Ryania diterpene ester A: ir ($CHCl_3$): 3590, 3510, 3455, 3310, 1701, and 1498 cm^{-1}; nmr ($CDCl_3$, after exchange with D_2O): 7.03, 6.88, and 6.28 (three double doublets for pyrrole ring hydrogens), 5.68 (s, 3-H), 4.02 (m, sharpens by irradiation at 3.49, 8-H_{eq}), 3.56 (s, 4-OCH_3), 3.49 (d, 3.3 Hz, 10-H_{eq}), 2.62 (d, 13.7 Hz) and 1.83 (d, 13.7 Hz) (AB pattern, 14-H_2), 2.24 (dd, 13.8, 3.8 Hz, 7-H_{ax}) and 1.82 (dd, 13.8, 2.9 Hz, 7-H_{eq}) (AB pattern), 2.23 (m, 9-H), 2.20 (m, 13-H), 1.40 (s, 17-H_3), 1.23 (d, 7.3 Hz, 21-H_3), 1.07 and 0.81 (two d, 6.7 and 6.4 Hz, 18-H_3 and 19-H_3), 0.97 (s, 20-H_3) (were exchanged by D_2O, peaks at 10.2, 5.85, 5.52, 3.61, 3.26, 2.78, and 2.50). *Exact Mass* (ms *m/e*) calcd.: 505.2311 ($M^+ - H_2O$); found: 505.2320.

Ryania diterpene ester B: ir ($CHCl_3$): 3580, 3510, 3450, 3300, 1681, and 1547 cm^{-1}; uv λ_{max}: 268 and 232 nm; nmr ($CDCl_3$, after exchange with D_2O): 7.11, 6.98, and 6.31 (three double doublets for pyrrole ring hydrogens), 6.70 (q, 1.6 Hz, 10-H), 5.27 (s, 3-H), 3.12 (d, 16 Hz) and 2.35 (d, 16 Hz) (AB pattern, 7-H_2), 2.53 (d, 13.9 Hz) and 1.93 (d, 13.9 Hz) (AB pattern, 14-H_2), 2.31 (m, 13-H), 1.89 (d, 1.6 Hz, 21-H_3), 1.41 (s, 17-H_3), 1.11 and 0.92 (two d, 6.7 and 6.4 Hz, 18-H_3 and 19-H_3), 0.87 (s, 20-H_3) (were exchanged by D_2O, peaks at 10.3, 6.13, 5.85, 3.71, 3.17, and 3.00). *Exact Mass* (ms *m/e*) calcd.: 489.1998 (M^+); found: 489.1992.

Ryania diterpene ester C_1: mp 188–190°C ($CHCl_3$); ir (Nujol): 3590, 3440, 3280, 1688, 1666, and 1548 cm^{-1}; nmr ($CDCl_3$, 10% pyridine-d_5, after exchange with D_2O): 6.96, 6.84, and 6.19 (three double doublets for pyrrole ring hydrogens), 5.73 (s, 3-H), 3.75 (broad singlet, sharpens by irradiating at 1.53, 10-H), 2.60 (d, 13.9 Hz) and 1.96 (d, 13.9 Hz) (AB pattern, 14-H_2), 2.25 (m, 13-H), 2.04 (m, 7-H_{ax}), 1.96 (m, 8-H_{ax}), 1.53 (m, 8-H_{eq}), 1.43 (s, 17-H_3), 1.32 (m, 7-H_{eq}), 1.21 (s, 21-H_3), 1.10 and 0.77 (two d, 6.7 and 6.4 Hz, 18-H_3 and 19-H_3), 0.90 (s, 20-H_3) (were exchanged by D_2O, peaks at 11.5, 8.39, 4.31, 3.40, and 3.18. *Exact Mass* (ms *m/e*) calcd.: 509.2260 (M^+); found: 509.2249.

Ryania diterpene ester C_2: mp 274–275°C ($CHCl_3$); ir (Nujol) 3590, 3450, 3390, 1745, 1705, 1687 (shoulder), 1577, and 1540 cm^{-1}; nmr ($CDCl_3$, 10% pyridine-d_5, after exchange with D_2O): 6.83, 6.73, and 6.04 (three double doublets for pyrrole ring hydrogens), 5.96 (q, 2.3 Hz, 3-H), 4.23 (s, 10-H_{ax}), 3.28 (d, 19.6 Hz) and 2.28 (d, 19.6 Hz) (AB pattern, 14-H_2), 2.47 (m, 13-H), 1.96 (m, 7-H_{ax}), 1.78 (d, 2.3 Hz, 17-H_3), 1.60 (m, 8-H_{ax} and 7-H_{eq}), 1.28 (m, 8-H_{eq}), 1.16 (s, 21-H_3), 0.87 and 0.59 (two d, 7.0 Hz, 18-H_3 and 19-H_3), 0.86 (s, 20-H_3) (were exchanged by D_2O, peaks at 11.5, 6.37, 6.14, 5.86, 4.63, 3.70, and 3.34). *Exact Mass* (ms *m/e*) calcd. for $C_{25}H_{33}O_9N - H_2O$: 473.2049; found: 473.2049 ($M^+ - H_2O$).

Ryania diterpene ester D: ir ($CHCl_3$): 3590, 3510, 3455, 3365, 1703, and 1548 cm^{-1}; nmr ($CDCl_3$, after exchange with D_2O): 7.04, 6.89, and 6.29 (three double doublets for pyrrole ring hydrogens), 5.64 (s, 3-H), 5.43 (d, 1.3 Hz) and 5.24 (d, 1.3 Hz) (21-H_2), 4.54 (m, 8-H_{eq}), 3.97 (broad s, sharpens by irradiation at 4.54, 10-H_{eq}), 3.34 (s, 4-OCH_3), 2.58 (d, 13.9 Hz) and 1.82 (two d, 13.9 Hz) (AB pattern, 14-H_2), 2.33 (dd, 13.9 and 4.2 Hz, 7-H_{ax}) and 1.88 (dd, 13.9 and 2.0 Hz, 7-H_{eq}) (AB pattern), 2.22 (m, 6.5 Hz, 13-H), 1.40 (s, 17-H_3), 1.08 and 0.84 (two d, 6.7 and 6.4 Hz, 18-H_3 and 19-H_3), 0.99 (s, 20-H_3) (were exchanged by D_2O, peaks at 11.4, 5.67, 5.61, 3.97, 3.17, 2.89, and 1.62). *Exact Mass* (ms *m/e*) calcd. for $C_{26}H_{35}O_{10}N$: 521.2260; found: 521.2260 (M^+).

Hydrogenation of dehydroryanodine (Δ^{9-20} ryanodine) (2)

Dehydroryanodine (27 mg) in ethanol (15 mL) was stirred under hydrogen in the presence of palladium 10% on carbon (40 mg) for 1.1 h at room temperature. The crude material (27 mg) isolated by filtration contained three compounds, which were separated by preparative thin-layer chromatography ($CHCl_3$/MeOH/40% aqueous CH_3NH_2 85:15:1.5). The least polar compound was ryanodine (**1**) (4.7 mg), the second one was epiryanodine (**10**) (9.7 mg), and the more polar one was isodehydroryanodine (**11**) (4.4 mg) (Δ^8-ryanodine).

9-Epiryanodine: nmr (CD_3OD): 7.08, 6.93, and 6.28 (three double doublets for pyrrole ring hydrogens), 5.67 (s, 3-H), 4.35 (d, 6.3 Hz, 10-H), 2.61 (d, 13.7 Hz) and 1.96 (d, 13.7 Hz) (AB pattern, 14-H_2), 2.31 (m, 13-H), 2.20 (m, 7-H_{ax}), 2.21, 2.05, and 1.46 (three multiplets, 9-H, 8-H_{ax}, and 8-H_{eq}), 1.44 (s, 17-H_3), 1.22 (m, 7-H_{eq}), 1.16 and 0.79 (two d, 6.7 and 6.4 Hz, 18-H_3 and 19-H_3), 1.16 (d, 7.3 Hz, 21-H_3), 0.94 (s, 20-H_3).

Isodehydroryanodine (Δ^8-ryanodine) (11): nmr (CD_3OD): 7.08, 6.93, and 6.29 (three double doublets for pyrrole ring hydrogens), 5.69 (s, 3-H), 5.39 (m, 8-H), 4.42 (m, 10-H), 2.69 (d, 14 Hz) and 2.04 (d, 14 Hz) (AB pattern, 14-H_2), 2.63 (m, 7-H_{ax}), 2.33 (m, 13-H), 1.83 (m, 21-H_3), 1.81 (m, 7-H_{eq}), 1.45 (s, 17-H_3), 1.16 and 0.80 (two d, 6.8 and 6.4 Hz, 18-H_3 and 19-H_3), 0.95 (s, 20-H_3); ms *m/e*: 491.

Hydrogenation of isodehydroryanodine (Δ^8-ryanodine) (11): pure isodehydroryanodine **11** was submitted to hydrogenation as above during 4 h. The crude product was shown (nmr) to be a mixture of ryanodine and epiryanodine (3:1, integration of 10-H doublets). The same result was obtained when Δ^{9-21}-ryanodine (**2**) was first submitted to the same catalyst in ethanol under argon (3 h), then hydrogenated.

Received January 31, 1985

MARK WHITTAKER, COLIN R. MCARTHUR, and CLIFFORD C. LEZNOFF. Can. J. Chem. **63**, 2844 (1985).

The key chiral synthons, (*R*)-3-isopropenyl-6-heptenoic acid and (*R*)-3-isopropenyl-6-heptenal, needed for the synthesis of (3*Z*,6*R*)-3-methyl-6-isopropenyl-3,9-decadien-1-yl acetate, a component of the sex pheromone of the California red scale, *Aonidiella aurantii*, have been prepared by asymmetric synthesis. The chiral acid was synthesized in 86% ee by an asymmetric 1,4-addition of isopropenylmagnesium bromide to the *l*-ephedrine amide derived from (*E*)-2,6-heptadienoic acid, followed by base hydrolysis. Acid hydrolysis gave the chiral 3-(3-buten-1-yl)-4,4-dimethylbutyrolactone. The chiral aldehyde was prepared in greater than 99% ee by an asymmetric 1,4-addition of isopropenylmagnesium bromide to the imine derived from (*S*)-(+)-*tert*-butyl 2-amino-3,3-dimethylbutyrate and (*E*)-2,6-heptadienal. The 1,4-addition reactions of *n*-butyllithium or isopropenyllithium to (4*S*,5*S*)-(+)-2-[1-(*E*-1,5-hexadienyl)]-4-methoxymethyl-5-phenyl-2-oxazoline gave the addition products, and sequential mild hydrolysis and reduction of these adducts yielded chiral 3-*n*-butyl-6-hepten-1-ol for the former adduct but a mixture of products was obtained from the latter adduct.

MARK WHITTAKER, COLIN R. MCARTHUR et CLIFFORD C. LEZNOFF. Can. J. Chem. **63**, 2844 (1985).

Utilisant une synthèse asymétrique, on a préparé les synthons chiraux clés, acide isopropényl-3(*R*) heptène-6 oïque et isopropényl-3(*R*) heptène-6 al, nécessaires à la synthèse de l'acétate du méthyl-3(*Z*) isopropényl-6(*R*) décadiène-3,9 yle-1, une composante de la phérémone sexuelle de l'écaille rouge de la Californie *Aonidiella aurantii*. On a préparé l'acide chiral avec un ee de 86% en faisant appel à une addition asymétrique-1,4 du bromure d'isopropénylmagnésium sur l'amide de la *l*-éphédrine provenant de l'acide heptadiène-2,6(*E*) oïque, suivie d'une hydrolyse basique. L'hydrolyse acide permet d'accéder à la (butène-3 yl-1)-3 diméthyl-4,4 butyrolactone chirale. On a préparé l'aldéhyde chiral avec un ee supérieur à 99% en procédant à une addition-1,4 asymétrique du bromure d'isopénylmagnésium sur l'imide obtenu par réaction du (+)-amino-2(*S*) diméthyl-3,3 butyrate de *tert*-butyle et de l'heptadiène-2,6(*E*) al. Les réactions d'additions-1,4 du *n*-butyllithium ou de l'isopropényllithium sur la (+)-[(hexadiène-1,5(*E*) yl)-1]-2 méthoxyméthyl-4(*S*) phényl-5(*S*) oxazoline-2 conduisent aux produits d'addition et une hydrolyse douce subséquente suivie d'une réduction de ces adduits conduit au *n*-butyl-3 heptène-6 ol-1 chiral lorsqu'on part du premier adduit; toutefois, le second adduit ne conduit qu'à un mélange de produits.

[Traduit par le journal]

The sex pheromones of the California red scale, *Aonidiella aurantii* (Maskell), an insect which is a severe pest of citrus in California, Australia, and the Mediterranean countries, were identified as a mixture of (3*Z*,6*R*)-3-methyl-6-isopropenyl-3,9-decadien-1-yl acetate (**1**) and (3*S*,6*R*)-3-methyl-6-isopropenyl-9-decen-1-yl acetate (**2**) (1–4). Each of these compounds exhibits equal independent ability to attract the male insects (4).

2

Our related interests in the synthesis of insect sex attractants on insoluble polymer supports (5) and the use of solid phases in asymmetric syntheses (6) have naturally led us to consider the possibilities of asymmetric synthesis of chiral sex pheromones on solid phases. Our attention focussed on compound **1** containing a single chiral centre. Component **1** was first synthesized from (*S*)-(+)-carvone in 2.6% overall yield (2). A racemic mixture of **1** and its enantiomer was subsequently synthesized in 32% (7) and 27% (8) yields, respectively. Two other preparations of **1** have been reported recently, starting from (*S*)-(+)-carvone (9). Thus, all syntheses of **1** (2, 9) started from the same naturally occurring chiral precursor. Our desire to prepare compound **1** using polymer-bound chiral auxillaries *via asymmetric synthesis* led us to examine satisfactory methods for the asymmetric synthesis of **1** in solution as a necessary prerequisite step.

A key chiral intermediate used in the synthesis of **1** was (*R*)-3-isopropenyl-6-heptenal (**3**), previously obtained by lengthy conversion of the natural product (*S*)-(+)-carvone (2, 9*a*). Compound **3** could potentially be made much more readily by asymmetric 1,4-additions to at least three different possible α,β-unsaturated functionalized precursors, and we can designate these routes as the ephedrine, the aldimine, and the oxazoline routes.

The ephedrine route

It has been shown that chiral α,β-unsaturated amides, prepared from (1*R*,2*S*)-(−)-α-(1-methylaminoethyl)benzyl alcohol (*l*-ephedrine) in 1,4-addition reactions with Grignard reagents, can give, after acid hydrolysis, chiral β-substituted carboxylic acids in greater than 95% enantiomeric excess (ee) (10). This initial report (10), however, used only simple aliphatic amides and Grignard reagents and it remained to be seen if this attractive asymmetric synthesis could be applied to the synthesis of a more complex β-substituted aldehyde such as **3**. The chiral α,β-unsaturated amide necessary for this synthesis is *N*-(*E*-2,6-heptadienoyl)-*l*-ephedrine (**4**) and is prepared as shown in Scheme 1.

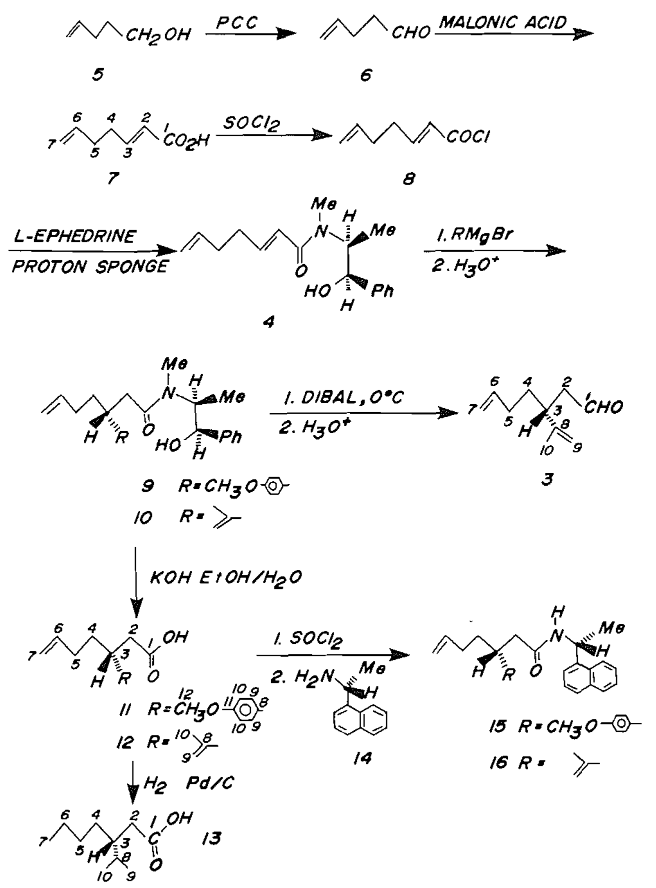
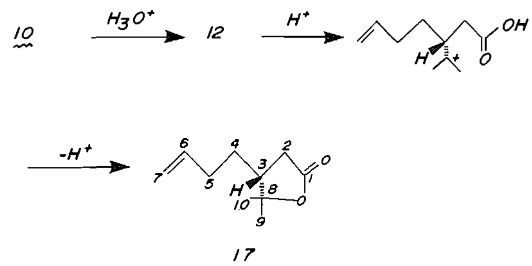


SCHEME 1

Oxidation of 4-penten-1-ol (**5**) with pyridinium chlorochromate (PCC) in methylene chloride (11) gave the volatile 4-pentenal (**6**) (12, 13) in 55% yield. Treatment of **6** with malonic acid in pyridine and pyrrolidine at 20°C overnight followed by refluxing for 5 h gives a 70–80% yield of (*E*)-2,6-heptadienoic acid (**7**) (13), contaminated by some of the *Z* isomer as shown by ^{13}C nmr. The mixture of (*E*) and (*Z*)-**7** was treated with thionyl chloride to give pure (*E*)-2,6-heptadienoyl chloride (**8**) in high yield with concomitant conversion of the minor (*Z*)-**7** isomer to the (*E*)-**7** isomer (14). Compound **8** was converted to the desired **4** by treatment with *l*-ephedrine in the presence of proton sponge (10). To test the usefulness of 1,4-addition reactions to adduct **4**, *p*-methoxyphenylmagnesium bromide in tetrahydrofuran (THF) was caused to react with **4** at 0°C for 24 h to give *N*-(3-*p*-methoxyphenyl-6-heptenoyl)-*l*-ephedrine (**9**) in 59% yield. Similarly, treatment of **4** with isopropenylmagnesium bromide in ether/THF mixtures at 0°C for 48 h gave *N*-(3-isopropenyl-6-heptenoyl)-*l*-ephedrine (**10**) in 51–69% yield. Compounds **9** and **10** were cleaved by base hydrolysis with a 10% potassium hydroxide in ethanol/water mixture to give optically active 3-*p*-methoxyphenyl-6-heptenoic acid (**11**) and 3-isopropenyl-6-heptenoic acid (**12**) in 49–57% and 63–80% yield, respectively. Hydrogenation of **12** gave the known compound (*R*)-3-isopropylheptanoic acid (**13**) (15), thus confirming the absolute configuration of **12** to be *R*, as desired. The absolute configuration of **11** has not been determined in this study, but it is considered likely that it is also *R*, since it possesses a negative optical rotation as has been reported (15) for a structurally related series of (*R*)-3-*o*-methoxyphenylalkanoic acids.



SCHEME 2

Determination of the enantiomeric excess of **12** by hydrogenation to **13** and comparison of the optical rotation with that reported in the literature was not reliable, because of some racemization occurring during the hydrogenation. Attempts to evaluate the enantiomeric excess in which acids **11** and **12** were formed, by hplc separation of the respective diastereomers of amides **9** and **10**, were not successful. Consequently, the method of Bergot *et al.* (16) was adopted. Acids **11** and **12** were converted to their acid chlorides and treated with (*R*)-(+)-1-(1-naphthyl)ethylamine (**14**) to give *N*-[(*R*)-1-(1-naphthyl)-ethyl]-3-*p*-methoxyphenyl-6-heptenamide (**15**) and (*R*)-*N*-[(*R*)-1-(1-naphthyl)ethyl]-3-isopropenyl-6-heptenamide (**16**). The chiral amides **15** and **16** were analysed by hplc (2, 16, 17) and the results indicated that the asymmetric 1,4-addition to **4** gave **9** and **10** having up to 86% ee (Table 1). In order to obtain this extent of asymmetric induction it was necessary to employ, in the 1,4-addition step, a high proportion of ether to THF. However, the use of pure ether was precluded by the instability of isopropenylmagnesium bromide in the absence of THF (18). It was found that the sluggish formation of this Grignard reagent at low THF concentrations could be ameliorated by ultrasonic irradiation (19). Compound **10** can be cleaved (20) with diisobutylaluminium hydride (DIBAL) at 0°C to **3**, albeit in low yield, and hence **3** has now been prepared via asymmetric synthesis.

Simple amides of *l*-ephedrine were cleaved under strong acid conditions (10). Acid hydrolysis of **10** did not give the free acid **12** but rather 3-(3-buten-1-yl)-4,4-dimethylbutyrolactone (**17**) in 75% yield. Compound **17** was optically active but its ee has not yet been determined. The mechanism of formation of **17** from **10** has not been explored but is likely to follow a pathway outlined in Scheme 2.

Although we had succeeded in preparing the key chiral pheromone intermediate **3** by an asymmetric synthesis route, several difficulties were still apparent. Firstly, the ee of **3**, although high, was not as high as **3** prepared via a natural product precursor such as (*S*)-(+)-carvone. Secondly, the direct cleavage of the amide **10** to **3** proceeded in low yield and hence **3** would have to be made via acid **12** which would most likely involve two more steps. Thirdly, the ephedrine route seemed less adaptable to solid phase methods than other possible routes and hence further approaches to the asymmetric synthesis of **3** were sought.

The aldimine route

The 1,4-addition of Grignard reagents to chiral α,β-unsaturated aldimines prepared from α,β-unsaturated aldehydes and chiral *tert*-butyl 2-amino-3,3-dimethylbutyrate (**26**) has been demonstrated (21) to give chiral β-substituted aldehydes in greater than 95% ee. Since the key intermediate (**3**) in the synthesis of **1** is a β-substituted aldehyde, we decided to attempt this method for the preparation of **3**. The original

TABLE 1. Results from asymmetric 1,4-addition reactions and subsequent cleavage

Entry	Substrate	Nucleophile (equivalents)	Solvent	Conditions (temp. (°C)/time (h))	Product after cleavage	Overall yield (%)	Optical rotation ($[\alpha]_D$ (c))[a]	Enantiomeric excess (%)

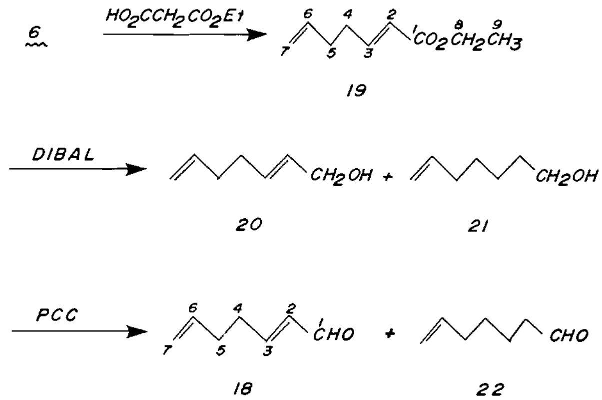
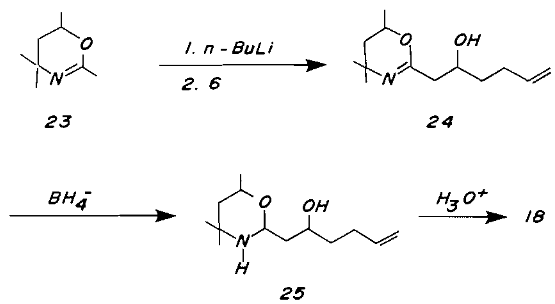
[a]Optical rotations measured at 21 ± 2°C using $CHCl_3$ as solvent.
[b]Enantiomeric excess determined indirectly by comparison of optical rotation with that of sample of known ee, as determined by hplc separation of diastereomeric amides.



SCHEME 3



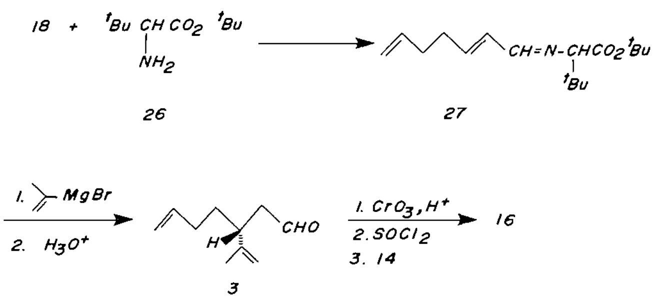
SCHEME 4

publication of this method was restricted to rather simple α,β-unsaturated aldimines, but we considered that this aldimine route would be successful even for more complicated substrates such as (E)-2,6-heptadienal (**18**) (Scheme 3).

Treatment of **6** with ethyl malonate (half-ester) in a pyridine/pyrrolidine mixture yielded ethyl 2,6-heptadienoate (**19**) in 79% yield. Reduction of **19** with two equivalents of diisobutylaluminium hydride at −25°C gave a 4:1 mixture of 2,6-heptadien-1-ol (**20**) and 6-hepten-1-ol (**21**) in 82% yield. Oxidation of this mixture by PCC yielded a mixture of 2,6-heptadienal (**18**) and 6-heptenal (**22**) as shown in Scheme 3. Compound **22** was removed from this mixture by washing with aqueous sodium bisulphite, giving pure **18** in 39% yield from **19**.

During the course of this work, Bestmann *et al.* (22) described the synthesis of **18** in 25% yield by the direct reaction of **6** with a stabilized ylide and indeed our own early synthesis by this route also gave **18** in 20% yield. The preparation of **18** according to Scheme 3 was unsatisfactory as a result of poor overall yields, contamination with **22**, and, in addition, the fact that **18** was obtained as a mixture of E and Z isomers. Many procedures described in the literature exist for the synthesis of α,β-unsaturated aldehydes from a simple aldehyde, but attempts to prepare **18** by various methods (23–25) were either unsuccessful or gave impure **18** in low yield. Finally, treatment of **6** with 2,4,4,6-tetramethyl-5,6-dihydro-1,3-oxazine (**23**) according to the procedure of Meyers *et al.* (26) gave the alcohol adduct (**24**). Reduction of **24** with sodium borohydride gave the tetrahydro-1,3-oxazine (**25**), which on mild acid hydrolysis gave **18** in 37% overall yield (Scheme 4).

Treatment of the α,β-unsaturated aldehyde **18** with racemic *tert*-butyl 2-amino-3,3-dimethylbutyrate (**26**) or (S)-(+)-**26** at 0°C in benzene overnight gave the crude α,β-unsaturated aldimine **27**. Addition of isopropenylmagnesium bromide in ether/THF (5:1) at −60°C gave, upon mild acid work-up, a



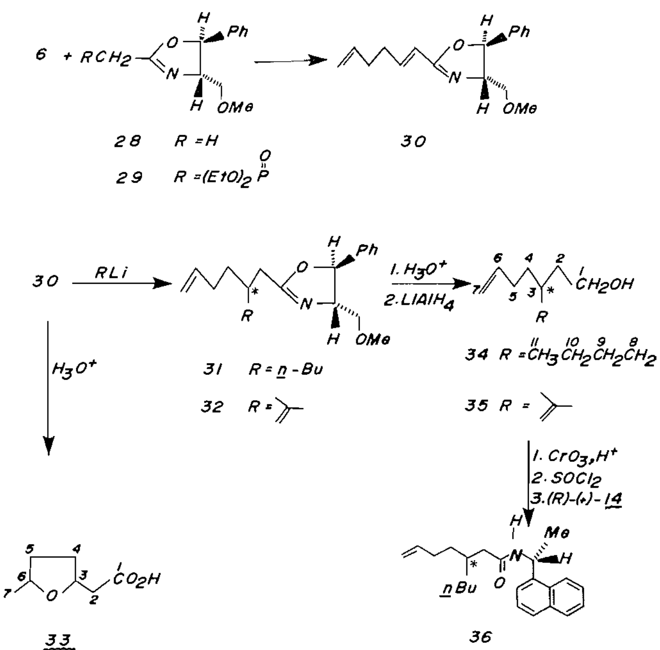
SCHEME 5

racemic mixture of **3** with its enantiomer or optically active **3** in a 43–50% yield. The enantiomeric purity of **3** was determined in a similar manner (2) to that described above for **12**. Thus oxidation of **3** gave **12**, which was converted to its acid chloride and treated with **14** to give **16**. The hplc analysis (2, 16, 17) of **16**, prepared from a racemic mixture of **3** and its enantiomer, resulted in complete resolution of the two equally abundant diastereomers, while **16** prepared from optically active **3** showed only one diastereomer and no trace of the other isomer. Furthermore, **16**, prepared from optically active **3** and (*S*)-(−)-1-(1-naphthyl)ethylamine (the enantiomer of **14**), showed only the other diastereomer by hplc analysis. The absolute configuration of pure **3** was determined to be *R*, by comparison of the hplc retention times of these diastereomeric amides (**16**) with those of **16** prepared from **12** in the ephedrine route described above. Thus, the asymmetric synthesis of **3** has been achieved in >99% ee ((*R*)-configuration), which is as high or higher than that derived from a natural product. In addition, the aldimine route lends itself particularly to development using solid-phase techniques, which would ensure ready recovery of the chiral auxiliary. The one limitation is the rather modest yield in the key coupling step. For this reason we examined even a third method for asymmetric 1,4-addition reactions.

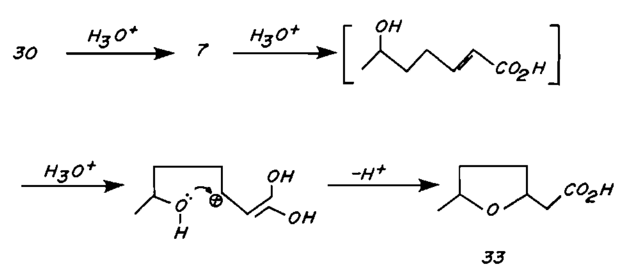
The oxazoline route

It has been reported that nucleophilic additon of organolithium reagents to chiral α,β-unsaturated oxazolines can lead to chiral β-substituted alkanoic acids having >90% ee (15). This strategy can be readily adapted to the synthesis of the key intermediate **3** as shown in Scheme 6. Treatment of **6** with (4*S*,5*S*)-(−)-4-methoxymethyl-2-methyl-5-phenyl-2-oxazoline (**28**) (15) or (4*S*,5*S*)-(−)-2-(diethylphosphonomethyl)-4-methoxymethyl-5-phenyl-2-oxazoline (**29**) (27) by reported methods gave (4*S*,5*S*)-(+)-2-[1-(*E*-1,5-hexadienyl)]-4-methoxymethyl-5-phenyl-2-oxazoline (**30**) in 26 and 84% yield, respectively. Since the 2-substituted oxazoline **30**, containing two olefinic groups, was more elaborate than the simpler oxazolines previously described, we wished to test the reactivity of **30** with a simple alkyllithium as well as the desired isopropenyllithium. The reaction of oxazoline **30** was thus carried out with either *n*-butyllithium or isopropenyllithium in THF at −78°C to give either (4*S*,5*S*)-2-[1-(3-*n*-butyl-5-hexenyl)]-4-methoxymethyl-5-phenyl-2-oxazoline (**31**) or (4*S*,5*S*)-2-[1-(3-isopropenyl-5-hexenyl)]-4-methoxymethyl-5-phenyl-2-oxazoline (**32**) in 90% and 63% yields, respectively.

The normal strong acid hydrolysis (15) of **31** gave a complex mixture of products, from which the desired 3-*n*-butyl-6-heptenoic acid could not be separated. Consequently the similar hydrolysis of **32** was not attempted. However, this result did lead us to examine the hydrolysis of the precursor α,β-



SCHEME 6



SCHEME 7

unsaturated oxazoline **30**, which we found gave 2-(5-methyltetrahydrofuranyl)acetic acid (**33**) in 62% yield, as did the strong acid treatment of **7**. Although the order and details of the mechanism of the hydrolysis of **30** have not been examined, a likely course of reaction, involving hydrolysis of the oxazoline with concomitant hydration of the terminal olefin, is outlined (Scheme 7). It is probable that hydration of the terminal olefin is also responsible for the mixture of products obtained from the hydrolysis of **31**.

The two-step procedure for the cleavage of oxazolines involving mild acid hydrolysis, followed by reduction with lithium aluminium hydride (28) of **31**, did give predominantly one enantiomer of 3-*n*-butyl-6-hepten-1-ol (**34**) in 44% yield, but an identical cleavage of **32** gave a complex mixture of products from which the desired 3-isopropenyl-6-hepten-1-ol (**35**) could not be isolated. Oxidation of **34** gave 3-*n*-butyl-6-heptenoic acid, which was converted to its acid chloride and treated with **14** to give *N*-[(*R*)-1-(1-naphthyl)ethyl]-3-*n*-butyl-6-heptenamide (**36**). Analysis of this diastereomeric amide by hplc, as described above for **15** and **16**, indicated that **34** had been formed in 96% ee. However, no attempts were made in this study to determine the absolute configuration of the enantiomer, **34**, that was formed.

Although the 1,4-addition of isopropenyllithium to the α,β-unsaturated oxazoline **30** proceeded well to give **32**, sufficiently mild methods of cleavage of **32** to give **3**, **12**, or **35** were not found. Various methods reported to cleave oxazolines

[a]The numbering of the carbon atoms in the above compounds follows that given for these structures in Schemes 1, 2, 3, and 6 and does not necessarily follow from the names of these compounds. All spectra were recorded, using $CDCl_3$ as solvent, at 300 MHz except for compounds **7** and **18**, whose spectra were recorded at 400 MHz. Inversion–recovery (*J*-modulated spin-echo) spectra were recorded for **11**–**13**, **33**, and **34** (p indicates a positive signal due to C or CH_2, n indicates a negative signal due to CH or CH_3).
[b]These assignments may be interchanged.
[c]These assignments may be interchanged.
[d]Minor signals due to *Z*-isomer are not reported.
[e]*Cis* and *trans* isomers give rise to a duplication of signals.

under mild conditions (29–31) were attempted using **31** as a model. However, either no reaction or low yields of cleavage products were observed. A new procedure for the cleavage of oxazolines has not been attempted (32).

In summary, we have shown that a chiral pheromone intermediate can be prepared in a satisfactory yield having an extremely high ee (Table 1) by asymmetric synthesis, which demonstrates that asymmetric synthesis can compete effectively with the synthesis of chiral molecules from natural products, or through resolution of racemates. The elaboration of the key intermediate **3**, by reaction with a ylide, to the red scale pheromone component **1** has not been attempted in this study, since a procedure for this transformation has been previously reported (2). Although this method lacked stereoselectivity, resulting in a 1:1 mixture of (*E*)- and (*Z*)-**1**, the problem has been overcome by Heath *et al.* (17) in the synthesis of (3*Z*,6*R*)-3,9-dimethyl-6-isopropenyl-3,9-decadien-1-yl propionate (the white peach scale pheromone) from a similar chiral synthon, (*R*)-6-methyl-3-isopropenyl-6-heptenal.

Experimental

Linde argon was used to maintain inert atmosphere conditions. Solvents required for reactions were dried and distilled before use. All reaction mixtures were stirred with a magnetic stirrer. Grignard reagents were prepared by slow addition of alkenyl or aryl bromide to activated magnesium turnings in an appropriate solvent, and sonication (19) of the reaction flask and contents in a 125-W Branson B220 ultrasonic bath filled with distilled water at 20°C. Most distillations were conducted using a Kugelrohr apparatus (bulb-to-bulb) and, for these, the temperature range of the heater at which the main fraction was collected is reported. Flash chromatography (33) was carried out using 20–45 μm silica gel as supplied by Terochem Laboratories Ltd., Toronto, Ont. High-performance liquid chromatography was conducted on a Spectra Physics SP8000 fitted with an analytical column (6.3 mm × 25 cm) of 10-μm Spherisorb silica gel and a mobile phase of 5–12.5% ethyl acetate in hexane (water saturated) with uv detection (254 nm). Melting points (mp) were determined using a Kofler hot stage melting point apparatus and are uncorrected. Optical rotations were determined using a Perkin–Elmer 141 polarimeter at 21 ± 2°C. Infrared spectra (ir) were recorded on a Pye Unicam SP1000 infrared spectrophotometer as neat films between NaCl discs unless specified otherwise. Nuclear magnetic resonance spectra for protons (^1H nmr) were recorded on a Varian EM360 (60 MHz), Bruker AM300 (300 MHz), or Bruker WH400 (400 MHz) spectrometer and are expressed in ppm (δ values) relative to tetramethylsilane as internal reference in deuteriochloroform. (The splittings of the signals are described as singlets (s), broad singlets (bs), doublets (d), triplets (t), quartets (q), doublet of doublets (dd), doublet of triplets (dt), or multiplets (m).) The ^{13}C nmr spectra were recorded in $CDCl_3$ on a Bruker AM300 (300 MHz) or a Bruker WH400 (400 MHz) and have been assigned using standard correlations (34) (Table 2). Mass spectra (ms) were recorded at 70 eV on a VG Micromass 16F mass spectrometer. Microanalyses were performed by Guelph Chemical Laboratories Ltd., Guelph, Ont., Dr. C. Daessele, Montreal, P.Q., or Canadian Microanalytical Service Ltd., Vancouver, B.C.

4-Pentenal (6)

Following the method of Corey and Suggs (11) 4-penten-1-ol (**5**) (8.51 g, 99 mmol) was oxidized by pyridinium chlorochromate (PCC) (38.4 g, 178 mmol) in methylene chloride (185 mL). Distillation and careful fractionation gave the volatile **6** (4.57 g, 55% yield); bp 102–104°C (lit. (35) bp 103–104°C); liquid; ir ν: 1735 (C=O) cm^{-1}; ^1H nmr (60 MHz) δ: 9.75 (t, 1H, *J* = 2 Hz, C*H*O), 6.30–5.50 (m, 1H, =C*H*—), 5.30–4.80 (m, 2H, CH_2=), 2.80–2.00 (m, 4H, CH_2CH_2). 2,4-Dinitrophenylhydrazone derivative; mp 119–120°C (lit. (34) mp 120°C).

2,6-Heptadienoic acid (7)

A mixture of **6** (4.38 g, 52 mmol), malonic acid (6.51 g, 63 mmol), pyridine (10 mL), and pyrrolidine (2 mL) was stirred overnight under argon and subsequently heated at 90°C for 5 h. The reaction mixture was cooled, acidified with 2 *N* hydrochloric acid, and extracted with ether. The combined organic extracts were washed with water and saturated brine, then dried over magnesium sulphate ($MgSO_4$) and concentrated. The residue was distilled (bulb-to-bulb, 1.0 Torr (1 Torr = 133.3 Pa), 74–84°C) to give **7** (5.16 g, 79% yield); liquid; ir ν: 3000 (O—H), 1710 (C=O) cm^{-1}; ^1H nmr (60 MHz) δ: 12.45 (s, 1H, disappears in D_2O, O*H*), 7.45–6.85 (m, 1H, C*H*=$CHCO_2H$), 6.15–5.50 (m, 2H, CH_2=C*H* and C*H*CO_2H), 5.25–4.85 (m, 2H, CH_2=CH), 2.55–2.15 (m, 4H, CH_2CH_2). *Anal.* calcd. for $C_7H_{10}O_2$: C 66.65, H 7.99; found: C 66.66, H 8.26.

(E)-2,6-Heptadienoyl chloride (8)

Freshly distilled thionyl chloride (7 mL) was added dropwise to **7**

(1.443 g, 11.5 mmol) at 0°C with stirring. The mixture was allowed to warm to ambient temperature, and after 1 h it was heated to reflux for 0.5 h before removing excess thionyl chloride by distillation. Distillation (bulb-to-bulb, 0.075 Torr, 60–70°C) of the residue gave **8** (1.570 g, 94% yield); liquid; ir ν: 1765 (C═O) cm^{-1}; ^{1}H nmr (60 MHz) δ: 7.60–7.05 (m, 1H, *CH*═CHCOCl), 6.30–5.50 (m, 2H, CH$_2$═*CH* and *CH*COCl), 5.30–4.85 (m, 2H, *CH$_2$*═CH), 2.60–2.20 (m, 4H, *CH$_2$CH$_2$*).

N-(E-*2,6-Heptadienoyl*)-l-*ephedrine* (*4*)

Compound **8** (1.494 g, 10.3 mmol) was added in one portion to a stirred mixture of proton sponge (2.20 g, 10.3 mmol) and *l*-ephedrine (1.697 g, 10.3 mmol) in THF (25 mL) at 0°C under argon. The mixture was allowed to warm up to room temperature and then stirred overnight. Cold 1 *N* hydrochloric acid (20 mL) was added and the product extracted with ethyl acetate, dried (MgSO$_4$), and concentrated. Flash chromatography (40% ethyl acetate/hexane) of the residue gave **4** (2.456 g, 88% yield); viscous oil; $[\alpha]_D$ −129.91° (*c* 2.62, CHCl$_3$); ir ν: 3390 (O—H), 1610 (C═O) cm^{-1}; ^{1}H nmr (400 MHz) δ: 7.32–7.16 (m, 5H, C$_6$*H*$_5$), 6.76 (dt, 0.7H, *J* = 15 Hz, *CH*═CHCON of *E*-amide[2]), 6.37 (dt, 0.3H, *J* = 15 Hz, *CH*═CHCON of *Z*-amide[2]), 6.10 (d, 0.7H, *J* = 15 Hz, C*H*CON of *E*-amide), 5.84 (d, 0.3H, *J* = 15 Hz, C*H*CON of *Z*-amide), 5.80–5.60 (m, 1H, CH$_2$═C*H*), 5.04–4.86 (m, 2H, C*H$_2$*═CH), 4.76 (d, 1H, *J* = 3 Hz, C*H*OH), 4.52–4.49 (m, 0.7H, NC*H*CH$_3$ of *E*-amide), 4.05–3.99 (m, 0.3H, NC*H*CH$_3$ of *Z*-amide), 2.77 (s, 0.7H, NC*H$_3$* of *E*-amide), 2.74 (s, 0.7H, NC*H$_3$* of *Z*-amide), 2.26–2.12 (m, 4H, C*H$_2$*C*H$_2$*), 2.06 (bs, 1H, O*H*), 1.27 (d, 0.3H, *J* = 7 Hz, NCHC*H$_3$* of *Z*-amide), 1.10 (d, 0.7H, *J* = 7 Hz, NCHC*H$_3$* of *E*-amide); ms *m/z*: 274 (M$^+$ + 1, 0.3), 255 (3), 166 (81), 109 (53), 81 (35), 79 (17), 58 (100), 55 (16). *Anal.* calcd. for C$_{17}$H$_{23}$NO$_2$: C 74.69, H 8.48, N 5.12; found: C 74.32, H 8.39, N 5.08.

N-(*3*-p-*Methoxyphenyl-6-heptenoyl*)-l-*ephedrine* (*9*)

To a stirred solution of the Grignard reagent, prepared from *p*-methoxyphenyl bromide (2.75 mL, 22 mmol) and magnesium (0.53 g, 22 mmol) in THF (20 mL), was added dropwise a solution of **4** (0.990 g, 3.6 mmol) in THF (5 mL) at 0°C under argon. After 14 h at 0°C a phosphate buffer solution (pH 7, 20 mL) was added and the resulting mixture filtered through Celite. The product was extracted into ethyl acetate, dried (MgSO$_4$), and concentrated. Flash chromatography (40% ethyl acetate/hexane) of the residue gave **9** (0.812 g, 59% yield); viscous oil; ir ν: 3400 (O—H), 1625 (C═O) cm^{-1}; ^{1}H nmr (300 MHz) δ: 7.33–7.22 (m, 5H, C$_6$*H$_5$*), 7.01 (AA′XX′, 4H, CH$_3$OC$_6$*H$_4$*), 5.84–5.68 (m, 1H, CH$_2$═C*H*), 4.95–4.89 (m, 2H, C*H$_2$*═CH), 4.70 (d, 1H, *J* = 3 Hz, C*H*OH), 4.42–4.29 (m, 1H, NC*H*CH$_3$), 3.75 (s, 3H, C*H$_3$*O), 3.19–3.07 (m, 1H, CH$_3$OC$_6$H$_4$C*H*), 2.90–2.74 (m, 2H, C*H$_2$*CON), 2.54 (s, 3H, NC*H$_3$*), 2.49–2.44 (bs, 1H, O*H*), 1.89–1.56 (m, 4H, C*H$_2$*C*H$_2$*), 1.06 (d, 3H, *J* = 7 Hz, CHC*H$_3$*); ms *m/z*: 382 (M$^+$ +1, 3), 275 (32), 274 (86), 175 (65), 134 (35), 121 (100), 79 (29), 58 (99). *Anal.* calcd. for C$_{24}$H$_{31}$NO$_3$: C 75.56, H 8.19, N 3.67; found: C 75.54, H 8.19, N 3.70.

N-(*3-Isopropenyl-6-heptenoyl*)-l-*ephedrine* (*10*)

In a manner similar to that described above for **9**, **4** was converted, under the conditions listed in Table 1, to **10** (51–69% yield); viscous oil; ir ν: 3480 (O—H), 1660 (C═O) cm^{-1}; ^{1}H nmr (300 MHz) δ: 7.35–7.22 (m, 5H, C$_6$*H$_5$*), 5.83–5.73 (m, 1H, CH$_2$═C*H*), 5.01–4.70 (m, 4H, C*H$_2$*═CH and C*H$_2$*═C), 4.61–4.42 (m, 1H, NC*H*CH$_3$), 4.36 (d, 1H, *J* = 3 Hz, C*H*OH), 2.70 (s and smaller s due to *E*- and *Z*-amide isomers, 3H, NC*H$_3$*), 2.64–2.55 (m, 1H, C*H*CH$_2$CON), 2.40–2.19 (m, 2H, C*H$_2$*CON), 2.16–1.76 (m, 2H, CH$_2$═CHC*H$_2$*), 1.66 (s and smaller s due to *E*- and *Z*-amide isomers, 3H, C*H$_3$*(CH$_2$═)C), 1.55–1.29 (m, 3H, CH$_2$═CHCH$_2$C*H$_2$* and O*H*), 1.16 (d, 3H, *J* = 7 Hz, CHC*H$_3$*); ms *m/z*: 316 (M$^+$ + 1, 0.8), 3.15 (M$^+$, 0.6), 209 (23), 208 (92), 109 (22), 81 (20), 67 (23), 58 (100), 55 (23). *Anal.* calcd. for C$_{20}$H$_{29}$NO$_2$: C 76.15, H 9.27, N 4.44; found: C 76.33, H 9.37, N 4.54.

3-p-*Methoxyphenyl-6-heptenoic acid* (*11*)

A solution of **9** (0.2401 g, 0.63 mmol) in 10% NaOH (20 mL, 1 : 1 EtOH/H$_2$O) was heated at reflux for 78 h. After cooling, the mixture was acidified with 2 *N* HCl, and the product extracted into ether, dried (MgSO$_4$), and concentrated. Distillation (bulb-to-bulb, 0.05 Torr, 120–130°C) gave **11** (0.0619 g, 42% yield); liquid; $[\alpha]_D$ −11.32° (*c* 3.28, CHCl$_3$); ir ν: 3200 (O—H), 1720 (C═O) cm^{-1}; ^{1}H nmr (300 MHz) δ: 10.10 (bs, 1H, O*H*), 6.96 (AA′XX′, 4H, CH$_3$OC$_6$*H$_4$*), 5.85–5.68 (m, 1H, CH$_2$═C*H*), 4.97–4.90 (m, 2H, C*H$_2$*═CH), 3.78 (s, 3H, C*H$_3$*O), 3.10–3.01 (m, 1H, C*H*CH$_2$CO$_2$H), 2.60 (t, 2H, *J* = 7 Hz, C*H$_2$*CO$_2$H), 1.95–1.60 (m, 4H, C*H$_2$*C*H$_2$*); ms *m/z*: 234 (M$^+$, 48), 192 (49), 179 (93), 175 (89), 137 (99), 134 (26), 121 (100), 91 (20). *Anal.* calcd. for C$_{14}$H$_{18}$O$_3$: C 71.77, H 7.74; found: C 71.72, H 7.99.

(R)-*3-Isopropenyl-6-heptenoic acid* (*12*)

In a manner similar to that described above for **11**, **10** was converted to **12** (distilled bulb-to-bulb, 0.05 Torr, 95–105°C, 63–80% yield); liquid; $[\alpha]_D$ see Table 1; ir ν: 3150 (O—H), 1730 (C═O) cm^{-1}; ^{1}H nmr (300 MHz) δ: 10.60 (bs, 1H, O*H*), 5.89–5.72 (m, 1H, CH$_2$═C*H*), 5.04–4.78 (m, 4H, C*H$_2$*═CH and C*H$_2$*═C), 2.69–2.57 (m, 1H, C*H*CH$_2$CO$_2$H), 2.41 (d, 2H, *J* = 7.5 Hz, C*H$_2$*CO$_2$H), 2.10–1.93 (m, 2H, CH$_2$═CHC*H$_2$*), 1.67 (s, 3H, C*H$_3$*), 1.52–1.45 (m, 2H, CH$_2$═CHCH$_2$C*H$_2$*); ms *m/z*: 168 (M$^+$, 4), 108 (63), 93 (38), 81 (52), 69 (100), 67 (46), 55 (67), 43 (50), 41 (90). *Anal.* calcd. for C$_{10}$H$_{16}$O$_2$: C 71.39, H 9.59; found: C 71.20, H 9.99.

(R)-*3-Isopropylheptanoic acid* (*13*)

Hydrogen was passed over a stirred mixture of **12** (0.0682 g, 0.41 mmol; $[\alpha]_D$ −3.13 (*c* 2.05, CHCl$_3$)) and 10% palladium on charcoal (0.0212 g) in ethanol (15 mL) for 16 h at room temperature. The solution was filtered, the solvent removed, and the resulting oil distilled (bulb-to-bulb, 0.1 Torr, 100–110°C) to give **13** (0.0677 g, 97% yield); liquid; $[\alpha]_D$ −0.45° (*c* 2.23, CHCl$_3$) (lit. (15) $[\alpha]_D$ −0.82° (neat)); ir ν: 3050 (O—H), 1720 (C═O) cm^{-1}; ^{1}H nmr (300 MHz) δ: 10.52 (bs, 1H, O*H*), 2.37–2.14 (m, 2H, C*H$_2$*CO$_2$H), 1.84–1.72 (m, 2H, (CH$_3$)$_2$C*H*C*H*), 1.41–1.18 (m, 6H, CH$_3$C*H$_2$*C*H$_2$*C*H$_2$*), 0.98–0.84 (m, 9H, C*H$_3$*CH$_2$ and (C*H$_3$*)$_2$CH); ms *m/z*: 173 (M$^+$ + 1, 2), 129 (42), 113 (78), 112 (69), 72 (56), 70 (71), 69 (100), 60 (40), 57 (99), 56 (54), 55 (64), 43 (68), 41 (76). *Anal.* calcd. for C$_{10}$H$_{20}$O$_2$: C 69.72, H 11.70; found: C 69.66, H 11.85.

N-[(R)-*1-(Naphthyl)ethyl*]-*3*-p-*methoxyphenyl-6-heptenamide* (*15*)

To a solution of **11** (0.0677 g, 0.29 mmol; $[\alpha]_D$ −16.90 (*c* 5.38), CHCl$_3$)) in ether (3 mL) containing a catalytic amount of *N,N*-dimethylformamide (5 μL) was added thionyl chloride (63 μL, 0.87 mmol). After stirring for 4 h at room temperature, the mixture was concentrated to remove excess thionyl chloride. Ether (5 mL) was added and the resulting solution cooled to 0°C, whereupon a solution of **14** (0.0744 g, 0.44 mmol) and proton sponge (0.0932 g, 0.44 mmol) in ether (5 mL) was added dropwise. A precipitate formed, and the reaction mixture was allowed to warm to room temperature and was stirred overnight. Ice-cold 1 *N* hydrochloric acid (15 mL) was added and the product extracted into ether, washed with brine, dried (MgSO$_4$), and concentrated to give crude **15** (0.1093 g, 98% yield). Crude **15** was analysed by hplc directly, to avoid fractionation. Separation of the two diastereomers was obtained in 0.8 h by using 10% ethyl acetate in hexane at 1.0 mL/min. The predominant diastereomer, the second to elute, was collected by hplc; ir ν: 3300 (N—H), 1650 (C═O) cm^{-1}; ^{1}H nmr (300 MHz) δ: 7.94–7.10 (m, 7H, C$_{10}$*H$_7$*), 6.84 (AA′XX′, 4H, CH$_3$OC$_6$*H$_4$*), 5.85–5.65 (m, 2H, C*H*NH and CH$_2$═C*H*), 5.41 (s, 1H, N*H*), 5.96–5.89 (m, 2H, C*H$_2$*═CH), 3.75 (s, 3H, C*H$_3$*O), 3.14–3.00 (m, 1H, C*H*CH$_2$CO$_2$H), 2.24–2.14 (m, 2H, C*H$_2$*CON), 1.84–1.60 (m, 4H, C*H$_2$*C*H$_2$*), 1.54 (d, 3H, C*H$_3$*CH).

(R)-N-[(R)-*1-(1-Naphthyl)ethyl*]-*3-isopropenyl-6-heptenamide* (*16*) *via route shown in Scheme 1*

In a manner similar to that described above for **15**, **12** was converted

[2] The *E*- and *Z*-amide isomers are distinguishable on the nmr time scale (36).

to **16** (78% crude yield) and analysed directly by hplc. Separation of the two diastereomers was achieved in 0.25 h using 12.5% ethyl acetate in hexane at 1.5 mL/min. The (*R,S*)-diastereomer (11 min) eluted prior to the predominant (*R,R*)-diastereomer (13 min); the identity of these diastereomers was confirmed as described below for the aldimine route. A sample of **16** was purified by flash chromatography (25% ethyl acetate/hexane); ir ν: 3320 (N—H), 1650 (C=O) cm^{-1}; ^{1}H nmr (300 MHz) δ: 8.12–7.40 (m, 7H, $C_{10}H_7$), 6.02–5.87 (m, 2H, N*H* and C*H*NH), 5.82–5.75 (m, 1H, CH_2=C*H*), 5.11–4.72 (m, 4H, CH_2=CH and CH_2=C), 2.68–2.55 (m, 1H, C*H*CH_2CON), 2.26–2.15 (m, 2H, CH_2CON), 2.07–1.88 (m, 2H, CH_2=CHCH_2), 1.61 (s and d, 6H, CH_3=C and CH_3CH), 1.50–1.33 (m, 2H, CH_2=CHCH_2CH_2).

(R)-3-Isopropenyl-6-heptenal (3) via route shown in Scheme 1

DIBAL (5.2 mL of a 1 *M* solution in hexane, 5.2 mmol) was added dropwise over 1.5 h to a stirred solution of **10** (0.544 g, 1.7 mmol) (Entry 5 in Table 1) in THF (10 mL) at 0°C under argon. After 0.5 h the mixture was quenched by the addition of ice-cold 10% sulphuric acid (30 mL), and then stirred for 1 h. The product was extracted with ether, washed with saturated NaCl, dried ($MgSO_4$), and concentrated. The residue was distilled (bulb-to-bulb, 0.05 Torr, 55–65°C) to give **3** (0.055 g, 21% yield); liquid; $[\alpha]_D$ −0.42° (*c* 2.53, $CHCl_3$); ir ν: 1735 (C=O), 1650 (C=C) cm^{-1}; ^{1}H nmr (300 MHz) δ: 9.66 (t, 1H, *J* = 2 Hz, C*H*O), 5.87–5.72 (m, 1H, CH_2=C*H*), 5.04–4.78 (m, 4H, CH_2=CH and CH_2=C), 2.78–2.67 (m, 1H, C*H*CH_2CO_2H), 2.49–2.42 (m, 2H, CH_2CO_2H), 2.07–1.93 (m, 2H, CH_2=CHCH_2), 1.66 (d, 3H, *J* = 0.9 Hz, CH_3), 1.56–1.42 (m, 2H, CH_2=CHCH_2CH_2); ms *m/z*: 152 (M^+, 0.2), 123 (12), 108 (11), 95 (26), 81 (24), 69 (100), 67 (29), 55 (21), 41 (16). 2,4-Dinitrophenylhydrazone derivative; mp 81–83°C. *Anal.* calcd. for $C_{16}H_{20}N_4O_4$: C 57.82, H 6.07, N 16.86; found: C 57.93, H 6.24, N 16.73.

(R)-3-(3-Buten-1-yl)-4,4-dimethylbutyrolactone (17)

Compound **10** (0.1239 g, 0.39 mmol) (Entry 3 in Table 1) was dissolved in ethanolic hydrochloric acid (5 mL of a solution prepared by the addition of 35% hydrochloric acid (4 mL) and ethanol (50 mL)) and the resulting mixture was refluxed overnight. After cooling, water (10 mL) was added and the product extracted with ether. The combined organic extracts were washed with saturated brine, dried ($MgSO_4$), and concentrated. The residue was distilled (bulb-to-bulb, 0.35 Torr, 110–120°C) to give **17** (0.0496 g, 75% yield); liquid; $[\alpha]_D$ −24.85° (*c* 0.780, $CHCl_3$); ir ν: 1780 (C=O) cm^{-1}; ^{1}H nmr (300 MHz) δ: 5.86–5.70 (m, 1H, CH_2=C*H*), 5.12–5.01 (m, 2H, CH_2=CH), 2.72–2.59 (m, 1H, C*H*CH_2CO_2), 2.37–1.95 (m, 4H, CH_2CO_2 and CH_2=CHCH_2), 1.67–1.53 (m, 2H, CH_2=CHCH_2-CH_2), 1.45 (s, 3H, CH_3), 1.26 (s, 3H, CH_3); ms *m/z*: 168 (M^+, 14), 153 (100), 135 (45), 110 (35), 82 (35), 67 (65), 59 (44), 41 (62). *Anal.* calcd. for $C_{10}H_{16}O_2$: C 71.39, H 9.59; found: C 71.20, H 9.59.

Ethyl 2,6-heptadienoate (19)

Following a similar procedure to that described for the preparation of **7**, the monoethyl ester of malonic acid (37) (13.2 g, 100 mmol) was reacted with **6** (6.5 g, 77 mmol) in a mixture of pyridine (8 mL) and pyrrolidine (1.5 mL). Distillation (bulb-to-bulb, 0.05 Torr, 50–55°C) gave **19** (9.42 g, 79% yield); liquid; ir ν: 1735 (C=O) cm^{-1}; ^{1}H nmr (60 MHz) δ: 7.50–6.80 (m, 1H, C*H*=$CHCO_2$), 6.10–5.50 (m, 2H, C*H*CO_2 and CH_2=C*H*), 5.30–4.80 (m, 2H, CH_2=CH), 4.18 (q, 2H, *J* = 7 Hz, CH_2CH_3), 2.55–2.15 (m, 4H, CH_2CH_2), 1.24 (t, 3H, *J* = 7 Hz, CH_3); ms *m/z*: 154 (M^+, 1), 109 (44), 81 (100), 80 (42), 79 (28), 55 (25), 41 (59), 39 (34). *Anal.* calcd. for $C_9H_{14}O_2$: C 70.10, H 9.15; found: C 69.64, H 9.50.

2,6-Heptadienal (18) via route shown in Scheme 3

To a stirred solution of **19** (2.029 g, 13.2 mmol) in hexane (40 mL), at −20°C under argon, was added dropwise DIBAL (26.5 mL of 1 *M* solution in hexane) over 1 h. The reaction mixture after 1 h was allowed to warm to 0°C. Methanol (4 mL) was added, followed by water (1 mL) and sufficient dilute hydrochloric acid to acidify the reaction mixture. The product was extracted with ether, washed with 1 *N* hydrochloric acid, saturated sodium hydrogen carbonate, saturated brine, dried ($MgSO_4$), and concentrated. The residue (1.218 g, 82% yield) was shown by ^{1}H nmr to be a 4:1 mixture of **20** and **21**; ^{1}H nmr (60 MHz) δ: 6.35–5.30 (m, 3.3H, C*H*=CHCH_2OH, CH_2=C*H* of **20** and CH_2=C*H* of **21**), 5.25–4.85 (m, 2.5H, CH_2=CH of **20** and of **21**), 3.67 (t, 0.5H, *J* = 5.5 Hz, CH_2OH of **21**), 2.90 (bs, 1.3H, disappears in D_2O, O*H* of **20** and of **21**), 2.40–1.85 (m, 5.5H, CH_2CH_2 of **20** and CH_2CH_2CH_2CH_2 of **21**).

The crude mixture of **20** and **21** (1.218 g, 10.8 mmol) was oxidized by PCC (3.00 g, 13.9 mmol) in methylene chloride (35 mL) following the procedure of Corey and Suggs (11). The crude product oil was washed with 0.4 *M* sodium metabisulphite (10 mL), extracted with ether, dried ($MgSO_4$), and concentrated. Distillation (bulb-to-bulb, 16 Torr, 60–71°C (lit. (22) bp 16 Torr, 58–65°C)), gave **18**, contaminated by 3% of **22**, (0.566 g, 39% yield from **19**); liquid; ir ν: 1700 (C=O) cm^{-1}; ^{1}H nmr (60 MHz) δ: 9.82 (t, 0.03H, *J* = 1.5 Hz, C*H*O of **22**), 9.55 (d, 1H, *J* = 8 Hz, C*H*O), 7.35–6.60 (m, 1H, C*H*=CHCHO), 6.40–5.50 (m, 2H, C*H*CHO and CH_2=C*H*), 5.30–4.85 (m, 2H, CH_2=CH), 2.60–2.10 (m, 4H, CH_2CH_2).

(E)-2,6-Heptadienal (18) via route shown in Scheme 4

Following the general procedure of Meyers *et al.* (26), 2,4,4,6-tetramethyl-5,6-dihydro-1,3-oxazine (3.613 g, 25.6 mmol) in THF (25 mL) was lithiated by the dropwise addition of *n*-butyllithium (17.6 mL of a 1.6 *M* solution in hexane, 28.2 mmol) at −78°C under argon over 1 h. After a yellow precipitate had formed, **6** (2.368 g, 28.2 mmol) in THF (5 mL) was added dropwise over 0.5 h. The reaction mixture was allowed to warm slowly to room temperature and worked up as described by Meyers *et al.* (26) to give crude **24** (4.787 g, 83% yield); liquid; ir ν: 3360 (O—H), 1670 (C=N) cm^{-1}. Reduction of crude **24** (3.574 g, 15.9 mmol) by sodium borohydride (0.613 g, 16.1 mmol) at pH 6–8 in the manner described by Meyers *et al.* (26) gave crude **25** (3.543 g, 98% yield); liquid; ir ν: 3350 (O—H) cm^{-1}. Crude **25** (3.543 g, 15.6 mmol) was added dropwise to a boiling aqueous solution (100 mL) of oxalic acid (7 g). The water azeotrope, which distilled off, was collected and the product extracted into ether, dried ($MgSO_4$), and concentrated to give **18** (0.769 g, 44% yield from **24**); liquid; ir ν: 1700 (C=O) cm^{-1}; ^{1}H nmr (300 MHz) δ: 9.51 (d, 1H, *J* = 8 Hz, C*H*O), 6.90–6.81 (m, 1H, C*H*=CHCHO), 6.18–6.09 (m, 1H, CH=C*H*CHO), 5.88–5.74 (m, 1H, CH_2=C*H*), 5.11–5.02 (m, 2H, CH_2=CH), 2.50–2.24 (m, 4H, CH_2CH_2); ms *m/z*: 110 (M^+, 4), 109 (14), 95 (32), 81 (100), 79 (42), 41 (71).

Racemic 3-isopropenyl-6-heptenal (3) via route shown in Scheme 5

Following the general procedure described by Hashimoto *et al.* (21), **18** (0.349 g, 3.17 mmol) was condensed with racemic **26** (0.592 g, 3.16 mmol) in benzene (16 mL) to afford, after work-up, crude **27** (0.838 g, 95% yield); oil; ir ν: 1735 (C=O), 1660 (C=N) cm^{-1}; ^{1}H nmr (300 MHz) δ: 7.76 (d, 1H, *J* = 9 Hz, C*H*=N), 6.43–6.15 (m, 2H, C*H*=C*H*CH=N), 5.90–5.72 (m, 1H, CH_2=C*H*), 5.11–4.92 (m, 2H, CH_2=CH), 3.30 (s, 1H, C*H*CO_2), 2.39–2.13 (m, 4H, CH_2CH_2), 1.47 (s, 9H, $CO_2C(CH_3)_3$), 0.98 (s, 9H, $CHC(CH_3)_3$). A solution of the total crude **27** in THF (5 mL) was added dropwise to a stirred solution of isopropenylmagnesium bromide, prepared from isopropenyl bromide (1.15 g, 9.5 mmol) and magnesium (0.23 g, 9.5 mmol), in THF (20 mL) at −70°C. After 3 h the reaction mixture was allowed to warm up to −15°C and was kept at this temperature overnight. Hydrolytic work-up, as described by Hashimoto *et al.* (21), followed by flash chromatography (10% ether/hexane) and subsequent distillation (bulb-to-bulb, 0.1 Torr, 65–75°C) gave racemic **3** (0.243 g, 50%), identical to **3** prepared via Scheme 1, as described above.

(R)-3-Isopropenyl-6-heptenal (3) via route shown in Scheme 5

In a manner similar to that described above for racemic **3**, **18** was condensed with chiral **26** and converted, under the conditions reported in Table 1, to **3** (43% yield); $[\alpha]_D$ −0.47° (*c* 7.89, $CHCl_3$).

(R)-N-[(R)-1-(1-Naphthyl)ethyl]-3-isopropenyl-6-heptenamide (16) via route shown in Scheme 5

Following the procedure described by Heath *et al.* (17), **3** (0.0883 g, 0.58 mmol) in acetone (15 mL) was oxidized by Jones reagent (38)

(0.3 mL, 0.8 mmol) to give crude **12** (0.0823 g, 84% yield). This compound was converted, in a manner similar to that described above, to crude **16** (0.0959 g, 52% overall yield) and analysed directly by hplc. At identical retention times to those reported above, the (*R*,*S*)-diastereomer (11 min) eluted prior to the predominant (*R*,*R*)-diastereomer (13 min). Under identical hplc conditions, a preparation of **16** from a racemic mixture of **3** and its enantiomer gave two peaks of identical area at 11 and 13 min, whereas for a preparation of **16** from optically active **3** and (*S*)-(−)-**14** the predominant (*S*,*R*)-diastereomer (11 min) eluted prior to the (*S*,*S*)-diastereomer (13 min).

(4S,5S)-(+)-2-[1-(E-1,5-Hexadienyl)]-4-methoxymethyl-5-phenyl-2-oxazoline (30)

Method A

Following the procedure described by Meyers *et al.* (15), **28** (6.00 g, 29.3 mmol) in THF (50 mL) was lithiated at −78°C, and **6** (2.50 g, 29.8 mmol) in THF (4 mL) was added dropwise. After the appropriate work-up the product was treated with trifluoroacetic acid (6 drops) in benzene (150 mL) and the mixture refluxed overnight; a Dean–Stark trap was employed to remove water. The cooled solution was washed with 5% sodium hydrogen carbonate, dried ($MgSO_4$), and concentrated. Flash chromatography (20% ether/hexane) gave **30** (3.30 g, 26% yield); oil; $[\alpha]_D$ 50.31° (*c* 1.60, $CHCl_3$); ir ν: 1680 (C=N) cm^{-1}; ^1H nmr (60 MHz) δ: 7.32 (s, 5H, C_6H_5), 7.04–6.51 (m, 1H, C*H*=CHC=N), 6.31–5.52 (m, 2H, CH_2=C*H* and C*H*C=N), 5.32 (d, 1H, *J* = 7 Hz, OC*H*), 5.24–5.01 (m, 2H, CH_2=CH), 4.32–4.00 (m, 1H, NC*H*), 3.66–3.46 (m, 2H, CH_2O), 3.40 (s, 3H, OCH_3), 2.45–2.12 (m, 4H, CH_2CH_2); ms *m/z*: 271 (M^+, 11), 241 (6), 226 (100), 182 (28), 151 (29), 134 (32), 119 (95), 109 (44), 91 (60), 74 (37), 45 (39).

Method B

Crude **29** (8.056 g, 24.6 mmol), prepared by the method of Ziegler and Gilligan (27), and **6** (2.94 g, 35.0 mmol) were dissolved in THF (25 mL, containing two drops of water) and cooled to −78°C. Potassium *tert*-butoxide (3.4 g, 30.0 mmol) in THF (20 mL) was added slowly and the reaction conducted and worked up in the manner described by Meyers *et al.* (15) to give **30** (5.88 g, 89% yield), identical to **30** prepared by method A, described above.

(4S,5S)-2-[1-(3-n-Butyl-5-hexenyl)]-4-methoxymethyl-5-phenyl-2-oxazoline (31)

A solution of **30** (2.707 g, 9.99 mmol) in THF (30 mL) was added dropwise over 1 h to *n*-butyllithium (13.8 mL of a 1.6 *M* solution in hexane, 22.1 mmol) in THF (125 mL) at −78°C under argon, and the mixture was stirred for 2.5 h at the same temperature. The reaction was quenched at −78°C by the addition of methanol (3 mL). The reaction mixture was allowed to warm up to ambient temperature, then treated with water (100 mL) and extracted with ether. The organic extracts were washed with brine, dried ($MgSO_4$), and concentrated to give crude **31** (2.949 g, 90% yield); ir ν: 1655 (C=N) cm^{-1}; ^1H nmr (60 MHz) δ: 7.36 (s, 5H, C_6H_5), 6.27–5.52 (m, 1H, CH_2=C*H*), 5.32 (d, 1H, *J* = 7 Hz, OC*H*), 4.31–3.98 (m, 1H, NC*H*), 3.80–3.47 (m, 2H, CH_2O), 3.40 (s, 3H, OCH_3), 2.60–0.75 (m, 16H, aliphatic envelope); ms *m/z*: 321 (M^+, 2), 284 (22), 222 (100), 180 (84), 152 (41), 124 (57), 99 (46), 83 (64), 55 (62), 41 (84).

(4S,5S)-2-[1-(3-Isopropenyl-5-hexenyl)]-4-methoxymethyl-5-phenyl-2-oxazoline (32)

In a manner similar to that described above for **31**, **30** was reacted with isopropenyllithium, prepared from *tert*-butyllithium and isopropenyl bromide (39), to give after flash chromatography (40% ethyl acetate/hexane) **32** (0.680 g, 63% yield); ir ν: 1660 (C=N) cm^{-1}; ^1H nmr (60 MHz) δ: 7.33 (s, 5H, C_6H_5), 6.25–5.51 (m, 1H, CH_2=C*H*), 5.30 (d, 1H, *J* = 7 Hz, OC*H*), 5.22–4.78 (m, 4H, CH_2=CH and CH_2=C), 4.32–3.95 (m, 1H, NC*H*), 3.75–3.50 (m, 2H, CH_2O), 3.43 (s, 3H, OCH_3), 2.70–1.05 (m, 10H, aliphatic envelope); ms *m/z*: 313 (M^+, 1), 224 (18), 193 (13), 165 (13), 136 (15), 109 (24), 74 (100), 55 (22), 43 (26).

2-(5-Methyltetrahydrofuranyl)acetic acid (33)

A solution of **30** or **7** (1.73–2.57 mmol) in 4 *N* sulphuric acid (10–15 mL) was refluxed for 4 h. The reaction mixture was allowed to cool, and then was extracted with ether. The ether extracts were washed with brine, dried ($MgSO_4$), concentrated, and distilled (bulb-to-bulb, 1.20 Torr, 125–135°C) to give **33** (62% yield from either **30** or **7**); liquid n_D^{23} 1.4532 (lit. (40) n_D^{25} 1.4520); ir ν: 3100 (O—H), 1720 (C=O) cm^{-1}; ^1H nmr (60 MHz) δ: 10.31 (s, 1H, O*H*), 4.65–3.75 (m, 2H, C*H*OC*H*), 2.55 (dt, 2H, *J* = 2 and 7 Hz, CH_2CO_2), 2.40–1.35 (m, 4H, CH_2CH_2), 1.23 (dd, 3H, *J* = 1.5 and 6 Hz, CH_3); ms *m/z*: 144 (M^+, 5), 111 (30), 102 (100), 85 (87), 84 (38), 56 (82), 55 (92), 43 (89), 41 (89). *Anal.* calcd. for $C_7H_{12}O_3$: C 58.32, H 8.39; found: C 58.32, H 8.32.

3-n-Butyl-6-hepten-1-ol (34)

A solution of crude **31** (0.416 g, 1.26 mmol) in 3% ethanolic hydrochloric acid (10 mL) was refluxed overnight. After cooling, the mixture was concentrated, water (10 mL) was added, and the resulting solution was neutralized and then extracted with ether. The organic extracts were dried ($MgSO_4$) and concentrated. The resulting viscous oil was dissolved in THF (7 mL), lithium aluminum hydride (0.15 g, 3.90 mmol) added, and the reaction mixture stirred overnight at ambient temperature. The reaction mixture was cooled to 0°C and the excess hydride destroyed by the slow addition of methanol (1 mL), followed by water (10 mL). The product was extracted into ether, washed with brine, dried ($MgSO_4$), concentrated, and distilled (bulb-to-bulb, 0.1 Torr, 66–77°C) to give **34** (0.094 g, 44% yield); liquid; $[\alpha]_D$ −1.18° (*c* 2.12, $CHCl_3$); ir ν: 3475 (O—H) cm^{-1}; ^1H nmr (300 MHz) δ: 5.81–5.66 (m, 1H, CH_2=C*H*), 4.98–4.83 (m, 2H, CH_2=CH), 3.54 (t, 2H, *J* = 7 Hz, CH_2OH), 3.11 (bs, 1H, O*H*), 2.06–1.92 (m, 2H, CH_2=CHCH_2), 1.50–0.75 (m, 14H, aliphatic envelope); ms *m/z*: 137 (M^+ − CH_3 and H_2O, 0.5), 124 (M^+ − CH_2=CH_2 and H_2O, 5), 123 (13), 113 (11), 110 (10), 109 (6), 95 (47), 81 (30), 69 (53), 67 (34), 55 (100), 43 (30), 41 (60). Compound **34** was oxidized by PCC to 3-*n*-butyl-6-heptenal (81% yield); ir ν: 1740 (C=O) cm^{-1}; ms *m/z*: 168 (M^+, 0.2), 150 (2). 2,4-Dinitrophenylhydrazone derivative; mp 65–67°C. *Anal.* calcd. for $C_{17}H_{24}N_4O_4$: C 58.61, H 6.94, N 16.08; found: C 58.42, H 6.87, N 15.80.

N-[(R)-1-(Naphthyl)ethyl]-3-n-butyl-6-heptenamide (36)

Jones reagent (38) (1.18 mL, 2.26 mmol) was used to oxidize **34** (0.1285 g, 0.76 mmol), in a manner similar to that described above for **3**, to give after distillation (bulb-to-bulb, 1.5 Torr, 130–140°C) 3-*n*-butyl-6-heptenoic acid (0.0605 g, 44% yield); ir ν: 3105 (O—H), 1720 (C=O) cm^{-1}; ^1H nmr (60 MHz) δ: 11.00 (bs, 1H, O*H*), 6.10–5.43 (m, 1H, CH_2=C*H*), 5.17–4.74 (m, 2H, CH_2=CH), 2.34 (d, 2H, *J* = 6 Hz, CH_2CO_2), 2.28–0.80 (m, 14H, aliphatic envelope). Following a procedure similar to that described above for **16**, 3-*n*-butyl-6-heptenoic acid was converted to crude **36** (0.1021 g, 92% yield) and analysed directly by hplc. Separation of the two diastereomers was achieved in 0.75 h using 5% ethyl acetate in hexane at 1.0 mL/min. The predominant diastereomer eluted first. A sample of **36** was purified by flash chromatography (20% ethyl acetate/hexane); ir ν: 3320 (N—H), 1640 (C=O) cm^{-1}; ^1H nmr (300 MHz) δ: 8.13–7.38 (m, 7H, $C_{10}H_7$), 5.98–5.86 (m, 2H, N*H* and C*H*NH), 5.78–5.62 (m, 1H, CH_2=C*H*), 4.97–4.86 (m, 2H, CH_2=CH), 2.14–1.85 (m, 5H, CH_2=CHCH_2CH_2C*H*CH_2), 1.63 (d, 3H, *J* = 6 Hz, CHCH_3), 1.39–1.16 (m, 8H, $(CH_2)_3CH_3$ and CH_2=CHCH$_2$CH_2), 0.86 (t, 3H, *J* = 6.5 Hz, CH$_2$CH_3); ms *m/z*: 337 (M^+, 15), 213 (29), 170 (19), 156 (38), 155 (100), 153 (17), 55 (19).

The synthetic route to 6-chloromercuricholest-5-en-3β-ol has been studied and the yield improved from 2% to 20%. The reaction of 6-chloromercuricholest-5-en-3β-ol with fluorine, chlorine, bromine, and iodine has been examined. 6-Bromocholest-5-en-3β-ol and 6-chlorocholest-5-en-3β-ol have been directly prepared from 6-iodocholest-5-en-3β-ol using cuprous halides. A new intermediate, 6-tosyloxycholest-5-en-3β-ol, has also been synthesized by the action of silver tosylate on 6-iodocholest-5-en-3β-ol. The structures of the compounds were proven by a combination of high-resolution ^{1}Hmr and ^{13}Cmr. A new crystal modification of 6-chloromercuricholest-5-en-3β-ol has been found.

On a étudié la voie d'accès au chloromercuri-6 cholestène-5 ol-3β et on a amélioré le rendement de 2% à 20%. On a étudié la réaction du chloromercuri-6 cholestène-5 ol-3β avec le fluor, le chlore, le brome et l'iode. Faisant appel à la réaction des halogénures cuivreux avec l'iodo-6 cholestène-5 ol-3β, on a réalisé des synthèses directes des bromo-6 et chloro-6 cholostène-5 ols-3β. On a également synthétisé un nouvel intermédiaire, le tosyloxy-6 cholestène-5 ol-3β, en faisant réagir le tosylate d'argent sur l'iodo-6 cholestène-5 ol-3β. La rmn du ^{1}H et du ^{13}C à haute résolution a permis d'élucider les structures des composés. On a trouvé une nouvelle modification cristalline du chloromercuri-6 cholestène-5 ol-3β.

[Traduit par le journal]

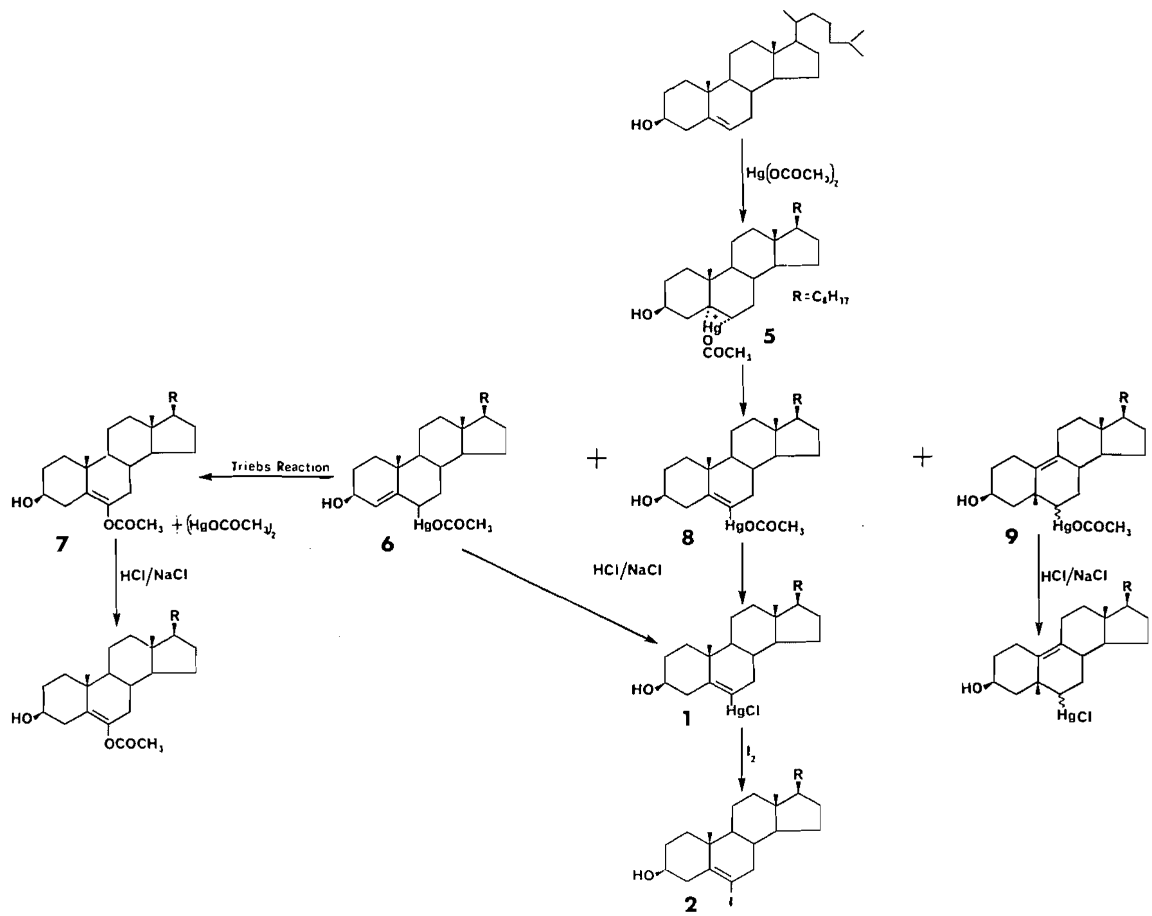
Introduction

The need for high speed stereospecific methods for the introduction of radioligands into organic molecules has necessitated the development of novel synthetic methods. Some of the newer methods developed recently involve the reaction of selected organoboron (1–3), organotin (4), and organothallium compounds (5) with elemental iodine. We have chosen to examine the feasibility of using organomercury compounds for this procedure. We felt that organomercury compounds offered a number of advantages over other organometallic intermediates in that they are easily accessible from organic halides, olefins, and aromatic amines. Such is not the case for organotin and especially organoboron compounds. Furthermore, organomercury compounds are known in the three common forms required for most labelling procedures, i.e. aliphatic, vinylic, and aromatic. We chose a vinyl organomercury compound as our first compound, as it would offer the most difficulties from the point of view of competing reactions since vinyl systems have considerable reactivity with the common halogens. A useful starting point for this study was 6-chloromercuricholest-5-en-3β-ol (**1**) first prepared by Merz (6, 7) in 1926. This compound has been used recently in the preparation of 6-iodocholest-5-en-3β-ol (**2**) which is the precursor for [^{131}I]-6-iodocholest-5-en-3β-ol (8, 9). This latter compound shows great promise as an adrenal imaging agent (10). This recent interest in the use of [^{131}I]-6-iodocholest-5-en-3β-ol for adrenal imaging has required the preparation of large quantities of this compound and its precursor, 6-chloromercuricholest-5-en-3β-ol (**1**). The standard approach has been the reaction of cholesterol with mercuric acetate, a method that proceeds with low yield. This reaction was examined in order to optimize the conditions and we have improved the yield from 2% to 20%. We have also prepared 6-bromocholest-5-en-3β-ol (**3**) and 6-chlorocholest-5-en-3β-ol (**4**) directly from **1** and indirectly from **2**. A detailed structural analysis (11) of these compounds was also carried out, since it is well known that rearrangements are very common in cholesterol molecules with functionalities at the 6-position (12, 13), and as part of an ongoing program to study structure–activity relationships in steroids.[1]

Discussion and results

The reaction of cholesterol with mercuric acetate is complicated by a number of competing routes (see Scheme 1). These arise out of the decomposition of the mercurinium ion (**5**) formed when mercuric acetate adds to the 5,6 double bond of cholesterol. Two of these routes comprise the major course of the reaction and result from the loss of a proton from **5** to form either a 4,5 or a 5,6 double bond. The formation of the 4,5 double bond gives the allylic mercuriacetate (**6**) which reacts further with mercuric acetate via the Triebs reaction (14, 15) to give the vinylic acetate (**7**). The percentage yield of this compound can be estimated from the recovered mercurous acetate, which precipitates out during the course of the reaction and is about 60%. The formation of a 5,6 double bond from the decomposition of **5** gives rise to the desired vinylic mercuri-

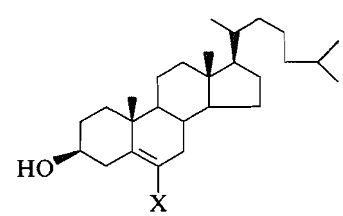
[1]This paper is Part 1 of a series. Part 2 is "High Specific Activity Syntheses of [^{125}I] and [^{131}I]-6-Iodocholest-5-en-3β-ol" and Part 3 is "The Synthesis of [^{77}Br] and [^{82}Br]-6-Bromocholest-5-en-3-β-ol".



SCHEME 1

acetate (**8**). This route would appear to be an unusual one for the decomposition of mercurinium ions, and very few examples exist in which mercuric acetate addition to a double bond results in substitution for a vinylic hydrogen (16, 17). Such examples as exist all involve mercurinium ions that possess good carbonium stabilization at one of the vinyl carbons. It would appear that a carbonium ion at C-5 of the cholesterol has some of these stable properties. The complexity of the product mixture is greatly simplified on treatment with 1% HCl in aqueous sodium chloride, giving rise to a further mixture consisting mainly of 6-acetoxycholest-5-en-3ol (**7**) (60%) and the desired product, 6-chloromercuricholest-5-en-3β-ol (**1**) (40%). Since the mixture becomes simplified, it is reasonable to assume that some of the components rearrange in the presence of acid to form **1**, the most likely candidate being **6**. This mixture can be separated by preparative centrifugal chromatography on silica gel and after crystallization from acetone the 6-chloromercuricholest-5-en-3β-ol is obtained in 20% yield.

The 6-chloromercuricholest-5-en-3β-ol prepared in this fashion generally has a melting point of 208°C but sometimes material with a melting point of 154°C is obtained. The lower melting allotrope is produced from highly saturated solutions and is quite amorphous when compared to the needles of the higher melting point allotrope. Merz (6) also observed this lower melting point form but ascribed it to a double compound of 6-chloromercuricholest-5-en-3β-ol and cholesterol. We have examined this lower melting allotrope extensively and found it to be pure 6-chloromercuricholest-5-en-3β-ol by both ^{13}Cmr (11) and combustion analysis. The lower melting allotrope can be converted to the higher melting allotrope by careful recrystallization from acetic acid. The lower melting allotrope appears to be the same crystal modification as found in all other 6-halocholest-5-en-3-ols that have melting points in the range 147–154°C. Such behaviour, in which molecules of similar structure have very similar melting points, is well known for cholesterol compounds (18–20).

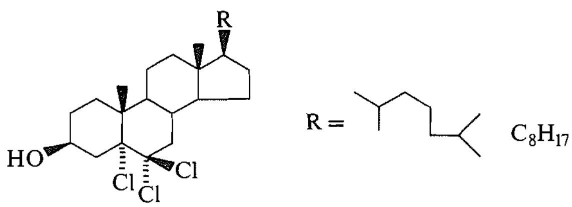


1 = HgCl
2 = I
3 = Br
4 = Cl
12 = F
13 = OTs

6-Chloromercuricholest-5-en-3β-ol reacts rapidly with elemental iodine at room temperature to give a quantitative yield of 6-iodocholest-5-en-3β-ol (**2**). We have tried this reaction in various solvents including methanol, ethanol, acetone, chloroform, and hexane and found it to proceed well in all. Shortly after the beginning of the reaction a violet precipitate of mercuric chloroiodide forms, which must be removed before the product is crystallized from the reaction solvent. A similar reaction occurs for iodine monochloride, giving only **2** and no measurable amount of 6-chlorocholest-5-en-3β-ol (**4**). This implies that the reaction of halogens with the carbon–mercury bond proceeds via a polarized intermediate state in which the more electropositive of the halide pair becomes joined to the carbon. This fact is of paramount importance for the use of these organomercury compounds as substrates for the introduction of halogen radiolabels into carbon skeletons.

The reaction of **1** with elemental bromine is quite similar to that for iodine, but is slower, and care must be taken to avoid an excess of bromine, in which case addition of bromine to the 5,6 double bond takes place. This is easily accomplished by slow addition of the bromine and by monitoring the disappearance of the yellow colour due to the excess bromine. An alternative solution to the problem of addition to the double bond is the use of *N*-bromosuccinimide. This reagent reacts smoothly with **1** to give the monobromo product **3**. This observation is particularly important for labelling applications since it allows the perparation of **3** using radiobromide. The reaction of **1** with pyridinium bromide perbromide is more controlled than that for elemental bromine but some addition to the double bond can still take place if an excess is present.

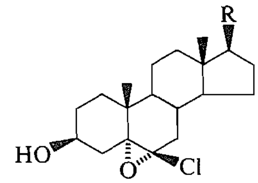
The reaction of 6-chloromercuricholest-5-en-3β-ol with chlorine gas is not successful, since the addition of chlorine to the 5,6 double bond proceeds faster than the cleavage of the carbon–mercury bond. The main product is 5,6,6-trichloro-5α-cholestan-3β-ol (**10**) resulting from addition to the double bond followed by cleavage of the carbon–mercury bond. The



10

use of very dilute solutions of chlorine in methanol in conjunction with slow addition resulted in the formation of some 6-chlorocholest-5-en-3β-ol, but the amount was less than 10%. *N*-Chlorosuccinimide does not react with the carbon–mercury bond of **1** nor does it add to the 5,6 double bond. This a very fortunate circumstance since *N*-chloro species are commonly used for oxidizing iodide to iodine monochloride in labelling reactions. This fact also allows for some improvement in the yield of **4** by generating the Cl_2 *in situ* using chloride ion and *N*-chlorosuccinimide in ethanol/water as solvent. This results in a small steady-state concentration of Cl_2 and permits a moderate improvement in the yield of **4** to 20%. Because it would appear that *N*-chloro bonds are not sufficiently reactive to attack the carbon–mercury bond, it was of interest to see if an *O*-chloro bond might achieve this goal, since oxygen is more electronegative and the *O*-chloro bond should be more polarized. Such is indeed the case and 6-chloromercuricholest-5-en-3β-ol undergoes a rapid reaction with *tert*-butyl hypochlorite to form a complex mixture. The major component of this mixture, upon examination by mass spectroscopy, appeared to be an oxychloro derivative (tentatively assigned structure **11**) but no further structural determination was carried out.

The reaction of **1** with fluorine gas was also investigated but no direct reaction of fluorine and the carbon–mercury bond could be detected and no 6-fluorocholest-5-en-3β-ol (**12**) could



11

be found in the resulting mixture. A number of different methods of introducing the fluorine gas were examined, including 5% fluorine in neon at various temperatures from −78 to 25°C and in various solvents such as carbon tetrachloride, Freon-11, chloroform, and acetic acid. Other reactions examined included the use of acetyl hypofluorite (21) and xenon difluoride. The chemical literature contains no record of chloromercury groups reacting with fluorine to form carbon–fluorine bonds.

6-Chlorocholest-5-en-3β-ol was produced by treating 6-iodocholest-5-en-3β-ol with excess cuprous chloride in DMF at 50°C for 24 h. The nature of the carbon–iodine bond in **2** is such that it is very resistant to nucleophilic exchange (8) but, since the mechanism for halide exchange with cuprous halides is a ligand exchange process, it proceeds well in this instance. The same method also allows exchange of bromine for iodine using Cu_2Br_2 and **2**, giving a quantitative yield of **3**. Since halide exchange using cuprous halides is known to proceed with retention of configuration (22) for vinyl halides, this correlation of the structure of 6-chloromercuricholest-5-en-3β-ol with the previously known 6-chlorocholest-5-en-3β-ol (18) offers the first chemical structure proof for **1**.

Nucleophilic exchange at the 6-position of cholesterol is very difficult and proceeds only for the iodo compound **2** (8). Elevated temperatures and a large excess of nucleophile are required. We have been unable to exchange the bromine atom in **3** or the chlorine atom in **4** using even the most forcing conditions without destroying the molecule, usually by loss of the C-3 hydroxyl group and with formation of a double bond. The methods examined for exchange included the melt method with lithium, sodium, and potassium halides, dipolar aprotic methods using solvents such as DMF and DMSO, and catalytic methods with cuprous cyanide, chloride, and acetate. This unusual stability of halides attached to the 6-position of cholesterol is of course a favourable circumstance since it probably contributes to the *in vivo* stability of such molecules and accounts at least in part for the success of [^{131}I]-6-iodocholest-5-en-3β-ol as an adrenal imaging agent. Since, as we have already shown, these halides can be introduced electrophilically, the resistance to nucleophilic exchange is an added advantage. 6-Tosyloxycholest-5-en-3β-ol (**13**) can be prepared by the reaction of **2** with excess silver tosylate in DMF at 110°C. As is the case with 6-halocholest-5-en-3β-ols, however, the tosyl group in this compound is difficult to exchange.

A major concern of this work was the confirmation of the proposed structure for **1** and the corresponding halides **2**, **3**, and **4**. In particular, we wished to prove that the chloromercury function in **1** was indeed attached at the 6-position. Despite the fact that **1** has been known since 1926, no rigorous determination of its structure has yet been made. Since the synthetic route to **1** is quite unusual and involves the substitution of a vinylic hydrogen of cholesterol by an acetoxymercury group, there is some real doubt as to the position of the mercury function in the molecule. Furthermore, since the mechanism of formation of **1** must involve either a carbonium ion at C-5 or

TABLE 1.[a] ^{13}C chemical shifts of 6-substituted cholest-5-en-3β-ols

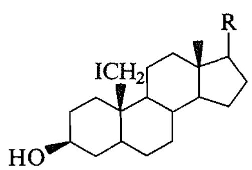
a mercurinium ion across the C-5,6 double bond, the possibility of a rearrangement must be taken into consideration. The homoallylic rearrangement has been found to occur for 19-iodonorcholesterol (**14**), a radiolabelled adrenal imaging agent (23).



14

A further reason for confirming the structure of these compounds was provided by their apparently different physical properties when compared to cholesterol. In this sense they are much more stable towards oxidative decomposition than cholesterol. Although **2**, **3**, and **4** would not be expected to react facilely via a nucleophilic mechanism, they exhibited an extraordinary resistance to any such reaction. These properties were mirrored in the excellent in vivo stability of both **2** (8) and **3** (see footnote 1, Part 3 and ref. 24). The vinyl iodide **2**, in particular, is one of the more stable iodides that we have yet studied (25). These properties, in conjunction with the mechanistic considerations mentioned earlier, led to some serious doubts as to the correct structure of this series of compounds. Because of the difficulties involved in chemical transformations of these compounds we chose to undertake a rigorous spectroscopic study. Since a major problem in the design of radiohalogen labelled radiopharmaceuticals is the subsequent in vivo loss of the label, it was hoped that the structural information collected in this fashion would help in the design of other radiolabelled pharmaceuticals with greater in vivo stability.

The ^{13}Cmr data for **1**, **2**, **3**, and **4** are contained in Table 1. The assignments of the various carbons were made by analogy with the published spectrum of cholesterol (26) and through the use of the gated ^{1}H decoupled ^{13}C spin echo technique (GASPE) developed in these laboratories (27, 28). This technique allows the facile determination of the multiplicity of an individual carbon resonance. The assumption was made that the structures were as proposed and, therefore, that differences between the spectra of **1**, **2**, **3**, **4**, and cholesterol could be rationalized on the basis of known shift parameters. Fortunately this was the case. If one considers the non-olefinic carbons, the only major differences discernible between the ^{13}Cmr spectra of cholesterol and the compounds under consideration occur for carbons 4, 7, 8, and 10. Since carbon 10 is a singlet and carbon 8 is a doublet these resonances are easily reassigned in their shifted positions. Carbons 4 and 7 are both triplets and their assignment therefore might lead to some ambiguity. When one compares the positions for these new triplets in the spectra of **1**, **2**, **3**, and **4** there is only one rational assignment that can be made, since such an assignment must conform to the known shift parameters for halogens. This required the arrangement of the resonances for C-4 and C-7 in such a manner that they both demonstrated a decreasing pattern of shifts from I to Cl. It was also noted that, whereas the olefinic resonances for cholesterol are a doublet and a singlet, in **1**, **2**, **3**, and **4** these resonances appear as singlets, confirming the presence of a functionality at C-6. The shifts observed on the introduction of the various functionalities into the cholesterol skeleton are given in Table 2. Also included in this table are the predicted values for these shifts where such values are available (29). These shifts are best considered in terms of α, β, γ, and δ effects. The high positive value for the shift observed in **2** at C-7, which is β to the iodine at C-6, is without precedent. Such an abnormally high value must be taken in the context of the abnormal negative value for the shift of the C-6 carbon. Apparently the iodine in **2** is electropositive with respect to the double bond and, if one assumes a partial negative charge at C-5 and a corresponding positive charge at C-6, one can explain the effect. This must also be partially responsible for the absence of any *observed γ-gauche* effect at C-4. In fact C-4 shows a downfield shift. However, no γ-*gauche* effect would be expected at C-8 or C-10 since these atoms are γ-*anti* to C-6. A γ-*gauche* effect of some degree would be expected at C-4, since it is known this effect is related to the removal of 1,3-diaxial hydrogen interactions (30) such as might be expected for the C-4 equatorial hydrogen and the C-6 pseudo-equatorial hydrogen. It appears that the absence of a γ-*gauche* effect at C-4 is due to an overiding downfield inductive effect, which is in turn caused by the partial negative charge at C-5. This inductive effect should be observed at both C-4 and C-10, although not necessarily to the same degree, and C-4 should have an additional upfield component due to an expected γ-*gauche* effect. The effects observed at C-8 should be due to the corresponding partial positive charge at C-6, and C-8 does indeed show small but consistent downfield shifts in the series **4** to **2**. In summary, although the γ effects observed are probably due to a combination of inductive and steric effects, they can be rationalized to some extent. Any further analysis of these effects is hampered by the lack of available literature values for alicyclic vinylic halides. The δ effects observed are too small to be significant and, futhermore, shifts in choles-

$J(^{13}C_8-^{199}Hg)$	160	157

[a]All coupling values are in hertz and were measured in deuterochloroform at ambient temperature. The expected values for C-5 and C-6 are taken from ref. 34 and the values for C-7 and C-8 are from ref. 35.

terol are known to be concentration and temperature dependent (31, 32).

Further evidence comes from the observation of the ^{199}Hg satellites in the spectrum of 6-chloromercuricholest-5-en-3β-ol (**1**). The natural abundance of ^{199}Hg is 16% and it is the only mercury isotope with a nuclear spin of 1/2. One might therefore expect to observe satellites on either side of selected carbon resonances in **1** with intensities of 8% each. In practice, the amplitude of these satellites is known to show solvent dependency (33) but is was nevertheless possible to observe three sets of such satellites. These were found for the resonances of carbons 5, 6, and 8. We also anticipated finding satellites on the resonance of C-7 but they were obscured by the close proximity of the resonances due to C-13, C-10, C-12, and C-24. It is also possible that the $^{13}C-^{199}Hg$ coupling is too small to be observed since such a coupling would be expected to be of the order of 30–50 Hz, which is close to the bandwidth at the base of the peak. The couplings observed correspond closely to those observed by other investigators (34). These coupling constants and their expected values are shown in Table 3. It was assumed, when choosing the expected values for the C-7 and C-8 coupling constants, that the B ring of the cholest-5-ene system was a quasi chair and that the expected values for the coupling constants would be intermediate between those found for boat and chair chloromercuri-cyclohexyl systems. Although a Karplus equation for the dependence of these couplings on bond angles has been developed (35), we found that the observed values bore an excellent similarity to those in conformationally mobile cyclohexyl systems and chose the latter on the assumption that those values, being an

average of boat and chair values, represented a quasi chair. Since $^{13}C-^{199}Hg$ coupling constants are very sensitive to changes in bond angles, the excellent correlation between the observed and expected constants serve to confirm the quasi-chair conformation of the B ring. This fact, in conjunction with the lack of any observed steric effects in ^{13}Cmr shifts of B ring carbons, implies that the introduction of bulky functional groups such a chloromercury group into the 6-position of cholesterol causes remarkably few conformational changes in that ring.

The ^{1}Hmr spectra for these compounds also provide some structural evidence. Generally, ^{1}Hmr spectroscopy of cholesterol species is complicated by the close proximity of all the resonances (36), and all the protons of cholesterol except the olefinic protons occur in an envelope of 3 ppm. This problem is lessened in the case of the current compounds because the functionalities at C-6 serve to shift the protons at C-4 and C-7 downfield. This is fortunate since it is these protons that provide the structural information. It is possible to clearly observe the resonances of the C-3, C-4, C-6, and, sometimes, the C-7 protons and in most cases to determine their coupling constants. The observable resonances for some of the A and B ring protons of **1**, **2**, **3**, and **4** are given in Table 4 and their coupling constants are given in Table 5. In the case of **2**, the ^{1}Hmr spectrum was measured in $CDCl_3$ and also in perdeuteropyridine in order to distinguish between the resonances of the 7ax and 4ax protons, which overlap in chloroform. Decoupling experiments were carried out only on **2** and **3** and the identity of the various resonances was deciphered in this manner. This information was then applied to the spectra of **1** and **4**. No major differences in shifts or couplings between the four compounds were observed but the spectrum of **1** was complicated by the additional couplings between ^{199}Hg and the various protons. In only a few cases was it possible to determine coupling constants. In the case of **2** it was possible to observe the 8ax proton and this provided some very useful information. This proton was shown to be coupled to the 7eq proton with the

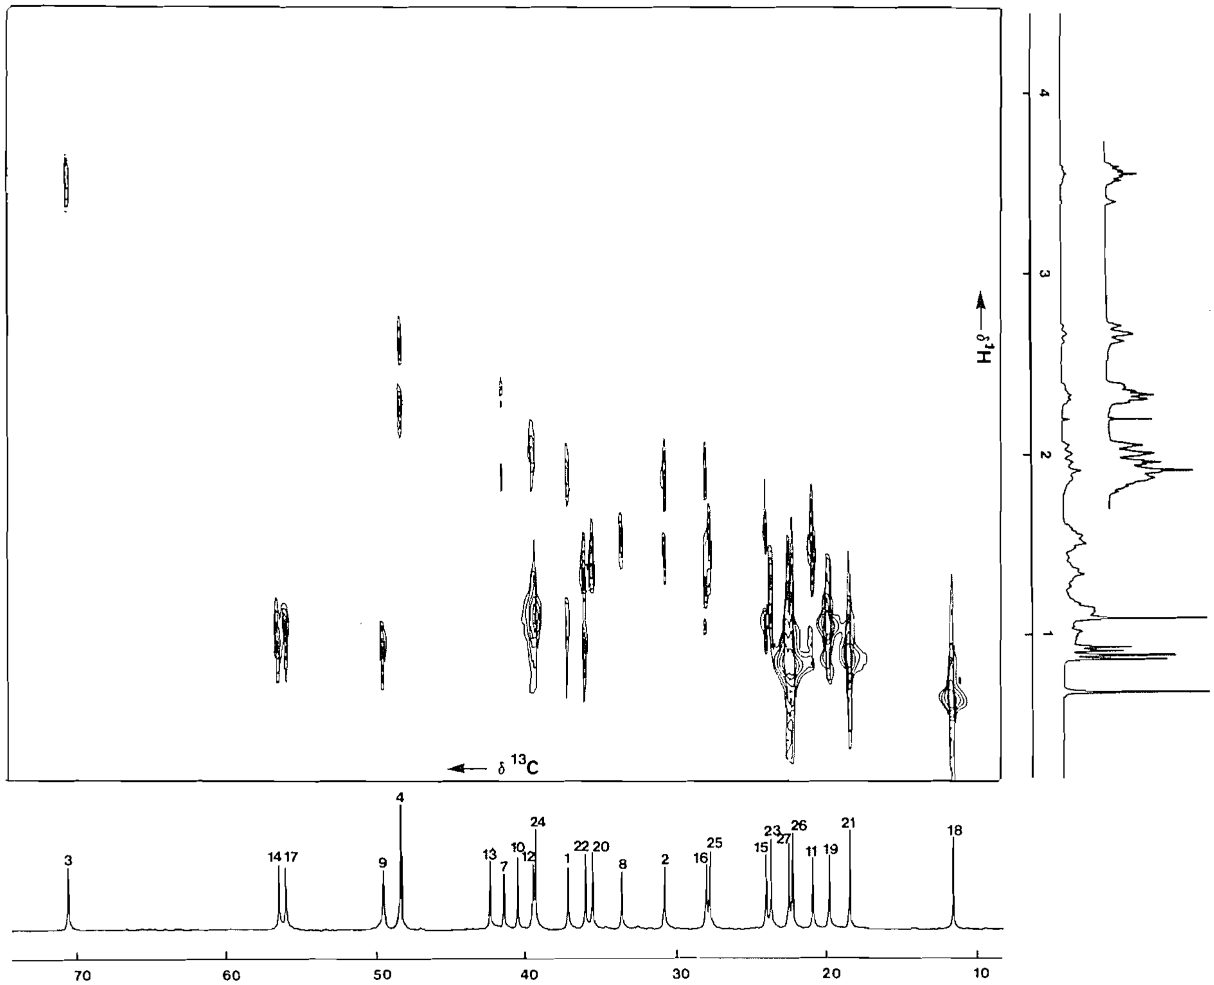

FIG. 1. Contour plot of the 2D heteronulcear $^{13}C-^{1}H$ shift correlation experiment.

expected *syn* coupling of 5.5 Hz. When 7eq was decoupled, 8ax collapsed to a symmetrical quartet with a coupling of 11 Hz. The implication of this was clear. There is only one proton in the entire ring system of cholesterol that has three *trans*-diaxial interactions, and that is the 8ax proton. This proton is also coupled in a *syn* manner to another proton that is shifted substantially downfield by the introduction of a chloromercury function or a halogen atom. Since there is only one proton that is *syn* to 8ax, and that is the 7eq proton, the introduced functionality must be at C-6. The observed proton–proton coupling constants, although less sensitive to changes in conformation than the corresponding carbon–mercury coupling constants, are in good agreement with the quasi-chair nature of the B ring.

A further experiment was undertaken to correlate the assignments of the ^{13}Cmr spectrum of **1** with that of the ^{1}Hmr spectrum. This involved a new technique developed in these laboratories (37) in which a two-dimensional spectrum is produced that shows which protons in the ^{1}Hmr spectrum are coupled to which carbons in the ^{13}Cmr spectrum. This two-dimensional spectrum is shown in Fig. 1. The vertical lines in the diagram correspond to correlations between the ^{13}Cmr and ^{1}Hmr spectra of **1**. It can be seen that the assignments for C-3, C-4, and C-7 in both spectra can be verified. The C-3 protons show as a multiplet, the C-4 protons as an AB doublet, and C-7 protons also as an AB doublet. Using this method it is possible to identify all the protons in the ^{1}Hmr spectrum and measure their shifts. As a result of this it was possible to confirm all the structural assignments made for **1** in both ^{13}Cmr and ^{1}Hmr.

The evidence presented so far serves to confirm the structural assignment made for **1**, **2**, **3**, and **4**. It was also of interest to see if this spectroscopic evidence could provide any further information to explain the unusual properties of these molecules. The first point to emerge is that there are remarkably few steric effects to be observed from the introduction of such bulky functional groups as chloromercury and iodine into the 6-position of cholesterol. This is evident from both ^{13}Cmr and ^{1}Hmr, where the observed shifts were explainable *mainly* on the basis of inductive effects. If the carbon skeleton of **1** or **2** were conformationally altered from that of cholesterol, then there would have been greater differences in the resonances of carbons outside the zone of inductive effect and this was not found.

The ^{13}Cmr data show that, compared to cholesterol, **2** demonstrates greater perturbations than **3**. This behaviour is mirrored in biological behaviour. The uptake of 6-iodocholest-5-en-3β-ol (**2**) in the adrenal glands is efficient but the evidence indicates that it becomes metabolically trapped there (10). In the case of the 6-bromocholest-5-en-3β-ol (**3**), where the ^{13}Cmr inductive effects are of a lesser degree than for **2**, both ^{13}Cmr and ^{1}Hmr indicate a remarkable similarity between this compound and cholesterol itself. The ^{13}Cmr shifts for C-5 and C-6 in **2** are practically identical to those for cholesterol and the greatest difference occurs for C-7 (+8.2 ppm). In fact **3** is taken up in the adrenals but, in addition, it passes through the metabolic chain and is released as a bromosteroid (see footnote 1, Part 3 and ref. 24).

We anticipate using nmr spectroscopy as a tool to evaluate structural activity relationships in the design of future radiopharmaceuticals. It would appear that ^{13}Cmr spectroscopy, with its wider range of resonances and its greater sensitivity to steric effects, is better suited to this task.

Experimental

All reagents and solvents were reagent grade and were used without further purification. Thin-layer chromatographic (tlc) analysis was carried out on silica gel Whatman MK6F micro plates using 7% methanol in chloroform as developing solvent. High-pressure liquid chromatographic (hplc) analysis was carried out using a Waters CN radial compression column and methanol/chloroform/hexane 10:20:70 as solvent. Preparative hplc separations were performed with a Whatman M9 10/50 PAC Partisil column and methanol/chloroform/hexane 5:20:75 as solvent. All melting points are uncorrected.

The ^{13}Cmr spectra were measured either on a Bruker WH-200 at 50.3 MHz or a Bruker AM-300 at 75.4 MHz. The ^{1}Hmr spectra were measured either on a Bruker WH-400, a Bruker WH-200, or a Bruker AM-300 at the stated frequencies. Except in the case of **2**, all spectra were measured in $CDCl_3$ at ambient temperature using tetramethylsilane as a reference. For the ^{1}H–^{13}C heteronuclear shift correlation experiment (38), the following pulse sequence was used:

$$(90x)\,{}^1\mathrm{H}-t_1/2-(180x)\,{}^{13}\mathrm{C}-t_1/2-\underbrace{\tau-(180x)\,{}^1\mathrm{H}(90\psi)\,{}^{13}\mathrm{C}-\tau-(\Theta\phi)\,{}^1\mathrm{H}(180x)\,{}^{13}\mathrm{C}}_{\text{DEPT}}-\tau-\text{acquis}\,{}^{13}\mathrm{C}$$

where $(90x)^1$H represents a 90° ^{1}H pulse directed along the x-axis. ψ and ϕ are phase cycled as follows: $\psi = x, y, -x, -y$ and $\phi = y, -x, -y, x$ to suppress the Boltzmann contribution to the ^{13}C signal and to allow quadrature detection in the f_1 domain. t_1 is incremented in the normal fashion, τ is fixed at $1/(2J_{CH})$, and the ^{13}C signal is acquired with ^{1}H broadband decoupling. Transverse ^{1}H magnetization is created by the first 90° ^{1}H pulse and is allowed to precess freely during the t_1 interval, thus labelling ^{1}H magnetization with their characteristic frequency (or chemical shift). The 180° ^{13}C pulse in the middle of this period serves to remove the large directly bonded coupling (38). Polarization transfer of the "labelled" ^{1}H magnetization to ^{13}C is accomplished by the Distortionless Enhancement by Polarization Transfer (DEPT) (39) part of the sequence. The amount of ^{1}H polarization transfer to the carbon spin is dependent upon the ϕ, the final ^{1}H pulse angle, and its functional form depends upon the number of protons directly attached to the carbon. The amplitude of the ^{13}C signals will be modulated at the chemical shift of the directly bonded ^{1}H as t_1 is incremented, and Fourier transformation along the f_1 domain will yield ^{1}H chemical shift information.

Mass spectra were measured with a Hewlett–Packard 5995 mass spectrometer and only significant peaks over 10% of the base peak are reported. Five percent fluorine in neon was supplied by Matheson Gas Products.

*6-Chloromercuricholest-5-en-3β-ol (**1**)*

Fifteen grams of cholesterol in 60 mL of boiling acetic acid was added to 36 g of mercuric acetate in 60 mL of boiling acetic acid. The mxiture was stirred vigorously while continuing to boil for another 6 min and then cooled to room temperature using an ice bath. Mercurous acetate started to precipitate at this point. The precipitate was collected and washed with 20 mL of acetic acid. The combined filtrates were then added to 800 mL of saturated NaCl solution containing 1% HCl and stirred for 2 h. The yellow precipitate was collected by filtration and air dried overnight. This precipitate was suspended in a mixture of 250 mL each of diethyl ether and water. The aqueous layer was discarded and the ether layer washed once with 1% sodium bicarbonate and twice with saturated sodium chloride solution. The ether layer was dried over calcium chloride and concentrated *in vacuo*. The yield at this point was 20 g of 50% pure material.

This crude material was chromatographed in batches of 3 g on 100 g of silica gel (tlc grade) using chloroform as solvent on a Hitachi CLC-3 centrifugal chromatograph. The 6-chloromercuricholesterol was the third fraction to exit and was 95% pure. The combined 6-chloromercuricholest-5-en-3β-ol fractions were dissolved in an excess of acetone and the solution let stand for 10 days at room temperature while the crystals of **1** slowly formed. Colourless needles (>99%) were collected; yield 5 g, 20% of theory; mp allotrope(1) 208°C, allotrope(2) 154°C; tlc, rf = 0.4; ^{1}Hmr($CDCl_3$): 3.6 (m, 1H), 2.69 (m, 1H), 2.35(m, 2H), 2.1–1.8(m, 5H), 1.6–0.65(complex); ms (DIP, EI 70 eV): 624(M$^+$, 0.2), 623(M$^+$, 0.2), 622(M$^+$, 0.5), 621(M$^+$, 0.3), 620(M$^+$, 0.4), 619(M$^+$, 0.3), 618(M$^+$, 0.2), 386(19), 385(14), 368(16), 318(10), 201(17), 159(20), 144(19), 133(30), 107(35), 105(37), 95(45), 91(43), 71(60), 57(100). *Anal.* calcd. for $C_{27}H_{45}OHgCl$: C 52.10, H 7.30, Cl 5.71; found: C 52.17, H 7.30, Cl 5.71.

*6-Iodocholest-5-en-3β-ol (**2**)*

To a solution of 30 mg of **1** in 10 mL of chloroform a saturated solution of iodine in chloroform was slowly added until the purple colour was sustained. The chloroform solution was washed with 10% sodium thiosulphate solution, dried, and concentrated *in vacuo* to yield an oil. This oil was taken up in 95% ethanol and on standing deposited colourless amorphous crystals of 6-iodocholest-5-en-3β-ol; yield 22 mg, 95% of theory; mp 157°C; tlc, rf = 0.6; ^{1}Hmr($CDCl_3$): 3.9(m, 1H), 3.5(m, 1H), 2.8(m, 1H), 2.7(m, 1H), 2.37(m, 1H), 2.15–0.7(complex); ms (DIP, EI 70 eV): 512(M$^+$, 78), 479(5), 386(15), 385(54), 159(27), 145(21), 119(46), 105(38), 93(30), 91(52), 57(100). *Anal.* calcd. for $C_{27}H_{45}OI$: C 63.20, H 8.85; found: C 63.32, H 8.92.

*6-Bromocholest-5-en-3β-ol (**3**)*

A solution of bromine in chloroform (40 mg, 0.25 mmol) was slowly added to a vigorously stirred solution of **1** (150 mg, 0.24 mmol) in chloroform. The rate of addition was such that the concentration of unreacted bromine was kept to a minimum. The chloroform solution was washed with 10% sodium thiosulphate solution, dried, and concentrated *in vacuo*. The residue was crystallized from 95% ethanol; yield 99 mg, 99% of theory; mp 155°C; tlc, rf = 0.55; ^{1}Hmr($CDCl_3$): 3.59(m, 1H), 3.2(m, 1H), 2.5(m, 1H), 2.2–0.7(complex); ms (DIP, EI 70 eV): 466(M$^+$, 9), 464(M$^+$, 9), 386(33), 385(86), 367(30), 173(27), 159(30), 135(30), 105(30), 100(50), 97(60), 95(57), 81(80), 71(82), 69(92), 57(100). *Anal.* calcd. for $C_{27}H_{45}OBr$: C 69.65, H 9.74, Br 17.16; found: C 69.61, H 9.70, Br 17.25.

*Reaction of 6-chloromercuricholest-5-en-3β-ol (**1**) with Cl_2 gas*

A solution of chlorine in methanol was slowly added to a solution of **1** (100 mg, 0.16 mmol) in chloroform. After 5 min the solution was examined by tlc, which indicated the absence of starting material and two new components. The major component (90%) appeared only on charring with H_2SO_4 and failed to quench the 254-nm fluorescence, implying that the double bond had been consumed. The smaller component did quench the uv indicator and was identified as 6-chlorocholest-5-en-3β-ol by tlc and ms. The major component was identified by its distinctive mass spectrum as 5,6,6-trichloro-5α-cholestan-3β-ol. Subsequent dechlorination experiments were carried out with this mixture since one of the components was the desired product; ms (DIP, EI 70 eV): 494(M$^+$, 8), 492(M$^+$, 23), 490(M$^+$, 25), 421(14), 420(21), 419(26), 418(28), 387(26), 386(15), 385(56), 384(27), 383(51), 159(33), 155(100). Dechlorination of this crude material with zinc in dioxane or THF was unsuccessful.

*6-Bromocholest-5-en-3β-ol (**3**) from **2** via Cu_2Br_2*

Cuprous bromide (dried at 120°C, 40 Torr; 1 Torr = 133.3 Pa) (1.44 g, 10 mmol) was added to a solution of **2** (512 mg, 1 mmol) in dry DMF (10 mL). The mixture was stirred at room temperature for 16 h and then filtered to remove solids. The solution was diluted with 5% aqueous $Na_2S_2O_3$ (100 mL) and extracted with chloroform (3 × 20 mL). The chloroform extracts were dried over $MgSO_4$ and concentrated *in vacuo* to give an off-white residue. Recrystallization from 95% ethanol gave **3** as colourless needles; yield 460 mg, 99% of theory; mp 155°C.

6-Chlorocholest-5-en-3β-ol (4) from 2 via Cu_2Cl_2

The procedure is similar to that for **3**. Cu_2Cl_2 (1.0 g, 10 mmol) was added to **2** (512 mg, 1 mmol) in DMF (20 mL) and the mixture stirred at 50°C for 24 h. Work-up as for **3** gave 6-chlorocholest-5-en-3β-ol (**4**) as colourless needles; yield 373 mg, 89% of theory; mp 156°C; tlc, rf = 0.45; ^{1}Hmr($CDCl_3$): 3.6(m, 1H), 3.28(m, 1H), 2.32(m, 1H); ms (DIP, EI 70 eV): 422(M^+, 6), 420(M^+, 18), 387(21), 386(14), 385(50), 384(26), 179(16), 177(15), 159(17), 95(36), 93(32), 57(93), 55(100).

6-Bromocholest-5-en-3β-ol (3) from 2 via N*-bromosuccinimide*

N-bromosuccinimide (150 mg, 5.2 mmol) was added to a solution of **2** (100 mg, 0.16 mmol) in chloroform (20 mL) and stirred at room temperature overnight. Analysis by tlc indicated a single product and complete consumption of starting material. The reaction mixture was washed with water, dried over $MgSO_4$, and concentrated *in vacuo* to give a residue that on crystallization from ethanol gave pure 6-bromocholest-5-en-3β-ol (**3**); yield 65 mg, 88% of theory; mp 155°C.

Attempted fluorination of 6-chloromercuricholest-5-en-3β-ol (1) using F_2 gas

A mixture of 5% fluorine in neon gas was bubbled through a solution of **1** in Freon 11 at −78°C. Examination of the reaction mixture indicated partial consumption of the starting material and the formation of a large number of new less-polar components. The same results were obtained in all other variations on this reaction.

The reaction of 1 with tert*-butyl hypochlorite*

tert-Butyl hypochlorite (40 mg, 0.37 mmol) was added to a solution of **1** (50 mg, 0.08 mmol) in chloroform (5 mL) and the solution stirred at room temperature for 30 min. Thin-layer chromatographic analysis indicated that the starting material had been consumed, with the formation of a number of products, one of which constituted the major component, 70%. The mixture was not separated but was analysed by mass spectrometry using the direct inlet probe method and a gradual increase in temperature to separate the components. In this fashion the mass spectrum of the major compound, which was tentatively assigned structure **11**, was obtained; ms (DIP, EI 70 eV): 438(M^+, 20), 436(M^+,6), 400(17), 385(20), 281(25), 161(17), 149(20), 119(23), 55(100).

6-Tosyloxycholest-5-en-3β-ol (13)

Silver tosylate (200 mg, 0.56 mmol) was added to a solution of **2** (250 mg, 0.40 mmol) in DMF (5 mL) and the mixture heated to 110°C for 30 min. By this time a grey precipitate had formed and tlc analysis of the reaction mixture indicated that all the starting material had been consumed. The solution was diluted with water (100 mL) and extracted with ether (3 × 20 mL). The extracts were dried over $MgSO_4$ and concentrated *in vacuo*. The residue was chromatographed on a Whatman PAC-Magnum 9 column and the major fraction collected. This material proved to be 6-tosyloxycholest-5-en-3β-ol (**13**) and was isolated as an oil; yield 90 mg, 40% of theory; ^{1}Hmr($CDCl_3$): 7.81(d, 2H, ArH), 7.42(d, 2H, ArH), 3.55(m, 1H, C3ax), 3.12(m, 1H, C4eq), 2.7(m, 2H, C7eq), 2.45(s, 3H), 2.30–0.7(42H); ms (DIP, EI 70 eV): 556(M^+, 2), 538(3), 402(8), 384(15), 365(10), 247(13), 185(14), 161(21), 121(44), 91(100), 57(54), 55(56).

JEAN CADET, LUCIENNE VOITURIEZ, FRANK E. HRUSKA, LOU-SING KAN, FRANK A. A. M. DE LEEUW, and CORNELIS ALTONA. Can. J. Chem. **63**, 2861 (1985).

We describe the preparation of the six configurationally distinct cyclobutane-type photodimers generated by the acetone-sensitized uv irradiation of thymidine in aqueous solution. Also prepared as minor photoproducts are the 5*R* and 5*S* diastereoisomers of 5,6-dihydrothymidine, and two novel molecules, the 5*R* and 5*S* diastereoisomers of 5-acetonyl-5,6-dihydrothymidine. The purification of the ten molecules by chromatographic techniques (hplc, tlc) is described, along with their extensive characterization by uv, ir, cd, FAB-ms and ^{1}H nmr. The proton chemical shifts and coupling constants are discussed in terms of the geometry of the pyrimidine, cyclobutane, and sugar rings.

JEAN CADET, LUCIENNE VOITURIEZ, FRANK E. HRUSKA, LOU-SING KAN, FRANK A. A. M. DE LEEUW et CORNELIS ALTONA. Can. J. Chem. **63**, 2861 (1985).

Les six diastéréoisomères possibles de la cyclobutidithymidine ont été préparés par photosensibilisation de la thymidine à la lumière du proche ultra-violet en utilisant l'acétone. Les diastéréoisomères 5*R* et 5*S* de la dihydro-5,6 thymidine et deux nouveaux photoproduits, les formes 5*R* et 5*S* de l'acétonyl-5 dihydro-5,6 thymidine ont aussi été isolés. L'identification de ces photoproduits a fait appel à diverses techniques spectroscopiques: uv, ir, dichroïsme circulaire, spectrométrie de masse par bombardement avec des atomes rapides et rmn ^{1}H. Les valeurs des paramètres de rmn (déplacements chimiques, constantes de couplage) sont discutées en termes de stéréochimie des cycles pyrimidiniques, cyclobutyles et osidiques.

Introduction

The cyclobutane-type of photoproduct formed from adjacent thymine bases is the most thoroughly studied of the lesions induced by uv irradiation of DNA (1). The biological significance of these thymine photodimers is evidenced by the existence of mechanisms for their removal (2). Several studies reveal that the presence of the dimers leads to distortions in nucleic acid structure (3–7) that could play a role in the recognition by the enzymes of the repair system and may account for the altered specificity of, for example, restriction enzymes which employ DNA as a substrate (8). The numerous studies of the photodimerized thymine bases, Thy⟨ ⟩Thy (R = H; Fig. 1), have provided valuable photochemical and structural information (1), but relatively fewer data are available for the corresponding thymidine derivatives, dThd⟨ ⟩dThd (R = 2-deoxy-β-D-ribose), which are the molecules of main interest in the present work. Wulff and Fraenkel (9) originally listed four isomeric forms of Thy⟨ ⟩Thy. Actually, six configurationally-distinct forms are possible, since the *trans–syn* (*ts*) and *cis–anti* (*ca*) isomers exist as enantiomeric pairs *ts*1, *ts*2 and *ca*1, *ca*2 whereas the *cis–syn* (*cs*) and *trans–anti* (*ta*) isomers exist as single (*meso*) molecules. Similarly, six dThd⟨ ⟩dThd are possible and are denoted CS, TS1, etc. according to the geometry of the Thy⟨ ⟩Thy fragment (Fig. 1). Partial characterization of the CS, TA, CA(+), and CA(−) diastereoisomers of dThd⟨ ⟩dThd has been made by Ben-Hur *et al.* (10) and Kuneida and Witkop (11).

In the present work we show that the six dThd⟨ ⟩dThd can be isolated from uv-irradiated aqueous solutions of dThd containing acetone as a photosensitizer. In addition to these dimers, which comprise 90% of the photoproduct mixture, we could isolate in smaller amounts the 5*R* and 5*S* diastereoisomers of 5,6-dihydrothymidine (DHT-*R* and DHT-*S*) and of the novel adducts 5-acetonyl-5,6-dihydrothymidine (ADT-*R*, ADT-*S*) (Fig. 2). The latter pair arise by the combination of the dihydrothymidin-5-yl and acetonyl radicals generated in the photosensitized solutions. The various products are characterized by cd, uv, ir, ^{1}H nmr, and mass spectrometric techniques.

There remains some uncertainty as to the structure of the photodimers formed in uv-irradiated DNA. Evidence has been provided (12) that the predominant product has the *cs* geometry; a minor *ts* product has also been detected (13), but its assignment to the *ts*1 or *ts*2 form was not made. Furthermore, it has been pointed out (4) that, though only a single *cs* isomer exists at the level of the photodimerized thymine bases or nucleosides, there are *two* possible diastereomers at the dinucleoside monophosphate level, d(T[p]T), each having a *cs* Thy⟨ ⟩Thy fragment but differing in the configurational relationship between the Thy⟨ ⟩Thy and sugarphosphate segments. (The two diastereomers were labelled A_1 and A_2 by Hruska *et al.* (4).) At present there is no information about the

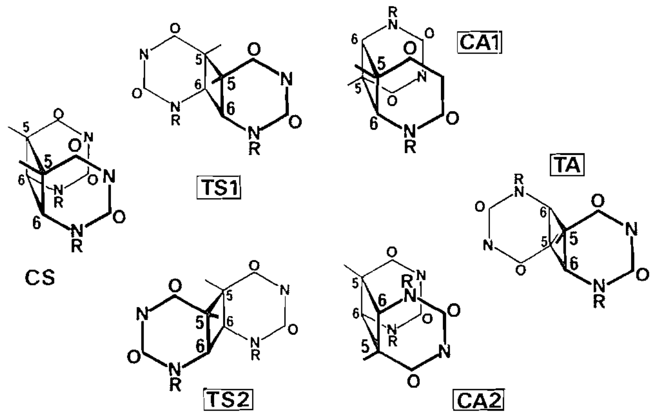

FIG. 1. Structure of the dThd⟨ ⟩dThd photodimers (R = 2-deoxy-D-ribose) with the *cis–syn* (CS), *trans–syn* (TS), *cis–anti* (CA), and *trans–anti* (TA) cyclobutane geometry. The corresponding Thy⟨ ⟩Thy (R = H) are denoted by *cs*, *ts*, *ca*, and *ta*.

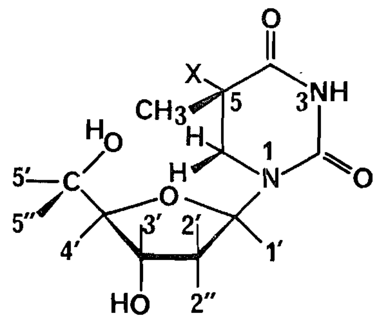

FIG. 2. Structure and atomic numbering of the 5*R* diastereoisomer of 5,6-dihydrothymidine (X = H) (DHT-*R*) and 5-acetonyl-5,6-dihydrothymidine (X = CH_3—CO—CH_2—) (ADT-*R*). Invert CH_3 and X at C5 to obtain *S* isomers, DHT-*S* and ADT-*S*.

proportion of the two isomers formed in uv-irradiated DNA, since characterization of the photodimers has been limited to the Thy⟨ ⟩Thy fragments after detachment from the sugars by acid hydrolysis of the *N*-glycosyl bonds (12). An additional question concerns the formation of the *ca* and *ta* forms. These are unlikely products of a uv-irradiated polynucleotide since geometrical constraints prevent their formation from thymines adjacent on a strand, and indeed they have not been detected above the base and nucleoside levels. However, the *ca* and *ta* forms could, in principle, result from fusion of distant bases of a properly folded strand, or from bases on separate strands.

Clearly there are important questions regarding the nature of the *cs* and *ts* products detected in DNA, and some interesting possibilities for the *ca* and *ta* forms. Our extensive data characterizing the six dThd⟨ ⟩dThd isomers could prove useful in these matters. Finally, our isolation of the novel acetonyl adducts should serve to caution those who use acetone as a uv photosensitizer to generate thymine dimers in DNA. Given the right conditions, these could be generated as minor products and would complicate the situation.

Results and discussion

Isolation of the molecules

Near uv photolysis (λ = 313 nm) of 2 m*M* dThd in acetone–water solution (35:65 v/v) gave rise to 10 photoproducts, which made up 95% of the product mixture, and a small amount of unidentified material. The 10 products were isolated by preparative thin-layer chromatography on silica gel plates and by reversed-phase hplc (14). Each showed with the cysteine – sulfuric acid reagent a pink coloration characteristic of 2′-deoxyribosides. Six of the products (**1**–**6**) constituting 90% of the mixture could be photoreversed to the starting material (dThd) by far uv light (λ > 250 nm), a feature of cyclobutadipyrimidines (15) and of the corresponding adducts formed by photocyclization of pyrimidine and psoralen ring systems (16). The other four, relatively minor products (**7**–**10**) did not undergo detectable photosplitting when exposed to far uv light. Evidence is presented below that they are the molecules represented in Fig. 2.

Structural assignments of the thymidine photodimers

Evidence of a dimeric structure for **1**–**6** is provided by their fast-atom bombardment (FAB) mass spectra. In the positive mode prominent peaks are observed at m/z 507 and m/z 485, which can be assigned, respectively, to the pseudomolecular $[M + Na]^+$ and $[M + H]^+$ ions of dThd⟨ ⟩dThd. The fragment at m/z 369 would reflect the loss of a single 2-deoxyribose unit from the dimeric species, whereas that at m/z 243 would reflect the cleavage of the cyclobutane ring to form the monomeric species $[\text{dThd} + H]^+$. In the negative FAB mode particularly prominent peaks at m/z 483 and m/z 241 would correspond to the $[M - H]^-$ and $[\text{dThd} - H]^-$ ions, respectively. The appearance of the molecular ions at high relative intensity (20–50%) demonstrates clearly the advantage of the soft-ionization FAB method for the analysis of the cyclobutane dimers. In her review, Fenselau (17) mentioned the unpublished report (S. Y. Wang, M. N. Khattak, and C. Fenselau) of molecular ions of a *fully-derivatized* Urd⟨ ⟩Urd generated at low relative intensity (ca. 2%) by electron impact ionization, but we are aware of no published report of molecular ions of an *underivatized* pyrimidine nucleoside photodimer that were generated by any of the commonly used ionization techniques. At the level of the photodimerized *bases*, Fenselau also noted (17) the unpublished report (H. Fales and S. Y. Wang) of molecular ions in the chemical ionization mass spectrum of Thy⟨ ⟩Thy (*cs*). However, this method would seem to be less useful for the corresponding nucleosides, due to their lower volatility. The absence of unambiguous molecular ion peaks in the electron impact mass spectra of cyclobutadipyrimidines has been widely reported (17), even when the bases are stabilized as their *N*-methyl derivatives. This has been attributed (17) to the facile fragmentation of the molecular ions as well as to the thermal fragmentation occurring before ionization.

Relative to dThd, photoproducts **1**–**6** show a bathochromic shift in their uv absorption maxima to about 220 nm, consistent with the saturation of their C5—C6 bonds (12). The upfield chemical shifts of 3.1–3.7 ppm in the H6 proton resonance and of 0.4 ppm in the methyl proton resonance are in line with the changes noted for thymine dimer formation in other systems (4, 9).

The configurations of **1**–**6** could be assigned following the release, by mild acid hydrolysis (12), of the corresponding Thy⟨ ⟩Thy fragment. Reasonable assignments of the *cs*, *ts*, *ca*, and *ta* isomers have been based on several X-ray crystallographic structure determinations (18), as well as on nmr (19) and ir (12) data. Thus, the major products **1** and **6**, were assigned the CS and TA configurations, respectively, by comparison of the hplc and ir characteristics of their Thy⟨ ⟩Thy fragments with those of Thy⟨ ⟩Thy prepared according to Weinblum and Johns (12). Furthermore, as expected for the *meso cs* and *ta* isomers, circular dichroic and optical rotation $[\alpha]_D$ measurements revealed no optical activity.

The acid hydrolysis of the two isomers (**4**, **5**) showing tlc behavior similar to that of **1** yielded Thy⟨ ⟩Thy which were assigned the *ca* geometry by considering their hplc and ir properties. Circular dichroic and optical rotation data identify the fragment from **4** as *ca*(+) and that from **5** as *ca*(−). The parent dThd⟨ ⟩dThd show the same sign of rotation as their Thy⟨ ⟩Thy and are denoted CA(+) and CA(−). Similarly **2** and **3** were shown to yield the fragments *ts*(+) and *ts*(−), respectively. **2** and **3** showed the same sign of rotation as their fragments and are denoted TS(+) and TS(−), respectively.

Unambiguous assignments of TS(+) and TS(−) to geometries TS1 and TS2, and of CA(+) and CA(−) to CA1 and CA2 (Fig. 1) are not possible in the absence of appropriate crystallographic data. Kuneida and Witkop (11) proposed a tentative assignment of CA(+) and CA(−) to CA2 and CA1, respectively, which was based on the assumption that the sign of the ord Cotton effect of CA2 would be the same as that of (*S*)-(−)-dihydrothymidine. (Note that these authors interchanged the CA and TS labels.) Extending their arguments to our cd spectra allows us to assign tentatively TS(+) and TS(−) to the TS1 and TS2 geometries, respectively. However, the Kuneida–Witkop reasoning seems to be based on the assumption that the sign of the Cotton effect associated with the C4 carbonyl absorption band is determined solely by the configuration of the methyl group at the contiguous C5 atom and is not inverted by the attachment of the second pyrimidine base. Examination of models of dThd⟨ ⟩dThd with reference to the octant rule (20) suggests that this assumption is open to discussion.

Structural assignment of the dihydrothymidines

Compounds **7** and **8** were assigned the structures DHT-*R* and DHT-*S*, respectively, by comparison of the ^{1}H nmr, uv, cd, and mass spectrometric properties with published data for these molecules (22). Evidence that photoproducts **9** and **10** involve the addition of an acetonyl fragment (Fig. 2) is provided by their FAB-ms spectra, which show the protonated molecular cation $(M + H)^+$ at m/z 301, the molecular anion $(M - H)^-$ at m/z 299, and the sodium adduct $(M + Na)^+$ at m/z 323. Support for the structure is provided by their 250-MHz ^{1}H nmr spectra, which show strong singlets at 1.3 ppm and 2.2 ppm that can be assigned to the C5 and acetonyl methyl groups, respectively. Furthermore, **9** and **10** show the expected AB patterns for the methylene hydrogen pairs of C6 centered at 3.4 ppm ($J(gem) = -12.5$ Hz) and of the acetonyl group centered at 3.1 ppm ($J(gem) = -18.7$ Hz). That no further splitting is seen in the AB patterns is consistent with the absence of a proton vicinal to either of these methylene groups. The diastereoisomeric relationship between **9** and **10** is indicated by the observation of a positive Cotton effect for **9** (hence ACD(+)) and a negative one for **10** (hence (ACD(−)). No absolute (*R*, *S*) assignment of **9** and **10** can be made at present.

The formation of thymine dimers via the triplet excited state is well documented (23–26). The generation of **7**–**10** via the triplet state also seems likely since we noted that it is inhibited in the presence of oxygen, a triplet state quencher (26). Analogous photoreductions and analogous photoadditions of acetonyl have been observed for olefins such as norbornene (27, 28) and dicyclopentadiene (29), with energy transfer to acetone from the triplet state of the olefin as the initial step of the process. Energy transfer to the acetone is expected to generate acetonyl radicals and hydrogen atoms (30). Addition of the hydrogen atoms to dThd (which occurs preferentially at C6 in aqueous solution and in the solid state (31, 32)) would generate the 5,6-dihydrothymidin-5-yl radical. Combination of this with an acetonyl radical could generate **9** and **10** in a process analogous to that involving the stable organic radical 2,2,6,6-tetramethyl-1,4-piperidone-*N*-oxyl, which has recently been reported (33). The competitive disproportionation involving two 5,6-dihydrothymidin-5-yl radicals would lead to **7** or **8**, and dThd (34). An additional mechanism for quenching by acetone that leads to oxetane derivatives has been noted in the near uv photolysis of uracil in aqueous solution (35). The corresponding oxetane derivatives of dThd were not noted here.

Nuclear magnetic resonance spectra of the thymidine photodimers

Additional evidence for the configurational assignments of dThd⟨ ⟩dThd follows from consideration of their symmetry properties and the appearance of the 600-MHz ^{1}H nmr spectra. The *ts* isomers of Thy⟨ ⟩Thy possess a two-fold rotation axis passing through the centres of the C5—C5 and C6—C6 bonds (Fig. 1). This axis is retained after attachment of the two deoxyribose sugars. The *ca* isomers possess a two-fold symmetry axis that is perpendicular to the cyclobutane ring at its centre and is retained after attachment of the two sugars. Thus, the two nucleoside units have "symmetrical equivalence" (36) in each of the four TS and TA isomers. This symmetry is reflected in their ^{1}H nmr spectra, which have the appearance of simple 2′-deoxyribonucleoside spectra, accountable for by a single set of chemical shifts (H6, etc.) and coupling constants ($J_{1'2'}$, etc.). In the sample spectrum of TS(+) (Fig. 3a) note in particular the single lines at 4.62 ppm and 1.37 ppm due to H6 and methyl protons, respectively.

In contrast, the *cs* isomer has a mirror plane perpendicular to the cyclobutane ring that bisects the C5—C5 and C6—C6 bonds, whereas *ta* is centrosymmetric. In neither case is the symmetry retained by the addition of the two D-sugars (it would be retained if one L-sugar replaced either of the D-sugars). Thus, the two nucleoside units are not symmetrically equivalent in CS and TA. This absence of symmetry is apparent in the ^{1}H nmr spectra of CS (Fig. 3b) and of TA, which show distinct signals from corresponding protons on the two fragments. Note in the CS spectrum the AB pattern centered at 4.32 ppm due to the nonequivalent H6 protons ($J_{66} = 5.3$ Hz) and the pair of single resonances at 1.49 ppm and 1.45 ppm due to the pair of methyl groups (Fig. 3b). By spin-decoupling experiments the sugar protons (but not H6 or the methyl group) could be associated with the "A" or "B" units of CS or of TA, but an absolute assignment of two units could not be made for either of these two isomers.

The magnitude of J_{66} in CS (5.3 Hz) is similar to that observed (19) in the ^{13}C satellite spectra of *cs* (4.8 Hz), which suggests that the extent of pucker of the cyclobutane ring is similar in the two molecules. A larger J_{66} (ca. 6.0 Hz) was noted in d(T[*p*]T) (*cs* isomer) which may be a reflection of a somewhat flatter ring in the photodimerized dinucleoside monophosphate (4). J_{66} is about 0 Hz in TA, consistent with the general attenuation of four-bond coupling constants (37). For the same reason the four-bond J_{66} in the TS and CA isomers is expected to be about zero. However, because of their equivalence in TS and CA, any coupling between the H6 protons would not be seen in their spectrum.

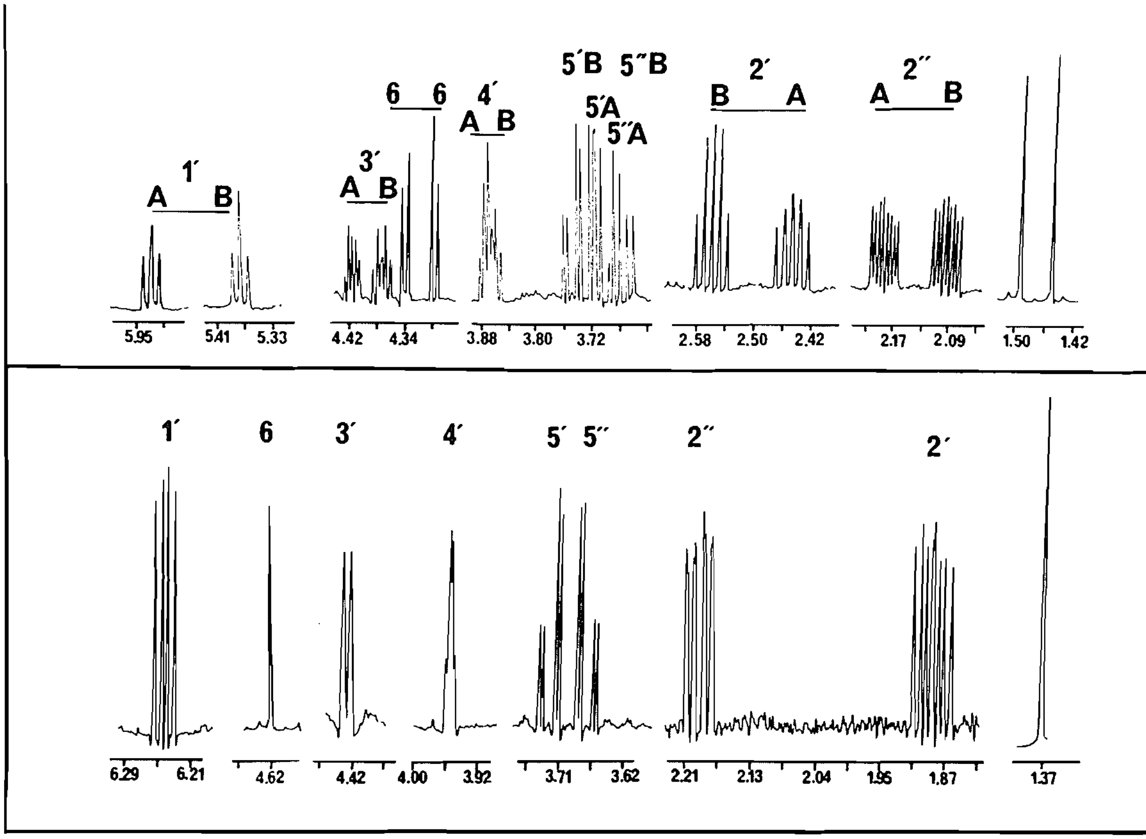

FIG. 3. The 600.1-MHz ^{1}H nmr spectra of (a) (bottom) **2**, or TS (+), and (b) (top) CS in aqueous solution relative to TSP. In b, the signals were assigned to the "A" or "B" nucleoside by homonuclear spin decoupling experiments. In a, the two units are symmetrically equivalent.

Sugar conformation

The ^{1}H chemical shifts and coupling constants (Tables 1, 2) reveal little conformational variation for the sugar rings of **7–10** (Table 3). The bias towards the *S*-type pucker (64–69%, estimated following de Leeuw and Altona (38)) is characteristic of 2′-deoxyribosides, but is slightly enhanced relative to 5,6-saturated pyrimidine 2′-deoxyribosides (60%) (39). The *J* data reveal no unusual behaviour in the phase angles of pseudorotation (P) or the amplitudes of pucker (τ_m). The $\Sigma(J_{4'5'} + J_{4'5''})$ values lie in the range 8.8–9.6 Hz, revealing values of 45 ± 4% for $\%g^{+}$ (C4′—C5′) which are marginally smaller than those noted for 5,6-unsaturated molecules (39). The ^{1}H chemical shifts of, in particular, H1′ and H2′ suggest no exceptional behavior in the *syn–anti* blend about the *N*-glycosyl linkage of **7–10**.

The dThd⟨ ⟩dThd show a greater variation in sugar *S*-type

population (Table 3). Thus, on the one hand, **1** (sugar rings A and B), **3**, **5**, and **6** (sugar B) resemble **7–10** in ring pucker (%*S*: 66–67%) and in the C4′—C5′ conformer distribution (%g: 40–53%) but, on the other hand, **2**, **4**, and **6** (sugar A) show increased importance of *S* pucker and the g^+ conformer about C4′—C5′. This trend is particularly strong in **2**, or TS(+) (96% *S*; 81% g^+). This exceptional behavior in TS(+) is accompanied by an unusually large upfield shift in H2′ to 1.89 ppm. In no other molecule has the H2′ signal been noted at less than 2 ppm from the TSP reference. Thus the geometrical constraints required for the formation of a cyclobutane ring system are reflected in the sugar conformation, as has been noted in d(T⟨p⟩T) (4). Finally, it is interesting to point to the prevailing trend in **1–10** for %g^+ to increase with increasing %*S*; a similar situation has been noted for other 5,6-saturated pyrimidine nucleosides (40).

Geometry of the pyrimidine ring in 7–10

Evidence points to a distorted half-chair conformation for 5,6-saturated pyrimidines in which C5 and C6 lie on opposite sides of the plane defined by N1, C2, N3, C4, with the substituents at C5 and C6 occupying pseudo-axial and pseudo-equatorial positions (16, 41–45). In **7** and **8** the pair of vicinal H–H coupling constants involving H5 with the methylene protons at C6 provide information about this geometry. Analysis of the ABX system yields vicinal couplings of 10.6 Hz and 6.0 Hz for **7**, and 9.4 Hz and 5.5 Hz in **8**. (A geminal H6–H6 coupling of about 12.5 Hz was noted in each case.) The larger of the couplings indicates that in **7** and in **8** H5 has a *trans*, diaxial relationship with one of the H6 hydrogens, and thus the preferred conformation of **7** and **8** must be as indicated in Fig. 4. The smaller of the couplings is in line (44) with the equatorial position for the second C6 proton. In each case the 5-methyl occupies an equatorial position, a preference that is apparent in the crystal state (16). It is interesting to note that the axial H6 is less shielded, by about 0.3–0.4 ppm, than the equatorial one. A similar analysis of the ring pucker of **9** and **10** can not be made.

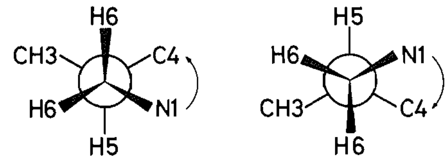

FIG. 4. Preferred conformation of DHT-*T* (left) and DHT-*S* (right) based on the magnitudes of the two vicinal H5–H6 coupling constants. View from C6 to C5.

Conclusion

We have shown that all six dThd⟨ ⟩dThd photodimers can be isolated from acetone-sensitized uv irradiation of aqueous thymidine solutions. Also produced as minor photoproducts are the 5*R* and 5*S* diastereomers of 5,6-dihydrothymidine and of the novel adduct 5-acetonyl-5,6-dihydrothymidine. Extensive spectroscopic and mass spectrometric data are provided for the ten molecules. Particularly important is the clear demonstration of the advantages of the FAB method for mass spectral analysis of thymidine photodimers.

Experimental

Spectroscopic measurements

The uv absorption spectra were recorded on a Beckman spectrophotometer (model 5230). The ir spectra (KBr micropellet method) were obtained on a Perkin–Elmer spectrophotometer (model 177). Fast atom bombardment (FAB) mass spectrometry was carried out on a Kratos spectrometer (model MS 50) equipped with a commercially available FAB gun; desorption of the molecules in a glycerol mull was effected by exposure to a 8-keV beam of xenon atoms.

Optical rotation and circular dichroism (cd) spectra were recorded in methanol or water with a Quick Jouan polarimeter and a Jobin–Yvon spectrometer respectively.

The decoupled and nondecoupled ^{1}H nmr spectra of the six dThd⟨ ⟩dThd isomers were recorded with resolution enhancement on a 600-MHz spectrometer located at the Carnegie–Mellon University (Pittsburgh, PA). The spectrometer is operated (20°C) in the fast-correlation spectrum mode using the HDO solvent resonance as the lock. 2,2-Dimethyl-2-silapentane (DSS) was used as the internal reference. Spectra for the four 5,6-dihydrothymidines and their 5-acetoxy derivatives were obtained on a 250-MHz Cameca TSN spectrometer (FT mode, 20°C). The nucleoside samples were lyophilized twice and dissolved in 99.9% D_2O to a concentration of 0.05 *M*. Metal ions were removed using Chelex-100 resin columns (Bio-Rad, Richmond, CA). Spectral analysis (LAOCOON III) and computer simulated spectra were the final test of the chemical shift (δ) and coupling constant (*J*) data listed in Tables 1 and 2. Pseudorotational parameters were calculated with the PSEUROT program (38) and are given in the relevant sections.

High performance liquid chromatography (hplc)

The high performance liquid equipment consists of a Model 6000 dual piston pump (Waters Associates, Milford, MA) and a Rheodyne Model 7100 loop injector (Berkeley, CA). The solutes were detected either by using a Model RI 401 refractometer index detector (Waters Associates) and (or) a Cecil Model CE 212 variable uv wavelength spectrophotometer (Cecil, Cambridge, U.K.) operating at 230 nm. It should be mentioned that no detectable photoreversion of any cyclobutadithymidine was observed under these detection conditions due to the very low intensity of the far uv light in the flow cell. Analytical stainless steel columns (25 × 0.47 cm id) were packed under 400 atm (1 atm = 101.3 kPa) with a Haskell pump (Chromatem, Paris, France) by using 10-μm octadecylsilyl silica gel bonded phase Lichrosorb RP-18 (Merck, Darmstadt, G.F.R.). Propan-1-ol was used as the dispersing agent for the preparation of the slurry, which was sonicated before the packing procedure.

Thin-layer chromatography

Two-dimensional thin-layer chromatography analyses were carried out on 20 × 20 cm precoated silica gel plates F_{254} (Merck). Eluent 1 was the lower phase of chloroform–methanol–water (4:2:1) v/v to which 5 mL of methanol was added for each 100 mL of the organic phase. Eluent 2 consisted of ethyl acetate – propan-2-ol – water (75:16:9).

Visualization of 2′-deoxyribonucleosides was made by spraying the chromatoplates with the cysteine – sulfuric acid reagent and subsequent heating for 5 min at 100°C. Cyclobutadithymidines were visualized by fluorescence quenching at 254 nm after photoreversal to thymidine upon exposure to wavelength lower than 230 nm.

Ultraviolet irradiation

Near uv irradiation was carried out in a Pyrex glass flask with a bank of 6 BLB lamps (λ_{max} centered about 313 nm). Thymidine (350 mg) (Sigma Chemical Co.) was dissolved in 180 mL of water and 100 mL of acetone. Prior to irradiation the solution was degassed for 30 min with a stream of nitrogen saturated with aqueous acetone. During photolysis the sample was air-cooled with a fan. The solution was irradiated for 18 h, giving over 95% decomposition of the starting material. The solution was evaporated to dryness, and the resulting yellow residue was applied to three precoated, thick-layer, preparative silica gel chromatographic plates (Merck, Darmstadt). The plates were developed with eluent system 1. Five bands could be detected by spraying the plates with a cysteine – sulfuric acid reagent, followed by heating at 100°C for 3 min.

(−) cis–anti *thymidine⟨⟩thymidine (5)*

The slowest moving zone (R_f 0.15) was scraped off and the resulting silica gel was extracted with 3 × 20 mL of water–methanol (1:1). Evaporation to dryness of the aqueous methanolic solution yielded 35 mg of an oily residue which contained two major compounds as shown by reversed-phase high performance liquid chromatography analysis. The mixture of photoproducts was dissolved in 2 mL of aqueous methanol (9:1) and 0.1 mL of the resulting solution was applied for each injection on the RP-18 octadecylsilylsilicagel column. Elution was accomplished with an aqueous solution of methanol (9:1) in an isocratic mode. The fractions containing the fastest eluting nucleoside (k' = 3.11), as monitored by its uv absorption at 230 nm, were collected. Evaporation to dryness of the resulting aqueous methanol solution afforded 14 mg of (−) *cis–anti* cyclobutadithymidine (2%) as a colorless hygroscopic solid; $[\alpha]_D^{22}$ − 45° (*c* 2.1, in H_2O); uv (λ_{max} H_2O): 220 nm; cd(*c* 2.1, H_2O): $[\theta]_{290}$ ≈0, $[\theta]_{280}$ −40, $[\theta]_{270}$ −1040, $[\theta]_{260}$ −4400, $[\theta]_{252}$ −5920, $[\theta]_{250}$ −5800, $[\theta]_{240}$ −2000, $[\theta]_{236}$ ≈0, $[\theta]_{230}$ +2800, $[\theta]_{227}$ +3200, $[\theta]_{220}$ +2160; FAB-ms, *m/e* (relative intensity), positive mode: 529 (6, M^+ + 2 Na), 507 (19, M^+ + Na), 447 (6), 391 (7, M^+ + Na − deoxyribose), 287 (15, thymidine + 2 Na), 265 (10, thymidine + Na), 150 (21), 116 (36); negative mode: 483 (19, M^- − H), 241 (24, thymidine − H), 125 (100, thymidine − H).

(+) cis–anti *thymidine⟨⟩thymidine (4)*

Evaporation to dryness of the second main hplc fractions (k' = 4.21) gave 13 mg of (+) *cis–anti* cyclobutadithymidine (1.9%) as a hygroscopic solid, which was recrystallized from aqueous methanol (95:5); mp 222–224°C (lit. (11) mp 150°C); $[\alpha]_D^{22}$ + 48.8° (*c* 1.8, in H_2O); uv (λ_{max} H_2O): 219 nm; cd (*c* 1.9, H_2O): $[\theta]_{300}$ ≈0, $[\theta]_{290}$ +80, $[\theta]_{280}$ +200, $[\theta]_{270}$ +1280, $[\theta]_{260}$ +4400, $[\theta]_{250}$ +6600, $[\theta]_{248}$ +6880, $[\theta]_{240}$ +4240, $[\theta]_{235}$ ≈0, $[\theta]_{224}$ −6360; FAB-ms, *m/e* (relative intensity), positive mode: 969 (2, $2M^+$ + H), 507 (22, M^+ + Na), 485 (17, M^+ + H), 369 (7, M^+ − deoxyribose), 335 (8, thymidine + glycerol), 243 (43, thymidine + H), 207 (84); negative mode: 967 (1, $2M^-$ − H), 483 (36, M^- − H), 241 (44, thymidine − H).

cis–syn *thymidine⟨⟩thymidine (1)*

The silica gel containing the main photoproduct **1** (R_f 0.22) was extracted with 3 × 10 mL of 50% aqueous methanol. The resulting solution was evaporated to dryness, giving 73 mg of a mixture of the three nucleosides **1**, **4**, and **5** with a preponderance of the *cis–syn* cyclobutidithymidine (**1**). The latter photoproduct was further purified by reversed-phase high performance liquid chromatography as reported above. The main uv absorbing fractions (k' = 9.50) were collected and evaporated to dryness under reduced pressure, yielding 60 mg of **1** (8.6%) as a white solid that was further recrystallized from aqueous methanol (95:5); mp 182–184°C (lit. (11) mp 184–188°C); $[\alpha]_D^{22}$ +10.2 (*c* 1.7, in H_2O); uv λ_{max} H_2O): 219 nm; cd (*c* 2.3, H_2O): $[\theta]_{280}$ ≈0, $[\theta]_{270}$ +20, $[\theta]_{260}$ +280, $[\theta]_{250}$ +800, $[\theta]_{240}$ +1500, $[\theta]_{233}$ +1720, $[\theta]_{230}$ +1340, $[\theta]_{226}$ ≈0, $[\theta]_{224}$ −1060; FAB-ms, *m/e* (relative intensity), positive mode: 507 (12, M^+ + Na), 485 (9, M^+ + H), 369 (11, M^+ − deoxyribose), 243 (9, thymidine + H), 127 (46, thymine + H), 117 (49, deoxyribose); negative mode: 483 (19, M^- − H), 367 (12, M^- − deoxyribose), 241 (10, thymidine − H), 125 (46, thymine − H).

(+) trans–syn *thymidine⟨⟩thymidine (2)*

The silica gel containing the three *trans* diastereoisomers of dThd⟨⟩dThd (R_f 0.34) was scraped off and further extracted with 3 × 20 mL of aqueous methanol (1:1). The solution was evaporated to dryness under reduced pressure. The resulting oily residue (96 mg) was shown to contain three main photoproducts, which were separated by reversed phase hplc on the RP-18 ODS column using water–methanol (9:1) as the isocratic solvent. The fastest eluting fractions (k' = 2.60) were collected and combined. Evaporation to dryness of the resulting solution afforded 8 mg of (+) *trans–syn* cyclobutadithymidine (**2**) (1.1%); $[\alpha]_D^{22}$ + 11.0 (*c* 2.2, in H_2O); uv (λ_{max} H_2O): 219 nm; cd (*c* 1.8, H_2O): $[\theta]_{290}$ ≈ 0, $[\theta]_{280}$ −290, $[\theta]_{270}$ −1680, $[\theta]_{260}$ −3920, $[\theta]_{255}$ −4400, $[\theta]_{250}$ −4000, $[\theta]_{240}$ ≈0, $[\theta]_{230}$ + 8800; FAB-ms, *m/e* (relative intensity), positive mode: 507 (10, M^+ + Na), 369 (8, M^+ − deoxyribose), 243 (20, thymidine + H), 127 (20, thymine + H); negative mode: 483 (29, M^- − H), 367 (12, M^- − deoxyribose), 241 (60, thymidine − H), 125 (100, thymine − H).

(−) trans–syn *Thymidine⟨⟩thymidine (3)*

The combined eluting fractions (k' = 3.23) containing the (−) *trans–syn* dThd⟨⟩dThd (**3**) as monitored by its uv absorption at 230 nm were evaporated to dryness under reduced pressure yielding 10 mg of **3** (1.4%) as an oily compound; $[\alpha]_D^{22}$ −38.6° (*c* 2.4, in H_2O); uv (λ_{max} H_2O): 218 nm; cd (*c* 2.0, H_2O): $[\theta]_{290}$ ≈0, $[\theta]_{280}$ +80, $[\theta]_{270}$ +1420, $[\theta]_{260}$ +5050, $[\theta]_{250}$ +7880, $[\theta]_{248}$ +8000, $[\theta]_{240}$ +5280, $[\theta]_{233}$ ≈0, $[\theta]_{230}$ −4240, $[\theta]_{227}$ −8000; FAB-ms, *m/e* (relative intensity), positive mode: 509 (2, M^+ + Na), 127 (30, thymine + H) 118 (59, deoxyribose + H); negative mode: 575 (2, M^- + glycerol), 483 (45, M^- − H), 367 (16, M^- − deoxyribose), 241 (23, thymidine − H), 219 (30), 192 (85), 152 (60), 125 (75, thymine − H).

trans–anti *Thymidine⟨⟩thymidine (6)*

Evaporation to dryness of the slowest eluting hplc fractions (k' = 11.00) gave 54 mg of *trans–anti* dThd⟨⟩dThd (9.8%) that was recrystallized from water–methanol (95:5) as a white solid; mp 170–172°C; $[\alpha]_D^{22}$ −3.0° (*c* 4.2, in H_2O); uv (λ_{max} H_2O): 219 nm; cd (*c* 2.1, H_2O): $[\theta]_{280}$ ≈0, $[\theta]_{270}$ −20, $[\theta]_{261}$ −40, $[\theta]_{260}$ −30, $[\theta]_{257}$ ≈0, $[\theta]_{250}$ +320, $[\theta]_{240}$ +1050, $[\theta]_{238}$ +1080, $[\theta]_{230}$ +40, $[\theta]_{229}$ ≈0, $[\theta]_{225}$ −1000; FAB-ms, *m/e* (relative intensity), positive mode: 507 (4, M^+ + Na), 485 (6, M^+ + H), 243 (29, thymidine + H), 127 (89, thymine + H); negative mode: 483 (4, M^- − H), 241 (5, thymidine − H), 125 (10, thymine − H).

(+) (5R)-*5,6-Dihydrothymidine (7)*

The fastest eluting tlc zone (R_f 0.53) was scraped off and the resulting silica gel was extracted with 3 × 20 mL of aqueous methanol (1:1). Evaporation to dryness of the resulting filtrate provided 33 mg of a mixture of the four dihydrothymidine derivatives **7**, **8**, **9**, and **10**, which was applied on the RP-18 ODS column. A complete separation of the four photoproducts was achieved using a mixture of methanol–water (9:1) as the solvent. Evaporation of the fastest eluting compound ($k' = 1.96$), which was detected by its uv absorption at 230 nm, yielded 6 mg of (+) (5*R*)-5,6-dihydrothymidine (1.7%) as a white solid; uv (λ_{max} H_2O) 219 nm; cd (*c* 4.7, methanol): $[\theta]_{275}$ ≈0, $[\theta]_{270}$ −40, $[\theta]_{260}$ −200, $[\theta]_{250}$ −900, $[\theta]_{240}$ −2100, $[\theta]_{239}$ −2400, $[\theta]_{230}$ −600. *Anal.* calcd. for $C_{10}H_{16}N_2O_5$: C 49.17, H 6.60, N 11.47; found: C 49.12, H 6.34, N 11.39.

(−) (5S)-*5,6-Dihydrothymidine (8)*

Evaporation to dryness under reduced pressure of the second eluting fractions ($k' = 2.24$) gave 7 mg of **8** (2%). This nucleoside was found to exhibit identical uv, ^{1}H nmr, and cd spectroscopic features to those of the authentic sample as prepared by catalytic hydrogenation of thymidine in the presence of Rhd/Al_2O_3; mp 154–155°C (lit. (21) mp 152–153°C); $[\alpha]_D^{22}$ −19.5° (*c* 1.4, in H_2O) (lit. (21) $[\alpha]_D^{22}$ = −20.5° (*c* 1.1, in H_2O); cd (*c* 5.2, methanol): $[\theta]_{275}$ ≈0, $[\theta]_{270}$ +30, $[\theta]_{260}$ +130, $[\theta]_{250}$ +660, $[\theta]_{240}$ +1750, $[\theta]_{238}$ +1800, $[\theta]_{230}$ +500. *Anal.* calcd. for $C_{10}H_{16}N_2O_5$: C 49.17, H 6.60, N 11.47; found: C 49.08, H 6.55, N 11.40.

(+) *5-Acetonyl-5,6-dihydrothymidine (9)*

The hplc fractions containing the photoproduct **9** ($k' = 2.89$) were combined and evaporated to dryness under reduced pressure. The resulting oily compound **9** (5 mg, 1.4%) was shown to be homogeneous by two-dimensional tlc analysis on precoated silica gel plates using eluents 1 and 2; uv (λ_{max} H_2O) 219 nm; cd (*c* 1.3, H_2O): $[\theta]_{280}$ ≈0, $[\theta]_{270}$ +40, $[\theta]_{250}$ +1560, $[\theta]_{240}$ +4040, $[\theta]_{238}$ + 4060, $[\theta]_{230}$ +1480, $[\theta]_{228}$ ≈0, $[\theta]_{224}$ −2920; FAB-ms, *m/e* (relative intensity), positive mode: 323 (11, M^+ + Na), 301 (10, M^+ + Na), 301 (10, M^+ + H), 117 (9, 2-deoxyribose); negative mode: 299 (5, M^- − H), 255 (5), 149 (15).

(−) *5-Acetonyl-5,6-dihydrothymidine (10)*

Evaporation to dryness of the slowest eluting hplc fraction (k' = 3.40), as detected by its absorption at 230 nm, yielded 6 mg of **10** (1.7%) as an oily homogeneous compound; uv (λ_{max} H_2O) 219 nm; cd (*c* 1.9, H_2O): $[\theta]_{290}$ ≈0, $[\theta]_{280}$ +40, $[\theta]_{270}$ ≈0, $[\theta]_{260}$ −160, $[\theta]_{250}$ −1360, $[\theta]_{240}$ −2920, $[\theta]_{239}$ −2980, $[\theta]_{230}$ −1080, $[\theta]_{228}$ ≈0, $[\theta]_{223}$ +2760; FAB-ms, *m/e* (relative intensity), positive mode: 323 (12, M^+ + Na), 301 (10, M^+ + H), 117 (11, deoxyribose); negative mode: 299 (7, M^- − H), 255 (8), 149 (18).

cis–syn *Thymine⟨⟩thymine*

A 10% HCl aqueous solution of 7 mg of the *cis–syn* cyclobutadithymidine (**1**) was heated at 90°C for 20 min. Then the aqueous solution was evaporated to dryness and the resulting residue was crystallized from water to give colorless prisms. This compound, which was found to be homogeneous by two-dimensional thin-layer chromatography, shows a similar capacity factor ($k' = 2.64$) to that of the authentic *cis–syn* cyclobutadithymine on an ODS-Nucleosil C_{18} column (14) by using water as the eluent. In addition, this compound, which does not exhibit any optical activity, has an identical ir spectrum to that of the *cis–syn* thymine cyclobutyl dimer (12).

trans–anti *Thymine⟨⟩thymine*

Acidic hydrolysis of 8 mg of *trans–anti* cyclobutadithymidine (**6**) under the above conditions yielded 3 mg of *trans–anti* cyclobutadithymine as a colorless solid, after crystallization from water. The retention times ($k' = 3.75$) and the ir spectrum were identical to those of the authentic *trans–anti* thymine dimer (12).

(+) cis–anti *Thymine⟨⟩thymine*

Acidic hydrolysis of 7 mg of the (+) *cis–anti* diastereoisomer of cyclobutadithymidine with 10% HCl for 20 min at 90°C gave quantitatively the (+) *cis–anti* enantiomer of the thymine cyclobutyl dimer. This compound, which was crystallized from water as colorless prisms (3 mg), has an identical capacity factor ($k' = 1.86$) and ir spectroscopic features to those of the racemic *cis–anti* cyclobutadithymine; cd (*c* 1.7, H_2O): $[\theta]_{280}$ ≈0, $[\theta]_{270}$ +1320, $[\theta]_{260}$ +6390, $[\theta]_{250}$ +9140, $[\theta]_{240}$ +5400, $[\theta]_{236}$ ≈0, $[\theta]_{230}$ −4070.

(−) cis–anti *Thymine⟨⟩thymine*

The levorotatory diasteroisomer (6 mg) of the *cis–anti* cyclobutadithymidine was hydrolyzed with 10% HCl at 90°C for 20 min. Evaporation of the solvent, followed by crystallization of the residue from water, gave 2.5 mg of (−) *cis–anti* cyclobutadithymine as colorless prisms. The ir spectrum and the hplc capacity factor ($k' = 1.85$) of this compound are identical to those of the *cis–anti* thymine cyclobutyl dimer; cd (*c* 1.9, H_2O): $[\theta]_{280}$ ≈0, $[\theta]_{270}$ −1350, $[\theta]_{260}$ −6400, $[\theta]_{250}$ −9150, $[\theta]_{240}$ −5400, $[\theta]_{236}$ ≈0, $[\theta]_{230}$ +4090.

Influence cinétique et chimique d'alcènes sur la pyrolyse d'alcanes: mise au point et nouveaux résultats

FRANCIS BILLAUD, FRANÇOIS BARONNET[1] ET MICHEL NICLAUSE
Département de chimie–physique des réactions, L.A. n° 328 C.N.R.S., I.N.P.L.–E.N.S.I.C., 1, rue Grandville, 54042 Nancy, France

Reçu le 22 novembre 1984

FRANCIS BILLAUD, FRANÇOIS BARONNET et MICHEL NICLAUSE. Can. J. Chem. **63**, 2869 (1985).

En tenant compte de résultats antérieurs et à partir de nouveaux résultats expérimentaux, nous présentons une mise au point sur l'influence cinétique et chimique d'alcènes sur la pyrolyse d'alcanes. L'ensemble de ces résultats confirme que les processus d'*addition* d'atomes libres H· sur la double liaison d'alcènes ne paraissent pas suffisants pour rendre compte de leur influence *cinétique* (inhibitrice) sur la pyrolyse d'alcanes. Nos résultats montrent en revanche que ces processus d'addition permettent d'interpréter l'effet *chimique* d'alcènes ajoutés sur la pyrolyse d'alcanes, c'est-à-dire les modifications apportées à la nature et à la répartition des produits de la réaction. La présente contribution permet de vérifier que l'addition de radicaux alcoyle sur la double liaison d'alcènes ne conduit pas à d'importants effets chimiques. Les résultats expérimentaux antérieurs (pyrolyse de l'éthane en présence d'éthylène ou de propène, pyrolyse du diméthyl-2,2 butane en présence de propène, d'isobutène ou de deux isopentènes) complétés par de nouveaux résultats (pyrolyse de l'éthane en présence d'isobutène, pyrolyse de l'isobutane en présence d'éthylène, de propène, de butène-2 *trans* ou de méthyl-2 butène-2) conduisent à proposer des règles générales relativement simples; elles permettent d'interpréter et de prévoir les modifications de la nature et de la répartition des produits de la pyrolyse d'un alcane vers 500°C (773 K) par l'addition d'un alcène. En dehors de leur aspect fondamental, ces observations et leurs conséquences mécanistiques peuvent se révéler utiles lors de la modélisation de réactions thermiques, en particulier pour la simplification de modèles complexes. Ces observations expliquent également un certain nombre d'observations effectuées sur des unités industrielles et peuvent apporter une contribution aux problèmes posés par le traitement des coupes pétrolières lourdes.

FRANCIS BILLAUD, FRANÇOIS BARONNET, and MICHEL NICLAUSE. Can. J. Chem. **63**, 2869 (1985).

On the basis of previously reported, as well as new, experimental results, a review is presented of the kinetic and chemical influences of alkenes on the pyrolysis of alkanes. The results confirm that the *addition* of free H· atoms to the double bonds of alkenes is not sufficient to explain their inhibiting influence on the pyrolysis of alkanes. On the contrary, our results show that the processes of addition can account for the *chemical* effects of added alkenes on the pyrolysis of alkanes, namely, the modifications brought to the nature and the ratio of the products formed during the reaction. The results presented here confirm that the addition of alkyl free radicals to the double bond of alkenes does not lead to important chemical effects. The previously reported experimental results (pyrolysis of ethane in the presence of ethylene or propene, the pyrolysis of 2,2-dimethylbutane in the presence of propene, isobutene, or two isopentenes), completed by our new results (pyrolysis of ethane in the presence of isobutene, pyrolysis of isobutane in the presence of ethylene, of propene, of *trans*-2-butene, or of 2-methyl-2-butene), can lead to very simple general rules, on the basis of which it is possible to explain the results and to predict the modifications (relating to the nature of the products and to their ratios) that will result from the addition of an alkene during the pyrolysis of an alkane at a temperature of 500°C (773 K). Aside from their fundamental aspects, these observations and their mechanistic consequences could be useful for the preparation of models for these thermal reactions, especially for the simplification of complex models. These observations also explain certain facts observed in industry and can help in solving some of the problems associated with the thermal cracking of heavy oils.

Introduction

L'influence d'alcènes, généralement de C_2 à C_4, sur la pyrolyse d'alcanes légers (de C_2 à C_5 ou C_6) a fait l'objet de nombreux travaux. Ces recherches avaient pour but principal d'élucider l'origine de l'effet inhibiteur exercé par ces alcènes sur la pyrolyse d'alcanes. Les alcènes peuvent être ajoutés à l'instant initial ou générés au cours de la réaction donnant lieu ainsi respectivement aux phénomènes d'inhibition ou d'auto-inhibition.

De tels travaux ont été menés de façon active dans différents laboratoires, en particulier à Nancy (Niclause et coll.) et à Swansea (Purnell et coll.). Ils ont conduit à une bonne compréhension des processus à l'origine de l'inhibition et de l'auto-inhibition de la pyrolyse d'alcanes par des alcènes. Ces effets cinétiques ont été interprétés par deux types de mécanismes dont les importances relatives peuvent varier en fonction de différents facteurs: nature de l'alcène, nature des radicaux porteurs de chaînes dans la pyrolyse de l'alcane, conditions opératoires, etc...

Le premier type de mécanismes consiste en l'*arrachement* d'un atome d'hydrogène de la molécule de l'alcène par un radical porteur de chaînes de la pyrolyse de l'alcane, conduisant à un radical stabilisé par résonance, donc relativement peu réactif. C'est ainsi que ce mécanisme a permis d'interpréter l'inhibition de la pyrolyse du néopentane par le propène (1) ou l'isobutène (2) et l'auto-inhibition de cette même réaction par l'isobutène formé (2–4). Il a fait également l'objet de généralisations par Niclause et coauteurs (5, 6).

Le second type de mécanismes consiste en l'*addition* d'un atome d'hydrogène, porteur de chaînes, sur la double liaison de la molécule d'alcène pour donner un radical relativement stable thermiquement lorsqu'il ne peut se décomposer unimoléculairement que par rupture d'une liaison C—H. Ce radical intervient alors dans des processus de terminaison. C'est ainsi que Purnell et coauteurs ont interprété l'auto-inhibition de la pyrolyse du propane par le propène (7) et celle de l'isobutane par l'isobutène (8), tout au moins à relativement "basse" température (423–462°C, 696–735 K) et "haute" pression (300–550 Torr; 1 Torr = 133.3 Pa).

Certaines controverses ont parfois eu lieu pour préciser la

[1] Auteur à qui adresser la correspondance.

part de chaque type de mécanisme pour rendre compte de l'auto-inhibition observée dans des exemples où les deux mécanismes pouvaient intervenir simultanément. En effet, les modèles mathématiques des lois de vitesse ont des formes voisines avec l'un ou l'autre des deux mécanismes possibles d'auto-inhibition (9). Des études complémentaires ont été réalisées, avec pour but de résoudre cette difficulté, sur les exemples de l'isobutane (10) et du propane (11), mais elles n'ont pas permis d'éliminer un des mécanismes possibles d'inhibition.

Par conséquent, à quelques détails mécanistiques près, l'ensemble des travaux effectués sur les pyrolyses d'alcanes légers a conduit à une bonne connaissance du rôle *cinétique* des alcènes sur ces pyrolyses.

Certaines études entreprises il y a une dizaine d'années avaient conduit à penser que, non seulement l'alcène ajouté ou généré dans la réaction avait l'effet cinétique mentionné ci-dessus, mais qu'il pouvait aussi, dans certains cas, modifier la répartition des produits issus de la pyrolyse de l'alcane et faire apparaître de nouveaux produits, c'est-à-dire avoir aussi un effet *chimique*.

De telles complications avaient été observées par Scacchi et coauteurs lors de l'étude de l'influence du butène-2 *trans* sur la pyrolyse de l'éthane (12) et par Rondeau *et al.* lors de l'étude de l'inhibition de la pyrolyse de l'isobutane par des alcènes (13). Ces premières observations avaient conduit à penser qu'il se produisait en réalité une *co-réaction* entre l'alcane et l'alcène. Des travaux de Purnell et Pacey (14, 15) allaient également dans ce sens.

Il nous a donc semblé opportun, tant d'un point de vue fondamental qu'en vue d'une meilleure maîtrise des réactions de craquage des hydrocarbures (optimalisation des rendements, amélioration de la sélectivité), d'entreprendre une étude systématique de ces effets chimiques sur des exemples significatifs. Notre but était une généralisation des premières conclusions des articles précités et la formulation de règles permettant de décrire et de prévoir les modifications envisageables dans la nature et la répartition des produits formés dans la réaction thermique d'un alcane vers 500°C (773 K) lors de l'addition d'un alcène.

Nous complèterons les études déjà publiées sur la pyrolyse de l'éthane en présence d'éthylène ou de propène (16, 17) et sur celle du diméthyl-2,2 butane en présence de divers alcènes (isobutène, méthyl-2 butène-2 et propène (18, 19)) par les nouvelles investigations suivantes: pyrolyse de l'éthane en présence d'isobutène; pyrolyse de l'isobutane en présence d'éthylène, de propène, de butène-2 *trans* ou de méthyl-2 butène-2.

À partir de cet ensemble de résultats, nous en proposerons une interprétation globale et synthétique.

Résultats expérimentaux et interprétation

1. *Généralités*

Afin d'obtenir une concision suffisante, nous ne rappellerons que les résultats indispensables à la compréhension de l'article sur les réactions de référence des alcanes purs et sur l'origine de l'inhibition et de l'auto-inhibition due aux alcènes. Les effets "chimiques", c'est-à-dire les modifications observées sur la répartition des produits de la réaction (modification de l'importance relative des diverses stoechiométries, apparition de stoechiométries nouvelles), seront abordés sur les exemples les plus significatifs et les résultats globaux présentés sous forme de tableaux.

Afin que nos résultats aient une ampleur suffisante pour pouvoir en déduire des conclusions généralisables, nous avons, dans le cadre de ces études, choisi trois alcanes caractéristiques pouvant constituer des modèles intéressants:

TABLEAU 1. Mélanges binaires alcane–alcène étudiés

	Alcane		
Alcène	Éthane	Isobutane	Diméthyl-2,2 butane
Éthylène	(17)	Présent travail	
Propène	(16)	Présent travail	(18) et présent travail
Isobutène	Présent travail		(18, 19)
Butène-2 (*trans*)		Présent travail	
Méthyl-2 butène-2		Présent travail	(18, 19)
Méthyl-2 butène-1			(18)

(*i*) l'*éthane*, parce ce que se décomposant selon une seule stoechiométrie primaire principale ($C_2H_6 = C_2H_4 + H_2$), ce qui rend les co-réactions avec des alcènes a priori plus faciles à aborder du point de vue de l'analyse des produits; cette réaction est assez faiblement auto-inhibée par l'éthylène formé (20);

(*ii*) l'*isobutane* se décomposant selon deux stoechiométries primaires principales, une de perte d'hydrogène ($i\text{-}C_4H_{10} = H_2 + i\text{-}C_4H_8$), l'autre de perte de méthane ($i\text{-}C_4H_{10} = CH_4 + C_3H_6$), et correspondant à un degré de complexité supplémentaire par rapport à l'éthane; la décomposition de l'isobutane est auto-inhibée par les alcènes formés, et l'isobutène, de par son abondance relative, joue un rôle prépondérant de ce point de vue (21);

(*iii*) le *diméthyl-2,2 butane* dont la décomposition se produit selon cinq stoechiométries primaires principales, ainsi que le montre l'étude que nous avons effectuée au laboratoire (22); ici encore, la réaction est auto-inhibée par les alcènes formés.

Nous avons regroupé dans le tableau 1 les systèmes déjà étudiés et ayant fait l'objet de publications et ceux qui ont été soumis à de nouvelles investigations. Notons que les références 18 et 19 constituent en réalité des notes relativement brèves.

Les résultats seront classés par alcane étudié; nous développerons davantage les cas éthane–isobutène et isobutane–alcènes.

2. *Montage expérimental*

Nous avons utilisé un montage statique à volume constant, réalisé en verre "Pyrex" très proche de ceux déjà utilisés au laboratoire (23).

L'ensemble four–réacteur a été modifié et nous avons repris, sur un montage statique, un dispositif plus récent mis au point au laboratoire sur un montage dynamique (24). Le réacteur est constitué d'un ballon de Pyrex ayant un volume de 80 cm^3 dont le chauffage est réalisé par un élément chauffant Thermocoax sous forme de deux coquilles montées au contact direct de la paroi extérieure. Par sa construction, la résistance chauffante Thermocoax assure un parfait isolement électrique tout en gardant une excellente conductibilité thermique. L'ensemble est calorifugé avec de la laine de quartz et monté dans un boitier cubique de protection.

Un thermocouple de régulation est positionné entre les parois du réacteur et les coquilles de Thermocoax; la régulation de température est assurée par un régulateur électronique Eurotherm. La température de réaction est mesurée par un thermocouple placé dans un doigt de gant arrivant au centre du réacteur.

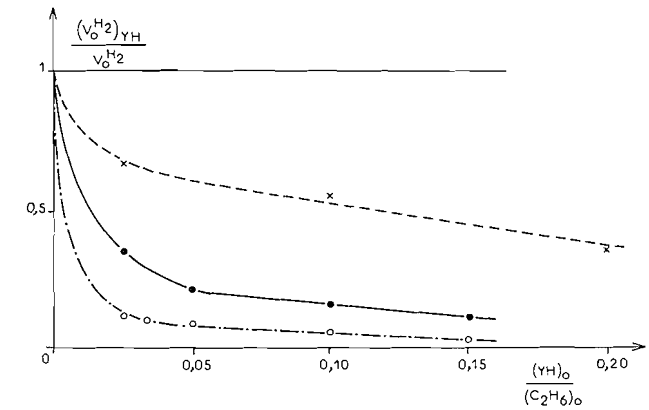

FIG. 1. Pyrolyse de l'éthane en présence d'un alcène YH vers 520°C ($P_0^{C_2H_6}$ = 100 Torr); —— YH ≡ i-C_4H_8 ●; —·— YH ≡ C_3H_6 ○ d'après réf. 16; ---- YH ≡ C_2H_4 × d'après réf. 17.

3. *Cas de l'éthane*

3.1. *Études de référence sur la pyrolyse de l'éthane pur*

Les essais de référence que nous avons effectués entre 500 et 556°C (773 et 825 K) se sont révélés en bon accord avec les résultats des autres auteurs (cf., par exemple, les références 20 et 25–27). L'ensemble des données relatives à la décomposition de l'éthane à faible avancement paraît très cohérent et cet exemple constitue ainsi une base sûre pour une étude approfondie de l'influence d'alcènes.

Rappelons que la pyrolyse de l'éthane peut être représentée, à l'instant initial, par le mécanisme radicalaire en chaînes suivant:

[1] Amorçage $C_2H_6 \rightarrow 2\ CH_3\cdot$

[2] Transfert $CH_3\cdot + C_2H_6 \rightarrow CH_4 + C_2H_5\cdot$

[3] Propagation [A] $C_2H_5\cdot \rightarrow C_2H_4 + H\cdot$
$C_2H_6 = C_2H_4 + H_2$

[4] $H\cdot + C_2H_6 \rightarrow H_2 + C_2H_5\cdot$

[μμ] Terminaison $2\ C_2H_5\cdot \rightarrow n\text{-}C_4H_{10}$; $\rightarrow C_2H_4 + C_2H_6$

La réaction étant en chaînes longues, ce mécanisme rend bien compte de l'équation stoechiométrique primaire principale [A] et du fait que CH_4 et n-C_4H_{10} se forment seulement en traces.

Le porteur de chaînes de type β (selon la terminologie de Goldfinger, Letort et Niclause (28)), c'est-à-dire réagissant bimoléculairement, est l'atome libre d'hydrogène; le porteur de chaînes de type μ, c'est-à-dire réagissant monomoléculairement, est le radical libre éthyle, $C_2H_5\cdot$; de par sa moindre réactivité, celui-ci est en concentration quasi-stationnaire nettement plus élevée que H·, $[C_2H_5\cdot]/[H\cdot] \simeq 350$, en accord avec le processus de terminaison retenu.

3.2. *Co-réaction éthane–isobutène*

3.21. *Étude cinétique*

En présence d'isobutène et vers 520°C (793 K), la vitesse initiale de formation de l'hydrogène est fortement diminuée. Cette diminution est d'autant plus grande que le mélange est riche en isobutène.

Sur la figure 1 nous avons représenté le rapport $(V_0^{H_2})_{i\text{-}C_4H_8}/V_0^{H_2}$ des vitesses initiales d'apparition d'hydrogène, en présence et en absence d'isobutène (à même concentration initiale et à 518°C, 791 K) en fonction du rapport $r = [i\text{-}C_4H_8]_0/[C_2H_6]_0$. Sur la même fig. 1 nous avons également repris des résultats sur d'autres co-réactions éthane–alcène (YH) étudiées précédemment (16, 17).

La réaction [A]: $C_2H_6 = C_2H_4 + H_2$ est donc fortement inhibée par l'isobutène. Cet effet cinétique peut s'interpréter par un mécanisme proche de celui décrit dans le cas des mélanges éthane–propène (16). Un des processus possibles à l'origine de l'inhibition est l'*arrachement* d'un atome d'hydrogène de la molécule d'isobutène par l'atome libre d'hydrogène H· (processus [5β])

[5β] $H\cdot + CH_2{=}C(CH_3)_2 \rightarrow CH_2{=}C(\dot{C}H_2)(CH_3) + H_2$

Le processus [5β] conduit au radical (i-$C_4H_7\cdot$) stabilisé par résonance et qui peut donc intervenir dans de nouveaux processus de terminaison de chaînes:

[YY] $2\ i\text{-}C_4H_7\cdot \rightarrow$ produits

[Yμ] $i\text{-}C_4H_7\cdot + C_2H_5\cdot \rightarrow$ produits

L'autre processus possible à l'origine de l'inhibition est l'*addition* de l'atome libre H· sur l'isobutène pour former un radical t-$C_4H_9\cdot$ (processus [5t] relativement stable puisqu'il ne peut se décomposer monomoléculairement que par le processus inverse de sa formation [−5t] (cf. règles de Leathard (7))[2]

[5t] et [−5t] $H\cdot + i\text{-}C_4H_8 \rightleftarrows t\text{-}C_4H_9\cdot$

Comme t-$C_4H_9\cdot$ est plus réactif que le radical stabilisé par résonance i-$C_4H_7\cdot$ nous avons également écrit le processus [6]:

[6] $t\text{-}C_4H_9\cdot + C_2H_6 \rightarrow i\text{-}C_4H_{10} + C_2H_5\cdot$

Le radical t-$C_4H_9\cdot$ peut aussi intervenir dans de nouveaux processus de terminaison de chaînes:

[tt] $2\ t\text{-}C_4H_9\cdot \rightarrow$ produits

[μt] $C_2H_5\cdot + t\text{-}C_4H_9\cdot \rightarrow$ produits

[tY] $t\text{-}C_4H_9\cdot + i\text{-}C_4H_7\cdot \rightarrow$ produits

Remarque à propos de la réactivité de t-$C_4H_9\cdot$:

Pour que les radicaux t-$C_4H_9\cdot$ puissent avoir une influence cinétique notable sur la réaction en intervenant dans les terminaisons, il faut que ces radicaux se détruisent assez facilement par combinaison et (ou) dismutation. Or, ceci est en contradiction avec les valeurs basses de la constante de combinaison et de dismutation de t-$C_4H_9\cdot$ qui avaient été avancées par certains auteurs (par exemple $10^{8,4}$ cm^3 mol^{-1} s^{-1} d'après Hiatt et Benson (29)). Dans un article paru en 1976, Parkes et Quinn (30) ont montré par une méthode de mesure directe que la valeur de la constante de recombinaison des radicaux t-$C_4H_9\cdot$ était de $10^{12,5}$ cm^3 m^{-1} s^{-1} et donc nettement plus élevée que celle admise auparavant.

Un article de Marshall *et al.* (31) a d'ailleurs confirmé ce point de vue en montrant que les valeurs basses admises pour les constantes de combinaison de certains radicaux alcoyles (dont le radical *tert*-butyle) provenaient vraisemblablement d'erreurs sur les données thermochimiques. Il semble que le travail de Parkes et Quinn (30) ait mis fin à cette controverse et que seule la valeur élevée soit à retenir, en accord avec les mécanismes que nous proposons.

3.22. *Étude chimique*

En présence d'isobutène, la pyrolyse de l'éthane n'est pas

[2] Le radical t-$C_4H_9\cdot$ ainsi formé par addition est en fait un radical vibrationnellement excité.

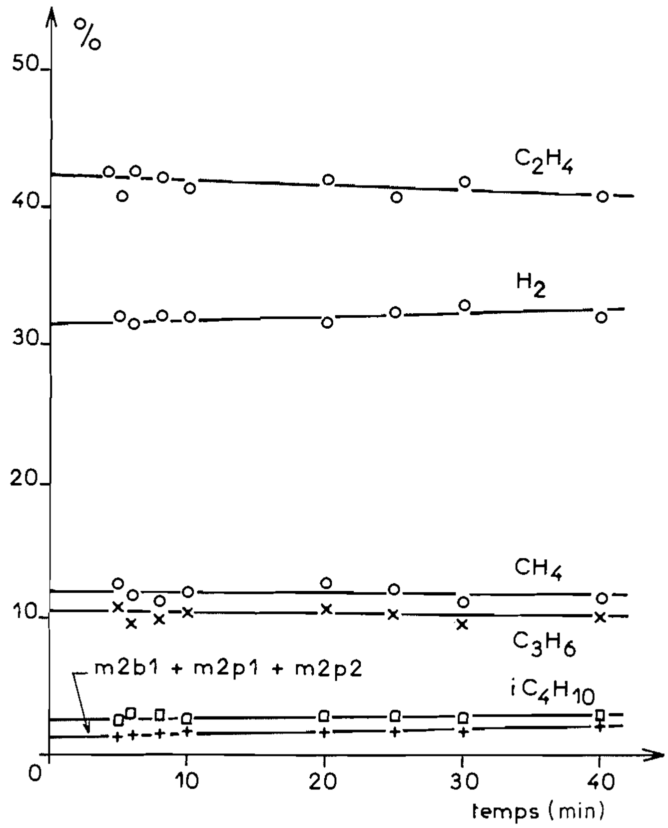

FIG. 2. Pyrolyse de l'éthane en présence d'isobutène; composition des produits primaires principaux (T = 518°C (791 K), $P_0^{C_2H_6}$ = 100 Torr, $r = [i\text{-}C_4H_8]_0/[C_2H_6]_0$ = 0,15); méthyl-2 butène-1 ≡ m2b1, méthyl-2 pentène-1 ≡ m2p1, méthyl-2 pentène-2 ≡ m2p2.

seulement inhibée mais la répartition des produits est modifiée. Il n'y a plus d'égalité entre C_2H_4 et H_2 et il se forme des quantités notables de méthane et de propène et un peu d'isobutane.

La figure 2 représente la composition des produits H_2, CH_4, C_2H_4, C_3H_6 et $i\text{-}C_4H_{10}$ en fonction du temps de pyrolyse (à 518°C, 791 K et pour une teneur en isobutène r = 0,15); il se forme aussi des traces de méthyl-2 butène-1, de méthyl-2 pentène-1 et de méthyl-2 pentène-2. Ces trois produits représentent à l'instant initial environ 1% de l'ensemble des produits mesurés.

On peut interpréter ces effets en considérant l'addition de l'atome libre H· sur la double liaison de la molécule d'isobutène. Cette addition peut conduire soit à un radical isobutyle primaire:

p-C_4H_9· 
soit à un radical isobutyle tertiaire:

t-C_4H_9· 
La formation de p-C_4H_9· peut effectivement interpréter la formation de méthane et de propène, si l'on considère la séquence fermée:

[5p] H· + i-C_4H_8 → p-C_4H_9·

[7] p-C_4H_9· → CH_3· + C_3H_6

[2] CH_3· + C_2H_6 → CH_4 + C_2H_5·

[3] C_2H_5· → H· + C_2H_4

correspondant à la stoechiométrie [B]

[B] C_2H_6 + i-C_4H_8 = C_2H_4 + C_3H_6 + CH_4

La formation de t-C_4H_9· en dehors de son rôle cinétique mentionné précédemment, permet d'interpréter la formation d'isobutane par la séquence fermée, où t-C_4H_9· réagit bimoléculairement avec une molécule d'éthane:

[5t] et [−5t] H· + i-C_4H_8 ⇄ t-C_4H_9·

[6] t-C_4H_9· + C_2H_6 → C_2H_5· + i-C_4H_{10}

[3] C_2H_5· → H· + C_2H_4

correspondant à la stoechiométrie [C]

[C] C_2H_6 + i-C_4H_8 = C_2H_4 + i-C_4H_{10}

Le radical tertiaire t-C_4H_9· doit être relativement moins réactif vis-à-vis d'une molécule d'éthane qu'un radical alcoyle plus léger et par conséquent la stoechiométrie [C] doit avoir une importance limitée devant [A] et [B].

Le mécanisme global de pyrolyse de l'éthane en présence d'isobutène qui permet d'interpréter les trois stoechiométries [A], [B] et [C] et donc les produits dosés en quantités les plus importantes H_2, CH_4, C_2H_4, C_3H_6 et i-C_4H_{10} peut être le suivant, en tenant compte des effets inhibiteurs et de leur interprétation, mentionnés dans ce qui précède.

Mécanisme de pyrolyse de l'éthane en présence d'isobutène (à faible avancement)

[1]	Amorçage	C_2H_6 → 2 CH_3·
[3]	Propagation [A]	C_2H_5· → H· + C_2H_4
[4]	C_2H_6 = C_2H_4 + H_2	H· + C_2H_6 → C_2H_5· + H_2
[5p]	Propagation [B]	H· + i-C_4H_8 → p-C_4H_9·
[7]		p-C_4H_9· → CH_3· + C_3H_6
[2]	C_2H_6 + i-C_4H_8 = C_2H_4 + CH_4 + C_3H_6	CH_3· + C_2H_6 → CH_4 + C_2H_5·
[5t] et [−5t]	Propagation [C]	H· + i-C_4H_8 ⇄ t-C_4H_9·
[6]	C_2H_6 + i-C_4H_8 = C_2H_4 + i-C_4H_{10}	t-C_4H_9· + C_2H_6 → C_2H_5· + i-C_4H_{10}
[5β]	Arrachement d'hydrogène	H· + i-C_4H_8 → i-C_4H_7· + H_2

[μμ]		$2\ C_2H_5\cdot \rightarrow$	
[Yμ]		$i\text{-}C_4H_7\cdot + C_2H_5\cdot \rightarrow$	
[YY]		$2\ i\text{-}C_4H_7\cdot \rightarrow$	
	Terminaison		produits
[μt]		$C_2H_5\cdot + t\text{-}C_4H_9\cdot \rightarrow$	
[tY]		$t\text{-}C_4H_9\cdot + i\text{-}C_4H_7\cdot \rightarrow$	
[tt]		$2\ t\text{-}C_4H_9\cdot \rightarrow$	

Les autres produits en quantités moins importantes sont expliqués par l'intervention de $C_2H_5\cdot$ qui peut s'additionner sur la molécule d'isobutène. Il suffit de construire des séquences fermées avec des processus du mécanisme général précédent. Les nouvelles stoechiométries obtenues rendent alors compte de la formation du méthyl-2 butène-1 (m2b1), du méthyl-2 pentène-1 (m2p1) et du méthyl-2 pentène-2 (m2p2):

1ère Possibilité: addition de $C_2H_5\cdot$ sur le carbone central:

[8A] et [−8A] 
[9] 
[2] $CH_3\cdot + C_2H_6 \rightarrow CH_4 + C_2H_5\cdot$

d'où:

[D] $C_2H_6 + i\text{-}C_4H_8 = CH_4 + C_5H_{10}$ (m2b1)

2ème Possibilité: addition de $C_2H_5\cdot$ sur le carbone terminal:

[8B] et [−8B] 
[10A] 
ou:

[10B] 
[4] $H\cdot + C_2H_6 \rightarrow H_2 + C_2H_5\cdot$

d'où:

[E] et [F] $C_2H_6 + i\text{-}C_4H_8 = H_2 + C_6H_{12}$ (m2p1 et m2p2)

Si l'on tient compte de l'ensemble des produits dosés (y compris les traces de méthyl-2 butène-1, de méthyl-2 pentène-1 et de méthyl-2 pentène-2), la décomposition thermique de l'éthane en présence d'isobutène peut être représentée par six stoechiométries primaires principales dont nous indiquons à titre d'exemple les importances relatives à l'instant initial (à 518°C, 791 K et r = 0,15):

[A]	$C_2H_6 = C_2H_4 + H_2$	66,6%
[B]	$C_2H_6 + i\text{-}C_4H_8 = CH_4 + C_2H_4 + C_3H_6$	23,6%
[C]	$C_2H_6 + i\text{-}C_4H_8 = C_2H_4 + i\text{-}C_4H_{10}$	6,4%
[D]	$C_2H_6 + i\text{-}C_4H_8 = CH_4 + C_5H_{10}$ (m2b1)	3,4%
[E]	$C_2H_6 + i\text{-}C_4H_8 = H_2 + C_6H_{12}$ (m2p1)	
[F]	$C_2H_6 + i\text{-}C_4H_8 = H_2 + C_6H_{12}$ (m2p2)	

Soit a = $(C_2H_4) - [(C_3H_6) + (i\text{-}C_4H_{10})]$, b = (C_3H_6), c = $(i\text{-}C_4H_{10})$, d = (m2b1) + (m2p1) + (m2p2). Les quantités a, b, c, d sont représentatives pour chaque temps de pyrolyse des stoechiométries [A], [B], [C] et [D] + [E] + [F]. L'extrapolation des droites obtenues (cf. figure 3) à avancement nul fournit la répartition des stoechiométries à l'instant initial.

Nous avons montré dans la partie "résultats expérimentaux" que la somme des produits caractéristiques des stoechiométries [D], [E] et [F] est de l'ordre d'un pour cent de l'ensemble des produits dosés (dans les conditions: T = 518°C, 791 K et r = 0,15). L'importance de ces stoechiométries qui résultent de l'addition du radical alcoyle $C_2H_5\cdot$ sur l'isobutène sera inférieure à un pour cent dans le cas des pyrolyses à plus haute température (540 et 556°C, 813 et 829 K). En effet, dans ces conditions, nous rappelons, comme dans le cas des mélanges C_2H_6–C_3H_6, que la vitesse des processus inverses (processus [−8A] ou [−8B]) augmente plus rapidement que celle des processus directs avec la température; l'énergie d'activation de ces processus inverses est plus grande que celle des processus directs.

Nos nouveaux résultats expérimentaux sur les mélanges éthane–isobutène peuvent donc en première approximation être correctement décrits par les seules stoechiométries [A], [B] et [C], avec [A] la stoechiométrie de l'éthane pur et [B] et [C] les stoechiométries déduites de l'addition de l'atome libre H· sur la double liaison de l'alcène ajouté.

TABLEAU 2. Pyrolyse de l'éthane en présence d'un alcène

Alcène ajouté	Radical(aux) potentiellement responsable(s) de l'inhibition	Radical(aux) responsable(s) de l'effet chimique	T (°C)	Stoechiométries		Importance relative† (%)
Isobutène	$CH_2{=}C(CH_2\cdot)CH_3$* (i-$C_4H_7\cdot$)	$\dot{C}H_2{-}CH(CH_3)_2$ (p-$C_4H_9\cdot$)	500–518	$C_2H_6 = C_2H_4 + H_2$	[A]	69,0
				$C_2H_6 + i\text{-}C_4H_8 = CH_4 + C_2H_4 + C_3H_6$	[B]	24,4
	$CH_3{-}\dot{C}(CH_3)_2$ (t-$C_4H_9\cdot$)	$CH_3{-}\dot{C}(CH_3)_2$ (t-$C_4H_9\cdot$)	540–556	$C_2H_6 + i\text{-}C_4H_8 = C_2H_4 + i\text{-}C_4H_{10}$	[C]	6,6
Propène	$\dot{C}H_2{-}CH{=}CH_2$*	$CH_3{-}CH_2{-}\dot{C}H_2$	500–520	$C_2H_6 = C_2H_4 + H_2$	[A]	59,6
				$C_2H_6 + C_3H_6 = CH_4 + 2C_2H_4$	[G]	29,0
	$CH_3{-}\dot{C}H{-}CH_3$	$CH_3{-}\dot{C}H{-}CH_3$	540–556	$C_2H_6 + C_3H_6 = C_2H_4 + C_3H_8$	[H]	11,4
Éthylène	$C_2H_5\cdot$	$C_2H_5\cdot$	500–520	$C_2H_6 = C_2H_4 + H_2$	[A]	93,2
				$C_2H_6 + C_2H_4 = 1\text{-}C_4H_8 + H_2$	[I]	3,8
			540–556	$C_2H_6 + C_2H_4 = CH_4 + C_3H_6$	[J]	3,0

*Radicaux formés par arrachement d'hydrogène sur l'alcène considéré, les autres radicaux sont formés par addition de H· sur l'alcène correspondant.
†Importances relatives des diverses stoechiométries (extrapolation à l'instant initial); T = 518°C (791 K), $P_0^{C_2H_6}$ = 100 Torr, r = [alcène]$_0$/[éthane]$_0$ = 0,15.

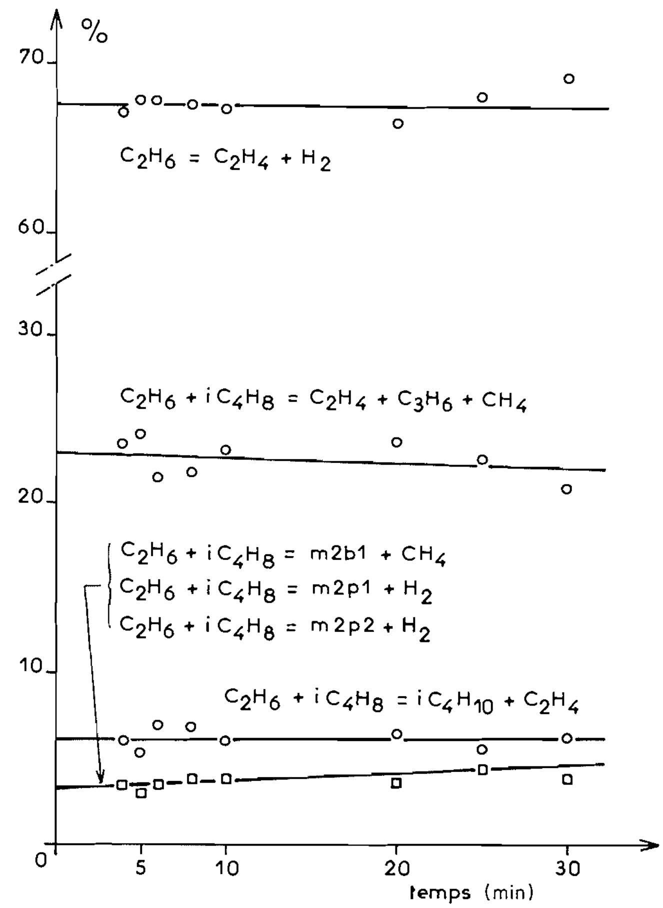

FIG. 3. Pyrolyse de l'éthane en présence d'isobutène. Répartition des stoechiométries primaires principales (T = 518°C (791 K), $P_0^{C_2H_6}$ = 100 Torr, r = [i-C_4H_8]$_0$/[C_2H_6]$_0$ = 0,15).

3.23. *Comparaison des résultats obtenus par addition d'isobutène avec ceux obtenus par addition de propène ou d'éthylène*

Nous avons regroupé l'ensemble de nos résultats et résumé leur interprétation mécanistique dans un même tableau (cf. tableau 2).

Pour les trois co-réactions éthane–alcène YH étudiées précédemment (éthylène, propène) et dans ce travail (isobutène), nous mentionnons quels sont les radicaux pouvant être à l'origine de l'auto-inhibition et les radicaux responsables des effets "chimiques" (nouvelles stoechiométries).

Sur le plan purement cinétique, la figure récapitulative (fig. 1) et la lecture du tableau 2, compte-tenu des interprétations mécanistiques proposées, permettent de penser que l'inhibition de la pyrolyse de l'éthane par un alcène sera relativement faible s'il n'y a pas, dans les radicaux potentiellement responsables de l'inhibition, un radical Y· formé par arrachement d'un atome d'hydrogène de la molécule d'alcène YH et stabilisé par résonance (radical de type allylique). Ce point de vue est corroboré par l'influence cinétique de l'éthylène sur la pyrolyse de l'éthane.

Ces résultats ne permettent pas de conclure que le mécanisme par arrachement d'hydrogène est suffisant pour rendre compte des influences inhibitrices et auto-inhibitrices d'alcènes; en effet, nous ne disposons pas, dans le cas de l'éthane, d'exemples de réactions avec un alcène YH où *seul* le mécanisme par arrachement d'hydrogène serait possible.

La lecture du tableau 2 fait apparaître que les importances relatives des nouvelles stoechiométries restent limitées dans le cas de mélanges C_2H_6–C_2H_4; rappelons que ces nouvelles stoechiométries sont attribuées à l'addition du radical libre éthyle sur la molécule d'éthylène et aux processus subséquents (17). Ceci suggère donc que, dans nos conditions expérimentales, les changements de nature et de répartition des produits lors de la pyrolyse de l'éthane en présence d'un alcène sont essentiellement dus à l'addition d'un atome libre H· sur la double liaison de la molécule d'alcène et aux processus subséquents des radicaux libres ainsi formés, s'ils réagissent par des processus élémentaires *autres* que par le processus inverse de leur formation, impliquant la rupture de liaisons carbone–carbone, plus fragiles que des liaisons carbone–hydrogène.

En revanche, lorsque l'on considère l'addition de radicaux alcoyles sur une double liaison d'un alcène, le processus inverse de la formation des nouveaux radicaux ainsi obtenus est par définition la rupture d'une liaison carbone–carbone. De par la relative fragilité de ce type de liaison, les nouvelles stoechiométries ne pourront pas prendre une importance appréciable. C'est naturellement le cas du radical éthyle dans le cas de l'éthane; comme on l'a vu précédemment, les stoechiométries nouvelles dérivées de l'addition de ce radical ne prennent pas une importance appréciable dans les co-réactions de consommation de l'éthane.

Cette analyse des schémas réactionnels a été facilitée grâce au nombre limité de produits de réaction, puisque l'éthane ne se pyrolyse que selon une seule équation stoechiométrique primaire principale.

Cependant, on peut se demander si les conclusions précédentes restent valables dans le cas beaucoup plus général d'alcanes qui se décomposent selon plusieurs équations stoechiométriques primaires principales, en particulier dans le cas où les porteurs de chaînes de type β (c'est-à-dire réagissant bimoléculairement) comprennent des espèces autres que l'atome libre d'hydrogène (radicaux alcoyles légers, en particulier $CH_3\cdot$, $C_2H_5\cdot$, ...) et dans les cas où il existe plusieurs formes isomères du radical $\mu\cdot$.

Afin d'évaluer la validité des conclusions précédentes, nous allons aborder d'autres exemples de pyrolyses d'alcanes en présence d'alcènes ajoutés; les alcanes choisis pour cette nouvelle comparaison seront l'isobutane dans une première série et le diméthyl-2,2 butane dans une seconde série.

4. *Cas de l'isobutane*

4.1. *Isobutane pur*

Nos essais de référence ont confirmé les caractéristiques déjà connues de cette pyrolyse, en particulier l'importance relative des deux stoechiométries primaires principales de décomposition déterminée par la composition des produits primaires qui d'ailleurs varie assez peu avec le temps. À titre d'exemple, nous avons mentionné la répartition des deux stoechiométries primaires principales, déterminée à 470°C (743 K) et pour une pression initiale d'isobutane de 100 Torr:

[A′] $\quad$ $i\text{-}C_4H_{10} = CH_4 + C_3H_6$ $\quad$ 25%

[B′] $\quad$ $i\text{-}C_4H_{10} = H_2 + i\text{-}C_4H_{10}$ $\quad$ 75%

Plus généralement, nos résultats de référence font apparaître un bon accord avec les études effectuées antérieurement sur cette réaction (cf., par exemple, les références 8, 10, 32, et 33).

Compte-tenu des travaux de Muller (32), de Konar *et al.* (8, 10) et des vérifications complémentaires que nous avons entreprises, le mécanisme de la pyrolyse de l'isobutane à relativement faible avancement que nous avons retenu s'écrit:

[11]	Amorçage	$i\text{-}C_4H_{10} \rightarrow$ radicaux libres
[7]	Propagation [A′]	$p\text{-}C_4H_9\cdot \rightarrow CH_3\cdot + C_3H_6$
[12p]	$i\text{-}C_4H_{10} = CH_4 + C_3H_6$	$CH_3\cdot + i\text{-}C_4H_{10} \rightarrow CH_4 + p\text{-}C_4H_9\cdot$
[12t]		$CH_3\cdot + i\text{-}C_4H_{10} \rightarrow CH_4 + t\text{-}C_4H_9\cdot$
[−5t] et [5t]	Propagation [B′]	$t\text{-}C_4H_9\cdot \rightleftarrows H\cdot + i\text{-}C_4H_8$
[13p]	$i\text{-}C_4H_{10} = H_2 + i\text{-}C_4H_8$	$H\cdot + i\text{-}C_4H_{10} \rightarrow H_2 + p\text{-}C_4H_9\cdot$
[13t]		$H\cdot + i\text{-}C_4H_{10} \rightarrow H_2 + t\text{-}C_4H_9\cdot$
[14] et [−14]	Isomérisation	$t\text{-}C_4H_9\cdot + i\text{-}C_4H_{10} \rightleftarrows p\text{-}C_4H_9\cdot + i\text{-}C_4H_{10}$
[5β]	Auto-inhibition	$H\cdot + i\text{-}C_4H_8 \rightarrow H_2 + i\text{-}C_4H_7\cdot$
	Terminaison	combinaison ou dismutation des radicaux: $CH_3\cdot$ (β·), $t\text{-}C_4H_9\cdot$ (μ·) et $i\text{-}C_4H_7\cdot$ (Y·)

La séquence fermée constituée des processus [7] et [12p] conduit à la stoechiométrie [A′]; celle constituée de [−5t] et [13p] conduit à la stoechiométrie [B′]. Il y a donc deux porteurs de chaînes de type β·, H· et $CH_3\cdot$, et deux formes isomères du radical μ·, $p\text{-}C_4H_9\cdot$ et $t\text{-}C_4H_9\cdot$, qui peuvent d'ailleurs s'isomériser également bimoléculairement par les processus [14] et [−14].

L'allure auto inhibée de la réaction (32, 8) s'explique par la formation des deux alcènes (propène et isobutène); l'isobutène joue un rôle prépondérant dans ce phénomène, parce qu'il est formé en quantités plus importantes que le propène (environ 3 fois plus); rappelons que dans nos conditions expérimentales, l'isobutène a une influence inhibitrice comparable à celle du propène (13), pour des quantités égales.

Il est admis, comme nous l'avons vu dans le cas de l'éthane, que deux types de processus peuvent être à l'origine de l'auto-inhibition d'une pyrolyse d'alcane; des processus d'arrachement d'hydrogène sur les molécules d'alcène et des processus d'addition de l'atome libre H· sur la double liaison. Si l'on admet que l'isobutène joue un rôle prépondérant dans ces phénomènes d'auto-inhibition de la pyrolyse de l'isobutane, on aura ainsi: par arrachement d'hydrogène de l'isobutène, formation de radicaux isobutényles $i\text{-}C_4H_7\cdot$ (processus [5β]), stabilisés par résonance et pouvant intervenir dans de nouveaux processus de terminaison des chaînes; par addition d'hydrogène sur l'isobutène, formation de radicaux *tert*-butyle (processus [5t]) relativement stables thermiquement parce que ne pouvant se décomposer que par rupture d'une liaison C—H et, de ce fait, intervenant également dans les processus de terminaison.

Il est difficile, dans l'état actuel de nos connaissances sur cette réaction, de préciser quelle est la part relative de chacun des mécanismes possibles dans le phénomène global d'auto-inhibition, mais il ne nous paraît pas possible de négliger a priori l'un devant l'autre. Ce point sera d'ailleurs évoqué plus loin. Ceci nous conduit donc à tenir compte, au cours du temps, de trois types de radicaux dans les processus de terminaison de la réaction: $CH_3\cdot$, $t\text{-}C_4H_9\cdot$ et $i\text{-}C_4H_7\cdot$. Les mesures d'ordre et les déterminations de vitesse initiale à partir d'un modèle de la réaction sont compatibles avec les considérations précédentes.

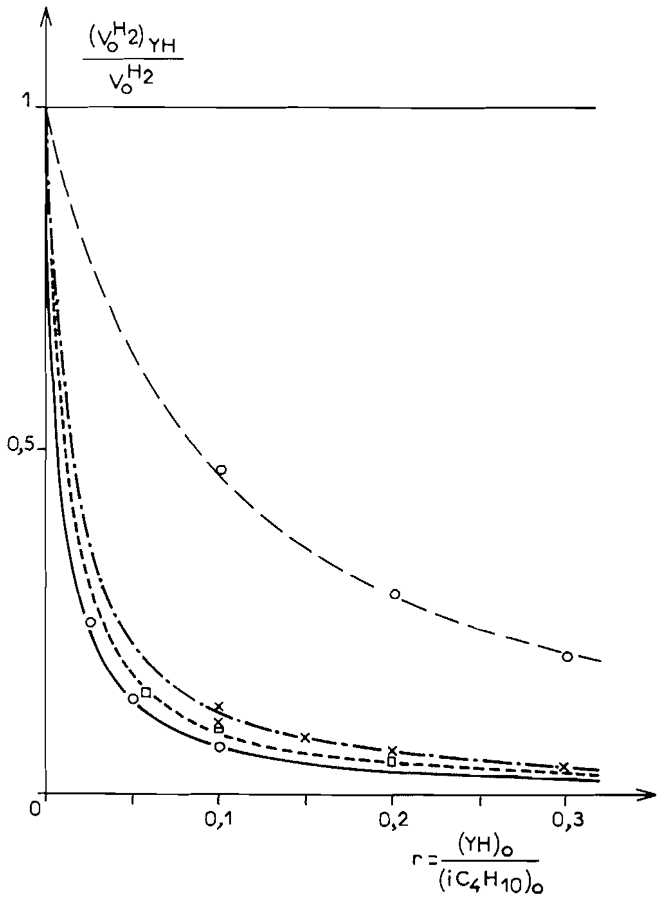

FIG. 4. Pyrolyse de l'isobutane en présence de propène et comparaison de l'effet cinétique du butène-2 *trans* et du méthyl-2 butène-2 sur la pyrolyse de l'isobutane par rapport au propène et à l'éthylène. Variation du rapport $(V_0^{H_2})_{YH}/V_0^{H_2}$ avec r = $[YH]_0/[i\text{-}C_4H_{10}]_0$; ---- YH = méthyl-2 butène-2; —— YH = butène-2 *trans*; -•-•- YH = propène; ——— YH = éthylène (T = 470°C (743 K), $P_0^{i\text{-}C_4H_{10}}$ = 100 Torr).

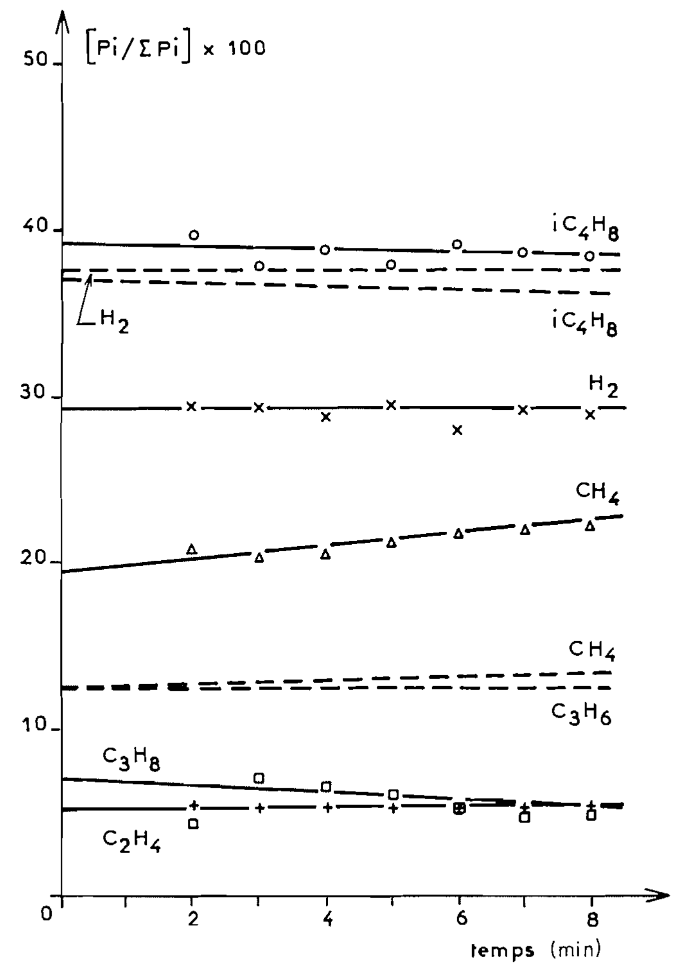

FIG. 5. Pyrolyse de l'isobutane en présence de propène. Répartition des produits primaires principaux de la réaction (T = 470°C (743 K), $P_0^{i\text{-}C_4H_{10}}$ = 100 Torr, r = $[C_3H_6]_0/[i\text{-}C_4H_{10}]_0$ = 0,10); ----- référence isobutane pur.

4.2. *Co-réaction isobutane–propène*

Nos résultats expérimentaux ont montré que l'addition de propène (10 à 30 Torr) à l'isobutane (pression initiale 100 Torr, température 470°C, 743 K) conduisait à une importante inhibition de la réaction, comparable à celle observée antérieurement dans le cas de l'éthane (16). Cette forte inhibition peut être expliquée par des processus analogues à ceux écrits dans le cas des mélanges éthane–propène, c'est-à-dire à la fois par des processus d'arrachement d'hydrogène de la molécule de propène conduisant au radical allyle stabilisé par résonance et par des processus d'addition d'hydrogène sur cette même molécule de propène et conduisant au radical isopropyle.

Sur la figure 4 nous avons représenté les effets cinétiques du propène et d'autres alcènes qui seront étudiés et comparés ensuite.

L'addition de propène exerce non seulement le fort effet cinétique mentionné ci-dessus et représenté en fig. 4, mais modifie aussi de façon importante la répartition des produits primaires principaux. Les égalités approximatives observées dans la pyrolyse de l'isobutane pur entre les concentrations des produits principaux extrapolées à l'instant initial rappelées en fig. 5 ($[H_2]_0 \simeq [i\text{-}C_4H_8]_0$ = 37,4%; $[CH_4]_0 \simeq [C_3H_6]_0 \simeq$ 12,6%) ne sont plus vérifiées et il se forme aussi primairement de l'éthylène et du propane. La figure 5 représente, en fonction du temps, à 470°C (743 K) et pour un rapport r = $[C_3H_6]_0/[i\text{-}C_4H_{10}]_0$ = 0,10, la répartition des produits exprimée en pourcentage de l'ensemble des produits dosés; les valeurs suivantes sont obtenues par extrapolation à l'instant initial: $[i\text{-}C_4H_8]_0 \simeq$ 39,2%; $[H_2]_0 \simeq$ 29,2%; $[CH_4]_0 \simeq$ 19,4%; $[C_2H_4]_0 \simeq$ 5,2%; $[C_3H_8]_0 \simeq$ 7%.

Les traces de produits plus lourds (des butènes-2 à des oléfines en C_7) sont pratiquement négligeables par rapport à ces produits (leur somme ne représente que 0,25% environ de l'ensemble des produits principaux dosés).

Nos résultats expérimentaux peuvent être décrits par quatre équations stoechiométriques primaires principales (leurs importances relatives extrapolées à l'instant initial sont données à 470°C (743 K) et pour un rapport r = 0,10).

[A′]	$i\text{-}C_4H_{10} = CH_4 + C_3H_6$	25,4%
[B′]	$i\text{-}C_4H_{10} = H_2 + i\text{-}C_4H_8$	51,7%
[C′]	$i\text{-}C_4H_{10} + C_3H_6 = C_3H_8 + i\text{-}C_4H_8$	13,7%
[D′]	$i\text{-}C_4H_{10} + C_3H_6 = CH_4 + C_2H_4 + i\text{-}C_4H_8$	9,2%

Nous avons regroupé dans ce qui suit les processus élémentaires de propagation et les séquences fermées qui conduisent aux quatre équations stoechiométriques précédentes; le mécanisme global de la pyrolyse de l'isobutane en présence de propène que nous proposons pour rendre compte de tous les effets observés s'écrit:

[11]	Amorçage	$i\text{-}C_4H_{10} \rightarrow$ radicaux libres
[7]	Propagation [A′]	$p\text{-}C_4H_9\cdot \rightarrow CH_3\cdot + C_3H_6$
[12p]	$i\text{-}C_4H_{10} = CH_4 + C_3H_6$	$CH_3\cdot + i\text{-}C_4H_{10} \rightarrow CH_4 + p\text{-}C_4H_9\cdot$
[12t]		$CH_3\cdot + i\text{-}C_4H_{10} \rightarrow CH_4 + t\text{-}C_4H_9\cdot$
[−5t]	Propagation [B′]	$t\text{-}C_4H_9\cdot \rightarrow H\cdot + i\text{-}C_4H_8$
[13p]	$i\text{-}C_4H_{10} = H_2 + i\text{-}C_4H_8$	$H\cdot + i\text{-}C_4H_{10} \rightarrow H_2 + p\text{-}C_4H_9\cdot$
[13t]		$H\cdot + i\text{-}C_4H_{10} \rightarrow H_2 + t\text{-}C_4H_9\cdot$
[15s] et [−15s]	Propagation [C′]	$H\cdot + C_3H_6 \rightleftarrows s\text{-}C_3H_7\cdot$
[16p]	$i\text{-}C_4H_{10} + C_3H_6 =$	$s\text{-}C_3H_7\cdot + i\text{-}C_4H_{10} \rightarrow C_3H_8 + p\text{-}C_4H_9\cdot$
[16t]	$C_3H_8 + i\text{-}C_4H_8$	$s\text{-}C_3H_7\cdot + i\text{-}C_4H_{10} \rightarrow C_3H_8 + t\text{-}C_4H_9\cdot$
[15p]	Propagation [D′][3] $i\text{-}C_4H_{10} + C_3H_6 =$	$H\cdot + C_3H_6 \rightarrow p\text{-}C_3H_7\cdot$
[17]	$CH_4 + C_2H_4 + i\text{-}C_4H_8$	$p\text{-}C_3H_7\cdot \rightarrow CH_3\cdot + C_2H_4$
[14] et [−14]	Isomérisation	$t\text{-}C_4H_9\cdot + i\text{-}C_4H_{10} \rightleftarrows p\text{-}C_4H_9\cdot + i\text{-}C_4H_{10}$
[18β]	Arrachement d'hydrogène	$H\cdot + C_3H_6 \rightarrow H_2 + CH_2 \overset{\cdot}{=} CH \overset{\cdot}{=} CH_2$
	Terminaison	combinaison ou dismutation impliquant les radicaux: $CH_3\cdot$, $C_3H_5\cdot$, $s\text{-}C_3H_7\cdot$, $t\text{-}C_4H_9\cdot$

Ceci montre à nouveau que l'addition de l'atome libre H· sur la double liaison du propène est susceptible d'expliquer l'essentiel des effets chimiques observés lors de la pyrolyse de l'isobutane en présence de propène. L'addition de radicaux alcoyles ($CH_3\cdot$, $s\text{-}C_3H_7\cdot$) sur la double liaison du propène est effectivement capable d'interpréter la formation de produits en traces mentionnés ci-dessus mais leur importance relative est négligeable comparée à celle des produits formés dans les stoechiométries [A′], [B′], [C′] et [D′].

Il apparaît donc que, malgré la présence d'un autre radical β· [$CH_3\cdot$] et l'existence de 2 formes isomères du radical μ· (isobutyle primaire et *tert*-butyle), l'addition de H· joue encore un rôle prépondérant dans les modifications observées dans la répartition des produits.

4.3. *Co-réaction isobutane–éthylène*

Les résultats obtenus sur cet exemple sont très proches de ceux observés dans l'étude des mélanges éthane–éthylène et décrits dans des publications antérieures (17): la réaction de décomposition de l'isobutane est inhibée par l'éthylène, mais nettement moins (environ 5 fois) que par le propène; la pyrolyse de l'isobutane est moins perturbée chimiquement par l'éthylène que par le propène; le seul produit nouveau qui apparaît est l'éthane et la répartition des produits primaires principaux peut être décrite par les trois équations stoechiométriques primaires principales suivantes:

[A′]	$i\text{-}C_4H_{10} = CH_4 + C_3H_6$	30,4%
[B′]	$i\text{-}C_4H_{10} = H_2 + i\text{-}C_4H_8$	55,8%
[E′]	$i\text{-}C_4H_{10} + C_2H_4 = C_2H_6 + i\text{-}C_4H_8$	13,8%

Les importances relatives des trois stoechiométries sont données ci-dessus à titre d'exemple, à une température de 470°C et pour un rapport $r = [C_2H_4]_0/[i\text{-}C_4H_{10}]_0$ de 0,10.

Nos résultats sont ici encore interprétables par l'addition (réversible) de l'atome libre H· sur la molécule d'éthylène, conduisant au radical libre $C_2H_5\cdot$ qui réagit bimoléculairement avec l'isobutane pour donner une molécule d'éthane et un radical *tert*-butyle, l'hydrogène tertiaire de l'isobutane étant nettement plus facile à arracher que les hydrogènes primaires; la stoechiométrie [E′] se déduit de la séquence ci-dessous:

[−3] et [3]	$H\cdot + C_2H_4 \rightleftarrows C_2H_5\cdot$
[19t]	$C_2H_5\cdot + i\text{-}C_4H_{10} \rightarrow C_2H_6 + t\text{-}C_4H_9\cdot$
[−5t]	$t\text{-}C_4H_9\cdot \rightarrow H\cdot + i\text{-}C_4H_8$

4.4. *Co-réaction de l'isobutane avec d'autres alcènes*

De la même manière et avec le même objectif, nous avons étudié l'influence du butène-2 *trans* (noté en abrégé $2\text{-}C_4H_8$) et du méthyl-2 butène-2 sur la décomposition thermique de l'isobutane. L'ensemble des cas étudiés sur l'exemple de l'isobutane est résumé dans le tableau 3, où nous avons également rappelé les résultats obtenus avec le propène et l'éthylène. Cette comparaison montre à nouveau le rôle fondamental de l'addition de l'atome libre H·.

Les études effectuées avec le butène-2 *trans* et le méthyl-2 butène-2 présentent un intérêt supplémentaire en ce qui concerne les mécanismes d'inhibition. L'effet inhibiteur du butène-2 *trans* et du méthyl-2 butène-2 sur la décomposition thermique de l'isobutane, contrairement à l'effet chimique, ne paraît pas attribuable à l'addition de l'atome libre H· sur la double liaison. En effet, les radicaux alcoyles ainsi obtenus ne possèdent pas de stabilité thermique particulière car ils peuvent se redécomposer par rupture d'une liaison carbone–carbone (radical $CH_3 \vdots CH_2—\dot{C}H—CH_3$ pour le butène-2, radicaux $CH_3—CH(\vdots CH_3)—\dot{C}H—CH_3$ et $CH_3—\dot{C}(CH_3)—CH_2 \vdots CH_3$ pour le méthyl-2 butène-2) et donc ne peuvent pas atteindre des concentrations quasi-stationnaires suffisantes pour jouer un rôle cinétique (inhibiteur) notable par leur intervention dans des processus de terminaison.

Malgré cette unicité de mécanisme d'inhibition envisageable, c'est-à-dire seulement le mécanisme par arrachement d'hydrogène conduisant à un radical allylique stabilisé par résonance, les effets inhibiteurs observés avec les deux alcènes précités sont du même ordre de grandeur, voire même supé-

[3] Complétée par [12t] et [−5t].

rieurs, à ceux obtenus en présence de propène (fig. 4); rappelons qu'avec le propène les deux mécanismes d'inhibition (addition d'un atome H· ou arrachement d'un atome d'hydrogène conduisant au radical allyle) pouvaient intervenir stimultanément.

Ces résultats tendent donc à prouver que le mécanisme par *arrachement d'hydrogène* est suffisant pour interpréter les effets inhibiteurs observés dans la pyrolyse d'alcanes en présence d'alcènes. Lorsque seul le mécanisme par addition est envisageable, comme c'est le cas en présence d'éthylène, les effets observés sont nettement moins importants (fig. 4). Ceci nous conduit à penser, de façon simplifiée, que les effets *cinétiques* (inhibition) sont attribuables essentiellement à l'*arrachement* d'un atome d'hydrogène sur la molécule d'alcène lorsque ce processus conduit à un radical libre stabilisé par résonance; les effets *chimiques*, c'est-à-dire les modifications de la répartition des produits de la réaction introduites par l'addition d'alcène, paraissent provenir essentiellement de l'*addition* de l'atome libre d'hydrogène sur la double liaison de la molécule d'oléfine et des processus subséquents des radicaux alcoyle ainsi obtenus.

En pratique, lorsqu'on s'intéresse au craquage d'alcanes liquides, on franchit encore un degré dans la complexité des schémas réactionnels. En effet, le nombre d'équations stoechiométriques décrivant la décomposition de l'alcane croît très vite avec le nombre d'atomes de carbone de celui-ci, ainsi que le nombre d'espèces radicalaires porteuses de chaînes. Pour contrôler la validité de nos observations dans un exemple se rapprochant de cette complexité, nous avons choisi comme alcane le diméthyl-2,2 butane.

5. *Cas du diméthyl-2,2 butane*

Pour la compréhension de ce mémoire et surtout dans un but de comparaison avec des résultats publiés antérieurement sur l'éthane (16, 17) ou mentionnés dans ce qui précède (réactions éthane–isobutène et réactions isobutane–alcène), il nous a paru nécessaire, compte-tenu de la relative complexité de cette réaction, de résumer les résultats obtenus sur la pyrolyse du diméthyl-2,2 butane pur (22).

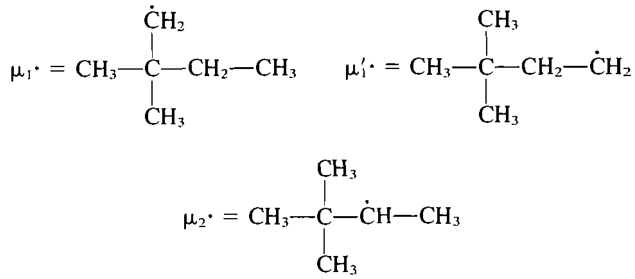
5.1. *Diméthyl-2,2 butane pur*

Vers 450°C (723 K), le diméthyl-2,2 butane se décompose selon cinq stoechiométries primaires principales qui décrivent l'ensemble des produits dosés:

[A″]	C_6H_{14} (2,2 DMB) = CH_4 + C_5H_{10} (m2b1)	4,2%
[B″]	C_6H_{14} (2,2 DMB) = H_2 + C_2H_4 + i-C_4H_8	35,6%
[C″]	C_6H_{14} (2,2 DMB) = C_2H_6 + i-C_4H_8	15,0%
[D″]	C_6H_{14} (2,2 DMB) = C_2H_4 + i-C_4H_{10}	1,6%
[E″]	C_6H_{14} (2,2 DMB) = CH_4 + C_5H_{10} (m2b2)	43,6%

Les valeurs reportées ci-dessus sont les importances relatives des stoechiométries à l'instant initial à 450°C (723 K) et pour une pression initiale de diméthyl-2,2 butane de 100 Torr.

Ces cinq stoechiométries peuvent s'interpréter par un mécanisme radicalaire en chaînes comportant 6 séquences fermées (la stoechiométrie [B″] est déduite de deux séquences fermées différentes). Si l'on appelle $\mu_1\cdot$, $\mu_1'\cdot$ et $\mu_2\cdot$ les trois formes isomères du radical $\mu\cdot$ dérivé de la molécule de diméthyl-2,2 butane μH par arrachement d'un atome d'hydrogène,



le mécanisme proposé (22) pour rendre compte de nos résultats expérimentaux est le suivant:

[20] Amorçage  → radicaux libres

[9]	Propagation [A″]	$\mu_1\cdot \rightarrow CH_3\cdot + C_5H_{10}$ (m2b1)
[21]	$C_6H_{14} = CH_4 + C_5H_{10}$ (m2b1)	$CH_3\cdot + C_6H_{14} \rightarrow CH_4 + \mu\cdot$
[−8A]	Propagation [B″]	$\mu_1\cdot \rightarrow C_2H_5\cdot$ + i-C_4H_8
[3]	$C_6H_{14} = H_2 + C_2H_4$ + i-C_4H_8	$C_2H_5\cdot \rightarrow H\cdot + C_2H_4$
[22]		$H\cdot + C_6H_{14} \rightarrow H_2 + \mu\cdot$
[23]	Propagation [B″ bis]	$\mu_1'\cdot \rightarrow$ *t*-$C_4H_9\cdot + C_2H_4$
[−5t]	$C_6H_{14} = H_2 + C_2H_4$ + i-C_4H_8	*t*-$C_4H_9\cdot \rightarrow H\cdot$ + i-C_4H_8
[22]		$H\cdot + C_6H_{14} \rightarrow H_2 + \mu\cdot$
[−8A]	Propagation [C″]	$\mu_1\cdot \rightarrow C_2H_5\cdot$ + i-C_4H_8
[24]	$C_6H_{14} = C_2H_6$ + i-C_4H_8	$C_2H_5\cdot + C_6H_{14} \rightarrow C_2H_6 + \mu\cdot$
[23]	Propagation [D″]	$\mu_1'\cdot \rightarrow$ *t*-$C_4H_9\cdot + C_2H_4$
[25]	$C_6H_{14} = C_2H_4$ + i-C_4H_{10}	*t*-$C_4H_9\cdot + C_6H_{14} \rightarrow$ i-$C_4H_{10} + \mu\cdot$
[26]	Propagation [E″]	$\mu_2\cdot \rightarrow CH_3\cdot + C_5H_{10}$ (m2b2)
[27]	$C_6H_{14} = CH_4 + C_5H_{10}$ (m2b2)	$CH_3\cdot + C_6H_{14} \rightarrow CH_4 + \mu\cdot$

Terminaison: combinaison ou dismutation des radicaux $CH_3\cdot$, $C_2H_5\cdot$ et *t*-$C_4H_9\cdot$

L'ordre global de la réaction est proche de 1; la constante de vitesse globale déterminée expérimentalement peut se mettre sous la forme:

$$k_0 = 10^{11}\ 10^{-\frac{51\,000}{4{,}577\,T}}\ \mathrm{s}^{-1}$$

L'allure auto-inhibée des courbes de formation de produits est attribuée, en accord avec ce qui précède, à la formation au cours du temps de méthyl-2 butène-2, de méthyl-2 butène-1 et d'isobutène (22).

5.2. *Co-réaction diméthyl-2,2 butane – alcène*

Les rappels précédents montrent donc que le mécanisme de pyrolyse est assez complexe; il y a trois formes isomères du radical $\mu\cdot$ et plusieurs porteurs de chaînes, dont certains d'entre eux peuvent à la fois réagir en $\beta\cdot$ et en $\mu\cdot$ (t-$C_4H_9\cdot$, $C_2H_5\cdot$). H· intervient également comme porteur de chaînes.

Pour éviter une trop longue et fastidieuse écriture de processus élémentaires, dont le nombre augmenterait encore en présence d'alcène ajouté, et qui, par ailleurs, sont fondamentalement de même nature que ceux écrits dans le cas de l'éthane ou de l'isobutane, nous présentons nos résultats expérimentaux sous forme d'un tableau récapitulatif (tableau 4). Nous ajouterons quelques commentaires sur les aspects les plus significatifs de ces résultats.

En additionnant l'atome libre d'hydrogène formé dans des processus de propagation sur la double liaison de l'alcène ajouté et en écrivant les processus élémentaires subséquents des radicaux libres ainsi formés, on peut rendre compte des modifications apportées à la distribution des produits de réaction par des schémas proches de ceux décrits précédemment.

Dans le cas où l'alcène ajouté est le *propène*, les nouvelles stoechiométries de co-réactions aboutissent à une transformation de l'alcène en C_n ($n = 3$) en alcène en C_{n-1} ($n - 1 = 2$, C_2H_4, stoechiométrie [F″]); on observe la formation de l'alcane correspondant au nombre d'atomes de carbone de l'alcène (ici, du propane, stoechiométrie [G″]) et la diminution parallèle des quantités relatives d'hydrogène moléculaire formé; la stoechiométrie [B″] passe de 35,6% dans le cas du diméthyl-2,2 butane pur à 20,8% dans le cas de mélanges diméthyl-2,2 butane – propène (rapport $r = [C_3H_6]_0/[2{,}2\ \mathrm{DMB}]_0 = 0{,}10$. L'importance relative de la stoechiométrie de perte de méthane [E″] est peu modifiée.

Les résultats observés en présence d'*isobutène* ajouté confirment ces observations qui peuvent également être traduites en termes de processus élémentaires qui, regroupés en séquences fermées, permettent de vérifier les équations stoechiométriques déduites des résultats expérimentaux.

Lorsque l'alcène ajouté est le méthyl-2 butène-2 ou le méthyl-2 butène-1, on peut remarquer (cf. tableau 4) que, par addition d'un atome libre d'hydrogène sur une des 2 extrémités de la double liaison, on ne forme plus, contrairement au cas des 2 alcènes précédents, un radical libre ne pouvant se décomposer que par rupture d'une liaison C—H (dans le cas du propène, il s'agissait du radical isopropyle, dans le cas de l'isobutène, du radical *tert*-butyle). Cette observation présente de l'intérêt pour l'interprétation de résultats expérimentaux: (*i*) sur le plan des effets chimiques, la stoechiométrie conduisant à un alcane ayant le même nombre d'atomes de carbone que l'alcène ajouté n'apparaît plus (cf. tableau 4). Par exemple, l'addition d'un méthyl-butène ne conduit pas à la formation de quantités appréciables d'isopentane, alors que celle de propène conduit à la formation de propane (stoechiométrie [G″], tableau 4). Ce résultat est logique, puisque dans le cas des méthyl-butènes, le radical précurseur de l'isopentane n'a pas

TABLEAU 3. Pyrolyse de l'isobutane en présence d'un alcène

Alcène ajouté	Radical(aux) responsable(s) de l'inhibition	Radical(aux) responsable(s) de l'effet chimique	T (°C)	Stoechiométries		Importance relative† (%)
Propène	$\dot{C}H_2—CH{=}CH_2$*	$CH_3—CH_2—\dot{C}H_2$	470, 490	$i\text{-}C_4H_{10} = CH_4 + C_3H_6$	[A′]	25,4

* Radicaux formés par arrachement d'hydrogène sur l'alcène considéré, les autres radicaux sont formés par addition de H· sur l'alcène correspondant.
† [D″] est déjà une stoechiométrie de la pyrolyse du produit pur.

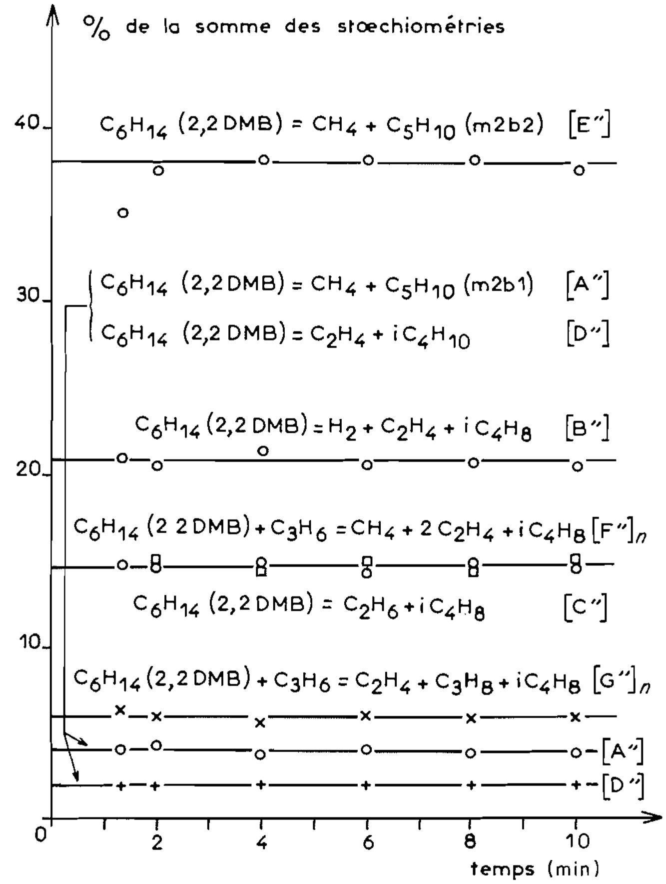

FIG. 6. Pyrolyse du diméthyl-2,2 butane en présence de propène. Répartition des stoechiométries primaires principales (T = 450°C (723 K), $P_0^{2,2\,\mathrm{DMB}}$ = 100 Torr, r = $[C_3H_6]_0/[2,2\ \mathrm{DMB}]_0$ = 0,10). L'indice n désigne les nouvelles stoechiométries qui apparaissent en présence de propène.

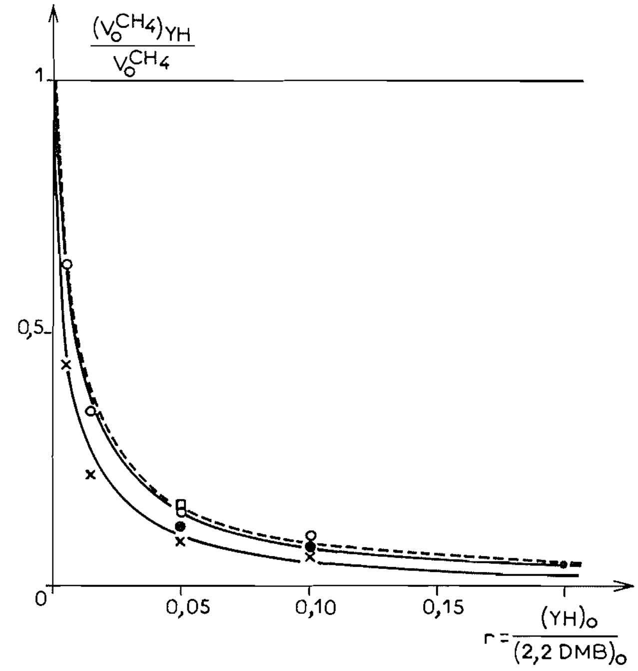

FIG. 7. Pyrolyse du diméthyl-2,2 butane en présence d'alcènes (YH) d'après Billaud *et al.* (18). Variation du rapport $(V_0^{CH_4})_{YH}/V_0^{CH_4}$ avec r = $[YH]_0/[2,2\ \mathrm{DMB}]_0$. YH = méthyl-2 butène-2 ×; YH = isobutène ●; YH = propène ○; YH = méthyl-2 butène-1 □; —— courbes calculées (T = 450°C (723 K), $P_0^{2,2\,\mathrm{DMB}}$ = 100 Torr).

une stabilité thermique suffisante pour se trouver en concentration stationnaire significative; (*ii*) sur le plan des effets cinétiques, dans le cas des méthyl-butènes, l'effet inhibiteur (ou auto-inhibiteur) ne peut pas être attribué, même partiellement, à l'addition de l'atome libre H· sur la double liaison de la molécule d'oléfine, en raison de la relativement faible stabilité thermique des radicaux alcoyle ainsi formés (décomposition unimoléculaire par rupture d'une liaison C—C, cf. ci-dessus). Cet effet inhibiteur peut être attribué *uniquement à des processus d'arrachement* d'un atome d'hydrogène conduisant à un radical de type allylique, stabilisé par résonance.

Les deux types d'effets observés sont donc très cohérents avec la stabilité thermique des radicaux.

Sur la figure 7, adaptée de la réf. 18, nous avons représenté le rapport $(V_0^{CH_4})_{YH}/V_0^{CH_4}$ des vitesses initiales de formation de méthane en présence et en absence d'alcène YH ajouté, en fonction du rapport r des concentrations initiales d'alcène $[YH]_0$ et de diméthyl-2,2 butane $[2,2\ \mathrm{DMB}]_0$; la température est de 450°C (723 K) et la pression initiale de diméthyl-2,2 butane est de 100 Torr.

Cette comparaison de l'effet inhibiteur de quatre alcènes montre à nouveau que le méthyl-2 butène-2 a un effet inhibiteur *légèrement supérieur à celui du propène*, bien que pouvant agir *uniquement par un mécanisme par arrachement d'hydrogène*. Le méthyl-2 butène-1 a un effet inhibiteur pratiquement identique à celui du propène.

Ceci paraît donc confirmer les observations faites sur l'exemple de l'isobutane.

Par conséquent, dans le cas de la pyrolyse du diméthyl-2,2 butane, dont le mécanisme est relativement complexe, nous avons encore vérifié les conclusions, tant sur le plan cinétique que sur le plan chimique, mises en évidence lors de l'étude de réactions thermiques d'alcanes plus légers (éthane et isobutane). Il faut d'ailleurs remarquer que, dans le cas du diméthyl-2,2 butane, contrairement aux cas de l'éthane et de l'isobutane, l'atome libre H· n'est pas formé par décomposition unimoléculaire d'une des formes isomères du radical μ·, mais provient de la décomposition soit du radical éthyle, soit du radical *tert*-butyle, ces radicaux étant issus de la décomposition unimoléculaire de μ·. H· n'est donc dans ce cas pas un porteur de chaînes β· "direct" comme il l'était dans les cas de l'éthane et de l'isobutane et il faut aussi noter que les radicaux dont il est issu (éthyle et *tert*-butyle) peuvent aussi agir comme porteurs de chaînes β· (stoechiométries [C″] et [D″]).

Malgré cette complexité plus grande des schémas cinétiques et des séquences de propagation, le rôle des additions de l'atome libre H· sur les alcènes ajoutés apparaît encore prépondérant pour rendre compte des modifications apportées à la répartition des produits.

L'addition d'autres porteurs de chaînes sur la double liaison des alcènes ajoutés ne permet pas de rendre compte des effets observés sur la répartition des produits; la raison fondamentale en est encore, sur cet exemple, la réversibilité du processus d'addition (rupture de la liaison C—C formée). Les additions de radicaux alcoyle permettent au plus de rendre compte de la formation d'un certain nombre de produits en traces, mais dont l'importance reste négligeable dans l'établissement d'un bilan entre réactifs consommées et produits formés.

Discussion et conclusion

Dans cette discussion, nous apporterons des éléments complémentaires sur le rôle de l'addition d'espèces radicalaires autres que H·; nous essaierons, à partir de nos résultats, de formuler des principes plus généraux régissant les modifications apportées à la répartition des produits et nous mentionnerons quelques applications envisageables de ces travaux.

1. *Rôle de l'addition d'espèces radicalaires autres que H·*

Pour corroborer les conclusions des études précédentes, nous avons recherché dans la littérature un exemple de pyrolyse d'alcane où il n'y a pas d'atomes libres d'hydrogène jouant le rôle de porteurs de chaînes β·. Le néopentane (diméthyl-2,2 propane), qui se décompose selon une seule équation stoechiométrique primaire principale:

[K] $\text{néo-}C_5H_{12} = CH_4 + \text{i-}C_4H_8$

répond à cette condition. En effet, des études détaillées effectuées par différents auteurs montrent que le seul porteur de chaînes de type β· (réagissant bimoléculairement) est le radical libre méthyle (cf., par exemple, les références 3, 4 et 34). La séquence de propagation conduisant à l'équation stoechiométrique ci-dessus s'écrit:

[28] $\text{néo-}C_5H_{11}\cdot \rightarrow \text{i-}C_4H_8 + CH_3\cdot$

[29] $CH_3\cdot + \text{néo-}C_5H_{12} \rightarrow CH_4 + \text{néo-}C_5H_{11}\cdot$

Dans le cas de la pyrolyse de mélanges néopentane–isobutène, Baronnet *et al.* (2) ont observé la formation primaire de petites quantités de méthyl-2 butène-1 et de méthyl-2 butène-2. Pour expliquer la formation de ces produits, il semble logique de considérer l'addition réversible de $CH_3\cdot$ sur la molécule d'isobutène conduisant à un radical *tert*-pentyle:

[30] $CH_3\cdot + CH_2{=}C(CH_3)_2 \rightleftarrows CH_3{-}CH_2{-}\dot{C}(CH_3)_2$

Ce radical peut aussi se décomposer, mais nettement moins facilement, par rupture d'une liaison carbone–hydrogène plus solide qu'une liaison C—C pour conduire à la formation de méthyl-butènes 1 et 2 selon:

[−10B] $CH_3{-}CH_2{-}\dot{C}(CH_3){-}CH_3 \rightarrow CH_3{-}CH_2{-}C(CH_3){=}CH_2 + H\cdot$

[−10A] $CH_3{-}CH_2{-}\dot{C}(CH_3){-}CH_3 \rightarrow CH_3{-}CH{=}C(CH_3){-}CH_3 + H\cdot$

H· réagit sur le néopentane pour former une molécule d'hydrogène et un radical néo-$C_5H_{11}\cdot$; la décomposition de celui-ci en $CH_3\cdot$ et isobutène conduit effectivement à une séquence fermée.

