$ = 6.0 Hz, H-3′), 2.63 (1H, qu, ^3J = 8.9 Hz, H-4), 2.95 (1H, d of d of d, $^3J_{1,5}$ = 10.8, $^3J_{1,5'}$ = 8.1, $^3J_{1,2}$ = 6.0 Hz, H-1), 5.21 (1H, t of d, $^3J_{2,1}$ = 6.0, $^3J_{2,3'}$ = 6.0, $^3J_{2,3}$ = 3.1 Hz, H-2), 6.84 (1H, br s, $CONH_2$), 7.29 (1H, br s, $CONH_2$), 12.29 (1H, br s, CO_2H); spin–spin decoupled at H-1, H-2, and H-4. D_2O exchange caused the disappearance of signals at δ 6.84, 7.29, and 12.29. *Anal.* calcd. for $C_9H_{13}O_5N$: C 50.23, H 6.09, N 6.51; found: C 49.98, H 6.14, N 6.53.

(±)-Methyl (1β,2β,4β)-2-acetoxy-4-carbamoylcyclopentane-carboxylate (5)

Diazomethane was prepared as described in Vogel (30) and was distilled into the flask containing **4** (30.8 g, 0.143 mol) in methanol (400 mL) until the reaction solution acquired a persistent bright yellow color. After several hours the yellow color faded and the product was crystallized in several crops by reducing the reaction solution's volume, diluting with ethyl acetate, and cooling to give **5** (25.94 g, 79.1%) as a crystalline solid, mp 122–124°C, and an orange oil (6.5 g) that was not examined further. An analytical sample of the solid was obtained by recrystallization from ethyl acetate; mp 123–124°C; [1]Hmr (200 MHz, Me_2SO-d_6) δ: 1.81 (1H, d of d of d, J_{gem} = 14.3, $^3J_{3,4}$ = 8.0, $^3J_{3,2}$ = 3.5 Hz, H-3), 1.90 (3H, s, OAc), 1.96–2.11 (2H, m, H-5 and H-5′), 2.21 (1H, m, J_{gem} = 14.3, $^3J_{3',4}$ = 9.6, $^3J_{3',2}$ = 6.2 Hz, H-3′), 2.64 (1H, qu, ^3J = 8.9 Hz, H-4), 3.06 (1H, m, $^3J_{1,5}$ = 11.0, $^3J_{1,5'}$ = 8.0, $^3J_{1,2}$ = 6.2 Hz, H-1), 3.58 (3H, s, OMe), 5.22 (1H, t of d, $^3J_{2,1}$ = 6.2, $^3J_{2,3'}$ = 6.2, $^3J_{2,3}$ = 3.5 Hz, H-2), 6.84 (1H, br s, $CONH_2$), 7.30 (1H, br s, $CONH_2$); spin–spin decoupled at H-1, H-2, and H-4. *Anal.* calcd. for $C_{10}H_{15}O_5N$: C 52.40, H 6.60, N 6.11; found: C 51.97, H 7.01, N 6.06.

(±)-(1β,3β,4β)-3-Hydroxy-4-(hydroxymethyl)cyclopentane-carboxamide (6)

A solution containing $LiBH_4$ (12.6 g, 0.578 mol) in tetrahydrofuran (500 mL, the Aldrich Chemical Company, 99+%) was heated at reflux temperature for 20 min and cooled to about 40°C. To this solution compound **5** (25.0 g, 0.109 mol) was added as a solid and the stirred reaction mixture was heated at reflux temperature for 20 min. The reaction mixture was cooled to ice-bath temperature, water (350 mL) was slowly added, and then Amberlite IR-120 resin (H^+ form) (350 mL). The mixture was stirred for 1.5 h, and the resin was removed by filtration and washed with water. The combined filtrate and washings were stored in the cold room overnight, the solvent was evaporated, and the residue was evaporated with methanol (4 × 100 mL) to remove boric acid. This procedure gave a viscous oil which was stirred overnight in the cold room in the presence of tetrahydrofuran (70 mL). The white solid (12.45 g) was collected by filtration; R_f 0.37 (tlc) (9:1 (v/v) acetonitrile–water). The volume of the mother liquor was reduced to about 10 mL; treatment with tetrahydrofuran (20 mL) as above gave a solid (1.56 g), R_f 0.37, and a trace of impurity having R_f 0.51, for a total yield of 14.01 g (81%). An analytical sample was prepared by recrystallization from methanol – ethyl acetate – hexanes; mp 135–136°C; [1]Hmr (200 MHz, Me_2SO-d_6) δ: 1.31–1.51 (1H, m, H-5), 1.65 (1H, d of d of d, J_{gem} = 13.6, $^3J_{2,1}$ = 5.0, $^3J_{2,3}$ = 2.7 Hz, H-2), 1.82 (1H, m, $^3J_{3,4}$ = 4.6 Hz, H-4), 1.8–2.0 (1H, m, H-5′), 1.93 (1H, m, J_{gem} = 13.6, $^3J_{2',1}$ = 9.6, $^3J_{2',3}$ = 4.9 Hz, H-2′), 2.65 (1H, m, $^3J_{1,2}$ = 5.0 Hz, H-1), 3.35 (1H, m, J_{gem} = 10.7, $^3J_{\text{to H-4}}$ = 5.9, $^3J_{\text{to OH}}$ = 5.3 Hz, C*H*$_2$OH), 3.59 (1H, m, J_{gem} = 10.7, $^3J_{\text{to H-4}}$ = 6.9, $^3J_{\text{to OH}}$ = 5.3 Hz, C*H*$_2$OH), 4.01 (1H, m, $^3J_{\text{to OH}}$ = 6.7, $^3J_{3,4}$ = 4.6, $^3J_{3,2'}$ = 4.9, $^3J_{3,2}$ = 2.7 Hz, H-3), 4.24 (1H, t, $^3J_{\text{to }CH_2OH}$ = 5.3 Hz, CH_2OH), 4.71 (1H, d, $^3J_{\text{to H-3}}$ = 6.7 Hz, OH at position 3), 6.92 (1H, br s, $CONH_2$), 7.45 (1H, br s, $CONH_2$); spin–spin decoupled at H-1, H-3, H-5, and C*H*$_2$OH. D_2O exchange caused the disappearance of signals at δ 4.24, 4.71, 6.92, and 7.45. *Anal.* calcd. for $C_7H_{13}O_3N$: C 52.82, H 8.23, N 8.80; found: C 53.00, H 8.03, N 8.91.

(±)-Methyl (1β,3β,4β)-3-acetoxy-4-carbamoylcyclopentane-carboxylate (9)

A solution of **3** (50.5 g, 0.255 mol) in anhydrous methanol (800 mL) was stirred at room temperature for 22 h. The methanol was evaporated to give **7** as an oil; [1]Hmr (200 MHz, Me_2SO-d_6) δ: 1.91 (3H, s, OAc), 1.91–2.33 (4H, m, H-3, H-3′, H-5, and H-5′), 2.87–3.08 (2H, m, H-1 and H-4), 3.62 (3H, s, OMe), 5.23 (1H, t of d, H-2), 12.33 (1H, br s, CO_2H). The oil was dissolved in benzene (950 mL) and 150 mL were distilled to remove traces of moisture. Heating was discontinued and $SOCl_2$ (85 mL) was added. The mixture was stirred for 5 min, pyridine (2 drops) was added, and stirring was continued until the vigorous evolution of gases had subsided. *N,N*-Dimethylformamide (2 drops) was then added, and the solution was heated at reflux temperature for 2 h. The solution was kept at room temperature overnight. The volatile components were evaporated to give **8** as an orange oil that was used immediately for the preparation of **9**. The oil (**8**) was dissolved in dry benzene (450 mL), and anhydrous ammonia was bubbled through the reaction solution for 30 min; there then was a 10-min purge with nitrogen. An additional 250 mL of benzene were added and the reaction mixture was heated to boiling, treated with charcoal, and filtered through a pad of Celite. The filtrate was evaporated to give an orange-brown oil (62.3 g) that was revealed by tlc (1:1 (v/v) acetone–toluene) to consist of a single major component having R_f 0.40 and several minor components. The oil was diluted with acetone (10 mL) to reduce its viscosity and resolved by liquid chromatography (Waters Associates PrepLC/System 500) to give the major component (42.2 g), mp 78–88°C, which was recrystallized from ethyl acetate – hexanes to give a white solid (35.7 g, 61.1%), mp 92–93°C. An analytical sample of **9** was prepared by a second recrystallization from ethyl acetate – hexanes, mp 93–94°C; [1]Hmr (200 MHz, Me_2SO-d_6) δ: 1.90 (3H, s, OAc), 1.90–2.27 (4H, m, H-2, H-2′, H-5, and H-5′), 2.78 (1H, d of d of d, $^3J_{4,5}$ = 11.1, $^3J_{4,5'}$ = 7.7, $^3J_{4,3}$ = 5.4 Hz, H-4), 2.91 (1H, q of d, ^3J = 9.4, ^3J = 6.5 Hz, H-1), 3.61 (3H, s, OMe), 5.24 (1H, t of d, ^3J = 5.4, $^3J_{3,2}$ = 2.9 Hz, H-3), 6.84 (1H, br s, $CONH_2$), 7.22 (1H, br s, $CONH_2$); spin–spin decoupled at H-3. *Anal.* calcd. for $C_{10}H_{15}O_5N$: C 52.40, H 6.60, N 6.11; found: C 52.15, H 6.91, N 6.05.

(±)-(1β,2β,4β)-2-Hydroxy-4-(hydroxymethyl)cyclopentane-carboxamide (10)

A solution of $LiBH_4$ (5.0 g, 228 mmol) in tetrahydrofuran (250 mL) was heated at reflux temperature for 1 h, cooled to about 40°C, **9** (13.1 g, 57 mmol) in tetrahydrofuran (60 mL) was added, and the heating was continued for 2 h. The reaction solution was then cooled to ice-bath temperature, water (200 mL) was added slowly, and then Amberlite IR-120 resin (H^+ form) (150 mL). The reaction mixture was stirred overnight, and the resin was removed by filtration and washed with water (300 mL). The pH of the combined filtrate and washings was adjusted to neutrality by treatment with Dowex 1-X8 resin (OH^- form) (~200 mL). The resin was removed by filtration and washed with water (~250 mL). The volume of the combined filtrate and washings was reduced by evaporation and the resulting oil was evaporated with methanol (3 × 50 mL). The oil was then stirred in the presence of tetrahydrofuran (45 mL). The white solid that formed (5.5 g, 60.6%) was collected by filtration; mp 113–116°C; R_f 0.44 (tlc) (3:1 (v/v) chloroform–methanol). An analytical sample was prepared by recrystallization from methanol – diethyl ether, mp 117–118°C; [1]Hmr (200 MHz, Me_2SO-d_6) δ: 1.34 (1H, d of d of d, J_{gem} = 13.4, $^3J_{3,4}$ = 5.0, $^3J_{3,2}$ = 2.6 Hz, H-3), 1.60 (1H, m, J_{gem} = 12.2, $^3J_{5,1}$ = 11.6, $^3J_{5,4}$ = 8.9 Hz, H-5), 1.75–1.89 (2H, m, H-3′ and H-5′), 2.04 (1H, m, H-4), 2.44 (1H, m, $^3J_{1,5}$ = 11.6, $^3J_{1,5'}$ = 7.0, $^3J_{1,2}$ = 4.6 Hz, H-1), 3.33 (2H, d of d, $^3J_{\text{to }CH_2OH}$ = 5.1, $^3J_{\text{to H-4}}$ = 6.6 Hz, C*H*$_2$OH), 4.18 (1H, m, $^3J_{2,3'}$ = 7.3, $^3J_{2,1}$ = 4.6, $^3J_{2,3}$ = 2.6, $^3J_{\text{to CHOH}}$ = 3.4 Hz, H-2), 4.58 (1H, t, $^3J_{\text{to }CH_2OH}$ = 5.1 Hz, CH_2OH), 4.84 (1H, d, $^3J_{\text{to H-2}}$ = 3.4 Hz, CHO*H*), 6.91 (1H, br s, $CONH_2$), 7.28 (1H, br s, $CONH_2$); spin–spin decoupled at H-1, H-2, H-3, H-4, and C*H*$_2$OH. *Anal.* calcd. for $C_7H_{13}O_3N$: C 52.82, H 8.23, N 8.80; found: C 52.90, H 8.02, N 8.85.

(±)-(1β,3β,4β)-4-Amino-3-hydroxycyclopentanemethanol (17)

A freshly prepared solution of $Ba(OH)_2 \cdot 8H_2O$ (90.9 g, 288 mmol) in water (1.85 L) was filtered to remove any $BaCO_3$ present and cooled to 5°C. To this solution was added Br_2 (3.6 mL, 70.3 mmol) and, immediately after the Br_2 had dissolved, compound **10** (10.2 g, 64 mmol) in water (50 mL) was added and the reaction solution was left to warm to room temperature during the next 2 h. The reaction solution was heated at 65–70°C for 1 h, cooled to about 10°C, acidified with 3 *M* H_2SO_4 (76 mL), and stirred for 1 h. The reaction mixture was kept in the cold room overnight and the $BaSO_4$ was removed by centrifugation. The solution was passed through Amberlite CG-120 resin (H^+ form) (150 g). The resin was then washed with water (1.1 L) and eluted with 2 *N* aqueous ammonia. Most of the product (**17**) was obtained after 1.5 L of 2 *N* ammonia solution had been used, and only traces were obtained with the next 0.5 L. The solvent was evaporated and the resulting oil was dissolved in ethanol; the solution was filtered to remove particulate matter and the filtrate was evaporated to give a pale orange oil (2.90 g, 34.5%). The ^{1}Hmr spectrum did not show any signals attributable to impurities; ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.08 (1H, d of t, J_{gem} = 12.5, ^3J = 7.5 Hz, H-5), 1.31 (1H, m, J_{gem} = 12.9, $^3J_{2,1}$ = 6.2, $^3J_{2,3}$ = 5.1 Hz, H-2), 1.71–1.89 (2H, m, H-2′ and H-5′), 1.85–2.08 (1H, m, H-1), 2.95 (1H, m, ^3J = 7, $^3J_{4,3}$ = 5.1 Hz, H-4), 3.29 (2H, d, $^3J_{\text{to H-1}}$ = 5.8 Hz, CH_2OH), 3.73 (1H, q, ^3J = 5.1 Hz, H-3); spin–spin decoupled at H-3, H-4, and H-5.

3-Ethoxypropenoyl chloride (14)

Ethyl 3-ethoxypropenoate (**11**) was prepared from ethyl bromoacetate and ethyl orthoformate by the Reformatsky reaction as described previously (20–22). The rate of elimination of ethanol from the crude acetal precursor was accelerated by the addition of *p*-toluenesulfonic acid or $KHSO_4$ to the refluxing solution; ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.20 (3H, t, ^3J = 7.1 Hz, CH_3), 1.25 (3H, t, ^3J = 7.1 Hz, CH_3), 3.97 (2H, q, ^3J = 7.1 Hz, —CH_2O—), 4.08 (2H, q, ^3J = 7.1 Hz, —CH_2O—), 5.24 (1H, d, ^3J = 12.5 Hz, H-2), 7.59 (1H, d, ^3J = 12.5 Hz, H-3); ^{1}Hmr (200 MHz, $CDCl_3$) δ: 1.28 (3H, t, ^3J = 7.2 Hz, CH_3), 1.35 (3H, t, ^3J = 7.1 Hz, CH_3), 3.91 (2H, q, ^3J = 7.1 Hz, —CH_2O—), 4.17 (2H, q, ^3J = 7.2 Hz, —CH_2O—), 5.19 (1H, d, ^3J = 12.9 Hz, H-2), 7.59 (1H, d, ^3J = 12.9 Hz, H-3).

The following compounds were prepared as described previously (21–22): 3-ethoxypropenoic acid (**12**) by alkaline hydrolysis of **11**; ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.24 (3H, t, ^3J = 7.1 Hz, CH_3), 3.94 (2H, q, ^3J = 7.1 Hz, —CH_2O—), 5.14 (1H, d, ^3J = 12.5 Hz, H-2), 7.52 (1H, d, ^3J = 12.5 Hz, H-3), 11.78 (1H, br s, CO_2H); ^{1}Hmr (200 MHz, $CDCl_3$) δ: 1.34 (3H, t, ^3J = 7.1 Hz, CH_3), 3.95 (2H, q, ^3J = 7.1 Hz, —CH_2O—), 5.19 (1H, d, ^3J = 12.6 Hz, H-2), 7.69 (1H, d, ^3J = 12.6 Hz, H-3), 12.15 (1H, br s, CO_2H); sodium 3-ethoxypropenoate (**13**) by neutralization of **12** with NaOH; ^{1}Hmr (200 MHz, Me_2SO-d_6 + D_2O) δ: 1.25 (3H, t, ^3J = 7.1 Hz, CH_3), 3.87 (2H, q, ^3J = 7.1 Hz, —CH_2O—), 5.16 (1H, d, ^3J = 12.7 Hz, H-2), 7.23 (1H, d, ^3J = 12.7 Hz, H-3); and 3-ethoxypropenoyl chloride (**14**) from **13**, using $SOCl_2$ in diethyl ether; ^{1}Hmr (200 MHz, $CDCl_3$) δ: 1.40 (3H, t, ^3J = 7.1 Hz, CH_3), 4.07 (2H, q, ^3J = 7.1 Hz, —CH_2O—), 5.51 (1H, d, ^3J = 12.1 Hz, H-2), 7.80 (1H, d, ^3J = 12.1 Hz, H-3).

3-Ethoxypropenoyl isocyanate (15) (refs. 22, 23)

A stirred mixture of silver cyanate (21.3 g, 142 mmol) in dry benzene (125 mL) was heated at reflux temperature for 0.5 h and 3-ethoxypropenoyl chloride (**14**) (9.57 g, 71 mmol) in benzene (25 mL) was added over a period of 10 min. The mixture was heated for an additional 0.5 h and stirred at room temperature for 2.5 h. The solid was allowed to settle and the solution of **15** was used immediately for the preparation of **18** and **23** as described below.

(±)-3-Ethoxy-N-{N′-[(1β,2β,4β)-2-hydroxy-4-(hydroxymethyl)-cyclopentyl]carbamoyl}propenamide (18)

To a dried (4 Å molecular sieves), cooled (−15°C) solution of compound **17** (2.06 g, 15.7 mmol) in *N,N*-dimethylformamide (50 mL) were added, under a nitrogen atmosphere, 40 mL of the solution of the isocyanate **15** obtained above; the reaction temperature was maintained below −10°C. After the addition of **15** was complete, the reaction solution was stirred at room temperature overnight. The solution was filtered and the solvents were removed under vacuum. The residue was evaporated with ethanol (2 × 20 mL) and fractionated by column chromatography on silica gel using toluene – ethyl acetate – 2-propanol (3:3:2, v/v/v) to give **18** (1.80 g, 42%, based on the amount of the amine) as a pale yellow solid, R_f 0.39 (tlc); ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.15–1.36 and 1.86–2.05 (5H, m, H-3′, H-3″, H-4′, H-5′, and H-5″), 1.25 (3H, t, ^3J = 7.1 Hz, CH_3), 3.28–3.40 (2H, m, CH_2OH), 3.76–4.08 (2H, m, H-1′ and H-2′), 3.94 (2H, q, ^3J = 7.1 Hz, CH_3CH_2O), 4.59 (1H, t, ^3J = 5.0 Hz, CH_2OH), 4.91 (1H, d, $^3J_{\text{to H-2}'}$ = 4.6 Hz, OH at position 2′), 5.51 (1H, d, $^3J_{2,3}$ = 12.3 Hz, H-2), 7.55 (1H, d, $^3J_{3,2}$ = 12.3 Hz, H-3), 8.74 (1H, br d, $^3J_{\text{to H-1}'}$ = 7.8 Hz, CONHCONH), 9.95 (1H, br s, CONHCO); spin–spin decoupled at δ 3.28–3.40, H-2 and δ 1.25.

(±)-1-[(1β,2β,4β)-2-Hydroxy-4-(hydroxymethyl)cyclopentyl]-2,4(1H,3H)-pyrimidinedione (19)

A solution of **18** (1.78 g, 6.54 mmol) in 2 *N* sulfuric acid (50 mL) was heated at reflux temperature under a nitrogen atmosphere for 30 min. The solution was cooled to room temperature, treated with charcoal, filtered, and the charcoal was washed with 10 mL of water. The combined filtrate and washings were cooled to ice-bath temperature and neutralized with 2 *N* sodium hydroxide. The solvent was evaporated and the residue was extracted with ethanol (4 × 20 mL). Evaporation of the ethanol gave an oil which was fractionated by column chromatography on silica gel to give **19** (1.00 g, 68%) as a white solid, R_f 0.34 (tlc) (1:1:1 (v/v/v) toluene – ethyl acetate – 2-propanol). An analytical sample was prepared by recrystallization from ethanol – diethyl ether, mp 158–160°C; uv λ_{max} (C_2H_5OH): 210 nm (ε 9480), 268 (11 100); λ_{max} (0.01 *N* HCl in C_2H_5OH): 210 nm (ε 9570), 268 (11 100); λ_{max} (0.01 *N* NaOH in C_2H_5OH): 220 nm (ε 9330), 265 (8310); ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.30 (1H, m, $^3J_{3',2'}$ = 2.0 Hz, H-3′), 1.62–1.90 (2H, m, H-4′ and H-5′), 1.96–2.16 (2H, m, H-3″ and H-5″), 3.33–3.42 (2H, m, CH_2OH), 4.02 (1H, m, H-2′), 4.49 (1H, m, $^3J_{\text{to H at 5}'}$ = 12.2, $^3J_{\text{to H at 5}'}$ = 7.1, $^3J_{1',2'}$ = 4.9 Hz, H-1′), 4.65 (1H, t, $^3J_{\text{to } CH_2OH}$ = 5.2 Hz, CH_2OH), 4.94 (1H, d, $^3J_{\text{to H-2}'}$ = 4.5 Hz, CHOH), 5.48 (1H, d of d, $^3J_{5,6}$ = 7.8, $^4J_{5,3}$ = 1.7 Hz, H-5), 7.60 (1H, d, $^3J_{6,5}$ = 7.8 Hz, H-6), 11.20 (1H, br s, H-3); spin–spin decoupled at H-3′, H-2′, and H-3. *Anal.* calcd. for $C_{10}H_{14}O_4N_2$: C 53.09, H 6.24, N 12.38; found: C 53.16, H 6.24, N 12.35.

3-Ethoxypropenoyl isothiocyanate (16)

Compound **16** was prepared from 3-ethoxypropenoyl chloride (**14**) and potassium thiocyanate as described by Shaw and Warrener (21) and was used immediately after distillation under vacuum to prepare compounds **20** and **25**.

(±)-3-Ethoxy-N-{N′-[(1β,2β,4β)-2-hydroxy-4-(hydroxymethyl)-cyclopentyl]thiocarbamoyl}propenamide (20)

To a solution of **17** (0.379 g, 2.89 mmol) in methanol (5 mL) and diethyl ether (10 mL) was added the isothiocyanate **16** (0.454 g, 2.89 mmol) at room temperature. The reaction solution was kept at room temperature overnight, filtered, and the filtrate was evaporated to give an orange oil (1.0 g) that was fractionated by column chromatography on silica gel to give **20** (0.57 g, 68%) as a pale yellow solid, R_f 0.48 (tlc) (4:4:1 (v/v/v) toluene – ethyl acetate – 2-propanol); ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.17–1.43 (2H, m, H-3′ and H-5′), 1.26 (3H, t, ^3J = 7.0 Hz, CH_3), 1.91–2.09 (2H, m, H-3″ and H-4′), 2.18 (1H, d of t, J_{gem} = 11.5, ^3J = 7.1 Hz, H-5″), 3.31–3.36 (2H, m, CH_2OH), 3.98 (2H, q, ^3J = 7.0 Hz, CH_3CH_2O), 3.99–4.03 (1H, m, H-2′), 4.31 (1H, m, H-1′), 4.64 (1H, t, $^3J_{\text{to } CH_2OH}$ = 5.1 Hz, CH_2OH), 5.15 (1H, d, $^3J_{\text{to H-2}'}$ = 4.9 Hz, OH at position 2′), 5.71 (1H, d, $^3J_{2,3}$ = 12.6 Hz, H-2), 7.59 (1H, d, $^3J_{3,2}$ = 12.6 Hz, H-3), 10.79 (1H, br s, CONHCS), 11.10 (1H, br d, $^3J_{\text{to H-1}'}$ = 7.7 Hz, CONHCSNH); spin–spin decoupled at H-1′, and δ 1.26 and 4.0.

(±)-2,3-Dihydro-1-[(1β,2β,4β)-2-hydroxy-4-(hydroxymethyl)-cyclopentyl]-2-thioxo-4(1H)-pyrimidinone (21)

A stirred solution of **20** (0.53 g, 1.84 mmol) in 15 *N* aqueous ammonia (20 mL) was heated in an oil bath at 100°C for 20 min. The reaction solution was cooled to room temperature and the solvent evaporated to give an oil, which was then evaporated with ethanol (3 × 10 mL). The residual oil was fractionated by column chromatography on silica gel to give **21** (0.135 g, 30%) as a white solid, R_f 0.40 (tlc) (2:2:1 (v/v/v) toluene – ethyl acetate – 2-propanol); mp 180–187°C. An analytical sample was prepared by recrystallization from methanol – diethyl ether, mp 184–186°C; uv λ_{max} (C_2H_5OH): 221 nm (ε 17 300), 274 (12 700); λ_{max} (0.01 *N* HCl in C_2H_5OH): 221 nm (ε 17 300), 274 (12 700); λ_{max} (0.01 *N* NaOH in C_2H_5OH): 241 nm (ε 21 300), 274 (15 400); ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.34 (1H, m, H-3′), 1.69–2.13 (4H, m, H-3″, H-4′, H-5′, and H-5″), 3.40 (2H, m, C*H*$_2$OH), 4.20 (1H, m, H-2′), 4.68 (1H, t, $^3J_{\text{to } CH_2OH}$ = 5.1 Hz, CH$_2$O*H*), 5.04 (1H, d, $^3J_{\text{to H-2}'}$ = 4.3 Hz, OH at position 2′), 5.41 (1H, m, $^3J_{1',5'}$ = 12.2, $^3J_{1',5''}$ = 6.8, $^3J_{1',2'}$ = 5.1 Hz, H-1′), 5.88 (1H, d of d, $^3J_{5,6}$ = 8.1, $^4J_{5,3}$ = 1.9 Hz, H-5), 7.75 (1H, d, $^3J_{6,5}$ = 8.1 Hz, H-6), 12.59 (1H, br s, H-3); spin–spin decoupled at δ 1.34, 4.20, 4.68, 5.04, 5.41, 5.88, and 7.75. *Anal.* calcd. for $C_{10}H_{14}O_3N_2S$: C 49.57, H 5.82, N 11.56, S 13.23; found: C 50.04, H 6.08, N 11.73, S 13.27.

(±)-(1β,2β,4β)-4-Amino-2-hydroxycyclopentanemethanol (22)

Compound **22** was prepared from **6** (9.74 g, 61.2 mmol), according to the procedure described for the preparation of **17**, to give an orange-brown oil (2.19 g, 27%). The ^{1}Hmr spectrum did not show any signals attributable to impurities; ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.12 (1H, m, H-5), 1.39 (1H, d of d of d, J_{gem} = 13.5, $^3J_{3,4}$ = 4.4, $^3J_{3,2}$ = 2.8 Hz, H-3), 1.71–1.97 (3H, m, H-1, H-3′, and H-5′), 3.23 (1H, m, H-4), 3.37 (1H, d of d, J_{gem} = 10.6, $^3J_{\text{to H-1}}$ = 6.2 Hz, C*H*$_2$OH), 3.59 (1H, d of d, J_{gem} = 10.6, $^3J_{\text{to H-1}}$ = 7.2 Hz, C*H*$_2$OH), 4.00 (1H, m, H-2); spin–spin decoupled at δ 1.12, 1.39, 3.59, and 4.00.

(±)-3-Ethoxy-N-{N′-[(1β,3β,4β)-3-hydroxy-4-(hydroxymethyl)-cyclopentyl]carbamoyl}propenamide (23)

Compound **23** was prepared from **22** (1.57 g, 12 mmol) and the solution of the isocyanate **15** (32 mL) according to the procedure described for the preparation of **18**. Fractionation by column chromatography on silica gel afforded a crude sample of **23** (1.5 g, 49%, based on the amount of the amine) as a pale yellow, oily solid, R_f 0.34 (tlc) (3:3:2 (v/v/v) toluene – ethyl acetate – 2-propanol). The ^{1}Hmr spectrum showed several minor signals attributable to impurities; ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.17–1.34 (1H, m, H-5′), 1.25 (3H, t, ^3J = 7.0 Hz, CH$_3$), 1.45 (1H, m, H-2′), 1.83 (1H, m, H-4′), 1.98–2.14 (2H, m, H-2″ and H-5″), 3.40 (1H, m, J_{gem} = 10.9, $^3J_{\text{to } CH_2OH \text{ and H-4}'}$ = 5.5 Hz, C*H*$_2$OH), 3.57 (1H, d of d of d, J_{gem} = 10.9, $^3J_{\text{to H-4}'}$ = 7.2, $^3J_{\text{to } CH_2OH}$ = 5.5 Hz, C*H*$_2$OH), 3.93 (2H, q, ^3J = 7.0 Hz, CH$_3$C*H*$_2$O), 4.03–4.22 (2H, m, H-1′ and H-3′), 4.28 (1H, t, $^3J_{\text{to } CH_2OH}$ = 5.5 Hz, CH$_2$O*H*), 4.57 (1H, d, $^3J_{\text{to H-3}'}$ = 3.8 Hz, OH at position 3′), 5.50 (1H, d, $^3J_{2,3}$ = 12.4 Hz, H-2), 7.53 (1H, d, $^3J_{3,2}$ = 12.4 Hz, H-3), 8.72 (1H, br d, $^3J_{\text{to H-1}'}$ = 8.3 Hz, CONHCON*H*), 9.92 (1H, br s, CON*H*CONH); spin–spin decoupled at δ 1.26 and 8.72.