[31] $H\cdot + \text{néo-}C_5H_{12} \rightarrow H_2 + \text{néo-}C_5H_{11}\cdot$

[28] $\text{néo-}C_5H_{11}\cdot \rightarrow CH_3\cdot + \text{i-}C_4H_8$

Les équations stoechiométriques dérivées des séquences fermées ainsi écrites rendent compte de la formation primaire des méthyl butènes lors de la pyrolyse du néopentane en présence d'isobutène. L'importance relative des 2 équations stoechiométriques correspondantes:

[L] $\text{néo-}C_5H_{12} = H_2 + C_5H_{10}$ (méthyl-2 butène-1)

[M] $\text{néo-}C_5H_{12} = H_2 + C_5H_{10}$ (méthyl-2 butène-2)

est représentée sur la figure 8 (d'après les résultats de F. Baronnet (35)).

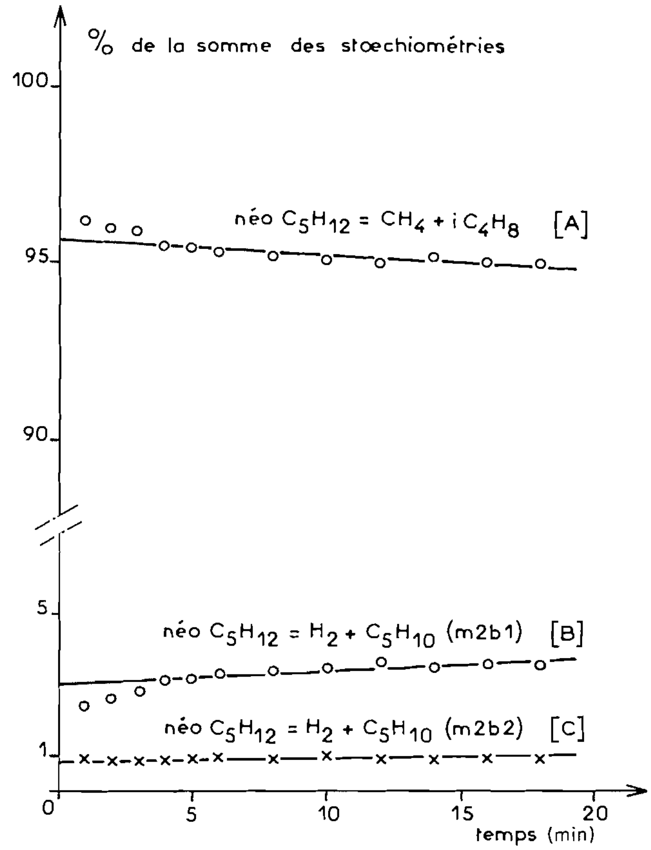

FIG. 8. Pyrolyse du néopentane en présence d'isobutène d'après les résultats de F. Baronnet (35). Répartition des stoechiométries primaires principales (T = 512°C (785 K), $P_0^{\text{néo}C_5H_{12}}$ = 100 Torr, $r = [\text{i-}C_4H_8]_0/[\text{néo }C_5H_{12}]_0 = 0{,}25$).

Ces résultats montrent qu'à 512°C (785 K), pour une pression initiale de néopentane de 100 Torr et un rapport des concentrations initiales $r = [\text{i-}C_4H_8]_0/[\text{néo-}C_5H_{12}]_0 = 0{,}25$, la répartition des stoechiométries extrapolée à l'instant initial est la suivante:

[K]	$\text{néo-}C_5H_{12} = CH_4 + \text{i-}C_4H_8$	95,7%
[L]	$\text{néo-}C_5H_{12} = H_2 + C_5H_{10}$ (m2bl)	3,0%
[M]	$\text{néo-}C_5H_{12} = H_2 + C_5H_{10}$ (m2b2)	1,3%

Ces deux nouvelles stoechiométries [L] et [M] correspondant à l'addition de $CH_3\cdot$ sur l'isobutène représentent seulement 4,3% des stoechiométries de consommation du néopentane alors que, dans des conditions comparables de température et de rapport de concentrations initiales, les stoechiométries dues à l'addition de H· sur l'isobutène lors de la pyrolyse de mélanges éthane–isobutène représentent environ 30% de l'ensemble des stoechiométries de consommation de l'éthane.

Un travail récent de P. Azay (36) sur la modélisation de réactions radicalaires complexes est en bon accord avec nos conclusions. En effet, Azay souligne que, malgré leur concentration relative généralement très faible par rapport à celle des autres radicaux libres présents dans le milieu, il faut *en premier lieu* écrire *systématiquement* les processus d'addition de H· sur les alcènes.

Pour tenir compte éventuellement de l'addition des *autres* radicaux libres, Azay estime que les concentrations relatives des espèces radicalaires considérées doivent être suffisantes. Ceci explique que, pour ses résultats, à température assez élevée, l'addition de $CH_3\cdot$ puisse être considérée, bien que jouant un rôle nettement moins important que celle de H·. L'addition d'autres espèces a un effet totalement négligeable.

2. *Essai de formulation des principes régissant les changements de stoechiométrie*

Leathard (37) a résumé en quatre règles les principes susceptibles de régir l'influence auto-inhibitrice (et donc inhibitrice) d'alcènes sur la pyrolyse d'alcanes; rappelons ces quatre règles:

(a) "De tous les radicaux alcoyle saturés qui peuvent être présents dans le milieu réactionnel, seuls les radicaux méthyle, éthyle, isopropyle et *tert*-butyle peuvent terminer les chaînes par des processus homogènes de combinaison."

(b) "L'addition de radicaux alcoyle à des oléfines ne peut pas conduire à l'apparition de l'auto-inhibition."

(c) "Les processus d'addition d'un atome libre d'hydrogène sur une oléfine peuvent conduire à des processus d'auto-inhibition lorsqu'ils forment des radicaux éthyle, isopropyle et *tert*-butyle."

(d) "L'arrachement d'hydrogène par des radicaux alcoyle sur un produit saturé, y compris l'hydrogène moléculaire, ne peut pas conduire à l'appartition d'auto-inhibition."

Ces quatre règles, initialement formulées par Leathard pour rendre compte des phénomènes d'auto-inhibition sont en très bon accord avec les observations faites dans des études d'inhibition (par des oléfines ajoutées) et avec les résultats précédents (point (b) en particulier).

Leathard ne s'est intéressé qu'à la *cinétique* des stoechiométries primaires principales et n'a pas abordé le problème des perturbations apportées à la distribution des produits. Rappelons également que de nombreux travaux du Laboratoire, confirmés d'ailleurs par des résultats décrits dans cet article, ont montré qu'il fallait également tenir compte des processus d'arrachement d'un atome d'hydrogène sur des oléfines pour décrire correctement les phénomènes d'inhibition et d'auto-inhibition; ces processus conduisent à la formation de radicaux libres stabilisés par résonance et peuvent même jouer un rôle prépondérant par rapport aux processus d'addition.

Compte-tenu des résultats précédents ainsi que de ceux de certains autres auteurs, nous pouvons compléter les règles de Leathard qui traitent de l'aspect *cinétique* par de nouvelles règles simples de formulation voisine et qui traiteront de l'aspect *chimique* des réactions de pyrolyse d'alcanes en présence d'oléfines, soit ajoutées à l'instant initial, soit formées par la réaction elle-même:

(a) Parmi tous les porteurs de chaînes de type β (réagissant bimoléculairement avec l'alcane pyrolysé), seul l'atome libre H·, par addition sur des oléfines, peut conduire à d'importants changements dans la répartition des stoechiométries de consommation de l'alcane et à l'apparition de nouvelles stoechiométries d'importance notable.

(b) L'addition de radicaux alcoyle à des oléfines ne conduit pas à d'importantes modifications de la répartition des stoechiométries.

(c) L'addition d'atomes d'hydrogène à des oléfines peut conduire à d'importants changements dans la répartition des stoechiométries lorsque le radical alcoyle ainsi formé se décompose par la rupture d'une liaison carbone—carbone.

(d) Alors que les processus d'arrachement d'hydrogène sur des oléfines ont généralement une influence cinétique (inhibitrice) importante, de tels processus n'ont pas d'influence notable sur la répartition des produits de la réaction.

Ces règles appellent un certain nombre de commentaires permettant en particulier de préciser leurs conditions d'application. Elles ont été déduites d'études de pyrolyses d'alcanes en présence de 20 à 25% d'une oléfine ajoutée, lors de réactions effectuées à relativement faible avancement, généralement inférieur à 5%. Les températures d'expérience se situent généralement dans le domaine 450—550°C (723—823 K), mais les résultats d'Azay (36) suggèrent que les conclusions obtenues demeurent valables jusque vers 700°C et pour des avancements de réaction nettement supérieurs à 5%.

Remarquons qu'un certain nombre de points développés dans ce qui précède avaient déjà été mis en évidence, plus ou moins partiellement, dans des travaux antérieurs (12—15). Nous pensons que la présentation qui en est faite ici leur donne un caractère plus complet et surtout plus synthétique.

3. *Applications possibles de ces résultats*

On pourrait se demander si de telles études nécessitant un nombre élevé d'expériences et des procédures analytiques souvent délicates et complexes restent compétitives par rapport à des approches totalement différentes, telles que celles d'Allara et Edelson (38) qui ont cherché à déterminer des mécanismes réactionnels par des méthodes informatiques. Ces auteurs ont mis au point un compilateur permettant d'écrire automatiquement l'ensemble des processus intervenant dans des réactions de pyrolyse d'alcanes linéaires légers. Les équations différentielles résultantes sont résolues par une adaptation de la méthode de Gear (39), en utilisant une évaluation des constantes de vitesse des processus élémentaires.

Le nombre de ceux-ci devient rapidement très élevé. Dans le cas du propane, il intervient 293 processus élémentaires impliquant 32 espèces de radicaux libres et 29 molécules hydrocarbonées. Ces nombres augmentent rapidement avec le nombre d'atomes de carbone de l'alcane linéaire de départ.

La complexité des mécanismes risquerait de devenir prohibitive dans le cas de molécules relativement lourdes; il se révèle indispensable de pouvoir simplifier le mécanisme en diminuant le nombre de processus à considérer, en ne tenant compte que des processus ayant de l'importance dans la formation des produits et la cinétique de la réaction.

Les considérations précédentes peuvent se révéler utiles dans de telles démarches simplificatrices. Elles montrent par exemple que, pour une description suffisamment réaliste de la réaction, il suffit, dans le cas des processus d'addition, de tenir compte seulement de l'addition de l'atome libre H· sur les oléfines, les additions des radicaux alcoyle pouvant être considérées comme négligeables.

Ces études peuvent également avoir des applications dans le craquage des alcanes légers, pour la production d'oléfines légères, en particulier de propène et d'éthylène. En effet, à la suite de la découverte de gisements de gaz en Mer du Nord, la modification de craqueurs en vue de leur alimentation à l'éthane et la construction de craqueurs nouveaux alimentés en éthane ont été entreprises.

Le présent travail montre que la présence d'atomes libres H· dans le milieu réactionnel est favorable à la transformation d'oléfines en C_n en oléfines en C_{n-1}. Par des co-réactions analogues à celles étudiées précédemment, il est possible de passer des butènes au propène et du propène à l'éthylène. Ceci laisse entrevoir des possibilités d'une meilleure adaptation des productions aux demandes du marché et de donner ainsi une certaine flexibilité aux unités de vapocraquage.

Nos résultats permettent aussi d'interpréter un certain nombre d'observations faites dans des unités industrielles. Il a été montré, par exemple, que le craquage de mélanges de propène et d'éthane donnait des rendements intéressants en éthylène, supérieurs à la somme des quantités issues des deux hydrocarbures craqués séparément. De même, il a été montré que le craquage simultané de naphta et d'éthane donnait de meilleurs rendements en éthylène que leur craquage séparé.

Ces observations s'expliquent logiquement par la génération *in situ* d'atomes libres H· par la co-pyrolyse de l'éthane. On peut estimer que la synergie est d'autant plus marquée que le rendement en hydrogène de l'alcane co-craqué est important; de ce point de vue, l'éthane est le meilleur alcane envisageable puisqu'il se craque en donnant une mole d'hydrogène (et une mole d'éthylène) pour une molécule d'éthane.

Enfin, on peut remarquer que des études analogues pourraient apporter une contribution substantielle à la connaissance des réactions thermiques de molécules hydrocarbonées relativement lourdes, ce qui présenterait un intérêt en vue de la valorisation de coupes pétrolières lourdes. Si la modification du rapport C/H est l'objectif essentiel des traitements, la génération *in situ* d'atomes libres d'hydrogène est vraisemblablement un outil plus efficace que de simples réactions en présence d'hydrogène moléculaire.

For the purpose of preparing the ring-expanded analogue of anthracene, 1,2,4,5-tetrakis[(1*E*,3*Z*)-4-methylhexa-1,3-dien-5-ynyl]benzene, **8**, and 1,2,4,5-tetrakis[(*Z*)-2(2-ethnylphenyl)ethenyl]benzene, **16**, were oxidatively coupled; however, both of them afforded *m*-bridged derivatives, i.e., 1,3:4,6-bis[(1*E*,3*Z*,9*Z*,11*E*)-4,9-dimethyldodeca-1,3,9,11-tetraene-5,7-diyne-1,12-diyl]benzene, **3**, and 1,3:4,6-bis[(1*E*,11*E*)-3,4:9,10-dibenzdodeca-1,11-diene-5,7-diyne-1,12-diyl]benzene, **5**. To ascertain the structures of **3** and **5**, the related model compounds were also prepared.

JURO OJIMA, HIROSHI KAKUMI, KAZUTO KITATANI, KAZUYO WADA, EMIKO EJIRI et TETSUYA NAKADA. Can. J. Chem. **63**, 2885 (1985).

Dans le but de préparer l'analogue de l'anthracène comportant un cycle ayant subit une extension, on a procédé à un couplage oxydant du tétrakis[méthyl-4 hexadiène-1,3(1*E*,3*Z*) yne-5 yl]-1,2,4,5 benzène (**8**) et du tétrakis[(éthynyl-2 phényl)-2(*Z*) éthènyl]-1,2,4,5 (**16**); toutefois, chacun de ces produits ne conduit qu'aux dérivés pontés en position *méta*, soit les bis[diméthyl-4,9 dodécatétraène-1,3,9,11 (1*E*,3*Z*,9*Z*,11*E*) diyne-5,7 diyl-1,12]-1,3:4,6 benzène (**3**) et bis[dibenzo-3,4:9,10 dodécadiène-1,11 (1*E*,11*E*) diyne-5,7 diyl-1,12]-1,3:4,6 benzène (**5**). Dans le but de s'assurer de la structure des composés **3** et **5**, on a aussi préparé des composés modèles apparentés.

[Traduit par le journal]

Introduction

A considerable number of monocyclic annulenes annelated with benzenoid rings (1) as well as annulenoannulenes (2) have been prepared, and an extensive examination of their properties is reviewed by Mitchell (3). Among them, the dimethylbisdehydro-2,3-naphtho[14]annulene, **1**, prepared by Walsgrove and Sondheimer (4), is only one example of the ring-expanded analogue of anthracene, in which a terminal 6π-ring has been formally expanded to a 14π-ring. Since no example of a benzannelated annulene fused with two bonds of an annelated benzenoid ring had ever been reported, we attempted a synthesis of the bis(dimethylbisdehydro[14]annulene) annelated benzene, **2**, in which two terminal rings of anthracene are formally expanded to 14π-rings. We considered that an examination of the properties of **2** might give further insight toward the understanding of benzannelated annulenes. However, an intramolecular oxidative coupling of the precursor did not afford the desired **2**, but the alternative cyclic compound, **3**.

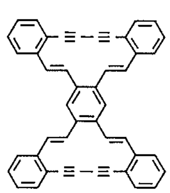
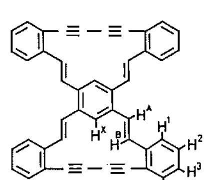
3



4



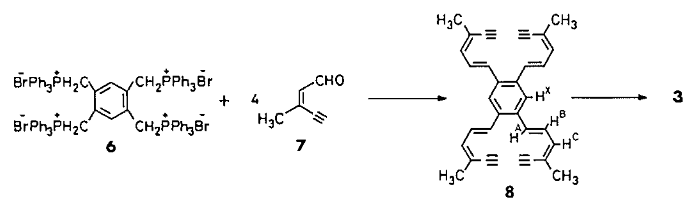
5

Since we had already reported the formation of the tetrabenzannelated derivative **4** from its precursor (5), the formation of **3** prompted us to reexamine the previous investigation. Examination of the spectral properties of the related model compounds revealed that this tetrabenzannelated derivative also had the *m*-bridged structure **5** corresponding to **3**. This paper describes these results in detail.

Results and discussion

I. *Formation of tricyclic compound, 3*

The Wittig reaction of 1,2,4,5-tetrakis(triphenylphosphoniomethyl)benzene tetrabromide, **6** (6), and 4 molar equivalents of (2*Z*)-3-methyl-2-penten-4-ynal, **7** (7), in THF with *n*-BuLi at −60°C yielded only the desired all-*trans* isomer, **8**, as crystals in 13% yield; **8** was rather unstable. Oxidative coupling of **8** was carried out with anhydrous $Cu(OAc)_2$ in pyridine and ether at 50°C (8). Column chromatography of the



product, followed by preparative tlc gave unstable red crystals in 7% yield. The [1]Hmr spectrum of this monomeric cyclic product is illustrated in Fig. 1. We considered from the spectrum that the compound is the *m*-bridged derivative, **3**. However, to ascertain this, we attempted to prepare the related model compound, **13**.

The double Wittig reaction of 2 molar equivalents of **7** and 1 molar equivalent of *m*-bis(triphenylphosphoniomethyl)benzene dibromide, **9** (9), in DMF with ethanolic lithium ethoxide at 80°C yielded an acyclic stereoisomeric mixture in 57% yield, from which the *cis–cis* isomer, **10**, the *cis–trans* isomer, **11**, and the *trans–trans* isomer, **12**, were isolated; the structures were assigned to these compounds based on their spectral properties, mainly on [1]Hmr spectra. Oxidative coupling of each isomer was carried out as described for **8**.

[1]Author to whom correspondence may be addressed.

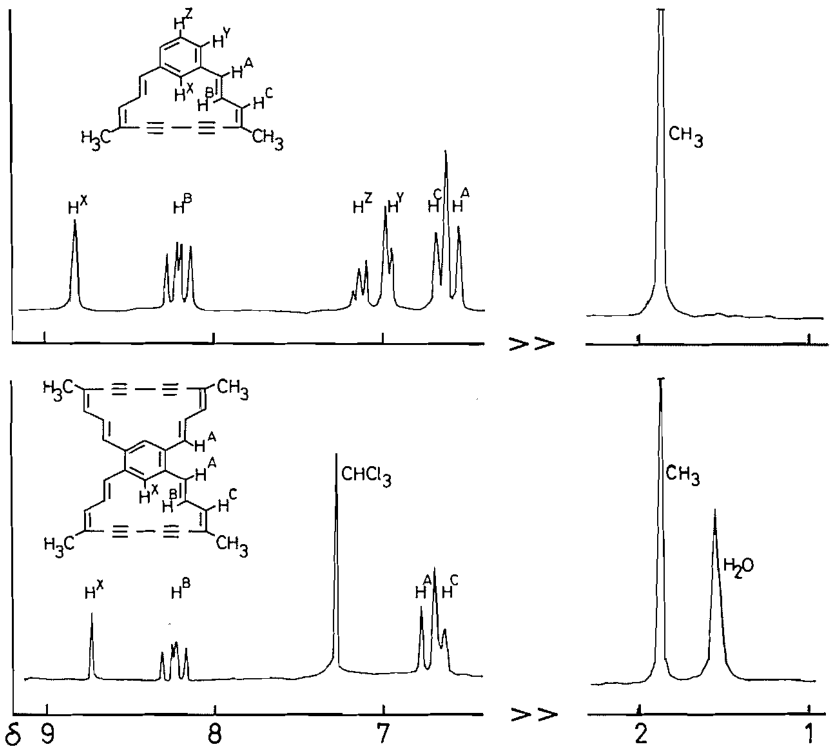


FIG. 1. Varian XL-200 [1]Hmr spectra of 3 and 13.

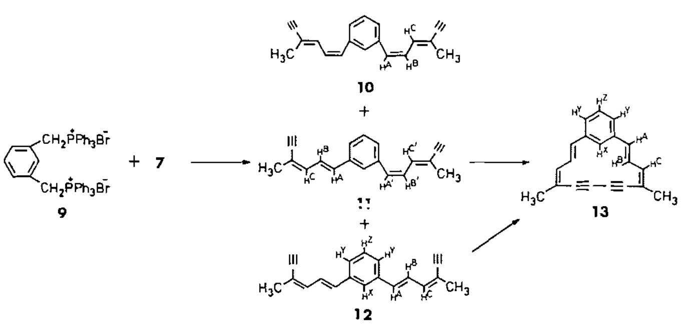
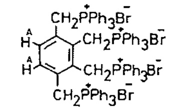
Although the di-*cis* isomer, **10**, gave no monomeric cyclic compound, both the mono-*cis*, **11**, and the di-*trans* isomer, **12**, gave the desired cyclic compound, **13**, in 3% and 23% yield, respectively; **13** was isolated as stable orange crystals and its [1]Hmr spectrum is also illustrated in Fig. 1. Variable-temperature [1]Hmr spectra of **13** were run at 90 MHz over the range −60 to 60°C, and the results show the spectra of **13** to be essentially temperature independent, excluding any conformational change of **13** between these temperatures. As is seen from Fig. 1, the spectra of both **3** and **13** are quite similar,



except that the H^A proton of **3** resonates at a lower field by 0.16 ppm (see Fig. 1 and Experimental) than the H^A proton of **13**, probably due to a steric compression effect between H^A and H^A protons of two large-membered rings in **3**. Thus it was confirmed that the cyclic compound from **8** has not the structure of **2**, but of **3**.

The Wittig reaction between **6** and (2*E*,4*Z*)-5-methylhepta-2,4-dien-6-ynal (10), a vinylogue of the above described aldehyde, **7**, was also attempted, but all attempts were unsuccessful.

In addition, the tetrabromide, **14**, was prepared to obtain the phenanthrene analogue corresponding to **2**. The reaction of 1,2,3,4-tetra(bromomethyl)benzene (11) with 4 molar equivalents of triphenylphosphine under reflux in acetylacetone afforded 1,2,3,4-tetrakis(triphenylphosphoniomethyl)benzene tetrabromide, **14**, in 91% yield as white crystals. The Wittig reaction between **7** and **14** under the conditions described for that between **6** and **7** was, however, unsuccessful.

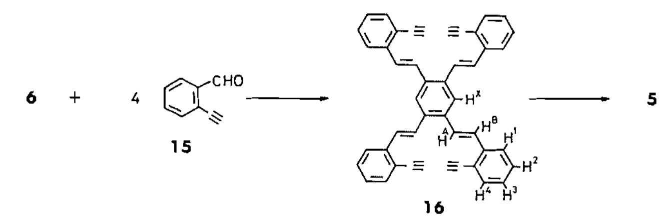


14

II. *Formation of tetrabenzannelated tricyclic compound, 5*

As described in I, it was found that the intramolecular oxidative coupling of **8** gives **3**, but not **2**. This suggested that the product from the corresponding tetrabenzannelated derivative of **8** might also be the *m*-bridged derivative, **5**, and not the *o*-bridged derivative, **4**, as we had previously reported (5).

The Wittig reaction of **6** with 4 molar equivalents of *o*-ethynylbenzaldehyde, **15** (12), yielded an acyclic stereoisomeric mixture in 27% yield, from which the all-*trans* isomer, **16**, was isolated in 6% yield as yellow crystals after chromatographic purification. The structural assignment of **16** was based on its [1]Hmr spectrum as well as elemental analysis.[2] Oxidative coupling of **16** yielded yellow crystals of **5** after



[2]In the previous study (ref. 5), we could not obtain a satisfactory elemental analysis for **16**.

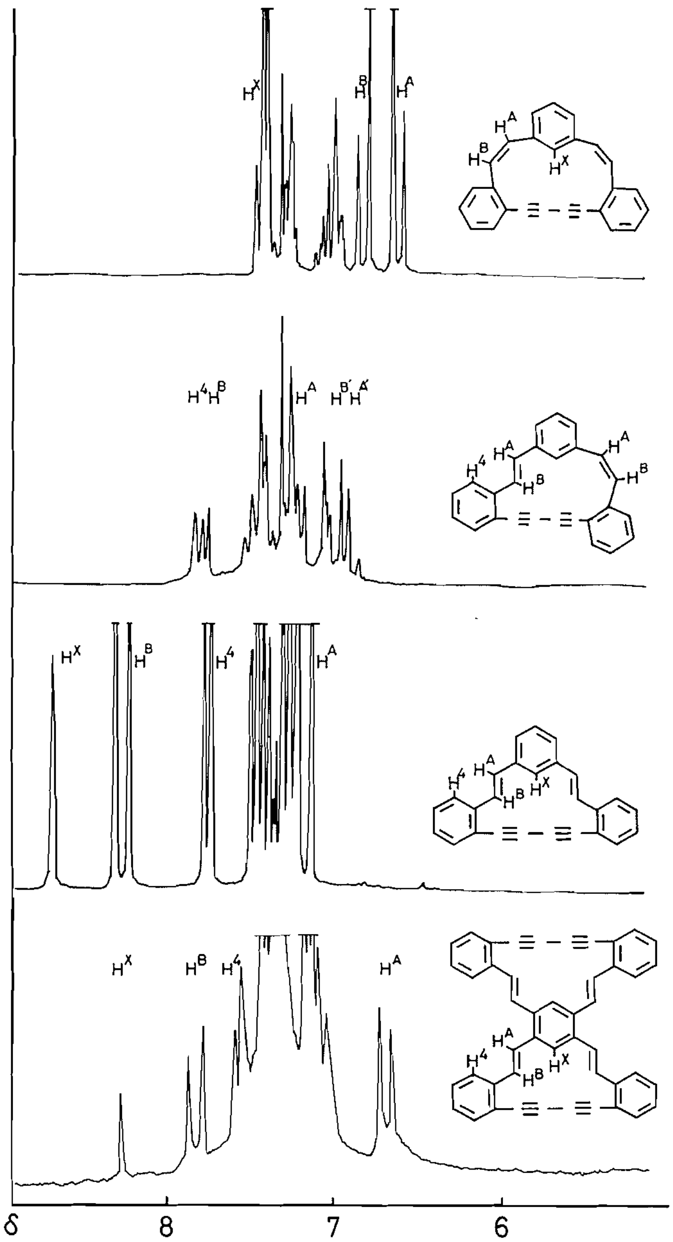


FIG. 2. Varian XL-200 ^{1}Hmr spectra of **5**, **27**, **28**, and **29**.

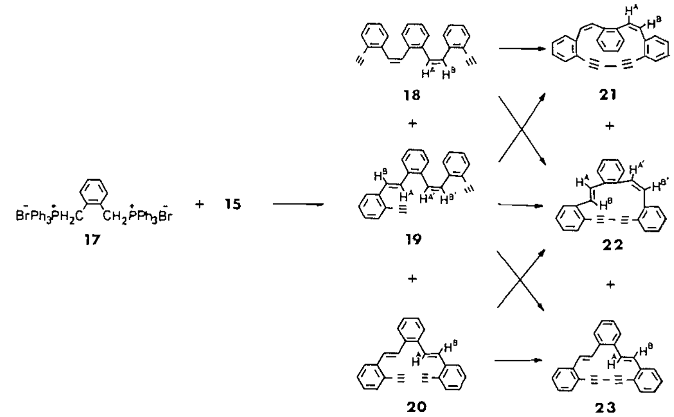
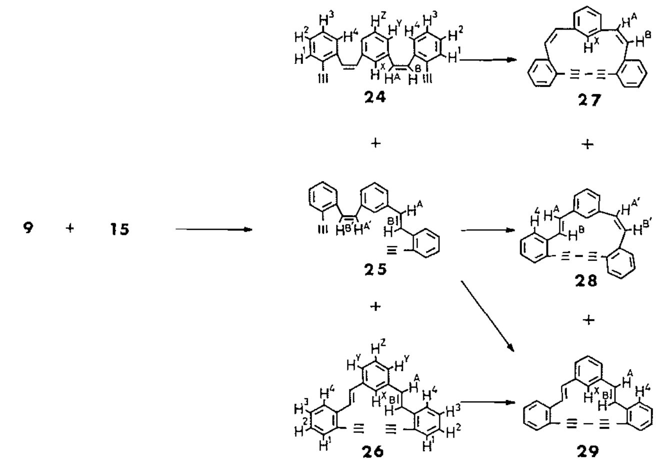
considerable chromatography. Its ^{1}Hmr spectrum is shown in Fig. 2. As described for the structural determination of **3**, we prepared the model compounds to determine whether structure **4** or **5** should be assigned to this product.

Firstly, the related *o*-bridged derivatives were prepared as illustrated in Scheme 1. The double Wittig reaction of 2 molar equivalents of **15** (12) and 1 molar equivalent of *o*-bis(triphenylphosphoniomethyl)benzene dibromide, **17** (13), in DMF with ethanolic lithium ethoxide at 80°C yielded an acyclic stereoisomeric mixture in 34% yield, from which the *cis–cis* isomer, **18**, the *cis–trans* isomer, **19**, and the *trans–trans* isomer, **20**, were isolated in a ratio 3:2:1 after chromatography.[3] Unexpectedly, the *trans–trans* isomer, **20**, was obtained in the smallest amount. Oxidative coupling of each isomer was performed as before. The acyclic di-*cis* isomer, **18**, gave the cyclic di-*cis*, **21**, and mono-*cis* isomer, **22**, and the acyclic mono-*cis* isomer, **19**, gave all of the three possible isomers, **21–23**. The acyclic di-*trans* isomer, **20**, gave the cyclic mono-*cis*, **22**, and di-*trans* isomer, **23**. Thus a configurational change of the double bond occurred during coupling reactions. A similar change has been observed in the formation of annulenones (14). By inspection of molecular models, the three fused benzene rings cannot lie in the same plane in the di-*cis*, **21**, and mono-*cis* isomer, **22**, but can do so in the di-*trans* isomer, **23**. This is reflected by the colours of their crystals.[3] The cyclic di-*cis*, **21**, is colourless, the mono-*cis* isomer, **22**, pale yellow, and the di-*trans* isomer, **23**, yellow.



SCHEME 1



SCHEME 2

The *m*-bridged derivatives **27–29** were prepared as shown in Scheme 2. The double Wittig reaction of 2 molar equivalents of **15** (12) and 1 molar equivalent of **9** (9) gave an acyclic stereoisomeric mixture in 80% yield, from which the *cis–cis* isomer, **24**, the *cis–trans* isomer, **25**, and the *trans–trans* isomer, **26**, were isolated in a ratio of ca. 3:4:1. Again the di-*trans* isomer, **26**, was obtained in the smallest amount. Oxidative coupling of each isomer was performed as before. The acyclic di-*cis* isomer, **24**, afforded only the cyclic di-*cis* isomer, **27**, and the mono-*cis* isomer, **25**, gave the cyclic mono-*cis*, **28**, and di-*trans* isomer, **29**. The di-*trans* isomer, **26**, gave only the cyclic di-*trans* isomer, **29**.

The ^{1}Hmr spectra of the three isomers of *o*-bridged **21–23** (tribenz[14]annulene series) are illustrated in Fig. 3. As is seen

[3]In the previous study (ref. 12), we could not separate the three possible isomers completely in both the acyclic and the cyclic compounds in this system. Therefore the acyclic and cyclic di-*trans* isomers reported in ref. 12 are in error.

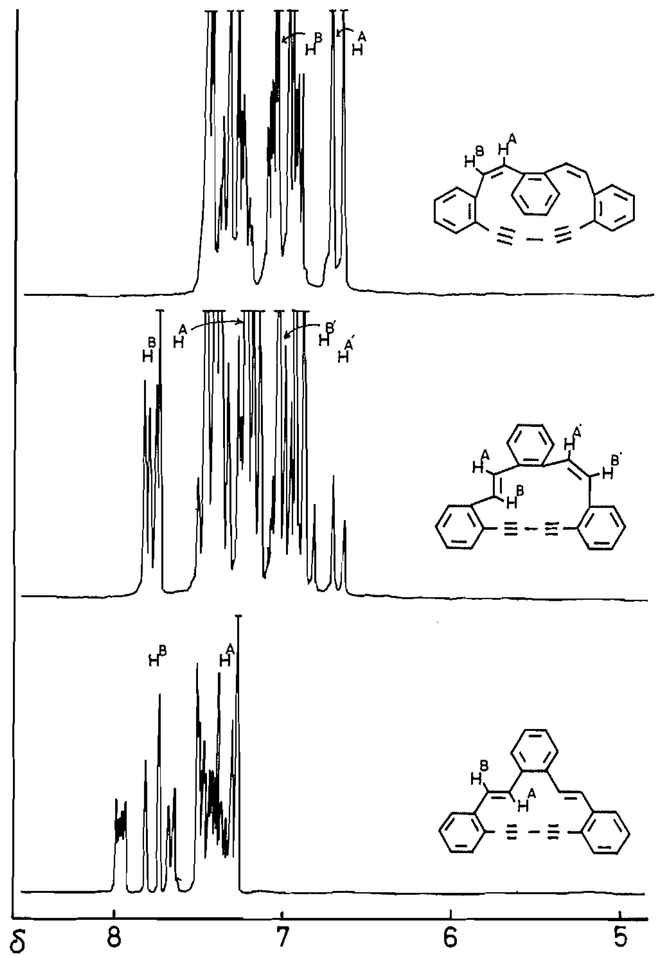


FIG. 3. Varian XL-200 ^{1}Hmr spectra of **21**, **22**, and **23**.

from Fig. 3, the resonances of the olefinic and benzenoid protons of the di-*cis*, **21**, and the mono-*cis* isomer, **22**, are at a higher field than 7δ, while the resonances of the protons of the di-*trans* isomer, **23**, are below 7δ. A similar observation is made in the ^{1}Hmr spectra of *m*-bridged model compounds, **27**–**29**, which are illustrated in Fig. 2. However, as is seen from the spectrum of the di-*trans* isomer, **29**, it is noted that the inner H^X and H^B protons of **29** resonate at considerably lower field than any proton of the other isomers, **21**–**23** and **27**–**28**.

As is shown in Fig. 2, the spectrum of the product from **16** has two doublets with the $J_{A,B}$ value of 16 Hz, indicating a *trans*–*trans* relationship of the H^A and H^B double bond, and, of the models, is most similar to that of the *m*-bridged di-*trans* isomer, **29**. This indicates that the product from **16** has the *m*-bridged structure, **5**, and not the *o*-bridged structure, **4**.

Thus it is a puzzle that neither **8** nor **16** gives an *o*-bridged tricyclic derivative.

Experimental

All melting points were determined on a hot stage apparatus and are uncorrected. The ir spectra were recorded on a Hitachi 260-50 spectrophotometer; only significant maxima are described. The uv spectra were measured for solutions in THF and run on a Hitachi 220-A spectrophotometer. Mass spectra were recorded with a JEOL JMS-200 spectrometer operating at 75 eV using a direct-inlet system, and the field desorption spectra were taken with a JEOL-OI-FG2 spectrometer. The ^{1}Hmr spectra were determined in $CDCl_3$ (unless otherwise stated) on a Varian EM-390 (90 MHz) or FX-90Q (90 MHz) or a Varian XL-200 (200 MHz) spectrometer using tetramethylsilane as internal standard. Merck alumina (activity II–III) was used for column chromatography and preparative thin-layer chromatography was carried out on 20 × 20 cm alumina plates (Merck, 0.5 or 2 mm thick). The progress of most reactions was followed by thin-layer chromatography using Merck precoated alumina. All evaporations were carried out under reduced pressure on a rotary evaporator below ca. 35°C. Extracts were dried with anhydrous sodium sulphate prior to solvent removal.

*1,2,4,5-Tetrakis[(1*E*,3*Z*)-4-methylhexa-1,3-dien-5-ynyl]benzene, 8*

To a stirred suspension of 1,2,4,5-tetrakis(triphenylphosphoniomethyl)benzene tetrabromide, **6** (6) (12.0 g, 8.0 mmol), in dry THF (60 mL) was added a solution of *n*-butyl lithium (19.4 mL, 1.85 *M*, 36 mmol) in hexane by a syringe over 10 min at −55 to −50°C under a nitrogen atmosphere. Then a solution of (2*Z*)-3-methyl-2-penten-4-ynal, **7** (7) (3.00 g, 36 mmol), in dry THF (13 mL) was added dropwise over 40 min at the same temperature. After stirring for a further 2.5 h at the same temperature, the temperature of the mixture was allowed to rise to room temperature and it was stirred for 1 h. After addition of ethyl acetate (16 mL), the mixture was poured into water and was extracted with benzene. The extracts were washed with brine, dried, and evaporated. The residual semi-solid was filtered through a short column of alumina (3.7 × 4 cm) and eluted with ether. The eluate, after solvent removal, was chromatographed on alumina (4 × 15 cm). The fractions eluted with hexane–ether (4:1) were collected and evaporated to give the desired compound, **8** (444 mg, 12.7%), as a solid. Recrystallization from hexane–benzene afforded yellow needles, mp 118°C (dec.); ir (KBr): 3290 (—C≡CH), 2090 (—C≡C—), and 965 (*trans* HC=CH) cm^{-1}; uv$_{max}$: 243 (25 000), 261 sh (21 800), 271 sh (17 100), 360 (49 000), 380 (48 100), and 404 nm sh (35 600); ^{1}Hmr (200 MHz) δ: 7.66 (s, 2H, H^X), 7.18 (dd, J = 15.5 and 11 Hz, 4H, H^B), 6.87 (d, J = 15.5 Hz, 4H, H^A), 6.51 (d, J = 11 Hz, 4H, H^C), 3.34 (s, 4H, —C≡CH), and 2.01 (s, 12H, CH_3); ms (field desorption method) *m/e*: 438, mol. wt. 438.5; *Anal.* calcd for $C_{34}H_{30}$: C 93.11, H 6.89; found: C 92.85, H 6.80.

The runs employing lithium ethoxide in DMF at 80°C or phenyllithium in THF at room temperature gave none of the desired product.

*1,3:4,6-Bis[(1*E*,3*Z*,9*Z*,11*E*)-4,9-dimethyldodeca-1,3,9,11-tetraene-5,7-diyne-1,12-diyl]benzene, 3*

A solution of **8** (2.80 g, 6.40 mmol) in pyridine (100 mL) and dry ether (33 mL) was added dropwise to a stirred solution of anhydrous $Cu(OAc)_2$ (15.9 g) in pyridine (556 mL) and dry ether (185 mL) over 5 h at 51–55°C. After stirring for 1 h at 50°C, the mixture was chilled and filtered through Hyflo Super-Cel. The precipitates formed were washed with benzene (100 mL × 3), and the filtrate was poured into water. The organic layer, combined with the benzene extracts from the aqueous layer, was washed successively with 5% HCl until it turned acidic, then with aqueous $NaHCO_3$ solution, and dried. The residual dark red liquid, after solvent removal, was chromatographed on alumina (3 × 22 cm). The fractions eluted with hexane–ether (4:1–2:3) were collected and evaporated to afford a red liquid, which was again chromatographed on alumina (3 × 22 cm). The fractions eluted with hexane–ether (1:4) were collected and evaporated to afford a partly crystallized liquid, which was further purified by preparative thin-layer chromatography. The fast-moving orange band gave the cyclic compound, **3** (193 mg, 6.95%), as a solid. It formed red microcrystals from benzene, mp 196–197°C (dec.); ir (KBr): 2160 (—C≡C—) and 960 (*trans* HC=CH) cm^{-1}; uv$_{max}$: 241 (34 300), 296 (58 800), 362 (55 400), and 421 nm sh (28 400); ^{1}Hmr (200 MHz) δ: 8.74 (s, 2H, H^X), 8.25 (dd, J = 16 and 12 Hz, 4H, H^B), 6.75 (d, J = 16 Hz, 4H, H^A), 6.68 (d, J = 12 Hz, 4H, H^C), and 1.89 (s, 12H, CH_3); see also Fig. 1; ms *m/e*: 434.2040 (M^+); calcd.: 434.2035. *Anal.* calcd. for $C_{34}H_{26}$: C 93.97, H 6.03; found: C 92.93, H 5.96. Attempts to improve the elemental analysis failed.

*The isomeric 1,3-bis(4-methylhexa-1,3-diene-5-ynyl)benzene, **10**, **11**, **12***

Lithium ethoxide prepared from lithium (740 mg, 0.106 g-atom) in absolute ethanol (280 mL) was added dropwise to a stirred solution of *m*-bis(triphenylphosphoniomethyl)benzene dibromide, **9** (9) (41.8 g, 53.0 mmol), and (2*Z*)-3-methyl-2-penten-4-ynal, **7** (7) (10.0 g, 0.106 mmol), in DMF (800 mL) over 1.5 h at 80°C under a nitrogen atmosphere. The solution was stirred for a further 0.5 h at 80°C. After being cooled, the solution was poured into water and extracted with benzene. The combined extracts were washed with brine and dried. The residual dark brown liquid, after solvent removal, was passed through a short column of alumina (4 × 9 cm). The fractions eluted with hexane–ether (1:1) were collected and evaporated to give a red liquid, which was chromatographed on alumina (4.5 × 20 cm). The initial fractions eluted with hexane were collected and evaporated to afford the *cis–cis* isomer, **10** (3.09 g, 22.5%), as a pale yellow liquid; ir (neat): 3290 (—C≡CH), 2090 (—C≡C—), and 700 (*cis* HC=CH) cm^{-1}; uv_{max}: 223 (9610), 235 (9390), and 303 nm (42 200); ^{1}Hmr (200 MHz) δ 7.34–7.16 (m, 4H, Ar-H), 6.77 (dd, J = 11 and 9.5 Hz, 2H, H^B), 6.69 (d, J = 11 Hz, 2H, H^A), 6.47 (d, J = 9.5 Hz, 2H, H^C), 3.33 (s, 2H, —C≡CH), and 1.93 (s, 6H, CH_3); ms m/e: 258 (relative intensity, M^+, 49%) and 228 (100), mol. wt. 258.3. *Anal.* calcd. for $C_{20}H_{18}$: C 92.98, H 7.02; found: C 93.23, H 7.24.

The following fractions eluted with 5–10% ether in hexane afforded the *cis–trans* isomer, **11** (1.68 g, 12.3%), as a yellow liquid. Crystallization from hexane afforded pale yellow needles, mp 41–42°C; ir (KBr): 3280 (—C≡CH), 2090 (—C≡C—), 965 (*trans* HC=CH), and 680 (*cis* HC=CH) cm^{-1}; uv_{max}: 226 (11 700), 236 sh (10 700), 305 sh (43 600), 316 (45 200), and 333 nm sh (29 300); ^{1}Hmr (200 MHz) δ: 7.36–7.20 (m, 4H, Ar-H), 7.26 (dd, J = 16 and 11 Hz, 1H, H^B), 6.79 (dd, J = 11 and 9.5 Hz, 1H, $H^{B'}$), 6.71 (d, J = 11 Hz, 1H, $H^{A'}$), 6.57 (d, J = 16 Hz, 1H, H^A), 6.50 (d, J = 9.5 Hz, 1H, $H^{C'}$), 6.43 (d, J = 11 Hz, 1H, H^C), 3.38 (s, 1H, —C≡CH), 3.36 (s, 1H, —C≡CH), and 1.96 (s, 6H, CH_3); ms m/e: 258 (M^+, 60%) and 228 (100), mol. wt. 258.3. *Anal.* calcd. for $C_{20}H_{18}$: C 92.98, H 7.02; found: C 93.22, H 6.89.

The later fractions, eluted with 15–40% ether in hexane, afforded the *trans–trans* isomer, **12** (3.05 g, 22.3%), as a solid. It formed yellow needles from hexane–benzene, mp 131–132°C; ir (KBr): 3280 (—C≡CH), 2090 (—C≡C—), 985, and 970 (*trans* HC=CH) cm^{-1}; uv_{max}: 228 (11 900), 234 sh (11 500), 306 sh (42 900), 319 (49 100), and 334 nm (39 200); ^{1}Hmr (200 MHz) δ: 7.44 (s, 1H, H^X), 7.38–7.25 (m, 3H, H^Y and H^Z), 7.25 (dd, J = 15.5 and 11 Hz, 2H, H^B), 6.58 (d, J = 15.5 Hz, 2H, H^A), 6.45 (d, J = 11 Hz, 2H, H^C), 3.35 (s, 2H, —C≡CH), and 1.97 (s, 6H, CH_3); ms m/e: 258 (M^+, 51%) and 228 (100), mol. wt. 258.3. *Anal.* calcd. for $C_{20}H_{18}$: C 92.98, H 7.02; found: C 93.23, H 6.96.

1,3-[(1E,3Z,9Z,11E)-4,9-Dimethyldodeca-1,3,9,11-tetraene-5,7-diyne-1,12-diyl]benzene, **13**

A solution of the acyclic di-*trans* isomer, **12** (2.57 g, 9.95 mmol), in pyridine – dry ether (3:1, 216 mL) was added dropwise over 4.5 h to a stirred solution of anhydrous $Cu(OAc)_2$ (12.2 g) in pyridine – dry ether (3:1, 468 mL) at 51–52°C. After stirring for 1 h at 51°C, the reaction was cooled to room temperature. After work-up as in the preparation of **3**, the residual dark brown liquid, after solvent removal, was chromatographed on alumina (5.7 × 14 cm). The fractions eluted with 5–10% ether in hexane were collected and evaporated to afford the desired cyclic compound, **13** (0.576 g, 22.6%), as a solid. It formed orange needles, mp 161–162°C; ir (KBr): 2160 (—C≡C—), and 965 (*trans* HC=CH) cm^{-1}; uv_{max}: 217 (13 900), 253 sh (14 300), 264 sh (18 400), 278 (25 400), and 306 nm (36 600); ^{1}Hmr (200 MHz) δ: 8.82 (s, 1H, H^X), 8.21 (dd, J = 16 and 12 Hz, 2H, H^B), 7.14 (t, J = 8 Hz, 1H, H^Z), 6.97 (d, J = 8 Hz, 2H, H^Y), 6.66 (d, J = 12 Hz, 1H, H^C), 6.60 (d, J = 16 Hz, 2H, H^A), and 1.88 (s, 6H, CH_3); see also Fig. 1; ms m/e: 256 (M^+, 47%) and 239 (100), mol. wt. 256.3. *Anal.* calcd. for $C_{20}H_{16}$: C 93.71, H 6.29; found: C 93.91, H 6.44.

The di-*cis* isomer, **10** (882 mg, 3.41 mmol), was also oxidatively coupled under the exactly same conditions as described for **12**, but none of monomeric cyclic product could be obtained.

The mono-*cis* isomer, **11** (730 mg, 2.82 mmol), was oxidatively coupled under the same conditions as for **12**, and only the cyclic di-*trans* isomer, **13** (17.9 mg, 3.0%), was obtained.

1,2,3,4-Tetrakis(triphenylphosphoniomethyl)benzene tetrabromide, **14**

A mixture of 1,2,3,4-tetra(bromomethyl)benzene (11) (35.8 g, 79.5 mmol) and triphenylphosphine (85.9 g, 0.327 mol) in 2,4-pentadione (240 mL) was heated under reflux for 1 h. A white, crystalline solid began to separate after 20–30 min. The mixture was allowed to cool to room temperature. The solid was collected and washed with ether to give the first crop of the desired product. The filtrate was diluted with ether and the solid formed was separated by filtration, washed with ether, and combined with the first crop to give a total of 110 g (90.7%) of tetraphosphonium salt, **14**. Recrystallization from absolute ethanol with decolourizing charcoal afforded white microcrystals, mp 307–308°C; ^{1}Hmr (90 MHz, CF_3COOD) δ: ca. 8.2–7.4 (m, 60H, Ar-H), 7.02 (d, J = 2 Hz, 2H, H^A), and 4.97–4.12 (m, 8H, —CH_2—). *Anal.* calcd. for $C_{82}H_{70}P_4Br_4$: C 65.67, H 4.71; found: C 65.35, H 4.82.

The reaction of **7** and **14** as well as that of **6** and (2*E*,4*Z*)-5-methylhepta-2,4-dien-6-ynal (10) was carried out under the same conditions as described for the reaction between **6** and **7**. However, all attempts were unsuccessful.

1,2,4,5-Tetra[(Z)-2(2-ethynylphenyl)ethenyl]benzene, **16**

Lithium ethoxide prepared from lithium (640 mg, 0.0922 g-atom) in absolute ethanol (240 mL) was added dropwise with stirring under a nitrogen atmosphere at 82–83°C over 3.5 h to *o*-ethynylbenzaldehyde, **15**, (12) (12.0 g, 0.0922 mmol), and 1,2,4,5-tetrakis-(triphenylphosphoniomethyl)benzene tetrabromide, **6** (6) (34.5 g, 0.0230 mmol), in DMF (950 mL). After completion of addition, the mixture was stirred at the same temperature for 1 h. After work-up as in the preparation of **12**, the dark brown semi-solid, after solvent removal, was passed through a short column of alumina (4 × 7.5 cm) and was eluted with ether. A red liquid, obtained on evaporation, was chromatographed on alumina (4 × 12.5 cm). The fractions eluted with 5–30% ether in hexane afforded, on evaporation, the acyclic stereoisomeric mixture (3.60 g, 26.9%) as a semi-solid, which was purified by preparative thin-layer chromatography. The fast-moving yellow band gave the desired all-*trans* isomer, **16** (0.801 g, 6.0%), as a solid. It formed yellow needles from benzene, mp 204°C (dec.); ir (KBr): 3290, 3280 (—C≡CH), 2110 (—C≡C—), and 960 (*trans* HC=CH) cm^{-1}; uv_{max}: 226 (51 800), 240 sh (46 700), 254 sh (40 900), 343 (58 300), and 377 nm sh (44 300); ^{1}Hmr (200 MHz) δ: 7.90 (s, 2H, H^X), 7.77 (d, J = 7.5 Hz, 4H, H^1), 7.67 (d, J = 16 Hz, 4H, H^A or H^B), 7.58 (d, J = 16 Hz, 4H, H^A or H^B), 7.56 (d, J = 7.5 Hz, 4H, H^4), 7.40 (t, J = 7.5 Hz, 4H, H^2), 7.26 (t, J = 7.5 Hz, 4H, H^3), and 3.28 (s, 4H, —C≡CH); ms (field desorption method) m/e: 582 (M^+), mol. wt. 582.7. *Anal.* calcd. for $C_{46}H_{30}$: C 94.81, H 5.19; found: C 94.90, H 5.11.

1,3:4,6-Bis[(1E,11E)-3,4:9,10-dibenzdodeca-1,11-diene-5,7-diyne-1,12-diyl]benzene, **5**

A solution of the acyclic all-*trans* isomer, **15** (898 mg, 1.54 mmol), in pyridine – dry ether (3:1, 34 mL) was added dropwise over 3 h to a stirred solution of anhydrous $Cu(OAc)_2$ (3.8 g) in pyridine – dry ether (3:1, 146 mL) at 50°C, and the solution was stirred for a further 1 h at the same temperature. After work-up as in the preparation of **13**, the residual brown liquid, after solvent removal, was chromatographed on alumina (3.7 × 9.0 cm). The fractions eluted with hexane–benzene (2:3) gave a yellow solid on evaporation. The solid was further purified by thin-layer chromatography. The fast-moving yellow band was collected and, on evaporation, afforded the monomeric cyclic compound, **5** (125 mg, 14%). Recrystallization from benzene afforded yellow cubes, mp 208–210°C (dec.); ir (KBr): 2200 (—C≡C—) and 970 (*trans* HC=CH) cm^{-1}; uv_{max}: 262 sh (52 700), 302 (55 400), 328 sh (42 000), 363 sh (19 400), 400 sh (9300), and 452 nm sh (2300); ^{1}Hmr (200 MHz) δ: 8.26 (s, 2H, H^X), 7.82 (d, J = 16 Hz, 4H, H^B), 7.56 (d, J = 8 Hz, 4H, H^1), 7.42–7.04 (m, 12H, H^2, H^3, and H^4), and 6.68 (d, J = 16 Hz, 4H, H^A); see also Fig. 2; ms m/e: 578 (M^+, 100%), mol. wt. 578.6. *Anal.* calcd. for

$C_{46}H_{26}$: C 95.27, H 4.53; found: C 95.47, H 4.77.

The isomeric 1,2-bis[2-(2-ethynylphenyl)ethenyl]benzene, ***18, 19, 20***

Lithium ethoxide prepared from lithium (323 mg, 0.046 g-atom) in absolute ethanol (120 mL) was added dropwise to a stirred solution of *o*-ethynylbenzaldehyde, **15** (12) (6.00 g, 0.046 mol), and 1,2-bis-(triphenylphosphoniomethyl)benzene dibromide, **17** (13) (18.6 g, 0.023 mol), in DMF (460 mL) over 1 h at 80–85°C under a nitrogen atmosphere. After completion of addition, the solution was stirred for a further 2 h at 85°C. After work-up as in the preparation of **12**, the residual dark brown liquid, after solvent removal, was passed through a short column of alumina (3.7 × 5 cm). The fractions eluted with ether were collected and on evaporation gave a red liquid, which was chromatographed on alumina (3.7 × 17 cm). The early fractions eluted with 20–30% ether in hexane afforded the *cis–cis* isomer, **18** (1.39 g, 17.6%), as a liquid. Crystallization from hexane–benzene afforded white needles, mp 92–93°C; ir (KBr): 3290 (—C≡CH), 2110 (—C≡C—), and 680 (*cis* HC=CH) cm^{-1}; uv_{max}: 218 (39 000), 249 sh (23 300), and 286 nm (17 800); ^{1}Hmr (90 MHz) δ: 7.53–7.43 (m, 2H, Ar-H), 7.16–6.89 (m, 10H, Ar-H), 6.96 (d, J = 12 Hz, 2H, H^B), 6.74 (d, J = 12 Hz, 2H, H^A), and 3.33 (s, 2H, —C≡CH); ms m/e: 330 (M^+, 100%), mol. wt. 330.4. *Anal.* calcd. for $C_{26}H_{18}$: C 94.51, H 5.49; found: C 94.68, H 5.39.

The following fractions eluted with 40–50% ether in hexane afforded the *cis–trans* isomer, **19** (0.890 g, 11.7%), as a pale yellow liquid; ir (neat): 3290 (—C≡CH), 2100 (—C≡C—), 965 (*trans* HC=CH), and 675 (*cis* HC=CH) cm^{-1}; uv_{max}: 220 (40 300), 250 (29 700), 295 (23 600), and 314 nm (23 700); ^{1}Hmr (90 MHz) δ: 7.43 (d, J = 16 Hz, 1H, H^B), 7.16 (d, J = 16 Hz, 1H, H^A), 7.70–6.95 (m, 12H, Ar-H), 6.95 (d, J = 12 Hz, 1H, $H^{B'}$), 6.74 (d, J = 12 Hz, 1H, $H^{A'}$), 3.34 (s, 1H, —C≡CH), and 3.32 (s, 1H, —C≡CH); ms m/e: 330 (M^+, 100%), mol. wt. 330.4. *Anal.* calcd. for $C_{26}H_{18}$: C 94.51, H 5.49; found: C 94.28, H 5.60.

The later fractions eluted with hexane–ether (2:3) – ether afforded the *trans–trans* isomer, **20** (0.382 g, 5.0%), as a solid. Recrystallization from hexane–benzene afforded white needles, mp 70–71°C; ir (KBr): 3300, 3290 (—C≡CH), 2100 (—C≡C—), 975, 970, and 960 (*trans* HC=CH) cm^{-1}; uv_{max}: 220 (37 600), 233 sh (32 400), 251 (32 100), 292 (29 100), and 326 nm (26 400); ^{1}Hmr (90 MHz) δ: 7.45 (d, J = 16 Hz, 2H, H^B), 7.19 (d, J = 16 Hz, 2H, H^A), 7.74–6.90 (m, 12H, Ar-H), and 3.24 (s, 2H, —C≡CH); ms m/e: 330 (M^+, 100%), mol. wt. 330.4; *Anal.* calcd. for $C_{26}H_{18}$: C 94.51, H 5.49; found: C 94.73, H 5.35.

*The isomeric 1,2-bis(3,4:9,10-dibenzdodeca-1,11-diene-5,7-diyne-1,12-diyl)benzene (tribenz[*a,e,i*]-11,13-bisdehydro[14]annulene),* ***21, 22, 23***

A solution of the acyclic di-*cis* isomer, **18** (0.995 mg, 3.01 mmol), in pyridine – dry ether (3:1, 66 mL) was added dropwise over 3 h to a stirred solution of anhydrous $Cu(OAc)_2$ (3.7 g) in pyridine – dry ether (3:1, 144 mL) at 51–53°C. The solution was stirred for 1 h at the same temperature. After work-up as in the preparation of **13**, the residual red liquid, after solvent removal, was chromatographed on alumina (3.7 × 8.5 cm). The fractions eluted with 2% ether in hexane afforded the cyclic mono-*cis* isomer, **22** (0.175 g, 17.7%), as a solid. Recrystallization from hexane–benzene afforded pale yellow cubes, mp 118°C (dec.); ir (KBr): 2110 (—C≡C—), 990, 975, 970 (*trans* HC=CH), and 710 (*cis* HC=CH) cm^{-1}; uv_{max}: 228 sh (33 600), 260 (50 800), 282 sh (28 300), 297 (27 000), and 354 nm sh (6400); ^{1}Hmr (200 MHz) δ: 7.76 (d, J = 8 Hz, 2H, Ar-H), 7.76 (d, J = 16 Hz, 1H, H^B), 7.50–6.80 (m, 14H, H^A, $H^{B'}$, and Ar-H), and 6.68 (d, J = 12.5 Hz, 1H, $H^{A'}$); see also Fig. 3; ms m/e: 328 (M^+, 66%) and 327 (100), mol. wt. 328.3. *Anal.* calcd. for $C_{26}H_{16}$: C 95.09, H 4.91; found: C 95.30, H 4.98.

The later fractions, eluted wth 3% ether in hexane, gave the cyclic di-*cis* isomer, **21** (0.0220 g, 22.3%), as a solid. Recrystallization from hexane–benzene afforded colourless cubes, mp 215–216°C; ir (KBr): 2210 (—C≡C—) and 720 (*cis* HC=CH) cm^{-1}; uv_{max}: 237 (29 700), 258 (22 900), 290 (40 500), 328 (14 500), and 355 nm (12 900); ^{1}Hmr (200 MHz) δ: 7.47–6.89 (m, 12H, Ar-H), 6.99 (d, J = 12.5 Hz, 2H, H^B), and 6.67 (d, J = 12.5 Hz, 2H, H^A); see also Fig. 3; ms m/e: 328 (M^+, 50%) and 327 (100), mol. wt. 328.3. *Anal.* calcd. for $C_{26}H_{16}$: C 95.09, H 4.91; found: C 95.22, H 4.87.

An oxidative coupling of the acyclic mono-*cis* isomer, **19** (630 mg, 1.91 mmol), was carried out under exactly the same conditions as described for **18**. The residual yellow liquid, after solvent removal, was chromatographed on alumina (3.7 × 10 cm). The early fractions eluted with 4% ether in hexane gave the cyclic mono-*cis* isomer, **22** (227 mg, 36.2%). The fractions following, eluted with 5% ether in hexane, afforded the cyclic di-*cis* isomer, **21** (87.5 mg, 14%).

The later fractions, eluted with 20% ether in hexane, afforded the cyclic di-*trans* isomer, **23** (47 mg, 7.5%), as a solid. Recrystallization from hexane–benzene afforded yellow cubes, mp 214–215°C; ir (KBr): 2200 (—C≡C—), and 965 (*trans* HC=CH) cm^{-1}; uv_{max}: 227 (20 700), 263 (19 300), 281 sh (21 800), 308 (37 200), and 360 nm (7200); ^{1}Hmr (200 MHz) δ: 7.98–7.92 (m, 2H, Ar-H), 7.77 (d, J = 16 Hz, 2H, H^B), 7.66 (d, J = 7.5 Hz, 2H, Ar-H), 7.51–7.27 (m, 8H, Ar-H), and 7.14 (d, J = 16 Hz, H^A); see also Fig. 3; ms m/e: 328 (M^+, 73%) and 327 (100), mol. wt. 328.3. *Anal.* calcd. for $C_{26}H_{16}$: C 95.09, H 4.91; found: C 95.01, H 4.67.

An oxidative coupling of the acyclic di-*trans* isomer, **20** (380 mg, 1.15 mmol), was also carried out under exactly the same conditions as described for **18**. The residual brown semi-solid, after solvent removal, was chromatographed on alumina (3.7 × 8 cm). The fractions eluted with 2–3% ether in hexane afforded the cyclic mono-*cis* isomer, **22** (59.9 mg, 15.9%). The following fractions eluted with 10–20% ether in hexane afforded the cyclic di-*trans* isomer, **23** (166 mg, 43.8%).

The isomeric 1,3-bis[2-(2-ethynylphenyl)ethenyl]benzene, ***24, 25, 26***

Lithium ethoxide prepared from lithium (270 mg, 0.039 g-atom) in absolute ethanol (100 mL) was added dropwise to a stirred solution of *o*-ethynylbenzaldehyde, **15** (12) (5.00 g, 0.038 mmol), and 1,3-bis(triphenylphosphoniomethyl)benzene dibromide, **9** (9) (15.5 g, 0.020 mol), in DMF (380 mL) over 2 h at 80–85°C under a nitrogen atmosphere. After completion of addition, the mixture was stirred for a further 2 h at the same temperature. After work-up as in the preparation of **16**, the residual red liquid, after solvent removal, was passed through a short column of alumina (3.7 × 4 cm). The fractions eluted with ether were collected and on evaporation gave a red liquid, which was chromatographed on alumina (3.7 × 10 cm). The fractions eluted with 2–3% ether in hexane afforded the acyclic *cis–cis* isomer, **24** (1.81 g, 28.8%), as a yellow liquid; ir (neat): 3290 (—C≡CH), 2110 (—C≡C—), and 700 (*cis* HC=CH) cm^{-1}; uv_{max}: 227 (25 600), 256 sh (22 800), 278 (19 200), and 314 nm sh (10 500); ^{1}Hmr (200 MHz) δ: 7.52 (d, J = 8 Hz, 2H, H^4), 7.22–6.10 (m, 10H, H^1, H^2, H^3, H^X, H^Y, H^Z), 6.81 (d, J = 12 Hz, 2H, H^B), 6.58 (d, J = 12 Hz, 2H, H^A), and 3.28 (s, 2H, —C≡CH); ms m/e: 330.1394 (M^+); calcd.: 330.1382. *Anal.* calcd. for $C_{26}H_{18}$: C 94.51, H 5.49; found: C 93.55, H 5.36. Attempts to improve the elemental analysis failed.

The following fractions eluted with 5% ether in hexane afforded the acyclic *cis–trans* isomer, **25** (2.42 g, 38.6%), as a yellow liquid; ir (neat): 3290 (—C≡CH), 2110 (—C≡C—), 965 (*trans* HC=CH), and 700 (*cis* HC=CH) cm^{-1}; uv_{max}: 228 sh (18 300), 234 sh (18 500), 252 (19 700), 260 sh (17 300), 307 (22 800), 324 sh (19 200), and 341 nm sh (9500); ^{1}Hmr (200 MHz) δ: 7.67–7.15 (m, 13H, H^B and Ar-H), 7.05 (d, J = 16.5 Hz, 1H, H^A), 6.92 (d, J = 12 Hz, 1H, $H^{B'}$), 6.74 (d, J = 12 Hz, 1H, $H^{A'}$), 3.36 (s, 1H, —C≡CH), and 3.33 (s, 1H, —C≡CH); ms m/e: 330.1376 (M^+), calcd.: 330.1346. *Anal.* calcd. for $C_{26}H_{18}$: C 94.51, H 5.49; found: C 93.07, H 5.56. Attempts to improve the elemental analysis failed.

The later fractions, eluted with 8% ether, in hexane afforded the acyclic di-*trans* isomer, **26** (0.681 g, 10.9%), as a yellow liquid; ir (neat): 3300 (—C≡CH), 2120 (—C≡C—), and 970 (*trans* HC=CH) cm^{-1}; uv_{max}: 233 (18 700), 251 (24 600), 258 sh (21 500), 308 (36 500), 318 sh (35 900), and 340 nm sh (19 200); ^{1}Hmr (200 MHz) δ: 7.71 (d, J = 8.5 Hz, 2H, H^4), 7.71 (d, J = 16.5 Hz, 2H, H^B), 7.56–7.17 (m, 10H, H^1, H^2, H^3, H^X, H^Y, H^Z), 7.18 (d, J = 16.5 Hz, 1H, H^A), and 3.39 (s, 2H, —C≡CH); ms m/e:

330.1361 (M^+); calcd.: 330.1356; *Anal.* calcd. for $C_{26}H_{18}$: C 94.51, H 5.49; found: C 93.02, H 5.59. Attempts to improve the elemental analysis failed.

The isomeric 1,3-bis(3,4:9,10-dibenzdodeca-1,11-diene-5,7-diyne-1,12-diyl)benzene, 27, 28, 29

A solution of the acyclic di-*cis* isomer, **24** (2.03 g, 6.15 mmol), in pyridine – dry ether (3:1, 134 mL) was added dropwise over 3 h to a stirred solution of anhydrous $Cu(OAc)_2$ (7.1 g) in pyridine – dry ether (3:1, 290 mL) at 50°C; the mixture was stirred for a further 1 h at the same temperature. After work-up as in the preparation of **13**, the residual red liquid, after solvent removal, was chromatographed on alumina (3.7 × 9 cm). The fractions eluted with 5–20% ether in hexane afforded the cyclic di-*cis* isomer, **27** (566 mg, 28%), as a solid. Recrystallization from hexane–benzene afforded colourless cubes, mp 225–227°C; ir (KBr): 2210 (—C≡C—) and 695 (*cis* HC=CH) cm^{-1}; uv_{max}: 223 (39 100), 232 (38 400), 273 (34 600), 288 sh (30 100), 336 (13 500), and 358 nm (11 600); ^{1}Hmr (200 MHz) δ: 7.44 (s, 1H, H^X), 7.40–6.93 (m, 11H, Ar-H), 6.80 (d, J = 13 Hz, 2H, H^B), and 6.59 (d, J = 13 Hz, 2H, H^A); see also Fig. 2; ms m/e: 328 (M^+, 53%) and 327 (100), mol. wt. 328.3. *Anal.* calcd. for $C_{26}H_{16}$: C 95.09, H 4.91; found: C 95.29, H 4.64.

An oxidative coupling of the acyclic mono-*cis* isomer, **25** (702 mg, 2.12 mmol), was carried out under exactly the same conditions as described for **24**. The dark red liquid, after solvent removal, was chromatographed on alumina (3.7 × 7.0 cm). The fractions eluted with 3% ether in hexane afforded the cyclic di-*trans* isomer, **29** (146 mg, 20.9%), as a solid. Recrystallization from benzene afforded yellow needles, mp 239–240°C; ir (KBr): 2200 (—C≡C—), 970, and 960 (*trans* HC=CH) cm^{-1}; uv_{max}: 227 (30 500), 296 (75 400), 311 sh (62 100), and 372 nm sh (4140); ^{1}Hmr (200 MHz) δ: 8.65 (s, 1H, H^X), 8.24 (d, J = 16.5 Hz, 2H, H^B), 7.73 (d, J = 8 Hz, 2H, H^4), 7.48–7.20 (m, 9H, Ar-H), and 7.10 (d, J = 16.5 Hz, 2H, H^A); see also Fig. 2; ms m/e: 328 (M^+, 56%) and 327 (100), mol. wt. 328.3. *Anal.* calcd. for $C_{26}H_{16}$: C 95.09, H 4.91; found: C 94.94, H 4.74.

The later fractions, eluted with 5% ether in hexane, afforded the cyclic mono-*cis* isomer, **28** (70.5 mg, 10.1%), as a solid. Recrystallization from hexane–benzene afforded colourless cubes, mp 228°C (dec.); ir (KBr): 2200 (—C≡C—), 960 (*trans* HC=CH), and 700 (*cis* HC=CH) cm^{-1}; uv_{max}: 222 (33 500), 268 (25 800), 285 sh (30 500), 303 sh (40 400), and 310 nm (41 200); ^{1}Hmr (200 MHz) δ: 7.76 (d, J = 16 Hz, 1H, H^B), 7.75 (d, J = 8 Hz, 1H, H^4), 7.50–7.00 (m, 11H, Ar-H), 7.18 (d, J = 16 Hz, 1H, H^A), 6.96 (d, J = 12 Hz, 1H, $H^{B'}$), and 6.85 (d, J = 12 Hz, 1H, $H^{A'}$); see also Fig. 2; ms m/e: 328 (M^+, 63%) and 327 (100), mol. wt. 328.3. *Anal.* calcd. for $C_{26}H_{16}$: C 95.09, H 4.91; found: C 94.80, H 5.19.

An oxidative coupling of the acyclic di-*trans* isomer, **26** (610 mg, 1.85 mmol), was carried out under the same conditions as described for **24**. The residual brown semi-solid, after solvent removal, was chromatographed on alumina (3.7 × 8 cm). The fractions eluted with 10–50% ether in hexane afforded only the cyclic di-*trans* isomer, **29** (472 mg, 77.9%).

Received November 19, 1984

C. OTERO and E. RODENAS. Can. J. Chem. **63**, 2892 (1985).

The basic dehydrohalogenation reactions of 1,1,1-trichloro-2,2-bis(*p*-chlorophenyl)ethane (DDT) and 1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethane (DDD) have been studied in cationic micelles of hexadecyltrimethylammonium bromide (CTAB) and hexadecyltrimethylammonium hydroxide (CTAOH). Different theoretical approaches are discussed, considering the fraction of micellar head group neutralized, β, as a constant, or supposing different kinds of variation in its value. The following two empirical expressions for β have been found: $\beta = 0.8 + 0.5$ ([NaOH] + [KBr]) for DDT, and $\beta = 0.8 + 1$ ([NaOH] + [KBr]) for DDD, and this is the best way to explain the experimental results.

C. OTERO et E. RODENAS. Can. J. Chem. **63**, 2892 (1985).

Opérant dans des micelles cationiques de bromure d'hexadécyltriméthylammonium (CTAB) et d'hydroxyde d'hexadécyltriméthylammonium (CTAOH), on a étudié la réaction de déshydrohalogénation basique du trichloro-1,1,1 bis(*p*-chlorophényl)-2,2 éthane, le DDT, et du dichloro-1,1 bis(*p*-chlorophényl)-2,2 éthane, le DDD. On discute de diverses approches théoriques en considérant la fraction du groupe micellaire neutralisé, β, comme étant égale à une constante ou en faisant diverses hypothèses relativement à sa variation. On a trouvé que les valeurs de β peuvent être exprimées par les expressions empiriques suivantes: $\beta = 0{,}8 + 0{,}5$ ([NaOH] + [KBr]) pour le DDT et $\beta = 0{,}8 + 1$ ([NaOH] + [KBr]) pour DDD; ceci correspond à la meilleure façon d'expliquer les résultats expérimentaux.

Introduction

Reactions between a hydrophobic organic substrate and ions in solution are too much affected by micellar systems (1–3). Rate acceleration (4) or inhibition (5) arises from different rates of reactions of the substrates in the micellar phase and in the bulk solution, and from the distribution of the substrate between these two phases. Most of the kinetic results can be explained with the pseudophase kinetic model proposed by Menger and Portnoy (6) and developed by Bunton (7) and Romsted (8), with the restriction of considering the fraction of micellar head group neutralized, β, as a constant independent of ion and surfactant concentration, although there is strong evidence showing that addition of counterions in solution increases β, and to consider it a constant is only an approximation (9, 10). The results in the literature at high concentration of ions in solution or when the reactive ion is too hydrophilic (11) cannot be explained by means of this model, in which it is necessary to make modifications (5, 12, 13) in order to explain the experimental results.

In this paper we have studied the basic dehydrohalogenation of 1,1,1-trichloro-2,2-bis(*p*-chlorophenyl)ethane (DDT) and 1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethane) (DDD) in cationic micelles of hexadecyltrimethylammonium bromide (CTAB) and hexadecyltrimethylammonium hydroxide (CTAOH). These reactions have very important biological implications (14), since micelles have also been used as single membrane models (15, 16), but also because these non-charged hydrophobic substrates are very appropriate in discussing the validity of different theoretical models in order to explain the experimental values. These reactions were first studied by Nome and co-workers in CTAB (17) and, currently, in CTAOH (18), and they found that the simple pseudophase kinetic model considering β as a constant cannot explain the results at high ion concentration.

[1] Author to whom correspondence may be addressed.

In this paper we discuss the validity of a model that considers independent distribution equilibria of ions between aqueous and micellar phases in which β varies with surfactant and ion concentrations. This model has been used, with success, to explain the basic hydrolysis of acetylsalicylate ester and homologs (19).

Theoretical description of the pseudophase kinetic model

The pseudophase kinetic model (6–8) considers the micelle as a different phase from the aqueous phase, the reaction occurring in both phases according to Scheme 1:

$$\begin{tikzcd} S_W + Dn \arrow[rr, shift left, "K_S"] \arrow[dr, "k'_W"'] & & S_M \arrow[ll, shift left] \arrow[dl, "k'_M"] \\ & \text{Products} & \end{tikzcd}$$

SCHEME 1

where the subscripts M and W denote the micellar and aqueous phases respectively, S is the substrate, Dn the micellized surfactant whose concentration is given by [Dn] = [D] − cmc, cmc is the critical micelle concentration, and K_S the binding constant of the substrate to the micelle written in terms of micellized surfactant:

$$[1] \quad K_S = \frac{[S_M]}{[S_W][Dn]}$$

k'_W and k_M are the pseudo-first-order rate constants in aqueous and micellar pseudophases respectively, given by

$$[2] \quad \begin{aligned} k'_W &= k_W\,[OH^-_W] \\ k'_M &= k_M\,[OH^-_M]/[Dn] \end{aligned}$$

where k_M is written in terms of the mole ratio of micellar OH^- bound to the micellar head groups. The pseudo-first-order rate constant can be easily derived as:

$$[3] \quad k_\psi = \frac{k_W[OH^-_T] + (k_M K_S - k_W)[OH^-_M]}{1 + K_S[Dn]}$$

where OH^-_M is the concentration of hydroxide ion bound to micelle.

For a reaction where the reactive ion OH^- is the micelle counterion, as CTAOH micelles (20), the distribution of this ion between aqueous and micellar pseudophases can be expressed by an equilibrium:

$$[4] \quad OH^-_W + Dn \overset{K'_{OH}}{\rightleftharpoons} OH^-_M$$

where

$$[5] \quad K'_{OH} = \frac{[OH^-_M]}{[OH^-_W]([Dn] - [OH^-_M])}$$

This equation reduces to:

$$[6] \quad K'_{OH}[OH^-_M]^2 - (K'_{OH}[Dn] + K'_{OH}[OH^-_T] + 1)[OH^-_M] + K'_{OH}[Dn][OH^-_T] = 0$$

with the fraction of micellar head groups neutralized, β, given by $\beta = [OH^-_M]/[Dn]$. Equation [5] predicts that β increases with surfactant concentration.

In the case of two ions competing for the micellar head groups, as CTAB micelles, Romsted (8) proposed a model considering β as a constant and that ions bind to micelles according to the exchange model developed for resins. For OH^- reactive ion and Br^- as micelle counterion the ion exchange equilibrium can be expressed by:

$$[7] \quad OH^-_M + Br^-_W \overset{K^{OH}_{Br}}{\rightleftharpoons} OH^-_W + Br^-_M$$

with an equilibrium constant:

$$[8] \quad K^{OH}_{Br} = \frac{[OH^-_W][Br^-_M]}{[OH^-_M][Br^-_W]}$$

and the fraction of micellar head groups neutralized given by:

$$[9] \quad \beta = m_{OH} + m_{Br}$$

where:

$$[10] \quad m_{OH} = [OH^-_M]/[Dn]; \qquad m_{Br} = [Br^-_M]/[Dn]$$

and

$$[11] \quad [OH^-_T] = [OH^-_W] + [OH^-_M]; \qquad [Br^-_T] = [Br^-_W] + [Br^-_M]$$

the following expression for m_{OH} can be easily deduced:

$$[12] \quad m^2_{OH} + m_{OH}\left[\frac{[OH^-_T] + K^{OH}_{Br}[Br^-_T]}{(K^{OH}_{Br} - 1)[Dn]} - \beta\right] - \frac{[OH^-_T]\,\beta}{(K^{OH}_{Br} - 1)[Dn]} = 0$$

We have developed a new approximation that considers independent distribution equilibria for each of the ions in solution, between the aqueous and micellar phase, so that for OH^- as reactive ion and Br^- as micelle counterion, the equilibrium constants K'_{OH} and K'_{Br} can be written as:

$$[13] \quad K'_{OH} = \frac{[OH^-_M]}{[OH^-_W]([Dn] - [OH^-_M] - [Br^-_M])}$$

$$[14] \quad K'_{Br} = \frac{[Br^-_M]}{[Br^-_W]([Dn] - [OH^-_M] - [Br^-_M])}$$

which reduce to:

$$[15] \quad K'_{OH}[OH^-_M]^2 - (K'_{OH}[Dn] - K'_{OH}[Br^-_M] + K'_{OH}[OH^-_T] + 1)[OH^-_M] + ([Dn] - [Br^-_M])K'_{OH}[OH^-_T] = 0$$

$$[16] \quad K'_{Br}[Br^-_M]^2 - (K'_{Br}[Dn] - K'_{Br}[OH^-_M] + K'_{Br}[Br^-_T] + 1)[Br^-_M] + ([Dn] - [OH^-_M])K'_{Br}[Br^-_T] = 0$$

This new treatment does not consider β as a constant, and its value, which depends on surfactant and ion concentrations, can be determined by solving eqs. [15] and [16] simultaneously with an iterative calculation method to give the values of $[OH^-_M]$ and $[Br^-_M]$ as a function of K'_{OH} and K'_{Br} for each surfactant and ion concentration.

Experimental

Materials

The surfactant CTAB, Merck, was recrystallized from MeOH/Et_2O. The surfactant CTAOH was prepared by ion exchange from CTAB (21) with anionic resin Amberlita 21-K. The absence of Br^- in CTAOH was tested with silver ion. This surfactant was prepared and kept under N_2 and it was used within 24 h of preparation. The pesticides DDT and DDD were purchased from U.S. Environmental Protection Agency Pesticides and Industrial Chemicals Repositori (MD-8). Other reactives, NaOH, KBr, Merck, were used without further purification.

Kinetics

All the reactions were run at 25 ± 0.1°C in the thermostated cuvettes of a Spectronic 2000 Bausch and Lomb spectrophotometer. Reactions were followed at 260 nm and 257 nm, which correspond to the absorbance products of reactions for DDT and DDD respectively. To the mixture of CTABr or CTAOH and NaOH at a given concentration in the thermostated cuvettes, 0.1 mL of DDT or DDD stock solution (10^{-3} *M* in acetonitrile) was added so that the amount of CH_3CN in the reaction mixture was 3%. The concentrations were: NaOH, 0–10^{-1} *M*; CTAB and CTAOH, 1×10^{-3} *M* to 7×10^{-2} *M*; and for both substrates, 3.3×10^{-5} *M*, in all experiments. The hydroxide ion concentration was in large excess over both substrates, and the experimental results, in both presence and absence of surfactants, fit very well the first-order rate equation:

$$[17] \quad \ln(A_\infty - A_t) = \ln(A_\infty - A_0) - kt$$

Values of pseudo-first-order rate constants were obtained by least-squares fit with correlation coefficients greater than 0.999.

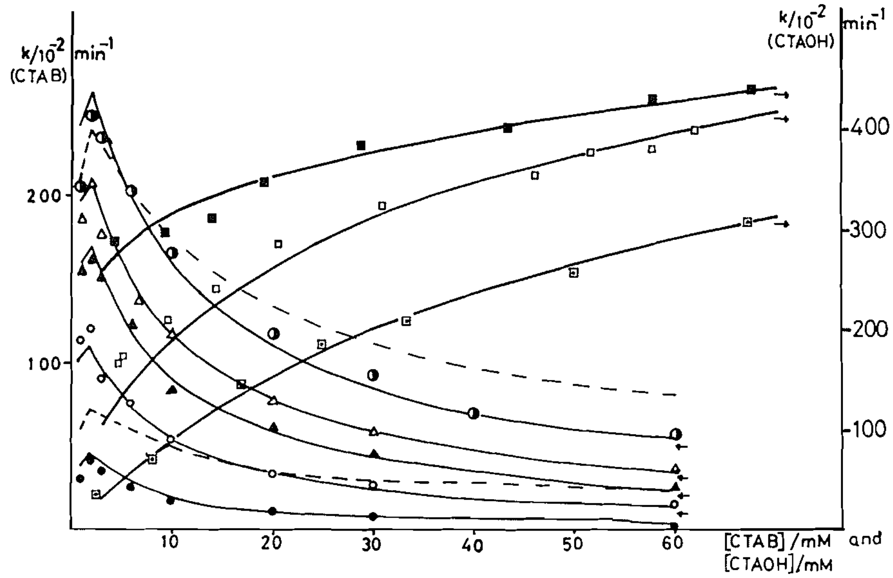

FIG. 1. Variation of the pseudo-first-order rate constant, k_ψ, for DDT in CTAOH (⊡ [NaOH] = 0 M, □ [NaOH] = 3.3 × 10^{-3} M, ■ [NaOH] = 3 × 10^{-2} M) and in CTAB (● [NaOH] = 0.33 × 10^{-2} M, ○ [NaOH] = 10^{-2} M, ▲ [NaOH] = 2 × 10^{-2} M, △ [NaOH] = 3 × 10^{-2} M, ◑ [NaOH] = 5 × 10^{-2} M). k(DDD) (10^{-3} min^{-1})	7.3	—	8.1	13	17	25	—

Results and discussion

Both substrates DDT and DDD are very insoluble in pure aqueous solution and the second-order rate constants for the reaction in water were obtained by extrapolating the pseudo-first-order rate constant obtained in different ethanol–water mixtures to zero amount of ethanol. The experimental pseudo-first-order rate constants at OH^- concentration 10^{-1} M are given in Table 1. The values found for the second-order rate constant were 0.126 L mol^{-1} min^{-1} and 0.02844 L mol^{-1} min^{-1} for DDT and DDD respectively, which agree with the values reported in the literature (17).

The experimental pseudo-first-order rate constants for DDT in CTAB and in CTAOH micelles at different OH^- concentrations are represented by dots in Fig. 1, and the experimental pseudo-first-order rate constants for DDD in CTAB and in CTAOH micelles at different OH^- concentrations are represented by dots in Fig. 2. In Figs. 3a and 3b are represented the

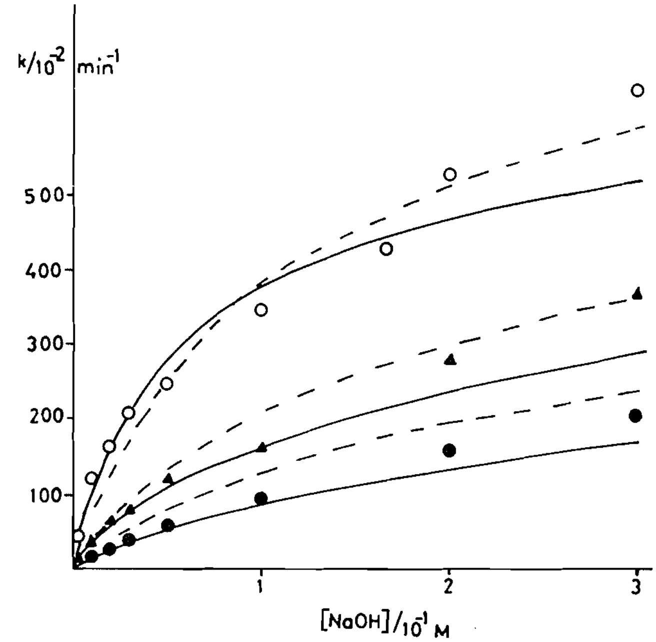

FIG. 3a. Variation of the pseudo-first-order rate constant, k_ψ, with NaOH concentration at fixed surfactant concentration for DDT (○ [CTAB] = 2 mM, ▲ [CTAB] = 20 mM, ● [CTAB] = 60 mM). Lines are predicted values with different models.

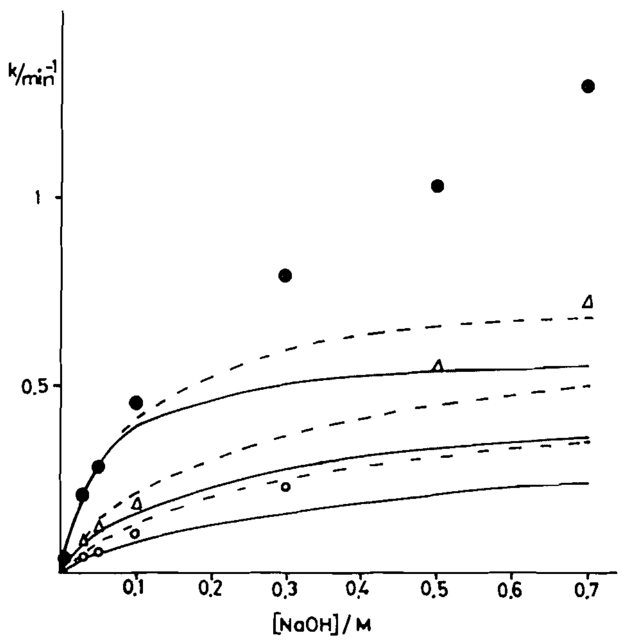

FIG. 3b. Variation of the pseudo-first-order rate constant, k_ψ, with NaOH concentration at fixed surfactant concentration for DDD (● [CTAB] = 2 mM, △ [CTAB] = 20 mM, ○ [CTAB] = 60 mM). Lines are predicted values with different models.

experimental pseudo-first-order rate constants at fixed CTAB concentration (2, 20, 60 mM) and different amounts of OH^- reactive ion, for the reactions with DDT and DDD respectively. Finally, in Figs. 4a and 4b are represented by dots the experimental pseudo-first-order rate constants for the reaction of both substrates at fixed CTAB concentration (2 and 20 mM) and different KBr concentrations.

The experimental rate constants for the reactions in CTAOH can be adapted to the pseudophase kinetic model proposed by

	1.00×10^{-1}	0.77	9000	30	0.88

Romsted (8) and Bunton (7), eqs. [3] and [6]. The procedure of adjusting the experimental results basically consists in calculating the value of pseudo-first-order rate constant, k_ψ, at different surfactant and ion concentrations using k_M, K_S, and K'_{OH} as arbitrary parameters. The calculated value for k_ψ does not depend on cmc value and, although the critical micellar concentration decreases slightly with electrolyte addition and with the hydrophobicity of the substrate, the value of cmc for the clear aqueous solution, cmc = 8.6×10^{-4} M, can be safely used (20). Table 2 gives the values of parameters that best fit the experimental results, and in Figs. 1 and 2 the values of k_ψ calculated with these parameters are represented by solid lines, for DDT and DDD respectively. K'_{OH} varies over a small range but, taking into account that small variations in the parameters will also fit the experimental results, K'_{OH} can be considered the same for both substrates, with an average value of $K'_{OH} \simeq 30$ M^{-1}. For DDT, small variations in the value of K_S also explain the experimental results but the K'_{OH} and k_M data are given satisfactorily in accord with the experimental error.

For the reaction in CTAB, the experimental rate constant can be adapted to the pseudophase kinetic model, proposed by Bunton (7) and Romsted (8), that considers β as a constant, eqs. [3] and [12]. In the procedure of adjusting the experimental results, k_W, cmc, and β are taken as known parameters while k_M, K_S, and K^{OH}_{Br} are taken as arbitrary ones. β can be taken as 0.8 for the case of CTAB micelles where the counterion, Br^-, binds strongly to the micelles (4, 5, 8). The calculated value of k_ψ at small surfactant concentration is too much affected by the value of critical micellar concentration and, as it decreases with electrolyte addition, the following empirical variation for cmc with ions (23) has been used in order to explain the experimental results:

$$[18] \quad \text{cmc} = 10 \times \exp(-3.7671 - 0.2133 \times \log(\text{cm} + [OH^-] + [Br^-]))$$

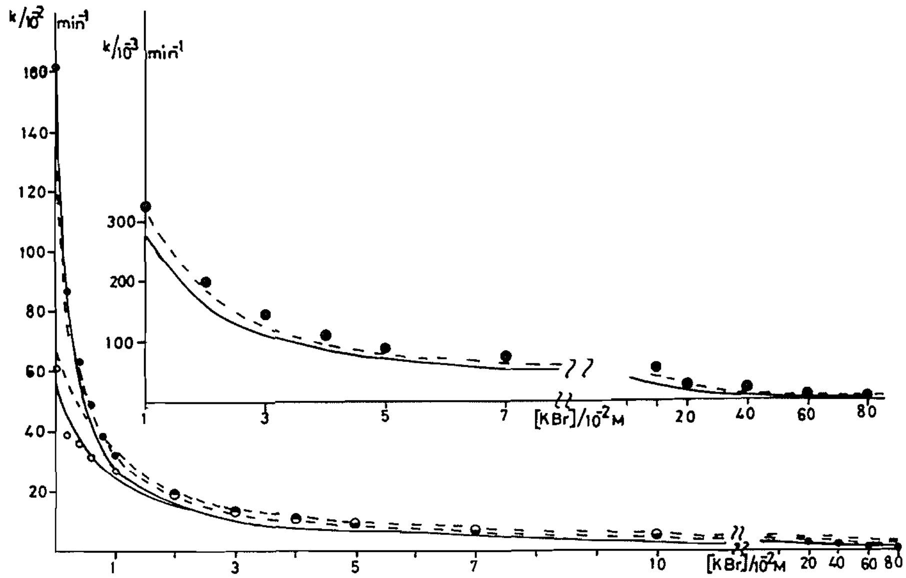

FIG. 4a. Variation of the pseudo-first-order rate constant, k_ψ, with KBr concentration at fixed surfactant and NaOH concentration for DDT (● [CTAB] = 2 mM and [NaOH] = 2 × 10^{-2} M, ○ [CTAB] = 20 mM and [NaOH] = 2 × 10^{-2} M). Lines are predicted values with different models.

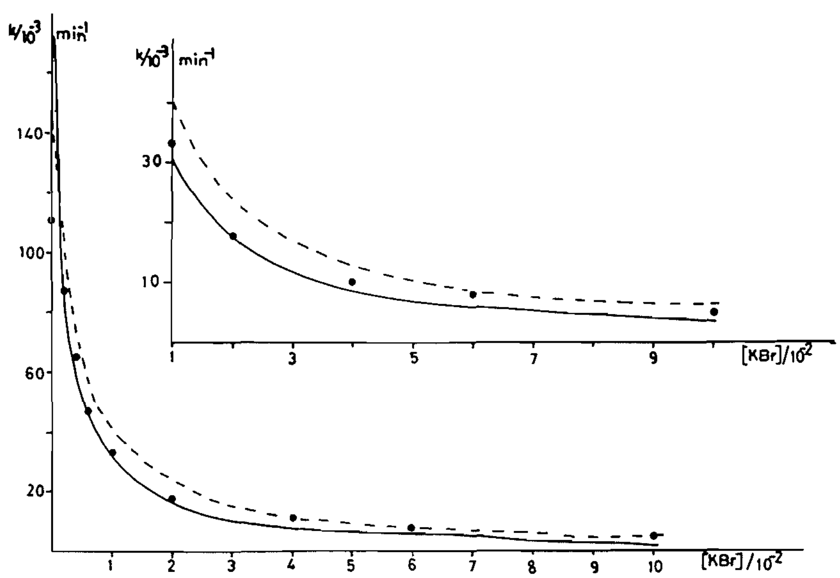

FIG. 4b. Variation of the pseudo-first-order rate constant, k_ψ, with KBr concentration at fixed surfactant and NaOH concentration for DDD (● [CTAB] = 2 mM and [NaOH] = 2 × 10^{-2} M). Lines are predicted values with different models.

where cm is the critical micellar concentration in clear aqueous solutions. Table 3 gives the values of parameters that best fit the experimental results using the above expression for cmc, and Figs. 1 and 2 show the calculated kinetic rate constant, k_ψ, with these parameters for DDT and DDD respectively (solid lines).

The values of k_M so determined are the same for the reactions in both surfactants CTAB and CTAOH, for each of the substrates. The substrate-to-micelles binding constants, K_S, for DDT are the same for the reaction in CTAOH and in CTAB, independent of ion concentration but, in the case of DDD for which higher concentrations of OH^- have been used, the value of K_S increases with increase of reactive ions in solution at these high concentrations, and this variation can be adapted to an empirical expression as:

$$[19] \quad K_S = 10^3\ (M^{-1}) + 7 \times 10^4\ (M^{-2}) \times ([\mathrm{NaOH}] + [\mathrm{KBr}])\ (M)$$

The same kind of the empirical expression for K_S can be used for DDT for the results at high OH^- concentrations.

$$[20] \quad K_S = 1500\ (M^{-1}) + 27\,000\ (M^{-2}) \times ([\mathrm{NaOH}] + [\mathrm{KBr}])\ (M)$$

This variation can be explained by the "salting-out" effect (13). These high values of K_S for both substrates agree with the results found in the literature for other hydrophobic substrates such as $(O_2NC_6H_4O)_2CO$, N—$C_{16}H_{33}$-3-CP, and PADA, with K_S values of 1000 (ref. 24), 3500 (refs. 25 and 26), and 2800 (ref. 27), respectively. The exchange constant, K_{Br}^{OH}, is the

TABLE 4. Parameters that best fit the kinetic results for DDT and DDD in CTAB, using an additional reaction step

DDD	0.77	1000 + 70000 ([NaOH] + [KBr])	900	35

same for both substrates while K'_{OH} shows some variations in its value. The value of K_{Br}^{OH} is in the range of literature values for other substrates: 2, 54, and 21 for acetylsalicylate ester (28), p-nitrophenyl acetate (29), and betaine (5) respectively.

In Figs. 3a and 3b the calculated values of k_ψ at different OH^- concentrations are represented by solid lines, with the values of parameters determined before, at fixed concentrations of CTAB (2, 20, 60 mM). This model, which considers β as a constant, only explains the results up to a concentration 0.1 M of OH^-. That means that this approximation to consider β constant is valid only at low OH^- concentrations when $m_{OH} \ll m_{Br}$ and $\beta = m_{Br}$. Some of the results in the literature at high OH^- concentrations had been explained by considering an additional pathway across the micellar boundary, in which the hydroxide ion in the aqueous phase would react with the organic substrate bound to the micelle (12, 30). With this new additional reaction step with a pseudo-first-order rate constant: $k'_{W/M} = k_{W/M} \times [OH_W^-]$, it is possible to explain the experimental results over the whole range of [OH^-] used, but it is necessary to suppose that $k_{W/M}$ depends on surfactant concentration. Table 4 shows the values of parameters that best fit the experimental results with this new additional reaction step.

The experimental results at high KBr concentration, at fixed concentrations of CTAB and OH^-, can also be explained with the model that considers β as a constant, up to a value of [KBr] = 10^{-2} M, with the same values of parameters determined before (solid lines in Figs. 4a and 4b). Nevertheless, the model is not satisfactory at high KBr concentrations.

In order to explain the experimental results at high ion concentration we used the model that considers independent distribution equilibria for each of the ions in solution between aqueous and micellar pseudophases, which gives values of β depending of surfactant and ion concentrations. The values of [OH_M^-] and [Br_M^-] as a function of K'_{OH} and K'_{Br}, eqs. [15] and [16], can be obtained with an iterative calculation method setting [OH_M^-] initially as 0.000001 M and determining [OH_M^-] and [Br_M^-] as a function of K'_{OH}, K'_{Br}, [OH_T^-], and [Br_T^-]. There is no ensemble of parameters that adapts the experimental results to the whole range of surfactant and ion concentrations studied. The values of K'_{OH} and k_M should be the values obtained for the reaction in CTAOH and the values of K'_{Br} and K_S have been taken as adjustable parameters.

The best values of the parameters are given in Table 5 and the calculated values of k_ψ are represented by broken lines in Fig. 1 for DDT ([OH^-] = 10^{-2} M and [OH^-] = 5×10^{-2} M) and in Fig. 2 for DDD ([OH^-] = 3×10^{-2} M and [OH^-] = 10^{-1} M). For DDT the calculated value of k_ψ reproduces the experimental results at low surfactant concentration for [OH^-] = 0.05 M but at high surfactant concentration the calculated value of k_ψ is above the experimental results. With decreasing OH^- concentration it is necessary to increase the values of k_M and K_S in order to adapt the results at low surfactant concentration, but the calculated value at high surfactant concentration is always above the experimental result. The same effects have been found for DDD.

The values of k_ψ calculated with the parameters in Table 5 for the reaction at high OH^- concentration, using this model that considers β not a constant, are represented in Figs. 3a and 3b (broken lines). At low OH^- concentration the predicted values of k_ψ, at small surfactant concentration, 2 mM, are too low to explain the experimental results, but with increasing surfactant concentration, 20 mM and 60 mM, the calculated values are always higher than the experimental results. The values of k_ψ for the results at different KBr concentrations, calculated with the parameters in Table 5 (broken lines in Figs. 4a and 4b), are too low to explain the experimental results at small KBr concentration but, on increasing the KBr concentration, the calculated values of k_ψ become closer than the calculated values using the model that considers β as a constant. However, they are not high enough to explain these experimental results.

It can be concluded that for the reactions of these two substrates, where the determined value of K'_{OH} is as low as 30 M^{-1}, the predicted values of β at small surfactant concentration and small ion concentration are too low to explain the experimental results but that on increasing surfactant concentration the predicted values of β become too high. It is interesting to point out that this model explains very well the experimental results for the hydrolysis of acetylsalicylate ester and homologs (19) where the determined value of K'_{OH} in CTAOH is 380 M^{-1}.

It is possible to explain all of these experimental results by using an empirical variation of β with ions, as had been done by some authors (13, 31). Accordingly, for the reaction of these two substrates, the following two expressions were found: β = 0.8 + 0.5 ([NaOH] + [KBr]) for DDT and β = 0.8 + 1 ([NaOH] + [KBr]) for DDD. In Table 6 are shown the experimental and the calculated values of pseudo-first-order

TABLE 6. Experimental and calculated values of pseudo-first-order rate constants for DDT: (a) in CTAB ($[OH^-] = 5 \times 10^{-2}$, Fig 1); (b) reaction at high OH^- concentration ([CTAB] = 2 m*M*, Fig. 3a), using the three theoretical models, (1) considering β as a constant, (2) considering independent equilibria: β variable, (3) with an empirical expression for β

rate constants for the reaction of DDT in CTAB ($[OH^-] = 5 \times 10^{-2}$) and the values for the reaction at high OH^- concentration ([CTAB] = 2 m*M*) using the three theoretical models:

(*1*) considering β as a constant (= 0.8)

(*2*) considering independent distribution equilibria for each of the ions in solution between the aqueous and micellar phase, with a variable β

(*3*) using the empirical expression for the value of β.
The same behavior is found for all the other results and it can be concluded that considering the empirical expression for β is the best way to explain the experimental kinetic results for the dehydrochlorination of DDT and DDD.

When 1 Torr of methane was decomposed in a radio-frequency glow discharge plasma, ethane, ethylene, and acetylene were produced as major products. In order to determine the relative importance of radical and ionic processes for the formation of these major products, iodine and ammonia were used as radical and ion scavengers, respectively. It was found that the major products were formed mainly by radical processes and the contribution of ionic processes is within the experimental error. The mechanisms for the formation of ethane, ethylene, acetylene, and $C_3 \sim C_4$ compounds were discussed.

K. HIRAOKA, K. AOYAMA et K. MORISE. Can. J. Chem. **63**, 2899 (1985).

Lorsqu'on décompose du méthane sous une pression de 1 torr et dans la lueur d'un plasma à décharge produit par une fréquence radio, les produits principaux sont l'éthane, l'éthylène et l'acétylène. Dans le but de déterminer l'importance relative des processus radicalaire et ionique dans la formation de ces produits principaux, on utilise respectivement l'iode et l'ammoniac comme pièges des radicaux et des ions. On a trouvé que les produits majoritaires se forment principalement par des processus radicalaires alors que la contribution des processus ioniques se situe à l'intérieur des limites des erreurs expérimentales. On discute du mécanisme de formation de l'éthane, de l'éthylène, de l'acétylène et des composés en C_3 et en C_4.

[Traduit par le journal]

Introduction

The elucidation of the reaction mechanisms of reactions in the plasma is largely impeded due to the complex nature of plasmas. The most difficult task is to determine the relative importance of ions and radicals in the reactions of plasmas. The estimation of the contribution of ions is much more difficult than that of radicals because the rates of ion–molecule reactions are too fast (often collision rate) to determine the precursor ions for the end products. The main objective of this work is to study the reaction mechanisms of methane in a glow discharge plasma in detail. In particular, we endeavored to evaluate the relative contribution of radical and ion mechanisms on the formation of reaction products.

Hiraoka and Kamada studied the reaction mechanisms of benzene in a radio-frequency glow discharge plasma using iodine as a radical scavenger (1). They found that acetylene and ethylene are produced directly from the decomposition of electronically excited benzene molecules. They claimed that radical scavengers can be used in the plasma chemistry for the study of reaction mechanisms. In this study, the reactions in the methane glow discharge plasma were investigated using iodine and ammonia as radical and ion scavengers, respectively, in order to determine the relative importance of radical and ionic processes in the glow discharge plasma of methane. Methane is the most suitable gas for the study of the reaction mechanisms because photolysis (2–5) and radiolysis (6–8) of methane were investigated in detail and the ion–molecule reactions of methane are well known (9). The use of scavengers is one method to intercept the consecutive reactions at early stage. By cooling the discharge tube at 77 K, it is also possible to avoid further decompositions and reactions of primary products in the plasma. The gaseous products condensible at 77 K are quickly trapped on the wall of the discharge tube and they escape from further decompositions in the plasmas. This method was found to give an important information about the reaction mechanisms.

Experimental

The pressure of methane (Taiyo Sanso, 99.9%) introduced to the vacuum line was controlled by adjusting a needle valve (Nupro SS-4BMG metering valve). The sample gas flowed continuously through the discharge tube and then passed through a trap cooled to liquid N_2 temperature and then pumped away by an oil-rotary pump with a capacity of 150 L/min. The experiments were done at three temperatures of the discharge tube, i.e. ~400, 195, and 77 K. Without cooling the discharge tube, its temperature reached to about 400 K by the inductive heating. By filling dry-ice acetone or liquid N_2 in the coaxial double cylindrical discharge tube, the temperatures of the discharge tube could be maintained at 195 and 77 K, respectively. Experiments at 77 K, all gaseous products were trapped on the wall of the discharge tube. For all experiments at ~400, 195, and 77 K, only a negligible amount of solid products was formed on the wall of the discharge tube. The sample gas was subjected to the plasma which is generated by a radio-frequency generator (Koike Engineering, 27 MHz) with a maximum power of 60 W.

For CH_4/I_2 experiments, the flow rate of iodine was controlled by dipping the iodine reservoir in a temperature-regulated water bath. Before the analysis of the gaseous products, the unreacted iodine and the hydrogen iodide produced were absorbed in the aqueous solution of sodium thiosulfate contained in the liquid N_2 trap by freeze–pump–thaw cycles.

For CH_4/NH_3 experiments, the known amounts of CH_4 and NH_3 were sampled in the 5 L flask at the total pressure of 760 Torr. The mixed gas was then flowed through the needle valve into the vacuum system. The unreacted ammonia trapped in a liquid N_2 trap was absorbed in a boric acid solution contained in the liquid N_2 trap by freeze–pump–thaw cycles.

For the analysis of gaseous products, the temperature of the trap was raised to dry-ice acetone temperature, and vaporized products were analysed by gc (Fig. 1) and gc–ms. The amounts of reaction products which are trapped at dry-ice acetone temperature were nil. The hydrogen which is one of the major gaseous products was not measured in this experiment because hydrogen cannot be trapped at 77 K.

Results and discussion

Application of scavengers in the plasma chemistry

Radical and ion scavengers have been widely used in the field of radiation chemistry. They give important information

on the mechanisms of reactions induced by the ionizing radiation. Although there seem to be no serious problems for the use of scavengers in the radiation chemistry, one should be very cautious for applications of scavengers in the plasma chemistry because plasma parameters such as electron temperature, plasma density, sheath potential, etc. are affected by the addition of scavengers in the plasma. For example, the electron temperature decreases sharply when a small amount of foreign gas is added whose ionization energy is lower than the major gas (10). It is desirable that scavengers have high ionization energies and negative electron affinities. Ironically, molecules can scavenge ions due to their low ionization energies. Besides, atoms and molecules which are used for radical scavengers generally have positive electron affinities. It seems intrinsically difficult to find "ideal" scavengers for the plasma chemistry. Thus it would be quite risky to draw out any quantitative conclusions from the results obtained by the use of scavengers in the plasma chemistry. However, if any drastic chemical changes could be observed by the addition of scavengers, we could appreciate them as important informations on the mechanisms of chemical reactions in the plasma. Because there are no other simple methods for the analysis of complicated reactions in the plasma, we dared to use ammonia and iodine as ion and radical scavengers, respectively, and see whether they are applicable in the plasma chemistry.

Use of ammonia as an ion scavenger

Although a number density of ions is generally many orders of magnitude smaller than that of free radicals in the plasma, it does not necessarily mean that the ion mechanism can be negligible compared to the free radical mechanism. This is because ions in a non-equilibrium plasma diffuse much much faster than neutral species and their lifetimes become much shorter than those of free radicals.

In a plasma, positive ions and electrons diffuse at the same rate, i.e., they diffuse by an ambipolar diffusion. The ambipolar diffusion coefficient D_a can be approximated to be (11)

$$[1]\quad D_a = \left(\frac{T_e}{T_i} + 1\right) D_i$$

where T_e is the electron temperature, T_i is the ion temperature, and D_i is the free diffusion coefficient of ions.

The characteristic diffusion length Λ for the cylindrical discharge tube can be given as (12)

$$[2]\quad \frac{1}{\Lambda^2} = \left(\frac{2.405}{r}\right)^2 + \left(\frac{\pi}{l}\right)^2$$

where r and l are radius and length of the cylinder, respectively. The value of Λ for the discharge tube used in this experiment (r = 5 mm and l = 70 mm) is calculated to be 1.7 mm. In the separate experiments (11), for the cavity with about the same value of Λ, the decay lifetime of ions in the thermal plasma ($T_e \cong T_i \cong T_{gas}$) of 1 Torr CH_4 was measured to be about 1 ms. In this case, the ambipolar diffusion coefficient D_a is larger than D_i by a factor of two, i.e. $D_a = 2D_i$ (eq. [1]).

Under the present experimental conditions where the plasma is nonthermal and $T_e \cong 100T_i$, D_a becomes about two orders of magnitude larger than D_i (eq. [1]). In such a condition, ions diffuse to the wall in ~10 μs by the ambipolar diffusion and they are neutralized there by the recombination reactions with electrons. On the other hand, free radicals are annihilated mainly by mutual recombination reactions and thus their lifetimes would be orders of magnitude longer than those of ions. Therefore, free radicals are accumulated in the plasma and their number density becomes much higher than that of ions. The large difference in the number densities between ions and free radicals in the non-thermal plasmas is mainly due to the difference in the rates of disappearance of ions and free radicals. In order to evaluate the relative importance of ion and free radical mechanisms, one should compare the *production rates* of ions and radicals instead of their densities. Numbers of ions and free radicals produced per unit time is proportional to the integral

$$\int_0^\infty Q(E)\,\sqrt{\frac{2E}{m}}\,f(E)\,\mathrm{d}E$$

where $Q(E)$ is the energy-dependent cross sections for ionization or dissociation of atoms or molecules, E is the energy of electron in the plasma, m is the mass of an electron, and $f(E)$ is the energy distribution function of electrons in a plasma. Accurate measurements of ionization and dissociation cross sections for methane are unfortunately not available. Using the available data for hydrogen (13), and assuming that the energy distribution of electrons in a plasma is Maxwellian and T_e = 5 eV, one finds that about one ionization event occurs for every ten dissociations of hydrogen molecules. This crude table calculation suggests that the relative contribution of ion mechanism is about one tenth of free radical mechanism in a hydrogen plasma. The experimental determination of the contribution of ion mechanism is very difficult because the rates of ion–molecule reactions are generally too fast to determine the precursor ions for the terminal products. Under such a situation, we think an ion–molecule reaction could be only controlled by an ion–molecule reaction itself, i.e., the use of ion scavengers.

The major ion in the methane plasma is known to be $C_2H_5^+$, the protonated ethylene (14). In order to scavenge this ion, the scavengers must have higher proton affinities than ethylene. We adopt ammonia as an ion scavenger because its proton affinity (205 kcal/mol) is much larger than those of alkanes, alkenes, and alkynes, and the protonated ammonia NH_4^+ is chemically unreactive toward hydrocarbons.

In the methane plasma, CH_3^+ and CH_4^+ are produced by the electron impact as primary product ions. They react with methane to produce $C_2H_5^+$ and CH_5^+, respectively (9).

[3] $CH_3^+ + CH_4 \rightarrow C_2H_5^+ + H_2$

[4] $CH_4^+ + CH_4 \rightarrow CH_5^+ + CH_3$

Rate constants for these reactions are of the order of 10^{-9} cm^3 molecule^{-1} s^{-1} (9). Thus lifetimes of CH_3^+ and CH_4^+ can be estimated to be ~20 ns under the present experimental conditions (1 Torr of methane). One of the main product ions CH_5^+ reacts only by a proton transfer reaction and regenerates CH_4. On the other hand, $C_2H_5^+$ has a variety of modes of reactions such as (9, 15, 16)

[5] $C_2H_5^+ + CH_4 \rightarrow C_3H_7^+ + H_2$

[6] $C_2H_5^+ + C_2H_6 \rightarrow C_4H_9^+ + H_2$

[7] $C_2H_5^+ + C_2H_4 \rightarrow C_3H_5^+ + CH_4$

[8] $C_2H_5^+ + C_2H_2 + CH_4 \rightarrow C_2H_5^+\cdot C_2H_2 + CH_4$

[9] $C_2H_5^+ + C_2H_2 \rightarrow C_3H_3^+ + CH_4$

By an addition of NH_3 in the plasma, $C_2H_5^+$ reacts with NH_3 to produce C_2H_4 by the proton transfer reaction [10],

[10] $C_2H_5^+ + NH_3 \rightarrow NH_4^+ + C_2H_4$

and reactions [5]–[9] must be suppressed. Thus, if the ion mechanism plays an important role in the methane plasma, the relative yield of C_2H_4 must be increased by an addition of NH_3.

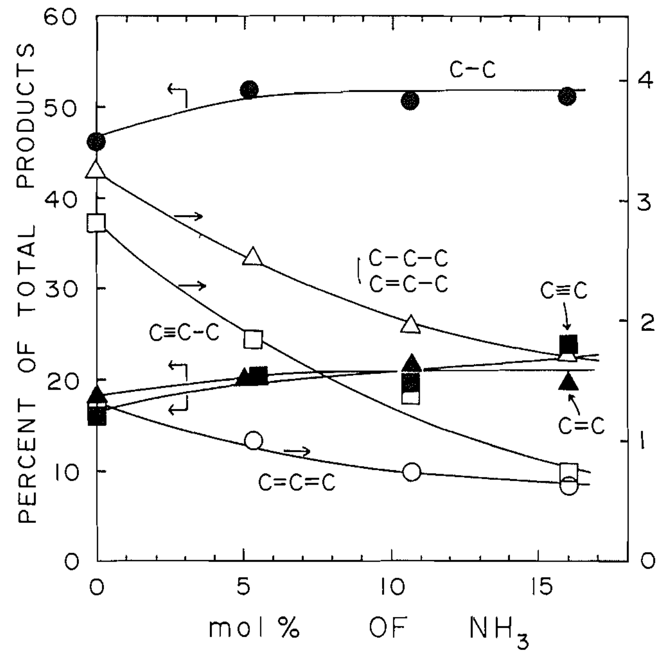

FIG. 2. The dependence of the relative yields of products on the amounts of added NH_3 in CH_4. Hydrogen is not included in the "total" products because it cannot be trapped at 77 K. The input power from the radio-frequency generator to the plasma was kept at 30 W for all measurements.

Figure 2 shows the dependence on the amount of added NH_3 of the relative yields of products. The relative yields of C_2H_6, C_2H_4, and C_2H_2 are nearly independent of the amounts of added NH_3. This result strongly suggests that the contribution of ion mechanism in the methane plasma is within the experimental error (5–10%).

Use of iodine as a radical scavenger

The results described in the previous section implicitly suggest that the free radicals play major roles in the reactions of methane plasma. To obtain further evidence, the iodine was introduced into the methane plasma as a radical scavenger. Figure 3 shows the dependence on the amounts added iodine of the relative yields of products. The yield of ethane decreases sharply with an increase of iodine, indicating that ethane is

TABLE 1. The relative yields of products from the decompositions of methane at 400, 195, and 77 K[a]

Temperature (K)	Relative yield								
	C_2H_4	C_2H_6	C_2H_2	C_3H_6 C_3H_8	C_3H_4[b]	C_3H_4[c]	C_4H_{10}	C_4H_2	C_6H_6

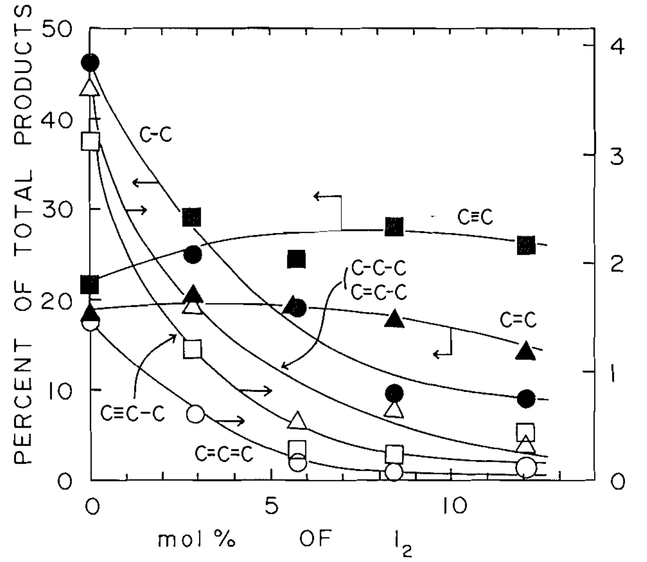

FIG. 3. The dependence of the relative yields of products on the amounts of added I_2 in CH_4. Hydrogen is not included in the "total" products because it cannot be trapped at 77 K. The input power from the radio-frequency generator to the plasma was kept at 30 W for all measurements.

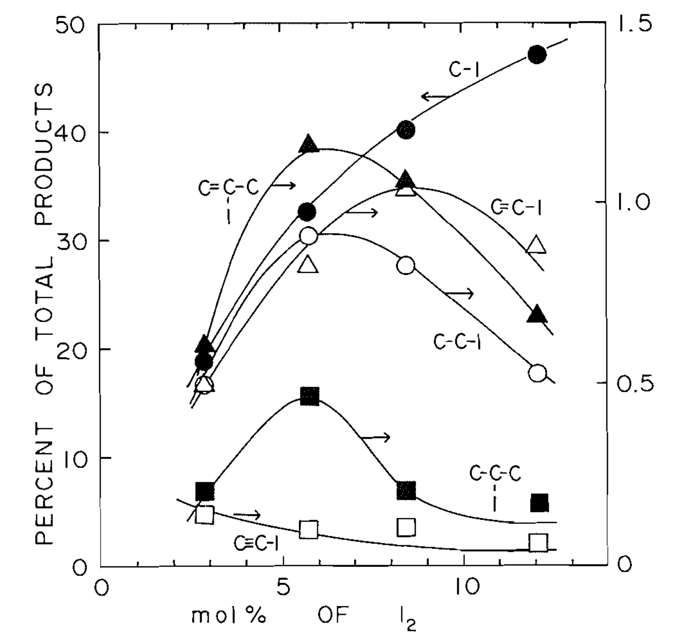

FIG. 4. The dependence of the relative yields of iodides on the amounts of added I_2 in CH_4.

produced by a radical mechanism. The yields of ethylene and acetylene are rather insensitive toward the amounts of added iodine. Iodine is considered to be less effective to scavenge precursors of ethylene and acetylene.

The benefit of using iodine as a radical scavenger is that the precursor radicals can be chemically frozen as iodides. Figure 4 shows the dependence on the amounts of added iodine of the relative yields of produced iodides. The produced CH_3I are by far the most abundant compared to other iodides and its yield shows a sharp increase with an increase of iodine. Considering results shown in Figs. 3 and 4, it can be concluded that ethane is formed by the recombination reaction of two methyl radicals,

[11] $2CH_3 \rightarrow [C_2H_6]^* \xrightarrow{M} C_2H_6$

where M represents a third body which collisionally stabilizes the intermediate complex $[C_2H_6]^*$.

Temperature effect on the relative yields of products

The lifetimes of the intermediate complexes in the radical reactions are more or less temperature dependent. The lower the temperature, the longer the lifetime of the intermediate complex. The intermediate complex has more chance to be stabilized at lower temperature. Thus the study of the temperature dependence on the plasma reactions would give some information on the reaction mechanisms. The experiment at 77 K is particularly interesting because the primary products are quickly trapped on the wall of the discharge tube and a further decomposition of primary products is expected to be greatly suppressed. In a sense, the cold wall acts as a scavenger by trapping primary products.

Table 1 summarizes the data obtained at ~400, 195, and 77 K. The relative yield of acetylene is almost independent on the temperature. The yield of ethane shows a steady increase with a decrease of temperature. Drastic decrease and increase of ethylene and *n*-butane, respectively, were observed at 77 K. This result suggests that ethylene and *n*-butane are formed from the same precursor. The detailed discussion about the reaction mechanisms will be described in the following section.

Reaction mechanisms of methane in a plasma

The major gaseous products from the decomposition of methane in a plasma were ethane, ethylene, and acetylene. The mechanisms for the formation of these products as well as C_3 and C_4 products will be considered here.

Radiolysis and photolysis of methane have been investigated in detail (2–8). The experimental evidence obtained by these investigations favors CH_2 and H_2 as the major products of the dissociation of methane. Mahan and Mandal, irradiating with a krypton resonance line (10.0 eV), found that CH_2 and H_2 were the dominant products (2). Magee (17), using a continuous hydrogen source (8.3 ~ 11.8 eV), concluded that an excited methane decomposes into CH_2 and H_2 85% of the time and into CH_3 and H 15% of the time. In a plasma, electrons have a wide range of energy and other radicals such as CH and C may also be produced as primary products. Besides, hydrogen atoms present as primary and secondary products in a methane plasma would abstract hydrogen atoms from CH_n radicals ($n \leq 3$).

[12] $CH_3 \xrightarrow{H} CH_2 \xrightarrow{H} CH \xrightarrow{H} C$

Thus the primary radicals in the methane plasma would be CH_2, CH, and C.

The CH_2 radical is known to insert into a C—H bond of methane to form internally excited $[C_2H_6]^*$ which decomposes unimolecularly into two CH_3 radicals (8, 18).

[13] $CH_2 + CH_4 \rightarrow [C_2H_6]^* \rightarrow 2CH_3$

This reaction would explain the large yield of CH_3I in the I_2 scavenger experiments (Fig. 4). Ausloos and co-worker found that $[C_2H_6]^*$ was collisionally stabilized at higher pressures (8). In the present experiments, the relative yield of ethane is increased at lower temperatures (Table 1). The lifetime of the intermediate complex $[C_2H_6]^*$ is supposed to be long enough to be collisionally stabilized in 1 Torr methane at 77 K.

Ethylene was found to be the main product from the reaction of CH with methane (3, 8).

[14] $CH + CH_4 \rightarrow [C_2H_5]^* \rightarrow C_2H_4 + H$

[15] $\xrightarrow{M} C_2H_5$

The lifetime of $[C_2H_5]^*$ was supposed to be short because the stabilization process [15] has not been observed at high pressures (8, 19). The short lifetime of $[C_2H_5]^*$ (4×10^{-13} s) has also been predicted by the theoretical RRKM calculations (19). In the present experiments at 77 K, however, the yield of C_2H_4 decreased markedly and this decrease was compensated by the increase of *n*-butane. This result suggests that there is some mechanism for the stabilization of $[C_2H_5]^*$ at 77 K which is followed by the recombination reaction [16] to form *n*-butane.

[16] $2C_2H_5 \xrightarrow{M} C_4H_{10}$

Considering that reactions [14] and [15] are 60 and 99 kcal/mol exothermic, it seems not likely that $[C_2H_5]^*$ can be stabilized even at 77 K in the gas phase. The $[C_2H_5]^*$ could be stabilized if the reaction of CH with CH_4 occurs on the cold wall. However, such an heterogeneous reaction cannot explain the large yield of *n*-butane at 77 K, and some other stabilization mechanisms might exist. For example at 77 K in the gas phase, van der Waals clusters $(CH_4)_n$ ($n \geq 2$) would be present at higher concentrations and they participate in the formation of C_2H_5 radical:

[17] $CH + (CH_4)_n \rightarrow C_2H_5 + (n - 1)CH_4$

The cluster $(CH_4)_n$ has built-in third-bodies in it and the exothermicity of the reaction could be released as kinetic energies of departing third bodies. This might explain the sudden decrease and increase of ethylene and *n*-butane, respectively, at 77 K.

If reaction [13] occurs at 77 K, the produced methyl radical would react with C_2H_5 to form C_3H_8. However, the yield of propane does not increase at 77 K (Table 1). These results suggest that a greater part of $[C_2H_6]^*$ is stabilized at 77 K.

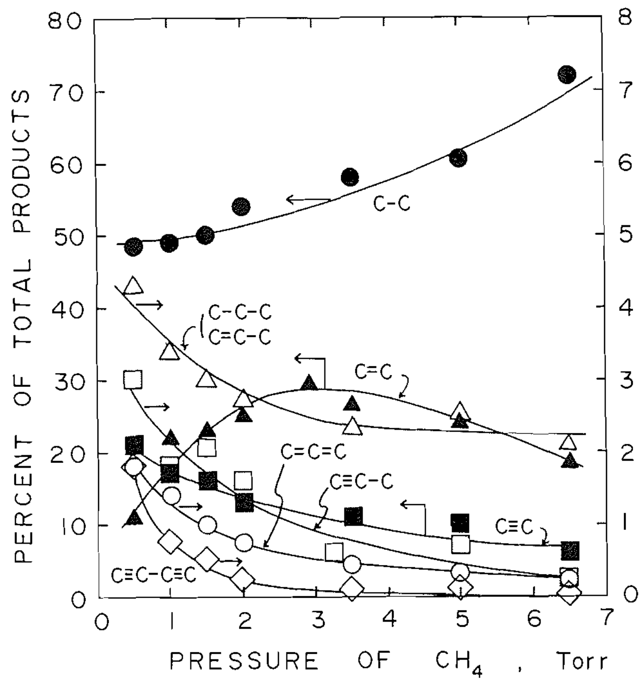

FIG. 5. The dependence of the relative yields of products on CH_4 pressure. The input power from the radio-frequency generator to the plasma was kept at 30 W for all measurements.

Braun *et al.* (20) and Husain *et al.* (21) found that acetylene is formed by the reaction of C with CH_4.

[18] $C + CH_4 \rightarrow [C_2H_4]^* \rightarrow C_2H_2 + H_2$

No evidence was obtained for the collisional stabilization of $[C_2H_4]^*$ at higher pressures (20), indicating that the lifetime of $[C_2H_4]^*$ is short.

As the pressure is decreased, the electron temperature in the plasma increases (10) and the residence time of gas molecules in a plasma gets longer because of the decrease of the linear gas velocity. Thus primary products experience more frequent secondary decompositions at lower pressures. Thus the lower the pressure becomes, the further the successive reactions [12] proceed. As shown in Fig. 5, the yield of ethane decreases steadily with decreasing pressure. The yield of ethylene increases initially, and after reaching the maximum, starts to decrease. The relative yield of acetylene is lowest at high pressures, but it increases steadily with decreasing pressure, and overcomes the yield of ethylene at low pressures. These results support the idea that CH_2, CH, and C are the precursors of ethane, ethylene, and acetylene, respectively. The power dependence on the relative yields of products as shown in Fig. 6 also supports the reaction mechanisms described above.

The ^1D state of carbon atom may be responsible for the formation of acetylene. The rate constant of the reaction of the ground state $C(^3P)$ with methane ($k < 2 \times 10^{-15}$ cm^3 molecule^{-1} s^{-1}) (22) is much smaller than that of the excited $C(^1D)$ ($k = 2 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}) (21). The energy difference between $C(^1D)$ and $C(^3P)$ is about 1 eV. The spin-forbidden excitation of $C(^3P)$ to $C(^1D)$ would occur efficiently in a nonequilibrium glow discharge plasma because electrons with energies of a few eV are abundant in a plasma (10). Recently, the diamond-like carbon films have been synthesized by radio-frequency plasma decomposition of CH_4 or mixed gases of CH_4 and H_2 (23). The hydrogen containing a small amount of CH_4 was found to be a suitable gas for the synthesis

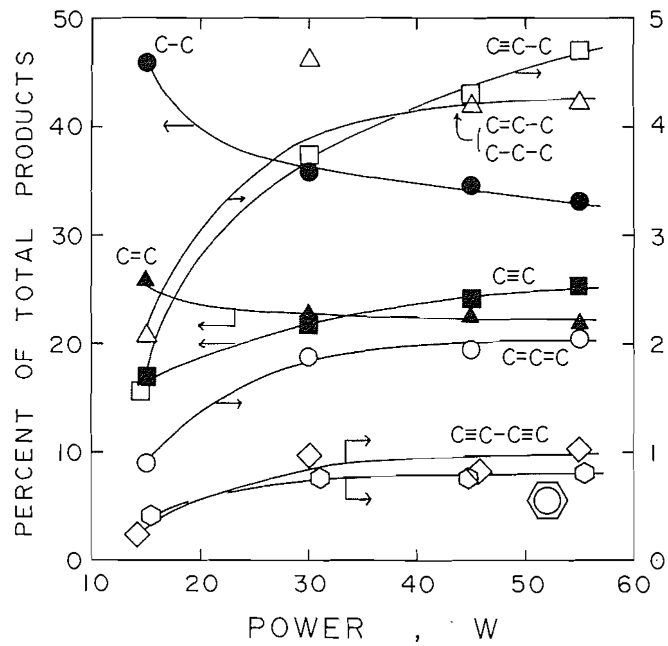

FIG. 6. The dependence of the relative yields of products on the input power to the plasma.

of diamond-like carbon film. Apparently, hydrogen atoms in a plasma play an important role to produce carbon atoms by the reactions (12). The produced $C(^1D)$ may contribute to the growth of the sp^3 skeleton of diamond-like film by the insertion reaction. The methane gas is intrinsically the best source of carbon atoms because its H/C ratio is largest in hydrocarbons and the contribution of reaction [12] is most effective for the production of carbon atoms.

Propane and propylene may be formed by reactions [19]–[22].

[19] $CH_3 + C_2H_5 \xrightarrow{M} C_3H_8$

[20] $CH_3 + C_2H_3 \xrightarrow{M} C_3H_6$

[21] $CH_2 + C_2H_6 \xrightarrow{M} C_3H_8$

[22] $CH_2 + C_2H_4 \xrightarrow{M} C_3H_6$

The formation of C_2H_5I and C_2H_3I in the I_2 scavenger experiments argues for reactions [19] and [20]. However, the possibility for reactions [21] and [22] cannot be rejected because the yields of propane and propylene do not show sharp decrease at 77 K where ethane and ethylene, which may be the precursors of C_2H_5 and C_2H_3 radicals, are trapped quickly on the wall of the discharge tube.

Baird found that allene is a principal product from the reaction of C with ethylene (24).

[23] $C + C_2H_4 \xrightarrow{M} C_3H_4$

If the precursor of allene produced in this experiment is ethylene, the yield of allene should decrease at 77 K because the yield of ethylene showed a sudden decrease at the same temperature. Table 1 shows that both yields of ethylene and allene drop sharply at 77 K. This result is a strong support for the occurrence of reaction [23] in the methane plasma.

The formation mechanism of methylacetylene seems somewhat different from that of allene, because the decrease in methylacetylene yield is not so drastic as allene at 77 K. Besides, with an increase of an input power, the yield of methylacetylene shows a steady increase but that of allene reaches a plateau (Fig. 6). Canosa-mas *et al.* found that the main product from the reaction of $CH_2(^1A_1)$ with acetylene is methylacetylene (25).

[24] $CH_2(^1A_1) + C_2H_2 \rightarrow C{\equiv}C{-}C$

All the results shown in Table 1 and Figs. 5 and 6 support the idea that the precursor of methylacetylene is acetylen (reaction [24]).

Important progress has been made by Lange and Wagner in understanding acetylene photochemistry (26). They have obtained the rate constant of the reaction,

[25] $C_2H + C_2H_2 \rightarrow C_4H_2 + H$

by measuring with the mass spectrometer the decay of C_2H and have obtained $k = 5 \times 10^{-11}$ cm^3 molecule^{-1} s^{-1}. They have also found the product to be mainly diacetylene. The very low yield of diacetylene at higher methane pressures (Fig. 5) may be due to the consumption of C_2H radical by reaction [26] (27).

[26] $C_2H + CH_4 \rightarrow C_2H_2 + CH_3$

Conclusion

Much information about the reaction mechanisms of reactions in the methane glow discharge plasma could be gained by the experiments using ammonia and iodine as ion and radical scavengers, respectively. It was found that the major products were formed mainly by radical processes and the contribution of ionic processes is within the experimental error. It is concluded that reactions of CH_2, CH, and C with methane produce ethane, ethylene, and acetylene, respectively, as major products in the methane glow discharge plasma.

A detailed study of complexation of the sodium ion by HMPA[2] has been made using the system

$NaAlEt_4$ – benzene – HMPA

where HMPA is observed to be a strong donor towards Na^+ but does not complex $AlEt_4^-$. This system forms two liquid phases at low HMPA:Na^+ molar ratios with the salt and the HMPA, up to a 4:1 HMPA:Na^+ ratio, occurring only in the lower phase. Based on a variety of experimental techniques, reasonable proposals of the solute species in the lower phase as a function of HMPA:Na^+ ratio are presented. A 2.5:1 ratio of HMPA:Na^+ is observed to be particularly significant. This ratio is rationalized in terms of a bridging HMPA molecule resulting in a cationic species with the stoichiometry $[2Na\cdot5HMPA]^{2+}$. It is found that the ^{27}Al and ^{1}H nmr spectra are determined primarily by quadrupole relaxation of the ^{27}Al nucleus rather than by exchange.

JAMES H. MEDLEY, NASEER AHMAD et MARION C. DAY. Can. J. Chem. **63**, 2906 (1985).

On étudié d'une façon systématique la complexation de l'ion sodium par le HMPA (hexaméthylphosphoramide) dans le système

$NaAlEt_4$ – benzène – HMPA

dans lequel il a été observé que le HMPA est un puissant donneur pour le Na^+ alors qu'il ne complexe pas l'ion $AlEt_4^-$. À des rapports molaires de HMPA:Na^+ qui sont faibles, c'est-à-dire à des rapports HMPA:Na^+ allant jusqu'à 4:1, ce système forme deux phases liquides et l'on ne retrouve le sel et le HMPA que dans la phase inférieure. En se basant sur plusieurs techniques expérimentales, on présente un certain nombre de propositions raisonnables pour expliquer la présence des espèces solutés dans la phase inférieure en fonction du rapport HMPA:Na^+. Un rapport de HMPA:Na^+ de 2,5:1 semble être important. On explique ce rapport en fonction de l'action d'une molécule de HMPA qui agit comme pont et qui conduit à l'existence d'une espèce cationique de stoichiométrie $[2Na\cdot5HMPA]^{2+}$. On a établi que les spectres rmn du ^{27}Al et du ^{1}H sont déterminés essentiellement par la relaxation quadrupolaire du noyau de ^{27}Al et non par un échange.

[Traduit par le journal]

Introduction

Because of their unique property of solubility in nonpolar solvents such as hexane and benzene, the sodium tetraalkylaluminate salts have proven to be particularly useful in the study of ion–ion and ion–solvent interactions (1). Thus, for instance, a solution of $NaAl(n\text{-butyl})_4$ dissolved in hexane permits one to observe specific interactions between the ions of the salt rather than between the solvated ions which would exist in conventional solvent systems. Further, using a system of the type

$NaAl(alkyl)_4$ – inert solvent – donor

where controlled amounts of the donor are added, one can observe the effects of specific solvation on the behavior of the solution. The first reported such system was (2)

$NaAl(n\text{-butyl})_4$ – cyclohexane – $(ethyl)_2O$

Since that first study, a number of examples of the use of this type of system have been reported.

One of the most unusual properties of this system is its tendency to form two liquid phases at relatively low ratios of donor:Na^+ with strong donors such as HMPA (3). The salt, $NaAlEt_4$, shows considerable solubility in hot benzene, but it is essentially insoluble in benzene at room temperature. The addition of stoichiometric amounts of HMPA to $NaAlEt_4$, up to a ratio of 4:1 HMPA:Na^+, in the absence of benzene results in crystalline solids. However, when HMPA is added to $NaAlEt_4$ in the presence of benzene, two liquid phases are formed. The lower phase contains the salt, HMPA, and some benzene whereas, at lower ratios of HMPA:Na^+, the upper phase contains only benzene.[3] As the ratio of HMPA:Na^+ is increased, there is an increase in the volume of the lower phase (*vide infra*). After an HMPA:Na^+ ratio of 4:1, HMPA appears in the upper phase. If large quantities of benzene are added to a system containing HMPA:Na^+ ratios greater than 4:1, excess HMPA can be extracted from the lower phase but always leaving a lower phase with an HMPA:Na^+ ratio of 4:1 and with the volume characteristic of that ratio. We have never observed any salt in the upper phase. It is interesting that two liquid phases are not generally formed when the donor is a weaker donor towards the Na^+ such as pyridine or tetrahydrofuran (3).

Here we wish to report on our studies of the two liquid phase system

$NaAlEt_4$ – benzene – HMPA

We have carried out an extensive study of this system with the intent of determining the structures of the solute species and, where possible, their chemical behavior.

Experimental procedures

Because of the pyrophoric nature of aluminum alkyls and their compounds, all manipulations involving preparation of solutions and loading nmr tubes, viscometers, and conductance cells were performed under an argon atmosphere in a stainless steel, inert atmosphere box of our own design.

[1]To whom all correspondence should be addressed.
[2]HMPA = hexamethylphosphoramide.
[3]Trace amounts of HMPA can be detected.

Preparation of sodium tetraalkylaluminates

Sodium tetraethylaluminate and sodium tetrabutylaluminate were prepared by the methods of Frey *et al.* (4*a*) and of Schaschel and Day (4*b*), respectively.

Purification of solvents

All hydrocarbon solvents were refluxed over calcium hydride under N_2 for at least 8 h prior to distillation. Hexamethylphosphoramide (HMPA) was refluxed for 24–48 h over CaH_2 in a one piece 30 cm path vacuum distillation apparatus at 0.5 Torr. Fresh HMPA was prepared at 2 week intervals throughout the study. Deuterated benzene, obtained as 99+ atom% from Aldrich Chemical Co., was checked for reactivity with the salt and used without further purification.

Lower phase volume

The volume of the lower phase as a function of mole ratio HMPA:salt was determined by HMPA titrations of salt solutions in benzene. The titrations were carried out on the pan of a top loading balance in the dry box using 0.500 g of $NaAlEt_4$ in 25 mL of benzene. After phase separation, the volume of the lower phase was determined with an estimated precision of ±0.05 mL, using a calibration curve for the volume of the container plus the stirrer.

The data were treated by a General Linear Model Procedure in SAS on an IBM 365/3033.

HMPA:Na^+ ratio	R^2	F	p
<1.5	0.94	199.48	0.0001
1.5–2.2	0.72	31.10	0.0001
2.2–2.8	0.87	110.60	0.0001
2.8–4.2	0.99	1552.02	0.0001

Conductivity measurements

Conductivity measurements were made in conductance cells of conventional design using methods described earlier (5). Concentrations were determined using the volume dependence curve for the lower phase.

Viscosity measurements

The viscosity of the lower phase was determined using Canon-Fenske viscometers modified for operation under an inert atmosphere.

Nuclear magnetic resonance measurements

Aluminum-27 nmr spectra were obtained at 52.148 MHz on a Bruker WP-200 spectrometer.

Proton nmr spectra were obtained on a Varian Associates A-60A, and a Varian HA-100 spectrometer. Aluminum-27 decoupled proton spectra were obtained on the HA-100 using a home-built heteronuclear decoupler. The decoupling scheme was based on the method of Burton and Hall (6).

X-ray measurements

Data collection was performed by ω–2θ scans on an Enraf–Nonius CAD 4 diffractometer equipped with CuKα radiation (λ = 1.54184 Å) and a graphite monochromator. The crystal was sealed in a thin-walled glass capillary. Positions of Na, Al, O, and some N atoms were deduced by heavy atom methods. R = 0.34 based on 672 observed reflections ($I > 1\sigma(I)$) of the 1881 unique data having $\sin\theta/\lambda <$ 0.421. Further elucidation was not possible because of low resolution, high thermal motion, and possible disorder.

The crystals were prepared by sealing a mixture of HMPA and $NaAlEt_4$ (4:1) in a glass container. The mixture was heated to its melting temperature and then slowly cooled to room temperature.

Discussion

Crystal structure of $NaAlEt_4 \cdot 4HMPA$

We have attempted to grow satisfactory crystals of $NaAlEt_4 \cdot x$HMPA where x = 1, 2, 3, 4. The results were generally unsuccessful, but a limited study of $NaAlEt_4 \cdot 4$HMPA was carried out. The following can be stated.

The crystals are orthorhombic, with space group *Pnma*, Z = 4, a = 21.355(3) Å, b = 14.717(5) Å, c = 18.649(4) Å, v = 5861(4) Å^3. The density ≃ 1.00 g cm^{-3}. Thermal motion in the crystal is very high, and resolution is low (worse than 1.5 Å). Unfortunately, the crystals fracture on cooling to 150 K. In addition to the above, it is strongly suspected that the Na^+ is approximately tetrahedrally coordinated by oxygen atoms of HMPA with the symmetry of Na(HMPA)$^+$ being $m(C_s)$ in the crystal. The coordination appears to be nearly linear (Na—O—P angles 150°–180°) with the minimum Na—Al distance of ~9.0 Å.

Solvation by HMPA

It is generally considered that HMPA is an especially strong complexing species and, in fact, it has the highest donor number (38.8) in the original Gutmann listing of solvent donicities (7). This position has recently been substantiated with respect to Na^+ (8).

Solvation number

In earlier studies on this system it has been shown that a 4:1 ratio of HMPA:Na^+ is sufficient to convert contact ion-pairs to solvent separated ion-pairs (9). This implies that the solvation number of HMPA towards Na^+ is four and, further, that the equilibrium

$$[Na \cdot 4HMPA]^+ \rightleftharpoons [Na \cdot 3HMPA]^+ + HMPA$$

lies predominantly to the left. The proposal of a Na^+ solvation number of four is also supported by ^{23}Na nmr studies (10).

Both of the above arguments, the conversion from contact to solvent separated ion-pairs and the solvation number of four as determined from the ^{23}Na nmr, are dependent on the symmetry which determines the quadrupolar relaxation rates of ^{27}Al and ^{23}Na, respectively. With respect to the distinction between contact and solvent separated ion-pairs, one can examine the spin–spin interactions between ^{27}Al and ^1H as reflected in the methylene group proton resonance patterns in $AlEt_4^-$ (11). In a solvent separated ion-pair or free anion where t_d symmetry is expected for the $AlEt_4^-$, a nine line pattern is obtained. On the other hand, a quartet signifies a highly distorted anion such as would be expected for a contact ion-pair. Lesser distortions are indicated by line broadening of various extents (*vide infra*).

Our ^{23}Na studies are based on the line widths, and these are determined by the magnitude of the electric field gradient at the sodium nucleus and the rotational correlation time, τ_c. These are discussed in detail elsewhere (10), but the conclusion is that the average lifetime of a solvated species is much longer than the correlation time. This implies that the solvation of the sodium ion by HMPA does not involve rapid exchange of HMPA molecules between solvated cations. A model for the solvation may then be proposed whereby a series of stable stepwise solvated species such as $[Na^+ \cdot 1HMPA|AlEt_4^-]_n^0$, $[Na^+ \cdot 2HMPA|AlEt_4^-]_n^0$, and $[Na^+ \cdot 3HMPA|AlEt_4^-]^0$ are formed. Here the subscript n symbolizes aggregation.

An argument against a maximum solvation number for the sodium ion with HMPA that is greater than four can be made from the ^{23}Na nmr studies. If a 5:1 solvate of the Na^+ exists with HMPA, the loss of t_d symmetry would result in a line broadening of the ^{23}Na resonance, and this should be observed at a 5:1 HMPA:Na^+ ratio relative to that of the 4:1 solvate. Such is not the case, as can be seen in Fig. 1.

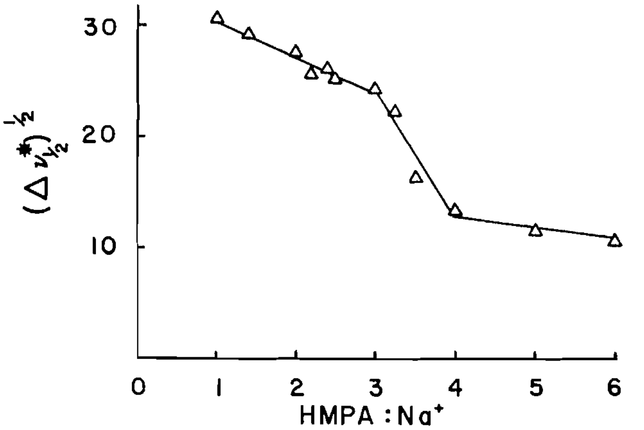

FIG. 1. Viscosity corrected linewidth measurements of ^{23}Na nmr spectra vs. HMPA:Na^+ ratio of 303 K (10).

Solution of $AlEt_4^-$

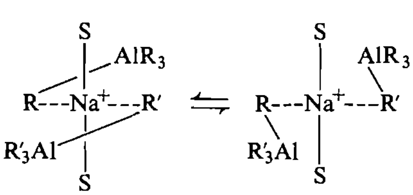
We can also utilize a symmetry argument to show that HMPA does not solvate the $AlEt_4^-$ anion. After a 4:1 ratio of HMPA:Na^+, the excess HMPA is available to solvate the anion. Such solvation, however, will destroy the cubic symmetry about the ^{27}Al nucleus and, correspondingly, result in the loss of the nine line pattern of the methylene proton resonances. This is not observed to occur even in pure HMPA as a solvent. In fact, a large variety of donors have been studied (8, 9), and we have never seen any indication of solvation of the anion. The ^{27}Al nmr studies reported later in this paper also support this view.

Kinetics

Using a system of the type

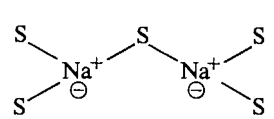
$NaAlR_4 - NaAlR'_4$ – benzene – HMPA

we have reported elsewhere (12) that exchange of alkyl groups occurs resulting in a statistical distribution of the various possible alkylaluminate ions. Of interest here is the fact that the rate of exchange is critically dependent on the HMPA:Na^+ ratio; effectively ceasing at an HMPA:Na^+ ratio of 2.5:1. The exchange reactions are interpreted as occurring within contact ion-pairs in which two or more aluminate anions occupy coordination sites on the same Na^+. The cessation of exchange at the HMPA:Na^+ ratio of 2.5:1 is attributed to the formation of solvent bridged species of stoichiometry $[2Na\cdot 5HMPA]^{2+}$. Thus, the mechanism involves mediation by the Na^+ whereby two anions are in contact as



S = HMPA

From the structure



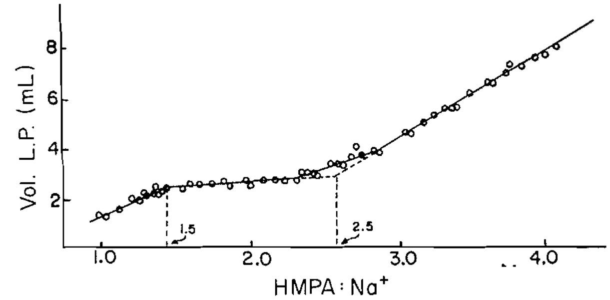


FIG. 2. Volume of the lower phase in mL as a function of mole ratio HMPA:Na^+ at ambient temperature (0.500 g $NaAlEt_4$ used).

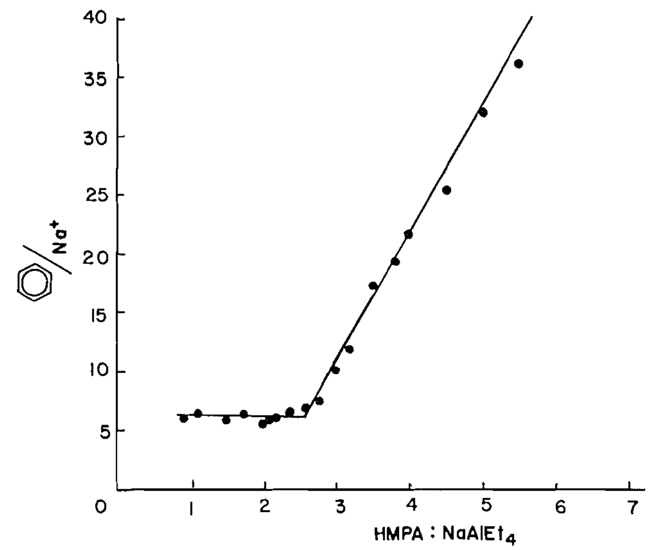

FIG. 3. Ratio of benzene:Na^+ as a function of mole ratio of HMPA:Na^+ at 303 K.

where we see a bridging HMPA molecule, it is apparent that at a HMPA:Na^+ ratio of 2.5:1 it is no longer possible to have two anions coordinated to a given Na^+ and still maintain a sodium ion coordination number of four.

Volume of the lower phase

In Fig. 2, a plot of the volume of the lower phase as a function of the molar HMPA:Na^+ ratio is shown. The curve is most conveniently treated as a collection of linear sections implying the existence of specific solute species at given HMPA:Na^+ ratios. Since there is some benzene in the lower phase, one would tend to attribute the volume increase with increasing HMPA:Na^+ ratio to an increase in the amount of benzene in that phase. However, it can be seen from Fig. 3, that this is not the case. Here the relative amount of benzene as a function of the HMPA:Na^+ ratio is presented. This was determined by integration of proton nmr peaks of benzene and $AlEt_4^-$. Up to an HMPA:Na^+ ratio of 2.5:1, the amount of benzene is seen to remain constant at approximately 6.2 times the salt concentration. Thus, since the quantity of salt (0.500 g) is constant and the HMPA is complexed to Na^+, the volume increase prior to an HMPA:Na^+ ratio of 2.5:1 as shown in Fig. 2, must be totally attributed to the HMPA–$NaAlEt_4$ structure.

Considering only the lower phase volume as a function of mole ratio, it can be noted that: (*1*) The salt concentration in this system is fixed for any given HMPA:Na^+ molar ratio. That is, a lower phase is formed having a particular volume. At a given temperature, this volume is determined only by the HMPA:Na^+ ratio. The relationship between the HMPA:Na^+ ratio and the lower phase volume is given in Table 1. (*2*) Recalling that a fixed quantity of $NaAlEt_4$ (0.500 g) is used and assuming that the HMPA is part of the salt since it is complexed to the Na^+, up to an HMPA:Na^+ ratio of 2.5:1; the weight percent of salt is roughly 50 (ranging from ~42 at an HMPA:Na^+ ratio of 1:1 to ~56 at an HMPA:Na^+ ratio of 2.5:1) but varies with the HMPA:Na^+ ratio. In contrast, the mole percent of salt is constant at ~14. (*3*) The volume increase with an increasing HMPA:Na^+ ratio cannot be attributed simply to the volume of the added HMPA. This is apparent from the relationships taken from Table 1.

HMPA:Na^+ ratio	Δ ratio	Δ volume
1.0:1 → 1.5:1	0.5	1.3 mL
1.5:1 → 2.5:1	1.0	0.7 mL

Here we see that an HMPA:Na^+ ratio change of 0.5 results in a volume change of 1.3 mL, whereas a ratio change of 1.0 (twice as large) results in a volume change of only 0.7 mL.

Solute structures in the lower phase

In attempting to rationalize these data, based on earlier studies, we can say with some confidence that in the system

$NaAlEt_4$ – benzene – HMPA

the following species are predominant in the solution at the indicated HMPA:Na^+ ratios.

Ratio HMPA:Na^+	Species	Reference
0:1	$[\oplus\ominus]_n^0$	13
1:1	$[\mathrm{S}—\oplus\ominus]_n^0$	10, 13
3:1		9, 10
4:1		9, 10

The structural identity of the 1.5:1 and 2.5:1 HMPA:Na^+ solvates is more complicated. If, however, we make the following assumptions, we can propose reasonable structures: (*a*) HMPA molecules can bridge between two sodium ions as indicated from the kinetic studies. (*b*) The maximum solvation number of Na^+ with HMPA is four. (*c*) HMPA is a better base towards Na^+ than is $AlEt_4^-$. (*d*) All Na^+ will be equivalent when possible.

Using these assumptions we can propose structures for the intermediate ratios of the general types, but not specifically

HMPA:Na^+ ratio	Structure
1:1	1.5:1	2.5:1	
The large increase in volume prior to a 1.5:1 HMPA:Na^+ ratio correlates with the change in structure from aggregates to the more open structure of the proposed 1.5:1 species. It can also be noted that the structural difference between the proposed 1.5:1 and 2.5:1 species is relatively small which corresponds to the relatively small volume change in this region. Finally the large change in volume that occurs after the 2.5:1 HMPA:Na^+ ratio is due to the take-up of benzene in the lower phase.

Two liquid phase systems

The observed benzene:Na^+ molar ratio shown in Fig. 3 is quite confusing. It is of the type found for the liquid clathrate behavior proposed by Atwood for somewhat similar systems (14). It is not at all obvious from structural considerations why this should occur.

The formation of two liquid phases is not particularly rare in non-aqueous solution chemistry. For example, Fuoss and Kraus (15) observed that $(i\text{-amyl})_4$Npicrate forms two liquid phases in benzene above a concentration of 0.1 *M*. Other examples are $HFeCl_4$ (16) and NH_4FeCl_4 (17) in diethylether and similarly Ga_2Cl_4 (17) and $(Bu)_4NAlBu_4$ (18) in benzene. In all of these cases the two phases occur only within a certain range referred to as the miscibility gap. A yet different type of two phase system has been reported by Atwood and co-workers (14) as well as this research group (3). Atwood attributes the two liquid phasing to the formation of liquid clathrates. The unique feature of the liquid clathrates is the apparent inclusion of a fixed number of aromatic molecules per ionic unit in the salt-containing phase. In contrast, Friedman and co-worker (17, 19) have proposed a thermodynamic theory of two phasing based on the effect of an ion-pair dipole on the solution dielectric constant. The dielectric constant of a solution containing predominantly ion-pairs would be expected to increase drastically as the concentration of ion-pairs increases. Ultimately this results in a separation into two phases with different concentrations. The liquid clathrate systems on the other hand

TABLE 1. Dependence of salt concentration on selected mole ratios at ambient temperature (0.500 g $NaAlEt_4$)

Ratio HMPA:$NaAlEt_4$	Lower phase volume (mL)	Salt conc. (mol/L)	Ratio HMPA:$NaAlEt_4$	Lower phase volume (mL)	Salt conc. (mol/L)

2.66	4.19	0.73	7.00	15.50	0.19

appear to contain no electrolyte in the upper phase. In this respect the two phase system

$NaAlEt_4$ – benzene – HMPA

does appear to resemble the liquid clathrate systems.

A third explanation is based upon the extent of solute aggregation. Myers and Metzler (20) observed two phases in the isopropylether extracts of aqueous solutions of HCl and $FeCl_3$. They were able to show that the two phasing results from an aggregation of the ion-pair species. In a system of the type used in the present study, Muller and Day (13) showed that aggregation does occur with the sodium tetraalkylaluminate salts, and that the extent of aggregation decreases with increasing ion–solvent interactions. It can be proposed then that the formation of two liquid phases is related to the extent of aggregation. This does not, however, explain the break in the benzene:Na^+ curve at 2.5:1 as shown in Fig. 3. In fact, none of the three theories is consistent with the observations of this system over the range of HMPA:Na^+ ratios studied, but the behavior up to a 2.5:1 HMPA:Na^+ ratio most closely correlates with the experimental observations of Atwood.

Equivalent conductance and viscosity

The temperature dependence of both the conductance and the viscosity of the system

$NaAlEt_4$ – benzene – HMPA

has been determined as a function of the HMPA:Na^+ ratio. Because of the unique character of this system, interpretations are not straightforward. It was mentioned earlier, for example, that up to an HMPA:Na^+ ratio of 2.5:1, the weight percent of the salt is roughly 50. Further, it can reasonably be assumed that the solute species change with a change in HMPA:Na^+ ratio. Nevertheless, there are some observations that correlate with our solute proposals.

The equivalent conductances of the salt as a function of temperature and HMPA:Na^+ ratio are presented in Fig. 4. If these data are fitted to the Arrhenius equation

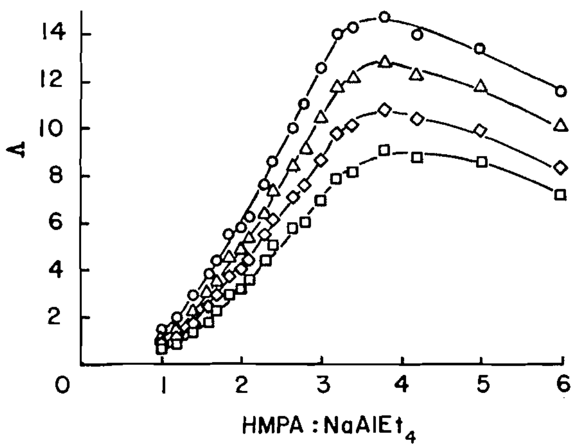

FIG. 4. Equivalent conductance as a function of HMPA:Na^+ ratio: ○, 60°C; △, 50°C; ◇, 40°C; □, 30°C.

$$\ln \Lambda = A - \frac{\Delta E_n^*}{RT}$$

we can obtain the activation energies for ionic mobility as a function of HMPA:Na^+ as shown in Fig. 5. The rapid drop in ΔE_n at a 1.5:1 ratio, a minimum at a 2.5:1 ratio, a leveling off at the 4.0:1 ratio, and a maximum at a 3.0:1 ratio all correlate qualitatively with the proposed structures.

The viscosity, as shown in Fig. 6, is of particular interest. Here we see a strong peak at an HMPA:Na^+ ratio of 2.5:1. The drop off after this maximum can readily be attributed to the increase in the amount of benzene in the lower phase. What is not obvious is the reason for the increase in viscosity prior to the 2.5:1 ratio. Note that in this region, the volume is actually increasing in spite of the fact that the number of moles of both benzene and salt remain constant. Thus, the increase in volume is apparently due to structural changes occurring in the salt on the addition of HMPA. These same structural changes must result in the observed viscosity increase. Qualitatively, this

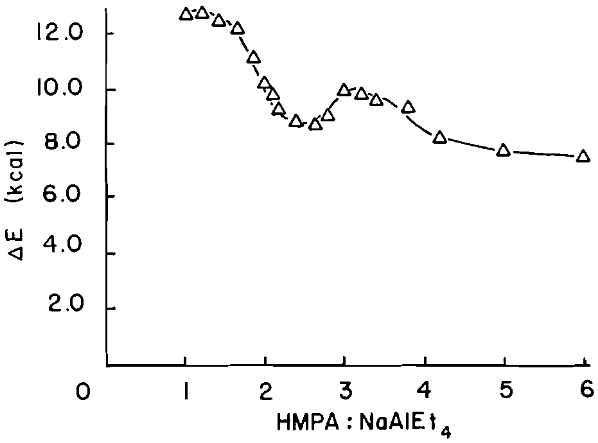

FIG. 5. Activation energy for ionic mobility as a function of HMPA:Na^+ ratio.

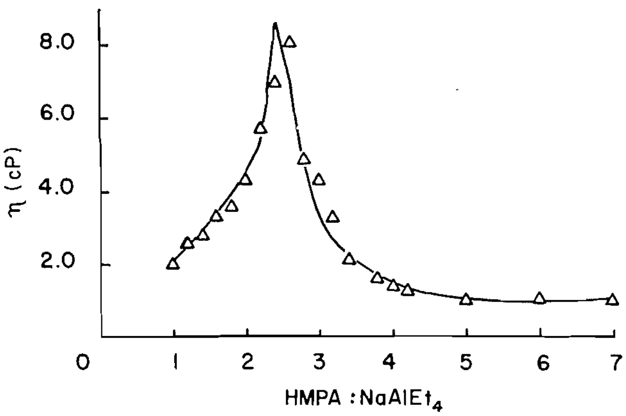

FIG. 6. Viscosity as a function of HMPA:Na^+ ratio at 30°C.

correlates well with the proposed change from a compact aggregate structure at lower HMPA:Na^+ ratios to more open chain-like structures in the 1.5:1 to 2.5:1 ratio range.

Nuclear magnetic resonance studies

The ^{23}Na nmr studies of the system

$NaAlEt_4$ – benzene – HMPA

have been discussed elsewhere (10). Here we will focus on the ^{27}Al and ^{1}H nmr studies of this system.

Aluminum nmr

The ^{27}Al linewidths are a full order of magnitude less than the corresponding sodium linewidths. There are several reasons for this. First, since the linewidth is proportional to the term $(2I + 3)/I^2(2I - 1)$, the spin 5/2 ^{27}Al nucleus has an intrinsically narrower linewidth than the spin 3/2 ^{23}Na nucleus. In addition, the quadrupole coupling constant (e^2qQ/h) for the aluminum nucleus must be significantly different from that for the sodium nucleus to give rise to such a great disparity in the linewidths. Since ^{27}Al and ^{23}Na have very similar quadrupole moments, $Q = 0.15$ and 0.14 Barnes, respectively, there must then be a much larger electric field gradient, q, produced at the sodium ion. This is certainly not unreasonable. It has been shown that the electric field gradient at the sodium ion is affected by both the number of HMPA molecules in the complex and by the proximity of the anion (10). On the other hand, since in this system solvation occurs only at the cation, the electric field gradient at the aluminum nucleus can, therefore,

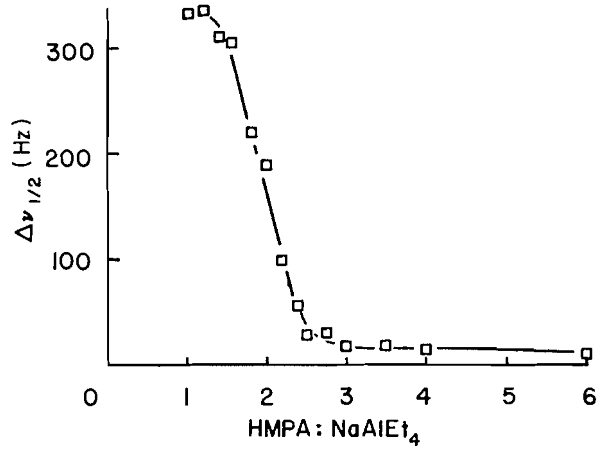

FIG. 7. ^{27}Al linewidth at half height (proton noise decoupled) vs. HMPA:Na^+ ratio at ambient temperature.

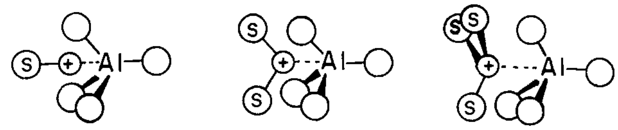

FIG. 8. Proposed effect of donor molecules on the proximity of a Na^+ to an $AlEt_4^-$ ion.

be affected only by the proximity of the cation. Because of the high molecular symmetry possessed by the unperturbed tetraalkylaluminate anion, the electric field gradient at the ^{27}Al nucleus should be particularly sensitive to interaction with the cation and, due to the spherical symmetry of the sodium ion, the interaction should depend only on the cation–anion distance and not the orientation.

The dependence of the proton-decoupled ^{27}Al linewidth on the mole ratio is given in Fig. 7. The important feature here is the sharp decrease in linewidth from a maximum at a 1:1 ratio with a leveling off at a 2.5:1 ratio of HMPA:Na^+. This implies that there is a significant decrease in the electric field gradient at a 2.5:1 ratio relative to that at a 1:1 ratio. The leveling off of the curve well before the formation of solvent separated ion-pairs implies that the electric field gradient relaxation broadening is less than the intrinsic linewidth of the ^{27}Al nucleus.

An explanation for this result is that there is an increase in the cation size upon successive complexation. This then imposes a steric restriction on the approach of the cation to the anion. Because of the stability of the $Na^+\cdot$HMPA complexes up to a 4:1 HMPA:Na^+ ratio and the greater basicity of HMPA than $AlEt_4^-$ towards the Na^+, qualitatively the expected effect might be as seen in Fig. 8. A minimum linewidth would be expected at a 4:1 ratio of HMPA:Na^+ and, in light of the structures proposed in Fig. 8, it would not be unexpected to see it approached at a 3:1 ratio. In addition, from the proposed bridged structure for the 2.5:1 HMPA:Na^+ ratio, it can be seen that the proximity of the cation to the anion is essentially the same as it is for the 3:1 complex. Consequently the approximately zero slope of the curve in this region (2.5–4.0) can be rationalized.

Further, the correlation time for the ^{27}Al resonance is not the same as for the ^{23}Na resonance. This is apparent from the lack of any viscosity dependence of the ^{27}Al linewidth as can be seen in Fig. 7, thereby ruling out the simple rotational diffusion model which adequately describes the ^{23}Na correlation time. If the same ion–ion interactions were responsible for the electric field gradient at the sodium nucleus and the aluminum nucleus, then the correlation function for both nuclei should be similar. This is apparently not the case.

This can be rationalized by again noting that solvation by HMPA occurs only at the cation. Therefore any electric field gradient produced by the presence of the HMPA will be directly affective only at the sodium ion. The electric field gradient at the sodium ion then depends on both ion–solvent and ion–ion interactions. In contrast, since there are no specific ion–solvent interactions at the anion, the electric field gradient at the aluminum nucleus will be dependent only on the ion–ion interactions. Thus, two separate correlation functions relating to the electric field gradient at the sodium ion and at the aluminum nucleus can be proposed. For the sodium ion, it has been shown that the rotational diffusion model is sufficient (10). However, for the aluminum nucleus, the fluctuating electric field gradient must be produced by a change in the ion–ion interactions. Such a change could result from either a rapid equilibrium between ion-pairs and free ions or a vibration of the ion-pair species. Ion-pair vibrations are well known and have been observed by Tsatsas and Risen (21) for $NaAlBu_4$. Therefore, it seems reasonable to attribute the fluctuating electric field gradient at the aluminum nucleus to an ion-pair vibrational motion.

Proton nmr

The scalar coupling between the proton resonance and the quadrupolar ^{27}Al nucleus renders the proton nmr spectra an excellent probe of ion–ion interactions. As was pointed out earlier, Ahmad and Day (9) used this to differentiate between contact and solvent separated ion-pairs in this system. For the donor, HMPA, it was shown that a well-defined quartet attributed to contact ion-pairs is observed at a 1:1 ratio of HMPA:Na^+ while a nine-line pattern attributed to solvent separated ion-pairs is observed at a 4:1 ratio. The exact mechanism for the transition between the two ion-pair types was not discussed. There are two possible mechanisms for such a transition. In the first mechanism, the complexed species can be considered to exist in only two forms, contact and solvent separated ion-pairs. All intermediate spectra would correspond to equilibrium distributions between the two ion-pair types. However, it has been shown by ^{23}Na nmr (10) that the complexation occurs via the formation of a series of stable complexes, and one can posit a characteristic ^1H nmr spectrum for each of these. This gradual transition via sequential complexes forms the second mechanism.

It is well recognized that the nmr signals arising from spin 1/2 nuclei which are scalar coupled to nuclei of spin greater than 1/2 are broadened by the rapid quadrupole-electric field gradient relaxation undergone by the latter. With respect to the scalar relaxation process responsible for the proton lineshape, Abragam (22) has defined two distinct processes: scalar relaxation of the first kind resulting from chemical exchange processes and scalar relaxation of the second kind resulting from scalar coupling to a rapidly relaxing nucleus. A significant result of Abragam's discussion is that the lineshape equation has the same functional form for both processes. Consequently, it is not a trivial problem to distinguish between chemical exchange broadening and quadrupole broadening.

The proton nmr spectrum of $NaAlEt_4$ may be viewed as a simple A_2M_3X system. Since the AM coupling is not affected

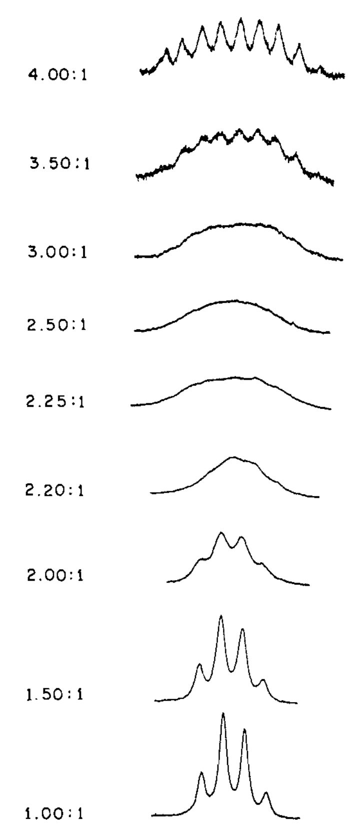

FIG. 9. ^1H nmr spectra of —CH_2— in $NaAlEt_4$ at different HMPA:Na^+ ratios at ambient temperature.

to any large extent by the quadrupole relaxation of X, the limiting spectra are a quartet resulting from J_{AM} and a multiplet resulting from both J_{AM} and J_{AX}. In the tetraethylaluminate anion, the values of J_{AM} and J_{AX} are such that, instead of the expected 24 lines, there are only nine lines (11*b*). Since J_{AM} can be determined from the quartet splitting, there is only one value of J_{AX} which will give rise to a symmetrical nine-line pattern. It is then possible to compare the quadrupole relaxation time with the value of J_{AX} and gain some insight into the expected lineshapes based upon a pure scalar relaxation process of the second kind.

The methylene resonance of the anion as a function of the mole ratio HMPA:$NaAlEt_4$ is shown in Fig. 9. It can be noted that the resolution of the quartet becomes lost completely at a ratio of 2.20:1. Additionally, the spectrum rapidly becomes a broad featureless hump showing no fine structure until approximately 3.5:1. Re-examining Fig. 7, it can be seen that the ^{27}Al relaxation time is undergoing a drastic increase in this region (1.5–2.5). According to Abragram's theoretical treatment of the A_3X case, the value of the relaxation time must drop to approximately $1/(10\pi J_{AX})$ in order to yield a sharp spectrum in which the AX coupling is not observed. Since the $^3J_{H-H}$ coupling constant is 7.5 Hz, the value of $^2J_{Al-H}$ can be calculated by a spectrum simulation program (PANIC.81 on the ASPECT 2000 computer) and is found to be 8.5 Hz. Therefore, by the relation $\Delta\nu_{1/2} = 1/\pi T_2$, and Abragam's relationship the linewidth of the ^{27}Al resonance should be in the vicinity of 85 Hz. The measured ^{27}Al linewidth at a ratio 2.2:1 is 99 Hz, thus providing a very strong indication that the proton lineshape is the result of a pure quadrupole broadening effect.

For scalar relaxation of the second kind, the effect of tem-

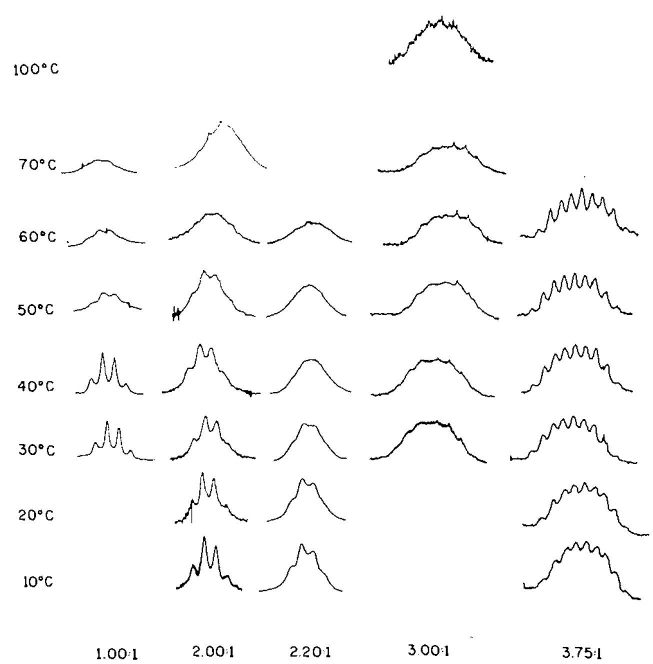

FIG. 10. Temperature dependence of ^{1}H nmr spectra of —CH_2— in $NaAlEt_4$ at different HMPA:Na^+ ratios.

perature should be to decrease the correlation time, τ_c, and increase the relaxation time by the equation

$$\frac{1}{T_1} = \frac{1}{T_2} = \frac{3}{40}\frac{2I+3}{I^2(2I-1)}\left(1+\frac{\sigma^2}{3}\right)\left(\frac{e^2Qq_{zz}}{\hbar}\right)^2\tau_c$$

Therefore, the ^{1}H spectra corresponding to longer relaxation times should be expected at higher temperatures. In Fig. 10, the temperature dependence of the ^{1}H spectra is shown for several ratios. It can be seen that the quartet becomes broadened at higher temperatures while the nine-line multiplet becomes better resolved, exactly as expected for a quadrupole broadening. However, it can also be argued that an exchange mechanism between ion-pairs and free ions would yield similar results. At high temperatures free ions would be more favored than at low temperatures.

In order to distinguish between a pure quadrupole mechanism and the equilibrium process, the ^{27}Al decoupled proton nmr spectrum was recorded for a 2.50:1 HMPA:Na^+ ratio. At this ratio, the proton line is extensively broadened. If the line broadening is the result of such an equilibrium then the chemical shift difference between contact ion-pairs and free ions should cause an extensive broadening to remain even in the complete absence of the aluminum-proton coupling. In Fig. 11, the ^{27}Al decoupled proton nmr spectra of a 2.5:1 ratio in toluene is shown as a function of temperature. There is no indication of any significant line broadening over the range of temperatures studied. On this basis, it can be concluded that the proton nmr lineshape does not result from any equilibrium process between ion-pair types. Rather, the lineshape is determined solely by the scalar coupling constants and the ^{27}Al spin–lattice relaxation time.

Summary

Of particular interest in this study is the fact that the HMPA:Na^+ ratio of 2.5:1 is a unique number for this system. A logical interpretation of the origin of this ratio is a bridging donor molecule between two Na^+ with the strongest support for

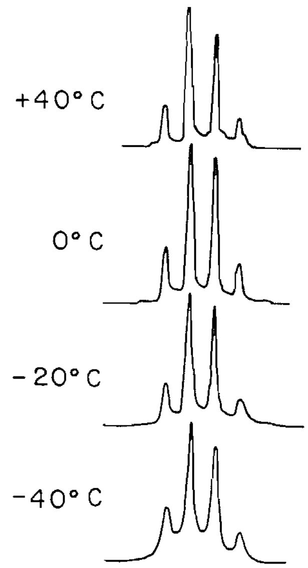

FIG. 11. Temperature dependence of ^{27}Al decoupled ^{1}H nmr spectra of —CH_2— in $NaAlEt_4$ for a 2.5:1 HMPA:$NaAlEt_4$ ratio in toluene.

this argument being found in the kinetic studies. It, however, is also observed in the viscosity, ^{27}Al nmr, transport activation energy, and both the volume of the lower phase and the benzene:Na^+ ratio as a function of HMPA:Na^+ ratio.

If previously determined solute structures are utilized along with the assumptions (*a*) HMPA molecules can bridge between two sodium ions as indicated from the kinetic studies; (*b*) the maximum solvation number of Na^+ is four towards HMPA; (*c*) HMPA is a better base towards Na^+ than is $AlEt_4^-$; (*d*) all Na^+ will be equivalent when possible reasonable solute structures can be proposed for HMPA:Na^+ ratios between 1:1 and 4:1.

A number of additional conclusions are supported by this study. These are (*1*) HMPA is a strong donor towards Na^+; (*2*) successive solvates (1:1, 2:1, 3:1, 4:1) of lifetimes that are long relative to the nmr time scale are formed; (*3*) the maximum solvation number of Na^+ by HMPA is four; (*4*) the $AlEt_4^-$ ion is not solvated by HMPA; (*5*) liquid clathrate type behavior is observed in this system up to an HMPA:Na^+ ratio of 2.5:1; (*6*) the viscosity change up to an HMPA:Na^+ ratio of 2.5:1 is dependent on structural changes of the solute; and (*7*) the ^{1}H and ^{27}Al nmr spectra are determined predominantly by quadrupole relaxation of the ^{27}Al nucleus rather than by exchange.

The products of a Pictet–Spengler condensation of tryptamine and of histamine with 2,5-anhydro-D-mannose have been studied by X-ray crystallography to establish their absolute configuration. 1(*S*)-(α-D-Arabinofuranosyl)-1,2,3,4-tetrahydro-β-carboline (**1**), $C_{16}H_{20}N_2O_4$, is monoclinic, $P2_1$ (No. 4), with cell dimensions a = 13.091(4), b = 5.365(1), c = 11.323(3) Å, β = 115.78(2)°, and Z = 2. 4-(α-D-Arabinofuranosyl)imidazo[4,5-*c*]-4,5,6,7-tetrahydropyridine (**3**), $C_{11}H_{17}N_3O_4$, is orthorhombic, $P2_12_12_1$ (No. 19), with cell dimensions a = 8.118(2), b = 13.715(4), c = 10.963(3) Å, and Z = 4. The structures were determined by direct methods and refined to R_1 = 0.0514, R_2 = 0.0642 for 3210 reflections in the case of **1**, and to R_1 = 0.0312, R_2 = 0.0335 for 1569 reflections in the case of **3**. Bond lengths and angles within both molecules are normal and agree well with those observed in related structures. In **3** the base and sugar adopt a *syn* arrangement, which is maintained by an internal hydrogen bond between O(2′) and N(3). The sugar adopts a normal $^2T_3$ twist conformation. The sugar has the opposite *anti* arrangement in the β-carboline **1** and the conformation of the sugar is unusual; it is close to an envelope conformation with O(4′) being the atom out of the plane. This conformation is caused by a strong intermolecular hydrogen bond from O(5′) in a symmetry-related molecule to O(4′). Both compounds are held together in the crystal by extensive hydrogen-bonding networks. The conformations of the compounds in solution have been investigated by ^{1}H nmr spectroscopy, and the results obtained were compared with those obtained by X-ray crystallography for **1** and **3**.

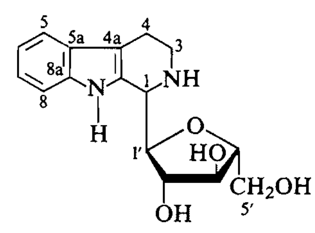
IAN M. PIPER, DAVID B. MACLEAN, ROMOLO FAGGIANI, COLIN J. L. LOCK et WALTER A. SZAREK. Can. J. Chem. **63**, 2915 (1985).

Faisant appel à la diffraction des rayons X, on a étudié la nature des produits de condensation du type Pictet–Spengler de la triptamine et de l'histamine avec l'anhydro-2,5 D-mannose et on a établi leur configuration absolue. Le composé (α-D-arabinofurannosyl)-1(*S*) tétrahydro-1,2,3,4 β-carboline (**1**), $C_{16}H_{20}N_2O_4$, appartient au groupe d'espace monoclinique $P2_1$ (No. 4), avec a = 13,091(4), b = 5,365(1), c = 11,323(3) Å, β = 115,78(2)° et Z = 2. Le composé (α-D-arabinofurannosyl)-4 imidazo[4,5-*c*] tétrahydro-4,5,6,7 pyridine (**3**), $C_{11}H_{17}N_3O_4$, appartient au groupe d'espace orthorhombique $P2_12_12_1$ (No. 19) avec a = 8,118(2), b = 13,715(4), c = 10,963(3) Å et Z = 4. On a déterminé les structures par des méthodes directes et on les a affinées jusqu'à des valeurs de R_1 = 0,0514 et de R_2 = 0,0642 pour 3210 réflexions dans le cas du composé **1** et à des valeurs de R_1 = 0,0312 et de R_2 = 0,0335 pour 1569 réflexions dans le cas du composé **3**. Les deux molécules ont des longueurs de liaisons et des angles normaux qui s'accordent bien avec ceux observés dans des structures apparentées. Dans le cas du composé **3**, l'unité de sucre et celle de la base adoptent un arrangement *syn* que des liaisons hydrogènes internes entre le O(2′) et le N(3) maintiennent en place. L'unité de sucre adopte une conformation croisée $^2T_3$ qui est normale. L'unité de sucre du composé β-carbolino **1** adopte l'arrangement opposé, *anti*, et sa conformation est inhabituelle. Elle se rapproche d'une conformation enveloppe avec l'atome O(4′) hors du plan. Cette conformation est due à une forte liaison hydrogène intermoléculaire entre le O(5′) d'une molécule apparemment symétrique et le O(4′). Les deux composés sont reliés dans le cristal par un réseau intense de liaisons hydrogènes. Faisant appel à la spectroscopie de rmn, on a étudié les conformations des composés **1** et **3** en solution et on a comparé les résultats à ceux obtenus par diffraction des rayons X sur les mêmes composés.

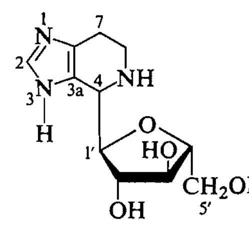
[Traduit par le journal]

Introduction

In a recent paper (1), the synthesis was reported of a number of novel *C*-nucleosides arising from the Pictet–Spengler condensation of biogenic amines with 2,5-anhydro-D-mannose. The compounds so obtained have in common an α-D-arabinofuranosyl moiety attached to a ring-fused tetrahydropyridine nucleus. We report here an X-ray crystallographic study of two of these compounds, **1** and **3**, which has established their absolute configuration, and hence that of the epimer (**2**) of **1**, at the carbon center at which the sugar unit is attached. Information about the conformations of the compounds in solution has been deduced from an ^{1}H nmr spectroscopic examination. The results obtained have been compared with those obtained by X-ray crystallography for the solid state.



1 1(*S*)-isomer
2 1(*R*)-isomer



3 4(*S*)-isomer

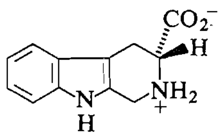
Results and discussion

The reaction of tryptamine hydrochloride and 2,5-anhydro-D-mannose was reported (1) to yield a mixture of two isomers, namely 1(*R*)- and 1(*S*)-(α-D-arabinofuranosyl)-1,2,3,4-

[1]Authors to whom correspondence may be addressed.

tetrahydro-β-carboline, in the approximate ratio of 40:60. Each of these was obtained pure; however, the configuration at C(1) was not determined. This information now has been obtained by an X-ray crystallographic structure determination. The structure of the major isomer **1** is illustrated in Fig. 1, from which it is evident that the configuration at C(1) is *S*; the minor isomer **2** then must have the *R* configuration at C(1).

In Table 1 are listed selected interatomic distances and angles for **1**. For the most part, the values obtained for bond lengths and angles within the β-carboline moiety agree well with those found for 1,2,3,4-tetrahydroharman-3-carboxylic acid (**4**) (2); the exceptions are the values obtained for the lengths of the C(1)–N(2) (1.475(5) Å) and N(2)–C(3) (1.487(4) Å) bonds, which are 0.047 Å and 0.030 Å shorter, respectively, in **1** than in the harman derivative. This difference is attributable presumably to the fact that the nitrogen atom in **4** is protonated. As a consequence of the shorter distances, the internal ring angles at C(1) and C(3) are slightly larger in **1** than in **4**. The values obtained for the bond lengths and angles in the sugar moiety are in good agreement with those for 9-α-D-



4

arabinofuranosyladenine (3) and the more accurate values for 9-β-D-arabinofuranosyladenine (4). The χ torsion angle, N(2)C(1)C(1′)O(4′), is −66(1)°, a value in the *anti* range, namely −30° to −72°, observed (5) for α-nucleosides.[2] The conformation at the exocyclic C(4′)—C(5′) bond is *gauche–trans*. The conformation of the furanoid ring is unusual and can be regarded as an envelope having O(4′) 0.544(4) Å out of the plane of the other four atoms. This unusual conformation is caused by a very strong intermolecular hydrogen bond (see below).

The packing of **1** is shown in Fig. 2. The important feature of the structure is the spiral chain of molecules up the *b* axis related by the 2_1 axis at $x = 1/2$, $z = 1/2$. A molecule in the chain is bound to the next by the N(9)—H(9)...O(5′) and O(5′)—H(5″)...O(4′) hydrogen bonds. These intermolecular hydrogen bonds determine the conformation of the molecule. The latter bond is particularly strong (O(1)...O(4′) 2.757(4) Å); in addition, there is a further hydrogen bond near the *c* face, O(3′)—H(3″)...O(2′), between translationally equivalent molecules along *c*. Interactions between these chains in the *a* and *c* directions are almost entirely van der Waals, the exception being an O(2′)—H(2′)...N(2) hydrogen bond in the *c* face.

The molecular structure of **3** is shown in Fig. 3 and selected interatomic distances and angles are given in Table 2. Bond lengths and angles in the nitrogen-containing moiety agree well with those found in histamine (6). The C(2)—N(3) distance (1.323(3) Å) is longer by 0.02 Å than the corresponding bond in histamine, and the C(6)—N(5) distance (1.483(3) Å) is longer by 0.035 Å. The bond angles N(1)—C(7a)—C(7) (125.6(2)), C(3a)—C(7a)—C(7) (125.6(2)), C(7a)—C(7)—C(6) (107.2(2)), and C(7)—C(6)—N(5) (110.3(2)°) are

[2]The values for the glycosyl torsion angle, χ(C(8)N(9)C(1′)O(4′)), in two crystallographically-independent molecules of 9-α-D-arabinofuranosyladenine have been found to be −64(2)° and −73(2)° (3).

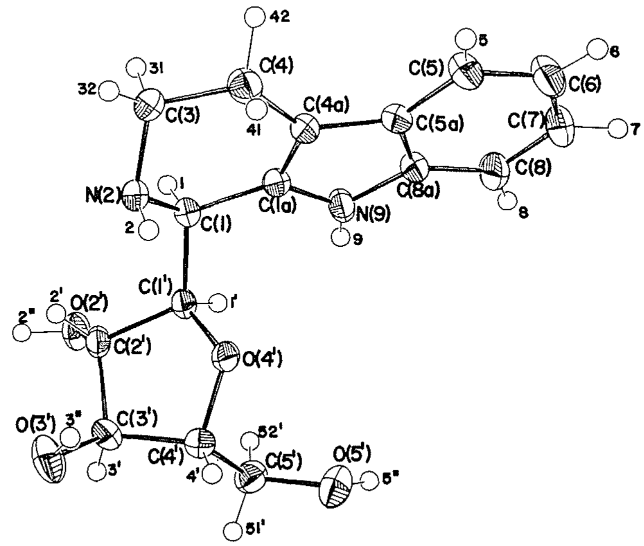


FIG. 1. The molecular structure of 1(*S*)-(α-D-arabinofuranosyl)-1,2,3,4-tetrahydro-β-carboline (**1**).

smaller by 2.9°, 5.8°, 7.6°, and 4.5°, respectively, than the corresponding angles in histamine. The changes in the bond angles and that in the distance of the C(6)—N(5) bond are a consequence of the differences in structure. The values obtained for the bond lengths and angles in the sugar moiety again agree well with those previously determined (3, 4). The χ torsion angle, N(5)C(4)C(1′)O(4′), is 73.7(2)°, a value consistent with a *syn* arrangement of the sugar moiety with respect to the base. The conformation of the furanoid ring is $^3T_2$ and the conformation at the exocyclic C(4′)—C(5′) bond is *gauche–trans*.

The packing of **3** is shown in Fig. 4 in which it is apparent that a strong three-dimensional hydrogen-bonding network holds the crystal together through the bonds N(1)—H(1)...O(5′), O(3′)—H(3″)...N(5), and O(5′)—H(5″)...O(3′).

Conformations in solution of the α-D-arabinofuranosyl moieties by ¹H nmr spectroscopy

The conformations of the sugar rings in the solid state in **1** and **3** were discussed in the previous section and it was of interest to compare these conformations with those in solution. ¹H nuclear magnetic resonance experiments have been widely used to study the conformation of β-nucleosides in solution (7) and we have applied this method to compounds **1–3**. The method relies upon the use of the Karplus relationship in relating the dihedral angle of C—H bonds on adjacent carbon atoms to the vicinal coupling constant between the H atoms. Recently, Ekiel *et al.* (8) have reported an extension of this method to the conformational analysis of α-D-arabinofuranosyl nucleosides. A central assumption of this method is the existence predominantly in solution of a two-state equilibrium, the extreme forms of which are shown (for the case of α-D-arabinofuranosyl nucleosides) in Fig. 5 (for rules of nomenclature, see ref. 9). Using this assumption, comparison of the observed vicinal coupling constants with calculated values for the extreme conformers permits an estimate of relative populations of $^3T_2$ (Type N) and $^2T_3$ (Type S) to be made, thereby giving the average conformation in solution.

The assumption of a two-state equilibrium has been described recently (10) as an oversimplification in studies of this

type, better results being obtained in several cases by invoking a three-state equilibrium involving $^3T_2$, $^2T_3$, and the conformation in the crystal (when the latter is neither $^3T_2$ nor $^2T_3$). However, Ekiel *et al.* (8) report in one case a close correlation between the crystal conformation and the observed conformation in solution.

In the present study, it is clear that the conformation in solution need not be related to the crystal conformation, be-

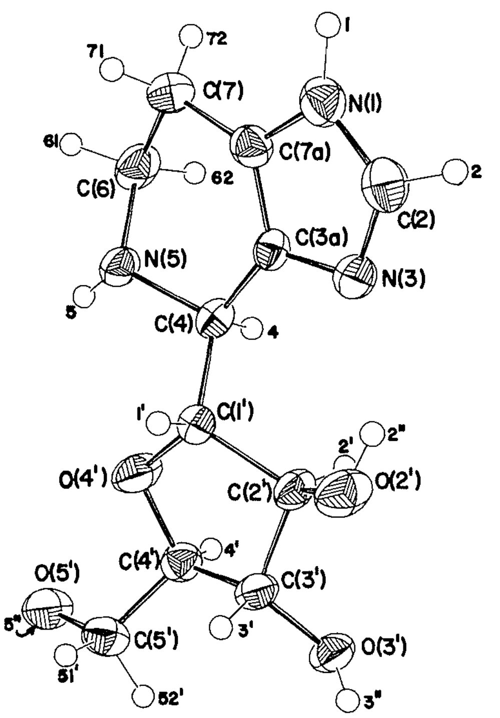

FIG. 3. The molecular structure of 4-(α-D-arabinofuranosyl)-imidazo[4,5-*c*]-4,5,6,7-tetrahydropyridine (**3**).

cause neither **1** nor **3** have strong intramolecular forces, the conformation in the solid state being determined primarily by intermolecular crystal forces. Therefore, although the compounds in the present study differ greatly in structure from other known α-D-arabinofuranosyl nucleosides (being *C*-nucleosides, and having a chiral centre in the base adjacent to C(1′) of the sugar moiety), it was thought useful to apply the procedure of Ekiel *et al.* (8) to our compounds, using the two-state equilibrium assumption.

Analysis of the 250-MHz ^{1}H nmr spectra of compounds **1**, **2**, and **3** was complicated by strongly overlapping signals, preventing direct measurement of chemical shifts and coupling constants. However, use of the nmr simulation program ITRCAL (11) enabled these values to be determined; the coupling constants are assembled in Table 3.

The coupling constants were used to obtain values for P_N (i.e. relative population of the N conformer) using eq. [1] (the mean of the three values obtained for each compound is reported in Table 3).

$$[1] \quad P_N = \frac{(J_{1',2'} - 0.5)}{7.5}; \quad P_N = \frac{J_{2',3'}}{8.3}; \quad P_N = \frac{J_{3',4'}}{10.0}$$

The values obtained for $J_{1',2'}$, $J_{2',3'}$, and $J_{3',4'}$ are in the same range as those reported for other α-D-arabinofuranosyl nucleosides, and thus lead to P_N values similar to those reported previously (8). While this indicates that the α-*C*-nucleosides in the present study behave in a fashion similar to the previously

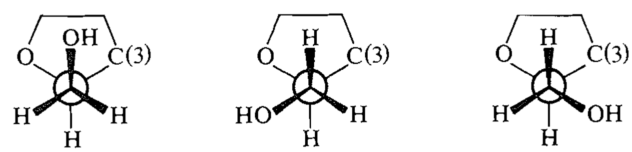
Type N, $^3T_2$ Type S, $^2T_3$

FIG. 5. Type N and Type S conformations for α-D-arabinofuranosides (see ref. 9).

reported examples (8), this may be an oversimplification, for the reasons described above. However, it seems clear that the crystal conformation of compound **1** is not present to any great extent in solution, because the all-eclipsed conformation would give much smaller vicinal coupling constants (~2–3 Hz) than those observed.

In the case of **3** the conformation of the sugar moiety in the solid is $^3T_2$, and this is also the dominant conformation calculated for this compound in solution. The calculated P_N values for **1** and **3** are very similar, as might be expected for compounds having the same sugar moiety and the same configuration at C(1) of the base, but differ from that of **2**, which has the opposite configuration at C(1). The fact that **1** has a different conformation in solution than in the solid is not surprising because the solid state conformation is a consequence of intermolecular hydrogen bonding as discussed in the preceding section. The intermolecular bonds of the solid would not be expected to survive in solution.

The C(5′) hydroxymethyl group of the arabinose unit may



gauche–gauche (g–g) *gauche–trans* (g–t) *trans–gauche* (t–g)

FIG. 6. Conformations at the C(5′)—C(4′) bond.

adopt three extreme conformations, as shown in Fig. 6. In the case of compounds **1** and **3** the crystal structures show that this group adopts the *gauche–trans* (g–t) conformation in the solid state. Studies of the crystal structures of a large group of nucleosides have shown that there is no direct correlation between the orientation of this group and the conformation of the sugar ring in the solid state, although such a correlation does hold in solution, as evidenced by the results of ^{1}H nmr experiments (see ref. 12, and refs. therein). Ekiel *et al.* (8) have shown such a correlation in the case of α-D-arabinofuranosyl nucleosides, finding that the g–g rotamer appeared to be associated with only the Type N conformation.

The populations of the g–g and g–t rotamers of **1**, **2**, and **3** were estimated using relationships developed by Wood *et al.* (13) and applied by others (10*a*). Equation [2] was used to calculate the value of $P_{g\text{-}g}$ and the values of $P_{g\text{-}t}$ were determined using eq. [3] (10*a*).

$$[2] \quad P_{g\text{-}g} = \frac{13 - (J_{4',5'} + J_{4',5''})}{10}$$

$$[3] \quad P_{g\text{-}t} = \frac{J_{4',5''} - 1.5}{10}$$

The values of $J_{4',5'}$ are similar to those observed by Ekiel *et al.* (8), although the values for $J_{4',5''}$ are considerably higher,

TABLE 4. Crystal data

leading (as shown in Table 3) to a lower population of the g−g rotamer and a higher population of the g−t rotamer than that previously observed. From these data examined, it is not possible to establish a correlation between the sugar conformation and the orientation of the side chain. Probably both features are strongly affected by the configuration at C(1), an aspect which deserves exploration. However, it may be noted that compounds **1** and **3** have similar coupling constants and conformer populations but which are different from those in compound **2**.

Experimental

The ^{1}H nmr spectra were recorded on a Bruker WM250FT spectrometer (250 MHz) in D_2O – DMSO-d_6 for **1** and **2** and D_2O for **3** (see ref. 1). The nmr simulations were obtained using the ITRCAL program (11). In all cases the program was iterated to give an rms error of less than 0.5 Hz between the observed and simulated spectra.

Compounds 1, 2, and 3

The preparation of **1**, **2**, and **3** has been reported (1). Crystals of **1** and **3** for X-ray examination were obtained by crystallization from water.

Collection of X-ray data

Colorless crystals of both compounds were selected for X-ray studies, after examination for perfection under a polarizing microscope. Precession photographs revealed the symmetry of the crystals, and unit cell parameters were obtained from least-squares fit of χ, ϕ, and 2θ from 15 reflections for each compound in the range $20.3° < 2\theta < 36.0°$ for **1**, $20.2° < 2\theta < 26.3°$ for **3**, recorded on a Nicolet P3 diffractometer in the case of **1**, and a Syntex $P2_1$ diffractometer in the case of **3**, using graphite-monochromatized MoK_α radiation (0.71069 Å at 22°C). Crystal data and other numbers related to data collection are summarized in Table 4.

Densities were obtained by flotation in acetone–bromoform. Intensities were measured on the Nicolet P3, in the case of **1**, and Syntex $P2_1$, in the case of **3**, diffractometers using a coupled θ(crystal) – 2θ (counter) scan. The methods of selection of scan rates and initial data treatment have been described (14, 15). Corrections were made for Lorentz polarization effects but not for absorption. This will give a maximum error in F of <1.0% for **1** and <1.6% for **3**.

Solution of the structures

For both compounds the phases were determined by direct methods using 242 reflections with $E > 1.66$ and 12 sets of starting phases. All non-hydrogen atoms were found in the subsequent E maps. The correct handedness for each structure was chosen by making the known configuration at C(1′) correct. The coordinates were refined by minimizing the function $\sum w(|F_o| - |F_c|)^2$, and subsequent difference maps revealed all of the hydrogen atoms. Further refinement using anisotropic temperature factors for all of the non-hydrogen atoms and isotropic temperature factors for the hydrogen atoms was terminated when the maximum shift/error dropped below 0.1. Scattering curves were taken from the International Tables (16). The atom parameters are listed in Tables 5 and 6.[3] Initial data treatment used programs from the X-RAY package (17). The structures were solved using programs from SHELX (18). The least-squares planes program was NRC-22 (19) and diagrams were prepared using ORTEP-II (20). All calculations were carried out on Cyber 170/730 and 170/815 computers.

Synthesis and study of new mesogen compounds: 4-alkoxy-2-hydroxy-4′-substituted-α,α′-dimethylbenzalazines. Correlation analysis between T_{N-I} transition and electronic parameters in five series of liquid crystals

MERCEDES MARCOS, ENRIQUE MELENDEZ, BLANCA ROS, AND JOSE LUIS SERRANO
Departamento de Química Orgánica, Facultad de Ciencias, Universidad de Zaragoza, 50009 Zaragoza, Spain

Received October 18, 1984

MERCEDES MARCOS, ENRIQUE MELENDEZ, BLANCA ROS, and JOSE LUIS SERRANO. Can. J. Chem. **63**, 2922 (1985).

Two new series of compounds with mesomorphic properties were synthesized: the 4-ethoxy and 4-octyloxy-4′-X-2-hydroxy-α,α′-dimethylbenzalazines (X = CN, NO_2, F, Cl, Br, CH_3, and $N(CH_3)_2$). Thermodynamic measurements were made. All the compounds gave mesogenic behaviour. Some of them exhibit polymorphism in the solid state. A study of the existent correlation between the temperatures at which the N−I transition appears in five series of mesogenic compounds and electronic parameters of the polar terminal chain was carried out. Seven terminal groups were studied: —F, —Cl, —Br, —CH_3, —OCH_3, —NO_2, and —CN. None of the electronic parameters used enabled us to obtain a good correlation with all the groups. However, when the methoxy group was omitted, the parameters that measured π electronic delocalization in the aromatic ring showed an excellent correlation with the T_{N-I}. The best correlation was obtained in all cases with Swain and Lupton's $\mathcal{R}$, which defined the resonance effect.

MERCEDES MARCOS, ENRIQUE MELENDEZ, BLANCA ROS et JOSE LUIS SERRANO. Can. J. Chem. **63**, 2922 (1985).

On a synthétisé deux nouvelles séries de composés mésomorphes, soit les éthoxy-4 et les octyloxy-4 X-4′ hydroxy-2 α,α′-diméthylbenzalazines (X = CN, NO_2, F, Cl, CH_3 et $N(CH_3)_2$). On a effectué des mesures thermodynamiques. Tous les composés ont un comportement mésogène. Certains d'entres-eux présentent du polymorphisme à l'état solide. On a effectué une étude sur les corrélations qui existent entre les températures auxquelles apparaissent les transitions N−I dans cinq séries de composés mésogènes et les paramètres électroniques de la chaîne polaire terminale. On a étudié sept groupes terminaux, soit les groupes —F, —Cl, —Br, —CH_3, —OCH_3, —NO_2 et —CN. Aucun des paramètres électroniques utilisés ne nous a permis d'obtenir une bonne corrélation avec tous les groupes. Cependant, si l'on omet le groupement méthoxy, les paramètres qui mesurent la délocalisation électronique π du noyau aromatique présentent une bonne corrélation avec le T_{N-I}. Dans tous les cas, on obtient la meilleure corrélation avec le paramètre R de Swain et Lupton qui définit l'effet de résonance.

[Traduit par le journal]

Introduction

One of the most interesting aspects of the study of liquid crystals is the relation between structure and mesogen activity.

Numerous papers of great interest have been published about this subject to date. Among them, the study of the influence of the terminal groups on the temperature at which nematic−isotropic liquid transition occurs (1, 2) is classic.

Basing themselves on the Maier−Saupe theory, Van der Veen (3, 4), Griffin (5), and others, have established the correlation between α (factor of molecular electronic polarizability) of the terminal groups and the N−I transition temperatures of nematogen compounds.

However, a thorough mathematical analysis makes it clear that these correlations, generally limited to the graphic method, are insufficient in many cases. Moreover, a large number of well-characterized empirical parameters of aromatic substituents are presently known (6), which has permitted us to study the correlation between some of these parameters and some molecular properties of the compounds that have those substituents, among them, the N−I transition temperatures in series of liquid crystals.

Unfortunately, it is not easy to find series of compounds with different terminal groups in order to make the correlation. Consequently, this study has been limited to five series of compounds which have terminal groups with different empirical parameters: —CN, —NO_2, —F, —Cl, —Br, —CH_3, —OCH_3 (see Fig. 1).

Two of these series of compounds were synthesized by us: the 4-ethoxy-(**I***a*) and 4-octyloxy-(**I***b*)-4′-substituted-2-hydroxy-α,α′-dimethylbenzalazines. In order to check the results obtained, the compounds of these series with the terminal groups X: —OC_2H_5 and —$N(CH_3)_2$ were synthesized.

The other series studied were taken from scientific literature. Two of them correspond to the compounds studied by Van der Veen (3), derivatives of *p*-*N*-alkoxybenzylidene-*p*-X-anilines (**II**) (4), and derivatives of the phenyl-*p*-benzoyloxybenzoates (**III**) described by Van Metter and Klanderman (7). The last series corresponds to derivatives of the *p*-phenylenedibenzoate compounds (**IV**) described by Schroeder and Bristol (8).

Experimental

Synthesis

While the compounds with the terminal group —OCH_3 (9) and —OC_2H_5 (9, 10) have already been described, the rest of them were synthesized for the first time for this study.

The general scheme of synthesis of the compounds studied in this paper was similar to the method described in a previous paper (10). The compounds were generally synthesized in three stages: (*1*) formation of the derivative hydrazone of 4-substituted ketone; (*2*) condensation of the preceding hydrazone and the 2,4-dihydroxyacetophenone and separation of the required product by column chromatography; and (*3*) alkylation of the OH group in position 4 of the compound obtained in the second stage.

The transition temperatures and enthalpy data of the compounds synthesized are gathered in Table 1.

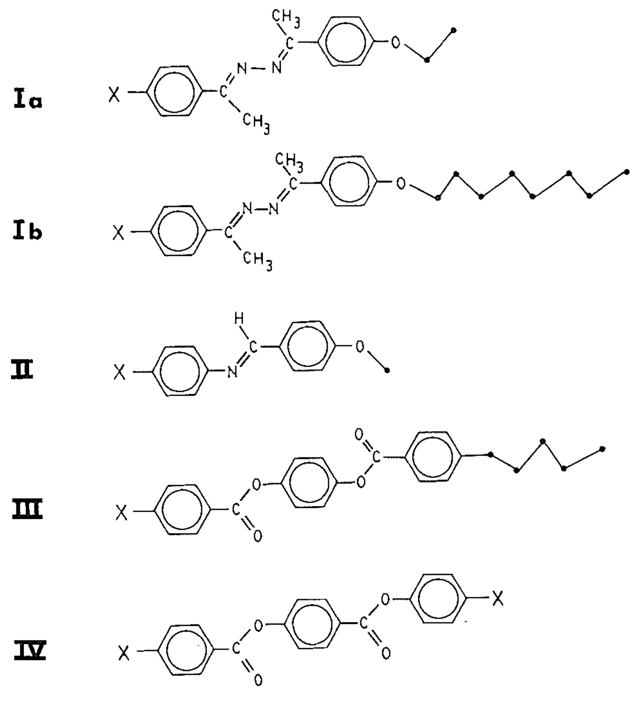
Textures observed

The mesophase textures were observed with a polarizing microscope using thin films of the samples mounted between a glass slide and a cover slip.

They were identified because of their similarity to the descriptions of the textures made by Demus and Richter (11).

Techniques

The melting points, transition temperatures, and enthalpies were determined using a Perkin-Elmer DSC-2 differential scanning calorimeter. The apparatus was calibrated by measuring the known melting



X = F, Cl, Br, CH_3, NO_2, CN, OCH_3.

FIG. 1. Structures of I*a*, I*b*, **II**, **III**, and **IV**.

points and fusion heat of benzoic acid (394.0 K, 141.7 J/g), indium (429.8 K, 28.42 J/g), and tin (505.0 K, 60.8 J/g).

The optical observations were made using a Reichert–Thermovar HT1 B11 polarizing microscope equipped with a heating stage.

The identification of the products was carried out by the usual spectroscopic methods: uv (Perkin–Elmer 200), ir (Perkin–Elmer 283), nmr (Perkin–Elmer R-12-B), and mass spectrometry (Hewett Packard 5943 A). The purity of the products was checked by the above-mentioned techniques and tlc.

The correlation analysis was carried out in a Digital VAX-11780 minicomputer using a subroutine of the SPSS programme (12): "multiple regression analysis: subprogramme regression".

Parameters of substituents used for correlation analysis

A previous study was carried out in which numerous electronic parameters of the substituents with T_{N-I} were correlated. After this preliminary study $\mathcal{R}$ and $\mathcal{F}$ (13), defined by Swain and Lupton, were selected as fundamental parameters. In order to make a comparative study the α-parameter used by Van der Veen (3) and others was also used in the study.

The values of all the parameters used for the correlation analysis are listed in Table 2.

Results and discussion

Correlation between the values of N–I transition temperatures of the five series of compounds

As can be observed in Table 3, a good correlation exists between the values of the N–I transition temperatures of the five series of the compounds studied, which confirms that the influence of the different types of substituents X, is almost the same in each of the series.

Only the slightly smaller values of the correlation found between series **II** and series I*b* and **III** (r_{II-Ib} = 0.864 and r_{II-III} = 0.884) are notable.

The compounds of these last two series have the longest molecules (Fig. 1), whereas the imino-derivatives (series **II**) have the shortest molecules. It seems, therefore, that besides the electronic influence of the common substituents X, the geometry of the molecule is also of fundamental importance.

zero resonance: effect of π electron delocalization normalized; $\sigma_{B\,RES}$, σ benzoic acid resonance: π electron delocalization from benzoic acid model; $\sigma_{A\,RES}$, σ aniline resonance: π electron delocalization from aniline model; σ_{RES+}, σ resonance plus: π electron delocalization from model structure with positive charge, e.g., solv. of cumyl chlorides; σ_L, σ localized; σ_{INDQ}, σ from quinuclidines, i.e., from sp^3 carbon; σ_{PRIME}, field effect through bicyclooctane ring; and σ_P, ionization of phenols.

Correlation between T_{N-I} and some electronic parameters of the substituents (see Appendix) indicated that the methoxy group behaved differently from the other six groups studied: —CN, —NO_2, —F, —Cl, —Br, and —CH_3.

Once this group was removed, it was observed that the T_{N-I} showed a good correlation with the electronic parameters that measured the effect of π electronic delocalization in the aromatic ring: $\mathcal{R}$ (13), $\sigma_{O\,RES}$ (14), $\sigma_{B\,RES}$ (14), $\sigma_{A\,RES}$ (14), σ_{RES+} (14).

However, the other parameters that measure the field effect $\mathcal{F}$ (13), σ_L (15), σ_{INDQ} (16), σ_{PRIME} (17) and the parameters that indicate the resonance effect and field effect σ_P (18), show very little or practically no correlation with T_{N-I}.

In some cases the value of F of each correlation is also indicated. The validity of the results was checked by means of Snedecor's F defined for a percentage of distribution points α of 0.05 (12).

As can be observed from Table 4, when the methoxy group is not present, the correlation obtained between T_{N-I} and $\mathcal{R}$ is much better than the one used by Van der Veen (3) between T_{N-I} and α.

The F value for the five series of compounds studied are higher than those used as references.

The F values for the correlation T_{N-I}—α are clearly lower than those observed for the correlation T_{N-I}—$\mathcal{R}$ and in some cases even lower (see series I*a* and II, Table 4) than the F of Snedecor used as a reference.

The correlation between T_{N-I} and $\mathcal{F}$ shows lower values still, which indicates that the interrelation between both factors is practically non-existent.

Figure 2 shows a graphic representation of the relation between T_{N-I} and $\mathcal{R}$ for the five series of compounds studied. The values of the constants and slope of the straight line of lineal regression with the six groups in each series (five in the case of the series **III** because the T_{N-I} data for the nitro group are unavailable) are also shown.

As can be seen in the figure, the regression straight line corresponding to the compounds with two X groups (series **IV**) has a much greater slope than those of the other series studied.

However, when the methoxy group is present correlation between T_{N-I} and $\mathcal{R}$ is almost non-existent (see Table 4). This group, of electronic-releasing character, behaves very differently from the rest of the groups. In fact when the T_{N-I} values of the compounds with the methoxy group are introduced in the regression straight line of each of the series, it is observed that they correspond to $\mathcal{R}$ values very different from the ones experimentally obtained (see Fig. 2).

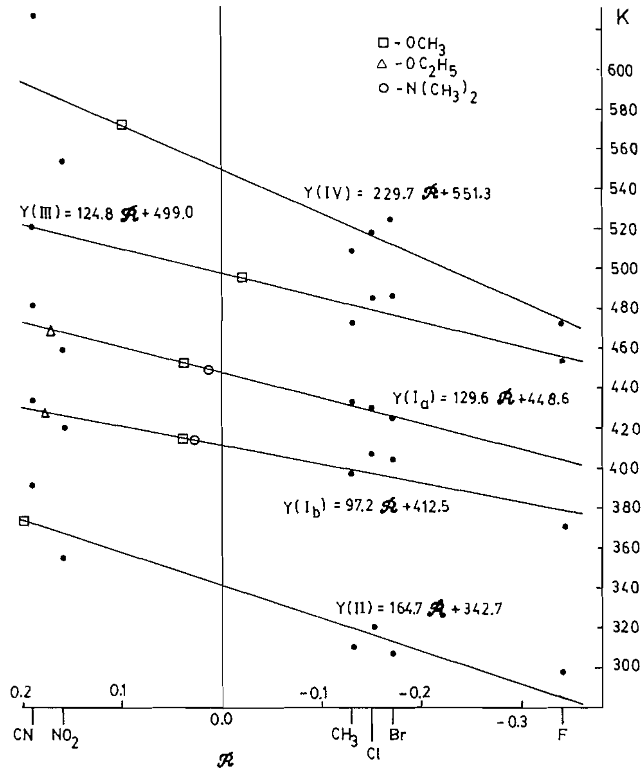

FIG. 2. Equations and graphic representation of the relation T_{N-I}—$\mathcal{R}$ for the five series of compounds studied.

In both the series of compounds synthesized by us, I*a* and I*b*, we can observe a type of behaviour in the $\mathcal{R}$ value of the methoxy group in the regression straight line similar to that defined by other six groups studied.

This effect was repeated when other compounds with strongly electron-releasing groups X: —OC_2H_5 and —$N(CH_3)_2$ were synthesized and studied. In both cases a behaviour similar to that of the methoxy group was observed.

As occurs with the methoxy group, the representation of T_{N-I} values in the regression straight line defined by other six groups, is similar in the series I*a* and I*b* (see Fig. 2).

Conclusions

The excellent correlation observed between the T_{N-I} of the five series of compounds studied confirms that the influence of the different terminal groups is similar in each of them. However, none of the electronic parameters of the terminal groups shows an excellent correlation with the T_{N-I} of all the compounds studied. Nevertheless, it is observed that the T_{N-I} of the compounds with electron-attracting or weakly electron-releasing substituents show a good correlation with the electronic parameters of the substituents which measure the π electronic delocalization in the aromatic ring, especially with Swain and Lupton's $\mathcal{R}$. In spite of the fact that the substituents with strong electron-releasing characteristics deviate from the general behaviour previously indicated, the contribution of these substituents is similar in all the cases studied.

The electronic modification introduced in the molecule by the electron-attracting or weakly electron-releasing terminal groups obviously has a considerable effect on T_{N-I}. However,

the influence of some other factors is fundamental, particularly, in the case of the substituents with strong electron-releasing characteristics. Logically, the attempt to quantify the inter- and intramolecular interactions which govern T_{N-I} is very difficult and the approximation that the electronic parameters allow is insufficient to explain all the results satisfactorily.

A multinuclear nuclear magnetic resonance study of *t*-butylthiol

SANDRA MOOIBROEK[1] AND RODERICK E. WASYLISHEN
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received February 12, 1985

SANDRA MOOIBROEK and RODERICK E. WASYLISHEN. Can. J. Chem. **63**, 2926 (1985).

Deuterium nmr lineshapes for polycrystalline samples of $(CD_3)_3CSH$ and $(CH_3)_3CSD$ have been investigated between 110 and 200 K. Unlike *t*-butylchloride-d_9 which undergoes line narrowing in three distinctive stages, *t*-butylthiol-d_9 undergoes almost complete motional line narrowing at 120 ± 5 K. Above the solid II ↔ solid I phase transition no quadrupolar splitting is observed, consistent with rapid "isotropic" reorientation in the solid I phase.

An analysis of the ^2H and ^{13}C spin–lattice relaxation times of $(CD_3)_3CSH$, $(CH_3)_3CSD$ and unlabelled *t*-butylthiol in both liquid and solid phases is also reported. The rotational correlation time is observed to decrease by an order of magnitude at the solid II → solid I transition and to increase slightly at the melting point. Deuterium T_1s in solids III and IV of the labelled species indicate abrupt changes at the phase transitions and motion slower than ω_0^{-1} in solid IV.

SANDRA MOOIBROEK et RODERICK E. WASYLISHEN. Can. J. Chem. **63**, 2926 (1985).

Opérant à 110 et 200 K et faisant appel à la rmn du ^2H, on a étudié la forme des pics d'échantillons polycristallins de $(CD_3)_3CSH$ et $(CH_3)_3CSD$. Contrairement à ce qui est observé avec le chlorure de *tert*-butyle-d_9 alors que les pics subissent un retrécissement impliquant trois étapes distinctes, les pics du *tert*-butylthiol-d_9 subissent un retrécissement qui est pratiquement complet à 120 ± 5 K. Au-dessus de la transition de phase solide II ↔ solide I, on n'observe pas de dédoublement quadrupolaire; ce resultat est accord avec une réorientation "isotopique" rapide dans la phase solide I.

On rapporte également une analyse des temps de relaxation spin–réseau du ^2H et du ^{13}C du $(CD_3)_3CSH$, $(CH_3)_3CSD$ et du *tert*-butylthiol non marqué tant dans la phase liquide que solide. On a observé que le temps de corrélation rotationnelle diminue d'un ordre de grandeur lors de la transition solide II → solide I et qu'il augmente légèrement au voisinage du point de fusion. Les valeurs du T_1s du deutérium dans les solides III et IV des espèces marquées indiquent qu'il se produit des changements radicaux lors des transitions de phase ainsi qu'un mouvement plus faible que ω_0^{-1} dans le solide IV.

[Traduit par le journal]

Introduction

2-Methyl-2-propanethiol (*t*-butylthiol) is one of a class of approximately spherical molecules which is capable of existing in one or more solid phases that are orientationally disordered (1). At atmospheric pressure, *t*-butylthiol is known to undergo three solid–solid phase transitions at 152, 157, and 199 K, with corresponding entropy changes of 3.22, 0.50, and 0.58 R (2, 3). The entropy change at the melting point of 274 K is small (1.09 R), a characteristic of orientationally disordered molecular solids (plastic crystals).

Deuterium nmr is a very attractive technique for studying plastic crystals since it provides a selective probe for detailed studies of molecular motion. In particular, changes in the absorption lineshape of a powder sample may, in favorable cases, yield information as to the type(s) of reorientational motion occurring at rates on the order of the quadrupolar interaction, which for deuterium, is approximately 10^{-5} to 10^{-6} s. Motions occurring on the timescale of the inverse Larmor frequency (nanosecond to picosecond range) can also be monitored by relaxation measurements, and hence, a fairly wide range of motional frequencies is accessible to nmr methods.

In this paper we present the results of a detailed deuterium nmr study of $(CD_3)_3CSH$ and $(CH_3)_3CSD$ between 110 and 330 K. Natural abundance ^{13}C nmr data are also reported for the liquid and two high temperature solid phases (I and II) of the unlabelled compound. The results of these measurements, together with earlier proton nmr (4, 5) and dielectric (5, 6) studies, have enabled us to better characterize the rotations occurring in the various phases of *t*-butylthiol. Comparisons are made with the related compounds *t*-butyl-X (see Fig. 1*a*) where X = CH_3, Cl, and Br.

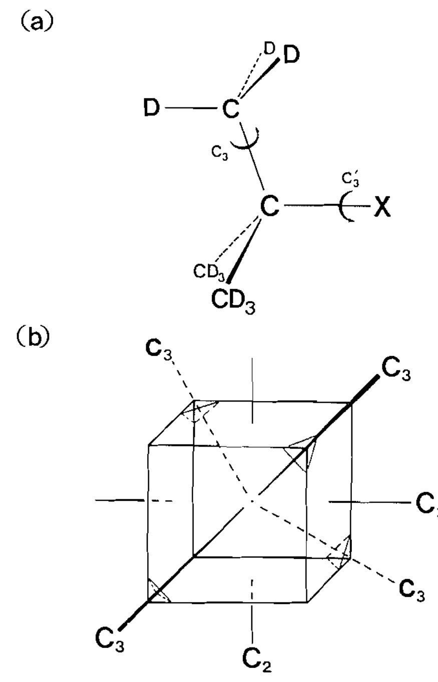

FIG. 1. (*a*) Depiction of $(CD_3)_3C$—X molecule indicating one of three C_3 axes and the C_3' axis. One D in each group is very nearly parallel to the C_3' axis, while the other two form an angle of 70.53°. (*b*) Representation of a tetrahedral molecule in a cube. Two of three orthogonal C_2 axes are indicated along with the C_3 axes.

Theory

A. Quadrupolar powder lineshapes

The ^2H nmr spectrum of labelled *t*-butylthiol is completely dominated by the electric quadrupole interaction, which in the

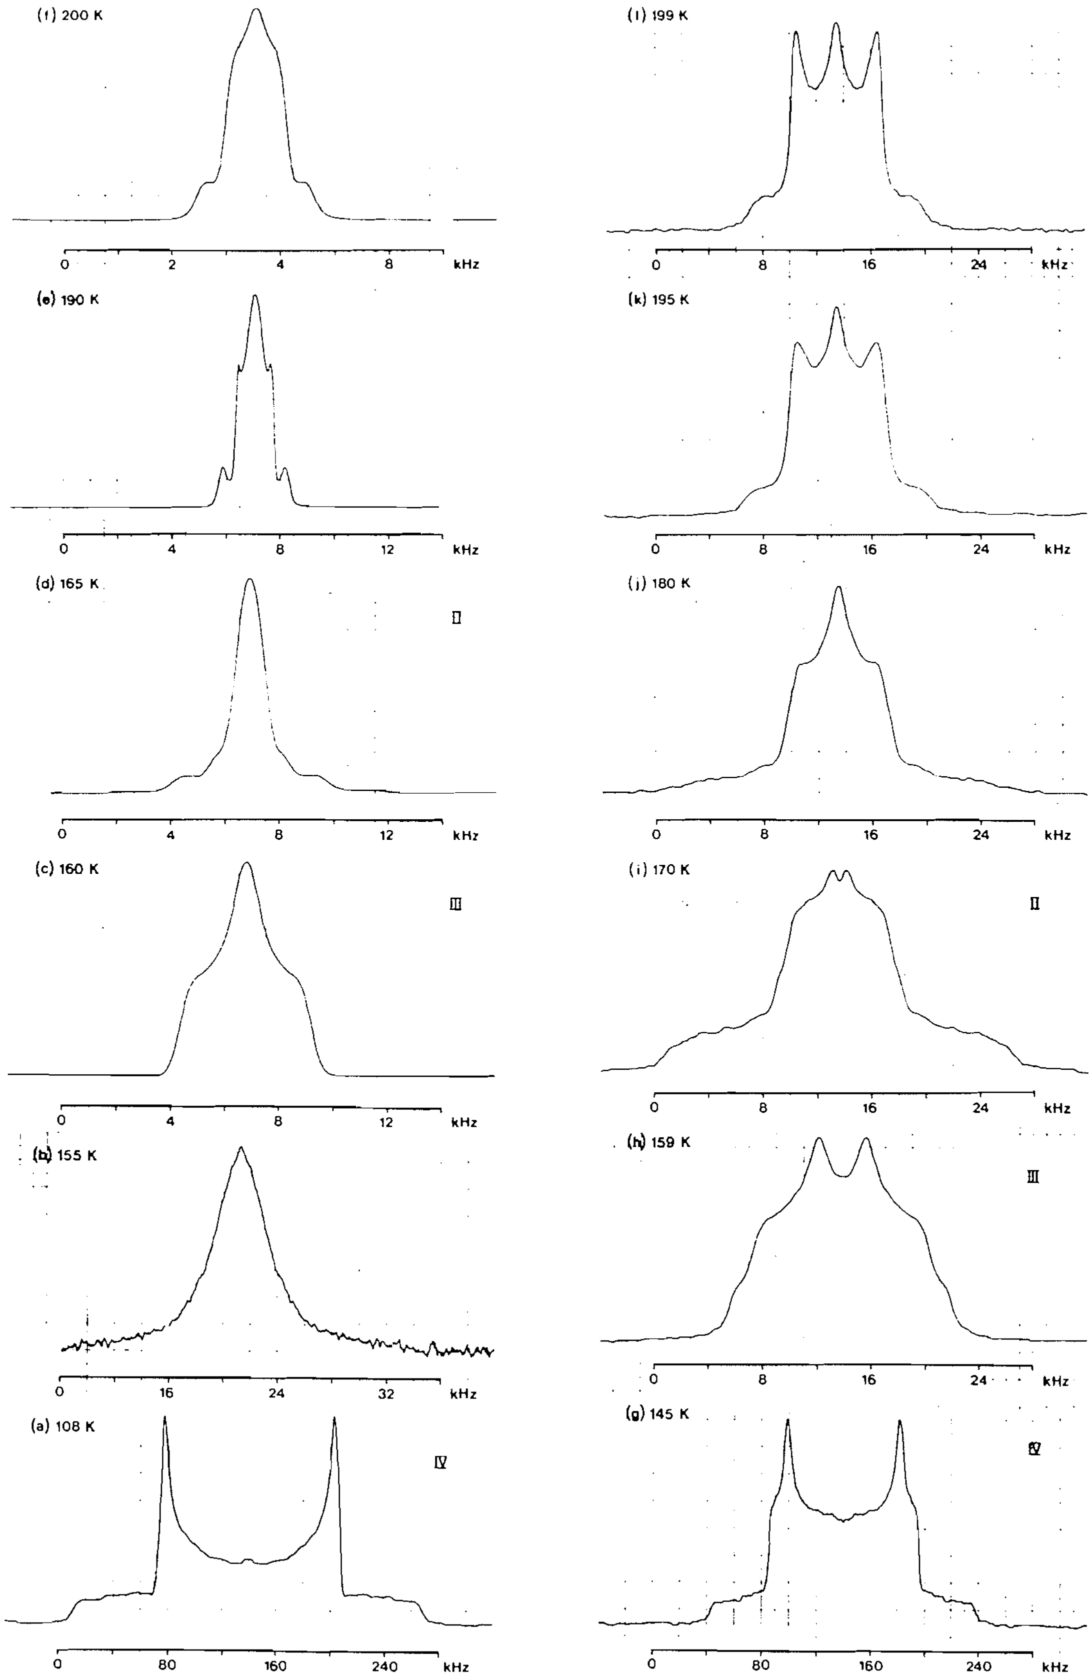

FIG. 2. Deuterium nmr powder spectra of (*a*)–(*f*) $(CD_3)_3CSH$ and (*g*)–(*l*) $(CH_3)_3CSD$ at various temperatures. Experimental conditions are described in the text.

absence of molecular motion, yields a characteristic spin $I = 1$ crystalline powder pattern (7). Figure 2*a*, the "rigid lattice" spectrum of $(CD_3)_3CSH$, is a typical powder pattern for an electric field gradient, $eq_{zz} = V_{zz}$, which is axially symmetric about the deuterium–carbon bond vector. In this case, the frequency separation between the singularities is $(3/4)\chi$ and between the edges it is $(3/2)\chi$, where χ is the quadrupolar coupling constant, $(e^2q_{zz}Q)/h$.

The field gradient of the sulfur bonded deuterium of *t*-butylthiol is not quite axially symmetric, as shown in Fig. 2*g*. Computer simulation of this powder pattern yields an asymmetry parameter $\eta = (V_{xx} - V_{yy})/V_{zz}$, $(0 \leq \eta \leq 1)$, of approximately 0.07. General expressions for the splitting between the spectral discontinuities in this case are given in refs. 8 and 9.

B. Effect of rapid molecular motion upon lineshape

For general *t*-butyl-X compounds, several different motions which influence the powder lineshape are possible: (*i*) internal rotations of the methyl groups about an approximate C_3 axis; (*ii*) internal rotations of the *t*-butyl group about the C—X axis, denoted C_3' rotations; (*iii*) general overall rotations of the molecules. For tetrahedral molecules such as neopentane, (Fig. 1*a*, X = CH_3), these latter rotations are generally regarded as consisting of motions about both the C_2 and the C_3 axes, illustrated in Fig. 1*b* (10).

Rotation about an axis may occur via continuous diffusion or by "jumps"; either will affect the powder lineshape when comparable to, or faster than (^{2}H) χ^{-1}. If motions can be treated independently, the rotationally averaged spectrum can be simulated using theoretical models (7–9, 11, 12).

The effect of rapid rotational diffusion is simply to reduce the splitting by a factor of $(1/2)\,(3\cos^2\beta - 1)$, where β is the angle between the axis of rotation and the C—D bond vector. The rotationally averaged spectrum is always axially symmetric when the motion is very rapid ($\tau \ll \Delta\nu_3^{-1}$). If perfect tetrahedral symmetry about each of the carbon sites in the *t*-butyl compounds is assumed (a good approximation in the gas phase, according to the geometry computed by ref. 13), the angles of interest are 1/2 the tetrahedral angle, or 54.74°, for C_2 rotation, and the complement to the tetrahedral angle, 70.53°, for C_3 rotations. The reduction factors for these angles are 0 and 1/3, respectively; therefore, one would expect rapid diffusion about a C_2 axis to completely collapse the quadrupolar splitting, and rapid diffusion about a C_3 axis to reduce it to one third the original value.

In the rapid motion limit, the effect of jumps between sites of three-fold or greater symmetry is exactly the same as for rotational diffusion. Once this limit is reached, one cannot distinguish, for example, between 120° jumps or continuous rotation about a C_3 axis. On the other hand, rapid jumps and diffusion about a C_2 axis yield substantially different spectra (7–9, 11, 12). Theory predicts that 180° flips about a C_2 axis in *t*-butyl compounds will result in an effective asymmetry parameter of 1, with $V_{xx} = V_{zz} = 64$ kHz for the methyl deuterons.

The situation for more complex motion — e.g. a combination of C_2 jumps and C_3 jumps about different axes — is much more complex, and will not be dealt with here.

C. Spin–lattice relaxation

The spin–lattice relaxation rate due to modulation of the electric quadrupole interaction of a spin 1 nucleus is given by

$$[1]\quad \frac{1}{T_1} = \frac{3}{20}\pi^2\chi^2(1 + \eta^2/3)\,\{J_1(\omega_0) + 4J_2(2\omega_0)\}$$

where $J_1(\omega_0)$ and $J_2(2\omega_0)$ are spectral density functions at the Larmor frequency ω_0 and at $2\omega_0$, respectively, such that $J(\omega) = 2\tau_{eff}/(1 + \omega^2\tau_{eff}^2)$. In this expression, τ_{eff} is an effective correlation time associated with the rotation of V_{zz}, and the function describing τ is assumed to have an exponential form. For $\omega_0\tau \ll 1$, the extreme narrowing condition which holds in all but the lowest solid phase of *t*-butylthiol, $J_1(\omega_0) = J_2(2\omega_0) = 2\tau_{eff}$.

In a similar manner, the relaxation rate of a proton decoupled methyl ^{13}C nucleus, in the extreme narrowing region, is given by

$$[2]\quad \frac{1}{T_1} = \frac{3\hbar^2\gamma_C^2\gamma_H^2\tau_{eff}}{r_{CH}^6}$$

where γ_C and γ_H refer to the magnetogyric ratios of ^{13}C and ^{1}H, respectively, and r_{CH} is the carbon–hydrogen internuclear separation. In this case, the carbon-13 nuclei are assumed to be relaxed solely by nearby protons via the dipole–dipole mechanism.[2]

The precise meaning of τ_{eff} in the above equations will be dependent on temperature and the particular phase of *t*-butylthiol under consideration. For the liquid phase, τ_{eff} can be related to rotational diffusion constants parallel and perpendicular to the C_3' axis illustrated in Fig. 1*a* (15). In the solid phases where the quadrupolar powder patterns are observed, i.e. II, III, and IV, τ_{eff} is related to the product of τ_2 and an order parameter (see ref. 16).

Experimental

Samples of $(CD_3)_3CSH$ and $(CH_3)_3CSD$ were purchased from Merck, Sharp, & Dohme Chemical Co.; $(CH_3)_3CSH$ (99+%) was obtained from Aldrich Chemical Co. The samples were transferred to 1 cm cylindrical microcells of 9 mm outer diameter, then de-gassed using repetitive freeze–pump–thaw cycles before sealing. Most of the experiments were performed on a Nicolet 360 narrow bore instrument, while some of the carbon-13 relaxation measurements were carried out on a Varian CFT-20. The low temperature deuterium spectra were obtained on a Bruker CXP 180 MHz instrument.

Temperature regulation is estimated to be within ±1 K. Typical $\pi/2$ pulse widths are in the range 35 to 45 μs for ^{2}H and 25 μs for ^{13}C on the Nicolet 360 and 22 μs for ^{13}C on the CFT-20. A phase-alternated quadrupole echo technique (17) was employed on the Bruker CXP spectrometer in order to obtain the spectra shown in Fig. 2. For these spectra, the echo-pulse spacing was ~40 μs with pulse widths of 3 μs. Dwell times of 0.5 μs were used to record 512 point quadrupole echoes (at very low temperatures, 1 μs dwell time and 1K points were used), which were zero-filled to 4K before Fourier transformation.

Spin–lattice relaxation times were measured by either standard inversion-recovery, or in some cases, inversion-recovery with a compensating pulse (18), using 10 or more τ values and a delay of at least 5 times T_1. Generally, only one scan was required to obtain satisfactory signal/noise ratios in the deuterium measurements; eight or more were required for the natural abundance carbon-13 study. The T_1 values were calculated using a 3-parameter-fit program in the Nicolet 1280 software package (19). Reproducibility is within 1–2%; errors are expected to be within 5%. Carbon-13 T_1s on the unlabelled compound and ^{2}H T_1s on $(CH_3)_3CSD$ were conducted over the temperature range 160 to 320 K, while ^{2}H measurements on $(CD_3)_3CSH$ were extended down to 140 K. For the low temperature phases, the T_1 data are obtained from measurement of the peak height of the central component.

[2] Within experimental error, a full nOe was observed up to ~315 K. Figure 3 does not include ^{13}C data above this temperature.

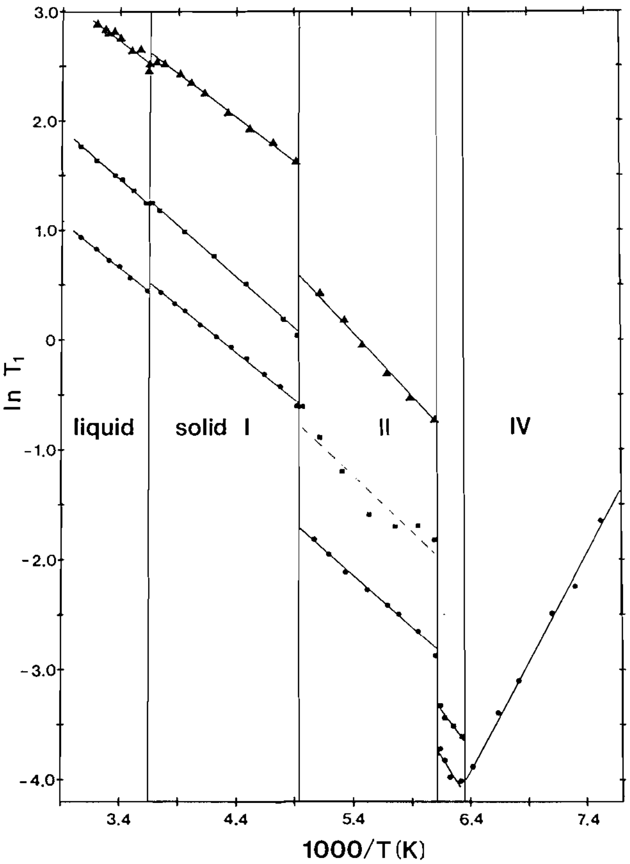

FIG. 3. Plot of ln $T_1(s)$ vs. reciprocal temperature for: (*a*) ^{13}C relaxation in unlabelled *t*-butylthiol (▲); (*b*) ^2H relaxation in $(CH_3)_3CSD$ (■); (*c*) ^2H relaxation in $(CD_3)_3CSH$ (●). The vertical lines represent the observed phase transition temperatures of 274 K (mp), 203 K (I/II), 164 K (II/III), and 158 K (III/IV).

Results and discussion

Deuterium nmr spectra of *t*-butylthiol at selected temperatures are shown in Fig. 2; spin–lattice relaxation data are summarized in Fig. 3 and Table 1.

A. Solid IV

The ^2H nmr spectrum of $(CD_3)_3CSH$ at 108 K (Fig. 2*a*), is the axially symmetric powder pattern, χ = 171 kHz, of the rigid solid. When the sample is warmed above ~120 K, the 128 kHz splitting between the singularities collapses to a broad, featureless peak of about 10 kHz in half-height width (Fig. 2*b*). We interpret this spectrum as arising from a combination of C_3 internal methyl and *t*-butyl group jumps occuring at a rate comparable to the inverse of the quadrupolar splitting (~10^{-6} s). This interpretation is based upon (*i*) comparison to the ^2H nmr spectra of other *t*-butyl-X compounds, (*ii*) the temperature dependence of the spin–lattice relaxation time, and (*iii*) the nmr powder pattern observed for $(CH_3)_3CSD$ in this phase.

The process of motional averaging of the ^2H nmr powder lineshape in several $(CD_3)C$—X compounds, including X = Cl, Br, I, and CHO, is accompanied by the observation of a spectrum similar to Fig. 2*b* upon warming the rigid solid. In *t*-butylchloride and *t*-butylbromide, however, the averaging process in the lowest temperature phase occurs stepwise (20–22). The first type of motion to become fast enough to average the quadrupolar interaction is reorientation about the C—X, or C_3' axis (21, 22). Since, in the absence of internal methyl rotation, two of the three C—D vectors in each methyl group form an angle of 70.53° with the C_3' axis, while the remaining C—D vector is parallel to this axis (Fig. 1*a*), two overlapping powder spectra are observed (21): one with the original static splitting, and one averaged to 1/3 the static value, or approximately 43 kHz. When the sample is heated another 30°, methyl rotation also becomes much faster than the inverse of the ^2H quadrupole interaction, roughly χ^{-1}, rendering the three deuterons in each methyl group equivalent. The averaged principal axes then lie along the C—C axes, 70.53° from the C—D bonds, and the quadrupolar splitting is again reduced by the 1/3 factor to ~14 kHz. Between these two steps, that is, in the approximately 20° temperature range in which C_3' rotation is relatively fast and C_3 (methyl) rotation is ~χ^{-1}, the equivalent of spectrum 2*b* is observed. *t*-Butyliodide and *t*-butylaldehyde show a similar progression in achieving the 14 kHz powder pattern, although in these compounds, as in *t*-butylthiol, averaging due to C_3' rotation is not established before C_3 rotation also affects the spectra (23).

^2H (SD)	0.921	11	2.7

t-Butylthiol is further distinguished from the other *t*-butyl-X compounds in that it undergoes a phase change before methyl rotation becomes rapid enough for the 14 kHz splitting to appear. This is borne out by the behaviour of the spin–lattice relaxation time in solid IV: the increasing T_1 with decreasing temperature (see Fig. 3) indicates that the motion causing relaxation must be slower than ω_0^{-1}. Using eq. [1], the observed T_1s correspond to τ_{eff} values of 1×10^{-5} s at approximately 133 K, and 1.1×10^{-6} s at the solid IV → solid III phase transition (158 K), consistent with rotation rapid enough to affect the spectrum yet not rapid enough to average it to the 14 kHz powder pattern.

The possibility that the broad, single peak of Fig. 2*b* represents averaging by molecular C_2 jumps with an asymmetry parameter approaching unity, or that the entire molecule reorients under C_3' jumps can be ruled out by the ^2H nmr spectrum of $(CH_3)_3CSD$. For this isotopomer, a full powder pattern (Fig. 2*g*) was observed throughout solid IV, indicating very slow or no motion of the thiol substituent in this phase. Using the geometry shown in Fig. 1*a*, with ∠CSD = 97.5° (13), we would expect rapid C_3 jumps about the C—S axis to average the quadrupolar splitting to less than half the static value, while C_2 jumps (Fig. 1*b*) would average the splitting to an even greater extent. The only conceivable motion which would not be detected in the ^{2}H nmr spectrum of $(CH_3)_3CSD$ would be rotation about an axis parallel or nearly parallel to the S—D bond vector; but this can be ruled out by the low dielectric constant (6), indicating that the dipole moment (oriented approximately perpendicular to the S—D bond axis (13)) is not reorienting.

Internal C_3 and C_3' rotations are also consistent with the results of Smith (4), who reports a decrease in the ^{1}H second moment from about 30 G^2 to ~2.4 G^2 over the temperature range 90 to 120 K.

B. Solid III and II

Although thermodynamic data (2, 3) report phase transitions at 151.6 and 157 K, no abrupt changes are observed in the ^{2}H solid IV spectra of either of the deuterium labelled *t*-butylthiol samples until they are heated to 158 K. At this temperature, the spectrum of $(CD_3)_3CSH$, Fig. 2*c*, sharpens to a powder pattern approximately 4 kHz in width with an effective asymmetry parameter of almost 1, while that of $(CH_3)_3CSD$, Fig. 2*h*, collapses from the rigid powder lineshape of χ = 130 kHz, η = 0.07, to a lineshape of ~9 kHz in width, with $\eta_{eff} \simeq 0.5$. We associate these spectral changes with the solid IV → solid III phase transition.

The short solid III phase can be clearly distinguished from solids II and IV by the discontinuities in the ln T_1 versus reciprocal temperature plots, Fig. 3. The slope of these plots indicates motion in the extreme narrowing region, and use of eq. [1] yields τ_{eff} values of 1.2×10^{-10} s for $(CD_3)_3CSH$ and 1.3×10^{-10} s for $(CH_3)_3CSD$ at 160 K. The similarity in these two results and the relatively narrow ^{2}H powder patterns demonstrates that overall molecular reorientation is the dominant motion causing relaxation in this phase. Since neither rapid diffusion or fast C_3 jumps predict $\eta_{eff} > 0$, the highly asymmetric lineshapes observed in this phase imply that C_2 jumps must be involved in the reorientation of the molecule.

Further discontinuous changes in the deuterium nmr lineshapes do not take place until 164 K (d_9 compound) or 166 K (SD isotopomer), corresponding to the solid III → solid II phase transition. At 164 K, the $(CD_3)_3CSH$ spectrum (Fig. 2*d*) undergoes further narrowing to a featureless peak of ~1 kHz in width with low intensity shoulders. The spectrum of $(CH_3)_3CSD$, Fig. 2*i*, undergoes a very unusual change at this transition: a broad component about 25 kHz in width appears along the baseline, accompanied by an increase in η_{eff} and a slight narrowing of the central component to 8 kHz.

Discrepancies between our transition temperatures and those reported by McCullough *et al.* (2, 3) for the IV → III and III → II transitions may be due to the relatively short periods (15 to 30 min) which we could allow for thermal equilibrium to be reached. The upwards shift of approximately 6° is rather large to be considered an isotope effect, although such shifts are not unusual in solid–solid phase transitions (1).

The occurrence of the solid III phase is apparent only upon heating. Upon cooling a sample displaying a solid II spectrum, no drastic changes occur until a solid IV spectrum is attained, which is observed at ~151 K for both the d_9 and the SD samples. Kondo (6) also reported "a thermal hysteresis of phase change" for $(CH_3)_3CSH$; he observed sharp discontinuities in the dielectric constant, ϵ, at 151.6 and 161.6 K upon heating, but only the corresponding drop in ϵ at 151.6 K upon cooling. The proton nmr second moment does not appear to be sensitive to the solid III → solid II transition, showing only an abrupt change at 153 K in this temperature range (4). Again, there is considerable hysteresis in the heating/cooling data, suggesting that *t*-butylthiol is very slow to reach equilibrium.

TABLE 2. Entropy change (in units of R) at the solid–solid phase transitions in *t*-butyl compounds

	Entropy change		
Transition	$(CH_3)_3CSH$[a]	$(CH_3)_3CCl$[b]	$(CH_3)_3CBr$[b]
I → liq	1.09	0.95	0.9
II → I	0.58	3.2	0.55
III → II	0.50	1.2	3.25
IV → III	3.22		

[a]References 2, 3.
[b]Reference 14.

Upon warming through the solid II temperature range, both $(CD_3)_3CSH$ and $(CH_3)_3CSD$ deuterium spectra evolve to very complex motionally averaged powder patterns, with fairly well defined shoulders and edges but also with relatively broad central components. In *t*-butylthiol-SD, Fig. 2(*j*, *k*), the powder splitting of the outer edges is about 8 kHz; in the d_9 compound, Fig. 2*e*, it is only 1–1.5 kHz. The unusual lineshapes might be due to a purely dynamic effect, but the spectra appear to consist of two overlapping powder patterns, indicative of more than one type of molecule in the unit cell. A lattice contribution to the electric field gradient from a non-cubic crystal structure also remains a distinct possibility (24).

The spin–lattice relaxation times obtained for solid II indicate that the rate of reorientation in this phase is an order of magnitude faster than in solid III. The activation energy also appears to have decreased somewhat, as shown in Table 1. The non-Arrhenius behaviour of the thiol deuteron T_1s in this phase is likely due to differing relaxation rates in the two overlapping powder patterns; the result underlines the difficulty in interpreting the T_1s from such unusual lineshapes, especially since the spectra continue to vary with temperature throughout the phase.

Just below the transition to solid I, which occurs at 204 K, the $(CD_3)_3CSH$ spectrum becomes increasingly asymmetric (Fig. 2*f*), while one component of the $(CH_3)_3CSD$ spectrum appears to be approaching $\eta_{eff} = 0$ (Fig. 2*l*). Entrance into the solid I phase is heralded by the collapse of all quadrupolar splitting in both ^{2}H spectra. When either sample is subsequently cooled back down into solid II, small non-reproducible splittings are observed, which are interpreted as the formation of a number of monocrystalline domains in the nmr tube, rather than a purely random collection of crystallites. This observation confirms the change in crystal structure at this transition first proposed by Guthrie and McCullough (3), and supported by Smith (4).

If the sample is cooled below 150 K and then re-heated, the extra splittings in the solid II spectrum appear to be somewhat smoothed, suggesting that another change in crystal structure occurs at the solid IV boundary, cracking some of the crystalline domains. In light of the large entropy change at this transition point, a change of crystal lattice as well as the gains in orientational freedom is not surprising.

It is of interest to compare our ^{2}H nmr powder patterns with those observed for other *t*-butyl-X compounds. *t*-Butylchloride appears to be the best behaved, with the 14 kHz splitting of the lowest temperature phase, solid III, remaining up to the II → I transition, where all quadrupolar splitting collapses (20). *t*-

TABLE 3. Rotational correlation times at the melting point of various t-butyl compounds

Molecule	τ_{eff} (ps)	Reference
t-Butylthiol-d_9	1.5 (liquid) 1.3 (solid I)	This work
t-Butylbromide-d_9	2.5 (liquid) 2.2 (solid I)	16
t-Butylchloride-d_9	2.0 (liquid) 1.8 (solid I)	25
Neopentane-d_{12}	0.9	28

Butylbromide, which also has only three solid phases, undergoes an abrupt change at the III → II transition (16): the ~14 kHz splitting of solid III becomes a tiny 400 Hz splitting in solid II. The spectrum retains an axially symmetric lineshape until, as in the other t-butyl-X ^2H spectra, all splitting disappears in solid I. The unique nature of the phase II deuterium powder lineshapes in these compounds, despite the similarity in transition entropies (Table 2) and behaviour in the low and high temperature solid phases, tells us that the transition from internal C_3 and C_3' rotations to near isotropic reorientational freedom is highly substituent dependent, and cannot be described in a simple, stepwise manner.

C. Solid I and liquid

The ^2H nmr spectra of $(CD_3)_3CSH$ and $(CH_3)_3CSD$ show identical single peaks in both liquid and solid I phases, indicating that the molecule reorients through all angles at a rate much faster than ω_0^{-1}. The two phases are distinguished, however, by a slight discontinuity in the temperature dependence of the ^2H and ^{13}C spin–lattice relaxation times, shown in Fig. 3. The size of the symbols in the diagram include at least a 5% error estimate, although reproducibility of the liquid/solid I data was much better than that.

The slight discontinuity, apparent in all three plots of ln T_1 versus reciprocal temperature, represents a decrease in τ_{eff} upon freezing. A similar result was obtained for t-butylbromide (16), and although not reported in an earlier ^2H study of t-butylchloride (20), we have also found a small discontinuity in $(CD_3)_3CCl$ T_1s at the melting point (25). The possibility that this discontinuity is solely due to a change in the electric field gradient (26, 27), i.e. χ, is ruled out by the ^{13}C data, which is not affected by $\hat{V}$. The slight decrease in τ_{eff} upon freezing indicates, at least initially, greater rotational freedom in the plastic phase. This is illustrated by comparison of the τ_{eff} values obtained at this transition to those obtained in other t-butyl compounds (see Table 3). Overall rotations of t-butylthiol are comparable to those observed for the chloride; symmetric neopentane, with a methyl group on the t-butyl moiety, rotates at about twice this rate (28).

The Arrhenius parameters obtained from least-squares fitting of the data are given in Table 1. Within experimental error, the pre-exponential factors and activation energies obtained from the carbon-13 and deuterium studies on the unlabelled and the d_9 compounds are the same, as they should be since both are monitoring rotation of the same vectors. A comparison of these τ_{eff} values with those obtained from the ^2H data on $(CH_3)_3CSD$ is a measure of the isotropy of the overall reorientation of the molecule. Interestingly, τ_{eff} of the S—D vector changes very little upon freezing.

Conclusions

The deuterium nmr data on t-butylthiol lend further support to the general conclusions of Smith (4). Internal reorientation of the methyl and t-butyl groups becomes significant on the ^2H nmr timescale at 120 K in solid IV, and above the solid IV → solid III transition rapid reorientation of the dipolar axis occurs as well. Molecular rotations are relatively free in solid I, being comparable to those in the liquid. In addition, a change in crystal structure is confirmed at the solid IV/solid III and solid II/solid I transition temperatures, as is a change in the rotational correlation time of approximately one order of magnitude at the III/II and II/I boundaries. Observation of quadrupolar splittings in the solid II phase suggest that this phase is not cubic. A more detailed analysis of the nature of molecular motions in solids II and III should be possible if the powder lineshapes can be simulated and a reasonable model to interpret the T_1 data is available.

A final note: careful measurements of the spin–lattice relaxation time are required to observe a discontinuity at the melting point; it is likely a more general phenomenon among plastic crystals than has been reported to date. Theoretical or statistical mechanical models of melting should account for this.

Acknowledgements

We are grateful to Dr. John Ripmeester of National Research Council of Canada, Ottawa, for his assistance in obtaining the low temperature ^2H nmr spectra in Fig. 2. All of the ^2H and most of the ^{13}C relaxation measurements were carried out at the Atlantic Regional NMR Centre. Our thanks to NSERC for financial support in establishing and maintaining this centre, and also for an operating grant (R.E.W.).

Moments analysis of restricted ternary diffusion: sodium sulfite + sodium hydroxide + water

DEREK G. LEAIST
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received February 19, 1985

DEREK G. LEAIST. Can. J. Chem. **63**, 2933 (1985).

Ternary diffusion coefficients can be determined from restricted-diffusion experiments by evaluating zeroth and first time moments of the difference in a concentration-dependent property measured at two levels along the diffusion column. The method is used to determine ternary diffusion coefficients for aqueous sodium sulfite + sodium hydroxide solutions from conductance measurements. It is shown that these data can be analyzed to obtain the ternary diffusivity of sulfur dioxide in strongly alkaline solutions where sulfite is the major transporting species for the sulfur dioxide component. At high pH values, coupled flow of hydroxide ions leads to a significant increase in the diffusivity of the sulfur dioxide component relative to its diffusivity in pure water. Binary diffusion coefficients for aqueous sodium sulfite solutions are also reported.

DEREK G. LEAIST. Can. J. Chem. **63**, 2933 (1985).

On peut déterminer les coefficients de diffusion ternaire à partir d'expériences de diffusion restreinte en évaluant les moments de temps zéro et un de la différence qui existe dans une propriété qui dépend de la concentration et qui est mesurée à deux niveaux le long de la colonne de diffusion. On a utilisé la méthode pour déterminer les coefficients de diffusion ternaire de solutions aqueuses de sulfite de sodium + hydroxyde de sodium à partir de mesures de conductivité. On montre que l'on peut analyser ces données de manière à obtenir la diffusivité ternaire du dioxyde de soufre dans des solutions fortement alcalines où le sulfite est le transporteur principal du dioxyde de soufre. À des pH élevés, le flux couplé d'ions hydroxydes conduit à une augmentation marquée de la diffusivité de la composante du dioxyde de soufre par rapport à sa diffusivité dans l'eau. On rapporte également les coefficients de diffusion binaire de solutions aqueuses de sulfite de sodium.

[Traduit par le journal]

1. Introduction

The Harned restricted-diffusion method is an important technique for determining diffusion coefficients of electrolyte solutions (1–4). In this technique flows of solute are measured by following changes in electrical conductance near the ends of short diffusion columns. The concentration gradients are sufficiently small that differential diffusion coefficients are determined directly without ambiguities arising from the concentration-dependence of the diffusivity. Cell calibration with materials of known diffusivity is not required. Furthermore, diffusion can be measured conductimetrically at low concentrations of theoretical interest where other methods are unreliable.

Soon after the Harned method was developed Fujita (5) proposed moments analyses that would extend conductimetric experiments to ternary mixed electrolytes and thus enable studies of coupled diffusion. Unlike pseudo-binary treatments of restricted-diffusion (6, 7) which rely on numerical differentiation of experimental data, moments methods employ inherently more-accurate integration of conductance data. Unfortunately, Fujita's treatment applies only to symmetrically-sheared cells in which the initial diffusion boundary is formed half-way along the diffusion channel. Experience has shown that cells of this design are unreliable for studies of multicomponent diffusion owing to convection currents formed when dilute solutions are sheared (6). Consequently, moments methods, despite their promise, have not been applied to restricted-diffusion experiments. Yet integration techniques for analysis of free-diffusion experiments are well-established and accurate (8–10).

Initial concentration gradients are formed in conventional Harned cells with a needle and syringe by injecting a small volume of concentrated (i.e. dense) solution into the bottom of the solution column (3, 4). In addition to minimizing convection the injection procedure simplifies construction and operation of the cells. The purpose of this paper is to adapt Fujita's moments analysis (5) to conventional cells in which initial boundaries are formed at arbitrary levels along the diffusion channel. The difficult task of determining ternary diffusion coefficients is then reduced to simple numerical integration of conductance data. The equations that are developed can also be used to analyze optical (11) or diaphragm cell experiments (12) in which a concentration-dependent property (such as density, refractive index, or optical absorbance) is monitored at two fixed levels along the path of diffusion.

The moments procedure is used to determine diffusion coefficients for aqueous sodium sulfite + sodium hydroxide solutions. The results are analyzed to obtain the ternary diffusivity of aqueous sulfur dioxide in alkaline solutions. Data for these systems are useful in order to describe transport of SO_2 in solutions used to scrub flue gases. At high pH values coupled flow of hydroxide ions is shown to produce a sharp increase in the diffusivity of the aqueous SO_2 component (i.e. total SO_2). To aid interpretation of the results binary diffusion coefficients for aqueous Na_2SO_3 solutions are also reported.

2. Experimental

Equipment and procedure

The diffusion cells had cylindrical diffusion channels (0.03–0.05 m height, 0.0127 m diameter) machined from polypropylene or polyethylene. Pairs of circular platinum electrodes (0.001 m diameter) were set in the cell walls at levels one-sixth and five-sixths of the distance between the top and bottom of the channels. Each cell was sealed with a greased glass slide.

Initial concentration gradients were prepared by injecting 0.1–0.5 mL of electrolyte into the bottom of each diffusion chamber. The concentrations were adjusted so that the initial gradient vanished for one of the solutes. Resistances were measured with a Jones bridge. Details of the equipment and procedure can be found elsewhere (3, 4, 6, 7).

Reagent grade Na_2SO_3 was dried in a vacuum oven at 130°C and used without further purification. Stock solutions of NaOH were prepared by dilution of saturated solutions that had been filtered through sintered glass to remove insoluble carbonate.

Binary diffusion

Binary diffusion coefficients for aqueous Na_2SO_3 solutions were determined from conductance readings using the equation (2, 4)

$$[1] \quad D = -(a^2/\pi^2)\mathrm{d} \ln \Delta K(t)/\mathrm{d}t$$

in which a is the length of the diffusion channel and $\Delta K(t) = (k_B/k_T)K_B(t) - K_T(t)$ is proportional to the difference in specific conductance between the bottom (B) and top (T) electrode pairs at time t. K_B and K_T are the measured reciprocal resistances and k_B/k_T is the cell constant ratio. The slope of ln $\Delta K(t)$ against t was estimated by least squares.

Ternary diffusion

Mass transport of two solutes in one dimension under isothermal, convection-free conditions is described by ternary diffusion equations

$$[2] \quad \partial c_1/\partial t = D_{11}\partial^2 c_1/\partial x^2 + D_{12}\partial^2 c_2/\partial x^2$$

$$[3] \quad \partial c_2/\partial t = D_{21}\partial^2 c_1/\partial x^2 + D_{22}\partial^2 c_2/\partial x^2$$

in which c_i are solute concentrations in moles per unit volume, t is the time, and x is the distance coordinate. Ternary diffusion coefficients D_{ik} are treated as constants. This approximation is valid for small concentration gradients.

For restricted diffusion in a column of height a, flows of solute through the bottom ($x = 0$) and top ($x = a$) of the column vanish.

$$[4] \quad \partial c_i/\partial x = 0 \qquad (x = 0 \text{ and } x = a, t > 0)$$

At time $t = 0$ a sharp initial boundary is formed at level $x = \epsilon a$

$$[5] \quad c_i = \bar{c}_i + (1 - \epsilon)\Delta c_{i0} \qquad (0 < x < \epsilon a, t = 0)$$

$$[6] \quad c_i = \bar{c}_i - \epsilon\Delta c_{i0} \qquad (\epsilon a < x < a, t = 0)$$

where $\bar{c}_i$ is the mean cell concentration for solute i and Δc_{i0} is the difference in concentration of solute i across the initial boundary. (For a symmetrically-sheared cell: $\epsilon = 0.5$. If the boundary is formed by injecting a small amount of electrolyte into the bottom of the solution column: $\epsilon \ll 0.5$.)

Solutions $c_i(x, t)$ to eqs. [2], [3] with boundary conditions [4] and initial conditions [5], [6] have been obtained by Fourier analysis (6). The series expression for the difference in solute concentrations between reference levels $x = a/6$ and $x = 5a/6$

$$[7] \quad \Delta c_i(t) = c_i(a/6, t) - c_i(5a/6, t)$$

converges so rapidly that after a short waiting period only the first terms are significant.

$$[8] \quad \Delta c_1(t) = Q\frac{\{[(D_{11} - D_2)\Delta c_{10} + D_{12}\Delta c_{20}] \exp(-\beta D_1 t) + [(D_{22} - D_2)\Delta c_{10} - D_{12}\Delta c_{20}] \exp(-\beta D_2 t)\}}{D_1 - D_2}$$

$$[9] \quad \Delta c_2(t) = Q\frac{\{[-D_{21}\Delta c_{10} + (D_{11} - D_1)\Delta c_{20}] \exp(-\beta D_1 t) + [D_{21}\Delta c_{10} + (D_{22} - D_1)\Delta c_{20}] \exp(-\beta D_2 t)\}}{D_2 - D_1}$$

where Q and β are geometric factors

$$[10] \quad \beta = \pi^2/a^2$$

$$[11] \quad Q = (2\sqrt{3}/\pi) \sin(\pi\epsilon/a)$$

and eigenvalues D_i are defined by

$$[12] \quad D_1 = \{D_{11} + D_{22} + (D_{11} - D_{22})[1 + 4D_{12}D_{21}/(D_{11} - D_{22})^2]^{1/2}\}/2$$

$$[13] \quad D_2 = \{D_{11} + D_{22} - (D_{11} - D_{22})[1 + 4D_{12}D_{21}/(D_{11} - D_{22})^2]^{1/2}\}/2$$

Because the solute concentration differences are small the difference in specific conductance $\Delta K(t)$ between the two reference levels for a weakly associated or a strong electrolyte mixture is a linear function of the differences in solute concentration

$$[14] \quad \frac{\Delta K(t)}{\Delta K(0)} = \frac{S_1\Delta c_1(t) + S_2\Delta c_2(t)}{S_1\Delta c_1(0) + S_2\Delta c_2(0)}$$

Partial specific conductances of the components, $S_i = \partial L/\partial c_i$, are evaluated at the final composition $\bar{c}_1$, $\bar{c}_2$. Upon substitution of eqs. [8] and [9] into eq. [14], we obtain

$$[15] \quad \Delta K(t)/\Delta K(0) = A_1 \exp(-\beta D_1 t) + (1 - A_1) \exp(-\beta D_2 t)$$

for the normalized conductance difference. Constant A_1 is given by

$$[16] \quad A_1 = \frac{(S_1/S_2)D_{12} - D_{11} + D_1 + X_1[(S_2/S_1)D_{21} - (S_1/S_2)D_{12} + 2D_{11} - D_1 - D_2]}{D_1 - D_2}$$

where X_1 is the fraction of the initial conductance difference due to solute 1

$$[17] \quad X_1 = S_1\Delta c_{10}/(S_1\Delta c_{10} + S_2\Delta c_{20})$$

Moments analysis

How can ternary diffusion coefficients be evaluated from measurements of $\Delta K(t)$? Following Fujita (5), consider zeroth and first time moments of the normalized conductance difference

$$[18] \quad I_0 = \int_0^\infty [\Delta K(t)/\Delta K(0)]\mathrm{d}t$$

$$[19] \quad I_1 = \int_0^\infty t[\Delta K(t)/\Delta K(0)]\mathrm{d}t$$

Integration gives expressions for the moments as functions of X_1

$$[20] \quad I_0(X_1) = I_0(0) + [I_0(1) - I_0(0)]X_1$$

$$[21] \quad I_1(X_1) = I_1(0) + [I_1(1) - I_1(0)]X_1$$

where

$$[22] \quad I_0(0) = [D_{11} - (S_1/S_2)D_{12})/\beta D_1 D_2$$

$$[23] \quad I_0(1) = [D_{22} - (S_2/S_1)D_{21}]/\beta D_1 D_2$$

$$[24] \quad I_1(0) = [D_{11}I_0(0) - (S_1/S_2)D_{12}I_0(1)]/\beta D_1 D_2$$

$$[25] \quad I_1(1) = [D_{22}I_0(1) - (S_2/S_1)D_{21}I_0(0)]/\beta D_1 D_2$$

After some algebra it develops that the ternary diffusion coefficients are remarkably simple functions of the lower moments

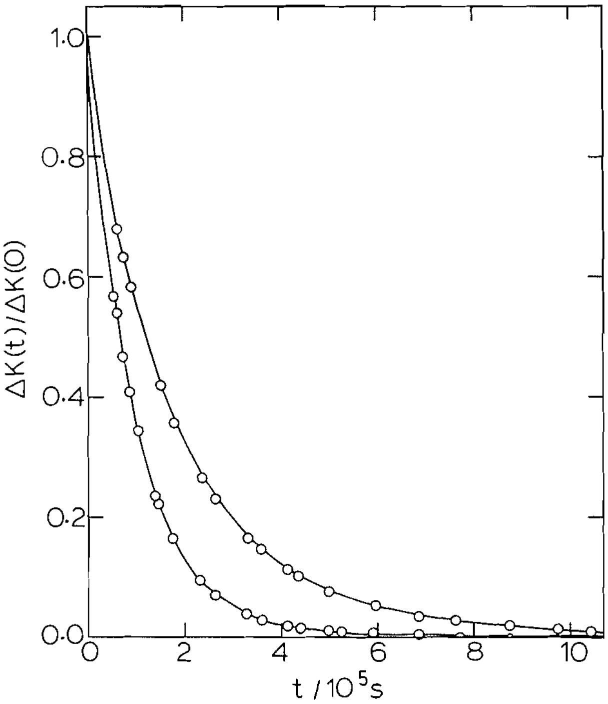

FIG. 1. Normalized conductance difference plotted against time for $c_1(Na_2SO_3) = 0.005$ mol dm^{-3} and $c_2(NaOH) = 0.035$ mol dm^{-3}. Areas under top curve (initial gradient in Na_2SO_3) and bottom curve (initial gradient in NaOH) determine moments $I_0(1)$ and $I_0(0)$, respectively.

[25] $D_{11} = [I_0(0)I_0(1) - I_1(0)]/F$

[26] $D_{12} = (S_2/S_1)[I_0(0)I_0(0) - I_1(0)]/F$

[27] $D_{21} = (S_1/S_2)[I_1(1) - I_0(1)I_0(1)]/F$

[28] $D_{22} = [I_1(1) - I_0(0)I_0(1)]/F$

[29] $F = \beta[I_0(0)I_1(1) - I_0(1)I_1(0)]$

Equations [25]–[29] reduce the difficult problem of computing ternary diffusion coefficients from conductance data to the much easier problem of determining moments. For simplicity, we chose to evaluate $I_0(0)$, $I_1(0)$, $I_0(1)$, and $I_1(1)$ by direct numerical integration of conductance vs. time data from two experiments: one with initial gradient entirely in solute 1 ($\Delta c_{20} = 0$, $X_1 = 1$), the other — performed in the same cell — with the initial gradient entirely in solute 2 ($\Delta c_{10} = 0$, $X_1 = 0$). Since I_0 and I_1 vary linearly with X_1, however, plotting measured values of I_0 and I_1 against X_1 for values of X_1 other than 0 or 1 would yield the required values of $I_0(0)$, $I_1(0)$ and $I_0(1)$, $I_1(1)$ as intercepts.

The analysis of conductimetric data is simplified by omission of higher order terms ($\sim\exp[-25\pi^2 D_i t/a^2]$) from eqs. [8], [9], and [15] (1). This approximation is valid provided conductance readings are taken for $t > a^2/50D_i$ where D_i is the smaller of the two eigenvalues. If $D_i \sim 1 \times 10^{-9}$ m^2 s^{-1} and $a \sim 0.05$ m, for example, conductance data may be analyzed for $t > 50\,000$ s, about one-half day.

By definition, moments I_0 and I_1 are obtained by integration of conductance data from $t = 0$ to infinity. When moments were evaluated from experimental data, it was necessary to estimate values of the conductance difference for values of t outside the interval of actual conductance measurements. Suppose conductance readings begin at $t = t_i$ and end at $t = t_f$. As a first approximation, values of D_{ik} were computed by integrating data available on the interval t_i to t_f. These D_{ik} values were used to estimate A_1, D_1, and D_2, and thus obtain an approximate expression for the conductance difference using eq. [15]. This expression was integrated analytically on intervals 0 to t_i and t_f to infinity to estimate contributions to I_0 and I_1 from outside the range

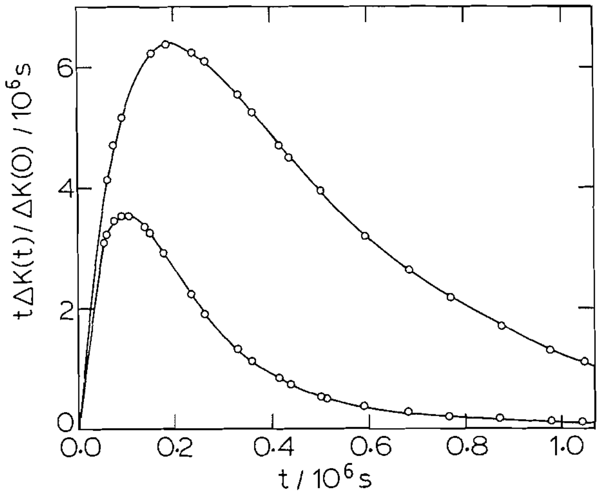

FIG. 2. $c_1(Na_2SO_3) = 0.005$ mol dm^{-3} and $c_2(NaOH) = 0.035$ mol dm^{-3}. Areas under the top curve (initial gradient in Na_2SO_3) and bottom curve (initial gradient in NaOH) determine $I_1(1)$ and $I_1(0)$.

of conductance readings. The cycle was repeated until changes in the estimates of D_{ik} were negligible. In practice only two or three iterations were required.

Unequally-spaced $\Delta K(t)/\Delta K(0)$ or $t\Delta K(t)/\Delta K(0)$ versus t data can be integrated numerically by using non-linear least-squares to fit the appropriate exponential function (eq. [15] for example) to the data, followed by analytic integration of the functions so obtained. We chose simply to fit each set of three adjacent points to a quadratic polynomial in t then integrated the polynomial, i.e. Simpson's rule on unequal intervals. Representative data are shown in Figs. 1 and 2. The excellent fits which were obtained provided a check on the internal consistency of the moments analysis procedure.

3. Results and discussion

Na_2SO_3 + H_2O

Binary diffusion coefficients for aqueous Na_2SO_3 solutions were determined at 25°C. The results of the measurements are summarized in Table 1. Uncertainties in the cell height ($\pm 2 \times 10^{-5}$ m) and cell constant ratio limit the accuracy of the data to $\pm 0.3\%$.

The limiting diffusion coefficient of the salt, D^0, was estimated from the data using the "self-consistent" equation for unsymmetrical electrolytes (13)

[30] $D(c) = (D^0 + \Delta_1)(1 + c\,d\ln y_\pm/dc)$

where Δ_1 is the first order electrophoretic correction and $y_\pm$ is the mean ionic activity coefficient on the molar-concentration scale. Thermodynamic factors $c\,d\ln y_\pm/dc$ were calculated from activities recommended by Goldberg (14). For this salt, however, accurate evaluation of D^0 was impossible because of large departures of the measured diffusion coefficients from values predicted by eq. [30]. This behavior may result from formation of ion pairs or from uncertainties in the activity coefficients, which at these low concentrations, are obtained by lengthy extrapolation of isopiestic data obtained above 0.2 mol dm^{-3} (14–16). Similar departures from predicted behavior have been observed for diffusion of aqueous Na_2SO_4 (17, 18).

In Fig. 3 diffusion coefficients for aqueous Na_2SO_3 solutions are compared with those for Na_2SO_4 obtained previously by optical (17) and conductimetric (20) methods at 25°C. D values observed for Na_2SO_3 solutions are displaced 0.04 (± 0.01) $\times 10^{-9}$ m^2 s^{-1} below those for Na_2SO_4 solutions. In order to

estimate $D^0(Na_2SO_3)$ and hence $\lambda^0(SO_3^{2-})$, we will assume that $D^0(Na_2SO_4) - D^0(Na_2SO_3) = 0.04 \times 10^{-9}$ m^2 s^{-1}. The value $D^0(Na_2SO_4) = 1.231 \times 10^{-9}$ m^2 s^{-1} is accurately known from conductances of Na^+ (19, 20) and SO_4^{2-} (21). Therefore, we obtain the approximate values of $D^0(Na_2SO_3) \cong 1.19 \times 10^{-9}$ m^2 s^{-1} and $\lambda^0(SO_3^{2-}) \cong 0.00735$ m^2 S equiv.$^{-1}$. For comparison: $\lambda^0(CO_3^{2-}) = 0.00693$ (22) and $\lambda^0(SO_4^{2-}) = 0.008002$ m^2 S equiv.$^{-1}$ (21).

$Na_2SO_3(c_1)$ + NaOH(c_2) + H_2O

Ternary diffusion coefficients for Na_2SO_3 + NaOH mixtures were determined by moments analysis at six compositions. Each experiment was performed in triplicate. The results are listed in Table 2. The conductance data were also analyzed by the pseudo-binary method (7); the results are shown in Table 3. The two methods gave ternary diffusion coefficients of similar precision that agreed within the suggested uncertainties (± two standard deviations). The moments analysis, however, was more direct and computationally simpler. As an additional check, L_{ik} coefficients defined by transport equations

$$[31] \quad -J_i = \sum_{k=1}^{2} L_{ik} \nabla \mu_k$$

were obtained from experimental D_{ik} values using the relation

$$[32] \quad D_{ik} = \sum_{m=1}^{2} L_{im} \partial \mu_m / \partial c_k$$

Values of $\partial \mu_m / \partial c_k$ shown in Table 4 were obtained by differentiation of the expressions

$$[33] \quad \mu_1 = \mu_1^0 + RT \ln [(2c_1 + c_2)^2 c_1 y_{\pm 1}^3]$$

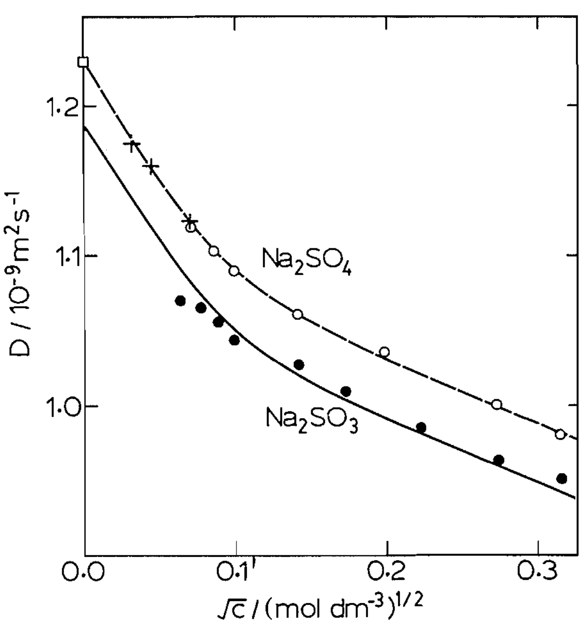

FIG. 3. Binary diffusion coefficients at 298.15 K plotted against concentration for: Na_2SO_4, top curve, + (Harned and Blake (18)), ○ (Rard and Miller (17)); Na_2SO_3, bottom curve, this work.

$$[34] \quad \mu_2 = \mu_2^0 + RT \ln [(2c_1 + c_2) c_2 y_{\pm 2}^2]$$

for the solute chemical potentials. Because the solutions were dilute (ionic strength ≤ 0.1 mol dm^{-3}), it was feasible to evaluate the activity-coefficient terms from Guggenheim

expressions (23)

[35] $$\ln \gamma_{\pm 1} = -[1.178\sqrt{I}/(1 + \sqrt{I})] + [(4B_1c_1 + (B_1 + 2B_2)c_2)/3]$$

[36] $$\ln \gamma_{\pm 2} = -[1.178\sqrt{I}/(1 + \sqrt{I})] + (0.5B_1 + B_2)c_1 + B_2c_2$$

The empirical ion-interaction coefficients $B_1 = 1.01$ and $B_2 = 0.08$ dm^2 mol^{-1} were determined from binary activity coefficients for each electrolyte (14, 24).

Experimental values of L_{ik} coefficients derived from the diffusion data are given in Table 5. Because it was necessary to take differences between numbers, the precision of the L_{ik} values is not as good as for the D_{ik} data. Nevertheless, the results are consistent with the Onsager reciprocal relation $L_{12} = L_{21}$ (25) which provides an independent check of the results.

Comparison of Tables 1 and 2 shows that the binary diffusivity for aqueous Na_2SO_3 solutions is similar to D_{11}, the ternary diffusivity of the salt in aqueous NaOH solutions. The mobility of Na^+ is about 35% larger than the mobility of SO_3^{2-}. When Na_2SO_3 diffuses, the induced electric field tends to slow down Na^+ and speed up SO_3^{2-} in order to keep the solution electrically neutral. If the solution contains NaOH, the electric field produces co-current flow of OH^-. Thus, values of the cross-diffusion coefficient D_{21} (which measure coupled flow of NaOH per unit gradient in concentration of Na_2SO_3) are positive. When NaOH diffuses in aqueous solutions of Na_2SO_3, highly mobile hydroxide ions ($\lambda^0(OH^-) = 0.01983$ m^2 S equiv.$^{-1}$ (26, 27)) can diffuse more rapidly than Na^+. In this case the relatively large electric field along the gradient in NaOH produces substantial counterflow of SO_3^{2-}. For this reason values of D_{12} are large and negative.

In Tables 2 and 5 experimental transport coefficients are compared with theoretical values estimated from the limiting mobilities of the diffusing ions by previously reported methods (28, 29). Though not quantitative, agreement is good. Trends in the observed transport coefficients are correctly predicted.

$SO_2(c_1') + NaOH(c_2') + H_2O$

Finally, we consider diffusion of sulfur dioxide dissolved in

		(2.83)	(−0.93)	(−3.18)	(2.59)

[a]Predicted values are in parentheses.

strongly alkaline solutions. If c_1', the formal concentration of the SO_2 component, is less than one-half of c_2', the formal concentration of the NaOH component, essentially all of the SO_2 component exists in solution not as molecular SO_2 but as Na_2SO_3 produced by the neutralization reaction (30)

$$SO_2(aq) + 2NaOH(aq) = Na_2SO_3(aq) + H_2O$$

$$K(298.15\ \mathrm{K}) = 1.05 \times 10^{19}\ (\mathrm{mol\ dm^{-3}})^{-2}$$

In this concentration region where SO_3^{2-} is the major transporting species for the SO_2 component the ternary diffusion coefficients D_{ik} for mixed electrolytes $Na_2SO_3(c_1)$ + $NaOH(c_2)$ are closely related to diffusion coefficients D_{ik}' for solutes $SO_2(c_1')$ + $NaOH(c_2')$.

What is the relation? Note that a solution of formal composition (c_1', c_2') is identical to one of composition (c_1, $c_2 + 2c_1$). The two sets of concentrations are related by

$$[37] \quad c_i' = \sum_{k=1}^{2} A_{ik} c_k$$

with $A_{11} = 1$, $A_{12} = 0$, $A_{21} = 2$, and $A_{22} = 1$. It is easily shown (7) that coefficients D_{ik} and D_{ik}' are related by the linear transformation

$$[38] \quad \mathbf{D}' = \mathbf{A}\mathbf{D}\mathbf{A}^{-1}$$

which gives

$$[39] \quad D_{11}' = D_{11} - 2D_{12}$$

$$[40] \quad D_{12}' = D_{12}$$

$$[41] \quad D_{21}' = 2D_{11} - 4D_{12} + D_{21} - 2D_{22}$$

$$[42] \quad D_{12}' = 2D_{12} + D_{22}$$

Table 6 gives diffusion coefficients for aqueous SO_2 + NaOH mixtures that were calculated from measurements on Na_2SO_3 + NaOH solutions.

The diffusivity of SO_2 in aqueous NaOH solutions, D_{11}', varies rapidly with composition. For solutions rich in NaOH, D_{11}' approaches the tracer diffusion coefficient of SO_3^{2-}, about 1.0×10^{-9} m^2 s^{-1} (6). But for higher proportions of SO_2, observed values of D_{11}' increase sharply and reach values significantly larger than the binary diffusivity of SO_2 at similar concentrations: 1.92×10^{-9} to 2.08×10^{-9} m^2 s^{-1} (31). The enhanced ternary diffusivity of the SO_2 component results from coupled flow of OH^-. When a gradient in concentration of the SO_2 component is formed in an aqueous solution of NaOH, the region of the system with the higher SO_2 concentration is depleted in free OH^- by formation of sulfite. As highly mobile OH^- diffuses rapidly towards this region, the induced electric field produces counterflow of SO_3^{2-} in order to maintain electroneutrality.

Received November 28, 1984

DONALD C. WIGFIELD and SEASON TSE. Can. J. Chem. **63**, 2940 (1985).

The kinetics of oxidation of zero-valent mercury by the horseradish peroxidase system are reported. The reaction is first order in mercury and first order in peroxidase compound I, and appear to obey these kinetics to completion of the reaction. The second order rate constant is 8.58×10^5 M^{-1} min^{-1} at 23°C. The data are consistent with a simple two-electron transfer from mercury to the iron–heme system of peroxidase with the enzyme acting as a chemical oxidant that is continually being regenerated by reaction with hydrogen peroxide.

DONALD C. WIGFIELD et SEASON TSE. Can. J. Chem. **63**, 2940 (1985).

On a déterminé la cinétique de l'oxydation du mercure (étant d'oxydation égal à zéro) par le système de la peroxydase du raifort. La réaction est du premier ordre en mercure et du premier ordre en composé I de la peroxydase et il semble que la réaction obéisse à cette loi jusqu'à ce qu'elle soit complète. La constante de vitesse du deuxième ordre est 8,58 × 10^5 M^{-1} min^{-1}, à 23°C. Les données sont en accord avec un transfert simple à deux électrons, du mercure au système fer–hème de la peroxydase, au cours duquel l'enzyme agit comme un oxydant chimique qui est constamment régénéré par une réaction avec le peroxyde d'hydrogène.

[Traduit par le journal]

One of the challenges of modern chemical toxicology is the transformation of chemical-induced clinical symptoms to the identification and study of the fundamental chemical reaction underlying the symptom. In the case of elemental mercury toxicity, much of the reaction identification work is already complete. Through the elegant and wide-ranging work of Clarkson, Magos, and Nielsen-Kudsk and their co-workers it has become clear that the crucial chemical step is the oxidation of zero-valent mercury to the divalent mercuric ion and that this oxidation is caused by the enzyme catalase (1–7). It is thought that this step occurs both in blood, where it would serve as a detoxifying reaction, preventing or lessening the migration of mercury to the brain, and also in the brain where the formation of mercuric ion would have disastrous consequences.

Recently we have demonstrated the utility of the cold vapor atomic absorption method for separate analysis of zero-valent and divalent mercury (8), and also established the conditions whereby the mercury oxidation by the catalase system can be studied in homogeneous solution (9). In addition, we found that the closely related enzyme peroxidase also acted effectively as an oxidant of mercury, although somewhat more slowly than the catalase oxidation (9). Although a detailed kinetic study of the catalase system has not yet been reported, we now wish to document the kinetics of the oxidation of mercury by peroxidase. These studies provide answers to some of the key questions on the mechanism of this fascinating reaction.

Results and discussion

Peroxidase, in common with catalase, is an enzyme possessing as a prosthetic group the ferriprotoporphyrin IX nucleus shown in Fig. 1. While peroxidases are widespread in both animal and plant sources, one of the richest is horseradish roots, and this enzyme (EC 1.11.1.7) has not only been extensively studied, but is also commercially available in purified form. Particularly good summaries of the structure and function of the peroxidases have been presented by Dunford and Stillman (1976) (10), and by Dunford (1982) (11). The molecular weight of horseradish peroxidase is about 42 000; it contains about 18% carbohydrate (11), and the primary structure of the polypeptide portion has been determined (12).

In considering the possible mechanisms by which mercury might be oxidized by peroxidase, we wished to address the following questions: (*1*) Is the oxidation a two-electron, one-step process, or a sequence of two one-electron steps? (*2*) What is the role, if any, of the mercurous state in the reaction? (*3*) What is the role of hydrogen peroxide in the reaction? (*4*) What is the species of enzyme that effects the oxidation? (*5*) What is the kinetic rate law and the overall rate constant for oxidation? (*6*) What is the active site on the enzyme that is used for mercury oxidation? (*7*) Is the oxidation truly enzymatic, or is the enzyme consumed in the process?

Our earlier work had shown a distinct difference in oxidizing capability between catalase and peroxidase (9). Catalase oxidizes mercury rapidly and effectively both in the presence and in the absence of hydrogen peroxide, perhaps indicating multiple mechanisms, but peroxidase, while oxidizing mercury effectively in the presence of hydrogen peroxide, was much more sluggish at achieving oxidation in its absence. The conditions we focussed on for the present study, then, had peroxidase, hydrogen peroxide, and elemental mercury as the species present. Figure 2 shows a typical disappearance of Hg^0 under these conditions, where the main variable is hydrogen peroxide concentration. Two features are noteworthy in this figure. Firstly, the problem of mercury adsorption is under control. This is a major technical problem in handling trace quantities of metals; however, the control points on the figure show that although approximately 10% of the mercury is lost in the first few seconds of the reaction, thereafter the amount of mercury remains essentially constant. The second point is that raising the hydrogen peroxide concentration from equimolar with peroxidase concentration over three orders of magnitude makes very little difference to the rate of mercury oxidation. Clearly the reaction is not dependent on the concentration of peroxide.

This is not a surprising result. Peroxidase is known to react rapidly and essentially irreversibly ($K \simeq 10^{14}$ M^{-1}) (13) to form the so-called peroxidase compound I (HRP-I), a species that contains one, and only one, atom of oxygen from peroxide attached to iron (14).

$$\text{HRP} \xrightleftharpoons{H_2O_2} \text{HRP-I}$$

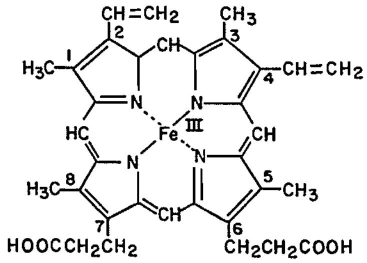

FIG. 1. The ferriprotoporphyrin IX prosthetic group of catalase and peroxidase.

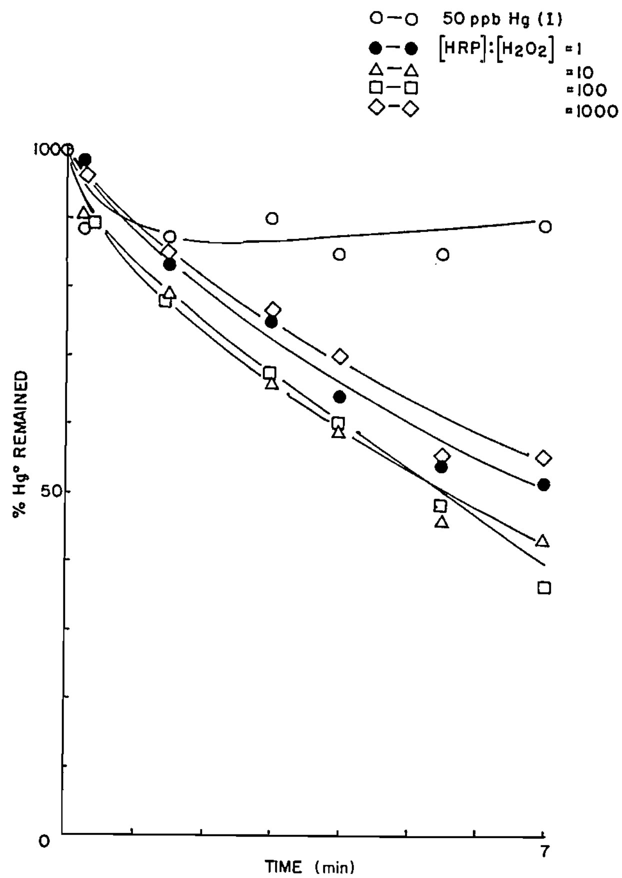

FIG. 2. Disappearance of mercury in the presence of HRP and variable concentrations of H_2O_2.

In the presence of adequate peroxide, then, the essentials of the reaction system consist only of mercury(0) and HRP-I.

Partly in order to avoid the adsorption complications that would arise from attempting to make many measurements on the initial portion of the reaction, in the classical enzyme kinetics fashion, we considered the possibility that the reaction would permit normal chemical kinetics treatment. Kinetically the reaction may be written:

$$\text{Rate} = k[\text{Hg}]^a[\text{HRP-I}]^b$$

and, if the rate law is unchanged throughout a significant portion of the reaction, the kinetic problem becomes one of determination of the powers a and b.

If hydrogen peroxide is in excess, and the consumed HRP-I can be rapidly recycled back to HRP-I by H_2O_2 (a critical assumption that is returned to later), the concentration of HRP-I throughout the reaction remains constant, and the system is set

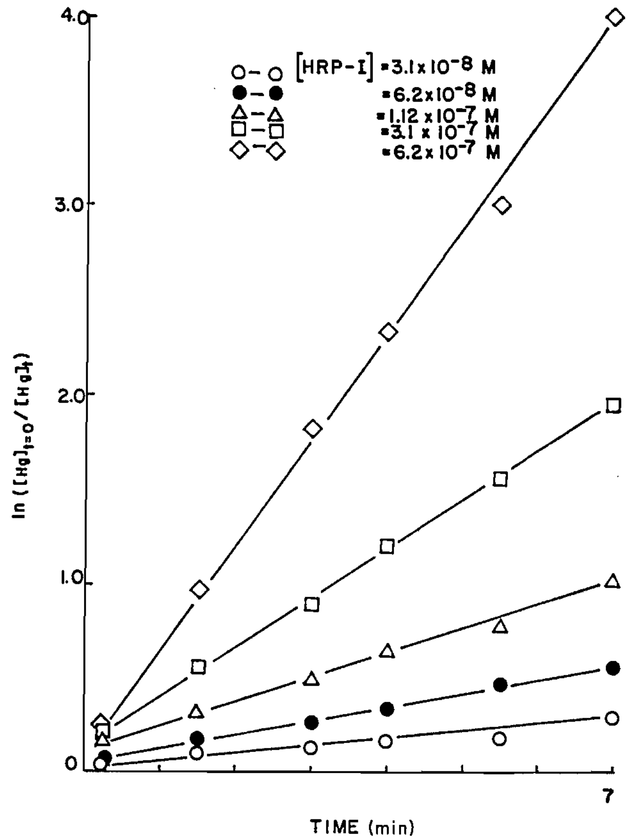

FIG. 3. First order plot of the logarithm of remaining Hg(0) as a function of time.

TABLE 1. Pseudo-first order rate constants for Hg(0) oxidation by HRP-I under homogeneous conditions; [Hg] = 1.24×10^{-7} M

[HRP] ($\times 10^8$ M)	[H_2O_2] ($\times 10^6$ M)	k (min^{-1})	Correlation coefficient
3.10	3.10	0.038±0.003	0.949
6.20	6.20	0.068±0.009	0.988
12.40	12.40	0.116±0.007	0.992

62.0	62.0	0.547±0.059	0.998

up for pseudo-order kinetics. The oxidation of mercury was therefore followed at various concentrations of HRP-I and the logarithmic first-order test of these data is shown in Fig. 3. The linearity of these plots clearly establish that the reaction is first order in mercury. It would be desirable to establish that the linearity of the first-order plots and the constancy of rate constant remain over a wide concentration range of mercury concentration. In practice, however, this cannot be done since there exists a factor of only about 20 between the maximum concentration of mercury obtainable in aqueous solution, and the minimum concentration that can reliably be analysed by cold vapor atomic absorption analysis.

The pseudo first order rate constants obtained at various concentrations of HRP-I are summarized in Table 1. To test whether the dependence on HRP-I was also first order, the plot of pseudo first order rate constant versus concentration is shown in Fig. 4 and is also linear. Thus the rate law may be written as:

$$\text{Rate} = k[\text{Hg(0)}]\,[\text{HRP-I}]$$

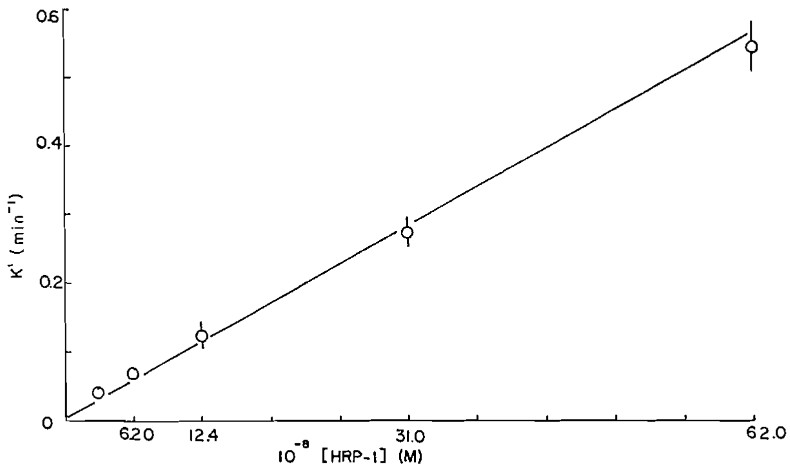

FIG. 4. Plot of pseudo first order rate constants of mercury oxidation as function of peroxidase compound I concentration.

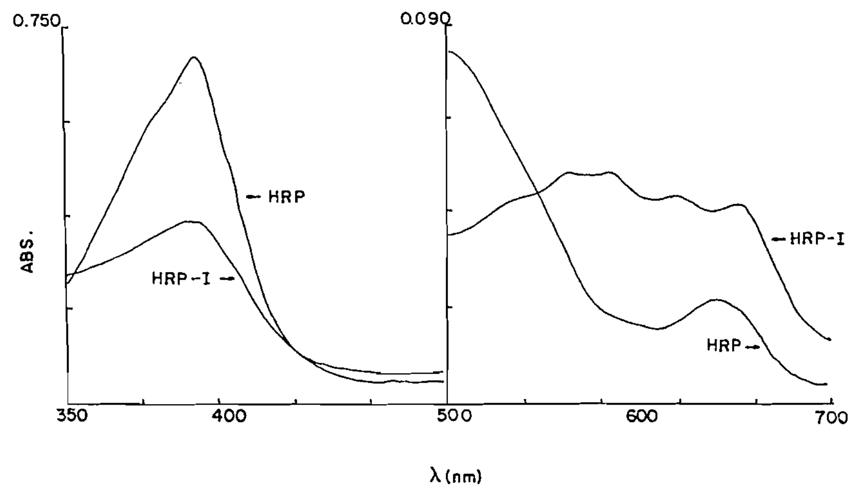

FIG. 5. Absorption spectra of HRP and HRP-I.

where $k = 8.58 \times 10^5\ M^{-1}\ \text{min}^{-1}$ at 23°C.

The fact that the reaction can be treated by this method, and in particular that pseudo-order kinetics hold, was based on the assumption of constant HRP-I concentration over a kinetic run, and this is an important finding that bears directly on the question of one- or two-electron steps in the oxidation. HRP-I is two oxidation states higher than native peroxidase. The complete oxidizing capability of hydrogen peroxide has been transferred to it. Between HRP-I and native enzyme, in terms of oxidation state, lies peroxidase compound II (HRP-II). This species is also an oxidizing agent, although less powerful than HRP-I. We have tested the oxidizing power of HRP-II to mercury and, as expected, mercury is oxidized although at a slower rate than by HRP-I. If HRP-I oxidizes mercury by a single two-electron step, then the HRP-I is reduced to native enzyme which can then be rapidly reconverted to HRP-I by hydrogen peroxide. The kinetic treatment above depends on this effective constant concentration of HRP-I, and the results are consistent with this scheme. On the other hand, if mercury were oxidized by a one-electron oxidation (initially to mercurous ion, which might then be further oxidized either directly or via disproportionation), HRP-I would be converted not to native enzyme but to HRP-II. This would severely upset the kinetics, because HRP-II can neither oxidize mercury as fast as HRP-I, nor can hydrogen peroxide rapidly convert HRP-II back to HRP-I. The only way in which the linear kinetics reported above, in which mercury and peroxidase are approximately equimolar, could be consistent with HRP-II formation would be the circumstance that HRP-II were an unusually effective oxidant of the mercurous ion, and experimentally this is not the case. It would appear, then, that the kinetic results are consistent only with a one-step two-electron oxidation of mercury directly to the mercuric ion.

Spectral confirmation of this conclusion was also obtained. The absorption spectra of HRP, HRP-I, and HRP-II are shown in Figs. 5 and 6 and are readily distinguishable. In fact most kinetic studies on peroxidase have made use of the spectral properties of the enzyme in order to follow reactions (11). Conducting the mercury oxidation by HRP-I, but not with excess hydrogen peroxide so that the enzyme cannot recycle back to HRP-I allows examination of the enzyme spectrum to see if there is any indication of HRP-II formation. In several trials, no such indication was obtained, consistent with the clean two-electron process deduced from the kinetic evidence.

Mechanistic conclusions

The questions posed at the outset of this article can now largely be answered. The species of enzyme that is the most

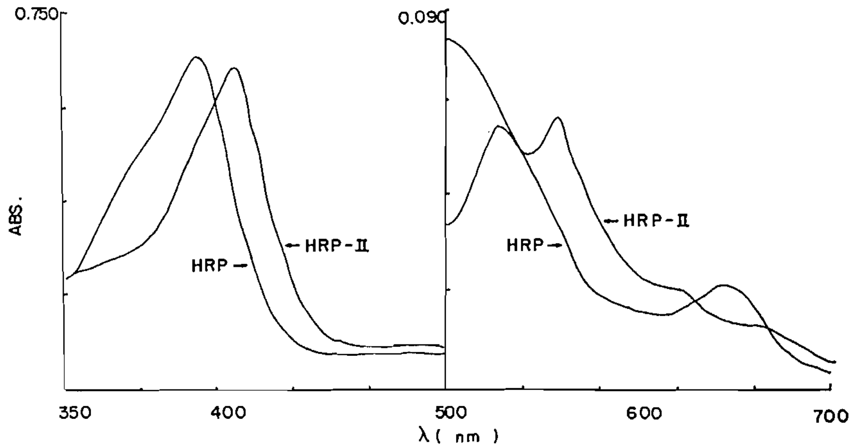

FIG. 6. Absorption spectra of HRP and HRP-II.

effective oxidant is HRP-I. This is a much more effective oxidant than native peroxidase and since the difference between these species is the addition of an oxygen atom at the iron of the heme prosthetic group, clearly, as in the case of all other reactions of peroxidase, this is the active site for the oxidation of mercury. The kinetics, supported by spectral evidence, show that the key step is a two-electron oxidation of Hg(0) to Hg(II), with HRP-I being converted back to native peroxidase in the process. The observation of linear chemical kinetics over all the observable reaction is itself of interest. On the one hand, it would appear that the reaction is a very simple one with HRP-I acting essentially as a recycling active oxidant rather than as a true enzyme; on the other hand, even in that case it is unusual that there is no evidence of product inhibition of the enzyme, since the mercuric ion would normally be expected to bind to almost any protein. This lack of product inhibition is probably a reflection of the total lack of involvement of any part of the enzyme in the reaction other than the heme prosthetic group.

The reaction may be summarized as follows:

$$\mathrm{Hg(0)} + \mathrm{HRP\text{-}I} \xrightarrow{k} \mathrm{HRP} + \mathrm{Hg(II)}$$

$$\mathrm{HRP} + \mathrm{H_2O_2} \xrightarrow{\text{fast}} \mathrm{HRP\text{-}I} + \mathrm{H_2O}$$

where $k = 8.58 \times 10^5\ M^{-1}\ \mathrm{min}^{-1}$.

The mechanism of HRP-I formation from HRP has already been extensively studied by Dunford and by others (11). The structure of HRP-I is now considered to involve the addition of a single oxygen atom to iron, with iron in the formal oxidation state of 5+. There is a great deal of evidence, however, that this oxidation state is more realistically depicted as 4+ by the transfer of an electron from the porphyrin ring system. This process may be represented as shown in Fig. 7. The crucial oxidation step following is presumably a simple two-electron transfer from mercury to oxygen, followed by cleavage of the iron-oxygen bond as shown in Fig. 7, thus producing mercury (II)[1] and iron (III).

[1]We have no further information on the subsequent fate of the Hg^{2+} formed. Although the usual form of HgO is zigzag—Hg—O—Hg— chains, it is soluble in water at the concentrations used here and is hydrolysed to form a so-called "hydroxide", actually an equilibrium mixture of several species. In the presence of other ions, other basic salts can be produced (15, 16).

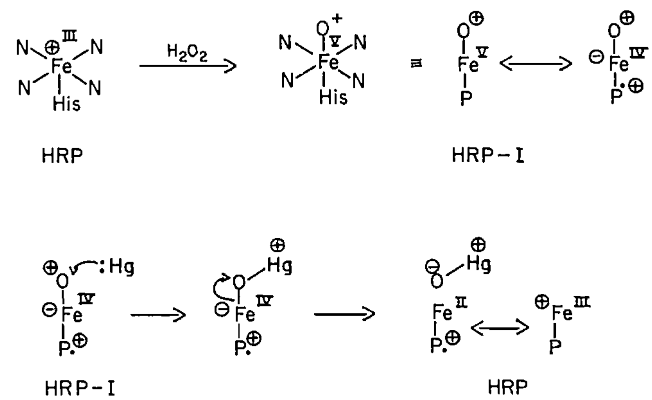

FIG. 7. Proposed mechanism of mercury oxidation.

Experimental

Reagents and solutions

Horseradish peroxidase (E.C.1.11.1.7, Type X)

Horseradish peroxidase was obtained as a $(NH_4)_2SO_4$ suspension (Sigma Chemical Co., St. Louis, MO., C-100). Solutions were freshly prepared by dissolving desired amounts of the enzyme in phosphate buffer (pH = 7.00, 0.05 M). The subsequent enzyme concentration was determined by the absorbance at 403 nm and the corresponding extinction coefficient (= $1.02 \times 10^4\ M^{-1}\ \mathrm{cm}^{-1}$). The R.I. value, an indicator of purity, was determined as the ratio of the absorbances at 403 and 280 nm.

Elemental mercury solutions

Phosphate buffer (250 mL, pH = 7.00, 0.05 M) was placed in a 500 mL two-neck round bottom flask, equipped with a septum and a side-arm. Distilled mercury (0.2 mL) was placed in the side arm and the vessel was shaken overnight, at room temperature, in a metabolic shaker.

Hydrogen peroxide

Hydrogen peroxide solutions were prepared daily from 30% stock solution (Anachemia Ltd., Montreal, Canada).

Mercury analysis

Mercury analysis by Cold Vapor Atomic Absorption, with separate determinations for elemental mercury and the mercuric ion, has been fully described previously (8).

Spectral studies

All spectral studies were performed in Beckman DU-7 U.V./Vis. Spectrophotometer. All scans were done using 1.5 mL quartz cells at a rate of 600 nm/min.

Preparation of HRP-I and HRP-II

HRP-I. Compound I was prepared by mixing (Vortex) 0.9 mL of phosphate buffer and the desired amount of HRP, and various equivalents of H_2O_2, in a 1.5 mL disposable micro test tube. Its presence was confirmed by obtaining the spectra prior to addition to mercury solutions.

HRP-II. One equivalent of HRP, H_2O_2, and ascorbic acid in phosphate buffer with a final volume of 1 mL, was mixed. The presence of HRP-II was confirmed by obtaining its absorption spectra prior to use.

Kinetic method

Into a 10 mL round bottom flask was placed 10 mL of buffered mercury solution. Initial mercury concentration was determined before the addition of any oxidants. The desired quantities of HRP and/or hydrogen peroxide were then added and mixing achieved by means of the sampling syringe for 15 s. The flask was stoppered with a glass stopper and sampling done with momentary removal of the stopper. Care was taken to ensure that the flask was neither shaken nor inverted, as these were found to contribute markedly to loss of mercury by surface adsorption. Control runs had mercury solution present, but no oxidant, and mixing and sampling were done in the same manner.

The thermal decomposition of cyclobutane-1,2-dione[1]

J.-R. CAO[2] AND R. A. BACK

Division of Chemistry, National Research Council of Canada, 100 Sussex Drive, Ottawa, Ont., Canada K1A 0R6

Received March 1, 1985

J.-R. CAO and R. A. BACK. Can. J. Chem. **63**, 2945 (1985).

The thermal decomposition of cyclobutane-1,2-dione has been studied in the gas phase at temperatures from 120 to 250°C and pressures from 0.2 to 1.5 Torr. Products were C_2H_4 + 2CO, apparently formed in a simple unimolecular process. The first-order rate constant was strongly pressure dependent, and values of k^∞ were obtained by extrapolation of plots of $1/k$ vs. $1/p$ to $1/p = 0$. Experiments in a packed reaction vessel showed that the reaction was enhanced by surface at the lower temperatures. Arrhenius parameters for k^∞, corrected for surface reaction, were $\log A$ (s^{-1}) = 15.07 (±0.3) and E = 39.3 (±2) kcal/mol. This activation energy seems too low for a biradical mechanism, and it is suggested that the decomposition is probably a concerted process. The vapor pressure of solid cyclobutane-1,2-dione was measured at temperatures from 22 to 62°C and a heat of sublimation of 13.1 kcal/mol was estimated.

J.-R. CAO et R. A. BACK. Can. J. Chem. **63**, 2945 (1985).

Opérant à des températures allant de 120 à 250°C et dans un intervalle de pression allant de 0,2 à 1,5 Torr, on a étudié la décomposition thermique de la cyclobutanedione-1,2. Les produits de la réaction sont le C_2H_4 + 2CO qui sont apparemment formés par une réaction unimoléculaire simple. La constante de vitesse d'ordre un dépend beaucoup de la température et l'extrapolation des courbes de $1/k$ vs. $1/p$ jusqu'à $1/p = 0$ permet d'obtenir la valeur de k^∞. Des expériences conduites dans un réacteur contenant un remplissage montrent que, à basse température, la surface de contact augmente la vitesse de la réaction. Les paramètres d'Arrhénius pour k^∞, corrigées pour tenir compte de la surface de contact, sont: $\log A$ (s^{-1}) = 15,07 (±0,3) et E = 39,3 (±2) kcal/mol. Cette énergie d'activation semble être trop faible pour un mécanisme biradicalaire et on suggère que la décomposition se fait probablement selon un mécanisme concerté. On a mesuré la tension de vapeur de la cyclobutanedione-1,2 solide à des températures allant de 22 à 62°C et on a évalué que sa chaleur de sublimation est égale à 13,1 kcal/mol.

[Traduit par le journal]

Introduction

Although cyclobutane-1,2-dione (hereafter CBD) was first prepared 14 years ago (1), no studies of its thermal or photochemical decomposition have been reported. It is an interesting example of an α-dicarbonyl compound locked into the usually less stable *cis* configuration; it is also of interest in relation to other cyclic ketones, especially cyclobutanone. Both cyclobutanone (2) and several simple α-dicarbonyl compounds (3–6) have been the subjects of recent research in this laboratory, and for comparison with these systems we have undertaken studies of the spectroscopy, photochemistry, and thermal decomposition of CBD in the vapor phase. The present paper describes the thermal decomposition.

Experimental

Apparatus and techniques were similar to those used previously (3–5). The thermal decomposition was studied in a simple static system, using a cylindrical quartz reaction vessel 11.5 cm long and 3.4 cm in diameter mounted in a tube furnace. A similar vessel packed with small quartz tubing was used to test surface effects. The gas-handling manifold, quartz-spiral pressure gauge, and reagent storage trap were all enclosed in an air thermostat usually held at 40°C, which permitted operation at vapor pressures up to 2.2 Torr (1 Torr = 133.3 Pa). Small quantities of CBD, a finely-divided yellow crystalline solid, were stored in a cold finger cooled by tap water. When required, this was warmed to 35°C, and the vapor allowed to accumulate in a reservoir at 40°C until the desired pressure was attained. A pyrolysis experiment was begun by expanding this vapor through a stopcock into the reaction vessel. This procedure, used previously with oxalic acid (7), was necessary because of the rather slow sublimation from the solid.

After the experiment, reagent and products were removed through traps held first at −196°C and then at −78°C, and products were measured by gas buret and by gas chromatography. Careful blank experiments were done to correct for small amounts of decomposition during the preparation and analysis procedures. CBD is light sensitive, and light was excluded throughout the experiments.

CBD was prepared by M. Hrytsak and his colleagues at the University of Ottawa, using methods in the literature (8). No impurities were detected by nmr and mass spectrometry, and the purity would appear to be ≥99%. It was sublimed once into the storage trap after thorough degassing, and sublimed again as described before use.

Results

Vapor pressure

The vapor pressure, not previously reported, was measured and is shown in a van't Hoff plot in Fig. 1. The straight line corresponds to $\log P$ (Torr) = 9.460 − (13100/2.3 RT) from which ΔH_{sub} = 13.1 kcal/mol.

Reaction products

The thermal decomposition was studied at temperatures of 120–250°C and pressures from 0.2 to 1.5 Torr. The only significant products observed were CO and C_2H_4; traces of CH_4 and CO_2 were seen, but these were less than 0.1% of the C_2H_4. The ratio C_2H_4/CO was found to be 0.48 ± 0.05, with perhaps a slight downward trend with increasing pressure within the experimental scatter. It appears that the thermal decomposition can be described to a good approximation by the simple reaction

[1]  ⟶ $C_2H_4 + 2CO$

Rate measurements

First-order rate constants were calculated for reaction [1] based on formation of C_2H_4, which could be more accurately

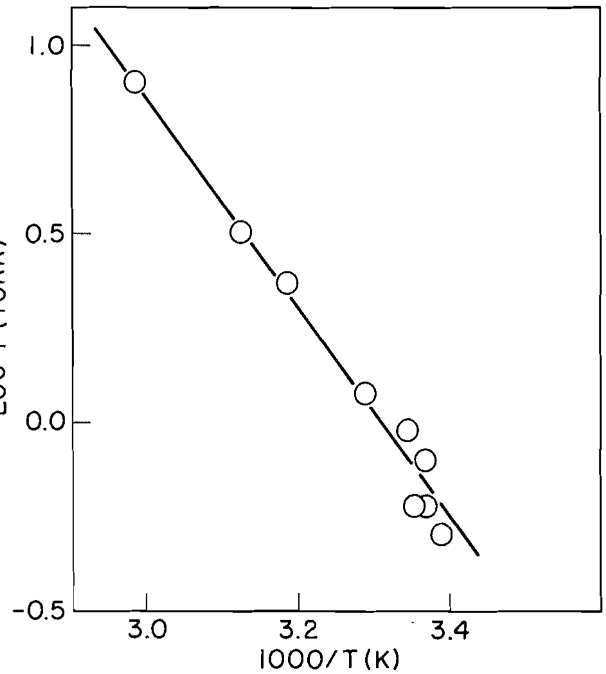

FIG. 1. The equilibrium vapor pressure of solid cyclobutane-1,2-dione.

TABLE 1. First-order rate constants for the decomposition of CBD ($s^{-1} \times 10^{-4}$)

T(°C)	k^{∞} (unpacked vessel)	k^{∞} (packed vessel)	k^0	k^{∞} (homogeneous)
175.6	1.05		0.20	0.85
181.0		4.41		
194.0	4.99		0.57	4.42
202.7		18.6		
206.4	20.1		1.2	18.9
225.9	83.3		0.04	83.8
235.9		112		
240.5	194		0.0	194

measured than CO. These were found to be independent of conversion (1–60%), confirming that no other reaction paths were important, but did show strong pressure dependence, increasing with increasing pressure (Fig. 2). Data for two temperatures are shown in a plot of $1/k$ vs. $1/p$ in Fig. 3, and from the intercepts of such plots, using least-squares analysis, values of k_1^{∞} were obtained, and are shown in Table 1.

Surface effects

Experiments in the packed vessel ($S/V = 5.6$, compared to 1.45 cm^{-1} in the unpacked vessel) showed enhanced rates of decomposition at temperatures below about 200°C. The first-order rate constants were again pressure dependent, and values of k_1^{∞} were obtained as before by extrapolation to $1/p = 0$, and are also shown in Table 1. Attempts to suppress the surface decomposition by the usual conditioning with a coating of pyrolytic carbon were unsuccessful, as this treatment had no significant effect in either reaction vessel. Surface reaction clearly makes a sizeable contribution at the lower temperatures, and initially a correction was made for this to the values of k_1^{∞} obtained in the unpacked vessel, based on the usual assumption that gas-phase and surface reactions were simply additive and that the latter was proportional to surface area. The corrected

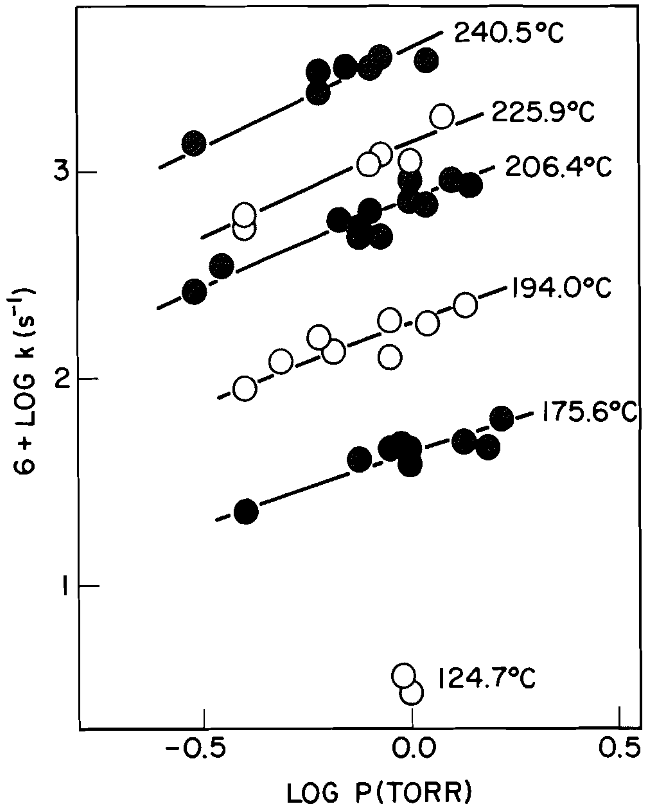

FIG. 2. The pressure dependence of the first-order rate constant, k_1, for the decomposition of cyclobutane-1,2-dione, measured in the unpacked reaction vessel and based on formation of ethylene.

values, however, led to an impossibly high frequency factor ($\sim 10^{17}$), and it appears that an overcorrection for surface reaction was made, probably through systematic differences in the extrapolation to $1/p = 0$ in the packed and unpacked vessels. Correction for surface reaction in the unpacked vessel was therefore finally made by a more direct method (suggested by a referee) in which K_1 at each temperature was extrapolated to $p = 0$ in a simple linear plot, and the intercept k^0 was taken as the first-order rate constant for the surface reaction. Values of k^0 were then simply subtracted from k^{∞} to yield corrected values of k^{∞} for the homogeneous reaction, all shown in Table 1. An Arrhenius plot of the corrected values (Fig. 4) gave $\log A$ (s^{-1}) = 15.07 (±0.3) and E = 39.3 (±2) kcal/mol.

Discussion

It seems well established that cyclobutane and most of its substituted derivatives decompose thermally by a biradical mechanism (9, 10). The case of cyclobutanone, however, most relevant to the present study, has been in some dispute. O'Neal and Benson (9, 10) calculated Arrhenius parameters for the biradical mechanism close to those observed for dissociation to $CH_2CO + C_2H_4$, with about equal rates for the two possible biradicals, $\dot{C}H_2CH_2CO\dot{C}H_2$ and $\dot{C}H_2CH_2CH_2\dot{C}O$, formed by β- and α-scission respectively. About 8 kcal/mol of resonance stabilization involving the carbonyl group appears to have been included in the calculation for both radicals, although it is not clear how this arises with $\dot{C}H_2CH_2CH_2\dot{C}O$. Subsequent measurements (11) of the heats of formation of the $\dot{C}H_2COCH_3$ and $\dot{C}H_2COC_2H_5$ radicals, however, gave estimates of the resonance stabilization of these species of 0 and 2.7 kcal/mol respectively, and it was suggested that the carbonyl group

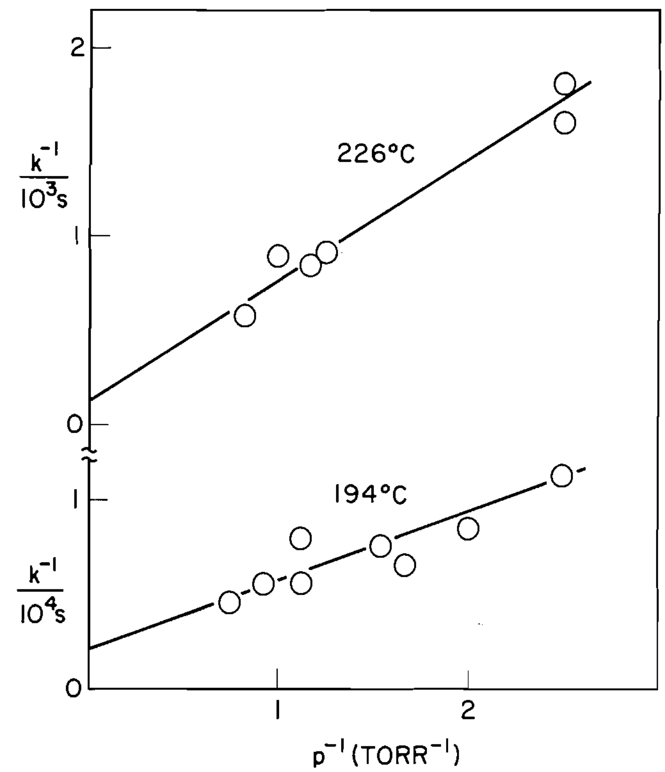

FIG. 3. Double reciprocal plots used to obtain k_1^∞.

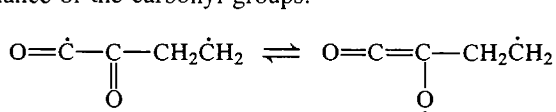
could not develop full allylic resonance. From these data, McGee and Schleifer (12) argued that the activation energy of 52 kcal/mol for dissociation of cyclobutanone was much too low to permit a biradical mechanism, and that the reaction must be concerted. Blades disputed this (13), arguing that uncertainties in the calculations were too great to allow any firm conclusion, and to the present time these arguments do not seem to have been resolved, at least in print. They are very relevant to the present work, since the biradical likely to yield C_2H_4 from CBD could be considerably stabilized by allylic resonance of the carbonyl groups:[3]



This biradical would also be stabilized relative to CBD by relief of the repulsion between the carbonyl groups, which can be taken as about 3 kcal/mol, the difference between the heats of formation of *cis-* and *trans-*glyoxal (6, 14). Taking this into account, an additional 10 kcal/mol of stabilization, persisting in the transition state, would still be needed to reach the 39.3 kcal/mol activation energy measured for CBD. All things considered, the activation energy seems much too low for a biradical mechanism, but in view of the uncertainties about the role of carbonyl groups in resonance structures, it is perhaps not impossible.

The alternative to a biradical mechanism is a concerted one, either a direct fragmentation to C_2H_4 + CO + CO, or perhaps to C_2H_4 + C_2O_2 followed by rapid dissociation of the latter, which appears to have little stability (15). It is interesting that

[3] The two other biradicals which could be formed from CBD would both tend to poduce ketene, which was not formed in the decomposition.

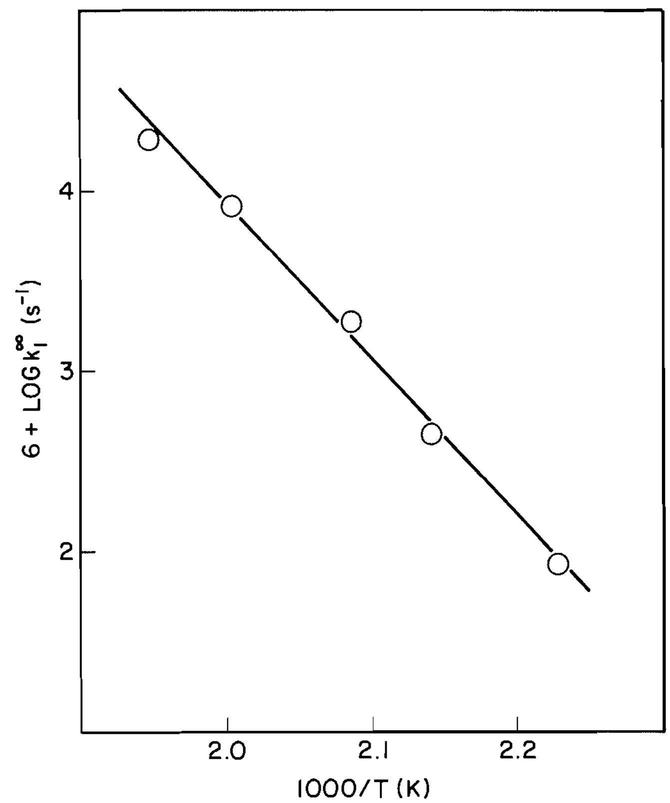


FIG. 4. Arrhenius plot of k_1^∞, corrected for surface reaction.

the analogous decomposition of *cis*-glyoxal to H_2 + 2CO is a major pathway in the thermal decomposition of glyoxal and in the dissociation of the vibrationally excited ground state excited photochemically (6, 16); Osamura *et al.* (17) have shown that the direct concerted dissociation to H_2 + CO + CO is an allowed process and appears to be the favored path of the reaction. The dissociation of CBD may be similar.

Finally, errors in the Arrhenius parameters are inherent in the need to correct simultaneously for dependence of k_1 on both pressure and surface reaction, both of which are in turn dependent on temperature. Extrapolations of k_1 to $1/p = 0$ and to $p = 0$ were relatively long and may have led to systematic errors; the confidence limits placed on the Arrhenius parameters reflect these uncertainties. Values of k^∞ at the higher temperatures, where surface effects were absent, should be fairly accurate, and since the frequency factor is relatively high when compared with those observed and calculated for many other biradical and concerted decompositions (9, 10), it seems unlikely that the activation energy can be much higher than 39 kcal/mol.

Controlled hydrolysis of *cis*-$[PtCl_2(PPh_2Cl)_2]$ gives *cis*-$[PtCl_2(PPh_2OH)_2]$ which crystallizes as a tetrahydrofuran solvate in the monoclinic space group $P2_1/n$, with a = 14.647(3), b = 15.089(3), c = 13.107(2) Å, β = 91.22(3)°. This is the first example of a complex containing a *cis*-$M(PR_2OH)_2$ group to be structurally characterized since further reaction to P—O---H---O—P ligand systems is the more usual outcome of such hydrolyses. An example of the latter type, $[Pd_2(\mu\text{-}Cl)_2\{(P(OEt)_2O)_2H\}_2]$, crystallizes in the monoclinic space group $P2_1/c$, a = 9.674(2), b = 20.722(5), c = 8.578(2) Å, β = 92.75(3)°. Complete X-ray diffraction studies are reported for both crystals. Synthesis and $^{31}P\{^1H\}$ and $^{195}Pt\{^1H\}$ nmr studies are reported for the complexes $[PtCl_2(PEt_3)(PR_2Cl)]$, R = OEt, Ph, Cy, Et, or Bu^t, which have *cis* stereochemistry except when R = Bu^t, and for *cis*-$[PtCl_2(PR_2Cl)_2]$, R = OEt, Ph, or Et, and also for the hydrolysis products, *cis*-$[PtCl_2(PEt_3)(PR_2OH)]$, R = OEt or Ph, and *cis*-$[PtCl_2(PR_2OH)_2]$, R = OEt, Ph, or Et. Analogous products for palladium are generally less stable and more difficult to characterize. The complex of products from hydrolysis of palladium/$P(OEt)_2Cl$ compounds is discussed in detail.

DAVID ERIC BERRY, KATHRYN ANNE BEVERIDGE, GORDON WILLIAM BUSHNELL et KEITH ROGER DIXON. Can. J. Chem. **63**, 2949 (1985).

L'hydrolyse contrôlée du $[PtCl_2(PPh_2Cl)_2]$-*cis* conduit au $[PtCl_2(PPh_2OH)_2]$-*cis* qui cristallise, sous la forme d'un produit de solvatation du tétrahydrofuranne, dans le groupe d'espace monoclinique $P2_1/n$ avec a = 14,647(3), b = 15,089(3), c = 13,107(2) Å, β = 91,22(3)°. Ce composé est le premier exemple d'un complexe comportant un groupement $M(PR_2OH)_2$-*cis* qui ait pu être caractérisé du point de vue de la structure; en effet, de telles hydrolyses provoquent des réactions subséquentes qui conduisent généralement au système de ligand P—O---H---O—P. Un exemple de ce dernier type, soit le $[Pd_2(\mu\text{-}Cl)_2\{(P(OEt)_2O)_2H\}_2]$, cristallise dans le groupe d'espace monoclinique $P2_1/c$ avec a = 9,674(2), b = 20,722(5), c = 8,578(2) Å et β = 92,75(3)°. On rapporte les études complètes de diffraction de rayons X pour les deux cristaux. On rapporte également la synthèse et des études de rmn du $^{31}Pt\{^1H\}$ et du $^{195}Pt\{^1H\}$ relatives aux complexes $[PtCl_2(PEt_3)(PR_2Cl)]$, R = OEt, Ph, Cy, Et ou *tert*-Bu, qui ont une stéréochimie *cis*, sauf dans le cas où R = *tert*-Bu, ainsi que pour les complexes $[PtCl_2(PR_2Cl)_2]$-*cis* où R = OEt, Ph ou Et et leurs produits d'hydrolyse, soit le $[PtCl_2(PEt_3)(PR_2OH)]$-*cis* où R = OEt ou Ph et le $[PtCl_2(PR_2OH)_2]$-*cis* où R = OEt, Ph ou Et. Les produits analogues du palladium sont en général moins stables et plus difficile à caractériser. On discute en détail des complexes résultant de l'hydrolyse des composés du type palladium/$P(OEt)_2Cl$.

[Traduit par le journal]

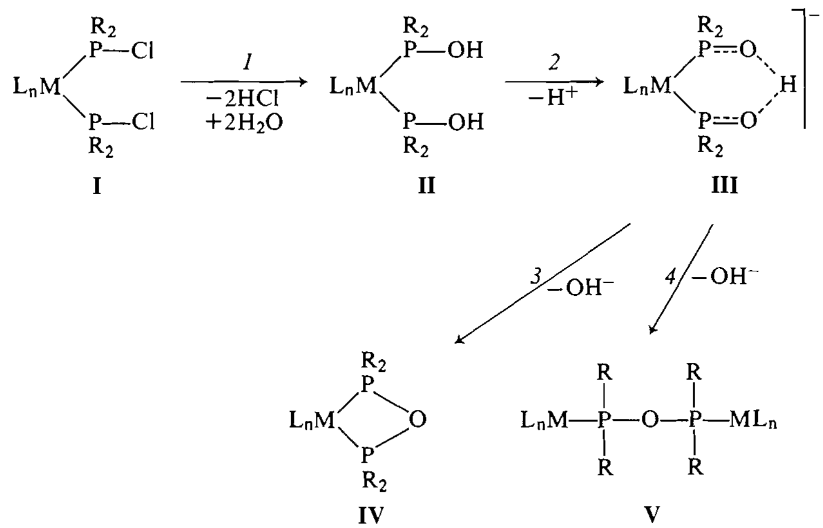
Introduction

The reactivity of phosphorus–chlorine bonds is of considerable importance in phosphorus ligand chemistry, since this group is the most usual choice of reactive function for the elaboration of phosphorus ligands (1). Typical examples are reactions with ROH reagents to form phosphorus ester linkages and reactions with Grignard or organolithium reagents to form phosphorus–carbon bonds. The added groups may be introduced to achieve steric or electronic modification of the ligand or sometimes to convert the ligand into a potential chelate or bridge; either using a group containing a second electron pair donor or a reactive function such as C—Cl which can be subsequently used to form another metal–ligand bond.

The chemistry of chlorine bound to coordinated phosphorus ligands is much less studied but potentially even more interesting, offering opportunities for the *in situ* elaboration of ligands or possibly the formation of bridges to other metal centres. Moreover, if *cis* arrangements of two chlorophosphine ligands can be obtained then template syntheses become a possibility. In this connection we note the contrast between the extensive development of chemistry of nitrogen macrocycles and the situation in phosphorus chemistry where macrocyclic ligands have been prepared only very recently (2), and where template syntheses are still a rarity (3).

Knowledge of hydrolysis reactions of these ligands is fundamental to any more extensive study, both to delineate possible reaction pathways and to prepare the ground for the ready identification of adventitious products in subsequent reactions. In the particular case of systems containing *cis*-$M(PR_2Cl)_2$ fragments one might expect a simple *cis*-$M(PR_2OH)_2$ group as the first hydrolysis product but in fact more complex and unusual products involving P—O—P and P—O---H---O—P linkages are normally isolated (4–11). As detailed below, the intermediacy of the hydroxyphosphine product is not well established but we propose that the hydrolysis reaction be logically divided into the steps shown in Scheme 1. The complete scheme has not been observed for any individual example and the actual sequence may vary. For example, the order of formation of **III** and **IV** (or **V**) is likely to depend on the acidity or basicity of the reaction medium and type **IV** complexes could also be intermediates in step **4**. However, Scheme 1 is a useful framework for discussion and a primary objective of the present work is to delineate each of the possible outcomes by structural studies.

In this paper we will report the first full characterisation and X-ray structural study of a type **II** complex, namely *cis*-$[PtCl_2(PPh_2OH)_2]$, obtained as the first hydrolysis product of *cis*-$[PtCl_2(PPh_2Cl)_2]$. Synthetic and spectroscopic results related to the first two steps of Scheme 1 will also be reported together with an X-ray diffraction study of a type **III** hydrolysis product, $[Pd_2(\mu\text{-}Cl)_2\{(P(OEt)_2O)_2H\}_2]$. In subsequent papers in this series we will report the details of novel hydrolysis prod-



SCHEME 1

ucts obtained when R = OEt; a structural study of a type **V** product; and further results on the chemistry and structure of metal complexes derived from type **III** products by the replacement of the hydrogen bonded proton by a metal.[1] It is therefore appropriate at the present stage to briefly review the principal literature relating to each step of Scheme 1.

Formation of a hydroxyphosphine complex as the first step in hydrolysis of a coordinated chlorophosphine is well established for cases where only a single chlorophosphine ligand is present. Early work by Chatt and Heaton (14) and by Kraihanzel and Bartish (15) showed, respectively, that *cis*-$[PtCl_2(PR_3)(PR_2Cl)]$ and $[Mo(PR_2Cl)(CO)_5]$ complexes are readily converted to the corresponding hydroxyphosphine derivatives. However, verification of the first step in hydrolysis of *cis*-$M(PR_2Cl)_2$ fragments is more difficult since the reaction normally continues on to type **III** complexes. Early thesis work by Austin (16) reported the formation of *cis*-$[MCl_2(PPh_2OH)_2]$ from the corresponding chlorophosphine complexes for both M = Pt and Pd but subsequent workers have isolated only type **III** products (5, 11). Thus, reaction of $PdCl_4^{2-}$ with PPh_2Cl in aqueous acetone yielded only the chlorobridged product, $[Pd_2Cl_2\{(PPh_2O)_2H\}_2]$ (11), and a reinvestigation of the hydrolysis of *cis*-$[PdCl_2(PPh_2Cl)_2]$ also failed to isolate the simple *cis*-$[PdCl_2(PPh_2OH)_2]$ species (5). Reaction of $PtCl_4^{2-}$ with PPh_2Cl in aqueous acetone gave essentially similar results (11) but the controlled hydrolysis of *cis*-$[PtCl_2(PPh_2Cl)_2]$ has not been reinvestigated. Results on complexes of other metals also indicate type **III** products as the most common end result of hydrolysis of *cis*-$M(PR_2Cl)_2$ fragments. Basic hydrolysis of *cis*-$[Mo(CO)_4(PPh_2Cl)_2]$ gives *cis*-$[Mo(CO)_4\{(PPh_2O)_2H\}]^-$ (5, 6); $[IrCl(COD)]_2$ with PPh_2Cl in aqueous methanol gives $[IrHCl(COD)\{(PPh_2O)_2H\}]$ (9, 10); and the corresponding reaction using $[RhCl(COD)]_2$ gives a triple chloride bridged product, $[Rh_2Cl_5\{(PPh_2O)_2H\}_2]^-$ (9). In the work on rhodium complexes the authors succeeded in isolating bis(hydroxyphosphine) derivatives, $[RhL_2\{P(OMe)_2OH\}_2]^+$, by direct reaction of $(MeO)_2P(O)H$ with hydrogenated $[Rh(diene)L_2]^+$ salts but not from hydrolyses of chlorophosphines (9). These workers have also observed the reverse of step *2* in Scheme 1. Thus $[IrHCl\{Ph_2As(CH_2)_2AsPh_2\}\{(PPh_2O)_2H\}]$ may be protonated by HBF_4 to give an unstable fluoroborate salt of the $[IrHCl\{Ph_2As(CH_2)_2AsPh_2\}(PPh_2OH)_2]^+$ cation. In $CHCl_3$ solution this salt spontaneously eliminates HF to give a BF_2 capped product, $[IrHCl\{Ph_2As(CH_2)_2AsPh_2\}\{(PPh_2O)_2BF_2\}]$ (10).

Conversion of a P—O---H---O—P to a chelating P—O—P ligand system (step *3* in Scheme 1) has been achieved by treatment of *cis*-$[Mo(CO)_4\{(PPh_2O)_2H\}]^-$ with either an acid chloride/triethylamine mixture (8) or with trifluoroacetic acid/anhydride mixture (7) to form *cis*-$[Mo(CO)_4(Ph_2POPPh_2)]$. The reaction can be reversed by base hydrolysis (7). This molybdenum complex and its chromium analog are the only known examples of chelating Ph_2POPPh_2 ligands and bridging or monodentate behaviour is much more common (7). It is therefore not surprising that we have not observed any type **IV** products in our studies of platinum and palladium complexes. However, details of the formation of $[Pt_2Cl_4\{(EtO)_2POP(OEt)_2\}_2]$, a type **V** complex with a double M—P—O—P—M bridge, by hydrolysis of *cis*-$[PtCl_2\{P(OEt)_2Cl\}_2]$ will be reported in a subsequent paper.

Results and discussion

(a) Synthesis and characterisation

During their early work on the hydrolysis of *cis*-$[PtCl_2(PEt_3)(PR_2Cl)]$ complexes, Chatt and Heaton (14) had only very limited ^{31}P nmr facilities available to them. This lack of data prompted us to begin our study with a re-examination and extension of these reactions. Cleavage of the chlorobridged dimer, $[Pt_2Cl_4(PEt_3)_2]$, with the chlorophosphines, PR_2Cl, R = OEt or Ph, followed by hydrolysis of the products essentially as described by Chatt and Heaton (14) confirmed the successive formation of *cis*-$[PtCl_2(PEt_3)(PR_2Cl)]$ and *cis*-$[PtCl_2(PEt_3)(PR_2OH)]$. We also prepared $[PtCl_2(PEt_3)(PR_2Cl)]$ complexes for R = Bu^t, Cy, or Et, and were able to establish the ^{31}P nmr data given in Table 1. These results require little comment. The shifts and coupling constants follow the expected trends with substituent electronegativity and the relatively small magnitudes of $^2J(P—P)$ combined with very large values of $^1J(Pt—P)$ indicate *cis* stereochemistry for all the complexes except $[PtCl_2(PEt_3)(PBu^t_2Cl)]$. In this last complex $^2J(P—P)$ is much larger and the Pt—P couplings correspondingly reduced, a clear indication that the high *trans* influence phosphorus ligands are mutually *trans* in the square plane.

[1]Preliminary accounts of parts of this work have been published previously (12, 13).

The only unusual result encountered in this preliminay work was the occasional formation of a novel triphosphite derivative, $[Pt_2Cl_3(PEt_3)_2\{\mu\text{-}P(O)(OP(OEt)_2)_2\}]$, during hydrolysis of *cis*-$[PtCl_2(PEt_3)\{P(OEt)_2Cl\}]$. This product has been the subject of a preliminary communication (12) and full details will be published in a subsequent paper. Under most conditions the hydrolysis results in the simple *cis*-$[PtCl_2(PEt_3)\{P(OEt)_2OH\}]$ complex described here.

The experience gained during this preliminary study suggested that derivatives of PPh_2Cl and $P(OEt)_2Cl$ were the most easily handled; with the former providing the greatest stability and the latter the greatest potential for unusual reactivity. In consequence we concentrated on these two cases in most of our further studies of *cis*-$M(PR_2Cl)_2$ fragments. Complexes containing these groupings are readily synthesized by reactions of $[MCl_2(PhCN)_2]$ complexes with the appropriate chlorophosphines and use of PPh_2Cl with *cis*-$[PtCl_2(PhCN)_2]$ in this process gave *cis*-$[PtCl_2(PPh_2Cl)_2]$ in high yield. A ^{31}P spectrum of this complex in dichloromethane solution showed a single resonance at +72.2 ppm with sidebands due to coupling to ^{195}Pt (^1J(Pt—P) = 4110 Hz); the large coupling being typical of phosphorus trans to chlorine and a clear proof of *cis* stereochemistry. Addition of 2 molar equiv. of water to this complex in tetrahydrofuran solution gave small changes in the nmr parameters (+70.7 ppm and 4065 Hz) which could easily be incorrectly dismissed as solvent effects. However, crystallization at −18°C, gave white crystals showing a very strong, moderately broad infrared absorption at 900 cm^{-1} comparable with the absorptions ca. 880 cm^{-1} reported by Chatt and Heaton for ν(P—OH) in *cis*-$[PtX_2(PR_3)(PR_2OH)]$ complexes (14). Broad absorption was also observed in the 3300−3400 cm^{-1} region as expected for ν(PO—H) (14), but the position and intensity of this absorption varied greatly with sample preparation as might occur with a variation in hydrogen bonding. Microanalysis and ^1H and ^{13}C nmr spectroscopy suggested the presence in the crystals of one molecule of tetrahydrofuran of crystallization.These preliminary data strongly suggested that the product was *cis*-$[PtCl_2(PPh_2OH)_2]$ but in view of previous doubts of the isolability of such species, coupled to our own experience with related Pd and $P(OEt)_2Cl$ systems we felt that confirmation by crystal structure determination was essential. The structure was confirmed by the diffraction results described below and we were subsequently able to demonstrate by microanalysis and ^{31}P nmr spectroscopy that *cis*-$[PtCl_2(PEt_2Cl)_2]$ can be prepared and converted to *cis*-$[PtCl_2(PEt_2OH)_2]$ in a similar manner (see Table 1 and Experimental section). Moreover, *cis*-$[PtCl_2(PPh_2OH)_2]$ can also be prepared by the simpler route of reaction of $Ph_2P(O)H$ with $[PtCl_2(COD)]$.

Thus our results support the early claim by Austin (16) to have isolated *cis*-$[PtCl_2(PPh_2OH)_2]$. With regard to the stability of these compounds it is interesting to note that in the reactions of MCl_4^{2-} salts with PPh_2Cl in aqueous acetone the primary product when M = Pt can be formulated as $[PtCl(PPh_2O)(PPh_2OH)_2]$ in contrast to the immediate formation of $[Pd_2(\mu\text{-}Cl)_2\{(PPh_2O)_2H\}_2]$ for the corresponding reaction when M = Pd (11). The platinum product probably does not contain a true $M(PPh_2OH)_2$ unit since infrared spectroscopy indicated that both hydrogens are involved in very strong hydrogen bonds to the oxygens (11), but in conjunction with the failure to isolate *cis*-$[PdCl_2(PPh_2Cl)_2]$ (5) the results do support the idea that POH groupings are generally more stable on Pt than they are on Pd.

The intermediacy of the type **II** complex in the hydrolysis to type **III** was confirmed by the ready reaction of *cis*-$[PtCl_2(PPh_2OH)_2]$ with 1,8-bis(dimethylamino)naphthalene ("proton sponge") to form $[Pt_2(\mu\text{-}Cl)_2\{(PPh_2O)_2H\}_2]$ in high yield.

Turning now to studies of $P(OEt)_2Cl$ complexes, we found that the hydrolyses were considerably more complex and that intermediate products are not easily isolated. Solutions of *cis*-$[MCl_2\{P(OEt)_2Cl\}_2]$ are readily prepared and characterised by ^{31}P nmr for both M = Pd (δ = +112.1 ppm) and M = Pt (δ = +83.4 ppm, ^1J(Pt—P) = 5777 Hz) but attempts to isolate solid products under normal laboratory conditions resulted in hydrolyzed derivatives of types **IV** or **V**. For M = Pt the product was the type **V** complex, $[Pt_2Cl_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$, which will be discussed more fully in a subsequent paper. The first hydrolysis product, *cis*-$[PtCl_2\{P(OEt)_2OH\}_2]$, was not isolated in this reaction but it can be prepared independently by the reaction of $[EtO)_2P(O)H$ with $[PtCl_2(COD)]$.

For M = Pd the type **III** product appears to be the most stable outcome as it was in the PPh_2Cl reactions mentioned above (11). In the present examples $[Pd_2(\mu\text{-}Cl)_2\{(P(OEt)_2O)_2H\}_2]$ is ultimately formed by hydrolysis of $P(OEt)_2Cl/[PdCl_2(PhCN)_2]$ reaction mixtures or by reaction of excess $(EtO)_2P(O)H$ with $[PdCl_2(PhCN)_2]$. The stability of the type **III** product was further illustrated by deliberate preparations of a type **V** product by reaction of $(EtO)_2POP(OEt)_2$ with $[PdCl_2(PhCN)_2]$ to give $[Pd_2Cl_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$. This product hydrolyzes in moist air, even in the solid state, to give $[Pd_2(\mu\text{-}Cl)_2\{(P(OEt)_2O)_2H\}_2]$. In view of the importance and stability of $[Pd_2(\mu\text{-}Cl)_2\{(P(OEt)_2O)_2H\}_2]$ we decided to undertake a full characterization by X-ray diffraction and details of this study are presented below. The detailed course of the reactions leading to $[Pd_2(\mu\text{-}Cl)_2\{(P(OEt)_2O)_2H\}_2]$ was much more difficult to establish because the sharpness and position of the ^{31}P resonances for the intermediate products tended to vary with solution conditions, most probably with water and acid concentration. These effects are probably caused by a complex series of pH dependent equilibria, most of which are rapid on the nmr time scale. The principal species involved in these reactions are: (*1*) *cis*-$[PdCl_2\{P(OEt)_2Cl\}_2]$, δ(P) +112.1 ppm (C_6H_6), observable as the first product of reaction of $P(OEt)_2Cl$ with $[PdCl_2(PhCN)_2]$; (*2*) *cis*-$[PdCl_2\{P(OEt)_2OH\}]_2$, δ(P) +81 to +82 ppm, observable as the first product of reaction of $(EtO)_2P(O)H$ with $[PdCl_2(PhCN)_2]$; (*3*) $[Pd_2Cl_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$, δ(P) +80.8 ppm ($CH_2Cl_2$), prepared by the reaction of $(EtO)_2POP(OEt)_2$ with $[PdCl_2(PhCN)_2]$ and also observed in some reactions of $P(OEt)_2Cl$; (*4*) $[Pd_2(\mu\text{-}Cl)_2\{(P(OEt)_2O)_2H\}_2]$, δ(P) +73.4 ppm ($CH_2Cl_2$), the ultimate product of most reactions under moist conditions; (*5*) A species with δ(P) +83.9 ppm (CH_2Cl_2), which results on addition of "proton sponge" to solutions of $[Pd_2(\mu\text{-}Cl)_2\{(P(OEt)_2O)_2H\}_2]$. This product is probably an anionic species resulting from proton abstraction; (*6*) a species with δ(P) +85.2 ppm, which results on addition of aqueous HCl to solutions of $[Pd_2(\mu\text{-}Cl)_2\{(P(OEt)_2O)_2H\}_2]$ in tetrahydrofuran. This product could be the result of bridge cleavage by chloride ion or possibly a dinuclear species containing *cis*-$Pd\{P(OEt)_2OH\}_2$ fragments formed by proton addition.

(b) Structures of cis-*$[PtCl_2(PPh_2OH)_2].C_4H_8O$, (I), and $[Pd_2(\mu\text{-}Cl)_2\{(P(OEt)_2O)_2H\}_2]$, (II)*

The atomic labelling schemes and the structures of single molecules of the complexes **I** and **II** are shown in Figs. 1 and 2, respectively. For **I** the associated tetrahydrofuran molecule

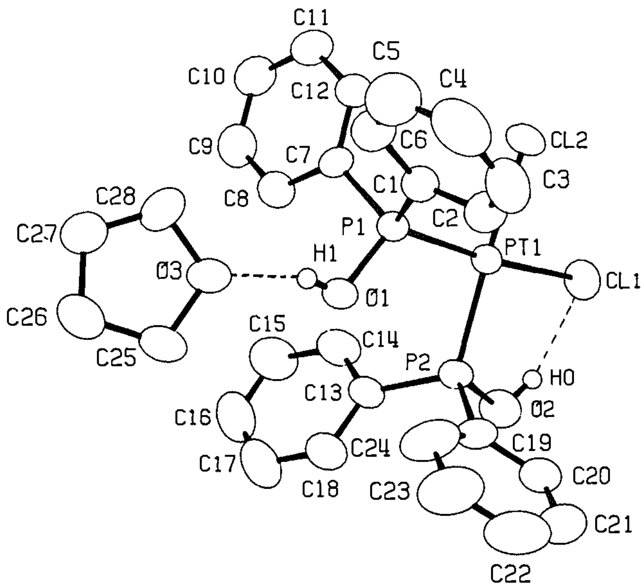


FIG. 1. ORTEP plot of compound **I**, *cis*-$[PtCl_2(PPh_2OH)_2].C_4H_8O$.

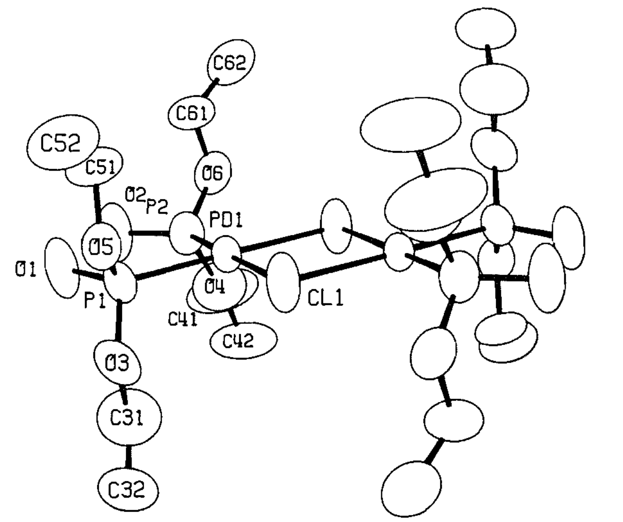

FIG. 2. ORTEP plot of compound **II**, $[Pd_2(\mu\text{-}Cl)_2\{(P(OEt)_2O)_2H\}_2]$. The unlabelled half of the molecule is related to the labelled half by a crystallographic centre of inversion.

is also shown. Fractional atomic coordinates and isotropic temperature parameters, bond lengths, and bond angles are collected in Tables 2–4 and 5–7, respectively. Further tables of atomic coordinates for the hydrogen atoms of **I**, together with anisotropic temperature factors, structure factors and selected intermolecular distances for both compounds have been deposited.[2]

The structure of **I** consists of a square planar platinum(II) centre in which the P(1)—Pt—P(2), 95.8(1)°, is slightly larger than the other three intraligand angles in order to accommodate the bulky PPh_2OH groups. The Pt—Cl lengths, average 2.364 Å, are entirely normal for chlorine *trans* to phosphorus, as are the Pt—P lengths, average 2.223 Å, for phosphorus *trans* to chlorine. For example the corresponding values in several complexes containing a *trans* Cl—Pt—P fragment ranged from 2.333 to 2.366 Å and from 2.241 to 2.262 Å, respectively (17). The angles at phosphorus which involve the platinum atom average 113°, considerably larger than the tetrahedral angle, but this is also a normal feature of tertiary phosphine complexes. The P—O bond lengths average 1.589 Å, somewhat longer than observed in the P—O---H---O—P complexes, $[Pd_2(\mu\text{-}SCN)_2\{(PPh_2O)_2H\}_2]$, 1.543 Å (18), $[Pd(S_2PMe_2)\{(PPh_2O)_2H\}]$, 1.545 Å (19), $[Mo(CO)_4\{(PPh_2O)_2H\}]^-$, 1.562 and 1.581 Å (20), and $[Mn(CO)_4\{(PPh_2O)_2H\}]$, 1.551 Å (21), but still well within the normal range of P—O single bonds (22).

The most interesting structural feature of **I** concerns the stabilization of the P—O—H groups by hydrogen bonding. This has been a consistent feature of all structures involving this group and in the present case is achieved for one ligand by intermolecular hydrogen bonding to the tetrahydrofuran of crystallization (O(1)---O(3) = 2.568(10) Å), and for the other ligand by an intramolecular hydrogen bond to a chlorine atom (O(2)---Cl(1) = 2.935(6) Å). These distances are longer than the 2.41 Å observed for intramolecular hydrogen bonds in the P—O---H---O—P complexes mentioned abvove (18–21) but, in the context of the ranges quoted by Stout and Jensen (23) for O---H---O (ca. 2.45–3.0 Å) and O---H---Cl (2.86–3.21 Å) hydrogen bonds, it is clear that all of the present values represent rather strong interactions. It is interesting that this is the second example which we have observed recently of involvement of a Pt—Cl group in an essentially ionic or electrostatic interaction to stabilize an unusual species. The other case was the Pt—Cl---Li---O—P linkage in *trans*-$[PtCl_2(PEt_3)\{CH(PPh_2O)_2Li\}]$ (24).

The structure of **II** confirms chlorine bridging rather than the alternative possibility of $P(OEt)_2O$ bridges with terminal chlorines and $P(OEt)_2OH$ groups. The two square planar palladium centres are separated by 3.488(1) Å and the Pd—Cl bonds average 2.393 Å which are normal distances for a bridged system without metal–metal interaction (25*a*). The Pd—P bonds average 2.220 Å, consistent with the low *trans* influence of chlorine (26–28) and the geometry of the P—O---H---O—P ligand is in accord with the previous studies of $[Pd_2(\mu\text{-}SCN)_2\{(PPh_2O)_2H\}_2]$ (18), $[Pd(S_2PMe_2)\{(PPh_2O)_2H\}]$ (19), $[Mo(CO)_4\{(PPh_2O)_2H\}]^-$ (20), and $[Mn(CO)_4\{(PPh_2O)_2H\}]$ (21). The intramolecular hydrogen bond, O(1)---O(2) 2.40 Å, is essentially identical in length to the previous examples (18–21) but the large temperature parameters associated with the ligand preclude any more detailed discussion of the bond lengths.

Experimental section

(a) Synthetic and spectroscopic studies

Data relating to the characterization of the complexes are given in Tables 1 to 7, the Results section, and in the preparative descriptions below. Microanalysis was by the Canadian Microanalytical Service, Vancouver, B.C., Canada. In general, the compounds tended to decompose on heating and melting points are not an especially useful method of characterization. Infrared spectra were recorded from 4000 to 200 cm^{-1} with an accuracy ±3 cm^{-1} on a Perkin–Elmer 283 spectrophotometer calibrated against polystyrene film. Solid samples were examined as Nujol mulls between caesium iodide plates.

^{31}P nmr spectra were recorded in appropriate solvents at either 24.3 MHz using a Nicolet TT14 Fourier transform spectrometer with a Varian HA60 magnet and an external C_6D_6 lock signal or at 101.3 MHz using a Bruker WP250 Fourier transform spectrometer locked to the solvent deuterium resonance. ^{195}Pt spectra were recorded at 53.5

[2]Copies of the depository material may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[a]Data from ref. 14. These workers used P_4O_6 as a phosphorus reference and we have converted the shifts assuming that P_4O_6 is at +113 ppm relative to 85% H_3PO_4.

[b]In d^8 THF solution, all other platinum spectra were recorded in $CDCl_3$.

[c]Chemical shifts (δ) are quoted in ppm relative to 85% H_3PO_4 for phosphorus and relative to $\Xi(^{195}Pt)$ = 21.4 MHz for platinum (see ref. 29). For the platinum resonances the absolute values of Ξ inMHz are also quoted. Coupling constants (*J*) are in Hz. The listed solvents are for the phosphorus spectra. Data for other ligands and complexes are included in the text.

MHz using the Bruker instrument. For both nuclei protons were decoupled by broad band ("noise") irradiation at appropriate frequencies. ^{31}P chemical shifts were measured relative to external $P(OMe)_3$ and are reported in ppm relative to 85% H_3PO_4 using a conversion factor of +141 ppm. ^{195}Pt chemical shifts are reported in ppm relative to $\Xi(^{195}Pt)$ = 21.4 MHz (29). Positive values are downfield of the references. Phosphorus chemical shifts for the various ligands employed in this work were as follows: PPh_2Cl, +83.0 ppm (THF or CH_2Cl_2); PEt_2Cl, +121.0 ppm (CH_2Cl_2); PCy_2Cl, +129.6 ppm (CH_2Cl_2); $PBu^t{}_2Cl$, +148.7 ppm (CH_2Cl_2); $P(OEt)_2Cl$, +167.3 ppm (CH_2Cl_2), +166.8 ppm (C_6H_6); $(EtO)_2P(O)H$, +8.2 ppm (CH_2Cl_2), +7.4 ppm (THF), +7.2 ppm (C_6H_6); $Ph_2P(O)H$, +26.5 ppm (CH_2Cl_2), +20.6 ppm (THF); $(EtO)_2POP(OEt)_2$, +129.5 ppm (CH_2Cl_2), +128.6 ppm (C_6H_6).

Except as noted below, all operations were carried out at ambient temperature (ca. 25°C) under an atmosphere of dry nitrogen using standard Schlenk tube techniques. Solvents were dried by reflux over appropriate reagents (phosphorus pentoxide for dichloromethane and potassium/benzophenone for tetrahydrofuran, toluene, benzene, and hexane) and were distilled under nitrogen prior to use.

The chlorophosphines PR_2Cl were commercially available, R = Ph or OEt (Aldrich Chemical Co.), R = Bu^t (Strem Chemicals Inc.), R = Et or Cy (Alfa Ventron Corporation), and were used as received, as were $(EtO)_2POP(OEt)_2$, $(EtO)_2P(O)H$, 1,8-bis(dimethylamino)naphthalene ("proton sponge"), and 1,5-cyclooctadiene (COD) from the Aldrich Chemical Co. [$MCl_2(PhCN)_2$], M = Pd or Pt (25*b*), [$PtCl_2$(COD)] (31), and [$Pt_2Cl_4(PEt_3)_2$] (32), were prepared as previously described.

Recrystallizations from solvent pairs were by dissolution of the complex in the first solvent (using about double the volume required for complete solution) followed by dropwise addition of sufficient second solvent to cause turbidity at ambient temperature. Crystallization was then completed either by continued very slow dropwise addition of the second solvent or, in those cases where a temperature is indicated in the detailed descriptions below, by setting the mixture aside at a reduced temperature.

[PtCl$_2$(PEt$_3$)(PR$_2$X)], X = Cl or OH

(i) R = Ph. These complexes were prepared essentially as described by Chatt and Heaton (14).

(ii) R = OEt. A typical reaction involved dropwise addition of $P(OEt)_2Cl$ (0.1 mL, 0.7 mmol) to a stirred solution of [$Pt_2Cl_4(PEt_3)_2$] (0.25 g, 0.33 mmol) in dichloromethane (20 mL). The initial yellow colour was immediately discharged but stirring was continued for 1 h before removal of the solvent *in vacuo*. Recrystallization of the residue from dichloromethane/pentane gave *cis*-[$PtCl_2(PEt_3)\{P(OEt)_2Cl\}$] (0.20 g, 0.37 mmol) as colourless crystals. *Anal.* calcd. for $C_{10}H_{25}Cl_3O_2P_2Pt$: C 22.2, H 4.66; found: C 22.5, H 4.73. In a separate experiment hydrolysis of the crude product was achieved by heating the residue for 4 h under reflux in a mixture of aqueous HCl (5 mL, 12 *M*) and acetone (20 mL). After removal of solvent under reduced pressure the residue was extracted with dichloromethane and the extract recrystallized from dichloromethane/pentane to give *cis*-[$PtCl_2(PEt_3)\{P(OEt)_2OH\}$] as yellow crystals (0.18 g, 0.34 mmol). *Anal.* calcd. for $C_{10}H_{26}Cl_2O_3P_2Pt$: C 23.0, H 5.02; found: C 22.8, H 4.97.

(iii) R = Bu^t, Et or Cy. Preparations of [$PtCl_2(PEt_3)(PR_2Cl)$] complexes for these R groups were similar to the above procedure for R = OEt except that the crystals for R = Bu^t were yellow, consistent with the *trans* stereochemistry of this product. *Anal.* R = Bu^t, calcd. for $C_{14}H_{33}Cl_3P_2Pt$: C 29.8, H 5.89; found: C 29.5, H 5.92; R = Cy, calcd. for $C_{18}H_{37}Cl_3P_2Pt$: C 35.0, H 6.05; found: C 35.0, H 6.13. The R = Et complex was identified by ^{31}P nmr (see Table 1) but could not be obtained analytically pure. Attempts at hydrolyses of all three complexes gave generally inconsistent results and pure products were not isolated.

cis-*[PtCl$_2$(PR$_2$X)$_2$], X = Cl or OH*

(i) R = Ph. PPh_2Cl (0.152 mL, 0.847 mmol) was added to a stirred solution of [$PtCl_2(PhCN)_2$] (0.200 g, 0.424 mmol) in dichloromethane. The initial yellow colour was discharged during stirring for 15 min,

[a]Estimated standard deviations are given in parentheses; coordinates $\times 10^n$ where n = 5, 5, 5, 4, 4, 3 for Pt, Cl, P, O, C, H; temperature parameters $\times 10^n$ where n = 4, 4, 4, 3, 3, 2 for Pt, Cl, P, O, C, H; U_{eq} = the equivalent isotropic temperature parameter = $(1/3)\Sigma_i\Sigma_j U_{ij} a_i^* a_j^* (\mathbf{a}_i \cdot \mathbf{a}_j)$; primed values indicate that U_{iso} is given; $T = \exp[-(8\pi^2 U_{iso} \sin^2\theta/\lambda^2)]$.

after which the solvent was removed *in vacuo* to leave *cis*-$[PtCl_2(PPh_2Cl)_2]$ as a white residue. Tetrahydrofuran (20 mL) and water (50 μL) were added and the resulting slurry stirred for 3 h. The solvent was removed *in vacuo* and the residue recrystallized from tetrahydrofuran/hexane at −20°C to give white crystals of *cis*-$[PtCl_2(PPh_2OH)_2]$.THF (0.177 g, 0.238 mmol). *Anal.* calcd. for $C_{28}H_{30}Cl_2O_3P_2Pt$: C 45.3, H 4.07; found: C 45.3, H 3.87.

In a separate experiment the intermediate *cis*-$[PtCl_2(PPh_2Cl)_2]$ complex was recrystallized from dichloromethane/pentane and characterized by ^{31}P nmr (see Table 1). *Anal.* calcd. for $C_{24}H_{20}Cl_4P_2Pt$: C 40.8, H 2.85; found: C 41.0, H 2.73.

(ii) R = Ph. Water (30 μL, 1.7 mmol) was added to a solution of PPh_2Cl (0.20 mL, 1.1 mmol) in tetrahydrofuran (2 mL). ^{31}P spectra showed complete conversion of PPh_2Cl (δ(P) +83.0 ppm) to $Ph_2P(O)H$ (δ(P) +20.6 ppm). Addition of this solution to $[PtCl_2(COD)]$ (0.186 g, 0.50 mmol) in tetrahydrofuran (10 mL) gave complete conversion to *cis*-$[PtCl_2(PPh_2OH)_2]$ as identified by ^{31}P nmr (see Table 1).

(iii) R = Ph, X = OH, reaction with 1,8-bis(dimethylamino)naphthalene. "Proton sponge" (0.043 g, 0.20 mmol) was added to a stirred solution of *cis*-$[PtCl_2(PPh_2OH)_2]$.THF (0.147 g, 0.20 mmol) in tetrahydrofuran (8 mL). After 1 h the ^{31}P spectrum showed complete conversion to $[Pt_2(\mu\text{-}Cl)_2\{(PPh_2O)_2H\}_2]$ (δ(P) +51.2 ppm, ^1J(Pt—P) 3960 Hz, Ξ(^{195}Pt) 21.385916 MHz, δ(^{195}Pt) −658 ppm in $CDCl_3$), the identity of which was confirmed by comparison with an authentic sample prepared as previously described (11).

[a]Estimated standard deviations are given in parentheses.

(iv) R = Et. PEt_2Cl (0.160 mL, 1.26 mmol) was added to a slurry of $[PtCl_2(PhCN)_2]$ (0.30 g, 0.64 mmol) in toluene (20 mL). Stirring was continued for 15 h but at the end of this time some yellow solid still remained and was removed by filtration. Evaporation of the supernatant *in vacuo* gave *cis*-$[PtCl_2(PEt_2Cl)_2]$ as a white residue, identified by ^{31}P nmr (see Table 1). Addition of 2 molar equiv. of water to a solution of this product in tetrahydrofuran (5 mL) gave total conversion to *cis*-$[PtCl_2(PEt_2OH)_2]$, identified by ^{31}P nmr (see Table 1). Removal of solvent *in vacuo* followed by recrystallization of the residue from tetrahydrofuran/hexane gave *cis*-$[PtCl_2(PEt_2OH)_2]$ as white crystals. *Anal.* calcd. for $C_8H_{22}Cl_2O_2P_2Pt$: C 20.1, H 4.64; found: C 20.5, H 4.53.

(v) R = OEt. $P(OEt)_2Cl$ (0.20 mL, 1.4 mmol) was added dropwise to a stirred solution of $[PtCl_2(PPhCN)_2]$ (0.30 g, 0.64 mmol) in dichloromethane (10 mL). The initial yellow colour was slowly discharged during stirring for 6 h. The solvent was removed *in vacuo* and the resulting colourless oil characterised as *cis*-$[PtCl_2\{P(OEt)_2Cl\}_2]$ by ^{31}P nmr (see Table 1). Repeated attempts at recrystallization caused conversion of the product to $[Pt_2Cl_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$ which will be discussed in detail in a subsequent paper.

(vi) R = OEt. $(EtO)_2P(O)H$ (0.200 mL, 1.55 mmol) was added to a suspension of $[PtCl_2(COD)]$ (0.273 g, 0.730 mmol) in tetrahydrofuran (15 mL). After stirring for 2 h the solvent was removed *in vacuo* and the residue recrystallized from tetrahydrofuran/hexane at −20°C to yield *cis*-$[PtCl_2\{P(OEt)_2OH\}_2]$ as colourless crystals. *Anal.* calcd. for $C_8H_{22}Cl_2O_6P_2Pt$: C 17.7, H 4.09; found: C 17.9, H 4.12.

Reactions of $[PdCl_2(PhCN)_2]$

(i) With $P(OEt)_2Cl$. A solution of $P(OEt)_2Cl$ (0.10 mL, 0.70 mmol) in benzene (2 mL) gave a ^{31}P nmr resonance at +166.8 ppm. Addition of $[PdCl_2(PhCN)_2]$ (0.135 g, 0.35 mmol) caused an almost immediate change to primarily a single resonance at +112.1 ppm attributed to *cis*-$[PdCl_2\{P(OEt)_2Cl\}_2]$. Approximately 2 molar equiv. of water were

[a]Estimated standard deviations are given in parentheses.

added and the resonance shifted to +87.3 ppm, consistent with the formation of $[Pd_2(\mu\text{-}Cl)_2\{(P(OEt)_2O)_2H\}_2]$ and HCl. Addition of "proton sponge" to absorb the HCl caused some precipitation but both the precipitate and the solid isolated from the supernatant showed a single ^{31}P nmr resonance at +84.3 ppm in dichloromethane. These reasonance positions may be compared with the +85.2 ppm and +83.9 ppm reported below for the respective deliberate addition of aqueous HCl or "proton sponge" to $[Pd_2(\mu\text{-}Cl)_2\{(P(OEt)_2O)_2H\}_2]$.

Attempts to employ this reaction on a preparative scale led to inconsistent results. On one occasion $[Pd_2Cl_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$ was probably isolated (δ(P) +80.8 ppm, lit. +80.3 ppm (33). *Anal.* calcd. for $C_{16}H_{40}Cl_4O_{10}P_4Pd_2$: C 22.1, H 4.63; found: C 22.3, H 4.09), a further indication of the sensitivity of these reactions to the precise conditions.

(ii) with $(EtO)_2P(O)H$. Excess $(EtO)_2P(O)H$ (0.5 mL, 3.9 mmol) was added dropwise to a stirred solution of $[PdCl_2(PhCN)_2]$ (0.2 g, 0.5 mmol) in dichloromethane (20 mL). After stirring for 4 h the initially orange solution had become colourless. Solvent and excess phosphite were removed *in vacuo* and the resulting oil washed with portions of hexane and dried *in vacuo* until $[Pd_2(\mu\text{-}Cl)_2\{(P(OEt)_2O)_2H\}_2]$ (0.058 g, 0.070 mmol) was obtained as a colourless solid.

TABLE 7. Bond angles (deg) for **II**, $[Pd_2(\mu\text{-}Cl)_2\{(P(OEt)_2O)_2H\}_2]$

Atoms	Angle	Atoms	Angle
P(1) —Pd(1) —Cl(1)	90.6(1)	P(2) —Pd(1) —Cl(1)	176.1(1)

[a]Estimated standard deviations are given in parentheses.

Anal. calcd. for $C_{16}H_{42}Cl_2O_{12}P_4Pd_2$: C 23.0, H 5.08; found: C 22.70, H 5.27. The structure of this product was confirmed by the X-ray diffraction study described below. Its ^{31}P nmr spectrum in dichloromethane showed a single resonance at +73.4 ppm shifting to +83.9 ppm on the addition of "proton sponge". Addition of a drop of aqueous HCl to a solution in tetrahydrofuran shifted the resonance to +85.2 ppm.

Other experiments showed that the use of stoichiometric quantities of $(EtO)_2P(O)H$ in the above procedure gave incomplete conversion of the starting materials and also showed the presence of an intermediate product, probably $[PdCl_2\{P(OEt)_2OH\}_2]$, with δ(P) in the range +81 to +82 ppm.

(iii) With $(EtO)_2POP(OEt)_2$. $(EtO)_2POP(OEt)_2$ (0.142 mL, 0.58 mmol) was added dropwise to a stirred solution of $[PdCl_2(PhCN)_2]$ (0.20 g, 0.52 mmol) in benzene (10 mL). An immediate colour change from orange to pale yellow was observed but stirring was continued for 30 min before removal of solvent *in vacuo*. The residue was recrystallized from dichloromethane/hexane at −20°C to give $[Pd_2Cl_4\{(\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$ as colourless crystals (0.096 g, 0.11 mmol) characterised by a single ^{31}P nmr resonance at +80.8 ppm in dichloromethane solution (lit. +80.3 (33)).

One batch of crystals was exposed to moist air for several days resulting in complete conversion to a new product with δ(P) +73.1 ppm in dichloromethane or tetrahydrofuran solution. A second batch of crystals was studied by ^{31}P nmr during gradual addition of water to a solution in tetrahydrofuran. The ultimate product showed a broad resonance at +74 ppm but intermediate spectra showed a gradual shift to this position and also a weak transient intermediate resonance at +68 ppm. Addition of proton sponge to the final solution resulted in a single sharp resonance at +83.9 ppm. These results are consistent with a complex pH dependent equilibrium as discussed in the Results and Discussion section. The ultimate hydrolysis product, δ(P) +74 ppm, is $[Pd_2(\mu\text{-}Cl)_2\{(P(OEt)_2O)_2H\}_2]$.

(b) X-ray data collection

Compound **I**, *cis*-$[PtCl_2(PPh_2OH)_2]$, was prepared by the first method described above (i.e. by hydrolysis of *cis*-$[PtCl_2(PPh_2Cl)_2]$) and crystals suitable for study by X-ray diffraction were grown at −18°C from a solution of the complex in tetrahydrofuran. The crystals subsequently proved to contain 1 mol of tetrahydrofuran. Compound **II**, $[Pd_2(\mu\text{-}Cl)_2\{(P(OEt)_2O)_2H\}_2]$ was crystallized by vapour diffusion of hexane into a solution of the complex in dichloromethane. Preliminary photographic work on both compounds was carried out with Weissenberg and precession cameras using Cu K_α radiation. After establishment of symmetry and approximate unit cells the crystals were transferred to a Picker 4-circle diffractometer automated with a PDP11/10 computer and utilising Zr filtered Mo K_α radiation (λ = 0.71069 Å). The unit cells were refined by least-squares methods employing, respectively, 31 and 11 pairs of centering measurements at ±2θ in the ranges |2θ| = 17−43° (**I**) and 19−30° (**II**). The crystals were mounted approximately along the *c* axes. The crystal data at approximately 24°C were as follows:

$C_{28}H_{30}Cl_2O_3P_2Pt$ mw = 742.49
Monoclinic, space group $P2_1/n$; a = 14.647(3), b = 15.089(3), c = 13.107(2) Å; β = 91.22(3)°; V(cell) = 2896(1) Å^3; D_m = 1.692 g cm^{-3} (flotation in $CCl_4/CHBr_3$), D_c = 1.705 g cm^{-3}; Z = 4; asymmetric unit = one molecule of complex with one molecule of tetrahydrofuran.

$C_{16}H_{42}Cl_2O_{12}P_4Pd_2$ mw = 834.10
Monoclinic, space group $P2_1/c$; a = 9.674(2), b = 20.722(5), c = 8.578(2) Å; β = 92.75(3)°; V(cell) = 1717.6(6) Å^3; D_m = 1.59 g cm^{-3} (flotation in CCl_4/*m*-xylene), D_c = 1.61 g cm^{-3}; Z = 2; asymmetric unit = half molecule.

Intensity measurements for both compounds were collected for two reciprocal space octants (h unrestricted, $k \geq 0$, $l \geq 0$). For **I** measurements extended up to 2θ = 50°. A θ/2θ step scan was used with 160 steps of 0.01° in 2θ, counting for 0.25 s per step. Background measurements were for 20 s at each end of the scan. Measurements for **II** were to 2θ = 50° with 200 steps of 0.01° in 2θ, counting for 0.25 s per step and with background measurements of 25 s each. Each batch of 50 reflections was preceded by the measurement of three standard reflections (**I**: 0, 0, 6; 4, 0, 0; 0, 8, 0; and **II**: 0, 0, 4; 2, 0, 0; 0, 8, 0). The Lorentz and polarization factors were applied and each batch was scaled to maintain the sum of the standard constants. There was no evidence of sample decomposition during the data collection for **I** but there was a 5.5% decline in the intensity of the standards for **II**. Absorption corrections were applied with a numerical integration procedure utilizing Gaussian grids (**I**: 6 × 6 × 6, and **II**: 6 × 6 × 10). The crystal shapes were defined by perpendicular distances to crystal faces from a central origin as follows: **I**: ±{100}, 0.248 mm; ±{010}, 0.184 mm; ±{10$\bar{1}$}, 0.215 mm; and **II**: ±{100}, 0.143 mm; ±{010}, 0.181 mm; ±{001}, 0.411 mm. The absorption coefficients were 54.24 and 13.83 cm^{-1}, respectively, and the ranges of transmission factors were 0.13−0.23 and 0.61−0.69. For compound **I**, reflections with intensity less than 2.5σ(I) were removed from the data set to give a final file containing 4347 independent reflections. For **II** the final file contained 3014 independent reflections.

(c) Structure solution and refinement

The structures were found and refined using the SHELX-76 program package (34), and illustrations were drawn using ORTEP (35). The atomic scattering factors used were for neutral atoms, with corrections for anomalous dispersion (30). The structures were solved by direct methods, completed by standard Fourier synthesis procedures using difference maps, and refined by the method of least-squares minimising $\Sigma w\Delta^2$ where $\Delta = |F_o| - |F_c|$. The weights were obtained from counting statistics using $w = 1/(\sigma^2(F) + 0.001F^2)$. For compound **I** hydrogen atoms were included in the refinement but, with the exception of H(0) and H(1), were fixed at 1.08 Å relative to their respective carbon atoms. Hydrogen atoms were not located for **II**. All non-hydrogen atoms were treated anisotropically and convergence was obtained with maximum shift/esd ratios of 0.47 and 0.154, respectively. For compound **I** the residuals were $R = 0.0380$ and $R_w = (\Sigma w\Delta^2/\Sigma wF_o^2)^{1/2} = 0.0496$. The final difference map had a maximum of +2.3 e Å^{-3} (at 1.05 Å from Pt) and a minimum of −1.7 e Å^{-3}. Corresponding figures for **II** were $R = 0.0940$, $R_w = 0.0763$, max = +0.64 e Å^{-3} (0.96 Å from Pd), min = −0.61 e Å^{-3}. Neither difference map gave any indication that any material had been overlooked. For compound **II** the molecular symmetry was $\bar{1}$ and for the coordinates given in Table 5 the centre of inversion is located at (1/2, 0, 0).

L'*o*-nitrobenzylidènediméthylsulfuranne: synthèse, réactivité

YANNICK LE STANC ET MAURICE LE CORRE[1]
Laboratoire de Synthèse Organique, UA CNRS 415, Avenue du Général Leclerc, 35042 Rennes Cédex, France

Reçu le 9 novembre 1984

YANNICK LE STANC ET MAURICE LE CORRE. Can. J. Chem. **63**, 2958 (1985).

Le bromure d'*o*-nitrobenzyldiméthylsulfonium et l'ylure correspondant sont des composés très instables qui évoluent, en milieu aqueux, en donnant selon les conditions: l'alcool *o*-nitrobenzylique, le sulfure d'*o*-nitrobenzyle ou le sulfure de méthyle et d'*o*-hydroxyméthylbenzyle. L'accès aux *o*-nitrophényloxirannes est possible, avec les aldéhydes, dans un système biphasique soude aqueuse/dichlorométhane.

YANNICK LE STANC AND MAURICE LE CORRE. Can. J. Chem. **63**, 2958 (1985).

In aqueous solution, *o*-nitrobenzyldimethylsulfonium bromide and the corresponding ylid give, depending upon the conditions, *o*-nitrobenzyl alcohol, *o*-nitrobenzylsulfide, or methyl *o*-hydroxymethylbenzyl sulfide. The *o*-nitrophenyloxiranes may be obtained by the reaction of nitrobenzylidenedimethylsulfurane with aldehydes in a two-phase aqueous sodium hydroxide/dichloromethane system.

Bien que les *o*-nitrophényloxirannes aient été signalés à plusieurs reprises dans la littérature (1), la voie d'accès la plus générale, qui consiste à partir de l'*o*-nitrobenzylidène sulfuranne, n'a jamais été décrite. Dans le cadre de nos recherches en série indolique, nous avons été amenés à préparer et à étudier le comportement du sel de sulfonium **1** et de l'ylure correspondant.

Cette étude a révélé que le sel **1** ne conduit pas aux oxirannes dans les conditions habituelles (action d'une base puis d'un dérivé carbonylé dans un solvant anhydre) par suite notamment d'une réaction concurrente mettant en jeu le groupement NO_2. L'analyse du produit réactionnel obtenu lors des différents essais préliminaires a révélé que le sel de sulfonium **1** est susceptible d'évoluer en milieu aqueux, selon plusieurs directions que l'on peut contrôler en modifiant la concentration et le pH du milieu. L'hydrolyse du sel **1** conduit essentiellement

SCHÉMA 2

[1]Auteur à qui adresser la correspondance.

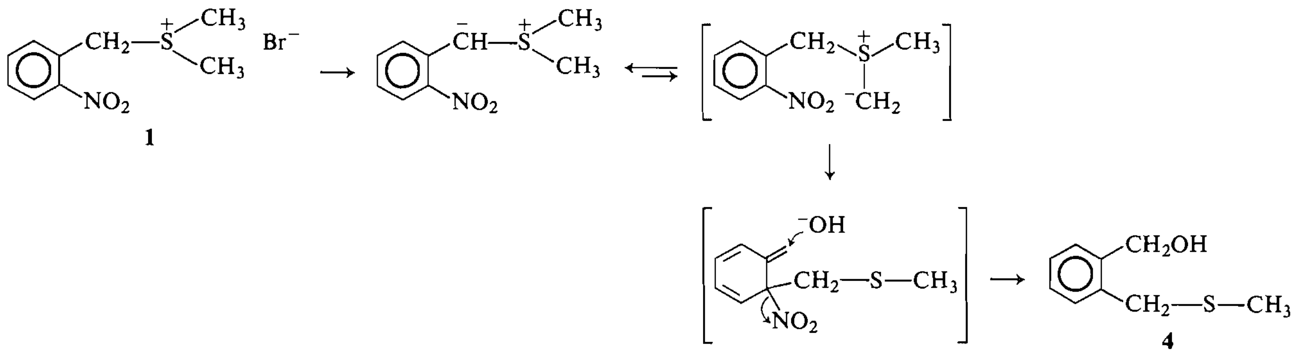

SCHÉMA 3

(schéma 1) à l'alcool *o*-nitrobenzylique **2** en solution diluée, au sulfure d'*o*-nitrobenzyle **3** en solution concentrée et au sulfure alcool **4** en milieu basique.

Interprétation

La différence d'évolution en fonction des conditions expérimentales peut s'interpréter (schéma 2) en admettant que: (*i*) en milieu dilué, la réaction principale est une hydrolyse qui conduit majoritairement à **2**; (*ii*) en milieu concentré l'attaque par les ions Br^-, présents en quantité importante, devient prépondérante et mène à un mélange des dérivés **5** et **6**.

L'hypothèse d'une hydrolyse du sulfure **6** en alcool **2** qui aurait pu expliquer la différence d'orientation de la réaction a été écartée; le sulfure **6** est en effet inattaqué après 18 h de reflux dans une solution aqueuse bromhydrique 1 *N*.

À partir de ces deux composés, la formation du sulfure **3** résulterait d'une alkylation du sulfure **6** par le dérivé bromé **5** suivie d'une hydrolyse de ce nouveau sel **7** en sulfure **3**. Il convient de remarquer que le problème de la régiosélectivité de l'hydrolyse n'intervient pas lors de cette dernière étape, puisque l'attaque du méthylène benzylique redonne les produits de départ.

La formation, tout à fait inattendue, du dérivé **4** peut s'interpréter par un réarrangement de Sommelet–Hauser au cours duquel le méthylène-cyclohexadiène intermédiaire évolue sous l'action de OH^- avec élimination du groupement NO_2 (schéma 3).

Ce résultat est à rapprocher des observations très récentes de Ta-Jyh Lee et Holts relatives aux sels de sulfonium *o*-chlorés (2) (schéma 4):

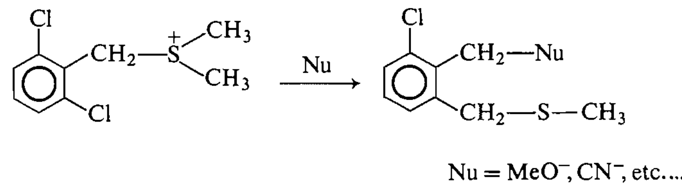

SCHÉMA 4

Il convient de noter que, dans le cas des dérivés chlorés la réaction d'élimination n'est possible que si la position *ortho* est également substituée par Cl ou SO_3R. Le résultat obtenu avec l'*o*-nitrobenzylidènesulfuranne confirme donc les excellentes propriétés nucléofuges du groupement NO_2, déjà observées dans d'autres réactions (3).

L'accès aux *o*-nitrophényloxirannes est cependant possible à partir du sel **1** si on libère l'ylure en présence du dérivé carbonylé, dans un système biphasique CH_2Cl_2/NaOH concentrée. En raison de l'instabilité de l'ylure, seuls les aldéhydes conduisent aux oxirannes (voir tableau 1). La stabilisation apportée par le groupement NO_2 est suffisante pour que, dans le cas de l'acroléine, la condensation évolue vers le formyl-cyclopropane (schéma 5):

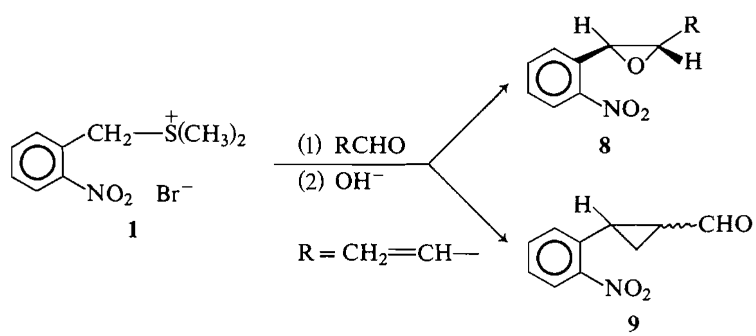

SCHÉMA 5

L'analyse par rmn ^{1}H du système époxydique (voir tableau 1) montre que la réaction est stéréospécifique et conduit exclusivement au composé *trans*.

La cyclopropanation, non stéréospécifique, conduit à un mélange *E*/*Z* dans le rapport 75:25.

Partie expérimentale

Les points de fusion ont été déterminés au banc Kofler. Sauf indication contraire, les spectres rmn ont été réalisés dans $CDCl_3$ avec comme référence le TMS. Spectres de rmn ^{1}H: Varian EM-360 L, spectres de masse: Varian MAT 311.

*Bromure d'*o*-nitrobenzyldiméthylsulfonium 1*

A 21,6 g (0,1 mol) d'α-bromo *o*-nitrotoluène dans 20 mL de chloroforme on ajoute 12,4 g (0,2 mol) de sulfure de méthyle. Après 24 h à 50°C, le sel de sulfonium, qui cristallise, est filtré, rincé avec 2 fois 5 mL de chloroforme et séché; Rtd: 96%; *F*(°C): 89–90; rmn ^{1}H

(D_2O): CH_3 à 2,05 (s, 6H), CH_2 à 4,10 (s, 2H), protons aromatiques de 6,8−7,5 (m, 4H). *Anal.* calc. pour $C_9H_{12}BrNO_2S$: C 38,84, H 4,31, Br 28,77; tr.: C 38,61, H 4,19, Br 28,62.

Alcool o-*nitrobenzylique 2*

On porte à reflux pendant 24 h une solution de 2,78 g (0,01 mol) de sel de sulfonium dans 150 mL d'eau. Le produit brut, obtenu par extraction au dichlorométhane et évaporation du solvant, est purifié par chromatographie sur acide silicique (70−230 mesh; dichlorométhane−éther 95:5); Rdt: 77%; F(°C): 71−72 (litt. (6) F 74°C); rmn ^{1}H: O—H à 3,20 (s, 1H), CH_2 à 5,06 (s, 2H), protons aromatiques à 7,2−8,1 (m, 4H).

*Sulfure d'*o-*nitrobenzyle 3*

On porte à reflux pendant 24 h une solution de 5,56 g (0,02 mol) de sel de sulfonium **1** dans 10 mL d'eau. Le produit brut obtenu par extraction au dichlorométhane, est dissout dans 30 mL d'éthanol au reflux. Le sulfure **4** cristallise au refroidissement, il est alors filtré et séché; Rdt: 48%; F(°C): 120−122; rmn ^{1}H: CH_2 à 4,10 (s, 4H), protons aromatiques à 7,3−8,1 (m, 8H). Spectre de masse: M calculée pour $C_{14}H_{12}N_2O_4S$: 304,052; trouvée: 304,051.

*Sulfure de méthyle et d'*o-*hydroxyméthyl benzyle 4*

On porte à reflux pendant 2 h une solution de 5,56 g (0,02 mol) de sel de sulfonium **1** dans 50 mL de soude 1 N. Après extraction au dichlorométhane et évaporation du solvant, on isole, à partir du mélange obtenu, le sulfure **5** par chromatographie sur acide silicique (70−230 mesh; dichlorométhane); Rdt: 45%; $E_{0,6}$ = 114−115°C; rmn ^{1}H: CH_3 à 1,97 (s, 3H), O—H à 3,10 (s, 1H), SCH_2 à 3,73 (s, 2H), OCH_2 à 4,70 (s, 2H), protons aromatiques à 7,2−7,5 (m, 4H). Spectre de masse: M calculée pour $C_9H_{12}OS$: 168,253; trouvée: 168,252.

o-*Nitrophényl-2 oxiranne 8*a

À une suspension de 13,9 g (0,05 mol) de sel de sulfonium **1** dans 25 mL de dichlorométhane et 4 mL d'une solution aqueuse de formaldéhyde à 37%, on ajoute sous vive agitation magnétique 37,5 mL de soude 10 N; la coloration mauve d'ylure apparaît aussitôt. Après disparition de la coloration de l'ylure (10 min environ) l'ensemble est dilué par addition de 30 mL d'eau, puis extrait par 2 fois 30 mL de dichlorométhane. La phase organique décantée est concentrée à l'évaporateur rotatif et l'huile obtenue distillée sous pression réduite; Rdt: 42%; $E_{0,5}$ = 94−96°C; F(°C): 63−64 (litt. (4) F 65°C); rmn ^{1}H: protons époxydiques à 3,26 (q, 1H, J_{AM} = 6 Hz, J_{AX} = 4 Hz), 2,60 (q, 1H, J_{AM} = 6 Hz, J_{MX} = 2 Hz), 4,46 (q, 1H, J_{AX} = 4 Hz, J_{MX} = 2 Hz), protons aromatiques à 7,1−8,13 (m, 9H).

o-*Nitrophényl-2 phényl-3 oxiranne 8*b

À une suspension de 13,9 g (0,05 mol) de sel de sulfonium **1** dans 25 mL de dichlorométhane contenant 0,075 mol d'aldéhyde on ajoute, sous vive agitation magnétique 40 mL de soude 10 N. Après 2 h à température ambiante, l'ensemble est dilué par addition de 30 mL d'eau, puis extrait par 2 fois 30 mL de dichlorométhane. La phase organique obtenue après décantation est constituée presque exclusivement de l'époxyde et d'aldéhyde en excès. Après élimination de l'aldéhyde par distillation sous pression réduite l'*o*-nitrophényl-2 phényl-3 oxiranne cristallise; Rdt: 92%; F(°C) éthanol: 98−100 (litt. (5) F 101−102°C); rmn ^{1}H: protons époxydiques à 3,73 (d, 1H, ^3J = 2 Hz) et 4,46 (d, 1H, ^3J = 2 Hz), protons aromatiques à 7,1−8,13 (m, 9H).

(Furyl-2)-2 o-*nitrophényl-3 oxiranne 8*c

"Mode opératoire" identique au précédent; Rdt: 94%; F(°C) hexane: 46−47; rmn ^{1}H: protons époxydiques à 3,73 (d, 1H, ^3J = 2 Hz) et 4,9 (d, 1H, ^3J = 2 Hz), protons furyliques à 6,36−6,66 (m, 2H), protons aromatiques à 7,2−8,3 (m, 5H). *Anal.* calc. pour $C_{12}H_9NO_4$: C 62,33, H 3,89, N 6,06; tr.: C 62,15, H 3,75, N 6,01.

o-*Nitrophényl-2* p-*nitrophényl-3 oxiranne 8*d

"Mode opératoire" identique à celui utilisé pour la préparation de **8***b* et **8***c*. Le produit réactionnel brut, obtenu après évaporation du solvant, est dissout dans 30 mL d'éthanol; l'*o*-nitrophényl-1 *p*-nitrophényl-3 oxiranne cristallise au refroidissement; il est ensuite filtré et séché; Rdt: 83%; F(°C): 165 (litt. (5) F 160−162°C); rmn ^{1}H: protons époxydiques à 3,86 (d, 1H, ^3J = 2 Hz) et 4,42 (d, 1H, ^3J = 2 Hz), protons aromatiques à 7,3−8,5 (m, 8H).

Formyl-1 o-*nitrophényl-2 cyclopropane 9*

À une solution de 4,2 g d'acroléine (0,075 mol) dans 25 mL de dichlorométhane, on ajoute 13,9 g (0,05 mol) de sel de sulfonium **1**, puis sous vive agitation, 40 mL de soude 1 N.

Après disparition de la coloration de l'ylure (10 min environ), on ajoute 30 mL d'eau, décante la phase organique puis extrait deux fois la phase aqueuse au dichlorométhane (60 mL). La phase organique est concentrée à l'évaporateur rotatif et l'huile obtenue distillée sous pression réduite; Rdt 83%; $E_{0,5}$ = 134°C; rmn ^{1}H: protons cyclopropaniques de 1,3 à 3,3 (m, 4H), protons aromatiques de 7,1 à 8,1 (m, 4H), C*H*O *cis* à 9,0 (d, J = 5 Hz), C*H*O *trans* à 9,4 (d, J = 5 Hz). *Anal.* calc. pour $C_{10}H_9NO_3$: C 62,82, H 4,71, N 7,32; tr.: C 62,70, H 4,68, N 7,27.

^{13}C magnetic resonance studies. 119.[1] Tricyclo[3.3.0.0] and [3.2.1.0]octanones from substituted norbornenones via cyclopropanation and homoketonization

ARTHUR J. RAGAUSKAS AND J. B. STOTHERS
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received February 5, 1985

ARTHUR J. RAGAUSKAS and J. B. STOTHERS. Can. J. Chem. **63**, 2961 (1985).

Simmons–Smith cyclopropanation of the trimethylsilyl enol ethers of 7-isopropylidene- and two 7-spirocyclopropyl-norbornenones leads directly to the 8-substituted 2-trimethylsilyl ethers of homoquadricyclene. Homoketonization of the unsaturated ether proceeds regiospecifically to the corresponding tricyclo[3.3.0.$0^{2,8}$]octan-4-one while the others give the tricyclo[3.2.1.$0^{2,6}$]octan-4-ones exclusively, all with high stereoselectivity favoring inversion of configuration. This difference in the regiochemistry of homoketonization can be attributed to a directive effect of β-functionalization overcoming thermodynamic control of cleavage.

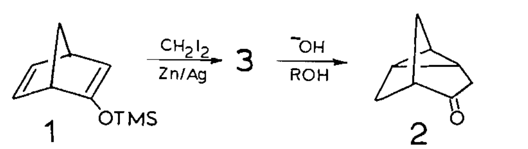
ARTHUR J. RAGAUSKAS et J. B. STOTHERS. Can. J. Chem. **63**, 2961 (1985).

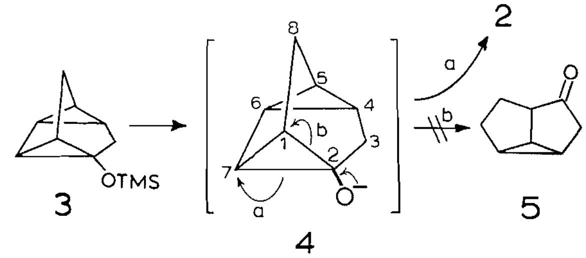
La réaction de cyclopropanation suivant Simmons–Smith des éthers énoliques triméthylesilyles de l'isopropylidène-7 et de deux spiro-7 cyclopropylnorbornénones conduit directement aux éthers triméthylsilyl-2 de l'homoquadricyclène substitués en position 8. L'homocétonisation de l'éther insaturé est régiospécifique et conduit à la tricyclo[3.3.0.$0^{2,8}$]octanone-4 correspondante tandis que les autres éthers conduisent exclusivement aux tricyclo[3.2.1.$0^{2,6}$]octanones-4; toutes ces réactions se produisent avec une très haute stéréosélectivité qui favorise une inversion de configuration. On attribue la différence de régiochimie dans l'homocétonisation à un effet directif de la fonction en β qui est plus puissant que le contrôle thermodynamique du clivage.

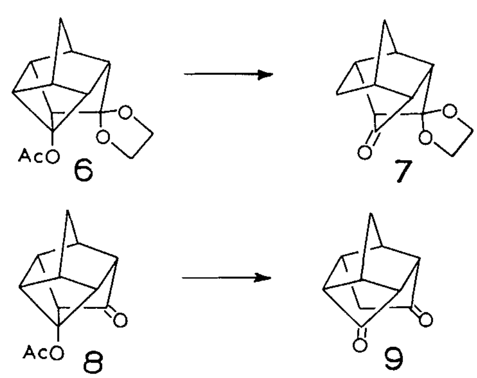
[Traduit par le journal]

Introduction

Our earlier unexpected discovery (1) of quantitative conversion of the trimethylsilyl enol ether of norbornenone (**1**) to tricyclo[3.2.1.$0^{2,7}$]octan-4-one (**2**) prompted us to examine the process in more detail. Specifically, we were interested in potential substituent effects on the course of the second step of the sequence, namely, the base-catalyzed cleavage of the homoquadricyclene addition product **3** formed by cyclopropanation of **1**. Although there are two paths for cleavage of cyclopropoxide **4** formed from **3**, its homoketonization was found to be regiospecific, yielding only **2**. If, however, one could alter the regioselectivity of cleavage to favor formation of tricyclo[3.3.0.$0^{2,8}$]octan-4-one (**5**) analogs, this would provide a new route to the latter system, examples of which have been utilized in a variety of syntheses of natural products (2).







The regioselectivity of homoketonization of several β-enolates, i.e., substituted cyclopropoxides, has been established (3) and the major governing factors found to be relief of strain, product stability, and the stability of the incipient carbanion. Cleavage of β-enolate **4**, by either path a or b, will lead to a secondary carbanion but that formed via a may be stabilized by the adjacent three-membered ring. On the other hand, product stability may be responsible for the remarkable dominance of cleavage by path a. In an attempt to shed additional light on the question, the 8-spirocyclopropyl and 8-isopropylidene derivatives of **4** were selected for study. In the case of the former, the additional cyclopropyl ring could conceivably stabilize the incipient carbanion generated by cleavage analogous to path b in **4**, thereby rendering the two pathways more nearly comparable provided stabilization by the neighboring three-membered ring is a significant factor in these homoketonizations. Introduction of a double bond at C-8 in **4** could be expected to afford even greater stabilization for a developing carbanion at C-1, i.e., via cleavage b, possibly altering the regioselectivity of homoketonization in a major way. Redirection of the homoketonization process has been illustrated. Zwanenburg and co-workers (4) found that while ketal acetate **6** yields **7** exclusively, presumably by thermodynamic control, cleavage of the analog **8** leads regiospecifically to **9**, demonstrating that conjugative stabilization of one of the possible carbanionic intermediates is sufficient to

[1] For Part 118 see ref. 15; for Part 117 see ref. 16; for Part 116 see ref. 17.

alter the regiochemistry of the homoketonization.

A second feature of the homoketonization process concerns the stereoselectivity of protonation of the homoenolate which, in general, is found to be high (3). However, in the case of β-enolates, high degrees of retention and inversion of configuration have been observed and definitive interpretation in terms of the principal governing factor is difficult. Nevertheless, there is some evidence that increasing strain in polycyclic systems causes a shift from predominant inversion to dominant retention. For example, β-enolate **10** opens with >95% inversion while the more strained analog **11** exhibits

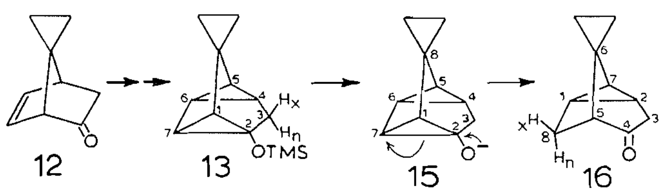
10 11

>95% retention (5). Our examination of **4** showed that ketonization proceeds with 92% inversion and, since the introduction of the spirocyclopropyl and isopropylidene substituents undoubtedly increases the strain in the corresponding β-enolates, it was of interest to establish the stereochemistry of homoketonization for the latter cases.

Results and discussion

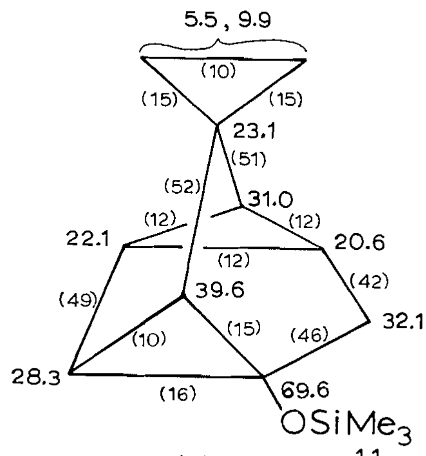
7-Spirocyclopropylnorbornenone

In the earlier study (1), we found that cyclopropanation of **1** with methylene iodide and a zinc–silver couple led directly to **3**, presumably by facile intramolecular cycloaddition after the initial addition of the methylene group to the enolic double bond. The same treatment of the 7-spirocyclopropyl analog gives an analogous result. Reaction of **12** with lithium diisopropylamide followed by treatment with trimethylsilyl chloride and triethylamine gave the corresponding enol ether in 85% yield. Cyclopropanation afforded an addition product **13**



having no olefinic absorption in either the ^{1}H or ^{13}Cmr spectra, and the molecular formula $C_{13}H_{20}OSi$, by precise mass measurement, confirmed the addition of a single methylene group. The ^{13}C spectrum contained three methylene signals (δ_C 5.4, 9.9, 32.1), five methine peaks (20.6, 22.1, 28.3, 31.0, 39.6), two quaternary signals (23.1, 69.6), and trimethylsilyl absorption at δ_C 1.1. On comparison with the results for **4**, these data are consistent with the expected homoquadricyclene structure. Although specific assignments for the spirocyclopropyl methylene carbons could not be made, the signals at δ_C 5.4 and 9.9 were readily attributed to these carbons. The order of linkage of the other carbons was obtained from a double-quantum coherence (INADEQUATE) spectrum (6); these results are summarized in **14** with the J_{CC} values in parentheses.

The proton spectrum provided additional confirmation for structure **13**. The 3-methylene protons appeared at lowest field with the *exo*-proton at δ 2.27, J = 11.7 Hz and the *endo*-proton at δ 2.12, J = 1.5, 5.1, 11.7 Hz. For the latter, the small 1.5-Hz coupling was common to a pattern at δ 1.24 (dt, 1H, J



14

= 1.5, 7.3 Hz) ascribable to H-1 which was also coupled to H-7 (dd, δ 1.98, J = 4.3, 7.3 Hz). The absorption for H-6 was found at δ 1.71 (dt, J = 4.3, 6.3 Hz) with H-4 at δ 1.11 (ddd, J = 5.1, 6.3, 8.1 Hz). Irradiation of the two-proton pattern at δ 0.68 collapsed the 8.1-Hz splitting in the H-4 multiplet, a 1.5-Hz coupling for H-1, and a 6.3-Hz splitting for H-6, thereby revealing the approximate position of H-5. The spirocyclopropyl methylene protons absorb at δ 0.37 (m, 2H), 0.68 (m, 1H), and 0.76 (m, 1H) but cannot be individually identified. All of the coupling interactions were confirmed by the appropriate decoupling experiments. Thus, the generation of **13** from **12** through Simmons–Smith cyclopropanation is strictly analogous to the conversion of norbornenone to **3**.

Treatment of **13** with base gave a single ketone in 90% yield having carbonyl absorption (ir 1725 cm^{-1}, δ_C 210.2) indicative of a six-membered ring ketone. In addition to the carbonyl peak, the ^{13}Cmr spectrum contained nine signals: δ_C 4.6, 9.9, 28.0, 33.8 (4 × CH_2), 10.5, 15.9, 21.7, 55.8 (4 × CH), and 24.7 (quat C). While the quaternary and the two highest field methylene signals could be attributed to the spirocyclopropyl group, the remaining signals were in reasonable agreement with expectations for structure **16** by comparison with the data for **2**, indicating that the cleavage of **15** was regiospecific and analogous to that of **3**. Initially, a chemical proof of structure was examined since hydrogenolysis of the three-membered rings in **16** could produce 6,6-dimethylbicyclo[2.2.2]octan-2-one, a known compound. However, hydrogenation of **16** using a platinum oxide catalyst afforded an alcohol and a single new ketone having the molecular formula $C_{10}H_{14}O$, by precise mass measurement. Clearly, only one of the cyclopropyl moieties suffered cleavage. The ^{13}Cmr spectrum contained signals for two methyl (δ_C 26.0, 26.7), two methylene (26.9, 33.4), four methine (10.5, 14.4, 23.5, 58.7), one quaternary (40.8), and a carbonyl carbon (212.1). We conclude that the ketone is 6,6-dimethyltricyclo[3.2.1.0^{2,7}]octan-4-one and, on the basis of its ^{13}C spectrum, the second product appeared to be the corresponding alcohol but was not fully characterized.

Definitive structural proof for **16** was obtained by nmr. To confirm tentative assignments of the ^{13}C signals an INADEQUATE spectrum was obtained and the results are summarized in **17**. Supporting evidence was provided by the ^{1}Hmr spectrum. The 3-methylene protons absorbed at lowest field, δ 2.65 (ddd, J = 0.8, 2.6, 20.0 Hz) and 2.57 (dd, J = 2.6, 20.0 Hz), readily identified by the 20.0-Hz geminal coupling. Doublets at δ 1.87 (J = 12.6 Hz) and 1.75 (J = 5.6 Hz) were assigned to *endo*-H-8 and H-5, respectively, since both have approxi-

TABLE 1. Cyclopropanation experiments with **19**

Temperature	Expt.	Time (h)	Molar ratio (CH_2I_2)/**19**	[**19**] ($M \times 10^{-1}$)	Product composition (%)[a] **20**	**21**	**18**

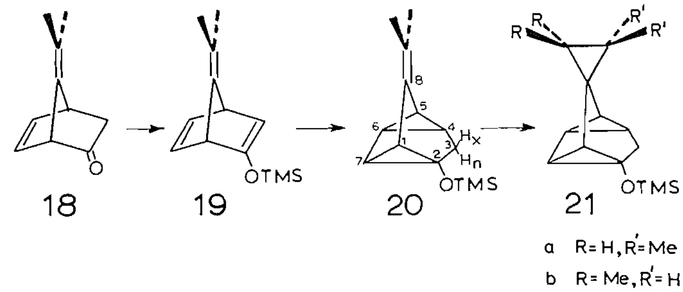
17

mately 90° dihedral angles with one of two vicinal neighbors. A multiplet at δ 2.23 containing splittings of 12.6, 5.6, 3.4, and 0.8 Hz must arise from *exo*-H-8 with the smallest coupling representing a long-range interaction with one of the 3-protons. A triplet of triplets at δ 1.11 (J = 2.6, 7.5 Hz) was readily assigned to H-2, with the larger coupling identifying the interaction with H-7, δ 0.90 (dd, J = 5.7, 7.5 Hz), and H-1, which gave rise to the remaining one-proton multiplet at δ 1.55 containing couplings of 7.5 (H-2), 5.7 (H-1), and 3.4 Hz (*exo*-H-8). A complex four-proton multiplet, δ 0.35–0.65, accounted for the four spirocyclopropyl methylene protons. Appropriate decoupling experiments confirmed each of the interactions noted.

The identification of **16** shows that the homoketonization of **13** is the same as that of **3**; clearly, the additional cyclopropyl ring does not affect the regiochemistry of cleavage.

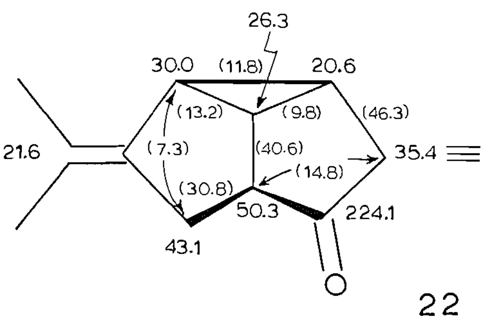
7-Isopropylidenenorbornenone

Enol ether **19** was prepared from 7-isopropylidenenorbornenone in 80% yield and, upon reaction with methylene iodide and a zinc–silver couple under conditions similar to those employed to generate **13**, gave a 50:50 mixture of two products in >90% yield. The composition of the mixture was assessed by ^{13}Cmr spectroscopy since the product decomposed upon attempted analysis by gas–liquid chromatography (FFAP, SE-30, and Carbowax) even with the use of new columns that was essential for success with **13**. The ^{13}C spectrum of the mixture contained signals for two non-protonated olefinic carbons (δ_C 121.0, 133.3), four quaternary carbons, two of which bear oxygen (17.4, 33.6, 70.1, 70.9), and three methylene carbons (25.0, 32.8, 33.0), together with six methyl and ten methine carbon peaks. These data indicated that initial cyclopropanation of the enolic double bond followed by intramolecular cycloaddition indeed occurred, but approximately half of this product underwent a second cyclopropanation at the isopropylidene double bond, i.e. **19** → **20** → **21**.

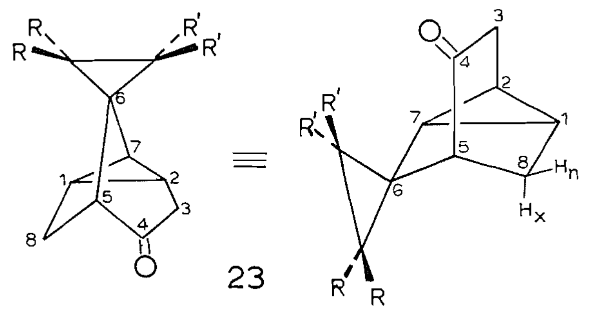


To obtain support for this suggestion, the reaction was repeated using a larger excess of methylene iodide and the resulting product gave rise to the same sets of ^{13}C signals with the important difference that the product ratio was 1:7, favoring the component lacking olefinic absorption. The ^{13}C spectrum for the major product included signals for five methyl (δ_C 1.5 (3), 24.2, 25.4), two methylene (25.0, 33.0), five methine (20.3, 22.7, 29.6, 29.9, 38.4), and three quaternary carbons (17.4, 33.6, 70.1). On comparison with the data for **13**, these results appeared to be consistent with structure **21**. Repetition of the reaction using a small excess of methylene iodide gave the same products in a 3:1 ratio favoring the unsaturated component, the ^{13}C spectrum of which included five methyl (δ_C 1.2 (3), 21.8, 22.0), one methylene (32.8), five methine (21.7, 24.9, 26.8, 30.4, 36.4), and three fully-substituted carbon signals (70.9, 121.0, 133.3). These data are consistent with structure **20** for the monocyclopropanated product. From the ratios of the products obtained with varying amounts of methylene iodide, it appeared that the second cyclopropanation was significantly slower than the initial methylene addition to the enolic double bond. Consequently, some experiments at lower temperature, varying the concentration of **19**, were carried out. Conditions were found that gave only the unsaturated addition product in 75% yield, contaminated with starting material according to the ^{13}C spectrum. The results of various trials are summarized in Table 1. Our tentative structural assignments for adducts **20** and **21** were confirmed by homoketonization experiments.

Upon treatment with base, the unsaturated adduct **20** gave rise to a single new ketone **22** whose carbonyl absorption (ir 1747 cm^{-1}, δ_C 224.1) indicated the presence of a cyclopentanone moiety. The molecular formula is $C_{11}H_{14}O$ by precise mass measurement. The ^{13}Cmr spectrum contained, in addition to the carbonyl signal, absorptions for two equivalent methyl (δ_C 21.6), two methylene (35.4, 43.1), four methine



22



23

a R=H, R'=Me

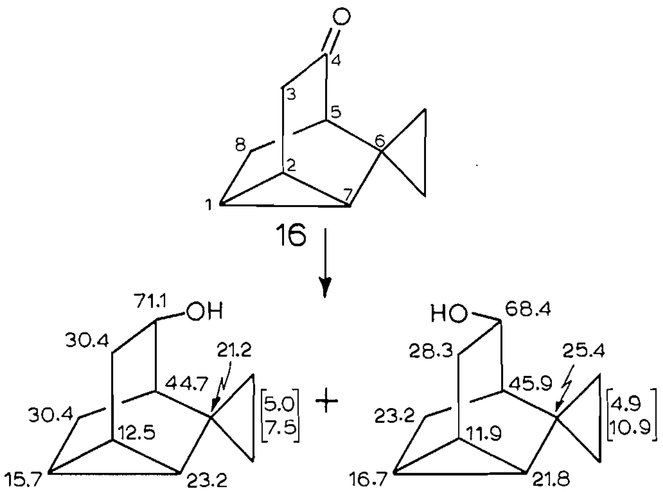
b R=Me, R'=H

(20.6, 26.3, 30.0, 50.3), and two fully-substituted olefinic carbons (126.5, 129.8); these data are consistent with structure **22** and this was confirmed by the results of an INADEQUATE spectrum. For this purpose, the reaction was repeated on a preparative scale using 700 mg of **19**; **22** was isolated in 67% yield by flash chromatography. Although **20** was contaminated with ketone **18** because of the relatively mild conditions employed for the cyclopropanation, it was found that **18** does not survive the basic conditions required for homoketonization, as expected (7), and the purification of **22** presented no difficulty. The $^{13}C-^{13}C$ coupling constants observed for the sp^3 carbons clearly established their order of linkage and are summarized in parentheses with the formula. The geminal couplings between the carbons flanking the sp^2 centres provided additional confirmatory evidence.

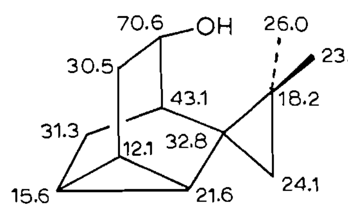
From these results it became clear that the conversion of **19** → **20** by Simmons–Smith cyclopropanation is strictly analogous to that found previously for the parent system **1** → **3**. Although homoketonization of each of **3** and **20** is regiospecific with each yielding a single ketone, different bonds open in the two homoquadricyclene species. The C-2,-7 bond is cleaved exclusively in the parent β-enolate **4** but only the C-1,-2 bond is opened in the isopropylidene derivative. For the latter, a developing carbanion at C-1 can be stabilized by the neighboring double bond since it is an allylic system. Apparently this is sufficient to change the course of the cleavage to furnish the [3.3.0.0] ketone **22** exclusively. It is interesting that a single ketone is observed since, in principle, the 7-isopropyl-Δ^6-isomer of **22** could arise from the allylic carbanion. However, the isomeric structure with an endocyclic double bond may be considerably more strained than its exocyclic counterpart **22**. In any event, the marked difference in the regiochemistry of homoketonization for **4** and **20** is neatly accounted for by increased stabilization of the incipient carbanion leading to **22**.

The cyclopropanation experiments with **19** at reflux temperature (Table 1) gave a mixture of two adducts that, upon homoketonization with base, furnished a corresponding mixture of two ketones, separable by glc. One of the products was **22** while the second, **23**, appeared to contain a six-membered ring ketone (ir 1725 cm^{-1}, δ_C 210.8). The molecular formula $C_{12}H_{16}O$, by precise mass measurement, confirmed the addition of two methylene groups to **19** and its ^{13}Cmr spectrum exhibited, in addition to the carbonyl peak, two methyl (δ_C 22.7, 23.5), three methylene (22.2, 29.3, 34.2), four methine (10.4, 15.8, 20.0, 53.8), and two quaternary signals (17.0, 33.0). Many of these shieldings are remarkably similar to those found for **16**, thus leading to structure **23**. Additional support for this structural assignment was obtained from the proton spectrum. Two nearly equivalent protons δ 2.54 and 2.57, J_{AB} = 20 Hz were easily assigned to the 3-protons, each of which was coupled by 2 Hz to a proton whose absorption was part of a complex two-proton multiplet, 0.98–1.17 ppm. Clean doublets at δ 1.87 (J = 12.4 Hz) and 2.07 (J = 5.8 Hz) clearly arose from *endo*-H-8 and H-5, respectively. An eight-line pattern at δ 2.25 (J = 3.1, 5.8, 12.4 Hz) readily accounted for *exo*-H-8 which, in addition to its interactions with H-5 (5.8 Hz) and *endo*-H-8 (12.4 Hz), is coupled to H-1 (3.1 Hz). The latter nucleus gave rise to a six-line pattern at δ 1.85 (dt, J = 3.1, 6.8 Hz) with the larger splitting attributable to coupling with H-2 and -7, which appear as a multiplet near δ 1.0. Finally, the spectrum contained methyl singlets at δ 1.03 and 1.17 together with a clean AB pattern for the cyclopropyl methylene protons, δ_A 0.28, δ_B 0.42, J_{AB} = 4.6 Hz. Each of the couplings noted above was confirmed by spin-decoupling experiments. Thus, homoketonization of **21** follows the same course as that found for **3** and **13**.

From the foregoing results, it was apparent that the second cyclopropanation furnishing **21** is stereospecific and it remained to distinguish between the two possible adducts **21***a* and *b*. Molecular models indicated that methylene addition leading to **21***b* may be hindered by the *exo*-3-hydrogen of **20**. On the other hand, the well-known ability of neighboring oxygen to direct methylene transfer could facilitate the formation of **21***b* but the oxygen in **20** may be too far from the double bond to influence the reaction course. To determine the position of the geminal methyl groups in **23**, the composition of the product obtained by LAH reduction was compared with that from **16**. The ratio of epimeric alcohols produced from **23***b* and **16** would be expected to be similar and distinctly different from that formed from **23***a* in which the geminal methyls can hinder the approach of the hydride donor to the *syn* face of the carbonyl group. Upon treatment with LAH, **16** gave an 85:15 mixture of two alcohols while a 95:5 mixture of alcohols was obtained from **23**. The ^{13}Cmr spectra of the alcohols formed from **16** indicate that hydride donation occurred preferentially at the face of the carbonyl group away from the spirocyclopropyl grouping. The major alcohol **24** gave rise to four methylene carbon signals, δ_C 5.0, 7.5, 30.4$_1$, 30.3$_8$, which may be compared with the corresponding signals for the minor alcohol **25** at δ_C 4.9, 10.9, 23.2, 28.3. In each case, the two signals at highest field arise from the spirocyclopropyl methylene carbons and the 7-ppm upfield shift found for one of the remaining methylene signals in the minor isomer must be due to a shielding effect of the hydroxyl group. Hence the hydroxyl is *syn* to C-8 in the minor isomer and *anti* in the major product **24**, which is consistent with preferential hydride donation to **16** from the less hindered side. The ^{13}C spectrum of the major alcohol **26** from **23** contained methylene absorption at δ_C 24.1, 30.5, and 31.3, of which the most shielded signal arises from the spirocyclopropyl group. The near-equivalence of the remaining two methylene carbons is comparable to the situation in **24** and, therefore, we conclude that the hydroxyl group is *anti* to C-8 as shown in **26**. The difference in the ratio of the two alcohols formed from **16** and **23** indicates a greater difference in hindrance to the approach of the hydride donor in **23**, and, hence, we conclude that the geminal methyl groups are *syn* to C-4 bearing the hydroxyl group. This conclusion was supported by the results of a shift reagent study, which revealed that the quaternary carbon bearing the geminal methyls was distinctly more sensitive to added $Pr(fod)_3$ than the spirocyclopropyl methylene carbon. It was also found that the methylene carbon at δ_C 30.5 moved upfield at twice the rate of that at 31.5, confirming their assignments to C-3 and -8, respectively. The greater sensitivity of one of the methyl carbons to added shift reagent led to the methyl assignments shown in **26**.



16 → **24** + **25**



26

Stereochemistry of homoenolization

Our earlier examination of the homoketonization of **3** revealed that the resulting cyclopropoxide **4** opened with high stereoselectivity (92 ± 1%) favoring inversion of configuration at C-7. As noted in the Introduction, it was of interest to learn whether the increased strain of the spirocyclopropyl and isopropylidene analogs **13**, **21***a*, and **20**, respectively, would affect the stereochemistry of ring opening. To examine this feature, their ketonizations were carried out in deuterated media.

Treatment of **13** with KOD/*t*-BuOD at room temperature furnished **16**-d_x containing 1.80 atoms ^{2}H/molecule by mass spectrometry. The ^{2}Hmr spectrum revealed four sites of deuterium incorporation for which the relative amounts were determined by integration. The ^{2}H signals, with their ^{2}H content, were found at δ 2.64 (0.60), 2.55 (0.40), 2.24 (0.725), 1.88 (0.065), which, from the analysis of the ^{1}H spectrum, are due to deuterons at C-3 and C-8. The relative intensities of the higher field pair of signals which arise from the *exo*- and *endo*-8-deuterons show that the stereochemistry of ring opening in **15** is the same as that found for **4** (1), strongly favoring inversion of configuration at C-7 (92 ± 1%).

As a sidelight, the 3:2 intensity ratio found for the lower field pair of signals shows that α-exchange in **16**, occurring upon its formation, apparently favors the less shielded site. In the ^{1}H spectrum, described earlier, this proton exhibits a 0.8-Hz coupling with *exo*-H-8, which suggests that it is *syn* to the spirocyclopropyl group. Additional confirmation that the *exo*-8-proton is involved in this long range interaction was provided by the ^{1}H spectrum of **16**-d_x since the 0.8-Hz splitting is not observed in the multiplet for the less shielded 3-proton. The 3-methylene pattern consisted of a pair of doublets of doublets, δ 2.656, 2.569 (J = 2.6, 20.0 Hz), arising from [8-$^2H_1$]-**16** and a pair of doublets of triplets, δ 2.635, 2.548 (J = 2.6, 3.1 Hz) due to each of the [3,8-$^2H_2$]-**16** species.

The ^{13}Cmr spectrum of **16**-d_x contained the characteristic triplets, centred upfield from the normal signals, arising from one-bond ^{13}C–^{2}H coupling, for the methylene carbons at δ_C 28.0 (J_{CD} = 20.5 Hz, isotope shift (Δ) = 323 ppb) and 33.8 (J_{CD} = 19.6 Hz, Δ = 336 ppb). Two-bond isotope shifts were apparent for C-5 (δ_C 55.8, Δ = 84 ppb) and C-1 (δ_C 15.9, Δ = 98 ppb), while two isotope-shifted components accompanied the normal C-2 signal at δ 10.5 (Δ = 100 ppb/^{2}H) arising from species having one and two deuterons at C-3.

Upon treatment of **21***a* with KOD/*t*-BuOD, **23***a*-d_x containing 1.50 atoms ^{2}H/molecule was isolated and found to exhibit three signals in its ^{2}Hmr spectrum since the 3-methylene peaks are nearly equivalent and, therefore, unresolved. This product was treated with KOH/MeOH to back-exchange the α-deuterium picked up by exchange after the cleavage and its ^{2}H spectrum contained a strong signal at δ 2.25 (*exo*-^{2}H-8) and a relatively small peak at δ 1.87 (*endo*-^{2}H-8). The intensity ratio of these signals showed that the homoketonization of **21***a* proceeds with high stereoselectivity favoring inversion of configuration (93 ± 1%), strictly analogous to the results for **3** and **13**.

The ^{13}C spectra of these **23**-d_x samples confirmed the earlier assignment. The absorption for C-8, δ 29.3, contained the characteristic triplet J_{CD} = 20.4 Hz, Δ = 328 ppb and a similar pattern was observed for C-3, δ_C 34.2, J_{CD} = 19.7 Hz, Δ = 349 ppb. Two-bond isotope shifts were also apparent for C-1 (δ_C 15.8, Δ = 85 ppb), C-5 (δ_C 53.8, Δ = 85 pb), and C-2 (δ_C 10.4, Δ = 97 ppb/^{2}H).

Base-catalyzed homoketonization of **20** in KOD/*t*-BuOD furnished a sample of **22**-d_x which was found to contain 2.74 atoms ^{2}H/molecule by mass spectrometry. The ^{2}Hmr spectrum consisted of three signals at δ 1.87, 2.15, and 2.48. Treatment of this product with KOD/*t*-BuOD to back-exchange the α-deuterium picked up by exchange after the formation of **22**-d_1 furnished a sample of **22**-d_1 containing 0.96 atoms ^{2}H/molecule, whose ^{2}Hmr spectrum exhibited a major peak at δ 2.48 with very small signals at 1.87 and 2.14. Clearly homoketonization of **20** is highly stereoselective. It may be noted that the mass spectrum of this sample gave the ^{2}H content as 4.6% d_0, 94.8% d_1, and 0.6% d_2, indicating that back-exchange of the α-deuterons was not quite complete. Thus, the observation of one major signal in the ^{2}H spectrum shows that the stereoselectivity is >99%, which is significantly higher than that found for the other homoquadricyclene derivatives **3**, **13**, and **21***a*. To establish the stereochemistry of the cleavage of

20, however, analysis of the proton spectrum was required.

The ^{1}H spectrum of **22** in C_6D_6 solution exhibited two-proton multiplets near δ 2.50 and 2.18, a three-proton multiplet at 1.75–1.90, and a multiplet at 1.25 (dt, $J \approx 6.2$, 6.7 Hz, 1H) together with methyl absorptions centred at δ 1.43 and 1.58, each of which was a broadened doublet, $J = 1.5$ and 2.5 Hz, respectively. As the first step in the analysis of this spectrum, a heteronuclear correlation experiment was done since the ^{13}C spectrum had been completely assigned (see above). As a result it was found that the lowest field proton pattern was due to the bridgehead H-5 and one of the 6-methylene protons, while the absorption near δ 2.18 arose from the second 6-methylene proton and one of the 3-methylene protons. The highest field proton pattern correlated with the C-2 signal. Unfortunately, the overlap of the various multiplets precluded a definitive analysis of the ^{1}H spectrum and a shift reagent study was required to obtain suitable dispersion of the individual patterns.

In the presence of 0.1 equivalents of Eu(fod)$_3$, eight one-proton multiplets were clearly resolved, permitting complete analysis. Methylene absorption consisting of a doublet at δ 4.17 (J = 18.8 Hz) and an eight-line pattern, δ 4.70 (J = 2.5, 6.2, 18.8 Hz), was readily assigned to the *endo*- and *exo*-3-protons, respectively, exhibiting shifts (Δδ) of 2.30 and 2.56 ppm with Eu(fod)$_3$. A second methylene pattern was apparent for the 6-protons as a doublet, δ 3.70 (Δδ 1.50, J = 15.4 Hz), and a complex multiplet, δ 3.38 (Δδ 0.90). A series of spin decoupling experiments revealed that the latter multiplet contained couplings to each of the methyl groups (J = 1.5, 2.5 Hz), to H-5 (J = 8.7 Hz), and to its geminal partner (J = 15.4 Hz). An inspection of molecular models indicated that the *endo*-6-proton has a dihedral angle of ca. 90° with respect to H-5; hence the doublet was assigned to *endo*-H-6. The *exo*-6-proton is nearly perpendicular to the π-plane of the double bond, which accounts nicely for the observed homoallylic coupling to each methyl group with the larger interaction presumably involving the *transoid* methyl protons, δ 1.88 (Δδ 0.30). Thus the *cisoid* methyl appears at δ 1.72 (Δδ 0.29). The four remaining multiplets in the Eu(fod)$_3$-shifted ^{1}H spectrum were readily assigned as follows: δ 4.75 (Δδ 2.25, J = 2.5, 4.6, 8.7 Hz, H-5), 2.54 (Δδ 0.77, J = 4.6, 6.7(2) Hz, H-1), 2.32 (Δδ 0.55, J = 6.7(2), H-8), 2.01 (Δδ 0.76, J = 6.2, 6.7(2) Hz, H-2). The 2.5-Hz splitting in the absorptions for *exo*-H-3 and H-5 is a long-range interaction. All of the spin couplings noted were confirmed by the appropriate decoupling experiments.

In the presence of Eu(fod)$_3$, the three signals in the ^{2}H spectrum of **22**-d_x exhibited shifts corresponding to those found for the *exo*-6, *exo*-3, and *endo*-3 protons, thus identifying the three deuterons. The first of these is the major peak in the ^{2}H spectrum of **22**-d_1, establishing that homoketonization of **20** proceeds with highly favored inversion of configuration.

The ^{13}Cmr spectrum of **22**-d_x, the initial product of homoketonization of **20** in KOD/*t*-BuOD, indicated the presence of deuterium at C-3 and -6 and the mass spectrum showed only traces of d_4 species in the sample. Consequently it was apparent that α-exchange in **22** occurred primarily at C-3 with little ^{2}H exchange of the α-bridgehead H-5. To confirm that bridgehead exchange is much slower than exchange at C-3, a sample of **22** was heated under reflux with NaOMe/MeOD for 90 min. The recovered **22**-d_y contained 1.58 atoms ^{2}H/molecule by mass spectrometry with no detectable d_3-species and the ^{13}C spectrum indicated deuterium incorporation only at C-3. The ^{2}Hmr spectrum of **22**-d_y consisted of two equally intense signals corresponding to *exo*- and *endo*-^{2}H-3. In a second experiment, the time of reflux was increased to 9 h but a complex mixture of products resulted that was not examined. In any event, it is clear that bridgehead exchange in **22** is a relatively slow process.

Conclusions

The foregoing results show that Simmons–Smith cyclopropanation of the 7-spirocyclopropyl and 7-isopropylidene derivatives of the trimethylsilyl enol ether of norbornenone follows the same reaction course as the parent, with the formation of the corresponding 8-substituted 2-trimethylsilyl ethers of homoquadricyclene in high yield. While homoketonization of these ethers is regiospecific, the regiochemistry of cleavage for the spirocyclopropyl analogs is the same as that of the parent but differs for the isopropylidene derivative. This finding indicates that increasing the stability of the incipient carbanion formed upon cleavage of the cyclopropoxide ring can alter the course of the reaction. Thus, the ring opening can be directed by β-functionalization. In each case, the stereochemistry of homoketonization is the same, namely, strongly favoring (≤92%) inversion of configuration at the carbanionic site.

Experimental

Boiling points are uncorrected. Gas–liquid chromatography (glc) was carried out with Varian 920 or 3700 instruments using columns of 10% Carbowax, 6% FFAP, or 10% SE-30 on Chromosorb W, as indicated. Tetrahydrofuran (THF) and ether were freshly distilled before use after drying over sodium. Diisopropylamine, triethylamine, and pyridine were distilled from CaH_2 and stored over 4A molecular sieves.

Infrared spectra were recorded with a Beckman 4250 spectrophotometer and mass spectra with a Varian MAT-311A system at 70 eV (direct inlet). Routine proton spectra were obtained with Varian T-60 or EM-360 instruments while data for pure samples and for the shift reagent studies were collected with Varian XL-200 and -300 spectrometers. The latter instruments were employed for the ^{2}H and ^{13}C spectra, and comparison of the fully-decoupled ^{13}C spectra with those obtained from either APT (8) or DEPT (9) experiments served to identify the methyl, methylene, methine, and quaternary carbon signals. Correlation of the ^{1}H and ^{13}C spectra for **22** was accomplished using the HETCOR sequence of the XL software with a 2048 × 256 data matrix, 1800 (^{13}C) and 600 (^{1}H) Hz spectral widths transforming 2048 and 512 points, respectively. Double quantum coherence or INADEQUATE spectra (6) were recorded with the C13SAT sequence of the XL software using spectral widths of 3600 (**13**), 3000 (**16**), and 2500 (**22**) Hz to observe only the sp^3 carbons, with repetition rates of 15 s, 60 000 points, and 64 K transforms. To determine the ^{2}H-induced isotope shifts required for the analyses of the ^{13}C spectra of the deuterated ketones produced by homoketonization in deuterated base, spectral widths of 7500 Hz with 60 000 data points and 64 K transforms were employed at 75 MHz. The isotope shifts are given in ppb (ppm × 10^3) with an estimated precision of 5 ppb.

7-Spirocyclopropylnorbornenone (12)

Following the procedure reported by Turro and Farrington (10) a mixture of spiro[2,4]hepta-4,6-diene (13.6 g, 148 mmol), prepared from cyclopentadiene and 1,2-dibromoethane according to the method described by Alder *et al.* (11), and 2-chloroacrylonitrile (15.6 g, 178 mmol) was stirred at 105°C for 5 h. Distillation afforded 16.0 g of the Diels–Alder adduct, 15.5 g of which was added to a mixture of ethylene glycol (107 mL) and KOH (26.5 g) and stirred at 95°C for 20 h. After the addition of 380 mL of 10% aqueous NaCl solution, the product was extracted with pentane (6 × 100 mL). The combined extracts were washed with brine (2 × 70 mL) and dried over $MgSO_4$. After removal of the solvent, the residue was distilled to give **12** (7.59

g), bp 89–90°C/16 Torr (1 Torr = 133.3 Pa) (lit. (10) bp 90–92°C/21 Torr) which was >85% pure by glc analysis (FFAP). Flash chromatography (Et_2O – petroleum ether, 25:75) furnished pure **20** (5.9 g, 51% yield); ir (film): 3076, 3000, 1745, 708 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.64 (bs, 4H), 1.98 (d, J = 16.2 Hz, *endo*-H-3), 2.28 (dd, J = 3.1, 16.2 Hz, *exo*-H-3), 2.50 (m, H-1 and -4), 6.20 (m, 1H), 6.62 (dd, J = 2.8, 5.6 Hz, 1H); ^{13}Cmr ($CDCl_3$) δ_C: 6.0, 7.0 (2 × CH_2), 38.3 (C-3), 46.0 (C-4), 46.1 (C-7), 60.8 (C-1), 129.4 (C-6), 142.0 (C-5), 212.7 (C-2). *Exact Mass* calcd. for $C_9H_{10}O$: 134.0732; found: 134.0729.

Trimethylsilyl enol ether of 12

This compound was prepared following the procedure reported for norbornenone (1) using diisopropylamine (0.84 mL), THF (8 mL), n-butyllithium (2.1 mL, 2.50 M in n-C_6), and **12** (0.50 g) with a quenching solution of trimethylsilyl chloride (0.76 mL), Et_3N (0.29 mL), and THF (1.5 mL). Kugelrohr distillation of the product isolated by pentane extraction gave crude enol ether (bp 102–106°C/12 Torr, 0.69 g, 90% yield) which glc analysis (Carbowax) indicated to be ~95% pure. An analytical sample was collected by preparative glc for characterization; ir (CCl_4): 3060, 2960, 1610, 1257, 839 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.10 (s, 9H, $(Me)_3Si$), 0.28–0.68 (m, 4H), 2.48 (m, 1H), 2.64 (m, 1H), 5.32 (dd, J = 1.3, 3.3 Hz, H-3) 6.88 (t, J ~ 1.9 Hz, 2H), ^{13}Cmr (C_6D_6) δ_C: 0.0 (Me_3Si), 10.4, 10.6 (2 × CH_2), 53.8 (C-4), 58.8 (C-1), 67.5 (C-7), 109.3 (C-3), 141.0 (C-6), 145.4 (C-5), 172.5 (C-2). *Exact Mass* calcd. for $C_{12}H_{18}OSi$: 206.1127; found: 206.1124.

8-Spirocyclopropyl-2-trimethylsiloxyhomoquadricyclene (13)

Cyclopropanation of the silyl enol ether of **12** was carried out as previously described for the parent norbornenone derivative using a zinc–silver couple (1.26 g) and CH_2I_2 (0.85 mL) in Et_2O (2 mL) with the TMS enol ether (1.2 g) in Et_2O (15.5 mL). The usual work-up furnished an oily liquid (1.14 g) which was ca. 80% pure by glc (SE-30). Pure **13** was obtained by preparative glc; ir (CCl_4): 3078, 2975, 1250, 1154, 840 cm^{-1}; ^{1}H and ^{13}Cmr (see text). *Exact Mass* calcd. for $C_{13}H_{20}OSi$: 220.1283; found: 220.1302.

Homoketonization of 13

To 20 mL of 3 M methanolic NaOH was added **13** (485 mg) and the mixture stirred overnight at room temperature. After the addition of H_2O (20 mL), the product was extracted with n-pentane (3 × 20 mL) and the combined extracts washed with H_2O (3 × 15 mL) before drying over $MgSO_4$. Removal of the solvent gave a yellow oil (330 mg) containing one ketonic component **16** (ca. 90% yield) that was purified by preparative glc (FFAP); ir (film): 3040, 2930, 1725 cm^{-1}; ^{1}H and ^{13}Cmr (see text). *Exact Mass* calcd. for $C_{10}H_{12}O$: 148.0888; found: 148.0882.

Preparation of 16-d$_x$

A sample of **13** (90 mg) was placed in a 1.3 M solution of KOD in t-BuOD (1.6 mL) and the mixture stirred at room temperature overnight. Isolation by pentane extraction (90% yield) and purification by glc (FFAP) gave **16**-d_x; ms: 4.6% d_0, 32.6% d_1, 41.7% d_2, 21.5% d_3 (total 1.80 atoms ^{2}H/molecule).

Hydrogenation of 16

To a solution of **16** (130 mg) in glacial acetic acid (4 mL) was added 27 mg of platinum oxide catalyst and the mixture hydrogenated at 50 psi (1 psi = 6.89 kPa) in a Parr shaker for 21 h. Dilution with H_2O (15 mL) and neutralization with $NaHCO_3$ were followed by removal of the catalyst by filtration. The product was extracted with n-pentane (3 × 10 mL) and the combined extracts dried over $MgSO_4$ before removal of the solvent by evaporation to furnish 130 mg of material. Gas–liquid chromatographic analysis (FFAP) indicated the presence of two components in comparable amounts and samples were collected by preparative glc. The ^{13}Cmr spectra of the samples showed one to be a 1:2 mixture of unreacted **16** and a new compound having signals at δ_C 26.7, 29.4 (2 × CH_3), 28.8, 30.8 (2 × CH_2), 13.1, 14.7, 24.7, 46.8, 71.8 (5 × CH), and 38.3 (quat C). These data indicate that the new product is probably 6,6-dimethyltricyclo[3.2.1.0^{2,7}]octan-4-ol but the compound was not further characterized. The second component obtained by preparative glc was a single ketone identified as 6,6-dimethyltricyclo[3.2.1.0^{2,7}]octan-4-one; ir (film): 3030, 2965, 1720 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.02 (s, 3H), 1.07 (s, 3H), 1.00–1.30 (m, 2H), 1.42 (dt, J = 3.4, 6.5 Hz, H-1), 1.75 (d, J = 13.3 Hz, *endo*-H-8), 2.04 (d, J = 5.5 Hz, H-5), 2.20 (ddd, J = 3.4, 5.5, 13.3 Hz, *exo*-H-8) and an AB pattern, 2.48, 2.55 (J_{AB} = 20.0 Hz, H-3) each exhibiting a 2.5-Hz splitting; ^{13}Cmr (see text). *Exact Mass* calcd. for $C_{10}H_{14}O$: 150.1044; found: 150.1041.

Reduction of 16

To a slurry of LAH (38 mg) in anhydrous Et_2O (2 mL) was added a solution of **16** (95 mg) in Et_2O (4 mL) and the mixture stirred overnight under reflux. On cooling to 0°C, excess LAH was destroyed by the cautious addition of H_2O and 10% aqueous NaOH solution (0.2 mL). After stirring, the precipitate was removed by filtration and the solvent removed after drying to furnish 75 mg of product which contained two components by glc analysis (FFAP) in a ratio of 6.5:1; both were isolated by preparative glc.

The major product, mp 67–68°C, was found to be alcohol **24**, primarily on the basis of its ^{13}C spectrum (see text); ir (CCl_4): 3630, 3040, 3000, 2940, 1055 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 3.69 (m, 1H), 2.44 (dddd, J ≈ 0.6, 3.0, 9.8, 14.8 Hz, 1H), 1.95 (dddd, J ≈ 0.6, 3.4, 6.5, 11.6 Hz, 1H), 1.80 (ddd, J ~ 2.2, 4.6, 14.8 Hz, 1H), 1.60 (m, 1H), 1.47 (d, J = 11.6 Hz, 1H), 1.28 (m, 2H), 0.65–0.93 (m, 4H), 0.05–0.30 (m, 2H). *Exact Mass* calcd. for $C_{10}H_{14}O$: 150.1044; found: 150.1045.

The minor product **25** was identified by its ^{13}Cmr spectrum (see text); ir (CCl_4): 3620, 3040, 2925, 1060 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 3.93 (m, 1H), 2.40 (ddd, J ≈ 3.1, 9.0, 15.0 Hz, 1H), 2.00 (d, J = 12.0 Hz, 1H), 1.75 (m, 1H), 1.65 (ddd, J ≈ 2.1, 4.2, 15.0 Hz, 1H), 1.55 (bs, OH), 1.10–1.40 (m, 3H), 0.22–0.90 (m, 5H). *Exact Mass* calcd. for $C_{10}H_{14}O$: 150.1044; found: 150.1042.

7-Isopropylidenenorbornenone (18)

A mixture of cyclopentadiene (66 g) and acetone (58 g) was cooled to 0°C before the dropwise addition of 20% ethanolic KOH solution (20 mL) with stirring (12). Stirring was continued overnight. The organic layer was separated and distilled to furnish 6,6-dimethylfulvene (32.5 g, 31%), bp 42–47°C/11 Torr (lit. (13) bp 44–46°C/10 Torr). A solution of 6,6-dimethylfulvene (3.06 g, 29 mmol) and 2-acetoxyacrylonitrile (10.00 g, 90 mmol) in dry pyridine (1.20 mL) was prepared and aliquots were transferred to six flame-dried, 5-mL thick walled Pyrex tubes under a N_2 atmosphere. The tubes were sealed under vacuum and placed in an oil bath at 90°C for 28 h (14). After cooling to room temperature, the contents of the tubes were taken up in CH_2Cl_2. The solvent was removed and the product isolated by flash chromatography using benzene as eluent to furnish an epimeric mixture (7:1) of the 2-acetoxy-2-cyano-7-isopropylidenebicyclo[2.2.1]hept-5-enes (6.0 g, 96% yield), favoring the *endo*-cyano isomer by comparison with the published data (14). This mixture was used directly for the next step.

The mixture of Diels–Alder adducts (2.0 g, 9.2 mmol) was dissolved in methanol (8.8 mL) and added, with stirring, to a 2 M solution of NaOMe in MeOH under a N_2 atmosphere. After stirring for 2.5 h, 10% aqueous NaCl solution (20 mL) was added and the product extracted with methylene chloride (4 × 20 mL). The combined extracts were washed with H_2O before drying over $MgSO_4$. Removal of the solvent gave **18** (1.0 g, 75% yield), which was >97% pure by glc (FFAP) analysis; ir (film): 3080, 2920, 1750 cm^{-1}; ^{13}Cmr ($CDCl_3$) δ: 19.4, 19.8 (2 × CH_3), 40.4 (CH_2), 42.0, 57.9, 130.9, 143.1 (4 × CH), 115.2, 146.2 (2 × olef. CH), 218.6 (C=O).

2-Trimethylsilyloxy-7-isopropylidenebicycloheptadiene (19)

Following our usual procedure, **18** (0.60 g, 4 mmol) in THF (2 mL) was added dropwise to a THF solution of LDA at −78°C. The LDA was prepared from diisopropylamine (0.92 mL, 6.6 mmol) in THF (5.5 mL) to which had been added 2.46 M n-BuLi in hexane (2.30 mL, 5.66 mmol). Quenching with chlorotrimethylsilane (0.93 mL, 7.3 mmol) and triethylamine (0.34 mL, 2.4 mmol) in THF (2 mL) and extraction with pentane as described earlier gave, after removal of the solvent, 0.71 g of oily **19** (80% yield); ir (film): 3050, 2965, 1610, 1250, 844 cm^{-1}; ^{1}Hmr (C_6D_6) δ: 0.0 (s, Me_3Si), 1.30 (s, Me), 1.33 (s, Me), 3.58 (m, 1H), 3.74 (m, 1H), 5.23 (dd, J = 1.3, 3.6 Hz, 1H), 6.78 (m, 2H); ^{13}Cmr ($CDCl_3$) δ_C: 0.1 (Me_3Si), 18.6, 18.7 (2 × CH_3), 48.9, 54.2 (2 × CH), 109.5, 141.3, 145.3 (3 × olef. CH), 93.4, 162.9, 171.8 (3 × quat C). *Exact Mass* calcd. for $C_{13}H_{20}OSi$: 220.1283; found: 220.1280.

*Cyclopropanation of **19***

Our general procedure was employed whereby a zinc–silver couple (0.53 g, 8.1 mmol) was placed in a nitrogen-purged flask and the apparatus was flame-dried. After cooling, methylene iodide in anhydrous Et_2O (2 mL) was added and the mixture warmed until refluxing occurred without external heating. Upon cessation of reflux, an ethereal solution of **19** (0.55 g, 2.4 mmol) was added and the mixture refluxed for several hours. After cooling to 0°C, a 50:50 mixture of pyridine–ether was added until no further precipitate formed. The precipitate was removed by filtration and the ether evaporated. The residue was taken up in *n*-pentane and the traces of precipitate were removed by filtration before evaporation of the solvent. The resulting oily product (0.51 g) was shown to contain a mixture of two adducts by ^{13}Cmr. All attempts to analyze the product by glc (FFAP, SE-30, Carbowax) led to decomposition even if freshly prepared glc columns were used. A series of experiments following this general procedure was carried out as summarized in Table 1.

A preparative run was carried out by reacting 710 mg of **19** in Et_2O (9.9 mL) with a zinc–silver couple (0.5 g) and CH_2I_2 (0.13 mL, 1.6 mmol) in Et_2O (3 mL) at room temperature for 5.5 h before the addition of more CH_2I_2 (0.13 mL, 1.6 mmol) and stirring for an additional 20 h. The reaction was quenched and the product isolated in the usual fashion as an oil (700 mg).

The major component in the product from Expt. 1 (Table 1) gave rise to a ^{13}C spectrum consistent with structure **20** (see text) while the major component from Expt. 3 exhibited a ^{13}C spectrum readily attributable to **21** as discussed in the text. These structural assignments were confirmed by unequivocal identification of their homoketonization products.

*Homoketonizations of **20** and **21**a*

The same procedure described above for homoketonization of **13** was employed.

Upon treatment with 3 *M* methanolic NaOH, the product from Expt. 5 (Table 1) afforded a single ketone by glc analysis (FFAP). Although the starting material was a mixture of **18** and **20**, it was apparent that **18** did not survive after several hours in base. The structure of the new ketone **22** was established by detailed analysis of its ^{13}C spectrum (see text); ir (CCl_4): 3060, 2910, 1747 cm^{-1}; ^{1}Hmr (see text). *Exact Mass* calcd. for $C_{11}H_{14}O$: 162.1045; found: 162.1039.

Homoketonization of the material from the preparative scale cyclopropanation gave 330 mg of **22**, after purification by flash chromatography (7% Et_2O – 93% petroleum ether (30–60°C), 64% overall yield from **19**).

The product from Expt. 4 (Table 1) was stirred at room temperature with 2 mL of 1 *M* KOD/*t*-BuOD overnight. The usual work-up furnished **22**-d_x containing 2.74 atoms ^{2}H/molecule; ^{13}Cmr ($CDCl_3$) δ_C (Δδ = isotope shift, ppb): 20.6 (163) C-2, 26.3 (50) C-8, 30.0 (50) C-1, 35.4 (J_{CD} = 20.4 Hz, 660) C-3, 43.4 (J = 20.2, 364) C-6, 50.3 (68) C-5, 129.8 (J_{CD} = 1.2 Hz, 23) C-7′, 26.5 (50) C-1; ms: 5.6% d_0, 1.1% d_1, 7.1% d_2, 86.0 d_3, 0.2% d_4.

A portion of **22**-d_x was treated with 3 *M* methanolic NaOH to furnish **22**-d_1 containing 0.96 atoms ^{2}H/molecule; ^{13}Cmr ($CDCl_3$) δ_C (Δδ = isotope shift, ppb): 43.4 (J = 20.2 Hz, 323) C-6, 50.3 (72) C-5, 126.5 (40) C-7, 129.8 (J_{CD} = 1.2 Hz, 50) C-7′; ms: 4.6% d_0, 94.8% d_1, 0.6% d_2.

Homoketonization of the mixture of adducts (210 mg) obtained in Expt. 3 (Table 1) gave an oily liquid (145 mg, 97% yield) shown to be a 78:12 mixture of **23** and **22** by glc (FFAP), readily separable by preparative glc. The ^{1}H and ^{13}Cmr spectra showed that **23** was a single compound; ir (CCl_4): 3050, 2925, 1725 cm^{-1}; ^{1}H and ^{13}Cmr (see text); *Exact Mass* calcd. for $C_{12}H_{16}O$: 176.1201; found: 176.1193. A second sample (130 mg) of the same starting material was treated with 1 *M* KOD/*t*-BuOD (2 mL) to furnish 85 mg (92% yield) of the mixture of **23**-d_x and **22**-d_x. After isolation by glc, ketone **23**-d_x was found to contain 1.50 atoms ^{2}H/molecule (30.0 d_0, 25.9% d_1, 34.2% d_2, 18.5% d_3). Back-exchange with 3 *M* methanolic NaOH afforded **23**-d_1; 42.0% d_0, 56.8% d_1, 1.1% d_2 (total 0.59 atoms ^{2}H/molecule).

*H/D exchange of **22***

A solution of **22** (35 mg) in 1 *M* MeONa/MeOD (2 mL) was heated under reflux for 90 min. After addition of D_2O (3 mL), the product was isolated by pentane extraction (3 × 8 mL); the combined extracts were washed with 10% aqueous NaCl solution before drying over $MgSO_4$. Evaporation of the solvent gave 30 mg of **22**-d_y and an analytical sample was obtained by glc (FFAP); ms: 6.4% d_0, 28.5% d_1, 65.4% d_2, 1.59 atoms ^{2}H/molecule. The ^{2}Hmr spectrum (C_6D_6) contained equally intense signals at δ 1.87 and 2.15 (*endo*- and *exo*-^{2}H-3, respectively).

*Reduction of **23**a*

Ketone **23** (30 mg) in Et_2O (2.2 mL) was added to a slurry of LAH (20 mg) in Et_2O (1 mL) under a N_2 atmosphere and stirred overnight. The usual work-up afforded an oil (30 mg), which by glc analysis contained two components in a ratio of 18.5:1. A sample of the major component was isolated by preparative glc and identified as **26** on the basis of its ^{13}C spectrum (see text); ir (CCl_4): 3630, 3050, 2940, 1175, 915 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.25 (d, J = 3.7 Hz, 1H), 0.90 (d, J = 3.7 Hz, 1H), 0.74–0.98 (m, 2H), 1.20 (s, Me), 1.25 (s, Me), 1.29 (m, 1H), 1.50 (dd, J = 2.4, 5.8 Hz, 1H), 1.60 (d, J = 11.6 Hz, 1H), 1.67 (ddd, J = 2.0, 5.8, 13.9 Hz, 1H), 1.95 (ddd, J = 3.6, 6.0, 11.6 Hz, 1H), 2.43 (ddd, J = 3.7, 10.0, 13.9 Hz, 1H), 3.72 (m, 1H). *Exact Mass* calcd. for $C_{12}H_{18}$: 178.1358; found: 178.1357.

^{13}C magnetic resonance studies. 120.[1] The Simmons–Smith reaction with some silyl enol ethers. Unusual ring expansions of some norcamphors

ARTHUR J. RAGAUSKAS[2] AND J. B. STOTHERS
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received March 13, 1985

ARTHUR J. RAGAUSKAS and J. B. STOTHERS. Can. J. Chem. **63**, 2969 (1985).

Unexpected difficulties with Simmons–Smith cyclopropanation of the trimethylsilyl enol ether of *exo*-tricyclo[3.2.1.0^{2,4}]-octan-6-one led to a reexamination of this reaction with the parent norcamphor derivative which under "concentrated" conditions gave ring-expanded allylic ethers in low yield. With the *tert*-butyldimethylsilyl ethers, however, the allylic product is formed in high yield in the norcamphor and *exo*-trimethylenenorcamphor (tricyclo[5.2.1.0^{2,6}]decan-8-one) systems. The *tert*-butyldimethylsilyl enol ethers of bicyclo[3.2.1]octan-6-one and nopinone do not undergo ring expansion under similar conditions but the silyl ether of 3-methylenenopinol is a major product in the latter case.

ARTHUR J. RAGAUSKAS et J. B. STOTHERS. Can. J. Chem. **63**, 2969 (1985).

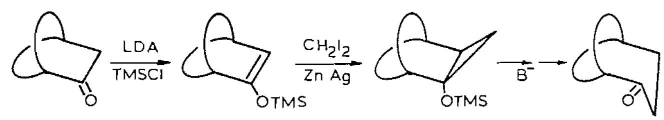
Les difficultés inattendues qui se sont manifestées lors de la réaction de cyclopropanation selon Simmons–Smith de l'éther énolique triméthylsilyle de la tricyclo[3.2.1.0^{2,4}]octanone-6 *exo* nous ont incité à réétudier cette réaction avec le dérivé norcamphre apparenté qui, lorsqu'il est soumis à des conditions "concentrées", conduit avec un faible rendement aux éthers allyliques ayant subi une expansion du cycle. Toutefois, avec les éthers *tert*-butyldiméthylsilyle du norcamphre et du triméthylènenorcamphre-*exo* (tricyclo[5.2.1.0^{2,6}]décanone-8), on obtient le produit allylique avec un rendement élevé. Dans des conditions analogues, les éthers énoliques *tert*-butyldiméthylsilyles de la bicyclo[3.2.1]octanone-6 et de la nopinone ne subissent pas d'extension de cycle; toutefois, dans ce dernier cas, le produit principal est l'éther silylé du méthylène-3 nopinol.

[Traduit par le journal]

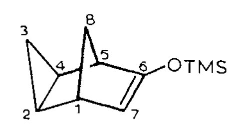
Introduction

Some years ago we described an efficient synthetic method for ring expansion of several bicyclic ketones (1). Our sequence involves generation of the trimethylsilyl enol ether followed by Simmons–Smith cyclopropanation and base-catalyzed cleavage of the cyclopropyl ether (Scheme 1). The cyclopropoxide produced by ether cleavage immediately undergoes homoketonization, which strongly favors ring expansion in [2.2.1], [2.2.2], and related systems. Subsequently this sequence was employed for ring expansion of a variety of polycyclic ketones (2–4). From these and other cases (5), we have collected more than 25 examples of the Simmons–Smith reaction with polycyclic trimethylsilyl enol ethers and, in each case, a single cyclopropanation product was obtained in good to high yield (70–95%) under a standard set of conditions ([CH_2I_2] = 0.5 *M*, [enol ether] = 0.3 *M* in ether).

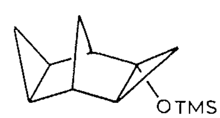
In the course of a recent study (6), however, we found that, with our standard conditions, 6-trimethylsilyloxy-*exo*-tricyclo-[3.2.1.0^{2,4}]oct-6-ene (**1**) presented unexpected difficulties, such that with reflux times of 20 h or more, which are typical for good results with all other systems investigated to date (1–5), a mixture of products resulted that was too complex to warrant detailed examination. With a reflux time of 15 h, the reaction led to a product containing, by gas–liquid chromatography (glc), one major component (65%) and a minor component (~15%) together with small amounts of additional material. The ^{13}Cmr spectra of the major and minor components showed each to be a mixture of isomers. The former fraction was a 4 : 1 mixture of **2**, the expected cyclopropanation product, and an isomer that also gave rise to 10 signals in its ^{13}C spectrum, including two methylene and two monoprotonated olefinic carbon absorptions, which is consistent with structure **3**. The minor component appeared to be a 1 : 1 mixture of isomers homologous to **2** and **3**, since each exhibited signals for 11



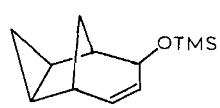
SCHEME 1



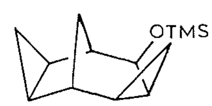
1



2



3



4

nonequivalent sp^3 carbons, which could be tentatively attributed to structure **4**. A further decrease in reflux time to 8 h finally accomplished the original goal, leading to the formation of **2** in 74% yield (6).

The apparent formation of the allylic ether **3** bears resemblance to the findings of Murai and co-workers (7, 8), who discovered that the concentration of the Simmons–Smith reagent is an important factor governing the ultimate product of cyclopropanation of monocyclic silyl enol ethers. Under their "diluted" conditions, which are comparable to our standard conditions, trimethylsilyl cycloalkenyl ethers **5** and **8** gave the

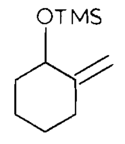
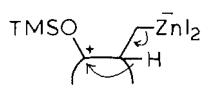
expected cyclopropanated products, e.g. **6**, in good yield, whereas, under "concentrated" conditions, efficient conversion of **5** → **7** (7) and **8***a* → **9** (8) was observed. With **8***b*, only the expected cyclopropyl ether formed regardless of the conditions employed. The cleavage of the initial product under concentrated conditions was ascribed to reaction with ZnI_2, formed in the first step, leading to intermediate **10** in the isomerization to



9



10

7. These workers showed that **6***b* was indeed isomerized to **7***b* upon refluxing with ZnI_2 in ether solution.

Our unexpected findings with **1** prompted us to examine the behavior of **1** and the parent ether **11***a* under more concentrated conditions, similar to those used by Murai and co-workers (7, 8). Results from these experiments led to the replacement of the trimethylsilyl group with the *tert*-butyldimethylsilyl moiety, and an examination of the silyl enol ethers **11***b* and **12–14** led us to examine the generality of our initial observations. We wish to describe the results of these investigations in the present paper.

Results and discussion

As noted in the Introduction, Simmons–Smith cyclopropanation of the tricyclic enol ether **1** generates **2** as the initial product but it is unstable under the usual reaction conditions, in sharp contrast to the behavior of many other polycyclic analogs (1–5) for which reflux times of 20–50 h are required for optimal results. After 15 h, **2** constitutes ca. 50% of the product but was inseparable from an isomeric impurity (~15%) which was tentatively assigned structure **3**, primarily on the basis of its ^{13}Cmr spectrum, δ_C: 0.4 (Me_3Si), 10.3, 23.5 (CH_2), 15.3, 26.3, 34.6, 42.6, 71.2, 128.3, 137.9 (CH). Signals for one methylene and two methine carbons at relatively high field (10.3, 15.3, 26.3) indicated that the original three-membered ring was intact but that the cyclopropyl ring formed by methylene addition in the Simmons–Smith reaction was not, since there was only one other methylene signal together with those for a methine carbon bearing oxygen (71.2) and two monoprotonated olefinic carbons (128.3, 137.9). A minor component constituting ca. 15% of the total product was also isolated by preparative glc and found to contain two isomers in nearly equal amounts, which may be an epimeric mixture of **4** presumably arising by cyclopropanation of **3**.

In view of the results described by Murai and co-workers (7, 8), we examined the reaction of **1** under significantly more concentrated conditions,[3] $[CH_2I_2]$ = 3.1 *M*, [**1**] = 1.9 *M*, and obtained a mixture of several products in each run. However, after 25 h reflux, the product mixture contained a major component (~35% yield) which was isolated by preparative glc and found to have the molecular formula, $C_{13}H_{22}OSi$, by precise mass measurement. The ^{13}Cmr spectrum contained eleven sp^3 carbon signals, δ_C 0.4 (Me_3Si), 6.2, 7.5, 17.8 (CH_2), 13.9, 15.2, 20.9, 21.5, 32.8, 42.7, 70.7 (CH), and is identical to that exhibited by one of the isomers in the minor component isolated from the 15-h run under our standard conditions. The molecular weight clearly shows that this material arose by double cyclopropanation and the ^{13}C absorptions for three methylene and four methine carbons at relatively high field are good evidence for structure **4**. Thus, under these conditions, the sequence **1** → **2** → **3** → **4** appears to constitute a significant part of the process but **1** is also consumed in undetermined ways.

With little indication that the three-membered ring in **1** is involved directly in the reactions with the Simmons–Smith reagent, it was of interest to examine the behavior of the parent enol ether **11***a* under comparable conditions. Under our standard conditions, **11***a* gave the expected cyclopropanated TMS ether in 72% yield (1). With $[CH_2I_2]$ = 3.1 *M* and [**11***a*] = 1.3 *M*, however, **11***a* gave a mixture of several products from which one component (~15% yield) was isolated by preparative glc and found to contain a 3:2 mixture of isomers, $C_{11}H_{20}OSi$, each giving rise to a set of nine signals in the ^{13}C spectrum. The major component exhibited absorptions for three methylene (δ_C 25.0, 31.2, 31.6), five methine (35.8, 41.5, 73.0, 126.6, 136.3), and the trimethylsilyl carbons (0.4_2) similar to those for the minor isomer, δ_C 21.9, 33.1, 37.8 (CH_2), 35.6, 42.7, 74.3, 128.9, 134.9 (CH), and 0.3_5 (Me_3Si). Each of these sets of signals is very similar to those exhibited by the *exo*- and *endo*-isomers of bicyclo[3.2.1]oct-3-en-2-ol, respectively (9), which led to their assignments as the *exo* (major) and *endo* (minor) epimers of **15**. Thus we concluded that the cyclopropyl ring introduced initially by the Simmons–Smith reaction suffers cleavage leading to the allylic ether **15**, which is analogous to the observations for the tricyclic system **1**, with low yields in both cases. Specific assignments for the ^{13}C spectra of **1–4** and the epimers of **15** are given in Table 1.

Since the instability of the trimethylsilyl ethers could be a factor contributing to these low conversions, the behavior of the *tert*-butyldimethylsilyl (*t*-BDMS) counterpart **11***b* was examined. Ether **11***b* was prepared in 80% yield using the procedure (LDA, Et_3N, *t*-BDMSCl in THF) analogous to that employed previously for a variety of TMS enol ethers (1–6). Since the completion of this study, however, two, more efficient, general methods for the preparation of *t*-BDMS enol ethers have been described (10). Under dilute conditions ($[CH_2I_2]$ = 0.7 *M*, [**11***b*] = 0.35 *M*), **11***b* gave the expected single product **16***b* in 69% yield having the molecular formula

[3] In all examples with either dilute or concentrated conditions the mole ratio of Zn/Ag:CH_2I_2 was 2:1.

$C_{14}H_{26}OSi$ by precise mass measurement, confirming the addition of one methylene group. Apart from the signals for the trialkylsilyl moieties, the ^{13}C spectrum of **16***b* was virtually the same as that recorded for the normal Simmons–Smith product **16***a* from **11***a* (1); these data are listed in Table 1. However, after 33 h reflux under concentrated conditions ($[CH_2I_2] = 3.2$ *M*, $[\mathbf{11}b] = 1.3$ *M*), **11***b* was converted in 93% yield to a mixture containing three components by glc analysis. The major product **17** (80% yield) was isolated by preparative glc and its molecular formula, $C_{14}H_{26}OSi$, determined by precise mass measurement, established the addition of one methylene group. Since the ^{13}C spectrum (Table 1) contained signals for only three methylene carbons together with those for a methine carbon bearing oxygen and two monoprotonated olefinic carbons, it was apparent that the initial cyclopropanation product had undergone cleavage of the cyclopropyl ring. The shieldings for the skeletal carbons were almost identical to those found for *exo*-**15**, confirming its structural assignment as **17**. One of the minor products (8% yield) was found to be **16***b* and the second minor product (~5%) exhibited a ^{13}C spectrum consistent with that expected for the cyclopropanation product of **17**, but all samples were contaminated with **17** and the material was not fully characterized.

By analogy with earlier findings of Murai and co-workers (7, 8), cleavage of the three-membered ring in **16** may proceed via **18**, where M, the Lewis acid (presumably zinc iodide), could be *exo* or *endo* dependent upon the stereochemistry of the ring opening. Subsequent hydride migration from C-3 would lead directly to the ring-expanded allylic ether **15** (**17**). Since **17** is the major product from **16***b*, the *exo* orientation of the silyloxy group is indicative of *endo*-H-3 migration to C-2, which in turn suggests that **18** with *exo*-M is formed preferentially from **16***b*, i.e., upon cleavage with inversion of configuration. It may be recalled that Nickon *et al.* (11) have demonstrated the remarkable effect of water on the stereochemistry of acid-catalyzed ring opening of a homoenol acetate. These workers observed strongly favored inversion of configuration in the absence of water and high degrees of retention with water present. Thus their results offer a precedent for the proposed stereoselectivity. Some supporting evidence for the proposed sequence was provided by the results of a cyclopropanation experiment using CD_2I_2. After 33 h reflux under concentrated conditions, glc analysis of the product showed it to contain two components in a 4:5 ratio in 77% yield, which were isolated by preparative glc. The smaller component was shown to be **16***b*-3-d_x by its ^{13}C spectrum, in which the C-3 signal was strongly attenuated and the C-2 and -4 absorptions contained two-bond isotope-shifted components (Δ = 145 and 130 ppb/D, respectively). The major product was **17**-d_x by ^{13}Cmr, for which the spectrum indicated substantial deuteration at C-2 (~70%) and C-3 (~90%). The difference in the product composition compared to that for the same reflux time with CH_2I_2 can be attributed to a kinetic isotope effect in the cleavage of **16***b* → **17**. In any event, the labelling pattern in **17**-d_x is consistent with hydride (deuteride) shift as in **18**.

The much higher conversion of the *tert*-butyldimethylsilyl ether **11***b* to a much simpler product mixture must be due to the increased stability of this derivative relative to its trimethylsilyl analog **11***a*. Because of the much higher yield it was of interest to examine the behavior of some related polycyclic silyl enol ethers as an indication of the scope of the reaction under concentrated conditions. To this end the *tert*-butyldimethylsilyl enol ethers **12**–**14** were prepared.

TABLE 1. ^{13}C shieldings[a] for several silyl enol ethers and derivatives

Compound	C-1	C-2	C-3	C-4	C-5	C-6	C-7	C-8	C-9	C-10	C-11	TMS	*t*-BDMS

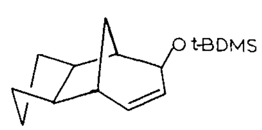
[a]In ppm from TMS for C_6D_6 solutions, using the central solvent line as reference, δ_C 128.0; similar values in parentheses may be interchanged.

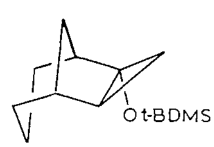
Upon reaction with CH_2I_2 (3.2 *M*) and Zn/Ag, **12** (1.2 *M*) gave, after 50 h, one major product (70% yield) having the molecular formula $C_{17}H_{30}OSi$ by precise mass measurement. The ^{13}Cmr spectrum gave no evidence of the presence of a cyclopropyl ring but rather contained signals for two monoprotonated olefinic carbons and a methine centre bearing oxygen. These and the remaining signals (Table 1) were entirely consistent with structure **19** for this product, showing that the reaction of **12** is strictly analogous to that of **11***b*. The specific assignments listed in Table 1 for **19** were aided by comparison with the results for some closely related tricyclo[5.3.1.0^{2,6}]undecane derivatives (2).

After 40 h reflux under comparable reaction conditions, **13** also gave rise to a single product having the formula $C_{15}H_{28}OSi$, by precise mass determination, showing the addition of one methylene group. In contrast to the preceding example, the ^{13}C spectrum of this product (75% yield) contained no olefinic absorption but included signals for a quaternary carbon bearing oxygen and a highly shielded methylene carbon, which is strong evidence for a cyclopropyl moiety. The spectrum is that expected for **20** arising from normal cyclopropanation. It may be noted that the shieldings (Table 1) for all skeletal carbons are very similar to those found for the cyclopropanated product obtained from the trimethylsilyl analog of **13** under our standard (dilute) conditions (1).

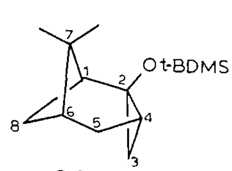
Under the concentrated conditions used for the Simmons–Smith reaction with **12** and **13**, **14** gave a product (80% yield) which was shown by glc analysis to contain two components in comparable amounts. Although pure samples of each could not be isolated, the ^{13}C spectra of the two components, each contaminated with ~10% of the other, readily revealed their structures as **21** and **22** (Table 1). The ^{13}C spectrum of **21** contained no olefinic absorption but exhibited highly shielded methylene (δ_C 19.8) and methine (16.5) carbons together with a quaternary signal typical of a cyclopropyl carbinyl carbon (60.6); these are entirely consistent with expectations for the compound arising from simple cyclopropanation. In addition, the shieldings for each of the skeletal carbons are very similar to those found for the product obtained by the Simmons–Smith



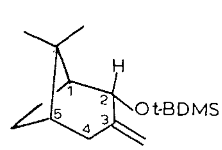
19



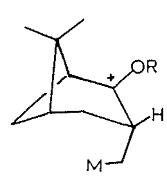
20



21



22



23

reaction, under dilute conditions, with the trimethylsilyl analog of **14**. The second product was identified as **22** by the appearance of olefinic signals for one fully substituted and one methylene carbon, δ_C 146.7 and 115.0, respectively, accompanied by signals for three methine carbons, one of which bears oxygen (73.4), two methyl, two methylene, and a quaternary carbon, as well as the absorptions for the *t*-BDMS grouping. An inspection of molecular models indicated that the initial cyclopropanation should favor the less hindered face of the double bond in **14** thereby generating **21**. Subsequent Lewis acid-catalyzed cleavage of the three-membered ring presumably proceeds through intermediate **23**, or equivalent, from which **22** is formed by hydride migration that dictates the orientation of the silyloxy grouping in **22**.

From these results, it is apparent that reagent concentration can be an important factor in the Simmons–Smith reaction of silyl enol ethers of polycyclic ketones. With a molar ratio of Zn/Ag:CH_2I_2:enol ether of 2:1:0:4 in Et_2O, the expected cyclopropyl silyl ether is obtained in good yield (70–90%) using dilute concentrations, typically $[CH_2I_2]$ = 0.5 *M*. Although in nearly all cases (1–8) relatively long reflux times (20–50 h) are required for optimum results, the reaction of **1** proceeds efficiently in 8 h. It may be noted that a single cyclopropanated ether has been obtained from each of the thirty polycyclic systems examined to date. Under these dilute conditions, the yields are comparable for the trimethylsilyl and *tert*-butyldimethylsilyl enol ethers. With the same molar ratio of reactants but with significantly less solvent, such that $[CH_2I_2] \geq 3$ *M*, the initial product may undergo further reaction whereby the cyclopropyl ether is cleaved to furnish an allylic ether. While the [2.2.1] derivatives **1**, **11**, and **12** yield the ring-expanded allylic ethers **3**, **15**, **17**, and **19**, the homologous [3.2.1] ether **13** gives only the expected cyclopropyl derivative **20**, indicating that the release of ring strain in species such as **2** and **16** provides the driving force for their isomerization to the ring-expanded products. The apparent instability of **21** and its isomerization to **22** can be ascribed to the relief of nonbonded interactions between the 3- and 8-methylene groups in **21**. In any event, these results clearly demonstrate two important features of the Simmons–Smith reaction with strained polycyclic silyl enol ethers. The concentrations of reactants can be a critical factor governing the composition of the reaction product, and the increased stability of the *tert*-butyldimethylsilyl derivatives relative to their trimethylsilyl counterparts leads to much more efficient conversion to allylic products arising from cleavage of the cyclopropyl ring.

Experimental

Boiling points are uncorrected. Gas–liquid chromatography (glc) was carried out on Varian 920 and 3700 instruments using columns of 10% Carbowax 20 M, 6% FFAP, or 10% SE-30 on Chromosorb W, as indicated. Tetrahydrofuran (THF) and ether were dried over sodium and freshly distilled before use. Diisopropylamine, triethylamine, and pyridine were distilled from CaH_2 and stored over 4A molecular sieves. Norcamphor and tricyclo[5.2.1.0^{2,6}]decan-8-one were available commercially and were used as purchased. Literature procedures were employed for the preparation of bicyclo[3.2.1]octan-6-one (12), 6,6-dimethylbicyclo[3.1.1]heptan-2-one (nopinone) (13), and 6-trimethylsilyloxy-*exo*-tricyclo[3.2.1.0^{2,4}]oct-6-ene (1, 6).

Infrared spectra were obtained with a Beckman 4250 spectrophotometer and mass spectra were recorded on a Varian MAT-311A instrument at 70 eV (direct inlet). Routine ^{1}Hmr spectra were obtained with either Varian T-60 or EM-360 instruments. The ^{13}Cmr spectra were obtained at 75.45 MHz with a Varian XL-300 instrument and comparison of fully decoupled ^{13}C spectra with those collected using either the APT (14) or DEPT (15) sequences identified the methyl, methylene, methine, and fully substituted carbon signals. All ^{13}C spectra were recorded for C_6D_6 solutions and the spectra calibrated using the central solvent peak (δ_C 128.0) as the reference line. Spectral widths of 200 ppm (δ_C −20 to 180) with pulse widths of 30° and 2-s repetition rates were employed for the decoupled spectra.

Preparation of silyl enol ethers

2-Trimethylsilyloxybicyclo[2.2.1]hept-2-ene (**11***a*) was prepared by the addition of norcamphor (2.0 g, 18.2 mmol) in 7 mL of THF to a stirred solution of LDA (formed from diisopropylamine (3.92 mL, 28 mmol), THF (16 mL), and *n*-BuLi (2.46 *M*, 9.74 mL) at −78°C, 30 min) under nitrogen and stirring was continued for 45 min. A quenching solution (prepared by centrifugation of a mixture of trimethylsilyl chloride (4.06 mL, 32 mmol) and Et_3N (1.40 mL, 10 mmol) in THF (7 mL) in a N_2-purged tube) was added, the mixture was allowed to warm to room temperature, and stirring continued for an additional 2.5 h. The reaction mixture was cooled to 0°C and, with vigorous stirring, a cold aqueous saturated solution of Na_2CO_3 (30 mL) was added. The product was isolated by pentane extraction (3 × 20 mL) and the combined extracts washed with saturated aqueous Na_2CO_3 solution and water before drying over $MgSO_4$. Removal of the solvent under reduced pressure gave crude **11***a*, which was purified by Kugelrohr distillation, bp 85–90°C/10 Torr (1 Torr = 133.3 Pa), 3.0 g, 84% yield, shown to be >90% pure by glc (FFAP). Preparative glc furnished an analytical sample for characterization; ir (film): 3080, 2960, 1605, 1334, 1225, 850 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.37 (s, 9H, Me_3Si), 1.0–1.9 (m, 6H), 2.65 (m, 1H), 2.87 (m, 1H), and 4.80 (d, 1H, *J* = 3.8 Hz); ^{13}Cmr: Table 1.

2-tert-*Butyldimethylsilyloxybicyclo[2.2.1]hept-2-ene* (**11***b*) was prepared in a manner analogous to that described for **11***a* using diisopropylamine (2.67 mL, 19 mmol) in THF (23 mL) with *n*-Buli (16.4 mmol) in *n*-C_6H_{12} (6.5 mL) at −78°C for 30 min to generate LDA before the addition of norcamphor (1.50 g, 13.6 mmol). The quenching solution consisted of Et_3N (0.20 mL, 1.4 mmol) and *tert*-butyldimethylsilyl chloride (3.30 g, 21.9 mmol) in THF (2 mL) and, after its addition, stirring was continued for 5 h before warming to room temperature and stirring for an additional 2 h. After isolation by pentane extraction as described above, Kugelrohr distillation afforded **11***b*, bp 83–87°C/0.4 Torr, 2.57 g, 84% yield, found to be >95% pure by glc (FFAP); ir (film): 3078, 2930, 1611, 1328, 1230, 830 cm^{-1}; ^{13}Cmr: Table 1. *Exact Mass* calcd. for $C_{13}H_{24}OSi$: 224.1596; found: 224.1601.

8-tert-*Butyldimethylsilyloxytricyclo[5.2.1.0^{2,6}]dec-8-ene* (**12**) was generated from tricyclo[5.2.1.0^{2,6}]decan-8-one (1.0 g, 6.7 mmol) using the preceding procedure except that no Et_3N was required in the quenching solution. Kugelrohr distillation furnished **12**; bp 105–110°C/0.2 Torr; 1.32 g, 75% yield, which glc (FFAP) indicated to be ~95% pure; ir (film): 3080, 2940, 1625, 874 cm^{-1}; ^{13}Cmr: Table 1. *Exact Mass* calcd. for $C_{16}H_{28}OSi$: 264.1909; found 264.1912.

6-tert-*Butyldimethylsilyloxybicyclo[3.2.1]oct-6-ene* (**13**) was obtained from bicyclo[3.2.1]octan-6-one (0.50 g, 4 mmol) following the procedure described for **11***b*. Kugelrohr distillation (60–67°C/0.3 Torr) gave **13** (0.65 g, 68% yield) which was >98% pure by glc analysis (FFAP); ir (CCl_4): 3080, 2930, 1625, 1227, 875 cm^{-1}; ^{13}Cmr: Table 1. *Exact Mass* calcd. for $C_{14}H_{26}OSi$: 238.1753; found: 238.1754.

6,6-Dimethyl-2-tert-*butyldimethylsilyloxybicyclo[3.1.1]hept-2-ene* (**14**) was prepared similarly. Nopinone (0.50 g, 3.6 mmol) gave **14** (0.53 g, 58% yield) after Kugelrohr distillation (60–64°C/1 Torr) which glc (FFAP) indicated to contain 8% nopinone. Preparative glc furnished pure material; ir (CCl_4): 2930, 1650, 860 cm^{-1}; ^{13}Cmr: Table 1. *Exact Mass* calcd. for $C_{15}H_{28}OSi$: 252.1909; found: 252.1915.

Cyclopropanation reactions

General procedure

To a flask fitted with a reflux condenser, nitrogen purge, and a magnetic stirrer was added zinc–silver couple and the apparatus was flame-dried. After cooling to room temperature, a solution of CH_2I_2 in Et_2O was added and the mixture warmed until refluxing occurred without external heating. Upon the cessation of reflux, an ethereal solution of the silyl enol ether was added and the reaction mixture refluxed for several hours. At intervals small aliquots were removed by syringe and analyzed by glc to monitor the disappearance of the enol ether. After cooling to 0°C, the reaction was quenched with a 1 : 1 solution of Et_2O/pyridine and the resulting precipitate removed by filtration. After evaporation of the Et_2O, the residue was taken up in *n*-pentane, and filtered again to remove the last traces of precipitate before drying over $MgSO_4$. Upon removal of the solvent, the product was analyzed by glc and the individual components isolated by preparative glc.

In all experiments the molar ratio of zinc–silver couple: CH_2I_2 was 2:1, typically using 5 mmol of CH_2I_2. Under dilute conditions: $[CH_2I_2]$ = 0.5 *M*, $[ROSiR'_3]$ = 0.3 *M*; our concentrated conditions were $[CH_2I_2]$ = 3.0 *M*, $[ROSiR'_3]$ = 1.3 *M*.

Enol ether 1

Under dilute conditions and 15 h reflux, **1** gave a product containing by glc (SE-30) one major component (~65%) together with five minor ones, the largest of which constituted ca. 15% of the total product. Preparative glc (SE-30) furnished samples of the major and the largest minor components for ^{13}Cmr examination. The former gave rise to two sets of signals in a 4:1 ratio ascribable to **2** and **3**; as listed in Table 1, **2** had been characterized earlier (6). The ^{13}C spectrum of the second component also contained two sets of signals, one of which could be attributed tentatively to **4** (see Table 1).

Under concentrated conditions, **1** (0.45 g) gave a product mixture (0.34 g) from which the major component **4** (~35%) was isolated by preparative glc (SE-30). The ^{13}Cmr data are listed in Table 1. *Exact Mass* calcd. for $C_{13}H_{22}OSi$: 222.1440; found: 222.1429.

Enol ethers 11

After 50 h reflux under concentrated conditions, **11***a* (0.40 g) was found to give 140 mg of a mixture containing several compounds by glc from which one band was isolated by preparative glc representing ~15% of the total. The ^{13}Cmr (see Table 1) of this component indicated it to contain a 3:2 mixture of isomers **15**; ir (film): 3040, 2960, 1250, 840 cm^{-1}. *Exact Mass* calcd. for $C_{11}H_{20}OSi$: 196.1283; found: 196.1289.

Under dilute conditions, **11***b* (0.49 g) gave, after 19 h reflux, **16***b* (0.36 g, 69% yield) >98% pure by glc (FFAP); ir (CCl_4): 3015, 2960, 1340 cm^{-1}; ^{13}Cmr: Table 1. *Exact Mass* calcd. for $C_{14}H_{26}OSi$: 238.1753; found: 238.1747.

After 33 h reflux under concentrated conditions, **11***b* (0.49 g) furnished 0.50 g of product consisting of **17** (80% yield) and **16***b* (8% yield) by glc. Preparative glc furnished pure samples of **17**; ir (CCl_4): 3025, 2910, 1070 cm^{-1}; ^{13}Cmr: Table 1. *Exact Mass* calcd. for $C_{11}H_{26}OSi$: 238.1753; found: 238.1754. This experiment was repeated using CD_2I_2 (ms: 2.1% d_0, 19.4% d_1, 77.8% d_2; 1.75 atoms D/molecule), prepared according to a literature procedure (16), from which **11***b* (0.40 g) gave rise to 0.36 g of product consisting of **16***b*-d_x and **17**-d_x in a 4:5 ratio by glc, representing 90% of the total product. For **16***b*-d_x (34% yield); ms: 1.4% d_0, 10.7% d_1, 87.7% d_2; 1.87 atoms D/molecule; **17**-d_x (43% yield); ms, 3.8 d_0, 29.8% d_1, 63.5 d_2; 1.64 atoms D/molecule; ^{13}Cmr: see text.

Enol ether 12

With concentrated conditions and a 50-h reflux period, **12** (0.40 g) gave 0.37 g of product, which glc (FFAP) indicated to contain 80% of **19** (70% yield); ^{13}Cmr: Table 1. *Exact Mass* calcd. for $C_{17}H_{30}OSi$: 278.2066; found: 278.2069.

Ether 13

With 50 h reflux under concentrated conditions, **13** (0.30 g) gave a single product **20** (0.24 g, 76% yield) by glc analysis (FFAP); ir (CCl_4): 3010, 2930, 1345, 920 cm^{-1}; ^{13}Cmr: Table 1. *Exact Mass* calcd. for $C_{15}H_{28}OSi$: 252.1909; found: 252.1910.

Enol ether 14

Under concentrated conditions with 43 h reflux, **14** (0.40 g) furnished 0.34 g (80% yield) of product mixture containing approximately equal quantities of **21** and **22**. Preparative glc failed to furnish pure samples of each component but the components were identified by their ^{13}C spectra (see text and Table 1).

JAMES D. HALLIDAY, PATRICK E. BINDNER, and SHAHSULTAN PADAMSHI. Can. J. Chem. **63**, 2975 (1985).

Nitrogen-14 quadrupole interactions broaden the ^1H nuclear magnetic resonances of the ammonium protons spin-coupled to ^{14}N in the methyl-substituted ammonium chlorides (methylammonium, dimethylammonium, and trimethylammonium). These proton lineshapes have been determined over the temperature range −8.3 to +93.6°C in 6 mol L^{-1} aqueous HCl solution. The ^{14}N spin-lifetimes, τ, have been calculated from the Arrhenius form equation ln τ vs. $1/T$ (K), and yield activation energies of 10.63 ± 0.92, 10.60 ± 0.52, and 11.12 ± 0.39 kJ mol^{-1} for the mono-, di-, and tri-methyl species, respectively. The ^{14}N nmr linewidths have been extracted from these data and a comparison is made with ^{14}N nmr spectra obtained by Ogg and Ray.

JAMES D. HALLIDAY, PATRICK E. BINDNER et SHAHSULTAN PADAMSHI. Can. J. Chem. **63**, 2975 (1985).

Les interactions quadrupolaires du ^{14}N élargissent les pics de rmn du ^1H des protons ammonium couplés par leurs spins au ^{14}N des chlorures d'ammonium portant des substituants méthyles (méthylammonium, diméthylammonium et triéthylammonium). On a déterminé la forme des pics de ces protons dans l'intervalle de température allant de −8,3 à +9,6°C, dans des solutions aqueuses à 6 mol L^{-1} HCl. On a calculé le temps de vie du spin du ^{14}N, τ, à partir d'une équation de type Arrhénius, ln τ vs. $1/T$ (K), et l'on en a tiré les énergies d'activation qui sont respectivement de 10,63 ± 0,92, 10,60 ± 0,52 et 11,12 ± 0,39 kJ mol^{-1} pour les espèces mono-, di- et triméthylammonium. À partir de ces données, on a déduit la largeur des pics de rmn du ^{14}N et on les a comparé avec les spectres de Ogg et Ray.

[Traduit par le journal]

Introduction

An efficient spin relaxation mechanism in compounds containing ^{14}N is provided through the interaction of the quadrupole moment of the ^{14}N nucleus with the electric field gradients present in the molecule. The spin-lifetimes and consequently the linewidths of the ^{14}N will vary with the magnitude of this interaction. Ogg and Ray (1) showed this qualitatively for the ammonium ion and a series of methyl-substituted ammonium ions. The ^{14}N linewidth in the symmetrical $\overset{+}{N}H_4$ ion is very narrow (long spin-lifetimes) and becomes much broader when one, two, or three methyl groups, which introduce increased asymmetry in the electric field gradients, are substituted (shorter spin-lifetimes). The ^{14}N spin-lifetimes may also be obtained from lineshape analysis (2, 3) of nuclei spin-coupled to the ^{14}N, i.e., ^1H for the ammonium ions. We have been able to use this latter technique to expand on the original report of Ogg and Ray (1) by determining the ^{14}N spin-lifetimes quantitatively for methyl-, dimethyl-, and trimethylammonium chlorides as a function of temperature.

Experimental

The mono-, di-, and trimethylammonium chlorides were prepared by the reaction of the corresponding free amines (Matheson, Eastman) with double distilled hydrochloric acid (Anachemia). The amines were first purified by repeated cryogenic (liquid N_2) vacuum distillation using a stainless steel and glass vacuum line. The nmr samples were 6 mol L^{-1} substituted ammonium salt in 6 mol L^{-1} aqueous HCl. A saturated solution of ammonium chloride was also prepared.

The nmr spectra of the samples in Wilmad 528 (5 mm) nmr tubes were obtained on a CW Bruker HX90 spectrometer equipped with a B-ST 100/700 variable temperature accessory (±0.5°C) and a Nicolet 1174 signal averager.

Results

The ^1H nmr spectra of the mono-, di-, and trimethylammonium chlorides and the unsubstituted ammonium chloride were recorded as a function of temperature between −8.3 and 93.6°C. Sample spectra run at 52°C are shown in Fig. 1. The coupling constants, $J_{^{14}NH}$ and $J_{HC^{14}NH}$, determined for these compounds are given in Table 1. The $J_{^{14}NH}$ were calculated from the $J_{^{15}NH}$, which are directly measurable from the spectra through the 0.37% natural abundance ^{15}N sidebands. These coupling constants are related through their gyromagnetic ratios in eq. [1].

TABLE 1. Coupling constants (^{14}N–H and H—C—^{14}N–H) in substituted ammonium ions

Compound	$J_{^{14}NH}$ (Hz)	$J_{HC^{14}NH}$ (Hz)
$\overset{+}{N}H_4$	52.5	—
NH_3[a]	43.8	—
$CH_3\overset{+}{N}H_3$	53.6	6.18
$(CH_3)_2\overset{+}{N}H_2$	54.5	5.69
$(CH_3)_3\overset{+}{N}H$	54.7	5.19

[a] Reference 4.

$$[1] \quad J_{^{14}NH} = -\frac{\gamma^{14}N}{\gamma^{15}N} \cdot J_{^{15}NH}$$

The ^{14}N spin-lifetimes found from lineshape analysis of the ^{14}N-H proton spectra are shown in Fig. 2. The method for determining these values using the theories of Sack and Pople (2, 3) has been described previously (5, 6), and is outlined briefly below for continuity.

The lineshape is given by eq. [2].

$$[2] \quad I(\nu) \propto Re(\mathbf{W} \cdot \mathbf{A}^{-1} \cdot \mathbf{1})$$

where $I(\nu)$ = line intensity at frequency ν, Re = "real part of", $\mathbf{W}$ = a vector containing the probabilities of the spin states in the ^{14}N, $\mathbf{A}$ = a lineshape matrix given by

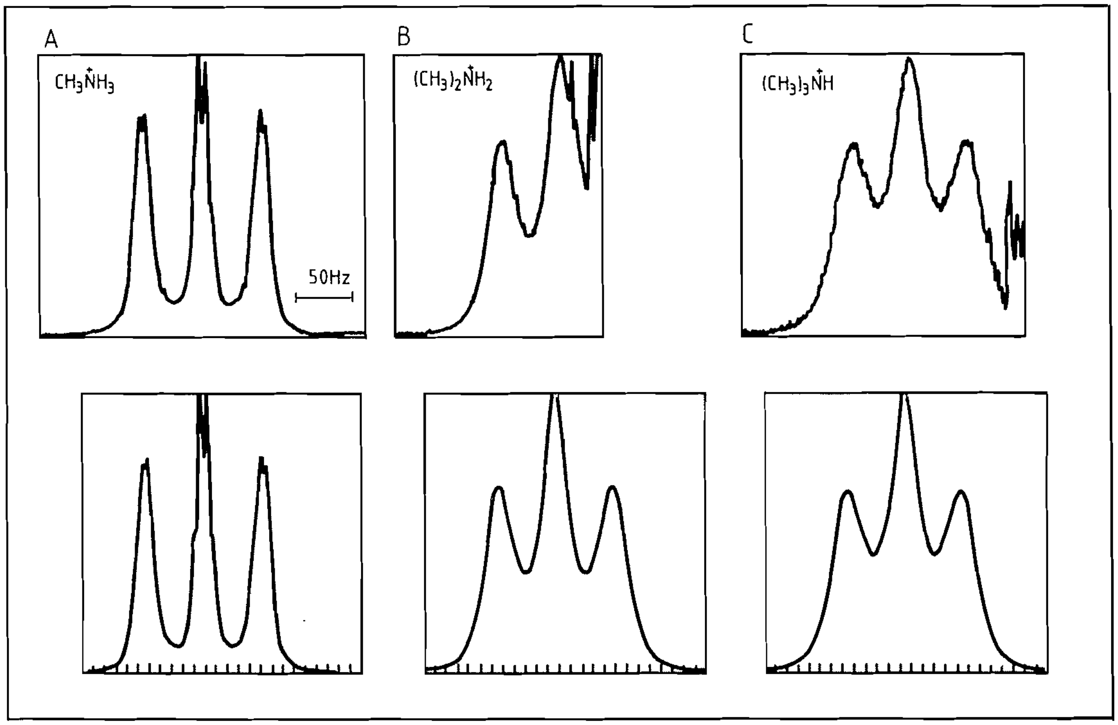

FIG. 1. Experimental methyl-substituted ammonium ion proton nmr spectra at 52°C for: (A) $CH_3\overset{+}{N}H_3$, (B) $(CH_3)_2\overset{+}{N}H_2$, and (C) $(CH_3)_3\overset{+}{N}H$, in 6 mol L^{-1} HCl. The calculated spectra are shown below each experimental one.

$$\mathbf{A} = \begin{bmatrix} \beta_1 & 1/\tau & 2/\tau \\ 1/\tau & \beta_2 & 1/\tau \\ 2/\tau & 1/\tau & \beta_3 \end{bmatrix}$$

The diagonal elements of **A** are defined by:

$$\beta_1 = i2\pi(\nu_0 - \nu + J_{^{14}NH}) - \frac{3}{\tau} - \frac{1}{T_2}$$

$$\beta_2 = i2\pi(\nu_0 - \nu) - \frac{2}{\tau} - \frac{1}{T_2}$$

$$\beta_3 = i2\pi(\nu_0 - \nu - J_{^{14}NH}) - \frac{3}{\tau} - \frac{1}{T_2}$$

with τ = ^{14}N spin-lifetime, T_2 = spin–spin relaxation time, and **1** = the unit matrix.

The fits of the simulated spectra to the experimental spectra showed small deviations at the higher temperatures and this is attributed to the onset of ammonium ion proton exchange. In these strongly acidic solutions ammonium ion proton exchange is effectively stopped on the nmr timescale at room temperature and below (7), but some exchange occurs as the temperature is raised to 93.6°C. This is consistent with some broadening of the methyl group resonances. Within the experimental error the $\ln \tau$ vs. $1/T$ plots do not show significant falloff in τ at the high temperature end and hence the effect of this exchange is considered small. Consequently no exchange parameter was included in the calculations of the lineshapes.

Discussion

The analysis of the ammonium ions' proton nmr lineshapes has enabled the extraction of the ^{14}N spin-lifetimes, τ, in solution as a function of temperature (Fig. 2). These τ may be used to calculate: (1) the ^{14}N spin lattice relaxation times, T_1; (2) the correlation times characterizing the quadrupolar or molecular reorientations in solution, τ_q; and (3) the activation parameters for the molecular reorientations.

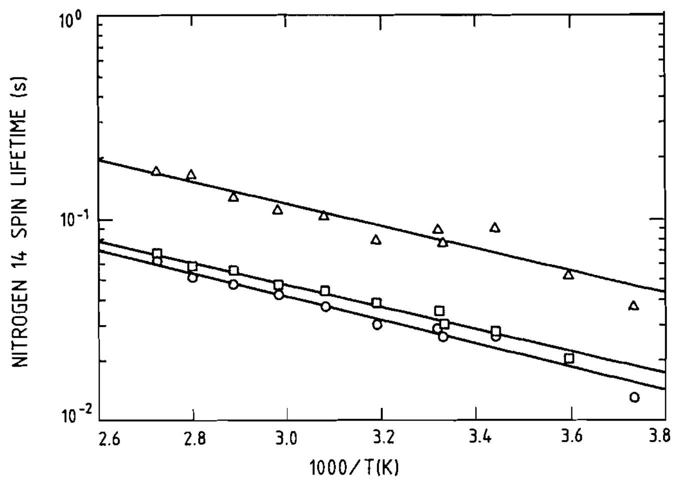

FIG. 2. Temperature dependence of the ^{14}N spin-lifetimes for the methyl-substituted ammonium ions (6 mol L^{-1} in 6 mol L^{-1} HCl): □- methyl, △- dimethyl, ○- trimethyl.

The ^{14}N T_1 are related to τ through eq. [3] (8)

[3] $\tau = 5T_1$

Since, under the conditions of observation, $T_1 = T_2$ (the spin–spin relaxation time), the ^{14}N linewidths in the absence of any spin coupling to protons may be determined by relation [4]

[4] $\Delta\nu_{1/2} = 1/\pi T_2$

Thus, the effect on the ^{14}N linewidths of substituting the ammonium ion's protons with methyl groups is shown quantitatively in Table 2.

A comparison can be made between our ^{14}N linewidth mea-

TABLE 2. Effect of methyl substitution on the ^{14}N linewidth in the ammonium ion (25°C)

Species	τ (ms)	T_1 ^{14}N (ms)	$\Delta\nu_{1/2}$ ^{14}N (Hz)	Ogg and Ray[b]
$\overset{+}{N}H_4$	>10000	>2000	<0.2	—
NH_3[a]	162.5	32.5	9.8	—
$CH_3\overset{+}{N}H_3$	49.7	9.93	32.1	32
$(CH_3)_2\overset{+}{N}H_2$	19.7	3.94	80.7	169
$(CH_3)_3\overset{+}{N}H$	16.5	3.30	96.4	146

surements obtained from proton spectra and the ^{14}N spectra measured directly by Ogg and Ray (1) on the methyl-substituted ammonium ions. The values noted in Table 2 for Ogg and Ray's results are qualitative only since they are calculated from the spectra shown in the paper. However, the differences are large enough to show that Ogg and Ray's ^{14}N linewidths for both the di- and trimethylammonium ions are much larger than the calculated ones. This is not the case for the monomethylammonium ion. Examination of Ogg and Ray's ^{14}N spectra shows a solution to this anomaly. The monomethylammonium ion has the expected quartet from coupling with the attached protons but there are no resolved couplings for either the di- or trimethylammonium ions. These unresolved proton couplings could account for the differences since the $J_{^{14}NH}$ is 54.5 Hz and 54.7 Hz respectively in these compounds, even though proton spin coupling was discounted in the original paper because no splitting was observed in the spectra. The linewidth in the unsubstituted ammonium ion is very small, indicating that the ^{14}N spin-lifetime is long. This reflects the high symmetry in the ion and the absence of any significant electric field gradients. Liquid ammonia is included in the table to show the effect of altering the symmetry by removal of a proton from the ammonium ion. The presence of the lone pair of electrons reduces by approximately two orders of magnitude the ^{14}N T_1 but, in contrast to the earlier studies (1), does not alter the electric field symmetry of the $\overset{+}{N}H_4$ as much as introducing a methyl group substituent. Table 2 also shows that there is a continued increase in the electric field asymmetry with the introduction of two and three methyl groups into the ammonium ion. Tetramethylammonium chloride does not have any ammonium protons, so a direct comparison with the ^{14}N spectrum of this compound cannot be made. However, since it is a highly symmetric species a small ^{14}N linewidth would be expected. This is confirmed through the very narrow well-resolved proton 1 : 1 : 1 triplet obtained from coupling of the ^{14}N to the methyl group protons (9); only a very long ^{14}N spin-lifetime would allow observation of this feature.

The quadrupolar (molecular reorientation) correlation time, τ_q, is related to the spin-lattice relaxation time, T_1, and the quadrupolar coupling constant, e^2qQ/h, through eq. [5] (8),

$$[5]\quad \frac{1}{T_1} = \frac{3}{40}\frac{2I+3}{I^2(2I-1)}\left(1+\frac{\eta^2}{3}\right)\left(\frac{e^2qQ}{\hbar}\right)^2\tau_q$$

For ^{14}N with $I = 1$ this equation simplifies to eq. [6] (10)

$$[6]\quad \frac{1}{T_1} = \frac{3}{8}\left(1+\frac{\eta^2}{3}\right)\chi^2\cdot 4\pi^2\cdot\tau_q$$

where η is the asymmetry parameter of the electric field gradient and $\chi = e^2qQ/h$. Unlike the methyl-substituted amines (11), values for χ in this system are not available, so τ_q cannot be calculated for these methyl-substituted ammonium ions.

TABLE 3. Activation energies for molecular reorientation of methyl-substituted ammonium chlorides

Compound	E_a (kJ mol^{-1})
NH_4Cl	—
NH_3	7.59 ± 0.23[a]
CH_3NH_3Cl	10.63 ± 0.92
$(CH_3)_2NH_2Cl$	10.60 ± 0.52
$(CH_3)_3NHCl$	11.12 ± 0.39

[a]Reference 4.

The temperature dependence of the ^{14}N spin-lifetimes (proportional to T_1) shown in Fig. 2 can be used to determine activation energies for quadrupolar (molecular reorientation) interactions in solution through the slopes of the Arrhenius plots. These are average values because the methyl-substituted ammonium ions are not spherically symmetric. The derivation of eq. [5] assumes the molecular reorientation to be isotropic with respect to the axes of the coupling tensor, and thus be described by a single τ_q. This is true only for molecule of high symmetry. The molecular reorientation energies for the methyl-substituted ammonium ions in aqueous acid solution are given in Table 3. Within the experimental error the number of methyl groups in the ammonium ion has no effect on its molecular reorientation activation energy in aqueous acid solution. However, for liquid ammonia the activation energy decreases by ~3 kJ mol^{-1}. The activation energy for the unsubstituted ammonium ion has not been determined because the spin-lifetimes of the ^{14}N are too long to measure accurately. The similarity of the activation energies for the methyl-substituted species indicates that hydrogen bonding in the aqueous phase has a more important effect than molecular geometry on molecular reorientation.

In conclusion, the nmr spectra of the protons spin-coupled to the ^{14}N of methyl-substituted ammonium ions have allowed a quantitative analysis of the ^{14}N linewidths of these ions in acid solution. Unresolved spin coupling between ^1H and ^{14}N has been shown to account for the broad lines originally observed by Ogg and Ray (1) using ^{14}N nmr. Methyl substitution in the series $\overset{+}{N}H_4 \rightarrow (CH_3)_3\overset{+}{N}H$ produced increased electric field gradients in the molecules with each additional methyl group. The similar activation energies for each methyl-substituted ammonium ion indicate that hydrogen bonding plays an important role in molecular reorientation in aqueous solution.

The X-ray crystal structure of a Corynanthé-type indole compound, $C_{22}H_{29}N_2O_4^+Br^-$, wherein an unprecedented triaxial conformation is preferred

ANGÈLE CHIARONI, CLAUDE RICHE, DAVID S. GRIERSON,[1] AND HENRI-PHILIPPE HUSSON
Institut de Chimie des Substances Naturelles, C.N.R.S., 91190 Gif s/Yvette, France

Received December 4, 1984

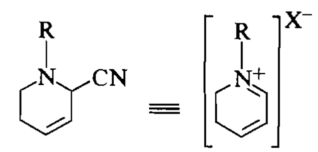
ANGÈLE CHIARONI, CLAUDE RICHE, DAVID S. GRIERSON, and HENRI-PHILIPPE HUSSON. Can. J. Chem. **63**, 2979 (1985).

On the basis of ^1H and ^{13}C nmr data, a conformation was proposed for the Corynanthé type indole compound **8** in which the substituents at C-3 (indole), C-14 (ethyl), and C-15 (malonyl) were all axial. An X-ray crystal study on the HBr salt of **8** confirmed that this a priori unexpected conformation is also preferred in the solid state.

ANGÈLE CHIARONI, CLAUDE RICHE, DAVID S. GRIERSON et HENRI-PHILIPPE HUSSON. Can. J. Chem. **63**, 2979 (1985).

Nous avions proposé, grâce à une étude de rmn de ^1H et de ^{13}C d'un composé **8**, analogue des alcaloïdes de type Corynanthé, une conformation pour laquelle les substituants en C-3 (noyau indole), en C-14 (chaîne éthyle) et en C-15 (groupement malonate) étaient tous axiaux. Une étude aux rayons X d'un cristal du bromhydrate de **8** a montré qu'une telle conformation a priori inattendue existe à l'état cristallin.

In a number of recent papers (1, 2) we have shown that 2-cyano Δ^3 piperideines **1** react efficiently with a wide range of nucleophiles, and that they thus represent stable "equivalent" forms of the corresponding 5,6-dihydropyridinium salts **2**.



1 **2**

Taking advantage of this reactivity we demonstrated, using a model system, that the C-15 substituted indoloquinolizidine unit typical of early members of the Corynanthé type indole alkaloids could be constructed in three steps from the 2-cyano Δ^3 piperideine **3** (3) (Scheme 1). This involved (a) condensation of aminonitrile **3** with sodium dimethylmalonate in the presence of $AgBF_4$ producing the enamine **4** (90% yield); (b) cleavage of the N_a (indole)-benzene sulfonyl deactivating group (Bu^tOK, THF; 80%); and (c) cyclization of the resulting intermediate **5** in acidic media (HCl/MeOH, 3 days). The three "inside" Corynanthé compounds **6**−**8** (4) were thus obtained in a combined overall yield of 45% from **3**.

For products **6** and **7**, the relative configuration of the C-3, C-14, and C-15 centers and the preferred conformations were readily deduced from a detailed analysis of their ^1H (400 MHz) and ^{13}C nmr spectra (Fig. 1). These assignments were supported by molecular mechanics calculations using the computer program SCRIPT (ROUSSEL−UCLAF) (5), which showed that the preferred conformations for **6** and **7** were at least 3 kcal/mol more stable than the alternative conformations examined (3).

For compound **8**, however, the situation was less evident. From the downfield position of the H-3 resonance (δ 3.93, d, J = 4.5 Hz) in the ^1H nmr spectrum and the absence of Wenkert−Bohlmann bands in the ir spectrum it was deduced that the molecule adopted a *cis* C/D ring conformation. It was further deduced from the observation of a single absorption (δ 1.80, qn) for the C-19 methylene protons and a hextet resonance for H-15 with $J_{15,20ax}$ = 4.5 Hz that both the C-14 ethyl and C-15 malonyl substituents were in axial orientations. Certain aspects of the ^{13}C nmr spectrum of **8**, in particular the ~4-ppm upfield α- and γ-effect shifts of the C-15 and C-21 absorptions produced by the malonyl groups, were in agreement with these assignments.

Although several features in both the ^1H and ^{13}C spectra remained unexplainable (i.e. the unusually high field position and small coupling constant (δ 3.44, J = 9 Hz) for the H-16 absorption, and the appearance of the C-6 resonance at δ 19.0, a position intermediate between that normally attributed to the *cis* (δ 16.0) and *trans* (δ 21.0) indoloquinolizidine systems (6)) we were forced to conclude that compound **8** possessed a *cis* indoloquinolizidine structure in which the C-3 indole, C-14 ethyl, and C-15 malonyl groups were all in *axial* positions.

This result was unprecedented[2] and rather difficult to accept for two major reasons: (1) in a structure such as **8***a* (Fig. 1) a highly unfavourable 1,3-diaxial interaction between the C-3 indole and C-15 malonyl groups would be predicted, and (2) in view of this interaction one would expect that an equilibration to the a priori more stable conformer **8***a* would occur, in which the three substituents adopt an all-equatorial orientation.[3]

To lay to rest all remaining doubts concerning the structure of this unusual molecule an X-ray crystal study of a suitable derivative (HBr salt) was undertaken. It was realized that even if the solid and solution state conformations of **8** did not correspond, the relative configuration at the C-3, C-14, and C-15 centers could still be established definitively.

Experimental

Crystals of the HBr salt of **8** were obtained by slow saturation of a methanol solution of **8**·HBr with ether, mp 185−187°C (dec.). A parallelepipedic crystal of dimensions 0.35 × 0.20 × 0.15 mm was used for data collection and determination of the unit cell on a Philips PW 1100 diffractometer using graphite monochromated Cu-Kα radiation (λ = 1.5418 Å). The crystal data are:

$C_{22}H_{29}N_2O_4^+Br^-$ Mol. wt. = 465.39

Orthorhombic; space group *Pbca*; a = 11.181 (4), b = 15.130 (6), c = 26.74 (1) Å; Z = 8; V = 4523 Å^3; F_{000} = 1936, μ = 25.27 cm^{-1}.

[2]Certain carbohydrates such as α-D idopyranose pentaacetate (10) also prefer a 1,2,3-triaxial conformation. This is due, however, to the strong tendency for such molecules to adopt the conformation in which the C-1 OR substituent is axial (anomeric effect) and the C-5 substituent is equatorial.

[3]The possibility that compound **8** adopts an all-equatorial conformation as in **8***a* or **8***b* was excluded on the basis of the small $J_{3,14}$ = 4.5 Hz and $J_{14,15}$ = 4.5 Hz coupling constants observed in the ^1H nmr spectrum.

FIG. 1. Three-dimensional representations of the preferred conformations of compounds **6** and **7**, and the principal conformations *a*–*c* of compound **8**.

Parameter values were obtained by the least-squares refinement of 12 well-centered reflections. The data were collected using the $\theta-2\theta$ scan technique with a speed of 0.05 deg s^{-1}, and a scan width of 1.2° + 0.2° tg θ. The three standard reflections monitored every 120 min did not show any appreciable variation in intensity during data collection. From 3360 independent intensities, 1902 with $I > 3\sigma(I)$ were considered as observed.

The structure was solved by the Patterson–Fourier method and refined by least-squares techniques which minimized the function $\Sigma w(|F_o| - |F_c|)^2$. All hydrogen atoms were located on successive difference Fourier maps and introduced in structure factor calculations in idealized positions ($d_{C—H}$ = 1.08 Å) with an isotropic temperature factor equivalent to that of the bonded atom. On the difference Fourier maps a water molecule (originating from the use of aqueous HBr to prepare the hydrogen bromide salt of **8**) displaying high thermal motion was found to be hydrogen bonded to O-22'. It was thus introduced into the refinement with an occupation factor of 0.50. This lowered the final R factor from 0.059 to 0.055 (R_w = 0.062). The weighting

Results and discussion

The X-ray crystal structure determined for the HBr salt of compound **8** is illustrated in the two 3-dimensional representations in Figs. 2a and 2b. One can see that in the solid state the molecule also adopts the *cis* indoloquinolizidine conformation where the C-3, C-14, and C-15 substituents are axially oriented. From calculations of the torsion angles (Table 3) one can further see that the D-ring is in a chair conformation that is slightly flattened in the region of carbons-3, -14, and -15. This flattening effect results in an opening of the angle between the C-2—C-3 and C-15—C-16 bonds by ~27° (with respect to an idealized chair conformation), thereby increasing the separation between the indole and malonyl substituents. A clear view of the disposition of these two substituents in the molecule is presented in Fig. 2b. It can be seen that the angle between C-16—H-16 and the normal to the indole plane is 115° and that the C-17—O-22 carbonyl groups are twisted out of the normal β-dicarbonyl W conformation so as to avoid interaction with the indole nucleus. From a measurement of the interatomic distances between H-16 and C-2 (2.55 Å), N-1 (2.85 Å), and the N-1 hydrogen (3.17 Å) it is evident that the indole and malonyl groups do not crowd each other and that the 1,3-diaxial interaction between them is, in fact, minimal.

Interestingly, the flattening of the D-ring results in a short N-1 hydrogen to H-14 distance (2.12 Å), indicating that the tendency of the molecule to maximize the separation of the large C-3 and C-15 substituents is counterbalanced by the generation of an unfavourable steric interaction between these two centres.