(±)-1-[(1β,3β,4β)-3-Hydroxy-4-(hydroxymethyl)cyclopentyl]-2,4(1H,3H)-pyrimidinedione (24)

Compound **24** was prepared from **23** (1.53 g, 5.6 mmol) according to the procedure described for the preparation of **19**. Fractionation by column chromatography on silica gel afforded **24** (0.726 g, 57%) as a white solid, R_f 0.31 (tlc) (1:1:1 (v/v/v) toluene – ethyl acetate – 2-propanol). An analytical sample was prepared by recrystallization from ethanol–hexanes; mp 154–155°C; uv λ_{max} (C_2H_5OH): 209 nm (ε 9120), 268 (10 300); λ_{max} (0.01 *N* HCl in C_2H_5OH): 210 nm (ε 9140), 268 (10 300); λ_{max} (0.01 *N* NaOH in C_2H_5OH): 221 nm (ε 8310), 265 (7610); ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.37 (1H, t of d, J_{gem} = $^3J_{5',4'}$ = 11.8, $^3J_{5',1'}$ = 9.0 Hz, H-5′), 1.51 (1H, d of d, J_{gem} = 15.1, $^3J_{2',1'}$ = 3.9 Hz, H-2′), 1.89 (1H, m, H-4′), 2.05 (1H, m, J_{gem} = 11.8, ^3J = 7.3 Hz, H-5″), 2.30 (1H, m, J_{gem} = 15.1, $^3J_{2'',1'}$ = 11.1, $^3J_{2'',3'}$ = 4.6 Hz, H-2″), 3.43 (1H, m, J_{gem} = 10.9, $^3J_{\text{to H-4}'}$ = 6.1, $^3J_{\text{to } CH_2OH}$ = 5.3 Hz, C*H*$_2$OH), 3.60 (1H, d of d of d, J_{gem} = 10.9, $^3J_{\text{to H-4}'}$ = 7.3, $^3J_{\text{to } CH_2OH}$ = 5.3 Hz, C*H*$_2$OH), 4.11 (1H, m, H-3′), 4.39 (1H, t, $^3J_{\text{to } CH_2OH}$ = 5.3 Hz, CH$_2$O*H*), 5.03 (1H, d, $^3J_{\text{to H-3}'}$ = 3.6 Hz, OH at position 3′), 5.04 (1H, m, H-1′), 5.67 (1H, d of d, $^3J_{5,6}$ = 8.2, $^4J_{5,3}$ = 2.0 Hz, H-5), 7.90 (1H, d, $^3J_{6,5}$ = 8.2 Hz, H-6), 11.20 (1H, br s, H-3); spin–spin decoupled at δ 4.11 and 4.39. *Anal.* calcd. for $C_{10}H_{14}O_4N_2$: C 53.09, H 6.24, N 12.38; found: C 53.13, H 6.41, N 12.34.

(±)-3-Ethoxy-N-{N′-[(1β,3β,4β)-3-hydroxy-4-(hydroxymethyl)-cyclopentyl]thiocarbamoyl}propenamide (25)

Compound **25** was prepared from **22** (0.234 g, 1.78 mmol) and **16** (0.285 g, 1.81 mmol) according to the procedure described for the preparation of **20**. Fractionation by column chromatography on silica gel afforded **25** (0.275 g, 54%) as a colorless oil, R_f 0.56 (tlc) (2:2:1 (v/v/v) toluene – ethyl acetate – 2-propanol); ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.20–1.35 (1H, m, H-5′), 1.25 (3H, t, ^3J = 7.0 Hz, CH$_3$), 1.56 (1H, m, J_{gem} = 14.1, $^3J_{2',1'}$ = 2.3 Hz, H-2′), 1.87 (1H, m, H-4′), 2.06 (1H, m, J_{gem} = 14.1, $^3J_{2'',1'}$ = 8.5, $^3J_{2'',3'}$ = 4.7 Hz, H-2″), 2.21 (1H, d of t, J_{gem} = 13.0, ^3J = 8.2 Hz, H-5″), 3.40 (1H, m, J_{gem} = 10.7, $^3J_{\text{to } CH_2OH}$ = 5.3, $^3J_{\text{to H-4}'}$ = 5.3 Hz, C*H*$_2$OH), 3.58 (1H, d of d of d, J_{gem} = 10.7, $^3J_{\text{to H-4}'}$ = 7.2, $^3J_{\text{to } CH_2OH}$ = 5.3 Hz, C*H*$_2$OH), 3.96 (2H, q, ^3J = 7.0 Hz, CH$_3$C*H*$_2$O), 4.10 (1H, m, H-3′), 4.31 (1H, t, $^3J_{\text{to } CH_2OH}$ = 5.3 Hz, C*H*$_2$OH), 4.58–4.73 (1H, m, H-1′), 4.64 (1H, d, $^3J_{\text{to H-3}'}$ = 3.3 Hz, OH at position 3′), 5.70 (1H, d, $^3J_{2,3}$ = 12.2 Hz, H-2), 7.57 (1H, d, $^3J_{3,2}$ = 12.2 Hz, H-3), 10.73 (1H, br s, CON*H*CSNH), 11.10 (1H, br d, $^3J_{\text{to H-1}'}$ = 8.0 Hz, CONHCSN*H*); spin–spin decoupled at δ 4.10 and 4.65.

(±)-2,3-Dihydro-1-[(1β,3β,4β)-3-hydroxy-4-(hydroxymethyl)-cyclopentyl]-2-thioxo-4(1H)-pyrimidinone (26)

Compound **26** was prepared from **25** (0.27 g, 0.94 mmol) according to the procedure described for the preparation of **21**. Fractionation by column chromatography on silica gel afforded **26** (0.153 g, 67%) as a white solid, R_f 0.44 (tlc) (2:2:1 (v/v/v) toluene – ethyl acetate – 2-propanol). An analytical sample was prepared by recrystallization from ethanol–hexanes, mp 156–157°C; uv λ_{max} (C_2H_5OH): 219 nm (ε 16 600), 273 (13 700); λ_{max} (0.01 *N* HCl in C_2H_5OH): 219 nm (ε 16 600), 273 (13 800); λ_{max} (0.01 *N* NaOH in C_2H_5OH): 240 nm (ε 19 400), 272 (16 200); ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.35 (1H, t of d, J_{gem} = 12.3, $^3J_{5',1'}$ = 9.3 Hz, H-5′), 1.56 (1H, d of d, J_{gem} = 15.4, $^3J_{2',1'}$ = 3.7 Hz, H-2′), 1.91 (1H, m, H-4′), 2.17 (1H, m, J_{gem} = 12.3, ^3J = 7.5 Hz, H-5″), 2.36 (1H, m, J_{gem} = 15.4, $^3J_{2'',1'}$ = 11.2, $^3J_{2'',3'}$ = 4.4 Hz, H-2″), 3.44 (1H, m, J_{gem} = 10.6, $^3J_{\text{to H-4}'}$ = 6.2, $^3J_{\text{to } CH_2OH}$ = 5.2 Hz, C*H*$_2$OH), 3.60 (1H, m, J_{gem} = 10.6, $^3J_{\text{to H-4}'}$ = 7.6, $^3J_{\text{to } CH_2OH}$ = 5.2 Hz, C*H*$_2$OH), 4.14 (1H, m, H-3′), 4.40 (1H, t, $^3J_{\text{to } CH_2OH}$ = 5.2 Hz, CH$_2$O*H*), 5.15 (1H, d, $^3J_{\text{to H-3}'}$ = 3.4 Hz, OH at position 3′), 5.99 (1H, m, H-1′), 6.09 (1H, d, $^3J_{5,6}$ = 8.2 Hz, H-5), 8.11 (1H, d, $^3J_{6,5}$ = 8.2 Hz, H-6), 12.55 (1H, br s, H-3); spin–spin decoupled at δ 4.14 and 5.99. *Anal.* calcd. for $C_{10}H_{14}O_3N_2S$: C 49.57, H 5.82, N 11.56, S 13.23; found: C 49.61, H 5.97, N 11.80, S 13.25.

(±)-(1β,6β,8β)-3,3-Dimethyl-2,4-dioxabicyclo[4.3.0]nonane-8-carboxamide (27)

To a stirred mixture of **6** (14.0 g, 88 mmol) in acetone (200 mL) and 2,2-dimethoxypropane (50 mL) was added *p*-toluenesulfonic acid monohydrate (~20 mg) and the mixture was heated gently at reflux temperature for 30 min. The reaction mixture was cooled to room temperature, and the white solid was collected by filtration and washed with acetone to give **27** (10.88 g), R_f 0.31 (tlc) (2:2:1 (v/v/v) toluene – ethyl acetate – 2-propanol). The volume of the mother liquor was reduced and a second crop of **27** (2.47 g) was obtained for a total yield of 13.35 g. The volatile components were evaporated from the filtrate and the resulting oil was dissolved in acetone (30 mL) and 2,2-dimethoxypropane (10 mL). About 10 mg of the acid catalyst was added and the reaction mixture was stirred at room temperature for 30 min to give an additional 2.08 g of **27** as a white solid for a total yield of 15.43 g (88%). Thin-layer chromatography showed that this material contained trace amounts of a second component having R_f 0.08.

An analytical sample was prepared by fractionation on a column of alumina gel followed by recrystallization of the material from acetone; mp 169°C; ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.22 (3H, s, CH_3), 1.35 (3H, s, CH_3), 1.65–1.95 (4H, m, H-6, H-7, H-7′, and H-9), 2.07 (1H, m, J_{gem} = 14.3, $^3J_{9',8}$ = 10.1, $^3J_{9',1}$ = 5.5 Hz, H-9′), 2.56 (1H, m, H-8), 3.54 (1H, d of d, J_{gem} = 11.7, $^3J_{5,6}$ = 2.3 Hz, H-5), 3.99 (1H, d of d, J_{gem} = 11.7, $^3J_{5',6}$ = 3.7 Hz, H-5′), 4.23 (1H, m, H-1), 6.75 (1H, br s, $CONH_2$), 7.13 (1H, br s, $CONH_2$); spin–spin decoupled at δ 3.99 and 4.23. *Anal.* calcd. for $C_{10}H_{17}O_3N$: C 60.28, H 8.60, N 7.03; found: C 60.01, H 8.74, N 7.19.

(±)-Methyl [(1β,6β,8β)-3,3-dimethyl-2,4-dioxabicyclo[4.3.0]non-8-yl]carbamate (28)

A solution of sodium (1.65 g, 0.0718 g atom) in methanol (50 mL) was added to a solution of **27** (7.16 g, 35.9 mmol) in methanol (65 mL). To this solution Br_2 (1.84 mL, 35.9 mmol) was added with thorough mixing and the reaction solution was heated on a steam bath for 10 min. The solution was made just acidic with acetic acid and the solvent was evaporated. The residue was washed with water (10 mL) and the solid was collected by filtration to give **28** (6.34 g, 77%), R_f 0.72 (tlc) (2:2:1 (v/v/v) toluene – ethyl acetate – 2-propanol); tlc showed that this material contained traces of more-polar components. A small, oily sample of **28** was obtained by column chromatography on silica gel; ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.25 (3H, s, CH_3C), 1.34 (3H, s, CH_3C), 1.39 (1H, d of d of d, J_{gem} = 14.4, $^3J_{9,8}$ = 6.5, $^3J_{9,1}$ = 1.9 Hz, H-9), 1.65–1.93 (3H, m, H-6, H-7, and H-7′), 2.18 (1H, m, J_{gem} = 14.4, $^3J_{9',8}$ = 8.8, $^3J_{9',1}$ = 5.7 Hz, H-9′), 3.51 (3H, s, CH_3O), 3.51 (1H, d of d, J_{gem} = 11.9, $^3J_{5,6}$ = 2.1 Hz, H-5), 3.84 (1H, m, H-8), 3.98 (1H, d of d, J_{gem} = 11.9, $^3J_{5',6}$ = 3.7 Hz, H-5′), 4.20 (1H, m, H-1), 7.02 (1H, br d, $^3J_{\text{to H-8}}$ = 7.7 Hz, NH); spin–spin decoupled at δ 2.18 and 4.20.

(±)-(1β,6β,8β)-8-Amino-3,3-dimethyl-2,4-dioxabicyclo[4.3.0]-nonane (29)

A solution of **28** (6.02 g, 26.2 mmol) in 5 *N* aqueous sodium hydroxide (60 mL) and methanol (30 mL) was heated at reflux temperature for 4 h. The reaction solution was cooled to room temperature and extracted with dichloromethane (40 mL). The dichloromethane extract was evaporated under vacuum to give **29** (3.55 g, 79%) as a light yellow-green oil, R_f 0.45 (tlc) (5:1 (v/v) acetonitrile – 15 *N* aqueous ammonia). The ^{1}Hmr spectrum did not show any signals attributable to impurities; ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.24 (3H, s, CH_3), 1.30 (1H, m, H-9), 1.34 (3H, s, CH_3), 1.47 (1H, m, J_{gem} = 10.8, ^3J = 7.6 Hz, H-7), 1.69–1.82 (1H, m, H-6), 1.87 (1H, d of t, J_{gem} = 10.8, ^3J = 7.2 Hz, H-7′), 2.04 (1H, d of d of d, J_{gem} = 13.5, $^3J_{9',8}$ = 8.4, $^3J_{9',1}$ = 5.5 Hz, H-9′), 3.15 (1H, m, H-8), 3.50 (1H, d of d, J_{gem} = 11.6, $^3J_{5,6}$ = 3.2 Hz, H-5), 3.96 (1H, d of d, J_{gem} = 11.6, $^3J_{5',6}$ = 4.2 Hz, H-5′), 4.17 (1H, m, $^3J_{1,9'}$ = 5.5, $^3J_{1,9}$ = 2.2 Hz, H-1); spin–spin decoupled at δ 1.47, 3.15, 3.96, and 4.17.

*(±)-Ethoxy-*N*-{*N*′-[(1β,6β,8β)-3,3-dimethyl-2,4-dioxabicyclo-[4.3.0]non-8-yl]carbamoyl}propenamide (30)*

Compound **29** (1.60 g, 9.3 mmol) was dissolved in benzene (16 mL) and ~2 mL were removed by distillation. The solution was cooled to ice-bath temperature and a benzene solution (45 mL) containing **15** (13.4 mmol) was added dropwise over a period of 12 min; the reaction solution was then stirred at room temperature overnight. The solvent was evaporated and the residual oil was evaporated with ethanol (2 × 10 mL). Fractionation by column chromatography on silica gel gave **30** (2.2 g, 76%, based on the amount of the amine), R_f 0.42 (tlc) (8:8:1 (v/v/v) toluene – ethyl acetate – 2-propanol); ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.24 (3H, t, ^3J = 7.1 Hz, CH_3CH_2), 1.31 (3H, s, CH_3C), 1.37 (3H, s, CH_3C), 1.49 (1H, m, J_{gem} = 14.4 Hz, H-9′), 1.62 (1H, m, J_{gem} = 12.5, ^3J = 9.7, ^3J = 5.4 Hz, H-7′), 1.83 (1H, m, H-6′), 2.03 (1H, m, J_{gem} = 14.4, ^3J = 8.8, ^3J = 4.7 Hz, H-9″), 2.15 (1H, d of t, J_{gem} = 12.5, ^3J = 8.3 Hz, H-7″), 3.53 (1H, d of d, J_{gem} = 11.7, $^3J_{5',6'}$ = 2.2 Hz, H-5′), 3.94 (2H, q, ^3J = 7.1 Hz, CH_3CH_2O), 4.03 (1H, d of d, J_{gem} = 11.7, $^3J_{5'',6'}$ = 3.9 Hz, H-5″), 4.18–4.35 (2H, m, H-1′ and H-8′), 5.49 (1H, d, $^3J_{2,3}$ = 12.3 Hz, H-2), 7.52 (1H, d, $^3J_{3,2}$ = 12.3 Hz, H-3), 8.77 (1H, br d, $^3J_{\text{to H-8'}}$ = 8.6 Hz, CONHCON*H*), 9.95 (1H, br s, CON*H*CONH); spin–spin decoupled at δ 1.83 and 3.53.

*Preparation of **24** from **30***

A stirred mixture of **30** (2.2 g, 70 mmol) in 2 *N* H_2SO_4 (70 mL) was heated at reflux temperature for 20 min. The solution was cooled to ice-bath temperature and neutralized with 2 *N* NaOH. The solvent was evaporated and the residue was extracted with warm ethanol. The ethanol extract was evaporated and the residual oil was fractionated by column chromatography on silica gel to give **24** (1.034 g, 65%) as a white solid having an R_f (tlc) and ^{1}Hmr spectrum identical to those of the sample of **24** prepared from **23**.

(±)-(3-Carboxycyclopent-3-enyl)amine hydrochloride (31)

To a 1 *N* NaOH solution (1 L) at 5°C was added bromine (7.3 mL, 142 mmol); as soon as the bromine had dissolved, **4** (25.77 g, 120 mmol) in 0.7 *N* NaOH solution (175 mL) was added. The reaction solution was left at room temperature for 1 h and then heated in a water bath at 70°C for 1 h. The solution was cooled to 0°C and acidified with concentrated HCl (93 mL). The reaction solution was then passed through Amberlite CG-120 cation-exchange resin (H^+ form) (500 g), and the resin was washed with water (3.5 L) and eluted with 2 *N* HCl; the elution was monitored by tlc using *n*-butanol – water – acetic acid (5:3:2, v/v/v) as the developing solvent. The first 2.2 L contained mostly NaCl and some **31**; the solvent was evaporated and the residue was extracted with methanol (6 × 50 mL) to yield a solid (4.8 g). The next 1.3 L contained mostly **31** and gave a white solid (12.4 g) after evaporation of solvent, for a total yield of 17.2 g (88% yield) of a solid containing predominantly **31**; the sample was used directly in the next reaction; ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 2.45–2.95 (4H, m, H-2, H-2′, H-5, and H-5′), 3.87 (1H, m, H-1), 6.60 (1H, m, H-4), 8.30 (3H, br s, $\overset{+}{N}H_3$), 12.50 (1H, br s, CO_2H).

(±)-[3-(Methoxycarbonyl)cyclopent-3-enyl]amine hydrochloride (32)

Anhydrous HCl was bubbled for 1 h through a solution of compound **31** (17.0 g) in dry methanol (800 mL). The solution was stirred for an additional 1 h with cooling and then at room temperature overnight. The clear liquid was decanted from a small amount of solid and evaporated to give an orange oil of crude **32**; ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 2.56–2.94 (4H, m, H-2, H-2′, H-5, and H-5′), 3.67 (3H, s, OMe), 3.78–3.96 (1H, m, H-1), 6.67 (1H, m, H-4), 8.42 (3H, br s, $\overset{+}{N}H_3$).

(±)-Methyl 4-acetamido-1-cyclopentenecarboxylate (33)

A solution of crude **32** in pyridine (500 mL) was cooled to Dry Ice – acetone bath temperature and acetic anhydride (175 mL) was added. The reaction solution was stirred at room temperature for 18 h and then the solvent was evaporated to give a red-brown oil (48 g). This oil was mixed with crushed ice (300 g) and the mixture was extracted with methylene chloride (4 × 200 mL). The organic layer was washed sequentially with ice-cold 3 *N* HCl (2 × 30 mL), a saturated solution (30 mL) of sodium hydrogen carbonate, and a saturated solution (30 mL) of sodium chloride. The organic layer was dried over Na_2SO_4 and the solvent evaporated to give an orange-brown oil (18.7 g). This material was kept for 2 days in the cold room; a crystalline solid separated, which was collected by filtration and which, after recrystallization from diethyl ether – hexanes, gave **33** (11.63 g, 53% from **4**), mp 74–76°C. An analytical sample was obtained by recrystallization from diethyl ether; mp 75–76°C; ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.77 (3H, s, OAc), 2.20–2.40 and 2.68–2.87 (4H, m, H-3, H-3′, H-5, and H-5′), 3.67 (3H, s, OMe), 4.33 (1H, m, H-4), 6.68 (1H, m, H-2), 8.10 (1H, br d, $^3J_{\text{to H-4}}$ = 6.4, N*H*COMe). Spin–spin decoupling was performed at δ 4.33; ^{1}Hmr (200 MHz, $CDCl_3$) δ: 2.28–2.51 and 2.88–3.08 (4H, m, H-3, H-3′, H-5, and H-5′), 3.75 (3H, s, OMe), 4.63 (1H, m, H-4), 5.69 (1H, br m, N*H*COMe), 6.74 (1H, m, H-2). *Anal.* calcd. for $C_9H_{13}O_3N$: C 59.00, H 7.15, N 7.65; found: C 58.87, H 7.04, N 8.06.

Ab initio molecular orbital theory was used to determine if $C_2H_6O_2^{+\cdot}$ and $C_3H_8O_2^{+\cdot}$ radical cations represented as hydrogen bridged radical cation molecular pairs, viz. $[H_2O\text{---}H\text{---}OCHCH_2]^{+\cdot}$ and $[CH_3OH\text{---}H\text{---}OCHCH_2]^{+\cdot}$ can be expected to exist as stable species in the gas phase.

The use of several basis sets was explored at the SCF level and it was found that the above species have appreciable stabilisation energies with respect to dissociation into $CH_2{=}CHOH^{+\cdot}$ and H_2O or CH_3OH. Using a 6-31**/4-31G basis set and applying BSSE (Basis Set Superposition Error) corrections, respective stabilisation energies of 88 kJ/mol and 84 kJ/mol were calculated. Preliminary calculations further indicate that conversion barriers towards isomeric structures are high and thus ions of this type may well have been observed by experiment. Several reaction profiles have been calculated at the STO-3G level and at the 4-31G level, which show that the ions can exist in a *syn* and an *anti* conformation having comparable energies, their interconversion barrier being small.

The structure parameters and stabilisation energies for these two hydrogen bridged ions are similar to those of the well known class of even electron species, usually designated as proton bound dimers.

RON POSTMA, PAUL J. A. RUTTINK, FRANS. B. VAN DUIJNEVELDT, JOHAN K. TERLOUW et JOHN L. HOLMES. Can. J. Chem. **63**, 2798 (1985).

Utilisant la théorie *ab initio* des orbitales moléculaires on a déterminé si les cations radicalaires $C_2H_6O_2^{+\cdot}$ et $C_3H_8O_2^{+\cdot}$, représentés sous la forme de paires de cations moléculaires reliés par des ponts hydrogènes comme $[H_2O\text{---}H\text{---}OCHCH_2]^{+\cdot}$ et $[CH_3OH\text{---}H\text{---}OCHCH_2]^{+\cdot}$, peuvent exister sous forme d'espèces stables en phase gazeuse.

On a utilisé plusieurs ensembles de base en champ auto-cohérent et on a trouvé que ces espèces ont des énergies de stabilisation remarquables par rapport à la dissociation en $CH_2{=}CHOH^{+\cdot}$ et en H_2O ou en CH_3OH. On a trouvé des énergies de stabilisation de 88 kJ/mol et de 84 kJ/mol respectivement en utilisant l'ensemble de base 6-31**/4-31G et en appliquant des corrections d'ensemble de base de superposition des erreurs (EBSE). Les calculs préliminaires indiquent de plus qu'il existe des barrières élevées à la transformation en structures isomères et que par conséquent, les ions de ce type peuvent être observés expérimentalement. On a calculé plusieurs profils de réactions au niveau STO-3G et au niveau 4-31G et ces calculs montrent que les ions peuvent exister sous des conformations *syn* et *anti* ayant des énergies comparables et que la barrières à leur interconversion est faibleé.

Les paramètres de structure et les énergies de stabilisation de ces deux ions reliés par des liaisons hydrogène sont semblables à ceux de la classe bien connue des espèces à nombre pair d'électrons que l'on appelle communément des dimères liés par un proton.

[Traduit par le journal]

Introduction

A combination of mass spectrometric measurements with the results of *ab initio* calculations has recently led to the identification and the energies of small stable organic cations of unconventional structure. For example, the radical cation $CH_2OH_2^{+\cdot}$, an isomer of ionised methanol, and a wide variety of analogues $[C_nH_{2n}\cdot XH]^{+\cdot}$ (X = OH, NH_2, SH, halogen, etc.) have been both observed by experiment and calculated to be stable species in the gas phase (1).

Recently, Terlouw *et al.* (2) reported an experimental study on the structure of the $C_2H_6O_2^{+\cdot}$ and $C_3H_8O_2^{+\cdot}$ ions generated by dissociative ionisation of butan1,4-diol and 4-methoxybutan-1-ol, respectively. The ions generated were proposed to have the formal structures $[CH_2{=}CHOH/H_2O]^{+\cdot}$ and $[CH_2{=}CHOH/CH_3OH]^{+\cdot}$, having respective stabilisation energies towards dissociation into $CH_2{=}CHOH^{+\cdot} + H_2O$ or CH_3OH, of >54 kJ/mol and 88 kJ/mol. However, the experiments did not establish to which of the carbon atoms in the vinyl alcohol moiety the H_2O or CH_3OH molecule is bound, i.e. whether isomers I*a*, *b*, or *c* in Fig. 1 are present. An additional possibility is that the ions have the structure $[H_2O\text{---}H\text{---}OCHCH_2]^{+\cdot}$, I*d* in Fig. 1. Ions of type I*a* and I*b* have been shown by *ab initio* calculations to exist in potential wells, but the structure and stability of odd electron hydrogen bonded ions of type I*d* have not yet been investigated. The existence of the *even* electron analogues (proton bound dimers) is well established by both theory and experiment (3, 4).

The present paper describes the results of LCAO-MO-SCF calculations on the species $[CH_2{=}CHO\text{---}H\text{---}OH_2]^{+\cdot}$ and $[CH_2{=}CHO\text{---}H\text{---}(OH)CH_3]^{+\cdot}$, using STO-3G, 4-31G, 6-31G*, and 6-31G** basis sets and applying Basis Set Superposition Error (BSSE) corrections. For the proton bound water dimer $[H_2O\text{---}H\text{---}OH_2]^{+\cdot}$ it has been shown that SCF calculations of the stabilisation energy are sufficiently accurate for

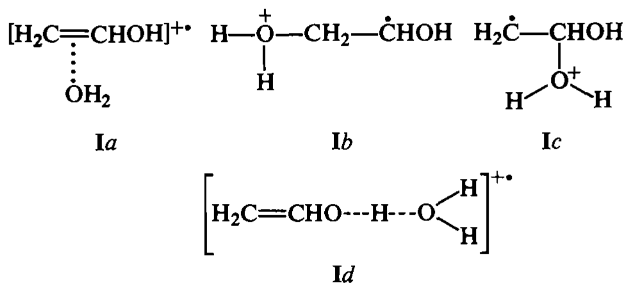

FIG. 1. Structures of $[CH_2{=}CHOH/H_2O]^{+\cdot}$ and $[CH_2{=}CHOH/CH_3OH]^{+\cdot}$ isomers.

our purpose (4). It will be shown that ions of this type are indeed stable species having two local minima corresponding to an *anti* and a *syn* conformation with comparable stabilisation energies.

Methods

Standard LCAO-MO-SCF calculations were performed using a modified version of the Gaussian 76 package (5), employing restricted (6, 7) and unrestricted (8) Hartree–Fock procedures, RHF and UHF, respectively. The basis sets used are the standard STO-3G (9), 4-31G (10), 6-31G* and 6-31G** (11) basis sets. Of these the 6-31G* and 6-31G** basis sets should give the most reliable results.

The geometries of the ions I*d* and II*d* (Fig. 1) were optimized at the STO-3G and 4-31G levels of accuracy. The results are given in Table 1 and Fig. 2, which also shows the labeling of the atoms in both species.

The stabilisation energies of the ions I*d* and II*d* were initially calculated using

$$[1] \quad E = E(\mathrm{A}) + E(\mathrm{B}) - E(\mathrm{AB})$$

where A is the vinyl alcohol radical cation and B is the water or methanol molecule. The results are given in the fourth column of Table 2 (*anti* conformation). As can be seen from Table 2 the stabilisation energy of the ions I*d* and II*d* calculated at the 4-31G level is considerably lower than that obtained with the STO-3G basis. This is consistent with the well-known tendency of small basis sets to overestimate analogous binding energies (4, 12). The difference in the stabilisation energies obtained by [1] might be accounted for by adding BSSE corrections. These were calculated using the so-called counterpoise method (13), where the dissociation energy D_e is given by

$$[2] \quad D_e = E - e(\mathrm{A}) - e(\mathrm{B})$$

with

$$[3] \quad \begin{aligned} e(\mathrm{A}) &= E(\mathrm{A}) - E_{\mathrm{AB}}(\mathrm{A}) \\ e(\mathrm{B}) &= E(\mathrm{B}) - E_{\mathrm{AB}}(\mathrm{B}) \end{aligned}$$

where $E_{\mathrm{AB}}(\mathrm{A})$ is the energy of A calculated with the basis set of the complex AB. The BSSE corrections $e(\mathrm{A})$ and $e(\mathrm{B})$ for both ions I*d* and II*d* are given in Table 3 (*anti* conformation).

Because geometry optimizations with larger basis sets are rather expensive, single point calculations were performed at the 6-31G* and 6-31G** levels, using either the STO-3G or the 4-31G optimized structures. These calculations are denoted by 6-31G*/STO-3G, etc. The results are also given in Tables 2 and 3.

In addition to the calculation of the stabilisation energies, several reaction profiles were examined for both species. Four of these are shown in Fig. 3 The reaction profiles 1 and 2 simulate the in-plane and the out-of-plane bending of the 3-center bond 01-H4-02. The reaction profiles 3 and 4 simulate the rotation of the —H—OH_2 or —H—$OHCH_3$ group around the C2—O1 bond and the variation of the C2—O1—H4 angle, respectively. A fifth reaction coordinate was selected, which lets the proton travel along the 3-center bond O1—H4—O2 at a fixed (optimized) O1—O2 distance. These reaction profiles were used to investigate the relation between the *anti* and *syn* conformations of the ions I*d* and II*d*.

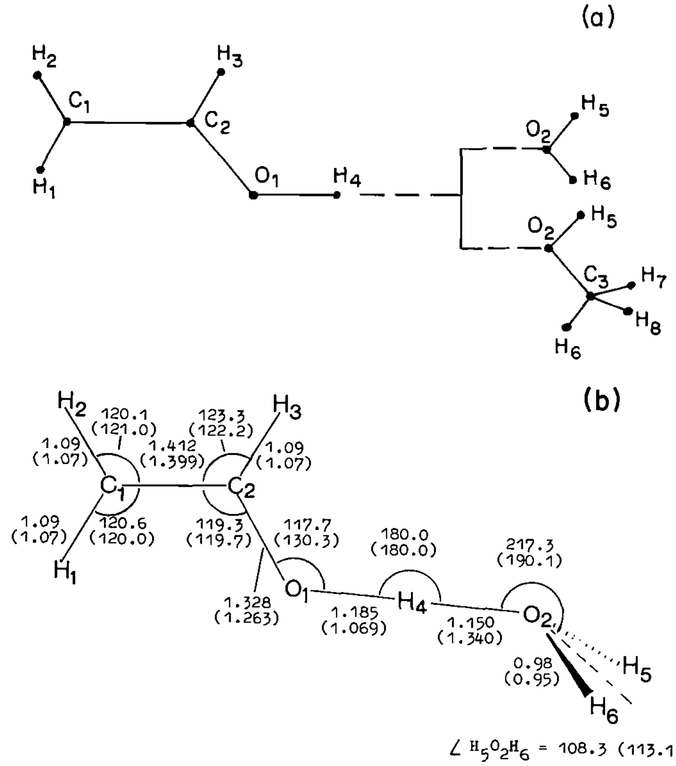

FIG. 2. (*a*) Identification of the atoms in the ions I*d* and II*d* of Fig. 1; (*b*) Optimized HF/STO-3G structure of ion I*d*, with HF/4-31G values of the structural parameters being shown in parentheses. Bond lengths are given in Å and bond angles in deg.