To summarize, as a result of an almost perpendicular disposition of the C-16—H bond relative to the indole ring, and of a minor distortion in the chair conformation of the D-ring, the steric interaction between the large indole and malonyl groups

[4]Tables of the anisotropic thermal parameters, hydrogen atom coordinates, and the observed and calculated structure amplitudes are available, and may be purchased, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

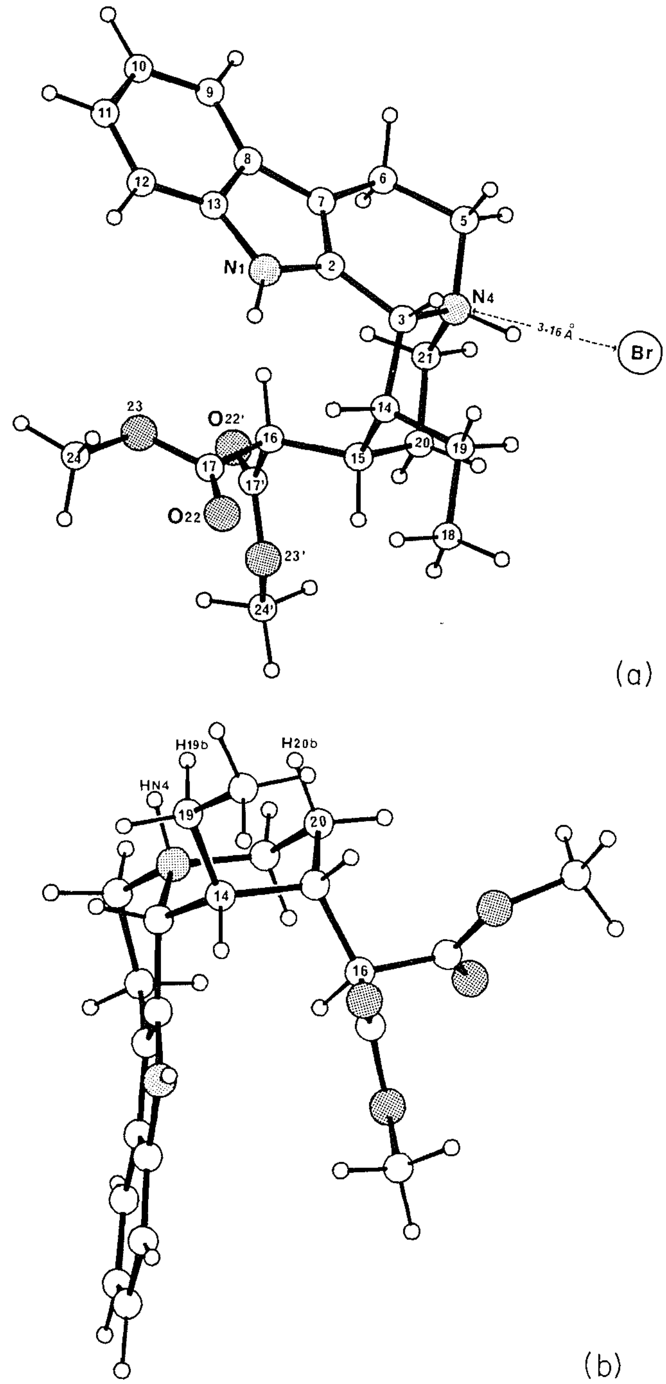

FIG. 2 a, b. An ORTEP (8) drawing of the hydrogen bromide salt of **8** with the atomic numbering.The bromide ion is hydrogen bonded to nitrogen atom N(4): distance 3.16 Å (angle $N_4—H_{N_4}\cdots Br$ of 151°).

is small. The molecule can thus accommodate their presence in axial positions, and in so doing avoid any interaction of these groups with the C-14 ethyl side chain.

This latter interaction would be particularly severe in the alternative all-equatorial conformer **8***a* (Fig. 1). In this conformation the indole ring is roughly parallel to the C-14—C-19 bond with the consequence that the N-1 hydrogen points directly at one of the C-19 methylene hydrogens ("*peri*" interaction (9)). Due to the presence of the malonyl group at C-15, release of this interaction by rotation of the ethyl side chain is not

possible. In the C/D *cis* conformer **8***b* the effect of nitrogen inversion is to tilt the C-3 indole unit away from the C-14—C-19 bond, which reduces the *peri* interaction to some extent. However, this gain in stabilization is counterbalanced by the corresponding increase in energy resulting from the change to a *cis* ring junction (11).

It can thus be concluded that in the conformationally mobile "inside" Corynanthé-type indole compound **8** it is the *gauche* interactions between adjacent equatorial substituents that paradoxically render the all-equatorial conformations **8***a* and **8***b* less stable than the triaxial conformation **8***c*.

The preparation of $[Ni(1,4,7\text{-triazacyclodecane})_2]^{3+}$, $(Ni(10\text{-aneN}_3)_2{}^{3+})$ is described. The existing procedure has been modified leading to good yields of the ligand trihydrochloride. The nickel(II) analogue (reported previously) is oxidised in a facile manner, either by $Co^{3+}{}_{aq}$ in acidic aqueous media or by NO^+ in CH_3CN. Since the octahedral NiN_6 chromophore is retained upon electron transfer, outer sphere reactions both of the Ni(II) and Ni(III) species have been studied. Rates of oxidation by various nickel(III) macrocycles have been measured and details are provided. Electrochemical oxidation of the Ni(II) complex is consistent with $E^0(Ni(10\text{-aneN}_3)_2{}^{3+/2+}) = 0.997$ V (vs. NHE). The data have been used in a Marcus correlation, leading to the self-exchange rate k_{11} for the couple $(Ni(10\text{-aneN}_3)_2{}^{3+/2+}) = (2 \pm 1) \times 10^4\ M^{-1}\ s^{-1}$. This value is compared with other data derived using octahedral Ni(II)/Ni(III) centres. The oxidation of the Ni(II) complex by $Co(III)_{aq}$ has been studied in both protonated and deuterated media. There is no evidence for any proton transfer (from the N—H) being coupled to the electron transfer step. The observed rate constant for the reaction of Co^{3+} with $Ni(II)(10\text{-aneN}_3)_2{}^{2+}$ (550 M^{-1} s^{-1}) may be compared with the calculated outer sphere rate (270 M^{-1} s^{-1}). An estimate of $k_{11}(CoOH^{2+/+}) \sim 3\ M^{-1}\ s^{-1}$ for the $CoOH^{2+/+}$ exchange is discussed.

M. G. FAIRBANK, A. MCAULEY, P. R. NORMAN et O. OLUBUYIDE. Can. J. Chem. **63**, 2983 (1985).

On décrit la préparation du $[Ni(\text{triaza-}1,4,7\text{ cyclodécane})_2]^{3+}$, $(Ni(N_3\text{-}10ane)_2{}^{3+})$. La modification de la méthode existante permet d'obtenir avec un bon rendement le trichlorhydrate du ligand. On peut facilement oxyder l'analogue du nickel(II) (qui a été décrit antérieurement) soit par le Co^{3+} en milieu acide aqueux ou par le NO^+ dans le CH_3CN. Considérant que le chromophore NiN_6 octaédrique est conservé lors du transfert d'électrons, on a étudié les réactions qui se produisent dans les sphères extérieures des espèces Ni(II) et Ni(III). On a mesuré les vitesses d'oxydation par différents macrocycles de Ni(II) et on rapporte les détails. L'oxydation électrochimique du complexe de Ni(II) répond à l'équation $E^0(Ni(N_3\text{-}10ane)_2{}^{3+/2+}) = 0{,}997$ V (vs. NHE). On a utilisé les données dans une corrélation de Marcus conduisant à une vitesse d'autoéchange k_{11} pour le couple $(Ni(N_3\text{-}10ane)_2{}^{3+/2+}) = (2 \pm 1) \times 10^4\ M^{-1}\ s^{-1}$. On a comparé cette valeur avec d'autres données dérivées en utilisant des centres octaédriques Ni(II)/Ni(III). On a étudié l'oxydation du complexe de Ni(II) par le $Co(III)_{aq}$ en milieu protoné et en milieu deutéré. Il n'y a aucune preuve de transfert de proton (à partir de N—H) lors de l'étape de transfert d'électron. On peut comparer la constante de vitesse observée pour la réaction de Co^{3+} avec $Ni(II)(N_3\text{-}10ane)_2{}^{2+}$ (550 M^{-1} s^{-1}) avec la vitesse calculée pour la réaction à l'extérieur de la sphère (270 M^{-1} s^{-1}). On discute d'une évaluation de $k_{11}(CoOH^{2+/+}) \sim 3\ M^{-1}$ s^{-1} pour l'échange $CoOH^{2+/+}$.

Introduction

Nickel(III) complexes stabilised by tetra-azamacrocyclic ligands (L) generally display octahedral symmetry with axial coordination of solvent or anions (1–3). In the case of $NiLCl_2{}^+$, for example (4, 5), a septet in the esr spectrum resulting from hyperfine interaction of the unpaired electron with each Cl nucleus confirms in solution what has been observed in the solid state (6). Only in relatively few instances (7) are five-coordinate species formed. In contrast, the geometry of the corresponding nickel(II) complex ions in solution is less well defined owing to the variations in extent of the square planar $\rightleftharpoons$ octahedral equilibrium. This lack of complete detail acts as a source of difficulty in the investigation of the energetics involved in reactions of $NiL^{3+/2+}$ redox couples.

Attempts have been made to address this problem using complex ions which retain the NiN_6 coordination in both oxidation states, and self exchange rate data have been determined for the tris-polypyridine (8) and bis-triazacyclononane (9) ligand systems. The use of such complexes, which show no proton equilibria in the acidity conditions used, ($[H^+] \sim 1.0$ M — pH ~ 4) also permits the assignment of reaction pathways where with the $NiL(OH_2)_2{}^{3+}$ species, ambiguities in reaction schemes deriving from proton equilibria may be envisaged.

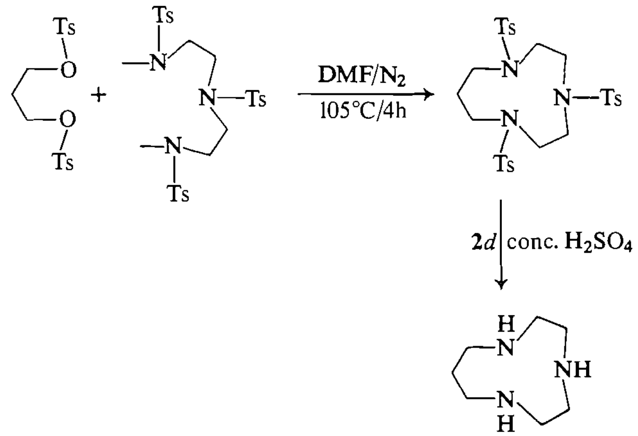
[2] Present address, Chemistry Department, University of Ife, Ile-Ife, Nigeria.

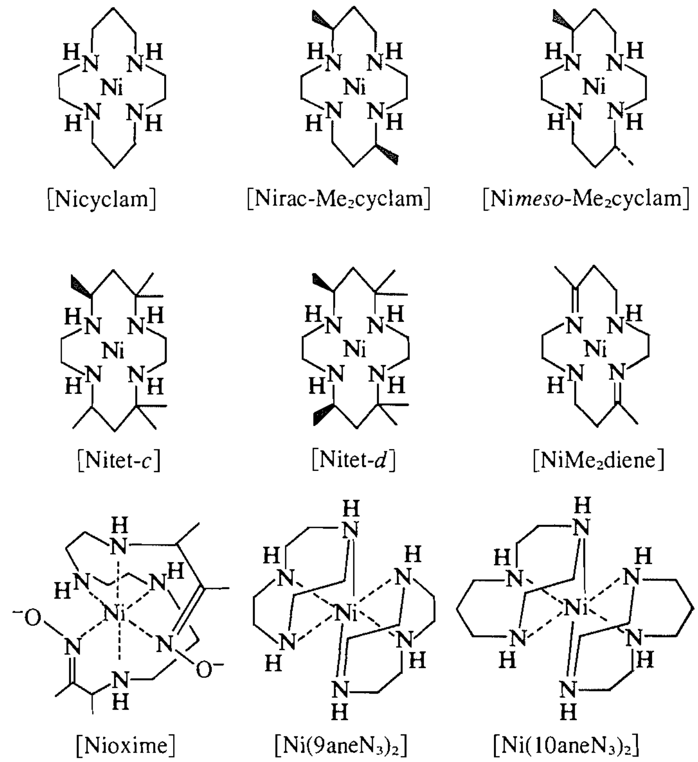
The present paper describes the preparation of a nickel(III) complex incorporating the 1,4,7-triazacyclodecane ligand, $(Ni(10\text{-aneN}_3)_2{}^{3+}$. Although not quite as stable kinetically in highly acidic media with respect to decomposition as the corresponding [9]-ane N_3 ion (9), the stability is such that kinetic measurement of redox reactions may be made. The data are of interest in that they permit an evaluation of the effects on the redox process of a departure from the near octahedral symmetry of the [9]-aneN_3 ion (10) to a more distorted environment as seen from the greatly increased anisotropic esr spectrum of the [10]-aneN_3 complex.

Experimental

The nickel(II) complex, $(Ni(10\text{-aneN}_3)_2{}^{2+}$, has been prepared previously by Zompa and Margulis (10), who have shown from X-ray measurements that the octahedral field is not symmetrical. The same complex was prepared in our laboratories by a different synthesis of the ligand. This was accomplished using a modification of the method described by Atkins, which utilises the high degree of cyclisation (11, 12) achieved by the reaction of the disodium salt of *N,N′,N″*-tritosyldiethylenetriamine with the di-tosyl derivative of 1,3-propanediol (Ts = *p*-toluenesulfonyl = tosyl). A similar method has also been described by Weatherburn in the preparation of (alkyl) ring-substituted copper complexes of these ligands (13). All ligand synthesis reactions were carried out under a stream of dry N_2.

N,N′,N″-Tritosyldiethylenetriamine was prepared as described (14), and the corresponding disodium salt formed using sodium metal in absolute ethanol (15).





SCHEME 1. Charges omitted for clarity.

Ditosylate of 1,3-propanediol

A 7.6 g sample of 1,3-propanediol was dissolved in 500 mL dry CH_2Cl_2 in a flask (three neck). After cooling the solution to 0°C under a stream of dry N_2, 50 mL triethylamine was added. Maintaining the temperature at 0°C, a solution of 38 g of *p*-toluenesulphonyl chloride in 250 mL dry CH_2Cl_2 was added over 45 min and the mixture stirred for a further 12 h. The solid Et_3NHCl formed was filtered off and the filtrate was washed successively with 250 mL 2 *M* HCl, two, 250 mL portions of H_2O and two, 250 mL volumes of saturated Na_2CO_3 solution. After reduction in volume, a white solid crystallised which was re-crystallised from EtOH/H_2O and washed with 100% ethanol and diethyl ether. Yield 95%.

1,4,7-Tritosyl-1,4,7-triazacyclodecane

The disodium salt of diethylenetriamine (53 g) was dissolved in 350 mL dry DMF (dry N_2) in a flask equipped with a mechanical stirrer. After heating with stirring to 90°C, a solution of 35 g of 1,3-propanediol ditosylate in 180 mL DMF was added over a 45 min period. Further heating at 105°C for 4 h produced a yellow solution. The cooled DMF solution was added dropwise to 2 L of rapidly stirred water, precipitating the product which was filtered, washed with water, cold 100% ethanol, and cold diethyl ether. Yield 70%. nmr δ2.2 (CH_3), 9H; δ3.35 (NCH_2), 12H; δ7.5 (CH), 12H.

1,4,7-Triazacyclodecane trihydrochloride

The detosylation was carried out by heating a solution of the tritosyl derivative in 125 mL conc. H_2SO_4 for 48 h. After cooling and slow neutralisation using a solution of 300 g NaOH in 600 mL H_2O, further reduction of the temperature to 0°C resulted in crystallisation of Na_2SO_4. The filtrate was extracted with 600 mL $CHCl_3$ on a continuous extraction apparatus for 3 days. The solvent was removed and following addition of 25 mL ethanol and further filtration to remove any undissolved impurities, the ligand trihydrochloride was precipitated by addition of 10 mL *conc.* HCl. The product was washed with ethanol and diethyl ether. Yield 60%.

[Ni(10-aneN_3)$_2$](ClO$_4$)$_2$: NiL_2(ClO$_4$)$_2$

The ligand trihydrochloride (1 g) was dissolved in 12 mL 1 *M* NaOH and warmed on a steam bath. To this was added 0.7 g $Ni(ClO_4)_2 \cdot 6H_2O$ in 15 mL of methanol. After adjustment of the pH to ~10 a pink colour formed and lowering the pH to ~5 and cooling resulted in the precipitation of lilac crystals. These were recrystallised from methanol and dried *in vacuo*. Uv–visible: λ = 475 nm, ϵ = 30 M^{-1} cm^{-1}; λ = 302 nm, ϵ = 24 M^{-1} cm^{-1}.

The corresponding nickel(III) complex ion was formed by oxidation in 0.5 *M* $HClO_4$ using a slight deficiency of Co^{3+} aq. The 3+ species formed was less stable kinetically than the corresponding 9-aneN_3 complex and could not be isolated as a perchlorate salt. Uv: λ = 290 nm, ϵ = 11 900 M^{-1} cm^{-1}.

The complexes (Scheme 1) [Ni(cyclam)](ClO$_4$)$_2$, (16) (cyclam = 1,4,8,11-tetra-azacyclotetradecane), [Ni(*meso*-Me_2cyclam)](ClO$_4$)$_2$ (17) (Me_2cyclam = (α)-C-*meso*,-5,12-dimethyl cyclam), [Ni(tet-*c*)](ClO$_4$)$_2$ (18) and [Ni(tet-*d*)](ClO$_4$)$_2$ (18), (tet-*c* and tet-*d* = C-*rac* and C-*meso* 5,5,7,12,12,14-hexamethylcyclam), [Ni(Me_2diene)](ClO$_4$)$_2$ (17), (Me_2diene = 5,12-dimethyl-1,4,8,11-tetraazacyclotetradeca-4,11-diene) [Ni(C-*rac*-Me_2cyclam)](ClO$_4$)$_2$ (17, 19) and [Ni(IV)-oxime](ClO$_4$)$_2$ (20) (Ni(IV)-oxime = 3,4-dimethyl-4,7,10,13-tetraazahexadeca-3,13-diene-2,15-dione dioximate (2−)) were prepared as described elsewhere. Their analytical purity was confirmed (Canadian Microanalytical Services).

Solutions containing 0.01–0.04 *M* Co(ClO$_4$)$_3$ were prepared electrolytically and stored at −5°C. Lithium nitrate (Reagent grade) was used as received. Lithium perchlorate, formed on reaction of Li_2CO_3 with ~3 *M* $HClO_4$ was recrystallised three times from distilled water.

The stopped-flow and data acquisition system were described previously (21). In many instances, nickel(III) macrocyclic complexes were prepared *in situ* by oxidation of the corresponding nickel(II) species with a stoichiometric deficiency of Co(III)$_{aq}$ (22). Ionic strengths were maintained constant (1.00 *M*) using $H^+/Li^+ClO_4^-$ or where solubility factors required, $Li^+/H^+NO_3^-$. Reactions were monitored over the range 350–500 nm. Using pseudo-first-order conditions of excess reductant, rate constants derived from least-squares plots (minimum 200 points) were linear for greater than three half-lives. For several of the systems studied, e.g. (Ni(10-aneN_3)$^{2+}$ and [Ni(*meso*-Me_2cyclam)]$^{3+}$, the E^0 values of the two reactants are similar in value, leading to reaction reversibility. Under conditions of excess [(Ni(10-aneN_3)$_2$$^{2+}$] and [Ni(*meso*-$Me_2$cyclam)$^{2+}$], both the forward and reverse reactions [1] may be treated as pseudo-first order

$$[1] \quad (\mathrm{Ni(10\text{-}aneN_3)_2})^{3+} + \mathrm{Ni}(meso\text{-}\mathrm{Me_2cyclam})^{2+} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \mathrm{Ni(10\text{-}aneN_3)_2}^{2+} + \mathrm{Ni}(meso\text{-}\mathrm{Me_2cyclam})^{3+}$$

The observed first-order rate constant may thus be expressed in the form

$$[2] \quad k_{obs} = k_1[\mathrm{Ni}(meso\text{-}\mathrm{Me_2cyclam})^{2+}] + k_2[\mathrm{Ni(10\text{-}aneN_3)_2}^{2+}]$$

At constant [Ni(10-aneN_3)$_2$$^{2+}$], plots of k_{obs} against [Ni(*meso*-Me_2cyclam)$^{2+}$] should be linear (slope k_1) (Fig. 1). Also from the intercepts, k_2 may be derived by varying [Ni(10-aneN_3)$_2$$^{2+}$]. It may be seen

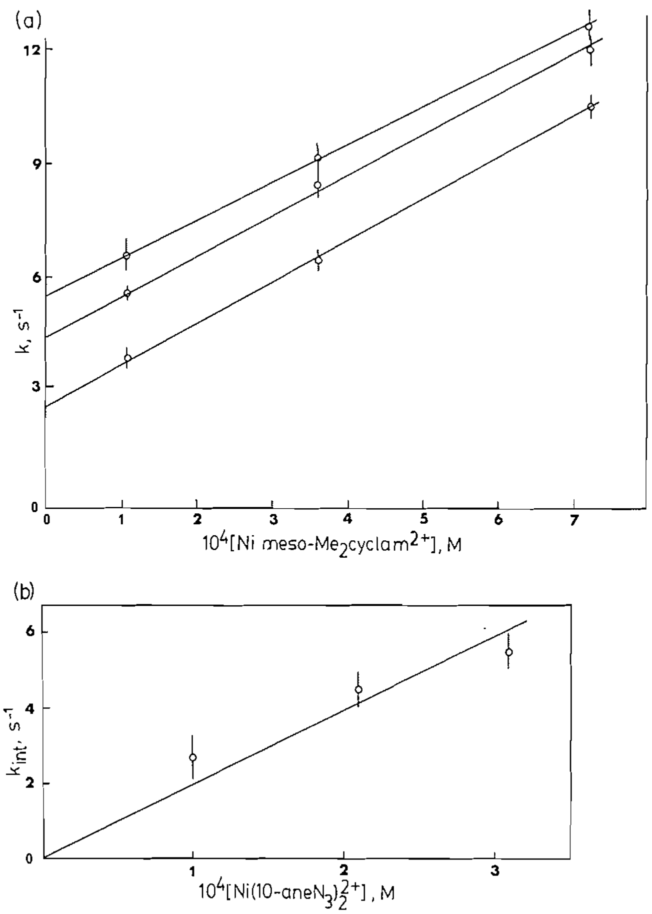


FIG. 1. (*a*) Reaction of $Ni(10\text{-}aneN_3)_2^{3+}$ with Ni(*meso*-Me_2-cyclam)$^{2+}$ (see eq. [1]). Pseudo first order behaviour observed in presence of excess $Ni(10\text{-}aneN_3)_2^{2+}$ and Ni(*meso*-Me_2cyclam)$^{2+}$ ions — see text; (*b*) k_{int} values derived graphically from plots as in (1*a*).

from Fig. 1 that $k_1 = (1.08 \pm 0.04) \times 10^4\ M^{-1}\ s^{-1}$ and $k_2 = (2.2 \pm 0.5) \times 10^4\ M^{-1}\ s^{-1}$.

Results

(a) Electron spin resonance and solution studies

The $Ni(II)(10\text{-}aneN_3)_2^{2+}$ ion may be oxidised readily to the corresponding nickel(III) species. The substantial increase in absorbance in the 300–350 nm range on reaction either in aqueous media (Co^{3+}, $S_2O_8^{2-}$) or NO^+ in CH_3CN is characteristic of the nickel(III) centre (5, 23). The low spin d^7 ion was confirmed using esr studies on the frozen aqueous solution at 77 K (Fig. 2). The $g_\perp$ and $g_\parallel$ components of the axial spectrum are identified. However, unlike the spectra for axially N-coordinated tetraazamacrocycles, where hyperfine interaction is seen in the $g_\parallel$ feature, (for N, $I = 1$) there is observed in the present system a broadening of the signal possibly owing to a smaller coupling constant. In the case of $Ni(cyclam)Cl_2^+$, $g_\perp \sim 2.18$ and $g_\parallel \sim 2.02$. For the $Ni(10\text{-}aneN_3)_2^{3+}$ species $g_\perp = 2.13$ and $g_\parallel = 2.06$ which are closer together in value. Comparison with the spectrum of the more symmetrical $Ni(9\text{-}aneN_3)_2^{3+}$ ion (15) where the extent of anisotropy is less ($g_\perp = 2.13$, $g_\parallel = 2.08$) suggests the symmetry is slightly more distorted for the 10-ane complex. This may result from the presence of an additional CH_2 group in the ligand ring. Little change is observed in the esr spectrum on the addition of high concentrations of SO_4^{2-} (3) or Cl^- (4) which are known to coordinate strongly in

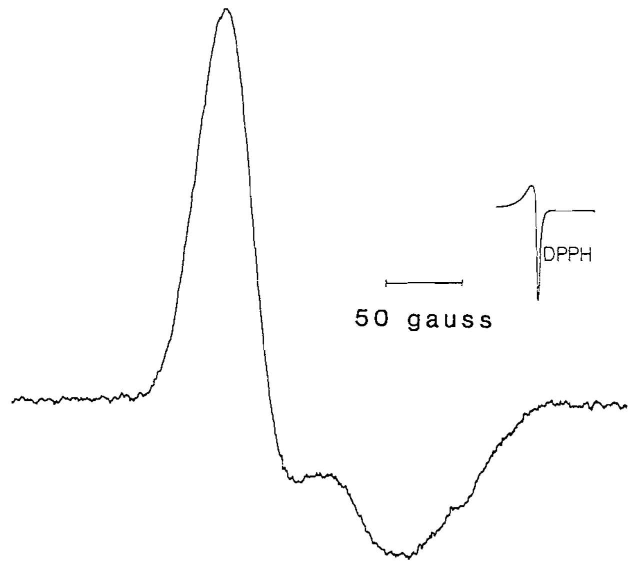

FIG. 2. Electron spin resonance spectrum of $Ni(10\text{-}aneN_3)_2^{3+}$.

the axial positions of the tetraazamacrocycles. There is thus good evidence that the octahedral NiN_6 chromophore remains intact during the redox process.

In acidic aqueous media, the $Ni(10\text{-}aneN_3)_2^{3+}$ ion is less stable kinetically than the corresponding 9-membered ring complex. (This is true also for the Ni(II) species.) In solutions of 0.1 M $HClO_4$ the half-life for the redox decomposition is ~3.5 h and at 1.0 M $[H^+]$ $t_{1/2} \sim 2.8$ h. Addition of Cl^- or SO_4^{2-} has little effect on the uv–visible spectrum. Cyclic voltammetry at 25°C (1.0 M H^+/Li^+ ClO_4^-) using a Pt electrode and calomel reference showed a 1-electron wave with quasi-reversible behaviour ($\Delta E = 78$ mV). This behaviour is typical of many Ni(III) systems (24) where deviation from the reversible 59 mV separation has been observed. The measured E^0 ($Ni(10\text{-}aneN_3)_2^{3+/2+}$) = 0.997 V vs. NHE lies in the range 0.95–1.1 V observed for most of the saturated nickel(II)/(III) macrocycles.

(b) Kinetic results

For all redox reactions studied, the stoichiometry may be represented (to ±2%) as a one-electron transfer.

$$[3] \quad Ni(II)(10\text{-}aneN_3)_2^{2+} + Ni(III)L^{3+} \rightarrow Ni(III)(10\text{-}aneN_3)_2^{3+} + Ni(II)L^{2+}$$

with the corresponding rate law

$$[4] \quad \text{Rate} = k_{12}[\text{oxidant}][\text{reductant}]$$

First order dependences of the observed rate constant (k_{obs}) were determined as is seen in Table 1. Only in the case of the Co(III) oxidation of the nickel(II) complex was a hydrogen ion dependence observed. For all other complexes, no rate variation was seen over the range $[H^+] = 0.1–1.0\ M$. Most systems were studied at 0.5 M $[H^+]$.

The rate of appearance of $Ni(10\text{-}aneN_3)_2^{3+}$ (λ 340 nm) was used to investigate the oxidation reaction involving aquocobalt(III) under conditions of excess reductant. The results are summarised in Table 1. At constant $[H^+]$ the rate law may be expressed as

$$[5] \quad d[Ni(III)]/dt = k_a[Ni(10\text{-}aneN_3)_2^{2+}][Co(III)]$$

A significant increase in k_a was observed on reducing $[H^+]$. The lack of any proton-related equilibria associated with the

Ni(II) complex as demonstrated by the invariance of rate of the Ni(III) oxidations with changing $[H^+]$, permits attribution of the hydrogen ion dependence to hydrolysis of the aquocobalt ion

$$[6]\quad (H_2O)_5Co(OH_2)^{3+} \overset{K_h}{\rightleftharpoons} (H_2O)_5CoOH^{2+} + H^+$$

$$K_h = \frac{[CoOH^{2+}][H^+]}{[Co^{3+}]}$$

Using the mechanism in which both Co(III) species react,

$$[7]\quad Ni(10\text{-aneN}_3)_2^{2+} + Co^{3+} \xrightarrow{k_\alpha} Co^{2+} + Ni(10\text{-aneN}_3)_2^{3+}$$

$$[8]\quad Ni(10\text{-aneN}_3)_2^{2+} + CoOH^{2+} \xrightarrow{k_\beta} Co(II) + Ni(10\text{-aneN}_3)_2^{3+}$$

the overall second order rate constant k_a may be expressed in the form

$$[9]\quad k_a = k_\alpha + k_\beta K_h/[H^+]$$

From the data in Table 1, $k_\alpha = 550 \pm 22\ M^{-1}\ s^{-1}$ and $k_\beta K_h = 579 \pm 8\ s^{-1}$. Using $K_h = 2 \times 10^{-3}\ M$ (25), $k_\beta = 2.9 \times 10^5\ M^{-1}\ s^{-1}$.

In reactions where ΔE^0 for the redox process is less than 50 mV, reversibility was observed as noted previously. It is possible to calculate the equilibrium constants for these reversible reactions. In most instances, K lies in the range 1–10 and agreement with the kinetic data is considered reasonable. For example, in the reactions with the $Ni(cyclam)^{2+}$ and with $Ni(meso\text{-}Me_2cyclam)^{2+}$ the K value of unit based on equilibrium data may be compared with the kinetic values of 0.2 and 0.5, respectively. Only in the case of the reaction with $Ni(9\text{-aneN}_3)_2^{2+}$ is there an inconsistency. Predicted value of the intercepts based on reactant concentration are 0.24 and 1.1 compared with observed values essentially zero. At present, we cannot explain this anomaly.

Discussion

From the variety of systems studied, both oxidations of Ni(II) and the reductions of $Ni(III)(10\text{-aneN}_3)_2^{3+}$ may be viewed as outer-sphere processes. We have therefore used the Marcus relationship (8, 26) to determine the self-exchange rate constant for the bis(10-aneN$_3$) complex. The rate constant, k_{12}, for an outer-sphere redox reaction may be related to the individual self-exchange reactions k_{11} and k_{22} and to the overall equilibrium constant, K_{12}, by the expression [10]

$$[10]\quad k_{12} = (k_{11}k_{22}K_{12}f_{12})^{1/2}\,W'_{12}$$

$$[11]\quad \ln f_{12} = \frac{[\ln K_{12} + (W_{12} - W_{21})/RT]^2}{4\left[\dfrac{\ln(k_{11}k_{22})}{A_{11}A_{22}} + \dfrac{W_{11} + W_{22}}{RT}\right]}$$

$$[12]\quad W'_{12} = \exp\,[W_{11} + W_{22} - W_{12} - W_{21})/2RT]$$

$$[13]\quad A_{ii} = \frac{[4\pi N\sigma^2\nu\gamma]_{ii}}{1000}$$

Values of A_{11} and A_{22} were used as calculated previously for Ni(III) complexes of this type (27) $A/\sigma^2 = 3 \times 10^{10}\ M^{-1}\ s^{-1}$ Å^{-2}) for the nickel complexes, $\sigma = 3.8 \pm 0.2$ Å, $Co^{3+} = 3.0$ Å and $Fe^{2+} = 3.3$ Å, respectively. Work terms W_{ii} refer to the energies associated with bringing together the reactants to the separation distance, r, within the activated complex. In most instances, 2+ and 3+ charged reactants were involved and work terms partially cancel. A_{ii} is the diffusion rate for species ii, ν the nuclear frequency which destroys the activated complex,and γ is the thickness of the reaction layer. Assuming log $W'_{12} = 1$, eq. [10] may be expressed as

$$[14]\quad \log k_{12} = (1/2)(\log K_{12}k_{11}f_{12}) + (1/2)\log k_{22}$$

Thermodynamic and kinetic parameters used in the Marcus correlation are presented in Table 2. Using the data in Table 2, the plot (Fig. 3) is obtained where the slope 0.48 ± 0.03 (least-square analysis with correlation factor 0.97) is in excellent agreement with the value (0.5) predicted theoretically. From the intercept, k_{22}, the rate constant for the $Ni(10\text{-aneN}_3)_2^{3+/2+}$ exchange may be evaluated as $(2 \pm 1) \times 10^4\ M^{-1}\ s^{-1}$. The value is slightly higher than that for the corresponding (9-aneN$_3$)$_2$ complex, $6 \times 10^3\ M^{-1}\ s^{-1}$. The corresponding rate constant for the tris-bipyridyl complex (8) is $2 \times 10^3\ M^{-1}\ s^{-1}$. For the *trans*-Ni(cyclam)$Cl_2^{+/0}$ couple, $k_{22} = 3.4 \times 10^4\ M^{-1}\ s^{-1}$ (28). It thus appears that for these octahedrally substituted complexes, rates are within one order of magnitude suggesting similar reorganizational energies for formation of the activated complex.

The present study also provides further information on the aquo Co(II)/(III) processes. Endicott *et al.* (29) have recently provided evidence that outer sphere reactions of Co^{3+}_{aq} are consistent with a self-exchange rate $k_{11}(Co^{3+/2+}) = 10^{-12}\ M^{-1}\ s^{-1}$. Using this value, the predicted value for $k_{12}(k_\alpha)$ is 270 M^{-1}

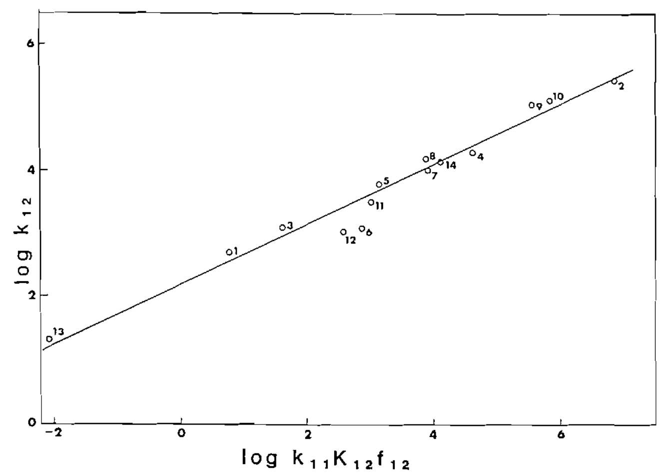

FIG. 3. Marcus plot eq. [14] used in derivation of self-exchange rate for $Ni(10\text{-aneN}_3)_2^{3+/2+}$.

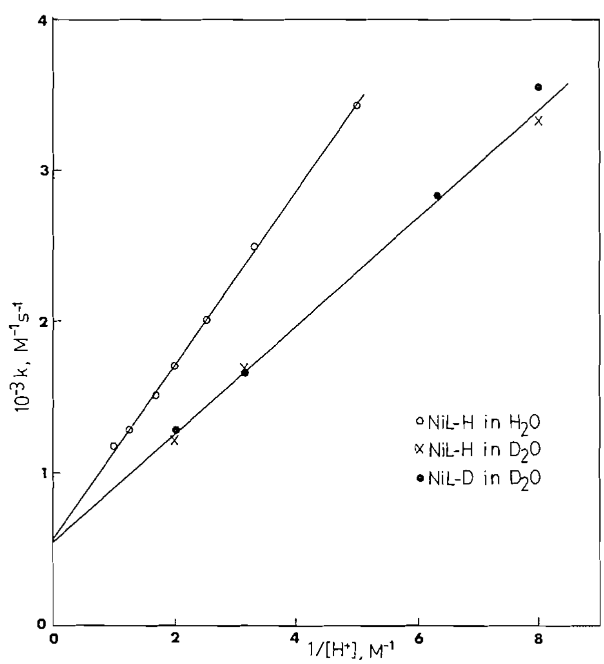

FIG. 4. Rate data for reactions of $Co(OH)^{2+}$ and $Co(OD)^{2+}$ with $Ni(10\text{-aneN}_3)_2^{2+}$ as a function of $[H^+]^{-1}$ ($[D^+]^{-1}$).

s^{-1} which compares favourably with the experimental value of 550 M^{-1} s^{-1}, given approximations made in the correlation. The question of the $CoOH^{2+/+}$ exchange is still the subject of discussion. This is in part due to the possibility of a preferred outer-sphere orientation (30) where H-bonding with the reducing substrate may be envisaged. There exists also the potential for the abstraction by $CoOH^{2+}$ of an H atom from the N—H ligand system in a "quasi inner-sphere" process. It is known that exchange of the N—H protons is a facile process in basic media (pH ~ 10) but in acidic conditions the N—H bonds are extremely inert. Using D_2O/NaOD, we have prepared the deuterated complex $Ni(10\text{-aneN}_3D_3)_2^{2+}$ and reacted this ion with both $Co(OD_2)_6^{3+}/DClO_4$ and $Co(OH_2)_6^{3+}/HClO_4$ as described above. The $[H^+]^{-1}$ ($[D^+]^{-1}$) dependences again demonstrated the existence of $Co(OH)^{2+}$ ($Co(OD)^{2+}$) reaction pathways. The kinetic data are shown in Fig. 4 where it is seen that there is a marked difference in rate between the protonated and deuterated solvent systems. In the latter, however, the complexes containing the N—H ligands react at the same rate as those containing the N—D centres. If a proton-coupled electron transfer were operative, a ratio of $k_H/k_D \sim 1.37$ would be anticipated owing to rupture of the N—D (N—H) bond. The reaction of $CoOH^{2+}$ may thus be treated as an outer-sphere process although the possibility remains of a precursor complex with OH^- located for hydroxide-mediated electron transfer. The stability constant of such a precursor would be expected to be small (there is no spectrophotometric evidence for its existence in our hands). An estimate (9) may be made of E^0 ($CoOH^{2+/+}$) = 1.44 V, and, if we treat the reaction as an outer-sphere process, the data from the cross reaction with Ni(II)-$(10\text{-aneN}_3)_2^{2+}$ may be used to obtain a value of k_{11}($CoOH^{2+/+}$)

$= 3\ M^{-1}\ s^{-1}$. This is close to that ($2\ M^{-1}\ s^{-1}$) derived (31) from the reaction of $CoOH^{2+}$ with Ni(IV)oxime^{2+}. From the corresponding reaction with Ni(9-aneN$_3$)$_2{}^{2+}$, an estimate of $k_{11} \sim 50\ M^{-1}\ s^{-1}$ may be obtained. Thus it appears that the self-exchange process for the $CoOH^{2+/+}$ couple is $\sim 10^{11}$ faster than that for the $Co^{3+/2+}$ exchange. The origin of such a large difference is not readily apparent. It is known that in most systems the contributions arising from Franck–Condon parameters outweigh any spin changes. Also significant differences (32) in rates have been identified in the exchange reactions of $Co(NH_3)_6{}^{3+/2+}$ and Co(sepulchrate)$^{3+/2+}$.

One interesting facet of the deuterium studies is that the rates of oxidation by $Co(OH_2)_6{}^{3+}$ and $Co(OD_2)_6{}^{3+}$ are indistinguishable (Fig. 4). The slopes (reactions of the hydroxo complexes), may be represented as $k_\beta K_h$ and $k_\beta K_d$. Assuming k_β constant, K_d, the dissociation constant for the deuterated ion may be evaluated. The ratio of slopes yields $K_h/K_d \approx 1.45$ and using $K_h = 2 \times 10^{-3}\ M$, $K_d = 1.4 \times 10^{-3}\ M$. As expected, the deuterated complex is less acidic, a fact noted for other aquo metal ions (33).

Substituent effects on acetylene stability. A comparison of STO-3G, 6-31G, 6-31G**, and 6-311G** calculations

PASCAL FURET, GEORGE HALLAK, ROBERT L. MATCHA, AND RICHARD FUCHS
Department of Chemistry, University of Houston, Houston, TX 77004, U.S.A.

Received March 11, 1985

PASCAL FURET, GEORGE HALLAK, ROBERT L. MATCHA, and RICHARD FUCHS. Can. J. Chem. **63**, 2990 (1985).

Ab initio calculations using STO-3G, 6-31G, 6-31G**, and 6-311G** basis sets and standard geometries, and 6-31G and 6-311G** basis sets with 6-31G optimized geometries have been performed on a series of acetylene derivatives (H—C≡C—R; –R is $—CH_3$, —Li, —C≡N, —C(=O)—H, —C(=O)—OH, $—NH_2$, —C≡CH, $—CH{=}CH_2$, and —F). Substituent effects on stability have been studied using isodesmic methyl exchange reactions (H—C≡C—R + CH_4 → H—C≡C—H + CH_3R). STO-3G and 6-31G calculations have been carried out for methyl exchange reactions involving several large substituents including phenyl, and for the *tert*-butyl exchange reactions of 10 substituents (H—C≡C—R + Me_3CH → H—C≡C—H + Me_3CR).

Geometry optimization has an appreciable effect only on the π donor substituents OCH_3 and NH_2. None of the smaller basis sets reproduces the order of stabilities or the absolute values of the 6-311G**//6-31G calculations. The latter are in satisfactory agreement with the very few experimentally based enthalpies of methyl exchange.

PASCAL FURET, GEORGE HALLAK, ROBERT L. MATCHA et RICHARD FUCHS. Can. J. Chem. **63**, 2990 (1985).

Utilisant des ensembles de base STO-3G, 6-31G, 6-31G** et 6-311G**avec des géométries normales ainsi que des ensembles de base 6-31G et 6-311G** avec des géométries optimisées à l'aide de l'ensemble 6-31G, on a effectué des calculs *ab initio* sur une série de dérivés de l'acétylène (H—C≡C—R où R est égal à $—CH_3$, —Li, —C≡N, —CHO, —COOH, $—NH_2$, —C≡CH, $—CH{=}CH_2$ et —F). Faisant appel aux réactions d'échanges de méthyles isodesmiques (H—C≡C—R + CH_4 → H—C≡C—H + CH_3R) on a étudié les effets des substituants sur la stabilité. On a réalisé des calculs aux niveaux STO-3G et 6-31G pour les réactions d'échanges de méthyles impliquant plusieurs substituants encombrants, y compris le phényle, et pour les réactions d'échange du *tert*-butyle de 10 substituants (H—C≡C—R + Me_3CH → H—C≡C—H + Me_3R).

L'optimisation de la géométrie n'a un effet appréciable que dans le cas des substituants donneurs pi, tels le OCH_3 et le NH_2. Les petits ensembles de base ne reproduisent pas l'ordre des stabilités ou les valeurs absolues des calculs faits à l'aide des ensembles 6-311G**//6-31G. Ces derniers sont en bon accord avec les quelques rares enthalpies expérimentales basées sur la réaction d'échange de méthyle.

[Traduit par le journal]

From the few available thermochemical data on gaseous heats of formation of substituted acetylene (1, 2) it appears that alkyl substituents have a stabilizing effect (in propyne, 1-butyne, 2-butyne), and cyano substituents destabilize (dicyanoacetylene). Heats of hydrogenation in solution (3) or heats of formation in the liquid state (2) have been reported for several conjugated acetylenic esters and acids, but these seriously disagree (over a 15 kcal/mol range) on the stabilizing or destabilizing effects. Furthermore, the corrections to the gaseous state (4) are unknown, and can only be crudely estimated.

Ab initio calculations at the 4-31G (5) and STO-3G (6) basis set levels have been published for some acetylene derivatives, but stabilizing or destabilizing effects have been determined mainly for small substituents.

We have carried out the present study with the objectives of (*a*) performing *ab initio* calculation using more extensive basis sets including polarization functions, (*b*) observing the effect of geometry optimization, and (*c*) examining the stabilizing or destabilizing effects of some larger common substituents.

Calculation methods

Isodesmic reactions

Stabilities of the compounds H—C≡C—R were studied using the following isodesmic reactions:

[1] H—C≡C—R + CH_4 → H—C≡C—H + CH_3R

[2] H—C≡C—R + $(CH_3)_3C$—H → H—C≡C—H + $(CH_3)_3C$—R

Reaction [1] is a simple isodesmic reaction of the type introduced by Pople and co-workers (5). In this reaction there is retention of the number of bonds of a given formal type (C≡C, C—H, C—R, etc.). Reaction [1] measures the stabilizing effect of the substituent R on acetylene, relative to the effect of R on methane. Reaction [2] has the advantage that each atom maintains both the number of bonds with each type of atom, and also equal numbers of primary, secondary, and tertiary carbon atoms on each side of the equation (6, 7). As a result, in [2] the energy changes due to factors other than electronic stabilization or destabilization should be small, and this should provide a more accurate model for the study of the stability of organic compounds.

Quantum mechanical method and geometric model

The method used was single determinant LCAO-MO-SCF theory. The calculations were made with the program GAUSSIAN 80 (8). Several basis sets were utilized, the minimum basis set STO-3G (9), the split valence set 6-31G (10), and the split valence with polarization functions basis sets 6-31G** and 6-311G** (11, 12). Where no geometry optimization was used a uniform treatment was applied to all the molecules of a given isodesmic reaction, employing a standard geometric model (13). The most stable conformation of each molecule was determined by a conformational study with the STO-3G basis set within the rigid rotor approximation. It has been established that this basis set gives reliable results in this application (14). 6-31G and 6-311G** calculations were also carried out using 6-31G geometry optimization with the con-

Results and discussion

Energies of the molecules

Table 1 lists the energies of molecules used in this study, calculated with various basis sets. The most extended basis sets (6-31G** and 6-311G**) were employed only for molecules with no more than five heavy atoms. Several literature values are also tabulated.

Reaction [1]

For eight of the acetylene derivatives with small substituents in Table 2 we have studied the influence of basis sets up to 6-311G**, and of 6-31G geometry optimization, on the calculated energies of isodesmic methyl exchange reactions. All calculations indicate that lithium is the most stabilizing substituent, and fluorine is most destabilizing. For other substituents the orders of decreasing stabilizing effect (destabilizing substituents in parentheses) are

STO-3G — $C{\equiv}CH > CH_3 > OCH_3 > CN > CHO > COOH$

6-31G — $NH_2 > CH_3 > C{\equiv}CH > CHO > CN > (COOH) > (OCH_3)$

6-31G//6-31G — $NH_2 > CH_3 > C{\equiv}CH > CHO > CN > (OCH_3) > (COOH)$

6-31G** — $CH_3 > C{\equiv}CH > CHO > OCH_3 > (CN) > (COOH)$

TABLE 3. 6-311G**//6-31G population analysis of $H—C{\equiv}C—R$ with small substituents, R

$—CH_3$	9.155	4.026	13.181
$—C{\equiv}N$	8.661	3.962	12.623
$—OCH_3$	8.666	4.169	12.835
$—C({=}O)—H$	9.021	3.960	12.981
—F	8.604	4.153	12.757
$—NH_2$	8.634	4.154	12.788
—Li	9.692	3.915	13.607

6-311G** — $CH_3 > NH_2 > C{\equiv}CH > CHO > (OCH_3) > (CN) > (COOH)$

6-311G**//6-31G — $NH_2 > CH_3 > C{\equiv}CH > OCH_3 > (CHO) > (CN) > (COOH)$

The calculated energies are of hypothetical vibrationless molecules, whereas the experimental values of ΔH (Table 2) are for gaseous molecules at 298 K. While the two are not precisely comparable, differences for isodesmic reactions are not expected to be large.

The stabilizing effect of the methyl substituent varies little (8.0−9.1 kcal/mol) with basis set or geometry optimization, and all calculations are in good agreement with the experimental enthalpy of -7.6 ± 0.6 kcal/mol. If one assumes that

[a]Based on ΔH_f(g) values from ref. 1.
[b]One-half of ΔH for the reaction of dicyanoacetylene.
[c]Calculated from the heat of hydrogenation (ref. 3) and estimated ΔH_v.
[d]Calculated from ΔH_f(l) (ref. 1) and ΔH_v (ref. 20).

ΔH for the methyl exchange reaction of cyanoacetylene (H—C≡C—CN + CH_4→ H—C≡C—H + CH_3CN) is half that for dicyanoacetylene (NC—C≡C—CN + $2CH_4$ → H—C≡C—H + $2CH_3CN$), cyano is slightly destabilizing. The other experimental ΔH values (Table 2) for the ethynyl and vinyl substituents are based on heats of formation (16) of unknown uncertainty. Some additional reliable experimental values are much needed.

With the above limitations in mind we tentatively conclude that 6-311G**//6-31G calculations reproduce experimental ΔH^{298} values satisfactorily (±0.4−2.0 kcal/mol). We may draw the following conclusions concerning simpler calculations. (*a*) STO-3G calculations in this system generally grossly overestimate the stabilizing effect of substituents by more than 6 kcal/mol. The predicted order of stabilities is appreciably incorrect. (*b*) 6-31G//6-31G results appear to overestimate the stabilizing influence of CN, CHO, NH_2, and C≡CH substituents, and underestimate OCH_3, usually by 2−3 kcal/mol. 4-31G//4-31G results (A. Greenberg, private communication) are often comparable. (*c*) 6-31G geometry optimization affects 6-31G and 6-311G** results appreciably (>0.4 kcal/mol) only in the case of the π donor substituents OCH_3 and NH_2. (*d*) Addition of polarization functions for heavy atoms and hydrogen (6-31G** vs. 6-31G) decreases slightly the predicted stabilization by substituents other than OCH_3. (*e*) Increased basis set size (6-311G** vs. 6-31G**) leads to a decrease (0.5−2.2 kcal/mol) in all predicted stabilizations. In calculations on substituted acetylenes a large basis set and polarization functions have a larger and more general influence on the results than does geometry optimization. However, all three of these features should be used in such calculations.

We have not considered whether electron correlation effects might influence the above results. A small number of data have recently become available (17), calculated using a Gaussian double zeta + polarization functions basis set, and second−fourth order single−quadruple excitations + renormalization correlation energies based on the many body Rayleigh−Schrödinger perturbation theory. The correlation energy contribution for methyl exchange of 1-propyne is negligible, but for butadiyne the value is 3.2 kcal/mol. The resulting ΔE value for butadiyne (Table 2) is in poorer agreement with the experimental ΔH than is the 6-311G**//6-31G ΔE value. New experimental measurements will be needed to resolve this question.

We have carried out a Mulliken population analysis (18) at the 6-311G**//6-31G level (Table 3), and find that electron withdrawal from the triple bond tends to be associated with destabilization, whereas electron donation favors stabilization. This is in agreement with a 4-31G study of other substituents (19). Dill, Greenberg, and Liebman (6) have pointed out that σ withdrawing substituents have a particularly strong destabilizing effect in acetylenes, whereas π withdrawal stabilizes. We feel this is a more generally useful viewpoint than consideration of the total $(\sigma + \pi)$ charge on the $\mathrm{H{-}C{\equiv}C{-}}$ unit.

Table 4 gives the energies of isodesmic methyl exchange reactions involving larger substituents with 6-31G** as the most extensive basis set used. Improved basis sets lead to decreased calculated energies of the individual compounds and decreased stabilization by substituents.

Reaction [2]

The size of the *tert*-butyl reference molecules only allowed the use of the STO-3G and 6-31G basis sets. According to the results for reaction [1] (Table 2) it is doubtful that the results for reaction [2] (Table 5) will be close to the experimental values, and this is verified by the two experimental values available. However, except for R = OCH_3 the order of stabilities is expected to be correct at the 6-31G level

$$\begin{aligned}\text{Phenyl} &> \mathrm{C{\equiv}C{-}CH_3} > \mathrm{CO{-}CH_3} > \mathrm{CH_2OCH_3} > \mathrm{CHO}\\ &> (\mathrm{CN}) > (\mathrm{OCH_3}) > (\mathrm{CO{-}OCH_3}) > (\mathrm{CO{-}OH})\end{aligned}$$

This is similar to the 6-31G order for methyl exchange (reaction [1])

$$\begin{aligned}\text{Phenyl} &> \mathrm{C{\equiv}C{-}CH_3} > \mathrm{CH_3} > \mathrm{CH_2OCH_3} > \mathrm{COCH_3} > \mathrm{CHO}\\ &> \mathrm{CN} > (\mathrm{CO{-}OCH_3}) > (\mathrm{CO{-}OH}) > (\mathrm{OCH_3})\end{aligned}$$

with OCH_3 the most notable exception.

Conclusions

For the isodesmic reactions considered, STO-3G calculations do not provide useful conclusions. The 6-31G basis set is somewhat better at predicting relative stabilities of the compounds and the stabilizing or destabilizing character of substituents. 6-31G geometry optimization is significant only when π donor substituents are present. The use of extended basis sets with polarization functions seems mandatory in order to closely reproduce experimental values. Methyl and *tert*-butyl exchange reactions give approximately the same order of stability for the compounds examined, but the advantage of the latter as a better model is lost due to the difficulty of applying larger basis sets. The electron donating substituent CH_3 stabilizes the triple bond. The molecules $\mathrm{H{-}C{\equiv}C{-}C{\equiv}C{-}H}$, $\mathrm{H{-}C{\equiv}C{-}C{\equiv}C{-}CH_3}$, $\mathrm{H{-}C{\equiv}C{-}CH{=}CH_2}$, and phenylacetylene exhibit substantial stabilization, in agreement with classical resonance theory, but $\mathrm{H{-}C{\equiv}C{-}C{\equiv}N}$, $\mathrm{H{-}C{\equiv}C{-}\underset{\underset{O}{\|}}{C}{-}OH}$, and $\mathrm{H{-}C{\equiv}C{-}\underset{\underset{O}{\|}}{C}{-}OCH_3}$ show destabilization.

Multiphoton absorption and decomposition studies of chloroform-*d* induced by a pulsed $^{13}CO_2$ laser[1]

ROBERT D. MCALPINE, J. W. GOODALE, AND D. K. EVANS

Physical Chemistry Branch, Atomic Energy of Canada Limited Research Company, Chalk River Nuclear Laboratories, Chalk River, Ont., Canada K0J 1J0

Received March 15, 1985

ROBERT D. MCALPINE, J. W. GOODALE, and D. K. EVANS. Can. J. Chem. **63**, 2995 (1985).

The multiphoton absorption (MPA) and decomposition (MPD) of chloroform-*d* induced by various $^{13}CO_2$ [00°1 → 10°0] lines were studied for pressures from 0.133 to 13.3 kPa. MPA results show a cross-section increasing with pressure up to a plateau value which is likely due to rotational hole-filling. A MPA "spectrum" of the average number of photons absorbed versus wavenumber for different $^{13}CO_2$ laser lines is shifted to lower wavenumbers compared to the small signal absorption spectrum by at least 5 cm^{-1} suggesting that a small amount of anharmonicity bottle-necking is occurring in $CDCl_3$. A comparison of the MPD probability versus fluence for $CDCl_3$ with that measured by other workers for fluoroform indicates that the $CDCl_3$ is decomposed at a slightly lower fluence by an appropriate line of a pulsed CO_2 laser.

For the pressure range (0.2 to 4.0 kPa) and laser pulse-width used, the MPD is second order in $CDCl_3$. The primary decomposition channel is elimination of DCl followed by reaction of CCl_2 to give C_2Cl_2, C_2Cl_4, and Cl_2. The DCl produced exchanges with a source of H_2O in the reaction cell to give significant quantities of HCl. A post-pulse reaction between (HCl + DCl) and C_2Cl_2. produces (C_2DCl_3 + C_2HCl_3). Significant quantities of CCl_4 are also produced by undetermined reactions.

ROBERT D. MCALPINE, J. W. GOODALE et D. K. EVANS. Can. J. Chem. **63**, 2995 (1985).

On a employé différentes raies, de la transition [00°1 → 10°0] du laser à $^{13}CO_2$ pour étudier l'absorption et la décomposition multiphotonique (AMP et DMP) de $CDCl_3$ à des pressions de $CDCl_3$ allant de 0,133 à 13,3 kPa. Les résultats AMP montrent une section efficace qui augmente jusqu'à un plateau; on peut probablement expliquer cette observation par l'effet de "rotational hole-filling". Un "spectre" AMP du nombre moyen des photons absorbés par molécule contre la longueur d'onde pour les raies diverses du laser à $^{13}CO_2$ était deplacé d'un certain nombre d'ondes plus bas que le spectre ordinaire d'au moins 5 cm^{-1}, ce qui suggère qu'une petite quantité d'"anharmonicity bottle-necking" a opéré dans le $CDCl_3$. La probabilité DMP contre fluence pour $CDCl_3$ est comparée avec celle mesurée par d'autres travailleurs pour CDF_3 et cette comparaison indique que l'on peut décomposer $CDCl_3$ un peu plus facilement que CDF_3 par la raie appropriée d'un laser à CO_2 opérant en mode pulsé.

Pour les pressions (0,2 à 4,0 kPa) et pour la durée d'impulsion constante employées, la DMP est de l'ordre de deux. Le canal primaire de la décomposition est l'élimination du DCl suivi par la réaction de CCl_2 pour donner C_2Cl_4, C_2Cl_2 et Cl_2. Le DCl produit s'échange avec une source d'H_2O dans la cellule de la réaction pour donner une quantité significative d'HCl. Une réaction, ayant lieu après l'impulsion, entre (HCl et DCl) et C_2Cl_2 produit (C_2DCl_3 et C_2HCl_3). Une quantité significative de CCl_4 est produite par des réactions actuellement indéterminées.

1. Introduction

The potential application of infrared multiphoton decomposition (MPD) processes (1) to isotope separation (2) has been the subject of many studies during the past decade (3). In particular, the separation of hydrogen isotopes, which has large scale application in the production of heavy water (deuterium from protium) for use in CANDU reactors, for the extraction of titrium from the moderator water in a CANDU reactor (tritium from deuterium), and during reprocessing of spent fuel (tritium from protium) has been pursued. In all three applications, the source of the isotope to be extracted is almost always water. However, since water does not undergo MPD efficiently (4), it is more efficient to exchange the desired isotope into a working molecule which will then undergo isotopically selective MPD (3).

Several molecules have been suggested as potentially suitable working molecules for heavy water production (3, 5). Of these, fluoroform is currently the one most promising (6–14) and may also be suitable for tritium recovery (15–18). However, there are two major obstacles to the use of fluoroform in a heavy water process: (*a*) efficient MPD of fluoroform requires fluences in excess of 20 J/cm^2, which, combined with the need to use short pulses (9) ($\Delta\tau \approx 1-2$ ns) leads to laser-induced damage of windows which complicate the design of the photolysis cell and (*b*) exchange of fluoroform with water or natural gas is too slow for a practical exchange step without the use of a catalyst (11). Consideration of a molecule which undergoes faster exchange with water would be advantageous.

As part of a search for working molecules which are improvements over fluoroform, we have considered MPD of the series CHX_3 where X = H, F, Cl, Br, and I. The enthalpies of decomposition (3) for members of this series are shown in Fig. 1.

For applications to isotope separation in a decomposition channel, such as channel 1, Fig. 1, which has the deuterium located in a stable molecule is preferred. This factor suggests the consideration of chloroform as a candidate molecule for hydrogen isotope separation. Two additional factors favour the consideration of chloroform: (*a*) The density of states increases more rapidly with excitation energy for chloroform versus fluoroform as is shown in Fig. 2. This suggests that chloroform may undergo MPD at lower fluences than fluoroform (4, 19, 20). (*b*) The isotopic exchange rate between chloroform and water is faster than between fluoroform and water (21).

In 1978, Marling and Herman (5) rejected chloroform as a potential candidate for heavy water production since $CDCl_3$ does not absorb any of the easily obtained lines of a $^{12}C^{16}O_2$ laser. However, since that time, the economic use of TEA lasers operating on $^{13}C^{16}O_2$ (producing lines which are selectively absorbed by $CDCl_3$) has been demonstrated (22). An earlier MPD study of $CDCl_3$ and $CHCl_3$ concluded that the D/H selectivity for mixtures of these isotopic species was small (23).

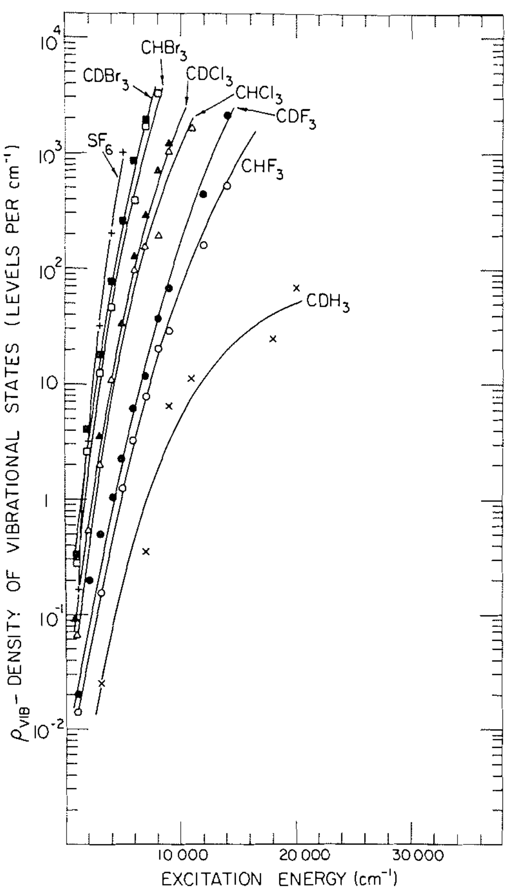

FIG. 2. The density of vibrational states as a function of excitation energy for the haloforms. The curve given for SF_6 is included for reference.

Chloroform is thought to be a suitable working molecule for tritium recovery and the selective MPD of $CDCl_3$ and $CTCl_3$ was studied using the 10P (50) line of a CO_2 laser and an NH_3 laser, respectively (24–27). Studies of the MPD of $CDCl_3$, in a molecular beam, show channel 1 of Fig. 1 to be the predominant MPD channel (25).

In this paper we report the results of a study of multiphoton absorption (MPA) and MPD of $CDCl_3$ using a $^{13}C^{16}O_2$ laser. The major stable products have been measured and a mechanism which accounts for them is discussed.

TABLE 1. MPA results for eliminate $CDCl_3$ as a function of pressure (P), pathlength (l), and fluence (Φ) for the $^{13}C^{16}O_2$ [00°1 → 10°0] P(8) line; these results were obtained by transmission techniques; for a definition of K, b, and Φ, see the text

2. Experimental

2.1 $^{13}C^{16}O_2$ laser

In order to conserve the charge of $^{13}C^{16}O_2$, a Lumonics model K-920 CO_2 laser kit was modified to ensure a good gas seal during operation and to permit partial evacuation during gas fill. The gas recirculating system contained a catalytic bed to recombine the CO and O_2 formed during laser operation thus preventing the arcing that would have occurred if these gases had been permitted to build up. The laser and gas recirculating system were filled with the mixture N_2:He:$^{13}C^{16}O_2$ = 1:3:1 as follows. The system was purged of air using a N_2, He mixture in the chosen proportion; then the system was evacuated to a N_2, He mixture pressure of 80 kPa and then was filled with $^{13}C^{16}O_2$ (MSD Isotopes, lot number 1246-G, 99 atom% ^{13}C) to a pressure of ~100 kPa. A single charge of $^{13}C^{16}O_2$ lasts at least one year and can be recovered by purging the system with He or N_2 through a cold trap (77 K) if servicing is required.

The laser was equipped with a Bausch and Lomb replica grating (135 lines/mm, blazed at λ = 7.4 μm) allowing single line tuning over the 00°1 → 10°0 and 00°1 → 02°0 $^{13}C^{16}O_2$ transitions. Intracavity irises were used to force single transverse mode operation. However, many longitudinal modes were active giving a multi-mode temporal profile with a spike (~200 ns) and a tail (~1 μs) similar to that obtained with conventional $^{12}C^{16}O_2$ lasers.

For the MPA experiments, lines with $\bar{\nu}_L$ = 886.1 to 938.8 cm^{-1}

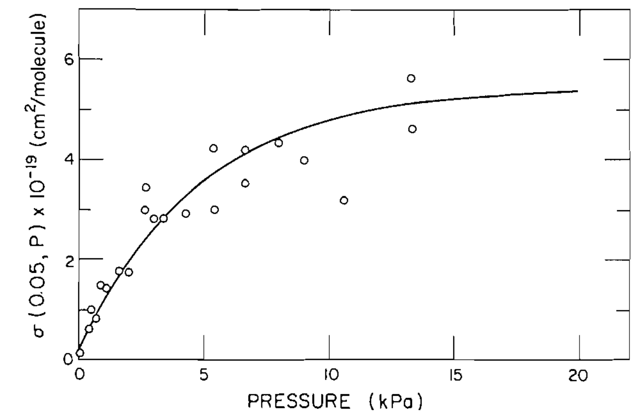

FIG. 3. The dependence of cross-section for absorption of the $^{13}CO_2$ [00°1 → 10°0] P(8) line as a function of $CDCl_3$ pressure for $\Phi = 0.05$ J/cm^2. The solid line is a plot of eq. [2] with $\sigma(0.05,0) = 2 \times 10^{-20}$, $\sigma(0.05,\infty) = 5.5 \times 10^{-19}$, and $P_0 = 5$ kPa.

were used and for MPD experiments only the P(8) line of the 00°1 → 10°0 transition ($\bar{\nu}_L = 908.4$ cm^{-1}) was used. Radiant energies were varied by use of calibrated BaF_2 attenuators.

2.2 MPA measurements

Both the automated photoacoustic data acquisition system (described in ref. 28) and transmission techniques (29) were used to obtain the results reported here. Absorption cross section, σ, and the average number of photons absorbed per molecule, $\langle n \rangle$, are expressed either as a function of fluence at beam center, ϕ, or as local fluence, Φ, as described elsewhere (9, 10, 30).

2.3. MPD measurements

MPD measurements were performed using the following two lens and cylindrical cell combinations: (*a*) a lens of focal length 55 cm and a cell of length 3.7 cm and volume 22.7 cm^3, (*b*) a lens of focal length 100 cm and a cell of length 11.0 cm and volume 53.1 cm^3. These combinations were selected to put the entire cell within the cylindrical region of the photolysis geometry.

A Finnegan model 1020B computerized gas chromatograph/mass spectrometer (equipped with a Poropak-P column) was used to identify gc peaks due to $CDCl_3$, C_2Cl_4, CCl_4, (C_2DCl_3 + C_2HCl_3), and C_2Cl_2. Quantitative analysis of these compounds was carried out on a Hewlett-Packard model 5700A gas chromatograph (3.7 m stainless steel column packed with Poropak-P, temperature 443 K, He carrier gas at a flow rate of 25 cm^3/min) equipped with a flame ionization detector. Except for C_2Cl_2, calibration curves of peak area versus concentration were obtained by injection of known amounts of authentic samples. No such curve could be obtained for C_2Cl_2 due to the problems of handling this compound; rather, stoichiometry was assumed (and is discussed in section 3.2) which provided a relationship between the C_2Cl_2 concentration and the $CDCl_3$ consumed.

A Bomem model DA3.02 Fourier Transform Infrared (FTIR) spectrometer was also used to observe $CDCl_3$ and the products DCl, HCl, C_2Cl_4, C_2Cl_2, CCl_4, C_2DCl_3, and C_2HCl_3.

3. Results and discussion

3.1. MPA measurements

The absorption as a function of pressure, P, and Φ was measured for MPA of the $^{13}CO_2$ [00°1 → 10°0] P(8) transition using transmission techniques (29). The absorption cross sections $\sigma(\Phi)$ were corrected for the Gaussian distribution of the beam and for changes in fluence along the beam as previously described (9, 10). The values of $\sigma(\Phi)$ were then found to fit well to the empirical form of (4, 9, 10, 29) of eq. [1].

$$[1] \quad \sigma(\Phi) = K\Phi^b$$

The results of these analyses are given in Table 1.

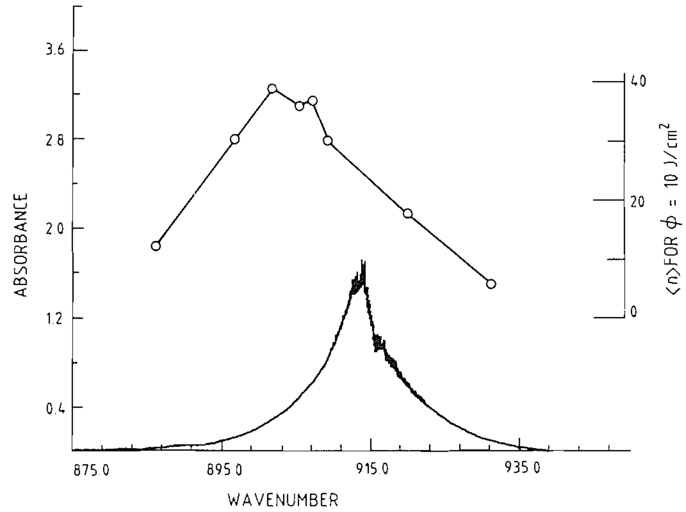

FIG. 4. The dependence of the average number of photons absorbed per molecule $\langle n \rangle$, of $CDCl_3$ on the laser wavenumber for $\phi = 10$ J/cm^2. The bottom trace is the small signal absorption spectrum of $CDCl_3$ for comparison.

The pressure dependence of σ for $\Phi = 0.05$ J/cm^2, $\sigma(0.05, P)$, calculated from the results of Table 1, is plotted in Fig. 3. These results show a behaviour similar to the $P\Delta\tau$ (where $\Delta\tau$ is laser pulse width) dependence observed for constant Φ for CDF_3 (31), CH_3OH (32), and cyclobutanone (33) and fits the empirical equation [2]

$$[2] \quad \sigma(0.05, P) = \sigma(0.05, \infty) + [\sigma(0.05, \infty) - \sigma(0.05, 0)] \times [1 - \exp(-P/P_0)]$$

A good fit to the results plotted in Fig. 3 is obtained for $\sigma(0.05, 0) = 2 \times 10^{-20}$ cm^2, $\sigma(0.05, \infty) = 5.5 \times 10^{-19}$ cm^2, $P_0 = 5$ kPa.

Due to the large σ values for low fluence (the b values in eq. [1] are negative), absorption of the laser light during transmission through the $CDCl_3$ significantly reduces ϕ in the region of the gas that the microphone samples. This, as has been discussed in ref. 32, leads to a large uncertainty in the results, and consequently we do not report σ values for the photoacoustic measurements. However, from the MPA results, $\langle n \rangle(\phi)$ for $\phi = 10$ J/cm^2 has been estimated using several laser lines. These results have an absolute accuracy of only a factor of 2 or 3 due to the absorption problem discussed above; however, the relative accuracy across the range of $\bar{\nu}_L$ is probably 20 to 30% allowing the "spectrum" of $\langle n \rangle$ (10) versus $\bar{\nu}_L$ to be qualitatively compared with the small signal spectrum. This is shown in Fig. 4. The observed peak of the large signal spectrum is shifted to lower energy by ≥ 5 cm^{-1} from that of the small signal spectrum. This is a larger shift than was observed for CDF_3 (10) and suggests that anharmonicity bottle-necking (34, 35) is more severe for $CDCl_3$ than CDF_3 (33, 36).

3.2. MPD measurements

The results of an MPD study of $CDCl_3$, as a function of pressure, fluence at beam centre, focal length, and the number of pulses are given in Table 2.

The results of Table 2 for $\phi = 18 \pm 0.5$ J/cm^2 and for focal length 55 cm are plotted as a second order plot in Fig. 5, demonstrating that the depletion of $CDCl_3$ is second order in $CDCl_3$ for the pressure range 0.2 to 4.0 kPa. Similar kinetics have been previously observed (for conditions of ≥2 collisions during the laser pulse) for HCOOH (36), CH_3OH (37, 38), and

TABLE 2. The results of a MPD study of $CDCl_3$ using the $^{13}CO_2$ $[00^{\circ}1 \rightarrow 10^{\circ}0]$ P(8) line as a function of pressure (P), fluence (ϕ), and number of laser pulses (m); the symbol N_m denotes the number of $CDCl_3$ in the cell after m pulses; the numbers in parentheses in columns 7 and 8 are respectively the quantities of C_2Cl_4* produced by reaction [6] and the quantity of C_2Cl_2 produced overall using the assumptions discussed in the text

CH_2O (39) and are indicative of a collisionally assisted MPD process. The decomposition probability, $f(\phi)$ (that is the fraction of the illuminated molecules which decompose) is given by

$$[3] \quad f(\phi) = \frac{k_2N_0}{(1-k_2N_0)}\frac{V_0}{V_l}$$

where k_2 is the second order rate constant, V_0 is the cell volume, and V_l is the volume of the photolysis zone given by

$$[4] \quad V_l = \frac{\pi(F\theta)^2 l}{4}$$

where F is the lens focal length, θ is the laser divergence (1.5 mrad in this case), and l is the cell length. Since the laser beam has a Gaussian rather than a "top-hat" radial distribution, the definition of the "cylindrical" photolysis zone depends on the radius chosen to define the beam width. In addition, since the MPD is second order, molecules initially outside the defined "photolysis zone" may, by collisional or diffusion processes, become excited and participate in MPD.

The following functional form for $f(\phi)$ in eq. [5] is similar to that suggested by Fuss (40), but with the addition of a scaling parameter, A.

$$[5] \quad f(\phi) = A \exp\,[-\phi_o/\phi]$$

A good fit of experimental results for MPD of 2,2,2-trifluoroethanol to the Fuss model was observed in our laboratory (20). In Fig. 6, $\log_e f(\phi)$ versus $1/\phi$ is plotted for the results of Table 1 corresponding to $P = 1.33 \pm 0.01$ kPa. From a linear least-squares fit to this plot, $A = 3.8$ and $\phi_0 = 18.0$ J/cm^2. The value $A > 1$ means that more molecules are participating in MPD than just those initially within the defined "photolysis zone". This could arise either from an underestimate of this zone for a laser beam with a Gaussian radical distribution or from the participation of molecules initially outside the photolysis zone by collisional or diffusion processes. A comparison of $CDCl_3$ results with those for CDF_3 (9) (the above results for $CDCl_3$, when analysed according to the formula used in ref. 9, give ϕ_{sat}, equal to 13.4 J/cm^2) is difficult due to the addition of buffer gases used in ref. 9; however, our results for $CDCl_3$ indicate that it undergoes MPD at slightly lower fluences than CDF_3, for comparable conditions. It would appear that the gain in ease of MPD due to a faster rising ρ_{VIB} vs excitation for $CDCl_3$ compared to CDF_3 is offset by a larger anharmonicity bottle-necking in $CDCl_3$.

3.3. Reaction mechanisms

A mechanism for the MPD of $CDCl_3$ was proposed by Herman, Magnotta, Buss, and Lee (25). Of the two likely primary steps (channels 1 and 4 of Fig. 1) they conclude that

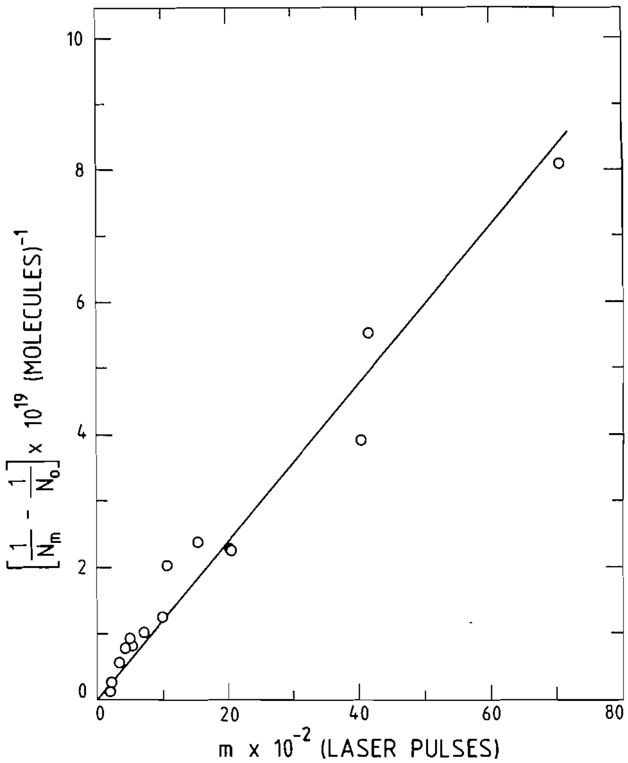

FIG. 5. Second order kinetic plot for depletion of $CDCl_3$ by $^{13}CO_2$ laser induced MPD, for ϕ = 18 J/cm^2 and F = 55 cm.

>99.1% of the decomposition occurs by channel 1 for fluence ≤35 J/cm^2.

The other major products observed by us (C_2Cl_4 and C_2Cl_2) may be accounted for as follows:

[6] $2CCl_2 \rightarrow C_2Cl_4{}^*$

[7] $C_2Cl_4{}^* \rightarrow C_2Cl_2 + Cl_2$

[8] $C_2Cl_4{}^* + M \rightarrow C_2Cl_4 + M$

[9a] $C_2Cl_4{}^* \xrightarrow{mh\nu} C_2Cl_2 + Cl_2$

[9b] $C_2Cl_4 \xrightarrow{ph\nu} C_2Cl_2 + Cl_2$

In this scheme, channel 1 is the only source of DCl and its concentration should be equal to the $CDCl_3$ depletion. To determine the relative yield of DCl by MPD, two experiments were performed. One 1.334 kPa sample and one 2.785 kPa sample were photolyzed by 2500 and 2000 laser pulses, respectively, using a 55 cm lens and appropriate cell combination. Each sample was then split into two approximately equal parts with one part being analysed by gas chromatography as for previous samples. The second part was shaken with 30 cm^3 of H_2O and the pH was measured, and from this, the number of DCl molecules produced was determined. For the 1.334 kPa sample the number of $CDCl_3$ molecules decomposed was 9.2×10^{18} and the number of C_2Cl_4 and DCl produced were 3.4×10^{18} and 1.2×10^{19}, respectively. For the 2.785 kPa sample these numbers were 3.0×10^{19}, 3.9×10^{18}, and 2.8×10^{19}, respectively. Thus, within the large error inherent in such experiments, one DCl molecule is produced for each $CDCl_3$ molecule decomposed.

As a prelude to studying the selective MPD of $CHCl_3/CDCl_3$ mixtures, a pure sample of $CDCl_3$ was photolyzed and the products were studied by observing their FTIR spectra. About 50% of the "hydrogen chloride" product consisted of HCl with the remainder as DCl. The appearance of HCl is due to exchange between DCl and a source of water in the cell.

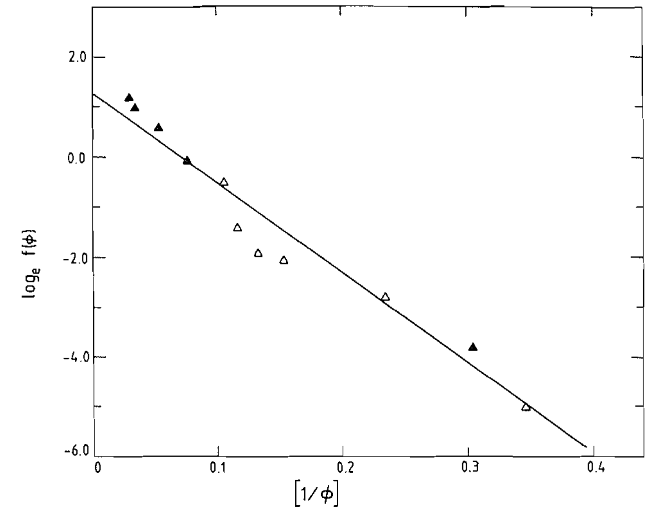

FIG. 6. A plot of $\log_e f(\phi)$ versus $1/\phi$ for MPD of $CDCl_3$ induced by a $^{13}CO_2$ laser for P = 1.33 kPa and F = 100 cm (△) and F = 55 cm (▲).

[10] $DCl + H_2O = HDO + HCl$

A similar exchange was observed for selective MPD of fluoroform (10). Attempts to study selective MPD of $CHCl_3/CDCl_3$ mixtures by observing FTIR depletion of $CHCl_3$ and $CDCl_3$ peaks was also unsuccessful since product FTIR peaks interfere with the $CDCl_3$ peaks in the spectrum.

A second order kinetic plot for C_2Cl_4, using the P = 1.0 and 2.7 kPa results, shows that the appearance of this product follows well the consumption of $CDCl_3$ with 0.24 molecule of C_2Cl_4 produced per molecule of $CDCl_3$ decomposed. If CCl_2 undergoes combination via reaction [6] followed by [8] then 0.5 molecule of C_2Cl_4 would be produced per $CDCl_3$ molecule consumed. Due to the highly reactive nature of C_2Cl_2, no absolute calibration was obtained for gas chromatography. However, if one assumes that reactions [7] and [9] are the only sources of C_2Cl_2 then the C_2Cl_2 concentrations will equal half the depletion of $CDCl_3$ minus C_2Cl_4. The numbers in parentheses in Table 2, column 8 are obtained in this way. To test the assumption that C_2Cl_2 is only formed via reactions [7] and [9] the calculated C_2Cl_2 concentrations were plotted versus the correspondingly observed gas chromatograph peak heights and this gave a straight line which passed through the origin which is consistent with the assumption. Samples of C_2Cl_4 were irradiated with the $^{13}C^{16}O_2$ [00°1 → 10°0] P(8) line; the FTIR spectrum showed that no decomposition occurred, thus reaction [9*b*] is eliminated as a source of C_2Cl_2.

Two minor products, CCl_4 and C_2DCl_3, also follow the depletion of $CDCl_3$ with 0.14 and 0.02 molecule, respectively, formed per $CDCl_3$ decomposed. The C_2DCl_3 may arise from reactions [11] (26), [12] (27), and [13].

[11] $CCl_2 + CDCl_3 \rightarrow C_2DCl_3 + Cl_2$

[12] $CDCl_2 + CDCl_3 \rightarrow C_2DCl_3 + DCl + Cl$

[13] $C_2Cl_2 + \begin{Bmatrix} DCl \\ HCl \end{Bmatrix} \rightarrow \begin{Bmatrix} C_2DCl_3 \\ C_2HCl_3 \end{Bmatrix}$

Reaction [11] represents a loss of CCl_2 and reaction [12] arises from the minor channel for MPD of $CDCl_3$ (25). Channel [13] is a reaction of products which occurs after the laser pulse, but before analysis has been performed. To determine whether [13] occurs to a significant degree, a sample of $CDCl_3$ of P = 0.54 kPa was photolyzed with 750 pulses using the [00°1 → 10°0] P(8) line, F = 55 cm, ϕ = 14 J/cm². FTIR spectra of the cell were taken of the photolyzed samples at various times up to 125 h following photolysis. Features centered near $\bar{\nu}$ = 783, 850, and 940 cm^{-1}, which are due to C_2HCl_3, were all observed to grow with time, and the 850 cm^{-1} feature was used to estimate the concentration of C_2HCl_3 as a function of time. Immediately following photolysis, the apparent C_2HCl_3 yield was 3.6×10^{16} molecules. This value became 5.4×10^{16}, 7.2×10^{16}, 1.5×10^{17}, and 2.9×10^{17} after 1 h, 2 h, 24 h, and 125 h, respectively. These results suggest that the reaction between the products of laser photolysis, reaction [13], may be the major source of C_2HCl_3 and C_2DCl_3 for MPD of $CDCl_3$.

4. Conclusions

$CDCl_3$ undergoes MPD at lower fluences than CDF_3; but the difference between the two molecules is small. This probably indicates that the small anharmonicity bottle-necking for the pumped mode of CDF_3 (9, 10, 41) compensates for the more slowly rising ρ_{VIB} versus excitation energy for CDF_3 compared to $CDCl_3$. Selective MPD measured elsewhere (23) indicates that D/H selectivity is smaller for $CDCl_3$ (with excitation at 11 μm) than for CDF_3. Thus use of $CDCl_3$ as a working molecule in an isotope enrichment process does not provide an advantage over CDF_3 from the photolysis point of view; however, redeuteration by exchange with water is easier for $CDCl_3$ than for CDF_3.

The primary decomposition channel, in agreement with other studies (24–27) is predominantly elimination of DCl followed by reactions [6]–[9*a*] but not [9*b*] with about 0.24 C_2Cl_4, 0.14 CCl_4, and 0.02 C_2DCl_3 and C_2HCl_3 molecules produced per $CDCl_3$ decomposed.

Two water-soluble ionic benzophenones containing a quaternized amine and a sulphonate group have been investigated by laser flash photolysis. The decay kinetics and spectra of their triplet states were studied and quenching constants by triethanolamine, isopropanol, and methyl viologen determined. These data are of interest when these benzophenones are used as initiators for photo-polymerizing water-soluble acrylates in homogeneous solution or in reverse micellar assemblies. The high water solubility of these compounds allows the bimolecular deactivations due to triplet–triplet (k_{TT}) and triplet–ground state (k_{SQ}) interactions to be determined more accurately than in the case of benzophenone itself.

D. J. LOUGNOT, P. JACQUES, J. P. FOUASSIER, H. L. CASAL, NGUYEN KIM-THUAN et J. C. SCAIANO. Can. J. Chem. **63**, 3001 (1985).

Utilisant la photolyse flash au laser, on a étudié deux benzophénones ioniques, solubles dans l'eau, qui contenaient à la fois un groupement amine quaternaire et un sulfonate. On a étudié les cinétiques de disparition ainsi que les spectres de leurs états triplets; de plus, on a déterminé les constantes de piégeage par la triéthanolamine, l'isopropanol et le viologène de méthyle. Ces données présentent de l'intérêt à cause du fait que l'on utilise ces benzophénones comme initiateurs pour la polymérisation photochimique des acrylates solubles dans l'eau, tant en solution homogène que sous forme d'agrégats micellaires inversés. La grande solubilité de ces composés dans l'eau permet de déterminer, d'une façon plus précise que dans le cas de la benzophénone elle-même, les désactivations bimoléculaires dues aux interactions triplet–triplet (k_{TT}) et triplet–état fondamental (k_{SQ}).

[Traduit par le journal]

I. Introduction

A series of water-soluble carbonyl compounds have been recently introduced (1) and their activity in photopolymerizable mixtures with water soluble monomers has been demonstrated (2). The water solubility is obtained by functionalizing benzophenone with a trimethylammonium chloride or sodium sulphonate group at one of the *para* positions.

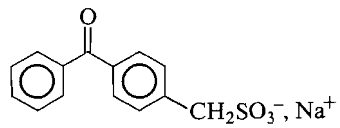
Photoactive initiators in polymerization experiments have been used in bulk as well as in homogeneous or microheterogeneous solutions (3). However, the photoinitiators generally used in these experiments are not suitable for water-soluble monomers due to their insolubility. In this work we examine two ionic, water-soluble benzophenones which can be used as photoinitiators. In addition to their use for this purpose, these molecules are of interest in other fields. Ionic benzophenones locate preferentially in water pools when dissolved in reverse micelles of AOT, and if an acrylic monomer is solubilized in the continuous oil phase, the segregation of the reactants results in a decrease of the interaction (usually quenching) between the excited state of the initiator and the monomer (3). Since the initiation quantum yield is essentially limited by this interaction (4, 5), the expected and observed consequences of compartmentalizing the reactants is a significant increase of the polymerization rate.

The same approach could be considered in the case of direct micelles. However, in this case, ionic benzophenones do not necessarily dissolve in the bulk water phase but rather locate in the immediate vicinity of the micelles, with loose interaction with the surfactant heads. Thus, the segregation between the reactants is poorly defined and as a consequence, the polymerization rates are not very affected when going from homogeneous solutions to micellar assemblies.

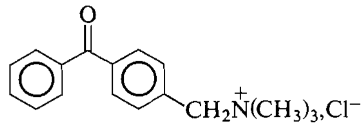
The study of water-soluble benzophenones yields information regarding the bimolecular interaction between two carbonyl molecules in their triplet state (i.e. annihilation) or between one excited state and one ground state molecule (i.e. self-quenching) in aqueous solution. In the case of benzophenone itself, the lifetime of the triplet state can be drastically affected by this type of deactivating interaction (6–11). However, while these processes are relatively well understood in organic solvents, the same does not hold in the case of aqueous solution (6, 7, 11), where the roles played by T–T annihilation and self-quenching are still subject to controversy. The main reason underlying this controversy is the poor solubility of benzophenone (BP) in water which limits the concentration range available and thereby the contribution of bimolecular processes relative to other modes of decay of the benzophenone triplet.

The compounds investigated here could help settle this question insofar as they behave basically as benzophenone itself. The present investigation is devoted to the study of the

[1]NRCC No. 24108.



1



2

photophysical behaviour of **1** (*p*-(methyl sodium sulphonate)-benzophenone) and **2** (*p*-methyltrimethylammonium chloride)-benzophenone in order to rationalize their use as photoinitiators for polymerizations in aqueous homogeneous or microheterogeneous solution. Due to their water solubility, these homologues of benzophenone lend themselves to many applications involving the photoreduction of carbonyl compounds by alcohols or amines. A study of the behaviour of radical-pairs derived from reactions of these benzophenones in micellar solution has already been reported (12).

II. Experimental

The compounds studied (**1** and **2**) were synthesized and purified according to a procedure recently described by Green and co-workers (1). The crude products are washed with ether and then recrystallized from adequate mixtures of isopropanol and water.

The laser photolysis experiments have been conducted with two types of apparatus: (*i*) The first one uses the pulses from a Molectron UV-24 nitrogen laser for excitation (337 nm, ~8 ns and up to 10 mJ), associated with an R-7912 Tektronix transient digitizer and a PDP-11/23 computer which also controls the experiment and provides suitable storage and hardcopy facilities. Further details have been given elsewhere (13). (*ii*) The second one uses the pulse train from a Quantel ruby laser working in mode-locked regime (347 nm after frequency doubling, ~30 ns and up to 200 mJ) (14).

The first device induces only weak conversions to the triplet state (0.1 to 1%) and is preferably used in the case of concentrated solutions (ca. 10^{-2} *M*). The second one is better adapted to the study of more diluted solutions (ca. 10^{-3} *M*) in which high conversions to the excited triplet state can be reached (20%).

Isopropanol and triethanolamine (Janssen Chimica) were used as received. Methyl viologen (Paraquat) from K & K was purified by recrystallization from methanol/acetone mixtures. Samples were prepared by dissolving **1** and **2** in distilled water. The pH was adjusted by adding hydrochloric acid or sodium hydroxide. In some cases, kinetic experiments involving pH control, were reproduced in the presence of a chemical buffer, in order to ensure the insensitivity of the kinetics to the buffer power.

All the samples used were deaerated by nitrogen bubbling and all experiments were carried out at 300 K.

III. Results and discussion

1. The ground state of 1 and 2

The spectroscopic and photophysical features of substrates **1** and **2** are similar to those of benzophenone (BP) and 4-methylbenzophenone (4MeBP), as expected.

The uv spectra of **1** and **2** in water show an intense band around 260 nm. In the case of BP in solvents with low polarities there is a weak band corresponding to the $n\pi^*$ transition. This band is not distinguishable in the spectra of **1** and **2** in water due to the shift induced by its negative solvatochromy. The results concerning the $\pi\pi^*$ transition are reported in Table 1 along with those for 4MeBP and BP obtained under the same experimental conditions.

The uv absorption maxima are practically insensitive to ionic substitution. The same applies to the characteristic infrared frequency for the carbonyl groups; these are 1652, 1653, 1656, and 1657 cm^{-1} for BP, 4MeBP, **1**, and **2** (in KBr pellets), respectively.

TABLE 1. Absorption maxima and extinction coefficients in water

	Value			
Parameter	BP	4MeBP	**1**	**2**
$\lambda_{max}^{\pi\pi^*}$ (nm)	258	264	262	255
log ϵ^a	4.18	4.24	4.30	4.26

[a] In units of M^{-1} cm^{-1}.

TABLE 2. Unimolecular (k_0) and bimolecular (k_{SQ} and k_{TT}) rate constants of benzophenone triplet decay in aqueous solution

k_0 (s^{-1})	k_{SQ} (M^{-1} s^{-1})	k_{TT} (M^{-1} s^{-1})	Ref.
10^4	$(1.8\pm0.4)\times10^8$	[a]	6
2.5×10^4	[a]	5×10^9	11
2.2×10^4	5×10^7	5×10^9	7

[a] Not detected.

The ground state absorption spectra of **1** and **2** remain unaffected through pH changes between 2 and 12; this, together with the ^{1}H nmr spectra in neutral D_2O are consistent with **1** and **2** being present solely in the keto form.

2. Self-quenching and T—T annihilation

Table 2 summarizes the values of the self-quenching (k_{SQ}) and T—T annihilation (k_{TT}) rate constants reported in the literature for BP. The explanation for the different values in Table 2 lies in the poor accuracy of the data obtained in water solution due to the low solubility of BP. The ground state optical density of a saturated aqueous solution of BP is <0.05 per cm in the wavelength range corresponding to the $n\pi^*$ transition; this poses many difficulties in any quantitative study of T—T or self-quenching bimolecular processes using nitrogen (337 nm), frequency-doubled ruby (347 nm), or frequency-tripled neodymium (353 nm) laser excitation.

None of the spectroscopic features or the photophysical behaviour of these molecules are basically affected by the presence of the charged substituent. Therefore, these molecules can be used as adequate substitutes for BP in highly polar solvents. The only exception to this may be in the case of interactions which may be induced by, or dependent upon, the localized charge carried by these compounds.

Figure 1 shows the transient signals recorded for **1** with high ground state concentration (~10^{-2} *M*) and low excitation energy (nitrogen laser at 337 nm) and with low ground state concentration (<10^{-3} *M*) and high excitation energy (ruby laser at 347 nm), respectively. From the observed initial decay rate of the triplet state and the initial transient absorbancy (7, 11),

$$[1] \quad \frac{d[^3BP]}{dt} = -\{k_0 + k_{SQ}[BP] + k_{TT}[^3BP]\}[^3BP]$$

or

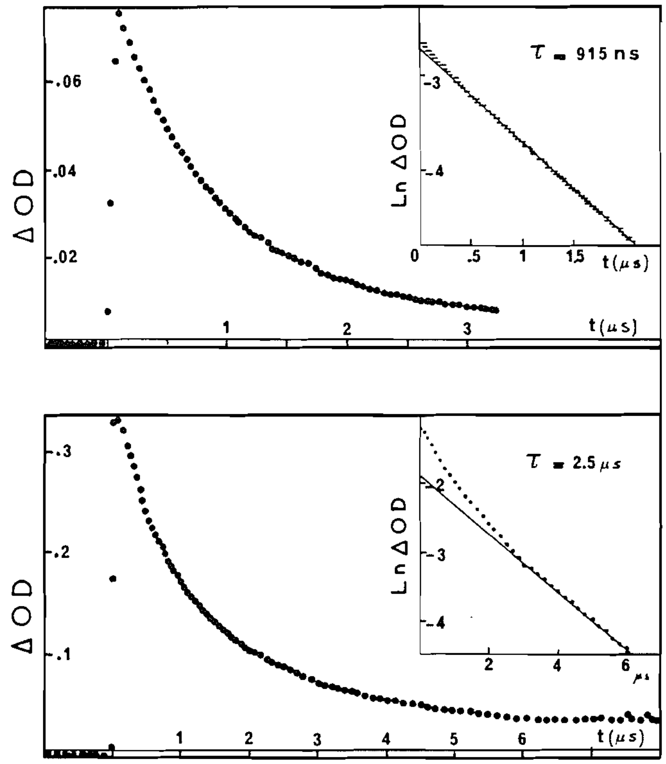


FIG. 1. Decay of the triplet state of **1**; traces obtained at λ = 525 nm. Top: λ(excitation) = 337 nm, [**1**] = 1.1×10^{-2} *M*. Bottom: λ(excitation) = 347 nm, [**1**] = 4×10^{-3} *M*.

$$[2] \quad -\frac{d}{dt} \ln [^3BP] = k_0 + k_{SQ}[BP] + k_{TT}[^3BP]$$

Thus, when the initial decay rate (at $t \rightarrow 0$) is plotted against the initial triplet concentration, the slope and intercept correspond to k_{TT} and to the pseudo first order decay rate ($k = k_0 + k_{SQ}[BP]$), respectively.

Analysis of the pseudo first order lifetimes and the initial rate constants determined from plots such as those in Fig. 1, shows that both, annihilation and self-quenching, may contribute to the decay of **1** in aqueous solution. An analysis of these bimolecular processes is possible in the case of **1** and leads to: $k_{SQ} = (7.3 \pm 0.1) \times 10^7 M^{-1} s^{-1}$ and $k_{TT} = (5.4 \pm 1.1) \times 10^9 M^{-1} s^{-1}$ (errors as two standard deviations, i.e. $\pm 2\sigma$). The same treatment is rather questionable in the case of **2**, due to traces of free amine which may originate in the poor stability of the ammonium function at neutral pH. Nonetheless, both these pathways seem active in the decay of the triplet state of **2**, in much the same way as for **1**.

This study confirms that **1** and **2** behave essentially as BP in aqueous solution, and that the rate constants corresponding to the bimolecular processes — i.e. k_{SQ} and k_{TT} — are not very sensitive to the presence of a charge. The spontaneous decay of the triplet states of **1** and **2** contributes almost insignificantly to their decay under the experimental conditions of the present study. Thus, it becomes very difficult to introduce a reliable value of k_0 which is any case lower than 10^5 s^{-1}. This is comparable in order of magnitude to the pseudo-first order decay rate expected for quenching by trace impurities.

3. T–T spectra in neutral aqueous solution

Figure 2 shows the T–T spectra of **1** and **2** recorded during the initial part of the decay, i.e. in a 200 ns time window after the laser pulse. These spectra exhibit maxima at 527 ± 3 nm (**1**) and 535 ± 3 nm (**2**) to be compared with values between 515 and 525 nm in the case of BP itself (7, 15). The small red shift observed here is probably the result of inductive effects due to the substituent, or to small changes in the dihedral angle between the rings. In the red side of these T–T absorption bands, there is a broad tail which becomes negligible only at λ > 800 nm, with two shoulders centered around 600 and 700 nm. The ratio between the extinction coefficients at the maximum and in the plateau region is in good agreement with the available data in the case of BP (15). At 800 nm, the extinction coefficients are still about 10% of the value at the corresponding maxima.

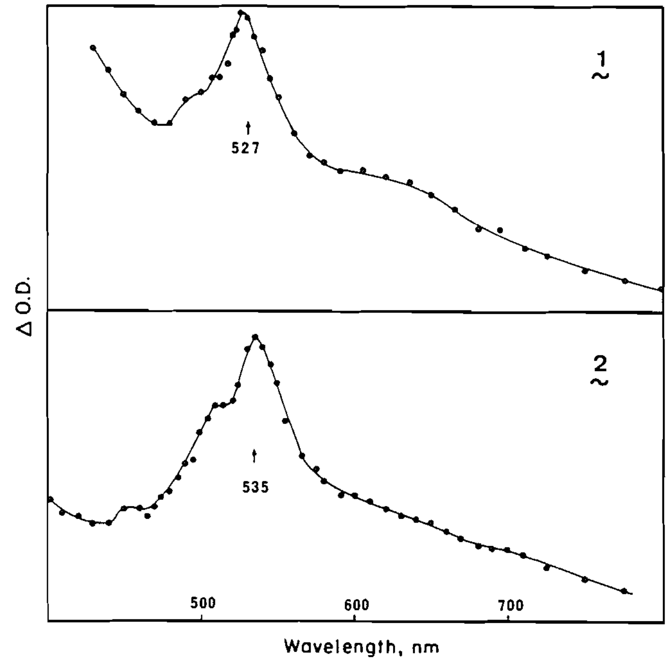

FIG. 2. T–T absorption spectra of **1** and **2** recorded at $0 < t <$ 230 ns; [**1**] = 8×10^{-3} *M*, [**2**] = 8.5×10^{-3} *M*.

The T–T spectra remain unaffected by pH changes between 3.0 and 13.0 for compound **1** and between 2.0 and 13.0 for compound **2**. In more acidic solution, the triplet lifetimes are drastically shortened due to protonation of the excited state (17). If the initial triplet intensity (ΔOD) is plotted against pH the curve obtained (Fig. 3) shows an inflexion which corresponds to p*K* (T_1). The p*K* of compound **1** is therefore estimated to be ~1.2. Owing to its poor stability, compound **2** does not lend itself easily to this kind of measurement; as a consequence, its p*K* (T) is only estimated to be lower than that for **1**.

The maximum of the T–T spectrum of protonated **1** is blue shifted by 13 nm (λ_{max} = 514 nm) with respect to the unprotonated form, and its red tail remains unaffected.

4. Interaction of 1 and 2 with water

The possibility of a direct reaction of triplet benzophenone with water to yield ketyl and OH˙ according to reaction [3] has been the subject of interest for over 10 years (6).

$$[3] \quad {}^3Ph_2CO^* + H_2O \xrightarrow{?} Ph_2\dot{C}OH + OH^{\cdot}$$

The water solubility of **1** made it possible to reexamine this question under rather favourable conditions. Our results show that photolysis of **1** in water yields ketyl radicals with yields in

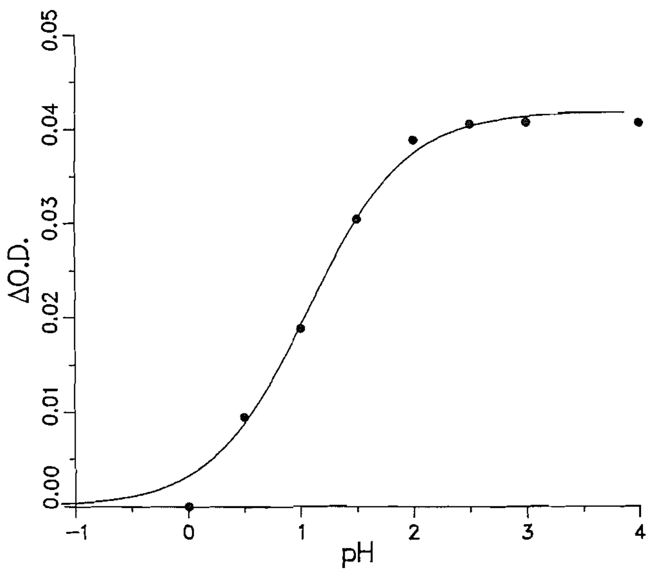

FIG. 3. Effect of pH on the changes in initial optical density at 525 nm for substrate **1**.

the 10−18% range. For example, Fig. 4 shows the decay kinetics of **1** in water at pH 6.0 observed at 625 nm (Fig. 4*A*), where the ketyl radical does not absorb and at 525 nm (T−T maximum) (Fig. 4*B*). The bottom trace (Fig. 4*C*) was obtained subtracting *a* from *b* after normalization of the initial optical density and shows that the ketyl radical is formed concurrently with triplet decay.

Time-resolved spectra showed that the weak residual absorption following triplet decay was due to the corresponding ketyl radical, with λ_{max} at 545 and 610 nm at pH 6.0 and 12.0, respectively. The band at 610 nm corresponds to the deprotonated form (15, 16, 18).

A comparison of optical densities immediately after the laser flash pulse, and after the initial triplet decay is complete leads to ketyl yields in the 10−18% range, after taking into account the known ratio of extinction coefficients for the triplet state and the ketyl radical (15, 16).

The question arises as to whether the ketyl radicals can result from reaction of the triplet state with water, or from other processes, to which impurity quenching and self-quenching could contribute.

A careful study of the laser photolysis of **1** in H_2O and D_2O, as a function of substrate concentration and laser dose leads us to the conclusion that there are no significant differences in the yield of ketyl radicals or the values of k_0, k_{SQ} or k_{TT}. Thus, we conclude that decay via triplet reaction with H_2O does not contribute significantly under our experimental conditions. This effectively puts an upper limit to the reaction of the triplet state with water of $k_H < 10^3\ M^{-1}\ s^{-1}$.

5. *Interaction of 1 and 2 with triethanolamine*

When benzophenone-based carbonyl compounds are used in photopolymerization experiments, it is necessary to incorporate a substrate capable of generating active radicals (19−22). For example, benzophenone is suitable as a photoinitiator in the presence of either:

(*a*) an amine with α-hydrogens, i.e.

$$[4] \quad \rangle C{=}O^* + \rangle N{-}CH\langle \rightarrow \rangle \dot{C}OH + \rangle N{-}\dot{C}\langle$$

(*b*) an alcohol or an ether giving direct hydrogen abstraction,

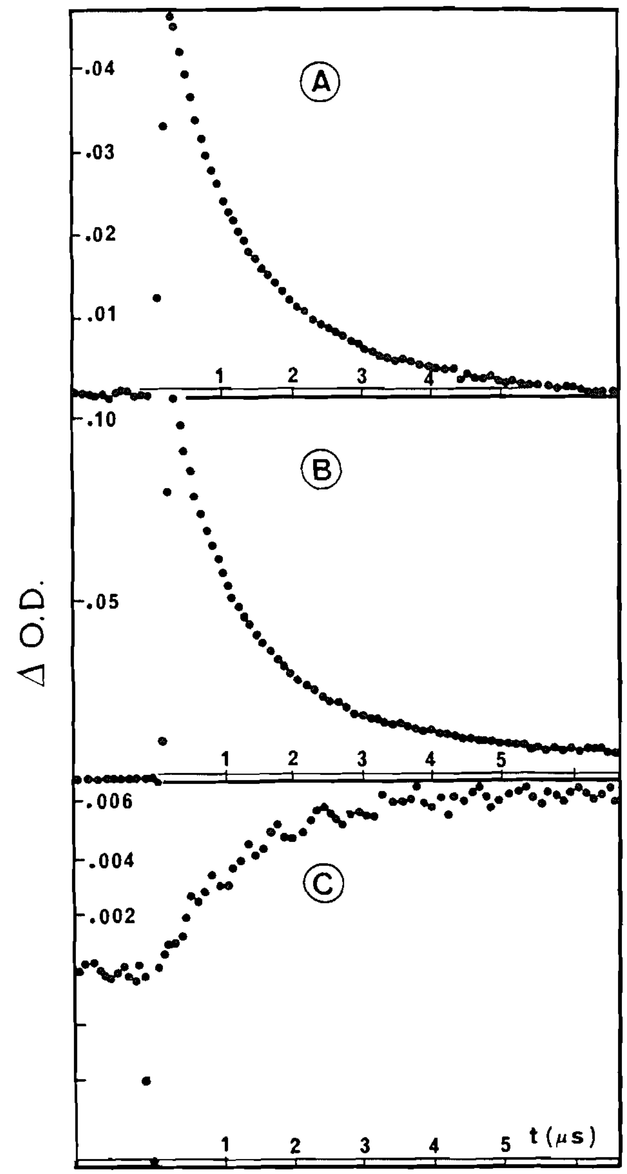

FIG. 4. Transient absorptions observed upon nitrogen laser excitation of **1**. (*A*) and (*B*): traces obtained at 625 and 525 nm, respectively. (*C*): deconvoluted trace obtained by subtracting the optical density at 625 nm from that at 525 nm after normalization at time zero ([**1**] = 0.011 *M* at pH 6.0).

e.g.

$$[5] \quad \rangle C{=}O^* + R_2CHOH \rightarrow \rangle \dot{C}OH + R_2\dot{C}OH$$

These two types of interaction were studied in the case of water-soluble benzophenones. Triethanolamine (TEA), which is water-soluble was selected to exemplify the interaction between **1** and **2** and amines. In order to eliminate any complications which could result from possible acid−base equilibrium the triplet lifetimes of **1** and **2** were measured at 525 nm. At this wavelength the extinction coefficients of the ketyl radical and of the anion radical are of the same order of magnitude (23). Thus, the total transient optical density due to ketyl radicals in neutral or anionic form is constant and the only variable component is the triplet absorption; proper kinetic analysis leads to the quenching rate constant for triethanolamine as illustrated in Fig. 5. The rate constants obtained are

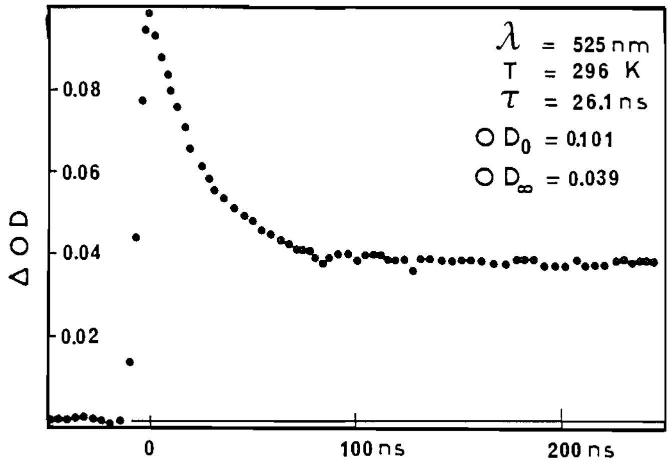

FIG. 5. Decay trace observed at 525 nm for **1** in the presence of triethanolamine; [**1**] = 8×10^{-3} *M*, [TEA] = 2.1×10^{-2} *M*.

$1.2 \times 10^9\ M^{-1}\ s^{-1}$ for **1** and $1.6 \times 10^9\ M^{-1}\ s^{-1}$ for **2**, respectively, in good agreement with the value measured for benzophenone ($1.5 \times 10^9\ M^{-1}\ s^{-1}$) under the same conditions (24).

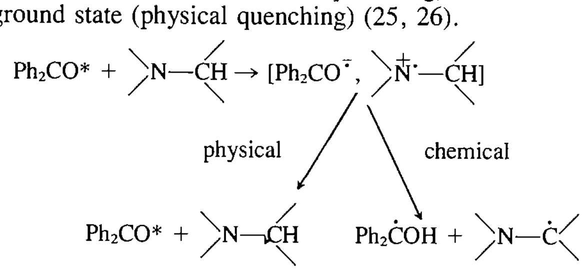
A last point is worth mentioning: the ratio, $\Delta OD_\infty^{525}/\Delta OD_0^{525}$ between the final optical density (ΔOD_∞^{525}) which corresponds to the sum:

$$[6]\quad \Delta OD_\infty^{525} = \{\epsilon_{\text{ketyl}}^{525}[\text{ketyl}] + \epsilon_{\text{anion}}^{525}[\text{anion}]\}l$$

and the initial one ΔOD_0^{525} which is exclusively due to the triplet state, gives access to another important parameter, i.e. the relative contributions of physical and chemical quenching of **1** and **2** by TEA.

The overall process (*vide supra*) accounts for the generation of amine-derived radicals which are the main active species in the initiation of photopolymerization. The analysis of rates and quantum yields can be carried out in terms of a mechanism involving a charge transfer complex which can decay either to the ketyl and amine radicals (chemical quenching) or to BP and amine ground state (physical quenching) (25, 26).

[7]



This ratio can be easily obtained from ΔOD_0 and ΔOD_∞ (see Fig. 5):

$$[8]\quad r = \frac{\text{"physical"}}{\text{"chemical"}} = \frac{\Delta OD_0 \times \left(\frac{\epsilon_K}{\epsilon_T}\right)_{525} - \Delta OD_\infty}{\Delta OD_\infty}$$

In the particular case of **1**, with $(\epsilon_K/\epsilon_T)_{525} \sim 0.37$ as mentioned before, *r* is estimated to be

$$r = \frac{0.101 \times 0.37 - 0.039}{0.039} \simeq 0$$

a result which supports an essentially quantitative chemical quenching (27).

6. Interaction of 1 and 2 with alcohols

Since compounds **1** and **2** have a lowest triplet state with $n\pi^*$ character (24), their behaviour is expected to resemble that of BP.

TABLE 3. Quenching of various benzophenones by methyl viologen in aqueous solution

Substrate	k_Q (water)	k_Q (acetate buffer, pH 4.8)
BP	$(3.7\pm0.4)\times10^9$	
	2.6×10^{9a}	
	1.03×10^{7b}	
1	$(7.8\pm0.6)\times10^9$	$(5.6\pm0.3)\times10^9$
2	$(6.5\pm0.7)\times10^8$	$(1.3\pm0.3)\times10^9$
3		$(1.7\pm0.7)\times10^9$

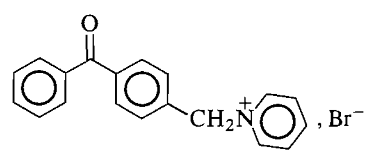
[a]From ref. 31.
[b]From ref. 32.

The rate constants measured in the systems **1** and **2** with isopropanol in water are $(1.5 \pm 0.2) \times 10^6$ and $(1.25 \pm 0.2) \times 10^6\ M^{-1}\ s^{-1}$, respectively; a value ca. $1.3 \times 10^6\ M^{-1}\ s^{-1}$ is generally accepted for BP (26, 28–30).

7. Interaction of 1 and 2 with methyl viologen

Das (31) has demonstrated that a number of triplet carbonyl compounds, including benzophenone, are quenched by methyl viologen (MV^{2+}), in a process that yields the readily detectable reduced form, $MV^{+\bullet}$, and presumably the ketone radical-cation, although the latter has so far escaped detection. Das's experiments for BP were carried out in 1:9 water: acetonitrile, and led to $k_Q = 2.6 \times 10^9\ M^{-1}\ s^{-1}$. Similar experiments by Chandrasekaran and Whitten (32) led to $k_Q = 1.03 \times 10^7\ M^{-1}\ s^{-1}$ in dry acetonitrile, based on phosphorescence measurements.

We have examined the electron transfer between the various benzophenones and methyl viologen in aqueous solution. The results have been summarized in Table 3, which also includes data for another ionic benzophenone, **3**.



3

The data in Table 3 show that electrostatic interactions play an important role in the case of fast electron transfer processes, with ca. one order of magnitude difference between the favourable (**1**) and unfavourable (**2**) cases. The reduced form, $MV^{+\bullet}$ was detected in good yields in all these systems.

IV. Conclusion

The behaviour of the two water-soluble benzophenones, **1** and **2** closely parallels that of benzophenone itself. The effectiveness of triplet–triplet annihilation and self-quenching has been demonstrated. The reaction of **1** and **2** with neutral substrates such as amines and alcohols occur with rate constants comparable with those for BP, while in the case of electron transfer to the methyl viologen dication the rates of electron transfer reflect the role of electrostatic interactions and follow the order **1** > BP > **2** ≃ **3**.

Gas-phase measurements of the influence of stepwise solvation on the kinetics of S_N2 reactions of solvated F^- with CH_3Cl and CH_3Br and of solvated Cl^- with CH_3Br

DIETHARD K. BOHME AND ASIT B. RAKSIT
Department of Chemistry and Centre for Research in Experimental Space Science, York University, Downsview, Ont., Canada M3J 1P3

Received February 14, 1985

DIETHARD K. BOHME and ASIT B. RAKSIT. Can. J. Chem. **63**, 3007 (1985).

Flowing afterglow measurements are reported which reveal the influence of stepwise solvation on the nucleophilicity of F^- and Cl^- in the gas phase at room temperature. The specific rates of nucleophilic displacement reactions with CH_3Cl and CH_3Br are followed for additions of up to three molecules of solvent for F^- solvated with D_2O, CH_3OH, and C_2H_5OH and for Cl^- solvated with CH_3OH, C_2H_5OH, CH_3COCH_3, HCOOH, and CH_3COOH. The observed precipitous response of the specific rate to solvation is attributed to intermediate features of plausible reaction energy profiles.

DIETHARD K. BOHME et ASIT B. RAKSIT. Can. J. Chem. **63**, 3007 (1985).

Les mesures des lueurs d'écoulement en phase gazeuse à la température ambiante révèlent l'influence de la solvatation graduelle sur le caractère nucléophile des ions F^- et Cl^-. On a étudié les vitesses spécifiques des réactions de déplacement nucléophile avec le CH_3Cl et le CH_3Br dans des additions impliquant jusqu'à trois molécules de solvant pour l'ion F^- solvaté avec D_2O, CH_3OH et C_2H_5OH et pour l'ion Cl^- solvaté avec CH_3OH, C_2H_5OH, CH_3COCH_3, HCOOH et CH_3COOH. On attribue la réponse en forme de pic observée pour la vitesse de solvatation, à des caractéristiques intermédiaires des profils d'énergie d'une réaction plausible.

[Traduit par le journal]

Introduction

The role of solvent in S_N2 reactions is exposed at its most fundamental level in reactions of type [1] which can now be executed and studied in the gas phase as a function of stepwise solvation of the nucleophile A^- (1, 2).

[1] $A^-\cdot S_n + CH_3B \rightarrow B^-\cdot S_m + [(n - m)S + CH_3A]$

In reactions of this type available solvent is limited to that associated directly with the reacting ion and, when the reaction proceeds in a dilute inert gas, the transport of solvent to the products must occur within the reaction complex rather than through the surrounding medium as is possible in solution. Gas-phase measurements of such reactions therefore allow the role of solvation in S_N2 displacement to be isolated and investigated at a molecular level of solvation hitherto inaccessible.

Recently we have reported measurements for reactions of type [1] between solvated *homoconjugate* anions, $A^-\cdot(AH)_n$, and the methyl halides CH_3Cl and CH_3Br with AH = H_2O, D_2O, CH_3OH, C_2H_5OH, HCOOH, CH_3COOH, and CH_3COCH_3 (1). Their specific rates were followed as a function of stepwise solvation for additions of up to three molecules of solvent and found to respond precipitously, in some instances already with the addition of just one molecule of solvent. The response appeared not to be controlled directly by the overall exothermicity of the solvated reaction but instead could be attributed to intermediate features in the appropriate potential energy profile. In this study we explore the solvent response of the specific rates of similar reactions involving solvated *heteroconjugate* anions, $A^-\cdot(BH)_n$ by subjecting CH_3Cl and CH_3Br to displacement by the halide ions F^- solvated with up to three molecules of D_2O, CH_3OH, and C_2H_5OH and Cl^- solvated with up to three molecules of CH_3OH, C_2H_5OH, HCOOH, CH_3COOH, and CH_3COCH_3.

Experimental

The measurements were taken with a flowing plasma mass spectrometer (flowing afterglow) system. Details of the instrument together with methods of operation and data analysis have been reported earlier (3, 4). Formation of solvated anions was initiated about 10 ms upstream of the reaction zone at total pressures of ca. 0.4 Torr in either a flowing helium or hydrogen buffer gas. Heteroconjugate anions were derived from solvent addition reactions of type [2].

[2] $A^-\cdot S_n + S + M = A^-\cdot S_{n+1} + M$

The parent gas of A^- was added upstream of the electron gun while the vapour of S was added just downstream in amounts of about 2×10^{18} to 2×10^{19} molecules s^{-1}. Experiments were performed with A^- = F^- derived from C_2F_6 (at about 1×10^{20} molecules s^{-1}), and Cl^- derived from CCl_4 (at about 4×10^{19} molecules s^{-1}) or CH_3Cl (at about 5×10^{20} molecules s^{-1}). The solvated ions which could be produced in this fashion were $F^-\cdot(D_2O)_n$, $F^-\cdot(CH_3COCH_3)_n$, $Cl^-\cdot(CH_3OH)_n$, $Cl^-\cdot(C_2H_5OH)_n$, $Cl^-\cdot(CH_3COCH_3)_n$, $Cl^-\cdot(HCOOH)_n$, and $Cl^-\cdot(CH_3COOH)_n$. The production of $F^-\cdot(CH_3OH)_n$ is illustrated in Fig. 1. F^- is a relatively strong base and was observed to react with CH_3COCH_3, HCOOH, and CH_3COOH primarily by proton transfer under the adopted experimental conditions. The initial relative populations of $A^-\cdot S_n$ could be varied by adjusting the amount of added vapour. As discussed previously (1, 5, 6), a wide range in the initial relative populations is desirable for the determination of rate constants because of losses associated with the depletion of the source ion, $A^-\cdot S_{n-1}$. The methyl chloride and methyl bromide used as reagents were of high purity (minimum 99.5 mol%).

Results

The results of the rate constant measurements which reveal the absolute degree to which step-wise solvation influences nucleophilicity are summarized in Table 1 *a* and *b*. The sources of uncertainty associated with the determination of rate constants have been described previously (3, 4). In deriving rate constants from the observed decays of solvated ions, account was taken of the initial decay which can arise due to the depletion of the precursor ion in the reaction region. The following section describes the results of the measurements in more detail.

$F^-\cdot(BH)_n$

F^- ions were readily solvated with up to three molecules of water and methanol and two molecules of ethanol. Figure 2 shows results of measurements taken with the addition of CH_3Cl into a $He/C_2F_6/D_2O$ plasma in which hydrated fluoride

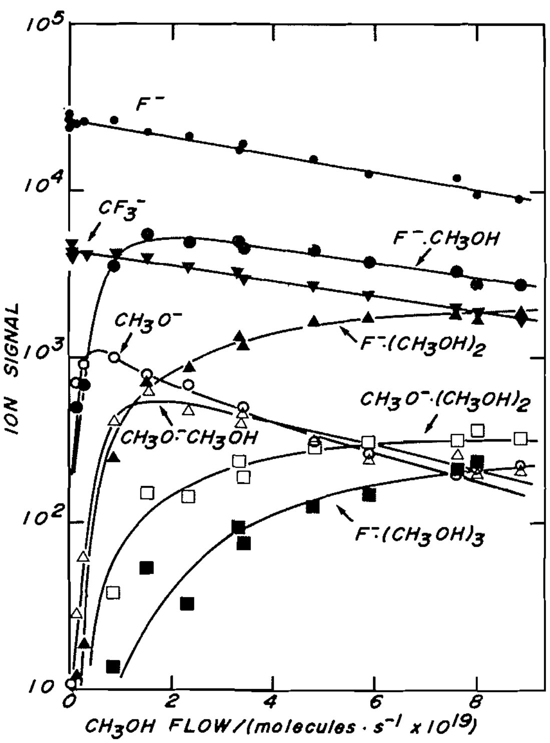

FIG. 1. The variation in dominant negative ions observed upon the addition of methanol as a 10% mixture in helium to a He/C_2F_6 plasma in which F^- and CF_3^- initially predominate. O^- and OH^- which are also present initially are not shown. T = 297 K, P = 0.320 Torr, $\bar{v}$ = 7.7 × 10^3 cm s^{-1}, L = 46 cm, flow of C_2F_6 = 2.4 × 10^{19} molecules s^{-1}.

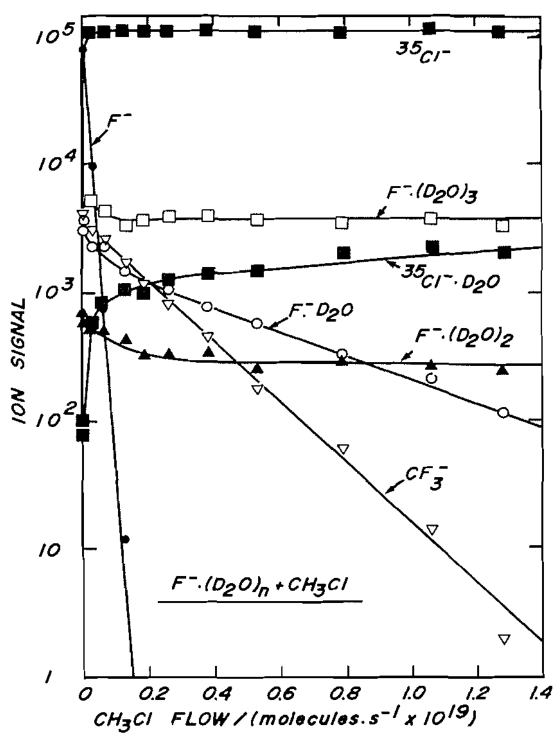

FIG. 2. Variations in ion signals recorded with the addition of CH_3Cl into a flowing $He/C_2F_6/D_2O$ plasma in which $F^- \cdot (D_2O)_n$ ions with n = 0 to 3 are initially predominant. T = 295 K, P = 0.347 Torr, $\bar{v}$ = 7.2 × 10^3 cm s^{-1}, and L = 46 cm.

ions have been established as dominant ions. Hydration is seen to reduce the reactivity of F^- already by a factor of about 100 with the addition of just one D_2O molecule. Further addition of D_2O molecules leads to immeasurably slow reactions. The slow reaction of $F^- \cdot D_2O$ with CH_3Cl appears to produce predominantly hydrated Cl^- product ions. With methanol and ethanol solvent the transition in reactivity was observed to be even more precipitous as solvation with just one solvent molecule resulted in immeasurably slow reactions.

More gradual transitions were observed with CH_3Br. The

singly solvated F^- ions were observed to react for all three solvents at a rate about 10 times less than that of the unsolvated F^- ion. There was evidence for substantial solvent retention only for the reaction of $F^- \cdot D_2O$. Figure 3 shows less than 10% solvent retention with $F^- \cdot CH_3OH$ which is similar to that observed with $F^- \cdot C_2H_5OH$. Further addition of solvent molecules resulted in a further drop in reactivity to levels which were not measurable. The reactivity of $F^- \cdot (D_2O)_3$ towards CH_3Br could not be explored because of overlap with $^{79}Br^-$ in the mass spectrum.

CF_3^-

With C_2F_6 as source gas significant amounts of CF_3^- were present initially in the flowing helium plasma. The CF_3^- was observed to react with both CH_3Cl (see Fig. 2) and CH_3Br (see Fig. 3) with rate constants of $(7 \pm 2) \times 10^{-11}$ and $(3 \pm 2) \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}, respectively. The reactions are believed to proceed by nucleophilic displacement and thus contribute to the appearance of Cl^- and Br^-, respectively, whose production is dominated by the reactions with F^- present under the same operating conditions.

$Cl^- \cdot (BH)_n$

Cl^- ions were readily solvated with up to three molecules of methanol, two molecules of ethanol, acetone and formic acid, and one molecule of acetic acid. Previous measurements in our laboratory had revealed only a very slow displacement reaction between unsolvated Cl^- and CH_3Br, $k = (2.1 \pm 0.4) \times 10^{-11}$ cm^3 molecule^{-1} s^{-1} (7). This result was reproduced in the present study as k was measured to be $(1.7 \pm 0.4) \times 10^{-11}$ cm^3 molecule^{-1} s^{-1} and it was also observed that solvation with just one molecule reduced the rate of reaction by more than a factor of 20 for each of the five solvents to values corresponding to the lower limit accessible with the technique.

Discussion

Intrinsic energetics and kinetics

The reactions of F^- and CF_3^- with CH_3Cl and CH_3Br and the reaction of Cl^- with CH_3Br are all exothermic in the absence of solvent. The methyl cation affinities in Table 2 indicate a range in exothermicity for the S_N2 reactions investigated in this study from 8 to 67 kcal mol^{-1}. The reactions with CH_3Br are 8 kcal mol^{-1} more exothermic than those with CH_3Cl.

We have previously reported rate constants of (1.8 ± 0.4) and $(1.9 \pm 0.4) \times 10^{-9}$ cm^3 molecule^{-1} s^{-1} for the reaction of F^- with CH_3Cl (7, 8), $(1.2 \pm 0.2) \times 10^{-9}$ cm^3 molecule^{-1} s^{-1} for F^- with CH_3Br (7), and $(2.1 \pm 0.4) \times 10^{-11}$ cm^3 molecule^{-1} s^{-1} for Cl^- with CH_3Br (7). These earlier flowing afterglow results agree with those obtained in the present study within experimental error. Pulsed ICR measurements have led to the lower values of (8.0 ± 0.9) and $(5.8 \pm 0.3) \times 10^{-10}$ cm^3 molecule^{-1} s^{-1} for F^- reacting with CH_3Cl (9, 10), $(6.0 \pm 0.6) \times 10^{-10}$ cm^3 molecule^{-1} s^{-1} for F^- reacting with CH_3Br (9), and

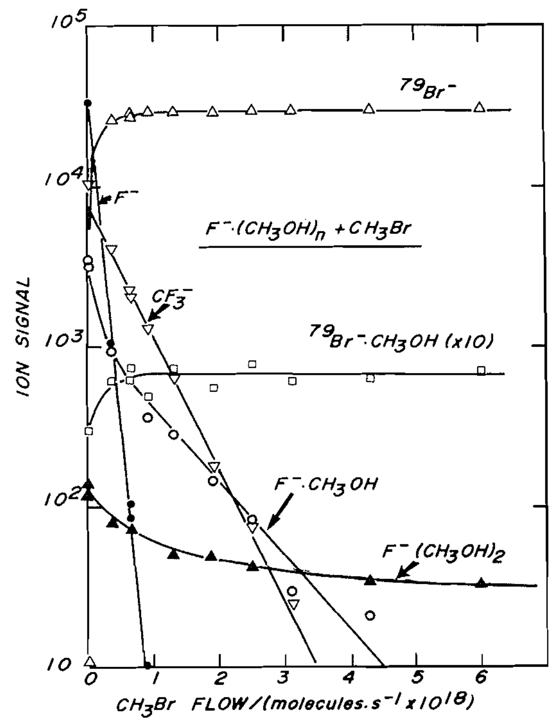

FIG. 3. Variations in ion signals recorded with the addition of CH_3Br into a flowing $He/C_2F_6/CH_3OH$ plasma in which $F^- \cdot (CH_3OH)_n$ ions with $n = 0$ to 2 are initially predominant. $T = 295$ K, $P = 0.306$ Torr, $\bar{v} = 7.7 \times 10^3$ cm s^{-1}, and $L = 46$ cm.

1.2×10^{-11} cm^3 molecule^{-1} s^{-1} for Cl^- reacting with CH_3Br (11) for which a value of $(8.0 \pm 1.0) \times 10^{-11}$ cm^3 molecule^{-1} s^{-1} had been reported earlier (9). The difference between the flowing afterglow and ICR results appears systematically to be about a factor of 2. Caldwell *et al.* have noted a similar difference for the reaction of Cl^- with CH_3Br for which they obtained a rate constant of 2.4×10^{-11} cm^3 molecule^{-1} s^{-1} at ca. 5 Torr (12) with a pulsed electron beam high pressure mass spectrometer. They have proposed that this difference can be expected as a result of the different pressures used in the different measurements. The expectation is based on a plausible "double-minimum" potential energy profile for reactions of this type. It is argued that when the energy of the central barrier in this profile lies below the initial energy of the system, as is the perception for the three reactions being considered here, collisional cooling of the excited adduct $A^- \cdot CH_3B$ will lead to an enhancement of formation of product as compared to decomposition back to reactants and so lead to an increase in the overall rate constant as the pressure is raised. Caldwell *et al.* also have provided crude model calculations which support the magnitude of the apparent pressure effect (12) but direct experimental verification has not yet been achieved so that systematic errors can not yet be ruled out to account for the disparity in

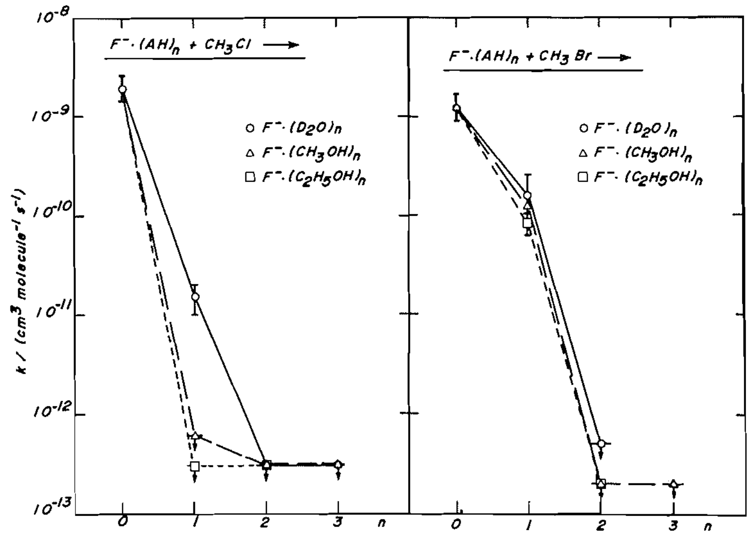

FIG. 4. Observed variations in the rate constant with the extent of solvation for gas-phase nucleophilic displacement reactions of solvated fluoride anions with methyl chloride and methyl bromide at room temperature.

results observed with the three techniques.

We have previously shown by experiment that the kinetic nucleophilicity of solvent-free S_N2 reactions in the gas phase, when expressed as a reaction probability per collision, has a dynamic range of more than 10^3. F^- exhibits nearly unit reactivity towards CH_3Cl and CH_3Br and so is among the most reactive nucleophiles in the gas phase. In comparison, the Cl^- reactivity towards CH_3Br is about 50 times smaller and puts Cl^- among anions of low nucleophilicity (7). The rate constants of $(7 \pm 2) \times 10^{-11}$ and $(3 \pm 2) \times 10^{-10}$ cm^3 molecule^{-1} s^{-1} for the reactions of CF_3^- with CH_3Cl and CH_3Br, respectively, correspond to reactivities of 0.03 and 0.2 so that this anion falls into the medium nucleophilicity range (7).

Kinetics of solvated S_N2 reactions

The results in Table 1 *a* and *b* indicate that the rate constants for the solvated reactions investigated become too small to measure with the addition of just two solvent molecules to the nucleophile or even, in some cases, just one. For the reactions of $F^- \cdot S_n$ this corresponds to a drop in the specific reaction rate in the gas phase of almost four orders of magnitude as is illustrated graphically in Fig. 4. In aqueous solution the specific rates of these S_N2 reactions are lower by another 15 to 16 orders of magnitude! The measured rate constants at 298 K for F^- reacting with CH_3Cl and CH_3Br in aqueous solution are 2.5×10^{-29} and 5.6×10^{-28} cm^3 molecule^{-1} s^{-1}, respectively (13). Also Fig. 4 shows that the rate of change of the rate constant with solvation is sensitive to the nature of both the methyl halide and the solvent. The reactions with CH_3Br show a remarkably similar decrease in specific rate with solvation for the three solvents D_2O, CH_3OH, and C_2H_5OH, but with CH_3Cl the drop in specific rate appears earlier with less solvation and is more distinct for the three solvents. A similar behaviour was evident for several of the S_N2 reactions of solvated homoconjugate anions with CH_3Cl and CH_3Br reported earlier (1). The reaction of Cl^- with CH_3Br is intrinsically about 100 times less efficient than the corresponding F^- reaction but nevertheless addition of one solvent molecule to Cl^- was observed to decrease the specific reaction rate by another factor of more than 20 for methanol, ethanol, acetone, formic acid, and acetic acid. Since the rate constant became immeasurably small for all five of these solvents with the addition of one solvent molecule, no information was available in this case on the relative sensitivity of the rate constant to the nature of the solvent. For solutions of water, methanol, and acetone, rate constants of 8.2×10^{-27}, 1.1×10^{-26}, and 5.3×10^{-21} cm^3 molecule^{-1} s^{-1}, respectively, have been reported for the S_N2 reaction of Cl^- at 298 K (13–15).

Overall energetics of solvated S_N2 reactions

The addition of solvent modifies the intrinsic exothermicity of the S_N2 reaction [1] by the solvation energies of the anions A^- and B^- entering and leaving the reaction and the neutral product D and "free" solvent S if these become solvated. A complete specification of the energetics of the solvated S_N2 reactions investigated in this study is not possible with the available data for solvation energies. Binding energies are available for additions of up to three molecules of water to F^-, Cl^-, and Br^- (16, 17). Also F^- and Cl^- affinities for single solvent molecules are available for some of the other solvents used in this study (18, 19). The available hydration energies for F^-, Cl^-, and Br^- allow the construction of the enthalpy diagrams in Fig. 5. These diagrams clearly show that hydration acts to decrease the overall exothermicities of the reactions of F^- with CH_3Cl and CH_3Br but that exothermic reaction channels remain available for additions of at least up to three water molecules, albeit, to preserve exothermicity, an increasing amount of retention of water by the product ion anion is required with increasing levels of hydration of the nucleophile. The observed kinetics for these two series of reactions therefore appear not to be controlled directly by the overall energetics, but must be attributed instead to intermediate features in the appropriate energy profiles.

Intermediate energy profiles

The intermediate features of the potential energy profiles of solvated S_N2 reactions are reasonably addressed in terms of double minima which evolve with step-wise solvation as the energy of the intermediate barrier increases relative to the initial energy of the reactants (11, 20). Morokuma has shown that several profiles are plausible at each level of solvation for the barrier itself depending on the mechanism of solvent transfer (21). For the singly solvated reactions the sequential solvate transfer and inversion mechanism indicated by reaction [3] will

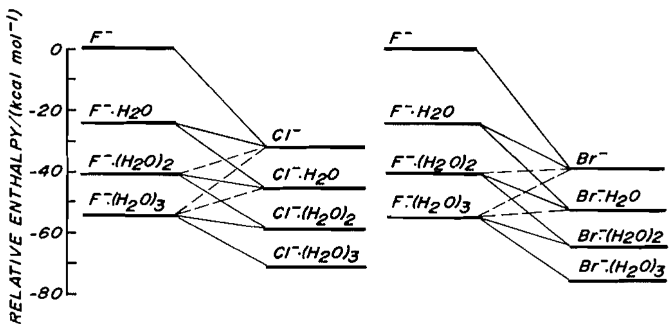

FIG. 5. Enthalpy diagrams for the gas-phase reactions of hydrated F^- with CH_3Cl and CH_3Br. The overall enthalpy changes ignore possible hydration of the neutral product CH_3F molecules. Solid diagonal lines correspond to exothermic channels while the dashed lines represent endothermic reaction channels.

be energetically unfavourable if the stability of $A^- \cdot CH_3B \cdot S$ is less than that of $A^- \cdot S + CH_3B$.

$$[3] \quad S \cdot A^- \cdot CH_3B \rightarrow A^- \cdot CH_3B \cdot S \rightarrow ACH_3 \cdot B^- \cdot S$$

Because of the substantial magnitude of fluoride and chloride solvent affinities (18, 19) this is expected to be the case for all of the singly solvated reactions in Table 1. These should therefore prefer to proceed by sequential inversion and solvate transfer as illustrated in reaction [4].

$$[4] \quad S \cdot A^- \cdot CH_3B \rightarrow S \cdot ACH_3 \cdot B^- \rightarrow ACH_3 \cdot B^- \cdot S$$

Concerted solvate transfer and inversion is expected to be less favourable on entropic grounds (22). The excess energy in the product isomer $S \cdot ACH_3 \cdot B^-$ formed in the inversion step in reaction [4] may be channeled directly into desolvation leaving unsolvated B^- as the principal product ion and so preempt the solvent transfer. Our observations are consistent with such a model. For the weakly exothermic reactions of $Cl^- \cdot S$ with CH_3Br the excess energy is insufficient to leave unsolvated Br^-. These reactions are therefore constrained to transfer solvent to the product anion but none do so with any measurably efficiency. The somewhat more exothermic reaction of $F^- \cdot D_2O$ with CH_3Cl appeared to produce $Cl^- \cdot D_2O$ exclusively but with low efficiency, while the most exothermic reactions of $F^- \cdot S$ with CH_3Br appeared to produce unsolvated Br^- preferentially.

Calculations (10, 12) suggest that the intermediate barriers for the solvent-free reactions of F^- with CH_3Cl and Cl^- with CH_3Br lie only about 1 or 2 kcal mol^{-1} below the corresponding energy of the reactants at room temperature. Consequently the intermediate barrier might be expected to emerge above the energy of the reactants already at very low levels of solvation. The results of the gas-phase measurements reported here suggest that this may indeed be the case already for the addition of one or two solvent molecules. Measurements in aqueous solution indicate that the energies of the intermediate barriers for these two reactions lie about 25 kcal mol^{-1} above the energies of the reactants (13). The observations in Fig. 4 for the reactions of $F^- \cdot S$ with CH_3Cl imply a relative enhancement of the energy of the intermediate barrier due to differential solvation by one solvent molecule which is less for D_2O than for CH_3OH and C_2H_5OH. The observations for the slightly more exothermic reactions of $F^- \cdot S$ with CH_3Br are consistent with an order of relative enhancement of $D_2O < CH_3OH < C_2H_5OH$ but the actual energies of the intermediate barriers still appear to lie below or close to the initial reactant energies since all three solvated reactions proceed with measurable efficiencies. This appears no longer to be the case at higher levels of solvation.

Étude physico-chimique, spectres de vibration et structure du sulfaméthoxazole

Luc Maury, Joëlle Rambaud, Bernard Pauvert, Yves Lasserre, G. Berge et Michel Audran
"Groupe polymorphisme et Biodisponibilité", U.F.R. de Pharmacie, Avenue Charles Flahaut, 34060 Montpellier, France

Reçu le 22 mars 1985

Luc Maury, Joëlle Rambaud, Bernard Pauvert, Yves Lasserre, G. Berge et Michel Audran. Can. J. Chem. **63**, 3012 (1985).

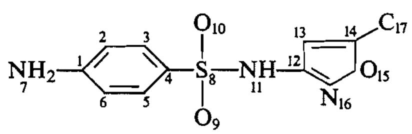
Les auteurs ont identifié et caractérisé deux polymorphes et une forme solvatée pour le sulfaméthoxazole en utilisant de nombreuses méthodes thermiques et spectrales. La structure de la forme II a été résolue et comparée à celle de la forme I déjà publiée: les différences portent essentiellement sur les longueurs des liaisons hydrogène intermoléculaires. L'analyse des spectres Raman et infrarouge a permis de proposer une attribution des vibrations caractéristiques des groupements amine, amide et sulfone impliqués dans les liaisons hydrogène.

Luc Maury, Joëlle Rambaud, Bernard Pauvert, Yves Lasserre, G. Berge, and Michel Audran. Can. J. Chem. **63**, 3012 (1985).

Two polymorphic and one solvate forms of sulfamethaxozole have been identified and characterized using various thermal and spectral methods. The crystal structure of form II has been solved and compared with that of form I recently published: the lengths of the intermolecular H bonds mainly differentiate the two polymorphic forms. An assignment of the fundamental vibrations of the amine, amide, and sulfone groups involved in the H intermolecular bonds has been proposed from the analysis of the Raman and infrared spectra.

Introduction

Poursuivant nos recherches sur le polymorphisme de substances médicamenteuses, nous avons entrepris l'étude du sulfaméthoxazole ou *N*-(méthyl-5 isoxazolyl-3) sulfanilamide.



Dans un travail antérieur (1) nous avons montré que seul l'emploi simultané de nombreuses techniques peut permettre d'affirmer la présence de plusieurs formes cristallines pour un même composé; c'est pourquoi nous avons utilisé dans cette étude des méthodes thermiques et spectrales traditionnelles—thermogravimétrie, analyses thermique et calorimétrique différentielles, spectrométrie d'absorption infrarouge et diffraction des rayons X—auxquelles nous avons ajouté la diffusion Raman, notamment dans le domaine des basses fréquences. Nous avons également résolu la structure du polymorphe II afin de la comparer à celle du polymorphe I, publiée antérieurement (2).

Shiu Shiang Yang et Guillory (3), dans un travail général sur les sulfamides, ont mis en évidence pour ce composé l'existence de trois formes polymorphes, dont deux seulement caractérisées par leur spectre infrarouge. Si nous retrouvons bien les formes I et II des auteurs précités, nous n'avons pu isoler la forme III; en revanche, nous avons identifié et caractérisé une forme solvatée non signalée précédemment.

Matériel et méthode

1. *Obtention des différentes formes*

Le sulfaméthoxazole (produit Roche) a été recristallisé dans plusieurs solvants (eau, acétone, éthanol, propanol, butanol et pentanol) ainsi que dans différents mélanges: eau−éthanol et eau−acétone. Pour chaque expérience, nous avons suivi la cristallogénèse en fonction de la température. Les cristaux recueillis après filtration étaient séchés sous vide durant 48 h.

2. *Analyse thermique*

L'analyse thermogravimétrique a été effectuée avec une balance Sétaram Ugine Eyraud B60, en double version ATD−ATG, équipée d'un programmateur de température RT 64. La prise d'essai était de 50 mg et la substance de référence l'alumine.

L'analyseur enthalpique différentiel Perkin Elmer DSC 1B nous a permis de différencier les changements d'états physiques en fonction de la température et de mesurer l'énergie calorifique qui accompagne ces changements d'états. Les prises d'essai étaient de 2 à 5 mg et la montée en température de 2 ou 4°C/min.

Les phénomènes thermiques ont été vérifiés par visualisation au microscope à platine chauffante Leitz.

3. *Méthodes spectrales*

Diffraction des rayons X

Les diagrammes ont été réalisés sur un diffractomètre CGR avec tube de cuivre et monochromateur à quartz monté sur un générateur Sigma 80.

Spectrométrie infrarouge

Les spectres infrarouge ont été enregistrés à température ambiante sur un spectromètre Perkin Elmer 457. Nous avons vérifié, par enregistrement des spectres Raman de la poudre en l'état ou comprimée, que le broyage et la mise sous forme de pastilles KBr n'entraînaient aucune modification des spectres.

Spectrométrie de diffusion Raman

Les spectres Raman ont été enregistrés à température ambiante sur un spectromètre de haute résolution Jobin et Yvon "Ramanor HG 2S". La technique utilisée était celle de diffusion à 90° en incidence normale, l'excitatrice étant la radiation 514,5 nm d'un laser Spectra Physics à argon ionisé. La puissance du laser sur l'échantillon était maintenue à une valeur faible de 100 mW, pour éviter tout risque de dégradation des composés.

4. *Détermination de la structure de la forme II*

Un monocristal de 0,20 × 0,15 × 0,25 mm a été soumis au rayonnement X sur un diffractomètre automatique Syntex $P2_1$. Quinze réflexions indépendantes ont permis de définir les paramètres de la maille cristalline. Les extinctions systématiques ont donné deux groupes d'espace *Cc* et *C*2/*c*. Sur 1769 intensités mesurées, 1246 étaient considérées comme observées conformément à $I \geq 2{,}5\ \sigma\ (I)$. La longueur d'onde utilisée était celle de la raie Kα du molybdène soit λ = 0,71069 Å, l'angle de Bragg maximum étant 2 θ = 47°. La résolution a été effectuée avec le programme MULTAN 80 (4). La carte de Fourier a donné cinq atomes. Trois synthèses de Fourier ont été requises pour faire apparaître tous les atomes non hydrogène de la molécule. L'affinement a été alors poursuivi avec le programme SHELX 76 (5). Les atomes lourds ont été affinés de façon anisotrope.

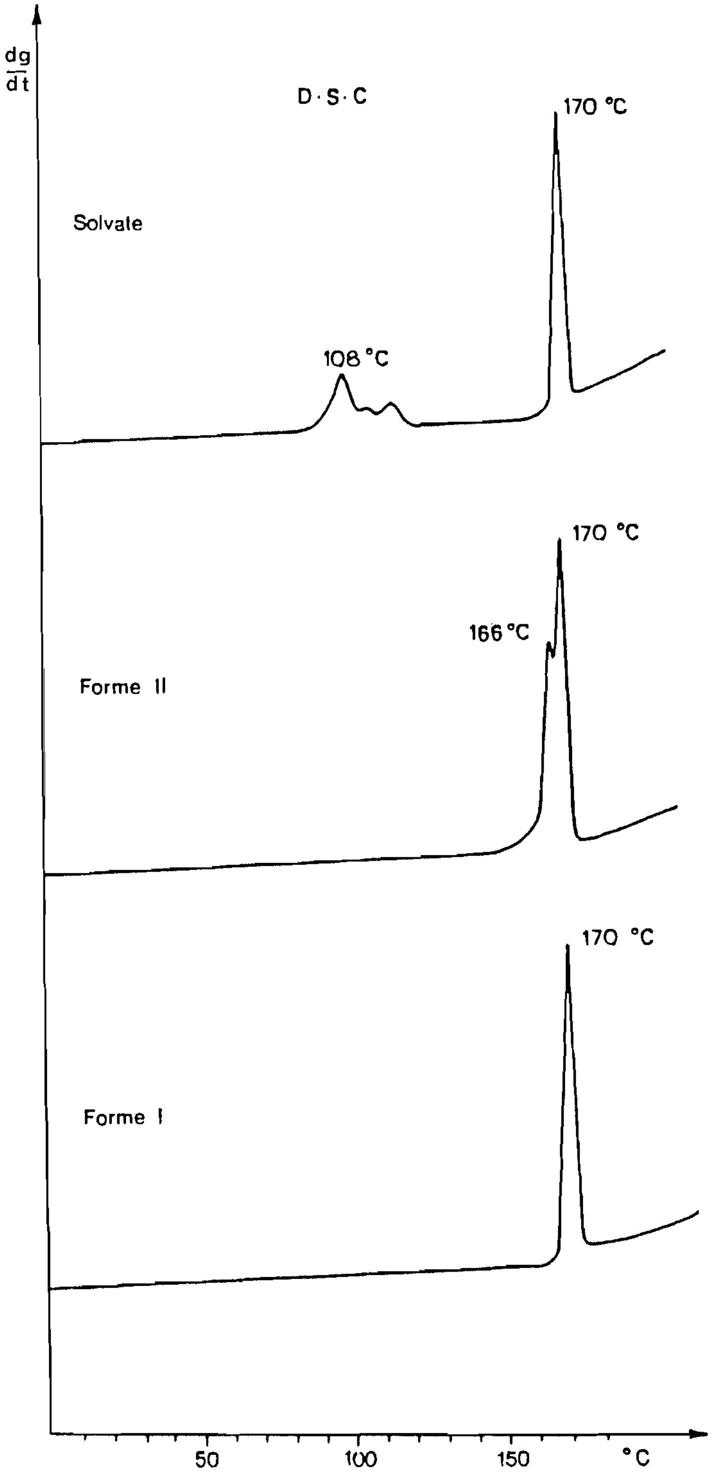


FIG. 1. Courbes d'analyse calorimétrique différentielle (vitesse 8°/min).

Les hydrogènes ont subit un affinement isotrope avec un B_{eq} de 9 Å.

Le groupe d'espace s'est avéré être $C2/c$. En fin d'affinement, le coefficient de reliabilité était R = 0,0408.

Résultats et discussion

Analyse thermique

Les courbes d'analyse calorimétrique différentielle donnent trois accidents endothermiques différents: à 108, 166 et 170°C (fig. 1).

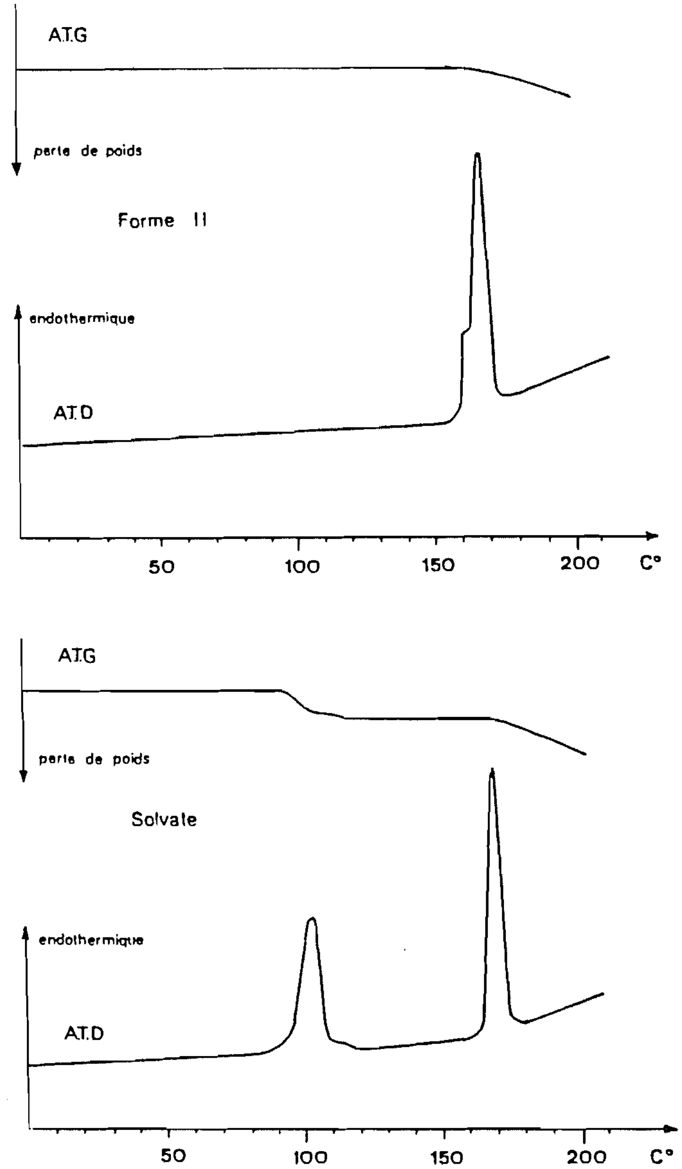

FIG. 2. Thermogrammes (ATG−ATD couplées) des trois cristallisations différentes.

Les thermogrammes obtenus pour ces trois accidents montrent que le premier s'accompagne d'une perte de poids de 3%, correspondant à la perte d'une demi-molécule d'eau (fig. 2). Les deux autres ne sont accompagnés d'aucune perte de poids. Il semble donc que l'on soit en présence de 2 polymorphes et d'un solvate. Les deux formes ont des températures de fusion très proches et il n'est possible de les séparer qu'en effectuant des mesures à une vitesse de 2°C/min.

La forme "haute température" a été obtenue dans tous les solvants. La forme solvatée est extraite par recristallisation dans un mélange eau−acétone ou dans l'eau. Il a été plus difficile d'obtenir la forme "basse température" (forme II), qui apparaît par traitement thermique de la forme I (fusion de la forme I et trempe à 0°C) ou par recristallisation dans le méthanol.

Le passage de la forme I à la forme II étant thermiquement réversible, nous en concluons que les deux formes sont énantiomorphes.

À partir des courbes d'analyse calorimétrique différentielle

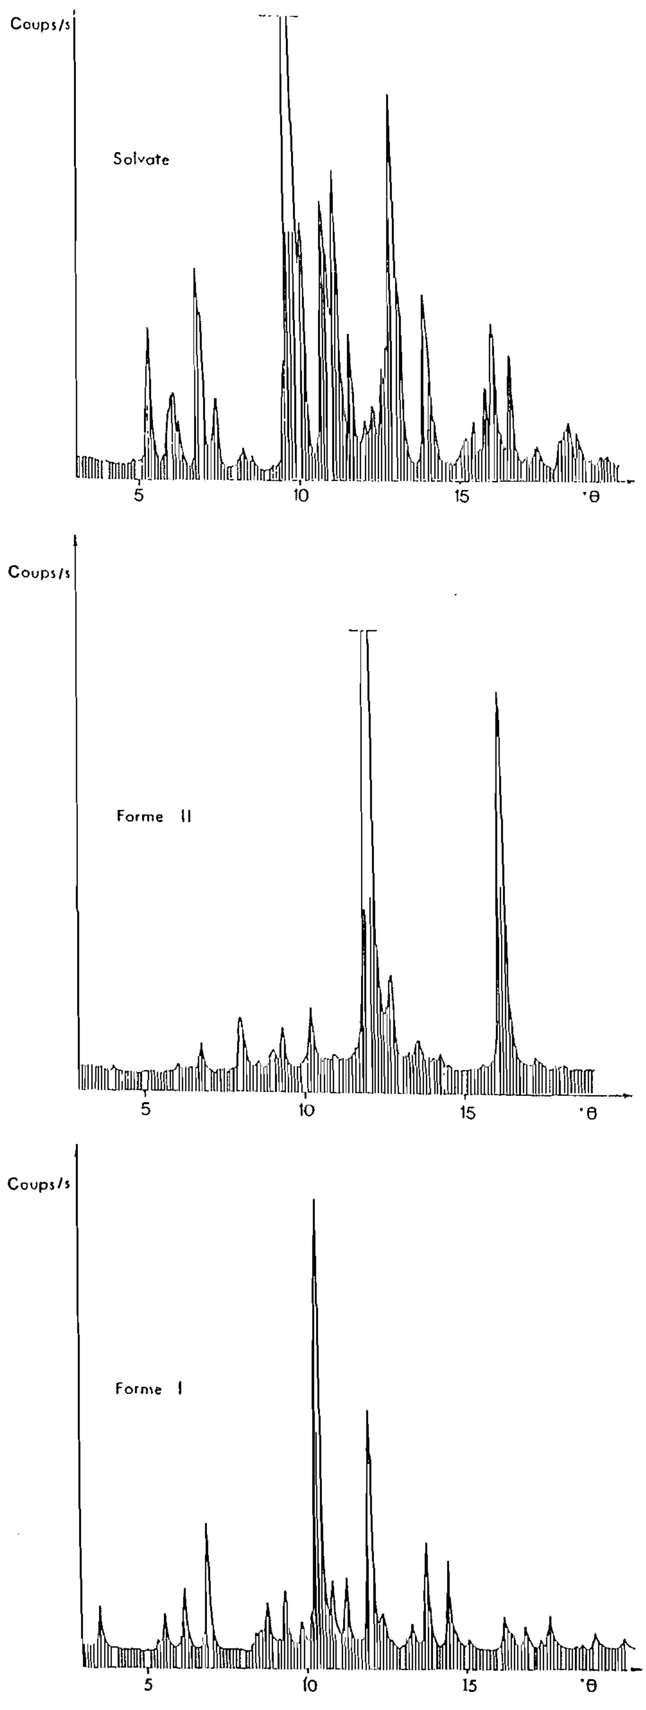

FIG. 3. Diagrammes de diffraction des rayons X.

TABLEAU 1. Distances interatomiques (Å) et angles de valence (deg) du polymorphe II

Atomes	Distance	Atomes	Angle
C1 ---C2	1,384(5)	C2 --C1 --C6	117,5(3)
C1 ---C6	1,397(5)	C2 --C1 --N7	122,6(3)

C14---C17	1,481(5)	S8 --N11--C12	122,4(2)
O15---N16	1,407(3)	N11--C12--C13	129,3(3)
		N11--C12--N16	119,1(3)
		C13--C12--N16	111,6(3)
		C12--C13--C14	104,7(3)
		C13--C14--O15	110,3(3)
		C13--C14--C17	133,7(4)
		O15--C14--C17	115,9(3)
		C14--O15--N16	108,0(3)
		C12--N16--O15	105,4(3)

(fig. 1), nous avons calculé les enthalpies de fusion soit:

$$\Delta H\ (f_{\mathrm{I}}) = -26{,}200 \text{ kJ mol}^{-1}$$
$$\Delta H\ (f_{\mathrm{II}}) = -24{,}300 \text{ kJ mol}^{-1}$$

ce qui donne en première approximation une enthalpie de transformation de 2,100 kJ mol^{-1} (6).

Diffraction des rayons X

Les diagrammes de poudre (fig. 3) des trois cristallisations permettent de mettre en évidence des raies spécifiques de chaque espèce:

forme I: 7, 10,5, 12,05 θ°
forme II: 8, 11,9, 16,30 θ°
solvate: 9,7, 10,7, 11,15, 12,9 θ°

Étude comparative des structures cristallines des deux formes

Cette étude est particulièrement intéressante; en effet, les deux formes cristallisent dans le même système (monoclinique) et le même groupe d'espace ($C2/c$): un fait analogue avait déjà été observé pour d'autres sulfamides (7, 8). De plus, les paramètres (a,b,c) de la forme I sont respectivement voisins des paramètres (c,b,a) de la forme II comme le montre le tableau suivant:

	Forme I	Forme II
a (Å)	16,046(5)	25,106(2)
b (Å)	5,470(2)	7,229(3)
c (Å)	25,747(1)	14,847(9)
β (dég)	96,12 (2)	117,9 (4)
V (Å^3)	2247	2381,3
d (g cm^{-3})	1,49	1,418
z	8	8

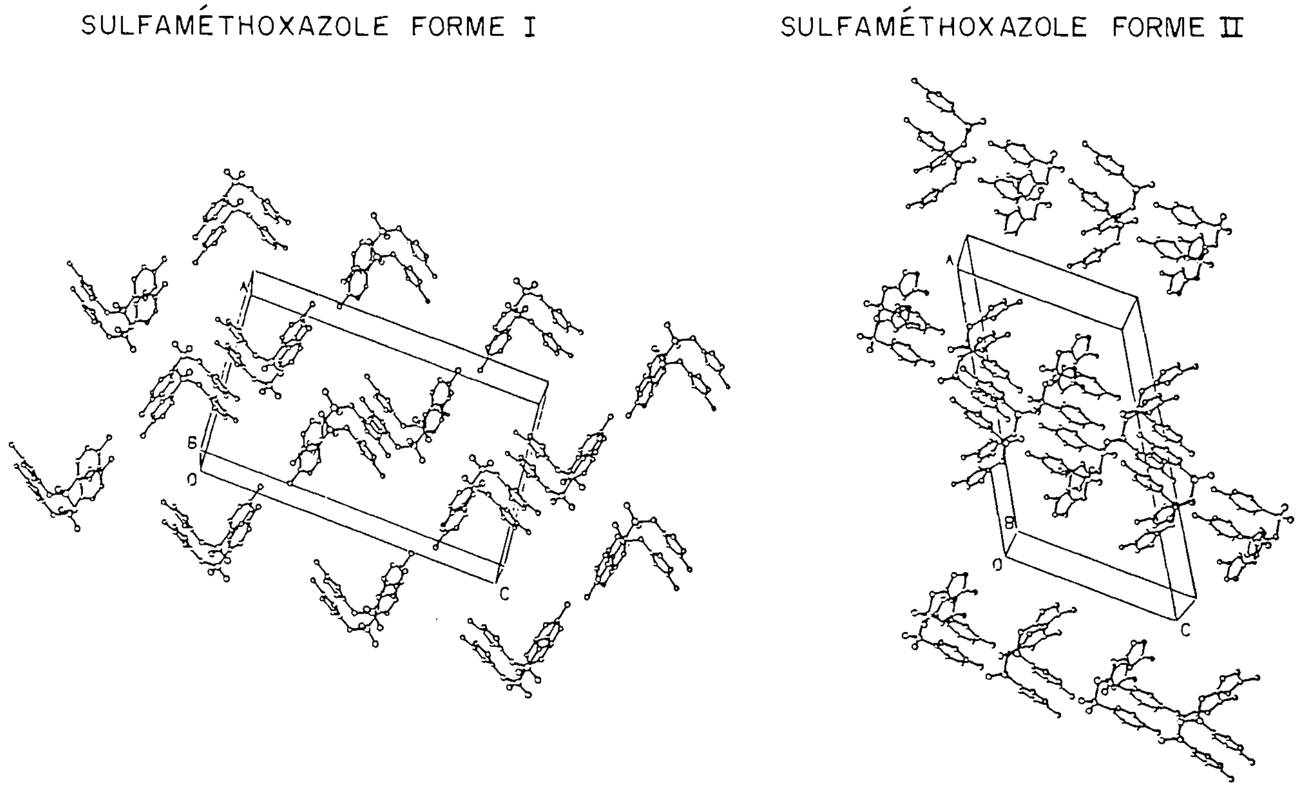

FIG. 4. Empilement moléculaire dans la maille des deux polymorphes (PLUTO (réf. 20)).

TABLEAU 2. Liaisons intermoléculaires "type hydrogène" des polymorphes I et II

Forme I		Forme II	
Code de symétrie		Code de symétrie	
I x, y, z		I x, y, z	
II $x, 1+y, z$		II $x, 1-y, -0{,}5+z$	
III $x, -1+y, z$		III $x, -y, -0{,}5+z$	
IV $0{,}5+x, 0{,}5+y, z$		IV $0{,}5-x, 0{,}5-y, z$	
N11 H11 - - - - $O9_{II}$	3,232 Å	N7 H7 - - - - $O9_{II}$	3,007 Å
C13 H13 - - - - $N16_{III}$	3,227 Å	N7 H7 - - - - $O10_{III}$	3,148 Å
N7 H7 - - - - $O10_{IV}$	3,275 Å	N11 H11 - - - - $N16_{IV}$	2,952 Å

L'ensemble des valeurs des angles de valence et des distances interatomiques de la forme II (tableau 1) fait apparaître un effet quinonique plus marqué que dans la forme I, avec des liaisons C1—N7, C2—C3 et C5—C6 plus courtes ($\Delta l = 0{,}02$ Å). Exceptées ces légères différences, les molécules I et II sont identiques et l'empilement moléculaire dans la maille (fig. 4), très semblable. Les écarts les plus marquants se situent au niveau des liaisons hydrogène (tableau 2). Les similitudes de ces deux polymorphes, tant au niveau des paramètres cristallins qu'au niveau des paramètres internes de la molécule, expliquent d'une part les points et chaleurs de fusion très voisins, d'autre part la difficulté à différencier ces deux formes.

Spectrométrie infrarouge et Raman

La spectrométrie infrarouge est une méthode utilisée depuis de nombreuses années pour mettre en évidence le polymorphisme de substances médicamenteuses, mais le domaine spectral généralement analysé s'étend seulement de 4000 à 200 cm^{-1} et ne porte donc que sur les vibrations internes de la molécule. Le polymorphisme pouvant n'influer que très peu sur les vibrations propres d'une molécule, l'absorption infrarouge—au moyen de spectromètres conventionnels—se révèle parfois insuffisante. En outre, la technique généralement adoptée de mise sous forme de pastilles KBr nécessite le broyage et la compression de la poudre, manipulations qui peuvent faire évoluer une forme instable vers une forme stable. La spectrométrie de diffusion Raman rend possible l'analyse d'un échantillon polycristallin sans lui faire subir de traitements susceptibles de le modifier. Elle permet en outre, comme l'absorption infrarouge, d'étudier le domaine des vibrations internes, mais elle trouve tout son intérêt dans l'obtention aisée du spectre des vibrations externes. Ces vibrations, qui correspondent aux mouvements de rotation et de translation des molécules au sein du réseau cristallin, sont d'un très grand intérêt pour caractériser le polymorphisme, qui se manifeste par des changements au niveau du réseau. Les raies caractéristiques apparaissent à des fréquences très basses et ne sont facilement accessibles que par diffusion Raman. Cette technique, d'application récente au médicament (9, 10), est très peu employée et nous l'avons déjà mise en oeuvre lors de l'étude de différents sulfamides (1, 11, 12, 21).

Domaine des vibrations externes

Les spectres Raman des vibrations du réseau, représentés sur la figure 5, permettent immédiatement d'identifier les deux polymorphes et le solvate. Le solvate se caractérise principalement par la raie 31 cm^{-1}, la plus intense de tout le spectre; les raies 49,5, 68 et 102 cm^{-1} peuvent également permettre de l'identifier. Les raies 41, 63, 79, 113 et 123 cm^{-1} peuvent être utilisées pour caractériser la forme II. Enfin, la forme I se reconnaît par la raie 88 cm^{-1} très intense, le massif centré à 130 cm^{-1} et le triplet 45, 37 et 31 cm^{-1}.

Domaine des vibrations internes

Les spectres Raman (fig. 6) et infrarouge (fig. 7) permettent

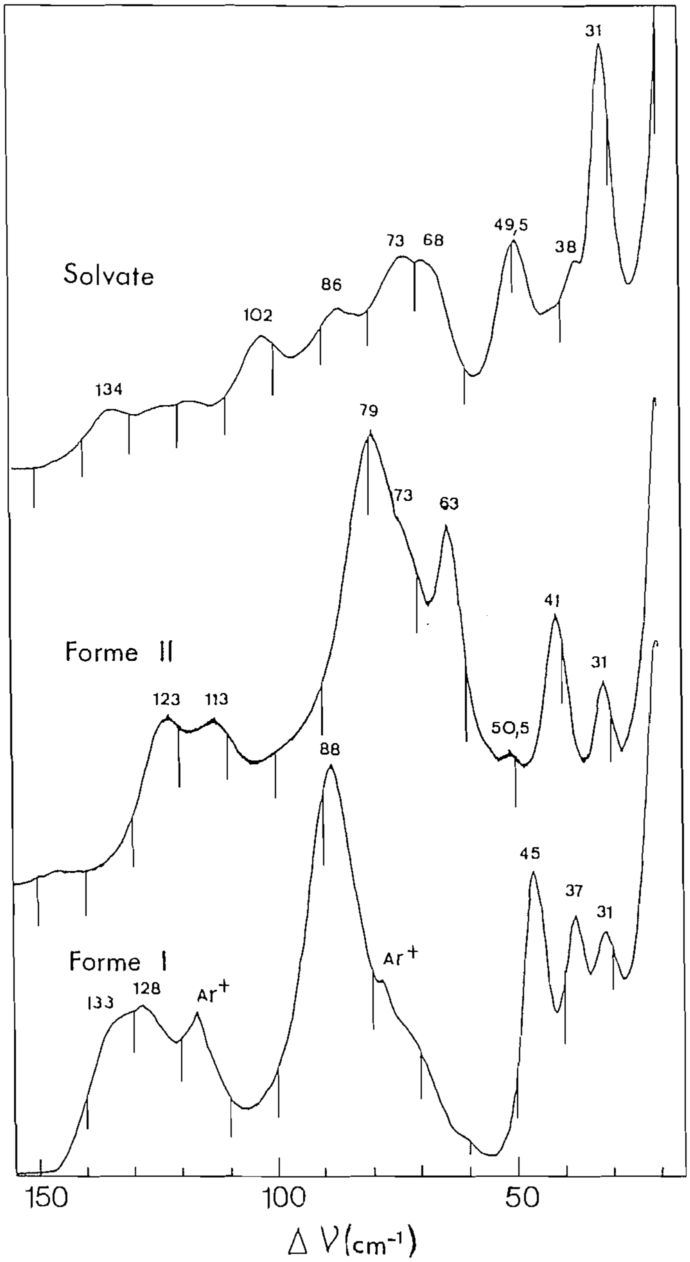

FIG. 5. Spectres Raman des vibrations du réseau du sulfaméthoxazole.

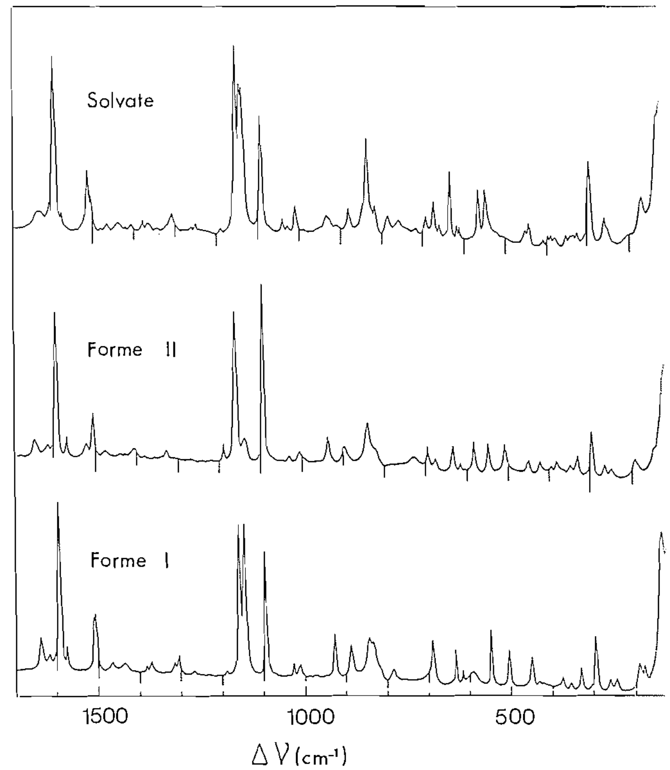

FIG. 6. Spectres Raman de trois formes de sulfaméthoxazole (1700–100 cm^{-1}).

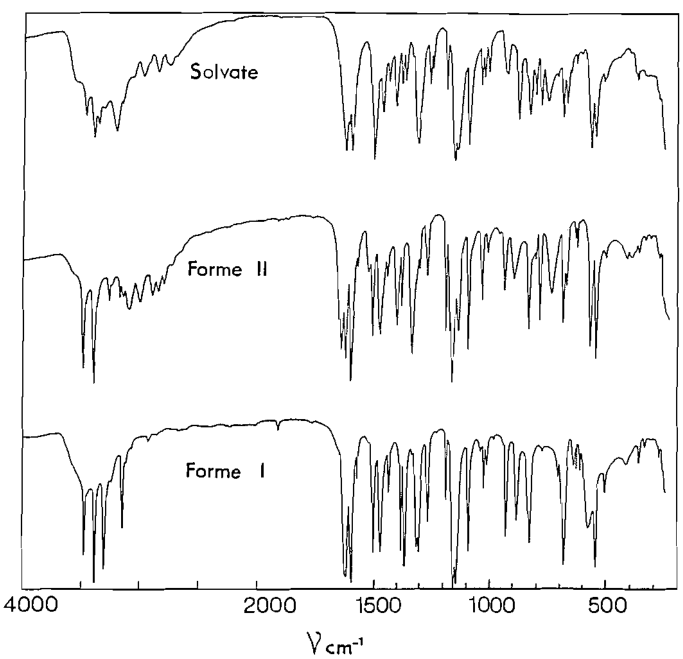

FIG. 7. Spectres infrarouge du sulfaméthoxazole.

de différencier les trois formes polymorphes bien que les différences, en particulier celles relevées sur les spectres Raman, soient moins significatives dans ce domaine que dans celui des vibrations externes.

La présence simultanée dans cette molécule d'un noyau benzénique et d'un noyau méthoxazole rend complexe l'interprétation des spectres de vibration. Nous avons signalé précédemment que les formes I et II présentent de nombreuses analogies structurales et diffèrent essentiellement par les liaisons hydrogène intermoléculaires, qui intéressent principalement les groupements amine, amide et sulfone. Par suite du nombre important de vibrations attendu et des nombreux couplages possibles nous limiterons nos propositions d'attribution à certains modes caractéristiques. Ces propositions sont basées d'une part sur les travaux antérieurs portant sur des molécules voisines, d'autre part sur la comparaison des spectres avec ceux de différents sulfamides déjà étudiés.

Région 4000–2000 cm^{-1}

Les spectres infrarouge des trois formes étudiées révèlent d'importantes modifications dans ce domaine. Les vibrations du groupement méthyle ne donnent lieu qu'à de faibles absorptions et ne seront pas discutées. En revanche, les vibrations $\nu(NH_2)$ et $\nu(NH)$ se traduisent par de fortes bandes infrarouge.

Les bandes 3475 et 3384 cm^{-1} de la forme I traduisent sans ambiguïté les modes antisymétrique et symétrique du groupement amine: ces valeurs sont en accord avec celles trouvées pour d'autres sulfamides (1, 10, 11, 12). Ces vibrations sont peu perturbées par les liaisons hydrogène dont les longueurs N—H. . .O (tableau 2) sont supérieures à 3,2 Å, ce qui confirme les conclusions de Novak et coll. (13), qui ont montré, qu'au delà d'une telle distance, l'influence de la liaison H sur la fréquence de vibration est peu importante. Dans la forme II, ces modes ν_{as} (NH_2) et ν_s (NH_2) apparaissent à des fréquences voisines de celles de la forme I, 3490 et 3400 cm^{-1}.

Si dans le solvate le mode ν_{as} (NH_2) est trouvé isolé à 3475 cm^{-1}, en revanche, le mode ν_s (NH_2) apparaît sous forme d'un doublet à 3400 et 3360 cm^{-1}: un tel dédoublement a été relié à la formation de dimères cycliques (14), comme cela a déjà été observé sur des barbituriques (15, 16) et le sulfaméthoxypyridazine (17). La détermination de la structure de ce solvate devrait nous permettre de confirmer cette hypothèse.

La fréquence ν (N—H) d'un groupement R—SO_2—NH—R′ est généralement attendue vers 3300 cm^{-1}: la raie 3305 cm^{-1} (forme I) correspond donc à cette vibration. Shiu Shiang Yang et Guillory (3) avaient attribué les raies 3300 et 3150 cm^{-1} à ce mouvement. Si l'attribution de la première fréquence nous paraît raisonnable, nous ne pensons pas que l'attribution de la seconde à ce même mode puisse être retenue; en effet, la raie 3145 cm^{-1} a été attribuée (17), dans des complexes d'aniline en particulier, au mode ν(N—H) engagé dans une liaison N—H. . .N. Or, la détermination de la structure montre qu'il n'existe pas de telle liaison dans la forme I. Nous proposons d'attribuer cette raie soit à une combinaison soit à une résonance de Fermi entre une vibration ν (CH) du noyau et l'harmonique de la raie 1592 cm^{-1}, ce qui justifierait son intensité. Sur les spectres du solvate, le mode ν(N—H) est abaissé à 3200 cm^{-1}, preuve que le vibrateur N—H est impliqué dans une liaison hydrogène.

La forme II, quant à elle, présente plusieurs bandes d'intensité moyenne entre 3300 et 2700 cm^{-1}, parmi lesquelles il est difficile de retrouver ce mode. L'étude structurale montre que dans ce polymorphe il existe une liaison N—H. . .N de longueur 2,952 Å, donc relativement forte pour une liaison de ce type (18); nous proposons d'attribuer la bande 3100 cm^{-1} au mode ν(N—H) engagé dans le pont hydrogène (18, 19).

Région 1700–200 cm^{-1}

Seules certaines vibrations caractéristiques seront discutées. Quelle que soit la forme, deux bandes intenses apparaissent vers 1600 et 1625 cm^{-1} la 1ère traduisant une vibration du noyau, la seconde le cisaillement δ (NH_2). La forme II présente en outre une bande supplémentaire à 1645 cm^{-1}, très intense, que nous proposons d'attribuer au mode δ(N—H) bien que cette fréquence soit élevée pour une telle vibration. À l'appui de cette attribution, signalons que Novak et coll. (13) ont montré que l'existence d'un pont hydrogène du type N—H. . .N abaisse la fréquence du mode ν(N—H) et déplace vers les hautes fréquences le mode δ(N—H) attendu vers 1400 cm^{-1}.

Les dernières fréquences que nous discuterons sont en rapport avec le groupement sulfone. Le mode antisymétrique ν_{as} (SO_2) apparaît très intense sur les spectres d'absorption, à 1365 cm^{-1} (forme I). La raie très fine 1383 cm^{-1} qui traduit une raie du noyau benzénique, est retrouvée à la même fréquence dans tous les composés. Cette vibration ν_{as}(SO_2) voit sa fréquence s'abaisser à 1335 cm^{-1} (forme II) et 1310 cm^{-1} (solvate). Ces abaissements de fréquence sont à mettre en relation avec l'existence des liaisons hydrogène. Cette influence se manifeste également au niveau du mode symétrique ν_s(SO_2), très intense en Raman, qui apparaît généralement sous forme d'un doublet (12). Dans la forme I, les spectres Raman et infrarouge révèlent à 1145–1160 (ir) et 1141–1156 (Raman) deux raies, d'égales intensités, attribuables à ce mode. En revanche, on observe une diminution très importante de la bande de plus basse fréquence (forme II) et un dédoublement de cette bande (solvate). Enfin, le cisaillement δ(SO_2) donne un doublet vers 545–572 cm^{-1} tant sur les spectres Raman qu'en infrarouge.

Conclusion

L'étude du sulfaméthoxazole nous a permis de mettre en évidence deux polymorphes et un solvate non répertorié dans la littérature.

Chaque forme a été identifiée et caractérisée par des méthodes thermiques et spectrales. L'analyse thermique différentielle nous a révélé l'existence du solvate qui a été caractérisé, comme les deux polymorphes, par son diagramme de rayons X et ses spectres infrarouge et Raman. La détermination de la structure cristalline de la forme II a été réalisée, ce qui nous a amené à la comparer à celle de la forme I déjà publiée. Cette comparaison révèle que les polymorphes I et II cristallisent dans le même système cristallin (monoclinique) et que l'empilement dans les mailles est très semblable. Les molécules I et II sont pratiquement identiques quant aux distances interatomiques et aux angles de valence, les différences les plus importantes se situant au niveau des liaisons hydrogène intermoléculaires.

L'existence de ces ponts hydrogène nous a conduit à réaliser une analyse, par spectrométrie d'absorption infrarouge et de diffusion Raman, des vibrations des groupements amine, amide et sulfone principalement intéressés par ces liaisons.

Nous proposons donc une attribution des modes caractéristiques de ces groupements en relation avec les longueurs des liaisons.

L'obtention de cristaux mesurables du solvate doit nous permettre de déterminer la structure de ce composé et d'effectuer une étude des cinétiques de dissolution des différentes formes.

The syntheses and characterization of a number of square-planar Rh(I) monocarbonyl complexes incorporating unsymmetrical, tridentate, pyrazolylgallate ligands in a meridional coordination mode are described. Oxidative addition reactions of these complexes are detailed and a facile migratory insertion reaction, following the addition of methyl iodide, has resulted in a five-coordinate square-pyramidal Rh(III) acetyl complex. Crystal structures of two compounds are presented, $[Me_2Gapz(OCH_2CH_2NH_2)]Rh(CO)$ and $[Me_2Gapz(OCH_2CH_2NMe_2)]Rh(COMe)I$, and confirm the molecular arrangements predicted on the basis of other physical measurements. Crystals of the former are monoclinic, a = 10.212(2), b = 7.8484(5), c = 16.733(2) Å, β = 105.133(6)°, z = 4, space group $P2_1/c$; and those of the latter are monoclinic, a = 10.0960(11), b = 11.5352(8), c = 15.871(2) Å, β = 105.764(6)°, z = 4, space group $P2_1/n$. Both structures were solved by conventional heavy atom methods and were refined by full-matrix least-square procedures to R = 0.026 and 0.036, respectively, for 2142 and 2941 reflections with $I \geq 3\sigma(I)$.

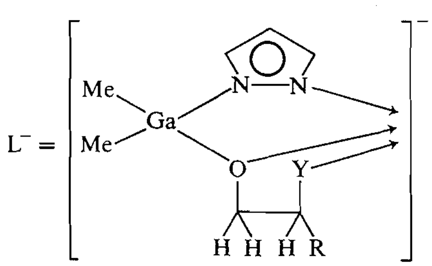
Brenda M. Louie, Steven J. Rettig, Alan Storr et James Trotter. Can. J. Chem. **63**, 3019 (1985).

On décrit la synthèse et la charactérisation de nombreux complexes carré-plans de Rh(I) monocarbonyle incorporant des ligands, tridentates, pyrazolylgallate dans un mode de coordination méridionale. On décrit des réactions d'addition oxydante de ces complexes et une réaction d'insertion migratoire facile suivie de l'addition de l'iodure de méthyle qui conduit à la formation d'un complexe acétylé de Rh(III) pentacoordonné et pyramidal carré. On présente les structures de ces deux composés: $[Me_2Gapz(OCH_2CH_2NH_2)]Rh(CO)$ et $[Me_2Gapz(OCH_2CH_2NMe_2)]Rh(COMe)I$, et on confirme les arrangements moléculaires prévues à partir d'autres mesures physiques. Les cristaux du premier composé appartiennent au groupe d'espace monoclinique $P2_1/c$ avec a = 10,212(2), b = 7,8484(5), c = 16,733(2) Å, β = 105,133(6)°, z = 4. Les cristaux du deuxième composé appartiennent au groupe d'espace monoclinique $P2_1/n$ avec a = 10,0960(11), b = 11,5352(8), c = 15,871(2) Å, β = 105,764(6)°, z = 4. On a résolu les deux structures par la méthode conventionnelle de l'atome lourd et on les a affinées par la méthode des moindres carrés jusqu'à des valeurs de R = 0,026 et de 0,036 respectivement pour 2142 et 2941 réflexions avec $I \geq 3\sigma(I)$.

[Traduit par le journal]

Introduction

Recently we reported the syntheses, properties, and structures of a number of Rh(I) complexes containing symmetrical bidentate pyrazolylgallate ligands (1). The novel compound, $(MeGapz_3)_2Rh_2(\mu\text{-}CO)_3$, incorporating symmetrical tridentate pyrazolylgallate ligands has also been described (2). The present paper details the synthesis of a number of square-planar Rh(I) monocarbonyl complexes, LRh(CO), containing unsymmetrical tridentate pyrazolylgallate ligands of the general formula:



1

where R = H, Y = NH_2, NMe_2, SPh or SMe; R = Me, Y = NH_2

The reactivity of selected LRh(CO) complexes towards MeI, CO, and other small molecules is described and the crystal structures of LRh(CO) (R = H and Y = NH_2) and LRh(COMe)I (R = H and Y = NMe_2) are presented.

Experimental

Starting materials

Air-sensitive materials were handled in a nitrogen atmosphere. Tetrahydrofuran (THF), benzene, CH_2Cl_2, and hexane were dried by refluxing over Na/benzophenone, potassium, CaH_2, and $CaSO_4$, respectively, followed by distillation. $[Rh(CO)_2Cl]_2$ (Strem Chemicals) was used as supplied or alternatively prepared from $RhCl_3 \cdot 3H_2O$ following a literature method (3). MeI was distilled from P_2O_5 before use and stored over a few mercury droplets. Dihalogens (Fisher Scientific) were used as supplied. Sodium salts of the unsymmetrical tridentate pyrazolylgallate ligands were prepared as standard THF solutions as described earlier (4).

Synthesis of LRh(CO)

The following general method was used to prepare the LRh(CO) complexes listed in Table 1. Two molar equivalents of Na^+L^- were added dropwise to ~100 mg of $[Rh(CO)_2Cl]_2$ dissolved in ~75 mL THF. The resulting mixture was refluxed until ir sampling indicated complete disappearance of the starting rhodium carbonyl dimer (~3 h). The THF was removed *in vacuo* from the cooled reaction solution and the remaining residue was redissolved in ~5 mL CH_2Cl_2 and filtered. Hexane (~5 mL) was then added to the filtrate and the solvents were allowed to slowly evaporate leaving lemon yellow or yellow green powders or crystals of the desired products in approximately 50–80% yield. Elemental analyses, ^1H nmr, and ir data for the LRh(CO) complexes are collected in Table 1.

Reactions of selected LRh(CO) complexes

(a) With MeI

A slight excess of MeI (0.02 g, 0.32 mmol) was added to $[Me_2Gapz(OCH_2CH_2NMe_2)]Rh(CO)$ (0.076 g, 0.20 mmol) dissolved

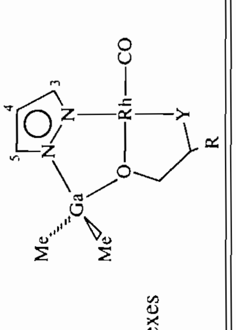


TABLE 1. Physical data for the complexes

† s = singlet, d = doublet, t = triplet, m = multiplet; $J_{HCCH} \simeq 2$ Hz for pyrazolyl protons.
‡ R = Me.

in ~15 mL CH_2Cl_2. After stirring for 15 min the initially yellow solution gradually changed to deep orange. An ir of the solution at this stage contained two new bands at 2063 and 1720 cm^{-1}. The solvent was then removed *in vacuo* leaving an orange powder of a single product in quantitative yield. Mp 109–111°C. *Anal.* calcd. for [$Me_2Gapz(OCH_2CH_2NMe_2)$]Rh(COMe)I: C 25.03, H 4.20, N 7.96; found: C 25.75, H 4.22, N 8.23, ν_{CO}: 1720 cm^{-1} (CH_2Cl_2), 1725 cm^{-1} (hexane). ^{1}H nmr (C_6D_6, τ values refer to $\tau_{C_6H_6}$ = 2.84 ppm): —$GaMe_2$, 10.09s, 10.10s; —NMe_2, 7.50s, 8.07s; CO—Me, 7.42s; pz—H^4, 3.91t; pz—H^5, 2.80d; pz—H^3, 0.97d (J_{HCCH} = ~2 Hz for pz protons). A sample of the product was recrystallized from CH_2Cl_2 at −78°C yielding orange crystals suitable for an X-ray crystal structure determination (see below).

(b) With CO

[$Me_2Gapz(OCH_2CH_2NH_2)$]Rh(CO) (0.020 g, 0.056 mmol, ν_{CO}: 1955 cm^{-1} (CH_2Cl_2)) was dissolved in ~10 mL CH_2Cl_2 and CO was bubbled through the solution. After 5 min an ir sample indicated the presence of two new bands at 2093 and 2028 cm^{-1} (CH_2Cl_2), attributed to [$Me_2Gapz(OCH_2CH_2NH_2)$]Rh$(CO)_2$, and complete loss of the band at 1955 cm^{-1}. Attempts to isolate this dicarbonyl species by reducing the solvent and/or crystallization were not successful. The black solids recovered contained mixtures of [$Me_2Gapz(OCH_2CH_2NH_2)$]Rh$(CO)_n$ (n = 1 and 2). The ^{1}H nmr spectrum of the n = 2 species was obtained by bubbling CO through a C_6D_6 solution of [$Me_2Gapz(OCH_2CH_2NH_2)$]Rh(CO) in an nmr tube fitted with a septum cap. ^{1}H nmr (C_6D_6, τ values refer to $\tau_{C_6H_6}$ = 2.84 ppm): —$GaMe_2$, 9.77s, 10.14s; O$CH_2$$CH_2$$NH_2$, 8.5m; $OCH_2$$CH_2$$NH_2$, 6.6m; pz—H^4, 4.02t; pz—H^5, 2.72d; pz—H^3, 2.69d (J_{HCCH} = ~2 Hz for pz protons).

(c) With PPh_3

Reaction of [$Me_2Gapz(OCH_2CH_2Y)$]Rh(CO) (Y = NMe_2 or NH_2) with 1 molar equivalent of PPh_3 in THF at −78, 0°C, and reflux temperatures resulted only in the formation of the known pyrazolyl bridged Rh dimers (1) viz.

$$[Me_2Gapz(OCH_2CH_2Y)]Rh(CO) + PPh_3 \xrightarrow{THF} \tfrac{1}{2}\,[(\mu\text{-pz})Rh(CO)(PPh_3)]_2 + \tfrac{1}{2}\,[Me_2Ga(OCH_2CH_2Y)]_2$$

The volatile gallium dimers also formed in this reaction have been previously characterized (5).

(d) With dihalogens, X_2 (X_2 = Br_2 or I_2)

A slight excess of the dihalogen dissolved in THF was added dropwise to ~50 mg of LRh(CO) (R = H, Y = NH_2 or NMe_2 in **1**) prepared *in situ* in THF as described above. In all cases addition of the oxidant caused an immediate colour change in the solution and a change in the ν_{CO} region of the ir spectrum. The ν_{CO} band attributable to the LRh(CO) starting material was completely gone after a few hours stirring at room temperature, being replaced by a single ν_{CO} band (CH_2Cl_2 solution) at 2081 cm^{-1} (Y = NH_2, X_2 = I_2), 2088 cm^{-1} (Y = NMe_2, X_2 = I_2), and 2100 cm^{-1} (Y = NMe_2, X_2 = Br_2). Although these spectra of the products suggested the presence of LRh(CO)X_2 species in solution, isolation of analytically pure compounds proved impossible.

(e) With H_2

The LRh(CO) complexes were recovered unchanged when dissolved in C_6H_6 or THF and exposed to an atmosphere of H_2 for 48 h. Furthermore no reaction was observed when H_2 was bubbled through a refluxing THF solution of [$Me_2Gapz(OCH_2CH_2NH_2)$]Rh(CO) for 28 h. In addition the LRh(CO) complexes did not catalyze the hydrogenation of 1-hexene in benzene at 30°C.

X-ray crystallographic analyses

*[Dimethyl(1-pyrazolyl)(2-aminoethoxy)gallato-*N,N,O*]carbonylrhodium(I)*

A crystal bounded by the six faces (followed by their distances in mm from a common origin): ±(1 0 0), 0.063, ±(0 0 1), 0.113, ±(0 2 −1), 0.295 was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections ($2\theta = 35-42°$) measured on a diffractometer with Mo-$K\alpha$ radiation ($\lambda(K\alpha_1) = 0.70930$, $\lambda(K\alpha_2) = 0.71359$ Å). Crystal data at 22°C are:

$C_8H_{15}GaN_3O_2Rh$ fw = 357.85

Monoclinic, $a = 10.212(2)$, $b = 7.8484(5)$, $c = 16.733(2)$ Å, $\beta = 105.133(6)°$, $V = 1294.6(3)$ Å^3, $Z = 4$, $\rho_c = 1.836$ Mg m^{-3}, $F(000) = 704$, μ(Mo-$K\alpha$) = 33.2 cm^{-1}. Absent reflections: $h0l$, l odd, and $0k0$, k odd, uniquely indicate the space group $P2_1/c$ (C^5_{2h}, No. 14).

Intensities were measured with graphite-monochromated Mo-$K\alpha$ radiation on an Enraf-Nonius CAD4-F diffractometer. An $\omega-2\theta$ scan at 0.91–10.06° min^{-1} over a range of ($0.60 + 0.35 \tan\theta$) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to $2\theta = 55°$. The intensities of three check reflections, measured every 3600 s throughout the data collection, remained constant to within 3%. After data reduction,[1] an absorption correction was applied using the analytical method (6, 7). Transmission factors ranged from 0.449 to 0.667. Of the 2967 independent reflections measured, 2142 (72.2%) had intensities greater than or equal to $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04\,(S - B))^2$ with S = scan count and B = normalized background count.

The structure was solved by conventional heavy atom methods, the coordinates of the Rh and Ga atoms being determined from the Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference map. After full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters to $R = 0.037$, a difference map gave the positions of all 15 hydrogen atoms. Hydrogen parameters were idealized (N—H = 0.94, C(sp^3)—H = 0.98, C(sp^2)—H = 0.97 Å, methyl positions based on observed peaks) and included in the refinement as fixed contributors. The scattering factors of ref. 8 were used for non-hydrogen atoms and those of ref. 9 for hydrogen atoms. Anomalous scattering factors from ref. 10 were used for the Rh and Ga atoms. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and $\sin\theta/\lambda$ and was employed in the final stages of full-matrix refinement of 137 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. An isotropic Type I extinction correction (Thornley–Nelmes definition of mosaic anisotropy with a Lorentzian distribution) was applied (11–13). The final value of g was $1.35(21) \times 10^4$. Convergence was reached at $R = 0.026$ and $R_w = 0.032$ for 2142 reflections with $I \geq 3\sigma(I)$. For all 2967 reflections $R = 0.055$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.02 and 0.18σ, respectively. The mean error in an observation of unit weight was 1.486. A final difference map showed maximum fluctuations of −0.55 to +0.73 e Å^{-3}, 0.6 and 0.9 Å from Rh, respectively, and was essentially featureless away from the heavy atoms. The final positional and thermal parameters appear in Tables 2 and 7,[2] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2]

*Acetyl(iodo)[dimethyl(1-pyrazolyl)(2-*N,N*-dimethylaminoethoxy)-gallato-*N,N,O*]rhodium(III)*

Experimental details are as above except where noted. The bounding planes of the crystal were: ±(1 0 −1), 0.050, ±(1 0 2), 0.107, ±(1 1 0), 0.263 mm (from a common origin). Reflections employed in the refinement of unit-cell parameters had $2\theta = 35-40°$. Crystal data are

$C_{11}H_{22}GaIN_3O_2RH$ fw = 527.84

Monoclinic, $a = 10.0960(11)$, $b = 11.5352(8)$, $c = 15.871(2)$ Å, $\beta = 105.764(6)°$, $V = 1778.8(3)$ Å^3, $Z = 4$, $\rho_c = 1.971$ Mg m^{-3}, $F(000) = 1016$, μ(Mo-$K\alpha$) = 41.4 cm^{-1}. Absent reflections: $h0l$, $h + l$ odd, and $0k0$, k odd, uniquely indicate the space group $P2_1/n$ (non-standard setting of $P2_1/c$ with equivalent positions: $\pm(x, y, z; 1/2 - x, 1/2 + y, 1/2 - z)$ chosen to give β nearer to 90°).

An $\omega-2\theta$ scan at 0.96–10.06° min^{-1} over a range of ($0.65 + 0.35 \tan\theta$)° in ω was employed. Of 5169 independent reflections measured (to $2\theta = 60°$), 2941 had intensities greater than $3\sigma(I)$ above background. The intensities of the standard reflections remained constant to within 3%. Data were corrected for absorption, transmission factors ranging from 0.410 to 0.680.

The I, Rh, and Ga coordinates were determined from the Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference map. Refinement of the non-hydrogen atoms with anisotropic thermal parameters reduced R to 0.042. In the final stages of refinement the hydrogen atoms were included as fixed contributors in idealized positions. Convergence was reached at $R = 0.036$ and $R_w = 0.040$ for 2941 reflections and 172 variables, for all 5169 reflections $R = 0.084$. The mean and maximum parameter shifts on the final

cycle of refinement corresponded to 0.01 and 0.08σ and the mean error in an observation of unit weight was 1.577. Anomalous scattering corrections were applied for I, Rh, and Ga atoms. A final difference map showed maximum fluctuations of -3.9 to $+1.4$ e Å^{-3} within 1.0 Å of I and was featureless away from the heavy atoms.

Bond lengths, bond angles, and intra-annular torsion angles for the two compounds appear in Tables 3–5, respectively. Calculated hydrogen coordinates and isotropic thermal parameters (Table 6) and complete listings of torsion angles (Table 8) are also included as deposited material.[2]

Physical measurements

Infrared spectra were recorded on a Perkin Elmer 598 spectrometer. ^{1}H nmr spectra were obtained on a Bruker WP 80 instrument using FT techniques. Mass spectra were recorded on either a Varian MAT CH4B or AES MS 50 spectrometer operating at 70 eV. Melting points were measured on a Gallenkamp apparatus in sealed capillary tubes and are uncorrected. Elemental analyses were performed by Mr. P. Borda of the U.B.C. Microanalytical Laboratory.

Results and discussion

Numerous carbonyl compounds incorporating tridentate pyrazolylgallate ligands of the type **1** have been reported for Cr, Mo, W, Mn, and Re (4, 14–18). In each of these complexes the pyrazolylgallate anions were found to coordinate exclusively in a *fac* mode, even though the chelating ligands are capable of meridional coordination. For example both the *fac* and *mer* isomers have been structurally characterized for the coordination compound $[Me_2Gapz(OCH_2CH_2NH_2)]_2Ni$ (19) and a meridional arrangement is observed in the novel five-coordinate iron dinitrosyl complex $[Me_2Gapz''(OCH_2CH_2NMe_2)]Fe(NO)_2$ (pz″ = 3,5-dimethylpyrazolyl, $N_2C_5H_7$) (20).

In previous publications we have often made comparisons between related transition metal complexes incorporating tridentate pyrazolylgallate, trispyrazolylborate, or cyclopentadienyl type ligands (e.g. ref. 21). Several directly analogous compounds have been prepared containing these ligands — not surprisingly since all three types of ligands are uninegative,

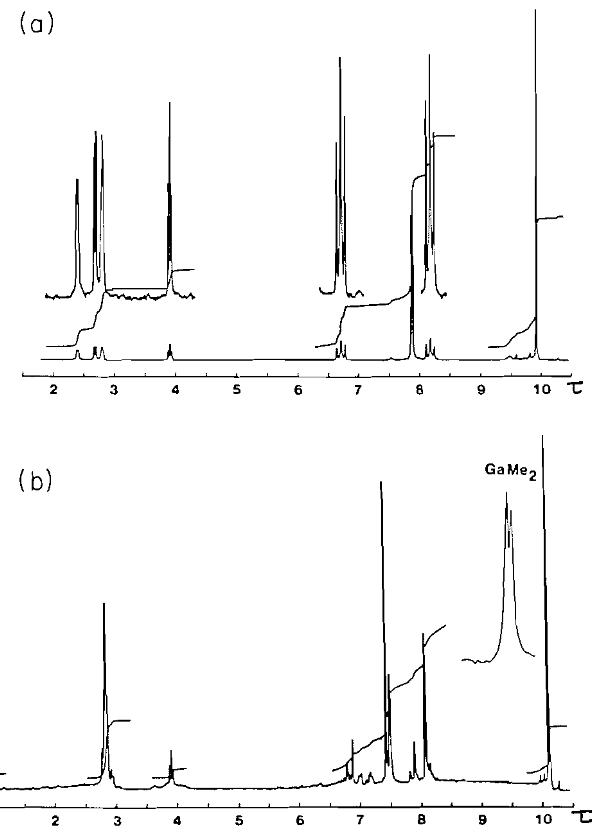

FIG. 1. Room temperature 80 MHz ^{1}H nmr spectra of (*a*) $[Me_2Gapz(OCH_2CH_2NMe_2)]Rh(CO)$ in C_6D_6; (*b*) $[Me_2Gapz(OCH_2CH_2NMe_2)]Rh(COMe)I$ in C_6D_6.

"tridentate", six-electron donors. However, the capability of the present unsymmetric pyrazolylgallate ligands to coordinate meridionally leads to markedly different behaviour when these anions are reacted with $[Rh(CO)_2Cl]_2$. For example, the preparation of $(\eta^5\text{-}C_5H_5)Rh(CO)_2$ from $[Rh(CO)_2Cl]_2$ and $Na^+(C_5H_5)^-$ has been known for some time (22). Similarly $[HB(pz'')_3]Rh(CO)_2$ can be prepared as stable yellow crystals in high yield (23, 24), although it is interesting that the ligands $MeGapz_3^-$ and $HBpz_3^-$ lead to the dinuclear rhodium species $(MeGapz_3)_2Rh_2(\mu\text{-}CO)_3$ (2) and $(HBpz_3)_2Rh_2(\mu\text{-}CO)_3$ (25). Our attempts to synthesize the analogous dicarbonyl rhodium species incorporating the "L" ligands **1** resulted instead in the isolation of stable, square-planar, 16-electron monocarbonyl complexes. The meridional configuration of the pyrazolylgallate ligand was clearly established by the presence of two triplets in the ^{1}H nmr spectrum for the O*CH*$_2$*CH*$_2$NMe$_2$ protons ($J \sim 5.5$ Hz) in the complex LRh(CO) (where R = H, Y = NMe_2) (see Fig. 1(*a*)). In addition the singlets observed for the NMe_2 and $GaMe_2$ groupings in this complex further substantiate this *mer* configuration of the "L" ligand. The remaining LRh(CO) complexes in Table 1 also display $GaMe_2$ singlets suggesting a similar planar Rh(I) species in all cases.

The mass spectra obtained for each of the LRh(CO) compounds displayed prominent signals due to the monomeric parent ion, P^+. In each case the highest intensity signals in the spectra were attributable to the $P - Me^+$ ion, with prominent signals due to the $P - CO^+$ and $P - Me - CO^+$ ions being observed.

Confirmation of a square-planar Rh(I) environment in the complex $[Me_2Gapz(OCH_2CH_2NH_2)]Rh(CO)$ has been established by an X-ray structure determination. The molecular ar-

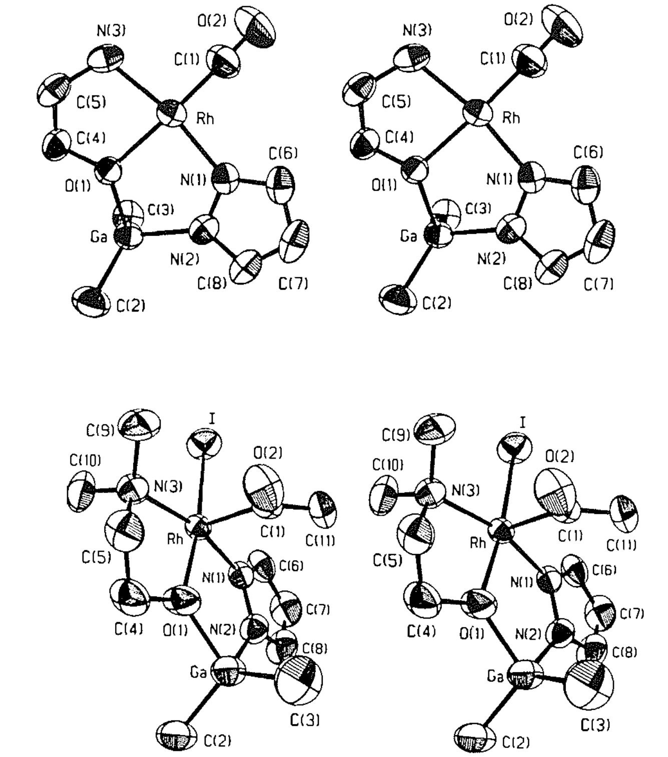

FIG. 2. Stereoscopic views of (*a*) $[Me_2Gapz(OCH_2CH_2NH_2)]$-Rh(CO) and (*b*) $[Me_2Gapz(OCH_2CH_2NMe_2)]$Rh(COMe)I. 50% probability thermal ellipsoids are shown. Hydrogen atoms have been omitted for clarity.

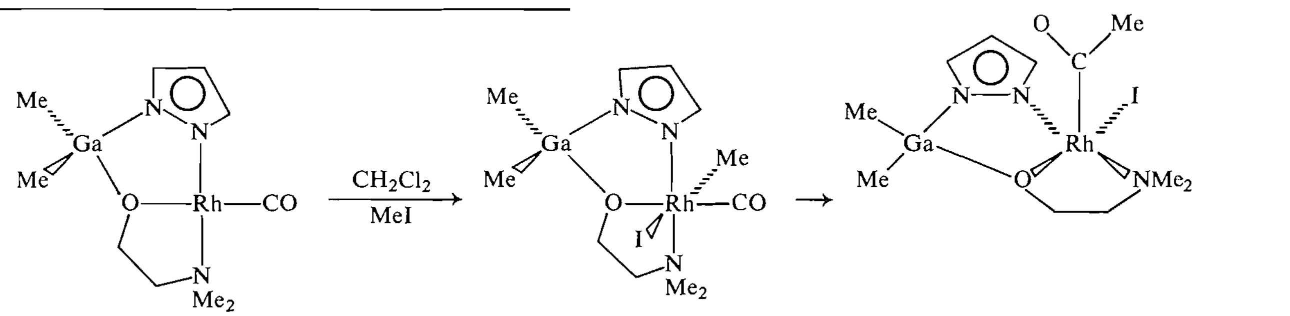
rangement is shown in Fig. 2(*a*). As expected the pyrazolylgallate ligand is meridionally disposed about the Rh(I) centre, with the CO ligand occupying the fourth coordination site in the square planar complex. The coordination group (RhN_2OC) is significantly non-planar (χ^2 = 541) although all five atoms lie within 0.055(6) Å of the mean plane. Bond distances involving Rh are Rh—O = 2.058(2), Rh—N(pz) = 2.035(3), Rh—N(amino) = 2.070(3), and Rh—CO = 1.776(5) Å. The carbonyl group is nearly linear, Rh—C—O = 176.8(2)°.

The pyrazolyl ring is planar to within experimental error (χ^2 = 6.5, maximum deviation from the mean plane = 0.006(5) Å) while the two five-membered chelate rings are both significantly non-planar, having irregular "puckered" conformations (see Table 5 for torsion angles). In the solid state molecules are linked by intermolecular N—H···O hydrogen bonds (N(3)—H(Nb)···O(1) ($1 - x$, $y - 1/2$, $1/2 - z$); H···O = 2.20, N···O = 3.088(4) Å, N—H···O = 158°) to form continuous spirals about the twofold screw axes along *b*. All other intermolecular distances correspond to normal van der Waals interactions.

The reaction between $[Me_2Gapz(OCH_2CH_2NMe_2)]$Rh(CO) and MeI in CH_2Cl_2 initially yielded solution ir evidence for a six-coordinate oxidative addition product. Thus the ν_{CO} band of the starting monocarbonyl species at 1958 cm^{-1} was replaced by two bands on addition of MeI at 2063 and 1720 cm^{-1}, the latter gaining in intensity with time. Attempts to isolate the species responsible for the 2063 cm^{-1} band resulted instead in crystals of a new Rh(III) compound containing a terminal acetyl group. Thus migratory insertion, as shown below, takes place readily at room temperature:



ν_{CO}: 1958 cm^{-1} (CH_2Cl_2) ν_{CO}: 2063 cm^{-1} (CH_2Cl_2) ν_{CO}: 1720 cm^{-1} (CH_2Cl_2)

The carbonyl stretching frequency for the proposed intermediate is similar to that reported for a related complex, (η^5-C_5Me_5)Ir(CO)(Me)I (ν_{CO}: 2002 cm^{-1} (CH_2Cl_2)) (26). Methyl migration does not take place with this stable Ir(III) compound, possibly due to the greater stability of Ir—C bonds compared to analogous Rh—C bonds. Interestingly related rhodium complexes containing σ-bonded methyl groups have not been observed during the reaction of MeI with cyclopentadienyl rhodium carbonyls. For example, the reaction of MeI with (η^5-C_5Me_5)$Rh(CO)_2$ proceeds directly to the (η^5-C_5Me_5)Rh(CO)(COMe)I complex at 50°C (27).

In addition to the diagnostic ν_{CO} band at 2063 cm^{-1} supportive evidence for the intermediate six-coordinate Rh(III) species emanates from the ^{1}H nmr spectra run on samples soon after the introduction of MeI to $[Me_2Gapz(OCH_2CH_2NMe_2)]$-Rh(CO) dissolved in C_6D_6. These show, in addition to peaks assignable to the five-coordinate product, patterns expected for the proposed intermediate, including a broad Rh—Me resonance at ~9 τ. With time these peaks due to the intermediate gradually disappear to leave a clean spectrum of the five-coordinate Rh(III) acetyl derivative.

The mass spectrum of $[Me_2Gapz(OCH_2CH_2NMe_2)]$Rh-(COMe)I indirectly supports the presence of an acetyl ligand. Signals corresponding to the ions P^+, $P - Me^+$, $P - Me - I^+$, and $P - 2Me - I^+$ ions are observed in the spectrum, but no evidence for the presence of the $P - Me - CO^+$ or $P - CO^+$ ions was obtained. Signals arising from these latter two ions are generally observed in the mass spectra of pyrazolylgallate transition metal complexes containing terminal carbonyl groups.

The absence of two well-defined triplets attributable to the methylene protons in the ^{1}H nmr spectrum of $[Me_2Gapz$-$(OCH_2CH_2NMe_2)]$Rh(COMe)I (Fig. 1(*b*)) is expected since

unlike the four-coordinate Rh(I) species, $[Me_2Gapz(OCH_2CH_2NMe_2)]Rh(CO)$ (Fig. 1(*a*)), this molecule does not possess a plane of symmetry. Thus the four methylene protons become individually unique and exhibit complex spin–spin interactions. A number of molecular arrangements are possible for the five-coordinate Rh(III) species, some of them necessarily involving concomitant meridional–facial rearrangement of the pyrazolylgallate ligand during the oxidative addition and migratory insertion reaction sequence. A definitive X-ray crystal structure of the complex $[Me_2Gapz(OCH_2CH_2NMe_2)]Rh(COMe)I$ (Fig. 2(*b*)) has shown that the pyrazolylgallate ligand in fact remains meridional, that the iodine atom replaces the CO ligand in the original square-planar arrangement, and the CO group becomes part of the acetyl moiety occupying the apical position in the observed square-pyramidal structure. The basal group (N_2OI) is planar to within 0.037(4) Å, the Rh atom being displaced from the mean plane by 0.1709(3) Å toward the apical carbon atom. Bond lengths involving Rh are Rh—I = 2.6300(5), Rh—O = 2.014(3), Rh—N(pz) = 2.033(4), Rh—N(amino) = 2.111(3), and Rh—C = 1.955(5) Å. The Rh—I distance is slightly shorter than the range of 2.65–2.69 Å observed for most Rh(III)—I distances, e.g. 2.643(3) Å in $RhI_2Me(PPh_3)_2$ (28) and 2.653(3) Å in $(\eta^5\text{-}C_5H_5)Rh(CO)(C_2F_5)I$ (29).

The pyrazolyl group is planar within experimental error (χ^2 = 0.2, maximum deviation = 0.001(5) Å) while the RhC(O)C group is slightly but significantly non-planar (χ^2 = 17.6, maximum deviation 0.018(5) Å). Both five-membered chelate rings are significantly non-planar and have "puckered" conformations. The RhNNGaO ring, however, is much more planar than that in LRh(CO) (see Table 5). In addition, the coordination about O(1) is planar compared with pyramidal in LRh(CO), the sum of angles about O(1) being 360.0° vs. 346.7° in LRh(CO).

In the solid state molecules are linked by weak C—H···O interactions (C(10)—H(10a)···O(2) (1/2 − *x*, *y* − 1/2, 1/2 − *z*); H···O = 2.42, C···O = 3.349(7) Å, C—H···O = 158°) to form continuous spirals about the twofold screw axes. The orientation of the acetyl group is determined by three weak anchoring interactions: C(5)—H(5b)···O(2), C(9)—H(9c)···O(2), and C(11)—H(11a)···N(1) (H···(O/N) = 2.50, 2.38, 2.55; C···(O/N) = 3.215(7), 3.084(8), 2.958(6) Å; C—H···(O/N) = 121, 128, 105°).

The observed reluctance of the square-pyramidal molecule, LRh(COMe)I, to accept a sixth ligand (CO or PPh_3) may result from the *trans* influence of the acetyl grouping. Cheng *et al.* have earlier described a number of 5-coordinate Rh(III) acyl derivatives in which the absence of a sixth ligand in the coordi-

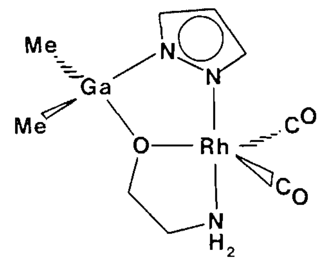
nation sphere of the metal was attributed to the discouragement of any possible *trans* ligation by the presence of the apical acyl ligand (30, 31). The structural influence of the acetyl grouping in the six-coordinate Rh(III) dimer species $[Rh_2I_4(CO)_2(\mu\text{-}I)_2(COMe)_2]^{2-}$, where the Rh—I *trans* to the acetyl group is 0.322(3) Å longer than the *cis* Rh—I distance, has also been documented (32). The Rh—COMe distance of 1.955(5) Å in the present complex is significantly shorter than those of 2.062(23) Å reported for the above dimer species and the Rh(III) – acyl carbon distances reported by Cheng *et al.* of 2.002(7) Å for $(AsPh_4)[RhI(COEt)(PPh_3)(mnt)]$ and 2.006(14) Å for $[RhI(CO^nPr)(PEt_3)_2(mnt)]$ (where mnt = maleonitriledithiolate). Three of these distances are considerably shorter than the Rh(III)—C σ-bond distances compiled by Collman *et al.* which cover a range of 2.05–2.26 Å (33). The shorter Rh(III) — acyl carbon bond distances may be attributed, in part, to the smaller covalent radius of sp^2 carbon versus sp^3 carbon and, in addition, to a certain degree of back-bonding from filled d_π orbitals on the Rh(III) centre to the π^* orbitals of the acyl ligand. The occurrence of the acyl grouping in the apical position in the present five-coordinate Rh(III) species is somewhat surprising since one might expect the migratory insertion reaction to position this ligand adjacent to a vacant coordination site.

The addition of bromine or iodine to a CH_2Cl_2 solution of LRh(CO) (R = H, Y = NH_2 or NMe_2) resulted in the immediate appearance of a new single carbonyl band at ~2090 cm^{-1} with concomitant total loss of the CO stretching frequency attributable to the starting LRh(CO) species. This new band has been assigned to $LRh(CO)X_2$ (X = Br or I) and is ~30–50 cm^{-1} higher than those reported for related cyclopentadienyl compounds (e.g., ref. 34) but is very similar to frequencies reported for related pyrazolylgallate (35) and -borate (24, 25) complexes. These higher wave numbers are unusual as they oppose the trend previously observed for other related com-



(a)

FIG. 3. (*a*) Trigonal bipyramidal and (*b*) square pyramidal structure.

plexes incorporating either cyclopentadienyl type or pyrazolylgallate anions (e.g., ref. 21). That is, pyrazolylgallate tridentate ligands, and the related isoelectronic tris(pyrazolyl)-borate anions, are generally regarded to be better electron-donating groups compared to the cyclopentadienyl ligand resulting in lower ν_{CO} values in analogous transition metal carbonyl complexes. Analytically pure samples of the $LRh(CO)X_2$ compounds could not be obtained, presumably due to the presence of trace amounts of dihalogens which could not be successfully removed. Difficulties in obtaining satisfactory elemental analyses for related pyrazolylborate dihalogen monocarbonyl species have been previously noted (24, 25). The mass spectra of the pyrazolylgallate dihalogen compounds, $LRh(CO)X_2$, exhibited the expected monomeric parent ion signals (~0.5%), in addition to signals attributable to ions arising from predictable fragmentation patterns of the parent species.

It has already been mentioned that 18-electron dicarbonyl Rh(I) complexes form with both the cyclopentadienyl and tris(3,5-dimethylpyrazolyl)borate anions. Monocarbonyl species are not observed with these ligand systems since the *pseudo* facial configuration geometrically imposed on these tridentate ligands would force an unfavourable tetrahedral symmetry around the Rh(I) centre. However, with the present unsymmetric pyrazolylgallate ligands square planar, 16-electron monocarbonyl products are isolated. These LRh(CO) complexes undergo reversible CO addition in solution. Thus bubbling CO through a hexane solution of $[Me_2Gapz(OCH_2CH_2NH_2)]Rh(CO)$ resulted in the appearance of two new bands in the carbonyl region of the ir spectrum at wavenumbers again ~50 cm^{-1} and ~90 cm^{-1} higher than those reported for the isoelectronic compounds $(\eta^5\text{-}C_5H_5)Rh(CO)_2$ (36) and $(\eta^5\text{-}C_5Me_5)Rh(CO)_2$ (27), respectively. $[Me_2Gapz(OCH_2CH_2NH_2)]Rh(CO)_2$ was unstable in solution, both in air and under a nitrogen atmosphere. With air exposure extensive sample decomposition was signaled by the precipitation of black insoluble materials. The solution, on standing under a nitrogen atmosphere, lost carbon monoxide slowly to give solutions containing both the mono- and dicarbonyl species. Complete conversion to the monocarbonyl could be effected by gently refluxing the solution.

The ^{1}H nmr of $[Me_2Gapz(OCH_2CH_2NH_2)]Rh(CO)_2$ was obtained by bubbling CO through a C_6D_6 solution of the monocarbonyl in an nmr tube. The most notable feature of this nmr spectrum was the loss of the triplets attributable to the methylene protons of the amino alcohol moiety of the pyrazolylgallate ligand, indicating that the symmetry of the starting LRh(CO) complex was lost. Therefore, the dicarbonyl is not a trigonal bipyramid as shown in Fig. 3(*a*) (as this configuration still possesses a mirror plane containing the three donor sites of L) but is more likely square pyramidal, as shown in Fig. 3(*b*). Furthermore, the two gallium methyl groups are inequivalent in the ^{1}H nmr spectrum of this complex, lending additional support for this square-pyramidal structure. Unfortunately the dicarbonyl could not be isolated as a crystalline sample and thus confirmation of this molecular arrangement was not possible via X-ray structure analysis. However, by comparison with the five-coordinate acetyl structure already discussed it seems most likely that in this molecule the pyrazolylgallate ligand again occupies three basal sites of a square pyramid.

The reaction of PPh_3 with the LRh(CO) complexes resulted in disproportionation of the rhodium complexes and the formation of the stable dimer species $[(\mu\text{-pz})Rh(CO)(PPh_3)]_2$.

The LRh(CO) complexes did not catalyze the hydrogenation of 1-hexene at 30°C, a lack of activity arising, no doubt, from the surprising indifference of these square planar Rh(I) species to the presence of molecular hydrogen under a variety of conditions. This observed nonreactivity can be compared with that of isosteric 16-electron square planar complexes containing meridional hybrid tridentate ligands $[Rh(L^\dagger)N(SiMe_2CH_2PPh_2)_2]$ ($L^\dagger$ = cyclooctene, PPh_3, or CO). When $L^\dagger$ = cyclooctene or PPh_3 this system is a catalyst precursor for the efficient hydrogenation of 1-hexene under mild reaction conditions (37). However, when $L^\dagger$ = CO no hydrogenation of olefins occurs (38). Assuming that for catalysis to take place a dihydride mechanism similar to that proposed by Halpern for Wilkinson's catalyst (39–41) most likely is operative, the presence of CO may discourage the formation of a six-coordinate "$LRh(H)_2(CO)$" intermediate. Alternatively, if the CO must dissociate before oxidative addition of H_2 will occur, the reluctance of the Rh—CO bond to break would account for the non-catalytic behaviour of the carbonyl complexes.

We are currently probing the reactions of tridentate pyrazolylgallate ligands with various rhodium phosphine and olefin complexes.

Antiferromagnetic super exchange and spectral studies on dimeric 8-quinolinolato complexes of copper(II) imides

C. L. SHARMA[1] AND V. MISHRA
Chemistry Department, University of Roorkee, Roorkee (U.P.), India – 247 667

Received January 7, 1985

C. L. SHARMA and V. MISHRA. Can. J. Chem. **63**, 3027 (1985).

The complexes of the type $[Cu(Q)(P)]_2$ and $[Cu(Q)(S)]_2$ where HQ = 8-hydroxyquinoline and P and S are deprotonated phthalimide and succinimide, respectively, were prepared and characterized on the basis of molecular mass determination, elemental analysis, X-ray diffraction, ir, electronic spectra, conductance, thermal analysis, and magnetic measurements. They were of tetrahedrally distorted square planar structure. The susceptibility data at different temperatures were fitted to the Bleaney–Bowers equation which indicated medium antiferromagnetic super exchange interaction within one dimeric unit. The values of exchange integral and g were found to be $-136\ cm^{-1}$ and 2.18, respectively, for the phthalimide complex and $-128\ cm^{-1}$ and 2.16, respectively, for the succinimide complex.

C. L. SHARMA et V. MISHRA. Can. J. Chem. **63**, 3027 (1985).

On a préparé des complexes du type $[Cu(Q)(P)]_2$ et $[Cu(Q)(S)]_2$, dans lesquels HQ = hydroxy-8 quinoline et P et S = les formes déprotonées de la phtalimide et de la succinimide, et on les a caractérisés en se basant sur la détermination de la masse moléculaire, de l'analyse élémentaire, de la diffraction des rayons X, de l'ir et de la spectroscopie électronique, de la conductance, de l'analyse thermique et de mesures magnétiques. Ces complexes ont une structure plan carré déformée d'une façon tétraédrique. On peut établir une corrélation des données de susceptibilité à différentes températures grâce à l'équation de Bleaney–Bowers et ceci suggère l'existence d'une interaction de superéchange antiferromagnétique moyenne à l'intérieur d'une unité dimère. Les valeurs d'intégrale d'échange et de g sont respectivement $-136\ cm^{-1}$ et 2,18 pour le complexe de la phtalimide et $-128\ cm^{-1}$ et 2,16 pour le complexe de la succinimide.

[Traduit par le journal]

Introduction

Studies on homodinuclear complexes have been of great importance because of their interesting magnetic and spectral properties of these materials (1–3). These complexes also serve as models for certain metalloproteins and metalloenzymes, particularly for those containing copper(II) where the biological functions are related to the metal centres in pairs (4–6). Recently, the structures and magnetic properties of a number of phenoxo-, alkoxo-, and hydroxo-bridged copper(II) dimers have been studied and some interesting correlations have been developed (7–12). The present article deals with the preparation and characterization of binuclear 8-hydroxyquinolinato complexes of copper(II) phthalimide and succinimide on the basis of molecular mass determinations, elemental analysis, thermal analysis, X-ray, ir, electronic spectra, conductance and magnetic measurements.

Experimental

Physical measurements

The magnetic measurements were carried out in the temperature range 70–300 K on a PARC digital vibrating sample magnetometer model VSM-155 under two different magnetic fields 5500 and 7000 G produced by a polytronic electromagnet type H.E.M.-200. The constancy of the magnetic field was maintained by a constant current regulator Polytronic type ccP-200. The temperature of the sample chamber was regulated by filling it with liquid nitrogen and then heating it using the automatic heating assembly provided within the instrument. The cryogenic temperature controller EG & G PARC model 152 which was attached with the magnetometer regulated the heating up to desired temperatures. The magnetometer was calibrated with ultrapure nickel metal and $[HgCo(NCS)_4]$ (13). The calibration was then cross-checked at cryogenic temperatures with hydrated cupric(II) acetate (14). The three calibrations agreed well and it was estimated that the limits of error in the susceptibility values were not more than ±1%. The data were corrected for diamagnetism of the lucite sample holder and of constituent atoms with the use of Pascal's constants (15). A value of 60×10^{-6} cgsu was assumed for the temperature independent paramagnetism of copper(II) (16).

Powder X-ray patterns of the complexes were recorded on a Philips X-ray diffractometer model PW-1140/90 attached with digital, graphical, and photographic assemblies using Cu Kα radiations at 12-mA current, 32-kV voltage.

Thermal studies were done on a Stanton Redcraft TG model-770 and Fisher Differential Thermoanalyzer model 260 P at a heating rate of 8°C/min and chart speed 6 in./h in a platinum crucible in the atmosphere of air using anhydrous alumina as a reference material.

All other physical methods were the same as reported earlier (17).

Copper was estimated by atomic absorption technique, nitrogen by Kjeldhal method, and carbon and hydrogen by Pregl method on a Hosli's micro-combustion apparatus type CHA-2. Molecular masses were determined cryoscopically in dioxane.

The computational work was performed on a DEC-2050 version 4 computer system.

Reagents

Phthalimide was obtained from Fluka A.G. Buchs SG (Switzerland) and succinimide and cupric chloride of AR (B.D.H.) grade from England were used. The solvents supplied by E. Merck India Ltd. were redistilled before use.

Preparation of the complexes

Copper(II) phthalimide $[Cu(C_8H_4NO_2)_2(H_2O)_4]$ and copper(II) succinimide $[Cu(C_4H_4NO_2)_2(H_2O)_4]$ were prepared by the same method as reported earlier (18). The 0.05 M methanolic solutions of copper(II) imide and 8-hydroxyquinoline were mixed in the ratio of 1 : 1 and then refluxed on a water bath for about half an hour which gave the crystals a yellowish-green colour. They were filtered, washed several times with methanol, and then dried in a desiccator over anhydrous silica gel. These complexes were found soluble in 1,4-dioxane and dimethylsulfoxide. They were analysed for the metal, carbon, hydrogen, and nitrogen.

Anal. calcd. for **I**, $[Cu(C_9H_6NO)(C_8H_4NO_2)]_2$: Cu 17.97, C 57.69, H 2.83, N 7.92; found: Cu 17.23, C 57.80, H 2.80, N 7.92.

Anal. calcd. for **II**, $[Cu(C_9H_6NO)(C_4H_4NO_2)]_2$: Cu 20.80, C 51.06, H 3.27, N 9.17; found: Cu 20.15, C 51.46, H 3.30, N 9.20.

Results and discussion

The values of molar conductances in dioxane, i.e., 5 and 10 ohm^{-1} cm^2 mol^{-1} in the case of the first and second complexes, respectively, indicated their nonelectrolytic nature. The molecular masses in dioxane were found to be 719 and 602 which corresponded to their dimeric forms. Thermogravimetry and differential-thermal-analysis curves were similar to those of other copper(II) complexes of 8-hydroxyquinoline (19). Analysis of these curves indicated the absence of any type of water (crystalline or coordinated).

Infrared studies

The imide molecule has two interesting, NH and CO stretching, frequency regions. The ir spectra of the complexes show the shifting of the CO stretching frequency from 1750 to 1700 cm^{-1} which could be the result of an electron withdrawal effect from the CO group as a result of nitrogen coordination (20, 21). The slight increase of ν_{CN} from 1480 to 1500 cm^{-1} supports this (22). On the basis of Lewis-acid concept, the negatively charged imide nitrogen will have better possibilities of being coordinated than oxygen (23). There will be steric hindrance also if the coordination is through oxygen. A strong band due to ν_{NH} observed at 3300 cm^{-1} in the spectrum of imide disappeared in the spectra of complexes indicating thereby the deprotonation of —NH and the coordination through nitrogen. The band obtained at 3100 cm^{-1} due to ν_{OH} in the spectrum of 8-hydroxyquinoline disappeared in the spectra of the complexes. The peak at 1090 cm^{-1} due to aryl oxygen vibration of the ligand was observed at higher position ≈1110 cm^{-1} confirming the coordination of metal ion with aryl oxygen of the 8-quinolinol. The upward shifts from 740 to 750 cm^{-1} due to out-of-plane ring deformation and from 480 to 500 cm^{-1} due to in-plane ring deformation modes indicated the coordination of the metal ion through oxygen and nitrogen of 8-hydroxyquinoline (24). The bands due to $\nu_{M—O}$ and $\nu_{M—N}$ were observed at 400 and 375 cm^{-1} respectively (25).

Electronic spectra

The spectra of complexes in dioxan gave a strong band of high intensity at 25 000 cm^{-1} ($\epsilon \approx 8800$). The imide ligands and their monomeric complexes prepared by the reported methods (26–28) do not absorb in this region. However, the monomeric copper(II) complexes of 8-hydroxyquinoline gave a band of low intensity and at lower energy, i.e., 23 200 cm^{-1} ($\epsilon \approx 7000$). The presence of this band and its shift to higher energy with increased intensity in the dimeric complexes may be attributed to the combined effect of intra-ligand transition and L → M charge transfer transitions, a characteristic feature of oxo-bridged copper(II) complexes (29, 30) and hence a diagnostic feature of a dimeric structure (31). Another band was observed at ≈14 000 cm^{-1} ($\epsilon \approx 150$) while the planar monomeric copper(II) complexes of 8-quinolinol (α) (27), succinimide, and phthalimide (28), gave the bands at 15 000 ($\epsilon \approx 110$), 15 000 ($\epsilon \approx 100$), and 14 900 cm^{-1} ($\epsilon \approx 110$), respectively. The bis(8-quinolinolato)copper(II) (β) which has a $T_d \leftrightarrow$ planar structure gave this band at 13 300 cm^{-1} ($\epsilon \approx 70$) (26). The absence of any new band in the dimeric derivatives of the above monomeric species indicated an identical ligand field environment around both the metal centres (32) and hence a *trans* structure of the dimeric complexes. Since the ligands do not show any band in the visible region, the above band was definitely a $d-d$ band of copper(II). Again, there was a red shift in this energy band from mono- to dimeric complexes which may be due to the combined effects of the changes in the stereochemistry and the ligand field energy indicating thereby the difference in the steric environment around the metal centre in these two types of complexes. Since the monomeric complexes are square planar, it appears that the present dimers are tetrahedrally distorted planar complexes. This is supported by the fact that the introduction of tetrahedral distortion in the planar complexes causes a shift in the absorption band to the lower energy side (33).

X-ray diffraction

The powder X-ray diffraction patterns were analysed by modified Lipson's (34) method. The patterns of both the complexes were successfully indexed for the tetragonal crystal

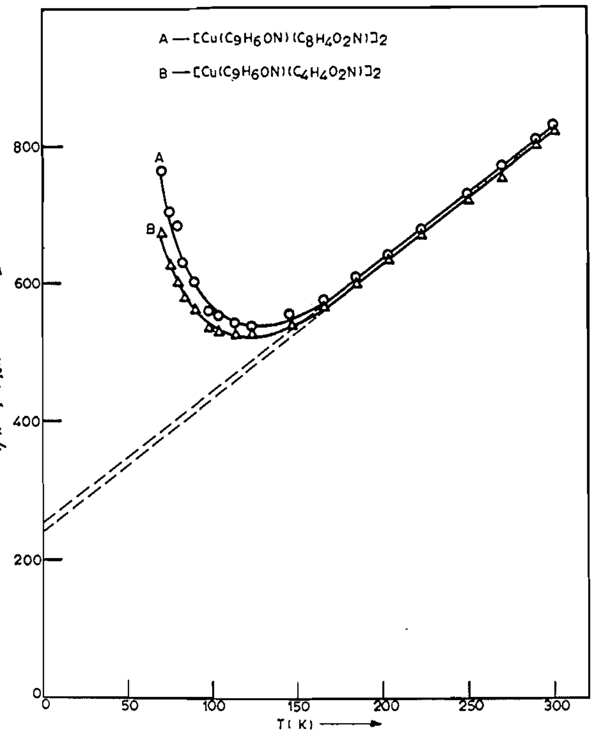

FIG. 2. Plot of $1/\chi$ vs. T for $[Cu(C_9H_6ON)(C_8H_4O_2N)]_2$ and $[Cu(C_9H_6ON)(C_4H_4O_2N)]_2$.

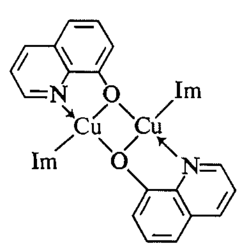
system (Table 1, supplementary material[2]). The observed densities, i.e., 2.10 and 1.05, in the case of complexes **I** and **II** respectively, indicated the presence of four molecules per unit cell. The lattice parameters were found to be a = 13.165 Å, c = 12.709 Å for complex **I** and a = 15.061 Å, c = 16.990 Å for complex **II**.

On the basis of the above information the following structure was proposed



Im = deprotonated imide molecule

Magnetic studies

The magnetic properties of exchange-coupled copper(II) complexes have been studied using isotropic HDVV model (35) as simplified to the isotropic Hamiltonian in the case of dimers

$$\mathcal{H} = -2J\mathbf{S}_1 \cdot \mathbf{S}_2$$

The susceptibility per copper(II) ion was obtained from the Van Vleck's equation (36) as simplified by Bleaney and Bowers (37)

$$\chi_{Cu^{2+}} = \frac{Ng^2\beta^2}{3kT}\left[1 + \frac{1}{3}\exp\left(\frac{-2J}{kT}\right)\right]^{-1} + N\alpha$$

[2]Supplementary material is available and may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

The exchange parameters were then evaluated by least square method. The value of the exchange integral $2J$ and g were found to be -136 cm^{-1} and 2.18 respectively in the case of complex **I** and -128 cm^{-1} and 2.16 respectively in the case of complex **II**. The curves (Fig. 1) obtained from experimental and calculated values of susceptibilities and magnetic moments at different temperatures are in good agreement with each other. The susceptibilities of both complexes at 5500 and 7000 G were nearly the same and hence anisotropy and field dependence were negligible. The values of magnetic moments at room temperature were 1.66 and 1.67 BM, i.e., sufficiently less than the spin-only value required for one unpaired electron indicating thereby the dimeric form of the complexes. The value of susceptibility increases with decreasing temperature, reaches a maximum, and beyond which it decreases while the values of magnetic moment decrease monotonically with decreasing temperature (Fig. 1). The complexes obey the Curie–Weiss law, $\chi = C/(T + \theta)$, in the temperature ranges of approximately 165–300 K for complex **I** and 145–300 K for complex **II**. For $[Cu(Q)(P)]_2$, C = 0.525, θ = 134°, while for $[Cu(Q)(S)]_2$, C = 0.515, θ = 126° (Fig. 2). In both compounds, however, the Curie–Weiss law is not obeyed at lower temperatures. This indicated the medium antiferromagnetic interaction within one dimeric unit (38, 39). The agreement between the calculated and experimental values (Fig. 1) ruled out any possibility of inter-dimer interactions. The electron exchange demagnetization in the dimers was considered to occur between pairs of oxygen-bridged copper(II) atoms (40). The antiferromagnetic interaction was therefore operative via super exchange pathway involving $d_{x^2-y^2}$ orbitals of Cu(II) and s and p orbitals of diamagnetic oxygen anion (41). The 90° cation–anion–cation exchange interaction mechanism (42) could successfully be applied to the present systems. Cu—O—Cu bridge angles, Cu—O bond lengths, the solid angle at the oxygen bridge, and the metal ion ground state, etc. may be the major contributing factors to the super-exchange.

Réaction de quelques pyrazolines substituées par deux groupes électroattracteurs géminés avec $Ce(NH_4)_2(NO_3)_6$: nouvelle synthèse de pyrones-2 électrophiles

HASSAN ABDALLAH,[1] RENÉ GRÉE ET ROBERT CARRIÉ

Groupe de Recherches de Physicochimie Structurale, U.A. n° 704 au C.N.R.S., laboratoire n° 3, Université de Rennes, 35042 Rennes Cédex, France

Reçu le 4 janvier 1985

HASSAN ABDALLAH, RENÉ GRÉE et ROBERT CARRIÉ. Can. J. Chem. **63**, 3031 (1985).

La réaction des pyrazolines acétals de formule générale **3** avec $Ce(NH_4)_2(NO_3)_6$ est étudiée. Elle conduit généralement aux oléfines **4** qui sont de bons substrats de départ pour la synthèse de pyrones électrophiles **5**. Dans deux cas une autre voie d'évolution, conduisant à des cyclobutanes, est observée.

HASSAN ABDALLAH, RENÉ GRÉE, and ROBERT CARRIÉ. Can. J. Chem. **63**, 3031 (1985).

Reaction of type **3** ketal pyrazolines with $Ce(NH_4)_2(NO_3)_6$ is studied. This leads generally to olefins **4**, which are good starting materials for the synthesis of electrophilic pyrones **5**. In two cases, another pathway leading to cyclobutanes is observed.

Les pyrazolines-1 portant en position géminée deux groupes électroattracteurs, peuvent en principe évoluer avec élimination d'azote selon trois voies: formation de cyclopropanes (voie A), migration de R (voie B) ou de H (voie C) conduisant dans les deux derniers cas à des oléfines (schéma 1).

Dans le cadre des travaux entrepris au laboratoire concernant l'utilisation en synthèse de la cycloaddition-1,3 dipolaire, nous avons montré précédemment l'intérêt synthétique du diazoacétal **1**, R′ = $(CH_3O)_2CH$, la photolyse des pyrazolines **3** correspondantes permettant l'obtention de cyclopropanes électrophiles à fonction aldéhyde libre ou masquée (1).

Le présent mémoire décrit l'évolution de ces mêmes pyrazolines **3** lorsqu'elles sont traitées par une petite quantité de $Ce(NH_4)_2(NO_3)_6$ (2). En général elles donnent avec de bons rendements les oléfines **4**, lesquelles traitées par HCO_2H conduisent à des pyrones-2 électrophiles régiospécifiquement substituées en 5 ouvrant ainsi une voie d'accès originale à ces composés (schéma 2). À notre connaissance, deux composés de ce type ont été décrits jusqu'à présent (3, 4). Les pyrones-2 électrophiles sont en outre des produits de départ intéressants en synthèse organique comme: (*i*) diènes (5–7) lors de réactions de Diels–Alder impliquées dans différentes synthèses de produits naturels; (*ii*) précurseurs de complexes cyclobutadiène – fer tricarbonyle (8).

Dans deux cas une voie d'évolution différente avec formation de dérivés cyclobutaniques est observée. Ces résultats apportent de nouveaux éléments sur le mécanisme d'évolution des pyrazolines en présence de Ce^{4+}.

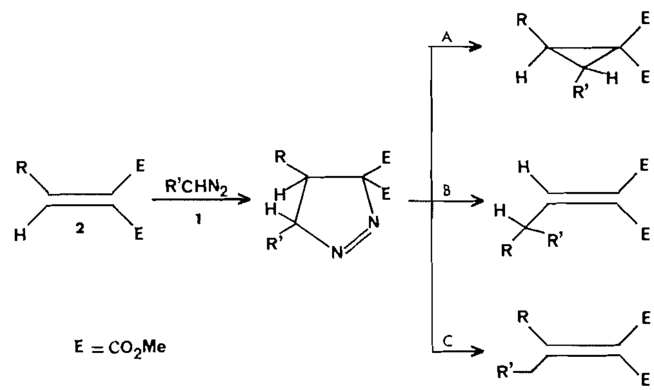

SCHÉMA 1

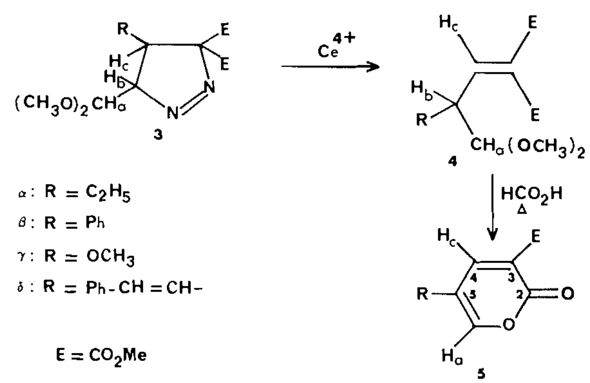

SCHÉMA 2

1. Synthèse de pyrones-2 électrophiles

Le principe de ces synthèses est résumé dans le schéma 2. Les pyrazolines **3**, traitées par $Ce(NH_4)_2(NO_3)_6$ (0,06–0,12 équiv.) dans l'acétone à 30°C pendant 3–25 h suivant la nature de R, conduisent aux oléfines **4** (Rdt 50–80% après distillation).

L'analyse (rmn ^1H) du produit brut de la réaction montre la formation exclusive des oléfines **4**. Les conditions expérimentales et les rendements sont indiqués dans le tableau 1.

Les caractéristiques de rmn[2] de ces oléfines (tableau 2) confirment leur structure. On note, en particulier, la présence de protons vinyliques H_c vers 7 ppm couplés avec le proton H_b vicinal.

Traités par HCO_2H en excès (10–20 équiv.) à chaud les composés **4** donnent les pyrones-2 électrophiles **5** (Rdt 47–83%, tableau 1). Les caractéristiques de rmn (tableau 3) confirment leur structure; elles sont en bon accord avec les données de la littérature concernant la pyrone-2 non substituée en position 5 (R = H) (6, 9).

Le mécanisme de la réaction de formation des pyrones n'a pas été établi; on notera seulement les points suivants:

Si on traite les oléfines **4** par HCO_2H pur sans solvant à la température ambiante, la formation des aldéhydes **6** (schéma 3), intermédiaires vraisemblables de la réaction, est observée.

[1]Boursier du Conseil National de la Recherche Scientifique libanais.

[2]Les notations des hydrogènes H_a, H_b, H_c qui facilitent la présentation des résultats de la rmn sont propres à chaque structure. Dans toute la mesure du possible une cohérence de notation a été maintenue pour les différentes structures.

TABLEAU 1. Conditions expérimentales de préparation des composés **4** et **5**

Composés	Equiv. de Ce^{4+} (durée 4 h)	Composés (Rdt %)	Equiv. de HCO_2H Température (°C) (durée, h)	Composés (Rdt %)*
3α	0,06	**4α** (78)	11 80 (2)	**5α** (71)
3β	0,06	**4β** (77)	20† 105–110 (2)	**5β** (83)
3γ	0,12	**4γ** (50)	20 100 (1)	**5γ** (71)
3δ	0,11	**4δ** (75)	16 50 (5)	**5δ** (47)

*Rendement par rapport à **4**.
†La réaction est effectuée dans le toluène (23 équivalents).

TABLEAU 2. Caractéristiques de rmn ^1H ($CDCl_3$) des composés **4**

Composés	$\delta(H_a)$	$\delta(H_b)$	$\delta(H_c)$	$\delta(OCH_3)$	δ(R) et (J)	J_{ab}	J_{bc}
4α	4,23	2,79	6,87	3,80 3,32 (6H) 3,76	CH_2: 1,49 (m) CH_3: 0,84 (t)	5,6	10,8
4β	4,60	4,17	7,38	3,74 3,35 3,72 3,28	Ph: 7,5–7,2 (5H, m)	5,5	10,0

TABLEAU 3. Caractéristiques de rmn ^1H* des pyrones **5**

Composés	$\delta(H_a)$	$\delta(H_c)$	$\delta(OCH_3)$	δ(R) et (J)	J_{ab}
5α	8,12	7,47	3,85	CH_2: 2,37 (q) CH_3: 1,13 (t) (J = 7,6 et 1,0)	2,7
5β	8,49	7,89	3,85	Ph: 7,41 (s, 5H)	2,8
5γ	8,01	7,42	3,87	OCH_3: 3,72	3,2
5δ	8,42	7,70	3,88	Ph: 7,6–7,1 (m, 5H) PhC*H*=C*H*: 6,88 (d), 6,66 (d) (J = 16,8)	2,6

*Solvant $CDCl_3$ sauf **8** ($(CD_3)_2CO$ + $CDCl_3$, 2:1).

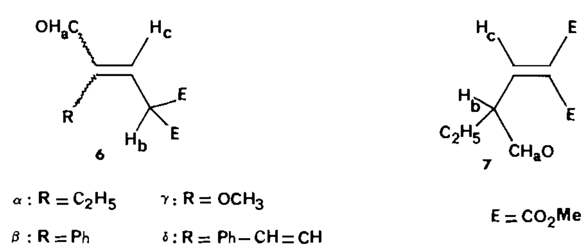

SCHÉMA 3

Placés dans les mêmes conditions (HCO_2H à chaud) ces aldéhydes conduisent également aux pyrones **5**.

Les caractéristiques de rmn des aldéhydes **6**, dont la stéréochimie n'est pas établie, sont en accord avec les structures indiquées (tableau 4).

Lors de l'évolution de **4α** en présence de HCO_2H (à la température ambiante) on observe d'abord la formation d'un composé auquel nous avons attribué la structure **7** sur la base de ses caractéristiques de rmn (tableau 4; on note en particulier un couplage J_{ab} de 1,5 Hz). Le composé **7** évolue ensuite (toujours à température ambiante) vers **6α** lequel chauffé dans HCO_2H conduit à la pyrone **5α**.

II. Réactions des pyrazolines 8 et 13. Formation de cyclobutanes

(a) *Pyrazoline 8*

Dans les mêmes conditions que précédemment, elle donne avec Ce^{4+} une réaction tout à fait différente (schéma 4). La rmn montre que le dérivé cyclobutanique **9** est le produit majoritaire de la réaction (63%). Il est accompagné du cyclopropane **10** (18%) et de l'oléfine **11** (19%). Ces trois produits sont séparés par chromatographie sur gel de silice. Les composés **10** et **11** ont été caractérisés antérieurement (1). La structure du cyclobutane **9** (un seul isomère est obtenu) est établie à l'aide de ses caractéristiques de rmn (tableaux 5 et 6): on note en particulier en rmn ^{13}C l'existence de trois atomes de carbone

TABLEAU 4. Caractéristiques de rmn ^1H* des composés **6** et **7**

Composés	δ(H_a)	δ(H_b)	δ(H_c)	δ(OCH_3)	δ(R)	J_{bc}
6α	9,51	4,57	6,67	3,82 (6H)	CH_2: 2,35 (q) CH_3: 1,01 (t)	10,0
6β	9,67	4,42	6,89	3,71 (6H)	Ph: 7,5–7,05 (m, 5H)	10,0
6γ	9,36	4,70	6,20	3,81 (6H)	CH_3O: 3,86	8,7
6δ	9,57†	4,77	6,68	3,75 (6H)	Ph: 7,6–7,0 (5H) PhC*H*=C*H*: 6,95–6,50 (2H) (m) non analysé	9,7

†J = 2,6.
‡J_{ab} = 1,5.

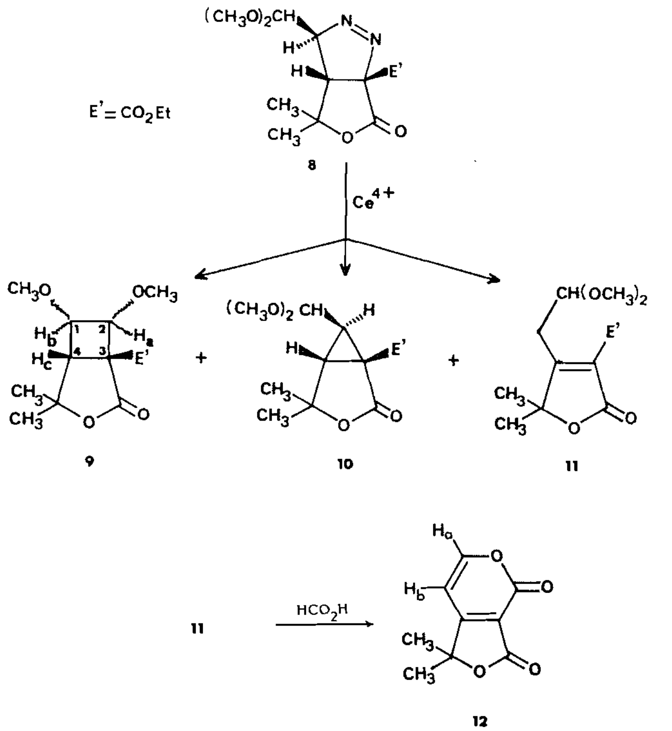

SCHÉMA 4

TABLEAU 5. Caractéristiques de rmn ^1H ($CDCl_3$) des composés **9** et **14**

Composés	δ(H_a)	δ(H_b)	δ(H_c)	δ(OCH_3)		$^3J_{ab}$	$^3J_{bc}$	$^4J_{ac}$
9*	4,22	3,79	2,56	3,50	3,39	5,3	5,0	1,0
14	4,07	4,23	2,88	3,84 3,76 3,75	3,48 3,46	6,4	7,4	1,0

*4,29 (q, OCH_2), 1,32 (t, OCH_2CH_3), 1,52 et 1,49 (2s, $C(CH_3)_2$).

présentant des couplages $^1J_{CH}$ de 150 Hz environ; *deux* de ces carbones ont des déplacements chimiques de 78,5 et 81,5 ppm et sont donc vraisemblablement en α d'un hétéroatome.

Les caractéristiques de rmn ^1H sont également en accord avec les données de la littérature (10) mais ne permettent pas d'attribuer la configuration relative des carbones cyclobutaniques, les constantes de couplage des protons vicinaux et les constantes ^4J n'étant pas caractéristiques (10).

Remarque: Le traitement du produit **11** avec HCO_2H à reflux permet d'obtenir la pyrone **12** avec un rendement de 79% (schéma 4). Ses caractéristiques spectroscopiques (cf. partie expérimentale) sont en accord avec la structure indiquée; on note, en particulier, les signaux rmn ^1H des protons H_a à 7,97 et H_b à 6,68 ppm (J = 5,2 Hz).

(b) *Pyrazolines **13***

La pyrazoline **13** donne dans les mêmes conditions un mélange complexe de sept produits (schéma 5): le cyclobutane **14** (38%), le cyclopropane **15** (7%), les oléfines **16** (34%) et **17** (6%), le dérivé **18** (5%) ainsi que deux autres produits (7% et 3%) dont la structure n'a pas été déterminée.

Les pourcentages des différents constituants sont déterminés à l'aide de la rmn et de la chromatographie de partage gaz–liquide. L'oléfine **17**, instable, a été caractérisé uniquement à l'aide de la rmn, par comparaison avec un échantillon authentique préparé au laboratoire (1); les autres composés ont été isolés par chromatographie sur colonne de SiO_2 et de partage gaz–liquide.

Les caractéristiques spectroscopiques du cyclobutane **14** (tableaux 5 et 6) sont très proches de celles trouvées pour **9**. On note également la présence de deux carbones ayant un couplage $^1J_{CH}$ de 155 Hz environ à 82,6 et 79,1 ppm et d'un troisième carbone à 45,8 ppm ($^1J_{CH}$ = 135 Hz).

Pour l'oléfine **16** on observe en rmn ^1H (cf. partie expérimentale) un triplet à 4,56 ppm couplé avec un CH_2 (doublet) à 2,96 ppm. Le traitement à HCO_2H de cette oléfine permet d'obtenir la pyrone **19**. Ce composé, fragile, a été caractérisé uniquement à l'aide de la rmn (protons H_a et H_b à 7,58 et 6,60 ppm respectivement (J = 5,4 Hz)). En ce qui concerne le composé **18** l'ensemble des caractéristiques spectroscopiques (cf. partie expérimentale) et la spectrométrie de masse (fragment m/z = 291, $C_{12}H_{19}O_8$, $[M - CH_3O]^+$ sont en accord avec la structure. Dans le spectre de rmn ^{13}C on observe un signal dû au carbone acétalique à 105,3 ppm et un signal à 80,5 ppm correspondant au carbone CH_b—OCH_3.

III. Essai de rationalisation des résultats

Les travaux antérieurs du laboratoire (2) nous ont conduit à proposer pour cette réaction de pyrazolines *gem* disubstituées par des groupements électroattracteurs avec Ce^{4+} le passage par un intermédiaire biradicalaire **20** (schéma 6).

Au vu des résultats précédents, deux points nous semblent particulièrement intéressants à noter:

1. La présence du groupe acétal en position 5 modifie sensiblement le cours de la réaction en favorisant la migration de R: ainsi dans le cas des pyrazolines avec R = Ph ou PhCH=CH pour R′ = H, on obtient environ 50% de cyclo-

TABLEAU 6. Caractéristiques de rmn ^{13}C ($CDCl_3$) des composés **9** et **14**

Composés	$\delta(C_1)$ et $\delta(C_2)(^1J)$	$\delta(C_3)$	$\delta(C_4)(^1J)$	$\delta(OCH_3)(^1J)$	$\delta(CO_2CH_2CH_3)$ ou $\delta(CO_2CH_3)(^1J)$	C=O
9*	81,5 (155)	55,7	56,4 (147)	57,7 (143)	CH_2 62,4 (148)	169,6
	78,5 (147)			56,8 (142)	CH_3 14,0 (127)	168,2
14	82,6 (154)	57,6	45,8 (135)	58,5 (144)	53,1 (148)	170,3
	79,1 (157)			57,7 (143)	52,9 (148)	170,0
					52,3 (147)	167,3

*84,5 ($(CH_3)_2C$), 27,8 et 22,2 ($(CH_3)_2C$, ^1J = 128 et 127).

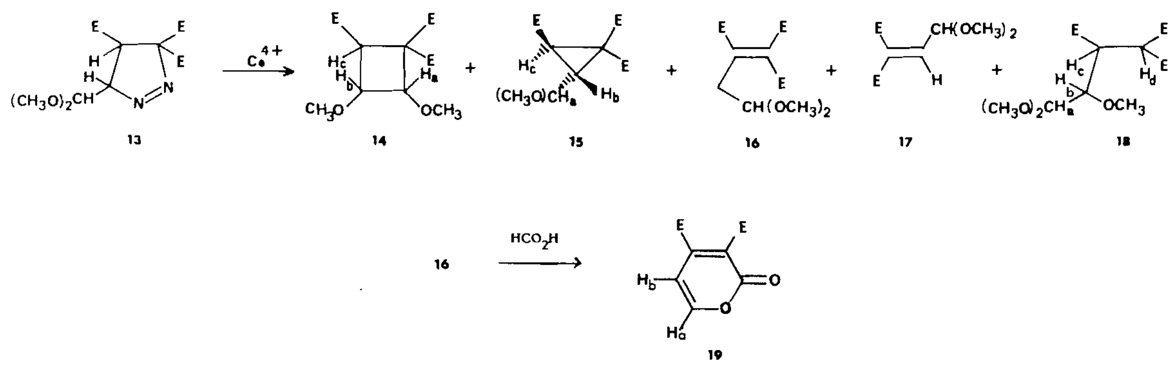

SCHÉMA 5

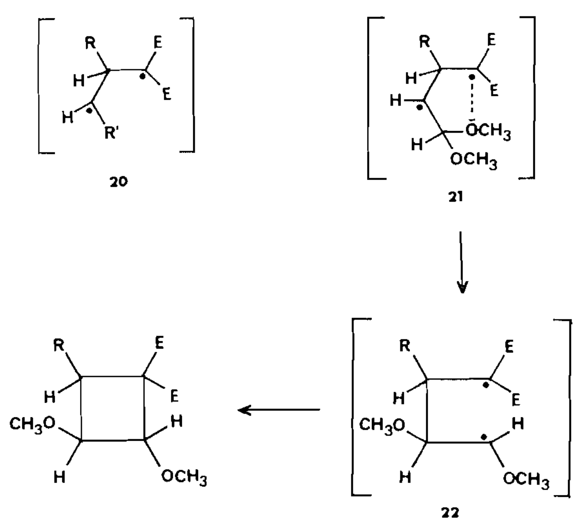

SCHÉMA 6

propanes (2) alors que pour R' = $CH(OCH_3)_2$, la migration exclusive de R est observée. On peut envisager dans ce dernier cas, une interaction entre le doublet de l'un des atomes d'oxygène acétalique et le site radicalaire à caractère électrophile que constitue le carbone portant les deux groupes esters (intermédiaire **21**). Il n'est pas surprenant dans ces conditions d'observer des réactions différentes.

2. Lorsque pour des raisons électroniques (dans le cas du produit **13** (R = CO_2Me) ou stériques (vraisemblablement dans le cas du produit **8**) le groupement R ne peut plus migrer, on observe une nouvelle voie d'évolution avec formation de cyclobutanes, évolution pour laquelle nous proposons le mécanisme suivant: une migration-1,2 d'un OCH_3 au niveau du biradical-1,3 intermédiaire **21** conduirait au biradical-1,4 **22** et serait suivie d'une fermeture en dérivé cyclobutanique (schéma 6).

Remarque: Le composé **18** correspond à l'addition (au moins formelle) de méthanol sur le biradical **21**. L'origine de **17** n'a pu être expliquée jusqu'à présent.[3]

En conclusion, les résultats précédents montrent que l'on peut moduler l'évolution des pyrazolines dérivées du diazoacétal. Si la photolyse conduit généralement aux cyclopropanes correspondants, les réactions avec Ce^{4+} donnent des produits de structure différente. Elles ouvrent ainsi une nouvelle voie d'accès à des pyrones électrophiles, composés dont l'intérêt en synthèse a été mentionné à diverses reprises dans la littérature. Une voie d'évolution originale conduisant à des dérivés cyclobutaniques a par ailleurs été mise en évidence.

Partie expérimentale

Les indications générales sont identiques à celles données précédemment (1).

1. *Pyrazolines-1*

(a) *Les pyrazolines 3α, 3β, 8 et 13* ont été décrites précédemment (1). La pyrazoline **3γ** est préparée par réaction du diazoacétal avec le méthoxyéthylidène malonate de méthyle (11).

(b) *Pyrazoline 3δ*

À 1 g ($4,1 \times 10^{-3}$ mol) de cinnamylidène malonate de méthyle (12), on ajoute sans solvant 1,1 équiv. de diazoacétal; le mélange est abandonné pendant 24 h à la température ambiante. La transformation du cinnamylidène malonate de méthyle est quantitative; **3δ** (huile jaune pâle) est caractérisée uniquement à l'aide de la rmn. **3δ**: rmn (C_6D_6) δ: 7,25–6,95 (m, aromatique), 6,70 (dd, PhC*H*=, *J* = 15,8 et 0,7), 5,97 (dd, PhCH=C*H*, *J* = 8,6), 4,95 (dd, H_b, J_{bc} = 7,4), 4,79 (d, H_a, J_{ab} = 3,8), 3,97 (m, H_c), 3,55 (3H), 3,25 (3H), 3,20 (3H) et 3,18 (3H)(OCH_3).

La présence de signaux à 6,37 ppm (d, *J* = 15,8 Hz) et à 5,92 (dd,

[3]Lors de la synthèse de la pyrazoline **13** (1) le spectre de rmn ^1H (80 MHz) du produit brut ne permet pas d'exclure la présence en faible quantité (~5%) d'un autre isomère résultant de l'orientation inverse de la cycloaddition. La rétrocycloaddition du diazoacétal pourrait alors expliquer la formation de **17**.

J = 10,6 et 15,8 Hz) indique vraisemblablement l'existence d'un second diastéréoisomère en faible quantité (<10%).

2. *Oléfines 4*

4α: À une solution de 850 mg (2,95 × 10^{-3} mol) de la pyrazoline **3**α dans 5 cm^3 d'acétone, on ajoute 100 mg (1,8 × 10^{-4} mol; 0,06 équiv.) de $Ce(NH_4)_2(NO_3)_6$. Maintenu 3 h à 30°C, le mélange est repris avec 75 cm^3 d'éther et lavé à l'eau (2 fois 50 cm^3) puis séché sur Na_2SO_4.

Après distillation du solvant, le mélange réactionnel est purifié d'abord sur une courte colonne de chromatographie (SiO_2, éluant éther – éther de pétrole 1:1) puis par distillation au four tubulaire: 95°C (3 × 10^{-3} Torr; 1 Torr = 133,3 Pa). On obtient 600 mg de **4**α (Rdt = 78%); ir (film liquide) ν: 1724 (C=O), 1640 (C=C). *Anal.* calc. pour $C_{12}H_{20}O_6$: % C 55,38, H 7,69; tr.: C 55,3, H 7,7.

De la même manière (voir tableau 1) nous avons préparé les oléfines:

4β: 135°C (4 × 10^{-3} Torr); Rdt = 77%; ir (film liquide) ν: 1720 (C=O), 1642 (C=C). *Anal.* calc. pour $C_{16}H_{20}O_6$: % C 62,34, H 6,49; tr.: C 62,2, H 6,6.

4γ: 110°C (8 × 10^{-4} Torr); Rdt = 50%; ir (film liquide) ν: 1728 (C=O), 1648 (C=C). *Anal.* calc. pour $C_{11}H_{18}O_7$: % C 50,38, H 6,87; tr.: C 50,1, H 7,1.

4δ: 195°C (3 × 10^{-3} Torr); Rdt = 75%; ir (film liquide) ν: 1722 (C=O), 1676 et 1636 (C=C). Spectre de masse: masse moléculaire calculée pour $C_{18}H_{22}O_6$: 334,142; trouvée: 334,140.

3. *Pyrones 5*

5α: À 600 mg (2,3 × 10^{-3} mol) de l'oléfine **4**α, on ajoute 1,2 g (2,61 × 10^{-2} mol) de HCO_2H pur, le mélange est maintenu à 80°C pendant 2 h. Après distillation de HCO_2Me et de HCO_2H, le produit solide obtenu est recristallisé dans l'éther, F = 74–75°C. On obtient 300 mg de **5**α (Rdt = 71%). ir (Nujol) ν: 1736 (large, C=O) et 1696 (large, C=O et C=C). *Anal.* calc. pour $C_9H_{10}O_4$: % C 59,34, H 5,49; tr.: C 59,3, H 5,3.

De la même manière (voir tableau 1) nous avons préparé les pyrones:

5β: F = 94–95°C (éther); Rdt = 83%; ir (Nujol) ν: 1780, 1762 (C=O) et 1704 (large, C=O et C=C). *Anal.* calc. pour $C_{13}H_{10}O_4$: % C 67,83, H 4,35; tr.: C 67,7, H 4,4.

5γ: F = 149–150°C (méthanol); Rdt = 71%; ir (Nujol) ν: 1736 (large) et 1704 (C=O) et 1630 (C=C). *Anal.* calc. pour $C_8H_8O_5$: % C 52,17, H 4,35; tr.: C 51,9, H 4,3.

5δ: F = 109°C (méthanol–éther 1:1); Rdt = 47%; ir (Nujol) ν: 1756 et 1704 (C=O) et 1640 (C=C). *Anal.* calc. pour $C_{15}H_{12}O_4$: % C 70,3, H 4,69; tr.: C 70,0, H 4,8.

4. *Composés **9**, **10** et **11***

À 1,6 g (5,3 × 10^{-3} mol) de la pyrazoline **8** en solution dans 7 cm^3 d'acétone, on ajoute 300 mg (5,4 × 10^{-4} mol; 0,1 équiv.) de $Ce(NH_4)_2(NO_3)_6$. Après 20 h à température ambiante, on ajoute 100 cm^3 d'éther. La phase organique est lavée à l'eau (2 fois 50 cm^3) puis séchée sur Na_2SO_4. Après élimination de l'éther on obtient 1,40 g d'un mélange dont les constituants sont séparés à l'aide de la chromatographie sur couche mince (SiO_2, mélange éluant: éther – éther de pétrole 1:1, 2 élutions).

9: R_f = 0,50; F = 74–75°C (éther); Rdt = 49%; ir (Nujol) ν: 1760 et 1712 (C=O). *Anal.* calc.: % C 57,35, H 7,35; tr.: C 57,1, H 7,5.

10: R_f = 0,30, 125°C (0,05 Torr) (l); Rdt = 15%.

11: R_f = 0,25, 130°C (0,004 Torr) (l); Rdt = 13%.

5. *Pyrone **12***

Une solution de 400 mg (1,5 × 10^{-3} mol) de la lactone **11** dans 5 g (0,11 mol) de HCO_2H est maintenue à reflux pendant 5 h. Après distillation de HCO_2H en excès et de HCO_2Me, le solide obtenu est recristallisé dans un mélange acétone–éther. On obtient 210 mg de la pyrone **12**; F = 220°C; Rdt = 79%; ir (Nujol) ν: 1794, 1772 et 1720 (C=O); rmn ($CDCl_3$ + CF_3CO_2H) δ: 7,97 (d, H_a, J_{ab} = 5,2), 6,68 (d, H_b), 1,69 (s, 6H, C(CH_3)$_2$). Spectre de masse: masse moléculaire calculée pour $C_9H_8O_4$: 180,042; trouvée: 180,043.

6. *Composés **14–18***

À 2,8 g (8,8 × 10^{-3} mol) de **13** dissous dans 7 cm^3 d'acétone, on ajoute 400 mg (0,08 équiv.) de $Ce(NH_4)_2(NO_3)_6$; le mélange réactionnel est abandonné à 30°C. Après 8 h, on ajoute 200 cm^3 d'éther, on lave à l'eau (2 fois 75 cm^3) et on sèche sur Na_2SO_4. Après élimination de l'éther et distillation au four tubulaire 125–130°C (3 × 10^{-3} Torr), on obtient 2,35 g d'un mélange des composés **14–18** formés (Rdt = 92%).

Les différents composés ont été séparés à l'aide de la chromatographie sur colonne suivie d'une chromatographie de partage gaz liquide.

La chromatographie sur colonne (70 g de SiO_2, mélange éluant: éther – éther de pétrole 1:2) de 2,50 g du produit brut de la réaction donne 110 mg de **15** (l); 200 mg d'un mélange des composés **15** et **16**; 350 mg de **16** contenant encore un peu de **15**; 250 mg d'un mélange de **15**, **17** et d'un produit **A** qui n'a pas été identifié; 400 mg d'un mélange de **14**, **15**, **17** et **A**; 340 mg d'un mélange de **14**, **16**, **17** (l) et **18** et enfin 270 mg d'un mélange de **14** et **18.**

La chromatographie de partage gaz–liquide des fractions précédentes est effectuée sur une colonne OV 225 (5% sur gas Chrom. Q 80–100 mesh), longueur 5 pieds, diamètre 1/4 pouce. Conditions de la chromatographie: T (injection) = 190°C, T(colonne) = 158°C, T (détecteur) = 200°C, T (collecteur) = 180°C, débit d'H_2 = 125 cm^3/min.

14: temps de rétention = 9 min; ir (film liquide) ν: 1728 (C=O). Spectre de masse: le pic de l'ion moléculaire est trop faible pour que la masse exacte puisse être mesurée. Masse calculée pour $[M - CH_3O]^+$, $C_{11}H_{15}O_7$ 259,082; trouvée: 259,082; pour $[M - CH_3OH]^{+\cdot}$, $C_{11}H_{14}O_7$ 258,074; trouvée: 258,074.

15: temps de rétention = 10,5 min; 105°C (0,01 Torr) (l).

16: temps de rétention = 15 min; ir (film liquide) ν: 1728 (C=O); rmn ($CDCl_3$) δ: 4,56 (t, $CH(OCH_3)_2$, J = 5,6), 3,84 (3H), 3,80 (6H) et 3,35 (6H) (3s, OCH_3), 2,96 (d, 2H, CH_2—C=). Spectre de masse: masse moléculaire calculée pour $C_{12}H_{18}O_8$: 290,100; masse trouvée: 290,100.

18: temps de rétention = 16,7 min; ir (film liquide) ν: 1734 (C=O); rmn ^1H (C_6D_6) δ: 4,63 (d, H_a, J_{ab} = 7,1), 4,35 (d, H_d, J_{cd} = 11,0), 4,00 (dd, H_c, J_{bc} = 2,7), 3,67 (dd, H_b), 3,44 (3H), 3,41 (3H), 3,36 (6H) et 3,24 (6H) (4s, OCH_3); rmn ^{13}C ($CDCl_3$) δ: 171,0, 168,9 et 168,5 (C=O), 105,3 ($CH(OCH_3)_2$), 80,5 ($CHOCH_3$), 60,0, 55,5, 52,8 et 52,1 (OCH_3), 50,8 ($CH(CO_2Me)_2$), 45,8 ($CHCO_2Me$). Spectre de masse: le pic de l'ion moléculaire est trop faible pour que la masse exacte puisse être mesurée. Masse calculée pour $[M - CH_3O]^+$ $C_{12}H_{19}O_8$: 291,108; trouvée 291,110.

Remarque: Le produit **A** de structure inconnue a un temps de rétention de 11,7 min; il représente environ 7% (intégration en chromatographie phase vapeur) du produit brut de la réaction. Un autre produit de structure inconnue (temps de rétention 29 min, abondance environ 3%) est mis en évidence dans le chromatogramme.

7. *Pyrone **19***

À 200 mg (6,9 × 10^{-4} mol) de l'oléfine **16** on ajoute 1 g (32 équiv.) de HCO_2H, le mélange est abandonné à 60°C pendant 6 h. La pyrone **19** est caractérisé uniquement à l'aide de la rmn. Ce composé est instable, il évolue lentement dans le milieu réactionnel et les essais de purification n'ont pas abouti. rmn ($CDCl_3$) δ: 7,60 (d, H_a, J_{ab} = 5,4), 6,62 (d, H_b), 3,92 (s, OCH_3, 6H).

JOHN T. GUPTON, GEORGE HERTEL, GARY DECRESCENZO, CESAR COLON, DONNA BARAN, DAN DUKESHERER, STEVE NOVICK, DENNIS LIOTTA, and JOHN P. IDOUX. Can. J. Chem. **63**, 3037 (1985).

A series of activated polyhalobenzenes and polyhaloheteroaromatic compounds have been reacted with a variety of fluoroalkoxide anions. In most cases, regioselective monosubstitution or polysubstitution was observed. The nature of these monosubstitution and polysubstitution reactions is described.

JOHN T. GUPTON, GEORGE HERTEL, GARY DECRESCENZO, CESAR COLON, DONNA BARAN, DAN DUKESHERER, STEVE NOVICK, DENNIS LIOTTA, et JOHN P. IDOUX. Can. J. Chem. **63**, 3037 (1985).

On a fait réagir une série de polyhalobenzènes et de composés polyhalohétéroaromatiques activés avec divers anions fluoroalcoolates. On observe, dans la plupart des cas, une mono ou une polysubstitution régiosélective. On décrit la nature de ces réactions de mono ou de polysubstitution.

[Traduit par le journal]

In a previous paper (1) we reported that activated monohalobenzenes and monohaloheterocycles could be reacted with fluoroalkoxide anions to produce the corresponding fluoroalkyl ethers. Such factors as the effect of solvent, time, temperature, nature of the leaving group, nature of the nucleophile, and nature of the activating group were discussed. Because of the diverse and important properties of organofluorine compounds (2) and since some of our previously reported fluoroalkyl ethers had been converted into "biologically active" derivatives,[3] we thought it would be useful to define further and delineate the scope of this reaction with regard to polyhalogenated substrates.

In related work, Tiecco *et al.* (3) have recently studied the reaction of polyhalogenated, non-activated benzenes with large excesses of alkanethiol anions in HMPA. In most of the examples reported, polysubstitution was obtained.

Because of our interest in this area we decided to examine the following factors with regard to polyhalocompounds: 1. the feasibility of polysubstitution; 2. the nature of the regiochemistry of a complete isomeric series (six isomers) of activated dihalobenzenes; 3. the halogen selectivity in the reaction; 4. the use of heteroaromatic substrates in the reaction; 5. the effect of the nucleophile in such reactions. The results of this study are reported in the subsequent sections.

Results and discussion

Reactions of activated dihalobenzenes with sodium 2,2,2-trifluoroethoxide

Our previous studies (1) involving the reaction of *o*-, *m*-, and *p*-chlorobenzonitriles and chloronitrobenzenes with sodium 2,2,2-trifluoroethoxide indicated that reaction at all three positions was possible. One would expect, however, that the relative order of reactivity might be *ortho* > *para* > *meta*. In fact, if one examines the reaction of 2,3-dichloronitrobenzene with one equivalent of 2,2,2-trifluoroethoxide (Table 1), the primary product results from substitution at the 2-position. In a like manner, 3,4-dichloronitrobenzene (**1***g*) gives mono substitution at the 4-position, and 2,5-dichloronitrobenzene (**1***d*) monosubstitutes at the 2-position. When the potential reaction sites were chemically equivalent, such as for 2,6-dichlorobenzonitrile (**1***e*) and 3,5-dichlorobenzonitrile (**1***i*), monosubstitution was also observed. When 2,4-dichloronitrobenzene (**1***b*) was examined under these conditions, a mixture of *ortho* and *para* substitution products was obtained in a ratio of 75:25, respectively. In order to make unambiguous structural assignments in these cases, the mono(trifluoroalkoxylated) substances (compounds **2***a*, **2***c*, **2***c'*, **2***f*, **2***g*, **2***i*, **2***j*, and **2***k*) were subjected to catalytic hydrogenolysis (4) to give the non-halogenated derivatives (Scheme 1).

Compounds such as **9** had been previously prepared (1) from the corresponding monohalo compounds and, therefore, a comparison by tlc and nmr of the various hydrogenolysis products enabled a straightforward structural assignment. 2-Chloro-6-fluorobenzonitrile (**1***f*) represented an interesting substrate in that it underwent regioselective reaction at the fluorine bearing carbon which provided a useful application of our previously reported (1) leaving-group reactivity study (NO_2, F > Cl > Br > I). Such a result, therefore, demonstrates the feasibility of selectively displacing one halogen in the presence of a second but different halogen.

The isomeric, activated dihalobenzenes were subsequently subjected to reaction with excess sodium 2,2,2-trifluoroethoxide. 2,6-Dichlorobenzonitrile (**1***e*), and 2,4-dichloronitrobenzene (**1***b*) underwent polysubstitution cleanly to give

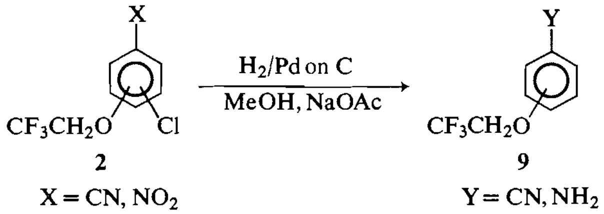
[a] All reactions were run for 15 h in DMF or HMPA at 150°C under nitrogen. These solvents (DMF and HMPA) are, for all practical purposes, interchangeable. The yields in parentheses refer to purified products. All products were subjected to gc analysis on a Shimadzu GC-7A gas chromatograph with a 1/8 in. × 6 ft 3% SB-2401 column at 100–200°C. Under these conditions, the products of the reactions were found to be greater than 90% pure. The only significant impurity which was found in some of the crude reaction mixtures was the respective starting material. When polyfluoroalkoxylation was desired, 2.2–3.0 equivalents of sodium hydride and 2,2,2-trifluoroethanol were used relative to the amount of the dihalobenzene or dihaloheteroaromatic substrate.



SCHEME 1

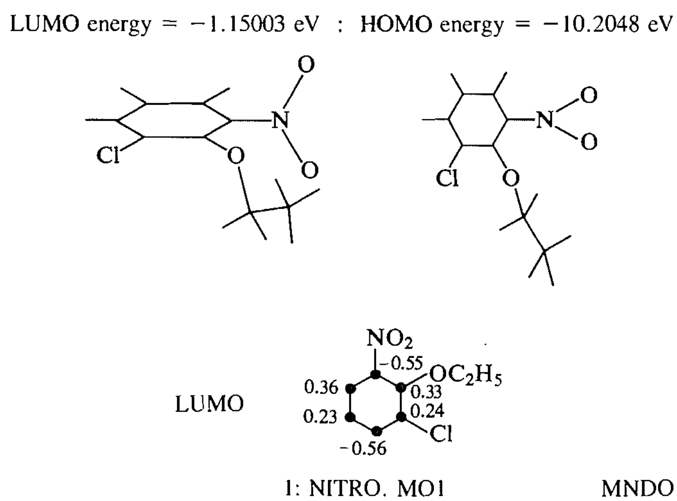


FIG. 1. 1-Chloro-2-ethoxy-3-nitrobenzene.

the respective di(trifluoroalkoxylated) derivatives. 3,4-Dichloronitrobenzene (**1***g*) was found to undergo only monosubstitution which indicated that the trifluoroalkoxy group at the 4-position was having a deactivating effect with regard to further reaction. 3,5-Dichlorobenzonitrile (**1***i*) gave monosubstitution also. Perhaps the most interesting and unusual substrate studied was 2,3-dichloronitrobenzene. This material produced 2,3-di(2,2,2-trifluoroethoxy)chlorobenzene (**2***b*) upon reaction with excess trifluoroethoxide ion. This structural assignment was based on nmr, ir, ms, and combustion analysis data. As a consequence, molecular orbital calculations with full geometric optimization, which indicate that the nitro group is distorted out of the plane of the benzene ring by 87 degrees, have been carried out on 3-chloro-2-ethoxynitrobenzene (Fig. 1). Based on the magnitude of the LUMO coefficients, these calculations further indicate that the preferred site of nucleophilic attack is the carbon bearing the nitro group. Presumably, the chlorine atom exhibits a buttressing effect on the alkoxy group and prohibits it from moving away from the nitro group; as a result, the nitro group must be non-planar with the ring in order to reduce steric repulsions. Work is now in progress to determine if this is a normal reaction for this system with other nucleophiles. 2,5-Dichloronitrobenzene (**1***d*) reacted with excess trifluoroalkoxide to give a gross mixture of products and this transformation was determined to be of little synthetic use.

Reaction of polychloroheterocycles with $NaOCH_2CF_3$

The purpose of this study was to examine the nature of mono(trifluoroalkoxylation) and poly(trifluoroalkoxylation) reactions of polyhaloheterocycles and the substrates studied are reported in Table 2. 3,6-Dichloropyridazine (**3***a*) was found to undergo cleanly both monosubstitution and disubstitution, depending on the amount of trifluoroalkoxide used. The nmr spectrum of the monosubstituted compound was easily differentiated from that of the disubstituted derivative since the monosubstituted pyridazine had two doublets in the aromatic region due to two, non-equivalent, adjacent, heteroaromatic hydrogens. The disubstituted compound was symmetric and, therefore, a singlet integrating for two hydrogens was observed in the aromatic region of the nmr spectrum. 2,4-Dichloropyrimidine (**3***b*) was also found to undergo polysubstitution cleanly but apparently this substance was too reactive to give a single monosubstitution product. 4,7-Dichloroquinoline (**3***c*) underwent selective monosubstitution at the 4-position. This was verified by catalytic hydrogenolysis of the monosubstitution product and subsequent nmr comparison of the material with the 7-chloro-4-(2,2,2-trifluoroethoxy) quinoline (**4***d*). Analysis of the nmr splitting patterns for hydrogens at positions two and three indicated no change from the set of doublets observed in the starting material. The 4,7-dichloroquinoline (**3***c*) was found to be unreactive with regard to further substitution at the 7-position when subjected to reaction with excess trifluoroalkoxide ion. 2,4,6-Trichloropyrimidine (**3***d*) represented an interesting example in that it was found to undergo substitution at all three positions to give a tris(trifluoroalkoxylated) derivative. The final example studied was 2,3-dichloro-5-trifluoromethylpyridine (**3***e*) which was found to react selectively at the 2-position.

Reaction of 3,4-dichloronitrobenzene and 3,6-dichloropyridazine with various sodium fluoroalkoxides

We had previously found (1) that fluoroalkoxide anions possessing more than four fluorines were relatively unreactive toward 4-chlorobenzonitrile. We decided to extend this study to 3,4-dichloronitrobenzene in order to determine the effect of additional halogens on the aromatic substrate. As indicated in Table 3, 1,1,1-trifluoroisopropoxide and 2,2,3,3-tetrafluoropropoxide reacted cleanly with 3,4-dichloronitrobenzene at the 4-position at room temperature in HMPA. Presumably the increased activating effect of the nitro group over the nitrile and the presence of an *ortho* chlorine allows this transformation to take place at room temperature. Perhaps even more interesting, 2,2,3,3,3-pentafluoropropoxide and 2,2,3,3,4,4,4-heptafluorobutoxide reacted with 3,4-dichloronitrobenzene at the 4-position also, albeit at a significantly higher temperature. Both of these alkoxide ions were found to be unreactive with 4-chlorobenzonitrile in our previous study. The significance of the reaction of the latter two nucleophiles is that more highly fluorinated alkoxide anions should also undergo such reactions since inductive effects would be expected to be negligible over a five-atom distance. Therefore, there should in principle be no limitation on this reaction based on the number of fluorines on the nucleophile if one chooses a sufficiently reactive aryl halide.

In order to determine the nature of polysubstitution reactions for such nucleophiles, the reaction of 3,6-dichloropyridazine with excess fluoroalkoxide anion was studied. As indicated in Table 4, 1,1,1-trifluoroisopropoxide and 2,2,3,3-tetrafluoropropoxide were found to give polysubstitution in DMF at 150°C. When dioxane was used as the solvent, both 2,2,3,3,3-pentafluoropropoxide and 2,2,3,3,4,4,4-heptafluorobutoxide were also found to undergo successful polysubstitution reactions. These latter two reactions proved to be of particular significance since they demonstrated that lower reaction temperatures (100°C) and less polar solvents could be successfully

[b]HMPA was used as the solvent in these reactions.

used if one chooses a reasonably reactive heteroaromatic halide as the substrate.

In conclusion, regioselective fluoroalkoxylation and polyfluoroalkoxylation have been achieved with a variety of polyhalogenated aromatic and heteroaromatic systems. Halogen selectivity has also been observed and the presence of additional fluorines in the nucleophile does not seem to affect adversely the nature of such substitution reactions.

Experimental

The following procedure is typical of the experimental conditions used for the reaction of activated aromatic and heteroaromatic compounds with fluorinated alkoxide anions. Infrared spectra were recorded on either a Perkin Elmer Model 1420 infrared spectrometer or a Nicolet MXS FT IR as thin films or Nujol mulls. The nmr spectra were obtained in CCl_4, $DCCl_3$, or Me_2SO-d_6 solutions ($(CH_3)_4Si$ internal standard) at 60 MHz with a Varian EM-360 spectrometer. All boiling points and melting points are uncorrected and melting points were recorded on a Fisher–Johns melting-point apparatus. With regard to the characterization of the reaction products, combustion analyses were carried out on representative samples (2*b*, 2*e*, 2*g*, 2*j*, 4*b*, and 4*c*). Compounds 2*a*, 2*c*, 2*c*′, 2*f*, 2*i*, 2*j*, and 2*k* were converted to substances that we have previously reported (1). Compounds 6*a*, 6*b*, 6*c*, and 6*d* were simple analogs of 2*i* and had the appropriate, and analogous, nmr absorptions. Compounds 8*a*, 8*b*, 8*c*, and 8*d* were simple analogs of 4*b* and had the appropriate, and analogous, nmr absorptions. Compounds 2*d*, 2*h*, 4*a*, 4*d*, 4*e*, and 4*f* had relatively

uncomplicated and unambiguous nmr spectral properties. All reaction products gave nmr, ir, and ms spectra consistent with their assigned structure and their homogeneity was determined by the use of glc or tlc techniques.

3-Chloro-4(2,2,2-trifluoroethoxy)nitrobenzene, **2**i

A dry, three-necked round-bottomed flask equipped with a condenser, thermometer, rubber septum, and magnetic stirrer was placed under a nitrogen atmosphere. Into the flask was placed 1.37 g (0.0286 mol) of a 50% sodium hydride – mineral oil mixture which was subsequently washed with hexane. To the sodium hydride was added 125 mL of DMF (dried over 4A molecular sieves) and 2.86 g (0.0286 mol) of 2,2,2-trifluoroethanol, respectively. The mixture was allowed to stir for 20 min and 5.00 g (0.0260 mol) of 3,4-dichloronitrobenzene was added in one portion. The resulting mixture was heated at reflux (150°C) for 18 h, cooled to room temperature, and the solvent was removed *in vacuo*. The residue was carefully diluted with 100 mL of ice water, extracted with ether (3 × 100 mL), and the combined extracts were washed with water (3 × 30 mL) and dried over anhydrous magnesium sulfate. After removing the drying agents, the organic phase was concentrated *in vacuo* to yield 5.30 g of a dark liquid. This material was distilled (Kugelrohr) to give 3.25 g (58% yield) of a solid, bp 77–78°C at 0.4 Torr (1 Torr = 133.3 Pa) and mp 48–49°C.

3-Chloro-2-(2,2,2-trifluoroethoxy)nitrobenzene, **2**a: bp 60–62°C (0.1 Torr); ir (thin film): 1595, 1535, 1460, 1360, 1290, 1250, 1170, 1080, 1045, 965, 870, 800, 860, 840, and 675 cm^{-1}; nmr ($CDCl_3$) δ: 4.55 (q, J = 8 Hz, 2H), 7.31 (t, J = 8 Hz, 1H), and 7.60–7.97 (m, 2H); mass spectrum, *m/e*: 255, 257 (M^+).

2,3-Di-(2,2,2-trifluoroethoxy)chlorobenzene, **2**b: bp 60°C (0.1 Torr); ir (thin film): 1585, 1480, 1455, 1285, 1265, 1165, 1080, 1050, 965, 895, 865, 770, 735, and 705 cm^{-1}; nmr ($CDCl_3$) δ: 4.40 (q, J = 8 Hz, 4H) and 6.78–7.30 (m, 3H); mass spectrum, *m/e*: 308, 310 (M^+). *Anal.* calcd. for $C_{10}H_7O_2ClF_6$: C 38.92, H 2.29, F 36.94; found: C 39.11, H 2.50, F 37.13.

*2-Chloro-4-(2,2,2-trifluoroethoxy)nitrobenzene (***2**c*) and 4-chloro-2-(2,2,2-trifluoroethoxy)nitrobenzene,* **2**c′

This reaction produced a mixture of *para* (**2**c) and *ortho* (**2**c′) substitution products as determined by glpc analysis. The relative composition was determined to be 75% of the *ortho* substitution product (**2**c′) and 25% of the *para* substitution product (**2**c): bp (mixture) 68–72°C (0.3 Torr); ir (thin film): 1605, 1580, 1530, 1350, 1295, 1250, 1175, 1090, 1060, 980, 970, 915, 840, and 660 cm^{-1}; nmr ($CDCl_3$, mixture of isomers, *ortho* substitution absorptions) δ: 4.53 (q, J = 8 Hz, 2H), 7.08–7.33 (m, 2H), and 7.91 (d, J = 10 Hz, 1H); nmr ($CDCl_3$, mixture of isomers, *para* substitution absorptions) δ: 4.48 (q, J = 8 Hz, 2H), 7.08–7.33 (m, 2H), and 8.05 (d, J = 10 Hz, 1H); mass spectrum, *m/e*: 255, 257 (M^+). The mixture of isomers was further characterized by catalytic hydrogenolysis with Pd on carbon in methanol with sodium acetate. This mixture of *ortho*- and *para*-(2,2,2-trifluoroethoxy) anilines was compared by nmr and tlc to the catalytic hydrogenation products obtained from reduction of the known (1) *o*-(2,2,2-trifluoroethoxy)nitrobenzene and *p*-(2,2,2-trifluoroethoxy)nitrobenzene.

2,4-Di-(2,2,2-trifluoroethoxy)nitrobenzene, **2**d: mp 110–113°C (recrystallized from iPrOH/H_2O); ir (Nujol): 1620, 1520, 1365, 1280, 1185, 970, 860, 840, 815, and 750 cm^{-1}; nmr ($CDCl_3$/acetone-d_6) δ: 4.70 (q, J = 8 Hz, 2H), 4.74 (q, J = 8 Hz, 2H), 6.88 (d of d, J = 8 Hz, J = 2 Hz, 1H), 7.03 (d, J = 2 Hz, 1H), and 8.06 (d, J = 8 Hz, 1H); mass spectrum, *m/e*: 319 (M^+).

2,4-Di-(2,2,2-trifluoroethoxy)benzonitrile, **2**e: mp 109–110°C (recrystallized from iPrOH/H_2O); ir (Nujol): 2240, 1620, 1285, 1180, 1070, 860, 845, 830, and 750 cm^{-1}; nmr ($CDCl_3$/Me_2SO-d_6) δ: 4.70 (q, J = 8 Hz, 2H), 4.78 (q, J = 8 Hz, 2H), 6.83 (d of d, J = 8 Hz, J = 2 Hz, 1H), 7.04 (d, J = 2 Hz, 1H), and 7.64 (d, J = 8 Hz, 1H); mass spectrum, *m/e*: 299 (M^+). *Anal.* calcd. for $C_{11}H_7NO_2F_6$: C 44.16, H 2.36, N 4.68; found: C 44.88, H 2.84, N 4.34.

5-Chloro-2-(2,2,2-trifluoroethoxy)nitrobenzene, **2**f: bp 60°C (0.3 Torr); ir ($CHCl_3$): 1610, 1535, 1485, 1350, 1295, 1260, 1170, 1120, 970, 960, 890, 865, 810, and 660 cm^{-1}; nmr ($CDCl_3$) δ: 4.52 (q, J = 8 Hz, 2H), 7.18 (d, J = 9 Hz, 1H), 7.64 (d of d, J = 2 Hz, J = 9 Hz, 1H), and 7.94 (d, J = 2 Hz, 1H); mass spectrum, *m/e*: 255, 257 (M^+).

2-Chloro-6-(2,2,2-trifluoroethoxy)benzonitrile, **2**g: mp 110–113°C (recrystallized from iPrOH/H_2O); ir (Nujol): 2235, 1590, 1580, 1470, 1270, 1170, 1075, 970, 900, 860, 780, and 710 cm^{-1}; nmr ($CDCl_3$) δ: 4.53 (q, J = 8 Hz, 2H), 6.96 (d of d, J = 1 Hz, J = 8 Hz, 1H), 7.19 (d of d, J = 1 Hz, J = 8 Hz, 1H), and 7.55 (t, J = 8 Hz, 1H); mass spectrum, *m/e*: 237, 235 (M^+). This reaction was run at 90°C as opposed to the normal reaction temperature of 150°C. *Anal.* calcd. for $C_9H_5NOClF_3$: C 45.88, H 2.14, N 5.95; found: C 45.88, H 2.37, N 5.78.

2,6-Di-(2,2,2-trifluoroethoxy)benzonitrile, **2**h: mp 86–90°C (recrystallized from iPrOH/H_2O); ir ($CHCl_3$): 2240, 1600, 1590, 1290, 1260, 1240, 1170, 1130, 715, and 685 cm^{-1}; nmr ($CDCl_3$) δ: 4.53 (q, J = 8 Hz, 4H), 6.88 (d, J = 8 Hz, 2H), and 7.63 (t, J = 8 Hz, 1H); mass spectrum, *m/e*: 299 (M^+).

3-Chloro-4-(2,2,2-trifluoroethoxy)nitrobenzene, **2**i: bp 77–78°C (0.4 Torr); mp 48–49°C; ir (CCl_4): 1590, 1525, 1490, 1345, 1290, 1250, 1170, 1075, 970, 900, and 860 cm^{-1}; nmr ($CDCl_3$) δ: 4.58 (q, J = 8 Hz, 2H), 7.10 (d, J = 8 Hz, 1H), 8.30 (d of d, J = 8 Hz, J = 2 Hz, 1H), and 8.40 (d, J = 2 Hz, 1H); mass spectrum, *m/e*: 257, 255 (M^+).

3-Chloro-4-(2,2,2-trifluoroethoxy)benzonitrile, **2**j: mp 74–75°C (recrystallized from MeOH/H_2O); ir (Nujol): 2230, 1595, 1495, 1310, 1295, 1255, 1180, 1085, 975, 900, 860, and 810 cm^{-1}; nmr ($CDCl_3$) δ: 4.52 (q, J = 8 Hz, 2H), 7.08 (d, J = 8 Hz, 1H), and 7.48–7.90 (m, 2H); mass spectrum, *m/e*: 237, 235 (M^+). *Anal.* calcd. for $C_9H_5NOF_3Cl$: C 45.88, H 2.14, N 5.95; found: C 46.06, H 2.30, N 5.89.

3-Chloro-5-(2,2,2-trifluoroethoxy)benzonitrile, **2**k: bp 62–64°C

(0.1 Torr); ir (Nujol): 2215, 1590, 1430, 1290, 1260, 1160, 1080, 970, 860, 695, and 670 cm^{-1}; nmr ($CDCl_3$) δ: 4.42 (q, J = 8 Hz, 2H) and 7.07–7.44 (m, 3H); mass spectrum, m/e: 235, 237 (M^+).

3-Chloro-6-(2,2,2-trifluoroethoxy)pyridazine, 4a: bp 62–65°C (0.3 Torr) ir (Nujol): 1585, 1410, 1265, 1165, 1050, 960, 860, 835, and 720 cm^{-1}; nmr ($CDCl_3$) δ: 4.96 (q, J = 8 Hz, 2H), 7.20 (d, J = 10 Hz, 1H), and 7.58 (d, J = 10 Hz, 1H); mass spectrum, m/e: 212, 214 (M^+).

3,6-Di-(2,2,2-trifluoroethoxy)pyridazine, 4b: mp 79–83°C; ir (Nujol): 1470, 1370, 1280, 1250, 1175, 1055, 960, 870, 840, 690, 655, and 630 cm^{-1}; nmr ($CDCl_3$) δ: 4.90 (q, J = 8 Hz, 4H) and 7.18 (s, 2H); mass spectrum, m/e: 276 (M^+). *Anal.* calcd. for $C_8H_6N_2O_2F_6$: C 34.79, H 2.19, N 10.15; found: C 35.59, H 2.58, N 9.89.

2,4-Di-(2,2,2-trifluoroethoxy)pyrimidine, 4c: bp 53°C (0.3 Torr); ir (thin film): 1590, 1465, 1450, 1420, 1380, 1270, 1170, 1110, 1060, 985, 960, 855, 820, 695, and 670 cm^{-1}; nmr ($CDCl_3$) δ: 4.82 (q, J = 8 Hz, 4H), 6.53 (d, J = 6 Hz, 1H), and 8.35 (d, J = 6 Hz, 1H); mass spectrum, m/e: 276 (M^+). *Anal.* calcd. for $C_8H_6N_2O_2F_6$: C 34.79, H 2.19, N 10.15; found: C 35.10, H 2.29, N 9.53.

7-Chloro-4-(2,2,2-trifluoroethoxy)quinoline, 4d: mp 93–97°C; ir (Nujol): 1620, 1590, 1565, 1505, 1380, 1120, 1295, 1265, 1165, 1130, 970, 905, 870, 860, 850, 825, 760, and 680 cm^{-1}; nmr ($CDCl_3$) δ: 4.60 (q, J = 8 Hz, 2H), 6.70 (d, J = 5 Hz, 1H), 7.55 (d of d, J = 2 Hz, J = 5 Hz, 1H), 8.02–8.40 (m, 2H), and 9.80 (d, J = 5 Hz, 1H); mass spectrum, m/e: 261, 263 (M^+).

2,4,6-Tri-(2,2,2-trifluoroethoxy)pyrimidine, 4e: bp 60–63°C (0.07 Torr); ir (thin film): 1610, 1585, 1440, 1420, 1380, 1270, 1175, 1125, 1080, 960, 860, 825, 695, and 665 cm^{-1}; nmr ($CDCl_3$) δ: 4.80 (q, J = 8 Hz, 2H), 4.84 (q, J = 8 Hz, 4H), and 6.13 (s, 1H); mass spectrum, m/e: 374 (M^+).

3-Chloro-5-trifluoromethyl-2-(2,2,2-trifluoroethoxy)pyridine, 4f: bp 35–37°C (0.8 Torr); ir (thin film): 1605, 1480, 1450, 1415, 1340, 1280, 1260, 1170, 1140, 1085, 1055, 965, 920, 860, 760, 720, and 660 cm^{-1}; nmr ($CDCl_3$) δ: 4.92 (q, J = 8 Hz, 2H), 8.01 (d, J = 2 Hz, 1H), and 8.44 (d, J = 2 Hz, 1H); mass spectrum, m/e: 279, 281 (M^+).

3-Chloro-4-(1,1,1-trifluoroisopropoxy)nitrobenzene, 6a: bp 70–82°C (0.15 Torr); ir (thin film): 1585, 1525, 1485, 1350, 1270, 1185, 1165, 1090, 1055, 1020, 940, 900, 755, and 670 cm^{-1}; nmr ($CDCl_3$) δ: 1.65 (d, J = 7 Hz, 3H), 4.90 (hept, J = 7 Hz, 1H), 7.17 (d, J = 9 Hz, 1H), 8.23 (d of d, J = 3 Hz, J = 9 Hz, 1H), and 8.38 (d, J = 3 Hz, 1H); mass spectrum, m/e: 269, 271 (M^+).

3-Chloro-4-(2,2,3,3-n-tetrafluoropropoxy)nitrobenzene, 6b: bp 77–87°C (0.15 Torr); ir (thin film): 1585, 1525, 1490, 1350, 1285, 1205, 1125, 1070, 900, 840, 820, 745, and 645 cm^{-1}; nmr ($CDCl_3$) δ: 4.57 (t, J = 12 Hz, 2H), 6.20 (t of t, J = 5 Hz, J = 53 Hz, 1H), 7.10 (d, J = 8 Hz, 1H), and 8.10–8.33 (m, 2H); mass spectrum, m/e: 287, 289 (M^+).

3-Chloro-4-(2,2,3,3,3-n-pentafluoropropoxy)nitrobenzene, 6c: bp 80–92°C (0.2 Torr); ir (thin film): 1585, 1570, 1490, 1350, 1285, 1200, 1150, 1100, 1075, 1015, 900, 820, 740, and 665 cm^{-1}; nmr ($CDCl_3$) δ: 4.60 (t, J = 12 Hz, 2H), 7.05 (d, J = 9 Hz, 1H), 8.18 (d of d, J = 2 Hz, J = 9 Hz, 1H), and 8.30 (d, J = 2 Hz, 1H); mass spectrum, m/e: 305, 307 (M^+).

3-Chloro-4-(2,2,3,3,4,4,4-n-heptafluorobutoxy)nitrobenzene, 6d: bp 60–80°C (0.1 Torr); ir (thin film): 1585, 1520, 1490, 1350, 1335, 1275, 1185, 1125, 1075, 1020, 920, 900, 740, and 650 cm^{-1}; nmr ($CDCl_3$) δ: 4.72 (t, J =12 Hz, 2H), 7.17 (d, J = 9 Hz, 1H), 8.30 (d of d, J = 9 Hz, J = 2 Hz, 1H), and 8.42 (d, J = 2 Hz, 1H); mass spectrum, m/e: 355, 357 (M^+).

3,6-Di-(1,1,1-trifluoroisopropoxy)pyridazine, 8a: bp 72–75°C (0.1 Torr); ir (thin film): 1440, 1380, 1360, 1265, 1180, 1160, 1110, 1090, 1020, 935, 840, 670, and 635 cm^{-1}; nmr ($CDCl_3$) δ: 1.45 (d, J = 7 Hz, 6H), 5.82 (hept, J = 7 Hz, 2H), and 7.08 (s, 2H); mass spectrum, m/e: 304 (M^+).

3,6-Di-(2,2,3,3-n-tetrafluoropropoxy)pyridazine, 8b: bp 55–75°C (0.1 Torr); ir (thin film): 1460, 1440, 1400, 1270, 1200, 1110, 1050, 945, 835, and 680 cm^{-1}; nmr ($CDCl_3$) δ: 4.83 (t, J = 12 Hz, 4H), 6.00 (t of t, J = 5 Hz, J = 53 Hz, 2H), and 7.13 (s, 2H); mass spectrum, m/e: 340 (M^+).

3,6-Di-(2,2,3,3,3-n-pentafluoropropoxy)pyridazine, 8c: bp 70–75°C (0.5 Torr); ir (thin film): 1470, 1445, 1400, 1365, 1350, 1280, 1200, 1150, 1110, 1060, 1015, 940, 840, 725, 670, and 640 cm^{-1}; nmr ($CDCl_3$) δ: 4.97 (t, J = 12 Hz, 4H) and 7.20 (s, 2H); mass spectrum, m/e: 376 (M^+).

3,6-Di-(2,2,3,3,4,4,4-n-heptafluorobutoxy)pyridazine, 8d: bp 74–80°C (1 Torr); ir (thin film): 1470, 1450, 1350, 1280, 1230, 1185, 1130, 1060, 1020, 965, 920, 840, 760, 740, and 650 cm^{-1}; nmr ($CDCl_3$) δ: 5.02 (t, J = 12 Hz, 4H) and 7.20 (s, 2H); mass spectrum, m/e: 476 (M^+).

Catalytic hydrogenolysis of 3-chloro-4-(2,2,2-trifluoroethoxy)benzonitrile, 2j

Into a Parr, low pressure, hydrogenation bottle was placed 0.300 g of 3-chloro-4-(2,2,2-trifluoroethoxy) benzonitrile, 100 mL of anhydrous methanol, 0.585 g of anhydrous sodium acetate, and 0.200 g of 5% Pd on carbon. This mixture was then placed in a Parr hydrogenation apparatus and evacuated several times to remove any traces of oxygen. Hydrogen was introduced into the reaction vessel until a pressure of 55 psi (1 psi = 6.89 kPa) was reached. The resulting mixture was shaken for 4 h, at which point a constant pressure was obtained. The system was then evacuated for 15 min to remove hydrogen and the Pd on carbon was removed by filtration. The filtrate was concentrated *in vacuo* and the residue was partitioned between water (50 mL) and chloroform (50 mL). The chloroform phase was dried over anhydrous magnesium sulfate, filtered, and concentrated *in vacuo*. The residue was subjected to nmr, ir, and tlc analysis (50% ethyl acetate, 50% chloroform on Silica gel 7GF) and subsequently compared with an authentic sample (1) of 4-(2,2,2-trifluoroethoxy) benzonitrile. The crude residue was found to correspond to the authentic sample under these conditions of analysis. Compounds **2***a*, **2***c*, **2***c'*, **2***f*, **2***g*, and **2***k* were treated in a similar fashion and compared with the appropriate authentic samples (1). In cases where the authentic samples were nitro compounds, these standards were also subjected to hydrogenolysis under the above conditions in order that direct comparisons (nmr, ir, and tlc) could be made. In all of the examples studied, the hydrogenolysis products and the respective authentic samples were found to be identical. Compound **4***d*, Table 2, was also subjected to analogous hydrogenolysis conditions.

Lithium triethylborohydride was shown to react with methyl 4,6-*O*-benzylidene-α-D-hexopyranoside 2- and 3-tosylates, and 2,3-ditosylates, in the *manno*, *allo*, and *altro* configurational series both by O—S fission (*O*-desulfonylation) and by C—O fission (*C*-desulfonyloxylation), to produce carbinol and deoxy functions, respectively. The results were compared with those previously obtained with the corresponding *gluco* and *galacto* isomers, and the degree of facility of the cleavage reactions was seen to depend on the position of the sulfonic ester groups and the overall configuration of the molecules. The mechanism of reductive desulfonyloxylation also depended on configuration and was demonstrated to involve intermediary epoxide formation or displacement by internal hydride shift as the principal paths; competing elimination and direct nucleophilic displacement were found to occur in the *allo* series, whereas reduction accompanied by ring contraction has thus far been encountered only in the conformationally less constrained, *cis*-fused acetal system of the *galacto* series. Like the borohydride reagent, lithium aluminum hydride was found to react (though much more slowly) with the *altro* 2,3-ditosylate by the epoxide-mediated mechanism, although the latter hydride is known to desulfonyloxylate the α-D-*gluco*-isomer by a different, intramolecular reduction mechanism.

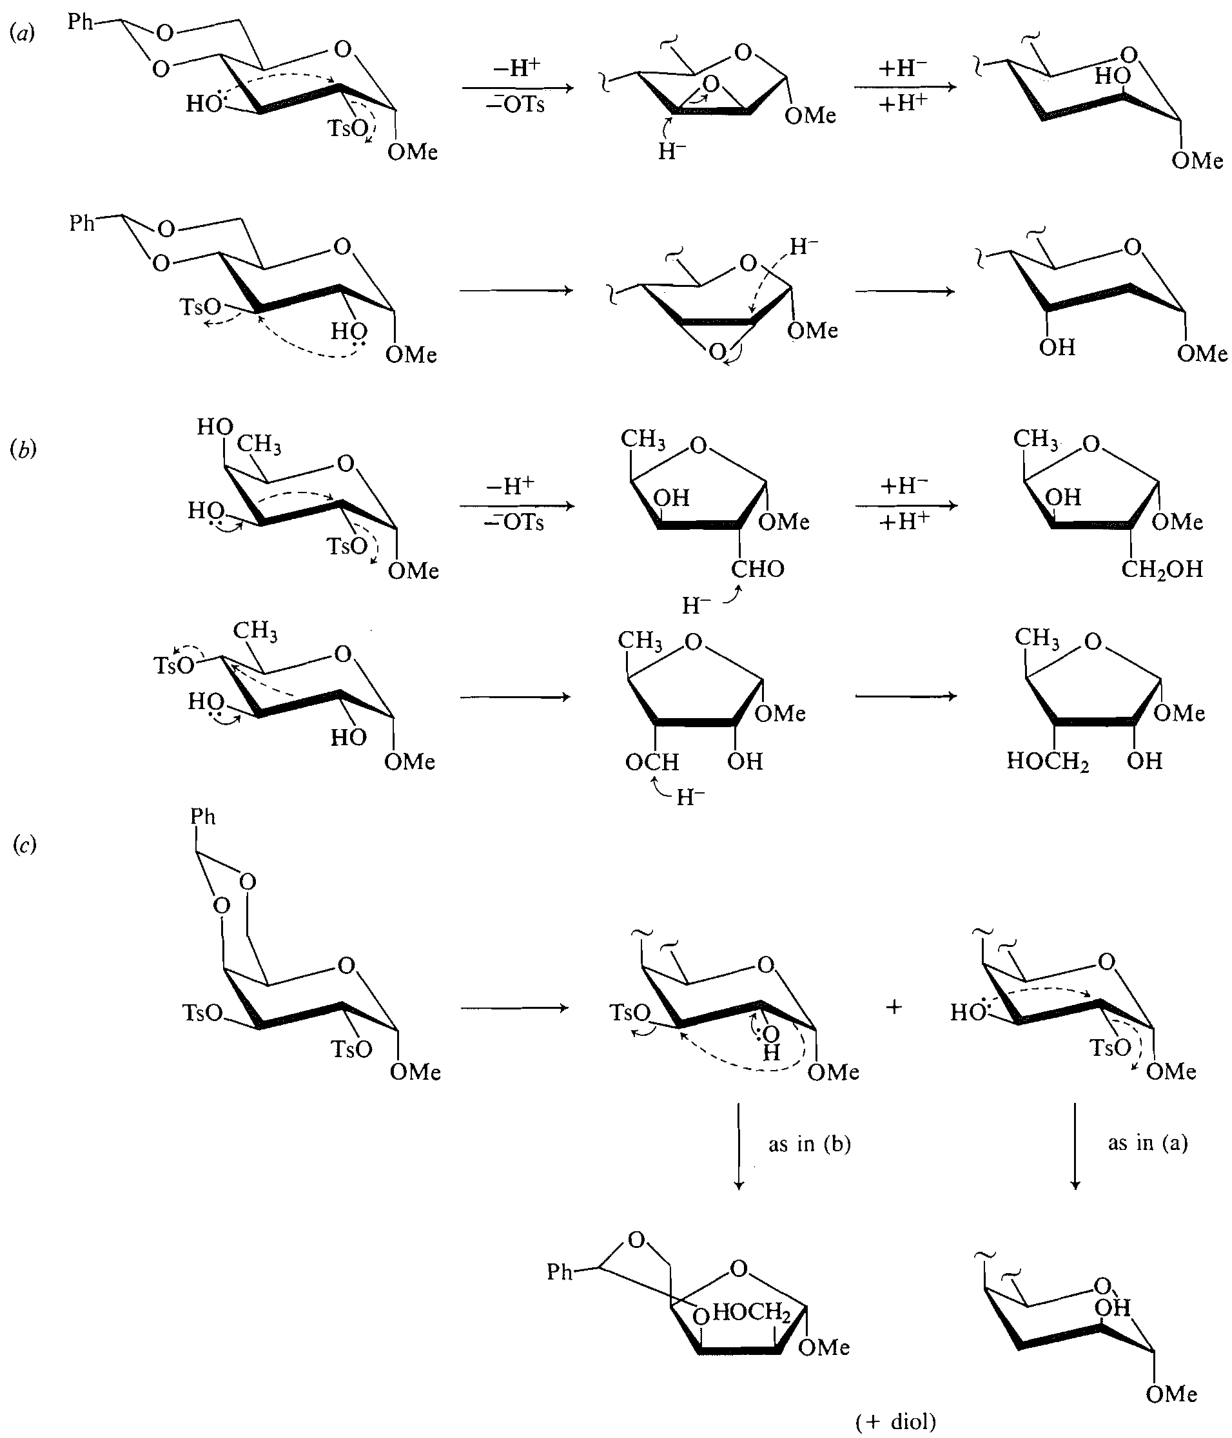
HANS H. BAER et MIROSLAWA MEKARSKA-FALICKI. Can. J. Chem. **63**, 3043 (1985).

Le borohydrure de triéthyllithium réagit avec les tosylates-2 et -3 et avec les ditosylates-2,3 du *O*-benzylidène-4,6 α-D-hexopyranosides de méthyle de configurations *manno*, *allo* et *altro* pour conduire, par fission de la liaison O—S (*O*-désulfonylation) et par fission de la liaison C—O (*C*-désulfonyloxylation), à des fonctions carbinol et désoxy respectivement. On a comparé les résultats à ceux obtenus antérieurement pour les isomères *gluco* et *galacto* correspondants et on a remarqué que le degré de facilité de les réactions de clivage dépend de la position des groupes esters sulfoniques et de la configuration générale des molécules. Le mécanisme principal de la désulfonyloxylation réductrice dépend également de la configuration et on démontre qu'il implique la formation intermédiaire d'un époxyde ou un déplacement par glissement interne d'hydrure. Dans la série *allo*, on note la présence d'une réaction compétitive d'élimination ainsi que celle d'un déplacement nucléophile direct; par ailleurs, une réduction accompagnée d'une contraction de cycle ne se produit que dans la série *galacto* contenant un système acétal *cis*-condensé ayant moins de contrainte conformationnelle. L'alanate de lithium, à l'instar du borohydrure, réagit (bien que beaucoup plus lentement) avec le ditosylate-2,3 *altro* selon un mécanisme impliquant un époxyde intermédiaire en dépit du fait qu'il est connu que ce dernier hydrure conduit à une désulfonyloxylation de l'isomère α-D-*gluco* selon un mécanisme de réduction intramoléculaire différent.

[Traduit par le journal]

Introduction

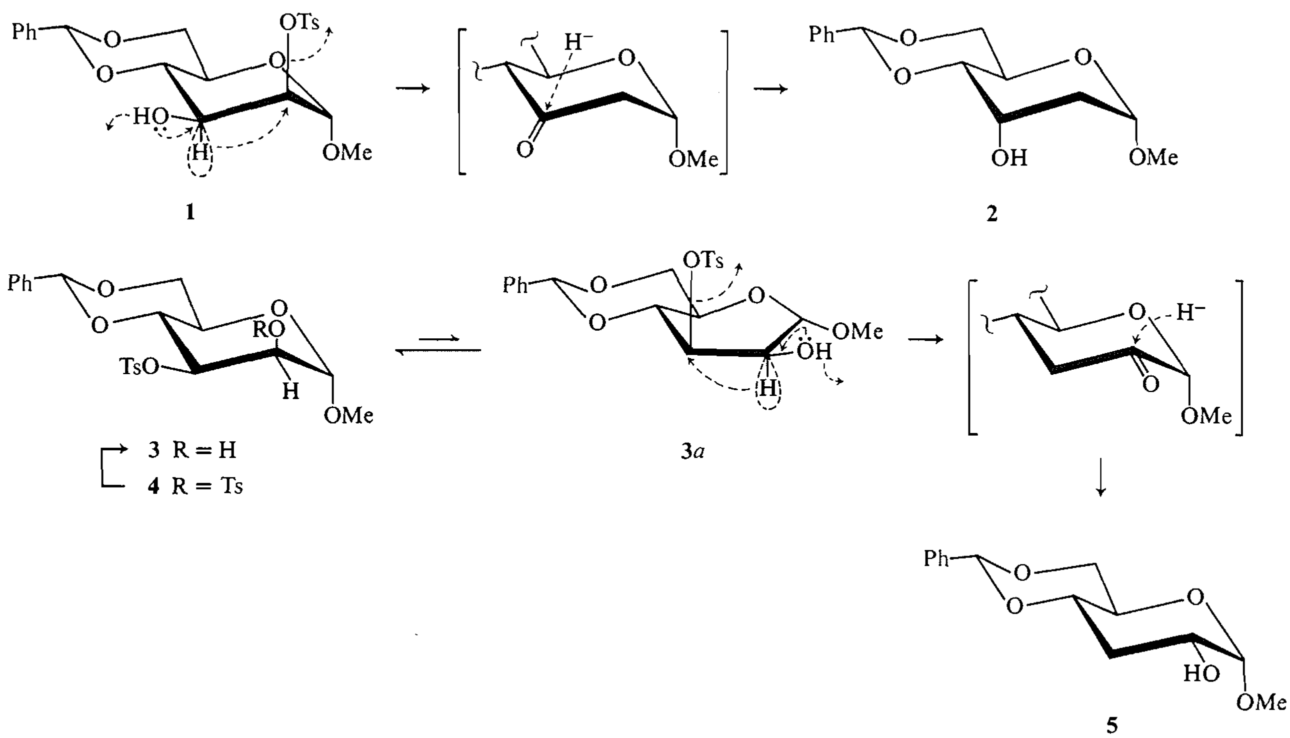
Lithium triethylborohydride (LTBH, Super Hydride®) is a powerful reagent for the deoxygenation of alcohols by reduction of their *p*-toluenesulfonic esters. It has been reported to react smoothly, not only with unhindered, primary tosylates but also with hindered ones as well as with secondary, cycloalkanol tosylates (1). Competing *O*-desulfonylation and (or) eliminative alkene formation are normally negligible or, at least, strongly curtailed in comparison to similar reduction with lithium aluminum hydride. An early application in carbohydrate chemistry (2) demonstrated the ready reduction of 1,2:3,5-di-*O*-methylidene-α-D-glucofuranose 6-tosylate to the corresponding 6-deoxy derivative; however, the secondary esters 6-deoxy-2,3-*O*-isopropylidene-5-*O*-*p*-tolylsulfonyl-α-L-manno- and -α-D-allofuranoside failed to give the desired 5,6-dideoxy derivatives (2). By contrast, we have successfully detosyloxylated secondary tosylates derived from methyl 4,6-*O*-benzylidene-α- and -β-D-glucopyranoside, achieving high yields (>90%) of 2- and 3-deoxyhexopyranosides (3). Our studies were recently extended (4) to several tosylates of a disaccharidic analog, namely, the 4,6:4′,6′-bisbenzylidene-acetal of α,α-trehalose (α-D-glucopyranosyl α-D-glucopyranoside). The results were quite similar in principle, although yields were not as high in these more complex systems. It appeared that the key to straightforward desulfonyloxylation in pyranosidic, secondary tosylates (which obviously are more hindered than cycloalkanol tosylates) is the presence of a free, or potentially free, hydroxyl group adjacent to the sulfonic ester function: When the alcohol was blocked as the methyl ether, C—O fission became very sluggish and S—O fission prevailed. In view of the hydroxy–tosyloxy *trans* relationship that exists in the glucopyranosides referred to, it could reasonably be assumed that desulfonyloxylation occurs by internal displacement via intermediary epoxides that are then reductively cleaved to give deoxyglycosides, and operation of this mechanism could in fact be proved by the isolation of such epoxides (3,4) (Scheme 1(a)). An intermediacy of epoxides has also been invoked recently to explain a number of products observed in the reductive dehalogenation of certain fluorohydrins by LTBH (5), and it is in harmony with studies (6) illustrating the general reactivity of epoxides towards that reagent. It was therefore rather surprising that various hexopyranoside tosylates which possessed a *trans*-vicinal hydroxyl group, but *lacked* the cyclic 4,6-acetal structure, were found to be desulfonyloxylated by LTBH in an entirely different way (7): The predominant course of events led to ring contraction, giving deoxy-*C*-hydroxymethylpentofuranosides (Scheme 1(b)). Although all details of the mechanism are not yet clear, it was shown that epoxides are not implicated in the formation of the rearranged products, and epoxides found in some of the reaction mixtures evidently were precursors for minor proportions of unrearranged deoxyhexopyranosides that arose in some in-



SCHEME 1

stances (7,8). The conclusion must be drawn that, under the conditions of the reaction with LTBH, carbon bond migration in the sense of Scheme 1(b) is favored over epoxide-forming internal displacement, even though the tosylates in question do produce epoxides readily when treated with such bases as sodium alkoxides (9). In view of this, it may be suggested for the case of the aforementioned glucopyranoside 4,6-acetals (Scheme 1(a)) that an intrinsically less-favored epoxide path is taken as an alternative to LTBH-induced ring contraction that, in these structures, woud lead to a highly strained, *trans*-fused bicyclo[4.3.0] system. This notion received support from the behavior of methyl 4,6-*O*-benzylidene-α-D-galactopyranoside 2,3-ditosylate, a less rigid, *cis*-fused bicyclic structure, which gave with LTBH a ring-contracted and an unrearranged product in the ratio 1.7:1 (7) (Scheme 1(c)).

Our interest was thus generated in examining the action of LTBH upon stereoisomeric glycoside tosylates in which no ring contraction should be predicted to occur because of the presence of a *trans*-fused acetal ring, and in which the epoxide option is also absent, owing to a vicinal *cis*-hydroxy – tosyloxy arrangement. Compounds meeting this description are the tosylates of methyl 4,6-*O*-benzylidenehexopyranosides having the *manno* or *allo* configuration, and the question to be answered was whether these would suffer simple and exclusive



SCHEME 2

O-desulfonylation, the *C*-desulfonyloxylation pathways just mentioned being barred, or whether they would be desulfonyloxylated by some other mechanism. Normal S_N2 displacement, known to be facile for cycloalkanol tosylates (1) and shown to be possible, if difficult, for *gluco* analogs (3), might become competitive; alternatively, displacement with involvement of an internal hydride shift might take place, as was recently demonstrated (10) for LTBH-induced deoxygenations of ribonucleoside 2- and 3-monotosylates.

Results and discussion

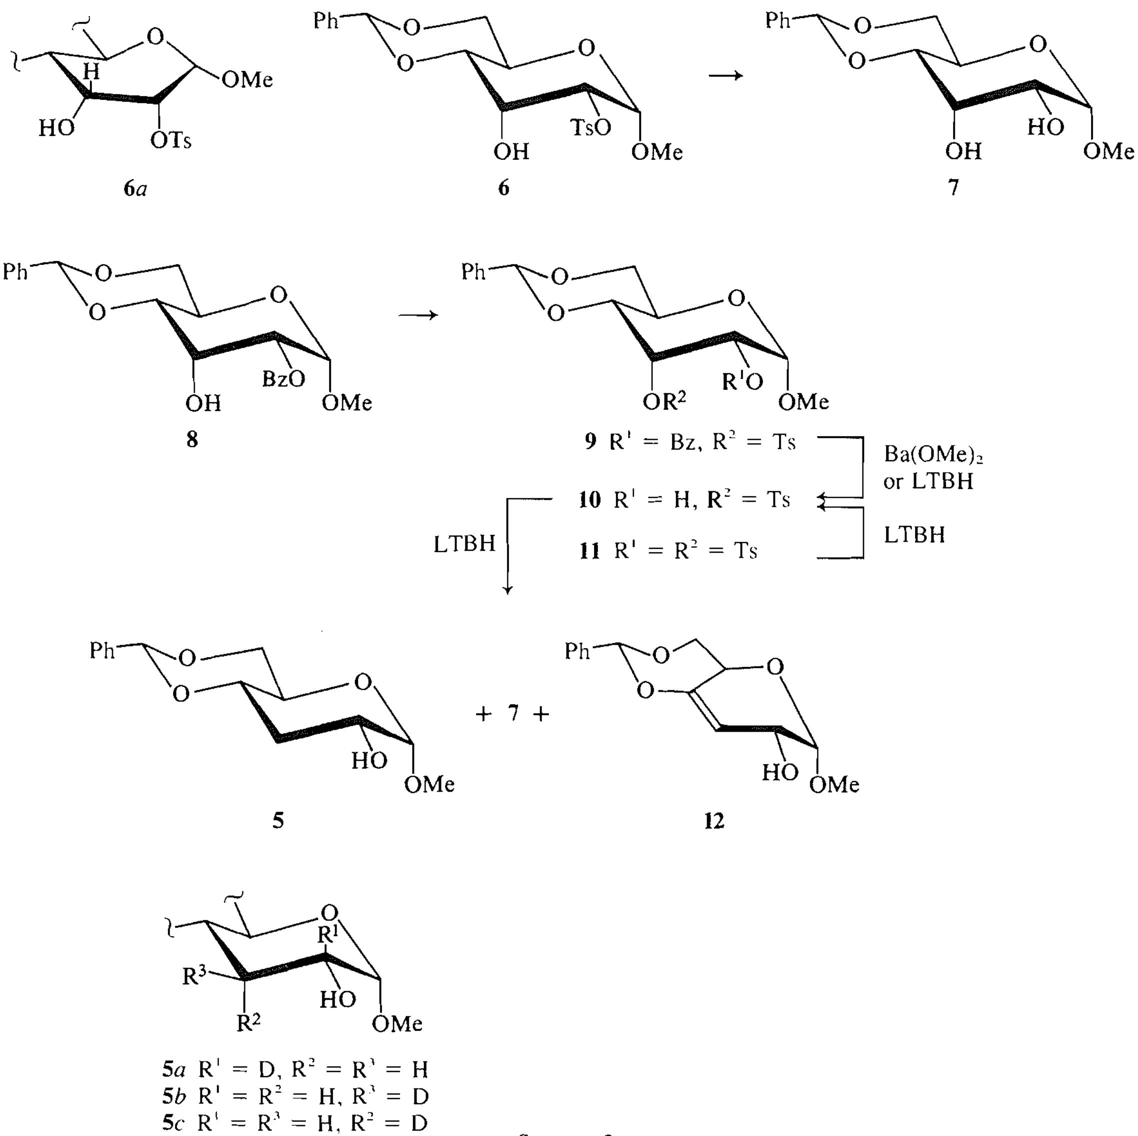
Methyl 4,6-*O*-benzylidene-2-*O*-*p*-tolysulfonyl-α-D-mannopyranoside (**1**) reacted with excess LTBH in boiling oxolane to give, within 30 min, the known 2-deoxy-α-D-*ribo*-hexopyranoside **2**, isolated crystalline in 66% yield. The isomeric 3-tosylate **3** similarly gave, after 90 min, a 77% yield of crystalline 3-deoxy-α-D-*ribo*-hexopyranoside **5**. A 56% yield of the same product was obtained from the 2,3-ditosylate **4** after a reaction time of 2 h. Evidently, *O*-desulfonylation at the more susceptible 2-position was the primary event in the latter case, converting **4** into **3**, which was then desulfonyloxylated as before. The initiating step was familiar from the behavior of α- and β-D-*gluco* analogs (3). The inversion of carbinol configuration in the reactions **1** → **2** and **3** → **5** clearly indicates that the tosyloxy displacement cannot have occurred by external hydride attack, in S_N2 fashion, but must have involved hydride shifts as shown in Scheme 2. The *trans*-diaxially disposed migrating hydrogen atom and leaving group in **1** are particularly conducive to such a process. In **3**, the migration presumably requires the molecule to assume a transition state conformation close to the skew form (**3***a*) shown, but this factor is not a serious impediment and it also applies to the facile epoxide formations represented in Scheme 1(a). On the other hand, S_N2 displacements at the 2- and 3-positions of α-D-mannopyranosides are known to be difficult, which can be explained (11) by considering dipolar and steric interactions that develop in the transition state. The results obtained with the mannosides are thus entirely plausible.[1]

In remarkable contrast to the mannose counterparts, the α-D-*allo* 2-tosylate **6** under the same reaction conditions underwent seemingly complete *O*-desulfonylation, producing within 75 min the parent diol **7**, which was isolated crystalline in 87% yield. No deoxyglycoside was detected. In order to incur a hydride shift with concomitant *C*-desulfonyloxylation, **6** would presumably have to attain the skew boat conformation **6***a*, which is the same as **3***a* but, in the present case, would appear to be strongly disfavored as the large 2-tosyloxy substituent is pointing "inwards" at a flagstaff position. This circumstance, coupled with the general ease of S—O fission at the 2-position, may explain the observed result.

To be studied next were the α-D-*allo* 3-tosylate **10** and the 2,3-ditosylate **11**. To prepare these heretofore unknown derivatives, methyl 2-*O*-benzoyl-4,6-*O*-benzylidene-α-D-allopyranoside (**8**) was tosylated to give compound **9**. Methanolysis of **9** in the presence of barium methoxide afforded **10**, which was tosylated to produce **11**.

The alloside esters **10** and **11** proved considerably less reactive toward LTBH than their stereoisomers **3** and **4**, respectively. Treatment of the benzoate **9** with an excess of reductant in boiling oxolane caused rapid removal of the benzoyl group, as was expected, but only traces of products other than **10** were seen, in tlc, after a reaction time of 20 min. Processing at this point gave **10**, isolated crystalline (73% yield) and identical with the product from methanolysis. Prolonged reaction of **10** under the same conditions gave increased amounts of chromatographically visible products, although a substantial proportion of **10** was still recoverable crystalline after 90 min, the

[1] In their article (5) on reduction of organofluorine compounds with LTBH, the authors remarked in passing, with reference to unpublished results, that a hydride shift occurs in the reduction of **1**. No details were provided.



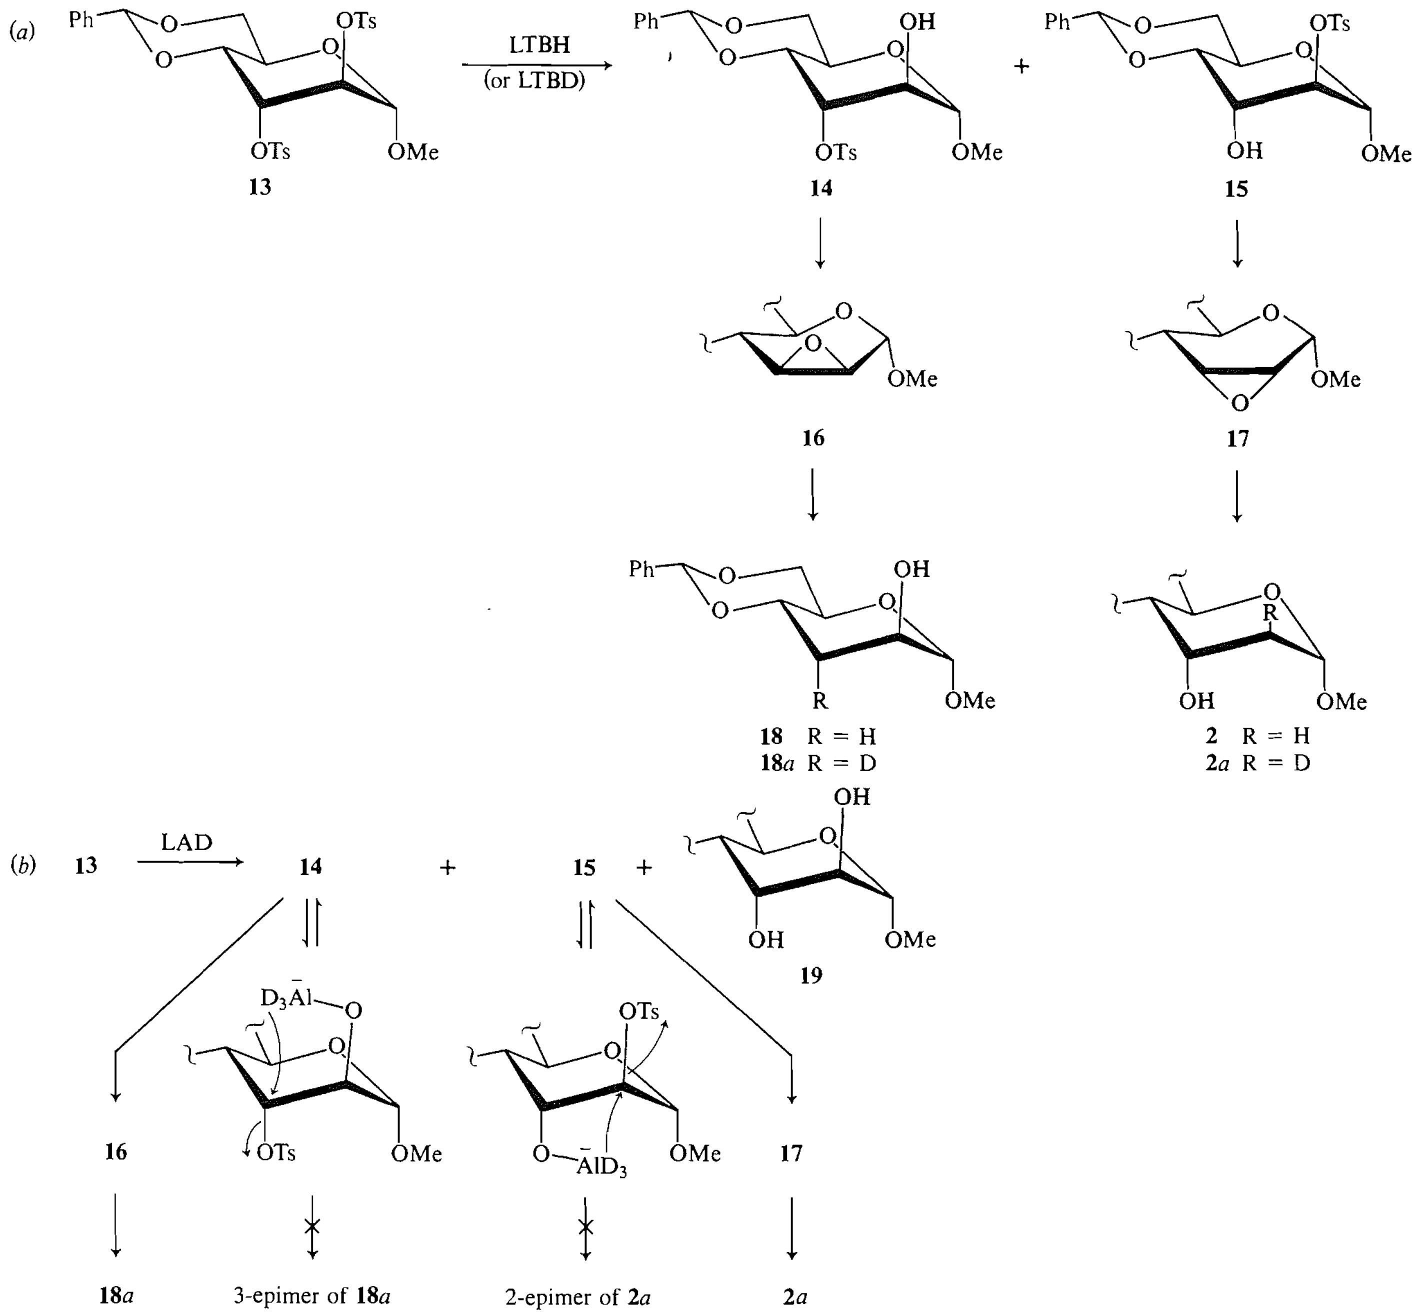
SCHEME 3

period after which the isomer **3** had been practically completely consumed. The tlc revealed formation of slow-moving diol **7** and smaller proportions of two faster-moving components. The same pattern emerged when the ditosylate **11** was used instead of **10** and, upon processing after 24 h, **7** was isolated crystalline in 36% yield, and the other products in yields of 20 and 28%. The first of the latter was identified as the 3-deoxyglycoside **5**, and the second was assigned the 3-enoside structure **12** on the basis of elemental analysis, mass spectrum, and nmr data.

The occurrence of a certain amount of elimination from **10** (or **11**), generating the enoside **12**, was not unexpected. Eliminations in 4,6-*O*-benzylidene-α-D-hexopyranosides bearing an axial 3-sulfonate group, to give such 3-enosides, have been observed previously, as reactions competing with S_N2 displacements (12); a related precedent was the formation of the β-anomer of **12**, which took place with 85% yield on treatment of the β-anomeric, 3-chloro-3-deoxy analog of **10** with sodium benzoate in boiling oxolane for 2 h (13). More surprising were the slow rate at which **5** was formed, and its modest yield, together with a relatively high proportion of diol **7**. One might have anticipated a facile desulfonyloxylation with hydride shift, as the mutual geometric dispositions of the migrating hydrogen atom and the leaving group are the same as those in **1** (but directionally inverse). In order to elucidate the mechanism operating in this case, **10** was reduced with lithium triethylborodeuteride, under otherwise unchanged conditions. The isolated 3-deoxyglycoside was revealed by nmr spectroscopy to be a ~7:3 mixture of the 2-deuterio compound **5***a* and the 3_{eq}-deuterio compound **5***b*, the former originating from reduction of the 2-ulose intermediate that is formed in the expected, hydride shift process, and the latter evidently arising through alternative S_N2 displacement, which was thus shown to compete to a considerable extent in this instance.[2] The formation of diol **7** will receive further comment below.

Finally, the action of LTBH upon methyl 4,6-*O*-benzylidene-2,3-di-*O*-*p*-tolylsulfonyl-α-D-altropyranoside (**13**) was examined. The compound was completely consumed within 1 h at 65°C, and tlc indicated the formation of two less-mobile

[2]Compounds **5***a* and **5***b* are readily distinguishable from their 3_{ax}-deuterio isomer **5***c*, for which proton nmr data have been recorded (14). Compound **5***c* arose from methyl 4,6-*O*-benzylidene-3-*O*-*p*-tolylsulfonyl-α-D-glucopyranoside as the chief product of deoxygenation with *lithium aluminum deuteride* (14); this reductant complexes with O-2 and then delivers a deuteride ion intramolecularly for displacement of the *trans*-oriented, adjacent tosyloxy group, in contradistinction to the action of LTBH (3) that is depicted in Scheme 1(a).



SCHEME 4

products showing roughly comparable spot intensities. The nmr spectra taken after chromatographic separation revealed the slightly preponderant product to be methyl 4,6-*O*-benzylidene-3-deoxy-α-D-*arabino*-hexopyranoside (**18**), and the less abundant product to be the 2-deoxy-α-D-*ribo* isomer **2**. Unlike **11**, **13** did not give its parent diol, nor a product of 3,4-elimination, in detectable amounts. Evidently, facile S—O fission takes place in **13** partly (and somewhat preferentially) on the 2-sulfonate, and partly on the 3-sulfonate group, and it is assumed that the two regioisomeric monoesters (**14** and **15**) so engendered undergo rapid, reductive desulfonyloxylation via the corresponding epoxides (**16** and **17**) to give the deoxyglycosides (Scheme 4(a)) in a manner analogous to the *gluco* isomers (compare Scheme 1(a)). This mechanism was proved by performance of the reaction with lithium triethylborodeuteride, which gave the axially deuterated products **18***a* and **2***a*.

Jarý and his co-workers (15) had previously reported the formation of **18** and **2**, isolated in yields of 60 and 12%, respectively, by reaction of **13** with lithium aluminum hydride (LAH) in boiling oxolane. The reaction was rather sluggish (incomplete after 18 h) and produced a significant proportion (11%) of the parent diol[3] **19**. The authors concluded that O—S fission of the 2-*O*-tosyl group was the prevalent, primary event,

[3]Significant double *O*-desulfonylation giving the diol was in line with the propensity of LAH for this mode of action, noted also in other configurational series (14–17) and confirmed by us (3) in comparison with the action of LTBH. For instance, the mannoside ditosylate **4** was desulfonylated by LAH without accompanying deoxygenation (16), in sharp contrast to its reduction by LTBH reported here.

which was then followed by tosyloxy displacement to give the main product **18**, and they recognized no immediate decision was possible as to whether the reduction proceeded through an intermediary epoxide or, alternatively, by intramolecular hydride transfer in the trihydridioaluminate complex of the carbinol as had been shown to occur (14, 16) in the α-D-*gluco* series (cf. footnote 2), because both mechanisms would in the *altro* series lead to the same products. The latter mechanism was considered "only probable", no epoxide products having been uncovered in the reaction mixture. We repeated the reaction of **13** with LAH as specified (15) and, in addition to confirming the formation of **18**, **2**, and **19**, found direct evidence by tlc and nmr spectroscopy for the intermediacy of the monotosylate **14** and the epoxide **16**. (The presumptive precursors **15** and **17** for the minor product **2** were not detected.) Upon performance of the reaction with lithium aluminum deuteride (LAD), **14** and **16** as well as the axially deuterated deoxyglycoside **18***a* could be isolated and firmly characterized by their 300-MHz ^{1}H nmr spectra. Clearly, the reaction takes place along the epoxide path; the internal displacement mechanism would have given the equatorially deuterated *epimers* of **18***a* and **2***a*, and these were not encountered (Scheme 4(b)).

The comparison that can now be made of the behavior of various methyl 4,6-*O*-benzylidenehexopyranoside 2,3-ditosylates toward LTBH not only illustrates how the different modes of *C*-desulfonyloxylation (via epoxide, by hydride shift, by direct displacement, or with ring contraction) depend on configuration, but it also invites comment upon the regioselectivity of O—S fission which precedes these processes. The *manno* 2,3-ditosylate **4** (Scheme 2) and its *gluco* isomer (3) were *O*-desulfonylated exclusively, or nearly so, at position 2, whereas selectivity was lower in the other series. Thus, the *allo* ditosylate **11** gave a large proportion (36%) of diol **7**, although desulfonylation in the 2-monotosylate **6** was faster than in the 3-monotosylate **10**, with the latter partially undergoing reductive desulfonyloxylation. Similarly, the *altro* isomer **13** must have suffered partial O—S fission in both positions, accounting for the observed products **18** and **2**. Whereas the greater lability of the 2-*O*-tosyl group found in all the series can be explained by an inductive effect of the anomeric center, the decreased stability of the 3-*O*-tosyl group in **11** and **13**, as compared to **4** and the *gluco* isomer, must be attributed to some other cause. It cannot be due solely to the axial disposition since the *galacto* isomer (Scheme 1 (C)) also exhibited diminished selectivity. Rather, there appears to be a correlation between the reactivity at O-3 and the total, non-bonded interactions present in the molecules as determined by their overall configurations. The conformational free energies in α-D-hexopyranosides increase in the order *gluco* < *manno* < *galacto* < *allo* < *altro* and are known to affect the rate of such reactions as, for example, acid hydrolysis (18). They may similarly account for the reactivity differences here discussed.

Experimental

General

General preparative methods and instrumental techniques used for performing reactions with LTBH (purchased from Aldrich Chemical Co. as a 1 *M* solution in oxolane), processing of reaction mixtures, and separation and identification of the products were the same as those previously employed (3, 4, 7). Unless indicated otherwise, optical rotations were measured at 25°C for chloroform solutions, and the ^{1}H nmr data refer to 300-MHz spectra obtained for solutions in $CDCl_3$ with a Varian XL-300 instrument. Column chromatography and tlc were performed with the following solvent systems (v/v): A, ethyl acetate −hexane, 1:2; B, the same solvents, but 2:3; C, the same, but 1:1; D, the same, but 4:1; E, the same, but 1:5; F, ethyl acetate − chloroform, 1:9; G, the same solvents, but 1:19; and H, the same, but 1:49.

Preparation of the starting glycoside p-*toluenesulfonates*

Authenticity and purity of the starting compounds were ascertained by nmr spectroscopy; see the data in Table 1.

(a) *Known compounds 1, 3, 4, 6, and 13*

Methyl 4,6-*O*-benzylidene-α-D-mannopyranoside (19) was monotosylated by the phase-transfer method (20) to give the *2-tosylate* **1** as a white, amorphous substance showing $[\alpha]_D$ +1.9° (*c* 1.1) in agreement with ref. 20 (+2°), but at variance with the value (−25°) recorded earlier (21).

Monotosylation of the above benzylidenemannoside in homogeneous phase at 0−20°C as directed (22) furnished the *3-tosylate* **3**, mp 149−150°C, $[\alpha]_D$ +19.0° (*c* 5.9) (lit. (22) mp 151−153°C, $[\alpha]_D$ +21°).

Complete tosylation (22) of the same acetal provided the *2,3-ditosylate* **4**, mp 166−168°C, $[\alpha]_D$ −5.7° (*c* 1.8) (lit. (22) mp 163−164°C, $[\alpha]_D$ −5.3°).

The α-D-*allo 2-tosylate* **6** was prepared from the parent methyl 4,6-*O*-benzylidene-α-D-allopyranoside **7** which, in turn, was obtained by reduction and deacylation, with sodium borohydride, of known (23) methyl 2-*O*-benzoyl-4,6-*O*-benzylidene-α-D-*ribo*-hexopyranosid-3-ulose according to the published procedure (24, 25). Compound **7**, obtained as anhydrous crystals from hot abolute ethanol, had mp 176−178°C, $[\alpha]_D$ +126.3° (*c* 1) (lit. (25) mp 173−177°C, $[\alpha]_D$ +117°; lit. (26) mp 167−168°C (from benzene), $[\alpha]_D$ +128°; and lit. (27) mp 175−177°C, $[\alpha]_D$ +117° (in DMF)). Compound **7** is also known as a dihydrate (24, 26). A solution of anhydrous **7** (400 mg), *p*-toluenesulfonyl chloride (300 mg), and *p*-dimethylaminopyridine (12 mg) in dry pyridine (2 mL) was allowed to stand at 0°C for 24 h and for 3 days at 25°C, with further tosyl chloride (500 mg) being added after the second day. Almost complete consumption of **7** (R_f 0.1) and the presence of **6** (R_f 0.5) and **11** (R_f 0.7) was then revealed by tlc (solvent B). The crude material (558 mg) obtained after conventional processing was dissolved in hot ethyl acetate −hexane (1:1), from which the *2-tosylate* **6** (385 mg) crystallized on cooling and addition of the some hexane; yield, 59%; mp 164−165°C, $[\alpha]_D$ +59° (*c* 0.8) (lit. (27) mp 166−167°C, $[\alpha]_D$ +35.6° (in DMF), for **6** prepared in a different way). We also obtained **6**, albeit in lower yield (39%), by applying the phase-transfer procedure for tosylation (20).

The α-D-*altro 2,3-ditosylate* **13** was prepared (28) from its parent diol by conventional tosylation. Recrystallized from ethyl acetate, it showed mp 182−183°C, $[\alpha]_D$ +44° (*c* 0.8) (lit. (28) mp 179°C, $[\alpha]_D$ +46.9° and lit. (15) mp 181−182°C, $[\alpha]_D$ +46.5°).

(b) *Methyl 2-*O*-benzoyl-4,6-*O*-benzylidene-3-*O*-p-tolylsulfonyl-α-D-allopyranoside (9)*

Methyl 2-*O*-benzoyl-4,6-*O*-benzylidene-α-D-*ribo*-hexopyranosid-3-ulose (23) was reduced with sodium borohydride at pH 6−7, to provide (25) methyl 2-*O*-benzoyl-4,6-*O*-benzylidene-α-D-allopyranoside (**8**), mp 105−107°C, $[\alpha]_D$ +73.3° (*c* 0.7) (lit. (25) mp 110−115°C, $[\alpha]_D$ +74°).

A solution of **8** (1.40 g) and *p*-toluenesulfonyl chloride (1.60 g) in chilled pyridine (7.5 mL) was stored at 0°C for 24 h and then at room temperature for 5 days, after which a strong spot for **9** (R_f 0.78) and a weak spot for remnant **8** (R_f 0.67) were seen in tlc (solvent F). Conventional processing of the mixture by treatment with ice water and extraction of the product with chloroform, followed by washing (water), drying, and evaporation of the extract, gave the crude reaction product (1.84 g). This was dissolved in hot ethanol and the solution cooled, whereby a semicrystalline gel separated. Trituration of the gel with ethanol−benzene and processing of the mother liquors gave chromatographically pure **9** (1.45 g, 74%) in several crops, which were washed with small amounts of cold ethanol followed by methanol; mp 165−166°C, $[\alpha]_D$ +67.8° (*c* 0.9). *Anal.* calcd. for $C_{28}H_{28}O_9S$ (540.6): C 62.21, H 5.22, S 5.93; found: C 62.07, H 5.36, S 5.74.

[a]In $CDCl_3$ solution unless otherwise indicated.
[b]Signal multiplicities are indicated as d (doublet), m (multiplet), sx (dt or ddd, appearing as a sextet), and t (triplet). The data refer to first-order analysis. The signals for *Ph*-CH, *O*-Me, and *aryl*-Me were singlets.
[c]Midpoints of the A and B parts (2 protons each) of the aromatic AB system.
[d]In acetone-d_6.
[e]In dimethyl sulfoxide-d_6.
[f]Triplet after D_2O exchange.
[g]Not determined accurately because of crowding with phenyl signals.
[h]Slightly broadened singlet representing a very narrow doublet.
[i]Not determined because of second-order effects.
[j]$J_{1,3} \approx 1$ Hz.

(c) *Methyl 4,6-*O*-benzylidene-3-*O*-*p*-tolylsulfonyl-α-D-allopyranoside (**10**)*

A suspension of **9** (2.6 g) and barium oxide (0.35 g) in dry methanol (130 mL) was boiled under reflux for 30 min, which converted **9** (R_f 0.75) into **10** (R_f 0.45, tlc with solvent C). The solvent was evaporated and the dry residue distributed between water and chloroform, with addition of brine to destabilize the emulsion that tended to form. The organic phase was dried (Na_2SO_4), and concentrated, and the product was recrystallized from methanol or ethanol, to give long needles (1.43 g, 68%), mp 198–199°C (dec.), $[\alpha]_D$ +110.8° (*c* 1). *Anal.* calcd. for $C_{21}H_{24}O_8S$ (436.5): C 57.79, H 5.53, S 7.35; found: C 57.71, H 5.69, S 7.53.

(d) *Methyl 4,6-*O*-benzylidene-2,3-di-*O*-*p*-tolylsulfonyl-α-D-allopyranoside (**11**)*

The monotosylate **10** (0.95 g) in pyridine (11 mL) was treated with *p*-toluenesulfonyl chloride (0.45 g), first at 0°C overnight and then at room temperature for 2 days. Processing with ice water, extraction of the product with chloroform, and evaporation of the washed and dried extract gave crude, crystalline **11** (1.50 g), from which pure **11** (1.05 g, 82%) was obtained by recrystallization from chloroform–ethanol; mp 195–197°C, $[\alpha]_D$ +48.7° (*c* 1.5). *Anal.* calcd. for $C_{28}H_{30}O_{10}S_2$ (590.6): C 56.93, H 5.12, S 10.86; found: C 56.87, H 5.14, S. 11.02.

Reactions of the glycoside p*-toluenesulfonates with LTBH*

(a) *General procedure*

The glycoside tosylate (0.5–2.5 mmol) was dissolved in dry (3,7) oxolane (1 mL per 100 mg of substrate), and 1 *M* LTBH solution was added by syringe, with exclusion of moisture in a reflux apparatus containing an atmosphere of dry nitrogen. The mixture was gently boiled under reflux and progress of the reaction was monitored by tlc on silica gel plates. Amounts of reactants and reaction times are stated in the individual sections, and R_f values refer to tlc using the solvent systems indicated. After completion of the reaction the mixture was allowed to cool, a few milliliters of methanol were carefully introduced to decompose the excess of hydride (until hydrogen evolution ceased), and refluxing was resumed for 10 min. The solution was cooled again, poured with stirring into ice water (50–150 mL), and neutralized against indicator paper with a solution of sodium hydrogen sulfate. (Care was taken not to render the solution acidic.) The mixture was stirred at ambient temperature for several hours (or overnight) and then concentrated under reduced pressure to a small volume, to remove the organic solvent and a large part of the water. The residue was extracted with dichloromethane (3 × 50 mL) or occasionally with chloroform, and the extract washed with water, dried (Na_2SO_4), and evaporated to give the product, which was then purified by crystallization or chromatography as indicated.

(b) *Reaction of 1*

The 2-tosylate **1** (200 mg, 0.46 mmol; R_f 0.7 with solvent C) was converted by LTBH (2 mL) into methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*ribo*-hexopyranoside (**2**) (R_f 0.4) during a reaction period of 30 min. The white solid (120 mg) obtained upon work-up was recrystallized from ethyl acetate to give **2** (98 mg, 80.3%), mp 126–128°C, raised to 128–130°C by another recrystallization; $[\alpha]_D$ +140° (*c* 0.5) (lit. (3) mp 130–131°C, $[\alpha]_D$ +140°); ^{1}H nmr, δ : 7.5 (m, 5H, Ph), 5.61 (s, *Ph*-CH), 4.77 (nm, H-1), 4.31 (dd, $J_{5,6e}$ = 5.0, $J_{6a,6e}$ = 10.1 Hz, H-6e), 4.22 (sx, H-5), 4.17 (m, narrowed after D_2O exchange, H-3), 3.76 (t, $J_{5,6a}$ = $J_{6a,6e}$ = 10.1 Hz, H-6a), 3.59 (dd, $J_{3,4}$ = 2.8, $J_{4,5}$ = 9.5 Hz, H-4), 3.40 (s, 3H, OMe), 3.01 (d, J = 6.7 Hz, removed by D_2O, OH-3), 2.18 (ddd, $J_{1,2e}$ ~ 1, $J_{2e,3}$ = 3.1, $J_{2a,2e}$ = 15 Hz, H-2e), and 1.98 (dt, $J_{1,2a}$ = $J_{2a,3}$ = 3.7, $J_{2a,2e}$ = 15 Hz, H-2a).

(c) *Reaction of 3*

The 3-tosylate **3** (1.13 g, 2.59 mmol; R_f 0.6 with solvent C) was allowed to react with LTBH (12 mL) for 45 min, and for a further 45 min after addition of another 3 mL of reductant. Crude methyl 4,6-*O*-benzylidene-3-deoxy-α-D-*ribo*-hexopyranoside (**5**) (R_f 0.45) was obtained as a white solid (0.70 g), which by recrystallization from ethyl acetate gave pure **5** (531 mg, 77%), mp 189–190°C, $[\alpha]_D$ +121.6° (*c* 0.7) (lit. (3) mp 187°C, $[\alpha]_D$ + 119.5°, and closely similar values (14, 16, 29)). The ^{1}H nmr spectrum confirmed the identity with **5** obtained previously (3); see also section (g).

(d) *Reaction of 4*

The 2,3-ditosylate **4** (1.44 g, 2.44 mmol) was allowed to react with LTBH (20 mL) for 1 h, after which traces of **4** (R_f 0.57, solvent A) were still visible in tlc. Boiling was continued for 50 min with added LTBH (5 mL), and processing then gave **5** (341 mg, 52.5%, after recrystallization from ethyl acetate) whose ^{1}H nmr spectrum was identical with that mentioned under (c); mp 172–173°C, raised to 185–186°C by further recrystallization; $[\alpha]_D$ +119.2° (*c* 0.75). The identity was confirmed, moreover, by ir spectra.

(e) *Reaction of 6*

The 2-tosylate **6** (250 mg, 0.57 mmol; R_f 0.85 with solvent D) was completely consumed after 75 min by reaction with LTBH (3 mL). The product was less polar (R_f 0.2 with solvent C) than the deoxyglycosides **2** and **5**; it was obtained as a white solid (158 mg) following its extraction with chloroform, and was recrystallized from ethanol to give the diol **7** (140 mg, 87%), mp 175–177°C, $[\alpha]_D$ +125.7° (*c* 0.8), with an ir spectrum superposable on that of **7** described in a preceding section.

(f) *Reaction of 9*

The 2-*O*-benzoyl 3-tosylate **9** (500 mg, 0.93 mmol) was treated with LTBH (6 mL) for 20 min, after which tlc (solvent C) indicated complete absence of **9** (R_f 0.8) and showed a strong spot for the 3-tosylate **10** (R_f 0.45), accompanied by weak spots for other products (R_f ~ 0.7 and 0.2). Processing furnished 296 mg (73.3%) of **10** (recrystallized from ethanol), mp 195–196°C (dec.), $[\alpha]_D$ +106° (*c* 0.5). Its ir and ^{1}H nmr spectra were identical with those of the product obtained from **9** by methanolysis.

(g) *Reaction of 10*

The 3-tosylate **10** (400 mg, 0.92 mmol) was allowed to react with LTBH (7 mL) during the course of 1.5 h. The tlc pattern then was similar as under (f). Processing gave a solid mixture of products (286 mg), which by recrystallization from ethanol gave a first crop of crystals, mp 195–196°C (dec.) that proved identical (ir) with starting **10** (109 mg, 27%). A second crop of crystals was a mixture of **10** and the deoxyglycosides **5** and **12**, as judged by comparison of its ir spectrum with the spectra of the pure components. (It was noted that **5** and **10** have similar R_f values of ~0.5 in tlc with solvent C.) The mother liquor showed a spot having R_f 0.2 (**7**).

In a similar experiment, **10** (307 mg, 0.7 mmol) was treated with a 1 *M* solution of lithium triethylborodeuteride (5.6 mL) in oxolane for an extended period of time (8 h). The crude product showed 3 well-separated spots in tlc (solvent C), having R_f 0.6, 0.45, and ~0.2, and the components of the mixture were isolated by column chromatography (10 g of silica gel) using 1:5 ethyl acetate – hexane as the eluant. The fast-moving product was identified by its ir and 300-MHz ^{1}H nmr spectra as **12** (38 mg); compare section (h). The material (47 mg) of intermediate mobility was a mixture of the deuterated analogs **5*a*** and **5*b*** of **5** (approximate ratio, 7:3), as was revealed by the following data.

The 500-MHz ^{1}H nmr data for **5** (in $CDCl_3$), δ: 7.47–7.45 and 7.34–7.32 (m, 2 + 3H, Ph), 5.50 (s, *Ph*-CH), 4.67 (d, $J_{1,2}$ = 3.7 Hz, H-1), 4.25 (dd, splittings[4] 10.3 and 15.9 Hz, H-6e), 3.77 (tdd, collapsing to ddd on D_2O exchange, $J_{1,2}$ = 3.8, $J_{2,3e}$ = 4.8, $J_{2,3a}$ ≈ $J_{2,OH}$ ≈ 11.5 Hz, H-2), 3.70–3.66 (m, 2H, H-5,6a), 3.52 (m, H-4), 3.46 (s, 3H, OMe), 2.29 (dt, $J_{2,3e}$ = $J_{3e,4}$ 4.6, $J_{3a,3e}$ = 11 Hz, H-3e), 2.03 (d, removed by D_2O, $J_{2,OH}$ = 11.3 Hz, OH), and 1.84 (q, $J_{2,3a}$ = $J_{3a,3e}$ = $J_{3a,4}$ = 11.6 Hz, H-3a). For the mixture of **5*a*** and **5*b*** (500 MHz, $CDCl_3$), δ: 4.67 (s for **5*a***, superposed on d, J = 3.5 Hz, for **5*b***, intensity ratio 7:3, H-1), 3.77 (m, ~0.3H, H-2 of **5*b***), 2.28 (dd, ~0.7H, $J_{3e,4}$ = 4.1, $J_{3a,3e}$ = 11.2 Hz, H-3e of **5*a***), 1.84 (t, ~0.7H, $J_{3a,3e}$ = 11.4 Hz, H-3a of **5*a***), and 1.83 (t, ~0.3H, $J_{2,3a}$ = $J_{3a,4}$ = 11.7 Hz, H-3a of **5*b***). The remaining signals were as for **5**.

The 125-MHz ^{13}C nmr data for **5** (in $CDCl_3$), δ: 128.97, 128.19, 126.05 (Ph), 101.64 (*Ph*-C), 98.96 (C-1), 76.19 (C-4), 69.21 (C-6), 67.53 (C-2), 63.81 (C-5), 55.15 (*O*-Me), and 33.68 (C-3). The mixture **5*a*** + **5*b*** showed the same, single peaks for the substituent carbon atoms and C-6, and two sets of signals in ~7:3 ratios for the sugar-ring carbons. Signals for **5*a***: 98.93 (C-1), 76.19 (C-4), 63.80 (C-5), and 33.57 (C-3), with the C-2 signal being absent; note the isotope effects of ^{2}H-2 on C-1 and C-3 (−0.03 and −0.09 ppm). Signals for **5*b***: 98.95 (C-1), 76.12 (C-4), 67.45 (C-2), and 63.78 (C-5); a C-3 signal was not observed. Note the isotope effects of ^{2}H-3 on C-2 and C-4 (−0.08 and −0.07 ppm).

(h) *Reaction of 11*

LTBH (15 mL) was added to a suspension of the 2,3-ditosylate **11** (0.99 g, 1.68 mmol) in oxolane (10 mL), and the mixture was heated to reflux, with magnetic stirring, for 24 h. It then showed 3 strong spots in tlc (solvent C), representing **7** (R_f 0.2), **5** (R_f 0.5), and **12** (R_f 0.65). The latter was a double spot having a violet front part; very faint, more-mobile traces were seen additionally. The product mixture obtained upon processing was chromatographed on a column of silica gel (25 g) by use of solvent E as the eluant. The following fractions (10 mL) were collected: 4–5 (impurities, 3 mg, discarded), 6–13 (**12** with satellite, 110 mg), 14–28 (pure **12**, 30 mg), 29–53 (pure **5**, 89 mg), and, by elution with pure ethyl acetate, a final fraction (large) that contained pure **7** (170 mg).

Fractions 6–13 were crystallized from ethyl acetate – hexane to give pure **12** (92 mg, free from the satellite component), for a total yield of 122 mg (27.5%); mp 150–151°C (151–153°C after recrystallization from ethanol), $[\alpha]_D$ +137.4° (*c* 0.8). The spectral data agreed with the structure of methyl 4,6-*O*-benzylidene-3-deoxy-α-D-*erythro*-hex-3-enopyranoside: ν_{max} (Nujol): 3300 (broad, OH) and 1700 cm^{-1} (C=C fused to acetal ring); ^{1}H nmr, δ: 7.5 and 7.4 (m, 2 + 3H, Ph), 5.56 (s, *Ph*-CH), 5.28 (nm, W_H = 4.8 Hz, H-3), 4.81 (d with broadened lines, $J_{1,2}$ = 4.7, $J_{1,3}$ ~ −0.8 Hz, H-1), 4.43 (broad m: quintet after D_2O exchange, $J_{1,2}$ = 4.7, $J_{2,3}$ ≈ $J_{2,5}$ ≈ 2 Hz, H-2), 4.31 (m, 2H, H-5,6e), 3.73 (dd, J = 12.2 and 12.6 Hz, H-6a), 3.53 (s, 3H, OMe), and 2.23 (br, removed by D_2O, OH); m/z (CI, ether): 265 (M^+ + 1), 247 (M^+ + 1 − H_2O), 233 (M^+ − MeOH). *Anal.* calcd. for $C_{14}H_{16}O_5$ (264.3): C 63.62, H 6.10; found: C 63.62, H 6.07.

The aforementioned, chromatographically homogeneous fractions 29–53 gave crystalline **5** (89 mg, 19.9%), showing up 191–192°C after recrysallization from ethanol; the ir spectrum was congruent with those of the products obtained from **3** and **4** (sections c and d). The crystalline diol **7** (170 mg, 35.9%) gave an ir spectrum superposable on those of an authentic sample and of the product obtained from **6** (section e). It is to be noted that the glycosides **2**, **5**, **7**, and **12** are readily distinguishable by the shape of their hydroxyl absorption bands

[4]Not true coupling constants because of second-order effect due to the near equality of chemical shifts for H-5 and H-6a. In acetone-d_6 at 300 MHz, the signal appeared as a dd with splittings of 4 and 10 Hz.

and by very detailed and characteristic band patterns in the region of 600–900 cm^{-1}.

(i) *Reaction of 13*

The 2,3-ditosylate **13** (1.06 g, 1.8 mmol) was allowed to react with LTBH (16 mL). After 30 min, a small proportion of **13** (R_f 0.68) had remained, but the reaction was complete after 1 h, having given two products, R_f 0.37 (black spot) and R_f 0.47 (brown spot) in tlc with solvent C. With solvent G, the relative mobilities were reversed (R_f 0.33 and 0.23), and in that order, too, the products were eluted by solvent H in column chromatography (15 g of SiO_2) to which the processed, crude mixture (0.45 g, 94%; syrup) was subjected. The first few, chromatographically homogeneous fractions yielded crystals (120 mg, mp 126°C), identified as the 2-deoxyglycoside **2** by comparison with **2** previously obtained from **1** (ir and 300-MHz nmr spectra, and tlc).

Subsequent, mixed fractions contained mainly the second product, and these were followed by nearly pure fractions (170 mg) of the same. After a further, chromatographic purification the material (130 mg) was identified as methyl 4,6-*O*-benzylidene-3-deoxy-α-D-*arabino*-hexopyranoside (**18**) by its 300-MHz ^{1}H nmr spectrum (in $CDCl_3$), δ: 7.5 and 7.35 (m, 2 and 3H, Ph), 5.55 (s, *Ph*-CH), 4.55 (broadened s, H-1), 4.23 (distorted dd, H-6e), 3.99 (narrow m, H-2), 3.95 (td, partially overlapped by the H-2 signal, H-4), 3.8 (m, 2H, consisting of a dt for H-5 and a t with 10-Hz splitting for H-6a), 3.40 (s, 3H, OMe), 2.09 (narrow m, H-3e), and 2.05 (dd, $J_{2,3a}$ = 3.2, $J_{3a,4}$ ~11 Hz, H-3a; geminal coupling was not observed). The data agreed with the 100-MHz data recorded (3)[5] for **18**.

Performance of the same reaction, but with *lithium triethylborodeuteride*, gave the 2-deoxy-2-deuterio- and 3-deoxy-3-deuterio-α-D-*altro* analogs **2*a*** and **18*a***, which were isolated chromatographically in the same way. In comparison with the ^{1}H nmr spectrum of **2** (section b), that of **2*a*** lacked the H-2a signal, the H-2e signal was reduced to a narrow dd, H-3 gave a t with $J_{2e,3} = J_{3,4}$ = 2.8 Hz (after D_2O exchange), and H-1 gave a slightly broadened s, whereas the resonances for H-4,5,6a,6e and the substituents were identical in **2** and **2*a***. The spectrum of **18*a*** was identical with that of **18** except that the characteristic dd for H-3a was lacking and the H-4 and partially overlapping H-2 signals were reduced in multiplicity.

*Reactions of **13** with lithium aluminum hydride and lithium aluminum deuteride*

Altroside ditosylate **13** (300 mg) was reduced with LAH (80 mg) in dry, boiling oxolane (4 mL) according to Jarý's procedure (15), but with a reaction time of 25 instead of 18 h. A small proportion of **13** (R_f 0.63) remained unconsumed even then; the main products gave a single spot having R_f 0.43 and an elongated double spot, R_f 0.37–0.17, that was colored reddish-brown in the front and brownish-black in the rear part. In addition, a trace product having R_f 0.75 was detected, migrating like an authentic sample (29) of the *manno* 2,3-epoxide **16** (tlc with solvent B). Processing of the reaction mixture as described (15), followed by multiple chromatography on silica gel using solvent E and similar solvent combinations (1:4 and 1:6), resulted in partial separation of the products. Part of the most abundant product (R_f 0.37; brown spot) was isolated pure and identified as **18** by its 300-MHz ^{1}H nmr spectrum. The minor product **2** (R_f 0.27, blackish spot) was obtained in a 2:3 mixture with **18**, but its presence was clearly indicated by its distinctive nmr signals. The compound having R_f 0.43 was isolated pure in a small amount and determined to be the 3-monotosylate **14** on account of its nmr spectrum (see Table 1).

When an identical experiment was performed, but with LAD, the chromatographic pattern was similar except that a somewhat larger proportion of starting **13** appeared to have remained (after 28 h), and the fast-moving spot attributed to **16** was slightly stronger than previously. Isolated chromatographically, **16** gave a 300-MHz ^{1}H nmr spectrum ($CDCl_3$) identical in every respect with that of an authentic sample and essentially agreeing with reported (30) data; δ: 7.46 and 7.37 (m, 2 and 3H, Ph), 5.54 (s, *Ph*-CH), 4.87b (s, $J_{1,2}$ = 0 Hz, H-1), 4.23 (q, splittings of 10 and 16 Hz, H-6e; compare footnote 4; misassigned as H-4 in ref. 30), 3.7–3.6 (m, 3H, H-4,5,6a), 3.45 (d, H-2 or H-3), 3.44 (s, 3H, OMe), and 3.14 (d, $J_{2,3}$ = 3.7 Hz, H-3 or H-2; note that $J_{3,4}$ = 0 Hz).

In an attempt to effect more complete reaction, **13** (300 mg) in oxolane (7 mL) was reduced with LAD (80 mg) as before, further LAD (80 mg) was added after 22 h, and boiling continued for another 24 h, whereafter **13** was no longer detectable by tlc. However, it was found upon processing (15) that the reaction had still not been entirely complete. The syrupy mixture of products (120 mg) was subjected to a single chromatography on a silica gel column (6 g) with 1:3 ethyl acetate – hexane. Various pure and mixed fractions of products totalling 70 mg were eluted. One small, mixed fraction (~8 mg) contained mainly **13**, and another small fraction (12 mg, crystalline) consisted of **14** (nmr). The fractions which contained the main product in more or less pure form amounted to 30 mg, and the 300-MHz ^{1}H nmr spectrum of a pure fraction was superposable on that of **18*a*** obtained in the LTBD reduction. Slow-moving material eluted from the column represented mixtures in which diol **19** appeared to be present.

[5]The dd observed at δ 4.23 was erroneously assigned to H-6a. It actually belonged to H-6e, and the recorded *J* values were not true coupling constants but splittings arising from second-order effects due to a near coincidence of the H-5 and H-6a chemical shifts. Compare also footnote 4.

Protonation of hypoxanthine, guanine, xanthine, and caffeine

ROBERT L. BENOIT AND MONIQUE FRÉCHETTE
Département de Chimie, Université de Montréal, Montréal (Qué.), Canada H3C 3V1

Received May 1, 1985

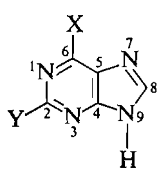
ROBERT L. BENOIT and MONIQUE FRÉCHETTE. Can. J. Chem. **63**, 3053 (1985).

The protonation equilibria of three hydroxypurines, hypoxanthine, guanine, and xanthine, and of related caffeine have been studied by ^{1}H and ^{13}C nmr and uv spectroscopies in aqueous sulfuric or perchloric acids. The results have been interpreted on the basis of the excess acidity method. The $pK_{BH_n^{n+}}$ values and the protonation sites are discussed and comparisons are made with results of recent theoretical calculations.

ROBERT L. BENOIT et MONIQUE FRÉCHETTE. Can. J. Chem. **63**, 3053 (1985).

Les équilibres de protonation de trois hydroxypurines, l'hypoxanthine, la guanine, la xanthine, et du composé voisin la caféine ont été étudiés par les spectroscopies rmn du ^{1}H et du ^{13}C et uv dans les acides sulfurique et perchlorique aqueux. On a interprété les résultats sur la base de la méthode dite "d'acidité en excès". Les valeurs des $pK_{BH_n^{n+}}$ et les sites de protonation sont examinés et des comparaisons sont faites avec les résultats de calculs théoriques récents.

In addition to their importance in biological systems, purines offer a challenging thermodynamic and structural problem specifically in the determination of the reactivity of their many basic sites. Establishing correlations between the reactivity of the purines basic sites with the proton and other electrophiles such as metal ions also presents an interesting challenge. We recently reported results of a study of the first protonation step of some purines and of the second and third protonation steps of purine and adenine in more acidic media (1). We have now extended our study to the protonation of 3 hydroxypurines,



X-6	Y-2	
OH*	H	hypoxanthine (Hyp)
OH*	NH_2	guanine (Gua)
OH*	OH*	xanthine (Xan)

*tautomerization to 
hypoxanthine (6-hydroxypurine), guanine (2-amino-6-hydroxypurine), and xanthine (2,6-dihydroxypurine), and of related caffeine (1,3,7-trimethylxanthine). For this work we abandoned the calorimetric method because a strong medium effect at high acidity interfered with the interpretation of the results, and we used, instead, uv spectroscopy. Adding uv spectroscopy to ^{13}C and ^{1}H nmr spectroscopies makes it also possible to compare data at widely different concentrations (10^{-4} M vs. 0.2 M).

The known pK_{BH^+} values for the first protonation step of hypoxanthine and guanine, which occur in dilute acid media, are respectively 1.9 (2) and 3.3 (2), while for xanthine the values quoted are 0.8 (3) and 1.2 (4) and for caffeine 0.5 (4). As for $pK_{BH_2^{2+}}$, the only value reported is −1.05 for guanine (5); $GuaH_2^{2+}$ has also been identified in both trifluoroacetic acid (TFA) and HSO_3F (6).

We present here the results of our study of the protonation reactions of the three hydroxypurines and caffeine between 0.05 and 18 M H_2SO_4. Our pK values as well as the protonation sites are discussed, and comparisons are made with results of recent theoretical calculations.

Experimental

Hypoxanthine (L. Light), guanine (L. Light), xanthine (L. Light and Aldrich), and caffeine (Baker) were used as received. Our uv spectra of $HypH^+$ and $GuaH^+$ were in agreement with those published (7). The spectra of Xan for both xanthine samples were similar to those reported (7, 8). Previous values of ϵ, the molar absorptivity, are somewhat lower than ours. We suspect that this was so because some decomposition of Xan takes place on standing. Sulfuric acid, H_2SO_4 fuming (15% SO_3) (Fisher) and 70% $HClO_4$ (Biopharm) were reagent grade. Triple-distilled HSO_3F (Aldrich) was used.

The uv spectra were recorded within 10 min of preparing the solutions on a 545 Perkin−Elmer spectrophotometer and absorbancies at a fixed wavelength were measured on a PMQ II Zeiss spectrophotometer. The ^{13}C nmr spectra were acquired at 28°C on a Bruker WP-80 spectrometer operating at 20.2 MHz. Data acquisition and Fourier transformation were performed with 8K data points. Proton decoupled spectra were recorded when needed to assist signal assignments. Carbon-13 chemical shifts were measured relative to external dioxane in D_2O (coaxial tube) and converted to the Me_4Si scale using the relationship $\delta_{Me_4Si} = \delta_{dioxane} + 67.40$ ppm. The ^{1}H nmr spectra were obtained on a Bruker WH-90 spectrometer operating at 90.0 MHz. The ^{1}H chemical shifts were determined by using the CH_3 protons of external DSS ($(CH_3)_3Si(CH_2)_3SO_3^-Na^+$) in D_2O and taking $\delta_{Me_4Si} = \delta_{DSS}$. The nmr samples were prepared by adding weighed portions of the solid bases to known volumes of titrated H_2SO_4 or $HClO_4$ solutions. The uv samples were obtained by diluting aliquots of the bases in acid solutions to 5 mL with titrated acid solutions.

Results and discussion

Chemical shifts

The nmr spectra were recorded for Hyp, Xan, and Caf with 0.05−18 M H_2SO_4 solutions and for Gua with 4−16 M H_2SO_4. For guanine, 0.5−6 M $HClO_4$ solutions were also used because of the low solubility of the base in H_2SO_4 below 4 M. In order to interpret our ^{13}C and ^{1}H shifts, H_0 values were computed from the corrected acid concentrations and literature data (9). These corrected concentrations were obtained by subtracting from the initial acid concentrations n times the concentrations of the protonated BH_n^{n+} species formed. In turn, these latter concentrations were obtained from the total base concentrations and eq. [2] and [3] given later in this discussion. The chemical shifts of the 5 carbons of Gua, Hyp, and Xan, those of C-8 and —CH_3 of Caf, and those of the H-8 protons of Gua and Xan were plotted against H_0. Carbons were assigned by using off-resonance spectra and data in Me_2SO.

The plots of ^{13}C and ^{1}H shifts are for the most part sigmoid curves indicative of protonation reactions. According to their pK_{BH^+}, Gua, Hyp, and Xan are all present as BH^+ at the lowest $HClO_4$ and H_2SO_4 concentrations used so that the ^{13}C curves show the formation of $GuaH_2^{2+}$ and $HypH_2^{2+}$. The sigmoid ^{1}H

TABLE 1. ^{13}C and ^{1}H shift values (ppm) of protonated species

Hydroxypurine	C-2	C-4	C-5	C-6	C-8	H-8
$GuaH^+$	155.9	150.7	108.7	155.9	138.2	8.67
$GuaH_2^{2+}$	152.3	137.9	110.1	152.3	138.8	8.89
$HypH^+$	150.4	148.1	116.1	155.1	139.9	—
$HypH_2^{2+}$	152.2	135.5	117.3	149.9	141.9	—
$XanH^+$	152.4	140.5	108.8	156.1	137.2	8.88
$CafH^+$	152.3	141.0	108.8	155.8	137.8	—

plot confirms $GuaH_2^{2+}$. In the case of Xan (and Caf), there is no clear evidence for BH_2^{2+}: C-8 is the only carbon noticeably shifted, but no plateau is reached, just as an early plateau, found when raw H-8 data were plotted, disappeared after bulk susceptibility corrections (10) were made.

The first protonation of Gua, Hyp, Xan, and Caf on the imidazole ring is well established (2) so that the choice of the second protonation site is restricted to N-3 or O-6 for Gua and Hyp. The shifts to high field of δC-4 and C-2 when passing from $GuaH^+$ to $GuaH_2^{2+}$ (Table 1) favour protonation at N-3 according to the α-protonation effect found by Pugmire and Grant for five- and six-membered nitrogen heterocycles (11). This assignment is in agreement with that of Wagner and von Philipsborn (6) deduced from ^1H nmr spectra in TFA at low temperature. However, these authors assumed that $GuaH_2^{2+}$ was the protonated species in TFA, whereas by comparing our ^{13}C data in TFA and H_2SO_4 we calculated that for TFA solutions $GuaH_2^{2+}/GuaH^+ = 1:1$. In the case of Hyp, C-4 shows a large upfield shift on passing from $HypH^+$ to Hyp_2^{2+}, as expected from protonation at N-3, and C-2 is moved to lower field as was observed for the third protonation of adenine at N-3 (1).

Ultraviolet spectra

On the basis of the nmr results, H_2SO_4 concentrations were selected to ensure the formation of BH^+ and BH_2^{2+}. The corresponding uv spectra were recorded and used to determine the most suitable wavelengths for measuring the absorbancies. Table 2 shows the H_2SO_4 concentrations used for the various protonated species together with the wavelengths of maximum absorption and the logarithms of the molar absorptivities ϵ. The plots of the absorbancies measured at several wavelengths (from 6 to 12 λ values) against H_0 were sigmoid curves and confirmed the formation of $GuaH_2^{2+}$ and $HypH_2^{2+}$. It is worth noting that the second protonation causes a hypsochromic shift. For Xan, there is also a hypsochromic shift of both absorption bands above 14.5 *M* H_2SO_4, but the absorbancies did not reach a plateau at 18 *M* H_2SO_4, and increasing the acidity further by adding oleum gave background absorbancies which were too high for meaningful measurements. Previous uv studies such as that for Gua (12) have already shown that it is difficult to assign the first protonation site on the basis of observed uv spectra, so that no attempt was made in this direction.

Calculation of pK_n

The values of pK_n for BH_n^{n+} were first calculated using the equation

$$[1] \quad H_0 = pK_n - m_n \log I$$

with

$$[2] \quad I = \frac{|BH_n^{n+}|}{|BH_{n-1}^{(n-1)+}|}$$

TABLE 2. Ultraviolet spectral data of hydroxypurines

Hydroxypurine	$[H_2SO_4]$ (*M*)	λ_{max} (nm)	Log ϵ
Gua	0	(246, 275)[a]	(4.01, 3.89)[a]
$GuaH^+$	0.11	248, 271	4.03, 3.85
$GuaH_2^{2+}$	10.85	236, 252	4.01, 3.95
Hyp	0	249[a]	(4.02)[a]
$HypH^+$	1.78	247	4.02
$HypH_2^{2+}$	18.09	241	4.00
Xan	0	267	3.99, (3.90)[a]
$XanH^+$	6.03−14.5	230, 259	3.87, 3.91
Caf	0	272.5	4.02
$CafH^+$	5.74	233, 265	3.79, 3.98

[a]Data from ref. 7.

The ratio *I* was obtained from the measured shifts δ and from the estimated limit chemical shifts δ_{n+} and $\delta_{(n-1)+}$ (Table 1) according to the standard equation

$$[3] \quad I = \frac{\delta - \delta_{(n-1)+}}{\delta_{n+} - \delta}$$

for the nmr shift data and the corresponding equation for the uv absorbancies data. However, the values of m_n were consistently well above 1.00, indicating that H_0 was not a satisfactory acidity function for following the protonation of these bases, just as it was not for adenine and purine (1). Two other acidity function, H_+ and H_A, were also used instead of H_0. Although H_A proved to be more satisfactory than H_+ and H_0, since our bases are very different from the amides used for H_A, we have finally chosen the Cox and Yates approach to calculated pK_n.

The excess acidity method (9) is based on the following equation:

$$[4] \quad \log I - \log C_{H^+} = m^*X + pK_n$$

Values for $\log C_{H^+}$ and *X* are independent of the bases and are taken from literature data (13) for each corrected H_2SO_4 or $HClO_4$ concentration. The program developed by Cox was used to solve simultaneously eqs. [3] and [4]. For each selected carbon and proton (or wavelength), values of C_{H^+}, *X*, δ, and the estimated values of δ_{n+} and $\delta_{(n-1)+}$ (or of the corresponding absorbancies data) were entered in the program. Thus, values of pK_n with their standard deviations (13) and m^* were obtained, as well as refined values of δ_{n+} and $\delta_{(n-1)+}$. These latter values differed from the estimated ones by less than 0.5 ppm (^{13}C), 0.01 ppm (^1H) (or 0.02 absorbancies unit). The pK_n values for the 4 bases, as well as those for adenine (Ade) and purine (Pur) (1) are summarized in Table 3. The differences found between the successive pK_n values are large enough to justify our treating the experimental data as if the protonation steps take place stepwise. An implicit, but reasonable, assumption in our treatment is that if tautomeric protonated species are present, their proportion is independent of the acid concentration. Since the agreement between pK_n values obtained by nmr and uv methods is generally satisfactory (although less so at higher acidities), considering the very different base concentrations used, 0.2 *M* vs. 10^{-4} *M*, large medium effects in one method can be ruled out. The presence of 2 isosbestic points in the uv spectra of Hyp (246 and 268 nm) between 1.8 and 18 *M* H_2SO_4 also suggests the absence of medium effect. Furthermore, no appreciable medium effect had previously been found for the protonation of Ade and Pur (1). For $XanH_2^+$, the uv pK_2 value is -10.0 ± 0.6. Additional nmr data taken on a HSO_3F

TABLE 3. pK values and protonation sites for hydroxypurines, caffeine, purine, and adenine

Hydroxypurine	pK (nmr)	pK (uv)	pK (lit.)	Protonation sites
$GuaH^+$			3.3[a]	N-7/N-9
$GuaH_2^{2+}$	-1.01 ± 0.03 (^{1}H and ^{13}C)	-0.99 ± 0.01	-1.05[b]	N-3
$HypH^+$			1.8,[a] 2.0[h]	N-7/N-9
$HypH_2^{2+}$	-3.12 ± 0.05 (^{13}C)	-3.65 ± 0.10		N-3
$XanH^+$		0.91 ± 0.01	0.8,[c] 1.2[d]	N-7/N-9
$XanH_2^{2+}$		-10.0 ± 0.6		O-6 (?)

solution ($-H_0$ = 15) of Xan and Caf to extend our results obtained with H_2SO_4 solutions ($-H_0 < 9.5$) and confirm $XanH_2^{2+}$ were inconclusive: C-8 moved further downfield and C-6 upfield but the shifts were small and no OH signal corresponding to C=O protonation could be detected at −75°C. The substantial downfield shift for the carbonyl carbons on protonation, which might have been expected with the formation of $XanH_2^{2+}$ and $CafH_2^{2+}$, is absent. Although this absence might be caused by conjugation effects, it nevertheless makes us consider the uv pK_2 value as tentative.

The discussion of the pK_n results for the ionization of the BH_n^{n+} species (Table 3) is a matter of some difficulty since the 3 tautomerized hydroxypurines first protonate on the imidazole ring while Ade and Pur first protonate on the pyrimidine ring. However, it is worth noting that for the 4 purines with successive protonations on N belonging on different rings, the differences between pK_2 and pK_1 correspond approximately to 6 kcal/mol.

Although it is difficult, we can try to relate our findings to the results of a recent molecular orbital study by Del Bene of the protonation of four DNA bases which include Gua and Ade as well as thymine and cytosine (14). The author computed the following protonation energies from optimized structures of the neutral and monoprotonated bases: for Gua, −245 kcal/mol (N-7), −233 (O-6 on the C-5 side), −228 (N-3), −220 (O-6 on the N-1 side), and for Ade, −241 (N-1), −240 (N-3), and −232 (N-7). Del Bene pointed out that these absolute values were overestimated because correlation and zero-point vibrational energy had to be neglected. In fact, Del Bene's calculated value for Ade, −241 kcal/mol, is at complete odds with the experimental gas phase proton affinity of −255 kcal/mol reported earlier by Meot-Ner (15). Furthermore, while the calculated value for thymine is right on Meot-Ner's −211 kcal/mol, for cytosine, Del Bene found a puzzling −249 kcal/mol to be contrasted with the experimental −225 kcal/mol. Thus, it is very difficult to say whether a discrepancy between data in Table 3 and Del Bene's values is due to the fact that the data in Table 3 were obtained in solution while the calculations refer to the gas phase, or to the unreliability of the reported MO calculations. For example, Gua is calculated by Del Bene to be 4 kcal/mol more basic than Ade, while the data in Table 3 indicate the reverse, with a 1.2 kcal/mol difference. This being said, her MO calculations should at least provide reasonable estimates of the relative protonation energies for the several basic sites of a given molecule. For Gua (but with the proton on N-9 although there is a N-7/N-9 tautomeric equilibrium (4, 16)), Del Bene found N-7 (−245 kcal/mol) to be the preferred protonation site and the solution data in Table 3 indicate N-7/N-9. Her next favored site is O-6 (on the C-5 side) (−233 kcal/mol) followed by N-3 (−288 kcal/mol). In contrast, our solution data show definitely that the second protonation takes place at N-3 rather than at O-6. It may be that the 5 kcal/mol difference between the calculated protonation energies at O-6 and N-3 is not high enough to counterbalance the repulsion which would exist between the second proton on O-6 (on the C-5 side) and the first proton on N-7. We must remember, however, that our results on successive protonations of the bases reflect factors additional to the relative intrinsic basicities of the various sites of the neutral bases.

Binuclear phthalocyanines in which the two phthalocyanine nuclei are covalently linked through four-atom bridges, derived from catechol, have been prepared and characterized. Metal-free 2,9,16,23-tetra-(3,3-dimethylbutyl)phthalocyanine and 2,9,16,23-tetra-(2-trimethylsilylethyl)phthalocyanine were prepared as examples of non-oxygenated mononuclear phthalocyanines soluble in organic solvents. Catalytic hydrogenation of 1,2-bis-(3,4-dicyanophenyl)ethyne and 1,4-bis-(3,4-dicyanophenyl)buta-1,3-diyne gave 1,2-bis-(3,4-dicyanophenyl)ethane and 1,4-bis-(3,4-dicyanophenyl)butane respectively. From these precursors, metal-free phthalocyanine dimers containing ethylene and tetramethylene bridges, joining the phthalocyanine nuclei, were prepared. Two of the two-atom bridge phthalocyanine dimers represent the first characterized phthalocyanine dimers not containing alkoxy or oxygenated groups.

On a préparé et on a caractérisé deux phtalocyanines binucléaires dans lesquelles deux noyaux phtalocyanines sont liés d'une façon covalente par quatre atomes de pont, dérivés du catéchol. On a préparé la tétra(diméthyl-3,3 butyl)-2,9,16,23 phtalocyanine et la tétra(triméthylsilyle-2 éthyle)-2,9,16,23 phtalocyanine exemptes de métal à titre d'exemples de phtalocyanines mononucléaires non oxygénées solubles dans des solvants organiques. Les hydrogénations catalytiques du bis(dicyano-3,4 phényl)-1,2 éthyne et du bis(dicyano-3,4 phényl)-1,4 butadiyne-1,3 conduisent respectivement au bis(dicyano-3,4 phényl)-1,2 éthane et au bis(dicyano-3,4 phényl)-1,4 butane. À l'aide de ces précurseurs, on a préparé des phtalocyanines dimères sans métal contenant des ponts éthylènes et tétraméthylène entre les noyaux phtalocyanines. Deux de ces phtalocyanines dimères correspondent aux premières phtalocyanines ne contenant pas de groupements alkoxyles ou oxygénés à être caractérisées.

The electrocatalytic properties of porphyrins and phthalocyanines have been the subject of intensive research (1). A dicobalt cofacial porphyrin dimer (2, 3) containing a four-atom covalent bridge has been prepared. The four-electron reduction of oxygen to water using this dimer has been achieved but the compound tends to lose its catalytic activity with time (2). Since the phthalocyanine nucleus is likely to be more stable (4) than the porphyrin nucleus, we have tried to synthesize the related, but hitherto unknown, phthalocyanine dimers. We have recently reported the synthesis and some properties of phthalocyanine dimers incorporating five-atom covalent bridges (5, 6). Unlike typical phthalocyanines, these dimers are very soluble in organic solvents and their great solubility facilitates their purification and characterization. Recent work on the synthesis of porphyrin dimers has shown that even dimers having one rigid covalent bridge can be held in a cofacial conformation thought to be necessary for electrocatalysis (7). Since a four-electron reduction of oxygen was not achieved using the five-atom bridge dimer (5), we wished to prepare phthalocyanine dimers separated by the key four-atom bridges (2, 3) and to provide binuclear phthalocyanines containing two-atom bridges or less as control electrocatalysts that cannot assume a cofacial conformation. In addition, we wished to study the possibility of synthesizing binuclear phthalocyanines devoid of alkoxy groups or any oxygen atoms. In this paper we describe the preparation of a partially constrained binuclear phthalocyanine, containing a four-atom covalent bridge derived from catechol units; a flexible tetramethylene four-atom bridged phthalocyanine dimer; and phthalocyanine dimers containing two-atom ethylene bridges.

Synthesis of binuclear phthalocyanines bridged covalently by catechol units

Treatment of 4-nitrophthalonitrile (**1**) with 4-*tert*-butylcatechol (**2***a*) or catechol (**2***b*) and anhydrous potassium carbonate in dry dimethylformamide (DMF) at 22°C for 36 h gave 1,2-bis-(3,4-dicyanophenoxy)-4-*tert*-butylbenzene (**3***a*)[3] and 1,2-bis-(3,4-dicyanophenoxy)benzene (**3***b*)[3] in 84 and 78% yields, respectively (9, 10). Compounds **3***a*,*b* were converted to their respective 1,3-diiminoisoindolines (**4***a*,*b*) by bubbling ammonia into a solution of **3***a* or **3***b* and sodium methoxide in dry methanol under reflux for 6 h or until an infrared spectrum of an aliquot of the reaction mixture no longer exhibited the typical nitrile absorption peak (5, 6, 11, 12). Condensation (5, 6, 11, 12) of **4***a* with 5-neopentoxy-1,3-diiminoisoindoline (**5**) in 2-*N*,*N*-dimethylaminoethanol for 60 h gave a green-black solution, which was diluted with water to give a blue coloured residue. Flash chromatography (13) of the residue taken up in toluene yielded, in the first fractions using toluene as eluant, 2,9,16,23-tetraneopentoxyphthalocyanine (**6**) (5, 6) as a mix-

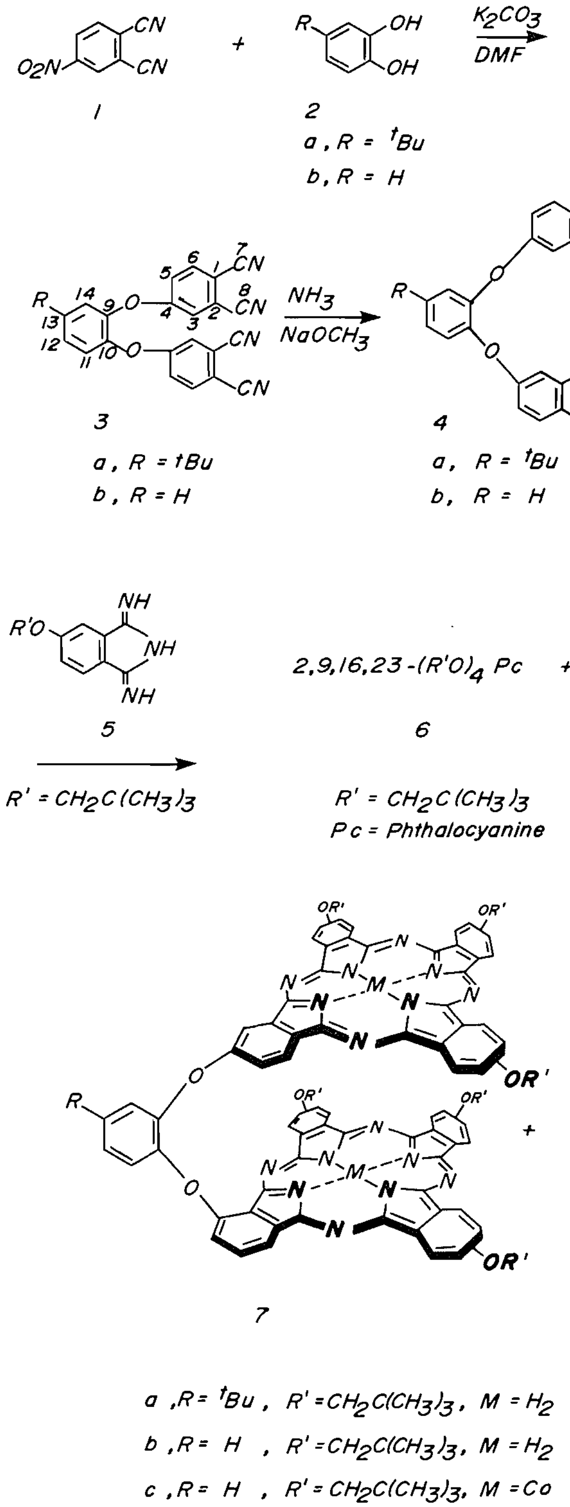
[a]Solubilities were determined at 24°C by visible spectroscopy of saturated solutions in CH_2Cl_2.
[b]Available small quantities of 7a were insufficient to obtain reliable data on this very soluble dimer.
[c]These absorption spectra were taken in $CHCl_3$.
[d]These absorption spectra were taken in *o*-dichlorobenzene.

ture of isomers. Further elution with toluene gave mixtures of **6** and 1,2-bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninoxy)-4-*tert*-butylbenzene (**7***a*) and some later fractions of pure **7***a* as shining dark purple plates.[4] Repetitive flash chromatography of the mixed fractions **6** and **7***a* gave pure **7***a* in 13% overall yield (Scheme 1). We initially selected 4-*tert*-butylcatechol (**2***a*) as the bridging moiety of binuclear phthalocyanines so that the resultant phthalocyanine dimer would be soluble in organic solvents. This idea was realized but **7***a* was actually too mobile chromatographically so that separation from the monomer **6** was tedious. The above synthesis was subsequently repeated but using catechol (**2***b*) as the bridging group. Thus, the 1,3-di-iminoisoindoline (**4***b*) was condensed with **5** as before. Flash chromatography (13) of the resultant blue-green mixture was much more facile, as monomer **6** eluted first in toluene, followed by mixed monomer−dimer fractions using toluene and toluene/2-methoxyethanol (50:1) as eluants.[4] Rechromatography of the mixed fractions gave pure 1,2-bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninoxy)benzene (**7***b*) in 10% yield. Phthalocyanine dimer **7***b* was readily converted to its di-cobalt(II) derivative **7***c* by heating **7***b* with $CoCl_2$ in toluene at 110°C for 30 h. Dimer **7***c* was purified as before by flash chromatography using toluene/2-methoxyethanol (50:1) as eluant. The structures of **3***a*,*b* and **7***a*−*c* have been fully characterized by spectroscopic data and elemental analysis (see Experimental). The absorption spectra of **7***a*−*c* are characteristic of metal-free and metallophthalocyanine dimers respectively (6) (Table 2). Most importantly, the fast atom bombardment (14) (FAB) mass spectra of the binuclear phthalocyanines **7***a*−*c* all exhibit parent ion clusters almost identical in intensity to those calculated for their respective isotopic compositions. It

[4]Continued elution with toluene and toluene/2-methoxyethanol mixtures gave an additional blue-green fraction which, by fast atom bombardment analysis (FAB) (14), was shown to have a molecular ion corresponding to a phthalocyanine trimer.



SCHEME 1

should be noted, however, that phthalocyanines 7*a* – *c* exist as a mixture of positional isomers about the phthalocyanine ring and that the depicted structure thus reflects this mixture. The broad absorbances in the ^{1}H nmr spectra of these compounds are indicative of this isomeric distribution (Table 3). On the other hand, the ^{13}C nmr spectra of 7*a* and 7*b* exhibit single resonances for the methyl and quaternary carbon groups of the neopentoxy substituents. Thus ^{13}C nmr spectra of 7*a*,*b* are diagnostic concerning their skeletal structure (Table 4), while the ^{1}H nmr spectra clearly identify the internal NH protons of 7*a*, *b* (Table 3).

Synthesis of 2,9,16,23-tetraalkylphthalocyanines

It has been shown (15, 16) that a wide variety of alkynes can couple with iodoarenes even at room temperature using cuprous iodide and bis(triphenylphosphine)palladium dichloride. We believed that this reaction could provide the basis for preparing the 4-alkylphthalonitriles and bisphthalonitriles needed for the preparation of mono and binuclear phthalocyanines containing no alkoxy substituents or oxygen atoms in the bridges of the phthalocyanines.

Catalytic hydrogenation of **1** in ethanol using 10% palladium on charcoal yielded 4-aminophthalonitrile (**8**) in 84% yield. Diazotization of **8** and subsequent reaction of the first-formed diazonium salt with potassium iodide gave 4-iodophthalonitrile (**9**)[3] in high yield. Coupling of **9** with trimethylsilylacetylene (**10**) (16) or 3,3-dimethyl-1-butyne (**11**) (15, 16) gave 4-(2-trimethylsilylethynyl)phthalonitrile (**12**)[3] or 4-(3,3-dimethyl-1-butynyl)phthalonitrile (**13**)[3] in 75% and 75% yield, respectively. Hydrogenation of **12** and **13** using palladium on charcoal as a catalyst gave the corresponding 4-alkyl derivatives, 4-(2-trimethylsilylethyl)phthalonitrile (**14**)[3] and 4-(3,3-dimethylbutyl)phthalonitrile (**15**)[3] in high yield. Conversion of **14** and **15** to their 1,3-diiminoisoindolines (**16**) and (**17**) as before (5, 6, 11, 12) and subsequent self-condensation in 2-*N*,*N*-dimethylaminoethanol gave 2,9,16,23-tetra-(2-trimethylsilylethyl)-phthalocyanine (**18**) and 2,9,16,23-tetra-(3,3-dimethylbutyl)-phthalocyanine (**19**) in 28% and 40% yields, respectively (Scheme 2). Phthalocyanine (**19**) was readily converted to its cobalt(II) derivative (**20**) as before (6, 11).

The mass spectra of **18**–**20** exhibited parent ions using the FAB technique (14). The ^{1}H nmr spectra of **18** and **19** were most informative and showed the inner NH absorptions (Table 3). In addition, the trimethylsilyl group of **18** and the *tert*-butyl group of **19** showed four and six peaks, respectively, corresponding to the eight different environments that these groups may experience in the four isomers possible for a tetrasubstituted phthalocyanine containing one substituent on each benzene ring. For 2,9,16,23-tetraneopentoxyphthalocyanine (**6**), the *tert*-butyl group gave an unresolved broad absorption peak in its ^{1}H nmr spectrum when recorded at high concentrations (6) but also exhibited 6 individual absorption peaks at lower concentrations (Table 3).

The ^{13}C nmr spectra of **18** and **19** exhibited only two peaks for the trimethyl group and the *tert*-butyl group while **6** showed only a single peak. On the other hand the —Si*C*H_2— group and —Si—CH_2*C*H_2— groups exhibited 8 and 6 peaks, respectively, indicating that all four isomers of **18** were indeed present (Table 4). Comparison of the solubilities of **18** and **19** with **6** showed that the tetraalkylphthalocyanines were less soluble than the tetraalkoxyphthalocyanine (6) (Table 2). The absorption spectra of **18** and **19** were consistent with the assigned structures (Table 2) (6).

Preparation of binuclear phthalocyanines covalently linked by dimethylene bridges

The dicoupling (15) of an acetylene to an iodoarene should provide the unknown bisphthalonitriles necessary to form binuclear phthalocyanines containing an all-carbon bridging group.

Thus treatment of 4-iodophthalonitrile (**9**) by methods previously described with acetylene (**21**) gave 1,2-bis-(3,4-dicyanophenyl)ethyne (**22**) in 90% yield. Compound **22** was very

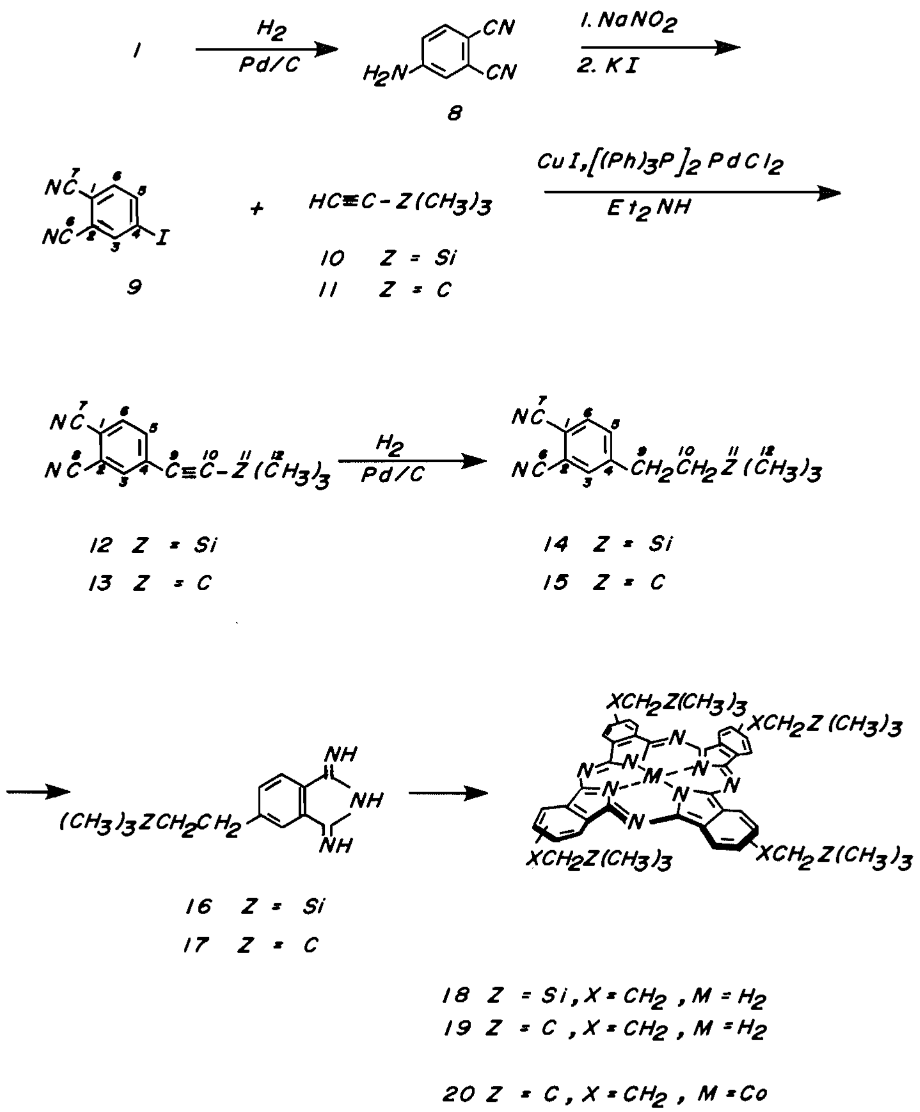
[a]These data were taken from ref. 6. A Bruker WH250 instrument was used to record this spectrum.
[b]These measurements were done on a Bruker WH400 instrument.
[c]The absorptions in this region were very weak.
[d]The absorption of the NH protons was studied in $CDCl_3$ at 22°C at 10^{-1}, 10^{-2}, 10^{-3}, 10^{-4}, and 10^{-5} *M* concentrations and gave values of −5.5(br), −3.0(v br) and 4.1(br), −3.0(br), −3.0(br), and −3.0(br), respectively
[e]Toluene-d_8.



SCHEME 2

insoluble in most solvents except acetonitrile. Thus a suspension of **22** in acetonitrile was hydrogenated for 4 h at room temperature with shaking over 10% palladium on charcoal to give, in 83% yield, 1,2-bis-(3,4-dicyanophenyl)ethane (**23**). Compound **23** was converted to its 1,3-diiminoisoindoline (**24**) as before (5, 6, 11, 12) and condensed with an excess of the 1,3-diiminoisoindolines **16**, **17**, or **5** to give, after chromatographic separation, large amounts of the mononuclear phthalocyanines **18**, **19**, or **6** and 7–10% yields of 1,2-bis-2′-(9′,-16′,23′-tri-(2-trimethylsilylethyl)phthalocyaninyl)ethane (**25**), 1,2-bis-2′-(9′,16′,23′-tri-(3,3-dimethylbutyl)phthalocyaninyl) ethane (**26**) and 1,2-bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninyl)ethane (**27**), respectively. Metal-free phthalocyanine **27** was readily converted to its dicobalt(II) derivative (**28**) (6, 11) (Scheme 3).

Binuclear phthalocyanines **25**–**27** exhibited the typical absorption spectra of metal-free binuclear phthalocyanines (6) while **28** exhibited the typical absorption of a metalated phthalocyanine dimer (Table 2). Compounds **25**–**28** all exhibited parent ions in their mass spectra using the FAB technique (14). Phthalocyanine dimers **25**–**28** were very much less soluble in organic solvents than the four-atom bridged catechol type dimers described above and the previously described five-atom bridged dimers (Table 2). The ^{1}H nmr of **25**–**27** were taken in dilute solutions and exhibited broad absorptions at the appropriate peak positions for the substituent groups (Table 3). The ^{1}H nmr spectra of the inner NH protons of **18**, **19**, and **6** are dependent on concentration, solvent, and temperature (Table 3). As a result of our initial examination of these effects on the ^{1}H nmr of **6** (Table 3), we generally run our samples in $CDCl_3$ or toluene-d_8 (C_7D_8) at concentrations of 10^{-3} to 10^{-4} *M* at room temperature. The effects of concentration, solvent, and temperature on porphyrin monomers and dimers have been studied and the effects noted here are consistent with those trends noted in porphyrin chemistry (17, 18).

Preparation of a binuclear phthalocyanine covalently linked by a tetramethylene bridge

As has been shown above in the preparation of **18**, 4-iodophthalonitrile (**9**) can readily couple with trimethylsilylethyne (**10**) to give **12**. Attempts to hydrolyze **12** as before (16) or by alternate procedures (19) resulted in solutions from which the desired 4-ethynylphthalonitrile (**29**)[3] could only be isolated in low yield. Hydrolysis of **12** under very mild conditions did

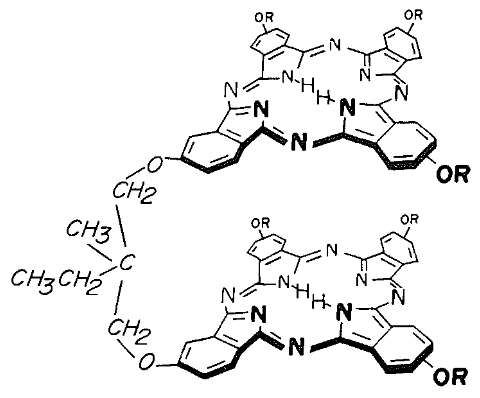
proceed in methanolic pyridine or in pyridine—$Cu(OAc)_2$ at room temperature to give **29** in high yield. Hydrogenation of **29** afforded 4-ethylphthalonitrile (**30**).[3] Since we wished to perform an oxidative dimerization (20, 21) of **29** to give 1,4-bis-(3,4-dicyanophenyl)-1,3-butadiyne (**31**) and since the conditions of this dimerization ($Cu(OAc)_2$, pyridine, methanol) are the very conditions that promote the hydrolysis of **12** to **29**, we felt that direct coupling of the precursor to **29**, i.e. **12**, should give the desired product **31**. Indeed, oxidative coupling of **12** yielded **31** in 76% yield. Catalytic hydrogenation of **31** as before gave 1,4-bis-(3,4-dicyanophenyl)butane (**32**)[3] in high yield. Conversion of **32** into its bis-1,3-diiminoisoindoline (**33**) as before (5, 6) and subsequent mixed condensation with **5** gave the undesired monomer **6** and the tetramethylene bridged dimer 1,4-bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninyl)-butane (**34**) in 1.4% yield (Scheme 4).

Physical and spectroscopic properties of mononuclear and binuclear phthalocyanines

We have shown (6) that binuclear metal-free and metallophthalocyanine exhibit characteristic absorption spectra differing from each other and from the well-known absorption spectra of mononuclear metal-free and metallophthalocyanines (4). Thus, the mononuclear phthalocyanines **18**—**20** exhibit the characteristic absorptions (Table 2) of monomers, while binuclear phthalocyanines *7a*—*c*, **25**—**28**, and **34** all exhibit absorptions more typical of dimeric phthalocyanines.

The visible spectra of *7a*, *b*, **25**—**27**, and **34** show double $\pi-\pi^*$ bands near 700 and 670 nm, but the bands near 640 and 620 nm exhibit enhanced intensities compared to the model monomers **6**, **18**, and **19**. In addition, compounds **7***c* and **28** exhibit bands at 680 and 620 nm similar to the cobalt(II) derivative of **6** (5) and **20**, but the intensity of the band at 620 is greatly enhanced, typical of aggregation (22, 23). Thus, the visible spectra of *7a*—*c*, **25**—**28**, and **34** indicate substantial interaction between the phthalocyanine nuclei. This interaction is intramolecular rather than intermolecular since the blue shift is unaffected by dilutions in the range of 10^{-5}—10^{-6} M. A full description of the absorption and emission spectra of mononuclear and binuclear metal-free phthalocyanines is in progress.

As we have previously reported (6), the ^1H nmr spectra of monomeric phthalocyanines such as **6** and dimeric phthalocyanines such as 1,3-bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninoxy)-2-ethyl-2-methylpropane (**35**) (Fig. 1) and, now, dimers *7a* and *7b* exhibit broad absorptions for internal NH protons in the region of −6.0 ppm when the spectra are run on samples at high concentrations (10^{-1} M) (Table 3). Although these data are consistent in general with those obtained by other workers for simple tetrasubstituted mononuclear phthalocyanines (24, 25), these workers do not record the concentrations of the phthalocyanines on which measurements were made and



35 $R = CH_2C(CH_3)_3$

FIG. 1

the reported NH absorbances vary from −2.0 (24) to −9.0 ppm (25), an effect very concentration dependent as shown herein. The effect of concentration on the observance of the NH absorbances of **6** is described in footnote *d* to Table 3 and effectively shows that the absorption changes from −5.5 at 10^{-1} *M* to −3.0 at 10^{-3} *M* and remains constant upon further dilution. Furthermore, at intermediate concentrations (10^{-2} *M*), the observation of two NH absorbances at −4.1 and −3.0 is noted and undoubtably represents a mixture of free and aggregated phthalocyanines. The effect of temperature on the ^{1}H nmr of **6** is somewhat complicated by the concomitant effect of solvent on the internal NH absorbances. Thus in toluene-d_8 the NH absorbance (at 10^{-4} *M*) at 80°C is −3.0, at 22°C is −2.60, and at −80°C is −0.9 ppm. On the other hand, in CD_2Cl_2 the NH absorbance is invariant between −70°C and 22°C and broadens greatly in $CDCl_3$ at 50°C. Most importantly, however, the higher temperature nmr spectra do not exhibit NH absorbances at significantly lower fields, and hence 10^{-3}−10^{-4} *M* solutions most likely represent free non-aggregated phthalocyanines even at room temperature. The lack of an upfield shift of the NH absorbances at lower temperatures indicates that conformational mobility is still high enough that aggregation does not appreciably occur at −70 to −80°C. The NH absorbances of the binuclear phthalocyanines (**7*b***) and **35** at −70°C in CD_2Cl_2 and +50°C in $CDCl_3$ again do not appreciably change their value of ~−3.1 ppm, which indicates that even at low temperatures in the binuclear phthalocyanines conformational mobility is high on the nmr time scale or that intramolecular cofacial interaction is insignificant. Thus the extent of cofacial conformations of binuclear phthalocyanines **7*a***, ***b***, **25**−**27**, and **34**−**35** cannot be evaluated at present using nmr techniques. The mononuclear phthalocyanine **6** exhibits only a broad absorption peak for the CH_3 groups of the *tert*-butyl substituent in its ^{1}H nmr spectra at high concentrations (10^{-1} *M*) (Table 3) (6) but in dilute solutions (10^{-3}−10^{-4} *M*) **6**, the Zn derivative of **6** (**6**Zn) (6), **18** (26), and **19** exhibit 6, 7, 4, and 6 peaks, respectively, corresponding to this *tert*-butyl group. It should be noted that **6**, **6**Zn, **18**, and **19** each exist as a mixture of four possible positional isomers and that these isomers give rise to a total of eight possible environments for the substituent groups. For dilute solutions, up to 7 of these different absorptions are seen for the *tert*-butyl group (Table 3). In fact, for **6**Zn we can clearly see seven single absorptions for the CH_2O group of the mixture of 4 isomers. For dimers **7*a***,***b***, **25**, **26**, **27**, and **34** the ^{1}H nmr substituent absorbances of the mixtures of isomers are generally broad and not resolvable. As previously reported (6), the ^{13}C nmr of **6** at high concentrations (10^{-1} *M*) exhibited only 1 absorption peak for the CH_3 group of the *tert*-butyl group and, indeed, dimers **7*a***, **7*b***, **27**, and **34**, based on the neopentoxy substituent, all exhibited only one or two peaks for this group. On the other hand, the ^{13}C nmr of monomers **18** and **19** exhibited a multiplicity of peaks, again representing the 8 environments in which the four isomers each of **18** and **19** exist (Table 4). Indeed, **18** exhibits two absorptions for the CH_3Si carbon, all eight absorptions for the CH_2Si carbons, and six absorptions for the CH_2CH_2Si carbon (Table 4). The much greater multiplicity of isomers of the dimers and their even greater numbers of environments actually generate rather deceptively simple spectra in which single or small numbers of $(CH_3)_3Z$ absorbances are observed (Table 4). Because of this multiplicity of environments, rather poorly resolved, very weak, absorbances are observed in the aromatic region, and the bridging carbons of the dimers and these absorbances are not listed for both ^{1}H and ^{13}C nmr spectra of compounds in which these absorbances are poorly defined.

All phthalocyanines exhibited parent ions in their mass spectra (27) using the FAB system (14) and *o*-nitrophenyl octyl ether (ONPOE) as the solvent (6). The infrared spectra of all metal-free phthalocyanines exhibited characteristics NH absorptions at 3300 and 1020 cm^{-1} (28), which disappeared on formation of their cobalt derivatives.

The mononuclear phthalocyanine bearing the isohexyl substituents (**19**) was clearly less soluble than the tetraneopentoxyphthalocyanine (**6**) but the tetra-(2-trimethylsilylethyl)phthalocyanine (**18**) was almost as soluble as **6** (Table 2). Thus if one wishes to prepare soluble multinuclear phthalocyanines bearing no oxygen atoms around the periphery of the phthalocyanine nucleus, it would be possible to use isoindoline **16** as a "partner" in condensation reactions, but use of isoindoline **17** gives rather insoluble dimeric phthalocyanines (Table 2). It appears that phthalocyanine dimers containing bridges having oxygen atoms (**7*a***, ***b***, **35**) are considerably more soluble than all carbon bridge dimers such as **25**−**27** and **34**. Perhaps, not surprisingly, the more flexible tetramethylene bridged dimer **34** is more soluble than the ethylene bridged dimer **27**. Indeed, only dimers **7*a*** and **34** in this work exhibit ^{13}C nmr peaks for bridging carbons (Table 4). It was not possible to measure the solubilities of all the phthalocyanines in the same solvent, as **6** and **18** are too soluble in $CHCl_3$ or *o*-dichlorobenzene (ODCB) to conveniently obtain data while dimers **25**−**28** and **34** were generally totally insoluble in CH_2Cl_2. Using the knowledge that the phthalocyanines are generally soluble in solvents in the following order: $CDCl_3 > CHCl_3 >$ ODCB $> CH_2Cl_2$, we can generalize from the data shown in Table 2 that the order of solubility of monomeric and dimeric phthalocyanines is **6** (6) > **18** > **6**Zn (6) > **35** − **7*b*** > **19** > **20** > **34** > **27** > **25** > **26** > **28**. Thus multinuclear phthalocyanines very soluble in organic solvents are most readily made using the 5-neopentoxyisoindoline **5**, rather than the less accessible 5-alkylisoindolines **16** and **17**, as a partner in mixed condensations with bisisoindolines. In addition, multinuclear phthalocyanines bridged only by carbon atoms are less soluble than their oxygen bridged analogs. This decreased solubility may render their electrocatalytic properties less amenable to study. Further research on the synthesis of binuclear and multinuclear phthalocyanines having a fixed cofacial structure is in progress.

Experimental

Matheson high purity argon was used to maintain inert atmosphere conditions. Infrared (ir) spectra were recorded on a Pye Unicam SP1000 infrared spectrophotometer using KBr discs for solids or as neat films between NaCl discs. Nuclear magnetic resonance (nmr) spectra for protons were recorded on a Varian LM 360 spectrometer using deuterochloroform as solvent and tetramethylsilane as the internal standard. The positions of the signals are reported in δ units. (The splittings of the signals are described as singlets (s), doublets (d), triplets (t), quartets (q), or multiplets (m).) A Bruker AM300 nmr spectrometer was used for all ^{13}C nmr spectra and for ^{1}H nmr spectra of all phthalocyanines unless otherwise stated. The ^{1}H nmr spectra of 10^{-4} *M* solutions of phthalocyanines were obtained by averaging 500–1000 scans over the absorption range, while ^{13}C nmr spectra on saturated solutions of phthalocyanine were obtained by averaging 5 000–15 000 scans over the absorption range.

The visible–ultraviolet spectra (uv) were recorded on a Hewlett Packard HP8451A Diode Array spectrophotometer. Mass spectra (ms) were recorded at 70 eV on a VG Micromass 16F mass spectrometer in the EI mode.

The FAB spectra were obtained with a Kratos MS-50 triple analyzer mass spectrometer equipped with a FAB ion source of standard Kratos design and an Ion Tech atom gun. The sample was dissolved in chloroform and a microliter of the resulting solution added to a microliter of *o*-nitrophenyl octyl ether on the probe tip. The spectra of the molecular ions of the binuclear phthalocyanines were obtained by signal averaging up to 256 scans over the appropriate mass range. The number in parentheses after the indicated ion shows the percentage of the base peak represented by that ion. Melting points (mp) were determined using a Kofler hot stage melting point apparatus and are uncorrected. Thin-layer chromatography (tlc) was performed using silica gel G as the adsorbent. Flash chromatography was performed using silica gel of particle size 20–45 μm. All reactions were stirred with a magnetic stirrer. All solvents were freshly distilled before use. Microanalyses were performed by Guelph Chemical Laboratories Ltd., Guelph, Ont.

*1,2-Bis-(3,4-dicyanophenoxy)-4-*tert-*butylbenzene (3*a*) and 1,2-bis-(3,4-dicyanophenoxy)benzene (3*b*)*

A solution of 3.90 g (22.5 mmol) of **1**, 1.66 g (10 mmol) of **2***a*, and 7.0 g (50 mmol) of anhydrous potassium carbonate (K_2CO_3) in 25 mL of dry dimethylformamide (DMF) (6, 9) was stirred at room temperature for 36 h. The reaction mixture was diluted with water (150 mL), extracted with ethyl acetate, washed with saturated potassium carbonate, 4 *M* HCl, water, and saturated sodium chloride, and dried over magnesium sulphate. Evaporation of the solvent gave a brown oil, which on recrystallization from ethyl acetate – petroleum ether gave, in 84% yield, 3.51 g of **3***a*, mp 143–143.5°C; ir (cm^{-1}): 2260 (CN), 1595, 1575; ^{1}H nmr ($CDCl_3$, 60 MHz) δ: 7.85–7.05 (m, 9H, ArH), 1.35 (s, 9H, *t*Bu); ms, *m/z*: 418 (M$^+$, 21), 537 (20), 283 (10), 243 (65), 240 (100), 183 (48), 144 (19), 105 (58). *Anal.* calcd. for $C_{26}H_{18}N_4O_2$: C 74.63, H 4.34, N 13.39; found: C 74.62, H 4.33, N 13.31.

Similarly, a solution of 3.90 g (22.5 mmol) of **1**, 1.1 g (10 mmol) of **2***b*, and 7.0 g (50 mmol) of K_2CO_3 in 25 mL of DMF was stirred for 36 h at room temperature. The reaction mixture was extracted with ethyl acetate and worked up as described above to give a crude crystalline product, contaminated by a small quantity of starting material **1**. Column chromatography of this crude mixture on silica gel and elution with 1:5 ethyl acetate – petroleum ether gave **1**. Further elution with 3:2 ethyl acetate – petroleum ether gave, in 78% yield, upon evaporation of the solvent and recrystallization from ethyl acetate – petroleum ether, 2.82 g of colourless needles of **3***b*, mp 189–190°C; ir (cm^{-1}): 2260, 1595, 1572; ^{1}H nmr ($CDCl_3$, 60 MHz) δ: 7.80–7.00 (m, 10H, ArH); ms, *m/z*: 363 (31), 362 (M$^+$, 100), 219 (30). *Anal.* calcd. for $C_{22}H_{10}N_4O_2$: C 72.93, H 2.78, N 15.46; found: C 73.07, H 2.56, N 15.48.

*Preparation of isoindolines 4*a and *4*b

The bis-1,3-diiminoisoindolines **4***a* and **4***b* were prepared as previously described (6, 12). In a typical example 20 mg of sodium was added to 40 mL of dry methanol under argon to form sodium methoxide. Nitrile **3***b* (500 mg, 1.38 mmol) was added and the oil bath heated to 60°C to dissolve the nitrile. Ammonia gas was bubbled into this solution as previously described (6) and the methanol evaporated to give crude **4***b*, which was used directly in the next step. An ir spectrum of the crude isoindolines must not exhibit any residual nitrile absorption.

*1,2-Bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninoxy)-4-*tert-*butylbenzene (7*a*) and 1,2-bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninoxy)benzene (7*b*)*

The crude bis-1,3-diiminoisoindoline (**4***a*) and 5-neopentoxy-1,3-diiminoisoindoline (**5**) obtained from 200 mg (0.48 mmol) of **3***a* and 2.5 g (11.68 mmol) of 4-neopentoxyphthalonitrile (5, 6) respectively, were heated at 150–160°C (oil bath) in 20 mL of 2-*N*,*N*-dimethylaminoethanol for 60 h under an argon atmosphere by methods similar to those previously described (6, 12). The reaction mixture was cooled, poured into water, filtered, and washed repeatedly with water. The crude reaction mixture was dissolved in 200 mL of toluene and stirred at 70°C for 5 h with 100 mL of 1 *M* KOH. The reaction mixture was cooled; the organic layer was separated from the aqueous layer and washed with water and saturated sodium chloride, and dried over magnesium sulphate. The toluene solution containing the phthalocyanine mixture was preadsorbed onto silica gel for flash chromatography (13). Elution with 600 mL of toluene – petroleum ether (5:1) followed by elution with pure toluene gave three initial fractions (200 mL each) followed by fifteen 100-mL fractions and, finally, two 1-L fractions. The early fractions contained pure 2,9,16,23-tetraneopentoxyphthalocyanine (**6**), the middle fractions mixtures of **6** and **7***a*, and the final fractions mixtures of **7***a* and another phthalocyanine thought to be a trinuclear phthalocyanine. The middle fractions containing **6** and **7***a* were rechromatographed on fresh silica by flash chromatography using toluene as eluant. Again monomer **6** eluted first, some mixed fractions eluted next, and pure **7***a* was finally isolated. All of **7***a* was eventually recovered by rechromatography of all mixed fractions. The yield of monomer **6** recovered was 58% (1.45 g). The final fractions containing dimer **7***a* and a trimer[4] were also separated by flash chromatography to give, in total, 108 mg (13% yield) of **7***a* as a dark, blue, shining solid, mp >300°C; ir (cm^{-1}): 3310 (NH), 1620, 1245, 1100, 1020 (NH); ms *m/z*: 1707.8 (100), 1706.8 (M$^+$, 87). *Anal.* calcd. for $C_{104}H_{106}N_{16}O_8$: C 73.13, H 6.25, N 13.12; found: C 72.97, H 6.32, N 13.57.

A small fraction of the dimer–trimer mixture was chromatographed on preparative tlc plates using toluene/2-methoxyethanol (200:1) as solvent. The slower moving blue-green fraction was extracted with toluene and finally purified by flash chromatography using toluene/2-methoxyethanol (50:1) as solvent to give a very small quantity of a blue green solid. *Mol. Wt.* (FAB ms) calcd. for $C_{156}N_{154}N_{24}O_{12}$: 2556.91; found 2556.2 (100), 2555.2 (M$^+$, 76).

Similarly, the crude bis-1,3-diiminoisoindoline (**4***b*) and **5**, obtained from 500 mg (1.38 mmol) of **3***b* and 7.5 g (35.0 mmol) of 4-neopentoxyphthalonitrile (5, 6), respectively, gave monomer **6** in the toluene fractions on flash chromatography of the crude product obtained from the reaction mixture. Further elution with toluene/2-methoxyethanol (100:1) and toluene/2-methoxyethanol (200:5) gave mixed monomer–dimer fractions and pure dimer fractions. Rechromatography of the mixed fractions gave a total of 3.15 g of pure monomer **6** in 42% yield and 222 mg (10% yield) of pure dimer **7***b* as a dark, blue, shining solid, mp >300°C; ir (cm^{-1}): 3310 (NH), 1625, 1248, 1105, 1020 (NH); ms *m/z*: 1651.8 (100), 1650.8 (M$^+$, 61). *Anal.* calcd. for $C_{100}H_{98}N_{16}O_8$: C 72.71, H 5.98, N 13.57; found: C 73.24, H 5.98, N 13.19.

*1,2-Bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninoxycobalt(II))benzene (7*c*)*

A solution of 100 mg (0.06 mmol) of **7***b* and 80 mg of cobalt(II) chloride in 10 mL of toluene/2-methoxyethanol (7:3) was heated at 110°C under argon for 30 h as previously described (6). Flash chromatography of the crude product using toluene/2-methoxyethanol (50:1) as eluant gave, in 69% yield, 73 mg of **7***c* as a shiny blue solid, mp >300°C; ir (cm^{-1}): 1620, 1250, 1105, 1070, 760; ms *m/z*: 1765.6

(100), 1764.6 (M^+, 62). *Anal.* calcd. for $C_{100}H_{94}N_{16}O_8Co_2$: C 68.06, H 5.37, N 12.70, Co 6.68; found: C 68.21, H 5.54, N 12.34, Co 6.44.

4-Aminophthalonitrile (8)

A suspension of 5.19 g (30 mmol) of 4-nitrophthalonitrile (**1**) (29) and 0.5–0.6 g of 10% palladium on charcoal in 150 mL of 95% ethanol was placed a 500-mL jar in a Parr hydrogenation apparatus and hydrogenated at 415 kPa according to the procedure of Rasmussen *et al.* (30). The crude product (4.2 g, mp 175–178°C) was chromatographed using normal grade silica gel. Elution with benzene – ethyl acetate (3:1) gave 3.6 g (84% yield) of pure white crystals of **8**, mp 179–180°C (lit. (30) mp 179–181°C). Compound **8** does deteriorate on standing and is usually directly converted into compound **9** described below.

4-Iodophthalonitrile (9)

A suspension of 4.29 g (30 mmol) of **8** in 60 mL of 2.5 *M* H_2SO_4 was cooled to −10°C. A solution of 2.4 g (34 mmol) of sodium nitrite in 5–8 mL of H_2O was added dropwise with stirring, while the temperature of the mixture was kept at −10 to 0°C. Stirring was continued at 0°C for 0.5 h to complete the reaction. The resulting mixture was rapidly filtered by suction filtration and the cool filtrate was added in a small portion to a cool solution of 5.4 g (32 mmol) of potassium iodide in 30 mL of water. The resulting black mixture was allowed to warm to room temperature with stirring. The precipitated black solid was collected by suction filtration, washed with cold water, and dissolved in benzene. The benzene solution was washed with cold water, 5% $NaHCO_3$, cold water, saturated $Na_2S_2O_3$, again with water, dried over $MgSO_4$, filtered, and concentrated to a small volume. Chromatography on 200 g of normal grade silica gel and elution with benzene gave, in 70% yield, 5.3 g of pure **9** as white crystals, mp 142–143°C (lit. (31) mp 141–142°C); ir (cm^{-1}): 3020–2960, 2240 (CN), 1580, 940, 850, 845; ^1H nmr ($CDCl_3$, 60 MHz) δ: 8.22–8.08 (m, 2H, ArH-3,6), 7.61–7.55 (m, 1H, ArH-5); ms m/z: 254 (M^+, 87), 127 (100), 100 (38).

4-(2-Trimethylsilylethynyl)phthalonitrile (12) and 4-(3,3-dimethyl-1-butynyl)phthalonitrile (13)

To a solution of 5.08 g (20 mmol) of **9** in 80 mL of dry, freshly distilled diethylamine was added 2.1 g (22 mmol) of triethylsilylacetylene (**10**), 38 mg (0.2 mmol) of copper(I) iodide, and 140 mg (0.2 mmol) of bis(triphenylphosphine)palladium dichloride under an argon atmosphere, using the procedure of Takahashi *et al.* (16). The reaction mixture was stirred at room temperature for 3 h, during which time a precipitate of diethylamine hydroiodide appears. The mixture was filtered to separate the precipitated salt and the filtrate was concentrated on the rotary evaporator. The residue was extracted into benzene and purified by column chromatography on neutral alumina, activity II–III, using benzene as the eluting solvent. Evaporation of the solvent gave an oil which, on distillation in a Kugelrohr apparatus at 110–120°C/0.01 Torr (1 Torr = 133.3 Pa), gave 3.4 g (75% yield) of a white solid (**12**), mp 74–75°C; ir (cm^{-1}): 3100, 2240 (CN), 1600, 1498, 1440, 1345, 1265, 1250, 860, 840; ^1H nmr (CCl_4, 60 MHz) δ: 7.65–7.52 (m, 3H, ArH), 0.05 (s, 9H, $(CH_3)_3Si$); ms m/z: 224 (M^+, 17), 209 (100), 179 (14), 73 (70), 59 (27), 43 (23). *Anal.* calcd. for $C_{13}H_{12}N_2Si$: C 69.59, H 5.39, N 12.49; found: C 69.51, H 5.53, N 12.19. Product **12** rapidly decomposed in the presence of water.

Similarly, a mixture of 2.54 g (10 mmol) of **9**, 0.82 g (10 mmol) of *tert*-butylacetylene (**11**), 20 mg (0.1 mmol) of copper(I) iodide, and 140 mg (0.2 mmol) of bis(triphenylphosphine)palladium dichloride in 50 mL of dry, freshly distilled diethylamine was stirred overnight under an argon atmosphere. Analysis by thin-layer chromatography (tlc), using ether–hexane 1:4 as eluant, showed the presence of unreacted **9**. An additional 0.16 g of **11** was added and stirring was continued for a further 12 h. A final addition of 0.16 g of **11** was added and, after stirring for a total of 72 h, the reaction was still not completed. The reaction mixture was worked up as described above. Flash chromatography of the crude product using 1:19 ether–hexane as eluant gave an oil, which on distillation in a Kugelrohr apparatus at 130–135°C/0.01 Torr yielded 1.6 g (75% yield) of pure **13**, mp 60–61°C; ir (cm^{-1}): 3100, 3000, 2250 (CN), 2235, 1600, 1490, 1370, 1320, 1275, 910, 880; ^1H nmr ($CDCl_3$, 300 MHz) δ: 7.77–7.67 (m, 3H, ArH), 1.32 (s, 9H, $(CH_3)_3C$); ms m/z: 208 (M^+, 20), 193 (100), 178 (13), 165 (18). *Anal.* calcd. for $C_{14}H_{12}N_2$: C 80.73, H 5.81, N 13.45; found: C 80.70, H 5.90, N 13.21.

4-(2-Trimethylsilylethyl)phthalonitrile (14), 4-ethylphthalonitrile (30), and 4-(3,3-dimethylbutyl)phthalonitrile (15)

A solution of 2.8 g (12.5 mmol) of **12** in 50 mL of dry ethyl acetate was hydrogenated over 10% palladium on charcoal at 275 kPa for 1 h. The catalyst was filtered and the filtrate evaporated to dryness. Column chromatography of the product on 150 g of normal grade silica gel using ethyl acetate – hexane (1:4) as eluant gave, upon evaporation of the solvent, 2.5 g (88% yield) of colourless needles. Distillation of the solid product in a Kugelrohr apparatus at 140–145°C/0.1 Torr gave pure **14**, mp 63–64°C; ir (cm^{-1}): 3090, 2970, 2240 (CN), 1605, 1498, 1345, 1265, 1250, 860, 840, 700; ^1H nmr ($CDCl_3$, 300 MHz) δ: 7.60–7.45 (m,3H, ArH), 2.71 (m, 2H, CH_2ArH), 0.84 (m, 2H, CH_2Si), 0.01 (s, 9H, $(CH_3)_3Si$); ms m/z: 228 (M^+, 41), 213 (35), 73 (100), 59 (68), 43 (17). *Anal.* calcd. for $C_{13}H_{16}N_2Si$: C 68.36, H 7.06, N 12.26; found: C 68.11, H 7.18, N 12.29.

Further elution of the silica gel gave 0.1 g of 4-ethylphthalonitrile **30**) as a white solid, mp 42–43°C; ir (cm^{-1}): 3000–2900, 2245 (CN), 1600, 1500, 1240, 1070, 870, 850; ^1H nmr ($CDCl_3$, 60 MHz) δ: 7.8–7.4 (m, 3H, ArH), 2.8 (q, J = 8 Hz, 2H, CH_2), 0.84 (t, J = 8 Hz, 3H, CH_3); ms m/z: 156 (M^+, 50), 141 (100), 114 (40). *Anal.* calcd. for $C_{10}H_8N_2$: C 76.90, H 5.16, N 17.94; found: C 77.23, H 5.33, N 17.99.

Similarly, hydrogenation of 3.6 g (17 mmol) of **13** in 100 mL of dry ethanol for 1 h as described above yielded a crude oil. Flash chromatography of this oil using ether–hexane (1:9) as eluant and distillation of product using a Kugelrohr apparatus gave 3.3 g (92% yield) of **15** as a colourless oil, bp 130–138°C/0.01 Torr; ir (neat, cm^{-1}): 2980, 2250 (CN), 1610, 1500, 1380, 1250, 850; ^1H nmr ($CDCl_3$, 300 MHz) δ: 7.80–7.78 (m, 1H, ArH), 7.65–7.58 (m, 2H, ArH), 2.74–2.68 (m, 2H, CH_2Ar), 1.54–1.48 (m, 2H, CH_2C), 1.33 (s, 9H, $(CH_3)_3C$). *Anal.* calcd. for $C_{14}H_{16}N_2$: C 79.20, H 7.59, N 13.20; found: C 79.05, H 7.49, N 13.05.

Preparation of 5-(2-trimethylsilylethyl)-1,3-diiminoisoindoline (16) and 5-(3,3-dimethylbutyl)-1,3-diiminoisoindoline (17)

All diiminoisoindolines were prepared as previously described (5, 6, 11, 12). In a typical example 115 mg (0.50 mmol) of **14** was added to a solution of 15 mg of sodium in 10 mL of dry methanol. The mixture was stirred at room temperature for 1 h and for 4 h under reflux conditions, during which ammonia gas was bubbled into the solution. Evaporation of the solvent gave crude **16**, which was used directly in condensation reactions without further purification. Compounds **16** and **17** did not exhibit nitrile absorptions in their ir spectra.

Preparation of 2,9,16,23-tetra-(2-trimethylsilylethyl)phthalocyanine (18) and 2,9,16,23-tetra-(3,3-dimethylbutyl)phthalocyanine (19)

The crude diiminoisoindoline **16**, obtained from 115 mg (0.50 mmol) of **14** in 2 mL of 2-*N*, *N*-dimethylaminoethanol, underwent self-condensation as previously described (5, 6, 11, 12) to give 60 mg of a crude reaction product. Flash chromatography of this product using toluene as eluant gave, upon evaporation of the solvent, 33 mg (28% yield) of **18** as a dark blue, shining solid; ir (cm^{-1}): 3310 (NH), 1620, 1255, 1100, 1015 (NH), 870, 840, 760; ms m/z: 915 (M^+, 100), 841 (28). *Anal.* calcd. for $C_{52}H_{66}N_8Si_4$: C 68.22, H 7.27, N 12.24; found: C 68.31, H 6.99, N 12.24.

Similarly, the crude diiminoisoindoline **17**, obtained from 118 mg (0.56 mmol) of **13** in 2 mL of 2-*N*,*N*-dimethylaminoethanol, underwent self-condensation as previously described (5, 6, 11, 12) to give 90 mg of a crude reaction product. Flash chromatography of this product using toluene as eluant gave, upon evaporation of the solvent, 48 mg (40% yield) of **19** as a dark blue, shining solid; ir (cm^{-1}): 3320 (NH), 1625, 1105, 1020 (NH), 760; ms m/z: 850 (M^+, 100), 791 (35), 424 (47). *Anal.* calcd. for $C_{56}H_{66}N_8$: C 79.02, H 7.82, N 13.16; found: C 78.71, H 7.76, N 13.09.

*2,9,16,23-Tetra-(3,3-dimethylbutyl)phthalocyaninatocobalt(II) (**20**)*

To a solution of 153 mg (0.18 mmol) of **19** in 15 mL of toluene and 5 mL of 2-methoxyethanol was added 91 mg (0.70 mmol) of anhydrous cobalt(II) chloride as previously described (6). The solution was stirred at 115°C (oil bath) under an argon atmosphere for 19 h. The crude reaction mixture was cooled to room temperature and the solvent evaporated. Flash chromatography of the residue using toluene as the eluting solvent gave, in 48% yield, 78 mg of **20** as a dark blue, shining solid; ir (cm^{-1}): 1625, 1105, 760; ms m/z: 908 (M$^+$, 75), 850 (21). *Anal.* calcd. for $C_{56}H_{64}N_8Co$: C 74.07, H 7.10, N 12.34, Co 6.49; found: C 74.50, H 7.64, N 11.58, Co 6.50.

*1,2-Bis-(3,4-dicyanophenyl)ethyne (**22**) and 1,2-bis-(3,4-dicyanophenyl)ethane (**23**)*

By the procedure described above for the preparation of **12** and **13**, 5.1 g (20 mmol) of **9**, 150 mL of dry, freshly distilled diethylamine, 38 mg (0.2 mmol) of copper(I) iodide, and 70 mg (0.1 mmol) of bis(triphenylphosphine)palladium dichloride was placed into a 250-mL two-necked flask, equipped with a magnetic stirrer, a condenser, and a gas inlet tube. The flask was flushed with argon and a moderate stream of dry acetylene was passed through the solution for 3 h at room temperature. The pale pink precipitate that was formed was collected by filtration from the brown solution. The crude product was washed with water, methanol, and ether, and air dried to give, in 90% yield, 2.5 g of **22**, mp 286–288°C. This product is sufficiently pure that it can be used directly without further purification. Two recrystallizations of a small sample of **22** from acetonitrile gave colourless crystals of pure **22**, mp 296–297°C; ir (cm^{-1}): 3090, 2240 (CN), 1600, 1500, 1260, 920, 865; ms m/z: 278 (M$^+$, 100), 251 (14), 224 (8), 149 (35), 139 (11), 85 (38), 57 (97), 43 (73). *Anal.* calcd. for $C_{18}H_6N_4$: C 77.69, H 2.17, N 20.13; found: C 77.97, H 1.96, N 20.01. Compound **22** is very insoluble in common organic solvents and is only slightly soluble in boiling acetonitrile (100 mg in 50 mL). The ^{1}H and ^{13}C nmr of **22** was not determined, as a suitable solvent was not found in which **22** was sufficiently soluble.

A suspension of 0.6 g (2.1 mmol) of **22** in 300 mL of acetonitrile, containing 100 mg of 10% palladium on charcoal, was hydrogenated at 415 kPa in a Parr hydrogenation bottle for 4 h at room temperature. The clear solution was filtered from the catalyst and concentrated. The compound was purified by flash chromatography using hot acetonitrile as eluant to give 0.5 g (83% yield) of **23** as white needles, mp 257–258°C; ir (cm^{-1}): 3100, 2980, 2240 (CN), 1600, 1490, 1390, 1240, 925, 860; ^{1}H nmr (CD_3CN, 400 MHz) δ: 7.81 (d, J = 8 Hz, 2H, ArH-5), 7.76 (s, 2H, ArH-2), 7.58 (d, J = 8 Hz, 2H, ArH-6), 3.05 (s, 4H, CH_2); ms m/z: 282 (M$^+$, 31), 141 (100), 114 (49), 57 (73), 39 (11). *Anal.* calcd. for $C_{18}H_{10}N_4$: C 76.58, H 3.57, N 19.84; found: C 76.76, H 3.47, N 19.94.

*Preparation of the bis-1,3-diiminoisoindoline (**24**)*

Compound **24** was prepared as previously described (6) for the preparation of 1,3-diiminoisoindolines derived from bisphthalonitriles only slightly soluble in methanol.

*1,2-Bis-2'-(9',16',23'-tri-(2-trimethylsilylethyl)phthalocyaninyl)ethane (**25**)*

The two crude diiminoisoindolines **16** and **24**, obtained from 4.80 g (21.1 mmol) of **14** and 203 mg (0.72 mmol) of **23**, respectively, in 30 mL of 2-N,N-dimethylaminoethanol, underwent a mixed condensation as previously described (5,6) to give 5 g of a crude reaction product. Flash chromatography on silica gel of this product on a 5-cm diameter column using toluene–hexane (1:1) as eluant gave 1.63 g of the monomeric **18** in 34% yield. Further elution with toluene gave a fraction consisting largely of dimer. This dimer fraction was purified further by flash chromatography on a 3-cm diameter column. Elution with toluene–hexane (1:1) removed all traces of monomer, as analyzed by tlc using toluene as eluant. Further elution with toluene gave a blue solid containing a trace of impurities, detected by tlc analysis and visualization with uv light. The blue solid was freed of these impurities by washing with methanol to give, in 7% yield, 83 mg of the binuclear phthalocyanine **25** as a dark blue, shining solid; ir (cm^{-1}): 3320 (NH), 1620, 1260, 1105, 1020 (NH), 870, 840, 760; ms m/z: 1659 (48), 1658 (63), 1657 (100), 1656 (91), 1655 (M$^+$, 65). *Anal.* calcd. for $C_{96}H_{110}N_{16}Si_6$: C 69.61, H 6.69, N 13.53; found: C 69.65, H 6.80, N 13.16.

*1,2-Bis-2'-(9',16',23'-tri-(3,3-dimethylbutyl)phthalocyaninyl)ethane (**26**)*

The two crude diiminoisoindolines **17** and **24**, obtained from 4.46 g (21.0 mmol) of **15** and 203 mg (0.72 mmol) of **23**, respectively, in 30 mL of 2-N,N-dimethylaminoethanol, underwent a mixed condensation as described for **7*a***, **7*b***, and **25** above and previously (5, 6) to give 5 g of a crude reaction product. Flash chromatography of this product on silica gel (5-cm diameter column) using toluene–hexane (1:1) and pure toluene gave 2.07 g of the monomeric phthalocyanine **19** containing traces of dimer, as analyzed by tlc using toluene as eluant. Further elution with 2-methoxyethanol/toluene (1:100) gave a fraction consisting largely of dimer containing traces of monomer. Finally, elution with 2-methoxyethanol/toluene (1:4) gave a green fraction consisting largely of trimer and impurities. The solid monomer fraction was placed in the thimble of a Soxhlet extractor and extracted with refluxing hexanes to give 0.52 g of pure monomer **19**. Using the Soxhlet extractor and refluxing toluene as solvent, a further 0.71 g of **19** was isolated from the extracting solvent on evaporation, leaving 0.84 g of insoluble monomer containing traces of dimer in the thimble. It is possible that some of the positional isomers of **19** are more soluble than others and that the above selective extraction has effected a partial separation of these isomers. The dimer fraction was purified by vacuum liquid chromatography (vlc) (32) using toluene–hexanes (1:1) as the eluting solvent followed by increasing amounts of 2-methoxyethanol/toluene (1:100 to 5:100). The vlc removed most of the monomer (but not all) and a final separation was achieved by flash chromatography (13) using the same eluting solvents as above to give, in 8% yield, 90 mg of the pure binuclear phthalocyanine **26** as a dark blue, shining solid; ir (cm^{-1}): 3320 (NH), 1625, 1105, 1015 (NH), 760; ms m/z: 1561 (84), 1560 (100), 1559 (M$^+$, 84). *Anal.* calcd. for $C_{102}H_{110}N_{16}$: C 78.53, H 7.11, N 14.36; found: C 79.36, H 7.62, N 13.49.

*1,2-Bis-2'-(9',16',23'-trineopentoxyphthalocyaninyl)ethane (**27**)*

The two crude diiminoisoindolines **5** and **24**, obtained from 6.0 g (28 mmol) of 4-neopentoxyphthalonitrile (5, 6) and 284 mg (1.0 mmol) of **23**, were heated to 150°C (oil bath) in 30 mL of 2-N,N-dimethylaminoethanol for 60 h under argon as previously described (5, 6). The crude product was purified by flash chromatography using a 5-cm diameter column packed with silica gel 12 cm high. The crude product was preabsorbed on silica and eluted with toluene to give 2.67 g of the monomeric **6** in 44% yield. Further elution with 2-methoxyethanol/toluene (1:100) gave a fraction consisting largely of dimer containing traces of monomer and some green material. Finally, elution with 2-methoxyethanol/toluene (1:4) gave a green fraction consisting largely of trimer and impurities. The dimer fraction was further purified by flash chromatography (3-cm diameter column). Elution with toluene removed all traces of monomer. Further elution with 2-methoxyethanol/toluene (5:200) gave a dark blue product. This product was washed with acetone to remove traces of fluorescent and light green impurities, detectable by tlc using toluene/2-methoxyethanol (200:5) as eluant, to give in 10% yield 159 mg of **27** as a dark blue, shining solid; ir (cm^{-1}): 3310 (NH), 1620, 1245, 1100, 1020 (NH), 755; ms m/z: 1574.8 (51), 1572.8 (90), 1571.8 (100), 1570.8 (M$^+$, 60). *Anal.* calcd. for $C_{96}H_{98}N_{16}O_6$: C 73.35, H 6.28, N 14.26; found: C 73.08, H 6.34, N 14.19.

The "trimer" fraction was further purified by flash chromatography (3-cm diameter column). Elution with 2-methoxyethanol/toluene (3:200) removed all traces of dimer. Further elution with 2-methoxyethanol/toluene 1:20 gave 280 mg of a dark, blue, shining solid in 25% yield. This product was not characterized.

*1,2-Bis-2'-(9',16',23'-trineopentoxyphthalocyaninyl cobalt(II))ethane (**28**)*

A mixture of 44 mg (0.028 mmol) of metal-free dimer **27** and

21 mg (0.16 mmol) of anhydrous cobalt(II) chloride in 13 mL of a 1:4 mixture of 2-methoxyethanol/toluene was heated at 120°C for 20 h under an argon atmosphere. Flash chromatography of the crude reaction mixture on a 3-cm diameter column of silica gel and elution with 2-methoxyethanol/toluene (1:20 and then 1:8) gave, in 55% yield, 26 mg of **28** as a dark blue, shining solid; ir (cm^{-1}): 1620, 1245, 1100, 760; ms *m/z*: 1687.6 (49), 1686.6 (80), 1685.6 (100), 1684.6 (M^+, 76), 1630.6 (38), 1629.6 (57), 1628.6 (72), 1627.6 (51). *Anal.* calcd. for $C_{96}H_{94}N_{16}O_6Co_2$: C 68.40, H 5.62, N 13.29, Co 6.99; found: C 68.06, H 5.75, N 12.95, Co 7.19.

4-Ethynylphthalonitrile (29)

Preliminary experiments conducted on the hydrolysis of **12** to **29** showed that hydrolysis was slow in pyridine alone, pyridine and methanol, or pyridine and copper(II) acetate, and that all three components are necessary for rapid hydrolysis. These conditions are identical with those necessary for the coupling of terminal alkynes by the Eglinton procedure (20) except that hydrolysis occurs at room temperature. A solution of 0.09 g (0.4 mmol) of **12**, 1.6 g of copper(II) acetate monohydrate, 0.8 mL of methanol, and 14 mL of pyridine was stirred for 1 h at room temperature. The reaction mixture was filtered and washed with pyridine and methanol. The filtrate was evaporated to dryness *in vacuo* and extracted with methylene chloride. The extract was washed with water, dilute hydrochloric acid, and water, and dried over $MgSO_4$. Evaporation of the solvent gave a product which was purified by flash chromatography, using ethyl acetate − hexane (1:4) as eluant. Evaporation of the eluant gave, in 82% yield, 50 mg of pure **29** as white crystals, mp 88–90°C; ir (Nujol, cm^{-1}): 3280 ($\equiv$C—H), 2250, 2135, 1600, 930, 850; ^{1}H nmr ($CDCl_3$, 60 MHz) δ: 8.0–7.8 (m, 3H, ArH), 3.45 (s, 1H, $\equiv$C—H); ms *m/z*: 152 (M^+, 100), 125 (46), 99 (28), 74 (26), 50 (37). *Anal.* calcd. for $C_{10}H_4N_2$: C 78.94, H 2.68, N 18.41; found: C 78.28, H 3.00, N 18.60.

Further elution of the silica gel gave 10 mg of **31** described below.

1,4-Bis-(3,4-dicyanophenyl)-1,3-butadiyne (31)

Using the Eglinton terminal alkyne coupling procedure (20) and recognizing that **12** gives **29** under the conditions of this reaction, 0.45 g (2.0) mmol) of **12** was mixed with 8.0 g of copper(II) acetate monohydrate in 70 mL of dry pyridine and 4 mL of dry methanol. The mixture was heated at 50–55°C for 0.75 h with stirring under argon. The reaction mixture was cooled to room temperature, filtered, and washed with pyridine and methanol. The filtrate was worked up as described for **29** above to give, in 76% yield, 0.23 g of a crude product, mp 299–302°C. Further purification by flash chromatography on silica gel using CH_2Cl_2 as eluant gave, upon evaporation of the solvent, in 70% total yield 0.21 g of pure white crystals of **31**, mp 303–304°C; ir (cm^{-1}): 3100, 2250 (CN), 2180 (C$\equiv$C), 1600, 1300, 1240, 925, 860; ^{1}H nmr (CD_2Cl_2, 60 MHz) δ: 7.9–7.7 (m, 6H, ArH); ms *m/z*: 302 (M^+, 100), 275 (7), 248 (5), 224 (8), 200 (8), 151 (8), 124 (4), 98 (4), 74 (4). *Anal.* calcd. for $C_{20}H_6N_4$: C 79.46, H 1.99, N 18.54; found: C 79.39, H 1.81, N 18.48.

1,4-Bis-(3,4-dicyanophenyl)butane (32)

A solution of 0.15 g (0.5 mmol) of **31** in 100 mL of dry tetrahydrofuran (THF) and 50 mg of 10% palladium on charcoal was hydrogenated at 275 kPa in a Parr hydrogenator for 1 h at room temperature. The catalyst was filtered over Celite and washed with THF. The filtrate was evaporated to give fine colourless crystals in quantitative yield. Further purification by flash chromatography on silica gel using CH_2Cl_2–ether (1:10) gave 0.13 g in 84% yield of pure **32**, mp 168–169°C; ir (cm^{-1}): 3100, 2950, 2240 (CN), 1600, 1500, 1250, 860, 850; ^{1}H nmr (CD_2Cl_2, 400 MHz) δ: 7.73 (d, J = 8 Hz, 2H, ArH-5), 7.62 (s, 2H, ArH-2), 7.53 (d, J = 8 Hz, ArH-6), 2.77 (t, J = 8 Hz, 4H, ArCH_2), 1.67 (m, 4H, CH_2); ms *m/z*: 310 (M^+, 39), 169 (26), 155 (58), 141 (100), 114 (41), 39 (13). *Anal.* calcd. for $C_{20}H_{14}N_4$: C 77.39, H 4.55, N 18.05; found: C 77.62, H 4.35, N 17.97.

Preparation of the bis-1,3-diiminoisoindoline (33)

Compound **33** was prepared as previously described (6) for the preparation of 1,3-diiminoisoindolines derived from bisphthalonitriles only slightly soluble in methanol.

1,4-Bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninyl)butane (34)

The two crude diiminoisoindolines **5** and **33**, obtained from 6.0 g (28 mmol) of 4-neopentoxyphthalonitrile (5, 6) and 310 mg (1.0 mmol) of **32**, respectively, were heated to 150°C (oil bath) in 30 mL of 2-*N*,*N*-dimethylaminoethanol for 60 h under argon as described for the preparation of **27**. Using a work-up identical to that for **27**, purification by flash chromatography as before gave 1.64g of monomer **6** in 27% yield and, in 1.4% yield, 23 mg of dimer **34** as a dark blue, shining solid; ir (cm^{-1}): 3320 (NH), 1620, 1250, 1105, 1020 (NH), 760; ms *m/z*: 1561.8 (25), 1560.8 (85), 1599.8 (100), 1598.8 (M^+, 64). *Anal.* calcd. for $C_{98}H_{102}N_{16}O_6$: C 73.57, H 6.42, N 14.01; found: C 72.91, H 6.62, N 13.65.

Qinghaosu: ^{1}H and ^{13}C nuclear magnetic resonance spectral assignments and luminescence[1]

WANG ZHONGSHAN,[2] THOMAS T. NAKASHIMA, KARL R. KOPECKY,[3] AND JOSÉ MOLINA
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received February 6, 1985

WANG ZHONGSHAN, THOMAS T. NAKASHIMA, KARL R. KOPECKY, and JOSÉ MOLINA. Can. J. Chem. **63**, 3070 (1985).

The complete assignment of the ^{1}H and ^{13}C nmr signals for Qinghaosu **1** has been made. Treatment of **1** with methoxide ion at 80°C results in bright luminescence when carried out in the presence of fluorescers. Several products are formed when methanol is present, but in toluene only one product is formed when methanol-free methoxide is used. Its structure is tentatively assigned as 1-(1-methoxycarbonylethyl)-2,6-dimethyl-2-hydroxybicyclo[3.3.1]nonan-9-one.

WANG ZHONGSHAN, THOMAS T. NAKASHIMA, KARL R. KOPECKY et JOSÉ MOLINA. Can. J. Chem. **63**, 3070 (1985).

On a complètement attribué les signaux de la rmn du ^{1}H et du ^{13}C du Qinghaosu, **1**. Le composé **1** réagit avec l'ion méthanolate à 80°C en présence de substances fluorescentes en provoquant une vive luminescence. En présence de méthanol, on obtient plusieurs produits; toutefois, dans le toluène, il ne se forme qu'un seul produit lorsqu'on utilise du méthanol exempt de méthanolate. On pense que le composé **1** est la (méthoxycarbonyl-1 éthyl)-1 diméthyl-2,6 hydroxy-2 bicyclo[3.3.1]nonanone-9.

[Traduit par le journal]

Qinghaosu **1**, isolated from *Artemisia annua* L., is the active constituent of the traditional Chinese herbal medicine Qinghao. It is a plasmocidal agent and there is intense interest in the possible use of this compound for the treatment of drug resistant malaria (1). An X-ray diffraction study of **1** shows it to be a sesquiterpene lactone containing an endoperoxide group (2). A total synthesis of **1** was reported recently (3).

The intriguing structure of **1**, one of few naturally occurring molecules containing a peroxide group, and its biological activity have led to the present nmr studies. The results should be of value for future biosynthetic studies of this molecule. Also, examination of **1** leads to the possibility that a dioxetane intermediate might be formed upon treatment with base by the sequence of reactions outlined in Chart 1.

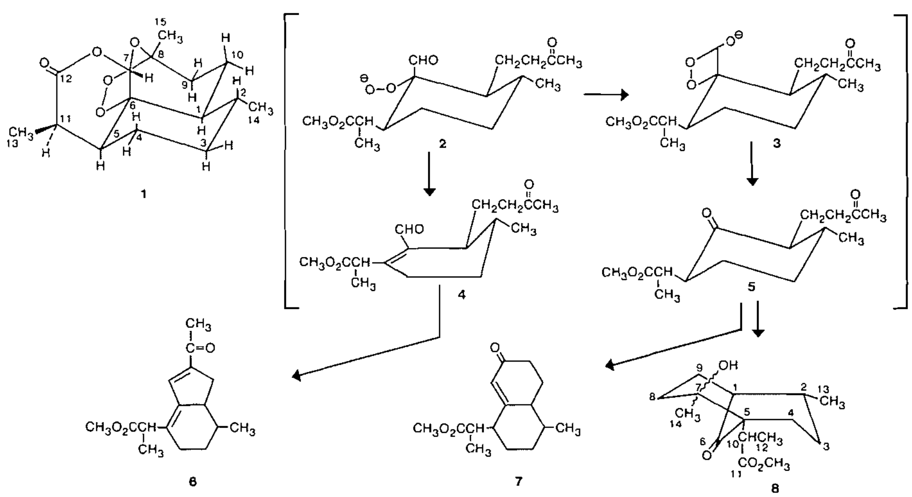

CHART 1

Decomposition of the dioxetane should be luminescent and this reaction could be the basis of a quantitative assay for **1**. In fact, a luminescent reaction does occur when **1** is treated with methoxide ion at 80°C. A tentative assignment has been made for a major product of the reaction. Consumption of the limited supply of **1** available prompts the report of the results at the present time.

Experimental

A sample of Qinghaosu was obtained from the Kunming Pharmaceutical Factory in China.

Mass spectra were taken on an AEI MS 12 (gc–ms) or MS 50 mass spectrometer using an electron impact of 70 eV.

All nmr spectra of **1** were recorded on Bruker WH200 or WH400 spectrometers in the pulsed Fourier transform mode using an Aspect 2000 computer with 16 or 32 K data points, and with sweep widths of 2500 or 5000 Hz and 12 500 or 25 000 Hz for ^{1}H and ^{13}C, respectively. The sample was dissolved in C_6D_6 or $CDCl_3$ at various concentrations to take advantage of induced solvent and concentration shifts to facilitate assignments. The chemical shifts and coupling constants were calculated to first order at 400 MHz and are reported to an accuracy of ±0.01 ppm (except as indicated), ±0.2 Hz for ^{1}H, and ±0.2 ppm and ±2 Hz for ^{13}C. The nOe (nuclear Overhauser effect) difference experiments were carried out in the standard manner (4) after removing oxygen from the solution by bubbling N_2 through it for several minutes. Multiplicities of the ^{13}C resonances were determined by the

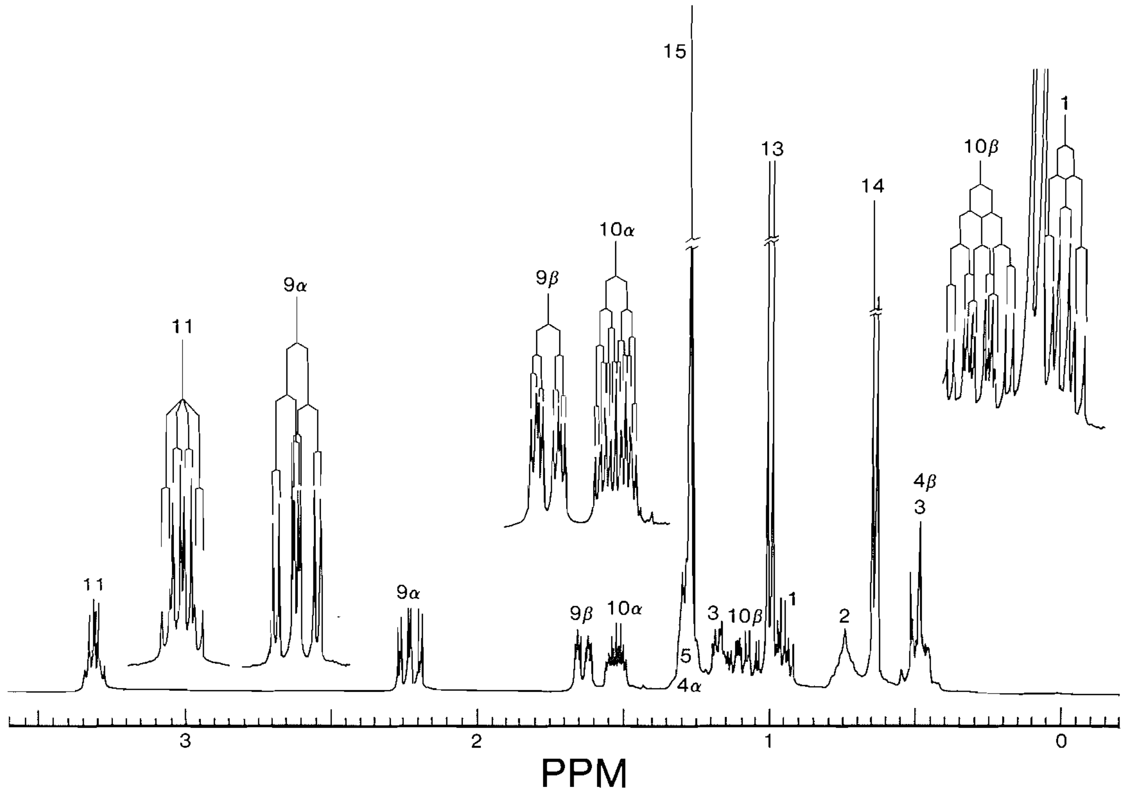

FIG. 1. The ^{1}H nmr spectrum of 0.14 *M* Qinghaosu in $CDCl_3$ at 25°C.

^{13}C spin echo technique with gated ^{1}H decoupling (5) using τ_2 = 0.0077 s, for which responses from doublets and quartets are 180° out of phase with those from singlets and triplets. The selective 2D-DEPT (6) experiment was used to correlate ^{1}H chemical shifts to ^{13}C chemical shifts. The pulse sequence used was $90_x(^1H-t_{1/2}-1/2J_{CH}-180_x(^1H)-90_y(^{13}C)-\theta_y(^1H)180_x(^1H)(^{13}C)-1/2J_{CH}$-acq. Only the θ_y = 30° 2D data set was collected, which yielded the correlation map for all $C(H)_n$ carbons. The value of $1/2(J_{CH})$ was chosen to be 0.00388.

*Reaction of **1** with methoxide ion*

A suspension of sodium methoxide in toluene was prepared by distilling a mixture of toluene and methanolic sodium methoxide until the vapor temperature reached 105°C. A solution of 0.1 g **1** in 20 mL toluene containing a suspension of two equiv. of sodium methoxide was heated at 100°C for 15 min. The cooled reaction mixture was acidified with acetic acid and evaporated to dryness. The residue was stirred with 5 mL chloroform, the resulting mixture cooled to −40°C, treated with ethereal diazomethane, and the solvent removed. Flash chromatography using ether – petroleum ether mixtures afforded 70 mg of **1** and 9 mg of **8**; ^{1}H nmr ($CDCl_3$) δ: 1.07 (3H, d, *J* = 7 Hz, H-13), 1.18 (3H, d, *J* = 7 Hz, H-12), 1.41–1.63 (3H, m), 1.66–2.09 (5H, m), 2.12 (3H, s, H-14), 2.22–2.70 (3H, m), 2.76 (1H, m, H-10), 3.67 (3H, s, O-CH_3); ms: 268 (M^+, 3), 250 ($M^+ - H_2O$, 100), 237 ($M^+ - OCH_3$, 9), 235 (8), 210 (13), 209 (21), 208 (22), 193 (17), 191 (23), 181 (15), 180 (47), 179 (34), 178 (28), 166 (14), 165 (26), 163 (41), 162 (20), 151 (42). *Exact Mass* calcd. for $C_{15}H_{24}O_4$: 268.1674; found: 268.1683. Smaller amounts of other products were formed which were not identified.

Treatment of **1** at 80°C for several min with sodium methoxide in a homogeneous toluene, benzene, or dimethoxyethane solution from which not all the methanol had been removed resulted in complete consumption of **1** and the formation of at least six products. All the four major products of this reaction were different from **8**. The products were not isolated. The most abundant ions in their mass spectra, obtained by gc–ms, are given here for the four major products, labelled A–D in the order of their elution from a SE30 gc column: A, 250 (M^+?, 30), 209 (10), 193 (10), 189 (11), 180 (21), 165 (19), 163 (21), 162 (15), 151 (23), 123 (15), 111 (17), 110 (13), 95 (21), 69 (16), 55 (22), 43 (100); B, 262 (M^+, 49), 203 (19), 175 (18), 161 (12), 131 (20), 43 (100); C, 262 (M^+, 25), 175 (40), 174 (12), 159 (13), 133 (20), 131 (35), 43 (100); D, 250 (M^+?, 38), 192 (14), 191 (100), 163 (71), 162 (25), 133 (13), 121 (20), 119 (14), 107 (21), 105 (19), 93 (16), 91 (27), 79 (19), 77 (14), 55 (26), 43 (14), 41 (21).

Formate ion was determined to be present in 30–50% yields in the aqueous extracts of these reaction mixtures. The aqueous extracts were evaporated to dryness and the formate ion was determined by a colorimetric method (7).

Results and discussion

*Nuclear magnetic resonance spectrum of **1***

The ^{1}H assignments and coupling constants for the nmr spectrum of **1**, in both $CDCl_3$, Fig. 1, and C_6D_6 are summarized in Table 1.[4,5] The assignments are based mainly on homonuclear decoupling and nOe experiments and the characteristic shifts expected for protons near certain functionalities. Assignments for H-2, H-7, H-11, H-13, H-14, and H-15 made previously (2*a*) were confirmed. Except for the resonance of H-7, the resonance of H-11, adjacent to the carbonyl group, is expected to occur at the lowest shielding. Decoupling of this resonance leads to the assignments of H-5 and H-13. The remaining methyl doublet must be H-14, irradiation of which identifies H-2. The resonance at δ 2.44 ($CDCl_3$) was assigned to H-9α because of its proximity to the endoperoxide group. The assignments of H-9β, H-10α, and H-10β were made on the basis of decoupling experiments and the values of the various coupling constants. Irradiation of H-10β and of H-2 identified H-1 and the two protons on C-3; however, the specific assignment of the

[4] The numbering is that used in the X-ray diffraction study (2).

[5] The nmr spectra of some dihydro derivatives of **1** have recently been reported (8).

signals to H-3α and H-3β could not be made. Saturation of H-7 led to the enhancement of the signal of H-2 and signals at δ 1.10 (C_6D_6), thereby confirming the assignment of H-10β, which had been made on the basis of decoupling experiments, and at δ 0.50 (C_6D_6). Inspection of molecular models shows that H-2, H-4β, and H-10β are near H-7. The signal at δ 0.50 must thus be due to H-4β. Irradiation of H-4β (and one of the protons of C-3) results in simplification of the signal of H-5, confirming that the two protons are on adjacent carbon atoms. H-4α was assigned using the ^{1}H−^{13}C shift correlation experiment.

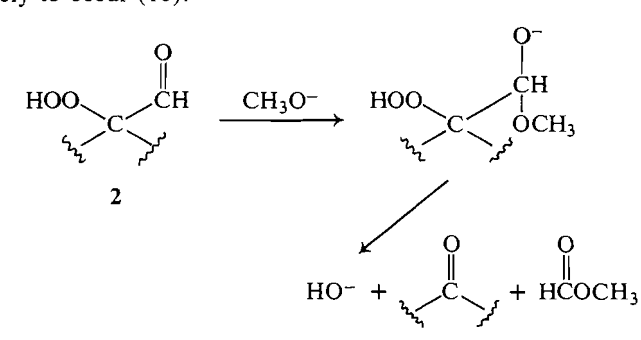
The ^{13}C chemical shifts of **1**, Table 2, were assigned based on expected characteristic shieldings and multiplicities of signals in the fully coupled spectrum, Fig. 2, multiplicities determined from the gated decoupling ^{13}C spin echo technique, and selective ^{1}H decoupling. The ^{13}C spectrum of **1** should contain three singlets, five doublets, four triplets, and three quartets, which was confirmed using the gated spin echo technique. The three singlets and the resonance of C-7 are readily assigned. Selective ^{1}H decoupling was performed at H-1, H-2, H-3, H-5, H-11, H-14, and H-15, collapsing each doublet or quartet to a singlet and allowing the assignment of the corresponding carbon resonances. The protons associated with C-3, C-4, C-9, and C-10 give rise to nonequivalent AB pairs in the ^{1}H nmr spectrum. Thus, irradiation of the high field signal of the H-3 protons and of H-4β, H-9β, and H-10β causes the resonances at δ 33.8, 23.4, 36.1, and 25, respectively, to change from a triplet in the coupled spectrum to a doublet. Assignment of C-3 and C-4 could not be on this basis because of overlap of the corresponding proton signals. Use of the shift reagent allowed the assignments to be made. The signals at δ 23.4 and 33.8 are shifted downfield 0.49 and 0.84 ppm, respectively, in the presence of the shift reagent. The signal of C-4 would be expected to be shifted more since C-4 is closer to the carbonyl group than is C-3.

The assignments made above were confirmed by the selective 2D-DEPT ^{1}H−^{13}C shift correlation experiment, which also allowed the assignment of H-4α. Since H-4β has already been assigned, the other proton which correlates with C-4 must be H-4α.

Luminescence of 1

The functional groups of **1** are all interconnected. A reaction between base and **1** can result in an extensive structural breakdown to give **2**, when methoxide is used. Chart 1 outlines further reactions that can occur with **2**. Reaction of the hydroperoxide anion in **2** with the adjacent aldehyde function would lead to the 1,2-dioxetane **3**, and cleavage of the dioxetane ring would lead to compound **5** and formate ion, a reaction which should be luminescent (9). In fact, a brief luminescence can be observed clearly in a darkened room when solutions of **1** in benzene, toluene, or dimethoxyethane are treated with methanolic sodium methoxide at temperatures above 60–70°C in the presence of 9,10-dibromoanthracene. No luminescence was observed at lower temperatures. A competing dark reaction which would lead to **5** and formate ion, eq. [1], is also likely to occur (10).

[1]



2 **5**

Exploratory experiments showed that at least six to eight products were formed and that **1** was consumed rapidly when appreciable amounts of methanol were present in the reaction

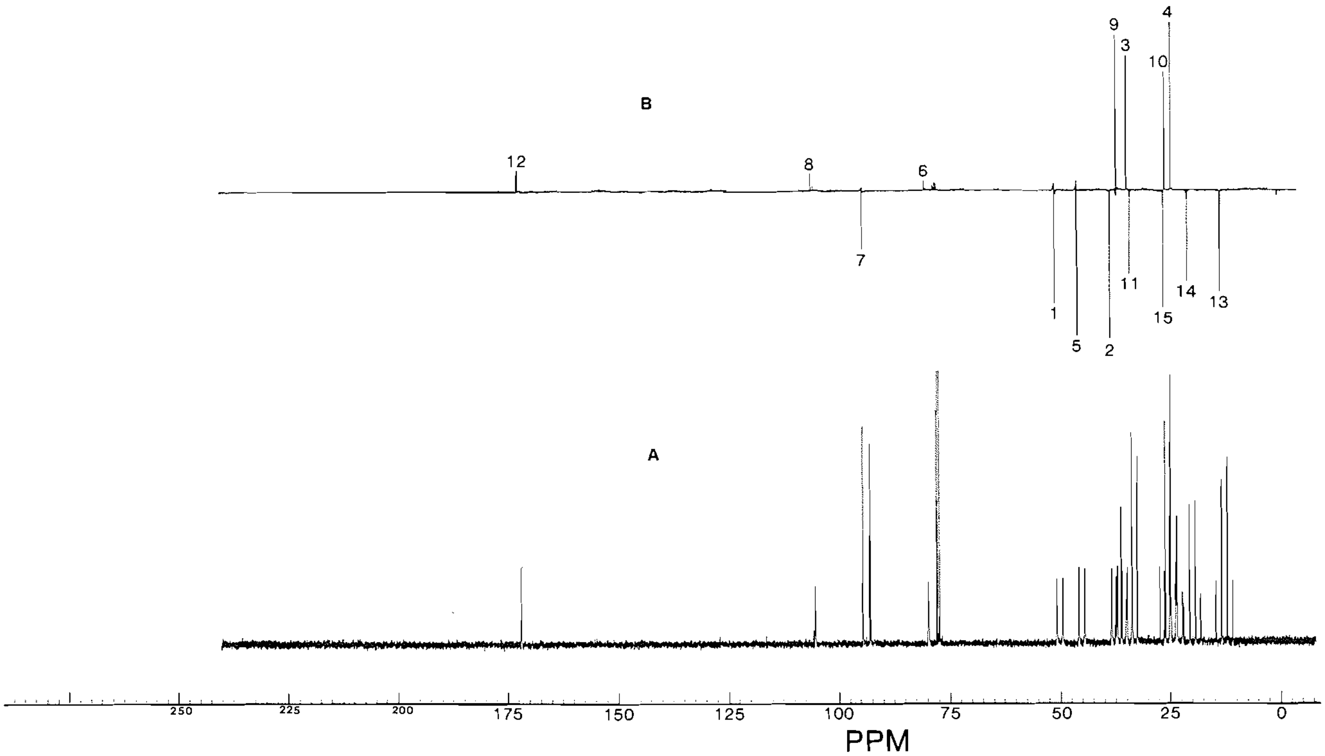


FIG. 2. Off-resonance decoupled, A, and spin echo, B, ^{13}C nmr spectrum of 1 *M* Qinghaosu in $CDCl_3$ at 25°C.

mixture. Consumption of **1** was much slower and only one main product was formed when methanol was first removed from a methanolic solution of sodium methoxide by azeotropic distillation. This product is tentatively assigned the bridged structure **8** on the basis of its mass and nmr spectra. The molecular ion, *m*/*e* 268, contains all the atoms of the presumed intermediate **5**. Loss of water gives the base peak, *m*/*e* 250. Dehydration of **8** will not occur in base, whereas intramolecular condensation of **5** to give a nonbridged ketol might lead to the formation of a dehydrated product such as **7**. The nmr spectrum contains peaks for four methyl groups: a singlet at δ 3.67 due to the methyl group of the ester, a singlet at δ 2.12, and doublets at δ 1.18 and 1.07 as required for structure **8**. The singlet at δ 2.12 is at lower field than normal for a methyl group bonded to a tertiary carbon atom. This indicates that the protons of C-14 are deshielded by one or both of the nearby carbonyl groups. The mass spectrum of the product lacked a peak at *m*/*e* 58, which should be prominent in the mass spectrum of a molecule of structure **5**. The nonbridged ketol that could be formed from **5** would have only three methyl groups.

It is interesting that little, if any, **8** was formed when the reactions with methoxide ion were carried out in the presence of methanol. There were four major products and several minor ones. Two of the products had molecular ion peaks at *m*/*e* 250, which indicates that they may be isomeric compounds of structure **7**, and two had molecular ion peaks at *m*/*e* 262 and base peaks at *m*/*e* 43. The latter peak may be $CH_3CO^{\cdot+}$, indicating that these products may be isomeric compounds of structure **6**. A compound such as **6** could result from the intramolecular condensation of **4** (or a double bond isomer), which, in turn, is a decomposition product of **2**. Such a decomposition of an α-hydroperoxy carbonyl compound does not appear to have been observed before. Previous careful studies of the base-catalyzed decompositions of these materials were carried out under much milder conditions (9, 10), but it is known that tertiary hydroperoxides are decomposed rapidly by base at elevated temperatures to give alcohols (11). Dehydration of the corresponding alcohol from **2** would produce **4**.

Other products have been isolated from the reaction between **1** and base at ambient temperatures (12). The cleavage of the intermediate **2** to give **5** as shown in Chart 1 and eq. [1] was not considered.

The luminescent reaction described here might be developed into a sensitive assay for **1**. A sensitive electrochemical assay for **1** has been described recently (13).

Effects of varying solvents and of the addition of sulfur on the rate of thiohydrolysis of aromatic nitriles

KHAMIS A. ABBAS[1] AND JOHN T. EDWARD
Department of Chemistry, McGill University, 801 Sherbrooke St. W., Montreal, P.Q., Canada H3A 2K6

Received October 12, 1984[2]

KHAMIS A. ABBAS and JOHN T. EDWARD. Can. J. Chem. **63**, 3075 (1985).

Maximal rates of formation of thioamides from *m*- and *p*-substituted benzonitriles were obtained by bubbling H_2S through solutions of the nitrile in pyridine containing a 0.11 mol fraction of triethylamine or in 95% ethanol containing about 0.22 mol fraction triethylamine; at other mol fractions the rate fell off sharply. The Hammett ρ value of +2.3 in pyridine indicates that HS^- is the reactive species. The addition of enough sulfur to saturate the solution leads to about a 3-fold enhancement of rate, probably because of the formation of polysulfide ions in trace amounts.

KHAMIS A. ABBAS et JOHN T. EDWARD. Can. J. Chem. **63**, 3075 (1985).

Les vitesses de formation de thioamides à partir de benzonitriles substitués en positions *méta* et *para* sont maximales lorsqu'on fait barboter du H_2S dans des solutions de nitriles dans de la pyridine contenant 0,11 fraction molaire de triéthylamine ou dans de l'éthanol à 95% contenant environ 0,22 fraction molaire de triéthylamine; la vitesse diminue nettement si on utilise d'autres fractions molaires. La valeur ρ de Hammett est égale à +2,3 dans la pyridine et ceci indique que l'espèce réactive est le HS^-. Si on ajoute suffisamment de soufre pour saturer la solution, la vitesse de la réaction est multipliée par trois et ce résultat est du probablement à la formation de faibles quantités d'ions polysulfures.

[Traduit par le journal]

Thioamides are usually prepared from nitriles by heating the latter under pressure with an alcoholic solution of an alkali-metal hydrosulfide (1), or an ammonium (2) or substituted ammonium hydrosulfide (1). However, Fairfull, Lowe, and Peak (3) found that in pyridine solution, in the presence of a strong base such as triethylamine, addition of hydrogen sulfide to aromatic nitriles took place with remarkable ease, being complete in 2–4 h at room temperature. They made no attempt to optimize conditions, and did not specify the precise compositions of the triethylamine–pyridine solutions which they used. They noted that the role of pyridine was not purely passive; triethylamine–chloroform was much less effective than triethylamine–pyridine.

Our need for an efficient method for the thiohydrolysis of nitriles prompted us to carry out a rough kinetic study of the reaction of Fairfull *et al.*, in order to optimize conditions, and further to study the effect of different solvents and of the addition of sulfur on the rate of the reaction.

Experimental

Materials

Nitriles were used as obtained from Aldrich Chemical Company. Solvents were not purified. Hydrogen sulfide was obtained from Matheson, Coleman and Bell Company Limited.

Preparation of substituted thiobenzamides

The following procedure, modified slightly from that of Fairfull *et al.*, gave yields of more than 95% of recrystallized thiobenzamide.

Hydrogen sulfide was bubbled for 6 h through a solution of benzonitrile or substituted benzonitrile (0.02 mol) in triethylamine (50 mL) – pyridine (150 mL). The solution, which turned dark green, was left overnight, except for *p*-methoxybenzonitrile and *p*-methylbenzonitrile solutions, which were left for 40 h. Nitrogen was bubbled through the solution for 3 h to remove most of the hydrogen sulfide, and the solvent was then removed by rotary evaporation. The solid residue was twice recrystallized from ethanol–water 1:4, and the thioamides thus obtained had melting points in agreement with the literature (3–5). Ultraviolet (uv) spectral characteristics (λ_{max} (nm) and ϵ (mol^{-1} cm^{-1}) (in parentheses)) of the substituted thiobenzamides (substituent indicated) dissolved in 95% ethanol were as follows: H: 291(6850) and 242(8480); *p*-Cl: 305(5860) and 250(10 100); *m*-Cl: 296(6620) and 237(9340); *p*-Br: 300(7350) and 253(12 300); *m*-Br: 298(6340); *p*-CH_3: 300(7590), 291.5(7700), and 257(9700); *p*-CH_3O: 306(1090) and 273(11 800).

Kinetic measurements

Hydrogen sulfide was bubbled for 1 h into 200 mL of triethylamine–solvent mixture, in the case of liquid benzonitriles, or into 190 mL of triethylamine–solvent mixture in the case of solid benzonitriles, 10 mL of triethylamine–solvent being retained in the latter case to dissolve the benzonitrile. The neat liquid or dissolved solid benzonitrile (0.00687 mol) was then injected through a septum into the H_2S-saturated solvent[3] (except for *p*-methoxybenzonitrile, when 0.00500 mol was injected). Bubbling of H_2S was continued, and 1.00-mL aliquots of the reaction mixture were withdrawn with a graduated syringe at different time intervals and diluted to 25.0 mL with 5% HCl in aqueous ethanol to stop the reaction. The acidic solution was diluted tenfold with distilled water and analyzed by uv absorbance at 305 nm for substituted thiobenzamide. In experiments in which weighed amounts of sulfur were added to the triethylamine–solvent mixture before saturating with H_2S, the acidic solutions obtained after reaction were diluted tenfold with saturated sodium chloride solution and left for 2 days for sulfur to crystallize out. The clear supernatant solution could then be drawn off and analyzed as before by uv spectrophotometry. Reactions followed pseudo-first-order kinetics with a precision of about ±5%.

Results and discussion

Effect of solvent

In spite of the relative crudeness of our experiments (temperature varying between 18 and 22°C, atmospheric pressure varying between 740 and 770 Torr (1 Torr = 133.3 Pa)) we found that we could obtain reasonably reproducible reaction rates for thiohydrolyses carried out under the conditions of Fairfull *et al.* (gaseous H_2S passed continuously into a solution of nitrile in triethylamine–pyridine). Rates followed pseudo-

[1] On leave from the Department of Chemistry, Yarmouk University, Irbid, Jordan.

[2] Revision received June 20, 1985.

[3] Saturation of pyridine–triethylamine with H_2S gave a deep green solution; saturation of other solvents gave greenish-yellow solutions.

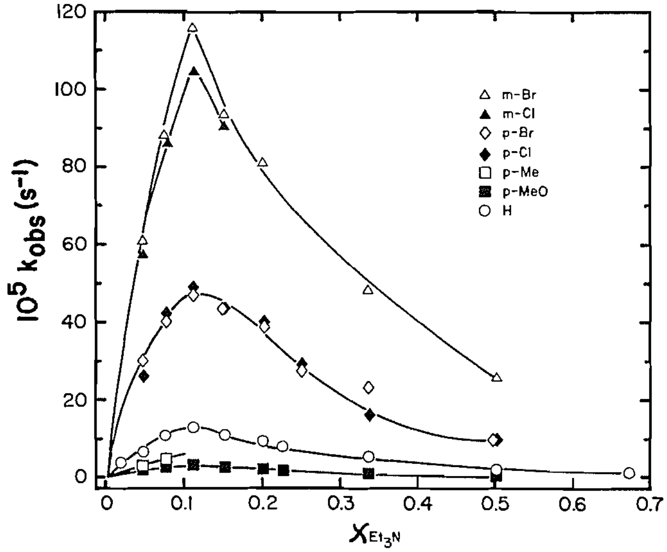

FIG. 1. Observed rate constant k_{obs} for thiohydrolysis of benzonitrile and of six *m*- and *p*-substituted benzonitriles, plotted against mol fraction χ_{Et_3N} of triethylamine in pyridine–triethylamine solvent mixtures.

first-order kinetics, and the experimental rate constants k_{obs} for seven *meta*- and *para*-substituted benzonitriles in triethylamine–pyridine mixtures of varying composition are shown in Fig. 1. Reaction was fastest for a triethylamine mol ratio χ of 0.11; triethylamine used alone as solvent was completely ineffective. In eight different triethylamine–pyridine solvent mixtures having χ varying from 0.045 to 0.499, the thiohydrolysis rate constants k_{obs} of the seven substituted benzonitriles fitted the Hammett $\rho\sigma$ relation (correlation coefficients 0.994 or better) with $\rho = 2.30 \pm 0.09$, which thus appeared unexpectedly independent of solvent composition. Kindler's results (5) for the thiohydrolysis of substituted benzonitriles by sodium hydrogen sulfide in ethanol at 61°C yield a ρ value of 2.15 (6), and hence it seems likely that in both pyridine and ethanol the bisulfide ion HS^- is the reactive entity.

Pyridine is not a uniquely effective solvent. In fact, as shown in Fig. 2, both ethanol and 95% ethanol are slightly more effective if the optimal amount of triethylamine is present. Again, beyond a certain optimal concentration, an increase in χ_{Et_3N} leads to a decrease in k_{obs}. On the other hand, toluene and thiophene proved vastly less effective than pyridine (see Fig. 2). This was not because of a greatly diminished solvent power for hydrogen sulfide, as can be seen in Table 1: the concentration of H_2S in saturated toluene–Et_3N 0.73:0.27 (mol/mol) is only 36% less than in saturated pyridine–Et_3N 0.89:0.11 (mol/mol).

No thiohydrolysis at room temperature was observed with various proportions of triethylamine in 50% aqueous ethanol, in 50% ethanol – 50% tetrahydrofuran, or in tetrahydrofuran, and with triethylamine in *tert*-butanol or n-decanol it was very slow.

Mechanistic considerations

The Hammett ρ value suggests that the rate-determining (r.d.) step in thiohydrolysis is attack of ^-SH on nitrile:

$$[1] \quad RCN + {}^-SH \xrightarrow[\text{r.d.}]{k} R{-}C{\overset{\bar{N}^-}{\underset{SH}{\lessgtr}}} \xrightarrow{\text{fast}} R{-}C{\overset{NH_2}{\underset{S}{\lessgtr}}}$$

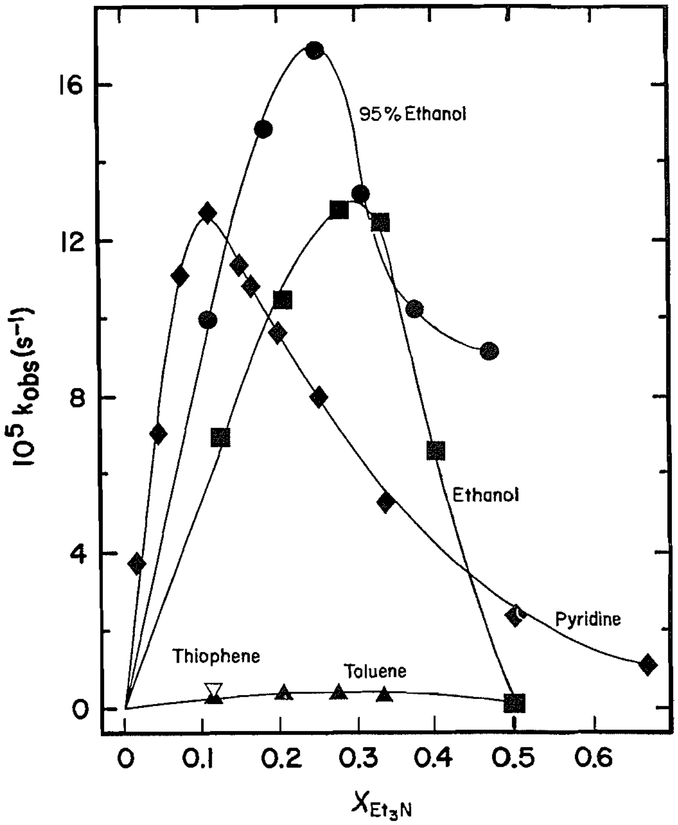

FIG. 2. Observed rate constant k_{obs} for thiohydrolysis of benzonitrile plotted against mol fraction χ_{Et_3N} of triethylamine in solvent mixtures of triethylamine–pyridine, –ethanol, – 95% ethanol, –toluene, and –thiophene.

TABLE 1. Concentrations $[S^{2-}]$ (as mg mL^{-1} of S^{2-}) of hydrogen sulfide in different solvents containing the mol fraction χ_{Et_3N} of triethylamine indicated, and saturated with H_2S at atmospheric pressure and 18–22°C

Solvent	χ_{Et_3N}	$[S^{2-}]$*
95% EtOH	0.250	34.5
EtOH	0.275	35.7
Pyridine	0.110	34.9
Toluene	0.274	22.4

* Measured by Bethge's titrimetric method (7).

The bisulfide ion ^-SH results from the equilibria:

$$[2] \quad Et_3N + H_2S \overset{K_{ion}}{\rightleftarrows} \underset{\mathbf{1}}{Et_3\overset{+}{N}{-}H\text{------}\overset{-}{S}{-}H} \overset{K_{diss}}{\rightleftarrows} Et_3\overset{+}{N}H + \overset{-}{S}H$$

In water, dissociation of the ion pair **1** will be essentially complete, and we can calculate from the pK_a values of Et_3NH^+ and H_2S (8) that in this solvent the formation of Et_3NH^+ and ^-SH will also be essentially complete, i.e. that $[^-SH] \approx [Et_3N]_{stoichiometric}$. However, in a solvent of lower dielectric constant such as ethanol, the proton transfer to form Et_3NH^+ and ^-SH will probably be incomplete (ref. 8, p. 46). Nonetheless, the lower concentration of ^-SH to be expected in absolute

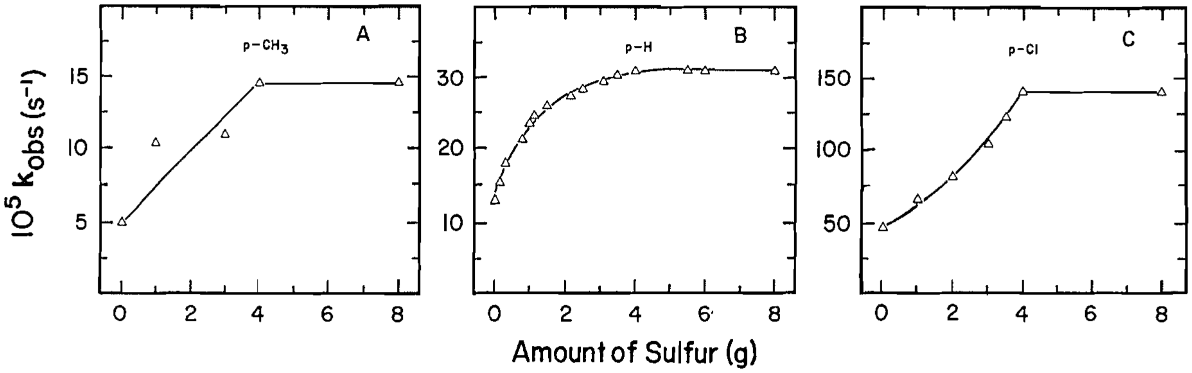

FIG. 3. Relation between k_{obs} for thiohydrolysis of benzonitrile (*p*-H), *p*-methylbenzonitrile (*p*-CH_3), and *p*-chlorobenzonitrile (*p*-Cl) and amount of sulfur added to 200 mL of pyridine–triethylamine 0.89:0.11 (mol/mol) solvent.

ethanol as compared with 50% aqueous ethanol is evidently more than compensated by the greater activity of ^{-}SH in absolute ethanol, since thiohydrolysis proceeds in the former and not in the latter solvent.

In toluene and thiophene both the extent of proton transfer (K_{ion}) and of dissociation of the ion pair (K_{diss}) should be drastically reduced, although the greater activity of ^{-}SH in these poorly-solvating media should compensate to some extent. In such non-hydrogen-bonding solvents homoconjugation often becomes of dominant importance (9):

[3] $$Et_3N + Et_3\overset{+}{N}H\text{-----}^{-}SH \rightleftarrows Et_3\overset{+}{N}H\text{-----}NEt_3 + {}^{-}SH$$
$$\mathbf{1} \qquad\qquad \mathbf{2}$$

However, in acetonitrile solution, formation of the homoconjugate ion **2** does not take place to any appreciable extent (9). In neat triethylamine the same may be true, but in toluene and thiophene a small amount may be formed, to account for the experimental results cited above. On the other hand, in pyridine solution the homoconjugate ion **3** can probably be formed more readily (cf. ref. 9):

[4] 
3

and the ^{-}SH ion will be very active because it will not be strongly stabilized by solvation in this aprotic solvent. This would account for the greater effectiveness of pyridine as compared with the other aprotic solvents investigated.

Effect of addition of sulfur

Sulfur dissolves in strongly alkaline aqueous solutions of sodium sulfide to form mixtures of sodium polysulfides in which the sulfur exists in chains **4** terminating with negative charges (10) (Scheme 1). Acidification of such a solution yields a mixture of hydrogen polysulfides (sulfuranes) **5**, chain compounds that, it is claimed (11–13), decompose completely to hydrogen sulfide and sulfur at normal temperatures. However, at 150°C hydrogen sulfide in molten sulfur exists in equilibrium with small amounts of hydrogen polysulfides (predominantly H_2S_n with $n \geq 6$) (14, 15), and it seems probable on thermodynamic grounds that even at 20°C the equilibrium constant for this reaction, though small, will not be zero. Furthermore it might be expected that $H—(S)_n—S^-$ would be very much more reactive than $H—S^-$ (cf. $H—O—O^-$, which is 10^4 times more effective than $H—O^-$ in the hydrolysis of benzonitrile (16)—an example of the α-effect (17)), and hence might affect the rate of thiohydrolysis even if present only in trace amounts.

$$S^{2-} + nS \xrightleftharpoons{K \gg 1} \bar{S}—(S)_{n-1}—S^- \;\; \mathbf{4}$$
$$\updownarrow H^+ \qquad\qquad \updownarrow H^+$$
$$H_2S + nS \xrightleftharpoons{K \ll 1} HS—(S)_{n-1}—SH \;\; \mathbf{5}$$

SCHEME 1

In fact, it was found that in pyridine k_{obs} for the formation of thiobenzamide and its *p*-methyl and *p*-chloro derivatives from the corresponding nitriles was increased with the addition of increasing amounts of sulfur to the reaction mixture. This is shown in Fig. 3. A limit to the rate enhancement was reached when 4 g of sulfur had been added to 200 mL of pyridine–triethylamine 0.89:0.11 (mol/mol). Beyond the limit some sulfur remained undissolved in the H_2S-saturated solvent mixture.

Sulfur is 30 times less soluble in ethanol than in pyridine at 20°C (18), and while its solubility in EtOH–Et_3N 0.725:0.275 (mol/mol) is not known, it is likely to be less than in pyridine–Et_3N 0.89:0.11 (mol/mol). Consequently, we would expect the limit to the effect of added sulfur to be reached sooner in ethanol–triethylamine than in pyridine–triethylamine. In fact, Fig. 4 shows that this limit is reached when about 1.2 g of sulfur has been added to 200 mL of ethanol–triethylamine 0.725:0.275 (mol/mol).

These kinetic results shed light on the thermodynamics of the H_2S–S_8 equilibrium at 20°C, since it is difficult to explain the enhanced rates other than by the formation of H_2S_n.[4] Previous studies (19) of the equilibrium between H_2S and molten sulfur indicated that the number-average chain length $\bar{n}$ of H_2S_n is about 27 sulfur atoms at 127°C, and increasing with temperature. In our solutions at lower temperatures and with lower concentrations of S_8, but with the possibility of preserving H_2S_n as the more stable anion $^{-}S—S_{n-2}—S^{-}$, it might be expected that $\bar{n}$ would be less than 27. Furthermore, in the various solvents saturated with H_2S and hence having $[H_2S]$ constant, $\bar{n}$ must vary with the concentration of S_8. Thus the concen-

[4] Since $[H_2S] \approx 1\ M$ in the first three solvent mixtures listed in Table 1, $[H_2S_n^-] \approx 10^{-4}\ M$ if the ion derived from it is 10^4 times more effective than ^{-}SH (see comparison of $H—O^-$ and $H—O—O^-$ above). Such a concentration might be difficult to detect by the usual spectroscopic techniques.

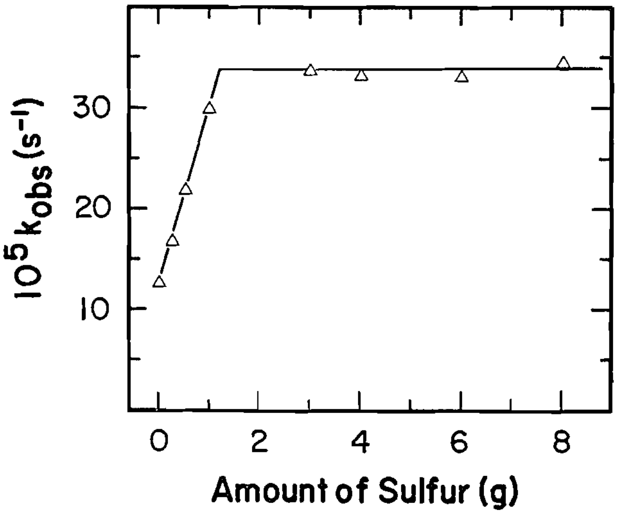

FIG. 4. Relation between k_{obs} for thiohydrolysis of benzonitrile and amount of sulfur added to 200 mL of ethanol–triethylamine 0.725:0.275 (mol/mol) solvent.

tration of H_2S_7 should follow $[S_8]^{0.75}$:

$$[5] \quad 8\,H_2S + 6\,S_8 \overset{K_7}{\rightleftarrows} 8\,H_2S_7$$

$$[6] \quad [H_2S_7] = (K_7[H_2S]^8[S_8]^6)^{1/8} = \text{const}_7\,[S_8]^{0.75}$$

and in general $[H_2S_n] = \text{const}_n[S_8]^{n-1/8}$. Hence $[H_2S_{23}]$, for example, should vary as $[S_8]^{2.75}$, and should increase more rapidly than $[H_2S_7]$ with increase in $[S_8]$. Thus $\bar{n}$ should increase with $[S_8]$.

These considerations serve to explain the effect of sulfur concentration on the rate of thiohydrolysis of the reactive nitrile, *p*-chlorobenzonitrile, if we assume that ions $^-S—S_n—S^-$ of varying lengths all have about the same reactivity. We may then write

$$[7] \quad k^S_{obs} = k_1[H_2S] + k_{\bar{n}}[H_2S_{\bar{n}}] = k^0_{obs} + k'_{\bar{n}}[S_8]^{\bar{n}-1/8}$$

where k^0_{obs} is the rate constant in the absence, and k^S_{obs} the rate constant in the presence of sulfur. From eq. [7] we obtain

$$[8] \quad \log \Delta k_{obs} = \log (k^S_{obs} - k^0_{obs}) = \log k'_{\bar{n}} + \frac{\bar{n}-1}{8} \log [S_8]$$

A plot of log Δk_{obs} of *p*-chlorobenzonitrile against log $[S_8]$ is concave upward until the plateau for the S_8-saturated solution is reached. At the lowest concentration of sulfur ($[S_8] = 0.019$ m L^{-1}), the slope of the curve is 0.73, implying (see eq. [6]) that $\bar{n} \approx 7$; at saturation ($[S_8] = 0.078$ m L^{-1}) the slope is 2.70, implying that $\bar{n} \approx 23$ (see above).

With the less reactive benzonitrile in triethylamine–pyridine or triethylamine–ethanol, the plot of log Δk_{obs} against log $[S_8]$ is concave downward, and so we can no longer assume that ions of different chain length are of equal reactivity, but rather must assume that shorter chains are more reactive. Obviously more work is required to correlate the shape of the curve with the reactivity of the nitrile.

The maximum rate enhancements caused by the addition of sulfur are modest (about threefold), presumably because of the minute amounts of H_2S_n formed, and so we made preliminary studies of the effectiveness of Na_2S_2, produced by dissolving the appropriate amount of sulfur in aqueous Na_2S (20). This proved completely ineffective in thiohydrolyzing benzonitrile at 20 ± 2°C. However, we saw above that HS^-, effective in 95% ethanol, becomes completely ineffective in 50% aqueous ethanol, and it is possible that in nonaqueous solutions Na_2S_2 might be useful.

Received February 4, 1985

ALLAN PALMER, SUZIE POULIN-DANDURAND, and FRANÇOIS BRISSE. Can. J. Chem. **63**, 3079 (1985).