Results and discussion

The results obtained with the 4-31G basis and corrected for BSSE indicate that the potential energy hypersurfaces have local minima corresponding to the ions I*d* and II*d*, respectively, and that these ions are stable with respect to dissociation into the vinyl alcohol radical cation and a neutral molecule. The stabilisation energies obtained at this level of accuracy are 134 kJ/mol for I*d* and 144 kJ/mol for II*d* (BSSE corrected).

The results obtained with the polarized basis sets lead to the following conclusions: (*i*) the stabilisation energy is considerably lowered by adding polarization functions; and (*ii*) the BSSE corrections are of the same order of magnitude as in the 4-31G calculations. It may be sufficient only to optimize the geometry at the STO-3G level and to obtain the final energies by single point energy calculations at the 4-31G or 6-31G* level of accuracy. For example, Bouma, MacLeod, and Radom (1*d*) showed that the relative energy results for $C_2H_4O^{+\cdot}$ isomers calculated at the 4-31G level compare well with the

TABLE 1. Calculated total energies, interatomic distances, and interatomic angles (the 4-31G results are given in parentheses) of SCF geometry optimized structures calculated with STO-3G and 4-31G basis sets (see Fig. 3 for the atom labeling)

4-31G/STO-3G results. Although it is not certain that this procedure can also be used for calculating the stabilisation energy of hydrogen bonded cations, for ion **I***d* a difference of 15 kJ/mol was found between the stabilisation energies calculated with 6-31G*/STO-3G and 6-31G*/4-31G, respectively (Table 2). Comparing the geometries used, it can be seen from Tables 1 and 2 that the O1—O2 distance and the position of the bridging hydrogen atom in the O1—H4—O2 3-center bond strongly depend on the basis set used and that the changes in the O1—O2 distance upon recombination are rather large and have opposite sign.

Because the STO-3G basis overestimates the ion-dipole interaction (see Table 2) the low value for the stabilisation energy obtained in the 6-31G*/STO-3G calculation may be explained by the artificially short O1—O2 distance in the STO-3G optimized structure. This will lead to a considerable destabilisation in the 6-31G*/STO-3G calculations. It is not clear whether STO-3G calculations yield reliable predictions for the other geometrical changes in the recombination and so this has been examined by performing a 6-31G* calculation, using the STO-3G reactant geometries together with relative orientation of the reactants as obtained in the 4-31G optimization. The resulting energy is 23 kJ/mol lower than the 6-31G*/STO-3G result. Therefore the difference between the 6-31G*/4-31G and 6-31G*/STO-3G results (15 kJ/mol) may be explained by the unsuitability of the STO-3G optimized structure for 6-31G* calculations. Consequently, the 4-31G optimized geometries will be used hereafter. Nevertheless the reliability of the 6-31G*/4-31G results should not be overestimated because the 4-31G optimized geometry may also be unreliable. This was checked by performing calculations using the 4-31G reactant geometries with the 4-31G result for the relative orientation of

[a]$e(CH_2CHOH)$ is the BSSE correction obtained for the vinyl alcohol ion in the presence of the atomic orbitals on the H_2O(I*d*) or CH_3OH(II*d*) molecules.
[b]$e(H_2O/CH_3OH)$ is the BSSE correction obtained from the H_2O(I*d*) or CH_3OH(II*d*) molecules in the presence of the atomic orbitals on the [CH_2CHOH] species.

the reactants. The results are −228.3399 au (4-31G) and −228.6525 au (6-31G*). Comparing these results with those in Table 2 it can be seen that the deformation energy in the 4-31G basis equals 10 kJ/mol, whereas the 6-31G* result lies 3 kJ/mol below the value obtained with the 6-31G*/4-31G calculation. These results indicate that the error in the 6-31G*/4-31G calculations is of the order of 3−10 kJ/mol.

The results of the BSSE corrections are shown in Table 3. The reason for the substantial difference between the BSSE values for CH_2CHOH and H_2O/CH_3OH (see Table 3) is that the orbital space of a H_2O or CH_3OH molecule will be more extended by the "ghost" orbitals of vinyl alcohol than will the orbital space of vinyl alcohol be extended by the "ghost" orbitals of H_2O or CH_3OH.

Although the polarized basis sets are large, these corrections are of the same order of magnitude as in the 4-31G basis. This result has also been found by Leclerq, Allavena, and Bouteiller (14). It can be seen from Tables 2 and 3 that the differences between the 6-31G* and 6-31G** results are small, with or without BSSE corrections. We therefore conclude that the errors introduced by using non-optimal geometries is probably larger than those caused by the use of incomplete basis sets.

Finally, it should be noted that these results might be sensitive to electron correlation effects, which have been ignored in the present calculations, particularly because open shell examples are involved (15). For example, calculations including correlation may lead to non-planar $CH_2{=}CHOH$ as in the analogous $C_2H_4^{+\bullet}$ system (16). Furthermore the UHF method used is known to occasionally run into problems due to spin contamination. We therefore checked the UHF results

(6-31G**/4-31G) of I*d* and II*d* (*anti*) with open shell RHF calculations (17), giving stabilisation energies of 91.5 and 84.0 kJ/mol, respectively. The discrepancies with the UHF results for I*d* and II*d* are 3.7 and 10.5 kJ/mol, respectively. These are of the same order of magnitude as the deformation errors given previously (3−10 kJ/mol). The S^2 expectation values for the isomers I*d* and II*d* with the 6-31G**/4-31G basis set are 0.7817 and 0.8134, respectively. According to the above discussion the final result for the stabilisation energy of ion I*d* (including BSSE corrections) is 90 ± 10 kJ/mol (*anti* conformation) and for ion II*d* D_e = 88 ± 10 kJ/mol. These values compare favourably with the experimental results ($D_e \geq$ 54 kJ/mol for ion I*d*, D_e = 88 kJ/mol for ion II*d* (2) and so these structures are possible candidates for the experimentally observed isomers of $C_2H_6O_2^{+\cdot}$ and $C_3H_8O_2^{+\cdot}$, respectively. As in the vinyl alcohol radical cation, the *syn* conformations are somewhat less stable than the *anti* conformations (D_e = 85 kJ/mol and 78 kJ/mol for I*d* and II*d*, respectively).

The results may also be compared to other dimers containing hydrogen bridges. Considering $(H_2O)_2$ and $(H_3O—H_2O)^+$ as prototype systems, it should be noted that the stabilisation energies for these are widely different, viz. 20 kJ/mol for $(H_2O)_2$ and 140 kJ/mol for $H_3O^+—H_2O$ (4). Indeed, various authors (18−20) have noted that the dimerisation energy for symmetrical hydrogen bound cations is largely independent of gas phase basicity and variation in functionality (water, alcohols, ethers, aldehydes, etc.). The high stability of these complexes arises from the electrostatic attraction between the positive charge and the water molecule dipole moment. Applying this argument to the ions I*d* and II*d*, then the decrease in stability of these ions with respect to $H_3O^+—H_2O$ may be explained in terms of the charge distribution in the vinyl alcohol moiety. According to a Mulliken population analysis of the vinyl alcohol radical cation the positive charge is distributed over all atoms but with the center of charge located near to the C2 atom. This corresponds to a 30% increase in the distance between the positive charge and the water molecule compared with the $(H_3O—H_2O)^+$ system. Since according to this simple model the interaction energy varies as R^{-2}, it may be expected that the stabilisation energy for both ions I*d* and II*d* is of the order of 80 kJ, in agreement with the present results. It is also noteworthy that the hydrogen bond energies given by Bomse and Beauchamp (20) for asymmetrical hydrogen bound cations are in the same range. Their values, estimated by using an empirical method (21), lie between 105 and 85 kJ/mol for dimers of the type $[A---H---OH_2]^+$ with A = CH_3OH, C_2H_5OH, $(CH_3)_2O$, *i*-C_3H_7OH, etc. Apparently the stabilisation energy of the ions I*d* and II*d* is not affected much by the open shell character of the vinyl radical cation. This is corroborated by the agrrement of the O—O distances in the ions I*d* and II*d* (2.409 Å and 2.387 Å, respectively) with those calculated by Hagler, Karpas, and Klein (22) and by Newton and Ehrenson (23) for hydrogen bonded cations of simple carbonyl compounds with water. Using the 4-31G basis these authors found O—O distances ranging from 2.34 to 2.39 Å for these compounds.

We have also investigated the O—H—O three center bond more closely by studying several reaction coordinates. The reaction profiles 1 and 2 (Fig. 3*a*) correspond to variations of the O—H—O bond angle. The results for these profiles (not shown explicitly) indicate that reactions along these coordinates are energetically unfavourable.

Reaction coordinate 3 (Fig. 3*b*) stands for the rotation of the

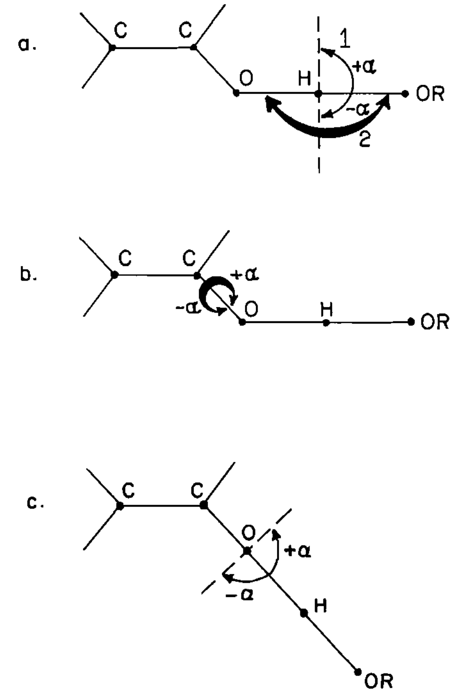

FIG. 3. R = H or CH_3. (*a*) Reaction coordinates 1 and 2, in-plane and out-of-plane bending of the O—H—O bond, respectively. (*b*) Reaction coordinate 3, rotation of the —H—OHR group around the CO bond. α = ±90° when the —H—OHR group is in the CH_2═CHO plane. α = 90° corresponds to the *anti* conformation, α = 90° to the *syn* conformation. (*c*) Reaction coordinate 4, in-plane bending of the C—O—H bond. α = 0 when the C—O—H bond is linear.

—H—OR group around the C2—O1 bond in the vinyl alcohol radical cation, whereas reaction coordinate 4 stands for a variation of the C2—O1—H4 bond angle (Fig. 3*c*). These reaction coordinates relate the *anti* conformation to the *syn* conformation. As shown in Fig. 4 *a* and *b* the corresponding STO-3G reaction profiles indicate that these conformations are separated by rather large energy barriers. However, these barriers virtually disappear with the 4-31G basis and if the position of the hydrogen atom in the O—H—O three center bond is varied. According to the STO-3G results the interconversion will take place along reaction coordinate 4, (i.e. in-plane bending) and so the 4-31G calculations were only performed for this reaction coordinate. In addition to using the optimized O1—H4 and O2—H4 distances, this reaction profile was investigated using the reversed values for these distances with respect to their optimized values. The results, shown in Fig. 5, indicate that the barrier only appears if the hydrogen atom is situated near to the CH_2CHO part of the ion. Note that the 4-31G geometry optimizations lead to opposite positions for the hydrogen atom in the ions I*d* and II*d*, respectively, cf. Table 1. Therefore the role of the curves for the two geometries used is reversed when going from ion I*d* to ion II*d*. That the energy barrier disappears when the hydrogen atom is removed from the vinyl alcohol radical cation may be explained by the absence of the energetically unfavourable distortion of the sp^2 hybridisation on O1 during the interconversion.

Finally, the O1—H4 distance was optimized for the *anti* conformations of ions I*d* and II*d* with a fixed O1—O2 distance, using the STO-3G, 4-31G, and 6-31G* basis sets. The results are shown in Fig. 6. The 6-31G* results place the

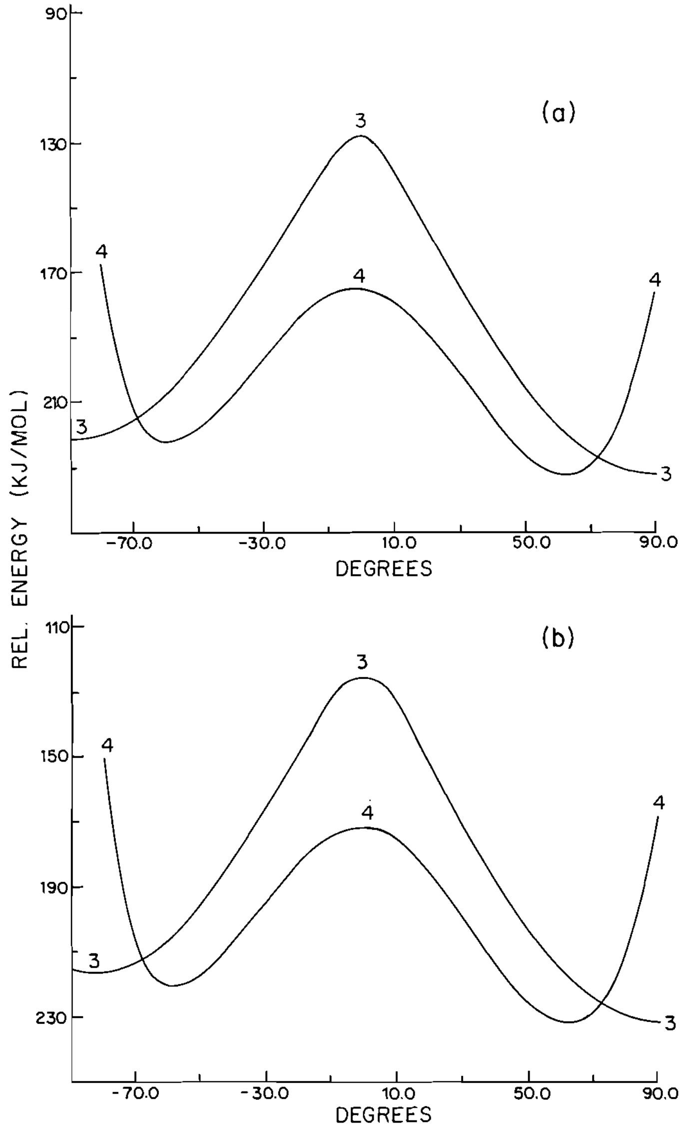

FIG. 4. (*a*) Reaction profiles 3 and 4 (see Fig. 3) for ion I*d* (STO-3G). (*b*) Reaction profiles 3 and 4 (see Fig. 3) for ion II*d* (STO-3G).

hydrogen atom near to the CH_2CHO part of the ion in both cases, and so it was concluded that the 4-31G basis is unsuitable for predicting the position of the hydrogen atom due to the flatness of the corresponding potential well, a result which has also been found in calculations on even electron proton bound dimers (24). The 6-31G* results are in agreement with the conclusions drawn by Larson and McMahon (18) from experimental data, viz. that the potential well for the bridged hydrogen atoms corresponds to a broad single minimum. The interconversion barriers separating the *anti* and *syn* conformations of the ions I*d* and II*d* were found to be small (<10 kJ/mol).

Summary

The hydrogen bonded radical cation molecule pairs $[H_2O\text{---}H\text{---}OCHCH_2]^{+\cdot}$ and $[CH_3OH\text{---}H\text{—}OCHCH_2]^{+\cdot}$ were both calculated to be stable with respect to dissociation into $CH_2CHOH^{+\cdot}$ and H_2O or CH_3OH. The *anti* and *syn* conformations have comparable energies with small interconversion barriers for both species. Thus it may be expected that both ions are observable species in gas phase ion chemistry. However, which conformation is most likely to be found cannot be predicted from the calculations. Both species have properties comparable to the well known class of even electron hydrogen bridged cations. The open shell character of the vinyl alcohol radical cation seems to have little effect on the stabilisation energy. This may be explained by the fact that the open shell electron is mainly localized away from the hydrogen bond, viz. in the $CH_2{=}CH$ part of the complex.

A comparative study with several basis sets showed that the inclusion of a polarization function is necessary for obtaining reliable results. The differences in stabilisation energy obtained by using basis sets such as STO-3G, 4-31G, 6-31G*, and 6-31G** can only partially be understood in terms of the basis set superposition errors. The remaining differences are probably due to other effects, such as the lack of short range repulsion in the STO-3G basis or an overestimation of dipole moments in the 4-31G basis. For accurate calculations on similar ions it may therefore be necessary to check the reliability of the geometries used in single point energy calculations using larger basis sets.

Heterogeneous reaction of nitric acid with methyl sulfide[1]

DONALD L. SINGLETON, ROBERT S. IRWIN, DONALD J. MCKENNEY,[2] AND GEORGE PARASKEVOPOULOS
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received February 21, 1985

DONALD L. SINGLETON, ROBERT S. IRWIN, DONALD J. MCKENNEY, and GEORGE PARASKEVOPOULOS. Can. J. Chem. **63**, 2805 (1985).

The reaction of gaseous mixtures of CH_3SCH_3 and HNO_3, studied by infrared spectroscopy and gas chromatography, was found to occur heterogeneously. The products detected were NO_2 and $CH_3S(O)CH_3$, and approximately one NO_2 was formed for each CH_3SCH_3 consumed. The initial rate of formation of NO_2 was first order in CH_3SCH_3 and zero order in HNO_3. The mechanism is discussed, and an upper limit is determined for the rate constant of the homogeneous reaction.

DONALD L. SINGLETON, ROBERT S. IRWIN, DONALD J. MCKENNEY et GEORGE PARASKEVOPOULOS. Can. J. Chem. **63**, 2805 (1985).

On a étudié la réaction de mélanges gazeux de CH_3SCH_3 et de HNO_3 en faisant appel à la spectroscopie infrarouge et la chromatographie en phase gazeuse et l'on a trouvé qu'elle se produit d'une façon hétérogène. Les produits que l'on a pu détecter sont le NO_2 et le $CH_3S(O)CH_3$; de plus, il se forme environ une molécule de NO_2 pour chaque molécule de CH_3SCH_3 qui est consommée. La vitesse initiale de formation du NO_2 est du premier ordre en CH_3SCH_3 et d'ordre zéro en HNO_3. On discute du mécanisme et l'on détermine une limite supérieure pour la constante de vitesse de la réaction homogène.

Introduction

Nitric acid has long been known to react readily with methyl sulfide in solution to form dimethyl sulfoxide, along with lesser amounts of more highly oxidized derivatives (1). Recent studies have examined the chemically-induced dynamic nuclear polarization of the protons (2) and the catalysis of the reaction by Au^{3+} (3). Thiols and disulfides are also known to undergo oxidation by HNO_3 in solution (4). However, to our knowledge, these reactions have not been investigated in the gas phase, where they would be of interest in studies of the oxidation of reduced sulfur compounds. In the troposphere, methyl sulfide is produced by biogenic and anthropogenic processes, and efforts have been made to understand its tropospheric chemistry. Studies of the mechanism of oxidation of methyl sulfide by OH (5–7), $O(^3P)$ (8), O_3 (9), and NO_2 (10) have recently been reported and reviewed (11).

Experimental

The reaction was studied by infrared spectroscopy using a Teflon-lined absorption cell with a volume of 5.66 L and an optical path length of 20.25 m. Pressures of reactants were measured with a capacitance manometer and introduced into the cell with a vacuum system free of mercury. When very low pressures of reactants were required in the reaction cell, they were measured on a smaller calibrated volume and swept into the cell using nitrogen. The total pressure was always brought up to 1 atm using nitrogen. The temperature was 296 ± 2 K.

Spectra were obtained with a Beckman model 4030 spectrometer operated in the double beam mode. The slit width provided resolution of 4 cm^{-1} above, and about 2.5 cm^{-1} below 2000 cm^{-1}, respectively. The products and reactants were monitored at selected wavelengths as a function of time, and the amounts were determined by converting the percentage transmission to absorbance and using experimentally determined Beer's law coefficients.

The rate of formation of nitrogen dioxide was followed at 1600 cm^{-1}, and consumption of nitric acid and of methyl sulfide was monitored at 1200 and 1015 cm^{-1}, respectively. Calibration mixtures indicated that the absorbance was linear with concentration over the useful range encountered in the experiments. Although dimethyl sulfoxide was found to have a distinctive absorption at 1100 cm^{-1} in the gas phase, it was not detected, and its low volatility prevented a quantitative determination of an upper limit. Neither was NO detected at 1890 cm^{-1}, which is not surprising since, if it were formed, it would react rapidly with nitric acid. Another possible product, N_2O, could not be determined because of interference by the strong absorption bands of nitric acid.

A few experiments were done in a 155 cm^3 quartz flask which could be evacuated and filled with reactants. After a specified reaction time in the dark, the reactants and gaseous products were quickly pumped from the cell for about 20 s, followed by filling the cell with 1 atm of nitrogen and injecting 1 cm^3 of acetone. The cell was shaken to ensure that any products adhering to the walls would be dissolved. Aliquots were removed by syringe and analyzed by gas chromatography on a 1.5 m stainless steel column of Porapak P. The amount of $CH_3S(O)CH_3$ present was determined by comparing its peak area, relative to acetone, with that of standard mixtures. This procedure was followed to recover the less volatile dimethyl sulfoxide from the walls, and yet minimize any reaction between nitric acid and methyl sulfide in the solvent. However, the possibility cannot be excluded of a small amount of direct reaction in the solvent or of further reaction of an adsorbed product once it is dissolved to form dimethyl sulfoxide.

Nitric acid was prepared in vacuum by the reaction of potassium nitrate with concentrated sulfuric acid. The HNO_3 was collected in a trap at 273 K, distilled under vacuum, and stored at liquid nitrogen temperature. Gas chromatography of liquid methyl sulfide (Matheson Coleman and Bell) indicated a purity of 99.89% based on peak areas and was degassed by freeze–pump–thaw cycles. Nitrogen (99.999%) was used directly from the cylinder.

Results

Dimethyl sulfoxide was observed as a product in the experiments in which the quartz reaction cell was rinsed with acetone. After 2 h, 2% of the methyl sulfide in a reaction mixture of 1.2 Torr HNO_3 and 3.1 Torr of CH_3SCH_3 was converted to $CH_3S(O)CH_3$. Methyl sulfone was not observed (a conversion of 0.04% would have been detectable). Dimethyl sulfoxide was not detectable in a similar experiment but without nitric acid present. The only product detected by infrared spectroscopy was NO_2. In separate experiments it was found that there was no significant dark reaction between NO_2 and CH_3SCH_3 under these experimental conditions, consistent with the rate constant

[a]Total pressure 760 Torr, 296 K. The initial rates, $r(NO_2)$, are measured values and have not been corrected for the rate of NO_2 formation in the absence of CH_3SCH_3.

[b]This value of $r(NO_2)$ in the absence of methyl sulfide is inexplicably larger than usual.

of 9×10^{-21} cm^3/molecule s reported by Balla and Heicklen (10). Typical plots of the time dependence of the formation of NO_2 are given in Fig. 1. The initial rate of formation of NO_2, over the first 10 min or less, was used to assess which experimental parameters significantly influenced the kinetics. The rate of formation of NO_2 was typically about 30% slower in the first experiment in a day than an otherwise identical experiment performed subsequently. It was found that essentially identical values could be obtained throughout the day by introducing a small pressure of nitric acid into the reaction cell for a few minutes, followed by pumping for several minutes to a pressure less than 0.01 Torr, prior to every experiment. This procedure led to the same values as had been obtained after the first experiment of the day. Additional experiments showed that the sequence of addition of reactants to the reactor did not affect the rate of formation of NO_2. Nonetheless, in all subsequent experiments HNO_3 was added prior to CH_3SCH_3.

Nitric acid slowly decomposes to form NO_2 even in the absence of methyl sulfide. The rates of NO_2 formation in the presence of methyl sulfide could be corrected accordingly. The rate data are given in Table 1. There was no observable decay of CH_3SCH_3 with time in the absence of HNO_3. In a few experiments, the reaction cell was exposed to 0.2 Torr of water for several minutes, then briefly evacuated and treated with nitric acid in the usual manner. This procedure had no significant effect on the initial rate of NO_2 formation.

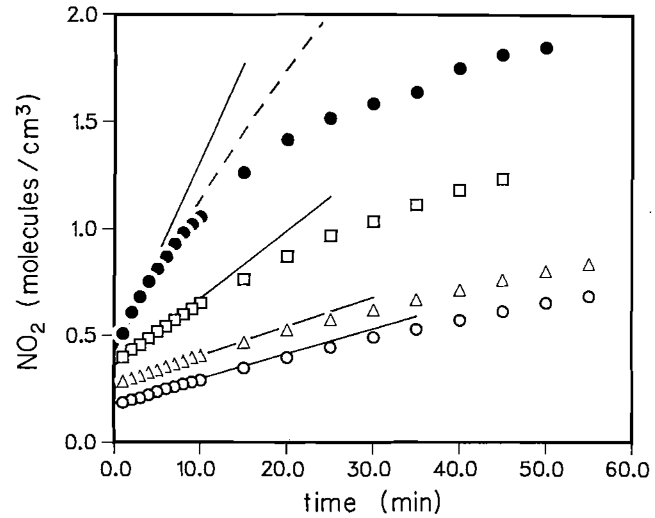

FIG. 1. Yields of NO_2 in the reaction of HNO_3 + CH_3SCH_3 as a function of time at 296 K and 760 Torr N_2. The dashed line is calculated as described in the text for the oversimplified model, $d[NO_2]/dt = k[CH_3SCH_3]$, with $[CH_3SCH_3]_0 = 0.35 \times 10^{16}$ molecules/cm^3. Initial amounts (molecules/cm^3 $\times 10^{-16}$): HNO_3, 2.0; CH_3SCH_3, ○ – 0.0, △ – 0.034, □ – 0.17, ● – 0.35.

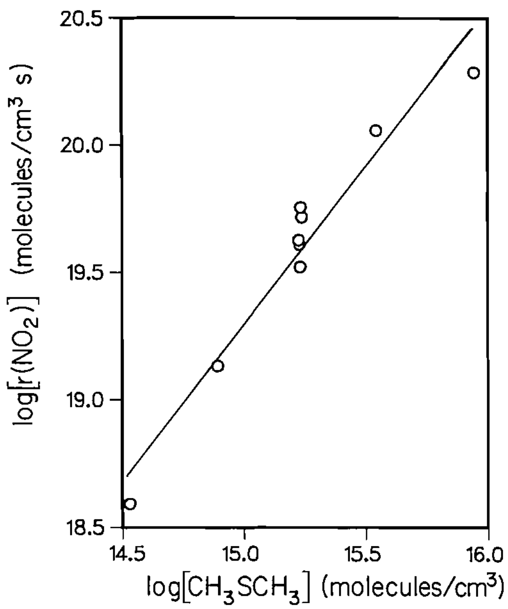

FIG. 2. Plot of the logarithm of the initial rate of NO_2 formation, $r(NO_2)$, against the logarithm of methyl sulfide concentration. Values of $r(NO_2)$ have been corrected for the rate of NO_2 formation in the absence of methyl sulfide. Total pressure, 760 Torr; 296 K.

The order of the reaction for each reactant was determined from the slopes of plots of log ($r(NO_2)$) against log $[CH_3SCH_3]$ at constant excess HNO_3 (Fig. 2), and of log ($r(NO_2)$) against log $[HNO_3]$ at constant excess CH_3SCH_3 (Fig. 3), where $r(NO_2)$ is the corrected initial rate of NO_2 formation. The slope of the former is 1.2 ± 0.3 and, the latter, 0.13 ± 0.17, where the indicated uncertainties are the 95% confidence limits. There is considerable uncertainty in the value of $r(NO_2)$ at higher pressures of CH_3SCH_3 as the initial rate approaches the time resolution of the experiment.

The stoichiometry with respect to CH_3SCH_3 and NO_2 was determined by infrared spectroscopy. The results for equal

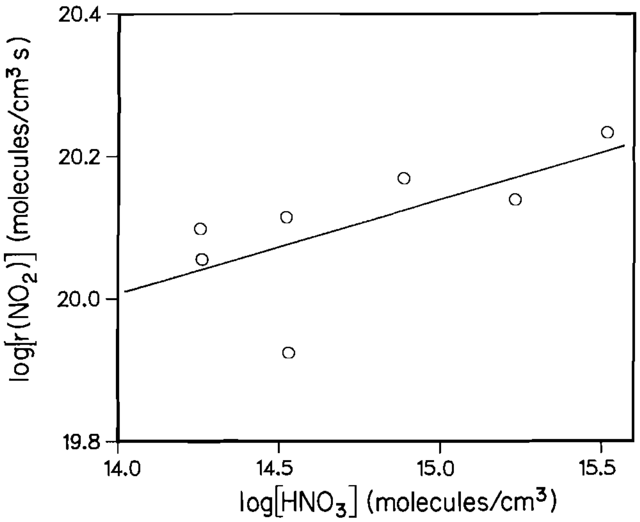

FIG. 3. Plot of the logarithm of the initial rate of NO_2 formation, $r(NO_2)$, against the logarithm of nitric acid concentration. Values of $r(NO_2)$ have been corrected for the rate of NO_2 formation in the absence of methyl sulfide. Total pressure, 760 Torr; 296 K.

initial amounts (0.1 Torr) of HNO_3 and CH_3SCH_3 were $\Delta[NO_2]/\Delta[CH_3SCH_3] = 0.89 \pm 0.09$ for reaction times of 8 to 37 min. Because the data for consumption of HNO_3 were erratic, it was not possible to obtain meaningful values of $\Delta[CH_3SCH_3]/\Delta[HNO_3]$.

Discussion

The observation that the rate of formation of NO_2 is essentially zero order in $[HNO_3]$ and that the rate increases to a reproducible value on pretreating the reaction cell with HNO_3 indicates that CH_3SCH_3 reacts with HNO_3 adsorbed on the walls of the reactor. An attempt was made to reproduce the time dependence of the observed yields of NO_2 using the integrated form of the rate law $d[NO_2]/dt = k[CH_3SCH_3]$, with the value of k obtained from the initial rate, and the time dependent value of the methyl sulfide concentration given by $[CH_3SCH_3] = [CH_3SCH_3]_0 - [NO_2]$, based on the stoichiometry measurements. Included in the calculation were the initial amount of NO_2 and the rate of NO_2 formation with HNO_3 alone in the cell. However, this model always gave NO_2 yields greater than those observed at longer times, as shown by the dashed line in Fig. 1. (Adjustment of the value of k to fit the NO_2 yields at about 50 min resulted in calculated NO_2 yields much smaller than those observed at intermediate times.) This decreasing rate of NO_2 formation may be due to the initially adsorbed HNO_3 not being replaced after reaction with methyl sulfide. The mechanism would be represented as follows, where S—HNO_3 represents nitric acid adsorbed on the wall, and the products include one molecule of NO_2 and some dimethyl sulfoxide.

[1] $HNO_3 + S \longrightarrow S\text{—}HNO_3$

[2] $S\text{—}HNO_3 + MSM \longrightarrow$ products

The rate of NO_2 formation can be represented as

$$d[NO_2]/dt = k_2[MSM][S\text{—}HNO_3]$$

where S—HNO_3 and CH_3SCH_3 are time-dependent quantities. This equation is consistent with the observation that the initial rate is proportional to the concentration of methyl sulfide and decreases as the reaction proceeds, and also with the reduction in initial rate if the reaction cell is not pre-treated with nitric acid prior to an experiment, which apparently serves to increase the initial amount of S—HNO_3 to a reproducible value. Unfortunately, there are no sufficient experimental data to allow formulation of a more detailed mechanism. In a recent study (2), the direct reaction in solution of HNO_3 with methyl sulfide was considered to be slow, with nitrous acid and dimethyl sulfoxide proposed as the products, and N_2O_4 the major oxidizing species. As mentioned above, there was no reaction between methyl sulfide and NO_2 at the concentrations encountered in the present work. However, the mechanism of the surface-catalyzed and aqueous phase reactions may be quite different.

In the discussion so far, it was assumed that reaction occurs on the Teflon-coated walls of the reactor. Although reaction could occur to some extent on the mirrors, which were nickel-plated with an aluminized reflecting surface, there was never any evidence of ir bands due to dimethyl sulfoxide.

The data indicate that any homogeneous path is very slow. If the homogeneous gas phase reaction were bimolecular, the data in Table 1 for $[HNO_3] = 2.0 \times 10^{16}$ and $[CH_3SCH_3] = 1.7 \times 10^{15}$ molecules/cm^3 would give, as a conservative upper limit, an apparent bimolecular rate constant of 1×10^{-20} cm^3/molecule s, based on NO_2 formation. This is only 10^{-8} of the rate constant of the $NO_3 + CH_3SCH_3$ reaction (12), which is indicated by recent work to dominate the nighttime chemistry of methyl sulfide in the troposphere (13). Even though the tropospheric concentration of HNO_3 (14) can be about 100 times greater than that of NO_3 (15), the $HNO_3 + CH_3SCH_3$ reaction would be insignificant.

Received May 13, 1985

ISHAK KARAKAYA and WILLIAM T. THOMPSON. Can. J. Chem. **63**, 2808 (1985).

A multiple linear regression technique to represent partial excess property data for one component (A) in a ternary A–B–C system is presented. The procedure, following the methodology of Pelton and Flengas, recognizes the need to satisfy Henry's law for components B and C in solutions rich in component A as well as independent experimental knowledge which may be available for the B–C binary.

ISHAK KARAKAYA et WILLIAM T. THOMPSON. Can. J. Chem. **63**, 2808 (1985).

On présente une technique de régression linéaire multiple qui permet de représenter les données relatives aux propriétés partielles en excès pour un composant (A) dans un système ternaire A–B–C. Cette technique, qui suit la méthodologie de Pelton et Flengas, reconnaît d'une part le besoin de satisfaire à la loi de Henry pour les composants B et C dans des solutions qui sont riches en A et d'autre part les connaissances expérimentales indépendantes qui peuvent être disponibles pour le mélange binaire B–C.

[Traduit par le journal]

For a ternary system A–B–C, Pelton and Flengas (1) proposed an analytical method to perform the Gibbs–Duhem integration. This is particularly well suited for use in phase diagram computations (2).

Let f_A, f_B, and f_C represent isothermal partial molar excess thermodynamic functions for components A, B, and C. The composition variation for these properties are defined by the coefficients a_{jk}, b_{jk}, and c_{jk} in the following expressions

$$[1]\quad f_A = \sum_{j=2}\sum_{k=0} a_{jk}y^j t^k$$

$$[2]\quad f_B = \sum_{j=0}\sum_{k=0} b_{jk}y^j t^k$$

$$[3]\quad f_C = \sum_{j=0}\sum_{k=0} c_{jk}y^j t^k$$

where the composition variables y and t are defined by

$$y = 1 - X_A$$

and

$$t = \frac{X_C}{X_B + X_C}$$

This choice of composition variables is particularly convenient for experimental purposes (3, 4), where concentrations of A may be altered in solutions of fixed B-to-C ratios. Coefficients a_{jk}, b_{jk}, and c_{jk} are related by the following recursion formulae (1):

$$[4]\quad b_{jk} = a_{jk} - \left(\frac{j+1-k}{j}\right)a_{(j+1)k} \text{ for } j \geq 1$$

$$[5]\quad c_{jk} = b_{jk} - \left(\frac{k+1}{j}\right)a_{(j+1)(k+1)} \text{ for } j \geq 1$$

The suggested method of applying these equations is to establish the coefficients a_{jk} for one of the components, say A, from experimental data using multiple linear regression methods (7). An example is given in ref. 1 for Cd–Bi–Sn system. It is suggested that the boundary conditions to give the complete expressions for f_B and f_C be obtained from an independent knowledge of the thermodynamic properties of the B–C binary system. However, this procedure always leads to slight thermodynamic inconsistencies in the behaviour of the partial properties of components B and C near concentrations very rich in component A (1, 4–6). In particular, the limiting properties for f_B and f_C for $X_A = 1$ are multivalued due to the indeterminacy of the variable t at this composition. This communication shows how this problem may be circumvented.

When for a given temperature, the expansion of the power series given by eq. [1] is written as

$$\begin{aligned}[6]\quad f_A = {} & (a_{20} + a_{21}t + a_{22}t^2 + \ldots + a_{2n}t^n)y^2 \\ & + (a_{30} + a_{31}t + a_{32}t^2 + \ldots + a_{3n}t^n)y^3 \\ & \cdot \\ & \cdot \\ & \cdot \\ & + (a_{m0} + a_{m1}t + a_{m2}t^2 + \ldots + a_{mn}t^n)y^m\end{aligned}$$

it follows that the series expansion of eq. [2] for the partial excess property of B must (to satisfy the Gibbs–Duhem equation) be given (1) by

$$\begin{aligned}[7]\quad f_B = {} & [(b_{00}) + (b_{01})t + (b_{02})t^2 + \ldots + (b_{0n})t^n] \\ & + \left[(-2a_{20}) + (-a_{21})t + 0 + \ldots + \left(-\frac{2-n}{1}a_{2n}\right)t^n\right]y \\ & + \left[\left(a_{20} - \frac{3}{2}a_{30}\right) + (a_{21} - a_{31})t + \left(a_{22} - \frac{1}{2}a_{32}\right)t^2 + \ldots + \left(a_{2n} - \frac{3-n}{2}a_{3n}\right)t^n\right]y^2 \\ & + \left[\left(a_{30} - \frac{4}{3}a_{40}\right) + (a_{31} - a_{41})t + \left(a_{32} - \frac{2}{3}a_{42}\right)t^2 + \ldots + \left(a_{3n} - \frac{4-n}{3}a_{4n}\right)t^n\right]y^3 \\ & \cdot \\ & \cdot \\ & + \left[(a_{m0}) + (a_{m1})t + (a_{m2})t^2 + \ldots + (a_{mn})t^n\right]y^m\end{aligned}$$

In eq. [7], coefficients b_{0k} are zero for $k \geq 1$. This simply recognizes that f_B has a fixed value in solutions approaching pure A in composition and is therefore necessarily independent of the value of the variable t which becomes indeterminate at $y = 0$ (pure A). In principle, the constant b_{00} can be determined from a knowledge of f_B at any composition (1). However, when this is done, it fixes the variation of f_B in the B−C binary where $y = 1$. Such a data treatment gives excess partial molar properties for B that are almost always inconsistent with independent experimental measurements of f_B in the B−C binary. The heart of this dilemma is the very sensitive nature of the coefficients in parentheses (eg. $(a_{21} - a_{31})$) in eq. [7] to the constants involved in eq. [6]. In other words, differences in the regression of f_A (due to very small experimental error, different number of data points etc.) which yield the coefficients a_{jk} can result in substantially different coefficients in eq. [7]. These in turn have a large effect on the calculated partial excess properties of B in the B−C binary. This difficulty may be overcome by introducing appropriate constraints into the statistical evaluation of coefficients a_{jk} so as to require behaviour in the B−C binary that is in agreement with direct experimental studies of this system.

If independently established integral excess properties in the B−C binary, f, are expressed in the form

$$[8] \quad f = p_1t + p_2t^2 + \ldots + p_nt^n$$

the partial excess thermodynamic property of B in this binary must be given by

$$[9] \quad f_B = -p_2t^2 - 2p_3t^3 + \ldots + (1 - n)p_nt^n$$

Equation [9] is eq. [7] for the case where $y = 1$. Noting that the parameter b_{01} automatically becomes zero by virtue of the Pelton−Flengas recursion relationships (1), it follows that

$$[10] \quad a_{22} = -p_2 - \frac{1}{2}a_{32} - \frac{1}{3}a_{42} - \ldots - \frac{1}{m-1}a_{m2}$$

$$\vdots$$

$$a_{2n} = -(n-1)p_n - \frac{1}{2}a_{3n} - \frac{1}{3}a_{4n} - \ldots - \frac{1}{m-1}a_{mn}$$

Incorporation of these relationships into eq. [6] gives, upon rearrangement,

$$\begin{aligned}
[11] \quad & [f_A + p_2t^2 + 2p_3t^3 + \ldots + (n-1)p_nt^n] \\
&= [a_{20}y^2 + a_{21}y^2t] \\
&+ \left[a_{30}y^3 + a_{31}y^3t + a_{32}t^2\left(y^3 - \frac{1}{2}y^2\right) + \ldots + a_{3n}t^n\left(y^3 - \frac{1}{2}y^2\right)\right] \\
&\vdots \\
&+ \left[a_{m0}y^m + a_{m1}y^mt + a_{m2}t^2\left(y^m - \frac{1}{m-1}y^2\right) + \ldots + a_{mn}t^n\left(y^m - \frac{1}{m-1}y^2\right)\right]
\end{aligned}$$

Since f_A is regarded as the measured partial excess property of A in the ternary system and the parameters p_i, we are supposing, can be obtained from an independent study of the B−C binary, the left hand side of the eq. [11] is known. The coefficients a_{jk} (other than a_{2k} for $k > 1$) can now be established by multiple linear regression in which the left hand side of eq. [11] is the dependent variable and the functions of t and y next to each coefficient are the independent variables. The procedure is completed by using eq. [10] to establish the coefficients a_{2k} for $k > 1$. In this way, it is possible to observe the constancy of the activity coefficient of B (and C at the same time) at virtually pure A as well as to incorporate independently established thermodynamic properties for the B−C binary.

The foregoing procedure has been applied to ternary salt systems investigated in this laboratory. It has been found that placing the suggested interrelationships on the coefficients does not reduce the quality of the analytical representation of the excess partial molar properties of component A.

Received June 24, 1985

BRUNO BERNET, PAUL M. BISHOP, MAURICE CARON, TAKESHI KAWAMATA, BERNARD L. ROY, LUC RUEST, GILLES SAUVÉ, PIERRE SOUCY, and PIERRE DESLONGCHAMPS. Can. J. Chem. **63**, 2810 (1985).

The total synthesis of compound **1**, a 1,7-dioxaspiro[5.5]undecane derivative of the seco acid methyl ester of erythronolide A, is reported.

BRUNO BERNET, PAUL M. BISHOP, MAURICE CARON, TAKESHI KAWAMATA, BERNARD L. ROY, LUC RUEST, GILLES SAUVÉ, PIERRE SOUCY et PIERRE DESLONGCHAMPS. Can. J. Chem. **63**, 2810 (1985).

La synthèse totale du composé **1**, un dérivé dioxa-1,7 spiro[5.5]undécane de l'ester méthylique de l'acide seco de l'érythronolide A, est rapportée.

We wish to report the stereocontrolled synthesis of the carbamate derivative **2** (Scheme 1) of erythronolide A seco acid methyl ester. Compound **2** is a key intermediate in the synthesis of erythromycin A reported by Woodward *et al.* (1). This work therefore formally constitutes a total synthesis of erythromycin A. Part I (this communication) describes the total synthesis of the 1,7-dioxaspiro[5.5]undecane derivative **1** of erythronolide A seco acid methyl ester. Part II reports the degradation of erythromycin A into the spiro derivative **1**, whereas Part III (see following communications) discloses the conversion of the spiro derivative **1** into Woodward's key intermediate carbamate **2**.[2]

Our synthetic strategy, which is based on the fact (3) that stereoelectronic effects control the conformation of the 1,7-dioxaspiro[5.5]undecane system, has been reported elsewhere (4, 5).[3]

The two starting materials used for the construction of the 1,7-dioxaspiro[5.5]undecane derivative **1** were 4-(biscarbomethoxy)-2-methyl-δ-valerolactone **3** (Scheme 2) and optically active R-5-hexyn-3-ol (**4**, R = H). The lactone **3**[4] was prepared from the Michael reaction of dimethyl malonate with methyl methacrylate followed by an aldol condensation with formaldehyde. Optically active R-5-hexyn-3-ol (**4**, R = H) was obtained by resolution (6) (chromatography of the *O*-methyl mandelic esters).

Condensation (7) of lactone **3** with the lithium acetylide of optically active **4** (R = $(CH_3)_3Si$) gave, after treatment with trimethylsilyl chloride, the adduct **5**.[5] Controlled catalytic hydrogenation (**5** → **6**) followed by cyclization catalyzed with trimethylsilyl triflate (9) gave the optically active spiro diesters **7*A*** and **7*B*** in a ~1:1 ratio. Equilibration (3) of this C-8 epimeric mixture (erythronolide numbering system) with pyridinium tosylate (10) gave solely the spiroisomer **7*B***, which has an absolute (and relative) configuration at C-8 and C-13 corresponding to that of **1** derived from erythromycin A.[6,7]

Allylic oxidation (SeO_2, PCC (11)) of isomer **7*B*** provided spiroenone **8** with a carbonyl group at C-12. Lithium dimethylcuprate 1,4-addition (12) on spiroenone **8** and reaction of the resulting enolate with dibenzoyl peroxide (13) gave compound **9** in 75% yield (Scheme 3). Reaction of **9** with methylmagnesium iodide at low temperature (14) gave stereospecifically compound **10** having the desired stereochemistry at C-8, C-10, C-11, C-12, and C-13.

The benzoate group was removed (**10** → **11**) under mild basic conditions and decarbalkoxylation gave a C-6 epimeric mixture in which the axial ester isomer **12*A*** predominates (15). The ester enolate derived from the epimeric mixture **12** was reacted with phenylselenyl bromide (16) to give predominantly the stereoisomer **13** having the axial carbomethoxy group.[8] Oxidation of **13** gave a ~1:1 mixture of spiro olefins **14*A*** and **14*B***. On heating the mixture **14*A*** and **14*B*** at 138°C in the presence of palladium–charcoal, spiro olefin **14*A*** underwent complete isomerization into the more conjugated spiro olefin **14*B***.

Reduction of **14*B*** with lithium aluminum hydride (LAH) gave the triol **15**, which was then esterified to give the bispropionate **16** in which the tertiary alcohol was protected by a methoxymethyl group (→ **17**) (17). Claisen rearrangement

Kawamata (1979–1981); Université de Sherbrooke: "titulaire de recherche" (L. Ruest) et "adjoint de recherche" (P. Soucy).

[2]For total synthesis of erythronolides reported by other groups, see ref. 2.

[3]Portions of this work have been presented at several international conferences, the first two being the "8th Natural Products Symposium", University of West Indies, Jamaica (January 1980) and the "International Symposium on Stereoelectronic Effects in Organic Chemistry", University of St. Andrews, Scotland (July 1980).

[4]For all new substances, the spectra (ir, 250-MHz and 60-MHz ^1H nmr, and high resolution mass spectra) were in complete agreement with the assigned structures. The ^{13}C nmr spectra were also recorded when necessary for structural assignment.

[5]One isomer is produced and tentatively assigned the stereostructure **5** on the basis of stereoelectronic control (see Chapt. 3 in ref. 4, and ref. 8 for a related example).

[6]Equilibration takes place via acetal cleavage, enol ether formation, and acetal reclosure, which allows epimerization at C-8. The equatorial isomer **7*B***, which exists in the conformation shown on the basis of stereoelectronic effects (3), is sterically less hindered than the axial isomer **7*A***.

[7]At the beginning of our investigation, racemic 5-hexyn-3-ol (±*4*, R = H) was used to develop the synthetic route and this led to the production of racemic intermediates (up to compound **20**).

[8]This selective reaction can be explained on the basis of stereoelectronic effects, see pp. 283–284 in ref. 4.

SCHEME 4

(18) of **17** gave exomethylene-carboxylic acid **18*A*** and its C-4 epimer (**18*B***, not shown) in a 4:1 ratio respectively. Iodolactonization (19) of the epimeric mixture **18** (→ **19**) followed by hydrogenolysis with Raney nickel gave an epimeric mixture at C-4 of lactones (ratio 7:3) from which the desired lactone **20*A*** was obtained pure by chromatography.

The above sequence has allowed the stereocontrolled introduction of the desired substituents at C-4, C-5, and C-6, and it remains to add a second propionic acid unit and to control the stereochemistry at C-2 and C-3 in order to complete the construction of the spiro derivative **1** of erythronolide A.

Reduction of **20*A*** with LAH gave triol **21** (Scheme 4) from which the primary and the secondary alcohols were respectively protected with a *tert*-butyldiphenylsilyl group (20) (→ **22**) and a benzoate (→ **23**). The remaining unprotected tertiary alcohol was converted into a benzyl ether (→ **24**), the silyl protecting group was then removed (→ **25**), and the primary alcohol was oxidized (11) to give the spiro aldehyde **26**.

Using the method of Evans and McGee (21), aldol condensation of **26** with the zirconium enolate of methyl propionate gave the adduct **27*A*** (Scheme 1) and its C-2 epimer (**27*B***, not shown), in a 20:1 ratio, which were separated by chromatography. The methoxymethyl protecting group of **27*A*** was removed under acid hydrolysis, and treatment of the resulting product **28** with potassium carbonate in methanol produced the 1,7-dioxaspiro[5.5]undecane derivative **1** of erythronolide A seco acid methyl ester. This compound was found to be identical (including optical rotation) with a sample of **1** prepared by degradation of erythromycin A as described in the next communication (Part II).

Degradation of erythromycin A gives spirocompound **18***A*. Compound **18***A* is then converted into the spirolactone **22** via **21**. Compound **21** is then reconverted into spiro product **18***A*.

Bruno Bernet, Paul M. Bishop, Maurice Caron, Takeshi Kawamata, Bernard L. Roy, Luc Ruest, Gilles Sauvé, Pierre Soucy et Pierre Deslongchamps. Can. J. Chem. **63**, 2814 (1985).

Par dégradation, l'érythromycine A fournit le composé spiro **18***A*. Ce dernier est ensuite transformé en spirolactone **22** via **21**. Le composé **21** est ensuite reconverti en produit spiro **18***A*.

This communication describes the transformation of erythromycin A (**1**) (Scheme 1) into the 1,7-dioxaspiro[5.5]undecane derivative **18***A* (Scheme 3) of the seco acid methyl ester of erythronolide A. The degradation of the side chain of triol ester **18***A* to give spirolactone **22** via the spiroaldehyde **21** is also reported, as well as the reconstruction of triol ester **18***A* from spiroaldehyde **21**.

Erythromycin A (**1**) was first converted into dihydroerythronolide A (**2**) (1) using the four-step sequence developed by Jones and Rowley (2). In the next operation, the four secondary alcohols were protected by converting **2** into the bis-acetonide **3**, and the remaining two tertiary alcohols were then protected by benzylation (**3** → **4**). Acid hydrolysis of **4** removed both acetonide protecting groups yielding the bis-benzyl ether tetraol **5**, which was then selectively converted into the monoacetonide bis-benzyl ether 9,11-diol **6** using pyridinium tosylate (3) and 2-methoxypropene.

In the next step, pyridinium chlorochromate oxidation of **6** gave the benzylideneacetonide ketone **7**. In this reaction, in addition to the oxidation of the secondary alcohol at C-9 (4), and unexpectedly, the benzyl ether at C-12 was selectively oxidized and transformed into a C(11)—C(12) benzylidene protecting group.

Treatment of **7** with aqueous acetic acid gave 6-benzyl ether-11,12-benzylidene derivative **8** of 8-epi-erythronolide A (Scheme 2). In this reaction, the acetonide group was selectively hydrolyzed with concomitant epimerization of the C-8 methyl group.[1] The seco acid methyl ester derivative **9** of 8-epi-erythronolide was then obtained from **8** using sodium methoxide in methanol. Treatment of **9** with aqueous acetic acid gave the dioxaspiro[5.5]undecane derivative **10**.[2]

The 8-epi-spiro derivative **10** was first converted into the

[1] The epimerization at C-8 has precedent in the literature (5). It was established by the fact that **8** gives the 8-epi-spiro **10** which, when converted into 8-epi-spirocarbonate **12**, undergoes equilibration to give the more stable spirocarbonate **17** (*vide infra*).

[2] In the sequence **9** → **10**, spiroacetalization took place prior to the hydrolysis of the benzylidene protecting group because the C(11)—C(12) benzylidine derivative of **10** can be isolated as an intermediate product when the reaction is stopped before completion.

C-11 phenoxycarbonate **11**, which was then transformed into the five-membered carbonate alcohol **12**. The carbonate acetate **13** obtained from **12** by acetylation yielded the substituted dihydropyran **14** on reaction with ferric chloride in wet acetone. Acetylation of **14** gave diacetate **15**. Spiroacetalization of **14** with *p*-toluenesulfonic acid in acetone gave the dioxaspiro[5.5]undecane acetate derivative **16**, having a configuration for the C-8 methyl group corresponding to that of erythromycin A. Also, on treatment with *p*-toluenesulfonic acid in acetone, 8-epi-spirocarbonate alcohol **12** can be directly converted in one step into the spirocarbonate alcohol **17**. Acetylation of **17** gave also **16**. Finally, mild basic hydrolysis of **17** with potassium carbonate in methanol provided the dioxaspiro-[5.5]undecane derivative **18***A* (Scheme 3) of the seco acid methyl ester of erythronolide A.

Degradation of the side chain of **18***A* was carried out in the following manner: **18***A* was first converted into the 3,11-dibenzoate **19**, which on treatment with sodium methoxide gave the conjugated methyl ester **20**.[3] Reduction of **20** with LAH, followed successively by acetylation and ozonolysis, gave spiro acetatealdehyde **21**. Hydrogenolysis of the benzyl ether group of **21** followed by oxidation gave spirolactone **22**. The spiro acetate-aldehyde **21** was also reacted with the zirconium enolate of methyl propionate (6, 7) to yield the adduct **23***A* and its C-2 epimer **23***B* (not shown), in a 10:1 ratio, which were separated by chromatography. Treatment of **23***A* with potassium carbonate in methanol gave spiro compound **18***A*.

The spirocompound **1** which was obtained by total synthesis (Part I) and by degradation from erythromycin (Part II) was converted into carbamate product **15**, a key intermediate in the Woodward's total synthesis of erythromycin A.

BRUNO BERNET, PAUL M. BISHOP, MAURICE CARON, TAKESHI KAWAMATA, BERNARD L. ROY, LUC RUEST, GILLES SAUVÉ, PIERRE SOUCY et PIERRE DESLONGCHAMPS. Can. J. Chem. **63**, 2818 (1985).

Le composé spiro **1** obtenu par synthèse totale (Partie I) et par dégradation de l'érythromycine A (Partie II) a été transformé en carbamate **15**, un intermédiaire clé de la synthèse totale de l'érythromycine A rapportée par Woodward et ses collaborateurs.

This communication describes the conversion of the dioxaspiro[5.5]undecane derivative **1** (Scheme 1) into the carbamate derivative **15** (Scheme 2) of the seco acid methyl ester of erythronolide A. Carbamate **15** is one of the key intermediates in the course of the total synthesis of erythromycin A carried out by Woodward et al. (1).

Optically active dioxaspiro[5.5]undecane derivative **1** was prepared by total synthesis and by degradation of erythromycin A (cf. preceding communications, Part I and Part II). Compound **1** was converted selectively into the 11-phenoxy-following manner: **18***A* was first converted into the 3,11-dibenzoate **19**, which on treatment with sodium methoxide gave the conjugated methyl ester **20**.[3] Reduction of **20** with LAH, followed successively by acetylation and ozonolysis, gave spiro acetatealdehyde **21**. Hydrogenolysis of the benzyl ether group of **21** followed by oxidation gave spirolactone **22**. The spiro acetate-aldehyde **21** was also reacted with the zirconium enolate of methyl propionate (6, 7) to yield the adduct **23***A* and its C-2 epimer **23***B* (not shown), in a 10:1 ratio, which were separated by chromatography. Treatment of **23***A* with potassium carbonate in methanol gave spiro compound **18***A*.

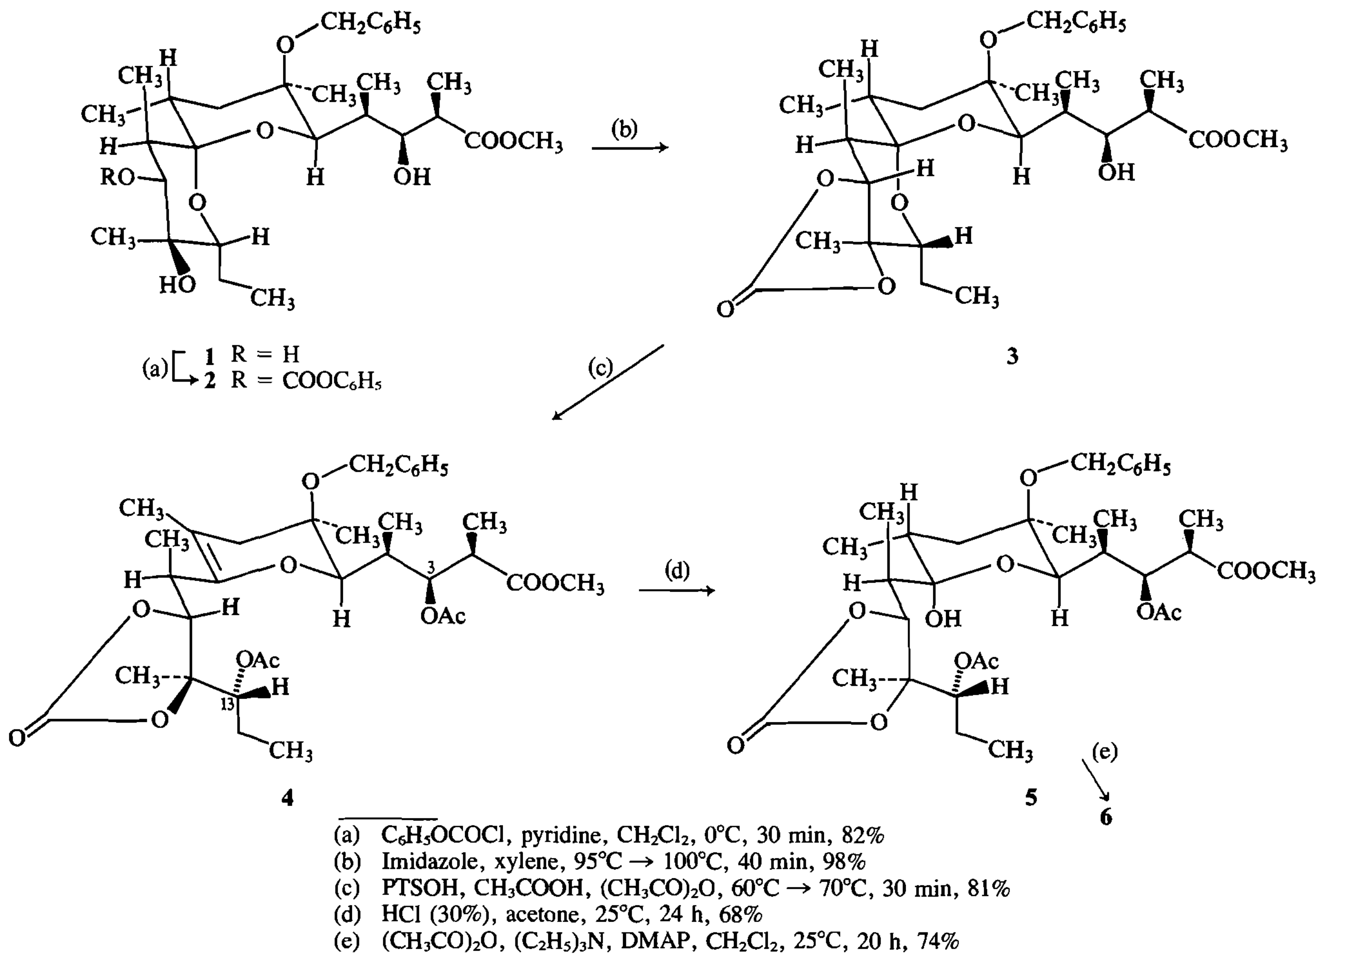
Le composé spiro **1** obtenu par synthèse totale (Partie I) et par dégradation de l'érythromycine A (Partie II) a été transformé en carbamate **15**, un intermédiaire clé de la synthèse totale de l'érythromycine A rapportée par Woodward et ses collaborateurs.

This communication describes the conversion of the dioxaspiro[5.5]undecane derivative **1** (Scheme 1) into the carbamate derivative **15** (Scheme 2) of the seco acid methyl ester of erythronolide A. Carbamate **15** is one of the key intermediates in the course of the total synthesis of erythromycin A carried out by Woodward et al. (1).