The crystal structures of tetramethylene glycol dibenzoate (**1**), tetramethylene glycol di-*para*-chlorobenzoate (**2**), and tetramethylene glycol di-*para*-nitrobenzoate (**3**) have been solved by direct methods in order to establish the possible conformations of the methylenic sequence in poly(tetramethylene terephthalate), poly(4GT). Compound **1** has a triclinic unit cell of dimensions a = 7.870(3), b = 8.574(3), c = 12.993(4) Å; α = 83.76(3), β = 89.92(3), γ = 64.68(3)°; Z = 2, space group $P\bar{1}$. For **2** the unit cell is also triclinic and has dimensions a = 5.916(3), b = 7.599(2), c = 10.404(2) Å; α = 67.81(2), β = 77.47(2), γ = 81.63(3)°; Z = 1, space group $P\bar{1}$. The unit cell dimensions of **3** are a = 6.086(1), b = 11.475(3), c = 13.162(3) Å and β = 101.93(2)°, Z = 2. The space group is $P2_1/c$. The structures were solved by direct methods using 2682, 969, and 781 observed reflections for **1**, **2**, and **3**, respectively. The refinements were concluded when R reached the values of 0.042, 0.046, and 0.045, respectively. The conformation of the methylenic sequence varies depending on the substituent on the benzoate group. The conformation observed in **1** is tg^-ttt, it is $ttttt$ for **2**, and tg^-tgt for **3** (t = *trans*, g = *gauche*). Although the equivalent fiber repeat of **3** coincides with the observed fiber repeat for α-poly(4GT), this does not imply that **3** and α-poly(4GT) have the same conformation. Compound **2** allows for the modelling of the β-form of poly(4GT). However, this does not lead to a clear choice between the two structures reported for this form. The two distinct conformations proposed for the β-form of poly(4GT) are distinguished on the basis of their ir and Raman spectra. The comparison of the spectra of the model compounds reveals that, in ir, for an all-*trans* conformation there is no absorption band at 1383 cm^{-1} but one is present at 1395 cm^{-1}. This situation that is observed in the ir spectra of β-poly(4GT) led us to propose that this form has the all-*trans* conformation as proposed by Hall and Pass. This choice is further supported by the presence of three bands at 1047, 1347, and 1405 cm^{-1} in the Raman spectra of β-poly(4GT). These three bands are only observed in the model compounds having the all-*trans* conformation.

ALLAN PALMER, SUZIE POULIN-DANDURAND et FRANÇOIS BRISSE. Can. J. Chem. **63**, 3079 (1985).

Les structures cristallines des bis(benzoate) (**1**), bis(*para*-chlorobenzoate) (**2**) et bis(*para*-nitrobenzoate (**3**) du tétraméthylène glycol ont été résolues dans le but d'établir les conformations possibles des séquences méthyléniques du poly-(téréphtalate de tétraméthylène), poly(4TG). Le composé **1** appartient au groupe d'espace triclinique $P\bar{1}$, avec a = 7,870(3), b = 8,574(3), c = 12,993(4) Å; α = 83,76(3), β = 89,92(3), γ = 64,68(3)° et Z = 2. Le composé **2** appartient également au groupe d'espace triclinique $P\bar{1}$, avec a = 5,916(3), b = 7,599(2), c = 10,404(2) Å; α = 67,81(2), β = 77,47(2), γ = 81,63(3)° et Z = 1. Le composé **3** appartient au groupe d'espace $P2_1/c$, avec a = 6,086(1), b = 11,475(3), c = 13,162(3) Å; β = 101,93(2)° et Z = 2. On a déterminé ces structures par méthodes-directes en faisant appel à 2682, 969 et 781 réflexions observées respectivement pour les composés **1**, **2**, et **3** et on les a affinées jusqu'à des valeurs respectives de R de 0,042, 0,046, et 0,045. La conformation de la séquence méthylénique dépend des substituants fixés sur le groupe benzoate. On a observé les conformations suivantes: tg^-ttt pour le composé **1**, $ttttt$ pour le composé **2** et tg^-tgt pour le composé **3** (t = *trans*, g = *gauche*). Le fait que la période de fibre équivalente du composé **3** coincide avec la période de fibre observée pour l'α-poly(4TG), n'implique pas nécessairement que ces deux composés ont la même conformation. Le composé **2** est considéré comme un modèle de la forme β du poly(4TG). Ces observations ne permettent pas d'opter clairement pour l'une ou l'autre des deux structures rapportées pour cette forme. C'est grâce aux techniques de spectroscopies infrarouge et Raman que l'on arrive à établir la conformation la plus probable de la forme β du poly(4GT). La comparaison des spectres infrarouges des composés modèles met en évidence la présence d'une bande d'absorption à 1395 cm^{-1} et l'absence de bande à 1383 cm^{-1} lorsque la conformation est entièrement *trans*. Cette situation, qui est observée sur le spectre infrarouge du poly(4GT) forme β, nous conduit à proposer que cette forme a bien la conformation entièrement *trans*, confirmant ainsi le modèle de Hall et Pass. Ce choix est renforcé par la présence de trois bandes à 1047, 1347 et 1405 cm^{-1} dans le spectre Raman du β-poly(4GT). Ces trois bandes ne sont en effet observées que dans le cas d'une conformation entièrement *trans*.

Introduction

Poly(tetramethylene terephthalate), or poly(4GT), has been shown to be dimorphic. The structures of both forms of poly(4GT) have been extensively studied in recent years. First, a model building technique allowed Joly, Nemoz, Douillard, and Vallet (1) to propose a structure for the relaxed α-form. Almost at the same time, Mencik (2) established unambiguously the structure of the α-form. The following year, Yokouchi *et al.* (3) and, independently, Hall and Pass (4) confirmed the structure of the α-form and each group proposed a structure for the newly reported stretched β-form of poly(4GT). However, the proposed conformations differ so drastically that clearly the structure of the β-form should be reinvestigated. We have recently shown (5) that the structures of well-chosen organic molecules often yield all the relevant geometrical and conformational data necessary to describe the flexible moiety of the parent polyester. Since, on the one hand, the various model compounds for a given polyester do not necessarily show the same conformation and, on the other hand, poly(4GT) is dimorphic, it was decided to synthesize and establish the crystal structure of three different model compounds of poly(4GT). The determinations of the crystal structure of tetramethylene glycol dibenzoate (**1**), tetramethylene glycol di-*para*-chlorobenzoate (**2**), and tetramethylene glycol di-*para*-nitrobenzoate (**3**) are reported here and the conformations of the methylenic sequences are compared to those of both forms of poly(4GT).

In various infrared and Raman studies of poly(2GT), poly(3GT), poly(4GT) (6, 7), and of several model compounds of

*Five and seven low-order reflections suffering from extinction were given zero weights in the final cycle of the least-squares refinement.

the latter (8) the authors have attempted to establish relations between specific vibrational bands and the various conformations of the molecular chains. In their infrared spectroscopic investigation of poly(4GT) and its model compounds, Gillette *et al.* (8) concluded that the conformation of the methylenic sequence in tetramethylene glycol dibenzoate was similar to that of the β-form of poly(4GT), i.e., an all-*trans* conformation. Since in the present paper we establish that the above mentioned conformation is not all *trans* but is tg^-ttt, we decided to reexamine the infrared and Raman spectra of the model compounds of poly(4GT).

Torsion angles with values of about 180, +60, −60° are defined as having *trans, gauche*$^+$, or *gauche*$^-$ conformations which are abbreviated as t, g, and g^- respectively.

Experimental

All three compounds (abbreviated as **1** or benzoate, **2** or chlorobenzoate, and **3** or nitrobenzoate) were prepared according to the method described by Heim and Poe (9), by reacting, in pyridine, solutions of tetramethylene glycol and of benzoyl chloride or of the *para*-chloro or of the *para*-nitro substituted benzoyl chlorides. Crystals of the benzoate were obtained by slow evaporation from an ethanol solution, the chlorobenzoate was recrystallized from a carbon tetrachloride solution, and the nitrobenzoate from a DMSO solution.

X-ray diffraction

A preliminary photographic investigation followed by accurate centering of 25 reflections on the Nonius CAD-4 diffractometer provided the space group and the unit cell dimensions which are listed with other crystal data in Table 1. The intensities were collected on the Nonius diffractometer by the $\omega/2\theta$ scan technique (Table 2). The stability of the crystals during the data collection was followed by measuring the intensities of three reference reflections every hour. These did not vary by more than 3%. An absorption correction based on the crystal shape was applied in all three cases.[1] The X-ray scattering factors used were those of Cromer and Mann (10) except for H atoms for which we used the values given by Stewart, Davidson, and Simpson (11). The anomalous dispersion correction for Cl was taken from Cromer and Liberman (12).

All three structures were solved by direct methods using the MULTAN program. The set of phases with the highest combined figure of merit always yielded all the nonhydrogen atoms among the

[1]The programs used here are modified versions of NRC-2, data reduction; NRC-3, absorption correction, NRC-10, bond distances and angles and NRC-22, mean planes (13); FORDAP, Fourier and Patterson maps; NUCLS, least-squares refinement (14); MULTAN, multisolution program (15); ORTEP, stereo views (16).

highest peaks listed. The full-matrix least-squares refinement of the atomic coordinates, using anisotropic temperature factors for nonhydrogen atoms and isotropic thermal parameters for H atoms, proceeded smoothly. The various criteria confirming the correctness of the structures are assembled in Table 2.

Conformational analysis

The potential energy calculated for a given conformation included the torsion energy about the different torsion angles, the nonbonded energies, and the electrostatic interactions. Intrinsic torsional potential with a three-fold barrier was assigned to rotations about the CH_2—CH_2 bonds while the torsional barrier for the C—O bond was taken to be zero. The tilt angle between the carboxy and the phenyl planes was kept fixed, since for most benzoates and terephthalates this angle reaches at the most 8°. The van der Waals interactions between nonbonded atoms were evaluated using 6−12 potential functions. Electrostatic interactions were computed by assigning partial charges to the atoms using a Coulomb's law potential function. Energies were calculated at 2° intervals in the area of the minima and at intervals of 5° elsewhere. Isoenergy contours were drawn at 1 kcal mol^{-1} intervals with respect to the minimum energy, which was arbitrarily set at zero. The parameters selected for this calculation are given in ref. 23.

Infrared and Raman spectroscopy

The infrared and Raman spectra of compounds **1**, **2**, and **3**, as well as those of trimethylene glycol dibenzoate, di-*para*-chlorobenzoate, pentamethylene glycol di-*para*-chlorobenzoate, di-*para*-nitrobenzoate, and hexamethylene glycol dibenzoate have been recorded. The crystalline model compounds were pressed into KBr pellets and their FTIR spectra were recorded on a Nicolet 7199-FTIR spectrometer. The sample spectra were signal-averaged with 500 scans while the background noise spectra were signal-averaged with 100 scans.

The Raman spectra were recorded with the Digital SPEX Ramalog spectrometer coupled with an Innova-90-5 He−Ar laser (λ = 514.5 nm). The power of the beam at the sample was 300 mW, the time constant was 1 s, and the intensity 22 A. The solid samples were kept in a small glass tube and the spectra were recorded at a scanning rate of 2 cm^{-1} s^{-1}.

Results and discussion

Structural considerations

The final positional parameters and their standard deviations are presented in Tables 3 a, b, and c.[2] The atomic numbering is shown in Fig. 1 and the various molecular structures are presented as stereopairs in Fig. 2. The final bond distances and angles of compounds **1**, **2**, and **3** are compared in Table 4 to those of 2,5-hexanediyl dibenzoate **4**, a compound related to those studied here (17). The bond distances, angles, and torsion angles of **1** are equal, within one esd, to those reported in a paper (18) that was published shortly after our own report on this compound (19).

The benzoate groups

The $C(sp^2)$—$C(sp^2)$ bond distances in the benzene rings average 1.381, 1.383, and 1.383 Å while the C—H distances average 0.96 and 1.02 Å for **1** and **2**, respectively, and were fixed at 0.95 Å for **3**. The C═O bond distances are all within 2σ of each other. The atoms in each of the benzene rings are coplanar. However, as reported earlier (20), the chlorine atom is displaced from the benzene mean plane by 0.040(1) Å. At the same time the ring bonds adjacent to the C—Cl bond are slightly shorter than the other ring bonds (1.376 vs. 1.384 Å) while the angle at the carbon atom to which Cl is bonded, with

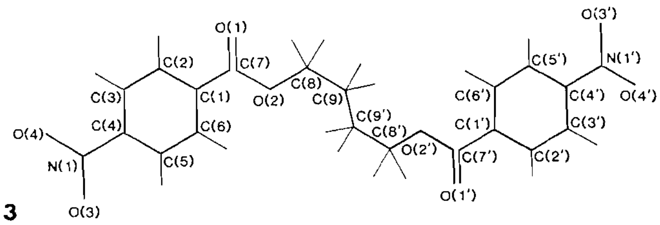

FIG. 1. Schematic representation of the molecules and atomic numbering.

a value of 122.1(4)°, is significantly larger than 120°. In the case of the nitrobenzoate, the plane of the NO_2 group is inclined by 7.4° with respect to the benzene ring mean plane. The NO_2 and carboxylate are tilted in the same way with respect to the benzene ring and are at 5.9° for each other. Finally, an important feature in a benzoate group is the dihedral angle between the benzene ring and the carboxylate group of atoms. These planes are here inclined with respect to one another by 1.2 and 6.2° for **1** and by 3.8° for both **2** and **3**. This real but limited flexibility, previously reported (21), has to be taken into account as a variable in the structural investigation of the related poly(*n*GT)'s.

The methylenic sequence

The O—$C(sp^3)$ distances ranging from 1.451(2) to 1.457(2) Å average 1.454 Å, in good agreement with published values. The $C(sp^3)$—$C(sp^3)$ distances in the three compounds studied here are as short as previously reported in hexamethylene dibenzoate (22). However, it should be noted that for **1** and **2** the middle C—C bond is longer (average 1.526 Å) than the adjacent bonds (average 1.505 Å). The C—C—C bond angles average 111.5° (range 110.3(3) to 113.0(5)°) while the O—C—C bond angles are all close to the average of 107.0°.

As can be seen in Fig. 2, the conformation of the "tetramethylene" part of the molecule is tg^-tgt in **1**, $ttttt$ in **2**, and tg^-tgt in **3**. The actual values of the conformational angles are listed in Table 5 where they are compared to the corresponding values for 2,5-hexanediyl dibenzoate **4**. One can note that among the various torsion angles describing the methylenic sequence, the angles ϕ_1 = C(7)—O(2)—C(8)—C(9) and especially ϕ_2 = O(2)—C(8)—C(9)—C(10), as well as their centrosymmetrically related counterparts, are the most flexible. That is, ϕ_1 and ϕ_2 deviate the most from 180°. It is

therefore reasonable to expect that torsions, if they do have to take place in the polymer, will do so around the O(2)—C(8), C(8)—C(9), C(9′)—C(8′), and C(8′)—O(2′) bonds.

The three compounds seen as models for poly(4GT)

Poly(tetramethylene terephthalate) is a member of a family of aromatic polyesters, the poly(nGT)'s, where n stands for the number of methylenic groups between the terephthaloyl moieties. It has been established experimentally that all poly(nGT)'s, from $n = 2$ to 6, crystallize in triclinic unit cells, space group $P\bar{1}$, and the polymeric chains are aligned with the c-axis, the fiber axis. Furthermore, when the poly(nGT)'s have an even number of methylene groups, the center of the terephthaloyl group and the midpoint of the central CH_2—CH_2 bond coincide with the centers of symmetry at (000) and ($00\frac{1}{2}$) respectively. In a conformational analysis of a theoretical model (23) the possible conformations of the poly(nGT)'s for $n = 2$ to 6 were investigated. In the case of poly(4GT), only two conformational angles need to be varied. These are the two angles ϕ_1 and ϕ_2, found in the model compounds to be the most flexible (see Table 5). The conformational energy map as a

†This is twice the distance between the center of one benzene ring to the midpoint of the methylenic sequence.

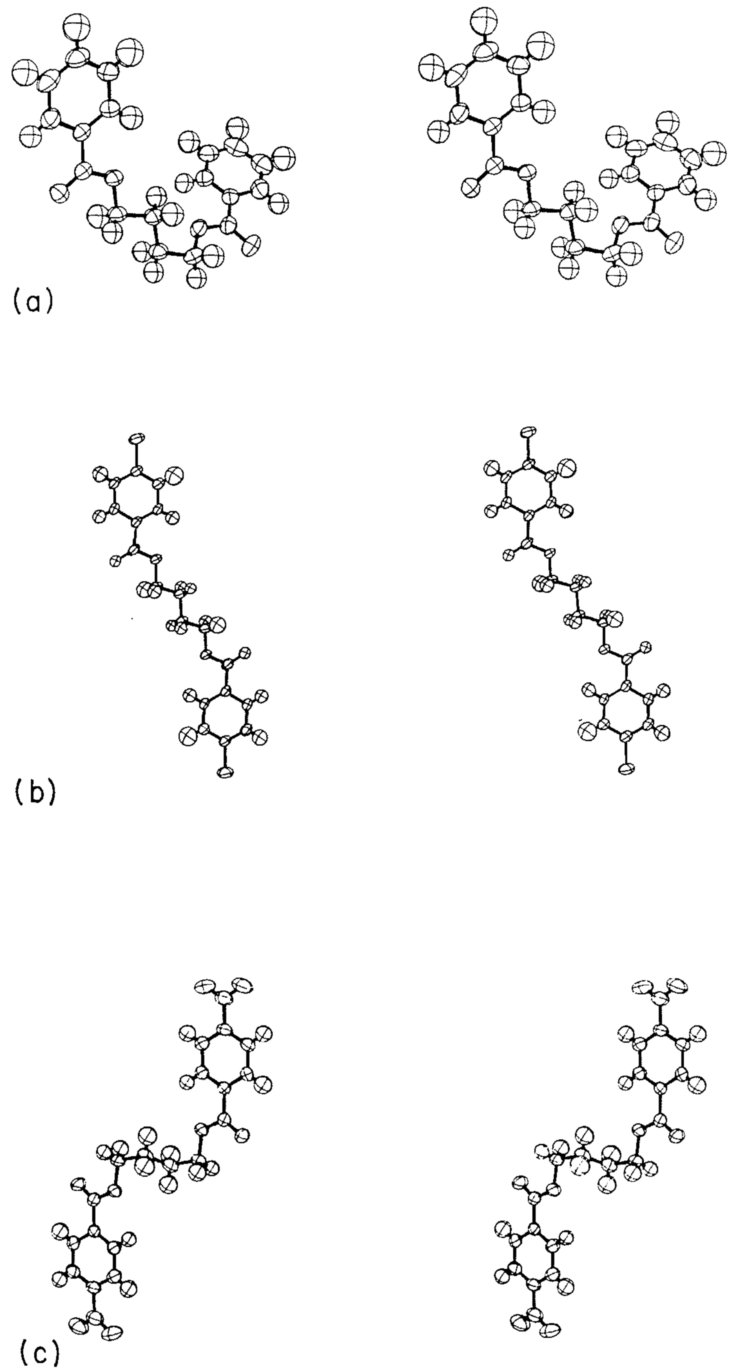

FIG. 2. Stereopairs of the three model compounds: (a) **1**, tetramethylene glycol dibenzoate; (b) **2**, tetramethylene glycol di-*para*-chlorobenzoate; (c) **3**, tetramethylene glycol di-*para*-nitrobenzoate.

function of ϕ_1 and ϕ_2, with the constraints that $\omega = \tau = 180°$, is shown in Fig. 3. The ϕ_1 and ϕ_2 combinations corresponding to the values of the fiber repeat for both the α- and the β-form of poly(4GT), which have values 11.60 and 13.00 Å respectively, have been drawn on this map. The reported conformations for the α- and β-forms of poly(4GT) have also been indicated on the conformational map. The conformations with the lowest energies are listed in Table 6.

The three model compounds studied in this work are related, as far as the conformation of the methylenic sequence is concerned, with one (or both) form(s) reported for poly(4GT).

The α-form

For instance, compound **1**, being noncentrosymmetric, may

† 1, ref. 2; 2, ref. 3; 3, ref. 4; 4, ref. 30.

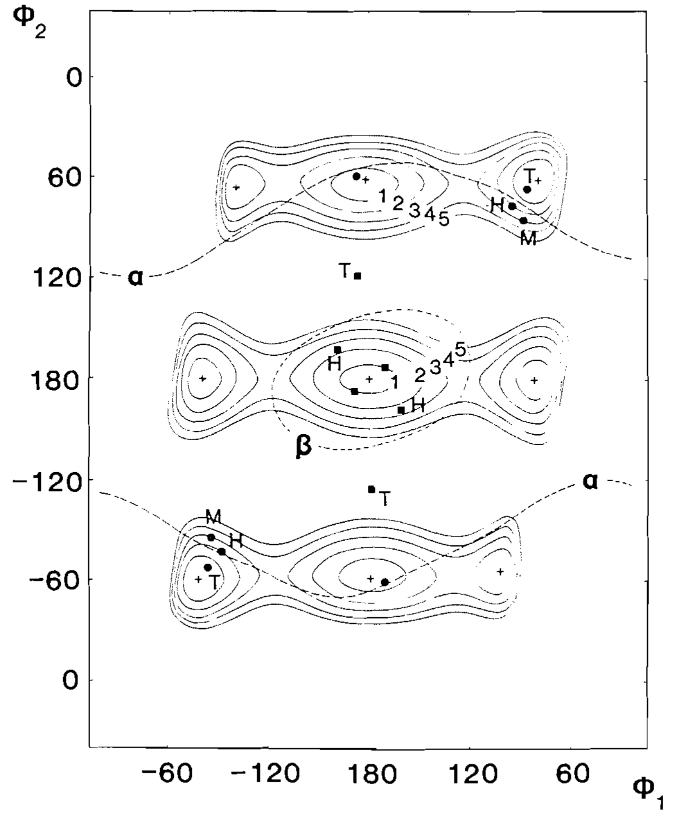

FIG. 3. Conformational energy map for poly(4GT). The energy minima are shown by (+). The black disks and squares represent the (ϕ_1, ϕ_2) combinations of the published poly(4GT) structures, α and β forms respectively. (M = ref. 2, T = ref. 3, and H = ref. 4). The unlabelled black disks correspond to the conformations found in the model compounds. The dotted lines correspond to the fiber repeat of α-poly(4GT) and β-poly(4GT).

be seen as two different half-molecules, each with a distinct conformation. Using the portion of the molecule that contains the torsion angle O(2)—C(8)—C(9)—C(10) = −59.6°, one may build a polymeric chain with a tg^-tgt conformation. In the case of compound **3**, the whole molecule with its tg^-tgt conformation has also been used as a chain generating model. These two compounds lead to calculated fiber repeat values of 11.62 Å and 11.68 Å, which are only slightly larger than the observed value of 11.60 Å for the fiber repeat of α-poly(4GT). The dot representing either of the above conformations on Fig. 3 comes close to the 11.60 Å fiber repeat as represented by the dotted line, and is also near one of the energy minima. This minimum is only 0.50 kcal mol^{-1} higher than the lowest calculated minimum that is associated with the g^-g^-tgg conformation proposed by all three authors for α-poly(4GT) (2−4). The conformational angles proposed, by various authors, for α- and β-poly(4GT) are compared in Table 7. Although energetically comparable, only one of the two conformations is acceptable. The best model can be chosen by comparing the values of the packing indexes, R_p, and the crystallographic agreement factors, $R = \Sigma||F_o| - |F_c|/\Sigma|F_o|$. The latter are obtained using our calculated structure factors, F_c, and the published F_o-values (2). The model with the tg^-tgt conformation has a packing index equal to 31.3 kcal mol^{-1} and the agreement factor between observed and calculated structure factors is R = 0.396, while these values are 13.6 kcal mol^{-1} and 0.148, respectively, when the g^-g^-tgg conformation is chosen. There is no doubt that the proposed model, with the g^-g^-tgg conformation, is the correct one. Consequently, great care should be exercised before using a model compound which seems to fit, as far as fiber repeat values and chain energy are concerned.

The β-form

Using the other half of molecule **1**, an all-*trans* conformation may be generated. A similar chain may be built using the whole methylenic sequence of the centrosymmetric molecule **2**. In both cases, the values of the conformational angles are near those proposed by Hall *et al.* (4) for β-poly(4GT). As a matter of fact, on the isoenergetic map, the values of ϕ_1 and ϕ_2 of our two model compounds are situated a little closer to the same energy minimum. The calculated fiber repeats (13.21 Å and 13.20 Å) are higher than the observed one (13.00 Å): this fact, coupled with the values of the conformational angles, seems to indicate that the polymer could adopt an even more "strained" form, if it could resist the applied tension up to that point.

Although these all-*trans* conformations, found in both model compounds, lead to calculated fiber repeats which are only slightly higher than the observed fiber repeat for β-poly(4GT), the intramolecular distances, bond and torsion angles of compound **2** (with its $ttttt$ conformation) were used to generate a model of the macromolecular chain. Since in these conditions the calculated fiber repeat is 13.24 Å, the flexible torsion angles ϕ_1 and ϕ_2 were altered so that the distance between the benzene ring centers would match the observed value (13.00 Å). The values of ϕ_1 = C(7)—O(2)—C(8)—C(9) and ϕ_2 = O(2)—C(8)—C(9)—C(10) were taken as 158.1° and 173.3°, respectively.

The resulting atomic parameters were then used to position this model chain in the observed unit cell. The chain was allowed to rotate about its axis, in order to minimize the interactions between neighboring chains, using Williams' packing program (24). A very reasonable value of the packing index

*(Absorbance), relative to that of the highest band, the C=O stretch at ~1720 cm^{-1}.

(RPACK), 15.8 kcal mol^{-1}, was reached. The atomic coordinates so obtained were introduced in a least-squares program, which compared the calculated structure factors (from the theoretical model) and those observed by Yokouchi *et al.* (3) on their X-ray fiber patterns for β-poly(4GT). In these conditions the final R factor was 0.220, a value slightly larger than the value of $R = 0.191$ reported by Yokouchi *et al.* (3). The torsion angles of the methylenic sequence published by Hall and Pass (4) are comparable to those in our own theoretical chain (see Table 9) and the values for R were either 0.218 or 0.223, depending upon which parameters were adjusted during their refinement procedure.

It is surprising to note that although different values of ϕ_2 were chosen by Yokouchi (113.0°) or by Hall (162.0°), both arrive at similar values for the calculated fiber repeat of 12.95 and 13.00 Å, and both lead to reasonable crystallographic R-factors ($R = 0.191$ and $R = 0.218$, respectively). The chain packing energies and the crystallographic R-factors for the proposed structures are indistinguishable and either may be considered an appropriate model for β-poly(4GT). Our own model compound, although it reinforces Hall's conformation, does not lead to better values of RPACK or the R-factor.

Spectroscopic study

Since our interest was in the conformation of the methylenic sequence in poly(4GT), the relevant spectral regions are 800–1050 cm^{-1} (methylene rocking) and 1300–1500 cm^{-1} (methylene bending). The FTIR and Raman bands observed in both these regions for the model compounds are compared in Tables 8 and 9 to the literature values for poly(4GT) (6). The band assignment follows the works of Snyder *et al.* (25–27) and Stokr *et al.* (28).

Infrared spectra

In FTIR, the 1300–1550 cm^{-1} region is difficult to work with because of the bands due to the mono- or di-substituted benzene rings, with their different *para*-substituents (H, Cl, or NO_2). We do, however, observe the following. There is only one very strong absorption band at 1383 cm^{-1} in the case of **3**; it is observed at 1385 cm^{-1} with a reduced intensity for **1** and it is completely absent from the spectrum of **2**. At the same time, there is no band around 1395 cm^{-1} for **3**, while **1** induces the appearance of a band of medium intensity at 1395 cm^{-1}, a band whose intensity increases significantly for compound **2**. Since we have a progression of conformations from tg^-tgt (**3**) to tg^-ttt (**1**) to $ttttt$ (**2**), the complete disappearance of the 1383 cm^{-1} band and the emergence of the 1395 cm^{-1} band are then indicative of an all-*trans* conformation, with torsion angles values near 180°, as in compound (**2**).

The 800–1050 cm^{-1} region does not reveal any significant fact such as the one above, where bands would appear or disappear according to the conformations. There is a band at 970 cm^{-1} and at 965 cm^{-1} for compounds **1** and **2**, which has been assigned to an O—CH_2 stretching mode (29), but it is not observed for compound **3**. Since all three compounds have a *trans* conformation for the C(7)—O(2)—C(8)—C(9) angle and compounds **1** and **2** have different conformations (tg^-ttt and $ttttt$), it is assumed that this particular band does not give any significant information about the overall conformation of the methylenic sequence.

The only other interesting fact is the absence of any band between 910 and 925 cm^{-1} for all three compounds, which is

TABLE 9. Raman bands in the regions 800–1050 cm^{-1} and 1300–1550 cm^{-1}

not peculiar in itself but which will acquire important significance when compared to the ir spectrum of poly(4GT).

Raman spectra

The spectral regions considered in the Raman spectra are the same as in FTIR, the 800–1050 cm^{-1} and 1300–1550 cm^{-1} domains, which contain some CH_2 rocking and bending modes (6, 26, 27). Because compound **3** was a yellow powder, no satisfactory Raman spectrum could be obtained. Even after recrystallization and production of a yellowish-white sample, the product still showed absorption problems while its spectrum was taken. Only the results for **1** and **2** will be given here.

In the first region, compound **1** has a band at 810 cm^{-1}, while **2** does not. This band could be related to a conformation containing at least one *gauche* torsion angle, as is the case in **1** (tg^-ttt). On the other hand, only **2** exhibits a band at 1047 cm^{-1}; its presence could be indicative of an all-*trans* conformation, *ttttt* as in **2**, or at least a *ttt* conformation implicating the torsion angles between the four carbon atoms in the chain.

The spectral region where CH_2 wagging and bending modes usually appear does contain some significant changes. The spectrum of **1** shows a band between 1383 and 1388 cm^{-1}, which is absent for **2**. On the spectrum of the latter, two new bands do appear at 1347 cm^{-1} and 1405 cm^{-1}. In conclusion, the presence of the band at ~1385 cm^{-1} suggests a *gauche* torsion angle in the methylenic sequence, while the 1347 cm^{-1} and 1405 cm^{-1} bands stand for at least a *ttt* sequence or even an all-*trans* conformation.

Unfortunately, the association of bands at 1047 cm^{-1}, 1347 cm^{-1}, and 1405 cm^{-1} to an all-*trans* conformation in **2** is not verified in the case of hexamethylene glycol dibenzoate, a model compound for poly(6GT). In this product the methylenic chain has a *ttttttt* conformation but its spectrum does not show any of the above-mentioned bands. The three bands observed in **2** might then be specifically associated to the entire all-*trans* sequence (*ttttt*), including the oxygen atoms which are at both ends of the methylenic sequence.

It has already been established by FTIR that some bands are representative of a given conformation for one model compound while others, by their appearance or disappearance, can be related to an evolution of conformational sequences (from tg^-tgt to *ttttt*). These conclusions can now be extended to the different forms of poly(4GT) (6, 8) and may shed some light on the reported discrepancies in the description of the conformation of β-poly(4GT), the stressed form of the polymer.

The FTIR spectroscopic results for the three model compounds supplied two important conclusions: first, that the complete disappearance of the absorption band at 1383 cm^{-1} and the emergence of the 1395 cm^{-1} band are indicative of an all-*trans* conformation, with torsion angle values near 180°. Upon examination of the 1350–1425 cm^{-1} region of the spectra for poly(4GT), one notes an absorption band at 1386 cm^{-1} for the annealed sample and the subsequent disappearance of this band, while another one appears at 1395 cm^{-1}, in the case of the stressed sample. Consequently, the β-form of poly(4GT) possesses an all-*trans* conformation, with torsion angle values near 180°.

The second conclusion concerns the fact that there is no band around 917 cm^{-1} for all three model compounds. The very absence of any absorption band on those spectra, while there is one present, and quite important, in the spectrum of the annealed α-poly(4GT), is indicative of a peculiar conformation. It has been stated that this strong absorption is characteristic of "α crystallinity" in poly(4GT) (6, 7) and of its *sstss* conformation (where *s* is non-*trans* non-*gauche* and φ, the corresponding torsion angle, is between 90° and 120°). The absorption band at 917 cm^{-1} is not observed in either of the three model compounds with different conformations ($tg^{-}ttt$, *ttttt*, and $tg^{-}tgt$) or in the spectra of other model compounds such as pentamethylene glycol di-*para*-nitrobenzoate (*tttttt*), pentamethylene glycol di-*para*-chlorobenzoate ($g^{-}tttg^{-}$), and hexamethylene glycol dibenzoate (*ttttttt*). This absorption band is only present when there is a non-*trans* non-*gauche* conformation in the methylenic sequence. Consequently, its presence in the spectrum of the annealed polymer, α-poly-(4GT), and its absence from the spectrum of the stressed sample indicates the absence of any non-*trans* non-*gauche* conformation in β-poly(4GT). In other words, the stressed polymer has torsion angle values not too different from 180° for its all-*trans* conformation.

The Raman study of the model compounds compared to that of poly(4GT) (6) confirms the conclusion reached above. More specifically, the three bands (1047 cm^{-1}, 1347 cm^{-1}, and 1405 cm^{-1}), which are associated with the entire all-*trans* sequence (*ttttt*) of the four-carbon chain and their neighboring oxygen atoms in the model compound are also observed in the Raman spectrum of β-poly(4GT), at 1044, 1348, and 1405 cm^{-1}. Simultaneously, the band observed at 1381 cm^{-1} in the spectrum of the annealed poly(4GT) has disappeared. This last band was not present on the spectrum of compound **2** (*ttttt*). Thus it is Hall's model, with an all-*trans* conformation and torsion angle values near 180°, which describes best the β-form of poly(4GT).

Received December 28, 1984

GILLES SAUVÉ, VANGA S. RAO, GILLES LAJOIE, and BERNARD BELLEAU. Can. J. Chem. **63**, 3089 (1985).

Reaction conditions for the synthesis of thioamide, amidoxime, and N-substituted amidine analogs of the peptide bond are described. Several new amidine analogs of the chemotactic peptide f-Met-Leu-Phe-OR were synthesized using the thioamides as precursors. The assignment of the *E*/*Z* configuration was accomplished by nuclear magnetic resonance. The biological activity of these analogs is briefly described.

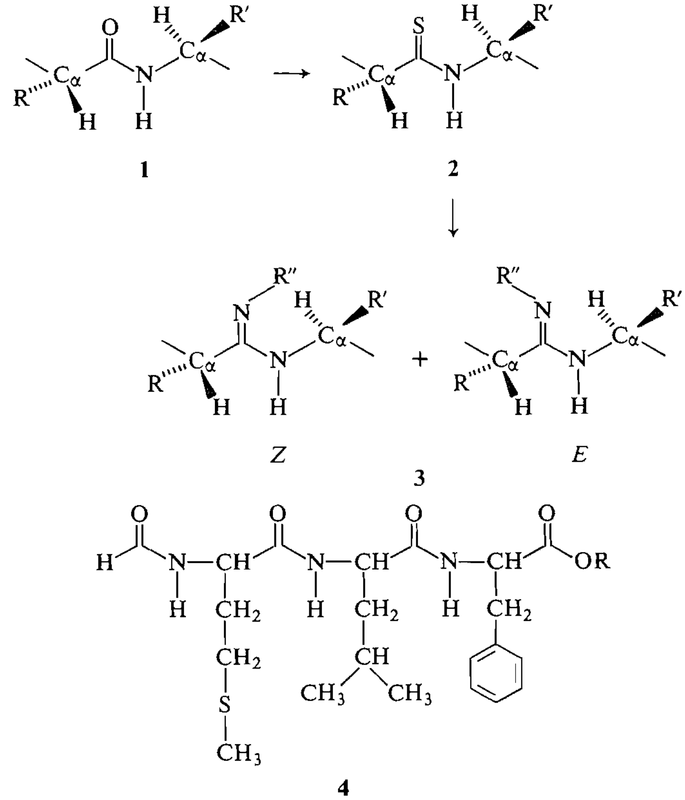
GILLES SAUVÉ, VANGA S. RAO, GILLES LAJOIE et BERNARD BELLEAU. Can. J. Chem. **63**, 3089 (1985).

Des conditions de réaction pour la synthèse de thioamides, d'amidoximes et d'amidines N-substituées analogues au lien peptidique sont décrites. Plusieurs analogues du peptide chimiotactique f-Met-Leu-Phe-OR contenant une fonction amidine N-substituée furent synthétisés à partir de précurseurs thioamidés. L'attribution de la configuration *E* et *Z* est faite par analyse spectroscopique de résonance magnétique nucléaire. L'activité biologique de ces analogues est décrite brièvement.

Introduction

Until recently, studies of structure–activity relationships in the field of oligopeptidic effectors were mainly concerned with modifications of the side chains (1). However, a growing number of peptide bond analogs have been generated in an attempt to delineate the role of the backbone peptide bonds in the process of active site recognition by receptors and enzymes for biologically active oligopeptides, a question having a direct bearing on the susceptibility of such effectors to peptidases (see ref. 2 for a general review of peptide backbone modifications). We have already described appropriate methodologies (3), preferable to previous ones (4) for reasons previously outlined, for the selective incorporation of thioamide functions (5) into peptide backbones and have recently illustrated the effects of such modifications on the pharmacological properties of the endogenous opiate Leu^5-enkephalin (6). The results of a similar study by others (7) have also been divulged and are in general concordance with ours. We now wish to describe an extension of our methodology for thiopeptide formation and to illustrate the use of the thioamide function (**2**) (Scheme 1) as the precursor of novel backbone analogs where the sulfur is replaced by substituted nitrogen functions (**3**). Although similar in structure to the amide function, amidine analogs as such were not synthesized because their strongly basic properties disqualify them as relevant peptide bond analogs.

The chemotactic peptide f-Met-Leu-Phe-OH (**4**) (8) has formed the subject of considerable interest as a prototype bioregulator of immune cells such as neutrophils and monocytes and extensive structure–activity relationships have been reported (9). Nearly all of these involved side chain alterations and substituent effects at the N— and C— terminals. Some of these changes were intended to impose conformational restrictions through steric constraints about the side chains (10).



SCHEME 1

Our strategy called for backbone modifications of the chemotactic peptide through selective amide bond replacement by thioamide linkages. The resulting thiopeptides may then be used as intermediates for the synthesis of amidoxime and N-substituted amidine analogs according to literature methods (11). The conformational changes induced by such backbone modifications may then be studied by nmr and computer

modeling methods (V. S. Rao, G. Sauvé, G. Lajoie, and B. Belleau, to be published).

Several methods are known for the synthesis of N-substituted amidines (12, 13). However, the reaction conditions employed in most cases are unsatisfactory for our purposes because of the relative inaccessibility of the precursors and the susceptibility of peptide substrates to racemization and decomposition under the prescribed conditions. Our recently developed methodology for the selective thionation of peptide linkages (3) provided the incentive to generate thiopeptidic analogs of f-Met-Leu-Phe-OR as key intermediates and as intrinsically valuable receptor probes. Under mild, controlled conditions, our thiophosphetane reagent[3] **17** can transform regioselectively protected oligopeptides into thiopeptides, the site of transformation being determined by the relative steric bulk of the side chains adjacent to the amide bonds (3). Subsequent replacement of the sulfur atom by nitrogen functionalities would yield still other novel types of backbone analogs such as the desired N-substituted amidines.

The purpose of the present report is to describe the synthetic methodologies (as outlined in Scheme 1) and the results of nmr studies of the configurational properties of these novel backbone-modified chemotactic peptides. The detailed biological activities of the analogs will be reported elsewhere.

Results and discussion

Synthesis of mono- and di-thionated peptide analogs of f-Met-Leu-Phe-OR (Scheme 2)

The methyl ester of L-phenylalanine (**5***a*) was prepared in the conventional manner (14) by adding L-phenylalanine to a solution of thionyl chloride in methanol, whereas the *tert*-butyl ester (**5***b*) was obtained by transesterification of L-phenylalanine with *tert*-butyl acetate in the presence of catalytic amounts of perchloric acid (15). Following standard reaction conditions, **5***a* and **5***b* were then elongated to the dipeptide, Boc-Leu-Phe-OR (R = CH_3, **6***a*; R = $C(CH_3)_3$, **6***b*) by coupling with Boc-Leu-OH in the presence of DCC and HOBt (16). The amino group of **6***a* was deprotected using formic acid (17) and the resulting formate salt was treated with triethylamine followed by coupling with Boc-Met-OH under standard conditions (DCC–HOBt) to give the tripeptide Boc-Met-Leu-Phe-OCH_3 (**9**). Removal of *t*-Boc group with formic acid and subsequent addition of EEDQ (18) to the formate salt yielded the N-formyl tripeptide f-Met-Leu-Phe-OCH_3 (**4***a*).

Thionation of **4***a* with reagent **17** under controlled conditions (0°C, 1 h) gave exclusively the corresponding thioformyl derivative (**8**). Boc-Met-Leu-Phe-OCH_3 (**9**) when reacted with **17** at 0°C for 3 days gave a mixture of monothionated **11** and **12** and dithionated derivatives **13** in a 4:4:2 ratio respectively. Removal of the *t*-Boc group from these derivatives followed by N-formylation as described above, gave the corresponding for-

[3]Thionation reagent: C_6H_5 (**17**) prepared from diphenyl ether and phosphorus pentasulfide.

mylated peptides **14**, **15**, and **16** which were separated on silica by flash chromatography. The *tert*-butyl ester **10** was obtained through selective removal of the N-Boc group from *7b* with *p*TSA[4] (19) followed by direct coupling with formylmethionine in the presence of DCC–HOBt. The precursor *7b* was obtained in turn by thionation of *6b* with **17**.

The structures and physical characteristics of the mono- and di-thiopeptides synthesized in this manner are assembled in Table 1. Their relevant nmr characteristics (^{1}H chemical shifts) are given in Table 3.

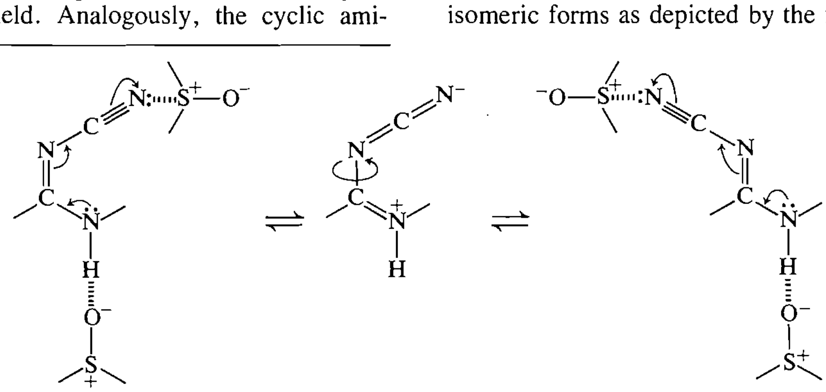
N-Substituted amidine backbone analogs. Syntheses and configurational determinations

The approach adopted for amidine-like analog synthesis relied on the inherent reactivity of thioamides toward nucleophiles or on electrophilic catalysis by the thiophilic mercuric ion. The high reactivity of thioamide **8** and of leucine thioamide together with the high nucleophilicity of the nucleophile hydroxylamine served to eliminate the need for electrophilic assistance in the formation of amidoximes **18** and **36** (Table 2). However, assistance by $Hg(OAc)_2$ was found necessary in all other cases, the thioamides being either less reactive or too sterically hindered for the nucleophile to react efficiently. The presence of $Hg(OAc)_2$ was even more necessary with the less nucleophilic reactant cyanamide (NH_2CN). For example, when Boc-Leu-ψ($CSNH_2$) (20) was treated with 1.1 equivalents of NH_2OH in THF at room temperature, amidoxime **18** Boc-Leu-ψ[C(=NOH)NH_2] was obtained in 62% yield. In contrast, generation of **19** and **20** from the corresponding precursor thioamides required assistance by mercuric ions in order to overcome unfavorable steric effects by the N-substituents of the substrates.

The structures of the mono-, di-, and tri-peptide N-substituted amidines synthesized in this manner, together with some relevant product characteristics, are given in Table 2, whereas their pertinent ^{1}H nmr band positions and shifts are assembled in Table 3. It is worth noting that when Boc-Leu-ψ(CSNH)-Phe-OCH_3 (*7a*) was treated with NH_2OH and $Hg(OAc)_2$ in the presence of $N(Et)_3$ in THF, the cyclic amidoxime lactone **21** was obtained in 44% yield. However, when the *tert*-butyl ester derivative of the N-CBZ protected peptide (CBZ-Leu-ψ(CSNH)-Phe-$OC(CH_3)_3$) was subjected to the same reaction conditions, the expected amidoxime analog **23** was obtained in 80% yield. Analogously, the cyclic amidrazone **22** was obtained when *7a* was reacted with NH_2—NH_2 under similar reaction conditions. This suggests that when either the amidoxime or the amidrazone derivative can adopt the *Z*- configuration, they spontaneously cyclize presumably because of favorable ϕ_3 and ψ_3 torsional angles around the Phe moiety as well as by the inherent reactivity of the terminal methyl ester function. These factors are obviously disfavored when a bulky *tert*-butyl ester function is used. To what extent the relative inductive properties of *tert*-butyl and methyl groups influence the course of the reaction is arguable (21). A similar reaction sequence led to the cyclic analogs of tripeptides **32** and **33** without interference from the terminal N-formyl groups. Some O-methyl amidoximes and N-cyanoamidines were similarly prepared using methoxamine and cyanamide as the nucleophiles and appropriate thiopeptide precursors (Table 2).[5] The O-acetyl amidoximes **29** and **42** were readily obtained by acetylation of amidoximes **28** and **36**, respectively. It is worth noting that under the adopted experimental conditions (where mercuric ions are present) the thioether functions of the methionine residues were left intact.

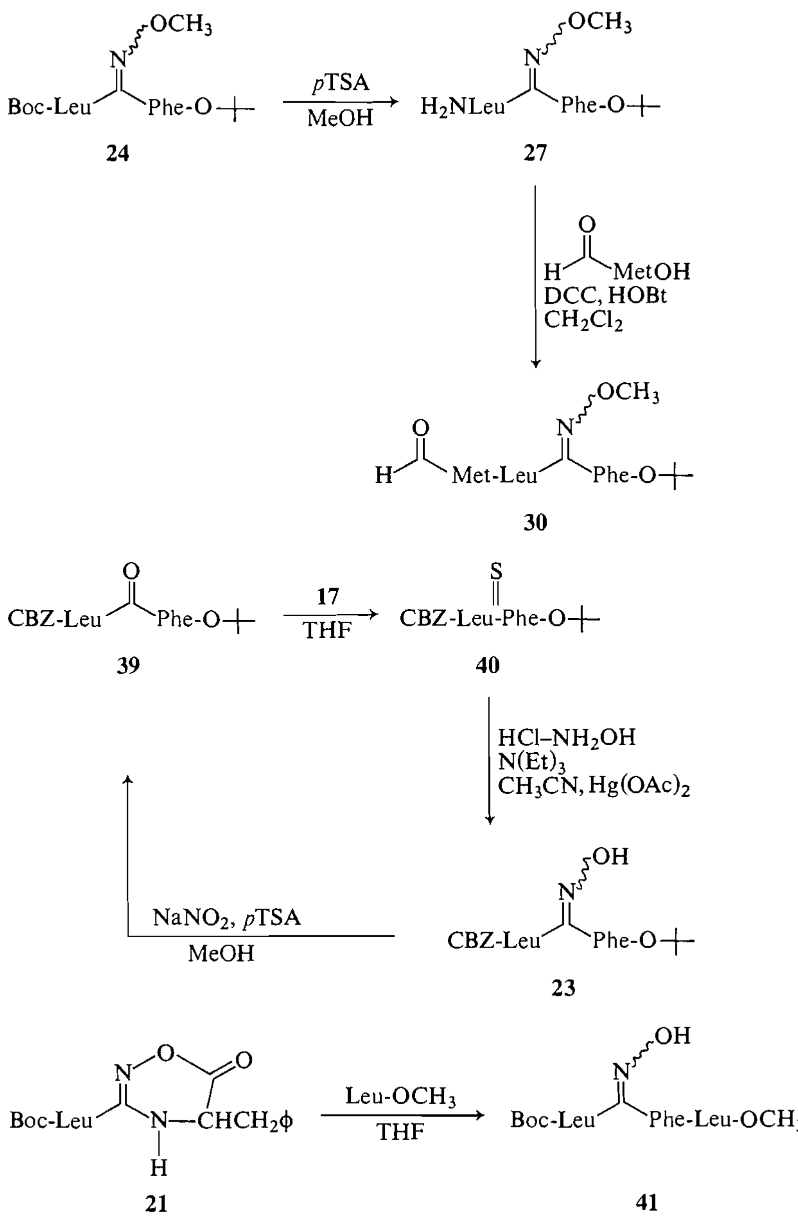
All the amidoxime analogs including their O-methyl derivatives (except for **36** and **38**) showed two sets of resonances (a major and a minor one) in their ^{1}H nmr spectra. With analog **30**, for example, the ratio between these two sets of signals was 63:37 in DMSO-d_6 as the solvent, and 77:23 in the less polar solvent $CDCl_3$, thus showing that these two sets of resonances originate from geometrical isomers about the amidine C=N bond and not from diastereoisomers as might have been produced through epimerization of the two α-carbons during the synthetic operations. This contention was conclusively proved by treating the geometrically inhomogeneous amidoxime **23** (Z/E = 83:17) with nitrous acid (generated *in situ* from $NaNO_2$ and *p*TSA) in methanol, which transformed the amidoxime into the parent amide function (Scheme 3). After isolation, the product was found to exhibit an ^{1}H nmr spectrum (200 MHz) and a specific rotation that were virtually identical to those of authentic CBZ-Leu-Phe-$OC(CH_3)_3$, thus confirming that no racemization occurred during the process of amidoxime **23** formation.

Interestingly, however, N-cyanoamidine derivatives **31**, **35**, and **37** (Table 2) exhibited only *one* set of relevant signals, implying in these cases the existence of either a single geometric form or the operation of a fast equilibration of two isomeric forms as depicted by the following mechanism:



[4]The use of HCOOH also cleaved the carboxyl *tert*-butyl ester. However, as expected, the methyl ester was stable under the same conditions.

[5]All the tripeptide amidine analogs were obtained directly from the corresponding thioamides, except in the case of **30** which was obtained from **24** by cleaving the Boc-group and coupling the resulting amine **27** with formyl-methionine under the usual conditions (Scheme 3).



SCHEME 3

However, analog **25**, which carries a N-BOC group instead of N-formyl, exhibited two sets of signals that collapsed into a single set at 80°C in DMSO. This contrasting behavior relative to **31**, **35**, and **37** suggests that *cis–trans* isomerism about the carbamate bond of **25** may best account for the appearance of two sets of signals. Other assignments of configuration were also made on the basis of nmr evidence. For example, in compound **30**, the $C_\alpha H$ proton of Leu^2 in the predominant isomer resonates at a higher field (4.36 δ) than that of the minor isomer (5.1 δ) (13, 22). This is consistent with the parallel finding that the $C_\alpha H$ proton of Phe^3 appears at a lower field (4.25 δ) in the former whereas in the minor isomer it appears at 4.01 δ. Also, in the case of **28**, the =NOH proton resonates at a lower field (9.56 δ) in the *Z*-isomer, whereas the same proton in the minor isomer appears at 8.96 δ (13). The ^{13}C chemical shifts for the major isomer (*Z*) of **30** in $CDCl_3$ were unequivocally assigned from the *two*-dimensional (2-D) $^{13}C-^{1}H$ shift correlated spectrum (400 MHz). As compared to the parent tripeptide f-Met-Leu-Phe-OBu^t (**4***b*), the C_α-carbon of Phe^3 in **30** is shifted to a lower field by 3.00 ppm whereas the Leu^2-C_α carbon is shifted upfield by 6.29 ppm. Interestingly, the more remote Met^1-C_α carbon of **30** experiences only a small downfield shift (0.05 ppm) by comparison with the shift for the corresponding carbon in **4***b*. These relative shifts are in agreement with the configurational assignment for the major (*Z*) isomer. The downfield shift for the Phe^3-C_α carbon may arise primarily from steric compression as a result of its proximity to the oxime oxygen atom in the *Z*-isomer.

Similarly, the configuration about the C=N bond in **34** could be inferred from the relative ^1H chemical shifts pattern. As in compound **28**, the minor isomer (25%) of **34** in DMSO-d_6 could be assigned the *E*-configuration on the basis of the proton chemical shifts of both the Met^1-$C_\alpha H$ (5.08 δ) and the Leu^2-$C_\alpha H$ (3.90 δ). The major isomer can thus be automatically assigned the *Z*-configuration ($C_\alpha H$ Leu^2: 3.98 δ; $C_\alpha H$ Met^1: 4.70 δ). The ^{13}C chemical shifts for the major isomer (*Z*)

of **34** in DMSO-d_6 were assigned from the $^1H-^{13}C$ shift correlated spectrum. The Met-C_α carbon in **34** is shifted upfield by 5.96 ppm relative to the shift for the corresponding carbon in **4***a* in $CDCl_3$.[6] The upfield shifts experienced by Met^1-C_α carbon in **34** and Leu^2-C_α in **30**, both of which have the *Z*-configuration, may be attributed to their *anti* orientation to the oxygen atom of the OH or OCH_3 group situated in the γ-position. This effect is similar to the upfield shift experienced by a carbon atom located at the γ-position and with an antiperiplanar orientation relative to an oxygen, nitrogen, or fluorine atom ("γ-*anti* effect") (23). A similar γ-*anti* upfield effect by the β-anomeric oxygen atom was also found to apply to aldopyranoses (24) despite the insertion of an O_5-ring oxygen atom. In the peptide amidoxime analogs **30** and **34** the upfield shifts experienced by the C_α carbons attached to the oxime carbon atom and in *anti* orientation relative to the OH or OCH_3 group appear to provide yet another example of this γ-*anti* effect,[7] it being transmitted not only through an intervening nitrogen atom but also incorporating a double bond where the nitrogen atom is an integral constituent. Whatever the reason for this upfield shift, it seems to be *diagnostic* of the *Z*-configuration around the C=N bond of the amidoxime moiety, an observation forming the basis of a simple method for the assignment of configuration in these peptide amidoxime analogs (25).

It is interesting to note that the *Z*-isomeric form predominates whether the *amidoxime* moiety is between Leu^2 and Phe^3 (**28**) or between Met^1 and Leu^2 (**34**). The preference for the *Z*-isomer in **28** may be rationalized on the basis that the *amidoxime* hydroxyl group avoids orienting itself towards the bulky leucine moiety. However, the preference for the same *Z* form in **34** appears contradictory in that context. In another report to be published and which centers on nmr and computer modeling studies, the *amidoxime* NH proton of **34** is shown to be involved in an intramolecular hydrogen bond with the C=O group of the N-terminal formyl group, thus favoring a $3 \rightarrow 1$ γ-turn (C_7 conformation). In the *Z*-isomer, the *amidoxime* OH group is oriented towards the leucine C_α carbon and this, in principle, may not be expected to interfere with rotation about the ψ_1 torsional angle. Such rotational freedom not only allows the molecule to adopt either of the two possible C_7 conformations ($\phi_1 = +75°$, $\psi_1 = -75°$; $\phi_1 = -75°$, $\psi_1 = +75°$) but also provides for conformational interconversion. On the other hand, in the *E*-isomer, the OH group being oriented towards the methionine C_α carbon may be expected to impose some restriction to free rotation around the ψ_1 torsional angle. In fact, in the C_7 conformation having $\phi_1 = +75°$ and $\psi_1 = -75°$ there seem to be no severe destabilizing interactions between the *amidoxime* OH group and the methionine moiety, whereas that conformation having $\phi_1 = -75°$ and $\psi_1 = +75°$ has the OH group in a destabilizing contact with the methionine

[6]The change in solvent does not preclude the comparison as the shift variation associated with it is found to be $\sim\pm 1$ ppm from similar peptide derivatives.

[7]It is difficult to estimate the magnitude of this effect because part of the upfield shift may be attributed to the apparent change involved in going from an amide to an amidoxime moiety ($C_\alpha-\overset{O}{\overset{\|}{C}}-N \rightarrow C_\alpha-\overset{NOR}{\overset{\|}{C}}-N$).

C_β hydrogen atoms. In other words, the *E*-isomer of **34** can adopt only a single C_7 conformation with $\phi_1 = +75°$ and $\psi_1 = -75°$ whereas the *Z*-isomer can adopt, in addition, another conformation with $\phi_1 = -75°$ and $\psi_1 = +75°$. This means a loss of entropy of mixing in the *E*-isomer which may, in part, be responsible for the preference for the *Z*-isomer of **34**. However, other steric factors such as interorbital interaction between nonbonded electrons at nitrogen and oxygen, dipolar interactions, etc. (26) may also be involved but are difficult to evaluate quantitatively at this time.

Finally, the cyclic amidoxime derivative **21** was tested for its potential ability to behave as an acylating species toward aminoacids, which would allow peptide elongation from the carboxyl terminal. Accordingly, **21** was reacted with Leu-OCH_3 in THF and, after standard processing, the expected tripeptide amidoxime **41** (Scheme 3) was obtained in 72% yield. In this reaction, which may proceed under nonequilibrating conditions, the *amidoxime* moiety of tripeptide **41** would be expected to assume the *Z*-configuration characteristic of the starting cyclic material **21**. In fact, in the ^1H nmr spectrum of **41** (in $CDCl_3$) there appeared only one set of relevant signals, in agreement with expectations. However, when the ^1H spectrum was recorded in DMSO-d_6 as solvent, two sets of signals were now observed in a ratio of 67:33, thus indicating that an equilibration similar to the one proposed for the case of the cyanoamidine derivative is taking place. The major isomer was assigned the *Z*-configuration (Boc-Leu-$C_\alpha H$: 3.86 δ) and the minor one the *E*-configuration (Boc-Leu-$C_\alpha H$: 4.91 δ). Assuming that the observed single set of signals for **41** in $CDCl_3$ reflects the presence of only one isomeric form (rather than an accidental overlap with the signals for the minor isomer), this method of elongation would appear valuable for the synthesis of single geometric isomers of backbone amidoxime analogs of oligopeptides.

All the tripeptide backbone analogs listed in Tables 1 and 2 were evaluated for their ability to induce the release of lysozyme from human neutrophils, a process known to reflect chemotactic activity (8). The relative activities were computed from complete dose–response curves as recently reported for a different class of superactive releasers (27) relative to f-Met-Leu-Phe-OCH_3 as the standard. The most significant findings may be summarized as follows (details to be reported elsewhere). The presence of thioamide functions on the backbone suppresses activity except when sulfur is present as a thioformyl group, which depresses activity by 60–70%. With amidoxime functions, on the other hand, activity is restored significantly but not with cyanoamidine linkages except at the terminal formyl group level. An especially meaningful finding is the strong activity associated with cyclic structures **32** and **33**, which are completely rigid about the terminal phenylalanine residue. The significance of these observations in relation to the receptor protein topography is under scrutiny.

Experimental

Melting points were determined on a Buchi SMP-20 and are uncorrected. The ir spectra were taken with a Perkin–Elmer 257 spectrophotometer. The uv spectra were recorded on a Varian–Carey 210 spectrophotometer. The optical rotations $[\alpha]_D$ were obtained with a Perkin–Elmer 141 instrument. Proton nmr spectra were recorded with a Bruker WM-250 and (or) WH-400 instrument. Chemical shifts are given in ppm (δ) relative to $CHCl_3$ (7.24 δ) or DMSO (2.49 δ). The high resolution mass spectra (ms) were obtained with a Vg Micromass ZAB-2F spectrometer. Elemental analyses were performed by the

Guelph Laboratories, Guelph, Ont. The numbers 1, 2, and 3 used as subscripts for the ϕ and ψ torsional angles denote methionine, leucine, and phenylalanine units respectively. After conventional work-ups, all solutions were evaporated below 40°C under reduced pressure. Eastman Chromagram plates of silica gel were used for thin-layer chromatography. Anhydrous sodium sulfate was used as the drying agent for all extracts. The purity of all products and intermediates was established by thin-layer chromatography using two solvent systems (hexanes and ethyl acetate) and their compositions confirmed by ^{1}H and ^{13}C nmr spectroscopy, mass spectrometry, and in some pertinent cases by elemental analyses. The relevant data are assembled in Tables 1–3.

The following general procedures were applied where similar standard reactions are involved.

Coupling between N-protected and C-protected amino acids or peptides by the HOBt–DCC procedure

To a solution of Boc-Leucine (2.50 g, 10.8 mmol) and HOBt (1.46 g, 10.8 mmol) in methylene chloride (20 mL) and dimethylformamide (5 mL) at 0°C under N_2 was added DCC (2.22 g, 10.8 mmol). The mixture was stirred for 1 h at 0°C and then a solution of phenylalanine methyl ester hydrochloride (2.32 g, 10.8 mmol) and dry triethylamine (1.10 g, 10.8 mmol) in methylene chloride (7 mL) was added and the mixture stirred at 0°C for 1 h and at room temperature for 16 h. The solvents were evaporated, and the residue suspended in ethyl acetate followed by filtration. The filtrate was washed with aqueous citric acid (5%, 1 × 15 mL), sodium bicarbonate solution (5%, 1 × 15 mL), and brine (15 mL). The organic phase was dried, the solvent evaporated, and the resulting solid recrystallized from ethyl acetate – hexane to yield pure Boc-Leu-Phe-OMe (**6*a***) (3.60 g, 85%) as a white powder.

Cleavage of N-Boc groups with formic acid

As a typical example, Boc-Leu-Phe-OCH_3 (**6*a***) (1.5 g, 3.8 mmol) was dissolved in formic acid (98%, 30 mL) and the mixture stirred for 4 h at room temperature under N_2. The excess acid was removed *in vacuo* at 25°C and the resulting formate salt used as such either for N-formylation or for coupling in the presence of triethylamine as described below.

N-Formylation with EEDQ and formic acid

The formate salt obtained as above after cleavage of the *t*-Boc group from Boc-Met-Leu-Phe-OMe (**9**) (1.5 g, 2.9 mmol) was dissolved in dry chloroform (40 mL) followed by the addition of EEDQ (780 mg, 3.0 mmol). The mixture was stirred at room temperature for 8 h under N_2, the solvent removed *in vacuo*, and the residue was dissolved in ethyl acetate. The solution (75 mL) was washed with aqueous citric acid (5%, 2 × 20 mL), sodium bicarbonate solution (5%, 2 × 20 mL), and brine (2 × 20 mL) and then dried. Evaporation of the solvent and precipitation of the residue from methanol–water gave a white solid (**4*a***) (1.17 g, 90% from **9**).

Amide thionation

The dipeptide Boc-Leu-Phe-$OC(CH_3)_3$ (**6*b***) (2.00 g, 4.6 mmol) was dissolved in dry tetrahydrofuran (40 mL), thionation reagent **17** (2.00 g, 3.70 mmol) added, and the mixture stirred at 40°C for 10 h under N_2. The solvent was evaporated and the residue purified by flash chromatography on silica gel (hexanes – ethyl acetate (85:15)) to give pure thiodipeptide, Boc-Leu-ψ(CSNH)-Phe-$OC(CH_3)_3$ (**7*b***) (1.76 g, 85%) as a powder.

Selective cleavage of a N-Boc group with p*-toluenesulfonic acid (*p*-TSA)*

To a solution of Boc-Leu-ψ(CSNH)-Phe-$OC(CH_3)_3$ (**7*b***) (200 mg, 0.444 mmol) in methanol (7 mL) was added *p*-toluenesulfonic acid (84 mg, 0.44 mmol) under N_2 and after 24 h an additional 84 mg of *p*-toluenesulfonic acid was added, followed by standing for 18 h. Saturated aqueous sodium bicarbonate (15 mL) was added, the mixture extracted with methylene chloride (4 × 15 mL), and the extract dried and evaporated to give a crude product that was used as such in coupling reactions.

Preparation of N-substituted amidines

A solution of thiotripeptide **10** (15.0 mg, 0.029 mmol) in dry acetonitrile (2 mL) was treated with triethylamine (9.0 mg, 0.088 mmol), hydroxylamine hydrochloride (3.0 mg, 0.044 mmol), and mercuric acetate (10 mg, 0.032 mmol). The mixture was stirred under N_2 and, after 6 h, additional portions of triethylamine (9.0 mg, 0.088 mmol), hydroxylamine hydrochloride (3.0 mg, 0.044 mmol), and mercuric acetate (10 mg, 0.032 mmol) were added. The mixture was allowed to stand for 16 h, after which time saturated aqueous NH_4Cl (7 mL) was added followed by extraction with methylene chloride (4 × 10 mL). The organic phase was dried, the solvent evaporated, and the residue purified by thick-layer chromatography on silica gel (EtOAc) to give pure amidoxime **28** (12 mg, 80%).

All the other amidine derivatives were obtained from using the appropriate nucleophile by the same general procedure.

*Cyclic amidoxime (**21**)*

To a solution of thiodipeptide **7*a*** (200 mg, 0.48 mmol) in tetrahydrofuran (15 mL) was added hydroxylamine hydrochloride (40 mg, 0.58 mmol), triethylamine (146 mg, 1.46 mmol), and mercuric acetate and the mixture stirred for 2 h under N_2, then diluted with ethyl acetate (20 mL) and the suspension filtered through Celite. The filtrate was evaporated and the residue purified by flash chromatography on silica gel (hexane – ethyl acetate (6:4)) to give the pure cyclic amidoxime **21** (88 mg, 44%).

*Regeneration of parent amide from amidoxime **23**: [—C(=NOH)—N → —C(=O)—N]*

To a solution of CBZ-Leu-ψ[(C=NOH)NH]-Phe-$OC(CH_3)_3$ (**23**) (40 mg, 0.083 mmol) in methanol (4 mL) was added *p*-toluenesulfonic acid (22 mg, 0.124 mmol) and sodium nitrite (9.0 mg, 0.124 mmol). After 16 h, *p*-toluenesulfonic acid (22 mg, 0.124 mmol) and sodium nitrite (9.0 mg, 0.124 mmol) were again added and after 6 h saturated aqueous sodium bicarbonate (7 mL) was added followed by extraction with methylene chloride (4 × 10 mL). The dried organic phase was evaporated and the residue purified by column chromatography on silica gel (hexane – ethyl acetate (7:3)) to give pure CBZ-Leu-Phe-$OC(CH_3)_3$ (**39**) as an oil (27 mg, 70%); $[\alpha]_D^{30}$ +17.4° (c 0.88, $CHCl_3$); ^{1}H nmr ($CDCl_3$) δ: 7.36–7.14 (8H, phenyl), 7.12 (dd, 2H, Phe-*ortho*, J_{ortho} 7.5, J_{meta} 2.0 Hz), 6.38 (d, 1H, NH-Phe, J_{N,C_α} 8.0 Hz), 5.08 (s, 2H, OCH_2), ~5.06 (overlap, 1H, NH-Leu), 4.69 (dd, 1H, C_αH-Phe, J_{N,C_α} 8.0, J_{C_α,C_β} 6.0 Hz), 4.13 (m, 1H, C_αH-Leu), 3.06 (d, 2H, $C_\beta H_2$-Phe, J_{C_α,C_β} 6.0 Hz), 1.7–1.4 (m, 3H, $C_\beta H_2$, C_γH-Leu), 1.38 (s, 9H, $OC(CH_3)_3$), 0.89 (d, 6H, $(CH_3)_2$-Leu); high resolution ms, calcd. for $C_{27}H_{36}N_2O_5$: m/e 468.2624 (M^+); found: m/e 468.2619 (M^+).

*Reaction of cyclic amidoxime (**21**) with L-leucine methyl ester*

A solution of cyclic amidoxime **21** (9.0 mg, 0.024 mmol) in tetrahydrofuran (1 mL) was treated dropwise with a solution of L-leucine methyl ester hydrochloride (5.0 mg, 0.027 mmol) and triethylamine (3 mg, 0.028 mmol) in tetrahydrofuran (2 mL). After 16 h at room temperature under N_2, additional portions of L-leucine methyl ester hydrochloride (5.0 mg, 0.027 mmol) and triethylamine (3 mg, 0.028 mmol) were added and, after 48 h, the solvent was evaporated and the residue purified by preparative tlc (silica gel, ethyl acetate – hexane 6:4) to yield the pure tripeptide **41** (9.0 mg, 72%); ^{1}H nmr ($CDCl_3$) δ: 7.36–7.10 (m, 8H, phenyl), 6.80 (d, 1H, NH-^{3}Leu, J_{N,C_α} 6.5 Hz), 5.36 (d, 1H, NH-^{1}Leu, J_{N,C_α} 8.5 Hz), 4.95 (d, 1H, NH-^{2}Phe, J_{N,C_α} 10 Hz), 4.54 (m, 1H, C_αH-^{3}Leu), 4.27 (m, 1H, C_αH-^{2}Phe), 4.14 (m, 1H, C_αH-^{1}Leu), 3.64 (s, 3H, OCH_3), 3.11, 3.01 (AB, 2H, $C_\beta H_2$-Phe, J_{A,C_α} 6.0, J_{B,C_α} 8.0, $J_{A,B(gem)}$ 14.0 Hz), 1.34 (s, 9H, $OC(CH_3)_3$), 0.86, 0.83 (2 doublets, 6H, $(CH_3)_2$-Leu, J 6.0 Hz), 0.76, 0.75 (2 doublets, 6H, $(CH_3)_2$-Leu, J 6.0 Hz); high resolution ms, calcd. for $C_{26}H_{44}N_4O_6$: m/e 520.3261 (M^+); found: m/e 520.3261 (M^+).

*Acetylation of **28***

A solution of amidoxime **28** (20.0 mg, 0.0393 mmol) in methylene chloride (5 mL) was treated with triethylamine (22 mg, 0.22 mmol) and acetic anhydride (32 mg, 0.32 mmol) and, after 3 h at room temperature under N_2, the solvent was evaporated *in vacuo* and the residue purified by tlc (silica gel, hexane – ethyl acetate 2:8) to give acetate **29** (17 mg, 81%).

Chemistry of 4-trimethylsilyl-3-dialkylaminocrotonate esters and the cycloaromatization reactions with enamines[1]

G. J. KANG AND T. H. CHAN[2]

Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received May 16, 1984[3]

G. J. KANG and T. H. CHAN. Can. J. Chem. **63**, 3102 (1985).

Methyl 4-trimethylsilyl-3-dialkylaminocrotonate is synthesized by the silylation of methyl 3-dialkylaminocrotonate. It reacts with carbonyl electrophiles at its γ-position. The unusual regiochemistry of this reaction is studied and rationalized. It reacts with enamines derived from acyclic ketones to give aromatic compounds in a 3C+3C combination and with enamines derived from cycloketones of 5- to 8-membered rings to give aromatic compounds in a 4C+2C combination. A mechanism for this cycloaromatization reaction is proposed.

G. J. KANG et T. H. CHAN. Can. J. Chem. **63**, 3102 (1985).

La silylation du dialkylamino-3 crotonate de méthyle conduit au dialkylamino-3 triméthylsilyl-4 crotonate de méthyle. Les carbonyles électrophiles réagissent en position γ de ce composé. On a étudié la régiochimie inhabituelle de cette réaction et on en fournit une explication. Ce composé réagit avec les énamines provenant des cétones acycliques pour donner des composés aromatiques dans une combinaison du type 3C+3C et avec les énamines issues des cétones cycliques comportant de 5 à 8 chaînons pour donner des composés aromatiques selon une combinaison du type 4C+2C. On propose un mécanisme réactionnel pour cette réaction de cycloaromatisation.

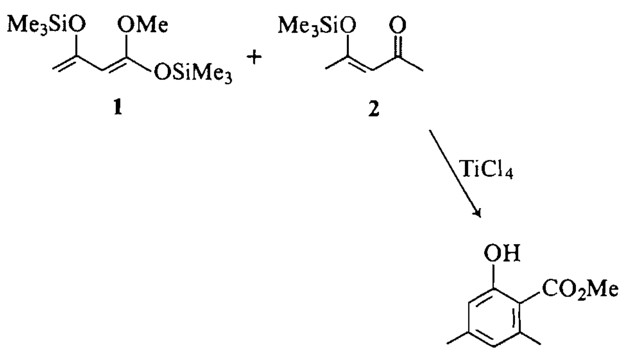
[Traduit par le journal]

Introduction

While tremendous progress has been made on reactions leading to the synthesis of acyclic and alicyclic compounds, less development has occurred in the domain of aromatic compounds. The problem is especially acute in the synthesis of highly substituted benzenoid compounds with multiple functional groups. The conventional approach of using electrophilic substitution reactions on simple aromatic precursors, with its tedious stepwise process and attendant problem of regioselection, has obvious limitations.

Recently, we proposed an approach for the synthesis of phenolic compounds (2, 3) by the cycloaromatization of acyclic precursors. The strategy involves the condensation of two 3-carbon units, one with two nucleophilic sites and the other containing two electrophilic sites. Compound **1** and similar bis-enol silyl ethers (2, 4) constitute the 3-carbon fragments with two nucleophilic sites. Various equivalents of β-dicarbonyl compounds (e.g. **2**) constitute the 3-carbon electrophilic components. Condensation of **1** and **2** under Lewis acid conditions (e.g. $TiCl_4$) according to eq. [1] gives the phenolic compound **3**. Furthermore, the regiochemistry of the reaction can be controlled by the differential reactivities of these sites. We have used this approach for the synthesis of sclerin (5), a plant-growth substance, and Δ^1-tetrahydrocannabinol (6), the active component of marijuana.

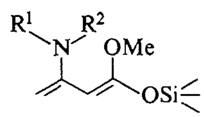
[1]



3

It is of some interest to know if this approach can be developed into a general strategy for the synthesis of all types of aromatic compounds. The possibility of a cycloaromatization reaction leading to highly substituted anilino compounds is particularly tantalizing since a number of natural products such as mitomycin and maytansine have a substituted aniline carbon skeleton.

An obvious way to modify eq. [1] for the synthesis of anilino compounds is to have an amino group in place of the 3-trimethylsiloxy group in **1**. Our first task is therefore to examine the preparation and the chemistry of 1-methoxy-1-trimethylsiloxy-3-dialkylaminobuta-1,3-dienes (**4**).



4

Chemistry of 4-trimethylsilyl-3-dialkylaminocrotonate esters

Methyl 3-dialkylaminocrotonate **5** was prepared by the usual water-separator method from the precursor methyl acetoacetate (**6**) with *p*-toluenesulfonic acid as the catalyst (7). Compound **5** was silylated by LDA in THF followed by quenching with trimethylchlorosilane. The result was, however, not the expected compound **4** but the C-silyl product, methyl 4-trimethylsilyl-3-dialkylaminocrotonate (**7**). Both **7***a* and **7***b* exist as one geometrical isomer. Sanchez and Bellanato studied a number of 3-dialkylaminocrotonate esters and concluded that all of them have *E* geometry (8). By noting the similarity of ^{1}H and ^{13}C nmr between **5** and **7**, **7** is assigned to have *E* geometry as well. The yields of the silylation reactions are greater than 90%, the products are ≥90% pure by ^{1}H nmr spectra before distillation, and **7** is thermally stable enough to be distilled under vacuum.

In the reaction of **7** with electrophiles, one would expect that

[1]For preliminary accounts of this work, see ref. 1.

the reaction probably occurs at the α-position because of the presence of the silyl group in **7** as well as the expected reactivity of the enamine. The reactions of allylsilanes with electrophiles have been well studied and usually show high regioselectivity (9) according to eq. [2]. Therefore it was surprising

[2] 
to us when we found that **7** reacted with a number of carbon electrophiles at the γ-position instead of the α-position (eq. [3]).

[3] 
7

When compound **7** reacted with benzaldehyde in the presence of one mole of titanium tetrachloride in CH_2Cl_2, compound **8** was obtained in fairly good yield. It is clear that **8** is formed from the condensation of **7** and benzaldehyde, followed by the elimination of a molecule of water. Compound **8** has been assigned the 2*E*,4*E* geometry according to its ^{1}H nmr.

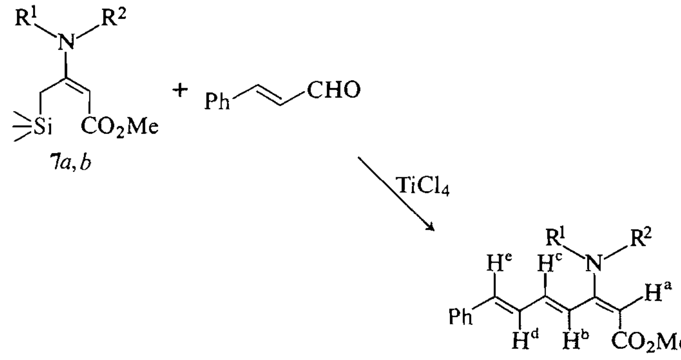
b: R^1, R^2 = $(CH_2CH_2)_2$—O

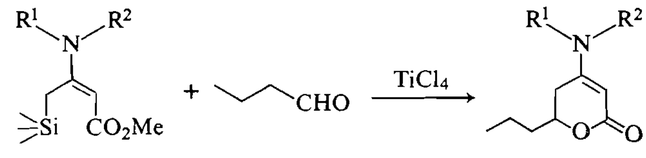
Condensation of **7** with cinnamaldehyde under the same condition gave the polyunsaturated ester **9** in good yield with the 2*E*,4*E*,6*E*-configuration. With butyraldehyde, condensation with **7** is followed by an intramolecular cyclization to give the δ-lactone **10**.

There are, however, differences in the reactivity between **7***a* and **7***b* (13). It seems that the morpholino compound **7***b* is more reactive than the pyrrolidino compound **7***a*. Thus with the less reactive ketone electrophiles, only **7***b* gave the corresponding products **11** and **12**. Compound **11** is the hydrolyzed product of its enamine precursor that occurs during the aqueous work-up.

When **7***a* was reacted with acetone under the same conditions, only compound **5***a* was shown in the product, apparently

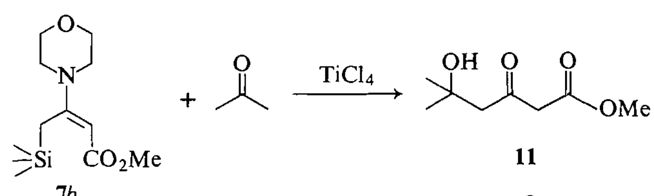


7*a*,*b* **9***a*,*b*

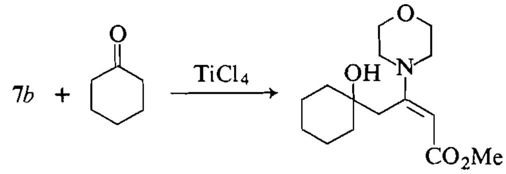


7*a*,*b* **10***a*,*b*

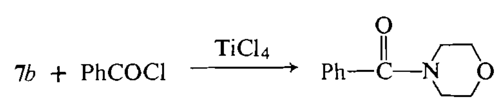
from the protodesilylation of the unreacted **7***a*. When cyclohexanone was used, the result was the same as the reaction of **7***a* with acetone. Even when dichloroethane was used as the solvent rather than methylene chloride, and the reaction mixture was refluxed overnight, no reaction between **7***a* and cyclohexanone was observed. With more reactive electrophiles, such as benzoyl chloride, only **7***a* gave γ-reaction product **13**, while **7***b* gave an N-substitution product, benzamide **14**.



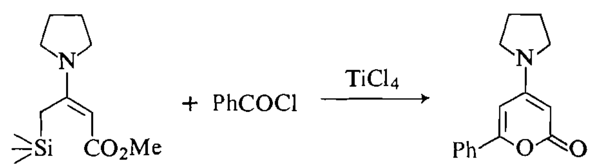
7*b* **11**



12

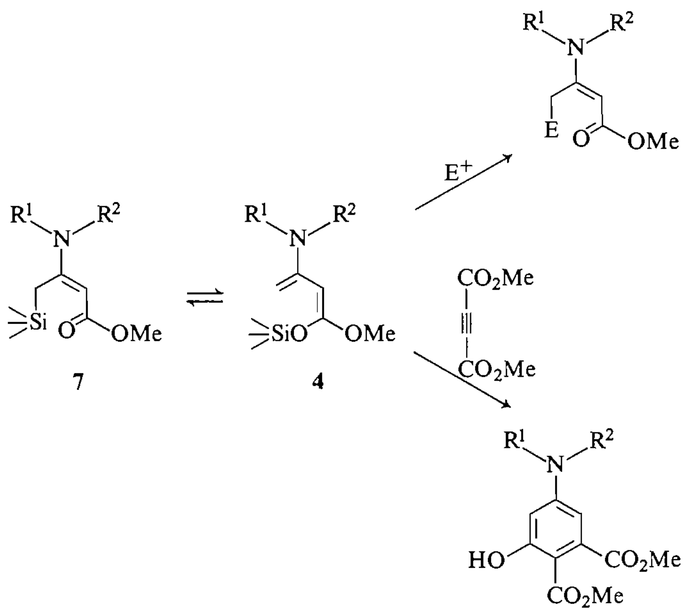


14



7*a* **13**

In order to explain the regiochemistry observed in the reaction of **7** with electrophiles in eq. [3], one possibility is that there is a dynamic equilibrium between **7** and **4** and it is **4** that selectively reacts with electrophiles to give the γ-products. In fact, 1,5-migration of the silyl group is well known. Diketone silyl enol ethers can exhibit silyl transmission (10). Similarly,



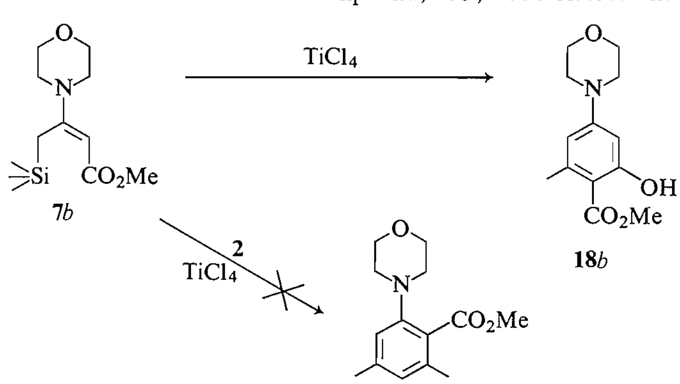
7 4 15

trimethylsilyl β-keto-esters can undergo a thermal silatropic rearrangement (11) to produce silyl enol ethers regiospecifically. The 1,5-migration of the silyl group from oxygen to carbon has also been reported (4, 12). It has been found that at room temperature compound **1** gradually rearranges to its C-silyl isomer. In our case, the *E*-geometry of compound **7** certainly renders this rearrangement process geometrically possible. In support of this explanation, when a mixture of **7***a* and dimethyl acetylenedicarboxylate was heated in benzene for 3 days, the diene **4** was indeed trapped as the Diels–Alder adduct **15**, which was isolated in 57% yield as a crystalline compound.

Self- and cross-condensations

Our initial strategy was to synthesize compound **4** and condense it with β-dielectrophiles to form aniline derivatives. Athough **4** has not been obtained directly from the silylation of methyl 3-dialkylaminocrotonate, compound **7** can be considered, in fact, as an equivalent of **4**, because we have evidence that **7** exists in a dynamic equilibrium of **7** ⇌ **4**.

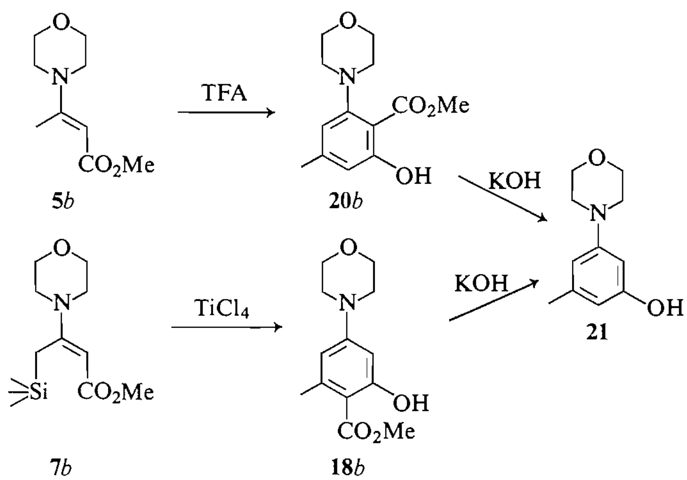
We examined, therefore, the reaction of **7***b* with several β-dielectrophiles. The first β-dielectrophile used was 4-trimethylsiloxy-3-penten-2-one (**2**). The reaction was carried out under similar conditions to the cycloaromatization reactions of eq. [1] with titanium tetrachloride as catalyst and CH_2Cl_2 as solvent. Indeed an aromatic compound, **18***b*, was isolated. The



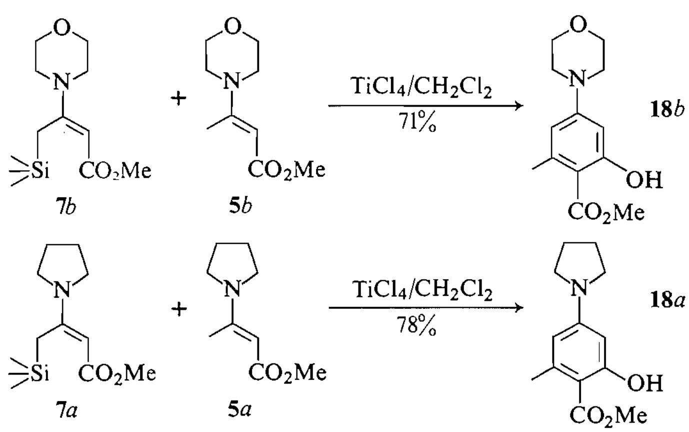
19

^{1}H nmr of **18***b* shows two aromatic protons (6.20 ppm, s, 2H), one methoxy group (3.90, s, 3H), one methyl group (2.53, s, 3H), an hydroxy group (11.7, s, 1H, D_2O exchangeable), and a morpholino group. From these data, it is definitely not the desired product **19**. Obviously **18***b* was derived from the self-condensation reaction of **7***b*. When only **7***b* was treated under the same conditions, **18***b* was obtained in 49% yield.

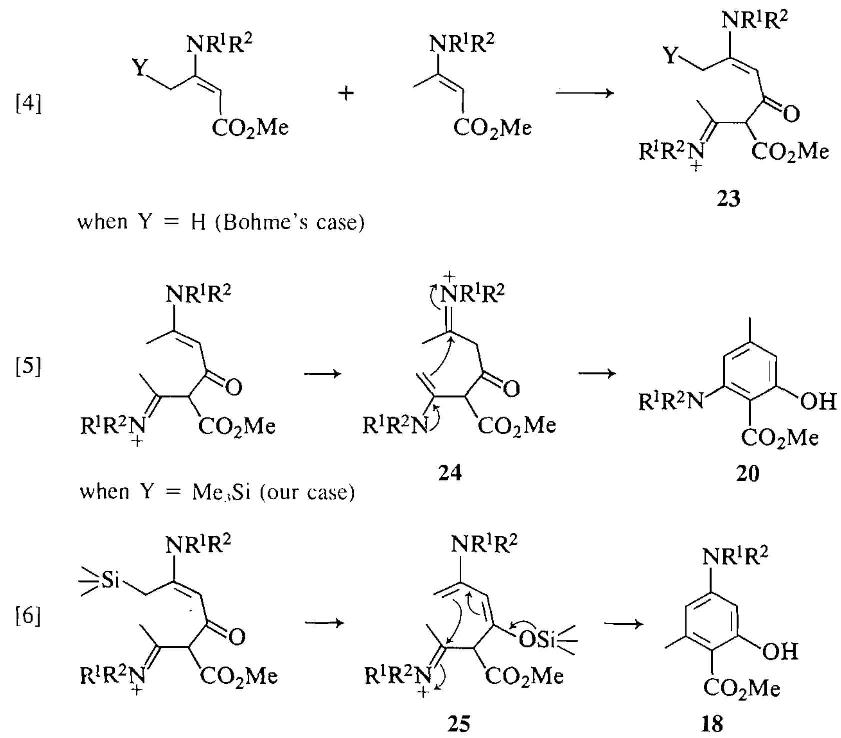
At this stage, it is relevant to mention the recent work by Bohme *et al.* (14), who found that 3-dialkylaminocrotonate esters (**5**) undergo self-condensation under trifluoroacetic acid conditions to give the anilino compounds **20**, sometimes in good yield. We thus repeated this reaction with **5***b* and found that the products from the two reactions, **18***b* and **20***b*, are quite different in their spectroscopic data. The two compounds are nevertheless isomeric with each other. In agreement with Bohme's observation, hydrolysis and decarboxylation of **20***b* gave **21**. It was found that the decarboxylation product of **18***b* was also **21**. From these experiments, as well as from the fact that the chemical shift of the hydroxy group in **18***b* is 11.7 ppm, which strongly suggests the existence of intramolecular hydrogen bonding, we assign structure **18***b* to the product derived from **7***b*.



In order to understand further the self-condensation reaction both of **7** and **5**, **7***b* was allowed to react with 1 equivalent of **5***b* in the presence of titanium tetrachloride. The same compound **18***b*, which was obtained from the self-condensation of **7***b*, was isolated in 71% yield. A similar reaction between **7***a*

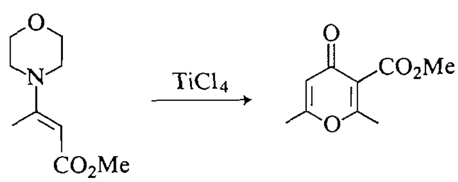


and **5***a* gave **18***a* in 78% yield. Since the yields are higher than 50%, **18***a* or **18***b* is formed from the cross-condensation between **7** and **5**. Furthermore, when **5***b* alone was treated under



SCHEME 1

identical conditions (i.e. $TiCl_4$) the product was not **18***b* but the pyrone **22** (75% yield).



5*b* **22**

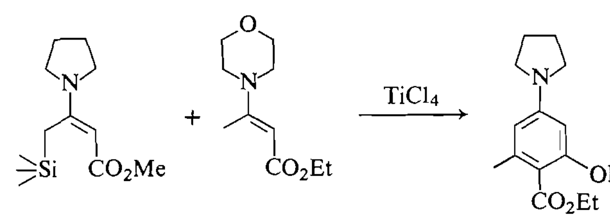
Mechanistic rationale

To facilitate subsequent discussion, we propose from the above experiments a working hypothesis to account for the cycloaromatization reactions observed in our case as well as in Bohme's case (Scheme 1).

The first step (eq. [4]) is the condensation of the enamine with the carboxyl group of another component to give the intermediate **23**. In the absence of further reaction, **23** hydrolyzes on aqueous work-up to give the pyrone **22**. In the case of Y = H (eq. [5]), TFA effects the isomerization of **23** to the deconjugated enamine **24**, which gives **20** by an intramolecular condensation in a 3C+3C combination. When Y = Me_3Si (eq. [6]), a 1,5-silyl shift causes the formation of **25**, which leads to **18** by way of an intramolecular condensation in a 4C+2C combination.

The reaction of **7***b* with **5***b* was repeated. Half of the reaction mixture was taken out of the reaction flask after 3 h at −78°C. After the usual work-up procedure, a 1 : 1 mixture of **22** and **18***b* was obtained. The other half of the reaction mixture was allowed to be stirred overnight at room temperature and then worked up. The product was found to be almost completely **18***b*, with very little **22**. This experiment supports the suggestion that **23** is indeed the intermediate in the cross-condensation reaction. Furthermore, the first step in Scheme 1 is faster than the second step.

According to the mechanism postulated in Scheme 1, in the cross-condensation between **7** and **5**, **7** acts as a four-carbon component and **5** acts as a two-carbon component. To verify this, we allowed methyl 4-trimethylsilyl-3-pyrrolidinocrotonate (**7***a*) to condense with ethyl 3-morpholinocrotonate (**26**) in the presence of $TiCl_4$. If the postulation is correct, the final product will contain pyrrolidino and ethyl groups. This was found to be the case. The product of the reaction was **27**.

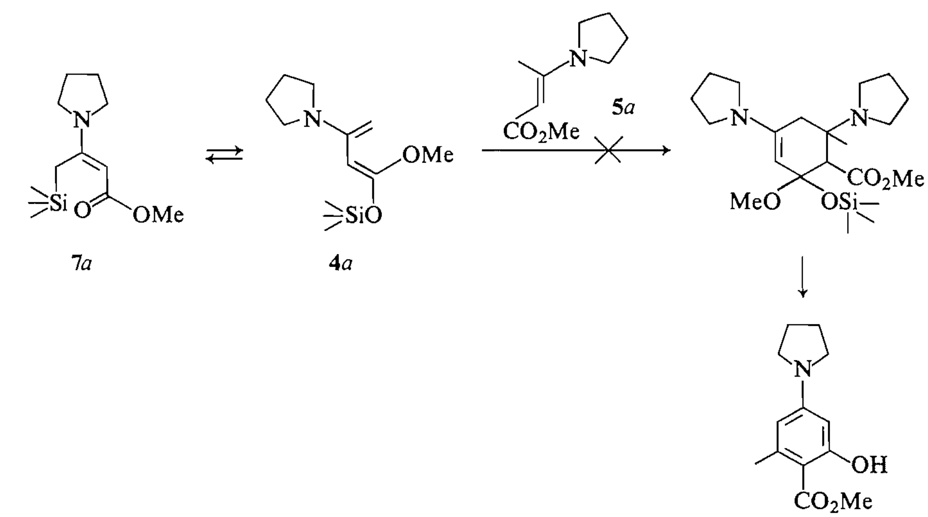


7*a* **26** **27**

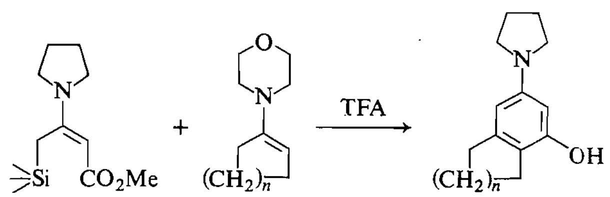
One might argue that another possible pathway for the cross-condensation is the Diels−Alder reaction. For example, Diels−Alder reaction between **7***a* (by way of **4***a*) and **5***a* can lead to **18***a* if the reaction proceeds with the regiochemistry indicated. To check this possibility, a 1 : 1 mixture of **7***a* and **5***a* was refluxed in benzene for 3 days. No change was detected by ^{1}H nmr spectroscopy, showing that it was still a 1 : 1 mixture of **7***a* and **5***a*. Therefore the possibility of a Diels−Alder reaction is ruled out, at least under these thermal conditions.

Cycloaromatization reactions with enamines

At this stage, the following conclusion appears to be reasonable. The reaction between **7** and **5** is a stepwise 4C+2C cycloaddition with **7** acting as the four-carbon component and **5** as the two-carbon component. One would expect, therefore, not only compound **5** but other enamines as well to have the potential to undergo the same kind of cycloaromatization reaction with **7**. We proceeded to examine this possibility. A



7a 4a 18a

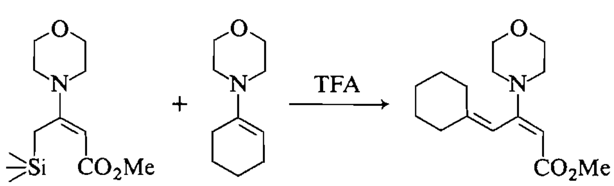


7a 28 ($n = 2$) 29 ($n = 2$)

1 : 1 mixture of 7*a* and the morpholine enamine of cyclohexanone plus two equivalents of trifluoroacetic acid was refluxed for two days in CH_2Cl_2. The reaction gave compound **29** in 63% yield.

Enamines derived from cyclopentanone, cycloheptanone, and cyclooctanone were also allowed to react with 7*a* under the same conditions except that the reaction mixtures were refluxed in dichloroethane. The yields of the corresponding cyclization products were found to be between 59 and 64% (see Table 1).

On the other hand, when the amino group in the silylcrotonate component is morpholine 7*b*, the reaction with **28** under identical conditions gave the γ-reaction product **30** instead. Since we have previously shown that 7*b* undergoes γ-reaction more readily than 7*a*, and **28** can be easily protonated to give

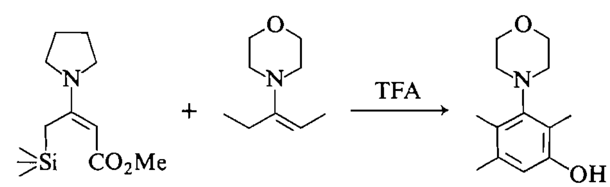


7b 28 30

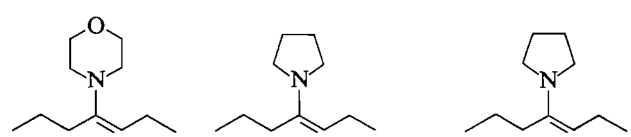
the corresponding imminium cation in the presence of TFA, the observed γ-reaction between 7*b* and **28** is understandable.

There remains the 3C+3C self-condensation observed in Bohme's case. If the postulated mechanism in Scheme 1 is correct, one would expect the same pathway to proceed between **7** and an enamine of acyclic ketones. The reactions between 7*a* and enamines derived from acyclic ketones were therefore next examined. The morpholine enamine of 3-pentanone (**31**) was reacted with 7*a* in the presence of TFA. The reaction mixture was refluxed for 48 h in dichloroethane and followed by the usual work-up. Compound **32** was isolated in about 30% yield. The main reason for the low yield is the self-condensation of 7*a*. In order to improve the yield of the cross-condensation product, two equivalents of **31** were used and the yield was raised to 41%. The same reaction was also carried out by using titanium tetrachloride as the catalyst instead of TFA, and the yield of **32** was 38%.

Several similar reactions were carried out by reacting 7*a* with **33**, **34**, and **35** respectively in the presence of TFA. In all cases the 3C+3C cyclization products were observed. The yields ranged from 36 to 42% (see Table 1).



7a 31 32



33 34 35

In summary, 4-trimethylsilyl-3-dialkylaminocrotonate esters react with enamines derived from cyclic ketones to give 4C+2C annelation with enamines acting as the 2C-component, but with enamines derived from acyclic ketones by a 3C+3C annelation. A mechanism in analogy to Scheme 1, which is consistent with the above observation, can be envisaged.

Conclusion

Even though our initial idea of a cycloaromatization reaction between **4** and various β-dicarbonyl equivalents to give anilino compounds turns out not to be feasible, reactions between 4-trimethylsilyl-3-dialkylaminocrotonate esters and enamines have been discovered. These reactions lead to the formation of highly substituted benzenoid compounds bearing an amino group.

ucts and were reagent grade. Melting and boiling points are uncorrected. The nmr spectra were taken on a Varian T-60A nmr spectrometer or an XL-200 nmr spectrometer. All ^{1}H and ^{13}C spectra are reported in chemical shift (δ) with tetramethylsilane as the reference. Infrared spectra were taken on a Perkin–Elmer Model 257 infrared spectrophotometer and were calibrated with the 1602 cm^{-1} band of polystyrene film. Mass spectra were obtained on a Dupont 21-492B mass spectrometer. Column chromatographs were done with silica gel unless otherwise specified. Chemical analyses were performed by Guelph Chemical Laboratories Ltd. Elemental analyses or exact mass measurements were performed on most new compounds. Exceptions were made in cases where a series of compounds of similar structures, with small differences in substituent, were prepared under the same reaction conditions. If their spectral (nmr, ms, etc.) data were similar and showed no unexpected feature, then analyses were performed on representative examples of the series to establish the general structure.

Preparation of enamines

The following enamines were made by the water separator method (7). Methyl 3-pyrrolidinocrotonate (**5***a*), 88%, bp 116–118°C (2.5 Torr; 1 Torr = 133.3 Pa); methyl 3-morpholinocrotonate (**5***b*), 79%, bp 131–132°C (4 Torr); ethyl 3-morpholinocrotonate (**26**), 77%, bp 106–109°C (0.4 Torr); 1-morpholinocyclopentene, 82%, bp 108–110°C (14 Torr) (lit. (15) bp 104–106°C (12 Torr)); 1-morpholinocyclohexene (**28**), 84%, bp 112–114°C (14 Torr) (lit. (15) bp 104–106°C (12 Torr)).

The following enamines were made by the procedure of White and Weingarten (16). 1-Morpholinocycloheptene, 54%, bp 130–133°C (15 Torr) (lit. (17) bp 133–135°C (17 Torr)); 1-morpholinocyclooctene, 61%, bp 81–83°C (1 Tor) (lit. (17) bp 83–85°C (0.01 Torr)); 3-morpholino-2-pentene (**31**), 52%, bp 50–51°C (0.5 Torr) (lit. (17) bp 77–78°C (9 Torr)); 4-morpholino-3-heptene (**33**), 57%, bp 67–69°C (0.2 Torr) (lit. (17) bp 102–106°C (12 Torr)); 3-pyrrolidino-2-pentene (**34**), 57%, bp 36–38°C (0.5 Torr) (lit. (17) bp 62–67°C (8 Torr)); 4-pyrrolidino-3-heptene (**35**), 60%, bp 56–58°C (0.2 Torr).

*Methyl 4-trimethylsilyl-3-pyrrolidinocrotonate (7*a*)*

Under N_2 at 0°C, to a solution of dry diisopropylamine (3.4 mL, 24 mmol) in THF (50 mL) was added n-BuLi (16 mL of 1.5 *M* in hexane, 24 mmol), followed by TMEDA (3.2 mL). The solution was cooled to −78°C and methyl 3-pyrrolidinocrotonate (**5***a*, 3.38 g, 20 mmol) was added. The reaction mixture was stirred for 0.5 h, and then quenched with trimethylchlorosilane (4 mL). The reaction mixture was allowed to warm to 0°C and concentrated on the rotary evaporator. The residue was triturated with dry hexane (100 mL) and filtered. The filtrate was concentrated (finally under high vacuum) to give 4.43 g of **7***a* as a yellowish oil (92%), >95% pure by ^{1}H nmr; bp 132–135°C (1 Torr); ir (film): 1665, 1550, 1150 cm^{-1}; ^{1}H nmr ($CDCl_3$): 0.1 (s, 9H), 1.80–2.03 (m, 4H), 2.73 (s, 2H), 3.20–3.43 (m, 4H), 3.60 (s, 3H), 4.47 (s, 1H); ^{13}C nmr ($CDCl_3$): −1.7, 21.6, 25.0, 48.0, 49.5, 81.0, 163.0, 169.3; ms *m/z* (rel. intensity): 241 (M^+, 26), 226 (39), 210 (33), 168 (77), 138 (84), 110 (100). *Exact Mass* calcd. for $C_{12}H_{23}O_2NSi$: 241.158; found: 241.152.

*Methyl 4-trimethylsilyl-3-morpholinocrotonate (7*b*)*

Compound **7***b* was made in the same way as **7***a* from **5***b* in 90% yield (>90% pure by ^{1}H nmr); ir (film): 1680, 1560, 1145 cm^{-1}; ^{1}H nmr ($CDCl_3$): 0.1 (s, 9H), 2.73 (s, 3H), 3.10–3.33 (m, 4H), 3.60 (s, 3H), 3.55–3.80 (m, 4H), 4.73 (s, 1H); ^{13}C nmr ($CDCl_3$): −0.9, 19.5, 47.1, 50.2, 66.6, 86.2, 165.7, 169.5; ms, *m/z* (rel. intensity): 257 (M^+, 26), 242 (58), 226 (62), 184 (72), 154 (30), 126 (34).

*Methyl 5-phenyl-3-pyrrolidinopenta-2*E*,4*E*-dienoate (8*a*)*

To a mixture of benzaldehyde (1 mmol) and $TiCl_4$ (1 mmol) in 3 mL of CH_2Cl_2 at −78°C under N_2 was added **7***a* (1 mmol). The reaction mixture was stirred for 3 h at −78°C, and then overnight at room temperature. The reaction mixture was quenched with saturated sodium carbonate solution and then extracted with ether. The ether extract was dried with $MgSO_4$ and evaporated to give an oil, which was column chromatographed (ether–hexane 2:1) to give **8***a* in 68% yield as a colorless liquid; ir (film): 1680, 1550, 1140 cm^{-1}; ^{1}H nmr ($CDCl_3$): 1.95 (m, 4H), 3.33 (m, 4H), 3.60 (s, 3H), 4.60 (s, 1H), 6.66 (d, 1H, *J* = 17 Hz), 7.20–7.60 (m, 6H); ms, *m/z* (rel. intensity): 257 (M^+, 12), 226 (18), 198 (100). *Exact Mass* calcd. for $C_{16}H_{19}O_2N$: 257.139; found: 257.138.

*Methyl 5-phenyl-3-morpholinopenta-2*E*,4*E*-dienoate (8*a*)*

The reaction was performed in the same way as the reaction between **7***a* and benzaldehyde to afford **8***b* in 60% yield as a colorless liquid; ir (film): 1695, 1565, 1150 cm^{-1}; ^{1}H nmr ($CDCl_3$): 3.07 (m, 4H), 3.56 (s, 3H), 3.70 (m, 4H), 4.84 (s, 1H), 6.75 (d, 1H, *J* = 16 Hz), 7.10–7.50 (m, 6H); ms, *m/z* (rel. intensity): 273 (M^+, 9), 242 (13), 214 (100).

*Methyl 7-phenyl-3-pyrrolidinohepta-2*E*,4*E*,6*E*-trienoate (9*a*)*

To a mixture of cinnamaldehyde (0.5 mmol) and $TiCl_4$ (0.5 mmol) in 3 mL of CH_2Cl_2 at −78°C under N_2 was added **7***a* (0.5 mmol). The mixture was stirred for 3 h at −78°C, then allowed to warm to room temperature. Saturated aqueous sodium carbonate solution was added and the mixture was extracted with ether. The ether extract was dried with $MgSO_4$ and filtered. The filtrate was concentrated to give a brown oil, which was purified by alumina column chromatography (ether–hexane 2:1) to give **9***a* in 81% yield; ir (film): 1670, 1540, 1145 cm^{-1}; ^{1}H nmr ($CDCl_3$, 200 MHz): 1.93 (m, 4H), 3.33 (m, 4H), 3.60 (s, 3H), 4.57 (s, 1H), 6.54 (d, 1H, *J* = 16 Hz), 6.50 (dd, 1H, *J* = 16 and 6 Hz), 6.84 (dd, 1H, *J* = 16 and 6 Hz), 6.86 (d, 1H, *J* = 16 Hz), 7.12–7.34 (m, 5H); ms, *m/z* (rel. intensity): 283 (M^+, 24), 252 (8), 224 (100).

*Methyl 7-phenyl-3-morpholinohepta-2*E*,4*E*,6*E*-trienoate (9*b*)*

This reaction was carried out in the same manner as the reaction between **7***a* and cinnamaldehyde. Compound **9***b* was obtained in 83% yield; ir (film): 1690, 1550, 1150 cm^{-1}; ^{1}H nmr ($CDCl_3$, 200 MHz): 3.10 (m, 4H), 3.63 (s, 3H), 3.73 (m, 4H), 4.90 (s, 1H), 6.62 (d, 1H, *J* = 16 Hz), 6.63 (dd, 1H, *J* = 16 and 6 Hz), 6.90 (dd, 1H, *J* = 16 and 6 Hz), 6.97 (d, 1H, *J* = 16 Hz), 7.16–7.38 (m, 5H); ms, *m/z* (rel. intensity): 299 (M^+, 41), 268 (9), 240 (100).

*4-Pyrrolidino-6-(n-propyl)-5,6-dihydro-1,2-pyrone (10*a*)*

The reaction was done in the same manner as the reaction of **7***a* with benzaldehyde, except that a 2:1 mixture of ether and acetonitrile was used as eluant in the flash chromatography. Compound **10***a* was obtained in 53% yield; ir (film): 1660, 1570, 1240 cm^{-1}; ^{1}H nmr ($CDCl_3$): 0.73–1.77 (m, 7H), 1.93 (m, 4H), 2.40 (d, 2H, *J* = 8 Hz), 3.27 (m, 4H), 4.20 (m, 1H), 4.63 (m, 1H); ms, *m/z* (rel. intensity): 209 (M^+, 33), 166 (100), 150 (29).

*4-Morpholino-6-(n-propyl)-5,6-dihydro-1,2-pyrone (10*b*)*

The reaction was performed in the same way as the reaction of **7***a* with butanal. Compound **10***b* was obtained in 49% yield; ir (film): 1660, 1565, 1230 cm^{-1}; ^{1}H nmr ($CDCl_3$): 0.80–1.90 (m, 7H), 2.40 (d, 2H, *J* = 7 Hz), 3.23 (m, 4H), 3.77 (m, 4H), 4.33 (m, 1H), 4.87 (s, 1H); ms, *m/z* (rel. intensity): 225 (M^+, 13), 182 (100), 166 (19). *Anal.* calcd.: C 64.04, H 8.44; found: C 63.84, H 8.54%.

Methyl 5-hydroxy-5-methyl-3-oxohexanoate (11)

To a mixture of acetone (2 mmol), which was freshly distilled over anhydrous K_2CO_3, and $TiCl_4$ (1 mmol) in 3 mL of CH_2Cl_2 at −78°C under N_2 was added **7***b* (1 mmol). The reaction mixture was stirred for 3 h at −78°C, then overnight at room temperature. Saturated sodium carbonate solution was added, and the mixture was extracted with ether. The ether extract was dried with $MgSO_4$ and filtered. The filtrate was concentrated to give an oil, which was purified by flash chromatography (hexane–ether 2:1). Compound **11** was obtained in 44% yield. Its spectroscopic data are identical to those reported in the literature (18).

Methyl 4-(1′-hydroxycyclohexanyl)-3-morpholinocrotonate (12)

The reaction was done by the same procedure as the reaction between **7***b* and acetone. Compound **12** was obtained in 56% yield; ir (film): 3400, 1650, 1570, 1165 cm^{-1}; ^{1}H nmr ($CDCl_3$): 1.57 (m, 10H), 3.07 (s, 2H), 3.23 (m, 4H), 3.50 (b, 1H), 3.68 (s, 3H), 3.77 (m, 4H), 5.03 (s, 1H); ms, *m/z* (rel. intensity): 283 (M^+, 1), 265 (4), 252 (5).

4-Pyrrolidino-6-phenyl-1,2-pyrone (13)

To a mixture of **7***a* (1 mmol) and benzoyl chloride (1 mmol) in 5 mL CH_2Cl_2, was added $TiCl_4$ (1 mmol) at 0°C under N_2. The reaction mixture was stirred for 3 h at 0°C, then overnight at room temperature. Saturated sodium carbonate solution was added and the mixture was extracted with ether. The ether extract was dried with $MgSO_4$ and filtered. The filtrate was evaporated to give a yellow oil, which was purified by flash chromatography (ethyl acetate) to give compound **13** in 44% yield; ir (film): 1675, 1635, 1545 cm^{-1}; ^{1}H nmr ($CDCl_3$): 1.93 (m, 4H), 3.30 (m, 4H), 4.87 (d, 1H, J = 2 Hz), 6.20 (d, 1H, J = 2 Hz), 7.17–7.80 (m, 5H); ms, *m/z* (rel. intensity): 240 (M^+, 100), 213 (51), 77 (51). *Anal.* calcd.: C 74.69, H 6.22; found: C 74.52, H 6.39%.

Benzoyl morpholine (14)

The reaction was done in the same manner as the reaction of **7***a* with benzoyl chloride. Benzoyl morpholine (**14**) was obtained in 61% yield.

*Dimethyl 3-hydroxy-5-pyrrolidino-*o*-phthalate (15)*

A mixture of **7***a* (1 mmol) and dimethyl acetylenedicarboxylate (2 mmol) in 15 mL of dry benzene was refluxed for 3 days. The reaction mixture was cooled to room temperature. A solution of 2 mL of 1.5 *N* HCl was added and the mixture was stirred for 0.5 h. Saturated sodium bicarbonate solution was added until the mixture was basic. The mixture was extracted with ether and the ether extract was dried with $MgSO_4$ and then filtered. The filtrate was concentrated by rotary evaporator to give a brown oil, which was purified by flash chromatography to give 156 mg of **15**, mp 128–130°C. The yield was 57%; ir ($CHCl_3$); 3100, 1725, 1650 cm^{-1}; ^{1}H nmr ($CDCl_3$): 1.83–2.07 (m, 4H), 3.17–3.38 (m, 4H), 3.80 (s, 3H), 3.83 (s, 3H), 5.93 (d, 1H, J = 3 Hz), 6.03 (d, 1H, J = 3 Hz), 11.03 (s, 1H); ms, *m/z* (rel. intensity): 279 (M^+, 91), 248 (57), 189 (100). *Exact Mass* calcd. for $C_{14}H_{17}NO_4$: 279.111; found: 279.107.

Methyl 2-methyl-4-morpholino-6-hydroxybenzoate (18b)

To a solution of 257 mg of **7***b* (1 mmol) in 5 mL CH_2Cl_2 was added 0.5 mmol of $TiCl_4$ under N_2 at −78°C, the reaction mixture was stirred for 3 h at −78°C, then overnight at room temperature. It was added to a saturated sodium carbonate solution, stirred for 0.5 h, and extracted with ether. The extract was dried with $MgSO_4$, filtered, and concentrated with a rotary evaporator to give a yellow oil, which was then purified by flash chromatography (ether–hexane 1:1). Compound **18***b*, mp 108–109°C, was obtained in 49% yield; ir (KBr): 1640, 1600, 1205 cm^{-1}; ^{1}H nmr ($CDCl_3$): 2.13 (s, 3H), 3.07–3.23 (m, 4H), 3.63–3.80 (m, 4H), 3.83 (s, 3H), 6.10 (s, 2H), 11.63 (s, 1H); ms, *m/z* (rel. intensity): 251 (M^+, 76), 220 (22), 219 (50), 161 (100), 133 (28).

3-(Methoxycarbonyl)-2,6-dimethyl-1,4-pyrone (22)

The reaction was performed with **5***b* in the same manner as the self-condensation of **7***b*. 3-(Methoxycarbonyl)-2,6-dimethyl-1,4-pyrone (**22**) was obtained in 75% yield; ir (film): 1735, 1670, 1635 cm^{-1}; ^{1}H nmr ($CDCl_3$): 2.27 (s, 3H), 2.37 (s, 3H), 3.88 (s, 3H), 6.13 (s, 1H); ms, *m/z* (rel. intensity): 182 (M^+, 10), 151 (17), 124 (29), 109 (11), 67 (64), 43 (100). *Exact Mass* calcd. for $C_9H_{10}O_4$: 182.058; found: 182.058.

Compound 18b from cross-condensation of 5b and 7b

To a mixture of 257 mg of **7***b* (1 mmol) and 185 mg of **5***b* (1 mmol) in 5 mL of CH_2Cl_2 was added 1 mmol of titanium tetrachloride under N_2 at −78°C. The reaction mixture was stirred for 3 h at −78°C and then overnight at room temperature. Saturated sodium carbonate solution was added, and the mixture was extracted with ether. The ether extract was dried with $MgSO_4$, filtered, and concentrated to give a yellow solid, which was purified by flash chromatography (ether–hexane 1:1). A quantity of 203 mg of **18***b* was obtained in 71% yield.

Methyl 2-methyl-4-pyrrolidino-6-hydroxybenzoate (18a)

The reaction was performed by the reaction of **5***a* with **7***a* in the same manner as the reaction of **7***b* and **5***b*. Compound **18***a*, mp 101–102°C, was obtained in 78% yield; ir (KBr): 1630, 1615, 1320 cm^{-1}; ^{1}H nmr ($CDCl_3$): 1.80–2.03 (m, 4H), 2.40 (s, 3H), 3.13–3.33 (m, 4H), 3.80 (s, 3H), 5.83 (s, 2H), 11.80 (s, 1H); ms, *m/z* (rel. intensity): 235 (M^+, 100), 204 (33), 203 (89), 175 (17), 147 (22).

Methyl 2-morpholino-4-methyl-6-hydroxybenzoate (20b)

The reaction was performed by Bohme's procedure (14). To 740 mg of **5***b* (4 mmol) was added 432 mg of TFA (4 mmol) at 0°C. The reaction mixture was stirred for 1 h at 0°C, then overnight at 40–50°C. The reaction mixture was diluted with 50 mL of ether, and washed with saturated sodium bicarbonate. The ether phase was dried with $MgSO_4$ and filtered. The filtrate was then concentrated by rotary evaporator to give 416 mg of **20***b*, mp 115–116°C (lit. (14) mp 116°C). The yield was 83%.

3-Morpholino-5-methylphenol (21) (14, 19)

To 50 mg of **18***b* was added 5 mL of 20% KOH. The reaction mixture was refluxed overnight. It was cooled to room temperature and a solution of 1 *N* HCl was added until the solution became acidic. The mixture was extracted with ether. The ether extract was dried with $MgSO_4$, filtered, and then concentrated to give 27 mg of **21**. Compound **21** had mp 126–127°C (lit. (19) mp 126–127°C); ir ($CHCl_3$): 3600, 1610, 1590, 1120 cm^{-1}; ^{1}H nmr ($CDCl_3$): 2.30 (s, 3H), 3.03–3.20 (m, 4H), 3.78–3.95 (m, 4H), 6.17–6.30 (m, 3H).

Decarboxylation of 20b

The reaction was carried out under identical conditions as used for the decarboxylation of **18***b*. A quantity of 30 mg of **21** was obtained. It is identical in all respects with the compound obtained from the decarboxylation of **18***b*.

Ethyl 2-methyl-4-pyrrolidino-6-hydroxybenzoate (27)

To a mixture of 241 mg of **7***a* (1 mmol) and 199 mg of **26** (1 mmol) in 5 mL of CH_2Cl_2 was added 1 mmol of titanium tetrachloride under N_2 at −78°C. The reaction mixture was stirred for 6 h at −78°C, then overnight at room temperature. Saturated sodium carbonate solution was added until the mixture became basic. The mixture was extracted with ether. The ether extract was dried with $MgSO_4$, filtered, and the filtrate was concentrated to give a yellow solid, which was purified by flash chromatography (ether–hexane, 1:1). A quantity of 162 mg of **27**, mp 83–84°C, was obtained. The yield was 65%; ir (KBr): 3400, 1635, 1310 cm^{-1}; ^{1}H nmr ($CDCl_3$): 1.37 (t, 3H, J = 7 Hz), 1.83–2.07 (m, 4H), 2.50 (s, 3H), 3.17–3.40 (m, 4H), 4.33 (q, 2H, J = 7 Hz), 5.90 (s, 2H), 11.90 (s, 1H); ms, *m/z* (rel. intensity): 249 (M^+, 94), 204 (80), 203 (100), 175 (76), 147 (75). *Exact Mass* calcd. for $C_{14}H_{19}NO_3$: 249.136; found: 249.134.

*7-Hydroxy-9-pyrrolidino-[4]-*ortho*-cyclophane (29)*

To a mixture of 241 mg of **7***a* (1 mmol) and 167 mg of **28** (1 mmol) in 25 mL of CH_2Cl_2 was added 228 mg of trifluoroacetic acid at 0°C. The reaction mixture was stirred for 1 h at 0°C, then refluxed for 24 h. The reaction mixture was diluted with 50 mL of ether and washed with saturated sodium bicarbonate. The organic phase was dried with $MgSO_4$, filtered, and then concentrated with a rotary evaporator to give a yellowish solid, which was purified by flash chromatography (eluted with ethyl acetate – hexane 1:1) to give 136 mg of **29**, mp 157–159°C. The yield of **29** was 63%; ir (KBr): 3400, 1620, 1580 cm^{-1}; ^{1}H nmr ($CDCl_3$): 1.67–2.20 (m, 8H), 2.40–2.83 (m, 4H), 4.60 (b, 1H), 5.97 (s, 2H); ms, *m/z* (rel. intensity): 217 (M^+, 100), 216 (99), 189 (55), 161 (40). *Anal.* calcd.: C 77.42, H 8.76; found: C 77.48, H 8.64%.

*7-Pyrrolidino-9-hydroxy-[3]-*ortho*-cyclophane*

To a mixture of 241 mg of **7***a* (1 mmol) and 153 mg of 1-morpholinocyclopentene (1 mmol) in 25 mL of 1,2-dichloroethane was added 228 mg of TFA (2 mmol) at 0°C. The reaction mixture was stirred for 1 h at 0°C and then refluxed for 24 h. The mixture was diluted with 50 mL of ether, and washed with saturated sodium bicarbonate solution. The organic layer was dried over $MgSO_4$ and filtered. The filtrate was concentrated to give a yellow solid, which was purified by flash chromatography (eluted with petroleum ether − ethyl acetate, 5:1) to give 7-pyrrolidino-9-hydroxy-[3]-*ortho*-cyclophane, mp 166−168°C, in 64% yield; ir (KBr): 3310, 1630, 1600, 1580 cm^{-1}; ^1H nmr ($CDCl_3$): 1.90−2.20 (m, 6H), 2.80 (t, 2H), 2.93 (t, 2H), 3.17−3.37 (m, 4H), 5.92 (d, 1H, J = 2 Hz), 6.13 (d, 1H, J = 2 Hz); ms, m/z (rel. intensity): 203 (M^+, 88), 202 (100), 174 (21), 147 (32), 133 (22).

*9-Pyrrolidino-11-hydroxy-[5]-*ortho*-cyclophane*

The reaction was performed in the same manner as the reaction between **7*a*** and 1-morpholinocyclopentene. 9-Pyrrolidino-11-hydroxy-[5]-*ortho*-cyclophane, mp 149−150°C, was obtained in 59% yield; ir (KBr): 3400, 1610, 1570, 1500 cm^{-1}; ^1H nmr ($CDCl_3$): 1.53−2.12 (m, 10H), 2.67−2.87 (m, 4H), 4.80 (b, 1H), 5.88 (d, 1H, J = 2 Hz), 6.05 (d, 1H, J = 2 Hz); ms, m/z (rel. intensity): 231 (M^+, 100), 230 (82), 203 (23), 202 (44).

*10-Pyrrolidino-12-hydroxy-[6]-*ortho*-cyclophane*

The reaction of **7*a*** with 1-morpholinocyclooctene was performed in the same manner as the reaction between **7*a*** and 1-morpholinocyclopentene. 10-Pyrrolidino-12-hydroxy-[6]-*ortho*-cyclophane, mp 157−159°C, was obtained in 67% yield; ir (KBr): 3400, 1610, 1570 cm^{-1}; ^1H nmr ($CDCl_3$): 1.47 (b, 8H), 1.87−2.08 (m, 4H), 2.63−2.83 (m, 4H), 4.73 (s, 1H), 6.00 (AB quartet, 2H, J = 2 Hz); ms, m/z (rel. intensity): 245 (M^+, 100), 244 (55), 217 (41), 202 (67). *Anal.* calcd.: C 78.37, H 9.37; found: C 78.30, H 9.51%.

Methyl 3-morpholino-4-cyclohexylidenecrotonate (30)

The reaction of **7*b*** with **28** was performed in the same manner as the reaction between **7*a*** and **28**. Compound **30** was isolated in 52% yield; ir ($CHCl_3$): 1685, 1560, 1145 cm^{-1}; ^1H nmr ($CDCl_3$): 1.57 (b, 6H), 2.00−2.40 (m, 4H), 3.25−3.45 (m, 4H), 2.63−3.83 (m, 4H), 3.65 (s, 3H), 4.83 (s, 1H), 5.83 (s, 1H); ms, m/z (rel. intensity): 265 (M^+, 60), 234 (25), 222 (69), 206 (67), 122 (100).

2,4,5-Trimethyl-3-morpholinophenol (32)

To a mixture of 241 mg of **7*a*** (1 mmol) and 310 mg of **31** (2 mmol) in 25 mL of 1,2-dichloroethane was added 342 mg of TFA (3 mmol) at 0°C. The reaction mixture was stirred for 1 h at 0°C, then refluxed for 48 h. It was allowed to cool to room temperature and was diluted with 50 mL of ether. The solution was washed with saturated sodium bicarbonate solution. The organic phase was dried with $MgSO_4$ and filtered. The filtrate was concentrated to give a brown oil, which was purified by flash chromatography (eluted with hexane − ethyl acetate, 2:1) to give 92 mg of **32**, mp 163−164°C, plus 54 mg of **18*a***. The yield for **32** was 41%; ir of **32** (KBr): 3300, 1600, 1585, 1100 cm^{-1}; ^1H nmr of **32** ($CDCl_3$): 2.20 (s, 6H), 2.23 (s, 3H), 3.03−3.18 (m, 4H), 3.73−3.88 (m, 4H), 4.83 (s, 1H), 6.50 (s, 1H); ms, m/z (rel. intensity): 221 (M^+, 91), 220 (55), 206 (32), 176 (63), 163 (100). *Anal.* calcd.: C 70.59, H 8.60; found: C 70.68, H 8.77%.

Reaction of 7a *with 31 in the presence of titanium tetrachloride*

To a mixture of 241 mg of **7*a*** (1 mmol) and 310 mg of **31** (2 mmol) in 10 mL of CH_2Cl_2 was added 0.17 mL of $TiCl_4$ (1.5 mmol), at −23°C under N_2. The reaction mixture was stirred for 3 h at −23°C and then overnight at room temperature. Concentrated sodium carbonate solution was added to the mixture. It was then extracted with ether. The organic layer was dried with $MgSO_4$ and filtered. The filtrate was concentrated by rotary evaporator to give a brown oil, which was purified by flash chromatography to give **32** in 38% yield. A quantity of 62 mg of self-condensation product of **7*a*** was also isolated.

2,4,5-Trimethyl-3-pyrrolidinophenol

The reaction of **7*a*** and **34** was performed under the same conditions as the reaction of **7*a*** with **31** in the presence of TFA. 2,4,5-Trimethyl-3-pyrrolidinophenol was obtained in 42% yield; ir ($CHCl_3$): 3600, 1580, 1460, 1070 cm^{-1}; ^1H nmr ($CDCl_3$): 1.93−2.13 (m, 4H), 2.13 (s, 3H), 2.16 (s, 3H), 2.22 (s, 3H), 3.10−3.30 (m, 4H), 4.48 (s, 1H), 6.50 (s, 1H); ms, m/z (rel. intensity): 205 (M^+, 99), 204 (100), 190 (58), 176 (66), 162 (70).

5-Methyl-2,4-diethyl-3-morpholinophenol

The reaction of **7*a*** with **33** was performed under the same condition as the reaction of **7*a*** with **31** in the presence of TFA. 5-Methyl-2,4-diethyl-3-morpholinophenol, mp 185−187°C, was obtained in 37% yield; ir (KBr): 3260, 1590, 1410, 1100 cm^{-1}; ^1H nmr ($CDCl_3$): 1.15 (t, 3H, J = 7 Hz), 1.23 (t, 3H, J = 7 Hz), 2.28 (s, 3H), 2.73 (q, 2H, J = 7 Hz), 2.77 (t, 2H, J = 7 Hz), 3.13−3.30 (m, 4H), 3.77−3.93 (m, 4H), 4.83 (s, 1H), 6.53 (s, 1H); ms, m/z (rel. intensity): 249 (M^+, 95), 234 (20), 220 (66), 170 (100). *Anal.* calcd.: C 72.29, H 9.24; found: C 72.20, H 9.17%.

5-Methyl-2,4-diethyl-3-pyrrolidinophenol

The reaction of **7*a*** with **35** was performed in the same manner as the reaction between **7*a*** and **31** in the presence of TFA. 5-Methyl-2,4-diethyl-3-pyrrolidinophenol was obtained in 36% yield; ir ($CHCl_3$): 3600, 1580, 1255, 1085 cm^{-1}; ^1H nmr ($CDCl_3$): 1.13 (t, 3H, J = 7 Hz), 1.23 (t, 3H, J = 7 Hz), 1.93−3.12 (m, 4H), 2.28 (s, 3H), 2.63 (q, 4H, J = 7 Hz), 3.13−3.33 (m, 4H), 6.50 (s, 1H); ms, m/z (rel. intensity): 233 (M^+, 100), 232 (73), 218 (95), 204 (87), 160 (31).

Kinetic mechanism of copper(II) transfer between the native sequence peptide representing the copper(II)-transport site of human serum albumin and L-histidine

MASAAKI TABATA[1] AND BIBUDHENDRA SARKAR[2]

Research Institute, The Hospital for Sick Children, Toronto, Ont., Canada M5G 1X8; and Department of Biochemistry, University of Toronto, Toronto, Ont., Canada M5S 1A8

Received January 28, 1985

MASAAKI TABATA and BIBUDHENDRA SARKAR. Can. J. Chem. **63**, 3111 (1985).

The kinetics for Cu(II)-transfer reaction of the native sequence tripeptide, L-aspartyl-L-alanyl-L-histidine-*N*-methyl amide (AAHNMA), representing the Cu(II)-transport site of human serum albumin (HSA), and L-histidine (L-His) was studied in the forward and reverse reactions in a pH range 6.5–10.0 at I = 0.2 and 25°. For the Cu(II)-transfer from Cu(II)-L-His_2 to native sequence peptide, the rate-determining step is a bond formation between Cu(II) and peptide nitrogen to form $CuH_{-1}AB$ from CuAB by deprotonation of peptide nitrogen atom, where A and B denote the anionic forms of AAHNMA and L-His, respectively. For the Cu(II)-transfer reaction from Cu(II)–peptide to L-His, the rate-determining step is a bond breaking between Cu(II) and peptide nitrogen to form CuAB from $CuH_{-1}AB$ by protonation to a peptide nitrogen. The effect of carboxyl group of aspartyl residue in the native sequence peptide on the kinetic and equilibrium constants are discussed.

MASAAKI TABATA et BIBUDHENDRA SARKAR. Can. J. Chem. **63**, 3111 (1985).

Opérant à 25°C, dans un intervalle de pH allant de 6,5 à 10,0 et avec une force I = 0,2, on a étudié la cinétique des réactions directe et inverse de transfert de Cu(II) de la L-histidine (L-His) au tripeptide naturel, L-aspartyl-L-alanyl-L-histidine-*N*-méthylamide (AAHNMA) qui représente le siège du transport de Cu(II) dans l'albumine du sérum humain (ASH). Dans la réaction de transfert de Cu(II) du Cu(II)-L-His_2 au peptide de la séquence naturelle, l'étape déterminante est la formation d'une liaison entre le Cu(II) et l'azote du peptide pour former du $CuH_{-1}AB$ à partir de CuAB par déprontonation de l'azote du peptide; dans ces formules, A et B représentent respectivement les formes anioniques de AAHNMA et de la L-His. Pour la réaction de transfert du Cu(II) du Cu(II)–peptide à la L-His, l'étape déterminante est la rupture de la liaison entre le Cu(II) et l'azote du peptide pour conduire à CuAB à partir de $CuH_{-1}AB$, par protonation d'un azote du peptide. On discute de l'effet du groupement carboxylique de l'unité aspartyle du peptide naturel sur la cinétique et sur les constantes d'équilibre.

[Traduit par le journal]

Introduction

The synthesis of the native sequence peptide, L-aspartyl-L-alanyl-L-histidine-*N*-methyl amide (AAHNMA) representing the actual Cu(II)-transport site of human serum albumin (HSA) has been reported previously (1, 2). The peptide binds Cu(II) in the same manner as does albumin (3, 4). This small peptide molecule permits studies which often cannot be applied to large protein molecules. These molecules possess extensive proton binding sites which give rise to ambiguities in elucidating the role of protons. It is considered that protonation or deprotonation step has important relevance in the Cu(II)-transfer mechanism.

The equilibrium and spectroscopic studies of the ternary system: Cu(II), the native sequence tripeptide and L-histidine (L-His) show the formation of mixed ligand complexes, $CuH_{-1}AB$ and CuAB (where A and B denote the anionic forms of AAHNMA and L-His, respectively) at physiological pH (5). Furthermore, the equilibrium study reveals that the native sequence which possesses a side chain carboxyl group decreases the stability constants of the mixed ligand complexes compared to those of glycylglycyl-L-histidine (GGH) (6). We wish to report in this paper a kinetic study of the Cu(II)-transfer reaction between the native sequence peptide representing the Cu(II)-transport site of HSA and L-His. The aim of this study is to elucidate which step is rate-determining in the Cu(II)-transfer reaction and what role the mixed ligand complexes play in the kinetics of the Cu(II)-transfer mechanism.

Experimental

Materials

The peptide, L-aspartyl-L-alanyl-L-histidine-*N*-methyl amide, was synthesized as described previously (1). L-Histidine-monohydrochloride ($[\alpha]_D^{20}$ + 10.0 ± 0.5) was obtained from Nutritional Biochemicals (Cleveland, OH). The purity of the peptide and the amino acid was checked by thin layer chromatography. All other reagents were of analytical grade.

Kinetic experiments

The Cu(II)-transfer reactions between AAHNMA and L-His were studied under pseudo-first order conditions. The faster reaction observed by mixing Cu(II)–L-His_2 with AAHNMA, was carried out on a Durrum–Gibson stopped-flow spectrophotometer at 25°C. The slower reaction, observed by mixing Cu(II)–AAHNMA with L-His, was carried out on a Beckman ACTA MVI spectrophotometer at 25°C. The change of absorbance was followed at both 640 nm (λ_{max} of Cu(II)–L-His_2) and 525 nm (λ_{max} of Cu(II)–AAHNMA). The values of the rate constants obtained were independent of the monitoring wave length. In all cases excellent first-order plots were obtained. The pH variation experiments were carried out by adjusting the pH of the *N*-ethylmorpholin–HCl buffer (0.1 *M*). At high pH (~9), L-His in large excess acted as its own buffer (pK_a = 9.11). All experiments were carried out at 25.0 ± 0.1°C and I = 0.2. Ionic strength was adjusted by sodium chloride and buffer.

Results

Reaction of Cu(II)-L-His_2 with AAHNMA

The reaction of Cu(II)–L-His with AAHNMA to form $CuH_{-2}A$ followed the first-order kinetic expression in eq. [1] under the large excess of CuB_2 compared to AAHNMA:

$$[1] \quad d[CuH_{-2}A]/dt = k_{obs}[A]_T$$

where k_{obs} is the conditional rate constant involving concen-

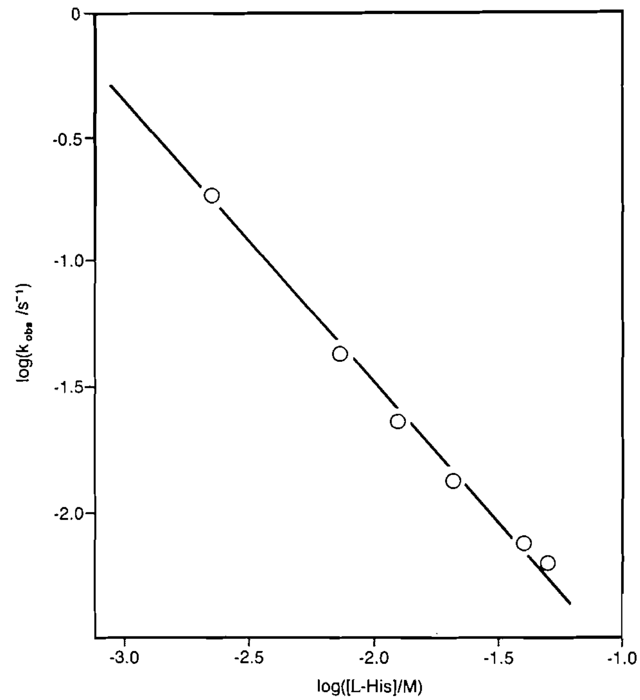

FIG. 1. Dependence of k_{obs} on L-histidine concentration for the reaction of Cu(II)–L-His$_2$ complex with the AAHNMA at 25°C. C_{Cu} = 3.90×10^{-3} M; C_{AAHNMA} = 3.00×10^{-4} M; pH = 7.50. AAHNMA = L-aspartyl-L-alanyl-L-histidine-N-methyl amide.

tration of hydrogen ion, Cu(II) and L-His. CuH$_{-2}$A is a Cu(II)-complex having two deprotonated peptide nitrogens and $[A]_T$ is the total concentration of AAHNMA. The Cu(II)-transfer reaction from Cu(II)–L-His$_2$ to AAHNMA was investigated from pH 6.5 to 10.0 in the various concentrations of L-His. The conditional rate constant (k_{obs}) is first-order in the concentration of CuB$_2$. Figure 1 shows the L-His dependence of conditional rate constant for the reaction of Cu(II)–L-His$_2$ with peptide. The rate constant decreases as the concentration of L-His increased. The slope in Fig. 1 is -1 and suggests that one molecule of L-His dissociates from CuB$_2$ before the rate-determining step as follows:

[2] $\quad \mathrm{Cu(II)\text{–}L\text{-}His_2 \rightleftharpoons Cu(II)\text{–}L\text{-}His + L\text{-}His}$

The dependence of k_{obs} upon pH is given in Fig. 2. Proceeding from pH 6.5 to 10.0, the slope increases and levels off, then again increases in higher pH region.

From the equilibrium study, the chemical species of Cu(II) under the present experimental conditions are CuB$_2$, CuH$_{-2}$A, CuAB, and CuH$_{-1}$AB. The reaction mechanism proposed to account for the observed L-His dependence and pH dependence of rate constants is given in reactions [3]–[7].

[3] $\quad \mathrm{CuB_2} + n\mathrm{H^+} \rightleftharpoons \mathrm{CuB} + \mathrm{H}_n\mathrm{B};\ K_1$

[4] $\quad \mathrm{CuB + A \rightleftharpoons CuAB};\ K_2$

[5] $\quad \mathrm{CuAB} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{CuH_{-1}AB + H^+}$

[6] $\quad \mathrm{CuAB + OH^-} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \mathrm{CuH_{-1}AB}$

[7] $\quad \mathrm{CuH_{-1}AB} \xrightarrow{k_3} \mathrm{CuH_{-2}A} + \mathrm{H}_n\mathrm{B} + \mathrm{OH^-}$

SCHEME 1

Since the rate of the reaction of Cu(II)–L-His$_2$ with AAHNMA decreases with increasing L-His concentration (Fig. 1), AAHNMA cannot react directly with Cu(II)–L-His$_2$ but it reacts with the 1:1 Cu(II)–L-His complex. It is followed by the formation of the mixed ligand complex CuAB in which peptide binds through amino nitrogen and peptide oxygen atoms (λ_{max} of CuAB 595 nm; ϵ_{max} = 97 M^{-1} cm^{-1}).

Hydroxide ion assists the deprotonation of peptide to form CuH$_{-1}$AB (reaction [6]). The solvent-assisted deprotonation path is shown in reaction [5]. CuH$_{-1}$AB is the main mixed ligand complex at physiological pH. By assuming steady-state concentrations of CuH$_{-1}$AB, the above mechanism yields the rate law for the formation of CuH$_{-2}$A as given in eqs. [8] and [9].

[8] $$\frac{d[\mathrm{CuH_{-2}A}]}{dt} = \left(\frac{k_2k_3[\mathrm{OH^-}] + k_1k_3}{k_{-1}[\mathrm{H^+}] + k_{-2} + k_3}\right)[\mathrm{CuAB}]$$

[9] $$k_{obs} = \left(\frac{k_2k_3[\mathrm{OH^-}] + k_1k_3}{k_{-1}[\mathrm{H^+}] + k_{-2} + k_3}\right)\left(\frac{\alpha_{B(H)}K_1K_2[\mathrm{CuB_2}]_T}{\alpha_{A(H)}[\mathrm{B}]_T}\right)$$

where K_1 and K_2 are equilibrium constants of reactions [3] and [4], respectively. $\alpha_{A(H)}$ and $\alpha_{B(H)}$ are protonation-reaction coefficients of A and B, respectively, and defined as follows (7):

[10] $$\alpha_{A(H)} = 1 + \beta_{0110}[\mathrm{H^+}] + \beta_{0120}[\mathrm{H^+}]^2 + \beta_{0130}[\mathrm{H^+}]^3$$

[11] $$\alpha_{B(H)} = 1 + \beta_{0101}[\mathrm{H^+}] + \beta_{0102}[\mathrm{H^+}]^2 + \beta_{0103}[\mathrm{H^+}]^3$$

Values for $\alpha_{A(H)}$ and $\alpha_{B(H)}$ were calculated from eqs. [10] and [11] by using the following β values (1, 8):

$$\beta_{0110} = [\mathrm{HA}][\mathrm{H^+}]^{-1}[\mathrm{A}]^{-1} = 10^{7.73}$$
$$\beta_{0120} = [\mathrm{H_2A}][\mathrm{H^+}]^{-2}[\mathrm{A}]^{-1} = 10^{14.29}$$
$$\beta_{0130} = [\mathrm{H_3A}][\mathrm{H^+}]^{-3}[\mathrm{A}]^{-1} = 10^{17.27}$$
$$\beta_{0101} = [\mathrm{HB}][\mathrm{H^+}]^{-1}[\mathrm{B}]^{-1} = 10^{9.11}$$
$$\beta_{0102} = [\mathrm{H_2B}][\mathrm{H^+}]^{-2}[\mathrm{B}]^{-1} = 10^{15.170}$$
$$\beta_{0103} = [\mathrm{H_3B}][\mathrm{H^+}]^{-3}[\mathrm{B}]^{-1} = 10^{16.999}$$

The hydroxide ion assisted pathway is predominant above pH 9.0. As the term $k_{-1}[\mathrm{H^+}] \ll k_2 + k_3$ at higher pH, the plots of

$$k_{obs} \times \left(\frac{\alpha_{A(H)}[\mathrm{B}]_T}{\alpha_{B(H)}K_1K_2[\mathrm{CuB_2}]_T}\right) \text{ vs. } [\mathrm{OH}]$$

gives a straight line with an intercept.

Kinetic parameters of $k_2k_3/(k_{-2} + k_3)$ and $k_1k_3/(k_{-2} + k_3)$ were calculated from the slope and the intercept. The value of k_2/k_1 is 1.50×10^6 M^{-1}. At lower pH, $k_2k_3[\mathrm{OH^-}]$ is much smaller than k_1k_3 to be negligible. The values of k_{-1}/k_1k_3 and $(k_{-2} + k_3)/k_1k_3$ are obtained as a slope and an intercept of plots of

$$\left(k_{obs}\frac{\alpha_{A(H)}[\mathrm{B}]_T}{\alpha_{B(H)}K_1K_2[\mathrm{CuB_2}]_T}\right)^{-1} \text{ vs. } [\mathrm{H^+}]$$

The value of k_{-1}/k_1k_3 is 3.80×10^7 M^{-1} s. By using the value of $k_1/k_{-1} = 10^{-6.61}$ M which is determined by equilibrium study, the values of $k_3 = 0.107$ s^{-1}. The curve in Fig. 2 was calculated from eq. [9] and above values.

Reaction of Cu(II)-AAHNMA with L-His

Rate of Cu(II)-transfer reaction from Cu(II)–peptide to L-His is slower than that from Cu(II)–L-His$_2$ to peptide. The reaction of Cu(II)–AAHNMA with L-His to form CuB$_2$ followed the first-order kinetic expression in eq. [12] under the large

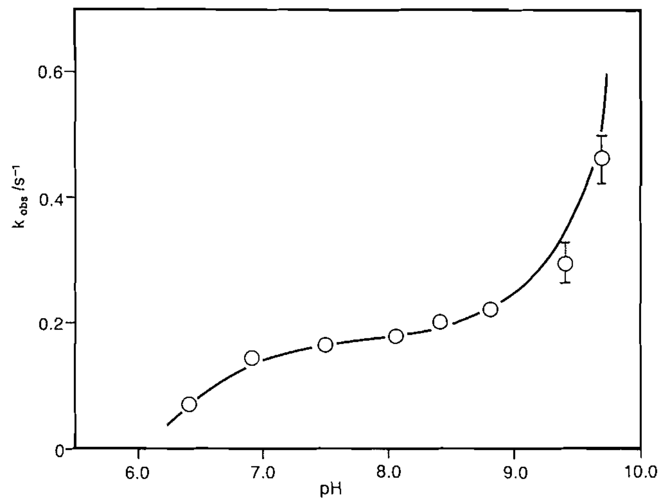

FIG. 2. Dependence of k_{obs} on pH for the reaction of Cu(II)–L-His$_2$ complex with AAHNMA at 25°C. $C_{Cu} = 3.90 \times 10^{-3}$ M; $C_{AAHNMA} = 3.00 \times 10^{-4}$ M; $C_{His} = 1.00 \times 10^{-2}$ M. AAHNMA = L-aspartyl-L-alanyl-L-histidine-N-methyl amide.

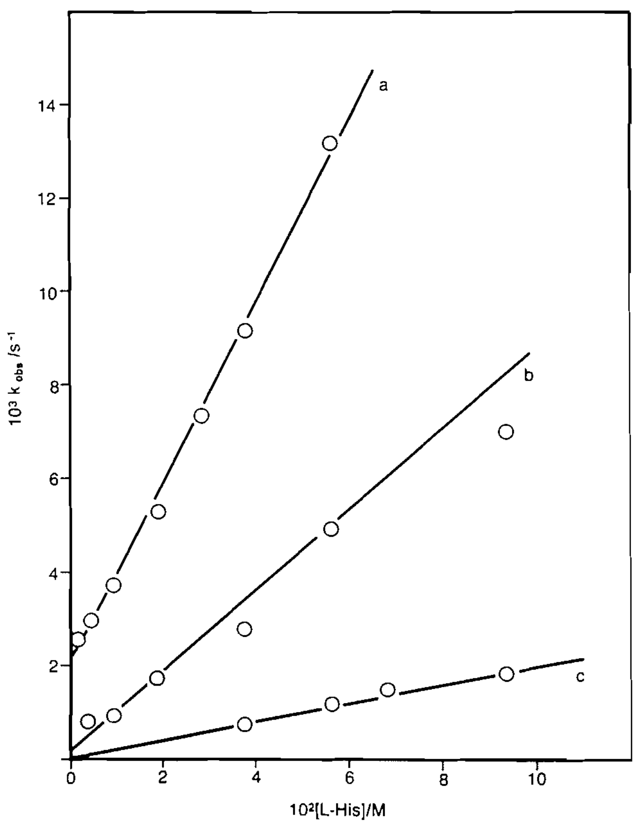

FIG. 3. Dependence of k_{obs} on L-histidine concentration for the reaction of CuH$_{-2}$A complex with L-histidine at 25°C. (a) $C_{Cu} = 6.09 \times 10^{-4}$ M, $C_A = 6.09 \times 10^{-4}$ M, pH = 7.00; (b) $C_{Cu} = 1.22 \times 10^{-4}$ M, $C_A = 1.22 \times 10^{-4}$ M, pH = 7.70; (c) $C_{Cu} = 2.44 \times 10^{-4}$ M, $C_A = 2.44 \times 10^{-4}$ M, pH = 8.50. A = L-aspartyl-L-alanyl-L-histidine-N-methyl amide.

excess of L-His compared to Cu(II)–AAHNMA:

$$[12]\quad d[CuB_2]/dt = -\,d[CuH_{-2}A]/dt = k_{obs}[CuH_{-2}A]$$

where k_{obs} is the conditional rate constant which is dependent on

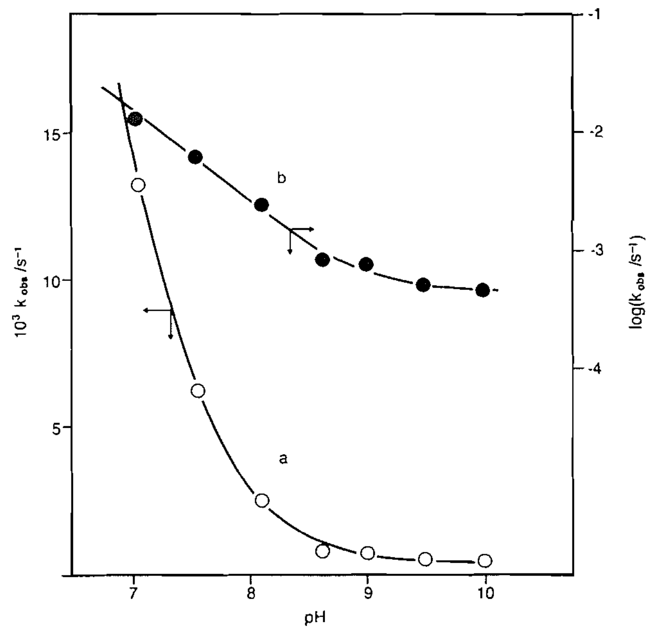

FIG. 4. Dependence of k_{obs} on pH for the reaction of Cu(H$_{-2}$A) complex with L-histidine at 25°C. $C_{Cu} = 2.44 \times 10^{-4}$ M; $C_A = 2.44 \times 10^{-4}$ M; $C_{His} = 5.63 \times 10^{-2}$ M. A = L-aspartyl-L-alanyl-L-histidine-N-methyl amide.

the concentrations of hydrogen ion and L-His. Main chemical species of Cu(II)–peptide is CuH$_{-2}$A in a pH range from 5 to 10. Figure 3 shows the effect of L-His concentration on the rate constant. The rate constant is first-order with respect to L-His. The dependence of k_{obs} on L-His becomes smaller at higher pH. Thus, the nucleophilic attack of L-His is characterized. At lower pH, there is a reaction pathway which is independent of L-His (Fig. 3a). The dependence of k_{obs} on pH is shown in Fig. 4. The observed rate constant decreases with the increasing pH and then levels off at higher pH.

The reaction mechanism proposed to account for the observed L-His dependence and pH dependence of rate constants is given in eqs. [13]–[16]:

$$[13]\quad CuH_{-2}A + HB \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} CuH_{-1}AB$$

$$[14]\quad CuH_{-1}AB + H^+ \xrightarrow{k_5} CuAB \xrightarrow{\text{rapid, B}} CuB_2 + A$$

$$[15]\quad CuH_{-2}A + H^+ \xrightarrow{k_6} CuH_{-1}A \xrightarrow{\text{rapid, B.H}^+} CuB_2 \text{ (final product)} + HA$$

$$[16]\quad CuH_{-2}A + B \xrightarrow{k_7} CuH_{-2}AB \xrightarrow{\text{rapid, B.H}^+} CuB_2 \text{ (final product)} + A$$

SCHEME 2

As the main chemical species of L-His is HB at physiological pH, HB attacks Cu(II)–peptide to form Cu$_{-1}$AB (λ_{max} 530 nm; $\epsilon = 90$ M^{-1} cm^{-1}). In the next step, proton attacks the peptide nitrogen of CuH$_{-1}$AB to break a bonding between peptide nitrogen and Cu(II), eq. [14]).

By assuming a steady-state of CuH$_{-1}$AB, the above mechanism yields the following rate equation for the formation of

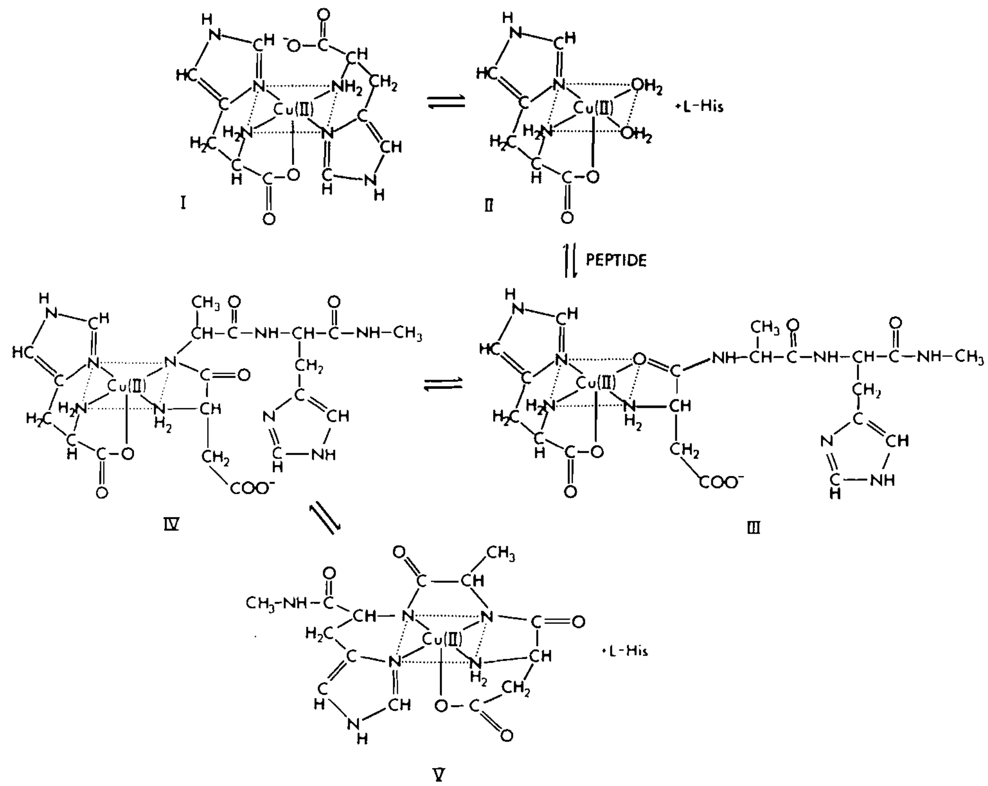

FIG. 5. Proposed reaction mechanism for the copper(II)-transfer involving Cu(II), L-aspartyl-L-alanyl-L-histidine-*N*-methyl amide (A) and L-histidine (B). **I**, CuB_2; **II**, CuB; **III**, CuAB; **IV**, $CuH_{-1}AB$; **V**, $CuH_{-2}A$.

CuB_2 as given by eq. [17]:

$$[17] \quad k_{obs} = \frac{k_4 k_5 [H^+][HB]}{k_{-4} + k_5[H^+]} + k_6[H^+] + k_7[B]$$

A plot of log k_{obs} against pH is shown in Fig. 4*b*. As pH increases from 6.5 to 8.5, the slope of the plot is -1, and then becomes less negative and levels off at high pH since L-His is converted to its free base form ($pK_a = 9.11$). Thus the rate eq. [17] is reduced to:

$$[18] \quad k_{obs} = \frac{k_4 k_5 [H^+][HB]}{k_{-4}} + k_6[H^+] + k_7[B]$$

$$[19] \quad = \frac{k_4 k_5 \beta_{0101} [H^+]^2[B]_T}{k_{-4}\,\alpha_{B(H)}} + k_6[H^+] + k_7 \frac{[B]_T}{\alpha_{B(H)}}$$

The predominant contribution to the rate at a pH lower than 8.5 is a proton and a protonated L-His pathway (eqs. [13]–[15]), and at higher pH it is a deprotonated L-His pathway (eq. [16]).

The values of k_4k_5/k_{-4}, k_6 and k_7 are $6.16 \times 10^6\ M^{-2}\ s^{-1}$, $2.06 \times 10^4\ M^{-1}\ s^{-1}$, and $1.25 \times 10^{-2}\ M^{-1}\ s^{-1}$, respectively.

Discussion

The physiological significance of the mixed ligand complex, albumin–Cu(II)–L-His in the biological transport of Cu(II) has been postulated earlier (9, 10). The preceeding equilibrium study of the ternary system containing the native sequence tripeptide (AAHNMA), Cu(II) and L-His indicates the presence of mixed ligand complexes (13% $CuH_{-1}AB$ and 3% CuAB) in addition to several binary species at physiological pH (5). The present kinetic investigation of the AAHNMA–Cu(II)–L-His ternary system shows the importance of the formation of mixed ligand complexes for the Cu(II)-transfer reaction (see Schemes 1 and 2), although the amounts of mixed ligand complexes formed are low. The combined results of the equilibrium and the kinetic studies demonstrate the mechanism and rate-controlling role played by the mixed ligand complexes in the Cu(II)-transfer reaction. A reaction scheme is derived in Fig. 5 taking into account the kinetic effect of pH, L-His, Cu(II)–L-His_2, and the distribution of chemical species in the ternary system. In this scheme, two mixed ligand complexes ($CuH_{-1}AB$, CuAB) are considered at physiological pH. In the Cu(II)-transfer from Cu(II)–L-His_2 to Cu(II)–AAHNMA, first step is the fast dissociation of one L-His molecule from Cu(II)–L-His (**I**) to form 1:1 Cu(II)–L-His complex (**II**). Two water molecules at equatorial position of 1:1 Cu(II)–L-His are substituted by the α-NH_2 nitrogen and the peptide oxygen of AAHNMA as anchoring points to form the mixed ligand complex (**III**) (CuAB, λ_{max} 595 nm). This is followed by deprotonation of the peptide nitrogen to form another mixed ligand complex (**IV**) $CuH_{-1}AB$, λ_{max} = 530 nm). Once the mixed ligand complex (**IV**) is formed, the displacement of amino and imidazole nitrogen atoms of L-His by the peptide nitrogen and imidazole nitrogen of AAHNMA would seem to be much more facilitated due to increased stability constant of tripeptide having a histidine residue (11). In the reverse reaction, the same rationale is also suggested. There is a nucleophilic attack of protonated L-His assisted by a proton to form mixed ligand complex $CuH_{-1}AB$. The mixed ligand complex $CuH_{-1}AB$ is protonated at peptide nitrogen to form another mixed ligand complex (CuAB), followed by the formation of Cu(II)–L-His.

From the kinetic data, the rate-controlling phenomenon can be determined at physiological pH. For the Cu(II)-transfer from Cu(II)–L-His_2 to native sequence peptide, the rate-determining step is a bond formation between Cu(II) and peptide nitrogen

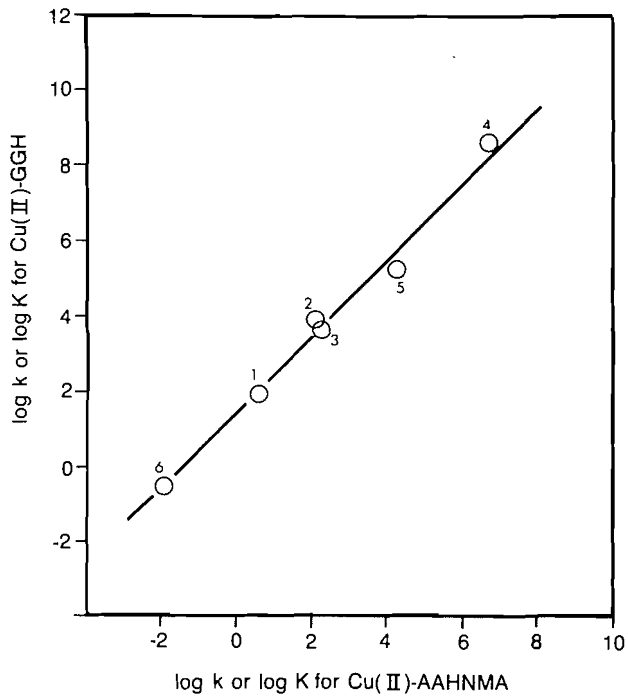

FIG. 6. Comparison of the reactivities and equilibrium constants of Cu(II)–GGH complex with those of Cu(II)–AAHNMA complex. (Refer to Table 1 for explanations of the numerical figures.) GGH = glycylglycyl-L-histidine, AAHNMA = L-aspartyl-L-alanyl-L-histidine-*N*-methyl amide.

to form $CuH_{-1}AB$ from CuAB by deprotonation of peptide nitrogen. For the Cu(II)-transfer from Cu(II)–peptide to L-His, the rate-determining step is a bond breaking between Cu(II) and peptide nitrogen to form CuAB from $CuH_{-1}AB$ by protonation to a peptide nitrogen. In both reactions, rate-determining step is a structural change of mixed ligand complex by protonation or deprotonation of peptide nitrogen.

It is interesting to compare the difference in Cu(II)-transfer reaction of peptides having different amino acid sequences. The carboxyl group of aspartyl residue of AAHNMA is bound to Cu(II) at its apical position in addition to the four nitrogen atoms in the square-plane forming a pentacoordinated structure (4, 12, 13). The ligand exchange reaction of Cu(II)–GGH complex has been reported earlier (14). The rate and equilibrium constants of reactions involving AAHNMA and GGH are shown in Table 1. The rate constants of the proton assisted nucleophilic pathway for the Cu(II)–AAHNMA complex is a factor of 65 times slower than for Cu(II)–GGH complex. Similar decreased rate constants in Cu(II)–AAHNMA are found for the nucleophilic attack pathway which is independent of L-His. Figure 6 shows a linear free energy relationship (15) between Cu(II)–AAHNMA and Cu(II)–GGH. The slope of the straight line is unity and the intercept is 1.4 (log value). This figure suggests that, in the Cu(II)-transfer reaction from Cu(II)–peptide to L-His, both peptides go through a similar activated complex in the process of bond breaking between Cu(II) and peptide. Carboxyl group of aspartyl residue in AAHNMA which coordinates to Cu(II) in an apical position (4) decreases the formation of mixed ligand complexes and makes the Cu(II)-transfer reaction from peptide to L-His difficult. Copper (II)-transfer reaction from peptide to L-His is dependent on the nature of the peptide. Hence, one should study the native sequence Cu(II)-transport site in order to delineate the kinetic mechanism of Cu(II)-transfer reaction involving albumin and L-His. The present finding suggests that the mixed ligand complexes formed by protonation or deprotonation are both kinetically and thermodynamically important intermediates in the Cu(II)-transfer reaction between albumin and L-histidine.

Equilibrium and spectroscopic studies of the ternary system: L-histidine, copper(II), and the native sequence peptide representing the copper(II)-transport site of human serum albumin

MASAAKI TABATA[1] AND BIBUDHENDRA SARKAR[2]

Research Institute, The Hospital for Sick Children, Toronto, Ont., Canada M5G 1X8; and Department of Biochemistry, University of Toronto, Toronto, Ont., Canada M5S 1A8

Received January 28, 1985

MASAAKI TABATA and BIBUDHENDRA SARKAR. Can. J. Chem. **63**, 3117 (1985).

Equilibrium and spectroscopic studies of Cu(II)-transfer of native sequence tripeptide, L-aspartyl-L-alanyl-L-histidine-*N*-methyl amide (AAHNMA), representing the Cu(II)-transport site of human serum albumin (HSA), and L-histidine (L-His) are reported. The equilibria in the ternary system, M–A–B (M = Cu(II), A = anionic form of AAHNMA, and B = anionic form of L-His) have been investigated by analytical potentiometry in I = 0.2 [(Na^+,H^+) (Cl^-,OH^-)] at 25°C. The ternary system shows the presence of five mixed ligand complexes: MH_2AB, MHAB, MAB, $MH_{-1}AB$, and $MH_{-2}AB$. The species distribution and their stability constants were evaluated by the mathematical analysis of the potentiometric data. The species were further confirmed by their individual spectra computed from the absorption measurements. At physiological pH, the equilibrium studies reveal the presence of 13% of $MH_{-1}AB$ (λ_{max} = 530 nm, ϵ = 90 M^{-1} cm^{-1}) and 3% MAB (λ_{max} = 595 nm, ϵ = 97 M^{-1} cm^{-1}). The combined results of equilibrium and spectroscopic studies indicate the mixed ligand complex $CuH_{-1}AB$ formed by deprotonation of peptide nitrogen as an important intermediate in the Cu(II)-transfer reaction. The stability constant of $CuH_{-1}AB$ is compared to those of other tripeptides which were designed to mimic the specific Cu(II)-transport site of human albumin.

MASAAKI TABATA et BIBUDHENDRA SARKAR. Can. J. Chem. **63**, 3117 (1985).

On rapporte des études spectroscopiques et d'équilibre relatives à la réaction de transfert du Cu(II) du tripeptide naturel L-aspartyl-L-alanyl-L-histidine-*N*-méthylamide (AAHNMA), qui est le siège du transport du Cu(II) dans l'albumine du sérum humain (ASH), à la L-histidine (L-His). Opérant à 25°C, avec I = 0,2 [(Na^+,H^+) (Cl^-,OH^-)] et faisant appel à la potentiométrie analytique, on a étudié l'équilibre du système ternaire M–A–B dans lequel M = Cu(II), A = forme anionique du AAHNMA et B = forme anionique de la L-His. Le système ternaire révèle la présence de cinq ligands complexes mixtes, soit MH_2AB, MHAB, MAB, $MH_{-1}AB$ et $MH_{-2}AB$. On a évalué la distribution des espèces et leur constante de stabilité en faisant appel à une analyse mathématique des données potentiométriques. Les spectres individuels calculés à partir des mesures d'absorption confirment l'existence de ces espèces. Les études d'équilibre à pH physiologique révèlent la présence de 13% de $MH_{-1}AB$ (λ_{max} = 538 nm, ϵ = 90 M^{-1} cm^{-1}) et de 3% de MAB (λ_{max} = 595 nm, ϵ = 97 M^{-1} cm^{-1}). Les résultats combinés des études d'équilibre et spectroscopiques indiquent que le complexe de ligand mixte $CuH_{-1}AB$, formé par la déprotonation de l'azote du peptide, est un intermédiaire important dans la réaction de transfert de Cu(II). On a comparé la constante de stabilité du $CuH_{-1}AB$ à celles des autres tripeptides qui ont été préparés pour reproduire le site spécifique du transport de Cu(II) dans l'albumine humaine.

Introduction

Copper is an essential trace element which plays an important role in many biological systems (1). The major portion of copper (90–95%) in mammalian plasma is in the form of ceruloplasmin which is not exchangeable *in vivo* (2). However, the remainder (5–10%) is bound to albumin and amino acids which are in rapid equilibrium with copper in tissues (3). Serum albumin is the major Cu(II)-transport protein and L-histidine (L-His) is the main Cu(II)-binding amino acid in blood (4–6). At physiological pH and concentrations, there is an equilibrium between albumin–Cu(II) and L-His–Cu(II) through a ternary complex, albumin–Cu(II)–L-His (7). It has been proposed that the ternary complex plays an important role as an intermediate in the transfer of Cu(II) from albumin to an amino acid and the Cu(II) – amino acid complex in turn is readily transported across the biological membrane (7).

Earlier studies led to the proposal that the Cu(II)-binding site of albumin involves the α-amino nitrogen, two peptide nitrogens and one imidazole nitrogen (8–10). Subsequent studies in this laboratory with synthetic peptides, glycylglycyl–L-histidine (GGH) and glycylglycyl–L-histidine-*N*-methyl amide (GGHNMA) revealed very similar Cu(II)-binding properties with those of albumin–Cu(II) complex (11–16). However, the studies with NH_2-terminal native sequence tripeptide, L-aspartyl-L-alanyl-L-histidine-*N*-methyl amide (AAHNMA) showed that the native sequence peptide resembled closer to albumin as far as their Cu(II)-binding affinity and dissociation are concerned (17). The latest results of Cu(II)-binding to AAHNMA by ^{13}C-nmr experiments suggest that, in addition to the four nitrogen ligands in a square-planar coordination as suggested before, there is the involvement of the side chain carboxyl group of aspartyl residue forming a pentacoordinated structure (18). This structure is confirmed by further studies of the Cu(II)-binding to the NH_2-terminal 24-residue fragment of human serum albumin (HSA) (19, 20). Copper(II) bound to L-His is the major physiologically important Cu(II) – amino acid complex; its detailed equilibrium and structural studies have also been reported (21, 22).

The above results prompted us to study the equilibria of the ternary system containing the native sequence peptide AAHNMA, Cu(II), and L-His. In this paper, we report detailed equilibrium studies of the ternary system. The species and their stability constants in the system, AAHNMA–Cu(II)–L-His in I = 0.2 [(Na^+,H^+) (Cl^-,OH^-)] at 25°C were determined by

Experiment

Materials

The peptide, L-aspartyl-L-alanyl-L-histidine-*N*-methyl amide, was synthesized according to the method described earlier (17). The purity of the peptide was checked by thin-layer chromatography. L-Histidine monohydrochloride ($[\alpha]_D^{20}$ + 10.0 ± 0.5) was obtained from Nutritional Biochemicals (Cleveland, OH). The purity was checked by thin-layer chromatography. It was dried at 110°C for 24 h and then stored over anhydrous calcium chloride at room temperature under vacuum. The peptide and L-His stock solutions were prepared in water and 40 m*M* HCl, respectively, and stored in cold and dark. All other reagents were of analytical grade.

Potentiometric titration

The potentiometric titrations were performed on a Radiometer automatic titration assembly consisting of a Radiometer PHM64 Research pH Meter, an automatic titrator, TTT60, an automatic recorder, REC61, an autoburette, ABU13, and a 50 mL titration vessel thermostated at 25.0 ± 0.1°C. The pH meter and electrodes were adjusted against standard buffers (pH 4.01, 7.00, and 9.18 at 25°C).

The 1.025 *M* sodium hydroxide was prepared carbonate-free and stored under argon atmosphere. It was standardized against phthalate (National Bureau of Standards). Analytical grade copper(II) chloride (Fisher Scientific Co.) was dissolved to give 1.0 *M* solution in 0.5 *M* HCl and standardized complexometrically with EDTA using murexide indicator. All the solutions contained 0.15 *M* NaCl and known amount of HCl to lower the starting pH. Since the stability constants of Cu(II)–L-His_2 and Cu(II)–AAHNMA complexes are very high, the formation of the chloride complex of Cu(II) is negligible. The solutions containing Cu(II), AAHNMA, and L-His were titrated with 1.025 *M* NaOH from pH 1.6 to 12.0. Ionic strength was 0.21 ± 0.01 [(Na^+,H^+) (Cl^-,OH^-)]. The slight change in ionic strength during the titration does not cause any change in the activity coefficient of hydrogen ion (25, 26). The concentrations of Cu(II) and ligands in each sample are listed in Table 1.

Spectrophotometry

The visible absorption spectra of the Cu(II)–AAHNMA–L-His ternary system were recorded on a Beckman ACTA MVI spectrophotometer as a function of pH in 0.15 *M* NaCl solution at 25°C.

Results

Determination of species distribution and stability constants

The complexation reaction in the ternary system involving metal ion M, proton H, ligands A and B can be represented as:

$$[1] \quad pM + qH + rA + sB \rightleftharpoons M_pH_qA_rB_s$$

where *p*, *q*, *r*, and *s* are the stoichiometric quantities of M, H, A, and B, respectively. A and B denote the anionic forms of AAHNMA and L-His, respectively. The stabilities of the species formed are expressed as the stoichiometric equilibrium constants β_{pqrs} in terms of concentrations at constant ionic strength, temperature, and pressure:

$$[3] \quad C_M = m + \Sigma p\beta_{pqrs}m^p h^q a^r b^s$$

$$[4] \quad C_H = h + \Sigma q\beta_{pqrs}m^p h^q a^r b^s$$

$$[5] \quad C_A = a + \Sigma r\beta_{pqrs}m^p h^q a^r b^s$$

$$[6] \quad C_B = b + \Sigma s\beta_{pqrs}m^p h^q a^r b^s$$

The experimental data and titration curves ($-\log h$ = *f*(base)) were obtained from solutions of defined concentrations of C_M, C_H, C_A, and C_B. The following relationships were used to obtain the values for the unbound portions of metal and the different ligands throughout the titration.

$$[7] \quad pM = pM_0 + \int_{pH_0}^{pH_i} \frac{\delta H_I^+}{\delta C_M} dpH$$

$$[8] \quad pA = pA_0 + \int_{pH_0}^{pH_i} \frac{\delta H_I^+}{\delta C_A} dpH$$

$$[9] \quad pB = pB_0 + \int_{pH_0}^{pH_i} \frac{\delta H_I^+}{\delta C_B} dpH$$

where pM = $-\log$ [free metal M], pA = $-\log$ [free ligand A], pH = $-\log h$, pB = $-\log$ [free ligand B], H_I^+ = moles of OH^- consumed to titrate hydrogen ions liberated through the complexation reactions. Subscript 0 denotes an initial known state of the system. The mathematical analyses of the titration data were performed by the sequential use of three computer programs, PLOT-3, GUESS-3, and LEASK-4 (written in BASIC language). The program PLOT-3 takes the numerical titration data and calculates the proton-liberation terms $\delta H_I^+/\delta C_M$, $\delta H_I^+/\delta C_A$, and $\delta H_I^+/\delta C_B$ and the amount of the free metal ion and ligands A and B at each selected pH value in eqs. [7]–[9], where H_I^+ means the released proton by complexation (24). The program GUESS-3, using data from PLOT-3, sets up a matrix of the terms $m^p h^q a^r b^s$ for each proposed species. This matrix then serves as an input to the program LEASK-4, which uses an iterative least-squares minimization procedure to calculate the stability constant β_{pqrs}. A detailed account of the data processing has been previously reported (17, 23, 24).

*Cu(II)-proton-L-aspartyl-L-alanyl-L-histidine-*N*-methyl amide-L-histidine*

In the metal-concentration variation experiments, solutions 1–3 in Table 1 were titrated, and in the ligand-concentration variation, solutions 4–6 for ligand A and solutions 7–9 for ligand B were used (Table 1). Titration curves are shown in Fig. 1. The data were processed likewise to yield $\delta H_I^+/\delta C_M$ (Fig. 2, curve *a*), $\delta H_I^+/\delta C_A$ (Fig. 2, curve *b*), and $\delta H_I^+/\delta C_B$ (Fig. 2, curve *c*) as a function of pH.

For the species selection of the complexes formed in the system, the following values for *p*, *q*, *r*, and *s* were used: *p* =

To solve for the stability constants of the ternary complexes, all previously determined stability constants from the binary system (17, 21) were kept constant and only those of the ternary species $M_pH_qA_rB_s$ were treated as variables. The minimum error solution for the ternary system permitted the presence of five ternary complexes, MH_2AB, MHAB, MAB, $MH_{-1}AB$, and $MH_{-2}AB$; their stability constants are included in Table 2, and the species distribution as a function of pH is shown in Fig. 3.

FIG. 3. Visible absorption spectra

The spectra of a solution containing a M:A:B molar ratio of 1:6:6 and 0.15 *M* NaCl were recorded at pH 2.6–10.0 in the visible region from 400 to 800 nm. The total Cu(II) concentration was 2.925×10^{-3} *M*.

Absorbance at a fixed wavelength is correlated with the concentration of $M_pH_qA_rB_s$ as follows:

$$[10] \quad A_\lambda = \sum_{pqrs} \epsilon_{\lambda,pqrs} [M_pH_qA_rB_s]$$

where A_λ is the absorbance at wavelength λ, 1 cm light path, and ε is the molar absorbance of the species $M_pH_qA_rB_s$ at that wavelength. The mathematical analyses, of eq. [10] for the

spectral data at various pH's were performed by the use of computer program LEASK-2 which gave the calculated spectra for individual species $M_pH_qA_rB_s$. Their spectral parameters are included in Table 3.

Discussion

The native sequence tripeptide, AAHNMA, represents the actual Cu(II)-transport site of human albumin. The Cu(II)–tripeptide complex exists as $CuH_{-2}A$ from pH 5 to 10 (17). In the ternary system containing AAHNMA, Cu(II) and L-His, analyses of titration results indicate the presence of five ternary complexes, namely MH_2AB, MHAB, MAB, $MH_{-1}AB$, $MH_{-2}AB$, in addition to several binary species. Owing to the extensive overlap of different species, especially in low pH, it is difficult to obtain clear information about the structural features of these mixed ligand complexes from combined results of the proton displacement, the species distribution, and the computed visible absorption spectra. However, the detection of about 16% of mixed ligand complexes at physiological pH suggests the possible significance of their presence in solution.

The predominant species $MH_{-2}A$, $MH_{-2}A_2$, $MH_{-1}AB$, and $MH_{-2}AB$ all seem to have computed maximal absorption around 525 nm which indicates that four nitrogens are ligated around the central Cu(II) ion. However, MAB has calculated λ_{max} of 595 nm. Judging from its occurrence at a slightly lower pH (~4.7), an oxygen of peptide carbonyl instead of peptide nitrogen is likely to be participating in the coordination (27).

The main mixed ligand complex is in the form of $MH_{-1}AB$ at physiological pH. This is consistent with the results obtained from GGH and GGHNMA (12, 13). Distribution of the mixed ligand complex $CuH_{-1}AB$ is very dependent on the nature of the tripeptide: maximum, 35% for GGHNMA, and 13% for AAHNMA. Since the formation of a mixed ligand complex involves the making of at least one coordination bond from L-His in the coordination square-plane, it would require the removal of at least one of the Cu(II)-coordinating nitrogens of the peptide. With higher stability constant of $MH_{-2}A$ complex for the tripeptide, we would expect lesser amounts of mixed ligand complexes to be formed. Comparing the stability constants of binary and ternary systems, as shown in Table 2, two tripeptide amides, GGHNMA and AAHNMA, have comparable stability constants (β_{1-21}, $CuH_{-2}A$) whereas AAHNMA shows a lower stability constant of mixed ligand complex ($\beta_{1\text{-}111}$, $CuH_{-1}AB$) compared to the other tripeptides. Furthermore, the stability constant of Cu(II)–AAHNMA (β_{1-21}) is 23 times higher than that of Cu(II)–GGH, and the stability constant of mixed ligand complex of Cu(II)–AAHNMA–L-His (β_{1-111}) is 53 times smaller than that of Cu(II)–GGH–L-His. The difference has also been observed in the ligand-exchange rate for Cu(II)–tripeptide with L-His. The Cu(II)-exchange rate between Cu(II)–GGH and L-His is 3.5×10^{-2} s^{-1} (28), which is 5 times greater than that found for Cu(II)–AAHNMA under the same experimental conditions. The observed differences are consistent with the stability constant of mixed ligand complex ($MH_{-1}AB$). Carboxyl group of aspartyl residue in AAHNMA which coordinates to Cu(II) in apical position (18) stabilizes Cu(II)–AAHNMA complex more compared to Cu(II)–GGH. This makes the formation of mixed ligand complex and the Cu(II)-transfer reaction from peptide to L-His more difficult.

X-ray crystal structure analysis of [Cu(L-His)(L-Thr)(H_2O)]·[H_2O] shows that L-His coordinates to Cu(II) through its amino and imidazole nitrogens with the carboxylate oxygen in the apical position and that L-Thr occupies the rest of the coordination plane with a glycine-like chelation in a *cis*-configuration with respect to the amino groups (29), where L-Thr denotes L-threonine. The stability constant of the mixed ligand complex, Cu(L-His)(L-Thr), was determined in 20% v/v dioxane–water and the overall stability constant (log β_{1011}) is 17.57 (30). Yamauchi and co-workers (30) also showed that the stability constants (log β_{1011}) for a ternary system containing Cu(II), L-His, and amino acid (glycine, L-alanine, L-valine, L-asparagine, L-glutamine, L-citrulline, L-serine, L-threonine, or L-homoserine) are in the range 17.4–18.0. The stability constants of Cu(L-His) (L-amino acid) are very close to those of Cu(L-His) tripeptide: log β_{1011} is 17.35 for Cu(L-His)–AAHNMA, and 17.56 for Cu(L-His)–GGH (see Table 2). This similarity suggests that L-His in CuAB coordinates to Cu(II) through its amino and imidazole-nitrogens in the square-plane and AAHNMA or GGH binds to Cu(II) as a bidentate ligand through amino nitrogen and peptide carbonyl oxygen. The characteristic spectral property (λ_{max} 595 nm) of CuAB also supports such a structure. At a higher pH, $CuH_{-1}AB$ appears with spectral change from λ_{max} 595 to 530 nm. In $CuH_{-1}AB$, coordination takes place with the peptide amide nitrogen instead of carbonyl oxygen. The proton dissociation constants (pK_a) of CuAB to form $CuH_{-1}AB$ are 6.61 for Cu(L-His)-AAHNMA and 6.51 for Cu(L-His)GGH, respectively.

The synthetic native sequence peptide, AAHNMA represents the actual Cu(II)-transport site of human albumin. It was possible to obtain more detailed information with the synthetic peptide which one could not obtain with intact HSA because of the inherent complexity associated with a protein molecule. The present findings indicate that the mixed ligand complex formation initiated by deprotonation of peptide nitrogen ($CuH_{-1}AB$) or by protonation of peptide nitrogen (CuAB) is an important intermediate in the Cu(II)-transfer reaction (31) between human serum albumin and L-His and that the side chain-carboxyl group of aspartyl residue decreases the formation of mixed ligand complexes of CuAB and $CuH_{-1}AB$.

Fletcher–Powell minimization of analytical potentiometric data by microcomputer: application to the Cu(II) complexes of biological polyamines

DOUGLAS M. TEMPLETON AND BIBUDHENDRA SARKAR
Research Institute, The Hospital for Sick Children, Toronto, Ont., Canada M5G 1X8, and Department of Biochemistry, University of Toronto, Toronto, Ont., Canada M5S 1A8

Received February 8, 1985

DOUGLAS M. TEMPLETON and BIBUDHENDRA SARKAR. Can. J. Chem. **63**, 3122 (1985).

The Fletcher–Powell minimization algorithm has been successfully implemented for the extraction of metal complex stability constants from analytical potentiometric data. The procedure has been adapted to run on a microcomputer with acceptable execution times, and several strategies are employed to speed convergence and avoid false minima. This allows economical minimization for a large number of models of speciation, and improves the reliability of the proposed best fit by encouraging the checking of more models than previously possible. The Ni(II)–glycine system has been analyzed and excellent agreement with the stability constants of an earlier multi-laboratory study has been attained. The system proves useful in the evaluation of both analytical and computational methods. The procedure has also been used for speciation analysis of the Cu(II) complexes of the growth regulating polyamines, spermine, and spermidine. Both systems form fully deprotonated complexes at physiological pH, which are relevant to their biological activity.

DOUGLAS M. TEMPLETON et BIBUDHENDRA SARKAR. Can. J. Chem. **63**, 3122 (1985).

On a utilisé avec succès l'algorithme de minimisation de Fletcher–Powell dans le but d'obtenir les constantes de stabilité des complexes métalliques à partir de données potentiométriques analytiques. On a modifié la méthode de façon à utiliser un microordinateur avec des délais d'exécution acceptables et on a utilisé plusieurs approches afin d'accélérer la convergence et d'éviter les faux minima. Ceci permet de minimiser d'une façon économique pour un grand nombre de modèles de spéciation et d'améliorer l'exactitude de cette méthode en permettant l'évaluation de plus de modèles que cela n'était possible jusqu'à maintenant. On a analysé le système Ni(II)–glycine et les résultats obtenus s'accordent parfaitement avec ceux obtenus antérieurement dans une étude réalisée conjointement par plusieurs laboratoires. Le système se révèle utile pour réaliser des évaluations tant de méthodes analytiques que de méthodes de calculs à l'aide d'ordinateurs. On a également utilisé cette méthode pour l'analyse de spéciation des complexes de Cu(II) des polyamines régularisatrices de la croissance, comme la spermine et la spermidine. Les deux systèmes forment, au pH physiologique, des complexes complètement déprotonés qui sont importants à cause de leur activité biologique.

Introduction

A technique for determining the free (uncomplexed) ligand concentration as a function of pH, in the presence of a metal ion, was developed by Österberg (1), based on a procedure by Lefebvre (2). Conveniently, it involved only potentiometric titration with a glass pH electrode. The method was extended by Sarkar and co-workers (3, 4) to allow both free metal and ligand concentrations to be extracted from a series of pH titrations in which both ligand and metal concentrations were systematically varied. Subsequently, this laboratory has used this technique of analytical potentiometry to study the binding of metals to a variety of ligands of biological interest (5–9), using a series of programs written for a main frame computer. A number of groups are now using variations of this technique (10–12), which we have called analytical potentiometry. This method presents the advantage over alternatives, that the free ion concentrations entering into the definition of the stability constants are calculated directly from experimental titration data in a model-independent procedure, and need not themselves be refined for each proposed speciation model.

We report here the use of the Fletcher–Powell (FP) algorithm (13) to expedite the microcomputer solution of metal complex stability constants from potentiometric data. We have tested the procedure by determining speciation of the Ni(II)–glycine system, chosen as a test system for a previous inter-laboratory procedure evaluation (14). We also report an analysis of the Cu(II) complexation of two polyamines of great biological interest (15, 16), spermidine (1,8-diamino-4-aza-octane) and spermine (1,12-diamino-4,9-diaza-dodecane).

Theory

Calculation of the free metal and ligand concentrations as a function of pH proceeds from the titration data in a straightforward manner (3). This allows direct calculation of all terms in eq. [1] except the stability constants:

$$[1] \quad \mathbf{C}\,|\beta\rangle = |m_b\rangle$$

Here $\mathbf{C}$ is a $k \times n$ coefficient matrix with terms $c_{ij} = pm^p h^q l^r$ for the jth species at the ith pH. There are k pH values and n species $M_pH_qL_r$ where p, q, r are the stoichiometric coefficients of metal (M), proton (H), and ligand (L), respectively, in the complex, and m, h, and l are the corresponding free ion concentrations. $|m_b\rangle$ is the column vector of bound metal concentrations with terms $m_{b1}, m_{b2}, \ldots m_{bk}$ calculated as $M_T - m_i$ at each pH$_i$, where M_T is the total analytical concentration of metal. $|\beta\rangle$ represents the column vector of n β values, the concentration stability constants, β_j for the jth species being defined as

$$[2] \quad \beta_j = [M_pH_qL_r]_j / m^p h^q l^r$$

The problem is then one of finding the best solution for the overdetermined ($k > n$) set of k equations in n unknowns (eq. [1]). In methods alternative to analytical potentiometry, the coefficient matrix $\mathbf{C}$ is itself modeled and refined, a computationally more demanding approach. In the most widely used of these methods, MINIQUAD (17), $\mathbf{C}$ is sparse, and some of the difficulties are overcome by factorization (18). We have sought to take advantage of our knowledge of $\mathbf{C}$ to solve eq. [1] for the least-squares solution of $|\beta\rangle$ directly by an iterative minimization technique.

The least squares solution is taken as that β which minimizes U, where

$$[3] \quad U = \sum_{i=1}^{k} \left\{ \left[\sum_{j=1}^{n} p\, (m_i^p h_i^q l_i^r)_j\, \beta_j \right] - m_{bi} \right\}^2$$

$$= \sum_{i=1}^{k} \left[\left(\sum_{j=1}^{n} c_{ij} \beta_j \right) - m_{bi} \right]^2$$

A major source of computational difficulty is presented by the preference to carry out the refinement with respect to β, and avoid a change of variables to log β values. It has been shown (19) that such a change of variables transforms the function into a highly non-linear, non-concave function which is extremely difficult to minimize by any method. The wide range of values necessitates effective scaling to achieve refinement, and also makes matrix inversion so prone to rounding errors (20) that techniques based on finding $\mathbf{C}^{-1}$ are virtually unusable. We require a method which will handle a wide range of values of C_{ij} and β (typically spanning 40 orders of magnitude), with rapid convergence and avoidance of false minima, which can be executed rapidly on a microcomputer. The FP method has been found superior to Gauss–Newton–Raphson and other gradient methods with respect to speed and reliability of convergence. It was tried with some success (18) in a forerunner of the MINIQUAD program, but was replaced by a faster, though less memory-efficient Gauss–Newton method in the final version. Because analytical potentiometric data require less computation, acceptable run times can be achieved using the FP method. Furthermore, it has allowed us to take advantage of specific strategies in solving for $|\beta\rangle$ (*vide infra*).

We define an $n \times n$ Hessian matrix $\mathbf{G}$ with terms

$$[4] \quad G_{ij} = \partial^2 U/\partial\beta_i \partial\beta_j = g_i g_j$$

where

$$[5] \quad g_x = (\partial/\partial\beta_x) \left\{ \sum_{i=1}^{k} [m_b^2 - 2m_b\,(C_{i1}\beta_1 + C_{i2}\beta_2 + \ldots + C_{ix}\beta_x + \ldots + C_{in}\beta_n) + (C_{i1}\beta_1 + C_{i2}\beta_2 + \ldots + C_{ix}\beta_x + \ldots + C_{in}\beta_n)^2] \right\}$$

$$= \sum_{i=1}^{k} \left[-2m_b C_{ix} + 2C_{ix} \left(\sum_{j=1}^{n} C_{ij}\beta_j \right) \right]$$

so that the displacement between a given point $|\beta\rangle$ and the minimum $|\beta_0\rangle$ is

$$[6] \quad |\beta_0\rangle - |\beta\rangle = -\mathbf{G}^{-1}\,|g\rangle$$

and $|g\rangle$ is the gradient vector $(g_1 \ldots, g_n)$. To avoid inverting $\mathbf{G}$, we use instead a positive definite matrix $\mathbf{H}$ and set a shift vector

$$[7] \quad |s^i\rangle = \mathbf{H}^i\,|g^i\rangle$$

at the ith iteration. We then take a step $|\sigma^i\rangle$ towards the minimum by setting

$$[8] \quad |\sigma^i\rangle = \alpha^i\,|s^i\rangle$$

and modifying $|\beta\rangle$ as

$$[9] \quad |\beta^{i+1}\rangle = |\beta^i\rangle + |\sigma^i\rangle$$

The minimization is most efficient when the scalar α^i is found to minimize $U(|\beta^i\rangle + \alpha^i\,|s^i\rangle)$ with respect to λ along $(|\beta^i\rangle + \lambda\,|s^i\rangle)$. λ is chosen and α^i found by Davidon's cubic interpolation, according to Fletcher and Powell (13).

TABLE 1. Stability constants of the Ni(II)–glycine system; entries are log β_{pqr} values for species $Ni_pH_qGly_r$[a]

pqr	A	B
011	9.65	9.653 ± 0.011
101	5.592	5.63 ± 0.071
102	10.44	10.391 ± 0.089
103	13.86	13.922 ± 0.191

[a]Column A: present work; 25°C, 0.15 M NaCl. Based on ligand variation at [Ni] = 1.08×10^{-4} M with [glycine] = 1.97×10^{-4}, 3.94×10^{-4}, 5.93×10^{-4}, 7.89×10^{-4}, 9.86×10^{-4}, and 1.18×10^{-3} M; and metal variation at [glycine] = 5.93×10^{-4} M with [Ni] = 3.60×10^{-5}, 7.20×10^{-5}, 1.08×10^{-4}, 1.44×10^{-4}, and 2.16×10^{-4} M. Standard deviation on the fit is 8.8×10^{-7}. Column B: data of ref. 14; values are mean ± SD, of the values from 7 independent laboratories; 25°C, 1 M NaCl, total concentration of reagents variable but not more than 0.1 M.

At each iterative step, $\mathbf{H}$ is also refined. We begin with $\mathbf{H}$ as a scaled unit matrix, and set

$$[10] \quad \mathbf{H}^{i+1} = \mathbf{H}^i + \frac{|\sigma^i\rangle\langle\sigma^i|}{\langle\sigma^i|y^i\rangle} - \frac{\mathbf{H}^i\,|y^i\rangle\langle y^i|\,\mathbf{H}^i}{\langle y^i|\,\mathbf{H}^i\,|y^i\rangle}$$

where $|y^i\rangle = |g^{i+1}\rangle - |g^i\rangle$, according to Fletcher and Powell. It can be shown (13) that, as the procedure converges, $\mathbf{H}$ tends to $\mathbf{G}^{-1}$.

In applying this algorithm, we use the additional strategy of initializing $\mathbf{H}$ as an $n \times n$ unit matrix, which is then scaled to ensure refinement of each β at each iteration. This is done as suggested earlier (19). An increment $\delta_i = k_\delta \beta_i$ is used to calculate

$$[11] \quad U^+ = U[\beta_1, \ldots, (\beta_i + \delta_i), \ldots, \beta_n]$$

$$U^- = U[\beta_1, \ldots, (\beta_i - \delta_i), \ldots, \beta_n]$$

where k_δ is chosen to esnure that $(U^\pm - U)$ are significant with respect to the expected precision of the final U. Then

$$[12] \quad \mathbf{H}_{ii} = \delta_i^2/|U^+ + U^- - 2U|$$

We have allowed re-initialization of $\mathbf{H}$ from partially refined solutions, retaining the current (partially refined) β values. This achieves three aims. First, it reverts to a steepest descent situation and thus speeds up convergence. Secondly, if a minimum is nearby, this steepened descent can cause wider oscillation about it, with the frequently observed result that we leap over and escape a false minimum. Finally, reinitializations allow approaching the minimum from different directions, increasing our confidence that a true minimum has been found.

Materials and methods

Chemicals

Spermidine trihydrochloride and spermine tetrahydrochloride were obtained from Sigma (St. Louis, MO) and recrystallized twice from ethanol–water. Purity was checked by high voltage paper electrophoresis at pH 5 (citrate buffer) and pH 8.9 (borate buffer), and estimated to be 99% by log K_A analysis following Motekaitis and

Martell (21) and by the proton liberation measurements. Glycine (crystalline ammonia free; Sigma) was recrystallized twice from hot ethanol–water 1:1 (v/v). Nickel(II) and Cu(II) were obtained as their chloride salts, of Anal R grade or equivalent, and their aqueous solutions were standardized against EDTA using murexide (nickel) or fast sulphon black F (copper) as indicators. Sodium hydroxide solutions for titration were prepared carbonate free, stored under argon, and standardized against N.B.S. grade potassium hydrogen phthalate. Absorption spectra were obtained with a Cary 15 spectrophotometer with a 10 cm path length cuvette. Digitized spectra were corrected for dilution with titrant following baseline subtraction.

Potentiometric titrations

Solutions were prepared from carbonate-free deionized water kept under argon. All glassware was acid washed. Titrations were performed on solutions with starting volumes of 48.00 mL and 0.15 M in NaCl, using a Radiometer ABU13/TTT60/PHM64 titration assembly. Electrodes (Radiometer G2040C glass and K4040 calomel) were calibrated against standard N.B.S. buffers. In all cases, ligand concentrations varied between 2×10^{-4} and 1×10^{-3} M, and metal concentrations between 4×10^{-5} and 2.4×10^{-4} M (Ni(II)) or 5×10^{-5} and 5×10^{-4} M (Cu(II)). The ratio of ligand in the metal variation titrations to metal in the ligand variation titrations was always 5:1. Up to 2×10^{-4} mol standardized HCl were used to lower the starting pH, and all titrations were carried out with 0.0951 ± 0.0008 M NaOH. At the common curve conditions in the Ni(II)–glycine system, for example, ionic strength varied from 0.155 to 0.150 over the course of the titration due to addition of base. From titrations of background electrolyte, pK_W = 13.8. All titrations were performed under an argon atmosphere in vessels thermostated at 25.0 ± 0.1°C.

Data analysis

Calculations were performed by a series of programs written in Basic for an Apple Macintosh microcomputer. PKAMART calculates the stepwise ligand protonation constants by employing the algorithm of Motekaitis and Martell (21). Based on these K_a's and the experimental titration curves, FREEML calculates the free ligand and metal concentrations as functions of pH, as outlined in (3). Using the output of FREEML, GMAT constructs the coefficient matrix corresponding to a given guessed set of species. DFPMIN then uses the FP method to find the least squares set of β values corresponding to the guessed coefficient matrix. When the best set of species and the corresponding β values have been found, SPECIES calculates the species distribution as a function of pH, entailed by the set $|\beta\rangle$ and the experimental m and l, by solving eq. [2]. Program listings are available from the authors on request.

Results

The Ni(II)–glycine system was analyzed above pH 4.5, where the glycine carboxyl group is fully ionized. Below pH 10, only the species Ni-gly, $Ni(gly)_2$, and $Ni(gly)_3$ were found. Their stability constants and the amino group K_a are compared with those of an earlier study (Table 1).

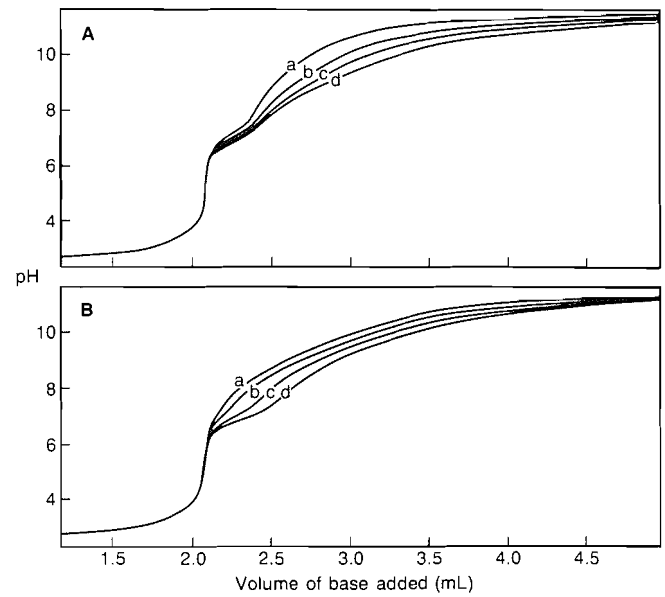

FIG. 1. Original titration data of the Cu(II)–spermidine system with 9.51×10^{-2} M NaOH. Conditions are given in the Materials and methods section. (A) Ligand variation at [Cu] = 1.964×10^{-4} M and [spermidine] = 4.252×10^{-4} M (a), 6.378×10^{-4} M (b), 8.504×10^{-4} M (c), and 1.063×10^{-3} M (d). (B) Metal variation at [spermidine] = 1.063×10^{-3} M and [Cu] = 4.910×10^{-5} M (a), 9.820×10^{-5} M (b), 1.964×10^{-4} M (c), and 2.946×10^{-4} M (d).

The three K_a's of spermidine are given in Table 2, and titration data for the Cu(II)–spermidine system are shown in Fig. 1. Complexation of Cu(II) by spermidine begins above pH 6 (Fig. 2). Complexation begins with the $CuHL^{3+}$ species, but this species deprotonates and the CuL^{2+} complex predominates over the range pH 7.5 to 9.5. At pH 8.5, this complex accounts for 90% of the total Cu(II). A variety of stable complexes are found in this system at higher pH. The data of the Cu(II)–spermidine system were re-analyzed on a GE400 series computer, using improved versions of the PLOT, GUESS, and LEASK programs reported previously (3), with consistent results. These data are summarized in Table 3.

In order to discriminate amongst the various models tested, the following statistical considerations apply. Minimization

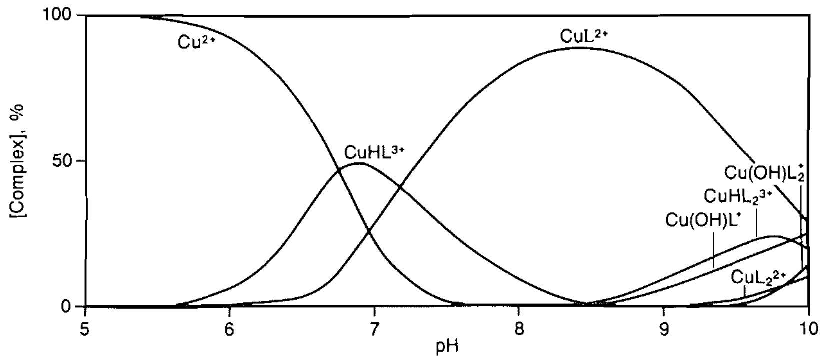

FIG. 2. Species distribution of the Cu(II)–spermidine system as a function of pH. L is spermidine. From the data of Table 3.

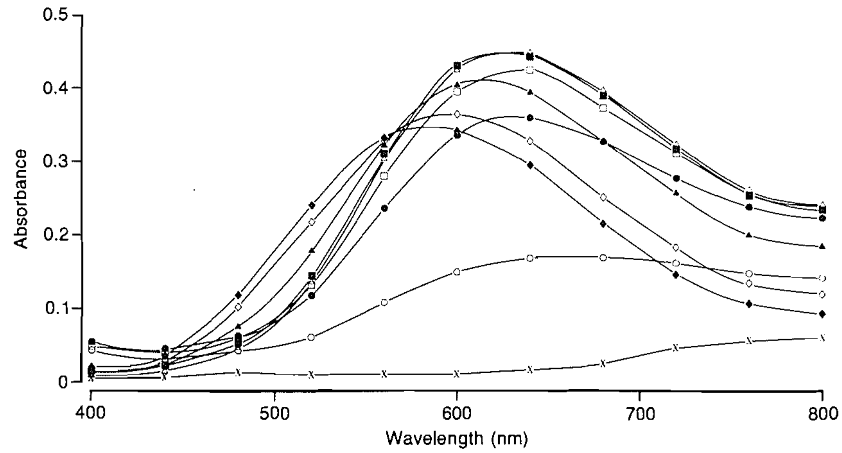

FIG. 3. Absorption spectra of the Cu(II)–spermidine system. [Cu] = 4.25×10^{-4} M, [spermidine] = 2.21×10^{-3} M. pH 2.72 ×; pH 6.51, ○; pH 6.91, ●; pH 7.24, □; pH 8.01, ■; pH 8.41, △; pH 9.26, ▲; pH 10.03 ◇; pH 10.89, ◆.

with respect to $|m_b\rangle$ gives a value of U from which the standard deviation of the overall fit can be calculated in terms of metal concentration. This may be expressed as a percentage of total metal. This does not allow the assignment of standard deviations to individual β values, which are not varied independently. These criteria, and their use in distinguishing amongst several better models, are illustrated in Table 4 for the Cu(II)–spermidine system.

The pH dependence of the absorption spectrum of the Cu(II)–spermidine system (Fig. 3) allows discernment of absorption due to the $CuHL^{3+}$ complex (λ_{max} = 655 nm, ϵ_{655} = 131 dm^3 mol^{-1} cm^{-1}) at pH 6.5 and due to the CuL^{2+} complex (λ_{max} = 626 nm, ϵ_{626} = 127 dm^3 mol^{-1} cm^{-1}) at pH 8.4. Above pH 10, where bis species are forming, the absorption shifts to higher energy ($\lambda_{max} \simeq$ 580 nm). Others have reported (25) an absorption (λ_{max} = 610 nm, ϵ_{610} = 117 dm^3 mol^{-1} cm^{-1}) in the Cu(II)–spermidine system, at unspecified pH. This was attributed to CuL^{2+}, and absorptions due to other complexes were not identified.

The Cu(II)–spermine system (Fig 4) is somewhat simpler. Complexation begins above pH 5 with the doubly protonated CuH_2L^{4+} species, but the fully deprotonated CuL^{2+} grows quickly and contains nearly 100% of the Cu(II) between pH 7 and 9. Fewer species form at high pH. Data for the Cu(II)–spermine system are summarized in Table 3 and Fig. 5. The absorption spectrum of this system (Fig. 6) is dominated by that of the CuL^{2+} complex (λ_{max} = 564 nm, ϵ_{564} = 162 dm^3 mol^{-1} cm^{-1}).

The most time consuming step in analysis is execution of the

DFPMIN program. For all sets of species checked in all systems, when convergence was achieved with DFPMIN, execution times were between 1 and 5 min.

Discussion

The major polyamines of biological interest are putrescine (1,4-diaminobutane), spermine, and spermidine (15). Metal complexation by these naturally occurring polydentate ligands has not been thoroughly investigated previously, although Cu(II) complexation by spermine and spermidine has been reported (24–26). Because there has been much recent interest in determining the factors which may influence the biological activity of these entities by altering their state of protonation (23), we wished to investigate the complete species distribution of these Cu(II)–polyamine systems across a wide range of pH.

Chelation by the aliphatic polyamines has been extensively studied following Bjerrum's early work (27). The series $H_2N—(CH_2)_2—[NH—(CH_2)_2]_n—NH_2$, beginning with ethylene diamine ($n = 0$), serves as the most straightforward example of the effect of the number of chelate rings on complex stability (28), while the bidentate diamines $H_2N—(CH_2)_n—NH_2$ demonstrate the role of ring size (29). The complexes of Cu(II) and Ni(II) with 1,3-propanediamine are much less stable than those with 1,2-ethanediamine. The $-\Delta H$ values for binding are larger with propanediamine, in keeping with its stronger basicity, but the stabilities are dominated by the more favorable entropy change when the 5-membered ring is formed (29). Loss of freedom of the ligand is so great with 7-membered ring formation that 1,4-butanediamine (putrescine) does not form Cu(II), Ni(II), or Zn(II) complexes in aqueous solution (29), although these complexes can be isolated from absolute alcohol (30). It has been estimated (24) that diamine–Cu(II) chelate rings of 5, 6, and 7 members add respectively 5.3–7.0, 4.6–6.1, and 2.0–3.0 to the log K_1 value for complex formation.

These considerations suggest the following interpretation of the Cu(II)–polyamine speciation observed here. In the Cu(II)–spermidine system, the $CuHL^{3+}$ complex forms at lower pH, with the 6-membered ring as the anchor site. This allows the stabilization from a second ring to aid formation of the less favorable 7-membered ring, which must form in the CuL^{2+} complex concomitant with a lowering of the highest p*K* by about 3 units. This $CuHL^{3+}$ complex is analogous to the CuH_2L^{4+} species of spermine. Again, in the latter complex, a 6-membered ring must form the anchor site. Failure to observe a $CuHL^{3+}$ species indicates no stepwise folding of the spermine, but rather formation of a second 6-membered ring is the driving force for formation of the CuL^{2+} complex. In the latter, the obligatory 7-membered ring is stabilized by two 6-membered rings and a 3-chelate ring effect. The additional stabilization is reflected in the increased stability constant of the CuL^{2+} species of spermine (log β = 14.7) compared to that of the CuL^{2+} spermidine complex (log β = 11.7). This observation is in contrast to that of Palmer and Powell (26) who report only CuL^{2+} and $CuHL^{3+}$ species in the Cu(II)–spermine system. By pH > 9, hydroxo species $(Cu(OH)L^{+}]$ begin to form in the Cu(II)–spermidine system, while deprotonation of uncomplexed ligand at this higher pH initiates formation of bis complexes. The increased stability of the CuL^{2+} complex of spermine preserves its tetradentate structure until higher pH. No hydroxo species are seen in this system up to pH 10.

The energy of the absorption of the CuL^{2+} complex of spermine (λ_{max} = 564 nm) is consistent with tetracoordination by nitrogen. This solution structure is supported by the crystal structure of spermine Cu(II) perchlorate, which shows square

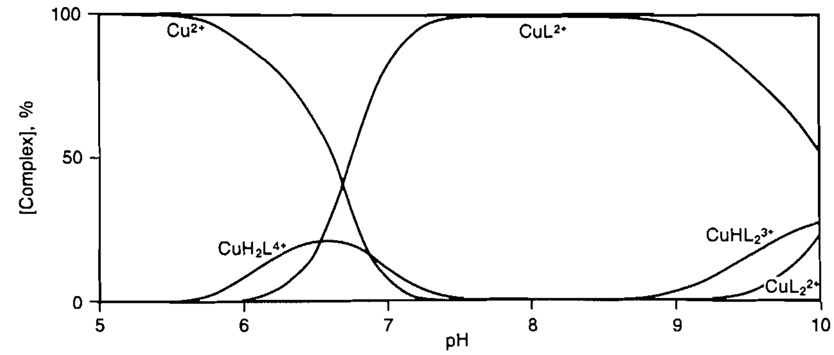

FIG. 5. Species distribution of the Cu(II)–spermine system as a function of pH. L is spermine. From the data of Table 3.

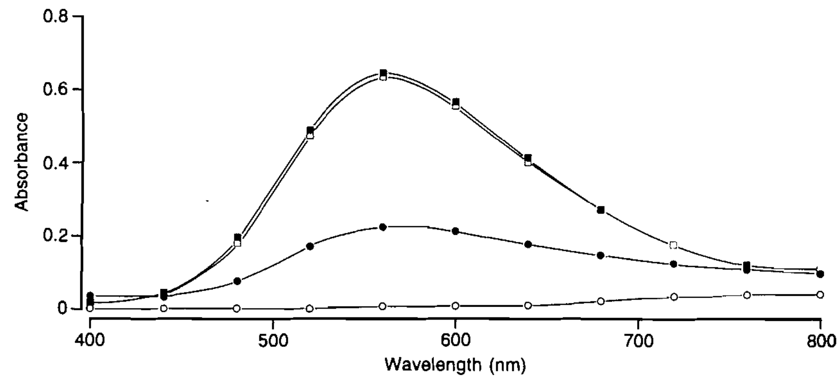

FIG. 6. Absorption spectra of the Cu(II)–spermine system. [Cu] = 4.25×10^{-4} *M*, [spermine] = 2.14×10^{-3} *M*. pH 2.65, ○; pH 6.36, ●; pH 7.36, □; pH 9.54, ■.

planar coordination of Cu by four nitrogen atoms of the same spermine molecule (31). In the Cu(II)–spermidine system, the corresponding CuL^{2+} species is tridentate. The resulting decrease in ligand field strength is reflected in the lowered energy of the transition (λ_{max} = 626 nm), which is lowered further (λ_{max} = 655 nm) when protonation of an amino group presumably removes another coordinating nitrogen atom (i.e. in the $CuHL^{3+}$ complex). The higher energy absorption (λ_{max} = 580 nm) at pH 10 supports the existence of bis complexes with 4 nitrogen ligands in a square planar geometry around Cu(II). This geometry may be more distorted than in the CuL^{2+} complex of spermine, in order to minimize intermolecular steric repulsion. In Cu(II)–spermine, geometrical requirements of accommodating the 7-membered ring are reflected in torsional strain and shortening of the C(5)—C(6) bond in the crystal (31).

The formation of stable metal complexes of spermine and spermidine *in vivo* could have profound implications for their biological function. Interaction of these polyprotonated molecules with nucleic acids at neutral pH is thought to underlie their growth regulating properties (15). Takeda *et al.* (23) have pointed out that dynamic conformational control of DNA by interaction with polyamines is likely in turn governed by the effects on protonation of small changes in the local environment, such as pH, ionic strength, and dielectric constant. To this list may now be added the more profound effect of local concentration of metal ions.

The microcomputer FP minimization of analytical potentiometric data has been applied with success to the above systems. Evaluation of both experimental and mathematical procedures has come primarily from the analysis of the Ni(II)–glycine system. This system was chosen as the subject of an interlaboratory study (14) as it provided a sufficient complexity, range of pH, and of β values, and at the same time, is a well defined system. The excellent agreement achieved by seven independent laboratories, using a variety of experimental and calculation techniques, demonstrates the variety of approaches which may be applied with success to the determination of stability constants. Interlaboratory differences in electrode type and response, liquid junction potential, electrode standardization, titration procedure, and reagent purity are clearly small. Against this yardstick, the methods reported here compare favorably.

Despite these successes, some unsolved problems remain in attempts to derive reliable stability constants of the more complicated metal complexes of biological relevance. These problems fall into two categories, the first resulting from the concentration dependence of the species distribution, the second from the poorly defined criteria for a satisfactory set of species to model the experimental data.

In a given metal : ligand system, the species distribution will depend on the ratio of the concentrations of metal-to-ligand. A more complete description, then, would be given by determining the surface in [pH, concentration, M:L ratio] space. The method of analytical potentiometry assumes that all titrations are done on a flat region of the [concentration, M:L ratio] plane, and it has been pointed out (10) that this is a potential source of experimental error. At present, there is no method for determining this surface for a sufficiently interesting system, with a manageable number of titrations.

The second type of outstanding problem has three facets. (*a*) It is never possible to know that one has found the best set of species for a given data set. It is not computationally feasible to check all combinations of possible species for any but the simplest systems, and one must always revert to some chemical intuition in deciding which combinations to minimize. The economy of microcomputer utilization encourages checking of an expanded set of possible species, however. Execution times for DFPMIN allow analysis of a large number of combinations. (*b*) The existence of false or degenerate least squares solutions could arise from systematic or random experimental errors. In light of this point, confidence in a given species distribution will increase as it is reproduced in independent studies, and ultimately corroborated by structural evidence. (*c*) Equation [1] usually represents an inconsistent set of equations. The least squares problem posed by eq. [1] is that of finding the norm $\|\mathbf{C}\beta - m_b\|$, which has an infinite number of solutions when the rank of $\mathbf{C} \neq n$, the number of species (20). This situation would be unlikely to arise unless the number of species was large or the pH range narrow, so that k approached n. Unless the rank of $\mathbf{C} = n$, there will be an infinite number of solution vectors $|\beta\rangle$, and the problem is one of finding the shortest.

Conclusions

1. A series of BASIC programs have been written which employ the Fletcher–Powell minimization method and allow metal speciation analysis to be performed on a microcomputer.

2. These programs have successfully solved the Ni(II)–glycine system. This system is one of the most carefully studied of such problems, and provides an excellent test of a given method of analysis.

3. A brief discussion has been given of some unsolved problems pertaining to the potentiometric determination of stability constants.

4. The polyamines spermidine and spermine have been shown to form complexes with Cu(II) in aqueous solution. The stability constants of these complexes have been derived by the above methods.

5. Interaction of Cu(II) with these biological polyamines causes their deprotonation at physiological pH. This could significantly influence the mechanism of dynamic control these entities exert upon DNA.

Thermodynamic dissociation constants $({}_sK)_m$ of 2,4,6-trinitrophenol have been determined at 25°C in aqueous mixtures containing 30, 50, 70, and 90% by weight of methanol and 30, 50, 70, 90, and 95% by weight of ethanol by spectrophotometric method. Solvent effect on the dissociation of the acid: $\delta(\Delta G^0) = 2.303RT[p({}_sK)_N - p({}_wK)_N]$ shows an unusual behaviour, the value decreases and passes through a minimum and ultimately becomes positive as the proportion of organic component in the solvent is progressively increased. The results have been compared with those of other uncharged acids like acetic acid, benzoic acid available from literature. The difference of behaviour (minimum characteristic in $\delta(\Delta G^0)$ curve) has been attributed to very strong dispersion interaction of trinitrophenolate anion with the organic component of the solvent. The overall behaviour of this acid indicates that solvent effect is an involved process being guided by electrostatic and dispersion interactions besides relative solvent basicities.

A. L. DE et A. K. ATTA. Can. J. Chem. **63**, 3129 (1985).

Faisent appel à des méthodes spectroscopiques et opérant à 25°C, on a étudié les constantes thermodynamiques de dissociation $({}_sK)_m$ du trinitro-2,4,6 phénol dans des solutions aqueuses contenant 30, 50, 70 et 90% en poids de méthanol et 30, 50, 70, 90 et 95% en poids d'éthanol. L'effet du solvant sur la dissociation de l'acide $\delta(\Delta G^0) = 2{,}303RT[p({}_sK)_N - p({}_wK)_N]$ montre un comportement inhabituel, la valeur diminue, passe par un minimum et finalement devient positive lorsqu'on augmente progressivement la proportion de composé organique du solvant. On a comparé les résultats avec ceux d'autres acides non chargés tels l'acide acétique, l'acide benzoique, répertoriés dans la littérature. On a attribué la différence de comportement (minimum caractéristique dans la courbe de $\delta(\Delta G^0)$ à une interaction de dispersion très forte de l'anion trinitrophénolate avec la partie organique du solvant. Le comportement global de cet acide indique que la participation de l'effet du solvant est gouvernée par des interactions de dispersion et électrostatiques en plus de la basicité relative du solvant.

Introduction

It is well known that the dissociation of acids is a complex phenomenon dictated by various types of interactions of the species involved in the ionization equilibrium. To understand the solvent effect on the dissociation equilibria, dissociation constants of some monopositively charged acids, nitroanilinium ions were determined earlier (1, 2) in some mixed solvents. This paper reports the dissociation constant of uncharged acid, 2,4,6-trinitrophenol, in aqueous mixtures of methanol and ethanol.

Experimental

Purification (3) of alcohols and water and the preparation (4) of mixed solvents as well as the solutions of HCl have been described. Synthetically prepared methanol (G. R., E. Merck) was refluxed with the metal magnesium and then fractionally distilled, the initial and final quarters of the distillate being rejected. The characteristic properties of methanol are density (25°C) = 0.7867 g mL^{-1}; bp (1 atm) = 64.5°C. Anhydrous ethanol prepared by fermentation (Bengal Chemicals & Pharmaceuticals Ltd., a Government of India Enterprise) was dried over freshly ignited calcium oxide for 3 days, decanted, and then distilled. The distillate was then successively refluxed (~12 h) and distilled over the metal magnesium and KOH. The finally distilled sample was preserved in a desiccator. The properties of ethanol are density (25°C) = 0.7851 g mL^{-1}; bp (1 atm) = 78.3°C. Recently Deshmukh and Coetzee (5) have shown that synthetically prepared alcohols contain 10^{-4} to 10^{-5} M alkylamine even after purification by standard methods. The maximum error introduced in the present study due to residual amine is, however, negligible being of the order of 0.001 to 0.004 pK unit depending on the proportion of alcohol in the solvent. 2,4,6-Trinitrophenol (Anal R) was used after recrystallizing twice from aqueous 95% ethanol and drying *in vacuo*. The dissociation constant in these aqueous mixtures of methanol and ethanol were determined spectrophotometrically using unbuffered solutions of HCl at different concentrations as in cases of some charged (1, 2) acids. A series of solutions were prepared in 10 cm^3 amounts by adding weighed amounts of HCl solution, indicator solution and the appropriate solvent. The spectral absorbances were determined at 25 ± 0.2°C with Carl Zeiss Jena (Germany, DDR) spectrophotometer with 1 cm cells at 355 nm where the absorbance shows a maximum for the base form. The limiting absorbances of the acid and base forms were determined in very concentrated solution of HCl (4 to 6 M) and in very dilute solution of sodium hydroxide (about 0.001 M), respectively (6), and absorbance readings were corrected, where necessary, for the identical concentration of the indicator. The indicator concentrations used in various solvent compositions were in the range 2×10^{-5} to 3×10^{-5} M.

The $p({}_sK)_m$ values in the molar scale were obtained by extrapolation of the plots of $p({}_sK)'_m$ of eq. [1] against μ to $\mu = 0$.

$$[1] \quad p({}_sK)'_m = -\log m_{SH_2^+} - \log[\alpha/(1-\alpha)] + 2S_f\sqrt{\mu}(1 + Ba_0\sqrt{\mu})^{-1} = p({}_sK)_m + f(\mu)$$

where $m_{SH_2^+}$ is the effective molality of H$^+$ in the solution, α and $1 - \alpha$ are the fractions of the indicator species present in ionic form (A$^-$) and neutral form (HA), S_f and B are Debye–Hückel constants, a_0 is the ion-size parameter, μ is the ionic strength being equal to $\mu = m_{HCl}, d_s$ where d_s is the density of the solvent. The concentration of the ionic species obtained from dissociation of acid being extremely small with respect to that of m_{HCl}, their contribution to ionic strength can be neglected. As indicator concentration is very small the value of $m_{SH_2^+}$ is practically the same as that of m_{HCl}. Density and dielectric constant values necessary for calculation of Debye–Hückel constants were available from literature (7). The values $\alpha/(1-\alpha) = (A - A_1)/(A_2 - A)$ were obtained from the absorbances A_1, A_2, and A of the completely acid form (HA), completely base form (A$^-$), and the mixture of the two forms measured at an identical concentration of the indicator in the same cell. In the calculation of $p({}_sK)'_m$, a_0 was taken to be zero, because this numerical value resulted in linear $p({}_sK)'_m$ plots.

Results

The values of m_{HCl}, spectral absorbances (A) and $p({}_sK)'_m$ are given in Tables 1 and 2. The $p({}_sK)_m$ values obtained in the molal scale in different solvents are given at the bottom of the column of $p({}_sK)'_m$. The uncertainty in the $p({}_sK)_m$ values is about ±0.02 unit. The literature value (8) of pK in water is 1.02 which compares favorably to our experimental value of 1.01.

Discussion

As a basis for comparison (9) in different solvents, the molal values of $p({}_sK)_m$ have been converted to the mole fraction scale $p({}_sK)_N$ by the usual relation (10) and are recorded in Table 3. The solvent effect on the dissociation of 2,4,6-trinitrophenol (HA) has been calculated (1) by using eq. [2].

$$[2]\quad \delta(\Delta G^0) = {}_s\Delta G^0 - {}_w\Delta G^0 = 2.303RT[p({}_sK)_N - p({}_wK)_N]$$

The values of $\delta(\Delta G^0)$ are recorded in Table 3.

$\delta(\Delta G^0)$ values on the mole fraction scale are plotted as a function of the mol% of nonaqueous component in Fig. 1. For comparison, the corresponding plots for acetic acid and benzoic acid are also shown. For acetic acid and benzoic acid $p({}_sK)$ values were reported in literature (11*b*) on molal scale and the values were converted to the mole fraction scale for computation of $\delta(\Delta G^0)$ values (Table 3). In case of trinitrophenol, $\delta(\Delta G^0)$ decreases when methanol or ethanol is added to a solvent that is initially pure water and passes through a minimum when mole fraction of nonaqueous component is about 0.3 and subsequently, reaches a positive value when mole fraction of water in the solvent becomes low. The $\delta(\Delta G^0)$ curve in ethanol–water lies below that in methanol–water indicating that the acid is stronger in ethanol–water for similar mol% nonaqueous component. This behaviour of trinitrophenol is in sharp contrast with those observed for uncharged acids like acetic acid, benzoic acid where no minimum in $\delta(\Delta G^0)$ curve appears and $\delta(\Delta G^0)$ rises from the very beginning (Fig. 1). In view of the fact that addition of methanol or ethanol to water produces a series of solvents of progressively decreasing dielectric constant and that the dissociation of HA is an ionogenic process, being accompanied by the creation of extra charges it is expected from electrostatic consideration that $\delta(\Delta G^0)$ will increase with increasing organic mol%. Minimum characteristic for trinitrophenol thus indicates highly specific nature of interaction of some of the species involved in the ionization process with the solvent.

TABLE 3. Values of $p({}_sK)_N$ for 2,4,6-trinitrophenol and $\delta(\Delta G^\circ)$ for 2,4,6-trinitrophenol, acetic acid, and benzoic acid in methanol–water and ethanol–water solvents at 25°C ($\delta(\Delta G^\circ)$ values are in mole fraction scale)

*Reference 11(*a*).

Solvent effect on the dissociation of HA is actually the resultant of the free energy transfer values of the individual species involved in the ionization and is given by (7, 12)

[3] $\delta(\Delta G^0) = \Delta G_t^0(H^+) + \Delta G_t^0(A^-) - \Delta G_t^0(HA)$

where $\Delta G_t^0(i)$ represents the free energy change accompanying the transfer of one mole of species i from the standard state in water to the standard state in the solvent concerned, both on the mole fraction scale.

Since $\Delta G_t^0(H^+)$ is common for all acids in a particular solvent system, it is evident that relative interaction of acid (HA) and its conjugate base (A^-) is very much different for 2,4,6-trinitrophenol as compared to that for acetic acid or benzoic acid. $\Delta G_t^0(H^+)$ values for methanol–water and ethanol–water solvent systems based on different extrathermodynamic assumptions are available in literature but since tetraphenyl borate assumption is most reasonable and consistent (13, 14) and is widely used (15, 16) we have utilized the $\Delta G_t^0(H^+)$ values based on *RE* (*RE* = Ph_4PBPh_4) (Ph = phenyl) based on the assumption that $\Delta G_t^0(Ph_4P^+) = \Delta G_t^0(Ph_4B^-) = \frac{1}{2}\Delta G_t^0(Ph_4PBPh_4)$ available from literature (15) to compute $\Delta G_t^0(A^-) - \Delta G_t^0(HA)$. For ethanol–water, however, reported values based on average of Ph_4PBPh_4 and Ph_4AsBPH_4 assumptions (15) have been used (results calculated via the two assumptions, however, differ by small amount which is within the range of experimental error (16).

$\Delta G_t^0(A^-) - \Delta G_t^0(HA)$ for 2,4,6-trinitrophenol, acetic acid, and benzoic acid, are reported in Table 4 which shows that for trinitrophenol it is negative in the solvent of lower mol% nonaqueous component and then becomes increasingly positive as the proportion of organic component increases in the solvent and thus passes through a minimum. Initial decrease of $\Delta G_t^0(A^-) - \Delta G_t^0(HA)$ suggests that $\Delta G_t^0(A^-) < \Delta G_t^0(HA)$; that is, trinitrophenolate anion is more stable than its conjugate acid. $\Delta G_t^0(HA)$ for trinitrophenol is likely to be negative since it contains an aromatic ring for dispersion interaction with the organic component of the solvent mixture. Thus $\Delta G_t^0(A^-)$ is appreciably large and negative and this occurs in spite of the positive contribution to the free energy transfer due to electrostatic interaction. Free energy of 2,4,6-trinitrophenolate ion which is delocalised oscillator is very much lowered by strong dispersion interaction with organic component of the solvent mixture (11, 17, 18). The very high polarisability of delocalized electrons in the trinitrophenolate ion promotes interaction with localized dispersion centre in nearby solvent molecules (11, 17, 18). The effective density of dispersion centres in the solvent molecules being found to increase in the sequence $H_2O < CH_3OH < C_2H_5OH$, dispersion interaction will be maximum in ethanol–water mixture. The minimum in $\Delta G_t^0(A^-) - \Delta G_t^0(HA)$ results from two opposing effects. $-\Delta G_t^0(HA)$ is positive and its contribution due to electrostatic

*Reference 15.

interaction to $\Delta G_t^0(A^-)$ is also positive, and their combined contribution simultaneously opposes the negative contribution to $\Delta G_t^0(A^-)$ due to very strong dispersion interaction leading to a minimum in $\Delta G_t^0(A) - \Delta G_t^0(HA)$.

For acetic acid and benzoic acid, $\Delta G_t^0(A^-) - \Delta G_t^0(HA)$ is very positive (Table 4) and is probably primarily due to electrostatic interaction of A^-. Unlike delocalised oscillator trinitrophenolate ion, the localized oscillator acetate and benzoate have weaker (11) dispersion interaction with organic component of the solvent mixture. The dispersion interactions of A^- and HA are not much different as in case of nitrophenol and electrostatic contribution to $\Delta G_t^0(A^-)$ is primarily responsible for variation of $\Delta G_t^0(A^-) - \Delta G_t^0(HA)$ in the case of acetic acid and benzoic acid.

In addition to the different forms of interaction described, hydrogen bonding interaction with negative charge oxygen centres of HA and A^- also operate, but this effect is not likely to contribute much to the combined term $\Delta G_t^0(A^-) - \Delta G_t^0(HA)$ in the aqueous mixtures of ethanol or methanol and particularly it has little role in the making of large difference of dissociation behaviour between 2,4,6-trinitrophenol and acetic acid or benzoic acid. Interaction of H^+ is reflected in $\Delta G_t^0(H^+)$ which may be taken as a measure of relative solvent basicities (5, 7). The detailed interpretation of the behaviour of $\Delta G_t^0(H^+)$ in aqueous mixtures of methanol and ethanol have been presented (15). The overall dissociation behaviour of different uncharged acids in aqueous mixtures of methanol and ethanol is thus understood in terms of interactions of the species HA, A^- and H^+ reflected in $\Delta G_t^0(i)$ of eq. [3].

Assignment of the deoxyribofuranose protons in short DNA oligomers by techniques such as homonuclear shift-correlated (COSY) 2-D nmr becomes difficult when there are overlapping diagonal signals. To solve this problem we have applied the method of relayed coherence transfer 2-D nmr to generate cross-peaks between protons such as 1′ and 3′, 3′ and 5′ and 5″ which are not coupled but belong to the same spin system. Plotting cross-sections through the diagonal peaks of the 3′ protons produced completely resolved spectra of the deoxyribofuranoside protons for each nucleotide. Chemical shifts were assigned by comparing each cross-section with the one-dimensional spectrum. A new phase-cycling procedure for the transmitter and receiver was determined and allowed data acquisition with suppression of p-type peaks. This technique is illustrated by the spectra of deoxycytidine and the deoxytriribonucleotide, dCpTpGp.

DONALD W. HUGHES, RUSSELL A. BELL, THOMAS NEILSON et ALEX D. BAIN. Can. J. Chem. **63**, 3133 (1985).

L'attribution des protons du déoxyfurannose des petits oligomères de l'ADN, en faisant appel à des techniques telle la spectroscopie de corrélation (COSY) en rmn 2-D, devient difficile lorsque les signaux diagonaux se recouvrent. Pour palier à cet inconvénient, nous avons utilisé la méthode du transfert de cohérence par relais en rmn 2-D pour générer des pics de référence entre les protons 1′ et 3′, 3′ et 5′ et 5″ qui ne sont pas couplés, mais qui appartiennent au même système de spin. La courbe des sections droites à travers les pics diagonaux des protons 3′ produit, pour chaque nucléotide, un spectre complètement résolu des protons du déoxyribofurannoside. On a attribué les déplacements chimiques en comparant chaque section droite avec un spectre unidimensionnel. On a déterminé une nouvelle méthode en phase cyclique pour l'émetteur et pour le récepteur. Elle permet l'acquisition de données en supprimant les pics du type p. Les spectres de la déoxycitidine et du déoxytriribonucléotide dCpTpGp illustrent cette technique.

Introduction

The structure in solution of DNA oligomers is currently undergoing intensive study by nmr spectroscopy. Increased interest in this area has resulted primarily from the improved chemical synthesis of DNA oligomers and from the ability of high field ^{1}H nmr to observe the conformational changes in the deoxyribofuranoside ring and in the phosphate backbone upon the binding of various antitumor drugs (1–4). Reid *et al.* (5) have reported a difference between the solution and solid-state helical structures of a self-complementary octamer. Therefore, it may be necessary to obtain a detailed knowledge of the structure in solution of certain base-paired oligomers even though the solid-state X-ray structure may be available.

Prior to the determination of the solution structure of an oligomer by nmr, the ^{1}H resonances must be correctly assigned to a specific nucleotide in the sequence. Several methodologies are available for analyzing one-dimensional ^{1}H nmr spectra and these include incremental analysis (6, 7), chemical shift parameters (8), and a set of empirically derived rules based on observations of several DNA oligomers (9). These techniques are generally restricted to high temperature spectra (≥70°C) of single strands where base stacking and base pairing are reduced. Nuclear Overhauser effect (nOe) difference spectroscopy has been used to sequence base-paired DNA oligomers (5, 10). Considerable growth has occurred in the application of two-dimensional nmr techniques because the improved resolution and high information content facilitates the assignment of the deoxyribofuranoside protons. The connectivity and assignment of the deoxyribofuranoside protons is usually achieved by COSY (11–14) and ^{1}H–^{31}P heteronuclear shift-correlated experiments (12, 15, 16). Two-dimensional double-quantum ^{1}H spectra of DNA tetramers were recently reported (17). Information on the sequence and spatial relationship of nucleotides in base-paired duplexes can be obtained by 2-D nOe methods (11, 13, 18–20).

A two-dimensional nmr experiment that can aid in assigning the ^{1}H spectra of short DNA oligomers is relayed coherence transfer. Initially reported by Bolton and Bodenhausen (21, 22) and Eich *et al.* (23), relayed coherence transfer is a modification of the shift-correlated experiments that produced cross-peaks between nuclei which are not coupled but which belong to the same spin system. The additional cross-peaks eliminate the uncertainties encountered in the COSY experiment that arise when different spin systems have protons with identical chemical shifts on the diagonal, resulting in several indistinguishable connectivities. Recent applications of homonuclear relayed coherence transfer have dealt with the assignment of the ^{1}H spectra of proteins (24, 25). We report here the use of homonuclear relayed coherence transfer 2-D nmr in assigning the deoxyribofuranoside ^{1}H resonances of short DNA oligomers. A phase-cycling procedure for the transmitter pulses and receiver is also presented, which allows suppression of p-type signals.

Relayed coherence transfer spectra are obtained by mod-

ifying the mixing pulse of the COSY experiment as follows.

Homonuclear shift-correlated (COSY):

$$90 - t_1 - 90 - \mathrm{ACQ}$$

Relayed coherence transfer:

$$90_{\phi^1} - t_1 - 90_{\phi^2} - \tau - 180_{\phi^3} - \tau - 90_{\phi^3} - \mathrm{ACQ}_{\theta}$$

To illustrate the effect of the relayed coherence transfer pulse sequence, the example of the three-spin system formed by protons 1′, 2′, and 3′ of the deoxyribofuranoside ring (Fig. 1) will be used. Protons 1′ and 2′, and 2′ and 3′ have three-bond coupling constants, while there is no observed coupling between 1′ and 3′. The first 90° pulse in the relayed coherence transfer experiment creates transverse magnetization, which is allowed to precess during the evolution period t_1. The second 90° pulse acts in a manner similar to the COSY mixing pulse in that magnetization from the transitions of the 1′ proton is transferred to the connected transitions of 2′. A 180° pulse is inserted between the second and third 90° pulses in order to remove the effects of chemical shift modulation during this time period. The final 90° pulse transfers magnetization from the 2′ transitions, which now contain frequency information from 1′, to the 3′ proton transitions. The signal from 3′ will therefore be modulated at frequencies corresponding to both 1′ and 2′ and result after 2-D Fourier transformation in a cross-peak at $\omega_1 = \delta 1'$ and $\omega_2 = \delta 3'$. COSY cross-peaks from coupled protons are also observed because they arise from transverse magnetization components not affected by the final pulse (25).

The intensities of the relayed coherence transfer cross-peaks depend strongly on the exact nature of the spin system, since additional spin couplings can provide additional routes for the

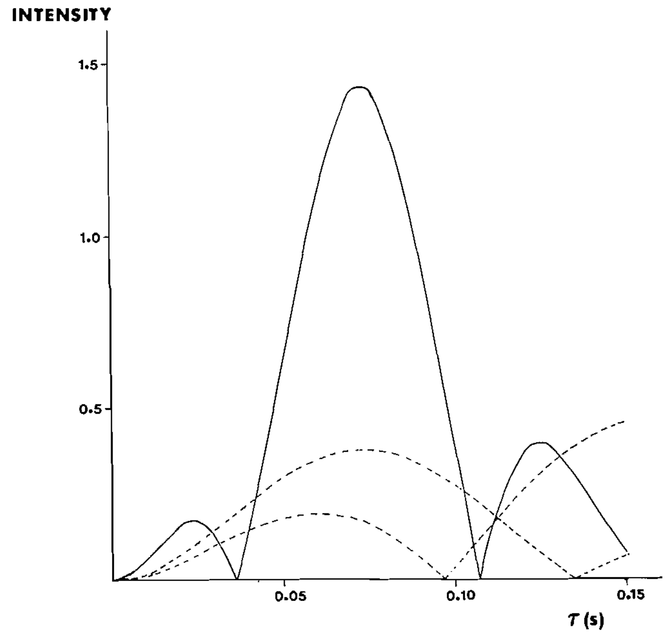

FIG. 2. Intensity of relayed cross-peaks as a function of τ for the pathway $1' \begin{smallmatrix}\nearrow 2' \searrow\\ \updownarrow\\ \searrow 2'' \nearrow\end{smallmatrix} 3'$ (solid line) and $3' \rightarrow 4' \begin{smallmatrix}\nearrow 5'\\ \searrow 5''\end{smallmatrix}$ (dashed line with higher intensity represents the 3′ to 5″ cross-peak) in deoxycytidine. Curves were calculated from eqs. [1] and [3] using an estimated T_2 value calculated from $T_2 = 1/\pi \cdot \nu_{1/2}$ with the halfwidth, $\nu_{1/2}$, of 1.0 Hz.

magnetization to follow during relayed coherence transfer (26, 27). In the present case we are interested in the relay of magnetization from A to X in an AMX spin system where $J_{AX} = 0$. If the spin M is also coupled to nuclei K, L, . . . etc. (other than A and X), then the efficiency of a relayed coherence transfer is given by (26–28)

$$[1] \quad \sin(\pi J_{AM} \tau) \sin(\pi J_{MX} \tau) \prod_{i=K,L,\ldots} \cos(\pi J_{Mi} \tau) \times \exp(-\tau/T_2(\mathrm{M}))$$

where τ is the fixed delay in the relayed coherence transfer pulse sequence and $T_2(\mathrm{M})$ is the spin–spin relaxation time of nucleus M. In particular, the intensity of the relay cross-peak between the 1′ proton and 3′ via 2′ is proportional to

$$[2] \quad \sin(\pi J_{1'2'} \tau) \sin(\pi J_{2'3'} \tau) \cos(\pi J_{2'2''} \tau) \exp(-\tau/T_2(2'))$$

There is an additional route for relaying the 1′ proton magnetization to 3′ and that is via 2″, which results in an efficiency given by an equation similar to eq. [2]. These two independent routes can be combined to provide an overall efficiency for the 1′ to 3′ relayed coherence transfer given by (27)

$$[3] \quad [\sin(\pi J_{1'2'} \tau) \sin(\pi J_{2'3'} \tau) \exp(-\tau/T_2(2')) + \sin(\pi J_{1'2''} \tau) \sin(\pi J_{2''3'} \tau) \exp(-\tau/T_2(2''))] \times \cos(\pi J_{2'2''} \tau)$$

Figure 2 shows a plot, derived from the above equations, of intensity versus τ for the 1′ to 3′ (solid line) and 3′ to 5′ and 5″ (dashed lines) relayed cross-peaks using the coupling constants for deoxycytidine (Table 1). Since the intensities of the

H-5″	3.737	$^3J_{56}$	7.6

peaks depend on the nature of the spin system and all the coupling constants, the choice of an optimum value for τ almost requires complete knowledge of the spin system before the experiment starts. Furthermore, the range of coupling constants and spin systems in deoxyribofuranoside molecules means that an optimum τ which provides both uniform magnetization transfer and minimum effect of T_2 relaxation is impossible for the whole oligomer. The non-uniform nature of the magnetization transfer can be seen in Fig. 2 where the relayed cross-peaks reach their maximum value near $\tau = 0.07$ s; however, there is considerable variation in their relative intensities. A value of τ was therefore chosen from an average of the coupling constants, since although the functional form of eq. [1] may be complicated there are relatively few values of τ for which eq. [1] is close to zero. As in other types of two-dimensional spectroscopy, the absence of a correlation peak does not mean the absence of a correlation.

A complex pulse sequence such as this not only creates the signals needed to make the correlation, but also many artifacts. The main type of artifact that needs to be suppressed is the so-called "p-type" peaks which appear symmetrically on the other side of $F_1 = 0$ from the desired peaks. By repeating the pulse sequence with different r.f. phases it is almost always possible to suppress the undesirable peaks which could lead to spurious correlations. The concept of a coherence pathway (29, 30) was used in designating the sequence of r.f. phases for this pulse sequence.

The spectra of deoxycytidine and the deoxytriribonucleotide,[3] dCpTpGp, were used to illustrate the application of relayed coherence transfer in assigning deoxyribofuranoside resonances.

Experimental

All ^{1}H nmr spectra were recorded at 250.13 MHz on a Bruker WM-250 spectrometer. The single-pulse spectra for deoxycytidine were recorded in 16 scans over a sweep width of 1474.93 Hz (5.554

[3] Abbreviations used: 2′-Deoxyribosyl 5′-dCpTpGp-3′. The deoxyoligoribonucleotide is written in the normal 5′ → 3′ sequence, and the bases are numbered from the 5′-end: dCpTpGp.

s acquisition time) while the dCpTpGp spectra were acquired in 48 scans using a 1748.25-Hz sweep width (4.686 s acquisition time). Spectra were acquired in 16 K data points. Suppression of the HDO resonance was achieved by irradiation during the 2.0-s relaxation delay prior to acquisition. Sample temperatures were ambient temperature (23°C) for deoxycytidine and 40.3 ± 1.0°C for dCpTpGp. The latter temperature was maintained by a Bruker BVT-1000 variable temperature unit and checked by thermocouple measurement. The free induction decays were processed using Gaussian multiplication for resolution enhancement and zero-filled to 32 K before Fourier transformation.

The ^{1}H shift-correlated (COSY) 2-D nmr spectra were acquired using the pulse sequence:

$$90^\circ - t_1 - \alpha^\circ - \mathrm{ACQ}$$

where $\alpha = 90^\circ$ for the deoxycytidine experiment and $\alpha = 45^\circ$ for dCpTpGp. The 90° pulse width was 6.4 μs. Relayed coherence transfer 2-D nmr experiments used the pulse sequence:

$$90^\circ_{\phi_1} - t_1 - 90^\circ_{\phi_2} - \tau - 180^\circ_{\phi_3} - \tau - 90^\circ_{\phi_3} - \mathrm{ACQ}_\theta$$

where $\tau = 0.046$ s. The phase cycling ϕ_1, ϕ_2, ϕ_3, and θ are given in Table 2. The HDO resonance was suppressed by pre-saturation during the 2.0-s relaxation delay and the evolution and fixed delay times prior to acquisition. The 2-D spectra of deoxycytidine were obtained in 16 scans for each of the 128 FID's which contained 512 data points in F2. Zero-filling in the F1 dimension during 2-D Fourier transformation produced a 256 × 256 data matrix with a digital resolution of 5.761 Hz/point in both dimensions. The dCpTpGp 2-D spectra consisted of 256 FID's (1 K data points in F2) acquired in 48 scans each. The data were zero-filled in F1 to a 512 × 512 matrix when transformed and the resolution was 3.415 Hz/point. All spectra were transformed with the application of the squared sine-bell function in both dimensions followed by symmetrization of the transformed matrix.

Samples were lyophilized twice from 99.8% D_2O and then dissolved in 100% D_2O (MSD Isotopes) to concentrations of 0.13 *M* for deoxycytidine and 0.017 *M* for dCpTpGp. Chemical shifts are reported in ppm relative to DSS (sodium 4,4-dimethyl-4-silapentan-1-sulfonate) using *tert*-butyl alcohol-OD (1.231 ppm) as internal reference.

Results and discussion

COSY and relayed coherence transfer 2-D nmr spectra were initially recorded on deoxycytidine (Fig. 1) in D_2O. Since the relayed coherence transfer experiment creates additional cross-peaks, a mononucleoside with well-resolved riboside proton

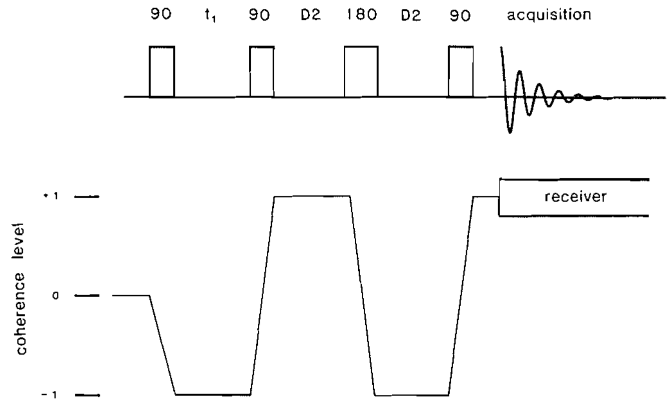

FIG. 4. Coherence pathway for the desired signals in the homonuclear relayed coherence transfer experiment. The solid line traces the changes in coherence level (see ref. 29) during the pulse sequence depicted at the top of the diagram. The phase cycling procedure in Table 2 allows this pathway to survive, but suppresses pathways that include coherence level +1 during the t_1 delay.

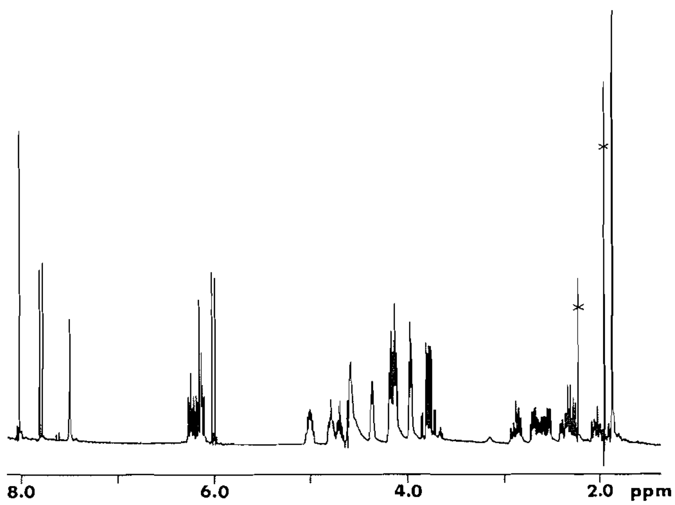

FIG. 5. The 250-MHz ^{1}H nmr spectrum of dCpTpGp in D_2O at 40.3°C. Peaks marked with (×) are impurities.

resonances was examined first in order to avoid any complications arising from overlapping multiplets. The chemical shifts and coupling constants for deoxycytidine are presented in Table 1 and the assignments are shown on the one-dimensional spectrum in Fig. 3a. Pyrimidine protons H-5 and H-6 form an AX spin system. The resonances from the seven deoxyribofuranoside protons can be grouped into three spin systems of the type ABX or ABM as follows: 1′, 2′, and 2″; 3′, 2′, and 2″; 4′, 5′, and 5″. From the contour plot of the COSY spectrum in Fig. 3a, the connectivity of the deoxycytidine riboside protons can be worked out by locating the appropriate cross-peaks indicated by the solid line. Cross-peaks of relatively high intensity were observed between 1′ and 2′, 2″ protons and similarly between 3′ and 2′, 2″. The digital resolution was insufficient to resolve the AB coupling between 2′ and 2″ protons. The connectivity pathway can be completed by following the 3′–4′ cross-peak through the 4′ diagonal peak to the cross-peak between the 4′ and 5′, 5″ protons.

With the connectivities between directly coupled riboside protons established from the COSY spectrum, the relayed coherence transfer experiment was then performed. The fixed

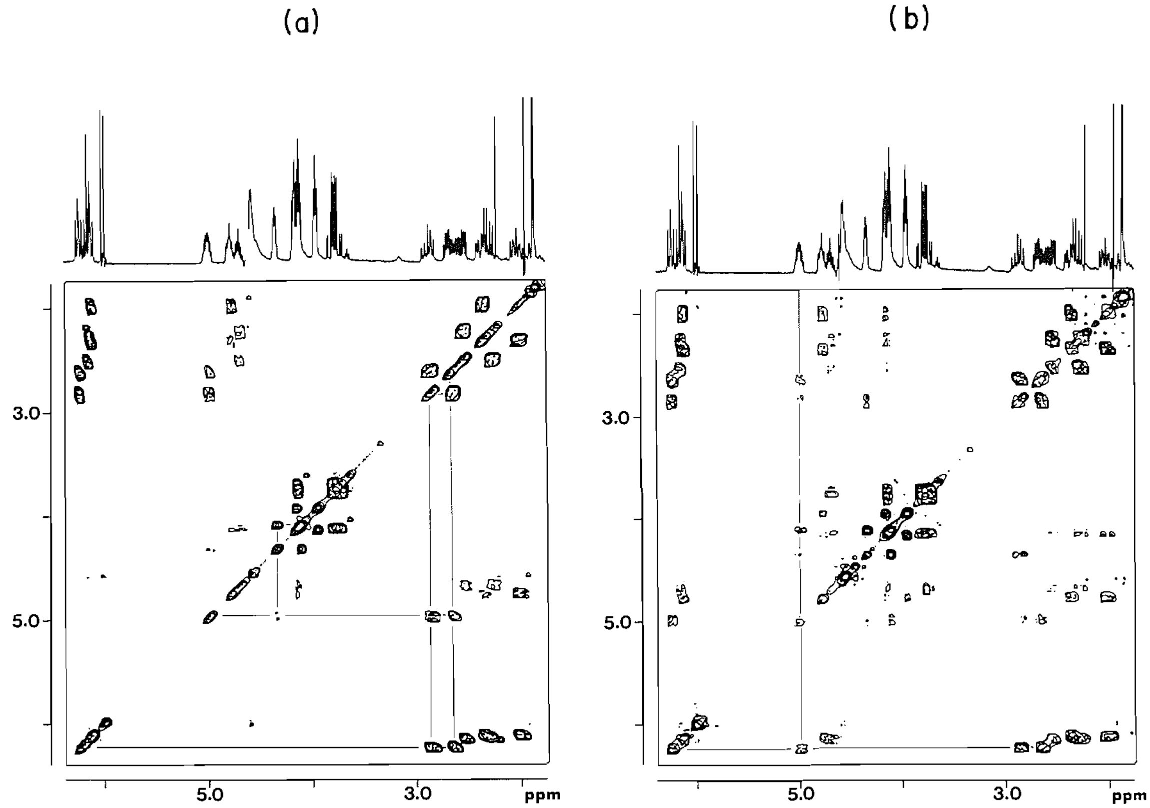

FIG. 6. (a) Contour plot of the 250-MHz ^{1}H COSY-45 2-D nmr spectrum of the deoxyribofuranoside protons of dCpTpGp in D_2O at 40.3°C. The solid line indicates the connectivity pathway through the deoxyguanosine furanoside protons. (b) Contour plot of the 250-MHz ^{1}H relayed coherence transfer 2-D nmr spectrum of dCpTpGp at 40.3°C. The vertical line indicates the COSY and relayed coherence transfer cross-peaks to the deoxyguanosine H-3′.

delay times in the pulse sequence were adjusted to produce a relayed coherence transfer cross-peak between the 1′ and 3′ protons. The advantages of a cross-peak between these protons are the large separation of the anomeric proton resonance from the other riboside proton signals and, in oligomers, the 1′ resonances are generally not overlapped. An additional advantage was that the 3′ proton chemical shift difference between phosphorylated and non-phosphorylated nucleosides could be used to identify the 3′-terminal nucleotide 1′ and 2′, 2″ protons.

The coherence pathway for the relayed transfer experiment is given in Fig. 4. The desired signals are those that are in coherence level -1 during the t_1 delay and then follow the solid line to the receiver; the p-type peaks arise from signals that are in coherence level $+1$ during t_1. There are three major routes by which the p-type signals can reach the receiver, and it can be shown by the methods in ref. 29 that the phase-cycling procedure in Table 2 eliminates all of them.

Using the phase-cycling technique in Table 2 and the fixed delay τ as 0.046 s, the relayed coherence transfer 2-D spectrum of deoxycytidine (in Fig. 3b) was acquired. The relayed coherence transfer cross-peak between 1′ and 3′ was observed along with the COSY cross-peaks. By drawing a horizontal line through the 1′–3′ cross-peak as shown in Fig. 3b, it is possible to identify four of the seven protons of the deoxyribofuranoside spin system. The particular value of τ used also gives a relatively intense cross-peak between 3′ and the 5′, 5″ protons, even though this is a different spin system (27). This additional relayed coherence transfer cross-peak arises because the 3′ proton is actually part of two magnetization transfer pathways: one from 1′ through 2′, 2″ to 3′ and the other from 3′ through 4′ to the 5′, 5″ protons. The delay τ of 0.046 s provides a balanced magnetization transfer throughout the entire deoxyriboside spin system and is derived from an average of all the deoxyriboside coupling constants of 5.5 Hz. From Fig. 2 it can be seen the $\tau = 0.046$ s results in cross-peaks that have considerably less variation in relative intensity and allow the relayed cross-peak between 3′ and the 5′ protons to be observed at a similar intensity level at the 1′ to 3′ cross-peaks. This avoids repeating the experiment with different τ values in order to obtain a specific correlation.