Optically active dioxaspiro[5.5]undecane derivative **1** was prepared by total synthesis and by degradation of erythromycin A (cf. preceding communications, Part I and Part II). Compound **1** was converted selectively into the 11-phenoxy-



SCHEME 1

carbonate **2**, which was then transformed into the five-membered carbonate derivative **3**.[1]

On treatment of intermediate **3** with *p*-toluenesulfonic acid in a mixture of acetic acid and acetic anhydride, spiroketal ring opening and acetylation took place to yield the substituted dihydropyran 3,13-diacetate **4**.[1] On treatment with 30% hydrochloric acid in acetone, hydration of the tetrasubstituted enol ether in **4** occurred to produce the hemi-ketal **5**.[2,3] Opening of the second ring of the spiroketal was readily achieved by treating hemi-ketal **5** under acetylating conditions, which gave the 6-benzyl 11,12-carbonate 3,5,13-triacetate derivative **6** (Scheme 2) of erythronolide A seco acid methyl ester.

Reduction with sodium borohydride of the ketone function in **6** gave a mixture of 9*R* alcohol **7***A* and the epimeric 9*S* alcohol **7***B* (not shown), in a 2:1 ratio, which were separated by chromatography. The 9*R* alcohol **7***A* was then converted into the 9*S* secondary amine **10** via the intermediate formation of the mesylate **8** and the azide **9** (3). On heating compound **10** in benzene, transacylation between the secondary amino group and the carbonate took place to produce the 6-benzyl 3,5,13-triacetate carbamate derivative **11**.

The next task consisted in removing the benzyl group at C-6 and the triacetate groups at C-3, C-5, and C-13 in order to obtain the Woodward's carbamate intermediate **15**. This could not be achieved directly in two steps and it was found that the methyl ester has to be removed prior to the hydrolysis of the acetate groups. Treatment of compound **11** with lithium iodide in pyridine (4) gave the carboxylic acid **12**, which produced, on basic hydrolysis with sodium hydroxide, the corresponding tetraol carboxylic acid **13**. Esterification of **13** with diazomethane gave the methyl ester **14** which, upon hydrogenolysis with palladium/charcoal, yielded the 9,11-carbamate deriva-

[1] This compound was also prepared by a different route from erythromycin A (cf. Part II).

[2] Compound **5** was produced with totally synthetic material as well as with material obtained by degradation of erythromycin A. The remaining work (**5** → **16**) was carried out with material derived from the degradation of erythromycin A.

[3] Stereochemical assignment at C-8 and C-9 was made on the basis that the most stable isomer is expected to be produced under those conditions and by taking into account the principle of stereoelectronic control (2).

Disproportionation of HDS in the liquid phase[1]

JAMES D. HALLIDAY AND PATRICK E. BINDNER
Physical Chemistry Branch, Atomic Energy of Canada Limited Research Company, Chalk River Nuclear Laboratories, Chalk River, Ont., Canada K0J 1J0

Received December 12, 1984

JAMES D. HALLIDAY and PATRICK E. BINDNER. Can. J. Chem. **63**, 2821 (1985).

The deuteron–proton liquid phase isotopic disproportionation constant in hydrogen sulphide, K_l, defined for the equilibrium

$$D_2S_l + H_2S_l \overset{K_l}{\rightleftharpoons} 2HDS$$

has been measured at 25.7°C. The value of K_l was 3.99±0.11, based upon direct measurements of the concentrations of the three molecular species H_2S, HDS, and D_2S by ^1H and ^2H nuclear magnetic resonance spectroscopy (nmr) of carefully purified samples. This compares with the theoretical vapour phase isotopic distribution constant K_v = 3.92, calculated from ideal gas vapour phase isotopic partition function ratios (1, 2).

JAMES D. HALLIDAY et PATRICK E. BINDNER. Can. J. Chem. **63**, 2821 (1985).

Opérant en phase liquid et à 27,5°C, on a mesuré la constante de dismutation isotopique deutéron–proton, K_l, dans le sulfure d'hydrogène; cette constante est définie par l'équilibre suivant:

$$D_2S_l + H_2S_l \overset{K_l}{\rightleftharpoons} 2HDS$$

La valeur de K_l est égale à 3,99 ± 0,11 si l'on se base sur des mesures directes des concentrations des trois espèces moléculaires H_2S, HDS et D_2S effectuées par spectroscopie rmn du ^1H et du ^2H sur des échantillons soigneusement purifiés. Cette valeur se compare à la constante de distribution isotopique théorique en phase vapeur, K_v = 3,92, calculée (1, 2) à partir des rapports des fonctions de partition isotopique idéales en phase vapeur.

[Tradiuit par le journal]

Introduction

A literature survey showed that the isotopic disproportionation constant for liquid HDS, K_l, represented by reaction [1], has not been experimentally determined, although a value for the comparable constant for the H_2O/D_2O system has been reported (3).

$$[1] \quad H_2S_l + D_2S_l \overset{K_l}{\rightleftharpoons} 2HDS$$

where $K_l = [HDS]_l^2/[H_2S]_l[D_2S]_l$. These equilibria are of considerable interest in that they are not subject to deviation (4, 5) from the Born–Oppenheimer (B.O.) approximation (6), generally taken as the framework for calculation of partition functions. Theoretical studies using isotopic partition function ratios to determine the isotope effect on vapour phase chemical equilibria have been done by Urey, and Bigeleisen and Mayer (1) and the theory has been recently compiled in functional form by Wolfsberg (2). Deviations from the B.O. approximation tend to reduce the equilibrium constants of exchange reactions between different molecular species (by as much as 2% for exchange between H_2 and H_2O (7)). However, Wolfsberg has shown that disproportionation reactions such as [1] are not subject to this phenomenon.

Although liquid phase disproportionation constants have not been measured, an experimental determination of the vapour phase isotopic distribution constant, K_v, for H_2S/D_2S by Pyper and Newbury (8) using a pulsed molecular beam quadrupole mass filter has yielded a value of 3.88±0.03 at 24.0±0.4 °C. This is in good agreement with the calculated value of 3.919 from Wolfsberg's [2] formulations which have been used to produce the theoretical values of K_v as a function of temperature shown in Fig. 1.

Application of the rule of the mean, to convert from vapour phase to liquid phase, gives $K_l = K_v$ for this system, eq. [2].

$$[2] \quad K_l = K_v \frac{P^0_{H_2S}\, P^0_{D_2S}}{P^0_{HDS}\, P^0_{HDS}} = K_v \frac{P^0_{H_2S}}{(P^0_{H_2S}P^0_{D_2S})^{0.5}} \frac{P^0_{D_2S}}{(P^0_{H_2S}P^0_{D_2S})^{0.5}} = K_v$$

where the P^0's are the saturation vapour pressure of each species (9) indicated by the subscripts.

Although deviations from the B.O. approximation are not expected in this system, experimental values may be different owing to departures from the rule of the mean. For the H_2O/D_2O (10) system, this departure leads to the K_l being 1.5% greater than K_v for water. Hence a similar deviation may be anticipated for the H_2S/D_2S system. Any attempt to verify this hypothesis requires a direct measurement of the liquid phase isotopic distribution constant. Nuclear magnetic resonance was the obvious choice since it does not perturb the equilibrium. Gold and Tomlinson (3) used it for the H_2O/D_2O system and found K_l = 3.94±0.12. However, all published nmr spectra for isotopic mixtures of H_2S/D_2S have not shown complete resolution of the lines for the HDS component (11, 12), a triplet for ^1H and a doublet for ^2H. We have shown that chemical exchange with trace impurities determines the linewidths in these solutions and consequently highly purified H_2S/D_2S samples can be used to obtain direct measurement of the liquid phase isotopic distribution constant, K_l, by nmr.

Experimental

Care had to be exercised in handling these poisonous samples of hydrogen sulphide in glass apparatus because at 25.7°C the vapour pressure above the liquid is 2.2 MPa (21.4 atm). The commercially obtained H_2S (Air Products) and D_2S (>98 atom percent; Merck, Sharp and Dohme) were purified by distillation from their lecture bottles at dry ice temperature into glass storage flasks. Known quantities of these gases (from calibrated volumes and pressures measured

with an MKS 1000 Torr electronic pressure transducer) were cryodistilled into a medium wall nmr tube (Wilmad 524) equipped with a valve. A 5 mm O-ring joint replaced the tapered one in the original design of the valved nmr tube (14). Tetramethylsilane (1%) was added to the H_2S/D_2S samples to provide a proton lock signal. All the glassware used in these experiments was pretreated by heating at 400°C for several hours to remove any exchangeable protons. This preparation technique consistently yielded nmr samples with well resolved HDS resonances (Fig. 2). Owing to the very small self-

protolysis constant for H_2S (2.5×10^{-33} (13)) and the removal of most exchange-causing impurities the rate of isotopic equilibration in the nmr tubes at room temperature was slow. Half-lives for equilibration in different samples were determined to be as long as 24 h.

^{1}H nmr spectra (90 MHz) were obtained on a CW Bruker HX90 spectrometer equipped with a Nicolet 1174 signal averager and a Bruker B-ST 100/700 variable temperature controller. ^{2}H nmr spectra (13.8 MHz) were also obtained on the HX90 and on a FT Bruker WH90 spectrometer in the Chemistry Department, McMaster University.

Results and discussion

(A) Temperature dependence of the hydrogen sulphide nmr spectra

The nmr parameters determined from the proton spectra in this study are summarized in Table 1. The isotopic shift was measured from the centre of the HDS multiplet (Fig. 2) to the H_2S singlet. The temperature dependence of the ^{1}H spectra was also recorded over the range 27.5 to −35.6°C. The chemical shift of the H_2S resonance with respect to TMS, Y_{H_2S}, as a function of temperature, t (°C) (Fig. 3), can be represented by

$$[3] \quad Y_{H_2S} = -0.3049t + 89.4142$$

The chemical shift of the centre line of the HDS triplet with respect to TMS, Y_{HDS}, as a function of t (°C) can be represented by

$$[4] \quad Y_{HDS} = -0.3057t + 86.8557$$

The temperature dependence of the isotopic shift, based on the slopes given in eqs. [3] and [4] is 0.0008±0.0004 Hz/°C. There was no observable temperature effect on the coupling constant J_{HSD}.

(B) Determination of the isotopic disproportionation constant

If the equation for the liquid phase isotopic disproportionation constant [1] is rearranged, i.e.,

$$[5] \quad K_l = [HDS]_l^2/[HDS]_l[D_2S]_l = \frac{[HDS]_l}{[H_2S]_l}\frac{[HDS]_l}{[D_2S]_l} = R_1R_2$$

K_l can be determined from the measurement of the two isotopic species ratios, R_1 by ^1H nmr and R_2 by ^2H nmr, independent of the starting concentrations of the protiated and deuterated species. An accurate determination of the starting concentrations for H_2S and D_2S for the small volume required for nmr measurements is difficult so this double ratio technique has a significant accuracy advantage over measuring only the protiated ratio and calculating the D_2S concentration. R_1 and R_2 for the approximately 1:1 mixture of H_2S and D_2S have been determined at 25.7°C as 1.860 ± 0.018 (26 determinations) and 2.144 ± 0.056 (14 determinations), respectively. The value calculated for K_l is 3.99 ± 0.11 (25.7°C). This measured value of K_l compares to $K_v = 3.920$ (25.7°C) calculated from Wolfsberg's isotopic partition function ratios method (2) (Fig. 1) and indicates that the deviation from the rule of the mean is as great as that found in the H_2O/D_2O system (10). However, the magnitude of the uncertainty in the measurement precludes any further discussion on deviations from the rule of the mean and the temperature dependence of K_l for comparison with that for K_v (Fig. 1).

The magnitudes of the errors in these measurements require some explanation. Firstly, on the CW HX90 spectrometer the very narrow nmr lines required long sweep times (5000 s) to avoid sweep distortions and low rf power levels to prevent saturation effects. Maintenance of a stable lock line over this time scale in these samples on our spectrometer was difficult, and spectrometer instabilities caused variations in the spectra. Secondly, on the WH90 spectrometer the internal deuterium lock saturated the deuteron signal from the D_2S and the external lock had field instabilities greater than the linewidth of the deuterons in the sample. As a result signal averaging could not be accomplished and the S/N obtainable from the Fourier transformation of a single free induction decay had to be used. The statistical error is principally due to the ^2H nmr measurements and, given a more stable spectrometer setup, could be improved upon. However, our measured K_l is comparable in accuracy to that for H_2O (3) and shows that nmr is capable of making this kind of determination in the liquid phase H_2S/D_2S system.

Excess volumes and excess viscosities of binary liquid mixtures: methylisobutylketone + benzene, toluene, chlorobenzene, bromobenzene, and nitrobenzene

T. JAYALAKSHMI AND KALLURU S. REDDY
Department of Chemistry, S. V. University, Tirupati, India

Received August 15, 1984[1]

T. JAYALAKSHMI and KALLURU S. REDDY. Can. J. Chem. **63**, 2824 (1985).

Excess volumes for the binary liquid mixtures of methylisobutylketone with benzene, toluene, chlorobenzene, bromobenzene, and nitrobenzene have been measured at 303.15 and 313.15 K. Excess volumes were negative for all the systems over the entire range of composition and at both the temperatures. The behaviour of V^E as a function of composition and temperature was studied. Viscosity data have also been determined for the five systems at 303.15 K. The excess viscosity, $\Delta \ln \eta$, has been calculated and its behaviour as a function of composition was investigated. The results of V^E and $\Delta \ln \eta$ have been discussed in terms of dipole − induced dipole and dipole−dipole interactions between the components. V^E and $\Delta \ln \eta$ were analysed in the light of Prigogine−Patterson−Flory equation of state theory and Bloomfield and Dewan's viscosity relations.

T. JAYALAKSHMI et KALLURU S. REDDY. Can. J. Chem. **63**, 2824 (1985).

Opérant à 303,15, et 313,15 K, on a mesuré les volumes en excès de mélanges liquides binaires de méthylisobutylcétone avec le benzène, le toluène, le chlorobenzène, le bromobenzène et le nitrobenzène. A toutes les compositions et aux deux températures utilisées, les volumes en excès de tous les systèmes sont négatifs. On a étudié le comportement de V^E en fonction de la composition et de la température. Opérant à 303,15 K, on a également obtenu des données relatives à la viscosité des cinq systèmes. On a calculé la viscosité en excès, $\Delta \ln \eta$, et l'on a étudié son comportement en fonction de la composition du mélange. On discute des résultats relatifs à V^E et de $\Delta \ln \eta$ en fonction d'interactions dipôle − dipôle induit et dipôle−dipôle entre les composants. On a analysé les valeurs de V^E et de $\Delta \ln \eta$ à la lumière de l'équation de la théorie d'état de Prigogine−Patterson−Flory et des relations de viscosité de Bloomfield et de Dewan.

[Traduit par le journal]

Introduction

As a part of a study on thermodynamic and physical properties of binary liquid mixtures containing aliphatic ketone as one of the components (1−4), we have reported here excess volumes and viscosities for five binary liquid mixtures. Excess volumes at 303.15 and 313.15 K and viscosities at 303.15 K have been measured for methylisobutylketone (MIBK) with benzene, toluene, chlorobenzene, bromobenzene, and nitrobenzene and the molecular interactions in these systems have been investigated. The systems have been selected with a view to study the effect of molecular interactions due to substitution of different groups on the phenyl ring. Further, a literature survey revealed that the two properties have not been studied for the five systems.

Prigogine−Patterson−Flory equation of state theory developed on the basis of van der Waals model for energy (5) has been applied quite successfully to predict excess volumes (6−9). Patterson (7, 8) has stressed the importance of cohesive energy factor in the prediction of V^E. We have applied the model for the five systems in which cohesive energy difference between the components changes gradually and V^E values are calculated using pure component parameters. Further, the viscosity expressions developed by Bloomfield and Dewan (10) have been used to obtain various contributions to excess viscosity.

Experimental

Excess volumes were measured using a dilatometer described earlier (2) and were accurate to ± 0.003 cm^3 mol^{-1}. Flow times were determined for pure liquids and liquid mixtures using an Ostwald viscometer and the values were accurate to ± 0.1 s. Densities for the pure components were measured using a bicapillary pycnometer and in case of mixtures densities were obtained from excess volumes using the relation

$$[1] \quad \rho = \frac{X_1M_1 + X_2M_2}{X_1V_1 + X_2V_2 + V^E}$$

Density values obtained from both the methods were accurate to $\pm 5 \times 10^{-5}$ g cm^{-3}. Viscosities were computed by the relative method using flow times and densities. Viscosity values were accurate to 0.5%. This dynamic viscosity is defined as a product of kinematic viscosity and density. Heat of mixing data were determined using adiabatic solution calorimeter for all the systems at 0.5 mole fraction. The results were accurate to ± 1 J/mol.

Methylisobutylketone (BDH), benzene (BDH), and toluene (BDH) were purified by the methods described earlier (3, 11). Chlorobenzene (BDH), bromobenzene (E. Merck), and nitrobenzene (BDH) were dried over calcium chloride and fractionally distilled. The purity of the samples were ascertained by comparing the values of density, boiling point, and refractive index with the literature (12).

Results and discussion

Excess volume data for the five binary mixtures measured at 303.15 and 313.15 K are presented graphically in Figs. 1 to 5. Experimental excess viscosity has been calculated using the relation

$$[2] \quad \Delta \ln \eta = \ln \eta_{mix} - (X_1 \ln \eta_1 + X_2 \ln \eta_2)$$

Excess viscosity versus mole fraction profiles are shown in Fig. 6. Excess volume and excess viscosity results are represented using the empirical equations of the form

$$[3] \quad V^E = X_1X_2[a_0 + a_1(X_1 - X_2) + a_2(X_1 - X_2)^2]$$

and

$$[4] \quad \Delta \ln \eta = X_1X_2[b_0 + b_1(X_1 - X_2) + b_2(X_1 - X_2)^2]$$

The coefficients in eqs. [3] and [4] are obtained by the method of least squares and are given in Tables 1 and 2 respectively along with the standard deviation.

[1]Revision received April 16, 1985.

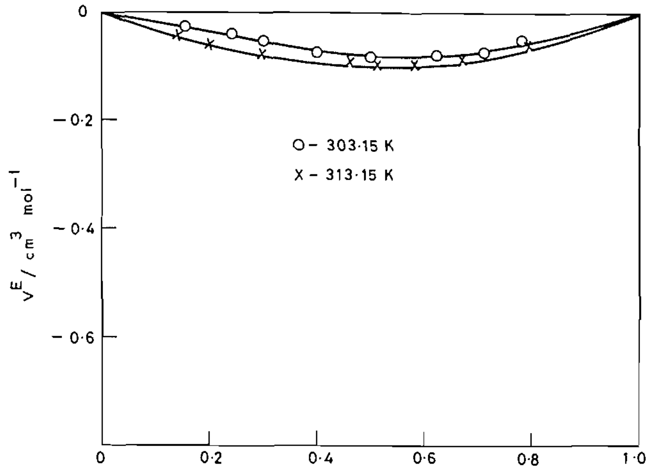

FIG. 1. Excess volume data for the methylisobutylketone and benzene binary mixture.

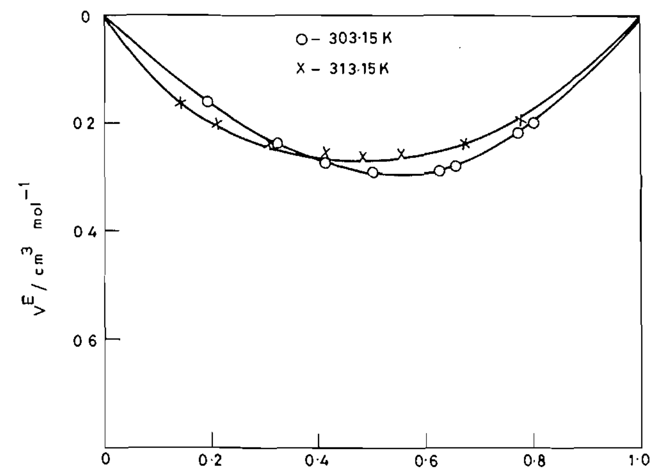

FIG. 2. Excess volume data for the methylisobutylketone and toluene binary mixture.

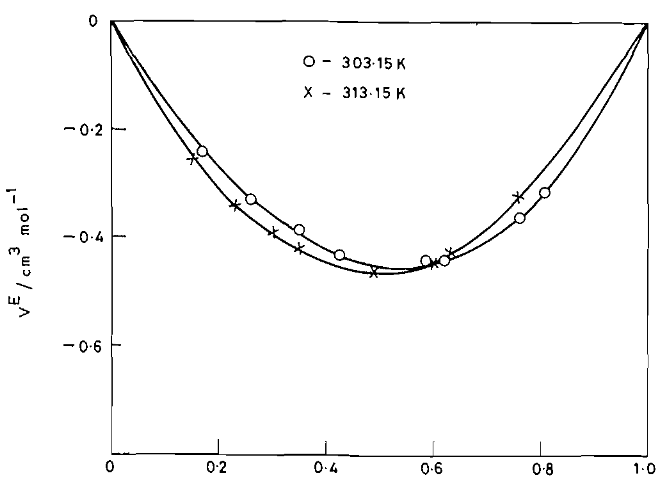

FIG. 3. Excess volume data for the methylisobutylketone and chlorobenzene binary mixture.

Excess volumes

V^E data exhibited negative deviation in all the systems over the entire range of mole fraction and at both the temperatures. The observed negative V^E values in the system methylisobutylketone with benzene may be attributed to the dominance of the interaction between ketoxy group of ketone and π-electrons of benzene over the other effects. V^E values are more negative in the system methylisobutylketone with toluene, which may be ascribed to the enhanced interaction between unlike molecules due to greater π-electron density of toluene. In the remaining systems the negative deviation in V^E is large and this behaviour may be attributed to the existence of strong dipole–dipole interaction between unlike molecules along with the n–π interaction. The algebraic values of V^E with respect to non-common component fall in the order: benzene > toluene > chlorobenzene ≈ bromobenzene > nitrobenzene. This order is similar to the order in their polarizabilities. The influence of temperature on V^E is small in the temperature interval studied: however, both positive and negative temperature coefficients are observed in these complex forming systems.

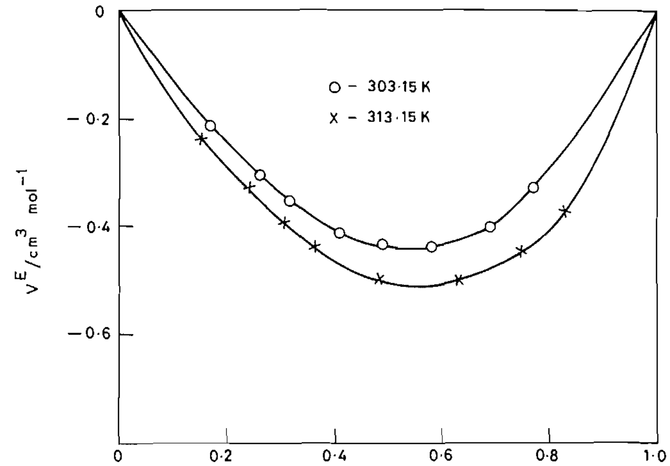

FIG. 4. Excess volume data for the methylisobutylketone and bromobenzene binary mixture.

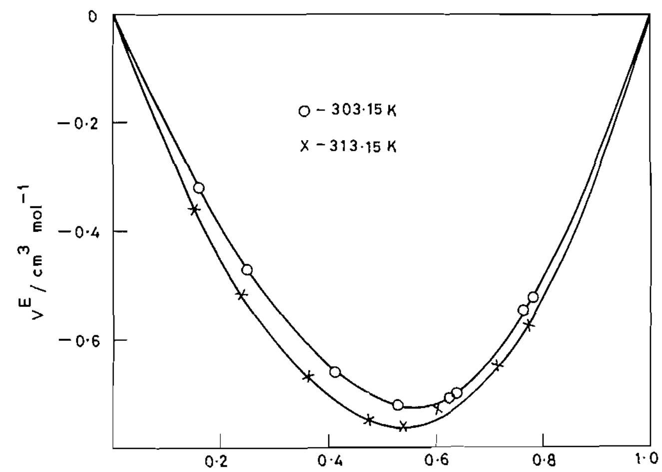

FIG. 5. Excess volume data for the methylisobutylketone and nitrobenzene binary mixture.

V^E values are predicted at 0.5 mole fraction using the following relation developed on the basis of van der Waals model [5]

$$[5]\quad \frac{V^E}{X_1V_1^* + X_2V_2^*} = \tilde{\tau}\frac{\partial\tilde{\vartheta}}{\partial\tilde{T}}\psi_1\theta_2X_{12}/P_1^* + (\tilde{\vartheta}_1 - \tilde{\vartheta}_2)(\psi_1 - \theta_1) - \frac{1}{2}\left[\frac{\tilde{\vartheta}_1 - \tilde{\vartheta}_2}{\partial\tilde{\vartheta}/\partial\tilde{T}}\right]^2\frac{\partial^2\tilde{\vartheta}}{\partial\tilde{T}^2}\{\psi_1\psi_2 + (\psi_1 - \theta_1)^2\}$$

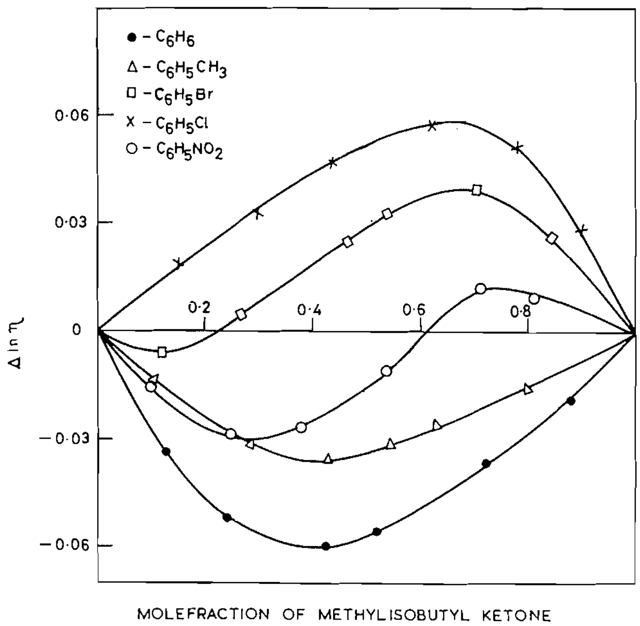

FIG. 6. Profiles of excess viscosity versus mole fraction of the binary mixtures.

The parameters in eq. [5] have their usual significance as described by Patterson and Delmas (5). The site fraction θ_2, and the interchange energy parameter X_{12} are obtained on the basis of Flory's relation (13, 14) using experimental heat of mixing data. The results of excess enthalpy are reported in Table 4. The values of the parameters of pure components are given in Table 3. The V^E value calculated from eq. [5] is a combination of three different contributions. The first term, $V^E(X_{12})$, in the equation indicates the disorder contribution to V^E due to difference in force field between unlike molecules. The contribution to V^E due to difference in internal pressure is obtained with the second term $V^E(P^*)$. The third term V^E (f.v.) is a measure of V^E contribution arises due to difference in free volume. These three contributions are given in Table 4 along with experimental and calculated V^E. The data reveal that the disorder contribution is positive in the system MIBK with nitrobenzene, this may be the reason for the negative excess viscosity observed at lower mole fraction of MIBK in this system, although its V^E values are more negative.

Excess viscosity

Excess viscosity values are negative in the systems methyl-

isobutylketone with benzene and toluene and the values are positive in the system methylisobutylketone and chlorobenzene over the whole range of mole fraction. Further, excess viscosity results exhibit an inversion in sign, from negative to positive, in the systems methylisobutylketone with nitrobenzene and bromobenzene. The algebraic values of $\Delta\ \ln\ \eta$ fall in the order: benzene < toluene < nitrobenzene < bromobenzene < chlorobenzene. Negative values in excess viscosity indicate that the mixtures are more fluid than the pure components and consequently the molecular interactions between unlike molecules are weak. Positive values in excess viscosity indicate that the molecular interactions are strong. Therefore, the order in the observed excess viscosity is similar with excess volume with respect to the systems methylisobutylketone with benzene and chlorobenzene but fails in the remaining systems. The discrepancy may be explained on the basis of the significance of different contributions to $\Delta\ \ln\ \eta$ due to the difference in free volume and free energy of activation of flow (15). According to Bloomfield and Dewan (10) excess viscosity can be represented as

$$[6] \quad \Delta\ \ln\ \eta_{\text{calcd}} = \ln\ \eta_H + \ln\ \eta_S + \ln\ \eta_V$$

where

$$\ln\ \eta_H = \frac{-\Delta H}{RT}, \qquad \ln\ \eta_S = \frac{\Delta S^R}{R}$$

and

$$\ln\ \eta_V = \frac{1}{\tilde{\vartheta} - 1} - \left[\frac{X_1}{\tilde{\vartheta}_1 - 1} + \frac{X_2}{\tilde{\vartheta}_2 - 1}\right]$$

This theory is used to predict excess viscosity at 0.5 mole fraction. The reduced volume $\tilde{\vartheta}$, has been obtained from experimental V^E values. Residual entropy of mixing ΔS^R, is then calculated using $\tilde{\vartheta}$ on the basis of Flory's equations (13, 14). Experimental excess enthalpy results have been used to calculate $\ln\ \eta_H$. Experimental and calculated excess viscosity and

the various contributions to excess viscosity are included in Table 5. An examination of the data indicates that the entropy contribution $\ln \eta_S$ is nearer to $\Delta \ln \eta_{exp}$ in the systems MIBK with benzene and toluene, $\ln \eta_V$ is close to $\Delta \ln \eta_{exp}$ in the system MIBK with nitrobenzene and the free energy contribution, $\ln \eta_G$, is close to $\Delta \ln \eta_{exp}$ in the systems MIBK with chlorobenzene and bromobenzene rather than $\Delta \ln \eta_{calcd}$ in any system. This type of behaviour is also observed in many systems earlier (4, 16, 17). The theory predicts better values in the systems studied here when considered the significance of various effects independently rather than as a combined effect.

A multinuclear (^{1}H, ^{31}P, ^{199}Hg) nuclear magnetic resonance study of some complexes of mercury(II) with ditertiary phosphines[1,2]

PHILIP A. W. DEAN[3] AND RADHEY S. SRIVASTAVA[4]
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received December 6, 1984

PHILIP A. W. DEAN and RADHEY S. SRIVASTAVA. Can. J. Chem. **63**, 2829 (1985).

From $Hg(SbF_6)_2$ and an appropriate amount of the ligands $Ph_2PCHRPPh_2$ (R = H or Me), 2:2, 1:2, and 1:3 M:L complexes have been prepared in $MeNO_2$ solution and characterized by ^{1}H, ^{31}P, and ^{199}Hg nmr spectroscopy. The 2:2 complexes are ligand-bridged, as are $[Hg(Ph_2PCH_2PPh_2)(Ph_2PCHMePPh_2)Hg]^{4+}$ and $[Hg(Ph_2PCH_2PPh_2)_2Ag]^{3+}$ (prepared from $Hg(SbF_6)_2$, $Ag(AsF_6)$, or $Ag(SbF_6)$ and the ligand), examined by nmr for comparison. The complex $[Hg(\mu\text{-}Ph_2PCHMePPh_2)_2Hg]^{4+}$ exists as two isomers, which interconvert slowly on the preparative timescale. The 1:2 complexes, and the analogous mixed ligand complex are shown by their nmr spectral properties to be examples of tetrahedral bis(chelate) complexes, which are very unusual for the $Ph_2PCHRPPh_2$ ligands. In the 1:3 complexes, and the one of the two possible mixed complexes identified, both η^1- and η^2-ligands appear to be present and these undergo rapid intramolecular η^1-to-η^2 exchange. The η^1-bonding mode of $Ph_2PCH_2PPh_2$ also occurs in $[(\eta^2\text{-}Ph_2P(CH_2)_2PPh_2)Hg(\eta^1\text{-}Ph_2PCH_2PPh_2)_2]^{2+}$ and $[Hg(\eta^1\text{-}Ph_2PCH_2PPh_2)_4]^{2+}$, as evidenced by their reduced temperature ^{31}P nmr spectra in Me_2CO—$MeNO_2$.

The complex $[Hg(\eta^2\text{-}Ph_2PCH_2PPh_2)_2]^{2+}$ has ^{31}P and ^{199}Hg nmr spectral properties significantly different from those of its acyclic analog $[Hg(PMePh_2)_4]^{2+}$. To place this anomaly in perspective, the ^{31}P and ^{199}Hg nmr spectra of a much wider series of new bis(chelate) complexes $[Hg(LL)(L'L')]^{2+}$ have been obtained, with the ligand combinations LL = L'L' = $Ph_2PNPhPPh_2$; LL = dppm, L'L' = $Ph_2PNPhPPh_2$; LL = L'L' = $Ph_2P(CH_2)_nPPh_2$(n = 2−4); LL = $Ph_2P(CH_2)_mPPh_2$, L'L' = $Ph_2P(CH_2)_nPPh_2$ ($m \neq n$; m = 1−3, n = 1−5). From the data for the last two series, it is found that only the bis(chelate) complex of $Ph_2PCH_2PPh_2$ shows a large anomaly in its ^{199}Hg chemical shift (anomalously high shielding), and that in $[Hg(LL)(L'L')]^{2+}$ values of ^2J(PP), ^1J(HgP), and ^{31}P chemical shifts vary systematically with the ligand combination; of particular note, ^1J(HgP) to LL decreases as the chelate ring size of L'L' increases. These observations are discussed in terms of the variation in the intra- and inter-chelate PHgP angles expected in the complexes.

PHILIP A. W. DEAN et RADHEY S. SRIVASTAVA. Can. J. Chem. **63**, 2829 (1985).

Opérant dans le $MeNO_2$ comme solvant et utilisant du $Hg(SbF_6)_2$ et des quantités appropriées de ligands $Ph_2PCHRPPh_2$ (R = H ou Me), on a préparé des complexes 2:2, 1:2 et 1:3 M:L et on les a caractérisés par la rmn du ^{1}H, du ^{31}P et du ^{199}Hg. Les complexes 2:2 sont reliés par un ligand, comme c'est le cas avec le $[Hg(Ph_2PCH_2PPh_2)(Ph_2PCH_2PPh_2)Hg]^{4+}$ et le $[Hg(Ph_2PCH_2PPh_2)_2Ag]^{3+}$ (préparés par réaction du $Hg(SbF_6)_2$, du $Ag(AsF_6)$ ou $Ag(SbF_6)$ avec le ligand) que l'on a aussi étudiés par rmn pour fins de comparaison. Le complexe de $[Hg(\mu\text{-}Ph_2PCHMePPh_2)_2Hg]^{4+}$ existe sous la forme de deux isomères qui, à l'échelle préparative, se transforment lentement l'un dans l'autre. Les propriétés spectrales en rmn des complexes 1:2 et des complexes analogues de ligands mixtes sont des exemples de complexes bis(chélatés) tétraédriques qui sont très inusités dans le cas des ligands $Ph_2PCHRPPh_2$. Dans les complexes 1:3 et dans l'un des deux complexes mixtes possibles identifiés, il semble que des ligands η^1 ainsi que η^2 sont présents et qu'ils subissent un échange intramoléculaire rapide η^1 à η^2. Sur la base de leurs spectres rmn du ^{31}P, déterminés dans le couple Me_2CO—$MeNO_2$ et à basse température, on a déterminé que le mode de liaison η^1 du $Ph_2PCH_2PPh_2$ s'établit également dans les complexes $[(\eta^2\text{-}Ph_2P(CH_2)_2PPh_2)Hg\text{-}(\eta^1\text{-}Ph_2PCH_2PPH_2)_2]^{2+}$ et $[Hg(\eta^1\text{-}Ph_2PCH_2PPh_2)_4]^{2+}$.

Les spectres rmn du ^{31}P et du ^{199}Hg du complexe $[Hg(\eta^2\text{-}Ph_2PCH_2PPh_2)_2]^{2+}$ sont très différents de ceux de son analogue acyclique $[Hg(PMePh_2)_4]^{2+}$. Dans le but d'expliquer cette anomalie, on a déterminé les spectres de rmn du ^{31}P et du ^{199}Hg d'une série beaucoup plus importante de nouveaux complexes bis(chélatés) $[Hg(LL)(L'L')]^{2+}$ comportant les combinaisons de ligands LL = L'L' = $Ph_2PNPhPPh_2$; LL = dppm, L'L' = $Ph_2PNPhPP_2$; LL = L'L' = $Ph_3P(CH_2)_nPPh_2$ (n = 2−4); LL = $Ph_2P(CH_2)_nPPh_2$, L'L' = $Ph_2P(CH_2)_mPPh_2$ ($m \neq n$); m = 1−3, n = 1−5. A partir des données se rapportant aux deux dernières séries, on a trouvé que le complexe bis(chélaté) de $Ph_2PCH_2PPh_2$ est le seul à présenter une grande anomalie dans son déplacement chimique du ^{199}Hg (blindage anormalement grand); par ailleurs, on a établi que, dans le complexe de $[Hg(LL)(L'L')]^{2+}$, les valeurs de ^2J(PP), de ^1J(HgP) ainsi que les déplacements chimiques du ^{31}P varient d'une façon systématique avec la combinaison de ligand alors qu'il faut particulièrement noter que la valeur de ^1J de HgP à LL diminue lorsque la taille du cycle du chélate L'L' augmente. On discute de ces observations en fonction de la variation que l'on peut prévoir pour les angles PHgP internes et entre les chélates dans les complexes.

[Traduit par le journal]

Introduction

Mercury(II)−phosphine complexes have been a subject of intense interest for many years; reviews of various aspects of mercury chemistry include discussion of these species (e.g. refs. 1−4). Likewise, complexes of bis(diphenylphosphino)-methane (dppm[5]) have been widely studied (5). However, to our knowledge there has been no detailed nmr spectroscopic study of the system Hg^{2+}−dppm. We felt that such a study would be illuminating in terms of both the nmr spectroscopic and the chemical properties of the complexes formed, as there is evidence for bridging, chelating and monodentate behaviour of dppm bound to mercury(II): $X_2Hg(\mu\text{-dppm})HgX_2$ (X = Cl, Br or I), $HgX_2(\eta^2\text{-dppm})$ (X = Cl or Br) and $HgI_2(\eta^1\text{-dppm})_2$ have been detected by titration calorimetry of dilute solutions in benzene (6), and, recently, heterobimetallic dppm-bridged

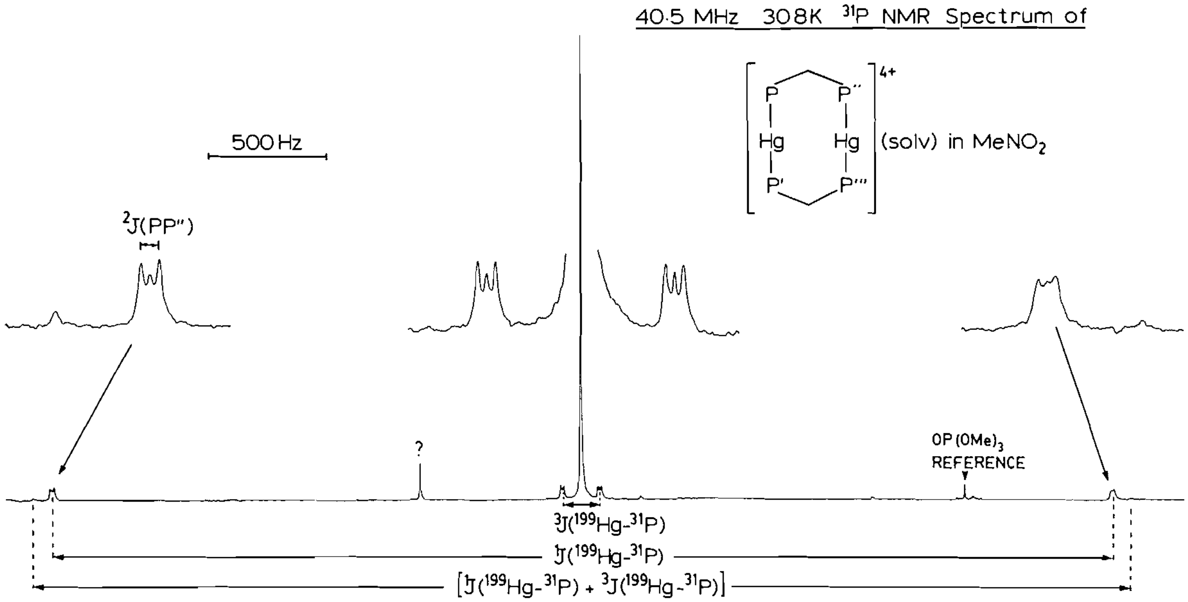

FIG. 1. The 40.54 MHz $^{31}P-\{^1H\}$ nmr spectrum of $[Hg(\mu\text{-dppm})_2Hg]^{4+}$ as the SbF_6^- salt in an $MeNO_2$ solution with 0.3 mol Hg/L of $MeNO_2$ at 308 K.

complexes of Pt(II) centres and mercuric halides have been synthesized and characterized in solution using ^{31}P nmr spectroscopy (7).

Tetrahedral complexes containing chelating dppm are rare (5), and even in square-planar complexes of η^2-dppm the metal and/or ^{31}P nmr parameters differ considerably from those found for complexes of longer-chain chelating diphosphines (e.g. refs. 8, 9). Therefore we anticipated (and indeed found) anomalous nmr spectroscopic behaviour for η^2-dppm complexes of mercury(II). To help quantify the extent of anomaly, we have obtained nmr spectra for a wide range of other bis(chelate) complexes $[Hg(LL)(L'L')]^{2+}$ with most possible combinations of the ligands[5] dppm, dppe, dppp, dppb, and dpppe and the possible combinations of dppa–dppm and dppm–mdppm. Although a variety of nmr data is available for complexes of the types $[Hg(PR_3)_4]^{2+}$ (e.g. refs. 10 and 11 and references therein) and $X_2Hg(LL)$(LL = ditertiary phosphine, X = various anions) (e.g. refs. 12 and 13), no such data seem to be available for the related bis(chelate)mercury(II) complexes; in fact few complexes of this type have been described (1–4).

In previous work from these laboratories (14) it was found that the combination of nitromethane, a weak donor solvent (15), and metal salts of the very weakly coordinating SbF_6^- anion promotes high denticity in Sn(II)– and Pb(II)–poly(tertiaryphosphine) complexes. By analogy, in the present work we have used $Hg(SbF_6)_2$ (16) as the acceptor and $MeNO_2$ (or, in a few cases, $MeNO_2$—Me_2CO) as solvent. In contrast, the $[Hg(PR_3)_4]^{2+}$ cations have usually been prepared with the ClO_4^- counterion and studied in CH_2Cl_2 solution (10, 11).

Results and discussion

Complexes of dppm, mdppm, and dppa

The ligand dppm is poorly soluble in $MeNO_2$ but dissolves in the presence of $Hg(SbF_6)_2$ if L/Hg $\lesssim$ 3.5, giving clear yellow solutions.

When dppm/$Hg(SbF_6)_2 \leq 1$, the $MeNO_2$ solutions contain a single species that is characterized by the ^{31}P and ^{199}Hg nmr[6] spectra shown in Figs. 1 and 2, respectively. These spectra demonstrate unambiguously the formation of the homobimetallic species[7] $[Hg(\mu\text{-dppm})_2Hg]^{4+}$, **1**, which, with ^{199}Hg present in natural abundance, exists as the three isotopomers **1***a–c* with populations of 69.2, 28.0, and 2.8%, respectively (17).

For **1***a*, a strong central singlet (an A_4 spectrum) is found in the ^{31}P nmr spectrum. Isotopomer **1***b* should have an AA′A″A‴X spectrum, where X = ^{199}Hg, assuming a negligible mercury isotope effect. The analysis of a spectrum of this type is well known (18, 19); the four triplets observed in the ^{31}P nmr spectrum are the components of the expected two four-spin subspectra, the shape of the triplets being consistent with the conditions $N \approx L$ where $N = J(AA'') + J(AA''')$ and $L = J(AA'') - J(AA''')$, i.e. $N \approx L \approx J(AA'')$, and $2J(AA') = 2J(A''A''') >> L$. The magnitudes of $J(AX)$ and $J(A''X)$ are given by the separations of the outer and inner pairs of triplets as shown in Fig. 1; these couplings are shown to be of the same sign by the small outermost satellite splitting shown in Fig. 1, which is due to **1**c and which gives $N' = J(AX) + J(A''X)$ for this AA′A″A‴XX′ spin system (20). The $^{199}Hg-\{^1H\}$ nmr spectrum of **1**, shown in Fig. 2, has as its major component a triplet of triplets which is the X part of the AA′A″A‴X spectrum of **1***b*; minor resonances, starred in Fig. 2, comprise part of the X part of the AA′A″A‴XX′ spectrum of **1***c* (there is considerable overlap with the spectrum of **1***b*). The proton nmr spectrum of **1** shows, in the methylene region, a quintet from

[5]Abbreviations used in this paper: $Ph_2PCH_2PPh_2$ = dppm; $Ph_2PCHMePPh_2$ = mdppm; $PhN(PPh_2)_2$ = dppa; $Ph_2P(CH_2)_2PPh_2$ = dppe; $Ph_2P(CH_2)_3PPh_2$ = dppp; $Ph_2P(CH_2)_4PPh_2$ = dppb; $Ph_2P(CH_2)_5PPh_2$ = dpppe; $Ph_2P(CH_2)_6PPh_2$ = dpph; $MePPh_2$ = dpmp.

[6] ^{31}P, 100% natural abundance, spin $I = 1/2$; ^{199}Hg, 16.84% natural abundance, spin $I = 1/2$; ^{107}Ag, 51.82% natural abundance, spin $I = 1/2$, $\mu = -0.11301\mu_N$; ^{109}Ag, 48.18% natural abundance, spin $I = 1/2$, $\mu = -0.12992\mu_N$.

[7]The extent of solvent and/or counteranion coordination in **1** and related species was not investigated, but the very large concentration dependence of ^1J(Hg—P) may indicate an appreciable equilibrium concentration of (labile) coordinated SbF_6^-.

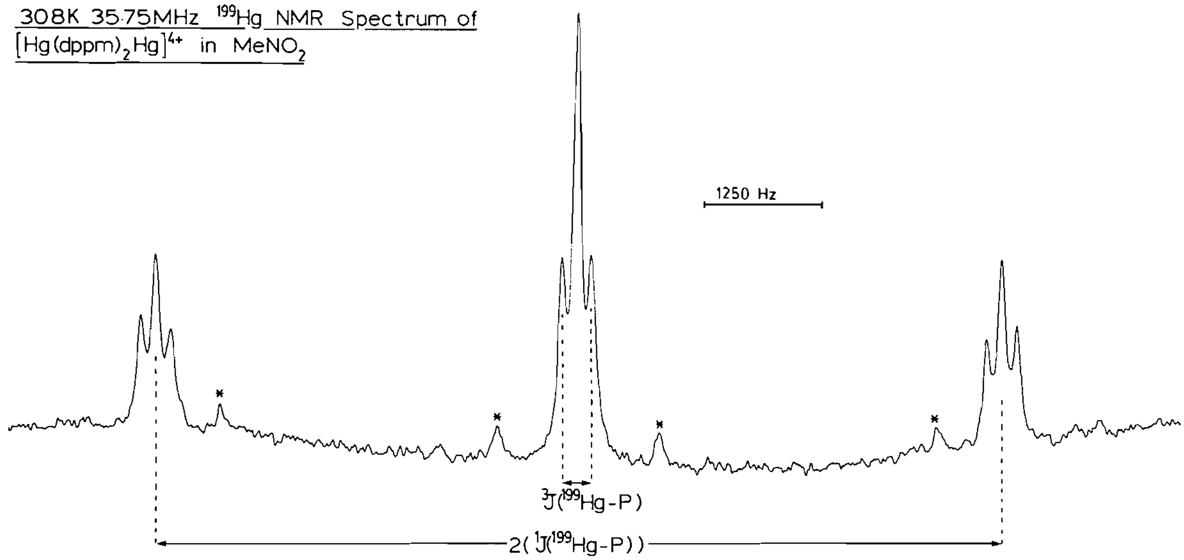

FIG. 2. The 35.75 MHz ^{199}Hg-{^{1}H} nmr spectrum of $[Hg(\mu\text{-dppm})_2Hg]^{4+}$ at 308 K in the same solution used to obtain the ^{31}P nmr spectrum of Fig. 1. Starred resonances are due to $[^{199}Hg(\mu\text{-dppm})_2{}^{199}Hg]^{4+}$. This spectrum was obtained using 61500 15μs (77°) pulses applied at $1\,s^{-1}$ with a spectral window of 25 kHz and an acquisition time of 0.64 s; an exponential factor equivalent to 20 Hz line broadening was applied to the FID.

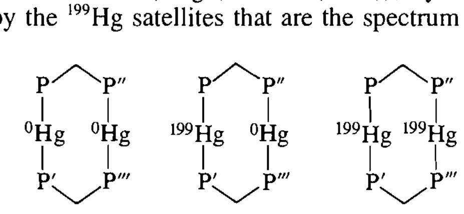
isotopomer **1***a* (which, to give rise to the observed splitting pattern, must have $^{2}J(PHgP) \gg {}^{2}J(PCH)$), symmetrically flanked by the ^{199}Hg satellites that are the spectrum of **1***b*.[8]



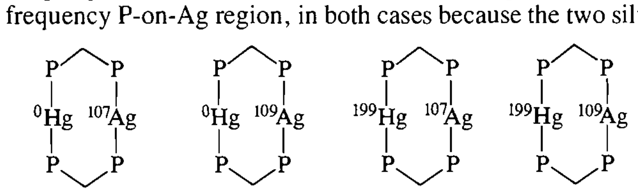
1*a* **1***b* **1***c*

Spectral parameters derived from the ^{1}H, ^{31}P, and ^{199}Hg nmr spectra of **1** are given in Table 1. The values of $^{1}J(HgP)$, 4496 Hz, and δ_{Hg}, 1250 ppm, for **1** are similar to those found for $Hg(PR_3)_2X_2$ in cases where R is an electron-donating group and X a weakly-coordinating anion (10, 11),[9] and probably signifies a near-linear PHgP skeleton as found, for instance, in $Hg(PCy_3)_2(ClO_4)_2$ (23). On the other hand, $^{1}J(HgP)$ is somewhat less than the values of 5495 and 5258 Hz reported for $[(p\text{-tolyl-C}{\equiv}C)_2Pt(\mu\text{-dppm})_2HgCl_2]$ (7*a*) and $[(NC)_2Pt(\mu\text{-dppm})_2HgCl_2]$ (7*b*), respectively, the difference presumably reflecting the relatively strong coordination of chloride to mercury in the Pt—Hg complexes.

The $^{199}Hg-{}^{199}Hg$ coupling found for $[^{199}Hg(\mu\text{-dppm})_2{}^{199}Hg]^{4+}$ found from the positions of the starred resonances in Fig. 2, is one of few such coupling reported (24, 25). The one-bond coupling in $[Hg—Hg—Hg]^{2+}$ has the remarkable value of 139.6 kHz (24*a*), so the ca. 1725 Hz coupling found in the present case need not imply significant Hg . . . Hg bonding, though the mercury atoms are undoubtedly in close proximity. (In $[(PhC{\equiv}C)_2Pt(\mu\text{-dppm})_2AgI]$, where no formal Pt—Ag bond exists, the Pt—Ag distance is 314.6(3) pm (7*a*).) As expected then, $^{4}J(^{199}Hg^{199}Hg)$ in **1** is less than the values of 2435−2959 Hz obtained for $^{2}J(^{199}HgP^{199}Hg)$ in ref. 25.

The value of $^{2}J(PHgP)$ could not be found from the various spectra of **1**. To obtain values for this coupling, as well as to support our assignments for **1** more generally, we have examined the nmr spectra of $[Hg(\mu\text{-dppm})_2Ag]^{3+}$, **2**, and $[Hg(\mu\text{-dppm})(\mu\text{-mdppm})Hg]^{4+}$, **3**, as well as the parent $[Hg(\mu\text{-mdppm})_2Hg]^{4+}$, **4**. The ^{1}H and ^{31}P nmr spectra of $[Ag(\mu\text{-dppm})_2Ag]^{2+}$ have been reported by others (26).

When equimolar amounts of $Hg(SbF_6)_2$ and $Ag(SbF_6)$ (or $AgAsF_6$) are mixed with two equivalents of dppm in $MeNO_2$, the ligand dissolves and the predominant species[7,10] is **2**, which, at 260 K gives the ^{31}P nmr spectrum shown in Fig. 3. As both silver and mercury have magnetically active nuclei,[6] this spectrum is a composite of the spectra of isotopomers **2***a*−*d* with populations of 43.1, 40.1, 8.7, and 8.1%, respectively (17). The species **2***a* and **2***b* both give rise to AA′FF′M spectra (M = $^{107/109}Ag$). These are superimposed in the higher frequency P-on-Hg region, where separate ^{107}Ag− and ^{109}Ag−P couplings could not be resolved, and overlap in the lower frequency P-on-Ag region, in both cases because the two silver



2*a* **2***b* **2***c* **2***d*

[8]These satellites are less well resolved than the centreband resonance, almost certainly as a result of relaxation of the linearly-coordinated ^{199}Hg via CSA (21). We also found (see Fig. 1) consistently poorer resolution of the lowest frequency satellite in the ^{31}P nmr spectrum of **1**; at present we have no explanation for this observation.

[9]When the ^{199}Hg nmr data of refs. 10 and 11, for example, are converted to $Hg(ClO_4)_2(aq)$ as reference, using $\delta_{Hg}(Hg(ClO_4)_2(aq), ext.) = \delta_{Hg}(HgMe_2, ext.) + 2253$ ppm $= \delta_{Hg}(1\,M$ PhHg(OAc), ext.) + 816 ppm (22), the shifts of the various $[Hg(PR_3)_2](ClO_4)_2$ reported therein cover the range 939−1297 ppm; $^{1}J(HgP)$ for these complexes covers the range 3174−5340 Hz.

[10]It is possible to prepare solutions of **2** containing no detectable amount of **1** or $[Ag(\mu\text{-dppm})_2Ag]^{2+}$ (identifiable by its reported (26) ^{31}P nmr spectrum); the redistribution $2\mathbf{2} \rightleftharpoons \mathbf{1} + [Ag(\mu\text{-dppm})_2Ag]^{2+}$ does not occur to a significant extent.

TABLE 1. Nuclear magnetic resonance spectral parameters of some ligand-bridged complexes of mercury(II) in nitromethane[a]

Complex	T (K)	δ_H[b] (ppm)	δ_P[c] (ppm)	δ_{Hg}[d] (ppm)	^1J(MP)[e] (Hz)	^3J(MP) (Hz)	^2J(PCP) (Hz)	^2J(PMP) (Hz)
$[Hg(dppm)_2Hg]^{4+}$	308	5.39(q)[f]	40.8	1250[g]	4496[h,i,j]	160±2[h,i]	15±1[k]	
$[Hg(mdppm)_2Hg]^{4+}$	308	1.63(dq),[l,m] 4.77[m]	54.2[l]	1239[n]	4343[h,i]	130±2[h,i]	34±2[k]	
			55.3[o]		~4165[h]			
$[Hg(dppm)(mdppm)Hg]^{4+}$[p]	308		41.1[q]		[r]			}~206
			53.1[s]		[r]			}
$[Hg(dppm)_2Ag]^{3+}$	260	4.74(dq)[t]	3.7[u]	1247[v]	548[w]	12±1[x]	86±1	~130[u,y]
			46.8[z]		4796[h,v]	[r]		~200[y,z]

[a] $[complex]_{total}$ = 0.15 mol/L of $MeNO_2$; abbreviations are as given in footnote 5 of the text. Phosphorus-31 and ^{199}Hg nmr spectra were measured with broadband proton decoupling. All chemical shifts are given using the convention that shifts to higher frequency than the reference are positive.

[b] Aliphatic protons, with observed splitting patterns parenthesized: q = quintet; dq = doublet of quintets; m = multiplet; at ambient probe temperature (18−23°C) unless noted otherwise.

[c] Measured relative to external 2% (v/v) $OP(OMe)_3$ in D_2O and corrected for sample-reference volume susceptibility difference (see Experimental Section); an approximate conversion to external 85% H_3PO_4 as reference, with susceptibility correction, is $\delta_P(H_3PO_4, ext) = \delta_P(OP(OMe)_3/D_2O, ext) + 3.8$ ppm; estimated error ±0.1 ppm(max); at 308 K, δ_P (uncorr) = −25.8 and −9.7 ppm for CH_2Cl_2 solutions of dppm and mdppm, respectively, from the 40.54 MHz ^{31}P nmr spectra.

[d] Measured relative to external 0.1 M $Hg(ClO_4)_2$ (aq) at 296 K; an approximate conversion to external $HgMe_2$ as reference is $\delta_{Hg}(HgMe_2, ext) = \delta_{Hg}$ (0.1 M $Hg(ClO_4)_2$(aq), ext) − 2253 ppm (22b); estimated error ±1 ppm.

[e] Estimated error in measurement ±5 Hz, except where noted; however, $^1J(^{199}Hg—^{31}P)$ are temperature and concentration dependent, and reproducibility is poorer than ±5 Hz.

[f] $|1/2(^4J(PH)) + 1/2(^2J(PH))| = 5.1 \pm 0.1$ Hz (= quintet splitting); ^3J(HgH) = 99 ± 1 Hz (broad satellites; see footnote 7 of the text).

[g] Resolved fine structure; see Fig. 2.

[h] M = ^{199}Hg.

[i] ^1J(HgP) and ^3J(HgP) have the same sign.

[j] $^4J(^{199}Hg—^{199}Hg) \approx 1725$ Hz in **1**c; see text and Fig. 2.

[k] $|^2J(PCP) + {}^4J(PMPCP)|$.

[l] Major isomer (see text).

[m] ^3J(HH) = 7.3 ± 0.1 Hz; $|1/2(^3J(PH)) + 1/2(^5J(PH))| = 8.2 \pm 0.1$ Hz.

[n] Incompletely resolved fine structure.

[o] Minor isomer (see text).

[p] In an equilibrated mixture of $[Hg(dppm)_2Hg]^{4+}$ and $[Hg(mdppm)_2Hg]^{4+}$.

[q] dppm resonance.

[r] Could not be observed with certainty.

[s] mdppm resonance.

[t] At 260 K; $|1/2(^2J(PH)) + 1/2(^4J(PH))| \approx 4.4$ Hz (the couplings from the chemically different ends of the complex appear to be equal); $^3J(^{107/109}AgP)$(ave) = 4.4 Hz; ^3J(HgP) ≈ 92 Hz (broad satellites; see footnote 8 of the text).

[u] P-on-Ag.

[v] No observable fine structure; at 308 K, δ_{Hg} and ^1J(HgP) are 1243 ppm and ~4723 Hz from the ^{199}Hg nmr spectrum.

[w] M = ^{109}Ag; $^1J(^{107}AgP)$ = 474 Hz; estimated errors ± 2 Hz.

[x] $^3J(^{107/109}AgP)$(ave).

[y] Most probable assignment (see text).

[z] P-on-Hg.

isotopes have similar magnetic moments.[6] Nevertheless the spectra can be analyzed straightforwardly, as can the AA′FF′MX spectra (M = $^{107/109}$Ag, X = ^{199}Hg) of **2**c and **2**d which result in the ^{199}Hg satellites of the P-on-Hg region.[11] (The P-on-Ag region of **2**c and **2**d is obscured by the more intense spectra of **2**a and **2**b).

The reduced temperature ^{199}Hg nmr spectrum of **2** shows only a triplet with splitting of ^1J(HgP); the linewidth of ca. 125 Hz at 260 K must obscure any $^{107/109}$Ag−^{199}Hg or longer-range Hg−P coupling. The ^{31}P nmr spectrum of **2** is less well resolved at 308 K than at 260 K, but not collapsed; in accord with this observation, the triplet ^{199}Hg nmr spectrum persists at 308 K, as do the ^{199}Hg satellites[6] in the methylene region of the proton spectrum, where the centreband is a doublet (from $^{107/109}$Ag−H coupling) of quintets (from virtual coupling to four phosphorus atoms).