The significance of the 3′–5′, 5″ relayed coherence transfer cross-peak became evident when a vertical line was drawn through the H-3′ diagonal peak (Fig. 3b). It was then possible to assign all the protons that belonged to the deoxyribofuranoside ring which contained that specific 3′ proton. Extending these results to short oligomers, it should be possible to exploit the effect of phosphorylation on the 3′ chemical shifts and be able to extract all the protons for each deoxyribofuranoside ring by examining both the COSY and relayed coherence transfer cross-peaks in vertical cross-sections through the 3′ protons.

In order to evaluate the ability of the relayed coherence transfer experiment to resolve the deoxyribofuranoside proton resonances of an oligomer, the deoxytriribonucleoside triphosphate, dCpTpGp (Fig. 1) was studied. The one-dimensional spectrum of dCpTpGp (Fig. 5) was recorded in D_2O at 40.3°C. At this temperature the residual HDO signal was not overlapped with deoxyribofuranoside proton resonances. A preliminary analysis of the one-dimensional spectrum permit-

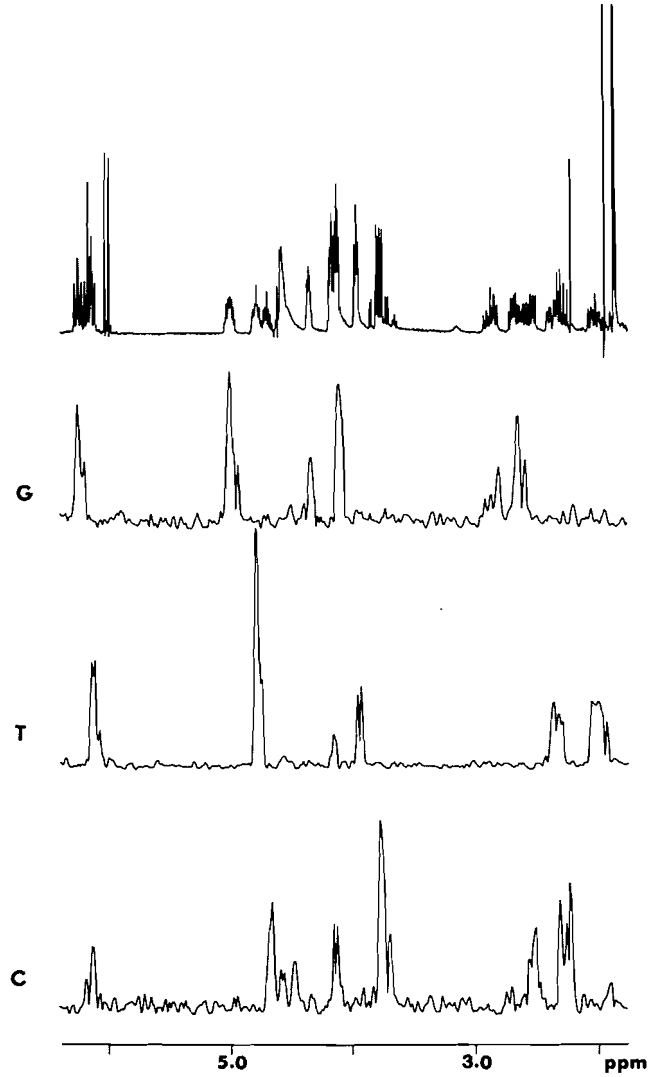

FIG. 7. Plots of the columns of the relayed coherence transfer 2-D data matrix through the H-3′ resonances showing the proton signals for each deoxyribofuranoside ring. The digital resolution of these vertical cross-sections was 3.415 Hz/point.

ted the identification of the type of deoxyribofuranose proton resonances as well as some assignments. Of the three anomeric proton signals, the H-1′ at 6.238 ppm was the only resolved multiplet, while the other H-1′ signals were overlapped. Multiplets attributed to the 3′ protons in the region of 4.7–5.0 ppm were each resolved, even though all 3′ hydroxyl groups were phosphorylated. The region from 4.0–4.4 ppm contained the 4′ protons and the 5′, 5″ protons from dT and dG. Centered near 3.9 ppm was the characteristic AB multiplet corresponding to the non-phosphorylated 5′ terminal dC 5′, 5″ protons. Between 2.0 and 3.0 ppm were the AB multiplets from the 2′, 2″ protons. Application of the rules developed by Tran-Dinh *et al.* (9) resulted in the assignment of the signals at 2.829 and 2.619 ppm to the dG H-2′ and H-2″, respectively. The highest field multiplet near 2.0 ppm had a splitting pattern characteristic of a dT H-2′ (9).

A COSY-45 spectrum (Fig. 6a) was then recorded to determine the connectivity of the deoxyribofuranoside protons. The 45° mixing pulse was used to produce a clearer representation of cross-peaks near the diagonal (31, 32). The only connectivity pathway that could be completed with reasonable certainty from Fig. 6a was that of the dG deoxyriboside protons. The dC and dT connectivities were complicated by the overlap of the H-1′ resonances and the H-4′ signals near 4.1 ppm. In the upper right corner of Fig. 6a the coupling of the dC and dT 2′ and 2″ protons could be readily observed because of the chemical shift separation of the individual AB multiplets. The chemical shift separation of the dC and dT 2′ and 2″ protons also helped to identify the coupling to the corresponding 3′ protons.

TABLE 3. ^{1}H chemical shifts for dCpTpGp at 40.3°C in D_2O

Proton	Chemical shifts C	T	G
H-6	7.792	7.491	
H-5	6.003		
H-8			8.016
H-1′	6.157	6.127	6.238
H-2′	2.272	2.015	2.829
H-2″	2.545	2.359	2.619
H-3′	4.695	4.780	4.994
H-4′	4.168	4.159	4.350
H-5′	3.803	3.954	4.116
H-5″	3.738	3.954	4.116
CH_3		1.939	

To clarify further the connectivity of the deoxyribofuranoside protons, the relayed coherence transfer spectrum of dCpTpGp was obtained with a fixed delay of 0.046 s. The contour plot of this spectrum is shown in Fig. 6b. A vertical line through the 3′ proton at 4.994 ppm identified all the deoxyriboside protons of dG. When this method was used to assign the dC and dT protons a number of problems arose in dealing with the contour plot. There was a loss of intensity of some of the 2′, 2″–3′ cross-peaks and a further reduction of the already low intensity 3′–4′ cross-peaks. The 1′–3′ relayed coherence transfer cross-peaks were reasonably intense, but those for dC and dT appeared overlapped. The intensity problems may be overcome by acquiring more scans and (or) optimizing fixed delay times for particular coupling constants. A more satisfactory approach than analyzing the contour plot was to compare the vertical cross-sections through each 3′ proton directly with the one-dimensional spectrum. This method, shown in Fig. 7, produced a spectrum for each nucleotide in the sequence without the problems of signal overlap from other deoxyribofuranoside protons. The cross-sections could be assigned to a specific nucleotide by identifying the resonances whose assignments could be made from the one-dimensional spectrum. The dC signals were determined by noting the alignment of the signal near 3.8–3.9 ppm in the bottom cross-section of Fig. 7 with the AB multiplet of the 5′, 5″ protons in the one-dimensional spectrum. As previously discussed, the dG 2′, 2″ protons generally appear at lower field than the pyrimidine 2′, 2″ protons (9). The signals in the top cross-section of Fig. 7 near 2.6–3.0 ppm correlated with the dG 2′, 2″ protons in the one-dimensional spectrum and therefore identified the dG cross-section. This confirmed the COSY-45 connectivities. The dT cross-section was assigned by elimination and confirmed by the alignment of the signal near 2.0 ppm with the multiplet attributed to the dT H-2′. The chemical shifts of dCpTpGp are presented in Table 3. These cross-sections were able to assign the dC and dT H-1′ resonances at 6.157 and

6.127 ppm, respectively. The dC and dT H-4′ signals were insufficiently resolved and the assignments given in Table 3 are tentative.

Conclusions

Relayed coherence transfer provides an effective means of assigning the deoxyribofuranoside ^{1}H resonances of each nucleotide in short DNA oligomers. The use of cross-sections through the 3′ protons avoids the ambiguities that arise during the analysis of complex shift-correlated contour plots. The ability of the cross-sections to resolve the deoxyribofuranoside protons should aid in performing other experiments such as spin decoupling and one-dimensional nOe's. It is generally recommended that the COSY spectrum also be recorded to avoid confusing the COSY and relayed coherence transfer cross-peaks in the contour plots. The successful application of this technique to DNA oligomers requires the resolution of the 3′ proton resonances and this will depend on the base composition and length of the sequence as well as the magnetic field strength.

Homolytic versus heterolytic cleavage for the photochemistry of 1-naphthylmethyl derivatives

B. ARNOLD, L. DONALD, A. JURGENS, AND J. A. PINCOCK[1]
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received February 28, 1985

This paper is dedicated to Professor Gerald E. Dunn on the occasion of his 65th birthday

B. ARNOLD, L. DONALD, A. JURGENS, and J. A. PINCOCK. Can. J. Chem. **63**, 3140 (1985).

The photochemical cleavage of the 1-naphthylmethyl derivatives, **1**–**7**, has been examined in methanol solvent under both direct and sensitized conditions. The competitition between homolytic and heterolytic cleavage as a function of multiplicity and leaving group has been studied in detail. Only substrates **1**, **2**, **3**, and **7** react on sensitization with xanthone but evidence is presented that the resulting reactivity of **1**, **2**, and **3** may not be triplet energy transfer but rather exciplex formation. A semi-quantitative scale for photofugacities of the leaving groups from the excited singlet states has been established.

B. ARNOLD, L. DONALD, A. JURGENS et J. A. PINCOCK. Can. J. Chem. **63**, 3140 (1985).

Utilisant le méthanol comme solvant, on a étudié le clivage photochimique des dérivés du naphtyl-1 méthyle **1** à **7** tant dans conditions directes que sous l'influence de sensibilisateurs. On a soigneusement étudié la compétition entre les clivages homolytique et hétérolytique en fonction tant de la multiplicité que du groupe labile. Seuls les substrats **1**, **2**, **3** et **7** réagissent lorsqu'on utilise le xanthone comme sensibilateur; toutefois, on prouve que la réactivité résultante des dérivés **1**, **2** et **3** n'est pas due à un transfert d'énergie du triplet mais plutôt à la formation d'un exciplex. On a établi une échelle semi-quantitative des photofugacités des groupes labiles à partir des états singulets excités.

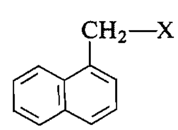
Introduction

Since the initial reports by Zimmerman *et al.* (1, 2) on the photocleavage of benzylic derivatives ($ArCH_2$—X) in nucleophilic solvents, there has been considerable interest in this seemingly simple process. Much of the work has focused on the competition between homolytic versus heterolytic cleavage as a function of the multiplicity of the excited state (i.e. direct versus sensitized irradiations) and the nature of the photofugal group (X = Cl (3–6), Br (5, 6), I (5–7), $\overset{+}{N}R_3$ (8–10), $\overset{+}{S}R_2$ (11), $\overset{+}{P}R_3$ (12), OOCR (5, 6, 13–16), SO_2—R (17, 18), OSO_2R (19)). A partial review, including a theoretical study of spin inversion in the radical pairs generated in triplet reactions, has also appeared (20). This earlier work was mainly qualitative in that usually only product ratios were determined although in some cases quantum yields are also available. However, an understanding of multiplicity effects in these studies is complicated for two reasons. First, the high triplet energy of the benzene chromophore makes unambiguous triplet energy transfer sensitization difficult. Second, in direct irradiations, the proportion of product derived from the triplet formed via intersystem crossing from the singlet as opposed to that formed directly from the singlet is unknown since detailed quenching studies were not attempted.

Recently the Cristol group has published (3, 4) an extensive quantitative study on the photolysis of a series of substituted benzyl chlorides in *tert*-butyl alcohol. The sensitization and quenching techniques used only allowed for information about triplet state reactivity. The conclusion was that two excited triplet states are important in these reactions, a lower one of longer lifetime, which reverts only back to ground-state reactant, and an upper one of shorter lifetime that gives photosolvolysis products. The other conclusion to be reached from this study is that benzyl halides are not the ideal substrates required to do the detailed rate–structure correlations that are necessary to fully understand the factors which control homolytic versus heterolytic cleavage. This is because the high excitation energy of the benzene chromophore (110 kcal/mol (3) for the singlet and 73–74 kcal/mol (21) for the triplet) allows photochemical cleavage of the benzyl carbon – chlorine bond (bond strength, 67–69 kcal/mol (22)) to be very exothermic and consequently rapid. Cristol's (4) estimates of the lifetime of the reactive excited states of 0.4 – 1.4 ns are at, or beyond, the limit of reliable measurement by normal quenching and single-photon counting lifetime techniques.

Our interest in the synthetic utility of benzylic cleavages (23, 24) led us to examine similar substrates using the naphthalene rather than the benzene chromophore and to initiate a systematic study of homolytic versus heterolytic cleavage. As Givens *et al.* (15) have outlined previously, the naphthyl chromophore absorbs beyond 300 nm so that quenching studies free of competitive absorption problems are possible and, as well, the lower triplet energy for naphthalenes of about 60 kcal/mol is suitable for unambiguous sensitization studies. Moreover, the lower excited state energies involved make it likely that a group, X, of low enough photofugacity can be found so that reaction rates will be slow enough for convenient measurement. With this in mind, we undertook and report here a study of the photochemistry of the 1-naphthylmethyl derivatives, **1**–**7** (from here on the 1-naphthyl ring will be abbreviated as N).



1, X = Cl; **2**, X = Br; **3**, X = $\overset{+}{S}(CH_3)_2\bar{B}F_4$;
4, X = $\overset{+}{N}(CH_3)_3Cl^-$; **5**, X = O_2CCH_3;
6, X = $O_2P(OCH_2CH_3)_2$; **7**, X = SO_2CH_3

The case for X = I was omitted because a recent study (7) indicates that this substrate reacts by a pathway quite different from that of the other X groups and involves the radical anion of molecular iodine.

Results and discussion

Direct irradiations

duction, direct photolysis of the derivatives **1–7** in methanol leads to the formation of several products resulting from excited state cleavage of the carbon–X bond, eq. [1].

$$[1]\quad \underset{\mathbf{1-7}}{NCH_2{-}X} \xrightarrow[CH_3OH]{h\nu} \underset{\mathbf{8}}{NCH_2{-}OCH_3} + \underset{\mathbf{9}}{NCH_2CH_2N} + \underset{\mathbf{10}}{NCH_3} + \underset{\mathbf{11}}{NCH_2CH_2OH}$$

The products are easily rationalized if both heterolytic and homolytic cleavage are involved. The ether **8** is formed by trapping of the 1-naphthylmethyl carbocation by the nucleophilic solvent, methanol. In contrast, the products, **9**, **10**, and **11**, are all formed from the 1-naphthylmethyl radical, **9** by coupling, **10** by hydrogen-atom abstraction from the solvent, and **11** by coupling with the hydroxymethyl radical formed from methanol. As will be discussed, the competition between the pathways for formation of **9**, **10**, **11** is determined by the nature of the leaving group, X, and the light intensity. However, the competition between **8** and (**9**, **10**, **11**) as a group is a reflection of the relative amounts of products derived from ionic and radical intermediates for these substrates.

The product distributions determined by calibrated hplc for the direct irradiations (Corex filter) of **1–7** are given in Table 1. As can be seen, the mass balance for the reactions is good (>85%) even with very high conversion runs, since the results reported are for complete disappearance of starting material. Because the products have essentially the same chromophore as the starting material there is an obvious internal filter effect which slows down the reactions as a function of percent conversion. However, the product ratios do not change and this was confirmed by demonstrating that all four photoproducts are stable to the reaction conditions for at least as long as any of the irradiation times. The results are best summarized by the column that gives the ratio of (**9** + **10** + **11**)/**8**; the values for the corresponding benzyl derivatives R/I, where known, are also given. Clearly, there is considerable variation in these values and this seems to be mainly a function of X, because the same trends are present for both the 1-naphthylmethyl and the benzyl derivatives. It is, of course, difficult to interpret these results for direct irradiations since, as discussed briefly in the Introduction, the multiplicity of the excited state that leads to photocleavage is unknown without results from sensitization and quenching studies. These will be presented in the next section.

The distribution of products from the radical cleavage (i.e. **9**/**10**/**11**) obviously varies with X. Normally, the 1-naphthylmethyl radical generated in methanol dimerizes to make **9** the major product rather than **10** (all substrates except **4**, X = $\overset{+}{N}(CH_3)_3Cl^-$). This is reasonable since abstraction of a hydrogen from methanol by the 1-naphthylmethyl radical will be endothermic by about 11 kcal/mol. This is based on the difference between the carbon–hydrogen bond strength in methanol (93 kcal/mol) (22) and the estimated carbon–hydrogen bond strength in 1-methylnaphthalene (82 kcal/mol, using 85 kcal/mol (22) for the bond strength in toluene and 3 kcal/mol (25) extra stabilization for the 1-naphthylmethyl radical relative to the benzyl radical). The only case, **4**, where methylnaphthalene is the major product is explained by the very favorable

$$[2]\quad NCH_2\cdot + CH_3{-}\overset{\cdot+}{N}(CH_3)_2 \rightarrow N{-}CH_3 + CH_2{=}\overset{+}{N}(CH_3)_2$$

$$[3]\quad NCH_2\cdot + CH_3{-}\overset{\cdot+}{S}CH_3 \rightarrow N{-}CH_3 + CH_2{=}\overset{+}{S}CH_3$$

step shown in eq. [2], where the radical cation of trimethylamine serves as the hydrogen atom donor. The corresponding case, eq. [3], where X is $\overset{+}{S}(CH_3)_2\bar{B}F_4$, should not be as favorable based on the known ability of nitrogen and sulfur to stabilize cations as indicated by σ^+ values of −1.7 for $-N(CH_3)_2$ and −0.6 for $-SCH_3$ (26). Finally, the only sub-

strate that gives significant amounts of NCH_2CH_2OH, **11**, is **1**, X = Cl. This is a result of the high value for the bond strength in hydrogen chloride (103 kcal/mol) (22) making the process, eq. [4], occur at a rate that allows competition between the dimerization of $NCH_2\cdot$ radicals and coupling of $NCH_2\cdot$ with

[4] $X\cdot + H\text{—}CH_2OH \rightarrow X\text{—}H + \cdot CH_2OH$

CH_2OH. For **2**, X = Br, the hydrogen bromide bond strength (87 kcal/mol) (22) makes the process in eq. [4] endothermic, by 16 kcal/mol, and unfavorable.

In order to sort out multiplicity effects in these reactions there are two possible approaches: (*i*) sensitization to determine the reactivity of the triplet state or (*ii*) selective quenching of the triplet state formed in a direct irradiation to determine the reactivity of the singlet state.

Sensitized irradiations

In the previous studies with benzyl derivatives, there have always been difficulties in determining the reactivity of the triplet state by sensitization techniques because there are no obvious sensitizers with triplet energies high enough to make triplet energy transfer to the benzene chromophore (~80 kcal/mol) exothermic. Acetone (E_T = 78 kcal/mol) is the logical compromise but it should only be used in non-hydrogen atom donating solvents and, therefore, if a nucleophilic alcohol is required as well, *tert*-butyl alcohol is the best choice. Concentrations of the sensitizer must be high (typically 10% or greater) to avoid competitive absorption by the benzene chromophores. The Cristol group (3) have used this method for a series of substituted benzyl chlorides and it is the observation of changes such as radical/ionic products of 60:26 in direct irradiation and 22:73 in sensitized irradiation that have attracted attention. How is the amount of ion-derived product increased if the multiplicity of the excited state changes from singlet (spin-paired) to triplet (spin-unpaired)?

Examination of this problem for the naphthyl derivatives reported here is, on the surface, more straightforward. The triplet energy of the substrates is around 60 kcal/mol (Table 2). The sensitizer chosen was xanthone, which has been shown by Scaiano (28) to have a triplet energy of 69 kcal/mol, a long wavelength absorption band with λ_{max} 338 nm (ϵ 6800), and a rate of reaction with methanol of ~$10^5\ M^{-1}\ s^{-1}$, which will not compete with the diffusion controlled quenching by the naphthalene derivatives.

The results for these sensitization experiments are given in Table 1. Three of the substrates, **4**, **5** and **6**, show no reaction on sensitization and therefore the direct irradiations must reflect singlet reactivity. The substrates **1**, X = Cl, and **2**, X = Br, have been examined in considerable detail recently by Slocum and Schuster (23) with the conclusion that this sensitization is actually exciplex formation and that the lowest triplet of these two substrates does not react. Cristol has reached the same conclusion for T_1 of benzyl chloride. Therefore the results for sensitized reactions of **1** and **2** probably have nothing to do with unimolecular excited state cleavage of the carbon–halogen bond but reflect bimolecular interactions with the sensitizer. The only questionable cases are **3** and **7**, which will be discussed in more detail in the next section on quenched irradiations.

That the sensitized photocleavage reactions do not involve complete electron transfer was confirmed by applying the Weller equation (29) to the redox potentials obtained for **1**, **7**, and xanthone, assuming the sensitizer was the donor and the substrate the acceptor. Both **1** and **7** exhibited irreversible reduction waves by cyclic voltammetry, the half-wave potentials being −2.23 and −2.05 V (vs. Ag/AgCl) respectively. Xanthone exhibits an irreversible wave on oxidation with a half-wave potential of +1.76 V. Using these redox values, singlet energy of 79 kcal/mol and triplet energy of 69 kcal/mol for xanthone and a Coulombic attraction term of 1.5 kcal/mol (ϵ of methanol = 32, encounter distance = 7 Å) in the Weller equation gives results that imply that electron transfer will be unfavorable for both **1** (ΔG singlet = 11.5 kcal/mol, ΔG triplet = 21.5 kcal/mol) and **7** (ΔG singlet = 7.3 kcal/mol, ΔG triplet = 17.3 kcal/mol).

The conclusion to reach from this section and in particular from the work of Cristol and Bindel (3, 4) and Slocum and Schuster (23) is that it will be very difficult to obtain reliable rate constants for the excited triplet states except by quenching of triplet states formed directly by intersystem crossing and applying Stern–Vollmer kinetic treatments. Even this approach is likely to be complicated because both singlet and triplet reaction may be occurring so that the quenching would have to be state selective.

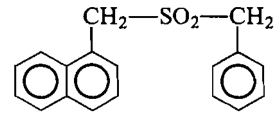
Quenched irradiations

The classic method of studying the reactivity of excited singlet states is to selectively quench the triplets by taking advantage of their longer lifetime. For benzyl derivatives this is in fact quite difficult because of the very short lifetime of even the triplet states; moreover, the concentration of typical quenchers (like dienes) can not be too high because of competitive absorption problems. Again the work by the Cristol group (3, 4) for benzyl chlorides has shown the potential of these methods since a combination of sensitization and quenching techniques indicated two triplets, a long-lived one of lifetime 3–26 ns, which did not photoreact, and a short-lived one of lifetime 0.4–1.4 ns, which led to photosolvolysis products. Schuster's work (23) has resulted in a different interpretation of these experiments and, more important, demonstrated that, for the naphthyl derivatives **1**, X = Cl, and **2**, X = Br, the triplet lifetimes are much longer, 180 ns and 175 ns, respectively. Thus they are easily quenchable. However, it is well known that the excited singlet states of naphthalene derivatives are also very efficiently quenched (30) by the usual dienes that are used as triplet quenchers. This process can be easily monitored by fluorescence quenching or by direct measurement of singlet lifetimes as a function of quencher concentration.

The singlet lifetimes in methanol at 20°C measured by single-photon counting for the substrates **1–7** are shown in Table 2. Compounds **1**, X = Cl, **2**, X = Br, and **3**, X = $\overset{+}{S}(CH_3)_2\overset{-}{B}F_4$ have lifetimes too short (<1 ns) to be determined. A recent (31) value for **1** of 490 ps has been reported. The longer-lived singlet states, as expected (29), are very efficiently quenched by 2,5-dimethyl-2,4-hexadiene. For example, Stern–Volmer fluorescence intensity quenching plots for **4** and **7** gave $k_q\tau$ values of 64 and 301 M^{-1} respectively. The lifetimes in Table 2 then give k_q values of $9.3 \times 10^9\ M^{-1}\ s^{-1}$ and $9.0 \times 10^9\ M^{-1}\ s^{-1}$ respectively that are close to the calculated value (32), $1.8 \times 10^{10}\ M^{-1}\ s^{-1}$, for diffusion in methanol.

The triplet states of these naphthalene derivatives will also be quenched at the diffusion controlled rate based on their triplet energies (58.8–62.0 kcal/mol, Table 2) and the known triplet energy of 2,5-dimethyl-2,4-hexadiene (58.7 kcal/mol (33)). However, the different lifetimes of the two excited states make selective quenching of the triplet state possible. For instance, for chloromethylnaphthalene, **1**, τ_S = 490 ps (31) and τ_T = 180 ns (23). At $10^{-2}\ M$ quencher, the singlet is unquenched because it is too short-lived, but 95% of the triplets are quenched. With these conditions, irradiation of **1** does not show any significant change in rate of photodecomposition or in product ratio (Table 1) relative to direct irradiations. Substrates **2** and **3** show considerable quenching of radical products but at the expense of a good mass balance. Likely radical intermediates generated from the unquenched singlet excited state react with the diene quencher rather than dimerize. Substrates **4**, **5**, and **6** do not react from the triplet state so quenched runs were unnecessary.

The results for **7** are different. The longer singlet lifetime (33 ns, Table 2) means that, even at quencher concentrations of $10^{-3}\ M$, 25% of the singlets are quenched. The amount of the triplet state quenched is unknown because the triplet lifetime for **7** is not known. However, the extensive studies by Givens and co-workers (18) on the photochemistry of sulfones indicates that, for 1-naphthylmethyl sulfones, photocleavage on direct irradiation occurs almost exclusively from the triplet state formed by intersystem crossing from the singlet. In addition, the triplet lifetime of the sulfone, **12**, in acetonitrile is 500 ns (18*c*). Since the triplet state of **12** is of the naphthalene type this is surely a good model for **7**. At this lifetime and $10^{-3}\ M$ in the diene quencher, 80% of the triplets will be quenched. In agreement with Givens' results for **12**, the photocleavage of **7** in the presence of the quencher becomes very slow and the mass balance is low, probably because the competititive singlet quenching leads to product formation by cycloaddition of the diene to the excited naphthalene (34).



12

The conclusion from these semiquantitative studies is that reliable rate constant information on photofugacities of leaving groups can be obtained for the excited singlet states of the substrates **1–6** but that the singlet of **7** reacts too slowly to be conveniently measured.

Quantum yields and photofugacities

The measurement of rate constants of reaction for excited singlet states is, in principle, straightforward according to eq. [5] where ϕ_r is the reaction quantum yield, k_r is the rate

$$[5]\quad \phi_r = \frac{k_r}{k_d} = k_r\tau_s$$

constant in question, and k_d is the total rate of decay of the excited singlet state or the reciprocal of the lifetime τ_s. The lifetimes of the substrates **4**, **5**, **6**, and **7** are directly measurable by single-photon counting of fluorescence decay; **1**, **2**, and **3** are too short-lived.

Reliable estimates of singlet lifetimes can often be made by using the expression, eq. [6], where ϕ_f is the quantum yield

$$[6]\quad \phi_f = \frac{k_f}{k_d} = k_f\tau_s$$

of fluorescence and k_f the corresponding rate constant. Estimates of k_f can be made from the integrated absorption band for the S_0–S_1 transition according to eq. [7] (35). For these

$$[7]\quad k_f = 2.88 \times 10^{-9}\ \lambda_{max}{}^2 n^2 \int \epsilon(\nu)d\nu$$

substrates, evaluation of τ_s by these methods is not very reliable. The value for the area of the integrated absorption band is uncertain because of overlap with the S_0–S_2 band. Our best estimates are in Table 2. For the bromide **2**, the S_0–S_1 band is in fact not even observable. However, the approximate constancy of these values for the other substrates is encouraging and allows a very crude estimate of k_f for **2** as the average of the others.

According to eq. [6] the values of ϕ_f for these substrates are also necessary to evaluate τ_s. Values for **1** and **2** have been reported previously: 0.0031 and 0.0017 respectively in cyclohexane at room temperature (23) and 0.003 and 0.001 in benzene at 298 K (36). Our values (Table 2) are lower than these and force us to be very uncertain about any of these determinations. These substrates are all synthesized from naphthalene derivatives and, moreover, photoreact to produce other naphthalene compounds. Photo-unreactive naphthalene derivatives have quantum yields of fluorescence of about 0.2. Therefore impurity levels of 0.5% will give spurious fluorescence quantum yields of 10^{-3}. In fact, without great care, the intensity of fluorescence for these substrates always increased during the irradiation time of the experiment. The values for **1**, **2**, and **3** in Table 2 are therefore the maximum values possible and the true values are very likely smaller. The larger values for **4**, **5**, **6**, and **7** are presumably reliable. A value of 0.19 in cyclohexane has been reported for **6**.[2]

Using eq. [6], values of τ_s can now be calculated for **4**, **5**, **6**,

7	—	0.001	0.005	—	0.2	0.14

[a] A value of 0.08 has been reported (see footnote 2).

and **7** (Table 2). They are uniformly larger than the observed values by a factor of 2 to 3. Even greater overestimations of singlet lifetimes by this method have been reported previously (37). For the cases reported here, the rigidity of the naphthalene ring will keep the geometry of the ground and excited states quite similar so the method should work well. The observed overestimations are likely due to overlap between the S_2 and S_1 absorption bands causing an overestimation of the S_0–S_1 probability. The singlet lifetimes of **1**, **2**, and **3** are then certainly below 0.5 ns.

Quantum yields for these photocleavages are reported in Table 3. All values are reported at conversions between 5 and 10% to avoid the internal filter effects that result because the products have the same chromophore as the starting materials. The dimer **9**, which is formed in the preparative scale irradiations, is now only a very minor product, presumably because of the lower light intensities on the quantum yield optical bench. Methylnaphthalene, **10**, is now a major product resulting from radical cleavage.

The rate constants for ionic cleavage, $k_8 = k_I$, radical cleavage, $k_{10+11} = k_R$, can now be calculated, but in fact only reliably for **4** (X = $\overset{+}{N}(CH_3)_3Cl^-$), **6** (X = O—$PO(OCH_2CH_3)_2$), and **7** (X = SO_2CH_3). Although a lifetime is available for the acetate **5**, the quantum yield for reaction is too small to be reliably measured. For **1** (X = Cl), **2** (X = Br), and **3** (X = $\overset{+}{S}(CH_3)_2\bar{B}F_4$) the very short lifetimes only allow lower limit estimates for these rate constants.

Although only estimates for photofugacity of most of the leaving groups studied here are available from our results, the large spread in the values is obvious, about 10^4 for the ionic and 10^3 for the radical process. Semi-quantitative trends are also obvious, so that a photofugacity order for the ionic process has $\overset{+}{S}(CH_3)_2 > Cl \simeq \overset{+}{N}(CH_3)_3 > O_2P(OEt)_2 > O_2CCH_3 > SO_2CH_3$ and for the radical process $Cl > \overset{+}{S}(CH_3)_2 \simeq Br > \overset{+}{N}(CH_3)_3 > O_2P(OEt)_2 \simeq SO_2CH_3 > O_2CCH_3$. The large range of rate constants is, in itself, somewhat surprising since from the excited singlet state of these naphthalene derivatives all of the bond cleavages are exothermic and might have been expected to be too fast for any selectivity in reaction rate. This is the observation made by Cristol (3, 4) for the excited triplets of benzylic chlorides. In fact, only two of the leaving groups, $\overset{+}{N}(CH_3)_3Cl^-$ and O—$PO(OCH_2CH_3)_2$, react with rates that are conveniently measured and create the opportunity to systematically study the effect of solvent, substituents, temperature, etc. on excited state rate constants for this simple bond cleavage process. Of these two, $\overset{+}{N}(CH_3)_3Cl^-$ is perhaps the best choice because it gives a more equal distribution of ionic and radical cleavage products, so that the effect of reaction conditions on this distribution could be studied.

Finally, we were hoping to answer questions about the two possible mechanistic pathways that have been proposed for these photocleavages. The first involves cleavage directly from the excited state to either a radical pair or an ion pair. Product distribution then reflects the partitioning of the excited state between these two pathways. The second involves initial excited state cleavage to only the radical pair and then exothermic electron transfer within the radical pair to the ion pair. Product distribution thus reflects the competition between diffusional separation of the radical pair and the rate of electron transfer.

In both of these mechanisms, the product formation and hence product distribution could be altered by return of either the ion pair or the radical pair to starting material by recombination. This is essentially a process of decay for the excited singlet, which lowers the quantum yield and rate constant for product formation. In fact, such internal return has been observed before for the photochemistry of benzylic sulfones (18*b*) in radical processes and benzylic acetates (16) in ionic processes but not for benzylic ammonium salts (38). However, even for the substrates where internal return has been observed, it is not an important enough process to change rate constants by an order of magnitude but only by at most a factor of two.

We were hopeful that some correlation between known properties of the C—X bonds in the substrates and the photochemical rates would be possible; for instance, C—X bond strength or radical cleavage and leaving group ability in solvolysis reactions for pK_a of the acid HX for ionic cleavage. We do not see trends in our results that allow correlations of this type to distinguish between the two possible mechanistic pathways.

Although bond strengths are unavailable for the leaving groups $\overset{+}{N}(CH_3)_3$ and $\overset{+}{S}(CH_3)_2$ so that a complete correlation is impossible, there are obvious discrepancies even for the known cases. Estimates[3] for the carbon–X band strength for **1** (X = Cl), 65 kcal/mol (22); **2** (X = Br), 51 kcal/mol (22); **3** (X = SO_2CH_3), 53 kcal/mol (39) predict that **7** and **2** should be similar in photolability and less reactive than **1**. As seen in Table 3, this is not true.

In terms of ionic cleavage, the order of ground state leaving group ability of X can be estimated from solvolysis data from the known logarithmic L scale for some of the leaving groups used here (40). Values for Br (1.0), Cl (−1.61), $\overset{+}{S}(CH_3)_2$ (−3.01), $\overset{+}{N}(CH_3)_3$ (−3.54), and O_2CCH_3 (−4.68) actually qualitatively follow the order in Table 3 for ionic photofugacity, but clearly not quantitatively. The sulfonium salt is

[3] The values for the corresponding benzylic cases are decreased by 3 kcal/mol (25).

closer in reactivity to the halides than it is to the ammonium salt. Similarly pK_a values for the conjugate acids H—X: Cl (−7.1) (40), Br (−7.7) (40), $\overset{+}{S}(CH_3)_2$ (−7) (41), SO_2CH_3 (−2.6) (42), $O_2P(OCH_3CH_3)_2$ (2.1) (43), O_2CCH_3 (4.7) (40), and $\overset{+}{N}(CH_3)_3$ (9.9) (40) seem to fit for the three reactive leaving groups but not at all for the four of lower reactivity.

In conclusion, we have established a qualitative scale for fugacities in photochemical benzylic cleavages from the excited singlet state. Perhaps not surprisingly, the order is not easily rationalized by comparison with related ground state reactions. More important, we have identified a leaving group $\overset{+}{N}(CH_3)_3Cl^-$ that reacts with a rate and product distribution that allows a systematic study of the variables that affect ionic versus radical cleavage. Such studies are in progress.

Experimental

Preparation and purification of 1-naphthylmethyl derivatives (NCH₂—X)

1, X = Cl: purchased from Aldrich Chemical Co. and purified by low temperature (Dry Ice) recrystallization from hexane; mp 33–34°C.

2, X = Br: 1-methylnaphthalene (3.0 g, 21 mmol), NBS (4.1 g, 23 mmol), and 40 mL of CCl_4 were irradiated with a 250-W tungsten lamp while a continuous stream of nitrogen was passed through the refluxing solution. After 4 h the mixture was cooled to 0°C and filtered. Evaporation of the solvent gave the crude bromide, which was recrystallized from pentane and sublimed to give 2.78 g (60%) of purified material; mp 54–55°C (lit (44) mp 56°C).

3, X = $\overset{+}{S}(CH_3)_2BF_4^-$: 1-mercaptomethylnaphthalene (17.4 g, 100 mmol) was added to a stirred solution of sodium methoxide (5.94 g, 150 mmol) in 150 mL of methanol. After 10 min, methyl iodide (14.2 g, 100 mmol) was added dropwise and the mixture stirred for 1 h. Addition of 100 mL of water, followed by extraction with 3 × 75 mL of CCl_4, druing with $MgSO_4$ and evaporation, gave 21 g of the crude sulfide. Vacuum distillation (bp 150–152°C at 4 Torr (1 Torr = 133.3 Pa)) gave 12.7 g (68%) of purified sulfide; nmr ($CDCl_3$) δ: 7.25–8.23 (m, 7H), 4.02 (s, 2H), 1.93 (s, 3H).

Trimethyloxonium fluoroborate (1.63 g, 11 mmol) was added to a stirred solution of the (1-naphthylmethyl) methyl sulfide (1.88 g, 10 mmol) in 20 mL of nitromethane. The resulting mixture was left at 0°C for 18 h and then filtered. The crude product was recrystallized at low temperature from 3-pentanone to give 2.17 g (75%) of purified salt: mp 150.5–151°C; ir (KBr): 950–1150 (br) cm^{-1}; nmr (acetone-d_6) δ: 7.5–8.4 (m, 7H), 5.35 (s, 2H), 3.12 (s, 6H). *Anal.* calcd. for $C_{13}H_{15}BF_4S$: C 53.82, H 5.21; found: C 53.62, H 5.17.

4, X = $\overset{+}{N}(CH_3)_3Cl^-$: trimethylamine was bubbled through a stirred solution of 1-chloromethylnaphthalene, **1** (1.88 g, 11 mmol), in 50 mL of absolute ethanol. The solvent was evaporated and the crude ammonium salt was recrystallized from acetonitrile to give 1.86 g (80%) of purified **4**; mp 231–232°C (lit. (45) mp 226–227°C); nmr (CD_3OD) δ: 7.5–8.2 (m, 7H), 5.18 (s, 2H), 3.23 (s, 9H).

5, X = O_2CCH_3. To 1-naphthylmethanol (1.6 g, 0.11 mmol) in 25 mL of dry pyridine was added, with stirring, acetyl chloride (1.0 g, 0.13 mmol). The mixture was extracted with 2 × 50 mL of 10% HCl and 50 mL of saturated aqueous NaCl. Evaporation of the solvent and distillation of the crude ester gave 1.5 g (73%) of a pale yellow oil. Two bulb-to-bulb distillations (65°C, 1 Torr; lit. (46) bp 90–92°C at 10 Torr) gave the purified ester; nmr ($CDCl_3$) δ: 7.2–8.4 (m, 7H), 5.47 (s, 2H), 2.00 (s, 3H).

6, X = $O_2P(OCH_2CH_3)_2$. This compound was supplied by Prof. R. Givens, Dept. of Chemistry, University of Kansas.

8, X = OCH_3. To a solution of sodium (0.51 g, 22 mmol) in 40 mL of absolute methanol was added 1-chloromethylnaphthalene, **1** (3.53 g, 21 mmol), and the mixture stirred for 18 h. It was then poured into 100 mL of water and extracted with 3 × 50 mL of pentane, then was combined, dried over Na_2SO_4, and concentrated to give 3.5 g (95%) of crude ether, **7**. Bulb-to-bulb distillation gave a purified sample; nmr δ: 7.2–8.4 (m, 7H), 4.90 (s, 2H), 3.43 (s, 3H).

9, 1,2-Di(1-naphthyl)ethane, X = CH_2N. This compound was isolated from photolysis mixtures of **1** and recrystallized from ethanol; mp 163–165°C (lit. (47) mp 160–161°C); nmr ($CDCl_3$) δ: 7.2–8.4 (m, 14H), 3.53 (s, 4H).

10, X = H. Purchased from Aldrich Chemical Co.

11, X = CH_2OH. Purchased from Aldrich Chemical Co.

Analytic procedure for 1-naphthylmethyl derivatives

All substrates were checked for purity by hplc (Waters) with a Brownlee 10μ RP-8 reverse phase column using 80% methanol/water as eluant and detection at 280 nm. Photolyses were monitored and products quantified by calibration of the detector with mixtures of known concentration.

Photolyses

Preparative scale irradiations were done using a 200-W medium pressure Hanovia mercury lamp in an immersion well with nitrogen purging. The following concentrations were used: direct irradiations, 200 mg of substrate, 310 mL of methanol, and a Corex filter sleeve; sensitized irradiations, 200 mg of substrate, 20 mg of xanthone, 310 mL of methanol, and a Pyrex filter sleeve; quenched irradiations were the same as direct except 2,5-dimethyl-2,5-hexadiene (Aldrich, sublimed) was added at concentrations determined by Stern–Volmer fluorescence quenching studies.

Quantum yield measurements

Quantum yields were determined using an optical bench equipped with a 450-W Hg/Xe lamp, a SPEX minimate monochromator, a beam splitter, and a reaction and reference cell. Calibration of light intensities and splitting ratios was by ferrioxalate actinometry (48). Samples were degassed by nitrogen purging, stirred, and thermostatted at 20°C during the irradiations. Quantum yields are based on appearance of products with total conversion of starting material between 5 and 10% to minimize the internal filter effects. In a typical run, a solution of **4**, X = $\overset{+}{N}(CH_3)_3Cl^-$ (2.12 × 10^{-3} M in 20 mL of CH_3OH), irradiated at 280 nm with 0.70 × 10^{-2} millieinstein gave 0.173 × 10^{-2} mmol of **8**, X = OCH_3, ϕ = 0.247, and 0.045 mmol of **10**, X = H, ϕ = 0.064, with a conversion to products of 5.8%. Values reported in Table 3 are the average of at least two runs with a mean deviation always <10%.

Fluorescence measurements

All samples for fluorescence measurements were degassed by four freeze–pump–thaw cycles and spectra obtained on an Aminco–Bowman spectrophotofluorometer. For quantum yields, naphthalene was used as a standard and concentrations used so that the absorbance at 280 nm was constant for all solutions at 0.8 (1.0 × $10^{-4}$$M$). The quantum yield of fluorescence of naphthalene is 0.24 in methanol based on a value of 0.23 (27) in cyclohexane.

Fluorescence lifetime measurements

All samples were degassed by four freeze–pump–thaw cycles and lifetimes measured by a PRA single photon counting apparatus with a hydrogen flash lamp of pulse width 0.8 ns and flash frequency of 30 kHz. The decay curves generated were deconvoluted using a program provided by Professor W. Ware, University of Western Ontario.

3-(η^6-Benzoyltricarbonylchromium)pyrrole. An example of how substitution isomerism in the ligand affects the type (σ or π) of complex formed

NIALL J. GOGAN, JAMES DOULL, AND JANE EVANS
Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received March 11, 1985

NIALL J. GOGAN, JAMES DOULL, and JANE EVANS. Can. J. Chem. **63**, 3147 (1985).

The reaction of 3-benzoylpyrrole and $Cr(CO)_6$ yields only the π-complex 3-(η^6-benzoyltricarbonylchromium)pyrrole, in contrast to the previously reported reaction of 2-benzoylpyrrole and $Cr(CO)_6$ that yielded only the σ-chelate, tris(2-benzoylpyrrolato)chromium(III). The difference in behaviour is explained by a preference for chelate formation that is allowed by the stereochemistry of 2-benzoylpyrrole but is not allowed by the stereochemistry of 3-benzoylpyrrole.

NIALL J. GOGAN, JAMES DOULL et JANE EVANS. Can. J. Chem. **63**, 3147 (1985).

La réaction du benzoyl-3 pyrrole avec le $Cr(CO)_6$ ne conduit qu'au complexe-π (η^6-benzoyltricarbonylchrome)-3 pyrrole alors qu'il a été rapporté antérieurement que la réaction du benzoyl-2 pyrrole avec le $Cr(CO)_6$ ne conduit qu'à un chélate-σ, le tris(benzoyl-2 pyrrolato)chrome(III). On explique la différence dans ces comportements par une préférence pour la formation du chélate qui est permise par la stéréochimie du benzoyl-2 pyrrole mais qui n'est pas permise par la stéréochime du benzoyl-3 pyrrole.

[Traduit par le journal]

Introduction

Benzoylpyrroles, when reacted with $Cr(CO)_6$, have the potential of forming either Cr(III) σ-coordinated complexes or π-$Cr(CO)_3$ complexes. We previously reported that 2-benzoylpyrrole forms the σ-chelate, tris(2-benzoylpyrrolato)chromium(III), when reacted with $Cr(CO)_6$ (1). No evidence of π-complexation was found. At the time of our earlier study, it was not possible to examine the effect of changing the substitution position of the benzoyl group because no readily available route to 3-benzoylpyrrole existed. Since then, Anderson, Loader and co-workers have developed successively better synthetic routes to 3-substituted pyrroles and have recently developed a good method for preparing 3-benzoylpyrroles (2). We now wish to report the result of the reaction of 3-benzoylpyrrole with $Cr(CO)_6$ and contrast the result with that obtained earlier for 2-benzoylpyrrole.

Experimental

Melting points are uncorrected. Elemental analyses were performed by Canadian Microanalytical Service, Vancouver, B.C. The ir spectra were recorded on a Perkin–Elmer 283 spectrophotometer in $CHCl_3$ solution. The ^1H nmr spectra were determined using a Bruker WP-80 instrument and are expressed in ppm (δ valves) relative to tetramethylsilane as internal reference in $CDCl_3$. Mass spectra were recorded on a VG Micromass 7070 HS spectrometer.

Reaction of hexacarbonylchromium(0) and 3-benzoylpyrrole

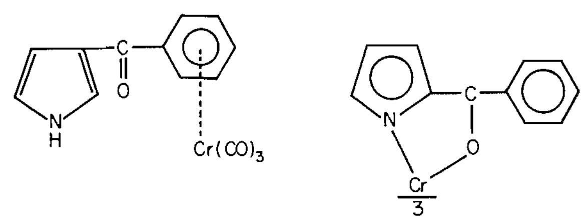
Hexacarbonylchromium (0.297 g; 1.30 mmol) and 3-benzoylpyrrole (0.203 g; 1.18 mmol) were allowed to react in 50 mL of di-n-butyl ether at reflux under a nitrogen atmosphere for 6 h using the general method previously described (3). The resulting orange solution was evaporated to yield an orange solid, which was recrystallized from methylene chloride/petroleum ether (60–80) to yield 0.258 g (71% yield assuming 3-benzoylpyrrole $Cr(CO)_3$) of orange crystals, mp 166–168°C. A small amount of decomposition product and some unreacted starting materials were the only other substances recovered from the reaction. *Anal.* calcd. for $C_{14}H_9O_4NCr$: C 54.72, H 2.95, N 4.56; found: C 54.57, H 2.71, N 4.58.

Results and discussion

The orange product shows two intense bands in the ir ($CHCl_3$) spectrum at 1986 and 1914 cm^{-1} characteristic of a $Cr(CO)_3$ group π-bonded to a benzene ring (4). The ketonic ν_{CO} is at 1636 cm^{-1}, virtually unchanged from the ligand (1635 cm^{-1}), and ν_{NH} is unchanged at 3470 cm^{-1}. This contrasts with tris(2-benzoylpyrrolato)chromium(III), which has no intense bands in the 1850–2100 cm^{-1} region, has the ketonic ν_{CO} shifted from 1621 cm^{-1} (ligand) to 1526 cm^{-1} (complex), and has no ν_{NH}. The product from 3-benzoylpyrrole has an ^1H nmr spectrum with benzene proton resonances (δ) at 5.36 (*meta*), 5.56 (*para*), and 6.10 (*ortho*) shifted upfield from the ligand values of 7.51, 7.39, and 7.85. These shifts are typical of a benzene ring π-bonded to a $Cr(CO)_3$ group (5). The pyrrole proton resonances are essentially unchanged. The ^1H nmr spectrum of the σ-complex from 2-benzoylpyrrole exhibits no signals, no doubt owing to its paramagnetism (μ_{eff} = 3.9 BM).

The elemental analyses agree with the values calculated for the π-complex of 3-benzoylpyrrole. The mass spectrum shows peaks at m/e: 307 (13, M^+), 279 (15), 251 (26), 223 (100), 171 (26), 94 (66), and 52 (75) corresponding to the molecular ion, successive loss of 3 COs, 3-benzoylpyrrole$^+$, $C_4H_4NCO^+$, and Cr^+.

From the above evidence, it is clear that the product from the reaction of 3-benzoylpyrrole and $Cr(CO)_6$ is 3-(η^6-benzoyltricarbonylchromium)pyrrole and has the structure shown in (a), whereas the product from the reaction of 2-benzoylpyrrole and $Cr(CO)_6$ has, in contrast, the structure shown in (b). This shows



(a) (b)

a dramatic difference in complexing behaviour, under the same reaction conditions, of ligands that only differ in the substitution position of the benzoyl group on the pyrrole ring. It can be explained by a strong preference for chelation through the pyrrole N and ketonic group O. This preference is allowed by the stereochemistry of 2-benzoylpyrrole, i.e. it has the correct "bite", but it is not allowed by the stereochemistry of

3-benzoylpyrrole. Thus, in this latter case π-complexation occurs by default.

Effects of neutral and anionic substituents on the carbonyl stretching bands of ring-substituted acetophenones

IVAN G. BINEV, TSONKO M. KOLEV, and IVAN N. JUCHNOVSKI
Institute of Organic Chemistry, Bulgarian Academy of Sciences, 1113 Sofia, Bulgaria

Received December 21, 1984

IVAN G. BINEV, TSONKO M. KOLEV, and IVAN N. JUCHNOVSKI. Can. J. Chem. **63**, 3149 (1985).

Satisfactory single-parameter (σ^+) and dual-parameter (according to Yukawa–Tsuno and Taft) correlations have been found between frequencies of the title bands (ν_{CO}) and substituent constants. It has been found that use of dimethyl sulphoxide instead of carbon tetrachloride as solvent does not lower the relative accuracy of the studied correlations. The integrated intensities of the ν_{CO} bands do not correlate with any type of substituent constants. The constants σ^+, σ^0, σ_I, σ_R^+, and $\Delta\sigma_R^+$ of the anionic substituents NC—HC$^-$, O$^-$, CH_3CON^-, and CO_2^-, recently determined on the basis of cyano infrared frequencies and intensities, have proved satisfactorily reliable with respect to the ν_{CO} of acetophenones. The σ^+ constants of *m*-$CH_2CO_2^-$ (-0.22 ± 0.08) and *m*-$C_6H_5CON^-$ (-0.66 ± 0.13) have been estimated on the basis of ν_{CO} data and ν_{CO}/σ^+ correlations (solvent DMSO).

IVAN G. BINEV, TSONKO M. KOLEV et IVAN N. JUCHNOVSKI. Can. J. Chem. **63**, 3149 (1985).

On a pu établir des corrélations satisfaisantes du paramètre unique (σ^+) et du paramètre double (de Yukawa–Tsuno et Taft) entre les fréquences des bandes principales mentionnées dans le titre (ν_{CO}) et les constantes des substituants. On a trouvé que l'utilisation comme solvant du diméthylsulfoxyde au lieu du tétrachlorure de carbone ne diminue aucunement la précision relative des corrélations étudiées. On n'a pas pu établir de corrélations entre les intensités intégrées des bandes ν_{CO} et les constantes des substituants. Les constantes σ^+, σ^0, σ_I, σ_R^+ et $\Delta\sigma_R^+$ des substituants anioniques NC—HC$^-$, O$^-$, CH_3CON^- et CO_2^-, qui ont été récemment déterminés sur la base des intensités et des fréquences infrarouges du groupe cyano, s'avèrent assez fiables par rapport au ν_{CO} des acétophénones. On a évalué respectivement à $-0,22 \pm 0,03$ et à $-0,66 \pm 0,13$ les constantes σ^+ du *m*-$CH_2CO_2^-$ et du *m*-$C_6H_5CON^-$ en se basant sur les données de ν_{CO} et sur les corrélations de ν_{CO}/σ^+ (avec du DMSO comme solvant).

[Traduit par le journal]

Introduction

Correlations of ν_{CO} of ring-substituted acetophenones have been studied repeatedly (1–17); correlations satisfactory, with σ (2–7), and excellent, with σ^+ (5, 7, 10, 11, 13, 17), have been found in this series; some of the *dual*- and *multi*-parameter correlations have also proved excellent (7, 8, 13). The data obtained have been used in studies on steric and mass effects of the substituents (3, 4, 13), studies on conformational equilibria (3, 13) and intramolecular hydrogen-bond formation (13) in some *ortho*-substituted acetophenones (criticism, see ref. 17), as well as for estimation of transmission coefficients of certain bridge groups (10). Together with other spectroscopic series, ν_{CO} of acetophenones have been used to check the reliability of various types of substituent constants (5–12, 16) and to compare the fit of Hammett-type correlations with that of the correlations with certain quantum-chemical indices (14, 15). The constants for some heterocycles have been determined on the basis of acetophenone ν_{CO} data; the results have been compared with those obtained by other methods (11).

In this paper we demonstrate that the use of dimethyl sulphoxide (DMSO) instead of carbon tetrachloride as solvent does not lower the relative accuracy of the correlations of ν_{CO} of acetophenones with substituent constants. This makes it possible to use this series as a reliability test for the constants of some anionic substituents, determined recently (18) on the basis of nitrile infrared frequencies and intensities. On the other hand, collecting all the data available (both our own and literature values for 45 compounds) on ν_{CO} of ring-substituted acetophenones in CCl_4 will allow us to specify the parameters of acetophenone ν_{CO} correlations with the most common types of substituent constants.

Experimental

Acetophenones not commercially available have been prepared and purified according to the literature. Acetophenones with anionic substituents have been obtained by metalation of the corresponding conjugate acids with dry sodium methoxide in DMSO. Spectra of CCl_4 and DMSO solutions have been recorded on a UR-20 Zeiss spectrophotometer in $CaCl_2$ cells, calibration according to the H_2O–gas spectrum. A current calibration (acetophenone in CCl_4, ν_{CO} = 1691.0), has also been used. ν_{CO} were reproducible within ± 0.2 cm^{-1}; the absolute accuracy of the ν_{CO} data also seems to be high: comparison of our data for compounds **1**, **2**, **15**, **16**, **22**, **24**, **27**, **33**, **38**, and **39** with those given in ref. 17 shows a maximum deviation ± 0.5 cm^{-1}, mean deviation < 0.1 cm^{-1}. Comparison with data taken from refs. 3, 4, 7, 9, and 13 shows a similarly good agreement (cf. Table 1, data under asterisks). On the other hand, high-accuracy ν_{CO} data for a few acetophenones have been obtained recently[1] by using a Bruker-113v IR Fourier spectrophotometer, as follows (compound no., solvent, ν_{CO}): **1**, CCl_4, 1690.8; **1**, DMSO, 1682.1; **24**, DMSO, 1672.9; **39**, DMSO, 1691.3 (cf. Table 1). The integrated intensities have been determined by direct integration according to Ramsay's method (19*a*), specially adapted (19*b*) for spectrometers of the UR series. The method takes into account both the slit width effects and band wings. A_{CO} thus determined were reproducible within $\pm 3\%$.

Results and discussion

A. *Acetophenones with neutral substituents*

The frequencies and integrated intensities of the carbonyl stretching bands of a series of acetophenones with neutral substituents are listed in Table 1. Statistical treatment data of the correlations of ν_{CO} with σ and σ^+ constants (values, see refs. 22, 23) according to the equations of Hammett (σ) and Brown–Okamoto (σ^+) (eq. [1]) are given in Table 2.

$$[1] \quad \nu_{CO} = \rho\bar{\sigma} + b \; (\bar{\sigma} = \sigma \text{ or } \sigma^+)$$

It is seen in Table 2 that comparing ν_{CO} of acetophenones with σ^+ gives excellent correlations (see also Figs. 1 and 4); those

with σ are considerably poorer. The pronounced predilection with respect to σ^+ in agreement with refs. 5, 7, 10, 11, 13, and 17 is due to the essential role of the direct resonance between electron-donating substituents and the carbonyl group. Frequencies of other electron-withdrawing groups also correlate with σ^+, as was shown in some earlier publications (5, 24, 25). It is also seen in Table 2 that use of the strongly polar DMSO instead of CCl_4 as solvent does not affect the accuracy of the correlations obtained. Similar results have been obtained in the ν_{CN} and A_{CN} series of benzonitriles (18) and ν_{CO} series of benzophenones, methylbenzoates, and ethylbenzoates (25). Correlations in the joint (*meta* and *para*) series are somewhat poorer, due to the slope differences of the *meta* and *para* series (Table 2, Fig. 1, and ref. 17). The deviation $\Delta\rho = \rho_{meta} - \rho_{para}$ of ca. 5.1 cm^{-1} found by Berthelot and Laurence remains practically the same in our correlations: 4.6 cm^{-1} (solvent CCl_4, series 7 and 9) and 5.2 cm^{-1} (solvent DMSO, series 8 and 10). We believe one should search for the origin of this kind of deviation in the different contribution of inductive and resonance effects to the total substituent effects in a given series (different, with respect to that in the standard series, in this case Brown–Okamoto's, cf. ref. 18).

It was therefore of interest to check the fit of the dual-parameter correlation equations of Yukawa–Tsuno (26) and Taft (27) (eqs. [2] and [3]) in the acetophenone ν_{CO} series.

$$[2] \quad \nu_{CO} = \rho(\sigma^0 + r'\Delta\sigma_R^+) + b$$

[3] $\nu_{CO} = \rho_I\sigma_I + \rho_R\bar{\sigma}_R + b; \qquad \bar{\sigma}_R = \sigma_R^{BA}$ and σ_R^+

The results of the statistical treatment of ν_{CO} data according to these equations (substituent constants, see refs. 28 and 29) are listed in Table 3. Comparison of the R and s.d. parameters of the Yukawa–Tsuno-type correlations (Table 3, series 13 and 14) with those of the best-fit single-parameter correlations (Table 2, series 11 and 12) shows that use of the Yukawa–Tsuno's equation results in some improvement of the studied correlations. The r' value obtained for the carbon tetrachloride solutions (series 13) is in a good agreement with $r' = 0.612$ found earlier (7) for a series of *para*-substituted acetophenones.

The correlations according to eq. [3] (σ values from ref. 29) are also satisfactory (Table 3); their accuracy is close to that of the corresponding best-fit single-parameter correlations (Table 2, series 7–10). A direct comparison of these results with Krueger's values (13) is not possible because of the differences in the σ values used.

In agreement with ref. 3, A_{CO} of acetophenones (solvents CCl_4 and DMSO) do not correlate well with any type of substituent constants; the "correlations" obtained have R values in the 0,5–0,7 range, so they cannot be used for any practical purposes. This result could be related to the one found in the studies on A_{CO} in the substituted benzophenones series. The lack of correlation of $A_{CO}^{1/2}$ with $\bar{\sigma}$ in that case has been observed by several authors (see the references in ref. 25*a*) and then

^{a,b,c}See Table 2.

explained (25*a*) by the presence of a coupling between the ν_{8a} (of the benzene ring) and ν_{CO} vibrations. We assume that there is no correlation in the present case for similar reasons. This assumption finds some support in the data given in Section B, viz. data for acetophenones with extremely strong electron-releasing substituents, e.g. O^- and NC—HC^-. In these cases ν_{CO} frequencies are close to ν_{8a}, and A_{CO} intensities are the lowest ones.

B. *Acetophenones with anionic substituents*

The good fit of the correlations of ν_{CO} of acetophenones (solvent DMSO) makes it possible to use this series as a test with respect to the reliability of the constants of certain anionic substituents, determined recently (18) on the basis of nitrile infrared frequencies and intensities.

We prepared acetophenones with anionic substituents by metalation of the corresponding conjugate C—H, N—H, and O—H acids (cf. Experimental). Metalation resulted in essential changes in the infrared spectra: decrease in both ν_{CO} and ν_{CN} frequencies, strong intensification of the ν_{CN} bands and those of the aromatic skeletal vibrations, etc. (Figs. 2 and 3). ν_{CO} and A_{CO} of a series of acetophenones with anionic substituents (solvent DMSO) are listed in Table 4 together with the corresponding substituent constants.

Adding data for anions in the correlations for the neutral acetophenones gives a new set of single- and dual-parameter correlations, valid for ν_{CO} of acetophenones with both neutral and anionic substituents (Table 5). A plot of ν_{CO} vs. σ^+ for the whole series is shown in Fig. 4.

Comparison of the R values in Table 5 with those from Tables 2 and 3 (series with corresponding numbers) shows that the addition of the data for acetophenones with anionic substituents to those for neutral compounds does not change significantly the relative accuracy of both single- and dual-parameter correlations. Thus, constants σ^+, σ^0, $\Delta\sigma_R^+$, σ_I, and σ_R^+ of the anionic substituents considered, determined on the basis of nitrile frequencies and intensities in polar aprotic solvents, prove satisfactorily reliable in the ν_{CO} series of ring-substituted acetophenones. We should note that the deviation $\Delta\rho$ in the new set of correlation equations is only 1.5 cm^{-1} (cf. series 8a and 10a). This result is obviously related to the one-sided charging of the correlations with data for acetophenones with very strong donors (anionic substituents), for which the σ^+ constants have a *spectroscopic origin*.

The σ^+ constants of the anionic substituents 3-$CH_2CO_2^-$ and 3-$C_6H_5CON^-$ are not known. In principle their values can be estimated on the basis of data from Table 4 and the correlation equations for either series 8 (Table 2) by extrapolation or series 8a (Table 5) by interpolation. The latter method seems better

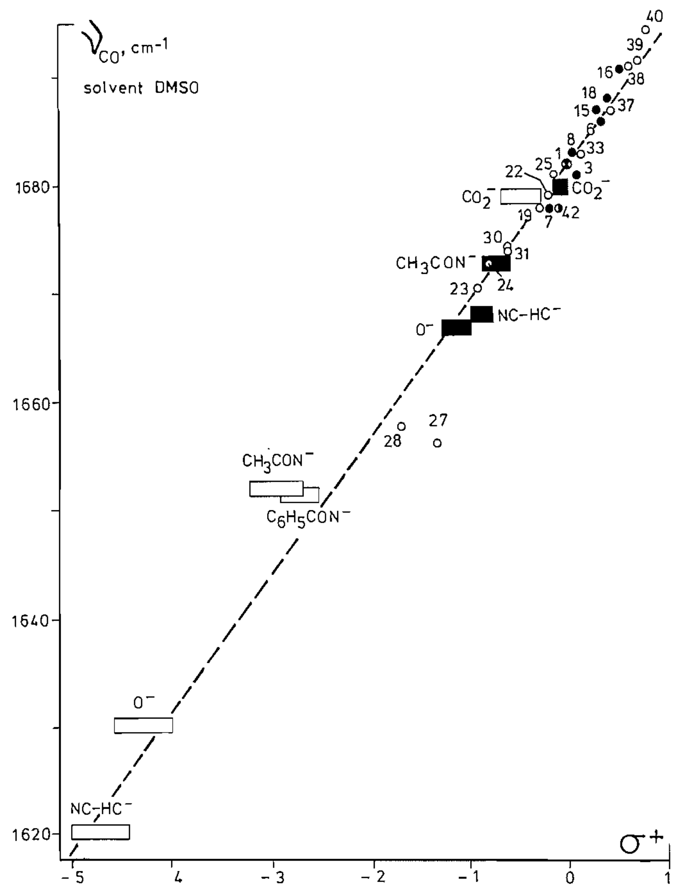

FIG. 4. Plot of ν_{CO} of acetophenones with *neutral* and *anionic* substituents (solvent DMSO) vs. σ^+ substituent constants; ●, *meta* substituted compounds; ○, *para* substituted compounds; ■ and □, compounds with *anionic* substituents. The abscissa width of the rectangular points corresponds to the inaccuracies (ref. 18) of σ^+ values of anionic substituents.

justified and it gives the following values: σ^+ (3-$CH_2CO_2^-$) = −0.22 ± 0.08; σ^+ (3-$C_6H_5CON^-$) = −0.66 ± 0.13. These values seem plausible, compared with σ^+ of other anionic substituents (18). Nevertheless, they are not of high reliability because substituent constants, determined in this way, depend strongly on the series of definition (30, 18).

Conclusion

Correlations found in this work can be used for predicting ν_{CO} of acetophenones with both neutral and anionic substituents in a wide frequency region. On the other hand, the satisfactory accuracy of these correlations could be considered as a proof of the reliability of the constants of the anionic substituents. As stated (18), further refinement of these constants could be achieved by including data for compounds with anionic substituents from other series, including ring-substituted acetophenones.

ROBERT D. COOK and MARLENE METNI. Can. J. Chem. **63**, 3155 (1985).

The hydrolysis of methyl dimethylphosphinothionate in D_2SO_4–D_2O solution gives as products the phosphinic acid and methyl dimethylphosphinate. The bell-shaped pH–rate profiles for both reactions as well as the values of Bunnett's w and w^* (3.31 and −0.21 respectively), Bunnett–Olsen's ϕ (0.82), and Yates–McClelland's r (6.56) support an A-2 pathway. The results are interpreted in terms of the presence of a common pentacoordinate intermediate along the reaction pathway. The pK_a of the above ester as well as that of methyl dimethylphosphinodithioate are reported (−5.53 and −5.38 respectively).

ROBERT D. COOK et MARLENE METNI. Can. J. Chem. **63**, 3155 (1985).

L'hydrolyse du diméthylphosphinothionate de méthyle dans une solution de D_2SO_4–D_2O conduit à de l'acide phosphinique et au diméthylphosphinate de méthyle. La courbe en cloche du pH en fonction de la vitesse, observée pour les deux réactions, ainsi que les valeurs w et w^* de Bunnett (3,31 et −0,21 respectivement), la valeur de ϕ (0,82) de Bunnett–Olsen ainsi que la valeur de r (6,56) de Yates–McClelland confirment l'existence d'un mécanisme du type A-2 pour les deux réactions. On interprète les résultats en fonction de la présence d'un intermédiaire commun pentacoordonné dans le processus réactionnel. On a déterminé la valeur du pK_a de l'ester ci-dessus ainsi que celle du diméthylphosphinodithioate de méthyle; ces valeurs sont respectivement −5,53 et −5,38.

[Traduit par le journal]

Introduction

From our previous studies on the acid-catalyzed hydrolysis of phosphinates we reported that methyl dialkylphosphinates hydrolyze by an A-2 process and, based on relative rate data for the esters **1**_a–d_ of 11:2.5:1.2:1, we suggested that water attacks the carbon of the protonated ester with subsequent C—O bond cleavage (2). On the other hand, McClelland has shown by O-18 studies that compounds **2**_a–c_ undergo acid-catalyzed hydrolysis with approximately 90% P—O bond cleavage (3). In the alkaline hydrolysis of phosphinates, P—O bond cleavage is the norm (4) except in the case when phosphorus is substituted with large alkyl groups like iC_3H_7 where Haake and Rahil (5) have shown that there is mixed cleavage (approximately 25% C—O cleavage). In other phosphorus esters P—O cleavage predominates in base and C—O cleavage in acid (6).

$R_2P(O)OCH_3$	R =	CH_3	C_2H_5	iC_3H_7	t-C_4H_9

$(CH_3)_2P(S)OCH_3$ **3**					

In the reactions in which nucleophilic attack on acyclic phosphorus esters takes place on phosphorus, two pathways have been suggested, one involving a direct displacement ($S_N2(P)$) (7) and the other by the formation of a pentacoordinate intermediate (4). There is, to date, only one report in the literature (8_a_) which gives direct support to intermediate formation in a displacement reaction on an acyclic phosphorus ester (phosphonate). The existence of intermediates is, however, well documented both in the displacement reactions on cyclic phosphorus esters (8_b_) as well as in the reactions of carboxylic esters (9).

Following the observations of Smith and O'Leary (10) and Edward, Wong, and Welch (11) that carboxylic thione esters undergo both hydrolysis and sulfur–oxygen exchange in acid solution and their suggestion that the reaction proceeds by a common tetrahedral intermediate, a study was undertaken on the hydrolysis in acid of a simple phosphorus analog, methyl dimethylphosphinothionate (**3**). The dimethyl ester was chosen in order to maximize the possibility of attack on phosphorus because only in this case will both hydrolysis and exchange be possible.

Results

Rate data

The hydrolysis of **3** in 25–85% D_2SO_4–D_2O solution gives not only the phosphinic acid but also methyl dimethylphosphinate (**1**_a_) (eq. [1]). The observed first-order rate constants

$$[1]\quad \mathbf{3} \xrightarrow{D_3O^+} \underset{\mathbf{4}}{(CH_3)_2P(S)OH} + \mathbf{1a} \longrightarrow \underset{\mathbf{5}}{(CH_3)_2P(O)OH}$$

for the conversion of **3** to **1**_a_ and **4** are given in Table 1. The pH–rate profiles for the above data are given in Fig. 1 and, for the sake of comparison, Fig. 2 gives the profiles for the hydrolysis reaction of **3** to **4** and of **1**_a_ to **5** (2).

Basicity data

The pK_a of **3** as well as that of another phosphinothionate,

methyl dimethylphosphinodithioate, were determined by the nmr method (14) and the results are given in Table 2. Included in Table 2 are the previously determined results for ester **1***a* (2). The value of m in Table 2 is the slope of the plot of $\log_{10}$ $[SD^+]/[S]$ versus $-D_0$ and its value indicates the extent of deviation of the individual substrate from Hammett basicity (anilines). Values above one are interpreted as less solvation of the substrate and values below one as more solvation of the substrate as compared to Hammett bases (14).

Treatment of the kinetic data

The rate data for the hydrolysis of **3** (k_{hyd}) were analyzed using the form of the Bunnett w and w^* equations (15), the Bunnett–Olsen ϕ equation (16), and the Yates–McClelland r

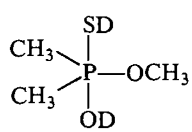
value equation (17) for a moderately basic substrate. The results for these analyses are given in Table 3 along with the results for ester **1**a (2). The r plot for **3** is given in Fig. 3.

Discussion

The bell-shaped pH–rate profiles for both reactions of **3**, indicating acid catalysis at lower acidities and acid inhibition at higher acidities, are usually interpreted in terms of an A-2 process (18). All of the other data from the treatment of the rate constants using the Bunnett, Bunnett–Olsen, and Yates–McClelland equations lend support to this conclusion. The concomitant hydrolysis of **3** to acid and exchange of oxygen for sulfur in an A-2 process can best be explained in terms of attack of water on protonated ester to give a pentacoordinate intermediate (**6**) followed by loss of either D_2S or $DOCH_3$. It can therefore be concluded that in this system there is attack on phosphorus with resultant P—O bond cleavage. There is no



6

evidence in the acid-catalyzed hydrolysis of phosphinates of reversibility and therefore it can be ruled out that **1**a is a result of the esterification of **5** (2).

These results are analogous to those obtained on thion esters (10, 11). In these latter systems loss of H_2S is faster than loss of alcohol at the lower acidities, the opposite of what is observed for compound **3**. Since apical departure from a pentacoordinate species is favored (8), loss of D_2S should proceed from **6** and loss of $DOCH_3$ from **7**. The structures **6** and **7** are mutually interconvertible by pseudorotation and therefore the relative rates for the loss of D_2S and $DOCH_3$ are independent of the relative amounts of **6** and **7**. Since it is likely that the transition state for breakdown of the intermediate involves an

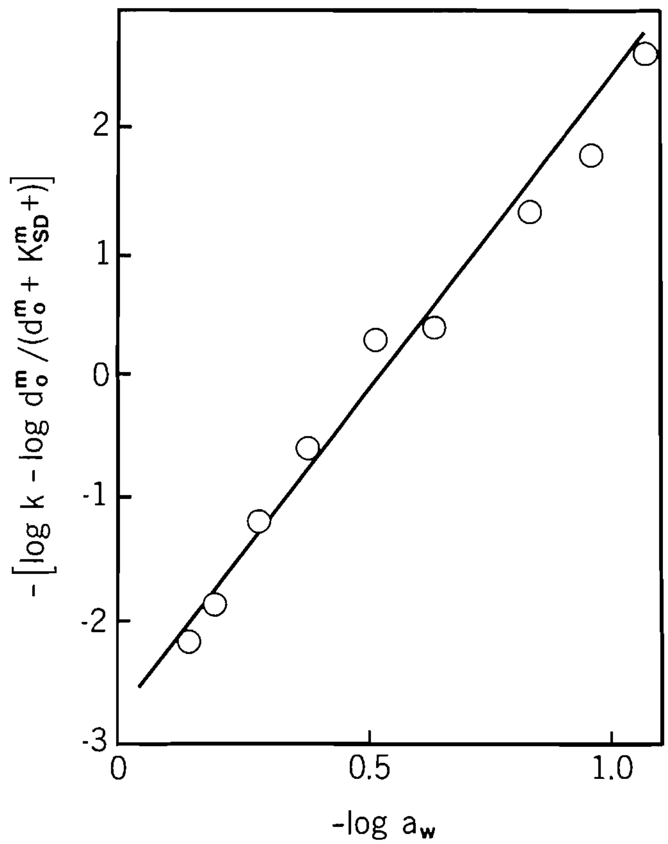


FIG. 3. Yates–McClelland r plot of the rate data obtained for methyl dimethylphosphinothionate hydrolysis.

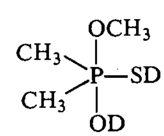


7

extra proton, the faster loss of alcohol could be due to the greater basicity of the oxygen center over the sulfur center.

The value of r of the Yates–McClelland equation is very high (it is typically 2 for carboxylic ester hydrolysis) and this is a direct result of the high m value for the ester **3**. For the five phosphinates that we have studied (ref. 2 and this work), which hydrolyze by an A-2 pathway, there is a linear relationship between r and m (using eq. [2]).

$$[2] \quad \log k_{obs} - \log \frac{h_0^m}{K_{SH^+}^m + h_0^m} = r \log a_{H_2O} + C$$

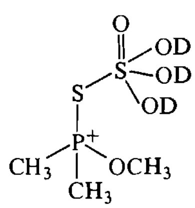
Qualitatively this is very reasonable since esters which are poorly solvated (high m values) will require more additional water in the rate-determining step (higher r value).

The sulfur exchange result is the best evidence to date in support of the formation of pentacoordinate intermediates in the displacement reactions at acyclic phosphinate esters.

The explanation proposed for these results supposes a common intermediate. We have no specific evidence on this point. It is possible that hydrolysis could proceed by a path different from sulfur to oxygen exchange, for example, by a S_N2 (P) reaction or a S_N2 process with C—O bond cleavage. The existence of an intermediate is only supported by the exchange reaction.

High acidity sulfur exchange

The upward curvature at high acidities of the pH–rate profile in hydrolysis reactions is usually associated with a change in mechanism from A-2 to A-1 (17). It is, however, difficult to contemplate the unimolecular cleavage of what is essentially a P=S double bond. This observed rate increase continues such that in 95% D_2SO_4 complete conversion of **3** to **1***a* takes only a few minutes at 75°C. Under these conditions no hydrolysis of either **3** or **1***a* is observed. If an A-1 process is not to be considered, then neither can a reaction involving water be considered, because of its vanishingly small activity at this acid concentration (18). Cox (19) has reported the changing activities of sulfuric acid related species over a large range of acid concentration. The only species with increasing activity in this high weight percent region is $D_3SO_4^+$. One possible pathway for the reaction would involve the formation of **8**, which results from the addition of **3** to $D_3SO_4^+$ (or protonated **3** to D_2SO_4) and which by loss of a proton would give a betaine similar to what is encountered in the Wittig reaction. The species **8** would then



8

decompose to **1***a* and $D_2S_2O_3$, thiosulfuric acid. We have no independent evidence to support this proposal.

Basicity of the P=S system

The esters containing the P=S linkage are approximately 2.5 pK_a units less basic than those with the P=O linkage. A similar decrease in basicity is observed for thione esters with respect to their oxygen analogs (11) and dimethyl sulfide is also reported to be less basic than dimethyl ether by a similar amount (20). There is ample evidence for p–d π-bonding in the P=O system (21) but much less evidence is available in support of p–d π-bonding in the P=S linkage. The low basicity of the phosphinothionates is good evidence in support of π-bonding and the almost constant decrease in going from a oxygen base to a sulfur base in the three systems suggests that the nature of the bonding must be similar within the three pairs.

It is interesting to note that the m value is approximately the same for the thione ester and the dithio ester and both are considerably larger than the value for the P=O ester. This slope parameter, m, reflects the deviation from Hammett basicity of the substrate and values greater than 1 are considered to be less solvated than Hammett's anilines and those less than 1 more solvated (14). The almost identical values for the sulfur-containing compounds suggest that it is essentially changes in solvation of the P=X (X = O or S) part of the molecule that determine the value of m.

Experimental

Synthesis of the esters

The ester **3** was prepared by the addition of an equimolar amount of sodium methoxide in methanol to dimethylphosphinothionyl chloride in benzene. The acid chloride was prepared by treating tetramethylbiphosphine disulfide with a equimolar amount of sulfuryl chloride in benzene (22). The disulfide was synthesized by adding trichlorophosphine sulfide (1 mole) to methylmagnesium iodide (3 moles) in ether (23). The boiling point of **3** is 79–80°C/2.5 Torr (uncorrected) (1 Torr = 133.3 Pa); ir (neat): (P=S) 665, 755 cm^{-1}; ^{1}H nmr δ: 3.55 (3H, d, J = 14 Hz) and 1.87 (6H, d, J = 14 Hz).

Kinetic measurements

The hydrolysis reactions of **3** were run in different weight percent solutions of D_2SO_4 in D_2O. The molarity of the acid was determined from a calibration curve prepared by titration. All rates were followed on a Varian Model EM 360L nmr spectrometer. For acidities below 50% D_2SO_4, where no sulfur exchange was observed, the reactions were monitored in a manner similar to that of our previous report (2). At higher acidities two regions of the spectra were examined, the downfield region represented by all OCH_3 groups and the upfield region represented by all P—CH_3 groups. In the downfield region there is a doublet for **3**, a doublet for **1***a*, a singlet for methanol, and another singlet for dimethyl ether (from the dehydration of methanol). The peaks could be integrated separately and the ratio of the areas of **1***a* to methanol and ether gives the ratio of the rate constants for their production (k_{hyd}/k_{ex}). In the upfield region only 4 peaks appear, a doublet for **3** and a doublet for the other 3 compounds (**1***a*, **4**, and **5**). Integration of the two areas gives us the rate constant for loss of **3** (k_{total}). All assignments were checked at each concentration by adding authentic samples to the nmr tubes. With a few of the concentrations overlap of peaks occurs. These samples were diluted with D_2O before analysis.

Under the reaction conditions **1***a* also undergoes hydrolysis to give **5** and therefore the ratio of k_{hyd}/k_{ex} slowly increases. The values used in Table 1 are from the initial points of the reaction.

We have no evidence as to whether or not acid **4** keeps its integrity under the reaction conditions. The chemical shift of the P—CH_3 groups of the two acids **4** and **5** are the same in sulfuric acid solution.

Measurement of the pK_a

The pK_a's of the esters were measured by the nmr method of Haake *et al.* (14) in D_2SO_4–D_2O solution at room temperature.

Proton affinities of the hydrogen, methyl, and trifluoromethyl halides from pulsed electron beam high pressure mass spectrometric equilibria measurements

T. B. McMahon[1] and P. Kebarle
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received March 19, 1985

T. B. McMahon and P. Kebarle. Can. J. Chem. **63**, 3160 (1985).

Pulsed electron beam high pressure mass spectrometric techniques have been used to investigate proton transfer equilibria involving hydrogen and trifluoromethyl halides. Methyl cation transfer equilibria have also been used to determine methyl cation affinities of hydrogen halides. Proton affinities obtained are HCl = 137.5, HBr = 142.9, HI = 150.9, CF_3Cl = 139.0, CF_3Br = 141.3, and CF_3I = 150.4 kcal mol^{-1}. Methyl cation affinities obtained are HF = 15 ± 2, HCl = 19.8, HBr = 21.3, and HI = 31.1 kcal mol^{-1}. The values of methyl cation affinity of hydrogen halides can in turn be used to calculate proton affinities of the methyl halides of CH_3Cl = 160.8; CH_3Br = 164.8; and CH_3I = 171 kcal mol^{-1}. Linear correlations are found between proton affinities and valence ionization potentials and between proton affinities and methyl cation affinities.

T. B. McMahon et P. Kebarle. Can. J. Chem. **63**, 3160 (1985).

Faisant appel à des technique de spectrométrie de masse à haute pression utilisant un faisceau pulsé d'électron, on a étudié les réactions d'équilibre de transfert de proton impliquant des halogénures d'hydrogène et de trifluorométhyle. On a également utilisé l'équilibre de transfert du cation méthyle dans le but de déterminer les affinités du cation méthyle pour les halogénures d'hydrogène. On a obtenu les affinités suivantes pour le proton: HCl = 137,5; HBr = 142,9; HI = 150,9; CF_3Cl = 139,0; CF_3Br = 141,3 et CF_3I = 150,4 kcal mol^{-1}. Les affinités pour le cation méthyle sont les suivantes: HF = 15 ± 2; HCl = 19,8; HBr = 21,3 et HI = 31,1 kcal mol^{-1}. Par la suite, on peut utiliser les valeurs des affinités du cation méthyle pour les halogénures d'hydrogène pour calculer les affinités du proton pour les halogénures de méthyle qui sont CH_3Cl = 160,8; CH_3Br = 164,8 et CH_3I = 171 kcal mol^{-1}. On a trouvé des corrélations linéaires entre les affinités du proton et les potentiels d'ionisation de valence et entre les affinités du proton et les affinités du cation méthyle.

[Traduit par le journal]

Introduction

Investigations of gas phase proton transfer equilibria during the past decade (for extensive reviews of gas phase basicities, see ref. 1) have provided a wealth of data concerning the intrinsic basicities of molecules in the absence of solvent effects.[2] These studies have led to many insights into factors governing structure, stability, and bonding in ionic species. However, while a great deal of data exists for traditional basic functional groups such as amines, carbonyls, ethers, alcohols, mercaptans, and sulphides, there have been no accurate quantitative equilibrium proton transfer data obtained for the weakly basic halide functional groups. These particular groups of compounds are of special interest since the stability, ready availability, and ease of handling of compounds of four members of the group (F, Cl, Br, I) provide an ideal opportunity to examine periodic trends not afforded by any other group of elements.

The hydrogen halides have been examined by a number of investigators. Foster and Beauchamp (3) obtained proton transfer equilibrium between HF and N_2, eq. [1], to arrive at $\Delta H_1^0 = -1.1$ kcal mol^{-1}. However, since no accurate proton affinity

$$[1] \quad H_2F^+ + N_2 \rightleftharpoons N_2H^+ + HF$$

was available for N_2, an approximate value of proton affinity of 112 ± 2 kcal mol^{-1} was assigned to HF. No other proton transfer equilibrium measurements have previously been reported for the remaining hydrogen halides. Polley and Munson (4) have carried out a series of experiments in which a variety of proton transfer reactions to hydrogen halides, and from the protonated hydrogen halides to other species, were examined. From such observations of occurrence or non-occurrence of proton transfer (bracketing technique) to species of known basicity, approximate proton affinity values for the hydrogen halides were obtained of 135 ± 2 kcal mol^{-1} for HCl, 140 ± 1 kcal mol^{-1} for HBr, and 147 ± 2 kcal mol^{-1} for HI. It must be noted, however, that these assignments were again limited by the relatively high uncertainty in proton affinity values of the reference species involved.

In an elegant series of experiments Lee and co-workers (5, 6) have determined absolute values for proton affinities of HF, HCl, and HBr based on photoionization appearance potential measurements of the corresponding protonated hydrogen halides, H_2X^+, from the corresponding van der Waals dimers, $(HX)_2$, formed in a supersonic expansion. The value obtained for PA(HF) of 95.5 ± 1.4 kcal mol^{-1} was in poor agreement with that of Foster and Beauchamp (3); however, the values of PA(HCl) of 135 ± 1 kcal mol^{-1} and PA(HBr) of 141 ± 1 kcal mol^{-1} were in excellent agreement with those of Polley and Munson (4).

No equilibrium proton transfer measurements involving methyl halides have been possible to date due to the rapid nucleophilic displacement reactions, eq. [2], of the protonated methyl halides (7) which compete effectively with proton transfer processes, preventing attainment of equilibrium. In a

$$[2] \quad CH_3XH^+ + CH_3X \rightarrow (CH_3)_2X^+, HX$$

systematic study of the gas phase ion chemistry of methyl and ethyl halides Beauchamp *et al.* (7) were able to bracket the proton affinities of these compounds approximately. The values obtained of $PA(CH_3F)$ = 151 kcal mol^{-1}, $PA(CH_3Cl)$ = 160 kcal mol^{-1}, $PA(CH_3Br)$ = 163 kcal mol^{-1}, and $PA(CH_3I)$ = 170 kcal mol^{-1} were again limited by the uncertainties in data for the reference species used.

A number of *ab initio* quantum chemical investigations of the proton affinities of HF, HCl, CH_3F, and CH_3Cl have been

[1] Address correspondence to this author at: Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1.

[2] The quantitative definition of gas phase basicity of a molecule M is the proton affinity, PA(M), defined as the negative of the enthalpy change for the gas phase reaction: $M + H^+ \rightarrow MH^+$ at 298 K.

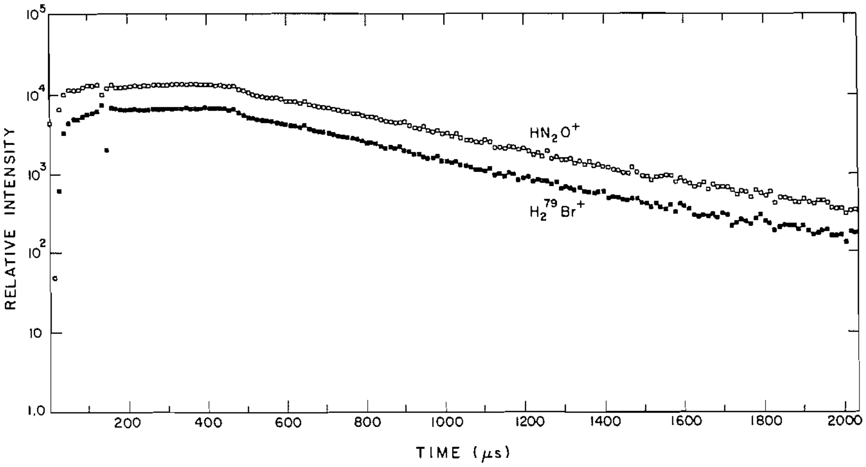

FIG. 1. Variation of relative ionic abundances as a function of time after initial ionization in a mixture of CH_4, N_2O, and HBr at a total ion source pressure of 3.0 Torr and a N_2O/HBr ratio of 2.5:1.

carried out. Diercksen *et al.* (8) carried out large basis set calculations on HF and H_2F^+ with complete geometry optimization to obtain a proton affinity of HF of 120 kcal mol^{-1}. Jorgensen and co-workers (9) have carried out calculations of each of the hydrogen and methyl fluorides and chlorides using a variety of basis sets and obtained proton affinities at the 6-31G* level of 121.4 kcal mol^{-1} for HF, 151.5 kcal mol^{-1} for CH_3F, 129.1 kcal mol^{-1} for HCl, and 151.3 kcal mol^{-1} for CH_3Cl. It should be emphasized that none of the above calculations included contributions due to zero point energy differences between ionic and neutral species or due to differences in proton affinity at 0 K and 298 K (10). Pople and co-workers (11) have carried out calculations for HF using a 6-31G** basis set incorporating fourth-order Moeller–Ploesset determinations of the correlation energies and including zero point energy differences to obtain a proton affinity of HF of 124.7 kcal mol^{-1}.

Very recently, extensive studies of proton transfer equilibria from this laboratory (12) have established a quantitative scale of gas phase basicities for the proton affinity region below water to species as weakly basic as methane. All of these data are anchored to the now well-established value for the proton affinity of ethylene (13–15). Included in this basicity scale are proton transfer equilibria involving the hydrogen halides HCl, HBr, and HI, thus establishing, for the first time, accurate values for the proton affinities of these species based on thermochemical equilibrium measurements.

As noted above, proton transfer equilibria involving methyl halides are not readily observable due to competition from nucleophilic displacement processes. However, also recently in this laboratory, we have devised techniques for the examination of methyl cation transfer equilibria, eq. [3] (16). When methyl cation transfer equilibria involving hydrogen halides

[3] $CH_3M^+ + HX \rightleftharpoons CH_3XH^+ + M$

are carried out, accurate thermochemical data for CH_3XH^+ species, i.e. protonated methyl halides, are obtained, which, when combined with known neutral thermochemistry, allow determination of accurate proton affinities of the methyl halides.

With the exception of some work on CF_4 by Bohme and co-workers (17), no information is available on protonation of any of the trifluoromethyl halides. These species are of interest because of the strongly destabilizing effect of the electronegative CF_3 substituent on basicities and because they provide another type of molecule where protonation on the halogen will occur. Fortunately, these species do not undergo nucleophilic displacement reactions and it was possible to incorporate CF_3Cl, CF_3Br, and CF_3I into the scale of proton transfer equilibrium basicity measurements.

The proton transfer equilibria involving hydrogen and trifluoromethyl halides and methyl cation transfer equilibria involving hydrogen halides provide accurate proton affinity data for HX, CH_3X, and CF_3X compounds. This makes possible an analysis of periodic trends and substituent effects in halogen basicities, described in the present study.

Experimental

All equilibrium measurements were carried out at 400 K using a pulsed electron beam high pressure mass spectrometer (hpms) described in detail previously (18), which has been recently updated incorporating a Lecroy Model 3921 Multichannel Analyzer allowing use of dwell times as short as 1 μs per channel.

For proton transfer equilibria involving HBr, HI, CF_3Cl, CF_3Br, and CF_3I the major gas used was CH_4, which was flowed through the high pressure ion source at pressures between 2 and 5 Torr (1 Torr = 133.3 Pa). Ion source pressures of the halides and reference compounds were in the range of 1–10 mTorr. Protonation of halides occurred by the well-known reaction sequence in methane, eqs. [4] and [5]. Data for a typical proton transfer equilibrium are illustrated in Fig. 1.

[4] $CH_4{}^+ + CH_4 \rightarrow CH_5{}^+ + CH_3$

[5] $CH_5{}^+ + RX \rightarrow RXH^+ + CH_4$

Proton transfer equilibria involving HCl and all methyl cation equilibria were carried out using nitrogen as the major bath gas. The use of nitrogen rather than methane for proton transfer to HCl was necessitated by the close proximity of CH_4 and HCl in proton affinity. The principle mode of formation of H_2Cl^+ is via the sequence of eqs. [6] and [7]. The use of N_2 as the major gas for methyl cation transfer equilibria arises because of the useful sequence of reactions, eqs. [8]–[11], which occurs in CH_3F–N_2 mixtures.

[6] $N_2{}^+ + HCl \rightarrow N_2H^+ + Cl$

[7] $N_2H^+ + HCl \rightarrow H_2Cl^+ + N_2$

[8] $N_2{}^+ + CH_3F \rightarrow N_2H^+ + CH_2F$

[9] $N_2H^+ + CH_3F \rightarrow CH_3FH^+ + N_2$

[10] $CH_3FH^+ + N_2 \rightarrow CH_3N_2{}^+ + HF$

[11] $CH_3N_2{}^+ + CH_3F \rightarrow (CH_3)_2F^+ + N_2$

The $\Delta H_f^0(CH_3N_2{}^+)$ and hence the methyl cation affinity (MCA) of N_2 is known from photoionization appearance potential measurements of $CH_3N_2{}^+$ from azomethane (19). In the presence of a large excess of N_2 eq. [11] reaches equilibrium, establishing the methyl cation affinity of CH_3F. This mixture of CH_3F–N_2 can then be used as a methylating medium and, when methyl cation transfer equilibrium is observed, accurate relative methyl cation binding energies may be obtained. A typical methyl cation transfer equilibrium is illustrated in Fig. 2.

In addition to the usual procedures for carring out hpms experiments for the present studies, all gases flowing from the gas handling system to the high pressure ion source were passed through a U-trap cooled by a variety of slush baths, typically to −95 to −150°C. This procedure was necessary to remove traces of H_2O. Due to the extremely low basicities of the compounds under study, the presence of H_2O even at the part per thousand level led to production of H_3O^+ and higher proton hydrates that precluded observations of the equilibrium of interest.

Results

Proton transfer equilibria between reference species, M, and the hydrogen and trifluoromethyl halides, RX, which have been used to obtain proton affinities for RX, are summarized in Table 1 together with the thermochemical data derived. Values for ΔS^0 have been estimated from experimentally known S^0 data. For ionic species these were taken from known data for isoelectronic neutral molecules (20). For example, $S^0(H_2Cl^+)$ was estimated as 49.7 cal mol^{-1} K^{-1} based on the value of $S^0(H_2S)$ of 49.2 cal mol^{-1} K^{-1} and a small correction for differences in translational entropy of H_2Cl^+ and H_2S.

Proton affinities of reference compounds CH_4, N_2O, CO, C_2H_6, SO_2F_2, and $(CF_3)_2CO$ were taken from recent data from this laboratory, in which a quantitative proton affinity scale between H_2O and CH_4 was constructed (12). Although these data did not extend to compounds as weakly basic as N_2, the values for PA(CO) and $PA(CH_4)$ may be combined with Bohme's data for compounds less basic than CH_4 (21) to yield $PA(N_2)$ = 122.0 kcal mol^{-1}. This then also permits PA(HF) to be calculated from the equilibrium data of Foster and Beauchamp (3) for eq. [7] as 120.9 kcal mol^{-1}.

Methyl cation transfer equilibria used to establish methyl cation affinities of the hydrogen halides are summarized in Table 2. The MCA scale is anchored to $MCA(N_2)$ which can be calculated from $\Delta H_f^0(CH_3N_2{}^+)$ obtained from photoionization appearance energy measurements of $CH_3N_2^+$ from $CH_3N{=}NCH_3$ (19). The $MCA(N_2)$ thus established is 51.9 kcal mol^{-1}. The thermochemical data derived from the methyl cation transfer equilibria, also summarized in Table 2, may be combined with $MCA(N_2)$ to obtain absolute methyl cation affinities of

each of the hydrogen halides as well as $\Delta H_f^0(CH_3XH^+)$ values. These latter quantities may then be used to calculate proton affinities of the methyl halides according to eq. [12], derived from the mechanism outlined in Scheme 1, where $X^-A(CH_3^+)$ represents the appropriate halide ion affinity of methyl cation.

[12] $PA(CH_3X) = MCA(HX) + PA(X^-) - X^-A(CH_3^+)$

The MCA(HX), $\Delta H_f^0(CH_3XH^+)$, and $PA(CH_3X)$ values thus obtained are also given in Table 2.

Due to difficulties in handling HF in the glass vacuum system of the hpms no experiments involving CH_3^+ transfer to HF were attempted. Based on the approximate proton affinity of CH_3F of 148 ± 2 kcal mol^{-1} (12) a value for MCA(HF) of 35 ± 2 kcal mol^{-1} is arrived at, substantially below that of N_2. This means that the MCA(HF) could not have been determined quantitatively, relative to N_2, in any case, owing to the large difference in methyl cation affinity between them. The proton affinity of CH_3F is evaluated as 148 ± 2 kcal mol^{-1}, based on the observation of reactions [13] and [14] and the recently determined values of PA(CO) = 145.6 kcal mol^{-1} and $PA(SO_2F_2)$ = 150 kcal mol^{-1} (12).

[13] $HCO^+ + CH_3F \rightarrow CH_3FH^+ + CO$

[14] $CH_3FH^+ + SO_2F_2 \rightarrow SO_2F_2H^+ + CH_3F$

Methyl cation transfer experiments with HI proceeded very slowly and equilibrium was not reached. However, the proton affinity of methyl iodide could be evaluated as 171 kcal mol^{-1}, based on the observation of reaction [15] in both forward and

[15] $H_3S^+ + CH_3I \leftrightharpoons CH_3IH^+ + H_2S$

reverse directions, with the conclusion that $PA(CH_3I) \simeq PA(H_2S)$ (7) and the known value of $PA(H_2S)$ = 169.7 kcal mol^{-1} (22). This proton affinity of CH_3I leads to a calculated methyl cation affinity for HI of 69.6 kcal mol^{-1}.

Discussion

The proton affinities of the hydrogen halides obtained in the present work are consistent with, and in basically good agreement with, previous data. The bracketing technique used by Polley and Munson (4) gave approximate values (±2 kcal mol^{-1}), which were also subject to some changes based on revisions in data for reference species used. For example, the proton affinity of HCl was bracketed as 135 ± 2 kcal mol^{-1}, based on PA(Br) < PA(HCl) < $PA(N_2O)$. In light of the recently redetermined value of $PA(N_2O)$ = 142.0 kcal mol^{-1} (12) and the established value of PA(Br) = 133 kcal mol^{-1} (22), the proton affinity of HCl based on Munson's experiment becomes 137.5 ± 4.5 kcal mol^{-1}. However, it was also observed that PA(HCl) > $PA(CH_4)$ and the value of $PA(CH_4)$ has again been recently redefined as 134.7 kcal mol^{-1} (12). Thus the bracketing experiments now define PA(HCl) as 138.5 ± 3.5 kcal mol^{-1}, which is entirely consistent with the value determined here of 137.6 kcal mol^{-1}.

Munson's bracketing data for HBr established $PA(N_2O)$ < PA(HBr) < PA(CO) with the new value of PA(CO) of 145.6 kcal mol^{-1} (12) and $PA(N_2O)$ of 142.0 kcal mol^{-1}, and defines PA(HBr) = 143.8 ± 1.8 kcal mol^{-1}, in agreement with the present determination of 142.9 kcal mol^{-1}.

The bracketing data for HI establish PA(HI) > PA(I) = 145.4 kcal mol^{-1}. The upper limit for PA(HI) was based on the observation of the dissociative hydride abstraction reaction, eq. [16]. It had been assumed that, in order for this reaction to

[16] $H_2I^+ + C_3H_8 \rightarrow s\text{-}C_3H_7^+ + H_2 + HI$

proceed, ΔH_{16}^0 must be negative; however, in reality the requirement for observation of this reaction is that ΔG_{16}^0 be negative. The entropy change for eq. [16] may be estimated fairly accurately as 20 cal mol^{-1} K^{-1}, which yields the enthalpy requirement that $\Delta H_{16}^0 \leq 6$ kcal mol^{-1}. Using recent data for $\Delta H_f^0(s\text{-}C_3H_7^+)$, the upper limit PA(HI) ≤ 156 kcal mol^{-1} is obtained, which allows assignment of PA(HI) = 151 ± 5 kcal mol^{-1}, again in agreement with the present determination of 150.9 kcal mol^{-1}.

The molecular beam photoionization data of Lee and coworkers (5, 6) potentially provide absolute values for the proton affinites of HF, HCl, and HBr based on threshold determinations for eq. [17]. These photo-ionization appearance

[17] $(HX)_2 \xrightarrow{h\nu} H_2X^+ + X$

potential measurements yield: PA(HF) = 95.5 ± 1.4 kcal mol^{-1}, PA(HCl) = 135 ± 1 kcal mol^{-1}, and PA(HBr) = 141 ± 1 kcal mol^{-1}. Previous similar studies for proton affinities of H_2O (6), H_2S (23), and NH_3 (24) have obtained agreement within ±1 kcal mol^{-1} of values arrived at by equilibrium proton transfer scales. It is immediately apparent, however, that the data for HF are in serious disagreement with the observations of proton transfer equilibrium between N_2 and HF, eq. [1], yielding PA(HF) = 120.9 kcal mol^{-1} (3). Lee and coworkers (5) have interpreted this discrepancy in terms of a non-adiabatic transition from $(HF)_2$ to $(HF)_2^+$ in which vibrationally excited $(HF)_2^+$ is produced well above the threshold for H_2F^+ formation. From an analysis of the shapes of the H_2Cl^+ and H_2Br^+ ionization efficiency curves near threshold, the authors concluded that these species are more likely to be produced in their ground states. The difference between proton affinity values for HCl and HBr determined here and in the photoionization experiment is 2.7 and 1.7 kcal mol^{-1}, with the present values both being higher. This difference could be caused by residual excitation of some 2 kcal mol^{-1} in H_2Cl^+ and H_2Br^+ produced at the observed threshold, presumably because the cross-section for production of H_2X^+ at the true adiabatic

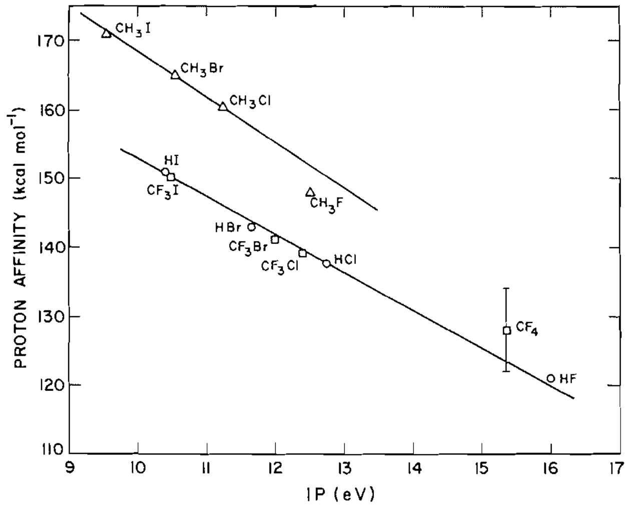

FIG. 3. Variation of proton affinities of HX, CH_3X, and CF_3X (X = F, Cl, Br, I) as a function of valence ionization potential.

limit has become sufficiently small to be beyond the detection limits of the apparatus.

Only approximate data for proton affinities of the methyl halides are available from bracketing experiments. As noted above, reactions [13] and [14] establish PA(CH_3F) as 148 ± 2 kcal mol^{-1}. Similarly, the proton affinity of CH_3Cl has previously been established (7) to be between those of C_2H_4 (162.6 kcal mol^{-1}) (9–11) and C_2H_2 (155.2 kcal mol^{-1}) (22), allowing an assignment of 159 ± 4 kcal mol^{-1}, in good agreement wih the value of 160.8 kcal mol^{-1} obtained here. The proton affinity of CH_3Br has again previously been determined to be between those of C_2H_4 and H_2O (166.4 kcal mol^{-1}) (12, 22), allowing an assignment of 164.5 ± 2 kcal mol^{-1}, again in good agreement with the value of 164.8 kcal mol^{-1} obtained here. As noted above, the proton affinity of CH_3I has been approximately determined as 171 ± 1 kcal mol^{-1} (7), based on observations of eq. [15].

No previous proton affinity measurements of any kind have been carried out for CF_3Cl, CF_3Br, or CF_3I. Bohme and coworkers (17) have bracketed the proton affinity of CF_4 by

[18] $N_2H^+ + CF_4 \rightarrow CF_4H^+ + N_2$

[19] $CF_4H^+ + CH_4 \rightarrow CH_5^+ + CF_4$

eqs. [18] and [19], allowing an assignment of PA(CF_4) = 128 ± 6 kcal mol^{-1}.

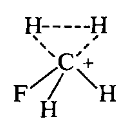
In addition to the absolute magnitudes of the proton affinities of the hydrogen, methyl, and trifluoromethyl halides, it is of interest to examine the relative changes within each group of halides, the relationships between each group, and the relationship between proton affinities and valence ionization potentials. This last relationship is illustrated in Fig. 3 in a plot of proton affinities of each of the types of halide as a function of the valence electron ionization potentials determined by either photoionization mass spectrometry or photoelectron spectroscopy. Examination of this plot reveals that there is a direct correspondence between proton affinity and ionization potential, which indicates that the factors affecting both the energy required to remove an electron from the highest occupied molecular orbital and the energy released when a proton is associated with the electrons in the highest occupied molecular orbital are similar in nature but different in magnitude. Interestingly, the points for both HX and CF_3X compounds appear to fit the

$$\begin{tikzcd} RX + H \arrow[r, "IP(H)"] \arrow[d, "IP(RX)"'] & RX + H^+ \arrow[d, "-PA(RX)"] \\ RX^+ + H \arrow[r, "-HA(RX^+)"'] & RXH^+ \end{tikzcd}$$

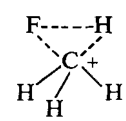
SCHEME 2

same line. The good proportionality between the two quantities suggests that more reliable data may be interpolated from the plot. For example, the PA(CF_4) of 128 ± 6 kcal mol^{-1} can be inferred to be at the lower end of this limit if it is assumed that CF_4 should fall on the correlation line for CF_3X compounds. If this is the case a PA(CF_4) of 123.5 kcal mol^{-1} is predicted.

The one important exception to the proton affinity – ionization potential correlation is the point for methyl fluoride. An examination of the photoelectron spectrum and molecular orbital assignments for CH_3F (24) reveals that the lowest energy ionization process does not correspond to removal of a 2p non-bonding electron, as is the case for the other CH_3X, but rather involves removal of an electron from the orbital that has primarily C—H bonding character in the methyl group. The proton affinity of CH_3F does not fall on the straight line defined by the other CH_3X for either of these ionization potentials of CH_3F. This failure to correlate with behaviour of the other methyl halides suggests that CH_3FH^+ may be structurally unlike the other CH_3XH^+ ions and may, in fact, more closely resemble CH_5^+ involving 3-centre 2-electron bond structures such as **I** or **II**.



I



II

The accurate ionization potential and proton affinity data may also be used to calculate the homolytic bond dissociation energies of RXH^+, also called the hydrogen atom affinities (HA) of RX^+. The relationship between proton affinity, ionization potential, and hydrogen atom affinity given by eq. [20] may be derived from examination of Scheme 2. Hydrogen atom affinities, proton affinities, and ionization potential data for

[20] $HA(RX^+) = PA(RX) + IP(RX) - IP(H)$

each of the compounds examined are summarized in Table 3. Also included for comparison are the homolytic bond dissociation energies in the hydrogen halides. The D(H—X) follow the same trend as the D(H—XH^+) with the difference that the hydrogen atom affinities are all somewhat larger. This difference in magnitude should be due to the electrostatic attractive interaction between HX^+ and H, which contributes to the bond energy in H—XH^+. The value for HA(CH_3F^+) can be seen to be anomalously low compared to the relative values for HA, CH_3X, and CF_3X compounds in the other halogen series. This is again associated with the fact that the lowest energy ionization in CH_3F, and used in the calculation of HA(CH_3F^+), does not correspond to the lone pair electron of the F atom (25). This result again suggests that the bonding in CH_3FH^+ may be unusual.

It is interesting to note the order of hydrogen atom affinities for each group of halogens. In the fluorides a variation of 15

TABLE 3. Ionization potentials, proton affinities, and halogen atom affinities for the hydrogen, methyl, and trifluoromethyl halides

Species (RX)	IP(RX)[a] (eV)	PA(RX)[d] (kcal mol^{-1})	HA(RX$^+$) (kcal mol^{-1})	D(H—X)[e] (kcal mol^{-1})

[e] Calculated from data from ref. 20.

kcal mol^{-1} is observed between HA(HF$^+$) and HA(CF_4^+), while for the corresponding chlorides the difference is only 6 kcal mol^{-1}; for the bromides the order actually inverts, with HA(CF_3Br^+) being larger than HA(HBr$^+$) by 6 kcal mol^{-1}, while in the iodides virtually no variation is observed. The inversion of order in the bromides and to a lesser extent the iodides can be seen, from eq. [20] and the data in Table 3, to result from the fact that IP(CF_3Br) > IP(HBr) and IP(CF_3I) > IP(HI). This may be purely a result of poor resolution in the photoelectron spectra of CF_3Br and CF_3I since only vertical rather than adiabatic ionization potentials are reported.

The magnitude of substituent effects of CH_3 and CF_3 on the proton affinities of halogen bases may be seen from the correlations shown in Fig. 4. The plot of PA(CH_3X) vs. PA(HX) gives a linear relationship with a slope of 0.74, indicating that the magnitude of the methyl substituent effect decreases in a manner proportional to the increase in basicity of the halogen, i.e. in the order X = F > Cl > Br > I. For example, replacement of hydrogen by methyl increases the basicity of F by 28 kcal mol^{-1} while only increasing that of I by 20 kcal mol^{-1}. The fact that the point for HF/CH_3F fits on the correlation line is noteworthy since it had been suggested above that the bonding in CH_3FH^+ might be fundamentally different than than in the other CH_3XH^+ species. The data of Fig. 4(a) would suggest otherwise. Evidently, the question regarding the structure of CH_3FH^+ can not be resolved on the basis of the experimental correlations considered in the present work.

The higher PA of the CH_3X relative to the HX compounds probably are largely due to stabilization of the positive charge in the CH_3XH^+ by the field effect and polarizability of the methyl group. The decreasing methyl stabilization energy with increasing size of X is then a consequence of the lengthening of the C—X bond and the resulting greater distance over which the methyl dipole and polarizability have to interact with the charge centre. The plot of PA(CF_3X) vs. PA(HX) again exhibits a good linear correlation with the exception of the point for CF_3Br. As noted above, the value for HA(CF_3Br^+) appeared anomalously high, while here the proton affinity of CF_3Br appears too low. For the present, CF_3Br must be regarded as an exceptional case.

TABLE 4. Methyl and trifluoromethyl cation affinities of the hydrogen halides

Species (HX)	D(CH_3^+—XH) (kcal mol^{-1})	D(CF_3^+—XH) (kcal mol^{-1})
HF	35 ± 2	15
HCl	55.1	19.8
HBr	61.2	21.3
HI	69.6	31.1

In all of the halogens the hydrogen halides and trifluoromethyl halides have similar basicities, indicating that the destabilizing field effect of the CF_3 group is almost exactly counterbalanced by the stabilizing through space polarization interaction of the CF_3 group.

It is also interesting to compare the methyl cation binding energies of the halogen acids to the proton affinities as shown in Fig. 4c. A good linear relationship between the two quantities is observed. The slope of 1.12 obtained indicates that methyl cation binding energies increase through the halogen series more rapidly than do proton affinities.

The proton affinity data for trifluoromethyl halides can also be used to calculate CF_3^+ binding energies for the hydrogen halides. These data are summarized in Table 4 together with the CH_3^+ binding energies. The plot of the CF_3^+ affinities of HX versus the corresponding CH_3^+ affinities, shown in Fig. 5, leads to a linear relationship with the exception of the point for HI.[3] This linear relationship, taken together with the relationship in Fig. 4c, demonstrates that the halogen acids, HX, display the same order of basicities twoards the three Lewis acids, H$^+$, CH_3^+, and CF_3^+.

[3] The deviation of the point for HI from the straight line correlation may in fact be due to a poorly defined value of D(CF_3^+—IH), arising from an uncertain value for $\Delta H_f^0(CF_3I)$.

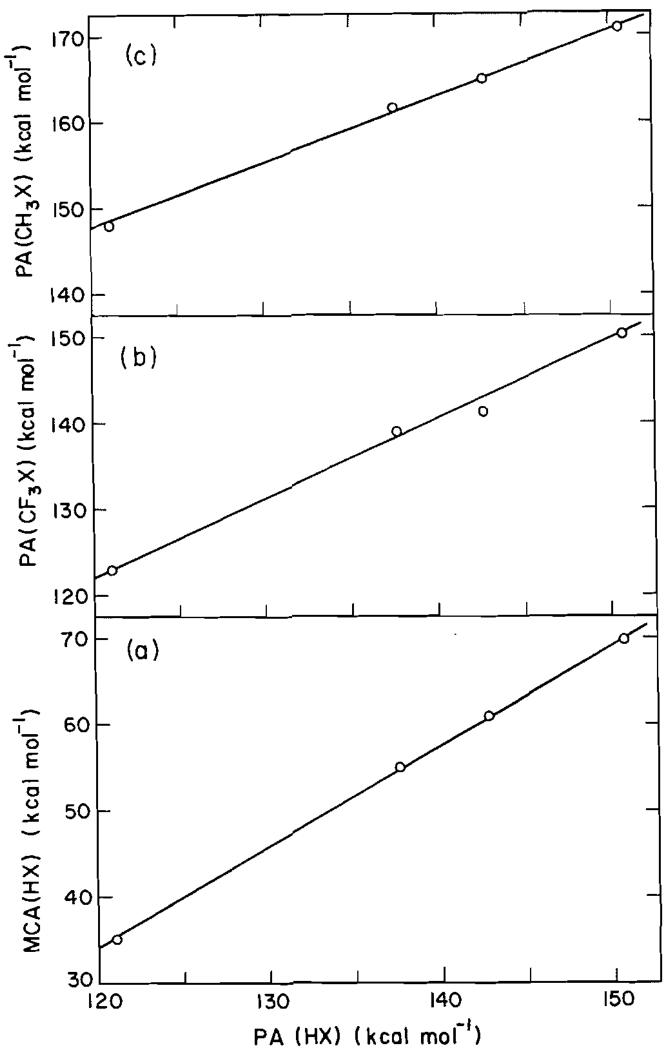

FIG. 4. Variation of (a) methyl cation affinity of HX (MCA(HX)); (b) proton affinity of CF_3X (PA(CF_3X)); (c) proton affinity of CH_3X (PA(CH_3X)) as a function of proton affinity of HX (PA(HX)); X = F, Cl, Br, I.

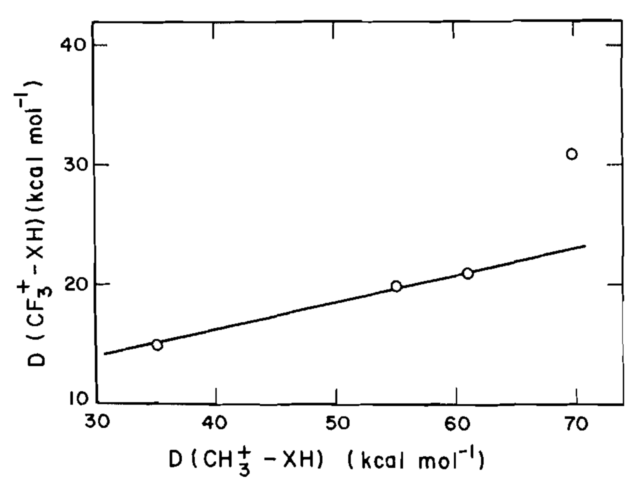

FIG. 5. Variation of CF_3^+ binding energy to HX (D(CF_3^+—XH)) as a function of CH_3^+ binding energy to HX (MCA(HX)).

The CH_3^+ affinities of HX are seen to be considerably larger than the corresponding CF_3^+ affinities (see Table 4 and Fig. 5). It is generally observed (27) that the R^+ affinities of HX, where R^+ are substituted methyl cations, decrease with increasing electronic stabilization of R^+. The present result taken in this context must mean that the CF_3^+ cation is more stable relative to CH_3^+, i.e. that stabilization by π donation from the F substituent is more important than the destabilization by the electron-withdrawing field-inductive effect of F.

Conclusion

Proton transfer and methyl cation transfer equilibrium experiments have been used to establish accurate gas phase proton affinities for hydrogen, methyl, and trifluoromethyl halides. The gas phase basicities of each series of halides are seen to correlate with valence ionization potentials and with each other. Further, the methyl cation affinities of HX correlated with the proton affinities, as do the CF_3^+ binding energies.

Isomérisation des radicaux insaturés. III. Radicaux α,α,β-, α,β,γ- et α,α,γ-triméthallyles

HÉLÈNE DESLAURIERS ET GUY J. COLLIN[1]

Département des sciences fondamentales, Université du Québec à Chicoutimi, Chicoutimi (Qué.), Canada G7H 2B1

Reçu le 21 décembre 1984

HÉLÈNE DESLAURIERS et GUY J. COLLIN. Can. J. Chem. **63**, 3168 (1985).

Nous avons généré les radicaux α,α,β-, α,β,γ- et α,α,γ-triméthallyles en photolysant à 147,0 nm les triméthyl-2,3,3 butène-1, diméthyl-3,4 pentène-2 et diméthyl-2,4 pentène-2 sous des pressions de quelques torr. Dans ces conditions, une part importante de ces radicaux ont une énergie interne suffisante pour se fragmenter en divers diènes-1,3 et un peu de diènes-1,2 et -2,3. Afin d'expliquer la formation de ces produits, on fait appel à un mécanisme d'isomérisation basé sur un transfert interne 1,4 d'un atome d'hydrogène. La fragmentation des radicaux allyles triméthylés se fait surtout par rupture d'un lien β(C—C), puis β(C—H) et, de façon beaucoup moindre, par celle d'un lien central C—CH_3.

HÉLÈNE DESLAURIERS and GUY J. COLLIN. Can. J. Chem. **63**, 3168 (1985).

α,α,β-, α,β,γ-, and α,α,γ-trimethallyl radicals have been generated in the 147.0-nm gas phase photolysis of 2,3,3-trimethyl-1-butene, 3,4-dimethyl-2-pentene, and 2,4-dimethyl-2-pentene, respectively. Under these conditions, the majority of allyl radicals have an internal energy sufficient for further decomposition: they give rise to the formation of various 1,3-dienes and small amounts of either 1,2- or 2,3-dienes. An internal sigmatropic 1,4-hydrogen atom transfer process is part of the proposed mechanism to explain such products. Moreover, the fragmentation of the trimethyl substituted allyl radicals involves the split of one β(C—C) bond, then one β(C—H), and, to a lesser extent, one central C—CH_3 bond.

Introduction

Dans de précédentes études, nous avons montré que la photolyse des alcènes entre 147,0 et 184,9 nm constitue une bonne source de radicaux allyles, puisque ceux-ci sont formés avec des rendements quantiques qui dépassent 0,5 et qui atteignent parfois 0,9 (1, 2). Ces radicaux sont cependant produits avec une énergie vibrationnelle relativement importante, de telle sorte que ces radicaux "chauds" se fragmentent pourvu que la pression soit suffisamment faible pour ne pas les stabiliser par collision (3, 4). Les précédents rapports de cette série ont de plus montré que ces réactions de fragmentation sont en compétition avec des réactions d'isomérisation. Par exemple, le radical α,β-diméthallyle s'isomérise vers la forme α,α-diméthallyle et inversement (5). Il en est de même du radical α,γ-diméthallyle qui s'isomérise vers la forme α-éthallyle et inversement (6).

Le but de ce rapport est de vérifier ces comportements sur les trois radicaux triméthallyles en scrutant leurs produits de fragmentation.

Méthode expérimentale

Les triméthyl-2,3,3 butène-1 (tM233B1), diméthyl-3,4 *cis*-pentène-2 (dM34P2) et diméthyl-2,4 pentène-2 (dM24P2) sont des produits API. Les puretés affichées de même que les analyses de ces monomères sont brièvement indiquées dans le tableau 1. L'oxygène (99,98%) et l'isobutène (99,9%) sont des produits Matheson du Canada (gaz de qualité recherche). Tous ces produits sont utilisés tels que reçus et manipulés à l'aide d'une rampe à vide en Pyrex (1–6).

Les photolyses sont effectuées à 147,0 nm en utilisant une lampe de résonance à xénon entraînée par un générateur micro-onde (7). La pureté spectrale de la lampe entre 120 et 250 nm est vérifiée à l'aide d'un monochromateur McPherson de $\frac{1}{2}$ m. L'actinométrie est réalisée en comparant les produits de décomposition à ceux obtenus dans la photolyse de l'isobutène Φ(allène) = 0,52 (8). Toutes les irradiations ont été faites à la température de la chambre ($T \simeq 20$°C). Les analyses sont faites par chromatographie en phase gazeuse en utilisant soit une colonne de squalane (9), soit une colonne de UCON (10) à la température de 50°C.

TABLEAU 1. Analyse des monomères

Monomère	Impureté affichée (%)	Impuretés visibles par chromatographie (ppm)
Isobutène	0,1	Isobutane: 920±50 Propane: 60±10
tM233B1	0,06±0,04	Diméthyl-3,3 butène-1: 15
dM34P2(*cis*)	0,11±0,08	Éthyl-2 méthyl-3 butène-1: 400±5
dM24P2	0,14±0,04	dM34P2 (*trans*): 650 Triméthyl-1,3,4 pentène-2 (?): 50

Résultats

Le tableau 2 montre les rendements quantiques des produits obtenus dans les photolyses des tM233B1, dM34P2 et dM24P2 en présence de 10% d'oxygène. On observe une formation de C_3 avec des rendements quantiques non négligeables. Par exemple, le rendement en C_3H_4 est 0,20 dans la photolyse du tM233B1. Par contre, les rendements en produits C_4 sont faibles et n'apparaissent que dans la photolyse du dM34P2. Les diènes-1,3 sont les produits majeurs dans chacun des cas. Le diméthyl-2,3 butadiène-1,3 est le produit majeur dans la photolyse du tM233B1. Dans le cas du dM34P2, l'isoprène et le méthyl-3 pentadiène-1,3 ont des rendements similaires et importants. Finalement, le dM24P2 donne lieu à la formation de méthyl-4 pentadiène-1,3, d'isoprène et de méthyl-2 pentadiène-1,3. L'effet de pression a été étudié dans le cas du mélange tM233B1–O_2 (100:10). On observe que les rendements en diméthyl-2,3 butadiène-1,3 (A) et en méthyl-3 butadiène-1,2 (B) décroissent avec l'augmentation de la pression et que $\Phi(A)/\Phi(B) = 7{,}5$ ($\sigma = 0{,}65$), quelle que soit la pression de monomère entre 2 et 50 Torr (1 Torr = 133,3 Pa). Cet effet de pression est rapporté dans la figure 1 sous la forme de courbes de type Stern–Volmer: $[\Phi(x)]^{-1} = f(P)$.

À ce point, il faut noter que les résultats semblent indiquer une certaine invariance des rendements entre 5 et 10 Torr, tout

[a] Pression de l'alcène: 5 Torr (665 N m^{-2}).
[b] 200 Torr de SF_6 ont été ajoutés.

au moins en ce qui concerne ceux obtenus dans les cas des tM233B1 et dM34P2. Précisons que sur une grande échelle de pression, il y a plutôt décroissance lente des rendements avec l'augmentation de la pression (fig. 1). Dans le cas du dM24P2, il semble au contraire y avoir une augmentation des rendements des produits avec l'augmentation de la pression (tableau 2, colonnes 6 et 7). Comme nous n'avons pas essayé d'étendre ces mesures sur une plus grande échelle de pression, et compte tenu des incertitudes expérimentales appréhendées (voir, par exemple, la distribution des résultats rapportés sur la figure 1), il semble prématuré de discuter plus à fond cette apparente augmentation des rendements.

Les dM34P2 et dM24P2 ont été photolysés sans aucun additif (tableau 3). On y a observé l'apparition d'un certain nombre de produits. L'éthane ($\Phi \simeq 0,5$) est le produit majeur. D'autres produits tels que l'isobutane, des heptanes, des heptènes et des octanes (tous ramifiés) sont aussi formés, alors qu'ils n'apparaissent pas dans les photolyses réalisées en présence d'oxygène.

Ces produits (sauf le méthane) sont formés par réactions de combinaison entre les radicaux méthyles et des radicaux allyliques C_7H_{11} ou saturés C_7H_{13}. On ne rediscutera pas plus loin de ces résultats. Il suffit ici de rappeler que ces produits (et leur mode de formation anticipée) appuient les schémas réactionnels proposés plus loin.

Discussion

Fragmentation des molécules photo-excitées

Il est maintenant bien établi que les alcènes photo-excités, électroniquement excités dans un état singulet, retournent vers

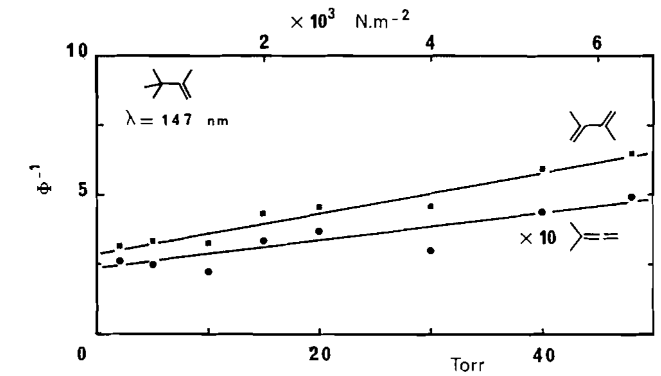

FIG. 1. Photolyse du mélange tM233B1–O_2 (100:10) à 147 nm, en fonction de la pression de l'alcène; ■: Φ(diméthyl-2,3 butadiène-1,3)$^{-1}$ (y = 2,91 + 0,072 P (Torr), r^2 = 0,97); ●: Φ(méthyl-3 butadiène-1,2)$^{-1}$.

leur état fondamental en transformant leur énergie électronique en énergie vibrationnelle, de sorte que la fragmentation observée est essentiellement le fait de la molécule vibrationnellement très chaude. Dans ces conditions, et en première approximation, la fragmentation implique la rupture du (des) lien(s) le(s) plus fragile(s). Les molécules photolysées à 147,0 nm ont toutes une liaison C—C située en position β par rapport à la double liaison. Comme ce sont des liens relativement fragiles (11–13), on ne peut que s'attendre à une scission primaire β(C—C) importante (1, 14).

[1] $CH_2{=}C(CH_3)C(CH_3)_3^{**} \rightarrow CH_3 + \overline{CH_2C(CH_3)C}(CH_3)_2^*$

[2] $CH_3CH{=}C(CH_3)CH(CH_3)_2 \rightarrow CH_3 + CH_3\overline{CHC(CH_3)CH}CH_3^*$

[3] $CH_3C(CH_3){=}CHCH(CH_3)_2 \rightarrow CH_3 + CH_3\overline{C(CH_3)CHCH}CH_3^*$

où le double astérisque dénote la molécule photo-excitée et l'astérisque simple, un radical allyle chaud. En effet, l'énergie du photon est de quelque 811 kJ einstein^{-1} auxquels il faut ajouter l'énergie thermique de la molécule à la température de la chambre, soit environ 12 kJ mol^{-1}. L'énergie du lien β(C—C) est de quelque 293 kJ mol^{-1} (11–13). L'excédent d'énergie du photon (≃530 kJ mol^{-1}) est distribué entre les tissus vibrationnels des deux fragments et leur énergie relative cinétique et rotationnelle (2–4).

D'autres réactions de fragmentation sont également possibles mais avec une probabilité beaucoup plus faible, puisque les chaleurs de liaison sont plus élevées. Des ruptures β(C—H_t) (cas des dMP2), α(C—C) et α(C—H) sont disponibles. La chaleur de liaison β(C—H_t) est d'environ 30 kJ mol^{-1} plus élevée que celle du lien β(C—C) (15). Les produits issus des fragmentations des radicaux allyles $C_7H_{13}^*$ (des C_7H_{12} et des C_6H_{10}) sont sans doute formés avec de faibles rendements et seulement certains d'entre eux peuvent interférer avec les produits mesurés ici.

Les produits en C_3, et probablement en C_4, apparaissant dans le tableau 2, sont certainement le résultat de fragmentation primaire α(C—C), avec des rendements limités. Par exemple, la formation de propyne et d'allène est raisonnablement expliquée sur la base du mécanisme impliquant la rupture primaire d'un lien α(C—C) avec fragmentation subséquente du radical propènyle-2 excité (16).

[4] $CH_3C(CH_3)_2C(CH_3){=}CH_2 \rightarrow t\text{-}C_4H_9 + CH_3\dot{C}{=}CH_2^*$

[5a] $CH_3\dot{C}{=}CH_2^* \rightarrow CH_3C{\equiv}CH + H$

[5b] $CH_3\dot{C}{=}CH_2^* \rightarrow CH_2{=}C{=}CH_2 + H$

De la même manière, le dM34P2 peut former le propyne, le propène et le butyne-2:

[6] $CH_3CH{=}C(CH_3)CH(CH_3)_2^{**} \rightarrow CH_3CH{=}\dot{C}CH_3^* + \text{iso-}C_3H_7^*$

[7] $CH_3CH{=}\dot{C}CH_3^* \rightarrow CH_3C{\equiv}CCH_3 + H$

[8] $\text{iso-}C_3H_7^* \rightarrow CH_3CH{=}CH_2 + H$

[9] $CH_3CH{=}C(CH_3)CH(CH_3)_2 \rightarrow \dot{C}H{=}C(CH_3)CH(CH_3)_2^* + CH_3$

[10] $\dot{C}H{=}C(CH_3)CH(CH_3)_2^* \rightarrow CH_3C{\equiv}CH + \text{iso-}C_3H_7 \ldots$

Compte tenu du fait que (i) le lien β(C—C) est le plus fragile, et (ii) la rupture β(C—H_t) semble moins probable, à tout le moins dans les cas du méthyl-3 butène-1 (17) et du diméthyl-2,3 butène-1 (5), l'intervention des intermédiaires résultant des fragmentations primaires β(C—H_t) peut être ignorée. Une preuve de la fragmentation de la molécule photo-excitée par rupture primaire du lien β(C—C) et de son importance peut être extraite de la lecture des rendements des produits d'origine radicalaire (tableau 3). On peut observer en effet la formation, en quantités appréciables, des radicaux méthyles (Φ ≃ 1,2 ± 0,2) à travers les formations d'éthane (CH_3 + CH_3), d'isobutane (CH_3 + iso-C_3H_7), de triméthyl pentanes (CH_3 + C_7H_{15}), de diméthylpentènes (CH_3 + C_6H_{11}), ... Il faut remarquer qu'un rendement supérieur à l'unité n'est pas anormal puisque, comme on le verra plus tard, à la rupture primaire principale, s'ajoutent des réactions secondaires libérant des radicaux méthyles avec formation concomitante de diènes en C_5. De la même manière, bien que ce soit de façon moins évidente sur le plan quantitatif, les structures des divers heptènes ramifiés formés sont compatibles avec soit le radical allyle formé dans la rupture primaire, soit les radicaux allyles issus de l'isomérisation du précédent par transfert interne d'un atome d'hydrogène entre les positions 1,4.

Radical α,α,β-*triméthallyle*

Formé dans la réaction [1], ce radical excité ne possède que des liaisons β(C—H) et une liaison centrale C—CH_3 susceptibles de se fragmenter.

[11*a*] $\overline{CH_2C(CH_3)C}(CH_3)_2^* \rightarrow H + CH_2{=}C(CH_3)C(CH_3){=}CH_2 \quad \Delta H \simeq 224\ \text{kJ mol}^{-1}$

[11*b*] $\overline{CH_2C(CH_3)C}(CH_3)_2^* \rightarrow CH_3 + CH_2{=}C{=}C(CH_3)_2 \quad \Delta H \simeq 233\ \text{kJ mol}^{-1}$

Les produits attendus sont ceux observés dans un rapport 7,5:1 à l'avantage de la formation du diméthyl-2,3 butadiène-1,3 (Φ = 0,30). Cette fragmentation est en accord avec les observations déjà réalisées dans la photochimie du tétraméthyléthylène – diméthyl-2,3 butène-2 (18). L'isomérisation du radical α,α,β-triméthallyle, par déplacement interne d'un atome d'hydrogène entre les positions 1 et 4, est triviale: elle reproduit le radical original.

Il faut noter que les réactions [11] sont endothermiques. La chaleur de formation du radical α,α,β-triméthallyle a éte mesurée: $\Delta H_f^0 \simeq 40 \pm 4$ kJ mol^{-1} (15). En admettant que l'énergie d'activation de la réaction (11*a*] est ≃5 kJ mol^{-1} (19) et celle de la réaction [11*b*], ≃ 25 kJ mol^{-1}, cela conduit à estimer les

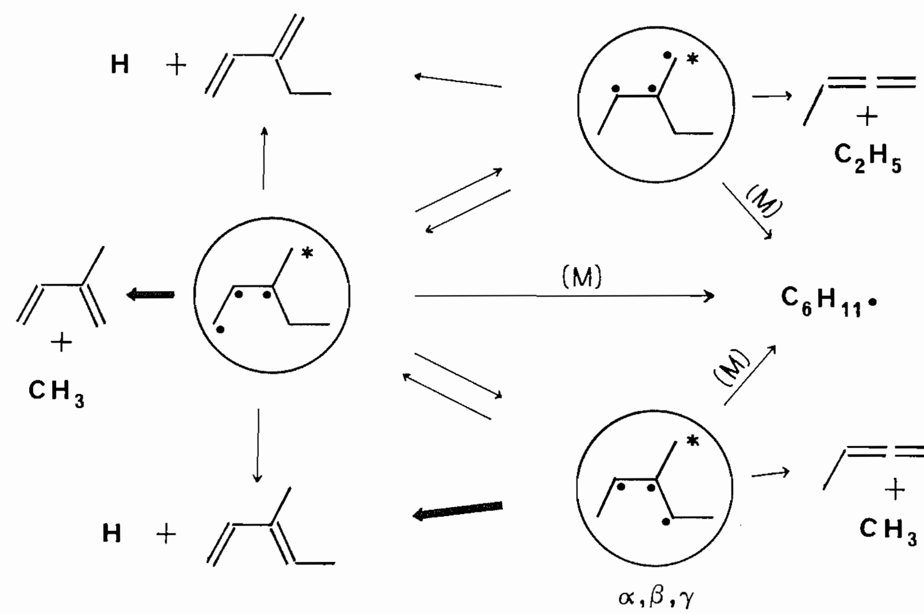

SCHÉMA 1. Évolution du radical α,β,γ-triméthallyle (cercle inférieur droit).

barrières de potentiel des réactions [11*a*] et [11*b*] à quelque 229 et 258 kJ mol^{-1}. Comme la distribution de l'excédent de l'énergie du photon dans les fragments primaires (processus [1]) se fait dans le tissu vibrationnel, il est fort probable qu'une part appréciable des radicaux $C_6H_{11}^*$ n'ont pas l'énergie interne suffisante pour passer par dessus ces barrières de potentiel ou leur vitesse de passage est si lente qu'ils sont stabilisés, refroidis par collision (fig. 1).

Radical α,β,γ-triméthallyle

Ce radical apparaît dans la photolyse du dM34P2: réaction [2]. Les réactions de fragmentation attendues impliquent à nouveau la rupture du lien β(C—H) ou du lien central C—CH_3. Les produits ainsi formés sont le méthyl-3 pentadiène (*cis* et *trans*) (Φ = 0,22) et le pentadiène-2,3 (Φ = 0,03). On remarque à nouveau que le rapport diène-1,3/diène-2,3 est de l'ordre de 7,5, en conformité avec l'observation faite précédemment sur les probabilités relatives des ruptures β(C—H) et du lien central C—CH_3 dans les radicaux allyles. On observe en outre, tableau 2, une formation importante d'isoprène (Φ = 0,20). Cette formation peut être expliquée sur la base du déplacement interne 1,4 d'un atome d'hydrogène dans le radical triméthallyle (5). Le schéma réactionnel 1 montre cette isomérisation qui produit le radical α-éthyl-α-méthallyle. Ce dernier possède une liaison β(C—C) et se fragmente en cette position avec libération concomitante d'isoprène, mais aussi d'un peu d'éthyl-2 butadiène-1,3 et de méthyl-3 pentadiène-1,3 par rupture de liens β(C—H). Par continuité, ce nouveau radical α-éthyl-α-méthallyle peut s'isomériser vers la structure α-méthyl-β-éthallyle avec les produits de fragmentation éventuels que sont le butadiène-1,2 et encore l'éthyl-2 butadiène-1,3. Si le rapport des ruptures β(C—H)/lien central C—CH_3 est encore de 7,5, et étant donné le faible rendement en éthyl-2 butadiène-1,3 le butadiène-1,2 est le résultat d'un autre processus. Peut-être est-il le résultat de la fragmentation d'un radical primaire formé dans une rupture primaire autre que β(C—C).

À ce point, il faut remarquer que le rendement en isoprène est presque égal à celui en méthyl-3 pentadiène-1,3. Ceci implique une isomérisation importante et rapide entre les deux formes α,β,γ-triméthallyles et α-éthyl-α-méthallyles. Le méthyl-3 pentadiène-1,3 est issu d'une rupture de lien β(C—H), tandis que l'isoprène est issu d'une rupture β(C—C). Ce dernier processus est probablement plus rapide que le précédent. Il s'en suit que les deux réservoirs de radicaux allyles ont chacun une grosse fuite d'inégale importance. L'équilibre est donc constamment déplacé vers la formation du radical α-éthyl-α-méthallyle. On ne peut donc avoir directement accès à la constante d'équilibre thermodynamique. Une seconde remarque concerne la somme des rendements quantiques des diènes: celle-ci est voisine de 0,46. Compte tenu du fait qu'une part des radicaux allyles sont stabilisés par collision (bien qu'on n'a pas fait ici d'études en fonction de la pression) ou n'ont pas l'énergie suffisante pour se fragmenter (voir plus haut), on obtient une preuve indirecte de l'importance de la fragmentation primaire β(C—C): processus [2].

De façon alternative, le schéma réactionnel 1 ne prévoit pas d'isomérisation directe entre les radicaux α,β,γ-triméthallyle et α-méthyl-β-éthallyle. Cette réaction commande la formation transitoire d'un intermédiaire cyclique à quatre côtés, dont la tension interne serait de l'ordre de 115 kJ mol^{-1} (20). Inversement, les transferts en 1,4 se font via la formation d'un état de transition à cinq côtés, ayant une tension interne de quelque 85 kJ mol^{-1} moins grande. Ces transferts en 1,3 d'atomes d'hydrogène sont d'ailleurs tenus pour fort rares (21) et impliquent des facteurs de fréquence plus bas que ceux des transferts en 1,4 (20).

Sur la base de la symétrie des orbitales moléculaires, ce transfert 1,3 d'un atome d'hydrogène est interdit dans la forme "supra" et extrêmement difficile dans la forme "antara" à cause de restrictions géométriques. Inversement, le transfert 1,4 a lieu par interaction entre l'orbitale 1*s* de l'atome d'hydrogène et la plus basse orbitale inoccupée du butadiène-1,3. Cette migration est permise selon les règles de conservation de la symétrie.

Radical α,α,γ-triméthallyle

La structure du dM24P2 est favorable à la formation de ce radical. Puisque ce dernier possède essentiellement des liens C—H situés en position β, le méthyl-4 pentadiène-1,3 (Φ =

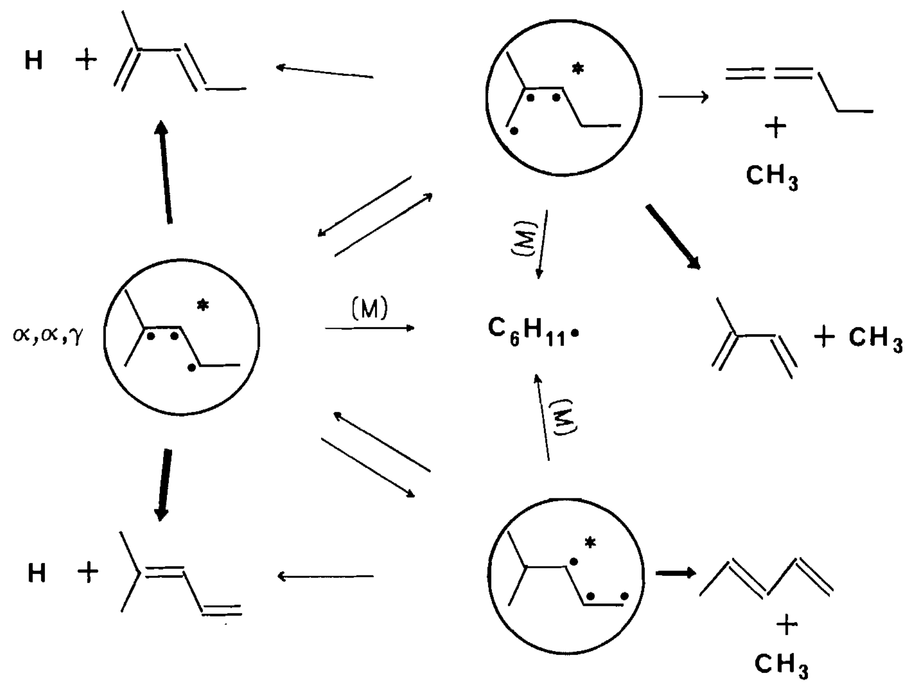

SCHÉMA 2. Évolution du radical α,α,γ-triméthallyle (cercle médian gauche).

0,13) et les méthyl-2 pentadiène-1,3 (*cis* et *trans*) (Φ = 0,06) sont les produits principaux probablement formés au prorata des atomes d'hydrogène disponibles. Le déplacement 1,4 d'un atome d'hydrogène produit les radicaux soit α-isopropyles, soit α-éthyl-β-méthallyles et on peut s'attendre à une formation subséquente de pentadiène-1,3 (*cis* et *trans*) (Φ = 0,04) et d'isoprène (Φ = 0,09).

L'importance relative de la formation de pentadiène-1,3 et d'isoprène est probablement le résultat de plusieurs facteurs. On peut cependant noter que le radical α,α,γ-triméthallyle a deux voies réactionnelles pour aller vers la forme α-éthyl-β-méthallyle et une seule vers la forme α-isopropylallyle. Cette proportion correspond au rapport Φ(pentadiène-1,3)/Φ(isoprène). Il est pertinent de revenir ici sur le mécanisme du transfert interne en 1,4 d'un atome d'hydrogène dans les radicaux méthallyles. La structure du groupe allyle est plane (22) et le radical méthyle est situé soit en position *cis*, soit en *trans* (fig. 2). Il est évident que, d'après cette figure, le déplacement 1,4 est nettement favorisé dans la structure *cis* et probablement beaucoup plus difficile dans le cas de la structure *trans*. Il faut rappeler que l'énergie interne des radicaux allyles qui se fragmentent est considérable (voir plus haut). Dans ces conditions, il est probable que les formes *cis* et *trans* sont en équilibre, en conformité avec ce qui est rapporté dans la littérature (23, 24). Une valeur ΔG comprise entre 52 et 88 kJ mol^{-1}, et probablement inférieure à 60 kJ mol^{-1}, a été estimée pour cet équilibre (24). Enfin, les schémas réactionnels 1 et 2 ne prévoient pas de transferts internes en 1,5 d'atome d'hydrogène. Ce type de transfert commande la formation transitoire d'un cycle à six côtés. On peut prévoir, dans ce cas, un facteur de fréquence plus favorable et une énergie de tension du cycle à peu près négligeable (20). Ce transfert ferait cependant disparaître l'énergie de résonance du groupe allyle, ce qui introduit une énergie d'activation de 50 kJ mol^{-1}. En outre, puisque l'atome échangé provient d'un méthyl terminal, cela ajoute quelques autres kilojoules par mole à l'énergie d'activation, puisque les liaisons C—H terminales sont plus rigides.

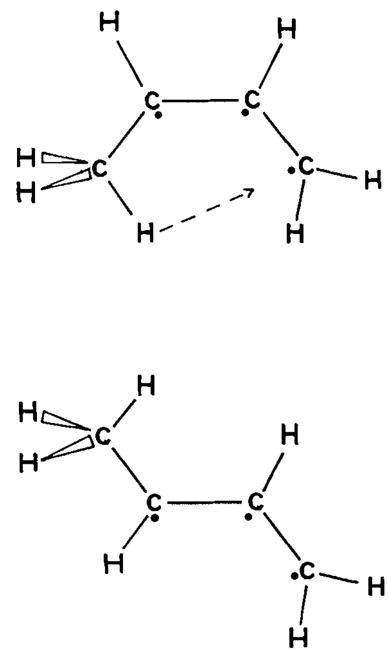

FIG. 2. Représentation schématique du transfert 1,4 de l'atome d'hydrogène dans le radical méthallyle.

Received December 5, 1984

R. R. REDDY, A. S. R. REDDY, and V. KRISHNA REDDY. Can. J. Chem. **63**, 3174 (1985).

New relations are proposed for the determination of bond dissociation energies of diatomic alkali-earth halides. The relations are

$$D_{AB} = \bar{D}_{AB} + 31.973e^{0.363\Delta x}$$

and

$$D_{AB} = \bar{D}_{AB}[1 - 0.2075(\Delta x)r_e] + 52.29\Delta x$$

where $\bar{D}_{AB} = (D_{AA}D_{BB})^{1/2}$, Δx represents Pauling's electronegativity differences $(X_A - X_B)$ and r_e is the internuclear distance. The estimated bond energies are in reasonably good agreement with the literature values. The errors calculated with our suggested relations for bond energies are 9.9% and 7.5% respectively. The corresponding errors evaluated from Matcha's and Pauling's equations are 6.1% and 48.2%, respectively. A simplified formula for the determination of bond orders of alkali-earth halides has been suggested. The formula has the form $q = 1.5783 \times 10^{-3}(\omega_e^2 r_e/B_e)^{1/2}$. The definition for bond order given by Parr and Borkman differs from that given by Politzer. Thorough investigation of the two statements reveals that the Politzer's definition is a better one.

R. R. REDDY, A. S. R. REDDY et V. KRISHNA REDDY. Can. J. Chem. **63**, 3174 (1985).

On propose de nouvelles relations pour la détermination des énergies de dissociation des liaisons des halogénures diatomiques de métaux alcalino-terreux. Ces relations sont les suivantes:

$$D_{AB} = \bar{D}_{AB} + 31{,}973e^{0.363\Delta x}$$

et

$$D_{AB} = \bar{D}_{AB}[1 - 0{,}2075(\Delta x)r_e] + 52{,}29\Delta x$$

où $\bar{D}_{AB} = (D_{AA}D_{BB})^{1/2}$ et Δx représente les différences d'électronégativité de Pauling $(X_A - X_B)$ alors que r_e représente la distance internucléaire. Les énergies de liaison évaluées sont en bon accord avec les valeurs répertoriées dans la littérature. Les erreurs calculées pour nos relations suggérées pour les énergies de liaisons sont respectivement de 9,9% et de 7,5%. Les erreurs correspondantes évaluées à partir des équations de Matcha et de Pauling sont respectivement de 6,1% et de 48,2%. On suggère une formule simplifié pour déterminer les ordres des liaisons des halogénures des métaux alcalino-terreux. La formule a la forme suivante: $q = 1{,}5783 \times 10^{-3} (\omega_e^2 r_e/B_e)^{1/2}$. La définition de l'ordre de liaison proposée par Parr et Borkman diffère de celle donnée par Politzer. Une étude soignée des deux définitions révèle que celle de Politzer est la meilleure.

Introduction

The bond dissociation energy of diatomic molecules is of great importance in thermochemistry and astrophysics studies (1, 2). In molecular orbital theory, the bond order, which is referred to as the amount of bond charge located on a bond, very important in the calculation of various molecular parameters; e.g., dipole moment and oscillator strength. One procedure for the computation of the total bond order in a molecule involves the linear combination, with suitable coefficients, of atomic orbitals of the two atoms joined by the bond. This makes the computation of total bond order a tedious job. The models suggested by Parr and Borkman (3, 4) and Politzer (5, 6) are found to be suitable for those molecules in which the ionic and covalent contributions to the binding are almost comparable. This idea has been extended by the present authors to test the validity of the model for those molecules in which ionic character is predominant. Hence, it is proposed to determine the bond dissociation energies and bond orders for diatomic alkali-earth halides with the simple formulae suggested.

(i) Bond dissociation energies

In continuation of our studies on bond dissociation energy and bond order (7, 8), we have proposed new relations for the determination of bond dissociation energies based on the relation of Pauling and Matcha (9, 12). The relations are

$$[1] \quad D_{AB} = \bar{D}_{AB} + 31.973e^{0.363\Delta x}$$

$$[2] \quad D_{AB} = \bar{D}_{AB}[1 - 0.2075(\Delta x)r_e] + 52.29\Delta x$$

Where $\bar{D}_{AB} = (D_{AA}D_{BB})^{1/2}$, Δx represents Pauling's electronegativity differences $(X_A - X_B)$ and r_e is the internuclear distance. The necessary constants for the present study are taken from the literature. The bond energy value of the homonuclear molecules of alkali-earth metals and halides are given in Table 1.

Matcha (12) has pointed out that Pauling's empirical relation $D_{AB} = \bar{D}_{AB} + 30(\Delta x)^2$ works badly for ionic molecules. Keeping this point in view, it is desirable to have an accurate relationship for ionic molecules. In the present study, the bond dissociation energies are evaluated using the relations [1] and [2]. For comparison, bond dissociation energies are also computed with Pauling's relation. Matcha (12) has derived an equation relating bond energies to electronegativity differences. This equation has the form

TABLE 1. Bond energies of homonuclear molecules of alkali-earth metals and halides

Molecule	Bond energy (kcal/mol)
Be_2	51.00
Mg_2	31.00
Ca_2	25.00
Sr_2	20.00
F_2	37.00
Cl_2	58.00
Br_2	45.46
I_2	35.55

$$[3] \quad D_{AB} = \bar{D}_{AB} + N[1 - \exp[-30(\Delta x)^2/N]]$$

where $N = 103$. He has not given the electronegativity values appropriate to his relation so far. In order to test the reliability of Matcha's relation for ionic molecules, we have used Pauling's electronegativities in his formula and estimated bond energies. Some conclusions have been drawn by using Pauling's electronegativity values in Matcha's formula (P-M relation).

(2) Bond order

The Parr and Borkman (3, 4) relation of the following form for bond order has been modified by the present authors.

$$[4] \quad q = (4R_c^3K_c/7e^2)^{1/2}$$

K_c in eq. [4] can be written as $\omega_c^2/B_cr_c^2$. From these two relations, the following simplified equation has been derived.

$$[5] \quad q = 1.5783 \times 10^{-3}(\omega_c^2r_c/B_c)^{1/2}$$

Here the experimental values of ω_c, r_c, and B_c determine the bond order. The necessary constants for the present study are taken from Huber and Herzberg (10).

In the present study the definitions for bond order 'q' given by Parr and Borkman (3, 4) and Politzer (5, 6) have been studied in detail and it has been found that the interpretation given by Politzer holds.

Results and discussion

The estimated bond energies for alkali-earth halides from relations [1] and [2], the P-M relation and Pauling's expression are presented in Table 2. The average percentage deviation

$$[5] \quad \frac{(D_0)_{\text{exptl.}} - (D_0)_{\text{calcd.}}}{(D_0)_{\text{exptl.}}} \times 100$$

is also given. The bond order values calculated from relation [5] are presented in Table 3.

The results obtained from eq. [2] reveal that the bond energy values for fluoride molecules deviate from the general trend. The predicted bond energies have higher values than the experimental value by 24 kcal/mol. Similar behaviour is observed in the case of alkali halides (7). This value is deducted from the dissociation energy values obtained from eq. [2] and the modified values are presented in Table 2. It is in good agreement with Kushawaha's view (16). Several explanations have been given for the deviation of fluoride from the other halides (13−16). This may be due to the lower electronic affinity and smaller atomic size of fluorine atom as suggested by Politzer (17). The estimated bond energy values obtained from relation [2] and P-M relation are in good agreement with the experimental values (11). Since the bond energy value for Ba_2 molecule is not available, we could not calculate the bond energies for barium halides. Some of the experimental bond energy values (11) are approximate. The correct percentage deviation may be calculated if reliable experimental data are available. The estimated bond energies from Matcha's relation suggest that Matcha's electronegativities (still to be estimated) and Pauling's electronegativities for the atoms Be, Mg, Ca, Sr, F, Cl, Br, and I do not differ greatly.

CaBr	2.362	2.363	1.405
CaI	2.405	2.407	1.203

Parr and Borkman suggested that q as defined in eq. [5], is a measure of charge located in the bond region and thus could be identified with bond order. By example, Politzer showed (5, 6) that the interpretation of q as bond order could be improved upon. According to him, a better definition of bond order is $q/(0.5r_c)^2$.

The values of q are computed for alkali-earth halides using relation [5]. It is obvious from Table 2 that if q is taken as the bond order it leads to ambiguity. As we go from F to I, the value of q increases while the binding energy decreases. According to Parr and Borkman, CaBr and CaCl; BeI, MgBr, and CaF have approximately the same values for q, 2.3 and 2.2, respectively (Table 2). It has no meaning to have the same bond order for all these molecules. The ambiguity can be removed by taking the relation $q/(0.5r_e)^2$ as the bond order given by Politzer. The present study supports the Politzer view that $q/(0.5r_e)^2$ is the correct definition for the bond order.

The pivaloyloxy methyl 6,6-dihalo penicillanates **1***a*, **1***b*, and **1***c* have been stereoselectively prepared from the reaction of pivaloyloxy methyl 6-diazo penicillanate **2** with either *N*-halosuccinimide/halide or the interhalogens XI (X = Cl, Br). The crystal structures of 3*S*,5*R*,6*R* pivaloyloxy methyl 6-bromo, 6-chloro penicillanate **1***a*; 3*S*,5*R*,6*R* pivaloyloxy methyl 6-iodo, 6-bromo penicillanate **1***b*, and 3S, 5R, 6R pivaloyloxymethyl 6-iodo, 6-chloro penicillanate **1***c* have been determined by X-ray single crystal analysis. The stereochemistry of the displacement reaction is discussed.

DIEGO U. BELINZONI, ORESTE A. MASCARETTI, PEDRO M. ALZARI, GRACIELA PUNTE, CARLOS FAERMAN et ALBERTO PODJARNY. Can. J. Chem. **63**, 3177 (1985).

Le diazo-6 pénicillinate de pivaloyloxyméthyle (**2**) réagit soit avec un mélange de *N*-halosuccinimide/halogénure soit avec les interhalogènes XI (X = Cl, Br) pour conduire de façon stéréosélective aux dihalo-6,6 penicillinates de pivaloyloxyméthyle **1***a*, **1***b* et **1***c*. On a déterminé, par cristallographie de rayons X sur un monocristal, la structure cristalline du bromo-6 chloro-6 pénicillinate de pivaloyloxyméthyle-3*S*,5*R*,6*R* (**1***a*); du bromo-6 iodo-6 pénicillinate de pivaloyloxyméthyle-3*S*,5*R*,6*R* (**1***b*) et du chloro-6 iodo-6 pénicillinate de pivaloyloxyméthyle-3*S*,5*R*,6*R* (**1***c*). On discute de la stéréochimie de la réaction de déplacement.

[Traduit par le journal]

Introduction

Preparation of mixed 6,6-dihalo penicillanic acids has been accomplished through the two-phase diazotization/halogenation procedure described by Volkmann *et al.* (1) or by the work of Kellogg and co-workers (2) through diazotization/halogenation in aqueous media (3). These authors did not, however, provide information regarding the stereochemistry at carbon-6.

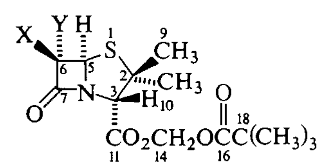
Based on mechanistic considerations (4,5), and taking into account the peculiar structural features of the cup-shaped penicillin molecule (6, 7), one should expect to observe a noticeable control on such type of substitution.

We therefore decided to study the substitution of a diazo group on carbon-6 of the penicillanic framework by either *N*-halosuccinimide/halide or interhalogens. In order to fully characterize the resulting 6,6-dihalo penicillanates, we chose to carry out an X-ray crystallographic analysis to establish the stereochemistry.

In this paper we present the synthesis, and crystal and molecular structures of three pivaloyloxy methyl mixed 6,6-dihalo penicillanates **1***a*, **1***b*, and **1***c*.

Discussion

6-Diazo penicillanic acid and its esters have been suggested by the work of McMillan and Stoodley (5) and Clayton (3) as



1*a* X = Br Y = Cl
1*b* X = I Y = Br
1*c* X = I Y = Cl

the key intermediates for the efficient synthesis of a wide variety of penicillin derivatives. In order to introduce two halogen atoms at C-6 we made use of the reaction of *N*-halosuccinimide/soft potassium or sodium halide[7] in the presence of a crown ether, or the interhalogens XI (X = Cl, Br) with pivaloyloxy methyl 6-diazo penicillanate **2**, in an organic medium (currently methylene dichloride or chloroform), a reaction which we found to be applicable to *N*-haloimides/soft pseudohalides. Following this procedure we were able to synthesize compounds **1***a*, **1***b*, and **1***c* (Scheme 1).

The starting intermediate **2** for these syntheses was prepared according to a known method (8, 9). Although this material can be isolated and spectroscopically characterized, it decomposes at room temperature. The yields of 6,6-dihalo derivatives obtained from the isolated diazo compound were noticeably low (ca. 20%) in comparison with those obtained when the diazo intermediate was generated *in situ* (ca. 80%), according to the procedure described by Volkmann *et al.* (1). It is important to point out that from both procedures only a single compound was detected in each case, with an R_f value within

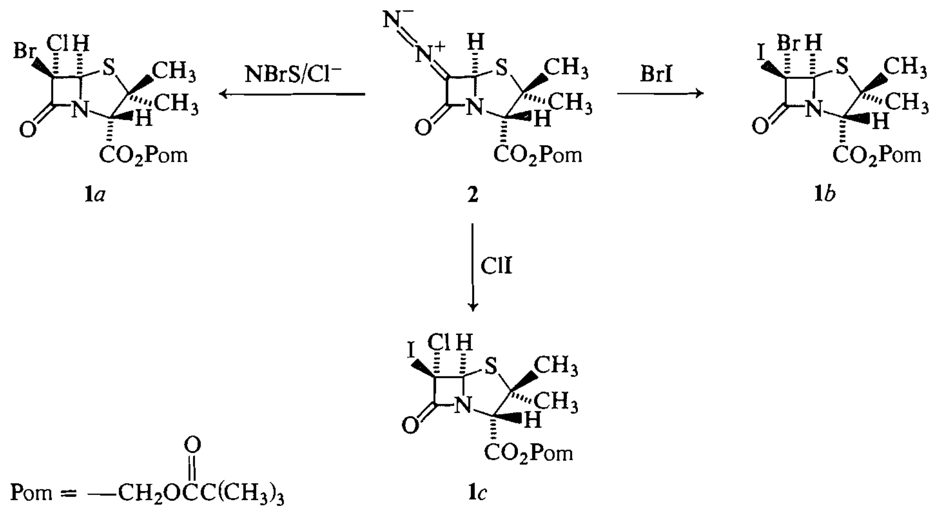
[7]This reaction did not appear useful for the combination N-halosuccinimide/hard halides; e.g. potassium or sodium fluorides.



SCHEME 1

the range of the 6-6-dihalo derivatives (tlc cyclohexane–dioxane, 8:2), **1***a* R_f: 0.84; **1***b* R_f: 0.79; and **1***c* R_f: 0.82). Such noticeable stereo control could be accounted for by taking into account the peculiar structural features of the penicillin molecule, that would greatly influence the diazo group substitution.

In order to fully characterize those compounds, the ir, mass spectra, and ^{1}H and ^{13}C nmr spectra were recorded. The low resolution mass spectra of compounds **1***a*, **1***b*, and **1***c* show, in addition to the ions arising from the known fragmentation pattern (13), the prominent peaks at m/e 57 and m/e 85, characteristic of the *tert*-butyl ester moiety. The ^{1}H nmr data are in complete agreement with those reported for similar compounds (1); the assignment of the ^{13}C nmr signals was carried out by the usual techniques: chemical shift theory, signal multiplicities, the APT pulse sequence (14), correlation with related compounds (15–17), and specific decoupling experiments. The most remarkable features are the high field signal (δ 0.7 ppm) for C-6 in the diazo compound **2**, and the heavy atom effect on the same carbon for compounds **1***b* and **1***c*. Nevertheless, none of the previously mentioned spectroscopic methods gave any valid information regarding the stereochemistry at C-6; we thus undertook a single crystal X-ray study to obtain the relative configuration for all the chiral centers in the molecule. The fact that the absolute configurations at C-3 and C-5 are already known allowed us to fully characterize compounds **1***a*, **1***b*, and **1***c* as follows: 3*S*,5*R*,6*R* pivaloyloxy methyl 6-bromo, 6-chloro penicillanate, 3*S*,5*R*,6*R* pivaloyloxy methyl 6-iodo, 6-bromo penicillanate, and 3*S*,5*R*,6*R* pivaloyloxy methyl 6-iodo, 6-chloro penicillanate.

Since all the compounds synthesized are isostructural, the molecular structures of only two of them, **1***a* and **1***b*, have been solved from diffractometric data. The configuration of the asymmetric carbon-6 of the other, **1***c*, was determined from photographic studies in projection.

Details of structure solution and refinement are presented in the experimental section. Final atomic and equivalent isotropic thermal parameters for **1***a* and **1***b* are given in Tables 1 and 2 respectively.[8] A view of molecular conformation and atom labelling of **1***a* is provided in Fig. 1.

The bond lengths and angles within the nucleus (β-lactam

[8]Tables of structure factors and anisotropic thermal parameters may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

and thiazolidine rings) agree with those of other penicillin derivatives. The thiazolidine ring adopts the α-COOR axial, α-CH_3 equatorial, and β-CH_3 axial configuration, similar to that reported for penicillin G and V (18), carfecillin (19), and oxacillins (20). Four of its five atoms are nearly coplanar with the remaining one (C-3) out of the plane. In the β-lactam ring N-4 lies out of the plane of the substituents and shows a pyramidal arrangement, the C6,C7,O8,N4 fragment is planar within experimental accuracy. Table 3 shows the main structural features of the β-lactam and thiazolidine rings for **1***a*, and **1***b*. The pivaloyloxy methyl ester side chain exhibits an extended conformation (the torsion angles are reported in Table 4).

Conclusions

The results of X-ray analysis showed that in all reactions the positive (electrophilic) halogen atoms are placed in a β-orientation, while the nucleophilic halide atom is in the

α-orientation in agreement with the proposed (4, 6, 7, 21) two-step mechanism for the displacement reaction. The fact that only one isomer was isolated in each case, with no other detected by tlc analysis of the crude reaction mixtures, strongly supports the S_N2 displacement of N_2 shown in Scheme 2, and reinforces the validity of a large number of structures for related compounds, proposed purely on the basis of mechanistic speculations.

Experimental

Apparatus and materials

Melting points were determined on a Metler FP 1 device and were corrected. The ir spectra were taken on a Perkin Elmer 700 A instrument. Mass spectra were recorded at 70 eV in a Varian-Mat CH-7 A mass spectrometer interfaced to a Varian-Mat Data System 166 computer. The ^{1}H and ^{13}C nmr spectra were taken on a Bruker WP 80SY instrument at 80.13 and 20.15 MHz, respectively, and chemical shifts are expressed in parts per million downfield from internal tetramethylsilane. The $[\alpha]_D$s were taken at 20–23°C in 0.5% chloroform solutions. Silica gel GF_{254} (Type 60 Merck) was utilized for tlc, and silica gel 60 H (Merck) for column chromatography.

Pivaloyloxy methyl 6-amino penicillanate hydrochloride

A previously described procedure (8) was used to prepare this compound.

Pivaloyloxy methyl 6-diazo penicillanate 2

This product was prepared from pivaloyloxy methyl 6-amino penicillanate hydrochloride following the method described by Wiering and Wynberg (9). Compound **2** was isolated as an amber glass (65%). This material gave essentially one spot on tlc (R_f 0.85) in benzene/acetonitrile (3:1); ir ($CHCl_3$): 2090 (N=N=C), 1760 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$): 1.22 (s, 9H), 1.46 (s, 3H), 1.64 (s, 3H), 4.39 (s, 1H), 5.80 (d, 1H, H-C14 AB system J = 5.6 Hz), 5.85 (d, 1H, H-C14 AB system J = 5.6 Hz); ^{13}Cmr ($CDCl_3$): 176.6 (C-16), 166.7 (C-11), 166.2 (C-7), 79.7 (C-14), 70.1 (C-3), 68.5 (C-5), 63.6 (C-2), 38.7 (C-18), 33.7 (C-9), 26.8 (C-19 – C-21), 25.7 (C-10), and 0.7 (C-6).

*Pivaloyloxy methyl 6-β-bromo, 6-α-chloro penicillanate 1*a

A mixture of 18-crown-6 (2.88 g, 10.9 mmol), 50 mL of anhydrous chloroform, and potassium chloride (0.813 g, 10.9 mmol) was stirred under nitrogen at room temperature for 30 min. To the resulting solution, cooled to −30°C, was added a crude solution ($CHCl_3$) of freshly prepared compound **2**, from pivaloyloxy methyl 6-amino penicillanate hydrochloride (4.0 g, 10.9 mmol), and the mixture stirred for 10 min at −30°C, followed by the addition of *N*-bromosuccinimide (1.94 g, 10.9 mmol) in 50 mL of anhydrous chloroform, over a period of 30 min. The reaction was then allowed to reach room temperature, the mixture was washed with cold 6% sodium sulfite (50 mL) and water (2 × 50 mL), and dried (Na_2SO_4). Removal of the solvent under reduced pressure gave an oil, which was chromatographed on a column of activated charcoal (Darco) and eluted with n-hexane, affording compound **1***a* as an oil. Crystallization from methanol gave 0.844 g of white crystals (18%), mp 98.0–99.5°C; $[\alpha]_D$ +168.5°; ir (KBr): 1790 (β-lactam), 1760 and 1740 (ester) cm^{-1}; ^{1}Hmr ($CDCl_3$): 1.22 (s, 9H), 1.49 (s, 3H), 1.62 (s, 3H), 4.56 (s, 1H), 5.63 (s, 1H), 5.83 (d, 1H, H-C14 AB system J = 5.6 Hz), 5.86 (d, 1H, H-C14 AB system J = 5.6 Hz); ^{13}Cmr ($CDCl_3$): 176.6 (C-16), 165.2 (C-11), 163.5 (C-7), 80.7 (C-14), 79.6 (C-5), 74.7 (C-6), 69.1 (C-3), 64.2 (C-2), 38.6 (C-18), 33.3 (C-9), 26.7 (C-19 – C-21), 25.6 (C-10); mass spectrum, *m/e* (relative intensity): 431, 429, 427 (1:4:3, 27) M$^+$, 317, 315, 313 (1:4:3, 13), 272, 270, 268 (1:4:3, 97), 217, 215, 213 (1:4:3, 23), 115 (4), 114 (55.4), 85 (61.6), 57 (100).

*Pivaloyloxy methyl 6-β-iodo, 6-α-bromo penicillanate 1*b

To a cooled (−63°C) solution ($CHCl_3$, 50 mL) of freshly prepared compound **2**, from pivaloyloxy methyl 6-amino penicillanate hydrochloride (0.793 g, 2.16 mmol), with stirring under N_2, was added dropwise a solution of iodine monobromide (0.450 g, 2.17 mmol) in 50 mL of chloroform until a persistent brown color was present (it consumed approximately 37 mL in 15 min). The mixture was allowed to reach room temperature and was washed with cold 6% sodium sulfite (50 mL) and water (2 × 50 mL) and dried (Na_2SO_4). Removal of the solvent under reduced pressure gave an orange oil (0.462 g), which was purified by short-column chromatography on silica gel under slight pressure of N_2 and eluted with benzene/chloroform (1:1). The first eluted material furnished a light brown oil which crystallized on standing. Recrystallization from methanol yielded white crystals of compound **1***b* (0.233 g, 21%), mp 125.7°C (dec.); $[\alpha]_D$ +185.9°; ir (KBr): 1790 (β-lactam), 1770 and 1750 (ester) cm^{-1}; ^{1}Hmr ($CDCl_3$): 1.22 (s, 9H), 1.46 (s, 3H), 1.67 (s, 3H), 4.57 (s, 1H), 5.58 (s, 1H), 5.81 (d, 1H, H-C14 AB system J = 5.6 Hz), 5.84 (d, 1H, H-C14 AB system J = 5.6 Hz); ^{13}Cmr ($CDCl_3$): 176.3 (C-18), 165.2 (C-11), 164.9 (C-7), 80.9 (C-5), 79.6 (C-14), 69.5 (C-3), 65.0 (C-2), 38.6 (C-18), 33.6 (C-9), 30.6 (C-6), 26.7 (C-19 – C-21), 26.3 (C-10); ms *m/e* (relative intensity): 521, 519 (1:1, 27) M$^+$, 407, 405 (1:1, 6), 362, 360 (1:1, 8), 307, 305 (1:1, 28.1), 115 (5.4), 114 (68.8), 85 (84.3), 57 (100).

*Pivaloyloxy methyl 6-β-iodo, 6-α-chloro penicillanate 1*c

This compound was prepared as described for **1***b* (starting with 1.000 g, 2.72 mmol of pivaloyloxy methyl 6-amino penicillanate and 2.72 mmol of iodine monochloride). After removal of the solvent, recrystallization from methanol gave compound **1***c* (0.570 g, 30%), mp 118.0–120.0°C; $[\alpha]_D$ +186.0°. Compound **1***c* can be also synthesized using the procedure described for **1***a*. In this method iodine monochloride (2.72 mmol) was generated *in situ* from *N*-chlorosuccinimide and potassium iodide (10, 11) (with 21% yield); ir (KBr): 1780 (β-lactam), 1760 and 1740 (ester) cm^{-1}; ^{1}Hmr ($CDCl_3$): 1.22 (s, 9H), 1.47 (s, 3H), 1.67 (s, 3H), 4.57 (s, 1H), 5.41 (s, 1H), 5.81 (d, 1H, H-C14 AB system J = 5.6 Hz), 5.84 (d, 1H, H-C14 AB system J = 5.6 Hz); ^{13}Cmr ($CDCl_3$): 176.5 (C-16), 165.4 (C-11), 164.3 (C-7), 81.4 (C-14), 79.7 (C-5), 69.3 (C-3), 65.0 (C-2), 50.2 (C-6), 38.7 (C-18), 33.6 (C-9), 26.8 (C-19 – C-21), 26.4 (C-10); ms *m/e* (relative intensity): 477, 475 (1:3, 6.8) M$^+$, 361 (2), 318, 316 (1:3, 4.0), 263, 261 (1:3, 9.0), 115 (2), 114 (22), 85 (26), 57 (100).

Crystallographic studies

Single crystals of **1***a*, **1***b*, and **1***c* were obtained by slow crystallization from methanol. Preliminary Weissenberg photographs showed that the three compounds are isomorphous and belong to the orthorhombic system, space group $P2_12_12_1$, Z = 4. Crystal data are given in Table 5.

3S,5R,6R Pivaloyloxy methyl 6-bromo, 6-chloro penicillanate 1a and 3S,5R,6R pivaloyloxy methyl 6-iodo, 6-bromo penicillanate 1b

Intensity data were collected on an Enraf–Nonius CAD-4 diffractometer with MoK α radiation, $\lambda = 0.71069$ Å (graphite monochromated), scan mode: $\theta-2\theta$, scan range (2θ): 2-54°. Lattice parameters were refined from the setting of 25 high-angle reflections. From the 2015 reflections measured for **1***a* (2235 for **1***b*), the 1661 unique for **1***a* (2028 for **1***b*) with $I > 2.5\sigma(I)$ were considered observed. The observed intensities, corrected for Lorentz polarization and absorption effects, were used to solve the structures by Patterson and Fourier methods. The hand of the model was assigned from the known absolute configurations at C-3 and C-5. The structures were refined by the full matrix least-squares method; anisotropic thermal parameters were used for the nonhydrogen atoms. The hydrogen atoms were stereochemically positioned and allowed to refine isotropically with constraints. The final refinements converged to R factors ($R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o|$) of 6.6% for both structures. The final difference maps showed some peaks of about 1 e Å^{-3} for **1***a* and 3 e Å^{-3} for **1***b* around the heaviest atoms. No attempt was made to carry out a Bijvoet analysis. All the calculations were performed on an IBM 4331 computer with the SHELX 76 system of programs (12).

3S,5R,6R Pivaloyloxy methyl 6-iodo, 6-chloro penicillanate 1c

Crystal data are given in Table 5. Accurate cell dimensions were obtained from least-squares fitting of precession film coordinates. From these data it is apparent that **1***c* is both isomorphous and isostructural with **1***a* and **1***b*. Accordingly, relative intensities for the *hk*O and *h*O*l* layers were measured on a rotating drum Optronics P1000 microdensitometer, at 100 μm scanning rasters, from precession photographic data. In order to get a qualitative R factor for the two possible configurations at the 6 position, these data were corrected for Lorentz and polarization effects and compared with the calculated ones using the structure of **1***b* as the model. Qualitative R factor values (%) for the two possible C-6 configurations of **1***c* were calculated: (1) assuming the α-chloro β-iodo configuration, $R(hk\mathrm{O}) = 18$, $R(h\mathrm{O}l) = 20$, and (2) assuming the α-iodo β-chloro configuration, $R(hk\mathrm{O}) = 60$, $R(h\mathrm{O}l) = 63$. Thus the C-6 configuration is α-chloro, β-iodo.

A formal enantiospecific synthesis of California red scale pheromone

JOHN H. HUTCHINSON AND THOMAS MONEY
Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received May 15, 1985

JOHN H. HUTCHINSON and THOMAS MONEY. Can. J. Chem. **63**, 3182 (1985).

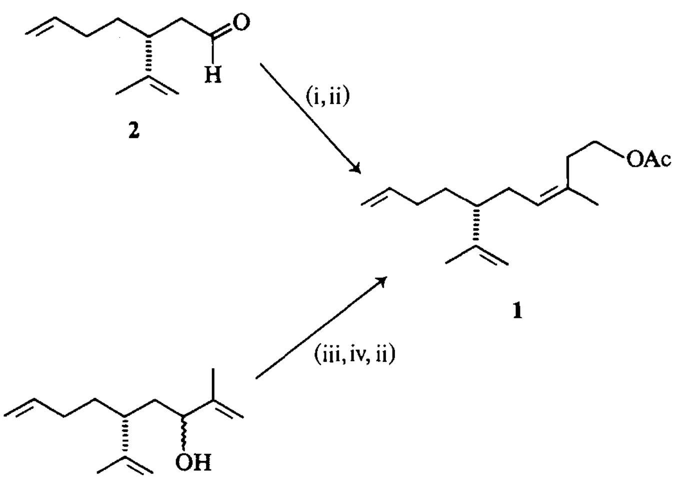
Cleavage of α,α-disubstituted β-bromoketone intermediates derived from (+)-camphor forms the basis of an alternative enantiospecific synthesis of (*Z*)-3-methyl-6-isopropenyl-3,9-decadien-1-yl acetate (**1**), one of the sex pheromones of the female California red scale, *Aonidiella aurantii* (Maskell).

JOHN H. HUTCHINSON et THOMAS MONEY. Can. J. Chem. **63**, 3182 (1985).

On a utilisé le clivage des β-bromocétones α,α-disubstituées intermédiaires qui proviennent du (+)-camphre comme base d'une nouvelle synthèse énantiospécifique de l'acétate de l'isopropényl-6 méthyl-3 décadiène-3,9 yle-(*Z*) (**1**), une des phérémones sexuelles de l'*Aonidiella aurantii* (Maskell).

[Traduit par le journal]

The isolation, structure, and enantiospecific synthesis of (*Z*)-3-methyl-6-isopropenyl-3,9-decadien-1-yl acetate (**1**), one of the sex pheromones of the female California red scale, *Aonidiella aurantii* (Maskell), has been described by Roelofs *et al.* (1). Other independent syntheses of racemic (2, 3) and optically active **1** (4) have also been reported. Diene-aldehyde **2** and trienol **3** are pentultimate intermediates in the synthetic



(i) $Ph_3P{=}C(CH_3)CH_2CH_2OLi$; (ii) Ac_2O/C_5H_5N; (iii) KH/Bu_3SnCH_2I; (iv) BuLi/−78°C

routes devised by Roelofs (1) and Still (2), respectively, and this report describes an alternative enantiospecific synthesis (Scheme 1) of these compounds from (+)-camphor (**4**).

Previous investigations in our laboratory have shown that (+)-camphor (**4**) can easily be converted to (+)-9,10-dibromocamphor (**6**) (5) and that the latter compound undergoes facile, efficient ring cleavage with sodium hydroxide or sodium methoxide to provide bromo-acid (**7**) or the corresponding ester in ~90% yield (6, 7). Reduction ($LiAlH_4$/THF) of acid **7** followed by ozonolysis ((*i*) O_3/MeOH, (*ii*) Me_2S) and protection of the hydroxyl group produced a cyclopentanone derivative (**10**), which, like 9,10-dibromocamphor (**6**),[1] is an α,α-disubstituted β-bromoketone and would therefore be expected to undergo Grob-type ring cleavage with base (8, 9). In the event, treatment of bromoketone **10** with sodium methoxide provided acyclic ester (9) **12** (~57%) and a ketone (~17%) which was tentatively assigned structure **13**[2] on the basis of ir (ν_{max} 1795 cm^{-1}) and nmr evidence. Attempts to reduce the proportion of bicyclic ketone **13** produced in the ring cleavage of bromoketone **10** by varying the time and temperature of the reaction did not lead to significant increases in the yield of acyclic ester **12**. Other studies in our laboratory indicated that ring cleavage of bromoketal MOM ether (**11**) can be achieved with sodium hydroxide. However, although cyclization did not seem to occur under these conditions, the product was difficult to purify and the estimated yield of acyclic acid was less than that obtained for the formation of acyclic ester **12**.

Reduction of ester **12** with $LiAlH_4$/THF followed by oxidation with PDC/CH_2Cl_2 provided an aldehyde (**17**), which on reaction wih methylenetriphenylphosphorane yielded diene **18** in ~50% overall yield from **12**. Our initial synthetic objective, diene-aldehyde **2**,[3] was then prepared from **18** by removal of the protecting group (Bu_4NF/THF) and oxidation of the alcohol **19**[4] with PDC/CH_2Cl_2. Finally, treatment of aldehyde 2 with 2-propenylmagnesium bromide provided diastereomeric trienols 3*a*, *b* (80% yield), which were easily separated by column chromatography. Since the stereoselective conversion of 3*a* and 3*b* to **1** has previously been reported (2), the sequence of reactions outlined in Scheme 1 represents a formal enantiospecific synthesis of one of the sex pheromones of California red scale[5] and also provides a further illustration of the versatility of camphor as a chiral starting material in natural product synthesis. (12).

Experimental

Melting points (mp) were determined on a Kofler micro heating stage and are uncorrected. Infrared spectra were recorded on a

[1] The yield of ~60% cited in this paper for the conversion of 3,9,10-tribromocamphor to 9,10-dibromocamphor has been increased to ~95% by using $Zn/HOAc/Et_2O$/0°C for 30 min.

[2] The structure and absolute configuration of the *p*-bromobenzoate derivative **15** derived from **13** has been confirmed by X-ray crystallographic analysis; S. J. Rettig and J. Trotter, unpublished results.

[3] We are grateful to Dr. Richard J. Anderson (Zoecon Corporation, Palo Alto, California) for providing us with comparative nmr and ir spectra for this compound.

[4] Investigations of an alternative and potentially more efficient route to dienol **19**, involving sequential treatment of bromoketal **8** with diborane and base (10), have so far been inconclusive.

[5] A total synthesis of the other pheromone of California red scale has also been described (11).

SCHEME 1

Perkin–Elmer 137 spectrophotometer and optical rotations were made on a Perkin–Elmer 141 polarimeter. The ^{1}H nmr spectra were recorded on Bruker WH-400, Bruker WP-80, or Nicolet-Oxford H-270 instruments. Signal positions are given in delta (δ) with tetramethylsilane (TMS) as internal reference (except for compounds containing trialkylsilyl groups where TMS was used as an external reference). The integrated areas and signal multiplicities are indicated in parentheses. Low resolution mass spectra were determined on a MAT CH-4 spectrometer and high resolution spectra were recorded on a Kratos MS-50 spectrometer. Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia. Column chromatography was done using Merck silica gel 60 (230–400 MHz) and thin-layer chromatography (tlc) utilizing silica gel 1B2-F (Baker-flex) sheets.

Bromoacid 7

Method A

To a solution of 9,10-dibromocamphor (**6**) (5) (1.5 g, 4.8 mmol) in dimethylsulphoxide (50 mL) was added potassium hydroxide (1.35 g, 24 mmol) in water (10 mL). After 1 h, the yellow solution was poured onto water and extracted once with ether. The ether layer was washed once with water and the combined aqueous layers were then carefully acidified with 6 *N* hydrochloric acid. This was extracted with ether, the ether layers then washed with brine, dried ($MgSO_4$), and evaporated to yield bromoacid **7** (1.2 g; 98%) as a white crystalline solid, one spot on tlc. Recrystallization of a small amount of this material from petroleum ether (30–60°C) afforded an analytically pure sample of bromoacid **7**, mp 62–64°C; $[\alpha]_D$ −48.5° (*c* 0.4, MeOH); ν_{max} ($CHCl_3$): 2950, 1705, 1640, 890 cm^{-1}; δ ($CDCl_3$, 400 MHz): 1.08 (3H, s), 1.39 (1H, m), 2.01 (1H, m), 2.18 (1H, dd, *J* = 16 Hz, 10 Hz), 2.32–2.48 (2H, m), 2.55 (1H, m), 2.63 (1H, dd, *J* = 16 Hz, 4 Hz), 3.39 (d) and 3.47 (d) (2H, AB quartet, *J* = 10 Hz), 4.86 (1H, t, *J* = 2 Hz), 5.00 (1H, t, *J* = 2 Hz); *m*/*e* (relative intensity): 248/246 (M^+, 0.4/0.4), 188/186 (4/4), 167 (7), 166 (17), 153 (100), 111 (32), 107 (98). *Anal.* calcd. for $C_{10}H_{15}O_2Br$: C 48.58, H 6.12, Br 32.35; found: C 48.47, H 6.16, Br 32.20.

Method B

9,10-Dibromocamphor (**6**) (1.0 g, 3.2 mmol), 0.5 *N* potassium hydroxide (80 mL, 40 mmol), and tetrahydrofuran (80 mL) were stirred at room temperature for 4.5 h. Work-up as before gave bromo acid **7** (0.75 g; 94% yield) as a white solid.

Bromoalcohol 8

To a solution of bromoacid **7** (2.53 g, 10.2 mmol) in tetrahydrofuran (80 mL) at 0°C under argon was added lithium aluminum hydride (0.66 g, 17.4 mmol) in portions over 15 min. After a further 15 min at 0°C, the reaction was warmed to room temperature and quenched with ice 3 h later. Water and ether were added and the aqueous phase carefully acidified with 1 *N* hydrochloric acid. Extraction with ether (2×) followed by work-up in the usual way yielded a pale yellow oil (2.30 g). Flash chromatography (silica gel; petroleum ether (30–60°C)/ether 3:2) gave bromoalcohol **8** (2.25 g, 95% yield) as a colourless oil; $[\alpha]_D$ −46.2° (*c* 1.0, MeOH); ν_{max} (film): 3350, 1650, 890 cm^{-1}; δ ($CDCl_3$, 400 MHz): 1.04 (3H, s), 1.25–1.47 (2H, m), 1.62 (1H, bs, D_2O exchangeable), 1.80 (1H, m), 1.92 (1H, m), 2.16 (1H, m), 2.33 (1H, m), 2.42 (1H, m), 3.42 (d) and 3.49 (d) (2H, AB quartet, *J* = 10 Hz), 2.68 (1H, m) and 2.75 (1H, m), 4.84 (1H, t, *J* = 2 Hz), 4.98 (1H, t, *J* = 2 Hz); *m/e* (relative intensity): 217/215 (26/27), 135 (43), 121 (39), 107 (66), 95 (100), 93 (89), 91 (71), 79 (74). *Anal.* calcd. for $C_{10}H_{17}OBr$: C 51.52, H 7.35, Br 34.27; found: C 51.81, H 7.27, Br 34.09.

Bromoketal 9 and bromoketal tert-*butyldimethylsilyl ether 10*

A solution of bromoalcohol **8** (796 mg, 3.4 mmol) in dry methanol (60 mL) was cooled to −78°C and subjected to a stream of ozone. After the solution turned blue it was flushed with oxygen until colourless, dimethyl sulphide (2 mL) was added, and the mixture stirred at room temperatue for 16 h. The methanol was removed under reduced pressure and the resulting oil redissolved in ether, filtered through silica gel, and the ether evaporated to yield crude bromoketol **9** (0.77 g); ν_{max} (film): 3400, 1720; δ ($CDCl_3$, 80 MHz): 1.00 (3H, s), 1.5–2.0 (4H, m, 1 proton exchangeable with D_2O), 3.3 (d) and 3.7 (d) (2H, AB quartet, *J* = 10 Hz), 3.8 (2H, bt, *J* = 6 Hz); *m/e* (relative intensity): 236/234 (M^+, 0.5/0.6), 155 (22), 97 (100), 95 (20), 93 (19), 91 (19); *Mol. Wt.* calcd. for $C_9H_{15}O_2Br$: 236.0235/234.0255; found (high resolution mass spectrometry): 236.0233/234.0245.

The crude bromoketol **9** (0.77 g), *tert*-butyldimethylsilyl chloride (0.98 g, 6.6 mmol, freshly sublimed), and 4-(*N*,*N*-dimethylamino)-pyridine (0.8 g, 6.6 mmol) were dissolved in dry dichloromethane (40 mL) under argon. After 24 h at room temperature the reaction was partitioned between water and ether and worked up in the usual way to provide a pale yellow mobile oil (1.41 g).

Purification by flash chromatography (silica gel, petroleum ether (30–60°C)/ether 9:1) yielded **10** (0.79 g) (67% yield over 2 steps); $[\alpha]_D$ −57.6° (*c* 0.55 MeOH); ν_{max} (film): 1740 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.07 (6H, s), 0.91 (9H, s), 0.94 (3H, s), 1.40–1.54 (2H, m), 1.74 (1H, m), 2.07–2.25 (2H, m), 2.37 (1H, m), 2.62 (1H, m), 3.29 (1H, d, *J* = 10 Hz), 3.61 (1H, d, *J* = 10 Hz), 3.67–3.80 (2H, m); *m/e* (relative intensity): 293/291 (9/9), 211 (10), 169 (9), 167 (8), 137 (100), 119 (36), 109 (53), 95 (82), 93 (73). *Anal.* calcd. for $C_{15}H_{29}O_2BrSi$: C 51.57, H 8.37, Br 22.87; found: C 51.83, H 8.45, Br 22.77.

Bromoketol MOM ether 11

To a solution of bromoketol **9** (309 mg, 1.3 mmol) and methylal (5 mL, 57.5 mmol, in dry dichloromethane (9 mL) under argon was added phosphorus pentoxide (1.5 g) in three portions. After 3 h the reaction was carefully quenched with ice-cold sodium carbonate solution. Ether extraction, followed by work-up in the usual way, provided a yellow oil (297 mg) which, after flash chromatography (silica gel; petroleum ether (30–60°C)/ether 1.5:1), gave **11** (287.5 mg; 78%) as a colourless oil; ν_{max} (film): 1740 cm^{-1}; δ ($CDCl_3$, 270 MHz): 0.94 (3H, s), 1.50 (2H, m), 1.81 (1H, m), 2.17 (2H, m), 2.38 (1H, m), 2.58 (1H, m), 3.28 (1H, d, *J* = 10 Hz), 3.37 (3H, s), 3.60 (1H, d, *J* = 10 Hz), 3.64 (2H, m), 4.63 (2H, s); *m/e* (relative intensity): 280/278 (M^+, 0.1/0.2), 199 (64), 167 (100), 149 (66), 107 (62), 97 (62), 95 (61). *Exact Mass* calcd. for $C_{11}H_{19}O_3$ (M − Br): 199.1334; found (high resolution mass spectrometry): 199.1326 (M − Br).

*Ring cleavage of bromoketone 10: formation of methyl 4-isopropenyl-6-*tert-*butyldimethylsilyloxyhexanoate 12 and bicyclic ketone 13*

Sodium metal (140 mg, 6.1 mmol) was added to dry methanol (5 mL) under argon. When all the sodium had reacted, bromoketone **10** (215 mg, 0.61 mmol) in dry methanol (6 mL) was added via a cannula needle and the reaction heated to 60°C (oil bath temperature). After 3.5 h the mixture was added to saturated ammonium chloride solution and extracted (3 times) with ethyl acetate. The combined organic layers were washed with brine, dried ($MgSO_4$), and the solvent removed. The residue (193 mg) was subjected to flash chromatography (silica gel; petroleum ether (30–60°C)/ether; 50:1) to yield ester **12** (105 mg, 57% yield; 61% yield based on recovered starting material); $[\alpha]_D$ −0.45° (*c* 0.66, MeOH); ν_{max} (film): 1745, 1650, 890 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.03 (6H, s), 0.89 (9H, s), 1.53–1.77 (7H, m), 2.13–2.33 (3H, m), 3.46–3.60 (2H, m), 3.65 (3H, s), 4.69 (1H, bs), 4.78 (1H, bs); *m/e* (relative intensity): 285 (1.4), 269 (2.6), 243 (73), 211 (16), 171 (40), 157 (40), 151 (100). *Anal.* calcd. for $C_{16}H_{32}OSi$: C 63.95, H 10.73; found: C 63.79, H 10.78.

Further elution with petroleum ether/ether (10:1) provided bicyclic ketone **13** (28.4 mg; 17% yield; 19% yield based on recovered starting material); $[\alpha]_D$ +54.1° (*c* 0.29, CH_2Cl_2); ν_{max} (film): 1790 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.04 (6H, s), 0.89 (9H, s), 1.20 (3H, s), 1.46–1.62 (4H, m), 1.84 (1H, m), 2.00–2.08 (2H, m), 2.83 (1H, bs), 3.55–3.72 (2H, m); *m/e* (relative intensity): 268 (M^+, 2), 253 (4), 227 (36), 211 (71), 183 (41), 165 (33), 119 (34), 107 (32), 93 (32), 75 (100), 73 (49). *Mol. Wt.* calcd. for $C_{15}H_{28}O_2Si$: 268.1859; found (high resolution mass spectrometry): 268.1864. *Anal.* calcd. for $C_{15}H_{28}O_2Si$: C 67.11, H 10.51; found: C 67.20, H 10.44.

The final fractions from the column provided starting material **10** (11.5 mg).

p-*Bromobenzoate (15) derived from bicyclic ketone 13*

To bicyclic ketone **13** (83 mg, 0.31 mmol) was added tetrabutylammonium fluoride (3.1 mL, 3.1 mmol, 1 *M* solution in THF) and the solution stirred under argon at room temperature for 2 h. The mixture was diluted with ether, washed with brine, dried ($MgSO_4$), and the solvent removed *in vacuo* to yield a yellow oil (104 mg) which, on column chromatography (silica gel; petroleum ether (30–60°C/ether 1:2) afforded bicyclic ketoalcohol **14** (32 mg, 67% yield); ν_{max} (film): 3300, 1790 cm^{-1}; δ ($CDCl_3$, 80 MHz): 1.18 (3H, s), 2.83 (1H, bs), 3.4–3.9 (2H, m); *m/e* (relative intensity): 154 (M^+, 1), 93 (87), 81 (100).

Ketoalcohol **14** (27.4 mg, 0.17 mmol) was dissolved in dry pyridine (2 mL) and *para*-bromobenzoyl chloride (77 mg, 0.35 mmol) added. The solution was stirred under argon for 24 h, then diluted with ether and poured onto 1 *N* hydrochloric acid. The ether layer was washed twice with 2 *N* potassium hydroxide solution, then with water (3 times). The crude product, after evaporation of the solvent, was chromatographed on silica gel (petroleum ether (30–60°C)/ether 4:1) to give *para*-bromobenzoate (**15**) (44 mg, 73% yield) as an oil that crystallized on standing. Crystallization from petroleum ether (30–60°C) provided **15**, mp 47.5–48.5°C; ν_{max} (film): 1780, 1720, 1595 cm^{-1}; δ ($CDCl_3$, 80 MHz): 1.28 (3H, s), 1.30–1.85 (4H, m), 1.85–2.33 (3H, m), 2.90 (1H, bs), 4.38 (2H, t, *J* = 7 Hz), 7.50–8.00 (4H, m); *m/e* (relative intensity): 338/336 (M^+, 0.3/0.4), 297/295 (414), 185 (99), 183 (100), 108 (58), 93 (71).

*4-Isopropenyl-6-*tert-*butyldimethylsilyloxyhexanal (17)*

Lithium aluminum hydride (76 mg, 2.0 mmol) was added in 4 portions to a cooled (0°C) solution of ester **11** (400 mg, 1.33 mmol) in tetrahydrofuran (30 mL) under argon. After 1 h at 0°C and 1 h at room temperature the solution was added to ice, carefully acidified (1 *N* hydrochloric acid), and extracted with ether. Work-up in the usual way gave a pale yellow oil (380 mg) which, on flash chromatography (silica gel; petroleum ether (30–60°C)/ether 1:2), provided 3-isopropenyl-1,6-hexanediol monosilyl ether **16** (326 mg, 90%) as a colourless oil: ν_{max} (film): 3350, 1640, 880 cm^{-1}; δ ($CDCl_3$, 80 MHz): 0.08 (6H, s), 0.95 (9H, s), 1.25–1.75 (10H, m), 2.05–2.30 (1H, m), 3.40–3.80 (4H, m), 4.75 (2H, m); *m/e* (relative intensity): 257 (0.2), 213 (13), 123 (47), 105 (33), 81 (60), 75 (100). *Exact Mass* calcd. for $C_{15}H_{31}SiO_2 - C_4H_9$: 215.1474; found (high resolution mass spectrometry): 215.1467.

A solution of alcohol **16** (170 mg, 0.63 mmol) and pyridinium dichromate (1.18 g, 3.13 mmol) in dry dichloromethane (20 mL) was stirred at room temperature under an argon atmosphere for 16 h. The reaction mixture was then diluted with ether, filtered (silica gel), and the solvent evaporated under reduced pressure. The residue was purified by chromatography (silica gel; petroleum ether (30–60°C)/ether 10:1) to give aldehyde **17** (129 mg, 76% yield) as a colourless oil, $[\alpha]_D$ −3.58° (*c* 0.81, CH_2Cl_2); ν_{max} (film): 3100, 2730, 1730, 1650, 895 cm^{-1}; δ ($CDCl_3$, 80 MHz): 0.08 (6H, s), 0.92 (9H, s), 1.45–1.85 (7H, m), 2.05–2.52 (3H, m), 3.55 (2H, t, *J* = 6 Hz), 4.72 (1H, bs), 4.80 (1H, m), 9.68 (1H, t, *J* = 4 Hz); *m/e* (relative intensity): 270 (M^+, 0.1), 269 (0.4), 255 (0.5), 243 (9), 213 (27), 121 (58), 93 (59), 75 (100). *Anal.* calcd. for $C_{15}H_{30}O_2Si$: C 66.60, H 11.18; found: C 66.70, H 11.25.

3-Isopropenyl-hept-6-en-1-ol tert-*butyldimethylsilyl ether (18)*

Methyltriphenylphosphonium bromide (259 mg, 0.73 mmol) was suspended in dry tetrahydrofuran (5 mL) under an atmosphere of argon and cooled to −78°C. n-Butyllithium (0.45 mL, 0.72 mmol; 1.6 *M* solution in hexane) was added and, after 10 min at −78°C, the solution stirred for a further 40 min at room temperature. Aldehyde **17** (97 mg, 0.36 mmol) in tetrahydrofuran (5 mL) was added and the reaction mixture stirred for 1 h. After dilution with hexane (20 mL), the solution was poured onto a prepacked column of Florisil and eluted with hexane. The crude product was then chromatographed on silica gel (petroleum ether (30–60°C/ether 250:1) to provide diene **18**, 68.3 mg (71% yield); ν_{max} (film): 3100, 1640, 910, 890 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.03 (6H, s), 0.88 (9H, s), 1.42 (2H, m), 1.56 (2H, m), 1.60 (3H, bs), 1.88–2.05 (2H, m), 2.20 (1H, m), 3.46–3.60 (2H, m), 4.69 (1H, bs), 4.75 (1H, bs), 4.92 (1H, bd, *J* = 10 Hz), 4.99 (1H, bd, *J* = 17 Hz), 5.80 (1H, overlapping ddt, *J* = 17, 10, 7 Hz); *m/e* (relative intensity): 253 (0.1), 211 (20), 129 (26), 101 (39), 75 (100), 73 (27). *Exact Mass* calcd. for $C_{16}H_{31}OSi - C_4H_9$: 211.1518; found (high resolution mass spectrometry): 211.1520.

(R)*-3-isopropenyl-6-heptenal (2)*

A solution of tetrabutylammonium fluoride (2.5 mL, 2.5 mmol; 1 *M* solution in tetrahydrofuran) was added to the diene **18** (67 mg, 0.48 mmol) under argon. After 2.5 h the reaction was diluted with ether and water. The aqueous layer was extracted twice more with ether and the ether layers were combined and washed twice with brine. After drying ($MgSO_4$), the ether was removed to yield 98.6 mg of a yellow oil. Purification by column chromatography (silica gel; petroleum ether (30–60°C)/ether 6:1) provided (*R*)-3-isopropenylhex-6-en-1-ol (**19**) (38 mg); ν_{max} (film): 3320, 3080, 1640, 905, 890 cm^{-1}; δ ($CDCl_3$, 80 MHz): 1.72 (3H, dd, *J* = 1, 1 Hz), 3.65 (2H, t, *J* = 6 Hz), 4.70–5.18 (4H, m), 5.82 (1H, 10-line multiplet); *m/e* (relative intensity): 154 (M^+, 6), 41 (100).

Alcohol **19** (26 mg, 0.17 mmol) in dry dichloromethane (7 mL) was treated with pyridinium dichromate (315 mg, 0.85 mmol) and the reaction stirred under argon for 14 h. The mixture was diluted with ether and filtered through a pad of silica gel. Removal of the solvent *in vacuo* at 0°C yielded 34.8 mg of crude product. Chromatography (silica gel; petroleum ether (30–60°C)/ether 4:1) gave aldehyde **2** (16 mg, 62% over 2 steps) as an unstable volatile oil: $[\alpha]_D$ +6.1° (*c* 0.74, CH_2Cl_2); ν_{max} (film): 3080, 2740, 1730, 1640, 890 cm^{-1} (lit. (1) ν_{max} (CCl_4): 3080, 1730 cm^{-1}); δ ($CDCl_3$, 270 MHz): 1.52 (2H, m), 1.69 (3H, bs), 2.04 (2H, m), 2.46 (2H, multiplet which simplified on irradiation at δ 9.66), 2.73 (1H, 5-line multiplet), 4.79 (1H, m), 4.83 (1H, m), 4.93–5.05 (2H, m), 5.80 (1H, ddt, *J* = 17, 11, 6 Hz), 9.66 (1H, t, *J* = 2 Hz), (lit. (1) δ ($CDCl_3$): 1.67 (3H, bs), 9.75 (1H, t, *J* = 2 Hz)); *m/e* (relative intensity): 151 (M^+ − H, 0.9), 1.37 (3), 108 (17), 95 (29), 93 (29), 81 (33), 79 (29), 69 (100), 67 (53). *Exact Mass* calcd. for $C_{10}H_{16}O$ − H: 151.1123; found (high resolution mass spectrometry): 151.1129 (*M* − 1).

*(*3R,5R*)- and (*3S,5S*)-5-isopropenyl-2-methyl-1,8-nonadien-3-ol (*3a, 3b*)*

A 3-neck flask fitted with a Dry Ice condenser and a pressure equalized dropping funnel, and flushed with agron, was charged with freshly crushed magnesium turnings (300 mg, 12.5 mmol). A crystal of iodine was added, followed by 2-bromopropene (0.75 mL, 8.3 mmol) in tetrahydrofuran (20 mL, dropwise). After the addition was complete, the mixture was refluxed for 30 min and cooled to room temperature. An aliquot of this solution (4 mL, approximately 1.6 mmol) was removed by syringe and added to a solution of the aldehyde **2** (31 mg, 0.2 mmol) in tetrahydrofuran (4 mL) at −15°C. The reaction mixture was stirred at this temperature for 30 min, then allowed to warm to room temperature over a further 30 min before being added to an ice/ammonium chloride solution. Extraction with ether and work-up in the usual way provided a crude product (56 mg) which was subjected to chromatography (silica gel; petroleum ether (30–60°C)/ether 12:1) to give, in order of elution, the following.

(*i*) Least polar diastereomer (**3***a* or **3***b*) (15.5 mg), R_f 0.46 (petroleum ether (30–60°C)/ether 1:1); $[\alpha]_D$ −15.47° (*c* 1.5, CH_2Cl_2); ν_{max} (film): 3400, 3100, 1645, 890 cm^{-1}; δ ($CDCl_3$, 400 MHz): 1.38–1.60 (5H, m, one proton D_2O exchangeable), 1.63 (3H, bs), 1.72 (3H, bs), 1.98 (2H, m), 2.39 (1H, 7-line multiplet), 4.00 (1H, dd, *J* = 9, 3 Hz), 4.81 (2H, bs), 4.84 (1H, bs), 4.90–5.03 (3H, m), 5.83 (1H, ddt, *J* = 17, 10, 6.5 Hz); *m/e* (relative intensity): 194 (M^+, 0.4), 179 (7), 135 (30), 109 (35), 107 (34), 95 (34), 93 (45), 84 (47), 81 (65), 71 (86), 70 (57), 69 (100), 67 (73). *Mol. Wt.* calcd. for $C_{13}H_{22}O$: 194.1671; found (high resolution mass spectrometry): 194.1680.

(*ii*) More polar diastereomer (**3***a* or **3***b*), 15.9 mg; R_f 0.32 (petroleum ether (30–60°C)/ether 1:1); $[\alpha]_D$ +50.15°C (*c* 1.34, CH_2Cl_2); ν_{max} (film): 3380, 3100, 1645, 890 cm^{-1}; δ ($CDCl_3$, 400 MHz): 1.45 (2H, m), 1.50–1.65 (3H, m, one proton D_2O exchangeable), 1.67 (3H, bs), 1.73 (3H, bs), 1.97 (2H, m), 2.14 (1H, 7-line multiplet), 4.08 (1H, t, *J* = 6.5 Hz), 4.75 (1H, bs), 4.80 (1H, bs), 4.84 (1H, bs), 4.90–5.05 (3H, m), 5.80 (1H, ddt, *J* = 17, 10, 7 Hz); *m/e* (relative intensity): 194 (0.6), 151 (5), 139 (5), 109 (20), 107 (26), 95 (24), 94 (35), 93 (24), 81 (49), 79 (35), 71 (100), 69 (82), 68 (78). *Exact Mass* calcd. for $C_{13}H_{22}O - H_2O$: 176.1565; found (high resolution mass spectrometry): 176.1561.

Total yield of alcohols **3***a*, *b*: 31.4 mg (79%). *Anal.* (**3***a*, *b*, mixture of diastereomers) calcd. for $C_{13}H_{22}O$: C 80.35, H 11.41; found: C 80.30, H 11.47.

ANTONIO DELGADO, RICARDO GRANADOS, DAVID MAULEON, INMACULADA SOUCHEIRON, and MIGUEL FELIZ. Can. J. Chem. **63**, 3186 (1985).

The synthesis of *cis*- and *trans*-2-amino-1-arylcyclohexanols **1**–**8**, conformationally restricted analogues of the α-adrenergic drugs norephedrine **9**, methoxamine **10**, and isopropylmethoxamine **11**, is described. *trans*-Aminoalcohols were obtained through reaction of epoxides **12** or **13** with isopropylamine (to afford **4** and **8**) or with sodium azide followed by lithium aluminum hydride reduction (to afford **2** and **6**), whereas *cis*-aminoalcohols **1** and **5** were obtained by condensation of 2-aminocyclohexanone hydrobromide **26** with the appropriate organometallic reagent. Treatment of **1** and **5** with acetone followed by sodium borohydride reduction gave isopropylaminoalcohols **3** and **7**. Configurational and conformational assignments of aminoalcohols **1**–**8** have been carried out on the basis of their ^{1}H nmr and ^{13}C nmr data and by comparison with reference diols **18** and **30**. The major or exclusive chair conformation observed for all the compounds has an equatorial aryl group.

ANTONIO DELGADO, RICARDO GRANADOS, DAVID MAULEON, INMACULADA SOUCHEIRON et MIGUEL FELIZ. Can. J. Chem. **63**, 3186 (1985).

On décrit la synthèse des amino-2 aryl-1 cyclohexanols-*cis* et -*trans* (**1**–**8**) qui sont des analogues à conformation restreinte de médicaments α-adrénergiques comme la noréphédrine **9**, la méthoxamine **10** et l'isopropylméthoxamine **11**. On a obtenu les aminoalcools-*trans* en faisant réagir les époxydes **12** ou **13** soit avec de l'isopropylamine (pour obtenir les composés **4** et **8**) soit avec l'azoture de sodium, puis avec de l'alanate de lithium (pour obtenir les composés **2** et **6**). On accède aux aminoalcools-*cis* (**1** et **5**) en faisant réagir le bromhydrate de l'amino-2 cyclohexanone **26** avec un dérivé organométallique approprié. La réaction des composés **1** et **5** avec l'acétone, suivie d'une réduction par le borohydrure de sodium, conduit aux isopropylaminoalcools **3** et **7**. On a procédé aux attributions configurationnelles et conformationnelles des aminoalcools **1**–**8** en se basant sur les données rmn du ^{1}H et du ^{13}C ainsi que par une comparaison avec les diols de référence **18** et **30**. Dans tous les composés, la conformation chaise observée de façon majoritaire ou exclusive comporte un groupement aryle en position équatoriale.

[Traduit par le journal]

Introduction

In connection with our studies on adrenergic agents, we focused our attention on the synthesis, by unambiguous routes, of *cis*- and *trans*-2-amino-1-arylcyclohexanols **1**–**8**, conformationally restricted analogues of the α-adrenergic stimulants norephedrine **9**, methoxamine **10**, and of the β-adrenergic blocker isopropylmethoxamine **11**.

Although cyclic aminoalcohols **1**–**8** exhibit a higher conformational limitation than the model compounds **9**–**11**, two chair conformations are still possible for each of them. Thus, while aryl and amino groups are synclinal in both chair conformations of the *trans*-aminoalcohols, in *cis*-isomers the aryl–axial conformation has antiperiplanar aryl and nitrogen groups. Since the pharmacological activity of arylethanolamines has been related to this last disposition (1), we also wish to study the conformation in solution of compounds **1**–**8**, both in the base and hydrochloride forms.

Synthesis of trans-*aminoalcohols*[3]

Synthesis of *trans*-aminoalcohols **2**, **4**, **6**, and **8** was initially attempted through reaction of epoxides **12** or **13** with the appropriate nucleophile. The preparation of the requisite epoxides was carried out according to the synthetic sequence outlined in Scheme 2.

1-Phenylcyclohexene **16** was obtained according to described methods (2). Similarly, 2-bromo-1,4-dimethoxybenzene **15** (3) was converted into the Grignard reagent which, on condensation with cyclohexanone followed by acid dehydration, afforded 1-(2,5-dimethoxyphenyl)cyclohexene **17**. According to the literature (4), direct epoxidation of **16** with peroxybenzoic acid leads to 1-phenylcyclohexene oxide **12**. However, rearrangement products are also obtained due to the high sensitivity of aryloxiranes, such as **12**, towards acids. In order to circumvent this problem, we attempted the epoxidation reaction of **16** with *m*-chloroperbenzoic acid (MCPBA) in a two-phase system of dichloromethane and 0.5 *M* aqueous sodium bicarbonate, a process which has been successfully applied to the synthesis of acid-sensitive epoxides (5). Epoxide **12** could be obtained by this procedure but was contaminated with variable amounts of *cis*-1-phenyl-1,2-cyclohexanediol **18**. This compound was identified on the basis of its ir (4) and nmr data (6); its formation, as well as the observed stereochemistry (7), can be explained by considering the oxirane ring opening by water, catalysed by protons from the MCPBA.

The use of a complex of MCPBA and fluoride ions in di-

SCHEME 2

chloromethane has recently been described for the synthesis of acid-sensitive epoxides, such as methylstyrene oxide (8). Application of this procedure to olefins **16** and **17** afforded the desired epoxides **12** and **13** in high purity and quantitative yield. Spectroscopic data of compound **12** were in agreement with those described in the literature (4). The nmr spectrum of 1-(2,5-dimethoxyphenyl)cyclohexene oxide **13** shows a multiplet at δ 2.76 due to the cyclohexane C(2)-H proton as the most characteristic signal. Epoxide **12** was also obtained from **16** in a two-step procedure via an intermediate bromohydrin which, upon treatment with excess sodium carbonate, afforded the desired epoxide in high yield. This method has been described for the preparation of sensitive epoxides, such as 2-vinylpyridine oxide (9).

trans-2-Amino-1-phenylcyclohexanol **2** and *trans*-2-amino-1-(2,5-dimethoxyphenyl)cyclohexanol **6** were obtained by reaction of the corresponding epoxides with sodium azide in *N*,*N*-dimethylformamide – water followed by reduction of the intermediate azidoalcohols with lithium aluminum hydride (Scheme 3). This procedure has been used for the synthesis of aminoalcohols related to ours (1*a*).

Reduction of the mixture of azides obtained from **12** with lithium aluminum hydride in ether afforded a mixture of two regioisomeric *trans*-aminoalcohols which were separated by column chromatography and identified as **2** and *trans*-2-amino-2-phenylcyclohexanol **23** (7:3 ratio). Similarly, *trans*-aminoalcohol **6** and *trans*-2-amino-2-(2,5-dimethoxyphenyl)cyclohexanol **24** (6:4 ratio) resulted from the starting epoxide **13**. Identification and conformational assignment of compounds **2** and **6** was carried out by ^{1}H nmr (200 MHz) and ^{13}C nmr, and will be described in the corresponding section (see below). Aminoalcohols **23** and **24** were identified in a similar way. Thus, the ^{1}H nmr spectrum (60 MHz) of **23** shows a broad singlet at δ 3.6 due to the C(1)-H proton of the cyclohexane ring, while compound **24** also shows a similar signal at δ 4.2. Equatorial disposition of this proton in both **23** and **24** was confirmed by the $W_{\frac{1}{2}}$ value near 8 Hz observed for the corresponding signal. The ^{13}C nmr spectra of these compounds (Table 2) confirmed the presence of a CH—O group (a doublet at 74.5 and 71.6 ppm in **23** and **24**, respectively). From these results it can be inferred that reaction of azide anion with epoxides **12** and **13** leads to a regioisomeric mixture of *trans*-azidoalcohols as a result of the nucleophilic attack upon C(1) and C(2) positions of the starting epoxides. While a *trans*-stereochemistry is the expected result for oxirane ring opening in alkaline conditions, the regioselectivity of the process depends on the steric hindrance around the two carbons of the ring (10), as well as on the benzylic nature of the epoxides, which can favour the attack of the nucleophile upon the more hindered benzylic carbon atom (11). The results of the overall process are similar to those described for the direct opening of epoxide **12** with ammonium hydroxyde (12).

Treatment of epoxides **12** and **13** with excess isopropylamine in ethanol (Scheme 4) afforded in each case a single product

which was identified through its ^{1}H and ^{13}C nmr spectra as *trans*-2-isopropylamino-1-phenylcyclohexanol **4** and *trans*-2-isopropylamino-1-(2,5-dimethoxyphenyl)cyclohexanol **8**, respectively (see below).

No trace of the regioisomeric 2-aryl-2-isopropylaminocyclohexanols, resulting from the attack of the amine upon the benzylic carbon atom of the starting epoxides, was detected in these reactions. This result is in agreement with the bulkier nature of isopropylamine compared to the azide anion, which prevents the former from the attack upon the more hindered position of the oxirane ring.

In an attempt to obtain *trans*-aminoalcohol **2** by an unambiguous route, we started from *cis*-diol **18**, aiming to convert its monomesylate **25** into the *trans*-azidoalcohol **19** (Scheme 5). Thus *cis*-diol **18** was treated with methanesulfonyl chloride in pyridine to afford *cis*-2-hydroxy-2-phenylcyclohexanol methanesulfonate **25**, whose ^{1}H nmr spectrum showed as characteristic signals an apparent triplet at δ 4.8 ($W_{\frac{1}{2}}$ = 18 Hz) due to the axial C(1)-H proton, as well as a singlet at δ 2.1 due to the methyl group.

Treatment of mesylate **25** with sodium azide in *N,N*-dimethylformamide – water failed to afford azidoalcohol **19**, and a mixture of nitrogen-free products was obtained instead. From this mixture, 2-phenylcyclohexanone and phenyl cyclopentyl ketone were isolated and identified by physical (12) and spectroscopic methods. These ketones are also formed when mesylate **25** is treated under the same conditions but in the absence of sodium azide, so they can result from rearrangement of the intermediate carbocation generated by loss of the mesyloxy group. S_N2 displacement of the mesyloxy group by the azide anion requires a high energy conformation in which the bulkiest groups must be axial.

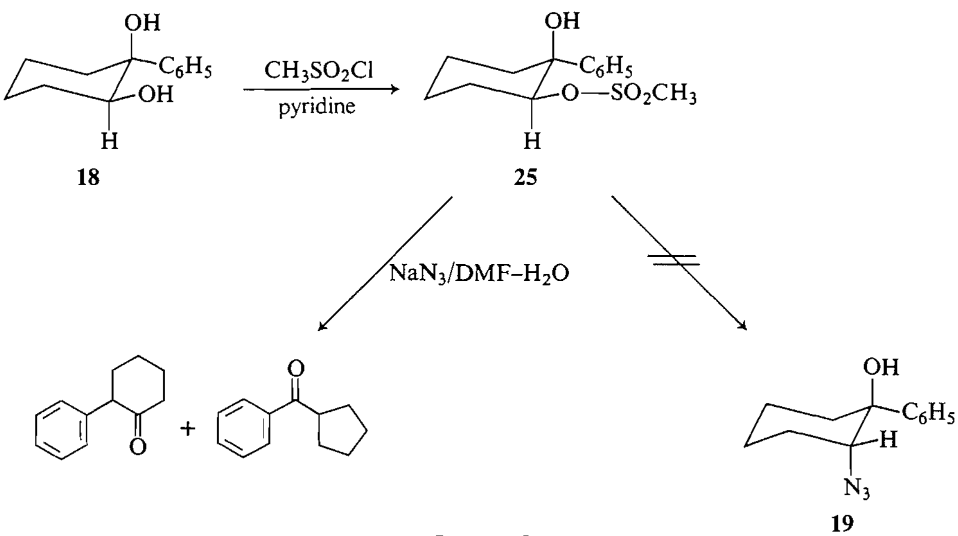
Synthesis of cis-*aminoalcohols*

Condensation of organometallic compounds with suitably substituted 2-aminoketones is a general synthetic method for *cis*-aminoalcohols related to ours (13). The stereochemistry of the resulting products can be rationalized according to Cherest and Felkin (14) as well as by application of the Cram–Kopecky model (15). Thus, synthesis of *cis*-2-amino-1-phenylcyclohexanol **1** is described in the literature (12) by condensation of 2-aminocyclohexanone hydrobromide **26** with phenylmagnesium bromide (5 equivalents) in ether at reflux temperature. According to this method, we have been able to obtain *cis*-aminoalcohol **1** in substantially improved yield (64% vs. 39%). However, a small amount of *trans*-isomer **2** (ratio **1**/**2** above 9:1 based on nmr) was also obtained. This approach was also useful for the synthesis of *cis*-2-amino-1-(2,5-dimethoxyphenyl)cyclohexanol **5**, not described in the literature. In this case, the Grignard reagent from 2-bromo-1,4-dimethoxybenzene gave poor yields of **5**, so we carried out the reaction with 2,5-dimethoxyphenyllithium **27**, more reactive towards carbonyl groups than the alternative organomagnesium reagent. By this procedure, *cis*-aminoalcohol **5** was obtained in moderate yield (38%), together with small amounts of the *trans*-isomer **6** and a considerable amount of 1,4-dimethoxybenzene, arising in part from an acid–base reaction between the organometallic reagent and the NH and (or) the α-CH protons of hydrobromide **26**.

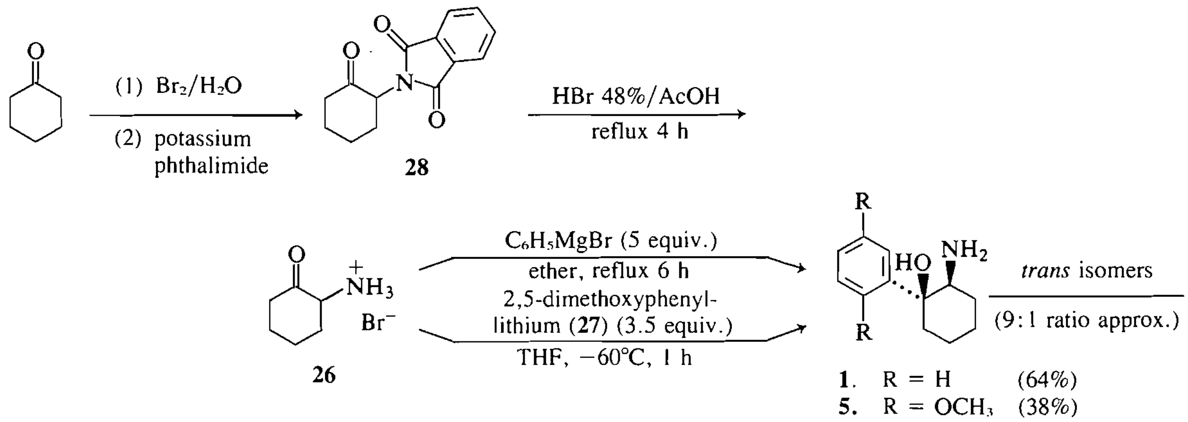
Compounds **1** and **5** were purified by column chromatography and crystallization; structural and conformational assignments were carried out by nmr spectroscopy, as described below.

Synthesis of 2-aminocyclohexanone hydrobromide **26** was effected through a combination of described procedures (12, 16). The whole synthetic pathway leading to *cis*-aminoalcohols **1** and **5** is depicted in Scheme 6.

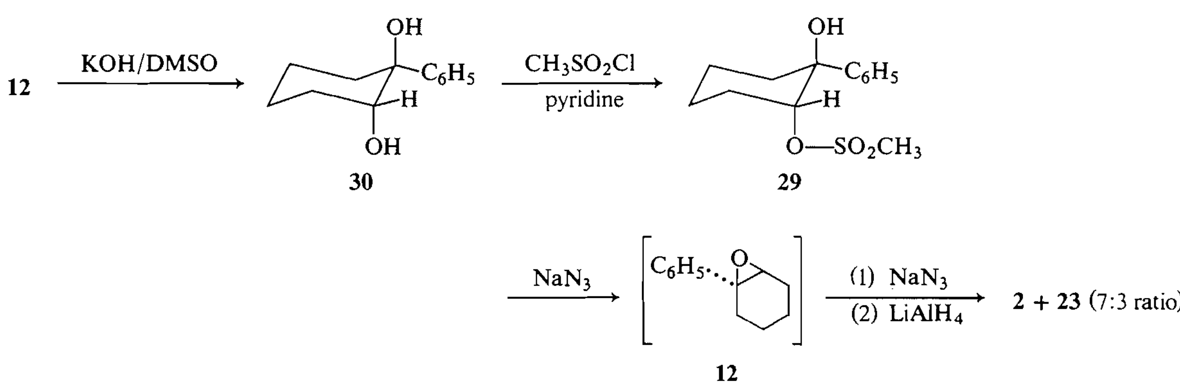
Aiming to obtain *cis*-aminoalcohols through an unambiguous route, we tested an alternative procedure in which the key step was the S_N2 displacement of the mesyloxy group of **29** with sodium azide. Subsequent reduction of the resulting azidoalcohol should lead to the desired *cis*-aminoalcohol **1**. This two-step sequence has been successfully applied to the transformation of *cis*-2-phenylcyclohexyl tosylate into *trans*-2-phenylcyclohexylamine with 100% inversion of configuration (13). *trans*-2-Hydroxy-2-phenylcyclohexyl methanesulfonate



SCHEME 5



SCHEME 6



SCHEME 7

29 was obtained in good yield from *trans*-1-phenyl-1,2-cyclohexanediol **30**, synthesized from epoxide **12** according to a described procedure (17). After azide treatment of **29** and lithium aluminum hydride reduction, a 7:3 mixture of *trans*-aminoalcohol **2** and its regioisomer **23** was isolated, and no *cis* isomers were found in the reaction mixture. We have interpreted this result as a consequence of the formation of epoxide **12** through intramolecular displacement of mesyloxy group by the C(1)-hydroxyl function (Scheme 7). Epoxide **12** would then react with the azide anion in the way we have previously stated (Scheme 3). Internal displacement of the mesyloxy group is a favoured process if we take into account the *trans*-diaxial disposition of the reacting groups in the most stable conformation.

cis-2-Isopropylamino-1-phenylcyclohexanol **3** and *cis*-1-(2,5-dimethoxyphenyl)-2-isopropylaminocyclohexanol **7** were synthesized from *cis*-aminoalcohols **1** and **5**, respectively, by condensation with excess acetone in refluxing benzene and sodium borohydride reduction of the intermediate imines (Scheme 8). Their structural and conformational assignment is described in the next section.

†A lack of data means that C(3)H_a and C(6)H_a protons appear at $\delta < 1.9$, unresolved from the rest of the cyclohexane protons. A δ interval is given when C(3)H_a and C(6)H_a give rise to a single complex signal.

Conformation of aminoalcohols 1−8

As it has been stated in the introductory part of this work, aminoalcohols **1**−**8** can be considered as semirigid analogues of the open-chain drugs ephedrine **9**, methoxamine **10**, and isopropylmethoxamine **11**. Since these cyclic analogues can adopt two chair conformations (designed as aryl-equatorial and aryl-axial) it is essential from a pharmacological standpoint to determine their preferred conformation in solution, especially in the protonated form. The only reported spectroscopic data referring to molecules related to ours are the ^1H nmr spectra (60 MHz) of *cis*- and *trans*-diols **18** and **30** (6).

Although the stereochemistry of compounds **18** and **30** had previously been confirmed by chemical methods (4), our findings in relation to the reactivity of their corresponding monomesylates **25** and **29** with sodium azide in *N,N*-dimethylformamide − water are also in agreement with a *cis* stereochemistry for **18** and a *trans* one for **30**. Accordingly, we have considered these diols as suitable model compounds both for the configurational and conformational study of aminoalcohols **1**−**8**.

Configurational assignments of aminoalcohols **1**−**8** have been carried out by comparison of their C(2)-H coupling constants and (or) $W_{\frac{1}{2}}$ values with those of the corresponding reference diols **18** and **30** (see Table 1), in which the phenyl-equatorial conformation is the preferred one for both of them despite the fact that it prevents *trans*-diol **30** from the achievement of an intramolecular hydrogen bond (6). Moreover, Δδ (δ *cis* − δ *trans*) for the C(2)-H proton in each pair of molecules confirms the given assignment. Thus, contrary to the expected for cyclohexanol systems, in **1**−**8**, **18**, and **30** C(2)-H equatorial protons usually appear at higher fields than C(2)-H axial ones. This has been explained for reference diols **18** and **30** as being a consequence of a variation in the rotameric equilibrium of the phenyl ring due to the presence of the vicinal hydroxyl group (6). In our case, the presence of an amino or isopropylamino group upon the C(2) position seems to act in the same way (see Table 1).

The ^1H nmr spectra of *cis*-aminoalcohols **1**, **3**, **5**, and **7** (Table 1) indicate in all cases an axial C(2)-H proton disposition with $W_{\frac{1}{2}}$ values similar to those described for *cis*-diol **18**. In the 200-MHz spectrum of **18**, we were able to determine coupling constant values of 10.7 Hz (J_{aa}) and 4.7 Hz (J_{ae}) for the C(2)-H proton, which are in agreement with an axial disposition. *cis*-Aminoalcohols **1**, **3**, **5**, and **7** all showed coupling constants of the same range (J_{aa} between 10.0 and 11.5 Hz). In order to ascertain the conformation of these molecules in a protonated form (the expected situation at physiological pH), we have studied ^1H nmr spectra of the corresponding hydrochlorides in D_2O, recording the spectra at different temperatures, from 22 to 90°C. No variation of the coupling constants was observed within this range of temperatures. From the above results we can conclude that *cis*-aminoalcohols **1**, **3**, **5**,

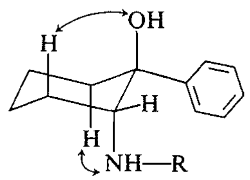
The superscripts * and # imply that the values may be interchanged.

and **7** adopt in solution, both in the base and hydrochloride forms, a chair conformation in which the aryl group is equatorial and, therefore, amino or isopropylamino groups are also equatorial. This conformation is favoured both for steric reasons and intramolecular NH/OH hydrogen bonding.

On the other hand, ^1H nmr spectra of *trans*-aminoalcohols **2**, **4**, **6**, and **8** (base and hydrochloride) show a signal due to the C(2)-H equatorial proton whose coupling constants and (or) $W_{\frac{1}{2}}$ values are again in agreement with those found for the reference compound *trans*-diol **30**. Thus in **2**, **6**, and **8** an apparent triplet with coupling constants between 3.0 and 4.0 Hz is observed (*trans*-diol **30**, 2.9–3.3 Hz). However, in compounds **4** and **4** · HCl, the coupling constant values are higher than those found in the above *trans*-aminoalcohols (Table 1), thus indicating an averaging of the C(2)-H equatorial and axial dispositions. Taking a J_{aa} value of 11.5 Hz (from the *cis* isomer **3** · HCl) and an approximate J_{ee} value of 3.6 Hz (from *trans* **2** · HCl), a ratio of 60:40 of phenyl-equatorial vs. phenyl-axial conformations can be calculated for compound **4** · HCl. Moreover, *trans*-aminoalcohols **2** and **4** show multiplets at about δ 2.4 and 2.0 due to the C(6)-H axial and C(3)-H axial protons, respectively. Comparable signals are also observed in the ^1H nmr spectra of the corresponding hydrochlorides as well as in that of the reference compound **30**. The assignment of these protons has been confirmed by spin-decoupling experiments and, in the case of **4**, through homonuclear chemical shift correlation $^1H-^1H$ that allowed the complete assignment of the chemical shifts of all the cyclohexane ring protons (see experimental section). The downfield chemical shift of C(6)-H and C(3)-H axial protons in the *trans* isomers (but not in the *cis* ones) can be explained by considering the anisotropic deshielding effect due to axial amino and hydroxyl groups, which confirms the preferred conformation of aminoalcohols **2** and **4**.

In the temperature range between 22 and 90°C, the ^1H nmr spectra of the hydrochlorides of aminoalcohols **2**, **4**, **6**, and **8** show a very small increment of the C(2)–H coupling constants (less than 0.5 Hz), not significant from a conformational standpoint.

Signals in the ^{13}C nmr spectra (Table 2) were assigned by their multiplicity (ADEPT program), comparison with model compounds (19), and also, in the case of **4** · HCl, through the heteronuclear chemical shift correlation $^{13}C/^1H$. *trans*-Aminoalcohols **2**, **4**, **6**, and **8**, as well as *trans*-diol **30**, showed



2. R = H
4. R = i-Pr

SCHEME 9

shielded C(4) and C(6) carbon atoms with respect to the corresponding C(6) and C(4) carbon atoms of *cis*-aminoalcohols **1**, **3**, **5**, and **7**, and *cis*-diol **18** (Δδ between 3.6 and 7.4 ppm). This shielding effect can be explained by considering a γ-*gauche* effect due to the axial C(2) amino (or C(2) hydroxyl) group in the *trans* isomers. On the other hand, Δδ (δ *cis* − δ *trans*) for the C(4) carbon atom in the pairs of stereoisomers **1**/**2**, **5**/**6**, and **7**/**8** is between 5.3 and 5.7 ppm, while in the pair **3**/**4** Δδ has a lower value of 3.7 ppm. This indicates again the existence in compound **4** of significant amounts of the phenyl-axial conformation, in which the C(4) position is not shielded.

Experimental

Melting points were determined in a capillary tube on a Büchi apparatus and are uncorrected. Infrared spectra were recorded on a Perkin–Elmer 577 spectrophotometer. Proton magnetic resonance were measured at 60 MHz with a Perkin–Elmer R 24B instrument or at 200 MHz with an FT Varian XL-200 spectrometer. Signal positions are reported in ppm downfield from tetramethylsilane (δ scale) as an internal standard, and $CDCl_3$ as a solvent, unless otherwise indicated; the number of protons, multiplicity, coupling constants, and proton assignments are indicated in parentheses. The ^{13}C nmr were measured at 50.3 MHz with a Varian XL-200 spectrometer, with internal tetramethylsilane as a reference. Multiplicity of the signals was determined by the ADEPT program (automatic distortionless enhancement by polarization transfer) (20). Homonuclear chemical shift correlation $^1H/^1H$ was determined by the HOMCOR program (21) and heteronuclear chemical shift correlation $^{13}C/^1H$ by the HETCOR program (22). Thin-layer chromatography and column chromatography were carried out on silica gel 60, Merck, 5–25 μm and 63–200 μm, respectively, and the spots were located with uv light or iodoplatinate reagent. All microdistillations were made on a Büchi GKR-50 Kugelrohr apparatus. Solutions in organic solvents were dried over anhydrous sodium sulfate and stripped of solvent with a Büchi rotary evaporator connected to a water aspirator. Microanalyses were performed by the Instituto de Química Bio-Orgánica, Barcelona.

*X stands for Cl or S according to the formula.
†Melting points described in the literature are indicated in brackets.
‡Crystallization, except for compound **17** (distillation).

was added to a solution of 8.8 g (0.0506 mol) of 1-phenylcyclohexene oxide **12** (4) in 350 mL of *N,N*-dimethylformamide. The reaction mixture was heated at 90°C for 14 h, then quenched with water and extracted with ether. The ethereal layers were washed thoroughly with water and saturated sodium chloride solution, dried, and evaporated to afford 9.4 g (85%) of a mixture of regioisomeric azidoalcohols **19** and **20** (ir neat: 2100 cm^{-1}, azide). A solution of the above mixture in 400 mL of dry ether was added dropwise with external cooling to a suspension of 6.8 g (0.181 mol) of lithium aluminum hydride in 400 mL of dry ether. After stirring for 2 h at room temperature, the reaction mixture was poured into 300 mL of 10 *N* sodium hydroxide solution. The ethereal layer was separated and the aqueous one was extracted with ether. The combined ethereal layers were extracted with 10% hydrochloric acid solution and the acidic aqueous phase was basified with 10 *N* sodium hydroxide solution and extracted with ether. The organic extracts were dried and evaporated to give 5.8 g of a mixture of aminoalcohols **2** and **23**, which were separated by column chromatography (eluent ether–diethylamine 97:3). Thus, 3.6 g (37%) of aminoalcohol **2** and 1.6 g (16.5%) of its regioisomer **23** were obtained (Table 3). Compound **2**, ^{1}H nmr (200 MHz) (see Table 1) δ: 1.30–2.00 (complex signal, 6H cyclohexane, 3H exchangeable), 2.08 (m, 1H, C(3)-H_a), 2.38 (m, 1H, C(6)-H_a), 3.06 (dd, 1H, C(2)-H), 7.1–7.7 (m, 5H, phenyl); ^{13}C nmr: Table 2. Compound **23**, ^{1}H nmr (60 MHz) δ: 1.2–1.9 (broad signal, 8H, cyclohexane and exchangeable), 3.6 (m, C(2)-H_e, $W_{\frac{1}{2}}$ = 8 Hz), 7.1–7.5 (m, 5H, phenyl); ^{13}C nmr: Table 2.

cis-2-Isopropylamino-1-phenylcyclohexanol (3)

A solution of 2.5 g (13.1 mmol) of *cis*-aminoalcohol **1** (12) and 3 g (51.6 mmol) of acetone in 40 mL of dry benzene was heated at reflux temperature in a Dean–Stark apparatus. After 5 h, the solvent was removed, the residue was dissolved in 40 mL of ethanol, and 0.75 g (20 mmol) of sodium borohydride was added portionwise with external cooling. After stirring for 3 h at room temperature, the reaction mixture was poured over ice-water, acidified with 2 *N* hydrochloric acid, and washed with ether. Basification of the aqueous layer with ammonium hydroxide and extraction with ether afforded, after evaporation of the dried extracts, 2.2 g (73%) of compound **3** (Table 3); ^{1}H nmr (200 MHz) (see Table 1) δ: 0.77 (d, *J* = 6.3 Hz, 3H, CH_3 isopropyl), 0.86 (d, *J* = 6.3 Hz, 3H, CH_3 isopropyl), 1.35–1.95 (complex signal, 8H cyclohexane and 2H exchangeable), 2.35 (m, 1H, CH isopropyl), 3.08 (dd, 1H, C(2)-H_a), 7.1–7.75 (m, 5H, phenyl); ^{13}C nmr: Table 2.

trans-2-Isopropylamino-1-phenylcyclohexanol (4)

A mixture of 4.2 g (24.2 mmol) of 1-phenylcyclohexene oxide **12** (4) and 8.6 g (146.3 mmol) of isopropylamine in 60 mL of absolute ethanol was heated at 120°C in a sealed tube for 15 h. After removing the solvent and the excess amine, the residue was made acidic with 2 *N* hydrochloric acid and washed with ether. The aqueous layer was basified and extracted with ether. The organic extracts were dried and evaporated to afford 4.0 g (72%) of compound **4** (Table 3); ^{1}H nmr (200 MHz, base) (see Table 1) δ: 0.72 (d, *J* = 6.2 Hz, 3H, CH_3), 0.88 (d, *J* = 6.2 Hz, 3H, CH_3), 1.45–1.67 (complex signal, 6H, cyclohexane), 2.01 (m, 1H, C(3)-H_a), 2.30–2.50 (m, 2H, CH isopropyl and C(6)-H_a), 2.82 (dd, 1H, C(2)-H_e), 7.14–7.62 (m, 5H, phenyl); homonuclear chemical shift correlation ^{1}H/^{1}H, cyclohexane protons, hydrochloride (D_2O) δ: 1.10 (CH_3), 1.19 (CH_3), 1.63 (C(4)-H_a and C(4)-H_e), 1.80 (C(5)-H_a and C(5)-H_e), 1.87 (C(3)-H_e), 1.93 (C(6)-H_e), 2.19 (C(3)-H_a), 2.35 (C(6)-H_a), 2.98 (CH isopropyl), 3.48 (C(2)-H_e); ^{13}C nmr: Table 2.

cis-2-Amino-1-(2,5-dimethoxyphenyl)cyclohexanol (5)

A solution of 6.7 g (30.9 mmol) of 2-bromo-1,4-dimethoxybenzene **15** (3) in 160 mL of dry tetrahydrofuran in a flask equipped with magnetic stirrer, gas inlet, and thermometer was treated at −70°C with 24 mL of 1.3 *N* butyllithium (31.2 mmol) in hexane. After 15 min, 1.5 g (7.7 mmol) of 2-aminocyclohexanone hydrobromide **26** (12) was added portionwise. After stirring at −60°C for 1.5 h, the mixture was poured into ice-water, acidified with 2 *N* hydrochloric acid, and extracted with ether. The organic layers were dried and evaporated to give 4.1 g of 1,4-dimethoxybenzene. The aqueous layer was made basic with concentrated ammonium hydroxide and extracted with ether to afford, after evaporation of the dried extracts, 0.75 g (38%) of *cis*-aminoalcohol **5** (Table 3); ^{1}H nmr (200 MHz) (see Table 1) δ: 1.20–2.16 (complex signal, 8H cyclohexane and 3H exchangeable), 3.47 (1H, C(2)-H_a), 3.66 (s, 6H, OCH_3), 6.54–6.76 (m, 3H, aromatic); ^{13}C nmr: Table 2.

trans-2-Amino-1-(2,5-dimethoxyphenyl)cyclohexanol (6)

A solution of 7.8 g (120 mmol) of sodium azide in 20 mL of water was added to a solution of 4.0 g (17.1 mmol) of epoxide **13** in 130 mL of *N,N*-dimethylformamide. The reaction mixture was heated at reflux temperature for 48 h and then quenched with water. Similar work-up to that described for the synthesis of **2** afforded 3.7 g (78%) of a mixture of azidoalcohols **21** and **22** (ir neat: 2100 cm^{-1}, azide). A solution of the above mixture in 150 mL of dry ether was treated with 2.0 g (53.1 mmol) of lithium aluminum hydride, under the same experimental conditions described for **2**, to afford 2.3 g of a mixture of *trans*-aminoalcohols **6** and **24**, which were separated by column chromatography. On elution with ether–diethylamine (98:2), 1.2 g (36%) of **6** was obtained (Table 3); ^{1}H nmr (200 MHz) (see Table 1) δ : 1.32–2.34 (complex signal, 8H cyclohexane and 3H exchangeable), 3.47 (1H, C(2)-H$_e$), 3.72 (s, 3H, OCH_3), 3.81 (s, 3H, OCH_3), 6.64–6.92 (m, 3H, aromatic); ^{13}C nmr: Table 2. On elution with ether–diethylamine (96:4), 1.02 g (30%) of **24** were obtained (Table 3); ^{1}H nmr (60 MHz) δ : 1.1–2.1 (complex signal, 8H cyclohexane and 3H exchangeable), 3.60 (s, 3H, OCH_3), 3.70 (s, 3H, OCH_3), 4.2 (br s, 1H, C(2)-H$_e$, $W_{\frac{1}{2}}$ = 8 Hz), 6.6 (m, 2H, aromatic), 6.8 (m, 1H, aromatic); ^{13}C nmr: Table 2.

cis-1-(2,5-Dimethoxyphenyl)-2-isopropylaminocyclohexanol (7)

By an identical procedure to that described for aminoalcohol **3**, 0.62 g (2.47 mmol) of aminoalcohol **5** afforded 0.51 g (70%) of compound **7** (Table 3); ^{1}H nmr (200 MHz) (see Table 1) δ : 0.74 (d, J = 6.3 Hz, 3H, CH_3 isopropyl), 0.86 (d, J = 6.3 Hz, 3H, CH_3 isopropyl), 1.28–1.89 (complex signal, 8H cyclohexane), 2.08 (m, 1H, CH isopropyl), 3.66 (1 H, C(2)-H$_a$), 3.79 (s, 3H, OCH_3), 3.81 (s, 3H, OCH_3), 6.76 (m, 2H, aromatic), 7.38 (m, 1H, aromatic); ^{13}C nmr: Table 2.

trans-1-(2,5-Dimethoxyphenyl)-2-isopropylaminocyclohexanol (8)

A solution of 1.5 g (6.4 mmol) of epoxide **13** and 6.0 g (100 mmol) of isopropylamine in 60 mL of absolute ethanol was heated in a sealed tube at 150°C for 72 h. Similar work-up to that described for compound **4** afforded 1.06 g (56%) of **8** (Table 3); ^{1}H nmr (200 MHz) (see Table 1) δ : 0.61 (d, J = 6.2 Hz, 3H, CH_3 isopropyl), 0.86 (d, J = 6.2 Hz, 3H, CH_3 isopropyl), 1.38–2.38 (complex signal, 8H cyclohexane and 2H exchangeable), 3.20 (1H, C(2)-H$_e$), 3.76 (s, 3H, OCH_3), 3.86 (s, 3H, OCH_3), 6.68–6.90 (m, 3H, aromatic); ^{13}C nmr: Table 2.

1-Phenylcyclohexene oxide (12)

Method A

To a stirred suspension of 1.32 g (31.4 mmol) of sodium fluoride in 200 mL of dry dichloromethane, 3.2 g (equivalent to 15.8 mmol) of 85% *m*-chloroperbenzoic acid was added. After 30 min, 1 g (6.32 mmol) of 1-phenylcyclohexene **16** (2) was added at once and the stirring was continued for 2.5 h at room temperature. The solids were removed by filtration and washed thoroughly with dichloromethane. The combined filtrates were washed with diluted sodium hydroxide solution and water and dried. Evaporation of the solvent afforded 1.07 g (97%) of epoxide **12**, which was used without further purification; ir (NaCl) (4): 1070 (C—O) cm^{-1}; ^{1}H nmr (60 MHz, CCl_4) δ : 1.1–2.3 (complex signal, 8H cyclohexane), 2.80 (m, 1H, C(2)-H), 6.9–7.3 (m, 5H, phenyl).

Method B

A solution of 10 g (63.2 mmol) of 1-phenylcyclohexene **16** (2) and 3.4 mL of acetic acid in 170 mL of dioxane–water (3:7) was treated portionwise with 12 g (67.0 mmol) of *N*-bromosuccinimide. The mixture was stirred for 1 h at room temperature, 13.3 g (125.6 mmol) of anhydrous sodium carbonate was added, and, after 12 h, the reaction mixture was poured into 300 mL of water and extracted with ether. The combined organic layers were dried and evaporated to afford 9.7 g (90%) of epoxide **12**.

1-(2,5-Dimethoxyphenyl)cyclohexene oxide (13)

To a stirred suspension of 3.0 g (13.7 mmol) of sodium fluoride in 150 mL of dry dichloromethane, 7.5 g (equivalent to 37 mmol) of 85% *m*-chloroperbenzoic acid was added. After stirring for 30 min at room temperature, the mixture was cooled to −10°C (acetone–CO_2 bath) and 3.0 g (13.7 mmol) of **17** was added in one portion. Stirring was continued at −5°C for 30 min and the reaction mixture was filtered. Solid materials were washed with small portions of dichloromethane and the combined filtrates were washed with 1 *N* sodium hydroxide solution and water and dried. Evaporation of the solvent afforded 2.8 g (87%) of epoxide **13** (Table 3); ir ($CHCl_3$): 1050 (C—O) cm^{-1}; ^{1}H nmr (60 MHz, CCl_4) δ : 1.1–2.1 (m, 8H, cyclohexane), 2.76 (m, 1H, C(2)-H), 3.56 (s, 3H, OCH_3), 3.63 (s, 3H, OCH_3), 6.43 (m, 2H, aromatic), 6.61 (m, 1H, aromatic).

1-(2,5-Dimethoxyphenyl)cyclohexene (17)

Magnesium turnings (2.75 g, 110 mmol) were placed in a three-neck flask fitted with a mechanical stirrer, a condenser, and a dropping funnel, and the entire system was flame dried. A few milliliters of a solution of bromide **15** (3) (23.5 g, 110 mmol) in 140 mL of dry ether were added to the turnings and the reaction was initiated with a small iodine crystal. The remaining solution was added dropwise over a 1-h period and the stirring was continued under reflux temperature for an additional 2 h. Cyclohexanone (10.7 g, 110 mmol) in 20 mL of dry ether was added under nitrogen to the cooled reaction mixture and the stirring was continued overnight. The reaction mixture was poured into 300 mL of saturated ammonium chloride solution, and the ethereal layer was separated, washed with water, and dried. Removal of the solvent afforded 26 g of a material which was treated with 50 mL of a freshly prepared mixture of sulfuric acid – acetic acid (1:4 by volume). The resulting mixture was swirled for 1 min and poured into ether–water (250 mL and 350 mL, respectively). The ethereal layer was washed with water and 1 *N* sodium hydroxide solution, dried, and evaporated. After distillation of the crude alkene, 9.8 g (41%) of compound **17** was obtained (Table 3); ^{1}H nmr (60 MHz, CCl_4) δ : 1.6 (m, 4H, C(4)H_2 and C(5)H_2), 2.2 (m, 4H, C(3)H_2 and C(6)H_2), 3.6 (s, 6H, OCH_3), 5.40 (m, 1H, =CH), 6.40 (s, 3H, aromatic).

cis-2-Hydroxy-2-phenylcyclohexyl methanesulfonate (25)

A solution of 4.1 g (35.7 mmol) of methanesulfonyl chloride in 25 mL of dry pyridine was added dropwise to an externally ice-cooled solution of *cis*-diol **18** (4) in 200 mL of dry pyridine. The mixture was stirred at room temperature for 24 h, poured into water, and extracted with benzene. The organic layer was washed thoroughly with 2 *N* hydrochloric acid and water, dried, and evaporated to afford 6.8 g (97%) of monomesylate **25** (Table 3); ir (KBr): 3500–3100 (OH), 1340 (SO_2) cm^{-1}; ^{1}H nmr (60 MHz) δ : 1.4–2.5 (complex signal, 8H cyclohexane and 1H exchangeable), 2.1 (s, 3H, CH_3—SO_2—), 4.8 (dd, 1H, C(1)-H$_a$, $W_{\frac{1}{2}}$ = 18 Hz), 7.1–7.6 (m, 5H, phenyl).

2-Phthalimidocyclohexanone (28)

To 24 g (129.5 mmol) of potassium phthalimide in 135 mL of *N,N*-dimethylformamide, 20 g (113 mmol) of 2-bromocyclohexanone (16) was added. After stirring at 100°C for 6 h, the mixture was poured into water and extracted with chloroform. The organic layer was washed with 2 *N* sodium hydroxide, water, and dried. Evaporation of the solvent afforded, after crystallization, 13.3 g (49%) of **28** (Table 3); ^{1}H nmr (60 MHz) δ : 1.4–2.8 (complex signal, 8H, cyclohexane), 4.6 (dd, 1H, C(2)-H), 7.2–7.6 (m, 4H, aromatic).

trans-2-Hydroxy-2-phenylcyclohexyl methanesulfonate (29)

Identical procedure to that described for mesylate **25** afforded **29** (94%, Table 3) from *trans*-diol **30** (17); ir (KBr): 3510 (OH), 1330 (SO_2) cm^{-1}; ^{1}H nmr (60 MHz, DMSO-d_6) δ : 1.2–2.4 (complex signal, 8H, cyclohexane), 2.1 (s, 3H, CH_3—SO_2—), 4.3 (br s, 1H, C(1)H$_e$, $W_{\frac{1}{2}}$ = 7 Hz), 5.2 (s, 1H, OH), 6.9–7.6 (m, 5H, phenyl).

Selenium isotopic fractionation during SeO_3^{2-} reduction to Se^0 and H_2Se

K. RASHID[1] AND H. R. KROUSE
Department of Physics, The University of Calgary, Calgary, Alta., Canada T2N 1N4

Received March 5, 1984[2]

K. RASHID and H. R. KROUSE. Can. J. Chem. **63**, 3195 (1985).

During reduction of SeO_3^{2-} to Se^0 by $NH_2OH.HCl$, the selenium isotope selectivity fits a two step model with the second step two orders of magnitude faster than the first. The ratios of the isotopic rate constants, k_{76}/k_{82}, are 1.007 and 1.020 for the first and second steps, respectively. The corresponding k_{76}/k_{80} values are 1.004_6 and 1.013_3. During the reduction of SeO_3^{2-} to H_2Se by a $H_3PO_2-HI-HCl$ mixture, the H_2Se was initially enriched but sporadically became depleted in the heavier isotopes as the reaction progressed. This is attributed to the formation of Se^0 as an intermediate and the subsequent reaction of its surface layers to produce H_2Se.

For all data, the relation $\delta^{82}Se = (1.5_4 \pm 0.02)\delta^{80}Se$ was observed as predicted theoretically.

K. RASHID et H. R. KROUSE. Can. J. Chem. **63**, 3195 (1985).

Lors de la réduction du SeO_3^{2-}, sous l'influence du $NH_2OH.HCl$, la sélectivité isotopique du sélénium correspond à un modèle en deux étapes où la vitesse de la deuxième étape est deux ordres de grandeur supérieur à celle de la première. Les rapports des constantes des vitesses isotopiques, k_{76}/k_{82}, sont respectivement de 1,007 et de 1,020 pour la première et la deuxième étape. Les valeurs correspondantes de k_{76}/k_{80} sont de $1{,}004_6$ et de $1{,}013_3$. Lors de la réduction du SeO_3^{2-} en H_2Se sous l'influence du mélange $H_3PO_2-HI-HCl$, le H_2Se s'enrichit au début mais il s'appauvrit sporadiquement en isotopes plus lourds au cours de la réaction. On attribué ceci à la formation intermédiaire de Se^0 et à la réaction subséquente de ses couches de surface pour conduire au H_2Se.

Conformément aux hypothèses, on observe pour toutes les données la relation $\delta^{82}Se = (1{,}5_4 \pm 0{,}02)\delta^{80}Se$.

[Traduit par le journal]

1. Introduction

Relatively little has been published on selenium isotope fractionation in contrast to the many reports on the isotopes of sulfur in the same chemical group.

Krouse and Thode (1) calculated the ^{76}Se to ^{82}Se partition function ratios for several selenium compounds and predicted fractionations of up to 6% in $^{76}Se - ^{82}Se$ equilibrium exchange processes. They also studied the fractionation of selenium isotopes during the reduction of selenite to elemental selenium by hydroxylamine hydrochloride. Assuming that the rate was controlled by one step in the competitive reactions,

$$^{76}SeO_3^{2-} \xrightarrow{k_{76}} {}^{76}Se^0$$

$$^{82}SeO_3^{2-} \xrightarrow{k_{82}} {}^{82}Se^0$$

they found the ratio of the isotopic rate constants k_{76}/k_{82} to be 1.015 at room temperature. The observed fractionation was attributed to the kinetic isotope effect in the initial Se—O bond rupture.

Rees and Thode (2) conducted several experiments on selenium isotope selectivity in the reduction of selenite and selenate by $C_6H_8O_6$. They found the rate constant for the $^{76}SeO_3^{2-}$ species to be about 1.019 times that for the $^{82}SeO_3^{2-}$ species. Their data were consistent with the activated complex having an isotopic partition function ratio similar to the starting SeO_3^{2-}, but missing one frequency term. One component of the doubly-degenerate E type asymmetric stretching vibration ν_3 ($\sim$730 cm^{-1}) was omitted since it corresponds to one oxygen atom moving away from the rest of the molecule.

Webster (3) studied SeO_3^{2-} reduction by $NH_2OH.HCl$ and found k_{74}/k_{80} to be 1.010. This ratio is nearly equivalent to k_{76}/k_{82} since the mass difference is 6 in each case.

Thus in the literature, k_{76}/k_{82} values or their equivalent, range from 1.010 to 1.019 for SeO_3^{2-} reduction to Se^0 (i.e., a factor of 20 greater than the mass spectrometry errors). This could indicate that the mechanism of reduction of SeO_3^{2-} by ascorbic acid differs markedly from that by $NH_2OH.HCl$. However, the best fitting models considered only Se and O atoms in the reduced mass term and ignored the reducing agent. Further, the differences found in $NH_2OH.HCl$ experiments by different laboratories require explanation.