The nmr spectral parameters of **2** are included in Table 1. It can be seen that the values of ^1J(HgP), δ_P (P-on-Hg region) and δ_{Hg} for **2** resemble those for **1** quite closely. Likewise, $^1J(^{107/109}AgP)$ and δ_P (in the P-on-Ag region) are similar to those of the structurally characterized (27) $[Ag(\mu\text{-}dppm)_2Ag]^{2+}$ ion ($^1J(^{109}AgP)$ = 583 Hz; δ_P (rel. 85% H_3PO_4(ext)) = 11.5 ppm, for the BF_4-salt in CD_2Cl_2 (26)). The two ^2J(PMP) (M = Ag or Hg) couplings found from the ^{31}P spectrum of **2** cannot be assigned unambiguously, but the larger coupling of ca. 200 Hz is close to the unambiguous value of ca. 206 Hz found for **3** (see below) and is presumably ^2J(PHgP). This can be compared with a zero or near-zero coupling in $HgCl_2(PBu_3)(PR_3)$ (R = 4-$MeOC_6H_4$) (28), 43 — ca. 74 Hz couplings in mixed ligand bis(chelate) complexes of mercury (Table 2 and see below), and a 567 Hz coupling in $[Hg\{P(OMe)_3\}\{P(OEt)_3\}]^{2+}$ (29), for instance.

When L/Hg < 1, fresh $MeNO_2$ solutions of mdppm and $Hg(SbF_6)_2$ give, at 308 K, ^{31}P nmr spectra showing *two* AA′A″A‴X spectra (X = ^{199}Hg) with approximately equal initial intensities. These we attribute to the isomers of **4** with

[11] As δ_P(P-on-Hg) − δ_P(P-on-Ag) is large relative to the various coupling constants, the AA′FF′ subspectra of the AA′FF′M spectra of **2**a and **2**b approach the limiting AA′XX′ case. Thus the ^{31}P nmr spectrum of **2**a, for instance, consists of a near-AA′XX′ spectrum doubled by the relatively large and relatively small couplings to ^{107}Ag in the P-on-Ag and P-on-Hg regions, respectively. In the complexes **2**c and **2**d, further observable doubling occurs in the P-on-Hg region from coupling to ^{199}Hg, giving rise to the ^{199}Hg satellites.

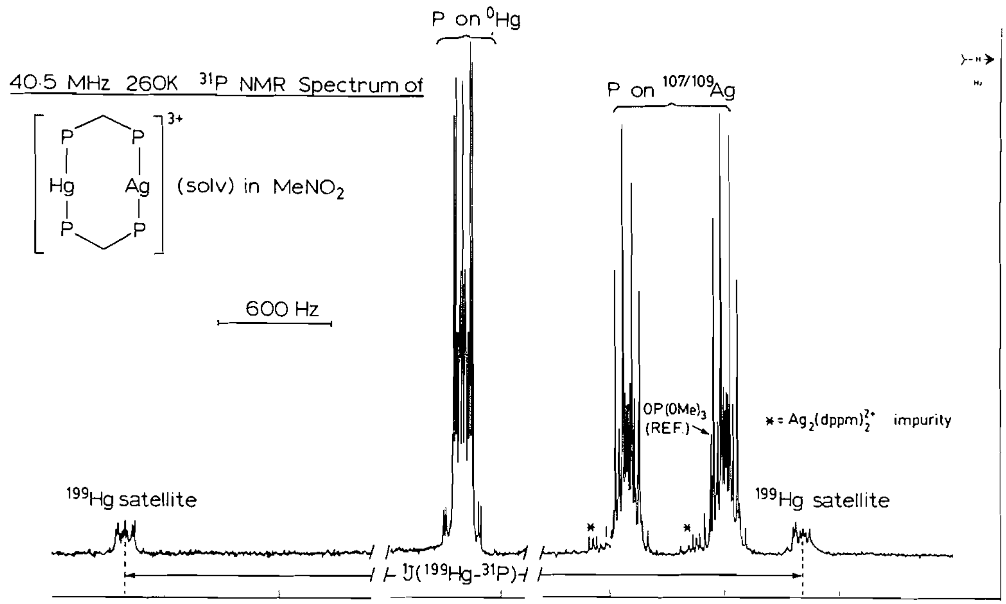


FIG. 3. The 40.54 MHz $^{31}P-\{^1H\}$ nmr spectrum of $[Hg(\mu\text{-dppm})_3Ag]^{3+}$ as the SbF_6^- salt in an $MeNO_2$ solution with 0.15 mol Hg/L of $MeNO_2$ at 260 K. Starred resonances are due to $[Ag(\mu\text{-dppm})_2Ag]^{2+}$ present as an impurity.

syn and *anti* arrangements of the methyl groups, though we cannot tell which spectrum should be assigned to which isomer. In the spectrometer probe at 308 K, the spectrum slowly changes, with the more shielded AA′A″A‴X spectrum growing at the expense of the less shielded until, at equilibrium after ca. 1.5 h [major isomer]/[minor isomer] > 10. Clearly intermolecular ligand exchange between the isomers is slow on both nmr and preparative timescales; our results for **1**–**4** mixtures (see below) suggest that intermolecular ligand exchange in **1** alone may also be slow on both timescales, but labelling studies would be needed to confirm this.

The ^{199}Hg nmr spectrum of an equilibrated solution of **4** consists of a triplet, each component of which appears to have further incompletely resolved fine structure. The poorer resolution found in the ^{199}Hg nmr spectrum of **4** compared with the corresponding spectrum of **1** (Fig. 2) is probably a result of the larger value of ^2J(PCP) in **4**.

The various nmr parameters of **4** are included in Table 1. The values of $\Delta\delta_P$, ^1J(HgP) and δ_{Hg}, particularly, are very similar to those of **1**. The ethylidene signals observed in the proton nmr spectrum confirm that there has been no loss of the methine proton(s) of the ligand(s); acid ionization did not seem an impossibility for **1**, **3**, and **4**, nominally 4+ ions.

When $MeNO_2$ solutions of **1** and **4** are mixed, the ^{31}P nmr spectrum at 308 K shows, initially, just the presence of **1** and **4**. However, equilibration occurs slowly over a period of ca. 2 h, and an apparent AB spectrum grows which we assign to **3**[12] on the basis of the chemical shifts. The apparent J(AB) of ca. 206 Hz is evidently ^2J(PHgP).[12]

[12]The centreband spectrum of **3** should be an AA′BB′ spectrum which can approximate an AB spectrum in the case that $J(AB) \gg J(AA'), J(BB')\, J(AB')$. The ^{199}Hg satellite spectrum of **3** should be an AA′BB′X spectrum (X = ^{199}Hg). Better resolution of the ^{31}P spectrum of **3** occurs at 260 K than at 308 K and further fine structure is evident. However, the spectrum is still basically of the AB type. Overlap of the centreband and satellite spectra of **3** with those of **1** and **4** in the equilibrium mixture unfortunately preclude a detailed analysis. $K = [\mathbf{3}]^2/[\mathbf{1}][\mathbf{4}] \approx 2$; this is the value expected for statistical scrambling of the ligands (17).

When additional dppm is added to an $MeNO_2$ solution of **1**, the 308 K ^{31}P nmr spectrum shows the formation of a new species, giving a singlet spectrum with ^{199}Hg satellites, that coexists with **1** when $1 < L/Hg < 2$ but is the only detectable species at L/Hg = 2. The system **4**-mdppm behaves in an analogous manner. Several lines of evidence confirm the formation of the 2:1 L:M complexes, $[Hg(dppm)_2]^{2+}$, **5**, and $[Hg(mdppm)_2]^{2+}$, **6**; these include the quartet pattern, from ^{199}Hg–P coupling, of their ^{199}Hg nmr spectra, and the formation of the single mixed complex $[Hg(mdppm)\,(dppm)]^{2+}$, **7**, when solutions of **5** and **6** are mixed. The mixed complex, formed rapidly on the preparative timescale, is characterized by a ^{31}P nmr spectrum of the A_2X_2 type (with ^{199}Hg satellites) and a ^{199}Hg nmr spectrum that is a triplet of triplets.

The nmr spectral parameters of **5**–**7** are included in Table 2. Alone they do not *prove* that in the 1:2 complexes the dppm and mdppm behave in a chelating manner, and such proof seems desirable, as tetrahedral complexes of chelating dppm are not well characterized (5). In support of our belief that dppm and mdppm *do* behave in a chelating manner, we can cite the similarity of their ^{199}Hg–P couplings to those of complexes such as $[Hg(dppe)_2]^{2+}$ and $[Hg(dppp)_2]^{2+}$ (Table 2) in which chelation is less contentious, as well as the systematic variation of ^{199}Hg–P coupling (to dppm) in the complexes $[Hg(dppm)(L'L')]^{2+}$, which parallels changes found in other mixed ligand complexes (Tables 2 and 4 and see also below). Thus **5**–**7** appear to be tetrahedral bis(chelate) complexes. However, this description of their geometry is perhaps misleading: Grdenić *et al.* have shown that in the compounds $Hg(phen)_2(NO_3)_2$ (30*a*) and $Hg(bipy)_2(NO_3)_2\cdot 2H_2O$ (30*b*), where the ligand bite angle is small, the geometry of the HgN_4 kernel is closer to square planar than to tetrahedral. We can expect similar distortion in the η^2-dppm/mdppm complexes and a structural study of **5** or **7** would be of some interest.

As shown by the data in Table 2, the ^{199}Hg nmr chemical shifts of **5**–**7** show significant shielding relative to the shifts found for bis(chelate) complexes of $Ph_2P(CH_2)_nPPh_2$ (n = 2–4). Detailed discussion of the trends found in Table 2 is given separately below, but we note here that the ^{199}Hg signal

[a]$[complex]_{total}$ = 0.15 mol/L of $MeNO_2$; abbreviations are as given in footnote 5 of the text; ^{31}P and ^{199}Hg nmr spectra were measured with broadband proton decoupling.

[b]Measured relative to 2% (v/v) $OP(OMe)_3$ in D_2O and corrected for sample-reference susceptibility difference (see Experimental section); an approximate conversion to external 85% H_3PO_4 as reference, with susceptibility correction, is $\delta_P(H_3PO_4, ext) = \delta_P(OP(OMe)_3/D_2O, ext) + 3.8$ ppm; estimated error ±0.1 ppm or less.

[c]Data for LL given first.

[d]$\Delta\delta_P = \delta_P(\text{complex}) - \delta_P(\text{free ligand})$. Values of δ_P(free ligand) were measured at 308 K using CH_2Cl_2 as solvent (this work and ref. 32); the data from Table 4 of ref. 32 were converted to $OP(OMe)_3/D_2O$ as reference using $\delta(OP(OMe)_3/D_2O) = \delta_P(OP(OMe)_3/(CD_3)_2CO) - 1.4$ ppm, but are otherwise uncorrected.

[e]Relative to external 0.1 M $Hg(ClO_4)_2$(aq) at 296 K; an approximate conversion to external $HgMe_2$ as reference is $\delta_{Hg}(HgMe_2, ext) = \delta_{Hg}(0.1\ M\ Hg(ClO_4)_2(aq), ext) - 2253$ ppm (22b); estimated error ± 1 ppm.

[f]Estimated error ±2 Hz, except where noted otherwise.

[g]Estimated error ±5 Hz, except where noted; these values are temperature and concentration dependent.

[h]In $(CD_3)_2CO$ at ambient probe temperature (18–23°C), $\delta_H(CH_2) = 4.41$ ppm, $^3J(^{199}HgH) \approx 103$ Hz, $^2J(PH)$ is not resolved. (The CH_2 resonance overlaps the proton resonance of CHD_2NO_2.)

[i]In CD_3NO_2 at ambient probe temperature (18–23°C), $\delta_H(C\mathit{H}Me) = 4.77$ ppm (incompletely resolved multiplet), $\delta_H(CH\mathit{Me}) = 1.63$ ppm (doublet of quintets: $^3J(HH) \approx |1/2(^3J(PH)) + 1/2(^5J(PH))| \approx 6.5$ Hz).

[j]Exchange-broadened lines are observed at 308 K.

[k]Complicated behaviour at 260 K (see text).

[l]Saturated solution.

[m]At 260 K.

of $[Hg(dppa)_2]^{2+}$ does not have a strongly anomalous chemical shift, pointing to a difference between dppa and dppm/mdppm as chelators. Perhaps significantly, we found no evidence for $[Hg(\mu\text{-dppa})_2Hg]^{4+}$; only $[Hg(dppa)_2]^{2+}$ is produced in $MeNO_2$ solutions where dppa/Hg = 1.

When further dppm is added to an $MeNO_2$ solution of **5**, a third Hg:dppm complex is formed which coexists with **5** when 2 < Hg < 3 and replaces the bis(chelate) complex completely at L/Hg = 3. Parallel behaviour is found for **7** with additional mdppm. The nmr spectral parameters of $[Hg(dppm)_3]^{2+}$, **8**, and $[Hg(mdppm)_3]^{2+}$, **9**, at 260 K, the temperature of best resolution, are included in Table 3. Both complexes show a singlet ^{31}P nmr spectrum, with ^{199}Hg satellites, down to the lowest accessible temperature (ca. −90°C, using $MeNO_2$–Me_2CO as solvent), with similar values of $\Delta\delta_P$ (= δ_P(complex) − δ_P(free ligand)) and J(HgP), the latter much smaller than found in **5**–**7**. Also, most notably, they both have ^{199}Hg resonances that are *septets*.[13]

When solutions of **8** and **9** are mixed, a new species is formed with its highest concentration at **8**:**9** ≈ 2:1. The ^{31}P nmr spectrum of this species consists of a triplet resonance (relative intensity 2) in the dppm region and a quintet resonance (relative intensity 1) in the mdppm region, both with ^{199}Hg satellites. Evidently $[Hg(dppm)_2(mdppm)]^{2+}$, **10** , is formed; we could find no definitive evidence for the other possible mixed complex. The nmr data for **10** are given in Table 3; the values of J(HgP) for this species are comparable to those of **8** and **9**, but the value of J(PP) in it is smaller than in any of the mixed-ligand bis(chelate) complexes studied (Table 2).

We discard the possibility that the septet ^{199}Hg nmr spectra of **8** and **9** indicate a static HgP_6 kernel; HgP_4 is the most

[13]To observe the full septet spectrum we used solutions of **8** and **9** with concentrations ca. 0.3 mol/L of $MeNO_2$.

TABLE 3. Nuclear magnetic resonance spectral parameters for some mercury(II) complexes of η^1-dppm and -mdppm[a,b]

Complex	Solvent	T (K)	δ_H[c] (ppm)	δ_P[d] (ppm)	δ_{Hg}[e] (ppm)	J(Hg—P)[f] (Hz)	J(P—P)[g] (Hz)
$[Hg(\eta^2\text{-dppe})(\eta^1\text{-dppm})_2]^{2+}$	$MeNO_2$—Me_2CO 1/2 (v/v)	198		−33.4[h] 12.5[j] 20.5[k]	[i]	— ~1430 ~2930	 73[l]
$[Hg(dppm)_3]^{2+}$	$MeNO_2$	260	3.80[m]	8.8[n]	1924[o]	1390[f]	
$[Hg(mdppm)_3]^{2+}$	$MeNO_2$	260	3.93,[m,p] 1.27[m,q]	29.6[n]	1688[o]	~1390[f]

[a]See text for further discussion of these species; abbreviations used are those given in footnote 5 of the text.

[b]$[Hg]_{total}$ = 0.15 and 0.05 mol/L of solvent for $MeNO_2$ and $MeNO_2-Me_2CO$ solutions, respectively; ^{31}P and ^{199}Hg nmr spectra were measured with broadband proton decoupling.

[c]Aliphatic protons.

[d]Measured relative to 2% (v/v) $OP(OMe)_3$ in D_2O and corrected for sample − reference susceptibility difference (see Experimental section); an approximate conversion to external 85% H_3PO_4 as reference, with susceptibility correction, is $\delta_P(H_3PO_4, \text{ext}) = \delta_P(OP(OMe)_3/D_2O, \text{ext}) + 3.8$ ppm; estimated error ±0.1 ppm or less. From the 40.54 MHz ^{31}P nmr spectra of CH_2Cl_2 solutions δ_P (relative to external $OP(OMe)_3/D_2O$; uncorrected) = −25.8, −9.7, and −16.0 ppm for dppm, mdppm, and dppe, respectively (ref. 32 and this work) (see also footnote *d* of Table 2).

[e]Relative to 0.1 *M* $Hg(ClO_4)_2$(aq) at 296 K; an approximate conversion to external $HgMe_2$ as reference is $\delta_{Hg}(HgMe_2, \text{ext}) = \delta_{Hg}(0.1\ M\ Hg(ClO_4)_2(aq), \text{ext}) - 2253$ ppm (22*b*); estimated error ± 1 ppm.

[f]Estimated error ±5 Hz, except where noted otherwise.

[g]Estimated error ± 2 Hz.

[h]Unresolved multiplet from unbound end of η^1-dppm, P_B (see text).

[i]Insufficient concentration for measurement.

[j]Triplet from chelating dppe, P_C, of **12** (see text).

[k]Multiplet from bound end of η^1-dppm, P_A (see text).

[l]$^2J(P_A—P_C)$ in **12** (see text).

[m]No fine structure resolved.

[n]Value averaged by intramolecular exchange (see text).

[o]Septet.

[p]C*H*Me.

[q]CH*Me*.

heavily coordinated kernel found for Hg(II) with phosphorus donors (see, for examples, refs. 10 and 29). Therefore we suggest that 8 and 9 should be formulated $Hg(\eta^2\text{-LL})\ (\eta^1\text{-LL})_2$ and that rapid intramolecular exchange of coordinated and uncoordinated phosphorus atoms occurs as in [1].

[1] 
Such an exchange process requires only an HgP_4 kernel, and in addition accounts for the observation of septet ^{199}Hg nmr spectra and small values of J(HgP) (now an average, $(1/3) \times J(HgP)_{chelate} + (1/3)J(HgP)_{\eta^1\text{-bound}} + (1/3)\ J(HgP)_{\eta^1\text{-unbound}}$, with the last term small) for **8** and **9**. Similarly, the values of J(HgP) found for **10** are weighted averages, as is J(PP).

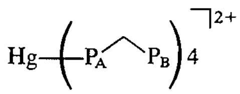
Intramolecular exchange of η^2-and η^1-dppm, at one metal centre, as in [1], does not seem to have been described previously, though possible examples of intramolecular exchange of free and bound ends of η^1-dppm have been reported (31).

Addition of dppm to $MeNO_2$ solutions of **8** causes broadening of the ^{31}P nmr spectra of both **8** and the free dppm, pointing to intermolecular exchange of dppm in a second order process. The species $[Hg(\eta^1\text{-dppm})_4]^{2+}$, **11**, is implicated as an intermediate or transition state. We have unambiguously identified the unusual species **11**; it is present at low concentration in $MeNO_2/Me_2CO$ (1/2 v/v) solutions[14] of **8** saturated with dppm, and can be detected by its low temperature ^{31}P nmr spectrum. At −75°C,[15] the spectrum consists of two approximately equally intense quintets, one somewhat broad and shielded relative to the free dppm signal (which has δ_P = −28.1 ppm in this solution), the other sharper, having ^{199}Hg satellites, and in the region expected for phosphorus bound to Hg(II). These are assigned to P_B and P_A, respectively of **11**, which should give an AA′A″A‴MM′M″M‴ spectrum (AA′A″A‴MM′M″M‴X (X = ^{199}Hg) for the ^{199}Hg satellites) if $^2J(PMP \gg |^2J(PCP) - {}^4J(PCPMP)|$ (20*b*), though the broadness of the P_B quintet suggests that the limiting spectrum may not quite have been reached. (P_B should be the resonance most affected by slow dppm exchange, as the free dppm resonance is nearby.) Coordination of one phosphorus of dppm is known to cause both shielding of the ^{31}P resonance of the uncoordinated phosphorus atom and an increase in $|^2J(PCP)|$ relative to the values for dppm (e.g. refs. 31−34). Still the value of 75 Hz calculated for $|(1/4)\ (^2J(PCP)) + (3/4)\ (^4J(PCPMP))|$ from the quintet splitting of the coordinated dppm resonance of **11** seems remarkably large.

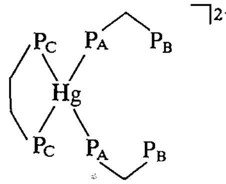
With dppe as a ligand we could find no evidence for $[Hg(dppe)_3]^{2+}$; $[Hg(dppe)_2]^{2+}$ and excess dppe co-exist in $MeNO_2$ solutions where dppe/Hg > 2. Therefore we sought to take advantage of the stability of chelating dppe to synthesize $[(\eta^2\text{-dppe})Hg(\eta^1\text{-dppm})_2]^{2+}$, **12**, in solution. Characterization of this η^1-dppm complex would support our formulation of **8** and **9**, thus providing further (indirect) evidence for the existence of process [1], as well as help confirm our assignments

[14][complex] = 0.05 mol/L of solvent in $MeNO_2$—Me_2CO.

[15]The spectrum collapses at higher temperatures.



11



12

for **11**. Accordingly we used ^{31}P nmr to follow the addition of solid dppe to a solution of **5** in $MeNO_2$ (for our first attempt) or $MeNO_2/Me_2CO$ (1/2 v/v)[13] (for subsequent attempts).

At least the equilibria [2]–[5] are involved in **5**:dppe mixtures:

[2] $3[Hg(dppm)_2]^{2+} + 2dppe \rightleftarrows [Hg(dppe)_2]^{2+} + 2[Hg(dppm)_3]^{2+}$

[3] $[Hg(dppm)_3]^{2+} + dppe \rightleftarrows [Hg(dppe)(dppm)_2]^{2+} + dppm$

[4] $2[Hg(dppe)(dppm)_2]^{2+} \rightleftarrows [Hg(dppe)_2]^{2+} + [Hg(dppm)_4]^{2+}$

[5] $[Hg(dppe)(dppm)_2]^{2+} + dppe \rightleftarrows [Hg(dppe)_2]^{2+} + 2dppm$

However, we have already measured the ^{31}P nmr spectra of all the species except **12** and hence the spectral features due to this complex can be identified. The spectrum consists of three approximately equally intense resonances: a broad signal, probably an incompletely-resolved multiplet, at −33.4 ppm, shielded relative to free dppm; a triplet at 12.5 ppm; and a symmetrical multiplet at 20.5 ppm, overlapping the centreband of the $[Hg(dppe)_2]^{2+}$ spectrum, and close to the resonance position of P_A in **11**. The two less-shielded resonances each have ^{199}Hg satellites. We attribute these signals to P_A, P_B, and P_C, respectively of **12**, and the triplet splitting of P_C to P_AP_C coupling. The overlap of the P_A signal with the spectra of **11** and $[Hg(dppe)_2]^{2+}$, and the broadness of the P_B resonance, preclude complete analysis of the six-spin spectrum of **12**, but there can be no doubt about the existence of the species. By analogy, our formulations of **8** and **9** and the suggestion of rapid intramolecular η^1-LL-to-η^2-LL exchange in these (eq. [1]) are supported, as are our assignments for the spectrum of **11**.

The proton nmr data for **1**, **2**, **5**, and **8**, and **4**, **6**, and **9**, included in Tables 1–3, together with the data given in ref. 26, show that the $\delta(CH_2)$ for the dppm complexes is **1** > **5** > **8** and **1** > **2** > $[Ag(\mu\text{-dppm})_2Ag]^{2+}$, while $\delta(CH\text{Me})$ for the mdppm complexes is **4** > **6** > **9** and **4** > $[Ag(\mu\text{-mdppm})_2Ag]^{2+}$. These findings are in concert with the suggestion of Grim and Walton (34) that in dppm complexes increasing positive charge on the phosphorus atoms leads to decreased shielding of the CH_2 group. It is noteworthy that $\delta(CH_2)$ for **1** is very similar to that for $Ph_2P^+(Me)CH_2P^+(Me)Ph_2$ ($\delta(CH_2)$ = 5.55 ppm (34)), emphasizing the very strong electrophilic character of mercury (II) in the phosphine complexes.

Other bis(ditertiaryphosphine)mercury(II) complexes; correlations in the nmr spectral parameters of $[Hg(LL)(L'L')]^{2+}$

We have measured the ^{31}P and ^{199}Hg nmr spectra of $[Hg(dpmp)_4]^{2+}$, **13** an acyclic analog of **5**,[16] to quantify any nmr spectral anomalies caused by the presence of chelating dppm in the latter. The results are given in Table 2. Comparison of the data for **5** and the dpmp complex shows that there are large differences between $\Delta\delta_P$ (**5** > **13**) and δ_{Hg} (**13** > **5**) for the two complexes, but that their values of ^1J(HgP) are similar. This is unlike the situation for $L_2Pt(dppm)$ versus *cis*-$L_2Pt(dpmp)_2$ (8, 9) where $\Delta\delta_P$, δ_{Pt}, *and* ^1J(PtP) differ, the differences in $\Delta\delta_P$ and δ_M being the reverse of the results for the Hg(II) complexes, viz. $\Delta\delta_P(L_2Pt(dppm)) < \Delta\delta_P(L_2Pt(dpmp)_2)$ ($\Delta\delta_P$ $L_2Pt(dppm)$ *negative*[17]), $\delta_{Pt}(L_2Pt(dppm)) > \delta_{Pt}(L_2Pt(dmpm)_2$; also ^1J(PtP) $(L_2Pt(dppm)) < {}^1J$(PtP) $(L_2Pt(dpmp)_2)$. Therefore we thought it would be instructive to study the nmr spectra of a wider range of complexes $[Hg(LL)(L'L')]^{2+}$ in which LL and L′L′ are selected from the series $Ph_2P(CH_2)_nPPh_2$ (n = 1–5). The nmr spectra of the species studied are included in Table 2.

The ligands dppe, dppp, and dppb are soluble in $MeNO_2$ when $L/Hg(SbF_6)_2 \leq 2$. At L/M = 2, the ^{31}P nmr spectrum in each case consists of a singlet with ^{199}Hg satellites, while the ^{199}Hg spectrum is a quintet with splitting ^1J(HgP). Evidently the bis(chelate) complexes $[Hg(dppe)_2]^{2+}$, $[Hg(dppp)_2]^{2+}$, and $[Hg(dppb)_2]^{2+}$ are formed. We found no evidence for formation of $[Hg(dpppe)_2]^{2+}$ under the same circumstances.[18]

When mixtures of $Hg(SbF_6)_2$ and the ligands $Ph_2P(CH_2)_mPPh_2$ and $Ph_2P(CH_2)_nPPh_2$ ($m \neq n$; m = 1–3, n = 1–5) or dppm–dppa or (see above) dppm—mdppm with $L_{total}/Hg(SbF_6)_2 \approx 2$ in $MeNO_2$ solution, are studied by ^{31}P nmr spectroscopy, unambiguous evidence for the formation of mixed ligand bis(chelate) complexes is found:[19] new A_2X_2 or A_2B_2 spectra with the appropriate ^{199}Hg satellites can be seen. These four-spin spectra are quite clean, pointing to monomeric structures, except in the case of $[Hg(dppe)(dpppe)]^{2+}$. At reduced temperatures this complex gives a first-order AFMX centreband spectrum consisting of four triplets, overlapping in pairs; incomplete collapse towards an A_2X_2 spectrum occurs at 308 K. Possibly $[Hg(dppe)(dpppe)]^{2+}$ exists in a fixed conformation at low temperature or is aggregated. Wherever the concentration of the mixed species was sufficient, the ^{199}Hg nmr spectrum was measured, and showed the triplet of triplets expected for $[Hg(LL)(L'L')]^{2+}$, together with the quintet spectra of the parents complexes if present in the equilibrium mixture; again no spectrum attributable to $[Hg(dpppe)_2]^{2+}$ was ever observed.

In the cases of $[Hg(dppm)(dppa)]^{2+}$ and $[Hg(dppm)(mdppm)]^{2+}$ the assignment of the A_2X_2 ^{31}P nmr spectra can be made in a straightforward manner based on the proximity of the A and X resonances to those of the parent complexes. Assignments made in the same manner seem reasonable for $[Hg(dppe)(L'L')]^{2+}$ (L′L′ = dppp or dppb) and $[Hg(dppp)(dppb)]^{2+}$ also, in which case we observe for the limited series $[Hg(LL)(L'L')]^{2+}$ (LL = dppe, L′L′ = dppe, dppp, or dppb; LL = dppp, L′L′ = dppp or dppb), that *one-bond ^{199}Hg–P coupling to LL decreases as that to L′L′ increases and vice-*

[16]References 10 and 11 contain data for other, less comparable, $[Hg(PR_3)_4]^{2+}$ complexes.

[17]To be consistent with our data, ref. 8 and the IUPAC Convention, we have reversed the signs of δ_P in ref. 9.

[18]The ligands dppe, dppp, dppb, and dpppe also form 1:1 complexes with $Hg(SbF_6)_2$ in $MeNO_2$. We have not studied these in detail but from their nmr spectra, e.g. $Hg(dppb)^{2+}$: δ_P = 47.9 ppm, ^1J(HgP) = 4356 Hz, δ_{Hg} = 968 ppm; Hg(dpppe): δ_P = 49.6 ppm, ^1J(HgP) = 4388, δ_{Hg} = 1020 ppm, all at 308 K, they apparently have linear or near-linear PHgP skeletons and are presumably aggregated.

[19]Chelation by dpppe, which does not form $[Hg(dpppe)_2]^{2+}$ under the same conditions, is worthy of note; however, we could find no evidence for chelation by dpph in any of our experiments.

TABLE 4. Differential changes in ^{31}P nmr chemical shifts and values of ^1J(Hg—P) for LL in the complexes $[Hg(LL)(L'L')]^{2+}$ in nitromethane[a,b]

		L′L′

[a]Abbreviations are those given in footnote 5 of the text.
[b]Values derived from the data in Table 2.
[c]$\delta\delta_P$ = (δ_P of LL in $[Hg(LL)(L'L')]^{2+}$) − $\delta_P[Hg(LL)_2]^{2+}$.
[d]ΔJ = (^1J(HgP) to LL in $[Hg(LL)(L'L')]^{2+}$) − (^1J(HgP) in $[Hg(LL)_2]^{2+}$).

versa. We have taken advantage of this empiricism to make the other assignments in Table 2. Assignments made this way show systematic variation in both ^1J(HgP) and δ_P. Variation relative to the values for the parent $[Hg(LL)_2]^{2+}$ can be quantified as ΔJ(= (^1J(HgP) to LL in $[Hg(LL)(L'L')]^{2+}$) − (^1J(HgP) in $[Hg(LL)_2]^{2+}$)) and $\delta\delta_P$ (= (δ_P for LL in $[Hg(LL)(L'L')]^{2+}$) − (δ_P for $[Hg(LL)_2]^{2+}$)); values of ΔJ and $\delta\delta_P$ are given in Table 4.

From the data in Table 4 it is evident that in $[Hg(LL)(L'L')]^{2+}$ ΔJ decreases by $2-3 \times 10^2$ Hz for each additional backbone carbon atom in the ligand L′L′, except that changing L′L′ from dppm to dppe produces an anomalously small decrease when LL = dppe, dppp, or dppb. Buergi, Pregosin, and co-workers (12) have demonstrated that in X_2HgP_2 ($P_2 = (PR_3)_2$ or various chelating diphosphines; X = various anions) J(HgP) can be expressed as $J(HgP) = a + b\theta(P, Hg, P) + c\theta(X, Hg, X)$ where θ(P, Hg, P) and θ(X, Hg, X) are the PHgP and XHgX bond angles, respectively, and the empirical coefficients a, b, and c have the values 5851 Hz, 25.1 Hz/deg, and −48.7 Hz/deg, respectively, for the range of compounds studied. Accordingly, the explanation we favour for the variation in ΔJ is based on systematic changes in PHgP angles[20]: in $[Hg(LL)(L'L')]^{2+}$ an increase in the chain length of L′L′ should open up the PHgP angle involving L′L′ (equivalent to θ(X, Hg, X) of ref. 12) at the expense of θ(P, Hg, P) in LL, and thus J (and ΔJ) (to LL) should decrease while J (and ΔJ) (to L′L′) should increase. The anomalous behaviour of the complexes $[Hg(LL)(L'L')]^{2+}$ (LL = dppe, dppp, or dppb, L′L′ = dppm or dppe) may reflect a saturation effect, with the intrachelate PHgP angles of LL having already reached a near maximum when combined with the relatively small dppe chelate.

The ^{31}P nmr chemical shifts of phosphorus chelate complexes frequently include a ring contribution, ΔR, where $\Delta R = \Delta\delta_P$ (chelate) − $\Delta\delta_P$ (analogous monodentate complex) (35). Comparison of $\Delta\delta_P$ for $[Hg(dpmp)_4]^{2+}$, $[Hg(dppe)_2]^{2+}$, $[Hg(dppp)_2]^{2+}$, and $[Hg(dppb)_2]^{2+}$ (Table 2) shows that ΔR for the three chelate complexes is very small. On the other hand ΔR for $[Hg(dppm)_2]^{2+}$ is substantial at ca. 25 ppm (and opposite in sign to that found for X_2Pt(dppm), as we have noted above). It seems likely that this sizeable ΔR should be associated with the small intra-chelate PHgP angle of dppm and the resulting chelate ring strain and/or geometry distortion. Significantly, it is only for dppm-containing complexes that large values of $\delta\delta_P$ are observed (Table 4): the overall trend in $\delta\delta_P$ for $[Hg(LL)(L'L')]^{2+}$ is that the LL resonance becomes shielded and the L′L′ resonance deshielded as the difference between the L′L′ and LL chelate ring sizes increases, and this effect is largest for the dppm-containing species. Thus in $[Hg(dppm)(L'L')]^{2+}$ the dppm resonance moves towads the "normal" ^{31}P chemical shift range and the L′L′ resonance away from that range as the ring size of L′L′ increases. Most likely this indicates a lessening of strain in the dppm at the expense of increasing strain in L′L′ as the two chelate ring sizes become more disparate.

The ^{199}Hg resonances of **3** and **5** are significantly shielded relative to the ^{199}Hg signals of $[Hg(LL)_2]^{2+}$ (LL = dppe, dppp, or dppb) (Table 2). It is interesting, however, that the ^{199}Hg resonances of $[Hg(LL)(L'L')]^{2+}$ (LL = dppm, L′L′ = dppe, dppp, dppb, or dpppe) fall in the same general region as the parent complexes of dppe, dppp, or dppb (and also, presumably, the hypothetical $[Hg(dpppe)_2]^{2+}$). A plausible rationalization of these observations is that coordination of *two* dppm ligands to Hg involves extensive strain/distortion, resulting in an anomalous ^{199}Hg chemical shift, whereas coordination of dppm to Hg along with a larger chelate allows a redistribution of PHgP angles (as discussed above) and to a reduction in overall strain/distortion and a more normal chemical shift.[21] Again it is worth noting that coordination of one dppm in L_2Pt(LL) causes *deshielding* of the ^{195}Pt resonance relative to those of complexes with LL = dppe, dppp, or dppb (9); this is the opposite of what we observe for the mercury complexes. At present we have no explanation for the difference.

From the ^{31}P nmr spectra of the mixed ligand complexes $[Hg(LL)(L'L')]^{2+}$, values of ^2J(PHgP) could be obtained. These are included in Table 2. For LL = dppm, dppe, or dppp, ^2J(PHgP) increases as the length of the —$(CH_2)_n$— backbone

[20]An alternative explanation, taking into account the expected increase in the basicity of $Ph_2P(CH_2)_nPPh_2$ with increase in n predicts the *reverse* of the observed trends, as J(HgP) is known to decrease with increasing basicity in $[Hg(PR_3)_4]^{2+}$ (11).

[21]We note, though, that $[Hg(dppm)(dppp)]^{2+}$ and $[Hg(dppm)(dppb)]^{2+}$ have the unusual (36) property of having δ_{Hg} outside the range of the parent complexes.

of the ligand L'L' is increased, the only discrepancy occurring between $[Hg(dppm)(dppe)]^{2+}$ and $[Hg(dppm)(dppp)]^{2+}$. However, the same trend is not observed in the fewer data available for LL = dppb or dpppe. We tentatively suggest that the results for LL = dppm, dppe, or dppp are a reflection of a decrease in the interchelate PHgP angle as n is increased in L'L', and that changes in this angle with n are less pronounced when LL = dppb or dpppe.

Experimental

Materials

Methyldiphenylphosphine and *N*,*N*-bis(diphenylphosphino)aniline (both from Aldrich Chemical Co., Inc.), α,ω-bis(diphenylphosphino)-ethane, -butane, -pentane, and -hexane (all from Strem Chemicals, Inc.), 1,3-bis(diphenylphosphino)propane (Pressure Chemical Co.), and 1,1-bis(diphenylphosphino)methane (Strem or Alfa Products) showed no significant impurities by ^{31}P nmr and were used as received. Nitromethane (Fisher Spectranalyzed) and acetone (Baker Analyzed) were freshly distilled on to 3A Molecular Sieves, and CD_3NO_2 (MSD Isotopes) dried using 3A Molecular Sieves; the solvents were deoxygenated with N_2 or Ar before use.

Literature methods were used to prepare $Hg(SbF_6)_2$ (16) and $AgSbF_6$ and $AgAsF_6$ (37). A small yield (ca. 10%) of 1,1-bis-(diphenylphosphino)ethane was obtained by route (*a*) of Sommer (38), and its authenticity confirmed by comparison of ^1H and ^{31}P-$\{^1H\}$ nmr spectra with those reported (26); at 308 K in CH_2Cl_2 solution, the 40.54 MHz ^{31}P-$\{^1H\}$ spectrum gives δ_P (rel. ext. $OP(OMe)_3/D_2O$) = −9.7 ppm.

Manipulations

All transfers of moisture-sensitive $Hg(SbF_6)_2$ and $AgSbF_6$ or $AgAsF_6$ and involatile air-sensitive ligands were carried out in an N_2-filled glove box in which the atmosphere was maintained by circulation through liquid nitrogen-filled traps. The more volatile $PMePh_2$ was handled in an N_2- or Ar-filled polyethylene glove bag. Glove bag or standard N_2-vacuum techniques were used in the preparation of Hg(II)- and Ag(I)-containing samples; here a freshly-prepared solution of the metal salt(s) was added to a slurry (solution for $PMePh_2$) of the ligand(s), causing dissolution, as described earlier for Sn(II) and Pb(II) complexes (14).

Bis[bis(diphenylphosphino)methane]mercury(II) silver(I)hexafluoroantimonate, $[Hg(dppm)_2Ag](SbF_6)_3$

Nitromethane solutions of $Hg(SbF_6)_2$ (0.336 g, 0.500 mmol) and $AgSbF_6$ (0.172 g, 0.501 mmol) were mixed and added to a slurry of dppm (0.460 g, 1.20 mmol), causing the dissolution of the ligand and production of a yellow solution. Removal of the $MeNO_2$ *in vacuo* left a yellowish-white solid. This was dissolved in CH_2Cl_2 containing a small amount of MeCN and cooled to −78°C, whereupon white crystals formed; these were filtered off at −78°C, washed with cold CH_2Cl_2 and a little MeCN, and dried *in vacuo*. The ^{31}P-$\{^1H\}$ nmr spectrum of this material showed the only phosphorus-containing impurity to be a trace of $[Ag_2(dppm)_2]^{2+}$, detected by its known (26) spectrum (see text). *Anal.* calcd. for $C_{50}H_{44}AgF_{18}HgP_4Sb_3$: C 33.65, H 2.48; found: C 33.76, H 1.53.

Nuclear magnetic resonance spectra

Samples for ^{31}P and ^{199}Hg nmr spectroscopy were prepared in 10 mm od nmr tubes under an atmosphere of N_2 or Ar. Because of the expected (see, for example, refs. 11 and 39) concentration dependence of, especially, $^1J(^{199}Hg—^{31}P)$, samples were normally prepared to have a total mercury concentration of 0.15 mol/L of solvent (0.30 mol/L for $[Hg(dppm)_2Hg]^{4+}$). Samples for ^1H nmr spectroscopy were made up in standard 5 mm od nmr tubes.

All nmr data are reported using the IUPAC convention: chemical shifts to higher frequency than the reference are taken as positive. Broad-band proton decoupling was used in obtaining all ^{31}P and ^{199}Hg nmr spectra.

Proton nmr spectra were measured using a Varian XL-200 or XL-300 spectrometer. Samples of ligands only were referenced to internal TMS in the usual manner, but for metal-containing solutions, spectra were referenced to the solvent resonance, for which the chemical shift relative to TMS under identical conditions was found separately.

Most of the ^{31}P-$\{^1H\}$ nmr spectra were measured at 40.54 MHz using a Varian XL-100 spectrometer; operating conditions, referencing to external $OP(OMe)_3$ in D_2O, and temperature measurements were made as described in earlier work from these laboratories (32). For these conditions, an approximate conversion to H_3PO_4 reference is $\delta_P(H_3PO_4, ext) = \delta_P(OP(OMe)_3/D_2O, ext) + 3.1$ ppm (before correction for susceptibility differences). Later ^{31}P nmr spectra were obtained at 80.94 MHz using a Varian XL-200 spectrometer operating unlocked (field drift ≪ 1 Hz/day). Also a few ligand spectra were measured at 121.4 MHz using a Varian XL-300 spectrometer. The temperatures of the XL-100 and XL-200 under conditions of broad-band proton decoupling were matched using the sharp, temperature-dependent ^{199}Hg satellite splitting of the spectrum of $[Hg(dppe)_2]^{2+}$ (see Table 2) and should agree within ±3°C. Using the XL-200, ^{31}P chemical shifts were measured by sample interchange with a 2% (v/v) solution of $OP(OMe)_3$ in D_2O. The different geometries of the superconducting solenoid of the XL-200 and the iron electromagnet of the XL-100 lead to different chemical shifts relative to the external reference (40). Therefore for convenience of comparison, all ^{31}P nmr chemical shift data have been corrected for sample-reference susceptibility difference using the expressions of ref. 40 and the volume susceptibility data of Gutmann and co-workers (41).

For ^{199}Hg nmr, 0.1 *M* $Hg(ClO_4)_2$ in 5% (v/v) $HClO_4$ solution was used as an external reference, with referencing made by sample interchange. An approximate conversion to $HgMe_2$ reference is $\delta_{Hg}(HgMe_2, ext) = \delta_{Hg}(Hg(ClO_4)_2, ext) - 2253$ ppm (22*b*). A few initial ^{199}Hg-$\{^1H\}$ nmr spectra were measured at 71.51 MHz using the Bruker WH-400 spectrometer of the S. W. Ontario NMR Centre in Guelph, but all of the ^{199}Hg-$\{^1H\}$ nmr data reported here were measured at 35.75 MHz using the Varian XL-200 spectrometer in this Dept., running without field/frequency lock. To obtain the spectra, typically 66° (11.5 μs) pulses were applid at 1 s^{-1} with a 0.64 s acquisition time and a 25 kHz spectral window; to reach satisfactory S/N required collection of $5-10 \times 10^3$ transients for a single species and $10-20 \times 10^3$ transients for a mixture of species. Linewidths at half height varied with sample and temperature, but were 40 Hz or more.

Simulation of nmr spectra

The ^{199}Hg nmr spectrum of $[^{199}Hg(dppm)_2\,^{199}Hg]^{4+}$ was simulated using the program LAOCN3 (42), with values of $^4J(^{199}Hg—^{199}Hg)$ selected by trial and error.

Chemical analysis

Carbon and hydrogen microanalyses were made by Guelph Chemical Laboratories Ltd.

Acknowledgments

This work was made possible by an Operating Grant to P.A.W.D. from the Natural Sciences and Engineering Research Council of Canada. Some initial high field nmr spectra were obtained at the Southwestern Ontario NMR Centre at Guelph which was funded by a Major Installation Grant from NSERC.

Investigation of the constituents of *Ryania Speciosa*

LUC RUEST, DAVID R. TAYLOR, AND PIERRE DESLONGCHAMPS
Laboratoire de synthèse organique, Département de chimie, Faculté des Sciences, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received March 20, 1985

LUC RUEST, DAVID R. TAYLOR, and PIERRE DESLONGCHAMPS. Can. J. Chem. **63**, 2840 (1985).

Six new metabolites (**2**, **5–9**) were isolated from the extracts of *Ryania Speciosa* Vahl. These compounds are closely related to ryanodine, the known insecticidal toxic alkaloid from this plant.

LUC RUEST, DAVID R. TAYLOR et PIERRE DESLONGCHAMPS. Can. J. Chem. **63**, 2840 (1985).

Six nouveaux métabolites (**2**, **5–9**) ont été isolés des extraits de la plante *Ryania Speciosa* Vahl. Ces composés sont étroitement reliés à la ryanodine, un alcaloïde toxique connu provenant de cette plante.

Although the insecticidal diterpene ester ryanodine (**1**) (1) has been isolated from *Ryania Speciosa* since 1948 (2), to our knowledge no other diterpene had been reported from this genus prior to 1984. Very recently Waterhouse, Holden, and Casida (3) reported the isolation and characterization of dehydroryanodine (**2**), the second most abundant toxic (3) alkaloid (besides ryanodine) from *Ryania Speciosa*. Ryanodine (**1**) is a complex, highly oxygenated diterpene in which the unrearranged geranyl–geraniol (**3**) unit is easily discerned as proposed by Wiesner (1). An examination of the constituents of *Ryania Speciosa* was undertaken to seek compounds related to ryanodine as (i) alternate synthetic targets;[1] (ii) possible precursors on the biogenetic pathway to ryanodine. The actual growing interest[2] in the toxic constituents of *Ryania Speciosa* prompted us to publish some results obtained some years ago in our laboratory.

This report describes the isolation and identification of six diterpene esters of α-pyrrole carboxylic acid closely related to ryanodine (**1**): the already known (3) dehydroryanodine (**2**), diterpene esters A (**5**), B (**6**), C_1 (**7**), C_2 (**8**), and D (**9**).

The structure of dehydroryanodine (**2**), the major new diterpene slightly more polar than ryanodine (see Experimental), was proven by spectral analysis and by catalytic hydrogenation to a mixture of ryanodine (**1**) and 9-epiryanodine (**10**). We will not discuss further the structure of this compound (cf. Experimental for details) since it has been at least partly described in ref. 3.

Compounds A, B, C_1, C_2, and D were isolated by chromatography of the crude extracts of powdered stems of *Ryania Speciosa* (2). Their R_f values are all greater than that of ryanodine and they are listed in order of increasing polarity, A being the least polar (see Experimental).

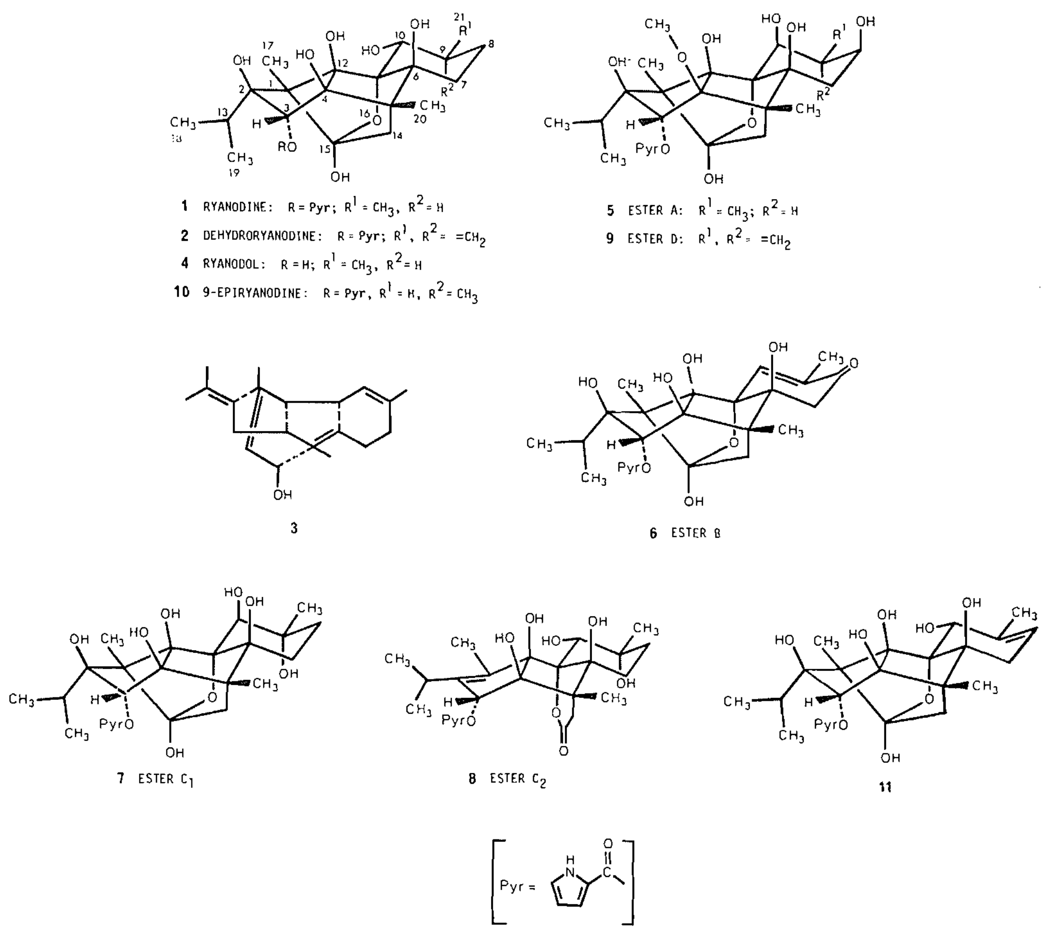
Spectral data of diterpene ester A (**5**) are in agreement in all respects with the proposed structure. The mass spectrum indicates a formula of $C_{26}H_{37}O_{10}N$, which is equivalent to the addition of CH_2O to ryanodine, suggesting that ester A has one more hydroxyl group than ryanodine and that one of the hydroxyl groups has been methylated. The structure is supported by nmr spectral analysis: it shows three multiplets from 6.2 to 7.1 δ (for the pyrrole-α-carboxylate moiety), a sharp singlet at 5.68 δ (3-H), a methoxy at 3.56 δ, an AB pattern at 2.62 and 1.83 δ (for 14-H_2 on the heterocyclic ring), two tertiary and three secondary methyl groups. In addition, after D_2O exchange (6 hydroxyls), a narrow multiplet at 4.01 δ (narrow doublet of triplets) and a doublet (J = 3.3 Hz) at 3.49 δ account for two hydrogens α to the secondary alcohols in positions 8 and 10, respectively. The magnitude of the coupling constants of these hydrogens suggests in each case an equatorial position.

Spectral analysis of diterpene ester D suggests that it is dehydroester A, $C_{26}H_{35}O_{10}N$. The major differences in the nmr spectra of esters A and D are (i) a secondary methyl signal (1.23 δ) in ester A has been replaced by two one-proton doublets (J = 1.32 Hz) at 5.24 and 5.43 δ in easter D; (ii) the doublet at 3.49 δ in A has become a singlet at 3.97 δ in D, and (iii) the multiplet at 4.01 δ in A has changed to a multiplet at 4.54 δ in D. The location and stereochemistry of the two secondary alcohols in ester D follow from the lack of allylic coupling between the vinylic proton of the exocyclic methylene (21-H_2) and the hydrogens in positions 8 and 10, indicating the coplanarity of the allylic protons with the double bond. In contrast, both vinylic protons in dehydroryanodine (**2**) occur as multiplets because of allylic coupling. Furthermore, in ester D there is an evident *W* coupling between the equatorial hydrogens 8-H and 10-H. This *W* coupling is also present in ester A. Being present in A, this coupling confirms the equatorial stereochemistry for 8-H and 10-H and suggests that the secondary methyl of position 9 is equatorial.

The location of the methoxyl in esters A and D follows from a consideration of the ir and nmr spectra and chemical data. The inertness of esters A and D to treatment with periodate shows that the α-glycol system present in ryanodine is blocked in A and D. Whereas the singlets for 3-H in ryanodine (**1**) and dehydroryanodine (**2**) appear at 5.35 and 5.38 δ respectively ($CDCl_3$), those for the same proton in esters A and D occur at 5.68 δ and 5.64 δ respectively. This indicates a difference in structure of these latter compounds, close to the ester function. In infrared ($CHCl_3$), the carboxylic ester absorbs at 1675 cm^{-1} in ryanodine and dehydroryanodine and at 1701 and 1703 cm^{-1} for esters A and D respectively. These data indicate that hydrogen bonding of the ester can take place in ryanodine and dehydroryanodine but not in A and D. Hence the location of the methoxyl is at the site of the hydroxyl (position 4), which is close enough to hydrogen bond with the ester carbonyl in ryanodine.

The mass spectrum of diterpene ester B (Δ^{9-10} 8-oxo ryanodine) is consistent with the formula $C_{25}H_{31}O_9N$. The nmr spectrum is similar to that of ryanodine except that the signals for 9-CH_3 and 10-H have been replaced by that for a vinyl methyl (d, 1.5 Hz) at 1.92 δ coupled to a vinylic proton (q, 1.5 Hz) at 6.70 δ. Ester B has a new AB pattern (additional to

[1] For a total synthesis of ryanodol (**4**) see ref. 4.
[2] At submicromolar concentrations, ryanodine interferes specifically with the relaxing mechanism of mammalian muscle (6).



SCHEME 1

14-H$_2$) at 3.12 and 2.35 δ for 7-H$_2$. These data, in agreement with a uv absorption at 232 nm and the infrared spectrum (1681 cm^{-1}), are consistent with the proposed structure for ester B.

The mass spectrum of ester C$_1$ (9*R*-hydroxy 10*S*-ryanodine) is consistent with the molecular formula $C_{25}H_{35}O_{10}N$, equivalent to the addition of one oxygen to ryanodine. The nmr spectrum shows that the secondary methyl at C-9 (1.05 δ, d) in ryanodine has been replaced by a singlet at 1.21 δ and that the 10.1-Hz doublet at 3.94 δ for the 10-H in ryanodine has now become a broad singlet at 3.75 δ (which sharpens by irradiation at 1.53 δ (8-H$_{eq}$), *W* coupling). These data are in agreement with the structure given for ester C$_1$.

Diterpene ester C$_2$ (9*R*-hydroxy anhydroryanodine) shows a mass spectrum consistent with the formula $C_{25}H_{33}O_9N$. The nmr spectrum shows in particular an AB pattern (J = 19.5 Hz) at 3.27 and 2.28 δ for the methylenic 14-H$_2$, α to the lactone carbonyl (1745 cm^{-1}), and a vinylic methyl doublet (1.78 δ, 2.3 Hz) coupled to a one-proton signal (3-H) (q, J = 2.3 Hz) at 5.96 δ. In addition, the nmr spectrum shows a signal for a tertiary methyl at 1.16 δ (9-CH$_3$) and a very sharp singlet at 4.23 δ (no *W* coupling with the equatorial 8-H) for the axial proton at position 10. Since C$_2$ has a lower R_f than C$_1$, it is unlikely to be the anhydro C$_1$ because anhydro derivatives have R_f values always greater than those of ryanodine, dehydroryanodine, and ryanodol. In agreement, acid catalysed dehydration of C$_1$ gave anhydro C$_1$ of much higher R_f than C$_2$. Structures given to diterpene esters C$_1$ and C$_2$ account for their spectral as well as their chemical properties. In these two compounds, the equatorial stereochemistry of the 9-CH$_3$ follows the nuclear Overhauser effect (nOe) analysis of that methyl group versus the axial hydrogen at position 7. In the course of the catalytic hydrogenation of dehydroryanodine (**2**), which yields **1** and **10**, an isomer of dehydroryanodine was also observed and isolated. Its structure was shown, by spectroscopic analysis, to be **11**. Reduction of **11** gives mainly ryanodine (**1**) containing a small proportion (3:1) of 9-epiryanodine (**10**).

Biological activity: biological activities of these new metabolites (esters A, B, C$_1$, C$_2$, and D) are currently under investigation.[3]

Experimental

The infrared (ir) spectra were taken on a Perkin–Elmer 257 spectrophotometer. The ultraviolet (uv) spectra were registered on a Varian Techtron 635 spectrophotometer. Proton nmr spectra were recorded on a Bruker WM-250 instrument: chemical shifts are reported in δ values relative to chloroform (7.26 δ) or methanol (3.35 δ) as internal standard. The mass spectra (ms) were registered on a ZAB-1F mass spectrometer. The melting points were taken on a Büchi or a Reichert melting point instrument and are not corrected.

General

The crude extracts of *Ryania Speciosa* Vahl were obtained mainly as indicated by Folkers and co-workers (2). Following these authors, the moist powder (500 g, 800 mL H$_2$O) was extracted continuously with chloroform (1.5 L) during 30 h. The volume of the solvent was reduced to ~200 mL and extracted with water (4 × 300 mL). The

[3] Dr. J. L. Sutko, Department of Physiology, University of Texas Health Science at Dallas, Dallas, Texas 75235, USA.

combined aqueous layers were saturated with NaCl and extracted with amyl acetate or ethyl acetate (5×200 mL). Removal of the solvent furnished a crude extract corresponding to ~0.25% (w/w) of the dry powdered *Ryania Speciosa* wood. The greatest part of ryanodine (**1**) and dehydroryanodine (Δ^{9-21} ryanodine) (**2**) cocrystallized (acetone) from this crude extract. Classical chromatography on silica column ($CHCl_3/CH_3OH$ 95:5) of the mother liquors led to a mixture of the minor metabolites A, B, C_1, C_2, and D, plus the same mixture of ryanodine and dehydroryanodine.

Separation of ryanodine (1) and dehydroryanodine (2)

A sample of the mixture was separated by preparative thin-layer chromatography (Merck, pre-coated tlc plates, silica gel 60F-254) by multiple elution technique ($CHCl_3$/MeOH/40% aqueous CH_3NH_2 85:15:2) or by flash chromatography (5) (same solvents respectively, 90:10:1.5). The less polar compound, forming a brown chromophore when heated on tlc plates (H_2SO_4 sprayed), was shown to be pure ryanodine (**1**) (mp 234–236°C) (lit. (3) mp 235–237°C; (*1b*) mp 228–229°C); ir ($CHCl_3$): 3580, 3500, 3450, 3330, 1676, and 1550 cm^{-1}; nmr ($CDCl_3$, after exchange with D_2O); 7.07, 6.97, and 6.32 (three double doublets for pyrrole ring hydrogens), 5.35 (s, 3-H), 3.94 (d, 10.1 Hz, 10-H), 2.38 (d, 13.8 Hz) and 1.93 (d, 13.8 Hz) (AB pattern, 14-H_2), 2.33 (m, 13-H), 2.04 (m, 7-H_{ax}), 1.85 (m, 9-H_{ax}), 1.58 (m, 8-H_{ax} and 7-H_{eq}), 1.44 (s, 17-H_3), 1.27 (m, 8-H_{eq}), 1.14 and 0.94 (two d, 6.7 Hz and 6.5 Hz, 18-H_3 and 19-H_3), 1.05 (d, 6.5 Hz, 21-H_3), 0.84 (s, 20-H_3) (were exchanged by D_2O, peaks at 10.2, 5.92, 5.59, 3.95, 3.78, 2.92, 2.86, and 1.99); *m/e*: M^+ 493. The more polar compound, forming a typical red chromophore when heated on tlc (H_2SO_4 sprayed), was shown to be dehydroryanodine (Δ^{9-21} ryanodine); mp 252–254°C (crystallized from acetone, lit. (3) mp 175–179°C); ir ($CHCl_3$): 3580, 3500, 3450, 3330, 1675, and 1547 cm^{-1}; nmr ($CDCl_3$, after exchange with D_2O): 7.07, 6.97, and 6.32 (three double doublets for pyrrole ring hydrogens), 5.38 (s, 3-H), 5.09 and 4.99 (two multiplets, 21-H_2) 4.87 (m, 10-H_{ax}), 2.62 (m, 8-H_{ax}), 2.38 (d, 13.8 Hz) and 1.92 (d, 13.8 Hz) (AB pattern, 14-H_2), 2.35 (m, 8-H_{eq} and 13-H), 2.05 (m, 7-H_{ax}), 1.44 (s, 17-H_3), 1.36 (m, 7-H_{eq}), 1.14 and 0.95 (two d, 6.7 and 6.4 Hz, 18-H_3 and 19-H_3), 0.89 (s, 20-H_3) (were exchanged by D_2O, peaks at 10.4, 5.74, 5.46, 3.73, 2.87, 2.82, and 2.13). *Exact Mass* (ms *m/e*) calcd.: 473.2049 ($M^+ - H_2O$); found: 473.2044.

Minor metabolites from Ryania Speciosa

The main constituents less polar than ryanodine were separated by preparative tlc ($CHCl_3$/MeOH/40% aqueous $MeNH_2$ 85:15:3). Each one represents ≈1–2% (w/w) of the crude extract. A first separation led to two fractions, the more polar of which contained esters B, C_1, C_2, and D. The less polar fraction was resubjected to preparative tlc (petroleum ether/acetone/acetic acid 50:50:3) to yield pure Ryania diterpene A. The more polar fraction was separated on tlc (petroleum ether/acetone/acetic acid 50:50:3) to give diterpene ester B (the top band), diterpene ester C_1 (second band), and ester C_2 (fourth band). The third band was rechromatographed ($CHCl_3$/MeOH/aqueous NH_3 90:10:1): the top band was ester C_2 and the bottom band was diterpene ester D.