Because of these apparent discrepancies and the potential for SeO_3^{2-} reduction to effect isotope fractionation in the terrestrial selenium cycle, the reaction was re-examined isotopically. Since one source of disagreement among data from different laboratories might be contaminants in the prepared samples, three isotopes ^{76}Se, ^{80}Se, and ^{82}Se were employed to check the consistency of the measured isotope effects and to verify their expected mass dependence.

In addition to the conversion of SeO_3^{2-} to Se, reduction to H_2Se was investigated.

2. Theory

For a one step first order conversion, the ratio of the isotopic rate constants can be calculated from the isotopic composition of the initial reactant and accumulated product by the relation;

$$[1] \quad \frac{k_1}{k_2} = \frac{\ln (1 - f)\dfrac{1 + A_{0_2}/A_{0_1}}{1 + X_2/X_1}}{\ln (1 - rf)\dfrac{1 + A_{0_2}/A_{0_1}}{1 + X_2/X_1}}$$

where f is the fraction of reactant converted

$$r = \frac{X_2/X_1}{A_{0_2}/A_{0_1}}$$

subscripts 1 and 2 refer to the lighter and heavier isotopic species, respectively; and X and A_0 refer to accumulated product and initial reactant, respectively.

---

[1]Present address: Department of Physics, College of Science and Technology, Abu-Dis, Jerusalem.

[2]Revision received April 10, 1985.

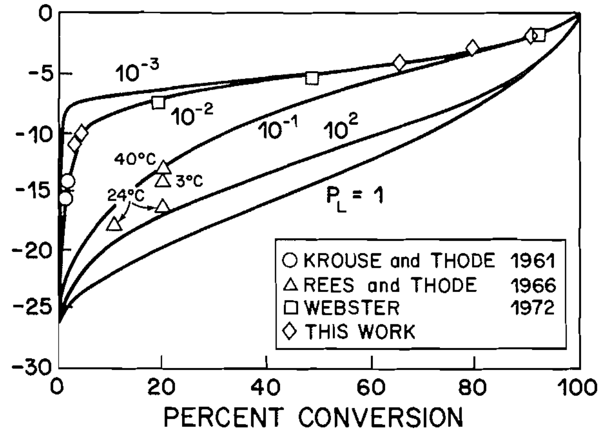

FIG. 1. Data from reduction by $NH_2OH.HCl$ (Krouse and Thode (1); Webster (3); this work), fit the plot with $P_L = 10^{-2}$, $K_1 = 1.007$, and $K_2 = 1.020$. Data from ascorbic acid reduction (Rees and Thode (2)) could fit a plot with the same K_1 and K_2 but larger P_L.

Two consecutive isotopically competitive first order irreversible reaction steps may be written:

$$[2] \quad \begin{array}{l} A_A^1 \xrightarrow{k_1} A_B^1 \xrightarrow{k_1'} A_C^1 \\ A_A^2 \xrightarrow{k_2} A_B^2 \xrightarrow{k_2'} A_C^2 \end{array}$$

where subscripts A, B, and C signify reactant, intermediate, and product, respectively. For this case, Monster (4) derived the following relation between the overall isotopic effect and the extent of reaction:

$$[3] \quad R = \left(\frac{A_C^2/A_C^1}{A_{A_0}^2/A_{A_0}^1}\right) = \frac{1 - \dfrac{K_1}{K_1 - K_2P_L}E^{1/K_1} + \dfrac{K_2P_L}{K_1 - K_2P_L}E^{1/K_2P_L}}{1 - \dfrac{E}{1 - P_L} + \dfrac{P_L}{1 - P_L}E^{1/P_L}}$$

where R = fractionation factor between the final product and the initial reactant. $(R - 1) \times 10^{-3}$ is approximately the δ value in ‰ (per mil) of the final product with respect to the initial reactant; $K_1 = k_1/k_2$ = ratio of the isotopic rate constants for the first reaction step; $K_2 = k_1'/k_2'$ = ratio of the isotopic rate constants for the second reaction step; $P_L = k_1/k_1'$ = ratio of the light isotopic rate constant for the first step over that of the second step; $E = e^{-T} = e^{-kt}$ defines the extent of the reaction.

The relation between E and the fraction of reaction f is

$$f = \frac{1 - P_L - E + P_L E^{1/P_L}}{1 - P_L}$$

A feature which emerges from Monster's derivation is that the isotopic fractionation depends on the ratios of rate constants and not their absolute values.

Figure 1 shows how the δ values of the final product behave as a function of percentage conversion. K_1 and K_2 have been chosen as 1.007 and 1.020, respectively. It is seen that isotopic effects sum for small extents of reaction. As the reaction proceeds, this summing is dependent upon the value of P_L. If $P_L = 1$, the summing effects are maximal with the δ value of the product behaving as if it were produced by a single step

TABLE 1. δ^{82}Se and δ^{80}Se values of components during a first-order one step process; $k_{76}/k_{82} = 1.018$, $k_{76}/k_{80} = 1.012$[a]

[a] $R = \delta^{82}\text{Se}/\delta^{80}\text{Se}$.

conversion with $k_1/k_2 = K_1K_2$. If $P_L \ll 1$, the δ value of the product quickly approaches the behaviour of a single step with a $k_1/k_2 = 1.007$. If $P_L \gg 1$, the δ value adjusts quickly to a behaviour consistent with a single step conversion with a $k_1/k_2 = 1.020$. In summary, the δ value of the product exhibits the summing behaviour for very small conversions but adjusts to the rate controlling step as the reaction proceeds dependent upon the ratio of the slower to faster rate constants.

It follows that if one step is much slower than the other, it dominates throughout most of the reaction and the k_1/k_2 of the faster step has little influence. For example, in Fig. 1, if $P_L = 10^{-3}$, then increasing K_2 to a higher value say 1.030 means that the initial product has a δ value of about 40‰, but for most of the reaction, the product still conforms to a $k_1/k_2 = 1.007$.

For three isotopes of masses M_1, M_2, and M_3 participating in a process with rate constants k_1, k_2, and k_3, respectively, C. E. Rees (private communication, 1978) developed a power series relationship. If $\left(\dfrac{(M_2 - M_1)}{M_1}\right)^2$ and higher terms are ignored, the following approximation arises:

$$[4] \quad \frac{(k_1/k_3) - 1}{(k_1/k_2) - 1} \approx \frac{M_3 - M_1}{M_2 - M_1}$$

If the rate constant does not depend solely on M, it may not be possible to ignore higher terms in the series. For selenium, if k_{76}, k_{80}, and k_{82} depend solely on the mass of ^{76}Se, ^{80}Se, and ^{82}Se, respectively, then

$$[5] \quad (k_{76}/k_{82}) - 1 = 1.5[(k_{76}/k_{80}) - 1]$$

In stable isotope research, it is customary to use δ values by virtue of the measurements process. For the current study, two δ scales are defined:

$$[6] \quad \delta^{80}\text{Se in ‰} = \left\{\frac{[^{80}\text{Se}/^{76}\text{Se}]_{\text{sample}}}{[^{80}\text{Se}/^{76}\text{Se}]_{\text{standard}}} - 1\right\} \times 1000$$

$$[7] \quad \delta^{82}\text{Se in ‰} = \left\{\frac{[^{82}\text{Se}/^{76}\text{Se}]_{\text{sample}}}{[^{82}\text{Se}/^{76}\text{Se}]_{\text{standard}}} - 1\right\} \times 1000$$

where ‰ (per mil) is parts per thousand.

^{80}Se/^{76}Se is the ratio of the number of ^{80}Se-to-^{76}Se isotopes in the sample or standard.

[a]$R^* = \delta^{82}Se/\delta^{76}Se$.

The standard was the initial selenite.

In Table 1, expression [1] has been used in combination with [6] and [7] to derive the δ values of remaining reactant and accumulated product in a one step first order conversion. k_{76}/k_{82} and k_{76}/k_{80} have been chosen as 1.018 and 1.012, thus meeting the condition of eq. [5]. The results show that $\delta^{82}Se$ is also equal to $1.5\delta^{80}Se$ for both the remaining reactant and accumulated product. Such a relationship was predicted in general terms by Rees.

3. Experimental

For studies of the reduction of Se_3^{2-} to Se^0, 0.5 g of Na_2SeO_3 were dissolved in 250 mL of distilled water, and reduced by adding predetermined amounts of $NH_2OH.HCl$ in solution at room temperature. After leaving over night, Se^0 was separated by centrifuging and washing with distilled water repeatedly and drying at room temperature for several hours. An excess of $NH_2OH.HCl$ solution was then added to the supernatant to reduce all the remaining SeO_3^{2-} and any intermediate forms in solution. This Se^0 was also centrifuged, washed, and dried.

When SeO_3^{2-} was reduced using reflux apparatus and the reducing mixture $HI - H_3PO_2 - HCl$ as described by Harrison and Thode (5), a dark red color was immediately evident in the solution, characteristic of elemental selenium. Purging with N_2 revealed that hydrogen selenide was also produced and could be trapped in a cadmium acetate solution. The H_2Se production rate was slow at room temperature and evolution continued for more than a week. Precipitated CdSe was removed every 24 h and converted to Ag_2Se by adding 0.1 N $AgNO_3$ solution.

The reduction mixture (50 mL) was also added to a single commercial selenium pellet and the evolved H_2Se treated as above.

Elemental Se and Ag_2Se were fluorinated to SeF_6 by reaction with F_2 for several hours in closed nickel reaction vessels at room temperature. The reaction vessel was then immersed in a liquid air bath which was subsequently replaced by a n-pentane slush bath (−130°C) to distill off excess F_2. For environmental purposes, the excess F_2 was passed over KBr at 200°C to form KF and Br_2. The Br_2 was trapped and bottled.

The stable isotope mass spectrometry was carried out on a 90°, 30.5 cm radius magnetic deflection instrument, built "in house". Ion currents of masses 171 ($^{76}Se^{19}F_5^+$), 175 ($^{80}Se^{19}F_5^+$), and 177 ($^{82}SeF_5^+$) were collected simultaneously. The outputs of each collector amplifier were fed to a Fluke 8300A digital voltmeter which had additional circuitry for measuring the ratio of any two voltages. The analyzer tube and ion source of the mass spectrometer were baked over-night at 200°C and kept at 100°C during analysis. Without baking, the resolution of the spectra tended to deteriorate within 20 min. The baking programme in combination with the use of ion pumps made it possible to maintain the background pressure below 1×10^{-9} mm Hg.

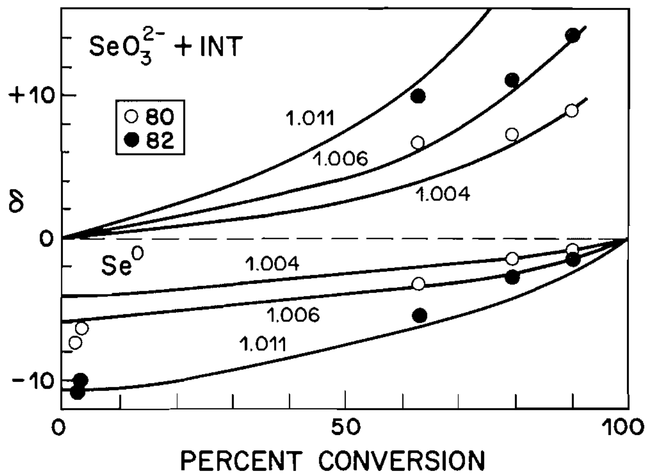

FIG. 2. $\delta^{82}Se$ and $\delta^{80}Se$ values for selenium isotope fractionation during reduction of SeO_3^{2-} by $NH_2OH.HCl$ compared to values predicted by a one step first order conversion using k_1/k_2 values of 1.004, 1.006, and 1.011. The lower curves are for the accumulated elemental selenium product while the upper curves correspond to unreacted SeO_3^{2-} plus intermediates.

4. Results

Chemical reduction of Se_3^{2-} to Se^0

$\delta^{82}Se$ and $\delta^{80}Se$ data for the reduction of SeO_3^{2-} to Se^0 using $NH_2OH.HCl$ are given in Table 2. For a given percentage reaction, k_{76}/k_{82} and k_{76}/k_{80} values are calculated from the δ values of both the accumulated product and the remaining reactant plus intermediates, using the single step approximation eq. [1]. The results from both calculations agreed to within the experimental error and hence only one entry is made in Table 2. There are no data for the remaining reactant plus possible intermediates at low conversions since the measured δ values would be smaller than the standard deviation of the measurements.

An obvious feature of Table 2 is that k_{76}/k_{82} and k_{76}/k_{80} decrease as the reaction progresses. These values represent averages for the reaction up to the percentage conversion noted. Since the k_{76}/k_{82} values are 1.011 in the initial steps but average 1.007 for all products formed up to 80% reaction, the instantaneous product formed near 80% conversion must have a k_{76}/k_{82} value considerably lower than 1.007. Alternatively, extrapolating the data back to smaller conversions gives values

TABLE 3. Selenium isotope fractionation during SeO_3^{2-} reduction to H_2Se

Trial number	Sample 1	Mass (mg) Ag_2Se	Mass (mg) Se	Conversion (%)	$\delta^{82}Se$	$\delta^{80}Se$

	2	5	2	19.0–26.0	+9.4	+6.0
	3	7	2	26.0–33.0	−1.1	−0.2
	4	22	6	33.0–51.0	−0.2	−0.1
	5	60	16	51.0–100.0	−1.2	−0.7

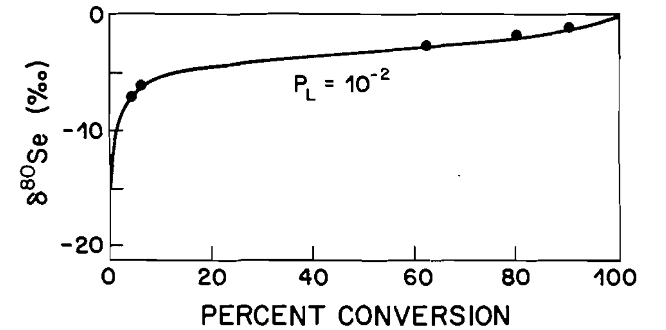

FIG. 3. $\delta^{80}Se$ data for SeO_3^{2-} reduction by $NH_2OH.HCl$ compared to a two step first order conversion with $K_1 = 1.0046$, $K_2 = 1.0133$, and $P_L = 0.01$. In comparison to Fig. 1, note that $(K_1 - 1) = 1.5(K_1' - 1)$ and $(K_2 - 1) = 1.5(K_2' - 1)$.

of k_{76}/k_{82} higher than 1.011. This inconsistency is further illustrated in Fig. 2. If one considers a k_{76}/k_{82} value of 1.006, the $\delta^{82}Se$ values at 80 and 90% reaction fall close to the curves for both the accumulated product and the remaining reactant. However, at small conversions, the $\delta^{82}Se$ values fall below the $k_{76}/k_{82} = 1.006$ curve by 5‰ or 10 times the measurement errors. Similarly, if k_{76}/k_{82} is chosen as 1.011, the data at small conversions and at 63% reaction fit well, but the data at 80 and 90% depart significantly from the curves. In the case of the remaining product curve, the departure at 90% conversion is about 20 times the measurement error. Therefore, a simple one step model is inadequate to describe the attending isotope fractionation. Accordingly, a two step model was investigated using eq. [3].

The inverse of eq. [3] has not been derived to date, i.e., one cannot obtain values for K_1, K_2, and P_L from R. Therefore, eq. [3] was programmed on an Apple II microcomputer to generate plots of δ values of product versus extent of reaction for selected values of K_1, K_2, and P_L. Experimental data were visually compared to these plots. There is considerable latitude in the choice of parameters which are consistent with the data. However, values of k_{76}/k_{82} of 1.007 and 1.020 for K_1 and K_2 and a P_L value of 10^2 give a reasonable fit (Fig. 1) which has chemical significance. 1.020 is the maximum k_{76}/k_{82} value reported for SeO_3^{2-} reduction (2) while 1.007 is the value frequently encountered during latter parts of the conversion (Table 2). It is also seen in Fig. 3 that the $\delta^{80}Se$ data fit a two-step model which is consistent with eq. [5].

Reduction of SeO_3^{2-} to H_2Se

$\delta^{82}Se$ and $\delta^{80}Se$ data for SeO_3^{2-} reduction to H_2Se by

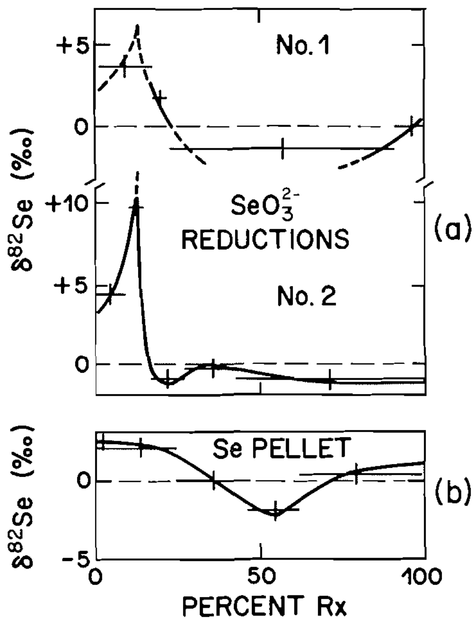

FIG. 4. (*a*) $\delta^{82}Se$ values for H_2Se evolved during reduction of SeO_3^{2-} by a $HCl-H_3PO_2-HI$ mixture at room temperature; (*b*) $\delta^{82}Se$ values for H_2Se evolved during reduction of a commercial pellet of elemental selenium at room temperature.

$HI-H_3PO_2-HCl$ are shown in Table 3, and in Fig. 4(*a*). These data differ from those for elemental selenium produced during selenite reduction. Whereas the initial Se^0 product is depleted in the heavier isotopes and its δ value increases as the reaction proceeds, the initially produced H_2Se is enriched in the heavier isotope with a tendency to become isotopically lighter in a sporadic fashion as the reaction proceeds. It is noted that in some partial runs, negative δ values ($\delta^{82}Se$ as low as −6.0‰) were obtained at earlier stages of the reaction but the usual tendency was that in Fig. 4.

Since elemental selenium precipitated during SeO_3^{2-} reduction prior to H_2Se formation, a separate experiment was conducted during which a single commercial selenium pellet was reduced by $HI-H_3PO_2-HCl$ to H_2Se. The isotopic variations were small (Table 4 and Fig. 4(*b*)).

The isotopic behaviour summarized in Table 4 and Fig. 4(*a*) is consistent with the observation that elemental selenium formation is significantly more rapid than the H_2Se generation. If the spherules of elemental selenium form and grow concentrically in the reaction medium, their centres will be depleted in the heavier isotopes, whereas the outer layers become iso-

TABLE 4. $\delta^{82}Se$ and $\delta^{80}Se$ for H_2Se evolved from one metallic selenium pellet by $HI-H_3PO_2-HCl$ reduction mixture at 100°C; original pellet mass, 54 mg

	Total 197	Total 53			

topically heavier with increased reduction of SeO_3^{2-}. If the production of H_2Se proceeds by peeling the Se^0 spherules layer by layer, the initially produced H_2Se is isotopically heavier. The lack of very positive $\delta^{82}Se$ values and the erratic behaviour of the isotopic release pattern possibly related to the different sizes of spherules and their different initiation times. A further complication which is difficult to demonstrate is that some H_2Se may have been produced in a parallel pathway which did not have Se^0 as an intermediate.

The small isotopic variations found with the pellet are beyond experimental uncertainties and possibly indicate isotopic partitioning between phases during manufacture. In this higher temperature process, one expects the isotopic composition of the pellet to be more uniform that that of spherules formed during the chemical reduction of SeO_3^{2-}.

5. Discussion

Selenium isotope fractionation during the chemical reduction of SeO_3^{2-} to Se^0 is more adequately described by a two step process than by the single step model which has been usually employed in similar investigations of kinetic isotope effects. The two step model derived from data of this report, is consistent with the data of Krouse and Thode (1). In addition, the $^{74}Se-^{80}Se$ data of Webster (3) which are nearly equivalent to the current $^{76}Se-^{82}Se$ data also fit the two step model (Fig. 1).

The question remains as to whether the current model is consistent with the data of Rees and Thode (2) using ascorbic acid as the reducing agent. Two points are relevant. At the same temperature (24°C), the k_{76}/k_{82} values at 10 and 20% reduction were found to be 1.020 and 1.019, respectively. Although the errors for these two determinations overlap, the trend is the same as in the current work. The second point is that different isotope selectivities have been noted in chemical reductions using different reducing agents. Whereas Harrison and Thode (5) obtained $k_{32}/k_{34} = 1.022$ for reduction of SO_4^{2-} by $HI-H_3PO_2-HCl$, Downes and Donnelly (6) obtained values as low as 1.015 using other reducing agents.

A consequence of the two-step model is that different overall isotopic fractionations result for the same K_1 and K_2 values if P_L is varied. Thus the data of Rees and Thode (2) at 24°C are consistent with the K_1 and K_2 values of the current experiments if a P_L value is chosen near 10^2 (Fig. 1). This interpretation means that the second step was more effective in rate-controlling in the reductions using $NH_2OH.HCl$. It also implies that the mass dependence of these two steps does not depend upon the reducing agent, but a particular reductant determines which step is more effective in controlling the overall rate. The relatively large variation with temperature for the $\delta^{82}Se$ values of product Se^0 (3°C, −14.6; 24°C, −16.9, −18.4; 40°C, −14.2, in ‰) during reduction by ascorbic acid could reflect variation of P_L with temperature.

The question arises as to the chemical nature of the two steps. Since the one step model was associated with the initial Se—O bond rupture, an obvious interpretation is that the two step model represents the consecutive removal of two oxygen atoms. The values of K_1 and K_2 chosen in the present work fall well within the calculated extreme values of 1.002 and 1.031 (2).

The unusual isotopic effects found during the conversion of SeO_3^{2-} to H_2Se can be attributed to the presence of Se^0 as a reaction intermediate. This has implications in natural environments where biogenic H_2Se may be formed with subsequent selenide mineral formation. During bacterial sulphate reduction, elemental sulphur is not an intermediate although it may form by subsequent reoxidation of sulphide. In these environments, significant depletions of the heavier sulphur isotopes in the sulphide phase are considered to be indicative of bacteriogenesis. In the case of sedimentary selenide deposits, the data of this report show that the analogous interpretation will be complicated if elemental selenium forms as an intermediate.

Finally, it is seen that the use of three isotopes in this investigation assures that the effects are real and not the consequence of contamination. This is particularly relevant when a sample is prepared as a fluoride since F_2 is very chemically reactive. For all data of this report, $\delta^{82}Se = (1.5_4 \pm 0.02)\delta^{80}Se$ with a multiple linear correlation coefficient of 0.998 and a probability of no correlation of less than 6×10^{-10}. Besides attesting to the experimental consistency, the data verify the relationship

$$[(k_1/k_3) - 1] = \frac{M_3 - M_1}{M_2 - M_1}.\ [(k_1/k_2) - 1]$$

as obtained by Rees (personal communication, 1978).

Densities and apparent molar volumes of aqueous NaCl–KBr mixtures at 298.15 K

ANIL KUMAR[1]

Chemical Engineering Division, National Chemical Laboratory, Pune 411 008, India

Received April 1, 1985

ANIL KUMAR. Can. J. Chem. **63**, 3200 (1985).

Experimental differences in densities Δd of aqueous NaCl–KBr mixtures at $I = 1, 2, 3$, and 4 mol kg^{-1} and at 298.15 K are reported from pure NaCl to pure KBr solutions. Mean apparent molar volumes ϕ_V^* are calculated and excess volumes of mixing ΔV_m^{ex} are correlated by Friedman equation. Δd and ϕ_V^* are analysed in terms of recently developed the Pitzer formalism without and with mixing terms. Pitzer equations can estimate the densities of such mixtures with uncommon cations and anions within $\pm 0.02\%$ at the high ionic strength of 4 mol kg^{-1}.

ANIL KUMAR. Can. J. Chem. **63**, 3200 (1985).

En se basant sur les valeurs obtenues pour des solutions allant du NaCl pur au KBr pur, on a déterminé les différences expérimentales de densités, Δd, de solutions aqueuses de NaCl–KBr à $I = 1, 2, 3$, and 4 mol kg^{-1}, à 298,15 K. On a calculé les volumes molaires apparents moyens, ϕ_V^*, et on a relié les volumes de mélange en excès ΔV_m^{ex} à l'équation de Friedman. On a analysé les valeurs de Δd et de ϕ_V^* en fonction du formalisme développé récemment par Pitzer avec ou sans les termes de mélange. Les équations de Pitzer peuvent évaluer les densités de ce type de mélanges contenant des cations et dex anions qui ne sont pas communs avec une précision de $\pm 0{,}02\%$, à une grande force ionique de 4 mol kg^{-1}.

[Traduit par le journal]

Introduction

Since the development of the Pitzer formalism (1, 2) in describing the thermodynamic properties of concentrated aqueous mixed electrolyte solutions, many papers (3) have appeared dealing with activity, osmotic coefficients, and enthalpies of concentrated aqueous electrolytes. Kumar *et al.* (4) and Kumar and Atkinson (5) were the first to extend successfully the Pitzer formalism to the volume properties of aqueous $NaCl–CaCl_2$ system in the ionic strength range of 0.3 to 20 mol kg^{-1} of water and in the temperature range of 278.15 to 308.15 K. The system studied had a common anion.

In the present investigation, we report the experimental densities of the mixture composed of aqueous NaCl with KBr at the constant ionic strengths of 1, 2, 3, and 4 mol kg^{-1} at 298.15 K and analyse them in terms of the Pitzer theory. This system has two different cations and two different anions and the densities of pure electrolyte solutions are significantly different.

Experimental

NaCl and KBr (Baker Analysed) were recrystallized twice before use. The stock solutions were prepared by mass in deionized water. The molalities of stock solutions were determined by gravimetric method using $AgNO_3$.

The densities of mixtures were measured with Paar vibrating tube densitometer. The relative densities, $\Delta d = (d - d_0)$, where d_0 is the density of pure water 0.997047 g cm^{-3} at 298.15 K, were obtained as reported earlier (4). Temperature of thermostat bath was controlled to ± 0.005 K and density differences were precise to $\pm 3 \times 10^{-6}$ g cm^{-3}. Experimental method and calibration were the same as discussed earlier (4, 5). Mixtures of various compositions were prepared by appropriate combination of NaCl and KBr solutions at a particular ionic strength.

Results and discussion

Table 1 reports the differences in densities Δd of mixtures at constant ionic strengths 1, 2, 3, and 4 mol kg^{-1} as a function of ionic strength fraction of KBr (y_B). In this paper A and B refer to NaCl and KBr, respectively, and $y_A + y_B = 1$. Table 1 also reports the mean apparent molar volumes of mixture ϕ_V^*, calculated by

$$[1] \qquad \phi_V^* = \frac{1000(d_0 - d_{expt})}{\sum_J m_J d_{expt} d_0} + \frac{\sum_J m_J M_J}{\sum_J m_J d_{expt}}$$

where $\Sigma\, m_J$ is the sum over molalities of electrolytes in mixture and M_J is molecular weight of the electrolytes.

Wirth (6) reported the densities of the same system at 298.15 K, where the concentration of NaCl was kept constant while KBr was added to the total ionic strength of 1.5 mol kg^{-1}. It was difficult to compare our densities with his values as his data were neither at constant ionic strength nor at constant ionic strength fraction.

Experimental Δd and ϕ_V^* can be examined using the Pitzer equations. Details of general equations of Pitzer are given elsewhere (4, 5) but a summary of useful expressions as modified for the mixtures of 1–1 type of electrolytes mixtures is given below.

Apparent molar volume, ϕ_V, of an 1–1 electrolyte (MX) based on the Pitzer formalism is

$$[2] \qquad \phi_V = \phi_V^0 + \frac{A_V}{b} \ln(1 + bI^{1/2}) + 2RT[mB_{MX}^V + m^2 C_{MX}^V]$$

where

$$[3] \qquad B_{MX}^V = \left(\frac{\partial \beta^{(0)}}{\partial P}\right)_T + \left(\frac{\partial \beta^{(1)}}{\partial P}\right)_T (2/\alpha^2 I) [1 - (1 + \alpha I^{1/2}) \exp(-\alpha I^{1/2})]$$

and

$$[4] \qquad C_{MX}^V = (\partial C^{\phi}/\partial P)_T/2$$

In above equations, $\alpha = 2.0$ (kg/mol)$^{1/2}$ and $b = 1.2$ (kg/mol)$^{1/2}$, $R = 83.1441$ cm^3 bar mol^{-1} K^{-1} and A_V is Pitzer–Debye–Hückel slope $= 1.874$ (cm^3/mol) (kg/mol)$^{1/2}$ at 298.15 K.

The mixture under study is composed of two cations Na^+ and K^+ and two anions Cl^- and Br^-. To use the Pitzer equations,

TABLE 2. Pitzer coefficients for cation–anion interactions

Cation–anion	ϕ_V^0 (cm^3 mol^{-1})	$\left(\frac{\partial\beta^{(0)}}{\partial P}\right)_T \times 10^5$	$\left(\frac{\partial\beta^{(1)}}{\partial P}\right)_T \times 10^5$	$\left(\frac{\partial C^{\phi}}{\partial P}\right)_T \times 10^6$	σ (cm^3 mol^{-1})	Ref.
Na–Cl	16.58	1.14	1.15	−1.11	0.01	5
K–Br	34.08	4.93	9.18	28.15	0.03	7
Na–Br	23.59	3.49	−4.09	27.18	0.02	7
K–Cl	26.92	1.49	−0.17	2.88	0.03	8

it is essential to calculate the coefficients $(\partial\beta^{(0)}/\partial P)_T$, $(\partial\beta^{(1)}/\partial P)_T$, and $(\partial C^{\phi}/\partial P)_T$ for cation–anion pairs as Na–Cl, Na–Br, K–Br, and K–Cl. Equation [2] was used to generate these Pitzer coefficients for these pairs. Single electrolyte ϕ_V data for analysis were taken from elsewhere (5, 7, 8). Table 2 lists these coefficients along with the standard deviation of fit. As clear from this table, single salt data can be accurately fitted with Pitzer equation.

Apparent molar volume of an ion in the mixture of 1–1 electrolytes is given by

$$[5] \quad \phi_{Vi} = \phi_{Vi}^0 + \frac{A_V}{2b}\ln(1 + bI^{1/2}) + RT\sum_i B_{ij}m_j + (RT/2)\sum_i C_{ij}m_J^2$$

where the sums are over all the jth ion sof opposite charge to the ion i. In eq. [5], Pitzer coefficients listed in Table 2 are used to estimate $\phi_{Vi}\cdot\phi_{Vi}$ thus determined lead to the theoretical mean apparent molar volume (ϕ_V^*) as

$$[6] \quad \phi_{V\text{cal}}^* = \frac{\sum_J m_J\phi_{VJ}}{\sum_J m_J}$$

where $\phi_{VJ} = \sum_i \nu_i\phi_{Vi}$, and ν_i is the stoichiometric factor of the ith ion in electrolyte.

Density of mixture can then be computed by relation:

$$[7] \quad d_{\text{cal}} = \frac{1000 + \sum_J m_J M_J}{1000/d_0 + \sum_J m_J\phi_{VJ}}$$

Equations [6] and [7] calculate ϕ_V^* and the density of mixture through ϕ_{Vi} calculated by the Pitzer equation. Table 3 lists the standard deviation of fit for ϕ_V^* and Δd in mixtures using the above relations and considering that the cation–anion interactions are predominent. Examination of this table shows that one can estimate the density of such mixtures at I = 4 mol kg^{-1} to within 0.05%. Similarly ϕ_V^* can be estimated to ±0.7%.

During the above treatment, the interactions between like charges ions are neglected. Their consideration need the evalu-

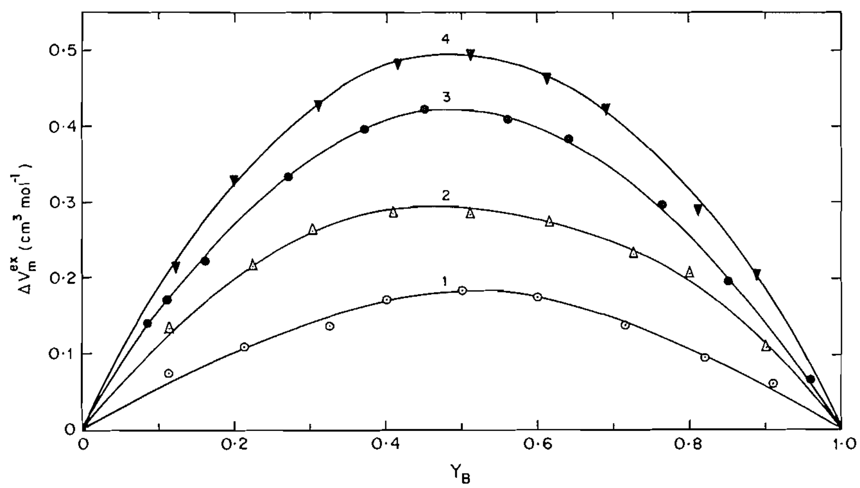

FIG. 1. ΔV_m^{ex} versus y_B for aqueous NaCl–KBr at I = 1, 2, 3, and 4 mol kg^{-1}.

TABLE 3. Standard deviation in relative densities (Δd) and ϕ_V^* of NaCl–KBr–H_2O at 298.15 K using Pitzer equations

I (mol kg^{-1})	In g cm^{-3} or cm^3 mol^{-1}	
	$\Delta d \times 10^3$	ϕ_V^*
1	0.092	0.034
	(0.061)[a]	(0.017)
2	0.255	0.056
	(0.143)	(0.023)
3	0.401	0.092
	(0.169)	(0.051)
4	0.675	0.210
	(0.254)	(0.070)

[a] Values in parentheses are the standard deviations with the use of binary mixing terms.

ation of mixing terms called as binary terms θ_{NaK} and θ_{ClBr}, and ternary terms as ψ_{NaKCl}, ψ_{NaKBr}, ψ_{NaBrCl}, and ψ_{KBrCl}. Binary interaction terms can easily be evaluated as discussed elsewhere (5). The extended Pitzer equation for evaluating ϕ_{Vi} in this mixture can be written by adding an additional term accounting for mixing as

$$[8] \quad \phi_{Vi} = \text{RHS of eq. [5]} + RT \sum_K \theta_{ik} m_k$$

where the summations are over the ions of same charge as on i.

The binary mixing terms θ_{Nak} and θ_{ClBr} calculated for these mixtures do not vary too widely with the range of I of interest. We have, therefore, used the average of the values in mixture calculations. The values of θ_{NaK} and θ_{ClBr} used are 6.31×10^{-6} and 2.83×10^{-6}, respectively. Use of these terms bring a remarkable improvement in the fit of Δd and ϕ_V^* as clear from the standard deviations listed in parentheses in Table 3. One now can estimate d and ϕ_V^* to ±0.02 and ±0.2%. The magnitude of ternary terms in this case was very small as was in NaCl–$CaCl_2$–H_2O (5).

Excess volumes of mixing ΔV_m^{ex} for this system were calculated by

$$[9] \quad \Delta V_m^{ex}/\sum_J m_J = \phi_{V\text{expt}} - \sum_J m_J \phi'_{VJ}$$

TABLE 4. Friedman parameters for correlating ΔV_m^{ex} and y_B by eq. [10]

I (mol kg^{-1})	v_0	v_1	v_2	σ (cm^3 mol^{-1})
1	0.727	−0.058	-9.019×10^{-5}	0.003
2	0.292	0.008	0.063	0.002
3	0.186	0.010	2.288×10^{-3}	0.002
4	0.124	0.003	-2.460×10^{-3}	0.002

In eq. [9], ϕ'_{VJ} indicates the ϕ_V of each electrolyte at the ionic strength of mixture. ΔV_m^{ex} thus obtained are listed in Table 1 and are fitted to Friedman equation [9],

$$[10] \quad \Delta V_m^{ex} = I^2 y_B(1 - y_B)[(v_0 + v_1(1 - 2y_B) + v_2(1 - 2y_B)^2]$$

Figure 1 presents ΔV_m^{ex} as a function of y_B and Table 4 reports the Friedman parameters along with standard deviations.

Above discussion shows that mixture density can accurately be estimated using the Pitzer equations. These equations emerge as powerful predicting tool.

Nous avons fait réagir dans le dichlorométhane les ozonides de plusieurs phosphites sur différents capteurs d'oxygène singulet ($^1O_2$): le rubrène **2**, la tétraphénylcyclopentadienone **4** et le diphényl-9,10-anthracène **6**. Ces ozonides réagissent lors de leur décomposition ($-47°C < t < 30°C$) sur ces capteurs. Les droites de Foote obtenues en faisant varier les concentrations respectives d'ozonides et de capteurs conduisent aux mêmes paramètres que ceux obtenus lors de la photooxydation par $^1O_2$ de ces capteurs. Cela confirme l'aptitude de ces ozonides à engendrer $^1O_2$. La valeur trouvée du rendement absolu en $^1O_2$ est de 100% ($\rho = 1$). Les résultats confirment aussi la grande efficacité vis-à-vis de $^1O_2$ du rubrène ($\gamma = 1$) et la valeur moyenne de la tétraphénylcyclopentadienone ($\gamma = 0,46$). La valeur faible ($\gamma = 0,3$) de l'efficacité du diphényl-9,10-anthracène **4** est par contre inattendue.

ANNE MARIE CAMINADE, FAYEZ EL KHATIB, MAX KOENIG, and JEAN MARIE AUBRY. Can. J. Chem. **63**, 3203 (1985).

The ozonides of several phosphites in solution in dichloromethane have been reacted with some scavengers of singlet oxygen ($^1O_2$) like rubrene (**2**), tetraphenylcyclopentadienone (**4**), and 9,10-diphenylanthracene (**6**). These ozonides react on the scavengers ($-47°C < t < 30°C$) upon their decomposition. The Foote curves obtained by varying the respective concentrations of ozonides and of scavengers lead to parameters similar to those obtained upon the photooxidation of the scavengers by $^1O_2$. Results confirm that these ozonides can lead to the formation of $^1O_2$. The absolute yield of $^1O_2$ is 100% ($\rho = 1$). These results also confirm the high efficiency of the rubrene toward $^1O_2$ ($\gamma = 1$) and the lower efficiency of the tetraphenylcyclopentadienone ($\gamma = 0.46$). However, the low value ($\gamma = 0.3$) for the efficiency of the 9,10-diphenylanthracene (**4**) is unexpected.

[Journal translation]

De nombreuses sources chimiques d'oxygène singulet ($^1O_2$) sont aujourd'hui facilement utilisables en milieu aqueux ou dans des solvants organiques (1). À cet égard, les ozonides de phosphite connus depuis 1961 (2) sont de bons générateurs d'oxygène activé lors de leur décomposition thermique (3–5). De nombreuses réactions d'oxydation ont été conduites à l'aide de ces ozonides (1): elles aboutissent dans le cas des cycloadditions-1,4 ou dans les ène-réactions aux mêmes résultats que les réactions de photooxydation (6–8). Toutefois certaines réactions comme les cycloadditions-1,2 se produisent à des températures inférieures à celle qui permet de libérer $^1O_2$ (9); de plus, certaines d'entre elles présentent une stéréospécificité différente des photooxydations (10). C'est ainsi que dans la littérature les réactions observées sont attribuées soit à l'oxygène singulet libéré par l'ozonide soit à la réactivité propre de l'ozonide (schéma 1).

Afin d'éclairer les mécanismes liés à la génération chimique d'oxygène activé, des mesures des paramètres cinétiques et du rendement absolu en $^1O_2$ ont été effectuées. C'est ainsi que pour la réaction $ClO^- + H_2O_2$ la valeur du rendement est de 100% (11, 12); elle est de 70% pour la décomposition des peracides (13, 14), et varie entre 35 et 95% pour les endoperoxydes (15). Dans le cas des ozonides de phosphite, le rendement en $^1O_2$, bien que considéré comme quantitatif par certains auteurs (6, 7, 16), n'a jamais été mesuré. Nous avons mesuré, dans le cas des réactions de cycloaddition-1,4 sur différents capteurs spécifiques d'$^1O_2$ **2**, **4**, **6** le coefficient de Foote (β), l'efficacité du capteur (γ) ainsi que le rendement en oxygène singulet (ρ).

SCHÉMA 1. Chemins réactionnels (i) et (ii) conduisant au produit d'oxydation AO_2 à partir d'ozonides de phosphite.

Résultats

Nous avons fait réagir dans le dichlorométhane les différents ozonides **1***a*–*d* sur trois capteurs classiques d'oxygène singulet: le rubrène **2**, la tétraphénylcyclopentadiènone **4** et le diphényl-9,10-anthracène **6**.

Les ozonides étudiés ne réagissent pas sur ces accepteurs à basse température (−78°C) mais ceux-ci sont oxydés à des températures correspondant à la décomposition thermique des ozonides (réaction [1], tableau 1).

$$[1] \quad (RO)_3PO_3 \xrightarrow{T(°C)} RO_3P{=}O + {}^1O_2$$

Le bilan de l'action des ozonides sur ces capteurs peut s'écrire selon les réactions [2], [3] et [4]. Les concentrations des produits d'oxydation obtenus dans chaque cas (**3**, **5**, **7**) sont mesurées par clhp ou uv.

Les paramètres cinétiques correspondant aux réactions [2], [3], [4] obtenus à partir des droites de Foote (figures 1, 2, 3) figurent dans le tableau 2.

L'oxydation du rubrène **2** par l'ozonide **1**a, pour des rapports [**1**a]/[**2**] variables, nous a permis d'obtenir une droite de Foote (fig. 1) dont la pente est $\beta = 2 \times 10^{-4}$ M et l'ordonnée à l'origine $\rho \times \gamma = 1$. Ces paramètres conduisent, à partir des valeurs de la durée de vie de $^1O_2$ dans CH_2Cl_2 (21, 22) à une constante de vitesse d'oxydation $k_r = 5,4 \times 10^7$ M^{-1} s^{-1} dont la valeur est la même (aux erreurs d'expérience près) que celle obtenue lors de la photooxydation de **2** par $^1O_2$ (23, 24). Ce résultat confirme que la voie d'oxydation la plus probable obtenue par l'ozonide **1**a est celle qui passe par la génération d'$^1O_2$ (25) (voie (ii), schéma 1).

De plus $\rho\gamma = 1$ entraîne $\rho = 1$, et $\gamma = 1$. Ces deux valeurs indiquent que le rendement absolu en $^1O_2$ de l'ozonide **1**a est de 100% et que l'efficacité du rubrène est totale puisqu'il ne désactive pas $^1O_2$ ($k_q \sim 0$).

L'oxydation de **4** par les ozonides **1**a, **1**b et **1**c conduit dans les mêmes conditions (fig. 2) aux paramètres $\beta = 1 \times 10^{-4}$ M et $\rho\gamma = 0,46$. Comme l'ozonide **1**a se trouve sur la droite de Foote, nous avons conservé sa valeur précédente $\rho = 1$ et attribué à γ la valeur 0,46. L'efficacité de la tétraphénylcyclopentadienone **4** est donc très moyenne (26). La constante de vitesse d'oxydation $k_r = 5 \times 10^7$ M^{-1} s^{-1} possède une valeur proche de celle de la constante de vitesse de désactivation k_q.

L'oxydation du diphényl-9,10-anthracène **6** par les ozonides **1**a, **1**b, **1**d (fig. 3) conduit à une valeur de la pente $\beta = 10 \times$

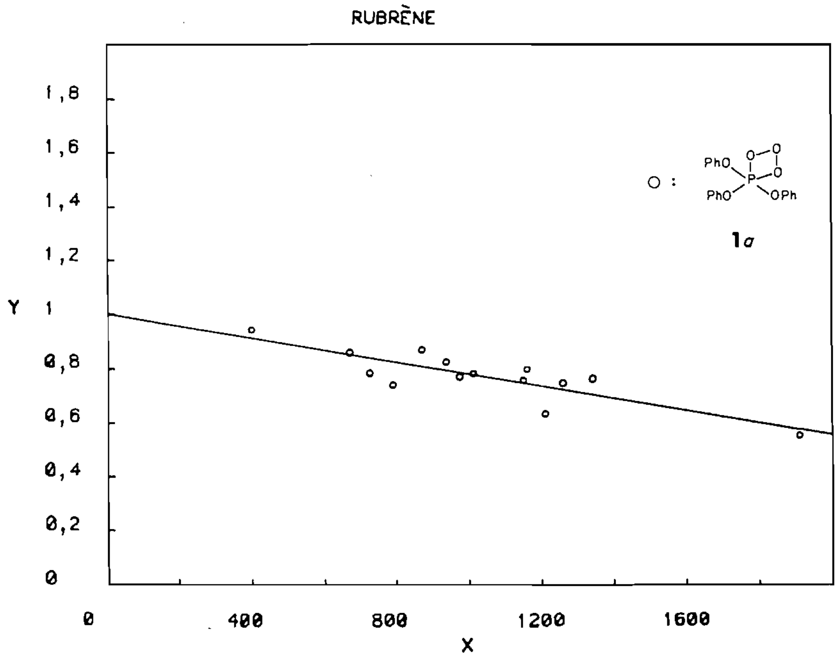

FIG. 1. Droite de Foote correspondant à l'oxydation de **2** par l'ozonide **1***a*.

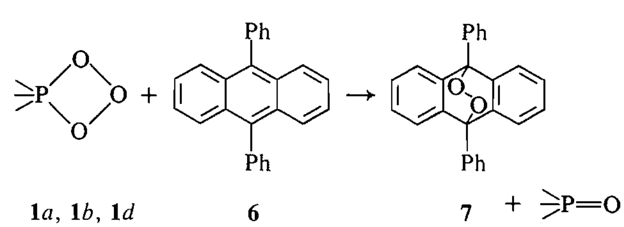
[4]



1*a*, **1***b*, **1***d* **6** **7**

10^{-4} *M*. Cette valeur élevée confirme la faible réactivité de **6** comparée à celle de **2** ($k_r = 4{,}2 \times 10^6\ s^{-1}$ et k_r (**2**)/k_r (**6**) ~ 10 (27), mais aussi sa faible efficacité puisque $\gamma = 0{,}3$.

Discussion

Comme les ozonides **1***a*–*d* ne réagissent pas sur les accepteurs **2**, **4** et **6** à basse température, nous avons écrit les réactions en considérant $^1O_2$ comme l'oxydant (nous aurions pu conduire le même calcul avec des équations similaires en considérant les ozonides et non $^1O_2$ comme l'oxydant).

Les réactions élémentaires mises en jeu peuvent s'écrire:

[5] $\quad >\!\!-PO_3 \xrightarrow{k_0} >\!\!-P{=}O + {}^1O_2$

[6] $\quad {}^1O_2 + S \xrightarrow{k_d} S + {}^3O_2$

[7] $\quad {}^1O_2 + A \xrightarrow{k_r} AO_2$

[8] $\quad {}^1O_2 + A \xrightarrow{k_q} A + {}^3O_2$

$>\!\!-PO_3$: **1***a*–*d*; A: capteurs **2**, **4**, **6**; S: solvant; AO_2: capteur oxydé.

La variation de la concentration en $^1O_2$ s'écrit alors:

$$\frac{d[{}^1O_2]}{dt} = \left(\frac{d[{}^1O_2]}{dt}\right)_f - k_d[{}^1O_2] - (k_r + k_q)[{}^1O_2][A]$$

où $(d[{}^1O_2]/dt)_f$ est la vitesse de formation de $^1O_2$ par décomposition de l'ozonide $\sim k_0[PO_3]$; en appliquant l'hypothèse des états quasi stationnaires à $^1O_2$, on obtient:

$$\frac{d[{}^1O_2]}{dt} = 0,\ [{}^1O_2] = \left(\frac{d[{}^1O_2]}{dt}\right)_f \times \frac{1}{k_d + (k_r + k_q)[A]}$$

d'autre part,

$$\frac{d[A]}{dt} = -k_r[{}^1O_2][A]$$

$$\frac{d[A]}{dt} = -\left(\frac{d[{}^1O_2]}{dt}\right)_f \times \frac{k_r[A]}{k_d + (k_r + k_q)[A]}$$

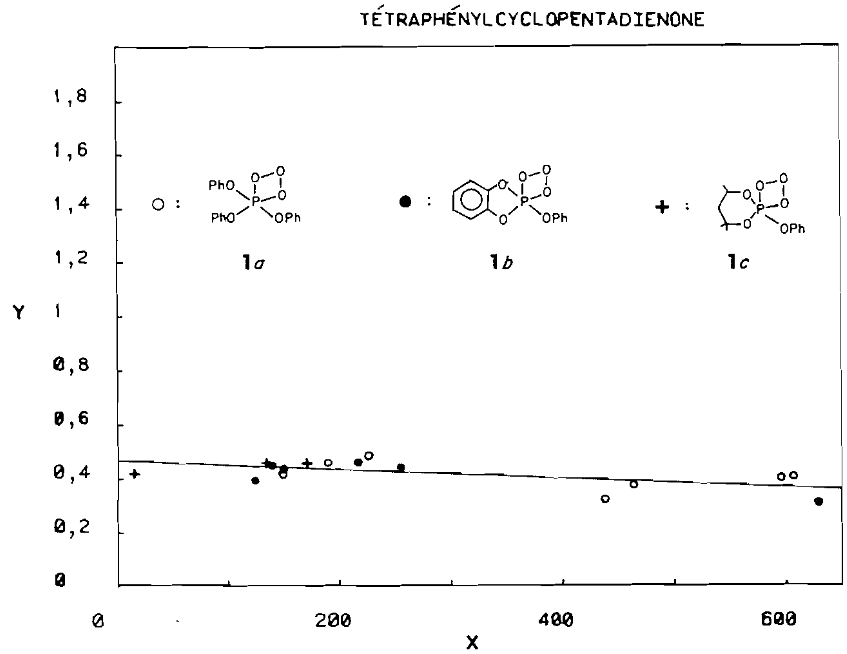


FIG. 2. Droite de Foote correspondant à l'oxydation de **4** par les ozonides **1**a, **1**b, **1**c.

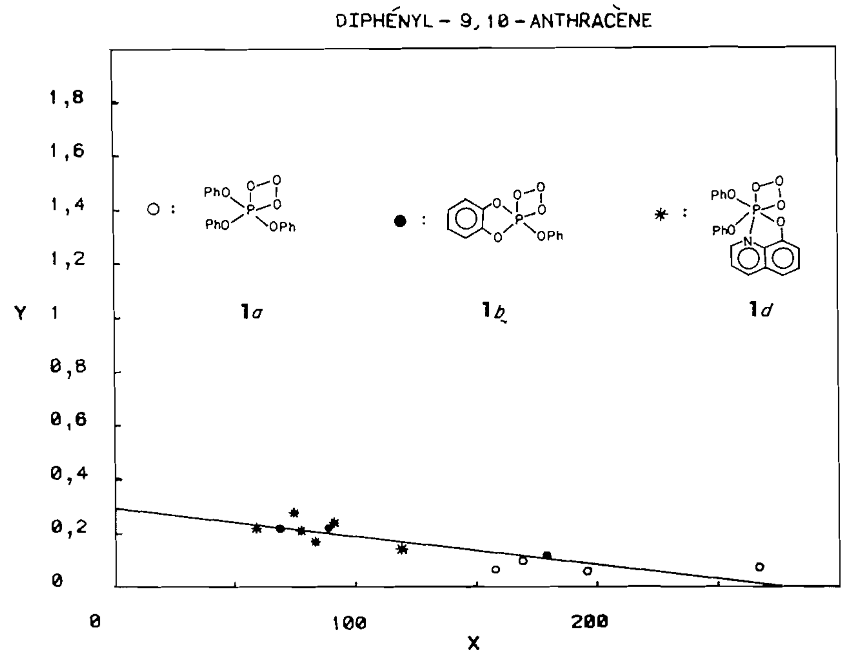

FIG. 3. Droite de Foote correspondant à l'oxydation de **6** par les ozonides **1**a, **1**b, **1**d.

L'intégration à $t \to \infty$ conduit alors à l'expression

$$\beta \ln \frac{[A]_0}{[A]_\infty} + [A]_0 - [A]_\infty = \gamma [^1O_2]_f$$

Soit en divisant par $[PO_3]_0$ concentration initiale d'ozonide

$$\gamma \frac{[^1O_2]_f}{[PO_3]_0} = \beta \frac{\ln [A]_0/[A]_\infty}{[PO_3]_0} + \frac{[A]_0 - [A]_\infty}{[PO_3]_0}$$

Avec $\beta = k_d/(k_r + k_q)$ coefficient de Foote, $\gamma = k_r/(k_r + k_q)$ efficacité du capteur et $\rho = [^1O_2]_f/[PO_3]_0$ rendement absolu en $^1O_2$, on obtient l'équation générale

$$[9] \quad \underbrace{\frac{[A]_0 - [A]_\infty}{[PO_3]_0}}_{Y} = -\beta \underbrace{\frac{\ln ([A]_0/[A]_\infty)}{[PO_3]_0}}_{X} + \rho\gamma$$

de la forme générale

$$[10] \quad Y = -\beta X + \rho\gamma$$

Cette expression est l'équation de la droite de Foote dont la pente donne β et l'ordonnée à l'origine le produit $\rho\gamma$. Dans le cas du rubrène et du diphénylanthracène, les valeurs des paramètres ainsi obtenus, en particulier k_r, sont proches de celles obtenues lors des photooxydations.

Par contre pour la tétraphénylcyclopentadienone, si la valeur de β est la même que celle obtenue par Evans et Tucker (26) la valeur de k_r diffère sensiblement. Cet écart est probablement dû aux incertitudes expérimentales mais aussi à la nature différente du solvant (CCl_2FCClF_2) et à l'estimation de la durée de vie de l'oxygène singulet dans ce solvant. Evidemment, cet écart peut aussi, dans ce cas, provenir d'un mécanisme différent.

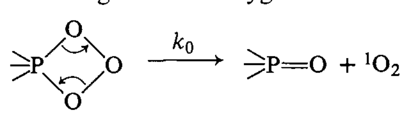
On remarquera également que les constantes de vitesses d'oxydation k_r sont peu sensibles aux variations de température (dans le domaine $-50°C < t < +20°C$) puisque les droites de Foote contiennent des valeurs de k_r obtenues à des températures différentes pour les ozonides **1***a–d*. Ces résultats confirment la grande efficacité du rubrène ($\gamma = 1$) (21, 23) et la valeur moyenne de la tétraphénylcyclopentadiénone ($\gamma = 0{,}46$) (21, 26). Par contre malgré certaines similitudes structurales, le comportement du rubrène et du diphényl anthracène vis-à-vis de $^1O_2$ sont très différents. Pour le diphénylanthracène la constante de vitesse k_r est 10 fois inférieure à celle du rubrène et de plus sur 10 molécules d'$^1O_2$ qui réagissent 7 sont quenchées ($\gamma = 0{,}3$). La désactivation d'$^1O_2$ est même supérieure dans ce cas à celle du diméthylanthracène ($\gamma = 0{,}6$) (21, 26).

Ainsi, il nous paraît raisonnable de considérer que les résultats obtenus confirment le schéma réactionnel proposé. En effet la formation des seuls endoperoxydes de rubrène et de diphenylanthracène est caractéristique de l'oxygène singulet. La valeur de 100% du rendement obtenu pour **2** avec l'ozonide **1***a* confirme bien l'observation suivant laquelle la quantité d'endoperoxyde formé correspond strictement à la disparition du rubrène.

Comme l'ozonide **1***a* se retrouve sur les droites de Foote des autres capteurs avec les autres ozonides, nous en concluons que le rendement en $^1O_2$ des ozonides **1***b*, **1***c* et **1***d* est le même que celui de **1***a*, soit 100%. Ceci nous amène à penser que si les substituants influent sur la stabilité des ozonides c'est-à-dire sur la température de décomposition, ils n'influent pas de manière sensible sur le mécanisme de décomposition.

En effet plusieurs mécanismes sont envisageables:

(a) *Un mécanisme concerté* qui conduit directement après rupture et réarrangement à l'oxygène activé et au phosphate:



(a)

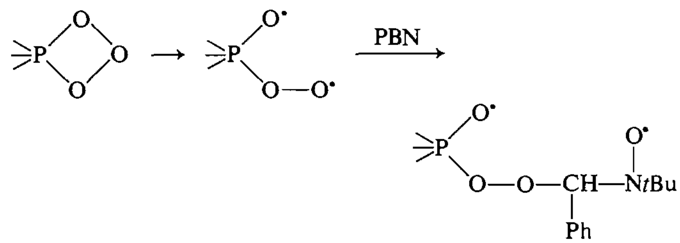
Ce mécanisme peut conduire directement à la production quantitative d'$^1O_2$. Une telle interprétation est compatible avec les résultats obtenus dans ce travail mais aussi avec le fait que les constantes de vitesse de décomposition k_0 mesurées à partir de cinétiques de dégagement d'oxygène (16–18) sont les mêmes lorsque ces cinétiques sont déterminées par rmn dans un champ magnétique de l'ordre de 23 000 gauss (19, 20).

De plus, toutes les valeurs d'entropie d'activation de la réaction [1] relevées dans la littérature, mesurées par des méthodes différentes (17–20, 28) sont négatives et comprises entre −10 et −20 u.e. Ces résultats sont en accord avec ceux obtenus par Turro *et al.* (15) dans l'étude de la thermolyse des endoperoxydes aromatiques. En effet ce dernier a établi une corrélation entre la valeur négative de l'entropie d'activation et les hauts rendements en $^1O_2$ obtenus par un mécanisme concerté de type (a).

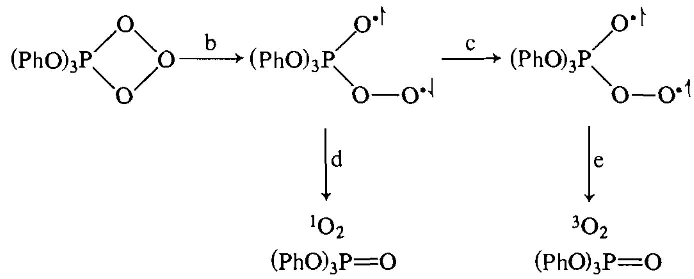
Toutefois ce mécanisme simple ne rend pas compte de la réactivité des ozonides à basse température ou de la présence de radicaux.

(b) *Un mécanisme de type biradicalaire* (29)

L'existence de ce biradical a été confirmée en rpe par Pryor et Govindan (30) lors de l'étude de la décomposition de $(PhO)_3PO_3$ en présence de "spin trap": α-phényl-*N*-*tert*-butylnitrone (PBN).



Un tel mécanisme a été envisagé dans le cas de la décomposition des endoperoxydes aromatiques par Turro *et al.* (15) et dans le cas des ozonides de phosphite par Mendenhall (16):



Selon ce schéma, une homolyse d'une des liaisons O—O de l'ozonide se produit (voie b) en fournissant un diradical singulet qui peut évoluer vers la formation d'oxygène singulet (voie d) ou vers un diradical triplet (voie c) par un croisement intersystème. Ce dernier peut se scinder à son tour en phosphate et en oxygène fondamental (voie e) par un processus autorisé par la règle de conservation des spins.

Les résultats de notre étude permettent d'éliminer l'hypothèse d'un intermédiaire diradicalaire à longue durée de vie qui conduirait à la formation d'une certaine proportion d'oxygène fondamental et à l'oxydation du rubrène en un produit différent de l'endoperoxyde **3**. En effet, la sensibilité aux radicaux peroxyles ROO$^\bullet$ des hydrocarbures aromatiques polycycliques en général (31) et du noyau rubrénique en particulier (12) est connue.

Toutefois nos expériences ne s'opposent pas à la proposition de Pryor (30) de l'intervention d'un diradical de faible durée de vie qui évoluerait rapidement, à température suffisante, vers la formation de $^1O_2$ (voie d) sans subir le processus relativement lent du croisement intersystème (voie c).

En conclusion, la dualité des deux processus (concerté et biradicalaire) subsiste. Cet aspect très général de nombreuses réactions est peut-être dans ce cas particulier lié à la nature complexe des états électroniques de l'oxygène singulet (1).

Partie expérimentale

1. *Oxydation du rubrène*

Les solutions d'ozonide de même concentration sont préparées à −80°C et rajoutées à cette température sur des solutions de rubrène **2** de concentrations variables. La formation d'endoperoxyde **3** est détectée par son absorption à 254 nm après séparation d'une prise d'essai du mélange réactionnel par chromatographie liquide haute performance (clhp).

(a) *Préparation des solutions*

Le solvant utilisé est du dichlorométhane 99,8% (Aldrich) conservé sur $NaHCO_3$ pour éviter l'isomérisation acido catalysée du rubrène en pseudo rubrène (32).

D'autre part le rubrène subit très facilement une photooxydation auto sensibilisée par la lumière ambiante lorsque de l'oxygène dissous est présent dans la solution (24, 33)

$$\mathbf{2} \xrightarrow{h\nu(400 < \lambda < 580 \text{ nm})} \mathbf{2}^*$$

$$\mathbf{2}^* + {}^3O_2 \rightarrow \mathbf{2} + {}^1O_2 \rightarrow \mathbf{3}$$

Il est donc nécessaire de protéger les réacteurs de la lumière et de travailler dans une pièce éclairée par une lampe émettant à $\lambda > 580$ nm. Toutes les mesures de volumes à température ambiante se font par pesée ($d_{CH_2Cl_2} = 1,326$). La concentration de la solution mère de rubrène est $[\mathbf{2}]_{\text{mère}} = 2,699 \times 10^{-3}$ M.

On fait ensuite 8 prélèvements entre 1,7 et 5 mL, de façon à obtenir 8 réacteurs contenant entre 4,52 et $13,42 \times 10^{-6}$ mol de rubrène.

On prépare également un "blanc" qui sera traité dans les mêmes conditions mais qui ne recevra pas d'ozonide, et une solution témoin contenant à la fois du rubrène et son endoperoxyde: $[\mathbf{2}] = 1,254 \times 10^{-3}$ M et $[\mathbf{3}] = 6,80 \times 10^{-4}$ M.

L'endoperoxyde **3** est préparé indépendamment en irradiant à $\lambda > 530$ nm une solution de **2** dans CH_2Cl_2 dans laquelle on fait barboter de l'oxygène jusqu'à décoloration complète. Le solvant est ensuite évaporé: le résidu est repris dans le méthanol, passé aux ultra-sons, centrifugé, repris dans l'éther, centrifugé à nouveau et séché sous vide.

(b) *Préparation de la solution d'ozonide*

La réaction d'ozonation de **1***a* ($4,98 \times 10^{-4}$ mol) se fait à -80°C (bain d'acétone/Carboglace) dans 10 mL de CH_2Cl_2. Le gaz vecteur utilisé à l'entrée de l'ozoneur est de l'oxygène, qualité aviation (concentration en eau inférieure à 20 mg/m^3). La concentration en ozone est 8×10^{-4} mol/L.

On fait passer 1,12 L de mélange O_3/O_2: l'excès d'ozone est dosé par iodométrie. Ce dosage montre que la totalité du phosphite a été oxydée avec une stoechiométrie [phosphite]/O_3 = 1:1.

La solution d'ozonide est ensuite purgée en faisant passer 8 L d'argon. Pour vérifier que cette solution ne contient plus de traces d'ozone, on fait un prélèvement maintenu à -80°C sur lequel on rajoute une solution très diluée de rubrène. On n'observe pas de décoloration de cette solution de rubrène à -80°C.

Le rendement en ozonide est déterminé par rmn ^{31}P à -80°C. En faisant varier le temps entre deux impulsions de 2,8 à 10,8 s on n'observe pas de modifications de l'intégration des pics correspondant à $(PhO)_3PO_3$ ($\delta = -62$) et $(PhO)_3P{=}O$ ($\delta = -18$). On trouve ainsi un rendement en ozonide de 85,5%. Cette solution initiale contenant 85,5% d'ozonide doit être diluée avant la réaction sur le rubrène. Pour cela on procède à des transferts dans des fioles jaugées à travers des aiguilles, par une surpression d'argon, puis on lave la fiole et l'aiguille par la quantité de CH_2Cl_2 nécessaire à la dilution.

Cette méthode est utilisée pour toutes les dilutions à -80°C. Le CH_2Cl_2 diminuant de volume à basse température, il est nécessaire de procéder à des corrections de volume. C'est ainsi que lorsqu'on passe de -80°C à la température ordinaire, on observe une augmentation de volume de 10% (mesurée par densité).

Au total, pour atteindre la concentration adéquate en ozonide, il est nécessaire de procéder à 4 transferts (2 pour une dilution et 2 pour transférer dans les solutions de rubrène). Ces transferts vont provoquer une certaine dégradation de l'ozonide. Nous avons effectué ces mêmes opérations de transfert sur une solution d'ozonide non diluée, puis nous avons mesuré par rmn de ^{31}P le pourcentage d'ozonide qui subsiste après ce traitement. On obtient alors une nouvelle valeur du rendement de 74,7% par rapport au phosphite de départ. Ce rendement servira de base aux calculs ultérieurs. Ainsi après dilution et rectifications dues à la dégradation on obtient une solution mère équivalent à $9,21 \times 10^{-4}$ M d'ozonide.

(c) *Réaction de la solution d'ozonide sur les solutions de rubrène*

On fait 8 prélèvements de 1,1 mL de la solution mère d'ozonide, dans les mêmes conditions que précédemment, que l'on transfère à -80°C sur les diverses solutions de rubrène et on complète par CH_2Cl_2 à 8,05 mL.

On laisse ensuite le mélange réactionnel remonter jusqu'à la température ambiante. On a 8 solutions de même concentration en ozonide $[\mathbf{1}a] = 1,26 \times 10^{-4}$ M et de concentration initiale en rubrène [**2**] variable:

$$5,61 \times 10^{-4}\, M < [\mathbf{2}] < 16,67 \times 10^{-4}\, M$$

(d) *Mesure de l'endoperoxyde formé par clhp*

La colonne utilisée a un diamètre de 5 mm et une longueur de 250 mm. Les particules de silice greffée phase inverse RP18 ont un diamètre de 10 μm.

Le mélange éluant est constitué par 85% d'éthanol, 15% d'eau.

Le débit est de 120 mL/h pour une pression de 200 atm. (1 atm = 101.3 kPa). La détection se fait par uv à 254 nm.

Le pic correspondant à l'endoperoxyde a un temps de rétention de 6 min, celui du rubrène de 9,4 min.

La solution témoin permet de relier la surface des pics de l'endoperoxyde (S_3) et du rubrène (S_2) ramenés à une même concentration. Pour [**2**] = [**3**] on trouve $S_3/S_2 = 2,15$.

On vérifie ensuite que le "blanc" (solution de rubrène n'ayant pas reçu d'ozonide) ne s'est pas oxydé. L'intégration des pics obtenus pour chaque solution de **1***a* + **2** permet de mesurer le pourcentage d'endoperoxyde formé

$$\% \, \mathbf{3} = S_3/(2,15\, S_2 + S_3)$$

On prend pour [**2**] une valeur moyenne

$$[\mathbf{2}] = \frac{2\,[\mathbf{2}_{\text{initial}}] - [\mathbf{3}]}{2}$$

On vérifie à $\lambda = 540$ nm que la disparition du rubrène est égale à l'apparition de son endoperoxyde.

2. *Oxydation de la tetraphénylcyclopentadienone **4** et du 9,10-diphénylanthracène **6***

(a) On prépare une solution mère de **4** ou de **6** dans CH_2Cl_2 de concentration 10^{-2} M. On prélève des quantités variables de **4** ou **6** refroidies à -80°C qui sont ajoutées sur des solutions d'ozonides **1***a*, **1***b*, **1***c*, **1***d*.

(b) *Préparation de la solution d'ozonide*

Une solution de phosphite de concentration 10^{-2} M est préparée. On prélève 1 mL de solution. Après ozonation on purge la solution avec de l'argon. Le pourcentage d'ozonide formé par rapport au phosphite de départ est obtenu par rmn ^{31}P à basse température. Il est de 80% pour les ozonides **1***a*, **1***b*, **1***c* et de 60% pour **1***d*.

(c) *Réaction de **4** et **6** sur les solutions d'ozonides*

On ajoute à -78°C des quantités croissantes de la solution mère de **4** ou **6** sur une solution d'ozonide. On laisse le mélange réactionnel revenir lentement à température ambiante. On effectue ensuite les dilutions nécessaires pour les mesures par uv des concentrations de produit non oxydée.

En effet **4** et **6** possèdent des bandes d'absorption dont les λ_{max} sont respectivement 510 nm et 370 nm. Nous avons vérifié que les esters phosphoriques correspondants et les produits d'oxydation de **4** et **6** n'absorbent pas ces longueurs d'ondes. La diminution d'absorption observée lors de la réaction par rapport à un témoin correspond à la concentration des produits oxydés.

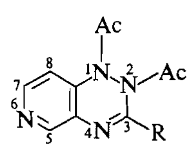
A conformational study of 1,4-diacetyl-1,4-dihydro-6,7-dimethylquinoxaline is carried out by low temperature nmr in CD_2Cl_2. Important acetyl rotation induced shifts have been observed for the *peri* and *ortho* protons. These results, together with low temperature nOe experiments, permit the determination of the structures and conformations of four diacetyl derivatives of dihydropyrido[3,4-*e*] *as*-triazines and of one diacetyl derivative of a dihydropyrido[4,3-*e*] *as*-triazine.

JOSEPH ARMAND, LINE BOULARES, MARIE-PAULE SIMONNIN, CHRISTIAN BELLEC, ODILE CONVERT, NELLY PLE et GUY QUEGUINER. Can. J. Chem. **63**, 3210 (1985).

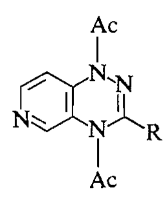
Une étude conformationnelle de la diacétyl-1,4 dihydro-1,4 diméthyl-6,7 quinoxaline a été effectuée par rmn à basse température dans le CD_2Cl_2. La rotation d'un groupe acétyle entraîne d'importantes variations de déplacements chimiques des protons situés en *péri* et en *ortho*. Ces résultats, complétés par des mesures d'effet nucléaire Overhauser à basse température ont permis la détermination des structures et des conformations de quatre dérivés diacétylés de dihydropyrido[3,4-*e*]*as*-triazines et d'un dérivé diacétylé d'une dihydropyrido[4,3-*e*] *as*-triazine.

Introduction

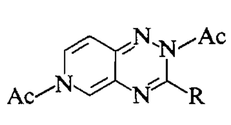
N,N'-diacetyl derivatives of dihydroquinoxalines and of dihydropyrido *as*-triazines can be obtained in different ways depending on the starting materials: (*i*) from quinoxalines and pyrido *as*-triazines, by electrochemical reduction in the presence of acetic anhydride; (*ii*) from their dihydro derivatives, by action either of acetic anhydride or of a mixture of acetic acid and ethylchloroformate. Theoretically, pyrido *as*-triazines can yield four *N,N'*-diacetyl derivatives; thus starting from pyrido[3,4-*e*] *as*-triazines, structures of type I, II, III, or IV may be expected. In fact, only one or two isomers among the four possible are obtained for each compound, giving rise to the problem of elucidating their structures.



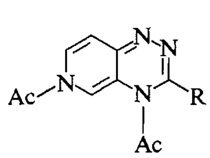
I



II

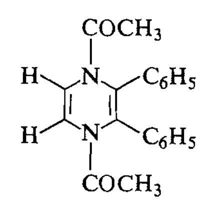


III



IV

^1H nuclear magnetic resonance and especially the nuclear Overhauser effect (nOe) have been shown to be the methods of choice in conformational studies of tertiary amides. This type of experiments, performed at low temperature, has been successfully used to carry out a conformational study of monacetyl derivatives of nitrogen heterocycles (1) and extended by our group (2) to the *N,N'*-diacetyl derivative **1**.



1

In the present work, we report a structural and conformational study in solution of various *N,N'*-diacetyl derivatives of nitrogen heterocycles. The conformation of 1,4-diacetyl-1,4-dihydro-6,7-dimethylquinoxaline **2** is first determined. The low temperature nmr data of **2** indicate that rotation of an acetyl group induces large changes in chemical shifts for protons located in the *peri* and *ortho* positions (the terms for the protons are according to R. H. Martin *et al.* (3)), while *meta* protons are little, or not at all, affected. The results thus obtained are applied to the determination of the structures and

conformations of diacetyl derivatives of dihydropyridotriazines and these are confirmed by low temperature nOe experiments.

Results

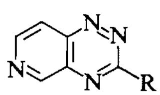
Preparations of N,N′*-diacetyl derivatives*

1,4-Diacetyl-1,4-dihydro-6,7-dimethylquinoxaline **2** is obtained by electrochemical reduction of 6,7-dimethylquinoxaline in the presence of acetic anhydride.

Heating the 1,4-dihydropyrido[3,4-*e*] *as*-triazine **4** (obtained by hydrogenation of **3** (4)) in acetic anhydride gives the 1,4-diacetyl-1,4-dihydropyrido[3,4-*e*] *as*-triazine **5**.

Heating **4** in an acetic acid – ethylchloroformate mixture leads to another derivative, the 2,6-diacetyl-2,6-dihydropyrido[3,4-*e*] *as*-triazine **6**. On heating in an excess of acetic anhydride for 15 h, compound **6** rearranges to the thermodynamically more stable derivative **5**.

Heating the 1,4-dihydro-3-phenylpyrido[3,4-*e*] *as*-triazine **8** (obtained by hydrogenation of **7** (4)) in Ac_2O yields the 1,4-diacetyl-1,4-dihydro-3-phenylpyrido[3,4-*e*] *as*-triazine **9**.



3 R = H
7 R = C_6H_5

Electrochemical reduction of **7** in the presence of Ac_2O gives the 1,2-diacetyl-1,2-dihydro-3-phenylpyrido[3,4-*e*] *as*-triazine **10**.

The reaction of acetic anhydride on 1,4-dihydropyrido[4,3-*e*] *as*-triazine gives the 1,4-diacetyl-1,4-dihydropyrido[4,3-*e*] *as*-triazine **11**.

Room temperature ^{1}H nuclear magnetic resonance spectra

The ^{1}H nmr spectra of the various *N,N′*-diacetyl derivatives, recorded at room temperature, indicate that rotation around both N—CO bonds is fast on the nmr time scale (Table 1). Due to its symmetrical structure, the spectrum of **2** displays only four singlets at 7.42, 6.41, 2.26, and 2.22 ppm, corresponding to the resonances of H5–H8, H2–H3, CH_3CO, and CH_3 respectively. The spectra of **5**, **6**, **9**, **10**, and **11** agree with the structures of these compounds and indicate the presence of two different acetyl groups.

The three protons H5, H7, and H8 (or H5, H6, and H8 in **11**) are strongly deshielded in **5**, **9**, **10**, and **11** and the same figures are observed for the vicinal coupling constant $^3J_{7-8}$ or $^3J_{5-6}$ (5.5 Hz) in these four derivatives. These δ and J values, which are close to those observed in pyridine (5), indicate that the pyridinic ring retains its aromatic character in **5**, **9**, **10**, and **11**; therefore these derivatives have structures of type I or II.

TABLE 2. Chemical shifts and relative amounts of the conformers of **2** in CD_2Cl_2 at −60°C

Conformer	%	δH2	δH3	δH5	δH8
2*a* Z_1Z_4	45	6.22		7.54	
2*b* Z_1E_4	45	6.31[a]	6.77[a]	6.85	7.59
2*c* E_1E_4	10	6.82		6.90	

[a] J_{H2-H3} = 5 Hz.

TABLE 3. Acetyl rotation induced shifts for the protons of **2**

Acetyl	Effect *peri*	*ortho*	*meta*
$CH_3CO(1)$[a]	+0.69(H8)	−0.51(H2)	−0.05(H3)
$CH_3CO(4)$[b]	+0.69(H5)	−0.55(H3)	−0.09(H2)

[a] Δδ = δ(**2***b*) − δ(**2***c*).
[b] Δδ = δ(**2***a*) − δ(**2***b*).

The resonances of H5, H7, and H8 move upfield in **6** and the vicinal coupling constant $^3J_{7-8}$ increases to 8 Hz, as previously observed in 1,4-dihydropyridines (6). Hence the pyridinic ring has lost its aromatic character in **6** and this compound has a structure of type III or IV.

The room temperature spectra give information on the nature of the pyridinic ring, but they give no indication of the location of the two acetyl groups.

Low temperature ^{1}H nuclear magnetic resonance spectra

At low temperature, if the rotation around the N—CO bonds becomes slow enough, an individual set of signals should be observed for each of the conformers. The low temperature ^{1}H spectra show the presence of the three expected conformers of **2**; the coexistence of the four possible conformers is observed only in the case of **10**, while for **5**, **6**, **9**, and **11** only two unequally populated conformers were detected within the limits of nmr detection.

Among the three conformers **2***a*, **2***b*, and **2***c* (Table 2), two (**2***a* and **2***c*) have a plane of symmetry. The signals of the methyl protons of the acetyl groups lie too close to be selectively irradiated in order to perform nOe experiments. However, the structural analogy between **1** and **2** and the similarity of their nmr data permit an unambiguous assignment of the signals due to H2 and H3, as ethylenic protons are less shielded when they are *syn* to the carbonyl oxygen (*E*) than when they are *anti* (*Z*). An identical sequence is observed for the *peri*

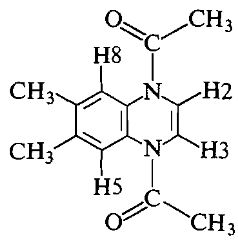
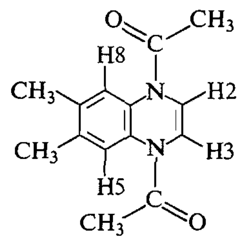
protons H5 and H8.

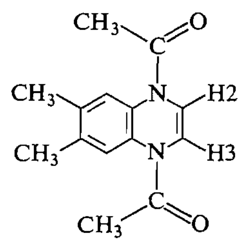
The differences between chemical shifts of the conformers **2***b* (Z_1E_4) and **2***c* (E_1E_4) lead to the values of Δδ related to the rotation of the 1-acetyl group for the *ortho* (H2), *meta* (H3), and *peri* (H8) protons. In the same way, Δδ values due to the rotation of the 4-acetyl group can be obtained from **2***a* (Z_1Z_4) and **2***b* (Z_1E_4). The differences Δδ = δ(**2***b*) − δ(**2***c*) and Δδ = δ(**2***a*) − δ(**2***b*), reported in Table 3, are positive for the *peri* protons and negative for the *ortho* and *meta* protons. These two series of values are very similar and mainly depend upon the



2*a*



2*b*



2*c*

ortho, *meta*, or *peri* position of the protons relative to the rotating acetyl group. It should be remarked that the shifts induced by an acetyl rotation are larger in *peri* than in *ortho* and that they become negligible in *meta* positions, i.e. they decrease when the distance increases. The effects at *ortho* and *meta* positions for **2** are very similar to those obtained for **1**, viz., Δδ *ortho*: −0.49 (H6) and −0.51 (H5); Δδ *meta*: −0.04 (H6) and −0.02 (H5).

The shift differences induced by the rotation of an acetyl group, applied to each pair of conformers in Table 4, allow the position of the rotating acetyl group to be determined, while nOe experiments have to be performed at low temperature to determine precisely the location of the second acetyl group; these experiments allow the position of the rotating acetyl group to be confirmed.

Structure of **5**

The differences between chemical shifts of conformers **5***a* and **5***b* are large and of opposite sign for H5 (0.65 ppm) and H3 (−0.52 ppm), but small for H7 (−0.08 ppm) and H8 (−0.01 ppm). These results, compared with those of Table 2, point to a *peri* position for H5 and to an *ortho* position for H3 with a 4-acetyl group which changes its orientation from **5***a* to **5***b*. Moreover, the low-field shift observed for H5 in the most populated conformer shows that H5 is *syn* to the carbonyl oxygen (E_4) in **5***a*.

The observation of only two conformers at −80°C, which differ in the orientation of the 4-acetyl group, does not tell anything about the position of the second acetyl group; it can be in position 1 (structure II) or in position 6 (structure IV). In both cases, either the rotation about the N′—CO bond is fast on the nmr time scale at −80°C, or the N′—$COCH_3$ adopts a

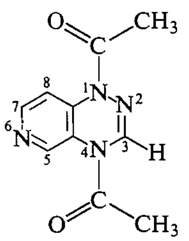
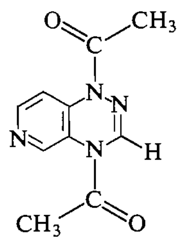
single preferred conformation. The nOe experiments were performed at −80°C. The methyl signals of the 4-acetyl group in **5**a and **5**b are too close (2.36 and 2.37 ppm) to be selectively irradiated. The simultaneous irradiation of both signals (2.365 ppm) leads to an enhancement of the signals of H3 (**5**a), H3 (**5**b), H5 (**5**a), and H5 (**5**b) (Table 5). These results clearly



5a
84% E_1E_4



5b
16% E_1Z_4

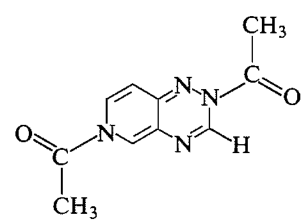
indicate that the temperature is not low enough to avoid spin saturation transfer; however, they confirm that the rotating acetyl group is in the 4-position.

The irradiation of the methyl protons of the second acetyl group (δ = 2.30 ppm), carried out at −80°C, does not lead to any enhancement of the different signals. This absence of an nOe enhancement excludes the presence of a 6-acetyl and can only be explained by a structure in which the *peri* proton H8 is *syn* to the carbonyl oxygen of a 1-acetyl group in **5**a and **5**b. Thus, compound **5** has a structure of type II and is the 1,4-diacetyl-1,4-dihydropyrido[3,4-*e*] *as*-triazine.

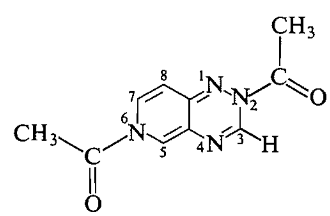
Structure of 6

Due to its poor solubility at low temperature, the spectrum of **6** was recorded at −40°C. The differences Δδ between the two conformers **6**a and **6**b are large and of opposite sign for H5 (−0.47 ppm) and H7 (+0.53 ppm), very small for H8 (+0.08 ppm), and zero for H3. These Δδ values indicate the presence of a 6-acetyl group which changes its orientation from **6**a (E) to **6**b (Z), i.e. H7 is *syn* to the carbonyl oxygen in **6**a. As the structure of **6** is of type III or IV, the second acetyl group can be in a 2- or 4-position. In this case, also, one can suppose that either the rotation about the N′—CO bond is rapid at −40°C, or that the N′—$COCH_3$ adopts a single preferred conformation.

The nOe experiments performed at −40°C by successive irradiation of the methyl signals of the 6-acetyl group in **6**a and **6**b (2.21 and 2.23 ppm) confirm the position of this acetyl, although there is spin saturation transfer (Table 5). The absence of nOe enhancement upon irradiation of the 2.05-ppm signal is consistent with a 2-acetyl group, H3 being *syn* to the carbonyl oxygen in both **6**a and **6**b. Therefore **6** is the 2,6-diacetyl-2,6-dihydropyrido[3,4-*e*] *as*-triazine.



6a
59% E_2E_6



6b
41% E_2Z_6

Structure of 9

The differences between chemical shifts of conformers **9**a and **9**b are much smaller than those observed for **2**, **5**, or **6**. The largest effect is observed for H5 (Δδ = 0.16 ppm), suggesting that a 4-acetyl group changes its orientation from **9**a to **9**b. This is confirmed by the nOe experiments carried out at −90°C. The selective irradiation of the acetyl signals at 1.84 and then at 2.24 ppm leads to an enhancement of the signals of H5 in both **9**a and **9**b. This result supports the presence of a 4-acetyl group and indicates that spin saturation transfer is occurring, i.e. the 4-acetyl group changes its conformation from **9**a (E) to **9**b (Z). On the contrary, the irradiation of the signal at 2.51 ppm does not lead to any nOe enhancement, as could be expected for a 1-acetyl group with an E type conformation, in which the oxygen is *syn* to H8 in **9**a and **9**b. Thus, **9** must be the 1,4-diacetyl-1,4-dihydro-3-phenylpyrido[3,4-*e*] *as*-triazine (structure of type II).

Structure of 10

Derivative **10**, in which the pyridine ring retains its aromatic

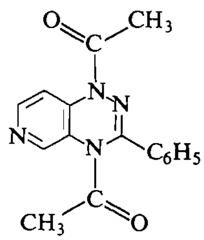
9*a*
60% E_1E_4



9*b*
40% E_1Z_4

character, but which is different from **9**, must have a structure of type I; i.e. it is the 1,2-diacetyl-1,2-dihydro-3-phenylpyrido-[3,4-*e*] *as*-triazine.

Among the four conformers observed at −70°C (Table 6), the population of **10***d* is so weak that the signals of H5, H7, and H8 cannot be assigned with certainty. The complexity of the spectrum and the closeness of the signals did not allow nOe experiments. However, it should be remarked that the presence of four conformers shows that rotation of the acetyl groups is not prevented, even though they are located on vicinal nitrogens.

*Structure of **11***

Results obtained with **11** at −90°C are very similar to those observed with **5**: the differences Δδ between chemical shifts of conformers **11***a* and **11***b* are large and of opposite sign for H5 (0.78 ppm) and H3 (−0.52 ppm), small for H6 (−0.07 ppm), and zero for H8, showing that a 4-acetyl group changes its orientation from **11***a* (E_4) to **11***b* (Z_4). This conclusion is supported by nOe experiments performed at −90°C. Simultaneous irradiation of both methyl signals of the 4-acetyl group in **11***a* and **11***b* (2.525 ppm) leads to an enhancement of the signals of H3 (**11***a*), H3 (**11***b*), H5 (**11***a*), and H5 (**11***b*) (Table 5).

No enhancement is observed when irradiating the methyl signal of the second acetyl group (δ = 2.43 ppm), i.e. this acetyl, located in a 1-position, adopts a single preferred conformation in which the *peri* proton H8 is *syn* to the carbonyl oxygen.

Thus compound **11** is the 1,4-diacetyl-1,4-dihydropyrido-[4,3-*e*] *as*-triazine.

Discussion

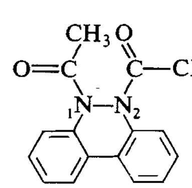
Results obtained in the course of this work indicate that low temperature ^{1}H nmr spectra are a powerful tool for determining the structure and conformation of various *N,N′*-diacetyl derivatives of dihydropyridotriazines. The location of a rotating acetyl group may be safely deduced from the difference between chemical shifts of the corresponding conformers. The shifts induced by an acetyl rotation mainly depend upon the position of a particular proton relative to the rotating acetyl group, and decrease from *peri* to *ortho* and to *meta* positions. When an acetyl group adopts a single preferred conformation, nOe experiments have to be performed at low temperature in order to indicate its precise position and its favoured conformation.

Several results deserve comment. Only two of the four possible conformers are observed in the low temperature spectra of derivatives **5**, **6**, **9**, and **11**. In each case, the acetyl group which adopts a single favoured conformation is located on a nitrogen atom next to an sp^2 hybridized nitrogen; moreover, the preferred conformation is the same in these four cases, i.e. the methyl group points towards the sp^2 nitrogen atom; the other conformation, in which the carbonyl oxygen would be *syn* to the sp^2 nitrogen, is not observed. This strongly suggests that an electrostatic repulsion between the lone pair of the sp^2 nitrogen and the negatively charged carbonyl oxygen disfavors such a conformation.

Compound **9**, which bears a phenyl in the 3-position, has a particular behavior as the shifts induced by rotation of the 4-acetyl group are much smaller than those observed for **5**, **6**, and **11**. This suggests that a steric hindrance, due to the presence of the 3-phenyl group, induces a distortion of the molecule resulting in an increased distance between H5 and the 4-acetyl group. Such a deformation would also explain that the nOe enhancements observed for **9** are smaller than those determined for the analogous structure **5**, as these effects decrease with the sixth power of the distance.

Solid-state investigations by X-ray crystallography have shown that compounds with a 1,4-diacetyl-1,4-dihydropyrazine structure (2, 7) adopt a boat conformation in which the two nitrogen atoms lie above the plane determined by the four carbon atoms. It seems likely that the triazine ring in **9** is similarly in a boat shape and that the presence of the 3-phenyl group pushes nitrogen N4 away from the mean plane formed by N2 and the three carbon atoms.

Finally, the existence of the four possible conformers **10***a*, **10***b*, **10***c*, and **10***d* implies the possibility of rotation of each of the two vicinal acetyl groups. The steric hindrance appears as rather small, which suggests that the acetyl groups are quite remote, as previously observed in the case of **12**. The solid



12

state structure of **12** (7) shows that the value of the dihedral angle $\widehat{C(1)N(1)C(2)N(2)}$ is 61°, and the acetyl groups are far enough apart so that they undergo no steric hindrance during their rotation.

Experimental

The ^{1}H nmr spectra were recorded on a Bruker 250 MHz spectrometer, using tetramethylsilane (TMS) as internal standard. The nOe experiments were performed using solutions carefully degassed by three freeze–pump–thaw cycles.

Preparation of 1,4-diacetyl-1,4-dihydro-6,7-dimethylquinoxaline ***2***

The compound was obtained by electrochemical reduction of 6,7-dimethylquinoxaline in acetonitrile in the presence of acetic anhydride according to the procedure used by H. Lund et J. Simonet (8) to prepare 1,4-diacetyl-1,4-dihydroquinoxaline from quinoxaline. Yield 46%; mp 246°C.

*Preparation of 1,4-diacetyl-1,4-dihydropyrido[3,4-*e*] as-triazine* ***5***

A solution of 0.5 g of 1,4-dihydropyrido[3,4-*e*] *as*-triazine (3.75×10^{-3} mol) in 20 mL of acetic anhydride was refluxed for 15 h. Acetic anhydride was evaporated under vacuum and the residue was washed with ethanol, filtered, and crystallized from ethanol–water (50:50); 350 mg (43%); mp 138°C.

*Preparation of 2,6-diacetyl-2,6-dihydropyrido[3,4-*e*] as-triazine* ***6***

To a solution of 0.18 g (3×10^{-3} mol) of acetic acid and 0.3 g (3×10^{-3} mol) of triethylamine in 20 mL of chloroform, at 0°C, was added 0.35 g (2.95×10^{-3} mol) of freshly distilled ethylchloroformate. The mixture was kept at 0°C for half an hour and then 0.3 g (2.23×10^{-3} mol) of 1,4-dihydropyrido[3,4-*e*] *as*-triazine was added. The temperature was then raised to 20°C. After being allowed to stand for $1\frac{1}{2}$ h, 150 mL of water were added. The organic layer was dried over magnesium sulfate and the solvent was evaporated. The residue was washed with ethanol, chloroform, and tetrahydrofuran to give 150 mg of **6** (31%); mp 140°C.

*Preparation of 1,4-diacetyl-1,4-dihydro-3-phenylpyrido[3,4-*e*] as-triazine* ***9***

Compound **8**, prepared according to ref. 4 (1 g), was heated under reflux for 12 h with acetic anhydride (20 mL). The excess acetic anhydride was evaporated and the residue poured into ethanol–water (50:50). The precipitate was filtered and recrystallized from ethanol–water (50:50) to give 1 g (71%) of **9**; mp 148°C.

*Preparation of 1,2-diacetyl-1,2-dihydro-3-phenylpyrido[3,4-*e*] as-triazine* ***10***

Electrolysis of **7** was carried out with the technique described previously (9) at $E = -1.4$ V (sce). The cathodic solution contained 60 mL of CH_3CN, 8 mL of acetic anhydride, 2.2 g of tetrabutylammonium iodide, and 1 g of **7**. During electrolysis a polymeric product precipitated. At the end of electrolysis (2 F/mol) the solution was filtered and the filtrate poured into 500 mL of water. The mixture was neutralized with $NaHCO_3$ and extracted with ether. The extracts were dried over Na_2SO_4 and evaporated. The residue was essentially (nmr spectrum) a mixture of **9** and **10** (25:75). Recrystallization from methanol gave 310 mg (22%) of **10**; mp 146°C.

*Preparation of 1,4-diacetyl-1,4-dihydropyrido[4,3-*e*] as-triazine* ***11***

With the same procedure as in the case of **5**, 0.5 g of 1,4-dihydropyrido[4,3-*e*] *as*-triazine gives 25 mg of **11** (3%); mp 149°C (dec.).

Synthèse d'une α-méthylene-γ-lactone: application des réactifs organiques du sélénium

HELENA MARIA CARVALHO FERRAZ[1] ET NICOLA PETRAGNANI
Instituto de Química, Universidade de São Paulo, C.P. 20780, São Paulo, SP., Brasil

Reçu le 10 août 1984[2]

HELENA MARIA CARVALHO FERRAZ et NICOLA PETRAGNANI. Can. J. Chem. **63**, 3216 (1985).

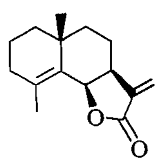
Nous avons développé une nouvelle synthèse de l'α-méthylène-γ-lactone **4**, qui est présente dans de nombreuses substances naturelles sesquiterpéniques.

HELENA MARIA CARVALHO FERRAZ and NICOLA PETRAGNANI. Can. J. Chem. **63**, 3216 (1985).

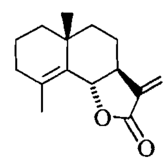
We have developed a new synthetic approach to the α-methylene-γ-lactone moiety **4**, which is present in numerous sesquiterpene natural products.

Introduction

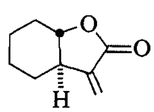
Le groupement α-méthylène-γ-lactone est présent dans de nombreuses substances naturelles telles que les lactones sesquiterpéniques (1). Ce groupement est responsable de l'activité pharmacologique de ces substances (2). L'intérêt de notre groupe de recherche dans ce domaine, tout comme dans la chimie des composés organiques du sélénium, nous a amenés à développer des méthodes sélectives d'obtention d'α-méthylène-γ-lactones bicycliques à jonction *cis* ou *trans*, dont le but est l'utilisation ultérieure dans la synthèse de substances telles que le Frullanolide **1** (3) et l'Arbusculine B **2** (4). Deux synthèses des α-méthylène-γ-lactones **3** et **4** ont déjà été décrites (5) et nous voulons maintenant en présenter une troisième.



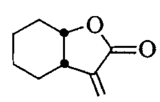
1



2

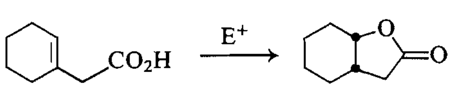


3



4

La formation de lactones par l'addition d'un électrophyle à des acides ou à des ésters β,γ ou γ,δ-insaturés est connue depuis longtemps et sa stéréochimie est bien établie: l'addition à la double liaison est toujours *trans* (6). Ainsi, la lactonisation de l'acide β,γ-insaturé **5**, par exemple, conduit à une jonction *cis* entre les deux cycles.



5

Cette réaction est, donc, d'une grande utilité dans la préparation stéréosélective de *cis*-lactones.

Par ailleurs, l'utilisation de réactifs organoséléniés, soit comme précurseurs de doubles liaisons, soit comme des électrophiles pour la lactonisation, a été dernièrement très explorée (7–9).

Dans un travail antérieur (5) nous avons illustré l'utilisation de l'acide 2-phénylséléno-propanoïque **6** pour la synthèse des α-méthylène-γ-lactones **3** (*trans*) et **4** (*cis*); plus récemment, nous avons employé le même acide **6** pour synthétiser le Frullanolide **1** (10).

$$H_3C—CH(SePh)—CO_2H$$

6

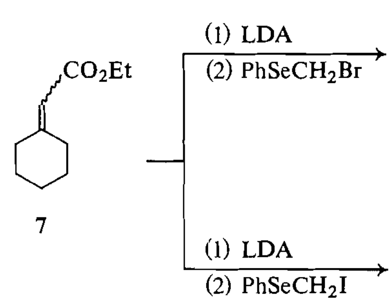
Nous présentons ici une nouvelle synthèse de la *cis*-lactone **4**, dont le précurseur possède le groupement sélénophényle en β du carbonyle, ce qui offre un avantage par rapport à la méthode antérieure: l'élimination du phénylsélénoxyde n'entraîne que la formation d'une double liaison exocyclique.

À partir d'une substance simple telle que la cyclohexanone, nous avons effectué la séquence réactionnelle représenteé dans le schéma 1.

Résultats et discussion

Le cyclohexylidène acétate d'éthyle **7** (11) a été obtenu par la réaction de Wittig entre la cyclohexanone et le carbéthoxyméthylènetriphénylphosphorane, avec un rendement de 80%. Ce produit a été hydrolysé en milieu basique, donnant l'acide cyclohéxylidène acétique **8** (12) avec un rendement de 81%. L'alkylation du dianion de l'acide **8** par le sélénure de bromométhylphényle a fourni 82% du produit **9**.

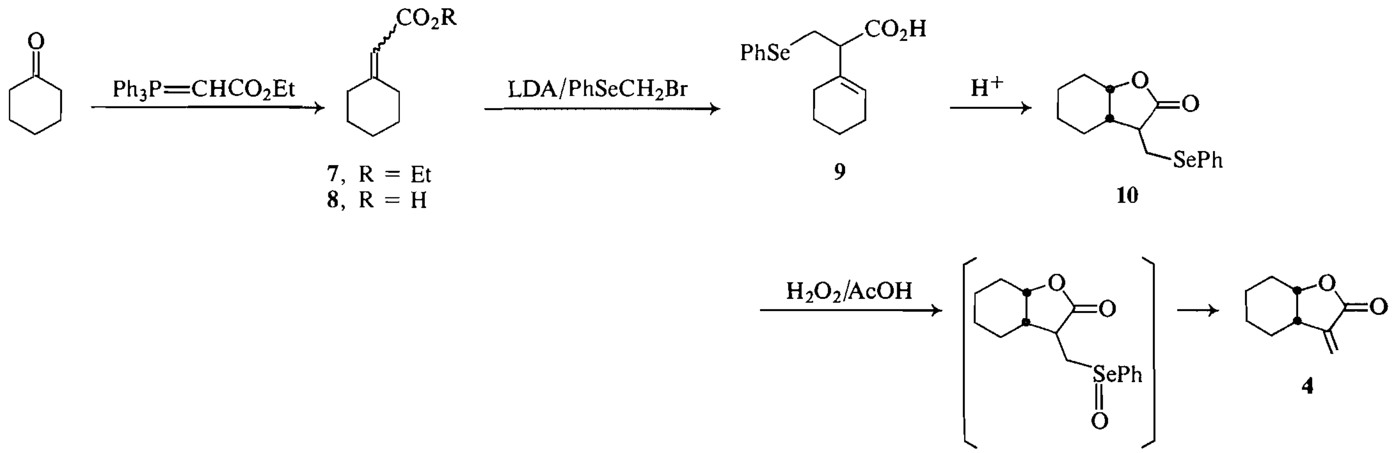
Nous avons éssayé d'inverser l'ordre séquentiel de ces deux dernières étapes, mais nous n'avons pas réussi à alkyler l'ester **7** par le même sélénure; le seul produit obtenu est l'ester β,γ-insaturé **11**. Le remplacement du réactif par le sélénure d'iodométhylphényle a donné l'alkylation, mais le rendement de la réaction n'a été que de 55%.



Pour l'étape suivante—lactonisation de **9** en milieu acide—plusieurs réactifs ont été employés (H_2SO_4, $HClO_4$, H_3PO_4, AcOH, acide *p*-toluènesulfonique). Dans tous les cas, nous

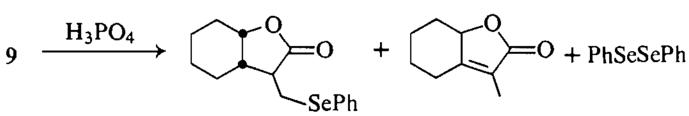
[1] Auteur à qui adresser la correspondance.

[2] Revision reçue le 28 mars 1985.



SCHEME 1

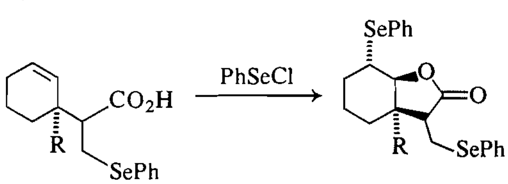
avons observé la formation d'un mélange complexe de substances, parmi lesquelles on a pu constater, outre le produit principal **10**, la présence en faible quantité de la lactone **12** (avec la double liaison endocyclique) et du disélénure de diphényle. Le meilleur résultat a été obtenu par traitement de **9** avec l'acide phosphorique, qui a produit 50% de la lactone attendue **10**.



10 **12**

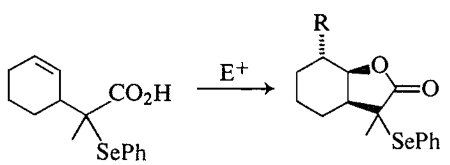
La formation de la lactone **12**, aussi bien que du disélénure, montre que la liaison C—Se s'est rompue; cependant, nous n'avons pas de données suffisantes pour suggérer le mécanisme de cette réaction indésirable.

Il faut bien noter que les réactions de lactonisation des acides γ,δ-insaturés portant le groupement sélénophényle n'offrent pas toujours de bons rendements (5, 13), comme on peut observer dans les exemples ci-dessous (nous n'avons trouvé dans la litérature aucun cas de lactonisation d'un acide sélénié β,γ-insaturé).



(Réf. 13)

R = H, 70%
R = Me, 61%



(Réf. 5)

E = I, 73%
E = H, 48%

Finalement, l'oxydation (14) de **10** a fourni l'α-méthylène-γ-lactone **4** avec un rendement de 81%.

En ce moment, nous sommes en train d'appliquer une variante de la séquence réactionnelle décrite ici aux synthèses du Frullanolide et de l'Arbusculine B.

Partie expérimentale

Les spectres ir ont été mesurés avec un spectrophotomètre Perkin–Elmer 457A. Les spectres de rmn ont été enregistrés sur un appareil Varian T-60 à 60 MHz et dans le CCl_4. Les analyses par chromatographie en phase gazeuse ont été effectuées sur un appareil Varian 2800 à ionisation de flamme; le gaz vecteur est l'azote et la colonne utilisée, la FFAP (10%) Chromosorb W 60–80 mesh. Les analyses (C, H) ont été effectuées par le Laboratoire de Microanalyse de l'Institut de Chimie de l'Université de S. Paulo.

Cyclohéxylidène acétate d'éthyle 7

Une solution de la cyclohexanone (29,4 g, 0,3 mol), du carbéthoxymethylènetriphénylphosphorane (21,0 g, 0,06 mol) et de l'acide benzoïque (2 g) dans le benzène anhydre (70 mL) est chauffée au reflux pendant 48 h, sous une atmosphère d'azote. Après la distillation du benzène, on ajoute de l'hexane et le triphenylphosphinoxide formé est filtré. La solution est lavée successivement avec une solution saturée de $NaHCO_3$, une solution dilutée de HCl et une solution saturée de NaCl. Le solvant et l'excès de la cyclohexanone sont éliminés par distillation; le résidu est distillé sous vide. Rendement: 8,1 g (80%); p.e. 116°C/30 Torr (1 Torr = 133,3 Pa).

Acide cyclohexylidène acétique 8

Une solution de l'ester **7** (5,0 g, 0,03 mol) dans l'éthanol (30 mL) est traitée par du NaOH (15 mL d'une solution à 30%). Au bout de 3 h à reflux, le mélange réactionnel est acidulé par une solution concentrée de HCl et la solution aqueuse est extraite par l'éther et sechée sur Na_2SO_4. Le résidu obtenu après l'élimination du solvant est recristallisé à partir du mélange acétate d'éthyle – hexane. Rendement: 3,4 g (81%); p.f. 90–91°C (lit. (11) p.f. 90–92°C).

Acide 3-phénylséléno-2-(1'-cyclohexényl)-propanoïque 9

À une solution de LDA (4,4 mmol) dans le THF anhydre (4,5 mL) à 0°C et sous une atmosphère d'azote, on ajoute une solution de l'acide **8** (0,28 g, 2 mmol) dans le THF (2 mL). Au bout de 1 h à 45°C, le mélange réactionnel est refroidi à 0°C et est additionné d'une solution du sélénure de bromométhylphényle (0,60 g, 2,4 mmol) dans le THF (2 mL). Après 2 h à 40°C, le mélange est acidulé par une solution concentrée de HCl, extrait par l'éther et séché sur Na_2SO_4. Le solvant est évaporé et le résidu est distillé sous vide (tube à boules). Rendement: 0,51 g (82%); p.e. 140°C/0,005 Torr; ir (Nujol) ν_{max}: 1705, 760, 730, 685 cm^{-1}; ^1H rmn (CCl_4) δ: 11,1 (s, 1H), 7,0–7,6 (m, 5H), 5,5–5,8 (m, 1H), 2,8–3,4 (m, 3H), 1,2–2,3 ppm (m, 8H). *Anal.* calc. pour $C_{15}H_{28}O_2Se$: C 58,27%, H 5,87%; trouvé: C 58,11%, H 5,78%.

*Lactone de l'acide 3-phenylséléno-2-(*cis*-2'-hydroxycyclohexyl)-propanoïque 10*

On traite l'acide **9** (0,124 g, 0,4 mmol) par de l'acide phosphorique (0,5 g) pendant 6 h à 110°C. Le mélange réactionnel est additionné d'eau (5 mL) et la solution aqueuse est extraite par $CHCl_3$. Par chromatographie sur gel de silice (par élution au mélange hexane–benzène – acétate d'éthyle, 5:3:2) on isole la lactone **10**, qui ne cristallise pas et qui est donc distillée sous vide (tube à boules). Rendement: 0,061 g (50%); p.e. 125°C/0,005 Torr; ir (film) ν_{max}: 1770, 740, 690 cm^{-1}; ^{1}H rmn (CCl_4) δ: 7,0–7,7 (m, 5H), 4,2–4,5 (m, 1H), 1,0–3,1 ppm (m, 12H). *Anal.* calc. pour $C_{15}H_{18}O_2Se$: C 58,27%, H 5,87%; trouvé: C 58,50%, H 5,69%.

*Lactone de l'acide 2-(*cis*-2'-hydroxycyclohexyl)-propénoïque 4*

Une solution de la lactone **10** (0,05 g, 0,16 mmol) et de l'acide acétique (0,03 mL) dans le THF (1 mL) est traitée par H_2O_2 à 30% (0,15 mL) pendant 30 min à 0°C. Le mélange réactionnel est additionné d'une solution saturée de $NaHCO_3$ (3 mL) et extrait par l'éther. La solution est lavée à l'eau, puis par une solution saturée de NaCl et enfin sechée sur Na_2SO_4. Le résidu obtenu après l'évaporation du solvant est chromatographié sur gel de silice (élué par le mélange hexane – acétate d'éthyle 1:1). Rendement: 0,02 g (81%). Les spectres de ^{1}H rmn et de ir sont identiques à ceux d'un échantillon preparé par une méthode différente (15).

Solvent-induced conformational changes in benzyl fluoride. Long-range C,F; H,H; H,F spin–spin couplings

TED SCHAEFER, JAMES PEELING,[1] AND RUDY SEBASTIAN
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received April 15, 1985

TED SCHAEFER, JAMES PEELING, and RUDY SEBASTIAN. Can. J. Chem. **63**, 3219 (1985).

The ^{1}H and ^{19}F nmr spectra of benzyl fluoride, although very tightly coupled at 300 MHz, are analyzed for dilute CS_2 and acetone solutions. ^{13}C, ^{19}F spin–spin coupling constants for benzyl fluoride in a series of solvents are also measured. Geometry-optimized STO 3G MO computations on benzyl fluoride indicate a small twofold barrier to rotation about the exocyclic C—C bond in the gas phase. All the long-range couplings between ^{19}F and ring protons or carbon-13 nuclei and between methylene and ring protons are consistent with the conclusion that the barrier to internal rotation in benzyl fluoride is small and that the conformation in which the C—F bond lies in a plane perpendicular to the benzene plane is stabilized by 2 kJ/mol in going from CS_2 to DMSO or acetone solutions. The solvent dependence of the internal barrier may account for the diversity of conformational conclusions in the literature. Furthermore, it is clear that the internal barrier will depend on the presence of substituents at any site in the ring.

TED SCHAEFER, JAMES PEELING, and RUDY SEBASTIAN. Can. J. Chem. **63**, 3219 (1985).

Même si les spectres rmn du ^{1}H et du ^{19}F du fluorure de benzyle sont intimement couplés à 300 MHz, on a pu les analyser pour des solutions diluées dans le CS_2 ou dans l'acétone. On a aussi mesuré les constantes de couplage spin–spin ^{13}C–^{19}F dans le fluorure de benzyle en solution dans divers solvants. Des calculs d'orbitales moléculaires STO 3G, optimisés pour la géométrie, effectués sur le fluorure de benzyle indiquent que, en phase gazeuse, il existe une légère barrière binaire à la rotation autour de la liaison exocyclique C—C. Toutes les constantes de couplage à longue distance entre le ^{19}F et les protons ou les noyaux ^{13}C du cycle ainsi que entre les protons méthyléniques et ceux du cycle sont en accord avec la conclusion selon laquelle la barrière à la rotation interne, dans le fluorure de benzyle, est petite et que la conformation dans laquelle la liaison C—F se trouve dans un plan perpendiculaire à celui du benzène est stabilisée par environ 2 kJ/mol lorsqu'on passe de solutions dans le CS_2 à des solutions dans le DMSO ou dans l'acétone. L'influence du solvant sur la barrière interne explique vraisemblablement la diversité des conclusions conformationnelles que l'on retrouve dans la littérature. De plus, il est clair que la barrière interne dépendra de la présence de substituants sur divers sites du cycles.

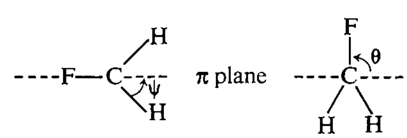
Introduction

The study of solvent effects on conformational equilibria has a long history (1, 2). The common observation that the more polar conformer becomes more stable in polar solvents is rationalized by reaction field theory (2, 3), although the model usually overestimates the degree of stabilization. Of course, the solvent is not a dielectric continuum and the origin of solvent effects must lie in the minutiae of intermolecular interactions (4), including electrostatic interactions as well as nonelectrostatic packing effects. Recent theoretical methods involving molecular dynamics and Monte Carlo statistical mechanics methods have had remarkable success in assessing the nature of the solvent-induced changes in conformational equilibria (4), although computational requirements have restricted the number of such calculations.

Experimentally, solvent effects on conformational distributions have been most often investigated by nuclear magnetic resonance, Raman, and infrared spectroscopies. These techniques suffer from various disadvantages. For example, with the latter two methods energy differences are usually obtained from the temperature dependence of equilibrium constants (assuming correct assignments of vibrational bands) under the assumption of temperature independent enthalpies. In principle, the latter assumption is surely incorrect in solution.

The nmr technique often uses angle dependent spin–spin vicinal couplings to assess energy differences between conformers, for instance in ethane derivatives (2). However, the approximation of an equilibrium between two or more rigid (*gauche* and *trans*) conformations (*n*-site model) is often made. Because conformations are not rigid, this model can lead to severe errors in the derived energy differences (5).

When the barrier to interconversion between the conformers is smaller than thermal energies, such an approach becomes useless. For example, benzyl fluoride can be thought to exist in two possible conformations, **1** and **2**. If the free energy difference between **1** and **2** were large, then a spin–spin coupling constant, J, known for **1** and **2**, could be employed as a straightforward indicator of this energy difference, that is, $\Delta G^0 = -RT \ln (p(\mathbf{1})/p(\mathbf{2}))$, and the observed J would then be given by $J(\mathbf{1})p(\mathbf{1}) + J(\mathbf{2})p(\mathbf{2})$ where $p(\mathbf{1}) + p(\mathbf{2})$ is unity.



1 $\theta = 0°$, $\psi = 60°$ **2** $\theta = 90°$, $\psi = 30°$

However, if the potential hindering rotation is rather flat, then the molecule samples all θ values with comparable probability magnitudes and a 2-site treatment is invalid. It becomes necessary to know the complete θ dependence of J *and* the functional form of the potential governing the internal rotation if a satisfactory treatment of the solvent dependence of the conformational equilibrium is to be presented. A measurement of J then yields the magnitude of the potential function.

For example, for ethylbenzene derivatives (6), both ^{6}J(H,H), the coupling over six bonds between the methylene and *para* ring protons, and ^{5}J(H,C), the coupling involving the *para* ^{13}C

[1]Permanent address: University of Petroleum and Minerals, Dhahran, Saudi Arabia.

nucleus, depend on $\sin^2\psi$ (replace F with CH_3 in **1** and **2**). Both couplings, when combined with a hindered rotor model (7), demonstrate that **2** is the stable conformer in solution and that the barrier, assumed twofold, is 5.2 kJ/mol.

Returning to benzyl fluoride, a rather extensive geometry optimization procedure at the STO 3G level of *ab initio* molecular orbital theory (see Experimental) yields the twofold potential V_2 (kJ mol^{-1}) = $(1.64 \pm 0.04) \sin^2 \theta$ at the 95% confidence level. Alternatively, the computed values can be fit to a potential curve which includes a fourfold component, $V = (1.61 \pm 0.05) \sin^2 \theta + (0.05 \pm 0.04) \sin^2 2\theta$. For the isolated molecule, therefore, the computation implies a flat, essentially twofold, internal rotational potential favoring **1**. The preference of an in-plane C—F bond is possibly related to an electrostatic preference, the C^+—F^- dipole lying near the *ortho* C—H^+ dipole (calculated net charges on fluorine and the *ortho* hydrogen are +0.06 and −0.15 in units of electron charge for **1**). An analogous eclipsing conformation is found to be most stable in 3-fluoropropene (8).

Now, on the assumption that the shape of the internal potential remains twofold in solution, it seems sensible, however, that its magnitude will change in the presence of solvent molecules because of packing effects, if for no other reason, since θ can adjust easily to optimize intermolecular interactions (4). In terms of a reaction field model, **2** might well be favored over **1** in polar solvents. The dipole moment of benzyl fluoride is 1.77 ± 0.05 D in benzene at 298 K (9). CNDO MO computations give accurate dipole moments for organic fluorine compounds (10) and yield 1.73 D for **1** and 1.86 D for **2** (Experimental). In terms of the reaction field model, **1** and **2** are stabilized by 1.09 and 1.30 kJ/mol, respectively, on going from the vapor to CS_2 solution (dipole approximation). If the polarizability of the solvent is taken into account, these numbers increase by a factor of 1.25. In acetone solution, **2** is more stabilized than **1** by 0.46 kJ/mol relative to the vapor. In other words, the simplest model suggests stabilization of **2** relative to **1** by only about 0.25 kJ/mol in passing from CS_2 to acetone solution. Combined with the STO 3G MO results, one has the prediction that the twofold barrier should be as low as 1.2 kJ/mol in acetone, **1** stable.

Numerous investigations of the conformational preferences of benzyl fluoride and its derivatives vary widely in their conclusions. Confining the discussion to benzyl fluoride itself, a combined gas phase electron diffraction and molecular mechanics investigation implied a preferred conformation with θ near 50 or 60°, together with a barrier to rotation of about 1.7 kJ/mol (11). A STO 3G MO calculation was also done. The geminal proton coupling constant in $CDCl_3$ solution was interpreted to mean that either θ was 54° or that a nonplanar conformation was preferred with a small barrier to rotation (11).

CNDO/2 and PCILO computations suggest that **1** is 12.3 kJ/mol more stable than **2** (12) and extensive measurements of ^{2}H relaxation times on partially and fully deuterated benzyl fluoride by the same group (13) are interpreted to yield an internal barrier of 11.3 kJ/mol in the neat liquids. It may be relevant that the temperature dependence of the viscosity of the neat liquid indicates an activation energy of 11.3 kJ/mol. In acetone and methanol solutions (14), the internal barriers were found to be 7.6 and 10.7 kJ/mol, respectively, from ^{2}H measurements.

The temperature dependence of the ^{19}F nmr chemical shifts of benzyl fluoride and some of its derivatives in acetone solution, together with MO calculations, was taken to mean (15) that **2** is most stable, by 1.7 kJ/mol.

TABLE 1. Values of ^nJ(C,F) in Hz for benzyl fluoride in a number of solvents at 300 K

Solvent^{a,b}	$-^1J$	^2J	^3J	$\lvert ^4J \rvert$	$^5J^{b,c,d}$
CS_2 (2.3)	170.52	17.50	5.93	0.91	2.76
CCl_4 (3.4)	169.66	17.52	5.98	0.92	2.81
C_6D_6 (3.3)	167.28	17.27	5.89	1.13	2.92
$CDCl_3$ (3.0)	166.19	17.10	5.87	1.31	3.09
Neat	165.44	16.98	5.78	1.33	3.08
CD_3OD (1.0)	164.53	16.96	5.79	1.39	3.13
$(CD_3)_2$=O (2.8)	163.72	16.90	5.75	1.43	3.15
DMSO (2.5)	161.92	16.62	5.68	1.53	3.24_5

^{a}Concentrations in mol% are given in parentheses.
^{b}All couplings are reproducible to better than 0.02 Hz in all cases. For example ^5J(C,F) in DMSO solution is 3.245 ± 0.005 Hz, as judged from repeated measurements.
^{c}^2J, ^3J, and ^5J are positive; see Experimental.
^{d}For benzotrifluoride, ^3J, ^4J, and ^5J in acetone and CS_2 solutions are 3.92(5), 3.85(1); 0.0, 0.0; and 1.39(3), 1.37(1) Hz, respectively. In $CDCl_3$ and CS_2 solutions ^1J is 272.1, 272.23 Hz, respectively, and ^2J is 32.2(1), 32.28(1) Hz. These data suggest minimal intrinsic solvent perturbations of sidechain ^{19}F nuclei and aromatic ^{13}C nuclei.

An interesting application of the stereospecific coupling over five bonds betwen ^{19}F and the ^{13}C nucleus in the *para* position, ^5J(C,F), was taken to imply that, in chloroform solution, there exists essentially free rotation of the fluoromethyl group in benzyl fluoride (16).

In view of this diversity of conclusions concerning the internal rotational potential in benzyl fluoride, part of which may well be caused by solvent effects, it seems sensible to measure the solvent dependence of some molecular properties of benzyl fluoride. For this purpose ^5J(C,F) was chosen and this paper reports on its solvent dependence. Furthermore, the ^{1}H and ^{19}F nmr spectra in CS_2 and acetone solutions at 300 MHz, although extremely highly coupled, are analyzable. They yield some H,H and H,F couplings that also depend on conformation.

Experimental

Dilute solutions of benzyl fluoride from Pierce Chem. Co. were prepared in a number of solvents (see Table 1). Proton decoupled ^{13}C nmr spectra were taken on an AM300 Bruker spectrometer at a probe temperature of 300 K. Typically, 64 FIDs were accumulated for each spectral region, e.g. a width of 400 Hz into 16K, with an acquisition time of 20.48 s. Two or more sets of spectra were obtained. A dilute solution of 3,5-dichlorobenzyl fluoride was used to determine the signs of ^2J(C,F), ^3J(C,F), and ^5J(C,F) relative to ^2J(H,F) by ^{13}C{^{1}H} experiments. Decoupling (17) of the methylene protons for a given spin state of ^{19}F caused characteristic collapses in the *ipso, para*, and *ortho* ^{13}C multiplets.

A 2.3 mol% solution of benzyl fluoride in CS_2, containing 10.0 mol% of C_6D_{12}, 0.5 mol% TMS, and a drop of C_6F_6 was transferred to a 5-mm od nmr sample tube. The solution was degassed by a number of freeze−pump−thaw cycles and the tube was then flame-sealed under vacuum. A similar procedure was applied to a 2.8 mol% solution of benzy fluoride in acetone-d_6, also containing some TMS and C_6F_6.

The ^{1}H and ^{19}F nmr spectra were accumulated at a probe temperature of 300 K on the AM300 instrument. Wide sweepwidth survey spectra were obtained in order to reference the spectra with respect to TMS and C_6F_6, and to obtain the locations of the aromatic and side-chain proton peaks. Each region was examined in detail, with sweep-width and data region adjusted to give acquisition times of approximately 40 s. Four to sixteen scans were acquired. Zero filling to twice the original data region was done before transforming the FIDs using a small amount of gaussian multiplication. Line widths at half height

TABLE 2. ^1H and ^{19}F spectral parameters for benzyl fluoride in CS_2 and acetone-d_6 solutions at 300 K

Parameter	Value		Parameter	Value	
	CS_2[a]	Acetone[b]		CS_2[a]	Acetone[b]

$^4J_{35}$	1.371(1)	1.378(3)	rms deviation	0.013_7[f]	0.013_7[g]
$^5J_{25}$	0.606(1)	0.619(1)			

[a]2.3 mol% containing some internal TMS, C_6D_{12}, and C_6F_6.
[b]As in *a* but 2.8 mol% and no C_6D_{12}.
[c]The ^1H shifts are in Hz at 300.135 MHz to low field of internal tetramethylsilane, TMS.
[d]The ^{19}F shifts are in Hz at 282.363 MHz to high field of internal C_6F_6 (same probe).
[e]The numbers in parentheses are the standard deviations in the last figure from the analysis with the program NUMARIT.
[f]There are no correlations as large as 0.3, but $^4J(H,CH_2)$ and $^3J_{34}$ correlate with −0.297.
[g]There are some substantial correlations, namely, −0.576 for $^5J(H,CH_2)$ and $^4J(H,CH_2)$; −0.473 for $^4J(H,F)$ and $^5J(H,F)$. Note that the shift difference between *ortho* and *meta* protons is just under 3 Hz.

were approximately 0.04 Hz.

STO 3G MO computations (18) on benzyl fluoride employed the program MONSTERGAUSS (19) and an Amdahl V8 system. Geometry optimization of all bond angles and bond lengths was done at 15° intervals for $0 \leq \theta \leq 90°$ with the proviso that the phenyl carbon framework remain a regular hexagon. INDO MO FPT calculations (20, 21) of various coupling constants in benzyl fluoride utilized the same computer, as did CNDO/2 computations (22) of dipole moments.

Results and discussion

Spectral analyses

$^nJ(C,F)$ could be measured as splittings in the ^1H decoupled ^{13}C nmr spectra, and values appear in Table 1. Two or more sets of measurements on a given sample gave an average error of less than 0.02 Hz. The partial decoupling experiments show that $^2J(C,F)$, $^3J(C,F)$, and $^5J(C,F)$ have the same sign as $^2J(H,F)$, which is positive (23). $^5J(C,F)$ is +1.98(2) Hz and $^3J(C,F)$ is +6.86(1) Hz in 3,5-dichlorobenzyl fluoride in CS_2 solution. Comparison with the numbers in Table 1 strongly implies the same signs for benzyl fluoride.

A full analysis of the ^1H and ^{19}F nmr spectra of benzyl fluoride in CS_2 and acetone solutions was performed with the computer program NUMARIT (24). The ensuing spectral parameters are found in Table 2. Although the ring proton shift range in CS_2 solution is less than 38 ppb, the spectral parameters are known with same precision (see explanatory notes in Table 2). Figure 1 displays the observed and calculated ^1H nmr spectra of the methylene protons in acetone solution. Figure 2 shows the calculated and observed ^1H nmr spectra of the aromatic protons for the CS_2 solution.

Coupling mechanisms

INDO MO FPT computations of the contact contribution to nuclear spin–spin coupling constants, J, do not normally agree quantitatively with experiment, due to the parameterization of the semiempirical approach, to neglect of noncontact contributions, and to deviations of the assumed from the actual geometry of the molecule (25). However, often the qualitative and

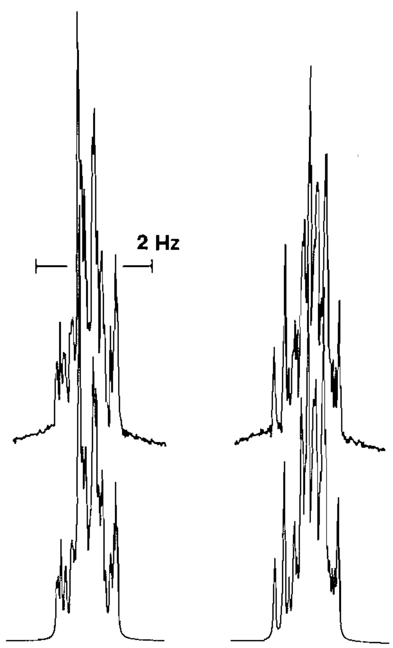

FIG. 1. The methylene proton nmr spectrum of a 2.8 mol% solution of benzyl fluoride in acetone-d_6 at 300.135 MHz and 300 K is compared to the spectrum calculated with the spectral parameters in Table 2. The computed spectrum assumes a line width at half height of 0.03 Hz.

sometimes even the quantitative conformational dependence of J is reproduced by such calculations, particularly for long-range couplings. For example, $^6J(H,H)$ in toluene depends on $\sin^2\psi$ (see **1** or **2**) and its value at $\psi = 90°$ is computed for a standard geometry as −1.22 Hz (26), in good agreement with an experimentally derived value of −1.20 Hz (27). Rather poorer agreement with experiment is obtained for $^6J(H,F)$ in *p*-fluorotoluene (28), yet its functional dependence on θ is most likely reproduced qualitatively (26, 28).

An extensive discussion of $^nJ(C,F)$ in benzotrifluoride (29)

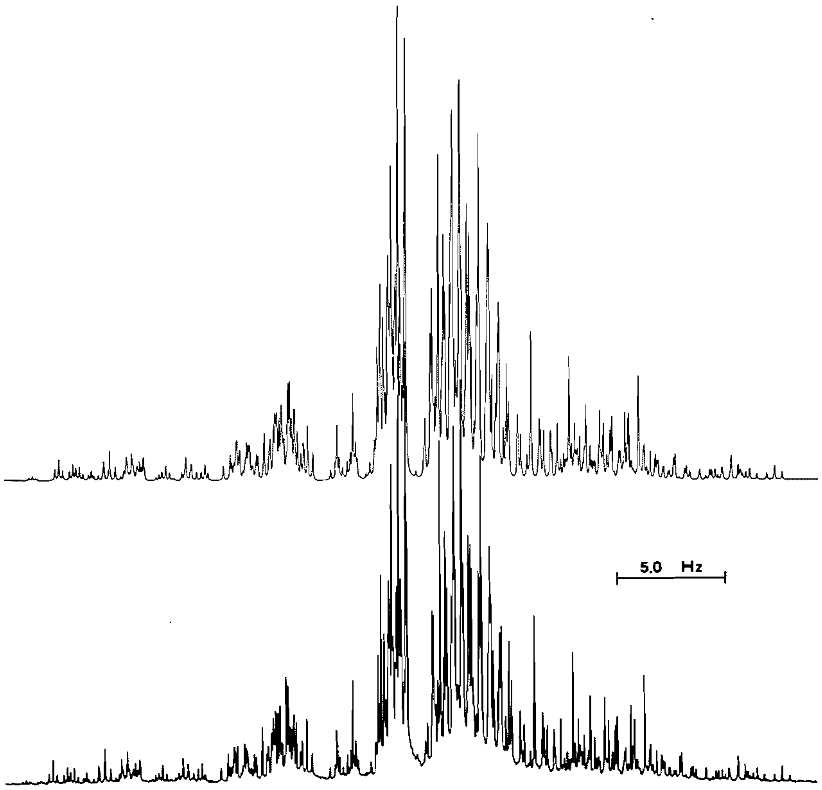

FIG. 2. The aromatic ring proton nmr spectrum of a 2.3 mol% solution of benzyl fluoride in CS_2/C_6D_{12}/TMS solution at 300.135 MHz and 300 K is compared to the spectrum calculated with the parameters in Table 2. The widths at half height of the observed peaks are about 0.04 Hz.

demonstrates the qualitative reliability of INDO MO FPT computations of many of these parameters. The calculated θ dependence of ^5J(C,F) and ^4J(C,F) can be used to rationalize the absence of ^4J(C,F), for example, as a cancellation of σ and $\sigma-\pi$ components of opposite sign; the former is dependent on $\sin^2(\theta/2)$ and the latter on $\sin^2\theta$.

In view of these remarks, computations of various couplings in benzyl fluoride were performed so as to have indications of their θ and ψ dependence. Because their absolute values are probably not very reliable, the results are not tabulated here. Their salient characteristics can be summarized as follows.

For the STO 3G MO geometry-optimized structure, in which the C—F bond length is 138.5 pm, the exocyclic C—C bond length is 154.1 pm, and the CCF bond angle is 111.9°, the θ dependence of ^6J(H,F) can be written as eq. [1]. The $\sigma-\pi$ mechanism is indicated by this equation, just as it is for ^6J(H,H)

$$[1] \quad ^6J(\mathrm{H,F})\ (\mathrm{Hz}) = -0.061 \pm 0.006 - 2.373 \pm 0.009 \sin^2\theta$$

in toluene (26). The angle-independent term may well be an artifact of the computation. As a $\sigma-\pi$ coupling, the computed ^6J(H,F) will depend strongly, probably exponentially (30), on the C—C distance. Thus, for a standard geometry (31), its computed values (32) can be written as eq. [2]. In other words, the value of ^6J(H,F) at $\theta = 90°$ cannot be certain. What is fairly

$$[2] \quad ^6J(\mathrm{H,F})\ (\mathrm{Hz}) = -0.06 \pm 0.01 - 3.12 \pm 0.01 \sin^2\theta$$

certain, however, is that the magnitude of ^6J(H,F) will increase as conformation **2** increases in stability relative to **1**. Again, because ^6J(H,H) is undoubtedly a $\sigma-\pi$ coupling (7) and because it depends on $\sin^2\psi$, its magnitude will decrease as **2** becomes more stable. It is known that the maximum magnitude of ^6J(H,H) depends on the electronegativity of the α-substituent (7), its value for benzyl fluoride not being certain. For a standard geometry, INDO methods suggest it as about -1.1 Hz (32). ^4J(H,H) and ^4J(H,F) will also contain large $\sigma-\pi$ components, whereas ^5J(H,H) and ^5J(H,F) probably consist of a $\sigma-\pi$ part together with a σ component of comparable magnitude and dependent (33) on $\sin^2(\psi/2)$ or $\sin^2(\theta/2)$.

Turning to ^nJ(C,F), the computations on the optimized geometry imply eq. [3] for ^5J(C,F) and therefore that it is a $\sigma-\pi$ coupling. The analogous ^5J(H,C) in toluene has been shown to

$$[3] \quad ^5J(\mathrm{C,F})\ (\mathrm{Hz}) = 0.26 \pm 0.04 + 7.73 \pm 0.07 \sin^2\theta$$

be a $\sigma-\pi$ coupling (6), in agreement with INDO MO FPT computations. Also, ^5J(C,F) in benzotrifluoride can be rationalized as a $\sigma-\pi$ coupling (29), although its magnitude is computed as too large. Similar remarks apply to eq. [3] but the sign agrees with that in Table 1.

^4J(C,F) in benzyl fluoride is computed as small and positive near $\theta = 0$ and 180°, becoming large and negative at 90°. In other words, it is predicted as a predominant $\sigma-\pi$ coupling. ^3J(C,F) is calculated to be large and positive at $\theta = 0$ and 180°, and decreasing for other values of θ, having a minimum near $\theta = 80°$. Its computed behavior in benzotrifluoride has been discussed in detail (29). A similar treatment could be done for ^3J(C,F) in benzyl fluoride but would not add to the present paper, except to note that its θ dependence resembles a modified Karplus behaviour. ^2J(C,F) is computed to become more negative as θ increases, as is ^1J(C,F). Both of these couplings may well contain some noncontact contributions (29).

In the next section it is pointed out that all the couplings in Tables 1 and 2 (except ^1J(C,F)), when compared with the computed trends, strongly indicate an increase in stability of **2** in the more polar solvents.

Conformational perturbations by solvent

(i) *Qualitative trends*

Qualitatively, it is clear from the long-range couplings that **2** (C—F bond in a plane perpendicular to the benzene plane) is increasingly favored over **1** as the dielectric constant of the solvent increases. Thus, ^5J(C,F) increases from 2.76 Hz in CS_2 to 3.25 Hz in DMSO solutions, as expected for a predominantly $\sigma-\pi$ coupling. If ^3J(C,F) displays a Karplus type behavior with a minimum near $\theta = 90°$ (as it apparently does in benzotrifluoride (29)), then its decrease in the polar solvents is reasonable. Again, ^6J(H,F) is larger in magnitude in acetone than in CS_2 solution, while ^6J(H,H) displays the opposite behavior (an increase in θ for the C—F bond implies a decrease in ψ). ^4J(H,F) and ^4J(H,H) display analogous trends, as expected if they are also mainly $\sigma-\pi$ couplings (26, 34).

^4J(C,F) in Table 1 increases in magnitude in the polar solvents. If it is negative as computed and is dominated by a negative $\sigma-\pi$ component, then this observation is also consistent with an increased stability of **2** in polar solvents. ^2J(C,F) decreases in magnitude in the polar solvents and is computed to decrease as **2** becomes preferred; ^2J(C,F) is large and positive in benzotrifluoride (29) and is very likely positive in benzyl fluoride.

Finally, ^1J(C,F) is no doubt negative, no positive values being known. It increases by about 9 Hz in going from CS_2 to DMSO solutions. The INDO MO FPT results suggest that ^1JC,F) *decreases* as θ increases. This single inconsistency between computation and observation may well arise from noncontact contributions to the coupling. Consequently, the theoretical result is not taken as evidence against a stabilization of **2** in the polar solvents.

(ii) *Estimates of changes in* V_2

The aim of this section is to demonstrate that the internal barrier is small in benzyl fluoride in solution and that it changes by about 2 kJ/mol in passing from CS_2 to DMSO solutions. In line with the geometry optimized STO 3G MO computations, a twofold potential barrier is assumed in the following discussion. A vanishing barrier would imply that the expectation values of $\sin^2\theta$ and θ are 0.5 and 45°, respectively.

Because of the uncertainties in the extremes of the $\sigma-\pi$ couplings, namely, their magnitudes when the C—H or C—F bonds are twisted by 90° out of the benzene plane, the following approach turns out to be useful. The various conformational conclusions in the literature are taken as reference points for V_2, the solvent-induced changes in V_2 are then deduced from ^5J(C,F), and a comparison with ^6J(H,H) and ^6J(H,F) is made in an attempt to find the most consistent set of data.

Assume that ^5J(C,F) is indeed proportional to $\sin^2\theta$ in benzyl fluoride. On the basis of ^5J(C,F) values in some model compounds (16), it is suggested that V_2 vanishes in $CDCl_3$ solution. Because ^5J(C,F) is 3.09 Hz (Table 1), $^5J_{90}$ follows as 6.18 Hz. Then $\langle\sin^2\theta\rangle$ in the other solvents follows as in Table 3. Tables (7, 35) of $\langle\sin^2\theta\rangle$ as a function of temperature and internal barrier yield the V_2 numbers in Table 3. In CS_2 solution, V_2 is 1.1 kJ/mol, **1** stable, and becomes 0.5 kJ/mol in DMSO solution, **2** preferred.

If **2** is favored by 1.7 kJ/mol in acetone solution, as deduced from ^{19}F chemical shifts (15), then $\langle\sin^2\theta\rangle$ follows as 0.585. $^5J_{90}$ becomes 5.38 Hz because ^5J(C,F) in acetone solution is 3.15 Hz (Table 1). Consequently, **2** is more stable than **1** by 0.2 kJ/mol in CS_2 solution. Increasing polarity of the solvent stabilizes **2**, until in DMSO solution **2** is more stable than **1** by 2.1 kJ/mol. V_2 has changed by about 2 kJ/mol. As usual (2), benzene behaves as a more polar solvent than its static dielectric constant would indicate.

TABLE 3. Values of the internal twofold barrier in benzyl fluoride in solution derived from different ^5J(C,F) values for $\theta = 90°$

Solvent	$\langle\sin^2\theta\rangle^a$	$V_2{}^b$	$V_2{}^c$	$V_2{}^{d,f}$	$V_2{}^e$ (kJ mol^{-1})
CS_2	0.446	1.1	0.2	0.6	0.0
CCl_4	0.455	0.9	0.4	0.8	0.2
C_6D_6	0.473	0.5	0.8	1.3	0.7
Neat	0.499	0.0	1.4	1.8	1.9
$CDCl_3$	0.500	0.0	1.4	1.8	1.9
CD_3OD	0.506	0.1	1.6	2.1	2.0
$(CD_3)_2C{=}O$	0.509	0.2	1.7	2.2	2.1
DMSO	0.525	0.5	2.1	2.6	2.5

[a]On the assumption that V_2 is zero in $CDCl_3$ solution (16). Because ^5J(C,F) is 3.09 Hz (Table 1, $^5J_{90}$ follows as 6.18 Hz because $\langle\sin^2\theta\rangle$ is 0.500 for a vanishing barrier.

[b]Following from $\langle\sin^2\theta\rangle$ in the preceding column. Values of $\langle\sin^2\theta\rangle$ less than 0.5 imply **1** as the preferred conformation. If $\langle\sin^2\theta\rangle$ is greater than 0.5, then **2** is preferred.

[c]Derived on the assumption that **2** is favored by 1.7 kJ/mol in acetone solution (15). In the latter ^5J(C,F) is 3.148(7)Hz (Table 1), so that $\langle\sin^2\theta\rangle$ becomes 0.581 and $^5J_{90}$ is 5.42 Hz. **2** is most stable in all solvents.

[d]On the assumption that ^5J(C,F) is 5,2 Hz at $\theta = 90°$, as implied by its values in 1-fluoroindan (16). **2** is most stable in all solvents.

[e]On the assumption that $^5J(C,F) = 0.3 + 4.9 \pm 0.3 \sin^2\theta$. Then **2** is the stable form in most solutions, but is of the same stability as **1** in CS_2 to within experimental error.

[f]A referee asks what consequences there are for V_2 if the extremes of 4.7 and 5.7 Hz for $^5J_{90}$(C,F) are assumed. For a value of 4.7 Hz, **2** is stable in all solvents, V_2 rising from 1.8 kJ/mol to 4.2 kJ/mol in passing from CS_2 to DMSO solution. If $^5J_{90}$ is 5.7 Hz, then **1** is stable in CS_2 solution with a V_2 of 0.3 kJ/mol and **2** is stable in DMSO solution with a V_2 of 1.4 kJ/mol.

Now, $^5J_{90}$ is computed as 5.2 ± 0.3 Hz from a value of 3.9 ± 0.2 Hz in the model compound, 1-fluoroindan, in which θ is taken as 60° (16). However, in 1-fluoro-4-methyl-1,2,3,4-tetrahydro-1,4-ethanonaphthalene, in which θ is very near 0°, ^5J(C,F) is 0.5 Hz (16). Conceivably, there exist additional coupling pathways in this bridged compound accounting for at least part of the 0.5 Hz. A similar statement would apply to the indan derivative. On the assumption that ^5J(C,F) contains an angle-independent component of 0.3 Hz, ^5J(C,F,) (Hz) = 0.3 + (4.9 ± 0.3) $\langle\sin^2\theta\rangle$. Table 3 also contains the V_2 values deduced from this equation. Then V_2 is essentially zero in CS_2 solution, becoming 2.5 kJ/mol in DMSO solution, **2** stable (uncertainties of ca. 0.5 kJ/mol).

If ^5J(C,F) (Hz) = 5.2 $\sin^2\theta$, then V_2 is 0.6 kJ/mol in CS_2 and increases to 2.6 kJ/mol in DMSO, **2** stable. These numbers are also given in Table 3. From all these comparisons, V_2 appears indeed to be small, changing by about 2 kJ/mol in passing from CS_2 to DMSO solutions.

In contrast, the relaxation data suggest an internal barrier of 11.8 kJ/mol in neat benzyl fluoride (13). If **1** is the stable form, then the value of ^5J(C,F) for $\theta = 90°$ follows as 23.4 Hz and as 15.7 Hz for a barrier of 7.6 kJ/mol deduced from relaxation data in acetone solution (14). Therefore **1** cannot be the preferred conformation if V_2 is large. If **2** is stable, then $^5J_{90}$ follows as 3.55, 3.94, and 3.65 Hz from the relaxation barriers in neat benzyl fluoride, acetone, and methanol, respectively, giving an average of 3.7 Hz. The ^5J(C,F) numbers in Table 1 then yield an internal barrier of 5.3 kJ/mol in CS_2 solution and 12.0 kJ/mol in DMSO solution. However, it is most unlikely that $^5J_{90}$ is as small as 3.7 Hz, the average of the numbers above.

This unlikelihood is emphasized by a consideration of ^6J(H,H) for benzyl fluoride in CS_2 and acetone solutions (Table 2). A relaxation barrier of 7.6 kJ/mol in acetone solution, **2** stable, implies a $\langle \sin^2 \psi \rangle$ of 0.351 (see **1** for the definition of ψ). Because ^6J(H,H) is a $\sigma-\pi$ coupling, it follows that its extreme at $\psi = 90°$ is $-0.409/0.351$ or -1.17 Hz (the barrier in CS_2 solution would then follow as 5.2 kJ/mol from the ^6J(H,H) of 0.452 Hz). This value of $^6J_{90}$ is much too large in magnitude. $^6J_{90}$ in toluene has recently been redetermined as -1.20 Hz (27) and it is known that the magnitude of $^6J_{90}$ decreases significantly as the electronegativity of the α-substituent increases (7). In particular, a detailed study of the solvent dependence of the conformational behavior of 2-hydroxybenzyl methyl ether (36) shows that $^6J_{90}$ is -1.02 Hz. Because fluorine is more electronegative than OCH_3, the magnitude of $^6J_{90}$ must be less than 1.02 Hz in benzyl fluoride. Assuming a linear dependence of $^6J_{90}$ on the electronegativity of the substituent (7, 35) and using the electronegativities deduced (37) from internal chemical shifts (see also refs. 38, 39), yields $^6J_{90}$ as -0.95 Hz in benzyl fluoride.

Concluding therefore that V_2 in benzyl fluoride in solution is indeed small, an attempt at discrimination between the V_2 sets in Table 3 essays as follows. From the relationship $\langle \sin^2 \psi \rangle = 0.75 - 0.5\langle \sin^2 \theta \rangle$, $-^6J_{90}$ for ^6J(H,H) is deduced in pairs (CS_2 and acetone): 0.878, 0.826 Hz if $V_2 = 0$ in $CDCl_3$; 0.894, 0.915 Hz if **2** is favored by 1.7 kJ/mol in acetone; and 0.964, 0.954 Hz if ^5J(C,F) is 4.9 Hz and no angle-independent contribution exists in the latter. If an angle-independent term of 0.3 Hz exists additionally, then $-^6J_{90}$ becomes 0.905, 0.891 Hz. If ^5J(C,F) (Hz) $= 5.2 \sin^2 \theta$, one has 0.933, 0.915 Hz for $-^6J_{90}$. These comparisons suggest a nonzero V_2 in $CDCl_3$ solution and that a reasonable relation is ^5J(C,F) (Hz) $= 4.9 \sin^2 \theta$. With the latter and ^6J(H,H) $= -0.959 \sin^2 \theta$, V_2 varies between 1.0 kJ/mol in CS_2 and 3.3 kJ/mol in DMSO solutions.

Similar tests for ^6J(H,F,) yield $-^6J_{90}$ as 3.45, 3.53 if V_2 vanishes in $CDCl_3$; 3.00, 3.08 if **2** is preferred by 1.7 kJ/mol in acetone; and 2.74, 2.80 Hz if ^5J(C,F) is 4.9 Hz at $\theta = 90°$ in the absence of an angle-independent component. In 2,6-dichlorobenzyl fluoride, ^6J(H,F,) is -2.43 Hz (32). Fully optimized STO 3G MO computations give V_2 (kJ/mol) $= 12.2 \cos^2 \theta - 2.0 \sin^2 2\theta$ for the internal potential. If the fourfold component is ignored, $\langle \sin^2 \theta \rangle$ is 0.879 and $^6J_{90}$ becomes -2.76 Hz. If the fourfold component is included, a classical average gives $\langle \sin^2 \theta \rangle$ as 0.844 and $^6J_{90}$ becomes -2.87 Hz. These numbers lie reasonably close to the assumption that ^5J(C,F) (Hz) $= 4.9\langle \sin^2 \theta \rangle$. Again, ^5J(C,F) is 4.0 ± 0.2 Hz in 2,6-dichlorobenzyl fluoride (16). The potential function above then implies $^5J_{90}$ as 4.7 ± 0.3 Hz for ^5J(C,F), again in reasonable agreement with the above assumption.

One further point must be made. In 2,6-dichloro-4-methylbenzyl fluoride in CS_2 solution, ^7J(F,CH_3) is 2.83 Hz (40), compared to a ^6J(H,F) of -2.43 Hz for 2,6-dichlorobenzyl fluoride in benzene solution (32). If the methyl substituent causes no change in V_2, then it follows that ^6J(H,F) contains a positive non $\sigma-\pi$ component of about 0.4 Hz, it being most unlikely that ^7J(F,CH_3) is other than a pure $\sigma-\pi$ coupling. Yet it is known that a *para* methyl group increases the stability of **2** in the absence of chlorine substituents (15, 40). Therefore part of the discrepancy above may arise in this manner. A small non $\sigma-\pi$ component of ^6J(F,H) may be present, however. The perturbation by ring substituents of the internal potential function in benzyl fluoride is significant. Thus, ^5J(C,F) is 2.0 Hz in 3,5-dichlorobenzyl fluoride in CS_2 solution (see Experimental) and, because *meta* substituents appear to cause very small changes in $\sigma-\pi$ couplings (7), it follows that V_2 is 1.9 kJ/mol with **1** as the stable form, if $^5J_{90}$ is taken as 4.9 Hz. ^6J(H,H) is $-0.537(0)$ Hz, implying **1** as more stable than **2** by 2.7 kJ/mol if $^6J_{90}$ is taken as -0.95 Hz. ^6J(H,F) is $-1.026(1)$ Hz and **1** is more stable than **2** by 2.8 kJ/mol if $^6J_{90}$ is -2.81_5 Hz, the mean of the two values above. Clearly, **1** in the 3,5-dichloro derivative is more stable than in benzyl fluoride by at least 2 kJ/mol. Our STO 3G MO calculations suggest a twofold barrier which is 0.8 kJ/mol larger than in benzyl fluoride, **1** stable. The conformational preference of a given benzyl fluoride derivative will be a function of the substituents *and* of the solvent.

In summary, there is little doubt that **2** in benzyl fluoride is stabilized relative to **1** by about 2 kJ/mol as the solvent changes from CS_2 to DMSO, in qualitative accord with simple dielectric continuum models. However, the long-range couplings used in this study, although in agreement with a rather small twofold internal barrier, leave some doubt as to the minimum in the potential function in CS_2 solution. The result most consistent with all three types of couplings is that the potential function is almost flat in this solvent, **2** being favored over **1** by perhaps as much as 1 kJ/mol.

(iii) *Conformational changes in other* ^nJ*(C,F)*

For benzotrifluoride, ^5J(C,F) was treated as a $\sigma-\pi$ coupling and the vanishing ^4J(C,F) could then be accounted for by a composite mechanism, consisting of a negative $\sigma-\pi$ component proportional to $\sin^2 \theta$ and a smaller positive σ component depending on $\sin^2 (\theta/2)$. The expectation value of $\sin^2 (\theta/2)$ is 0.5 for a twofold barrier. On the assumption that ^4J(C,F) behaves similarly in benzyl fluoride, one may write $^4J(C,F) = {}^4J_{90} \langle \sin^2 \theta \rangle + 0.5\,{}^4J_{180}$. Use of V_2 values in the last column of Table 3 for CS_2 and DMSO solutions to find $\langle \sin^2 \theta \rangle$ yields $^4J^{\pi}_{90}$ as -5.12 Hz and $^4J_{180}$ as 3.30 Hz. These numbers assume a negative ^4J in Table 1. A positive ^4J would yield a positive $^4J^{\pi}_{90}$, rather unlikely because of spin correlation (29). This parameterization can be tested for the other solvents with the result that the mean deviation between observed and calculated values for the other six solvents is 0.03 Hz, 6% of the observed change. In other words, the present formulation of the θ dependence of ^4J is consistent with an increased stability of **2** in the more polar solvents. However, the values of $^4J^{\pi}_{90}$ and $^4J^{\sigma}_{180}$ must be considered as approximate. Furthermore, ^4J(C,F) vanishes in 3,5-dichlorobenzyl fluoride, so that this coupling is strongly substituent dependent. In 4-methylbenzyl fluoride in CS_2 solution ^4J(C,F) is 1.34 ± 0.06 Hz. If negative and unperturbed by the methyl group, $\langle \sin^2 \theta \rangle$ follows as 0.58 ± 0.12 from the above parameterization, in rough agreement with the 0.64 ± 0.04 deduced (40) from ^7J(F,CH_3).

^2J(C,F) is $+18.3 \pm 0.1$ Hz in 3,5-dichlorobenzyl fluoride in CS_2 solution. In benzyl fluoride, ^2J(C,F) is therefore no doubt positive as well, decreasing from 17.5 Hz in CS_2 to 16.6 Hz in DMSO solutions. This decrease is consistent with the qualitative indications from the INDO MO FPT computations if **2** increases in stability in the polar solvents. The higher observed value in the 3,5-dichloro derivative is expected if, as deduced above, the stability of **1** is enhanced by the ring substituents.

^1J(C,F) changes from -170.5 Hz in CS_2 solution to -161.9 Hz in DMSO solution. For the sake of argument, write ^1J(C,F) as $A + B \sin^2 \theta$. Then, using the V_2 values in the last column of Table 3, one has $A = -206.4$ Hz and $B = 71.5_5$ Hz. In 3,5-dichlorobenzyl fluoride, ${}^1J(C,F)$ is -173.7 Hz, corresponding to a $\langle \sin^2 \theta \rangle$ of 0.457. Then **1** is favored by 0.9 kJ/mol for his molecule, differing by 1 kJ/mol from the value implied by ${}^5J(C,F)$ above. Any intrinsic substituent effect on ${}^1J(C,F)$ has been ignored in this comparison. Certainly, *para* and *ortho* substituents should perturb ${}^1J(C,F)$ as they do ${}^1J(H,C)$, for example (41). Therefore, further comparisons will not be done.

Conclusions

The perpendicular conformer of benzyl fluoride, in which the C—F bond lies in a plane perpendicular to the benzene plane, is stabilized by about 2 kJ/mol in passing from CS_2 to DMSO solutions. This magnitude is about equal to the error in Raman and infrared measurements of solvent effects on conformational equilibria (4). It is likely that in CS_2 solution the conformational preference is very weak at 300 K, the twofold barrier to internal rotation being very near zero. Each benzyl fluoride derivative will have its own internal barrier and this will also be solvent dependent, particularly for *meta* and *para* substituted compounds.

Correlations between nuclear magnetic resonance shifts and atomic charges of nitrogen in selected alkylamines, nitroalkanes, isonitriles, and azines consistently follow the general trends observed for carbon and oxygen nuclei. In azines, any increase in total electronic population on nitrogen, resulting from a gain in π charge prevailing over a concurrent loss of σ electrons, is accompanied by an upfield resonance shift—as found for aromatic and ethylenic carbon and carbonyl oxygen atoms. On the other hand, any gain in total charge dictated by that of σ populations translates into a downfield ^{15}N shift, which is the trend exhibited by alkylamines, nitroalkanes, and isonitriles—a situation encountered earlier with sp^3-hybridized carbon, carbonyl carbon, and dialkyl ether oxygen atoms.

M. COMEAU, M.-T. BÉRALDIN, E. C. VAUTHIER et S. FLISZÁR. Can. J. Chem. **63**, 3226 (1985).

Les corrélations, en rmn, entre les déplacements chimiques et les charges électroniques portées par les azotes d'alkylamines, de nitroalcanes, d'isonitriles et d'azines choisis ont le même comportement que celui précédemment établi pour les noyaux de carbone et d'oxygène. Dans le cas des azines, une augmentation de la charge électronique totale sur l'azote—qui provient d'une augmentation de la charge π au détriment de la charge σ—est accompagnée d'un déplacement chimique vers les champs forts; ce comportement est identique à celui déjà rencontré pour les ^{13}C de composés aromatiques et éthyléniques et pour les atomes d'oxygène de groupements carbonyles. Par contre, pour les alkylamines, les nitroalcanes et les isonitriles, une augmentation de la charge électronique totale sur l'azote—provenant d'un gain en électrons σ—provoque un glissement vers les champs faibles pour ce noyau; cette situation a déjà été rencontrée pour les carbones hybridés sp^3 des alcanes, pour les ^{13}C de groupements carbonyles et pour les atomes d'oxygène d'éthers dialkylés.

[Traduit par le journal]

Introduction

Correlations between atomic charges and nuclear magnetic resonance shifts have become best known for ^{13}C and ^{17}O nuclei (1, 2): in some cases they are excellent (albeit not free from conceptual difficulties) (3−5) and of considerable help in the accurate evaluation of charge effects governing molecular energies (2, 6). Unfortunately, no corresponding information is presently available for ^{15}N nuclei—a problem attacked here with a critical examination of possible charge−shift correlations for nitrogen atoms.

Indeed, a theoretical analysis of the nuclear magnetic shielding of ^{15}N in a well-diversified variety of compounds (amines, azines, etc.) reveals that the changes in total shielding are almost entirely dictated by those of the local paramagnetic contribution (i.e., $\Delta\sigma_{\text{total}} \simeq \Delta\sigma_{\text{local}}^{\text{param.}}$), in a range covering ~400 ppm (7). This result suggests possible correlations between ^{15}N nmr shifts and atomic charges which, of course, are essentially local in character. The fact, however, that $\Delta\sigma_{\text{total}} \simeq \Delta\sigma_{\text{local}}^{\text{param.}}$ holds true for different types of N atoms does not imply that all of them are covered by a single charge−shift relationship. The nature of the latter depends, indeed, on the way $\Delta\sigma_{\text{local}}^{\text{param.}}$ varies with a change in local electron density, hence the reason for distinguishing N atoms belonging to different classes of compounds.

Calculation of charges

All SCF calculations were performed by means of Pople's STO-3G method (8), using the Gaussian 76 set of programs (9). Molecular geometries and all ζ parameters were optimized in most cases, a point which is important because atomic charges are very sensitive to the molecular environment and, hence, to ζ optimization: the internally most consistent charge results are obtained when these optimizations are carried out at their best for each atom (or group of equivalent atoms) of the molecules under study, until stable charges are obtained (2). This task is practically feasible only in minimal basis set calculations, hence our choice for the fully optimized STO-3G method.

Population analyses were carried out following Mulliken (10). Of course, atomic charges deduced in this manner should *not* be taken at their face value because they are strongly basis set dependent (2, 11); *they should only be used in comparisons between like atoms* (e.g., between nitrogen atoms of primary amines, or nitrogen atoms of secondary amines, etc.), in which case the trends indicated by Mulliken's population analysis are valid (2). This restriction is important, indeed, because Mulliken's charges include, throughout, a half-and-half partitioning of overlap populations in their computation, a circumstance which may carry an error in situations involving heteronuclear atom pairs (2) (as in the NH, NC, and CH bonds, in the present case), but, as discussed below, this is not the only reason. (Typical examples illustrating the effect of lifting the equipartitioning of overlap population terms in STO-3G charge analyses based on Mulliken's scheme are found in charge − nmr shift comparisons offered for alkanes (12) and alkyl-substituted ethylenes (13).) With these reservations in mind, Mulliken charges deduced from optimized STO-3G wave functions are of undisputed value in comparative studies like the one presented below. In more realistic charge calculations, however, larger basis sets *and* inclusion of configuration interaction become a must (14).

Results

Alkylamines

Fully optimized STO-3G results obtained for selected mono-, di-, and trialkylamines are indicated in Table 1. Within each series, a comparison with known adiabatic ionization potentials (15) reveals that the latter decrease as electronic charge

13 Diethyl, methyl-N	1.9952	1.5773	3.7083	−280.8	334.3	

[a]The numbering corresponds to that of Fig. 1.
[b]In this convention, increasingly larger $\delta(^{15}N)$ values indicate upfield resonance shifts.
[c]The STO-3G Mulliken net charges (2) of carbon replacing N in the analogous hydrocarbons (see text) are, in me, −21.0 (**1**), −22.6 (**2**), −23.1 (**3**), −23.8 (**4**), −26.4 (**5**), −28.5 (**6**), 6.1 (**7**), 3.5 (**8**), 2.2 (**9**), 0.8 (**10**), 33.6 (**11**), 32.2 (**12**), and 30.2 (**13**).

tends to build up on nitrogen, as one would normally expect in a rough first approximation, thus suggesting that the charges calculated here are, indeed, in the right order. On the other hand, a gain in electronic charge also appears to be accompanied by a concurring downfield ^{15}N chemical shift (Fig. 1). This trend is similar to that encountered earlier with typical sp^3 carbon atoms (in normal and branched paraffins and in the cyclohexane series, including polycyclic hydrocarbons constructed from chair and (or) boat cyclohexane rings), with carbonyl carbon atoms, and with the oxygen atoms in dialkylethers (1, 2, 16).

Separate correlation lines are observed for mono-, di-, and trialkylamines—a fact which may *partially* be accounted for by the present use of Mulliken charges, as in the case of saturated and ethylenic hydrocarbons (2, 12, 13). Each of these charge–shift correlations can be represented by $\Delta\delta(^{15}N) = a_N \Delta q_N$. The slope, a_N, for tertiary amines would appear to differ significantly from what is found for mono- and dialkylamines. There are reasons to suspect, however, that this apparent change in a_N reflects, at least in part, a computational artefact in the evaluation of charges, rather than a genuine physical effect. Consider here the parent alkanes obtained by relacing N with CH and compare the charge of each nitrogen with that of the carbon replacing it. The slope relating the Δq_N's to the corresponding "parent" Δq_C's appears to be ~2.5 times larger for tertiary than for secondary and primary nitrogen atoms. This observation casts serious doubts concerning the balance of the present STO-3G nitrogen charges because tertiary nitrogen should not be all that exceptional as regards the regular patterns of partial charge transfers accompanying equal substitutions at N and CH. Of course, if the Δq_N's of tertiary amines were, indeed, in error by a factor ~2.5 (relative to the results deduced for the other amines), the readjusted slopes, $\Delta\delta(^{15}N)/\Delta q_N = a_N$, of Fig. 1 would be nearly the same. It must be made clear that charge analyses are plagued at the outset by an unbalance in the hydrogen basis sets currently used in *ab initio* calculations (11, 18–21), which alters significantly the description of nitrogen itself. Basis set superposition errors were evaluated (11) by replacing Pople's standard 6-31G* basis by an extended form in which the basis of the ammonia H atoms and that of the methyl groups of trimethylamine were retained in the treatment of each alkylamine (i.e., mono-, di-, and trimethylamine) and of ammonia itself: the results indicated that the quality of the treatment of amine nitrogen atoms is strongly dependent on the number of methyl groups because the replacement of alkyl groups by hydrogens greatly impoverishes the basis. On these grounds, a new, augmented basis was proposed for hydrogen, which appears to be reasonably well balanced. Comparison with familiar (e.g., 6-31G*) calculations revealed in what manner the treatment of nitrogen is worsened when even just one methyl group is replaced by hydrogen, unless the impoverishment of the basis is suitably taken care of. The effect on nitrogen atomic charges is spectacular in that only minor variations seem to occur in going from ammonia to trimethylamine (~−0.53 e for NH_3, CH_3NH_2, and $(CH_3)_2NH$; ~−0.54 e for $(CH_3)_3N$), quite unlike the trends displayed in Table 1. This and related studies (19–21) warn against reaching hasty conclusions concerning charge distributions in alkylamines, namely, as regards a direct comparison between mono-, di-, and trimethylamine. Presently we feel unable to go beyond comparisons restricted to individual series with the same number of alkyl substituents, following the approach described in the text, in which case distortions arising from superposition effects are minimized.

Adding to the theoretical difficulties, there is also the problem of assessing the appropriateness of the nmr data selected for use in comparisons like those described here, because solvent and concentration effects are often much larger for nitrogen-15 than for carbon-13 nmr spectra (22). Litchman and co-workers (23), for example, investigated in detail the effects of binding of the solvent protons to the nitrogen lone pair and (or) influences of solvent lone pairs binding with the protons on nitrogen, concluding that different solvent effects are generally to be expected for primary and tertiary amines, and probably for secondary amines as well. Besides hydrogen bonding, other possible causes for the solvent effects on ^{15}N chemical shifts include polarization of solute molecules in a very polar medium and conformational changes resulting from strong solvent–solute interactions. The large solvent effects on propylamines have been rationalized on the basis of changes in the populations of the *gauche* conformers (17, 24). The importance of these interactions is revealed by the correlations observed for the ^{15}N chemical shifts of the saturated amines with the ^{13}C shifts of the corresponding carbons in analogous hydrocarbons (17, 24–26), namely, by the very existence of separate, solvent-sensitive, linear correlations for primary, secondary, and closely related groups of tertiary amines. Results of this sort, obtained with great care for a large variety of compounds and interpreted in detail by Roberts and co-workers (17, 24–26), are instrumental in a more balanced assessment of the charge–shift correlations shown in Fig. 1. It appears, indeed, that the charges to be used in this type of correlations should not be those of the isolated amines but rather those of the (still ill-known) aggregates as they are physically present in shift measurements. However, the linearity of the $^{15}N/^{13}C$ correlations, as well as the corresponding ones between atomic charges, supports the overall validity of correlations involving observed ^{15}N shifts and nitrogen charges of model isolated amines, at least as regards general charge–shift trends within series of closely related compounds.

Hence, despite the theoretical and solvent-related difficulties outlined above, it may be concluded from the present results that any increase in electronic charge at amine nitrogen atoms translates into a downfield chemical shift. This trend is also followed by other types of nitrogen atoms.

TABLE 2. Orbital populations, N (e), net atomic charges,[a] q_N (me), and ^{14}N resonance shifts of nitroalkanes R—NO_2

[a]From standard STO-3G calculations using the scale factors and geometries indicated by Hehre and Pople (29), namely, those of nitromethane for N, O, C, and H in the α-position, and those determined for hydrocarbons otherwise.

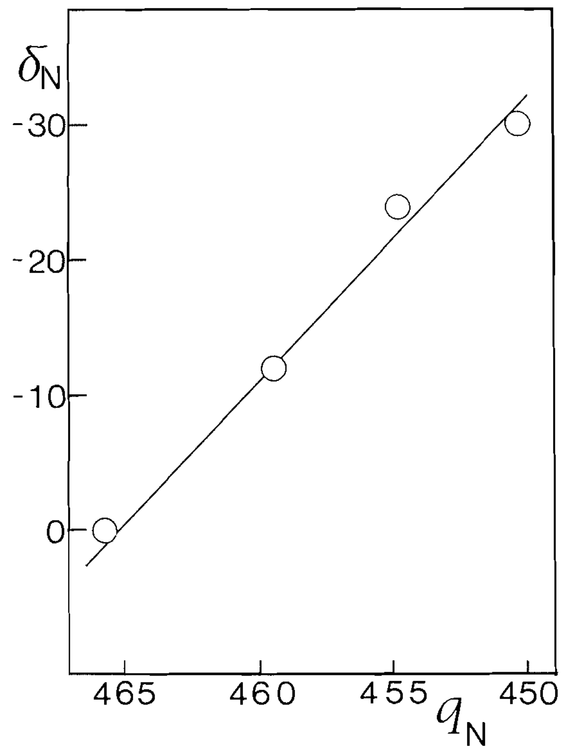

FIG. 2. Comparison between net charges and resonance shifts (ppm, downfield from CH_3NO_2) of nitrogen in selected nitroalkanes.

Nitroalkanes

In nitroalkanes, R—NO_2, a regular upfield shift of the nitrogen resonance with increasing electronegativity of R is observed and obeys simple additivity rules (27). Upon replacing hydrogen atoms in CH_3NO_2 with alkyl groups, a downfield shift of ~10 ppm takes place—a trend similar to that encoun-

R	$N(1s)$	$N(2s)$	$N(2p)$	q_N	$\delta(^{14}N)$
CH_3	1.9957	1.4227	3.9153	−333.8	218.0
C_2H_5	1.9958	1.4268	3.9163	−338.9	203.0
iso-C_3H_7	1.9958	1.4301	3.9170	−342.9	189.7
tert-C_4H_9	1.9958	1.4327	3.9176	−346.1	181.2

[a]From standard STO-3G calculations, using geometries defined by Pople and Gordon (31), and scale factors of ref. 8. A distance of 1.16 Å was used for NC.

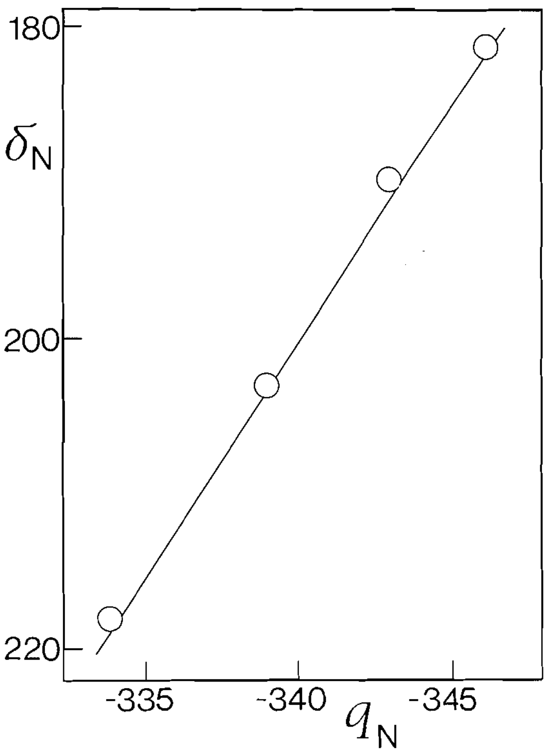

FIG. 3. Comparison between chemical shifts (ppm, upfield from NO_3^-) and atomic charges of nitrogen in selected isonitriles.

tered with amine nitrogen resonances. This trend visibly reflects the usual electron-releasing ability of alkyl groups, in the order *tert*-C_4H_9 > i-C_3H_7 > C_2H_5 > CH_3. Charge analyses at the STO-3G level, as well as the appropriate shift data (28) (downfield from nitromethane, for neat compounds) are indicated in Table 2.

Again, these are basis set dependent Mulliken charges which should not be taken at their face value. The trend indicating an electron enrichment at N for increasingly better electron-donating substituent, however, certainly corresponds to what would be expected. Figure 2 illustrates that a gain in electronic charge at nitrogen translates linearly into a downfield nmr shift in the case of nitroalkanes. Interestingly, the slope (~2 ppm/me) is similar to those found for alkylamines (2.3 ppm/me) and dialkylamines (2.1 ppm/me).

Isonitriles

The nitrogen resonance signal of isonitriles moves to higher fields (30) with increasing electronegativity of the group R in R—NC. The shift is very regular, about 15 ppm downfield for each H atom in CH_3—NC replaced with an alkyl group. This resembles the trends observed for amines and nitro groups.

TABLE 4. Nitrogen σ, π, and total (σ + π) Mulliken net charges (me) and ^{15}N resonance shifts of 4-substituted pyridines (**1–9**) and of selected azines (**10–13**)

11 Pyridine	−186.6	−53.8	−240.4	63.5
12 1,3-Diazine	−180.8	−84.1	−264.9	84.5
13 1,3,5-Triazine	−183.3	−101.3	−284.6	98.5

[a]Molecules **1–9** were partially optimized as described in the text; the results for **10–13** were derived with full (geometry and scale factor) optimization.

[b]In ppm from pyridine (= $\delta_{pyr} - \delta_X$) for **1–9**; ppm from external $MeNO_2$ for **10–13** (from ref. 22). In these scales, large $\delta(^{15}N)$ values indicate downfield shifts (**1–9**), viz. upfield shifts (**10–13**).

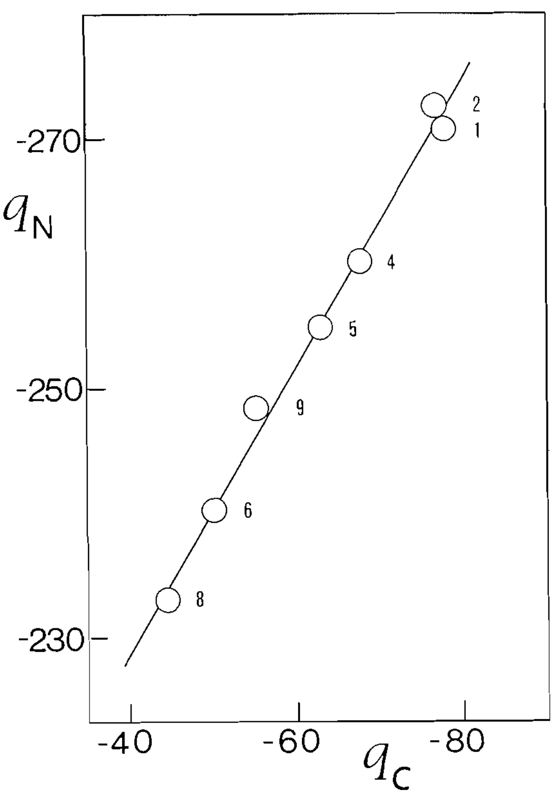

FIG. 4. Correlation between the nitrogen net charges of selected 4-R-pyridines and those of C-4 in the analogous R-substituted benzenes (5). (A similar correlation holds also for the corresponding π charges.)

STO-3G charges (Table 3) and Fig. 3 show, indeed, that the nitrogen signal (30) is farther downfield as electronic charge increases at this atom, with a slope of ~3 ppm/me.

Azines

Using the experimental geometry of pyridine (32), the STO-3G optimization of its scale factors was performed until charges

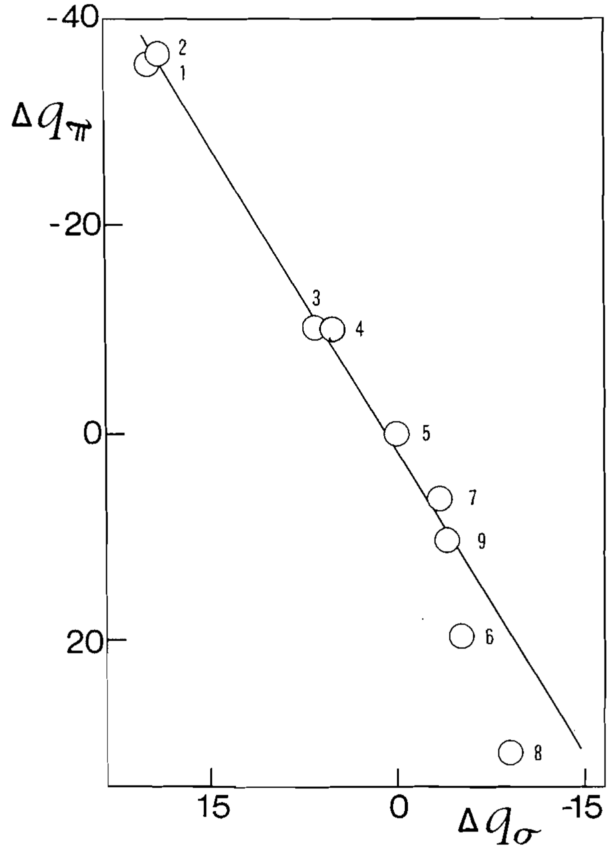

FIG. 5. Comparison between nitrogen σ and π net charges in 4-R-pyridines.

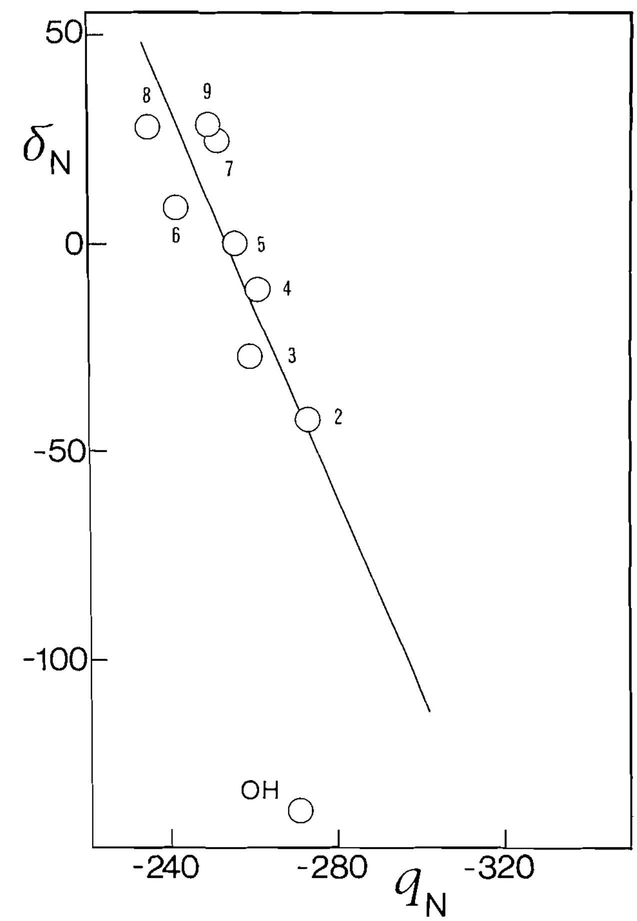

FIG. 6. Correlation between nmr shifts and net charges of nitrogen in substituted pyridines (neat for **5**, **7**, **9**; otherwise in acetone), suggesting that some scatter may be due to solvent effects and experimental uncertainties (~6 ppm for **3**, **8**, **9**; ~12 ppm for **7**).

were stable to within ~0.01 me. Taking advantage of Del Bene's work (33) showing that the pyridine ring is essentially unchanged in the equilibrium structures of 4-R-pyridines, only the geometries and scale factors of the substituents were subsequently optimized for the 4-substituted derivatives, under the appropriate symmetry constraints (C_{2v} for NO_2 and NH_2, C_s otherwise). The results are indicated in Table 4.

Electron-releasing substituents (NH_2, OH, OCH_3, CH_3) appear to increase the π (and total) charge of the ring nitrogen, whereas the opposite is true for electron-withdrawing groups (NO_2, CHO, CN, $COCH_3$), in accord with common expectation. These results match those of Hehre, Taft, and Topsom (5) showing that carbon-4 in substituted benzenes gains or loses charge depending on whether the substituent donates or withdraws electrons: earlier studies by Pople and co-workers (34) on related systems similarly concluded that theoretical charge distributions do, indeed, support many of the ideas of classical organic chemistry. The parallelism between the behavior of nitrogen in 4-substituted pyridines and that of the corresponding carbon in substituted benzenes is illustrated in Fig. 4.

The results of Table 4 reveal another important similarity between 4-pyridine nitrogens and aromatic carbons. As is the case for the latter (1, 2, 5) σ and π populations of the ring nitrogens vary in inverse manner, the changes in π charge being predominant (Fig. 5).

Finally, the correlation between resonance shifts (35) and atomic charges of the pyridine nitrogen atoms also follows the pattern which is so well known for their aromatic carbon analogs, i.e., an upfield shift accompanying a gain in total ($\sigma + \pi$) electron population (Fig. 6). 4-Hydroxypyridine is not included in this correlation because its tautomeric equilibrium is predominantly shifted in the direction of the corresponding pyridone form (36–38). Of course, because of the linear inverse relationship between σ and π charges (Fig. 5), the correlation with total charges also implies the existence of individual linear correlations with σ and π populations, namely, upfield shifts for increasing π-electron densities, just as in the case of aromatic hydrocarbons. The latter result also follows from Pariser–Parr–Pople calculations of π charge densities reported by Witanowski *et al.* (39). All the above considerations apply equally well to the series including pyridine, 1,3-diazine, 1,4- diazine, and 1,3,5-triazine (Fig. 7), as revealed by recently determined ^{15}N spectra (40).

It is clear that solvent and concentration effects should not be disregarded in the present evaluation of charge–shift correlations. Shielding solvent effects affecting the ^{15}N resonances of pyridines, and indeed more generally of sp^2-hybridized nitrogens, are associated with hydrogen bonding to the nitrogen unshared pairs. Such hydrogen bonding changes the $n \rightarrow \pi^*$ transition energies and, hence, the paramagnetic screening that appears to be the dominant influence on the chemical shifts of these compounds (41). Because of a careful selection of suitable "standard" experimental conditions, however, these solvent effects should not impair the overall validity of the present conclusions, namely, that any gain in total charge at azine nitrogens translates into an upfield shift—in sharp contrast with

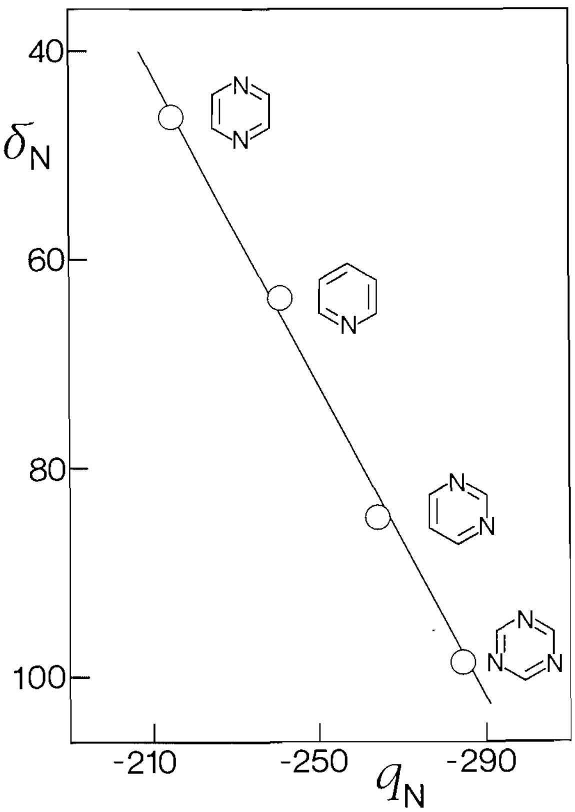

FIG. 7. Comparison between the net charges and resonance shifts of nitrogen in pyridine, 1,3-diazine, 1,4-diazine, and 1,3,5-triazine, in DMSO solution.

the results obtained for amines, nitroalkanes, and isonitriles.

Conclusions

Linear correlations between nitrogen-15 nmr shifts and atomic populations closely resemble similar empirical correlations existing for carbon-13 and oxygen-17 nuclei, namely, as regards their sign (upfield or downfield resonance shifts accompanying a gain in local charge density). Supporting evidence is offered by linear correlations involving the resonance shifts of ^{15}N nuclei and those of the corresponding carbon nuclei in analogous hydrocarbons, showing that for a large variety of substituents (i.e., over a wide chemical shift range) shielding of the ^{15}N and ^{13}C nuclei in aromatic (42) and nonaromatic (17, 24, 25, 43) systems is governed by the same electronic factors. This holds true for ^{17}O as well (44).

Nitrogen atoms contained in aromatic structures exhibit the same behavior as aromatic and ethylenic carbon atoms and carbonyl oxygen (ref. 1): an increase in total electronic population is accompanied by an upfield resonance shift when the electron enrichment results from a gain in π charge prevailing over the concurrent loss in σ electrons. On the other hand, nitrogen in alkylamines, nitroalkanes, and isonitriles behaves like typical sp^3-carbons, carbonyl carbon, and dialkyl ether oxygen atoms: any increase in total electronic population translates into a downfield resonance shift when the gain in charge is dictated by that of the σ population. For amines and nitroalkanes, STO-3G calculations indicate that charges vary in the same direction both at the 2s level (~30%) and the 2p level (~70%), whereas the 2p population remains virtually unchanged in alkylisonitriles.

Inclusion of nitrogen in a unified picture encompassing carbon and oxygen nuclei in a variety of situations hopefully paves the way to a better assessment of circumstances that may be encountered in the study of charge–shift relationships, also as regards possible drawbacks introduced by an indiscriminate use of theoretical charges. The latter, of course, depend on the basis set chosen. In addition, the inherent difficulties associated with the overlap populations of the Mulliken scheme must always be borne in mind: simply using an extended basis set is not a panacea. In our experience, the relevant trends in series of closely related compounds are, indeed, adequately described by optimized minimal basis set calculations.

In a widely accepted formulation of the local paramagnetic term (45), there are a number of variables in addition to those that may be correlated with atomic charges: thus, there is no *a priori* reason to expect good charge–shift correlations. The fact that different, but good, correlations are observed for different types of atoms is certainly of interest, moreover, as the same patterns of behavior have now been shown to exist for carbon, nitrogen, and oxygen. This observation should encourage future reexamination of the challenging question regarding the dependence of the local paramagnetic term on the local charge. In the meantime, the possibility of retrieving atomic charges from critically established empirical correlations is of interest because it opens a convenient access to the study of charge-related molecular properties, such as the energies (2).

PELAYO CAMPS, JOSÉ ALIAGA, MARTA FIGUEREDO, ROSA MARÍA ORTUÑO, ANTONIO GIL DE GÓMEZ, MARÍA TERESA SANTOS, JOAN CASTAÑÉ, and MIGUEL FELIZ. Can. J. Chem. **63**, 3233 (1985).

A synthesis of dimethyl tetracyclo[5.2.1.0^{2,6}.0^{3,8}]decane-7,8-dicarboxylate, **3**, whose key step implies the formation of the C1—C2 bond by regioselective intramolecular C—H insertion of a carbene generated from dimethyl (1*R*,2*S*,6*R*,7*S*)-10-oxotricyclo[5.2.1.0^{2,6}]decane-2,6-dicarboxylate, **1** via its tosylhydrazone, is described. Attempts to synthesize diester **3** or compounds containing its carbon skeleton, by forming the same C—C bond, starting from dimethyl (1*R*,2*R*,6*S*,7*S*)-4-oxotricyclo[5.2.1.0^{2,6}]decane-2,6-dicarboxylate, **2**, or the corresponding anhydride, **13**, are also included.

PELAYO CAMPS, JOSÉ ALIAGA, MARTA FIGUEREDO, ROSA MARÍA ORTUÑO, ANTONIO GIL DE GÓMEZ, MARÍA TERESA SANTOS, JOAN CASTAÑÉ et MIGUEL FELIZ. Can. J. Chem. **63**, 3233 (1985).

On décrit une synthèse du tétracyclo[5.2.1.0^{2,6}.0^{3,8}] décane dicarboxylate-7,8 de diméthyle (**3**) dont l'étape clé implique la formation d'une liaison C1—C2 par une insertion C—H intramoléculaire régiosélective d'un carbène généré, par le biais de sa tosylhydrazone, à partir de l'oxo-10 tricyclo[5.2.1.0^{2,6}] décane dicarboxylate de diméthyle-1*R*,2*S*,6*R*,7*S* (**1**). On a aussi inclus la description d'essais effectués dans le but de synthétiser le diester **3**, ou des composés contenant son squelette carboné, en faisant appel à la formation de la même liaison C—C à partir de l'oxo-4 tricyclo[5.2.1.0^{2,6}] décane dicarboxylate de diméthyle-1*R*,2*R*,6*S*,7*S*, **2**, ou de l'anhydride correspondant, **13**.

[Traduit par le journal]

Recently, Paquette *et al.* have published the first syntheses of dodecahedrane (1) and its methyl (2) and 1,16-dimethyl derivatives (3), the first compounds containing such a type of carbocyclic skeleton. The synthesis of dodecahedrane, however, implies 23 consecutive steps from cyclopentadiene, the overall yield being in the range of 0.1%, which limits its supply. Consequently it is still a challenge to obtain it through a shorter and higher yielding sequence (4).

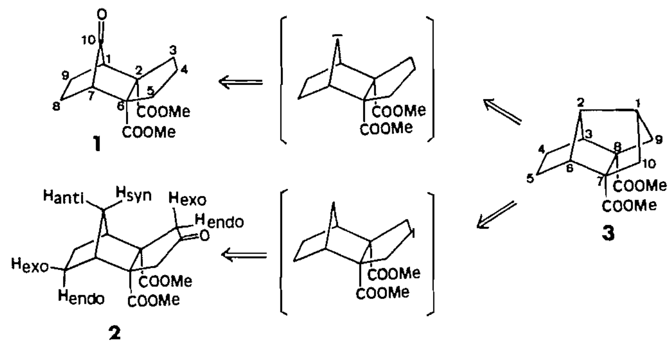
As part of our contribution to polyquinane chemistry (5–7), we describe herein the studies that have led to the successful synthesis of dimethyl tetracyclo[5.2.1.0^{2,6}.0^{3,8}]decane-7,8-dicarboxylate, **3**, a possible intermediate for a convergent synthesis of dodecahedrane.

The retrosynthetic analysis of diester **3** shows that cleavage of the strategic (8) C1—C2 bond gives the well-known tricyclo[5.2.1.0^{2,6}]decane skeleton, in contrast with other cleavages, which give precursors that are not easily accessible. Since the C1 and C2 atoms and their neighbours in compound **3** have no functionality, intramolecular C—H insertion of a carbene was considered to be the reaction of choice to form the C1—C2 bond. As shown in Scheme 1, there exist two ways to carry out such a transformation, depending on the carbon atom at which the carbene is generated. In fact, Neff and Nordlander (9) had utilized the first way in order to synthesize tetracyclo[5.2.1.0^{2,6}.0^{3,8}]decane from tricyclo[5.2.1.0^{2,6}]decan-10-one.

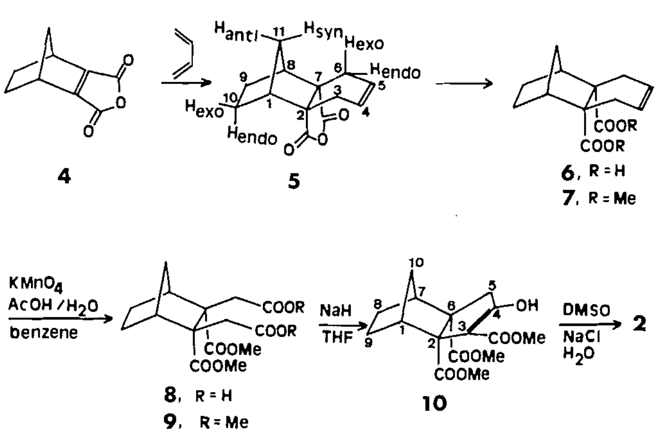
Because the synthesis of dimethyl (1*R*,2*R*,6*S*,7*S*)-4-oxotricyclo[5.2.1.0^{2,6}]decane-2,6-dicarboxylate, **2**, appeared to be easier (5) than that of dimethyl (1*R*,2*S*,6*R*,7*S*)-10-oxotricyclo[5.2.1.0^{2,6}]decane-2,6-dicarboxylate, **1**, and because we were looking for a new entry into this carbocyclic skeleton (9, 10), we undertook the preparation of ketodiester **2** through the sequence depicted in Scheme 2.

The starting product for this synthesis was bicyclo[2.2.1]hept-2-ene-2,3-dicarboxylic anhydride, **4** (11). Reaction of anhydride **4** with excess butadiene gave (1*R*,2*R*,7*S*,8*S*)-tricyclo[6.2.1.0^{2,7}]undec-4-ene-2,7-dicarboxylic anhydride, *5*, in 81% yield. This compound had been previously prepared by Alder and Backendorf (12), but its configuration was not established. However, owing to the fact that reaction of bicyclo[2.2.1]hepta-2,5-diene-2,3-dicarboxylic anhydride with butadiene (13) gives a 1:1 mixture of the *endo* and *exo* adducts, it seems reasonable that anhydride **4**, with the C4—C5 bond

[1]Author to whom correspondence may be addressed.



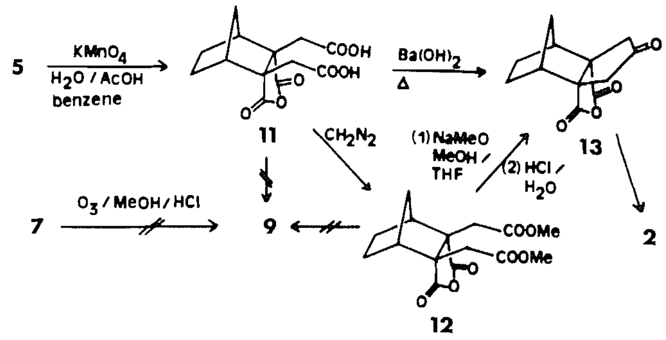
SCHEME 1



SCHEME 2

saturated, would give mainly the *exo* adduct **5** on reaction with butadiene, whether the control of the reaction is kinetic or thermodynamic. Saponification of anhydride **5** gave the corresponding diacid **6**, a compound that readily reverts to its anhydride. Thus, a solid sample of diacid **6** after several days at room temperature gave anhydride **5** nearly quantitatively, and the observed mp for diacid **6** was the same as that for anhydride **5**. For this reason, diacid **6** was esterified with an ethereal solution of diazomethane immediately after its preparation, giving rise to dimethyl (1*R*,2*R*,7*S*,8*S*)-tricyclo[6.2.1.0^{2,7}]-undec-4-ene-2,7-dicarboxylate, **7**, contaminated with a small quantity (less than 10%) of anhydride **5**. Low pressure column chromatography (14) using silica gel (230–400 mesh) and methylene chloride as eluent gave pure diester **7** (96% yield if **5** was recovered). The comparison of the 200-MHz ^{1}H nmr spectra of anhydride **5** and diester **7** showed that the H9(10)*endo* protons of **7** are deshielded by 0.45 ppm with respect to **5**. This fact is in accord with the assumed configuration of anhydride **5**, since the change of its rigid anhydride function by the freely rotating methoxycarbonyl groups of **7** must deshield the H9(10)*endo* protons, due to the contribution of conformations in which the carbonyl oxygen atoms are close to these protons (6, 15).

Oxidation of diester **7** with potassium permanganate under the phase transfer conditions described by Krapcho *et al.* (16) gave dimethyl (1*R*,2*R*,3*S*,4*S*)-2,3-bishydroxycarbonylmethylbicyclo[2.2.1]heptane-2,3-dicarboxylate, **8**, in low yield (less than 30%). The analytical sample was obtained by crystallization from ether. For preparative purposes, the crude diacid **8** was directly esterified with ethereal solution of diazomethane to give, after crystallization from methanol, pure dimethyl (1*R*,2*R*,3*S*,4*S*)-2,3-bismethoxycarbonylbicyclo[2.2.1]heptane-



SCHEME 3

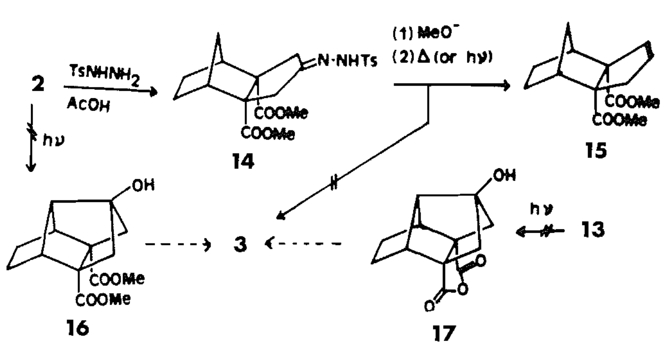
2,3-diacetate, **9**, in 13% overall yield from diester **7**. The low yield oxidation of diester **7** contrasts with the high yield (75%) oxidation of the related compound, dimethyl *cis*-bicyclo-[4.3.0]non-3-ene-1,6-dicarboxylate, under similar reaction conditions (5). However, several attempts to increase the yield of that oxidation were fruitless.

Reaction of tetraester **9** with excess sodium hydride in anhydrous tetrahydrofuran gave trimethyl (1*RS*,2*RS*,6*SR*,7*SR*)-4-hydroxytricyclo[5.2.1.0^{2,6}]dec-3-ene-2,3,6-tricarboxylate, **10**, in 99% yield. This compound exists mainly in the indicated enol form, as shown by its spectroscopic data (ir, ^{1}H and ^{13}C nmr). Decarbomethoxylation of compound **10** was easily achieved using the Krapcho and Lovey reaction conditions (17), giving rise to ketodiester **2** in 88% yield.

Since the yield of the described conversion of anhydride **5** into ketodiester **2** was very low, the transformations shown in Scheme 3 were carried out in order to increase it.

Oxidation of anhydride **5** with potassium permanganate, under the same phase transfer conditions utilized to oxidize diester **7**, gave (1*R*,2*R*,3*S*,4*S*)-2,3-bishydroxycarbonylmethylbicyclo[2.2.1]heptane-2,3-dicarboxylic anhydride, **11**, in 83% yield. This unexpected result opened the possibility of developing a higher yielding synthesis of ketodiester **2**. Conversion of compound **11** into tetraester **9** seemed the most obvious way. However, all attempts to carry out such a transformation were fruitless. Alkaline hydrolysis of **11** followed by reaction with excess dimethyl sulfate in dimethyl formamide gave, quantitatively, (1*R*,2*R*,3*S*,4*S*)-2,3-bismethoxycarbonylmethylbicyclo[2.2.1]heptane-2,3-dicarboxylic anhydride, **12**. Probably **12** is formed from the corresponding diacid during the work-up. Compound **12** was also prepared in 86% yield by esterification of **11** with an ethereal solution of diazomethane. Attempted esterification of the tetraacid corresponding to **11** with diazomethane gave, quantitatively, diester **12**. Reaction of **12** with one equivalent of sodium methoxide in methanol followed by acidification and treatment with an ethereal solution of diazomethane gave the starting product, probably reformed during acidification.

Pyrolysis of an intimate mixture of compound **11** and barium hydroxide gave (1*R*,2*R*,6*S*,7*S*)-4-oxotricyclo[5.2.1.0^{2,6}]decane-2,6-dicarboxylic anhydride, **13**, in only 25% yield. However, compound **13** could be obtained in 60% yield by reaction of compound **12** with 12 equivalents of sodium hydride in a mixture of anhydrous tetrahydrofuran and methanol, followed by heating the crude product under reflux with aqueous hydrochloric acid 1 : 1. Alkaline hydrolysis of ketoanhydride **13** gave the corresponding diacid, which was esterified with an ethereal solution of diazomethane to give ketodiester **3** in 73% yield. Thus, the overall yield for the conversion of anhydride **5** into



SCHEME 4

ketodiester **2** was 33%. An attempt to convert diester **7** directly into tetraester **9** by ozonolysis (18) in methanol solution containing 10% hydrogen chloride was fruitless.

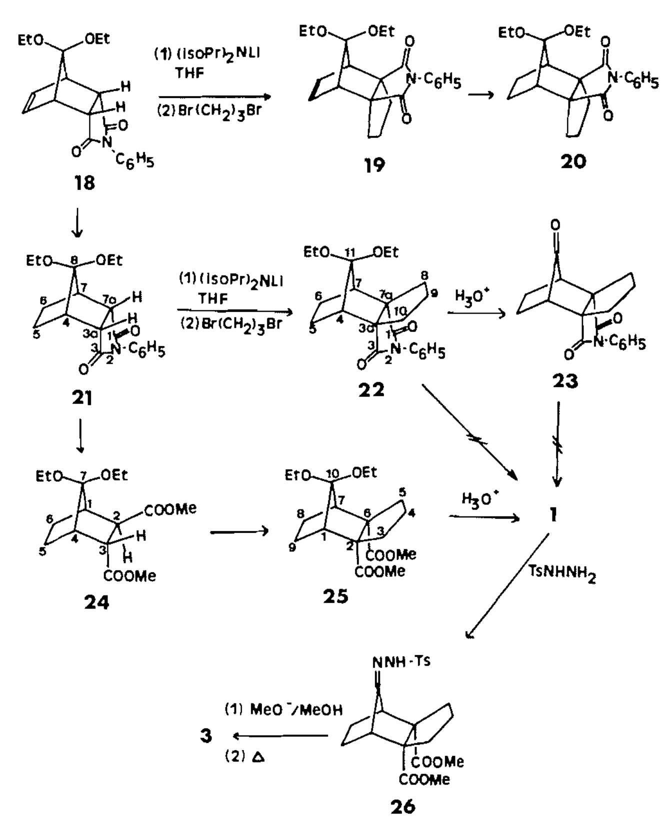
According to the retrosynthetic analysis shown in Scheme 1, insertion of the intermediate carbene generated from the ketonic function of compound **2** into the C10—H_{syn} bond would give diester **3**. To carry out such a transformation, the Bamford–Stevens reaction (19) was chosen (see Scheme 4).

Reaction of ketodiester **2** with tosylhydrazide in glacial acetic acid gave the corresponding tosylhydrazone, dimethyl (1*R*,2*R*,6*S*,7*S*)-4-(*p*-toluenesulfonylhydrazono)tricyclo-[5.2.1.$0^{2,6}$]decane-2,6-dicarboxylate, **14**, in 78% yield. The sodium salt of **14** was obtained by heating under reflux a solution of **14** and a slight molar excess of sodium methoxide in anhydrous methanol. Pyrolysis of the dried sodium salt of **14** in a rotary microdistillation apparatus at 136°C/0.1 Torr (1 Torr = 133.3 Pa) gave in 93% yield a single compound, which was characterized as dimethyl (1*RS*,2*RS*,6*SR*,7*SR*)-tricyclo-[5.2.1.$0^{2,6}$]dec-3-ene-2,6-dicarboxylate, **15**. A similar result was obtained by pyrolysis of the lithium salt of **14** following the procedure described by Neff and Nordlander (9) for a related case. Photochemical decomposition of the sodium salt of **14** in a Pyrex reactor utilizing a 125-W uv lamp, in dimethoxyethane as solvent, gave a mixture of compound **15** and ketodiester **2** (probably formed by hydrolysis of the sodium salt of **14** under the reaction conditions) in the ratio 2:5, as shown by glc/ms analysis. Formation of diester **3** was not observed in all these reactions. These results must be related to the preference of the intermediate carbene, whether generated thermally or photochemically, to experience insertion at a neighbouring C—H bond rather than at the C10—H_{syn} one. Consequently, the use of other methods to generate the intermediate carbene from ketodiester **2** was not considered.

Another approach to the carbocyclic skeleton of **3** from diester **2** might be the ketone to cyclopentanol photocyclization reaction utilized three times by Paquette (1) in his synthesis of dodecahedrane (see Scheme 4). However, irradiation of ketodiester **2**, in benzene solution for 40 h utilizing a 400-W uv quartz lamp, left the starting product unchanged, while by utilizing a mixture benzene/*tert*-butyl alcohol 5:1 as solvent, the formation of a new compound, probably by addition of *tert*-butyl alcohol to **2**, was observed (glc/ms). Similar results were obtained on irradiation of ketoanhydride **13**. Formation of hydroxydiester **16** or hydroxyanhydride **17** could not be detected in all these reactions.

Just after this work had been finished, Trost and Renaut (20) published a synthesis of (±)-albene, in which the compounds **2** and **15** were prepared by an entirely different approach.

In view of the preceding results, we prepared ketodiester **1** in a non-stereoselective way from the *endo* adduct between 6,6-dimethylfulvene and cyclopent-1-ene-1,2-dicarboxylic anhydride (6). Moreover, a stereoselective synthesis of compound **1** was carried out from the Diels–Alder adduct, **18**, between 5,5-diethoxycyclopentadiene and *N*-phenylmaleimide, as shown in Scheme 5 (published as a preliminary communication (7)).



SCHEME 5

While annelation of the dianion derived from adduct **18** with 1,3-dibromopropane takes place mainly by the *endo* face (21) to give dicarboximide **19**, the corresponding reaction of the dianion derived from (3a*R*,4*S*,7*R*,7a*S*)-8,8-diethoxy-2-phenyl-3a,5,6,7a-tetrahydro-1*H*,3*H*-4,7-methanoisoindol-1,3-dione, **21**, takes place preferently by the *exo* face to give (3a*R*,4*S*,7*R*,7a*S*)-11,11-diethoxy-5,6-dihydro-2-phenyl-1*H*,3*H*-4,7-methano-3a,7a-propanoisoindol-1,3-dione, **22**. The configuration of compound **22** was clearly established (7) by comparison of its ^{13}C nmr spectrum with that of (3a*R*,4*R*,7*S*,7a*S*)-11,11-diethoxy-5,6-dihydro-2-phenyl-1*H*,3*H*-4,7-methano-3a,7a-propanoisoindol-1,3-dione, **20**, obtained by hydrogenation of compound **19**.

The conversion of dicarboximide **22** into ketodiester **1** required only two transformations: (a) hydrolysis of the acetal function, and (b) hydrolysis of the dicarboximide group followed by esterification. While the first transformation could be easily carried out by reaction of **22** with aqueous perchloric acid, giving rise to (3a*R*,4*S*,7*R*,7a*S*)-5,6-dihydro-2-phenyl-1*H*,3*H*-4,7-methano-3a,7a-propanoisoindol-1,3,11-trione, **23**, in 95% yield, we were able to hydrolyze the dicarboximide function of neither compound **22** nor **23**, under a variety of basic and acidic conditions.

The synthesis of ketodiester **1** from dicarboximide **21** was achieved by carrying out first the hydrolysis of the dicarboximide function and then the annelation with 1,3-dibromopropane. Thus, basic hydrolysis of compound **21**, followed by esterification of the corresponding diacid with an ethereal solution of diazomethane, gave dimethyl (1*RS*,2*RS*,3*RS*,4*SR*)-7,7-diethoxybicyclo[2.2.1]heptane-2,3-dicarboxylate, **24**, slightly contaminated with the *meso* stereoisomers, in 60% yield. Reaction of the dianion derived from diester **24** with 1,3-dibromopropane gave dimethyl (1*R*,2*S*,6*R*,7*S*)-10,10-diethoxytricyclo[5.2.1.$0^{2,6}$]decane-2,6-dicarboxylate, **25**, in 29% yield (22), which was easily converted into ketodiester **1** in 83% yield by reaction with aqueous perchloric acid. This compound was identical (mp, mixed mp, glc, ir, and ^{1}H nmr) to the product we had previously obtained (6), confirming the expected annelation of the dianion derived from diester **24** by the *exo* face.

Reaction of ketodiester **1** with tosylhydrazide under the conditions utilized to prepare tosylhydrazone **14** left the starting product unchanged. However, by heating under reflux for 28 h an equimolar mixture of ketodiester **1** and tosylhydrazide in isopropanol to which a catalytic amount of concentrated hydrochloric acid was added, dimethyl (1*R*,2*S*,6*R*,7*S*)-10-(*p*-toluenesulfonylhydrazono)tricyclo[5.2.1.$0^{2,6}$]decane-2,6-dicarboxylate, **26**, was obtained in 75% yield. Reaction of tosylhydrazone **26** with sodium methoxide in anhydrous methanol gave the corresponding sodium salt, which after drying was pyrolyzed at 170°C/1 Torr. The distillate was shown to be mainly a unique compound (glc, 97% relative area, 89% yield) that, crystallized from isopropanol, showed mp 62–63°C. The spectroscopic data (ir, ^{1}H and ^{13}C nmr, and ms) and elemental analysis were concordant with expectations for diester **3**. In particular, the ^{13}C nmr spectrum clearly showed its symmetry (eight carbon resonances), thus ruling out other possible products derived from the insertion of the intermediate carbene into C—H bonds different from the C4—H.

The synthesis of diester **3** opens a rapid access to complex polyquinanes, a matter that is currently being investigated.

Experimental

Infrared spectra were recorded on Perkin–Elmer model 710B, 720, or 1310 spectrometers. The ^{1}H and ^{13}C nmr spectra, unless otherwise stated, were taken at 200 MHz and 50 MHz respectively, on a Varian XL 200 spectrometer, while 80-MHz ^{1}H and 20-MHz ^{13}C nmr spectra were recorded on a Bruker model WP80SY, and 60-MHz ^{1}H nmr spectra on a Perkin–Elmer R-12A spectrometer. Chemical shifts are given in ppm relative to internal TMS (δ scale). Mass spectra and glc/ms analyses were performed on a Hewlett–Packard model 5930 mass spectrometer working at 70 eV. Gas–liquid chromatographic (glc) analyses were carried out on Perkin–Elmer models Sigma-1 and Sigma 3B and Hewlett–Packard model 5830A chromatographs. Medium pressure 125- or 400-W mercury lamps were utilized in the photochemical reactions. Melting points were determined on a Kofler hot-stage or on a Büchi SMP-20 apparatus and are uncorrected. Microanalyses were carried out at the Analytical Section of the "Instituto de Química Bio-orgánica de Barcelona (C.S.I.C.)", Spain.

Spectral data of (1R,2R,7S,8S)-tricyclo[6.2.1.$0^{2,7}$]undec-4-ene-2,7-dicarboxylic anhydride, 5

Proton nmr ($CDCl_3$)δ: 1.42 (m, 2H, H9(10)*endo*), 1.56 (br d, J = 11 Hz, 1H, H11*anti*), 1.61 (m, 2H, H9(10)*exo*), 1.96 (d, J = 15 Hz, H3(6)*exo*), 2.02 (br d, J = 11 Hz, 1H, H11*syn*), 2.43 (br s, 2H, H1(8)), 2.75 (ddd, J = 15 Hz, J' = 5 Hz, J'' = 3.5 Hz, 2H, H3(6)*endo*), 5.85 (m, 2H, H4(5)). On irradiation at δ 2.43, the absorption at δ 2.02 became a dt, J = 11 Hz, J' = 2.5 Hz; ^{13}C nmr ($CDCl_3$) δ: 25.9 (t, C9(10)), 29.5 (t, C3(6)), 39.3 (t, C11), 47.2 (d, C1(8)), 60.4 (s, C2(7)), 127.8 (d, C4(5)), 175.8 (s, —*C*OO—).

Dimethyl (1R,2R,7S,8S)-tricyclo[6.2.1.$0^{2,7}$]undec-4-ene-2,7-dicarboxylate, 7

A mixture of 6.63 g (30.4 mmol) of anhydride **5**, 3.0 g (75 mmol) NaOH, and 25 mL water was heated under reflux for 4 h. The solution was cooled in an ice bath, 10 g ice was added, and then it was acidified with 6 *N* HCl. The precipitate was filtered and the filtrate extracted with ether (2 × 20 mL). The ether extracts and the precipitate were combined and, immediately after, treated with an ethereal solution of diazomethane until the yellow colour of diazomethane persisted. Evaporation of the volatile products from the dried solution (anhydrous Na_2SO_4) gave 7.75 g of a mixture of diester **7** and starting anhydride. This mixture was chromatographed through 120 g silica gel (230–400 mesh) using a slight overpressure (14) and CH_2Cl_2 as eluent to give 7.01 g of **7** and 0.60 g of **5**. Yield of **7**, if **5** was recovered, 96%. A sample of **7** crystallized from hexane showed mp 71–73°C; ir ($CHCl_3$) ν: 1730 (s) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.34 (br d, J = 10 Hz, 1H, H11*anti*), 1.48 (m, 2H, H9(10)*exo*), 1.87 (m, 2H, H9(10)*endo*), 2.03 (d, J = 15 Hz, 2H, H3(6)*exo*), 2.19 (br d, J = 10 Hz, 1H, H11*syn*), 2.27 (br s, 2H, H1(8)), 2.58 (ddd, J = 15 Hz, J' = 4 Hz, J'' = 2.5 Hz, 2H, H3(6)*endo*), 3.60 (s, 6H, —OCH_3), 5.90 (m, 2H, H4(5)). On irradiation at δ 2.27, the absorption at δ 1.34 became a sharp doublet and that at δ 2.19, a dt, J = 10 Hz, J' = 2.5 Hz. On irradiation at δ 1.48, the absorption at δ 1.87 became a doublet J = 2.5 Hz; ^{13}C nmr ($CDCl_3$) δ: 25.8 (t, C9(10)), 33.5 (t, C3(6)), 37.1 (t, C11), 49.6 (d, C1(8)), 51.4 (q, —OCH_3), 58.7 (s, C2(7)), 127.3 (d, C4(5)), 175.2 (s, —*C*OOMe). *Anal.* calcd. for $C_{15}H_{20}O_4$: C 68.16, H 7.63; found: C 68.36, H 7.79.

Dimethyl (1R,2R,3S,4S)-2,3-bishydroxycarbonylmethylbicyclo-[2.2.1]heptane-2,3-dicarboxylate, 8

To a cold (0°C) solution of 0.41 g (2.0 mmol) $KMnO_4$ in 5 mL water, 200 mg (0.76 mmol) diester **7** in 10 mL benzene, 3 mg tetra-*n*-butylammonium bromide, and 3 mL glacial acetic acid were added, and the mixture vigorously stirred magnetically at room temperature for 16 h. The mixture was cooled in an ice bath, 445 mg (3.5 mmol) Na_2SO_3 was added at once, and then, 0.9 mL 6 *N* HCl dropwise and with stirring, the final solution being slightly acidic. The organic phase was separated and the aqueous one extracted with benzene (5 × 4 mL). The organic phase and the benzene extracts were combined and washed with water (1 × 2 mL). Evaporation of the solvent from the dried extracts (anhydrous Na_2SO_4) gave 130 mg of an unidentified residue. The aqueous phase was extracted with ether (5 × 6 mL), and the combined ether extracts washed with water (1 × 2 mL) and dried over anhydrous Na_2SO_4. Evaporation of the volatile products gave 80 mg of a product consisting mainly of diacid **8**. Crystallization from ether gave pure **8**, mp 163–167°C (dec.); ir (KBr) ν: 3600–2400 (s), 1740 (s), 1710 (s) cm^{-1}; 60-MHz ^{1}H nmr (acetone-d_6) δ: 1.20–1.90 (m, 6H), 2.62 (m, 2H, H2(3)), 2.84 (s, 4H, —CH_2COOH), 3.60 (s, 6H). *Anal.* calcd. for $C_{15}H_{20}O_8$: C 54.88, H 6.14; found: C 54.94, H 6.28.

Dimethyl (1R,2R,3S,4S)-2,3-bismethoxycarbonylbicyclo[2.2.1]-heptane-2,3-diacetate, 9

An ethereal solution of diazomethane was added to 2.9 g of crude **8** (obtained from 7 g diester **7** as described before) until the yellow colour persisted. Evaporation of the dried solution (anhydrous Na_2SO_4) gave 2.6 g of a product that crystallized from methanol, yielding 1.2 g of pure **9**, bp 160–165°C (oven)/0.1 Torr, mp 109–110°C. Evaporation of the mother liquors of crystallization gave a residue whose ^{1}H nmr spectrum showed that it did not contain more **9**. Total yield of **9** from diester **7**, 13%; ir ($CHCl_3$) ν: 1750 (s), 1740 (s) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.34 (dm, J = 10.8 Hz, 1H, H7*anti*), 1.42–1.56 (m, 2H, H5(6)*exo*), 1.80–1.94 (m, 3H, H5(6)*endo* and H7*syn*), 2.45 (br s, 2H, H1(4)), 2.78 (s, 4H, —CH_2COOMe), 3.67 (s, 6H), 3.69 (s, 6H); ^{13}C nmr ($CDCl_3$) δ: 24.7 (t, C5(6)), 35.7 (t, C7), 40.4 (t, —CH_2COOMe), 47.3 (d, C1(4)), 51.7 (q) and 51.9 (q) (—COOCH_3), 57.6 (s, C2(3)), 170.9 (s, —CH_2—*C*OOMe), 173.1

(s, —C—COOMe). *Anal.* calcd. for $C_{17}H_{24}O_8$: C 57.30, H 6.79; found: C 57.23, H 6.77.

Trimethyl (1RS,2RS,6SR,7SR)-4-hydroxytricyclo[5.2.1.0^{2,6}]dec-3-ene-2,3,6-tricarboxylate, ***10***

In a 50-mL flask was placed 185 mg NaH (70% in mineral oil, 5.4 mmol). After washing with anhydrous THF (3 × 10 mL), the solid was covered with a small volume of the same solvent, and the mixture cooled in an ice bath. A solution of 600 mg tetraester **9** (1.69 mmol) in 20 mL anhydrous THF was added with care, a reflux condenser with a $CaCl_2$ tube was adapted to the flask, and the reaction mixture heated under reflux for 3 h. The mixture was cooled to 0°C and treated with 6 *N* HCl until neutral pH, then made slightly acidic with 0.1 *N* HCl. The organic phase was separated and the aqueous one extracted with $CHCl_3$ (4 × 7 mL). The extracts and the organic phase were combined, washed with water (2 × 2 mL), and dried over anhydrous Na_2SO_4. Evaporation of the solvent from the extracts gave 544 mg (1.68 mmol) of **10** as a viscous liquid that solidified on standing, bp 140–145°C (oven)/0.1 Torr, mp 105–108°C (methanol), 99% yield. Gas–liquid chromatographic analysis (column SE-30, 2 m; oven temperature 180°C; injector temperature 200°C; flow 20 mL N_2/min) of this compound gave a unique signal whose rt (retention time) (4.04 min) was the same as ketodiester **2**, showing that decarbomethoxylation of **10** to **2** took place in the injection chamber. Infrared ($CHCl_3$) ν: 3600–2850 (m), 1740 (s), 1660 (s), 1620 (m) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.20–1.45 (m, 3H, H8*exo*, H9*exo*, and H10*anti*), 1.50–1.80 (m, 2H, H8*endo* and H9*endo*), 2.21 (br s, 1H, H7), 2.46 (m, 1H, H10*syn*), 2.58 (d, *J* = 19 Hz, 1H) and 3.36 (d, *J* = 19 Hz, 1H) (H5*exo* and H5*endo*), 2.65 (br s, 1H, H1), 3.60 (s, 3H), 3.69 (s, 3H), 3.74 (s, 3H); ^{13}C nmr ($CDCl_3$) δ: 23.3 (t, C8), 26.4 (t, C9), 35.7 (t, C10), 42.8 (d, C7), 43.2 (t, C5), 50.6 (d, C1), 51.4 (q), 51.5 (q), and 52.0 (q) (—O—CH_3), 58.5 (s, C6), 64.3 (s, C2), 104.4 (s, C3), 168.9 (s, C4), 173.0 (s), 173.4 (s), and 176.0 (s) (—*C*OOMe). *Anal.* calcd. for $C_{16}H_{20}O_7$: C 59.25, H 6.22; found: C 59.85, H 6.41.

Dimethyl (1R,2R,6S,7S)-4-oxotricyclo[5.2.1.0^{2,6}]decane-2,6-dicarboxylate, ***2***

A mixture of 544 mg (1.68 mmol) of **10**, 100 mg NaCl (1.7 mmol), 100 mg water (5.6 mmol), and 10 mL DMSO was heated at 120°C with magnetic stirring for 2 h. To the cold (room temperature) mixture, 25 mL water was added, and then it was extracted with $CHCl_3$ (5 × 10 mL). The chloroform extracts were combined, washed with water (3 × 7 mL), and dried over anhydrous Na_2SO_4. Evaporation of the volatile products and distillation of the residue in a microdistillation apparatus gave 395 mg of **2** (1.48 mmol, 88% yield), bp 120°C (oven)/0.1 Torr, mp 84–88°C (methanol/water); ir ($CHCl_3$) ν: 1740 (s) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.30–1.60 (m, 4H, H10*syn*, H10*anti*, and H8(9)*exo*), 1.68–1.82 (m, 2H, H8(9)*endo*), 2.28 (br s, 2H, H1(7)), 2.34 (d, *J* = 19.8 Hz, 2H), 2.98 (d, *J* = 19.8 Hz, 2H) (H3(5)*exo* and H3(5)*endo*), 3.62 (s, 6H); ^{13}C nmr ($CDCl_3$) δ: 25.0 (t, C8(9)), 35.5 (t, C10), 48.5 (d, C1(7)), 50.1 (t, C3(5)), 51.9 (q, —O—CH_3), 59.1 (s, C2(6)), 174.0 (s, —*C*OOMe), 214.5 (s, C4). *Anal.* calcd. for $C_{14}H_{18}O_5$: C 63.15, H 6.81; found: C 62.92, H 6.79.

(1R,2R,3S,4S)-2,3-bishydroxycarbonylmethylbicyclo[2.2.1]-heptane-2,3-dicarboxylic anhydride, ***11***

To a cold solution (0°C) of 2.48 g (15.7 mmol) $KMnO_4$ in 25 mL water, a solution of 1.0 g (4.6 mmol) anhydride **5** in 75 mL benzene, 16 mg tetra-*n*-butylammonium bromide, and 17 mL glacial acetic acid were added. The mixture was efficiently stirred magnetically at room temperature for 16 h. After cooling in an ice bath, 2.7 g (21.4 mmol) Na_2SO_3 was added at once and then, dropwise and with stirring, 5.5 mL 6 *N* HCl, the final pH being slightly acidic. The organic phase was separated and the aqueous one extracted with benzene (2 × 10 mL). The benzene extracts and the organic phase were combined, washed with water (1 × 2 mL), and dried over anhydrous Na_2SO_4. Evaporation of the solvent yielded 40 mg of an unidentified residue. The aqueous phase was extracted with ether (5 × 20 mL) and the combined ether extracts were washed with water (1 × 2 mL) and dried over anhydrous Na_2SO_4. Evaporation of the solvent left a residue that was dried in a desiccator containing KOH pellets, to give 940 mg of **11**. Continuous extraction of the aqueous phase with ether for 16 h gave 140 mg more product. Total yield 1.08 g (3.83 mmol, 83%). An analytical sample obtained by crystallization from ether showed a poorly defined mp at 240–248°C (dec.) with changes near 210°C; ir (KBr) ν: 3340–2040 (s), 1860 (m), 1780 (s), 1710 (s) cm^{-1}; 60-MHz ^{1}H nmr (acetone-d_6) δ: 1.2–1.9 (complex absorption, 6H), 2.9 (br s, 6H, H1(4)) and —CH_2COOH), 9.9 (br absorption, 2H). *Anal.* calcd. for $C_{13}H_{14}O_7$: C 55.32, H 5.00; found: C 55.57, H 5.05.

(1R,2R,6S,7S)-4-oxotricyclo[5.2.1.0^{2,6}]decane-2,6-dicarboxylic anhydride, ***13***

An intimate mixture of 930 mg (3.30 mmol) diacid **11** and 40 mg (0.20 mmol) anhydrous $Ba(OH)_2$ was heated in the oven of a rotary microdistillation apparatus at 170°C/0.05 Torr, giving rise to 185 mg (0.84 mmol) of **13**, 25% yield. Crystallized from $CHCl_3$/ether, the product showed mp 185–190°C (not well-defined); ir ($CHCl_3$) ν: 1880 (w), 1860 (w), 1780 (s), 1750 (s) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.46–1.90 (m, 6H), 2.54 (d, *J* = 20.7 Hz, 2H), 2.68 (br s, 2H, H1(7)), 2.99 (d, *J* = 20.7 Hz, 2H); ^{13}C nmr ($CDCl_3$) δ: 25.3 (t, C8(9)), 38.0 (t, C10), 46.1 (t, C3(5)), 47.0 (d, C1(7)), 61.3 (s, C2(6)), 173.8 (s, —COO—), 212.5 (s, C4). *Anal.* calcd. for $C_{12}H_{12}O_4$: C 65.45, H 5.49; found: C 65.57, H 5.72.

(1R,2R,3S,4S)-2,3-bismethoxycarbonylmethylbicyclo[2.2.1]-heptane-2,3-dicarboxylic anhydride, ***12***

To a solution of 500 mg diacid **11** (1.77 mmol) in 25 mL ether was added excess ethereal solution of diazomethane. After 1 h at room temperature, the volatile material was evaporated at reduced pressure and the solid residue (600 mg) crystallized from benzene/hexane to give 470 mg of diester **12**, mp 158–160°C, 86% yield; ir ($CHCl_3$) ν: 1840 (m), 1780 (s), 1740 (s) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.50–1.90 (m, 6H, H5(6)*endo*, H5(6)*exo*, H7*syn*, and H7*anti*), 2.79 (s, 4H, —CH_2COOMe), 2.83 (br s, 2H, H1(4)), 3.73 (s, 6H, —OCH_3); ^{13}C nmr ($CDCl_3$) δ: 25.3 (t, C5(6)), 36.7 (t, —CH_2COOMe), 38.2 (t, C7), 47.1 (d, C1(4)), 52.5 (q, —OCH_3), 59.2 (s, C2(3)), 171.3 (s, —*C*OOMe), 173.5 (s, —COO—). *Anal.* calcd. for $C_{15}H_{18}O_7$: C 58.06, H 5.85; found: C 57.90, H 5.88.

Attempted synthesis of dimethyl (1R,2R,3S,4S)-bismethoxycarbonylbicyclo[2.2.1]heptane-2,3-diacetate, 9 1. From (1R,2R,3S,4S)-2,3-bishydroxycarbonylmethylbicyclo[2.2.1]-heptane-2,3-dicarboxylic anhydride, ***11***. *Obtention of dimethyl (1R,2R,3S,4S)-2,3-bismethoxycarbonylmethylbicyclo[2.2.1]-heptane-2,3-dicarboxylic anhydride,* ***12***

(a) A mixture of 213 mg of compound **11** (0.76 mmol), 500 mg NaOH (12.5 mmol), and 5 mL water was heated under reflux for 4 h. The solution was evaporated to dryness *in vacuo*. The ir spectrum of the residue did not show the carbonyl anhydride absorption. This residue was dissolved in 2 mL water, 100 mg tetra-*n*-butylammonium bromide added, and the solution cooled in an ice bath. An ethereal solution of hydrogen chloride was added with vigorous stirring until the aqueous phase became slightly acidic and, immediately after, it was treated with an ethereal solution of diazomethane until a yellow colour persisted. Evaporation of the dried organic phase gave 268 mg of crude diester **12**.

(b) A mixture of 208 mg of compound **11** (0.74 mmol), 120 mg NaOH (3 mmol), and 5 mL water was heated under reflux for 4 h. The solution was evaporated to dryness *in vacuo*. Anhydrous DMF (5 mL) and 370 mg dimethyl sulfate (2.9 mmol) were added to the residue and the mixture heated under reflux for 16 h. The solvent was evaporated at reduced pressure and the solid residue washed with water and extracted with ether (5 × 10 mL). Evaporation of the solvent from the dried solution gave 260 mg of crude diester **12**.

2. *From (1R,2R,3S,4S)-2,3-bismethoxycarbonylmethylbicyclo-[2.2.1]heptane-2,3-dicarboxylic anhydride,* ***12***

A mixture of 470 mg diester **12** (1.7 mmol), 220 mg anhydrous sodium methoxide (4 mmol), and 5 mL anhydrous methanol was heated under reflux for 16 h. The mixture was cooled to 0°C and neutralized with concentrated HCl. The solvent was removed *in vacuo* without heating and the residue was treated with excess ethereal solution of diazomethane. Evaporation of the solvent left a crude mixture consisting mainly of the starting product.

Attempted conversion of (1R,2R,3S,4S)-2,3-bismethoxycarbonylmethylbicyclo[2.2.1]heptane-2,3-dicarboxylic anhydride, ***12****, into (1R,2R,3S,4S)-4-oxotricyclo[5.2.1.0^{2,6}]decane-2,6-dicarboxylic anhydride,* ***13***

A 50% dispersion of NaH in mineral oil (375 mg, 7.8 mmol) was washed with anhydrous THF (3 × 5 mL). A solution of 515 mg diester **12** (1.6 mmol) in 5 mL anhydrous THF was added and the mixture heated under reflux for 4 h. The cold mixture was acidified with aqueous 0.5 *N* HCl and extracted with ether (5 × 10 mL). After the usual work-up, a crude mixture consisting mainly of the starting product was obtained.

(1R,2R,3S,4S)-4-oxotricyclo[5.2.1.0^{2,6}]decane-2,6-dicarboxylic anhydride, ***13***

A 50% dispersion of NaH in mineral oil (600 mg, 12.5 mmol) was washed with anhydrous THF (3 × 5 mL). A solution of 211 mg of compound **12** (0.68 mmol) in 4 mL anhydrous THF and 4 mL anhydrous methanol was added and the mixture heated under reflux for 4 h. Aqueous 1 *N* HCl was added until pH 3, and the mixture extracted with $CHCl_3$. After the usual work-up a product was obtained (140 mg), which was heated under reflux with 20 mL 6 *N* HCl for 4 h. Evaporation of the volatile products *in vacuo* left a solid residue, which was washed with aqueous 7% $NaHCO_3$. The insoluble material was washed with water and dried in a desiccator to give 89.3 mg of compound **13**, 60% yield, identical (60-MHz ^{1}H nmr) to the product previously obtained.

Dimethyl (1R,2R,6S,7S)-4-oxotricyclo[5.2.1.0^{2,6}]decane-2,6-dicarboxylate, ***2***

A mixture of 91.8 mg anhydride **13** (0.42 mmol), 1.0 g NaOH, and 5 mL water was heated under reflux for 4 h. The cold solution (ice bath) was acidified with concentrated H_2SO_4. An ethereal solution of diazomethane was added with vigorous stirring until the yellow colour of diazomethane persisted. The organic layer was dried and evaporated, and the residue purified by passing it through a small column of silica gel using $CHCl_3$ as eluent, giving rise to 81.9 mg of diester **2** (0.308 mmol), 73% yield.

Dimethyl (1R,2R,6S,7S)-4-(p-toluenesulfonylhydrazono)tricyclo-[5.2.1.0^{2,6}]decane-2,6-dicarboxylate, ***14***

To a solution of 100 mg ketodiester **2** (0.376 mmol) in 3 mL glacial acetic acid, a solution of 140 mg *p*-toluenesulfonylhydrazide (0.75 mmol) in 3 mL of the same solvent was added and the reaction mixture left to stand at room temperature for 2 h. Water was added until turbidity, and the mixture allowed to stand in the refrigerator (0°C) for 16 h. The precipitate was filtered, washed with water, and dried in a desiccator containing KOH pellets, giving rise to 128 mg (0.29 mmol) of tosylhydrazone **14** (78% yield), mp 151–155°C; ir ($CHCl_3$) ν: 3325 (w), 3240 (w), 3050 (m), 1740 (s) cm^{-1}; 60-MHz ^{1}H nmr ($CDCl_3$) δ: 1.10–1.85 (m, 6H), 2.15–3.42 (complex absorption, 2.45 (s), total 9H), 3.60 (s, 6H), 7.30 (d, J = 8 Hz, 2H), 7.5–8.0 (complex absorption, 7.80 (d, J = 8 Hz), total 3H). *Anal.* calcd. for $C_{21}H_{26}N_2O_6S$: C 58.06, H 6.03, N 6.45; found: C 57.68, H 5.97, N 6.67.

Dimethyl (1RS,2RS,6SR,7SR)-tricyclo[5.2.1.0^{2,6}]dec-3-ene-2,6-dicarboxylate, ***15***

In a 10-mL flask fitted with a reflux condenser with a $CaCl_2$ tube, 64 mg (0.147 mmol) tosylhydrazone **14**, 9.7 mg (0.180 mmol) sodium methoxide, and 5 mL anhydrous methanol were placed. The mixture was heated under reflux for 2 h, the solvent was removed in a rotary evaporator without heating, and the residue dried *in vacuo* (1 Torr). The flask was connected to a microdistillation apparatus and heated progressively, the pressure in the system being 0.1 Torr. A liquid, which solidified as white crystals, distilled at 136°C/0.1 Torr, sublimed at 60–65°C/0.1 Torr, and showed mp 52–56°C. It was characterized as alkene **15**; yield, 34 mg (0.136 mmol), 93%; ir ($CHCl_3$) ν: 1740 (s), 1640 (w) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.22 (br d, J = 10 Hz, 1H, H10*anti*), 1.44–1.56 (m, 2H, H8*exo* and H9*exo*), 1.66–2.00 (m, 3H, H8*endo*, H9*endo*, and H10*syn*), 2.29 (complex absorption, 3H, H1(7) and H5*endo* or H5*exo*), 2.99 (dt, J = 17.6 Hz, J' = 2.5 Hz, 1H, H5*exo* or H5*endo*), 3.63 (s, 3H), 3.66 (s, 3H), 5.64 (dt, J = 6 Hz, J' = 2.5 Hz, 1H) and 5.83 (dt, J = 6 Hz, J' = 2.5 Hz, 1H) (H3 and H4); ^{13}C nmr ($CDCl_3$) δ: 24.7 (t, C8), 25.6 (t, C9), 34.8 (t, C10), 46.6 (d, C7), 47.3 (t, C5), 47.7 (d, C1), 51.4 (q) and 51.6 (q) (—OCH_3), 60.4 (s, C6), 70.9 (s, C2), 132.0 (d) and 132.5 (d) (C3 and C4), 173.2 (s) and 175.1 (s) (—COOMe). *Anal.* calcd. for $C_{14}H_{18}O_4$: C 67.18, H 7.25; found: C 67.36, H 7.39.

Photochemical decomposition of the sodium salt of tosylhydrazone ***14***

A solution of 50 mg of the sodium salt of **14** (0.112 mmol), obtained as described before, in 15 mL anhydrous DME was placed in a Pyrex photoreactor and deoxygenated by bubbling nitrogen. The reactor was stoppered, and the mixture, magnetically stirred, was irradiated with a 125-W lamp for 16 h. The solvent was evaporated, the residue treated with 5 mL $CHCl_3$, and the suspension filtered; glc analysis of the filtrate (column, SE-30, 2 m; injector temperature 200°C; oven temperature, 160°C; flow, 20 mL N_2/min) showed it to contain mainly ketodiester **2** (rt 8.22 min, 66% relative area) and alkene **15** (rt 4.02 min, 26% relative area).

Thermal decomposition of the lithium salt of tosylhydrazone ***14***

To a cold solution (0°C) of 70 mg tosylhydrazone **14** (0.16 mmol) in 5 mL anhydrous ether, magnetically stirred under an argon atmosphere, 0.11 mL of a 1.6 *M* solution of *n*-butyllithium in hexane was added with the aid of a syringe. The mixture was stirred at room temperature for 1 h, the solvent was evaporated at reduced pressure without heating, and the residue dried *in vacuo* (1 Torr). The dry lithium salt was placed in a 10-mL flask, connected to a microdistillation apparatus, and heated gradually up to 135°C/0.2 Torr, giving rise to 25 mg of alkene **15**, 62% yield.

Attempted conversion of ketodiester ***2*** *into dimethyl 1-hydroxytetracyclo[5.2.1.0^{2,6}.0^{3,8}]decane-7,8-dicarboxylate,* ***16***

(a) *In anhydrous benzene*

A solution of 50 mg of **2** (0.188 mmol) in 5 mL benzene was placed in a quartz cell, and dry argon was bubbled through the solution for 20 min. The cell was stoppered and leaned against the refrigeration jacket of a 400-W uv lamp. The reaction was followed by glc (column SE-30, 2 m; injector temperature, 200°C; oven temperature, 180°C; flow, 20 mL N_2/min) and, after irradiating for 40 h, only the starting product (rt 3.95 min) was detected.

(b) *In benzene/*tert*-butyl alcohol*

The procedure described before, except for the use of a 5:1 benzene/*tert*-butyl alcohol mixture as solvent, was followed. After irradiating for 68 h, a new compound (rt 7.19 min) was formed, whose relative area with respect to **2** was 1.43. After irradiating for 40 h more, this ratio remained unchanged; glc/ms analysis of this mixture showed that the compound of rt 7.19 min was not the desired hydroxydiester **16**, but probably a product of addition of *tert*-butyl alcohol. Mass spectrum of the compound of rt 7.19 min: 267(5), 253(5), 252(5), 218(18), 186(20), 185(22), 153(13), 140(14), 119(14), 105(14), 91(25), 79(17), 77(18), 67(23), 59(45), 57(100).

Attempted conversion of ketoanhydride ***13*** *into 1-hydroxytetracyclo-[5.2.1.0^{2,6}.0^{3,8}]decane-7,8-dicarboxylic anhydride,* ***17***

(a) *In benzene*

The same procedure described before for compound **2** was followed, but starting with 25 mg (0.114 mmol) ketoanhydride **13**. After irradiating for 100 h, only the starting product was detected by glc analysis (rt 5.22 min, using the same conditions as before).

(b) *In benzene/*tert-*butyl alcohol*

The procedure described before was followed, using a 5:1 benzene/*tert*-butyl alcohol mixture as solvent, and starting with 20 mg of **13** (0.091 mmol). After irradiating for 90 h, the starting product had disappeared and a new compound (rt 5.90 min, 70% relative area) had been formed; glc/ms analysis showed that this compound was not the desired hydroxyanhydride **17**, but probably a product of addition of *tert*-butyl alcohol. Mass spectrum of the compound of rt 5.90 min: 279(3), 239(12), 238(10), 222(5), 221(23), 193(18), 166(28), 138(38), 91(35), 77(31), 67(34), 57(100).

*(3a*R*,4*S*,7*R*,7a*S*)-8,8-Diethoxy-2-phenyl-3a,5,6,7a-tetrahydro-1*H*,3*H*-4,7-methanoisoindol-1,3-dione,* ***21***

A mixture of 27.9 g dicarboximide **18** (85.3 mmol), 1.0 g of 10% Pd on charcoal, and 150 mL ethyl acetate was hydrogenated in a medium pressure hydrogenation apparatus at 4.2 atm for 82 h. Additional quantities of catalyst (0.5 g) were introduced after 48 and 72 h reaction. Most of the starting and reaction product remained undissolved during hydrogenation. Ethyl acetate was added to dissolve all the organic material, the mixture was filtered, and the solvent evaporated from the filtrate at reduced pressure to give 27.35 g of **21** (97% yield), mp 149–152°C (methanol); ir ($CHCl_3$) ν: 1710 (s) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.24 (t, J = 7 Hz, 6H), 1.38–1.52 (m, 2H, H5(6)*endo*), 1.86–2.02 (m, 2H, H5(6)*exo*), 2.66–2.74 (m, 2H, H4(7)), 3.40–3.48 (m, 2H, H3a(7a)), 3.57 (q, J = 7 Hz) and 3.59 (q, J = 7 Hz) (total 4H), 7.24–7.54 (m, 5H); ^{13}C nmr ($CDCl_3$) δ: 15.40 (q) and 15.44 (q) (—OCH_2CH_3), 22.7 (t, C5(6)), 41.4 (d, C4(7)), 46.1 (d, C3a(7a)), 58.8 (t) and 59.0 (t) (—OCH_2CH_3), 115.1 (s, C8), 126.7 (d, —CH= *ortho*), 128.7 (d, —CH= *para*), 129.2 (d, —CH= *meta*), 132.0 (s, —C= *ipso*), 177.7 (s, —CO—). *Anal.* calcd. for $C_{19}H_{23}NO_4$: C 69.28, H 7.04, N 4.25; found: C 69.20, H 7.01, N 4.15.

*(3a*R*,4*S*,7*R*,7a*S*)-11,11-Diethoxy-5,6-dihydro-2-phenyl-1*H*,3*H*-4,7-methano-3a,7a-propanoisoindol-1,3-dione,* ***22***

In a one-liter three-necked flask equipped with low temperature thermometer, addition funnel, magnetic stirrer, and dry nitrogen atmosphere were placed 300 mL anhydrous THF, 4.0 g (30 mmol) naphthalene, and 2.1 g of a dispersion of lithium in solid paraffin containing 0.84 g lithium. The mixture was vigorously stirred for 10 min, taking on a dark-green colour. Diisopropylamine (18 mL, 120 mmol) was added with stirring and keeping the temperature below 30°C. The mixture was stirred until all the lithium had reacted, showing at this time an orange colour. The mixture was cooled at −78°C and 13.2 g of dicarboximide **21** (40 mmol) in 200 mL anhydrous THF was added at once. After 45 min stirring, the mixture was allowed to reach 0°C, and 4.1 mL 1,3-dibromopropane (40 mmol) was slowly added. After 1 h stirring at this temperature, most of the THF was evaporated at reduced pressure, and then 200 mL water and 200 mL $CHCl_3$ were added. The aqueous phase was acidified with dilute HCl, separated from the organic phase, and extracted with $CHCl_3$ (5 × 100 mL). The organic phase and the extracts were combined, washed with an aqueous solution of $NaHCO_3$ and water, and dried over anhydrous Na_2SO_4. Evaporation of the solvents at reduced pressure left a viscous residue that was extracted with hot hexane (5 × 50 mL), giving rise on cooling to 5.94 g of dicarboximide **22** as yellow crystals (40% yield). The product was dissolved in $CHCl_3$, decolorized with active charcoal, and crystallized from hexane, mp 132–134°C; ir ($CHCl_3$) ν: 1765 (s), 1700 (s), 1590 (w) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.20 (t, J = 7 Hz, 3H), 1.22 (t, J = 7 Hz, 3H), 1.26–1.56 (m, 3H), 1.78–2.00 (m, 3H), 2.14–2.36 (m, 4H), 2.52–2.62 (m, 2H, H4(7)), 3.51 (q, J = 7 Hz, 2H), 3.52 (q, J = 7 Hz, 2H), 7.20–7.54 (m, 5H); ^{13}C nmr ($CDCl_3$) δ: 14.5 (q) and 15.2 (q) (—OCH_2CH_3), 23.6 (t, C5(6)), 25.4 (t, C9), 34.3 (t, C8(10)), 43.2 (d, C4(7)), 57.8 (t) and 58.4 (t) (—OCH_2CH_3), 63.1 (s, C3a(7a)), 115.4 (s, C11), 126.6 (d, —CH= *ortho*), 128.7 (d, —CH= *para*), 129.2 (d, —CH= *meta*), 132.1 (s, —C= *ipso*), 181.3 (s, —CO—). *Anal.* calcd. for $C_{22}H_{27}NO_4$: C 71.52, H 7.34, N 3.79; found: C 71.44, H 7.39, N 3.79.

*Dimethyl (1*R*,2*S*,6*R*,7*S*)-10,10-diethoxytricyclo[5.2.1.0^{2,6}]decane-2,6-dicarboxylate, 25*

In a 250-mL three-necked flask equipped with low temperature thermometer, addition funnel, magnetic stirrer, and dry nitrogen atmosphere were placed 100 mL anhydrous THF, 1.5 g (10 mmol) naphthalene, and 0.71 g of a dispersion of lithium in solid paraffin containing 0.284 g lithium. The mixture was vigorously stirred for 15 min, taking on a dark-green colour. Diisopropylamine (4.5 mL, 30 mmol) was added with stirring and keeping the temperature of the reaction mixture below 30°C. The mixture was stirred until all lithium had reacted, showing at this time an orange colour. After cooling at −78°C, 3.0 g of diester **24** (10 mmol) in 50 mL anhydrous THF was added at once. The mixture was stirred for 1h and allowed to reach 0°C. 1,3-Dibromopropane (1.1 mL, 10 mmol) was slowly added, and the mixture stirred for 75 min at this temperature. The solvent was evaporated at reduced pressure, 75 mL water and 75 mL $CHCl_3$ were added, and the aqueous phase made acidic with 25 mL dilute HCl. The organic phase was separated and the aqueous one extracted with $CHCl_3$ (3 × 30 mL). The combined organic phase and extracts were washed with water and dried over anhydrous Na_2SO_4. Evaporation of the solvent left a liquid residue that was chromatographed through silica gel, giving rise, on elution with CH_2Cl_2, to 1.7 g of a mixture of starting product and **25**, which was fractionally distilled in a rotary microdistillation apparatus. Obtained was 1.0 g of **25**, bp 200–210°C (oven)/0.2 Torr, 29% yield; ir ($CHCl_3$) ν: 1730 (s) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.16 (t, J = 7.1 Hz, 3H), 1.19 (t, J = 7.1 Hz, 3H), 1.5–2.1 (m, 6H), 2.1–2.5 (m, 6H), 3.47 (q, J = 7.1 Hz, 2H), 3.49 (q, J = 7.1 Hz, 2H), 3.63 (s, 6H); ^{13}C nmr ($CDCl_3$) δ: 14.4 (q) and 15.1 (q) (—OCH_2CH_3), 22.5 (m, C8(9)), 26.1 (t, C4), 38.1 (m, C3(5)), 46.6 (d, C1(7)), 51.4 (q, —OCH_3), 57.4 (t) and 58.2 (t) (—OCH_2CH_3), 63.7 (s, C2(6)), 112.6 (s, C10), 175.2 (s, —COOMe). *Anal.* calcd. for $C_{18}H_{28}O_6$: C 63.51, H 8.29; found: C 63.93, H 8.35.

*Dimethyl (1*R*,2*S*,6*R*,7*S*)-10-oxotricyclo[5.2.1.0^{2,6}]decane-2,6-dicarboxylate, 1*

A mixture of 0.45 g diester **25** and 6.75 mL 15% aqueous $HClO_4$ was heated under reflux for 5 h. The cold mixture was extracted with $CHCl_3$ (3 × 20 mL). The combined extracts were washed with water and dried over anhydrous Na_2SO_4. Evaporation of the solvent left 0.28 g of a solid that crystallized from methanol, and showed mp 78–81°C. Ketodiester **1**, prepared by the procedure previously described (7), melts at 81–83°C. The mixture mp was 79–82°C. The spectroscopic data (ir and 60-MHz ^{1}H nmr) and glc analysis confirm the identity of both compounds.

*Dimethyl (1*R*,2*S*,6*R*,7*S*)-10-(*p*-toluenesulfonylhydrazono)tricyclo-[5.2.1.0^{2,6}]decane-2,6-dicarboxylate, 26*

A mixture of 2.66 g ketodiester **1** (10 mmol), 2.05 g tosylhydrazide (11 mmol), 16 mL isopropanol, and four drops of concentrated HCl was heated under reflux for 28 h. The mixture was cooled in the refrigerator (−10°C) for 8 days and the precipitated white crystals were filtered and dried *in vacuo* (0.05 Torr) to give 3.26 g of **26**, mp 170–172°C, 75% yield. Recrystallized from isopropanol, the mp remained unchanged; ir (KBr) ν: 3175 (m), 1732 (s), 1705 (s), 1600 (m) cm^{-1}; 80-MHz ^{1}H nmr ($CDCl_3$) δ: 0.9–2.6 (complex absorption, 14H, 2.50 (s)), 2.92 (m, 1H), 3.60 (s, 6H), 7.35 (d, J = 8 Hz, 2H), 7.85 (d, J = 8 Hz, 2H), 8.1 (br absorption, 1H); 20-MHz ^{13}C nmr ($CDCl_3$) δ: 21.2 (m) and 22.0 (m) (C8 and C9), 21.5 (q, =C—CH_3), 24.9 (t, C4), 38.5 (t) and 39.5 (t) (C3 and C5), 43.2 (d) and 49.2 (d) (C1 and C7), 51.7 (q, —OCH_3), 60.9 (s) and 61.6 (s) (C2 and C6), 127.9 (d) and 129.5 (d) (—CH=), 135.5 (s, =C—CH_3), 144.1 (s, =C—SO_2—), 167.1 (s, C10), 173.4 (s) and 173.6 (s) (—COOMe). *Anal.* calcd. for $C_{21}H_{26}N_2SO_6$: C 58.05, H 6.03, N 6.45; found: C 57.99, H 5.88, N 6.26.

Dimethyl tetracyclo[5.2.1.0^{2,6},0^{3,8}]decane-7,8-dicarboxylate, 3

In a 250-mL flask fitted with a reflux condenser with a $CaCl_2$ tube was placed a solution of 2.25 g of tosylhydrazone **26** (5.18 mmol) in 60 mL anhydrous methanol. Then a solution of 286 mg anhydrous sodium methoxide (5.3 mmol) in 40 mL anhydrous methanol was added, and the mixture heated under reflux for 2 h. The solvent was removed at reduced pressure (30 Torr) and the residue dried at 0.1 Torr for 1.5 h. The flask containing the sodium salt of **26** was connected to a rotary microdistillation apparatus and heated at 170°C/1 Torr, to give 1.14 g of a colourless viscous distillate consisting mainly of **3** (glc analysis, column OV-1, 2 m; injector temperature 250°C; oven temperature 160°C; flow, 25 mL N_2/min; rt 5.80 min; relative area 97%). Crystallization from isopropanol gave needles, mp 62–63°C, 89% yield; ir (KBr) ν: 1725 (s) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.44–1.60 (m, 2H), 1.82–2.08 (m, 7H), 2.36–2.48 (m, 3H), 3.67 (s, 6H); 20-MHz ^{13}C nmr ($CDCl_3$) δ: 21.7 (t, C4(5)), 34.3 (d, C1), 49.6 (t, C9(10)), 49.9 (d, C2), 50.8 (q, —OCH_3), 57.4 (d, C3(6)), 57.8 (s, C7(8)), 172. 4 (s, —COOMe); ms: 250(M^+, 3), 219(38), 218(100), 191(11), 190(41), 159(22), 158(24), 132(16), 131(100), 130(30), 129(27), 128(14), 125(24), 124(14),119(14), 117(14), 116(16), 115(22), 93(14), 92(8), 91(38), 79(16), 78(11), 77(24), 65(11), 64(8), 63(19), 59(19). *Anal.* calcd. for $C_{14}H_{18}O_4$: C 67.18, H 7.25; found: C 67.09, H 7.31.

Une étude quantochimique sur le motif phosphazène a été effectuée par le biais de calculs réalisés en base *ab initio* double zeta (ζ) de valence sur des composés neutres et ioniques. La nature de la liaison P—N dans l'iminophosphane H_3PNH est à rapprocher de celle de la liaison P—C des ylures du phosphore. Les caractéristiques électroniques des formes cationiques $(H_2PNH_3)^+$, $(H_3PNH_2)^+$ et anioniques $(HPNH_2)^-$, $(H_2PNH)^-$ dérivées de l'iminophosphane et de sa forme tautomère, l'aminophosphane, ont été analysées. Les résultats obtenus permettent d'interpréter raisonnablement les données expérimentales obtenues pour ce type d'entités.

Ab initio molecular orbital calculations have been performed on the phosphazene bond using a split valence basis set on neutral and ionic compounds. The nature of the P—N multiple bond in H_3PNH shows similarities with that of the P—C bond in phosphorus ylides. Electronic characteristics of cations $(H_2PNH_3)^+$, $(H_3PNH_2)^+$ and anions $(HPNH_2)^-$, $(H_2PNH)^-$ related to H_3PNH and its tautomer H_2PNH_2 were investigated. The results obtained were used to explain experimental observations for this type of compounds.

1. Introduction

L'étude quantique antérieure réalisée sur la liaison phosphazène P═N concernait l'espèce neutre à coordinence deux HP═NH (1). Nous avons étendu cette approche, d'une part, à la coordinence quatre H_3P═NH et, d'autre part, à certains modèles cationiques $(H_3PNH_2)^+$, $(H_2PNH_3)^+$ et anioniques $(HPNH_2)^-$, $(H_2PNH)^-$ correspondant pour certains à des entités récemment synthétisées; pour ces dérivés, la nature de la liaison P—N avait été établie sur la base de leur réactivité ou d'après des données spectroscopiques essentiellement de résonance magnétique nucléaire.

L'objet de ce travail est de préciser la structure électronique de ces espèces et de généraliser les degrés de polarité et de polarisabilité respectifs des atomes de phosphore et d'azote selon l'environnement.

2. Conditions de calcul

Tous les calculs ont été réalisés à l'aide du programme MONSTERGAUSS 80 (2).

Une base *ab initio* double ζ de valence 4-31G (3) avec orbitales de polarisation de type *d* sur les hétéro-atomes a été utilisée (une orbitale gaussienne de type *d*, ζ_P^d = 0,57, ζ_N^d = 0,8).

Les paramètres géométriques ont été optimisés avec la base ainsi définie, grâce à un processus de minimisation à métrique variable, avec évaluation du gradient selon l'algorithme de Broyden–Fletcher–Goldfard-Shanno.

Toutefois, afin d'obtenir une description correcte des espèces anioniques (4), nous avons ultérieurement effectué des calculs simples en introduisant, sur les deux hétéro-atomes, un jeu de fonctions diffuses de type *s* et *p* avec les exposants 0,053 pour N et 0,032 pour P, précédemment optimisés par Lohr et Ponas (4*b*).

Les calculs sur les anions $(H_2PNH)^-$ et $(HPNH_2)^-$ ont été effectués sur le Cray One du Centre de calcul vectoriel pour la recherche (École polytechnique, Palaiseau) dans le cadre de l'ATP Cray 1984.

3. Analyse des résultats

3.1 *Iminophosphane* H_3P═NH

3.1.1 *Structure géométrique, orbitales moléculaires, populations de Mulliken*

À notre connaissance, seule une approche théorique en méthode CNDO/2 a été réalisée sur ce modèle (5).

Les valeurs optimisées des paramètres géométriques pour l'iminophosphane sont présentées dans le tableau 1.

La structure énergétiquement privilégiée de cette molécule correspond à un état d'hybridation de type sp^2 de l'atome d'azote et à une position décalée de la liaison N—H vis-à-vis du groupement PH_3 tétraédrique.

La principale caractéristique concerne la longueur, particulièrement courte (1,532 Å), de la liaison P—N. Quoique très nettement différente de celle évaluée par d'autres auteurs en CNDO/2 (1,66 Å) (5), celle-ci tout à fait en accord avec les données expérimentales obtenues par ailleurs (6*a*).

De plus, une population de recouvrement de 0,51 pour la liaison P—N révèle bien une liaison à caractère multiple; pour la double liaison P═N dans HP═NH, nous avions observé une valeur de 0,45.

Par le biais d'une analyse des populations de Mulliken et des orbitales moléculaires, nous avons cherché à préciser la nature de cette liaison.

La molécule d'iminophosphane peut être considérée comme le produit de réaction d'une phosphine et d'un nitrène singulet,
